If it is assumed that various matrices in Equation (1) are block circulate matrix, it can be solved in discrete frequency domain. Assuming R_{ff} and R_{nn} are block circulant matrix, implicit image and noise signals are stationary random signal, then two-dimensional frequency domain solution is:

$$F(l) = \frac{S_{ff}(l) H^*(l) Y(l)}{S_{ff}(l) \left|H^*(l)\right|^2 + S_{nn}(l)} \tag{2}$$

Since the spectral density of original image and noise is not known in advance in reality, noise spectral density is generally estimated in smoothing region of lower quality image observed and the original image spectral density is replaced by the spectra density of degraded image.

Wiener filtering adjusts the filter's output in accordance to local variance of the image. The larger the local variance is, the stronger the effect of smoothing filter is. It has better selectivity than the corresponding linear filter and has better preservation effect for image edge and high-frequency detail information.

This paper uses an achievable two-dimensional adaptive Wiener filter. The adaptive Wiener filter for pixels is implemented. It estimates the method according to the statistical properties of the pixel local neighborhood. It is calculated as follows.

First, the local mean of the pixels and variance are estimated:

$$\mu = \frac{1}{MN} \sum_{n_1, n_2 \in \eta} a(n_1, n_2) \tag{3}$$

$$\sigma^2 = \frac{1}{MN} \sum_{n_1, n_2 \in \eta} a^2(n_1, n_2) - \mu^2 \tag{4}$$

Where η is M ×N neighborhood of each pixel in the image. T hen gray value for each pixel is estimated using Wiener filtering:

$$b(n_1, n_2) = \mu + \frac{\sigma^2 - v^2}{\sigma^2} (a(n_1, n_2) - \mu) \tag{5}$$

where v^2 is the noise variance of the image.

PAVEMENT CRACKS RECOGNITION BY WIENER FILTERING

Characteristics Analysis of Pavement Crack Image

Identification system of pavement cracks based on CCD works in complex environment and is affected by many factors, such as uneven pavement materials and a variety of dark spots. Meanwhile, the greatest impact on the image feature is whether or not to use auxiliary lighting. Even though a uniform illumination condition is provided, uneven background still exists in the images. Generally speaking, the brightness at the center of the image is higher and is gradually darkening from center to edge. In natural light, there are more influencing factors so that there is a shadow on the pavement and the contrast of each image varies with the intensity of sunlight. In addition, image contrast also varies with the auxiliary lighting intensity for the same equipment. Another effect on image quality is from the camera installation angle relative to the pavement. Due to the impact of field of view, the video image will produce geometric distortion. In addition, installation height of the camera will also affect the image quality. In general, the images include two types of objects: pavement, i.e. the background and the detecting goals such as cracks. Therefore, the digital image pixels can be classified into two sets: the pixels representative of the background and pixels representative of cracks. In ideal circumstances, the cracks should be darker than the background. However, the specific situation is more complex due to following influencing factors:

(1) The uneven road surface materials and uniform road surface texture result into larger changing image background.

(2) Different cracks are different in size, type and severity. If there are as many large particles as the cracks and even brighter than the background color, the cracks image color will be diversified. However, cracks in the image are darker than the normal pavement in general.

(3) The pixels quantity of the cracks is far less than that of the background pixels.

(4) There is the same part of gray value between normal pavement and cracks.

(5) Cracks are composed by a lot of short intertwined and even disconnected lines which are randomly distributed.

(6) Due to the inherent characteristics of CCD cameras, uneven image brightness exists.

Based on the above road surface cracks image characteristics and the basic principle of Wiener filtering, it is reasonable in theory that cracks signal and noise signal in the road image is treated as a random signal. Therefore, crack identification in the complex pavement image is feasible based on Wiener filtering. The following two typical examples are analyzed.

Examples

According to the above theoretical analysis, Wiener filtering is used to deal with the pavement images to extract cracks. The results are as follows.

Figure 2. One of Original Image

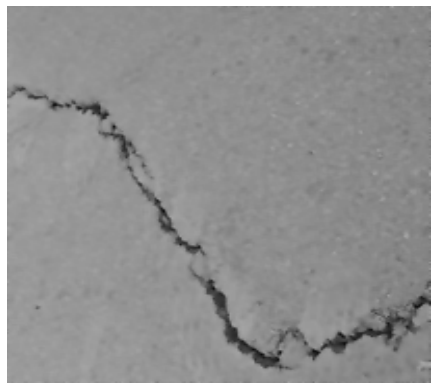

Figure 3 Wiener filtering Result of Fig.2

It can be seen from Figure 3 that Wiener filtering improves the image quality by not only the stress on cracks but also removing parts of noise signal.

In order to analyze more directly the effect of Wiener filter, Wiener filtering and median filtering is separately used in the same image and then Sobel operator is used to detect the crack edge. Figure 4 is a repaired crack with serious tire print on it, which is very difficult to recognize. Figure 5 is the result by Wiener filtering for Figure 4, Figure 6 is the result by Wiener filtering and edge detection by Sobel Operator for Figure 4 and Figure 7 is that by the median filter and edge detection of Figure 4.

Figure 4. One of Original Image

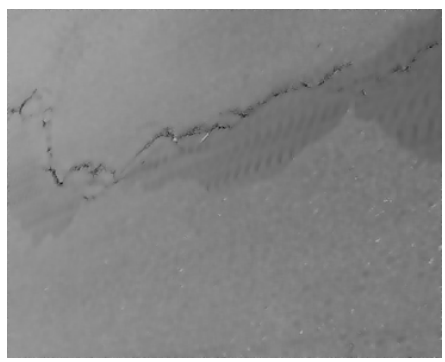

Figure 5. The Result by Wiener filtering

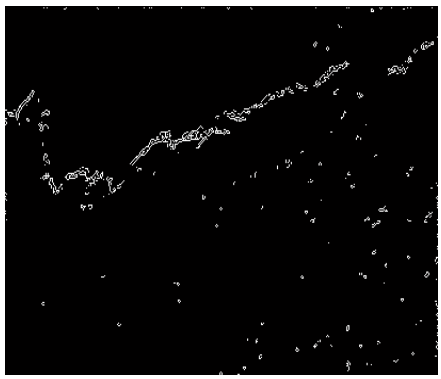

Figure 6. The Result by Sobel

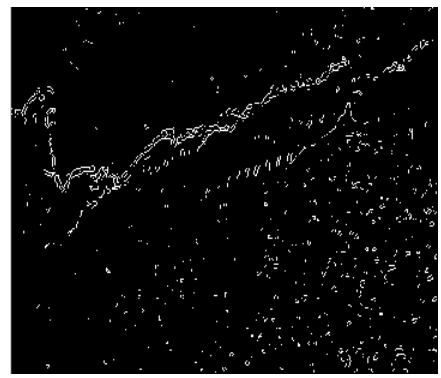

Figure 7. The Result by median filtering

From the comparison, it can be seen that the repaired crack can be clearly detected by Wiener filtering. This also shows that the Wiener filtering has better adaptability to the road conditions. Therefore, it is feasible to improve the road surface image quality by Wiener filtering.

CONCLUSION

How to make use of Wiener filtering to improve the image quality was studied based on the analysis of the characteristics of the road image. Through the experiments, the Wiener filtering can be used to improve road image and can provide a reliable basis for crack extraction, crack evaluation and pavement evaluation. The result has practical significance in the development of automatic identification system.

ABSTRACT

In order to determine optimum pavement milling thickness when old asphalt pavement structure strength deteriorates to some degree，the back calculation method is usually considered. Based on the multi-layer elastic system theory, the change law of the deflection before and after old pavement milling is calculated using the theory of orthogonal design. The change law of the deflection before old pavement milling and old road equivalent rebound modulus after milling is also calculated using the uniform design method. Meanwhile, this paper developed correlations between the deflections before and after old pavement milling for different milling thickness, and the relationship between the deflection before old pavement milling and the old road modulus after milling using regression analysis. The results indicate that the exponential equation usually gives better correlation. When the deflection value before old pavement milling and milling thickness value are small, the difference between the deflection before and after old pavement milling is relatively small. Finally, according to the calculation results, the design criterion of asphalt pavement milling based on the old pavement surface deflection control is proposed. The example indicates that this criterion is simple and reasonable, and has a good practical value, which can provide the basis for the determination of asphalt pavement milling thickness and the design of asphalt overlay.

Keyword: road engineering, asphalt pavement, pavement surface deflection, milling, design

Nowadays, it's a common practice to control the milling thickness of asphalt pavement according to the level of pavement distress and pavement structure strength, using empirical methods or based on specifications (Wang 2008). If pavement structure strength could not meet certain requirements, two methods are often used to determine the milling thickness of old asphalt pavement. The first method is FWD back calculation (Zha 2002； Wang and Lytton ,1993, which means back calculating each layer's module according to FWD test data and thickness of these layers, and then determining
milling thickness by reference to each layer's module. The second method is to

design the milling thickness based on experiences, representative deflection value of old pavement, design deflection value of overlay and Chinese standard Technical Specifications for Maintenance of Highway Asphalt Pavement (JTJ073.2-2001). This method obtains pavement structure strength index（SSI）according to representative deflection value of old pavement and design deflection value of overlay. Depending on different SSI values, different milling strategies are used. If SSI is very high, only functional recovery is applied after distress treatment. If SSI is high, the asphalt pavement surface is usually milled according to the type of distress. When SSI value is medium, the entire asphalt pavement should be milled. If base strength is deficient, the pavement needs to be milled to the bottom of the base. If the SSI value is poor, engineers mill the whole old pavement structure layers.

In the first method, non-destructive testing is often used to determine each layer's thickness. The FWD back calculated modulus is dynamic modulus which needs to be transferred to static one, so this method is inexact and only used by a few Chinese design unit. When it comes to the second method, if SSI is good and the pavement distress is mild, there is no need to mill the entire asphalt surface, as it will increase the construction cost. . However, how to make further deflection separation to determine whether to mill upper surface, middle surface, or the entire surface, , as well as determine optimum pavement milling thickness according to different pavement surface deflection are still a difficult problem in highway engineering. . Some Chinese and international experts suggest first mill part of the pavement (or a layer of pavement) and then do deflection test, which is not only time-consuming and tedious ,but also could not be accepted by design as well as construction unit.

Consequently, considering the difficulty in controlling milling thickness of old asphalt pavement, it's necessary to propose old asphalt pavement milling criterion based on the old pavement surface deflection control by theoretical analysis, which will provide scientific basis to old pavement milling thickness determination as well as overlay design.

1. Old Asphalt Pavement Milling Thickness Determination

According to the calculation formula of SSI（SSI = l_T/l_s）given in the Chinese Standard Technical Specifications for Maintenance of Highway Asphalt Pavement (JTJ073.2-2001), , the level of representative deflection value l_s can be determined by design deflection value l_T. If l_s is superior, medium or poor, the pavement will be treated accordingly using functional recovery, whole surface milling or whole structure layers milling. In the next paragraph, back calculation method is used to analyze how to determine reasonable surface milling thickness on the basis of design deflection value as well as representative deflection value.

Assume that old pavement milling thickness as well as the maximum overlay asphalt thickness is known, which means the thickness of asphalt overlay is determined. Then, based on overlay design modulus and design deflection value,

back calculate the old road modulus after old pavement milling that meets design requirements and to determine old surface representative deflection value after old pavement milling. However, if the old road modulus after old pavement milling or old surface representative deflection value is known, old asphalt pavement milling thickness meeting corresponding design requirements could be obtained. Because old surface representative deflection value is often tested, deflection value after old pavement milling could not be used as control criterion. If there is relationship between deflection before and after old pavement milling, or there is relationship between deflection before milling and old road modulus after milling, old road representative deflection before milling can be determined by old road deflection or modulus after milling. , This old surface representative deflection value can then be used as control criterion. Therefore, the key of milling design criterion determination is to establish relationship between the deflection before and after old pavement milling, or between the deflection before old pavement milling and the old road modulus after old pavement milling.

2 Analysis of the Change Law of Deflection Before and After Old Pavement Milling

2.1 Orthogonal test calculation

Orthogonal design has advantages such as homogeneous dispersion and unified comparability. If appropriate experimental quantity is designed, the results will be more homogeneous and of a broad range. Consequently, in order to determine the relationship between deflection before and after old pavement milling more properly, orthogonal test analysis method is used. The old asphalt pavement structure is divided into two layers: asphalt surface course as well as base course (those beneath the surface course are equivalent to base), and their Poisson's ratios are 0.25 and 0.3, respectively. Meanwhile, assume that it's half-continuous and half-smooth between surface course and base, and the old pavement has no crack. Then, in the range of variation, four typical levels of modulus of surface course, equivalent rebound modulus of basis, and the thickness of asphalt surface course are selected. When pavement milling thickness is during 4～8cm, the thickness of old asphalt surface course is generally around 4～8cm; while milling more than 8cm, the thickness of old asphalt surface course is generally around 15～18cm. Therefore, the thickness of old asphalt surface course should changes with milling thickness.

According to the table 1, there are 3 varying factors and every factor has 4 numerical levels. Then, to establish orthogonal test table L16 (4^5), , the old road deflection before and after old pavement milling when milling 4cm、6cm、8cm、10cm、12cm are calculated based on multi-layer elastic system theory (the total of thickness of upper and middle surface course is generally no more than 12cm）

Table 1. Calculation Parameter of Pavement Structure

Influence factors	Levels			
	Level 2	Level 3	Level 4	Level 5
（milling between 4～8cm） old asphalt surface course thickness (cm)	10	12	15	18
（milling more than 8cm） old asphalt surface course thickness (cm)	15	16	17	18
modulus of asphalt surface course (MPa)	800	1000	1200	1400
equivalent rebound modulus of base course (MPa)	100	200	300	400

2.2 Results analysis and deflection correlation

In order to establish the relationship between deflection before and after old pavement milling more accurately, SPSS statistical software is applied to analyze the correlation between different data sets, including deflections and their differences before and after milling, and the percentage of deflection increase after milling. The results showed that the deflection before and after milling correlates very well , with R^2 values 0.96 or higher, as given in Figure 1 and Table 2.

According to Figure 1, deflections before and after milling are further treated separately through linear regression fitting and exponentiation regression fitting.

As shown in Figure 1, when the deflection values before and after milling are small, their differences are also relatively small indicating the little effect of milling. . Table 2 indicates that exponential correlation gives a better fit for the deflection relationship before and after milling, and such correlation is recommended for future calculation. . If milling thickness is different from those given in table 2, the deflection before milling can be determined by linear interpolation.

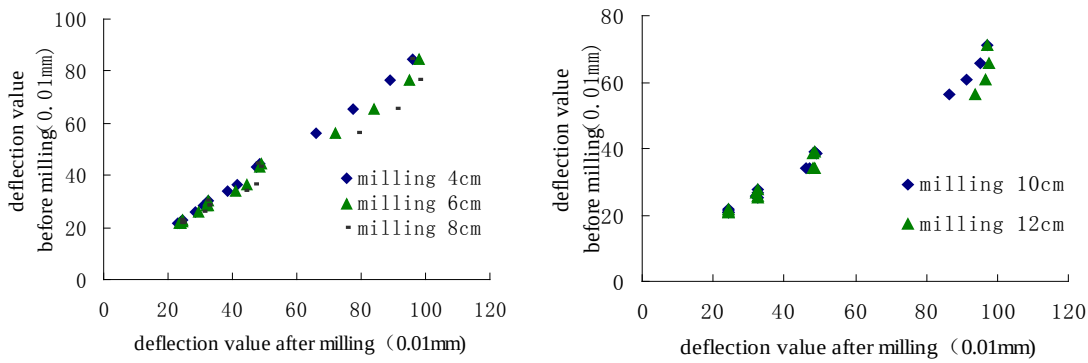

Figure1. Change of the Deflection Before and After Old Pavement Milling

Annotation: l' means deflection before milling, l means deflection after milling.

3. Correlation Between Deflection Before Milling and Old Road Equivalent Rebound Modulus After Milling

In order to establish correlation between deflection before milling and old road equivalent rebound modulus after milling, the correlation equations between deflection before and after milling in Table 2 could be utilized. , Then these correlation equations of deflections and the prediction equation of modulus as given in the highway asphalt pavement design criterion (JTG D50-2006): $E_t = 1000\dfrac{2p\delta}{l_0}m_1m_2$ should be combined. However, other research shows that this equation has some uncertainty and it changes with environment and structure. Therefore, to make correlation equation between deflection before milling and old road equivalent rebound modulus after milling more representative, and to make milling design process more simple and cost effective, it is necessary to analyze deflection before milling and old road equivalent rebound modulus after milling from theoretical aspect, and explore correlations between them.

In order to conduct the structural analysis, old asphalt pavement structure is divided into two layers: asphalt surface course and base (those beneath the surface course are equivalent to base), and their Poisson's ratios are 0.25 and 0.3 respectively. Furthermore, it is assumed that the interface between the surface and the base course is half-continuous and half-smooth, and the old pavement has no crack. For the determination of parameters, , uniform test analysis method is used to ensure a reasonable development of the equations because this method makes

parameters more homogeneous and dispersed, and it is suitable for establishing regression equations between calculation results and parameters. Then, in the range of variation, seventeen typical levels of modulus of surface course and equivalent rebound modulus of base course are selected to calculate deflections before milling when milling thickness varies from 2 to 14 cm. Finally, the relationship between surface deflection and the equivalent rebound modulus of base course is established.

Using SPSS statistical software to analyze data in Table3, it can be found that exponential equation gives the best fit between surface deflection and equivalent rebound modulus of base course. Therefore, the exponential fitting is used to correlate deflection under different asphalt course thickness to old road equivalent rebound modulus after milling (see Table3). If milling thickness is different from those mentioned above, linear interpolation can be used to determine deflection before milling

Table3. Regression Fitting of the Deflection Before Milling and the Rebound Modulus After Milling

4 DETERMINE MILLING THICKNESS CONTROLLED BY DEFLECTION

4.1 Milling design criterion controlled by deflection

(1) Determine the maximum old pavement surface representative deflection l_1 suitable for direct overlay

According to pavement elevation, determine the maximum thickness h_1 and design modulus E_1 which are suitable for direct overlay. Combined with the design deflection l_0, the old pavement surface minimum rebound modulus E_{t1} suitable for direct overlay can be back calculated using the overlay design method, (from

regression equation The old pavement surface maximum representative deflection l_1 suitable for direct overlay can then be determined based on the regression equation $E_t = 1000\frac{2p\delta}{l}m_1m_2$. Figure 1 shows that, when both the design deflection of old pavement and overlay thickness are small, the old pavement surface maximum and representative deflection l_1 of direct overlay is similar to the design deflection l_0, and they can be considered as equal.

(2) Determine the old pavement surface maximum representative deflection l_2 before milling top layer

First, determine the maximum thickness of overlay $h_2 = h_1 + h_t$ and design modulus E_2 (when the pavement is multi-layer, the design modulus is more than one), where h_t is the thinkness of milling top layer. Combined with design deflection l_0, the old pavement surface minimum rebound modulus E_{t2} before milling top layer can be back calculated. The old pavement representative deflection l_2 before milling top layer can then be determined according to Table 3.

(3) Determine the old pavement surface maximum representative deflection l_3 before milling both top and middle layer

First determine the maximum thickness of overlay $h_3 = h_1 + h_t + h_m$ and design modulus E_3 (when the pavement is multi-layer, the design modulus is more than one), where $(h_t + h_m)$ is the thickness of milling both top and middle layer Combined with design deflection l_0, the old pavement surface minimum rebound modulus E_{t3} before milling both top and middle layer can be back calculated. The old pavement representative deflection l_3 before milling both top and middle layer can then be determined according to Table 3.

(4)Determine the old pavement surface maximum representative deflection l_i before milling some layer

The maximum overlay thickness $h = h_1 + h_i$ and the design modulus E (when the pavement is multi-layer, the design modulus is more than one) are first determined when the milling thickness is unknown (h_i =2cm、3cm、4cm…). Combined with design deflection l_0, the old pavement surface minimum rebound modulus E_{ti} can be back calculated. Finally according to Table 3, the old pavement representative deflection l_i before milling some thickness can be determined.

(5) Determine milling thickness based on deflection control

If the pavement condition with respect to surface deflection is excellent, perform functional recovery.

If the old pavement surface representative deflection $l \le l_1$, the pavement distress is not treated and an overlay asphalt layer can be placed directly.

If the old pavement surface representative deflection $l_1 < l \le l_i$, mill the pavement to the bottom of h_i, and overlay asphalt layer.

If the old pavement surface representative deflection $l_1 < l \le l_2$, mill the pavement to the top layer, and overlay asphalt layer.

If the old pavement surface representative deflection $l_2<l\leq l_3$, mill the pavement to the top and middle layer, and overlay asphalt layer.

If the old pavement surface representative deflection $l>l_3$, and the deflection assessment ranking is good, overlay asphalt layer after all asphalt layers are excavated.

If the assessment ranking of the old pavement surface representative deflection is medium, mill all asphalt layers, excavate part or all base, meanwhile, add flexible or semi-rigid reinforcement layer,, and then overlay the asphalt layer.

If the assessment ranking of the old pavement surface representative deflection is poor, the whole pavement structure should be replaced.

Above are the milling thickness design criterion based on deflection control. In practical engineering application, it is suggested including pavement distress consideration into the milling thickness design.

4.2 Analysis Example

The deflection control milling thickness design is further explained using a Northwestern Expressway project as design example.

The old pavement structure includes a 4cm medium-grained asphalt concrete, a 5cm coarse-grained asphalt concrete, a 7cm hot mix asphalt macadam, a 20cm cement stabilized macadam base, and a 35cm lime-stabilized soil subbase. The design deflection of this old pavement rehabilitation project is 29.3 (0.01mm）. The direct overlay thickness is 4cm, and the design modulus is 1200MPa. It is assumed that the overlay material and the thickness after milling surface layer are the same as the old pavement. The design modulus of adding top layer after milling top layer is 1200 MPa, the design modulus of adding middle layer after milling middle layer is 1000 MPa, and the design modulus of adding lower layer after milling lower layer is 800 MPa.

According to step (1), the old pavement surface maximum representative deflection, which is directly overlaid, is determinated. As to this expressway, both the design deflection of old pavement and overlay thickness are small, so take l_1 as 29.3 (0.01mm); According to step(2), the old pavement surface maximum representative deflection before milling top layer can be determined, l_2 = 30.0(0.01mm). According to step(3), the old pavement surface maximum representative deflection before milling top and middle layer can be determined, l_3= 32.6 (0.01mm）. Then, based on the calculation formula of pavement strength evaluation and structure strength index, SSI=pavement surface design deflection / pavement surface representative deflection, the pavement surface representative deflection for different pavement condition and different highway classification can be calculated, as shown in table 4.

Table4. Assessment Ranking Range of the Surface Deflection

standard	excellent	good	medium	poor	bad

highway grade	expressway, first-class highway	expressway, first-class highway	expressway, first-class highway	expressway, first-class highway	expressway, first-class highway
deflection（0.01mm）	<29.3	29.3～35.3	35.3～44.4	44.4～58.6	>58.6

Therefore, the milling design standard can be determined according to the deflection:

If the old pavement surface representative deflection $l \leq 29.3$(0.01mm），no surface treatment is needed, and only direct asphalt overlay or functional recovery is considered.

If the old pavement surface representative deflection 29.3 (0.01mm）$< l \leq 30.0$ (0.01mm）, mill the top layer, and overlay asphalt layer.

If the old pavement surface representative deflection 30.0 (0.01mm）$< l \leq 32.6$ (0.01mm）, mill the top and middle layer, and overlay asphalt layer.

If the old pavement surface representative deflection 32.6 (0.01mm）$< l < 35.3$ (0.01mm）, and the deflection assessment ranking is good, overlay asphalt layer after all asphalt layers are excavated.

If the old pavement surface representative deflection 35.3 (0.01mm）$\leq l < 44.4$ (0.01mm）, mill all asphalt layer, excavate partial or the entire base, meanwhile, add flexible or semi-rigid reinforcement layer, and then overlay asphalt layer.

If the old pavement surface representative deflection $l \geq 44.4$ (0.01mm）, replace the whole pavement structure. It is suggested that make the milling criterion further determined, considering pavement disease.

5. CONCLUSION

This paper aims to determine the milling thickness of old asphalt pavement based on old pavement surface deflection. According to the calculation results, the design criterion of old asphalt pavement milling thickness based on pavement surface deflection control is proposed. The example indicates that this criterion is simple and reasonable, which has good practical value. It can provide the basis for the determination of asphalt pavement milling thickness and the design of asphalt overlay. In practical engineering application, it is suggested including pavement distress consideration into the milling thickness design.

ABSTRACT

This analysis is based on a highway project in Guangdong province, involving a tall, steep, and rock-excavating slope with cataclastic structures. Quantitative analysis of the stress-strain trend, possible failure models and safety factors during the slope excavation were investigated by the discrete element program UDEC. The following results were obtained: (1) The slope with joint fissure developed was in anticlinal core and the stability was greatly influenced by the extroversion of rock level. (2) The primitive balance of the slope was broken during the excavation, which induced large range shear failure zone in the internal part of the slope, and the whole circle-broken similar to soil slope appeared. (3) The excavation slope was in a critically stable state, but wide area landslide could be induced by certain triggering factors. Based on these results, a comprehensive treatment scheme was adopted and implemented through the methods, such as reinforcing the broken rock with concrete lattice beam-anchor (cable); minimizing erosion and preserving the slope strength with an efficient drainage system; and protecting the slope with grouted rubble. The integrity of the high standard highway was maintained and the slope was reinforced during time the plan was carried out.

INTRODUCTION

During the construction process of high-level highways in mountainic areas, cutting slope with a cataclastic structure is always a challenge. At present, the inadequate understanding of the deformation and damage laws of this kind of slope, together with lack of quantitative analyses on the validity during designed anchors, result in the increase of invalidity cases (Song et al 2003, Luo et al 2004, Quan et al 2004, Yu et al 2005). The tall and steep slope excavated, from K93+946 to K94+082 of S223 highway in Guangdong, is located at the middle and lower reaches of the Mei Jiang River. This section belongs to friable and brittle rock excavating slope, over 100 meters high, steeply gradient. There is a power station downstream of the slope, and the distance between power station and the slope is 100 meters approximately. It is possible that a large-scale global landslide would occur under certain triggering factors, which is a great threat to the highway, power station and reservoir downstream. Therfore, it is urgent to find a reliable reinforcement scheme.

Based on the results of engineering geological investigations, a possible destruction pattern during excavation was analyzed by UDEC, and the relative safety factor was calculated. Finally, a specific reinforcing scheme was proposed.

ENGINEERING GEOLOGICAL CONDITION

According to geological conditions of this region, the slope is under the impact of the northeastern regional normal fault and the northwestern regional reverse fault, with original vertical fissures developed, easily weathered superficial zone. Rock strata are intensively cracked under the pressure. The rock masses are mainly made up of flagstone, and partly grooved of thick-bedded easily weathered mulberry sandstone, which are generally inclined to the inside of the slope. Under the impact of long-termed weathering, part of the shallow rock is inclined to the outside of the slope with a low-pitched inclination of NE315°~345°∠9°~30°. The main attitudes of the rock masses are composed of ① NE5°~24°∠7°~21°, ② NE105°~145°∠59°~80°, ③ NE150°~170°∠5°~24°. The rock masses were cut into fragments with the length of 10~20 centimeters by the bedding surface and joint plane, and is approximate to the loose cataclastic structure. The main types of the groundwater are loose rock pore water and base rock fissure water. The groundwater varies with seasons, and often springs out especially in rainy seasons.

STABILITY ANALYSIS

Numerical simulation analysis. The original design scheme of the slope is shown as Fig.1. The excavation height is 66.19 meters with 9 steps. The gradient of the two lower steps is 1:0.5 and the others are 1:0.75. Each step is 8 meters high with a one-meter-width bench. In order to simulate the effects of fractional excavation and the impact of rainfall (annual rainfall is 1400~1700mm), the program of UDEC3.1 (Cundall 1987) was used to investigate changes of the stress and strain state of the slope during excavation under conditions of gravity, and gravity plus rainstorms. Moreover, safety factors of the above two conditions were calculated using the Geo-slope program.

Numerical model and parameters. According to the observed data, the typical section K94+005 was chosen as the calculated cross section and the slope numerical model using discrete element method is established in Figure 2. The thickness of the rock strata is 0.1~0.3m with an inclination of 15°. The distance of each joint is 1.5m with an inclination of 59°~80°. The boundary of the left- and right-hand sides is fixed from movement in horizontal direction and the bottom boundary is fixed from movement in both vertical and horizontal directions. A large deformation mode has been adopted and the constitutive relations of rock masses are assumed to be a Molar-Coulomb model. The physical mechanical parameters are determined based on the results of the geological survey, degree of crushing and weathering of the rock masses, and engineering experiences. The parameters are shown in Table.1.

Table 1. Rock Mechanical Parameters.

Rock mass	Gravity	Cohesive Strength	Internal friction angle	Young's modulus	Poisson's ratio	Tangent stiffness	Normal stiffness
	ρ /g.cm^{-3}	C /kPa	φ / ^{0}	E /MPa	μ	K_s/kPa.m$^-$	K_n/kPa.

						^{1}	m^{-1}
Sandstone	2.5~2.6	20~80	23~40	35000	0.23	-	-
Jointing	-	0~50	20~25	-	-	1×10^{6}	10×10^{6}

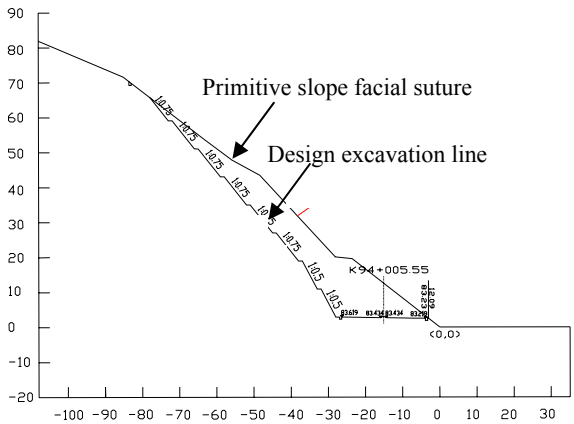

Figure 1. The typical profile of slope excavation scheme.

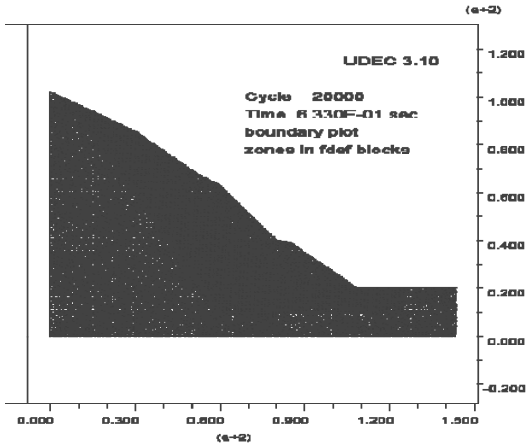

Figure 2. Discrete element model of the slope section.

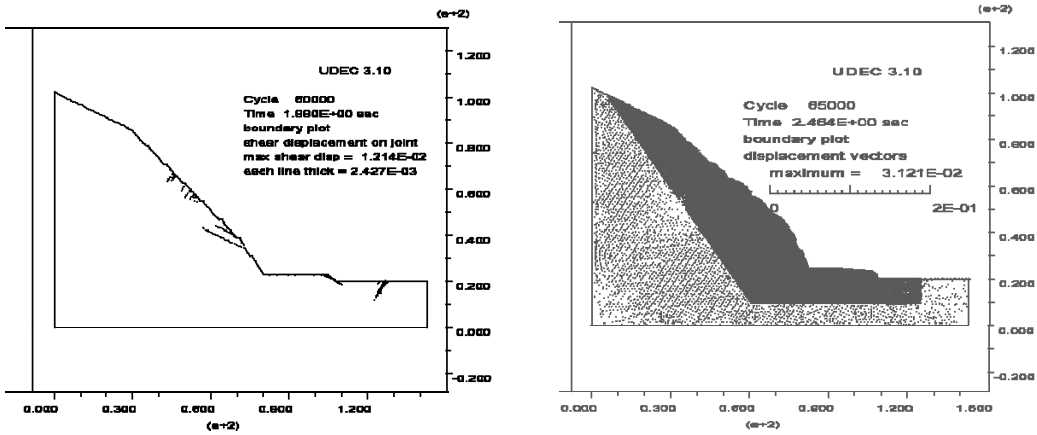
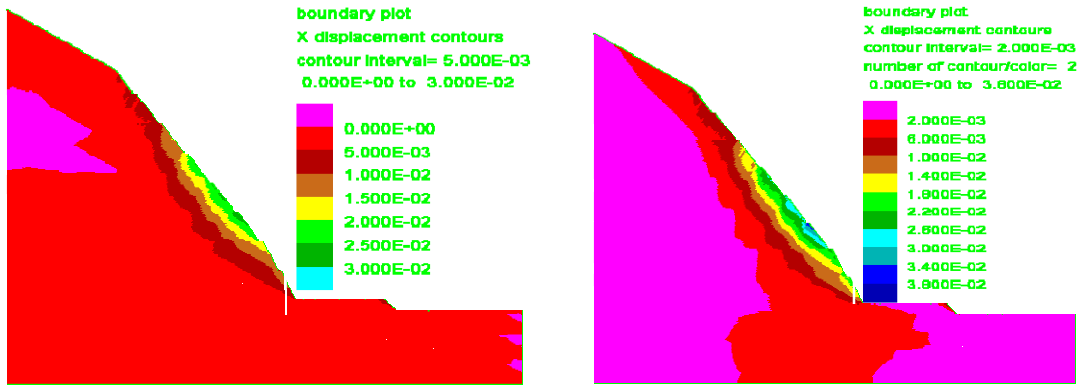
Results analysis. According to the simulation of UDEC, the stress and displacement results for before and after slope excavation are shown in Figure 3. The geo-stress of the natural slope is uniformly distributed and tensile stress only partly shows on the slope surface. With the process of the excavation, the slope stress field changes visibly. The excavation volume is considerable because of the great excavation height. Under the influence of pressure, the stress near the surface is greatly reduced and the principal stress trajectory is deflected. Moreover, tensile stress is shown not only at free face but also at the slope crest. Stress concentration emerges at the slope free face and the slope toe where the maximum principal stress is increased significantly while the minimum principal stress decreased. The minimum principal stress is translated into tensile stress which results in the compressive tension face parallel to the slope.

According to Figure 4 (a), the slope deformation is concentrated at the middle of the slope after excavation and a series of fissures, as well as continual slip (failure) planes are found at the slope. The slip plane is similar to an arc and the maximum displacement is 30mm. This situation is mainly related to the abundance in joint fissures and serious weathering; the entire slope can be assumed to be a cataclastic texture which is appropriate to soil. According to Figure 4 (b), the horizontal displacement has increased with the maximum displacement of 38mm under the conditions of gravity plus rainstorms, which means an increase of 26.67%, compared to that based on conditions of gravity only. The comparison result indicates rainstorms directly influence the stability of the slope; thus drainage should be seriously considered in the slope design.



(a) Shear deformation **(b) Displacement vector**

Figure 3. Slope stress and displacement after excavation.



(a) Natural state **(b) Condition of gravity plus rainstorm**

Figure 4. Horizontal displacement comparison.

Stability Evaluation. According to the results of the UDEC program, the sliding slope appeared to be in a curved shape, similar to **that for a** soil slope. The Geo-slope program was used and the Morgenstern-Price method was adopted in the analysis. The physical mechanical parameters are shown in Table 1, and the calculated results are presented in Table 2. The safety factor calculated by Geo-slope program was appropriated to the value calculated by the UDEC.

Table 2. Safety Factor under Different Condition.

Operating mode	Before excavating	After excavating completes	
	Condition	Condition	Condition of gravity plus Rainstorm
Safety coefficient	1.205	1.049	0.964

Before excavation, the safety factor of the slope is 1.205 and the slope is stable. After excavation, the safety factor is only 1.049 under the condition of gravity, which puts the slope basically in critical state. Adding the effects of heavy rains, the factor of safety further decreases to only 0.964, which indicates that the slope is

unstable. The underground water has a great influence on the stability of the high and steep slopes of cataclastic structures along with weathering and rainfalls. The stability level would be quite low if excavated according to the original design and large scale landslides could occur under certain negative conditions. Thus, reinforcement work must be done.

SLOPE REINFORCEMENT SCHEME

At present, even though engineers have obtained much experience in reinforcing slopes, there are still many uncertainties surrounding various conditions such as tall and massive excavation, steep slope, seriously rock mass weathering, potential slip plane, land restrictions, and engineering cost, etc. All of these require that the slope surface excavated according to the original design be well maintained. Moreover, the abundant rainfalls make it even more difficult to maintain the stability of the slope. In order to maintain the slope's long-term effectiveness and cost efficiency, scientific analyses of reinforcement effects are required for the actual situation. Based on full research and analysis on the formation of structures, trends of distortion and damage, and other factors affecting the stability, the following comprehensive reinforcement schemes were proposed through numerical experiments and simulations, as shown in Figure 6.

Water control before slope improvement. Intercepting ditches should be set at about 5 meters away from the top of the cutting and at each of the slope benches. Drains should be set on both sides of the slope, and roadside ditches should be set at the toe of the slope, all of which form a storm sewer system that can drain storm water quickly, thereby preventing the erosion or build up of the hydrostatic pressure on the slope.

Reinforcing toe of the slope. Stress is typically concentrated the most at the toe of the slope, which could cause instability. Accordingly, a reinforced concrete lattic frame beam-anchor bar (cable) is proposed to strengthen the first step of the slope. The anchor is made of full-bond cement mortar and the designed withdrawal resistance is 60kN. The anchored force can be enhanced through second-time high pressure grout. Part of the rock mass that has inferior stability is grouted with cement mortar in order to improve its shear strength and to enhance the sliding resistance of the toe of the slope.

Strengthening slope waist. Because of the high and steep excavation, the slope is highly likely to be unstable under the adverse factors. Thus, the reinforced concrete lattic frame beam-anchor bar (cable) should be applied to the 2nd, 3rd, 5th, and 6th steps in order to enhance the global stability. The total length of anchor cable is 24.0~31.0m in which the length of the anchorage is 10.0m; the designed tension and the lock tension can be reach to 550kN, 600kN respectively through the second-time high pressure grouting.

Slope protection. In order to prevent instability of the slope and reinforce the cataclastic rock mass, the reinforced concrete lattic frame beams-anchor bars

(cable) are also applied to the 4th, 7th, and 8th steps. The anchor is a kind of full-bond cement mortar and second-time high pressure grouting. The anchor's designed tensions for the 4th, 7th and 8th steps are 90kN, 90kN, and 60kN respectively. The M10 mortar rubble masonry pavement of 0.4m thick is applied to the 9th step and both sides of each step. The slope benches adopt M7.5 mortar rubble masonry pavement of 0.3m thick. Moreover, the slope surfaces are protected by grass with six rows of brick, which can prevent slope erosion, rainfall seepage and maintain stability of the slope.

The safety factor for the K94+ 005 section is improved to 1.297 and 1.264 under the conditions of gravity, gravity plus rainstorms respectively through the above measures, which satisfies the design code.

CONCLUSION

The UDEC program can be well utilized to analyze the change of stress and strain during excavation of the cataclastic structure slope. According to the simulation results, mechanism of the damage, stability evaluation, and prediction can be used to optimize design and information-based construction.

If the original design approach is implemented, numerical results indicate that large-scale shear plastic area will occur and the failure plane appropriates to be an arc; the factor of safety is only 1.049 under the condition of gravity, which indicates that the slope is in critical state. Considering the additional adverse effects from heavy rains, the slope will be unstable. Thus reinforcing work needs be done.

The comprehensive reinforcing scheme includes the lattice beam-anchor (anchor cable) system, slope waist strengthening, slope protection, and a proper storm sewer system. It helps satisfy the integrity of a highway through reinforcing the stability of the slope. This reinforcing scheme can be used as a reference to similar rock slope engineering work.

ABSTRACT

Although cracking-seating technology has been applied to engineering practices successfully, the mechanism of this technology in preventing reflective cracks is not very clear yet. This article starts with the expansion mode of reflective cracks, then goes on to study the redistribution of load stress in the fragments by using fracture mechanics theory and finite element methods. By framing analysis model with the method of ANSYS, the article analyzes the change of shear stress and tensile stress in the construction process and reveals how cracking-seating technology can reduce reflective cracks, vehicle load stresses and alleviate the stress concentration in the overlay effectively.

INTRODUCTION

The cement concrete pavements in our country have shown damage to various degrees, among which reflective cracks have been an ever-harassing problem for the highway department. Now the highways in some provinces and cities have entered the stage of conservation and maintenance. So how to conserve and repair damaged roads effectively is the key point in improving the service property and prolonging the lifespan of the roads.

There are many ways for transforming cement concrete pavements, but how to reduce reflective cracks after the transformation effectively is a technical problem. Engineering practices at home and abroad have proved that cracking-seating methods can restrain the emergence and development of reflective cracks.

In the cracking-seating technology, Impact Rollers are used to impact the pavement with low-frequency and high-amplitude vibrations and thus crack the original cement concrete pavement into small-scale fragments of various sizes. In this way the spacing at the bottom of the original cement panel can be eliminated and excessive displacement of the plate which occurs when it is under vehicle loads can

be avoided. On the one hand, this technology enables the usage of the strength of the original concrete; on the other hand, it can reduce waste and thus save the construction investment, which meets the requirements of environmental protection.

THE DEVELOPMENT OF REFLECTION CRACKS

The fact that reflection cracks appear in the asphalt surface when the cement concrete pavement has been modified is mainly caused by the existence of cracks or joints in the original cement slab. According to fracture mechanics, the joints exist in the old cement concrete pavement as original defects, and the tensile stress and shear stress cause stress concentration at the joints, which results in the emergence and expansion of cracks. The vehicle loads will cause shear-type reflective cracks in the added layers. Under partial vehicle loads the deflection and margin of the cracks at the joints will be so increased that it causes the shear destruction of the added layer. The cracks in the joints are shown in Figure 1 and reflective cracks in overlap are shown in Figure 2.

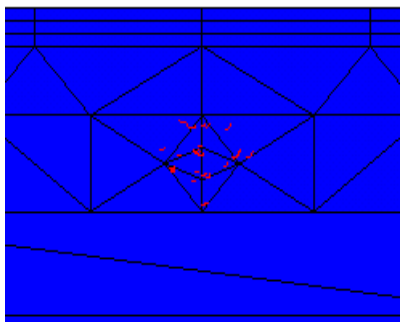

Figure 1. Fracture distribution in the joints

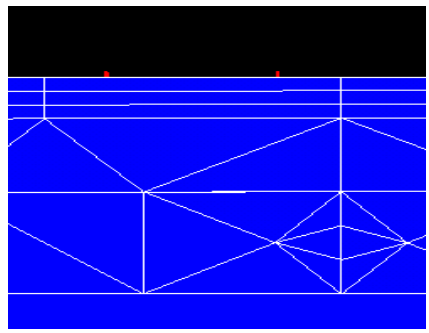

Figure 2. Reflection cracks in the overlay

From all the results above, we can conclude that the main reason for the emergence of reflection cracks is that the stress will be concentrated and accumulated when the joints are under the pressure of vehicle loads, and the repeating vehicle loads will have the cracks reflected to the surface. In Figure 1, the cracks concentrate at the seams of the concrete, and in Figure 2, the cracks are reflected to the surface.

THE MECHANISM OF CRACKING-SEATING TECHNOLOGY

ANSYS finite element methods are adopted to analyze the change of the stress and strain in the joints of cement concrete when cracking-seating technology is applied to old cement pavements.

Model

For the cement concrete pavement, the unit of solid concrete 65 will be chosen and for the grass-roots and soil the unit of solid 45 will be chosen. And the assumptions will be made as follows:

(1) Each structural layer is made of homogeneous, continuous, isotropic, and

linear elastic materials;

(2) The layers are completely and continuously connected with each other;

(3) Interactions between layers are to be taken into consideration.

(4) The overall model: cement board 5m×4m×0.25m, grass-roots 35m × 28m × 0.30m , soil 35m×28m×20 m;

(5) The grass-roots and soil are constrained from all directions while the cement concrete pavement is free from constraint.

The schemes of the units are shown in Figure3, and the schemes of the impact roller position are shown in Figure 4.

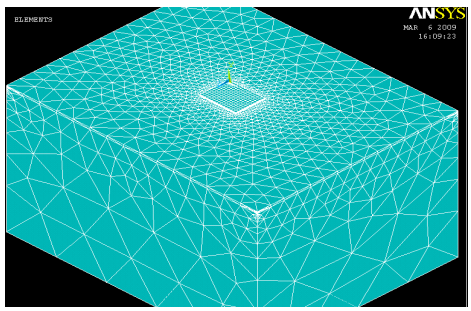

Figure3. Schemes of the units.

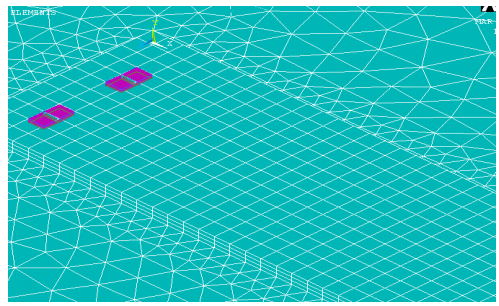

Figure 4. Schemes of the impact roller position.

STRUCTURE ANALYSIS

The development of cracks

In the process of construction, it can be found that when the impact wheel is walking along the central line of the panel, the transverse cracks appear more while the longitudinal cracks develop faster. With the times of impact compaction increasing, the longitudinal cracks begin to appear throughout the panel when it is impacted for the 2nd time. When the loads are on the edge of the plate, the cracks develop from the top to the bottom, forming the longitudinal cracks. When the loads are on the central part of the plate, the cracks will be reflected from the bottom to the top, forming the transverse cracks. The distribution of cracks in the plate and the relationship between tensile stress and compaction times are shown in Figure 5 and Figure 6, respectively.

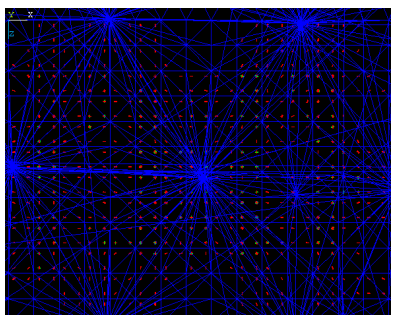

Figure 5. The crack distribution after impact.

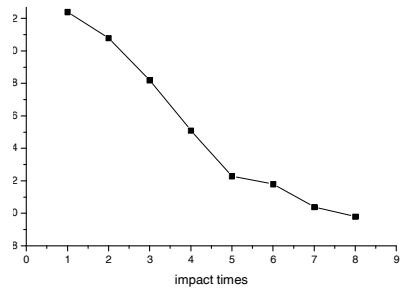

Figure 6. The tensile stress change with compaction times.

Processed by the cracking-seating technology, the cement concrete panels are cracked into small pieces. In this way, all the pieces of the cement fragments can bear the vehicle loads together, which will alleviate the stress concentration at the seams of the cement concrete panels. The stress in the plate under vehicle loads will be reduced as shown in Figure 6, which can be explained as stress release.

MECHANISM OF PREVENTING REFLECTIVE CRACKS

The stress in cement plate before impact

By analyzing the whole process of cracking construction, we can find that before impact stress in the juncture of the plate is concentrated with a maximum shear stress of 0.4MPa and a minimum of 0.025MPa, as shown in Figure 7. The tensile stress in the asphalt concrete layer concentrates at the top of the cement concrete board (which is also the bottom of the asphalt layer) with a maximum of 0.94MPa, as shown in Figure 8. Thus the asphalt surface is easily cracked by the action of repeating vehicle loads and reflective cracks develop. Figure 9 shows the curve of shear stress changing with load position, and Figure 10 shows the curve of tensile stress changing with load position.

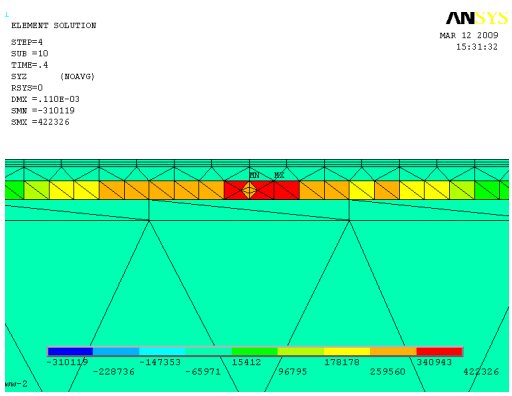

Figure 7. Diagram of shear stress under vehicle loads before cracking.

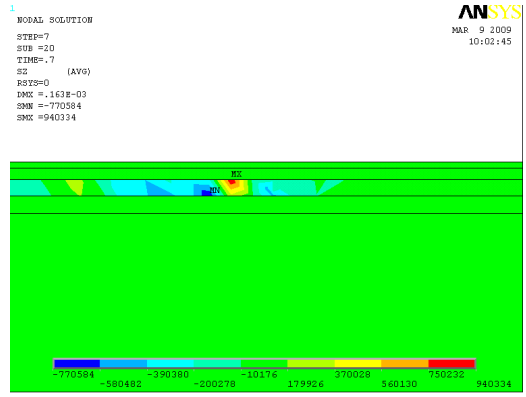

Figure 8. Diagram of tensile stress under vehicle loads before cracking.

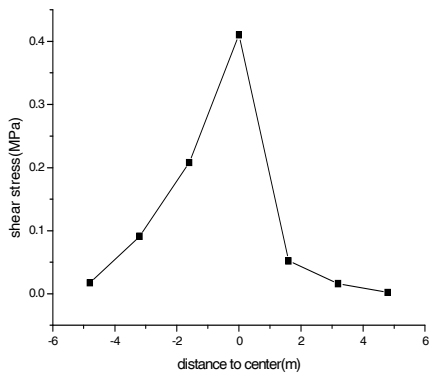

Figure 9. The curve of shear stress changing with load position.

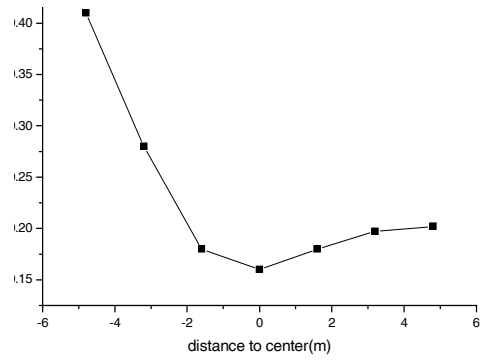

Figure 10. The curve of tensile stress changing with load position.

It is shown in Figure 9 that the shear stress in the seams changes with load position. When the load is at the joint, the value of shear stress is at its largest of 0.4MPa. Figure 10 shows how tensile stress at the bottom of the overlay varies with the change of load position. The tensile stress concentrates mainly upon the bottom of the overlay. Analyzing the stress distribution in the depth direction, we can find that the tensile stress exists in a zone of about one third the thickness of the cement concrete plate. The distribution of the tensile stress is consistent with the bending deformation of the plate.

The stress in the plate after impact

The tensile stress at the bottom after impact is given out in Figure 11, and the shear stress at the juncture after impact is given out in Figure 12.

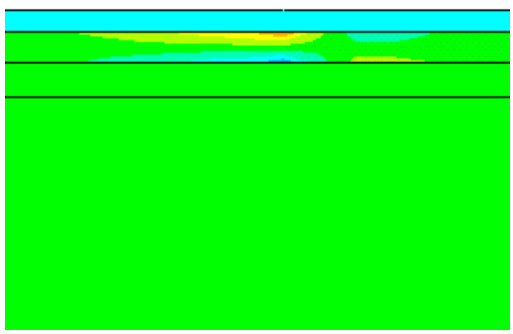

Figure 11. Tensile stress at the bottom after impact.

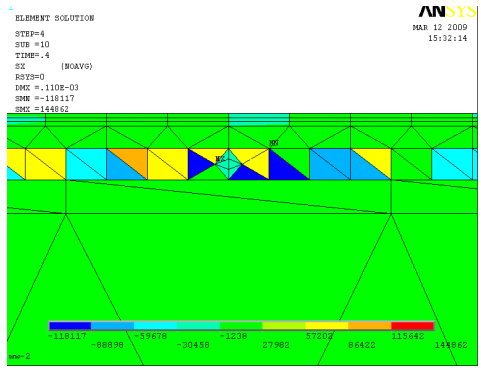

Figure 12. Shear stress at the juncture after impact.

After cracking, the maximum shear stress at the joints under vehicle loads is 0.15MPa, the tensile stress in the asphalt layer is 0.7MPa, and the stress distribution is comparatively even without just concentrating on the deflection joints. It shows that after cracking and seating the stress in the cement panel which is caused by vehicle loads will be reduced significantly. Moreover, comparing Figure 7 and Figure 12, we can see that before cracking the shear stress at the joints is more intensive while after cracking and seating more dispersive.

CONCLUSION

Cracking-seating technology can effectively reduce the emergence and development of reflection cracks. This article is based on using ANSYS to analyze the shear stress and tensile stress before and after the pavement is cracked, then comes to a conclusion that the cracking-seating can reduce reflective cracks effectively :

(1) Owing to the redistribution of the stress in the cement concrete panel, the tensile stress at the bottom and shear stress at the juncture which are caused by vehicle loads are obviously reduced;

(2) As the original cement board is cracked into small pieces, the stress

distribution is more even and the stress concentration is alleviated so that the development of reflective cracks is restrained effectively.

Abstract: Rutting and fatigue cracks have been common hazards for pavement with the development of traffic. The correlation of wheel tracking transverse distribution and pavement fatigue failure is studied in this paper to propose a new pavement maintenance method which changes wheel tracks transverse distribution after drivers' vision is intervened. This new method not only prolongs pavement fatigue life but also improves driving safety. Finite element models are established to analyze fatigue life of asphalt pavement in theory. Results show that this new method can prolong pavement service life by 10%-30% when wheel tracks are shifted 25-50cm.

Key words: pavement, vision transverse intervention, wheel tracks transverse distribution, fatigue life

1 Introduction

With the development of transportation in China and higher traffic volume, rutting and fatigue cracks become common hazards (Shen 2004; Zhang and Sun 2004). Currently, fatigue failures in high class highway have a lot to do with vehicle load and traffic channeling. Aiming at solving these problems, typical highways are surveyed and vehicle wheel tracks transverse distribution is studied, and then a method for highway maintenance based on drivers' vision intervention is proposed which will make vehicles stay away from its customary route to achieve a well-distributed vehicle load. As a result, anti-fatigue performance of pavement is exploited, service life of pavement is prolonged and driving safety is improved. It has offered a new method for pavement maintenance and management.

2 Traffic Survey and Analysis on Vehicle Wheel Tracks Transverse Distribution

2.1 Selection of Survey Highways

Vehicle transverse distribution is influenced by many factors such as highway cross section, types of pavement, lane width, traffic volume, traffic composition and driving habits, etc. However, it is stated in many documents (Fwa and Li 2007; Liu and Sun 2005) that vehicle transverse distribution still has a certain discipline under the influence of the factors above. Jiasong north highway located in Shanghai Jiading district and Jingfu freeway in Shandong province are selected as survey roads, seen in the table 1.

Table 1. Basic Information of Highways Surveyed.

Name	Number of lanes	Lane width	Class	Median strip
Jiasong north	4	3.75	first class	Yes
Jingfu	6	3.75	freeway	Yes

2.2 Survey Methods and Data Analysis

The pavement is divided into a number of strips before transverse distribution of vehicle tracks is surveyed. The narrower the strips are divided, the more accurate the result of tracks distribution is. But if strips are too narrow, it will be difficult to survey, so the width of the strip is assumed as 25cm considering 25cm grounding width for single tire and 50cm for double tires. Video camera is employed to shoot at appropriate cross sections for a relatively long time. Video datum is analyzed to get vehicle wheel tracks transverse distribution in laboratory.

2.2.1 Discipline of Wheel Tracks Transverse Distribution of Mixed Traffic.

For mixed traffic, video datum is analyzed to obtain the discipline of transverse distribution. Take Jiasong North road for example with the result shown in figue1.

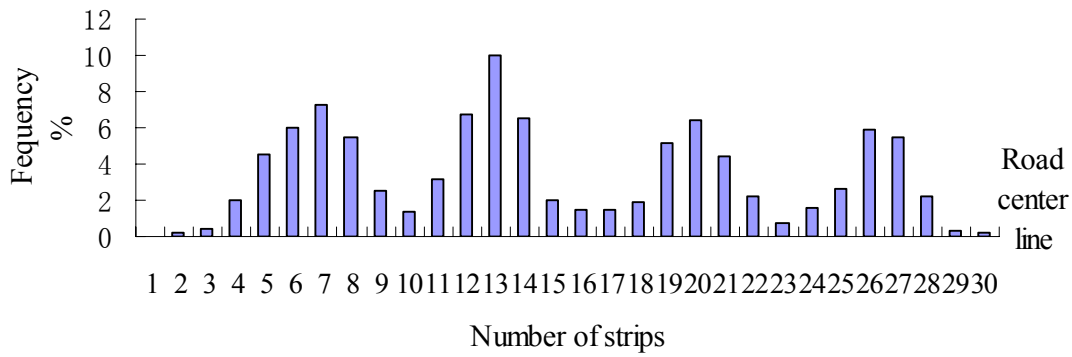

Figure 1. Vehicle wheel tracks transverse distribution for mixed traffic on Jiasong north highway.

From figure 1 it can be known that vehicle tracks are concentrated on just a few strips; more vehicles are distributed in slow lane than in traffic lane.

2.2.2 Vehicle wheel Tracks Transverse Distribution for Standard Axle Load

Damage to the pavement caused by small cars can be neglected when pavement

is designed (Ministry of Communications of the People's Republic of China 2004). When vehicles are converted into standard axle load, wheel tracks transverse distribution of Jiasong North highway is shown as figure 2 and distribution of various kinds of vehicles in different lanes in Jingfu freeway is shown in table 2.

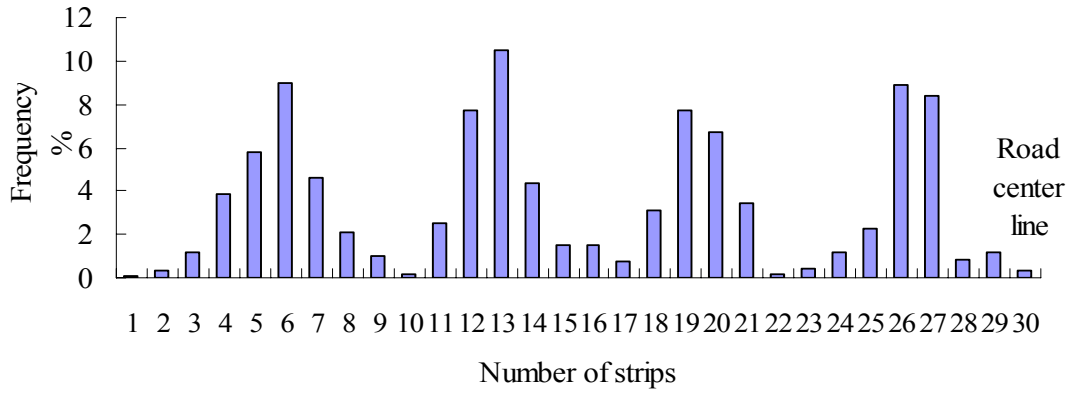

Figure 2. Vehicle wheel tracks transverse distribution for standard load on Jiasong north highway.

From figure 2, it is found that vehicle tracks transverse distribution is more concentrated.

Table 2. Proportion of various vehicles in different lanes of Jingfu freeway.

type of vehicle	slow lane	traffic lane	overtaking lane
special large trucks	0.41	0.48	0.11
large trucks	0.29	0.56	0.14
medium truck	0.38	0.52	0.10
large bus	0.38	0.30	0.33
small car	0.17	0.27	0.55

From the table above, it is known that trucks travel mainly in slow lane and traffic lane with small amount traffic in speed lane; large buses travel in good distribution; cars mainly travel in speed lane with a small amount in slow lane and traffic lane.

3 Principle of Transverse Intervention and Feasibility Analysis

3.1 Principle of Drivers' Vision Transverse Intervention

Basic conception about drivers' vision intervention is that when drivers' vision is intervened by traffic marking or mobile traffic signs, drivers will adjust traffic routes on condition that driving safety is guaranteed.

Documents reveal that with more than 80% of information coming from drivers' vision when driving (Yin et al. 2007)，drivers will adjust their driving behaviors according to what they have seen. If certain kinds of traffic markings or mobile

traffic signs are set up to intervene in drivers' behaviors to make vehicles stay away from its original routes, vehicle load distribution will be changed. The gap between peak point and low point of wheel tracks distribution is 50~100cm, see figure 3. A period after the highway is open, transverse intervention is applied, the peak point of vehicle load distribution is shifted to a position where vehicle load was once less concentrated which makes vehicle load distribution more even in the end. That is the basic principle of drivers' vision transverse intervention.

3.2 Feasibility Analysis for Transverse Intervention

Width of lane is related to highway class and design speed. According to Technical Standard of Highway Engineering (Ministry of Communications of the People's Republic of China 2004), width of lane is 3.75 m if design speed exceeds 80km/h.

According to the related traffic survey (see figure 1), there are more than 95% vehicles traveled within the width of 3.0-3.5m, so there is room for vehicle wheel tracks to be adjusted.

In Japan where traffic accident rate is among the lowest in the world, width of travel lane is 3.5m for high class highways, 3.0m for ordinary roads. Compared with that, 25cm can be adjusted for high class highways in China.

In addition, when traffic markings or signs are used to intervene in drivers' vision in this method without changing width of original lanes, the compressed space becomes fault-tolerance space. Through exploratory experience on freeways in some provinces in China, this method not only adjusts wheel tracks distribution but also warns drivers against fatigue driving to improve driving safety.

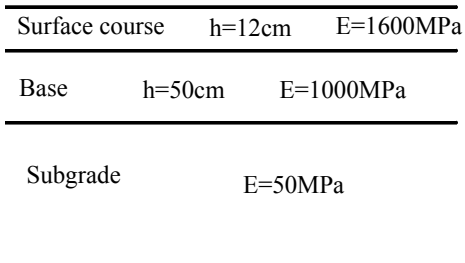
4 Finite Element Analysis of Asphalt Pavement Fatigue Life with Vehicle Load Shifting

4.1 Finite Element Model

Two-dimensional finite element model seen in figure 4 is established according to actual pavement structure shown as figure 3. The model length is 1000cm with a total height of 662cm including 600cm subgrade, 50cm base and 12cm pavement. Boundary conditions are: displacement of model bottom is zero, right boundary in direction X is zero and free in direction Y, left boundary is free in X and Y direction.

Considering both model size and loading method, 25*25cm square elements are employed in subgrade and base, 12*25cm rectangular elements are used in pavement.

Calculation reveals that the most vulnerable positions are the places where vehicle wheel tracks are most concentrated, i.e. the peak position of load distribution. The four points A B C and D are selected as fatigue failure calculating points on which vehicle wheel tracks are most concentrated, see figure 4.



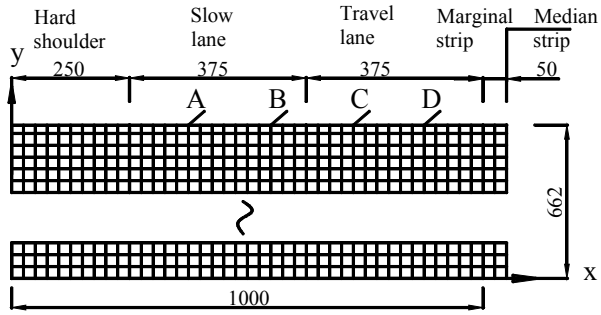


Figure 3. Pavement structure. **Figure 4. Pavement finite element model.**

4.2 Loading Combination and Loading Times Design

4.2.1 Loading Combination Design

After the highway has served for a period, vision transverse intervention is applied, as a result, vehicle wheel tracks are shifted reducing fatigue loss in the positions of A B C and D but increasing fatigue loss in the new positions where wheel tracks distribution concentrates. Based on the consideration above, when the loading times are applied for one half, loading positions are shifted, then the other half loading times are applied which will prolong the pavement service life without causing other points losing fatigue life more than the calculating points.

Loading positions are divided into: original position, shifting 25cm, shifting 50cm and shifting 100cm. Standard load which is 0.7Mpa is applied for 12million times in all. Loading combination cases are: 12million times on original position; 6million times on original positions+6million times shifting 25 cm; 6million times on original positions+6million times shifting 50cm; 6million times on original positions+6million times shifting 100 cm.

4.2.2 Loading Positions and Loading Times

For the convenience of load application, 50cm strips are employed to calculate loading distribution frequency which is used to calculate loading times in 15 positions according to total times, seen in Table 3. The repeated standard load is applied to their own positions according to the calculated times. After repeated load is applied for one position, fatigue analysis is carried out. The loading positions for the four cases are shown as figure 5.

Table 3. Loading Times in 15 Positions (ten thousand).

Total	Positions														
times	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
1200	3.6	61.2	180	80.4	14.4	120	180	36	46.8	168	43.2	19.2	138	98.4	10.8
600	1.8	30.6	90	40.2	7.2	60	90	18	23.4	84	21.6	9.6	69	49.2	5.4

Note：This table is used to calculate loading times in 15 different positions on condition that total loading times are 12 or 6 million. Loading for the four cases

should refer to this table.

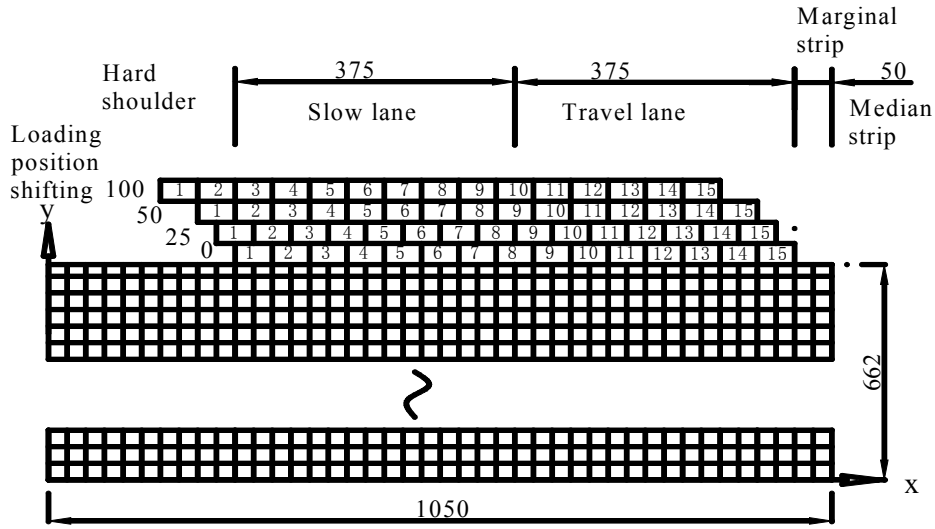

Figure 5. Loading positions (cm).

4.3 Performance of Asphalt Pavement Fatigue Failure

Properties of asphalt mixture fatigue failure vary greatly which are influenced by many factors, such as types of asphalt, porosity of concrete, asphalt content, variation of temperature, test methods, etc. Many scholars (Hugoet al. 2007; Insoo et al. 2008; Zheng et al.2005; Wang 2002.) have studied performance of asphalt mixture with diversified conclusions. Equation (1) is employed as basis in this paper to analyze fatigue life of asphalt pavement (Wang 2002).

$$N_e=N_f\times7\times40\times365/60/0.5=13.7\times10^6\times A_a\times A_g/A_c\times\sigma^{-4.17} \quad (1)$$

Where: N_f fatigue life in laboratory, $N_f = 4025\times A_a\times A_g/A_c\times\sigma^{-4.17}$

A_a coefficient of asphalt type

A_g coefficient of asphalt mixture

A_c coefficient of highway class

The influence from weather is neglected in this paper and vehicle wheel tracks transverse distribution discipline has been in consideration, so weather factor and coefficient of lanes should be ignored, other parameters can be assumed as $A_a=1$, $A_g=1$, $A_c=1$. Then equation (1) will be:

$$N_e=N_f\times7\times40=4025\times280\times A_a\times A_g/A_c\times\sigma^{-4.17}=1127000\times\sigma^{-4.17} \quad (2)$$

Equation (2) is taken as standard for calculating asphalt pavement fatigue life.

4.4 Result Analysis

According to the loading combination cases, loading positions and loading

times, fatigue analysis is carried out. Fatigue life usage coefficient-FLUC (loading times/allowable loading times with the same stress) in position A B C and D can be obtained. The results are shown as figure 6, figure 7, figure 8 and figure 9.

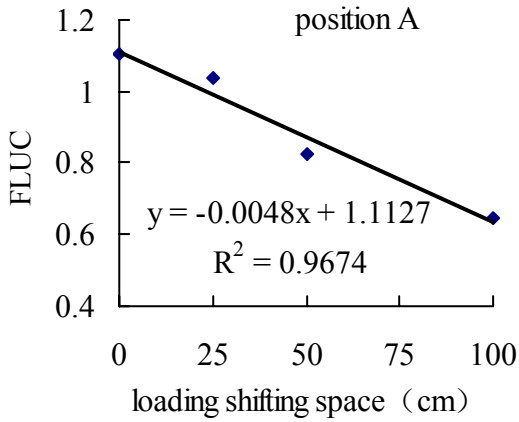

Figure 6. Relationship between fatigue loss in position A and loading shifting space.

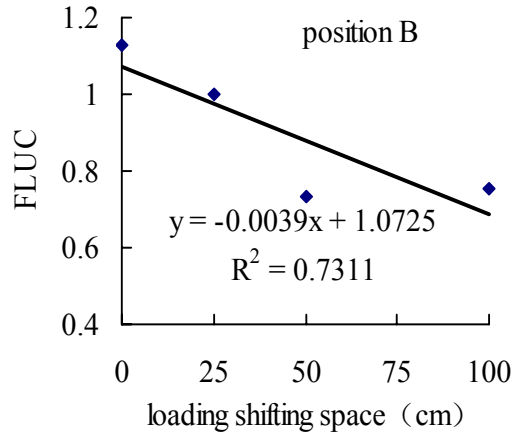

Figure 7. Relationship between fatigue loss in position B and loading shifting Space.

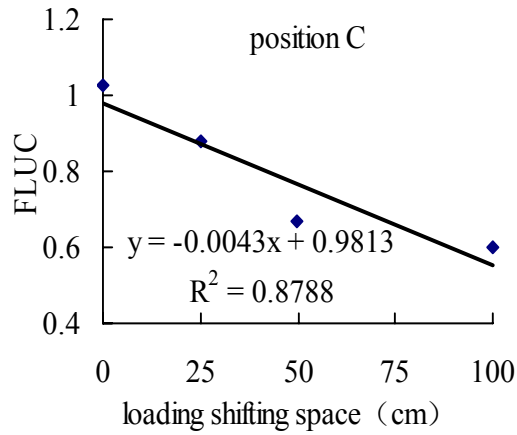

Figure 8. Relationship between fatigue loss in position C and loading shifting space.

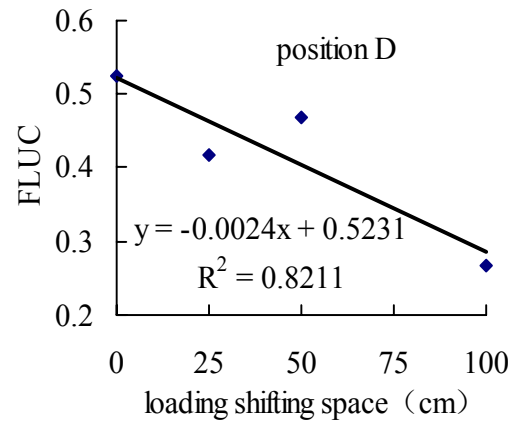

Figure 9. Relationship between fatigue loss in position D and loading shifting space.

From the four figures above, it is known that after loading positions are shifted, the fatigue life usage coefficients in position A B C and D which used to be mostly vulnerable are reduced remarkably although the total loading times is not changed. Calculation reveals that when shifting space is 25cm, fatigue life in position A B C and D are prolonged 7%, 13%, 15% and 11% respectively; when 50cm, they are prolonged 27%, 39%, 35% and 6% respectively; when 100cm, they are prolonged 45%, 37%, 42% and 26% respectively. From the analysis it is known that the larger

the space is shifted, the longer the fatigue life is prolonged within a certain range. Considering limited shifting range and practicability of construction, the best shifting space recommended in this paper is 25~50cm.

5 Vehicle Wheel Tracks Shifting and Improvement of Anti-skid Performance

High friction coefficient and good anti-skid performance of pavement will contribute to driving safety. With the increase of vehicle loading times, surface of pavement is worn that decreases friction coefficient as well as driving safety. With high degree of traffic channeling in high class highways, vehicles usually travel along relatively fixed routes where friction coefficient decreases remarkably threatening driving safety. Related documents (Jing 1990) have manifested it, seen in figure 10.

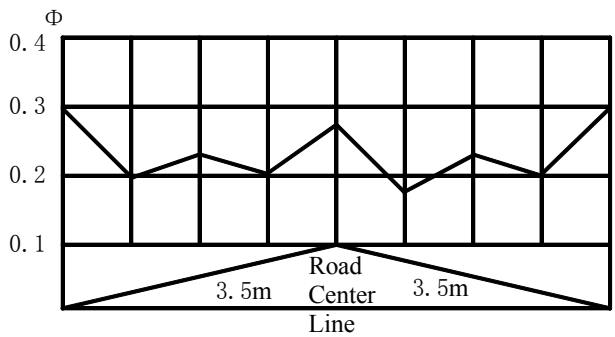

Figure 10.Variation of Friction Coefficient in Different Positions.

When transverse intervention is applied, vehicle load distribution will be shifted, the area with good anti-skid performance can be fully utilized to improve driving safety.

6 Conclusions

The study of vehicle wheel tracks transverse distribution reveals that wheel tracks are concentrated on minor range in lanes which is one of the main reasons causing pavement premature damage. In order to prolong highway service life effectively, a method for highway pavement maintenance and management based on drivers' vision intervention is proposed. Feasibility of this method is analyzed and the finite element models are established according to actual pavement structure. Fatigue analysis on the most vulnerable points is carried out according to vehicle load transverse distribution and certain fatigue properties of asphalt pavement. The results show that when loading positions are shifted 25cm, fatigue life is prolonged about 10%, when shifted 50cm, it is about 30%, when shifted 100cm, it is about 40%. 25~50cm shifting space is recommended based on analysis of the results and construction practicability. Also some related documents are employed to discuss the variation of friction coefficient in travel lanes and concluded that when vehicle wheel tracks are shifted, anti-skid performance of the pavement can be fully utilized for the

improvement of driving safety.

ABSTRACT

Driving conditions and durability of pavement skid-resistant are important factors that influence traffic safety of expressway tunnel. To understant the present conditions of pavement skid-resistant performance, mean texture depth (MTD) and British pendulum number (BPN) were measured in different places on an expressway tunnel pavement. Residual life of pavement skid-resistant was predicted based on surveyed traffic volume. Fuzzy cluster was used to analyze pavement skid-resistant performance. The analysis results showed that skid-resistant performance of asphalt concrete pavement is better than that of cement concrete pavement and skid-resistant performance of different places in tunnel has certain regularity, which matched the actual situation well. This paper provided scientific basis to select pavement maintenance strategies and to set speed limits in tunnel, which will lead to a decrease in traffic accidents..

KEY WORDS: expressway tunnel; pavement skid-resistant performance; pavement reliability; fuzzy cluster analysis

1 INTRODUCTION

Expressway tunnel is the bottleneck of highway transportation with poor driving environment and a high occurrence of traffic accidents. Pavement skid-resistance is one of the primary factors that influence the safety of tunnel. Statistical data have indicated that traffic accident rate

of expressway tunnel was 1.34 to 8 times higher than that of other expressway parts. About 81% of the traffic accidents were related to the poor pavement skid-resistance, which led to vehicle side-slip and 19% were related to other factors. These accidents resulted in enormous economic loss. For example, the direct economic loss is up to 2.1 hundred million Euro annually in Europe due to traffic accidents of tunnel and the indirect one is more than 3 to 4.5 hundred million Euro (Shen 2002; Yao, 1985; Ma, et al., 2008).

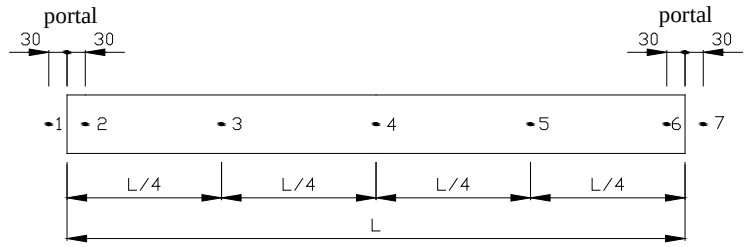
Pavement skid-resistance is influenced by many factors and these factors are changing all the time, which cannot be described and analyzed quantitatively through traditional mathematical methods. Many variables can be considered in fuzzy cluster analysis; therefore fuzzy cluster analysis has obviously advantages than regression analysis and other traditional methods. In order to learn about the present pavement skid-resistance of tunnels, field tests were conducted and test data were analyzed using fuzzy cluster analysis method. Furthermore, residual life of pavement skid-resistant performance was predicted based on present traffic volume and traffic growth rate. This research provided scientific basis to establish pavement maintenance plan and to take effective measures to improve pavement skid-resistance, which, will lead to a decrease or avoidance in traffic accidents.

The projects discussed in this paper included two separated tunnels of one expressway with four lanes in two ways. One tunnel is 3011m long and the other is 3056m. The tunnels lie in the transition zone between loess plateau and Qinghai-Tibet plateau with semi-arid climate of continental plateau. Asphalt concrete pavement was used outside the tunnels and cement concrete pavement inside.

2 FUZZY CLUSTER ANALYSIS OF PAVEMENT SKID-RESISTANT PERFORMANCE

2.1 EXPRESSION OF FUZZY EQUIVALENT RELATIONSHIP

In order to learn about the whole pavement behavior of the two tunnels, 14 points in different places (See figure 1) were tested by using pavement test equipment.



Unit: m

Figure 1. Layout of test points.

Three variables, pavement type, British pendulum number (BPN) and mean texture depth (MTD), were used to express each point. Besides, each variable was determined by the mean test value of three different points at the same cross section of each tunnel. Test data were showed in table 1.

Table 1. Test Value of Tunnel Pavement Skid-resistant Performance.

Points	Pavement type	BPN	MTD(mm)
Z1	0	63	0.39
Z2	1	62	0.26
Z3	1	64	0.35
Z4	1	65.5	0.32
Z5	1	65	0.30
Z6	1	64	0.30
Z7	0	72.5	0.37
Y1	0	60	0.36
Y2	1	59	0.27
Y3	1	62	0.32
Y4	1	63.5	0.34
Y5	1	63	0.33
Y6	1	64	0.36
Y7	0	69	0.36

In table 1, 0 represents asphalt concrete pavement, 1 cement concrete pavement, Z the left tunnel and Y the right tunnel. In order to preclude random effect, test data have to be treated by means of standardization of data range.

Canonical matrix can be obtained based on standardization of data range. Similarity coefficient which used to weigh sample level of similarity can be calculated with cape cosine equation, expressed as:

$$\gamma_{ij} = \frac{\sum_{k=1}^{m} X_{ik} \cdot X_{jk}}{(\sum_{k=1}^{m} X_{ik}^{\ 2} \cdot \sum_{k=1}^{m} X_{jk}^{\ 2})^{\frac{1}{2}}} \qquad (1)$$

where γ_{ij} is the similarity coefficient; X_{ik} is the i-th standard data of the k-th variable; X_{jk} is the j-th standard data of the k-th variable; and m is the number of variables.

According to Eq. (1), fuzzy similarity matrix R was calculated and equation $R^8=R^4$ was derived by means of transitive closure method. Therefore, R^4 is the fuzzy equivalent matrix, which is listed below.

1.00	0.64	0.64	0.64	0.64	0.64	0.89	0.98	0.64	0.64	0.64	0.64	0.64	0.89

2.2 CLUSTER RESULTS

Different level cut sets λ were selected for fuzzy cluster analysis. If the corresponding elements are completely identical, they can be put into the same class and new fuzzy equivalent matrixes can be obtained. For example, If λ =0.89, two classes can be obtained such as (Z1, Z7, Y1, Y7) and (Z2, Z3, Z4, Z5, Z6, Y2, Y3, Y4, Y5, Y6). If λ =0.98, six classes can be obtained such as (Z1), (Z2), (Z3, Z4, Z5, Z6, Y3, Y4, Y5, Y6), (Y1), (Y2) and (Z7, Y7). Based on the results, the following observations are made:

1) Skid-resistant performance of asphalt concrete pavement is better than that of cement concrete and skid-resistant performance durability of asphalt concrete pavement is better than that of cement concrete. Besides, pavement skid-resistant performance outside the tunnel is better than that inside the tunnel.

2) In order to adapt to the tunnel environment, continuous deceleration was done by all the drivers when they travel through the tunnel. Therefore, vehicle density increased and pavement skid-resistance performance reduced accordingly. As the frequent brake and deceleration, Z2 and Y2 became the worst points in terms of pavement skid- resistance performance. Point Z7 and Y7 is in the same class, so their pavement skid-resistance performances are the same.

3) Unctuous and thin film often comes into being on top of the pavement as tunnel environment is closed and as the pavement is hygroscopic. Attachment coefficient of point Z3, Z4, Z5, Z6, Y3, Y4, Y5 and Y6 lie in the tunnel decreased in value greatly. So pavement skid-resistance performance in tunnel is worse than that of other parts of expressway.

According to actual survey, the fuzzy cluster results discussed above matched the actual condition well.

3 RESIDUAL LIFE PREDICTION OF PAVEMENT SKID-RESISTANT PERFORMANCE

Pavement skid-resistant performance reduced quickly under traffic loads and then gradually turned to be stable. (Yang 2001; Yang et al. 2002) Residual life of tunnel pavement skid-resistant performance can be predicted based on present traffic volume and traffic growth rate. The tunnels under study have open to traffic for 4 years. The current annual average daily traffic of the left tunnel is 6500veh/d and traffic growth rate is about 10% in initial operation period. Therefore, accumulated applications of standard axle (Ne) can be calculated. According to British pendulum number and texture depth, attenuation rate (K) of tunnel pavement skid-resistant performance can be expressed as

$$K = -\frac{dTD^*(BPN^*)}{dN} = \frac{TD_0(BPN_0) - TD(BPN)}{N\mathrm{e}} \qquad (2)$$

where TD(BPN) is the value of pavement skid-resistant performance in the application period; $TD_0(BPN_0)$ is the value of pavement skid-resistant

performance in the stage of opening to traffic; N is the accumulated applications of standard axle; and $TD^*(BPN^*)$ is the relative value of pavement skid-resistant performance. $TD^*(BPN^*)$ can be calculated as

$$TD^*(BPN^*) = TD(BPN) - TD_S(BPN_S) \quad (3)$$

where $TD_S(BPN_S)$ is the finial stable value.

According to the field test data and laboratory experiments, attenuation equation can be expressed as

$$TD^*(BPN^*) = A_{TD(BPN)} e^{-B_{TD(BPN)}N} \quad (4)$$

where $A_{TD(BPN)}$ is the maximum attenuation fall of skid-resistant performance and $B_{TD(BPN)}$ is the ratio of attenuation rate to the relative value of pavement skid-resistant performance.

$TD_0(BPN_0)$ can be obtained from technical specifications (Ministry of Transport of the People's Republic of China 2001). According to calculation, the residual life of pavement skid-resistant performance of the left tunnel entrance is no more than 0.85 years, which means that the pavement skid-resistant performance will fall to unacceptable level in 0.85 years.

4 CONCLUSIONS

1) The pavement skid-resistance performance of expressway tunnel is different in different places because of vehicle actions, pavement materials, highway traffic environment, etc.

(2) Pavement skid-resistance performance reduced gradually with the increase in traffic volume and the residual life of pavement skid-resistant performance can be predicted based on traffic volume and its growth rate. The results showed that attenuation rate decreased quickly in tunnel entrance. Therefore, some effective measures should be taken to improve pavement skid-resistant performance.

(3) Highway traffic safety is influenced by pavement skid-resistant performance. This paper provided an evaluation method of pavement performance. Besides, this research can also be regarded as references for reliability analysis of the whole tunnel structure.

ABSTRACT

Old concrete pavement with major damage can be reconstructed by paving the asphalt surface after cracked and stabilized with punching technique. But the cracked size is different in every country and there is no corresponding theory basis. Using 3-D finite element method, the relationships between cracked size for concrete slab and load stress, thermal stress, and coupling stress in asphalt overlay together with pressure stress on base surface were analyzed. The results show that the influence of cracked size on thermal stress and coupling stress is much greater than that of load stress. When cracked size decreases, thermal stress and coupling stress in asphalt overlay decrease rapidly. Also, the stress centralization at joints and cracks lessens evidently, while the pressure stress on base surface increases. Considering the factors synthetically, it is reasonable for the cracked size to range from 80 cm to 100 cm.

INTRODUCTION

When old cement concrete pavement slab is largely damaged, it can be reconstructed by paving asphalt surface after it is cracked and stabilized with punching technique. It has been widely used in America and South Africa, and now in some regions of China. There is no consensus about the cracked size of old concrete slab, and no corresponding design and construction specifications in China. Li (1997) suggests that the cracked results of old cement concrete pavement should be blocks with length of sides of 45~60cm, some blocks about 75cm, and blocks exceeding 60cm should be less than 70%. Yao (1999) suggests supplying concrete crack machines to break concrete slab into blocks of 60~100cm, and then using a heavy tyre roller on the blocks. In the United States, the cracked size of concrete pavement, listed in Table 1, differs greatly among the states. The cracked size varies greatly from the minimum size of 45cm to a maximum size of 180cm.

Research shows that the cracked size of old cement concrete pavement slab has great influence on the performance of asphalt overlay. Using an experimental road and adopting a finite element method, this paper studies the relationships of cracked concrete slab size and load stress, thermal stress, coupling stress in asphalt

overlay and pressure stress on base surface in order to determine a reasonable cracked size for old cement concrete slab.

Table 1. Empirical cracked size of cement concrete pavement in American

State	*Cracked size of cement concrete pavement*
Iowa	1.8m
California	1.2～1.8m
Minnesota	0.9～1.2m
New York	0.9m
North Dakota	0.9m
Illinois	0.45～0.6m
Kentucky	0.45～0.6m
Michigan	0.45～0.6m
West Virginia	0.45～0.6m

1 CALCULATION MODEL AND PARAMETERS

We begin with a pavement structure as an elastic layered system. The object of study is composed of asphalt overlay, cracked and stabilized slab of different size and subgrade. The paper utilizes a model of three-dimensional space and takes the length direction as the x axle, width direction as y axle, and depth direction as z axle. To reflect the characters of semi-infinite space subgrade, the subgrade is simulated with expansion size and the model and grid system are shown in Figure 1. In the model, the joint width of old cement concrete pavement is assumed to be 1 cm, and there is no load transmission capability at joints.

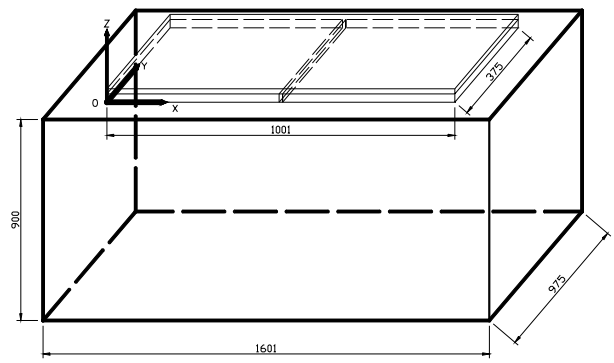

Figure 1. Structure calculation model (unit: cm).

The plane size of cement concrete pavement slab before cracked adopts 500cm×375cm, and the expansion dimension of subgrade is decided as 16.01m×9.75m×9m. The average size of slabs after cracked separately adopts 250cm×188cm, 100cm×94cm, 50cm×54cm.

The traffic load adopts standard axle load BZZ-100 and the tyre inner pressure is 0.7MPa. The loading pattern is shown in Figures 2 and 3.

The reference temperature is approximately adopted as the temperature of -5℃ when calculating thermal stress. The temperature ranging between -10℃ and +10℃. Since the influence of negative difference in temperature is more

unfavourable for pavement structure, the temperature decline of -10□ on an overlay surface is set to calculate thermal temperature. The other main calculation parameters are listed in Table 2.

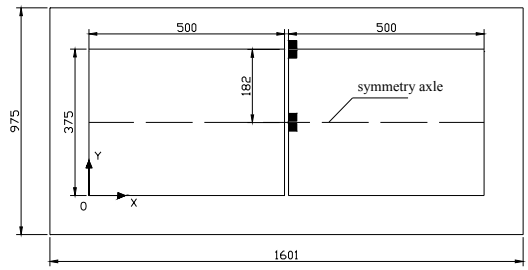

Figure 2. Wheel loading plane (unit: cm).

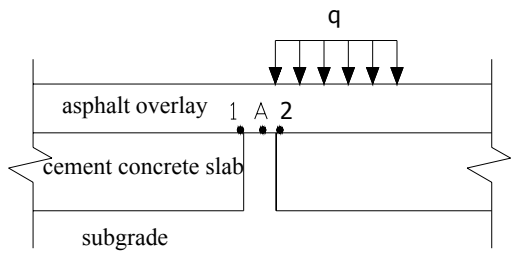

Figure 3. Diagrammatic sketch of wheel loading

Table 2. Main parameters

Structure layer	Thickness/cm	Elastic modulus/ MPa	Passion ratio	Coefficient of heat conductivity /w·(m·□)$^{-1}$	Coefficient of linear expansion /(□$^{-1}$)
Asphalt overlay	12	1200	0.25	1.2	2.1×10^{-5}
Cracking and Stabilized slab	22	30000	0.15	1.5	1.0×10^{-5}
Subgrade	—	100	0.35	1.0	0.5×10^{-5}

Besides, since the crack can transmit shearing, but cannot transmit bending moment and tensile force, the influence of crack contact condition should be considered when calculating the vehicle load stress of overlay. Calculation results show that the equivalent stress σ_e and maximum shearing stress τ_{max} of asphalt overlay decrease with the friction coefficient between crack increasing under the action of vehicle load. Therefore, the calculations are all carried out under the most unfavourable bearing conditions of asphalt overlay, namely the friction coefficient between a crack is 0.

2 Influence of cracked slab size on asphalt overlay stress

When traffic load is 100KN, the reference temperature of pavement structure is -5° and the temperature decline range of asphalt overlay surface is -10°. The influence of pavement slab cracked size on load stress, thermal stress and coupling stress of overlay is calculated and the results are shown in Table 3.

Table 3. Load stress, thermal stress and coupling stress of asphalt overlay.

Cracked slab size /cm×cm	Load type	Stress /MPa										
		σ_x	σ_y	σ_z	τ_{xy}	τ_{yz}	τ_{xz}	σ_1	σ_2	σ_3	σ_e	τ_{max}

2.1 Influence of cracked size on overlay load stress

It can be seen from Table 3 and Figure 4 that the maximum principal stress σ_1 at the bottom of asphalt overlay at joints increases a little with the cracked size of cement concrete slab and decreases under the traffic load action. But the value of σ_1 is always negative. This shows the overlay is under the favourable compressive condition all along, while the equivalent stress σ_e and the maximum shearing stress τ_{max} decline slowly with cracked slab size decreasing, which shows that reducing slab size can decrease the load stress concentration at joints of old cement concrete at a certain extent.

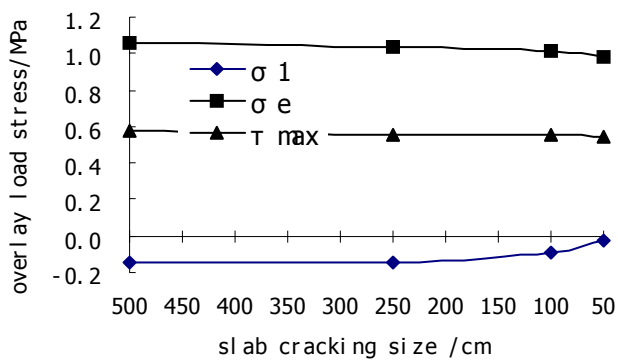

Figure 4. Load stress of asphalt overlay along with cracked slab size variety.

Figure 5 shows that the compressive stress on base surface increases with cracked slab size decreasing. When the cracked size is less than 100cm×94cm, the compressive stress increases quickly.

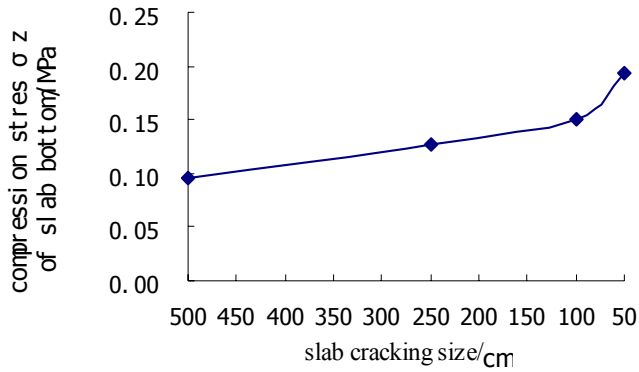

Figure 5. Compressive stress at slab bottom along with cracked slab size variety.

2.2 Influence of cracked slab size on overlay thermal stress

The calculation results of overlay thermal stress are shown as Figure 6, which indicates that the thermal stresses σ_1, σ_e and τ_{max} of asphalt overlay fall quickly with the decreasing size of cracked slab. When the slab size reduces from 500cm×375cm to 50cm×54cm, the values of σ_1, σ_e and τ_{max} decline by 61.5%, 61.7% and 61.3%, which shows that the slab size has great influence on overlay thermal stress.

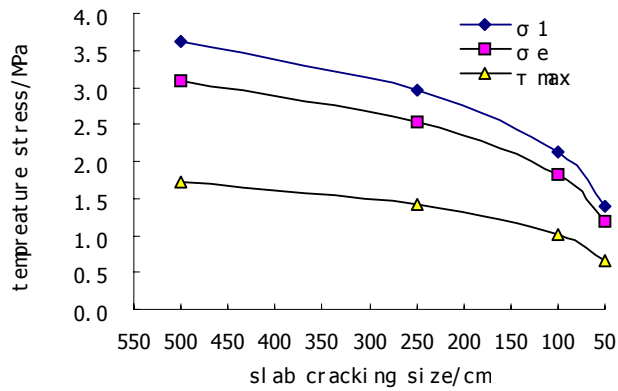

Figure 6. Thermal stress of asphalt overlay with cracked slab size variety.

2.3 Influence of cracked slab size on overlay coupling stress

Table 3 and Figure 7 show that the coupling stressed σ_1, σ_e and τ_{max} of asphalt overlay formed by the joint action of load and temperature decline along with the decreasing size of cracked slab. When the slab size reduces from 500cm×375cm to 100cm×94cm, the values decline by 70.0%, 57.3% and 56.2%, which indicates that the coupling stress of asphalt overlay falls greatly when cement concrete slab is cracked and divided into small slabs.

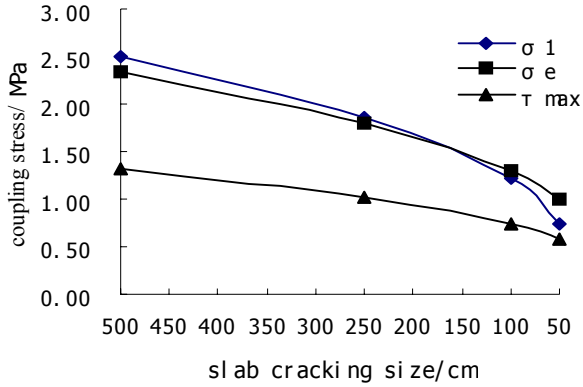

Figure 7. Coupling stress of asphalt overlay along with cracked slab size variety.

3 CONCLUSIONS

(1) The cracked size of pavement slab has some influence on the load stress of asphalt overlay, and the equivalent stress σ_e and maximum shearing stress τ_{max} of overlay have a small decrease along with smaller cracked slab size. The cracked size has great influence on the compressive stress on the base surface, which increases with cracked slab size decrease.

(2) The influence of cracked slab size on thermal stress and coupling stress of asphalt is greater than that on load stress. The thermal stress and coupling stress decline quickly and the stress concentration at joints weakens obviously along with the decrease of cracked slab size.

(3) Based on comprehensive consideration of the influence of cracked slab size on load stress, thermal stress and coupling stress of asphalt overlay, compressive stress on the base surface, research findings are that it is reasonable for the cracked size to be 80~100cm when using punching technique to crack and stabilize cement concrete pavement slab.

Abstract: As a complex system, there are lots of complex non-linear characteristics in excavating slopes. Stability of rock slope was analyzed with the catastrophe theory. A mechanistic model for assessment of the slope stability was derived in this paper. Based on it, the criterion for the mechanistic conditions that can cause the failure and instability of slope were inferred. Compared with the deficiency of the limit equilibrium stability analysis method applied in rigid bodies, it was proved that using catastrophe theory to analyze the stability of rock slope was feasible in practical engineering.

Key words: *rock slope; stability; catastrophe theory; mechanistic model*

0 Introductions

Parameters of the slope system, which is an open system with complex structure and behavior, are uncertain and random. In evolution process of the slope system, mass, energy and information exchange with the out world continually. In fact, the mechanical behavior of rock slope instability is a dynamic, nonreversible and non-linear evolution process and the non-linearity is the basic attribute (Huang Runqiu, Xu Qiang 1996, Huang Zhiquan 2005). Using the catastrophe theory, researchers in China and other countries proposed a number of mechanistic models of slope instability to study the stability of rock slope. However, to the rock slope of the reservoir bank and riverbank, these models don't include the erosion effect of water and the influence of water pressure of posterior margin in slope fissures on the stability of excavating rock slope (Liang Guilan, Xu Weiya, He Yuzhi 2008, Lou Yiqing, Gu Shijun, Li Jun 2008, Qin Siqing 2000, Jiang Yongdong, Xian Xuefu, Yang Gang 2008). Voluminous facts indicate that 90% of landslides are caused by water, which fully demonstrate that, water is an important factor affecting the stability of slope (Xiong Junming 2008, He Keqiang, Wang Ronglu, Li Xinzhi 2008, Liu Bingshan, Li Shihai, Zhao Qing 2008). Considering the influence of water on the stability of excavating slope and compared with the deficiency of the limit equilibrium stability analysis method in evaluating the stability of rock slope, this paper established a the catastrophe theory of rock slope, and furthermore verified the feasibility of using it to analyze the stability of excavating rock slope in engineering.

1. Mechanistic model

Assuming the gliding plane is homogenous and the sheering stress of various point in gliding plane reached the limit damage state at the same time, the limit equilibrium stability analysis method, which determines whether a slope is stable by getting the slide safety coefficient of the sliding block at the moment of destroying the equilibrium of the rock slider, is a common method to analyze slope stability (Chen Zuyu, Wang Xiaogang, Yang Jian 2005). Qin Siqing (2000) and Liu Yaoru (2007) believe that, slope slip surface was not homogenous and it is impossible for the sliding force to reach the limit at the same time. The limit equilibrium stability method could not reflect the real state of gliding plane. Considering the slope was non-homogenous, the mechanistic model, built by Qin Siqing, assumed that the gliding plane was a non-homogenous soft interlayer and the upper rock was a rigid body. Based on the above conditions, the unit width of landslide is studied in this paper. *H, L,* , *h* and *Mg* represent the average height of the upper rock of landslide, the length of landslide, the slope angle, the thick of the soft interlayer and the weight of landslide respectively. Where, $Mg = HL(\rho g + \gamma_w)$ and γ_w is the unit weight of water and g is the acceleration of gravity. Maybe $_w$ is a variable because of the rainfall. Along soft interlayer, rock mass has a displacement represented by u (Fig. 1). In certain section of soft interlayer, where the intensity of medium is great such as locked patch, or suffered shearing stress is little, the medium has flexibility and strain-hardening effect, and the ability of deformation resistant was increased by the increasing of deformation，however, in other sections such as toe of slope, for the medium is crushing, the argillization of water or the medium has the capability of strain-weakening properties because the suffered stress is so great that the stress beyond the peak stress, the ability of deformation resistant is decreased by the increasing of deformation.

In order to simplify the analysis and focus on the physical nature of instability, it is assumed that, the soft interlayer is composed of two different medium, having different mechanical properties with one of strain weakening and the other one of flexibility. Fig.2 shows the relationship between the shearing stress and the deformation of two-section medium.

The constitutive relationship of the medium of flexible section in soft interlayer is,

$$\tau_1 = G_1 \frac{u}{h} \quad (u \le u_1) \qquad \tau_1 = \tau_m \quad (u \succ u_1) \tag{1}$$

where τ_1 is the shearing stress of the medium of flexible section, G_1 is the shearing modules of the medium of flexible section, u_1 is the displacement

corresponded to the peak value of shearing stress and τ_m is the residual shearing intensity of the medium of flexible section.

The constitutive relationship of the medium of strain weakening section in soft interlayer is,

$$\tau_2 = G_2 \frac{u}{h} \exp\left[-\frac{u}{u_2}\right] \qquad (2)$$

where τ_2 is the shearing stress of the medium of strain weakening section, G_2 is the shearing modules of the medium of strain weakening section and u_2 is the displacement corresponded to the peak value of shearing stress.

In equation (2), when $\frac{d^2\tau_2}{du^2} = 0$, it could identify the inflection point of the curve of shearing stress and deformation. The displacement of the medium of soft section is $2u_2$ and the inclination is $-\frac{G_2 e^{-2}}{h}$.

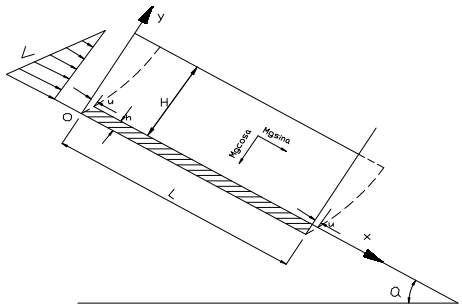

Fig.1 Analysis model of slope gliding

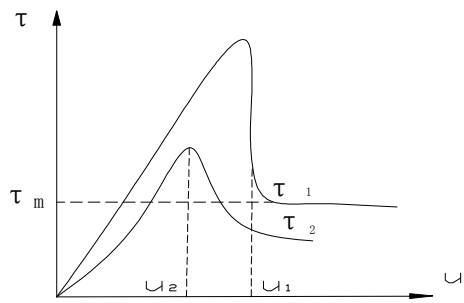

Fig. 2 Relationship between deformation and shearing stress of the medium of two-section soft interlayer

In order to reflect the effect of ground water, Jiang Yongdong (2008) introduced a function reflecting the water-caused weakening effect on the gliding plane.

$$f_{(w)} = (1-\eta)(1-w)^2 + \eta \qquad (3)$$

where w is the saturation and η is softening coefficient of rock body.

Equation (3) is descending monotonously. When slope is dry, $w=0$, $f_{(0)}=1$ and when water is saturated, $w=1$, $f_{(1)}=\eta<1$, the constitutive relationship of the medium of two sections under water-caused weakening effect is,

$$\tau_1 = f_1(w_1)G_1\frac{u}{h} \quad (4)$$

where w_1 is the saturation of the medium of flexible section.

$$\tau_2 = f_2(w_2)G_2\frac{u}{h}\exp\left[-\frac{u}{u_2}\right] \quad (5)$$

where w_2 is the saturation of the medium of strain softening section.

To rock landslide, the fissure water pressure in posterior margin of fracture should be considered. The fissure water pressure is calculated by equation (6).

$$V = \frac{1}{2}r_w h_w^2 \quad (6)$$

where V is the fissure water pressure, kN/m, r_w is the water unit weight and h_w is the height of water in fissure, *m*.

2. Cusp catastrophe model

The total potential energy function of a slope system could be induced by mechanistic model.

$$V_{(u)} = \int_0^u \left| f_1(w_1)l_1\frac{G_1 u}{h} + f_2(w_2)l_2\frac{G_2 u}{h}\exp[-\frac{u}{u_2}] \right| d_u - \left[HL(\rho g + \gamma_w)\sin\alpha + \frac{1}{2}\gamma_w h_w^2 \right] u \quad (7)$$

where l_1, l_2 is the length of flexible section of gliding surface and the length of weakening section of gliding surface respectively and $L = l_1 + l_2$.

Chosen u as a state mutation variable and calculated the derivative of equation (7), the equilibrium surface of slope stability analysis could be achieved.

$$V'_{(u)} = f_1(w_1)l_1\frac{G_1 u}{h} + f_2(w_2)l_2\frac{G_2 u}{h}\exp[-\frac{u}{u_2}] - \left[HL(\rho g + \gamma_w)\sin\alpha + \frac{1}{2}\gamma_w h_w^2 \right] = 0 \quad (8)$$

Equation (8) is the equilibrium condition of force. According to the smooth property of equilibrium, the shear displacement of the equilibrium conditions cusp is $u = u_1 = 2u_2$ by solving $V''_{(U)} = 0$, namely the displacement in cusp is just the inflection point of the constitutive relationship curve of the medium of weakening section.

The equilibrium surface is transformed to equation (9) by using the cubic polynomial of Taylor expansions of equation (8) at state variable u_1 in the cusp point.

$$\frac{2}{3}\frac{f_2(w_2)l_2G_2u_1e^{-2}}{h}\left|\left|\frac{u-u_1}{u_1}\right|^3+\frac{3}{2}\left|\frac{f_1(w_1)l_1G_1e^2}{f_2(w_2)l_2G_2}-1\right|\left|\frac{u-u_1}{u_1}\right|+\frac{3}{2}\left|1+\frac{f_1(w_1)l_1G_1e^2}{f_2(w_2)l_2G_2}-\frac{\left|HL(\rho g+\gamma_w)\sin\alpha+\frac{1}{2}\gamma_w h_w^2\right|he^2}{f_2(w_2)l_2G_2u_1}\right|\right|=0 \quad (9)$$

The equilibrium surface, which is the standard form of the cusp catastrophe theory, could be achieved by carrying out variable substitution of equation (9).

$$V'(x)=x^3+bx^2+c=0 \quad (10)$$

Where, $x=(u-u_1)/u_1$ (11)

$$b=3(fk-1)/2 \quad (12)$$

$$c=\frac{3}{2}\left|1+fk-\frac{\xi}{f_2w_2}\right| \quad (13)$$

$$k=\frac{l_1G_1e^2}{l_2G_2} \quad (14)$$

$$\xi=\frac{\left[HL(\rho g+\gamma_w)+\frac{1}{2}\gamma_w h_w^2\right]he^2\sin\alpha}{l_2G_2u_1} \quad (15)$$

$$f=\frac{f_1(w_1)}{f_2(w_2)} \quad (16)$$

where x is a state variable of the system, b and c are the control variables of the system, k is the stiffness ratio of the medium of flexible section in the softening interlayer to the rigidity of the inflection point of the constitutive section of the medium in strain weakening section, f is the ratio of water-caused weakening coefficient of the medium of flexible section in softening interlayer to water-caused weakening coefficient of strain weakening section, namely the ratio of water-induced weakening coefficient and ξ, related to the weight of the medium, the physical dimension of the system, parameters of the medium and etc, are called geometry-mechanical parameters.

The bifurcation set is: $\Delta=4b^3+27c^3=0$ (17)

By substituting equation (12) and equation (13) into equation (17), it could achieve,

$$2(fk-1)^3+9\left|1+fk-\frac{\xi}{f_2w_2}\right|^2=0 \quad (18)$$

Equation (18) is a necessary and sufficient mechanical condition to determine whether the slope is suddenly instable gliding along softening surface. Only when $b\le 0$, crossing the bifurcations set, the system could mutate. The necessary condition is:

$$k \le \frac{1}{f} \tag{19}$$

Equation (19) shows that, when the stiffness ratio k is smaller than a certain impact factor of the ground water, the system will be instable; in other words, the saturation of the gliding band determines the mutation of the system. Equation (20) could be derived by equation (14) and equation (19).

$$k = \frac{l_1 G_1 e^2}{l_2 G_2} \le \frac{1}{f} \tag{20}$$

Equation (20) shows that, the stiffness ratio is determined by the physical dimension and material properties of the system and mutation of rock are determined by internal property of material and saturation of softening interlayer. The smaller the rigidity in flexible section is and the bigger the rigidity in the weakening section is, the easier the mutation of the system is. The longer the flexible section is or the lower the saturation in the weakening section is, the harder the mutation of system is.

When crossing the left branch of bifurcation set, namely $c \prec 0$, the corresponding point is in the instable state and x will leap suddenly. The displacement at the critical instable point could be calculated using equation (10) and equation (17).

$$u^* = u_1 \left| 1 - \frac{\sqrt{2}}{2}(1- fk)^{\frac{1}{2}} \right| \tag{21}$$

When the control variable satisfies

$$2(fk-1)^3 + 9\left| 1 + fk - \frac{\xi}{f_2(w_2)} \right|^2 \prec 0 \qquad (fk \prec 1) \tag{22}$$

It means that, although the slope body is in the limited equilibrium state, the equilibrium state will have a minor change when control variable has a minor change, which corresponds to the creep phenomena of the slope.

3. Comparison with the limit equilibrium method

Equation (18) could be simplified to

$$\frac{f_2(w_2) G_2 l_2}{\left[HL(\rho g + \gamma_w) + \frac{1}{2}\gamma_w h_w^2 \right] h \sin\alpha} = \frac{e^2}{2u_2 \left| 1 + fk \pm \frac{\sqrt{2}}{3}(1- fk)^{\frac{3}{2}} \right|} \qquad (fk \prec 1) \tag{23}$$

When $b \prec 0$, system cross the left branch of the bifurcation set resulting in the instability and positive sign is taken in equation (23).

$$\frac{f_2(w_2) G_2 l_2}{\left[HL(\rho g + \gamma_w) + \frac{1}{2}\gamma_w h_w^2 \right] h \sin\alpha} = \frac{e^2}{2u_2 \left| 1 + fk + \frac{\sqrt{2}}{3}(1- fk)^{\frac{3}{2}} \right|} \qquad (fk \prec 1) \tag{24}$$

According to the limit equilibrium stability analysis method, the stable coefficient of slope is a ratio of skid resistance to downslide force.

$$K = \frac{f_2(w_2)G_2 l_2 u \exp\left[-\frac{u}{u_2}\right] + f_1(w_1)G_1 l_1 u}{HL(\rho g + \gamma_w) + \frac{1}{2}\gamma_w h_w^2} = \frac{f_2(w_2)G_2 l_2}{HL(\rho g + \gamma_w) + \frac{1}{2}\gamma_w h_w^2}\left[u\exp\left[-\frac{u}{u_2}\right] + fke^{-2}u\right] \quad (25)$$

By substituting equation (24) into equation (25), it could get equation (26)

$$K = \frac{e^2\left|u\exp\left[-\frac{u}{u_2}\right] + fke^{-2}u\right|}{2u_2\left|1 + fk + \frac{\sqrt{2}}{3}(1-fk)^{\frac{3}{2}}\right|} \quad (26)$$

Equation (26) shows that, coefficient of slope stability K is correlated to the stiffness ratio k, u/u_2 and the water-weakening coefficient. K is increased with the increase of u. When the slope is in the critical instability state, namely $u = u^*$, the critical instability coefficient K_c could be obtained by substituting equation (21) into equation (26).

$$K_c = \frac{\left|1 - \frac{\sqrt{2}}{2}(1-fk)^{\frac{1}{2}}\right|\left|\exp\left[2(1-fk)\right]^{\frac{1}{2}} - fk\right|}{1 + fk + \frac{\sqrt{2}}{3}(1-fk)^{\frac{3}{2}}} \quad (27)$$

Equation (27) demonstrates that K_c is related to f and k.

4. Case study

Rock slope topography of the subgrade of the Shan-Man expressway from K110+809 to K110+872 is a steep slope in middle-low mountain and the slope angle is around 45°. Geologic lithology of the rock slope is metamorphic schist which is fulvous and strongly weathered and the structure of rock body is broken. 15 meters below the top of slope, there is a mudstone interbed which is about 10cm thick and the slope with a tendency of landslide.

According to field observation and indoor and outdoor experiments, when the slope was excavated, the saturation of flexible section of soft mudstone interbed is 0.2, the softening coefficient is 0.7, the length is 0.85 meters，shear modulus of medium is 1.47×10^{10}Pa, the saturation of strain weakening section is 0.3, the softening coefficient is 0.5, the length is 18.5 meters and the shearing modules of medium is 0.43×10^{10}Pa.

By equation (3), it could obtained $f_1 = 0.892, f_2 = 0.745$ and $f = \frac{f_1}{f_2} = 1.197$，

$\frac{1}{f} = 0.835$.

By equation (14), it could obtained $k = 1.16 \succ 0.835$. According to equation (19), the slope is stable and the sudden instability will not be happened.

By equation (27), it could obtained $K_c = 0.857$. The limit equilibrium stability analysis method suppose that, if only skid resistant is less than downslide strength, namely the stable coefficient of critical gliding K_c <1, the landslide will be happened. According to this theory, the slope is instable and the landslide will be happened conflicting with the result of the cusp catastrophe theory. However, the fact is, this slope is stable when excavated and not destroyed for instability which better proved that using the cusp catastrophe theory to analyze the stability of excavating rock slope is feasible. The calculated result of limit equilibrium stability analysis method is conservative，resulting waste in engineering.

5. Conclusion

By building the geo-mechanistic model of slope and using the catastrophe theory, the internal and external factors were taken into account, especially the effects of the water-caused weakening factor and the fissure water pressure in posterior margin of fracture and a more perfect cusp catastrophe model was built. Through analyzing influences of certain factors on stability of the slope, the mechanical conditions criterion of the unstable failure of slope was derived. After engineering calculation, analysis and comparing with the deficiency of the limit equilibrium analysis method, it was proved that, using catastrophe theory to analyze the stability of excavating slope was more feasible in practical engineering.

ABSTRACT

Traffic congestion on highways causes decreased efficiency in road operation and increased energy consumption and environmental pollution. Various measures for traffic control have been considered for easing traffic congestion. In this paper, we propose the use of ramp metering control by introducing the reinforcement learning model in artificial intelligence, which is then combined with a dynamic micro traffic style simulation. Numerical simulation showed that when effective Reinforcement Learning ramp metering control is completed in the on-ramp section, traffic confusion can be prevented in advance.

INTRODUCTION

A model to simulate the dynamic changes in traffic congestion and to create a control model is needed. Wang and Miyagi created the simulation model which added the lane change model, i.e., the IDM (Intelligent Driver Model), originally developed by Treiber et al. (2000). The phase transition phenomenon that localized clusters and homogeneous congested traffic was pointed out by Kerner (2004). Moreover, the amount of vehicles inflow of the main line and an on ramp is a basic factor of traffic congestion based on the sensitivity-analysis result of the parameters in a simulation by Wang (2007). When effective control of traffic inflow is completed in the on-ramp section, traffic confusion can be prevented in advance and a smooth traffic style can be achieved.

The purpose of this research is to propose the ramp metering of an effective on-ramp section by introducing the reinforcement learning model using artificial intelligence that is then combined with a dynamic micro traffic simulation.

In the following section, the reinforcement learning ramp metering is elucidated. Moreover, reinforcement learning ramp is verified by traffic simulation by metering, and conclusions of our findings are given subsequently.

THE REINFORCEMENT LEARNING RAMP METERING

In order to solve the problem of the ramp metering, reinforcement learning ramp metering is proposed, of which the formula used is rewritten as follows.

$$Q(qin_t, r_t) \leftarrow Q(qin_t, r_t) + a\left[qout + \gamma \max Q(qin_{t+1}, r) - Q(qin_t, r_t)\right] \quad (1)$$

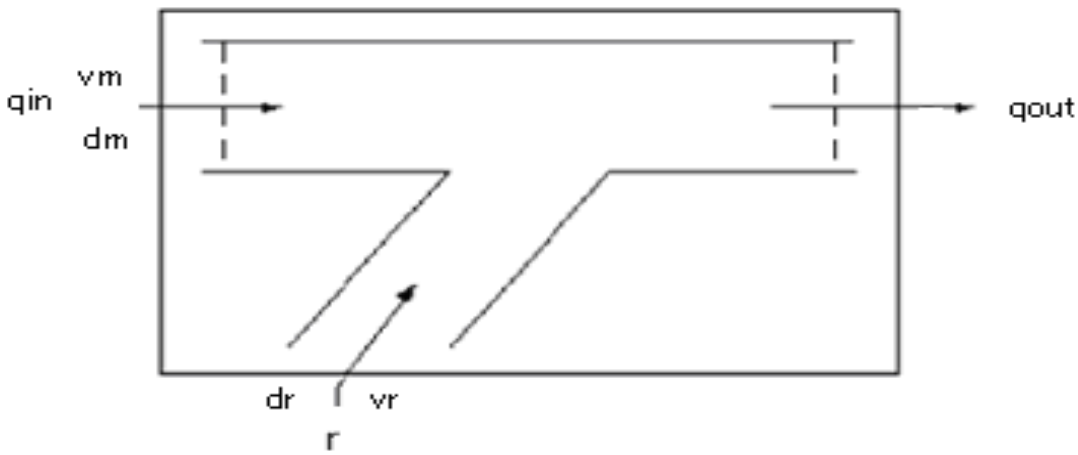

Figure 1. The reinforcement ramp metering.

In Figure 1, the *qin* is the main line upper stream traffic, *r* is the ramp inflow traffic, *qout* is the main line downstream traffic, *dm* is the main line upper stream density, *dr* is the ramp density, *vm* is the main line upper stream average speed, and *vr* is the ramp average speed.

$$q = qin + r - qout \quad (2)$$

In consideration of the stay traffic volume *q,* upper traffic is updated by the following formula.

$$qin_{t+1} \leftarrow qin_{t+1} + q \quad (3)$$

The upper traffic *qin* shall be obtained by observation and treated as a known variable. The ramp inflow traffic volume *r* is set with a selection-action variable as an amount of control. Moreover, *qout* is the reward accompanying action selection. Optimal *Q* is decided using a simulation. Optimization conditions are shown below:

(a) Traffic congestion does not occur in the main line.
(b) Traffic congestion does not occur with a ramp.
(c) Down-stream traffic becomes the maximum.

It is possible that the main line speed is larger than the simulation result by Wang and Miyagi, which could lead to large traffic congestion occurrences, the following conditions (a) and (b) are therefore established.

$$dm < 15 \qquad dr < 15 \tag{4}$$

$$vm < 15 \qquad vr < 10 \tag{5}$$

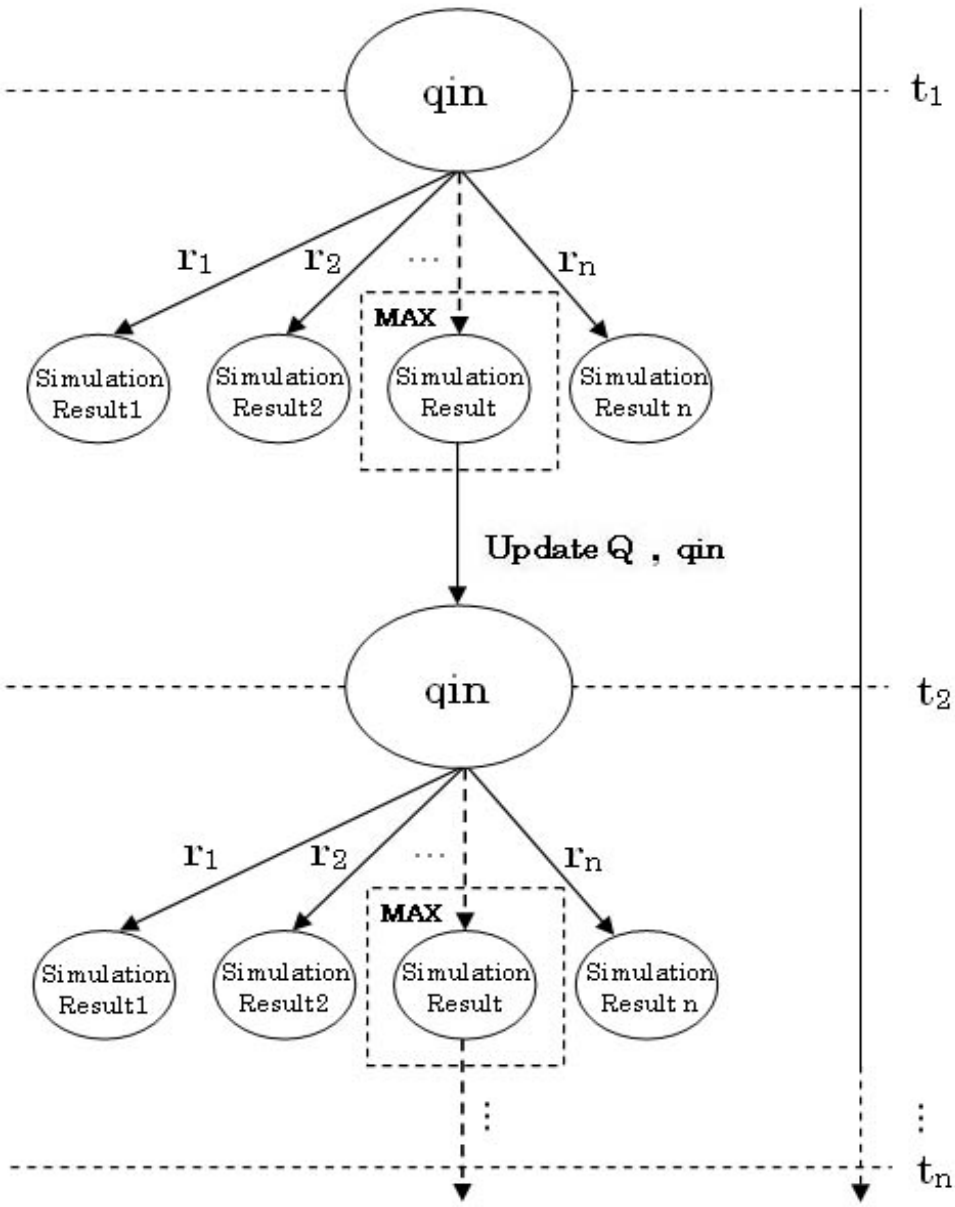

Figure 2. The procedure of td ramp metering.

The procedure of reinforcement learning ramp metering is shown in Figure 2 and follows the steps below:

(1) Input of main line upper stream traffic volume.
(2) Choose action (the amount of ramp traffic inflow), and perform a simulation.
(3) By using the results of the simulation, an optimal control action is selected.
(4) Update total outflow traffic Q and main line upper stream inflow traffic volume.
(5) Perform a repetition at a time unit.
(6) Stop repetition if it is the end of time.

VERIFICATION OF THE REINFORCEMENT LEARNING RAMP METERING

As shown in Figure 3, the merging section consists of a main lane and a side lane 100 m long. Vehicles on the ramp enter the main lane through the side lane. Various combinations of traffic flows of the main lane and the ramp were tested.

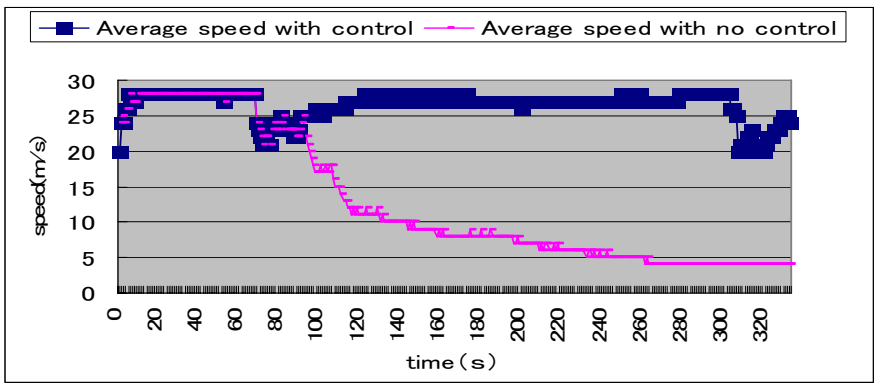

Figure 4. Time change of average speed in case B.

Table 1. Setup of a parameter, and selection of the optimal control action.

Case	time-axis (minute)	Main line traffic volume pcu (passenger car unit)	Ramp traffic volume pcu (passenger car unit)	
			with no control	with control
A	1.5	600	800	800
	3	1200		600
	4.5	1800		0
	6	2200		600
B	1.5	1200	800	800
	3	1800		600
	4.5	2200		0
	6	1600		600
C	1.5	600	800	800
	3	800		600
	4.5	1000		0
	6	1200		600

Table 2. The control effect by traffic and average travel time.

	Case	with no control	with control	The amount of change	Traffic congestion relief rate
A	Traffic volume (passenger car unit)	1850	1860	10	0.54%
	Average travel time (s/ car unit)	73	40	-33	-45.38%
B	Traffic volume (passenger car unit)	1840	2120	280	15.22%
	Average travel time (s/ car unit)	78	38	-40	-51.28%
C	Traffic volume (passenger car unit)	1560	1680	120	7.69%
	Average travel time (s/ car unit)	38	43	5	10.97%

As shown in Table 1, Cases A, B, and C were set up. In "having no control", ramp average traffic volume was set up in 800 pcu (passenger car unit). In the case of "with control", the optimal action brought a result shown in Table 1. If main line traffic volume increases to be 1600~1,800 pcu during traffic congestion, inflow control will be needed for Case B, and the result of choosing action (600 pcu) will be obtained. Moreover, time change of the average speed at this time is shown in Figure 4. If it continues permitting inflow by "he has no control", it will fall to 4 m/s after traffic congestion generating; however, in the case of "with control", average speed can be reduced to approximately 25 m/s. If the traffic volume exceeds 2,000 pcu, it will be necessary to close a ramp temporarily.

The effect of ramp metering by passage traffic and average travel time are shown in Table 2. As for traffic volume, it would increase 280 pcu to Case B, and a traffic congestion relaxation effect would become 15.22%. Moreover, when looking at the average travel time, it decreased for 40 (s/car unit), and the traffic congestion relief rate became 51.28%. The traffic congestion relief rate became 45% or more in the cases of A and B. On the other hand, main lane traffic volume, although traffic volume increased 120 pcu, leads to a few cases of C at average travel time, which takes five more seconds. When there was much main lane traffic, it turned out that the effect of the proposed control measure is large.

CONCLUSION

In order to reduce the traffic congestion in the on-ramp sections, the reinforcement learning ramp metering is investigated and proven to be effective. In this research, the simulation of the main lane upper stream traffic which changes momentarily was conducted. The reinforcement learning ramp metering was proposed to be used as an optimal action selection tool. It was used as a means to verify if a traffic style is carried out smoothly. As for future development, actual field data will be studied and the reinforcement learning ramp metering will be validated.

Abstract

This research focuses on the use of Bonifibers as the reinforcement for improving the fatigue endurance of asphalt mixture, which is an important property of the pavement structure. Fiber reinforcement as an available attempt has been proved to be effective in improving the toughness of asphalt concrete, and is becoming a new method for highway maintenance. For the purpose of examining the influence of the addition of Bonifibers on the durability of asphalt concrete pavement, a fatigue test was developed on MTS-810. 96 beam specimens of two kinds of asphalt mixture including AC-20 densely-graded bituminous concrete and SMA-13 stone mastic asphalt were fabricated and tested. The test results showed that the addition of the fibers decelerates the deflection development and crack evolution significantly. It was concluded that, polyester fiber reinforced asphalt mixtures behaves much better in the resistance to fatigue than that of plain concrete. They are the excellent pavement materials for heavy loading road applications.

Introduction

Fatigue is one of the main deterioration modes of flexible pavements for it induces the major distresses that contribute to the degradation and ultimate failure of asphalt concrete. The study on fatigue performance of asphalt pavements is important not only for the new roads but also for the maintenance of existing pavement. Flexible fiber as a kind of reinforced material is well used in the pavement construction and maintenance because of its wonderful effect on improving the pavement performance, as well as its convenience for construction process. Numerous field trials and laboratory investigation have illustrated that fiber inclusions are effective for reinforcing the asphalt concrete (Dean and Gerald 1989), improving the capacity of deformation (P Peltonen 1991), and retarding the development of reflective crack (Molenaar and M.Nods 1996). Numerous experiments with several types of reinforced fibers, different aggregates and asphalts (Hossam et al. 2005; Vikas Sharma and Shweta Goyal 2006) have demonstrated the significant improvement of fibers on the general performance of asphalt concrete. However, the research on fatigue behavior remains to be improved and some critical

questions need to be answered. The primary purpose of this study is to investigate the reinforcement effect of polyester fibers on the durability of asphalt concrete by fatigue tests.

Materials

The binder is a styrene butadiene styrene modified asphalt. Two gradations including densely-graded asphalt mixture AC-20 and stone matrix asphalt SMA-13 were used in this research. Crushed limestone with the maximal normal size of 20 mm was employed as the coarse grade aggregate of AC-20, while in SMA-13 mixture crushed basalt with maximal normal size of 13 mm was used. Limestone was chosen as fine grade aggregate for both materials. And limestone powder as filler was added into the materials. The gradation of the test materials is described in Table 1.

Table 1. AC-20 and SMA-13 Gradations

Sieve size (mm)	Percent passing (AC-20)	Sieve size (mm)	Percent passing (SMA-13)
26.5	100	16	100
19	95.9	11.4	93
16	87.8	9.5	75.7
13.2	72.5	8	56.2
9.5	57.7	5.6	26.9
4.75	38.4	4.75	23.9
2.36	26.3	2.36	22.5
1.18	19.0	1.18	18.2
0.6	13.5	0.6	14.9
0.3	8.9	0.3	12.7
0.15	6.9	0.15	11.7
0.075	5.6	0.075	10.5

Two kinds of fiber adopted in current experiment included xylogen and Bonifibers. Xylogen is a kind of flocculent fiber that could increase the viscidity of asphalt. Bonifibers as a kind of polyester fiber extracted from petroleum have good workability with bituminous. The properties of Bonifiber are shown in Table 2.

Experiments

Table 2. Properties of Bonifibers

Characteristic	Value
Length (mm)	6±1.5
Diameter (μm)	20±5
Density (g/cm^3)	1.36±0.04
Melting point (℃)	>250
Tensile strength (MPa)	>517 MPa
Strain at failure(%)	50
Water absorption (%)	9%

Binder and Fiber Contents (by weight). The Marshall test was used to define the optimum asphalt and fiber contents. With few experiments, the results showed the optimum asphalt contents of four experiment materials. For AC-20, Bonifibers of 0.20% in weight were added comparing with that without fibers. For SMA-13, the weight fraction of fiber inclusions was 0.10% with Bonifibers and 0.20% with xylogen. The results of Marshall tests are shown in Table 3.

It can be seen that the addition of Bonifibers allowed AC-20 mixture with richer bitumen. The content of asphalt was reduced by 3.0% for Bonifiber reinforced SMA-13, because the viscosity between xylogen and asphalt was prior to that of Bonifibers. As it is shown in Table 4, the stability value and Marshall flow for Bonifiber modified mixture had increased for AC-20. For SMA-13 with Bonifibers, both Marshall parameters decreased. Voids filled with binder were decreased while air voids were increased for both reinforced mixtures. From these aspects, adding Bonifibers may disturb the initial gradation structures.

Table 3. Marshall Test Results

Characteristic	Materials			
	AC-20		SMA-13	
Bonifiber content (%)	0	0.20	0	0.10
Optimum asphalt content (%)	4.17	4.46	6.50	6.30
Marshall density (g/cm^3)	2.472	2.458	2.463	2.468
Air voids (%)	3.2	3.5	3.6	3.8
VMA (%)	12.1	12.8	18.5	18.2
Voids filled with asphalt (%)	73.4	72.7	80.4	79.2
VCA (%)	—	—	39.0	38.8
Marshall stability (kN)	14.53	15.22	9.72	9.32
Flow (mm)	3.22	3.99	4.39	4.29

Fatigue Test. Fatigue tests were conducted on asphalt concrete beams under stress-controlled loading in the laboratory. The beams were cut from the rutting specimens with the size of approximately 300*300*50 mm. The size of the beam samples was 250*30*35 mm. The bending fatigue test was performed by MTS (Material Test System), which is a computer controlled hydraulic loading system. Four point bending test was used. The loading frequency was 10 Hz, without intermittent time. The loading level was adjusted for different conditions in the experiments, and was designed as 0.1 to 0.5 initially. The room temperature was effectively constant, 15℃ and was maintained within ±1℃. During the test period, the displacement of the sample surface was continuously measured and recorded. Loading level of fatigue test was based on the static bending failure test. The test was stopped when the crack propagated to the upper surface of the beam and the failure criterion was set up. A total of 96 specimens were tested.

Table 4. Static Bending Test Results

Characteristic	Materials			
	AC-20		SMA-13	
Bonifiber content (%)	0	0.20	0	0.10
Ultimate loading (kN)	0.979	1.109	1.049	1.448
Deformation (mm)	2.879	3.178	3.894	2.220
Tensile strength (MPa)	3.996	4.527	4.282	5.910
Maximum strain ($\times 10^{-2}$)	2.103	2.321	2.844	1.622
Bending Stiffness (MPa)	190.01	195.05	150.56	364.36

Test Results and Analysis

Bending Failure Test Results. The results of the static bending failure test

are shown in Table 4.

It is seen from table 4 that the reinforcement effects of Bonifibers are significant in ultimate loading, strength and stiffness. Especially for SMA-13 with Bonifibers, the bending stiffness increased 142% compared to plain concrete.

Fatigue Test Results. The stress levels used in the fatigue test and corresponding test results for each mixture are summarized in table 5.

Based on the theory of fatigue life, a fatigue equation was obtained through the regression of the fatigue test results. A linear regression model was developed between Log of the number of load repetitions to failure and Log of the tensile stress as:

$$\log N_f = k - n\log\sigma$$

where N_f is fatigue life (loading times for crack propagating to the top of the specimen); σ is applied tensile stress; k and n are coefficients determined by experiments. The fatigue equations for 4 mixtures obtained from the regression of the fatigue test results were listed in table 6. The high R values in Table 6 indicate the excellent model accuracy for the results of the fatigue tests.

Table 5. Fatigue Test Results

The fatigue property of AC-20 is shown in figure 1. By looking at the trend, it is clearly shown that Bonifibers reinforced asphalt mixture has better fatigue performance than that of plain concrete for AC-20. The addition of Bonifibers increases the slop of the $\log N - \log\sigma$ fatigue curve. When tensile stress changes the same degree, the diversification of the fatigue life for Bonifibers reinforced asphalt concrete is slighter than that of plain concrete, which means

Table 6. Fatigue Equation

Material	Fatigue equation	Correlation coefficient R
AC20-0%	$\log N_f = 4.380172 - 2.48348\log\sigma$	0.93621
AC20-0.20%	$\log N_f = 4.47672 - 2.25943\log\sigma$	0.97322
SMA13-0%	$\log N_f = 3.99435 - 2.79501\log\sigma$	0.99345
SMA13-0.10%	$\log N_f = 4.87079 - 4.05696\log\sigma$	0.98496

that adding Bonifibers in AC-20 mixture reduces the sensibility of fatigue life to stress level. With the help of fatigue equations, we realize clearly that, comparing to the plain AC-2,0 fatigue life of Bonifibers reinforced mixture is increased by 18.8% at applied stress of 0.8 MPa. And when stress is increased to 1.61 MPa, the growth of the fatigue life of Bonifiber reinforced mixture is 38.9%. It can be seen that with the increasing stress level, the growth of the fatigue life due to Bonifiber reinforcement is more significant compared to that of plain concrete. The closeness of the two curves suggests that the application of Bonifibers did not influence much on the fatigue life of AC-20 mixture.

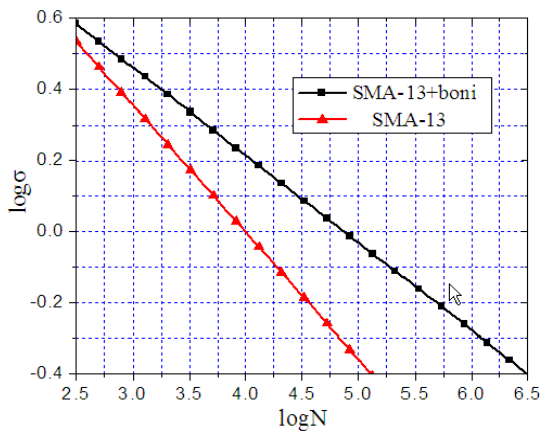

Figure 1. Fatigue curve of AC-20

Figure 2 shows the fatigue curves of SMA-13. From regression curves, we recognize that Bonifibers reinforced asphalt mixture performs much better in fatigue resistance ability compared to that of plain concrete for SMA-13. The exchanging of some xylogen with Bonifibers reduced the slop of the $\log N - \log \sigma$ fatigue curve. It is shown that fatigue life of Bonifibers reinforced asphalt concrete changes more remarkably compared to plain concrete when tensile stress changes the same degree, which means that adding Bonifibers in SMA-13 mixture increased the sensibility of fatigue life to stress level. From the figure we can see that, compared to plain SMA-13 the fatigue life of Boni-fibers reinforced mixture is increased by 1334% at stress of 0.6 MPa. And when the stress applied to specimen is increased to 1.25 MPa, the growth of the fatigue life of Bonifibers reinforced mixture is 475%. The fatigue performance of SMA-13 is different from that of AC-20.

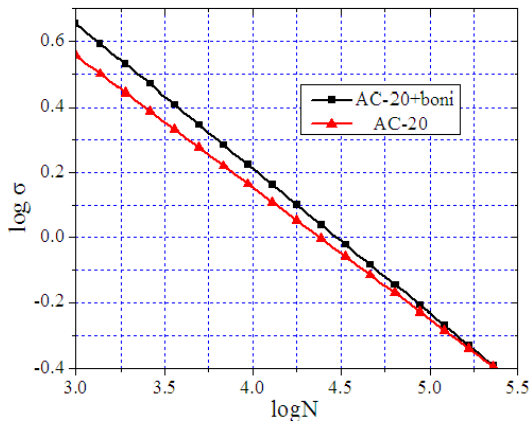

Figure 2. Fatigue curve of SMA-13

The process of fatigue failure for stone matrix asphalt was quite different from that of densely graded asphalt mixture. During the damage process of AC-20 specimens, the cracks started, propagated until penetrating the whole sample. The fatigue failure of SMA-13 specimens did not depend on the crack size, but the extrusion of discontinuously graded aggregate and the cohesive force of asphalt matrix. The coarse aggregates of SMA-13 headed together to bearing the fatigue

loading when the deformation of specimen gradually increased, the asphalt layer blended with aggregates was stretched and became thinner, and the phenomenon was clearly seen during the test period of SMA-13(figure 3). For SMA-13, the cracks appeared in the interface between asphalt and aggregates where asphalt was stretched to thin. For AC-20, the cracks appeared in the location where micro-cracks existed. During the test process of AC-20, there was no phenomenon that asphalt was stretched to thin as that of SMA-13. Cracks appeared later in SMA-13 than in AC-20, and the size of most cracks was smaller in SMA-13. The observations from the fatigue test were conducted to prove that the fatigue test process of AC-20 and SMA-13 was not completely the same.

Conclusions

1) Bending fatigue test perfectly reflected the fatigue performance of asphalt mixture. The fatigue prediction model used for regression was obtained from beam blending fatigue test results; the obtained parameters may reflect the relationship between fatigue life and the loading times. The observations of high R values are also indicative of excellent model accuracy for the results of the fatigue tests.

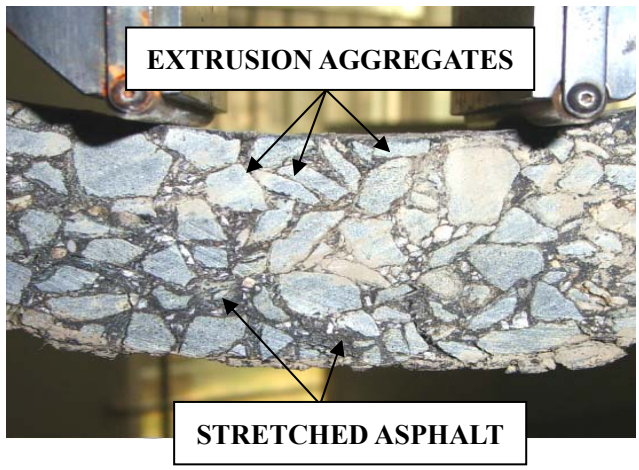

Figure 3. Fatigue phenomenon of SMA-13

2) The addition of Bonifibers to AC-20 mixture improves the fatigue performance of asphalt concrete. Bonifibers modified AC-20 mixture is the perfect material for heavy loading roads. For SMA-13, Bonifibers reinforced asphalt mixture performed much better in fatigue resistance compared to that of plain concrete.

ANALYSIS METHOD FOR THE PRESTRESSED CONCRETE BRIDGES BASED ON TIME-DEPENDENT THEORY

Wu Hong-Lin

School of Transportation Science and Engineering, Harbin Institute of Technology, Harbin, P.O. Box 2524, Harbin, 204 Haihe Rd; PH 8615804505529; email: whlhitb@163.com

ABSTRACT

Based on the equilibrium equation of the section and structure, an analytical method for predicting properties of the bridge structure is proposed in this paper. In the method, time-dependent factors such as shrinkage and creep in concrete, relaxation in the tendon, as well as temperature are synthetically considered. It is shown that the method is more comprehensive, easier, and more accurate than traditional methods. With this method, a long-term evaluation for stresses and deformation on any section of pre-stressed concrete beams at any time from the beginning of construction to opening, even to many years later, can be completed. The results based on the theoretical analysis is proven by practical engineering.

BASIC PRINCIPLE OF TIME-DEPENDENT ANALYSIS

Basic principle on time-dependent analysis. The precise calculation of deformation or secondary internal force of the structure is difficult because of the complexity, even if a partial differential equation can be established (Tang, 1982) Time-dependent analysis is based on numerical calculation, so the following assumptions are given:

(a) Concrete and steel are the ideal elastic material. The modulus of elasticity of concrete is constant.

(b) Section deformation is in accordance with the plane section assumption.

(c) Adopt liner creep theory.

(d) The constitutive relations such as shrinkage and creep in concrete and relaxation in the tendon are known.

(e) When considering the temperature effect, the distribution mode of temperature on the section is known.

1. Stresses and strains relations on the section

Take any beam block section along the span (Figure 1.a). Assume that the longitudinal strain at the bottom surface of the section (x=0) is ε_o and the actual curvature on the central section of the beam block is χ (Figure 1.b, χ is minus) under the whole external load, and shrinkage and creep in concrete, and relaxation in the

tendon. The actual strain of any point (Height is x.) along section ε can be determined as (Figure 1.b)

$$\varepsilon_{act} = \varepsilon_o - \chi\, x \tag{1}$$

Assume the strain on any slice (Height is x) caused by shrinkage and creep in concrete is ε_f (Figure 1.c) and the strain caused by relaxation in the tendon is ε_{sf} under no restriction. All of the above strains are called free strains. The free strains can also include the temperature strains increment when temperature distribution exists on the section. The strains corresponding with elastic stresses in every slice ε_σ can be determined as (Figure 1.d)

$$\varepsilon_\sigma = \varepsilon_f - \varepsilon_{act} \tag{2}$$

The stresses and strains in concrete and the tendon along the section (Height is x) can be determined as:

(a) Stresses and strains relations of concrete:

Actual strains in concrete:

$$\varepsilon_{act} = \varepsilon_o - \chi\, x$$

Stresses in concrete:

$$\sigma = Eh\varepsilon\ \sigma = Eh(\varepsilon_f - \varepsilon_o + \chi\, x) \tag{3-1}$$

(b) Stresses and strains relations of tendon:

Actual strains in tendon:

$$\varepsilon_{sact} = \varepsilon_o - \chi\, x$$

Stresses in tendon:

$$\sigma_s = E_s\varepsilon_{\sigma s} = E_s(\varepsilon_{sf} - \varepsilon_o + \chi\, x_s) \tag{3-2}$$

2. Establishing the equilibrium equation of the section

For pre-stressed concrete bridges, there is often bending moment M and axle

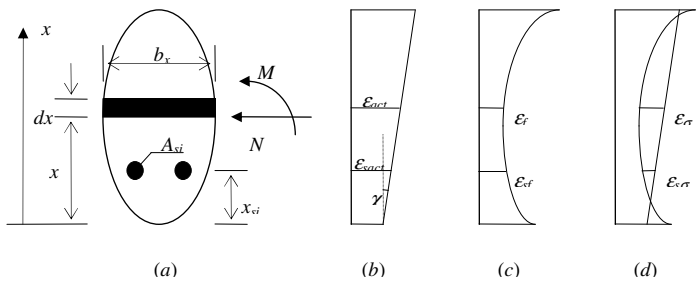

Figure 1. Stresses and strains relations on section

force N on the sections. Shear Q is not considered here. According to the equilibrium between the internal force on the section and the total forces of stresses in concrete and the tendon, the equations can be determined as:

(a) The equation of horizontal force

$$\int_h \sigma dA + \sum_{i=1}^{ns} \sigma_{si} A_{si} - \sum_{i=1}^{ns} E_h \varepsilon_{si} A_{si} = N \qquad (A)$$

in which, n_s is the number of tendon.

(b) The equation of bending moment

$$\int_h x\sigma dA + \sum_{i=1}^{n_s} x_{si}\sigma_{si} A_{si} - \sum_{i=1}^{n_s} E_h x_{si}\varepsilon_{si} A_{si} = M + N \cdot y_x \qquad (B)$$

Considering: $m = E_s / E_h$, then taking equation (1)and (2) to (A) and (B).

Noting that:

$$A_0 = \int_h dA + (m-1)\sum_{ns} A_{si}$$

is the area of transformed section, and

$$A_1 = \int_h x dA + (m-1)\sum_{ns} x_{si} A_{si}$$

is the moment to bottom of transformed section, and

$$A_2 = \int_h x^2 dA + (m-1)\sum_{ns} x_{si}^2 A_{si}$$

is the second moment to bottom of transformed section.

N is the axle force caused by loads on the section; IF there is no axle force, N=0; M is the bending moment caused by loads on section. Therefore, a set of the equilibrium equations (4) on section could be deduced, that is,

$$\begin{cases} \varepsilon_o \left[\int_h dA + (m-1)\sum_{i=1}^{n_s} A_{si} \right] - \chi \left[\int_h x dA + (m-1)\sum x_{si} A_{si} \right] \\ \qquad = \int_h \varepsilon_f dA + (m-1)\sum_{i=1}^{n_s} \varepsilon_{sfi} A_{si} - \frac{N}{E_h} \\ \varepsilon_o \left[\int_h x dA + (m-1)\sum_{i=1}^{ns} x_{si} A_{si} \right] - \chi \left[\int_h x^2 dA + (m-1)\sum x_{si}^2 A_{si} \right] \\ \qquad = \int_h x\varepsilon_f dA + (m-1)\sum_{i=1}^{n_s} x_s \varepsilon_{sfi} A_{si} - \left(\frac{M + N \cdot x_c}{E_h} \right) \end{cases} \qquad (4)$$

Solving the above equations (4), then the solutions on he longitudinal strain ε_o and the actual curvature on central section of beam block χ could be found in formula (5).

$$\begin{cases} \chi = \dfrac{1}{A_0 A_2 - A_1^2} \left[A_0 \xi - A_1 \eta + \dfrac{A_0 M}{E} \right] \\ \varepsilon_o = \dfrac{1}{A_0 A_2 - A_1^2} \left[A_2 \xi - A_1 \eta + \dfrac{A_1 M - A_2 N}{E} \right] \end{cases} \qquad (5)$$

In the equation (5) the parameters ξ and η are related to free strains and

geometric performance of a section, and determined by the following equations:

$$\xi = \int_h \varepsilon_f \, dA + (m-1) \sum_{ns} \varepsilon_{sfi} A_{si}$$

$$\eta = \int_h x \varepsilon_f \, dA + (m-1) \sum_{ns} x_{fi} \varepsilon_{sfi} A_{si}$$

The stresses and strains at any point on a section can be determined by taking curvature χ and strain εo to equation (3-1) and (3-2).

CONCLUSIONS

Based on the equilibrium equation of the section and structure, an analytical method for predicting long-term properties of pre-stressed concrete bridge structures is proposed in this paper, in which time-dependent factors such as shrinkage, creep in concrete, and relaxation in the tendon, as well as temperature are synthetically considered. The following actions, such as interactive action between concrete and tendon, the characteristic of relaxation in tendon, and the interactive effect on sections, could be determined truly by the proposed method in this paper.

The time-dependant analysis theory has been taken into the traditional force method and displacement method, so that the solving of the structure problem becomes easier and more comprehensive. The time-dependant analysis theory can be easily used in pre-stressed concrete bridge structures such as continuous beams, continuous rigid frames, and cable-stayed bridges with the numeric analysis method. By this method, the stresses, strains, internal forces, and deformation at any time from the beginning of construction to the operating stage could be determined easily in the above bridges.

It is unnecessary to save the history of strain and stress changes of elements by the FEM method proposed in the paper. The increment of strains and the total deformation during a period of time are the only factors needed to be saved. Therefore, the method is more suitable to be used in FEM in PC structures. The program based on the above time-dependent theory has been proven successfully in practical engineering.

ABSTRACT

This paper presents an analytical method to predict the confidence level of service life for bridge structures. The analysis uses the Monte-Carlo Analysis to build the resistance model and load model of bridge structures. With the reliability module of ANSYS program, the material properties and load character were set as time-dependant variables. The distribute shape of each variable was also considered. Based on the stress and deformation output of the bridges, the different confidence levels at different time were obtained using two reliability determination criterions. The bridge's time-dependant confidence level curve can be drawn, based on which the confidence level at different time can be directly read.

INTRODUCTION

Research in structural reliability has recently made significant progress in China. Due to the lack of a reasonable assessment mechanism of their service life, a number of collapse accidents occurred to the bridges built in the 1980's or earlier. Within this context, it is urgent to propose a reliability-theory-based method to assess the service life of the old bridges, based on which their rehabilitation and reconstruction can be conducted.

CALCULATION METHOD

Commonly used methods for the reliability analysis of bridge structures include the first-order second-moment central point method, the first-order second-moment check-point method and methods based on their improvements. In recent years, methods for reliability calculation such as Monte Carlo method and response surface method have come into use, b having both advantages and disadvantages. Because of the clarity and simplicity of its structural utility function, hence the ease of its use, the first-order second-moment method is commonly used for structural calculation. When the utility function of a structure takes no specific expressions; however, such use is usually difficult. In such cases, the Monte Carlo method can be used instead.

Monte Carlo method is a numerical simulation to solve practical engineering problems related to random variables. In the current reliability calculation of bridges, it is taken as a relatively precise method. The numerical simulation of random variables is equivalent to a "trial";

the Monte Carlo method is therefore also known as the common method for statistical test. The commonly used methods of sampling include direct Monte Carlo sampling, Latin super cube sample method, and self define method. In the following section, the reliability analysis of life expectancy of bridges will be demonstrated using reinforced concrete bridges for their universal use.

PROPOSED BRIDGE STRUCTURE MODEL

Model of time-varying strength of concrete. The mean and standard deviation functions t (Zou 1998) as an arbitrary point of time can be taken as

$$\mu_f(t) = 1.3998\mu_{fo}e^{\left[-0.0195\left(\ln\left(t+0.0892\right)-1.7322\right)^2\right]} \tag{1}$$

$$\sigma_f(t) = \sigma_{fo}\left[0.318(t+0.03742)+0.9881\right] \tag{2}$$

in which μ_{fo} - average of compressive strength of concrete in 28d; and

σ_{fo} - Standard deviation of compressive strength of concrete in 28d.

Model of time-varying strength of reinforcement. The time-varying strength of reinforcement (Zou 1998) can be expressed as

$$f_{sk} = f_{yk}(0.986 - 1.1992\eta_s) \tag{3}$$

in which f_{sk} - characteristic value of the nominal yield strength of corroded reinforcement;

f_{yk} - characteristic value of the yield strength specified in the current code, and is taken as 320MPa in this paper; and

η_s - corrosion ratio of the cross sectional area of reinforcement (the ratio of corroded cross sectional area to the original one).

Model for the change in cross sectional area of reinforcement. After t years of use, the mean and standard deviation of the cross sectional area of a rebar (Jin and Zhao 2002) can be expressed as Equations 4 and 5, in which μ_0 and σ_0 are the mean and standard deviation of the initial cross sectional area of a reinforcement respectively.

$$\mu_{As}(t) = \lambda(t)\mu_0 \tag{4}$$

$$\sigma_{As}(t) = \eta(t)\sigma_0 \tag{5}$$

$$\lambda(t) = c_1 + c_2\cdot(t-52.5) + c_3\cdot(t-52.5)^2 + c_4\cdot(t-52.5)^3 \tag{6}$$

$$\eta(t) = d_1 + d_2 \cdot (t - 52.5) + d_3 \cdot (t - 52.5)^2 + d_4 \cdot (t - 52.5)^3 \quad (7)$$

In addition, the resistance of a bridge is related to the density of materials, which follows the standard normal distribution in the analysis hereafter.

ANSYS MODULE FOR PREDICTING LIFE EXPECTANCY OF R/C BRIDGES

Introduction has been given to the distribution functions of parameters taken as random variables with respect to time for RC bridges. In the following, from the viewpoint of ANSYS calculation, study will be focused on how to determine the uncertainty level of outcome variables to be found through the uncertainty of parameters in a model. The failure probability of a bridge resulting from the uncertainty of input parameters will then be determined on the basis of certain criteria. The remaining service life can be determined also.

For a R/C bridge, its strength, cross sectional area, and density of reinforcement, tensile and compressive strength of concrete, and its density all follow certain distribution functions. Because of structural failure takes a certain period of time, in the analysis with ANSYS program, it is unnecessary to simulate the reliability of a bridge under load at every minute in a dynamic analysis. This article will, therefore, first divide the service life of a bridge (typically 100 years) into a number of time intervals. At the ends of the time interval the value of each parameter will be taken. For example, when t=10 is substituted into the corresponding time-varying functions for strength, cross sectional area and density, the material properties at the time point will be calculated. The calculated parameters are then assumed to follow normal distributions, with which the reliability of the bridge can be determined using the ANSYS analysis procedures

Reliability calculation of Life expectancy of RC bridge. Below a R/C simply supported girder bridge will be taken as an example for calculating the reliability and analyzing the service life.

A five-girder fabricated simply supported RC bridge was built in 1970, with its flanges rigidly jointed. Its concrete is of C25, calculation span is 20.0 meters, with a net deck width of 7.0 meters. The average thickness of asphalt concrete bridge deck is 9cm (a 4cm-asphalt layer overlying a 5cm concrete one). The full-bridge layout, cross-section and one piece of girder are shown in Figures 1,2 and 3 respectively.

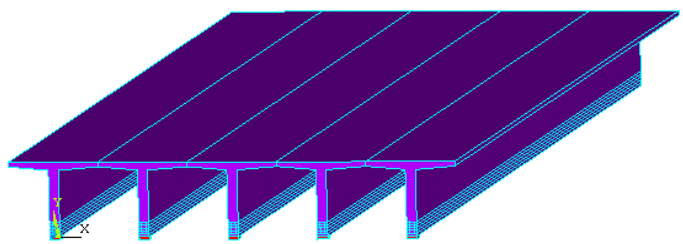

Figure 1. Overall layout of full-bridge.

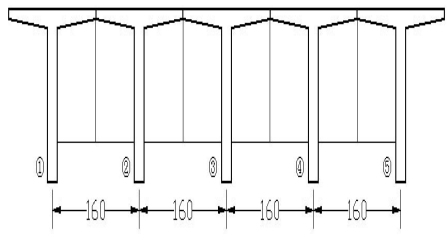

Figure 2. Full-bridge section size (cm).

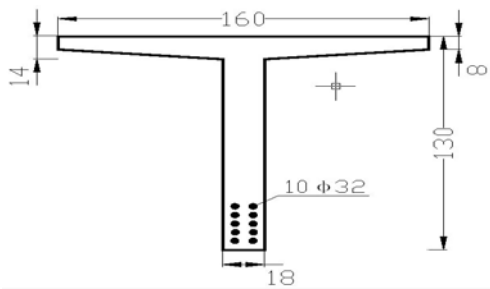

Figure 3.Girder cross-section (cm).

According to rigid cross beam method, Bridge Doctor has been used to find its coefficients of transverse distribution as given in the Table 1.

Table 1. Coefficients of transverse distribution.

Girder No. / Load	1	2	3	4	5
Automotive	0.522	0.461	0.400	0.461	0.523

Criteria for the assessment of RC bridge reliability.

(1) Stress, deformation criteria

a. Stress criteria

Characteristic value of concrete strength of reinforced concrete girders are listed in Table 2 below.

Table 2. Characteristic values of concrete strength (MPa).

Types of strength		Symbol	Concrete grade						
			15	20	25	30	40	50	60
Characteristic value	Axial compressive	R_a	10.5	14.0	17.5	21.0	28.0	35.0	42.0
	Tensile	R_l	1.3	1.60	1.90	2.10	2.60	3.00	3.40

b. Deformation criteria

As far as reinforced concrete bridges are concerned, the calculated maximum vertical deflection of the supper structure under the automobile load shall not exceed the following allowable value: the midspan deflection of girder bridges ≤ L/600 (Li Yang Hai 1997).

(2) Failure probability criteria

For the existing structures, the reliability of assessment criteria is usually based on the reliable indexes, and Dalian University of Technology has conducted a lot of research in this aspect. Taking βt <0.85βo as a criterion of structural failure, that is, at this moment, a structure has come to the end of its service life. The target reliability indexes with design reference period T = 100 years are as listed in Table 3.

Table 3. Target reliability indexes of Road and Bridge structural members.

Structure class / Combination action effect	First class		Second class		Third class	
	Ductile failure	Brittle failure	Ductile failure	Brittle failure	Ductile failure	Brittle failure
Primary combination	4.7	5.2	4.2	4.7	3.7	4.2
Additional combination	4.2	4.7	3.7	4.2	3.2	3.7

In this paper, the reliability of a structure is judged on the basis of its failure probability. At the same time because all the material variables involved obey normal distributions, live loads generally obey type-I extreme distribution, hence the stresses and deformations obtained all follow normal distributions, so that it is reasonable to calculate its failure probability theoretically in terms of 0.85 β_o by using normal distributions. In addition, the calculated results also follow normal distribution. The detailed results obtained are as listed in table 4.In this paper, examples of secondary roads are of ductile failure, so that β_o = 4.2, and 0.85 β_o = 3.57, which is in the interval [3.5, 4.0]. From Table 4 is can be found that P_f = 0.0002, so that when the failure probability of the bridge is less than 0.0002, the structure is considered to be safe.

Table 4. Corresponding relationship between β and P_f.

β	P_f	β	P_f	β	P_f
1.0	0.159	2.5	0.00621	4.0	0.0000317
1.5	0.0668	3.0	0.00135	4.5	0.0000034
2.0	0.0228	3.5	0.000233	5.0	0.00000029

Calculation of the life expectancy of RC bridges. It is known from the coefficients of transverse distribution that maximum values occurs at side girders; therefore, as long as the calculated stresses and deformations of these girders meet requirements of failure criteria, the whole bridge will be safe (Zhao Shang-chuan 2001). In this analysis, t the structural responses of only the first piece of girder are calculated.

(1) The distribution curve of the material properties at time t

With the elapse of time, the material properties of a RC bridge change, hence its carrying capacity. The key point of this paper is to determine when the bridge can no longer carry the imposed loads. In the structural analysis, it is assumed that the material properties follow normal distributions. Figure 4 shows the distribution curves of the material properties at the t = 30 years.

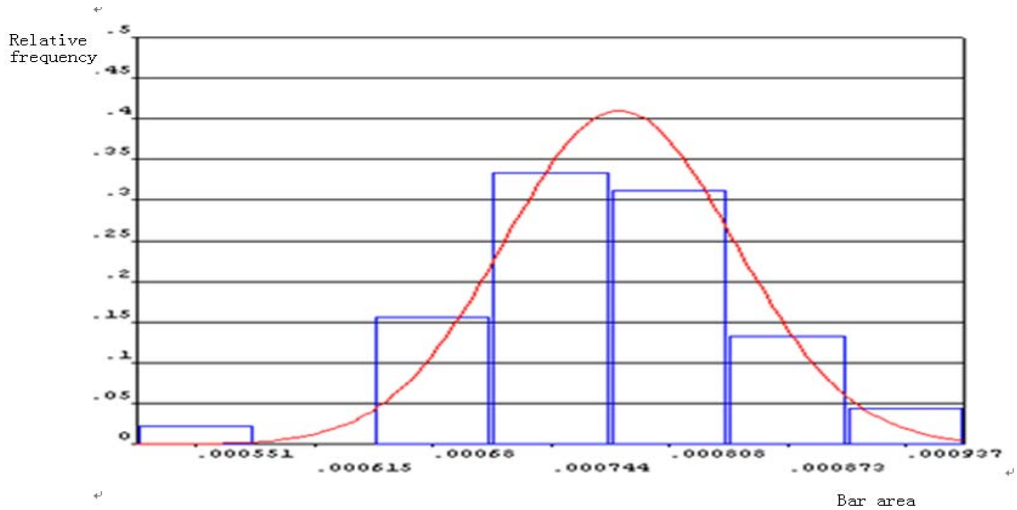

Figure 4. Distribution curves of the material properties (t = 30).

(2) Types of bridge failure under loads

The largest cross-sectional area of concrete: A = 0.11×1.6 +0.18×1.19 = 0.390 m^2, when t = 0, Ag (0) = 10×π×0.0162 = 0.00804 m^2. At this point, reinforcement ratio μ= (0.00804/0.390)% = 2.1%> 1.5%, when t = 100, Ag (100) =$\lambda(t)$, μ_o= 0.858 × Ag (0) = 0.00690 m^2 . At this point, reinforcement ratio μ= (0.00690/0.390)% = 1.8%> 1.5%

Therefore, through out its service life, the girder always acts as an under reinforced concrete one, which is characterized by the occurrence horizontal longitudinal cracks in its compression zone, followed by the crushing of concrete when concrete at the extreme fibers of compression zone reaches the ultimate compression strain of concrete. Therefore, in the simulation of its deformations, only when the compressive stress of concrete in the compression zone reaches the ultimate strength of concrete, or structural deformation exceeds L/600 (the reliable probability is beyond the corresponding allowable limits), can its failure be considered to have occurred.

(3) Deformations, stress distribution curves and probability distribution curve

For the convenience of curve plotting during the stress and deformation analyses, the negative sign of compressive stress was plotted in the curves. However, since what is concerned with is the failure mode when the concrete compressive stress reaches its ultimate value at the time of failure, negative sign is always implicitly inferred. In addition, the girder deflects downward under loads, which is opposite to the positive direction of longitudinal axis of the coordinate system, the deflection is also negative. The two boundary curves for the distribution functions of stresses and deformation indicate the ranges of reliability when the confidence level is 98%.The structure is always safe in these ranges.

At t = 20 years the results of reliability analysis of the bridge are shown in the following figures.

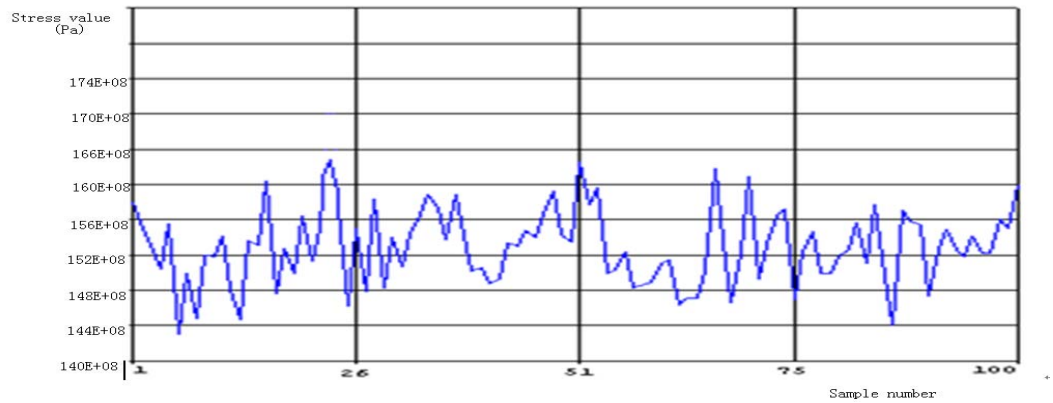

Figure 5. Curve of the sampled stresses.

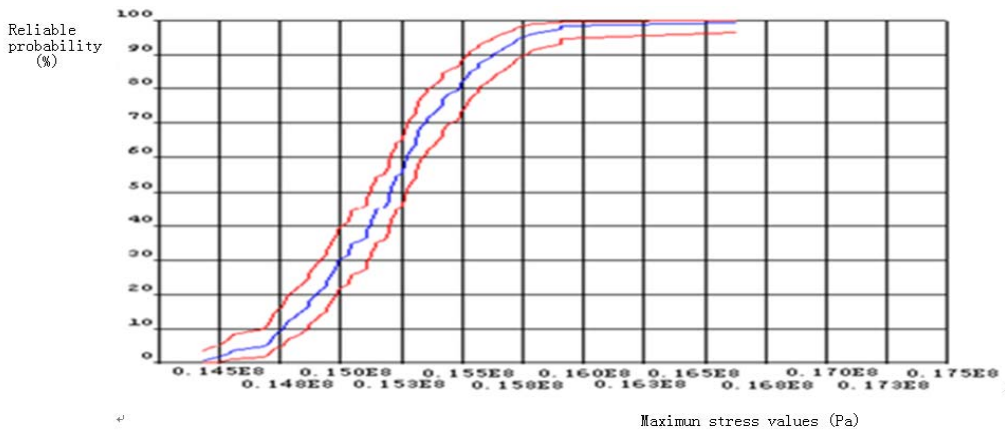

Figure 6. Curve of stress distribution function.

From the curve of sampled stresses in Figure 5, we can clearly see the range of the maximum stress in the sampling process, and the sampled values are all under the characteristic strength of 17.5MPa, thus at t = 20 years the bridge is safe.

In Figure 6, if a vertical line is drawn at characteristic strength of x = 17.5 MPa, it will intersect the curve of stress distribution function at the ordinate of 1.0, at the reliability of 1. It shows the structure is fully reliable at this time. In the following section, the o direct output

module of probability is used to analyze the reliable probability. In the probability output module of program, we select executable documents and the smax for option of reliability design variable, and then fill in the limit with the characteristic strength of 17.5 MPa while keeping the confidence level as 0.98. Running the module at such a condition gives the reliability of 1.0 if the stress is less than 17.5 MPa (see Figure 7) (GE Jun-yin, WANG Li-you 2007).

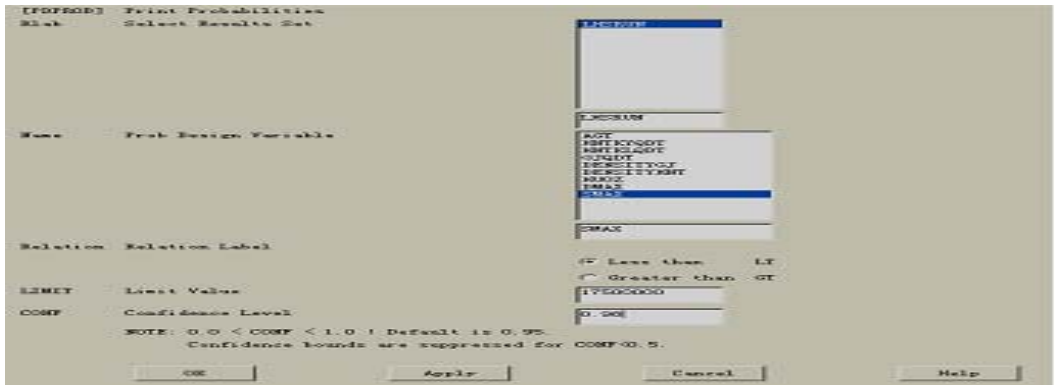

Figure 7. Direct numerical method for reliability.

From the curve of sampled deformations in Figure 8, it can be seen that the sampled maximum deformations are all smaller than the required value of L/600 = 0.033m, hence, from the distribution of deformations the bridge is completely safe at the t = 20 years.

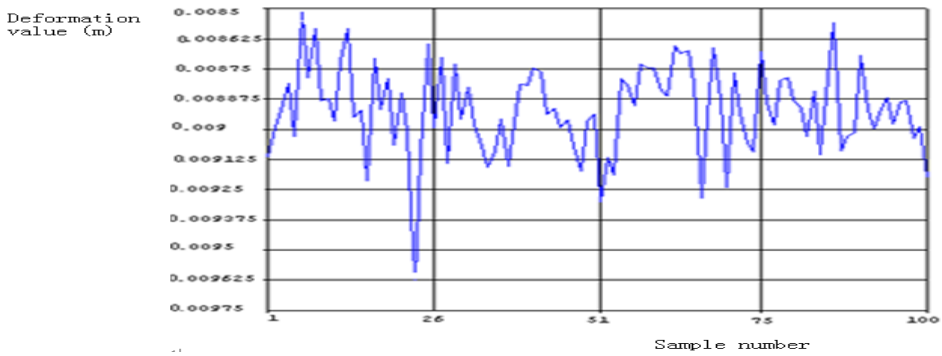

Figure 8. Curve of sampled deformations.

In the curve of deformation distribution function in Figure 9, if a vertical line is drawn at deflection x = 0.033m, it will intersect the curve of the distribution function at the ordinate 1.0. Again, we can use the direct output probability value method to carry out the reliable probability analysis. In Figure 7, we firstly select the executable documents and the dmax in the option of variable selections, and then fill in 0.033m as the value of deflection limit while taking confidence level as 0.98, the reliable probability can be obtained as 1.0 if the deformation is less than 0.033m.

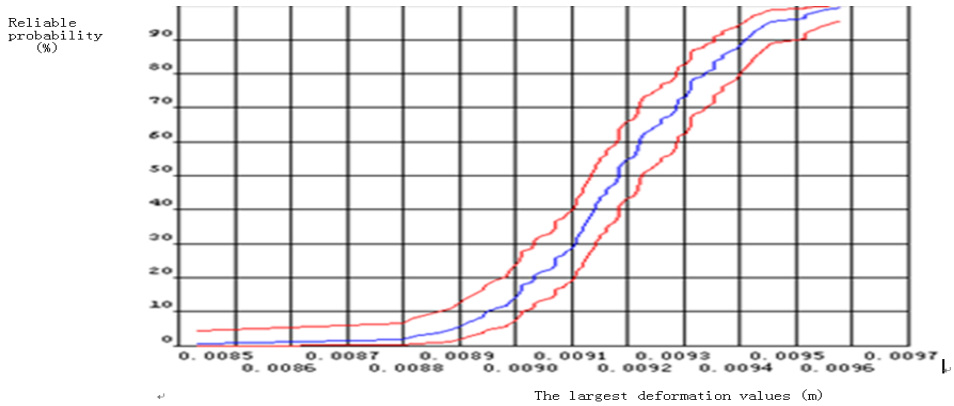

Figure 9. Curve of deformation distribution function.

From the argument above, the stress and deformation of the bridge after 20 years operation are all within ranges of limits. With the reliability of 1, the structure is reliably safe.

Table 5. Time-probability relationship.

Time (years)	20	40	60	75	76	77	78	79	80	81	85
Reliable probability	1.0	1.0	1.0	0.99999	0.99996	0.99993	0.9999	0.99987	0.99984	0.9998	0.998

Using the same method, reliable probability at other time can be obtained as shown by the function between time and reliable probability in Table 5 and Figure 10.

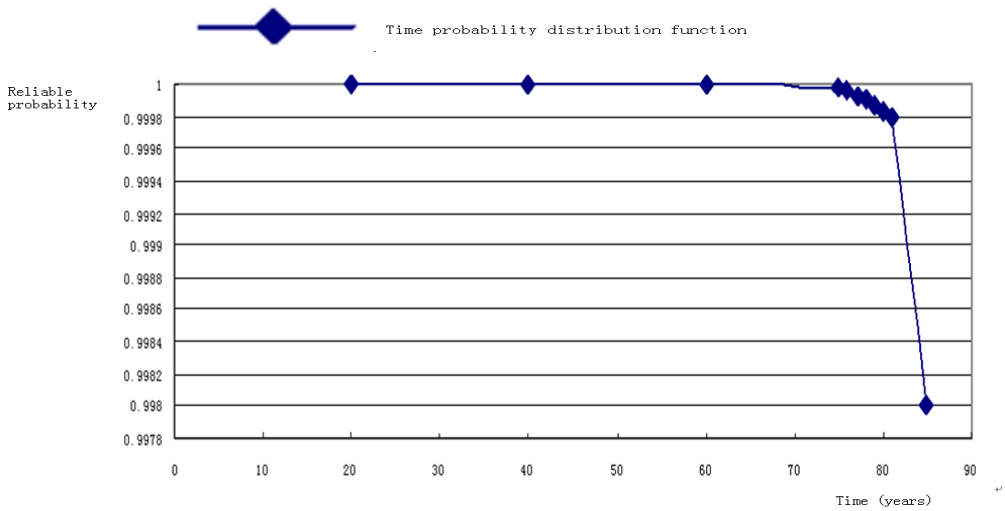

Figure 10. Curve of probability distribution function with time.

Solution of the remaining service life of bridges. As mentioned above, there are various methods for calculating the remaining service life of bridges. As long as the service life of a

bridge can be accurately calculated, its remaining service life can be precisely obtained by directly subtracting the year of operation from its service life. The life of RC bridge algorithm are described in detail above; also it has been obtained that the service life of a certain RC simply supported girder bridge is 81 years; therefore, after operation over 35 years, the bridge is reliably safe. Moreover, the bridge can operate 46 years without overhauls.

CONCLUSION

This paper describes a method which uses the analytical module of ANSYS to determine the stress and deformation of a simply supported R/C girder bridge. The remaining service life of the bridge was subsequently determined in terms of two criteria. The methodology developed provides a theoretical basis for assessing the bridge reliability, calculating their service life, and rehabilitating or rebuilding the bridges.

ABSTRACT

Partial depth Cold In-place Recycling (CIR) is a cost-effective method for the preventive and corrective maintenance of existing pavements. In recent years, the asphalt emulsion CIR has been used in asphalt pavement preservation and maintenance in China. This study focused on asphalt emulsion CIR mixtures that are used as binder course on roads of various traffic volumes. Performance related testing and evaluation of specification properties of six different recycling mixtures were conducted. In addition the field post-project monitoring has also been evaluated. Based on lab and field performance, it was discovered that emulsion CIR was an effective method for the preventive and corrective maintenance of existing pavement as binder course. Then, performance related specifications of asphalt emulsion CIR mixtures used as binder course was recommended to a local highway agency.

INTRODUCTION

Background

Jiangsu provincial trunk highway network usually has a relative good structural bearing capacity, but it still has some severe distresses, such as rutting, cracking, shoveling, patching, etc in asphalt pavements. Based on the distressed types of old asphalt pavement in Jiangsu, the technology of asphalt emulsion partial depth CIR is a very ideal rehabilitation candidate. This paper presented a study to evaluate the suitability of emulsion recycling mixture used as pavement binder course from lab and field performance aspects.

CIR process

The partial depth CIR process is a single-unit CIR process conducting milling and mixing on existing asphalt pavement with potential addition of new aggregates (if necessary) and asphalt emulsion and cement in proportion. Then it places the mixed material on the ground. A pick-up machine, a paver and a set of compactors will continuously finish the processes of elevating, paving and

compacting the recycled materials under natural environment temperature. Typically, the layer/lift thickness is from 50 to 120 mm.

Project description

Six-project roads having different traffic volumes that belong to Jiangsu provincial trunk highway network were evaluated by Falling Weight Deflectometer (FWD) testing and visual inspection. Pavement conditions including PCI (Pavement Condition Index) and SSI (Structure Strength Index) are listed in Table 1. The typical distresses of the these roads included rutting, moisture damage, cracking, flushing, corrugation and patching. Even the PCIs of G328, S239-I, S239-II, S336 and G104 show good conditions, their rutting is very unstable in summer,. It was shown that all project roads had good structural bearing capacity. Hence, these roads were ideal candidates for using asphalt emulsion partial depth CIR technology based on the distress types.

Table 1. The conditions of old asphalt pavements

Road	Performance Evaluation				Length (km)	AADT
	PCI	PCI Grade	SSI	SSI Grade		
S229	68.8	Fair	0.65	Fair	0.5	16,000
S239-I	68.5	Fair	0.74	Good	2.0	10,000
S239-II	65.3	Fair	0.74	Good	8.0	10,000
S336	56.9	Fair	1.88	Excellent	3.68	8,000
G104	56.0	Weakness	0.88	Good	1.0	5,000
G328	84.4	Good	0.94	Good	0.8	25,000

SAMPLE PREPARATION

Original material

All testing RAP was taken from the original old asphalt pavement of the each project road. RAP is regarded as “black rock” (Forsberg et al., 2002). This research will not study the effect of recovered old asphalt in RAP.

Virgin coarse aggregate was added to enhance the aggregate skeleton and provide higher internal frictional resistance (JTRI 2005). Meanwhile, the fine aggregate can form emulsion-cement / fine mortar to improve the cohesion between asphalt and RAP.

Portland cement was limitedly selected for improving early strength, moisture stability and high temperature stability of recycled mix despite of a little sacrificing its fatigue performance.

An engineered asphalt emulsion that was classified as cationic slow setting was applied on each project. This engineered emulsion had been assessed as compatible with the RAP / virgin aggregate blend to ensure quick mixing, complete coating, quick early strength development, resistance to moisture damage through many projects. Typically, the engineered emulsion has high residue content (not less

than 63%) in order to guarantee a thick asphalt coating film.

Pre-mix water has multiple functions. Chief among these functions is to improve coating of the RAP and virgin aggregate, to lubricate mixture during compaction, and to facilitate / accelerate the cement hydration reaction.

A vary emulsion dosage and pre-mix water content were selected in mix design of each project. The contents of original material used in recycled mixes of CIR projects are listed in Table 2.

Table 2. The contents of original materials used in recycled mixes

Project	RAP	New Aggregate			Portland Cement	
	(%)	Type	Size (mm)	Ratio (%)	Type	Ratio (%)
S229	85	Coarse	10-25	15	32.5	2.0
S239-I	85	Fine	0-3	10	32.5	2.0
		Coarse	15-25	5		
S239-II	84	Fine	0-3	8	42.5	2.0
		Coarse	15-25	8		
S336	85	Coarse	10-20	15	42.5	2.0
G104	85	Coarse	10-25	15	42.5	2.0
G328	85	Coarse	10-20	15	42.5	1.5

Gradation design

The gradation of the combined RAP and virgin aggregate was designed to meet guidelines and specifications from worldwide research road authorities and associations, such as DOTs of U.S., the Federal Highway Administration and the Asphalt Reclamation and Recycling Association (FHWA 1997; Iwoa DOT 2005; Montana DOT 2005; ARRA 2006). To meet the recommended total aggregate gradation, different amounts of coarse aggregate (by mass of recycling mixture) was blended with RAP aggregate. The sieve analysis results of this blended gradation are shown in Figure 1.

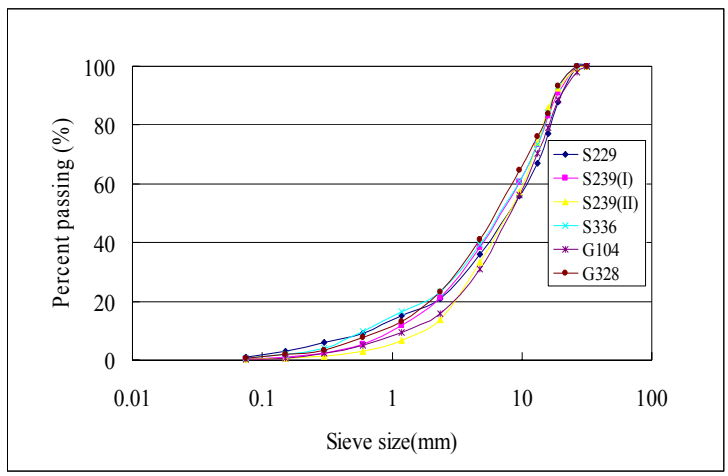

Figure 1. Recycling blended gradation curves

Experimental procedures

Specimen preparation and curing

A laboratory mechanical mixer was used for cold mixing. Superpave™ gyratory compactor was applied for preparing the specimens with 100mm in diameter and 63.5 ± 2.0 mm in height with 30 gyrations (Lee et al., 2003; Tan et al., 2005). The compacted specimens were initially cured at room temperature for 12 hours, and then were cured at 60℃ for 48 hours.

Test methods

The Marshall stability testing was carried out on two sets of specimen at 40 ± 1℃ testing temperature. One set of three replicates was tested directly without conditioning. Another set of replicates was conditioned in water bath at 25℃ for 23 hours. The percentage of retained stability can be expressed as follows:

$$RS = IMS / MS * 100\ \% \quad [1]$$

Where RS, IMS and MS represent retained stability, immersion Marshall stability, and Marshall stability, respectively.

The indirect tensile test (IDT) was conducted with two sets of specimen at 15℃ testing temperature. One set of three replicates was tested directly without condition, and another set of replicates was conditioned in water bath at 25℃ for 23 hours. The percentage of indirect tensile strength ratio is calculated as follows:

$$DWTSR = WIDT / DIDT * 100\% \quad [2]$$

In equation [2], the DWTSR, WIDT and DIDT represent dry-wet tensile strength ratio, immersion IDT strength, and dry IDT strength, respectively.

The freeze-thaw indirect tensile tests were performed at 25°C testing temperature. One set of three replicates was tested directly without conditioning, and the other set of three replicate specimens were vacuum saturated to 55-75% and conditioned at -18°C for 16 hours, and then placed in a water bath at 60°C for 24 hours.

Rut testing was performed with a 0.7 MPa rubber wheel load at a test temperature of 60 ± 1°C for three replicate specimens. The rutting specimen dimensions are 300 mm × 300 mm × 60 mm.

RESULTS AND DISCUSSION

Marshall test

Figure 2 shows that the Marshall stability (MS) has different trend patterns for different recycling mixes. MS no less than 6kN is the criterion for cold recycling mixture used as binder course, and retained stability should be greater than 75％.

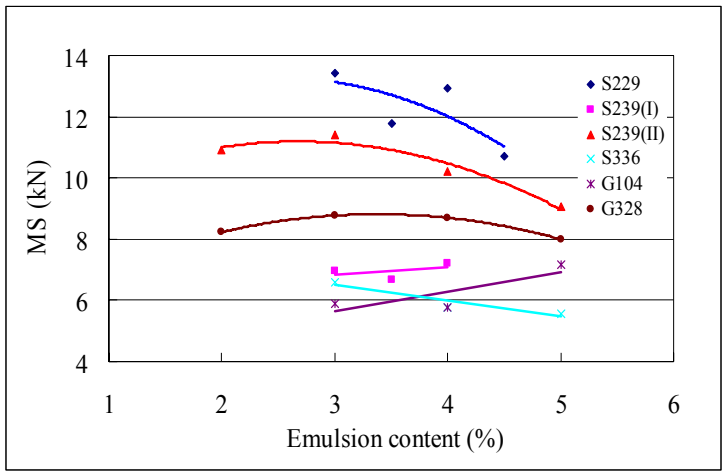

Figure 2. Marshall Stability trend curves

Indirect tensile test

Indirect tensile strength is the most important factor in optimum emulsion content evaluation. Figure 3 shows IDT strength trend patterns of each mix.

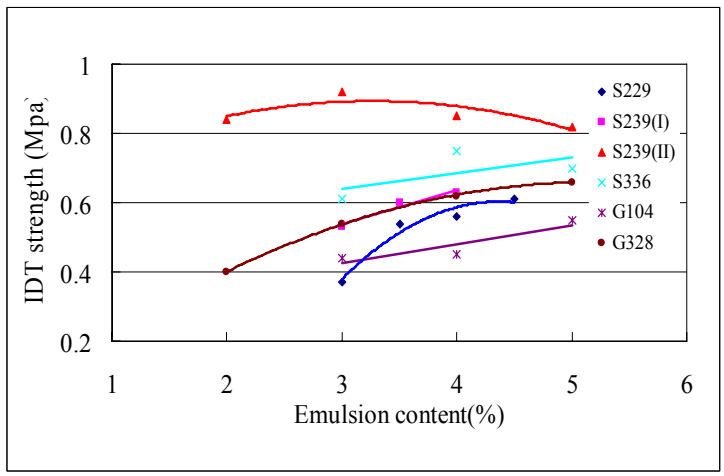

Figure 3. IDT strengths trend curves

Optimum emulsion content and validation test

The optimum emulsion content selection is an integrated judgment that includes all mechanical performance and mixture volumetric properties. The pre-mix water content is determinate by compromise of total liquid content between maximum density and minimum coating requirement.

Table 3 shows that all validation tests were conducted on the optimum formulated with cement, emulsion and water contents for each project. A note is made here: all tensile strength ratios (TSR) are greater than 70% and the Chinese Dynamic Stability (DS) test is more than 2500 times/mm, which indicates that the recycling mixture has good water resistance and high temperature stability and respectively.

Post-project monitoring

For each project, a usual 3-5cm HMA surface course was applied on the CIR binder course. FWD inspection of four roads showed good structural bearing capacity after one year traffic and snow disaster in the winter of 2007. No crack and and no more than 3 mm rutting had been found in all projects. The FWD values of the four pavements were listed in Table 4. It was shown that all trial projects have typical asphalt pavement deflection level with Chinese Semi-Rigid Base.

The recommended Performance Related CIR Specifications

Based on the results of performance evaluation and post-project monitoring, for Jiangsu province trunk highway network in China, a summary of the performance specifications recommended for CIR mixture used as binder course is presented in Table 5. However, for the suggested performance specifications, raveling test, fatigue test and low-temperature cracking test will be considered in the next research plan. Highway Bureau of Jiangsu Provincial Communication Department will adopt the specifications after more CIR projects are implemented.

Table 5. The performance related specifications for CIR

Property	Criteria	Purpose
Gyratory Compactor	1.25°, 600 kPa, 30 gyrations	Density Indicator
Voids	8-14%	Compacted Density
Gradation for RAP	Report	Mix design
Marshall stability, 40℃	6kN min	Stability Indicator
Retained stability	75% min	Moisture susceptibility
IDT, 15℃	0.5 MPa min	Strength Indicator

Retained IDT	75% min	Moisture susceptibility
Freeze-thaw IDT, 25℃	70% min	Moisture stability
Rutting test, 60℃	2500 times/mm min	High temperature stability

Discussion

For some project test results, RS and DWTSR ratios were higher than 100%. The possible explanation is that the rest cement continued to undergo strength-building hydration reactions during the immersion process.

The study process used herein involved laboratory performance evaluations and established emulsion percentages that would yield recycled mixes for six projects that met the recommended performance specifications with Superpave™ gyratory compactor. Additional performance tests, such as the raveling test and low-temperature cracking test (Thomas et al., 2003) will be considered in the next research plan, as well as quality evaluation of RAP from the six projects.

CONCLUSIONS

This research work aimed at studying the characteristics of asphalt emulsion recycled mixtures as binder course on six roads with different traffic volumes in Jiangsu province, China. Based on the studies here, the following conclusions were drawn:

According to asphalt emulsion CIR mixture mix design procedures, the performance characteristics of cement asphalt emulsion recycling mixtures that were used as binder course can be evaluated with varying emulsion contents. For the six projects with different traffic volumes, the optimum emulsion contents that are from 3.5% to 4.3% exhibit the most satisfactory performance properties.

Post-project monitoring showed that recycled pavement had good structural bearing capacity after one-year traffic using FWD inspection. Even rut was the major distress on old pavements, only minor rutting about 3mm was observed on recycled pavements. It may be affected by the HMA surface course due to high temperature stability of recycled mixes as shown in results of rut testing.

CIR is the most cost-effective, environmental friendly and socially conscious pavement preservation and maintenance options. Based on performance evaluation and post-project monitoring, the performance specification for asphalt emulsion CIR mixture used as binder course is recommended in Jiangsu province trunk highway network in China.

ACKNOWLEDGEMENTS

This study was a co-operation with South East University and all data was supported by Jiangsu Provincial Transportation Science and Technology Project. We would like to thank Li Xiaoming, Dr. Everett Crews, Dr. Ma Xiang, Li Jian, Xu Biao who assisted in the lab testing and field construction.

Optimization of Vehicle Routing for Plowing and Snow Disposal

Zhang Dali[1]

[1]Highway Administration of Heilongjiang Province, No.169, Yiman Street, Nangang District, Harbin, Heilongjiang Province, PRC, 150090, PH:(86) 13766862168; email: hitliugang@live.cn

ABSTRACT

Plowing, snow loading, and hauling operations involve a number of vehicle routing problems where roads have to be traversed by plows, snow blowers, and trucks. This paper analyzes the problem of designing efficient routes for plowing and hauling trucks in snow emergencies. The plow routing and haul routing problems are determining a set of routes, each performed by a vehicle that starts and ends at its own depot, so that all the road segments are serviced, all the operational constraints are satisfied, and the total deadhead distance is minimized. Firstly, the typical characteristics of vehicle routing problems related to plowing and snow disposal operations are analyzed by considering their main components. Then, by using network transformation, a Capacitated Arc Routing Problem (CARP) is formulated to find the routes for vehicles. Heuristic procedures are applied because the problem has been shown to be NP-hard..

INTRODUCTION

Cleaning or reducing snow and ice in time on roads can improve the safety. Snow on pavement may be removed by chemical, thermal, or mechanical techniques. Plowing and snow disposal operations are usually performed on a regular basis in urban regions with frozen precipitation or significant snowfall (Blackburn et al, 2004). The snow removal and disposal problem includes many sub-problems including: what kind and how much deicer to use; where to locate the depots; how to assign snow emergency routes for the vehicles; and how to schedule the personnel. These problems are very difficult because of the diversity of operation conditions. Many solutions based on local search techniques are proposed. However, many planning and routing decisions are not so efficient. Recent developments in modeling and algorithmic tools, the increased performance of computers, and the increased pressure of maintaining or enhancing service levels and minimizing environmental impacts, all motivate the more widespread use of optimization models (Perrier et al, 2006a).

Plowing and snow disposal involve a number of vehicle routing problems where streets have to be traversed by plows, snow blowers, and trucks. The routes must satisfy several operational constraints imposed by the level of service policies and the characteristics of the transportation network, road segments, sectors, vehicles, and crews. This problem has many features. First, the snow route design problem can be classified into the category of Arc Routing Problems (ARP) in which the vehicles should service some or all arcs in a network. Second, in snow emergency operations we are dealing with a network in which every link has a direction. Since a truck can service two lanes at the same time, some two-lane streets can be serviced in one pass

from either direction. Therefore, these streets in the network do not have direction. That means some links are directed and some are not. Third, the underlying network is a hierarchical network. This means that there is a precedence structure for servicing the roads. Since most primary highways that are in the snow emergency route network belong to the 1st class, we have only focused on this class and do not deal with the different classes of roads (Perrier et al, 2006b).

In general, the route design in snow emergency operations is classified as Capacitated Arc Routing Problem (CARP). Based on the operational extensions，it can be viewed as a multiple Hierarchical Chinese Postman Problem (m-HCPP) with class upgrading possibilities and vehicle-road segment dependencies. The m-HCPP generalizes the hierarchical Chinese Postman Problem (HCPP), calling for the determination of a single route starting and ending at a depot and servicing all road segments of a network in such a way that the service hierarchy is satisfied and a time objective is minimized. The HCPP is NP-hard, but can be solved in polynomial time if the precedence relation is linear and all subgraphs induced by the classes are connected. Since the HCPP with no assumption on class connectivity is a special case of the m-HCPP, it follows that the m-HCPP is NP-hard. Ghiani and Improta (2000) have described exact algorithms for this case. Cabral et al. (2004) showed that it is possible to solve the HCPP with linear precedence relations and no assumption on class connectivity by transforming it into a rural postman problem. The heuristic could sequentially solve the HCPP for each class, starting with the highest class, considering all traversed edges in any of the classes of lower priority as already serviced. As highlighted by Korteweg and Volgenant (2006), declaring a deadheading edge as already serviced could not increase total completion time, but may generate routes with a shorter time.

Dealing with snow emergencies involves a number of different operations. Because each area has its own unique environmental conditions, most papers published for this problem have different operational area backgrounds. For example, Campbell and Langevin (1994) were dealing with snow removal and disposal problem for Montreal Urban Community. Because different areas have different operations, the formulation and solution approaches can be very different. The previous literature focuses more on heuristic algorithms instead of finding exact solution algorithms and mathematical formulations. The main reason for this is that the field operations have many constraints that are very hard to be described mathematically. And even if we can find a mathematical formulation for the problem, it is very hard to solve.

Campbell and Langevin (1994) provide a detailed description of the snow removal and disposal operation in Montreal. They also list major problems related to snow operations. These problems include site location, section design, section assignment, fleet mix and routing. An Integer programming formulation for snow disposal site location and assignment problem (SLAP) is given and a decision support system is discussed in that paper, but no routing algorithm or formulation is suggested or discussed. Eglese (1994) presents a heuristic to minimize the distance traveled by gritting vehicles. The solution procedure includes partitioning the network, creating the cycle node network and constructing the route. The heuristic allows multiple depots and different road priorities. Simulated Annealing is used to

solve the constrained problem. Perrier et al. (2006c) give a formulation models for general precedence relation constraints with no assumption on class connectivity, different service and deadhead speed possibilities, separate pass requirements for multi-lane road segments, class upgrading possibilities, and vehicle-road segment dependencies. Two objectives are considered: a hierarchical objective and a make span objective. The resulting model is based on a multi-commodity network flow structure to impose the connectivity of the route performed by each vehicle.

An integrated overview of the most relevant operations research literature on arc routing was presented by Eiselt et al (1995a, 1995b). The paper gives a directed transportation network G (V, A) with arc demands q_{ij} for each $\text{arc}(i, j) \in A$. It must be satisfied by a fleet of vehicles k, each of which has a capacity W_k, The number of cycles (routes) which pass always through the arcs and satisfy the demands at minimal total cost are found. The geographical region (or network) is usually partitioned into non-overlapping subareas (sub networks), called districts, each including one depot at which a number of vehicles are based. The traditional approach for the design of districts in the context of winter road maintenance consists in partitioning the road network into districts by assigning road segments to their closest depot. Kandula and Wright (1995, 1997) and Muyldermans et al (2002, 2003) used this approach for designing districts for plowing and spreading operations. A similar approach for designing small clusters of streets in the context of snow disposal operations was developed by Labelle et al. (2002) and Perrier et al (2008). For a recent survey of optimization models and algorithms for the design of districts for winter road maintenance, the reader is referred to the work of Perrier et al. (2007a, 2007b).

In this research, we focus on how to design the service routes for snow emergency operations. Efficient route design and planning for snow vehicles can not only save agencies operational cost, but also improve level of service and social benefits. The objective of this research is to reduce the total cost of snow emergency operations. As discussed earlier, the total cost includes operational costs and social costs. There is a tradeoff between the two components. We can reduce one by increasing the other. For example, we can reduce the service time (social cost) by increasing the number of trucks. In an extreme case, every truck can service only one link in the network. In this research, our objective is to minimize the operating costs given operational conditions while improving or maintaining the level of service to reduce the social costs. The operation cost is mainly composed of the truck costs, the personnel costs and the fuel costs. The objective is to reduce the total deadhead distance, so the fuel and other costs are reduced and the level of service is improved since the overall execution time is reduced.

MATHEMATICAL FORMULATIONS

In this chapter, we will try to formulate the Snow Emergency Routing Problem as Capacitated Arc Routing Problem with several extensions that are required for field operations. Service continuity constraint is very important for practicality of the operation. The service continuity can be defined as follows: the links that are serviced by one truck should be connected. Also we need to expand the

single depot formulation to multi-depot formulation. After expanding to multi-depot formulation, the original illegal sub-tour elimination methods in CARP formulation cannot be applied directly. The details of this problem will be discussed later. A network transformation that duplicates the depots is needed to make sure that illegal sub-tours can be eliminated. As discussed before, the objective is to find the minimum deadhead distance for a given number of trucks.

We can deal with a mixed network as directed network and add constraints for the undirected links that ensures that the sum of the service of both directions should be one. The load balancing extension is also easy to implement. We can simply add a lower bound for total demands of the links in an assignment. The multi-depot extension is a little difficult, because the illegal sub-tour breaking constraints will not work in this case directly. Some network transformations are needed to eliminate the illegal sub-tours. In this section, we will present the formulation.

The following notation is defined:

G	A directed network
V	The vertex set $\{1,\cdots,q,\cdots q+n\}$
V_d	Set of depots $\{V_1,\cdots,V_q\}$
A	$\{\tau_i \mid i=1,2,\cdots,m\}$ is the arc set
$\omega(\tau_i)$	The cost of arc τ_i
R	The set of the arcs that is need service, $R \subset A$
λ	1 Only if $\tau_i \in R$
	0 Otherwise
X	The number of the vehicle fleet
W_l	The capacity of the vehicle $1 \le l \le X$
q_{ij}	The demand of arc $\{(i,j)\}$
M	$\{T_i,T_i,\cdots,T_K\}$ is the set of routes
$\mathrm{X}_{ij\|T_i\|}$	1 Only if edge $\{(i,j)\}$ is traversed from vertex i to vertex j on route T_i
	0 Otherwise
$\mathrm{Y}_{ij\|T_i\|}$	1 Only if edge $\{(i,j)\}$ is serviced from vertex i to vertex j on route T_i
	0 Otherwise
R_k	The set of serviced arcs on route k
A_{kt}	The number of the serviced arcs on route k
A_{kr}	The number of the traversed arcs on route k
v_w	The average servicing speed
v_f	The average traversing speed
L	The maximum working time

The problem formulation is as follows:

Minimize

$$\sum_{T_i \in M} \sum_{(i,j) \in A} \omega(\tau_i) X_{ij|T_i|} \tag{1}$$

Subject to:

$$\sum_{(i,j) \in A} X_{ji|T_i|} - \sum_{(i,j) \in A} X_{ij|T_i|} = 0 \qquad i \in V \text{ for all } T_i \tag{2}$$

$$\sum_{i=1}^{k} |T_i| = \xi \tag{3}$$

$$R_k = \left\{ T_{ki} \mid T_{ki} \in \left\{ T_k, \cdots, T_{k|T_k|} \right\} \right\} \tag{4}$$

$$R_i \cap R_j = \varnothing \ (i \neq j; 1 \leq i, j \leq K) \tag{5}$$

$$Y_{ij|T_i|} - Y_{ji|T_i|} = 0 \qquad \text{For all k, and } (i,j) \in A \tag{6}$$

$$\sum_{(i,j) \in A} q_{ij} Y_{ij|T_i|} \leq W_l \qquad \text{For all } T_i \tag{7}$$

$$\sum_{i \in V_d} X_{ji|T_i|} = 1 \qquad \text{For all } T_i \tag{8}$$

$$0 \leq |T_i| \leq \xi \ \ (1 \leq i \leq K) \tag{9}$$

$$\sum_{k=1}^{N_l} \left(\sum_{i=1}^{A_{kt}} \frac{\tau_i}{v_W} + \sum_{j=1}^{A_{kr}} \frac{\tau_j}{v_f} \right) \leq L \quad (l = 1, 2, \cdots, X) \tag{10}$$

$$\begin{cases} \sum_{i,j \in S} X_{ij|T_i|} \leq |S| - 1 + n^2 u_k^s \\ \sum_{i \in S} \sum_{j \notin S} X_{ij|T_i|} + w_k^s \geq 1 \\ u_k^s + w_k^s \leq 1 \\ u_k^s, w_k^s \in \{0,1\} \end{cases} \qquad \text{For all k}, S \in V / V_d \tag{11}$$

$$X_{ij|T_i|}, Y_{ij|T_i|} \in \{0,1\} \qquad \text{For all k, and } (i,j) \in A \tag{12}$$

The objective function (1) seeks to minimize the total travel distance for all trucks. Constraints (2) ensure the route continuity. Constraints (3), (4) and (5) ensure that each arc should be serviced as required. Constraints (6) require that both directions of a link be serviced by the same trucks. Constraints (7) are the capacity constraints. Constraints (8) require that the in-degree of a depot should be one for each route. Constraints (9) require that the serviced arcs of one route are less than the serviced arcs of all routes. Constraints (10) require that the working time of every truck is less than the maximum working time. Constraints (11) are the sub-tour breaking constraints.

HEURISTIC SOLUTION

Based on the basic operations in the arc routing problems, we proposed an algorithms to generate an initial solution. In the proposed algorithm, the network is initialized as follows. The network is composed of a vector of nodes and a vector of links. The vector of nodes contains the information about the index of the nodes, for example, node No. 0 means that the node is the depot. The vector of links contains

the links pertinent information that include start node, end node, start service time, end service time, cost (distance), travel time, number of times of service, etc. In network initialization, we also maintain the information regarding the shortest paths and distances between any pair of nodes. Since we use the shortest paths and distances frequently, when we initialize the network we use Floyd's shortest path algorithm to generate all pair-wise shortest paths and distances and save the information for later use.

The steps of the procedure are as follows:

Step 1. For existing links that are not serviced, find the furthest link to the depot.
Step 2. Find the shortest path from the depot to the start node of this link and from the end node of this link to the depot. Establish an initial route using the links in the shortest path and the link found in step 1.
Step 3. Find the nearest link to the current route.
Step 4. Insert the link found in step 3 in the route.
Step 5. Loop until the capacity constraint for vehicle is violated.
Step 6. Loop until no link that requires service remains.

CONCLUSION

The mathematical formulation of the Snow Emergency Routing Problem is presented and discussed for the traditional CARP. The difficulties come from the mufti-depot extension. By duplicating the depots and their related links, we expanded the single depot CARP formulation into a mufti-depot formulation. One formulation is based on the dynamic binding of subset of links that a vehicle services. Since CARP is a NP-complete problem, we try to find the good lower bounds to assess the solutions generated by heuristic algorithms.

From the CARP formulation, most decision variables result was observed. Actually, not all of these constraints are necessary. If the solution consists of an illegal sub-tour, then we just add the respective illegal sub-tour elimination constraints to the problem and solve it again. This method uses the same basic idea of cutting plane methods. A branch and cut method can be used if the relaxed problem is still difficult to solve. Finding good lower bound for NP-complete problem is always a challenging work for researchers. For a field application, it is more important to find a good or acceptable solution efficiently. From this aspect, it is more important to design a good algorithm.

ABSTRACT

The gray model GM(1,1,λ) method was applied to fit the pavement performance indexes (international roughness index, pavement deflection value , BPN)of asphalt expressway. To obtain the optimal value of parameter λ, the random search method and the cyclic search method were established by minimizing the mean absolute error, the average relative error or the average square of Absolute Error. The results show that forecast precision of gray model GM(1,1,λ) method is higher than that of GM(1,1) method. The optimal value of parameter λ can be obtained easily and accurately by random search method and the cyclic search method. The parameter λ is very close to 0.5 by minimizing the average square of Absolute Error. To improve the forecast precision，it is more appropriate to minimize the mean absolute error or the average relative error.

INTRODUCTION

Pavement-performance indexes prediction model is the core of the highway facilities-management system. Viewing of the different type of road facilities, there are many kinds of models. Up to date, the models have been divided into deterministic model and probabilistic model(Yao,1993). The deterministic model has been further divided into mechanical-model, mechanical-empirical-model and regressive-model(Hass,1994). The regressive-model and the Markov-chain- model are the most popular. For the regressive-model, the multiple regression is used to predict the pavement-performance indexes influenced by the influencing variables, such as service time，traffic flow and pavement structure. The three following models all belong to regressive-model: The PSI prediction model drawn from the American AASHO test road, the PCI prediction model of the American air-force PAVER management system and the general deterioration equation for pavement performance established by Sun li-jun. In the regressive-model，the statistical fitting method is used. Its authenticity not only depends on the information adequacy and accuracy, but also on how the researchers interpret the relationship between the pavement-performance indexes and the influencing variables. The Markov-chain-model can reveal uncertainty of the pavement-performance indexes. But considering the current management level, the administrators are unwilling to accept this model. And because the model is established on the regressive method, the error can not be ignored.

Some researchers adopted other methods to investigate the subject(Bi,1999), such as the Bayesian-method of the Canadian-strategic-expressway-research-project, the dynamic- model and the adaptive- algorithm method adopted by Zou pei-guo. In

recent years, the artificial neural network began to apply in this field (Wang,2001;Zhou,2006). But for the above models, large sample size is needed and can not be obtained in the engineering practice. Because of its nonlinear character, the artificial neural network can take the vehicle load factor and the environmental factor into account simultaneously. But it can not avoid the influence of the local least value, and requires trial calculation.

Some researchers adopted gray theory to study the pavement performance (Hu,2006;Wang,2002). Gray theory focuses on uncertainty system. The theory is quite easy, its forecast precision is rather high, and it is convenient for programming. For example, based on discrete data sequence of the independent variables and dependant-variables, the traditional gray model GM(1,1,λ) can be applied to establish explicit functions for data fitting and prediction(Liu,2004). But for ordinary data sequence, the fitting and forecast precision is rather low.

In view of this background and condition, the purpose of this paper is to modify the traditional gray model GM(1,1) by introducing the parameter-λ and improving the adjacent-data weight. So the new gray model GM(1,1,λ) method is established, and the forecast precision is improved. To obtain the optimal value of parameter λ, the random search method and the cyclic search method are used .By minimizing the mean absolute error, the average relative error or the average square of absolute error, the feasibility and characteristic of GM(1,1,λ) method is discussed .

1 GRAY MODEL GM(1,1,λ) METHOD(Xu,2003;Xie,2000)

N-gram vector is supposed to be $\left\{X_i^{(0)}\right\}$, $i=1,2,\ldots,N$

By one-accumulating，the generating sequence is $\left\{X_i^{(1)}\right\}$, $i=1,2,\ldots,N$

$$B=\begin{pmatrix} -(\lambda X_1^{(1)}+(1-\lambda)X_2^{(1)}) & 1 \\ -(\lambda X_2^{(1)}+(1-\lambda)X_3^{(1)} & 1 \\ \cdot & \cdot \\ \cdot & \cdot \\ -(\lambda X_{N-1}^{(1)}+(1-\lambda)X_N^{(1)} & 1 \end{pmatrix} \tag{1}$$

$$Y_N=(X_2^{(0)},X_3^{(0)},\ldots,X_N^{(0)})^T \tag{2}$$

According to Least Square Principle：

$$\begin{pmatrix} a \\ b \end{pmatrix}=\left(B^TB\right)^{-1}B^TY_N \tag{3}$$

The formula(3)can be converted to：

$$a=\frac{\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]\sum_{i=2}^{N}X_i^{(0)}-(N-1)\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]X_i^{(0)}}{(N-1)\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]^2-\{\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]\}^2} \tag{4}$$

$$b=\frac{\sum_{i=2}^{N}X_i^{(0)}\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]^2-\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]X_i^{(0)}}{(N-1)\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]^2-\{\sum_{i=2}^{N}[\lambda X_{i-1}^{(1)}+(1-\lambda)X_i^{(1)}]\}^2} \tag{5}$$

So the model data is generated：

$$\hat{X}_{i+1}^{(1)} = e^{-ai}(x_1^{(0)} - \frac{b}{a}) + \frac{b}{a} \quad (6)$$

where i is Generally regarded as integral number($1,2,\ldots,N$). It can also be regarded as decimal. By inverse accumulated generating operation of model data, data restoration is realized.

2 PARAMETER DETERMINATION FOR GM(1,1,λ) METHOD

For the original sequence, the parameter λ is the decisive factor for the forecast precision of gray model GM(1,1,λ) method. To obtain the optimal value of parameter λ, the error-fitting minimization principles are established by minimizing the mean absolute error, the average relative error or the average square of Absolute Error. The concrete method is discussed in the below.

2.1 Random search method

(1) The error-fitting minimization principle should be established by choosing one form the above there principles. The initial value of parameter λ is λ_1 and can be supposed to 0.5.

(2) If the value of parameter λ equals to λ_i, the fitting error ε_i is obtained based on gray theory.

(3) The random search method is used within certain interval according to the following method: $\lambda_{i+1} = \lambda_i + [0.5 - rand(0,1)] \cdot T$, where $rand(0,1)$ is random number satisfying uniform distribution on [0, 1] interval; T has an effect on the chasing step, and the value can be defined within [0.01, 0.001] interval.

(4) The value of ε_{i+1} is obtained. If ε_{i+1} is less than ε_i, λ equals to λ_{i+1}, the feedback information is obtained as follows: with the value of parameter λ changing form λ_i to λ_{i+1}, the corresponding fitting error decreases. So the value of λ can be successively changed into $2\lambda_{i+1} - \lambda_i$, $3\lambda_{i+1} - 2\lambda_i$, $4\lambda_{i+1} - 3\lambda_i$ ……, and the procedure should continue until the last error is greater than the last but one error; If not, the procedure should return to (3);

(5)The procedure from (3) to (4) should be repeated until the minimization of the fitting error tends to be stable. Then the optimal value of parameter λ is obtained and the corresponding fitting error ε is got.

2.2 Cyclic search method

(1) The error-fitting minimization principle is established by minimizing the mean absolute error, the average relative error or the average square of Absolute Error. The initial interval $[\lambda_b, \lambda_t]$ of parameter λ is generally determined as interval $[0,1]$.

(2)The interval $[\lambda_b, \lambda_t]$ is divided equally into m parts, and the coordinate of segmentation point λ_k ($k = 0,1,\ldots,m$)is obtained.

(3) If the value of parameter λ equals to λ_i, the fitting error ε_k is obtained based on loop calculation.

(4)The minimum fitting error $\varepsilon_{\min}$ is determined and the corresponding value

of parameter λ is obtained.

(5)The latest value of parameter λ is used as the loop interval center of the next time, and the chasing step of the last time is used as the loop interval of the next time. Then the obtained loop interval is divided equally into m' parts (m' can be equal to m), and the coordinate value of segmentation point $x_{k'}$ ($k' = 0,1,\ldots,m'$)is obtained.

(6) The procedure from (3) to (5) should be repeated until the step is small enough or the fitting error ε of the last time is very close to the fitting error of the last but one time.

3 INSTANCE STUDY

In this paper, the measured pavement-performance indexes of asphalt expressway (Shenda Expressway, some expressway in Jiangsu, Hujia Expressway) in recent years are provided(Hu,2006;Wang,2002;Highway,2007). The indexes consists of international roughness index(IRI), pavement deflection value(l) , British pendulum number(BPN). Based on the gray model GM(1,1,λ) method , the random search method and the cyclic search method are applied to imitate and forecast these indexes. The relative percentage error between the fitted values and the measured values is given in the table 1 and table 2. In the row"0", the fitting errors based on GM(1,1) method are shown(C=0.5). In the row"1" 、"2"、"3", the fitting error based on GM(1,1,λ) method is shown. For the row"1"，the corresponding error fitting minimization principle is established by minimizing the mean absolute error；for the row "2"，the average relative error and for the row "3"，the average square of Absolute Error.

Based on the result of table 1 and table 2，the conclusion is drawn as follows：

(1)For the three pavement-performance indexes (IRI, pavement deflection value , BPN)，based on different model and different error-fitting minimization principle，the results of the same year are different and the fitting errors are either negative or positive.

(2)Because of the gray model's own characteristics, no matter what kind of model and error-fitting minimization principle are used, the fitting error of the first data is zero.

(3)For IRI of road A, the maximum value of the relative fitting error is close to 8%，the minimum value is close to 0,and the mean of absolute value is 3.5%; for the pavement deflection value of road A, the maximum value of the relative fitting error is close to 2%，the minimum value is close to 0,and the mean of absolute value is 0.8%; for BPN of road A, the maximum value of the relative fitting error is close to 1%，the minimum value is close to 0,and the mean of absolute value is 0.3%.Generally speaking, the fitting error of pavement deflection value is smaller than that of IRI, and the fitting error of BPN is smallest.

(4) For the IRI of road B, the maximum value of the relative fitting error is close to 0.7%，the minimum value is close to 0,and the mean of absolute value is 0.25%; for the pavement deflection value of road B, the maximum value of the relative fitting error is close to 6%，the minimum value is close to 0,and the mean of absolute value is 3.2%; for BPN of road B, the maximum value of the relative fitting error is close to 12%，the minimum value is close to 0,and the mean of absolute value is 6%.Generally speaking, the fitting error of pavement deflection value is smaller than that of BPN, and the fitting error of IRI is smallest.

(5) For the IRI of road C, the maximum value of the relative fitting error is close to 1%，the minimum value is close to 0,and the mean of absolute value is 0.5%; for the pavement deflection value of road C, the maximum value of the relative fitting error is close to 0.8%，the minimum value is close to 0,and the mean of absolute value is 0.44%; for BPN of road C, the maximum value of the relative fitting error is close to 0.4%，the minimum value is close to 0,and the mean of absolute value is 0.17%. Generally speaking, the fitting error of pavement deflection value is smaller than that of IRI, and the fitting error of BPN is smallest.

(6)The results show that for the three indexes，it is difficult to choose which one is most suitable for the gray model to fit.

(7)For the three pavement-performance indexes，the fitting-error values of the different year is independent on the error-fitting minimization principle.

(8)For the three pavement-performance indexes，the absolute-values mean of the fitting-error based on different principles is very close. So it is very difficult to determine which principle is most reasonable. In general, based on the minimizing the mean absolute error principle or minimizing the average relative error principle, the relative fitting error is rather small. It also reflects the advantage of the GM(1,1,λ) model. But , for the problem discussed in this paper, the fitting precision of the GM(1,1,λ) model and the traditional GM(1,1) model is rather close.

For the three pavement-performance indexes, the mean absolute error, the average relative error, the average square of absolute error and the corresponding parameter λ are all listed in Tab.3.

Table 3 Average fitting errors of pavement performance index

index		λ		mean absolute error		λ		average relative error		λ		average square of absolute error	
Highway A	IRI	0.5	0.4949	0.0528	0.0525	0.5	0.4556	3.1337	3.1163	0.5	0.4998	0.0050	0.0050
	l	0.5	0.5405	0.2565	0.2502	0.5	0.5416	0.7380	0.7303	0.5	0.5035	0.0990	0.0990
	BPN	0.5	0.5104	0.1092	0.1079	0.5	0.5104	0.2531	0.2514	0.5	0.4969	0.0224	0.0224
Highway B	IRI	0.5	0.5378	0.0040	0.0034	0.5	0.5378	0.1997	0.1757	0.5	0.5046	0.0000	0.0000
	l	0.5	0.5819	0.5006	0.4780	0.5	0.5819	2.5321	2.5162	0.5	0.5105	0.3888	0.3879
	BPN	0.5	1.4117	2.1504	2.1428	0.5	1.4117	4.6813	4.4427	0.5	0.4962	6.0175	6.0174
Highway C	IRI	0.5	0.4268	0.0101	0.0101	0.5	0.4268	0.3986	0.3972	0.5	0.5036	0.0001	0.0001
	l	0.	0.47	0.09	0.09	0.	0.47	0.35	0.34	0.	0.50	0.01	0.01

		5	55	66	61	5	55	02	94	5	67	21	18
	BPN	0.5	0.4016	0.0549	0.0549	0.5	0.5753	0.1311	0.1309	0.5	0.4955	0.0039	0.0039

Form Tab.3, we can conclude that:

(1)The fitting error of the GM(1,1,λ)method is lower than that of GM(1,1) method.

(2)For the three indexes of the highway discussed in the paper, the relationship between 0.5 and the value of λadopted by model GM(1,1,λ) is uncertain.

(3)Under most conditions, the value of λis within the interval(0.4,0.6).While for the BPN of highway B, the value is 1.4117. It shows the optimal value of λwill be far from 0.5 when the a set of data is not suitable for gray method fitting. So the optimal value of λ can be used to decide whether the data is suitable for gray method fitting.

(4) For highway A and C the average-relative fitting-error of IRI, pavement deflection value , BPN decreased successively; For highway B, the average-relative fitting-error value of IRI, pavement deflection value , BPN increased successively. So it is difficult to choose which index is fit for gray method fitting.

(5)For IRI, the fitting error of highway B、 C、 A is increasing successively;for pavement deflection value and BPN, the fitting error of highway C、A、B are increasing successively. So it is difficult to choose which highway is fit for gray method fitting.

The relationship between the fitting error of different error principle and the parameter λ is listed in Fig. 1. For the feasibility of comparison, the different coefficient is multiplied to unify the range.

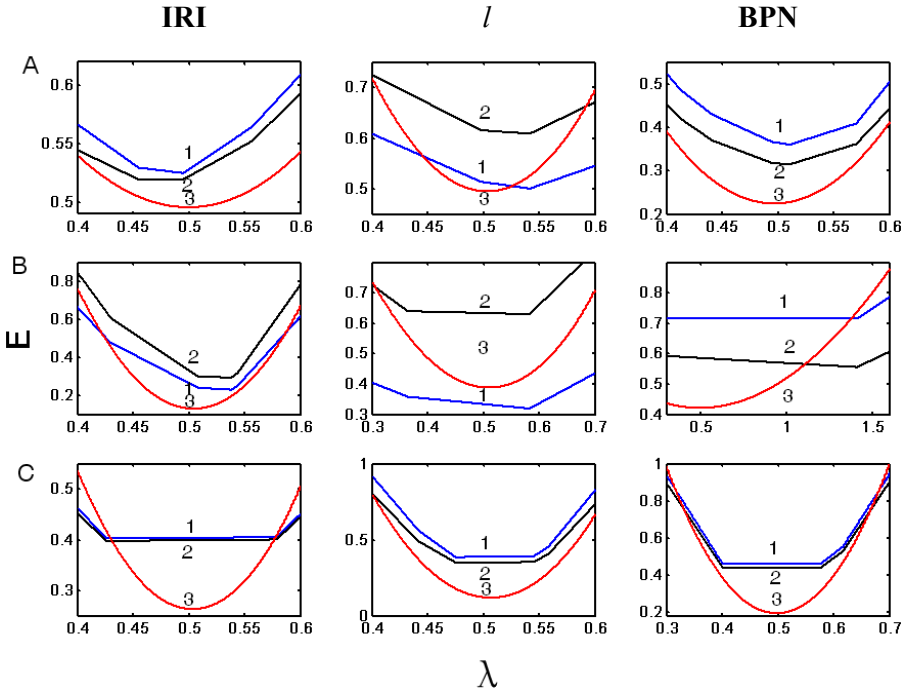

Fig.1 Graphs of pavement performance index fitting error versus parameter λ

(1)When the third principle (minimizing the average square of absolute error) is used, the fitting error and the parameter λ is Symmetric with 0.5. In other words, 0.5 is approximately regarded as the optimal value of λ based on least-square theory. There is second order relationship between the average square of Absolute Error and λ.

(2) When the first or second principle (minimizing the mean absolute error or the average relative error) is used, there is piecewise-linear relationship between the mean absolute error (or the average relative error) and λ. Especially for express C, when λ is approximate to 0.5, the error doesn't change. While λ falls into the bilateral of the interval, the error is increasing and is basically symmetric with the vertical axis(whenλ=0.5).

(3)When the first or second error principle (minimizing the mean absolute error or the average relative error) is used, the relationship curve between the mean absolute error (or the average relative error) and λ is similar, and the turning point of the curve is also similar.

4 CONCLUSIONS

(1)In this paper, the feasibility of GM(1,1,λ) method applied to fit the pavement performance indexes(IRI, pavement deflection value , BPN) is discussed. The method is proved to be feasible by practice. But it is difficult to choose which index is most suitable for GM(1,1,λ) method to fit.

(2) To obtain the optimal value of parameter λ, the random search method and the cyclic search method were established. It shows the methods are shortcut and accurate.

(3) The forecast precision of gray model GM(1,1,λ) method is higher than that of GM(1,1) method, but the difference is not large. By minimizing the average square of Absolute Error, the GM(1,1,λ) will degenerate into GM(1,1) based on least square principle. To improve the forecast precision，it is more appropriate to minimize the mean absolute error or the average relative error.

ABSTRACT:

The objective of this paper is to develop regression functions of material properties based on experimental results and finite element method (FEM) model to simulate shrinkage behavior in cement stabilized aggregate base. Firstly, material properties were obtained from physical property tests. The correlations were established among cement content, strength, modulus and shrinkage coefficients by statistics regression. Secondly, a FEM model was developed to simulate dry and thermal shrinkage in base. Thirdly, a simplified method to predict shrinkage cracking spacing was obtained. Finally, FEM model was validated by comparison analysis with analytical solutions and field observations in roller compacted concrete (RCC) pavement due to similar shrinkage behavior. It is discovered that the strength and shrinkage properties of cement stabilized aggregate have good correlations with the 7-day unconfined compressive strength. It is also observed that from relationships of pavement length and shrinkage stresses, shrinkage cracking spacing can be predicted by FEM calculation. It is proved that proposed FEM model is an accurate tool to simulate shrinkage behavior and prediction results are consistent with actual pavement performance.

INTRODUCTION

One of major distresses for cement stabilized aggregate base is shrinkage cracking at the early stages after construction. It appears in the base when accumulated tensile stresses caused by dry and thermal shrinkage reach material

strength. Eventually, cracks would reflect up to asphalt surface under combined effects of traffic, temperature and moisture, and thus accelerate pavement deterioration rate.

There are many factors contributing to shrinkage cracking in cement stabilized aggregate base, such as moisture loss, cooling, interface friction, and material properties, etc.(George,1968). Historically, cement content is accepted as an important factor for shrinkage. Some researchers concluded that shrinkage decreased with increasing cement content, while others indicated that there was optimal cement content existing to minimize shrinkage; however, still others found no relationship between cement content and shrinkage (Sebesta,2005). With regard to theoretical research, the performance and space distribution of shrinkage cracking were analyzed during base construction period (Sun et al. 2003). Based on the elastic theory and concrete strength theory, a theoretical model for predicting thermal cracking spacing in cement stabilized base was developed (Shi et al. 2004).

The goal of this study is to develop regression functions of material properties based on experimental results and FEM model to simulate shrinkage behavior in cement stabilized aggregate base.

MATERIAL PROPERTIES

The 32.5 composite silicate cement and typical gradation of cement stabilized aggregate used in China were selected for tests, as shown in Table 1.

Table 1. Aggregate Gradation.

Sieve Size(mm)	*31.5*	*26.5*	*19*	*9.5*	*4.75*	*2.36*	*0.6*	**0.075**
Percent Passing	100.0	94.7	82.6	54.3	42.0	27.2	13.9	2.5

The following laboratory and filed tests were performed:

- Unconfined compressive strength test: The 150 mm diameter×150 mm height cylindrical specimens sealed in plastic bags at optimum moisture content are kept in standard curing room (temperature=25℃, moisture≥95％), and then immerged in the water for 24 hours before testing.
- Indirect tensile strength (IDT) test: The same specimens as compressive strength test are tested by MTS with a loading rate of 1mm/min.
- Dry shrinkage test: Test system consists of static resistance strain surveying instruments, transform boxes, resistance strain gauges and connection lines. Initial temperature and moisture conditions in the lab were 25℃ and 50％,

respectively. Specimen size is 100 mm length×100 mm (width) × 400 mm (height).

- Temperature shrinkage test: It is operated in high-low temperature cycling box where the temperature decreases from 55℃ to -25℃ with a rate of 1℃/min. When accumulated decrease reaches 10℃, test is paused and temperature is kept constant for 2 hours before restarting.
- Field tests: FWD test is carried out in test pavement sections and cored samples from field are obtained for laboratory strength test.

Empirical correlations among cement content, laboratory strength, in-situ strength, resilient modulus and shrinkage coefficients of cement stabilized aggregate were developed from test results. Using σ_w as an intermediate variable, functions for material properties are shown in Equation (1)-(5). If σ_w or σ_7, which can be obtained more easily from labtests, are known, other parameters such as resilient modulus, shrinkage coefficients and IDT strength can be calculated from these functions.

$$\alpha_d = 1.1688\sigma_w^2 - 21.9181\sigma_w + 151.56 \quad (1)$$

$$\alpha_T = 0.1243\sigma_w + 0.601 \quad (2)$$

$$\sigma_{IDT} = 0.05164\sigma_w^{1.0407} \quad (3)$$

$$\sigma_w = \frac{-161.63 + \sqrt{26124.26 - 140.72(400.5 - E)}}{70.36} \quad (4)$$

$$\sigma_w = 2.4353\sigma_7 = 2.7361X \quad (5)$$

where, σ_w=unconfined compressive strength of cored specimens from field, MPa; σ_{IDT} =IDT strength, MPa; α_d =average dry shrinkage coefficient, 10^{-6}/%; α_T =average thermal shrinkage coefficient, 10^{-6}/℃; E=resilient modulus, MPa; σ_7=7-day unconfined compressive strength, MPa; X =cement content, %.

DEVELOPMENT OF FEM MODEL

The FEM model is based on following assumptions: (1) Mixture for each layer is homogeneous, isotropic and linear elastic, using analysis method of concrete pavement for reference. (2) Dry shrinkage strain distributes evenly in whole base, and (3) thermal shrinkage strain also distributes evenly in whole base. Thus, the model can be simplified to a plane strain problem.

Exponential functions (Wu et al, 1996) were used to simulate temperature distribution, while dry shrinkage stress was achieved by converting moisture loss to temperature decrease with equivalent shrinkage strain. The interface contact friction between base and lower layer has a significant effect on shrinkage stresses in base.

The Coulomb friction model was introduced to simulate interface contact between two layers (Dowson, 2003). The 8-node plane parametric finite element was used for calculation in this research. A contact pair was applied between the base and subbase to simulate interface constraint. A total depth of one meter was modeled since significant effect of temperature variation on pavement structure usually occurred within the thickness. Due to the symmetry, only half of the system needed to be modeled. In order to save calculation cost, mesh was designed to be coarser and coarser from middle to edges, seen in Figure 1. Minimum mess size was 5mm.

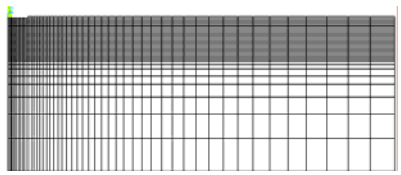

Figure 1. FEM model mess.

DETERMINATION OF SHRINKAGE CRACKING SPACING

In order to determine shrinkage cracking space in cement stabilized aggregate base, relationships of pavement length and shrinkage stresses need to be determined first. Pavement structure used in this analysis consisted of 30 cm base, 30 cm subbase (E-1000MPa, α_T-10^{-5}/℃), and Subgrade (E-60MPa, α_T-2×10^{-5}/℃). The material properties of cement stabilized aggregate base, as shown in Table 2, were calculated from Equation (1)-(5).

Table 2. Material Properties of Cement Stabilized Aggregate.

Structure	Resilient Modulus E (MPa)	IDT Strength R_{sp} (MPa)	Dry shrinkage coefficient α_d (10^{-6}/%)	Thermal shrinkage coefficient α_T (10^{-6}/℃)
1	2000	0.27	70.4	6.7
2	4000	0.45	51.2	7.0
3	6000	0.60	50.4	7.3
4	8000	0.72	60.8	7.6

(a) Dry shrinkage stress (Δw=1%) (b) Thermal shrinkage stress (ΔT=10℃)

Figure 2. Effect of pavement length on shrinkage stresses.

Figure 2 shows that higher dry shrinkage stress tends to occur in longer base, while there is negligible effect of thermal shrinkage stress on pavement length. Thus, if no-cracking section is shorter than a certain value, shrinkage stresses can be controlled below tensile strength, which can be utilized to predict shrinkage cracking spacing in cement stabilized base. In other words, shrinkage cracking spacing is the same as critical pavement length in which shrinkage stresses are equal to material tensile strength under certain shrinkage condition. The fracture criterion is expressed by failure stress, as seen in Equation (6).

$$\gamma_r \sigma_m \le \sigma_{IDT} \tag{6}$$

where, σ_m=shrinkage stress, MPa; σ_{IDT} =IDT strength, MPa; γ_r= reliability coefficient 1.20-1.33 for the 95% target reliability.

Using this FEM model, a sensitivity analysis was performed and the results indicated that the base course with lower modulus has less shrinkage cracking and there are no radical changes in shrinkage stresses with different intervals of construction time between asphalt surface and base (Ni et al, 2008).

VALIDATION OF FEM MODEL

The accuracy of theoretic methods for shrinkage prediction in RCC has been well documented in previous studies (Yu et al, 1997). Because of lack of field data on cement stabilized aggregate base and in order to validate the proposed FEM model, a RCC pavement, due to similar shrinkage behavior, was employed as a trial object. The comparison of predicted results by FEM model with existing theoretic solutions and field observations could be used to judge the accuracy of the model. Only dry shrinkage was considered in this simulation since it is the key factor to determine the slab size for RCC. Analytical solutions of shrinkage stress were obtained from thermal stress equations for pavement slab induced by interface friction (Zhu et al, 1985), substituting dry strain for thermal strain. The selected pavement structure for simulation consisted of 24 cm RCC (E-33000MPa,

α_d-2-4×10^{-4}/℃), 15cm lime-fly-ash stabilized base (E-1500MPa, α_d-8×10^{-5}/℃) and subgrade (E-60 MPa). It was assumed that moisture of RCC pavement changed from the optimum moisture content 5.5% to final state 2%.

Table 3. Comparison of FEM and Analytical Solutions.

Shrinkage coefficients (10^{-6}/%)	Slab length (m)	FEM Solutions (MPa)	Analytical Solutions (MPa)	Error
200	5	0.544	0.564	3.7%
	10	1.315	1.352	2.8%
	15	2.214	2.150	-2.9%
	20	3.332	3.492	4.8%
300	5	0.815	0.844	3.5%
	10	1.969	1.993	1.2%
	15	3.316	3.217	-3.0%
	20	4.989	4.949	-0.8%
400	5	1.089	1.141	4.8%
	10	2.63	2.564	-2.5%
	15	4.429	4.495	1.5%
	20	6.666	6.713	0.7%

For engineering practice, Table 3 shows that FEM model is accurate enough to simulate shrinkage stresses in pavement, since maximum relative error is less than 5%. As general tensile strength of RCC is 2.9MPa, predicted control slab lengths is 18.2m, 13.4m and 10.7m for shrinkage coefficients 200×10^{-6}/%, 300×10^{-6}/% and 400×10^{-6}/%, respectively. Transverse shrinkage spacing in field is often between 10m and 20m for RCC (Yu et al, 1997). Thus, it is proved that the simulation results are consistent with actual pavement performance.

CONCLUSIONS

From many lab and field experiments of cement stabilized aggregate, 7-day unconfined compressive strength, which can be obtained easily in the lab, is found to have good correlations with other parameters and can be used to predict strength and shrinkage properties as an intermediate variable. From the FEM analysis, it is found that higher shrinkage stresses occur in longer base. Thus, in combination with failure stress, relationships of pavement length and shrinkage stresses are introduced to predict shrinkage spacing cracking in cement stabilized aggregate base. Verified by research results in RCC pavement, the proposed model is proved to be an accurate tool to simulate shrinkage behavior in pavement.

ABSTRACT

In order to identify pavement sag deformation automatically，this article proposed an automatic identification method of pavement sag deformation: fitting base level method based on assumption pavement flatness. This method is based on the 3-D data collected by automatic pavement distress detection system, and the theory in mathematics morphology: how to identify the character of vertex in concave/convex polygon. The automatic identification of pavement sag deformation can be realized by using this method. In this method, the influence like rutting, cracking etc. on the identification progress was excluded. A computer programme was compiled for automatic identification, location, classification, area calculation and graduation of pavement sag deformation. The method and compiled programme were examined by comparing data of programme and data of actual measurement in pavement sag deformation. The result shows that this method can reflect the actual configuration of pavement sag deformation and perceive the parameters of the sag deformation accurately.

INTRODUCTION

There will be a variety of road damage when asphalt pavement is in use, and sag deformation is one of pavement damages. Sag deformation will have negative impact to the road and traffic. For example, excessive deformation would affect pavement roughness; rain water depressed region could lead to vehicle drift slide and impact on traffic safety; at the same time, water easily penetrate into the pavement, and induce other damage. To ensure good pavement performance, traffic safety & riding comfort, and carry out maintenance of pavement in a timely manner, it is necessary to collect information on pavement damage timely and accurately (David.H.K et al. 1997).

Compare with other pavement damage like pavement cracking, rutting, it is more difficult to detect and identify pavement sag deformation. The realization of automatic identification sag deformation is conducive to accurate and automated data processing of the pavement, as well as to develop countermeasure of pavement maintenance for scientific basis. Apart from the manually identification, the pavement photo information is used as the main method to identify sag deformation (Jiebo Luo et al. 2002). And the researchers used digital image processing technology, pattern recognition, neural networks, mathematical morphology and other methods to conduct in-depth study. Because of complicated reasons for road surface deformation and diversity of sag deformation, the existing methods are complex to use. In addition, poor real-time data, difficult to classify and accuracy for recognition do not meet use requirements (Rucckert D. et al. 1996, Serve Belongie 2002). Thus, this paper proposed an identification

method of pavement sag deformation: fitting base level method based on assumption pavement flatness.

SPECIATION ANALYSIS OF SAG DEFORMATION

Pot hole and depression are the basic types of sag deformation. For pot hole the elevation change in is relatively small in damaged area, but the elevation change is relatively large in damaged edge and non-damaged areas. For depression the elevation changes slowly in depression area; elevation change is small between adjacent points; and the difference of elevation between edge area and non-depression area is not significant. Because pavement depression is mainly caused by sub-grade depression or pavement structural damage, deformation of the scope usually is larger.

AUTOMATIC IDENTIFICATION METHOD OF PAVEMENT SAG DEFORMATION: FITTING BASE LEVEL METHOD BASED ON ASSUMPTION PAVEMENT FLATNESS BASIC DATA

The pavement surface elevation data comes from three-dimensional data acquired by the integrated road surface detection system. Data form is that horizontal & vertical spacing of 20cm; and detection width in the road cross-section is 3m. Rows and columns of the matrix elements correspond to measuring point elevation values of the road cross-section and the longitudinal section respectively. The impact of longitudinal gradient of the road can be ignored because the data collected is the relative difference of the uneven pavement and longitudinal gradient impact of the road offsets each other in the difference. The impact of road cross slope can be ignored also (Tsai Du Ming, 1997).

BASIC IDEA OF AUTOMATIC IDENTIFICATION METHOD OF PAVEMENT SAG DEFORMATION

The algorithm is by simulating the original pavement design lines, the original calculation of the road line and the actual measured surface elevation points online counterparts to determine the points of the embossing; thus the number of lines constitutes a cross-section mesh-like surface. Given a minimum depth of depression and minimum area threshold, depression can be identified. The level of depression is classified by the maximum depth value and the area value. Algorithm process is shown in **Figure 1**.

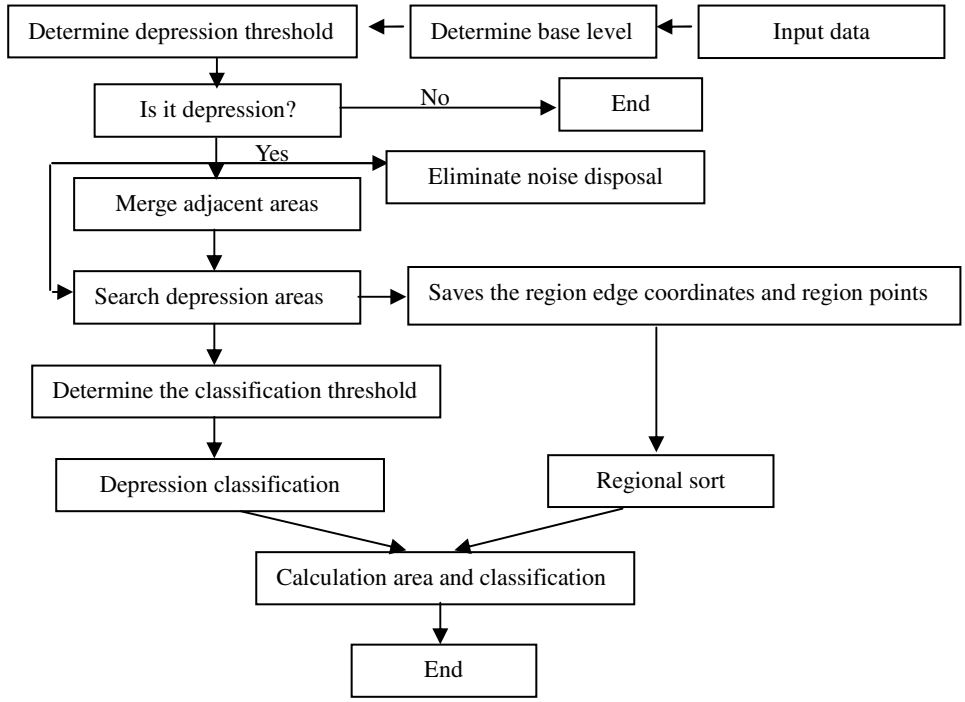

Figure 1. Algorithm flow chart of automatic identification

BASE LEVEL DETERMINATION

It is assumed that the average value measured in the longitudinal direction (longitudinal section) is as the original surface elevation line. Because of existence of a lot of small depression and rut, local data would have large deviation impact for fitting results. Hence it is needed for an amendment to the value. First calculate the average value and standard deviation of every longitudinal elevation, and then amend three-dimensional data on the road by using the method of 2 times square deviation.

$$\overline{h^j} = \frac{\sum_{i=1}^{n} h_i^j}{n} \qquad (1)$$

$$\sigma^j = \sqrt{\frac{\sum_{i=1}^{n} \left(h_i^j\right)^2 - \frac{\left(\sum_{i=1}^{n} h_i^j\right)^2}{n}}{n-1}} \qquad (2)$$

Note: h_i^j — elevation data of measure point i (i =1,2,……,n) in jth longitudinal section(j=1,2,……,m)

$\overline{h^j}$ 、 σ^j — average value and standard deviation of h_i^j

n — the number of measure point in every longitudinal section

m — the number of measure point in every cross-section(the number of longitudinal section)

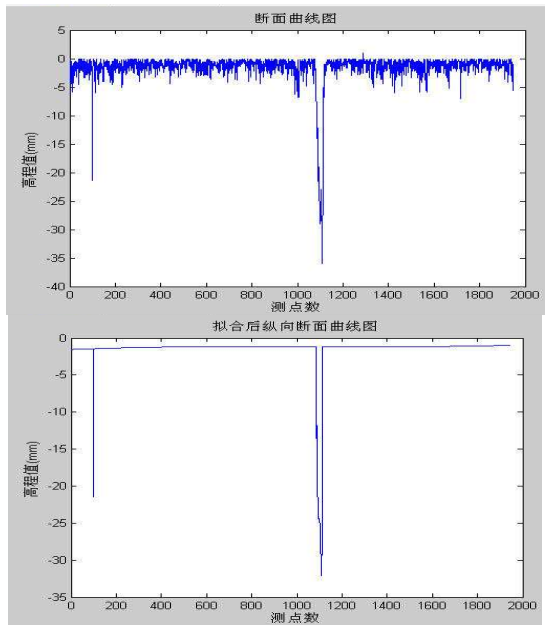
Method of amendment:

When $h_i^j > \overline{h^j} + \sigma^j$, $h_i^j = \overline{h^j}$

When $h_i^j < \overline{h^j} - \sigma^j$, $h_i^j = \overline{h^j}$

When $\overline{h^j} - \sigma^j \le h_i^j \le \overline{h^j} + \sigma^j$, $h_i^j = \overline{h^j}$

The amended data would be used of cubic polynomial fitting and the data after fitting would be used as base level data. As seen from Figure 2, the curve on behalf of the original road changes is in the larger bump. If the datum directly fitting, then the larger part of the value of the convex-concave fitting results have a greater impact. Thus it is necessary to amend the data, remove the impact of embossing in larger parts, and make longitudinal section curve to be shown as a smooth curve which close to the design line of the road. Finally a number of longitudinal and cross section fitting base level line of the road constitute a fitting base level.



(a) Longitudinal section before fitting (b) Longitudinal section after fitting

Figure 2. Comparison of longitudinal section before & after fitting

IDENTIFICATION OF SAG DEFORMATION

After determining the base level of assumption, the high-margin data of corresponding points between base level and actual measurement data would be calculated. If the difference is greater than the minimum depth of depression, it is deemed to be one of the points in the depression region and it would be recorded. This article assumes that the minimum depth of depression in line with the normal distribution and mathematical Statistics 3σ theory would be used as original data for testing. When 3σ and 5σ are used respectively as a minimum depth of surface depression to identify the value of the results in comparative analysis, the result shows that when the value of the minimum depth is 5 times the standard deviation, the identification accuracy is higher, and it is in line with the true extent of the traffic. Therefore when difference of which corresponding points between base level and actual measurement data of road curves greater than 5 times the standard deviation, the point would be considered as feature point in depression area.

DETERMINATION OF THE EDGE OF DEPRESSION

Because of the depression minimum depth value has some limitations; it can be used to identify significant regional of sag depression only and sometimes it cannot reflect the actual border of sag depression completely. The elevation

changes of original position in depression edge are often in the framework of pavement roughness, but it belongs to a point in depression area. Therefore secondary search is used in algorithm for such areas in marginal depression. The performance for such a depression is shown in Figure 3.

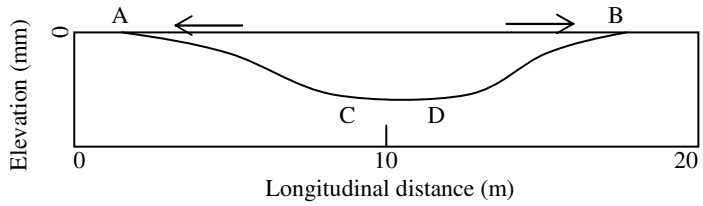


Figure 3. Depression form

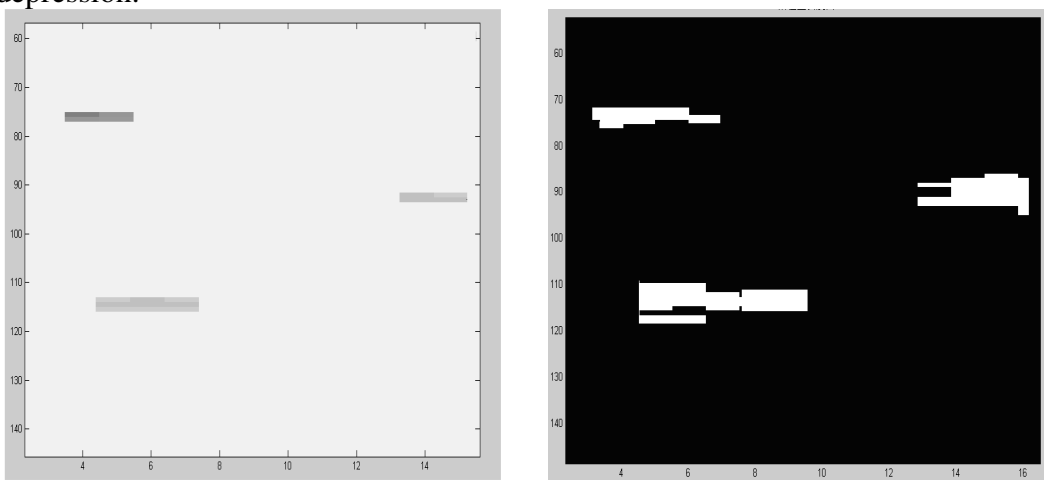
As it can be seen from Figure 3, the trend of elevation changes in the edge of the depression regional is the same as its adjacent area, but the elevation changes is smaller of prior one. Based on this result, this method is used in edge searching in depression area of this algorithm (e.g. searching edge changing point A and B). Coordinates C and D are starting points in recorded depression area and the searching direction is along the arrow. From points C, D out, the elevation difference between previous coordinate point and next coordinate point is calculated point by point. If the difference is more than 0, then it means that the trend of elevation changes of these two points is the same as previous two points. Keep calculating till the difference closed to the given threshold. Then recording the last point of the two points; this point is the final point of the edge of the depression.



(a) Before searching edge changing point (b) After searching edge changing point

Figure 4. Depression area (abscissa: cross-sectional measurement points; ordinate: longitudinal section measurement points)

From figure 4, it can be seen that there is less data in depression area before searching edge changing point. The reasons are: the minimum depression determining value provided by algorithm is relatively big; only the significant deformation of depression area would be identified; the slight deformation of depression area may be ignored. After searching edge changing point, there is more slight depression can be identified. Thus recognition effect and calculation accuracy of depression are increased.

DEPRESSION CLASSIFICATION

By comparing the elevation changes between edge of depression region

and edge of non-depression region, pot hole and depression can be identified. The main difference between pot hole depression and depression is reflected in the depth of its marginal changes. In this paper, the edge density factor λ (formula 3) is used to determine the type of depression. When the density factor λ larger than 5, the point (i, j) would be recorded. By comparison of a large number of the actual pot holes and depression in edge area, it is defined that the depression area is pot hole when these points are more than 80% of the total number of border points; otherwise it is defined to be depression. After a large number of calculations and artificial identification test comparison, it is proofed that this method is good for identification.

$$\lambda = \frac{\Delta h_i^j}{\Delta h_i'^j} \quad \text{(i= 1,2,3,……,n)} \qquad (3)$$

Note: λ —depression edge density factor

Δh_i^j —elevation changes of row i, column j in depression area

$\Delta h_i'^j$ —elevation changes of row i, column j in the edge of non-depression area

CALCULATION OF DEPRESSION AREA

The data spacing is 0.2m, and every measure point represents a square with side length of 0.2m. So every measure point represents 0.04 m2 and the depression area S is equal to the cell area times the number of measure points.

$$S=0.2 \times 0.2 \times n \qquad (4)$$

CONCLUSION

Based on the research of characteristics of pavement sag deformation, this paper proposed minimum depth of depression and edge density factor as the characteristic parameters for identifying and classifying depression and fitting base level method based on amendment of 2 times square deviation. By using this method, it can realize automatic identification, location, classification, area calculation and graduation of pavement sag deformation. It is simple and fast to get the result. After a large number of calculations and artificial identification test comparison, it is proofed that this method is good for identification.

ABSTRACT

Five kinds of herbaceous plants commonly distributed in cold regions were selected as experiment plants for protecting slopes. According to the study of coverage, proportion of the root system, and shear strength of root-soil composite in the growth period of plants, the affectivity of slope protection of herbaceous plants in cold regions was verified. By experimentation of the root system, the Lucerne and June grass have a large extent of root system sand robust main roots. In the experiment of the shear strength of root-soil composite, the Lucerne had the largest shear strength and was followed by the White clover. The results of experiments verified that the herbaceous plants selected with good adaptability could protect slopes and enhanced slope stability, which produces better landscape effects under representative soil conditions in cold regions.

Key words: cold region, herbaceous plant, slope protection

Since slope protection using plants can effectively decrease noise and light pollution, it has a significant impact on reducing drivers' fatigue and ensuring traffic safety, promoting the degradation of organic pollutants, purifying the atmosphere and regulating micro-climate, and so on. In September 1994, the first international conference specifically for the slope protection plants was held at Oxford University, which marked that slope protection using plants had been paid extensive attention in the world by the academic community. The conference also effectively enhanced the awareness of using vegetation in slope protection, restoring the damaged eco-environment, and set up an idea to study systematically the plants in slope protection. This paper selected five kinds of herbs that are commonly used for slope protection in the north to carry out the experimental study systemically on plants for slope stability. The study results of this paper can provide scientific and effective methods and technique bases for road slope protection in cold regions.

1 Experiment site

The experiment site is located in the experimental forest farm of Northeast Forestry University in Harbin, Heilongjiang Province. Harbin City is located in south of Heilongjiang Province, Northeast China (125°42' - 130°10' E, 44°04' -46°40' N). It is dominated by the temperate continental monsoon climate with long winters and the short summers. It has four distinct seasons in the year. The annual mean temperature

was 3.1 ℃, the extreme minimum and maximum temperatures reached -41.1 ℃ and 36.2 ℃ respectively, the annual average rainfall was 400-600mm, and the annual frost-free and ice period was 150d and 190d respectively.

The slope gradient of the experiment site was 1:1.5 and the soil was clay soil, which is a common type in the Northeast. The soil was measured by the potentiometry method to be alkaline with a PH value of 8.69. The organic matter content was measured by the ferrous sulfate titration method (GB7848-7858-87) to be 1.198%. These measurements showed that the slope soil has low nutrients and a strong alkaline, which is the common after-construction soil of the highway slopes in Heilongjiang.

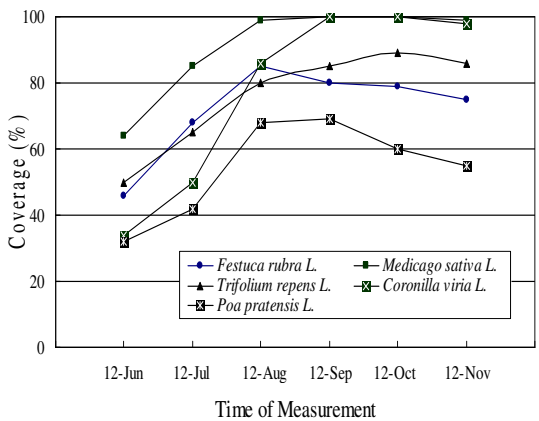
2 Coverage of herbaceous plants

The highway vegetation has the functions of cutting off rainfall and reducing the landslides in shallow slopes[5]. The herbaceous plants and litters may decrease the sediment loss of the slope surface. If there was no vegetation cover on the slope, the runoff capacity carrying sediment is enhanced. The greater the coverage the less the carrying sediment content with runoff. The herbaceous plants and litter on the slope increased the surface roughness, thereby reduced sediment loss. A good herbaceous vegetation cover on slope can effectively control runoff and reduce soil erosion, which plays an important role to protect the slope. The function can be described as equation 1.

$$E = \begin{cases} veg \cdot p & (P \le P') \\ E' & (P > P') \end{cases} \qquad (1)$$

Where, E is rainfall cut off by vegetation, veg is vegetation coverage, E' is maximum cut-off rainfall, P' is critical rainfall, and P is rainfall.

For each species, the acupuncture method was employed every month to measure the plant coverage after grass seed germinating.



Experiments showed the overall trend that the coverage of all grass species increased first and decreased afterwards. The first measure was carried out in June 12, 2006 while plants were still in the seedling stage, so the coverage values for all species were relatively low. During July and August, with good rainfall condition, all plants grew fast and the coverage increased rapidly, approaching or reaching the maximum. **Figure1 Grass coverage in different periods.** At Harbin, the temperature started to drop in September and the average temperature was less than 10℃ from then on. During this period, the metabolism ability of plants was lower and coverage no longer increased. With further temperature drops, the coverage

lowered slightly while plant leaves started to become yellow, wilt, and the plants even died. The measurement results of each grass species showed that, the coverage of *Medicago sativa L.* is in a leading position followed by that of *Coronilla varia L.*, *Trrifolium repens L* and *Festuca rubra L.*, and the last one is that of *Poa pratensis L.*

3 Proportion of herbaceous root system

The shape of the plant root system affects the touching area between roots and soil, consequently the shear strength of soil-with-roots. L. DUPUY and T. FOURCAUD conducted the detailed studies with regard to this. They analyzed the deformation angle of roots, the number of fibers, touching area of root-soil, root volume, root diameter, and other factors on the ability of resisting pullout power and accordingly evaluated the root capability to stabilize soil. Our experiment started from September 12, 2007, and the root systems of all alternative plants were extracted and shown in Figure2 to Figure 6.

Figure4*Coronilla varia L. root.*

Figure5 ***Poa pratensis L root.***

Figure6 ***Medicago sativa L .root.***

Table1. Status of the root system of different herbs.

Herbs	Root density (Five-month growing period)	Fibre (or root)diameter/ mm	Root status
Festuca rubra L.	97-98% of roots distributed within 0-50cm depth of soil, and only about 2-3% of roots distributed in greater than 50cm depth of soil.	<0.2	Developed fibres
Poa pratensis L.	95-97% of roots distributed within 0-50mm depth of soil, and only about 3-5% of roots distributed in greater than 50cm depth of soil.	3.0-5.0	Robust main roots, and more lateral roots
Trrifolium repens L.	Roots distributed in the soil within 0-10cm depth, and the root density steadily declined as soil depth increasing.	1.5-2.0	Obvious main roots, and developed lateral roots
Medicago sativa L.	85-90% of roots distributed within 0-30cm depth of soil, and the root density declined rapidly within 30-50cm depth of soil.	3.0-5.0	Robust main roots, and less lateral roots
Coronilla varia L.	88-92% of roots distributed within 0-30cm depth of soil, and the root density declined rapidly within 30-50cm depth of soil.	<0.2	More fibres

4 Principles of slope protection using herbs

Losing stability, which leads to soil slide, is mainly due to weakened soil shear strength. Many scholars found that by mixing a small amount of reinforcement materials the shear strength of soil can be significantly improved[7]. Herbaceous roots distribution can reinforce soil just as the same as fibers do, and their acting model is shown in Figure 7.

From the observation of the plant root system, we could find that herbs root system can fully access soil particles and had apparent effects on reinforcing soil. Study on root-soil composite shear strength may explain the mechanics action of stabilizing soil and slope by the root system and further reveal the soil mechanics performance of stabilizing soil and slope by trees and herbaceous vegetation.

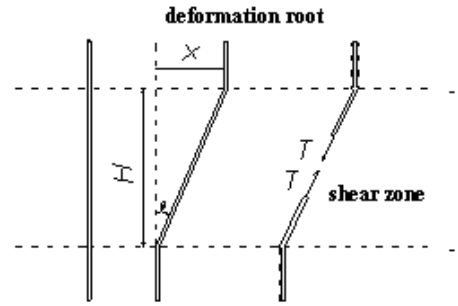

Figure7 Interaction model between single root and soil.

The root-soil composite shear strength is in line with Coulomb's law and it is described as equation (2):

$$\tau = c + (\sigma - \mu)\tan\varphi = (c_0 + \Delta c) + \sigma(\mu \quad)\tan(\varphi_0 + \Delta \quad) \qquad (2)$$

The paper analyzed the stress state of slope soil according to the principle of reinforced soil, which considers the soil distribution as the three dimensional fiber-reinforced distribution. This reinforcement provided additional cohesion Δc for soil. On one hand, it moved the original shear strength of soil up over in distance Δc; on the other hand, the maximum shear stress decreased due to limiting the lateral expansion of soil. Both actions improved the loading capacity of slope soil.

5 Experiment of soil moisture content

Soil moisture content very closely relates to both slope stability and strength. Before the experiment, the soil moisture content of each experiment point was calculated by averaging three measures at the same point. Meanwhile, using the same method, the soil moisture content of the upper, central, and lower part of the slope were measured. It can be seen that the soil moisture contents of experiment slopes were sorted as follows: slope soil without vegetation >*Coronilla varia L.* >*Festuca rubra L.* > *Trrifolium repens L.* > *Poa pratensis L.* > *Medicago sativa L.*

The water consumptions of different plants were varied since their rates of photosynthesis were different. Moreover, the rainfall cutoff and surface runoff were varied among different plants due to the different vegetation coverage. Furthermore, the slope soil moisture content was affected. The moisture contents of tested soil with *Festuca rubra L.*, *Trrifolium repens L.*, *Poa pratensis L.* and *Medicago sativa L.* were similar, *Coronilla varia L.* was higher.

4 Shear experiment

Starting from September 12, 2007, we extracted the soil samples with roots of the site-planted herbs from depths of 0-50cm underground. Soil samples with roots were

used for the shear experiment and comparing the shear strength of soil-with-roots of herbs. In this experiment, the non-consolidated and un-drained fast-shear mode was employed and the speed of the electric hand wheel of the direct-shear instrument was 4r/min. For each of the four soil samples, this test was carried out at 5kPa, 10kPa, 15kPa and 20kPa, respectively, under the vertical pressure.

(1)Experiment data

In the experiment, the shear stress was equal to the dynamometer readings multiplied by the dynamometer coefficient. The stress-strain relationship diagram was established using shear stress as the horizontal axis and shear displacement as the vertical axis. We considered the shear stress peak in curves as the shear strength of soil samples under the corresponding vertical pressure. Under the vertical pressure, the root-soil composite shear strength of 4 duplicate experiments for each herb is shown in Figure 8.

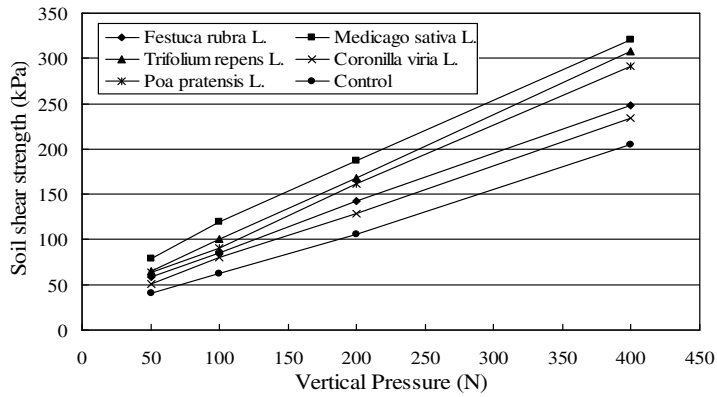

Fig8 Shear strength curves of soil-with-roots and soil-without-roots of herbs.

Table2 Equations of shear strength curves of different soil-with-roots.

	Linear expressions of shear strength	Correlation coefficient	Effective cohesion *c* /kPa	Internal friction angle /(°)
Festuca rubra L.	y_1=0.5446*x*+31.297	0.9995	31.297	28
Medicago sativa L.	y_2=0.6808*x*+48.852	0.9995	48.852	34
Trrifolium repens L.	y_3=0.6932+30.741	0.9999	30.741	34
Coronilla varia L.	y_4=0.519*x*+26.084	0.9994	26.084	27
Poa pratensis L.	y_5=0.6545*x*+29.194	0.9993	29.194	33
Soil-without-roots	y_6=0.4726*x*+14.657	0.9991	14.657	25

(*x* represents the vertical pressure, and y_i (*i*=1、2、3、4、5、6) represents the shear strength of different herbs)

(2) Data analysis

There were shear strength differences between samples of soil-with-roots and soil-without-roots. With increasing vertical pressure, the shear strength of each soil increased; the shear strength differences among soils increased also. From individuals, the shear strength of *Medicago sativa L.* was higher under each of the

vertical pressures, so its shear strength line is always at the top. It is followed by *Trrifolium repens L.*, *Poa pratensis L.*, *Coronilla varia L.* and soil-without-roots respectively. The effective cohesion *c* of soil-with-roots was significantly higher than that of soil-without-roots, which agreed with many other scholars' conclusion that plant roots can enhance the soil shear strength.

5 Conclusions

Slope protection plants on roads can effectively reduce the slope surface erosion and reduce the sliding of shallow slopes. Within the range of roots entangled, the soil with roots can be seen as composite material of soil and roots. The roots of the herbaceous plants played the same role as the fiber did. The number of roots contained in the soil of per unit volume is varied from the herb species. The greater number of roots, the greater the soil shear strength. Roots can not only improve soil cohesion but also improve the friction angle of soil, thereby increasing the shear strength of soil and enhancing the stability of the slope. All these indicators showed that, among all alternative herbaceous plants, the *Medicago sativa L.* is the most suitable species to protect the highway slopes in cold regions.

In the work of slope protection, in order to meet the requirements of road slope stability and landscape, we can determine the protection of plant varieties, planting plants, and reasonable configuration of the shrubs and herbaceous plants from the basis of scientific data.

Effect of Inorganic Salts on Frost Resistance of Concrete

Yong Ge[1], Wencui Yang[2], Jie Yuan[3], Baosheng Zhang[4]

[1]School of Transportation Science and Engineering, Harbin Institute of Technology, 202 Haihe Road, Nangang District, Harbin 150090, P.R. China; PH (86)45186282191; email: [1]hitbm@163.com, [2]keriy@126.com, [3]hityuanj@163.com, hitzbs@163.com

ABSTRACT

Effects of water-binder ratio and inorganic salt additive，including NaCl, $NaNO_2$ and Na_2SO_4, on frost resistance of concrete were investigated using the orthogonal experimental test. There were two criteria, i.e., the relative dynamic elastic modulus (RDEM) and weight loss that can be used to evaluate the resistance of concrete subjected to fast freeze-thaw tests. The results show that the effect of water-binder ratio on frost resistance of concrete is obvious and that the salts have different effects: adding NaCl and Na_2SO_4 into concrete decreases frost resistance and that the worst effect occurs when the dosage of NaCl and Na_2SO_4 is about 0.5% and 1.25% of cement, respectively. Adding $NaNO_2$ into concrete improves frost resistance but the effect is not obvious. The influential effects of these salts are ranked to be NaCl>Na_2SO_4>$NaNO_2$.

INTRODUCTION

In cold regions of China, chemical admixtures are widely used in concrete as antifreeze agents or high-early strength agents including many inorganic salts such as chloride, sulfate, nitrite, nitrate, carbonate, and some organic admixtures such as triethanolamine, formate, acetate, propionate (Wang 2005, Chen 2004). In fact, some inorganic salts used as high-early strength agents can improve hydration of cement and increase the early strength of concrete; some inorganic salts used as antifreeze agents can lower freezing point of solution in pores and make concrete ice-free before hardening. However, inorganic salts also cause some problems. For example, steel corrosion of reinforced concrete structures is usually enhanced by chlorides used as traditional antifreeze agents. Studies on alkali-silica reaction, corrosion of steel induced by chlorides and effect of corrosion inhibitors have been reported (Sideris 2005, Tritthart 2001, Muralidharan 2004, and Rivard 2003).

Orthogonal test is a mathematical method to carry out multifactor experiments. It is based on the principle of statistics and orthogonal theory. Orthogonal tests select sufficient typical and representative sample tests to analyze the relationship among the factors and the test results. Orthogonal test is widely used since it could handle a complex issue with much lower cost and less time. There is a series of orthogonal tables in correspondence with different amounts of factors and values. Different orthogonal tables are applied when the numbers of factors or values are different.

Frost resistance of concrete is very important in cold weather and is affected by inorganic salts when antifreeze agents or high-early strength agents are used. Research of concrete deterioration due to freeze-thaw action in Heilongjiang province and east of Inner-Mongolia showed that deterioration of concrete with high-early strength agents or antifreeze agents was more severe. Within this context, frost resistance of concrete containing inorganic salts was investigated by orthogonal experimental test in this study.

EXPERIMENTAL PROCEDURE

Scheme of the experiment. Orthogonal tests were applied to analyze the influence of four factors on the frost resistance of concrete. Experimental factors to be considered were water-binder ratio, NaCl dosage, $NaNO_2$ dosage, and Na_2SO_4 dosage. Four levels of each factor should be mentioned. According to the orthogonal tables, $L_{16}(4^5)$ orthogonal table was applied in this paper. Experiment schemes used are shown in Table 1.

Table 1. Orthogonal table, $L_{16}(4^5)$, for frost resistance of concrete

Factors / Levels	*W*/*B*	NaCl dosage (%)	$NaNO_2$ dosage (%)	Na_2SO_4 dosage (%)	Blank
1	0.55	0.0	0.0	0.0	—
2	0.42	0.50	1.0	0.50	—
3	0.34	1.25	2.0	1.25	—
4	0.26	2.00	3.0	2.00	—

Materials and mix proportions. The raw materials used in test and their properties are shown in Table 2. A series of non-air-entrained concrete were prepared with water-binder ratio values of 0.55, 0.42, 0.34 and 0.26, respectively. The water-reducing agent dosage was adjusted to keep the slump of fresh mixed ordinary concrete in the range of 70mm~90mm. The proportions of concrete mixes are given in Table 3.

Table 2. Raw materials and properties.

cement	Chinese standard 42.5 ordinary Portland cement
river sand	fineness modulus of 2.49 and apparent density of 2590kg/m^3
crushed basalt stone	maximum size of 20mm and apparent density of 2740kg/m^3
Grade I fly ash	15% weight replacement for cement
water-reducing agent	Naphthalene-type water-reducing agent, UNF-5

Samples and testing programs. The specimens with size of 100mm×100mm×200mm were cast for each mixture. All specimens were demolded 24 hours later and cured for 24 days in standard condition (20±2℃ and 95% RH), and then immersed in water for 4 days before being subjected to freezing and thawing cycles. Three specimens were tested for each mixture. The sound velocity and weight

of the specimens were measured at different freeze-thaw cycles. The relative dynamic modulus of elasticity (RDEM) is the ratio of the dynamic modulus of elasticity for a certain cycles to the initial value before subjected to freeze-thaw cycles. The RDEM is calculated by the following expression: RDEM $=E_n/E_0=(V_n/V_0)^2$, where E_n is the dynamic modulus of elasticity of n cycles and E_0 is the initial value. V_n and V_0 are the sound velocity of n cycles and initial value, respectively.

Table 3. Proportions of concrete mixes.

W/*B*	Cement (kg/m^3)	Water (kg/m^3)	Sand (kg/m^3)	Coarse aggregate (kg/m^3)	Fly ash (kg/m^3)
0.55	222	150	720	1305	51
0.42	290	150	667	1273	67
0.34	359	150	616	1240	82
0.26	469	150	547	1171	108

The weight of specimens was measured using electronic balance with a precision of 0.1 g. According to the test procedures, the specimen failed if its RDEM dropped to below 60% or its weight loss exceeded 5.0%.

RESULTS AND ANALYSIS

Table 4. Number of freeze-thaw cycles of concrete.

No.	*W*/*B*	NaCl dosage (%)	$NaNO_2$ dosage (%)	Na_2SO_4 dosage (%)	Blank	Number of freeze-thaw cycles
F1	0.55	0	0	0	—	55
F2	0.55	0.5	1.0	0.5	—	25
F3	0.55	1.25	2.0	1.25	—	23
F4	0.55	2.0	3.0	2.0	—	24
F5	0.42	0	1.0	1.25	—	53
F6	0.42	0.5	0	2.0	—	81
F7	0.42	1.25	3.0	0	—	82
F8	0.42	2.0	2.0	0.5	—	85
F9	0.34	0	2.0	2.0	—	213
F10	0.34	0.5	3.0	1.25	—	115
F11	0.34	1.25	0	0.5	—	61
F12	0.34	2.0	1.0	0	—	138
F13	0.26	0	3.0	0.5	—	403
F14	0.26	0.5	2.0	0	—	296
F15	0.26	1.25	1.0	2.0	—	384
F16	0.26	2.0	0	1.25	—	347

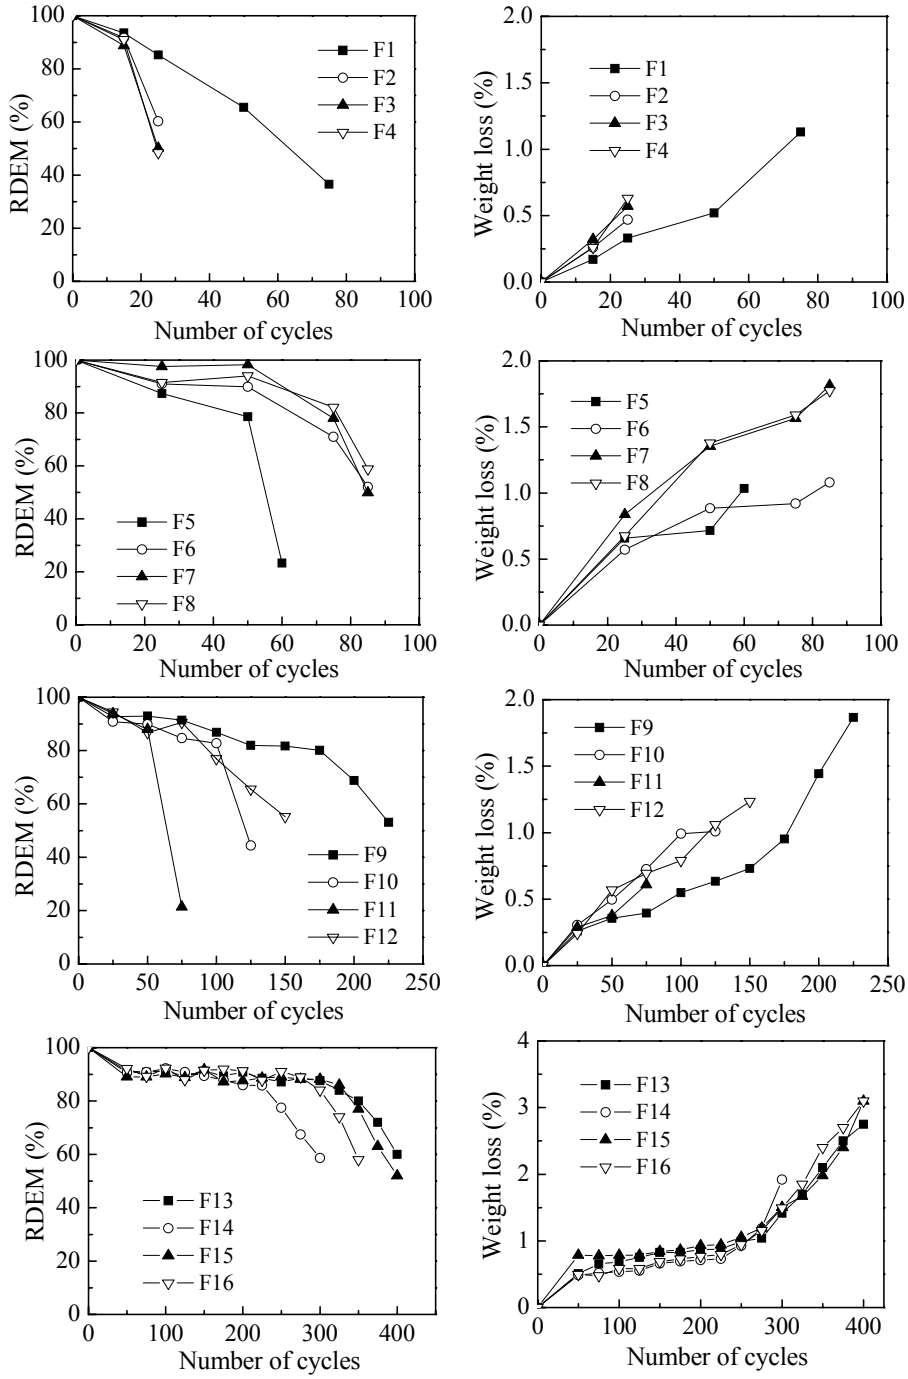

Figure 1. RDEM and weight loss of concrete subjected to freeze-thaw cycles.

Experiment results. Frost test results of the specimens prepared in the experiments are shown in Table 4 and Figure 1. It could be seen from Figure 1 that the drop of dynamic modulus of elasticity was faster than that of the weight loss. So all specimens failed due to the RDEM below 60%. The effect of *W*/*B* on frost resistance of concrete was obvious. For the concrete with the same *W*/*B*, RDEM and weight loss

after some freeze-thaw cycles were very different, which indicated that inorganic salts added into concrete had influence on frost resistance. Moreover, the effects of salts were remarkable on frost resistance of concrete with higher *W*/*B*.

Mean values of every four numbers of cycles corresponding to the same factor were calculated as shown in Table 5. Considering the differences between the maximum mean value and the minimum mean value of each factor, it is obvious that the most effective factor affecting frost resistance of concrete is *W*/*B*, followed by the material in the order of NaCl, Na_2SO_4 and $NaNO_2$.

Table 5. Mean value of each factor in correspondence with levels.

No.	*W*/*B*	NaCl dosage (%)	$NaNO_2$ dosage (%)	Na_2SO_4 dosage (%)	Blank
1.	31.750	181.000	136.000	142.750	159.750
2.	75.250	129.250	150.000	143.500	166.750
3.	131.750	137.500	154.250	134.500	161.250
4.	357.500	148.500	156.000	175.500	108.250
Difference of the mean value	325.750	51.750	20.000	41.000	58.250

Taking the levels of the experimental factors as X-coordinate and the corresponding mean values of damping ratio results as Y-coordinate, the trend curves showing the relationship between the considered factor levels and damping ratio results could be drawn as shown in the Figure 2.

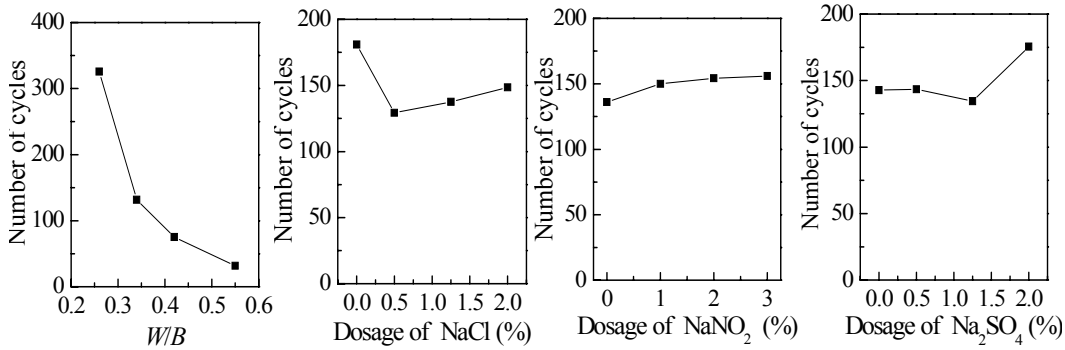

Figure 2. Effects of four factors on number of cycles.

It could be seen from Figure 2 that as *W*/*B* decreased, cycles of concrete subjected to action of freeze-thaw increased. The average number of cycles of four concrete with *W*/*B* of 0.55 were 32, which rose to 75 when the *W*/*B* of concrete was 0.42. Cycles of the four concrete samples with *W*/*B* of 0.26 can exceed 300. As dosage of NaCl increased, the number of cycles first decreased and then increased. The minimum cycles was obtained when NaCl dosage was 0.5%. Moreover, the number of cycles of concrete with NaCl was lower than the concrete without salt. $NaNO_2$ had no side effects as a frost resistance agent for concrete. Frost resistance of concrete was improved appreciably when $NaNO_2$ was used. Effect of Na_2SO_4 dosage

on number of cycles was similar to that of NaCl. As the dosage of Na_2SO_4 increased from 0% to 1.25%, the number of cycles decreased and the minimum cycles was obtained at the dosage of 1.25%.

CONCLUSIONS

(1) Orthogonal test was carried out and results show that water-binder ratio is the most important factor affecting frost resistance of concrete. Inorganic salts also have influence on frost resistance of concrete, and effect of NaCl is obvious, followed by the Na_2SO_4 and $NaNO_2$.

(2) NaCl and Na_2SO_4 could reduce frost resistance of concrete. Number of freeze-thaw cycles for concrete with salt is minimum when NaCl dosage is 0.5% or Na_2SO_4 dosage is 1.25%. $NaNO_2$ can improve frost resistance of concrete appreciably at the dosage between 1.0% and3%.

(3) When inorganic salts are used as antifreeze agents or high-early strength agents in concrete, the water-cement ratio or water-binder ratio should be reduced properly to avoid harmful effects of salts on frost resistance of concrete.

ABSTRACT

A study of the efficiency of lightweight aggregate (LWA) in controlling restrained shrinkage cracking of low water-to-cement ratio concrete is presented. Free autogenous shrinkage test of concrete specimens and restrained test with ASTM C 1581-04 were performed. Autogenous shrinkage and restrained stress of concrete with different moisture content (0%, 20%, 40%, 60%, and 100%) LWA at the same water-to-cement ratio of 0.30 were investigated by experiments that provided date on free autogenous shrinkage and restrained shrinkage. The results showed that the pre-wetting LWA effectively reduced autogenous shrinkage, restrained shrinkage and tensile stress in the restrained conditions. Also, it was found that the shrinkage stress was relaxed more and more with degree of saturation of LWA increasing, and can be mitigated by 45.7% in the concrete with the saturated LWA.

Concrete; lightweight aggregate; autogenous shrinkage; restrained shrinkage; tensile stress

1. INTRODUCTION

Development of high-performance concrete (HPC) with high-performance and improved durability has brought new opportunities to the construction industry. However, some attention was given to characteristics of such concrete, in particular with respect to their cracking sensitivity. HPC is generally made of a low water-cement ratio, which makes it susceptible to self-desiccation (Jensen, 1996). This self-desiccation process is directly related to autogenous shrinkage. Autogenous shrinkage results in tensile stresses in the cement paste, due to the external restraint. It has been argued and demonstrated experimentally that a low water-to-cement ratio concrete may undergoes shrinkage due to self-desiccation. If this shrinkage is restrained, the concrete may crack. This autogenous shrinkage cracking is a major concern for the durability and aesthetic of concrete structures (Takafumi Noguchi, 2005). One possible method to reduce the adverse effects of cracking due to autogenous shrinkage is the addition of LWA for internal curing (Hammer, 1992).The pre-wetted porous LWA can be used as an internal source of water and release gradually in the internal concrete under the capillary tension function.

The research on the effect of water absorption and desorption of LWA on adjusting the internal relative humidity of concrete and improving the properties of fracture and deformation is very necessary. This article addresses the issues outlined above both with experiments and with calculations. Autogenous deformation of LWAC realized with pre-wetted LWA (ceramsite) was measured. The aims at evaluating mechanical properties of concrete such as various types of strain and shrinkage stress with pre-wetted LWA, which were measured on the corresponding normal weight concrete (NWC) mix.

2. EXPERIMENTAL PROGRAM

2.1 MATERIALS AND MIX PROPORTIONS

Mixtures were prepared using P·O 42.5 cement. The fine aggregate is river sand with a specific gravity of 2.61 and fineness modulus of 2.82. In the corresponding normal weight concrete (NWC) case, with a continuous grading of 5mm~20mm. Specific gravity of the crushed limestone coarse aggregate is 2.81. The non-air entrained and high-effective naphthalene-based superplasticiser (SP) used was a type of UNF-5, with a water reducing ratio of 20%. The LWA used was one type of shale ceramisite(BY) with a maximum size of 16mm and cylinder compressive strength of 5.9MPa, with an water-absorbing ratio 6.6% for 1hrs, a saturated water content of 24%, The variations curves of shale ceramsite water absorption and desorption versus time were shown in Figure 1.

The shale ceramsite were pre-wetted before mixing. The drying ceramsite was soaked in water (saturation refers to maintain 20 min in water under 5 MPa hydraulic pressure. The saturation level of the LWA obtained by impregnating under pressure was higher compared to vacuum impregnation, other pre-wetting treatment refers to atmospheric pressure) for a specified time to make them have five different saturated water contents (100%, 60%, 40%, 20% and 0%), so the ceramsite would have different initial water content. The LWA concrete and normal weight concrete were prepared with a water-cement ratio of 0.3, a cement dosage of 500kg/m^3, a fine aggregate dosage of 678kg/m^3. The LWA concrete were prepared with a ceramsite dosage of 495kg/m^3, normal weight concrete was prepared with crushed aggregate dosage of 1067kg/m^3. In order to study the autogenous shrinkage, the restrained shrinkage and the restrained tensile stresses by contrast, the used proportions are shown in Table 1.

2.2 TEST PROCEDURE

The primary tests that will be described in this paper consist of ring test that was performed using a ring with a steel wall thickness of 12.5 mm, an inner diameter of 305 mm, an outer diameter of 330 mm, a specimen outer diameter of 406 mm, and a height of 75 mm. Four strain gages were fixed to each steel ring at mid-height and their strain was measured at 10 minute intervals from the time water came into contact with the cement (MA Xinwei, 2006). After removing the mould at an age of 24 hours, the rings were sealed with duct tape around their outer circumference, in

this research the specimens were allowed to dry from the top to the bottom surface.

Table 1 Mix proportions of concrete and properties of concrete specimens

Sign of concrete	Degree of Pre-wet /%	Net Time-to-Cracking /Days	Steel Ring Strain at cracking /μ-strain	Maximum restrained Stress (σ_{max}) /MPa	Tensile Strength at cracking /MPa	Compression strength at 28d /MPa
NWC	0	3.71	54.40	3.57	4.38	62.80
IC00	0	5.08	35.60	3.01	3.62	41.80
IC20	20	6.96	41.34	2.71	3.54	40.60
IC40	40	10.40	40.34	2.65	3.42	40.50
IC60	60	13.46	37.70	2.48	2.98	40.30
IC100	100	26.08	29.43	1.94	2.54	39.50

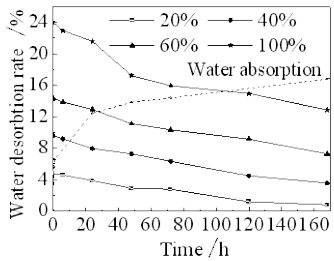

Fig.1 Water desorption rate of ceramsite at RH=91%

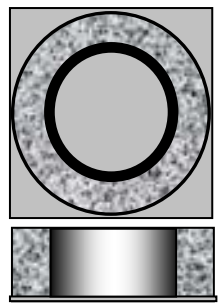

Fig.2 Top view and cross sectional view of the ring specimens

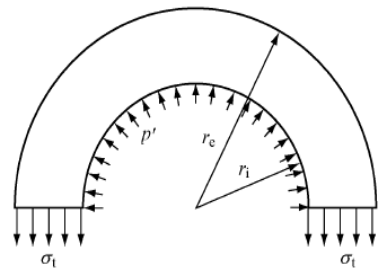

Fig.3 Stress of concrete under ring restrained condition

The restrained tensile stresses of concrete ring can be calculated by Equation 1:

$$\sigma_t = \frac{p \cdot r_{ic}}{h_c} \tag{1}$$

where: σ_t is the restrained tensile stresses of concrete ring; p is the internal pressure of the concrete ring; r_{ic} is the inner radius of the concrete ring; h_c is the thickness of the concrete ring.

The fictitious pressure acting on the steel (at the interface with concrete) can be calculated by Equation 2, which incorporates the strain value that is equivalent to the strain measured in the steel ring.

$$\sigma_{st} = E_{st} \cdot \varepsilon_{st} = \frac{p \cdot r_{es}}{h_{st}} \tag{2}$$

where: σ_{st} is the pressure stresses of the steel ring; E_{st} is the elastic modulus of the steel ring, where is 200GPa; r_{es} is the inner radius of steel ring; ε_{st} is the strain pressure of steel ring; h_{st} is the thickness of the steel ring.

The strain that develops at the inner surface of the steel ring can be used to determine the force that is exerted by the shrinking concrete. After recording the

strain in the steel at ten minute intervals, the ring system is analyzed by separating the problem into one that considers a steel ring with a fictitious external pressure and a concrete ring with a fictitious internal pressure. Equilibrium requires that the fictitious external pressure equals the fictitious internal pressure. So, combining Equation 1 and Equation 2 and allowing the stress to be computed when $r_{ic} = r_{es}$ enables the maximum tensile stress σ_t that develops in the ring to be calculated using the measured strain $\varepsilon_{st}(t)$ as shown in Equation 3:

$$\sigma_t = \frac{E_{st} \cdot h_{st}}{h_c} \cdot \varepsilon_{st}(t) \tag{3}$$

In order to avoid deviation due to the move of the specimen (Dong Shuhui, 2008), one micrometer gauge was fixed on each specimen to measure the length change of it. Autogenous shrinkage was tested with the equipment. Three specimens were cast in cylindrical mould (100mm×400mm) for each mix ratio and a temperature probe embedded in the specimens. After casting, specimens were sealed immediately and set up in the test equipment. The measurement of autogenous shrinkage began 3hrs after casting and measurement of temperature began.. All autogenous shrinkage data used in analysis were averages of the data of three specimens. As change of internal temperature in concrete due to hydration has great impact on autogenous shrinkage of concrete, so a method from literature (Ahmed Loukili, 2000, Erika E Holt, 2001) was adopted to amend the experimental data for autogenous shrinkage to eliminate this impact. Amendment was also made to erase effect of settlement during plastic stage.

3. RESULTS AND DISCUSSIONS

3.1 EFFECT OF LWA WATER CONTENT ON CONCRETE AUTOGENOUS SHRINKAGE

The effect of water content of ceramsite on concrete autogenous shrinkage was studied, the test result were shown in Figure 4.

The test results indicate that, autogenous shrinkage of concrete develops very quickly at the early age, the majority completes within 48hrs. For later period shringkage grows slowly. Autogenous shrinkage value of the LWA concrete at the age of 12h is about 50%~70% of that at the age of 120h, but the normal weight concrete reaches 80%. With the increase of ceramsite initial water content, the autogenouse shrinkage of LWA concrete reduces obviously, and also lower than that of normal weight concrete.

In the hardening process, a great amount of free waters is consumed for the cement hydration, so the concrete internal humidity decreases steadily, and the water stored in pre-wetted ceramsite would migrate to the cement paste around under the capillary tension, and provide water for the no hydrated cement particles, this could reduce the capillary water consumption, thereby reduce the self-desiccation shrinkage. The higher the ceramsite water content and the more the migration water,

the compensation effect for the concrete self-desiccation shrinkage becomes more significantly. It can be seen that, the addition of pre-wetted LWAs has obviously effect on eliminating the autogenous shrinkage.

3.2 EFFECT OF SATURATION DEGREES OF LWA ON RESTRAINED SHRINKAGE OF CONCRETE

Three replicates were prepared for each specimen and average of two closer values was considered. In Figure 5, the restrained shrinkage of concrete with different degrees saturation of the ceramsite and 30NWC were presented.

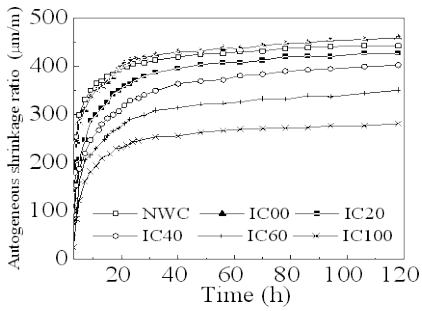

Fig.4 Effect of ceramsite water content on autogerous shrinkage

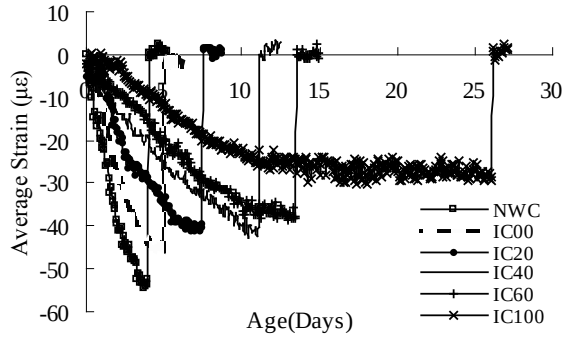

Fig.5 Effect of saturation degrees of ceramsite on restrained shrinkage

It was observed that the rate of restrained shrinkage development in each of the specimens was dissimilar before the specimen cracked. The restrained shrinkage was initialized at zero at the setting time of concrete. The restrained shrinkages of NWC specimens occurred at a rapid rate in the first few days and the shrinkage reached a maximum of 54.4 μstrain at 3.71days. The restrained shrinkages of IC00 specimens occurred at a rapid rate in the first few days but the shrinkage reached a maximum of 35.6 μstrain at 5.08 days, lower and later than NWC. The restrained shrinkage of IC100 specimens reached a maximum of 29.43 μstrain at 26.08 days and the shrinkage rate was the lowest than other mix specimens. That was, with the increase of ceramsite initial degree of saturation, the restrained shrinkage of concrete reduces obviously, and the time of reaching maximum restrained shrinkage had a much delay, also lower than that of normal weight concrete.

However, as was shown in Figure 5, an abrupt change of shrinkage was observed in several instances for all specimens at different age, which corresponds to cracking in the specimen. It was observed that this abrupt change in shrinkage for all specimens corresponds to the age of visible cracking in the specimen. The residual shrinkage in ring specimens was found to be reduced to almost zero after the visible crack developed.

3.3 EFFECT OF SATURATION DEGREES OF LWA ON RESTRAINED TENSILE STRESSES OF CONCRETE

Figure 6 shown the development of tensile stresses of all specimens that were computed using the measured strain values obtained (using Equation 3) for the

mixtures tested in this study. The trend of tensile stress development in each specimen was found to be fairly similar as the restrained shrinkage development, before the specimen cracked. The concrete specimens NWC restrained stress occurred from the start of setting. The stress reached a maximum of 3.57MPa at 3.71 days, an abrupt change of stress was observed after the peak. The mixture with 100% saturated ceramsite showed slowly development rate of restrained stress in the all stage of measuring. After 26.08 days the stress peak occurred, reaching a maximum of 1.94MPa. Figure 6 illustrated the stress that had developed before and after visible cracking occurred in all specimens. The restrained stress in the ring specimen was found to be reduced to almost zero after the first crack developed in the specimens.

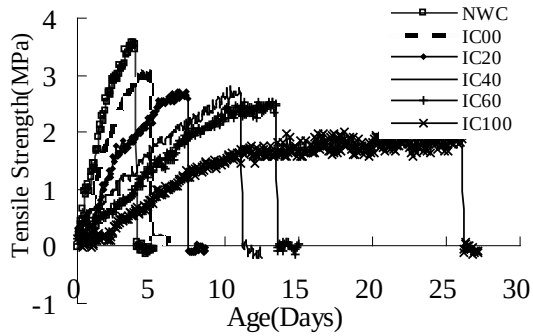

Fig. 6 Effect of saturation degrees of ceramsite on tensile stresses

The effect of the degree of saturation of the aggregate on the stress development is significant. For the mixtures with an actual degree of saturation of 0% and 20%, stresses are higher than those of the mixtures with an actual degree of saturation of 60% and 100%. These maximum stresses were 3.01 MPa and 2.71 MPa, respectively. With the increase of ceramsite initial degree of saturation, the restrained stress of concrete reduces obviously, and the time of reaching maximum restrained stress had a much put off, also lower than that of normal weight concrete. The maximum restrained stress value (1.94MPa) of the mixture with 100% saturated ceramsite can reduce to 54.3% than the value of the corresponding normal weight concrete. Test results of compressive strength at 28 days and splitting tensile strength at crack occurring were shown in Table 1. The results represent the average value of three 100×100×100mm concrete specimens. The measured splitting tensile strength values higher than the computed restrained stress values in every mixture.

The theory of pre-wetting LWA can reduce the restrained shrinkage and the restrained stress of low water-cement ratio concrete was conform to the reason of autogenous shrinkage reduction.

4. CONCLUSIONS

(1) The addition of pre-wetting LWA can obviously reduce the autogenous shrinkage of high-performance concrete with low water-cement ratio, at early age. When the initial degree of saturation of ceramsite increases from 20% to 100%, the 120h-shrinkage values of LWA concrete reduces from 3.6% to 36.4% respectively as compared to that of normal weight concrete.

(2) With the increase of ceramsite initial degree of saturation, the restrained shrinkage of concrete reduces obviously, and there is a big delay on the time to reach maximum restrained shrinkage. When the initial degree of saturation of ceramsite are 60% and 100%, the restrained shrinkage values of LWA concrete reduces 30.7% and 45.9% respectively as compared to that of normal weight concrete.

(3) With the increase of ceramsite initial degree of saturation, the restrained stress of concrete reduces obviously, and the time to reach maximum restrained stress had a much put off, also lower than that of normal weight concrete. The pre-wetting LWA effectively reduced tensile stress in the restrained conditions. It was found that the restrained stress was relaxed more and more with degree of saturation of LWA increasing, and can be mitigated by 45.9% in the concrete with the saturated LWA.

ABSTRACT

It has been recognized that asphalt pavement performance will be weakened with the presence of water within pavement structure. However, current mechanistic analysis does not take into account the moisture influence on the dynamic response of pavement appropriately. In this paper, finite element meshing, boundary conditions, material properties and dynamic loading were introduced, followed with the analysis of typical time history pore pressure. Then, the mechanism of premature failure related to water damage was discussed based on on-site damage phenomenon combined with the finite element simulation according to the spatial distribution of pore pressure and the comparison between the saturated and dry cases. Finally, the influence of surface drainage conditions on the dynamic response of saturated pavement is presented here. The result indicates that the presence of water changes stress distribution in pavement structure. What's more, it is interesting to find that the worst positions are the middle and bottom HMA layer according to the distribution of pore pressure, which was consistent with the initial failure phenomenon of asphalt pavement due to water.

INTRODUCTION

It is generally accepted that newly placed HMA pavements are placed at a higher air void (6-7%) than designed value with the assumption that traffic loadings will decrease the air void content over time. The air void can allow water to move through the pavement. Infiltration of water into the pavement can develop pore pressure leading to excessive deflection, cracking and reduction in load carrying capacity of pavement.

It is general that all pavements have some degree of saturation, which indicates that water should not be ignored in asphalt pavement mechanics analysis.

Therefore, some related researches have been done. Masad et al. (2003) used two dimensional SEEP/W finite element modeling to study the relationship between the water flow patterns and the gradients in percent air voids in HMA. Novak et al. (2002) used theory of mixture to describe the saturated asphalt pavement and studied the effects of vehicle speed and permeability on pore pressure by a two dimensional finite element code-PlasFEM. Kringos et al.(2005) developed a finite element tool RoAM (Raveling of Asphalt Mixes) to describe the raveling of asphalt Mixes due to moisture damage from the micro-mechanics point of view. Dong (2006) carried out theoretical derivation and FEM simulation for the saturated pavement subject to transient vehicle loading.

FINITE ELEMENT MODELING

Three dimensional finite element meshes are shown in Figure 1. Eight-node brick element is used. The nodes, when analyzed in a transient dynamic saturated state, have seven degrees of freedom corresponding to fluid and solid displacements in X, Y and Z direction as well as pore pressure. The size of the finite element model is 3.0m by 3.0m by 3.0m. Elements are finer near the top and middle (where the wheel load will be applied) and gradually grow coarser towards the sides and bottom of the pavement.

For solid phase, it was assumed that there is no vertical, transverse or horizontal movement at the bottom of the model, thus the bottom of the model was completely restrained. The top was free to move in all directions. Horizontal movement perpendicular to the perimeters was also restrained whereas the remaining two directions were considered free. For fluid phase, the surround boundaries and upper boundary, except for the loading area, were pervious while the bottom boundary and loading area were impervious.

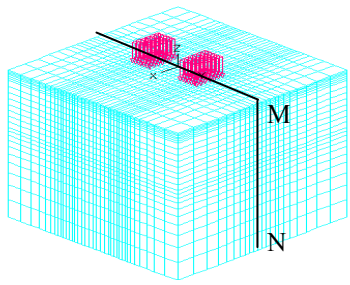

Figure 1. Three dimensional finite element meshes.

TRANSIENT DYNAMIC LOADING

The standard wheel load was assumed to be 0.24m long and 0.16m wide with a contact pressure of 651kPa for a single rectangle loading area, and the distance between the two loading areas is assumed to be 0.24m. A transient haversine loading function with a recovery time is used to simulate the actual vehicle loading action on asphalt pavement. The peak of uniform loading is defined

as $P_{\max}$, loading duration as T and the whole analysis time as T_a. At any time t in the analysis period, the applying uniform loading is:

$$p = \begin{cases} P_{\max} \sin(\frac{\pi t}{T}) & 0 \le t \le T \\ 0 & T < t \le T_a \end{cases} \quad (1)$$

The duration of the load is based upon the vehicle speed v and the assumption that the tire, with length l, has no effect at a distance of $6l$. This paper looked at a wheel load traveling at 60 km/h, or haversine load duration of 0.0864s.

MATERIAL PARAMETERS

Typical material parameters of asphalt pavement are used, shown in Table 1.

Table 1. Material parameters of saturated asphalt pavement.

Layer	Thickness cm	Young's modulus/MPa	Poisson Ratio	Density kg/m^3	Permeability cm/s
Upper HMA	5	1400	0.3	2400	1.0E-04
Middle HMA	6	1400	0.35	2400	1.0E-05
Bottom HMA	8	1400	0.35	2400	1.0E-05
Upper Base	20	1600	0.2	2100	1.0E-04
Bottom Base	20	600	0.3	1900	1.0E-05
Subgrade	250	50	0.4	1900	1.0E-06

ANALYSIS OF TIME HISTORY OF PORE PRESSURE

Figure 2 shows the time history of pore pressures at different depths on the longitudinal center section (M-N section) of the applied load. As shown in Figure 2, the pore pressures increase very rapidly as load increases at the initial stage, as the applied load is transferred to the fluid in the voids. Subsequently, as the fluid starts to escape the voids, the pore pressures decrease. Then the positive pore pressures change to negative suction pressures and the surrounding material skeleton recovers from the load and sucks the water back into the voids between the aggregates gradually. The maximum negative suction pressure reaches when the wheel load is almost gone. Finally, as the loading is gone the negative pressure starts to dissipate. It is noted that the peak time of pore pressure is earlier than that of applied loading, after the initial stage of loading there has certain time for the fluid to escape through the around interconnected void. Although the applied loading reaches its peak value, the transferred pressure to fluid can't continue to increase.

The similar reversals from positive pore pressures to sizable suction, as the wheel load is applied, are found at all the depth, while the different point is their peak value.

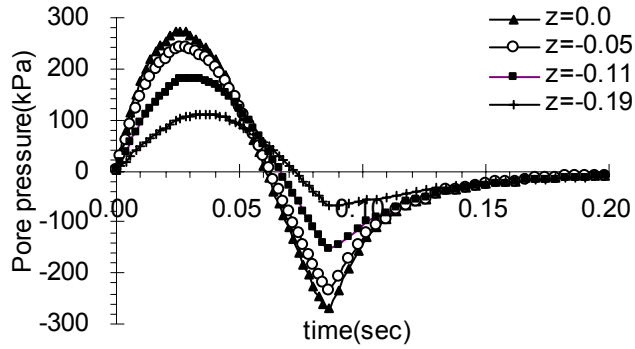

Figure 2. Pore pressure histories at different depths.

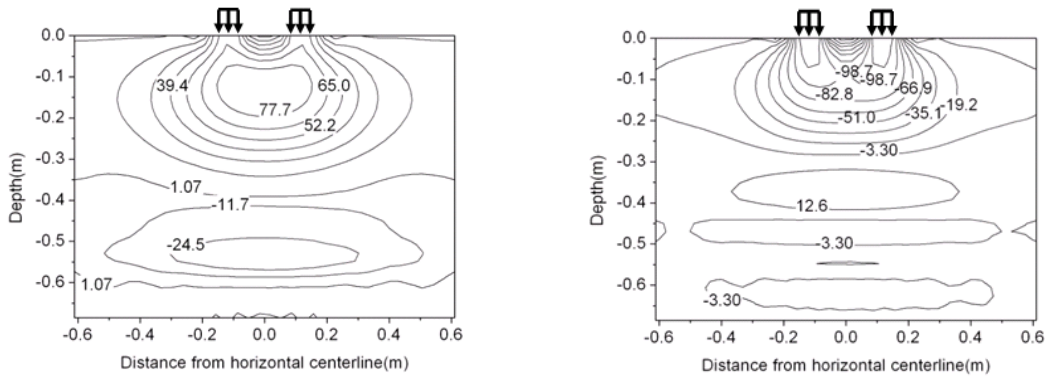
PRELIMINARY ANALYSIS OF PREMATURE DAMAGE DUE TO WATER

Figure 3 shows the pore pressure distribution at different times for M-N section. Pore pressures mainly focus on asphalt layers within the depth of 0.2m, both in the arising and dissipating phases. What's more, the transverse influence scope is the biggest at the depth from 0.05 to 0.2m, which is just the middle and bottom asphalt layer. This means that the worst position is the middle and bottom asphalt layer once water enters the pavement structure, consistent with the initial failure phenomenon of asphalt pavement due to water. This can be thought as one of the reasons for the premature failure caused by water similar to Figure 4, from the theoretical point of view.



(a) t=0.026(sec) **(b) t=0.082(sec)**

Figure 3. Pore pressure distribution for different time.

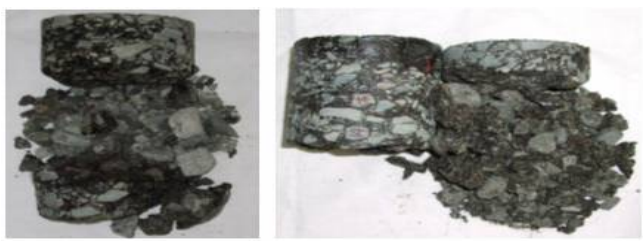


Figure 4. Coring results from the initial failure site of asphalt pavement.

INFLUENCE OF SURFACE DRAINAGE CONDITION

When carrying out theoretical calculation and analysis about the dynamic response of saturated asphalt pavement, surface drainage condition needs to be considered, i.e. surface draining condition and surface non-draining condition. Surface draining condition is defined that water near the surface can flow freely to get into or get out of pavement structure. Generally, asphalt pavement with no sealing or water-proofing should use this boundary condition. Surface non-draining is defined that water cannot be drained out of the pavement structure. When surface course is used for sealing or water resisting such as slurry seal and Micro-surfacing, it should be regarded as non-drainage condition. Figure 5 gives the results of pore pressure distribution along the depth at *t=0.036s* and *t=0.075s* for surface draining condition and surface non-draining condition.

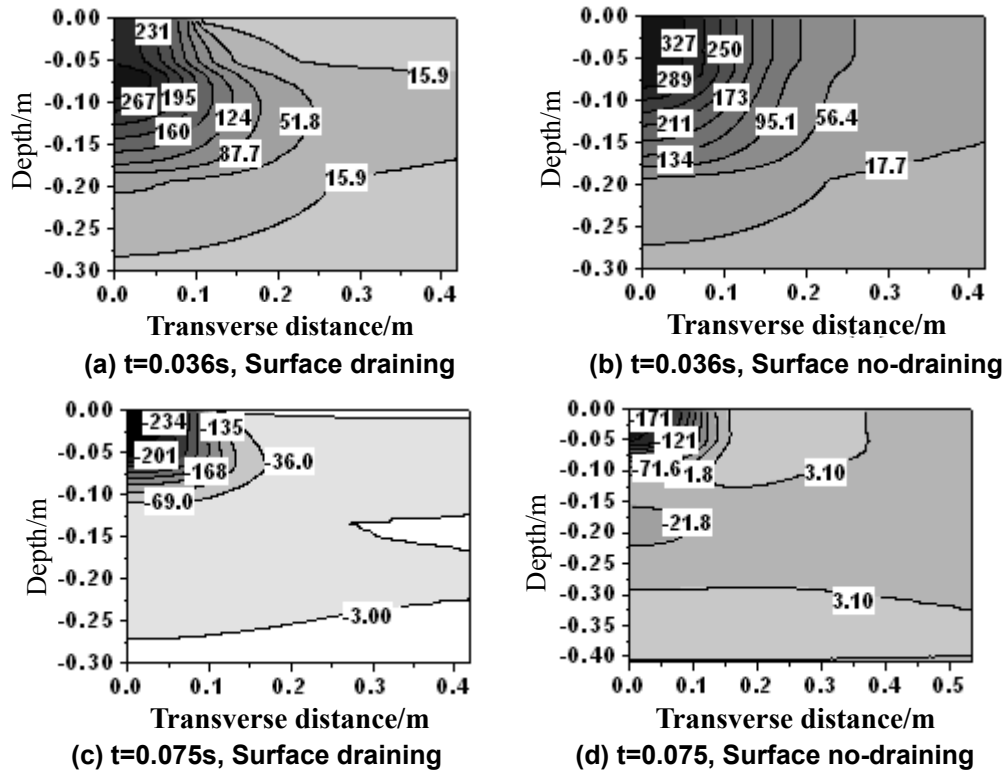

Figure 5. Pore pressure distribution along depth

It can be seen that the distributions are different for the two cases. For the draining condition, the absolute value of positive and negative pore pressure is roughly equal, while for the non-draining condition, the absolute value of negative pore pressure is obviously lower than the former. What's more, the pore pressure distributions are different. Influence of pore pressure is mainly concentrated on wheel load region, and along the depth. This region gradually expands to maximum

width at the middle asphalt layer in surface draining condition. The largest influence of pore pressure is at surface asphalt layer because water can't be discharged. With the depth increasing, the influence reduces gradually in surface non-draining condition. According to the comparison, it shows it is more detrimental for pavement structure in surface draining case.

CONCLUSIONS

This paper presents three dimensional finite element simulation of dynamic response for a saturated pavement system subject to the dynamic vehicle loads. It shows that a reversal of pore pressures occurs in saturated asphalt pavement due to dynamic vehicle loading, which may induce stripping and raveling damage. The worst position is the middle and bottom layer of pavements because the arising and dissipating of pore pressure concentrates at here, which is consistent with the initial failure phenomenon of asphalt pavement due to water. Furthermore, it is more detrimental for pavement structure in surface draining case, as the influence of pore pressure is the largest at the surface of asphalt layer because water can't be discharged

It is recommended that analysis between permeability and pore pressure should be performed, as the former highly influences the latter. Further laboratory test considering the action of pore pressure induced by vehicle loading should be carried out.

ABSTRACT

Permanent deformation(PD) of asphalt mixture caused by high temperature (above 50°C), instead of the accumulative deformation caused by moderate temperature (20°C to 50°C), attracts more attention. First, distributions of pavement temperature based on continued hourly average pavement temperature data in Shanghai and Wilson County were introduced. The result indicated that percentage frequency of pavement temperature below 50°C is more than 90%, and that above 50°C is less than 5. Second, PD of two asphalt mixtures measured by APA (asphalt pavement analyzer), dynamic stability (DS) of four mixtures tested by wheel tracking device and shear strength of five mixtures tested by uniaxial penetration test were introduced. The results show that PD at 40℃ is almost 50 percent of that at 60°C, and that the ranking of high temperature performance for the same mixture changes with temperatures. At last, result of rutting depths calculated by the Mechanistic-Empirical Pavement Design Guide (MEPDG) suggests that rutting depth for high temperature months is almost two to three times of that for moderate temperature months. Therefore, PD of asphalt mixtures should be evaluated considering pavement temperature distribution.

INTRODUCTION

Rutting of asphalt pavements is a serious concern for a long time due to the increased traffic and wheel loads in China. Thus, it is necessary to predict the PD of a mixture before construction. Several test methods are in practice to assess the PD. The commonly used test methods include diametral tests, uniaxial tests, triaxial tests, shear tests, empirical tests, simple shear tests and simulative tests which are basically accelerated laboratory PD prediction tests (Sousa et al., 1991). However, almost all the tests evaluate the PD at constant high temperature such as 60°C or PG (performance grade) high temperature, while PD at moderate temperature was

nearly neglected. In fact, rutting occurs at both high temperature and moderate temperatures. In addition, pavement temperature changes frequently. For a certain mixture, it is difficult to conclude whether it is enough to evaluate high temperature performance at one temperature. Consequently, the PD characteristic should be investigated considering the distribution of pavement temperature at different depths of asphalt layers and taking pavement temperature variation into account.

DISTRIBUTION OF PAVEMENT TEMPERATURE

The temperature profile in asphalt pavement structure plays an important role on performance of asphalt pavement owing to the susceptibility of asphalt mixture. Many researches have been carried out to measure and predict the temperature distribution in asphalt pavement.

Distribution of Pavement Temperature in Shanghai

Qin (2005) measured pavement temperature data of asphalt pavement sections in Shanghai. In the test section, there were 12 thermal-probes were instilled at different depths in the asphalt layers. The frequency histograms of hourly average pavement temperature for different averaging intervals are given in Figure 1 based on collected data at four depths in asphalt layers from August 20th to September 14th, 2002. The time region represented typical high temperature season in Shanghai, and the depths were 5mm, 17mm, 39mm and 61mm below the surface.

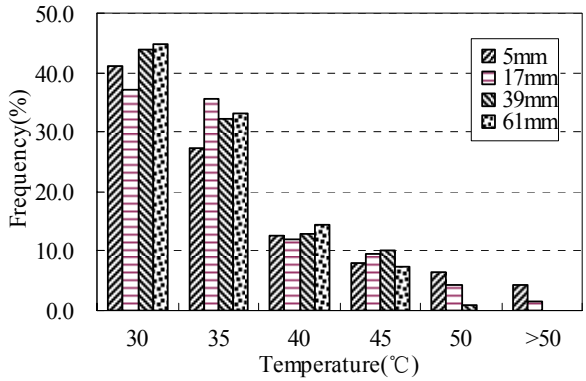

Figure 1. Hourly average pavement temperature distribution for different averaging intervals in Shanghai.

As shown in Figure 1, percentage frequency of pavement temperature interval from 30 to 40°C is about 70, while that from 40 to 50°C is about 20 and that above 50°C is less than 5 at four depths. As a result, moderate temperature contributes large proportion even in high temperature season.

Distribution of Pavement Temperature in Texas

There are three pavement temperature measurement methods in the LTPP program: infrared surface pavement temperature, manual in-depth pavement temperatures and Seasonal Monitoring Program (SMP) pavement temperatures (Drumm et al., 2003). All SMP sites are monitored with temperature, moisture, and

weather instrumentation. The temperature instrumentation in the pavement consisted of 300-mm stainless steel tubes or rods fitted with three thermistors, one at each end and one in the middle. A data logger monitored the thermistors and the weather instruments, with a recording frequency of one minute. A data logger recorded the average hourly reading at the end of each hour(LTPP, 1994).

Since all the SMP data was available online, SMP section 48-1122-1 in Wilson County, Texas was selected. This site is located southern of the United States. Hourly average pavement temperature distribution for different averaging intervals at three depths (1.3cm, 4.0cm and 12.3cm) in 1994 was analyzed. Frequency histograms are shown in Figure 2. Cumulative frequency of moderate temperature exceeds 90, while frequency of pavement temperature above 50°C is less than 5 for three depths.

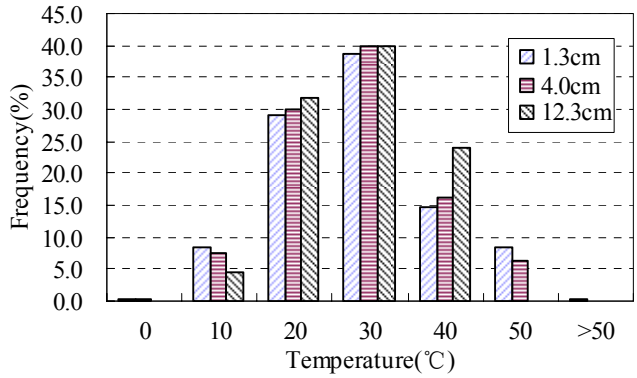

Figure 2. Hourly average pavement temperature distributions for different averaging intervals.

In conclusion, whether in Shanghai (China) or Wilson County(Texas), the proportion of high temperature in a year is far lower than that of moderate temperature. Then, is it proper to state that PD of asphalt mixtures should be evaluated at moderate temperature as well?

PD OF ASPHALT MIXTURES TESTED BY DIFFERENT METHODS

The performance tests are basically accelerated laboratory PD prediction tests and relatively easy to use and ready for immediate adoption. There are several performance tests in practice. Of the different laboratory rut testers, APA is a widely used load wheel tester. In addition, Hamburg Wheel Tracking Device and wheel tracking tester are also wildly used in their respectively country.

PD of Asphalt Mixtures Tested by APA

PD can be evaluated by using APA test which simulates the traffic loading and temperature effects on compacted asphalt mixtures. The APA allows for an accelerated evaluation of rutting potential after volumetric design of mixes. Cylindrical specimens compacted using the Superpave gyratory compactor (SGC) of two gradations with the same aggregates and asphalt were chosen. The testing time

used in this study was 135 minutes (8000 cycles). A load of 100 pounds and a hose pressure of 100 psi were used for all tests (Pavement Technology INC, 2003). Temperatures used in APA test were 20, 30, 40, 50 and 60°C .

In order to simplify the explanation, two surface course mixtures (13.2 mm mixtures) with the same aggregate sources (diabase for coarse aggregates and limestone for fine aggregates) and asphalt binder were used to prepare mixtures. The penetration of base asphalt was 68(0.1mm) at 25℃. The two gradations meet the requirement of *technical specifications for construction of highway asphalt pavements* in China. Two design aggregate structures are given in Table 1.

TABLE 1 Aggregate Gradation for Two Mixtures

Sieve Size(mm)	Percent Passing (%)										Actual air void content (%)
	16	13.2	9.5	4.75	2.36	1.18	0.6	0.3	0.15	0.075	
Upper limit of gradation	100	100	85	68	50	38	28	20	15	8	
Lower limit of gradation	100	90	68	38	24	15	10	7	5	4	
Design gradation 1	100	95	70	41.5	30	22.5	16.5	12.5	8.5	6	4.03
Design gradation 2	100	96	84	60	45	30	19.5	13.5	8	5	4.11

PD of two mixtures at five temperatures is shown in Figure 3. PD increased with temperature for both mixtures. In addition, the PD of design gradation 1 was higher than that of design gradation 2 at all the temperatures except for 40°C. PD at 40°C was almost 50% of that at 60°C for these two mixtures, which indicates that the PD at moderate temperature can be compared to that at high temperature even if without distribution of pavement temperature considered.

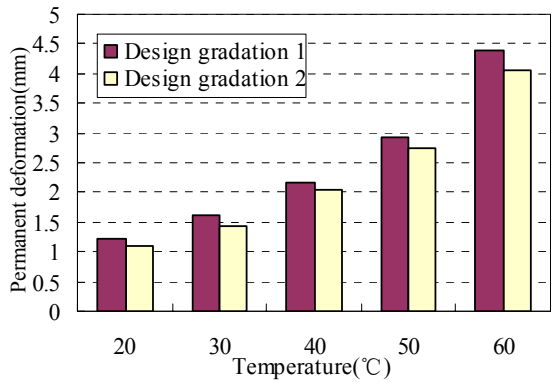

Figure 3. PD at five temperatures for two mixtures tested by APA.

DS of Four Asphalt Mixtures Tested by Wheel Tracking Device

The wheel tracking test measures rut depth and the number of passes of tire loads at high temperatures to evaluate the PD characteristics of mixtures. Test results are presented by a curve relating deformation with loading time (or loading cycles). The rate of rut depth (i.e., rut depth per minute) was monitored during 15 minutes of testing (from 45 to 60 minutes during the test) and was considred as an indicator to estimate DS. At present, wheel tracking device is widely used in China to assess

high temperature performance of asphalt mixtures with DS as evaluation index. Test results of four mixtures (HXL, LHE, SLI and CHA) typically used in China were analyzed. Results of these four mixtures are shown in Figure 4.

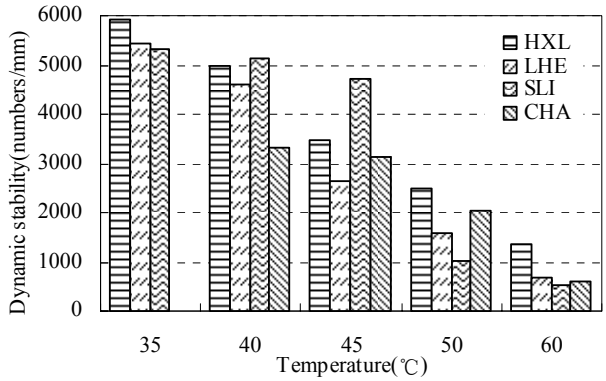

Figure 4. DS of four mixtures at five temperatures tested by Wheel tracking device in China.

As shown in Figure 4, DS of four mixtures decreased with the increase of temperature. The general trend of was that HXL presented higher DS, followed by LHE, CHA, and SLI at 60°C. The trend changes as HXL presented higher DS followed by CHA, LHE and SLI at 50°C. At 45°C, DS of SLI had highest DS, followed by HXL, CHA and LHE. For 40°C, SLI still ranks first, however followed by HXL, LHE and CHA. HXL again had highest DS at 35°C, followed by LHE and SLI. The change of ranking at different temperatures indicates that these four mixtures had different temperature sensibility. In other words, the trends of DS variation with temperature are different. Therefore, it is misleading to assess PD characteristic only at constant high temperature?

Shear strength of Asphalt Mixtures Tested by Shear test

As it was previously mentioned, shear test is another test used to assess high temperature performance of asphalt mixtures. Considering the deficiencies in the existing shear tests, a surrogate test method, the uniaxial penetration test (UPT), was developed by Sun (2006), as illustrated in Figure 5. Compared with triaxial shear test, the UPT can directly determine the shear strength of asphalt mixture in pavement structure.

Figure 5. The Uniaxial Penetration Test (Lijun Sun, 2006).

The cylindrical specimens were with both diameter (R) and the height (H) 100mm. The diameter and height of the plunger for the uniaxial penetration test were respectively 28.5mm and 50mm. In addition, the test temperature was from 20°C to 60°C, and the loading rate was set to 1mm/s. The mixtures are the same as that tested by APA. Mixture 1 and mixture 2 correspond to design gradation 1 and design gradation 2. Shear strength of both mixtures are given in Figure 6.

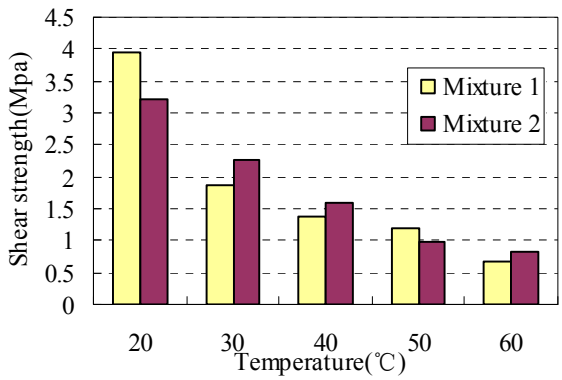

Figure 6. The uniaxial penetration test result of two mixtures.

Figure 6 shows that shear strength decreased with the increase of temperature. In addition, the shear strength of mixture 1 is higher than mixture 2 at 20℃ and 50℃. However, the trend is opposite at the other temperatures. In other word, the fact that the high temperature performance was good at a constant high temperature does not mean its high temperature performance would be good at other temperatures.

RUTTING PREDICTION OF ASPHALT PAVEMENT USING MEPDG

The MEPDG released by the National Cooperative Highway Research Program (NCHRP), is a significant improvement in pavement performance prediction methodology. Therefore, result of rutting prediction was imported to analyze the difference of PD at months with high temperature and the other months. The difference of parameters would not influence the result of this research so much. For this reason, level 3 was chosen and hypothetical data was input to the software in this study. The site is located in Texas, and the design life was 15 years. The

climate data was also from Texas. Rutting prediction for asphalt layers is given in Figure 7.

As shown in Figure 7, rutting of asphalt layers increased with pavement age. At the end of design life (180 months), rutting depth was up to 10mm, while rutting depth reached to 2mm at the end of the first year. Afterwards, increment of rutting for each year decreased gradually. Average pavement temperatures for June, July and August all exceeded 35℃, and were defined as high temperature months. The other months were defined as moderate temperature months. Then rutting depth of high temperature months and moderate temperature months were compared for the first nine years. Histogram of rutting depth with pavement age is given in Figure 8.

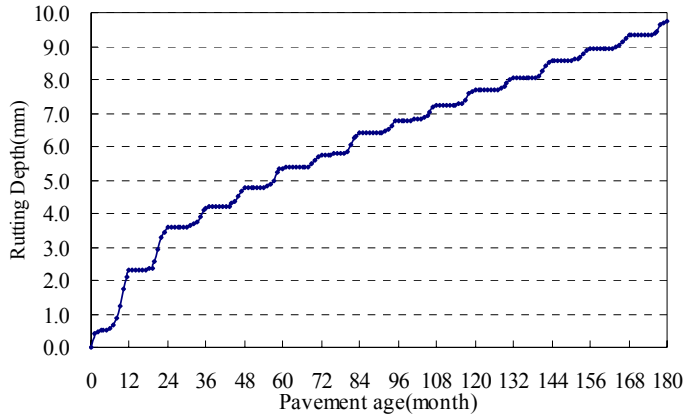

Figure 7. Rutting predictions for asphalt layers using MEPDG.

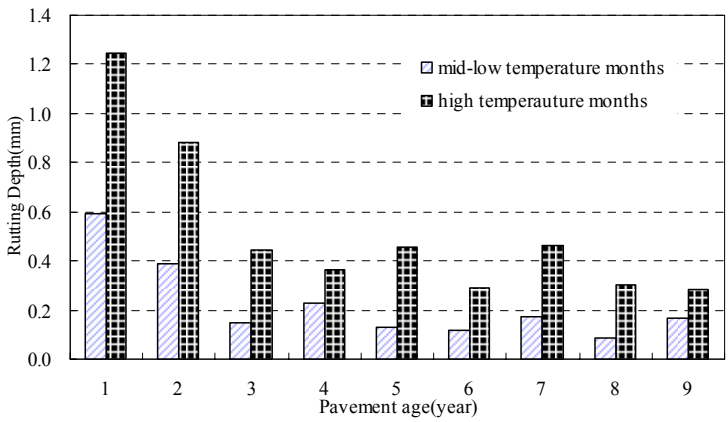

Figure 8. Comparison of rutting depth for high temperature months and moderate temperature months.

As shown in Figure 8, rutting depth at high temperature months was only two to three times of that at moderate temperature months. It indicates that rutting depth for moderate temperature months should not be ignored.

In conclusion, results of PD characteristic of asphalt mixtures measured by several test methods showed that the PD property at moderate temperature was of the equivalent importance as that at high temperature. Furthermore, research on the

PD property with varying temperature is of benefit to better understand the PD property of asphalt mixture and to more rationally estimate the rutting in asphalt pavement.

CONCLUSIONS

Based on the testing and analysis presented, the following conclusions may be made:

1. The frequency of high pavement temperature is less than 5%, while that of moderate temperature is more than 90% according to pavement temperature data in Shanghai and Wilson County.
2. PD or other evaluation indexes at moderate temperature is close to or compared with that at high temperature.
3. The high temperature performance is good at a constant high temperature does not mean its high temperature performance would be good at other temperatures.
4. PD of asphalt mixtures should be evaluated considering pavement temperature distribution.

Basic Study on Fractal Characteristic of Pore Structure in Cement Mortar

JIN Shanshan, ZHANG Jinxi, LI Shuang, FAN Meng

Key Laboratory of Traffic Engineering, Beijing University of Technology, Beijing 100124, P.R. China; Tel: +86-10-67391583 (O); Fax: +86-10-67391509; email: zhangjinxi@bjut.edu.cn

ABSTRACT

Mercury intrusion porosimetry (called MIP) was used to test the pore structure of cement mortar with different water-cement ratios at different ages. The fractal characteristic of the pore structure of cement mortar was studied, and the pore surface fractal dimension was computed based on the Menger sponge model. The relations between the fractal dimension and water-cement ratio, age, strength were investigated. The results indicated that, the fractal dimension was not unique in the whole range of pore size tested by MIP, and it could be divided into three regions by pore diameter: larger than 100nm, between 10nm and 100nm and smaller than 10nm. The pore fractal characteristic in the regions of larger than 100nm and between 10nm and 100nm were remarkable. The regular relations between pore surface fractal dimension and water-cement ratio, age and strength were obtained.

KEY WORDS: Fractal; Pore size; Mortar; Strength

1 INTRODUCTION

The pore structure is a very important part of the microstructure of concrete. It strongly influences the macroscopical physical and mechanical performance of concrete. The result of the SEM indicates that the pore structure of concrete is so disordered that its complexity cannot be described effectively by traditional methods (Tang and Huang, 2007). Therefore, the fractal theory as a new method describing the material complexity is used in the study of pore structure of concrete. Fractal theory can express the complexity of pore structure as fractal dimension quantitatively. It brings a new way on study of the complexity of concrete pore structure and the relation between pore structure and macroscopical performance of concrete. In recent years, fractal theory has been advanced greatly (Hu, 1997; Tang, 2000; Tang and Huang, 2007; Zhang and Li, 1995), and becomes a very important research direction gradually on the study of concrete pore structure. However, at the present time, the study of concrete pore fractal characteristic is still at the initial stage. The physical meaning of the pore fractal dimension is not very clear; and the pore test technology and pore fractal modeling method are different. All of these have caused the experimental results of pore fractal dimension to be terribly various. Therefore, the study on fractal characteristic of concrete pore structure is urgently needed.

Mercury intrusion porosimetry (called MIP) was used to test the pore structure of cement mortar with different water-cement ratios at different ages in the research. The pore surface fractal dimension of cement mortar was computed based on the Menger sponge model, and the relations between the pore surface fractal dimension and water-cement ratio, age and strength were analyzed.

2 RAW MATERIAL AND TEST METHOD

2.1 Raw materials and mix proportion

The raw materials included: Chinese standard P·O 42.5 Portland Cement, nature sand and artificial sand, water and water reducing agent. The fine aggregate was mixed with nature sand and artificial sand with the ratio of 4:6. The fineness module of the fine aggregate is 2.85. The mix proportion of the mortar is shown in Table 1.

Table 1. Mix proportion of cement mortar/ (kg /m^3)

Water-cement ratio	Cement	Natural sand	Artificial sand	Water	Water reducing agent
0.4	510	612	918	204	13.3
0.5	510	612	918	255	—
0.6	510	612	918	306	—

2.2 Strength test

The experimental methods were referred to "Test Methods of Cement and Concrete for Highway Engineering (JTG E30-2005)". The specimen size for strength experiment is 4cm×4cm×16cm. The specimens should be placed in the standard curing room with 20±2℃ and more than 90% relative humidity after demoulding. The flexural strength and compressive strength were tested at prescriptive age.

2.3 Pore structure test

The AutoPore IV 9510 MIP, which is manufactured by Micromeritics Instrument Corporation of USA, was used in this study. The MIP test parameters are as follows: the initial pressure of the low pressure is 1.03Psi, the terminal pressure is 30Psi; the initial pressure of the high pressure is 30Psi; the terminal pressure is 60000Psi. The tested range of diameter is between 3.3nm and 360000nm.

3 FRACTAL MODEL OF PORE STRUCTURE

Concrete contains pores of a large diameter interval, so it can be associated to the Menger sponge fractal model. The construction process of the Menger sponge fractal model is as following. A cube with edge R is assumed, and then the cube is divided into m^3 small cubes. In a designated rule, there are N_1 small cubes left after removing parts of the small cubes. Repeating the above process step by step. Consequently the size of the remained cubes continuously decreases but the number of the cubes unceasingly increases. Finally, after k times, edge length of the remnant cubes is $r_k=R/m^k$, and the remnant cubes quantity is $N_k = (r_k/R)^{-D_f}$. D_f represents the fractal dimension (Zhu, 2004). Linking it to MIP test, the remnant cubes constitute

the substrate of the material, and their volumes are $V_k = N_k \cdot r_k^3$; and the removed small cubes in different steps constitute the different steps' pore of material, and their volumes are $V_\phi = R^3 - V_k$. V_ϕ can be calculated with cumulative intrusion volume of mercury V at a given pressure P, r_k is the pore diameter D at the same pressure. It is deduced that the intrusion volume curve should obey the relation (Tang, 2000):

$$\lg\left(-\frac{dV}{dD}\right) \propto \left(2 - D_f\right)\lg D \tag{1}$$

Using the relations in Eq.1, the surface fractal dimension can be calculated. The logarithm of derivative cumulative intrusion volume is plotted vs. diameter logarithm, and if pore surface is fractal between a range of pore diameters, a linear tendency should be observed, and from the slope of that line D_f is calculated.

4 DATA PROCESSING METHOD

The experimental data of MIP were imported into Microsoft Office Excel. Lg(−dV/dD) and LgD at different pressures were calculated and scatter plots were made in Excel. The linear equation and Correlation coefficient were obtained by adding the trend line for Lg(−dV/dD) ~ LgD. If the Correlation coefficient is high, the fractal characteristic is remarkable. According to Eq.1, the pore surface fractal dimension can be calculated by the slope of the trend line of Lg(−dV/dD) ~ LgD.

The scatter plot of Lg(−dV/dD) ~ LgD for cement mortar with 0.6 water-cement ratio at 3d age is shown in Figure 1(a). It can be seen that the trend line of Lg(−dV/dD) ~ LgD is not linear in the whole range of pore size tested by MIP, and there are inflexion points. The plot can be divided into three regions according to the inflexion points as shown in Figure 1(a). Taking inflexion points and pore classification method in account, the three regions divided by pore diameter were: D>100nm, 10nm<D<100nm and D<10nm. The scatter plot of Lg(−dV/dD) ~ LgD, linear regression equation and the correlation coefficient in three regions are shown in Figure 1 (b), (c) and (d) respectively. It can be seen that the correlation coefficient is higher in the region of D>100nm and 10nm<D<100nm, so the fractal characteristic is remarkable for these two regions. The correlation coefficient is equal to 0.4812 in the region of D <10nm, so the fractal characteristic is not remarkable. The reason may be that the error exists in the data of MIP at the small pore size near to the test limit. The absorption method can be used to study the pore fractal characteristic in the region of D <10nm. For analysis convenience, D_{f1} and D_{f2} were proposed to represent the pore surface fractal dimension for the region of D >100nm and 10nm<D<100nm respectively.

The pore surface fractal dimension (D_{f1} and D_{f2}), correlation coefficient (R^2), compressive strength (R_c) and flexural strength (R_f) with different water-cement ratios (w/c) and ages are shown in Table 2. The fractal dimensions calculated in two pore size regions are different. D_{f1} is large, and general between 3.1 and 3.5; D_{f2} is small, and general between 2.6 and 3.2. The correlation coefficients show that, the

correlation coefficients of D_{f1} are high, which are general greater than 0.97. Relatively, the correlation coefficients of D_{f2} are lower, most of which are greater than 0.80 with some between 0.7 and 0.8. It indicates that the pore fractal characteristic of mortar is more obvious with the pore diameter D>100nm. According to fractal dimension definition (Zhu, 2004), the surface fractal dimension should be between 2 and 3, but some pore surface fractal dimensions calculated in the study are large than 3. The reasons why this happened need to be further studied. .

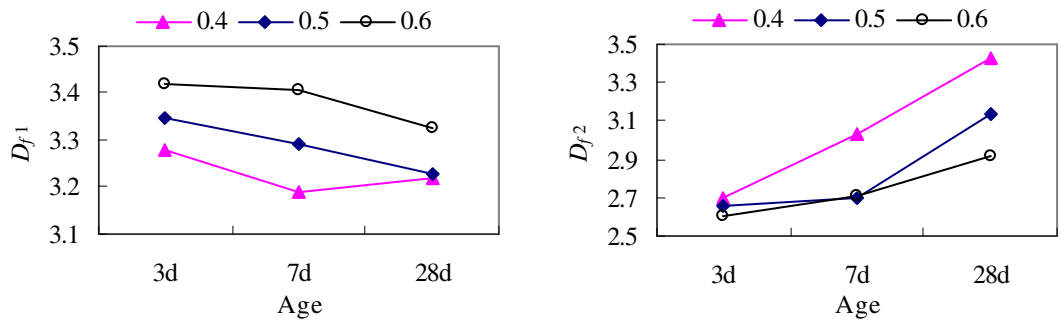
5 EXPERIMENT RESULTS AND DISCUSSION

5.1 Influence of water-cement ratio and age on pore surface fractal dimension

The pore surface fractal dimension with different water-cement ratios and

ages are plotted in Figure 2. From Figure 2, it can be seen that the pore surface fractal dimension varies with water-cement ratio and age regularly, but the relations between the fractal dimensions D_{f1}, D_{f2} and age, water-cement ratio are different. For D_{f1}, the pore surface fractal dimension becomes lower as the age of mortar grows and water-cement ratio decreases . For D_{f2}, the relations are just opposite from D_{f1}.



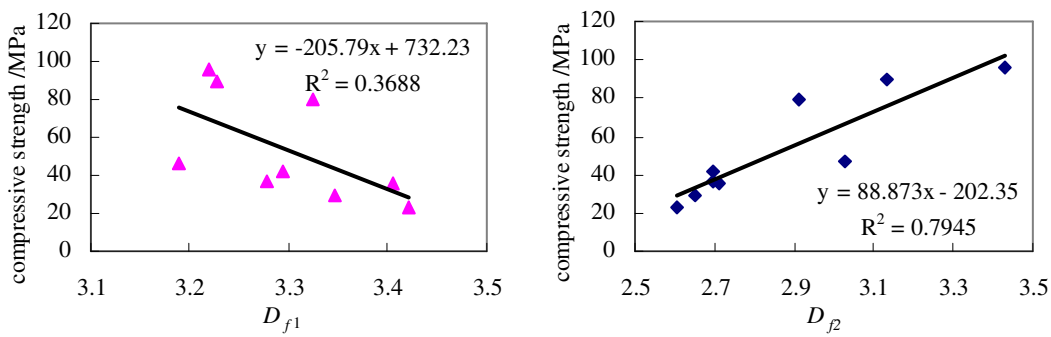
(a) D_{f1} ~ Age (b) D_{f2} ~ Age

Figure 2. Pore surface fractal dimension varies with water-cement ratio and age

The larger the fractal dimension is, the more complex is the surface, so the results show that as the hydration progresses and the water-cement ratio decreases, the pore distribution (D >100nm) becomes simpler, and the pore distribution (10nm<D<100nm) becomes more complex. It means that the number of larger pores decreases and the number of small pores increases when age grows and water-cement ratio decreases , which fits the development rule of pore structure in mortar. Therefore it is suitable for using pore surface fractal dimension to describe the pores characteristic.

5.2 The relationship between strength and pore surface fractal dimension

Strength is the most important macroscopical performance parameter of cement-based materials, and it is influenced by pore structure strongly. The scatter plots of compressive strength and flexural strength with pore surface fractal dimension are shown in Figure 3 and Figure 4.

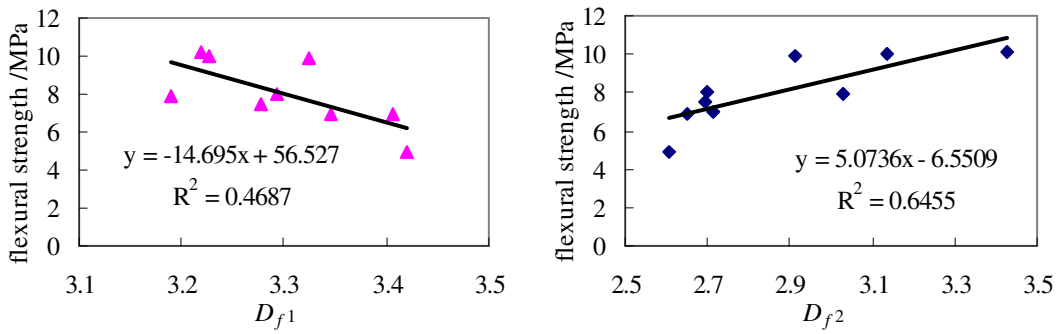


(a) Compressive strength~ D_{f1} (b) Compressive strength~ D_{f2}

Figure 3. Relations between compressive strength and surface fractal dimension

It can be concluded that the compressive strength and flexural strength vary

with pore surface fractal dimension regularly, and the regular patterns are the same. That is, the compressive strength and flexural strength grow to higher as D_{f1} decreases and D_{f2} increases. Considering the influence of water-cement ratio and age on pore surface fractal dimension, as pore surface fractal dimension D_{f1} decreases and D_{f2} increases, the number of large pores gets smaller and the number of small pores gets bigger. Therefore the specific surface area of the pores gets larger. It means that the pore structure becomes optimized, and so the compressive strength and the flexural strength increase.



(a) Flexural strength ~ D_{f1} (b) Flexural strength ~ D_{f2}

Figure 4. Relations between flexural strength and surface fractal dimension

6 CONCLUSIONS

(1) The fractal dimension is not unique in the whole range of pore size tested by MIP. Three regions divided by pore diameter were: D>100nm, 10nm<D< 100nm and D<10nm. The pore fractal characteristic in the regions of D>100nm and 10nm<D<100nm are more remarkable, and the pore surface fractal dimensions calculated in the two regions are general in range of 3.1~3.5 and 2.6~3.2 respectively.

(2) The pore surface fractal dimension varies with water-cement ratio and age of the cement mortar regularly. As the age grows and water-cement ratio decreases , the pore surface fractal dimension D_{f1} becomes smaller and D_{f2} becomes larger .

(3) The compressive strength and flexural strength of mortar vary with pore surface fractal dimensions regularly. Their regular patterns are the same. The compressive strength and the flexural strength increases as D_{f1} decreases and D_{f2} increases.

ABSTRACT

Port is an important hub of the integrated transport network. It is necessary to build the logistics centre in the port industrial zone, which will provide comfortable logistics services and enhance the competitiveness. Based on the theory of the node important degree, the traffic location and the indexes of the nodes, the paper calculates the importance of the logistics node index, which uses Analytic Hierarchy Process (AHP) to determine the weights. Combined with related data and documents, the paper analyzes the logistics node of the iron and steel industry of Caofeidian.

INTRODUCTION

The analysis of the logistics node important degree is an important aspect for the logistics center building and investment decisions. Determining the logistics node is one of the main subjects for Industrial Park Planning. A reasonable set of logistics nodes can ease the operation pressure of a logistics center and increase the investment profit of the logistics node.

NODE IMPORTANCE DEGREE

The concept of node is widely used in graph theory, economic geography, regional science and other fields. Traffic location theory believes that a small number of the region (1/3) node traffic generated by the corresponding region accounts for all the traffic generated most of the (2/3).As a result, the logistics node analysis of the characteristics of the traffic is particularly important. Node important degree is a quantitative indicator that studies the transport network represented by the proposed distribution node transport capacity and has become the main basis that is used to measure the importance of the transportation hub in road planning.

NODE IMPORTANCE DEGREE CALCULATION

Modeling

Node important degree is an important index of relative degree that describes a node in the region and compares different functions of the strength of the relativity between nodes. It is a comprehensive measure of importance for every node in the area. In industrial areas of logistics planning, the choice of logistics distribution, warehousing centers for the consideration of the link nodes, and its importance

degree by the following formula:

$$D_i = \sum_{j=1}^{m} \omega_i \frac{P_{ij}}{\sum_{k=1}^{n} P_{kj}} \qquad (1)$$

Where: n = the number of nodes; m = the evaluation of the number of indicators; and P_{ij} = the i-node department j (j = 1,2, ..., m) index value.

Model

Although the Equation 1 is given all nodes importance degree of quantitative terms, it cannot reflect the limits of the division of nodes, which means that it cannot be given an important degree of range. In this system, analysis of the cluster ideas was used. According to the major index, summing all nodes into the required categories must be done in order to better determine the extent of the important nodes.

Suppose there are n samples: X_1, X_2... X_n, and each of the samples were found to have m characteristics or indicators. These indicators will be quantified (that is to use the digital representation of their targets), for each sample corresponding to a set of indicators for its characterization of a number of Y_1, Y_2... Y_m. This group represents the number of samples for m-value targets. It is clear that a different sample of the corresponding indicator is not the same as that used in this X_{ij}. The first i samples of the first j-value targets are not the same, so the targets of the n samples are shown in Table 1.

Table 1. Method of samples.

Sample	Index			
	index 1	index 2	…	index m
X_1	X_{11}	X_{12}	…	X_{1m}
X_2	X_{21}	X_{22}	…	X_{2m}
…	…	…	…	…
X_n	X_{n1}	X_{n2}	…	X_{nm}

We can see from Table 1, samples X_i can be lined up (X_{i1}, X_{i2}... X_{im},) and recorded for X_i = (X_{i1}, X_{i2}... X_{im}) from the broad use of standardized square Euclidean distance to reflect the close of the two samples between X_i and X_j, the formula becomes:

$$D_k = | X_i - X_j | = \sum \frac{(X_{ik} - X_{jk})^2}{S_k^2} \qquad (2)$$

Where: K = 1, 2... m; D_k for between two points the generalized distance; and S_k for the X variable variance.

This comprehensive reflection of the distance between the two samples of the different indicators of size, the smaller of $| X_i - X_j |$ the smaller differences and closer in the two samples and can be grouped into the same otherwise the greater of $| X_i - X_j |$, that is the larger different samples, and not in the same category. The specific approach is as follows.

Step 1: calculate the distance between the sample $|X_i–X_j|$ and seek min ($|X_i–X_j|$)

Step 2: make the samples with min ($|X_i–X_j|$) characteristics in the same category and form a new sample and make the assignment. Samples of the new indicators represent the value of the average of all the corresponding samples.

Step 3: repeat steps 1 and 2 above and place all the samples into a category.

Following the above classification process,Figure 1 shows:

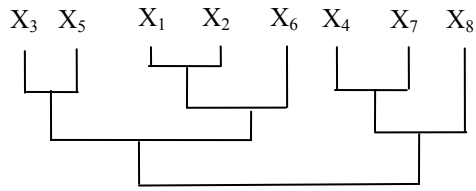

Figure 1. Clustering logistics node hierarchy.

The cluster analysis is to better partition node types, determine the different levels of the main line, and carry out the layout of the road network well. On the basis of cluster analysis principles and methods calculating all nodes importance degree of group cities node, the node can generally be divided into three categories: the firstly important node, the secondly nodes and the generally nodes.

NODE IMPORTANCE DEGREE ANALYSIS

The logistics node function is closely related to the material flow and personnel flow. As a result, material and human traffic flow are the important indexes of decision logistics nodes importance degree. At the same time, relevant economic indicators directly impact important nodes, such as the evaluation of the economic efficiency of enterprises in selected logistics park business profits tax. Usually calculated the node important degrees use the Analytic Hierarchy Process (AHP). AHP has been widely applied in many fields. This paper mainly relates using the methods to analyze the importance node process. Specific theories can be found in the reference section.

Indicators Weight

Determining the index weight is a clear indicator influencing the degree of the target level. The extent of the impact of the target layer is often based on experience and the weight of certain subjectivity. The Analytic Hierarchy Process makes the rules of the quantitative process to reduce the weight determined by the subject and to improve accuracy.

To establish the hierarchy model. The hierarchy model is the result of the analysis of the study and makes all factors at division different levels, such as the target layer, indicators layer, and programs layer and so on. Using the diagram shows the form of note-level hierarchical structure and factors of affiliation.

The chart below is the location of logistics nodes analysis hierarchy model. .

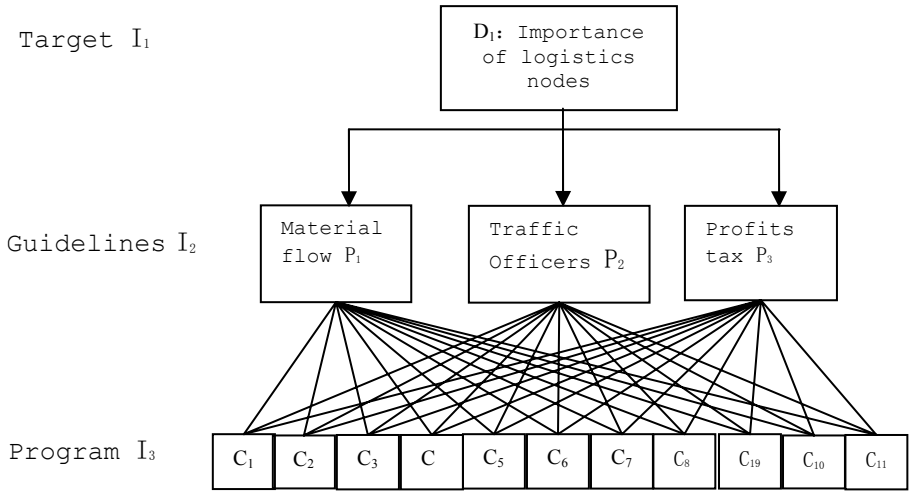

Figure 2. Logistics node location hierarchy.

Node important degree evaluation indicators

According to the AHP, create the target level (logistics nodes important degrees) and indicators layer (materials flow, personnel flow, profits tax) that impact on the important node concrete structure shown in Table 2.

Table 2. Nodes important undicator of its analysis of weight.

Target layer I_1	Indicators layer I_2	I_2 to I_1 weight ω_i
Importance of logistics nodes D_i	Material flow P_1	0.65
	Traffic officers P_2	0.13
	Profits tax P_3	0.22

Node important degree calculations

Access to the index weight, and calculate the logistics node i (i = 1, 2,…, n) index major D_i. According to the State has approved Caofeidian harbor planning documents and related materials summarized Caofeidian the logistics center of the relevant data show in Table 3.

Based on the above data, calculate the importance of the logistics nodes. Importance of coal distribution centers, D_1 , is：

$$D_1 = 0.65\times\frac{6280}{4279.245}+0.13\times\frac{0.07}{1.25}+0.22\times\frac{0.314}{4.495}=0.97$$

By the same token, power plant $D_2 = 0.215$, cement plant $D_3 = 1.754$, iron and steel industrial base $D_4 = 4.37$, cement logistics center $D_5 = 0.121$, railway station $D_6 = 2.061$, building materials plant $D_7 = 0.104$, ore logistics center $D_8 = 1.907$, steel logistics center $D_9 = 0.635$, steel wharf $D_{10} = 0.256$, and plastic logistics center $D_{11} = 0.031$.

Table 3. Caofeidian data summary.

Serial number	**Logistics node name**	**In total material handling / 10,000**	**The number of district /**	**Tax**

		tons	thousand	profits / billion
1	Coal logistics center	6280	0.7	0.314

11	Plastic logistics center	135	0.04	0.128

Table 4. Node importance.

Serial number	Logistics node name	Important node index	Importance ranking
1	Coal logistics center	0.088	4
2	Power plant	0.019	8
3	Cement plant	0.028	6
4	Iron and steel industrial base	0.398	1
5	Cement logistics center	0.011	9
6	Railway station	0.188	2
7	Building materials Plant	0.007	10
8	Ore logistics center	0.174	3
9	Steel logistics center	0.058	5
10	Steel wharf	0.024	7
11	Plastic logistics center	0.003	11

Table 5. Node importance.

Important node	Logistics node name	Iron and steel industrial base	Railway station	Ore logistics center	
	Importance	0.398	0.188	0.174	
Major node	Logistics node name	Coal logistics center	Steel logistics center	Cement plant	Steel wharf
	Importance	0.088	0.058	0.028	0.024
General node	Logistics node name	Power plant	Cement logistics center	Building Materials Plant	Plastic logistics center
	Importance	0.019	0.011	0.007	0.003

Table 4 and Table 5 show all nodes important degree, but the Caofeidian iron and steel Industrial Zone logistics center construction sequence program is not in accordance with the node important degree or the planning of a logistics center size to building. It's based on node important degree, considered Caofeidian Industrial Zone of development direction in the future and the cycle of economic models and other factors to sort. It can reflect the Caofeidian Industrial Zone Logistics Center construction and Industrial Zone circular economy is consistent patterns.

CONCLUSION

The evaluation index system of logistics node is complex and effective solutions are not yet presented because of the lack of the standards of a logistics market in China. In this paper, the AHP is applied to calculate the relative weightings of the major factors and the important index of the nodes is calculated in terms of theory of transportation, where an authentic and operable solution is given to determine the index system and evaluate the logistics nodes.

ABSTRACT

International roughness index has become a well-recognized standard for measurement of pavement roughness in the world. In China, the current evaluation rules are such that the average value of IRI measured from road test sections is used to evaluate road quality. However this evaluation method is not proper in judging road quality in practical application. In this study, moment method is utilized to statistically analyze the IRI data distribution of expressway pavement. In Beijing city, 8 expressways of different road ages are selected as test samples, and then a time series of IRI data are employed .By statistical analysis, a comprehensive evaluation system, which is composed of 3 indictors such as the average of IRI, skewness coefficient and kurtosis coefficient is established. Practical application testified that the evaluation system can truly reflect expressway riding quality.

KEY WORDS

Expressway, Roughness evaluation, Riding quality, Moment method

1 INTRODUCTION

Pavement roughness as an important indicator to evaluate pavement serviceability directly reflects traffic comfortability and safety level (Zhang, 2005). International roughness index (IRI) is a standardized roughness indicator, which uses mathematical model to simulate quarter-car driving on test road section (M.W., 1986). The relative displacement between the sprung masses and un-sprung masses at 80Km/h caused by the dynamic suspension system is called IRI. IRI has two advantages: time stability and easy conversion between different test equipments, and then it has a wide use all around the world. According to the current specification: "highway performance assessment standards" (JTG H20 - 2007), expressway pavement riding quality is also assessed by average of IRI (AOI) in China. At present, an IRI value per 100m is defined as an evaluation unit, ultimately the arithmetic mean value of all units is calculated to judge road riding quality.

Table 1 shows two expressways' IRI test value in Beijing city (Cui, 2006). The evaluated section of A expressway is 45.6Km long and B expressway's assessed

section has a distance of 9.5 Km. A expressway had 456 IRI values and B expressway had 95 IRI values. The arithmetic means of the IRI of two expressways are calculated separately and the results are 0.78m/Km for A expressway and 2.24 m / Km for B expressway. According to specification JTG H20 - 2007, when expressway's IRI is less than 2.3 m/Km in Ride Quality Index (called RQI) of roads is defined as excellent. Therefore, it can be seen that two expressways' RQI are both excellent. Careful analysis of Table 1 finds out that all the IRI sample values of A road are less than 2.3 m/Km, that is, all samples can meet the criteria. The number of units of B highway with AOI greater than 2.3 m/Km is 30, which account for 31.6 percent of all assessed units. It means that only 68.4 percent of the units should be excellent. Clearly, there is a significant careless omission in the present evaluation indictor AOI, which can't accurately reflect the actual riding quality of expressway.

Table 1. Test result and evaluation of IRI of expressway.

IRI (m/Km)		0.7	0.9	1.1	1.3	1.5	1.7	1.9	2.1	2.3	2.5	2.7	2.9	3.1	3.3	3.5	3.7	3.9	4.1
Nu.	A	282	166	6	2	0	0	0	0	0	0	0	0	0	0	0	0	0	0
	B	1	1	8	14	16	6	5	10	4	2	9	4	4	2	5	3	0	1
Tot.	A	456		Mean	A	0.78													
	B	67			B	2.24													

Note: 1. Nu. represents the number of samples per IRI zone.
2. Tot. represents the total number of samples.
3. Mean represents the IRI average of tested expressway.

2 METHODLOGIES

Moment method(*Wang,2008*) is one statistical methods ,and it is based on two important statistical indicators which are used to describe the numerical distribution of variable values, namely, skewness coefficient (SC) and kurtosis coefficient (KC). So the moment method is also named skewness and kurtosis test method.

SC and KC of random variable x respectively represent standardized variables x's third-order center moment and fourth-order center moment. When random variable x are subordinated to normal distribution， g_1(represent SC) and g_2 (represent KC) from the overall samples are:

$$g_1 = B_3 / B_2^{3/2} \quad , \quad g_2 = B_4 / B_2^2 \tag{1}$$

Among them, B_K (k = 2, 3, 4) represents k-order center moment of samples.

If random variable x obeys normal distribution, it can be certified when n is sufficiently large. The approximations are:

$$g_1 \sim N(0, \frac{6(n-2)}{(n+1)(n+3)}), \qquad g_2 \sim N(3-\frac{6}{n+1}, \frac{24n(n-2)(n-3)}{(n+1)^2(n+3)(n+5)})$$

Generally, SC reflects the degree and direction of single-peak distribution, and the distribution corresponding to $g_1 > 0$, $g_1 = 0$, $g_1 < 0$ is separately known as the normal-skewness, positive skewness and negative skewness.

KC reflects the kurtosis case of single-peak distribution, with $g_2 > 3$, $g_2 = 3$, $g_2 < 3$, the corresponding peak is called leptokurtosis, normal peak kurtosis and flat kurtosis respectively.

3 TEST CONDITIONS OF EXPRESSWAY

Eight expressways located in Beijing are selected as test samples for evaluating the riding quality. Table.2 shows the construction structure, design life, completion time and road age of 8 expressways. All 8 expressways have similar structure composed of semi-rigid base plus asphalt surface, belong to the same climate zone, and the traffic volume of them has an insignificant difference, so the samples data can approximately be used to analyze the IRI-age relationship. Data used in this study were collected in 2004, and then road age is calculated accordingly.

Table 2. Structure Conditions of Expressway.

Expressway Name	Pavement structure of expressway	Design Life (year)	Completion time (year)	Road ages (year)
1	asphalt chip surface 2cm Medium-grained asphalt concrete 4cm Bituminous macadam mixture 5cm Inorganic binder base36cm Lime stabilized soil 18cm	15	1990	14
2	Medium-grained asphalt concrete 3.5cm Coarse-grained asphalt concrete 4.5cm Bituminous macadam 7cm Lime and fly-ash stabilized gravel 40cm Lime stabilized gravel 20cm	15	1993	11

4 DATA ANALYSIS

4.1 IRI analysis of expressway with different ages.

Expressway test sections are selected randomly, and then IRI values are measured by laser road condition test equipment. Sampling frequency is one IRI value per 100 m. IRI distribution curves of test expressways are mapped as shown in Fig.1, in which abscissa value represents IRI, longitudinal coordinates represent frequency number. As can be seen from Fig.1, with the road ages increasing, the peak of the distribution curve gradually decreases, the AOI increases and the slope grow flatter.

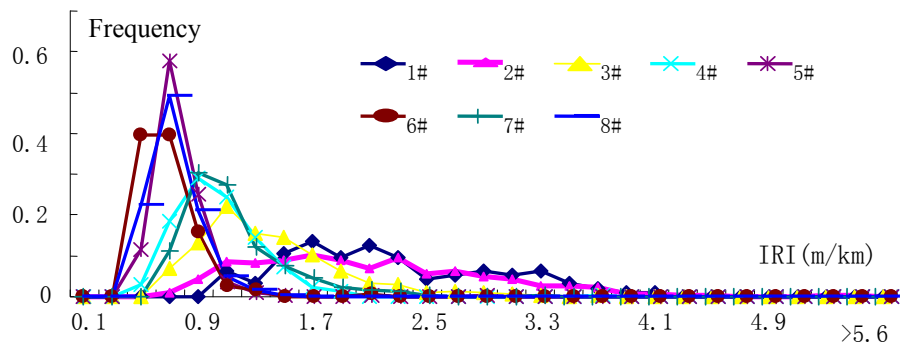

Figure 1. IRI distribution curve of different expressway

4.2 SC and KC analysis of expressway with different ages

Based on the theory of moment method , normality test of all the curves in Fig.1 is conducted, in which it is found that only IRI distribution of 1 # expressway was subordinated to normal distribution. SC and KC of each curve are calculated separately, and then the rules that SC and KC gradually decrease with the increase of road ages is found (see Figure 2 and Figure 3).

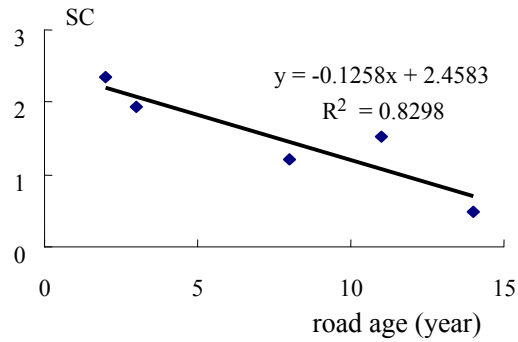

Figure 2 SC-age-related regression curve

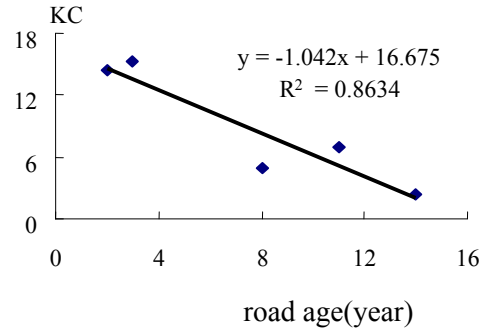

Figure 3 KC-age-related regression curve

Because expressway with road age of 2 years includes two roads and expressway with road age of 3 years does so, then the average of SC and KC is defined as SC and KC value corresponding to these two kinds of road age. When road age is one year old, SC and KC value are all larger than those of other road ages, which makes it impossible to establish a better correlation between different road ages. Taking into account the excellent practicality of one year road age expressway, SC and KC of one year road age are discarded. Data of SC and KC from five kinds of road age was mapped into scatter chart and made a straight-line fitting separately (see Figure.2 and Figure.3). The square of correlation coefficient between SC and road age is 0.8298, and it is 0.8634 between KC and road age.

4.3 Evaluation system establishment

According to these expressway s' IRI data, IRI decay curves varying with road age were given (Cui, 2006). Fig.4 shows the IRI-age-related regression curve of expressway with road age below 5 years. The IRI-age-related regression curve of expressway with road age above 5 years is shown in Fig.5.

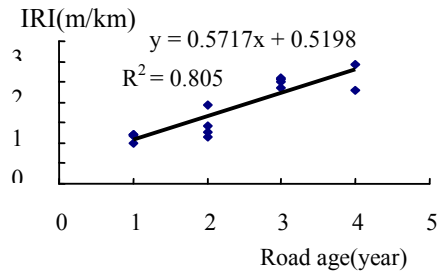

Figure4. IRI-younger road age regression curve

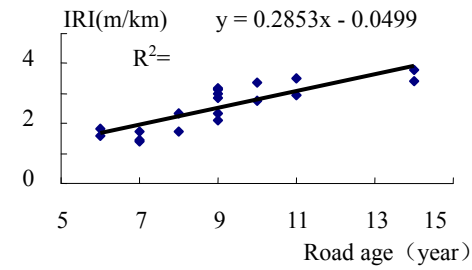

Figure5. IRI-older road age regression curve

In accordance with the RQI-IRI relationships ruled by " Highway Performance Assessment Standards" (JTG H20-2007), comparing IRI value of each grade to Fig. 4 and Fig.5 respectively, then the corresponding road age is obtained according with every RQI level (or IRI level)(see table 3).

Then according to the conclusions of Figure 2 and Figure 3, SC and KC value corresponding to road age obtained above can be found. Filling all the data in Table 3, and then a comprehensive evaluation system is established based on the AOI, SC and KC. i.e., when 3 indictors simultaneously meet the demand in Tab.3, the quality grade of RQI could be judged. When 3 indictors locate in three

different RQI Levels, the treatment should accord with the most adverse situation.

Table3. RQI – IRI – g_1 –g_2 corresponding relationship.

RQI(score)	90（excellent）	80（good）	70（medium）	60（bad）
IRI	2.3	3.5	4.3	5.0
Road age(year)	3.1	12.4	15.3	17.7
g_1 (SC)	2.07	0.90	0.53	0.23
g_2 (KC)	13.44	3.75	0.73	-1.77

5 PRACTICAL APPLICATIONS

Computing SC and KC of B expressway (shown as Table1.) based on moment method, the results are 0.49，2.40 respectively. From the above analysis, when AOI is less than 2.3m/km, RQI has a score larger than 90 points. But the road SC value falls into the scope between 70 ~ 60 scores, by interpolation method, RQI score is 68.7; then by KC's interpolation value, RQI score is 75.5. In accordance with the most disadvantaged rules, the riding quality score is 68.7 points, and this score can truly reflect riding quality of B expressway.

The calculation formula of g_1 and g_2 is attached as below:

$$A_1=\frac{1}{n}\sum_{i=1}^{n}x_i\ ;\qquad A_2=\frac{1}{n}\sum_{i=1}^{n}x_i^2\ ;\qquad A_3=\frac{1}{n}\sum_{i=1}^{n}x_i^3\ ;\qquad A_4=\frac{1}{n}\sum_{i=1}^{n}x_i^4\ ;$$

$$B_2=A_2-A_1^2\ ;\qquad B_3=A_3-3A_2A_1+2A_1^3;\qquad B_4=A_4-4A_3A_1+6A_2A_1^2-3A_1^4;$$

$$g_1=\frac{B_3}{B_2^{3/2}},\qquad g_2=\frac{B_4}{B_2^2}$$

6 CONCLUSIONS

6.1 Findings

In this study, moment method theory is utilized to analyze IRI data. SC-age-related and KC-age-related regression curve were set up. Based the rule of current "Highway Performance Assessment Standard" (JTG H20-2007) and Cui Yaping's study conclusions, an evaluation system was established, which is composed of 3 indictors including mean IRI, SC and KC. When 3 indictors located in three different score region, the lowest value is suggested as RQI score by the most disadvantaged principle. Testified by practical application, the evaluation system has a better effect on evaluating RQI and can diminished the bad effect caused by the single indictor-AOI. The evaluation system is practical in use and is very useful in the maintenance and management of expressway.

6.2 Future

This study is based on statistic principle, so the sample data should further

increase in order to obtain more accurate result. In data acquisition, the tested IRI's error caused by irregular maintenance should be avoided. RQI evaluation system should be separately set up corresponding to road grade and climate region, because asphalt pavement performance is greatly affected by materials, construction techniques, climatic factors and traffic volume etc.

ABSTRACT

At present, competition among domestic logistic enterprises is fierce. If they want to endure and become more advanced, they must calculate cost accurately and control cost effectively. Based on the management characteristics of logistic enterprises, this paper brings the Activity-Based Cost (ABC) into cost control practice in order to probe a new method to reinforce cost control and raise economic benefit in the logistic enterprises.

INTRODUCTION

Since the 1980s, enterprises' direct artificial cost has dropped and indirect expense has increases greatly. The information cost obtained by indirect expense assignment, based on sole quantity traditionally, has been serious distorted. Staubus (1971) and Cooper (1988, 1992) explained that ABC can not only provide more accurate cost information, but also has vital significance in cost control, budget management, new product design and development and more. The application domain of ABC has also expanded from the initial advanced manufacturing industry to commercial, financial, transportation enterprises, as well as the logistics industry. Since the 1990s, Yu (1995), and Wang (1999) have conducted extensive research on utilization theory and its practical application and significance and on prospects for the application of ABC. Jian's (2004) has done research on logistics enterprises activity cost calculation, but there is little research on cost control in logistics enterprises with the ABC method.

ASCERTAINING THE BEST DESIGNED ABILITY OF ACTIVITY OF LOGISTICS ENTERPRISE

Logistics enterprise designed ability of activity refers to the activity ability that enterprises design or the contract stipulates. The designed ability of activity cost is cost caused by the enterprise signing an agreement to buy resources in advance. We can summarize Its characteristics: Before satisfying the activity demand, the enterprise has obtained the activity ability, by the way of cost, either by payment or by pledging future payment by contract or agreement. The result is that, whether these activity abilities are used or not, the activity ability cost will surely occur. The designed ability of activity

cost is the sum of the surplus activity ability cost and already used activity ability cost. If the logistics enterprise is able to ascertain the designed ability of activity according to the future demand change of logistics activity, it may clearly understand and measure the surplus activity ability or the bottleneck activity ability. The enterprise's manager can make decisions scientifically at the right moment, change the designed ability of activity level in future periods, and thus control the ability of activity cost effectively.

Assuming we know the standard cost of each increment of value activity, this paper ascertains the best designed ability of activity for a logistics enterprise. The basic approach is: First, scientifically forecast the enterprise future logistics demand; next, ascertain the future activity demand according to logistics demand; then, ascertain the expectation cost of activity function according to the mutual existing relationship of activity and the cost; and, finally, in the situation of satisfying the logistics demand, extract the designed ability of activity with the smallest expectation cost of activity, namely the best designed ability of activity. The concrete method follows:

Supposing that the logistics enterprise has many kinds of activities $j = 1,2,\cdots,J$, provides many kinds of logistics service products $i = 1,2,\cdots,I$, faces uncertain demand market, and later observes an incomplete demand signal vector $\Psi = (\Psi_1, \Psi_2, \cdots, \Psi_i)$ (Ψ_1 is the demand signal of logistics service product of 1, Ψ_i is the demand signal of logistics service product of i) of each logistics service product. Suppose as well that the logistics enterprise has a designed ability of activity level of j is $\overline{Y}_j$, $\bar{x}_i(\Psi_i)$ is the anticipated demand for logistics service product i observed by the enterprise of demand signal Ψ_i, η_i is the random variable or the random error of uncertain market elements related to the anticipated demand, with the expectation value $E(\eta_i) = 0$, the variance of Ψ_i is $V_{ar}(\Psi_i) < \infty$. Then the enterprise actual service level $x_i(\Psi_i)$ is:

$$x_i(\Psi_i) = \bar{x}_i(\Psi_i) + \eta_i \qquad (1)$$

According to incomplete demand signal $\bar{x}_i(\Psi_i)$ that determines the best logistics service level $x_i^*(\Psi_i)$, as a result of the uncertainty of market and the influence of internal factors, the actual demand $x_i(\phi_i)$ may not be equal to the best logistics service level.

The consumption of activity demand is a linear model, supposing y'_{ij} represents activity demand j of providing i service product, then provides x_i unit service product actually consuming j activity demand $Y_{ij} = y'_{ij}x_i$, the actual activity demand $Y_j(\phi)$ of activity j that all services products consume is:

$$Y_j(\phi) = \sum_{i=1}^{1} y'_{ij}x_i(\phi_i) + \varepsilon_j \qquad (2)$$

In the formula, ε_j represents the correlative measuring error of activity

consumption linear function, supposing the random error ε_j and x_i with Ψ_i is independent and not related, then $\mathrm{E}(\varepsilon_j)=0$.

According to the principle of the ABC method, the cost of product consuming each activity is equal to product of the quantity of consumed resources and the price, that is the product of resources agent quantity and the resources agent rate. Each activity cost can be divided into the fixed part and the variable part. Thus, the activity cost function $ZC_j(\overline{\mathrm{Y}}_j, \mathrm{Y}_j)$ of activity j may be described as follows:

$$ZC_j = b_j \mathrm{Y}_j + \overline{d}_j \overline{\mathrm{Y}}_j + \theta_j \overline{d}_j \Delta \mathrm{Y}_j + \delta_j \quad (3)$$

In the formula: b_j expresses unit activity variable cost of activity j; $\overline{d}_j$ expresses designed ability of activity cost of activity j; $b_j\mathrm{Y}_j$ is the variable cost of activity j; $\overline{d}_j$ is the fixed cost of activity j; δ_j is the disturbance factor independent with Ψ_i ,and $\mathrm{E}(\delta_j)=0$; supposing θ_j is the exceeded activity cost coefficient of activity j, it is equal to the ratio of the resources price of the part that actual need activity ability surpasses the designed ability of activity ($\theta_j > 1$), $\theta_j \overline{d}_j$ indicates exceeded activity cost of the activity unit j; $\Delta \mathrm{Y}_j$ is the quantity that the demand surpasses the designed ability of activity, $\Delta \mathrm{Y}_j = \mathrm{Y}_j - \overline{\mathrm{Y}}_j$, （ $\mathrm{Y}_j > \overline{\mathrm{Y}}_j$ ）.

Make $\overline{\mathrm{Y}}$ and Y separately represent the designed activity ($\overline{\mathrm{Y}}_1 \sim \overline{\mathrm{Y}}_j$) and the vector of actual consumed activity ($\mathrm{Y}_1 \sim \mathrm{Y}_j$), after it observes the demand signal Ψ_i and before it realizes the actual demand, the enterprise needs to choose the level of designed activity resources $\overline{\mathrm{Y}}$. Considering the formula of (1), (2), (3), the relations of expectation activity cost the signal Ψ is like the formula (4) showing.

$$\mathrm{E}[ZC(\overline{\mathrm{Y}}, \mathrm{Y}(\Psi) \mid \Psi)] = \mathrm{E}[\sum_{j=1}^{J} ZC_j(\overline{\mathrm{Y}}_j, \mathrm{Y}_j(\Psi) \mid \Psi)] = \mathrm{E}[\sum_{j=1}^{J} (b_j \mathrm{Y}_j(\Psi) + \overline{d}_j \overline{\mathrm{Y}}_j + \theta_j \overline{d}_j \cdot \Delta \mathrm{Y}_j(\Psi) + \delta_j) \mid \Psi]$$
$$= \mathrm{E}[\sum_{j=1}^{J} (b_j \mathrm{Y}_j(\Psi) + \theta_j \overline{d}_j \Delta \mathrm{Y}_j(\Psi) \mid \Psi] + \sum_{j=1}^{J} \overline{d}_j \overline{\mathrm{Y}}_j \quad (4)$$

Insert formula (1) into formula (2):

$\mathrm{Y}_j(\Psi) = \sum_{i=1}^{\mathrm{I}} y'_{ij} \overline{x}_i(\Psi) + \sum_{i=1}^{\mathrm{I}} y'_{ij} \eta_i + \varepsilon_j$, supposing $\mathrm{Z}_j(\Psi) = \sum_{i=1}^{\mathrm{I}} y'_{ij} \overline{x}_i(\Psi)$ and $h_j = \sum_{i=1}^{\mathrm{I}} y'_{ij} \eta_i + \varepsilon_j$, then $\mathrm{Y}_j(\Psi) = \mathrm{Z}_j(\Psi) + h_j$, in the formula, $\mathrm{Z}_j(\Psi)$expresses anticipated demand $\overline{x}_i(\Psi)$ of service product i that corresponds to anticipated activity j, h_j expresses the probability density function set of the probability density function of η_i and ε_j , and $\mathrm{E}(h_j) = \mathrm{E}(h_j \mid \Psi) = 0$. Supposing $f(h_j)$ represents the boundary probability density function of h_j, $F(h_j)$ is the corresponding accumulation density function, because the distribution of h_j has nothing to do with Ψ (because η_i and ε_j is

independent with Ψ), therefore the formula (4) can be transfigured as follows:

$$\mathrm{E}[ZC(\overline{\mathrm{Y}}, \mathrm{Y}(\Psi) \mid \Psi)] = \sum_{j=1}^{J} [b_j \mathrm{Z}_j(\Psi) + \overline{d}_j \overline{\mathrm{Y}}_j + \theta_j \overline{d}_j \int_{\overline{\mathrm{Y}}_j - \mathrm{Z}_j}^{\infty} (\mathrm{Z}_j(\Psi) + h_j - \overline{\mathrm{Y}}_j) f(h_j) dh_j] \quad (5)$$

$$= \sum_{j=1}^{J} [b_j \mathrm{Z}_j(\Psi) + \overline{d}_j \overline{\mathrm{Y}}_j + \theta_j \overline{d}_j (\mathrm{Z}_j(\Psi) - \overline{\mathrm{Y}}_j) \int_{\overline{\mathrm{Y}}_j - \mathrm{Z}_j}^{\infty} f(h_j) dh_j + \theta_j \overline{d}_j \int_{\overline{\mathrm{Y}}_j - \mathrm{Z}_j}^{\infty} h_j f(h_j) dh_j$$

In order to get the best designed ability of activity level, suppose the first derivative of $\overline{\mathrm{Y}}_j$ is equal to 0, namely

$$\frac{\partial \mathrm{E}(ZC)}{\partial \overline{\mathrm{Y}}_j} = \overline{d}_j - \theta_j \overline{d}_j \int_{\overline{\mathrm{Y}}_j - \mathrm{Z}_j}^{\infty} f(h_j) dh_j = \overline{d}_j - \theta_j \overline{d}_j [1 - F(\overline{\mathrm{Y}}_j - \mathrm{Z}_j)] = 0 \quad (6)$$

We can get the best designed ability of activity level $\overline{\mathrm{Y}}_j^*(\Psi)$

$$\overline{\mathrm{Y}}_j^*(\Psi) = \mathrm{Z}_j(\Psi) + G_j = \sum_{i=1}^{1} y'_{ij} \overline{x}_i(\Psi) + G_j \quad (7)$$

In the formula, $G_j = F^{-1}(1 - 1/\theta_j)$ is the inverse function of the accumulation density function of h_j which has nothing to do with Ψ .

From the formula (7), the best designed ability of activity level is mainly determined by the demand of anticipated logistics service and the activity amount of each activity.

CASE ANALYSIS

A logistics enterprise provides three kinds of logistics service of 1, 2 and 3, their anticipated demand is 30000 pieces, 100000 pieces and 30000 pieces respectively. Each freight vehicle may install 1,000 pieces of $\overline{x}_1$, each freight vehicle may install 2,000 pieces of $\overline{x}_2$, and each freight vehicle may install 500 pieces of $\overline{x}_3$. In order to simplify the question, suppose an enterprise's actual demand and the anticipated demand are same, and it only determines four kinds of best designed ability of activity. The amount of activity and the existing ability of activities for three different activity levels are shown in Table1 as follows.

Table 1. The amount of activity and the existing ability of activities for different activities.

Level of Activity	Logistics service demand	$\overline{x}_1$	$\overline{x}_2$	$\overline{x}_3$
Unit level	Unit load and unload time (hour/vehicle)	1	1	2
	The most load and unload ability (hour)			260
	Product quantity of each value-added service (piece/ time)	1000	1000	500
Batch level	Preparing time of each value-added service d （hour/ time）	2	2	4
	Preparing ability of value-added service （hour）			500

	Product quantity of each distribution e （piece /set）	4000	4000	1000
	Distribution time of each batch c (time/batch)	5	8	12
	Distribution ability （time）			950
Product level	Information disposal time of each logistics service k （hour）	100	100	300
	Logistics information disposal ability （hour）			600

Calculating four kinds of activities according to the formula (7) and the above data, the best designed ability of activity is:

The best designed ability of activity in unit level activity loading and unloading

$$\overline{Y}_{\text{loading and unloading}}^{*} = \overline{x}_1 / 100 \times y'_{11} + \overline{x}_2 / 200 \times y'_{21} + \overline{x}_3 / 50 \times y'_{31} = 200 \ hours$$

The best designed ability of activity of preparing ability of value-added service and distribution in batch level

$$\overline{Y}_{\text{value-added}}^{*} = \overline{x}_1 \times y'_{12} + \overline{x}_2 \times y'_{22} + \overline{x}_3 \times y'_{32} = \overline{x}_1 \times d_1 / b_1 + \overline{x}_2 \times d_2 / b_2 + \overline{x}_3 \times d_3 / b_3$$

$$= 500 \ hours$$

$$\overline{Y}_{distribution}^{*} = \overline{x}_1 \times y'_{13} + \overline{x}_2 \times y'_{23} + \overline{x}_3 \times y'_{33} = \overline{x}_1 \times c_1 / e_1 + \overline{x}_2 \times c_2 / e_2 + \overline{x}_3 \times c_3 / e_3$$

$$= 1000 \ times$$

The best designed ability of activity of logistics information processing ability of activity in product level

$$\overline{Y}_{\text{logistics information processing}}^{*} = k_1 + k_2 + k_3 = 500 \ hours$$

According to the existing activity ability of the four kinds of activities in Table1, through further calculation one may get: This enterprise has 60-hour surplus abilities of loading and unloading activity. The logistics information processing activity also has a 100-hour surplus processing ability left. Value-added service preparation has no surplus ability. Distribution activity is insufficient, and still lacks fifty times distribution.

CONCLUSION

The best designed ability of activity level $\overline{Y}_j^*$, obtained above of four kinds of activities, will be the theoretical basis of management making future correct decisions for the logistics enterprise.

(1) When the existing activity ability $\overline{Y}_j > \overline{Y}_j^*$, the difference of $\overline{Y}_j$ and $\overline{Y}_j^*$ is the surplus activity ability, just like the handling operation and the logistics information processing activity in the example above. In the situation that business income is invariable, the enterprise may through a series of measures, like the reduction of unnecessary temporary workers, reducing the wage disbursement of temporary workers, selling or the hiring unnecessary equipment and property and so on, reduce extra

resources consumption or reduce surplus activity ability, increasing profit, or develop the new logistics service through resources shifting to fully use surplus activity ability to increase business income, thus enabling the enterprise to squeeze out profit from the use of activity ability.

(2) When $\overline{Y}_j < \overline{Y}_j^*$, the difference of $\overline{Y}_j$ and $\overline{Y}_j^*$ is the insufficient activity ability, like the distribution activity in the example above. In this situation, the enterprise needs to decide whether to expand its own designed ability of activity or to outsource to supplement the insufficient productivity. In the situation that it expands, the enterprise may consider the method of introducing new technology and so on, enhancing the activity efficiency, expanding the bottleneck activity productivity, to satisfy the enterprise's demand of this activity productivity. Because the bottleneck activity is an important economic influence in the enterprise, it has vital significance in determining what enterprise's bottleneck activity is for the continuous improving and increasing profit.

(3) When $\overline{Y}_j = \overline{Y}_j^*$ is the latent restrained activity ability, like the value-added service preparation activity in the example above, this kind of activity will transform into insufficient activity ability when the enterprise will fully use the surplus activity ability to develop new logistics service or the future logistics demand will expand further.

Therefore, it is the important to ascertain the activity with the greatest potential, as well as the latent restrained work in the process of continuous improving of the logistics enterprise, to enhance the activity efficiency and the ability to implement the activity cost management.

ABSTRACT

Since the influence of a moving bottleneck varies with time and space, a climbing lane is proposed to alleviate it based on the effect law of trucks. The north section of Beijing-Zhuhai Freeway in Guangdong Province of China is selected as the experiment site. A Corsim model in TSIS which has been calibrated is used, and a cost-effectiveness graph is chosen to analyze the investment effect under conditions of different volumes and percentages of trucks.

INTRODUCTION

With an increase in volume, freeway level of service (LOS) decreases rapidly. As far as the causes are concerned, only a few freeways achieve capacity. On most of China's freeways, there are many overloaded and overrun vehicles with poor performances mixed with other high-speed vehicles in freeways. This leads to a great number of "moving bottlenecks" (Gazis and Herman, 1992) on the freeways. Different from a fixed physical bottleneck, a moving bottleneck causes widespread problems. How to choose a reasonable method to relieve the effect of a "moving bottleneck" on freeways has become a top priority in China's traffic system. Based on an investigation and analysis of the law of "moving bottleneck" in trucks, a climbing lane is proposed by selecting the north section of Beijing-Zhuhai Freeway as test section. A simulation confirms the calibrated and validated model.

DEVELOPMENT OF MOVING BOTTLENECKS

Gazis and Herman (1992) noticed that some heavy trucks cause several or even a large number of cars to decelerate and follow. This creates a clustered fleet in low speed contradicting normal freeway traffic flow. They developed the concept "Moving Bottleneck" to describe this phenomenon. When a truck moves on a multi-lane freeway, it often causes the cars behind to queue. This is not an actual obstacle on the lane, but rather it happens when the flow behind the trucks accumulates a certain amount because of speed differences.

Later, moving obstructions were introduced into the kinematic wave theory of Lighthill and Whitham (1955) and Richards (1956). This lead to a complete theory of moving bottlenecks (Newell, 1998). Additional work was done on moving bottleneck parameter investigation (Munoz, 2002) and the discretization method (Daganzo, 2002,

among others. However, relevant research is just beginning in China.

THE INFLUENCE OF TRUCKS

Investigation was done on the Xiaotang-Gantang section. A rader gun was used to collect speed data, and the data from the freeway monitoring system was applied. Table 1 and Table 2 indicate the data.

Table 1. Volume and Percentage of Trucks on Xiaotang -Gantang Section.

Detector number	Stake number	2006.12.25				2006.12.26			
		Volume(veh/h)		% of trucks		volume (veh/h)		% of trucks

Table 2. S peed on Xiaotang -Gantang Section.

Stake number	Direction	Grade (%)	Speed of each vehicle type（km/h）			
			car	Medium truck	Large truck	coach
K29+700	N	-1	107	67	63	97
K43+250	N	2	76	38	29	65
K31+300	S	2	77	37	34	64
K37+000	S	5	72	31	24	57
K38+900	S	4	75	30	24	54
K44+700	S	-3	99	62	56	91

Notes: 1. The survey time is 2007.4.23-28. The percentage of trucks and the flow are obtained by detectors, the speed is measured by Rader gun.

2. The upgrade sections are all sustained upgrades.

As can be seen from Table 1, the two-way average daily traffic is not so large, ranging from 200veh/h to 400veh/h, and belongs to LOS 1. But the percentage of trucks is relative high, mostly exceeding 40%. Table 2 also shows that the speed of cars slows down under the condition of low volumes, and the phenomenon becomes more obvious on the upgrade section. It occurs mainly because of the speed reduction of trucks on the upgrade section and the intensified influence the moving bottleneck has enforced. Meanwhile, the data reflect the present situation of Chinese freeways: the flow is not large, but the percentage of trucks is high, and the delay of other vehicles is relatively large as well (Lin Hangfei, 2007).

The entry of heavy vehicles such as trucks into the traffic stream affects the number of vehicles that can be served. Heavy vehicles have poorer operating capabilities than passenger cars, particularly with respect to acceleration, deceleration, and the ability to maintain speed on upgrades. The inability of heavy vehicles to keep pace with passenger cars in many situations creates large gaps in the traffic stream, which are difficult to fill by passing maneuvers. The resulting inefficiencies in the use of roadway space cannot be completely overcome (HCM2000) and leads to the increasing delay of passenger cars, thus forming a moving bottleneck.

CLIMBING LANE

The paper proposes to establish a climbing lane for heavy trucks in order to reduce the influence of moving bottlenecks. When the flow increases in the future, other parts can be extended into three lanes in each direction. According to the "Design Specification for Highway Alignment", when the running speed of a loaded truck which moves along the sustained upgrades is slowed down to the minimal allowable speed as shown in Table 3, it is better to establish climbing lanes on the right side of the driving lane. It is obvious that all the speeds in Tabel 2 are lower than the minimal allowable one, and that meets the requirement.

Table 3. The Minimum Allowable Speed on the Upgr ade Section.

Design speed（km/h）	120	100	80	60	40
The minimum allowable speed（km/h）	60	55	50	40	25

APPLICATION OF MICROSCOPIC SIMULATION

The Xiaotang-Gantang segment (K28+000~K48+000) of Beijing-Zhuhai Freeway in the north of Guangdong Province with sustained upgrades and complicated terrain is selected as the section for research. Microscopic Simulation Software TSIS was used to verify the effectiveness of climbing lanes.

Calibration of CORSIM model. In the CORSIM model, parameter calibration is divided into known parameter calibration and unknown parameter calibration.

First, we analyze the model parameters and calibrate known parameters according to the data from the survey, and then find the sensitive parameters by adjusting unknown parameters. Based on Tables 1 and 2, the evaluating indexes of volume and mean speed will be tested until the model is calibrated successfully.

1. Known parameters: From the road design materials and traffic investigation, we can obtain road geometric parameters and traffic composition. In China, there are many types of vehicles, quite different from their counterparts abroad in terms of classification criteria. Therefore, it is significant to calibrate vehicle types. The paper divides vehicles into four types, i.e. passenger car, coach, medium truck, and large truck. For the purpose of matching the actual vehicle situation (trucks are featured by low capability and overloading in China) with the vehicle types in TSIS, the parameters of simulated vehicles (such as geometrical features, dynamic performance, etc.) must be adjusted,

especially the performance index of acceleration which directly reflects different climbing performances.

2. Unknown parameters should be adjusted constantly according to the actual traffic situations. Upon sensitive analysis, cars following the sensitivity multiplier in the car-following model, advantage threshold for discretionary lane change in lane changing model, and free-flow speed multiplier are highly sensitive parameters.

Roadway Conditions. 1. Scheme 1: The basic section of two-lane freeway in each direction K28+000 ~K48+000, with a total length of 20 km. This scheme is to simulate existing roads. 2. Scheme 2: Three-lane freeway in each direction K28+000~K48+000 extended from two lanes, with a total length of 20 km. 3. Scheme 3: Setting climbing lanes. Based on the vehicle operating situation, several climbing lanes were set at the northbound and southbound directions.

Traffic Conditions. To verify the effectiveness of climbing lanes, volume is divided into four grades: 500, 1000, 1500, 2000 veh/h (those over 2000veh/h will not be discussed here, for they have exceeded the capacity of this section), and the percentage of trucks selected is 30%, 40%, 50%, and 60%. With a 95% confidence level and a 5% allowable error range, after running ten times, the effectiveness of setting the climbing lanes is verified in terms of different flows and percentages of trucks.

Selection of Index. The influence of trucks is multi-dimensional, such as speed reduction, increased delay, density changes and so on. Speed is not significantly affected by volume over a wide range of demand (HCM2000). If speed does not vary with flow rate over a broad range of flows, it becomes difficult to use speed as the sole measure. This important characteristic is the major reason why such measures as density have been introduced as primary measures of effectiveness, with travel time playing a secondary role.

ANALYSIS OF RESULTS

According to the simulation model calibration and the condition settings above, travel time (min/veh), density(pcu/km/ln) and LOS with different road conditions and percentage of trucks are gained after the simulation experiments (see Tables 4, 5, 6)

Table 4. MOEs of Scheme 1.

% of trucks	Volume（veh/h）											
	500			1000			1500			2000		
	TT	D	LOS	TT	D	LOS	TT	D	LOS	TT	D	LOS
30	19.3	6	1	21.6	12	2	23.1	18	2	25.1	25	3
40	19.7	6	1	22.4	12	2	23.6	19	3	26.5	25	3
50	20.3	6	1	22.8	13	2	24.0	19	3	27.6	26	4
60	21.2	6	1	23.0	13	2	24.1	19	3	27.9	26	4

Table 5. MO Es of Scheme 2.

% of trucks	Volume（veh/h）											
	500			1000			1500			2000		
	TT	D	LOS	TT	D	LOS	TT	D	LOS	TT	D	LOS
30	15.7	4	1	18.6	7	1	20.0	11	2	21.7	15	2
40	16.8	4	1	19.5	8	2	21.3	11	2	22.4	16	2
50	17.7	4	1	20.6	8	2	21.9	12	2	23.0	16	2
60	18.6	4	1	21.1	8	2	22.5	12	2	23.4	16	2

Table 6. MOEs of Scheme 3.

% of trucks	Volume（veh/h）											
	500			1000			1500			2000		
	TT	D	LOS	TT	D	LOS	TT	D	LOS	TT	D	LOS
30	16.3	5	1	19.5	10	2	22.4	16	2	27.0	21	3
40	17.6	5	1	20.7	10	2	23.6	16	2	28.6	21	3
50	18.5	5	1	21.5	10	2	24.5	16	2	29.7	21	3
60	19.1	5	1	22.1	10	2	25.4	16	2	30.9	20	3

It can be observed that the road conditions in Scheme 2 and Scheme 3 are obviously improved, compared with Scheme 1. For instance, the density gets smaller and the travel time becomes shorter at varied levels. Scheme 3 still keeps its LOS even after the flow has increased to 1500 veh/h and reduces the influence of moving bottlenecks effectively on the freeway.

However, the investment varies from different schemes. Whether to choose Scheme 2 or Scheme 3 is up to decision-makers after the two schemes are compared in terms of investment benefits. A cost-effective graph is used in this paper (HCM2000). According to the associated cost, the travel time of different schemes is shown as Figure 1. I represents scheme 1, II and III are extension schemes, respectively representing schemes 2 and 3. The solid lines indicate the relative cost effectiveness of moving from I to II or I to III. The slope of the line between the schemes represents the travel time saved per dollar of cost. The steeper the slope, the better the effectiveness.

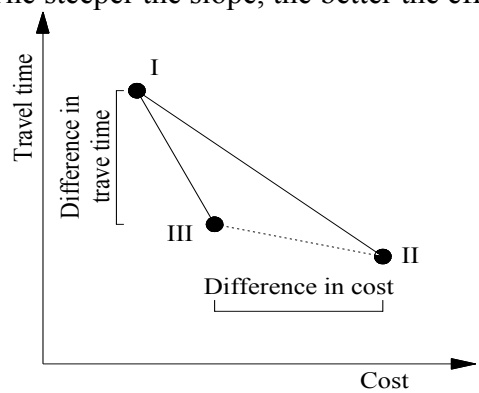

Figure 1. Example of a Cost -Effectiveness Graph.

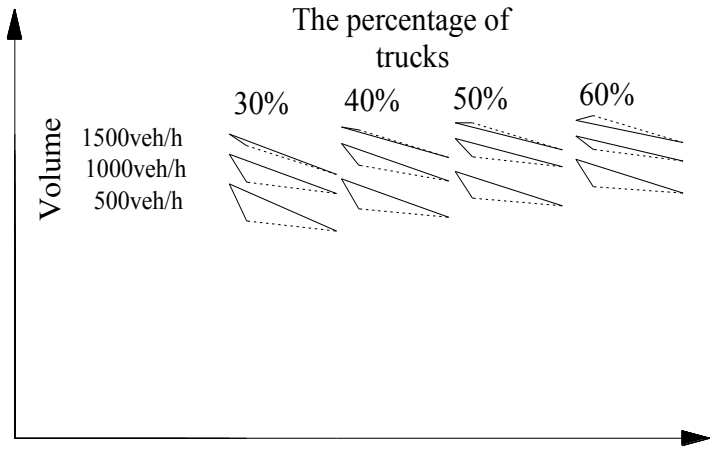

Figure 2. Cost -Effectiveness Graph with Schemes.

From Figure 2, conclusions are drawn as follows:

1. The cost-effectiveness ratios of Scheme 2 and Scheme 3 are various with different flows and percentage of trucks, so reasonable schemes according to different traffic conditions should be selected in the formulation of the extension scheme.

2. When the percentage of trucks is 30% or 40%, the slope of Scheme 3 is bigger, and the cost-effectiveness of setting climbing lanes is obviously better.

3. When the percentage of trucks reaches 50% or 60% and the volume is below 1500 veh/h, the slope of Scheme 3 remains comparatively bigger, so the effect of setting climbing lanes is still notable. However, when the flow is above 1500 veh/h, Scheme 2 has a bigger slope, and then it will be time to consider the extension of the road into six lanes.

Analyzing the cost-effectiveness graph, it is proposed that the setting of climbing lanes can effectively shorten travel time within a certain range of flows and percentage of trucks. It is feasible for the small volume and high percentage of trucks on freeways in China. This method costs less and produces more investment benefits and, thus, it can be carried out during the initial period of freeway reconstruction and extension.

CONCLUSION

The current traffic of most two-lane freeways in each direction in China has not reached the capacity yet, but the percentage of trucks is relatively high. After setting climbing lanes on the sustained upgrades, the travel time and delay can evidently be reduced. In addition, its investment cost is lower than that of extending it into a six-lane, and its adaptability is good as well. Nevertheless, the climbing lane can not be applied for all situations. For example, when the volume and the percentage of trucks are high, the fixed bottleneck and insecurity factors might appear at the merge segment. Then an extension to six-lane freeways should be considered.

ABSTRACT

The non–uniform bus timetable is presented, and then the optimization model is formulated. The Genetic Algorithm (GA) and Taboo Search (TS) algorithm are analyzed and combined to become hybrid Genetic Algorithms, namely GATS. The GATS is used to solve the bus timetable model and the non–uniform bus timetable is obtained. The final results of the simulation indicate GATS has higher efficiency than simple GA and is one effective way to solve the bus timetable. Simultaneously, it is proved that the non–uniform bus timetable can reduce the passengers' waiting time and meet the passengers' need and also could improve agency efficiency.

INTRODUCTION

The bus operation and dispatching plan is the core basic content of the public transportation system. The bus timetable is one of the most important steps in the bus planning process (Wang, 2001). A better bus operation plan can improve a city's traffic environment, resident travel status and agency services and products.

The bus timetable problem is a typical multi-objective optimization problem. It also is a None-determinist Polynomial time hard problem, because it must take into account the passengers' waiting time and the bus agency's benefit. Many researchers have formulated the bus timetable by analyzing the bus dispatching process and computed it by traditional methods and Genetic Algorithm (Hurdle, 1973; Chakroborty, 1995; Zhang, 2003). Traditional methods have difficulty with the problem, because of increscent dimensions and computing complexity. The Genetic algorithm also has difficulty reaching the optimal solution, because of slow evolving and early convergence. Much research on the bus timetable utilizes a uniform time interval in the time period. This ignores the difference of passenger numbers and so it can not better meet the needs of passengers and the agency. In addition, with the application of the intelligent transportation system's advanced technologies, it is now feasible and convenient for the bus to be dispatched on a none-uniform timetable. Based on above analysis, the GA and Taboo Search are combined to become Hybrid Genetic Algorithms, namely GATS, which can overcome the shortcomings of GA. Simultaneously the none-uniform bus timetable in the time period is computed.

BUS TIMETABLE OPTIMIZATION MODEL

The bus timetable is related to the passengers' waiting time and the bus agency's

benefit. So the passenger waiting time and the cost for the bus agency are computed, and then the bus timetable model is formulated. Its objective is to minimize the passengers' waiting time and the bus agency's operating cost.

Cost for the passenger . The cost for passenger relates to the passenger waiting time at station, and this is the sum of all passengers' waiting time at every station. If the arrival rate of passenger at station k is $P_{ak}(t)$, then the formula of the passengers' waiting time at all stations in the day as follows:

$$T_{pw} = \sum_{k}\sum_{m}\int_{t_{ak,m-1}}^{t_{ak,m}} P_{ak}(t)\times(t_{ak,m}-t)dt \qquad (1)$$

Where k is the index of station, m is the index of bus, $P_{ak}(t)$ is arrival rate of passenger at station k, and $t_{ak,m}$ is the time of bus m arrival at station k.

Based on the Eq.1, we obtain the passenger cost as the formula:

$$E_{pw} = r_{pw} * T_{pw} = r_{pw}\sum_{k}\sum_{m}\int_{t_{ak,m-1}}^{t_{ak,m}} P_{ak}(t)\times(t_{ak,m}-t)dt \qquad (2)$$

Where r_{pw} is the value of passenger waiting time (yuan per minute).

Cost for the a gency. The cost for the agency consists of the fixed and variable fare. The fixed fare comes from the depot and bus line building, and so on. The variable fare mainly includes the fare of vehicle parts, oil fee and depreciation charge (Wang, 2001). The bus timetable problem relates to the variable fare, so if we can compute the variable cost for the bus running the whole route once, the cost for the agency can be computed as the formula:

$$E_a = r_a \times N \qquad (3)$$

Where r_a is the variable cost for the bus running the route once (yuan per bus), N is the bus number of the whole operation time.

The optimization model . Based on the Eq.1, Eq.2 and Eq.3, we can compute the total cost of the day for the agency and passenger, so the objective function is expressed as follows:

$$\text{Min} \quad r_{pw}\sum_{k}\sum_{m}\int_{t_{ak,m-1}}^{t_{ak,m}} P_{ak}(t)\times(t_{ak,m}-t)dt + r_a N \qquad (4)$$

Subject to: $t_{ak,m} - t_{ak,m-1} \leq h^{max}$

$t_{ak,m} - t_{ak,m-1} \geq h^{min}$

Where h^{max} is the maximal headway, h^{min} is the minimal headway.

THE HYBRID GENETIC TABOO SEARCH ALGORITHM

Genetic Algorithm . GA was first put forward by Holland in 1975 (Holland.,1992). It is a biologically inspired method for function optimization that is loosely based on the theory of evolution. GA starts from a population of pairs, with

their coded attributes and their fitness, and then selection, crossover and mutation will result in the next generation population. Lastly, the population converges to the global optimum or proximately optimum.

GA can simultaneously explore many points in the search space and does not require problem specific auxiliary knowledge. Also, it has proved to be robust in the selection of optimization parameters and noise. It is not necessary to give specific rules for parameter settings and the number of mutation and crossover operators can be selected freely. However, GA's shortcomings are that it evolves slowly and converges early.

Taboo Search Algorithm . Taboo Search was developed by Glover (1986). Taboo Search is an expanding local neighborhood search, an iterative optimization procedure, and a simulation for human intelligent activity It is also a newer heuristic optimization algorithm.

TS searches the solution space by flexible memory system and aspiration criteria, and the best solution in the neighborhood is always selected, even if it is worse than the current solution. So TS has the stronger ability of "hill climbing", and can escape from the local optima, then finds the global optima solution. However, it relies on the initial solution excessively and its search process is from one solution to another, so it reduces the probabilities of finding global solution.

Genetic Algorithm Taboo Search . To overcome GA's evolving slowly and convergence earliness, one solving method is to combine GA with another artificial intelligent search method to become hybrid genetic algorithms (Wang, 2001). A TS algorithm has the characteristic of short memory and can escape the local optima. In this paper we bring TS into GA and combine them to become Hybrid Genetic Algorithm, namely GATS (Genetic algorithm taboo search). In GATS, GA is the whole frame, while TS is adopted to explore the local space to generate new and better population. The major steps of the GATS algorithms are as follows:

(1) Determine the parameters, such as population size, crossover probability, mutation probability, and so on.

(2) Initialize population by randomly generating a set of feasible solutions.

(3) Compute the fitness value and employ selection operation to the population.

(4) Apply crossover and mutation operator to produce new population.

(5) Apply TS algorithm to the new population, improve the individuals' quality and generate newer population.

(6) If the stopping rule is met, then out put the optimal solution and terminate, others return to step (3).

SIMULATION AND DISCUSSION

This paper examines one route of some city and optimizes the route direction bus timetable. The route has thirteen stations, and the bus start and end time is known. The passenger arrival rate of every station during operating time is given, i.e.

Figure 1. We assume the bus departs the station on time. The optimization objective is to find the none-uniform timetable which minimizes the cost of the passenger and the bus agency.

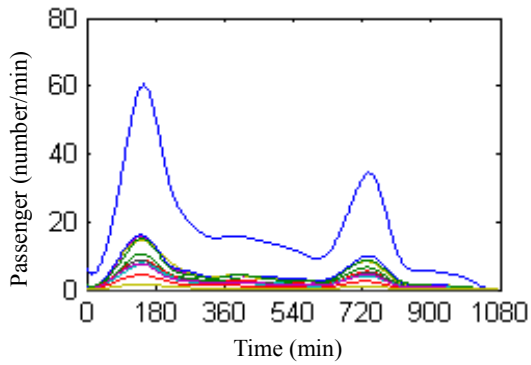

Figure 1. Passenger arrival rate at station.

Design GATS parameters . (1) Chromosome coding. The binary coding method is chosen and genes consist of zero and one. The size of the chromosome is the length of the bus dispatching time T, and it is sixty in this paper. The gene of the chromosome is corresponding to the minute in the time T, and also it represents the state of the bus, namely "1" presents bus depart at this time and "0" is others.

(2) Chromosome decoding. Find and record the position of "1" in the chromosome and compute the number of one state, so the bus timetable and the bus frequency can be determined.

(3) Fitness function. Fitness function can compute the good degree of every chromosome approaching optimal solution. Fitness value must be not negative generally, and the bus timetable optimization belongs to minimizing the objective problem, so the fitness function can be derived as follows:

$$F(X) = C_{max} - f(X)$$

Where $F(X)$ is fitness function, $f(x)$ is the objective value based on Eq.4 and C_{max} is the maximal objective value of the same population.

(4) Selection operation. A fitness proportional model is used in GA. The selection probability can be computed as follows:

$$G_i = f(X_i) / \sum_{i=1}^{n} f(X_i)$$

Where G_i is the probability of chromosome X_i, X_i is the i chromosome in the population, $f(X_i)$ is the fitness value of chromosome X_i, n is the population size.

At the same time a penalty operation is applied. When the bus operation term is not met, the individual fitness will be given a maximum. This will forbid the individual passing down.

(5) Crossover and mutation operation. Single point crossover and uniform mutation are selected in GA.

(6) Neighborhood structure. The TS algorithm is based on the neighborhood search and the neighborhood structure is very important in TS. The solution of bus scheduling is headway serial, which can be expressed in one point of multi-dimension space or solution space, and the space is made up of all points which meet the bus operation constraints. In the solution space the neighbor points of

every point combine the neighbor set.

Simulation and t he result analysis . The optimization model is set up based on the Eq. 4 in the one hour and the timetable is computed by applying the standard GA algorithm and hybrid GATS algorithm to the model respectively. In the GA and GATS algorithm the population size is 200, the crossover probability P_c is 0.85, mutation probability P_m is 0.005 and generation number is 200 after many test simulations. Moreover, the uniform timetable is computed by GA in order to compare with the non-uniform timetable.

Figure 2 compares the convergence process between GA and GATS. Table 1 is the results of a computed non-uniform timetable and uniform timetable by GA and GATS algorithms.

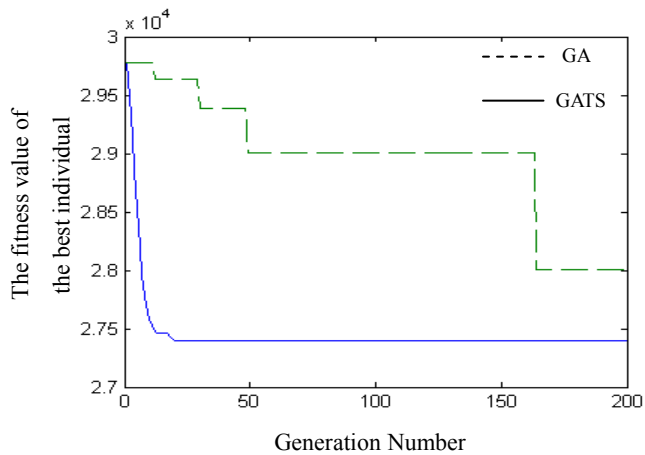

Figure 2. The convergence of G ATS and SA .

Table 1 . Results of different cases .

	Method	Bus number	Cost for Passenger (yuan)	Cost for agency (yuan)	The total cost (yuan)
Non-uniform Timetable	GATS	7	13393	14000	27393
	GA	8	12001	16000	28001
Uniform timetable	GA	7	13767	14000	27767

Figure 2 shows that the GATS algorithm converges earlier and gets the better solution than standard GA. This also shows that GATS overcomes the evolving slow and convergence earliness of GA. From Table 1 we see that GATS achieves the better timetable, the low cost of passenger and the agency. Standard GA gets the local solution of the timetable problem, so this is also confirmed with results in Figure 2. Furthermore, we see that the non-uniform timetable of GATS can make the passengers' waiting time short and can meet the passengers' need better than the uniform timetable from Table 1. Finally, the bus number is equal in the uniform and non-uniform timetable, but reducing the passengers' waiting time needs to reduce the bus depart time interval in the uniform timetable. This must result in an increasing number of buses and so wastes resources.

CONCLUSIONS

In this paper a model is formulated based on the benefits for the passenger and agency to research and solve the bus timetable problem. A Taboo search algorithm is merged into GA to develop a hybrid GATS which overcomes the bad local search capability of GA. Finally, GATS and GA are designed and applied to the bus timetable problem respectively. Results have proved GATS algorithms to be efficient tools for the development of an optimal bus timetable. Findings also indicate that the non-uniform timetable can better meet the needs of passengers and reduce the resource waste than can the uniform timetable.

ABSTRACT

The formation of a virtual intermodal freight-transportation enterprise and the determination of the core enterprise strategy is the primary solution for the cooperation and competition between freight-transportation enterprises. This paper seeks maximization of business income in the core freight business through analysis of the economic benefits of the core freight-transportation business with virtual intermodal freight-transportation enterprise, individually and cooperatively. The paper seeks to establish a gain matrix based on Game Theory. In sum, when the business income of cooperatively-constructed enterprise is higher than the individual one, two enterprises will choose to construct cooperatively. When two enterprises with the same characteristics are in different cities, the optimal strategy is cooperative construction. When other enterprises are unwilling to develop an intermodal transportation business, the core enterprise should seize the opportunity to establish the virtual intermodal freight-transportation enterprise individually. The results of a computational example show that every enterprise can use the conclusion to make useful decisions.

INTRODUCTION

With the establishment and improvement of a market economy and the rapid development of transportation in China, the development of an integrated transportation system has become a basic national policy. Zhang (2008) observes that the focus in the establishment of an integrated transportation system is to set up the chain of integrated multimodal transportation. Luo (2002) suggests that how to cope with relationships of cooperation and competition in different modes of transportation enterprise is becoming an important issue in transportation development. Zhang (2001) and Liu (2001) studied core enterprise partner choice in different enterprises. Others, using a fuzzy evaluation model, optimal technology and GIS space technology, examined the capacity and dispatch of combined transport in different enterprises. Xie (2004) and Chen (2005) identified two types of organization in cooperative-transport. Based on the work of Ye and Sun (2005) on the concepts and features of virtual enterprise, this paper solves the problem of cooperation and competition in different modes of transport enterprises through the construction of virtual intermodal freight-transportation enterprise. In the process of

the virtual enterprise, the core freight-transportation enterprise will have a wide range of choices. This paper sets up a gain matrix of core-transportation freight-transportation enterprises based on the game theory and discusses the decision of core freight-transportation enterprises with the purpose of maximization of benefits.

THE CONCEPT OF THE CORE FREIGHT -TRANSPORTATION ENTERPRISE

The core freight-transportation enterprise is the transport enterprises in the virtual intermodal freight-transportation enterprise with several functions, such as collecting information to identify market opportunities, confirming the core competitiveness and identifying risks, identifying and choosing partners, perfecting the comprehensive information infrastructure, establishing a leadership structure and supervising partner's operation. This enterprise has the capacity to collect information, recognize market opportunities, confirm their own core competitiveness and avoid risk, distinguish and select their partners, have an information infrastructure, and can establish the lead agency. In terms of technical features and business models of transportation, the core freight-transportation enterprise must have the ability to take the major transport trip, such as railway, waterway and air transport enterprises.

ANALYSIS OF THE EFFECTIVENESS IN CORE FREIGHT - TRANSPORTATION ENTERPRISE

In the intermodal transportation network, transport enterprises are separated in geo-spatial location. Each enterprise has a spatial superiority which is one of the basic conditions for them to cooperate with each other. Meanwhile, every enterprise has its own customer resources, include long-term and retail customers. There is no competition for customers between enterprises. So the core freight-transportation enterprise in the intermodal transportation network can make use of the other enterprise's resources to achieve mutual benefits and reduce the overall cost of the intermodal transportation system.

Set up the virtual intermodal freight -transportation enterprise individually

For enterprise A in city A, which sets up the virtual intermodal freight-transportation enterprise individually to deliver goods between city A and city B, enterprise A should associate with motor transport enterprises and ship cargoes to the warehouse of enterprise A. Then enterprise A must transport goods to city B and distribute them to customers in city B. When enterprise A transports goods from city A to city B, it should also do the same work. Through such an organization, enterprise A sets up a Virtual Intermodal Freight-Transportation Enterprise V_A, if the

transportation costs are C_A per unit, and the total Traffic is x_A. Then, enterprise B can do the same work, and the transportation costs are C_B per unit, and the total traffic is x_B. We assume that the coefficient of income distribution of enterprise A includes the business income from V_A is k_A, $0.5<k_A<1$. In the same way, the coefficient of enterprise B includes the business income from V_B is k_B, $0.5< k_B <1$. Then V_A and V_B provide the same transportation services between the two cities. Based on the demand function which is commonly used in the transport industry (Chen 2002), the inverse demand function of transportation services is $P = a - x_A - x_B$. Then the decision of V_A about this market is

$$\max\{\pi_A = (a - x_A - x_B)x_A - x_A C_A\} \quad . \qquad (1)$$

Derivative expression (1) we can obtain $x_A = (a - x_B - C_A)/2$. On the same principle, the decision of V_B about this market is

$$\max\{\pi_B = (a - x_A - x_B)x_B - x_B C_B\} . \qquad (2)$$

Derivative expression (2) we yield $x_B = (a - x_A - C_B)/2$. Then we can get the solutions $x_{A*} = (a - 2C_A + C_B)/3$ and $x_{B*} = (a - 2C_B + C_A)/3$. Then the business income of V_A and V_B are $\pi_A = (a - 2C_A + C_B)^2/9$ and $\pi_B = (a - 2C_B + C_A)^2/9$. So the business income of enterprise A and B are $m_A = k_A(a - 2C_A + C_B)^2/9$ and $m_B = k_B(a - 2C_B + C_A)^2/9$.

Cooperatively set up the virtual intermodal freight -transportation enterprise

If enterprise A and B cooperate and they set up a new virtual intermodal freight- transportation enterprise V_C, then the transportation costs are C_c per unit, and the total traffic is x_c. The inverse demand function of transportation services is $P = a' - x_C$ ($a' > a$). And the two core freight-transportation enterprises have the same status in V_C, Assuming the coefficients of enterprise A and B got in business income from V_C are equal, $k_C = k_{A*} = k_{B*} < 0.5$; and the decision of V_C about this market is

$$\max\{\pi_C = (a' - x_C)x_C - x_C C_C\} . \qquad (3)$$

Derivative expression (3) we have $x_C = (a' - C_C)/2$. Then the business income of V_C

is $\pi_C = (a' - C_C)^2/4$. So the business income enterprise A and B receive from V_C are $m_{A*} = m_{B*} = k_C(a' - C_C)^2/4$.

The game analysis of the cor e freight -transportation enterprises

In conclusion, there are two choices when a core freight-transportation enterprise wants to set up a virtual intermodal freight-transportation enterprise. That is to say, every enterprise will have two choices for this decision, 'cooperatively' or 'individually'. The core freight-transportation enterprise must decide which strategy is the better one and how to select the better one. Game theory can help enterprise management do this. The analysis above leads to the following table:

Tab le 1.The strategy about business income matrix of each enterprise A and B .

enterprise		core enterprise B	
	strategy	individually	cooperatively
core enterprise A	individually	(m_A, m_B)	(m_A, m_{B*})
	united	(m_{A*}, m_B)	(m_{A*}, m_{B*})

From the work of Nash (1997, 2007) and Gardner (2003), we know that there are two Nash equilibria, which are (individually, individually) and (cooperatively, cooperatively). When $m_{A*} > m_A$ and $m_{B*} > m_B$, the Nash equilibrium is (cooperatively, cooperatively). If $m_A > m_{A*}$ and $m_B > m_{B*}$, the Nash equilibrium is (individually, individually). Generally, if two enterprises in different cities cooperate, they will save the cost at opposite city where they want to establish an institution. They will reduce the no-load rate, so the costs are lower than they are individually. Namely: $C_C < C_A$, $C_C < C_B$. Then we will discuss the conditions of those two Nash equilibria.

1) When $m_{A*} > m_A$ and $m_{B*} > m_B$, namely

$$m_{A*} - m_A = \frac{k_C(a' - C_C)^2}{4} - \frac{k_A(a - 2C_A + C_B)^2}{9} > 0; \quad (4)$$

$$m_{B*} - m_B = \frac{k_C(a' - C_C)^2}{4} - \frac{k_B(a - 2C_B + C_A)^2}{9} > 0. \quad (5)$$

Only when expression (4) and (5) are satisfied simultaneously do enterprises A and B in different cities unite and set up a virtual intermodal freight-transportation enterprise V_C, deformation expression (4) and (5), namely

$$3(a' - C_C)\sqrt{k_C} > 2(a - 2C_A + C_B)\sqrt{k_A}, 3(a' - C_C)\sqrt{k_C} > 2(a - 2C_B + C_A)\sqrt{k_B}. \quad (6)$$

It can reach the following conclusions, if the costs of the transportation services are low enough, namely $C_A \to 0$, $C_B \to 0$ and $C_C \to 0$, and the limits of expression (6) are $k_C > 4k_A/9$ and $k_C > 4k_B/9$. In practice, the transportation costs cannot be zero, if the conditions $k_C < 4k_A/9$ and $k_C < 4k_B/9$ exist, organizing the enterprise together is

impossible.

2) If the transportation costs and profit distribution rate of two transport enterprises are equal, namely C_A=C_B and k_A=k_B. Then considering geospatial characteristics of the two cities, distribution partner enterprise of the two core transport enterprises are of the same quantity, assuming the profit distribution rate is unchanged. In this case, we can think that $k_C \approx \frac{1}{2} k_A$, $k_C \approx \frac{1}{2} k_B$. Let $C = C_A = C_B$, $k = k_A = k_B$, and we have $3(a' - C_C) > 2\sqrt{2}(a - C)$. In this expression, from C_C< C, we have a'- C_C >a -C, the expression is obviously hold. Then the only difference between the two transport enterprises is they are in different cities. Their optimal strategy is setting up a virtual intermodal freight-transportation enterprise cooperatively.

3) When only one core transport enterprise identifies the market opportunity, the other core transport enterprise does not know it and does not want to join in the alliance. Assumping it is enterprise A, the decision-making model of enterprise A is

$$\max\{\pi_{A*} = (a - x_A)x_A - x_A C_A\}. \quad (7)$$

Then the business income of V_A is $\pi_A = (a - C_A)^2/4$. So the business income of enterprise A can get from V_A is $m_A = k_A(a - C_A)^2/4$.

In this case, only one enterprise develops combined transport service, and the core enterprise can earn more profits than the preceding two modes. Moreover, this enterprise will have the dominant market position for the future.

CASE STUDY

For enterprise A in city A, enterprise A sets up V_A, and the transportation costs are C_A=20 YUAN/kg, and the total traffic is x_A. And for V_B , the transportation costs are C_B=20 YUAN/kg, and the total traffic is x_B, and k_A= k_B =0.7. The demand function is $P = 200 - x_A - x_B$. For V_C , the transportation costs are C_B=10 YUAN/kg, and k_C= 0.4, the demand function is $P = 400 - x_C$. The analysis above leads to the following table:

Tab le 2. The business income matrix of each enterprise A and B (YUAN) .

enterprise		core enterprise B	
	strategy	individually	cooperatively
core enterprise A	individually	（2,662，2,662）	（2,662，3,083）
	united	（3,083，2,662）	（3,083，3,083）

We can see from Table 2 that when the two core transportation enterprises construct the virtual intermodal freight-transportation enterprise cooperatively, they will earn 3,083 YUAN. This is more than they earn individually (2,662 YUAN). The results indicate that each enterprise can use the above conclusion to adopt a strategy

that will produce more business income.

CONCLUSIONS

We conclude from the market opportunities analysis in two cities the appropriate strategies for transport enterprises: When the two core transportation enterprises are iso-enterprises, the optimal solution is to cooperatively construct the virtual intermodal freight-transportation enterprise. When they both want to provide combined transport services, they will get more profit when they cooperate. When the other core transportation enterprise is unwilling to develop the intermodal transportation business, the core transportation enterprise should grab the chance to construct the virtual intermodal freight-transportation enterprise.

Optimization of Transportation Enterprises Pricing Strategies

Bailing. Wang[1] and Hui. Li[1]

[1]Transportation Management College, Dalian Maritime University, DaLian, 11602 China; PH/FAX (0411) 8472-6998; email: wanda_519@yahoo.com.cn

ABSTRACT

The market adaptability of the price mechanism of China's transportation is still relatively weak. Many of the effective regulatory mechanisms have not yet been established, so prices can not adapt to transport demand changes in the market. As a result, building a scientific and reasonable optimization model of the transportation pricing system is very important for the development of the industry. According to economic theory, transportation enterprises can get the highest profits from a pricing model consistent with the theory of price elasticity. A price discrimination strategy can help transportation enterprises establish the best price to keep high profit levels and competitive advantages in the transportation market.

INTRODUCTION

As is well known, price is a permanent problem faced by any enterprise. Both parties in a transaction are very sensitive to it. Transportation enterprises are not an exception. The profitability and competitiveness of an enterprise are relative to transportation price to a great extent. In addition, the products of transportation enterprises have their own special properties. That is to say, production and sale are realized simultaneously. This makes the pricing in the transportation market more complicated than that of other product markets.

The government has strictly conrolled prices in China's transportation market for many years. The flexible change mechanism of price is affected and restricted by various factors. China railway transportation is basically owned and operated solely by the government. The transportation price of the stated-owned railway is generally controlled by the central government (Wang, 2009).

However, civil aviation transportation in China has many airlines, including some foreign airlines, in the market. Competition in the civil aviation system has been very fierce, and the flexibility of price change is obviously higher here than for rail transportation.

The competitive mechanism in highway and water transportation has been formed. There is no need to mention maritime enterprises, where price is completely decided by the supply and demand in the international shipping market. There is keen competition among various transportation modes, and this requires a relatively uniform transportation price policy.

MAIN FACTORS AF FECTING TRANSPORTATION ENTERPRISES

Transportation enterprises find that setting prices is complicated and that many factors affect the process. These factors usually include the following:

Transportation cost is an important basis for pricing, because it is the basic measure of the labour expended in producing transportation services. Production in successful transportation enterprises require prices that generate sufficient revenue to compensate for their costs. Therefore, transportation enterprises widely adopt a pricing method on the basis of cost.

Profit level is also a basis of pricing. Profit level is a very important factor affecting price. Transportation price is generally charged on the basis of cost plus fixed proportional profit.

The state of market supply and demand affects pricing as well. Generally, when the demand for transportation increases, the transportation price should rise accordingly. When the demand for transportation decreases, the transportation price should drop. Under the circumstances of constant development of the market economy and the gradual improvement of transportation market, transportation pricing according to market supply and demand is a significant feature of transportation price formation.

Transportation pr ice policies, usually instructed and supervised by state macroeconomic policies, are important because transportation is a basic industry of national economy. State regulation of transportation prices may shift over time, from quite stringent to rather relaxed. In either case, transportation price policies are very important factors that affect the pricing.

OPTIMAL MODEL OF TRANSPORTATION ENTERPRISE PRICING

Here the optimal pricing model analyzes the best price for enterprises' greatest profit, according to the demand elasticity index of transportation service under the economics elasticity theory. No consideration is given to other influential factors except price, and we then correct the price with other influential factors changing. The theoretical model is applicable for China's shipping companies, airlines and road transport businesses with a relatively high degree of marketization.

Demand function and elasticity index of demand. The transportation demand function reflects the relationship between demand and supply of transportation. Setting up the demand function of transportation enterprise is the essential prerequisite. Suppose transportation demand and price satisfy Q=f (p). Actual equations can be calculated and regressed according to the historical data. This then sets up the possible mode of demand function and decides the parameters in that demand function. Demand price elasticity index can be calculated by deriving the demand function as: $|Ed| = \frac{dQ}{dP} \cdot \frac{P}{Q}$

Defining the theoretical price adjusting rang e. Suppose the present price of a transportation enterprise is P_0, the amount is Q_0, fixed transportation cost is F, variable cost is V, price adjusting range is ΔP, the change in amount of transportation caused by price adjusting is ΔQ. We can get:

The profit before adjusting price = $P_0Q_0 - F - VQ_0$ （1）

The profit after adjusting price （2）

The change in the profit: $\Delta\pi = \pi_1 - \pi_2 = P_1Q_1 - P_0Q_0 - \Delta QV$ （3）

And $P_1 = P_0 + \Delta P$, $Q_1 = Q_0 + \Delta Q$, put them in （3）, and we get:

$$\Delta\pi = \Delta QP_0 + \Delta PQ_0 + \Delta P\Delta Q - \Delta QV \quad (4)$$

From （4） we know ΔQP_0 is the change in income caused by transport amount changes; ΔPQ_0 is the change in income caused by transport price changes; $\Delta P\Delta Q$ is the change in income caused by both changes in price and amount at the same time; ΔQV is the change in cost caused by transport amount. According to the principle of economics, the demand elasticity index is:

$$|Ed| = \frac{dQ}{dP} \cdot \frac{P}{Q}$$

Bringing it into（4）, we get:

$$\Delta\pi = \Delta PQ_0\left[1 - |Ed|(1 - \tfrac{V-\Delta P}{P_0})\right] \quad (5)$$

The first and the second derivative of （5）are:

$$\frac{d\Delta\pi}{d\Delta p} = Q_0 - (1 - |Ed|) + \frac{|Ed|VQ_0}{P_0} - \frac{2|Ed|\Delta PQ_0}{P_0}$$

$\frac{d^2\Delta\pi}{d(\Delta p)^2} = \frac{2|Ed|Q_0}{P_0} \prec 0$, so $\Delta\pi$ must have the optimal result. Suppose $\frac{d^2\Delta\pi}{d(\Delta p)^2} = 0$, we can get the most optimal price adjusting range theoretically:

$$\Delta P = \tfrac{1}{2}(\tfrac{P_0}{|Ed|} - P_0 + V) \quad (6)$$

From （6）we can see the most optimal price adjusting range varies inversely with the demand elasticity index when the original price and variable cost are relatively stable. So if the demand elasticity index of an transportation enterprise is greater, the price adjusting range is more narrow for the maximization of its profit,

and vice versa.

APPLICATION OF PRICE DISCRIMINATION STRATEGY IN PRICING OF TRANSPORTATION

According to the above model, we know that different enterprises' optimal pricing is decided by demand elasticity in the transportation market. Different transport enterprises under any transport mode have different price elasticity. Generally speaking, a transport enterprise with better service quality, more security, higher waiting cost of customers, and more additional services to satisfy customers, will have a lower degree of demand elasticity in the transport service market and have more room for pricing. So the theoretical price adjusting model of transportation enterprise determines the feasibility of applying a price discrimination strategy in the transportation market.

Definition of price discrimination. According to economic theory, any enterprise with some degree of market power can decide its output and market price, which leads to the greatest possible monopoly profits through a price discrimination strategy. Charging different buyers different prices (third-level price discrimination) or charging the same buyer with different buying amounts different prices (second-level price discrimination) for the same goods or service is a practice known as price discrimination (Schiller, 1996). This pricing can not appear in the fully competitive market, because in the fully competitive market individual firms cannot affect prices. Rather they are passive acceptors of market prices, but enterprises with some degree of market power can definitely influence price.

Enterprises with some degree of market power use price discrimination in order to obtain monopoly profits. Successful implementation of a price discrimination strategy requires that the market should have the following characteristics:

The market is incomplete. When market competition is insufficient, with poor market information and lots of segmentations for various reasons, the enterprises with market power can take advantage of these features and utilize a price discrimination strategy. At present, many modes of China's transport markets are in this situation.

Different customers have different price elasticity for even the same product or service, and enterprises have the ability to grasp and to distinguish this difference. Thus, enterprises charge different consumers different prices. In fact, different transportation modes and enterprises are able to do so.

Differences in transport services and the expectations of the owners determine the application of price discrimination. As the price mechanism of China's transportation is perfected and effective regulatory mechanisms are established, the price system can adapt to market demand changes more fully. Further, differences in transport enterprises' service quality, transit time, security, and

customers' other special requirements should be necessarily reflected through the pricing system. Given its service products, transport enterprise pricing also should follow the law of supply and demand in the market (Wohl and Hendrickson 2004.

With the increasing opening of a transport market, competition has strengthened. Differences among different transport modes and differences among different enterprises in the same mode of transport are also growing significantly. So, many enterprises pay more attention to upgrading their service quality, which is reflected in saving transport time, improving transportation quality, strengthening security, meeting the special requirements of goods, and so on.

The above differences must bring different utilities to clients (the owner). The price elasticity of demand for different clients is not the same, so transport enterprises can set different prices, that is, to implement a price discrimination strategy as an important tool to realize the highest profits (Dewan and Mendelson, 1990).Therefore, transport enterprises should flexibly adjust prices, taking full account of demand elasticity reflected by the enterprise (industry) and external market conditions.

INFLUEN TIAL F ACTORS FOR TRANSPORTATION PRICING STRATEGY

The situation of supply and demand between transport capacity and transport demand. In the case that the transport capacity is greater than the demand, the elasticity of demand is bigger, price level should be appropriately reduced; if the transport capacity is less than the demand, the demand in that market becomes inelastic, and therefore the price has more room to rise.

Alternative modes of transport or numbers of enterprises which can provide the same service. If there are more alternative transport modes and substitutive enterprises, then this transport has the greater elasticity of demand and there is a need for lower prices.

Seasonal factors, such as low season and busy season. For example, the railway should adjust prices throughout the year according to traffic volume changes. Prices can be raised in the transport peak period and reduced appropriately in the low season.

Customer (the owner) market division factors. Offer differential pricing for different transport customers (shippers) with different elasticities of demand. For example, the tourist train, football fans train, the students train, high speed carriage and general speed carriage, and so on, may have targeted and specific tariffs.

Transport time, speed and comfort factors. Compared with competitors, a transport business with more timely, faster, and more comfortable services has lower elasticity and can enjoy higher prices and more revenue than competitors.

Regional factors. Affordability for clients from different economic regions is not the same. That is, differences in income level in different regions determine different levels of tariffs. Transport enterprise should activate market through

flexible, different forms of pricing. In addition, the situation of socio-economic conditions, inflation, the proportion of freight in cost and other factors should also be taken into account.

In fact, in recent years, various means of transportation have utilized a flexible pricing strategy to stimulate demand and expand market share. For example, since 1998, a number of railways have stimulated market demand greatly through flexible pricing (Dequan, 2007). Civil aviation companies and shipping enterprises also often employ a discount fare strategy to attract more customers.

CONCLUSIONS

The application of a price discrimination strategy in the transport market can help transport companies make optimal prices to maximize profits based on projections of demand elasticity. At the same time, it will help them appreciate the importance of market research and improvement in their transport service quality, develop characteristic transport services, enhance security and convenience, and pay attention to energy-saving and emission reduction.

Price system reform must also be synchronized with the reform of management mechanisms. Based on different investment relations, different tariff forms and implementation scope, the implementation of layered decision-making in railway freight is needed. This may result in the formation of new management mechanisms organized at different levels of the central and local governments, the railway authorities, and railway transportation enterprises.

ABSTRACT

Transportation System and Socio-economic System have mutual connections and influences. Their coordinated development has become an important guarantee to achieve the overall optimization of national economy. But in reality the situation is that one is often relatively ahead of or legged behind the other. So it becomes necessary for us to research on their coordinated development. Structural Equation Model (SEM) is a combination of Factor analysis and Path analysis, and it is suitable for dealing with such problems of finding out the relationship between large-scaled systems that contain lots of attributes and targets. For this reason, this paper has established a SEM-based model to study the situation of coordinated development between Transportation System and Socio-economic System. In the model, we build an evaluation index system, and take Wuhan City Circle for empirical study on its status of coordinated development between Highway-Waterway Transportation System and Socio-economic System. The paper gives out the path figure by LISREL and calculates out the coordination degree according to the coordination degree model; at last it puts forward some strategies for improving the coordination between the two systems.

INTRODUCTION

The coordination between Transportation System and Socio-economic System refers to the ability of coherency and sustainable development of all aspects of the two systems; it also can be understood as the problem of how to develop the Transportation System at a certain stage or level of Socio-economic System. When Transportation System is able to adjust to Socio-economic development, it can stimulate the Socio-economic growth; when it lags behind the development of Socio-economic, it plays the role of "dragging down"; and high speed of Socio-economic development also tends to generate new transportation need, thereby promoting the development of transportation industry. So it is of great guiding significance to know clearly the mutual coordination between them in the process of making investment decisions. As an integrated statistical technique of Factor and Path analysis, Structural Equation Modeling (SEM) is suitable for dealing with problems of researching the relationship between

large-scaled systems that contain many goals and properties. By SEM, this paper makes a structural validity evaluation on the given evaluation index system and gets the correlation between the two systems and their indicators. Then we apply the coordination degree model to calculate the coordination degree of the Highway-Waterway Transportation and Socio-economic System of Wuhan City Circle. In the end, this paper puts forward some strategies for improving the coordination between the two systems.

THEORIES OF SEM

Structural Equation Model supposes that there exists a causal relationship between latent variables; these variables can be calculated by a group of significant variables, and they are linear combinations of a number of significant variables. By verifying the covariance between significant variables, we can get the estimated coefficients in linear regression models. Then we may decide whether the assumed model is suitable for research in statistical. If confirmed appropriate, it can be said that the relationships between latent variables are reasonable. Structural Equation Model is composed of measurement model and structural model, and it can be represented by three matrix equations. When using SEM, we should assume a necessary pre-model (such as a given evaluation index system). Once set, we can do parameter estimation based on variance and covariance variables. The estimation process of SEM is different from traditional statistical methods. It derivates a variance and covariance matrix or correlation matrix from the variable covariance matrix or correlation matrix and makes the matrix elements as close as possible to observed variance and covariance matrix. If the model performs well, it will be very close to the original matrix, so the process is estimated to use a special fitting function so that the difference between the two matrixes becomes minimal.

Traditional multivariate statistical methods, such as Factor analysis and Path analysis, provide a powerful theoretical support and analytical tool to a certain extent for researchers to explain the relationship between variables, but each of them can only test single relation between the independent variables and dependent variables. Despite that the multi-variance analysis can deal with the relationship between multiple dependent variables and independent variables, this relationship is also single. SEM combines Regression analysis, Factor analysis, Path analysis and other methods. When dealing with the relationship between multiple variables, it simultaneously changes the test capacity from exploratory analysis to verifying analysis. It supplies strong theoretical support on statistical hypothesis testing, and also permits measurement errors of independent variables and dependent variables. These make it possible to analyze the structural relationship between potential variables.

Therefore, this article builds an evaluation index system of Highway-Waterway Transportation System and Socio-economic System of Wuhan City Circle. Each of the two systems has six indicators. Through questionnaire survey, this paper uses LISREL to make an evaluation of constructed validity of the index system. The result shows that it performs well.

Through the path figure, this paper gets the correlation between system and its indicators. These lay foundation for calculating coordination degree between the two systems.

EMPIRICAL STUDIES

In this paper, we select Socio-economic System and the Highway-Waterway Transport System of Wuhan City Circle as the research object, and establish an evaluation index system as shown in Table 1 .

Table 1.E valuation Index System .

Socio-economic System	Added value of Primary industry(X1)
	Added value of Secondary industry(X2)
	Added value of Third industry(X3)
	Total retail sales of society(X4)
	The level of urbanization(X5)
	Engel Coefficient(X6)
Highway-Waterway Transportation System	Transportation net connectivity(Y1)
	Transportation scale of matching(Y2)
	Road network density(Y3)
	Port throughput capacity fitness(Y4)
	Passenger volume(Y5)
	Cargo turnover(Y6)

In order to define the correlation between the indicators, this paper carries out a questionnaire on the index system. We use Likert-scale (5 scales) for the evaluation. Each title has 5 options: not important (1), not so important (2), general (3), important (4), very important (5). In the survey, we release 150 pieces, and recover 150 one week later; the recovery rate was 100%. According to survey results, we apply LISREL, and the programming is as follows:

```

After running the programming, we get the path figure as shown in Figure 1:

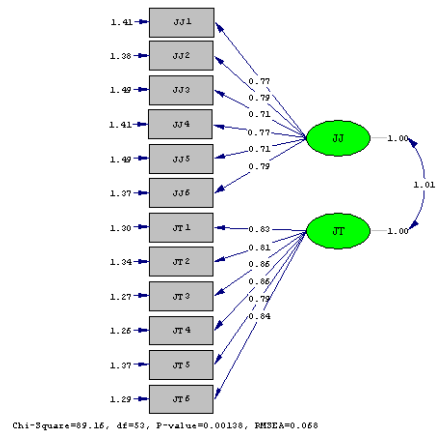

Figure 1. Path Figure in LISREL.

In addition, the main fitting parameters of the model are given in Table 2:

Table 2. Main fitting parameters and their s tandard values .

fitting parameters	X^2	RMSEA	NFI	NNFI	CFI	GFI
standard values	Near 0	≤0.08	Near 1	Near 1	Near 1	Near 1
fitting parameters	89.16	0.068	0.89	0.93	0.94	0.91

From the table, we can see that the main fitting parameters such as X^2, RMSEA, CFI and NNFI are close to their standard values. It means that the fitting situation is good, the constructed validity of the index system is permit and it can be used for evaluating the two systems in this article. According to the calculation method of coordination degree, the article is required to calculate the respective system-ordering of the two systems in advance. From the path figure, we can get the correlations between the two systems and their indicators. Combining the original data (as shown in Table 3) of the two systems in Year 2000-2007, we can calculate the system-orderings out. In addition, the formula of coordination degree is as follows: $D(t) = \sqrt{\frac{2 f_1 f_2}{f_1 + f_2}}$, where f_1 expresses Socio-economic System, f_2 expresses Waterway-Highway Transport System. The coefficients can be calculated by normalizing the coefficient in the Figure 1.

Table 3. Original data and Calculated C oefficients.

	2000	2001	2002	2003	2004	2005	2006	2007	Coefficients

Y4	0.1531	0.1624	0.1711	0.1885	0.209	0.2231	0.2288	0.2444	0.172
Y5	1643104	1672545	1765998	1680901	1724582	2377600	2586829	2814470	0.158
Y6	2151866	2077667	2260381	2451248	3837621	5152600	5970318	6917807	0.168

After normalizing and further calculating, we can get the coordination degree.

Table 4. C oordination Degree of all the years.

	2000	2001	2002	2003	2004	2005	2006	2007
f_1	1.000	1.061	1.136	1.224	1.363	1.493	1.608	1.741
f_2	1.004	1.018	1.051	1.093	1.252	1.449	1.551	1.681
D(t)	0.99	0.98	0.95	0.93	0.87	0.82	0.79	0.76

The respective system-ordering degrees are as follows:

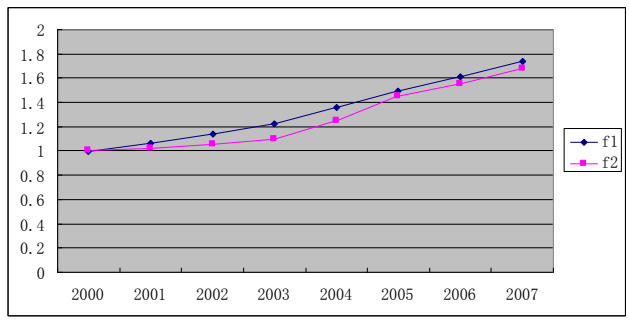

Figure 2 . Respective system -order ings of Year 2000 -2007.

From Table 5 and 6 , we can finally see the coordination degree grading.

Table 5. C oordination Degree grading standard.

D(t)	0.9-1.0	0.80-0.90	0.70-0.80	0-0.70
Grading	Overall adapting	Basically adapting	Lagging behind	Seriously constraint

Table 6. C oordination Degree grading in Year 2000 -2007.

	2000	2001	2002	2003	2004	2005	2006	2007
Grading	Overall adapting	Overall adapting	Overall adapting	Overall adapting	Basically adapting	Basically adapting	Lagging behind	Lagging behind

From the situation of system-ordering in Figure 2, we can see that the system- orderings of Socio-economic System are basically lower than those of the Highway- Waterway Transport System. We can also see that the coordination degrees change from overall adaptation to basically adaptation, and then to

lagging behind. The reason lies in fast development of socio-economic in recent years, while insufficient investment in the Highway-Waterway Transport System. These make the coordination between the two systems worse gradually. These are problems that relevant departments should pay attention to. The local government should make full use of the market. Through competition, it should enhance the vitality of market, improve its efficiency to speed up the development of Transportation system and implement reasonable division and efficient operation of various transportation modes in order to adapt to the development of Socio-economic System.

CONCLUSIONS

The innovation of this paper is that we apply Structural Equation Model to evaluate the constructed validity of the given index system, and get the correlation between the system and its indicators. After these, by combining the original data of Wuhan City Circle in recent years and the coordination degree model, we calculate out the values of coordination degree and divide the coordination grades. This article can provide some references for relevant departments in the process of making investment decisions.

College of Transport Management, Dalian Maritime University, Dalian, 116026, China; TEL/FAX (0411) 8472-6756; E-mail: yangzhongzhen@263.net

Abstract : This paper presents a method to construct an integrated transport network model based on the attributes and structures of the modes and path choice behavior of users. First, a conception of integrated transport networks is given and the meanings of dummy links and their construction methods are discussed. Three kinds of dummy links are created. Then three kinds of network models are constructed for the Chinese Northeast region, and their performance is evaluated. Finally, we evaluate some logistics techniques and policies with the integrated transport network.

INTRODUCTION

An integrated transport network is a network consisting of links and nodes of several kinds of transport modes (Jin et al, 2006). When organizing multi-mode transport, the cost, time and reliability of the combination of different modes must be considered; therefore, the shortest path between the origin and destination, the mode combination of the shortest path and the transfer cost/time from one mode to another should be considered. Thus integrated networks are necessary to analyze multi-mode transport schemes. Recently, many studies have focused on integrated transport, among them a quantitative analysis mainly focused on terminal location (Guo et al, 2001), and an analysis of multi-mode transport and path choice (Beuthe et al, 2001, Sun and Yang, 2005, Zhang and Guo, 2002). In the field of integrated transport networks, many researchers have built simple network models and have developed the shortest path algorithms (Lozano and Storchi, 2001, Wei et al, 2006, Kozan, 2001). There is scant literature discussing the transfer process in the integrated network. Based on the analysis of the attributes and structures of each mode, and path choice behaviors of users, this paper presents a method for constructing integrated transport networks. Three kinds of construction methods are presented based on different kinds of links, and a set of logistics techniques and policies are listed and evaluated based on the network.

INTEGRATED TRANSPORT NETWORK MODEL

The integrated transport network model means a mathematical configuration recorded in the computer, which can represent the topological structure of the combination of multi-mode transport networks in the real world (Southworth and

Peterson, 2000, Wang and Wang, 2005). In the network, ordinary links represent railways, highways, waterways and airways, and dummy links represent the transfer routes. The ordinary links have the attributes of time, cost and capacity, while dummy links have time and cost attributes. Figure 1 is a simple example, which contains highway, railway, and dummy links and transfer terminals. The main task in constructing a integrated network model is to represent the dummy links suitably.

DUMMY LINKS IN AN INTEGRATED TRANSPORT NETWORK MODEL

Transfer Attributes based Dummy Links

Figure 2 shows the method of creating dummy links based on transfer attributes, where the attributes of dummy links record the needed time, cost and reliability of the transfer. On a macro level, the node to connect highway and railway may not be in the same location but at two terminals in a city; thus urban roads will be used for transfer. Consequently, the static shortest path is one attribute of a dummy link, and the cost and time of loading, unloading and storage are the others.

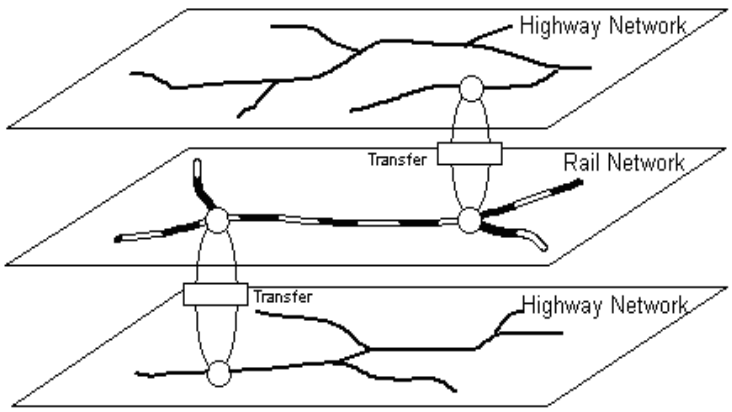

Figure 1. Integrated Transport Network

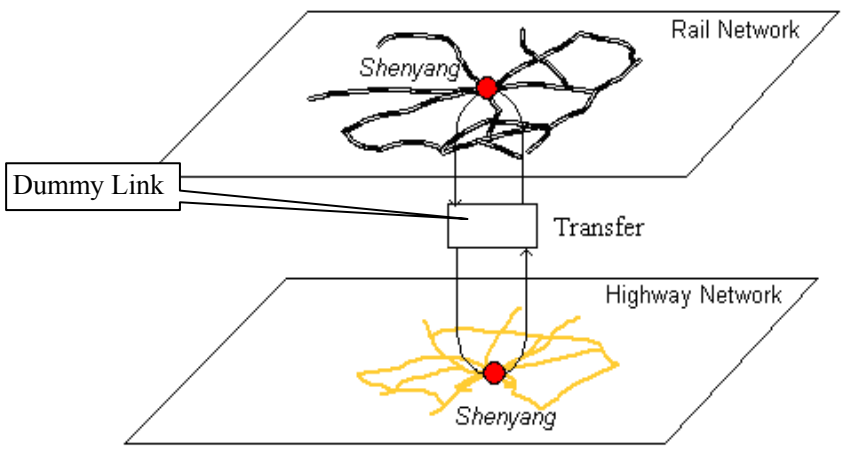

Figure 2. Transfer Attributes based Dummy Links

There may be more than one dummy link for a node because freight with different destinations may require different paths, resulting in different needed time and costs in urban road network. Moreover, due to the different schedules of trains, waiting time and costs in stations may differ; different dummy links should be created correspondingly. An integrated network model based on this method has a simple structure and is easy for computing. However, the disadvantage is that the method for representing dummy links is too simple to precisely account for the dynamic attributes of road traffic.

Urban Road Ne twork based D ummy Links

In this method, dummy links are the connectors linking urban road networks and highway networks; thus the integrated transport network model with these dummy links contains railway links, highway links, urban road links, transfer terminals and dummy links, where railway and highway are at the same macro level and an urban road is represented in micro degree. The solid line in Figure 3 represents the dummy link, and the dash line represents the direct connected roads without any impedance. This is because that urban road commonly links directly with inter-city highways.

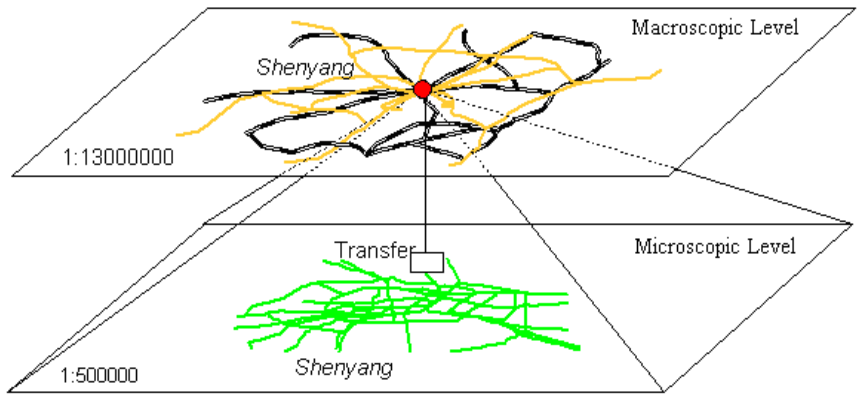

Figure 3. Urban Road Network based Dummy Links

Compared with the first kind of dummy link, dummy links here only represent the transfer process, and movement of freight in a city can be shown clearly with urban road networks. The integrated network model here can reflect the transfer process, the moving status of trucks in a city and the impact of trucks specifically on urban traffic. However, when the corresponding region is too large, the network model also becomes large, since many urban roads should be included. Therefore, in this kind of network, urban road networks should be simplified.

Multi -scale based Dummy Links

Different scales represent different information densities (Hu & Yan, 2006). Spatial data can be represented as different geometrical forms under different scales. Here we use two scales to represent an integrated transport network model. As

shown in Figure 4, under macroscopic level (small scale), attributes of dummy links are used to represent the information of urban roads and terminals, while under microscopic level (large scale), both attributes of dummy links and urban roads are used.

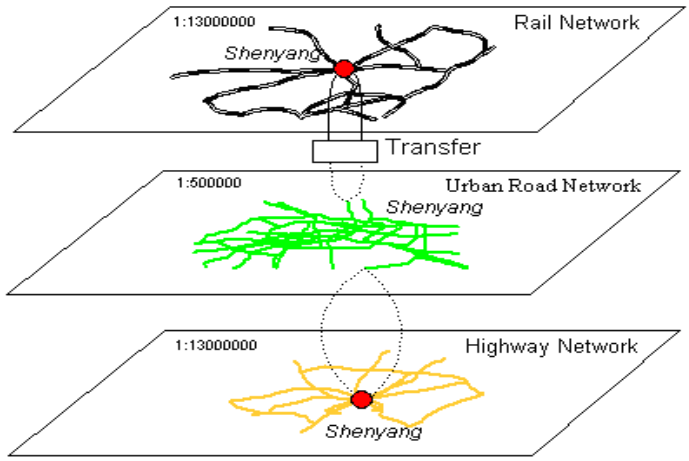

Figure 4. Multi -scale based Dummy Links

This means that at the macroscopic level, the transfer process is abstracted as dummy links; while at the microscopic level, the dummy links are changed back to urban road network and transfer links. The multi-scale based dummy links are stored in two levels: the first includes railway, highway and dummy links, and the second includes urban roads and dummy links to represent the transfers. The two layers are connected with indexes. This integrated transport network uses two kinds of dummy links and connects urban road networks, highway networks and railway networks closely.

PERFORMANCE OF THE THREE KINDS OF MODELS

The first kind of integrated network model presents transfer in urban road and terminals with dummy links. The network is simple, but highly generalized dummy links make it difficult to analyze truck behaviors in urban roads. The second kind connects urban road networks with inter-city highway networks; it reflects the interaction between truck flow and urban traffic flow. However, with the addition of urban road networks, it becomes larger and more complicated. The third one divides the whole model into two scales. Therefore, for finding the shortest path, we can search the nodes at the macroscopic level. Then, the information of urban road networks is obtained by indexing the dummy links at the macroscopic level, and thus Dijsktra's algorithm can be used in urban road networks by taking the entrance node into the urban road network as the origin and terminal as the destination. Finally, the two level shortest paths obtained are integrated by their scales and indexes. Therefore, this method can not only depict the detailed moving

characteristics of trucks in urban road networks, but also avoids the undue increase of search space through the macroscopic-level dummy links.

To evaluate the performance of the three methods, we constructed three kinds of integrated transport network models for the Chinese Northeast region, where roads, railways, dummy links and terminals etc. are included and urban road networks in Dalian, Shenyang, Changchun, Harbin, Yanji, Manzhouli are constructed. Table 1 shows their attributes. We found that the attribute of the first model is similar to that of the second one, and their physical structures are also same. The only difference is the number of nodes and links.

Table 1. Links in the Integrated Transport Network Models

Model Type	Link Number	Link Length (km)
Attributes based dummy link		
Road sub-network	224	29,823
Rail sub-network	232	20,844
Dummy links	67	332
Urban road network based dummy link		
Road sub-network	224	29,823
Rail sub-network	232	20,844
City sub-network	523	1,263
Dummy links	67	0
Multi-scale based dummy link		
Road sub-network	224	29,823
Rail sub-network	232	20,844
City sub-network	523	1,263
Dummy links	134	332

We used Dijsktra's algorithm to test the three models; the calculation times for them are 0.30s, 0.62s and 0.47s, respectively (CPU=Pentium 2.2G).We can see that the first model needs the least time due to having the fewest links, dummy links and nodes. The third model balances the calculation efficiency and the details of the network well. Because the third model uses two scales to express the information and has two levels of physical structure, thus the process of Dijsktra's algorithm is divided into steps as follows.

- Step 1: Find the shortest path by Dijsktra's algorithm at the macroscopic level. If there are transfers in the path, go to Step 2; otherwise, stop;
- Step 2: Find all the dummy links in the shortest path; get urban road information among them by the index of dummy links, use Dijsktra's algorithm to find the shortest path in the urban road network with taking the entrance node into the urban road network as the origin and the terminal as the destination;

- Step 3: Integrate the two shortest paths with their scales and indexes to meet the output demand for different scales.

EFFECTS OF SOME TRANSPORT POLICIES AND TECHNIQUES

We summarized 11 policies or techniques used to improve the container integrated transport. They are: 1) operation of railway liner; 2) use of double-deck container trains; 3) increment of liner frequency; 4) raising railway speed; 5) setting freight dedicated railway; 6) price discounts; 7) construction of expressways to connect ports and railway terminals; 8) construction of container yards; 9) use of new handing equipment; 10) construction of information systems for integrated transportation; and 11) digitally managed container yards. Through combination of these policies and techniques we developed the following improvement schemes.

Schemes 1=without any change; Schemes 2=7)+ 8)+ 9)+ 10)+ 11)；Schemes 3=4)+ 5)+ 6); Schemes 4=1)+ 2)+ 3); Schemes 5=1)+ 4)+ 7); Schemes 6=1)+ 2)+ 4)+ 5)+ 7)+ 8)+ 9); Schemes 7=1)+ 2)+ 3)+ 4)+ 5)+ 6)+ 7)+ 8)+ 9)+ 10)+ 11).

Then by taking Dalian, Shenyang, Changchun, Harbin and Manzhouli as centers, we built an integrated network and five transport zones (Figure 5) and obtained the container OD metric per two weeks as Table 2 shows. Assigning the OD onto the networks corresponding to the 7 schemes with the least cost rule, we obtained transport costs as shown in Table 3.

Table 2. Regional Containers O -D (TEU)

O/D	1	2	3	4	5
1	0	506	168	96	24
2	4900	0	402	154	14
3	1634	186	0	152	12
4	922	106	98	0	32
5	230	26	16	12	0

Figure 5. Network and the Zon e

We found that compared with Scheme 1, Scheme 2 saves 1.2 million RMB, Scheme 3 and Scheme 4 save 2 million RMB respectively. The effects of Scheme 3 and Scheme 4 are more obvious because of the increment of railway capacity, although the increment is limited subject to transfer capacity. In Scheme 2 only transfer methods were taken, and thus transfer cost is reduced but transfer quantity did not change. Schemes 5, 6 and 7 implemented a series of policies and techniques and resulted in more obvious outputs. Through the comparison it can be understood that effects of a single method are much less than the effects of a set of methods, meaning that multi-model transport is a whole system; improved efficiency and cost savings are realized only through cooperating and compromising policies and methods. Then the advantages of the integrated transport can be realized.

Table 3. Transport Costs obtained through Traffic Assignment (million RMB)

Scheme	Cost on Road	Cost on Rail	Transfer Cost	Total
1	18.91	1.08	0.35	20.33
2	17.96	1.01	0.14	19.10
3	15.27	2.19	0.88	18.34
4	13.93	3.06	1.08	18.08
5	14.07	2.63	0.83	17.53
6	13.93	2.55	0.76	17.24
7	12.83	2.72	0.60	16.15

CONCLUSION

This paper studied the method of building integrated transport networks. In the integrated network model, transfer terminals are abstracted as dummy links. Three methods of constructing dummy links were proposed. The performances of the three kinds of models were evaluated. Through testing the Shortest Path Searching, it was found that the integrated network model, made up of multi-scale-based dummy links, is more efficient and can reflect the transfer behaviors in the networks precisely.

We also used the integrated network model of multi-scale-based dummy links to test policies or techniques that are designed to improve the efficiency or reduce the cost of the transport. We found that the increment of railway capacity can reduce transport cost, and that a combined set of policies and techniques are better than a single policy or technique.

[1]College of Traffic and Transportation, Southwest Jiaotong University, Chengdu, Sichuan, 610031, China; PH(+86)28-87634680;email: tianzhiqiang_1128@126.com

ABSTRACT

Crew scheduling is an important part of the passenger dedicated line plan system, and also the main factor influencing operating expenses of passenger dedicated lines. After analyzing a crew scheduling problem, the following two steps are chosen to solve this problem. First, the train running paths are divided into crew paths, which are then combined into crew routes according to related constraint conditions of the crew scheduling plan, the relationship between train numbers and the motor train set routes. Then, a mathematical model is given with the aim of minimizing the operating expenses of the crew scheduling problem, and a Genetic Ant Colony Algorithm is designed for solving this model.

1. INTRODUCTION

Crew scheduling is an important problem faced by every transportation method. In airline transport and urban transport, the cost of a crew is second only to the total production cost; in railway transport and maritime transport, the cost of a crew is also an important part of the total cost.

In response to market demands, the adjustment of train diagrams becomes more frequent, and so too does the corresponding adjustment of the crew scheduling become more frequent too. If we still use the manual weaving method, long time will be needed, thus not fitting the need of the transport organization. According to these factors, we apply an effective optimization method and utilize computers to weave crew scheduling as the only choice to satisfy the transport organization.

2. PROBLEM FORMULATION

In ZhaoPeng et al. (1998), the crew scheduling problem was divided into two sub problems: the crew scheduling problem and the crew rostering problem. Crew scheduling consists of all crew routes, which indicates the total crew members needed by the crew works of the train diagram and the detail of the crew routing. A crew rostering plan is such a plan that stipulates the work and the rest dispatched to every crew member. This paper only focuses on the research of the crew scheduling problem.

The existing research results have usually treated the crew scheduling problem as a Set Covering Problem (SCP) or a Set Partition Problem (SPP), and

various algorithms have been developed to solve it. J.E. Beasley et al. (1996) adopted a tree search algorithm to solving the crew scheduling problem, and the lower bound of the problem was found by Lagrangian relaxation. Shangyao Yan et al. (2002) have pointed out that the pure network model can be used to represent crew scheduling problems when the scale of the problem is relatively small. However, using a Genetic Ant Colony Algorithm to solve the crew scheduling problem has not been explored in previous research. The related knowledge of Genetic Algorithm and Ant Colony Algorithm could refer to J.E. Beasley (1996) and Marco Dorigo (2006).

3. MODELING

The crew scheduling of passenger dedicated lines is a very difficult problem; to reduce the complexity of the problem, we adopted a method which divides the weaving problem into the following two steps: (1) divide the travel line into crew paths based on the distribution of the relief station; (2) combine the crew paths into crew routes that qualify all restrictions.

3.1 The division of crew paths

The travel line can be divided into crew paths based on two factors: first, the distribution of the relief stations, and second, the stops on the stations stipulated by the train diagram (excluding the direct trains). The divided crew paths could be expressed as follows:

$$p_i = (TN, n_i, JN, S_i^s, T_i^s, S_i^e, T_i^e) \qquad i = 1, 2, ..., m$$

where *TN* is the train number of the crew path; n_i is the *No.* of the crew path; *JN* is the motor train set route number of the crew path; S_i^s is the start station of crew path *i*; T_i^s is the start time of crew path *i*; S_i^e is the end station of crew path *i*; T_i^e is the end time of crew path *i*; *m* is the total number of all crew paths.

3.2 The combination conditions of the crew paths

Constrained by the distribution of the relief station, the length of the crew paths is usually not very long , so when forming the crew route, we could combine the divided crew paths into crew routes with ideal length by satisfying all restrictions such as total working time criterion, relief time criterion etc.

In this process, the following restrictions should be satisfied:

(1) Every crew path should belong to one and only one crew route. (2) For the connected two crew paths, the end station of the first crew path and the start station of the second crew path should be the same station. (3) The time interval between two crew paths must be longer than the relief time criterion. (4) The total time of each crew route should not exceed the maximum working time. (5) The continuous working time in each crew route should be no longer than the criterion.

The constructed crew routes can be expressed as follows:

$R_j = (RN, k_j, S_j^s, T_j^s, S_j^e, T_j^e)$

Where k_j is the relief time happened in crew route j, other variables have the similar definition with crew path.

3.3 Optimization model

The most important goal of the crew scheduling problem is to minimize the cost of the crew operation. In order to reduce the difficulty of the problem, some of the researchers only considered the number of the crew members in the optimization model, but in practicality, the various costs involved by the crew scheduling plan may affect the result of the scheduling. The set-covering model of crew scheduling problem is as follows:

$$\min Z = \sum_{j=1}^{n} c_j \cdot x_j + \sum_{i=1}^{m} \left(T_i \cdot c_{zc} + \left(\sum_{j=1}^{n} a_{ij} \cdot x_j - 1 \right) T_i \cdot \beta \cdot c_{zc} \right) \quad (1)$$

$$c_j = c_{wage} + k_j \cdot c_h + \sum_{l=1}^{k_j} (\omega_l - T_{hc}) \cdot c_{zc} \cdot \alpha$$

Subject to:

$$\sum_{j=1}^{n} a_{ij} x_j \geq 1 \qquad i = 1, 2, ..., m \quad (2)$$

In the objective function, each crew path should be covered at least one time. Once the crew path is decided, the total time of it is fixed, so the objective function can be simplified as follows:

$$\min Z = \sum_{j=1}^{n} c_j \cdot x_j + \sum_{i=1}^{m} \left(\left(\sum_{j=1}^{n} a_{ij} \cdot x_j - 1 \right) T_i \cdot \beta \cdot c_{zc} \right)$$

When constructing a feasible solution, the following constraint should be satisfied:

$$S_{i_1}^e x_{i_1 j} = S_{i_2}^s x_{i_2 j} \qquad 1 \leq i_1 \leq m, \ \ 1 \leq i_2 \leq m, \ \ i_1 \neq i_2, \ \ j = 1, 2, ..., n \quad (3)$$

$$T_{i_2 j}^s - T_{i_1 j}^e \geq x_{i_1 j} x_{i_2 j} T_{hc} \ 1 \leq i_1 \leq m, \ \ 1 \leq i_2 \leq m, \ \ i_1 \neq i_2, \ \ T_{i_2}^s > T_{i_1}^e, \ \ j = 1, 2, ..., n \quad (4)$$

$$T_j^e - T_j^s \leq T_{bz} \qquad j = 1, 2, ..., n \quad (5)$$

$$T_{v+\delta}^s - T_v^e \leq T_{lx} \qquad \prod_{v}^{v+\delta} r_i = 1 \qquad 1 \leq v < v + \delta \leq n_j \qquad j = 1, 2, ..., n \quad (6)$$

In the optimization model, m is the number of all crew paths, n is the number of the crew routes, x_j is a 0-1 binary value that equals 1 if crew route R_j was selected and 0 otherwise. c_j is the total cost of crew route j which consists of fixed costs and variable costs. The fixed cost consists mainly of the basic wage of crews c_{wage}; the variable cost is determined by the duty time T_j, the number of relief times k_j and the

length of invalid relief time $\sum_{l=1}^{k_j}(\omega_l - T_{hc})$, ω_l is the time spent in each relief, T_{hc} is the time criteria of the relief, c_h is the average relief cost, c_{zc} is the cost of the crew duty per time unit, α is the coefficient of invalid relief time versus normal duty, β is the coefficient of invalid relief time versus normal duty, a_{ij} is a 0-1 variable that equals 1 if crew path p_i belong to crew route R_j and zero otherwise, n_j is the total number of crew paths in crew route R_j, T_{bz} is the maximum working time in one route, T_{lx} is the continuous working time, δ is the number that undertaken by one crew continuously, r_i is a 0-1 binary value that equals 1 if the connection time after crew path i longer than the rest time and 0 otherwise.

The restrictions (2)-(6) correspond to the combination rules of crew paths in 3.2, respectively.

4 GENETIC ANT COLONY ALGORITHMS (GACA)

4.1 The basic steps of GACA

The basic steps of GACA used in this paper are as follows:

Step1: Generate some relatively better solutions to the problem by genetic algorithm and initial the pheromones by these solutions,

Step2: $nc \leftarrow 0$，(nc is the number of iterations).

Step3: Place m ants on the starting node of the construction graph, and for each ant k (k=1, 2,…, m), choose the next node j with the probability decided by the pheromones and the heuristic information until the construction of the solutions is finished.

Step4: Choose some pair of solutions to carry out the crossover operation according to the crossover probability. Receive the new solutions generated by crossover if the value of the objective function has been improved, and reject otherwise.

Step5: Decide whether to carry out the mutation or not according the mutation probability. Receive the new solution generated by mutation if the value of the objective function has been improved, and reject otherwise.

Step6: Calculate the length of each route L_k (k=1, 2,…, m) and update the best-so-far solution.

Step7: Select the best s solutions to update the pheromones of the edges by the update equation.

Step8: $nc \leftarrow nc+1$.

Step9: Turn to step 3 if nc is less than the given iteration times and without degradation, otherwise, turn to step 10.

Step10: Output the best-so-far solution.

4.1 Coding of the problem

This paper uses a column-based method to represent the solution of the crew scheduling problem, forming the n columns of the problem by sorting the feasible

crew routes in certain sequence. Then it describes the solution with a binary character string in which 1 means the column *i* is contained in the final solution.

4.2 The operations of Genetic Algorithm

(1) The generation of the initial solution

We selected some crew routes randomly from the set of all crew routes to generate the initial solution of the problem, considered the feasibility of these solutions, and adopted the repair method and post optimization technology. We repeated this procedure several times to get the initial group and then chose the better initial solution of the problem by their fitness value.

(2) Selection

The selection method used in this paper is roulette wheel selection.

(3) Crossover

The crossover adopted is the crossover operator based on the fitness value which both considered the construction and fitness value of the parents.

Let P_1, P_2 be the chromosome of the parents, and f_{p1}, f_{p2} be the fitness value of the parents, C represent the chromosome of the child, so the crossover can be represented as follow:

When $P_1[i] = P_2[i]$, let $C[i] = P_1[i] = P_2[i]$, otherwise, let $C[i] = P_1[i]$ by the probability of $p = f_{P2} / (f_{P1} + f_{P2})$ and let $C[i] = P_2[i]$ by the probability of $1 - p$.

Because the feasibility of the solution can not be ensured after the crossover operation, the repair method and the post optimization technology is adopted to handle the solutions determined by the crossover.

(4) Mutation

The purpose of mutation is to preserve diversity and it avoids local optima entrapment. Each chromosome carries out mutation by the mutation probability. The method adopted is turnover one of the gene in the chromosome by small probability. In order to assure the feasibility of the solution, the repair method and the post optimization technology is used after the mutation.

4.3 The operations of Ant Colony Algorithm

(1) The representation, update and initialization of pheromones

Pheromones τ_j is the expectation that crew route *j* is contained in the final solution, the larger τ_j is, the greater the probability of selecting the crew route *j* into the final solution. The formulation for update the pheromone is as follows:

$$\tau_j(n+1) = \rho \tau_j(n) + \Delta \tau_j \tag{7}$$

Where ρ is the evaporation rate, *n* is the iteration times, $\Delta\tau_j$ is the quantity of pheromones laid on column *j* by the ants.

(2) The construction of the solution

The construction of the solution is an important content in ant colony

algorithm. In this paper, each ant starts from an empty solution and constructs the solution by adding the crew routes step by step. The probability of choosing crew route *j* is as follows:

$$p_j^k(t) = \frac{\tau_j[\eta_j]^\beta}{\sum_{l \in N^k} \tau_j[\eta_j]^\beta}, \qquad if \ \ j \in N^k \tag{8}$$

Where η_j is the heuristic information that equals c_j / e_j, e_j is the row number covered by column *j*, so η_j indicates the average cost of the newly covered rows when adding column *j* into the solution.

After the construction, the post optimization technology is used to ensure there are no redundant columns in the solution.

4.4 The termination condition

The algorithm will be terminated when one of the following conditions is satisfied:

(1) The algorithm has already found the best solution whose value equals f^*, or the solution found located in an expected range with the best solution.

(2) The solution found by the algorithm or the iteration time of the algorithm has reached maximum.

(3) The CPU time of the algorithm has reached maximum.

(4) The algorithm has stagnated.

5 CONCLUSION

This paper analyzed the crew scheduling problem and created a mathematical model to minimize the total cost of crew expense. The model considered almost all costs that will affect the result of the crew scheduling, therefore describing the crew scheduling problem accurately. However, this paper researched only the crew scheduling problem and does not address the problem that must be faced in the second stage when weaving the crew plan—the crew rostering problem. Therefore, a key point for future work will be creating a reasonable mathematic model of the crew rostering problem and designing an effective solution algorithm.

Analysis for Principal-agent Relationship between Owner and Construction Agent of Agent-construction Project

Wenyi ZHAO[1], Xuancang WANG[1] and Ting ZHAN[1]

[1]School of Highway, Chang'an University, Xi'an China, PH (86) 29-82334387; email: chd-zwy@163.com

ABSTRACT

According to the basic logic of principal-agent theory in information economics, and in combination with the connotation of management mode for agent-construction project, a principal-agent model for the relationship between owners and constructions agent was established. The model has been used to analyze the principal-agent problem of owners and construction agents. As is shown in the analysis results, incentive mechanisms and supervision mechanisms can stimulate construction agents to do better; however, the traditional mode that increases in fixed remuneration has no effect on it. In addition, an increase in fixed remuneration is only the precondition for cooperation between owner and construction agent. A supervision mechanism has a negative impact on the construction agent; for the owner, it is necessary to use it with caution.

1 INTRODUCTION

An agent-construction project means a project is constructed by adopting a management mode of principal-agent. It originally came from innovations in the management mode of governmental investment projects; however, it has been widely used in non-governmental investment projects, including private, government-private, foreign investment projects, and so on in this day and age (Zhao 2006). The essential characteristic of the agent construction mode is that the agent-construction owner decides who owns project on its behalf (Yin and Yan 2006). In the agent construction mode, the owner must sign a contract with the construction agent. Normally, what the construction agent can earn is predetermined agent-construction fees and part of the project investment remainder. In the view of information economics, the relationship between the owner and the construction agent belongs to the principal-agent.

The principal-agent theory of information economics attempts to model the following issues: the principal is originally intent to make agent action as the former's advantages, however, principal can not get to know what the agent do, in addition, all that the principal can observe are just other variables. These variables are affected by the agent's action and other random factors, so that the principal only gets incomplete information about the agent. The principal's main problems is how to award or punish the agent according to the information gained from observations

so as to inspire the agent to choose the most beneficial action (Zhang 2007). The owner of the agent-construction project is the principal and the construction agent works for the owner. The construction agent's fees are fixed, but the project investment remainder can serve to inspire the agent. This paper tries to analyze the relationship between the owner and the agent through the principal-agent model, and provides references for the design of an incentive and supervision mechanism.

2 HYPOTHESES AND ILLUSTRATION OF MODEL

Assume a is a one-dimensional endeavor variable, and productive function is linear form, as is shown in (1). k_1 expresses productive coefficient of endeavor variable. θ is a random variable which mean = 0 and variance = σ_θ^2. It represents uncertain exterior factors. The supervisory signal, p, is the benefit to supervise and calculate a. Because a is related to p and affected by it, so p is a function of a. As is shown in (2), in which ε is a random variable which mean = 0 and variance = σ_ε^2 (Yang and Zhang 2008).

Productive function:

$$\pi = k_1 a + \theta \qquad \theta \sim N(0, \sigma_\theta^2) \tag{1}$$

Supervisory signal:

$$p = k_2 a + \varepsilon \qquad \varepsilon \sim N(0, \sigma_\varepsilon^2) \tag{2}$$

Var(θ)= σ_θ^2 reflects ectogenic environmental risk. Var(ε)= σ_ε^2 reflects accuracy of monitoring signal. θ and ε are both independent, so we can get covariance cov(θ, ε)=0.

Under the condition of the monitoring signal, the reward payment function of the owner not only depends on production π but also depends on the monitoring signal p, so we can get (3).

$$s(\pi, p) = \alpha + \beta\pi + \delta p \tag{3}$$

Where α is fixed income of the construction agent; β is the productive share of the construction agent under the condition of $0 \le \beta \le 1$; δ reflects the reward of the construction agent regarded the monitoring signal as a reference. Then, the expectant utility function of the owner is:

$$E(v) = E[\pi - s(\pi, p)] \tag{4}$$

Suppose the expectant utility function of the construction agent has the invariable character of absolute risk elusion, i.e. $U = -e^{-\rho\omega}$. Where ρ is the absolute risk elusion degree; ω is practical currency income. Supposing the effort cost of the

construction agent is $c(a)=\frac{b}{2}a^2$， here, $b(b>0)$is cost coefficient; negative effect of a increases with increase of b. Then, the practical income of construction agent can be expressed as follows:

$$\omega = s(\pi, p) - c(a) \tag{5}$$

Determining equivalent income is:

$$E(\omega)-\frac{\rho}{2}(\beta^2\sigma_\theta^2+\delta^2\sigma_\varepsilon^2)=\alpha+(k_1\beta+k_2\delta)a-\frac{b}{2}a^2-\frac{\rho}{2}(\beta^2\sigma_\theta^2+\delta^2\sigma_\varepsilon^2) \tag{6}$$

Where $E(\omega)$ is expectant income of construction agent; $\frac{\rho}{2}(\beta^2\sigma_\theta^2+\delta^2\sigma_\varepsilon^2)$ is risk cost of construction agent. Supposing $\overline{\omega}$ is reserved income level of construction agent, participation restriction of construction agent can be expressed as follows:

$$\alpha+(k_1\beta+k_2\delta)a-\frac{b}{2}a^2-\frac{\rho}{2}(\beta^2\sigma_\theta^2+\delta^2\sigma_\varepsilon^2)\geq\overline{\omega} \tag{7}$$

Maximizing left side of (7), we can get a by inducement.

$$a=\frac{k_1\beta+k_2\delta}{b} \tag{8}$$

3 ESTABLISHMENT AND ANALYSIS OF MODEL

3.1 Establishment of Model

Through analyzing and supposing of chapter 1 in the paper, selection of （α,β） and optimization problem as follows should be considered by owner (Chen 2006).

$$\max E(v)=k_1a-E(\alpha+\beta\pi+\delta p)$$

$$\text{s.t.}\quad (\text{IR})\quad \alpha+(k_1\beta+k_2\delta)a-\frac{b}{2}a^2-\frac{\rho}{2}(\beta^2\sigma_\theta^2+\delta^2\sigma_\varepsilon^2)\geq\overline{\omega}$$

$$(\text{IC})\quad a=\frac{k_1\beta+k_2\delta}{b}$$

By substituting (IC) into (IR), we can get

$$\alpha=\overline{\omega}-\frac{(k_1\beta+k_2\delta)^2}{2b}+\frac{\rho}{2}(\beta^2\sigma_\theta^2+\delta^2\sigma_\varepsilon^2) \tag{9}$$

$$\max E(v)=k_1\frac{k_1\beta+k_2\delta}{b}-\overline{\omega}+\frac{(k_1\beta+k_2\delta)^2}{2b}-\frac{\rho}{2}(\beta^2\sigma_\theta^2+\delta^2\sigma_\varepsilon^2)$$

$$-\beta k_1 \frac{k_1\beta + k_2\delta}{b} - \delta k_2 \frac{k_1\beta + k_2\delta}{b}$$

The first order condition of β is

$$\beta = \frac{k_1^2 - k_1 k_2 \delta}{k_1^2 + b\rho\sigma_\theta^2} \tag{10}$$

The first order condition of δ is

$$\delta = \frac{k_1 k_2 - k_1 k_2 \beta}{k_2^2 + b\rho\sigma_\varepsilon^2} \tag{11}$$

In order to discuss conveniently and universally, supposing k_1 and k_2 both equal to 1, combined with Eq.(10)and Eq.(11), we can get

$$\beta = \frac{1-\delta}{1+b\rho\sigma_\theta^2} \tag{12}$$

$$\delta = \frac{1-\beta}{1+b\rho\sigma_\varepsilon^2} \tag{13}$$

3.2 Analysis of Model

(1) Influence of incentive mechanism and supervision mechanism on effort of construction agent is analyzed. According to(8), an increase of β>0 or δ>0 makes increase of a. It shows that a productive share and a monitoring signal can induce or encourage the effort of the construction agent. If the owner hopes to increase the construction agent's level of effort, the productive share should be increased to stimulate construction the agent under weak monitoring ability of owner. The effort of the construction agent is realized by β and by monitoring signal under δ=0 and β=0 respectively.

(2) An increase of the fixed reward has no incentive effect on the effort of the construction agent. According to (8), the construction agent's degree of effort does not relate to the fixed reward of the construction agent. It shows that the fixed reward institution can not incent the construction agent. Especially when β and δ are all equal to 0, we can get a=0 by (8). It means that the construction agent's degree of effort is 0 without incentive and supervision mechanisms because of the lack of incentive mechanisms to construction agent, but it does not mean that design of fixed reward is not necessary in agent-construction contract. According to (9), when the fixed reward of construction agent reaches necessity of (9) at least, payment for the project provided for owner will be accepted by construction agent. Otherwise, they will not cooperate with each other and the benefit of owner will not be realized.

(3) The relation between the productive share and the monitoring signal is studied. According to (12) and (13), β decreases with increase of δ and β increases with decrease of δ. It indicates that productive share and monitoring signal are correlative in the establishment of a substitute contract. When δ tends to 0, β is determined by the risk abominating degree of the construction agent and environment risk. When δ tends to 1, the productive share is 0, agent-construction contract is only designed by using monitoring information.

4 CONCLUSIONS

Incentive mechanisms and supervision mechanisms of the agent-construction owner's relationship to the construction agent can be combined with each other by principal-agent theory. It can provide beneficial information for the design of an agent-construction contract. Both incentive mechanisms and supervision mechanisms can encourage efforts of construction agents; productive share will increase with a decrease of supervision; and supervision will increase with a decrease of productive share; increasing of a fixed reward has no incentive effect on the efforts of the construction agent.

ABSTRACT

The objective of the paper is to solve the new problems in freeway financial post-evaluation stage. Considering normal operating conditions, major freeway maintenance or expansion construction, Build-Operate-Transfer (BOT), Build-Transfer (BT) etc., an investigation was made on calculating the evaluation periods from 4 circumstances. The influencing factors of the residual value rate include design service life of different freeway structures, recycling of discarded building materials due to scientific advancements, appreciation of scarce resources, and sustainable freeway use. Then, based on current laws and regulations on financial evaluation and freeway post-evaluation in China, with a combination of quantitative and qualitative analysis, a methodology was then developed to calculate the residual value rate. Finally, we demonstrated how to determine the two parameters according the actual situation of Huanghuang (HH) freeway in Hubei province.

Key words : freeway; financial post-evaluation; evaluation period; residual value rate

INTRODUCTION

Economic post-evaluation of a freeway is generally carried out after operation and is seen as an important part of investment decision-making and management. However, new financing modes, such as BT and BOT, freeway major maintenance required ahead of schedule as a result of poor quality, and other new problems have emerged in economic post-evaluation. Hence, it is necessary to investigate the evaluation period (EP) and residual value (RV). With occurrence of situations such as

BOT, major freeway maintenance or expansion construction, there will be a number of evaluation periods, making it difficult to determine the EP. In accordance with relevant laws and regulations, RV of a freeway is usually calculated by qualitative methods. However, considering that different parts of a freeway have different values at the end of EP, the decision of whether or not to adopt quantitative methods to calculate residual value rate (RVR) has a significant impact on the accuracy of results. Wang Mei (2006) pointed out that there are problems in the calculation of EP and RV in financial evaluation of BOT projects. She argued that the operation period had best consistent with the concession period and that calculating RV or not has impacts on evaluation results. But she did not investigate the parameters of calculation. The existing research and practices in economic evaluation (Hui,2001; Ruan,2000; Zhu,2007; Robert,1997; Luenberg,1998) which do not solve these new problems, calculated the two parameters only based on current laws and regulations. In this paper, according to laws and regulations, a methodology combining quantitative analysis with qualitative analysis was developed to calculate EP and RVR.

EVALUATION PERIOD

Economic Evaluation Methods and Parameters of Construction Project (3rd Edition) (EEMPCP) says that the EP of a project in economic evaluation refers to the period for dynamic analysis, including the construction period and operation period. The construction period should be determined reasonably based on the construction time limit or construction plan. The operation period is determined according to the reasonable economic service life of projects (NDRC and MC 2006). EP mostly depends on characteristics of projects and therefore can not be calculated uniformly. In general, a project corresponds to an EP.

In general, the EP is the sum of the construction and operation periods, as shown in Table 1. Compared with the construction period, a number of factors need to be considered to define the operation period. So the EP should be developed based on a variety of factors. Considering the conditions of normal operation, freeway major maintenance or expansion construction, BOT, BT etc., the thesis investigated the calculation of the EP from 4 circumstances.

1)BOT Transfer of Freeway. The freeway transferee recovers its investment and profits through tolling in the toll period. Whether or not to consider the toll period in calculating the EP has great effects on evaluation results. Therefore, the EP should be calculated to the end of toll period, in order to reflect the investors' actual financial situation and to ensure the investors' proceeds in a reasonable scope. Thus, the EP includes the construction period, the operated period and the toll period. The formula is offered in Table 1.

2)Freeway major maintenance or expansion construction happened ahead of schedule during the design service life. This extends its service life. The EP, which includes the construction period, the operated period and the service life after major

maintenance or expansion construction, should be calculated to the extended freeway service life, as seen in Table 1. This helps to maintain the continuity of freeway finance and further study the effectiveness of investment decision-making.

3) Both BOT transfer and freeway major maintenance or expansion construction. Combining the two calculation methods, the EP should be calculated in chronological order. If they happened successively, the EP is calculated to the latter, as seen in Table 1. If they happened simultaneously, the EP could be calculated to the greater one. The formula is given in Table 1.

4) Project financing of BT. After completion the project is transferred to the government from the investors at the agreed price. Then the government operates it. Hence, the EP contains the construction period and the operation period. Under normal circumstances, the operation period is the service life. When freeway major maintenance or expansion construction happens ahead of schedule due to freeway quality, the EP should be calculated to the freeway service life, as seen in Table 1.

Table 1. Calculation Methods of Evaluation Period .

Type	Calculation Method
Normal Situation	$T = T_C + T_O$, T =EP, T_C =construction period, T_O =operation period
BOT Projects	$T = T_C + T_{HO} + T_B$, T_{HO} =the operated period, T_B = the toll period of BOT
Major Maintenance or Expansion Construction of A Freeway	$T = T_C + T_{HO} + T_{MM}$, T_{MM} = the extended service life of freeway after major maintenance or expansion construction
Both BOT and Major Maintenance or Expansion Construction	If the two happened successively, $T = T_C + T_{HO} + T_1 + T_2$, T_1=the interval between the two(namely, the actual period happened), T_2 =the period of the latter(namely, $T_2 = T_B$ or $T_2 = T_{MM}$); If the two happened simultaneously, $T = T_C + T_{HO} + \max\{T_B, T_{MM}\}$
Project financing of BT	$T = T_C + T_O$
Both BT and Major Maintenance or Expansion Construction	$T = T_C + T_{HO} + T_{MM}$

Transfer Rules of Rights and Interests of Toll Roads (TRRITR) says that the cumulative sum of toll periods of toll-repayment road is not more than 20 years (toll-repayment roads from the country's central and western provinces, autonomous regions and municipalities directly under the Central Government, 25 years) and that the cumulative sum of toll periods of operating roads should not be longer than 25 years (operational roads from the country's central and western provinces, autonomous regions and municipalities directly under the central Government, 30 years). According to freeway classification and location region, the longest toll period is selected, that is, the longest operation period, T_O^{max}. In conclusion, the EP is

calculated by the following formula: $T_O \le T_O^{max}$, $T = T_C + T_O$; $T_O > T_O^{max}$, $T = T_C + T_O^{max}$.

In addition, the results of each evaluation require vertical comparison to verify the effectiveness of investment decision-making. Therefore, the current EP should be consistent with the former one. In brief, according to specific circumstances and needs of projects, more than one period can be determined to meet different purposes.

RESIDUAL VALUE RATE

Economic Evaluation Practices of Highway Construction Project (EEPHCP) shows that RV of a freeway generally accounts for 50 percent of the project expenditure, in the form of negative value reckoning in costs(MCs, 1996). But at the end of the EP, different freeways correspond to different RV. The RV of components of a freeway must be estimated in order to improve the accuracy of evaluation.

Different parts of a freeway have different values. In light of particularities of individual freeways, the RVR of a freeway should be calculated by integrating its components' values. The factors variables set of RV, $A = \{a_1, a_2, \cdots\cdots, a_m\}$, was set up where a_i is the initial value of factors variables, m is the number of factors variables. After operation in EP, the freeway value reduces in the overall trend. Then variables set $B = \{b_1, b_2, \cdots\cdots, b_m\}$ was set up, where b_i is the final value of factors variables. This paper selects five variables to calculate RV, such as design service life of different freeway structures, recycling of discarded building materials due to scientific advancement, appreciation of scarce resources, sustainable use of a freeway, and rest value.

1) Design Service Life of Different Freeway Structures. The factor mainly includes the design service life of freeway structures and service area buildings. Individual parts of a freeway vary in their design life, the lowest being 20 years, and the longest, of grand bridges, 100 years. Freeway structures and buildings will depreciate. Then the remaining freeway value which has not depreciated at the end of EP is calculated, i.e. RV of freeway structures and buildings. The formula is presented in Table 2. Financial Management Practices Of the Freeway Company: Adopting the Workload Method, the freeway structures are depreciated without expected RV. The paper adopts a depreciation period of 30 years. The depreciation method used for service area buildings is the Average Period Method, taking a 40-year depreciation period.

2) Recycle Use. With the development of science and technology, the discarded materials of a freeway with recycling values should be classified and recycled, including road pavement and so on. The abandoned pavement can be smashed and processed on-site and used as base course and subgrade or other products. Value of recycle use is calculated in term of market price for various uses and discounted to the base year. The formula is presented in Table 2.

3) Value Appreciation. With economic development land is a scarce resource, and land occupied by freeways is appreciating with time. This appreciation is another

important production factor. Therefore it is necessary to estimate the land value reasonably by the method referring to the estimation model of land prices. Regional population, economy, land area and other factors are considered to amend the growth factors of land prices. Then the land value is discounted to the base year. A specific calculation is offered in Table 2.

4) Continuous Utilization. This type includes the freeway subgrade and so on. Due to continuous development of transportation, traffic demands are on the rise, requiring corresponding traffic supplies. At the end of the EP, the freeway will not be abandoned, but rather will be used continuously, and the life expectancy of the subgrade is greater than 20 years. So the freeway subgrade has both function value and use value and could be used in reconstruction and expended construction. Freeway subgrade does not need depreciation. Value of continuous utilization is calculated according to the construction cost of subgrade in reconstruction or expansion construction of a freeway, discounting to the base year. The formula is provided in Table 2.

Table 2. Calculation of Influence Variable s of Residual Value Rate .

Type	Component	Calculation Method
Design Service life of different structures	Bridge, culvert, tunnel, intersection projects and service area buildings etc.	$b_1 = V_K - \sum_{i=1}^{T-T_C} D_i + D[40-(T-T_C)]$, annual depreciation values of structures $D_i = \frac{V_K}{W} \times \omega_i$, annual depreciation values of buildings $D = \frac{V_K - V_L}{N}$, where, V_K=original value of fixed assets, V_L=expected net residual value of fixed assets, W=predicted traffic volume in depreciation period, ω_i=actual or predicted annual traffic volume, N=depreciation period, other parameters as noted before
Recycle Use	Freeway Pavement etc.	$b_2 = C_{recycle} \times (1+i_d)^{-T}$, $C_{recycle}$=recycle value of pavement, i_d=discount rate
Value Appreciation	Land occupied by the freeway etc.	$b_3 = S \times V_{bm} \times \lambda_{amend} \times (1+i_d)^{-T}$, S=land area, V_{bm}=benchmark land price, λ_{amend}=amended growth factor of land price
Continuous Utilization	Freeway subgrade etc.	$b_4 = C_{subgrade} \times (1+i_d)^{-T}$, $C_{subgrade}$=cost of subgrade in reconstruction and expended construction
Rest Value	Rest projects and facilities etc.	$b_5 = \beta a_5$, β=RV of the rest projects and facilities

RVR is calculated by the following formula.

$$R = \frac{V_K - \sum_{i=1}^{T-T_c} D_i + D[40-(T-T_c)] + (C_{recycle} \times S_{bm} \lambda_{amend} C_{subgrade}(1-i)^{-T_i}) + \beta_d}{\sum a_i}$$

where R is RVR, a_i is the initial value of factors variables, b_i is the final value of factors variables.

CASE STUDY

Project Description

HH freeway has two parts: the mainline from Huangshi to Huangmei and the lateral from Huangmei to Jiujiang Yangtze River Bridge. The freeway was started in November 1996 and put into operation in January 2000. In April 2003, Hubei Provincial Communications Department officially signed the assignment contract with Hong Kong Fude Company. The transfer period of tolling equity is 20 years, beginning January 1, 2003. The expansion construction was started in April 2005 and completed in May 2006. In this study, the mainline will be evaluated as an example.

Financial Evaluation Period

As to the particularity of HH freeway, the transfer of tolling equity and the major maintenance happened successively. In accordance with the foregoing methods, the calculation of the EP should consider the following two aspects.

1) Occurrence of BOT and major maintenance. The major maintenance was carried out in 2005 because of the decline in pavement quality and the service life is 20 years. Based on the above methods, EP is calculated as follows: $T = 3 + 4 + 4 + 20 = 31$ years.

2) In the project feasibility research report, the EP takes on the values of 23 years, of which the operation period is 20 years. Therefore, EP is offered as follows: $T = 23$ years.

HH freeway is located in the central and western regions of China and is considered an operational road. The calculation operation period (28 years) is less than the longest accumulated tolling period of freeway (30 years). Therefore, this paper identified two EPs to carry on financial evaluation respectively, namely: 1) EP I is 23 years, from 1996 to 2018; 2) EP II is 31 years, from 1996 to 2026.

Residual Value Rate

After calculation of the EP, a combination of quantitative and qualitative analysis was used to calculate RVR. Based on the circumstances of HH freeway, five influence variables were taken into account and provided in Table 3. According to the project assets statistics of HH freeway, RVR was calculated, as shown in Table 3.

Table 3. Calculation of Residual Value Rate (Unit: 10 Thousand Yuan).

Type	Initial Value of Variables(a)	Final Value of Variables(b)
Design life of different structures	87472.90	10915.75

Recycle use	45402.90	27468.75
Value appreciation	14215.65	50490.30
Continuous utilization	45170.10	45170.10
Rest value	33589.35	1007.68
Summation	225850.90	135052.59

In accordance with the factual situation of Hubei Province and areas along HH freeway, the aforementioned methods were used to calculate the RV of every factor, and finally RVR is obtained: $R = \frac{135052.59}{225850.90} = 0.589 = 58.9\%$.

Evaluation Parameters and Indicators

Evaluation parameters and indicators are selected in accordance with EEMPCP, EEPHCP, and other relevant laws and regulations. The main indicators adopted by the project are Financial Internal Rate of Return (FIRR), Financial Net Present Value (FNPV), Payback Period (Pt), Loan Repayment Period (Pd) and Financial Benefit-cost Ratio (FBCR)(NDRC and MC,2006;MCs,1996).

Financial Evaluation and Evaluation Conclusion

Financial costs and benefits were calculated. Then annual financial costs and benefits are discounted to the present value of the base year using dynamic discount methods. The discount rate is selected according to the relevant regulations, 6.5%. Finally, financial evaluation indicators were calculated, as given in Table 4. In conclusion, calculating the appropriate EP and RVR, it is proved that the project is feasible from a financial point of view.

Table 4. Values of Main Financial Evaluation Indicators .

Evaluation items	Mainline(1996-2018)		Mainline(1996-2026)	
Evaluation indicators	After income tax	Before income tax	After income tax	Before income tax
Pt (Year)	20.1	17.5	20.1	18.7
FNPV (10,000 Yuan)	38898.0	134347.8	143184.2	432668.9
FIRR (%)	8.47	9.63	11.03	12.22
FBCR	1.11	1.22	1.30	1.50

SUMMARY

Major maintenance or expansion construction of a freeway carried out during the operation period requires substantial funds. As a result, value of the freeway increases and service life is extended. The freeway company could have the right to toll continually, in theory. But as it is a policy-oriented concern, the freeway toll period needs taking into account the national legislation and policies.

If BOT took place before the promulgation of TRRITR and the transfer toll

period of a freeway exceeds the cumulative sum of toll periods by law, there is a conflict between the transfer contract protected by relevant national laws and regulations and TRRITR. Therefore, a post-evaluation period of this type should be further studied.

ABSTRACT

The objective of this paper is to take two typical highways as examples to discuss the applicable principles for the Barrier System and the Closed System which are currently applied to the most toll collection systems of Chinese highways. For the first step, this paper picks out two typical highways from Xinjiang Uygur Autonomous Region highway network. The first highway is the Tulufan to Urumqi (TU) highway whose toll collection system applies the Barrier System. The second highway is the Heshuo to Korla (HK) highway whose toll collection system implements the Closed System. For the second step, this paper analyzes the historical data on the toll systems of these two highways respectively, including the cost of construction and management which was spent on the toll collection system before the year of 2005, the historical data of traffic volume and every year's total charges of these two highways. Based on these data, this paper forecasts the traffic volume, total charges and management cost about these two highways by applying several kinds of forecasting model comprehensively. Fully considering the influence of time value of funds, this paper analyzes the difference of economic benefit between these two types of toll mode. At the end, several applicable principles for the Barrier System and the Closed System are concluded respectively by taking synthetically economic analysis, considering the traffic flow characteristics of these two highways. The initial data of this paper comes from the research report--Toll Collection Technique Research on Xinjiang Uygur Autonomous Region Roads, which is the key research for the Department of Transport of Xinjiang Uygur Autonomous Region.

MAIN IDEA AND ANALYTICAL METHODS

Since the 1980s, traffic mileage of Chinese highway has been grown rapidly. By the end of 2008, the total mileage of Chinese highway has surpassed 60,300 km, ranking second in the world. More than 90% of these highways are toll highways. The discussing objectives of this paper are toll highways, and the following are referred to the highways. At present, the Barrier System and the Closed System are implemented on most of Chinese toll highways. It is showed that the choice of toll

mode has a significant impact on the selection of highway toll collection facilities, and it will affect the whole highway's investment benefit (YANG, 2008).

The initial data of this paper comes from the research report--Toll Collection Technique Research on Xinjiang Uygur Autonomous Region Roads. For the first, two typical highways are selected as analytic objects from Xinjiang Uygur Autonomous Region highway network. The first highway is the Tulufan to Urumqi (TU) highway whose toll collection system applies the Barrier System. The second highway is the Heshuo to Korla (HK) highway whose toll collection system implements the Closed System. For the second step, this paper analyzes the historical data about toll systems of these two highways respectively, including the cost of construction and management which were spent on the toll collection system before the year of 2005. Based on the historical data of traffic volume and total charges of every year, this paper forecasts the traffic volume and total sum of toll about these two highways respectively, applying several kinds of forecasting model comprehensively. Considering the influence of time value of funds and the increase of management cost, this paper obtains the income and expenses of these two highway's toll systems. At last, based on the traffic flow characteristics of these two highways, this paper discusses application principles of the Barrier System and the Closed System.

In short, this article obtains the economic benefits difference between these two kinds of toll mode, and sums up some application principles for these two types of toll mode. It is hoped this article can provide a reference for the highway toll mode selection.

COLLECTED DATA

The highway toll collection facilities mentioned in this paper belongs to subsidiary facilities of highway, including the toll station building, toll plaza and other electro-mechanical Systems.

Kinds of data collected for those two sample highways toll collection facilities by this paper include:

(1) the traffic volume and vehicle composition data for the sample highways;
(2) the sum of toll for the sample highways;
(3) the construction costs and facilities update costs for the samples highways;
(4) the annual management costs for the samples highways;
(5) toll period limited and loan interest for the samples highways.

THE EVALUATION INDICATORS

Because the toll collection facilities are parts of toll highway, toll fees collected by

toll collection facilities are generated by the whole toll highway. According to "the principle of consistency between cost and benefit"(The World Band Research Report (1998)), the toll collection facilities can not be evaluated separately for its investment and economic benefits. So this paper uses such two indicators as net income and ratio of income to expenditure.

(1) Net income

Net income = charges-expenditure, divided into annual net income and total net income of toll period limited separately.

Expenditures include all kinds of cost (including building construction and electro-mechanical Systems investment) and all kinds of the business expenses (including management expenses and interest expense). The level of net income depends on the toll highway's characteristics and the rationality of toll collection facilities. When there are multiple toll modes available, this indicator should play an important role (The World Band Research Report (1998)). The dynamic analysis method of the net present value concept (FNPV) is used in the calculation of net income.

$$FNPV = \sum_{t=1}^{n} (CI - CO)_t (1 + i_c)^{-t}$$

Where: Cl: cash inflow; CO: cash outflow; $(Cl\text{-}CO)_t$: the t years of net cash flows; n: the calculation period the number of years; i_c: discount rate. (The World Band Research Report (1998))

(2) Ratio of income to expenditure

the ratio = Toll station revenue expenditure / Toll station charges, divided into annual ratio and total ratio. The indicator reflects the efficiency of toll station.

The World Bank provided a set of experience data in the assessment report for Jingjintang highway: In the effective operations, the Barrier System ratio of income to expenditure is 5% ~ 10%for the Barrier System and 10% ~ 15% for the Closed System. In poor management the ratio of income to expenditure for the Closed System may be as high as 30%. (The World Band Research Report (1998))

PREDICTION METHOD

In order to predict the total charge of every year for these two highways, multiple linear regression method and Elasticity coefficient prediction are used to predict the increase of area traffic productions and attractions related these two highways. Second, Fratar method is applied in the prediction of the trip distribution. The third, this paper obtains the traffic volume of these two highways by using stochastic user equilibrium model in the traffic distribution. Considering the charge rate of these two highways, this paper works out the total charges of every year about these two highways. Besides, this paper predicts the management cost on the basis of related provisions. At last, this paper obtains the Ratio of income to expenditure of these two

highways' toll system.

CASE STUDY

ANALYSIS OF THE TU HIGHWAY TOLL CLLECTION FACILITIES

The TU highway was opened to traffic in 1998, passing through the city of Turpan and Urumqi. This highway had a dramatic impact on connection between Urumqi and its surrounding cities (YANG, 2006).

After investigation, TU highway traffic flow characteristics are as follows((YANG, 2006):

(1) the traffic flow of Urumqi to Turpan vary from large to small and is composed mainly by long-distance and cross-border vehicles. The AADT of Urumqi to Chaiwopu interchange reaches to the 6000 ~ 8000 pcu/d. However the AADT of Turpan toll station falls to 4000 pcu/d.

(2) Few vehicles pass through the interchanges along this highway. The interchange of Jidong owns the most heavy traffic flow among those interchanges, which can reach 1600 pcu/d. Other interchange's traffic flow are less than 1000 pcu/d y and even some interchange's traffic are less than 100 pcu/d.

After comprehensive analysis, the main economic indicators of the TU highway toll station are showed as follows in table 1 below:

Monetary unit: Million RMB

Toll Station	Traffic Flow(pcu/d)	Total Income FNPV	Total Expenditure FNPV	Ratio of Income to Expenditure
Wulabai Main line Toll Station	7,594	477	64	13.5%
Nanquanzi Main line Toll Station	1,988	610	51	8.2%
Toutunhe Main line Toll Station	5,968	1479	74	5.0%

Table 1: the main economic indicators for the TU highway toll stations

ANALYSIS OF THE HK HIGHWAY TOLL COLLECTION FACILITIES

The HK Highway is an important component of Chinese State Highway 314, whose total length is 92.4km. Its starting point connects with Tuokexun to Heshuo Highway. After comprehensive adjustment, a length of 41.17km highway from Wushitala to

Heshuo is merged into the HK highway. The toll mode of this highway is the Closed System, with a total of seven toll stations and a management center (YANG, 2006).

This highway is the unique highway connecting the northern and the southern of Xinjiang Uygur Autonomous Region across the Tianshan Mountains. Because cities and towns distribute relatively sparsely, the main line traffic flow takes the most portion of total highway volume. The traffic volumes of most interchanges are low, except the interchanges entering the city of Heshuo and Korla (YANG, 2006).

Applying such analytical methods mentioned above, the total net income and total expenditure is 1.35 billion Yuan and 316 million Yuan respectively for the toll period limited of the HK highway, and the ratio of income to expenditure is 18.9%, which is less than optimal operational efficiency. The main economic indicators of the HK highway toll station are illustrated as follows in table 2 below:

Monetary unit: Million Yuan

Toll Station	Traffic Flow(pcu/d)	Total Income FNPV	Total Expenditure FNPV	Ratio of Income to Expenditure
Korla Main line Toll Station	5,343	629.3	62.2	9.9%
Tashidian Ramp Toll Station	715	23	38.5	167.6%
Ziniquan Ramp Toll Station	967	29.5	35.9	121.8%
Yanqi Ramp Toll Station	2,558	166.2	48.8	29.4%
Gaoqiao Ramp Toll Station	607	71.9	36.9	51.3%
Heshuo Ramp Toll Station	722	75.4	39	51.7 %
Heshuo Main line Toll Station	1,649	355.7	54.8	15.4%

Table 2: the main economic indicators for the HK highway toll stations

Supplementary Analysis for Table 2

(1) because the 41.17km of Wushitala to Heshuo highway is merged into this highway toll range, the charge length of the HK highway increases by near 1/3. Therefore, the main economic indicators have been greatly improved. But the management efficiency of this highway is still less than ideal. The conclusion is that

the Closed System does not fit in this highway's traffic flow characteristics and has a negative effect on the HK highway's investment benefit.

(2) The traffic flow of the HK highway is very concentrated, and the traffic volume of interchange along this highway is very small. Among the seven toll stations, Korla Main line Toll Station, Heshuo Main line Toll Station and Yanqi Ramp Toll Station own larger traffic flow and better operational efficiency. The total charge of this three toll stations accounts for 85.2 percent of whole highway income. The charge of other four toll stations is low and operating efficiency is poor. For example, the income of Tashidian Ramp Toll Station is lower than its expenditure and the same situation happens to the Ziniquan Ramp Toll Station. The income proportions of these seven toll station are showed as detailed in Figure 1.

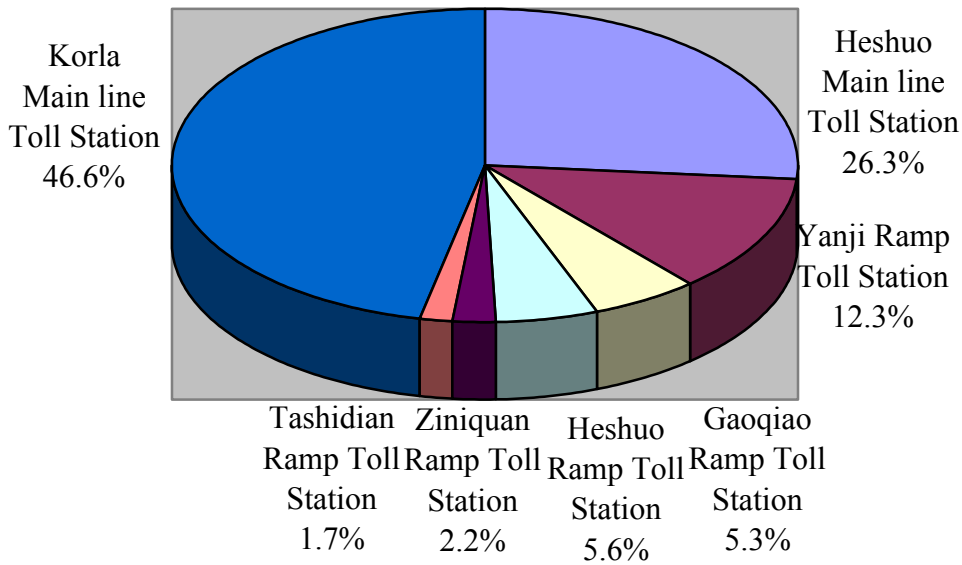

Figure1: The income proportion of the HK highway toll stations

CONCLUSION

Based on the analysis above, this paper obtains two conclusions for the Barrier System and the Closed System:

(1) In the area where cities and towns distribute relatively sparse, the Barrier System is more appropriate than the Closed System. Because the Barrier System's economical efficiency is good than the Closed System. As long as there is no major turning traffic flow, the toll range of the Barrier System toll station should be extended as far as possible to reduce its ratio of income to expenditure. On the other side, in the areas where the cities and road network are relatively intensive, the Closed System is a more reasonable choice. It is suitable for highway whose traffic

flow distributes more evenly and the traffic volume of every interchange along the highway is relatively large.

(2)If the traffic flow has such characteristics as cities and towns along the highway distribute relatively sparsely, main line traffic flow of the highway is low and most of interchanges traffic flow except connection with large and medium-sized cities is very small, the highway toll system should adopt the Barrier System. The Barrier System applied in the TU highway match the characteristics of the highway, so its economic indicator is well. On the other hand, the HK highway toll system's economic indicator is not ideal because the Closed System does not match with the highway traffic flow characteristics. To sum up, different kinds of toll model play an important influence on the highway's investment benefit. All in all, highway toll system should be carefully chosen in order to enhance the highway's investment benefit, based on the characteristics of the highway's traffic flow.

ABSTRACT

During the Olympic Games, Beijing implemented a series of transport demand management (TDM) measures that have effectively reduced traffic congestion. It would be useful if we could get a clearer understanding of behavior changes in the influence of TDM measures. Drawing on data from the household interview travel survey, this paper analyzes the travel behavior changes of Beijing residents under the influence of TDM. Data concerning trip rate, trip purpose, ridership of motor vehicles, mode share, and travel time were collected to reflect travel behavior changes. The accumulated travel behavior data will help long-term TDM measures research.

INTRODUCTION

The Beijing 2008 Summer Olympic Games were held from August 8 to August 24 and placed Beijing in the world spotlight. The Beijing 2008 Olympic Games have completed successfully. During the 16 days of competition, hundreds of thousands of visitors flooded to Beijing, presenting a challenge to the urban transport system. There were more than 200 International Olympic Committees, more than 5,000 officials of 28 events, more than 16,000 athletes and 2,500 team officials, more than 22,000 members of the media and 40,000 sponsors, more than one million staff and volunteers, and more than 6 million spectators (Beijing Transportation Research Center 2008, Yan 2008). At the same time, with the urban population and the ownership of motor vehicles increasing rapidly, traffic congestion in Beijing is becoming heavier. Coordinating the huge Olympic transport demand along with the daily travel demand of local residents is one of the most important things. From other countries' experiences, we find examples; the Atlanta Olympic Games implemented reducing commuter travel, and the Sydney Olympic Games implemented a free public transport policy, increased parking fees, etc. Based on the experiences of these countries holding mega events, implementing transport demand

management (TDM) measures is a good solution to transport system (Guo, J. *et. al.* 2008).

During the Olympic Games, Beijing implemented a series of TDM measures from Jul. 20 to Sep. 20, including the following: stopping all registered motor vehicles according to the last number of the license; odd number motor vehicles running only on odd days, and even number vehicles running on even days; motor vehicles owned by the Beijing government and company reduced by 70% of total numbers; and the establishment of a prohibited area within the 5th ring road of Beijing city proper area (Beijing Municipal Committee of Communications 2008).

The TDM measures greatly affected the people's travel behavior. It would be useful to get a clearer understanding of behavior changes resulting from the TDM measures. Drawing on data from the household interview travel survey, this paper analyzes the travel behavior changes of Beijing residents under the influence of TDM. Trip rates, trip purpose, occupancy rate of motor vehicles, mode share, and travel time were collected to reflect travel behavior changes. The accumulated travel behavior data also will help to long-term research of TDM measures.

QUESTIONNAIRE SURVEY

The Beijing household interview travel survey was a cross-sectional travel-diary survey of household travel behavior changes in Beijing before and under Olympic TDM measures. The household interview survey was carried out during two periods. The first survey period ran from May 10 to 28 without TDM measures, and the second survey period was from Aug. 8 to 28, during Olympic Games with TDM measures.

Sample size

The sample size was about 3600 households (net response) for each period. The survey compiled data on travel behavior, providing information on approximately 18,000 trips made by 10,000 individuals during each period.

Survey scope

The samples were distributed at random within the 5th ring road of Beijing city proper area, shown in Figure 1.

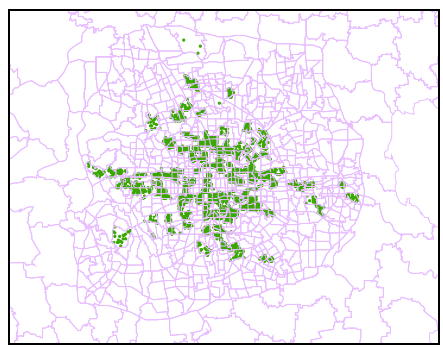

Figure 1. survey samples distribution.

Questionnaire includes three kinds of data:

- Basic household information, including household members, age, occupation, income, car ownership, etc.
- Travel diary of days during which car use is limited for household members, including travel time, trip purpose, travel mode, etc.
- Travel diary of days during which car use is permitted for household members, including travel time, trip purpose, travel mode, etc.

HOUSEHOLD BASIC INFORMATION FROM SURVEY

Car ownership rate

There are 35.6% households owning cars from survey data. Of these, 96% households have only one car; 4% households have more than one car..

Age distribution

Participants ranging from 26 to 55 years old account for 60% of the samples and within this age range, and 45 to 55 years old participants cover the highest proportion, accounting for 25%. Moreover, survey data indicates that middle-aged (35-55 years old) persons are the primary group of car users.

Occupation distribution

Occupation in the questionnaire includes worker, government staff, student, teacher, retiree, professional driver, police, independently employed, and unemployed person. The top three occupations of car owners within the samples are government staff, independently employed, and worker, which accounts for 87.2% of the total. Notably, government staff owned cars account for 60.2%, followed by those independently employed, accounting for 16.8%.

Household income distribution

From the survey data, we found that groups owning cars are high-income groups. In the samples, groups having monthly household income of 3,500-5,500 RMB Yuan reach 40.7%. Groups having monthly household income of more than 5,500-10,000 Yuan account for 30.1%.

TRAVEL BEHAVIOR CHANGES UNDER TDM MEASURES

TDM measures have triggered changes in daily travel patterns. For example, changes in trip rate, trip purpose, trip destinations choice, and travel mode choice were noted (Gärling 2002, Loukopoulos 2005).The survey results show travel behavior changes under car-use-restriction during Olympic Games.

Average trip rate of residents

Survey data indicated that average trip rate of all residents generally reduced from 1.88 times/day to 1.70 times/day under TDM measures, or a 9% decline. In particular, trip rate change of persons with cars was most apparent, from 1.9 times/day to 1.61 times/day, a 15.3% decrease; the trip rate among persons without cars fell by only 5.4%.

Comparison of car limited running and permitted running day

Moreover, there were different results when cars were limited or permitted. When car use was limited, it presented much travel inconvenience to car users. The trip rate was 1.59 times/day when car was limited, while 1.76 times/day when car was permitted, accounting for a 9.6% reduction in use when cars were limited.

Comparison of different occupations

From the survey data, we concluded that different occupations have different trip rates, mainly shown in Figure 2.

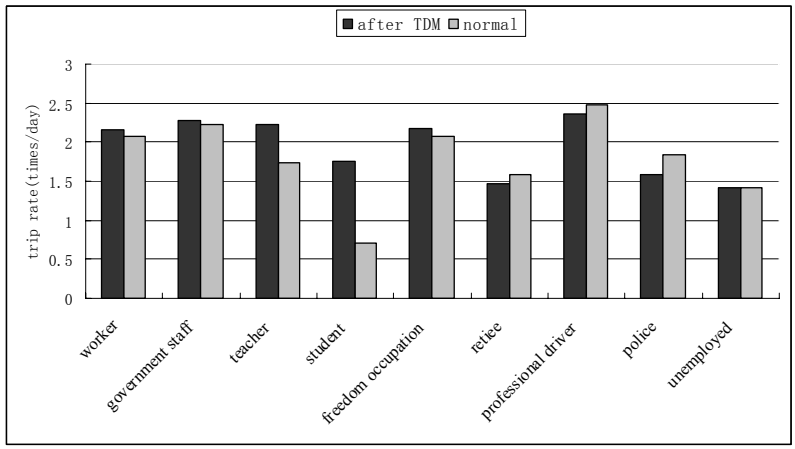

Figure 2. Trip rate changes by occupation under TDM measures.

The trip rates of worker, government staff, teacher, student, freedom occupation and unemployed persons decreased. Most notably, the trip rate of students declined significantly, from 1.75 times/day to 0.70 times/day, because temporary vacation policies were carried out for less school-related travel. School vacation schedules were prolonged according to the Olympic Games, and students enjoyed their Olympic vacation from June 28 to August 31. Trip rates of full-time drivers, police, and retiree increased a little, by about 10%. The reason for this was that use of motor vehicles owned by the Beijing government and company was reduced by 70%, which resulted in an increase in the trip rate of full-time drivers. Moreover, in order to achieve the "peace Olympics" goal, more security measures and volunteer missions resulted in the trip rate of police and retirees increasing.

Car using characteristic changes: Car using rate

Generally speaking, rate of car use declined under the influence of TDM measures. The use rate of private cars reduced from 2.26 times/day to 2.22 times/day, accounting for a 1.8% reduction. While the use rate of official car increased from 2.62 times/day to 3.32 times/day, accounting for a 26.7% increase, fewer cars were given almost the same assignments because motor vehicles owned Beijing Government and company were reduced by 70% of total numbers.

Car using characteristic changes: Ridership rate of car

Because half of the total number of cars were limited every day during the

Olympic Games, car-pooling became more popular. Ridership rates of car increased under TDM measures. Ridership of private cars increased from 1.17 persons/car to 1.27 persons/car; ridership rate of official cars increased even more, from1.19 persons/car to 1.51 persons/car.

Trip purpose

Trips are commonly divided into mandatory trips and elastic trips. From the survey data, we found that the proportion of mandatory trips increased, such as work commuter travel, while elastic travel decreased, such as shopping, leisure, work-related business, etc. Elastic trips accounted for 40% of the total reduced trips, shown in Figure3.

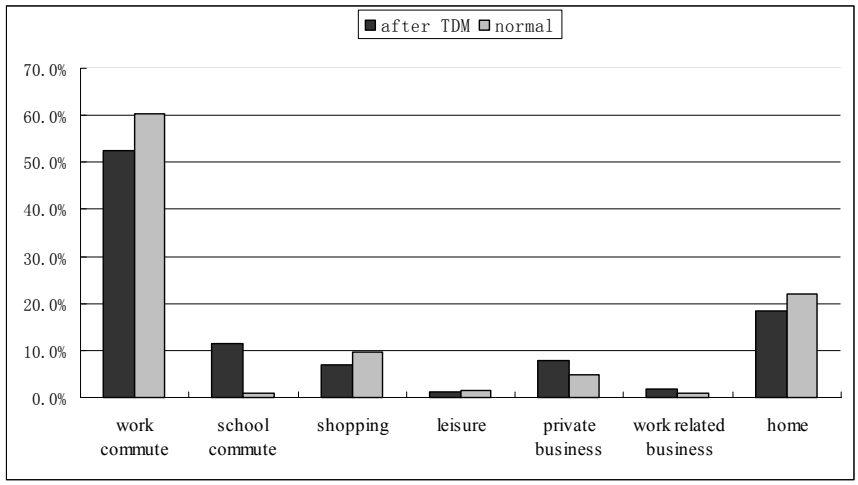

Figure 3. Trip purpose changes under TDM measures.

Mode share

Car-use-restriction policy resulted in obvious changes to mode share, namely a sharp decline in car share and promotion of the use of mass transit, such as bus and metro. In conclusion, bus, metro and bicycle became the major alternative travel modes. When the car was permitted, car share of car-owners reached 94.2%. When the car was limited, bus share increased 32.8%, bicycle share increased 22.5%, walk share increased 11.3%, metro share increased 9.4%, and taxi share increased 7.3%. Figure 4 shows the mode share shift under TDM measures influence.

Moreover, the shift of transport mode differs slightly for different travel purposes. For example, mass transit was the major alternative to commuting trips, taxi was the main alternative to work-related business trips, while bus and bicycle were the main alternative modes to private business trip.

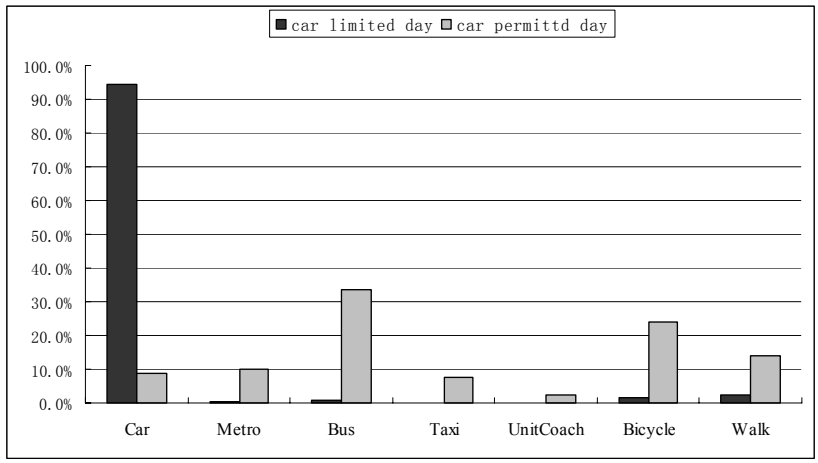

Figure 4. Trip purpose changes under TDM measures.

Travel time

Car and bus travel time shortened by 8 minutes under the TDM measures, and metro travel time decreased by 12 minutes. Table 1 lists the travel time changes during the AM peak period under TDM measures.

Table 1. Travel time changes in AM peak period under TDM measures

Travel time (min)	car	metro	bus	bicycle	walk
Normal	44.6	72.6	63.5	21.4	12.1
After TDM	36.2	60.5	55.1	21.7	11.1

CONCLUSION

The implementation of TDM measures during the Olympic Games has effectively reduced urban traffic congestion and ensured Olympic transport success. The traffic volumes of road networks decreased by 23% and the average travel speed of road networks increased by 26.9%, reaching 30.2 km/h in AM peak period. The passenger volumes reached 15 million per day for bus systems and 3.8 million per day for metro systems, accounting for 15.3% increases.

Also, drawing on data from the household interview travel survey before and after TDM measures, we determined the travel behavior changes of Beijing residents under TDM influence. We found that the residents' average trip rate fell from 1.88 times/day to 1.70 times/day. Moreover TDM measures have considerable effects on car-owners, whose average trip rate fell from 1.90 times/day to 1.59 times/day. The use rate of private cars declined 0.07 times/day and the ridership rate increased 0.10 person/car, while the official cars' use rate increased 0.70 times/ day and ridership rate increased 0.32 person/car. The implementation of TDM measures changed travel patterns and modified travel demand. Trips for schooling, shopping and leisure purposes decreased. The mode share of public transport increased sharply.

The travel time of subway, bus and car decreased by 12 min., 8 min., and 8 min., respectively.

In conclusion, Beijing hosted a special and successful Olympic Games and left a unique transport legacy to China and to the world.

ABSTRACT

Making use of bus lanes' excess capacity by opening them to carpool vehicles is a method that can effectively mitigate traffic jams and improve the operating efficiency of roads. In order not to influence buses' operation in bus lanes, congestion pricing is needed to regulate the volume of carpool vehicles in bus lanes. This paper analyzed the travel choice between carpool vehicles and single-occupancy vehicles when congestion pricing is used in bus lanes, and then proposes the congestion pricing model, in which the lowest average people cost and maximum road operating efficiency are the upper-layer objective model and the user equilibrium is the lower-layer objective model. The objective function of the model was solved by an advanced heuristic solution algorithm based on sensitivity analysis. Finally, a simple numerical example is given to illustrate the proposed model and algorithm.

INTRODUCTION

With the rapid increase in the number of the urban vehicles, the limited road traffic resources are becoming more and more strained. The problems of traffic congestion, traffic pollution, and traffic safety, which are caused by the large number of travelers' trips, have also become important restrictive factors in cities' development. Devoting major efforts to develop urban public transport is one of the most effective measures to solve the problem, and the operating efficiency of buses is further improved by opening bus lanes to give the exclusive right-of-way to the buses. However, during peak periods it is not uncommon to see fewer buses in bus lanes and excessive private vehicles in other lanes, reducing the total efficiency of the road system. Allowing carpool vehicles to take advantage of the excess capacity of the bus lanes can effectively alleviate the problem of congestion and improve the efficiency of the road operation. This paper proposed a travel choice model of travelers following research of traffic impedance and utility function, and then put forward the two-layer congestion pricing model, in which the lowest average people cost and maximum road operating efficiency are the upper objective function and the user equilibrium model is the lower objective function. The influence of traffic congestion pricing on travelers' model choice and road operation efficiency is analyzed by the advanced heuristic solution algorithm based on sensitivity analysis.

UTILITY ANALYSIS OF THE METHOD

The method of carpool vehicles using excess capacity of the bus lanes combines bus lanes and pricing strategies by allowing carpool vehicles carrying more than two passengers to gain access to bus lanes by paying a toll.

Figure 1 illustrates how the concept of excess capacity for bus lanes can be used to manage overall roadway congestion. The excess capacity is the white gap from the curve line to the top. The key to effective use of this strategy is to actively manage, using dynamic toll collection, how many vehicles can use the excess capacity. The traveler has the option of paying for a congestion-free restricted freeway lane or traveling freely on a congested general purpose freeway lane.

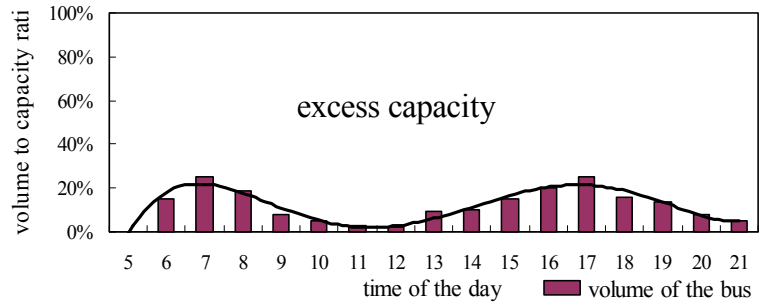

Fig 1. The excess capacity of bus lane.

When the method is applied, the toll-paying carpool vehicles move into bus lanes and the demand on the mixed flow lanes is reduced, as shown in Figure 2. The initial maximum delay is the upper dashed horizontal line. After the carpool vehicles move to the bus lanes, the maximum delay is reduced to a portion of that line. The total delay is reduced by the area between the initial and final demand, and the traffic congestion disappeared earlier than ever.

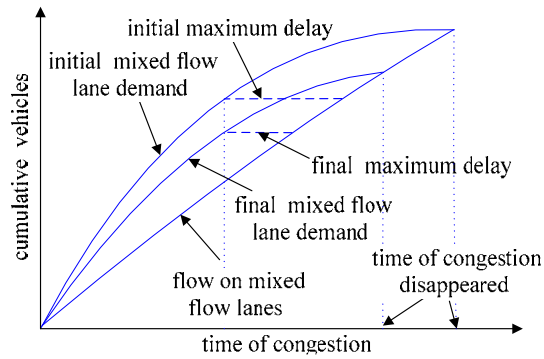

Fig 2. The utility of the method for reducing the traffic congestion.

The intent of the method is not to force individuals to make changes against their will. Rather, the objective is to provide a cost-effective travel alternative that a significant volume of commuters will find attractive enough to change from driving alone to use a carpool vehicle mode. So, with both travel time savings and more predictable travel times, the person-movement capacity of the roadway is increased by carrying more people in fewer vehicles.

THE ANALYSIS OF IMPEDANCE AND TRAVEL CHOICE

Impedance Function

By empirical formula (Wu 2008) and considering the influences among the different types of vehicles in different lanes, we get the impedance function as:

$$t_{k1g1} = t^0_{k1g1}[1+\alpha_{11}(f_{k1g1}/c_{k1})^{\beta_{11}}]\times[1+\alpha_{12}(f_{k1g2}/c_{k2})^{\beta_{12}}]+u_{k1g1} \quad (1)$$

$$t_{k1g2} = t^0_{k1g2}[1+\alpha_{21}(f_{k1g1}/c_{k1})^{\beta_{21}}]\times[1+\alpha_{22}(f_{k1g2}/c_{k1})^{\beta_{22}}]+u_{k1g2} \quad (2)$$

$$t_{k2g2} = t^0_{k2g2}[1+\alpha_{31}(f_{k2g2}/c_{k2})^{\beta_{31}}]\times[1+\alpha_{32}(f_{k2g3}/c_{k2})^{\beta_{32}}]+u_{k2g2} \quad (3)$$

$$t_{k2g3} = t^0_{k2g3}[1+\alpha_{41}(f_{k2g2}/c_{k2)}^{\beta_{41}}]\times[1+\alpha_{42}(f_{k2g3}/c_{k2})^{\beta_{42}}]+u_{k2g3} \quad (4)$$

Where k is the type of the lanes, *k1* represents mixed flow lanes, *k2* represents bus lanes; g is traffic modes, *g1* represents the mode of single-occupancy vehicle, $g2$ represents the mode of the carpool vehicle, *g3* represents the mode of the bus; t_{kg}, t^0_{kg} are the traffic impedance and the free flow time of the traffic mode type g in lane type k; f_{kg}, u_{kg} are the traffic volume and the congestion toll rate of the traffic mode type g in lane type k; α、β are the regression parameters, often taken value of 0.15 and 4, respectively.

Travel Choice Model

A disaggregate modal-split model can be used to analyze the relationship between the traffic mode split rate and the congestion toll rate (Xu 2008). The probability of the traveler choosing traffic mode i is as:

$$p(i) = e^{U_i}/\sum_{i=1}^{4} e^{U_i} = e^{\xi_i+mF_i^*+nB_i^*+kT_i^*}/\sum_{i=1}^{4} e^{\xi_i+mF_i^*+nB_i^*+kT_i^*} = e^{-\theta t_{kg}}/\sum_{k\in K}\sum_{g\in G} e^{-\theta t_{kg}} \quad (5)$$

where F is the cost that can be saved under the condition of traffic congestion tolls; B is the ratio between economic profit and personal income; T is the cost that can be saved when choosing one type of traffic mode; ξ_i is the constant for model adjustment; m, n, k denote respectively the constant of toll rate, economic benefit, and travel time; θ is an nonnegative constant, represent the travelers' comprehensive degree of travel cost.

BI-LEVEL MODEL OF TRAFFIC CONGESTION

Upper Model (P1): $$\min F(u) = \sum_{k\in K}\sum_{g\in G}\lambda_g f_{kg}(u) t_{kg}(f_{kg},u) \quad (6)$$

$$s.t. \quad u_{kg} \ge 0;\ \sum_{k\in K} d_g f_{kg} \le C_k;\ f^{\min}_{bus} \le f_{k2g3} \le f^{\max}_{bus} \quad (7), (8), (9)$$

where λ is the weight coefficient, it is proportional to the average number of passengers of the vehicle type g; d_g is the equivalent conversion factor to a standard vehicle; $f^{\min}_{bus}$ and $f^{\max}_{bus}$ are the lower limit and upper limit of the volume of the buses.

Lower Model (P2): $$\min Z = \frac{1}{\theta}\left\{\sum_{k\in K}\sum_{g\in G}[\Gamma_g f_{kg}(\ln f_{kg} - 1)] - \sum_{g\in G}[\Gamma_g q_g(\ln q_g - 1)]\right\}$$

$$+\sum_{g\in G}\Gamma_g \Phi_g(u_g + y_g)q_g - \sum_{g\in G}\Gamma_g\int_0^{q_g}[D_g(f)]^{-1}df + \int_0^{q} t(f)df \quad (10)$$

$$s.t. \quad \sum_{g\in G} q_g = \sum_{k\in K}\sum_{g\in G} f_{kg};\ \ q_g \ge 0;\ f_{kg} \ge 0 \quad (11), (12), (13)$$

where Γ_g is the influence coefficient of the vehicle of the traffic mode type g

compared with standard car to traffic flow; q_g is the volume of the traffic mode type g; Φ_g is the conversion factor between toll and time value; y_g is the sum of travel costs and individual preference costs of the vehicle of the traffic mode type g; D_g is travel demand function of traffic mode type g.

HEURISTIC ALGORITHM BASED ON SENSITIVITY ANALYSIS

Sensitivity Analysis

In the problem of bi-level programs, it is necessary to gain a feasible descending searching direction when solving upper-level problems, which requires the gradient to decision variable from the objective function (Zhou 2001).

Make the decision variable u of upper-level as the lower-level's disturbing variable of users' equilibrium distribution, then derive the gradient ${}^{u}_{\Delta}f$ of f to u by sensitivity analysis. Using Kuhn-Tucker's first condition, for a given solution u^0 of upper-level problem, $(\mathbf{f}^{*T}, \mathbf{m}^{*T}, \mathbf{I}^{*T})$ is made as the optimal path volume and Lagrange multiplier vectors of lower-level problem .Because the Lagrange multiplier vector has no effect, assume it as 0. So Kuhn-Tucker's condition can be simplified as:

$$\ln f_{kg}{}^{*} + \theta \sum_{g \in G} \Phi_g (u_g + y_g) q_g + \int_0^q t(f)df - m_k{}^{*} - l^{*} = 0, k \in K, g \in G; \tag{14}$$

$$\sum_{k \in K} \sum_{g \in G} f_{kg}{}^{*} - C_k = 0; \quad \sum_{k \in K} \sum_{g \in G} f_{kg} = \sum_{g \in G} q_g = q \tag{15), (16}$$

where q_g is related to cost vector $\mathbf{u}$, multiplier l, and $m = (m_1, m_2, \cdots)$, so to simplify, the above equations can be represented by vectors as:

$$\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0}) - A^{T}\mathbf{m}^{*} - B^{T}\mathbf{I}^{*} = 0, \quad A\mathbf{f}^{*} - \mathbf{C}^{*} = 0, \quad B\mathbf{f}^{*} - \mathbf{q}(\mathbf{u}^{0}, \mathbf{m}^{*}, \mathbf{I}^{*}) = 0 \tag{17}$$

$\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{*})$ is the vector composed by element of $\ln f_{kg}{}^{*} + \theta \sum_{g \in G} \Phi_g (u_g + y_g)$,

let: $\mu = \begin{vmatrix} \mathbf{m} \\ \mathbf{I} \end{vmatrix}$, $\Lambda = \begin{vmatrix} A \\ B \end{vmatrix}$, $z(\mathbf{u}^0, \mu^0) = \begin{vmatrix} \mathbf{k} \\ \mathbf{g}(\mathbf{u}^0, \mu^*) \end{vmatrix}$,

then: $\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0}) - \Lambda^{T}\mu^{*} = \mathbf{0}$, $\Lambda\mathbf{f}^{*} - \mathbf{z}(\mathbf{u}^{0}, \mu^{*}) = \mathbf{0}$ (18)

The Jacobian matrix of $(\mathbf{f}^{T}, \mu^{T})$ at $\mathbf{u}^0$ of the equation mentioned above is:

$$J_{f,\mu}{}^{*} = \begin{vmatrix} {}^{f}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0}) & -\Lambda^{T} \\ \Lambda & -{}^{\mu}_{\Delta}z \end{vmatrix} \tag{19}$$

let: $[J_{f,\mu}{}^{*}]^{-1} = \begin{vmatrix} J_{11} & J_{12} \\ J_{21} & J_{22} \end{vmatrix}$, according to the formula of inverse matrix:

$$J_{11} = {}^{f}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0})[I + \Lambda^{T}J_{21}], \quad J_{12} = {}^{f}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0})\Lambda^{T}J_{22}, \tag{20), (21}$$

$$J_{21} = -J_{22}\Lambda {}^{f}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0}), \quad J_{22} = [-{}^{\mu}_{\Delta}z + \Lambda {}^{f}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0})\Lambda^{T}]^{-1}, \tag{22), (23}$$

I represents the proper dimension unit matrix in the above formula. For ${}^{f}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*}, \mathbf{u}^{0})$ is a diagonal matrix containing diagonal element $1/f_r^{w^*}$, it must be positive definite. According to the quantitative method of nonlinear programming in sensitivity analysis,

Then: $\begin{vmatrix} {}^{u}_{\Delta}\mathbf{f} \\ {}^{u}_{\Delta}\mu \end{vmatrix} = -J^{*}_{f,\mu}{}^{-1} J^{*}_{u}$;

$$ {}^{u}_{\Delta}\mathbf{f} = -J_{11}\ {}^{u}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*},\mathbf{u}^{0}) + J_{12}\ {}^{u}_{\Delta}z(\mathbf{f}^{0},\mu^{*}) \quad (24) $$

$$ {}^{u}_{\Delta}\mu = -J_{21}\ {}^{u}_{\Delta}\mathbf{\Phi}(\mathbf{f}^{*},\mathbf{u}^{0}) + J_{22}\ {}^{u}_{\Delta}z(\mathbf{u}^{0},\mu^{*}) \quad (25) $$

Because of positive definiteness of the matrix, the derivative above exists (Tobin, 1988). Thus the heuristic algorithm based on sensitivity analysis can be used to solve the problem of a bi-level program.

Heuristic Algorithm Based on Sensitivity Analysis

For the obtained solution $\mathbf{u}^{0}$, solve the lower-level problem and get the corresponding solution $v(\mathbf{u}^{0})$,then linearize the upper-level problem at $\mathbf{u}^{0}$and get the linear programming problem as (LP1),

$$ \min\left|\partial\mathbf{F}(\mathbf{u}^{0})/\partial\mathbf{u} + (\partial\mathbf{F}/\partial f)\,{}^{u}_{\Delta}f(\mathbf{u}^{0})\right|^{T}(\mathbf{u}-\mathbf{u}^{0}) \quad \text{s.t.}\ \ \mathbf{u}^{\min} \le \mathbf{u} \qquad (26),(27) $$

Solving the linear programming problem above yields the optimal solution $\mathbf{u}'$, $\mathbf{u}'$–$\mathbf{u}^{0}$ is the feasible descending direction. Finally, we get the heuristic algorithm of bi-level programming problem, the algorithm steps are as:

Step 1 Give an initial structure of congestion pricing u which is feasible;

Step 2 Solve problem (P2) with **u**, then we can get f;

Step 3 Calculate the information of sensitivity analysis ${}^{u}_{\Delta}f$;

Step 4 Linearize the problem (P1) at **u**, we can get the problem (LP1);

Step 5 Calculate $\mathbf{u}: = \mathbf{u} + \alpha(\mathbf{u}'–\mathbf{u})$, which α is the step size in search;

Step 6 If the **u** is closed enough at two adjacent times, iterative is end; if not, return to step2.

NUMERICAL EXAMPLE

Supposing the road is composed of mixed flow lanes and bus lanes, the types of vehicles driving in the lanes are composed of: single-occupancy vehicles, carpool vehicles and buses. t^{0}_{k1g1}, t^{0}_{k1g2} are equal to 8unit time value t^{0}_{k2g2}, t^{0}_{k2g3} are equal to 6 unit time value; λ_{g1}=1, λ_{g2}=3, λ_{g3}=50; c_{k1}=400, c_{k2}=500. In a peak hour, supposing the initial volume of the single-occupancy vehicles, carpool vehicles and buses are 300, 200, and 10, respectively, the simulation results of the model are as follows:

Table 1. Traffic flow distribution and the optimal toll with different θ

θ	Optimal toll	f_{k1g1}	f_{k1g2}	f_{k2g2}	f_{k2g3}
0.1	3	300	158	42	10
0.5	2.1	280	155	65	10
2	1.9	230	187	83	10

Table 2. The volume ratio of different vehicle types with different θ

θ	the volume ratio of different vehicle types		
	single-occupancy vehicle	carpool vehicle	bus
0.1	60%	38%	2%
0.5	56%	42%	2%
2	46%	52%	2%

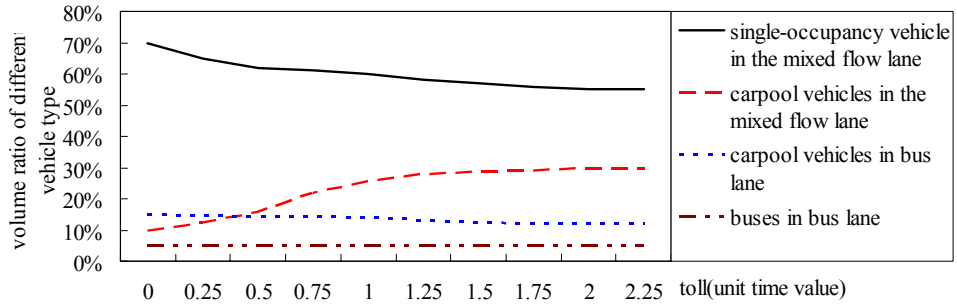

Fig 3. The volume ratio of different vehicle types with different toll rate.

From the tables and the figures above, it is clear that: (1) With the increase of θ, more travelers convert from single-occupancy vehicles to carpool vehicles, because the more the travelers learn about the traffic situation the better they can choose the most suitable trip modes to avoid traffic jams. Therefore it is important to provide real-time information to travelers. (2) With the increase of toll, the number of carpool vehicles converting to the bus lanes reduced, and when the toll decreased the situation reverses, so the toll is an effective way to regulate the number of carpool vehicles in bus lanes .

CONCLUSION

In this paper, we proposed that carpool vehicles utilize excess capacity of bus lanes as well as the implementation of congestion pricing in order to to regulate the number of carpool vehicles in bus lanes. We then put forward a bi-level programming model, using an advanced heuristic solution algorithm based on sensitivity analysis to solve a numerical example. The paper found that traffic volume changes with the changing of θ and toll, and the optimal toll in the condition of different volumes is also supposed. The method and the model proposed by the paper are therefore practical.

ABSTRACT

Based on the viewpoint of system theory and synergetics, this paper advocates the coordinated development among transportation modes and cooperation among modes. According to the component of every transportation mode, an index system was built up from quantity and quality aspects, and principal component analysis was used to evaluate the development level of every mode from 1995-2005. Then the model of degree of membership was established to evaluate the coordinated state among modes. The results indicate that the average static coordinated degree is 0.298, and that all modes develop quickly, but their developments are not coordinated. The ways to change the situation are to develop a united development plan, combine policies, and exploit and use all modes fully, building a true comprehensive transportation hub and so on.

0 INTRODUCTION

In recent years, five transportation modes have made substantial progress and have exerted the best history role. But a misbalanced comprehensive transportation system is still prominent, and does not correspond with the development of a national economy, for each transportation mode emphasizes its own benefits. These affect the system's exerting function, so promoting more coordinated development needs to be a priority. The coordinated development of a comprehensive transportation system includes three aspects, which are the coordinated development between the system and economy, among transportation modes, and among sub-systems of every mode. This paper only studies the coordinated development among transportation modes.

Numerous scholars have contributed research on the coordinated development of comprehensive transportation systems, but the results are not abundant. Zhang et al. (2002) theoretically discussed the coordinated development of transportation systems, but a suitable method does not now exist to realize quantitative evaluation according to his viewpoint. Xiong et al. (2006) used DEA to quantitatively evaluate the coordinated development state among transportation modes, but the indexes chosen were too simple. Xu et al. (2003) quantitatively analyzed the principle and character of the coordinated development among transportation modes. This paper builds upon previous research by systematically setting up an index system that can reflect the developing level of every transportation mode from the angle of its composition, and according to system theory and synergetics, attempts to analyze the principle and evaluate the state of the coordinated development among modes.

1 COMPONENT OF TRANSPORTATION MODE

To analyze the principle and evaluate the state of coordinated development among transportation modes, every mode is separated into five sub-systems from the angle of its component in the paper: (1) Route infrastructure sub-system (RIS), for example, aviation routes, shipping routes, highways, railways, and pipelines;(2) transportation infrastructure sub-system (TIFS), which provides conditions for the transportation instrument's working normally on the route, mainly including stations, hubs, monitoring facilities, communication facilities, and other auxiliary facilities; (3) transportation instrument sub-system (TISS), which is set up around the transportation instrument's operation; (4) transportation human resources sub-system (THRS), which includes all kinds of personnel relating to transportation supply; and (5) transportation software sub-system (TSS), which includes transportation organization and management, traffic science, technology and others.

2 PRINCIPLES ON COORDINATED DEVELOPMENT AMONG TRANSPORTATION MODES

In accordance with system theory, character, function, and move law of a system shows only as a whole. If all elements of one system cooperate with each other, the function of the whole system is greater than the sum of every element's function. Therefore, in order to have the transportation system's function optimized, the coordinated development among transportation modes is necessary.

Synergetics puts forward that the function which one system displays is the result that its sub-systems reach the synergetic state by self-organizing under some condition. In the self-organizing process, the coordinated development among sub-systems plays a decisive role in realizing the system's order, and there are several key factors, called order parameters, which indicate the ordered structure and type of a system and display the sum of all sub-systems' contributions to the synergetic movement. So if order parameters are found, the developing state of a system can be described. According to synergetics, under the conditions of a market economy, the self-organization among five transportation modes is the process that each of them develops in its own proper field and they cooperate with each other in some fields, and that any of them cannot finish tasks individually at the same time, ultimately making the transportation system more and more ordered as a whole.

Summarizing the above analysis, the coordinated development among transportation modes is not that they develop complying with the stable static proportion, but the developing trends that they adapt to, promoting and cooperating with each other to realize the overall objective of the system. Based on this, the paper attempts to make successive research.

3 DEVELOPING LEVEL INDEX SYSTEM OF TRANSPORTATION MODE

According to the layer, system, reality, representation, and other principles, the indexes which can describe the state of every mode's sub-systems and every whole mode are chosen from the quantity and the quality aspects—because pipeline transportation has little relationship with the other four modes and in order to simplify the calculation, it is not addressed in this paper. Moreover, the indexes of TSS are very difficultly divided into the quantity indexes and the quality indexes, so

they are not chosen separately. The index system is shown in Table 1.

Table 1. Developing level Index system of transportation modes.

		Quantity index	Quality index
Railway	RIS	Length of national railways in operation	(Double tracking,automatic blocking) length proportion of national railways in operation, railway density
	TIFS		
	TISS	(Locomotives, passenger coaches, freight cars) number of national railway	(Diesel locomotives, electric locomotives, berth coaches, non-general freight cars) proportion of national railway, technical speed of passenger (freight) trains of national railway
	THRS	Number of staff and workers	Average wage of staff and workers
	TSS	(Punctuality rate at departure, punctuality rate in running, traveling speed)of passenger (freight) trains of national railway, daily distance per passenger (freight) locomotive of national railway, average transport distance of passengers(freight)	
	Whole mode	Passenger (freight) (traffic, ton kilometers), fixed assets investment	{ Passenger (freight) (traffic, ton kilometers)} proportion
Highway	RIS	Length of highways, highway and bridge construction investment	Expressway proportion, highway density
	TIFS		
	TISS	Possession of (civil vehicles, trucks, civil passenger vehicles), possession of (vehicles, trucks, passenger vehicles) for highway transportation	Proportion of (large passenger vehicles, non-ordinary trucks)for highway transportation
	THRS	Number of staff and workers	Average wage of staff and workers
	TSS	Average transport distance of passengers(freight)	
	Whole mode	Passenger (freight) (traffic, ton kilometers), highway construction investment	{ Passenger (freight) (traffic, ton kilometers)} proportion
Water	RIS	Length of navigable inland waterways, waterways and navigation mark construction investment	
	TIFS	Number of berths in major coastal ports for productive use, port construction investment	Ratio of berths in major coastal ports 10000 ton class for productive use, cargo handled at seaports per berth
	TISS	Possession of civil transport vessels	Proportion of civil transport (motor vessels, barges)
	THRS	Number of staff and workers	Average wage of staff and workers
	TSS	Average transport distance of passengers(freight)	
	Whole mode	Passenger (freight) (traffic, ton kilometers), water transport construction investment	{ Passenger (freight) (traffic, ton kilometers)} proportion
Air	RIS	Number(length) of civil aviation routes	Number (length) proportion of civil aviation international routes
	TIFS	Number of civil airports	
	TISS	Number of (civil aircraft, civil aero transport)	Large and medium civil aircraft proportion
	THRS	Number of staff and workers	Average wage of staff and workers
	TSS	Utilization rate of aero transport, average loading rate, average passenger seated rate, average transport distance of passengers(freight)	
	Whole mode	Passenger (freight) (traffic, ton kilometers), fixed assets investment	{ Passenger (freight) (traffic, ton kilometers)} proportion

4 STATE EVALUATION OF COORDINATED DEVELOPMENT AMONG TRANSPORTATION MODES

4.1 DEVELOPING LEVEL EVALUATION OF EVERY MODE

There are many quantitative methods on evaluating a system's development level, but none has been generally accepted at this point. Principal component analysis is chosen to evaluate every transportation mode's developing level in this paper because according to this method weight for indicators are distributed objectively, and a set of correlated variables are transformed into a set of uncorrelated ones, which are ordered by reducing variability, and the uncorrelated ones are linear combinations of the original variables with minimum loss of real data. Order parameters controlling every mode's development situation can be obtained by this method. Its main steps are: (1) make the index data x_{ij} $(i = 1,2,\cdots, p, j = 1,2,\cdots n)$ standardized:

$$y_{ij} = (x_{ij} - \overline{x_j})/\sigma_j, \quad \overline{x_j} = \frac{1}{p}\sum_{i=1}^{p} x_{ij}, \sigma_j = \sqrt{\frac{1}{p}\sum_{i=1}^{p}(x_{ij} - \overline{x_j})^2};$$

(2)construct matrix $R = (r_{kj})_{n\times n}$, $r_{kj} = \frac{1}{p}\sum_{s=1}^{p} y_{ik} y_{ij}$, $k = 1,2,\cdots, n$;

(3) calculate R's eigenvalue λ_k and assume $\lambda_{k+1} \geq \lambda_k$, and its feature vector is $\beta_k = (\beta_{k1}, \beta_{k2}, \cdots, \beta_{kn})^T$;

(4)calculate every component's contribution ratio: $p_j = \lambda_j / \sum_{i=1}^{n} \lambda_k$;

(5)calculate the score of type-i sample in the direction of every principal component: $\begin{bmatrix} Z_1^i \\ Z_2^i \\ M \\ Z_m^i \end{bmatrix} = \begin{bmatrix} \beta_{11} & \beta_{12} & \cdots & \beta_{1n} \\ \beta_{21} & \beta_{22} & \cdots & \beta_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ \beta_{m1} & \beta_{m2} & \cdots & \beta_{mn} \end{bmatrix} \begin{bmatrix} y_{i1} \\ y_{i2} \\ \cdots \\ y_{in} \end{bmatrix}$, $m(m < n)$ is the minimum positive number which satisfies with $\sum_{j=1}^{m} \lambda_j / \sum_{j=1}^{n} \lambda_j \geq e$, generally e=0.85;

(6)calculate the score of type-i sample: $q_i = p_1 \left|Z_1^i\right| + p_2 \left|Z_2^i\right| + \ldots + p_m \left|Z_m^i\right|$.

The data of the indexes was collected from 1995-2005 in China; SPSS12.0 is used to go on principal component analysis, and the developing level value of every transportation mode is obtained (listed in Table 2). According to Table 2, the developing level value of every mode increased year by year, which illustrated that all of them had realized continuous and rapid development during those years.

Table 2. Developing level of every transportation mode.

Year	Railway	Highway	Water	Air
1995	-4.850	-4.698	-4.150	-4.488

2005	5.937	5.794	5.625	5.816

4.2 EVALUATION OF COORDINATED DEGREE AMONG MODES

Coordinated development is an indistinct concept, in which content is definite and its extension is indefinite, so its link with fuzzy mathematics is quoted to describe it. The coordinated degree function is set up to reflect the change law of system's coordinated extent, and its formula is:

$$U = \exp\left\{-(w - w')^2 / s^2\right\} \quad (1)$$

In (1): U stands for static coordinated degree, w stands for actual value, w' stands for coordinated value, s^2 stands for variance.

To illustrate conveniently, X_i , X_j , X_k and X_l respectively stands for railway, highway ,water and air transportation.

$U_{i/j}$ is the coordinated degree of X_i to X_j and describe the degree that X_i's actual value is approach to the coordinated value of X_j demanding X_i, the others also comply with this rule. So $U_{i/j}$ and $U_{j/i}$ describe the coordinated degree of one system to another, the coordinated degree between X_i and X_j is $U_{i,j}$, its formula is:

$$U_{i,j} = \min\left(U_{i/j}, U_{j/i}\right) / \max\left(U_{i/j}, U_{j/i}\right) \quad (2)$$

According to the same law, the coordinated degree among 3 systems and among 4 systems can be determined, and the formulas are:

$$U_{i,j,k} = (U_{i/j,k}U_{j,k} + U_{j/i,k}U_{i,k} + U_{k/i,j}U_{i,j}) / (U_{j,k} + U_{i,k} + U_{i,k}) \quad (3)$$

$$U_{i,j,k,l} = (U_{i/j,k,l}U_{j,k,l} + U_{j/i,k,l}U_{i,k,l} + U_{k/i,j,l}U_{i,j,l} + U_{l/i,j,k}U_{i,j,k}) / (U_{j,k,l} + U_{i,k,l} + U_{i,j,l} + U_{i,j,k}) \quad (4)$$

In the above formulas, the coordinated value is the value that one system adapts to another, and linear regression analysis is used to get it. The evaluation of the coordinated degree among systems need be gone on from the static and the dynamic ways, and relative definitions are given:

Definition 1: $U(t)$ stands for the static coordinated degree among systems at time t, and it can be determined with the formula (2) ~ (4), $0 \le U(t) \le 1$.In general, define $U(t) < 0.5$ as uncoordinated, $0.5 \le U(t) < 0.8$ as approximately uncoordinated, $0.8 \le U(t) < 0.9$ as approximately coordinated, $0.9 \le U(t) \le 1$ as coordinated.

Definition 2: $U(t-T+1)$, $U(t-T+2)$,…, $U(t-1)$, $U(t)$ are the static coordinated degree among systems at the different times during time $(t-T+1)$ to t. And $\overline{U}(t) = \frac{1}{T}\sum_{i=0}^{T-1} U(t-i)$ is the dynamic degree, T is the starting time. Assume $t_2 > t_1$ (two randomly different times); if $\overline{U}(t)$ does not keep decreasing, the system is approaching the coordinated state (Wang, 1998).

Using the above formulas and definitions, the static and the dynamic coordinated degree among 4 transportation modes (listed in the table 3) is obtained. According to Table 3, from 1995-2005 the average static coordinated degree among 4 modes was 0.298<0.800, which indicates that 4 modes were in the uncoordinated development situation in China; and the dynamic coordinated degree displays that

the uncoordinated situation among them had been improving since the year 2000, but the trend was not obvious. As a result, the conclusion is that the transportation modes developed uncoordinatedly in China those years, and the uncoordinated state did not markedly improve.

5 CAUSES AFFECTING COORDINATED DEVELOPMENT

(1) The prevalent management system in China leads to the absence of a united plan for whole transportation system development, and there has not been one real comprehensive perfectly functioning hub to this point. (2) The goal of transportation policies is not clear and the systematization is not strong. For example, the united price implemented hinders the railway freight transport development to some extent. (3) The theories guiding the coordinated development of transportation systems are not complete. (4) Every mode does not hold its proper position in the market and somewhat blindly competes with other modes (Wu et al., 2006).

Table 3. Static coordinated degree and dynamic coordinated degree.

year	1995	1996	1997	1998	1999	2000
$U_{i,j,k,l}$	0.209	0.091	0.187	0.058	0.259	0.637
$\overline{U}_{i,j,k,l}$	0.209	0.150	0.162	0.136	0.161	0.240
year	2001	2002	2003	2004	2005	average
$U_{i,j,k,l}$	0.381	0.193	0.441	0.193	0.628	0.298
$\overline{U}_{i,j,k,l}$	0.260	0.252	0.273	0.265	0.298	

6 COUNTERMEASURES FOR COORDINATED DEVELOPMENT

(1) A united transportation management system should be established quickly, and a real comprehensive hub should be built. (2) To provide a better development environment for transportation modes, the policies should be drafted and reform efforts should be particularly focused on investment and financing policy and price policy. (3) The special research on development of transportation system should be consolidated, and the operative theories and methods should be put forward. (4) Every transportation mode should set the proper position to develop in the market, at the same time, strengthens cooperation with other modes (Antoni et al., 2005).

7 CONCLUSIONS

According to the paper's research results, all transportation modes in China are developing quickly but uncoordinatedly. Therefore, all divisions of departments in charge of traffic should take measures to promote the coordinated development among transportation modes, so that every mode can develop in its proper field and cooperate effectively with other modes.

Evaluating the Equity Impacts of Rural Road Investment Projects on Household Welfare Based on a Quantile Regression Approach: Evidence from Fujian Province

Y. Tian[1], Y. Li[2], and X. Chen[3]

[1]Key Laboratory of Road and Traffic Engineering of Ministry of Education, School of Transportation Engineering, Tongji University, 201804 BOX13#604, Shanghai, Caoan Road 4800; PH 13764488423; E-mail: tianyuandy@126.com

ABSTRACT

The basic purpose of public investment in rural roads is to increase the social benefits in rural areas. However, it has been difficult to precisely quantify the size and especially the distribution of benefits of rural road investments, due to methodological constraints and data limitations. This paper develops and implements a method for nonparametrically estimating whether the impact of Rural Roads Improvement Projects (RRIP) is equitable. Furthermore, a panel data surveying project and control villages before and after program implementation from Fujian Province is applied to estimate the welfare gain as an empirical approach. It is shown that the proposed quantile nonparametric regression approach can examine whether the rural road projects efficiently reduce inequity in the targeted population.

1. INTRODUCTION

Improved roads can create opportunities for economic growth and poverty reduction through a range of mechanisms. Roads reduce transportation costs and the costs of consumption and production of goods and services. With easier access to markets and technology, improved roads expand farm and nonfarm production through increased availability of relevant inputs and lower input costs (Binswanger, Khandker, and Rosenzweig 1993; Levy 1996). At the household level, road development contributes to higher productivity and demand for labor (World Bank 2000), and improved education and health, including those for women and girls (Bryceson and Howe 1993; Levy 1996). Road-related studies have also suggested that household consumption is likely to get a boost from increased household income, consequently reducing poverty (Fan, Hazell, and Thorat 2000). This problem is compounded by the fact that the effects of rural roads are also long-term, and thus cannot be captured through the use of cross-sectional data, particularly since unobserved fixed area characteristics influence the placement of road investment in a village or community (Binswanger, Khandker and Rosenzweig 1993).

It has been difficult to precisely quantify the benefits of roads, due to methodological constraints and data limitations. The traditional estimates of the

returns on rural roads investments using the internal rate of return approach have also been criticized for not being able to capture the true distributional benefits to the targeted population, particularly to the poor (van de Walle 2002). This paper, applying the data from the Rural Roads Improvement Program (RRIP) in Fujian Province, offers an empirical assessment of the impact and role of roads on economic behavior across different income groups by using a fixed-effects quantile estimation approach.

2. DATA AND ITS CHARACTERISTICS

The data used for the analysis, collected by the Fujian Provincial Communications Department (FPCD), is based on household and community surveys prior to, and following, implementation of RRIP, funded by the World Bank in Fujian province, that allowed identification of control and treated villages. The datasets have a true before/after and with/without structure and are reasonably large, allowing a study of community-level and household-level impacts. The data covers all villages covered by the household surveys; there is complete overlap between these data. This permits the use of both community and households information for analysis.

In the surveys, a multistage PPS random sampling method was used to choose sample villages, and 12 households were selected from each sample village using a stratified random sampling procedure. The distribution of the sample in the survey is showed in Table 1, and Table 2 presents means for outcomes and explanatory variables across project and control households, for both rounds of each survey.

3. METHODOLOGY

In this section, we examine the distributional issue of gains from RRIP investment using quantile regression analysis (Khandker, Bakht, and Koolwal 2006). It is potentially important to investigate changes in outcomes observed at different points in the income distribution. Simply investigating changes in the mean may not be sufficient when the entire shape of the distribution changes significantly (Buchinsky 1998). Studying the distributional impact also sheds light on political constraints on the allocation of infrastructural investment (Jacoby 2002).

Following the model proposed by Koenker and Bassett (1978), assume y_i, i=1,…, n is a sample of observations on the log income, and that x_i is a K x 1 vector (comprising the RRIP (R), household (H), and village (V) level characteristics controlled on the right-hand side of equation (1)).

$$\ln Y_{ij} = \alpha H_{ij} + \beta V_j + \gamma R_j + \varepsilon_{ij} \tag{1}$$

Where Y_{ij} is the per capita income of i-th household living in j-th village, H is set of observed household characteristics, R is an indicator of the road development project at the village level, V represents observed non-road village-level characteristics, and ε is a vector of errors term.

The quantile regression model can be expressed as:

$$y_i = x_i'\beta_\tau + \varepsilon_{\tau i},\ Q_\tau(y_i \mid x_i) = x_i'\beta_\tau, \qquad \tau \in (0,1) \tag{2}$$

Where $Q_\tau(y_i|x_i)$ denotes the quantile τ of log per capita income conditional on the vector of covariates (x) and $Q_\tau(\varepsilon_{\tau i} \mid x_i) = 0$. In general, the τ-th sample quantile of y solves:

$$\min_\beta \frac{1}{n}\left[\sum_{i:y_i \geq x_i'\beta} \tau\left|y_i - x_i'\beta_\tau\right| + \sum_{i:y_i < x_i'\beta}(1-\tau)\left|y_i - x_i'\beta_\tau\right|\right] \tag{3}$$

Parameters using the quantile regression approach are estimated semi-parametrically by minimizing the sum of weighted absolute deviations, which fits medians to a linear function of covariates, and can be performed using linear programming methods (Buchinsky, 1998). Specifically, the quantile's coefficients can be interpreted as the partial derivative of the conditional quantile of Y with respect to one of the regressors such as a road development status variable.

One potential obstacle to applying quantile estimation in this paper is the

difficulty in extending fixed-effects methods to quantile estimation. Unlike Gaussian models, quantiles are not linear operators and thus differencing the dependent and independent variables will not in general be equal to the difference in the conditional quantiles:

$$Q_\tau(y_{i2} - y_{i1} \mid x_i) \neq Q_\tau(y_{i2} \mid x_i) - Q_\tau(y_{i1} \mid x_i) \tag{4}$$

To overcome this, Koenker (2004) proposes a model for fixed-effects quantile regression where the unobserved fixed effect is a location shift on the distribution of the dependent variable; i.e. it is the same for each value of τ. Abrevaya and Dahl (2005) take this approach further and characterize the fixed effect using Chamberlain's unobserved effects model. In this paper, we implement Abrevaya and Dahl's procedure; following Chamberlain's model, we specify η_i as follows:

$$\eta_i = \phi + x_{i1}'\lambda_1 + x_{i2}'\lambda_2 + \omega_i \tag{5}$$

where Ø is a scalar and ω_i is an error term uncorrelated with x_{it}, t=1, 2. Given $y_{it} = x_{it}'\beta + \eta_i + \varepsilon_{it}$, substituting equation (5) yields the following equations for periods 1 and 2:

$$y_{i1} = \phi + x_{i1}'(\beta + \lambda_1) + x_{i2}'\lambda_2 + \omega_i + \varepsilon_{i1} \tag{6a}$$

$$y_{i2} = \varphi + x_{i1}'\lambda_1 + x_{i2}'(\beta + \lambda_2) + \omega_i + \varepsilon_{i2} \tag{6b}$$

If we assume all of the error disturbances (ω_i, ε_{i1}, ε_{i2}) are independent of x_{it}, the conditional quantiles also take the analogous forms:

$$Q_\tau(y_{i1} \mid x_i) = \phi_\tau^1 + x_{i1}'(\beta + \lambda_\tau^1) + x_{i2}'\lambda_\tau^2 \tag{7a}$$

$$Q_\tau(y_{i2} \mid x_i) = \phi_\tau^2 + x_{i1}'\lambda_\tau^1 + x_{i2}'(\beta + \lambda_\tau^2) \tag{7b}$$

Where φ_τ^1 and ϕ_τ^2 are location shifts in the conditional quantiles for each year, λ_τ^1 is the unobserved effect λ_1 for the τ^{th} quantile and λ_τ^2 is the unobserved effect λ_2 for the τ^{th} quantile. Without the independence assumption, the conditional quantile functions would in most cases not assume a linear form; this is also true for most cross-sectional quantile estimations, even if the data-generating process is linear in the covariates. Based on equations (6a) and (6b), we run a pooled linear quantile regression where the observations corresponding to the same household are stacked as a pair. Specifically, a quantile regression (using the estimator for the τ^{th} quantile) would be run using:

$$\begin{bmatrix} y_{11} \\ y_{12} \\ \cdots \\ y_{21} \\ y_{22} \\ \cdots \\ \vdots \\ \cdots \\ y_{N1} \\ y_{N2} \end{bmatrix} = \begin{bmatrix} 1 & 0 & x'_{11} & x'_{11} & x'_{12} \\ 1 & 1 & x'_{12} & x'_{11} & x'_{12} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 1 & 0 & x'_{21} & x'_{21} & x'_{22} \\ 1 & 1 & x'_{22} & x'_{21} & x'_{22} \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ & & \vdots & & \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 1 & 0 & x'_{N1} & x'_{N1} & x'_{N2} \\ 1 & 1 & x'_{N2} & x'_{N1} & x'_{N2} \end{bmatrix} \begin{bmatrix} \phi \\ \pi \\ \beta \\ \lambda_1 \\ \lambda_2 \end{bmatrix} + \begin{bmatrix} \upsilon_{11} \\ \upsilon_{12} \\ \cdots \\ \upsilon_{21} \\ \upsilon_{22} \\ \cdots \\ \vdots \\ \cdots \\ \upsilon_{N1} \\ \upsilon_{N2} \end{bmatrix} \tag{8}$$

Along with the parameters ($\varnothing$ β, λ_1, λ_2), the parameter π is also estimated (representing the "year effect"). Next, since observations are clustered and hence not independent, standard errors for the estimators are obtained via a bootstrap method that repeatedly draws (with replacement) a household from the sample of households, including both observations on that household (Abrevaya and Dahl 2005).

4. RESULTS

The equity impacts assessment of rural roads include horizontal and vertical appraisal; the former refers to the equity of different income level households, and the latter represents the equity in different periods.

Table 3 presents the panel quantile estimates for β (using the software of Stata 10) to assess the distributional effects of the road project on log per capita annual income. There are five quantiles, 0.05, 0.25, 0.50, 0.75, and 0.95. For the observed effect β, the road impact is significant and positive for all quantiles in the RRIP sample, with effects varying between 11 and 21 percent. The results indicate that gains from road investment do not necessarily accrue only to relatively wealthier households. Furthermore, the benefits of road investments are focused primarily among the poor.

The Lorenz curve and Gini coefficient are shown in Figure 1 before and after RRIP. The Lorenz curve is presented by statistician Lorenz and the Gini coefficient by economist Gini. The two indexes are the equity indicators in common use, which can quantify the equity of policy or projects. The diagonal represents the absolute average (AP) which implies that the proximity of the curve to *AP* connotes greater equity. The Gini coefficient after RRIP is 0.339 and 0.437 before the projects, reflecting an equity effect over time, because the small coefficient value expresses the high equity.

5. CONCLUSION

Rural investment constitutes a major portfolio of public investment in rural areas, reinforcing the notion that rural income depends critically on roads and other public investments. This paper investigates the effects of rural road investments in Fujian Province. It evaluates the equity impact of rehabilitation of rural roads on household wellbeing. The empirical approach for project impact evaluation utilizes the panel structure of the data to control for time-invariant unobservable at the community-level by quantile regression approach – a method of semi-parametric.

The results indicate RRIP returns for HH per income average about 11-21 percent across different per HH income quantiles (with the highest return for households in the 50^{th} quantile), and the households in the 15^{th} to 50^{th} quantiles of the main distribution, with the highest impact for the poorest households. Thus, rural road projects do benefit poorer households.

ABSTRACT

The definition of the special boundary of the expressway is crucial in analyzing the expressway's social and economic benefits. This paper constructed a boundary method based on a gravitational force model, which describes the traffic intensity between traffic zonings and expressways. Then the spatial influence radius of a crossing was obtained based on the weighting travel distance of the traffic intensity, which can describe the crossing influence zone. Based on the spatial influence radius of all crossings of the expressway, this paper roughly outlines the expressway influence zone, and then adjusts it for topography, and accordingly the special boundary of the expressway influence zone can be identified. Finally, the practicality of this method was explained through an example.

KEY WORDS: expressway; crossing; influence zone; OD traffic flow

INTRODUCTION

Expressways can improve conditions of a regional economy, attract economic development and new various resources, and then change the extent of land use of the main urban area along the route of the expressway. The expressway utilizes each interchange to influence land use along the line mainly, and all crossings form the basic expanding point of the expressway, continuing land influence from key city to peripheral area (David and Wei 2007; Robert and William 2000). How to scientifically determine the border and intensity where expressway crossings influence land development is of great significance in order to accurately analyze economic contribution of areas along the expressway. However, there is still no practical method to solve this problem. This paper

constructed a boundary method based on a gravitational force model, which describes the traffic intensity between traffic zoning and expressways, and then finally makes an empirical study on it.

THE WAYS EXP RESSWAY CROSSINGS AF FECT LAND USE

Expressways have expanded the hinterland of regional traffic area along the line while improving key cities, expanding communication systems of areas from city centers to peripheral regions, and have helped to spread economic areas as well (Zhang et al. 2002; Thomas 2004). Because cars can not leave expressways freely, we consider that the expressway utilizes its crossings to produce connections and exchange between goods, materials, funds and information with the surrounding area. While defining the range of expressway land utilization and economic coverage of urban areas along the line, we usually regard expressway crossings as the target.

THE NEW METHOD TO ID ENTIFY THE SPECIAL B OUNDARY OF THE EXPRESSWAY INFLUENCE ZONE B ASED ON OD TRAFFIC F LOW

C**rossing's** Traffic Intensity of Single Traffic Zoning

At present, freight charges and time are often used as the decisive index to define boundary models (Lu and Huang 2007). But actually, average freight charges and determination of transportation time are limited by numerous conditions such as choosing a route, how to get regional road freight off the route and so on. In addition, the radius of the expressway influence zone is determined by different complex factors. The expressway already put into operation has already formed steady OD traffic flow; the larger the flow is, and the closer to interflow connection to the outside, the greater economic traction will be gained by the area along the line. But in a sense, under the situation of lacking freight charges and time-consuming technical or data, we can use OD traffic flow and its space distribution to indirectly analyze a crossing's traffic intensity of traffic zoning along the line.

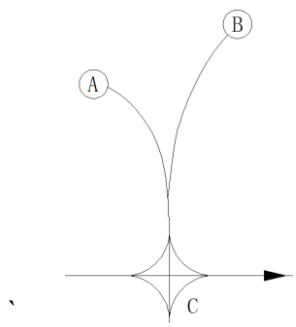

Figure 1. The sketch map for **connecting route between expressway's** crossing and traffic zonings .

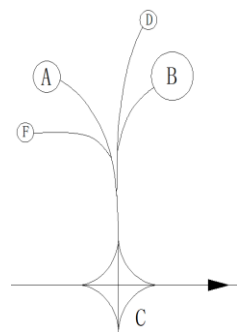

Figure 2. Sketch map for traffic flow between **expressway's** crossing and traffic zonings .

In the Figure1, traffic zonings A and B are separately connected to crossing C by branch lines, which is a result of an expressway having been put into the operation. Because of freight and distance, time consumption and traffic flow among A , B and C had different requirements, and these requirements can be interpreted as interacting forces formed by the traffic flow among A , B and C, just as gravitational forces interacting intimately on each other. In this paper, the above interacting forces are defined as the crossing's traffic intensity, F .

For describing a crossing's traffic intensity numerically, sequence $d=(d_1,d_2,\cdots,d_i,\cdots,d_n)$ denotes the distance of the connecting route (m); sequence $n=(1,2,\cdots,i,\cdots,n)$ denotes the number of traffic zonings connected to crossing by branch lines, so d_i is the distance from traffic zoning i to the crossing; sequence $O=(O_1,O_2,\cdots,O_i,\cdots,O_n)$ denotes origin flow formed from the crossing (pcu), so O_i is the origin flow from the crossing to i ; sequence $D=(D_1,D_2,\cdots,D_i,\cdots,D_n)$ denotes destination flow formed from the crossing (pcu), so D_i is the destination flow from i to the crossing. Then the crossing's traffic intensity of traffic zoning i , F_i (pcu), is as follows:

$$F_i=(F_{Oi},F_{Di})$$

$$\begin{cases} F_{Oi}=G\dfrac{O\cdot O_i}{d_i^2} & (1) \\ F_{Di}=G\dfrac{D\cdot D_i}{d_i^2} & (2) \end{cases}$$

Where Eq. (1) = the crossing's traffic intensity from the origin flow point of view, and in it , $G=\dfrac{O}{\sum_{i=1}^{n}OO_id_i^{-2}}$; Eq. (2) = the crossing's traffic intensity from the destination flow point of view, and in it, $G=\dfrac{D}{\sum_{i=1}^{n}DD_id_i^{-2}}$. More importantly, it is necessary to satisfy $O=\sum_{i=1}^{n}F_{Oi}$ and $D=\sum_{i=1}^{n}F_{Di}$ when G were calculated.

Comprehensive Land Influence Radius of Single Crossing

The above analysis has described the traffic intensity among single traffic zonings and crossings. Under realistic conditions, it should be huge origin-destination traffic flow creating from traffic zonings to all crossings of the expressway, and the traffic zonings do not scatter in the same region space with

different traffic intensity, as shown in Figure 2, the round size expresses the traffic intensity size of traffic zoning contacting to crossing.

In order to scientifically delimit a crossing's traffic intensity of sequence n=(1,2,…,i,…,n),which denotes the number of the traffic zonings connected to the crossing by branch lines, sequence $F_O = (F_{O1}, F_{O2}, \ldots F_{On})$ denotes the crossing' s origin traffic intensity formed from crossing to all traffic zonings connected to it, while sequence $F_D = (F_{D1}, F_{D2}, \ldots F_{Dn})$ denotes the crossing's destination traffic intensity formed from crossing to all traffic zonings connected to it; R_{F_O} denotes the corresponding comprehensive land influence radius of crossing of sequence F_O,while R_{F_D} denotes the corresponding comprehensive land influence radius of crossing of sequence F_d. Based on above-mentioned, the comprehensive land influence radius of a crossing R (km), was obtained found on the weighting travel distance of the traffic intensity, that is:

$$R = \frac{\sum_{i=1}^{n} \alpha_i d_i}{(\alpha_1 + \alpha_2 + \cdots \alpha_n)} \tag{3}$$

where α_i denotes the weight factor of corresponding traffic zoning i , and its value can be applied by the crossing's traffic intensity. R_{F_O} and R_{F_D} can be calculated separately by Eq. (3), and the ultimately reasonable comprehensive land influence radius takes the form as follows:

$$R = \max\left\{R_{F_O}, R_{F_D}\right\} \tag{4}$$

Determination of Expressway Influence Zone of Crossings

According to the calculation method of comprehensive land influence radius in the above chapters, sequence (R_{11},R_{21},…R_{n1}) and sequence (R_{12},R_{22},…R_{n2}) can be calculated appropriately, which denote the influence zone on both sides of crossings on expressway's tending axis. Finally, the zonal shape of the comprehensive land influence radius of all crossings can be outlined, as shown in Figure 3.

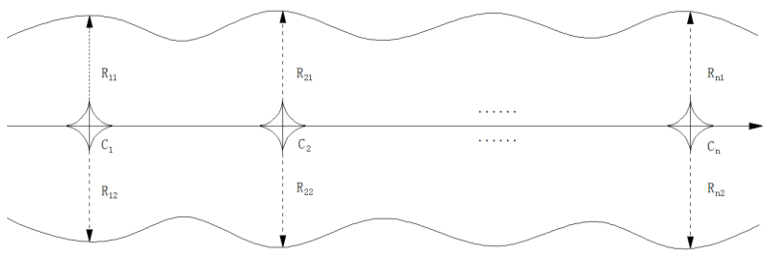

Figure 3. The zonal shape of comprehensive land influence radius of all crossings

Thanks to the different factors of traffic zoning on both sides of crossings, such as natural environment, topography and development of traffic networks, the comprehensive land influence radius of different sides of a single crossing are not the same, so we can calculate the irregular land influence radius of all crossings, and the average land influence radius on both sides of the expressway are different. With social economic development and completion of traffic network construction, the economic belt of an expressway will expand, and the land influence radius of crossings will continue to expand; therefore the influence radius of the whole expressway will increase, too.

CASE STUDY

In this paper, we choose Huang-huang expressway as an analytical object for case study. After an origin-destination study of four important crossings (Sanhua, Qichun, Wuxue, Huangmei), we determined average annual daily traffic of the crossings in 2007. According to the new method of identifying the special boundary of the expressway influence zone based on OD traffic flow, the result of calculations of the comprehensive land influence radius of all crossings is shown in Table 1.

Table1. The comprehensive land influence radius of all crossings

Project \ Crossing		Sanhua	Qichun	Wuxue	Huang mei
On north side of crossing	R_{F_O} (km)	27.43	39.15	33.03	57.54
	R_{F_D} (km)	26.81	41.97	35.84	66.39
	R (km)	27.43	41.97	35.84	66.39
The taking value		27.4	42.0	35.8	66.4
On south side of crossing	R_{F_O} (km)	8.87	21.25	16.86	24.37
	R_{F_D} (km)	8.67	23.32	16.85	23.32
	R (km)	8.87	23.32	16.86	24.37
The taking value		8.9	23.3	16.9	24.4

TransCAD can help outline the zonal shape of the comprehensive land influence radius of the whole expressway, as shown in Figure 4.

As shown in Figure 4, pie charts denote the traffic flow from different crossings to different traffic zonings; real arcs denote the comprehensive land influence radius of all crossings identified by the new boundary method. On the basis of calculations, according to the space position of Huang-huang expressway, it delineates the zonal shape of the comprehensive land influence radius of the expressway with a dashed line. A dotted line shows the comprehensive land influence radius on the north side of the crossing in Wuxue, included in the areas of the crossings in Qichun and Huang Mei; the Changjiang River is south of the crossings in Qichun, Wuxue and Huang Mei, so the comprehensive land influence

radius of the three crossings are limited, for they can not be delineated beyond the Changjiang River.

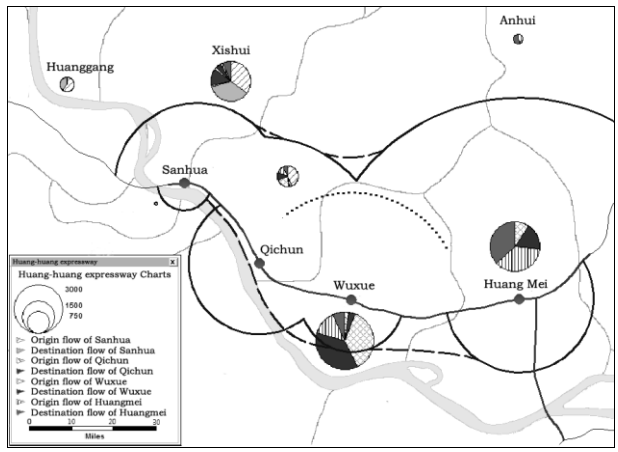

Figure 4. Sketch map for the comprehensive land influence radius of Huang -huang expressway

The radiating range of advantage of industries in counties and cities along the line of the expressway has been widened, and the most important economic zones, such as the Provincial Economic Development Zones of important economic counties and cities, Biochemical Science and Technology Park and Hi-Tech Park, are all in the influence boundary estimated by new method. To sum up, the practicality and rationality of the new method was further explained by this case.

DISCUSSION AND CONCL USION

In this paper, the new method of OD traffic flow used to identify the special boundary of the expressway influence zone does not take into consideration intermodal operation of the comprehensive transportation ways, so it narrows expressway influence zones. To solve this insufficient point, we can analyze indirect influence zones produced by intermodal operation: First, we divide important transport junctions into traffic zonings, then investigate their passenger-cargo through transport OD traffic flow and analyze their space distribution.

How best to identify the expressway influence zone correctly is determined by complex factors such as the characteristics of expressways and traffic characteristics of interrelated traffic networks, peripheral land utilization, topography, etc. At present, finding out one particular influence radius to portray the expressway influence zone still needs to be studied in greater depth.

ABSTRACT

It is stated that an advanced transport system will help enhance economic performance and promote economic growth. This paper discusses the transport strategy for sustainable development of the Jiao Dong economic region in Shandong province, based on the analysis of the correlation between Yantai's GDP and its total transport volume as a logistics hub, because Yantai is centrally located in the region. Both marginal analysis and elasticity analysis of the correlation of Yantai's economy, along with its transport volume, demonstrates that the contribution of transport to economic growth and development has not yet realized its maximum potential. We conclude that Yantai's transport system could be expanded and improved to promote its economic growth, and thereby to promote regionally sustainable development. To accomplish this, several major steps are in order. First, it should quickly build comprehensive traffic networks to encompass a one-hour economic circle within the region. Second, it should fully engage in traffic infrastructure construction to draw internal demand, and lastly, it should establish an intelligent public traffic system to improve passenger transport services.

1. INTRODUCTION

A transport system that can support and drive national and regional development processes must consist of two basic components, namely, traffic infrastructure and transport services, developed in tandem. It is universally recognized that transport service is crucial for sustained economic growth and modernization of a nation. Transport demand, both freight and passenger, is linked to the level of economic activity and development needs (Kulshreshtha et al. 2001). On the other hand, adequacy of traffic infrastructure is an important determinant of the success of a nation's efforts to diversify its production base, expand trade and link together resources and markets into an integrated economy. It is also necessary

for connecting villages with towns and market centers, and in bringing remote and developing regions closer to one another.

In addition to and because of its primary task of efficient and cost-effective movement of people and goods, transport also has a significant impact on the lives of many people through increased employment opportunities and improved accessibility to social infrastructure and services (Morash and Clinton 1997).

Jiao Dong peninsula cities are mainly composed of Qingdao, Yantai and Weihai (exclusive of Wei fang here) with No.1, No.2 and No.9 GDP rankings respectively in the entire Shandong province. The GDP of this region represents one third of the province.

Geographically, Yantai is located between Qingdao and Weihai, which is a link connecting these three cities. Although Yantai's GDP ranks second in Shandong province, its third industry ratio (about 30%) is lower than that of the average of the province (about 33%). Analyzing the relationship of Yantai's transport system with its economic contribution and providing some strategies as an example are appropriate means of promoting the sustainable development of Jiao Dong peninsula economy and thereby Shandong province's economy.

Following the interpretation of economic impacts of transport and analysis of Yantai's transport to economic contribution, this paper provides some strategies for Jiao dong peninsula's sustainable economic development using Yantai as an example.

2. THE RELATIONSHIP OF TRANSPORT AND SUSTAINABLE ECONOMIC DEVELOPMEMT

2.1 Micro impacts of transport

From the microeconomic view point, traffic and transport infrastructure improvements not only reduce distances between origins and destinations but also reduce congestion and thereby travel time by adding links to a network or enhancing the capacity of existing links. They also provide many new services, such as logistics, by improving networks. In these ways, they make it possible to increase traffic and transportation capacity and to offer freight transportation services less expensively and more reliably. The overall effect is a reduction in the movement cost and yielding direct efficiency. Further gains, however, can arise through a number of mechanisms. Freight transport firms not only provide traditional material flow faster, cheaper and more reliably than before, they also offer new types of transport and logistical services. These new services are characterized by reliability, timeliness, strategic outsourcing of a corporation's distribution functions, and flexibility in destination choices for customer firms. Such new service attributes thereby offer manufacturers and customers additional production value and strategic comparative advantages. Further transportation and distribution concerns are increasingly integrated into strategic decisions of firms. These include where to

locate their production and warehouse facilities, where to source their intermediate goods, and how to manage their value chains. Through these processes, the new transport services firms help gain system-wide cost reduction and value addition. The illustration of microeconomic impacts of transport infrastructure improvements is as depicted in Figure 1 (Lakshmanan and Anderson 2002).

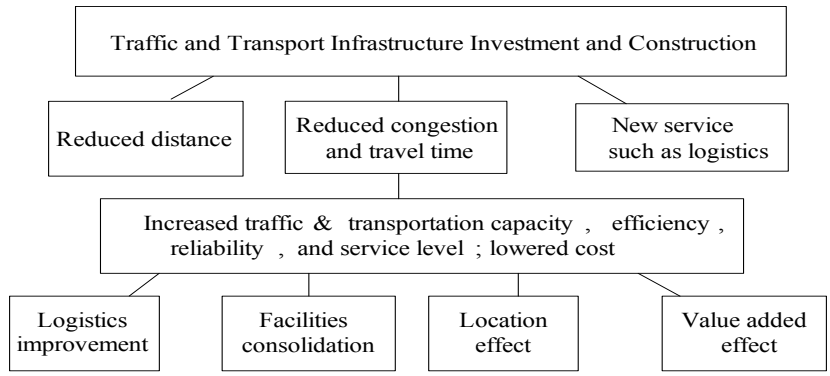

Figure 1. Microeconomic Impacts of Traffic and Transportation .

2.2 Transport infrastructure and full economic effects

When infrastructure networks are improved, as noted above, transport firms will gain lowered costs, efficiency, reliability and more logistics services. All these attributes will help increase the accessibility of inputting suppliers and labor, and customers and realize market expansion and integration. Opportunities for exporting and importing goods are enhanced, in turn opening up several channels of economic effects, both in product markets and in factor markets. The macroeconomic effects of traffic and transport infrastructure are as shown in Figure 2(2002).

First, export expansion will lead to higher levels of output, which allows higher sales to cover fixed costs of operation, yielding efficiencies. Second, increasing imports puts competitive pressures on local prices, which leads not only to the removal of monopoly rents but also to improved efficiency. This is achieved both via the restructuring of the economy (as firms enter and exit) and by promoting leaner production processes, which lower costs of production and raise productivity.

Third, lower transport costs and increased accessibility enlarge the markets for labor and other factor inputs. Firms will likely draw labor from a broader area and with a greater range of attributes, improving labor supply and lowering costs.

Finally, Figure 2 suggests two mechanisms in the oval boxes: one dealing with innovation, and the other with spatial arrangements in the economy. These two mechanisms create, in the context of transport infrastructure improvements, conditions which enhance economic performance, and promote total factor productivity, competitiveness, and internal growth.

Transport improvements can have an internal growth effect to the degree they impact the rate of innovation and transfer of technology, thereby promoting

total factor productivity (TFP) growth and competitiveness. Such impacts of transport improvements can derive from the following sources: industrial restructuring resulting from the entry and exit of firms and the opening of larger markets; the benefits accruing to various economic actors from the likely parallel increase in information flows, especially in locations where industries are spatially agglomerated. Impacts from both of these sources can impact the pace of technology transfer and innovation, thereby increasing economic growth.

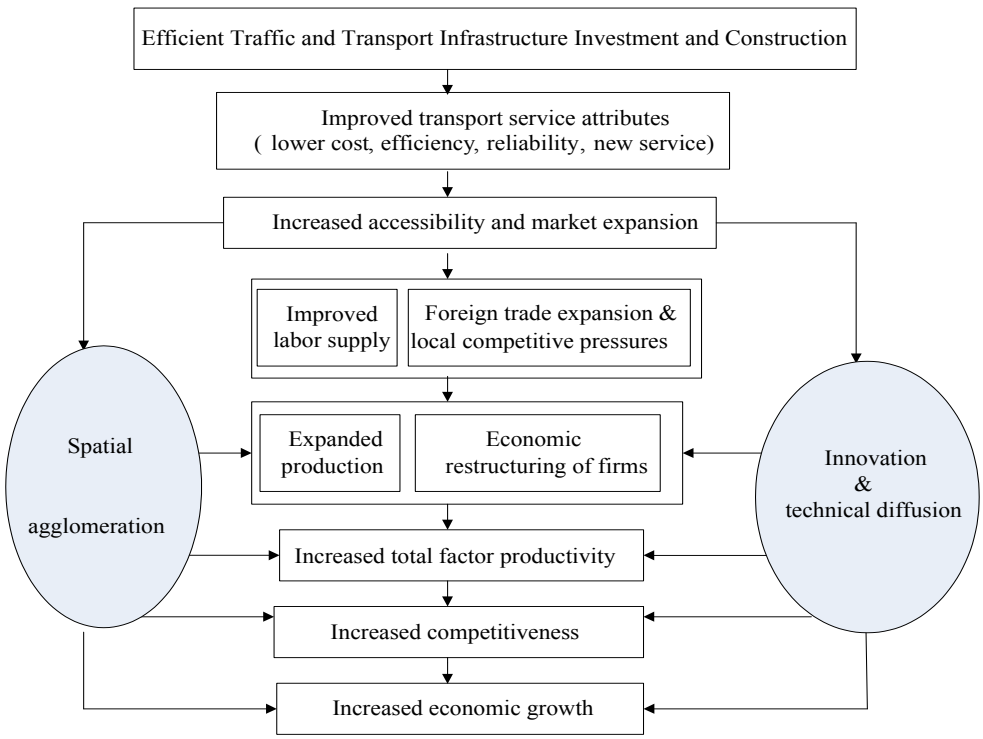

Figure 2 . Transport Infrastructure and its Full Economic Effects.

3. CORRELATION OF YANTAI 'S GDP AND ITS TRANSPORT VOLUME

3.1 Regression analysis of Yantai 's GDP and its transport volu me

From scatter diagram analysis, GDP possesses a positive correlation to transport volume, but the growth is non-linear, showing an S curve feature (2006). This research utilizes the logistic equation to fit the relations of regional GDP growth to total transport volume.

The logistic function is as follows:

$$Y = \frac{1}{C + Ae^{-BX}} \qquad (1)$$

Here, $A > 0, 0 < B \neq 1, \ 0 < C \to 1/Y$

X : The total transport volume in 10 thousand tons

Y : Yantai's GDP in 100 million RMB

Total transport volume shown in Table 1 is the sum of freight and the equivalent of passengers to freight, calculated based on the correlation function of freight volume (G) and passenger volume (L) per G = 241431n(L) – 205514..

Table 1 . Data of Yantai 's Total Transport Volume and its GDP .

Year	t	X	Y
2001	0	15862.43515	980
2002	1	21131.63276	1115
2003	2	21651.76766	1316
2004	3	26244.22941	1639
2005	4	31337.38232	2012.46
2006	5	33002.68034	2402.1
2007	6	38746.82319	2878.97
2008	7	45794.42	3434.19
2015	14	7320.73	8000

Through the transformation and C value estimated, utilizing the least squares method, the logistic function is as follows:

$$Y = \frac{1}{\frac{1}{8000} + 0.00188 * e^{-0.0000424X}} \qquad (2)$$

Here, $A = 0.00188$, $B = 0.0000424$, $C = 1/8000$

3.2 Marginal analysis

Through the marginal analysis according to the function of $Mf = \frac{dY}{dX} = \frac{ABe^{-BX}}{\left(C + Ae^{-BX}\right)^2}$, it is found that the increase of transport volume per ten thousand tons results in 0.0733 of 100 million Yuan GDP increase .

On the other hand, according to the second derivative of $\frac{d^2Y}{dX^2} = AB^2 \frac{Ae^{-BX} - C}{\left(C + Ae^{-BX}\right)^3} e^{-BX}$, the critical value of total transport volume equals 63985.68 units.

Since in 2008 Yantai's transport volume was about 45794.42 units, lower than the above derived critical value, we conclude that the increase of transport per unit would result in a further increase of Yantai's GDP. That is, Yantai should greatly develop a transport system in order to promote the regional GDP growth.

3.3 Elasticity analysis

Through the elasticity analysis based on the equation of $\xi = \frac{dY}{dX} \cdot \frac{X}{Y} = \frac{ABXe^{-BX}}{C + Ae^{-BX}}$ (ξ: the elasticity coefficient of transport to GDP) and $\frac{d\xi}{dX} = AB\frac{Ae^{-BX} - BCX + C}{\left(C + Ae^{-BX}\right)^2}e^{-BX}$ as well as the Newton's method of numerical analysis, the inflection point of the elasticity coefficient is of 1.39 with X nearing 56300 units.

However, in year 2008, Yantai's total transport volume of 45794.42 units was less than the inflection point value of 56300 units, giving an elasticity coefficient of 1.27, lower than the inflection point value of 1.39. We thus conclude that in Yantai the contribution of each 1% transport increment to the economy hadn't realized its optimal level, and therefore, transport should be expanded to promote the increase in GDP increments in the future.

4. STRATEGY OF YANTAI 'S TRANSPORT FOR JIAO DONG ECONOMIC REGION 'S SUSTAINABLE DEVELOPMENT

4.1 Building comprehensive traffic networks to realize one -hour economic circle of Jiao Dong peninsula

To quickly star t the construction of Qingdao -Yantai -Weihai light railway . In order to cope with the financial crisis, the State plans to appropriate 4 trillion RMB to support the construction of infrastructure, and Shandong province should receive about 667.8 billion RMB in the next three years. Qingdao-Yantai-Weihai light railway construction has been planned as part of the program. It is advisable to accelerate the construction pace and put it into operation as soon as possible.

To construct Yantai -Qingdao freeway . To intensify the links with the core city of Qingdao, it is necessary to build a direct freeway between Yantai and Qingdao. The freeway will serve as a major bridge for connecting with air, ports and other transport modes and will therefore accelerate economic and cultural exchanges.

To strength en the links of Yantai -Weihai -Qingdao -Weifang traffic networks. Since the construction of inter-city railways has been included in the agenda, the relevant road network planning and construction must be kept up to ensure the smoothness of intra / inter-city traffic networks.

4.2 Fully embarking on other traffic infrastructure construction

To quickly begin civil airport construction . In order to fully meet domestic and international demands, Yantai should accelerate its construction pace of the civil airport to expand additional domestic passenger routes and international routes, especially the Northeast and Southeast Asia routes. Meanwhile, cargo air transport and its feeder transport should be developed as well.

To impr ove railway coverage and standards . Firstly, it should accelerate the construction of De-Long-Yan Railway to act as the port access of Yantai, Longkou, Weifang, Dongying, Binzhou and the east-west provincial passageway. Secondly, it should accelerate the electrification and informational connectivity, of Lan-Yan railway to facilitate communication between Yantai and the Northeast region, the Yangtze River Delta region and the central and western regions, and expand radiation to the landlocked hinterland (Wang, 2006). Thirdly, it should further enhance the role of the Yantai-Dalian railway ferry to consolidate the economic link of North-east and Shan dong province.

To speed u p port construction . Accelerating the port construction should concentrate on a deep container berth of the new Yantai port and Longkou for coal and liquid chemicals as well as Laizhou for grains and a salt terminal.

4.3 Setting up an intelligent public traffic system

First, it's necessary to issue compatible transport fare cards within the whole urban area for bus transport, taxi transport, short-hall passenger transport and public parking lots. Second, it must expand the card-purchasing channels. In addition to Evergreen Bank, some machines should be installed at Wal-Mart, RT-Mart, business malls, and so forth. Third, the unified-card should be expanded to other businesses, such as tourism, shopping, etc. Lastly, favorable polices should be drafted to encourage use of the cards, for example, giving discounts for more spending.

Besides, Yantai should pay attention to developing contemporary logistics, especially, cold chain logistics, green logistics and bonded logistics.

CONCLUSION

Theoretically, transport systems can contribute to competitiveness and economic growth and promote the sustainable development of regional economy. Both the marginal analysis and elasticity analysis of the correlation of Yantai's GDP and transport as an example of the Jiao Dong peninsula cities demonstrates that the contribution of transport to economic growth and increase has not realized their maximum potential. In the future, the city should greatly develop transport systems to promote economy growth and increase and that of Jiao Dong economic region. The transport strategy may include the construction of comprehensive traffic networks to realize a one-hour economic circle of the region and other traffic infrastructures, including the establishment of an intelligent public traffic system.

ABSTRACT

Many studies have shown that air pollution is typically affected by road transportation. In order to further discuss the relationship between road transportation and regional environment carrying capacity, this article has built a road transportation ecological footprint model. In order to explain how to use this model, quantitative calculation with data derived from China Yearbook has been applied. Calculation results can show that the road transportation ecological footprint mainly consists of a fossil energy ecological footprint, and both of them show a tendency of increasing in recent years. Therefore, it can be concluded that fossil energy consumption and greenhouse gas emission are main factors for restricting road transportation's sustainable development. As a result, to make sure road transportation is developed in a sustainable way, many effective measures should be taken.

INTRODUCTION

With the rapid development of the national economy, road transportation has shown significant growth since 2000, as shown in Fig.1. As we all know, the automobile has made travel convenient for the public, but it is also a major source of energy consumption and air pollution. When totaling the forms of energy consumption in China's transportation system, road transportation accounts for approximately 51.6% (Xi J P. 2008), as shown in Fig.2. Moreover, more than 50% of air pollutants arise from automobile in China. What is worse, more than 80% of CO and more than 40% of NO_X are produced by automobiles in big cities such as Beijing and Guangzhou (National Development and Reform Commission. 2007). Therefore, attention must be paid to the relationship between road transportation, energy consumption, environment protection and sustainable development. Up until now,

many scholars have widely used an ecological footprint model in regional environment evaluations, but no one has used this model in a transportation sustainable development study. This article attempts to do research in this area.

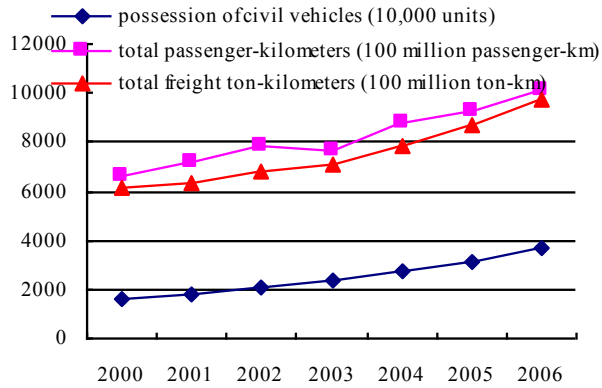

Figure 1. Changes in China's Road Transportation from 2000 to 2006.

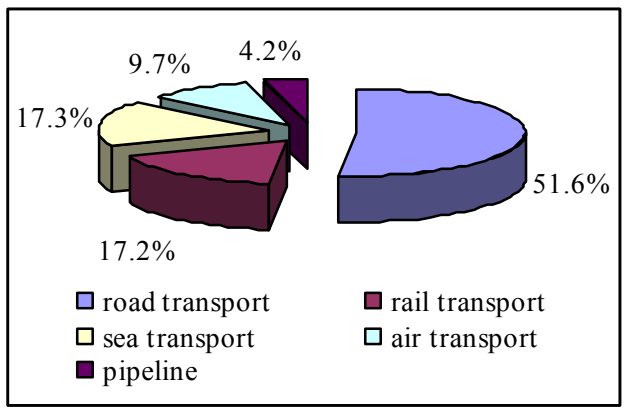

Figure 2. Composition of Energy Consumption of Transportation Systems.

ROAD TRANSPORTATION ECOLOGICAL FOOTPRIN MODEL

Summariz ation of Ecological Footprint Model. The ecological footprint model can clearly demonstrate environmental pressure by comparing ecological footprint demand and ecological carrying capacity. This becomes a quantitative method for the measurement of sustainable development degree.

$$EFD = N \times ef = N \times (\sum r_j \times A_j) = N \times [(\sum r_j \times (O_i + I_i - E_i)/(P_i \cdot N)] \quad (1)$$

Where, EFD is regional ecological footprint demand; N is total population; ef is per capita ecological footprint demand; r_j is balance factors for various biological productivity land (Wackernagel classified biological productivity land as arable land, grassland, forest land, construction land, fossil energy land and waters (Wackernagel

et al. 1999; 2007).), which is determined by unified value (Luan Y, et al. 2008), as shown in Table 1; A_j is per capita No. j kind of biological productivity land; O_i is annual output of No. i kind of consumer items; I_i is annual import volume of No. i kind of consumer items; E_i is annual export volume of No. i kind of consumer items; P_i is annual average production capacity of No. i kind of consumer items.

$$EC = N \times ec = N \times \sum (r_j \times y_j \times a_j) \quad (2)$$

Where, EC is regional ecological carrying capacity; N is total population; ec is per capita ecological carrying capacity; y_j is yield factors, according to value chosen by UN Food and Agriculture Organization , Wackernagel and others who have calculated China's ecological footprint. Yield factors are as follows: arable land and construction land both equal 1.66, grassland is 0.19, fossil energy land and forest land both are 0.91; a_j is per capita No. j kind of biologically productive land.

Table 1: Balance Factors for Six Types of Biologically Productive Land.

land type	arable land	grassland	forest land	construction land	fossil energy land	waters
r_j	2.8	0.5	1.1	2.8	1.1	0.2

Meanwhile, ecological deficit (usually abbreviated as ED) is defined when the ecological footprint demand exceeds ecological carrying capacity. That also indicates regional sustainable development is threatened. Conversely, ecological surplus (usually abbreviated as ES) is defined. That is,

$$ED = EC - EFD \quad (\text{while } EC < EFD) \quad (3)$$

$$ES = EC - EFD \quad (\text{while } EC \geq EFD) \quad (4)$$

Road Transportation Ecological Footprint Model. As the smooth operation of road transportation relies on highways, parking lots, toll station and other facilities, as well as on a large amount of gasoline, diesel oil, natural gas and other energy, biologically productive land mainly refers to construction land and fossil energy land.

(1) Ecological footprint demand for construction land

$$EFD_1 = N' \times \sum (S_i / N') \quad (5)$$

Where, EFD_1 is demand for construction land ecological footprint; N' is total possession of civil vehicles; S_i is an area occupied by No. i kind of transport facility.

(2) Ecological footprint demand for fossil energy land

When an automobile travels, it needs to burn energy to generate driving force. However, at the same time, it will generate numerous pollutants. Because the absorptive capacity of forest for greenhouse gas and pollutants is characterized by heat, it needs to convert energy consumption into heat according to its combustion efficiency. Conversion standards use world united value, as shown in Table 2.

$$EFD_2 = \sum \frac{N_i C_i \lambda_i}{K_i} = \sum \frac{C_i' \lambda_i}{K_i} \quad (6)$$

Where, EFD_2 is demand for fossil energy land ecological footprint; N_i is possession of civil motor vehicles, which burn NO. i kind of energy; C_i is per vehicle consumption of NO. i kind of fossil fuel; C_i' is total consumption of NO. i kind of energy; λ_i is conversion coefficient for NO. i kind of energy; K_i is average calorie absorptive capacity of forest for per energy.

Table 2: Average Calorie Absorptive Capacity of Per Energy and its Conversion Coefficient.

	coal	crude oil	fuel oil	gasoline	diesel oil	natural gas	electricity
absorptive capacity (joule per hectare)	55	93	71	93	93	93	1000
conversion coefficient	20.93①	41.87①	50.20①	43.12①	42.71①	0.034②	0.0036③

Note: ①Joule per ton; ②Joule per cum; ③Joule per KWH

(3) Road transportation ecological footprint demand

$$EFD' = r_1 \times EFD_1 + r_2 \times EFD_2 = r_1 \times N' \times \sum (S_i / N') + r_2 \times \sum \frac{C_i' \lambda_i}{K_i} \quad (7)$$

Where, EFD' is road transportation ecological footprint demand; r_1 is balance factors for construction land, and r_1 equals to 2.8, as shown in table 1; r_2 is balance factors for fossil energy land, and r_2 equals to 1.1, as shown in table 1.

(4) Road transportation ecological carrying capacity

$$EC' = N' \times \sum (r_j \times y_j \times a_j') \quad (8)$$

Where, EC' is road transportation ecological carrying capacity; N' is total possession of civil motor vehicles; r_j is balance factors; y_j is yield factors; a_j' is No. j kind of biological productivity land occupied by per vehicle.

In addition, according to reports from the World Commission on Environment and Development (WCED), 12% of biologically productive land should be set apart to protect biology. Therefore, road transportation effective ecological carrying capacity is gained after 12% of biologically productive land is deducted. That is,

$$REC = (1-12\%)EC = (1-12\%)N \times \sum (r_j \times y_j \times a_j') \quad (9)$$

Where, REC is effective ecological carrying capacity.

As REC is more reasonable than EC when calculating ED or ES, the following formulation is used in this article.

$$ED = REC - EFD' \quad (REC < EFD') \tag{10}$$

$$ES = REC - EFD' \quad (REC \geq EFD') \tag{11}$$

CALCULATION EXAMPLE OF ROAD TRANSPORTATION ECOLOGICAL FOOTPRINT

Example . Because energy consumption of transportation systems is usually calculated together with that of storage as well as with that of post in China, and special statistical data for road transportation energy consumption is lacking, so energy consumption of road transportation is calculated based on the China Yearbook and estimated proportion (In China, gasoline consumption of transportation system occupies about 40% of national gasoline consumption now. Meanwhile its consumption of diesel oil accounts for about 38% of total diesel oil consumed. Beyond that, its consumption of fuel oil accounts for about 10% of total fuel oil consumption.). Road transportation energy consumption is shown in Table 3.

Table 3: Basic Condition of Road Transportation System from 2000 to 2006 .

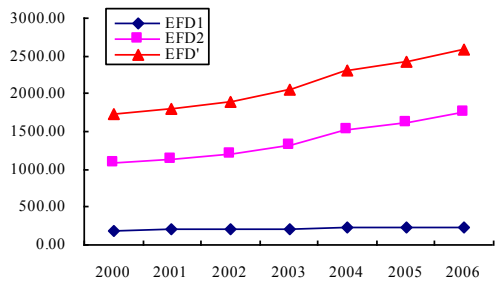
year	length of highways (10,000 km)	possession of civil vehicles (10,000 units)	possession of private vehicles (10,000 units)	road transport land (10,000 hectare)	gasoline (10,000 ton)	diesel oil (10,000 ton)	fuel oil (10,000 ton)	electricity (100 million KWH)	natural gas (100 million cum)
2000	140.27	1608.91	625.33	192.50	723.42	1328.30	199.84	23.80	0.85
2001	169.80	1802.04	770.78	198.60	742.58	1393.82	207.21	44.50	1.30
2002	176.52	2053.17	968.98	205.70	773.94	1503.52	199.89	58.10	1.95
2003	180.98	2382.93	1219.23	214.52	840.46	1648.99	217.78	59.70	3.20
2004	187.07	2693.71	1481.66	223.32	969.20	1940.24	246.83	68.20	3.60
2005	334.52	3159.66	1848.07	230.90	1001.72	2151.48	218.89	73.80	3.92
2006	345.70	3697.35	2333.32	239.50	1081.89	2320.79	225.41	81.90	4.35

Based on formulation (5) to formulation (11), road transportation ecological footprint demand and ecological carrying capacity are gained, as shown in table 4.

Table 4 Results of road transportation ecological fo otprint (10,000 hectares).

Year	EFD1	EFD2	EFD'	EC'	REC	ES or ED
2000	192.50	1090.70	1738.77	1986.53	1748.14	9.38
2001	198.60	1137.27	1807.08	2061.50	1814.12	7.04
2002	205.70	1199.88	1895.83	2157.17	1898.31	2.48
2003	214.52	1314.81	2046.94	2313.21	2035.62	-11.32
2004	223.32	1530.56	2308.91	2570.08	2261.67	-47.24
2005	230.90	1624.27	2433.21	2699.11	2375.22	-57.99
2006	239.50	1745.67	2590.83	2860.61	2517.34	-73.50

Analysis of Calculation Results. Looking at Fig.3, the following conclusions can be made: Changes in EFD' are similar to that of EFD_2 and both of them show similar rising characteristics year after year, indicating EFD' mainly consists of EFD_2. In addition, EFD_2 is bigger than EFD_1 and their difference is larger and larger as time goes by, indicating EFD_2 contributes more to EFD' than EFD_1 as well as indicating EFD_2 is a main factor for restricting road transportation's sustainable development. Especially in 2003, there is an obvious increase for EFD_2, mainly because there is also an obvious increase in possession of private vehicles (see table 3). Further, energy saving consciousness was weak that year, resulting in larger consumption of fossil energy.



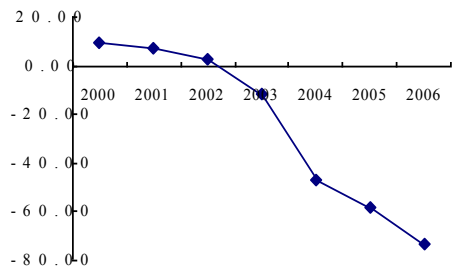


Figure 3. Changes of EFD_1, EFD_2 and EFD. Figure 4. Changes of ES or ED.

In Fig.4, positive values which are above the lateral axis denote ES, while negative values which are below the lateral axis denote ED. From 2000 to 2002, the road transportation ecological footprint is in ES state, indicating road transportation development in a sustainable way. Since 2003, negative values have appeared and continue to increase, indicating that road transportation sustainable development is threatened and will possibly continue to deteriorate. Therefore, in order to adjust ED state to ES state, energy consumption must be saved, greenhouse gas emission must be decreased and road transport construction land must be restricted.

Suggestions. In order to realize the sustainable development of road transportation, it is urgent to strengthen transportation management with the following measures.

First, the energy saving consciousness of road staff must be raised. Good driving habits should be encouraged such as stepping gently on the accelerator pedal, reducing unnecessary braking, cutting down on engine idle time, decreasing air-conditioning use, etc.

Second, energy consumption of vehicles must be decreased. Today, the increase in use of private vehicles can be restricted, and vehicles that are old and high-energy consumption may have to be eliminated.

Third, in order to control the increase of the construction land ecological footprint, maintenance and management of highways must be strengthened. The additional use of road transport land should be reasonably restricted.

CONCLUSIONS

(1) Raising energy saving awareness of road staff, decreasing energy consumption of automobiles, as well as strengthening maintenance of highways is important to realizing road transportation's sustainable development.

(2) This article has only calculated the ecological footprint of gasoline, diesel oil, fuel oil, electricity and natural gas due to availability of data, so the fossil energy land ecological footprint is smaller than its actual value. This discrepancy will be the focus of future study.

ABSTRACT

Because traffic delays and queues have a serious impact on intersections and even entire roadway networks, this paper attempts to study the optimization algorithm of signal timing for individual intersections. The non-linear optimization model which is applicable for an individual intersection can be built up by using an ant colony algorithm based on mesh strategy. The programs are made by MATLAB in which some relevant parameters and algorithm rules are ameliorated. Taking some typical intersections in Beijing as an example, the non-linear model is established through programming in MATLAB. The optimization model is verified by estimating some targets after conducting a contrast study between the ones made by the Webster Method and the current timing condition derived from an ant colony algorithm. The results suggest that the ant colony algorithm based on mesh strategy is suitable for solving the problem of signal timing during peak periods. This new optimization algorithm can improve the condition at signalized intersections and provide a new effective method for solving the problem of signal timing at intersections.

1. INTRODUCTION

The key to solving the signal timing problem at intersections is seeking an optimal signal cycle length and green time. Solving the traffic control problem plays a crucial role in decreasing the delay time and the number of stops at intersections, as well as the road network. At present, foreign scholars' studies for the method of signal timing includes: F. Webster and B. Cobber who put forth an F-B algorithm for fixed signal timing problems in a single-point intersection which had been used for decades. Later some scholars made a few additional and amending suggests for the

F-B algorithm, such as R. Kimber who advanced the algorithm called TRRL. R. Aksay introduced the parameter of "stop compensation factor", that is, ARRB algorithm. The most widely-used and effective systems for signal control include: the TRANSYT system using climbing method, the SCOOT system for optimization with smaller step, the SCATS system with the strategy of comparison-selection, the Cabal system using genetic algorithm and so on.

In China, professor Yang Xiaoguang introduced the stopping-line delay model which improved the traditional algorithm of "F-B" (Yang Xiaoguang et al. 1993). Pu Qi modified the formula for calculating the delay and described the delay time as a discrete variable (Pu Qi et al. 1999). Yang Dongyuan considered the fuzzy-correlation among the parameters of cycle length with flow rate, the number of stops, queue length and volume for critical lane group and came to the conclusion that the factor most associated with cycle length is saturation, followed by flow rate, delay and number of stops (Yang Jindong et al. 2001).

With regard to controlling algorithm, Zhang Shengrui solved the optimization model and obtained some better values with a genetic algorithm and a genetic simulated annealing algorithm (Wang Qiuping et al. 2006). Wang Huiqiu put forth a study method of self-organization in real-time traffic signal control which combined fuzzy control and artificial neural network (Wang Huiqiu et al. 2005). Xu Xunqian used an elite ant colony algorithm to solve a multi-phase real-time model and validated the rationale and effectiveness of this optimal algorithm (Xu Xunqian et al. 2005).

2. SIGNAL TIMING OPTIMIZATION MODEL

In accordance with the actual traffic demands at the intersection, the optimization model is set up with the bound of saturation, which is a single-goal function by two real-time weighted coefficients in order to minimize the delay time and the number of stops. The optimization model is as follows:

$$\begin{aligned} &\min\ f(g_{e1}, g_{e2}, g_{e3}) = \sum_{i=1}^{n} K_i^1 D_i + \sum_{i=1}^{n} K_i^2 H_i \\ &g_{ei,\min} \le g_{ei} \le g_{ei,\max}, 1 \le i \le n; \\ \text{s.t.}\quad &\sum_{i=1}^{n} (g_{ei} + l_i) \le C_{\max}, 1 \le i \le n; \\ &x_{\min} \le \frac{q_i}{\lambda_i s_i} \le x_{\max}, 1 \le i \le n; \\ &x_i \ge 0, 1 \le i \le n. \end{aligned} \tag{1}$$

Where: $g_{ei,\min}$、$g_{ei,\max}$ = the minimum and maximum of effective green time for phase i; l_i = lost time for phase i; $C_{\max}$ = the maximum of cycle length; $x_{\min}$、$x_{\max}$ = the minimum and maximum of ratio; Delay time for phase i

is $D_i = \frac{(C-g_i)^2}{2C(1-q_i/s_i)} + \frac{C-g_i}{2Cq_i} + \frac{q_i C^2}{2s_i g_i (s_i g_i - q_i C)}$; The number of stops for vehicles is $H_i = 0.9 \times \frac{1-\lambda_i}{1-y_i}$; K_i^1， K_i^2 are the weighted coefficients of delay time and the number of stops respectively, $K_i^1 = 2s_i y_i (1-Y)$， $K_i^2 = s_i y_i \frac{1-Y}{0.9}$.

3. ANT COLONY ALGORITHM FOR CONTINUOUS DOMAI N BASED ON MESH STRATEGY

3.1 Basic Idea and Solving Steps for this Algorithm

In the study of signal timing optimization, the application of fuzzy theory, neural networks, traffic flow simulation and genetic algorithms are involved. However, some studies show that the practical application of self-adaptive systems for signal control has poor effectiveness. Most of them use complicated algorithms produce large amounts of calculation and can't satisfy the requirements of real-time control in the actual application. Yan Yanxia and others have used the basic ant colony algorithm to work on the signal timing optimization model (Yan Yanxia et al. 2006). But the basic ant colony algorithm based on discrete theory is aimed at the shortest closed path and the process for searching for solutions. It is a way of hopping based on the analysis of discrete points. An ant colony algorithm for continuous domain based on mesh strategy can overcome these shortcomings, which aims at searching for the most optimal value by making it a gradual iterative search to points and their affected areas. This optimized algorithm has shown very good performance in a series of nonlinear optimization problems.

The idea of the ant colony algorithm based on mesh for a continuous domain has the following features: First, according to the nature of the continuous optimization problem, the range of variables can be estimated. Then, a grid in the variable region is built up. One of the grid points in this space corresponds to a state. Ants moved between these grid points and left different amounts of messaging in terms of the value of goal function at that point, as an impact on the moving direction for the next ant group. After cycling for a period of time, the point with a smaller value of goal function has a larger amount of messages between two adjacent nodes. It would be selected and the range of variables would be narrowed. There the next ant group continues moving. Repeat this process until the conditions of this algorithm have been met (Duan 2005).

The assumption that a variable should be divided into n equal parameters makes the problem have n determined levels. In each level there are n+1 nodes so that the total number of nodes is (n+1)×n which make a connection from the first level to the level n, as a solution space as follows:

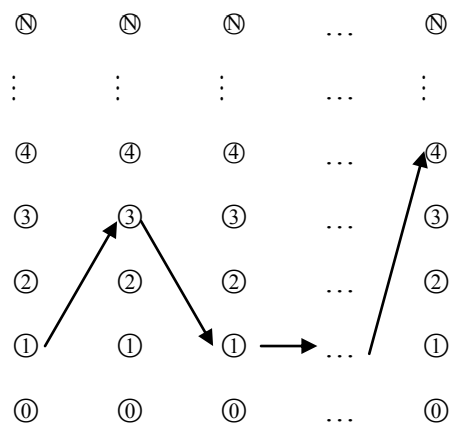

Figure 1 . Diagram of State Space .

As shown in the chart above, the state in this space is (1, 3, 1,…, 4). Its corresponding solution is

$$\begin{aligned}(x_1, x_2, x_3, \ldots, x_n) = (\ & x_{1lower} + \frac{x_{1upper} - x_{1lower}}{N} \times 1, \\ & x_{2lower} + \frac{x_{2upper} - x_{2lower}}{N} \times 3, \\ & x_{3lower} + \frac{x_{3upper} - x_{3lower}}{N} \times 1, \ldots, \\ & x_{nlower} + \frac{x_{nupper} - x_{nlower}}{N} \times 4) \end{aligned} \tag{2}$$

The state-transition probability from the first level to level N can be calculated by the formula as followings:

$$P_{ij} = \frac{\tau_{ij}}{\sum_{i=1}^{N} \tau_{ij}} \tag{3}$$

Assume τ_{ij} to be the node i in the level j, the update equation is

$$\tau_{ij}^{new} = (1-\rho)\tau_{ij}^{old} + \frac{Q}{f} \tag{4}$$

Where, f is the value of goal function.

The solution steps of this algorithm are:

(1) To estimate the range of variables: $x_{jlower} \le x_j \le x_{jupper}\ (j=1,2,...,n)$;

(2) To divide each variable into N equal parameters: $h_j = \frac{x_{jupper} - x_{jlower}}{N}\ (j=1,2,...,n)$;

(3) If $\max(h_1, h_2, ..., h_n) < \varepsilon$, the algorithm stops. The most optimal solution is $x_j^* = \frac{x_{jlower} + x_{jupper}}{2}\ (j=1,2,...,n)$; Otherwise jump to step (4);

(4) When the number of cycle $N_c \leftarrow 0$, give the matrix τ_{ij} the same value and set initial value to Q, ρ and $N_{c\max}$;

(5) Assume the number of ants is num_ant , each ant can select next node by formula (4);

(6) Modify the value of message by the update equation, $N_c \leftarrow N_c + 1$;

(7) If $N_c < N_{c\max}$, jump to step (5); Otherwise select the row what the maximum in each column corresponds in matrix τ_{ij} and narrow the range of variables: $x_{jlower} \leftarrow x_{jlower} + (m_j - \Delta)h_j$, $x_{jupper} \leftarrow x_{jlower} + (m_j + \Delta)h_j$, where $j = 1,2,...,n$, then jump to step (2).

In the process of making programs, some improvements have been made for an ant colony algorithm for continuous domain based on mesh strategy: The proliferation and stagnation problem appeared easily and cannot be ignored. The amount of messaging left on the optimizing path should be restricted within $[\tau_{\min}, \tau_{\max}]$. After every cycle, the most optimized path was saved. Only the ant with the shortest path can modify the value of $\tau_{ij}(t)$. We can select and determine threshold in accordance with the following formula:

$$\tau_{ij}(t+n) = \begin{cases} \tau_{\min}, & \tau_{ij}(t) \le \tau_{\min} \\ \tau_{ij}(t), & \tau_{\min} < \tau_{ij}(t) \le \tau_{\max} \\ \tau_{\max}, & \tau_{ij}(t) > \tau_{\max} \end{cases} \quad (5)$$

3.2 Algorithm Validation

3.2.1 The Case

Using “Xueyuan Southern Road and Zaojunmiao Road” intersection as an example, the survey was conducted at morning, afternoon and evening peak hours in

light of all the necessary parameters that are base dates for signal timing. Volumes in each direction have been recorded in Table 1:

Table 1. Timing Parameters of Each Phase During Morning Peak Period .

Parameters in Webster method	The first phase		The second phase		The third phase			
	Through lane in southern	Through lane in northern	Left lane in southern	Left lane in northern	Through -left lane in eastern	Through-left lane in western	Through lane in eastern	Through -right lane in western
Volume q_i	930	1554	280	190	550	426	550	708
Flow rate S_i	2000×3	2000×3	1800	1800	1500	1500	1698	1674
Flow ratio	0.155	0.259	0.156	0.106	0.367	0.284	0.324	0.423
Flow ratio of critical lane y_i	0.259		0.156		0.423			

3.2.2 Parameter Calibration

Calculating programs of ant colony algorithms for continuous domain based on mesh strategy are made in Matlab 6.5, which is used to calculate the results of signal timing. In this algorithm, initial parameters are calibrated as follows: pheromone evaporation coefficient ρ =0.6; pheromone intensity Q=10000; the number of ants ant=20; the number of cycles NCmax=10; iteration steps step=10; the number of equal parts n=10.

(1) Value of ρ

Ants in this algorithm have human memory function. With time flying, messages left earlier will gradually disappear. Parameter ρ is directly related to global search ability and convergence speed. 1-ρ reflects the interaction between individual ants. When ρ becomes bigger, the path searched preciously would be more likely to be chosen. That affects the randomness and the global search capability of this algorithm; On the other hand, the randomness and search capability can be improved by reducing ρ. But the convergence speed of the algorithm will be reduced. In this case, parameter ρ was set at 0.6 by a large number of experiences with experimental verification.

(2) Value of Q

Q is the total number of messages whose function is to search the global optimal solution under reasonable speed by using the global feedback number of messages in directed graph in the positive-feedback system.。When Q gets bigger, the convergence speed becomes larger and can enhance the ability of positive-feedback. In this case, Q values 10000 in accordance to the goal value under the Webster method whose magnitude is 10^4. From equation (4), we can see the messages have obviously been updated.

(3) Values of ant、NCmax and step

An ant colony algorithm searches the optimal solution from several candidate solutions. If the number of ants is larger; the capacity of global search and stability would be stronger. But when the number of ants increases substantially, the change in solutions tends to average out. At the same time, the capability of positive feedback is reduced and the convergence speed gets lower. In contrast, if there are only a few ants, randomness capability would get weak. Although the algorithm has a high convergence speed, with the stability reduced, the phenomenon of premature stagnation appears.

The scale of this case is small and there are only three variables in the controlling model. In the process of program debugging, ant, NCmax and step should not be too large. In order to avoid searching for a long time, their product should be controlled within 10^3-10^4. After repeated debugging, set ant=20，NCmax=10，step=10。

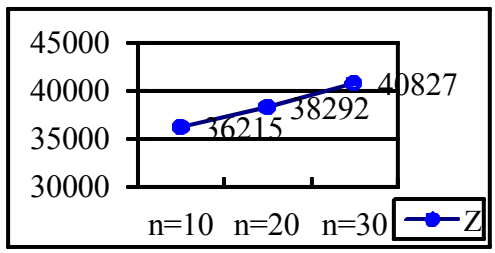
(4) Value of n

Using the data obtained during morning peak hours as an example, an analysis about the value of n has been implemented. When n is 10, 20, 30, respectively; the results are calculated as follows:

Table 2. Results with Different n .

	g_{e1}	g_{e2}	g_{e3}	C	Z
n=10	36	21	58	130	36215
n=20	38	24	62	137	38292
n=30	40	26	66	146	40827
⋮	⋮	⋮	⋮	⋮	⋮

Figure 2 . Trends of Goal Function Value .



From Table 2 it can been seen that, with n increasing, the effective green time of each phase and cycle length have all increased. As shown in Figure 2, the value of optimal target becomes larger as the value of n increases. The goal of an optimal controlling model is to search the solution which makes the target value the most optimal, or the smallest. In Table 2, when n is 10, the value of the target is the smallest one.

3.2.3 The Calibration of Initial Value of Effective Green Time for Phase i

In this algorithm, it is necessary to set the initial search scope for solutions. According to the results of the Webster method, we calibrate a different search scope for each phase at three periods:

A. Morning peak hours：ylow=[20，20，20]，ymax=[80，80，80]；

B. Afternoon hours：ylow=[5，5，5]，ymax=[35，35，35]；

C. Evening peak hours：ylow=[10，10，10]，ymax=[50，50，50]。

Where ：“y” represents effective green time for phase i.

3.2.4 Algorithm Rule

In this case, Applying the program-making procedure to this case, the original

rule for this algorithm can be described as follows: First, a solution matrix is generated, and then it is determined whether these solutions meet the constraint. If they do, save them and select the best solution. With this kind of rule, satisfying solutions occupies only a very small proportion of the solution matrix at the stage where the original solutions are generated. Consequently, the final solution doesn't achieve the desired optimal result. After modifying the program many times, the algorithm rules would be replaced as follows:

Make the restrictive conditions a determining factor when generating the solution matrix. In other words, whenever a group of solutions is generated, a judgement must be made on whether these solutions meet the demands. If they don't, the program must re-generate a new group of solutions until all of the initial solutions meet the conditions. Finally, a feasible solution matrix is obtained, from which we are able to search the most optimal solution. Thus there is a significant improvement on the optimizing effect.

4. EVALUATION OF ANT CO LONY ALGORITHM

4.1 Comparative Analysis of Calculation Results

The simulation calculation of the ant colony algorithm for continuous domain based on mesh strategy could be done in MATLAB. The results obtained from the ant colony algorithm compared with the ones of the Webster method are shown on the following table:

Table 3 . Comparison of Results .

Period	The name of algorithm	g_1	g_2	g_3	C	$\overline{d_i}$	$\overline{h_i}$
Morning	Ant colony algorithm	37	19	56	130	44.428	0.875
	Webster method	46	25	71	159	53.540	0.877
	Present condition	47	15	72	150	54.441	0.882
Afternoon	Ant colony algorithm	9	2	12	41	15.374	0.873
	Webster method	14	6	24	62	21.315	0.824
	Present condition	31	13	57	117	48.776	0.768
Evening	Ant colony algorithm	18	7	32	75	26.060	0.856
	Webster method	21	8	41	88	29.992	0.870
	Ant colony algorithm	45	27	75	163	51.293	0.886

From Table 1 it can be seen that the average delay time calculated in an ant colony algorithm for continuous domain based on mesh strategy is less than the ones obtained from Webster during any period of the day. It also shows that this algorithm also affects the average delay time at intersections. In addition, the average number

of stops derived from the ant colony algorithm is less than the ones in the Webster method for both morning and evening peak hours. But for the noon peak period, the number of stops with the ant colony algorithm is more than that in the Webster method. Therefore, this algorithm has an apparent effect on decreasing the number of stops during peak periods.

5. CONCOUSION

The simulation results show that the ant colony algorithm is applicable to solving the signal timing problem during peak hours at intersections. Average delay time has been significantly optimized, followed by the number of stops. In this case, the results reveal some bias because saturation flow rates were all taken during morning peak hours. As a result, the signal timing results of the noon period are too small. We should pay more attention to modifying saturation flow rates. From this case, a conclusion can be made that solving the nonlinear optimal model of signal timing with the ant colony algorithm has fully taken the actual situation of the "Xueyuan Southern Road and Zaojunmiao Road" intersection into account. General applicability of this algorithm should be studied for further use.

In conclusion, we can get some satisfactory optimal results by using this new optimization algorithm which can obviously improve the conditions at signalized intersections and provide a new, effective method for solving the problem of signal timing at individual intersections.

ABSTRACT

Informed by Vehicle Routing Problems with time windows (mainly soft time windows), this paper incorporates time windows into vessel scheduling problems. After a relevant literature review, this paper proposes an optimization of vessel scheduling design that could control the time deviation from designed discharging time. This optimization is especially important in view of the rough times the shipping market is experiencing as a result of the worldwide economic crisis . . This design of vessel scheduling could effectively yield a comparatively high daily net profit.

1. INTRODUCTION

In traditional Vehicle Routing Problem (VRP) studies, due to a time limitation set by clients, Soft Time Windows (STWs) are often introduced. This means that the service is potentially performed off schedule, but clients should be compensated for this inconvenience. In voyage charters, expenses incurred while waiting for berth are typically charged to the owners' account if the vessel enters the port ahead of time. Wharf storage charges will typically be paid if the vessel voyage is moved up for the next voyage charter party on time. If vessel owners fail to deliver the cargo on time, possible revenue and reputation losses will occur. So every voyage charter party has its corresponding soft time window and the vessel owner will incur punitive charges if this cargo fails to be delivered within its time window.

In practice, vessel owners usually canvass for cargoes first and then after negotiation, sign with charterer's fixture notes or voyage charter parties in which lay days and a cancellation date (LAYCAN) and sometimes estimated time of arrival (ETA) are clearly stipulated. According to these fixture notes or charter parties, vessel owners develop a design for the vessel's schedule.

2. DESCRIPTION OF VESSEL SCHEDULING PROBLEMS

Suppose a certain vessel owner has a fleet of K short-sea sailing vessels with the same dead weight tonnage Q and all these vessels are launched into voyage charter services in the East China/Japan/Korea area. Before vessels sail from the port

of departure, M cargoes are fixed. Each cargo m has a quantity of G_m and is to be carried with a freight rate of R_m. According to the charter parties, the total number of ports to be called is N and every cargo is requested by the charterer to arrive at its discharging port within a time period of $[a_m, b_m]$. If the cargo m is discharged at its port of destination before a_m because of earlier completion of the former voyage or quicker sailing speed, the vessel owner is required to pay an extra wharf storage charge for this cargo; and if cargo m is discharged at its port of destination after b_m because of severe weather, breakdown of machinery and so on, the vessel owner should make reparation for losses suffered by the charterers (Fan et al. 2005). To maximize the vessel owner's daily net profit in respect to the fleet as a whole, how should the vessel scheduling be designed?

3. ASSUMPTIONS AND EXPLANATIONS

In voyage charters, both loading and discharge work exists at every port of call. In other words, a certain cargo is discharged at a port where another cargo is waiting to be loaded onto the same vessel, so the vessel fulfills two voyages consecutively. Cargo m is loaded and discharged at port N_{lm} and N_{dm} respectively, and N_{lm} could be any port among the above defined N ports.

For every vessel among K launched into voyage charter services, it is not supposed to call at the same port more than once. During the voyage, any one vessel should sail in ballast or carry at most one cargo.

Generally, the cargo quantity G_m is mildly less than αQ, α meaning that the vessel's loading capacity will be adjusted according to the utilization of capacity, quantity of gross stores and constant, $\alpha \in (0, 1)$.

For every vessel k in service, the fixed cost per operating day is f. In general situations, the business tax rate is 3% and the rate of commission is 2.5%.

4. MATHEMATICAL MODEL

Define M_n as the number of cargoes that canvassed for port n. Because every vessel could call at every port just once, at most, the number of vessels launched must satisfy the requirement that all the cargoes fixed for each port will be carried. So,

$K = \max\ M_n,\ n \in \{1,\ 2,\ ...,\ N\}$.

Define x_{ijk} and y_{ijk} as binary variables, the port of departure is marked 0 and other ports of call are marked 1, 2, ..., N, then

$$x_{ijk} = \begin{cases} 1, \text{ vessel } k \text{ carries one cargo from port } i \text{ directly to port } j \\ 0, \text{ otherwise} \end{cases}, \text{ and}$$

$$y_{ijk} = \begin{cases} 1, \text{ vessel } k \text{ sails in ballast from port } i \text{ to port } j \\ 0, \text{ otherwise} \end{cases}.$$

So, after vessel k has been loaded at one port of loading, sailed at sea, arrived at the designated port of discharge and the discharge work of cargo has been completed, the time then is defined as t_{jk}.

$$t_{jk} = \sum_{i=0}^{N} x_{ijk}(t_{ik} + t_{li} + t_{ij} + t_{dj}) + y_{ijk}(t_{ik} + t_{ij}^{'}), \qquad j \in \{1,\ 2,\ ...,\ \mathrm{N}\},$$

where t_{ik} refers to the time that vessel k has arrived at port i and completed discharge of previous cargo, and $t_{0k} = 0$; t_{li} refers to the time spent loading at port i; t_{ij} refers to the sailing time of the laden vessel from port i directly to port j, and $i, j \in \{0,\ 1,\ ...,\ N\}$; $t_{ij}^{'}$ refers to the sailing time of the vessel in ballast from port i directly to port j, and $i, j \in \{0,\ 1,\ ...,\ N\}$; and t_{dj} refers to the time spent on discharging at port j.

The total fixed costs and the total variable costs for the fleet could be expressed as $f \times \sum_{k=1}^{K} MAX(t_{jk})$ and $\sum_{i=0}^{N}\sum_{j=0}^{N}\sum_{k=1}^{K}(V_{ij} \cdot x_{ijk} + V_{ij}^{'} \cdot y_{ijk})$ respectively, where V_{ij} refers to the variable costs for a laden vessel and $V_{ij}^{'}$ a vessel sailing in ballast.

In this model, d represents the wharf storage charge per time unit due to an earlier discharge, and e represents punitive charges per time unit because of a delay in delivery of cargo. If the cargo m is discharged at port N_{dm} before a_m, the inconvenience cost is $d_m(a_m - t_{N_{dm}k})$; and if the cargo m is discharged at port N_{dm}

after b_m, the inconvenience cost is $e_m(t_{N_{dm}k} - b_m)$.

The mathematical model for optimization of vessel scheduling with soft time windows under voyage charter is stated below. Its objective function is for the highest daily net profit (Han 2008).

$$\max Z = \left\{ \sum_{m=1}^{M} G_m \times R_m \times 94.5\% - \sum_{i=0}^{N}\sum_{j=0}^{N}\sum_{k=1}^{K}\left(V_{ij}\cdot x_{ijk} + V_{ij}^{'}\cdot y_{ijk}\right) - f \times \sum_{k=1}^{K} MAX(t_{jk}) \right.$$

$$\left. - \sum_{m=1}^{M}\sum_{k=1}^{K} x_{N_{lm}N_{dm}k} \times \left[d_m \times \max(a_m - t_{N_{dm}k},\ 0) + e_m \times \max(t_{N_{dm}k} - b_m,\ 0) \right] \right\} \div \sum_{k=1}^{K} MAX(t_{jk})$$

s. t.
$$\sum_{j=0}^{N} x_{ijk} = 1, \quad \forall i \in N,\ \forall k \in K \tag{1}$$

$$\sum_{i=0}^{N} x_{ijk} = 1, \quad \forall j \in N,\ \forall k \in K \tag{2}$$

$$\sum_{k=1}^{K} x_{N_{lm}N_{dm}k} = 1,\ \forall m \in M \tag{3}$$

Among the above examples, constraint (1) and (2) restrict that any vessel in service could not call at the same port twice or more, and constraint (3) makes sure that every cargo will be carried to its discharging port as designated.

5. EXAMPLE AND ALGORITHMS

5.1 Example

Suppose the owner has two vessels named A and B with both $Q = 10000$ metric tons and a sailing speed 12 knots. There are five cargoes fixed before the vessels start sailing from Shanghai. Distances between ports of loading and ports of discharge are listed in Table 1, and the data of the cargoes and vessels are listed in Table 2. Suppose rates of loading and discharging are 2000 metric tons per day at the five ports. Inconvenience costs are d = USD 40/h and e = USD 60/h.

Table 1. Distances Between Related Ports (Nautical Miles).

	Shanghai (SHG)	Busan (BSN)	Kobe (KOB)	Guangzhou (GGZ)	Qingdao (QDO)
Shanghai		492	783	928	399
Busan			365	1223	502
Kobe				1455	808
Guangzhou					1183
Qingdao					

Table 2. Data of the Cargoes and Vessels.

m	G_m	R_m (USD)	a_m (h)	b_m (h)	f (USD/h)	V (USD/h)	V' (USD/h)	POL	POD
1	8000	12	200	250	125	146	120	Shanghai	Busan
2	7600	25	400	500	125	146	120	Busan	Guangzhou
3	7800	13	300	350	125	146	120	Busan	Qingdao
4	8000	23	700	800	125	146	120	Guangzhou	Qingdao
5	7200	18	550	650	125	146	120	Qingdao	Kobe

An optimum solution could be achieved by spreadsheet linear programming. (see Table 3.) The optimum scheduling of vessel A is Shanghai – Busan – Guangzhou – Qingdao, and the optimum scheduling of vessel B is Shanghai – Busan (in ballast) – Qingdao – Kobe. The value of the objective fuction is $\max Z = \text{USD } 12953.80$.

QDO	0	0	0	0	0

Using this model, we can develop an optimum vessel scheduling design and obtain the theoretically highest daily net profit. Besides this advantage, in a situation where vessel owners are extremely expert at canvassing cargoes or where a shipping market is prospering with a great number of cargo supplies, this model could be used to assess whether a new fixture note or charter party is worth signing or not. Whenever M or G_m is altered, a new daily net profit is obtained. After comparing the new daily net profit with the original one, an optimum choice of cargoes could be determined.

If the vessel owner is insightful enough to pursue a long harmonious relationship with certain cargo owners, this model d_m and e_m could be magnified

to ensure that the cargoes of these owners will be carried and delivered punctually.

5.2 Algorithms

The Vehicle Routing Problem was first proposed by Dantizig and Ramser in 1956. Since then, studies on VRP have yielded additional results including VRPTW. If a large number of nodes exists, then routing becomes an NP-hard problem (Liu et al. 2005). In the above model, if the numbers of cargoes and ports are more, a "combinatorial explosion" problem exists in respect to accurate algorithms, and time problem solving increases exponentially. The improved heuristic algorithms for near optimum solutions include Taboo Search, Genetic Algorithm (Bin et al. 2003), Immune Algorithm, Ant Algorithm (Li 2008) and so on, all of which could apply to the above vessel scheduling problem model. However, each of these solutions has its own deficiencies. Even though studies on VRPTW models have brought about many achievements and the algorithms have been much improved, further improvements still need to be made in these algorithms, especially when VRPTW models are combined with concrete decision-making problems and optimization problems.

6. CONCLUSION

Based on traditional Vehicle Routing Problems, this paper proposed a solution to tvessel scheduling problems with soft time windows under voyage charter parties. Considering the current situation in shipping markets, this paper discussed the problem under the assumption that cargoes are fixed ahead. This model could reduce costs while establishing a reputation for punctual delivery, winning the fleet a strong place in the stagnant shipping market. But the algorithm for this model still needs to be further studied, taking into consideration the practices of voyage charter and the shipping market.

ABSTRACT

A congestion pricing revenue redistribution strategy is the key to the effective implementation of congestion pricing, whose design is based on mastering travelers' traffic decision behaviors. This paper analyzes the change of travel costs and impact on choice of travel mode and route for different redistribution modes, and then constructs the bi-level planning model of congestion pricing revenue redistribution in a transportation system, which is composed of a transportation plan designer and road user. The upper level model aims to maximize the benefit of the road network and the lower level model is described as a Stochastic User Equilibrium problem. The transportation plan designer acts first, framing the charge strategies and revenue redistribution. The users determine their own travel modes according to the strategies and the network traffic conditions. The transportation plan designer responds to the the users' decisions before they frame the strategies. The results of the calculation examples analysis demonstrates that this bi-level model can effectively mix the the decisions of travelers and traffic managers with proper consideration of the benefits to be gained by both sides.

INTRODUCTION

A strategy for congestion pricing revenue redistribution is the key to the effective implementation of congestion pricing, whose design is based on mastering travelers' traffic decision behaviors, such as traveling modes and route choices. However, present studies on revenue redistribution of congestion pricing are not in-depth. Overall, the greatest difference can be shown as the two views below. Most of the work in this area has concentrated on qualitative analysis or case study of revenue redistribution of congestion pricing. Representative researchers include Hau (1998), Goodwin (1989), Small (1992), Litman (1996), Armelius (2006). Only a limited number of quantitative models of revenue redistribution were established under simple network conditions for direct presentation of distribution policy, or the benefit of traffic management agencies. Representative researchers include Bernstein (1993), Jeffrey (2001), Kockelman and Kalmanje (2005) , Ferrari (2005).

Current road congestion pricing revenue redistribution research focuses on qualitative mode analysis or case studies, and fails to focus on traffic behavioral analysis under congestion pricing revenue redistribution. It should be noted that

traveler utility must be changed after redistribution of revenue from road congestion pricing, a factor that will result in a change in traveler behavior, especially the choice of travel mode. Relative research papers establish models that only benefit traffic management agencies while ignoring travelers' response to traffic policy. Therefore, analysis of traffic behavior is the basic premise of establishing practical policy of redistribution. Research results contain important theoretical and practical approaches to improve road congestion and enhance transportation efficiency.

ANALYSIS OF TRAFFIC BEHAVIORS UNDER DIFFERENT SITUATIONS

Modes of redistribution of revenue from road congestion pricing can be considered under the following three types of situations: The first mode is to compensate motor vehicle travelers by returning cash or through tax offsetting. The second mode is to use the revenue to extend road capacity. The third mode is to improve the running speed, departing frequency, convenience, and reduce fare of public transport. According to efficiency and equity criteria, the first mode goes against efficiency criteria and is not the best way. The second mode improves road capacity and supply ability. In short terms, this mode can improve transport efficiency, but it is not the best long-term plan because the capacity cannot increase infinitely due to the limited earth. The third mode can improve the service of public traffic, decrease operating costs and increase the demand of public traffic. Extending road capacity and improving public transport service are accepted methods and the best way to distribute congestion pricing revenue when we can't extend road capacity.

When the revenue of road congestion pricing is used to extend road capacity, we assume B_a as capacity of vehicle on road a. The new capacity is g_a, c_a, $\overline{c}_a$ is general travel costs of road a for private and public transports after pricing, which can be expressed as:

$$c_a = t(x_a, g_a) + u(x_a) = t_0[1 + \alpha(\frac{x_a}{B_a + g_a})^{\beta}] + u(x_a) \quad (1)$$

$$\overline{c}_a = t(\overline{x}_a, g_a) + \overline{u}(\overline{x}_a) = \overline{t}_0[1 + \alpha(\frac{\overline{x}_a}{B_a + g_a})^{\beta}] + \overline{u}(\overline{x}_a) \quad (2)$$

Where, t_0, $\overline{t}_0$ is the driving time of private and public transport under free flow through road a; u_a, $\overline{u}_a$ is the pricing fee of private transport and bus fare for road a; x_a, $\overline{x}_a$ is private and public traffic flow on road a, α, β are the parameters of road fee function BPR which shows the relationship between travel time and flow of vehicles. Road congestion pricing revenue is used to increase road capacity which will decrease fees and improve welfare when travelers use the road a.

When the revenue of congestion pricing is used to improving public transport service, including decreasing bus fare and increasing send-out frequency, waiting

time is reduced at the bus station. We assume c_m, $\overline{c}_m$ as the generalized cost of private traffic and public traffic each trip between r-s, which can be expressed as:

$$c_m = b_0 + b_1 t_1 + b_2 t_2 + b_3 (c_d + u) \tag{3}$$

$$\overline{c}_m = \overline{b}_0 + \overline{b}_1 \overline{t}_1 + \overline{b}_2 \overline{t}_2 + \overline{b}_3 \overline{u} = \overline{b}_0 + \overline{b}_1 \frac{1}{y} + \overline{b}_2 \overline{t}_2 + \overline{b}_3 \overline{u} \tag{4}$$

Where, b_i, $\overline{b}_i$ are the corresponding factors of private traffic and public traffic, $i = 0,1,2,3$; t_j, $\overline{t}_j$ denotes wait time, in-vehicle time of private traffic and public traffic, $j = 1,2$; c_d denotes vehicle depreciation and fuel costs. y denotes the bus departure frequency. We can find $\overline{c}_m$ will decrease when u is used to the decreasing of $\overline{u}$ and increasing of y in the formula.

According to MNL model, the probability can be derived as follows if private transport and public transport travelers choose path k:

$$p_k^{rs} = \frac{\exp(-\alpha c_k^{rs})}{\sum_k \exp(-\alpha c_k^{rs})}, \quad \overline{p}_k^{rs} = \frac{\exp(-\alpha \overline{c}_k^{rs})}{\sum_k \exp(-\alpha \overline{c}_k^{rs})} \tag{5}$$

Where, c_k^{rs}, $\tilde{c}_k^{rs}$ are the generalized costs of private traffic and public traffic on path k, which can be expressed as:

$$c_k^{rs} = \sum_a c_a(x_a, u_a)\delta_{a,k}^{rs}, \quad \overline{c}_k^{rs} = \sum_a \overline{c}_a(\overline{x}_a, \overline{u}_a)\overline{\delta}_{a,k}^{rs} \tag{6}$$

Where, $\hat{\delta}_{a,k}^{rs}$ $\tilde{\delta}_{a,k}^{rs}$ are the 0-1 variables, they are equal to 1 if private transport or public transport trips' road a is on route k.

The probability can be derived as follows if travelers choose private transport or public transport:：

$$p_{rs} = \frac{1}{1 + e^{\theta(\overline{c}_m - c_m)}}, \quad \overline{p}_{rs} = \frac{1}{1 + e^{\theta(c_m - \overline{c}_m)}} \tag{7}$$

A MODEL FOR CONGESTION PRICING REVENUE REDISTRIBUTION BASED ON TRAFFIC BEHAVIOR

This paper regards the transport system as a mix of transportation planning managers and users of complex systems, where transportation planning managers become the upper decision makers, and network users become the lower decision makers. The establishment of upper planning objectives is based on meeting the city's traffic management objectives. In this paper, road congestion pricing revenue is used for road expansion or public transport. We set the amount of investment for the road expansion at $\sum \varphi(g_a) = d_a g_a$, d_a is the parameter for the investment function, the amount of subsidies for the public transport is $S = C_p y - \overline{uq}$, C_p is the operating costs of each bus travel between the O-D pairs, including vehicle depreciation, maintenance, drivers and conductors' wages, plus related costs such as fuel consumption for each travel. Then the Upper Level Planning Model of road congestion pricing revenue redistribution can be expressed as:

$$\max_{u,\tilde{u},y,g} H = \sum_{rs}\int_0^{q_{rs}} D_{rs}^{-1}(x)dx - \sum_a t_a\left(x_a(u,g),g_a\right)x_a + \sum_{rs}\int_0^{\bar{q}_{rs}} \bar{D}_{rs}^{-1}(x)dx - \sum_a \bar{t}_a\left(\bar{x}_a(\bar{u},\bar{g}),\bar{g}_a\right)\bar{x}_a - S - \sum_{a\in A}\varphi_a(g_a) \quad (8)$$

$$s.t. \quad x_a(u) + \tau\bar{x}_a(\bar{u}) \le B_a + g_a \quad (9)$$

$$\sum_a \varphi(g_a) + S \le \sum_a u x_a \quad (10)$$

$$u_a, \bar{u}_a, g_a \ge 0 \quad (11)$$

Where, τ denote the vehicles' conversion coefficient; q_{rs}, $\bar{q}_{rs}$ denote the demand of private and public transport between r-s.

The lower planning model can be expressed as:

$$\min_{x,v,\hat{q},\tilde{q}} G = \sum_{rs}\sum_k \hat{f}_k^{rs}(\ln \hat{f}_k^{rs} - 1) - \sum_a \hat{q}_{rs}(\ln \hat{q}_{rs} - 1) + \alpha\left[\sum_a\int_0^{x_a} \hat{c}_a(w,\hat{u}_a,g_a)dw - \sum_{rs}\int_0^{q_{rs}} \hat{D}_{rs}^{-1}(w)dw\right] + \sum_{rs}\sum_k \tilde{f}_k^{rs}(\ln \tilde{f}_k^{rs} - 1) - \sum_a \tilde{q}_{rs}(\ln \tilde{q}_{rs} - 1) + \alpha\left[\sum_a\int_0^{v_a} \tilde{c}_a(w,\tilde{u}_a,g_a)dw - \sum_\omega\int_0^{\tilde{q}_{rs}} \tilde{D}_{rs}^{-1}(w)dw\right] \quad (12)$$

$$st. \quad \sum_k f_k^{rs} = q_{rs}, \quad \sum_k \bar{f}_k^{rs} = \bar{q}_{rs} \quad (13)$$

$$x_a = \sum_r\sum_s\sum_k f_k^{rs}\delta_{a,k}^{rs}, \quad \bar{x}_a = \sum_r\sum_s\sum_k \bar{f}_k^{rs}\bar{\delta}_{a,k}^{rs} \quad (14)$$

$$q_{rs} + \bar{q}_{rs} = \hat{q}_{rs} \quad (15)$$

$$q_{rs}, \bar{q}_{rs}, \hat{q}_{rs}, f_k^{rs}, \bar{f}_k^{rs}, x_a, \bar{x}_a \ge 0 \quad (16)$$

Where, α is a parameter of plus values. $\hat{q}_{rs}$ denotes the total demand between r-s, f_k^{rs}, $\bar{f}_k^{rs}$ denote the private and public transport flow on path k.

Because the above-mentioned bi-level optimization model is notsmooth, such traditional methods as interactive and bundle methods are not appropriate for using the bi-level optimization model. The Genetic Algorithms based on natural selection and biogenetics have few limitations on optimization, and are likely to be optimal solutions to the models. Practice proves GA is an efficient tool for the solving of optimization problems, so GA is used here. For more detail see literature (S. An, 2004).

CASE STUDY

When considering the existence of private cars and buses traveling on the road network, most scholars usually choose a four-square city region composed of public transportation grid lines as a numerical example. This example arranged by Holroyd, is the best road network in that all OD are uniformly distributed rectangular lines (Newell, 1979). This paper selects this example of the road network as the basic framework (Ying J. Q & Yang H, 2005), shown in Figure 1.

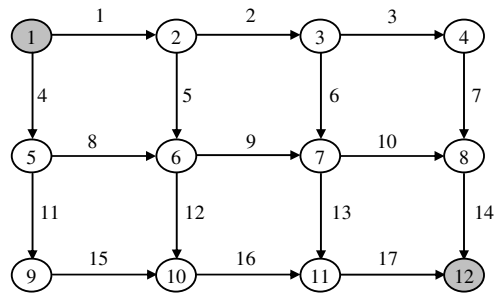

Figure 1: The Network Used for the Numerical Example.

The road network, as shown in Figure 1, consists of 1 O-D pair, 12 nodes and 17 links. We assume that buses share the same streets with private vehicles. Corresponding parameters of road sections are shown in Table 1.

The demand between (1,12) equals 3750, that is $\hat{q}_{rs} = q_{rs} + \overline{q}_{rs} = 3750$. According to congestion pricing revenue redistribution models and the GA algorithm, bus departure frequency y is 8veh/h. The optimal bus fare $\overline{u}$ is 0.51 yuan/veh between (1,12) when revenue from congestion pricing is used to extend road capacity, decreasing bus fare and increasing bus departure frequency. Road congestion pricing and road capacity extension is shown in Table 2.

CONCLUSION

This paper proposes that the revenue of congestion pricing can be used to extend road capacity and support public transport. Under two redistribution modes，it is concluded from all of the results of analyses obtained that the costs of private

and public transport will increase, which will cause more use of public transport. On this basis, this paper establishes the bi-level model of congestion pricing revenue redistribution. The results of the calculation examples analysis demonstrate that this bi-level model can represent the variability of transportation demand and the randomness of road user's behavior better than that of traffic managers.

ABSTRACT

Highways characteristically provide a basic service, public and social welfare, and economic benefits. The government and the market should both play a role in highway construction. Different types of highways require significantly different types of financing capability. A positive fiscal policy could bring a typical "financial driving-effect" to highway construction. Based on the analysis of influence aroused by the macroeconomic environment change in the period of the "11th five-year plan" (abbreviated as "11FYP") - two aspects of the fiscal policy change and the tax reform, or four suggestions on highway construction investment and financing strategy are put forth regarding legislation, orientation, approach and layout.

INTRODUCTION

Changes in Economic and Social Development During the 11FYP. China's macroeconomic situation continues to develop as a basic "V" during the 11FYP period. There are two reasons for the formation of this trough. On one hand, China's foreign trade dependency is up to 70%. Because of the weakened foreign requirement, the world financial crisis has had negative effects on China's economic development. On the other hand, the domestic economy is in an economic structure transformation and cyclical adjustment, and the economic operation status is the inevitable reflection of "double factors superposition." In view of this, during this period, China's macro-control measures should transform rapidly and policies quickly adjust. Up until now, there have been two big shifts from "two prevents," (prevent the economy from overheating and prevent inflation) to "one keep and one prevent" (keep the economy growing steadily, but prevent the price level from becoming too high). Now there is a focus on "one keep" (keep economic growth at a rate of no less than 8%). Prudent fiscal policy has transformed from a tight to a positive one from the beginning to the mid-term of 11FYP. Financial monetary policy has emerged with a corresponding change. Furthermore, the China State Council has issued an economic stimulus plan for this investment with a scale of

RMB 4 trillion projected by the end of 11FYP, Nearly 38% of this amount is slated for the areas of transportation and water conservancy infrastructure construction. The orientation of the positive Mac policy and coordinated structure adjustments provide an opportunity for rapid highway construction development.

Implementation of Highway Construction Investment Planning in t he Mid-term of 1 1FYP. During the period of 2006-2008, national highway construction has raised funds of 1.68 trillion RMB. Of these funds, the central government fund is 13.5%. Highway construction finished the investment of 1.96 trillion RMB. The total highway length increases 338 thousand kilometers, which means 91% of the task will be completed as part of the "China Highway and Waterway Transportation Development for 11FYP" (hereinafter briefly as "the plan"). The expressway increases by 19 thousand kilometers, which completes 79% of the task in "the plan". Highway that is above II-grade technical condition increases by 67 thousand kilometers and is 54% complete. Rural roads increase 294 thousand kilometers and will be 91% complete. Ninety-three percent of townships and 91.9% of villages have road connections. Twelve national trunk highways run through and national expressway network construction is involved in large-scale construction.

Despite overall highway construction progress and improvements in the highway infrastructure that have happened up until the mid-term of 11FYP, the plan is inevitably affected in the face of great changes in China's macroeconomic policy.

INFLUENCE ANALYSIS

Highway Infrastructure's Attributes and Financing Capability Analysis

1.）Attributes and Characteristics

The highway is a kind of public infrastructure and a means of transporting quasi-public goods. It plays a fundamental role in the national economy and almost all social and economic activities as personnel and goods are moved., Thus, highways have the attribute of providing a basic service function.

Highways will spread and transfer many benefits for social welfare and life, but it is hard to ask for a return and prevent a spillover effect for all users. So the highway has the characteristic of serving public and social welfare.

The cycle of highway construction is long and the investment is huge. But once the highway network is formed, it brings far more social and economic effectiveness than the composition of single roads. Therefore, the highway has net scale economic benefits.

2.）Financing Capability Analysis

Highway financing capability is closely related to the characteristics of its attributes. Since highways are a kind of quasi-public goods, its investment potential is often determined by the government and the market. Under certain conditions, it can be determined by the government, or by the market, or both.

The economic factors and traffic level are important factors that can impact the financing ability of highway projects. For general highways in low-grade technical condition, the investment should come entirely from state and local governments for they have an interest public welfare and low financing capability.

Actually, this should be the government responsibility.

Highways with the higher level of technical condition can provide better services for users, and are used for transporting merchandise. Because toll rights are involved in the deal, they have certain financing capability. However, even the expressway, which has the strong financing capability in the highway construction market, faces problems in the face of rising financing costs and risks. According to the calculations, most of the expressway projects' financial internal rate of return is much lower than the average social discount rate. If there is no guide and support of the related policy and no proportion of direct investment, it is almost impossible for highway investment and construction to completely depending on the market.

HIGHWAY CONSTRUCTION INVESTMENT AND FINANCING INFLUENCE ANALYSIS

The Change of the Central Finance Policy . Central finance capital is not only used in the direct investment in highway construction, but is also used to increase the capital fund, so it can significantly increase project financing capability and then promote input of bank loans and local funds. In fact, the banks regard fiscal funding as the "invisible" support of the government and involvement of this kind helps prevent risks.

From the beginning of 11FYP, the national fiscal and monetary policy has been "tightening" until the fourth quarter of 2008. This affects the total capital in the national budget applied to highway infrastructure, and applications for construction land and bank loans have become harder and harder to obtain. The ratio between highway construction investment and social investment in fixed assets and the ratio between capital of the national budget and financing funds decrease gradually. The growth rate of newly increased highway fixed assets also slows sharply (see Table 1).

Table 1. Highway Construction Investment and Financing Funded Scale from 2004 to 2008.

	Highway construction investment ① (billion RMB)	Rate[1] (%)	Rate[2] (%)	Capital of the National Budget in Highway ② (billion RMB)	Rate[3] (%)
2004	464.50	6.6	26.9	13.75	3.3
2005	541.31	6.1	16.5	11.82	2.6
2006	613.88	5.6	13.4	8.13	1.6
2007	640.01	4.7	4.3	7.74	1.4
2008	675.52	3.9	5.5	15.92	2.7

Note: Rate[1]=①/Social investment in fixed Assets, Rate[2]=annual rate of growth of ①, Rate[3]=②/ Highway construction financing funded.

At the end of 2008, highway construction projects included in the "program with the central budget of 10 billion RMB" have obtained national funding. Highway projects have gained more financing opportunities in the environment of "loose" monetary and fiscal policy. Those projects are promised 15.6 billion RMB in

supporting funds from local government, national banks and even some foreign banks. In the new cycle of stimulating domestic demand and accelerating fixed asset construction, it is expected that highway construction will drive nearly another 2 trillion of total investment scale at the end of the11FYP period.

To meet the requirement of sustainable and balanced development, full use should be made of the existing financing channels and challenged by expanding investment scale to meet the needs of the present economic development, as well as greatly raising investment efficiency in order to strengthen construction structure and quality. That is the real challenge for transportation management departments in "the super-ministries" transformation.

The Influence Analysis of Tax Reform on Highway Construction . Since 2009, fuel tax reform has been carried out in China. After enterprise income tax and value-added tax system reform, it is another very important tax reform. Fuel tax has replaced maintenance fees, additional expenses for the passenger and goods transport, and administration fees for highway and waterway facilities and transport. In addition, the toll fees of the highways above II-grade technical condition whose debts are paid by the local governments will be canceled step by step. On one hand, fuel tax reform rationalizes China's taxation system and establishes the internal mechanism of energy consumption mediation. On the other hand, it changes the pattern from "giving priority fees to tax" to "giving priority tax to fees.". That is, the new tax system primarily takes fuel and vehicles purchase taxes, and takes the toll fees from highways in higher-grade technical condition as auxiliary fees. At the same time, vehicles purchase tax for vehicles whose displacement is less than 1.6 liters is reduced to 5% from January 20th to December 31st 2009.

According to estimates, vehicle purchase tax collected by the State Taxation Administration will decrease about 8 billion RMB, and less than 10% of the total vehicles purchased taxation in 2009. In view of the recent annual vehicles purchase tax contribution to highway construction, which is less than 90% of the amount collected, the effect of vehicle purchase tax expenditure is almost negligible. However, the implementation of fuel tax reform will bring about great influence.

First, the local transport management departments collected and expended the fees mentioned above before the establishment of the new tax system. The central government just macro controlled the criteria and scope of collected fees. Local transport management departments play an active and generative role. They maintain the highways from collected fees, simplify the procedure and administrative of levels of spending and appropriation so as to adapt to seasonal highway construction. After the establishment of the new tax system, tax agencies will impose the fuel tax and hand it over to state finance. State financial departments will arrange the tax according to the strict budget plan that will subordinate financial departments . Financial departments will then transfer it to transport management departments. The capital turnover takes a long time. This pattern may have some problems in the cases of capital used for any purpose other than highway construction and capital not meeting the construction demand of general highways in the lower grade technical condition.

Second, local transport management departments lost the possibility to use fees (such as maintenance and administration fees) as the financial guarantee or backing the need to apply to banks for loans because national financial capital cannot be used as the debt guarantee. To a certain extent, that impacts the construction and the financing channels of highways in higher-grade technical condition. Highway projects that have used transportation fees as the financial guarantee must be handled accordingly. In addition, under the new tax system, highway construction fund management is changed from the non-budgetary pattern to the national financial management pattern, run strictly according to "separate income and expense management." Appropriation is directly paid to construction units. This will cause cash flow reduction and a unitary financing structure for local highway construction. The ability to finance a single project is relatively weak. While investment entities that can replace local transport management departments with finance capital have not been established, the financing capability of highway construction units is weakened. This requires reforming and adjusting the current capital management and financing systems.

COUNTERMEASURE

Highway construction needs to complete the targets and tasks it will be facing as a consequence of the changes that will occur in the later period of 11FYP. So the following strategies and suggestion from the perspective of the government are suggested based on the influence analysis of highway construction investment and financing environment:

The government sho uld lay a solid foundation for highway construction by establishing and improving laws and regulations. There is only the "Highway Law of the People's Republic of China" which rarely includes specific provisions for highway construction investment and financing. The law is hard to comply with and implement. Relevant government orders and administrative regulations about capital financing also exist, but they could not meet the requirements for highway construction because of artificial factors and the vulnerable policy environment. It is urgent to establish laws that will provide the excellent macro environment for investment and financing activity. New laws and regulations should provide stable and legal financing channels or approaches under a fair, reasonable and legal framework, and guarantee the rationalization, supervision of the capital scale, as well as recourses and uses for highway construction.

The government should restrict , guide and coordinate highway construction. On one hand, this would ensure annual financial input by arranging key highway project investments in the public finance system framework, while increasing financial budget appropriations in the field of general highways building and rebuilding. On the other hand, it would make the vehicles purchase tax and fuel tax truly a main and reliable source of policy funds. The government would restrict, guide and coordinate, all aspects of not only scale, but also layout and structure.

The government should ma ke full use of existing financing approaches and social capital, actively expanding financing channels. At present, the existing

financing approaches are effective financing channels for highway construction. These channels include issuing bonds and stocks, utilizing foreign investment, BOT (Build-Operation-Transfer) mode etc. and should continue to be used to help set up the standard operation and management systems for highway construction. In addition, Asset-Backed-Securitization (ABS) is also a suitable financing channel for highway construction when domestic capital markets are allowed. The government can enliven the investment and financing market by encouraging and supporting enterprise capital, social capital and overseas capital access while reducing permission restrictions so as to gradually form a relatively reasonable investment structure and possibly meet the needs of highway construction.

The government should arrange to rationally investment in rural road construction and rea lize the healthy development of highway construction. Solving the problems of "peasant-village-agriculture" is one of the government's and transport management's priority tasks. Rural road construction should be adopted in the framework of public finance where local governments give priority to township and social input. Central financing capital can be the oriented funds which drive and mobilize local financing capital at various levels so as to promote local economic development as well as guarantee national highway construction.

CONCLUSION

Highway infrastructure should take advantage of the opportunities that the government is providing as part of the positive fiscal and monetary policy that will occur during the latter part of 11FYP and adapt to the changes and requirements of the new tax reform. Transportation management departments should set up and improve laws and regulations concerning highway construction investment and financing, broaden the financing channels, optimize capital layout, explore the mechanism established to promote coordinated and sustainable development of highway construction, and lay the solid foundation for the 12FYP of China's highway transportation development.

A Study on the Financing Mode of Assets Securitiz ation in Port Project

Yu Su[1]

[1]MBA education center of Shanghai Maritime University, Cell phone: 13918184850; email: yusu@sem.shmtu.edu.cn

ABSTRACT

Through analyzing the asset property of ports, this paper maintains that the high efficiency of port asset provision needs wide multi-channel financing on the basis of clear responsibility. As to the financing channels and mode, this paper combines the theory and operating characteristics of assets securitization, by mainly investigating the function and implementing pattern of port assets securitization. It further proposes an assets securitization financing mode and blueprint for Chinese port projects, and finally proposes an "immune" plan against the possible assets value risk of this financing mode.

INTRODUCTION

Background . China, as an emerging economic power, has 18,000 islands, a coastline of more than 18,000 kilometers and an inland waterway of more than 100,000 kilometers. However, the insufficient investment of port facilities means that the port construction pace cannot catch up with the economic growth rate, a bottleneck which is a difficult situation in port construction financing. While asset securitization is a developing trend in international financing, the investment channel of Chinese civilian capital is very limited. With few investment choices, and a single form of capital market, the stock market is facing high risks. At the same time, port assets have a large capacity for absorbing capital and a steady return, but very few such companies are listed in the security market. Thus, the possibility of expanding port construction through stock market financing is an import subject that we must currently deal with.

The Purpose of the Research . According to international experience, asset securitization is a supplementary financing method that can be used in China. In this essay, I first analyze the property of port project assets, then by combining the theory and operating characteristics of assets securitization, I introduce a feasible mode for port asset securitization financing, and propose a corresponding plan.

PROPERTIES OF PORT ASSETS

Public goods are non-rival in consumption and non-excludable. Based on the efficiency of public goods provision, different types of port assets are provided by different parties, as can be seen in the following table:

Table 1 . Different Types of Port Assets Provision in Chin a.

Types of products	Types of port project	Types of port assets	Investment mainbody
Public goods	Public investment project	The water and land way. Buildings and sites for customs, inspection and quarantine officials, etc.	Government, by levying a tax on the users according to the relevant rules and regulations
Quasi-public goods	fundamental investment project	Wharfs, berths, cable fastening facilities and other floating vessel parking facilities, etc.	Examined and approved by the government ， invest and run by the enterprises
Private goods	Competing investment project	Loading and unloading equipment, transportation conveyance, warehousing facilities	Enterprises, individuals, non-governmental organizations or commercially loaned capital.

The classification in Table 1 is not absolute. There are enterprises in other countries that invest in sea routes and charge for them. There are also governments who invest in the public wharf and make it free to the public.

ENVISION OF THE MODES OF ASSET **SECURITIZATION IN CHINA'S** PORT PROJECT

Single mode of securitization financing for a new port . The precondition of applying this mode is: the newly built port must be developed on virgin soil; there is no existing infrastructure or corresponding facilities that can be borrowed from, such as the Shanghai Luchao port construction project.

To finance a new port project, the government should shoulder the responsibility of infrastructure construction at the early stage of port financing. In the case of a tight budget imposed by the financial department, assets securitization can help fill the gap. The securitization mode conceived in this paper can be illustrated in the following simplified model:

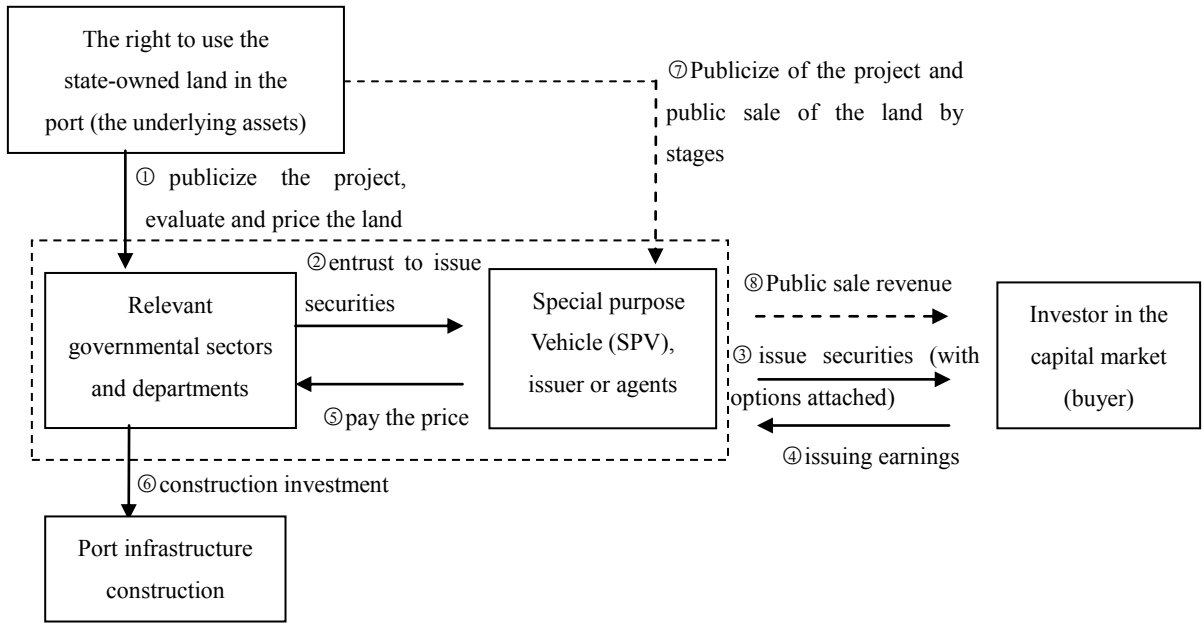

Figure 1 . Single Mode of Securitization Financing for a New Port.

The above mode can be a win-win solution. The government gets the future land-sale proceeds at one time and invests in infrastructure construction of the port. The investor hedges its risks by attached options and get the extra profits of the land.

Mode of Securitization Financing Based on First Phase Project Assets for the Second Phase Construction . The previous financing mode can be extended, when the first phase of the project has been completed. The income gained from the project assets leasing can be used as the underlying assets for the securitized financing of the second phase project. The following chart will give the details:

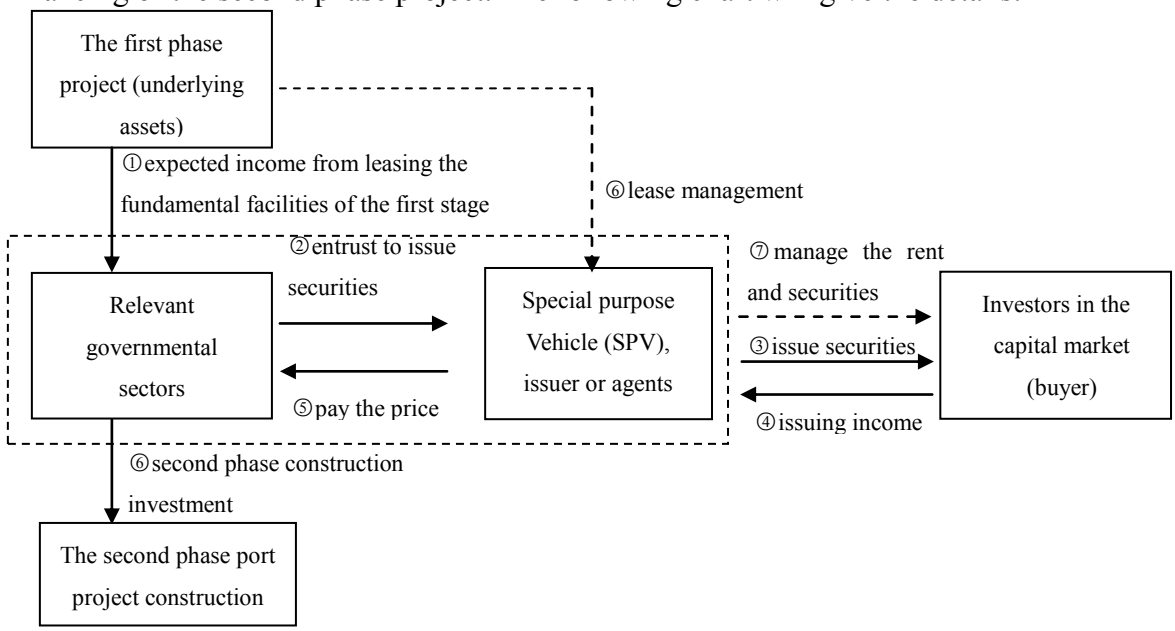

Figure 2 . An Extended Financing Mode.

PROBLEMS OF CAPITAL MANAGEMENT AFTER ASSET S SECURITIZATION IN PORT PROJECT

Duration of Securitized Assets . Capital management after securitized financing is the key factor to the success of the whole project. As the income capital flow of port assets does not match the expenditure cash flow at each term, exposure risk exists all the time. Therefore, we need to introduce "duration" to match these positions, which will be illustrated later.

Macaulay Dration(D): $D = \dfrac{\sum_{i=1}^{n}\left[\dfrac{CF_i}{(1+r)^i}\cdot i\right]}{\sum_{t=1}^{n} PV(CF_i)}$, Modified Duration(MD): $MD = \dfrac{D}{1+r}$

Then we have: $\dfrac{dP}{P} = -MD\cdot dr$

Suppose some securitizable port assets can bring 10 billion Yuan RMB revenue per year (which can be seen as an expected cash flow of 10 billion Yuan/year in the next 5 years). The market yield for a 5-year financial product is 5%. When discounting the yield over the next five years, we can get the present value of the expected yield in the following table:

Table 3 .The Present Value of the Expected Yields (in 100million Yuan) .

Term (year)	1	2	3	4	5
Expected annual yield	10	10	10	10	10
PV of the expected annual yield	9.5238	9.0703	8.6384	8.2270	7.8353

The total present value of five years' expected proceeds is:

$$P = \sum_{i=1}^{5} PV(CF)_i = \sum_{i=1}^{5} \frac{CF_i}{(1+r)^i} = 9.5238+9.0703+8.6384+8.2270+7.8353 = 43.2948$$

Suppose we decide the size of securities issuing according to the present value of the assets, or 4.32984 billion Yuan. We issue the debt securities at face value with coupons attached, and then the real yield rate is 5%, equal to the market rate. We can calculate the cash flow of the debt securities in the next five years:

Table 4. The Present Value of the Expected Payment (in 100million Yuan) .

Term (year)	1	2	3	4	5
Expected annual payment	2.1647	2.1647	2.1647	2.1647	4.5.4595
PV of the expected annual payment	2.0616	1.9634	1.8699	1.7809	3.5.6187

From the above two tables we can see that securitized financing for port assets by issuing the debt securities with coupons attached will mean that the yield and payment cash flow won't match. More specifically, during the first four terms, the cash flow of yield far exceeds that of payment, while in the fifth term, the cash flow of payment far exceeds that of yield.

The Macaulay Duration of expected value of yield:

$$D_1 = \frac{\sum_{i=1}^{n}\left[\frac{PV(CF)_i}{(1+r)^i}\cdot i\right]}{\sum_{t=1}^{n} PV(CF_i)} = \frac{9.5238\times 1 + 9.0703\times 2 + 8.6384\times 3 + 8.2270\times 4 + 7.8353\times 5}{43.2948} = 2.9025$$

Modified duration: $MD_1 = \frac{D_1}{1+r} = \frac{2.9025}{1.05} = 2.7642$

The Macaulay Duration of expected value of payment:

$$D_2 = \frac{\sum_{i=1}^{n}\left[\frac{PV(CF)_i}{(1+r)^i}\cdot i\right]}{\sum_{t=1}^{n} PV(CF_i)} = \frac{2.0616\times 1 + 1.9634\times 2 + 1.8699\times 3 + 1.7809\times 4 + 35.6187\times 5}{43.2948} = 4.5459$$

Modified duration: $MD_2 = \frac{D_2}{1+r} = \frac{4.5459}{1.05} = 4.3294$

The market value of assets is calculated according to the net present value. In the above case, the five-year assets yield 4.32948 billion Yuan, with the Modified Duration being 2.7642; while the total present value of securitized assets is also 4.32948 billion Yuan, but the Modified Duration is 4.3294. This means that when the market rate changes, there will be big differences in these two values. In the end, the market risk will be out of control.

Risk Immunity o f Cash Flow Management . From the duration value calculated above, we can see that there is a big difference between the duration of expected payment of debt securities and the duration of expected yields of the assets. Further, the cash flow of future yields cannot offset that of the payment, which suggests that the position exposure may cause large market risk. The change rate of the value of expected payment will be 56.62% larger than that of the market yield, in which case the market value formed after the securitized assets are listed on the market will fluctuate asymmetrically. This brings great risks to the management of these assets.

As the expected income of port assets is uncontrollable and unchangeable, the

only way to solve the above problem is to change the structure and proportion of expected income that is to change the compound duration of expected income. To reach this goal, we can change the structure of securities issued to combine the issuance of short-term securities, median-term securities, and long-term securities to get a compound duration of payment that is in correspondence with that of the expected income at any time.

To be specific, we can issue a one-year short-term debt security, three at the rate of 3% in addition to the previous five-year debt securities. As there is only one expected future payment cash flow for the one-year debt securities, the Macaulay Duration is $D_3 = 1$

the modified duration is: $MD_3 = 0.9709$

Then, use the risk-immune way to balance the duration, we get:

$$\begin{cases} MD_1 = W_2 \times MD_2 + W_3 \times MD_3 \\ W_2 + W_3 = 100\% \end{cases} \quad \begin{cases} 2.7642 = W_2 \times 4.3294 + W_3 \times 0.9709 \\ W_2 + W_3 = 100\% \end{cases},$$

$W_2 = 53.40\%$; $W3 = 46.60\%$

Therefore, as long as we issue the long-term and short-term securities according to a certain proportion, the interest rate fluctuating risk of future cash flow will be in control.

CONCLUSION

Port asset securitization in China has just come into being, and many problems are still waiting to be explored. There is rarely any past experience to follow in China, and it is also impractical to copy successful examples from foreign counterparts due to systematic differences. In the article, the author first designs two models to analyze port asset securitization in China. The models are based on the basic theories of asset securitization and are adjusted for Chinese port asset classifications. The author then studies the cash flow patterns after port asset securitization, and based on the results, uses duration theory to probe into risk management issues during the securitization, and raises a simple but effective method to control the risk.

As China's security market continues to improve, the theory of duration in risk management will certainly be utilized on a greater scale. This article has only taken the first step in discussing issues in financing process and financing risk in China's port asset management, and the conclusions and suggestions in the article carry the author's intent to invite more contributions to this field of research.

ABSTRACT

In the big cities of China, pedestrians and bicycles have a great impact on the capacity of right-turn lane vehicle movement at signalized intersections. In most cases, pedestrians become the main factor in the capacity of movement in the right-turn lane, This paper attempts to explore the potential capacity of right turn movement when there are conflicts between right-turn vehicles and pedestrians at signalized intersections. In order to take this impact into account in the capacity calculation, it is assumed that all pedestrians obey the traffic regulations, which means pedestrians cross the intersection only when the pedestrians' signal indication is on. The objective of this study is to quantitatively analyze the impact of pedestrians on the capacity of right-turn vehicles at signalized intersections with regard to different signal phases. In order to reach this objective, a new concept of "Pedestrian Group" is introduced in this paper, where the capacity model of the right-turn lane at signalized intersection is based on gap acceptance theory. The results of this study has great importance for the development of capacity analysis and our own Manual.

INTRODUCTION

The traffic conditions at intersections in China are relatively complicated as compared to other countries. At intersections, there are heavy conflicts between pedestrian traffic and vehicular traffic. Based on traffic regulations, those making a right turn can make that turn during any signal indications for the majority of signalized intersections in China. However there is a conflict between right turn vehicles and pedestrians crossing at intersections during green indication. On these occasions, pedestrians have a great impact on the right turn capacity at signalized intersections. The Highway Capacity Manual (HCM) estimates an adjustment of saturation flow rate of right turn movement during different phases and lane use, but

it does not provide the approaches to estimate the effect of pedestrians. In China, many approaches also do not estimate the effect of pedestrian movement. Therefore, the motivation behind conducting this study is to model the potential capacity of right turn movement under the presence of through pedestrian flow at signalized intersections. This model can, to some extent, represent the real state of signalized intersections in China. This model can also help traffic engineers conduct capacity analysis under mixed traffic conditions. In addition, the results of this study provide useful information for traffic management at signalized intersections.

METHODOLOGY

Analysis of characteristics of right -turn movement

At signalized intersections, right turn vehicles conflict with through pedestrians from two directions. As shown in Figure 1, during the green indication right-turn vehicles have to yield to through pedestrian traffic based on traffic regulations. As a result, the capacity of right- turn movement will definitely decline.

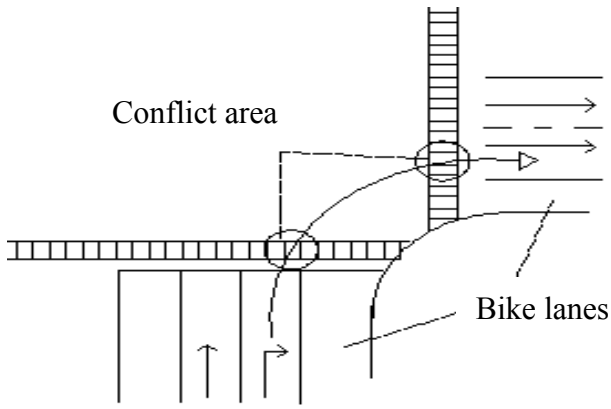

Figure 1. Illustration of Conflicts Between Pedestrians and Rig ht-turn Vehicles.

Characteristics of conflicts

Right turn vehicles and pedestrians have three types of conflict:

(1) No conflict

Because of traffic signal control, pedestrians should wait for crossing at the sidewalk during the red indication for pedestrians. At this time. right turn vehicles have no conflict with through pedestrians.

In this case, the maximum number of right-turn vehicles through the intersection can be estimated by equation 1.

$$n_l = \frac{3600}{T}\left(\frac{t_g}{h_l}\right) \quad (1)$$

Where, n_1 = the number of right turn vehicles through the intersection (veh);
T = cycle length (s);
t_g = green time for right turn movement (s);
h_t = headway of right turn vehicles (s).

(2) At early stage of green indication the number of right-turn vehicles through intersection is n_2.Pedestrians are in constant arrival during the red indication and concentrate at the intersection. When the pedestrian signal turns yellow, pedestrians will be the first to enter the crosswalk. The right turn vehicles must wait for pedestrians to cross at this time. In this case n_2=0.

(3) Pedestrians arrive in a random manner. The number of right turn vehicles through the intersection is n_3.

Pedestrians randomly arrive at the intersection during this period. The right turn vehicles pass through the intersection according to the distance between the pedestrian's flow. The gap acceptance theory is then used to simulate the process of right turn movement traversing through pedestrian flow. Note that pedestrian movement has its own characteristics in passing through the intersection. They often pass through the intersection one-by-one or in groups. However, the traditional gap acceptance model is applied to passing through in a single-stream only. In this paper, pedestrians are divided into groups in accordance with their characteristics of movement. In this way, gap acceptance model can be applied to compute the potential capacity of the right-turn vehicles. The capacity of the right turn lane can be estimated by applying the following equation 2.

$$n = n_1 + n_2 + n_3 \quad (2)$$

Where, n_1 = the number of right turn vehicles through the intersection when there is no pedestrian crossing,
n_2 = its value is 0
n_3 = the number of right turn vehicles through the intersection when pedestrians randomly arrive at intersection.

Estimation of n_3 based on gap acceptance model

Pedestrians have unique characteristics when they pass through the intersection., We can put pedestrians into groups based on these characteristics. Taking pedestrian groups as a study object, we can use the gap acceptance model to estimate the potential quantity of the right turn vehicles.

Analysis of pedestrian group

Movement of pedestrians on crosswalks shows some obvious common features. These features are elaborated in the Highway Capacity Manual (HCM). The common features are as follows:

1) Pedestrian often travel together. They often arrive at the intersection in groups.
2) To avoid collision, when two pedestrians pass each other each should have about 2.5ft of walkway width.
3) Most of pedestrians believe that right-turn vehicles should yield to pedestrian traffic

Based on these features, the "pedestrian group" concept is proposed in this study to explore the potential capacity of right turn movement influenced by pedestrians taking 10 typical signalized intersections in Beijing as study subjects. Pedestrian group is defined as a group of pedestrian who possess the same location and the move at the same speed.\

Approach of dividing pedestrian groups

Pedestrians can be divided into groups based on the distance between two adjacent persons. When the distance between two adjacent persons is greater than L (L is pre-set value that can be calculated according to time and speed).A separated point can be set up. The relationship between pedestrian groups and separated points is as follows:

$$G_P = k + 1 \tag{3}$$

Where

G_P = the number of pedestrian groups;

k = the number of separated point.

According to the distribution of time-headway between pedestrians, the probability P(H>t)can be calculated. H is the time-headway between two adjacent pedestrians. When the traffic volume is Q, the separated points K can be calculated with equation 4.

$$k = QP(H \geq t) \tag{4}$$

The number of pedestrian group can be calculated by equation 5

$$G_P = QP(H \geq t) + 1 \tag{5}$$

We can compute the number of pedestrian groups once we know the distribution of pedestrian arrival with this method.

3 Determine the distribution of pedestrians

After investigating 10 intersections in Beijing, it is found that the arrival of pedestrians complies with the Poisson distribution when the flow of pedestrians is not excessive. Taking Xi Dawang-Bai Ziwan intersection as an example to analyze the distribution of the pedestrian arrival, survey data is

shown in Table 1 with a counting interval of 1 min.

Table 1. Volume Data Obtained from Intersections .

Arrive number	0	1	2	3	4	5	6	7	8	9	〉=10	aggregate
frequency	1	3	8	6	5	5	4	10	1	0	2	41

K-S testing for the above data is conducted by using SPSS software. The outputs are shown in Table 2.

Table 2. k -s Test for the Distribution of Pedestrian Arrival .

		frequence
N		11
Poisson Parameter (a,b)	Mean	4.09
Most Extreme Differences	Absolute	.188
	Positive	.188
	Negative	-.125
Kolmogorov-Smirnov Z		.622
Asymp. Sig. (2-tailed)		.834

From the output it is known that the value of P=0.834>0.05 for this 2-tailed test, which demonstrates that the pedestrian arrival of north-south bound movement complies with the Poisson distribution at this intersection. Likewise, based on the data of east-west bound movement, it can be proved that the pedestrian arrival of east-west movement also complies with the Poisson distribution.

After grouping pedestrians and realizing the pedestrian impact on right turn vehicles pedestrian groups became the object of our study. Gap acceptance theory can be used to simulate the process of right turn movement traversing through pedestrian groups flow as is shown below:

$$n_3 = \frac{G_p \cdot e^{-\lambda t_c}}{1 - e^{-\lambda t_f}} \tag{6}$$

Where

n_3 = potential capacity of right turn vehicle during green indication (veh);

t_f = follow-up time of right-turn vehicle in second (s);

t_c = critical gap for right-turn vehicle in second (s);

G_p = number of the pedestrian groups (s).

MODEL BUILD -UP

Based on the above analysis, the capacity of right turn lane can be calculated by equation 7

$$c = \frac{3600}{T}\left(\frac{t_g}{h_t}\right) + \frac{G_p e^{-\lambda t_c}}{1 - e^{-\lambda t_f}} \quad (7)$$

Where

T = cycle length (s);

t_g = no impact time of right turn vehicles (s);

h_t = headway of through stop-line of right turn vehicles (s);

t_f = follow-up time of right turn vehicle in second (s);

t_c = critical gap for right turn vehicle in second (s);

G_p = number of the pedestrian groups (s);

MODEL VALIDATION

For the validation of the model we cite Xi Dawang-Bai Ziwan intersection as an example. The correlative data is shown in Table 3.

Table 3. Data from Intersection .

	North-south	East-west
Pedestrian volume	293	176
Green time	90s	27s

For this intersection the cycle length is 120 seconds, yellow time is three seconds. The critical gaps and follow-up times for right turn vehicles traversing bicycle flow were observed from video tapes. Critical gap is 5 seconds in this study. The follow-up time is 3 seconds. The pedestrian arrival of this intersection obeys Poisson distribution. When the travel time between two adjacent persons is more than 2 seconds, a separated point can be set up. The separated points K can be calculated with equation 4.

Number of pedestrian groups:

$$m = 187 + 1 = 188$$

Number of right turn vehicles through the intersection during green time (north-south direction):

$$n_3 = \frac{188 \times e^{-0.0814 \times 5}}{1 - e^{-0.0814 \times 3}} = 568$$

Number of right turn vehicles through the intersection during green time (east-west direction) is 195. The capacity of the right turn lane is 568+195=763

(PCE/H)

For two-phase intersections, the right-turn vehicles are always impacted by pedestrians. Therefore, there is no need to calculate n_1. But, for three or four-phase intersections, pedestrians will not interfere with right-turn vehicles. In this case we need to calculate n_1.

CONCLUSION AND FURTH ER STUDY

It is concluded from this study that pedestrian traffic at signalized intersections has a big impact on the capacity of right turn movement. To model the relationship between pedestrian movement and the potential capacity of right turn movement will help traffic engineers and management better understand performances under the mixed traffic conditions at intersections. The concept of pedestrian groups was proposed in this paper to facilitate building up this model. This concept plays a key role in the model building because the movement of pedestrian traffic is different from the movement of automobiles.

This is a preliminary study for the capacity analysis of vehicular traffic under the presence of pedestrians. The follow-up study will be carried out to develop all details of the impact of mixed traffic on the performances of intersections. The mutual impact of both pedestrians and bicycles at signalized intersections will be the focus of further studies in order to fully and completely reflect China's characteristics of traffic movement at intersections.

ABSTRACT

In this paper, which regards highway capacity as scarce resource, we study the ramp metering strategies that have a great effect on commuters' travel behavior. A spatial residence location problem has been incorporated in the travel choice model. Two representative strategies, namely space equality and commuter equality, are investigated. It has been proven that both strategies attract the same total trip demand,. However, while space equality will have less social cost than commuter equality, this is not consistent with our general belief. For long-term planning purposes, local authorities should insist on adopting the space equality ramp metering strategy, which can alleviate traffic congestion and cause no harm to total demand.

INTRODUCTION

Urban traffic congestion is recognized as a significant type of externality arising from vehicle usage in both developed and developing countries (Small et al., 1989). Recently, Lago and Daganzo (2007) focused on an idealized two-origin, single-destination network with limited storage space to analytically study queue spillovers and merging competition phenomena. They found that not considering merging competition will cause the total cost to be over estimated, as the point-queue model did, and with proper ramp metering, may cause some drivers too be better-off without hurting the others. Because the spillover queue will spread backward and may even gridlock the highway by several blocks during peak periods, urban authorities generally want to prevent artery highways from hyper-congesting and maintain traffic flow into the Central Business District (CBD hereafter) at the highway's maximum flow rate.

Shen and Zhang (2009) studied the morning commute problem in a freeway with multiple on-ramp accesses. They analyzed the properties of the system optimum and designed a dynamic road pricing policy to achieve the optimum. The ramp metering strategies, however, are not taken into consideration in their work.

Their ramp metering is obviously an effective tool in helping urban authorities regulate traffic flow. Their paper is focused on investigating the effect of the various ramp metering strategies on social welfare.

In this paper, we study the morning commute problem in a corridor network with multiple bottlenecks along the highway by characterizing the ramp metering strategy. Our analysis considers both departure time and residence location choice. The congestion costs arising from the departure time choice is captured by the bottleneck model formula, , while the residence location choice is based on a general spatial equilibrium model. In the next section, we formulate the basic model and illustrate the two representative ramp metering strategies. Then, we derive the equilibrium trip demand and trip cost based a general spatial equilibrium. Some comparisons between the two strategies are made in the last section to show the core result of our paper. We conclude the paper with remarks and introduce some our on-going work in this areai.

2. BASIC MODEL

As shown in Fig. 1, imagine a linear city where CBD is located at the center (origin of coordinate) and residential areas are developed around the CBD. The land area of the CBD is negligible and the characteristic of each residential location is represented solely by the distance from the CBD. It is assumed that all residents in the city are homogeneous and they have the same desirable arrival time at the CBD, (the same value of time and the same arrival early/late penalty). A highway, B kms long, connects the CBD with the outlying areas of the city. The width of the highway is uniform and the highway capacity is μ vehicles per unit time.

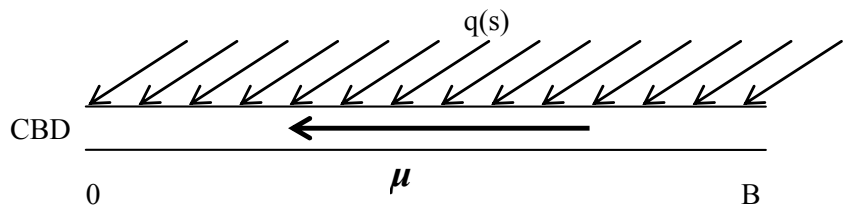

Figure 1. The Study Network.

On each work day morning, an individual makes trips from his/her residence to the CBD by private car. Other types of trips are neglected. Let s be the distance from the CBD, and q(s) denotes the trip demand of a resident located at s. In this section, we assume the trip demand exogenous. Then the (inverse) trip demand function is given as

$$p\big(q(s)\big) = a - bq(s), \quad \forall s \in [0, B] \tag{1}$$

where a, b are positive constants and p(q(s)) represents the private benefit of a trip.

Because the highway is uniform and has limited capacity, some ramp metering strategies must be adopted to assure the total traffic volume will not overstep the limit. Otherwise, there will be a gridlock or even a spill-back phenomenon on the highway, which is a disaster to all commuters and regarded as huge waste (Lago and Daganzo, 2007). Let r(s) denotes the on-ramp capacity of location s, and then we have the conservation condition for highway capacity.

$$\int_0^B r(s)ds = \mu \tag{2}$$

If the trip demand of location s, q(s), exceeds the on-ramp capacity, r(s), the commuters cannot all arrive at the CBD on time and a queue will form in the front of the on-ramp access. Only a small fraction of people who endure the longest waiting time can arrive at the CBD on time. According to the classic bottleneck model (Vickrey, 1969), at user equilibrium the congestion cost of commuters from location s can be expressed as $\theta q(s)/r(s)$, where θ, a positive constant, usually be regarded as the schedule delay parameter (Arnott, et al., 1993).

The total cost of a trip from s to the CBD, C(s), is given by

$$C(s) = f_l + \alpha \cdot s + \theta \cdot \frac{q(s)}{r(s)} \tag{3}$$

where f_l is the fixed cost of travel, such as the maintenance cost of a private car; α is the cost of unit travel distance; The second term of Eqn. (3) is the travel cost of individual from residence s with free flow speed on the highway. The third term of Eqn. (3) reflects the congestion effect of location s.

Because highway capacity is a scarce resource, the ramp metering strategy $\{r(s), s \in [0,B]\}$ plays an important role. In the rest of this section, we will investigate two of the most popular on-ramp strategies.

2.1. Space Equality Strategy

In this subsection, we investigate the space equality ramp metering strategy, which distributes the main road capacity to each access location equally to ensure that commuters from different residences have the same access opportunity to the highway. Then we have

$$r_I(s) = \mu / B, \quad \forall s \in [0, B] \tag{4}$$

where the subscript I represents the space equality strategy hereafter. Substituting Eqn. (4) into Eqn. (3), we have the trip cost

$$C_I(s) = f_l + \alpha \cdot s + \theta \cdot \frac{q(s)}{\mu / B} \tag{5}$$

2.2 Commuter Equality Strategy

One public opinion on the ramp metering strategy is that longer access time should be given to the locations with a larger population. In other words, all the commuters along the corridor should have the same access opportunity. We refer to it as the commuter equality strategy. Then we have

$$r_{II}(s) = \frac{q(s)}{\int_0^B q(y)dy}\mu, \quad \forall s \in [0, B] \tag{6}$$

where the subscript II represents the commuter equality strategy hereafter. Substituting Eqn. (6) into Eqn. (3), we have the trip cost

$$C_{II}(s) = f_l + \alpha \cdot s + \theta \cdot \frac{q(s)}{r_{II}(s)} \tag{7}$$

SPATIAL EQUILIBRIUM

In this section, we assume the trip demand distribution q(s) to be endogenous and follow a general spatial equilibrium. Then, under the space equality ramp metering strategy, we have

$$p(q_I(s)) = C_I(s), \quad \forall s \in [0, B] \tag{8}$$

Substituting equation (1) and (5) into equation. (8) yields

$$q_I(s) = \frac{\mu}{\theta B + \mu b}(a - f_l - \alpha s) \tag{9}$$

Substituting equation. (9) into equation. (1) yields

$$C_I(s) = \frac{\alpha\mu b \cdot s + \theta B a + \mu b f_l}{\theta B + \mu b} \tag{10}$$

From equation. (9) and (10), we can see that the trip demand decreases and the trip cost increases linearly with the distance far away from the CBD.

Under the commuter equality ramp metering strategy, we have

$$p(q_{II}(s)) = C_{II}(s), \quad \forall s \in [0, B] \tag{11}$$

Substituting equation (1) and (7) into equation (11) yields

$$q_{II}(s) = \frac{\mu}{\theta B + \mu b}\left[(a - f_l) + \frac{\alpha\theta B^2}{\mu b} - \frac{\alpha(\theta B + \mu b)}{\mu b}s\right] \quad (12)$$

Substituting equation (12 into) equation (1) yields

$$C_{II}(s) = \frac{\alpha(\theta B + \mu b)\cdot s + \theta Ba + \mu b f_l - \alpha\theta B^2}{\theta B + \mu b} \quad (13)$$

We can also find, for equation(12) and (13), that the trip demand decreases and the trip cost increases linearly with the distance far away from the CBD.

Under the different ramp metering strategies, both the trip demands and the trip costs vary. In the next section, we will compare the characters of these two strategies in detail.

4. COMPARISON OF THE TWO STRATEGIES

It is very easy to verify that $q_{II}(0) > q_I(0)$ and $q'_{II}(0) > q'_I(0)$. As shown in Figure 2, the trip demand is steeper under the commuter equality strategy. The areas between different q(s) and the vertical and horizontal axis, however, are equal to each other.

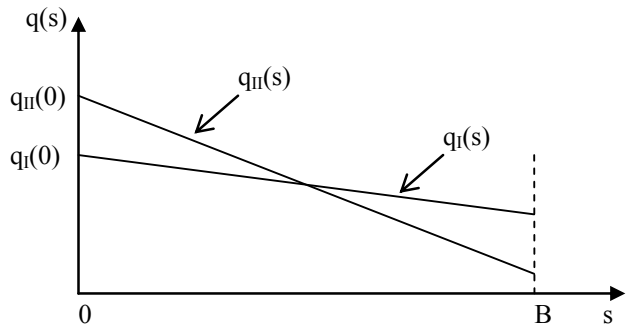

Figure 2. Travel demand under different ramp metering strategies.

We can derive the following proposition with equation. (9) and (12).

Proposition 1. Although the trip demand distribution is different under the two ramp metering strategies, the total trip demand along the corridor is the same. Additionally, under the commuter equality strategy, the trip demand will be more centralized to the CBD.

From Proposition 1, we find that the larger θ is less total demand along the corridor. This can be explained by a tough "on-time" work policy; less people will select work in the CBD. We also find that larger f_l and α also leads to lower population. This is because higher trip costs will force more people to work at home. Furthermore, we investigate the total trip cost along the corridor, namely

$\int_0^B C(s) \cdot q(s) ds$, which is the social cost in this paper, and derive the Proposition 2 as below.

Proposition 2. The total trip cost along the corridor is larger under the commuter equality strategy than under the space equality strategy.

Thus, the space equality strategy is actually more efficient with less total social cost. In reality, the commuter equality strategy is usually more popular with local authorities who believe that that more highway capacity should be given to the residential areas with a higher population. However, for long-term planning purposes authorities should allocate the access priority equally along the corridor to alleviate the traffic congestion and lower the total social cost.

CONCLUSION

In this paper, we study ramp metering strategies' effects in a corridor network. Both space equality and commuter equality strategies are taken into account. We have proven that as both of these ramp metering strategies attract the same total trip demand, space equality will result in less social cost than commuter equality does, which is different from our general belief. These results will be very useful for local authority's urban transportation management purposes.

Our on-going work is to extend the model to a discrete multi-origin framework similar to that of Tian et al. (2007) which is similar to the so-called "corridor problem" in transportation economics. Considering more general demand function will be also an interesting endeavor.

ABSTRACT

In stochastic traffic assignments, if the total perceived travel cost of all users is used as the system performance index, the stochastic system optimum (SSO) assignment will then be to minimize the total perceived travel cost. In this study, we investigate the efficiency loss caused by the stochastic user equilibrium (SUE) traffic assignment against the SSO assignment. The efficiency loss is defined as the difference between these two assignments. Two variational inequality (VI) models are presented to formulate the time-based and monetary-based SUE route choice behaviors respectively, in traffic networks with multiple user classes and fixed demand. The upper bounds of the efficiency losses caused by these two kinds of behaviors are analytically derived and their relations to some network parameters are discussed.

INTRODUCTION

Wardrop (1952) presented two famous principles regarding users' route choice behavior in traffic networks, namely the user equilibrium (UE) traffic assignment and system optimum (SO). The UE principle states that every traveler tries to minimize her/his own cost, so that no traveler can reduce it by unilaterally changing her/his choice at equilibrium. In the case of SO, it is assumed that a central organization exists to minimize the total cost of the system. In stochastic circumstances where travelers cannot accurately compute their costs, a stochastic user equilibrium (SUE) may be achieved, i.e., travelers choose routes for minimizing their perceived travel costs. At the SUE, the perceived travel costs of all actually used paths between each O-D pair are identical and minimal. It is natural to define the stochastic system optimum (SSO) as that which makes the system's total perceived travel cost to be minimal. Yang (1999) proposed a SSO model with a single user class and fixed demand. Maher et al. (2005) further formulated a logit-based SSO model.

It is well known that the UE is generally not identical with but has more or less efficiency loss than the SO, i.e., the UE renders the total travel cost of the whole network as more (Yang and Huang, 2005). Roughgarden and Tardos (2002) introduced the notion of coordination ratio or the price of anarchy, which was first defined by Koutsoupias and Papadimitriou (1999) to quantify the inefficiency of UE

decision making in networks. Since then, many researchers (Roughgarden and Tardos, 2003; Chau and Sim, 2003; Correa et al, 2004; Huang et al, 2006) have extended the investigation on the efficiency loss of the deterministic UE traffic assignment.

However, up to now, few studies have been done to investigate efficiency loss of the equilibrium assignment with multiple user classes. Obviously, different classes of users have different route choice preferences due to their differences in income, age, gender, education, travel destination and so on. Some users may like time-based criterion and others monetary-based ones for route choice. Recently, Liu et al, (2007) investigated the inefficiency of mixed travel behavior in networks with advanced travel information systems. Han and Yang (2008) derived the upper bounds of efficiency loss caused by the multiclass and multicriteria traffic equilibrium. However, the aforementioned researches are just subject to the deterministic traffic assignment.

In this study, we focus our attention on the efficiency loss caused by logit-based SUE and extend the work of Guo et al. (2009) to the case of multiple user classes. All users are classified into several groups according to their values of time. We first formulate the time-based and monetary-based VI models for this multiclass problem, and then derive the upper bounds of the inefficiency caused by the SUE against the SSO. Finally, we examine the relationships between bounds and the network parameters. The value of our study lies in more understanding of complex route choice behavior and their consequences on system performance.

THE MULTICLASS, MULTICRITERIA STOCHASTIC TRAFFIC EQUILIBRIUN MODEL WITH FIXED DEMAND

Notation and assumptions . Let $G=(N, A)$ be a directed transportation network, where N and A denote the sets of nodes and links, respectively. Let W be set of O-D pairs; R_w be set of paths between O-D pair w. There are travel demands that can be subdivided into M classes corresponding to groups of users with difference values of time; $\beta_m > 0$ be the average value of time of user class m. Let d_w^m be the demand of user class m between w, which is assumed to be constant in this paper; v_a^m be the flow of user class m and v_a be the total flow on link $a \in A$; f_{rw}^m be the flow of user class m on path $r \in R_w$, $w \in W$. The travel time function $t_a(v_a)$ is assumed to be continuously differentiable and monotonically increasing.

Let $c_a^m(v_a)$ be the experienced travel cost function of class m on link $a \in A$, C_{rw}^m and c_{rw}^m be the perceived travel cost and experienced one of user class m on path $r \in R_w$, respectively. Therefore, the following relationship must be satisfied, i.e.

$$c_{rw}^m = \sum_{a \in A} c_a^m \delta_{ar}^w, \forall r \in R_w, w \in W, \ m=1,\cdots, M. \tag{1}$$

The flow conservation conditions and nonnegative constraint conditions are

$$v_a^m = \sum_{w \in W} \sum_{r \in R_w} f_{rw}^m \delta_{ar}^w, \forall a \in A, \ m=1,\cdots, M, \tag{2}$$

$$v_a = \sum_{m=1}^{M} v_a^m, \forall a \in A, \tag{3}$$

$$\sum_{r \in R_w} f_{rw}^m = d_w^m, \forall w \in W, \ m = 1, \cdots, M, \tag{4}$$

$$f_{rw}^m \geq 0, \forall r \in R_w, w \in W, \ m = 1, \cdots, M. \tag{5}$$

Where δ_{ar}^w is equal to 1 if the path r between OD pair $w \in W$ otherwise traverses link $a \in A$, and 0. We denote $\Omega_v = \{v \mid v \text{ satisfying (2)-(5) }\}$ and $\Omega_f = \{f \mid f \text{ satisfying (2)-(5)}\}$. Clearly, Ω_v and Ω_f are both closed and convex sets.

The SUE model . Under SUE condition, the multiclass multicriteria stochastic user equilibrium traffic assignment can be formulated as VI (Xu and Zhu, 2007). Therefore, we have the following Lemma 1.

Lemma 1. Under the logit-based path choice assumption, the multiclass SUE with fixed demand is equivalent to the following VI, i.e., find $\bar{f} \in \Omega_f$, such that

$$\sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} \left\langle c_{rw}^m(\bar{f}) + \frac{1}{\theta} \ln \bar{f}_{rw}^m, \ f_{rw}^m - \bar{f}_{rw}^m \right\rangle \geq 0, \forall f \in \Omega_f . \tag{6}$$

Under the time-based criterion, $c_a^m(v_a) = t_a(v_a), a \in A, m = 1, \cdots, M$. Comparably, under the monetary-based criterion, $c_a^m(v_a) = \beta_m t_a(v_a), a \in A, m = 1, \cdots, M$. Therefore, the time-based VI model can be formulated as

$$\sum_{a \in A} t_a(\bar{v})(v_a - \bar{v}_a) + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} \ln \bar{f}_{rw}^m \left(f_{rw}^m - \bar{f}_{rw}^m \right) \geq 0, \forall f \in \Omega_f , \tag{7}$$

Similarly, the monetary-based VI model can be formulated as

$$\sum_{a \in A} \sum_{m=1}^{M} \beta_m t_a(\bar{v})(v_a^m - \bar{v}_a^m) + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} \ln \bar{f}_{rw}^m \left(f_{rw}^m - \bar{f}_{rw}^m \right) \geq 0, \forall f \in \Omega_f . \tag{8}$$

Defining the SSO . Following the work of Maher et al. (2005), the total perceived travel cost under the multiclass SUE with fixed demand can be given as

$$F(f) = \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} c_{rw}^m(f) f_{rw}^m + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} f_{rw}^m \ln f_{rw}^m - \frac{1}{\theta} \sum_{w \in W} \sum_{m=1}^{M} d_w^m \ln d_w^m . \tag{9}$$

The SSO problem is to minimize the total perceived travel cost, namely

$$\min_{f \in \Omega_f} F(f). \tag{10}$$

As a result, we can easily obtain the SSO path flow vectors, $\hat{f}$ and $\tilde{f}$, and the SSO link flow vectors, $\hat{v}$ and $\tilde{v}$, through solving the following minimization problems under time-based and monetary-based criterions, respectively. That is

$$F_{sso}^t = \min_{f \in \Omega_f} F^t(f) = \sum_{a \in A} t_a(v_a) v_a + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} f_{rw}^m \ln f_{rw}^m - \frac{1}{\theta} \sum_{w \in W} \sum_{m=1}^{M} d_w^m \ln d_w^m , \tag{11}$$

$$F_{sso}^{c} = \min_{f \in \Omega_f} F^{c}(f) = \sum_{a \in A} \sum_{m=1}^{M} \beta_m t_a(v_a) v_a^m + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} f_{rw}^m \ln f_{rw}^m - \frac{1}{\theta} \sum_{w \in W} \sum_{m=1}^{M} d_w^m \ln d_w^m \quad . \tag{12}$$

BOUNDING THE EFFICIENCY LOSS OF THE TIME -BASED SUE AGAINST THE SSO

Let $\bar{v} \in \Omega_v$ and $\bar{f} \in \Omega_f$ be the link and path flow vectors under the time-based SUE, respectively. Correspondingly, the total experienced travel time and the total perceived one is, respectively, $T_{sue}^{t} = \sum_{a \in A} t_a(\bar{v}_a)\bar{v}_a$ and $F_{sue}^{t} = \sum_{a \in A} t_a(\bar{v}_a)\bar{v}_a + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} \bar{f}_{rw}^m \ln \bar{f}_{rw}^m - \frac{1}{\theta} \sum_{w \in W} \sum_{m=1}^{M} d_w^m \ln d_w^m$. The efficiency loss of the time-based SUE against the SSO is formulated as $F_{sue}^{t} - F_{sso}^{t}$. Clearly, $F_{sue}^{t} - F_{sso}^{t}$ is generally positive.

Let $f = \hat{f}$ in the VI (7), and then lead to

$$F_{sue}^{t} - F_{sso}^{t} \le \sum_{a \in A} \left(t_a(\bar{v}_a) - t_a(\hat{v}_a) \right) \hat{v}_a + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} \hat{f}_{rw}^m \left(\ln \bar{f}_{rw}^m - \ln \hat{f}_{rw}^m \right). \tag{13}$$

Next, we introduce how to get upper bounds on the two terms of the right-hand side of (13). For the first term, its upper bound can be obtained following the method adopted in Yang and Huang (2005). For each link travel time function $t_a = t_a(z_a)$ and nonnegative link flow z_a, we define the following parameter

$$\gamma_a(t_a, z_a) = \max_{v_a \ge 0} \frac{\left(t_a(z_a) - t_a(v_a) \right) v_a}{t_a(z_a) z_a}. \tag{14}$$

Here 0/0=0 by convention. For a given class L of link travel time functions, we let

$$\gamma(L) = \max_{t_a \in \mathcal{L}, z_a \ge 0} \gamma_a(t_a, z_a). \tag{15}$$

Then we have

$$\sum_{a \in A} \left(t_a(\bar{v}_a) - t_a(\hat{v}_a) \right) \hat{v}_a \le \sum_{a \in A} \gamma(L)\, t_a(\bar{v}_a)\bar{v}_a = \gamma(L)\, T_{sue}^{t}. \tag{16}$$

From Gibbs' inequality, we readily have a zero upper bound of the second term of the right-hand side of (13). Namely, the following inequality holds

$$\sum_{r \in R_w} \hat{f}_{rw}^m \left(\ln \bar{f}_{rw}^m - \ln \hat{f}_{rw}^m \right) \le 0, \quad w \in W, \ m = 1, \cdots, M. \tag{17}$$

Substituting (16) and (17) into (13), we have the following theorem.

Theorem 1. For a given separable link travel time function class L, Let T_{sue}^{t} and F_{sue}^{t} be, respectively, the total experienced travel time cost and the total perceived one at the time-based SUE, and F_{sso}^{t} be the minimum total perceived travel time cost, then

$$F_{sue}^{t} - F_{sso}^{t} \le \gamma(L) T_{sue}^{t}. \quad (18)$$

BOUNDING THE EFFICIENCY LOSS OF THE MONETARY -BASED SUE AGAINST THE SSO

In this section, we let $\bar{v} \in \Omega_v$ and $\bar{f} \in \Omega_f$ are the link and path flow vectors under the monetary-based SUE.. Correspondingly, the total perceived travel monetary cost and experienced one are, respectively, $F_{sue}^{c} = \sum_{a \in A} \sum_{m=1}^{M} \beta_m t_a(\bar{v}_a) \bar{v}_a^m +$

$\frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} \bar{f}_{rw}^m \ln \bar{f}_{rw}^m - \frac{1}{\theta} \sum_{w \in W} \sum_{m=1}^{M} d_w^m \ln d_w^m$ and $T_{sue}^{c} = \sum_{a \in A} \sum_{m=1}^{M} \beta_m t_a(\bar{v}_a) \bar{v}_a^m$ .The efficiency loss of the monetary -based SUE against the SSO is formulated as $F_{sue}^{c} - F_{sso}^{c}$. Clearly, $F_{sue}^{c} - F_{sso}^{c}$ is generally positive.

Let $f = \tilde{f}$ in the VI (8), then leads to

$$F_{sue}^{c} - F_{sso}^{c} \le \sum_{a \in A} \sum_{m=1}^{M} \beta_m \left(t_a(\bar{v}_a) - t_a(\tilde{v}_a) \right) \tilde{v}_a^m + \frac{1}{\theta} \sum_{w \in W} \sum_{r \in R_w} \sum_{m=1}^{M} \tilde{f}_{rw}^m \left(\ln \bar{f}_{rw}^m - \ln \tilde{f}_{rw}^m \right). \quad (19)$$

For the first term on the right-hand side of (19), its upper bound can be obtained using the method in Han and Yang (2008). For each link travel time function $t_a = t_a(z_a)$ and nonnegative link flow $z_a \ge 0$ and value of time $\beta_m, m = 1, \cdots, M$, define the following parameters:

$$\gamma_a(z_a, t_a, \beta) = \frac{1}{\left(\sum_{m=1}^{M} \beta_m z_a^m \right) t_a(z_a)} \max_{v_a^m \ge 0} \left\{ \left(\sum_{m=1}^{M} \beta_m v_a^m \right) \left(t_a(z_a) - t_a(y_a) \right) \right\}. \quad (20)$$

$$\gamma_a(t_a, \beta) = \sup_{z_a \ge 0} \gamma_a(z_a, t_a, \beta), \gamma(L, \beta) = \sup_{t_a \in \mathscr{L}} \gamma_a(t_a, \beta). \quad (21)$$

Where L is a given class of link travel time functions on link $a \in A$.

From definition (20) and (21), we have

$$\sum_{m=1}^{M} \beta_m \tilde{v}_a^m \left(t_a(\bar{v}_a) - t_a(\tilde{v}_a) \right) \le \gamma_a(\bar{y}_a, t_a, \beta) \sum_{m=1}^{M} \beta_m \bar{v}_a^m t_a(\bar{v}_a) \le \gamma(L, \beta) T_{sue}^{c}. \quad (22)$$

From Gibbs' inequality, we can obtain

$$\sum_{r \in R_w} \tilde{f}_{rw}^m \left(\ln \bar{f}_{rw}^m - \ln \tilde{f}_{rw}^m \right) \le 0, \; w \in W, \; m = 1, \cdots, M. \quad (23)$$

Substituting (22) and (23) into (19), we have the following theorem.

Theorem 2 . For a given separable link trav el time function class L, let T_{sue}^{c} and F_{sue}^{c} be, respectively, the total experienced travel monetary cost and the total perceived one at the monetary-based SUE, and let F_{sso}^{c} be the minimum total perceived travel monetary cost, then

$$F_{sue}^{c} - F_{sso}^{c} \le \gamma(L, \beta) T_{sue}^{c}. \quad (24)$$

CONCLUSION

In this paper, we have investigated the efficiency loss of multiclass, multicriteria stochastic user equilibrium traffic assignment against stochastic system optimization. Specifically, when considering two kinds of the decision criteria, i.e., time-based or monetary-based, the upper bounds of the efficiency loss under time-based and monetary-based criteria are both independent of network topology and depend on the class of link travel functions and the experienced total travel cost. Furthermore, at the monetary-based SUE, the upper bound is also dependent on the users' socio-economic characteristics. Our ongoing work will focus on examples that validate and study the inefficiency loss of multiclass, multicriteria stochastic traffic equilibrium with elastic demand.

ABSTRACT

Establishing a train working diagram system and realizing the modernization of a train working diagram's compilation, management and service is important to railway information construction in China. In this paper, the deficiency of the existing system architecture is apparent after analyzing the features of the existing network-based train working diagram computerized compilation system. Furthermore, the three-layer architectural model is a setup that uses TUXEDO middleware to implement the network-based train working diagram computerized compilation system. Considering the train working diagram system's characteristics, the implementation methods of this system are expounded upon including an analysis of business process division service design and TUXEDO application and development. By verifying the architecture, it is proven that this architecture can well solve the inadequacy of the original one and can meet the needs.

1. INTRODUCTION

A train working diagram is the most important fundamental plan by which different departments organize their railway transportation activities. It reflects the quality level of the railway's service for the other fields of the national economy. The College of Traffic and Transportation of Southwest Jiaotong University has been doing considerable research on train working diagram computerized compilation and has established and put into practicle application a network-based railway passenger train working diagram computerized compilation system based on LAN (Shao Quanni 2001).

When compiling a network-based train working diagram, all users can check any data. Each user's authority is set according to the railway bureau's jurisdiction to which the user belongs. Once one user changes the data, the other user's data must be immediately synchronized. The train working diagram includes lots of data, such as railway line, station, section, train trip route, train running time, train interval and display section, etc. In order to accomplish the train working diagram computerized compilation based on network environment, the network needs to transmit large amounts of data in high frequency. Therefore, the request of the system's network

communication is comparatively high. At present, the architecture of this system adopts C/S 2-layer architecture and realizes the network communication between server and client by using SOCKET (Shaoquan Ni 2003). Practical application indicates that the current architecture still has the following problems: ① the amount of concurrency is limited; ② the stability and safety of network transmission can not be guaranteed; ③ the data logic, business logic and presentation logic's division is not clear. The disposition is very difficult after update. The reusability of the business logic and interface logic is very poor; ④ the data integrity and consistency is difficult to guarantee; ⑤ the system's expansibility and flexibility is comparatively poor.

2. SYSTEM ARCHITECTU RE DESIGN

TUXEDO middleware is the platform software on which a three-layer C/S critical business system can be developed and managed in the distributed computing environment such as enterprise and the Internet. It has unprecedented on-line transaction performance, high reliability and unlimited flexibility, and can provide a powerful supporting platform which can establish, operate and manage a large-scale, high performance and distributed critical business system for enterprise. This middleware provides seven communication mechanisms: synchronous and asynchronous invoking, pipeline, session, broadcast notification, queue and a communication pipeline which releases subscription of a three-layer structure application. It has the advantages of load balancing, failover, etc (Wei Jiang 2008).

Therefore, the three-layer architecture based on TUXEDO middleware can be used for dividing applied user logic, business logic and data logic into three different processing layers. The application system which adopts this architecture not only possesses mainframe performance, such as stability, safety and high processing capacity, but also has numerous advantages such as open systems, e.g. low cost, strong extensibility and short development cycle.

In order to realize the three-layer architecture ground on TUXEDO middleware and reduce modifications to a minimum, the enhancement can be done on the basis of the original architecture. The main modification is as follows: move the client business logic and data logic to the TUXEDO application server and keep the interface logic with the client; replace the original environment with the TUXEDO application service platform; replace the SOCKET communication with TUXEDO communication; bring about service of the server's module according to standards of service interface and service realization.

The logic architecture shown in Figure 1 is composed of a presentation layer, business logic layer and data layer. The main contents of the presentation layer are data input interface, train working diagram graphic display, and interactive adjustment function for client front interface. For the purpose of realizing front interface flexibility and diversification, the presentation layer keeps the configuration

files locally and defines the interface elements and interactive action to bring about a customizable front interface.

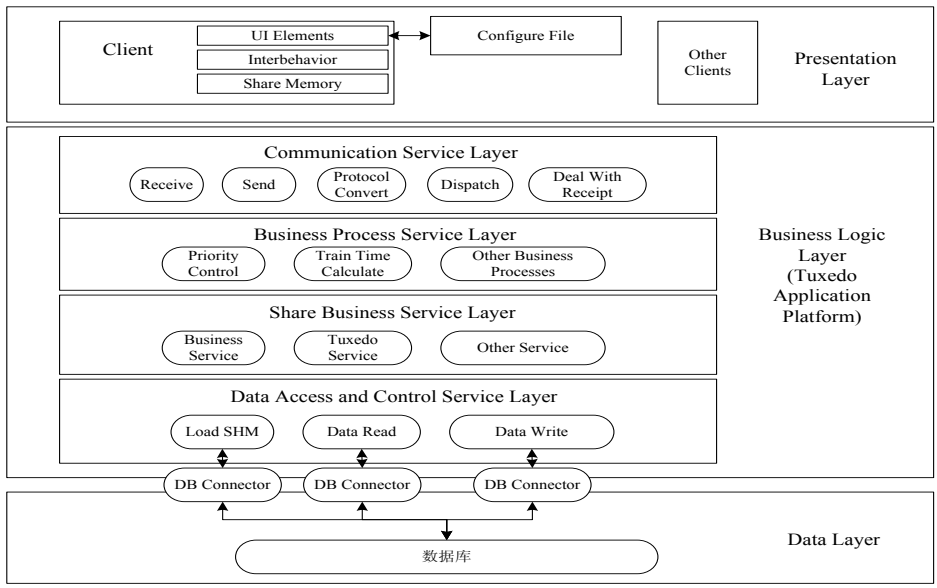

Fig. 1. Logic Architecture .

The business logic layer is on the TUXEDO application server and mainly contains business logic processing, such as pushing line (calculating the train running line), user register, user privileges control, train running time calculation, data synchronization, data storage, etc. According to the necessary functions, this layer can be divided into a communication service layer, a business processing service layer, a sharing business service layer and a data access control layer. The communication service layer mainly contains the TUXEDO communication function, such as receiving/sending data, protocol conversion and distribution service. The business processing service layer primarily includes business logic function of the original architecture, such as privileges control, train running time calculation, pushing line calculation, etc. The sharing business service layer mainly contains some common services. The data access control layer interacts with the data layer and contains services, such as reading/writing data control and loading shared memory data.

3. SYSTEM REALIZATION

In network-based train working diagram computerized compilation systems, the most basic and frequently used operation is train line operation, such as forward direction pushing line, backward direction pushing line, dragging train line, etc. In the following example, the pushing line operation is used in order to elaborate on how to utilize TUXEDO middleware to realize the logic architecture presented in Figure 1.

3.1 Service Designs

The object-oriented application is based on classes and objects. Through modeling technology, the relative objects are classified to a single component according to business function. For function call of cross-components, exposes that in the form of interface and decouples the definition and specific realization of the interface. The above mentioned then forms the corresponding service.

The way to discover service is top-down, bottom-up and align middle mode. The top-down mode is derived from business and carries on domain decomposition, flow decomposition and change analysis of business. Bottom-up is used for the realization of service using existing assets. The existing assets include existing systems, suite and custom applications, occupational standards or service model. Align middle mode is used to help find the align-business services and ensure no omission of critical services during flow decomposition and existing assets analysis.

In this paper, the top-down mode is adopted. Considering the pushing line flow, the service can be determined as follows:

① Data Transmission Service (SHMSVC): Retrieves data from service shared memory and transmits it to the client. ② Service Registry (REG): Client runtime connects with the server and registers through this service. ③ Un-register Service (UNREG): Cancellation through this service when the client logs off. ④ Pushing Line Service (PUSHLINESVC): Receives pushing line operation order from client, calculates pushing line results and sends them to notification service. ⑤ Notification Service (NOTIFY): Sends calculation results to all registered clients. ⑥ Data loading Service (DBLOAD): Acquires data from database and loads it to server shared memory. ⑦Writing Shared Memory Service (SAVESHM): Saves pushing line operation results in shared memory. ⑧Database Update Service (UPDATEDB): Saves pushing line operation results in database.

3.2 Data Packet Size Design

After launching, the client needs to request data from the server and then downloads the train working diagram data whose data size is larger than 100M. The size of the network data packet will directly influence the network performance. In view of determining a reasonable size for the data packet, it is necessary to test the network's occupation and the time-consuming factors of the different data packet sizes. Currently, the railway network-based train working diagram computerized compilation's network environment is 1Gbps, network card 1000M, total amount of test data 100M. The test results are shown in Figure 2.

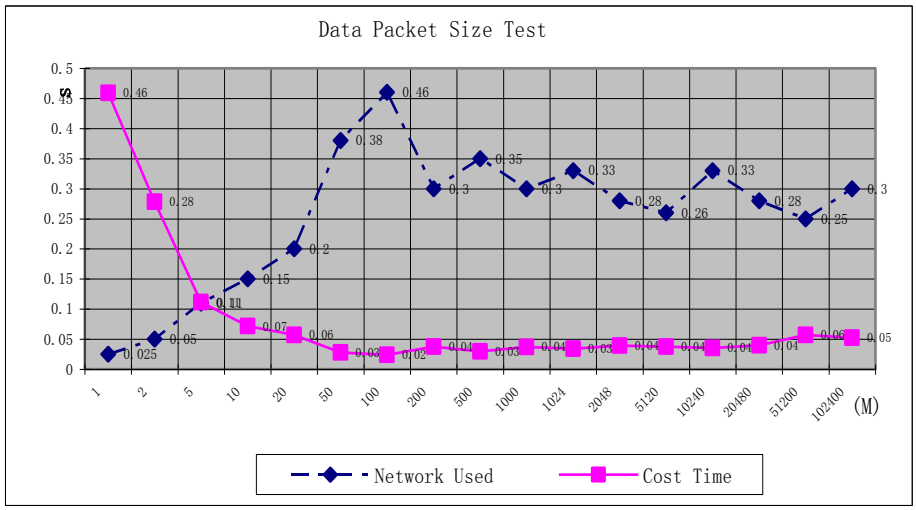

Fig. 2. Result of data packet size test .

An analysis of the test results leads to a number of conclusions as follows: If the data packet is comparatively small, the occupation of network bandwidth is comparatively small, but time-consuming is comparatively larger. With the gradual increase of data packet size, the occupation of network bandwidth gradually increases initially and then reduces and fluctuates around 30M. However, the time-consuming gradually reduces at first, and then increases with the lapse of time, comparatively stable on the whole. It can be clearly seen that “bigger is not better” in the case of the data packet’s size. Through the analysis of Figure 3 and the balance of network bandwidth and time-consuming factors, the selected data packet size under this network environment is 1M. At this time, the time-consuming of 100M data’s transmission is 3.42s, and the occupation network bandwidth is 33M

3.3 TUXEDO Application Development

The application development processes are often divided into compiling and loading configuration files, editing and compiling server programs, editing and compiling client programs and startup application programs.

TUXEDO configuration files contain the various parameters of system operation, including the connection information with databases, service information provided by the server, authentication information necessary for calling service by client, and so on. Through the tmloadcf command, the binary file TUXONFIG is generated for the TUXEDO system runtime to acquire relative information. During startup of the TUXEDO service, TUXEDO will read relatively useful information from TUXCONFIG and then support the realization of the service.

Server and client programs are all written in C language, then the server program and client program are compiled using the buildserver command and buildclient commands respectively. After that, the TUXEDO server service is

launched using the tmboot command and waits for the client's call.

Pushing line service (PUSHLINESVC) is the key part of the pushing line operation. The flow of the client's call of this service is shown in Figure 3. PUSHLINESVC service receives the client's pushing line operation command, calculates the pushing line results, and sends them to NOTIFY service. Afterwards, the NOTIFY service informs all registered clients to update client data and client display.

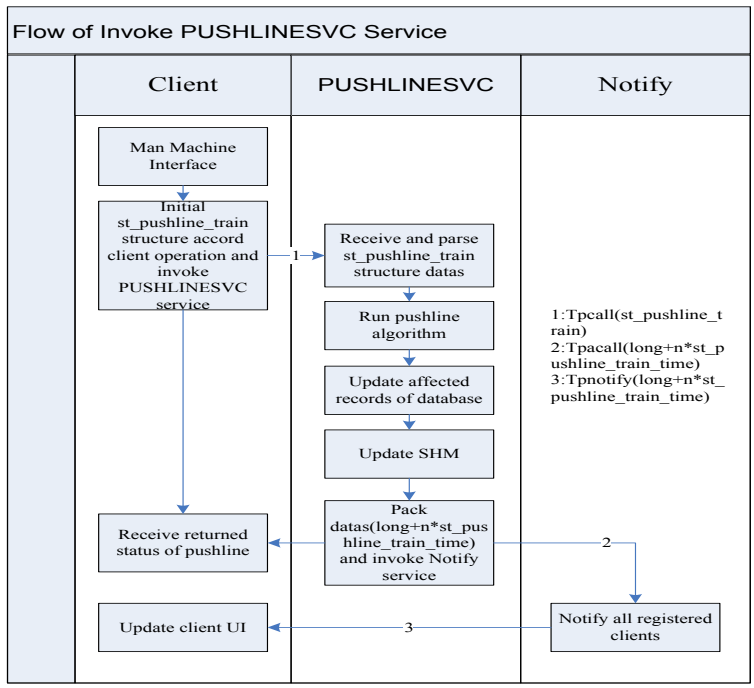

Fig. 3. Flow of Invoke PUSHLINESVC Service .

The pushing line operation command structure (st_pushline_train) includes train number, original station name, destination station name, departure time, parameter setting, etc. The train number is used to select the train to be operated. The original and destination station are used for ascertaining the pushing line's influence scope. The departure time is applied to determine the offset compared to the original time. The pushing line parameter setup is applied in order to decide the input parameters of the pushing line algorithm. Calculation result structure (st_pushline_train_time) includes train number, station index, station name, train arrival time, train departure time and the order number of occupied receiving-departure tracks. The train number is used to select a train. Station index, train arrival time, train departure time and the order number of occupied receiving-departure tracks are used for ascertaining the train's receiving time, departure time and occupied receiving-departure track in the station after pushing line operation.

4. CONCLUSION

This paper accomplishes the verification of network-based railway train working diagram computerized compilation system's transformation from a two-layer architecture to a three-layer architecture. Thus, the stability, safety, and the amount of concurrency of this system have received some improvement and are in accordance with the request of network-based railway train working diagram computerized compilation. Nevertheless, the reality of the fact that the client directly connects with the server creates a little disorder in management of the TUXEDO application at present. We can add Enterprise Service Bus (ESB) between the client and the server to solve this problem. The management of service and the client's call of backend service through ESB will be achieved in the course of future research.

ACKNOWLEDGEMENTS

This paper was prepared based on research project sponsored by Natural Science Foundation of China (No.60870004).

ABSTRACT

The study on the interaction between the growth of the maritime industries and the output of other industries is important to the shipping center in Dalian. Based on an input-output table, this paper first selects five maritime industries according to the construction plan of the Shipping Center and the attributes of the maritime industries. Second, DIM (Dynamic Inverse Matrix) is calculated with the regional input-output table for six years. Then, the contributions of other industries to maritime ones and contributions of the maritime industries to increments of residential and governmental demands are analyzed. The results show that Petroleum and Chemistry, Energy Mining and Supply, Metal Mining and Products industries closely relate to the maritime industries in terms of input and output.

DATA

The I-O model is quite useful for analyzing the sector issues in the national economic context because it recognizes the interdependence of all sectors of the economy. Therefore, the interaction between the maritime industries and others in Liaoning can be explained by the I-O model.

The study uses two sets of 1997, 2002 I-O tables in Liaoning. For the sake of maritime sector-based analysis, original tables (42-sectors) are aggregated into 15-sector tables according to the plan of the Shipping Center and the attributes of the maritime industries (Diao.2006). The main maritime sectors are embodied by ind.7, ind. 8, ind.10, ind.11, and ind.12, as described in Table 1. The paper sets 2000 as the object year and 1997-2001 as the planning years.

The coefficients of and labour means the input of capital and labour in one unit output for every sector. The coefficients of 1997-2002 are from the I-O Table in Liaoning, and the coefficients of 1998 to 2001 are acquired by interpolation.

Table 1. The 15 sectors a fter aggregat ion.

Ind.1	Agriculture	Ind.2	Energy Mining and Supply
Ind.3	Metal Mining and Products	Ind.4	Nonmetal Ores Mining and Products
Ind.5	Processing from Agricultural Products and Light Industry	Ind.6	Petroleum and Chemistry

Ind.9	Manufacture of Other Manufacturing	Ind.10	The Service for Maritime Operation
Ind.11	The Service for Employed Persons in Maritime	Ind.12	The Harbor Construction
Ind.13	Business	Ind.14	Education and Science
Ind.15	Public Service		

METHOD AND ASSUMPTIONS

Dynamic input-output analysis is derived from the static through consideration of lags of change over time of sectoral interdependences. A dynamic model has the following form:

$$(I - A - B)X_t - B(X_{t+1} - X_t) = \tilde{Y}_t \quad (1)$$

Where I is identity matrix; X is the total gross output in sector; A is a matrix of technical coefficients, which mean the inter-industry purchases; and Y is the final demand for products. In this paper, the technical coefficients matrix A is calculated from the data of the 2002 I-O table in Liaoning and is assumed as fixed in all planning years and the object year; B is the matrix of fixed capital coefficients, $\tilde{Y}_t$ is the vector of final demand, excluding fixed capital investment; t refers to the time period.

We deduce capital coefficients matrix B under the assumption that the demand to intermediate production is the same as the demand to investment for sector j from sector i. It is shown as:

$$\Delta Z_{ij} / \sum_{j=1}^{n} \Delta Z_{ij} = k_{ij} / \sum_{j=1}^{n} k_{ij} = k_{ij} / I_i, i, j = 1,.....n \quad (2)$$

Where, ΔZ_{ij} is the intermediate goods increment, then $\Delta Z_{ij} = a_{ij} \times \Delta X_j$, ΔX_j is the total outputs increment from (t+1) year to t year; k_{ij} is the investment demand of sector j from sector i in t year; I_i is the investment of sector i in t year. The capital coefficients can be calculated as follow:

$$b_{ij} = k_{ij} / \Delta X_j \tag{3}$$

Where, b_{ij}, capital coefficients, defines the stock of products of industry j required per unit of capacity output of industry i and is thus a stock-flow ratio. The date from the 2002 I-O table and 2003、2004 statistical Yearbook in Liaoning is used to calculate the capital coefficients matrix B, which is assumed as fixed in all planning years as well as the object year.

In Eq.1, we set $(I - A + B) = G$ and t=1,2,…,m, hence have a system of n difference equations in difference years:

$$\begin{bmatrix} X(-m) \\ \cdots \\ X(-1) \\ X(0) \end{bmatrix} = \begin{bmatrix} G^{-1} & \cdots & R^{m-1}G^{-1} & R^{m}G^{-1} \\ & \cdots & \cdots & \cdots \\ & & G^{-1} & RG^{-1} \\ & & & G^{-1} \end{bmatrix} \begin{bmatrix} \tilde{Y}(m) \\ \cdots \\ \tilde{Y}(-1) \\ \tilde{Y}(0) \end{bmatrix} \tag{4}$$

Where, $R = G^{-1}B$, it can be described in abbreviated form as $X = U^{-1}\tilde{Y}$. U^{-1} is Leontief's DIM (D. Kendrick.1972). That means the direct and indirect input in all planning years from sector i to sector j which has a one unit increase of final demand in the object year.

RESULTS AND ANALYSIS

In the following analysis in Liaoning, the contributions of the output of other industries to the maritime ones which have one unit increase in demand will be evident. When we also increase the government and citizen demand with one unit in the object year, the input of output labor and capital of maritime industries is received. (0:object year,-1~--5:planning years)

Input from the Output of Other Industries to Maritime Industr ies

The Analysis to I nd. 7. Table 2 shows that the input from most industries to Transportation (ind.7) ascends gradually and steadily except for Education and Science (ind.14). That means most industries directly sustain the development of transportation with the top industry Petroleum and Chemistry (ind.6). The result is consistent with the real condition of Liaoning. Ind.6 is the most important maritime industry in Dalian and most cargo passing through the Dalian Port comes from it. So the growth of input from Ind.6 can meet the increasing demand of Transportation (ind.7).

Table 2.Input from Other Industries with One Unit Increase in Demand of Ind.7 (Unit : 100 million/100 million) .

	-5	-4	-3	-2	-1	0

ind.15	0.00000	0.00032	0.00136	0.00561	0.01716	0.01528

Additionally, based on a consideration of relationships among maritime industries, we see that, Transportation (ind.7), and Harbor Construction (ind.12) falls below the 0 line which means that Ind.12 is the key devotion to the early development of Transportation (ind.7). So during the construction of the Shipping Center in Dalian, the investment in harbor should be completed before the development of transportation.

Analysis to Ind. 8, Ind. 10, Ind. 11 and Ind. 12. Table 3 shows that most input into Manufacture of Transport Equipment (ind.8), which has one unit increase in demand, come from Metal Mining and Products (ind.3). The development of Ind. 8 depends greatly on the contribution of Ind.3. In addition, the input of Transportation (ind.7) is mostly in favor of the realization of increase in demand of Ind.8.

Table 3. Input from Other Industries with One Unit Increase in Demand of Ind. 8 (Unit : 100 million/100 million) .

ind.7	0.00021	0.00089	0.00383	0.01634	0.06014	0.03303
ind.9	0.00001	0.00004	0.00017	0.00071	0.00312	0.01605
ind.10	0.00018	0.00075	0.00316	0.01282	0.04339	0.03040
ind.11	0.00006	0.00025	0.00105	0.00434	0.01559	0.03454
ind.12	0.00001	0.00004	0.00018	0.00064	0.00083	-0.00051
ind.13	0.00015	0.00064	0.00272	0.01169	0.05273	0.14029
ind.14	0.00007	0.00029	0.00125	0.00526	0.01854	-0.01801
ind.15	0.00000	0.00048	0.00201	0.00808	0.02376	0.02081

We also calculate the input from other industries to the Service Maritime Operation (ind.10), Service for Employed Persons in Maritime (ind.11), and Harbor Construction (ind.12). The results indicate that the biggest contribution to Ind.10 is Transport Equipment (ind.8). For Ind.11 it is agriculture (ind.1) and Processing from Agricultural Products and Light Industry (ind.5). For Ind. 12 it is Nonmetal Ores Mining and Products (ind.4) and Metal Mining and Products (ind.3). These results are consistent with the development character of maritime industries in Liaoning.

Input Analysis of Maritime Industries with Increase in Gov. and Cit. Demand .

Input from the Output of Maritime Industries

The demand of government and citizens is the important component of general demand. In order to meet one unit of increase in demand of government and citizens in the object year, the direct and indirect contributions from maritime industries in planning years are achieved with DIM. (cd: citizen demand; gd: government demand)

From the Fig.1, we can see that to meet one unit of growth in demand from government and citizens, the contribution of Transportation (ind.7) is the greatest. On the other hand, for each maritime industry, the level of input induced by the growth of demand from government is more than from citizens, which means the effect of the increase in government demand on the development of maritime industry is more important in Liaoning.

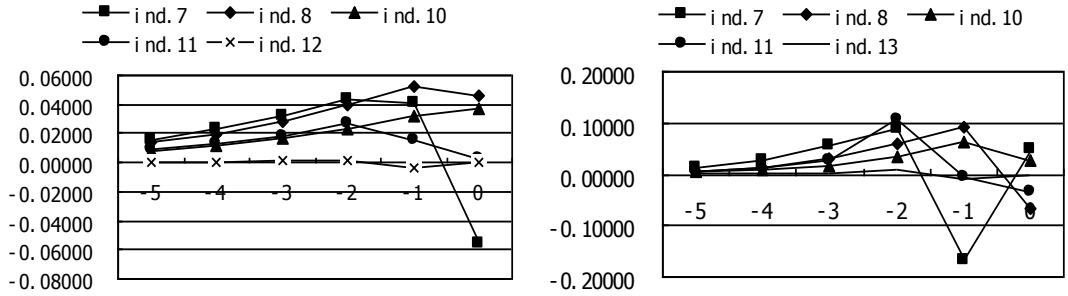

Figure 1: the Input of Maritime Ind. by cd (left) and the Input of Maritime Ind. by gd (right) (unit : 100 million/100 million).

In Fig.1 (left), it can be seen that the time series values of the DIM of most industries are over the 0 line besides Transportation (ind.7), which indicates that the input of most maritime industries to meet the growth in citizen demand is continuously growing. From Fig.1 (right), apart from the Service for Maritime Operation (ind.10), the contributions of other industries are below the 0 line in the object year or before, which indicates that more input during the planning years of the maritime industries in Liaoning is necessary to meeting the increase in the demand of government in the object year.

Labor and Capital Input of Maritime Industries . Fig.2 (left) shows labor input of maritime industries with one unit increase in the demand of government and citizens. The gd-curve is smooth, and in the object year falls below the 0 line, which means the increase in demand of government will inspire more labor input from maritime industries in the early planning years. Fig.2 (right) reflects the required amount of capital input. The input induced by the increase in demand of government and citizens reached the maximum in the last year before the object year, and the gd-curve is higher than the cd-curve. This means the effect of pulling force from the demand increase of government on the development of maritime industries is greater than from citizens.

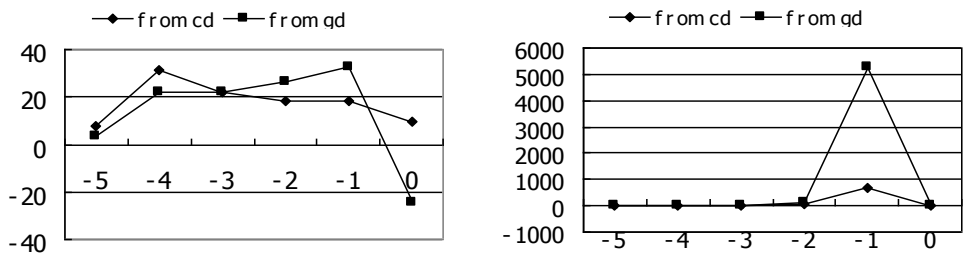

Figure 2: the Lab. Input of Maritime Industries (left) and the Cap. Input of Maritime Industries (right) (unit: 100 people/100 million, million /100 million).

CONCLUSION

Based on the I-O table of Liaoning, this study employs DIM of I-O analysis to examine the character of inter-industry linkage effects on the construction of the international shipping center in Dalian. It can be summarized

that first, the increase of maritime industries in Liaoning needs a different level of input from others, which can provide some guidelines to optimize and allocate investments for the different maritime industries. Second, it can be concluded that the input of maritime industries has a closer relationship to the demand from government than from citizens. The early input during the planning years from the maritime industries is important to accomplishing the increase in government demand. This is helpful in constituting the policy measures for construction of the shipping center in Dalian.

Although the economic level of and the maritime industry of the Dalian Shipping Center accounts for a large proportion in Liaoning, the disadvantage that becomes apparent in this paper is that it will be more typical if we can separate the maritime industries of Dalian from the I-O table of Liaoning. In addition, the industry of raw and processed materials would not be fully reflected in the calculated results because the sectors in the I-O table are combined and a number of irregular factors are off-sett. Those problems provide a focus for further research.

ABSTRACT

Transport equality is necessary to a harmonious society. Transport equality is illustrated by means of an assignment of transport resources and reallocation of transportation benefits, and it is carried out by the balanced relationship among all social members' payment for and gain from our society's transportation system, including two aspects of its practical burden and its duty. In order to build a harmonious society and realize transport equality, we need to improve rural economy, health and social service by enhancing rural massive transit services,. Based on historical and realistic rules of transport equality, in this paper optimization theory is adopted to analyze the equilibrium relationship under market conditions of admittance, among power preferences of administrative organization and operational effectiveness of rural transit service and benefit protection of consumers using data of rural residents' income, cluster level of inhabitancy and transport demand of people in the relative areas. Economic data in three rural areas of Hunan province are also used to correct parameters of the game theory model. Results of the model show that proper restriction of administrative power and a reasonable government subsidy policy are useful to motivate the effectiveness and profitability of rural massive transit service. In addition, some practical stratagem can gain consulates from these results.

INTRODUCTION

Passenger transport demand is the required ability to pay which is requested by the social and economic life about the spatial displacement of passengers, and it must possess two conditions: one is the ability to realize this displacement and the other is the ability to pay. Rural passenger transport happens in a range of cities or counties which generally have no other transportation modes except the highway, as in Wang Wei, XU Ji-qian and Yang Tao, et al (1998), and Liu Can-qi (2001). No matter how high the transportation price, when peasants have a need to travel, the highway provides the only transportation mode, (Yu Hong-jun, Li Xu-hong, XuYuan. A, (2002); Yin Hongbin, Wen Huiying, Jin Wenzhou, (2001); Wen Huiying, Zou Xianmin, Xu Jianmin, (2003). The approving system of the passenger transport market leads to the fact that the market is not open and the transportation price is determined by the government while it is not influenced by the market, so that the demand and the supply of the rural transportation is frequently inconsistent. Nowadays, the contradiction between the demand and the supply of rural

transportation has become a bottleneck which constrains development of economic and social aspects in rural areas. In order to accelerate construction of rural public passenger transport systems, promote traffic justice and build a harmonious society, this paper refers to the game theory and basic household income level data, the aggregation degree of residential and travel demand. Research was then applied which is under the regulation of historicity and concreteness of justice in traffic, on a game model of market access regulation about the equilibrium between the management organizations' rights preferences, the efficiency and benefit of management body and interest protection. The optimization model in this paper, which is calibrated by the technical and economic index of a typical area, elaborates the invigorative function and the functional range of which the constraint for the management organization and reasonable policy guidance influences the management body, and will play a guiding role in promoting passenger transport management in rural areas.

1. AN ANALYSIS OF BASIC CHARACTERISTICS OF RURAL PASSENGER TRANSPORT DEMAND DURING THE TRANSITIONAL PERIOD

With the acceleration of the urbanization process in our country, the dualistic social structure of urban and rural areas, which can be described as "urban/industry, countryside/ agriculture", will definitely evolve into urban-rural integration and urban-rural coordinated development. The main characteristics of rural passenger transport during the transitional period are shown as follows:

1) The rural passenger demand is a derived demand. It is derived from the demand of social and economic activities and is designed to serve production or living objectives, while completing spatial displacement which is just as necessary to achieve real aims. The main objectives of social and economic activity include business (the circulation of agricultural products and agricultural means of production), public affairs, visiting relatives, seeking treatment, tourism, and so on.

2) Rural passenger demand is weakly influenced by ticket price. Generally, in a range of city or county, there is no other transportation mode except the highway, so the highway is an irreplaceable service. No matter how much it costs, when peasants have a need to travel, the highway is the only transportation mode available.,. The approving system of the passenger transport market means that the market is not open and the transportation price is determined by the government and is not influenced by the market, so the ticket price is wekly influenced by passenger demand.

3) The heterogeneity and partial substitution of rural passenger transport demand. Because of scattered living conditions, the rural passenger transport demand is heterogeneous in its management of transport quality, technological requirements, transportation distance, direction, time and speed. With the development of modern communication technology, there is a reduction of passengers in rural areas due to smooth information transmission.

4) Certain regularity conditions exist in rural passenger demand during the transitional period. The demand of rural passenger transport is derived from social

and economic activities. Generally, the prosperity of the rural economy can bring growth to passenger transport demand, while the depression of it can cause decline. This imbalance in rural passenger demand can be reflected in the time, space and direction. The imbalance of the time arises mainly from the seasonality of agricultural production, slack and peak seasons of trade activities, holidays, the tourist season and so on. The imbalance of space and direction are mainly caused by productivity, industrial distribution, economic development level, layout of the transportation network, and so on. During the transitional period of urban-rural integration, extremely strong regularity exists in the shift of the rural/surplus labor force, which can be divided into three types: **1)** Living at home but abstaining from the land, which means that labor transfers from agriculture to non-agriculture in the local areas. **2)** Leaving home, but not going to the city, which means that labor shifts betweem different rural areas. **3)** Leaving home and abstaining from the land, which means that rural surplus labor shifts to t urbanareas. As is shown in the Figure 1, M1 and M2 belong to "living at home but abstaining from the land," M5 and M6 belong to "leaving home and abstaining from the land," M3 and M4 belong to "leaving home but not going to city." The different levels of the social and economic development in different areas determines the structure and proportion of the rural surplus labor force flow, which will influence the size and volatility of the rural passenger transport demand. We should notice the differences between the rural passenger transport demand between different areas where the surplus labor force flows in or out. The economics of the former are developed and a large number of the labor force flows in, and the flowing population is one of the main sources of the passenger transport in the daily and holiday period. This can cause the rural passenger transport to change enormously and the scale of it fluctuates according to the proportion of the flowing rural surplus labor force. With the population base M fixed, and letting N_1, N_2, N_3 and $\alpha_1, \alpha_2, \alpha_3$ represent the different average travel times per year and the different proportion in the flowing population of the three different types of flowing population, which is "living home but abstaining from the land," "leaving home but not going to the city" and "leaving home and abstaining from the land." So, due to the flow of the rural surplus labor force, the demand of the rural passenger transport in the areas where surplus labor force flows can be calculated as follows:

$$D = M(N_1\alpha_1 + N_2\alpha_2 + N_3\alpha_3) \quad (1)$$

Even if M and N_1, N_2, N_3 keep invariant, the demand of the rural passenger transport will change greatly when $\alpha_1, \alpha_2, \alpha_3$ keeps different proportion. The figure 2 has shown the change chart when $M = 5000$, N_1, N_2, N_3 equal to 4.5，0.6，0.75 and the different proportion of $\alpha_1, \alpha_2, \alpha_3$ is 3:5:2, 2:7:1and 5:4:1respectively. The different proportion of $\alpha_1, \alpha_2, \alpha_3$ just reflects the configuration effect of how the market and the opportunity cost influences human resources. We can also assume that the change value of the rural passenger transport demand is determined by the portion of the surplus labor force which is absorbed by the local area.

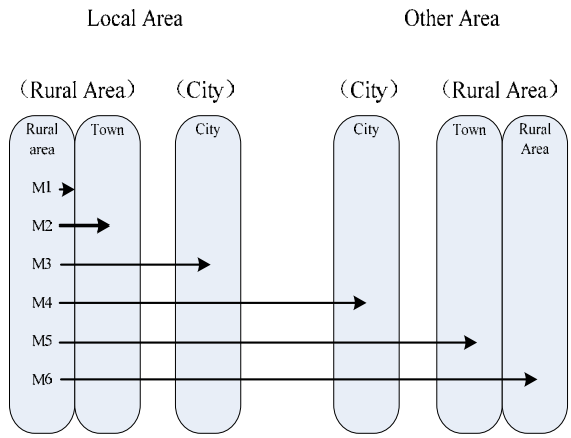

Figure 1 The flowing mode of the rural surplus labor force

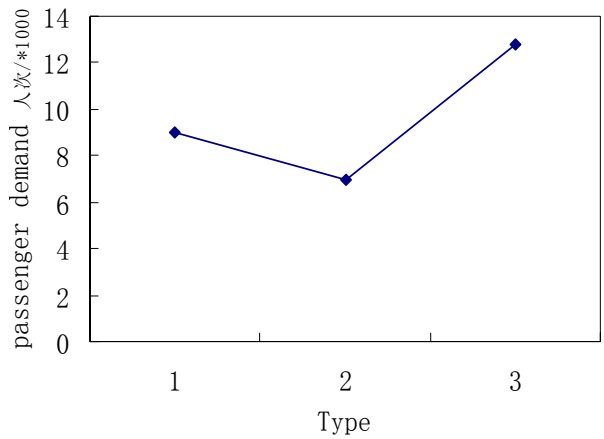

Figure 2. different passenger transport demand under different structure of surplus labor.

These basic characteristics determine that the amount of the occurrence and attraction of the rural passenger transport can be separated into two parts: one caused by the flow of the rural surplus labor force and the other derivative, due to the social and economic activities of other rural areas. Based on basic factors such as gross domestic product, industrial and agricultural output value and population scale, the regression analysis method is most popular in predicting traffic volume which is derived from rural social and economic activities. There are other methods, such as the growth speed method, the growth curve prediction method, the gray system prediction method and so on, as in Jun Zhicai (1998), Zhang Weiying (1999) and Wang Jianjun, Yan Baojie (2004). The traffic volume due to the flow of the rural surplus labor force is determined by the structure and proportion of the flowing labor force. The volume of the rural passenger transport due to the first transferring mode of the labor force which is “living home but abstaining from the land,” is larger and more equal to the other two modes which are “leaving home but not going to city” and “leaving home and abstaining from the land.” However, the volume of

rural passenger transport will change enormously during holidays, when the amount of the labor force due to the two latter modes becomes very large.

2. THE GAME OF RURAL PASSENGER TRANSPORT MANAGEMENT UNDER THE REGULATION OF JUSTICE

Maintaining balance between supply and demand is one of the main objectives of management in rural passenger transportation. Under the regulation of justice in traffic, in order to guarantee that justice is implemented in the balance of the supply and demand in rural passenger transportation, the traffic governing department, which represents the government, must ensure the supply service level of the rural passenger transport on one hand, and the economic benefit which corresponds to the management body of the rural passenger transport on the other hand. Otherwise, harmonious development in rural areas will be hindered and social contradiction will be intensified, or the supply of rural passenger transport will suffer a serious shortage due to the lack of guarantee of economic benefit to the management body in rural passenger transportation. We also need to do our best to help the market invigorate the demand of rural passenger transportation,which is under the regulation of justice and arouses the participation of social resources in the supply of rural passenger transportation.

According to the above analysis, rural passenger transportation has a basic demand fluctuation. For convenience purposes, this paper uses the whole range passenger volume per day Q, which converts the passengers who get on or off at midway to the whole range of passengers and reflects the average traffic flow of the whole range, to describe the demand of the rural passenger transport. $g(Q)$ and $F(Q)$ represents the probability density function and the probability distribution function of the whole range passenger volume Q respectively. The balance between the supply and the demand of the rural passenger transport is reflected by that of the demand of the passenger transport route in the rural areas and is satisfied in some service levels because of the bus service on the route. According to the regulation of justice in traffic, the probability that the passenger transport demand is satisfied by the transport capacity of the daily employee, is no less than β_1 in the normal period or β_2 in the peak period. IC represents the fixed cost of the operation per month which includes management and parking fees, insurance, maintenance costs, bank loans, booking clerk wages and so on. OC represents the oil costs of every employee bus. The normal times of each employee bus on each route per day is t_1, and the average maximum of overtime work times for each employee bus per day is t_2. SN. φ represents the fixed seating number and the maximum of overloading rate for each employee bus respectively. C and MR represent the whole range price of each employee bus on the route and the average income per month in the local area. The number of employee buses on route x should satisfy the normal and peak period service level:

$$\beta_1 < \int_0^{SN \cdot t_1 \cdot x} g(Q)dQ \tag{2}$$

$$\beta_2 < \int_0^{SN\cdot\varphi\cdot t_2\cdot x} g(Q)dQ \tag{3}$$

Second, the number of the buses arranged on route x should satisfy the demand for reasonable profit of the operational bodies:

$$\begin{aligned}&[\int_0^{SN\cdot\phi\cdot t_1\cdot x} Q\cdot c\cdot g(Q)dQ+\int_{SN\cdot\phi\cdot t_1\cdot x}^{SN\cdot\phi\cdot t_2\cdot x}\left\lfloor\frac{Q}{SN\cdot\phi}\right\rfloor\cdot SN\cdot\phi\cdot c\cdot g(Q)dQ\\&+\int_{SN\cdot\phi\cdot t_2\cdot x}^{\infty} t_2\cdot SN\cdot\phi\cdot x\cdot c\cdot g(Q)dQ]\times 30-IC\cdot x-OC\cdot[\int_0^{SN\cdot\phi\cdot t_1\cdot x} t_1\cdot x\cdot g(Q)dQ\\&+\int_{SN\cdot\phi\cdot t_1\cdot x}^{SN\cdot\phi\cdot t_2\cdot x}\left\lfloor\frac{Q}{SN\cdot\phi}\right\rfloor\cdot g(Q)dQ+\int_{SN\cdot\phi\cdot t_2\cdot x}^{\infty} t_2\cdot x\cdot g(Q)dQ]\times 30>2\cdot MR\cdot x\end{aligned} \tag{4}$$

$\lfloor * \rfloor$ represents the integral function here, for example, $\lfloor 3.5 \rfloor = 3$.

According to regulation of justice in traffic, the governing department should make the daily operating cost of route Z smallest when they design the route and number of employee buses. Considering the limited number of buses on the route, we can postulate the maximum number of buses is $V_{\max}$. So the number of the employee buses, which are on the route that are a balance between the supply and the demand of the rural passenger transport under regulation of justice in traffic, should satisfy as:

$$\begin{aligned}&MIN \quad Z = IC\cdot x + OC\cdot x\cdot t_1\\&s.t. \quad (2),(3),(4)\\&\qquad x\in 0,1,2,\cdots,V_{\max}\end{aligned} \tag{5}$$

As shown in the Figure 3, the formulas (2) and (3) of the linear programming above represent the service levels of the daily and peak periods respectively, and formula (4) represents the reasonable profit that the operating body should receive.

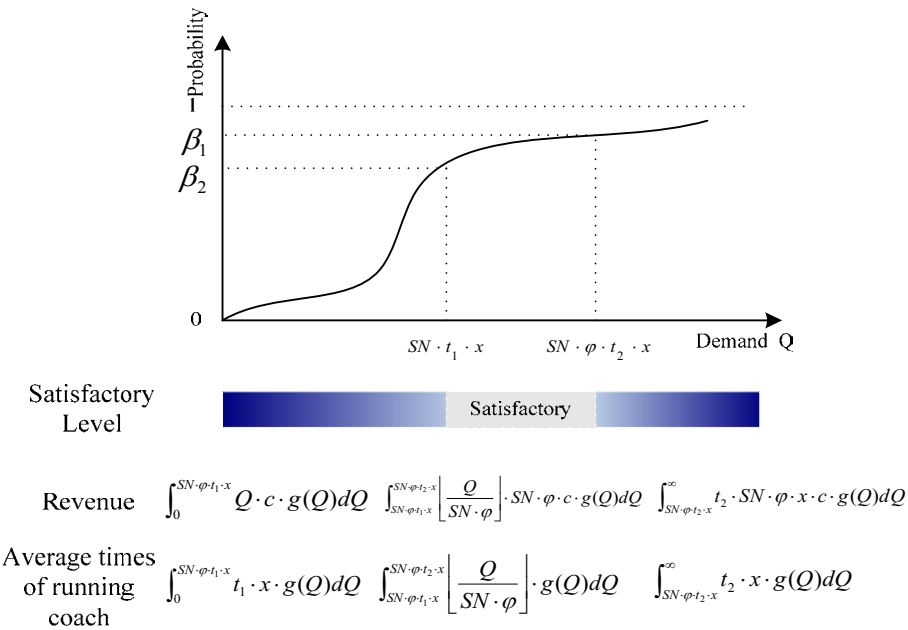

Figure 3. Schematic Diagram of Rural Passenger Management Optimization.

The linear programming (5) can be solved easily by the branch-and-boundor enumeration methods, and the solution can be simplified if the integration can be determined in advance. If the constraint conditions (2), (3) and (4) do not have a feasible region, it shows that the demand of passenger transport is too small to ensure the probability that the transport capacity of the daily employee bus can satisfy the demand because it is higher than the service level β_1, while it is higher than β_2 in the peak period. At this point, relevant policies should be implemented or the service level should be decreased by government in order to keep the balance between passenger transport supply and demand in relevant rural areas.

3. EXAMPLE ANALYSIS

This paper assumes that the daily passenger volume of the whole range Q obeys normal distribution, namely $Q \sim N(585,12^2)$; the fixed cost of and the fuel fees for each employee bus are 7700 yuan per month and 50 yuan per day respectively, and the other parameters are shown as follows:

Table 1. Table of Parameters and Value.

Parameters	β_1	β_2	t_1	t_2	SN (person)	φ	C (yuan)	MR (yuan/month)
Value	0.75	0.9	5	5.4	17	1.2	7	650

Because the number of the employee buses x is an integral, we can solve the linear programming problem with the enumeration method. For $x = 1,2,3,...,n$, we can verify each of the restrictive conditions (2), (3) and (4) as satisfied or not. We also can obtain all of the objective functional values Z for every x, and then the optimum number of the employee buses x can be selected. The solution procedure of the linear programming (5) is simple, so we will not elaborate on that here.

After solving linear programming (5), we can get $x = 7$, which means optimum transport supply is seven employee buses. The value of the objective function is a minimum value, $Z = 55650$. At this time the service level of the normal and peak period is 0.9983 and 0.9999, which satisfies restrictive conditions (2) and (3). The average profit per month of the operational body is 16490 yuan, which is bigger than the average income of 9100 yuan of the local area. So the restrictive condition (4) can be satisfied

If a feasible solution for linear programming (5) cannot be found, it is assumed that the passenger demand in the normal and peak periods will not be satisfied simultaneously with the operating body running sustainably without a subsidy from the government. That means the passenger transportation operational body will never operate well without a subsidy from the government.

We considered that the employee buses are not allowed to overload during the normal or peak period. In this situation, the maximum of overloading rate φ equals 1. We can get $x = 7$, but the service level will drop to 0.7977 in the normal period.

4 CONCLUSIONS

a. Variation is a basic characteristic of rural passenger transport demand curing the transformation period, which determines that the amount of occurrences and attraction of rural passenger transport can be separated into two parts: one is caused by the immigration of the rural surplus labor force and the other one is derived from social and economic activity in rural areas.

b. Under the justice in traffic rule, and in order to guarantee that justice si implemented in the balance of supply and demand in rural passenger transportation, the traffic governing department, which represents the government, must ensure a supply service level of rural passenger transport on one hand, and protection of the economic benefit that corresponds to the running body of rural passenger transport. Otherwise, harmonious development in the rural areas will be hindered and social contradiction will be intensified, or the supply of rural passenger transport will be seriously diminished because the economic benefit of the running body in rural passenger transportation will not be guaranteed. The optimal allocation for daily employee bus transport capacity in rural areas must refer to normal and peak period service levels.

Analyzing the Motivation of Queue-jumping Driving-action on Transportation Systems by Prospect Theory

Maosheng Li [1], Qinglong Zhong[1], and Dafei Chen [1]

[1] College of Transportation Planning and Traffic Engineering, Central South University, Changsha city, Hunan Province, 410075, China; Phone numbers: +86-0731-2655640; Email: maosheng.li@163.com

ABSTRACT

This paper researches the motivation of queue-jumping driving-action on transportation systemsas compared to the expected utility theory . The drawback of the expected utility theory, which fails to explain the motivation of the queue-jumping driving-action, is illustrated. In addition, when considering three underlying factors, traffic management policy, the delayed time after taking queue-jumping action and audit probability, a critical function about expected disutility, which can reveal whether the driver has the motivation to jump the queue or not relative to these underlying factors, is established. The model established in this paper, which is rooted in the prospect theory for describing the complicated relationships among the three aspects of underlying factors, is calibrated by actual data collected from intersections. Based on the quantitative analysis results, three approaches are offered to decrease the possibility of taking queue-jumping driving-action when a driver encounters a queue. Finally, conclusions and some future research problems are summarized.

1. INTRODUCTION

Although differences exist in eastern and western countries queue-jumping driving-actions in the transportation system can be spotted in our daily lives; , especially in congested urban settings. The minor peccadilloes that occur as a consequence of these actions will subsequently cause different kinds of confusion, from a very short delay of traffic flow to heavy congestion of the transportation system in some areas. Managers all over the world take great efforts to eliminate the affect of queue-jumping driving-actions by different means and transportation policies. The motivation of queue-jumping driving-actions varies under different factors, such as traffic management policy, the exogenous delay time due to the queue, the audit probability and lack of stigmatization from moral a moral standpoint. These actions occur only when there is a queue ahead and the extra-free space is adequate enough for a driver to take a queue-jumping driving-action. For example, some drivers may occupy a left turn lane cheating by going straight instead of turning left, which is followed by a go-ahead phase on the in-leg of the intersection. There is a high probability that this may cause confusion near the outter edge of the intersection. In this paper, we aim to explore the relationship between the motivation of queue-jumping driving-actions and underlying factors in order that most of the queue-jumping driving-actions, except for the motivation of saving somebody's life, will be help up by well planned mechanisms.

The cause of a vehicle's movement can be classified into two types: one is

simple or standard situations that can be well predicted, in which the motion of the mixed agents can be described as if they would be subject to social forces(Helbing and Molnar., 1995). The other is the complex or new situations that may occur with probabilistic models such as expected utility theory (EUT) which is a useful tool for analyzing route choice decisions (Sheffi, 1985). But there is a failure to explain the motivation of queue-jumping driving-action as described in Section 3. The cell transit model (Wolfram, 1983; Daganzo, 1994; Lo, 2002a) which is rooted in Wolfram's rule 184 succeeds in simulating the effect of queue-jumping driving-actions in links or areas of the transportation system and adapts its probability to capture this effect. Although underlying stimuli relationships exist among traffic management policies (i.e. penalty on the action), and the delay time after taking queue-jumping action, audit probability remains to be a mystery.

In this paper, we adopt prospect theory to describe the complicated relationships between traffic management policy, the exogenous delay time due to queue and audit probability. We also offer a critical function that can reveal whether a driver is motivated to jump the queue or not relative to these underlying factors. The new results from an economic standpoint would be useful for designing width of lane and evaluating transportation management policies.

2. A BRIEF INTRODUCTION TO PROSPECT THEORY

Prospect theory is based on the following five main ideas: reference dependence, declining sensitivity, loss aversion, non-linear weighting of probabilities, and susceptibility to frame effects. Unlike EUT, where the utility carriers are equivalent to final levels of wealth (or incomes or commodities), the utility carriers for prospect theory are equivalent to both gains and losses relative to the reference point. Declining sensitivity means that the utility function is concave in the domain of gains and convex in the domain of losses. Loss aversion is based on the idea that losses are more salient than gains. Given an amount of money, $x > 0$, and a utility function, $v(x)$, loss aversion implies that $v(x) < -v(-x)$. Agents facing uncertain situations over evaluate small probabilities but under evaluate large ones. Finally, agents' preferences are influenced by the way a problem is presented. There is a substantial body of evidence to support these building blocks of prospect theory (Tvershy and Kahneman, 2000).

Prospect theory has been successfully used to explain a range of puzzles in economics, such as the disposition effect, asymmetric price elasticity, the elasticity of labor supplies that are inconsistent with standard models of labor supply, the excess sensitivity of consumption to income, and the tax evasion puzzle (Dhami and al-Nowaihi 2006, 2007). But to the best ov my knowledge, there is little literature on the application of prospect theory to solve transportation problems.

3. QUEUE-JUMPING DRIVING-ACTION UNDER PROSPECT THEORY

Facing a queue situation in a transportation system, a driver will encounter exogenous delay time $D > 0$, more than normal transverse time $W > 0$ in a non-queue situation. If the exogenous delay time D could be cut down to some level of proportion $\phi(0 \le \phi < 1)$ of delay time by taking a queue-jumping action, the driver

would possibly be motivated to implement it. Despite the fact that the delay time ϕD that the driver will encounter after taking queue-jumping action is shorter than the exogenous delay time D under taking no action, the queue-jumping driving-action is not always encouraged because it is punished at constant rate s if the action is caught by a policeman. If the queue-jumping driving-action caught by a policeman is recorded as a traffic citation, the driver would suffer additional stigma rate λ. In this paper, we assume that both the penalty rate s and stigma rate λ are relative to exogenous delay time D, and their values are converted to time units rather than money. We also assume that the driver is caught with a probability $P(D) \in [D]$, in which $P(D)$ is continuously differentiable and $P^{'}(D) \geq 0$ (i.e. the driver who takes queue-jumping driving-action is more likely to be caught if the length of queue is too long). Denoted by Y_C and Y_{NC}, respectively, the transverse time of taking queue-jumping action under a queue situation in the transportation system when he is "caught" and when he is "not caught", respectively:

$$Y_C = W + \phi D \tag{1}$$

$$Y_C = W + tD + sD + \lambda D = W + (t + s + \lambda)D \tag{2}$$

When he is caught while taking a queue-jumping action, the transverse time through the queue area is usual longer than the exogenous delay time D. In this paper we assume that the extra delay time is $tD(t \geq 1)$, and the driver has a strictly decreasing, strictly concave and twice continuously differentiable disutility function, $u(Y)$. Under expected utility theory (EUT), his expected disutility is:

$$U(D, s, \lambda, W) = p(D)u(Y_C) + [1 - p(D)]u(Y_{NC}) \tag{3}$$

When combined with equations (1)-(3), we find that the driver's expected disutility is relative to normal transverse time W, which is illogical in our experience. Results indicate that the motivation behind queue-jumping driving-action iss not relative to normal transverse time W. You can image that a driver's willingness to engage in queue-jumping driving-action is very low if the exogenous delay time D approaches zero, although normal transverse time W may probably be long enough in this situation. So we turn to prospect theory to find a reasonable explanation for the motivation behind queue-jumping driving-action.

Let R be the reference transverse time of the driver under a queue situation, and let the time relative to this reference point be:

$$X_i = Y_i - R \tag{4}$$

Where i = C or NC denotes the two states "caught" and "not caught," As in Tversky and Kahneman (1992), and Dhami and al-Nowaihi (2007), the utility associated with a gain (i.e. time-saving) or loss (i.e. time-consuming, penalty and stigma rate) X_i is $v(X_i)$ with minor modifications, and

$$v(X_i) = \begin{cases} (-X_i)^{\beta} & if\ X_i \leq 0 \\ -\theta\, X_i^{\beta} & if\ X_i > 0 \end{cases} \tag{5}$$

Here, $\beta \in [0,1]$ and $\theta > 1$ are preference parameters and v is called the value function. The parameter θ is the parameter of loss aversion. It encapsulates the basic

idea that a loss of x hours (or dollars) is more painful than the pleasure derived from a gain of x hours (or dollars). Based on experimental evidence, Tversky and Kahneman (1992) suggested that $\beta = 0.88$ while $\theta = 2.25$.

Although prospect theory does not provide sufficient guidance to determine the reference point in each possible situation, specifying a suitable reference point is often essential for a successful application of prospect theory.

We take the legal transverse time as the reference point in this paper, so

$$R = W + D \tag{6}$$

The assumption below shows that this will be the case if, and only if, the reference point is the legal transverse time of queuing link or area.

Assumption: For a driver who jumps the queue, if both the penalty rate s and stigma rate λ are larger than zero, he/she is in the domain of gains if not caught, $X_{NC} \le 0$, but in the domain of losses if caught, $X_C > 0$. If both the penalty rate s and stigma rate λ equal zero, he/she is in the domain of gains no matter whether he/she is caught or not. Then the reference point must be $R = W + D$.

Using equations (4) and (6), we get:

$$X_{NC} = -(1-\phi)D \le 0 \tag{7}$$

$$X_C = (t + s + \lambda)D > 0 \tag{8}$$

Let w^+ and w^- be the driver's probability weighting function for the domains of gains and losses, respectively. Then, according to cumulative prospect theory, the driver maximizes:

$$V(D, \phi, s, \lambda) = w^-[p(D)]v(X_C) + w^+[1 - p(D)]v(X_{NC}) \tag{9}$$

Comparing equation (9) with the analogous expression for expected utility theory, equation (3), we see the following differences. First, the carriers of utility in prospect theory are gains and losses relative to some reference point rather than levels. Second, one uses decision weights in prospect theory to aggregate outcomes while one uses objective probabilities under expected utility theory. From equations (5), (7), (8) and (9), we get:

$$V(D,\ \phi, s, \lambda) = -\theta w^-[p(D)][(t + s + \lambda)D]^\beta + w^+[1 - p(D)][(1-\phi)D]^\beta \tag{10}$$

Let:

$$h(\phi,\ s, \lambda) = -\theta w^-[p(D)](t + s + \lambda)^\beta + w^+[1 - p(D)](1-\phi)^\beta \tag{11}$$

Equation.(10) can be rewritten in the following form:

$$V(D, \phi,\ s, \lambda) = D^\beta h(\phi, s, \lambda) \tag{12}$$

The value of function (12) reveals whether a driver has motivation to jump the queue or not. He will take queue-jumping driving-action if $V(D, \phi, s, \lambda) > 0$, and takes no action to jump queue if $V(D, \phi, s, \lambda) < 0$. If $V(D, \phi, s, \lambda) = 0$. The driver who

is risk-preferring is more likely to jump the queue because he/she does not care about the losses if he/she is caught. The driver who is risk-averse is more likely to not jump the queue. Comparing function (12) with equation (3), we see the difference that the value of equation (3) is related to both the exogenous delay time D and normal transverse time W, but the value of function (12) is only relative to the exogenous delay time D. The above is summarized by the following assumption:

4. MODEL CALIBRATION

4.1 The Probability Weighting Function

For our calibration exercise, we adopt the weighting function of Prelec (1998) because it is parsimonious, which is consistent with much of the available empirical evidence and has an axiomatic foundation. Let P be the case of audit probability $P(D)$. The Prelec weighting function has the following form:

$$w^+(p) = w^-(p) = w(p) = e^{-(-\ln p)^\alpha} \text{ for } p \in (0,1],\ w(0) = 0 \text{ and } 0 < \alpha < 1 \tag{13}$$

Note that $w(p)$ is a strictly increasing function onto $[0,1]$, $w(0) = 0$, $w(1) = 1$, $w(e^{-1}) = e^{-1} \cong 0.37$, $w(p)$ is strictly concave on $(0, e^{-1})$ with $w(p) > p$, $w(p)$ is strictly convex on $(0, e^{-1})$ with $w(p) < p$. Using Eq.(12) and the Prelec weighting function (13), the $(t + s + \lambda, p)$ locus at the value $V(D, \phi, s, \lambda) = 0$ under prospect theory while other parameters be assumed to be fixed is given by:

$$(t + s + \lambda) = (1 - \phi)\Gamma(p)^{(1/\beta)}\theta^{-(1/\beta)}\left(\frac{1-p}{p}\right)^{(1/\beta)} \tag{14}$$

Where $\Gamma(p) = \exp(-\ln p)^{0.35} - (-\ln(1-p))^{0.35}]$, we have substituted the value of $\alpha = 0.35$ in $\Gamma(p)$ in this paper.

4.2 Queue-jumping Driving-action in Front of the Intersection

The queue caused by the red light at the intersection is ubiquitous in the transportation system. If a driver decides to jump the queue while he faces it and the extra-free space is wide enough, the expected delay time $E(\phi D) = E(\phi)D$ which the driver will encounter after taking queue-jumping action is $0.5D$. Equuation.(14) takes expected value in both sides, then we get:

$$(t + s + \lambda) = 0.5\Gamma(p)^{(1/\beta)}\theta^{-(1/\beta)}\left(\frac{1-p}{p}\right)^{(1/\beta)} \tag{15}$$

According to equation (15), the relationship between the penalty adding stigma rate $t + s + \lambda$ and the audit probability p is given in Table 1, and is also depicted in Figure 1, while $t = 1$. A policeman who works eight hours per day is in charge of four legs of the intersection, so the audit probability p for queue-jumping driving-actions

by the policeman is no more than (1/4)*(8/24) in front of the intersection, which is 0.075, because he can only monitor one of four legs of the intersection at any moment. Table 1 gives 18 groups of value for $(t+s+\lambda, p)$. When audit probability p increases in range of intervals 0.001-0.01, value of $t+s+\lambda$ drops very fast. That means very small improvements in audit probability, and more saved in the value of p. We can see that this measure, where auto-surveillance cameras are installed in front of an intersection to increase audit probability p in some countries, is very effective. This is why the possibility of taking queue-jumping driving-actions in front of an intersection drops quickly after auto-surveillance cameras are installed though the value of penalty and stigma rate $t+s+\lambda$ is actually very low.

Table. 1 Value of $(t+s+\lambda, p)$ at Critical Point of Equation(12) While $\phi=0.5$.

Items	Audit probability p	Penalty & stigma rate $t+s+\lambda$ (dollar)	Items	Audit probability p	Penalty & stigma rate $t+s+\lambda$ (dollar)
1	0.001	566.5251	9	0.009	31.0524
2	0.002	230.8286	10	0.01	26.8731
3	0.003	135.6122	11	0.02	10.1901
4	0.004	92.6554	12	0.03	5.6710
5	0.005	68.7959	13	0.04	3.7007
6	0.006	53.8521	14	0.05	2.6371
7	0.007	43.7258	15	0.06	1.9876
8	0.008	36.4708	16	0.07	1.5576

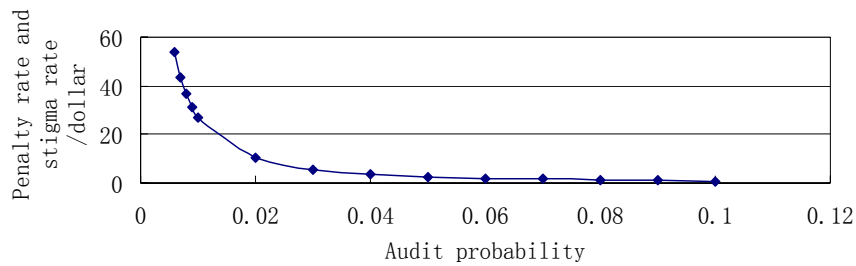

Figure 1. Relationship Between Penalty and Stigma Rate and Audit Probability Described by Equation (14) While $\phi=$ 0.5.

In Figure.1, the horizontal axis represents the audit probability p, and the vertical axis represents the penalty rate adding stigma rate $t+s+\lambda$. Considering that the actual penalty rate is about \$25-\$50 and the stigma rate is very small in most Chinese cities today, we can deduce that the actual audit probability of queue-jumping driving-action is in the range 0.006-0.01, so the horizontal axis is shown as a maximum value of 0.011. We can also see from Figure 1 that the higher the actual probability p is, the less the penalty rate adding stigma rate $t+s+\lambda$ needs to be for

keeping the value function of equation (12) equal to zero, namely, let the critical point of the value function appear.

Equation(10) can be rewritten as:

$$V(D,\phi,\ s,\lambda) = D^{\beta}[-\theta \cdot e^{-(-\ln p)^{\alpha}} \cdot (t+s+\lambda)^{\beta} + e^{-[-\ln(1-p)]} \cdot (1-p) \cdot (1- \quad (16)$$

From equation. (16), we observe that there are three basic ways to change the value of $V(D,\phi,s,\lambda)$. By changing the value of one of the variances, the penalty rate adding stigma rate $t+s+\lambda$, the audit probability p and the proportion ϕ of delay time we arrive at:

Approach 1. The first approach is to set a proper level of penalty and stigma rate on queue-jumping driving-action. For example, the penalty rate remains in the range of \$25-\$50 and we increase stigma rate up to \$25 or more. Other parameters remain unchanged, because the audit record of the transportation system is not employed to cite personal credit, and the current stigma rate equals close to zero in most Chinese cities. On the contrary, the stigma rate in European countries and America is very high. This is a very important reason why drivers in western countries are willing to follow queues in intersections without taking queue-jumping driving-action. A high penalty rate is not currently favored by Chinese drivers or governors.

Approach 2. The second option is to increase the audit probability on queue-jumping driving-action, such as installing auto-surveillance cameras in front of the intersection. This way requires more policemen or cameras to supervise drivers so the cost of transportation management is increased. Although a small improvement in audit probability will cause a large decrease in queue-jumping driving-action as seen in Figure1 or Table 1, achieving a small improvement in audit probability is very hard.

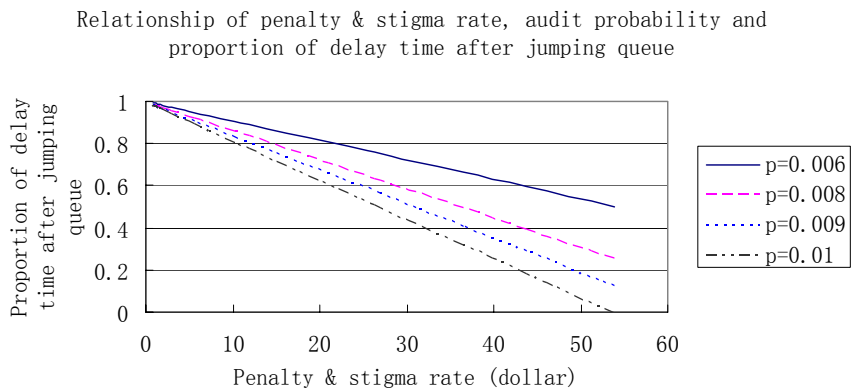

Figure 2. Relationship of Penalty and Stigma Rate, Audit Probability and Proportion of Delay Time After Jumping Queue at Critical Point.

Approach 3. The last option is that the delay time which the driver will encounter after taking queue-jumping action is connected to the exogenous delay time of taking no action by some methods (i.e. changing audit place, setting a limited width of the lane entering the intersection or other means so that the delay time is hard to cut after a driver makes a queue-jumping driving-action.).

An integrated policy may be more effective in decreasing queue-jumping driving action.. The larger the value of proportion ϕ, shorter the saving time will be when a driver makes a queue-jumping action. To provide deterrents to jumping queue, Figure 2 clearly depicts the relationship of the penalty and stigma rate, the audit probability and the proportion of delay time y.

5. CONCLUSION

The motivation behind queue-jumping driving-action is researched under prospect theory while considering three aspects of underlying factors: traffic management policy (i.e. penalty, stigma rate on the action), the delay time after taking queue-jumping action, and the audit probability. Some new characteristics of prospect theory allow us to get some new results. , These include where the carriers of utility in prospect theory are gains and losses relative to some reference points rather than levels in expected utility theory (EUT), as well as where decision weight in prospect theory is used to aggregate outcome while objective probability is employed under EUT.. These quantitative analysis results show that there are three approaches to decrease the possibility of a driver's taking queue-jumping driving-action when he encounters a queue.

The first approach is to set a proper level of the penalty rate on queue-jumping driving-action and increase the stigma up to $25 or more. The second approach is to increase the audit probability on queue-jumping driving-action.

The last approach is to delay the time the driver will encounter after taking queue-jumping action, tending to the exogenous delay time of taking no action by some methods.

The data of queue-jumping driving-action collected near four legs of the intersection is used to calibrate the model. Queue can be classified into two classes: recurrence and non-recurrence., While the proposed analysis method is suitable for non-recurrence cases, A method for the elimination of cases of non-recurrence queues is worthy of further research.

Modeling Passenger Choice Behavior in Chinese Multi-Airport Regions

LIU Jiangtao[1]

[1]School of Economics, Wuhan University of Technology, Hubei, 430070, P. R. China; email: liujiangtaoljt@sohu.com

ABSTRACT

Passenger choice is a crucial factor in determining airports' success or failure. As a developing country, Chinese travelers have their own choice indicators. Application of existing models of passenger choice behavior developed by countries outside of China has not had any effect on passenger choice behavior in China. In this paper, a nested logit model is constructed to predict airport choice in a multiple-airport region and estimated using passenger data from Chinese metropolitan areas. A two level nested logit model with the airport choice at the top level and the access mode choice at the lower level is preferred. The estimation results show that business travelers have higher access time elasticity than leisure travelers, while leisure travelers have higher fare elasticity. In addition, airport access time and passenger experience are of great importance in Chinese airport choice behavior for both business and leisure travelers.

INTRODUCTION

Intercity travel has grown steadily over the past decade, and recent studies suggest that such travel is only likely to grow over the next two decades (Basar and Bhat 2004). Within the development of Chinese economy and its standard of living, air travel is the fastest growing intercity mode of travel in China. Many of the world's largest cities are served by more than one commercial airport and this is not dissimilar for Chinese metropolitan areas. Airports in a multiple airport region have to compete with other airports for passengers. Therefore, airport choice is an important air travel-related decision in multiple airport regions.

The study of such multiple-airport systems has long been considered an important research area. To date, a number of papers have modeled airport choice in multi-airport regions. Most studies use the discrete choice models, such as the binomial or multinomial logit approach to investigate the primary determinants of passengers' airport-choice decisions, e.g. airfare, airport access time, airport access cost, and flight frequencies. Some of these studies have focused on airport choice in isolation (e.g. Skinner 1976; Harvey 1987; Thompson and Caves 1993), while others have examined airport choice along with other dimensions of air travel (Furuichi and Koppelman,1994; Pels et al. 2001, 2003; Warnock-Smith and Potter, 2005; and Hess et al. 2007). These studies have important implications for airport managers and planners. However, the choice of airport access mode has been studied only sporadically in the literature. Harvey (1986) studies the airport access mode in the San Francisco Bay Area, and, finds that travel time and travel costs are strong determinants of the airport access mode. Bondzio (1996) estimated nested logit models to explain the joint access mode-departure airport choice for German airports, using access time to the airport, access costs, and frequency of service as explanatory

variables. Pels et al. (2001, 2003) finds that a nested logit model with the airport choice at the upper level and the airline choice at the lower level best explains the joint airport–airline choice for both business and leisure travelers in the San Francisco Bay Area. However, airfare was not included in the analysis. In this paper, airfare is included, but since it is not available for all airlines (only average fares on a route level are available), the airline choice deleted from the model and the access mode choice is included.

In addition, previous researchers generally studied airport choice in developed countries and seldom concern themselves with the multi-airport regions in developing countries. This paper aims to provide insight into passenger sensitivity to fare, frequency, airport access time, airport access cost, and passenger experience, and furthermore, we extend the research on airport choice to developing countries. A nested logit (NL) model is constructed to predict airport choice in a multiple-airport region and estimated use of passenger data from Chinese metropolitan areas. The modeling results indicate that business travelers have higher access time elasticity than leisure travelers, while leisure travelers have higher fare elasticity. In general, airport access time and passenger experience is of greater importance in airport choice behavior for both business travelers and leisure travelers.

PROPOSED MODEL

Suppose a traveler has decided to fly to a particular airport. The traveler then has to choose a departure airport (d) and an airport access mode (a). The log of the average fare on a route will be used as an explanatory variable for the airport choice. There are two options for modeling these choices. In the simple option, airport and access mode are made independently; first one chooses an airport and later one chooses the access mode. Although travel time to the airport may depend on the access mode, while the airport is chosen, the passenger does not decide on the access mode. At a later stage, the passenger decides on the access mode based on access time, access cost, and experience. For example, a passenger buys a ticket at the airport and thus has to choose in advance what airport is preferred and how to get there, or, a ticket is bought in advance, but this choice, which also includes the airport choice, also depends on access mode; the passenger chooses the alternative, which maximizes the total utility of the airport access mode combination.

Let there be a set (d) of airports and set (a) of access modes. The probability model for choosing alternative (airport) (d) in the first option is:

$$P(d) = \frac{\exp[\alpha_d + \alpha_{fare} \ln fare_d + \alpha_{freq} \ln freq_d + \alpha_{expe} \cdot expe_d]}{\sum_{d \in D} \exp[\alpha_d + \alpha_{fare} fare_d + \alpha_{freq} \ln freq_d + \alpha_{expe} \cdot expe_d]} \quad (1)$$

for the airport choice and:

$$P(a) = \frac{\exp[\beta_a + \beta_{cost} \cos t_a + \beta_{time} time_a]}{\sum_{a \in A} \exp[\beta_a + \beta_{cost} \cos t_a + \beta_{time} time_a]} \quad (2)$$

for the access mode choice. In Equation (1), $freq_d$ is the daily frequency of service, included in logarithmic form, as it is an indication of the "size" of an airline in a market to a certain destination; $\alpha_{freq}>0$. The average fare and distance to the airport are also included; $\alpha_{fare}<0$ and $\alpha_{expe}>0$. α_d is an airport-specific constant. In Equation (2), β_a is a mode-specific constant, cost is the access cost and time is the

access time.

In the second option, the passenger chooses the airport and access mode simultaneously. The chosen alternative is therefore a combination of an airport and an access mode. According to the independence from irrelevant alternatives (IIA) assumption, a passenger's choice probability ratio of two alternatives is not affected by the utilities of other alternatives. To overcome this problem, we specify a nested logit model, which recognizes that there are clusters of alternatives of which the utilities are correlated through random disturbances. In this case, clusters of alternatives can have a common airport or a common access mode. If we specify the model with nests determined by a common airport, we have:

$$P(a/d)=\frac{\exp[\frac{\beta_a+\beta_{cost}\cos t_{a,d}+\beta_{time}time_{a,d}}{\mu_d}]}{\sum_{a\in A(d)}\exp[\frac{\beta_a+\beta_{cost}\cos t_{a,d}+\beta_{time}time_{a,d}}{\mu_d}]} \quad (3)$$

$$P(d)=\frac{\exp[\alpha_d+\alpha_{fare}\ln fare_d+\alpha_{freq}\ln freq_d+\alpha_{expe}\cdot expe_d+U_1]}{\sum_{a\in A(d)}\exp[\alpha_d+\alpha_{fare}\ln fare_d+\alpha_{freq}\ln freq_d+\alpha_{expe}\cdot expe_d+U_1]} \quad (4)$$

$$U_1=\mu_d\ln\left\{\sum_{a\in A(d)}\exp[\frac{\beta_a+\beta_{cost}\cos t_a+\beta_{time}time_a}{\mu_d}]\right\} \quad (5)$$

U_1 is the maximum expected utility. The passenger chooses an access mode based on the access cost and access time, and an airport based on the fare, frequency and the expected value of the subset of access modes available to the airport. Simply put, if an airport has better accessibility in terms of access time, access cost and the number of available modes, it has a higher probability of being chosen. μ_d is an inclusive value parameter, which can also be interpreted as a heterogeneity parameter; alternatives within a nest become closer substitutes if μ_d gets closer to 0. In theory, a heterogeneity parameter could also be included in similar fashion in Equation (4), but this parameter is standardized to 1. The model in Equations (3) through (5) is consistent with the theory of utility maximization if $0<\mu_d<1$. When $\mu_d=1$, the model reduces to the multinomial logit (MNL) model.

We can also formulate a model with nests determined by access modes. Since the access time and access cost are dependent on the departure airport, these variables now appear in the airport's utility function. The conditional probability of choosing airport (d), conditional on the choice of access mode (a) is:

$$P(d/a)=\frac{\exp[\frac{\beta'_a+\beta'_{cost}\cos t_{a,d}+\beta'_{time}time_{a,d}+\alpha_{fare}\ln fare_d+\alpha_{freq}\ln freq_d+\alpha_{expe}\cdot expe_d}{\mu_a}]}{\sum_{d\in D(a)}\exp[\frac{\beta'_a+\beta'_{cost}\cos t_{a,d}+\beta'_{time}time_{a,d}+\alpha_{fare}\ln fare_d+\alpha_{freq}\ln freq_d+\alpha_{expe}\cdot expe_d}{\mu_a}]} \quad (6)$$

The marginal probability of choosing access mode (a) depends on mode-specific factors and the log of the denominator of (6) multiplied by μ_a. In this model, the access mode choice is dependent on the fares, frequencies, and experiences.

SURVEY DATA

Data for calibrating the models were collected in the Shanghai region from the passenger survey conducted by four university students in the study area during the summer of 2007. In the survey, the passengers were asked to provide information on their recent trip (e.g., trip destination and purpose of trip), ground access trip to the airport (e.g., origin of trip, ground access mode, access time, and access cost), airport choice (e.g., primary reasons for choosing airport over other airports and other airports considered), experience (that is, whether or not a passenger has ever used a candidate airport in the past, and the times every year, and his/her impression in the airport), and their personal characteristics (e.g., age, sex and income). The survey was distributed to the passengers in the study area by the intercept survey. The four students worked on 4-hour shifts for two weeks, one week at each airport. Their shifts were carefully scheduled on every day of the week. Only those passengers who lived in the study area were surveyed. The number of surveys collected included 112 business travelers and 98 leisure travelers in airport I; and 126 and 109 in airport II, respectively.

In the airport-choice studies, we use the following airport-choice variables: (a) airfare at each airport, (b) flight frequency to the passenger's destination from each airport, (c) access time to each airport, (d) access time to each airport, (e) passenger's experience with airports. The airfare variable measures a passenger's perceived level of airfare at each airport. Flight frequency was obtained by counting the number of scheduled flights from each airport to the passenger's destination using the official airline guide. The access time to each airport and experience variables were collected directly from the survey data. The value of passenger experience is -4, 2, 0, 2, and 4. "-4" denotes that the traveler has a very bad experience in this airport; "0" denotes no experience or common experience; "4" represents a very pleasant experience.

ESTIMATION RESULTS

Estimation results of the nested logit model for choice of airport and access mode are presented in Table 1. Estimation results suggest that, if everything else is equal, a passenger tends to choose the airports that have lower average airfares, more flight frequency, prior good experience, and less access time and access cost. These five variables explaining the conditional access mode choice are proved to be insignificant.

From the estimations in Table 1 we can calculate the value of time based on access cost and access time parameters. For business travelers the value of time is 0.125/0.44=2.84 yuan/min, while that for leisure travelers is 0.092/0.048=1.92 yuan/min.

Table 1. Estimation results of the nested logit model.

Variables	Business travelers		Leisure travelers	
	Coefficients	Error level	Coefficients	Error level
Ln(fares)	-0.168	0.005	-0.249	0.004
Ln(frequency)	0.857	0.093	0.638	0.086
Experience	1.592	0.030	1.251	0.036
Access time	-0.125	0.085	-0.092	0.092
Access cost	-0.044	0.032	-0.048	0.036

Table 2. Elasticity of choice probabilities of airport and access model.

	Conditional				*Marginal*		
	Time	**Cost**	**Fares**	**Frequency**	**Experience**	**Time**	**Cost**
Business travelers	**-1.43**	**-0.10**	**-0.69**	**0.85**	**1.23**	**-1.91**	**-0.12**
Leisure travelers	**-1.16**	**-0.16**	**-0.85**	**0.56**	**1.06**	**-1.32**	**-0.15**

As shown in Table 2, access time and experience are two dominant explanatory factors of airport choice. Airport access time, as well as experience, is clearly higher elasticity than fare, flight frequency or access cost. This implies that access time and experience are of greater importance in the competition between airports in a multiple airport region.

CONCLUSION

This paper has extended the studies of multi-airport choice into Chinese metropolitan areas using a nested logit model. The most significant findings are the following:

(a) The important airport-choice variables in Chinese multi-airport choice are airfares, experience, access time, access cost, and flight frequency.

(b) Business travelers and leisure travelers have different elasticities. Business travelers have higher access time elasticity than leisure travelers, while leisure travelers have higher fare elasticity.

(c) Airport access time and passenger experience are of greater importance in the airport choice behavior for both business travelers and leisure travelers. A passenger tends to choose airports that have less access time. In addition, passengers who have used an airport will tend to continue to use the same airport, all other factors being equal. Airport managers may benefit by attempting to attract nonusers and providing high-quality service.

ABSTRACT

With the development of modern transportation methods, there is huge body of transportation data related to road, railway, waterway, and air transportation networks. A decision-making and analysis system is requisite in intelligent management and transportation planning. Using the Visual C++ platform and MapInfo, GIS software, the national integrated transportation decision-making and analysis assistant system is designed and realized in this paper. The system has many characteristics, such as friendly interface, handy operation, intuitive query and analysis result, convenient management, etc. The system not only can be used in the analysis of transportation actuality and the data extraction of traffic information, but also is a basic condition of the scientific and data management in the integrated transportation fields.

INTRODUCTION

With the continuing development of roads, railways, water ways, and air transportation, there is an accumulation of valuable traffic data and information such as road traffic, passenger-cargo traffic volume of railways, water ways, and air transportation, etc. It is crucial, therefore, to mine this data with particular emphasis placed on researching the developing law and trends.

The electronic map of various national transportation systems can be viewed on MapInfo software and can assist in the understanding of national integrated transportation information decision-making and analysis assistance system that functions with the electronic map, data query statistic analysis, and data mining, etc. combined with traffic volume for the past several years. Only then can the

information management level be improved and a better system given for a modern, reasonable and intelligent control of transportation information.

SYSTEM REQUIREMENT ANALYSIS

Feasibility analysis. In recent years, the Ministry of Communications, Civil Aviation Administration, and the Ministry of Railway have done and continue to do more about traffic information statistics related to various transportation modes, such as the handbook of national highways traffic, national railways passenger-cargo traffic schematics, the passenger-cargo throughput schematics about some main seaports and airports, etc. so that traffic information collection is practicable. From a technical viewpoint, the continual development of the hardware and software is feasible (Wang, Yuan, and Li 2004). The windows platform Visual C++, which can form 32-bit application as a powerful and complicated development tool, is simple and quick to be utilized. The MapInfo software system has a powerful image function with which the bidirectional conversion of many types of data platforms can be accomplished. Suitable program language, Map Basic, makes the data maintenance, management, and application convenient and clear.

Necessity analysis. The traffic networks of four traffic modes differ from each other in spatial distribution. The traditional data management in report form does not meet the current requirement of traffic data statistics and analysis, convenient deep data mining, and difficulty with actual problems solving (Feng, Tong and Wang 2004). In order to relieve traffic conflicts and other traffic problems, it is imperative to improve the traffic management level and construct a more integrated transportation information management system that takes full advantage of GIS (geographical information systems) and computer technology.

SYSTEM DESIGN

System functional design. In this paper, the main objective of the system discussed is to collect shared data from data rooted in multi-channels, then organize real time data and the prevenient data, and at last realizing the intuitionistic query, statistic analysis, and types of thematic maps and statistic report forms about the transportation data of various transportation means. Thereby, the development law of national integrated transportation is researched and a basic platform is supplied for the deep analysis.

According to the system functions, the system includes four modules: electronic map operation model, information query model, statistic analysis model, and thematic map analysis model (Zhang and Shao 2007).

The electronic map model is shown in Figure 3.1. Transportation information about roads, railways, water ways, and air transportation can be shown in different layers. The user can do some basic work, such as move, zoom, choose shown layer and label the information of the map element, e.g., traffic point or traffic line.

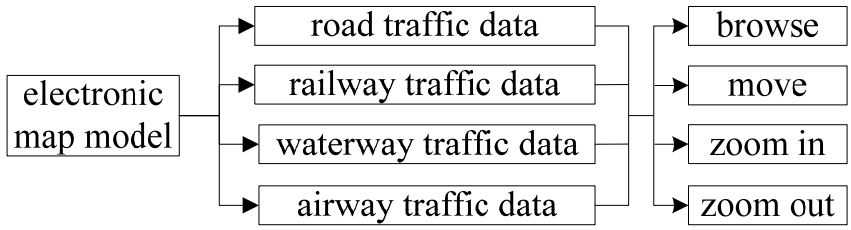

Figure 3.1. Electronic map model.

The information query model is shown in Figure 3.2. There are two parts to this model: attribute query and condition query. The attribute query means choosing one specific traffic point or line and finding its attribute information, such as the orientation and the throughput of a port. The condition query refers to screening out the attribute information of one or more map elements and fixing a position according to one specific restriction condition (e.g. screening out airlines from one particular airport from the national air transportation network).

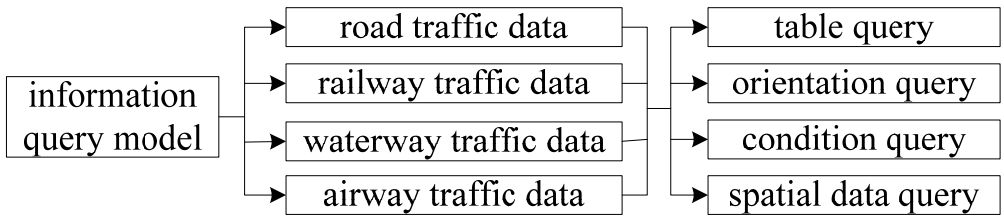

Figure 3.2. Information query model.

The statistic and analysis model is shown in Figure 3.3. The function means, according to different province, traffic line or traffic point, comparing and analyzing the structure and distribution of corresponding passenger-cargo volume, and viewing the statistic reform forms. For example, the amplitude of the passenger-cargo volume in the past five years at one certain port.

The thematic map analysis model is shown in Figure 3.4, mainly contains thematic map about different provinces' traffic distribution of a given transportation mean and thematic map about different traffic load. In the thematic map, different colors and different linewidths express different traffic loads, and then the traffic volume distribution and the traffic load of national transportation networks can be viewed intuitively.

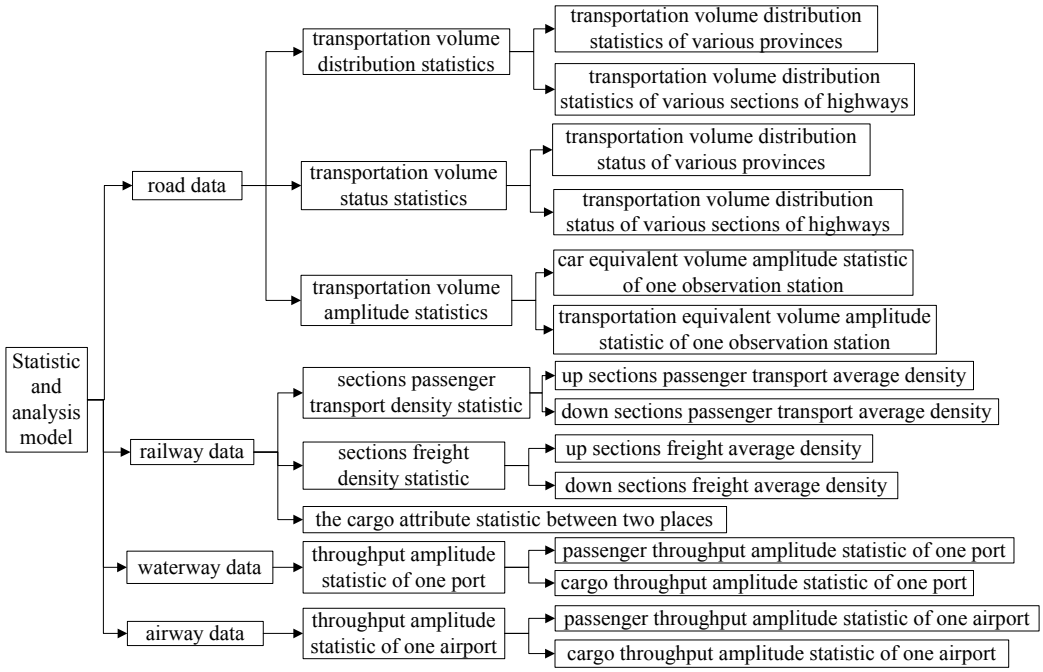

Figure 3.3. Statistic and analysis model.

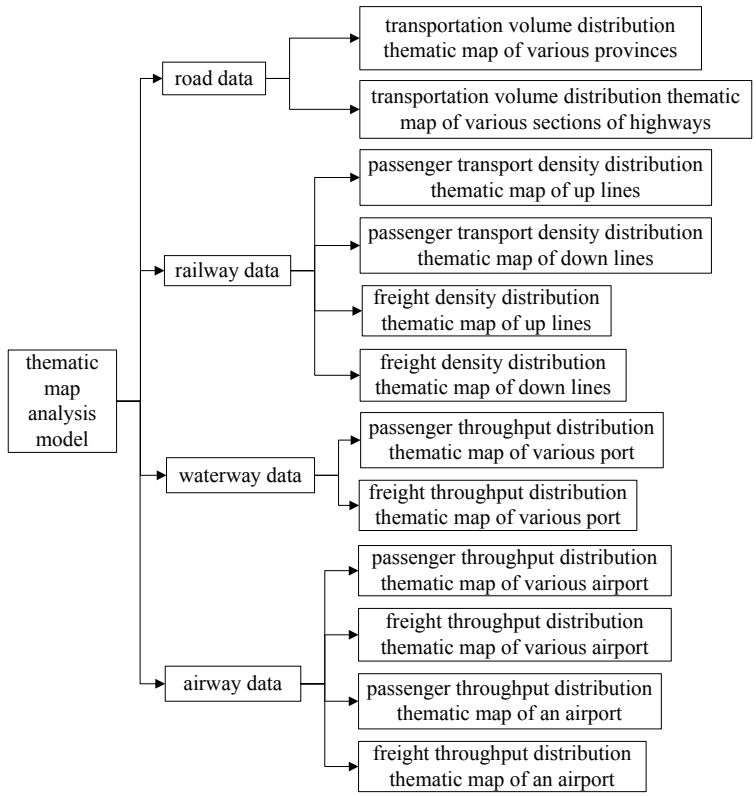

Figure 3.4. Thematic map analysis model.

Database design. Database design includes the creation of attribute database, the creation of spatial database, and a design about the attribute table and the attribute relationship (Wang, Zhu, and Zhou 2005). The hard core is the creation of the relationship pattern with complete content even the one-to-one relation between attribute database and spatial database according to the 3NF law.

The creation of attribute database refers to designing field type and field length of the data record, and appending the key words. The creation of spatial database means gathering and compiling the traffic information with different spatial geography character, and then the different data types can be converted to one identified and used by the computer. Then the spatial data could be managed conformably. At the same time, the independency and the data integrality should be ensured and the data redundancy should be avoided in order to conveniently realize the maintenance and update of the spatial data, and the user's requirement of the timely and quick visit.

METHOD AND KEY TECHNIQUE

Result. Spatial data processing is realized in MapInfo software system with the data processing algorithm compiled by the matched program language Map Basic, and then the attribute data and the spatial data would be matched.

On the basis of the national integrated transportation information database, the functions of the system realized are illustrated as follows:

Figure 4.1 shows the distribution of national main airports. In the map, after choosing Lanzhou airport, the take-off and landing number, and the passenger-cargo throughput about the airport could be viewed. Figure 4.2 shows the amplitude statistic analysis of the passenger-cargo throughput from the year 2000 to 2005 about Xi'an airport. Figure 4.3 shows the thematic map about passenger-cargo throughput of national main ports. Figure 4.4 shows the thematic map about the traffic volume of the airlines passed Urumqi airport, and in the figure, the traffic load was expressed by various shades of gray.

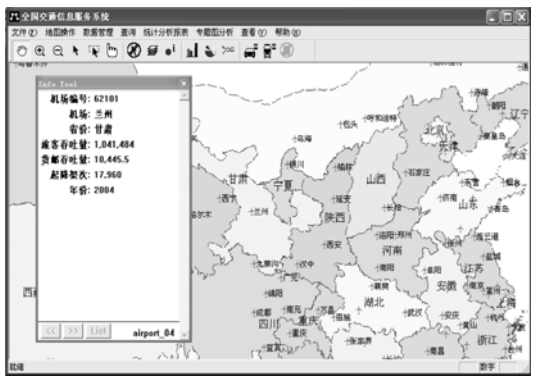

Figure 4.1. Distribution of national amplitude, main airports.

Figure 4.2. Passenger-cargo throughput statistical analysis about Xi'an airport.

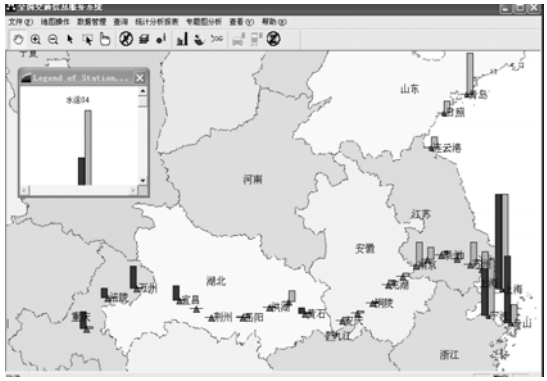

Figure 4.3. Passenger-cargo throughput thematic map about national airport main ports.

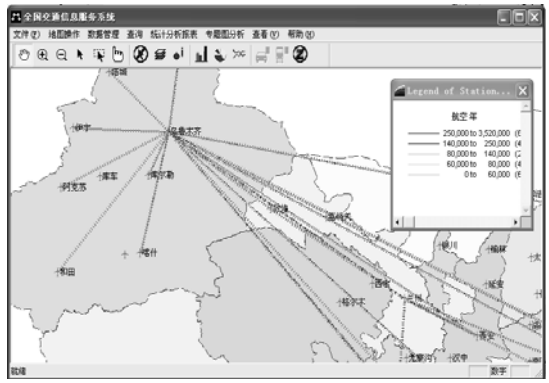

Figure 4.4. Traffic volume thematic map about the airlines passed Urumqi airport

Key technology. *Integrated secondary development*. Integrated secondary development refers to an integrated development integrated professional MapInfo software that can be used to realize the basic GIS functions on an universal visual software, such as Visual C++ (Shang, Wang, and Li 2005). In the whole process, the OLE (Object Linking and Embedding) automation technology is the core (Li, Lu, and Che 2004). The foreground application is developed by Visual C++ and the GIS software is executed in the background through OLE automation technology, and at last all the spatial data processing would be realized.

Integrated secondary development can not only take full advantage of the management and analysis about the spatial data of MapInfo software, but also the advantages of visual programming language, such as high efficiency, convenience etc. Therefore, the development efficiency of the system would be greatly advanced with these advantages and the application developed by visual programming language would have more elegant appearance, a more powerful database, better reliability, and easier to manage system maintenance and updating.

Call-back technology. The information query is realized mainly through the call-back technology of MapInfo software. After a map element is chosen, the corresponding coordinate would be queried from the database via a match made between the map information and the coordinate saved in the database. The attribute data corresponding to the selected map element would then be returned through call back technology by the map element number, the unique identifier (Zhang and Shao 2007).

Thematic map. One of the most powerful functions of MapInfo software is intuitively visual analysis to the data, mainly for statistic map and thematic map in the system, such as, statistic report forms, amplitude passenger-cargo traffic volume statistic analysis, the distribution thematic map of the traffic volume and the traffic load, etc. On the thematic map, the attributing data would be intuitively viewed in the form of figure, so that the changing law and trend of the traffic data can be showed through the intuitive graphical show of traffic distribution.

Data mining. Data mining (also called KDD – Knowledge Discovery in Database) refers to a process of extracting the connotative but useful information from a great deal incomplete and random data. The large amount of transportation data reflects a certain law after a long data accumulation. For the traffic management and development research departments, it is favorable to find the underlying and valuable information, the contributing factors, even the intuitive graphical representation about traffic data to do assistant analysis. The main data mining technology used in the realization of the system functions are as follows: first, data mining of the basic attribute information about spatial map elements the intuitive graphic representations. It is relatively simple and less strict in the complexity of spatial data, e.g., the traffic volume structure statistic of all national highways. Second, the data mining of the time series and the spatial series for spatial map elements data, the changing law varied along with time would be researched after the analysis of the spatial data influenced by time series and spatial series. Therefore, the intending traffic would be forecasted by the changing law. For example, the changing trends of one particular port's passenger-cargo throughput from the year 2000 to 2005. Third, the data mining of the spatial distribution law about the traffic volume according to different data sorts. For example, the distribution law of the traffic volume by air about different airlines.

CONCLUSIONS

Based on MapInfo software system, the integrated transportation database is built using national transportation data about roads, railways, water ways and air transportation, and then national integrated transportation information decision-making and analysis assistant system is developed on the platform Visual C++ by integrated secondary development technology. In the system, the MapInfo server is called backstage by OLE automatic technology. It can realize the query and representation of the basic attribution of traffic lines and traffic points regarding various transportation means. From this, traffic data mining based on time series and spatial series is understood. The system provides a data mining platform, a new assistant method for the analysis, and statistical information of traffic data and an advanced technology for the planning and management of national traffic network. Thereby, the management level of various transportation modes is advanced and a solid foundation is laid for the reasonable, intelligent, and integrated transportation information decision-making and management system.

ABSTRACT

Many researchers have studied the pricing model for expressways with the economic principle of marginal cost pricing. However, there is also much interesting and important work to still do. The objective of this paper is to enhance the insights into the expressway pricing mechanism with elastic demand. We proposed two specific models by considering the scenario under different market conditions, including the monopoly model and the monopolistic competition model. This paper analyzed the differences between the two scenarios. A numerical example is presented in order to illustrate how the pricing policies affect the demand and the social-welfare of the whole transportation system.

KEY WORDS

Road pricing; network equilibrium; elastic demand; monopoly; monopolistic competition

1. INTRODUCTION

Road-use pricing as an effective means of both managing road traffic demand and raising additional revenue for road construction has been studied extensively by both transportation researchers and economists.

Roth stated that private firm can provide public roads which is an efficient answer to deal with rapid growing traffic demand (Roth 1996). Gomez-Ibanez considers that the public sector may simply be unable to finance facilities that the private sector would be willing and able to undertake for a profit (Gomez-Ibanez 1991). Huang analyze a bi-modal system will be significantly different from that of a single mode system (Huang and Yang 1996). Yang presents a rigorous quantitative modeling of a highway B-O-T project under different market condition (Yang and Meng 2000).

This paper presents two models of an expressway pricing problem by considering the scenario under different market conditions, including the monopoly model and the monopolistic competition model. Private firm profit and total social welfare gain generated from an expressway system are investigated under each condition. Mathematical models are developed to characterize price under either monopolistic or monopolistic competitive markets. The characteristics of the problem are illustrated with a numerical example.

2. MARKET STRUCTURE AND THE OBJECTIVES OF COMPANY

2.1 Notations

C_a capacity of link a
x_a flow on link a
rs OD pair index, rs $\in$ RS
d_{rs} OD demand between pair rs, it depends on p
f_{rs} commuter path flow on rs
k_{rs} path between OD pair rs
$\delta_{a,k}^{rs}$ link-path incidence parameter; 1 if link a is on path k, zero otherwise
t_a travel time on link a
α a parameter that represents value per hour
β a parameter in the SUE
d a vector of all O-D demands
x a vector of all link flows
r required rate of return by the company
r_{tax} tax rate
Dep annual depreciation
Inv initial investment which is given
N the number of years of the project existing
l_a the length of the link a
c_a the variable cost of the link a per kilometer per vehicle
p_a price of the link a which charges the users
NPV net present value of the project

2.2 The objectives of firm

The firms use several important criteria to evaluate capital investment (Richard Brealey, Stewart Myers 2007). The most comprehensive measures of whether a project is profitable or unprofitable is the net present value (NPV), which is the present value of the future after-tax cash flow minus the investment outlay, or

$$NPV = \sum_{t=1}^{n} \frac{CF_t}{(1+r)^t} - Inv \tag{1}$$

Because the NPV is the amount by which the investor's wealth increases as a result of the investment, the objective of the firm is to obtain the largest NPV.

Annual after-tax operating cash flow CF_t:

$$\begin{aligned} CF_t &= (\text{Sales} - \text{Variable Cost})(1\text{-tax rate}) + \text{tax rate} \times \text{Depreciation} \\ &= (\sum_a (l_a x_a p_a - l_a x_a c_a) - Dep)(1 - r_{tax}) + Dep \times r_{tax} \end{aligned} \tag{2}$$

The required rate of return form the project can be computed from CAPM and is equal to the risk-free interest rate plus the risk premium:

$$r = r_f + \beta_1 (r_m - r_f) \tag{3}$$

2.3 Monopoly model

When only one supplier exists in the market, we call the firm a monopolist. Because there is no competition, a monopolistic firm does not respond to price changes. The firm that monopolizes its industry finds the price and output rate that maximizes profit. The monopolist is a "price maker," not a "price taker." The model is formulated as:

$$\max_{p} \ \mathrm{NPV} = \sum_{i}^{N} \left[\frac{(\sum_{a} (l_a x_a p_a - l_a x_a c_a) - \mathrm{Dep})(1 - r_{tax}) + \mathrm{Dep} \times r_{tax}}{(1+r)^i} \right] - \mathrm{Inv} \qquad (4)$$

That means the firm finds an optimal price which maximizes the NPV of the project.

2.4 Monopolistic competition model

Monopolistic competition is a common market form. Monopolistically competitive markets have the following characteristics:

1. There are many producers and many consumers in a given market.
2. Consumers perceive that there are non-price differences among the competitors' products.
3. There are few barriers to entry and exit.
4. Producers have a degree of control over price.

The characteristics of a monopolistically competitive market are almost the same as in perfect competition, with the exception of heterogeneous products and the fact that that monopolistic competition involves a great deal of non-price competition. A firm making profits in the short run will break even in the long run because demand will decrease and average total cost will increase. This means that in the long run a monopolistically competitive firm will make zero economic profit.

$$\mathrm{NPV} = \sum_{i}^{N} \left[\frac{(\sum_{a} (l_a x_a p_a - l_a x_a c_a) - \mathrm{Dep})(1 - r_{tax}) + \mathrm{Dep} \times r_{tax}}{(1+r)^i} \right] - \mathrm{Inv} = 0 \qquad (5)$$

That means that in the long-run the NPV of the project is zero.

3. MODEL FORMULATION

3.1 A bi-level framework for the pricing problem

The pricing problem is to determine the optimal price to maximize some measures, while taking into account the effects of the implementation of the price toward the travel demand and link flow. The problem can be generally formulated as follows:

$$\max_{p} F(d, x) \qquad (6)$$

Subject to: $G(d, x) \le 0$ (7)

$$\min \sum_a \int_0^{x_a} [t_a(\omega) + \alpha p_a l_a] d(\omega) + \frac{1}{\beta} \sum_k f_k^{rs} (\ln f_k^{rs} - 1) \quad (8)$$

$$\text{st:} \quad \sum_k f_k^{rs} = d_{rs}(p) \quad \forall r, s \quad (9)$$

$$f_k^{rs} \geq 0 \qquad \forall r, s \quad (10)$$

Where link flow is defined by:

$$x_a = \sum_r \sum_s \sum_k f_k^{rs} \delta_{a,k}^{rs} \quad \forall a \quad (11)$$

The low-level sub problem (9)-(12) is a SUE network equilibrium problem with variable demand. The up-level sub problem has been descried in Section 2.

3.2 Evaluat ing the social-welfare

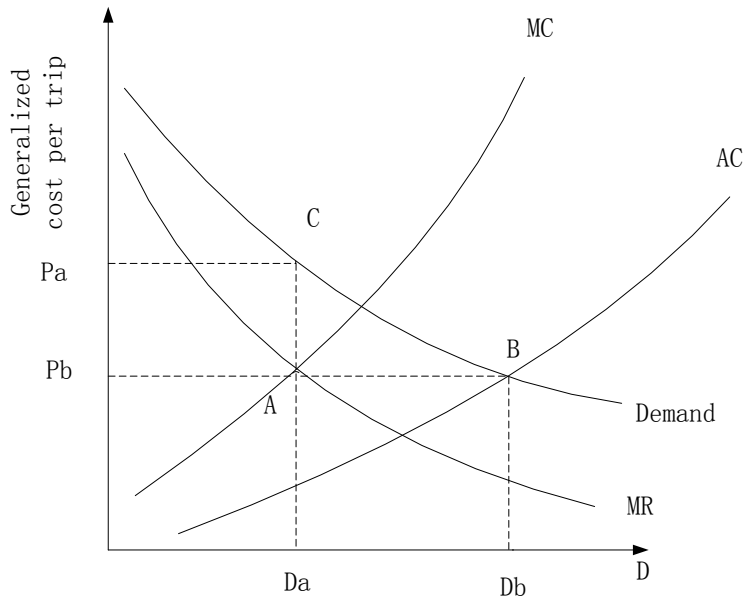

Figure 1. Equilibrium under Monopoly and Monopolistic competition

As shown in Figure 1, the AC curve represents the average cost of the firm, and the MC curve represents the marginal cost of the firm, which is the additional cost of adding one extra vehicle to the expressways.

Under the monopoly model, monopolist will maximize its profit by supply Da where MR=MC (Point A in Figure 1). Under the monopolistic competition model, the firm earns zero profit where P=AC (Point B in Figure 1).

The total network user benefit (UB) from travel is evaluated as:

$$UB = \sum_{rs \in RS} \int_0^{d_{rs}} d_{rs}^{-1}(x) dx \quad (12)$$

The firm cost (FC) incurred by all network links is given by:

$$FC = \sum_a l_a x_a c_a + \frac{1}{N} \times Inv \quad (13)$$

Therefore, the social-welfare of the whole transportation system can be formulated as:

$$SW = UB - FC = \sum_{rs \in RS} \int_0^{d_{rs}} d_{rs}^{-1}(x)\,dx - \left(\sum_a l_a x_a c_a + \frac{1}{N} \times Inv\right) \quad (14)$$

4. NUMERCIAL SAMPLE

4.1 Problem setting

Here we use a simple numerical example to demonstrate some interesting characteristics of the pricing problem. The network is depicted in Figure 2 with 1 O-D pair. The following form of the O-D demand function is adopted:

$$d_{rs} = d_0 - p \times \gamma \quad (15)$$

Where d_0 is the demand under zero price, here d_0=1000. γ is a scaling parameter which reflects the sensitivity of demand to price, here γ=10.

The following link volume-delay function is used:

$$t_a = t_0\left(1 + 0.15\left(\frac{x_a}{C_a}\right)^4\right) \quad (16)$$

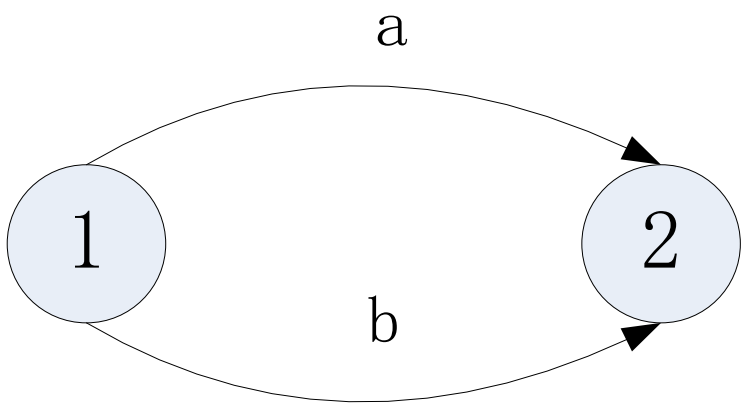

Figure 2. The network used for the numerical example

Table 1 . Input data for the link volume -delay function

Link No.	Free-flow travel time(h)	$c_a l_a$(RMB/(veh)	Link capacity (veh/h)	Length(km)
a	4	50	500	100
b	5	50	300	120

4.2 Numerical results

The changes in the OD demand, link flow, price, profit and welfare gain generated by the expressway under the two models are depicted in Table 2.

Table 2. Numerical results

	Monopoly	Monopolistic competition
d_{12}	250	490
p	75	51
x_a	215	421.4
x_b	35	68.6
t_a	4.14	4.26
t_b	5	5
NPV	5750	0
social-welfare	8875	11995

In this sample, the monopolist supplies a lower quantity of goods at a higher price than firms would in a monopolistic competitive market, which leads to a lower social-welfare. The monopoly will secure monopoly profits by appropriating some or all security of the stop consumer surplus. Since the loss in consumer surplus is higher than the monopolist's gain, it creates deadweight loss, which is inefficient and a form of market failure.

5. CONCLUSION

This paper proposed the model of an expressway in equilibrium networks. Our study differs from the conventional analytical economic analyses mainly in three aspects. Firstly, the traffic demand is not constant but depends on the price which is charged by the firm. Secondly, profit, price, demand, and social welfare are considered under two different scenarios, including the monopoly model and the monopolistic competition model. Thirdly, the firm operates the expressway system over many periods which makes it consider maximizing the NPV of the project instead of the profit. The result of the numerical sample demonstrates that the monopoly leads to deadweight loss and inefficiency. Therefore, our modeling approach is significant to help government regulate the firms that invest in the expressway system.

ABSTRACT

In order to analyze traffic flow running characteristics and provide basis for capacity research on urban road intersection, velocity characteristics and occupied space resources of bicycle, electric bicycle and pedestrian were studied. Based on method of time-space resource occupancy, models calculating conversion coefficients between bicycle, electric bicycle and pedestrian were established. Then, taking pedestrian as a conversion standard, conversion coefficient values, 1.67 and 1.58, of bicycle and electric bicycle were obtained. Taking the bicycle as a conversion standard, conversion coefficient values 0.60 and 0.95 of pedestrian and electric bicycle respectively were obtained as well. This research indicates that time-space resources occupied by bicycle, electric bicycle and pedestrian are different and the conversion coefficient values and effects of them on motor vehicles are different as well.

INTRODUCTION

There are many bicycles, electric bicycles and pedestrians on urban road intersections in China. This activity forms remarkable characteristics of the intersection and has considerable impact on powered vehicles. Because time-space resources occupied by bicycle, electric bicycle and pedestrian are different when they pass through intersections, their effects on vehicles are different as well. Thus, in order to analyze the combined effect of them on powered vehicles, it is necessary to study conversion coefficients between bicycle, electric bicycle, and pedestrian.

Until now, most research results about conversion coefficients have concerned vehicles (Yuan 2001, Li 2001, Cesar 1987, Benekohal et al. 2000, Elefteriadou et al. 1996). There is only limited research on the bicycle, electric bicycle, and pedestrian, especially on urban road intersections. Zhao (2004) studied conversion coefficients among bicycle, pedestrian, and pedestrians pushing bicycles on urban road intersection. Li (2004) and Li et al. (2006) researched conversion coefficients between bicycle, electric bicycle, and pedestrian on a street crosswalk. Until now, there has been no research studying conversion coefficients between bicycle, electric bicycle, and pedestrian on urban road intersection. Taking time-space resources occupied by bicycle, electric bicycle, and pedestrian into consideration, based on method of time-space resource occupancy, the conversion

coefficients between them on urban road intersections are studied. This research lays the foundation for further study on traffic flow running characteristics and capacity on urban road intersections.

VELOCITIES

In order to get velocity characteristics of bicycle, electric bicycle, and pedestrian on urban road intersections, an investigation was made on Shuguang-Guangming intersections in Pingdingshan, Henan Province. Statistical analyses of velocity samples of 206 for each of them were made. The results are shown in Figure 1, 2, and 3 and Table 1. It can be seen that the velocities of bicycle, electric bicycle, and pedestrian all followed normal distribution. Taking velocity mean as its velocity value, let v_b, v_e and v_p be velocity of bicycle, electric bicycle, and pedestrian respectively, then v_b=3.08 m/s, v_e=3.75 m/s and v_p=1.22 m/s.

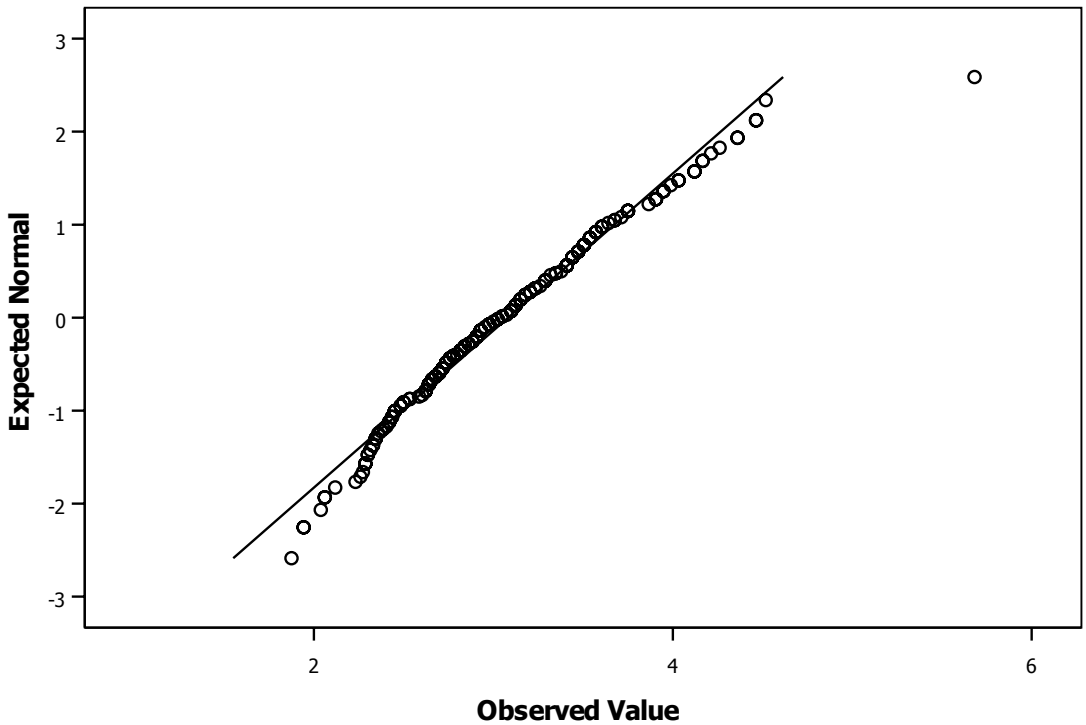

Figure 1. Q-Q normal probability graph of bicycle velocity.

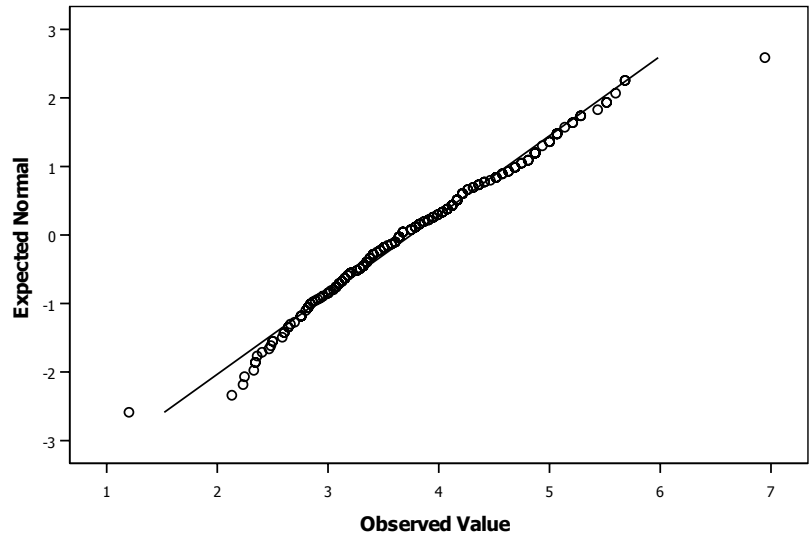

Figure 2. Q-Q normal probability graph of electric bicycle velocity.

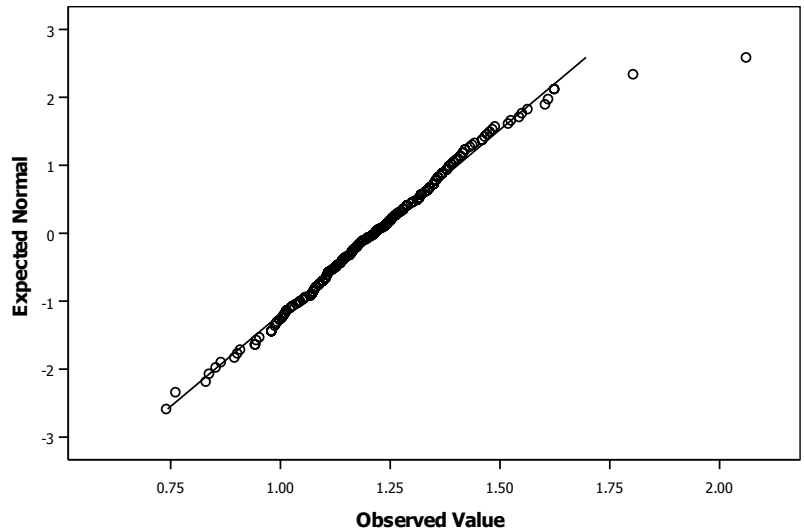

Figure 3. Q-Q normal probability graph of pedestrian velocity.

Table 1. Velocities of bicycle, electric bicycle and pedestrian.

Traffic Flow	Sample Number	Average Velocity (m/s)	Sample Standard Deviation (m/s)	95% Confidence Interval
Bicycle	206	3.08	0.59	3.00~3.16
Electric Bicycle	206	3.75	0.86	3.63~3.87
Pedestrian	206	1.22	0.18	1.19~1.24

ROAD SPACE RESOURCES

When bicycle, electric bicycle, and pedestrian pass though a street, road space resources occupied by them can be expressed by following equation:

$$S_i = l_i \cdot w_i \quad (1)$$

where S_i = road area occupied by a bicycle, electric bicycle, and pedestrian when they pass through a street (m^2), $i = b$, e and p, respectively; and l_i , w_i = dynamic length and width of a bicycle, electric bicycle, and pedestrian when they pass through a street (m), $i = b$, e and p, respectively.

Road Area Occupied by a Bicycle. From Equation (1), road area occupied by a bicycle when it passes through a street is $S_b = l_b \times w_b$. Dynamic length of a bicycle can be expressed as $l_b = v_b t / 3.6 + v_b^2 / 254(\varphi \pm i) + l_0 + l_v$, where t = reaction time (s), φ = adhesion coefficient; i = road longitudinal gradient; l_0 = safety stopping distance (m); and l_v = vehicle length (m) (Li et al. 2006).

Through analysis in section 2, let v_b = 3.08 m/s. Let t = 0.7 s, φ = 0.5, i =0, l_0 = 0.8 m, and l_v = 1.9 m. Then:

$$l_b = v_b t / 3.6 + v_b^2 / 254(\varphi \pm i) + l_0 + l_v = 3.08 \times 0.7 / 3.6 + 3.08^2 / (254 \times 0.5) + 0.8 + 1.9 = 3.37(\text{m}) .$$

Let w_b =1 m, thus $S_b = l_b \times w_b$ = 3.37 m^2.

Road Area Occupied by an Electric Bicycle. From Equation (1), road area occupied by an electric bicycle when it passes through a street is $S_e = l_e \times w_e$. Dynamic length of an electric bicycle can be expressed as $l_e = v_e t / 3.6 + v_e^2 / 254(\varphi \pm i) + l_0 + l_v$ (Li et al. 2006). Through analysis in section 2, let v_e =3.75 m/s. Let t = 0.7s, φ = 0.5, i =0, l_0 = 0.8 m, and l_v = 1.9 m. Then:

$$l_e = v_e t / 3.6 + v_e^2 / 254(\varphi \pm i) + l_0 + l_v = 3.75 \times 0.7 / 3.6 + 3.75^2 / (254 \times 0.5) + 0.8 + 1.9 = 3.54(\text{m}) .$$

Let w_e =1.1 m, thus $S_e = l_e \times w_e$ = 3.89 m^2.

Road Area Occupied by a Pedestrian. From Equation (1), road area occupied by a pedestrian when he passes through a street is $S_p = l_p \times w_p$.

A pedestrian's walking stride is about 0.66 m. When a pedestrian is walking, the distance before and after their position is one and a half steps approximately, so let l_p = 1 m. Dynamic width of a walking pedestrian is about 0.8 m, so let w_p = 0.8 m. Thus $S_p = l_p \times w_p$ = 0.8 m^2.

CONVERSION COEFFICIENT VALUES

Taking Pedestrian as a Conversion Standard. Taking a pedestrian as a conversion standard, let its conversion coefficient value be one, namely let pce_p = 1. Based on method of time-space resource occupancy, the conversion coefficient calculation formulas of bicycle and electric bicycle can be expressed as follows:

$$pce_b = S_b t_b / S_p t_p = S_b v_p / S_p v_b = l_b \cdot w_b \cdot v_p / l_p \cdot w_p \cdot v_b \quad (2)$$

$$pce_e = S_e t_e / S_p t_p = S_e v_p / S_p v_e = l_e \cdot w_e \cdot v_p / l_p \cdot w_p \cdot v_e \quad (3)$$

where pce_b, pce_e = conversion coefficient of bicycle and electric bicycle respectively; t_i = walking time of bicycle, electric bicycle, and a pedestrian passing though the same length road section, $i = b$, e and p, respectively.

Substitute parameters into Equations (2) and (3), conversion coefficient values of bicycle and electric bicycle are as follows: $pce_b = S_b v_p / S_p v_b = 3.37 \times 1.22/(0.8 \times 3.08) = 1.67$, and $pce_e = S_e v_p / S_p v_e = 3.89 \times 1.22/(0.8 \times 3.75) = 1.58$.

Taking a Bicycle as a Conversion Standard. By traffic investigation, on some urban road intersections, the number of bicycles and electric bicycles are greater than pedestrians at peak period. So it is necessary to calculate conversion coefficient values of pedestrian and electric bicycle taking a bicycle as a conversion standard.

Taking bicycle as a conversion standard, let $pce_b = 1$. Based on method of time-space resource occupancy, the conversion coefficient calculation formulas of pedestrian and electric bicycle are as follows:

$$pce_p = S_p t_p / S_b t_b = S_p v_b / S_b v_p = l_p \cdot w_p \cdot v_b / l_b \cdot w_b \cdot v_p \quad (4)$$

$$pce_e = S_e t_e / S_b t_b = S_e v_b / S_b v_e = l_e \cdot w_e \cdot v_b / l_b \cdot w_b \cdot v_e \quad (5)$$

Substitute parameters into Equations (4) and (5), conversion coefficient values of pedestrian and electric bicycle are as follows: $pce_p = S_p v_b / S_b v_p = 0.8 \times 3.08/(3.37 \times 1.22) = 0.60$, and $pce_e = S_e v_b / S_b v_e = 3.89 \times 3.08/(3.37 \times 3.75) = 0.95$.

CONCLUSIONS

Here we may draw the following three conclusions. First, velocity characteristics of bicycle, electric bicycle, and pedestrian on urban road intersections were analyzed. Velocities of the three all followed normal distribution. Their velocity values are 3.08, 3.75, and 1.22 m/s respectively.

Second, space resources occupied by a bicycle, electric bicycle, and a pedestrian on urban road intersections were studied. Road areas occupied by them are 3.37, 3.89, and 0.8 m^2 respectively.

Third, based on the method of time-space resource occupancy, taking the pedestrian as a conversion standard, conversion coefficient values, 1.67 and 1.58, of bicycle and electric bicycles were obtained. Taking bicycle as a conversion standard, conversion coefficient values, 0.60 and 0.95 of bicycle and electric bicycle were obtained as well.

ABSTRACT

Merging area is a typical type of carrying out merging on urban expressway; It is usually a traffic congested bottleneck. Under the heavy traffic demand, it easily occurs when vehicles on the mainline and on ramp contesting the right way without any regulation, and making the 'forced entry' manoeuvre at the junction of merging area. This disturbance results in a severe decrease of traffic capacity. The alternate traffic rules, however, could make an orderly merging. Starting from analysis of merging mechanism, the comparative traffic flow models are established based on the Cellular Automata Model, using alternate rules or no alternate rules. The effects of a new alternate strategy are obtained by numerical simulation. Finally, this paper presents a conclusion that traffic state with these rules is much better than not using these rules, and the capacity is improved to some extent as well.

KEY WORDS: alternate rules, merging area, expressway, Cellular Automata Model

1. INTRODUCTION

Traffic congestion has been one of the major challenges facing contemporary cities around the world, which adversely affects mobility, safety, and air quality. The majority traffic jams frequently occur at bottleneck sections. As a significant amount of daily commuting time is spent on urban expressway, it plays a greater role in alleviating traffic pressure. However, more and more sections and bottlenecks fall into serious jam. Not-unblocked passing at merging area has been innegligible in treating expressway management. Uncontrolled free entering flow from on-ramp is the main reason, especially, when the traffic demand is heavy (Jiang, R. *et al.* 2002). Therefore, it occurs easily that drivers from the mainline and ramp contest the right way at this bottleneck. In addition, various traffic streams competed merging freely, inevitably causing potential conflicts which may induce frequent accidents

Microscopic simulation of road traffic has received increasing attention in the last decades. Cellular Automata Models comprise a type of particle hopping models and are hence of microscopic nature while being quite efficient in

computational time. The first cellular automata model for traffic simulation was proposed by Nagel and Schreckenberg (1992) (often referred to as the NaSch model). And since then the several modifications have been used for traffic applications more frequently.

2. LITERATURE

Helbing, D. *et al.* (1998) observed the hysteretic transitions to "synchronized traffic" with high values of both density and traffic flow on German freeways. And the results suggest a general mechanism for the formation of probably the most common form of congested traffic.

Lee, H. Y. *et al.* (1998) found that the presence of the external vehicle flux through ramps generates a new state of “recurring humps” with the hydrodynamic traffic flow model. This novel dynamic state is characterized by temporal oscillations of the vehicle density and velocity which are localized near ramps, and found to be the origin of the synchronized traffic flow reported recently.

The phase diagram of different kinds of congested traffic which are triggered by disturbances were presented by Helbing, D. *et al*.(1999), when passing ramps or other spatial inhomogeneities of a freeway. They allowed one to understand the observed transitions between free and various congested traffic conditions, among them were localized clusters, stop-and-go waves, and different types of "synchronized" traffic.

Pedersen, M. M. *et al*. (2002) described a way of including entry ramps in the NaSch traffic model by placing what is so-called shadow cars on a highway next to cars on entry ramps, which enables the drivers to take ramp cars into account. The model is shown to capture important real-life traffic phenomena that have not been included in previous models.

How to manage the merging at the merging area? In article 44 of Law of the People's Republic of China on Road Traffic Safety，it has been clearly stipulated that “The motor vehicles shall, when driving on a road section or at a road junction where the driveways are decreasing, or when parked for waiting in a queue or running slowly at an intersection without any traffic signal lamp, traffic sign, or command of traffic policeman, pass alternately in turn.” What influence do the alternate rules have on traffic, when the mainline has multi-lanes instead of single lane (Lei, L *et al*.2007, Li, F. 2007)? The paper aims at conducting research on the traffic characteristics pre-and post alternate rules enforcement, based on modeling the traffic flow under various traffic flows with improved Cellular Automata model.

3. THE MODEL

Both on-ramp systems are divided into three sections: the upstream, consisting of *A1, A2* lanes (*A*); the downstream with two lanes, *C1* and *C2*(*C*) (see Figure 1 and 2). The length of each section is indicated as shown. Differently, in the current on-ramp, the two-lanes of on-ramp merge into a single lane in front of the junction firstly, just like status quo (Current Free Merging Model) (see Figure 1). Meanwhile, in order to simulate the phenomenon of contesting the right of way, an additional short section is set up in current free merging model, which is a

virtual lane just as shown in the shaded parts. Comparatively, the system with alternate rules is shown in the Figure 2 (Alternate Rules Model), which means vehicles from the ramp and mainline will pass alternately in turn (the familiar signal control is used to state the rules more convenient instead of the alternate rules).

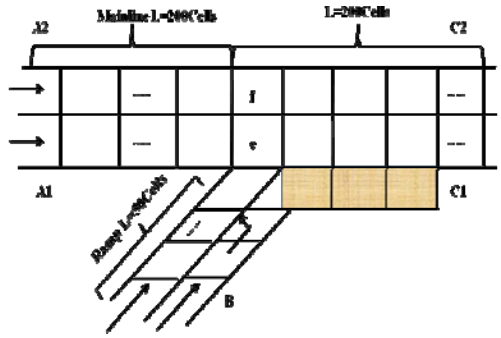

Figure 1. The illustration of the current free merging on-ramp system

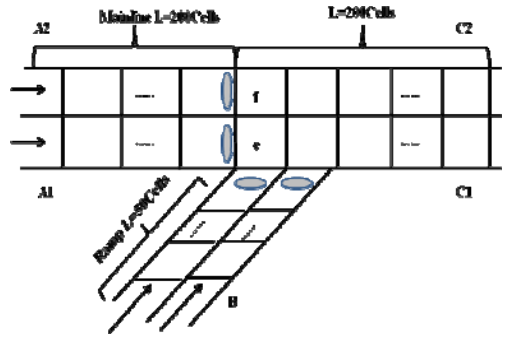

Figure 2. The illustration of the system with alternate rules

In this paper, the simulated system is within open boundaries and the model will be based on NaSch model with additional rules of lane changing. In the discrete NaSch model, each lane is represented by one dimensional chain of cells of length 5*m*, each cell could be empty or occupied by just one vehicle. The velocity of each vehicle can take one of the value varying from 0; 1;…; v_{max} (v_{max}=4 *cells/s*). At each step of discrete time, from t to t+1, the state of the road can be obtained by applying the following rules to all vehicles at the same time (parallel dynamics):

Step 1: Acceleration: $v_n \rightarrow \min(v_n+1, v_{max})$;

Step 2: Braking: $v_n \rightarrow \min(v_n, d_n-1)$;

Step 3: Randomization with probability P: $v_n \rightarrow \max(v_n-1, 0)$;

Step 4: Driving: $x_n \rightarrow x_n + v_n$. (1)

Where: x_n and v_n denote the position and velocity of the car *n* respectively. d_n(d_n=x_{i-1}-x_i-1)is the gap of the vehicle *n* (it is assumed vehicle *n-1* precedes *n*). The maximum velocity and slowdown parameter are denoted by v_{max}, *P* respectively.

In the condition of two-lane traffic, it's necessary to introduce an additional set of rules that determine the changing cars between lanes. And the merging means the process of vehicles from on-ramp entering into the mainline, which can also be viewed as a special form of mandatory lane-changing (Kou C.C, 1997). Usually, the updated step is divided into two sub-steps: in the first sub-step, cars may change lanes in parallel according to lane-changing rules and in the second sub-step the two lanes are considered as independent single-lane NaSch models. For all the cars in the sections with two-lanes, we use a symmetric rule set where vehicles change lanes if the following criteria are fulfilled (Chowdhury, D. *et al*.1997):

$$d_n < \min(v_n+1, v_{max}) \text{ and } d_{n,other} > d_n \text{ and } d_{n,back} > d_{safe}$$

(2)

Here denotes the number of empty cells between the n_{th} vehicle and its two neighbor vehicles on the destination lane at time step of t, respectively; d_{safe} is a safety distance to avoid crash.

In the current free merging model, the section of shadow needs a set of different rules for changing lane, so as to model the messy merging in the case of heavy traffic. We assume that only a certain percentage of drivers from the ramp are allowed to entry into this lane to fulfill merging while it is hard for merging on ramp. The maximum velocity of the vehicles on the additional lane is 1*cell/s*; it keeps steady speed when it has accelerated to the maximum. It would finish merging while it meets the condition of $d_{n,other}>d_n$ and $d_{n,back}>d_{safe}$; or else it will wait at the end until the above condition fits after it has come to the end of this lane. If there is one vehicle on this lane, the velocity of the lag-behind vehicle on the adjacent outside lane of the mainline shouldn't be more than 1*cell/s* and the leading car on ramp couldn't entry into the mainline or the additional lane.

Contrastively, in the alternate rules model, we use the traffic signal control instead of this set of rules for convenient statement. To make the problem simple, the color of traffic signal is divided into only two types: green and red. We denote the leading car on road H*A*H and *B* as HA_{lead}H and HB_{lead}H, the last car on road H*C*H as HC_{last}H. When the car HA_{lead}H or HB_{lead}H arrive at the lattice of the junction, H*e*H or *f*, it must stop before the lattice if the signal is red in front, or else it may enter the road H*C*H allodially just as the free merging model. The update of traffic signals on the road H*A*H and H*B*H is alternate, namely when the traffic signal on the main road is green, and red for the on-ramp, vice versa. And in the simulation, the signal will become red from green on the following condition is fulfilled:

$$T_{green}=(t-t_{red})\ mod\ T \qquad (3)$$

Here T_{green} denotes passage time of vehicle in the condition of green signal on the mainline; t and t_{red} means the time step, the end point of last red phase; T is the traffic signal cycle; Green ratio= T_{green}/T.

When vehicles are approaching the lattice of *e* or *f*, they are inevitably influenced by the traffic red signal in front. So an additional set of special update rules are taken for the vehicles in front of the junction. If the vehicle *n* is the leading car on the road *A* or *B* and approaching the junction of *e* or *f*, then it should be pointed out that $d_n=x_{signal}-x_n-1$, where x_{signal} is the position of traffic signal, or else $d_n=x_{n-1}-x_n-1$. In one time step, after all the vehicles of the system are updated, we check the signal time to decide whether to update the color of traffic signal or not.

4. NUMERICAL RESULTS

In this section, the presented simulation results are analyzed and discussed. The simulation system, completed with C# programming language, uses the open boundary condition. A new vehicle with velocity of v_{max} would be injected with probability of $\alpha_1(\alpha_2)$, if x_{Alast} (x_{Blast})> v_{max}, at the left end of mainline and ramp. The first 10,000 time steps are discarded to let the transient time die

out. The results are obtained by the virtual detectors in the simulation system, as shown in figure 3-6.

The flow of free merging against α_1 and α_2 in the downstream of merging area(C), shows the capacity under various traffic flows without any regulation (see Figure 3). From this figure, the traffic flow occurs a transition from free flow to congested flow at a certain value of α_1 according to different given value ofα_2. Generally, they appears a similar characteristic, such as the flow increases with the growth ofα_1 when it is not very large , following that it would become saturated and get into congestion. However, by a comparison, whenα_2 takes a various given value, it can affect the downstream flow state to a large extent. With the continuous increment ofα_2, the downstream would get into congestion at a smaller value ofα_1, and the maximum flow, which we can consider it as its capacity in the given case of constant probability, has a decreasing trend generally. The reason is that, when cars are in the progress of entering into the mainline, an increase in time of waiting would result in drivers' willingness to accept smaller gaps, consequently, in their performing a "forced entry" maneuver to merge into the mainline. As a result, due to this messy merging order which caused by the respectable forced entry, the capacity of the system has a notable reduction, while the traffic demand is heavy.

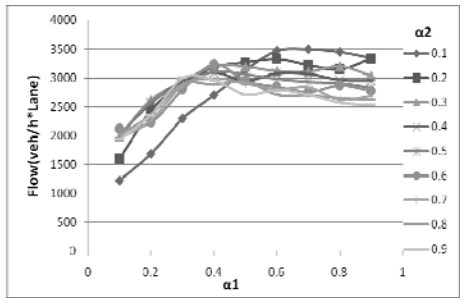

Figure 3. The variations of flow against α_1 about the current system

Expressway merging area performance is dependent upon the ability of the stream to absorb vehicles entering via the on-ramp. Thus we ought to investigate the effect of alternate rules comparing to the current free merging model. The parameters of alternate rules model are obtained by numerical simulation in the below.

The downstream flow changes against various green ratios (which equals to HT_{green}H/T), whenα_1 (α_2) is given by a different value (see Figure 4). To make the problem simple, we just studied the cases of various green ratio in the case ofα_1=α_2. When the probability is not more than 0.3, the flow curve presented a symmetric reversed "bowl-shape". When the probability is larger, the bottom of the "bowl" is narrower until it becomes a reversed "n-shape". Simultaneously, the maximum as well as the minimum flow increases with the growth of the probability. Subsequently, with the increment ofα_1(α_2), the flow nearly presents an approximately linear shape, and appreciably upwarping with the raise of green ratio. The downstream flow has little difference, without consideration of the driver's response delay (see Figure 4). While the traffic demand is very light,

namely$\alpha_1(\alpha_2)$ <0.3, the flow ascends with the growth of$\alpha_1(\alpha_2)$ rapidly. After a rapid increment, meanwhile, the flow reaches its capacity, and keeps stable on a large range of the probability (see Figure 4).

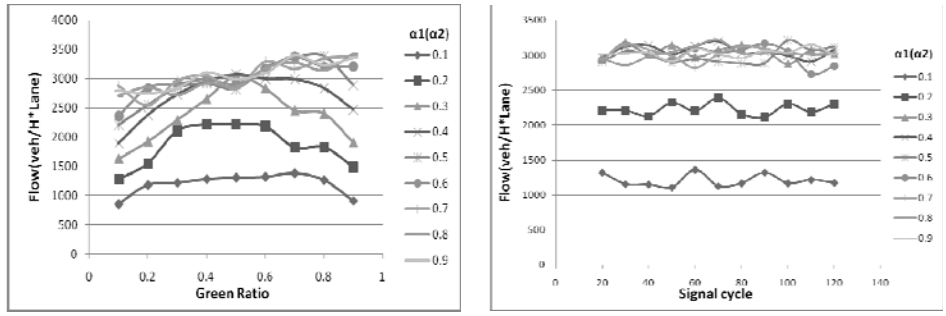

Figure 4. The figures of flow against green ratio and signal cycle

Generally, on the urban expressway, while carrying out the alternate rules, there isn't sufficient parking space for the ramp vehicles queuing on ramp. And from the analysis above, signal cycle has little influence upon capacity. While green ratio equals to 0.5, the optimization of the system could always be investigated under various traffic flow in the condition of$\alpha_1 = \alpha_2$. Therefore, it's feasible to choose the cycle equals to 60s and green ratio is 0.5 for the alternate rules model.

When$\alpha_1(\alpha_2)$ <0.3, the maximum flow of the two models has little difference, that means the alternate rules cannot raise the capacity. With the increase of$\alpha_1(\alpha_2)$, between 0.3 and 0.6, the alternate rules model still do not have any advantage, even the flow of free merging is larger. And when the probability is more than 0.6, the flow would decrease due to the messy merging in free merging model; while in the alternate rules model it has almost no influence on the flow, owing to the regularly orderly merging under the rules (see Figure 5). Against the probability ofα, the ideal flow of single lane increases firstly, which indicates the maximum flow in different conditions. After the growth it occurs that the transition from free flow to congested flow (see Figure 6). Combined with figure 5, it's known that when the averagely original flow of each lane in the upper stream is more than 1400*veh/h*lane*, alternate rules would get the advantage over free merging. The reason for the raise of capacity by these rules is that a stable and ordered merging could always be in progress, which make possible to pass through the system at a steady and large flow.

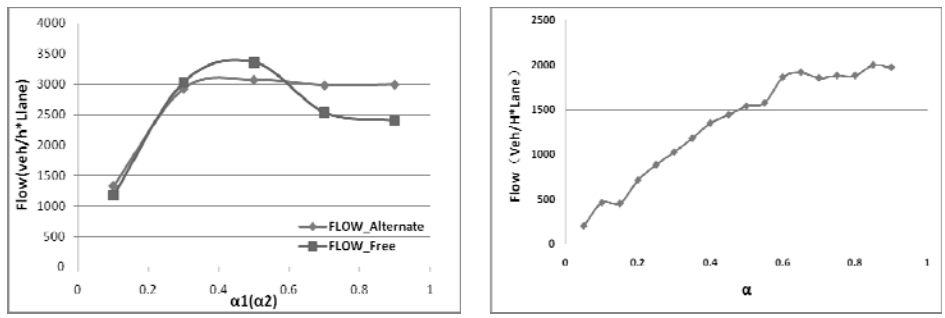

Figure 5. Comparison of flow variation pre & post enforcing alternate method

Figure 6. The diagram of ideal flow against the probability ofαon a single lane

Based on the above research, the alternate rules' enforcement needs the following precondition: Two or multi-lanes merge into one lane; the flow is heavy enough to have apparent synchronization or congestion due to the messy merging.

5. CONCLUSION

By the comparative numerical simulation study, the results indicate that the traffic improvement is significant, especially while the mainline and ramp are under heavy traffic demand(α_1(α_2)>0.6). Whereas, hardly does the model have any improvement when the flow is on the condition ofα_1(α_2)<0.6. Meanwhile, with the help of this set of rules, traffic order could have been improved, and the reduction of mandatory lane-changing could avoid accident possibly.

ABSTRACT

In this study, the delay of buses at bus stops is defined and classified. According to this classification, parameters that result in bus delay are then proposed. A concept of "bus arrival occupancy rate" is also introduced in this study to quantitatively explain the situation at a bus stop with reference to a typical bus stop in Beijing. A relationship is then established between bus delay and bus arrival occupancy rate. The study also proposes a delay estimation model for buses at two types of bus stops: a bus bay and a curbside bus stop.

Key words: bus stop, delay, bus arrival occupancy rate, bus bay, curbside bus stop

INTRODUCTION

A bus stop is an area on urban roadways where one or more buses load and unload passengers (TCRP 1996). When additional bus lines are added to a bus stop, the frequency of buses using the bus stop increases and a larger portion of the bus stop platform is used. As a result, the bus stop becomes more congested and the bus delay increases. The delay of buses at the bus stop impacts the running and operating efficiency of the public transportation buses. These delays are an inconvenience and a discomfort to commuters who use the public transportation buses.

There are many qualitative researches being conducted by researchers and scholars from home and abroad about delay at or near the bus stops but the quantitative estimation of delay at the bus stops are very few. For example that Ma Hong Wei analyzed the factors which have impact on the bus movement and made a conclusion that the style of platform affect delay (Ma et al. 2006). Zhu Wei and Chen Xue Wu introduced some examples of buses delayed at the urban hub terminals, and based on investigations of some typical terminals, made analysis of the main factors causing such delay with relevant solutions thereto (Zhu et al. 2002). Han Bao Rui also made a qualitative analysis on the factor which impact the delay and got a conclusion that decreasing the bus arrival rate and the time of bus staying at bus stop can make a good help in reducing the delay time (Han et al. 2004). Reebu Zachariah Koshy analyzed the influence of bus stops on traffic flow under heterogeneous traffic conditions using a simulation

technique (Reebu et al. 2005). They examined the effects of variation of the basic parameters, such as bus dwell time, road width and traffic flow for both bus bays and curbside bus stops. However, they did not come up with a formula for calculating delay.

In conclusion, most studies that have been conducted on bus delay at bus stops focus mainly on the qualitative analysis of factors that affect the delays. However, there are very few references discussing delays from a quantitative point of view. For this reason, it is necessary to estimate delay in a quantitative manner, in order to evaluate the level of service of a bus stop and provide a very useful tool to plan, redesign, and manage a bus stop.

DEFINITION AND CATEGORIES OF DELAY AT A BUS STOP

Definition of Delay at a Bus Stop. The process of a bus stopping at a bus stop consists of three parts: the deceleration of the bus into the bus stop, the loading and unloading of passengers, and the acceleration of the bus as it pulls out of the bus stop to rejoin the traffic stream. The delay of a bus at a bus stop is defined as the sum of all delays that happen during this process. Delay is equal to the time the bus is actually dwelling at a bus stop minus the time the bus is expected to be at the bus stop. The expectation time is equal to the time it takes a bus to drive in and pull out of a bus stop without experiencing any difficulties, including the time to load and unload passengers when following a schedule made by its bus company. The difficulties a bus may encounter include a more-than-average number of passengers wanting to enter or leave the bus at a bus stop, engine shutdown, or any man-made incident.

Categories of Delay at a Bus Stop. Based on the movement of buses and the causes of bus delay times, the two categories of bus delay can be described as follows: service delay and non-service delay. Service delay is the extra time a bus may need to load and unload passengers beyond what is expected. Non-service delay is related to the overall time a bus requires from when it pulls into a bus stop to when it exits and is the extra time required beyond the time that a bus typically takes to pull in and pull out of a bus stop without any interruption. The delay of a bus at and near a bus stop is the sum of the service delay and non-service delay, which can be expressed mathematically as follows:

$$d_T = d_1 + d_2$$

Where: d_T -- Delay of the bus at a bus stop, s;

d_1 -- Service delay, s;

d_2 --Non-service delay, s.

FACTORS RESULTING IN DELAY AT A BUS STOP

A bus stop system is composed of three parts: passengers, buses, and the bus stop itself. In this system, passengers and buses form the main dynamic factors and these main factors cause the delay at bus stops.

Passenger Factors . A passenger is an important element of service delay because of two factors including: (a) passenger density and (b) follow-up type of

passengers entering and exiting a bus.

- Passenger Density

If there are many passengers on a bus or there are many passengers waiting at a bus stop, the process of loading and unloading passengers will not be continuous because of the high density of passengers at the bus stop and inside the bus. As a result of these circumstances, a bus will experience a service delay. When passenger density increases, the service delay will significantly increase.

- Follow-up Type of Passengers Entering and Exiting a Bus

If passengers do not enter and exit a bus in a one-by-one fashion, then the bus will again experience a service delay.

Bus Factors . There are two types of bus factors, including bus arrival rate and spacing of buses at bus stops.

- Bus Arrival Rate

When the bus arrival rate exceeds the capacity of a bus stop, buses will eventually form a queue beyond the limits of the bus stop and into the curb lanes. In this situation, the buses movement can be best described as stop-and-go movement and this is how a bus experiences non-service delay.

- Spacing of Buses at Bus Stops

The spacing of buses at bus stops should be done properly when buses stop at bus stops to allow enough space for themselves and buses around them to exit the bus stop when they finish loading and unloading passengers. When the space between stopped buses becomes too small, a bus will not be able to move out of the bus stop when they finish loading and unloading. Consequently, buses have to wait for available space to move out. As a result, the bus that has to wait for available space incurs a non-service delay.

Other Factors . Apart from the factors enumerated above, there are two other factors including (a) traffic organization at bus stops and (b) volume of vehicles near the bus stop. The explanation of these factors is given below:

- Traffic Organization at Bus Stops

Traffic organization has a great impact on the process of buses pulling into and out of a bus stop. As a result of an unreasonable organization of traffic, buses pulling into and out of a bus stop will be out of order, resulting in non-service delays. This is also the reason that buses experience a stop-and-go type movement at a bus stop.

- Volume of Vehicles Near a Bus Stop

If there is a high volume of traffic flow near a bus stop, the process of buses pulling into and out of a bus stop will be heavily influenced. Both deceleration and acceleration time will increase as well. A bus experiences a non-service delay in this situation.

APPROACH TO DELAY ESTIMATION

Bus Arrival Occupancy Rate. A new concept of bus arrival occupancy rate is introduced in this study. It is defined as the ratio of the bus arrival rate to the number of berths at a bus stop. This can be expressed mathematically as follows:

$$\Lambda = \frac{\lambda}{N}$$

Where: Λ--bus arrival occupancy rate, veh$\cdot h^{-1}$;
λ --bus arrival rate, veh$\cdot h^{-1}$;
N--the number of berths at bus stop.

Bus arrival rate only reflects the demand intensity at a bus stop. However, bus arrival occupancy rate considers both the demand intensity at a bus stop and the service capacity at a bus stop. By taking into account both of these two bus stop factors, bus arrival occupancy rate is considered the better indicator for describing the operation of bus stops. Bus arrival occupancy rate is a more objective indicator because it can reflect the actual supply and demand of a bus stop.

Principle of Delay Estimation . When one of the following two conditions is met, it can be assumed that there is no delay and data can be collected for a non-interference situation:

(a) The passengers both inside a bus and on the platform of a bus stop are not crowded. The processes of bus deceleration and bus acceleration are not internally or externally obstructed. There is only one bus that arrives at a particular time at the bus stop. When all of these conditions are met, it can be assumed that this bus experiences no delay at this bus stop.

(b) The passengers both inside a bus and on the platform of a bus stop are not crowded. The processes of bus deceleration and bus acceleration are not internally and externally obstructed. If there are two or more buses arriving at the bus stop at the same time, then it can be assumed that the first bus experiences no delay at this bus stop.

Based on the two basic types of bus stops, namely curbside bus stops and bus bay bus stops, a detailed survey has been conducted to collect field data of bus deceleration time, bus acceleration time, bus dwell time, driver perception-reaction time, the number of berths at the bus stop, bus arrival rate, and the number of passengers that get on and get off the bus. The actual time of the overall bus stop process minus the normal bus deceleration time, bus acceleration time, driver perception-reaction time and the normal time it takes for passengers to get on and get off the bus gives the delay time of a bus. The total delay time is the sum of all delays experienced by buses in the period of an hour and it can be expressed mathematically as follows:

$$d_T = \sum_{1}^{n} (t_i - t_1 - t_2 - t_3 \cdot \max\{m_1, m_2\})$$

Where: d_T -- Total delay time, s;

t_i --Actual total time of a bus from starting to decelerate to a stop, bus dwell time, and time of bus acceleration to join the traffic stream to attain steady speed, s;

t_1 --Average bus deceleration time without any interference from other vehicles, s;

t_2 --Average bus acceleration time without any interference from other vehicles, s;

t_3 --Average time of a passenger boarding or alighting from the bus without any interference from other passengers, s;

n --Bus arrival volume

m_1 --Number of passengers boarding a bus;

m_2 --Number of passengers alighting from a bus.

Data Collection. A total of fifteen bus bays and six curbside bus stops have been selected in Beijing for data collection. The selected bus stops should satisfy the following conditions. First, there should be an area where a digital video camera can be mounted so that it can tape the entire zone affected by the bus stop, or the whole traffic area affected, to ensure that video graphing and on-site observations give valuable, representative, and practical data covering all categories of buses on the road-site. Normally, locations close to the bus stop, such as an overpass for pedestrians, a high-rise building, or flyovers, are good places to mount a video camera. Secondly, the traffic on sections of road near the bus stop should be relatively high, but not to a point of congestion at the bus stop. Thirdly, bus stops selected should be along sections of road where the road is typical, void of interference of basic at-grade intersections, has a larger roadway gradient, and has entrances or exits from the main roads on which the bus stops are located. Fourthly, bus stops located at or near bus terminals of bus lines or bus routes are to be excluded. These could affect bus traffic flow and data collection. Lastly, the selections of the bus stop locations are to be carried out uniformly and equal in all directions as shown in Figure 1. The collection of data from these locations serves as the data for building a model of objectivity and practical value.

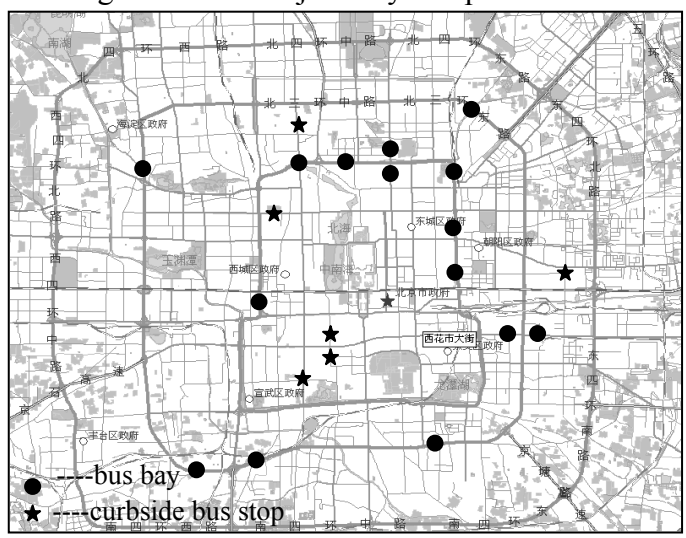

FIGURE 1: Geographical Locations of Selected Bus Stops Surveyed in Beijing

Delay **E**stimation.

- Bus Average Deceleration and Acceleration Time Without Interference

Based on the two scenarios above, average bus deceleration time and average bus acceleration time without interference have been obtained from both curbside bus stops and bus bays. The data distribution is illustrated in Figure 2 and Figure 3.

Table1. Average bus deceleration/ acceleration times under non-interference situation

Types of Bus stops	Average bus deceleration time	Average bus accelera tion time
Bus bay	9.0s	10.7s
Curbside bus stop	8.5s	10.9s

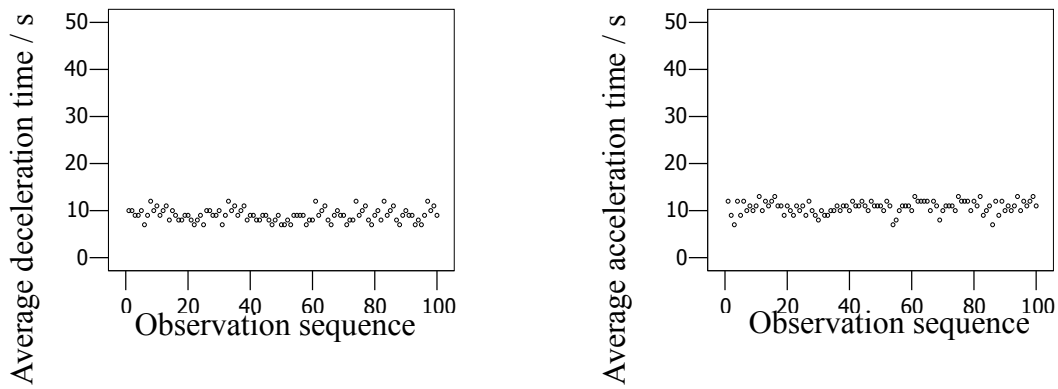

FIGURE2. Distribution of deceleration and acceleration time at bus bay without any interference

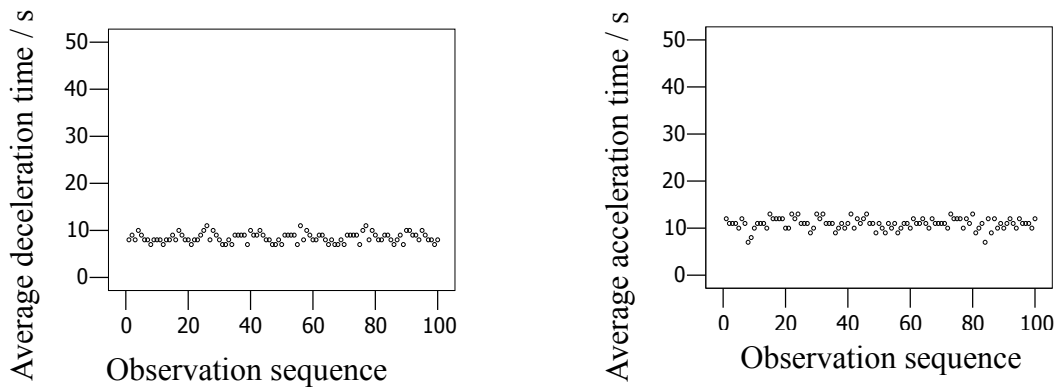

FIGURE 3. Distribution of deceleration and acceleration time at curbside bus sto p without any interference

- Average Time that Passengers take to get On and Off the Bus

In Beijing, the vast majority of bus fares are paid through the IC card. According to the survey, the doors of buses can be divided into the narrow ones and wide ones. The average time for a passenger to get on and get off a bus is quite different between these two types of doors. The results of the average time for passengers to get on and get off a bus, both with the narrow and with the wide doors, are shown in Table 2. Figure 4 and Figure 5 show the distributions of the time for passengers getting on and off the bus.

Table2. Average times of passengers boarding and alighting from the buses

Type of Door	Average time of get on and out of the bus
Narrow door	2.1s
Wide door	1.7s

- Driver Perception-Reaction Time

In this study, the driver door operation time consists of two parts: (a) time taken by the driver to open the door for the first passenger to get on board or alight and (b) time taken by the driver to close the bus door for the bus to start moving again. From the survey of these two types of driver door operations, the times are both less than one second. Therefore, the driver door operation time is not considered or taken into account during the calculation.

- Delay Estimation of Bus Bay Bus Stops

The final processed data has been analyzed with the aid of a Statistical Program for Social Sciences (SPSS 13) for Windows. The scatter plot and the curve of best fit are shown below for the regression analysis of the bus bay:

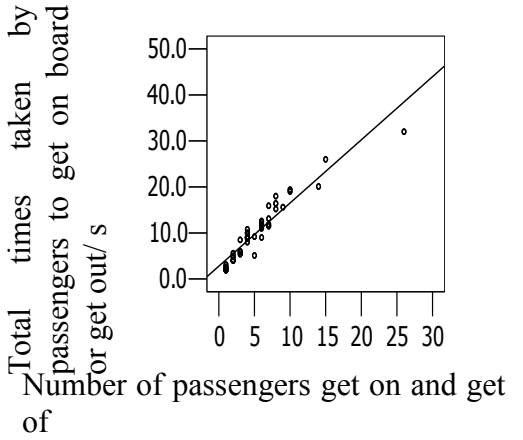

Figure 4. Graph of total times taken by passengers to board or to alight versus number of passengers getting on or off the bus. (Narrow door)

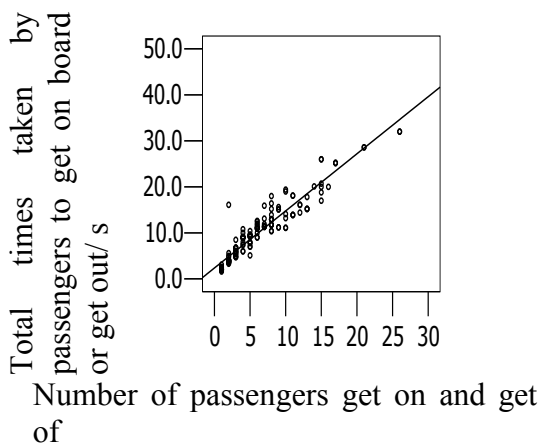

Figure 5. Graph of total times taken by passengers to board or to alight versus number of passengers getting on or off the bus. (Wide doors)

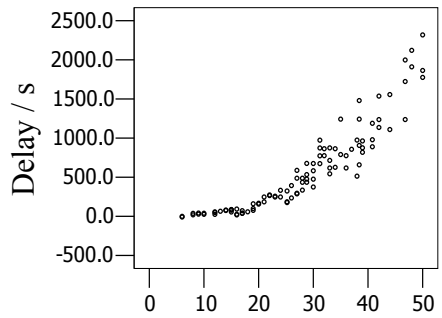

FIGURE 6. Scatter plots of the delay and bus arrival occupancy rate of bus bay

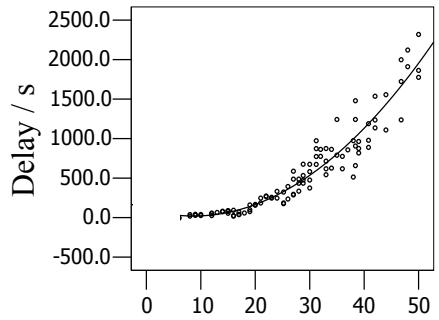

FIGURE 7. A curve of best fit of regression analysis for bus bay surveyed data

From Figure 7 above, when the bus arrival occupancy rate is less than 20veh/h, it is observed that delay at a bus bay bus stop is quite small. As the bus arrival occupancy rate increases to more than 30veh/h, the delay at a bus bay bus stop increases significantly. Using a logarithmic model, quadratic model and linear model, and comparing their test parameters (R^2 – square of correlation coefficient and F-statistic test), the model which has the highest value is selected. Table 3 illustrates the summary of the three models and the estimate of parameters or the results of regression analysis for various regression models.

Table3 . Model Summary and Parameter Estimates (bus bay)

Model		R^2	F
Logarithmic model	$T = b_0+b_1 ln\lambda$	0.652	183.9
Quadratic model	$T = b_0+b_1\lambda+b_2\lambda^2$	0.912	505.7
Linear model	$T = b_0+b_1\lambda$	0.830	476.9

The results of the statistical correlation (Model Summary and Parameter Estimates), as shown in Table 3, show that the best fit curve comes from the Quadratic Model because the R-square and F-test parameters proved to be of the highest values for the Quadratic Model when compared to the test parameters of the Logarithmic and Linear models. Therefore, for bus bay bus stops, the correlation between bus arrival occupancy rate (Λ) and delay time (d_T) can best be expressed as:

$$d_T = 105.5-19.666\Lambda+1.133\Lambda^2 \quad (\Lambda>20\text{veh/h})$$

➢ Delay Estimation of Curbside Bus Stops

The scatter plot and the curve of best fit for the regression analysis of curbside bus stops are shown below:

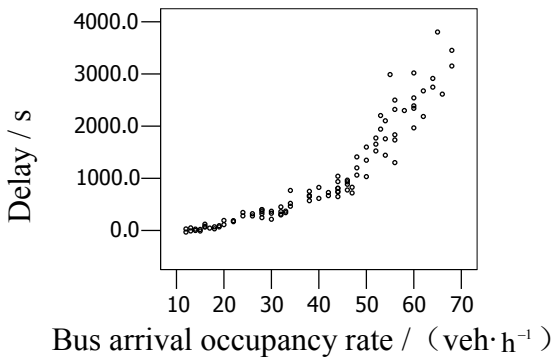

FIGURE 8. Scatter plots of the delay and bus arrival occupancy rate of curbside bus stop

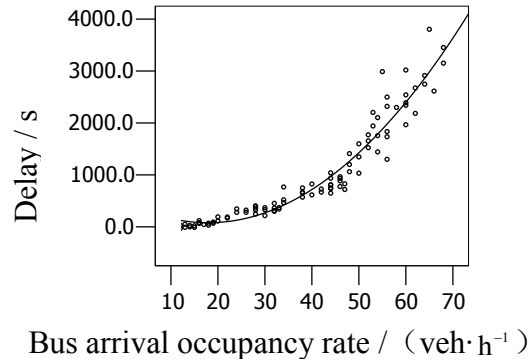

FIGURE 9. A curve of best fit of regression analysis for curbside bus stops surveyed data

From Figure 9, we can clearly see that the situation for curbside bus stops is quite the same as for bus bay bus stops. When the bus arrival occupancy rate is less than 20veh/h, it is obvious that delay at a curbside bus stop is quite small. As the bus arrival occupancy rate increases to more than 30veh/h, the delay at a curbside bus stop increases significantly. We again use the logarithmic model, quadratic model and linear model with regression analysis and choose R^2 and F as our test parameters. Table 4 illustrates the summary of the three models and the estimation of the parameters or the results of regression analysis for various regression models.

Table4. Model Summary and Parameter Estimates (curbside bus stop)

Model		R^2	F
Logarithmic model	$T = b_0+b_1 ln\lambda$	0.680	199.7
Quadratic model	$T = b_0+b_1\lambda+b_2\lambda^2$	0.929	612.5
Linear model	$T = b_0+b_1\lambda$	0.826	445.6

The results of the statistical correlation (Model Summary and Parameter Estimates), as shown in Table 4, indicate that the best fit curve for curbside bus stops is the Quadratic Model because the R-square and F-statistics test values proved to be the highest for the Quadratic Model when compared to the values of the Logarithmic and Linear models. Therefore, for curbside bus stops, the correlation between bus arrival occupancy rate (Λ) and delay time (d_T) can best be expressed with a quadratic relationship as follows:

$$d_T = 498.8-46.944\Lambda+1.31\Lambda^2 \quad (\Lambda>20\text{veh/h})$$

CONCLUSIONS

From the analysis of the bus bay bus stop and curbside bus stop surveyed data, it is concluded that bus arrival occupancy rate has a statistical correlation

with delay at and near the bus stops. A concept of "bus arrival occupancy rate" is introduced in this study to explain the situation near and at the bus stop. From this study, it has been shown that when the bus arrival occupancy rate of a bus stop is less than 20veh/h, the delay at the bus bay bus stop is quite small. When the bus arrival occupancy rate increases to more than 30veh/h, the delay a bus experiences at a bus bay bus stop increases significantly. From the analysis, a bus arrival occupancy rate of 30veh/h can be used as the reference for bus stop design standards. If the bus arrival occupancy rate is more than 30veh/h, steps can be taken to zone the platform of a bus stop into two or more zones in order to maximize the operating efficiency of the bus stop.

Empirical models have been set up for bus arrival occupancy rate and delay for both bus bay and curbside bus stops, which are used to estimate the delay at the bus stops, and also to provide a basis for determining the level of service of a bus stop.

ABSTRACT

An internet stated preference (SP) survey was developed in order to investigate an operational strategy in practice for a new kind of personal travel assistance mode - Low Speed Private Transportation Mode (LSPTM) system. This article outlines the idea and methodology of developing an SP survey which applies the recent innovations of Google-map API and Ajax models. Details regarding the dynamic location based information provision through various overlapping elements on Google-map and the experimental design with respect to different respondents/situations are explained. Results proved that the combination of environmental information provision through Google-map and efficient generation of attribute settings allows for an attractive SP survey design.

INTRODUCTION

Recently, a new kind of personal travel assistance mode (e.g. iSwing, iUnit, Segway, and so on) that was designed for improving the mobility and flexibility of personal transportation is receiving increasing attention. This kind of generally Low Speed PrivateTransportation Mode (LSPTM) is recognized as a possible link or complement to existing travel modes within city areas. A deeper behavioral understanding of traveler response to LSPTM is necessary, which will increase insight into policy issues for projecting a strategy of new travel mode service as a mobility management tool.

Stated Preference (SP) survey was proved to be an efficient method for modeling stated choices under various conditions and believed to offer a reliable treatment of influence factors (Hensor, D.A. 1994). Since almost all possible responders had no user experiences of LSPTM up to now, it is really not so easy for them to imagine the established settings and make a decision on use or not. It is certainly better to interview test riders, whereas a more flexible alternative that will

be introduced in this article is to develop a web application system which supports the visualization of LSPTM vehicles and maps of real urban networks.

Seymour and his colleagues (2007) developed a traveler assistance system in which a large amount of traffic related information were overlapped onto Google maps and can be easily accessed through the internet. It is our opinion that the advanced web technologies may extend/enrich the flexibility and efficiency of SP survey by providing respondents more location-based environmental information, as well as by offering more flexibility in the environmental attributes setting. This article aims at developing a Google-map integrated web-based SP discrete choice survey system. The main objective focus is on the implementation of embedding Google-map into the internet SP survey and the experimental design implemented through internet technology, rather than the discussion of a discrete choice model. To our knowledge this study is the first SP experiment survey by which the web functions are resorted to fully performed in order to realize the merits of web-based SP survey.

The remainder of the contents are organized as follows. The next section reviews some existing Internet-based SP surveys and Google-map incorporated web applications in transportation fields. Section 3 focuses on the architecture and technologies for survey design and SP experimental design. Subsequently, a test survey of intentions of LSPTM usage in Kobe Sannomiya area, as well as the preliminary analysis, is depicted. This article ends with our conclusions and future research proposal.

LITERATURE REVIEW

During the last decade, transport surveys through e-mails or web sites were promoted significantly and have been employed for wide applications (e.g. Iragüen and Ortúzar, 2004; Arentze et. al, 2005; Polydoropoulou and Papola, 2006; Fleming and Bowden, 2007). These studies provided valuable references on fully performed web survey design and various discrete choice analyses. Arentze and his colleges (2005) alleged that well designed internet-based surveys are even capable of providing reliable data for quite complex stated adaptation experiments.

Among all recent innovations in web technologies, Google-map API and Ajax model allow for implementation of more advanced SP surveys, more flexibility (with more possible cases for various changing conditions), and better amusement (dynamic provided contents with interesting expression, such as location-based information).

Since the Google map Application Programming Interface (API) was released in 2005, Google's mapping capabilities have been incorporated freely into various web applications. Seymour and his colleagues (2007) developed an Internet–based

traffic information system. Similarly, Welch and his colleagues (2007) reported a traffic data management and archive system. Wu and Wang (2008) established a Google-map-based online platform, GATI, for arterial traveler information broadcast and analysis, which has operated online using the City of Bellevue's data since January 1, 2007. These significant works generate an efficient framework for Google-map API applications in transportation fields. The methodology of embedding Google-map into a web site is omitted in this article due to space limitation. Please refer to above literatures and the web site of Google API (http://code.google.com/apis/maps/) for detailed instructions. Google-map API also provides many other functions, such as dynamic map behaviors (zoom, pan, and so on), open/close information window, and overlapping elements (points, polylines and polygons) with expected color, shape, and transparency, which do extend the way of presentation of location-based information and enrich the flexibility of SP experimental design.

Ajax (shorthand for Asynchronous JavaScript + XML) is another recent web innovation which incorporates several technologies for improving the interactive communication between web servers and user interfaces. Google-map is actually a successful example of the Ajax application.

SURVEY FRAMEWORK AND EMPERIMENT DESIGN

The core of survey design is to embed Google-map into the survey contents and to provide various-situations-specified information, considering that the location-based information may enrich interviewees' knowledge and therefore make choices easier. Besides realizing the affluent information through Google-map, another innovation of this web-based SP survey is the way of experimental design. Here the Ajax model is employed to efficiently exploit the way in which various attribute combination settings are generated. The popular combination of Apache-PHP-MySQL was chosen as the web server because it is free of charge and is an abundant open-source. Moreover, numerous features are built-into the PHP language which allows web applications to be quickly developed.

Giving an imaging leisure trip from their homes to the city center at weekends, all participants are informed that they have to initially go to one of the car parks near the destination by private vehicle or one of the nearest stations by train. Upon arrival they are asked to make a choice of terminal mode among electric bicycle, LSPTM, and walk, for arriving at the destination. The web survey (in Japanese) was framed into three main categories: Category 1 made an introduction on the survey objective and LSPTM characteristics with an image photo of iReal vehicle; Category 2 concerned participants' personal characteristics and their usually choice of travel mode (by train or by private car), as well as comparative ride frequency in case of

both mode users, for a weekend leisure trip to their resident city center; Category 3 focused on the stated choice survey designed for three groups: car user, train user, and both mode users. The survey architecture is depicted in Figure 1.

A hypothetic private-car forbidden area around the destination, as a common traffic regulation practice during events, is established (as shown in Fig. 2). At least one nearest park outside is no more than 300m away (about 4mins by walk) from the destination. For all three groups, two types of situations differentiated by providing unique or two available transfer place(s) as included. Subsequently participants are asked to select an egress mode. Considering that it is better to keep a moderate level of complexity , three egress modes are set to be available for the case of unique transfer place (randomly selected from four pre-set parks with differing distances to the destination shop) while only walk and LSPTM are set to be available for the case of two transfer places. The first type of situation provides three alternatives and the second one has four alternatives. Each situation consists of five settings and participants are asked to make a total of 10 to 15 choices.

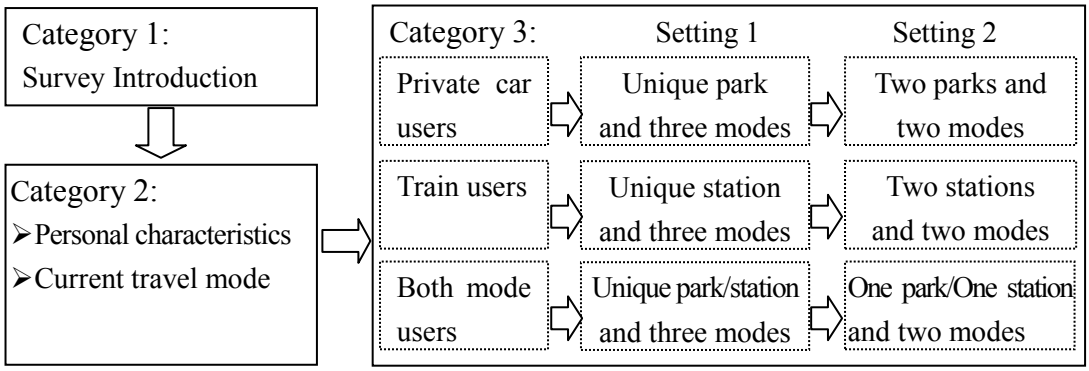

Figure 1: The architecture of survey

Location-based information, such as the stated destination, private-car forbidden area (polylines or polygons), as well as available locations for car parks and LSPTM parking garages (points), are provided overlapping Google-map (see Figure 2). Respondents can also explore information through the zoom in and drag functions of Google map.

Figure 2: Location -based information overlapping on Google -map

The fractional factorial experiment design (Henser, D.A. 1994) was employed to optimize these independent variables in order to generate a more efficient attribute combination. Each attribute was set to have several levels; parking charges have 7 levels from 200 JPY /2h to 500 JPY/2h, travel times depend on the real route distances (with 4 levels for each mode), waiting times have 3 levels (with 1min, 5mins and 10mins for each mode), and 3 levels for rental charges (with 50JPY, 100JPY and 200JPY for bicycle and LSPTM, and zero for walk). In order to reduce the number of choices for respondents, the yielded attribute combinations were separated into four groups and each group included 5 sets. One group of sets was randomly chosen and sent from the server database to the user interface if respondents press the "Start choices" button when they have already understood the environment settings and have determined their choices. Weather and temperature information are also provided randomly as two-level dummy variables, that is, raining or sunny for weather, and sizzling hot or comfortable for temperature.

In order to take advantage of not only Google-map's enormous database, but also the appealing map behaviors that comes with it, some dynamic map functions were designed. For example, the blinking marks highlighted available car parks, and information windows dynamically appear as "mouse-on" events happen, and so on.

DATA COLLECTION AND PRELIMINARY MODELING RESULTS

The beta-test version of this internet-based SP survey was has been available since December 20, 2008. The test area is Kobe city, Japan, and the destination is set as Kobe municipal museum. Data collected from a pre-test (on Dec.21, 2008 and Jan.5, 2009) by 25 students/researchers members is used to check the effectiveness of this web survey and investigate the implication of LSPTM characteristics and environmental attributes. All interviewees proved the efficiency of the web survey and enjoyed both the ease and interactive method of filling form fields in comparison

to conventional paper-based survey methods.

Multinomial logit (MNL) model and nested logit (NL) model are used separately to model the choice behaviors associated with two types of situations. A total of 100 samples was used for the first situation and 105 samples for the second situation. Personal attributes are not considered this time because of sample limitation. The results of estimated parameters for both models are omitted here due to space limitation. The preliminary results show that the waiting/running time and the usage/parking charge are significant influence factors. It is disclosed that respondents when confronted with rain or sizzling heat are more likely to choose LSPTM. An interesting result is that for the case of second situation (two available car parks and two transfer modes), students have a tendency to walk and females tend to use LSPTM, while no trend can be found for the first situation (unique station and three transfer modes).

CONCLUSIONS

This article focuses on an introduction of an Internet-based stated choice survey which was developed to collect the data and model personal mobility needs. The electric-derived LSPTM vehicles are designed for improving personal mobility within the city, while the operational strategy that satisfies both environment sustainability and personal mobility needs is still an open issue.

Some advanced web technologies were employed to take our web survey to new levels of power and usability, especially Google Maps and the Ajax model. It is proved that the embedded location-based environmental information through dynamic Google maps improve the understanding of interviewees, and the Ajax model when incorporated with experimental design methods provides a more efficient choice attribute design. In short, these web technologies provide more likely conversation survey possibility than paper-based methodologies.

The large-scale data collection is still in progress and only a portion of preliminary results are reported in this article. More analysis and models will be carried out in the near future. Also, more consideration on the sampling frame and sampling bias, the typical pitfalls of Internet-based surveys showed by Arentze and his colleges (2005), are necessary in future studies.

ABSTRACT

The Supervision Engineer's performance plays an important role in the investment control of a construction project. The effect of the Supervision Engineer's control over investment can be evaluated from two aspects. One aspect is the Employer's target. The other is the interest of the Contractor. Control over investment requires the Supervision Engineer to provide good professional consultation and management service by imposing strict audits and effective control over the contractor's expenses involving management work in technique, contract, organization, coordination and measurement, etc. The factors that influence the Supervision Engineer's performance in these two aspects are complicated: some factors are common to both aspects while others are particular to only one. In order to use the AHP method to appraise the performance of the Supervision Engineer's performance in investment control, these factors are divided into certain indicators and an analytical hierarchy model is formed. The relative significance of the factors in each hierarchy are judged based on expert experience and quantitatively expressed with the weights of superiority of the factors of each hierarchy determined mathematically.

INTRODUCTION

As a useful tool in multi-target analysis, AHP (Analytical Hierarchy Process) was first introduced to China in the 1980s. AHP has been widely adopted for systemic analysis and decision-making process due to its advantage in combining qualitative analysis with quantitative analysis of concerned elements. AHP decomposes the decision problem into a hierarchy of more easily comprehended sub-problems, each of which can be analyzed independently. Decision makers then systematically evaluate its various elements, comparing one to another in pairs. AHP converts these evaluations to numerical values that can be processed and compared over the entire range of the problem. A numerical weight or priority is derived for each element of the hierarchy. In the final step of the process, numerical priorities are derived for each of the decision alternatives (Yang et al. 2006).

The effect of the Supervision Engineer's control over investment can be

evaluated from two aspects. One aspect is the Employer's target. The other is the interest of the Contractor. Control over investment requires the Supervision Engineer to provide good professional consultation and management service by imposing strict audits and effective control over the contractor's expenses involving management work in technique, contract, organization, coordination and measurement, etc (Huang et al. 2002). In order to use the AHP method to appraise the performance of the Supervision Engineer's performance in investment control, the elements that influence the Supervision Engineer's performance are divided into certain sub-elements, as explained below.

STRUCTURING OF THE P ROBLEM INTO A HIERARCHY

According to the above discussion and based on practical experience in construction management, the appraisal model of the Supervision Engineer's investment control effect can be structured as shown in Figure 1, involving five levels and seven influencing factors (C_1~C_7). These are further divided into fourteen elements (D_1~D_{14}) (Liang 2004).

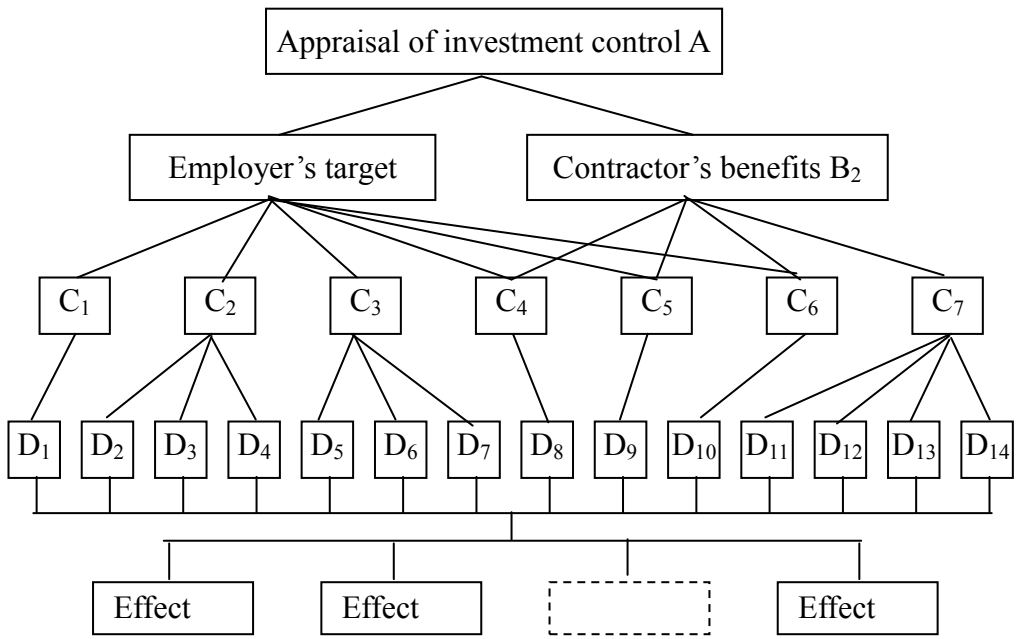

Figure 1. Appraisal model of investment control effect.

The seven influencing factors and fourteen elements as shown in Figure 1 are defined as follows:

C_1 (Supervision defficiency) . Supervision Engineer's defficiency rate D1 = (loss due to supervision engineer's defficiency)/(project total cost estimate).

C_2 (Reduction through Control) . Budget reduction rate D_2 = (budget reduction)/(budget total). Certified reduction rate D_3 = (certified reduction)/(certified total). Final payment reduction rate D_4 = (final payment reduction)/(final payment total).

C_3 (Economic measures) . Claim reduction rate D_5 = (relative claim reduction)/(relative claim original). Total cost reduction rate D_6 = (relative cost reduction)/(estimated cost total). Advice-based reduction rate D_7 = (relative reduction)/(estimated cost total).

C_4 (Coordination) . Coordinate disputes between parties D_8.

C_5 (Contract management) . Urge each party to perform in accordance with the Contract D_9.

C_6 (Technological Man agement) . Checking and approving technological plans D_{10}.

C_7 (Contractor 's Measurement) . Budget compensation rate D_{11} = (budget compensation)/(estimated cost total). Certified compensation rate D_{12} = (certified compensation)/(certified total). Final payment compensation rate D_{13} = (final payment compensation)/(final payment total). Employer's claim reduction rate D14 = (Employer's claim reduction)/(relative claim original).

COMPARISON MATRIX

The comparison matrix reflects the relative significance of each element at one level to the related elements at the preceding level, which is accomplished through pair comparisons and quantified with 1-9 scales as shown in Table 1.

Table 1 . Meanings of Different Scale Values .

Scale	Meaning
1	elements u_i and u_j have equal significance
3	u_i is slightly more significant than u_j
5	u_i is remarkably more significant than u_j
7	u_i is intensely more significant than u_j
9	u_i is extremely more significant than u_j
2, 4, 6,8	Medium values of 1-3, 3-5, 5-7, 7-9

ELEMENT PRIORITY

Individual element priority reflects the influence of each individual element at one level on a specific element at the upper level. Individual element priority can be established by calculating the feature vector of the comparison matrix. The root method can be conveniently used to calculate the feature vector with required accuracy.

(1) Calculate the product M_i of the elements at each row of Matrix A:

$$M_i = \prod_{j=1}^{n} a_{ij}, \quad i = 1, \quad 2, \quad \cdots, \quad n$$

(2) Calculate the nth root of M_i, $\overline{W_i}$, $\overline{W_i} = \sqrt[n]{M_i}$

(3) Normalizing vector $\overline{W} = \left| \overline{W_1} \quad \overline{W_2} \quad \cdots \quad \overline{W_n} \right|^T$, $W_i = \dfrac{\overline{W_i}}{\sum_{j=1}^{n} \overline{W_i}}$

Hence the feature vector: $W = [W_1, \quad W_2, \quad \cdots, \quad W_n]^T$

CONSISTENCY CHECKING

For consistency checking, use the following method:

(1) Calculate the maximum feature root of the comparison matrix:

$$\lambda \max = \frac{1}{n} \sum_{i=1}^{n} \frac{|AW_i|}{W_i}$$

Where: AW_i is the ith element of AW, the vector obtained by multiplying comparison matrix A and its feature vector W.

(2) Calculate the consistency index CI: $CI = \dfrac{\lambda \max - n}{n-1}$

If CI = 0, the comparison matrix is completely consistent and the checking is over. If CI ≠ 0, then continue to the next step.

(3) Calculate random consistency CR: $CR = \dfrac{CI}{RI}$

Where: the value of RI can be obtained by referring to Table 2.

If CR < 0.1, the consistency of the comparison matrix and individual element priority is acceptable, otherwise, the elements of the comparison matrix need to be

revalued.

Table 2 . Average Random Consistency Index (RI) .

Order	1	2	3	4	5	6	7	8	9	10
RI	0.00	0.00	0.58	0.96	1.12	1.24	1.32	1.41	1.45	1.49

GENERAL PRIORITY

General Priority reflects the relative significance of all elements of each level to the upmost level. The priority value of a certain level is calculated based on the General Priority value of the previous level and the individual element priority values of this level, thus the General Priority must be calculated from the upmost level downwards. Consistency should also be checked from up to down.

SUPERVISION EFFECT EVALUATION

The indexes include qualitative indexes (D_8, D_9 and D_{10}) and quantitative indexes (D_1~D_7, D_{11}~D_{14}). Among the quantitative indexes, some prefer lower values, such as D_1. In this case, the ratio of two effects on index D_i may be calculated:

$$Q_{12}^{(i)}, Q_{12}^{(i)} = \frac{M_1^{(i)}}{M_2^{(i)}} \times 100\%$$

Where: $M_1^{(i)}$ —the actual value of effect M_1 on index D_i;

$M_2^{(i)}$ —the actual value of effect M_2 on index D_i.

Consult Table 3 for the corresponding comparison scale value $D_{12}^{(i)}$, establish the comparison matrix, and calculate the individual priority of the effect.

Some other quantitative indexes prefer higher values (D_2~D_7, D_{11}~D_{14}). If this is the case, then consult Table 3 with $\frac{1}{Q_{12}^{(i)}}$ to obtain $D_{12}^{(i)}$. For index D_6, if one effect is negative, adopt 9 for $D_{12}^{(i)}$. If both are negative, then consult Table 3 with $Q_{12}^{(i)} = \frac{\left|M_1^{(i)}\right|}{\left|M_2^{(i)}\right|} \times 100\%$ to get $D_{12}^{(i)}$.

Table 3 . Scale Valuation .

$Q_{12}^{(i)}$ %	<50	50~ 60	65~ 75	85~ 95	98~ 102	105~ 115	125~ 135	140~ 150	>150
$D_{12}^{(i)}$	9	7	5	3	1	1/3	1/5	1/7	1/9

APPLICATION IN ENGINEERING CASES

In order to minimize the unfairness of the supervision effect evaluation,

projects should be properly classified into several categories by location, function or structure, etc., and by the qualifications of the contractor. Supervision effects should be compared only between projects in the same category. It should also be noted that the cost only refers to the cost of the project in construction stage, and does not include the expenditures incurred in the stages prior to construction, such as land, removal, and resettlement, etc.

M_1 and M_2 are two highway construction projects of the same category that are supervised by Supervision Company S_1 and S_2 respectively. According to the statistical data at completion, the related indexes are given in Table 4.

Table 4 . Indexes for Evaluation of Investment Control for M_1 and M_2 (%).

	D_1	D_2	D_3	D_4	D_5	D_6	D_7	D_{11}	D_{12}	D_{13}	D_{14}
M_1	0	18.94	30.70	5.69	52.17	11.35	2.42	1.16	1.61	0.55	17.62
M_2	0.13	12.39	43.24	6.61	45.71	8.66	5.28	1.78	2.32	0.83	12.79

According to the structure model as shown in Figure 1 and the quantification procedure described above, the comparison matrix can be established, individual element priority can be obtained, and consistency can be checked. Calculations are then made for General Priority. Finally, the priority values of investment control effects of the two supervision companies are obtained as shown in Table 5.

Table 5 . Calculation Result of GP for Investment Control Effect of M_1 and M_2.

Index	Weight	$M_1^{(i)}$%	$M_2^{(i)}$%	$1/Q_{12}^{(i)}$%	$Q_{12}^{(i)}$%	$D_{12}^{(i)}$	$W_1^{(i)}$	$W_2^{(i)}$
D_1	0.060	0	0.13	-	0	9	0.90	0.10
D_2	0.049	18.94	12.39	65.4	152.9	5	0.83	0.17
D_3	0.096	30.70	43.24	140.8	71	1/7	0.125	0.875
D_4	0.024	5.69	6.61	116.2	86.1	1/4	0.20	0.80
D_5	0.042	52.17	45.71	87.6	114.1	3	0.75	0.25
D_6	0.140	11.35	8.66	76.3	131.1	4	0.80	0.20
D_7	0.078	2.42	5.28	218.2	45.8	1/9	0.10	0.80
D_8	0.130	-	-	-	-	2	0.667	0.333
D_9	0.130	-	-	-	-	1/2	0.333	0.667
D_{10}	0.130	-	-	-	-	3	0.75	0.25
D_{11}	0.032	1.16	1.78	153.4	65.2	1/9	0.10	0.90
D_{12}	0.052	1.61	2.34	145.3	68.8	1/7	0.125	0.875
D_{13}	0.020	0.55	0.83	150.9	66.3	1/9	0.10	0.90
D_{14}	0.017	17.62	12.79	72.6	137.8	5	0.83	0.17
GP							0.516	0.484

As shown in Table 5, the General Priority value for M_1 and M_2 are 0.516 and 0.484 respectively. Thus it is concluded that supervision company S_1 has achieved a better investment control effect than supervision company S_2.

CONCLUSION

The elements that influence the Supervision Engineer's performance are complicated. These elements, however, can be divided into certain sub-elements and an analytical hierarchy model formed. The relative significance of the elements in the hierarchy can be judged based on expert experience and quantitatively expressed with the weights of priority of each element determined mathematically. AHP provides a useful method to appraise the performance of the Supervision Engineer in investment control, which may be used as reference for employers in their choice of good supervision companies in the consulting market.

Technical Efficiency of Container Terminals in China Using a Multi-Activity Data Envelopment Analysis Model

LI Ying[1], MIAO Lixin[1]

[1]Research Centre for Modern Logistics, Graduate School at Shenzhen, Tsinghua University, Shenzhen 518055; PH (86) 755-26036772; FAX (86) 755-26036005; email: lying99@mails.tsinghua.edu.cn

ABSTRACT

The aim of this paper is to provide a multi-activity data envelopment analysis (DEA) model which can represent both quayside and landside operations in a unified framework. The model is applied to simultaneously estimate the overall container terminal efficiency: quayside operation efficiency and landside operation efficiency. To do this, 20 selected container terminals in China for the year 2006 are selected for empirical applications. The results show that the average quayside operation efficiency is higher than the average landside operation efficiency (0.630 vs. 0.588), but these measures differ significantly for individual terminals. The main advantage of the multi-activity DEA model is that it can be utilized to detect the source of poor performance of container terminals rather than just evaluating the overall efficiency as in the traditional DEA model.

INTRODUCTION

To remain competitive, a container port must satisfy the specific demands of its customers and facilitate cost reductions. In short, the port must improve its operational efficiency. As a consequence, many researchers have focused attention on the measurement of efficiency in the container port or terminals. For example, Valentine (2001), Tongzon (2001) and Cullinane (2006) all apply various single-measure DEA models to study the port performance of different countries.

However, the current literature still treats these sub-technologies as a "black box" with no information about what happens inside container terminals. If the performance measurement model enables a description of the sub-activities: quayside and landside operations, it will provide extra management information that the traditional DEA models cannot address. Therefore, measuring quayside operations efficiency (QTE), landside operations efficiency (LTE), and the overall efficiency (TE) in a unified multi-activity DEA analysis model provides for a more realistic and reasonable view of container terminal systems.

With these objectives, the rest of this paper is structured as follows. The following section describes the framework for the estimate of a container terminal system and is followed by the proposed methodology for assessing QTE, LTE and TE for container terminals in a unified framework. The sample data is then described, the

three measures are estimated, and the results are discussed.

FRAMEWORK OF CONTAINER TERMINALS PERFORMANCE ESTIMATE

Container terminals can be described as open systems of material flow with two main activities. These activities are the quayside operations dealing with loading and unloading of ships, and the landside operations where containers are stored in stacks in the yard area and then loaded and unloaded onto and off of trucks and trains.

Specific cranes are used in terminal operations. The quay crane (QC) is used for loading and unloading ships in quayside operations. The stack crane (SC) is applied to stacks in landside operations. Container trailer (TRL) is a shared resource employed for the horizontal transport between both quayside and landside. Container throughput (THRT) is the most important output for container terminals system to reflect its handling capacity. Both quayside and landside operations contribute to the value-added services on container throughput.

The analytical framework portrayed in Figure 1 describes two vital parts of container terminals' operations, the specific inputs (QL, QC and SC), the shared input (TRL) and shared product produced (THRT) among these activities.

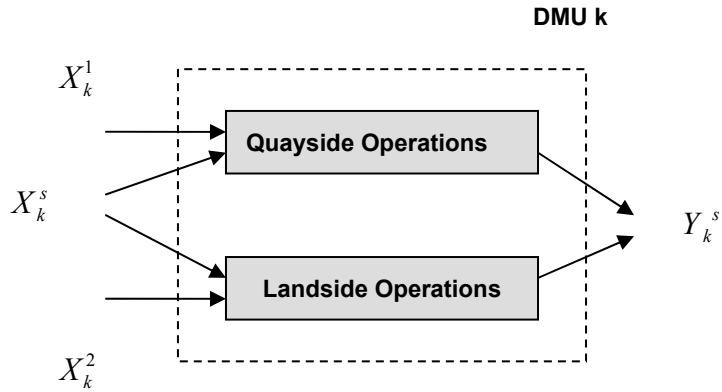

Figure 1. Analytical framework in multi-activity DEA model for port.

METHODOLOGY

First developed by Charnes et al. (1978), DEA is a non-parametric programming technique used to evaluate the relative efficiency with which a DMU transforms inputs into outputs. In most real applications, a single measure of production efficiency provided by DEA is an adequate and useful means for comparing performances and identifying best practices.

Assume that there is a set of container terminals $k = \{1, 2...n\}$. Each uses the input quantities $X_k^{\ 1}, X_k^{\ 2}, X_k^{\ s}$ to generate final output $Y_k^{\ s}$ shown in Figure 1. The input, output, and other variables used in the model are shown in Tables 1 and 2.

Table 1. Input and output used in the model.

Input		Output	
QL	**Quay length (m)**	**THRT**	Total throughput (1000 TEU)
QC	**No. of quay cranes**		
SC	**No. of stack cranes**		
TRL	No. of container trailers		

Table 2. Variables used in the model.

Variables (DMU k)	
$X_k^{\ 1}$	Dedicated input for quayside operations, including QL and QC
$X_k^{\ 2}$	Dedicated input for landside operations, including SC
$X_k^{\ s}$	Shard input for both activities, including TRL
$Y_k^{\ s}$	The sole shared output for both activities, including THRT
α_1	portion of working time per X_k^s distributed between two activities with a range [0,1]
α_2	portion of processing time per $Y_k^{\ s}$ distributed between two activities with a range [0,1]
μ^{s1}, μ^{s2}	multiplier vectors of two activities respectively for Y_k^s, the created value ratio by per Y_k^s to two activities
v^{s1}, v^{s2}	multiplier vectors of two activities respectively for $X_k^{\ s}$, the created cost ratio by per $X_k^{\ s}$ to two activities
v^1, v^2	multiplier vectors for $X_k^{\ 1}$ and $X_k^{\ 2}$ respectively the created cost ratio by per $X_k^{\ 1}$ and $X_k^{\ 2}$ respectively

To maximize the overall efficiency, consider the following multi-activity DEA model of container terminals portrayed in Figure1 for some DMU *o*:

$$\max \quad e_o^a$$

$$\text{s.t.} \quad TE = e_k^a = \frac{\mu^{s1}(\alpha_2 Y_k^s) + \mu^{s2}[(1-\alpha_2)Y_k^s]}{v^1 X_k^1 + v^{s1}(\alpha_1 X_k^s) + v^2 X_k^2 + v^{s2}[(1-\alpha_1)X_k^s]} \le 1, \qquad \forall k$$

$$QTE = e_k^1 = \frac{\mu^{s1}(\alpha_2 Y_k^s)}{v^1 X_k^1 + v^{s1}(\alpha_1 X_k^s)} \le 1, \qquad \forall k$$

$$LTE = e_k^2 = \frac{\mu^{s2}[(1-\alpha_2)Y_k^s]}{v^2 X_k^2 + v^{s2}[(1-\alpha_1)X_k^s]} \le 1, \qquad \forall k \qquad (1)$$

$$0 \le \alpha_i \le 1, \qquad \forall i$$

$$(\mu^{s1}, \mu^{s2}) \in S_1, \ (v^1, v^{s1}, v^{s2}, v^2) \in S_2$$

$$\mu_j^{\ s1}, \mu_j^{\ s2}, v_j^{\ 1}, v_j^{\ 2}, v_j^{\ s1}, v_j^{\ s2} \ge \delta, \qquad \forall j$$

The sets S_1 and S_2 are assurance regions defined by any restrictions imposed on the multipliers according to their respective measurement meanings. The multi-activity DEA model (1) can be transformed to the alternative form (Cook et al 2000):

$$
\begin{aligned}
&\max\ e_o^a = \mu^{s1}(\alpha_2 Y_o^s) + \mu^{s2}[(1-\alpha_2)Y_o^s] \\
&\text{s.t.}\ \ v^1 X_o^1 + v^{s1}(\alpha_1 X_o^s) + v^{s2}[(1-\alpha_1)X_o^s] + v^2 X_o^2 = 1 \\
&\quad \mu^{s1}(\alpha_2 Y_k^s) + \mu^{s2}[(1-\alpha_2)Y_k^s] - v^1 X_k^1 - v^{s1}(\alpha_1 X_k^s) - v^{s2}[(1-\alpha_1)X_k^s] - v^2 X_k^2 \le 0, \forall k \\
&\quad \mu^{s1}(\alpha_2 Y_k^s) - v^1 X_k^1 - v^{s1}(\alpha_1 X_k^s) \le 0, \qquad \forall k \\
&\quad \mu^{s2}[(1-\alpha_2)Y_k^s] - v^{s2}[(1-\alpha_1)X_k^s] - v^2 X_k^2 \le 0, \qquad \forall k \\
&\quad 0 \le \alpha_i \le 1, \qquad \forall i \\
&\quad (\mu^{s1}, \mu^{s2}) \in S_1, \quad (v^1, v^{s1}, v^{s2}, v^2) \in S_2 \\
&\quad \mu_j^{s1}, \mu_j^{s2}, v_j^1, v_j^2, v_j^{s1}, v_j^{s2} \ge \delta \qquad \forall j
\end{aligned}
\tag{2}
$$

EMPIRICAL STUDY

Data. The required data are mainly taken from *Yearbook of Ports in China* (2006) with a size of 20. Important statistics related to the sample are summarized in Table 3.

For solution purposes, we have restricted α_1 and α_2 to lie in the range 1/3–2/3. For shared input and output we take $2 \le \mu^{s1} : \mu^{s2} \le 3$ and $0.5 \le v^{s1} : v^{s2} \le 2$ by the realistic conditions of container terminals.

Table 3. Descriptive statistics for the input and output.

	Input			**Output**	
	QL	**QC**	**SC**	**TRL**	THRT
Max	**3,418**	**38**	**154**	**670**	8,295.657
Min	**231**	**1**	**2**	**4**	19.147
Mean	**1,137.37**	**10.78**	**29.86**	**60.67**	1,464.322
S.D.	**894.16**	**10.28**	**33.71**	**100.62**	1,809.968
Count	49	49	49	49	49

Results. The results for TE, QTE, LTE, and the distribution of the shared input and output are shown in Table 4. The average QTE is higher than the average LTE (0.630 vs. 0.588).

Table 4. Performance comparison and the distribution of shared inputs and output.

Container terminal	TE	QTE	LTE	α_1	α_2
1. Dalian Dagang	**0.618**	**0.637**	**0.525**	**0.373**	0.667
2. Dalian Port	**0.069**	**0.067**	**0.071**	**0.333**	0.333
3. Dalian Container Terminals	**0.852**	**0.865**	**0.776**	**0.333**	0.667
4. Fuzhou Qingzhou	**0.846**	**0.848**	**0.837**	**0.366**	0.667
5. Guangzhou Nansha	**0.741**	**0.766**	**0.618**	**0.667**	0.667
6. Guangzhou	**0.665**	**0.700**	**0.511**	**0.333**	0.667
7. Haikou	**0.945**	**1.000**	**0.712**	**0.667**	0.667
8. Jinzhou New Age	**0.299**	**0.281**	**0.320**	**0.333**	0.333
9. Lianyungang New-Oriental	**1.000**	**1.000**	**1.000**	**0.472**	0.333
10. Longkou Haishen	**0.243**	**0.188**	**0.344**	**0.333**	0.333
11. Port of Nanjing Longtan	**0.563**	**0.521**	**0.613**	**0.333**	0.333
12. Nantong Port	**0.437**	**0.374**	**0.525**	**0.333**	0.333
13. Ningbo Port Beilun	**0.964**	**1.000**	**0.795**	**0.667**	0.667
14. Port of Ningbo Daxie	**0.056**	**0.046**	**0.073**	**0.667**	0.333
15. Daxie Ningbo China Merchants	**0.259**	**0.264**	**0.230**	**0.667**	0.667
16. Ningbo Port Beilun 2nd	**0.964**	**1.000**	**0.791**	**0.333**	0.667
17. Ningbo Port-Gangji	**0.488**	**0.514**	**0.374**	**0.667**	0.667
18. Ningbo Port- Gangwu	**0.589**	**0.536**	**0.652**	**0.667**	0.333
19. Qingdao Port-Qianwan	**1.000**	**1.000**	**1.000**	**0.333**	0.667
20. Qingdao Port-Yuangang	**0.995**	**0.990**	**1.000**	**0.333**	0.333
Average	*0.630*	*0.630*	*0.588*	*0.461*	*0.517*

Table 4 reveals that some container terminals, such as Lianyungang New-Oriental (no. 9) and Qingdao Port-Qianwan (no. 19) are technically efficient both in quayside and landside production terms. Some others appear to have relatively greater difference between QTE and LTE. In such cases, the higher QTE or LTE does not imply a higher corresponding TE.

The average share of container trailers assigned to quayside is lower than that assigned to landside (0. 461 vs. 0.539). As for throughput, the average share of TEUs assigned to quayside is higher than that of landside (0.517 vs. 0.463). However, their distributions among different container terminals differ greatly.

Management implications. Based on the results, we construct the TE matrix in which the horizontal axis represents QTE and the vertical axis LTE, and where each container terminal is located. We can divide the matrix into four sub-matrixes based on the average scores as shown in Figure 2.

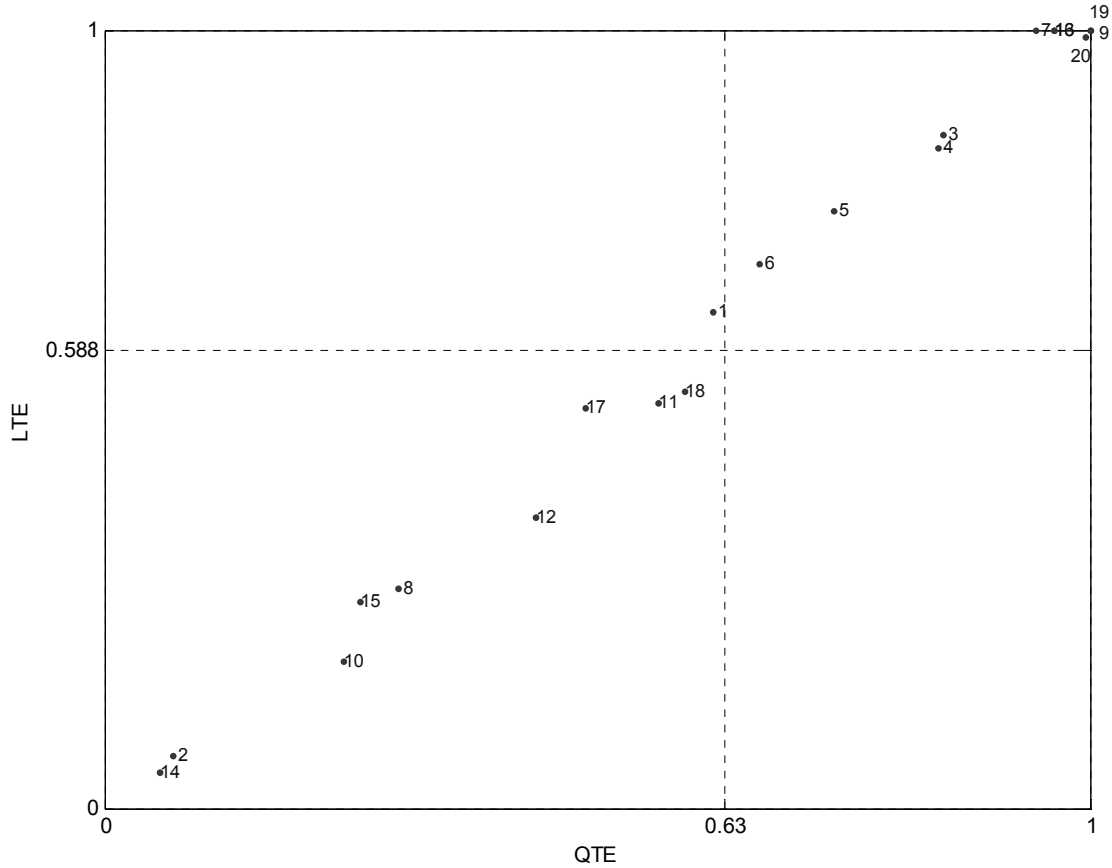

Figure 2. The efficiency distribution of quayside and landside operations.

Those container terminals located in the second quadrant (for instance, Dalian Dagang (no.1) represents lower QTE but higher LTE. A management implication for these container terminals is that they need to first improve quayside operations before their landside operations. Those terminals located in the third quadrant should consider improving both operations. There are no terminals located in the fourth quadrant that exhibit higher QTE but lower LTE.

CONCLUSION

This paper has proposed a multi-activity DEA model different from traditional DEA models in evaluating multiple activities in the container terminals simultaneously. Using the multi-activity model proposed in this paper, one can further identify the sources of poor performance and gain a proper understanding for improving a ports performance in quayside or landside operations.

In this study, we made some strong assumption on the constraints of multipliers imposed on the input and output due to the lack of available data from the annual yearbook. If the data difficulties are to be overcome in future research, a more

rational approach will necessitate construction of improved models of container terminals.

ABSTRACT

Expressway operation financial benefit evaluation is the basis of expressway operation decision-making. There are many uncertain factors in the expressway operation process. In this paper, the main factors influencing the operation financial benefit are analyzed. An expressway operation financial benefit evaluation model based on Monte-Carlo simulation method is proposed. The evaluation model is applied to an expressway operation financial benefit evaluation and the simulation is carried out with SciPy, a Python science library. The results show that the proposed evaluation model is practical and effective.

INTRODUCTION

The expressway is a type of capital intensive project, the demand for which increases with economic development. In many countries where investment in expressways exceeds the capability of the government, private investors are permitted to participate in expressway building. In developing countries, private funds become the main sources of expressway construction investment (Walker 1995). The duration for expressway operation is very long and the operation benefit can be influenced by many factors, such as transportation policy, land use, currency exchange rate, etc. At present, the main methods for financial benefit evaluation assume a deterministic environment and most uncertain factors are not considered (Froud 2003; Al-Bahar 1990). Most researchers undergo these kinds of studies before the expressway construction phase, so few studies are undertaken during the expressway operation period (Chuan-de 2006; Subprasom 2001). Expressway operation financial benefit evaluation is the basis for scientific operation decision-making. Therefore, it is of great importance to research expressway operation financial benefit evaluation method under uncertainty.

OPERATION FINANCIAL BENEFIT AND UNCERTAINTY ANALYSIS

Calculation **method** of **financial benefit** under **uncertainty.** When private

capital has been involved in expressway construction, the expressway has obvious commodity characteristics. Because maximizing profit is one of the most important goals for an expressway operation company, managers pay more and more attention on financial benefit. Expressway operation financial benefit evaluation is to evaluate the financial benefit during the operating period and it is of great help for the companies to promote the decision-making level and to reduce the operation risk.

There are many uncertain factors in expressway operation, but the classic financial evaluation methods do not reflect this feature. The evaluation result under uncertainty must at least contain two kinds of information, one is the value which indicates the level and the other is the possibility of this level.

Uncertainty **analysis.** The factors that influence the expressway operation financial benefit include internal and external factors. Internal factors are factors that can be controlled directly by the company, such as operation cost, management level, and operation efficiency. External factors are harder to control, such as traffic policy, currency exchange rate, and regional road network planning.

Traffic demand is one of the main uncertain factors in expressway operation. At present, traffic volume forecast methods are made without consideration of uncertainty. In fact, most of the factors related with traffic volume are uncertain, such as social and economic development, population growth, and so on (Chen et al 2003; Feng and Chen 2003). According to research by Skamris and Flyvbjerg, travel demand forecasts often deviate at least 20% to 60% when compared with real world data (Skamris and Flyvbjerg 1996). According to the mechanism of traffic volume, there are uncertainties in the process of traffic demand production, distribution, assignment, and the modal split.

There are many factors that impact traffic demand. Firstly, traffic demand is impacted by the toll rate. Expressway toll is the main income of an expressway operation company and for some Chinese expressway operation companies, toll is their only income. The uncertainty of travel demand is mainly due to social and economical progress influenced by the international environment, the country's policy, and so on. There are also many other factors that can influence travel demand, such as road network structure, land use patterns, traveler's driving behavior, etc. Many studies show that traffic demand is determined by the potential demand and the travel time (Subprason 2004).

Expressway toll rate is a prime uncertain factor. The toll rate will influence the financial income and the profit of the project directly. At present, there is no uniform standard of the toll rate and every road has its own standard.

Another uncertain factor in expressway operation is interest rate. Interest rate is one of the most important parameters of the project financial benefit evaluation

and it is also the basis of the basic discount rate calculation. One main factor that influences the interest rate is social average profitability.

The fourth uncertain factor in expressway operation is exchange rate. Usually, the financial evaluation indexes are calculated without considering inflation and assuming the internal value of the currency remains stable. The profit index of the project using foreign funds may change if the exchange rate varies during the operation period (Chandra and Chang 2000). There are many factors that determine exchange rate. During a given period, the main factor is international payments, but over a long period, the exchange rate is determined by the economy's development and the growth rate of the currency.

EVALUATION METHOD BASED ON MONTE-CARLO SIMULATION METHOD

Evaluation index calculation under uncertainty. Financial benefit evaluation indexes that do not take into account uncertainty include FIRR, FBCR, FIRR and FRP. These kinds of indexes can not reflect uncertainties of the real world. From these indexes, we can know their value, but we can not learn their probability. Monte-Carlo is an efficient simulation method whereby we can discern the real situation of expressway operation.

Principle of Monte-Carlo **simulation method.** Monte-Carlo simulation is a method for resolving mathematical and physics problems. Its mechanism is as follows. Once the probability model is confirmed to have common features with the target problem, a relationship between the two of them is established on the basis of these common features (such as the mean of the random parameter, variance, and so on). A random simulation analysis or sampling method is applied to the model and the statistic and estimation values of the results are considered as the approximate solution of the mathematical computing problem.

Random numbers are generated according to a certain distribution that is the same as the distribution of the random parameter related to the problem. Experiments are carried out using this data and then statistical analysis is applied on the forecast random parameters. The statistic and estimation values are consider as the statistic eigenvalues of the random parameter.

EVALUATION METHOD

Selection of main factors and determination of distribution functions. First, select the main factors from all of the uncertain factors. Then, determine the distribution functions that may be normal, triangular, uniform, lognormal or others. The possibility distribution function can be determined empirically or fitted by the survey data.

Long-term forecasted data such as traffic volume is considered as a random variable with a normal distribution function. The forecasted result is considered as the most probable event; the shorter the forecasting period, the more precise the forecasted result, and the smaller the standard deviation (see Figure 1). For example, the distribution function of traffic volume is considered as $N(\mu,\sigma^2)$, where μ is the traffic volume forecasted, $\sigma=\mu\times(at+b)\%, t=1,2,\cdots$ a , b are coefficients.

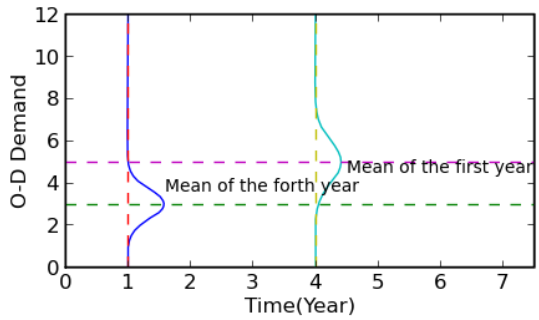

Figure 1. Stochastic O-D demand.

Financial benefit evaluation index calculation. Generate the numbers according to the possibility distribution function of the variable parameter as the input data. Calculate the evaluation index to get n samples.

Result analysis. Provide the distribution an assumption according to the sample and test the distribution. Then, estimate the parameters of the distribution functions that are to be tested. After this, the expressway operation financial benefit can be analyzed using these distribution functions. The index risk and index reliability are calculated as follow:

$$FD=\frac{VAX-(EX-X_0)}{EX} \tag{1}$$

Where VAX is standard deviation. EX is the mean. X_0 is the value of a certain parameter. The reliability is:

$$p=\{x\le x_0\}=\int_{-\infty}^{x_0} f(x)d_x \tag{2}$$

, Where x_0 is a preset value and p is the reliability.

CASE STUDY

Project **introduction.** Tan-Shao expressway is located in Hunan province south of China. Ten-Shao is a segment of the national ShangHai-RuiLi expressway and is a part of the national highway network. The 218 kilometer long expressway

goes through XiangTan, LouDi, and ShaoYang, including 10 counties. The financial indexes calculated during the feasibility study stage were as follows: FIRR=9.96%, FNPV=95321million Yuan, FBCR=1.37 and FRP=16 year.

Financial benefit evaluation under uncertainty. The distribution functions of the random variables of the uncertain factors were determined by the data from the experts and the expressway operation data between 2003 and 2006 offered by Tang-Shao Expressway Operation Company. The simulation model is carried out with Python, an open-source programming language. With the help of the statistic model from the SciPy library of scientific tools, the Monte-Carlo simulation can be implemented easily. The output is plot with the Python library matplotlib. Indexes such as FNPV, FIRR, FBCR and FRP are calculated in the experiment. The simulation is made 1000 times and the statical result is shown as Figure 2.

According to the statistical results (Figure 2), the probability that the FNPV can reach 95321 is 55% and the probability that the FNPV is between 24000 and 10000 is 92.5%. The operating state of the expressway is therefore good. The project is profitable and quite capable of resisting risks (Table 1). Depending on the results from the Monte-Carlo simulation model, a decision-maker can make a more effective decision according to their risk-bearing capability than with an evaluation that does not consider uncertainty.

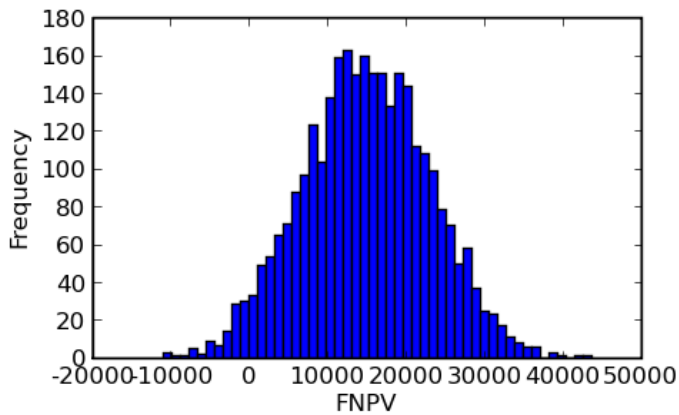

Figure2. Stochastic NPVR.

Table 1. Financial benefit evaluation indexes.

	value	stability	risk	mean
FNPV	95321	0.551	0.73	5061
FBCR	1.37	0.45	0.82	1.16
FIRR	9.96%	0.553	0.73	7.4%
FRP	16	0.68	0.63	19

CONCLUSION AND RECOMMENDATIONS FOR FUTURE RESEARCH

The main factors that influence the operation financial benefit are analyzed and the distribution functions of the uncertain factors are confirmed. An evaluation model based on the Monte-Carlo simulation method is proposed and the reliability index and risk index are also proposed in the evaluation process. According to the result of the application of the evaluation model on Tan-Shao expressway operation financial benefit evaluation, the proposed model is deemed practical. Using this evaluation model, both values and probabilities can be obtained from the expressway operation evaluation indexes. With this evaluation model, the state of the expressway operation can be estimated with precision, thus supporting the operation decision-making process.

ABSTRACT

There are distinct differences among the regional economic and transportation aspects of the three regions of China (eastern, middle and western). This paper investigates differences between the indexes of GDP, GDP per capita, freight turnover, and the Average Density of Transport Line (ADTL) from 1996 to 2007. Indexes in eastern China were found to be significantly higher than those in the middle and west. Moreover, the coefficients of differences in ADTL were estimated among the three regions, and their developing trends were explored by employing the R/S analysis method within fractal theory. The result indicates that the differences in transportation development would decrease from 2008 to 2019 among the three economical regions, but would increase gradually from 2015 to 2019.

INTRODUCTION

As China reforms and opens up, the differences in regional economic and transportation develop rapidly, especially among the three regions in China (eastern, middle and western). In recent years, the differences between the three regions in China have attracted wide attention both at home and abroad.

In this paper, the eastern region includes 11 provinces (municipalities and districts): Beijing, Tianjin, Liaoning, Hebei, Shandong, Shanghai, Jiangsu, Zhejiang, Fujian, Guangdong and Hainan. The middle region comprises 8 provinces including Heilongjiang, Jilin, Shanxi, Anhui, Jiangxi, Henan, Hubei, and Hunan. The western region comprises 12 provinces including Inner Mongolia, Guangxi, Chongqing, Sichuan, Guizhou, Yunnan, Tibet, Shaanxi, Gansu, Qinghai, Ningxia, and Xinjiang.

Utilizing data from 1996 to 2007, this paper investigates the differences in the indexes of GDP, GDP per person, freight turnover, and the Average Density of Transport Line (ADTL) by. The coefficients of differences in ADTL are estimated among the three regions, and their developing trends further explored by employing the R/S analysis method within Fractal Theory.

DISCUSSION ON DIFFERENCES IN CHINA'S REGIONAL ECONOM Y AND TRANSPORTATION AMONG THE THREE REGIONS

This section investigates the differences in the indexes of GDP, GDP per capita, freight turnover and ADTL from 1996 to 2007. The trends of indexes can be seen in the figures below:

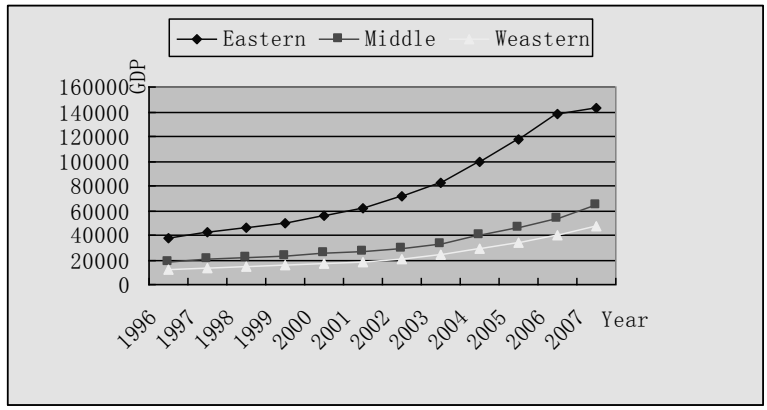

Figure 1. GDP among the three regions from 1996 to 2007 .

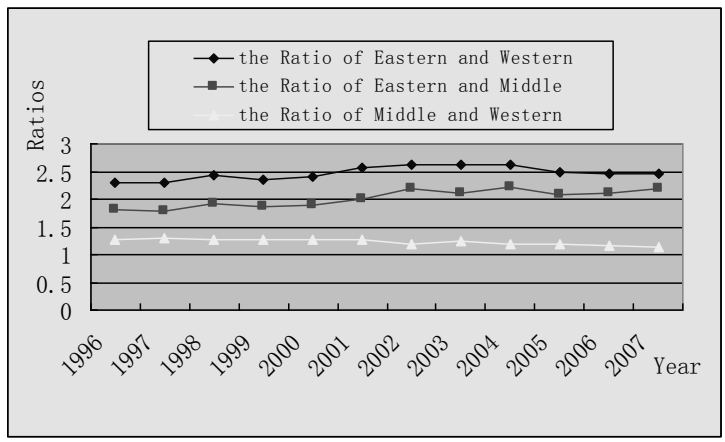

Figure 2. Ratio of GDP per capita among the three regions from 1996 to 2007 .

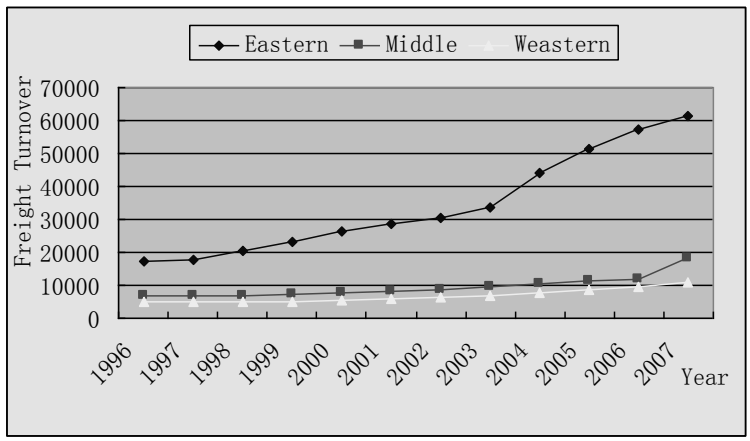

Figure 3 . Freight turnover among the three regions from 1996 to 2007.

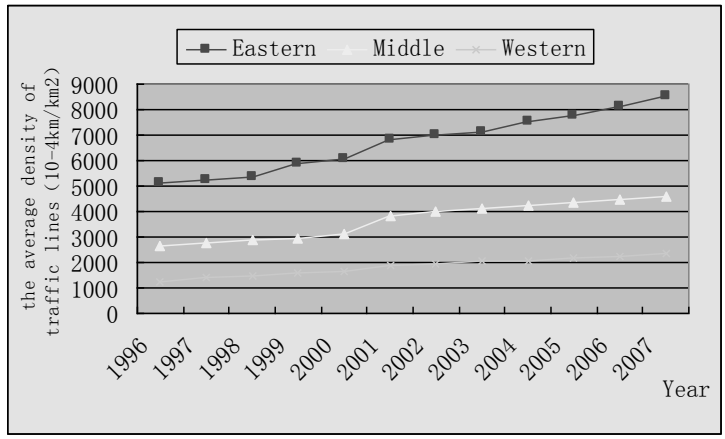

Figure 4. ADTL among the three regi ons from 1996 to 2007.

As shown in Figures 1, 3 and 4, the indexes of GDP, GDP per capita, and ADTL in the eastern region are significantly higher than those in the middle and western regions. The trend is similar between the middle and the western regions. As shown in Figure 2, there are significant changes between the ratios of eastern and western as well as eastern and middle, while it changes little between the ratio of middle and western.

THE ORIES

A fractal is a mathematical abstraction of an irregular shape, the basic characteristic of it being neither smooth nor continuous and the constituent parts of which, when broken down, are self-similar. The birth of fractal theory came in 1975 when Benoît Mandelbrot, a French-American mathematician, published Fractal: Form, Chance and Dimension. Using R/S analysis (Rescaled Range Analysis) in fractal theory, we can study a fractal's characteristics, identify the change laws, and predict its trend. The Hurst Exponent (H) is a statistic named after Harold Hurst, a British hydrologist who did long term research on the water level of Nile River. While inspecting a pre-existing time-series $B(t)$ (Cv in this paper, Table 1), Hurst found that R/S can be described in the following empirical formula:

$$R/S = (a\tau)^H$$

Where: R is the range of the cumulative deviation, S is standard deviation, τ is the observed frequency, and a is a constant (we make $a = 0.5$ in this paper). According to statistics, when $H \neq 0.5$, the observation is not independent and each

observation has its initial case's memory. This memory will continue to exist ad infinitum. The impact of recent events is greater than long-term, and the impact's residue will persist indefinitely. Theoretically it is proven by the correlation function as follows:

$$C(t) = \frac{[-\Delta B(-t)\Delta B(t)]}{[\Delta B(t)^2]} = 2^{2H-1} - 1$$

Then, we can obtain H using the Least Square Method in the double logarithmic coordinates $(\ln(a\tau), \ln R/S)$. H has three types.

1. When $H = 0.5$, $C(t) = 0$, the last increment $\Delta B(-t)$ has nothing to do with the future increments $\Delta B(t)$, and this means the sequence is random.
2. When $H < 0.5$, $C(t) < 0$, there is a negative correlation of time series, that is, the last increment $\Delta B(-t)$ has a negative correlation with the future increments $B(t)$. This feature relies on the closeness of H to 0.
3. When $H > 0.5$, $C(t) > 0$, it shows that $B(t)$ and $\Delta B(-t)$ have a positive correlation. If the last increment is up (below), then the future increment will continue to be up (below). This feature relies on the closeness of H to 1.

Compared with the traditional forecasting methods (i.e., linear regression, gray theory, and neural networks, etc.), R/S analysis starts from the historical data and predicts the trends in the same environment. The environment of the Global Financial Crises which burst in 2008 is similar to that of the Southeast Asian's Financial Storm in 1997. In addition, China takes the increasing input of the transport infrastructure as the economic stimulus program. So in similar situation, using R/S analysis is more appropriate. In general, while the accuracy of forecasts falls rapidly when using traditional forecasting methods, R/S analysis is less influenced by time.

EMPIRICAL STUDIES

Inputs of the model. This section analyzes the differences of regional economic and transportation among the three regions from 1996 to 2007. Using R/S analysis, this section calculates the coefficient of variation (Cv) of ADTL to perform further research on the differences of regional transportation. The difference coefficient of ADTL is calculated as follows:

$$Cv = \frac{S}{\bar{x}} = \bar{x}\sqrt{\sum_{i=1}^{n}\left(x_i - \bar{x}\right)/\left(n-1\right)} = \sqrt{\frac{\sum_{i=1}^{n}\left(k_i - 1\right)^2}{n-1}} \quad , \quad \text{where} \left(k_i = \frac{x_i}{\bar{x}}\right) \quad (i=1,2,\cdots,n)$$

Notes: S expresses the sample standard deviation; x_i, $\bar{x}$ express ADTL in the area i and sample mean respectively; the formula indicates that the greater the Cv values, the more extent of the disparities is, and vice versa. The results are shown in Table 1.

Table 1. Coefficient of variation of ADTL among the three regions .

Year	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007
Cv	0.654	0.612	0.606	0.628	0.623	0.597	0.585	0.578	0.596	0.590	0.595	0.605

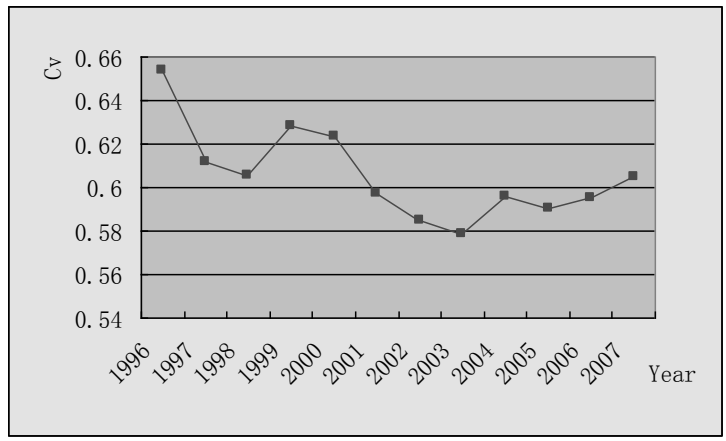

Figure 5. Coefficient of variat ion of ADTL among the three regions .

Results. Based on the R/S analysis, input the time-series $B(t)$ (Cv in this paper, Table 1), the results showing the Hurst exponent are as follows: (see Table 2)

Table 2.R/S analysis results: Hurst exponent .

	1996	1997	1998	1999	2000	2001	2002	2003	2004
1999	0.5883								
2000	0.5852	0.8537							
2001	0.8032	0.5971	0.5995						
2002	0.7630	0.6307	0.6583	0.7018					
2003	0.6903	0.6217	0.6404	0.7106	0.7499				
2004	0.4104	0.7669	0.861	0.6457	0.6471	0.8132			
2005	0.4207	0.7094	0.7713	0.6379	0.6338	0.7546	0.8531		
2006	0.4358	0.7397	0.7979	0.7245	0.7519	0.5942	0.6049	0.5441	
2007	0.5388	0.7672	0.8234	0.7979	0.8061	0.6683	0.4167	0.7188	0.7554

From Table 2, we can see, H (1996-2007) = 0.5388 > 0.5, C (t) > 0. Therefore, in the years 2008-2019, the differences in regional development will have the same development trend as in the years 1996-2007. Since H is closer to 0.5, regional differences will be reduced overall, but relatively have strong randomness. H (1996-1999) = 0.5883 > 0.5, C (t) > 0, and thus the difference between 2008 and 2011 will have the same trend with the year 1996-1999. H (1999-2003) =0.7106 > 0.5, C (t) > 0, and thus the regional differences will continue to decrease in 2011-2015. H (2003-2007) = 0.7188 > 0.5, C (t) > 0: because the regional differences between the three regions significantly expanded from 2003-2007, so regional differences will continue to expand from 2015-2019.

CONCLUSION S

From a theoretical perspective, the following conclusions are reached. Firstly, according to the indicators about the indexes of GDP, GDP per capita, the freight turnover and ADTL from 1996 to 2007, the indexes in the eastern region are significantly higher than those in the western and middle regions (especially GDP and freight turnover). Due to the open-door policy in coastal cities, the economy of the eastern region has developed faster, and so the differences of the three regions are more obvious. Secondly, the R/S analysis indicates that the differences in transportation development will decrease from 2008 to 2019. From 2008 to 2011, they will decrease, but still have the potential to expand. Between 2015 and 2019, the regional differences will continue to expand. The results of this paper can provide a theoretical basis to the traffic department on planning and decision-making.

ABSTRACT

This paper proposes a nonlinear integer optimization model which takes into account both economic and environmental effects in order to evaluate the benefits of government subsidies for alternative energy public transit vehicles. When an interim assessment of a five-year transit fleet conversion plan requires evaluation due to budget limitations, this model can inform an optimal choice between economy and environmental protection to achieve a win-win situation for both government and transit agencies. The government achieves pollution reduction and maximizes social benefits while the budget stimulates the innovation of transit agencies. This paper uses data from the Beijing Public Transportation Group to employ the proposed model to analyze the operational and environmental costs of replacing an existing bus fleet with new hybrid electric buses over several years. The results show that altering the preference variable of economic/environmental benefits influences the results. Governments should consider a range of preference variables when making optimum proposals.

INTRODUCTION

After World War II, only five major American cities—Cleveland, Detroit, New York, San Francisco, and Seattle—owned and operated their transit systems; by the 1970s most transit systems in large American cities were operated by the public sector (Saltzman, 1992). Since the 1990s, when the public transit systems of cities in China became market based and opened to the private sector, the negative effects of marketization practices in several cities have caused them to return to public sector operation. Government subsidies play an increasingly important role in public

transit systems, as urban public transport companies usually operate under deficit conditions (Ubbels, 2002). These subsidies represent an income transfer from taxpayers to transit users (Iseki, 2001).

The aim of subsidies is to create more efficient, less costly, and less energy-dependent urban transport, as well as a better urban environment (Bly, 1980). Subsidised public transport also provides environmental benefits, as private urban transportation contributes to climate change and is associated with other negative environmental effects such as traffic congestion and air pollution. For example, Beijing suffers from high local external costs due to motor vehicle use that, together with global climate change externalities, cost the equivalent of between 7.5% and 15.0% of Beijing's GDP (Creutzig, 2009). Since burning gasoline and diesel fuel is unfriendly to the environment, and the costs of these fuels is rapidly increasing, the purchase and operation of buses that use alternative energy sources has become a target of public transit subsidies. Although electric vehicles contribute least to local air pollution, hybrid electric vehicles, which use both conventional internal combustion engines and electric motors as their major sources of power (Tzeng, 2005), can provide an interim solution until the development of viable electric vehicles.

The economic and environmental impacts of subsidies for low emission vehicles (LEVs) are difficult to quantify. A bootstrap data envelopment analysis (DEA) method was applied to estimate technical efficiency scores for Canadian urban transit systems (Attah, 2004). However, it was difficult to attain accurate figures for cost savings and emissions reductions, since much of the shortfall can be attributed to the elimination or significant delay of anticipated grant programs for installing fast fuel stations and other fueling infrastructure (Haller, 2007).

This paper proposes an original Subsidy Optimization Model (SOM) which considers both economic revenue of the public transit company and environmental benefits for the whole society. It then uses this SOM to analyze options for subsidy distribution for Beijing's public transit system over a five year period. Optimized results and limitations of the proposed model are considered, and conclusions are summarized.

SUBSIDY OPTIMIZATION MODEL

Government subsidies for LEVs for public transit offer two separate benefits, the economic benefit to public transit companies and the environmental benefit to the whole society. In order to optimize these benefits we have formulated a Subsidy Optimization Model (SOM) structured as a nonlinear integer optimizing problem.

The parameters are defined as follows:

F: Total revenue over T years under investment program $x_1, x_2, \ldots x_T$;

T: Time duration in years;

A: Total budget over T years;

β: Weighting coefficient of economic benefits;

m: Number of projects included in cost calculation system;

x_i: Subsidies during year i;

$c_j(x_i)$: Cost variance of project j in year i with subsidy x_i;

d_i: Environment cost of year i without subsidy x_i;

$f(x_1, x_2, \ldots, x_T)$: Environment cost over T years with subsidy x_i;

$n_i(x_i)$: Number of LEVs purchased in year i with subsidy x_i;

L: Limitation on the number of LEVs purchased each year.

The general objective function for total revenue is as follows:

$F = \Delta P_{BC} + \Delta E$

The two terms on the right side are the changes in economic (P) and environmental (E) costs after subsidies contribute to transit companies. Changes in economic costs may include the following:

- purchase costs of LEVs;
- cost of energy use of LEVs;
- operation and maintenance costs of LEVs;
- Construction and maintenance of gas stations/service stations etc.

Changes in environmental costs may include the following:

- reduction in CO_2 emissions caused by reduction in fuel consumption;
- reduction in major pollutants including HC (hydrocarbons), CO (carbon monoxide), NO_x (nitrogen oxide), and $PM_{10}/PM_{2.5}$ (respirable suspended particulates).

In the equation below, β represents the weighting of economic benefits while 1-β represents the weighting of environmental benefits.

$$F = \beta \sum_{i=1}^{T} [x_i - \sum_{j=1}^{m} c_j(x_i)] + (1-\beta) \sum_{i=1}^{T} d_i - f(x_1, \ldots, x_T)$$

The SOM can then be expressed in the following form:

$$\max \quad F = \beta \sum_{i=1}^{T} [x_i - \sum_{j=1}^{m} c_j(x_i)] + (1-\beta) \sum_{i=1}^{T} d_i - f(x_1, \ldots, x_T)$$

$$s.t. \begin{cases} \sum_{i=1}^{T} x_i \le A \\ n_i(x_i) \le L, (i = 1, 2, \ldots, T) \\ x_i = 0, \quad \sum_{j=1}^{m} c_j(x_i) \le 0, (i = 1, 2, \ldots, T) \end{cases}$$

1) The total amount of subsidy does not exceed a total budget of A over T years;

2) The number of LEVs purchased each year does not exceed a specific number (or a certain proportion when the total number of vehicles changes);

3) The amount of subsidy is less than the loss of revenue resulting from purchase and operation of LEVs in each year.

CASE STUDY

The adaptability and accuracy of this model was tested with data from the Beijing Public Transportation Group. For this experiment the following conditions were assumed:

- Bus companies receive ￥5 billion in government subsidies to support the purchase and operation of LEVs over five years;
- Bus companies plan to buy parallel hybrid electric vehicles (PHEVs) to replace diesel hauled buses (DHBs);
- Bus companies will spend all the subsidy money available to purchase PHEVs.

Table 1. Cost Calculation System (10,000￥).

Power	Cost calculation system	2009	2010	2011	2012	2013
DHB	Acquisition cost	73.40	72.67	71.94	71.22	70.51
	Fuel cost	126.10	129.89	133.78	137.80	141.93
	Maintenance cost	10.80	10.80	10.80	10.80	10.80
	Total economic cost	**210.30**	**213.36**	**216.52**	**219.82**	**223.24**
	Upper environmental cost	11.22	12.34	13.58	14.93	16.43
	Lower environmental cost	18.62	20.48	22.53	24.78	27.26
	Total environmental cost	**29.84**	**32.82**	**36.11**	**39.71**	**43.69**
PHEV	Acquisition cost	123.60	102.42	91.06	81.95	75.47
	Fuel cost	113.49	115.73	118.01	120.33	122.70
	Maintenance cost	11.88	11.77	11.67	11.59	11.51
	Total economic cost	**225.67**	**221.92**	**220.74**	**220.87**	**221.68**
	Upper environmental cost	10.10	11.00	11.98	13.04	14.20
	Lower environmental cost	16.76	18.25	19.87	21.64	23.57
	Total environmental cost	**26.86**	**29.25**	**31.85**	**34.68**	**37.77**

Source: Beijing Public Transit Group

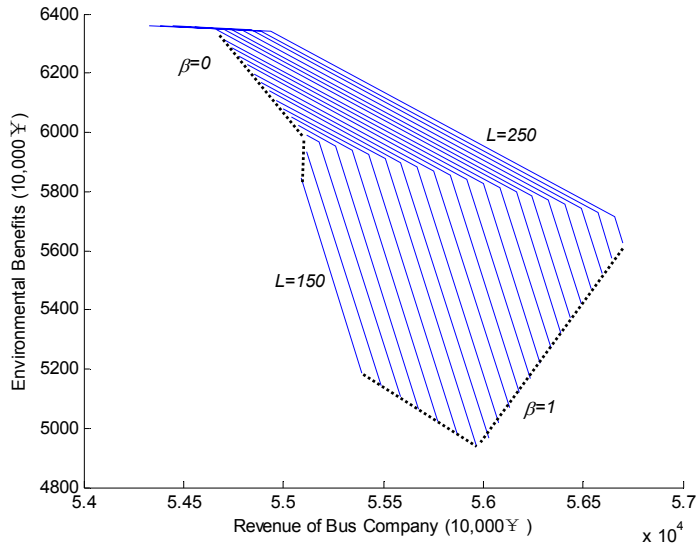

Figure 1. Optimizing Results under Different Scenarios.

Values were calculated using the following assumptions:

- The cost of PHEV acquisition includes the cost of engines/motors/batteries, research and development, and non-power systems;
- Price trends over the period of analysis were corrected for linearity;
- Vehicles travel 50,000 kilometers each year;
- Fuel consumption of a DHB (diesel-hauled bus) is 40 liters per 100 kilometers, while PHEVs are assumed to consume 90% of this rate and to reduce every year;
- Diesel fuel prices increase 3% annually;
- The environmental cost of CO_2 increases 10% annually.

Using these assumptions, the model was optimized for values of β between 0.00 and 1.00 in increments of 0.01; and for values of L between 150 and 250 in increments of 5. The resulting graph is shown in Figure 1, and selected results are shown in Table 2.

Table 2. Optimized Results (x_1~ x_5, **10,000￥**).

β	L	x_1	x_2	x_3	x_4	x_5
0.00	150	18510	15405	13785	2300	0
0.50	150	18510	15405	13785	2300	0
1.00	150	8630	15405	13785	12180	0
0.00	250	30850	19150	0	0	0
0.50	250	1350	25675	22975	0	0
1.00	250	0	25675	22975	1350	0

The results showed that the optimal strategy changes for different weightings of benefits preference. When β is relatively small and more concern is given to environmental benefits, environmental benefits are higher in earlier years and thus subsidies should be focused on earlier years. As β increases and concern for environmental benefits decreases, benefits are higher in later years and thus subsidies should be focused on later years. The value of limitation on the number of PHEVs bus companies purchase (L) also influences the optimization results, in that the total revenue boundary extends as the limitation constraint increases.

The results show that increasing weighting of environmental benefits may greatly decrease economic benefits; this is indicated by the dotted lines in Figure 1, whose slope are relatively small. It is therefore important to fix an appropriate value for β to balance between the economic interests of bus companies and the environmental interests of society.

CONCLUSIONS

This paper proposes a metrological model to evaluate and optimize the subsidy strategies of encouraging transit companies to purchase and operate LEVs, using different weightings of environmental benefits. The results of the case study using this model show that varying the weighting coefficient has the potential to influence the optimal result.

ABSTRACT

It is very important for the gas engine to improve its fuel economy, low emission and power performance. To solve this problem, the air fuel ratio should be controlled accurately. In order to keep the air fuel ratio around 16.7, an air-fuel ratio parallel control method, which is based on CMAC neural network and PID, is adopted and its arithmetic is elaborated in this paper. The parallel control method is also compared with the one using PID only. The simulation result shows that air fuel ratio could be controlled at the range of 16.7 by the parallel control method.

PURPOSE OF CONTROL SYSTEM

The A/F ratio control system could adjust the gas injection automatically when its concentration changes, so that the A/F ratio keeps at the range of the ideal value. Therefore, the engine could operate steadily, and the power and rotate instability, the inlet backfire, the blow of the outlet could be avoided.

DESIGN PROPOSAL OF THE CONTROL SYSTEM

The control system as shown by Fig. 1 consists of four parts: sensor signals\sensor processing circuit, A/F ratio controller, gas injecting valve.

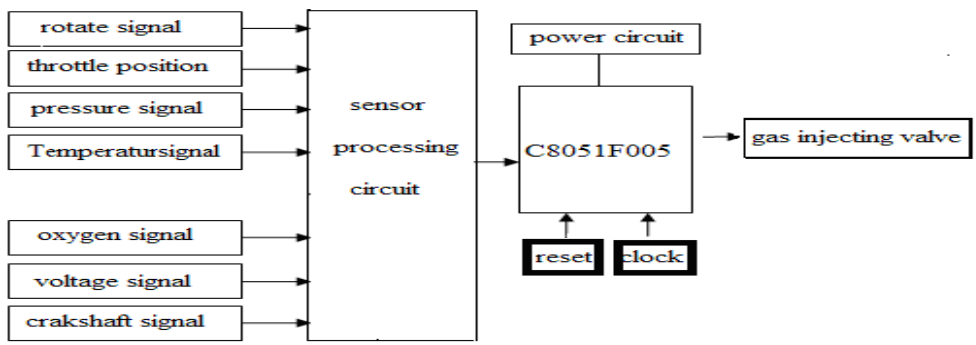

Fig. 1. Gas engine A/F ration control schematic.

After processing, sensor signals are put into the electronic control unit (ECU). With analysis, the needed optimal A/F ratio is determined and according to the A/F ratio, the injecting pulse is calculated. The single chip microcontroller (SCM) then adopts the PWM to adjust the suitable pulse width.

REACH ON CONTROL STRATEGY OF SYSTEM

The core of the control system is to determine and realize the control arithmetic (*Martin Brown, 1994*). The suitable control arithmetic should have the tiny steady state error, quick dynamic response, and good robustness. In terms of A/F control system, the purpose is to make the A/F ratio mean value of the steady working condition close to the ideal value. Besides, the A/F ratio deviates from the target value as the engine working condition changes suddenly, at that moment, the control system should respond quickly and control the A/F close to the target value, wile avoiding the situation occurrence of poor engine emission. In view of the engine high nonlinearity and its time delay, the A/F ratio control method based on CMAC and PID parallel control is put forward.

PID Control Theory and Its Problem. PID control has strong robustness, little dependence on model, and is prone to realize in engineering, so it is widely used in industry. The control method only using PID could not realize the control of large pure-lag and big inertia segments. Additionaly, the controlled plant has some variability, the conventional PID parameters possess no self-adapting ability, and it is difficult to meet the actual control needs. At the present time, the setting and optimizing of PID parameters depends mainly on the technicist regulating manually and the control effect is limited by their experience and level largely, besides, plenty of manpower, physical resources and time are wasted.

Summarize of the CMAC. Cerebellar Model Articulation Controller (CMAC) is a query by form self-adapting neural network; it is used to express complicated nonlinear functions (*C. C. Lin, 2001*). The network could change the content of the form by learning and has the ability to store information classically.

CMAC is acknowledged as the important part of the associate memory neural network. It could learn any dimensions nonlinear mapping (*Hecht-Nielsen R, 1989*). CMAC arithmetic could be effectively used in nonlinear approximation of function, dynamic modeling, control system designing, and so on. CMAC has better nonlinear approaching ability, is suitable to control nonlinearly, and is timely in the complex dynamic situation.

CMAC consists of an input layer, a middle layer, and an output layer. Between the input layer and middle layer, the function relation is the input layer nonlinear mapping, and between the middle layer and the output layer is the output weight self-adapting linear mapping.

CMAC designing way consists of three steps:

(1) Quantizing (concept mapping)

In the input layer, the N-dimension space is divided, and every input is in the hypercube unit of N-dimension grid. To any input, the output is a nonzero value only in several space intervals. The number of the nonzero value space

intervals is norm parameter C, and the size influencing the network output area in the inner network is determined by the norm parameter.

(2) Address mapping (actual mapping)

By dividing the remainder, the input sample is mapped to the concept storage address, and divide a number, the remainder is the actual storage address. That is, C numbers of units in the concept storage are mapped to the C numbers of addresses in the actual storage.

(3) CMAC function calculating (CMAC output)

After the input is mapped to C numbers of units of the actual storage, every unit store the corresponding weight value, and the CMAC output is the weighting sum of C numbers of actual storage units.

Gas Injection Control Strategy of Gas Engine Based on CMAC and PID Parallel Control. CMAC and PID parallel control method is adopted in the control system, CMAC is the feed forward control, and PID realizes the feedback control of the inverse dynamics model of the controlled plant. The stability of the system is guaranteed and the perturbation is inhibited. That makes the system have better stability and robustness in the high-responding speed and nonlinear conditions (*Lino Guzzella, 1995*). A control diagram is shown in Fig.2. Firstly, the A/F value is compared with the setting value, adjusted by the PID controller, and the output controls the system; the sampled rotate signal, throttle position signal, cylinder temperature signal, gas pressure signal, and the oxygen signal is processed. Those and the output of the PID controller are then both used to train the CMAC control arithmetic.

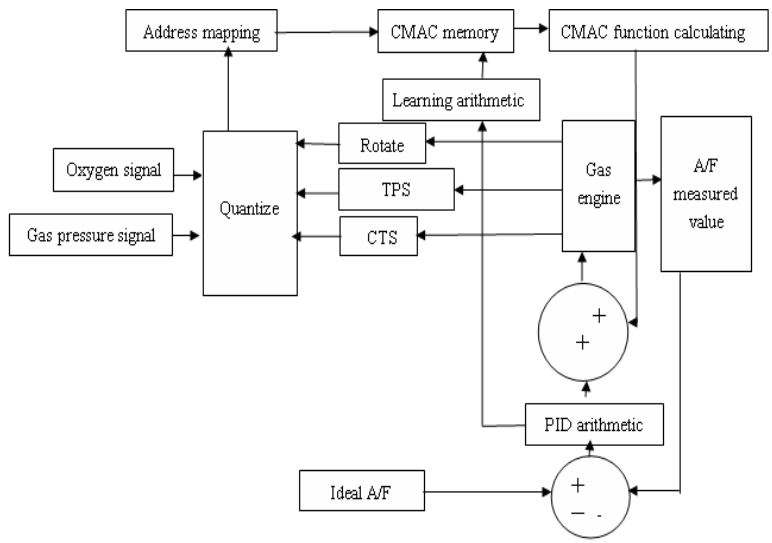

Fig. 2. CMAC and PID parallel control diagram.

SIMULATING AND ANALYZING OF THE CONTROL STRATEGY

The A/F control method of coal bed gas engine is simulated by Simulink. Fig.3 shows the simulation diagram based on the PID and the control diagram based on the CMAC and PID parallel control is shown in Fig.4.

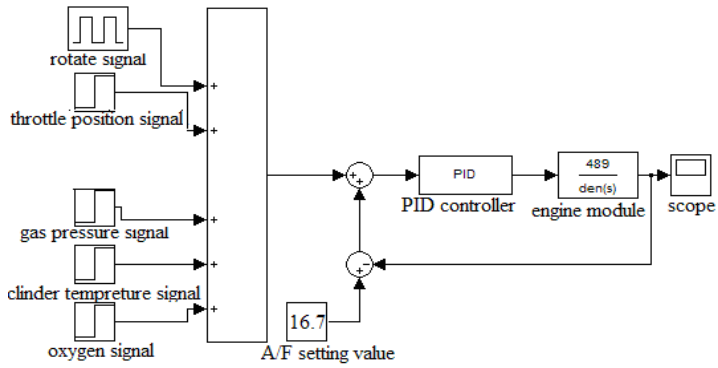

Fig. 3. Simulating diagram of A/F control based on PID.

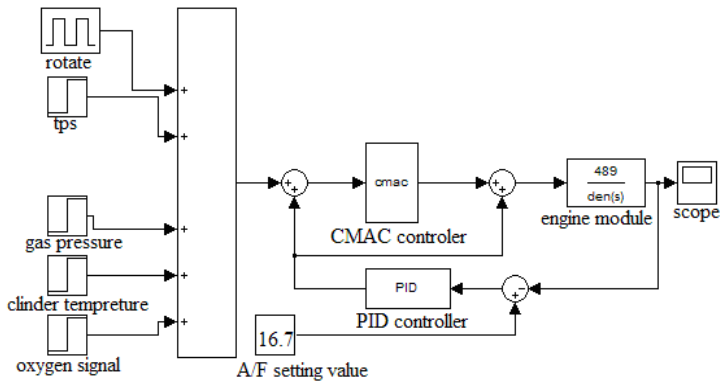

Fig. 4. Simulation diagram of A/F parallel control based on CMAC and PID.

The input signals include a rotate signal, throttle position signal, cylinder temperature signal, gas pressure signal, and A/F setting value and measuring value. When simulating, the step signal or pulse signal are the input signals. The A/F setting value is 16.7, and PID controller calls for the PID function of the simulation toolbox and CMAC is compiled using M-function.

Fig.5 and Fig.6 shows the simulation results.

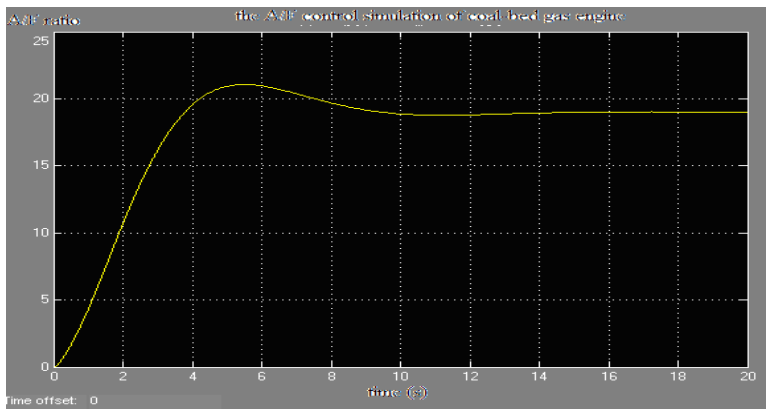

Fig. 5. Simulation result of A/F control based on PID.

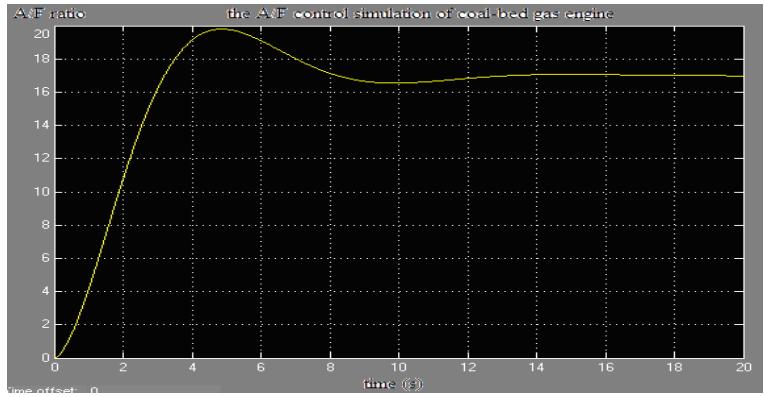

Fig. 6. Simulation result of A/F parallel control based on CMAC and PID.

The simulation result shows that:

(1) Steady state response

After adjusted by PID, the A/F is only controlled about 19, and the steady error is bigger; however, by the parallel control based on CMAC and PID, the A/F could be steadily kept among the range of 16.7.

(2) Dynamic response

After adjusted by PID, the overshoot, adjusting time, raising time and peak-time is shown in Table 1.

But by the parallel control based on CMAC and PID, the overshoot, adjusting time, raising time and peak-time is shown in Table 2.

Table 1. Dynamic PID response.

overshoot (δ_p)	adjusting time (t_s)	raising time (t_r)	peak-time (t_p)
$\delta_p \approx 30\%$	$t_s \approx 11s$	$t_r \approx 3.5s$	$t_p \approx 5.5s$

Table 2. Dynamic CMAC and PID response.

overshoot (δ_p)	adjusting time (t_s)	raising time (t_r)	peak-time (t_p)
$\delta_p \approx 17\%$	$t_s \approx 13s$	$t_r \approx 3s$	$t_p \approx 5s$

From the results, we can come to the conclusion that by adding CMAC, the steadily state error becomes smaller and the control accuracy is improved, while the overshoot becomes smaller.

CONCLUSIONS

The simulation results show that at the beginning, only the conventional PID controller takes effect in the parallel controller based on CMAC and PID. After learning from the output of conventional controller, the CMAC plays the role of controlling instead of PID gradually. In this method, some drawbacks that the conventional controller could not avoid, are overcome to some extent, and the

control effect is improved accordingly. The controller in the paper has better self-adapting ability and strong robustness and could follow the desired value of engine A/F well. The power performance and fuel economy are both improved in addition to avoiding a less effective emission

Design of Intelligent Decision Module for Storage Location Assignment in AS/RS

ZHU Yanru [1], ZHOU Guiliang[1] and MAO Lina[1]

[1]Transport Engineering Department, Huaiyin Institute of Technology, Huaian 223003, China; e-mail: zgl_transport@126.com

Abstract: The paper points out the importance of storage location optimization in Automated Storage and Retrieval Systems to the logistics enterprises, analyzes the general situation of current storage location assignment methods and reveals their shortcomings. It then designs the intelligent decision module for storage location assignment, including the background and flow of the design, the mathematical model construction on optimizing the storage location assignment, the model solution based on the genetic algorithm, the operation tested by simulation, etc. Finally, it concludes that the module provides technical support for the logistics enterprises to develop the automated warehouses, and has positive significance for leading the development of automated warehouse to intellectualized direction.
Key words: AS/RS, storage location assignment, optimization, simulation

1 Introduction

The Automated Storage and Retrieval Systems (AS/RS) is a modern logistics facility which integrates storing, handling, conveying, and distribution into one system. It is an important part of plant logistics system. In order to manage the AS/RS effectively, improve the whole operation efficiency, reduce the cost of goods handling and storing, decrease the overstocking of the funds, reduce the time loss during the process of storing and handling, and then reduce the logistics cost, and increase the income accordingly, it is necessary to optimize the storage location. It is based on this thought that the paper constructs the intelligent decision module on storage location assignment by making use of the intelligent, information technologies. It plays an important role in promoting the utilization ratio of the storage location, cutting down unnecessary workload, and saves large amounts of manpower and material resources and helps the managers to make rapid, proper decisions in the increasingly fierce competition.

2 Analysis on the Methods of Storage Location Assignment in AS/RS

For the storage location assignment in AS/RS, there are primarily three types of principles: random storage, designated storage and classified storage. Aiming at that there are some shortcomings in practical application of the principles mentioned above, for example, the storage location assignment policy lacks pertinence in the

real-time operation of stacker, the paper constructs the intelligent decision module for storage location assignment by taking the minimum stacker travel time as principle and using the simulation optimization technology to avoid these problems.

3 The Intelligent Decision Module Design on Storage Location Assignment in AS/RS

3.1 Environment and flow of the intelligent decision module design

The paper takes the AS/RS of Jiangsu Feiliks International Logistics Inc. as an example to study. The warehouses of Feiliks contain general warehouse, constant temperature warehouse and high-value warehouse. The functional areas of warehouses are divided into receiving area, pending disposal area and dispatch area, etc. The area of general warehouse is 26,000 square meters; the shelves are standardized 20 floors entirely, with 29,500 storage locations. The handling operation equipments consist of 7 sets of forklifts and stackers respectively. It is the background and basis to design the intelligent decision module. The module has taken Microsoft Access 2000 as the back-end database, the advanced language Microsoft Visual Basic6.0 as the front-end development tool (Chen, Ning et al 2007). It has integrated the optimization simulation model with GA optimization algorithm and Flexsim simulation platform. The design has adopted the object oriented idea and made full use of the flexibility and reliability of the Intelligent Decision Support System (IDSS). The design flow chart of the module is shown in figure 1.

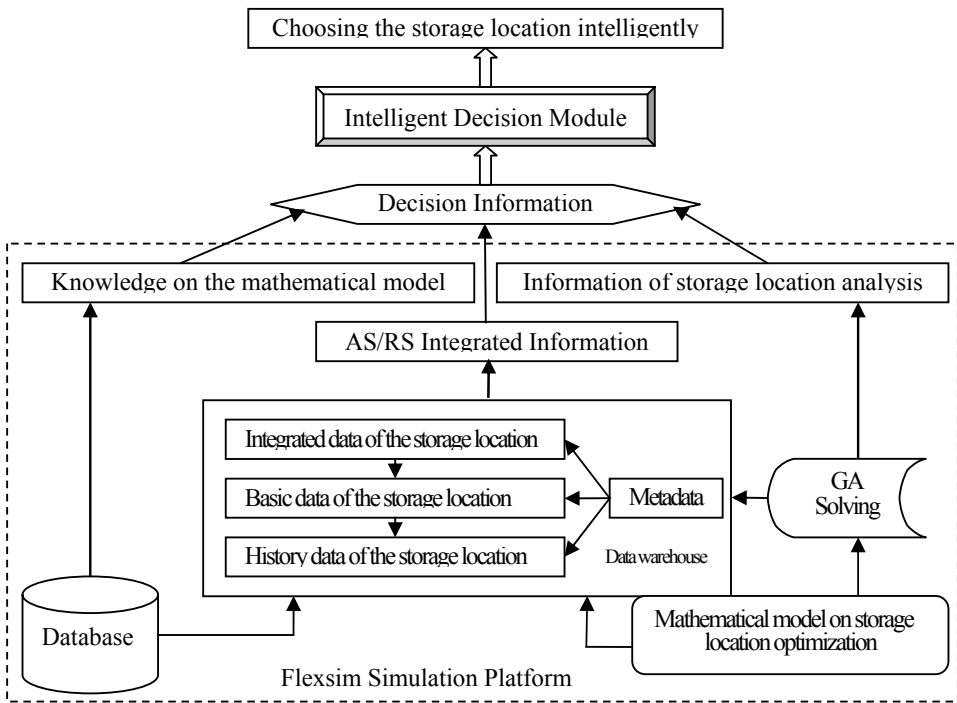

Figure 1. Design flow chart of the module

3.2 Constructing of the mathematical model on storage location optimization

Due to the complexity and diversity of the goods stored in AS/RS, we construct the mathematical model on storage location optimization with main considerations of several principles as below: (1) Heavy cargoes should be placed on the lower shelves in warehouse and light cargoes should be placed on the upper shelves, as to stabilize the force on shelves. The materials should be stored dispersedly lest the excessively concentrated storage lead to uneven loading on the shelves (Cou, Yang et al 2003). (2) When assigning the storage location, it is necessary to take improving the warehousein/warehouseout efficiency into account as much as possible. (3) The goods should be dispersedly placed beside several laneways lest the obstruction of certain laneway affect the passing of some materials. (4) Adopt the "First In First Out" principle (FIFO), that is, for the same kind of goods, the earlier it enters the warehouse, the earlier it leaves, as to accelerate the turnover of the materials and avoid loss caused by overstocked materials (Liu, S. C. et al 2003). In order to optimize the storage location in AS/RS, the paper makes pre-division of the storage location with consideration of the stacker running speed; and then establishes a mathematical model on the assignment problem considering many comprehensive affecting factors such as the storage characteristic code of the goods and so on.

Given the actual situation of the AS/RS in the example, the warehouse area is divided into 7 parts: A, B, C, D, E, F, and G. There are 7 laneways, 14 rows of shelves in total. Each shelf has 20 floors in a row and 20 columns in a floor with 500×500 cell-grids. In the process of calculating the operating cycle, the given constants are: the horizontal velocity of the stacker v_x =80m/min, the vertical velocity of the stacker v_z =63 m/min, the height of the shelf H=10,000mm. The mathematical model on storage location optimization is constructed as below:

$$\min \sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{k=1}^{n} a_k \frac{2\times abs\{\max[\frac{(Z-1)h_0}{v_z}\ ;\frac{(X-1)l_0}{v_x}]\}}{t_c} x_{ijk}$$

In:

$$\sum_{i=1}^{n_1} x_{ijk}=1 \qquad j,k=1,2,3,...,n; \qquad \sum_{j=1}^{n_2} x_{ijk}=1 \qquad i,k=1,2,3,...,n;$$

$$\sum_{k=1}^{n_3} x_{ijk}=1 \qquad i,j=1,2,3,...,n; \qquad x_{ijk}=0 or 1 \qquad i,j,k=1,2,3,...,n$$

$x_{ijk}=1$ Denotes that the goods j be placed in area i by using NO. k stacker;

a_k ——the gravity effect coefficient on the shelf when using the NO. k stacker;

t_c——storage time of the goods ; Z——layer numbers ; X——number of columns ; v_z——the vertical velocity of the stacker; v_x——the horizontal velocity of the stacker; h_0——height of single storage location; l_0——width of single storage location.

3.3 Solving of the mathematical model

There are many methods to solve the mathematical model, mainly including Hungary algorithm and GA. Considering the actual situation of the model and example and the convenient operation, strong robustness and optimizing ability of the GA on solving the combinatorial optimization problem, the paper mainly uses GA to optimize the storage location assignment problem. The paper has constructed GA to solve the decision problem on goods warehousein by using the ergodicity of optimization and the searching mechanism of GA. The basic idea is: coding the alternative storage location with the natural number through the natural number coding method. The genic value of each individual in chromosome is the storage location of corresponding goods. In the genetic operation, in order to avoid the partial optimum and accelerate the searching speed, the adaptive adjusting crossover and mutation probability is adopted. The parameters of the model are chosen as bellows: the population number of the GA P=20, the crossover probability pc=0.7, the mutation probability pm=0.02. The fitness value graph of solving the model by GA is shown in Figure 2. By solving the basic steps such as obtaining the algorithm data, calculating the fitness value of the current chromosome, choosing the fitness value for the function, judging the ending criterion, carrying out crossover and mutation on chromosomes and outputting the final solution, etc. The final solving results of the model are shown in Table 1.

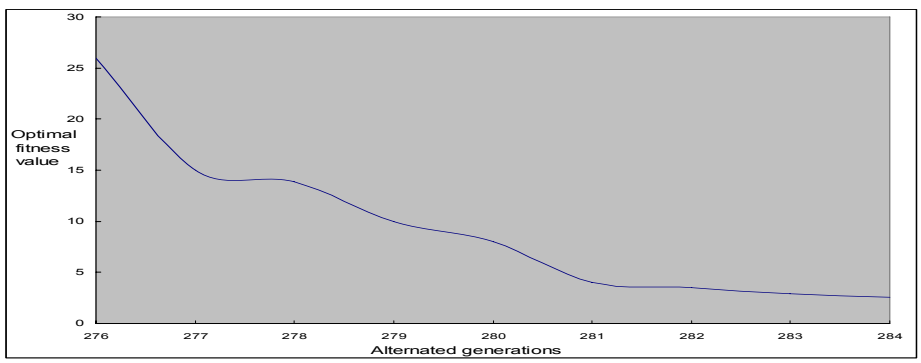

Figure 2. The fitness value graph of solving the model by GA

Table 1. Solving results of the intelligent decision model on storage location assignment

Number of the warehousing goods	Sub area number	Length (mm)	Width (mm)	Height (mm)	Weight (kg)	Results of manual decision	Results of algorithm decision
						Storage location number	Storage location number
20090211822	A	450	300	380	18	A020413	A020413
20090211823	A	450	300	250	12	A020515	A020512
20090211824	G	480	450	450	25	G140205	G140205
20090211825	C	300	300	300	10	C091618	C091717
20090211826	D	300	350	380	14	D100713	D100714
20090211827	B	480	300	300	16	B070609	B070609

From figure 2 and table 1, we can see that the model algorithm can choose the suitable storage location for each goods to be put into the warehouse quickly. With the increase of the cyclic alternated generations, the optimization effects become more obvious.

3.4 Simulation of the intelligent decision module

In order to evaluate the mathematical model above, we need to carry out simulation for it. We choose Flexsim as the simulation tool. The Flexsim has adopted the object-oriented technology and possessed the three-dimensional display (3D) function. Moreover, the important characteristics of the software lie in quick and convenient modeling and the powerful displaying ability. The functions provided by this software contain original data fitting, input modeling, graphic model constructing, virtual reality (VR) displaying, operating the model to do simulation tests, optimizing the results and generating the 3D animation image files, etc. The running interface of the intelligent decision module through Flexsim is shown in figure 3. The dynamic variation graph of the storage location during certain time segment is shown in figure 4.

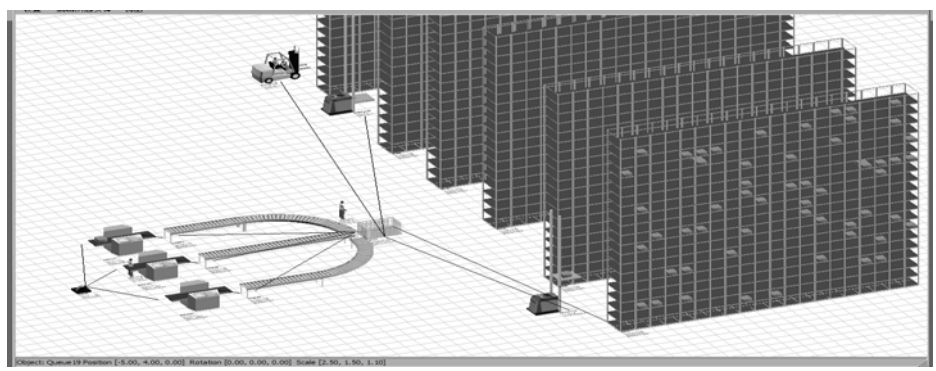

Figure 3. The simulation running interface of the module

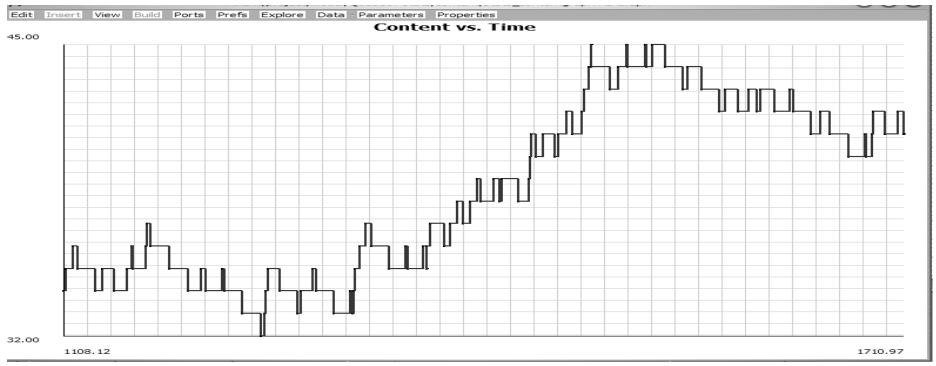

Figure 4. The dynamic variation graph of the storage location during certain time segment

According to the simulation running situation, the intelligent decision module for storage location assignment has promoted the warehousein/warehouseout efficiency of the goods, shortened the operating path of the stacker and achieved comparatively satisfactory results.

4 Conclusions

Based on the simulation result and practical application, the intelligent decision module for storage location assignment is able to choose the appropriate storage location relatively correctly according to the nature and characteristics of the goods. Meanwhile, it has reduced the waiting time of the warehousein/warehouseout operation evidently and has the ability to respond to much higher frequency operations. Thus, it has provided technology support for establishing rapid and efficient material warehousing system with high flexibility as to adapt to the increasingly fierce market competition and the diversity and convenience requirements of the customers. It has positive significance for leading the development of automated warehouse to intellectualized direction.

Optimization of Open Vehicle Route to Reduce Fuel Consumption Based on Genetic Algorithm

PENG Yong[1], ZHU Haiying

[1]Key Laboratary of Traffic & Transportation, Chongqing Jiaotong Univ., Chongqing 400074, China; Phone: (86)13637948336; Email: pengyong818@sohu.com

Abstract: In the classical version of Vehicle Routing Problems, the vehicles are required to return to the depot after completing service. In open Vehicle Routing Problems, however, the vehicles need not do so. Just like Vehicle Routing Problems, almost all the research papers of open Vehicle Routing Problems focus on minimizing the sum of travel distance. However, vehicle managers are also interested in vehicle routing schedules that minimize fuel consumption. This paper presents a new open vehicle routing problem based on reducing fuel consumption. That is, the optimization objective of the open vehicle routing problem is to minimize the fuel consumption. Then the paper formulates a mathematical model for this problem and develops a genetic algorithm to solve this NP-hard problem. A numerical example is used to demonstrate the operation validation of our genetic algorithm, and to compare the different routing schedules of the open and closed versions of the same problem.

Keywords: open VRP, fuel consumption, routing schedule, genetic algorithm

1 Introduction

In the classical version of Vehicle Routing Problems (VRPs), the vehicles are required to return to the depot after completing service. In open VRPs (Tarantilis, C. D. et al 2005; Li, L. and Fu, Z., 2002; Tarantilis, C. D. et al 2002; Fu, Z. et al 2005), however, the vehicles need not do so. As a result, the vehicle routes are not closed paths but open ones, starting at the depot and ending at one of the customers. Just like VRPs, almost all the research papers of open VRPs focus on minimizing the sum of travel distance (travel time). However, vehicle managers are also interested in vehicle routing schedules which minimize fuel consumption due to two factors. First, reducing fuel consumption means reducing the service cost. Second, reducing fuel consumption means reducing its impact on our environment (green-house effect), our health (air pollutants), and our economy (increased fuel prices).

This paper will present a new open vehicle routing problem based on reducing fuel consumption. That is, the optimization objective of the open vehicle routing problem is to minimize the fuel consumption. Then the paper will provide this problem's mathematical model and develop a genetic algorithm (GA) to solve this NP-hard problem. A numerical example will be used to demonstrate the

operation validation of our genetic algorithm, and to compare the different routing schedules of the open and closed versions of the same problem.

2 Problem Formulation

Our problem can be formally described in the following way: there is one central depot, which uses some independent delivery vehicles with identical delivery capacity to serve demands of some customers. We know the amount of fuel consumption for each kilometer without load, and the addition amount of fuel consumption for each kilometer with unit load. The vehicles must accomplish the delivery with minimum total fuel consumption.

Let N denote the set of indices of customers with node 0 denoting the depot, and V denote the set of indices of vehicles. All feasible vehicle routes correspond to paths start from one depot and end at the same depot. Let $d_{ij}, i, j \in N$ be the distance from i to j. Let $d_{i0} = 0, i \in N$, then we can treat the open vehicle routing problem as VRP.

Let $q_i, i \in N$ be the demand of node i, and C be the capacity of vehicle. Since node 0 denotes the depot, let $q_0 = 0$. Let $Q_{ik}, i \in N, k \in V$ be the load on the vehicle k when arriving at node i. Let c_0 be the amount of fuel consumption for unit distance without load. Let c_1 be the addition amount of fuel consumption for unit distance with unit load.

We define the decision variables $x_{ijk} = 1(i, j \in N, i \neq j, k \in V)$ if arc ij is part of the route for vehicle k, otherwise, $x_{ijk} = 0(i, j \in N, k \in V)$. Since the vehicle k loads goods of all the customers at the depot (node 0), let $Q_{0k} = \sum_{j \in N} q_j x_{ijk}$.

Then the problem can be formulated as follows:

$$\min \quad z = \sum_{k \in V} \sum_{i \in N \setminus \{0\}} \sum_{j \in N, j \neq i} (c_0 + c_1 Q_{jk}) d_{ij} x_{ijk} \tag{1}$$

s.t.

$$\sum_{j \in N} \sum_{i \in N, i \neq j} q_j x_{ijk} \leq C, \forall k \in V \tag{2}$$

$$\sum_{i \in N} x_{ijk} = \sum_{i \in N} x_{jik}, \forall j \in N, \forall k \in V \tag{3}$$

$$\sum_{k\in V}\sum_{i\in N} x_{ijk} = 1, \forall j \in N \setminus \{0\} \tag{4}$$

$$\sum_{i\in N} x_{0ik} \le 1, \forall k \in V \tag{5}$$

$$\sum_{k\in V}\sum_{i,j\in U} x_{ijk} \le |U| - 1, \forall U \subseteq N \setminus \{0\} \tag{6}$$

$$(Q_{ik} - q_i - Q_{jk}) x_{ijk} = 0, \forall i \in N, \forall j \in N \setminus \{0\} \tag{7}$$

The objective function (1) is to find the vehicle routing schedule with minimal fuel consumption. Constraint (2) ensures that the load of each vehicle cannot exceed its capacity. Equation (3) tells us that if vehicle k visits a node then it will also leave from the same node. Equation (4) guarantees that every customer is served by one and only one vehicle. Constraint (5) ensures that a vehicle departs only once from depot 0. Constraint (6) forbids routes that are not connected with depot 0. Constraint (7) ensures that, when $x_{ijk} = 1$, the load Q_{jk} of vehicle k between node i and node j equals the load Q_{ik} of vehicle k arriving at node i minus the demand q_i of node i unloading at node i.

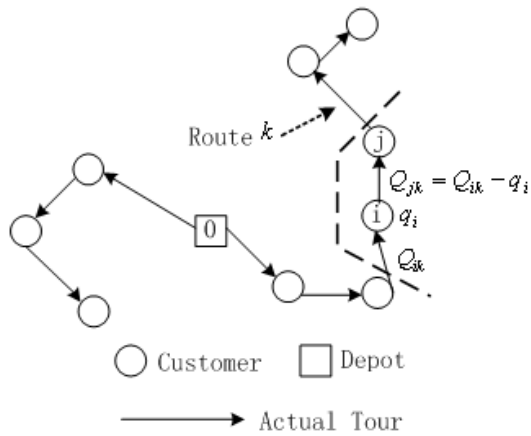

Fig.1 The relationship between Q_{ik} and Q_{jk}

3 GA algorithm for our problem

3.1 Encoding

To solve our problem with GAs, we can represent each individual by just one chromosome, which is a chain of integers, each of them representing a customer or a vehicle. So that each vehicle identifier represents in the chromosome a separator between two different routes, and a string of customer identifiers represents the sequence of deliveries that must cover a vehicle during its route. In the figure below

we can see a representation of a possible solution for our problem with 9 customers and 4 vehicles. Each route begins at the depot (it will be assigned the number 0) and ends at the last customer of the route. If we find in a solution two vehicle identifiers not separated by any customer identifier, we will understand that the route is empty and, therefore, it will not be necessary to use all the vehicles available.

$$\underbrace{1 \to 3 \to 2}_{\text{route1}} \to 10 \to \underbrace{7 \to 4 \to 9 \to 6}_{\text{route2}} \to 12 \to 11 \to \underbrace{5 \to 8}_{\text{route3}}$$

Fig.2 A representation of One Individual

3.2 Fitness function

The fitness function is given by the following equation:

$$fitness \qquad z = \sum (\sum \sum (c_0 + c_1 Q_{jk}) d_{ij} + \psi)$$

Where, ψ is a large number if constraint (2) is violated. Otherwise, $\psi = 0$.

3.3 GA algorithm

Now, we can provide the GA algorithm based on Inver-over operator (Michalewicz Z. et al., 2000) as follows.

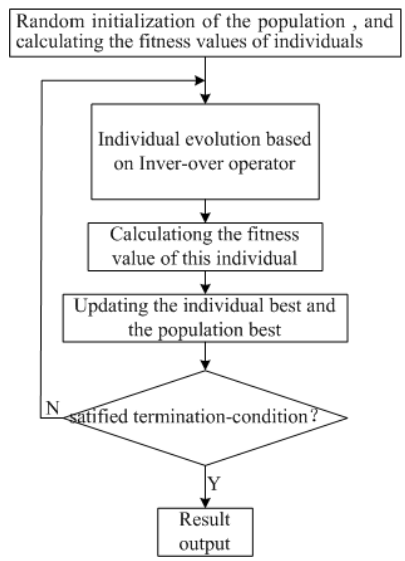

Fig.3 The calculating process of our GA

4 Numerical Example

Provided that there are 20 customers, all the information is shown as follow.

Table 1 Customer Data

Index	Location	Demand	Index	Location	Demand
0(depot)	(94,99)	-	-	-	-
1	(98,43)	6	11	(49,19)	4
2	(58,90)	6	12	(19,73)	1
3	(97,93)	2	13	(38,23)	3
4	(11,65)	5	14	(67,17)	2
5	(75,85)	5	15	(38,5)	3
6	(69,36)	2	16	(74,36)	1
7	(30,85)	2	17	(63,68)	1
8	(22,14)	3	18	(12,68)	3
9	(57,16)	4	19	(103,8)	1
10	(55,13)	1	20	(71,15)	2

Table 2 Model Parameter Settings

Parameter	Value
Vehicle Capacity	20
c_0	0.1
c_1	0.0005

Let the population size be 50, maximum generation be 2000, and $p = 0.2$ (the selection probability our GA based on Inver-operator needs). With our GA, the result suggests that the vehicle number is 4. The total optimal fuel consumption is 43.006. Figure 4 gives one of the solutions by our GA.

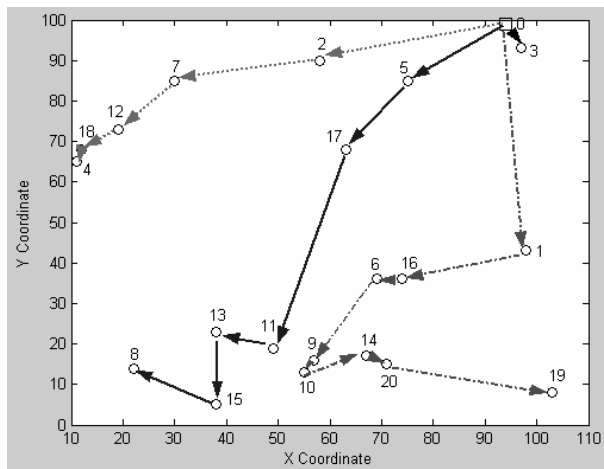

Fig.4 One solution by our GA

The routes are:

$0 \to 1 \to 16 \to 6 \to 9 \to 10 \to 14 \to 20 \to 19$;

$0 \to 5 \to 17 \to 11 \to 13 \to 15 \to 8$;

$0 \to 2 \to 7 \to 12 \to 18 \to 4$;

$0 \to 3$.

Compared to the closed version of the same problem shown in figure 5, the open version of this problem really has a different routing schedule. If we restrict the

vehicle number to 3, we get the solution shown in figure 6, the fuel consumption of which increases to 48.166.

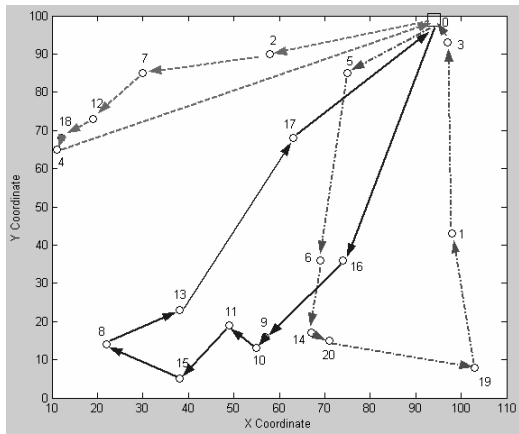

Fig.5 Solution of the closed version of the same problem

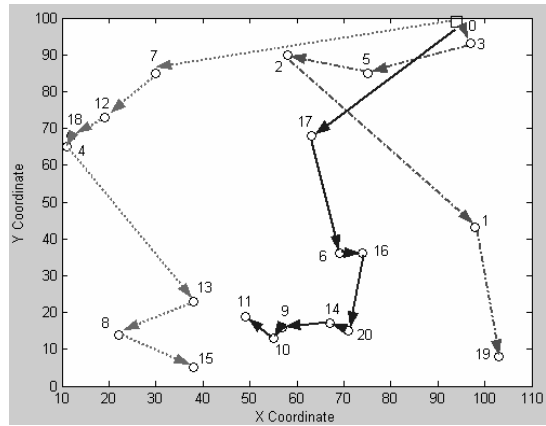

Fig.6 Solution of our problem with 3 vehicles

5 Conclusion

Due to various reasons, vehicle managers are interested in the open vehicle routing schedules which minimize fuel consumption. This paper presents a new open vehicle routing problem based on reducing fuel consumption. That is, the optimization objective of the open vehicle routing problem is to minimize the fuel consumption. Then the paper provides this problem's mathematical formulation and develops a genetic algorithm to solve this NP-hard problem. A numerical example is used to demonstrate the operation validation of our genetic algorithm, and to compare the different routing schedule of open and closed versions of the same problem.

Research on Location of Railway Logistics Center

Xionghuan Jin, Haihong Xie, Bo Jiang, Lan Xu

MOE Key Laboratory for Transportation Complex Systems Theory and Technology, School of Traffic and Transportation, Beijing Jiaotong University, Beijing 100044, China. Email: 07121344@bjtu.edu.cn. Tel: (0086)13811921647

Abstract: Transportation has been greatly influenced by the development of logistics with its characteristics of new management concept and organizational form. Logistics center has been a new trend for railway freight stations. This paper brings forward a location method for logistics center based on existing railway freight stations. It first analyzes location influencing factors of railway logistics centers and proposes to select alternative logistics centers by cluster analysis. It then constructs a mathematical location model to re-select within alternative logistics centers. At the same time, genetic algorithm is applied to seek the optimal solution, and the result is that one or more freight stations are selected to be developed into logistics centers. Finally, a numerical example is given to validate this method.
Key word: Railway logistics, genetic algorithms, cluster analysis, location

INTRODUCTION

Railway transportation has played a crucial role in general freight transportation in China with its outstanding advantages of large volume, round-the-clock operation, less pollution and safety. But the development of modern logistics in railway industry lags behind the requirements of society and China's economy, which hinders the complete utilization of abundant resources and capability of railway transportation, making it difficult to improve the efficiency and benefit of railway transportation. The small-scale, scattered and disorderly freight stations are the main reason that limits the development of modern railway logistics. Thanks to the massive railway construction and layout optimization of railway transportation capability as a whole, it's possible today to transform some existing freight stations into logistics centers. Taking into consideration of regional economic characteristics, technology, equipment conditions and railway facilities, this article preliminary explores the location method of railway logistics center based on the existing freight stations, so as to provide technical reference for railway system planning. This article first adopts cluster analysis to obtain alternative logistics centers after analyzing the location influencing factors of railway logistics center, then constructs mathematical location model and solves this model. The optimal site is determined at the end. It gradually narrows the scope of options in accordance with macro to micro principle.

INFLUENCING FACTORS OF RAILWAY LOGISTICS CENTER LOCATION

To determine the location of railway logistics center, we should first

understand the influencing factors of railway logistics center location. Since this location is based on existing freight stations and environment of economic logistics associated, we can consider it from the areas of the economic environment, policy environment, transport facilities, natural environment and geographical environment.

Table 1 Influencing factors of railway logistics center location

Influencing factors	Detailed influencing factors	Variables and description	
Economic and traffic	Railway turnover	A_{11}	
	Road network density	A_{12}	
	GDP per capita	A_{13}	
	Number of logistics enterprises in the area	A_{14}, take average distance between stations as radius	
	Number of transport hub node	A_{15}, take average distance between stations as radius	
	Land price	A_{16}, take local average level as criteria	
Policy environment	Degree of district administration	$A_{11,}$ according to relative degree, records as 1 to3 individually from low to high	
	Regional supporting policy	A_{22}, 1 expresses enjoyed ,otherwise 0	
Conditions of transport infrastructure	Area of freight station	A_{31}	
	Line capacity	A_{32}	
	Available area of logistics operation	A_{33}	
	External traffic conditions	A_{34}, according to convenience and timeliness, records as 1to3 from low to high	
	Outspread of station	A_{35}, according to degree, of expansion, records as 1 to3	
	Technical condition of railway lines: degree of railway, number of lines, limiting slope, minimum curve radius, traction type, locomotive type, effective length of railway, method of blocking	A_{36}, according to the degree of appropriate, records as 1 to3 from low to high	
	Railway station circumstances: drainage system, box area, road, subgrade and land, yard	A_{37}, same as above	
Natural geographical conditions	Weather conditions	A_{41}	according to the degree of appropriate, records as 1 to3 from low to high
	Hydrological conditions	A_{42}	
	Terrain conditions	A_{43}	

Economic environment is the inherent condition for logistics. The more developed the economy is, the faster the freight flows. Thus it will be more appropriate to set up logistics center. Policy environment is the external condition for the promotion of logistics and is associated with national planning, regional planning and special support; Environmental advantages and disadvantages of transport facilities for the railway system are especially important since the cost of infrastructure transformation of railway lines and stations is relatively high; Natural environment is a main factor to be taken into account. Some factors above are qualitative factors which need to be quantified. Description and treatment of influencing factors are shown in Table 1.

LOCATION MODEL OF RAILWAY LOGISTICS CENTER

Alternative logistics center meets requirements in the railway and economic environment. The following discusses re-location optimization by applying genetic algorithm from the economic view. Railway logistics centers are divided into different types based on their functions. The type of logistics center discussed in this article is mainly based on transportation and has taken other business into account.

Model assumptions

(1) The category and quantity of demand and supply can be predicted in future years. Here it is replaced by existing data;

(2) Railway logistics center collects and distributes bulk cargo, and there are several categories. Here the cost rate is simplified to a unified rate based on the proportion of every cargo;

(3) Transportation costs are linear function;

(4) Railway logistics center is not only the transport entity, but also a third-party service center. Its operating costs is a concave function of flow inside, $W^{\theta} \in (0,1)$, and θ equals 0.5 in this model.

Description of model and parameter

Objective function:

$$\min f(x,z) = \sum_{i=1}^{m}\sum_{k=1}^{l} a_{ik}x_{ik} + \sum_{k=1}^{l}\sum_{j=1}^{n} b_{kj}y_{kj} + \sum_{k=1}^{l} z_k \frac{C}{1+q_k} + \sum_{k=1}^{l} z_k V_k W_k^{\theta}$$

Subject to:

$$\sum_{k=1}^{l} x_{ik} \le S_i \qquad i = 1,2,3.....m$$

$$\sum_{k=1}^{l} y_{kj} \ge D_j \qquad j = 1,2,3.....n$$

$$\sum_{i=1}^{m} x_{ik} = \sum_{j=1}^{n} y_{kj} \qquad k = 1,2,3.....l$$

$$\sum_{i=1}^{m} x_{ik} \le z_k M_k \qquad k = 1,2,3.....l$$

$$\sum_{k=1}^{l} z_k \le P \qquad P = 1,2,3.....N$$

$x_{ik} \ge 0$, $y_{kj} \ge 0$ $(i = 1,2,3.....m\ ;\ j = 1,2,3.....n\ ;\ k = 1,2,3.....l)$

Where:

α_{ik}, x_{ik} ——Unit rates, flow from supply place i to alternative logistics center k;

b_{kj}, y_{kj} ——Unit rates, flow from alternative logistics center k to demand place j;

z_k ——0, 1 variable, 1 expresses selected, otherwise 0;

V_k ——Changeable cost coefficient of alternative logistics center k;

W_k ——Flow of alternative logistics center k (flow of arrival equals flow of departure);

M_k ——Maximum limit flow of alternative logistics center k;

D_j ——User's demand of No j;

S_i ——Supplier's supply of No i;

P ——Max number of railway logistics center in the area;

$\frac{C}{1+q_k}$ ——Fixed operating cost of alternative logistics center k;

Denote $\frac{C}{1+q_k}$ as F_k can be divided into two parts. One is the fixed operating cost for the station, and the other is construction cost of the logistics center. Construction cost varies greatly because of different investment conditions, but here we do not consider it much. The fixed operating cost is mainly incurred by occupying tracks and tasks in tracks. In order to represent the advantages of stations with private lines or potentials of direct transport, denote fixed cost as $\frac{C}{1+q_k}$, in which constant C is the total construction cost, q_k is the number of private lines of station k.

Model solution

The calculation process of genetic algorithm is a typical continuous iterative process. Key steps and parameters are described as follows:

(1) Initialize groups. Choose binary code to give some 5-bit binary string in initialization. The string represents five alternative logistics centers. 1 indicates the alternative logistics center is selected. 0 indicates it is not selected.

(2) If the stop rules are satisfied, the algorithm stops and outputs the result. Otherwise, calculate $f(x,z)$ for every gene code according to the objective function, compare the values of $f(x,z)$, and select the largest $f(x,z)$ and save it in $C_{\max}$ in each generation.

(3) Take $g(x,z) = C_{\max} - f(x,z)$ as fitness function; $C_{\max}$ varies with different

generations. If C_{max} in the next round of iteration appears better than the previous one, upgrade C_{max} as the optimal solution.

(4) In this paper, the standard roulette method is applied to select outstanding code in groups. Adopt decreasing function to obtain crossover probability, from 75% of the first generation to 25% of the last generation, while mutation probability increases with the evolutionary process. The above two tasks ensure fast convergence. Adjust genetic code according to the probability of crossover and mutation of each evolutionary, and prepares for the next round of iteration.

EXAMPLE AND SOLUTION

To verify the correctness of the above algorithm, simulation is done with sample data. Suppose that there are 4 supply places (the largest supply volume are 40, 60, 50, 50), 10 large customers (customer demands are 20, 25, 25, 20, 20, 25, 20, 15, 20, 10 respectively), 5 alternative logistics centers, and no more than 2 logistics centers should be selected. C equals 100 in this model, other relevant data are shown in Table 2 and 3.

Table 2 Rates table

Alternative logistics center	Supply point to the alternative logistics center a_{ik}				From Alternative logistics center to demand points b_{kj}									
	1	2	3	4	1	2	3	4	5	6	7	8	9	10
1	8	7	9	12	7	8	8	7	17	6	9	10	8	7
2	7	9	10	10	9	12	13	6	20	5	7	9	12	11
3	12	17	15	7	12	13	7	9	8	6	5	8	7	8
4	13	14	17	8	6	5	7	9	10	4	3	3	6	5
5	19	13	10	5	6	8	8	7	13	8	9	5	7	9

Table 3 Cost parameters of alternative logistics center

Alternative logistics center (C_j)	1	2	3	4	5
The maximum limit traffic (M_k)	120	100	110	130	105
Fixed costs ($F_k/(1+q_k)$)	100	100	100/3	100	50
Variable cost coefficient (V_k)	75	80	75	80	75

After applying genetic algorithm, the result shows that one logistics center couldn't meet the demand (because the maximum volume for any alternative logistics center is less than 200). The optimal code is 00101, which means the best solution is to choose the third and the fifth alternative logistics center. If iterations are more than 700 times, the fitness value is stabilized at around 900, and the volume through the 2 railway logistics center shows little difference.

Takes 790 times of iteration as example, its fitness value and flow is shown in Table 4.

Table 4 Results of allocation

Optimal genetic code	0	0	1	0	1
Fitness value	0	0	914.0	0	902.0
Flow volume	0	0	57.0	0	47.9

If the amount of supply and demand is stable, we can also perform linear programming to further determine the amount from supply place to railway logistics center and from railway logistics center to the place of demand.

CONCLUSIONS

In this paper, an optimization method of railway logistics center location is proposed. Due to the complexity of the railway system, the factors that need to be considered are complex. We choose cluster analysis method to do hierarchical analysis in macro-level for the purpose of finding alternative logistics centers. As for re-selection, combine railway characteristics to set up the model and introduce genetic algorithm to solve it. The result is some freight stations are selected from the view of economy. Finally it verifies with a numerical example that this method is feasible and reasonable. This paper seeks to make the model match railway operations to the maximum extent. However, the uncertainty of railway flow pathway and diversity of technical standards of railway lines increases the difficulty. Future work is needed to address these issues.

ABSTRACT

At present, the development of the logistics industry is very rapid. Logistics centers play a very important role in a logistics system, and so their location is very important for the effective operation of a logistics system. Introducing the relevant research, this paper presents a logistics center location bi-level programming model based on competition. The bi-level programming model takes into consideration two decision-makers, the distribution center (DC) location planner and the consumer, and also addresses the problem of consumer selection after the distribution center is built. This model has great significance for weighing the total costs of the decision-makers and customers and for studying the optimal location of logistic centers over a long period based on the upper- and lower-level decision-makers in logistic centers. The paper solves the bi-level programming model with a genetic algorithm and proves the model to be more practical.

Key words: Logistics; distribution center; bi-level programming model; genetic algorithm

INTRODUCTION

At present, the development of the logistics industry is very vigorous. Logistics centers play an important role in a logistics system, and their location is very important to the effective functioning of a logistics system. Logistics center location refers to the planning process of selecting a place to establish a logistics center at supply sites and needs sites. A good logistics center location program should take into account adaptability, coordination, economic efficiency, and strategic principles. A logistic center can store, transport, and distribute goods, thus increasing efficiency.

In recent years, many methods related to logistics center location and

network layout have been researched and developed as part of location theory. Regardless of which method is used, the necessary preconditions for success are obtaining accurate data and applying various models. The traditional models of logistics center location have advantages and disadvantages. Table 1 shows an analysis and comparison of variety of methods (Hong, 2004; Xiaodong et al., 2004; Huijun et al., 2003).

Table 1. Analysis and Comparison of Variety of Methods.

	Advantage	Disadvantage	Scope of Application
Gravity Model Approach	Simple principle, convenient computation, easy to solve.	Only for a single center location; sometimes has large difference with the actual situation when the actual road conditions are replaced for straight lines.	For a single location, and in the region, the actual distance and straight-line distance have less difference.
Wolfe's Method	Provides a simple heuristics.	Cannot guarantee that ultimate solution is optimal solution; solution does not involve new distribution center fixed investment costs.	Factory to distribution center costs and distribution center to user's less-than-truckload transportation costs have a linear relationship to carryings into the user's location; the demand is known.
CFLP	Intuitive modeling, can improve model according to the actual situation.	Difficult to get pre-determined options set; lack of theoretical proof.	Alternative set determined according to actual situation and influencing factors; a stepwise refinement process.
BLP	Can concurrently analyze two different, conflicting objectives in decision-making process, can clearly show interaction of higher level policy-making departments and public	Bi-level programming problem is NP-hard problem, so difficult to solve.	Many people involved in making decisions at different levels; decentralized decision-making system optimization.

In this paper, a bi-level programming model based on competition for logistics center location is established and solved according to the analysis listed in Table 1 for a variety of models and approaches. Validity is shown through an example.

MODEL

The bi-level programming model is a system optimization model of a two-layer hierarchical structure. Decision-making variables in the model will affect the two participants in decision-making. The upper-level decision makers and the lower-level decision-makers have their own objective functions and constraints; the upper-level decision-makers give decision-making variables, and the subsystems of lower-level decision-makers use the variables as parameters to achieve optimal value and provide feedback to the upper-level decision makers. The upper-level decision-makers then find the overall optimal solution according to the reflections of the lower-level decision-makers (Amouzegar, 1999).

Upper Model

Upper programming (U) can be described as determining the best location of the new logistics center to minimize the total costs within the fixed range that is allowed, while the lower programming (L) describes the distribution patterns of customer demands between different logistics centers in conditions where there are a number of logistics centers; the goal is for every customer to have the lowest costs. Specific models are shown below.

$$U: \quad \min F = \sum_i \sum_j c_{ij} x_{ij} + \sum_j f_j z_j + \sum_j \sum_q p_{jq} w_{jq} \tag{2-1}$$

$$s.t. \quad \sum_{j=1}^{n} f_j z_j \le B \tag{2-2}$$

$$\sum_{j=1}^{n} z_j \ge 1 \tag{2-3}$$

$$\sum_{j=1}^{n} w_{jq} \le M_q \qquad \forall q = 1, \ldots, p \tag{2-4}$$

$$\sum_{i=1}^{m} w_{ik} \le V_i \tag{2-5}$$

$$\sum_{i=1}^{m} x_{ij} = \sum_{q=1}^{p} w_{jq} \qquad \forall j = 1, \ldots, n \tag{2-6}$$

$$z_j \in \{0,1\} \tag{2-7}$$

Where

c_{ij} - unit cost for distribution center j services the customer i

x_{ij} - demand satisfied at distribution center j of customer i

f_j - fixed investment costs of building the distribution center j

z_j - if build distribution center j, this value is 1, otherwise 0

B - total investment budget to construct the distribution center

w_{jq} - traffic from factory q to distribution center j

P_{jq} - transportation unit price from factory q to distribution center j

M_q - supply capacity of factory q

V_i - supply capacity of distribution center i

Lower Model

In a real distribution system, a distribution center cannot satisfy the demand of a single customer, and there is much competition from other distribution centers. Therefore, in the lower target planning, if there is a distribution center, then the K customers distribute their demands between n+1 distribution centers. This problem can be described as follows:

$$L: \quad \min T = \sum_i \sum_k x_{ik} y_{ik} \tag{2-8}$$

$$s.t. \quad \sum_{k=1}^{n+l} x_{ik} = A_i \qquad \forall i = 1, \ldots, m \tag{2-9}$$

$$\sum_{i=1}^{m} x_{ik} \le v_k \qquad \forall k = 1, \ldots, n+1 \tag{2-10}$$

$$x_{ik} \le M \cdot z_k \qquad \forall i = 1, \ldots, m; \forall k = 1, \ldots, n+1 \tag{2-11}$$

$$x_{ik} \ge 0 \tag{2-12}$$

Where

x_{ik} - demand satisfied at distribution center k of customer i

Y_{ik} - unit cost needed when customer i selects distribution center k to be serviced

A_i - total demand of customer i

V_k - total supply capacity of distribution center k

M - arbitrary large positive number

MODEL SOLUTION

Genetic Algorithm

A genetic algorithm is a search algorithm that combines survival of the fittest rules in the biological evolution process and the same group of chromosomes random information exchange mechanism. A genetic algorithm solves optimization problems by the initial population variation, crossover and recombination, and natural selection, etc. It can receive the most suitable new individual through limited iteration, which is the overall (or similar) optimization solution of the problem (Xiaoping et al., 2002). Figure 1 shows the basic flow diagram of a simple genetic algorithm.

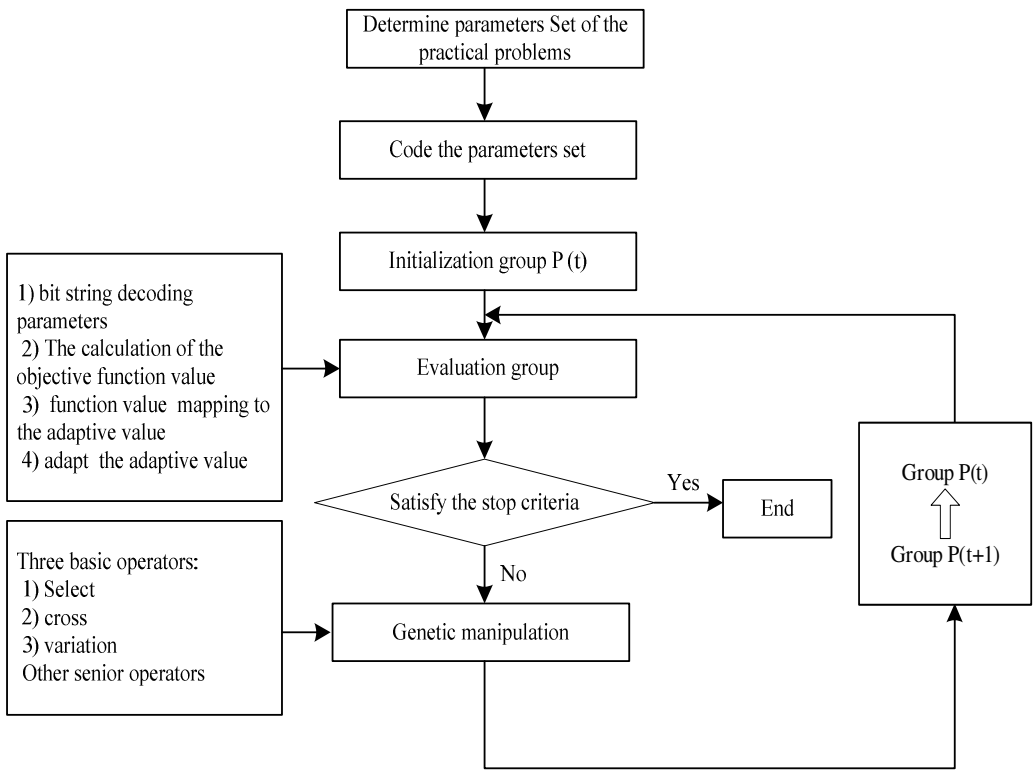

Figure 1. Basic flow diagram of simple genetic algorithm.

Process of Solving the Model

Thinking that some variables are discrete variables in these issues, we can see from the analysis of L, restrictive condition (2-11) shows the relationship between the demand distributed by every customer at distribution centers and the distribution center site selection program under an equilibrium state. That is, for the lower problem, z_k is known; if z_k=0, then x_{ik}=0, this restrictive condition can be deleted. If z_k=1, then $x_{ik} \le M$. M is an arbitrarily large number. This constraint naturally is okay and can be deleted. However, to get the concrete form of response function, restrictive condition (2-11) can be changed into the following form (but not to join the model).

$$x_{ik} = M \cdot z_k - s_{ik} \quad i = 1, \ldots, m; \qquad k = 1, \ldots, n \tag{3-1}$$

Here, s_{ik} is the slack variable. When z_k=0, we can get the values of x_{ik} and s_{ik} .When z_k=1, solve L using the existing methods, then we get customer demand x_{ik}^* in every distribution center under a balanced state. Then, the value of the slack variable s_{ik} is calculated using (3-1). Thus, all the functions can be written as follows:

$$x_{ik} = M \cdot z_k - s_{ik}^* \tag{3-2}$$

The above relationship is put into the upper objective function, and then the function is solved. For the optimal solution from the upper problem, we solve the lower problem once again to get the customer demand distribution between the distribution centers. Repeating the processes, we can get a new location program. Such double counting, the final is expected to converge to the optimal solution of the top programming model. Specific calculation steps are as follows:

Step 1: Set an initial solution z_k^0, the number of iterations r=0

Step 2: For given z_k^r, solving the lower problem, we get x_{ik}^r

Step 3: According to (3-2), calculate s_{ik}^r, put $x_{ik} = Mz_k - s_{ik}^r$ into the upper objective function; solving the upper problem combined with C_{ik}^r, we can get a new value z_k^{r+1}

Step 4: If $\left|F^{r+1} - F^r\right| \le \varepsilon$, stop. Otherwise, set r=r+1, turn to the second step; ε is the iterative precision.

EMPIRICAL STUDY OF LOGISTICS CENTER LOCATION

Case Description

A Dairy (Group) Company Limited is China's largest milk collection agricultural industrialization enterprise. The company has a factory in a region where there is a distribution center. Products are shipped to the distribution center first, then shipped by special vehicles from the distribution center to a retail shop where customers buy the products. The company now needs to establish at least one new distribution center at three candidate sites because of the expanding needs. In addition, the region has a number of other distribution centers that have a unified name, "social distribution center." These centers also serve customers in this region, so there is competition for this company. The demands of the five distribution centers are 7,000, 15,000, 13,000, 10,000, and 9,000. The network is shown in Figure 2. Related costs and a list of known parameters are shown in Table 2 - Table 6.

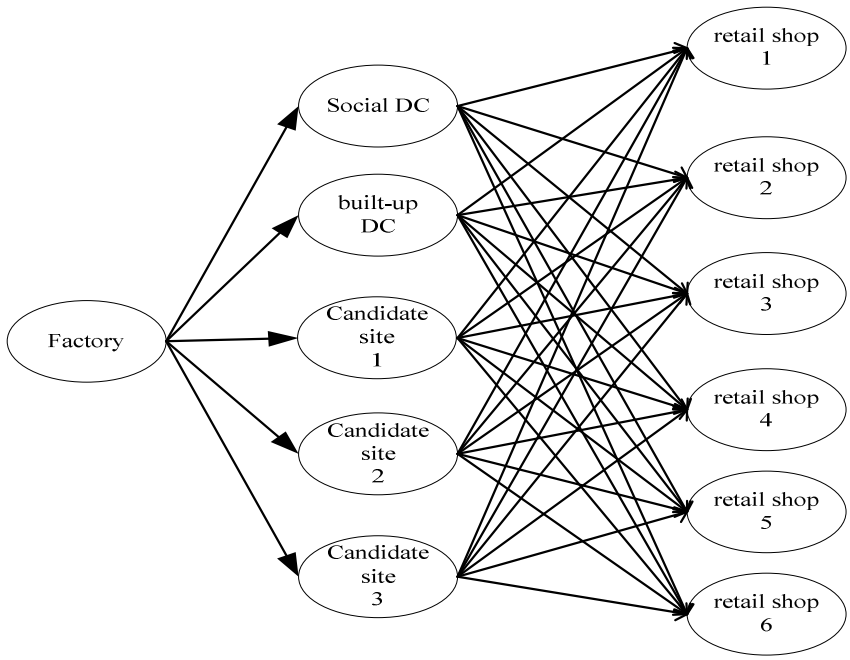

Figure 2. Network diagram.

Transportation price (Yuan/box)	11	10	12	15
Distance	165	120	190	155

CASE ANALYSIS

We solve the problem with the bi-level goal programming location model. In the upper planning, the upper objective function makes the total costs of the construction of distribution centers and the costs that are used to meet the consumers' demand the smallest from the decision-makers' point of view. The

lower objective function aims at distributing the demands among all distribution centers to achieve the lowest customer spending costs from the customers' (distributors') point of view. In this case, the corresponding parameter settings are as follows:

Population size (popsize) = 80
Cross-rate (pcross) = 0.6
Mutation rate (pmutation) = 0.05

The main program of solving the example using MATLAB is:

[x endPop bpop trace] = ga([0 1] 'fitness'[][][1e-6 1 1],'maxGenTerm'20 'normGeomSelect', [0.08] ['arithXover'] [2 0] 'nonUnifMutation', [2 1 3])

The genetic algorithm used to obtain a general approximate optimal solution, rather than the optimal solution and the convergence of genetic algorithm, is related to its initial value. So we repeat the commands many times to get the approximate optimal solution, using different initial groups randomly. Table 7 shows the final results of the five running programs.

Table 7. Location Probability of Candidate Sites 1, 2, 3.

	1	2	3	4	5
Candidate Site 1	0.8964	0.9871	0.8878	0.9827	0.9053
Candidate Site 2	0.1381	0.631	0.5818	0.0841	0.6976
Candidate Site 3	0.2239	0.3461	0.3938	0.1287	0.591

According to the varying methods of the encoding scheme, we conclude the location is not here when the location probability is between [0, 0.8]; when the location probability is larger than 0.8, then the site is here. From the results above, we conclude it is better to build a new distribution center at Candidate Site 1. Figure 3 shows the tracking chart for optimizing performance of the genetic algorithm. As can be seen from the chart, when the genetic algebra reaches 20 generations, the changes in solution and the average population begins to stablize.

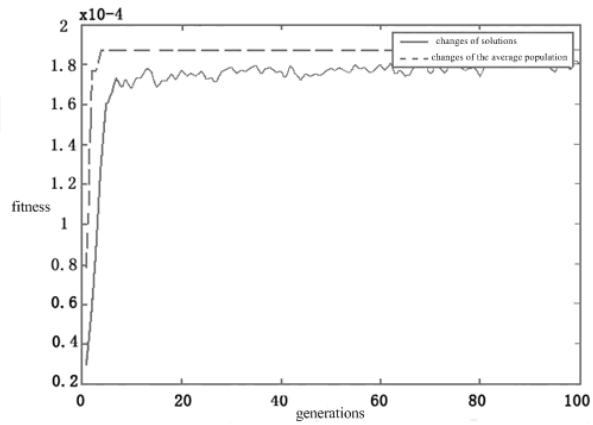

Figure 3. Changes of solutions and populations.

From the examples above, we can see the model is effective. This model has better adaptability and cost savings than the common location models and is more convenient and faster.

CONCLUDING REMARKS

This paper presents a logistics center location bi-level programming model based on competition. Upper programming (U) can be described as determining the best location for the new logistics center to minimize total costs within an allowed fixed range, while lower programming (L) describes the distribution patterns of customer demands between different logistics centers under the condition that there are several logistics centers. The goal is to make every customer have the lowest costs. The upper objective function makes the total costs of the construction of distribution centers and the costs that are used to meet the consumers' demand the smallest from the decision-makers' point of view. The lower objective function aims at distributing the demands among all distribution centers to achieve the least customer spending costs from the customers' (distributors') point of view. This paper analyzes the model and algorithm by means of a case study of a milk company and shows that the model and algorithm are both effective and practical.

A Model and Heuristic Algorithm for Inventory Routing Problem in Emergency Logistics

Xie Binglei and Hu Xiaoming

Shenzhen Graduate School, Harbin Institute of Technology, Shenzhen, Guangdong, 518055，China;Email: xbl7586@tom.com, frank0127@126.com

ABSTRACT

Model and heuristic algorithm are designed to solve inventory routing problem in emergency logistics with fuzzy demands and split delivery. Fuzzy demands are converted to deterministic demands by Yager's fuzzy number ranking method. A model which considers effects of stock-out is designed to optimize distribution period of the affected areas. Meanwhile, a modified vehicle routing model with split delivery is provided by tightening some constraints in order to decrease search space. A heuristic algorithm is used to coordinate inventory control and route optimization for minimizing total cost. The result shows that the benefits can be obtained from the integration of inventory and transportation.

Key words: emergency logistics; inventory routing problem; fuzzy demand; split delivery

INTRODUCTION

In recent years, as disasters which may occur abruptly and come with enormous consequences have brought great loss to human beings, such as Wenchuan Sichuan earthquake (2008), SARS (2003) in China, the 911 terrorist attack in US (2000), efficient and effective emergency logistics has became a worldwide noticeable problem.

One of the main missions in emergency logistics is to carry out relief delivery from distribution centers to affected areas. Both inventory controlling and vehicle routing are two fundamental and crucial items in logistics management. The inter-relationship between inventory and vehicle routing has recently motivated some authors to model these two activities simultaneously, which is known as the integrated Inventory Routing Problem (IRP). IRP can be seen as an extension of Vehicle Routing Problem (VRP). However, IRP does not include delivery routes only but also quantity to deliver to each customer as well as time for delivery.

Most researchers employ some strategies that allow IRP to be decomposed into two underlying problems, namely inventory problem and travelling salesman problem. The inventory problem is solved to determine replenishment quantities as well as replenishment times. The solution methods either find the routes first and then solve IRP formulation, or solve the inventory control problem first and then construct the routes for each demander. However, emergency system is unique in many aspects that may amplify complexity and difficulty in solving IRP. For example, in most of disaster cases demand information is provided by affected people under emergency conditions. Such information is rather fuzzy and hardly predicted due to lack of relative historical data, especially in the immediate

aftermath.

In the paper, a model and heuristic algorithm is designed to solve inventory routing problem in emergency logistics with fuzzy demands and split delivery.

DESCRIPTION OF THE IRP WITH FUZZY DEMAND AND SPLIT DELIVERY

The problem can be described as follow: a emergency distribution center serves affected areas which are geographically dispersed in a given area. Let 0 represent the distribution center, {1, 2, …, N} represents a set of affected areas. In a planning horizon T, every affected area faces a fuzzy, independent demand per day in which the membership function is known. Distribution is fulfilled without any delay by a fleet of homogenous vehicles with limited capacity V. No backorder is allowed at each area but each area may hold a local inventory used to meet future demands with a holding cost. The delivery to each area in each period can be performed by multiple vehicles. The objective is to minimize total cost, which includes fixed cost, cost of stock-out, cost of storage, and routing cost. Hereafter, notations are defined as follows

(1) *Parameters*

$c = \{c_{ij}\}$ Transportation cost of a vehicle send out product per unit from i to j where satisfy $c_{ij} = c_{ji}$ and $c_{ik} \le c_{ij} + c_{jk}$, for any i, j, k

$c^e = \{c^e_{ij}\}$ Transportation cost of an empty vehicle from i to j

$\tilde{\xi} = \{\tilde{\xi}_i\}$ Fuzzy demand of affected area i per day, $\tilde{\xi}_i$ and $\tilde{\xi}_j$ are independent for any $i \neq j$

s Price of product per unit

$p = \{p_i\}$ Stock-out penalty cost of product per unit per day in area i

$h = \{h_i\}$ Holding cost of product per unit per day in area i

(2) *Decision variables*

$q = \{q_{ij}\}$ Quantity of products transported through a directed arc (i, j)

$x = \{x_{ij}\}$ Number of vehicles visited a directed arc (i, j)

$d = \{d_i\}$ The optimal replenishment period of affected area i

SOLVING IRP WITH FUZZY DEMAND AND SPLIT DELIVERY

Inventory problem with fuzzy demand

In emergency logistics, the demand is believed subjectively to be a fuzzy number $\tilde{\xi}$. It's described as a general membership function $\mu_{\tilde{\xi}}(x)$

$$\mu_{\tilde{\xi}}(x) = \begin{cases} L(x), & r_1 \le x \le r_2, \\ R(x), & r_2 \le x \le r_3, \\ 0, else \end{cases} \tag{1}$$

where $L(x)$ and $R(x)$ are left and right shape functions。

In order to solve IRP with fuzzy demand in emergency logistics, a fuzzy demand is converted to a deterministic demand. Assuming the deterministic demand

is Q, increment cost $\tilde{T}(Q)$ between fuzzy demand and deterministic demand is

$$\tilde{T}(Q) = sQ + p\max\{0, \tilde{\xi} - Q\} + (h - s)\max\{0, Q - \tilde{\xi}\} \quad (2)$$

For a specified order quantity Q, the cost is only dependent on real demand x. Because $T(x|Q)$ is a linear function about x, the demand x and the cost $T(x|Q)$ have the same membership grade. In other words, the memberships functions of $\tilde{\xi}$ and $\tilde{T}(Q)$ have the same shape.

Since $\tilde{T}(Q)$ is a fuzzy variable, whose membership function is unknown, it can be ranked by the existing ranking methods. Chiang Kao and Wen-Kai Hsu (2000) had given a process of dealing with fuzzy variable with unknown membership function by Yager fuzzy number ranking method (1981). Therefore the calculation process is omitted here. The computing formula of Q is

$$Q = \begin{cases} L^{-1}(2(p-s)/(p+h-s)), & p < s+h, \\ R^{-1}(2h/(p+h-s)), & p \geq s+h, \end{cases} \quad (3)$$

On one side, decision makers can adjust subjectively the deterministic demand by controlling penalty cost p. On the other side, the transformation that $\tilde{\xi}$ is substituted by Q avoids solving complex fuzzy demand.

In IRP, if total cost is the sum of fixed cost (FC), cost of stock-out (OC), cost of storage (SC), and routing cost (RC) in a distribution period, average cost in per day is

$$AC = (FC + RC + OC)/d + hdQ/2 \quad (4)$$

Claudia、Savelsbergh and Speranza (2006) showed that the ratio of the optimal cost of the SDVRP over that of the corresponding VRP approaches 1/2 when the number of demand points goes to infinite. Here, $(cdQ + c^e)/2$ is used to estimate routing cost.

At the beginning of day 1, there are enough products. Assuming that if a stock-out happens on ith ($i \neq d$) day, then a replenishment is made immediately on that day and next replenishment is updated to $d+i$ and so on. Defining $OC(T,d)$ to be total cost of stock-out.

Let $p_i (1 \leq i \leq d)$ be the credibility that a stock-out first happens on day i, so the credibility that a stock-out happens in the next d days is $\sum_{i=1}^{d} p_i$, the credibility of no stock-out happens during period is $p_{d+1} = 1 - \sum_{i=1}^{d} p_i$. Here, the credibility p_i is give as: $p_i = Cr((i-1)\tilde{\xi} \leq dQ < i\tilde{\xi})$. The following relationships are hold

For $d \geq T \geq 2$, $OC(T,d) = \sum_{j=1}^{T} p_j (OC(T-j,d) + P)$; (5)

For $T \geq d+1$, $OC(T,d) = \sum_{j=1}^{d} p_j (OC(T-j,d) + P) + p_{d+1} OC(T-d,d)$; (6)

where P is the loss of a stock-out which is a constant。

For a fixed period d, $OC(T,d)$ is dependent on T. Defining $y_T = OC(T,d)$, the following equations are obtained.

$$y_T = \begin{cases} \sum_{j=1}^{T} p_j y_{T-j} + P\sum_{j=1}^{T} p_j, 2 \le T \le d \\ \sum_{j=1}^{d} p_j y_{T-j} + P\sum_{j=1}^{d} p_j + p_{d+1} y_{T-d}, T \ge d+1 \end{cases}, y_1 = 0 \quad (7)$$

However, only the condition that $T \ge d+1$ is considered. From the associated homogeneous equation $y_T - \sum_{j=1}^{d} p_j y_{T-j} - p_{d+1} y_{T-d} = 0$, $y_T = f(T,d) + \alpha(d)$ is hold, where $f(T,d) = \sum_{i=1}^{d-1} \omega_i r_i^T$ ($r_i (|r_i| \le 1)$ is the solution of the equation, ω_i is a constant, $\alpha(d)$ is independent on T). Subsequently, a particular solution needs to be found. Assuming the form of a particular solution is $y_T = \beta(d)T$ where $\beta(d)$ is independent on T. Replacing y_T by $\beta(d)T$, the formulation of $\beta(d)$ is obtained.

$$\beta(d) = P\sum_{j=1}^{d} p_j / (\sum_{j=1}^{d} j p_j + d p_{d+1}) \quad (8)$$

Therefore, the total cost of stock-out for $T \ge d+1$ is described as follow.

$$OC(T,d) = f(T,d) + \alpha(d) + \beta(d)T \quad (9)$$

Noticing that $\lim_{T \cdots d} OC_T(d)/T = \beta(d)$, let $\beta(d)$ be the average cost of stock out during period. Therefore, the optimal replenishment period d^* needs to satisfy the condition that $d^* = \min_d (\beta(d) + dhQ/2 + (FC + 0.5c^e)/d)$.

Modified SDVRP model

Split delivery vehicle routing problems (SDVRPs) were introduced by Dror and Trudeau in 1989. Unlike VRPs, SDVRPs allow delivery to a demand point to be split by two or more vehicle. Since SDVRPs are NP-hard, instances of realistic size is difficult to solve directly. Heuristics algorithms are often used to find good solutions to various routing problems in reasonable time. In this section, a modified SDVRP model is provided by tightening some constraints in order to decrease search space.

Theorem 1 (Dror and Trudeau, 1990). If $c_{ij}, i, j = 1, \cdots, N, i \ne j$ satisfy the triangle inequality, then no two routes in optimal solution have more than one common customer.

From theorem 1, it's easy to deduce that $x_{ij} \in \{0,1\}$, and $x_{0i}, x_{0j} \ge 0$ are integers.

Property 1. If the same conditions of Theorem 1 hold, then the optimal solution (x^*, q^*) satisfies $x_{0i}^* = [q_{0i}^*/V], i = 1, \cdots, N$. Here, $[q_{0i}^*/V]$ is the nearest integer less than or equal to q_{0i}^*/V.

Proof: Because $x_{0i}^*, i = 1, \cdots, N$ are integers, $x_{0i}^* \ge [q_{0i}^*/V], i = 1, \cdots, N$ holds. If in optimal solution (x^*, q^*), there exists $i \in \{1, \cdots, N\}$ not satisfying $x_{0i}^* = [q_{0i}^*/V]$, namely $x_{0i}^* \ge [q_{0i}^*/V] + 1$. Consequently, there exits another demand area j satisfying $x_{ij}^* = 1$ and $q_{0i}^* \ge q_{ij}^*$. Variables $x_{ij} = x_{ij}^* - 1 = 0$, $x_{0i} = x_{0i}^* - 1$, $x_{0j} = x_{0j}^* + 1$, $q_{0i} = q_{0i}^* - q_{ij}^*$, $q_{ij} = 0$, $q_{0j} = q_{0j}^* + q_{ij}^*$ are substituted in the solution, and other variables remain unchanged. The modified solution is also a feasible solution of the problem. However, the transportation cost of the new solution is reduced by

$(c_{0i}+c_{ij}-c_{0j})q_{ij}^*$. The above operation can be repeated until $x_{0i}^*=[q_{0i}^*/V]$. Therefore, $q_{0i}^*/V \le x_{0i}^* < q_{0i}^*/V+1$ holds. Furthermore, $x_{ij}^*=0$ holds when $q_{ij}^*=0$. So $q_{ij}/V \le x_{ij} < q_{ij}/V+1, i=0,1,\cdots,M, j=1,\cdots,M$ and $q_{ij}(1-x_{ij})=0$ is hold. With the above theorem and property, a modified model of SDVRP with tighter constraints can be proposed.

A Heuristic algorithm

After distribution periods are determined, the problem is similar to a periodic IRP. A heuristic algorithm to integration inventory and vehicle routing problem is designed as follows.

Step 1: Determining the initial optimal replenishment period and quantity of every affected area.

Step 2: Computing the expect cost include inventory cost and routing cost. Let iterative time $NC=0$ and $t'=1$.

Step 3: Improving the value of objective by modulating distribution dates in the planning period. Calculating increment inventory cost and routing cost of each affected area by moving the next replenish time t up to $t'(t'<t)$.

Step 4: Using greed algorithm to choose the substitute plan. The total cost and relevant information are updated.

Step 5: $t'=t'+1$. If $t'=T$, outputting the total cost, else go to step 3.

Step 6: $NC=NC+1, t'=1$. If NC is more than the maximal iterative time, the algorithm is terminated; otherwise, go to step 3.

NUMERICAL STUDY

The main purpose of numerical study is to demonstrate efficiency of the proposed method that can save cost by integrating inventory and vehicle routing in emergency logistics. Given a planning period 10 days, 20 affected area dispersed stochastically and consistently in region of [-5,5]×[-5,5], in which the coordinate of the distribution center is assumed to be (0,0). The capacity of vehicle V is equal to 100, and demands are supposed to be triangle fuzzy numbers simply. Other parameters are generated stochastically by computer.

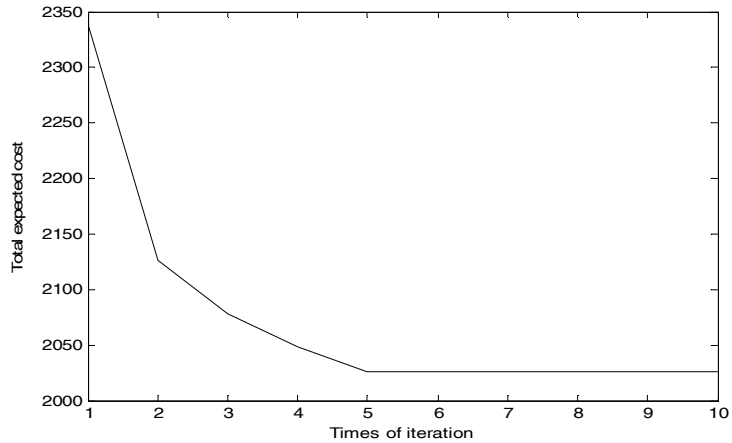

Figure 1. Iterations of the heuristic algorithm

Here, total cost is the sum of fixed cost, cost of stock-out, cost of storage and

routing cost in planning horizon T. From **Figure. 1**, in the early iteration, the value of total cost is improved obviously, but with development of iteration, the improvement is decelerated gradually until the cost is stable. The total cost goes down by 12.9% which is caused by integrating inventory and vehicle routing.

CONCLUSIONS

In the paper, minimizing total cost of IRP, a model and heuristic algorithm to solve the IRP in emergency logistics have been presented. The proposed approach involves four major steps: (1) describing demands in emergency logistics by fuzzy numbers, and converting fuzzy demands to deterministic demands with Yager fuzzy number ranking method; (2) optimizing distribution period by minimizing average expect cost; (3) modifying split delivery vehicle routing problem with tightened some constrains; (4) integrating inventory and vehicle routing by heuristic algorithm.

A numerical study was provided to illustrate efficiency of the method in solving IRP in emergency logistic. By comparing the total cost at initial step with that at convergence step, the numerical results reveal that cost could go down by 12.9%, resulting from the integration inventory and vehicle routing.

Nevertheless, there is still a great potential for improving performance of IRP in emergency logistics. One orientation is integrating time window and resource constrains. Furthermore, it will be conducted to improve the proposed algorithm. Alternative heuristic rules and meta-heuristic features will be examined to enhance efficiency and reducing computational time.

Study on Multi-dimensional Structure Model for Agricultural Products Logistics Organization in China

Yao Xinsheng, Xu Guangyin, Qu Jianhua, Wei Jianguang and Fan Shasha

College of Mechanical and Electrical Engineering, Henan Agricultural University, P.O. Box 450002, Zhengzhou, Wenhua ST 95; PH (086) 0371-63978179; FAX (086) 0371-63558368; email: yaoxsh@163.com

ABSTRACT

Affected by the traditional consciousness of small-scale peasant economy and the related national basic policy, the small and medium-sized self-employed individuals have been the main parts in the agricultural products logistics in China for a long time. Such agricultural products logistics have many shortcomings, such as its chaotic and dissipative nature and the low efficiency. In this paper, a multi-dimensional structure model of agricultural products logistics organization is developed, based on operating order, space order, time order, evaluation order and its evolution mechanism. The logistics elements evolved from the two-dimensional discrete operation point, to the three-dimensional independent logistics line, and then to the four-dimensional value added curve. Through the evolution of logistics elements, the efficiency of the agricultural products logistics organization can be improved continuously. At last, the implementations of the model are discussed.

1 INTRODUCTION

In recent years, the development of the agricultural products logistics in China has been behind the development of the socioeconomics, not only in operation but also in efficiency and benefit. It is very necessary to study the structural characteristics and the internal evolution rule of agricultural products logistics organization, in order to improve its efficiency and ensure its healthy development. Previous studies on agricultural products logistics are generally based on qualitative macro analysis rather than the basic law of organization. According to the problems in logistics organization of agricultural products in China, this paper investigates the inherent law of logistics organization of agricultural products and discusses the effective ways to promote its development.

2 THE CURRENT SITUATION

Agricultural products are the main sources of farmers' income and the basic insurance of their public life. With the continuous increase of living standard, the demand for the diversity, safety and timeliness of the agricultural products also increases. Agricultural products logistics is an economic activity to meet the user's needs by realizing the value of agricultural products and providing relevant information between producers and consumers. It includes a series of activities, such as gathering, transportation, storage, loading and unloading, packaging, processing, distribution and logistics information. Through this process the value of agricultural

products and the organizational objectives are realized. (Huang, 2005). The typical structure of the process of agricultural products logistics is shown in Figure 1.

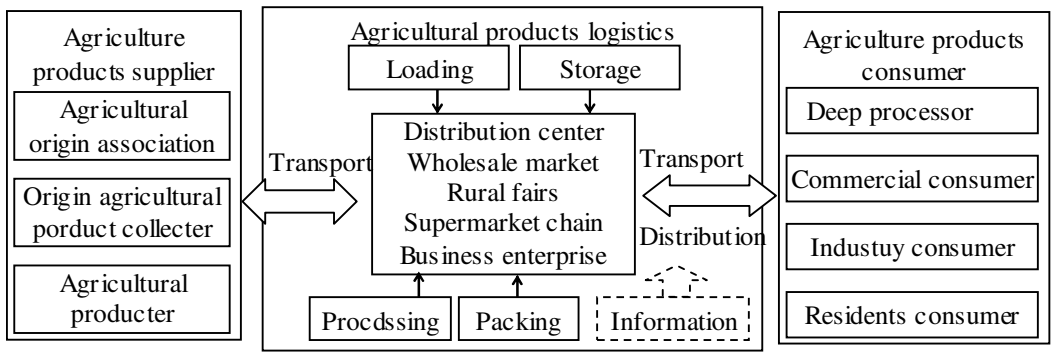

Figure 1. Typical processes of agricultural products logistics in China

In recent years, the National "Three Agriculture" policies have been promoting the development of agriculture in a new phase. Except that only small parts of agriculture products are for farmers' self-use, most of the products are put into agricultural commodity circulation, which generates the real or potential great logistics. In Henan province in 2007, for example, there are 9.46 million hectares of crops, 12.2 thousand hectares more than the previous year; 52.45 million tons of grain yield, increased by 2.6 million tons; 483.98 tons of oil production, increased by 5.2%; 74.74 tons of aquatic products, increased by 21.7% (NBS, 2007). The year-round logistics added 863.1 billion RMB, increased by 12.9%. The average annual growth rates of vegetable planting in China are nearly 10% in the 1980s and 14.5% in the 1990s. In 2007, 260 million Mu (a unit of area in China, 1 Mu is approximately equal to 666.67 square meter) of vegetable planting yields the total output of 565 million tons. However, compared with the developed countries, China's current agricultural products logistics has many problems, which seriously restrict its development. The agricultural logistics in China appears with low efficiency, high cost, high loss and laggard technology (see Table 1).

Table 1. The comparison of the agricultural products logistics

County	Logistics cost	Loss Rate	Processing proportion	Processing added	Supermarket chain operation proportion
Developed county	10%	5%	80%	1:(3-4)	80%-95%
China	40%(corps)	15%	10%	1:0.8	Less 30%
	60%(Fruits and vegetables)	25%	10%	1:0.8	Less 30%

According to the statistics of FAO, China's fruit planting area and the aggregate yields accounted for 18% and 13% of the entire world, while the vegetable planting area and the aggregated yields accounted for 43% and 49% of the entire world. All of these percentages rank first among other countries in the world. However, the logistics costs of vegetable and fruit are high. Every year there are

nearly 1200 tons and 1.3 million tons of corrosion damages for fruit and vegetable respectively, with the total economic losses more than hundred billions RMB (Zhang, 2007). In logistics organization, the market system has some faultiness, leading to the results that some agricultural products cannot be put into circulation or realize their value. (1) Because of the numerous small-scale, unregulated business owners, the overall intensive degree is too low. These small farmers, who lack market power, can hardly respond to the impact of the market and modern large-scale logistics enterprises. (2) The level of information technology for agricultural products logistics is too low. The required information of supply chain is distorted seriously, which greatly destroys the coordination in supply chain. (3) Harvesting, drying, sorting, portage and other logistics operation are mostly conducted manually. The major transportation is by ragtops. Only 30% of the transportation vehicles are vans and less than 1/10 vehicles are equipped with refrigeration machinery. In some rural regions, transportation system is inadequate without inter-modal transportation network. (4) There is no specialized training system or intelligent mechanism for agricultural products logistics in China. The agricultural products logistics personnel are in short supply. (5) Government has issued many policies to promote the legislation and investment for the agricultural cooperation, but its implementation is inadequate.

3 DATUM ORDER FOR AGRICULTURAL PRODUCTS LOGISTICS ORGANIZATION

Agricultural products logistics can be a network, a chain, or a combination of some chains (Bouckova, 2002). Before logistics, there exists “former logistics business”, including agricultural production, agricultural planning, material supply and other supporting activities. After logistics, there exists “latter logistics business," including fashioning, marketing and many other activities related to food market.

Affected by the small-scale peasant economy, agricultural products logistics reveals obvious scattered characteristic. The logistics of agricultural products need to be fully considered with the time and regional characteristics. This paper investigates the agricultural products logistics organization in four datum orders: the operation order, the time order, the space order and the evaluation order. The operation order, which includes type and volume, is the basis of the agricultural products logistics. The type includes five general logistic operations and other additional content. The volume is the number of indicators. For a real logistics business it is the actual business volume. The time order refers to the relationship of the agricultural products logistics in the time dimension, including the specific logistic business relations before and after order, as well as the connections among other logistic operations. The space order refers to the location-based geographic relationships involved in agricultural products logistics. The evaluation order is the overall evaluation of the completed agricultural products logistics, including quality indicator, efficiency indicator and benefic indicator.

4 EVOLUTIONAL ORGANIZATION STRUCTURE MODEL

Based on the datum orders of organization degree of the agricultural products logistics, this paper analyzes the different levels of agricultural organizations. Figure

2 represents three modes of agricultural products logistics organizations in the evolution of three typical logistics patterns in China.

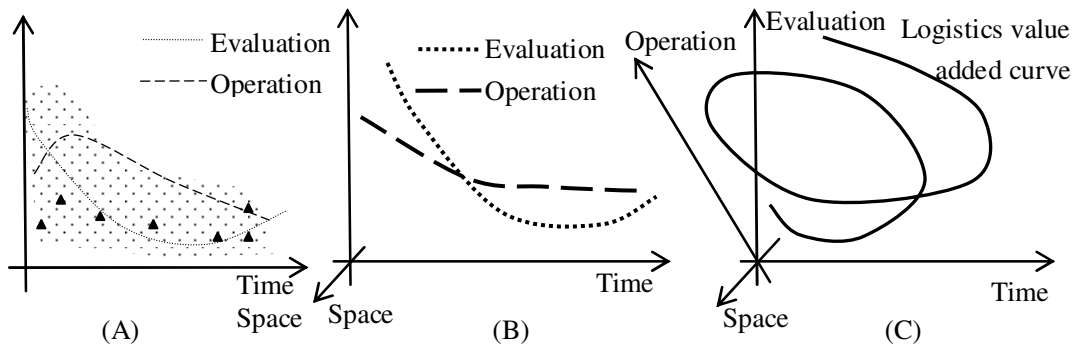

Figure 2. Organization degree of agricultural products logistics and its evolution

Figure 2A represents the primary stage of the agricultural products logistics. At this stage, the logistics is at a very low level. Many so-called logistic companies can only complete a few types of operations and low logistic volume. There is no collaboration or sustainability among the logistics operations. In the time dimension, it is mainly short-term, showing that the longer the time interval the less the period logistic demand there is. In space dimension, it is mainly regional, indicating that the bigger the space the smaller the operation volume will be. Moreover, logistics mainly focuses on small areas. The greater the space interval, the greater the time interval is. The supply chain for agricultural products is almost nonexistent. There is no contact between the various logistic segments. Thus the overall evaluation is bad. Only few rapid or long-distance logistics have a better evaluation. As shown in the figure, all the logistic business are presented as some sporadic scattered points; the volume and type of operation are not increased with the space and time. Most logistics of the agricultural products wholesales, distributions and markets in rural areas and towns in China were still in this stage.

By integrating some operations, the logistic operation mode of agricultural products has made great progress. The logistics of agricultural products has a certain development and has gradually evolved into three-dimensional logistic curve, which is shown in Figure 2B. At this stage, some entities reveal the archetypal features of logistics enterprises. They are able to complete two or more kinds of logistic operation and engage in a relatively stable and professional agricultural logistics system. Moreover, they have a certain amount of logistics volume, and a certain extension in time order and space order. However, it is still at a relatively low-level stage and it is not a completely continuous logistic curve. The overall evaluation is also ordinary. Currently, China's major logistic enterprises related to agricultural products, including some 3PL and 4PL, as well as some supermarkets and wholesale markets for agricultural products, are in this stage.

Based on the analysis of the previous two stages, this paper proposes a higher-level organizational model for agricultural products logistics, which is shown in Figure 2C. In this stage, the participated logistic enterprises can be involved in at least 2-4 types of logistic operations and professionally engage in logistics operation activities. In the time demission, most operation can be realized as an effective link

of all logistics operation to a certain extent. Some business can achieve JIT. In the space demission, the logistics can cross geographical boundary and cover a relatively large area. It has a certain degree of industrial concentration and forms a relatively stable industrial chain. Therefore, the logistic organization in this stage can achieve higher evaluation in quality, efficiency, effectiveness, social service and other aspects. It develops continuously and forms a logistic value curve. At present, there are hardly any logistic enterprises in China in this stage. Some model enterprises, such as Shuanghui Group and Sunxin Agriculture have shown the preliminary features. In this stage, "company + production + farmers" business model would be more prevalent. The awareness of quality, safety and efficiency is improved obviously. In addition, the integrated entity or enterprise, which combines production, processing, logistics, management and service, is being brought up gradually.

5 MEASURES TO IMPROVE THE ORGANIZATION LEVEL

In view of the industrial organization, we hope the logistics of agricultural products have a high level of organization, so that it can be improved in scale, efficiency, effectiveness, quality, etc. There are already a lot of approaches to improve the logistics organization level, such as the methods of information, networks, decision-making and administration proposed by many scholars and entrepreneurs. With this understanding, this paper proposes several ways to improve the organization degree of agricultural products logistics, based on the theories of swarm intelligence.

Considering logistics individuals of agricultural products have the similar characteristics with the intelligent agents, and the dynamic alliance or enterprises can be formed with scale economies. In order to save logistic resources and to achieve the maximum social benefits, the swarm intelligence theory is adopted as the solution algorithm. For a given logistic business, there is a four-dimensional order in time, space, operation and evaluation, where the intelligent agents can move. Through the collaboration of the autonomous action of multiple agents, the logistics value is enhanced. The algorithm is described as follows. Assume the data set of logistic business members is $B=\{Bi=(b_{i1}, b_{i2}, \ldots,b_{im}), i=1,2,\ldots,N\}$, representing the set of N members in agricultural products logistic enterprise. For one logistic enterprise Oi, $o_{i1},o_{i2},\ldots,o_{im}$ are the performance index, and m equals 4.

$$\text{Consider } d_{ij} = \left\| P(B_i - B_j) \right\| = \sqrt{\sum_{k=1}^{m} w_k (b_{ik} - b_{jk})^2}$$

where $dij(B_i, B_j)$ is the Euclidean distances between B_i and B_j, representing the cooperation likelihood between B_i and B_j in the real world. P represents the weighted integration and w is the weight. For the virtual enterprise, the weight w of the operation may be bigger, while for the dynamic alliance, the performance indices for the time and space may be bigger. The candidate *area* (B_i, r) represents the cooperation field of data object B_i, which expresses a group of logistics individuals who cooperate closely. r is a four-dimensional radius. In operation, individual selects its cooperation set $A = \{Ai=(a_{i1},a_{i2},\ldots,a_{ik}), a_{ik}\in O\}$ in $area(O_i,r)$, by optimizing the objectives using the multiple-agent algorithm. In application, the cooperation must be optimized in some aspects. The detailed algorithm can be found in other studies (e.g. Yao, 2008).

In addition, other measures should be made to improve the organization level of agricultural products logistics, such as reinforcing information construction, improving market mechanism and vitality, talented personnel training, system standardization construction, improving industrial concentration, and so on.

6 CONCLUSION

Efficient logistics can reduce the costs of production and circulation of agriculture and promote the process of modernization of agriculture. Moreover, it can also increase the flow speed and protect the fundamental profit of both urban and rural residents, in order to improve the overall benefit of agriculture. At present, the small and medium-sized self-employed individuals are the main parts in the agricultural products logistics in China. The agricultural products logistics is in a mess, low efficient and dissipative. Therefore, the theoretical study which focuses on the organization structure of the agricultural products logistics is very essential.

In this paper we present the problems in agriculture products logistics in China, such as the high costs and loss rate, less value-added capability, the lack of specialied logistic personnel etc. We then propose a multi-dimensional organization evolution model of agricultural products logistics in theory. At last, based on the swarm intelligence theory, we discuss the information standardization technology and other recommendations to improve the efficiency of the logistics organization of agricultural products in China. This study intends to explore the suitable development path and to provide some theoretical reference for the healthy and rapid development of agriculture products logistics industry, and thus to promote the agricultural production and rural economy in China.

Mean-CVaR Model of Wholesale Price Contracts and Dual Purchase Contracts in the Supply Chain

Y. G. Mu, Q. Mai, Z. B. Zhao, Y. J. Feng

Harbin Institute of Technology, No.92, West Da-Zhi Street, Harbin 150001, P.R. China; PH (86) 0451-86412866; FAX (86) 451-86412866; email: muyg_hit@163.com

ABSTRACT

Wholesale price contracts and dual purchase contracts are the most common contract styles in the supply chain because they are price-only contracts. The CVaR model of loss in revenue of retailers in the two styles of contracts under a two-level supply chain is proposed in this paper according to the definition of Conditional Value at Risk (CVaR), which previously has been used in financial engineering. Consequently, the mean-CVaR model, which aims at revenue maximization with CVaR risk explosion constraints, is proposed. The numerical results indicate that dual purchase contracts achieve strict Pareto improvement over wholesale price contracts, with more revenue and less risk explosion.

INTRODUCTION

Supply chain contracts can ensure the cooperation between both parties of a contract and realize the "win-win" condition based on information-sharing. As Arrow (1985) and Lariviere and Porteus (2001) point out, most of the research on these contracts ignores the administrative costs that occur in reality. The difficulties associated with administering complex contracts are also criticized by many practitioners. This paper focuses on price-only contracts, wholesale price contracts (WPC), and dual purchase contracts (DPC).

Research on wholesale price contracts falls into three areas. In the first, some papers examine the effect of wholesale price contracts on profit improvements in a supply chain. Cachon (2004) researched the order of retail after and before demand realization and addressed inventory risk-sharing based on a news vendor model. Taylor (2006) addressed the impact of forecast updating on order timing. Ye Fei (2006) investigated the mechanism of supply chain coordination under flexible demand. The second area studies forecast information asymmetry, such as Ozer and Wei (2006). The third area focuses on the effect of advance ordering on the supply chain.

None of these papers consider the risk aversion of the decision maker. This paper introduces the Conditional Value at Risk (CVaR), which is broadly used in finance engineering, into wholesale price contracts and dual purchase

contracts to consider the risk aversion of the decision maker. Mean-CVaR models are proposed in a two-level supply chain constituted by some suppliers and some retailers under random market demand. Based on the simulation analysis, this paper shows the effect on supply chain profit by risk aversion and the Pareto improvement caused by dual purchase contracts.

MEAN CVaR MODEL

In the research of Jiang Min et al. (2007) and Yu Chun-yun et al. (2007), the objective was to minimize α-CVaR. But, according to the research of Krokhmal (2002), by considering different expected returns, an efficient frontier can be generated. Theorem 3 in that research proves that the following three optimization problems are equivalent in the sense that they produce the same efficient frontier.

Theorem 1 Considering the function $\Phi(\mathrm{x})$ and $\Pi(\mathrm{x})$ dependent on the decision vector x, and the following three problems:

$$\text{(P1)} \qquad \min_{\mathrm{x}} \quad \Phi(\mathrm{x}) - \beta\Pi(\mathrm{x}), \quad \mathrm{x} \in X \quad \beta \geq 0$$

$$\text{(P2)} \qquad \min_{\mathrm{x}} \quad \Phi(\mathrm{x}), \quad \Pi(\mathrm{x}) \geq \rho \quad \mathrm{x} \in X$$

$$\text{(P3)} \qquad \min_{\mathrm{x}} \quad -\Pi(\mathrm{x}), \quad \Phi(\mathrm{x}) \leq \varpi \quad \mathrm{x} \in X$$

If $\Phi(\mathrm{x})$is convex, $\Pi(\mathrm{x})$ is concave and the set x is convex, then the three problems, (P1)-(P3), generate the same efficient frontier.

Based on the above theorem, the following part will adopt the structure of model (P3). The objective of optimization programming is to minimize the negative expectation of revenue, and the CVaR will be considered as a constraint. In this way, when maximizing the expectation of revenue, the risk will be controlled within a given bound. This method can give many effective frontiers based on different risk level.

Mean-CVaR Model under Dual Purchase Contracts

Revenue and Loss Function. In dual purchase contracts, there are two prices, an advance purchase price w_b and the regular wholesale price w. The retailer pays w_b for each unit ordered before observing the forecast update and w after the forecast. The sequence of events for the retailer is as follows: (1) he parties agree on a w_b and w; (2) the retailer decides how much to order in advance of obtaining the forecast update and pays w_b per unit of advance order; (3) the retailer obtains the forecast update and decides how much more to order and pays w per unit; (4) market uncertainty is realized, and the retailer satisfies the demand from on-hand inventory as much as possible at a per-unit price.

Based on the above assumptions, the revenue function of the retailer in a

dual purchase contract is

$$\Pi^r(\mathrm{x}_1,\mathrm{x}_2,\mu_1,\mu_2) = \mathrm{r}E_{\mu_1}E_{\mu_2}\min\{\mathrm{x}_1+\mathrm{x}_2,\mu_1+\mu_2\}-\mathrm{w}_b\mathrm{x}_1-\mathrm{w}\mathrm{x}_2 \quad (1)$$

Similarly, substituting $\min\{\mathrm{x},\mu\}=\mathrm{x}-(\mathrm{x}-\mu)^+$ into equation (1), we get

$$\Pi^r(\mathrm{x}_1,\mathrm{x}_2,\mu_1,\mu_2) = \mathrm{x}_1(\mathrm{r}-\mathrm{w}_b)+\mathrm{x}_2(\mathrm{r}-\mathrm{w})-\mathrm{r}E_{\mu_1}E_{\mu_2}(\mathrm{x}_1+\mathrm{x}_2-\mu_1-\mu_2)^+ \quad (2)$$

Then, in a dual purchase contract, the loss in revenue of retailer is given by

$$f^r(\mathrm{x}_1,\mathrm{x}_2,\mu_1,\mu_2) = \mathrm{r}E_{\mu_1}E_{\mu_2}(\mathrm{x}_1+\mathrm{x}_2-\mu_1-\mu_2)^+-\mathrm{x}_1(\mathrm{r}-\mathrm{w}_b)-\mathrm{x}_2(\mathrm{r}-\mathrm{w}) \quad (3)$$

CVaR Constraint. If $\varpi \in R$ is the threshold of loss risk explosion, risk function $\Phi_\alpha(\mathrm{x}_1,\mathrm{x}_2)$ α-CVaR of loss function, then the linear constraints of α-CVaR can be given by

$$\varsigma+(J(1-\alpha))^{-1}\sum_{j=1}^{J}z_j \le \varpi$$

$$z_j \ge \sum_{i=1}^{n}\left(r_i\left(x_{1i}+x_{2i}-\mu_{1ij}-\mu_{2ij}\right)-x_{1i}\left(r_i-w_{bi}\right)-x_{2i}\left(r_i-w_i\right)\right)-\varsigma$$

$$z_j \ge 0, \qquad j=1,\ldots,J \quad (4)$$

Bounds on Ordering Quantity. Similar to a wholesale price contract, the size of the ordering quantity can affect the price. This also considers the bounds on ordering quantity. Therefore, the ordering quantity about x_1 and x_2 can be bounded as

$$0 \le \underline{x}_{1i} \le x_{1i} \le \bar{x}_{1i},$$

$$0 \le \underline{x}_{2i} \le x_{2i} \le \bar{x}_{2i} \qquad i=1,\ldots,n \quad (5)$$

The Optimization Problem. Based on the above assumptions and models, the optimization problem, whose objective is to maximize the revenue of retailer with α-CVaR constraints about loss in revenue, is given by

$$\min_{\mathrm{x}_1,\mathrm{x}_2,\varsigma} \quad \sum_{i=1}^{n}\mathrm{w}_{bi}\mathrm{x}_{1i}+\mathrm{w}_i\mathrm{x}_{2i}-\mathrm{r}E\min\left(\mathrm{x}_{1i}+\mathrm{x}_{2i},\mu_{1ij}+\mu_{2ij}\right) \quad (6)$$

subject to

$$\varsigma+(J(1-\alpha))^{-1}\sum_{j=1}^{J}z_j \le \varpi$$

$$z_j \ge \sum_{i=1}^{n}\left(r_i v_{ij}-x_{1i}\left(r_i-w_{bi}\right)-x_{2i}\left(r_i-w_i\right)\right)-\varsigma$$

$$z_j \ge 0 \qquad j=1,\ldots,J$$

$$v_{ij} \ge x_{1i}+x_{2i}-\mu_{1ij}-\mu_{2ij}, \quad v_{ij} \ge 0$$

$$0 \le \underline{x}_{1i} \le x_{1i} \le \bar{x}_{1i}$$

$$0 \le \underline{x}_{2i} \le x_{2i} \le \bar{x}_{2i}, \qquad i=1,\ldots,n$$

Mean-CVaR Model under Wholesale Price Contracts

In a wholesale price contract, the sequence of events for the retailer is as follows: (1) the parties agree on a wholesale price $\mathrm{w} \in R^N$ and sign the contract; (2) the retailer orders N products $\mathrm{x} \in R^N$ according to the forecast of market demand; (3) the retailer satisfies the demand from on-hand inventory at a fixed price.

Based on the above assumptions and models, the optimization problem, whose objective is to maximize the revenue of retailer with α-CVaR constraints about loss in revenue, is given by

$$\min_{\mathrm{x},\varsigma} \sum_{i=1}^{n} \left(w_i x_i - r_i E \min\left(x_i, \mu_{ij}\right)\right) \tag{7}$$

subject to

$$\varsigma + \left(J\left(1-\alpha\right)\right)^{-1} \sum_{j=1}^{J} z_j \le \varpi$$

$$z_j \ge \sum_{i=1}^{n} \left(r_i v_{ij} - \left(r_i - w_i\right)x_i\right) - \varsigma, \quad z_j \ge 0 \quad j = 1,\ldots,J$$

$$v_{ij} \ge x_i - \mu_{ij}, \quad v_{ij} \ge 0$$

$$0 \le \underline{x}_i \le x_i \le \overline{x}_i, \qquad i = 1,\ldots,n$$

By solving this problem, we get the optimal vector x^*, which is the optimal ordering quantity, and the corresponding VaR, which equals ς^*. The efficient return-CVaR frontier is obtained by taking different risk tolerance level ϖ.

NUMERICAL EXAMPLE

This section proposes a numerical example to compare revenue considering the CVaR constraints under wholesale price contracts and dual purchase contracts. For simplicity, the retailer orders only two products from the manufacturer. Assume the market demand for the first product follows truncated normal distribution on $[8,24]$ with mean 16 and standard deviation 4; the market demand of the second product follows truncated normal distribution on $[-8,8]$ with mean 24 and standard deviation 2. The forecasts for the two products all follow truncated normal distribution on $[-8,8]$ with mean 0 and standard deviation 5. The per-unit market prices of the two products are 10 and 6, respectively. Based on these assumptions, Table 1 illustrates the revenue and VaR of the retailer under different α and different contract prices, giving the fixed risk explosion threshold 10.

Table 1. Revenue and VaR of Retailer with Fixed Risk Explosion Threshold of 10.

α	Wholesale Price Contract (7,4)		Dual Purchase Contract (5,7;3,4)	
	Revenue	VaR	Revenue	VaR
0.6	143	6.9	294.4	4.8
0.75	142.5	8.8	291.6	3.3
0.95	142	10	284.9	10

Table 2 illustrates the revenue and VaR of the retailer under different risk explosion thresholds and different contract prices, giving the fixed α, which is 0.75.

Based on the above solutions, we get following results:

(1) By comparing the revenue and VaR in Table 1 and Table 2, we see that the revenue under a dual purchase contract is larger than that under a wholesale price contract, and the VaR under a dual purchase contract is less than that under a wholesale price contract. Therefore, although the forecast of market demand by the retailer requires more uncertainty, the dual purchase contract not only improves the revenue but also decreases the risk explosion of revenue. In another word, this kind of contract provides the strict Pareto improvement.

Table 2. Revenue and VaR of Retailer with Fixed α 0.75.

Risk Explosion Threshold	Wholesale Price Contract (7,4)		Dual Purchase Contract (5,7;3,4)	
	Revenue	VaR	Revenue	VaR
10	142.5	8.8	291.6	3.3
15	145	13.8	296.6	8.3
20	147.5	18.8	301.6	13.3

(2) Table 1 illustrates that the revenue of the retailer decreases and the VaR increases under not only a wholesale price contract but also a dual purchase contract, with the gradually increasing of confidence level α. This means that the revenue decreases when the retailer is more risk averse. But the effect is not outstanding, because when confidence level α changes to 0.95 from 0.6, which means the probability of loss in revenue not exceeding 10 increases to 0.95 from 0.6, the revenue under a wholesale price contract decreases 1, and the revenue under a dual purchase contract decreases 10, not reaching the 3.5% of initial revenue. Accordingly, it is absolute to fix a little small confidence level α, which can guarantee a higher revenue while satisfying the risk preference.

(3) Table 2 illustrates that the revenue of the retailer increases under not only a wholesale price contract but also a dual purchase contract, with the

gradually increasing threshold of risk explosion. This means that the revenue increases when the retailer is risk preference. But the table also illustrates that when the threshold of risk explosion increases times two, from 10 to 20, revenue under a wholesale price contract decreases 5, and revenue under a dual purchase contract decreases 10, which does not reach the 3.5% of initial revenue. Accordingly, it is good to be risk preference for the retailer. Under a fixed confidence level, revenue will be higher if given a lower threshold of risk explosion.

CONCLUSION

This paper researched the risk caused by the uncertainty of market demand and the forecast of market demand in a two-level supply chain constructed by manufacturers and retailers. Based on the risk model, this paper proposes Mean-CVaR models under wholesale price contracts and dual purchase contracts, which have been transformed into linear programming to get the optimal order quantity under the two contracts. The numerical example illustrates that dual purchase contracts increase retailer revenue and decrease the VaR, hence creating strict Pareto improvement. If the retailer is a risk preference and the confidence level is lower, the revenue of the retailer will reach a higher level while satisfying the risk threshold of risk explosion.

ABSTRACT

It is a very important task to build a structured system for modern logistics development from the experiences of logistics developmental stages. However, at present the construction idea of modern logistics lack a complete and scientific structured system. First, several concerned points of developmental stages of modern logistics are elucidated. Secondly, a structured system model of modern logistics is proposed to be build, with characteristics of: one subject, two systems, three platforms, four logistics developmental modes, and five logistics service styles, in order to provide scientific guidance. According to the structure system model, the characteristics of specific components are analyzed from five aspects: subject, policy, platform, developmental mode and service style.

KEYWORDS

modern logistics; structure system model; guiding analysis

1 INTRODUCTION

The key to develop modern logistics mainly focuses on promotion and reformation of traditional logistics from the aspect of management ideas and operation. In the management ideas aspect, the goal is to realize optimal deployment of resources. In the operational aspect, the goal is to reflect advantages from service, management, technology and efficiency. Fen, H proposed a modern regional logistic system (Fen, H. 2006). He suggested that the full system of regional logistics include a logistics subject, two support systems and two basic platforms. His points mainly focus on management ideas of logistic without the operation aspect. We propose a structure system model of modern logistics with its characteristics for both management idea and operation aspects.

2 GUIDING ANALYSIS ON DEVELOPMENT STAGES OF MODERN LOGISTICS

2.1 Stage I: Resource Integration for Intensive Construction

Resource integration for intensive construction is the short-term goal of modern logistics development. In this step, new logistics projects are launched and logistics platforms of infrastructures are established by creating new logistics resources and integrating existing ones. A series of goals should be determined at this stage, ranging from production value of modern logistics, economic contribution, to the number of cultivated logistics enterprises with demonstration or leading effect.

2.2 Stage II: Platform Creation for Rapid Development

The second stage focuses on the improvement of the logistics network systems,

the construction of logistics information and organization platforms, and the maturation of policy systems. The construction of logistics network architecture is finished with logistics parks, logistics centers, distributing centers and logistics service stations as basic elements. Logistics industries are also encouraged to seek for their own characteristics and gradually increase the scales and the benefits of intensive management. Lastly, large-scale and professional modern logistics enterprise groups should be cultivated with band strength and core competitiveness.

2.3 Stage III: Function Enhancement for System Perfection

The third stage focuses on the overall enhancement and sustainable development of logistics system's functions. It is suggested that we should explore new developing spaces for industrial logistics, improve the service quality of various industrial logistics, and finally arrive at a real system with its own industrial characteristics. This system will rely on local area, radiating surrounding regions facing China, and aimed at the international world.

3 STRUCTURE SYSTEM MODEL OF MODERN LOGISTICS

The system model of modern logistics industry structure could be summarized in a numbered style as: one subject, two systems, three platforms, four logistics developmental modes, and five logistics service styles. This relationship is illustrated in Figure 1.

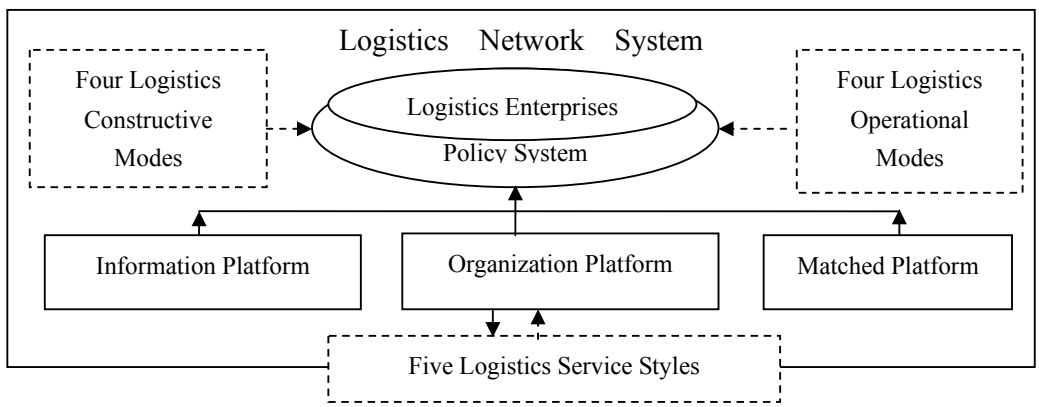

Figure 1. Structure System Model of Modern Logistics

3.1 One Subject

Traditional logistics enterprises, such as transportation enterprise, storage enterprise, agent enterprise and internal logistics department, are guided to transform to be third-party logistics enterprises. They are to improve competitiveness of logistics enterprises during modern logistics development.

3.2 Two systems

3.2.1 Policy system

In the process of policy system establishment, we should abide by the characteristics of market rules and benefits in accordance with city economics

features (Wen, K. 2007). Table 1 outlines the logistic policy system classes in detail.

Table 1 Logistics Policy System

Class	Detailed Content
Supportive Policy	Transportation management policy, tax policy, land-use policy, financing policy, government investment policy
Guiding Policy	Structure leading policy of logistics industry, network spatial layout leading policy, business firm leading policy
Developmental Policy	Cultivation policy for key logistics enterprises, introduction policies for foreign logistics enterprises and talents

3.2.2 Logistics Network System

The key elements of modern logistics network system, outlined in Figure 2, include logistics nodes hierarchical layout and logistics channel system (J. Bloomberg, D. 2004). The major task in this process is to make explicit the logistics nodes' location and the function orientation.

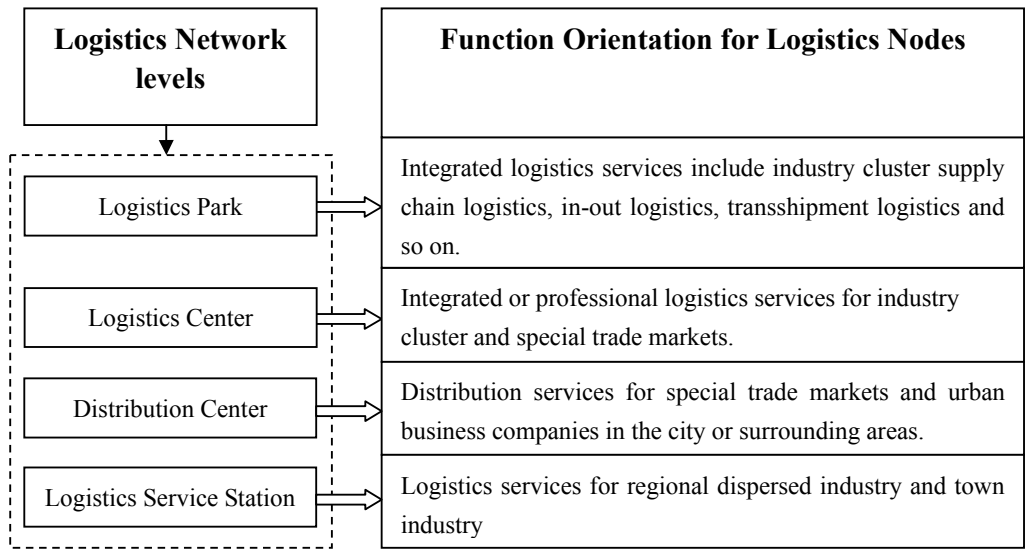

Figure 2. Logistics Network and Function Orientation

3.3 Three Platforms to Be Created

3.3.1 Infrastructure and Supporting Facility Platform

The planning for logistics infrastructure and supporting facility platforms focuses mainly on three aspects.

1. specifying the building object at all levels of the logistics network system;
2. according to local land using status, designing the spatial distribution of logistics nodes in detail, and establishing a structured system of logistics spatial distribution consisting of major logistics nodes and related transport routes as logistics channels,

3. planning the logistics nodes in detail.

3.3.2 Logistics Information Platform

It is expected that enterprises, markets, logistics nodes and some specific external interfaces be considered. Consequently, this provides a series of approaches for information exchange with provincial and municipal information platforms in the upper level, information resources sharing with platforms of other cities in the same level. In the lower level, a variety of accesses to information system of logistics nodes is provided as well as industrial management departments.

3.3.3 Logistics Organization Platform

Mainly by creating logistics industry association, logistics organization platforms are expected to play an important role in broadcasting industrial management standards, safeguarding legitimate rights and interests, promoting technical standards, exchanging industrial development information, and contacting with industrial enterprises (Liu Yinbing, L. X., Xiong Li 2008).

3.4 Four Logistics Developmental Modes

3.4.1 Four Logistics Constructive Modes

3.4.1.1 Trade logistics mode based on specialized market

In the background of existed regional commodity circulation, this mode converges on several links such as market trade service, storage, packaging and processing, and commodity distribution depicted in Figure 3. In the course of logistics activities, the characteristics are embodied as small batch and multi-batch, with diversification of logistics entities circulation varieties. The main businesses are focused on storage and commodity distribution. The key to run it effectively is the consistency of commercial flow and logistics and agility degree of information service.

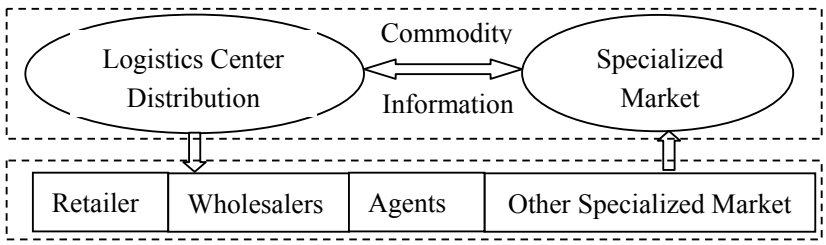

Figure 3. Trade Logistics Mode Based on Specialized Market

3.4.1.2 Integrated Logistics Mode Based on Freight Transit Hub

This mode undertakes regional logistics activities or logistics activities inner city with freight transit hub's function. It is base on special geographical position, such as ports and airport terminals. In the course of logistics activities, the characteristics are: embodied as huge batch of handling, loading and storage, scale and special logistics facilities and equipments, logistics value-added services such as health quarantine, insurance, declaring dutiable goods, international freight

forwarding, vessel-agency and so on. The key how to run it effectively is construction and operation capacity of logistics infrastructure. Logistics value added services based on freight transit hubs are outlined in Figure 4.

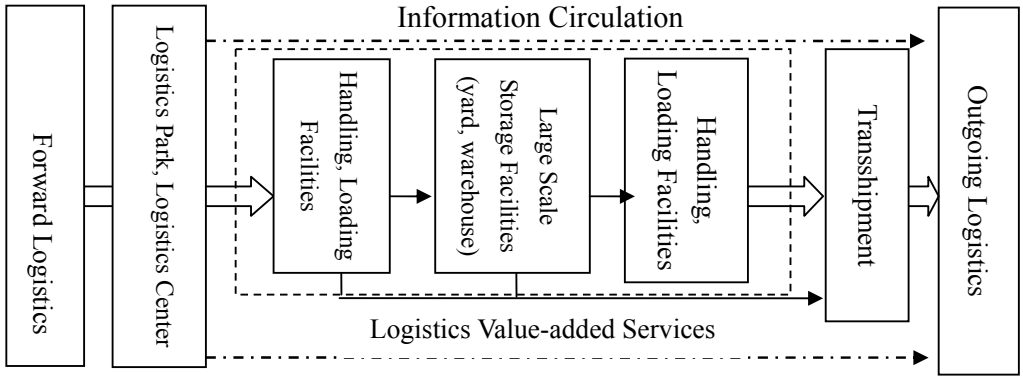

Figure 4. Integrated Logistics Mode Based on Freight Transit Hub

3.4.1.3 Multifunctional service logistics mode based on industry cluster district

The logistics layout relies on the geographical position and regional transportation condition. The different industries, depicted in Figure 5, in the cluster district are the main service objects. The mode demands establish a perfect logistics network which covers a certain range. Logistics demands service presents the characteristics of diversification. Logistics enterprises begin to supply customization and specialized logistics services.

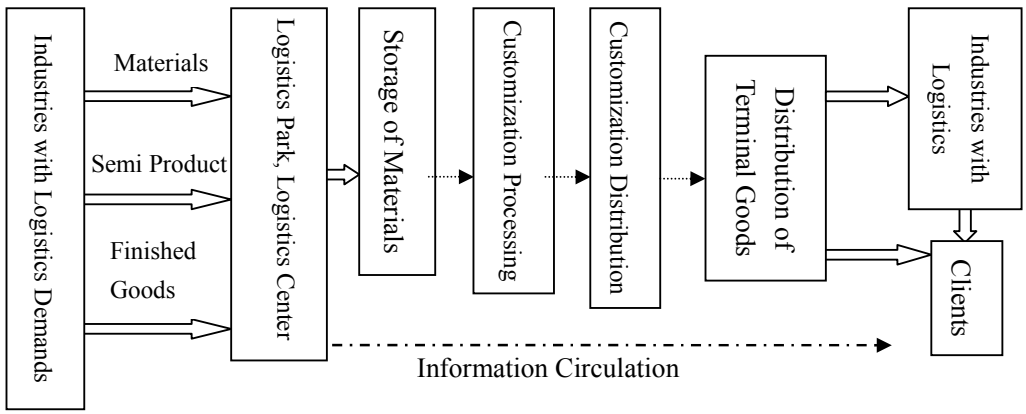

Figure 5. Multifunctional Service Logistics Mode Based on Industry Cluster District

3.4.1.4 Integrated purvey chain service logistics

The mode main supply stable purvey chain logistics service is the lead in the industry. In the logistics course, flow volume, flow direction, process and variety of freight in the purvey chain are grossly fixed. Logistics activities mainly emphasize distribution speed and quality assurance. According to order information and feedback information, logistics business request “just in time” logistics offer high

quality protection. Besides, it is necessary to set an exact regulation. Figure 6 provides order information and feedback for integrated purvey chain service logistics.

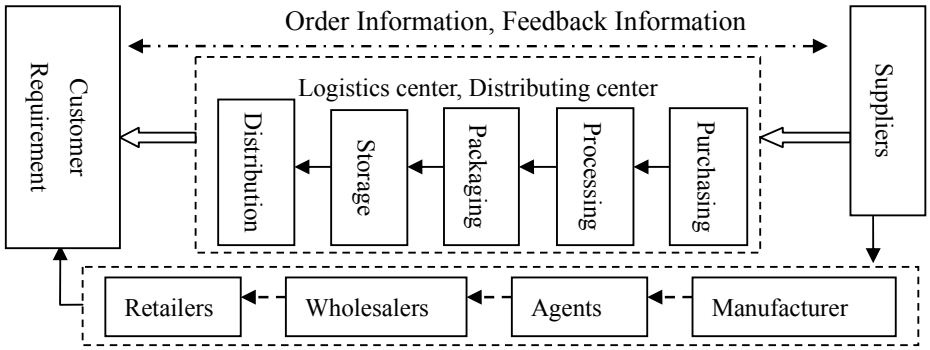

Figure 6. Integrated Purvey Chain Service Logistics

3.4.2 Four Logistics Operational Modes

The economic development zone mode treats logistics parks as a project similar to an economic, industrial, or high-tech development zone. One for well-organized development and construction is often under the organization of particular planning, policies, and development departments. The principle enterprises leading mode, which is the most commonly used operation mode today, allocates logistics and industrial resources effectively from the view of the market economy development. It performs business operation using logistics technology, offers preferential supports to enterprises advanced in enterprise supply chain management, and finally step by step realizes the aggregation of industries under the guidance of reasonable macroeconomic polices and the introduction of industrial and commercial enterprises based on logistics environments.

Industrial real-estate dealer mode considers the construction of logistics nodes as industrial real estate projects. Industrial park developers conduct the investing and building of logistics warehouse, other infrastructures and basic equipments, while managing these infrastructures in terms of lease, transfer, joint venture and cooperative operation under appropriate policies. Comprehensive operation mode is the comprehensive application of the above three modes.

3.5 Logistics Service Styles

Comprehensive logistics service style expands its services to city-wide, regional and international scope. The comprehensive logistics service style could offer services including some value-added logistics services. Industrial logistics service center style provides complete logistics services to a cluster of enterprises from a single industry or enterprises from various industries with the aid of manufacturing, processing industries and others in the industrial agglomeration zone, with related industrial bases as logistics regions. It is in this approach that, port

logistics service style provides logistics bulk freight services using harbors as transportation junction. The radiation of this style could cover the regional or even the entire international scope.

Professional trade market service style mainly delivers logistics services to local markets based on the professional trade market. The main logistics service function of the commerce distribution logistics service style lies in warehousing and distribution. Its service area focuses on the commercial industries in the city.

4 CONCLUSIONS

The modern logistics structure system is comprehensively concerned with enterprises, market, network system, infrastructure and information and policy & organization management. Combined with different main points of development, the characteristics of modern logistics structure system model could be illustrated as "one subject, two systems, three platforms, four logistics developmental modes, and five logistics service styles".

ABSTRACT

Intermodal transport can improve the efficiency, safety, and adaptability in the transportation process, and to a certain extent, it can reduce transport costs. Due to the time-varying characteristics of transport network, market demand and natural conditions, the goods' transport price and travel time are uncertain. Since it is often difficult for the carriers to correctly forecast the transport costs and travel time, intermodal transport is by natural an optimization problem of transportation choices under uncertain environment. This paper describes the uncertain environments by interval numbers, and establishes a multi-objective interval number intermodal transport model. We first create the intermodal virtual transport network by expanding every transfer node into multiple inflow and outflow nodes. The problem boils down to a multi-objective shortest path problem, which can be solved by Dijkstra's algorithm. An example is provided to demonstrate the effectiveness of the model.

Keywords: *uncertain environment, intermodal transport, interval number, multi-objective model*

1 INTRODUCTION

Intermodal transport uses two or more transport modes to deliverer the goods from the origin to the destination, and is the best way in modern logistics system (Bontekoning et al. 2004). The research on transport mode choice problem in intermodal transport system has vital practical significance (Copperman et al. 2004), because it can achieve cost or time savings, improve the transport level of service, competitiveness, and social benefits or efficiency,. Researchers often chose the total transport time (Ziliaskopoulos et al. 2000), the total transport cost (Reddy et al. 1995), or the level of service (Boardman et al. 1997) as the objective in the intermodal transport mode choice problem, and eventually transformed the problem

into a shortest path model (Ziliaskopoulos et al. 2000; Reddy et al. 1995), or a multi-objective combinatorial optimization model (Chang, 2008).

None of the studies mentioned above considers the integration of transport time and transport costs, and the studies only focus on the cases with deterministic freight transport costs and time. However, due to the uncertain characteristics of transport network, market demand and natural conditions, it is often difficult for the carriers to grasp and identify the information of a variety of costs and transport time, and thus impossible to accurately forecast them. Therefore, intermodal transport is an optimization problem of transportation choices under uncertain environment. For uncertainty problem, interval analysis is an essential mathematical tool. The use of interval numbers may describe the complex real-world uncertain problem more realistically, and is more consistent with people's fuzzy thinking habits.

This paper describes the uncertain environments by interval numbers, and establishes a multi-objective interval number intermodal transport model. We first create the intermodal virtual transport network by expanding every transfer node into multiple inflow and outflow nodes. The problem then becomes a multi-objective shortest path problem. Taking the decision-makers' preferences information into account, we introduce decision-makers' preference operator and then use Dijkstra's algorithm to solve for the shortest path.

2 MULTI-OBJECTIVE INTERVAL NUMBER MODEL OF INTERMODAL TRANSPORT UNDER UNCERTAIN ENVIRONMENT

2.1 Problem Description

Suppose intermodal transport carriers attempt to establish an intermodal transport path from city O to city D. There are n cities as internal nodes, where adjacent cities have a number of transport modes in between. The problem is to determine the best transport routes and modes combination, which has the minimum total transport cost and total transport time. The basic assumptions of this paper are as follows:

1) The transport network can be divided into phases. There is no path within the same phase and between non-adjacent phases;

2) The freight can not be divided at a node, that is, between a particular nodes pair only one transport mode can be chosen, and transfer only happens at the interim node;

3) The transport times and costs of different transport modes are different between any two adjacent cities, and the capacity of each mode is large enough;

4) There is transfer time and cost associated with mode transfer.

2.2 Model Foundation

Similar to Ziliaskopoulos et al. (2000) and Reddy et al. (1995), we establish the multi-objective interval number model for intermodal transport problem under uncertain environment as follows:

$$z = \min\left(\sum_i \sum_k x_{i,i+1}^k \tilde{c}_{i,i+1}^k + \sum_i \sum_k \sum_l y_i^{kl} \tilde{f}_i^{kl} + \sum_i \sum_k x_{i,i+1}^k \tilde{t}_{i,i+1}^k + \sum_i \sum_k \sum_l y_i^{kl} \tilde{g}_i^{kl} \right) \quad (1)$$

Subject to:

$$\sum_k x_{i,i+1}^k = 1, \forall i \in N \quad (1\text{-}1)$$

$$\sum_k \sum_l y_i^{kl} \le 1, \forall i \in N, k \in K, l \in K \tag{1-2}$$

$$x_{i-1,i}^k + x_{i,i+1}^l \ge 2 y_i^{kl}, \forall i \in I, k \in K, l \in K \tag{1-3}$$

$$y_i^{kl}, x_{i,i+1}^k \in \{0,1\}, \forall i \in I, k \in K, l \in K \tag{1-4}$$

$$x_{i,i+1}^k = \begin{cases} 1 & \text{if mode } k \text{ is chosen from node } i \text{ to node } i+1 \\ 0 & \text{otherwise} \end{cases}$$

$$y_i^{kl} = \begin{cases} 1 & \text{if transfer from mode } k \text{ to mode } l \text{ at node } i \\ 0 & \text{otherwise} \end{cases}$$

Here $\tilde{c}_{i,i+1}^k = \left[c_{i,i+1}^{k-}, c_{i,i+1}^{k+}\right]$ is the interval number associated with the transport cost of mode k from node i to node $i+1$; $\tilde{f}_i^{kl} = \left[f_i^{kl-}, f_i^{kl+}\right]$ is the interval number for transfer cost from mode k to mode l at node i; $\tilde{t}_{i,i+1}^k = \left[t_{i,i+1}^{k-}, t_{i,i+1}^{k+}\right]$ is the interval number for transport time of mode k from node i to node $i+1$; $\tilde{g}_i^{kl} = \left[g_i^{kl-}, g_i^{kl+}\right]$ is the interval number for transfer time from mode k to mode l at node i; K is the set of available transport modes; and N is the set of all nodes.

For the constraints, (1-1) guarantees only one mode of transport is chosen between two adjacent nodes; (1-2) means at each node only one transport mode change is allowed; (1-3) ensures the transport continuity and internal consistency, if mode transfer occurs at node i from mode k to mode l, then mode k must be used from node $i-1$ to i, and similarly mode l must be chosen from node i to $i+1$; and (1-4) shows the decision variables are 0-1 variables.

2.3 Model Conversion

The objective function of model (1) is a function of various costs and time. Since the units of these costs and time might be different, they are not directly additive. Here we use the occupancy cost rate of capital per unit time and the total value of goods for the time-cost conversion. For transport time, if the occupancy cost rate of capital per unit time is $\rho_{i,i+1}$, the total value of goods is $p_{i,i+1}$, then the transport time can be converted to $p_{i,i+1}\left[\left(1+\rho_{i,i+1}\right)^{x_{i,i+1}^k \tilde{t}_{i,i+1}^k} - 1\right]$. For transfer time, if the occupancy cost rate of capital per unit time is ρ_i, the total value of goods is p_i, then the transfer time can be converted to $p_i\left[\left(1+\rho_i\right)^{y_i^{kl} \tilde{g}_i^{kl}} - 1\right]$.

The generalized transport cost of using mode k from node i to node $i+1$ includes transport cost and transport time cost, which can be expressed as $\vec{C}_{i,i+1}^k = x_{i,i+1}^k \tilde{c}_{i,i+1}^k + p_{i,i+1}\left[\left(1+\rho_{i,i+1}\right)^{x_{i,i+1}^k \tilde{t}_{i,i+1}^k} - 1\right]$. The generalized transfer cost from mode k to mode l at node i includes transfer cost and transfer time cost, which can be expressed as $\vec{C}_i^{k,l} = y_i^{kl} \tilde{f}_i^{kl} + p_i\left[\left(1+\rho_i\right)^{y_i^{kl} \tilde{g}_i^{kl}} - 1\right]$. The objective function of model (1) can then be converted to the generalized total cost, which can be expressed as:

$$\tilde{z} = \min\left(\sum_i \sum_k \left(x_{i,i+1}^k \tilde{c}_{i,i+1}^k + p_{i,i+1} \left[\left(1+\rho_{i,i+1}\right)^{x_{i,i+1}^k \tilde{t}_{i,i+1}^k} - 1 \right] \right) + \sum_i \sum_k \sum_l \left(y_i^{kl} \tilde{f}_i^{kl} + p_i \left[\left(1+\rho_i\right)^{y_i^{kl} \tilde{g}_i^{kl}} - 1 \right] \right) \right)$$

$$= \min\left(\sum_i \sum_k \vec{C}_{i,i+1}^k + \sum_i \sum_k \sum_l \vec{C}_i^{k,l} \right)$$

In order to reduce the cost-time multi-objective model into a single objective one, we adopt the interval number conversion method. By defining a decision-maker's preference operator, it is possible to map the sequence relationship of the interval numbers to the ordering relationship of real number. The order of the interval numbers can be sorted as:

$$O: I \to R, w_\lambda(\tilde{a}) = m(\tilde{a}) + \lambda w(\tilde{a})$$

where I is the interval number scale, R is the real number scale, and λ is the preference operator, $m(\tilde{a}) = 1/2 \cdot \left(a^- + a^+\right)$ is the center of interval $\tilde{a}$, and $w(\tilde{a}) = a^+ - a^-$ is the width of interval $\tilde{a}$. We let $-1/2 \le \lambda < 0$ for risk-taking, $\lambda = 0$ for risk-neutral, and $0 < \lambda \le 1/2$ for risk-averse decision-makers. This way we are able to map the interval numbers to real numbers, and incorporate decision-makers' preference as a parameter into the shortest path selection. We then use Dijkstra's algorithm to find the shortest paths under different preferences.

3 THE CONSTRUCTION OF INTERMODAL TRANSPORT NETWORK

The basic intermodal transport network is composed by nodes and arcs between adjacent nodes, where each arc is associated with one mode. Denote N as the set of nodes, K the set of transport modes, and A the arc set. Any arc $a \in A$ can be expressed by $(i, i+1, k)$, where $i, i+1 \in N$ and $k \in K$.

1) If mode transfer is not allowed, we will leave the basic network as it is, with parallel links connecting two adjacent nodes, where each link is associated with one possible mode and its generalized transport costs.

2) If mode transfer is allowed, each transfer node will be expanded into two groups: inflow and outflow nodes. Virtual transfer lines are introduced into the network as shown in Figure 1.

3) According to the above expansion idea, we construct the intermodal virtual transport network. In a complex intermodal transport network, mode transfer may occur at every node. Therefore, every node except the origin node O is expanded to k virtual nodes. For the purpose of computation convenience, we introduce a virtual destination D', where the transfer time and cost between every destination node D_i and D' is equal to 0.

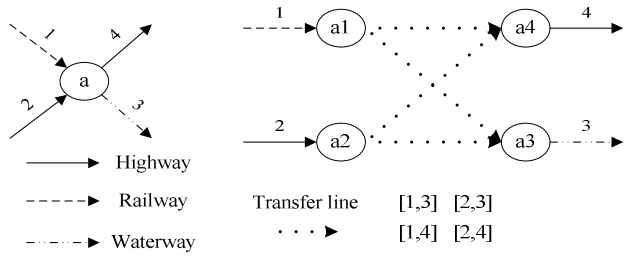

Figure 1. The expansion of transfer node

4 EXAMPLE ANALYSIS

Assume there are six internal nodes, n_1 to n_6, from the original node O to destination D. According to the node expansion idea, we construct the intermodal virtual transport network, as shown in Figure 2. Outgoing arcs of virtual nodes P_{i1} are associated with the railway, those of P_{i2} take highway as the transport mode, and those of P_{i3} refer to waterway.

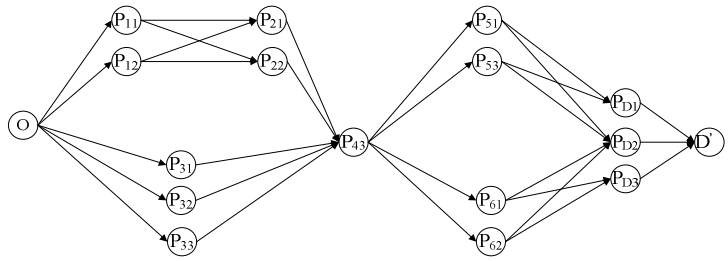

Figure 2. The intermodal virtual transport network of the example

The transport costs / transport time costs of alternative transport modes between the nodes are shown in Table 1, and blank cell means the corresponding mode is not available between the two cities. Table 2 shows the transfer costs / transfer time costs between different modes. According to different values of the decision-maker's preference parameter λ, three cases are solved. For each case, the shortest paths with respect to cost, time, and the multi-objective function value are obtained respectively. The results, as shown in Table 3, provide optimal integrated route and mode choices for the intermodal transport routing problem.

Table 1. The transport costs / transport time costs of alternative transport modes between the nodes

	O-n1	O-n3	n1-n2	n2-n4	n3-n4	n4-n5	n4-n6	n5-D	n6-D
Railway	[2,4]/[4,8]	[3,5]/[5,9]	[2,4]/[4,6]			[6,10]/[9,15]	[6,10]/[10,16]	[7,11]/[12,18]	
Highway	[3,5]/[4,6]	[2,4]/[4,8]	[1,3]/[4,8]				[5,9]/[8,14]	[8,12]/[10.16]	[6,10]/[11,17]
Waterway		[1,3]/[8,12]		[2,4]/[9,15]	[4,6]/[11,17]	[4,6]/[12,20]			[4,8]/[12,20]

Table 2. The transfer costs/transfer time costs between different modes

Transport modes	Railway	Highway	Waterway
Railway	0/0	[1,3]/[1,3]	[2,4]/[2,4]
Highway	[1,3]/[1,3]	0/0	[3,5]/[1,3]
Waterway	[2,4]/[2,4]	[3,5]/[1,3]	0/0

Table 3. The solving results of intermodal transport routing model

	Path and transport modes		Transport cost	Transfer cost	Transport time cost	Transfer time cost	Total cost
	the shortest cost	O -P_{33}-P_{43}-P_{53}-P_{D1}- D'	16	2	--	--	18
$\lambda = -1/2$	the shortest time	O -P_{32}-P_{43}-P_{62}-P_{D2}- D'	--	--	34	2	36
	multi-objective	O -P_{33}-P_{43}-P_{62}-P_{D2}- D'	16	3	38	1	58
	the shortest cost	O -P_{33}-P_{43}-P_{53}-P_{D1}- D'	21	3	--	--	24
$\lambda = 0$	the shortest time	O -P_{32}-P_{43}-P_{62}-P_{D2}- D'	--	--	45	4	49
	multi-objective	O -P_{33}-P_{43}-P_{62}-P_{D2}- D'	22	4	49	2	77
	the shortest cost	O -P_{33}-P_{43}-P_{53}-P_{D1}- D'	26	4	--	--	30
$\lambda = 1/2$	the shortest time	O -P_{32}-P_{43}-P_{62}-P_{D2}- D'	--	--	56	6	62
	multi-objective	O -P_{33}-P_{43}-P_{62}-P_{D2}- D'	28	5	60	3	96

5 CONCLUSIONS

From the numerical example, we educe the following conclusions:

1) Single-objective model has different optimal paths for different objective functions, i.e., the shortest cost path and the shortest time path are not the same. And by taking into account both the transport costs and time, the optimal solution to the multi-objective model may vary with different weighting factors.

2) The optimal path remains the same but has different total cost for different values of the decision-maker's preference parameter λ. According to the numerical results, the cost of the minimal cost / time path is [18, 30] and [36, 62] respectively, and the total cost of the minimal multi-objective path is [58, 96].

ABSTRACT

This paper proposes a new approach to evaluate the total risk degree for emergency guarantee mechanism of food logistics. Firstly, it reveals the composition of emergency guarantee mechanism of food logistics. Secondly, it puts forward a two-level risk evaluation index system on the basis of path analysis with AHP method. Thirdly, it develops a model which combines fuzzy comprehensive evaluation with hierarchy variable weight method, in order to improve the accuracy and reliability of risk evaluation by solving the deferred problem of risk. Finally, the paper verifies the efficiency and applicability of the model with a simulation example.

KEY WORDS: fuzzy comprehensive evaluation; hierarchy variable weight; emergency guarantee mechanism; food logistics; risk evaluation

INTRODUCTION

Emergency guarantee refers to the process of controlling, handling and managing various activities in sudden events by effectively integrating relevant resources (Ji et al., 2006). Therefore emergency guarantee mechanism is provided to react to various emergencies during all phases of emergency management (Yao and Gao, 2006). It may include but is not limited to the following five components: early warning mechanism, monitoring mechanism, rapid reaction mechanism, urgent disposal mechanism and rehabilitation mechanism (Zhao et al., 2006). However, the supply of rescue materials, especially food, is often affected by sudden events. Perishable loss often happens in food logistics during transportation, handling and storage (Xu, 2007). Thus, how to recognize and prevent the risks in emergency guarantee process of food logistics is extremely crucial.

Many researches have studied the risk analysis and evaluation methods, such as investigation method, Delphi, net present value method, hierarchy analysis, antd sensitivity analysis, etc. (Yan et al., 2004). But most methods regard the uncertainty of risk as randomness, and measure it by means of probability distribution. However, the uncertainty of risk is not only random but also fuzzy in nature (Steed, 2000). Furthermore, it's very important to deal with the deferred characteristic of risk in its

evaluation, which means that the risk in early stage will be gradually enlarging during its backward transmission. Therefore, the hierarchy variable weight method can be used to improve the accuracy of risk evaluation (Li et al., 2004).

This paper proposes a two-level risk evaluation index system for emergency guarantee mechanism of food logistics on the basis of path analysis with AHP method. A model which combines fuzzy comprehensive evaluation with hierarchy variable weighting method is then built. Finally, a simulation example is conducted to verify the applicability and effectiveness of the model. The model can also be considered as the means of recognizing and preventing risks.

RISK EVALUATION INDEX SYSTEM

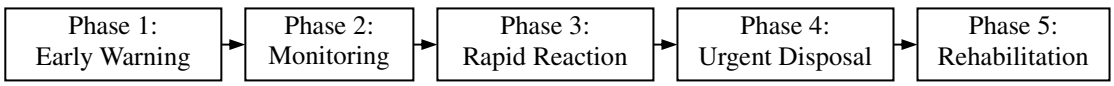

Figure 1. Horizontal path map of emergency guarantee mechanism.

First of all, according to the five corresponding components of the emergency guarantee mechanism, a path which is composed of five phases can be obtained through Path Analysis (PA) as shown in Figure 1. We can outspread the above path longitudinally, and arrange the risk factors within each phase through AHP method. Considering the special characteristics of food logistics, this paper establishes a two-level risk evaluation index system for emergency guarantee mechanism of food logistics as shown in Table 1.

MODEL CONSTRUCTION

Building factor sets and weight sets. As shown in Table 1, the factor set of the top-level indexes is $U = \{U_1, \cdots, U_5\}$, and the relative weight set is $A = \{A_1, \cdots, A_5\}$. The sub-factor set of the sub-level indexes is $U_i = \{u_{i1}, \cdots, u_{ij}\}$, while the relative weight set is $A_i = \{a_{i1}, \cdots, a_{ij}\}$, where $i = 1, \cdots, 5$ and j is the number of the sub-factors (i.e., sub-level indexes) corresponding to U_i.

Constructing the risk degree-marking vector. In order to effectively describe the risk evaluation of all factors, the five-grade marking system can be used. The risk degree of a certain factor is slim as its marking value is 1, and it is large when the value is 5. Then we may construct the risk degree marking vector as $V = (v_1, v_2, v_3, v_4, v_5) = (1, 2, 3, 4, 5)$.

Calculating the fuzzy evaluation values. The fuzzy evaluation value c_{ij} of each sub-factor u_{ij} can be calculated by fuzzy statistics method. Firstly, experts can be invited to evaluate the risk degree of each sub-factor u_{ij} according to the given evaluation criterion. They independently give the evaluation marking values for each sub-factor u_{ij}. Then we can summarize the frequency of $u_{ij} \in v_k (k = 1,2,3,4,5)$, and make further calculations as follows:

$$m_{v_k}(u_{ij}) = w_{ij}^{(v_k)} / N \qquad (0 \le m_{v_k}(u_{ij}) \le 1)$$

where $m_{v_k}(u_{ij})$ is a fuzzy membership function, which denotes the fuzzy membership degree of $u_{ij} \in v_k (k = 1,2,3,4,5)$; $w_{ij}^{(v_k)}$ refers to the frequency of $u_{ij} \in v_k (k = 1,2,3,4,5)$; N is the number of experts. Therefore, the fuzzy membership vector of each u_{ij} is $M_{ij} = \left(m_{v_1}(u_{ij}), m_{v_2}(u_{ij}), m_{v_3}(u_{ij}), m_{v_4}(u_{ij}), m_{v_5}(u_{ij})\right)$, and the fuzzy evaluation value c_{ij} of u_{ij} can be calculated as follows:

$$c_{ij} = V \times M_{ij}^T = \sum_{k=1}^{5} v_k \times m_{v_k}(u_{ij}) \qquad (1 \le c_{ij} \le 5)$$

Table 1. Risk Evaluation Index System.

No.	The top-level indexes	Evaluating variables	The sub-level indexes	Evaluating variables
1	Early Warning	U_1	early warning on large-scale sudden events outbreak	u_{11}
			early warning on food manufacture and supply shortage	u_{12}
			early warning on food safety threat	u_{13}
			early warning on food logistics condition	u_{14}
2	Monitoring	U_2	Monitoring on food resources	u_{21}
			Monitoring on food safety	u_{22}
			Monitoring on food transportation and distribution	u_{23}
			Monitoring on organization	u_{24}
			Monitoring on tech equipments	u_{25}
3	Rapid Reaction	U_3	rapid reaction on emergency food manufacture and supply	u_{31}
			rapid reaction on emergency food safety inspection	u_{32}
			rapid reaction on emergency food transportation and distribution	u_{33}
4	Urgent Disposal	U_4	urgent disposal on food manufacture and supply interruption	u_{41}
			urgent disposal on food safety hazard	u_{42}
			urgent disposal on food transportation and distribution disturbance	u_{43}
			urgent disposal on food redistribution and compensation	u_{44}
5	Rehabilitation	U_5	rehabilitation on food manufacture and supply accident	u_{51}
			rehabilitation on food safety accident	u_{52}
			rehabilitation on food transportation and distribution accident	u_{53}
			rehabilitation on organization disorder	u_{54}
			Rehabilitation on tech equipments failure	u_{55}

Constructing the state vectors. The state vector value x_{ij} of u_{ij} can be calculated as follows:

$$x_{ij} = c_{ij} / \sum_j c_{ij} \qquad (0 \le x_{ij} \le 1)$$

Then we may construct the state vectors $X_i = (x_{i1}, \cdots, x_{ij})$ of factors $U_i (i = 1, \cdots, 5)$.

Constructing the state variable weight vectors. The state variable weight vectors $S_i = (s_{i1}, \cdots, s_{ij})$ of factors U_i can be constructed according to the relative state vectors $X_i = (x_{i1}, \cdots, x_{ij})$ (Li et al., 2004). There are three types of state variable weight vectors, which are punishment-type, stimulation-type and hybrid-type. They denote three kinds of variable weight methods respectively (Hou et al., 2005). The state variable weight value s_{ij} of u_{ij} can be defined as follows:

$$s_{ij} = x_{ij}^{\alpha} \qquad (0 < \alpha \le 1)$$

It is obvious that state variables weight vector $S_i = (s_{i1}, \cdots, s_{ij}) = (x_{i1}^{\alpha}, \cdots, x_{ij}^{\alpha})$ belongs to the stimulation type as $0 < \alpha \le 1$. Furthermore, if α becomes smaller and smaller, the "stimulation" effect of variable weight method becomes more and more strong, indicating that the deferred characteristic of risk become larger.

Calculating the variable weight evaluation value. The variable weight a_{ij}^* of u_{ij} can be calculated as follows:

$$a_{ij}^* = a_{ij} s_{ij} \Big/ \sum_j a_{ij} s_{ij}$$

Therefore, the variable weight evaluation value U_i^* of corresponding top-level factor U_i can be calculated as follows:

$$U_i^* = A_i^* \times X_i^T = \sum_j (a_{ij}^* \times x_{ij}) \qquad (i = 1, \cdots, 5)$$

Then we may construct the top-level variable weight evaluation vector as $U^* = (U_1^*, \cdots, U_5^*)$. Eventually, the weight evaluation value for the top-level variable U^*, which describes the total risk degree for the emergency guarantee mechanism of food logistics, can be obtained by this vector through the same calculation.

SIMULATION EXAMPLE

In order to illustrate the application of this model, a simulation example is given below. It takes source data from a certain simulative emergency guarantee process of food logistics by using simulation software.

Fuzzy evaluation calculation. We may calculate the fuzzy membership degree $m_{v_k}(u_{ij})$ of u_{ij} according to experts' evaluation marking values, then obtain c_{ij} and x_{ij} of u_{ij} as in Table 2.

Calculation for hierarchy weight fuzzy evaluation. Considering the deferred characteristic of risk, the α value in the first four phases of emergency guarantee process should be add one fixed value. The fixed added value of α is 0.15 in the paper, and $\alpha = 1$ for the last phase (i.e., phase 5). Then the calculation is demonstrated in Table 3.

Table 2. Fuzzy Evaluation Calculation.

U_i	u_{ij}	a_{ij}	$m_{v_1}(u_{ij})$	$m_{v_2}(u_{ij})$	$m_{v_3}(u_{ij})$	$m_{v_4}(u_{ij})$	$m_{v_5}(u_{ij})$	c_{ij}	x_{ij}

	u_{43}	0.26	0.5	0.25	0.15	0.05	0.05	1.9	0.1949
	u_{44}	0.22	0.15	0.15	0.25	0.3	0.15	3.15	0.3231
U_5	u_{51}	0.21	0.5	0.2	0.15	0.1	0.05	2	0.1843
	u_{52}	0.23	0.3	0.3	0.15	0.1	0.15	2.5	0.2304
	u_{53}	0.18	0.2	0.3	0.3	0.2	0	2.5	0.2304
	u_{54}	0.16	0.3	0.2	0.2	0.2	0.1	2.6	0.2396
	u_{55}	0.22	0.8	0.15	0.05	0	0	1.25	0.1152

As is shown in Table 3, the top-level state variable weight vector can be constructed as $U^* = (0.2491, 0.1990, 0.3385, 0.2548, 0.2083)$. In the same way, we implement the variable weight calculation on vector U^* as shown in Table 4.

Eventually, the top-level hierarchy variable weight fuzzy comprehensive evaluation value of U^* is 0.2232.

Evaluating the total risk degree. Since evaluation value varies from 0 to 1, this paper proposes a five-grade rating system for evaluating the total risk degree according to its value interval, i.e. [0, 0.2] is “slim”, [0.2, 0.4] is “small”, [0.4, 0.6] is “general”, [0.6, 0.8] is “big”, and [0.8, 1] is “large”. Therefore the total risk degree is evaluated as “small”, which shows that the emergency guarantee mechanism basically plays a safe and reliable role in sudden events.

CONCLUSION

This paper thoroughly investigates the risk evaluation for emergency guarantee mechanism of food logistics. The simulation example verifies the applicability and effectiveness of the proposed model. It makes relatively objective evaluation on total risk degree which helps to recognize and prevent the risks effectively. Future research will focus on continuous improvement of evaluation index system and various models under more complicated conditions.

ABSTRACT

On the basis of discussing the characteristics of logistics demand of communication information, communication information is divided into three categories which include dynamic, static and relevance. In order to fully grasp the dynamic communication information, a three layer platform of logistics distribution information system is designed. This is based on the 3rd generation mobile communication technology (3G), and expounding the composition and working principle of regional distribution centers. Then on-board information devices are designed, which is one of the most important logistics information terminals. The benefits of regional distribution information systems, based on 3G mobile communications technology, is illustrated using the example of taking on–board information devices together with real-time communication information to locate the shortest time line. The system can make vehicles receive communication information at anytime and anywhere, so it is more suitable to the characteristics of time-varying and dynamics of regional distribution information.

KEYWORDS

Intelligent regional distribution systems; 3rd generation mobile communication technology; communication information center; on-board information device

1 FORWORD

Logistics is a complicated system touching on several aspects of social economic life. In the course of the logistics process, distribution is an important aspect. The process of logistics distribution is to plan, execute and control the practical process of raw material or final products from the place of origin to the place of usage. Every link in the logistics process involves the problem about how to deal with enormous spatial data and attributive data to shorten logistics time and lower the cost. In general, the transmission of data information adopts wired and wireless styles. The dynamic characteristics of the logistics distribution process decide which of the wireless communication styles should be adopted in the terminal (YANG Li Qiang, 2007). Compared with the wired style, wireless transmission has the features of lower cost, short construction cycle, good adaptability and extension,and easiness of safeguard.

Widely used 2nd mobile communication technology is not suitable for transmitting the multi-media logistics distribution information with enormous data, because of the weakness of a slow transmission rate. Through the combination of the

3rd generation mobile communication technology with other information technology, and the popularization of the 3rd generation mobile communication technology (with the transmission rate of 384kbps to 3Mbps faster) (ZHAO Zhen, 2008), the alternation of logistics distribution information and real-time transmission can be realized effectively. The paper will discuss the application of the 3rd generation mobile communication technology and other relevant information technology in logistics distribution.

2 REQUIREMENTS ANALYSIS OF THE REGIONAL LOGISTICS INFORMATION SYSTEM

The major objective of the regional logistics information platform is oriented to every-grade customer in a given region (HE Jie, 2003). There are related logistics management departments in the government, professional third-party logistics enterprises, manufacturing enterprises demanding logistics services and some units providing services to the links of logistics. Through the perspective of systematical requirements specifications, the principal function should include the following aspects.

(1) Rational distribution scheme: logistics distribution from distribution to custom is a very complex process. In the process, the most difficult issue is how to arrange the distribution plan according to the quantity and time. Formulating the distribution scheme includes the following sub-process: selection of logistics center; selection of vehicle; vehicle loading scheme; and vehicle routing arrangement. In order to reduce cost, if the capacity of the vehicle allows, it is best to put the goods of many customs together. It leads to many problems such as the arrangement of vehicle route, and the decision of dispatching time. The above sub-processes are not independent; they will influence each other (YANG Deng, 2008).

(2) The dynamic acquisition of the distribution information: on-time delivery, determination of the dynamic location.

(3) The storage and disposal of information

(4) Information analysis: the aim of information analysis lies in calculating the process cost and realizing maximization of profit through analyzing the distribution and sales data, vehicle route, and the stock of the distribution center.

(5) Real-time information transmission

(6) Disposal of the distribution sheet

3 STRUCTURE DESIGN OF THE LOGISTICS DISTRIBUTION INFORMATION SYSTEM

3.1 Logistics distribution system structure design

Based on the demand of the logistics distribution system, the system involves seven models: gathering model, distribution pattern model, preprocessing model, distribution model, transportation optimization model, allocating model and tabulating model (WANG Xiaokun, 2008). The seven models are included in the model base. In addition, ten relevant databases should be built for the data

procession of the models. They are: custom applying for delivering database, inventory database, overall application database, overall stock database, commodity distribution database, distance matrix database, good allocation database and distribution center database. In order to combine the model part and data part, a general control program should be built. It is conducive to the process of every model and the effective storage of data. The structure of the process is as follows in Figure 1.

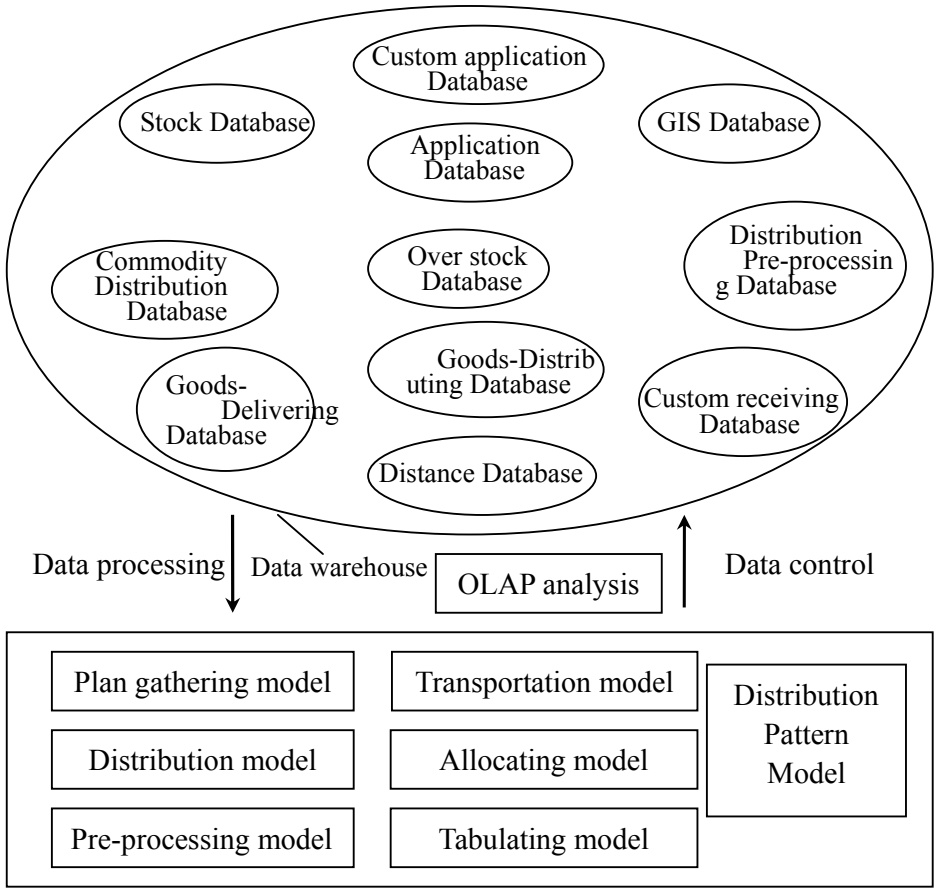

Figure 1. The overall structure of the logistics distribution system.

3.2 The information pack of distribution business

In the general construction design of the logistics distribution system, the design of the data warehouse is very important. During the construction of the data warehouse, the information pack oriented to the data warehouse of logistics distribution is adopted, as Figure 2 demonstrates. When constructing the data warehouse, there are many kinds of parameters to define. In order to make the data warehouse both effective and simple, it is important to choose correct parameters to make detailed descriptions of the distributed goods. The following dimensions are

defined in the figure of information pack: time dimension, goods dimension and vehicle dimension.

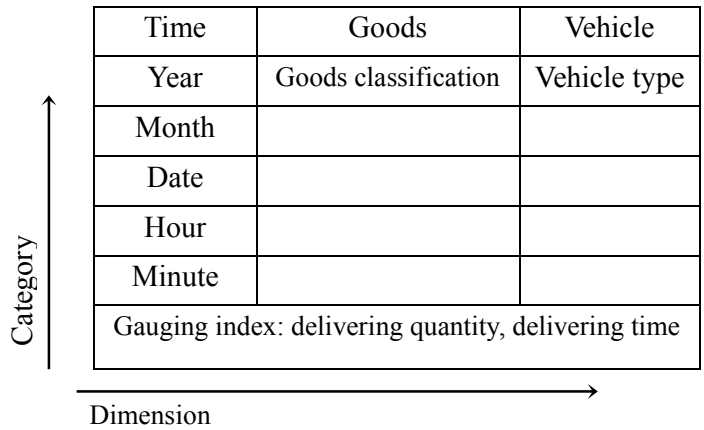

Figure 2. Information pack of distribution business.

Through the comprehensive analysis of the distribution business pack, we can get the details of the distribution business. For example, through the analysis on vehicle dimension and time dimension, we can check the situation of the vehicle. Through the analysis on vehicle dimensions and goods dimensions, we can check the status of distributing goods and analyze the loading capacity of every vehicle. Different dimensions have different polymerization levels. In the logic design of a data warehouse, an important issue is to decide the grading division level of the data warehouse, whether the grading division level is suitable or not will have influence on the data quantity in the data warehouse and suitable query type (YANG Feng, 2008).

3.3 The design of the distribution platform scheme

Every kind of business information in the distribution process can be acquired by automatic collection and artificial collection. Having been standardized, they can be transmitted to the information disposal centers through special medium and provide the function of data query, data classification and data storage for realizing the function of the distribution information system. The function of collecting, classifying and processing all dynamic information, static information and relevant information, as well as searching for the optimal distribution route, will be accomplished automatically in the system. Due to the large quantity of data disposal, we use the 3rd generation mobile communication network to acquire the dynamic data. Depending on the 3rd generation network, the transmission of real-time information can be accomplished conveniently. With the fast development of the logistics industry, constructing the special 3rd generation network based on logistics usage and forming the logistics information platform utilizing the 3rd generation technology as the core provides the best choice. The platform scheme includes a

distribution business operation layer, a distribution business management layer and a distribution business decision layer, as shown in Figure 3. The effective implementation of a higher layer is based on the implementation of the lower ones. At the same time, the higher layers play the role of managing the lower ones (XU Wei, 2008).

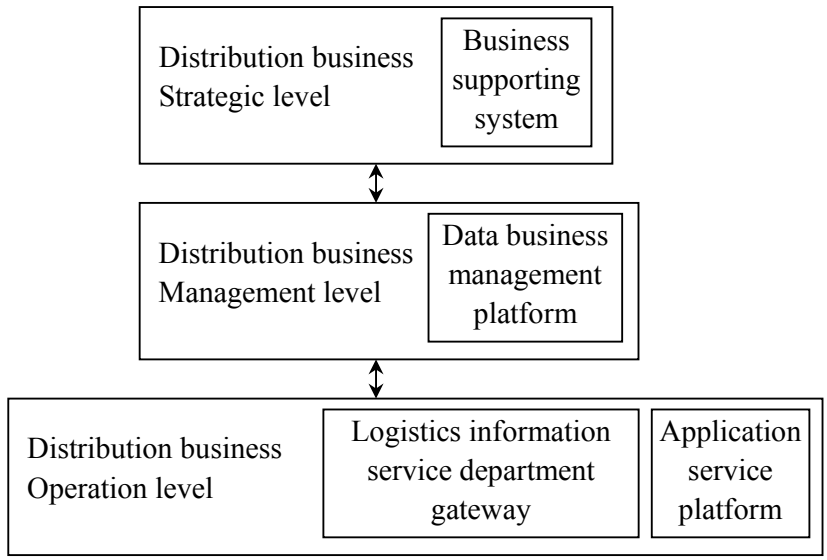

Figure 3. Logistics information platform scheme based on 3G.

4 THE ANALYSIS OF THE SYSTEMATIC FUNCTION

Using the distribution system, we can conduct online analytical processing conveniently. For example, during the distribution process, we can analyze the rate of arriving in the right place, the expenditures, vehicle distribution and vehicle route, etc.

4.1 The analysis of arriving in the right place

In data warehouse design, we consider the vehicle dimension and time dimension but not the route dimension. When the place of distribution is determined, the distance from the distribution to every demand point is fixed. Using the shortest route model (LI Yuming, 2008), the optimal route will be found. To find out if the distribution missions arrive in the right place can be determined by the analysis based on the time window constrained model and the operation on the rate in vehicle dimension table and on the earliest arriving time and latest arriving time in the time dimension table.

4.2 The analysis of the expenditure condition

The best method to make profit is by reducing the fixed cost and variable cost by using the present resources. Variable cost includes manpower cost such as drivers, loaders and vehicle attrition. Fixed cost includes the purchasing cost and depreciation cost of the vehicle. Putting the above mentioned cost together is the

distribution cost. Using the least expenditure model, the expenditure of every distribution mission is calculated. The monthly or the yearly sheet is determined by adding the above expenditure. Through the analysis on the monthly or yearly sheet, more detail about the operation condition itself can be beneficial to lay down the strategic plan in the future.

4.3 The analysis of the vehicle distribution

In many circumstances, a truck loaded with as many items of a single good cannot be fully loaded due to the dimension constraints of the single good. At that time, the goods will be mixed-loaded to improve the processing efficiency of the vehicle. In data warehouse design, we have planned the vehicle dimension and goods dimension to satisfy the demand of mix-loading the goods. Through analyzing the load capacity in vehicle dimension and the unit weight in goods dimension we can get the optimal distribution scheme to make use of the load capacity of the vehicle and give full play to the maximum processing efficiency of the vehicle.

4.4 The analysis of the vehicle route

The analysis of the vehicle route mainly depends on the shortest route model. Because the location of every distribution center is fixed, the selection of route lies in the location of every demand point. The execution of distribution mission is a route. Through the long-term data accumulation and analysis on the data, the enterprise is able to find an optimal route (ZHAO Zhengfen, 2004).

4.5 The structure of the on-board information device

A vehicle running in the city should be provided with the function of position and navigation. The drivers can find the traffic information by interactive equipment. The hardware composition of the on-board information device is as follows in Figure 4.

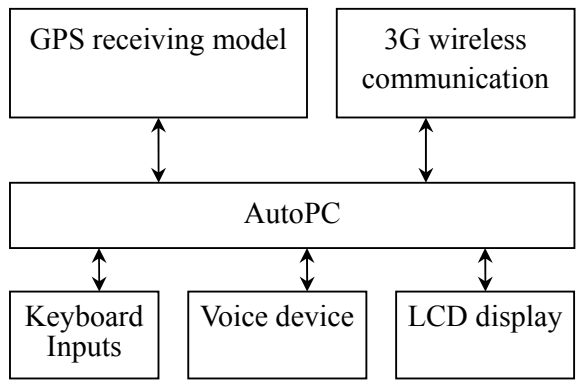

Figure 4. Hardware composition of the on-board information devices.

The vehicle supplies power to the on-board information device. The GPS receiving model calculates the function of position and the function of map-matching and provides navigating by LCD display equipment. Drivers control the query of traffic information by the input device such as keyboard; by 3rd generation mobile communication model, the interconnection between the on-board information device

and TIC is realized. At the same time, voice equipment broadcasts sound information.

4.6 Inquiring traffic information by the on-board device

The drivers can acquire the shortest route from A to B by inquiring the on-board device.

The software calculating the shortest route is installed on the AutoPC. Due to the dynamic traffic information, the shortest route from A to B is continuously changing. So the information interaction is conducted at the crossing. The on-board device makes the suitable regulation based on the dynamic real-time traffic condition to ensure the route shortest (Schumann, 1993).

5 THE MANAGEMENT OF THE DISTRIBUTION SYSTEM

In the distribution information system, to identify the goods, the most convenient method is through Radio Frequency Identification, called RFID. RFID is a non-contact auto-recognition technology. It recognizes the object through radio frequency signals and can track the goods and exchange data quickly. In recognition work, there is no man needed, it can work in adverse circumstances. RFID technology can recognize high speed moving objects and recognize several labels at the same time with easy operation. It benefits for the accomplishment of ERP (enterprise resource planning) and CRM (customer relationship management) business systems and can improve the business and commercial model greatly. Recently, RFID got a great deal of attention because of long-distance readability and high capacity. RFID not only help logistics enterprises improve the efficiency of goods and information management, but connects logistics enterprises with manufacturing enterprises. We can now receive the feedback information, control the demand information, optimize the whole supply chain, and improve the operative efficiency of the logistics information system better.

5.1 The operating principle of RFID

The composition of RFID system: (1) Tag: consists of coupling cells and chips, there is an antenna in the tag for communicating with radio frequency antennas. (2) Reader: to fetch the information in the tag. (3) Antenna: transmit radio frequency information between tag and reader. Some RFID systems can be connected with outer computers through reader's interface of RS232 or RS485 to exchange data.

The operation process of RFID systems is as follows: the reader transmits radio frequency signals through the antenna with a given frequency. When tag comes into the antenna's working area, it will generate induction current. Tag will be activated through the energy, and then it will transmit the code information through the antenna. The system antenna receives the carrier signals and transmits them to the reader through the antenna regulator. The reader modulates and decodes the signals, then sending them to the background system for processing. The principal system will justify the signal by logic operation then take corresponding actions depending on the different situation and send out command signals.

5.2 The features of RFID

The principal features of RFID lie in:

(1) Non-contact information collection, auto-recognition and auto-management.

(2) Supplying the supply chain management and logistics information system with bilateral communication of logistics and information flow.

(3) Satisfying the ever more improved demand for high-capacity information and high processing speed.

(4) Improving the automation degree of collecting data.

(5) Solving the problem of managing information in movement.

(6) Solving the problem of data error and data-filtering by adopting the RFID integrated middle-ware, meanwhile making the seamless integration with present the ERP system come true.

5.3 The advantages of the system

The system is an integration of RFID technology and 3rd mobile communication systems. So, it integrates both the advantages of a RFID system and a 3rd generation mobile communication system. The advantages of the system can be summarized as follows.

(1) The rapid and accurate data-processing. RFID's non-contact technique makes it possible to identify and label parameters of the goods in logistics distribution systems.

(2) Multi-media identification system. The 3rd generation mobile communication technology can provide video images when communicating. This is helpful to identify goods more intuitively.

(3) The system makes it possible to improve the distribution efficiency and lower distribution cost. And, the distribution speed is faster, which means we can improve the efficiency of the whole logistics system.

5.4 The possible disadvantages of the system

As the distribution system is based on the 3rd generation mobile communication system, if something is wrong with the mobile system, the distribution system may be halted. In order to make the system more stable, efforts to keeping the mobile communication system stable is very important. Thanks to the matured technology of 3rd generation mobile communication technology, the system is quite stable with a small margin of error.

In case of any error of the 3rd generation mobile communication sytem, a man-aided module is invented in the system to keep the system operating. When the mobile system is failed, the distribution system can operate well by way of the man-aided module though the speed may not be as fast as normal.

6 CONCLUSIONS

The paper discusses the construction design and platform composition of modern logistics distribution information systems based on 3rd generation mobile communication technology and analyzes the function of the system. In the platform

design, 3rd generation mobile communication technology is adopted to give full play to the function of dealing with a large quantity of data quickly. In database design of the information structure, data warehouse technology is used to integrate several databases. In addition, we conduct data analysis by using OLAP technology, dramatically improving efficiency and accuracy. In identifying the distribution goods, RFID technology is used to make the identification more correct, timely and dynamic with the development of information technology. Constantly reinventing the logistics distribution information platform by using every kind of relevant information technology will be the tendency of the logistics information system, at the same time, the information technology will provide the logistics industry with better technology support.

ABSTRACT

In this paper, correlation stability and profit allocation of supply chain are studied. Stability theory of dynamical system is introduced to study the supply chain system. The paper defines correlation stability of supply chain, and analyzes its mechanism. Nonlinear model of the integrated supply chain is then formulated, and its stability is evaluated by Lyapunov stability criterion. Based on the correlation stability analysis, new profit allocation method is proposed. The method considers system stability as a basic condition of reasonable profit allocation. The original profit allocation should be adjusted if system stability condition is not satisfied.

INTRODUCTION

Nowadays fierce competition exists between supply chains. Supply chain members compete and cooperate at the same time. How to coordinate with partners and to make decision jointly is essential for the entire system to operate stably.

In this paper, stability theory in the field of dynamical system is introduced to analyze supply chains. Stability is an important mechanism for system to survive and develop. How to evaluate the stability and to find the measures to guarantee system stability is very important for the system to operate normally. From the end of the 19th century to the beginning of this century, French mathematician Poincaré gave the definition of dynamical system in his studies of classical mechanics and differential equation theories (Ledyaev and Sontag, 1999; Retchkiman, 1998). In 1892, the Russian mathematician Alexander Mikhailovitch Lyapunov introduced his famous stability theory for nonlinear and linear systems (McConley et al., 1998). A complete English translation of Lyapunov's doctoral dissertation "*The general problem of the stability of motion*" was published in the *International Journal of Control* in March 1992 (Buse and Barbu, 1997; Penzl, 1998). He studied the motion stability problem of dynamical system described by differential equations and proposed the architecture and approach of stability theory, which is still widely used now.

Profit allocation is another important problem in supply chain coordination. In these years, cooperative game is applied to solve this problem successfully. The methods include Shapley value method, MRCS method, Nash negotiation method and so on (Nagarajan and Sosic, 2008; Guardiola et al., 2007; Giannoccaro and

Pontrandolfo, 2004). In this paper, new profit allocation method based on stability criteria is presented.

CORRELATION STABILITY ANALYSIS OF SUPPLY CHAIN MEMBERS

Lyapunov Exponent Stability

Supply chain is a network that includes material provider, manufacturer, distributor, retailer, customers and so on. For supply chain, correlation stability means that its members shall keep efficient operation and normal fluctuation when satisfying the customers' demands. They can corporate and coordinate with each other. In the product life cycle, all members adjust their own strategies to optimize the performance of the entire system. Therefore, correlation stability focuses on how supply chain members react to their partners and how their reactions affect system stability.

Lyapunov exponent is an important concept in nonlinear dynamics. It is also a reliable and simple quantitative approach to measure chaos. Lyapunov exponent is useful for distinguishing various types of orbits. It works for discrete as well as continuous systems (Xing, 2000; Benettin et al., 1980; Gukenheimer, 1982).

A stability criterion with the largest Lyapunov exponent is described as blow (Lu, 2004). Consider a dynamical system which satisfies

$$X_{k+1} = F\left(X_k\right) \tag{1}$$

We assume that ΔX_k satisfies

$$\Delta X_{k+1} = \left(\frac{\partial F}{\partial X}\Big|_{X=X_k}\right) \Delta X_k = J_k \Delta X_k$$

Define J_k to be the Jacobian matrix of F at X_k, then

$$\Delta X_{k+1} = J_k \Delta X_k = J_k J_{k-1} \ldots J_1 \Delta X_1$$

where $J^{(k)} = J_k J_{k-1} \ldots J_1$ and $\Delta X_{k+1} = J^{(k)} \Delta X_1$. For dynamical system (1), let $T\left(X\right) = \lim_{k \to \infty} \left[\left(J^{(k)}\right)^T J^{(k)} \right]^{\frac{1}{2k}}$, and denote λ_i its eigenvalue.

The Lyapunov exponent of equation (1) is

$$\sigma_i = \ln\left|\lambda_i\right|, (i = 1, 2, \ldots n)$$

According to the definition of Lyapunov exponent and its relationship with system stability, the stability criterion with the largest Lyapunov exponent is stated in theorems 1 and 2.

Theorem 1. For nonlinear dynamical system (1), we assume the largest Lyapunov exponent of its spectrum is $\sigma_m \left(m \in i, i = 1, 2, \ldots, n\right)$. If $\sigma_m < 0$, this system is stable. If $\sigma_m > 0$, the system is unstable.

Theorem 2. For nonlinear dynamical system (1), if $\left|\lambda_i\right| < 1$ for all *i*, this system is stable. If there exists any $\left|\lambda_i\right| > 1$, the system is unstable.

Theorem 2 is recommended for the nonlinear model of supply chain in this paper, because using theorem 2 we only need to verify whether $\left|\lambda_i\right| > 1$ or not in stead of finding out the exact values of all Lyapunov exponents.

Nonlinear Model of the Supply Chain

Traditionally, some factors are neglected in supply chain modeling, and external environment is often simplified to linearize the nonlinear system. However, this approximation method is not able to describe practical systems accurately. Inspired by the research in the field of dynamical system, similar methods are introduced to evaluate system stability and to analyze the key elements affecting stability.

Without loss of generality, we consider a simplified supply chain system with three phases: product manufacturing, storage and distribution to customers. Our study in this paper can be applied to virtually all supply chains.

The inventory process of the manufacturer is:

$$x_{t+1} = x_t + P_{t+1} - S_{t+1} \ (t = 1, 2, ..., N) \tag{2}$$

where x_t is the inventory level of the manufacturer at the end of period t, P_{t+1} is the manufacturer production quantity in period $t+1$, and S_t is the amount of products sent to storage providers by the manufacturer in period t. In reality, manufacturers often attempt to decrease costs, improve core competence and achieve the goal of zero inventories. Therefore, we assume the manufacturer sends all products to the storage provider once they are produced. Equation (2) can then be written as blow:

$$S_{t+1} = P_{t+1}$$

According to the production model with constant elasticity of substitution (Zhang, 1999), the initial production quantity of the manufacturer can be written as

$$P_1 = A(\omega_1 L^{-\tau} + \omega_2 K^{-\tau})^{-(h/\tau)}$$

where ω_1 and ω_2 are distribution parameters that reflect the weights of labor and capital investments with $\omega_1 + \omega_2 = 1$, h is the order parameter, and $\tau = \frac{1}{\sigma} - 1$ is the substitution parameter. Substitution elasticity σ is the ratio of the capital increasing rate to the labor income increasing rate. To model the production in all other periods, we denote the retailers' actual sales volume in period t as Q_t. We assume Q_t can be observed by all upstream enterprises at the end of period t. The assumption is reasonable because advanced information technology is often utilized nowadays to guarantee high speed information transmission. Moreover, the production of the manufacturer is closely related to the existing inventory and sales volume. The production level is often forecasted based on the demand in the last period, the season factor, the promotion factor and so on. Adopting the promotion response model (Huang, 2000), the production in period $t+1$ can be expressed as:

$$P_{t+1} = N(t)M(\varsigma)\left\{k \tanh\left[k\left(t_f - t\right)\right]\left(y_d - y_t\right) + Q_t\right\} \tag{3}$$

where $k = \sqrt{\frac{h}{C}}$, and h and C are constant weighting factors. y_d is the ideal inventory level, y_t is the inventory level of the storage provider at the end of period t, and $\tanh = \frac{e^x - e^{-x}}{e^x + e^{-x}}$. $N(t)$ is the season exponent, which represents the

changes caused by season or holiday factors. $M(\varsigma)$ is the promotion exponent, which reflects the effects caused by reduced prices, advertisements or other promotions:

$$M(\varsigma) = \prod_{i=1}^{k} \Omega \left[\left(\varsigma_i \Big/ \varsigma_i^* \right) \right]^{V_i}$$

where ς_i is the market variable, and ς_i^* denotes its standard value, and V_i is the elasticity or sensitivity of the market variable. According to equation (3), the manufacturer adjusts its production level based on the sales condition as well as the inventory level. When the actual inventory is more than the ideal level, manufacturing speed decreases; otherwise, it increases.

The inventory process of the storage provider is

$$y_{t+1} = \theta y_t + \delta S_{t+1} - D_{t+1} \quad (t = 1,2,...,N)$$

where $1-\theta$ is the inventory damage rate of the storage provider, $1-\delta$ is the damage rate of the products during delivery from the manufacturer to the storage provider, and D_{t+1} is the amount of products sent from the storage provider to the distributor during period t+1.

In VMI mode, distribution companies manage the inventory levels of the retailers. To reduce retailers' inventory costs, the distributor's lot size must be controlled. On the other hand, storage providers have the incentive to send more products to the distributor to reduce their own costs. Therefore, it is necessary for them to coordinate in determining the distributor's lot size. We assume that when the storage provider's inventory level y_t is higher than the expected value y^*, the distributor agrees to take a portion of the excess to its own lot from the storage providers' warehouse. Therefore, distributor's lot size depends not only on the predicted retailer demands, but also the storage provider's inventory level. The distributor's lot size in period t+1 can then be expressed as:

$$\begin{aligned} D_{t+1} &= \left(D_{l,t+1} + D_{c,t+1} \right) - \rho z_t \\ &= \left[R_{t+1} + \eta \left(y_t - y^* \right) \right] - \rho z_t \end{aligned} \tag{4}$$

where $D_{l,t+1}$ is the delivering lot size for the predicted retailer demands at period t+1, $D_{c,t+1}$ is the amount of excess inventory the distributor takes from the storage provider, z_t is the total inventory level of all retailers during period t, and the damage rate of the retailers' inventory is $1-\rho$. The first term in equation (4) equals to the predicted retailer sales volume R_{t+1}. According to Bass model (Steffens and Murthy, 1992) and the index number smoothing method (Disney and Towill, 2002), R_{t+1} satisfies the following equation:

$$\begin{cases} R_{t+1} = \alpha Q_t + (1-\alpha) R_t, \ t = 1,2,....N \\ R_1 = k \cdot \dfrac{1 - e^{-(a+bk)}}{1 + \dfrac{bk}{a} e^{-(a+bk)}} \end{cases}$$

where k is the potential amount of customers, and a, b, and α are predetermined parameters. Based on the discussion above, the second term in equation (4) equals to $\eta(y_t - y^*)$, where η is the proportion parameter. Variable η is a crucial element to the coordination between the storage provider and the distributor, which directly affects the lot size of the distributor and the inventory level of the storage provider, as well as their profits. In this paper, we treat η as a decision variable of the supply chain system. Obviously, if $y_t < y^*$ then $\eta = 0$; if $y_t > y^*$, η should be greater than zero. The relationship between the parameter η and the stability of the system will be analyzed in the following section to help the players in the supply chain make their decisions.

We assume the distributor delivers products at the end of every period, and retailers receive products at the beginning of the next period. For the distributor, the delivering lot size in period t is the sum of the quantities ordered by all retailers:

$$D_t = \sum_{i=1}^{n} D_{it}, (t = 1, 2, ..., N)$$

And for each retailer i, its inventory at the end of period $t+1$ is

$$z_{i,t+1} = \rho z_{it} + \xi D_{it} - Q_{i,t+1}$$

where the delivering damage rate is $1-\xi$, z_{it} is the inventory level of retailer i at the end of period t, and $Q_{i,t+1}$ is the actual sales volume of retailer i in period $t+1$, which satisfies

$$Q_{t+1} = \sum_{i} Q_{i,t+1}$$

The total retailer inventory level in period $t+1$ is then

$$z_{t+1} = \rho z_t + \xi D_t - Q_{t+1}$$

Finally the dynamical nonlinear model of the supply chain is

$$\begin{cases} y_{t+1} = \theta y_t + \delta P_{t+1} - D_{t+1} \\ z_{t+1} = \rho z_t + \xi D_{t+1} - Q_{t+1} \\ P_{t+1} = N(t)M(\varsigma)\left\{k \tanh\left[k(t_f - t)\right](y_d - y_t) + Q_t\right\} \\ D_{t+1} = \left[\eta(y_t - y^*) + R_{t+1}\right] - \rho z_t \\ R_{t+1} = \alpha Q_t + (1-\alpha) R_t \end{cases} \tag{5}$$

Enterprise Correlation Stability Analysis Based on Lyapunov Exponent Criterion

In this section, enterprise correlation stability will be analyzed by means of Lyapunov exponent criterion. The matrix of model (5) is

$$A = \begin{pmatrix} \theta - \delta u - \eta & \rho & 0 & 0 & -(1-\alpha) \\ \xi\eta & \rho\xi - \rho & 0 & \xi & \alpha(1-\xi) \\ -u & 0 & 0 & 0 & 0 \\ \eta & -\rho & 0 & 0 & 1-\alpha \\ 0 & 0 & 0 & 0 & 1-\alpha \end{pmatrix}$$

where $u = N(t)M(\varsigma)k\tanh\left[k\left(t_f - t\right)\right]$.

We obtain the characteristic equation

$$\lambda^2\left[\lambda - (1-\alpha)\right]\left[\lambda^2 - (\theta - \delta u - \eta + \rho\xi)\lambda + (\rho\xi\theta - \rho\xi\delta u - \rho\xi\eta - \rho\eta)\right] = 0,$$

and

$$\Delta = (\rho + \theta - \eta - \delta u + \rho\xi)^2 - 4\left[\rho\xi\theta - \rho\xi\delta u - \rho\xi\eta - \rho\eta + \rho\eta\right].$$
$$= (\theta - \delta u - \eta - \rho + \rho\xi)^2 + 4\rho\xi\eta$$

Since $0 \le \rho$, $\xi \le 1$ and $\eta \ge 0$, there exists a $\Delta \ge 0$. The solutions to the characteristic equation are

$$\lambda_{1,2} = 0, \quad \lambda_3 = 1-\alpha, \quad \lambda_{4,5} = \frac{\rho + \theta - \delta u - \eta - \rho\xi \pm \sqrt{\Delta}}{2}$$

According to theorem 2, when the absolute values of all characteristic roots are smaller than 1, the supply chain system is stable in the sense of Lyapunov.

PROFIT ALLOCATION BASED ON SYSTEM STABILITY EVALUATION

We discuss the profit allocation problem between supply chain members in this section. In our method, profit allocation must guarantee the stability of supply chain, because considering stability and coordination between supply chain members may lead to reasonable profit allocation and sustainable supply chain operation.

More specifically, the profit allocation method consists of two steps: one fundamental and one modified allocation. Fundamental allocation refers to original allocation between supply chain members, while modified allocation further adjusts the original allocation based on some criteria value obtained from the previous section. It is worth mentioning that it may require multiple modifications before the stability condition is satisfied.

Due to the page limit, the detailed profit allocation model and the case study are omitted. We found that the method is more reasonable and applicable, and taking stability into consideration for profit allocation helps us to analyze cooperation and coordination relationship between enterprises and helps the supply chain to sustain.

CONCLUSIONS

In this paper, we introduce stability theory into the study of supply chains, and construct a dynamical nonlinear model for integrated supply chain. The stability of the proposed model is analyzed by the largest Lyapunov exponent theorem. More specifically, to guarantee the system stability, the value domains of dynamical parameters are discussed and simulated. Based on the investigation of the impact of the dynamical parameter disturbance on the supply chain system, this paper proves that the supply chain system will be unstable if the value of some dynamical parameter exceeds its domain. For example, if the proportion the distributor takes

from the storage provider when the inventory level of the latter is high is too large, the system will lose its stability. This indicates that the entire supply chain system will be unstable if its members make their decisions in terms of local optimization. Finally, a profit allocation method based on correlation stability is proposed.

Abstract: In assemble-to-order system, the substitution of higher-class components for lower-class components is often applied when the latter are stock-out. But the decision for substitution should be made in advance in practice. How to manage the substitution in such a system is of managerial interest. We model this scenario as a two-stage mathematical programming where the first step is to determine how many to order for each product at the beginning of the selling season, and the second step is to explore the substitution rule. We exploit the structural properties of the substitution rule and present a dynamic substitution policy. Then we show that our substitution policy is a threshold policy and present the upper bound of the threshold.

Key Words: *assemble-to-order, dynamic substitution policy, threshold, inventory*

1. Introduction

In this paper, we consider a simple assemble-to-order system, where substitution of components is allowed in assembling end-products. We only allow a one-way downward substitution structure in that demand for lower-class components may be satisfied by using the higher-class ones; however the demand for higher-class components can not be satisfied by using the lower-class ones. This downward substitution structure occurs in several practical settings such as semiconductor chips (Hsu and Bassok, 1999), hotel booking, airline seats allocation (Zhao and Zheng, 2001), as well as resource allocation and risk mitigation in news-vendor networks (Van Mieghem, 2007) etc. It has also been adopted as an aid for the mass customization strategies. Besides improving customer service, this substitution policy can mitigate the risk that the types of products may increase rapidly due to customization, especially for products with short life cycle.

Wang et al. (2007) adopts downward substitution and forecast updating to reduce demand uncertainty in a supply chain system, where mass customization and traditional production process exist simultaneously. The authors focus on two stages

of decisions: prior to final demand is known, how many components to purchase; and once demand is realized, how to allocate those components in a profit maximizing manner. However, in today's saturated markets, customers demand greater flexibility and faster reaction from their suppliers. The two-stage process might not serve their needs in practice. Terms like Quick Response and Just-in-Time are becoming increasingly prevalent in business literature and practical management process.

2. The Model

2.1 Symbols and Assumptions

We consider two components denoted by 1 and 2, where component 1 can substitute for component 2 but the opposite is not allowed. We also assume the following events occur in sequence: 1) At the beginning of the selling season, the order is placed based on the initial inventory level and is delivered immediately; 2) Demands for two components are realized; 3) Excess stock of each component is salvaged at the end of each period. Before we proceed our study, we first introduce the following basic notations: c_i –wholesale price per unit of component i; p_i–sales price per unit for component i; $_i$–loss for shortage per unit of component i; s_i–salvage value per unit for component i; h_i–holding cost per unit for component i; Q_i–order quantity for component i, that is, the inventory level of component i at the start time of the selling season. We also define $r_i = _i + p_i$ and the net salvage value of component i to be $v_i = s_i - h_i$.

Further, we make the following assumptions.

Assumption 1. $c_1 \geq c_2$; $p_1 \geq p_2$, $\pi_1 \geq _2$; $v_1 \geq v_2$

Assumption 2. $r_2 \geq v_1$, i.e., $_2 + p_2 \geq v_1$;

Assumption 3. If component 1 is substituted for component 2, then charge p_2 (not p_1)

Assumption 4. $p_i \geq c_i \geq v_i > 0 (i = 1, 2)$.

Assumption 5. Unmet demands of component 1 and 2 after the possible substitution is exercised are lost.

Assumption 6. Customers are allowed to buy only one final product each, and arrive according to a Poisson process with density $_i(t)$ at time t.

2.2 Model Formulation

Let T be the length of the selling season. Let t be the time left until the end of the selling season. The time interval between t_1 and t_2 with $t_1 > t_2$ is denoted by (t_1, t_2) or $[t_1, t_2)$ if t_1 is included. Let the inventory level of component i at the start time of selling season be Q_i $(i = 1, 2)$. Our aim is to find the optimum order quantity Q_i for component i $(i = 1, 2)$, as well as the stopping time for substitution, in order to obtain the highest expected revenue during the whole selling season. In our model we assume that once substitution is ended at a time point, it will not be allowed to restart. We will proceed in two steps: first, to find the optimal stopping time for given Q_1 and Q_2; second, to determine the optimal order quantity Q^*_i for component i $(i = 1, 2)$. We first begin with step 1. Let t_i be the time point when the inventory level of component i $(i = 1,2)$ drops to zero, that is, the hitting/trigger time for stock-out. It is easy to see that substitution is possible only when $t_1 < t_2$, that is, only when there are stocks left for component 1 while demands still arrive for component 2 but its stocks have been used up. Recall that t is the time left until the end of selling season. At any

time $t \in [t_2, 0)$, let $x_1(t)$ be the total number of component 1 that has been sold and $y_1(t) = Q_1 - x_1(t)$ the inventory level at time t. We will make our decisions on whether to exercise substitution, that is, to meet the demand for component 2 by using the stocks of component 1. Clearly, this should be based on $y_1(t)$, the inventory level of component 1, as well as t, the time left until the end of the selling season. Thus, it is an optimal stopping problem. A stopping rule can be characterized by a stopping region S contained in $[t_2, 0) \times \{0, 1. . . \quad Q_1\}$.

Let $N_i(t, s)$, $(t > s)$, denote the total demand for component i (i = 1,2) that occurs between t and s, that is, the number of customers who buy component i. It follows that $N_i(t, s)$ is a Possion random variable with mean $\int_s^t \lambda_i(\tau)\, d\tau$ (which is clearly continuous in t). Let $J_S(y_1, t)$ denote the expected revenue accrued in $[t, 0)$, under a given stopping rule S, starting with y_1 ($y_1 > 0$) left for component 1 while the stocks for component 2 have been used up at time t. Then we have

$$\begin{aligned} J_S(y_1, t) = E[&p_1 N_1(t, s) + p_1 \min\{N_1(s, 0), y_1 - N_1(t, s) - N_2(t, s)\} \\ &+ p_2 N_2(t, s) + v_1 (y_1 - N_1(t, s) - N_2(t, s) - N_1(s, 0))^+ \\ &- \quad _1 (N_1(s, 0) - y_1 + N_1(t, s) + N_2(t, s))^+ - \quad _2 N_2(s, 0)] \end{aligned}$$

where s is the stopping time determined by stopping rule S. We can ensure the non-negativity of $y_1 - N_1(t, s) - N_2(t, s)$ by requiring that $[T, 0) \times \{0\} \quad \subset S$, i.e., substitution is automatically ended as soon as all the stocks for component 1 are used up.

3. Optimal Substitution Policy

3.1 Optimality Conditions and Results

Let $f(y, t)$ be the maximum expected revenue starting with y component 1 in stock at time t, i.e., $f(y,t) = \sup_s J_s(y,t)$. Let $g(y, t)$ be the expected revenue over $[t, 0)$ with y component 1 left and with substitution ended already by time t. Then the optimal stopping region $S^* = \{(s, y) | f(y, s) = g(y, s), s \in [t_2, 0)\}$. On the other hand, if $(t, y) \notin S^*$, $f(y, t) > g(y, t)$ and it is optimal to keep substituting component 1 for 2. Because $g(y, t)$ is the expected revenue accrued in $[t, 0)$ where only the demand for component 1 is met, we have

$$\begin{aligned} g(y_1, t) = E\,[&p_1 \min\{N_1(t, 0), y_1\} \\ &+ v_1 (y_1 - N_1(t, 0))^+ - \quad _1 (N_1(t, 0) - y_1)^+ - \quad _2 N_2(t, 0)] \end{aligned}$$

It is easy to see that, for any fixed y, $g(y, t)$ is continuous in t (because the mean of $N_1(t, 0)$ is continuous in t). For any fixed t, $g(y, t)$ can be determined inductively by the following equations:

$$g(y + 1, t) - g(y, t) = r_1 P_r\{N_1(t, 0) \geq y + 1\} + v_1 P_r\{N_1(t, 0) \leq y\}, \qquad (1)$$

Equation (1) indicates that the expected marginal revenue of component 1 when the substitution is ended equals to the sum of r_1 times the probability that the stocks for component 1 can be used up and v_1 times the probability that there are still stocks left for component 1 at the end of selling season.

We proceed to present the Bellman equation for our dynamic program. At any time t, when the substitution has already been ended, there is no further decision to make. In this case, because both the demand processes of component 1 and component 2 follow Possion distibution, we have

$$g(y, t) = \quad _1(t) \quad t(p_1 + g(y - 1, \quad t - \quad t))$$

$$+(1 - \lambda_1(t)\,\Delta t)(g(y, t - \Delta t) - \lambda_2 c_2(t)\,\Delta t + o(\Delta t) \quad (2)$$

where Δt is the length of a small time interval $[t, t-\Delta t)$. Hence, the first term is the expected total revenue if one unit of component 1 is sold during $(t, t-\Delta t)$, the second is the total expected revenue of component 1 otherwise, and the third is the expected loss for unmet demand of one unit of component 2 during $(t, t-\Delta t)$. Rearranging terms and letting Δt decrease to 0, we obtain the differential form of equation (2).

$$\frac{\partial g(y,t)}{\partial t} = \lambda_1(t)[p_1 + g(y-1,t)] - \lambda_1(t)g(y,t) + \pi\lambda_2 c_2(t)$$

If it is optimal to keep on substitution at (y, t), we have the following dynamic programming equation,

$$f(y, t) = \lambda_1(t)\,\Delta t(p_1 + f(y-1, t-\Delta t)) + \lambda_2(t)\,\Delta t(p_2 + f(y-1, t-\Delta t)) + (1 - \lambda_1(t)\,\Delta t - \lambda_2(t)\,\Delta t)f(y, t-\Delta t) + o(\Delta t)$$

Rearranging terms and letting Δt go to 0, we get the differential form of the dynamic programming equation

$$\frac{\partial f(y,t)}{\partial t} = \lambda_1(t)[p_1 + f(y-1,t)] + \lambda_2(t)(p_2 + f(y-1,t)) - (\lambda_1(t) + \lambda_2(t))f(y,t)$$

The above equation only holds when $(t, y) \notin S^*$. When $(t, y) \in S^*$, we have $f(y, t) = g(y, t)$. Clearly, $f(y, t)$ is continuous in t when $(t, y) \in S^*$. Now we present our dynamic substitution rule: keep on substitution if and only if

$$r_2 > r_1 P_r\{N_1(t, 0) \geq y\} + v_1 P_r\{N_1(t, 0) < y\} \quad (3)$$

where y is the inventory level of component 1 at time t. The rule is optimal for the following static model. Assume that the remaining demand for component 1 is $N_1(t, 0)$ with a known (static) probability distribution. The decision is how many stocks of component 1 should be protected at the time point. The optimality of this rule in this static model is based on the following simple marginal analysis: the left hand side of equation (3) is the revenue accrued from meeting the demands for component 2 with the stocks of component 1; the right hand side is the opportunity cost of the last component 2. The substitution should be kept on if the left hand side is greater. Although intuitive and convenient, the above substitution rule is not optimal but only a heuristic for our dynamic model. It is compelling to know how good it is compared to the optimal dynamic policy. Therefore, in the next subsection, we will pursue the relationship between our substitution rule and the optimal dynamic policy.

For dynamic model, the above substitution rule specifies a stopping region with

$$\{(t, y) | r_2 \leq r_1 Pr\{N_1(t, 0) \geq y\} + v_1 Pr\{N_1(t, 0) \leq y\}\} = \{(t, y) | r_2 - v_1 \leq (r_1 - v_1) Pr\{N_1(t, 0) \geq y\}\}$$

Because $Pr\{N_1(t, 0) \geq y\}$ decreases in y ($Pr\{N_1(t, 0) \geq y_2\} = Pr\{N_1(t, 0) \geq y_1\} + Pr\{y_2 \leq N_1(t, 0) < y_1\} \geq Pr\{N_1(t, 0) \geq y_1\}$ holds when $y_1 \geq y_2$), the above stopping rule is a threshold policy, i.e., there exists $y^*_L(t)$ such that the substitution should be ended if $y(t) \leq y^*_L(t)$.

It is clear that $N_1(t, 0)$, the remaining demand for component 1, is stochastically non-increasing over time, i.e., for any given y, $Pr\{N_1(t_1, 0) \geq y\} \geq Pr\{N_1(t_2, 0) \geq y\}$ for all $t_1 > t_2$. As a result, the threshold is non-increasing over time.

PROPOSITION 1. $y^*_L(t)$ is non-increasing over time, i.e., the closer to the end of the selling season, the lower the threshold.

3.2 Structure of Optimal Policies

In this subsection, we first show that the optimal dynamic policy is a threshold policy. That is, there exists a threshold $y^*(t)$ such that the optimal dynamic policy is to cancel substitution whenever $y(t) \le y^*(t)$.

The optimality of a threshold policy is based on the following observation: the expected marginal revenue is smaller when the substitution has been ended.

LEMMA 1. For any t and y, $f(y+1, t) - f(y, t) \ge g(y+1, t) - g(y, t)$ (4)

Inequality (4) can be rewritten as

$$f(y+1, t) - g(y+1, t) \ge f(y, t) - g(y, t) \quad (5)$$

Inequality (5) indicates that if it is optimal to end substitution at $(y+1, t)$, that is, $f(y+1, t) = g(y+1, t)$, then it must be optimal to end substitution at (y, t), because it follows that $f(y, t) = g(y, t)$ from inequality (5). Therefore, we have shown:

THEOREM 1. The optimal policy is a threshold policy, i.e., there exists a threshold $y^*(t)$ such that it is optimal to end substitution whenever $y(t) \le y^*(t)$, where

$$y^*(t) = \max\{y | f(y, t) = g(y, t)\}.$$

PROPOSITION 2. For any t, $y^*_L(t) \ge y^*(t)$.

PROPOSITION 3. $y^*(t)$ is non-decreasing in t.

4. Determination of Optimal Order Quantities of Q^*_1 and Q^*_2

4.1 Optimal Replenishment Policies

Let $V(Q_1, Q_2, T)$ be the optimal expected revenue accrued from a stock Q_i of component i ($i = 1, 2$) when the time left is T until the end of selling season (see Rahim et al., 2000). Let the stockout of component 2 start at time t with $0 \le t \le T$, and let k denote the quantity of component i sold before the stockout of component 2 was observed. We then have the following:

$$V(Q_1, Q_2, T \mid 0 \le t \le T) = \sum_{k=0}^{Q_1-1} [\max_s J_s(Q_1 - k, t) \quad p_1 k p_{1,k}(T, t)] + \sum_{k=Q_1}^{+\infty} p_1 Q_1 p_{1,k}(T, t) + p_2 Q_2$$

where $p_{i,k}(T, t)$ is the possibility that the sales quantity of component i (i=1,2), which equals the number of customers who purchase this component, is k in a time interval $[T, t]$. Thus,

$$p_{i,k}(T, t) = \frac{1}{k!}\left(\int_t^T \lambda_i(\tau)\, d\tau\right)^k e^{-\int_t^T \lambda_i(\tau)\, d\tau}, (i = 1, 2).$$

On the other hand, if the stockout of component 2 occurs at time t with $t < 0$, that is, there are always stocks left for component 2 throughout the selling season, then

$$V(Q_1, Q_2, T \mid t < 0) = \sum_{k=0}^{Q_1-1} p_1 k p_{1,k}(T, 0) + \sum_{k=Q_1}^{+\infty} p_1 Q_1 p_{1,k}(T, 0) + \sum_{k=0}^{Q_2} p_2 k \; p_{2,k}(T, 0)$$

Thus, we can obtain the optimum order quantity Q^*_i for component i ($i = 1, 2$) by solving the following programming problem:

$$V(Q^*_1, Q^*_2, T) = \max_{Q_1 \geq 0,\, Q2 \geq 0} V(Q_1, Q_2, T)$$

4.2 Numerical Examples

For computational purposes, we discretize $[T, 0]$ into N periods of equal length $\Delta t = \frac{T}{N}$. When N is large, the discrete-time approximation is close to the continuous time model. Let $F[y, n] = f(y, n\Delta t)$, $G[y, n] = g(y, n\Delta t)$, $_i[n] = _i(n\Delta t)\ \Delta t$, $F[y, 0] = 0$, $F[0, t] = 0$, $G[y, 0] = 0$, $G[0, t] = 0$, and $g[y, n] = \max\{ _1[n](p_1 + F[y-1, n-1]) + _2[n](p_2 + F[y-1, n-1]) + (1 - _1[n] - _2[n])F[y, n-1],\ G[y, n]\}$.

Note that y^*_n, the optimal threshold, is the largest y such that $F[y, n] = G[y, n]$.

EXAMPLE 1. We set $T = 100$, $N = 200$, $p_1 = 200$, $p_2 = 100$, $c_1 = 100$, $c_2 = 40$, $_1 = 50$, $_2 = 30$, $s_1 = 60$, $s_2 = 20$, $h_1 = 10$, $h_2 = 8$, $Q_1 = 30$, $Q_2 = 20$, $_1(t) = 0.5$, and $_2(t) = 0.8$. The result indicates that the system obtains its optimal expected revenue, 124.3912 with the order quantity $Q_1 = 10$ and $Q_2 = 2$.

5. Conclusions

In this paper, we have established a two-component inventory model with downward demand substitution and presented a dynamic substitution rule. We have shown that the optimal policy is a threshold policy, which is relatively easy to determine and implement. One of the contributions of this paper is that for the first time, we show that although our substitution rules are not optimal, they are close to optimal. We also have shown that the static threshold determined by our dynamic substitution rule is the upper bound of the optimal dynamic threshold.

Abstract: This paper investigates the manufacturer's optimal wholesale price and return policy as well as the retailer's optimum order size and price decisions in a supply chain, where deterioration begins at a random time point. In the current study we assume that the retail price can only be adjusted once at that point according to the lifetime of product in the cycle and current stock level. The numerical example illustrates that the channel coordination of supply chain can be obtained if the manufacturer offers a reasonable wholesale price and return price where they refund retailer full credit for all unsold goods.

Keywords: *Supply Chain, Channel coordination, Return policy, Deterioration*

1. Introduction

In recent years, perishable goods have attracted many supply chain management researchers' attention because of their conspicuous characteristics, such as short sales period, low salvage value, and volatile market environment. They abound in any field in the world, for instance, flight seats, fresh bakery products, personal computer, Christmas trees, etc. Zhao et al. (2004) examines the game of two-stage supply chain for perishable goods in the e-marketplace. However, most related studies are based on the assumption that the deterioration begins at the start point of the operation cycle while the sales price and customer demand rate remain constant during the whole cycle. With the development of inventory management, the advanced storage technology and storage condition have significantly improved the quality of the goods stored. More often, the occurrence of the deterioration depends on some stochastic factors, such as the instrument disruption, natural factor, emergency, etc. It is important to explore the supply chain with perishable products, especially when the deterioration begins at a stochastic time point.

In the current study, we focus on the optimal policies of inventory and price when the start time point of deterioration is stochastic. This paper is organized as follows: section 2 reviews previous literature on return and price policy of a supply chain. Section 3 describes the basic model when deterioration begins at a stochastic time point. Section 4 provides a summary of results and future research directions.

2. Model Formulation

In this paper, we consider a simple supply chain composed of only one manufacturer/supplier and one independent retailer. In such a supply chain, the supplier sells her products at wholesale to the retailer and then the retailer resells the products to the end customers, under the assumption that the item is perishable and the deterioration begins randomly in time. To make the problem traceable, we make the following assumptions: (i) only one selling season or operation cycle is considered; (ii) retailer makes order at the start of the selling season and there is only one opportunity for her to do so during the whole cycle; (iii) once the order is placed, the goods are immediately in stock, i.e. the goods ordered arrive instantly; (iv) retailer sells goods until either all the stock is depleted or the end of selling season; (v) retailer will incur good-will losses when all the stock goods have been sold out, but there is still demand request; (vi) the leftover unsold goods could be returned to manufacturer at the promised return price at the end of selling season. The selling process is divided into two stages. In the first stage, the deterioration does not occur and the items are sold at the original price per unit. In the second stage, the deterioration starts and the sales price is lowered down according to the leftover inventory level and the residual life of leftover stock, in order to promote the sale.

The notations used in the models are as follows:

t – the remaining time until the end of the selling season. Thus, $t=T$ denotes the starting point and $t = 0$ denotes the conclusion of selling season;

w – wholesale price at which the retailer purchases goods from the supplier;

s – retail price before deterioration happens;

c_{sr} – goodwill loss incurred by retailer due to the stock out per unit;

c_r – return price per unit committed to retailer by manufacturer;

c_M – production cost per unit for manufacturer;

$q(t)$ – inventory level when the remaining time is t;

$x(q, t)$ – selling price when the stock level is q and the residual time is t, given that deterioration has started;

$V(q, t)$ – optimal value of expected revenue that can be generated from a stock of size q in t units of time given that deterioration has not yet begun;

$V(q, t; x)$ – expected value of revenue that can be generated from a stock of size q in t units of time when the selling price during the remainder of the period is x and deterioration has started.

To make the study traceable, we further assume $c_M < w < s$ and $c_r \leq w < p$.

2.1 Integrated Supply Chain

We first present and analyze a supply chain under a centralized decision maker (i.e. the manufacturer). We regard this integrated supply chain as a benchmark. The integrated supply chain maximizes the sum of the retailer's profit and the supplier's profit. Let us denote Q^*_T as the optimum order quantity when the residual time is T. Thus, we have

$$V(Q^*_T, T) - c_M Q^*_T = \max_{Q \geq 0} \{V(Q, T) - c_M Q\} \quad (1)$$

2.2 Retailer's Order Policy

The retailer's purpose is to seek his optimum order quantity Q^*_R. Thus we have

$$V(Q^*_R, T) + wQ^*_R = \max_{Q \geq 0}\{V(Q, T) + wQ\} \quad (2)$$

2.3 Retailer's Optimal Order Quantity

We discuss two scenarios as follows.

(i) Let the deterioration start at time t with $t < T$ and let k denote the number of products sold before deterioration is observed. Thus, we have the following:

$$V(Q,T|t<T) = \sum_{k=0}^{Q-1}[\max_x V(Q-k, T-t; x) + ksp_k(t)] + \sum_{k=Q}^{+\infty}[Q(s - c_{sr}(k-Q)]p_k(t) \quad (3)$$

where $p_k(t)$ is the possibility that k items are demanded during t, given that the sales price is s and mean demand rate is . Thus,

$$p_k(t) = (\lambda t)^k(\frac{\exp(-\lambda t)}{k!}). \quad (4)$$

(ii)Let the deterioration start at time t with $t \geq T$, then

$$V(Q,T|t \geq T) = \sum_{k=0}^{Q-1}[ks + c_r(Q-k)]p_k(T) + \sum_{k=Q}^{+\infty}[Q(s - c_{sr}(k-Q)]p_k(T) \quad (5)$$

Therefore,

$$V(Q,T) = \int_0^T V(Q,T|t<T)dF(t) + V(Q,T|t \geq T)[1-F(T)] \quad (6)$$

In order to compute the integral numerically, we propose the following discretization approximation of (5):

$$V(Q,T) = \sum_{t=1}^{T}\{[F(t)-F(t-1)][\sum_{k=0}^{Q-1}(\max_x V(Q-k, T-t; x) + ks)p_k(t)]$$
$$+\sum_{k=Q}^{+\infty}[(Q_s - c_{sr}(k-Q))p_k(t)] + \sum_{k=0}^{Q-1}(ks + c_r(Q-k))p_k(T) \quad (6)$$
$$+\sum_{k=Q}^{+\infty}[(Q_s - c_{sr}(k-Q))p_k(T)][1-F(T)]$$

We could now evaluate $V(q, t; x)$. Suppose that the deterioration is first observed when the residual time is t and the interval of time is δt. If the arrival follows a Poisson process and the decay follows an exponential model, one of the following circumstances would occur when $\delta t \to 0$: (i) no arrival and no decay; (ii) one arrival and no decay; or (iii) no arrival and one decay. Thus, we have the following expression:

$$V(q,t;x) = \{1-[\alpha(x) + q\mu]\delta t\}V(q, t-\delta t; x) + \alpha(x)\delta t(1-\mu\delta t)[V(q-1, t-\delta t; x) + c_r - c_{sr}]$$
$$+\{q\mu\delta t[1-\alpha(x)\delta t]\}[V(q-1, t-\delta t; x) + c_r - c_{sr}] \quad (7)$$

Therefore, taking limits as $\delta t \to 0$, we have

$$\frac{\partial V(q,t;x)}{\partial t} = [\alpha(x) + q\mu][-V(q,t;x) + V(q-1,t;x)] + \alpha(x)(c_r - c_{sr}) + [(x)\mu q] \quad (8)$$

With the boundary conditions

$$V(0, t; x) = 0 \quad (9a)$$
$$V(q, 0; x) = c_r q \quad (9b)$$

In order to determine the optimum value of x for given q and t, we need to maximize $V(q, t; x)$ over x. The following lemma can be used to determine the solution to (8) to obtain $V(q, t; x)$ for $q = 1, 2, \ldots$.

Lemma 1 for $q \geq 1$, the solution to (8) is given by the following:

$$V(q,t;x) = C_{0q} + \sum_{i=1}^{q} C_{iq} \exp\{-[\alpha(x) + \mu_1]t\} \tag{10a}$$

Where,

$$C_{0q} = xa(x)\sum_{i=1}^{q} \frac{1}{a(x) + i\mu_1} - q(c_r - c_{sr}) \tag{10b}$$

$$C_{iq} = C_{i,q-1}\frac{a(x) + q\mu_1}{(q-i)\mu_1}, i = 1, 2, ..., q-1, q > i \tag{10c}$$

$$C_{qq} = c_r q - \sum_{i=0}^{q-1} C_{iq} \tag{10d}$$

The complete proof is omitted here due to the page limit. Interested readers may contact with the authors.

For given values of x, $V(q, t; x)$ can be computed numerically. A Fibonacci search technique can be used to maximize $V(q, t; x)$ with respect to x. This will yield the optimal selling price $x^*(q, t)$ for the given value of stock size q at the residual time t. Equations (1) – (10) will yield an optimum order size of Q^*.

2.4 Numerical Example

For illustrative purposes, we present a very simple example for our model. Consider a single sale season and a situation in which the deterioration of a well-preserved stock is initiated by a sudden shock such as mechanical failure or natural calamities. Let the deterioration occur at a random point in time and follow an exponential distribution. Assume the demand rate (*x*), which depends on the selling price *x*, satisfies (*s*) ≥ . Let the parameters be $F(t) = e^{\theta.1t}$, T=7, s=3.0, (*x*) = 19 2 x^2, w=1.76, = 1, c_{sr}= 0.15, c_r= 1.0, μ_1= 0.1. The computed results for the model are given in Tables 1-3.

Table 1 The Optimal Sales Price

q	$x^*(q, t)$						
	t=1	t=2	t=3	t=4	t=5	T=6	t=7
1	2.84	2.91	2.92	2.93	2.93	2.93	2.93

7	10.00	11.20	11.51	11.58	11.59	11.59	11.59
8	11.03	12.49	12.89	12.99	13.00	13.00	13.00
9	12.00	13.70	14.22	14.34	14.36	14.37	14.37
10	12.92	14.86	15.50	15.66	15.69	15.69	15.69
11	13.80	15.97	16.73	16.94	16.97	16.98	16.98
12	14.67	17.02	17.92	18.17	18.22	18.23	18.23

Table 3 Optimum Order Quantity

Order Quantity	1	2	3	4	5	6	7	8	9	10	11	12
Retailer's Profit	0.53	1.75	2.83	3.75	4.46	4.95	5.20	5.21	5.02	4.67	4.21	3.66

Table 1 shows the optimal selling price x when the stock level is q and the residual time left is t, given that deterioration has started. Table 2 shows the optimal value of the expected revenue generated from a stock of size q in t units of time when the optimal selling price x per unit remains constant over the residual cycle time, given that deterioration has started. From Table 3 we may find that the optimal order quantity is eight units.

2.5 Coordination Policies of Supply Chain

The retailer will decide his optimum order quantity Q^*_R to maximize his own profit. Thus in order to improve the channel revenue (i.e. the performance of supply chain), the manufacturer will properly set the value of parameter w and c_r to encourage the retailer to order $Q^*_R = Q^*_T$ units of products. Let the parameter be $F(t) = e^{\theta.1t}$, T=7, s=3.0, $(x) = 19 - 2x^2$, c_M= 1.75, = 1, c_{sr}= 0.15, c_r= 0.8, μ_1= 0.1, c_s= 0.3. By using the above method, we can find from Table 4 that the optimum order quantity is eight units, which maximize the revenue of the whole supply chain. In order to maximize the profit of the whole supply chain or to coordinate the supply chain, that is to say, let Q^*_R equals Q^*_T, the manufacturer needs to set the value of parameter as w = 1.76 and c_r= 1.0. The computed results are given in Table4.

Table 4 Optimum Order Quantity for Entire Supply Chain

Order Quantity	1	2	3	4	5	6	7	8	9	10	11	12
Total Profit	-0.09	1.31	2.59	3.70	4.61	5.27	5.66	5.80	5.71	5.44	5.04	4.55

The manufacturer will also set the value of parameter as w = 1.77 and c_r=1.0.The computed results are given in Table 5.

Table 5 Optimum Order Quantity for Entire Supply Chain

Order Quantity	1	2	3	4	5	6	7	8	9	10	11	12
Total Profit	0.52	1.73	2.80	3.71	4.41	4.89	5.12	5.13	4.93	4.57	4.10	3.54

3. Conclusions and Future Research

In this paper we investigate the coordination of supply chain in the case that deterioration begins at a stochastic time point. We found that it is possible to obtain the coordination of the supply chain if the manufacturer offers his wholesale price and promised return price properly as well as guarantees to accept the retailer's return of all leftover stock. It is a very interesting conclusion, for it gives us a suggestion on how to improve the performance of the supply chain and how to alleviate the well-studied problem of double marginalization. For future research, we shall investigate the manufacturer's optimal policy, such as wholesale price, return price and the percentage of returned goods, etc., as well as the retailer's optimum order quantity.

Grey Correlation Analysis on Logistics Energy Consumption

Lei Zhiyi

College of Traffic and Ocean, Hohai University, 210098, Nanjing, China; PH (86) 025-83787354; email: Lei_zhiyi@hotmail.com

ABSTRACT

Based on related energy statistical data, the general situation of logistics energy consumption in China is explained in this paper. The indicator system of the region's logistics consumption is established and, with grey correlation theory, each indicator and correlation degrees are analyzed quantitatively. At the end, with the data of Jiangsu Province and the nation, the correlation degree is analyzed contrastively, and the order of factors about logistics energy consumption is arranged. The correlation degrees calculated can be the instruction basis for logistics development and energy savings in certain areas.

Key words: Logistics energy consumption; indicator system; grey correlation

INTRODUCTION

Modern logistics is one of the basics of regional economic development, and an efficient logistics system is an important factor in the core competence of regional economics. People have been unfamiliar with logistics systems, especially their energy consumption. Furthermore, there are no subdivisions in the statistics of energy consumption in China, which makes research difficult, but the grey theory can resolve this problem.

GREY CORRELATION ANALYSIS OF LOGISTICS OF ENERGY CONSUMPTION

Model of grey correlation. The basic fundamental of grey correlation is judging correlations among sequence curves according to their comparability. To analyze an abstract system, the data sequence is first chosen, which is the mapping value of the system. Based on the Eigen value and related data, the graphs of every sequence can be obtained and analyzed.

The comparative sequence and the referenced sequence. Essential to grey correlation analysis is the comparability of the geometry of compared sequences. In general, the more approximate their geometries, the closer the correlations are.

Suppose X_0 is a system factor, with the measured values of $X_0(k)$, $k=1,2,,n$, which can be written as $X_0 = \{X_0(k), k = 1,2,\cdots n\}$, namely behavior sequence. If k means time number, $X_0 = \{X_0(k), k = 1,2,\cdots n\}$ is the behavior

time sequence; if k denotes indicator, $X_0 = \{X_0(k), k = 1,2,\cdots n\}$ is the behavior indicator sequence; if k denotes measured object number, $X_0 = \{X_0(k), k = 1,2,\cdots n\}$ indicates behavior transverse sequence. The time sequence, indicator sequence, or transverse sequence can be analyzed by grey correlation.

In this paper, the referenced sequence can be written as $X_0 = \{X_0(k), k = 1,2,\cdots n\}$, and the compared sequence can be written as $X_i = \{X_i(k), k = 1,2,\cdots n\}$.

Initialization. It is necessary to initialize the data because of the different dimensions or units of each factor.

$$x_0^{'}(k) = \frac{x_0(k)}{x_0(l)}, \quad k = 1,2,\cdots l \quad \text{and} \quad x_i^{'}(k) = \frac{x_i(k)}{x_i(l)}, \quad k = 1,2,\cdots l$$

We get the referenced sequence $X_0^{'}(t)$ and compared reference $X_i^{'}(t)$ after initialization.

Absolute difference. The absolute difference of the comparative sequence and the referenced sequence can be obtained by $\Delta_{0i}(k) = \left| X_i^{'}(k) - X_0^{'}(k) \right|$

Extremum. Mark $M = \max_i \max_k \Delta_{0i}(k)$, in which $\max_k \Delta_{0i}(k)$ indicates the maximum distance between each point on curve X_i and the related points on curve X_0. $\max_k \Delta_{0i}(k) = \max\{\max \Delta_{0i}(1), \max \Delta_{0i}(2), \cdots, \max \Delta_{0i}(l)\}$.

Mark $m = \min_i \min_k \Delta_{0i}(k)$, in which $\min_k \Delta_{0i}(k)$ means the minimum distance between each point on curve X_i and the related points on curve X_0. $\min_k \Delta_{0i}(k) = \min\{\min \Delta_{0i}(1), \min \Delta_{0i}(2), \cdots, \min \Delta_{0i}(l)\}$.

Calculate coefficient in grey correlation. We get the coefficients of grey correlation by $\xi_{0i}(k) = \frac{m + \rho M}{\Delta_{0i}(k) + \rho M}, \quad k = 1,2,\cdots l; i = 1,2,\cdots, n$, in which $\rho \in (0,\infty)$ is the distinguishing coefficient, which has an inverse ratio of resolution. We take it generally $\rho = 0.5$.

Calculating grey correlation. The grey correlation can be obtained by the formula $\gamma_{0i} = \frac{1}{l}\sum_{k=1}^{l} \xi_{0i}(k), \quad k = 1,2,\cdots l; i = 1,2,\cdots, n$.

Arranging and analyzing grey correlations. The influence of each comparative sequence on a referenced sequence will be clear, from the arrangement of γ.

INDICATOR SYSTEM FOR GREY CORRELATION ANALYSIS

It is necessary first to establish the indicator system of a logistics system and other systems in the national economy, namely the mapping value of system behavior, and then to research the relationship among logistic energy consumption and other systems by studying the relationships among those systems' mapping values.

For the faultiness of logistics in China, the general indicator system that reflects the logistics status has not been established yet. Some scholars have

researched the indicator system of logistics and the evaluation methods and obtained valuable results. But it is difficult to establish a simple and general evaluation model because of the nonlinear, opening, and dynamic logistics system.

This research has established an indicator system for logistics energy consumption from three aspects: environment, resource, and requirement, as seen in Figure 1. The environment includes the exterior factors influencing logistics requirements and service supply, such as management system and service level. Environment is the exterior factor, while resources and requirements are interior factors.

The indicator of requirements is composed of gross products of primary industries, gross products of secondary industries, total foreign trade value, total retail sales of consumer goods, and total investment in logistics fixed assets. The gross products of primary and secondary industries reflect social economic development; total retail sale of consumer goods is the mapping value of production, consumption, and circulation, reflecting the status and scale of logistics requirements. The more the social consumption is, the more the logistics requirement is, and the more the energy consumption is. In addition, the logistics fixed assets can also influence indirectly logistics energy consumption.

It is noteworthy that there is an absence of statistical data of total social logistics energy consumption in China because of the faultiness of the statistics system and method. The consumption data in the China Statistical Yearbook for transportation (including passenger transport), storage, and the post and telecommunications industries are calculated for logistics energy consumption.

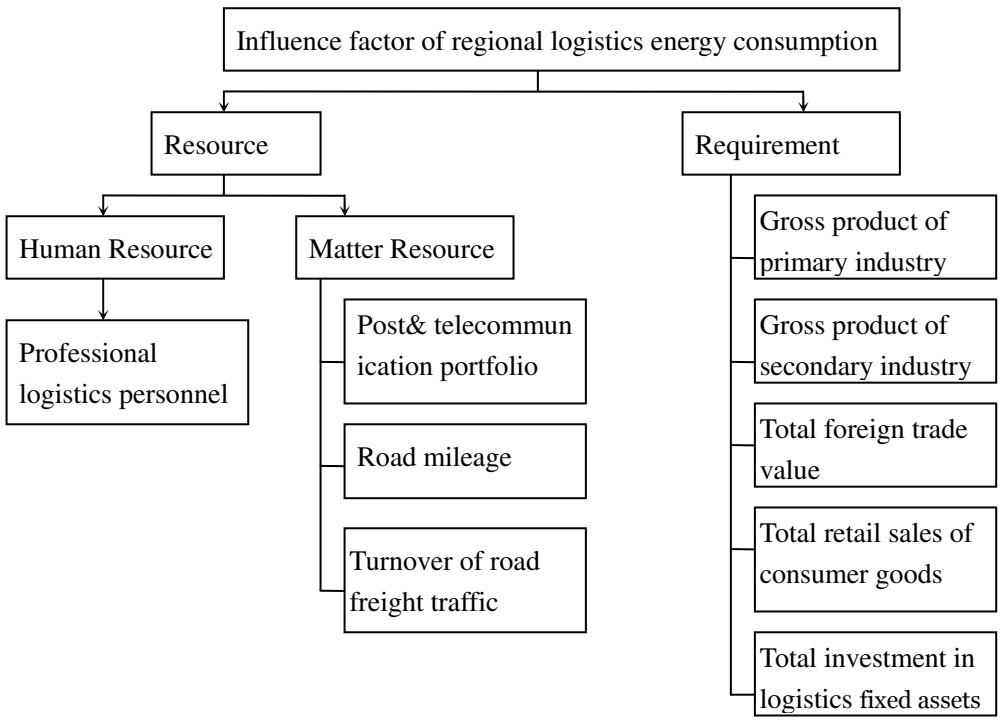

Figure 1. Indicator system of regional logistics.

DEMONSTRATION

To quantify road logistics energy consumption, the referenced sequence is composed of the number of personnel for the transportation, storage, and post and telecommunication industries, X_1; the post and telecommunication portfolio, X_2; road mileage, X_3; turnover of road freight traffic, X_4; gross product of primary industry, X_5; gross product of secondary industry, X_6; total foreign trade value, X_7; retail sales of consumer goods, X_8; and investment in fixed assets of transportation, storage, and post and telecommunication industry, X_9. In this grey system of variable X_i, with the data of Jiangsu Province and the nation from 2003 to 2007, the degree of grey correlations of influence among referenced variables and compared variables X_0 are calculated and arranged, as shown in Table 1 and Table 2.

Table 1. Grey Correlation Degree between Logistics Energy-Consumption and its Influential Factors in Jiangsu Province.

	Degree of Grey Correlation	*Indicators Order*
Personnel in logistics (10,000 people) X_1	0.795	4
Post and telecommunication portfolio (10,000 Yuan) X_2	0.593	9
Road mileage (kilometer) X_3	0.895	2
Turnover of road freight traffic (100 M ton kilometer) X_4	0.919	1
Gross product of primary industry (100 M Yuan) X_5	0.864	3
Gross product of secondary industry (100 M Yuan) X_6	0.747	6
Total foreign trade value (10,000 US dollar) X_7	0.658	7
Retail sales of consumer goods (100 M Yuan) X_8	0.755	5
Investment in fixed assets of logistics (10,000 Yuan) X_9	0.614	8

Table 2. Grey Correlation Degree between Logistics Energy-Consumption and its Influential Factors in China.

Degree of Grey correlation	*Indicators Order*
Personnel in logistics (10,000 people) X_1	0.640	8
The post and telecommunication portfolio (10,000 Yuan) X_2	0.632	9
Road mileage (kilometer) X_3	0.904	2
Turnover of road freight traffic (100 M ton kilometer) X_4	0.949	1
Gross product of primary industry (100 M Yuan) X_5	0.847	6
Gross product of secondary industry (100 M Yuan) X_6	0.860	5
Total foreign trade value (10,000 US dollar) X_7	0.734	7
Retail sales of consumer goods (100 M Yuan) X_8	0.881	4
Investment in fixed assets of logistics (10,000 Yuan) X_9	0.898	3

The grey correlations among logistics energy consumption and its related

factors in Jiangsu Province are calculated, and the order is arranged as follows:

> Turnover of road freight traffic γ_4> road mileage γ_3> gross product of primary industry γ_5> personnel in logistics γ_1> retail sales of consumer goods γ_8> gross product of secondary industry γ_6> total foreign trade value γ_7> investment in fixed assets of logistics γ_9> post and telecommunication portfolio γ_2

The grey correlations among logistics energy consumption and its related factors in China are calculated, and the order is arranged as follows:

> Turnover of road freight traffic γ_4> road mileage γ_3> investment in fixed assets of logistics γ_9> retail sales of consumer goods γ_8> gross product of secondary industry γ_6> gross product of primary industry γ_5> total foreign trade value γ_7> personnel in logistics γ_1> post and telecommunication portfolio γ_2

ANAYSIS

From the arrangement result of the grey correlation coefficients, some conclusions are obtained:

(1) Whether in China or in Jiangsu Province, the correlation degrees between logistics energy consumption and the turnover of road freight traffic, road mileage, and total foreign trade value are in accord and are the same in the qualitative analysis. The correlation between total foreign trade value and logistics energy consumption is not very tight here because only road transport is considered in this paper, while railway transport and water transport are usually included in international logistics. Also, the Yangtze River crosses Jiangsu Province, in which the water transport capacity is very large.

(2) The results also show that the correlations between investments in fixed assets of logistics and logistics energy consumption is very different in China and in Jiangsu Province, namely 3rd and 8th, respectively. This indicates that investment in the fixed assets of logistics are not enough in Jiangsu Province; it must be reinforced by software and hardware.

(3) It is also clear from the results that the correlations between gross product of primary industry and logistics energy consumption are 3rd and 6th, respectively, in Jiangsu Province and China. In Jiangsu Province, agricultural products are the main focus of logistics because Jiangsu is an agricultural province.

(4) The correlation between logistics personnel and energy consumption in Jiangsu is 4th, while it is 8th in China. This indicates that more attention should be paid to training logistics personnel to reduce energy consumption.

The correlations among logistics energy consumption and related economic factors are quantified, which provides some useful recommendations.

CONCLUSION

Through grey correlation analysis, the correlations between logistics consumption and relative economic factors can be analyzed quantitatively, and the influencing degrees calculated can be the instruction basis for logistics development and energy savings in certain areas. But with dynamic logistics development, the main influencing factors will changed, so further analysis should be done to improve the sample's quality for accuracy and reliability.

ABSTRACT:MDLRPPD (Multi-depot Location Routing Problem with Pickups and Deliveries)to be studied in this paper is a kind of problem very close to reality in the optimization of logistics system. In this paper, the complementary restraint relationship between depot selection, transports, pickups and deliveries is analyzed, the mathematical model with the lowest total cost in the logistics system is established, and the verification of correctness of mathematical model established through the application of LINGO software under the condition of small-scale data is conducted. Because of its NP-hard property, the paper designs the taboo-simulated annealing combinatorial optimization algorithm to require a solution, and applies C++ language programming to realize this combinatorial optimization algorithm. Through the comparison with optimum solution obtained from the application of LINGO software, the results show that the taboo-simulated annealing combinatorial optimization algorithm proposed in this paper proves to be a rapid and effective approach in solving MDLRPPD.
KEY WORDS: Logistics System, Location Routing, Pickups and Deliveries, Simulated Annealing, Taboo Search.

1. INTRODUCTION

The exercise of optimal design for logistics system and the provision of logistics optimization solutions for logistics enterprises serve as one of main businesses for the fourth party logistics to carry out the logistics consulting services. MDLRPPD (Multi-depot Location Routing Problem with Pickups and Deliveries), considered as a kind of problem very close to the reality in the optimization of logistics system, is an extension and branch of LRP (Location Routing Problem)model.

Foreign scholars have already begun the research on the issue of logistics system optimization as early as 1980s(Hu Dawei 2008). For example, the comprehensive study (Hu Dawei etal. 2007) on LRP and VRPPD(Vehicle Routing Problem with Pickups and Deliveries)was conducted. However, the current research on LRPPD is basically in a blank. LRPPD optimizes LRP under the premise that the synchronization of pickups and deliveries is taken into consideration. LRPPD, if compared with the traditional logistics system optimization, is closer to the complicated actual characteristics of logistics system.

The paper has analyzed the complementary restraint relationship between depot selection, transports, pickups and deliveries, established the mathematical model with the lowest total cost of logistics system, and conducted the verification of

established mathematical model by utilizing Lingo software under the condition of small-scale data. Because of its NP-hard property, the paper has designed the taboo-simulated annealing combinatorial optimization algorithm to require a solution, applied fairly large scale test data to conduct simulation calculation, and carried out the efficiency analysis on the computed results.

2. MODEL BUILDING

MDLRPPD model to be studied in this paper is based on the following assumptions:

(1) Number, location and demands of customers are known.

(2) Location and capacity of alternative facilities are known.

(3) All the customer demands can be met, and each customer is only served by one specific vehicle.

(4) Each vehicle returns to the starting point after completing all the transport missions.

(5) Overload is not permitted among transport vehicles in all the routes.

(6) Vehicle types are stated in advance.

Definition of variables and parameters:

Decision variable:

x_{ijk} is 1 if the point i is before j on route k, otherwise, it will be 0;y_i is 1 if facility i is to be constructed,otherwise, it will be 0;z_{ij} is 1 if facility i provides service for customer j,otherwise, it will be 0.

Parameters:

R Potential location assembly of facility point;

J Assembly of all the customer points;

V Assembly of all the vehicles;

N Quantity of representative customers;

C_{ij} Distance from point i to point j;

$S = R \cup J$ Assembly of all the customer points and potential facility points;

G_r Fixed costs of construction and operation of facility r;

F_k Fixed costs of vehicle k to be applied;

V_r Maximum capacity of facility r;

p_j Traffic volume of customer j;

q_j Demand of customer j;

Q_k Capacity of vehicle k;

U_{lk} Auxiliary variable.

In the light of problem definition, MDLRPPD can be represented by the following mixed integer linear programming model.

$$Min \qquad \sum_{r \in R} G_r y_r + \sum_{i \in S} \sum_{j \in S} \sum_{k \in V} C_{ij} x_{ijk} + \sum_{k \in V} F_k \sum_{r \in R} \sum_{j \in J} x_{ijk}$$

S.t.

$$\sum_{k \in V} \sum_{i \in S} x_{ijk} = 1, \ j \in J \qquad (1)$$

$$\sum_{i \in S} \sum_{j \in J} p_j x_{ijk} \le Q_k, \ k \in V \qquad (2)$$

$$\sum_{i\in S}\sum_{j\notin J} q_j x_{ijk} \le Q_k,\ k\in V \tag{3}$$

$$\sum_{j\in J} p_j z_{rj} - V_r y_r \le 0, r\in R, \tag{4}$$

$$\sum_{j\in J} q_j z_{rj} - V_r y_r \le 0, r\in R, \tag{5}$$

$$\sum_{i\in S} x_{ipk} - \sum_{j\notin S} x_{pjk} = 0,\ k\in V,\quad p\in S \tag{6}$$

$$\sum_{r\in R}\sum_{j\notin J} x_{rjk} \le 1,\ k\in V \tag{7}$$

$$\sum_{l\in S}(x_{rlk} + x_{ljk}) \le 1 + z_{rj},\quad r\in R,\quad j\in J,\quad k\in V \tag{8}$$

$$U_{lk} - U_{jk} + Nx_{ljk} \le N - 1,\quad l,j\in J, k\in V \tag{9}$$

$$x_{ijk} = 0\ or\ 1,\quad i,j\in S, k\in V, i\ne j \tag{10}$$

$$y_r = 0\ or\ 1,\quad r\in R \tag{11}$$

$$z_{ij} = 0\ or\ 1,\quad i\in R,\ j\in J \tag{12}$$

$$U_{lk} \ge 0,\ l\in J, k\in V \tag{13}$$

In the above-mentioned model, the objective function is the lowest total cost (including the costs of facility construction and operation, transportation cost and running cost of vehicle). Constraint (1) ensures that each customer is only served by one specific vehicle. Constraint (2)-(3) serve as the constraint condition for the capacity of transport vehicles; Constraint (4)-(5) serve as the capacity restrictive conditions for warehouse; Constraint (6) ensure the route continuity; Constraint (7) ensures that the route of every single transport vehicle can only leave from one facility; Constraint (8) ensures that the customers can only be served by the selected facility. Constraint (9) serve as the sub-path restriction; Constraint (10)-(12) stand for 0 & 1 variable restriction; Constraint (13) serve as the auxiliary variables restriction.

3. DESIGN OF TABOO-SIMULATED ANNEALING COMBINATORIAL HEURISTIC ALGORITHM

3.1 Mentality of algorithm design

Taboo search algorithm is the popularization of partial neighborhood searching algorithm, and its features are that taboo technology is applied to avoid getting caught up in local optimum (Xing Wenxun etal. 2005); However, the iterative process of this algorithm is serial. It is only transformation in a single state instead of parallel search, and thus, it leads to longer consumption of search time of this

algorithm. Therefore, with the increase of problem scale to be solved, the computation time experiences rapid growth, and it is likely to bring about the infeasibility of algorithm due to the time relationship in the end. Simulated annealing algorithm, irrelevant to the original value and provided with asymptotic convergence property, has been theoretically proved to be a kind of optimal solution of global optimization algorithm using converge to overall situation with probability (Hu Dawei etal. 2006). Based on the characteristics of these two algorithms, the paper raises the adoption of taboo-simulated annealing combinatorial optimization heuristic algorithm to solve the model. The flow chart is shown in **Figure 1**.

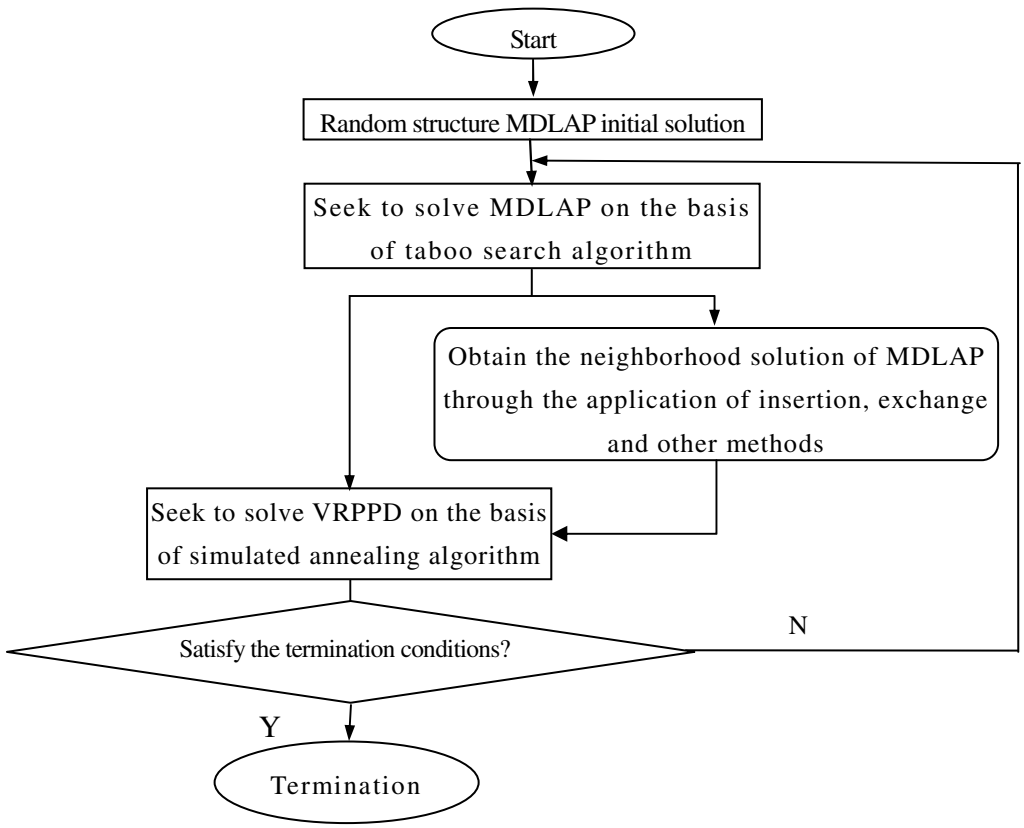

Figure 1. Flow chart for solution of MDLRPPD through application of taboo-simulated annealing combinatorial optimization algorithm.

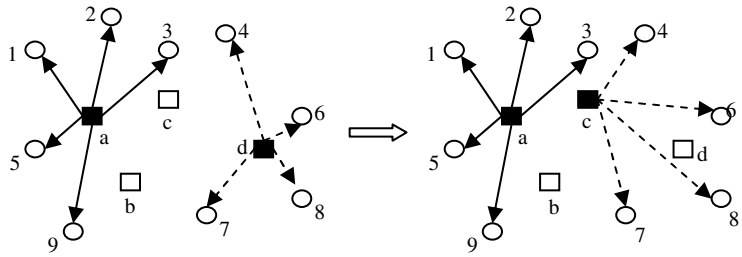
3.2 Design of initial solution structure and neighborhood search.

In this paper, it is planned to apply the encoding mode directly arranged by customer. Use the natural number from 1 to N to represent the customers, and the random arrangement of these natural numbers is precisely a solution. Sequentially arrange every number (customer) of solution into the delivery route of vehicle according to the constrained condition of questions. Take 12346789 as an example, at first, arrange customer 1 into the first delivery route, and judge whether the constrained condition of questions can be met. If so, the delivery route in terms of 0-1-0 is thus formed. Next, arrange customer 2 into this delivery route, and the rest can be done in the same manner. If the constrained condition of questions can not be met, it shows that customer 2 can not be delivered via this delivery route. At this moment, it is necessary to restart the generation of new delivery route of 0-2-0. Keep

repeating this process until all the customers are arranged into the delivery route.

The taboo search algorithm designed in this paper is mainly to solve MDLAP model. Three kinds of neighborhood search methods, namely, "Depot exchange", "customer exchange" and "customer insertion" operation, are designed in this paper. It is possible to randomly select one kind from these three kinds of neighborhood search methods to generate neighborhood solution, which can strengthen the search performance of taboo search algorithm, expand the search area, and facilitate the avoidance of locally optimal solution.

The schematic diagrams of depot exchange are shown in **Figures 2**.

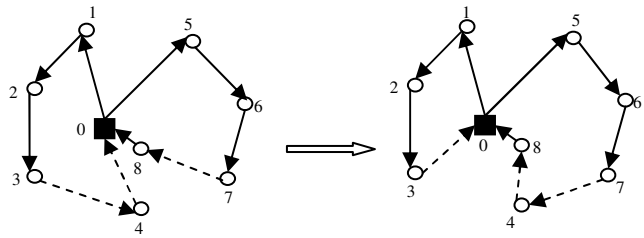


■ Stands for the selected facility □ Stands for the unselected facility
○ Stands for the customers ⟶ And ⇢ Stands for the routes

Figure 2. Schematic diagram of depot exchange method.

The simulated annealing algorithm designed in this paper is mainly to solve VRPPD model. At the stage of route optimization, it is designed to randomly select one kind from three neighborhood search methods in terms of insertion method, 2-swap within the route and 2-swap between the routes to carry out neighborhood transformation, and conduct the route optimization by utilizing 2-opt (Osman, I. H. 1993a) algorithm so as to generate the neighborhood solution. In this way, the optimal performance of simulated annealing algorithm is strengthened, and the optimal solution of search range is expanded so that the better improvement can be obtained in the aspect of vehicle running costs.

The schematic diagrams of insertion method are shown in **Figure 3**.



■ Stands for the selected DC
○ Stands for the customers ⟶ And ⇢ Stand for the routes

Figure 3. Schematic diagram of insertion method.

4. ALGORITHM VERIFICATION

The test data proposed by Solomon in 1987 is commonly used in VRP. The data acquisition is divided into six types. The customer locations of R1 and R2 are randomly distributed, customers of C1 and C2 are in the state of aggregation (namely, the node distribution is clustered according to the geographical position), RC1 and RC2 are in the state of semi-aggregation. At the actual problems, the customer

distribution is closer to the states of random and semi-aggregation reflected in R class and RC class data acquisitions in most cases. For this reason, the paper, based on R101 data series of Solomon 25 customers, applies the statement a=rand()%25+1 to generate three random numbers within the range of 1~25, and take the customer coordinates corresponding to these three serial numbers in original data source as the coordinates for alternative facility point in this calculation example. The same method can be applied to once again randomly generate the data corresponding to five customer points from the remaining nodes, and randomly give the supply volume (subject to change according to the actual conditions). A number of parameters for alternative facility points and customer points randomly generated in this way are shown in **Table 1** and **Table 2**. The vehicle capacity is taken as 40 while the fixed cost of vehicle is taken as 30.

Table 1. Coordinates, Capacity and Construction Cost of Potential Facility Points.

	D1	D2	D3
X-coordinate	35	25	10
Y-coordinate	35	30	43
Capacity of facility point	70	70	70
Construction cost	200	200	200

Table 2. Coordinate and Demand of Customer Point.

	C1	C2	C3	C4	C5
X-coordinate	30	50	10	45	45
Y-coordinate	60	35	20	65	10
Customer demand	16	19	19	9	18
Customer supply volume	18	21	14	23	18

Lingo 10.0 is applied to conduct programming calculation for MDLRPPD model so as to obtain the optimal solution, and the results are shown in **Table 3** (calculation time is 39s).The results show that two facilities have been chosen and the corresponding objective function value is 708.47.

Table 3. Computed Result of Lingo.

Selected facility points	Customer route
D1	V1: D1-C1-C2-D1 V3: D1-C4-D1
D2	V2: D2-C5-C3-D2

In order to verify the effectiveness of taboo-simulated annealing combinatorial algorithm designed in this paper, it is to substitute the data in **Table 1** and **Table 2** into the combinatorial algorithm program for the purpose of calculation. The results is fully consistent with the calculation results of Lingo 10.0 (shown in **Table 3**), but the calculation time (203 millisecond) is saved around 200 times. It indicates that the taboo-simulated annealing combinatorial algorithm designed in this paper is rapid and effective in providing solution for this model.

5. CONCLUSION

In this paper, the mathematical model with the lowest total cost of logistics system is established, and the correctness of mathematical model is verified through the application of Lingo software for small-scale data. Because of its NP-hard

property, the paper designs the taboo-simulated annealing combinatorial optimization heuristic algorithm to require a solution, and uses C++ language programming to realize this combinatorial optimization algorithm. It is planned to apply the afore-mentioned same small-scale data to calculate, and the results are completely the same as that of the optimal solution obtained through the application of LINGO. As the heuristic combinatorial algorithm has great advantage in terms of calculation time, it shows that the taboo--simulated annealing combinatorial optimization algorithm is of very practical value in solving the large-scale MDLRPPD model.

Electrical Appliance Reversion Logistics Network Planning

Zhao Gang, Nan Xi, Lu Kecong

School of Transportation, Shanghai Maritime University; PH (021) 58855200-2310; email: zhaogd@online.sh.cn

ABSTRACT

This article studies obsolete electrical appliance reverse logistics recycling network design. A MILP (Mixed Integer Linear Programming) model is given to optimize the logistics system, and the locations of various facilities are determined. Finally, an example that considers the logistics system of a refrigerator company is taken to demonstrate the model presented in the paper. Linggo8.0 soft is used to resolve the model, and a satisfactory result was gained.

Key words: reverse logistics, network of logistics, Obsolete Electrical Appliances

INTRODUCTION

With the development of the economy and the popularity of electrical appliances, the recycling and reuse of obsolete electrical appliances (OEA) has become a serious problem. Effective recycling and reuse can save resources and energy, lower costs of production. It can also greatly lower the emission of waste, reduce pressure on the environment, and plays an active role in sustainable economic development. From the logistics point of view, this type of cycle (use – recycle – dispose – reuse), used for obsolete products and materials, is leading a new research branch in logistics - reverse logistics.

In the reverse logistics of obsolete electrical appliances, a network should be designed that can reasonably assure that the structure of distribution channels for the obsolete electrical appliances, including various types of reverse logistics facilities, the number and location of facilities, and the transport mode between the facilities of the obsolete products is sensible.

RESEARCH STATUS QUO

Fleischmann et al. (2000) defined the basic characteristics of a reverse logistics network system and determined its design principles. Fleischmann et al. (2002) studied the network structure in which reusable parts could be obtained from the obsolete products and evaluated the financial impact on a company's revenue. Jayarama et al. (1999) analyzed the typical logistics network structure of the American Electronic Equipment Rebuild Company and established a model that can determine storage capacities and locations based on the process in which obsolete products (or core parts) are collected, reused, and redistributed.

Xuhui et al. (2003) described enterprise integration based on the management of the supply chain and the reverse supply chain and introduced the design principles for a product reverse logistics network. Zujun et al. (2004) studied the functions of reverse logistics. Qinli et al. (2004) analyzed the structure of logistics networks, suggesting they could be categorized into open-loop systems and closed-loop systems.

KEY FUNCTIONS OF A REVERSE LOGISTICS NETWORK

Key functions of a Reverse Logistics Network for Obsolete Electrical Appliances (RLNOEA) could be concluded as follows.

Collection This is the starting point of an RLNOEA. Collecting worn-out appliances could be on a paid basis or simply for public interest. Considering the contemporary social situation, the collected items in this study were paid for.

Recycling process This is a primary function of an RLNOEA, which can be divided into three stages: checking, disassembling, and reusing.

Disposal Sometimes disassembled products cannot be recycled due to technical or economic limitations, resulting in burial or burning. However, with the development of recycling technology, this situation has become more and more scarce.

Redistribution Recycled products, parts, or raw materials from this process can be returned to the market.

Although an RLNOEA has distinguishing features, it also shares the same functions of a common system: transporting, stockpiling, moving, and packaging.

RLNOEA PLANNING MODEL

In supply chain management, reverse logistics will impact the production plan, distribution, inventory strategies, and a series of decision-making for forward logistics. This study sets up an integrated logistics network that combines forward logistics and reverse logistics. The network includes factories (remanufacturing plants), distribution centers, recycling centers (testing centers), regional consumption of renewable materials, integrated distribution centers/recycling centers, obsolete product disposal centers, etc.

Parameters and Variables

Let $G=\{1,\cdots,\mathrm{G}\}$,$J=\{1,\cdots,\mathrm{J}\}$,$H=\{1,\cdots,\mathrm{H}\}$,$T=\{1,\cdots,\mathrm{T}\}$denote the set of indices of potential locations for a new plant, a new distribution center, a new recycling center, and a new waste disposal center, respectively. For each g $\in G$, j $\in J$, h $\in H$ and t $\in T$, let c_g^1 , c_j^2, c_h^3 and c_t^4 be the cost for opening a factory, distribution center, recycling center, and waste disposal center, respectively..

Let $F=\{1,\cdots,\mathrm{F}\}$,$I=\{1,\cdots,\mathrm{I}\}$,$L=\{1,\cdots,\mathrm{L}\}$,$S=\{1,\cdots,\mathrm{S}\}$denote the set of indices of locations for the existing plants, existing distribution center, existing recycling center, and existing waste disposal center, respectively. Let $K=\{1,\cdots,\mathrm{K}\}$ denote the set of indices of consumption districts. Let $E=\{1,\cdots,\mathrm{E}\}$ denote the set of indices of the materials market. For $f,i \in F \cup I$, let d_{fi}^1 denote the distance between existing factory f and existing distribution center i, and we define d_{fj}^2, d_{gi}^3, d_{gj}^4, d_{ik}^5, d_{jk}^6, d_{kh}^7, d_{hf}^8, d_{hg}^9, d_{hs}^{10}, d_{ht}^{11}, d_{he}^{12} alike.

For each $k \in K$, let n_k denote the demand for new products in consumption area k each year. Let v_f^1 and v_g^2 denote the production cost of unit products in factory f and g. Let v_i^3 and v_j^4 denote the operation cost of unit products in distribution center i and j. Let v_h^5 , v_s^6 and v_t^7 denote the unit cost of dealing with waste products in recycling center h and waste disposal centers s and t, respectively. Let v_k^8 denote the price of unit new production in

consumption area k. Let w_1 denote the reproducible rate of the product; w_2 the recycle rate of the product material; and w_3 the recycle rate of the waste product. Let a denote the transportation cost for unit mass in unit distance; n the quantity of product delivery to the consumer area; B the proceeds from the recycling material of the unit product; L the proceeds from re-manufactured products of the unit product; R the weight of the unit product. Let A_f^1 and A_g^2 denote the maximum production capacity of the plants each year; A_i^3 and A_j^4 the maximum treatment capacity of distribution centers each year; A_h^5 , A_t^7 and A_s^6 the maximum treatment capacity of recycling centers and waste disposal centers each year. Let α_g, β_j , χ_h and δ_t denote the 0 or 1 that stands for whether to establish a new factory, a new distribution center, a new recycling center, and/or a new waste disposal center or not，1 for positive and 0 for negative.

For $f,i \in F \cup I$, let x_{fi}^1 denote the quantity of product delivery from factory f to distribution center i, and we define x_{fj}^2, x_{gi}^3, x_{gj}^4, y_{ik}^1, y_{jk}^2, z_{kh}, p_{hf}^1, p_{hg}^2, q_{hs}^1, q_{ht}^2, r_{he} alike.

Objective Function

$$\text{MAX } f(c) = \varphi(t) - \varphi(\alpha, \beta, \chi, \delta) - \varphi(x, z, q) - \varphi(x, y, z, p, q) \quad (1)$$

where

$\varphi(t)$ - the proceeds of sale and recycling

$\varphi(\alpha, \beta, \chi, \delta)$- fixed investment of facilities

$\varphi(x, z, q)$ - operation cost

$\varphi(x, y, z, p, q)$- transportation cost

$$\varphi(t) = \sum_{k=1}^{K} v_k^8 \left(\sum_{i=1}^{I} y_{ik}^1 + \sum_{j=1}^{J} y_{jk}^2 \right) + L \left(\sum_{h=1}^{H} \sum_{f=1}^{F} p_{hf}^1 + \sum_{h=1}^{H} \sum_{g=1}^{G} p_{hg}^2 \right) + B \sum_{h=1}^{H} \sum_{e=1}^{E} r_{he}$$

where the first item is the proceeds of the sale; the second item is the proceeds of the re-manufactured products, and the third item is the material's recycle revenue.

$$\varphi(\alpha, \beta, \chi, \delta) = \sum_{g=1}^{G} c_g^1 \alpha_g + \sum_{j=1}^{J} c_j^2 \beta_j + \sum_{h=1}^{H} c_h^3 \chi_h + \sum_{t=1}^{T} c_t^4 \delta_t$$

where the four items denote the fixed cost of building factories, distribution centers, recycling centers, and waste disposal centers, respectively.

$$\varphi(x, z, q) = \sum_{f=1}^{F} \sum_{i=1}^{I} x_{fi}^1 v_f^1 + \sum_{f=1}^{F} \sum_{j=1}^{J} x_{fj}^2 v_f^1 + \sum_{g=1}^{G} \sum_{i=1}^{I} x_{gi}^3 v_g^2 + \sum_{g=1}^{G} \sum_{j=1}^{J} x_{gj}^4 v_g^2 +$$

$$\sum_{f=1}^{F} \sum_{i=1}^{I} x_{fi}^1 v_i^3 + \sum_{f=1}^{F} \sum_{j=1}^{J} x_{fj}^2 v_j^4 + \sum_{g=1}^{G} \sum_{i=1}^{I} x_{gi}^3 v_i^3 + \sum_{g=1}^{G} \sum_{j=1}^{J} x_{gj}^4 v_j^4 + \sum_{k=1}^{K} \sum_{h=1}^{H} z_{kh} v_h^5 + \sum_{h=1}^{H} \sum_{s=1}^{S} q_{hs}^1 v_s^6$$

$$+\sum_{h=1}^{H}\sum_{t=1}^{T} q_{ht}^{2} v_{t}^{7}$$

where the first four items denote the production cost in the factory; the second four items denote the operation cost in the distribution center; the ninth item denotes the operation cost in the recycling center, and the last two items denote the operation cost in the waste disposal center.

$$\varphi(x,\ y,\ z,\ p,\ q)=aR\left(\sum_{f=1}^{F}\sum_{i=1}^{I} x_{fi}^{1} d_{fi}^{1}+\sum_{f=1}^{F}\sum_{j=1}^{J} x_{fj}^{2} d_{fj}^{2}+\sum_{g=1}^{G}\sum_{i=1}^{I} x_{gi}^{3} d_{gi}^{3}+\sum_{g=1}^{G}\sum_{j=1}^{J} x_{gj}^{4} d_{gj}^{4}\right)+$$
$$aR\left(\sum_{i=1}^{I}\sum_{k=1}^{K} y_{ik}^{1} d_{ik}^{5}+\sum_{j=1}^{J}\sum_{k=1}^{K} y_{jk}^{2} d_{jk}^{6}\right)+aR\sum_{k=1}^{K}\sum_{h=1}^{H} z_{kh} d_{kh}^{7}+aR\left(\sum_{h=1}^{H}\sum_{f=1}^{F} p_{hf}^{1} d_{hf}^{8}+\sum_{h=1}^{H}\sum_{g=1}^{G} P_{hg}^{2} d_{hg}^{9}\right)$$
$$+aR\left(\sum_{h=1}^{H}\sum_{s=1}^{S} q_{hs}^{1} d_{hs}^{10}+\sum_{h=1}^{H}\sum_{t=1}^{T} q_{ht}^{2} d_{ht}^{11}\right)+aR\sum_{h=1}^{H}\sum_{e=1}^{E} r_{he} d_{he}^{12}$$

where the first item denotes the product's transportation cost from factory to distribution center, the second item from distribution center to consumption area, and the third item from consumption area to recycling center; the fourth item denotes the waste product's transportation cost from recycling center to factory, the fifth item from recycling center to waste disposal center, and the sixth item from recycling center to renewable materials market.

Constraint Conditions

$$\alpha_g, \beta_j, \chi_h, \delta_t \in \{0,\ 1\} \quad (2)$$

$$\sum_{i=1}^{I} x_{fi}^{1}+\sum_{j=1}^{J} x_{fj}^{2} \le A_f^{1} \ (f=1,2,....F) \quad (3)$$

$$\sum_{i=1}^{I} x_{gi}^{3}+\sum_{j=1}^{J} x_{gj}^{4} \le A_g^{2}\alpha_g \ (g=1,2,....G) \quad (4)$$

$$\sum_{k=1}^{K} y_{ik}^{1} \le A_i^{3} \qquad (i=1,2,....I) \quad (5)$$

$$\sum_{k=1}^{K} y_{jk}^{2} \le A_j^{4}\beta_j \qquad (j=1,2,....J) \quad (6)$$

$$\sum_{k=1}^{K} z_{kh} \le A_h^{5}\chi_h \qquad (h=1,2,....H) \quad (7)$$

$$\sum_{h=1}^{H} q_{hs}^{1} \le A_s^{6} \qquad (s=1,2,.....S) \quad (8)$$

$$\sum_{h=1}^{H} q_{ht}^{2} \le A_t^{7}\delta_t \qquad (t=1,2,.....T) \quad (9)$$

$$\sum_{i=1}^{I} y_{ik}^{1}+\sum_{j=1}^{J} y_{jk}^{2} \le n_k \qquad (k=1,2,.....K) \quad (10)$$

$$\sum_{h=1}^{H} z_{kh} \le w_3 n_k \qquad (k=1,2,.....K) \quad (11)$$

$$\sum_{k=1}^{K} y_{ik}^{1}=\sum_{f=1}^{F} x_{fi}^{1}+\sum_{g=1}^{G} x_{gi}^{3} \qquad (i=1,2,....I) \quad (12)$$

$$\sum_{k=1}^{K} y_{jk}^{2}=\sum_{f=1}^{F} x_{fj}^{2}+\sum_{g=1}^{G} x_{gj}^{4} \qquad (j=1,2,....J) \quad (13)$$

$$w_1\sum_{k=1}^{K} z_{kh}=(\sum_{f=1}^{F} p_{hf}^{1}+\sum_{g=1}^{G} p_{hg}^{2})(h=1,2,....H) \quad (14)$$

$$\sum_{h=1}^{H} q_{hs}^{1}+\sum_{h=1}^{H} q_{ht}^{2}=(1-w_1-w_2)\sum_{k=1}^{K} z_{kh}(h=1,2,....H) \quad (15)$$

All the variables are integer value, which is not less than zero

Constraint (2) sets out the parameters for the 0-1 variables. Constraints (3) - (11) show that the handling volume of facilities such as factory, distribution center, recycling center, and waste disposal center will not to exceed the volume of their capacity. Constraints (12) - (15) express that the commodity volume inbound to and outbound from the distribution centers, consumption districts, and recycling centers is equal.

The above model is a mixed integer linear programming (MILP) model.

CASE STUDY

A refrigerator manufacturer in the area wants to develop a reverse logistics network for its products. According to traffic and transport conditions and the region's products consumption and scrapping situations, the region is divided into 17 districts. After analyzing the various candidates according to the various factors, we can identify the potential locations of various facilities initially. Then we can adopt the above modeling method to confirm the various facilities' quantity and locations. The demand in various districts of the company's refrigerators each year is shown in Table 1.

Table 1. Demand in Various Districts Each Year (unit: piece).

City	D1	D2	D3	D4	D5	D6	D7	D8	D9
Demand	3700	2870	1830	1750	1660	580	5080	1000	1230
City	D10	D11	D12	D13	D14	D15	D16	D17	
Demand	3580	6700	4420	4910	5500	2250	3700	1300	

The company has a factory in D1 already, with a production capacity of A_1^1 = 200,000 (pieces/year). The production cost of each unit is A_1^1 = 200,000 yuan. The distribution centers which have already been built are located in D1, D2, D3, D7. The disposal capacity of the distribution center is $A_1^3 = A_2^3 = A_3^3 = A_7^3 =$ 30,000 (piece/year). The operation cost of each unit is $v_1^3 = v_2^3 = v_3^3 = v_7^3 =$ 10 (yuan/piece). Existing waste disposal centers are located in D1, D9. The maximum disposal capacity is $A_1^6 = A_9^6 =$ 1,500 ton/year (2,500 pieces/year). The cost to deal with each obsolete product is $v_1^6 = v_9^6 =$ 80 yuan/ton (4.8 yuan/piece). The existing renewable materials market region is located in D8.

After analyzing the various candidates according to the various factors, we develop an initial plan: D2, D7 to be an optional factory; D11, D12, D15, D17 to be optional distribution centers; D1, D2, D3, D7, D9, D11, D12, D13, D15, D17 to be optional recycling centers; and D3, D5 to be optional waste disposal centers. According to products and materials market conditions, we can confirm the product price and the prices of recycled materials. The product price is v_k^8 = 2,400 yuan/piece, with $k = 1,2,3,.....16,17$. The unit profit of the remanufactured product is L = 200 yuan. The weight of the refrigerator is R = 60kg. The prices of the materials are shown in Table 2.

Table 2 Materials of Product Composition and Price.

Material	Steel	Copper	Aluminium	Plastic	Other
Percent (%)	49.00	3.5	2.2	43.3	2.0
Price(yuan/ kg)	1.2	20.0	14.5	1.9	6.0

From the above data, we can see a product of reusable material recycling has the profitof B = 40%(60×49%×1.2 + 60×3.5%×20.0 + 60×2.2%×14.5 + 60×43.3%×1.9 +60×2.0%×6.0) = 61 yuan.

The fixed cost of building a new factory is $c_2^1 = c_7^1 =$ 1,000,000 yuan. The production capacity is $A_2^2 = A_7^2 =$200,000 pieces/year; the production cost of each unit is $v_2^2 = v_7^2 =$ 2,000 yuan. The fixed cost of building a new distribution center is $c_{11}^2 = c_{12}^2 = c_{15}^2 = c_{17}^2 =$ 100,000 yuan. The disposal capacity is $A_{11}^4 = A_{12}^4 = A_{15}^4 = A_{17}^4 =$ 330,000 pieces/year. The operation cost of each unit is $v_{11}^4 = v_{12}^4 = v_{15}^4 = v_{17}^4 =$ 10 yuan/piece. The fixed cost of building a new recycling center is $c_1^3 = c_2^3 = c_3^3 = c_7^3 = c_9^3 = c_{11}^3 = c_{12}^3 = c_{13}^3 = c_{15}^3 = c_{17}^3 =$ 100,000 yuan. The disposal capacity is $A_1^5 = A_2^5 = A_3^5 = A_7^5 = A_9^5 = A_{11}^5 = A_{12}^5 = A_{13}^5 = A_{15}^5 = A_{17}^5 =$ 300,00 piece/year. The cost to deal with each obsolete product is $v_1^5 = v_2^5 = v_3^5 = v_7^5 = v_9^5 = v_{11}^5 = v_{12}^5 = v_{13}^5 = v_{15}^5 = v_{17}^5 =$ 20 yuan/piece. The fixed cost of building a new obsolete product disposal center is $c_3^4 = c_5^4 =$ 200,000 yuan. The Maximum is $A_3^7 = A_5^7 =$ 1,500 ton/year (2,500 pieces/year). The cost to deal with each obsolete product is $v_3^7 = v_5^7 =$ 80 yuan/ton (4.8 yuan/piece). Each heavy-duty truck used for transportation has the loading capacity of 15 tons; the transportation cost is 0.3 yuan/ton-kilometer. The maximum manufacture rate is $w_1 =$ 40%. The product material recycle rate is $w_2 =$ 40%. The obsolete product recycle rate is $w_3 =$ 60%.

Using the case data in the model and using *lingo8.0* to get the Maximum of the object function, the max profit is $f(c) =$ 2,024,633 yuan. The optimal of related decision variables are $\beta_{12} = \chi_9 = \chi_{12} = \delta_5 =$1, $x_{17}^1 =$ 22,110, $x_{1,12}^2 =$ 30,000, $y_{72}^1 =$ 2,670, $y_{74}^1 =$ 1,750, $y_{75}^1 =$ 1,660, $y_{7,11}^1 =$6700, $y_{7,12}^1 =$ 4,420, $y_{7,13}^1 =$ 4,910, $y_{12,1}^2 =$3700, $y_{12,2}^2 =$ 200, $y_{12,3}^2 =$ 1,830, $y_{12,6}^2 =$ 580, $y_{12,7}^2 =$ 5,080, $y_{12,8}^2 =$ 1,000, $y_{12,9}^2 =$ 1,230, $y_{12,10}^2 =$ 3,580, $y_{12,14}^2 =$ 5,500, $y_{12,15}^2 =$ 2,250, $y_{12,16}^2 =$ 3,750, $y_{12,17}^2 =$ 1,300, $z_{19} =$1, $z_{29} =$ 1,722, $z_{49} =$ 1,050, $z_{59} =$ 996, $z_{10,9} =$ 2,148, $z_{11,9} =$ 4,020, $z_{12,9} =$ 2,652, $z_{13,9} =$ 2,946, $z_{14,9} =$ 3,300, $z_{1,12} =$ 2,218, $z_{3,12} =$ 1,098, $z_{6,12} =$ 348, $z_{7,12} =$ 3,048, $z_{8,12} =$ 600, $z_{9,12} =$ 738, $z_{15,12} =$ 1,350, $z_{16,12} =$ 2,250, $z_{17,12} =$ 780, $p_{91}^2 =$ 7,534, $p_{12,1}^2 =$ 4,972, $q_{91}^1 =$ 1,267, $q_{95}^2 =$ 2,500, $q_{12,9}^1 =$ 2,486, and the others are zero.

According to the value of the variables, we can make sure that D1 is the location of the factory, with no need to build a new factory; D1, D2, D3, D7, and D12 are distribution centers, and D12 is the new distribution center; D9 and D12 are the new recycling centers; D1, D9, and D5 are the obsolete product disposal centers;

D5 is the new obsolete product disposal center.

CONCLUSION

An optimization model for the design of an integrated logistics network that combines a forward logistics and reverse logistics network is set up and applied to a refrigerator factory's integrated logistics network design. The results were satisfactory.

ABSTRACT

Most projects exist as part of a multi-project environment in the Eleventh Five-Year Program of China and the 2010 Shanghai World Expo, meaning that an era of multi-project management has come. This article suggests that a new organizational model suited for owners' multi-project management should be built and expressed with an organizational structure chart from the owners' perspective, with the owners at the core, and analyzes the relationship of stakeholders with game theory. It also describes the main point of the organizational structure model's implementation to ensure that the organizational structure can be implemented smoothly.

Key words: Multi-project management, organizational structure pattern, owners

INTRODUCTION

In recent years, as key transport infrastructure projects of the National Eleventh Five-Year Plan are carried out and implemented gradually, owners are facing new challenges related to carrying out and coordinating multiple projects simultaneously. With the external environment and conditions changing, the competitive environment of society is increasing. High operating costs of projects are causing owner organizations to examine multi-project management behaviors. They strive to find a new multi-project management pattern to reduce multi-project operating costs, promote the professionalization management, and cultivate the core competitiveness of organizations. This will improve the overall efficiency of organizations and achieve the goal of sustainable development.

CURRENT MULTI-PROJECT MANAGEMENT PATTERN OF OWNERS

In single-project management, project management patterns include self-management projects, namely the traditional triangle pattern of "owners + supervision departments + contractors"; a combination of self-management and commissioned management; and owners' commissioned management. In China, the most common are consultation, total-control, physical, contracting, construction agent patterns, etc. (Yin 2008).

Current multi-project management often adopts the project-centered management pattern (see Figure 1). This project management pattern, which puts the owners, supervision, and contractor together by means of professional project management departments, neglects the central role of owners within the project life cycle.

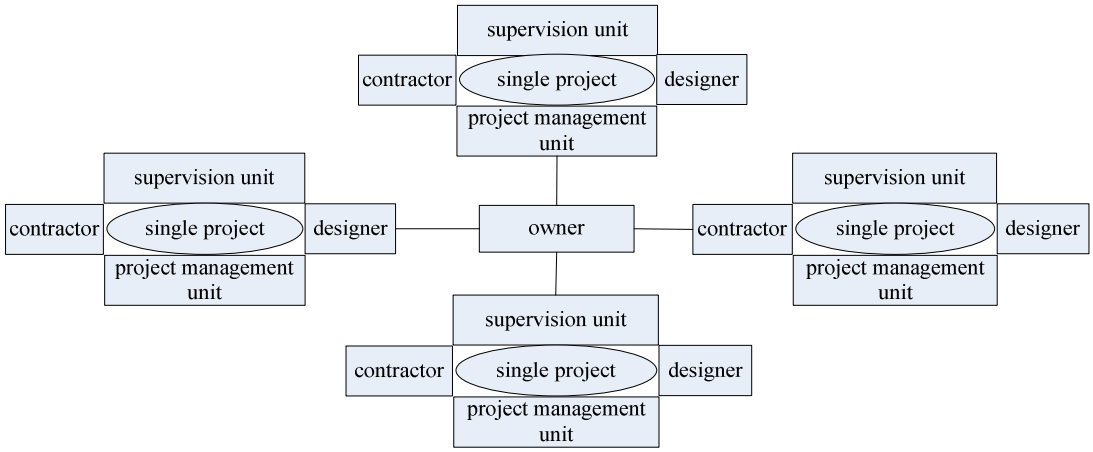

Figure 1. Project-centered multi-project management model.

GAME ANALYSIS OF PROJECT PARTICIPANTS

Single-layer principal-agent game pattern of supervision departments directly commissioned by owners. Assumed conditions are as follows.

In the game, there are owners, contractors, and supervision departments. To increase personal income, contractors use speculative behavior by colluding with (bribing) supervision departments, which decreases project earnings.

Contractors have two choices: to bribe or not bribe; if contractors choose to bribe, supervision departments have two options: to accept or not accept.

If the contractor does not bribe the supervision department, both sides have benefited from zero, and the project has a normal income - the assumption here is zero; If contractors bribe the supervision unit and the supervision unit accepts, the contractor will have an additional income X_1, and bribery amounts X_2. If the supervision unit accepts a bribe, it has the probability of being discovered and can be punished by a fine, an expected loss of X_3. Because of collusion between the two sides, the project is at risk of loss for S. If the contractor offers a bribe and the supervision unit does not accept, then the benefit of both sides is zero and the project has a normal income (see Figure 2). The benefit matrix separately expresses contractor benefit, supervision unit benefit, and project benefit.

We can get a perfect information dynamic game. Sub-game perfect Nash equilibrium is as follows: If X2>X3 and X1>X2, the contractor chooses bribery and the supervision unit chooses accepting bribery. Then the three parties' benefit is (X1-X2, X2-X3,-S). The project suffers from risk losses. If X1<X2, the contractor

chooses not to bribe, the game terminates, and the project proceeds normally.

To prevent project risk caused by the two sides' collusion, it is necessary to prevent the emergence of the balance outcome for the two sides. The keys lie in greater control and punishment of supervision departments.

Double-layer principal-agent game pattern of project management departments and supervision units. Assumed conditions are as follows:

The supervision departments oversee the project implementation of the contractor. For personal enhancement, the contractor may bribe the supervision departments, and the project management department has oversight responsibility for the supervision departments. Once the supervision departments are found to have accepted bribes and are punished, to mitigate punishment, supervision departments have the tendency to bribe the project management department.

Contractors have two choices: to bribe or not bribe. If contractors select bribery, the supervision departments have two options: to accept or not accept. If the supervision departments accept a bribe, they have two choices: to bribe or not bribe. The same project management department has two choices. Both sides benefit, as shown in Figure 3.

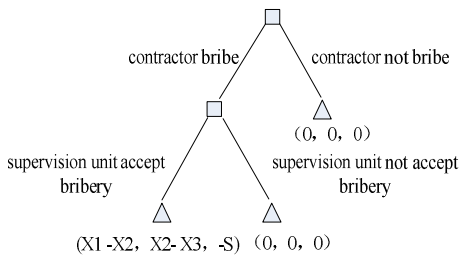

Figure 2. Single-layer principal-agent game model.

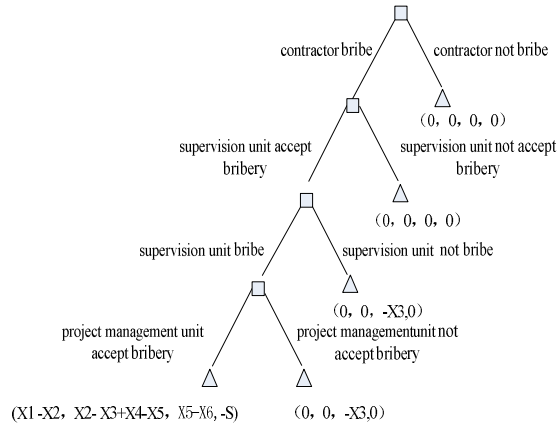

Figure 3. Double-layer principal-agent game model.

Where X1 is the additional revenue of the contractor for the irregularities; X2 is the amount that the contractor bribes supervision departments; X3 is financial penalties of the supervision departments for accepting a bribe; X4 is the reduced punishment amount of the supervision departments for bribing the project management department; X5 is amount of the project management department accepting bribery from the supervision departments; X6 is the punished expectations of the project management department for accepting a bribe; S is the losses of the project.

When X1>X2, X4>X5>X6, X2-X3+X4-X5>0, the sub-game perfect Nash equilibrium for (bribery, accept bribery, bribery, accept bribery), that contractors

bribe supervision departments, supervision departments accept bribery, and, to reduce the punishment amount, they then bribe project management, the project management department accepts bribes, and the owner has the loss of X4+S-X6-X3. X6<X4, so X6+X3-X4-S<X3-S. That is, with the layers of principal-agent increasing, the agent costs of the owner increased X4-X6. When the contractors, supervision departments, and project management departments have collusive behaviors at the same time, the project will have the risk of loss of S. With layers of principal-agent increased, the uncertainty of project income would continue to increase, which is mainly embodied in the risk losses and risk probability (Linchang 2007).

According to the above game analysis, it can be drawn that, with principal-agent layers between owner and supervision units increasing, the probability of the supervision departments' speculative behavior will be great. That is, the damage caused by the contractors' collusion is quite possible. Therefore, this article advocates a project management pattern in which the owner directly commissions the supervision unit as well as increases the punishment, which could be achieved through improved management of the current supervision system.

Game analysis between owners and contractors. To allow the project to be completed ahead of schedule, the owner could award the contractor for early completion. To receive these rewards, the contractor can speed up their own work or adopt jerry-building to shorten project completion time. At the same time, the contractor would like to receive progress payments as soon as possible to reduce advance funds. The owner in capital-limited circumstances, in order to allow multiple projects to proceed smoothly, will try to reduce cost payments. Under conditions of asymmetric information between the two sides in the game, in such a game it is very difficult to achieve a balance of interests.

To resolve the principal-agent disposable game Nash equilibrium problem, vulgar theorem is introduced in the game theory. Based on vulgar theorem, the multi-project organization pattern can choose a two-way principal-agent relationship to form closed circulation, which will achieve infinite repeated game. Repeated game allows both sides to know each other's information to a greater extent, makes more private information become public information for both sides of game, and makes the "eye for an eye" type of retaliation achievable (Zhang 2008).

A two-way principal-agent relationship can be set up between owner and the contractor. After repeated game, both sides will make trade-offs between their short-term benefits and the overall interests of the organization.

Game analysis between owner and project management department. In multi-project management, the owner will entrust projects to project management agencies separately. To achieve the greatest project interest, the project management organization will stand in the perspective of a single item to choose its own behavior. This will cause a difference between the "individual action" of the project organization and the "collective action" of the owner.

Maximizing individual benefit, which is pursued by the project organization, will hamper the strategic goals of the project center to maximize the collective benefits. Contradictions and conflicts between both sides lie in the authority of the owners, the development of incentives, and the reward and punishment mechanisms. Therefore, we can see the relationship between the owner and the project management agency as a commissioned agent relationship. As the client, the owner is responsible for overseeing the agent, supervising the project management organization, and implementing the reward and punishment systems for project management agencies. Every project management organization takes action according to the combination of the project management body of the project and the owners' action. Through analysis on the dual principal-agent pattern, we can see that setting up the double principal-agent relationship between the owner and project management organization can achieve balance after repeated game.

MULTI-PROJECT MANAGEMENT PATTERN WITH THE OWNERS AT THE CORE POSITION BASED ON GAME ANALYSIS

In multi-projects system, the owners are in the core position and coordinate the various participants in overall scheduling. Based on game analysis of the relationship between the project participants, every participant in the projects should be incorporated into the management system to reduce the participants' speculation from the regime. Project management patterns take direct commission as the major style, which can effectively reduce the speculation of the supervision department. For the participants, it will bring the collection into the multi-project management system and set up a double-layer principal-agent project management pattern. In a long-term game, it will eliminate participants who are adverse, introduce new participants, and implement dynamic management.

ADJUST THE ORGANIZATIONAL STRUCTURE OF THE OWNER UNDER NEW MULTI-PROJECT MANAGEMENT PATTERN

In an existing organization, the basic individual projects are at the core, which cannot raise good project management to a multi-project system. With owners of multi-project management, there are a variety of internal and external conflicts of interest.

In the new organizational structure (see Figure 4), increasing the project management center, which is the center of the deployment of resources, will assist the decision-making nerve, achieve coordination of the relationship of the project participation side, organize the internal coordination of various projects, assist in decision-making, increase the group flow of department in the vertical. Pre-planning ministers manage the design departments set, total workers manage the supervision departments set, project engineering ministers manage the contractor set, and materials ministers manage the suppliers set.

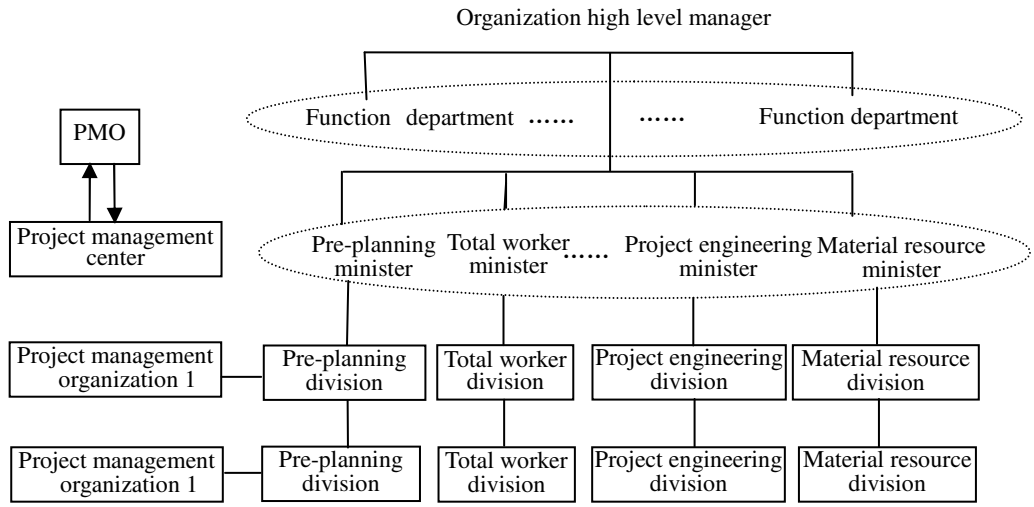

Figure 4. New owner project management organization model.

Increasing this layer changes the previous occlusion information between functional departments and can reduce communication difficulties. These ministers of the flow departments will send professionals to assume the corresponding professional work. The professionals will be commanded and coordinated by the leadership of project management body and can directly report to it. Department managers no longer intervene in the specific aspects of project management and pay more attention to the employment, promotion, career development and learning, and training of department employees and are responsible for the assessment of the staff's professional skills. The project management center coordinates a number of projects, which is a strong decision-making control area, sets a clear separation of powers, authorizes the leadership, and supervises and controls the project management body. According to the information about each project, they determine the input of all project resources and punishments.

The highest decision-making level in the organization setup is the office of project leaders, who are the highest decision-makers on multi-projects and are responsible for the multi-projects, long-term strategic decision-making, and the formation of objectives. The responsible person in the command center manages multi-projects to ensure that the strategic objectives are consistent the highest goals of organization.

CONCLUSION

This article recommends a project-centered multi-project management pattern with the owners and management at the core. The internal organizational structure of the traditional owners should be adjusted to achieve more effective multi-project management. This will improve the overall efficiency of the owner, reduce management costs, and ultimately achieve the strategic objectives of organizations.

ABSTRACT

Along with the growth of the National Economy and intensive readjustment of industrial structure, the road logistics demands are increasing quickly in quality and quantity. Oppositely, the scattered, weak and disorderly structure adversely affects the healthy development of the road logistics. It is essential to study the logistics service mode suitable for the increasing demands of the road logistics. The paper analyzes the common characteristics between the road logistics individual and the ant colony. Then, by the ant colony intelligence, the dynamic alliance of road logistics is presented, the construction algorithm and the application method are given too. The paper provides a better operable development mode for the road logistics in China, which has a direct impact on improving logistics efficiency for the construction of a harmonious society.

1 INTRODUCTION

Benefited from the quick development of macro economy in recent years, the demands of logistics in China are increasing quickly in quality and quantity. The road logistics is a main mode, which undertakes the majority in volume. However, influenced by the traditional economy thought of 'emphasized production, despised circulation' in China, logistics in China started late and developed slowly, characterized by small-scale, which limits the logistics development seriously (Ding, 2008). Thus, it is very necessary to study the logistics service mode suitable for the increasing demands of the logistics.

At present, there are various problems in the road logistics in China, including low efficiency, poor quality, lack of information and manpower etc. For the logistics individual, there are various modes, including the large-size enterprise, medium-size enterprise, small-size enterprise, self-employed individuals and part-time individuals. Among these individuals, there are great differences in operation, management, specialty, lacking organization and platform. In particular, there are few road logistics enterprises that can operate most types of logistics. In fact, many logistics individuals are competing repeatedly in low efficiency, low-level market.

For the rapid development of the logistics market and to solve the problems

of the logistics individual, it is essential to integrate the road logistics service. The integration targets include enterprises, material suppliers, primary product collectors, and packing, transportation, warehousing, and marketing, product planning, and information service. However, there are a lot of unresolved problems in operation management and benefit distribution, making the integration on entity difficult. And it is impossible for long-term stable organization to exist, since there is many differences between the individuals in domain, manpower, ability and idea etc. Thus, the dynamic logistic organization has more advantages. Researches about logistics integration are mainly on industry logistics (Dai, 2001), and few are on road logistics.

The paper reveals that the road logistics individuals have the characteristic similar to the intelligent individual. By ant colony, the dynamic alliance of road logistics is presented, the forming algorithm and the management of the alliance member are analyzed. Then, the process to create, run, dissolve the road logistics dynamic alliance is discussed.

2 ANT COLONY ALGORITHM AND ROAD LOGISTICS ALLIANCE

Road logistics individuals, with a familiar cognition with itself, can make one or some logistics operation, which is viewed as an individual with some level of intelligence. By ant colony, some road logistics may build up a dynamic alliance according to the coming logistic job.

2.1 Intelligence individual and road logistics individual

The intelligence mainly appears as some form as software or hardware of computer. Yet, they all have some common features, such as highly adaptability and autonomy. Shoham (1993) regards that an entity is intelligence individual if its state includes the psychosis, such as knowledge, idea, promise, ability etc.

An individual who implements some operation of logistics, as an independent entity with knowledge, idea, ability and social duty, can be looked as an intelligence individual. Then, the road logistics individual, as an intelligence individual, has the common features: autonomy, social ability, flexibility, mobility, reaction, consciousness. This is the foundation for making the Ant Colony Algorithm alliance operation.

In general, ant colony shows the characteristic that the entity without intelligence behaves intelligently. Ant colony algorithm provides an approach to solve the distributed problem without centralized control and global model. By applying ant colony, some algorithm has the characteristic of intelligence. Through the interaction between the individual and environment, the algorithm has some self-organization function, robustly and visually. And, the theory of multi individual system is from distributed artificial intelligence, which has been widely adopted in many domains. Multi individual system mainly studies the corresponded intelligence

action of the multi individual separated in logic or physics, and at last solves the problem.

The ant colony algorithm in the paper based on multi individual, not only exerts the initiative and independence of the individual, but also makes the colony to have additional function than the simply combined members have and to present more intelligence function than normal intelligence individual does.

2.2 Road logistics dynamic alliance

Under the well cooperation mechanism and fellowship, road logistics individuals connect and cooperate in related logistics work, and they can build up logistics alliance. In fact, the logistics alliance is an integration platform based on information (Gunasekaran, 2004). The road logistics alliance includes the function like a real logistics enterprise and can implement the same operation, such as warehousing, transportation, packing etc.

In the environment of road logistics integration, the relation between the individuals is the cooperative partnership based on credit and cooperation. Like the traditional integration mode, the fixed logistics alliance has many disadvantages, such as the low adaptability for operation etc. Therefore the alliance needs to form and dissolve frequently to adapt to the logistics demands, which will waste more manpower and resource, increase the cost, reduce the efficiency, and affect the partnership between the individuals.

By the multi individual swarm intelligence, the paper abstracts the fellowship in the forming of the alliance, then build up the road logistics dynamic alliance adapted to the logistics need. Based on the dynamic alliance mechanism, every member understands the participant logistics operation deeply. Then, in cooperation, the members can implement the logistics work that cannot be done by a single member. The dynamic organization is more responsive to the market, can exert more superiority and scale merit compared to a large enterprise.

3 THE MECHANISM OF THE ROAD LOGISTICS DYNAMIC ALLIANCE

The road logistics dynamic alliance is highly active, can be created for the logistics task and disjointed as the task end in a timely manner. Firstly, the system is driven by the upcoming logistics task; the task is then analyzed and decomposed. According to the sub task, the first generation combination of the logistics individual is generated randomly. Each sub task can include one or several logistics individuals. Then, each selected individual can select group cooperation with good fellowship. Repeating the process until the combination is stable. That will be the last generation combination that the task needs.

3.1 Road logistics individuals database management

Based on the understanding of the logistics need, the road logistics individual member database is formed. The database keeps the information of the logistics

member, including operation service area, operation type, enterprise scale, facility, cooperator, operation comprehensive evaluation etc. The system formats the candidate logistics individual and adds it into the database. The system can also maintain and make other operation to the member. Logistics individual member database and its management areshown in figure 1. There, the operation service range includes: the pre-logistics of agriculture products, primary gathering, primary processing, and warehousing, packing, transportation, distributing and information service. There are two types of basic individual, one is the entity logistics enterprise, which is the same as in the real world; the other is the virtual logistics enterprise, which may be a department of a logistics enterprise, or a virtual enterprise combined with certain approach. Some large road logistics enterprise can be added into the database as an enterprise, or be decomposed as several virtual logistics operation and then added into the database. Apparently, these virtual logistics enterprise decomposed from a large enterprise have closer relationship and may select each other for cooperation. However, in other environment, for efficiency and some other reason, some integrated enterprise will select other fellows to complete a logistics work though it may have sub enterprise for that work.

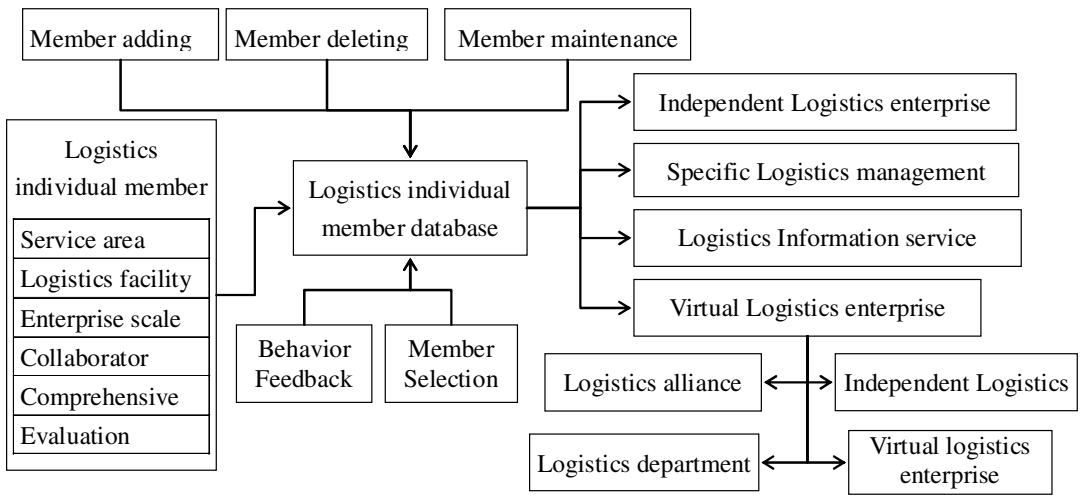

Figure 1. Road logistics individual member management in dynamic alliance

3.2 The Algorithm of road logistics dynamic alliance

For a given logistics task, a multi-dimensional index space with multi order is formed, including the operation, time, place, and service estimate of the logistics task. The same type of intelligence individuals are placed in the multi-dimensional space randomly, where each intelligence individual is assigned to a logistics sub task. The intelligence individuals are moving in the space and evaluated (Himoff, 2004). At last, they are integrated by the multi-dimensional indexes.

Assume that the logistics member data set is $X=\{X_i=(x_{i1}, x_{i2}, \ldots,x_{im}), i=1,2,\ldots,N\}$, is a set including N road logistics enterprise members. For a logistics

intelligence individual xi, x_{i1}, x_{i2}, …, x_{im} are the performance index. The step is as follows:

(1) The logistics task from the management system is analyzed and decomposed. Then, by the task source, select the initial point (member). The selection condition can be the latest distance in space or time.

(2) Initialization. Set the parameters, including the cluster ratio r, cluster error ε and basic probability p_0.

(3) Calculate the Euclidean distances $d_{ij}(X_i, X_j)$

$$d_{ij} = \left\| P(X_i - X_j) \right\| = \sqrt{\sum_{k=1}^{m} p_k (x_{ik} - x_{jk})^2}$$

(4) Calculate the probability, $p_{ij} = t_{ij}^{\alpha} \eta_{ij}^{\beta} / \sum_{s \in S} t_{ij}^{\alpha} \eta_{ij}^{\beta}$

Where, if $d_{ij} > r$, $t_{ij} = 0$, if $d_{ij} \le r$, $t_{ij} = 1$.

(5) If p_{ij} is greater than p_0, X_i and X_j are clustered together.

(6) Return to step 5, until all logistics members are calculated and clustered. Then calculate the total error ε.

(7) If ε is smaller than ε_0, go to the next step; otherwise go to step 1, and select the initial point and Initialization again.

(8) Assign the task to the real enterprise and implement it.

(9) After the task, by the performance of the member in this task, adjust the estimate of the logistics individual member and give feedback in the database.

4 THE IMPLEMENT OF THE ROAD LOGISTICS DYNAMIC ALLIANCE

Road logistics dynamic alliance, centered around the cooperative relation selection algorithm based on the multi individual swarm, driven by logistics task, sustained by logistics individual database management system, implementing the integration of the road logistics (Yao, 2008). The main structure is shown in figure 2.

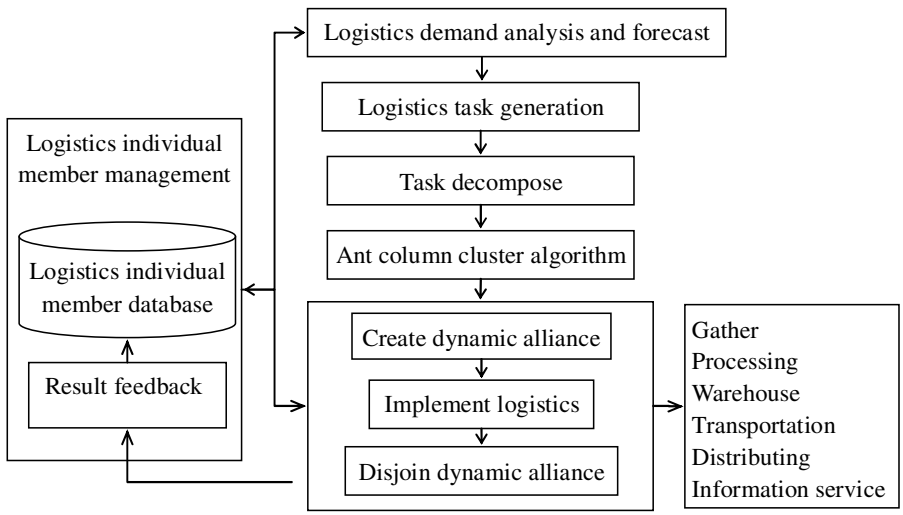

Figure 2. The implement of the road logistics dynamic alliance

The operation of the agriculture products dynamic alliance includes the creating, running and disjointing the alliance. Each member implements one logistics operation, and with the cooperation completes the logistics task in the end. During implementation, the management system and information platform provide the connection for the logistics individuals (Zhao, 2008). There, each member logistics individual can accept task, query the logistics individual database in the information platform, run the algorithm, form the dynamic alliance and execute it.

CONCLUSION

There is serious disharmony between the quickly increasing demands of road logistics and the undeveloped service. Road logistics dynamic alliance provided a suitable mode for road logistics. The paper presents a member cooperative selection algorithm based on ant colony. By using this algorithm, logistics individuals can be dynamically organized together. On one hand, this method can exert the advantage and improve the efficiency of the member; on the other hand, the service ability and quality can be improved. Based on the algorithm, the paper studies the creating, running, disjoining of the road logistics dynamic alliance. The test selects 12 logistics enterprises, including 3 professional road logistics enterprise, 7 traditional road transportation enterprises and 2 part-time logistics individual. For 6 logistics task given, the logistics dynamic alliance generated by the method presented in this paper shows better result than the general selection by the experts.

At last, in application, there are many questions needed further consideration and study, including the operation legislation, member management, credit management, profit assignment and performance evaluation.

ABSTRACT

To pursue the greatest time benefit and the least cost in emergency logistics, an improved emergency logistics system is designed and an operation process in emergency logistics system is proposed by comparing the differences between emergency logistics and common commercial logistics. A multi-material dispatching model is constructed, based on the double objective of the earliest emergency start time and the least cost of emergency logistics. The optimal solution for the model is obtained by an adaptive genetic algorithm (AGA), which has proven to be an effective algorithm. An application example simulated by MATLAB is presented, which shows that AGA has better optimizing resistance than GA; thus, the emergency material dispatching model can be effectively used in the emergency logistics field.

Key words: Emergency logistics; material dispatching; adaptive genetic algorithm (AGA)

PREFACE

China is a country, in which natural disasters occur frequently, and previous earthquakes, floods, etc., have caused tremendous loss, e.g., building damage, personnel casualties, and so on. Massive disaster relief equipment and materials cannot be supplied and distributed in a timely manner due to traffic impediments caused by the disaster. The process of time effects and space effects in logistics is difficult to realize in disaster relief. To minimize losses created by the disaster and to operate the emergency logistics system, there is an urgent need to optimize the dispatching scheme of emergency materials.

In recent years, many domestic and foreign scholars have conducted research on emergency material dispatch problems under different constraints. Hale and Moberg (2005) mainly studied the choice of emergency logistics supply nodes, especially according to the emergency material storage of the nodes, and established a quantitative model. Chunlin et al. (2001) discussed the urgent material dispatch problem under the material demand constraints at several rescue points. This paper, based on the status of China's emergency logistics system construction, presents the design for an improved emergency logistics system and solves the emergency material dispatching problem and selects the appropriate emergency points between them and the transportation line.

ANALYSIS OF EMERGENCY LOGISTICS CHARACTERISTICS

Emergency logistics is a specialized logistics activity for the purpose of providing emergency materials for natural disasters, public health incidents, emergencies, etc., and the pursuit of maximizing time efficiency and minimizing losses in disasters.

Emergency logistics, like common commercial logistics, have space effects, time effects, and form quality effects. However, emergency logistics also has characteristics that are different from common commercial logistics, including paroxysm, uncertainty, emergency of time constraints, and weak economic factors. This study conducted a comparative analysis between emergency logistics and common commercial logistics at the points of purpose, logistics distribution network, and the external environment. The specific content is shown in Table 1.

Table 1. Differences between Emergency Logistics and Common Commercial Logistics.

Sort	Common Commercial Logistics	Emergency Logistics
Purpose	Minimize costs or maximize profits	Primary purpose is to minimize delay time for satisfying demand; secondary purpose is to minimize costs
Logistics Distribution Network	**Characteristics of facility**: permanent **Network structure**: designed distribution nodes and function of network based on demand **Participation role**: various types of economic entities closely linked, such as manufacturers, distributors, transportation companies, etc.	**Characteristics of facility**: temporary **Network structure**: structure and function are simplified **Participation role:** institutions or organizations that are not closely linked such as relevant government departments, various donors, as well as the provisional established
External Environment	Full information, difficult to change	Information missing, easy to change

EMERGENCY LOGISTICS SYSTEM AND OPERATION PROCESS

The rapid and accurate flow of information relies on advanced communications and information transfer mechanisms; the efficient and orderly flow of work relies on sound and rigorous protection mechanisms and related rules and regulations. Quick and timely logistics must rely on the coordinated operation of the procurement of supplies, reserves, transport, and logistics centers. Based on these requirements, emergency logistics systems are made up of an emergency logistics command platform, an emergency logistics information platform, an emergency logistics warehouse platform, emergency logistics transport and distribution platforms, and an emergency logistics policy platform.

When major emergencies occur, the command platform promptly initiates the corresponding level of response in accordance with the type and level of incidents, publishes timely and authoritative information related to the disaster to the public, assesses the type and quantity of materials that disaster-stricken masses

require, organizes rescue materials and issues to the unit the mission, objectives, and requirements and a clear division of responsibilities and specified time node. Adjustments must be flexible according to the actual situation by continuously tracking supervision on the implementation of the operation and timely feedback and information collection. The executive departments organize capable forces and take effective measures to ensure the smooth implementation of emergency logistics of the mission. The information platform conducts real-time tracking of the delivery of materials and timely information collection about changes related to the disaster to make a new materials distribution program. The process is shown in Figure 1.

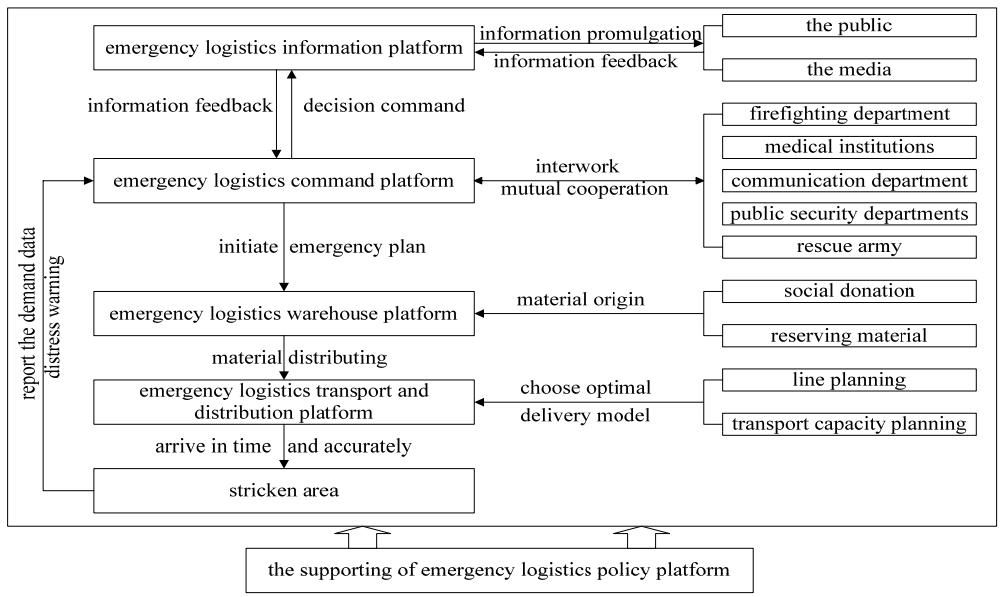

Figure 1. Operation process of emergency logistics.

MULTIPLE EMERGENCY MATERIAL DISPATCHING MODEL

The emergency material arriving at demand points for the first time is important to the successful operation of an emergency logistics system. Emergency logistics seeks the greatest time benefit and realizes the space effects of rescue materials in the shortest delay time, satisfying the rescue materials demand for sudden events disposal. However, China is a developing country, and the capital invested in disaster prevention and rescue is limited. In addition, natural disasters and accidents occur frequently, so it is necessary to spend the limited funds on the most needed aspects of the system. Therefore, this paper considers two goals: how to make the emergency start time the earliest and how to make the emergency cost the least.

Suppose there is an emergency point A at a sudden event, which needs a number of emergency materials $m(m>1)$. The demand of emergency material j is $x_j > 0(j=1,2,\cdots,m)$. There exist $n(n>1)$ emergency rescue points that can provide sufficient emergency materials to A (denoted by $A_1, A_2, \cdots, A_n$), and rescue point i can provide $x_{ij} > 0(i=1,2,\cdots,n; j=1,2,\cdots,m)$ emergency material j ,which x_{ij} satisfies to $\sum_{i=1}^{n} x_{ij} \geq x_j, (j=1,2,\cdots,m)$. The time of the

emergency material from rescue point A_i to emergency point A is $t_i > 0(i = 1,2,\cdots,n)$, and $t_1 < t_2 < \cdots < t_n$. The function $f_j(t)$ is the consumption of material j at the time t.

Because of traffic slowdowns caused by the disaster, transport line planning must adapt to the actual situation after the disaster. This paper considers vehicle travel cost and the cost caused by changing the transport mode; therefore, some parameters display as

CT^r - the transportation cost of the unit section of unit material of transport mode r

$CE_g^{jrr'}$ - the transport mode change cost of unit material j at point g, changing transport mode from r to r'

d_{ef} - the distance from point e to point f

X_{ef}^j - the flow of material j on a radial truck arc (e, f)

$X_g^{jrr'}$ - the flow of material j at point g, changing transport mode from r to r'

$ACAP_{ef}^r$ - the road capacity of transport mode r on a radial truck arc (e, f)

R - the set of transport mode

EF - the set of intermediate transit points

J - the set of materials

For each kind of material j exists various feasible emergency dispatching schemes; that is, for each scheme at any time t arrived material no less than material demand taking t_{sj} as the emergency start time till t. Each scheme corresponds to an earliest emergency time t'_{sj}, and all earliest emergency start times form the set C'_{s_j}. Then the earliest emergency time of emergency material j is $t_{Sj} = \min_{C'sj}(S'_j)$. For one of the emergency material j dispatching schemes $F_j^p = \{(A_1, y_j^1), (A_2, y_j^2), \cdots, (A_p, y_j^p)\}$, $A_i(i = 1,2,\cdots,p)$ is the material supply point, $y_j^i(i = 1,2,\cdots,p)$ is the material quantity of the material supply point i. Then the earliest emergency time of this dispatching scheme is $t_{S_j^p} = \max[t_j^i - t_j^k] \quad i \in \{1,2,\cdots,p\}$, in which t_j^i is the required time of transporting material j from material supply point i to emergency service point. t_j^k is the duration of transport time for material j that has reached emergency point. Its value can be obtained from the type $\sum_{i=1}^{n} x_{ij}^{t_j^k} = \int_0^{t_j^k} [f_j(t)]dt$. ($\sum_{i=1}^{n} x_{ij}^{t_j^k}$ is the emergency material quantity before the time t_j^k arrives at the emergency service point, and $\int_0^{t_j^k} [f_j(t)]dt$ is the material consumption disposing sudden event at the time t_j^k).

In the above analysis, the emergency material dispatching model of the non-uniform speed material continuous consumption with multi-objectives and multi-resources is established and given as follows:

$$\min(\omega_1 \cdot f_1 + \omega_2 \cdot f_2)$$
$$f_1 = \min_{C_{S_j} \neq \phi} S_j \tag{1}$$
$$f_2 = \min \sum_{r \in R} \sum_{e \in EF} \sum_{f \in EF} CT^r \times d_{ef} \times X_{ef}^r + \sum_{j \in J} \sum_{g \in EF} \sum_{r \in R} \sum_{r' \in R} CE_g^{jrr'} \times X_g^{jrr'}$$
$$S.T. \begin{cases} \sum_{i=1}^{n} x_{ij} \geq \int_0^{t_j} f_j(t)dt \\ \sum_{e \in EF} X_{ef}^r = \sum_{r' \in R} X_g^{jrr'} + \sum_{e' \in EF} X_{fe'}^r \\ 0 \leq X_{ef}^r \leq ACAP_{ef}^r \\ X_g^{jrr'} \geq 0 \\ \omega_1 + \omega_2 = 1, \omega_1, \omega_2 \in [0,1] \\ i = 1,2,\cdots,n;\ j = 1,2,\cdots,m \end{cases}$$

OPTIMIZATION SOLUTION TO MODEL BASED ON ADAPTIVE GENETIC ALGORITHM

Since the 1980s, the genetic algorithm, the solution to complex combination optimization problems having general adaptability, has undergone rapid development and is widely used; however, the optimization of the genetic algorithm is easy to fall into local peak, i.e. convergence occurring before mature, but adaptive genetic algorithm's crossover and mutation rates (denoted by p_c and p_m) can adaptively adjust in accordance with the fitness value. When the fitness value of individual in the population tends to be uniform or tends to stick on local optimum, increasing p_c and p_m can help jump out local optimal solution. Nevertheless, when the population fitness value is quite dispersible, decreasing p_c and p_m is benefit for the fine individual survival. Therefore, adaptive crossover and mutation rates can provide the best crossover and mutation rates that relate to some solutions. AGA not only maintains population diversity but also guarantees its convergence. The adaptive parameter formula is as follows:

$$p_c = \begin{cases} p_{c1}, & f < f_{avg} \\ p_{c1} - \dfrac{(p_{c1} - p_{c2})(f' - f_{avg})}{f_{\max} - f_{avg}}, & f \geq f_{avg} \end{cases} \tag{2}$$

$$p_m = \begin{cases} p_{m1}, & f' < f_{avg} \\ p_{m1} - \dfrac{(p_{m1} - p_{m2})(f' - f_{avg})}{f_{\max} - f_{avg}}, & f' \geq f_{avg} \end{cases} \tag{3}$$

Where f_{avg} and $f_{\max}$ are the average fitness value and the maximal fitness value of the population, respectively. f' is the larger of the fitness values of two individuals to be crossed, and f is the fitness value of the individual to be mutated. p_{c1} and p_{c2} are the maximum and minimum crossover rates, respectively, and p_{m1} and p_{m2} are the maximum and minimum mutation rates, respectively.

Based on the above model, the ideal solution L^*_{1j} and L^*_{2j} under the two optimization objectives of the earliest emergency time and the least emergency

cost can be regarded as a special case when weights are $\omega_1 = 1$ and $\omega_2 = 1$. Aiming at any weight ω_1 and ω_2, this paper uses an adaptive genetic algorithm to solve the problem, the concrete steps of AGA is as follows:

Step 1: Initialize the population.
Step 2: Calculate the fitness values
including individual fitness values and average fitness values of the population.
Step 3: Compute the crossover and
mutation rates according to formulas (2) and (3).
Step 4: Execute genetic operations
including selection, crossover and mutation.
Step 5: When the current generation is less than the maximal generation, return to Step 2. otherwise, terminate the program and return to the optimal solutions.

The process is shown in Figure 2.

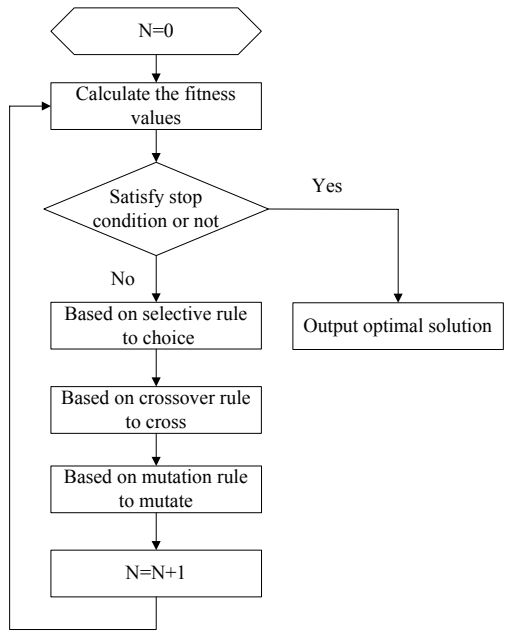

Figure 2. Flow chart of AGA.

ANALYSIS OF EXAMPLE

Suppose at point A a sudden event occurred that required two emergency materials. The numbers of material quantity are X_1 =200 and X_2 =120. Six material supply points exist, $A_1, A_2, \cdots, A_6$. The material quantity of the six material supply points and the arrival time at the emergency service point are shown in Table 2. Suppose the material demand curves are $f_1(t) = -t^2 + 10t$ and $f_2(t) = -t^2 + 4t$, respectively.

Table 2. Supply of Sites and Reach Time from Sites to Facility A.

Supply point	A_1	A_2	A_3	A_4	A_5	A_6
t_i (hour)	2	3	4	11	12	14
x_1	40	30	30	120	60	110
x_2	20	80	20	40	40	160

Assume two transport modes (I and II) can be used after the event. Figure 3 shows the transport line topological graphs. There are two numbers on the arc; the left is the arc's distance (unit: km) and the right is the arc's capacity. Suppose the carry rate of transport mode I is 300, the carry rate of transport mode II is 1,000, and the transformation rate is 260.

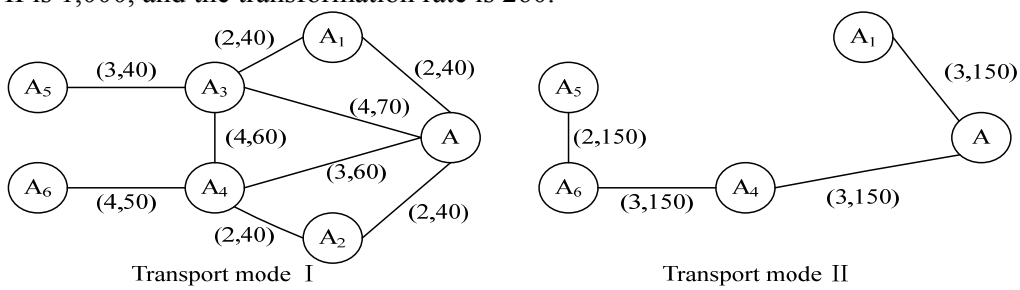

Figure 3. Transport line topological graphs.

Suppose the population size of the algorithm is 50, the maximum evolutional generation is 100. In the genetic algorithm, p_c=0.8, p_m=0.05, and in the adaptive genetic algorithm, p_{c1}=0.8, p_{c2}=0.6, p_{m1}=0.05, p_{m2}=0.005. The scheduling schemes run by MATLAB are:

$$F_1^* = \{(A_1,40),(A_2,30),(A_3,30),(A_4,60),(A_5,40)\}, \text{ and}$$

$$F_2^* = \{(A_1,20),(A_2,40),(A_3,20),(A_4,40)\}$$

The earliest emergency arrival time is 1.5 hours after the sudden event occurred. The relationship of the optimal individual fitness degree and the evolutional generation are shown in Figure 4 and Figure 5.

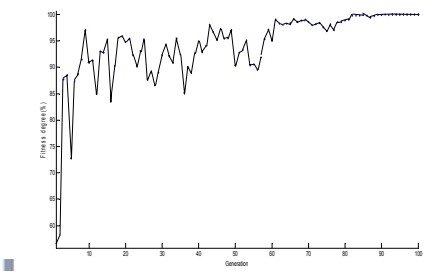

Figure 4. The result of GA.

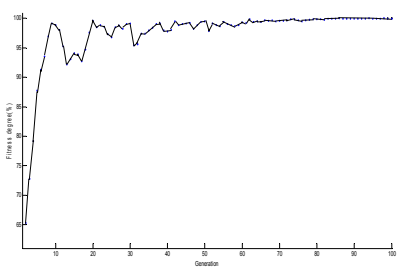

Figure 5. The result of AGA.

Comparing the above figures, the adaptive genetic algorithm has a faster convergence speed and better optimizing resistance than the genetic algorithm; thus, it proves the robustness and effectiveness of AGA, so AGA is effective for the optional solution of the model.

CONCLUSIONS

By the analysis of the adaptive genetic algorithm to the solution of model, we can obtain the optimal transportation route and optimize resource distribution. Applying the model to a practical situation realizes the process of time effects and space effects in emergency logistics and can save manpower, material resources, and financial resources. In this paper, an emergency material dispatch model is constructed under several constraint conditions, but in practicality, many constraint conditions affect emergency material dispatch, so the emergency material dispatch model should be further researched.

ABSTRACT

The vehicle routing problem with soft time windows is studied in this paper. Multiple types of vehicles with different capacities are considered. A mixed-integer programming model subject to capacity and soft time windows constraints is formulated. An algorithm based on tabu search technique is designed to solve the developed model. Initial solution is generated by improved insertion heuristics. Finally, the developed model and algorithm are successfully tested with the help of a numerical example.

INTRODUCTION

Logistics is the process of freight transport activities that considers the social, environment, economic, financial and energy impacts of freight movement. Logistics can facilitate the implementation of cooperative freight transportation and meet various needs in supply chain management systems. The planning and design of vehicle route and service order is very important to the logistics operation process. The Vehicle Routing Problem (VRP) was proposed by Dantzig and Ramser (1959). The classical VRP involves the design of the best set of routes for a fleet of delivery vehicles based at one depot or several depots to distribute goods to a number of customers geographically dispersed, while minimizing the total travel distance or distribution cost.

In the past years, many mathematical models and algorithms have been proposed to the VRP. Solmon (1987) proposed an algorithm for the vehicle routing and scheduling problem with time windows constraints. Balakrishnan (1993) presented a simple heuristics for the VRP with soft time windows. Gendreau and Laporte (1996) proposed a tabu search (TS) heuristic for the VRP with stochastic demand and customers. Dan and Lang (2005) presented a model of multi-vehicle distribution scheduling problem based on TS algorithm. Kara et al. (2007) studied the energy minimizing VRP.

In the previous studies, the objective of VRP research mainly focuses on the total travel distance or distribution cost. However, the real cost of a vehicle traveling between two nodes also depends on the load of the vehicle. Therefore, it is more reasonable to minimize the product of the travel distance and the vehicle load. In

this paper, we proposed a new model for multi-types VRP with soft time windows to minimize the total cost, where the transportation cost is computed as the product of the travel cost per ton per kilometer, the distance traveled and the vehicle load. If the model only considers the distance as the objective, it cannot ensure which customer is served first by the vehicle in a given route. But with our model, it is ensured that the vehicle serves the nearest customer and customers with lager demand first. A TS algorithm is designed to solve the proposed model. We adopt insertion heuristics to construct the initial solution, and three different strategies to generate the neighborhood solutions.

The remaining sections of the paper are organized as follows. In Section 2, we describe the model of the multi-types VRP with soft time windows. The TS solution algorithm is presented in Section 3. And in Section 4, a numerical example is conducted to test the algorithm. Finally, we conclude the paper and outline the potential for future research in related areas.

FORMULATION

Let $G=(N,A)$ denote a network, where $N=\{0,1,\cdots,n\}$ is a set of nodes with 0 denoting the central depot and the remaining nodes representing customers, and $A=\{(i,j)\mid i,j\in N, i\neq j\}$ is a set of arcs. There is a fleet of vehicles $K=\{1,2,\cdots,m\}$ to deliver goods, and Q_k is the capacity of vehicle k. Each customer i has a demand q_i and a time window $[e_i,l_i]$, and requires a service time s_i. For the central depot, $q_0=0$ and $s_0=0$. Let C_f denote the fixed cost of dispatching a vehicle from the depot, d_{ij} the distance between customers i and j, and C_v the vehicle travel cost per ton per kilometer. We then define $C_{ij}=C_v d_{ij}$, which is the vehicle travel cost per ton along arc (i,j).

Let T_i^k be the time vehicle k arrived at customer i, T_0^k the departure time of vehicle k from the central depot, v_{ij}^k and T_{ij}^k the travel speed and travel time of vehicle k from customer i to customer j respectively. If a vehicle k does not arrive at a customer i within its time window, there will be an associated penalty cost denoted as PT_i^k, with p_e and p_l as the corresponding unit time penalty with respect to early and late arrivals respectively. We assume $0<p_e<p_l$.

Decision variable x_{ij}^k takes the value 1 if vehicle k travels directly from customer i to customer j, and 0 otherwise. Decision variable y_{ij}^k, called flow, represents the actually load of vehicle k if vehicle k travels from customer i to customer j, and 0 otherwise.

We can now state the model as follows.

$$Min \quad Z = \sum_{i=1}^{n}\sum_{k=1}^{m} C_f x_{0i}^k + \sum_{i=0}^{n}\sum_{j=0}^{n}\sum_{k=1}^{m} C_{ij} y_{ij}^k + \sum_{i=0}^{n}\sum_{k=1}^{m} PT_i^k$$

s.t.

$$\sum_{\substack{j=0 \\ j\neq i}}^{n} y_{ij}^k - \sum_{\substack{j=0 \\ j\neq i}}^{n} y_{ji}^k = q_i \qquad i \in N \setminus \{0\}; k \in K \tag{1}$$

$$y_{ij}^k \le (Q_k - q_i) x_{ij}^k \qquad i \neq j, i, j \in N; k \in K \tag{2}$$

$$y_{ij}^k \ge q_j x_{ij}^k \qquad i \neq j, i, j \in N; k \in K \tag{3}$$

$$\sum_{i=1}^{n}\sum_{k=1}^{m} x_{ij}^k = 1 \qquad j \in N \setminus \{0\}; k \in K \tag{4}$$

$$\sum_{j=1}^{n}\sum_{k=1}^{m} x_{ij}^k = 1 \qquad i \in N \setminus \{0\}; k \in K \tag{5}$$

$$\sum_{j=1}^{n} x_{0j}^k = 1 \qquad k \in K \tag{6}$$

$$\sum_{\substack{i=0 \\ i\neq h}}^{n} x_{ih}^k - \sum_{\substack{j=0 \\ j\neq h}}^{n} x_{hj}^k = 0 \qquad h \in N \setminus \{0\}; k \in K \tag{7}$$

$$\sum_{i=1}^{n} x_{i0}^k = 1 \qquad k \in K \tag{8}$$

$$T_{ij}^k = d_{ij} \big/ v_{ij}^k \qquad i, j \in N; k \in K \tag{9}$$

$$T_j^k = T_i^k + T_{ij}^k + s_i \qquad i, j \in N; k \in K \tag{10}$$

$$PT_i^k = \max\{p_e(e_i - T_i^k), 0, p_l(T_i^k - l_i)\} \tag{11}$$

$$x_{ij}^k = 0,1 \qquad i, j \in N; k \in K \tag{12}$$

In the above formulation, the objective function is composed of fixed dispatching cost, total travel cost and penalty cost. Constraint (1) is the flow conservation equation balancing inflow and outflow of each node, which also prohibits any illegal subtours. Constraint (2) ensures the capacity restriction, and that y_{ij}^k takes 0 if the arc (i, j) is not on the route of any vehicle. Constraint (3) is the lower bound for the arc flow. Constraint (4) ensures that each customer is served by one and only one vehicle. Constraint (5) ensures that after serving customer *i*, one and only one vehicle leaves. Constraints (6) – (8) ensure that all vehicles will leave and return to the central depot. Constraints (9) – (11) compute the penalty cost associated with early or late arrivals. Constraint (12) defines that decision variable x_{ij}^k is a binary variable.

SOLUTION ALGORITHM

Considered the characteristics of multi-types vehicles, the solution is a combination of the sequence of customers served by a vehicle and the corresponding loads at each customer node.

Initial solution. The calculation formula of the maximum and minimum

numbers of the vehicles needed is as follows:

$$\min_v = \left\lfloor \frac{\sum_{i=1}^{n} q_i}{\max_{1\le k\le m}\{Q_k\}} \right\rfloor + 1, \quad \max_v = \left\lfloor \frac{\sum_{i=1}^{n} q_i}{\min_{1\le k\le m}\{Q_k\}} \right\rfloor + 1$$

An integer as the initial number of vehicles is randomly selected from the interval $[\min_v, \max_v]$. We employ insertion heuristics to construct the initial solution. The feasibility of inserting customer j between $i-1$ and i can be checked by $q_i \le Q_k - q_r^k$ (q_r^k denote the sum of the delivery quantities currently assigned to the route of vehicle k). We add a vehicle to carry the rest goods if the delivery cannot be accomplished by those selected vehicles.

Neighborhood structure. We generate neighborhood solutions using three operations, namely the interchanging, the exchanging and the inserting operations.

In interchanging operation, we switch the orders of two randomly selected customers in a given route. For example, supposed we have a route 0-1-3-5-2-0, and the two elements of random selection are 1 and 2, the new route after the interchanging operation is then 0-2-3-5-1-0.

In exchanging operation, we randomly select one customer each from two different routes, and switch their positions. For example, suppose we select customer 3 from route 1, 0-1-3-5-2-0, and customer 4 from route 2, 0-6-7-4-0. The new routes after exchanging operation are 0-1-4-5-2-0 and 0-6-7-3-0.

In inserting operation, we remove a segment in one route and insert it into another route. Supposed the elements of random selection are as above, we then move nodes 1, 3 from route 1 to route 2. The new routes are denoted by 0-5-2-0 and 0-6-7-1-3-4-0.

Short memory and related parameters. A number of neighbor solutions of the current solution are generated as candidate solutions. The tabu list is composed of three parts: the type of the strategy, the tabu nodes and the mark (0 or 1) that represents whether the tabu solution is improved or not. The algorithm maintains two types of tabu lists: the local and the global tabu list. Local tabu lists record the tabu nodes generated by the three different strategies respectively, And the global tabu list records the common tabu nodes. The size of the tabu list is fixed. The aspiration level is based on the rule of search directions. The algorithm will stop if the best solution remains the same in a given step. The fitness function is calculated according to the following relationship.

$$f = Z + \alpha \cdot \max\{\sum_{j=1}^{n} (y_{0j}^k - Q_k x_{0j}^k), 0\}$$

where α is a lager positive number.

NUMERICAL EXAMPLE

In our numerical example, we assume that there are 8 customers to be served, and there are two types of vehicles with capacities of 10 and 8 respectively. The travel speed of any vehicle is 50km/h. The fixed cost is 10 and the travel cost per ton per kilometer is 2. The time penalty factors are set to $p_e = 100$ and $p_l = 200$.

Table 1 further shows the demand, service time, time window, and coordinates (X, Y) of each customer.

Table 1. Demand, Service time, Time windows and Coordinates

	0	1	2	3	4	5	6	7	8
q_i	0	2	1.5	4.5	3	1.5	4	2.5	3
s_i	0	1	2	1	3	2	2.5	3	0.8
$[e_i, l_i]$	[0,24]	[1,4]	[4,6]	[1,2]	[4,7]	[3,5.5]	[2,5]	[5,8]	[1.5,4]
X	35	41	55	55	15	25	20	10	55
Y	35	17	45	20	30	30	50	43	60

In order to evaluate the effectiveness of the TS algorithm, a genetic algorithm (GA) is also proposed. The proposed algorithms are coded with MATLAB in the Windows environment. Two cases of the problem are solved, one with total distance as the objective function and the other with total cost. The purpose of the former case is to validate our model.

The computational results of both cases are presented in Table 2. Column "Pop" reports the size of the initial population used in GA. The cross probability and mutation probability are set to 0.8 and 0.05 respectively in GA. Column "N" presents the size of the tabu list in TS. We stop the TS algorithm if the objective value is not improved any more within 20 iterations. We conduct multiple runs to compare the two algorithms, and the total number or runs is reported under column "Tn". Columns "Max" and "Min" are the maximum and minimum objective values observed in the multiple runs. Column "MinD" reports the total distance of the optimal solution obtained with respect to the total cost.

Table 2. Computational Results

	Pop	N	Total Distance				Total Cost				
			Tn	Max	Min	Time(sec)	Tn	Max	Min	MinD	Time(sec)
GA	50		18	486.94	480.70	16.5	18	1591.59	1488.90	548.16	18.4
	100		18	480.70	446.46	29.2	18	1591.59	1484.29	431.87	31.0
	200		18	480.70	429.25	55.4	18	1583.99	1481.23	574.99	60.0
		3	18	457.89	429.25	5.6	18	1497.53	1474.91	429.25	4.3
TS		7	18	446.47	429.25	11.3	18	1497.53	1474.91	429.25	10.8
		9	18	434.45	429.25	15.4	18	1573.93	1474.91	429.25	14.9

The comparison indicates that TS performs better and is more efficient. GA also leads to acceptable solutions, but the search time is much longer compared to TS. TS is a good algorithm for this problem in terms of both the computation time and the quality of the solution. Although TS is more complicated to design than GA is in order to reduce the computation time, TS has a great advantage in dealing with optimization problems with complex constraints. Therefore, TS might be the best solution algorithm for VRP with soft time-window constraints.

CONCLUSION

In this paper, a model for multi-types VRP with soft time windows is proposed, where the vehicle loads are treated as decision variables. A TS algorithm

with insertion heuristics is designed. The major contributions of this paper are the incorporation of vehicle load decision variables in the model and the application of insertion heuristics in the solution algorithm. Our future research will take into account more realistic settings such as multi-costs and dynamic environment. This may lead to more valuable and practical models of VRP.

ABSTRACT

Based on requirements and short-term weather forecasting, this paper presents a model to calculate dynamic safety stock in MRP (Materials Requirements Planning). Through the setting of dynamic safety stock and advance orders, the model can lower risks in the decline of dynamic safety stock, which may be caused by delivery delay due to weather factors, making the stock better meet our needs and improving the competitiveness of enterprises.

INTRODUCTION

Factors such as market-requirement trends, season, and circle should normally be taken into account in the requirements plan of an enterprise (Hao, 2005; Ho, 2001). For some special parts, an enterprise may increase the safety stock in MRP (Materials Requirements Planning) calculation to meet the timely production in the MRP system.

In reality, safety stock is generally fixed when the supplier's plans for goods in the MRP system are generated, and the risks of decline of dynamic safety stock are ignored, which may cause delivery delay due to weather factors. Rain and fog in the summer significantly affect highway transportation in the south of China, and ice and snow in winter also cause the highway transportation cycle to be lengthened in the north. If the system uses a fixed lead time, the goods may not arrive on time.

This paper takes the highway transportation into consideration and presents a method based on short-term weather forecasting that can dynamically change safety stock and the leading pre-ordered safety stock so as to maintain parts inventory levels. This method ensures that an enterprise will better meet production needs by using leading safety stock even if weather is a factor. As demand is a rolling demand, the supply plan must also be dynamic, so even if high-safety stock is reduced in the next cycle as a result of weather forecasting in the former cycle, the dynamic safety stock would not lead to a high inventory level for long.

DIVISION OF CYCLES IN PROSPECTIVE WEATHER FORECASTING AND THE CALCULATION OF AVERAGE IMPACT FACTORS

In practice, the supply plan generated from the MRP can often be categorized as short-term, medium-term, and long-term. A specific division of time must be set in accordance with the actual situation of the enterprise (Ho, 2001). Normally, a short-term supply plan is an accurate requirements plan; the supplier must provide the goods according to accurate requirements. The medium- and long-term plans can be taken as a forecasting; the supplier must prepare for production according to the forecast. In a short-term supply plan, goods are generally supplied by the week (Xie, 2006; Yu, 2005). This is taken into account for this paper.

Future weather forecasting cycles also can be categorized into short-term, medium-term, and long-term. In short-term weather forecasting, the cycle is divided by the week. According to the characteristics of highway transportation, weather factors that affect the transport cycle can be summarized as Rainfall (R), Fog (F), Snow (S), and Wind (W). Through EDI, information on future weather forecasting can be obtained from the weather bureau; these data can be brought into the system, or an individual weather forecasting database can be established for analysis.

Each weather factor is ranked according to the degree it affects the transport cycle: Rainfall R (0~1), Fog F (0~1), Snow S (0~1), and Wind W (0~1); 0 is the weakest influence, while 1 is the strongest .

Suppose the weather factors of the day are R_j, F_j, S_j, W_j. Each weather factor is ranked by a weight according to the degree it affects the transport cycle. Supposed the weights are PR_j, PF_j, PS_j, PW_j. With the weighted average method, we obtain the average impact factor.

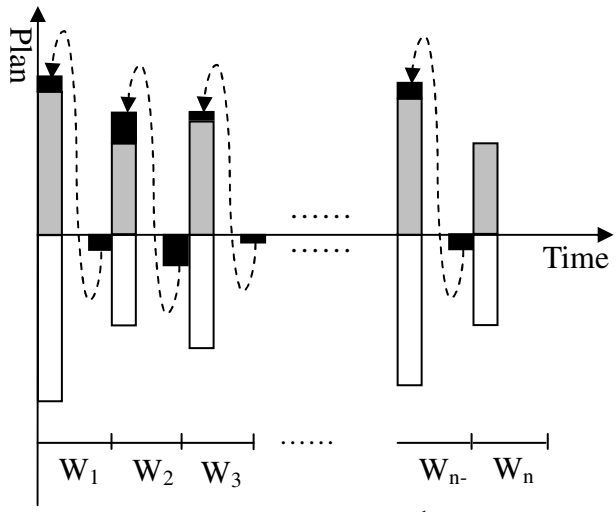
$$G_i = \sum_{j=1}^{7} (R_j * PR_j + Fj * PF_j + S_j * PS_j + W_j * PW_j) / 7$$

$$\text{Restrict: } \begin{array}{l} 0 \le R_j \le 1 \quad 0 \le PR_j \le 1 \\ 0 \le F_j \le 1 \quad 0 \le PF_j \le 1 \\ 0 \le S_j \le 1 \quad 0 \le PS_j \le 1 \\ 0 \le W_j \le 1 \quad 0 \le PW_j \le 1 \\ PR_j + PF_j + PS_j + PW_j = 1 \end{array} \qquad (1)$$

Weights should be dynamically set up to the actual situation in light of MRP. Because it rains a lot in summer, rainfall has a larger weight; it snows a lot in winter, so the weight of snow is larger. According to the method above, the short-term average impact factor per week can be calculated as G_i; it ranks from 0~1. According to the degree it affects, G_i can be divided into grading intervals [0~0.3], [0.4~0.6], [0.7~1]. The weight that each interval affects the supply can be defined as $T_i (i = 1, 2, 3)$, where $T_1 + T_2 + T_3 = 1$. The weights can make some adjustments to the actual situation before the operation of MRP (Xu, 2004).

DYNAMIC SAFETY STOCK CALCULATION MODEL BASED ON SHORT-TERM WEATHER FORECASTING

Suppose the order cycle time is $W_i(1,2,3\ldots\ldots n)$, where n presents the weeks of the short-term order; we can define the main production plan of each cycle $M_i(1,2,3\ldots\ldots n)$, the average weather impact factor, $G_i(1,2,3\ldots\ldots n)$ and the corresponding weights of each level $T_j(j=1,2,3)$, so the dynamic safety stock calculation model are as follows (Figure 1):



Gross requirements.
Requirements plan except for dynamic safety stock after MRP
Dynamic safety stock in the next cycle
Requirements plan including the dynamic safety stock of the next cycle

Figure 1. Sketch map for the dynamic safety stock model.

1) According to the main production plan MPS and the BOM (Bill of Materials) structure of the products, the gross requirements plan $D_i(i=1,2,3\ldots\ldots n)$ of the parts in each cycle can be obtained (Rabinovich, 2002).

2) Calculating in MRP, we take into consideration the lot-sizing strategy of lot-for-lot and the actual physical inventory. Then an accurate requirements plan $L_i(i=1,2,3\ldots\ldots n)$ in each cycle of the short-term can generated.

3) According to the requirements plan, the average weather impact factor, and the corresponding weights of the coming week, the dynamic safety stock $S_i(i=1,2,3\ldots\ldots n)$ caused by weather can be calculated, where

$$\begin{aligned} S_1 &= L_2 * G_2 * \{T_1 \mid T_2 \mid T_3\} \\ S_2 &= L_3 * G_3 * \{T_1 \mid T_2 \mid T_3\} \\ S_3 &= L_4 * G_4 * \{T_1 \mid T_2 \mid T_3\} \\ &\cdots\cdots \\ S_{n-1} &= L_n * G_n * \{T_1 \mid T_2 \mid T_3\} \end{aligned} \qquad (2)$$

4) Define the requirements plan in each cycle of the short-term $P_i(i=1,2,3\ldots\ldots n)$, Where

$$\begin{aligned} P_1 &= L_1 + S_1 \\ P_2 &= L_2 + S_2 \\ P_3 &= L_3 + S_3 \\ &\cdots\cdots \\ P_{n-1} &= L_{n-1} + S_{n-1} \\ P_n &= L_n \end{aligned} \tag{3}$$

CASE ANALYSIS

Suppose the four-week main production plan of product A is $M_i(1,2,3,4) = (100,200,100,300)$. The BOM structure is as follows (Figure 2):

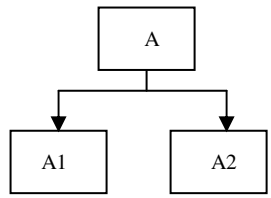


Figure 2. BOM structure of product A.

According to the MPS and BOM of product A, we can draw the four-weeks gross requirements plan of part A_1, $D_i(1,2,3,4) = (100,200,100,300)$.

Suppose the requirements plan except for the dynamic safety stock after MRP is $L_i(1,2,3,4) = (90,195,101,293)$.

Suppose G_i ranks in [0~0.3] in the weight for $T_1 = 0.2$ [0.4~0.6] in the weight for $T_2 = 0.3$ [0.6~1] in the weight for $T_3 = 0.5$.

Calculations for the supply plan for the first week need to consider the dynamic safety stock caused by weather factors in the second week, so the weather forecasting information of the 2-4 weeks obtained from the Bureau of Meteorology through EDI is shown in Table 1.

0.6/0.4 means the grade of rainfall is 0.6, and the corresponding weight is 0.4, so the average impact factor and its corresponding weight of the 2-4 weeks can be calculated according to formula (1): $G_2 = 0.16$

weight of the corresponding grade $T_1 = 0.2, G_3 = 0.13$

weight of the corresponding grade $T_1 = 0.2$ $G_4 = 0.06$

weight of the corresponding grade $T_1 = 0.2$

According to formula (2), the calculated safety stocks of each week are as follows:

$$\begin{aligned} S_1 &= L_2 \times G_2 \times T_1 = 195 \times 0.16 \times 0.2 \approx 6 \\ S_2 &= L_3 \times G_3 \times T_1 = 101 \times 0.13 \times 0.2 \approx 3 \\ S_3 &= L_4 \times G_4 \times T_1 = 293 \times 0.06 \times 0.2 \approx 4 \end{aligned}$$

Table 1. Weather conditions of every day in the fourth week.

Week	Rainfall	Fog	Snow	Wind
2	0.3/0.3	0/0.4	0/0.1	0.1/0.2
	0.4/0.3	0/0.4	0/0.1	0.2/0.2
	0.6/0.3	0/0.4	0/0.1	0.4/0.2
	0/0.3	0/0.4	0/0.1	0.5/0.2
	0/0.3	0.6/0.4	0/0.1	0.1/0.2
	0/0.3	0/0.4	0/0.1	0/0.2
	0.7/0.3	0/0.4	0/0.1	0.2/0.2
3	0.5/0.3	0/0.4	0/0.1	0.3/0.2
	0.4/0.3	0/0.4	0/0.1	0.2/0.2
	0.1/0.3	0/0.4	0/0.1	0/0.2
	0/0.3	0.4/0.4	0/0.1	0/0.2
	0/0.3	0.6/0.4	0/0.1	0/0.2
	0/0.3	0/0.4	0/0.1	0.2/0.2
	0/0.3	0/0.4	0/0.1	0/0.2
4	0/0.3	0/0.4	0/0.1	0.2/0.2
	0/0.3	0/0.4	0/0.1	0/0.2
	0/0.3	0/0.4	0/0.1	0/0.2
	0/0.3	0.6/0.4	0/0.1	0/0.2
	0/0.3	0/0.4	0/0.1	0/0.2
	0.5/0.3	0/0.4	0/0.1	0.2/0.2
	0.2/0.3	0/0.4	0/0.1	0/0.2

According to formula (3), the requirements plan of each week combined with the dynamic safety stock of the former and the coming week could be calculated as follows:

$$P_1 = L_1 + S_1 = 90 + 6 = 96$$
$$P_2 = L_2 + S_2 = 195 + 3 = 198$$
$$P_3 = L_3 + S_3 = 101 + 4 = 105$$
$$P_4 = L_4 = 293$$

We can draw that the total order quality regardless of weather is $L_1 + L_2 + L_3 + L_{34} = 90 + 195 + 101 + 293 = 679$; the four-week total order quality in consideration of the dynamic safety stock is $P_1 + P_2 + P_3 + P_4 = 96 + 198 + 105 + 293 = 692$. With an increase of 2%, the part of the safe stocks can temporarily meet the demands under some special condition.

CONCLUSION

Based on weather forecasting data, this paper presents a model that dynamic safety stock can be calculated through the use of average weather impact factors and their corresponding weights. The additional safety stocks calculated from the model were added to the requirements plan of the former cycle, so that the risks in decline of dynamic safety stock which may be caused by delivery delay due to weather factors would be reduced through advance orders of safety

stock; meanwhile, the increased resilience ensures the continuity and timeliness of the parts supply. As demand is a rolling demand, the supply plan must also be a dynamic one, so that high-safety stock is reduced automatically in the next cycle as the result of the inaccuracy brought on by weather forecasting in the former cycle.

ABSTRACT

The transportation of hazardous materials (HAZMAT) is a growing problem worldwide due to increasing transportation volumes. In this paper, the problems of risk assessment methods and the characteristics of hazmat vehicles are discussed. This research is based on a case study in Shenzhen, China. The operation data is acquired with global positioning system (GPS) data acquisition technology. The characteristics of hazmat transportation are obtained through analyzing the vehicle operation characteristics changing by time and space, and the relationship between the hazmat transportation route and urban transportation system. With the conclusions above, the paper gives some advice to support the Government's decision-making about the assessment of the transport risk for hazmat and the planning of the hazmat transportation.

KEYWORDS: hazmat vehicles, GPS data processing, risk assessment, operational characteristics

1. INTRODUCTION

Hazardous materials transportation is a special logistic. Hazardous materials, or dangerous goods, include explosives, gases, flammable liquids and solids, oxidizing substance, poisonous and infectious substance, radioactive materials, corrosive substances, and hazardous wastes. Clearly hazmat transport is an essential component of the nation's freight transportation system.

At the same time, the transportation of hazardous materials (hazmat) is a growing issue worldwide due to the increasing transported volumes. Once a spill occurs during the hazardous materials transportation, it has the potential for great danger which could spread to an enormous area, threaten residents' lives and property, as well as damaging important facilities of communication, electric power and transportation.

In recent years, the Floating Car Data (FCD) is used more and more as an advanced method to get real-time traffic information on the road (Bowen Du, 2008).

For example, in Shenzhen, the city's taxis, buses and hazmat vehicles are all installed with GPS.

With the development of the city intelligent traffic information platform, the authority has a conditional ability to combine GPS information of all logistics firms. Therefore the massive data of the hazmat vehicles may be obtained, which reflect the running characteristics of the vehicles.

This paper is organized as follows: Section 2includes a review of existing related research of hazmat transportation, then describes the problem of calculating the risk. In Section 3, the methods of processing the GPS data are introduced. In Section 4, an analysis of the operation characteristics of the hazmat vehicles in the City of Shenzhen is conducted, with GPS data obtained from the control center. This is followed by some concluding remarks in Section 5.

2. RELATED RESEARCH

2.1 Risk Assessment

The difference between the shipments of hazmat and other materials is the risk associated with an accidental release of these materials during transportation. Almost all the research of hazmat transportation is associated with risk assessment and route selection.

It is common to define the risk of hazmat transport as the consequences of the incident and the probability of the incident. Generally, the consequences of the incident is proportional to the size of the neighborhood population of the incident, where the size of the neighborhood depends on the substance carried; and the probability of an incident occurring depends on the substance carried and the road circumstances.

Using the traditional risk definition (E.Erkut, 1998), the risk of transporting hazmat B over a road link A can be written as:

$$R_{AB} = P_{AB} C_{AB}$$

where

P_{AB} = probability of an incident on the unit road link A for hazmat B, and

C_{AB} = population along the unit road link A within the neighborhood associated with hazmat B.

A path is a collection of several links. Hence, we can express the risk of transporting a pre-specified hazmat along path P as follows:

$$R(P) = \sum_{i \in P} P_i C_i$$

The above formulas show the basic sample model of calculating the risk. In general, we tend to find a path with the lowest level of risk. Risks imposed on the residents living near transport routes can be reduced by explicitly taking the risk of the shipments into account in selecting routes. Thus, the risk minimization problem can be solved by using a shortest path algorithm.

With the development of the research, many factors, such as weather, time, and the distance from the hospital, are taken into account. It is easy to see that risk assessment of hazmat transportation is data intensive and its analysis requires several data sources such as: population density, value of property and environment that could be impacted by a hazmat truck release, and impact radius by hazmat type. However, it was difficult to obtaining all of the data sources. First, it is quite unrealistic to expect the generation of these data sources for all links of a network. Second, the human dose-response for many toxic chemicals is not known; and third, several link attributes, such as the wind direction, the traffic volume and the population in the neighborhood, usually changed by the time (William Carl Frank, 2001).

In China, we don't have the exact information since the GIS platform is not built in many cities. Furthermore, many basic data sources such as the accident rates of the specific road have not been recorded. Meanwhile, a great number of new roads have been built and accident records for these roads are not available. All of the above situations demonstrate that estimating the exact risk of all the links is an impossible task.

2.2 Hazmat Vehicles

In view of the special circumstances of hazmat vehicles, the Department of Transportation regulates hazmat transportation in many countries. The most famous regulation is the European Agreements concerning the international carriage of Dangerous Goods by Road (ADR). ADR has developed many of the technical specifications of the vehicles such as the electrical equipment, the braking equipment and the prevention of fire risks. In China, we also have such regulations. The trucks carrying flammable, explosive or toxic materials over 2 tons are required to install a compression ignition engine and speed limiting device. The maximum speed of a limiting device should be lower than 90 km/h. Many vehicle manufacturers, such as VOLVO, are making features like electronic braking systems (EBS), anti-brake lock system (ABS), air suspension, and GPS equipment that meet ADR regulations. These updates of the vehicle structure will certainly impact the operation characteristics.

Past studies have not sought to address the characteristics of the hazmat vehicles. Ren Changxing & Wu Zongzhi found that traffic accidents were a leading cause of hazmat transport spills, and they happened in a certain random manner through the statistical analysis on 200 typical road transportation accidents of hazmat in China. This paper is confined to considering the risk imposed on hazmat vehicle operation characteristics and the relationship between the hazmat transportation route and urban transportation systems.

3. PROPOSED METHODS AND ILLUSTRATIVE EXAMPLES

Having discussed the methods and the problems of risk assessment, the methods of analyzing the GPS data is discussed. In this section, the data processing

is divided into several steps.

3.1 Data Sources

The GPS data was obtained from the hazmat vehicles equipped with GPS from the Traffic Control Center. Table 1 shows the GPS data format of the hazmat vehicles in Shenzhen.

Table 1. GPS data format of the hazmat vehicles

Field	Examples
Date	20060405
Time	150236
Vehicle ID	13510232563
Firm ID	H
Longitude	114.114117
Latitude	22.550917
Velocity (km/h)	66
Azimuth angle	4
Operation status	1
Usefulness	True/False

3.2 Data Preprocessing

The data preprocessing mainly includes two aspects: excluded invalid data and coordinate transformation.

Invalid data was excluded: (1) when the equipment is under abnormal status or the data when the longitude or the latitude is beyond the scope of the road network; (2) when the velocity is zero since the intent was to analyze the operation characteristics on the road.

Coordinate transformation included transforming the longitude and the latitude of the vehicle data sources, making it consistent with the road network coordinate system.

3.3 Map Matching

Map matching is a method of using digital map data and GPS data to locate the vehicles position relative to the digital map. In general, the vehicle location is not necessarily on the road of the digital map. We try to filter the unreasonable GPS data and remove the biases of GPS signals by using a map-matching system.

After the map matching process, the next work is to match the trajectory of the vehicles data with the corresponding links in the digital map. Since the sampling interval of most GPS data is 30 to 60 seconds, the assumption was made that the vehicle travels along the shortest path between two points in our algorithm. The whole process is carried out by the program through the combination between Visual Basic and Map Object.

3.4 Spatial Distributions of Hazmat Vehicles

By analyzing the GPS data generated by hazmat vehicles from 9:00AM

to11:00AM on Tuesday May 13, 2008 in Shenzhen, 50460 useful data records of 3298 links were obtained.

The distribution of the hazmat vehicles in road networks in Shenzhen are given in Figure 1. It is shown that hazmat vehicles mainly concentrate on the expressway and arterial roads around the city. The roads that connect the harbor to the city are also the main corridor for hazmat transportation.

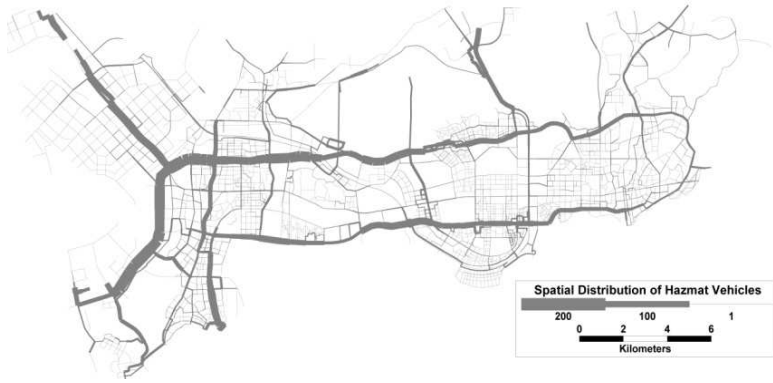

Figure 1. The spatial distribution of hazmat vehicles

Figure 2 shows the distribution of the hazmat vehicles in different road types in Shenzhen. Because of the limitation of the data source amount, 50460 links covered by vehicles trajectories, which account for 67.6% of all road links in the digital map, are collected.

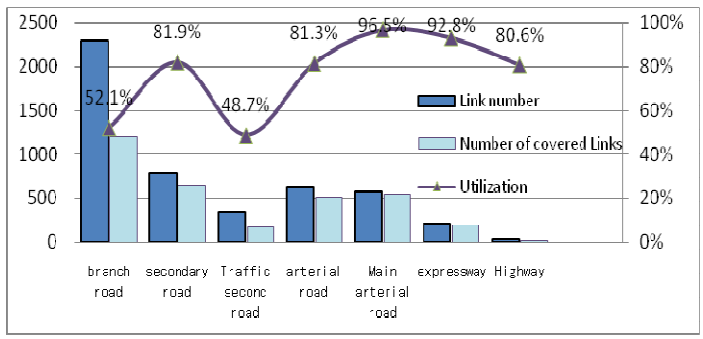

Figure 2. The distribution of hazmat vehicles of different road types

We define utilization as the number of links covered by trajectories according to a certain amount of historical data. It can be seen from Figure 2 that the arterial roads and expressway account for low percentage but high utilization; the circumstances of the secondary roads and the brand roads perform the opposite. In the analysis of the historical data, the trajectories cover the majority of the expressway and the arterial road. The distribution of hazmat vehicles in different road types is consistent with our previous analysis. The distribution of hazmat transportation reflects the authority's management policies at a certain extent.

3.5 Travel Speed of Hazmat Vehicles

After the process of map matching, the trajectory data of the vehicles on the digital map is obtained. The travel speed of each link can be determined since the

time interval of two adjacent points is known.

When studying the running characteristics of certain types of vehicles, the most important indicator is the travel speed. Travel speed impacts the two most important objectives of hazmat vehicles directly – efficiency and safety (see Figure 3).

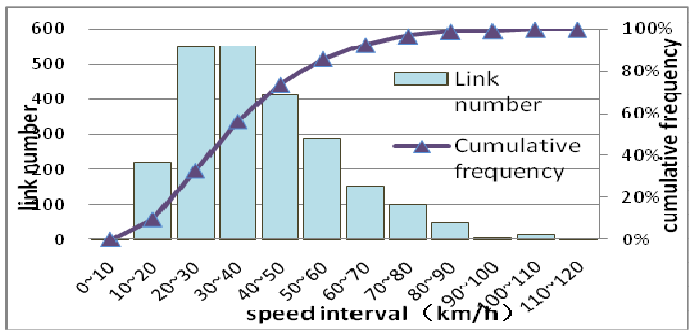

Figure 3. The accumulation histogram of travel speed

We find that most of the link speeds are below 50km/h, the speed between 30km/h and 50km/h account for nearly 60% of all records.

As is shown in Figure 4, the ring line and the roads connecting the conglomerations of the city have a high speed. The roads that connect the harbor to the city and the city roads have a relatively lower speed. Generally, they appear to have a similar characteristic with the spatial distribution.

Figure 4. The distribution of the average speed in the network

The percentage of speed interval on different road types in the road network is quite different. Figure 5 is the distribution.

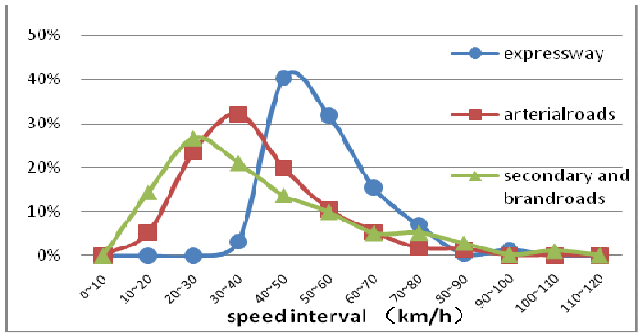

Figure 5. The distribution of vehicle speed of different road types

It can be seen from this figure that the three road types present an arithmetic progression. The speeds of different roads are consistent with the road type. Their average speeds are 50km/h, 40km/h and 30km/h separately. The speed is relatively lower than the cars on the city road.

There are many reasons for the speed difference between hazmat vehicles and cars. Hazmat vehicles are typical large goods trucks and their design speed is much lower than cars, which will lead to the speed difference on the road. Also, the transportation regulations in many countries also specify the requirements of the structure and other ancillary facilities of the hazmat vehicles.

5. CONCLUSIONS

By analyzing the GPS data of hazmat vehicles, the operation characteristics of hazmat vehicles in Shenzhen were obtained. In addition, the identification of spatial distributions and travel speed of hazmat vehicles in the network were acquired. It was determined that the assumption of the risk may also be generalized to incorporate more realistic approaches depending not only on the type of hazmat and the road attributes but also on the operation characteristics of hazmat vehicles.

As the hazmat vehicles mainly concentrate on several road types in the urban network, the authority should pay special attention to these roads; yet it is reasonable for the authority to make some roads of the city inaccessible to truck traffic at different times of the day, which may improve the traffic order of the hazmat transportation, and reduce the accident rate to a large extent. Continued research in the future will analyze other types of vehicles in the road network, which may enable us to find the difference of operation characteristics between hazmat vehicle and other vehicles.

ABSTRACT

Construction of a logistics park has a high risk because of large investment, a long development cycle, etc., and it is influenced by many factors. The failure of logistics park construction can cause large losses, which are difficult to restore. This paper builds an index system on risk evaluation for construction of logistics parks and discusses the problem of how to determine overall risk using individual risk in the risk evaluation. A risk evaluation model is also presented with a concrete example based on principal component analysis by the MATLAB function.

Key words: Logistics park; construction project; risk evaluation; principal component analysis (PCA); model; index system

INTRODUCTION

Logistics parks, which first appeared in Tokyo in 1965, are of great significance for improving logistics at the organization level and intensification degree. In recent years, a logistics park construction wave has emerged rapidly in China. The construction of logistics parks has the following characteristics: large scale land purchase and investment, long development cycle, high specification, long payback period, etc. The failure of logistics park construction can cause large losses over a long period, which are difficult to restore. Risk evaluation and management have become key factors in the success of such construction projects.

Many scholars at home and abroad have presented the concept of risk management for construction projects (Buchan 1994; Miller and Lessard 2000) and have achieved valuable results in theoretical research on risk evaluation methods, such as fuzzy synthetic evaluation (CUI et al. 2002), AHP (Wang et al.2004), ANN (Yang et al. 2004), PERT (Li,2007). Risk grade is determined after the risks occurred in these methods. As a result, there are more disparities between conclusions and the actual state.

This paper presents a risk evaluation index system based on the multi-dimension, multi-layer, and comprehensiveness of logistics park construction connotation referred to in the existing literature on the subject. The paper also presents a risk evaluation model for logistics park construction with a concrete example based on PCA using the MATLAB function, which provides a new idea and approach to risk evaluation of logistics park construction.

ESTABLISHMENT OF INDEX SYSTEM FOR RISK EVALUATION

An index system is the foundation for determining whether the outcome of an evaluation is scientific or not. To establish a scientific risk evaluation index system for logistics park construction, we should consider not only comprehensiveness, systematics, and operability as the index design principles, but also take into account the practical application of methods. Hence, we designed and screened out 15 specific indicators for a risk evaluation index system for logistics park construction from five aspects (Table 1). This was done by analyzing the risk factors for logistics park construction and consulting many experts who having rich practical experience using the Delphi method and by referring to a large number of previous studies.

BASIC PRINCIPLES OF PCA AND MODELING STEPS

Basic Principles

Principal component analysis (PCA), invented in 1901 by Karl Pearson, is a mathematical method of reorganizing information in a data set of samples. PCA

involves a mathematical procedure that transforms a number of possibly correlated variables into a smaller number of new, uncorrelated variables called "principal components" which accounts for the majority of the variability in the data. The first principal component accounts for as much of the variability in the data as possible, and each succeeding component accounts for as much of the remaining variability as possible. Depending on the field of application, it is also named the discrete KarhunenŁoève transform (KLT), the Hotelling transform, or proper orthogonal decomposition (POD). Currently, it is primarily used as a tool in exploratory data analysis and for making predictive models.

Modeling Steps

a) To collect original data x_{ij} (i=1…n, j=1…n), where x_{ij} is evaluation value of expert i to indicator j.

b) To standardize sample value of original matrix $X = (x_{ij})_{n\times m}$ to avoid the influence of difference in dimension and value.

$$y_{ij} = (x_{ij} - \bar{x}_j)/\sigma_j \qquad i=1,2\ldots,n;\ j=1,2\ldots,m \tag{1}$$

Where, $\bar{x}_j = \frac{1}{n}\sum_{i=1}^{n} x_{ij}, \sigma_j = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(x_{ij} - \bar{x}_j)^2}$, σ_j can be achieved by using function *std* in MATLAB. We can get the standardization sample matrix $Y = (y_{ij})_{n\times m}$.

c) To get eigenvalues($\lambda_1 \ge \lambda_2 \ge \cdots \ge \lambda_m \ge 0$) of principal components matrix and covariance matrix by using fuction *princomp* in MATLAB, and to calculate the contribution rate h_j and cumulative contribution rate th_j of eigenvalues.

Where, $h_j = \lambda_j / \sum_{k=1}^{m} \lambda_k, th_j = \sum_{k=1}^{j} \lambda_k / \sum_{k=1}^{m} \lambda_k \ (j = 1,2\cdots m)$

d) To select the principal components and build up the comprehensive evaluation function. According to the size of the contribution rate, to select S principal components F_1, F_2 , …, F_s based on the conditions $\sum_{i=1}^{s} \lambda_i / \sum_{j=1}^{m} \lambda_j \ge 85\%$, thus, the linear combination of pre-s elements as follows:

$$F_i = Z_{i1}x_1 + Z_{i2}x_2 + \cdots + Z_{im}x_m, i = 1,2,\cdots,s \tag{2}$$

To use the compressed S principal components as new decision-making indicators, the principal component decision-making matrix with low-dimensional indicators can be achieved as follows:

$$F = [F_1, F_2 \cdots, F_s] \tag{3}$$

The model for risk evaluation for logistics park construction, which based on S principal components $F_1,F_2,\ldots,F_s$ and their variance contribution rate $h_1,h_2,\ldots,h_s$, is:

$$F = h_1F_1 + h_2F_2 + \cdots + h_sF_s \tag{4}$$

Thus, the total risk value for logistics park construction can be calculated using the comprehensive evaluation function, and the greater F is, the greater the risk of the project.

APPLICATION EXAMPLE

In view of the actual situation of insufficient historical data on the construction of logistics parks, to control the risks from occurring in the construction effectively, relevant departments acquired sample spaces of risk evaluation by inviting senior experts in the related fields to score each type of risk that might exist in the logistics park construction in Chengdu, China. The authors evaluated the risks using PCA.

(1) Experts scored 7 projects of the logistics park/center construction for risk types shown in Table 1. To improve the accuracy of scoring and the objectivity and impartiality of evaluation, the Delphi method was adopted by an group of 15 proficient and experienced experts. Organizers provided the statistical data and evaluation requirements to the group in written form and requested them to give an evaluation value to each risk index of every project independently. The final evaluation value was achieved by integrating all expert evaluation values. If the experts had different opinions, feedback was used so the experts' opinions tend to be in unity. After scoring by the 15 experts and based on the principle of a 1 ~ 10 scoring system, the risk evaluations in Table 2 emerged. The lower the score, the lower the risk.

Table 2. Risk Evaluation Table for Logistics Park Construction.

Risk / Projects	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8	X_9	X_{10}	X_{11}	X_{12}	X_{13}	X_{14}	X_{15}
A	4	5	2	4	3	8	5	1	2	5	8	7	4	4	3
B	5	4	3	3	2	4	3	4	3	4	7	8	3	5	4
C	4	6	4	4	3	6	6	2	5	6	6	4	5	8	7
D	3	3	1	3	2	7	5	3	3	4	5	3	2	5	6
E	3	6	4	5	1	5	2	5	3	3	6	5	5	4	5
F	5	4	5	3	3	8	4	6	2	6	4	7	6	6	4
G	4	5	6	4	1	7	6	2	2	6	7	8	7	6	2

(2) The above data were transformed into the matrix P for processing. For small data discrepancies, data standardizing was not needed, and we can directly carry out PCA to the above data using MATLAB.

(3) To carry on PCA to matrix *P* using PCA function *princomp* in MATLAB.

To input the matrix *P* and [pc, score, latent, tsquare] = *princomp* (p), and run it.

Arranged in order of size, the positive eigenvalues of the covariance matrix, the contribution rate and the cumulative contribution rate are shown in Table 3.

Table 3. Eigenvalues, Contribution Rate, and Cumulative Contribution Rate on Covariance Matrix.

Indicators	Eigenvalues	Contribution rate（%）	Cumulative Contribution Rate（%）
1	10.2848	33.91	33.91
2	6.9557	22.93	56.84
3	5.8986	19.44	76.28
4	3.8704	12.76	89.04
5	2.3447	7.73	96.77
6	0.9791	3.23	100

(4) As shown in Table 3, the cumulative contribution rate of the first four principal components has reached 89.04%(more than 85%), which contains almost all the basic information of the indicators, so *S* is 4.

According to the eigenvectors corresponding to the first four eigenvalues, we can get the four following principal components:

$$F_1=-0.1365X_1-0.0247X_2+0.0406X_3+0.1223X_4-0.3916X_5+0.2113X_6-0.1005X_7+0.3373X_8+0.2063X_9+0.0145X_{10}-0.4275X_{11}-0.4277X_{12}+0.1332X_{13}+0.2770X_{14}+0.3733\ X_{15}$$

$$F_2=-0.0794X_1+0.0957X_2+0.0951X_3-0.4502X_4+0.1788X_5+0.4483X_6-0.0930X_7+0.4600X_8-0.0088X_9-0.0659X_{10}-0.1215X_{11}+0.4395X_{12}-0.2851X_{12}+0.1572X_{14}-0.0356X_{15}$$

$$F_3=-0.4190X_1+0.0855X_2+0.3974X_3-0.1749X_4+0.0475X_5-0.2041X_6-0.2910X_7-0.1995X_8+0.2160X_9-0.1071X_{10}+0.2071X_{11}-0.1747X_{12}-0.4361X_{12}-0.1650X_{14}+0.3336X_{15}$$

$$F_4=-0.0261X_1-0.0005X_2+0.0209X_3-0.2907X_4+0.2969X_5+0.1696X_6+0.1089X_7-0.2640X_8-0.3011X_9+0.2291X_{10}-0.4966X_{11}-0.4757X_{12}-0.1733X_{12}-0.1761X_{14}-0.1971X_{15}$$

The model of comprehensive evaluation function for overall risk,which built up by using F_1， F_2 ， ……， F_s and h_1 ， h_2 …h_s , is:

$$F=33.91F_1+22.93F_2+19.44F_3+12.76F_4$$

By comparing the size of the principal component coefficients, it can be seen that the first principal component reflects bidding and contract management and change of engineering quantity; the second reflects materials and equipment prices rise; the third reflects engineering geology and hydrogeology; and the fourth reflects capital supply. According to the calculation, we find that the risk degree from high to low is D, F, C, E, B, G, A.

CONCLUSIONS

Risk evaluation for logistics park construction is a typical multi-indicator problem which involves many factors. We can quantitatively evaluate project risk degree on logistics park construction using the comprehensive evaluation function F, and the greater F is, the greater the risk of the project. Furthermore, we can obtain principal risk factors, which can provide information for circumventing risk by comparing the size of the coefficients of each principal component. The advantages of evaluating construction risk for logistics parks using PCA are as follows:

(1) It reduces the complexity of the risk evaluation and weakens multiple correlations among the indicators through dimensionality reduction. Furthermore, the using of data processing functions in MATLAB reduces the complexity of risk evaluation in the calculation.

(2) The principal components determined by using PCA can better measure the influence extent of specific risks to total risk, which provides a scientific basis for investors or relevant personnel in the logistics park construction to circumvent risk.

Parameter Sensitivity Analysis of Accident Reconstruction Model Based on Orthogonal Design

Zou Tiefang[1], Yu Zhi[1], Cai Ming[1] and Liu Jike[1]

[1]School of Engineering, Sun Yat-sen University, Guangzhou, 510275, China; email: tiefang@163.com

Abstract: Parameters used in accident reconstruction models are uncertain. How these uncertain parameters influence calculation results can be obtained through parameter sensitivity analysis and then more regard should be paid to these sensitivity parameters in accident measurement. Based on orthogonal design, a parameter sensitivity analysis method in accident reconstruction is proposed. A numerical case is used to illustrate the applications of the presented method, then the influence of uncertain parameters and the interactions between them on calculation results are obtained. Results show that the most sensitive parameter obtained by applying the orthogonal design method is the same as other scholar's; what's more, this method provides availability to inspect the influence of interactions between uncertain parameters on calculation results and the development trend of calculation results versus the variation of parameters.

Key words: *traffic engineering; accident reconstruction; orthogonal design; parameter sensitivity analysis*

1. Introduction

The uncertainty problem is an important issue in accident reconstruction; there are two topics in it: one is uncertainty analysis; the other is parameter sensitivity analysis. Uncertainty analysis has been studied extensively in recent years. Many uncertainty analysis method were presented, such as finite difference method (Wade Bartlett, 2003), Monte Carlo method (Wojciech Wach, 2007; Zbigniew Lozia, 2005), etc. Parameter sensitivity analysis has been studied by some scholars also, like analyzing parameter sensitivity in typical (PEI Jian-ping, 2002) and two-dimension impact (Zou Tie-fang, 2007) model, but the method used in these two papers can not analyze the influence of interactions between uncertain parameters on calculation results. In order to consider the influence, of not only parameters but also interactions between them, on calculation results, some new parameter sensitivity analysis techniques are needed.

In this paper, based on orthogonal design method, a parameter sensitivity analysis method in accident reconstruction is proposed. After that, a numerical case is used to illustrate the applications of the method.

2. Problem description

Models in accident reconstruction vary with the accident modality, the selected methods and many other parameters. But no matter which model is adopted, it can be

described by

$$Y = f(X),\ \mathrm{X} = (x_1, \ldots, x_s)^T \in T \tag{1}$$

where Y is the accident reconstruction results vector, which commonly represents the pre-impact velocity and the collision location; X is independent parameters vector, for example, dimension of vehicle; s is the number of independent parameters; T is the range of the X; f is an equation which characterizes the model.

If the influence of uncertain parameters, not only X but also the interactions between them, on output Y is known, then these sensitivity parameters can be paid more regard in measurement. Therefore, the reconstruction results will be more accurate because of the more accurate inputs. So how these uncertain parameters influence Y is an important issue to be considered. A parameter sensitivity analysis method based on orthogonal design will be proposed in the paper to solve this issue.

3. Parameter sensitivity analysis method based on orthogonal design

Orthogonal design is a kind of multi-factor experiments method. It is a quite efficient method of fraction factorial design (Zhao Xuan-min, 2006).

The basic tool of orthogonal design is the orthogonal table, which can be written as $L_n(t^q)$, where, L represents symbol of orthogonal table, n represents the number of tests, t represents number of levels, and q represents the number of columns in the orthogonal table. For an example, test with 3 parameters and 3 levels, the orthogonal table can be selected as $L_9(3^4)$. When the orthogonal table is chosen, the test table can be got after level translation, and then test results can be obtained through conducting tests according to the test table strictly.

There are two statistical analysis techniques to analyze the test results, which are the extremum difference analysis method and the variance analysis method. The extremum difference analysis method is simple and intuitive, the primary and secondary of parameters sensitivity can be got through a few calculations on the test results, but the test error can not be evaluated by this method. The variance analysis method distinguishes the influence of parameters and error, and then the conclusion, whether the influence of uncertain parameters and/or the difference between different levels of an uncertain factor is significant or not, can be obtained through comparison.

So steps of parameter sensitivity analysis method based on orthogonal design can be given:

1. To select uncertain parameters. There are many uncertain parameters in one issue, and each parameter may influence calculation results. To consider the influence of all parameters will be very hard and not necessary. According to the character of the accident reconstruction model and experience, select the appropriate parameters, and obtain the uncertainty of these parameters.

2. To determine levels of parameters and specify interactions between parameters which need to be estimated. This is the basis for selecting the orthogonal table. Determine these properly according to the actual requirements.

3. To select an appropriate orthogonal table. According to the number and levels of parameters, choose the appropriate orthogonal table, and then arrange the uncertain parameters and their interactions into the chosen orthogonal table. After level translation, the test table can be obtained.

4. To conduct a test, conduct the test according to the experiment table strictly and record the results.

5. To analyze the test results, select the extremum difference analysis method or variance analysis method to analyze the test results.

6. Conclusions, the sensitivity of parameters, interactions between them and the development trend of the calculation results, can be obtained according to step 5.

4. Numerical case

A vehicle impaction pedestrian accident is given in this paper. The model used here can be written as

$$V = \mu\sqrt{2g}\left(\sqrt{h+\frac{l}{\mu}}-\sqrt{h}\right) \tag{2}$$

where V is the velocity of the accident vehicle; l is the throw-out distance of pedestrian, l=18.8±0.5 m; μ is the friction coefficient between the pedestrian and ground, μ=0.6±0.1; h is the throw-out height of the pedestrian, h=0.93±0.1 m; g is acceleration of gravity, g=9.8 m/s^2. The model is validated by Li (Li Yi-bing, 2004) through some tests data once more. All these data of this case are cited from Li.

In this numerical case, the index is V. There are three parameters: μ, h and s. In order to study the nonlinear relationship of index versus parameters, three levels of each factor were selected. Levels of all parameters can be found in Table 1. Therefore, the orthogonal table $L_{27}(3^{13})$ should be selected. The three parameters are arranged in line 1, 2 and 5 respectively, and the interactions items can be arranged according to the interactions tables, test scheme and test results can be found in Table 2. Use the variance analysis method to analyze the test results. The variance analysis results can be found in Table 3. Considering that the experiment error is almost zero here, the significant test on parameters will make no sense because all parameters will have significant effect, so this part will be ignored.

Table 1. Level of all parameters.

Parameters / levels	h [m]	s [m]	μ
1	0.83	18.3	0.5
2	0.93	18.8	0.6
3	1.03	19.3	0.7

*A , B and C represent h, l and μ respectively. AB represents the interactions between A and B; AC and BC are similar. I, II and III are the sum of index V corresponding to level 1, 2 and 3 of each factor respectively. Em represents Empty; it means that there is no parameter arranged in this line. T is the total sum of index V.

Table 3. Variance analysis*.

Origin of variance		Sum of squares of deviations	Freedom	Mean square value
h		0.235586	2	0.117793
l		0.680202	2	0.340101
μ		13.67903	2	6.839513
interactions	*hl*	1.1E-06	4	2.8E-07
	hμ	0.0036	4	0.0009
	lμ	0.003	4	0.0008
Error		4E-08	8	5E-09
Sum		14.60138	26	

* *hl*, *hμ* and *lμ* represent the interaction between *h* and *l*, *h* and*μ*, *l* and*μ* respectively.

Through Table 3, the sensitivity of parameters and interactions between them can be ordered as: *μ*>*l* >*h* >*hμ*>*lμ*>*hl*. We can conclude that the friction coefficient between the pedestrian and ground is the most sensitive parameter for the calculation result in model (1); this conclusion is in line with LI's. And the influence on index *V* of the interactions between parameters is little, so we can conclude that only the friction coefficient between pedestrian and ground should pay more regard in accident measurement. In order to make the analysis results intuitive, with the level of parameter as x-coordinate and the sum of velocity, corresponding to the level *i* (*i*=1, 2, 3) of parameters, as y-coordinate, the development trend of velocity versus the variation of parameters can be drawn (Figure 1), the interactions between parameters is consider as factors here.

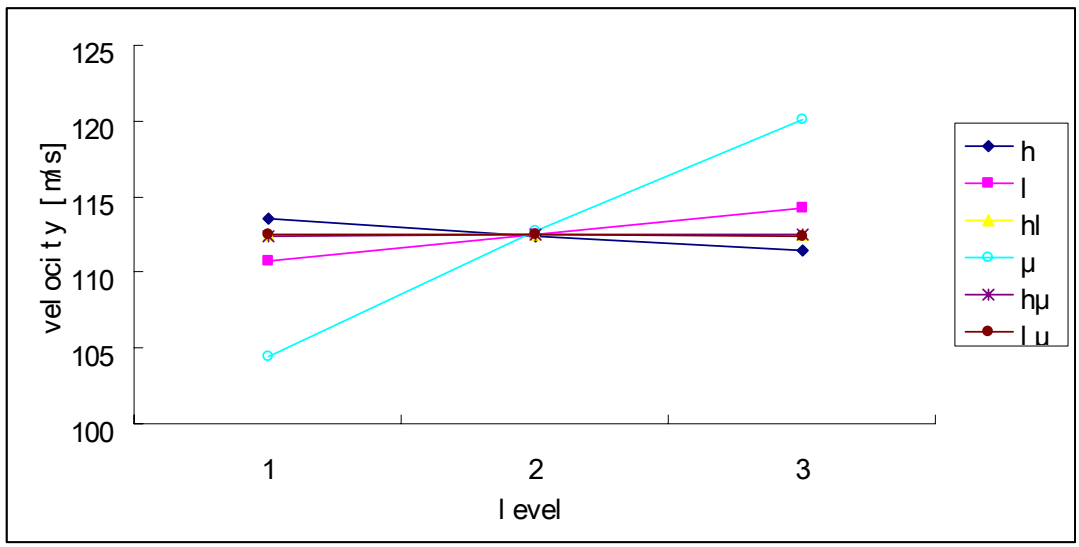

Figure 1. The development trend of velocity versus the variation of level of parameters

From Figure 1, the oblique line with maximum slope is the line represent by μ, the slopes of all of the other lines are small, which means that other parameters and interactions between them influence the calculation results V less. And equation (2) is a nonlinear function, but in Figure 1, the development trend of velocity is approximately linear, which means that equation (2) can be explained by an approximate linear model when the uncertainty of uncertain parameters is small.

5. Conclusions

Based on orthogonal design, a parameter sensitivity analysis method in accident reconstruction is proposed. Using this method to study parameter sensitivity analysis of accident reconstruction, the model can not only study the influence on the index of the parameters, but also the interactions between them, and the development trend of the index versus inputs can also be obtained. It is a useful method in parameter sensitivity analysis, and can be used in the accident reconstruction field.

ABSTRACT

This paper is aimed to realize the numerical simulation, using SCFD, on all functions of PMM (Planar Motion Mechanism) and CMT (circular motion test), in order to get all of the hydrodynamic derivatives, which are vital to ship-maneuverability-design research. So 9 kinds of motions were generalized from captive model tests. And based on the motions' characteristic, the numerical simulations of static drift test, pure sway test , pure yaw test and circular motion test(CMT) were realized, by means of "change inlet-flow's velocity", "Dynamic Meshes" and "region shape design" method. The ship model in this paper is DTMB5415, and in order to advance calculational precision and efficiency, a series of studies on grids, discrimination scheme, scales of computational domain, turbulence model and free surface simulation. The simulation results showed good agreement with that of tank test.

ITRODUCTION

Maneuverability is an important performance of vessels. At present, Captive model test is acknowledged to be the best method which can obtain the hydrodynamic force precisely and be satisfied in engineering. Planar Motion Mechanism (PMM) is one of captive model tests, which can get all of Hydrodynamic derivatives. But the disadvantage of PMM is costly and time consuming; furthermore, modifying the data of ship model is difficult.

Ship Computational Fluid Dynamics（SCFD）method can remedy the disadvantage of PMM fitly, which has the advantage of low consume, time saving and modifying convenient. SCFD has been applied in the ship's investigation more and more widely. But researcher of SCFD has not focused on the numerical simulation of PMM to get all of hydrodynamic derivatives.

The author of this paper attempts to use SCFD method to get hydrodynamic derivatives. This method may offer a new research fundament of numerical tank towing. The thinking that the author studies is: to solve RANS equation in given computational region, based on CFD software "FLUENT", in order to realize the numerical simulation on static drift test, pure sway test , pure yaw test (Figure.1)and circular motion test(CMT).

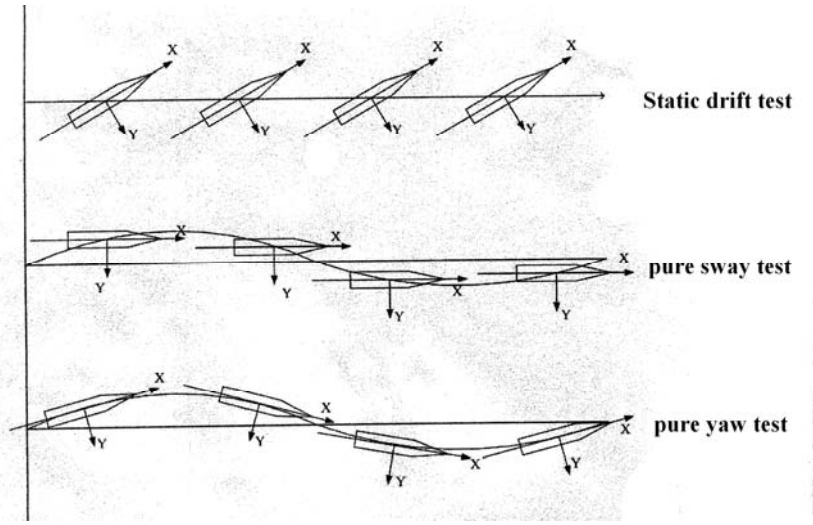

Figure1 all kinds of PMM

2 Implementary scheme of captive model tests' numeric simulation

2.1 Design of implementary scheme

All functions of captive model tests in this paper are summarized to static drift test, static rudder angle test, static drift and rudder angle test, pure sway test, pure yaw test, unstatic drift pure yaw test, zreo drift of CMT, static drift of CMT, and static drift and rudder angle of CMT, amounts to 9 kinds.

In Table 1, all of the schemes are listed.

Table 1 implementary scheme of captive model tests' numeric simulation

Experimental project	Design of simulation	Region and grid	Hydrodynamic derivatives
Static drift test		partition hybrid grid	Y_V'、Y_{VVV}'、N_V'、N_{VVV}'

static rudder angle test		partition hybrid grid	Y_δ'、$Y_{\delta\delta\delta}'$、N_δ'、$N_{\delta\delta\delta}'$
Static drift and rudder angle test		partition hybrid grid	$Y_{V\delta\delta}'$、$Y_{VV\delta}'$ $N_{V\delta\delta}'$、$N_{VV\delta}'$
Pure sway test		unstructured grid	Y_V'、$Y_{\dot{V}}'$、N_V'、$N_{\dot{V}}'$
Pure yaw test		unstructured grid Dynamic Meshes	Y_r'、$Y_{\dot{r}}'$、N_r' $N_{\dot{r}}'$、Y_{rrr}'、N_{rrr}'
unstatic drift pure yaw test		unstructured grid Dynamic Meshes	Y_{rrr}'、Y_{VVr}'、Y_{Vrr}' Y_{VVV}'、N_{rrr}'、N_{VVr}' N_{Vrr}'、N_{VVV}'
zreo drift of CMT		fan-shaped region partition hybrid grid MRF(Multiple Rotating Reference Frames)	Y_r'、N_r'

static drift of CMT		fan-shaped region partition hybrid grid MRF	Y_{Vrr}'、Y_{VVr}'、Y_{rrr}' N_{Vrr}'、N_{VVr}'、N_{rrr}'
static drift and rudder angle of CMT		fan-shaped region partition hybrid grid MRF	$Y_{r\delta\delta}'$、$Y_{\delta rr}'$、$Y_{Vr\delta}'$ $N_{r\delta\delta}'$、$N_{\delta rr}'$、$N_{Vr\delta}'$

2.2 Model

In order to validate the feasibility and credibility of this scheme, the author uses DTMB5415 model, which is announced of ITTC. Model's parameters are listed as follows:

Model Length	LPP=4.0023m
Draft	T=0.1736m
Beam	B=0.5382m
Wetted surface area	S=1.571m^2

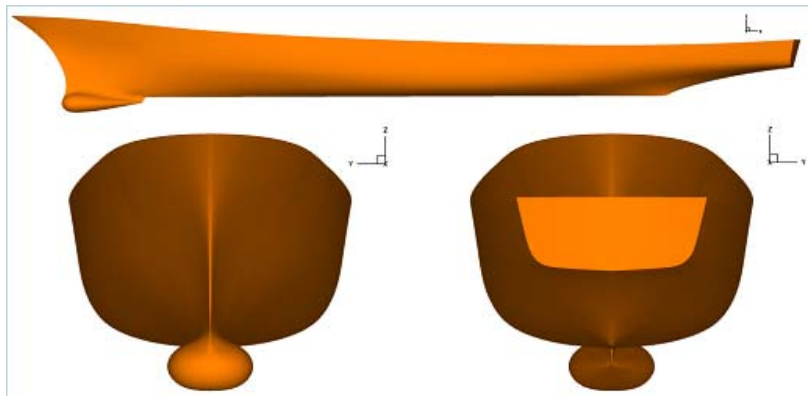

Figure 2 DTMB5415

2.3 Setup of computational region and Generation of grid

2.3.1 Computational region of static drift test, pure sway test and pure yaw test

Computational region of static drift test, pure sway test and pure yaw test is listed as Figure 3. 'L' is Model Length.

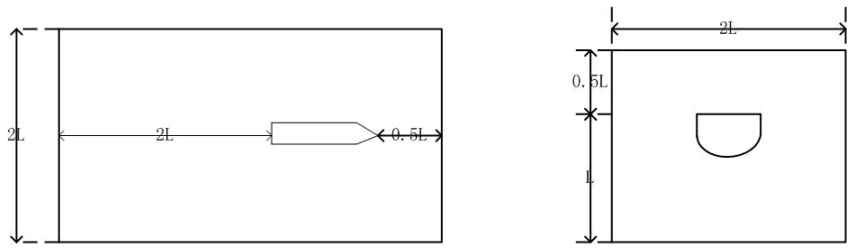

Figure 3 Computational region of PMM

2.3.2 Computation region of CMT

Computation region of CMT is listed as Figure 4. 'L' is Model Length.

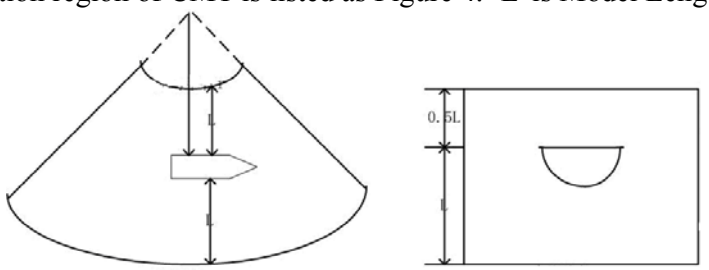

Figure 4 Computational region of CMT

2.3.3 Generation of grid

Different kinds of grid are requested to different PMM numeric simulation test. Such as static drift test is requested to use partition hybrid grid(As Figure. 5 shows), and pure yaw test and pure sway test are requested to use unstructured grid(As Figure. 6 shows).

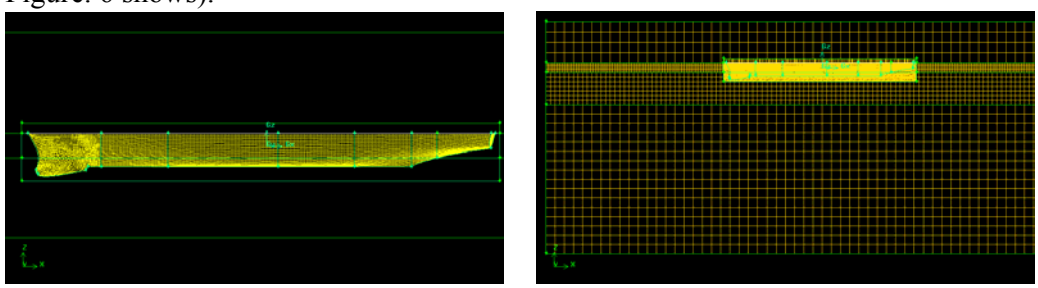

Figure 5 partition hybrid grid

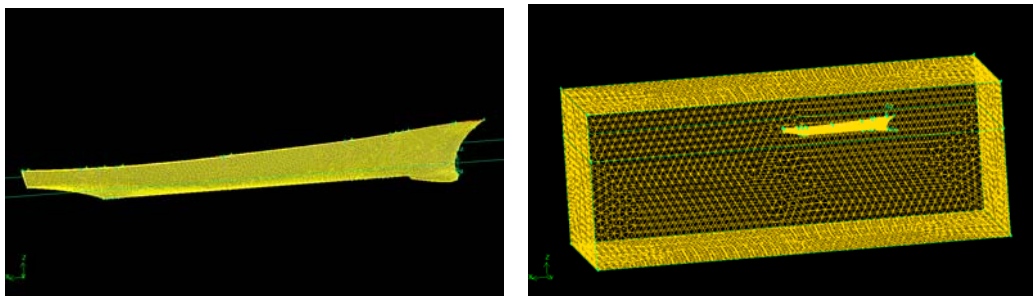

Figure 6 unstructured grid

3 Governing equations

3.1 Continuity equation and momentum equation

Continuity equation

$$\frac{\partial u_i}{\partial x_i}=0 \tag{1}$$

momentum equation

$$\frac{\partial u_i}{\partial t}+\frac{\partial}{\partial x_j}\left(u_i u_j\right)=-\frac{\partial P}{\partial x_i}+\frac{\partial}{\partial x_j}\left(\mu\frac{\partial u_i}{\partial x_j}-\overline{u_i' u_j'}\right) \tag{2}$$

3.2 RNG $k-\varepsilon$ turbulence model

The flow features are very complex in captive model tests' region. So the author chooses RNG $k-\varepsilon$ turbulence model to solve this problem.

$$\frac{\partial \kappa}{\partial t}+\frac{\partial \kappa u_i}{\partial x_i}=\frac{\partial}{\partial x_j}\left(\alpha_\kappa \mu_{eff}\frac{\partial \kappa}{\partial x_j}\right)+G_K+\varepsilon \tag{3}$$

$$\frac{\partial \varepsilon}{\partial t}+\frac{\partial \varepsilon u_i}{\partial x_i}=\frac{\partial}{\partial x_j}\left(\alpha_\varepsilon \mu_{eff}\frac{\partial \varepsilon}{\partial x_j}\right)+\frac{C_{1\varepsilon}^{*}\varepsilon}{\kappa}G_K+C_{2\varepsilon}\frac{\varepsilon^2}{\kappa} \tag{4}$$

3.3 VOF model

To simulate free surface, the author uses the VOF model(volume of fluids model).

The VOF model can model two or more immiscible fluids by solving a single set of momentum equations and tracking the volume fraction of each of the fluids throughout the domain. If the q fluid's volume fraction in the cell is denoted as C_q, then the following three conditions are possible:

$C_q=0$: The cell is empty (of the q fluid).

$C_q=1$: The cell is full (of the fluid).

$0<C_q<1$: The cell contains the interface between the q fluid and one or more other fluids.

Based on the local value of C_q, the appropriate properties and variables will be assigned to each control volume within the domain.

3.4 Solver

The author solves the three-dimensional viscidity incompress RANS equation directly. The discretization scheme of differential eguation is Finite Volume Method (FVM). Second order upwind scheme is used to convective term and diffusive term.

In order to solve the coupled equation of pressure, the author uses SIMPLE method. The dispersed algebraic equation is solved with Gauss-Seidel method.

4 Several typical tests result

4.1 Resistance test

As Fr =0.280 test is the example, the calculational result of resistance force (X force) is showed in Figure. 7, and free-surface wave feature is showed in Figure 8.

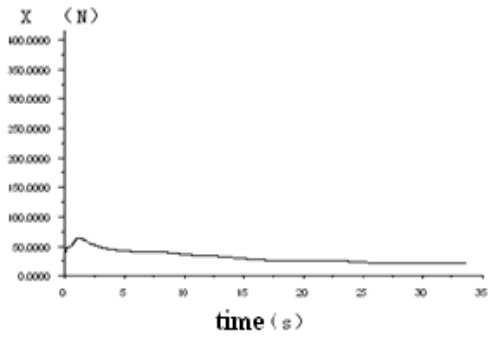

Figure 7 result of X force

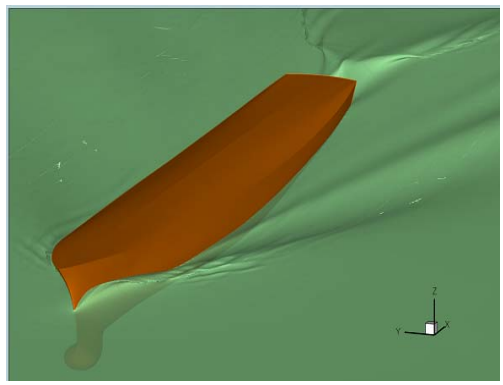

Figure 8 free-surface wave feature

The calculational result and test data from the towing tank are listed as follows:

Table 2 calculational result and test data from the towing tank

Project	Resistance force(N)
Test data from the towing tank	18.797
calculational result	19.45

4.2 Static drift test result

The calculational result and test data from the towing tank are listed as follows:

Table 3 calculational result and test data from the towing tank

Project	Fr=0.138，β=12°		Fr=0.138，β=20°	
	X force(N)	Y force(N)	X force(N)	Y force(N)
Test data from the towing tank	4.3712	21.745	4.6670	48.359
calculational result	4.5722	24.372	4.90	50.839

In order to achieve $Y'(\beta)$ and $N'(\beta)$ curve, the calculational result of β=6°,β=12°, β=15°, β=20° will be non-dimensionalized. Curve slope of zero is hydrodynamic derivative Y'_v or N'_v.

Table 4 hydrodynamic derivative Y'_v and N'_v

Project	Y'_v	N'_v
Test data from the towing tank	0. 2785	0. 002870
calculational result	0. 2964	0. 002681

4.3 Pure sway test result

As Fr =0.280 test is the example, the calculational result of Y force is showed in Figure 9.

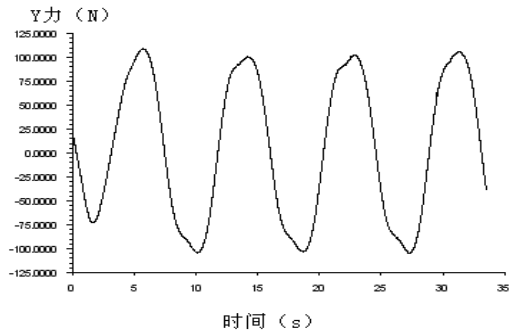

Figure 9 result of Y force

The calculational result of hydrodynamic derivatives are listed as follows:

Table 5 hydrodynamic derivative Y'_V and $Y'_{\dot{V}}$

Project	Y force (N)	transverse displacement (m)	Phasic value (rad)	Y'_V	$Y'_{\dot{V}}$
Test data from the towing tank	108	0. 4292	0. 5872	0. 3120	0. 4500
calculational result	142. 47	0. 4191	0. 5315	0. 4215	0. 5483

4.4 Pure yaw test result

As Fr =0.280 test is the example, the calculational result of Y force is showed in Figure 10.

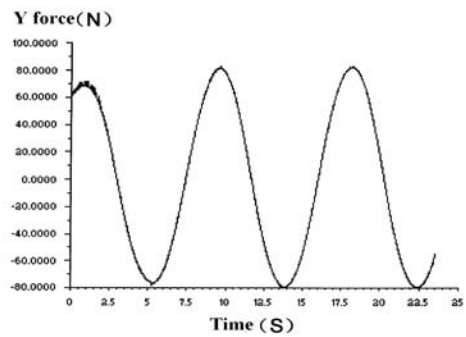

Figure 10 result of Y force

The calculational result of hydrodynamic derivatives are listed as follows:

Table 6 hydrodynamic derivative Y'_{γ} and $Y'_{\dot{\gamma}}$

Project	Y force (N)	transverse displacement (m)	Phasic value (rad)	Y'_{γ}	$Y'_{\dot{\gamma}}$
Test data from the towing tank	79.0	0.4292	1.5414	0.4228	0.06947
calculational result	80.55	0.3270	1.53	0.4159	0.06385

CONCLUSION

(1) CFD simulation of all kinds of captive model tests can achieve all of the hydrodynamic derivatives which are vital in ship maneuverability design research and analysis, especially in nonlinear ship maneuverability application. So it is of great theoretical and practical values to deepen the research of this field.
(2) The effective method of the numerical simulation of all functions of PMM(Planar Motion Mechanism) may be, based on the motion features of model tests, to combine the following three aspects: change of inlet-flow's velocity(include MRF), dynamic change of the ship model (include periodic change) and computational domain (include fan-shaped computational domain). And dynamic meshes is also necessary.
(3) In order to obtain more accurate and more efficient simulation results, the integer simulation design, including the ship features, instead of one special aspect should be taken into account. The simulation design should include discrimination scheme, the quantity and amount of the grids, turbulence model, free surface simulation, computational domain, boundary conditions, and etc.

Simulation and Analysis for Stick-slip Vibration of Locomotive with Hollow-shaft Drive System

Jianxin Liu[1], Huaiyun Zhao[1], and Wanming Zhai[1]

[1] Traction Power State Key Laboratory, Southwest Jiaotong University; P.O. Box 610031, Chengdu, China; PH (0086) 28-87600290; email: jxliu@home.swjtu.edu.cn

ABSTRACT

For the purpose of investigating the stick-slip vibration of the locomotive with a hollow-shaft drive system, a coupled dynamic model of locomotive and slab track is established based on the theory of the vehicle-track coupled dynamics. The dynamic equations are set up considering the nonlinear relationship between slip velocity and the adhesion coefficient. A simulation program is then compiled using MATLAB/SIMULINK. Simulation results show that the phase trajectories of the torsional vibrations are a set of stable limit cycles when the slip velocity is located at the descending slope of the adhesion coefficient curve, indicating that self-excited torsional vibrations are occurred in the drive system.

1 INTRODUCTION

In railways, the adhesion force between the wheel and the track is the ultimate motivation force to drive the train forward. The adhesion force is directly proportional to the adhesion coefficient, which varies with the slip velocity and the various track conditions (Koan-Sok Baek, 2007). A sudden change of the adhesion force from a high level to a low level leads to the self-excited torsional vibration of the drive system and the excessive slip of the wheels, known as stick-slip vibration (HIROTSU Tetsuji, 1987). The self-excited torsional vibration will cause excessive stress in the drive system, which prevents the train from achieving its best adhesion performance. Moreover, it is well agreed that stick-slip vibration can cause rail corrugations (Clark R.A, 1984) and generate noise which becomes a significant environmental nuisance (W.X. Wu, 1998).

Some research indicated that the main cause of the self-excited torsional vibration of the drive system was the adhesion force became smaller as the slip rate increased (ZHENG Lianzhu, 1996). The adhesion force is also closely related to the locomotive dynamics. This paper will establish a locomotive-track coupled model and study it based on the theory of the vehicle-track coupled dynamics (ZHAI Wanming, 2007).

2 ANALYSIS MODEL AND DIFFERENTIAL EQUATIONS

A complete dynamic model of locomotive is established based on a 2B0 locomotive. This locomotive's bogie is a high-speed power bogie with a wheelset hollow-shaft drive device. Each motor is mounted on the bogie frame by three points, one on the end beam (point A) and the others on the lateral beam (point B and C). The track in the model is slab track.

2.1 Drive system torsional model and dynamic equations

The model of the hollow-shaft drive system torsional dynamics is shown in Figure1, and we can get the torsional dynamic equations below.

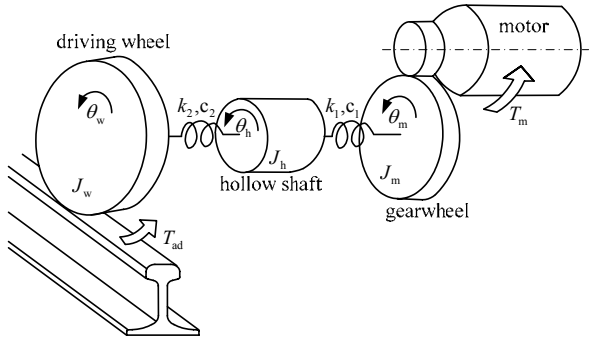

Figure 1. Hollow-shaft drive system torsional model.

$$\begin{cases} J_{\mathrm{m}}\ddot{\theta}_{\mathrm{m}} + c_1(\dot{\theta}_{\mathrm{m}} - \dot{\theta}_{\mathrm{h}}) + k_1(\theta_{\mathrm{m}} - \theta_{\mathrm{h}}) = T_{\mathrm{m}} \\ J_{\mathrm{h}}\ddot{\theta}_{\mathrm{m}} + c_1(\dot{\theta}_{\mathrm{h}} - \dot{\theta}_{\mathrm{m}}) + c_2(\dot{\theta}_{\mathrm{h}} - \dot{\theta}_{\mathrm{w}}) + k_1(\theta_{\mathrm{h}} - \theta_{\mathrm{m}}) + k_2(\theta_{\mathrm{h}} - \theta_{\mathrm{w}}) = 0 \\ J_{\mathrm{w}}\ddot{\theta}_{\mathrm{w}} + c_2(\dot{\theta}_{\mathrm{w}} - \dot{\theta}_{\mathrm{h}}) + k_2(\theta_{\mathrm{w}} - \theta_{\mathrm{h}}) = -T_{\mathrm{ad}} \end{cases} \tag{1}$$

Where T_{m} is the motor traction torque; T_{ad} is the adhesion torque; J_{m} is the motor and gear equivalent moment of inertia; θ_{m} is the torsional angle of the gearwheel; J_{h} is the hollow-shaft moment of inertia; θ_{h} is the torsional angle of the hollow-shaft; J_{w} is the wheelset moment of inertia; θ_{w} is the torsional angle of the wheelset; the c_1, k_1 are the equivalent damping and stiffness between the motor and hollow-shaft, the c_2, k_2 are the equivalent damping and stiffness between the hollow-shaft and wheelset.

The self-excited torsional vibrations are mainly the relative vibrations of the drive parts to the motor. By defining $\Delta\theta_1 = \theta_{\mathrm{h}} - \theta_{\mathrm{m}}$, $\Delta\theta_2 = \theta_{\mathrm{w}} - \theta_{\mathrm{h}}$, equation (1) becomes:

$$\begin{pmatrix} J_{\mathrm{h}} & \\ & J_{\mathrm{w}} \end{pmatrix}\begin{pmatrix} \Delta\ddot{\theta}_1 \\ \Delta\ddot{\theta}_2 \end{pmatrix} + \begin{pmatrix} (1+\dfrac{J_{\mathrm{h}}}{J_{\mathrm{m}}})c_1 & -c_2 \\ -\dfrac{J_{\mathrm{w}}}{J_{\mathrm{h}}}c_1 & (1+\dfrac{J_{\mathrm{w}}}{J_{\mathrm{h}}})c_2 \end{pmatrix}\begin{pmatrix} \Delta\dot{\theta}_1 \\ \Delta\dot{\theta}_2 \end{pmatrix} + \begin{pmatrix} (1+\dfrac{J_{\mathrm{h}}}{J_{\mathrm{m}}})k_1 & -k_2 \\ -\dfrac{J_{\mathrm{w}}}{J_{\mathrm{h}}}k_1 & (1+\dfrac{J_{\mathrm{w}}}{J_{\mathrm{h}}})k_2 \end{pmatrix}\begin{pmatrix} \Delta\theta_1 \\ \Delta\theta_2 \end{pmatrix} = \begin{pmatrix} -\dfrac{J_{\mathrm{h}}}{J_{\mathrm{m}}}T_{\mathrm{m}} \\ -T_{\mathrm{ad}} \end{pmatrix} \tag{2}$$

2.2 Vertical locomotive-track coupled model and dynamic equations

Based on the theory of vehicle-track coupled dynamics, the vertical coupled model of locomotive and slab track and dynamic equations can be as following:

Vertical motion of the carbody:

$$M_{\mathrm{c}}\ddot{Z}_{\mathrm{c}} + C_{\mathrm{s2}}(2\dot{Z}_{\mathrm{c}} - \dot{Z}_{\mathrm{t1}} - \dot{Z}_{\mathrm{t2}}) + K_{\mathrm{s2}}(2Z_{\mathrm{c}} - Z_{\mathrm{t1}} - Z_{\mathrm{t2}}) = M_{\mathrm{c}}g \tag{3}$$

Pitch motion of the carbody:

$$J_{\mathrm{c}}\ddot{\beta}_{\mathrm{c}} + C_{\mathrm{s2}}l_{\mathrm{c}}(2\dot{\beta}_{\mathrm{c}}l_{\mathrm{c}} - \dot{Z}_{\mathrm{t1}} + \dot{Z}_{\mathrm{t2}}) + K_{\mathrm{s2}}l_{\mathrm{c}}(2\beta_{\mathrm{c}}l_{\mathrm{c}} - Z_{\mathrm{t1}} + Z_{\mathrm{t2}}) = 0 \tag{4}$$

Vertical motion of the front bogie:

$$M_t\ddot{Z}_{t1}+C_{s1}(2\dot{Z}_{t1}-\dot{Z}_{w1}-\dot{Z}_{w2})+C_{s2}(\dot{Z}_{t1}-\dot{Z}_c-\dot{\beta}_c l_c)+K_{s1}(2Z_{t1}-Z_{w1}-Z_{w2})+$$
$$K_{s2}(Z_{t1}-Z_c-\beta_c l_c)+K_{tm_A}(2Z_{t1}-Z_{m1}-Z_{m2}-\beta_{m1}l_{m_A}+\beta_{m2}l_{m_A})+ \quad (5)$$
$$K_{tm_BC}(2Z_{t1}-Z_{m1}-Z_{m2}+\beta_{m1}l_{m_BC}-\beta_{m2}l_{m_BC})=M_t g$$

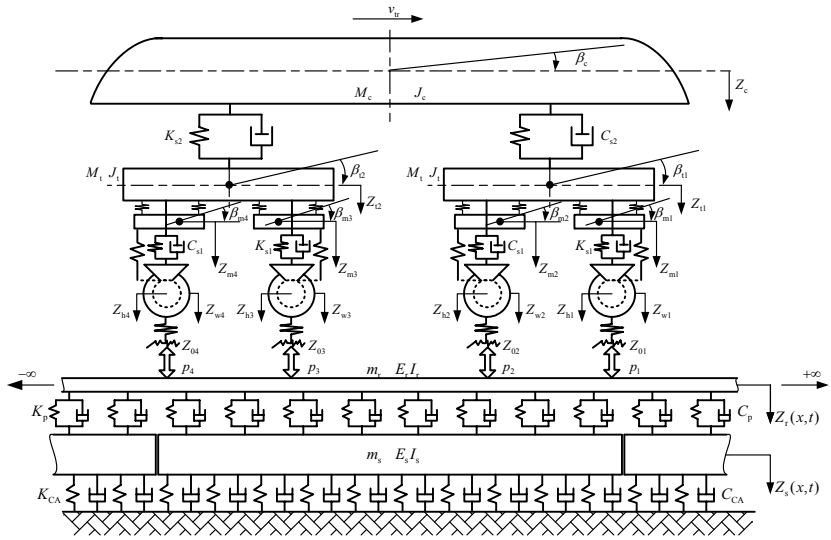

Figure 2. Vertical locomotive-track coupled model

Pitch motion of the front bogie:

$$J_t\ddot{\beta}_{t1}+K_{tm_A}l_{tm_A}(Z_{m2}-Z_{m1}+2\beta_{t1}l_{tm_A}-\beta_{m1}l_{m_A}-\beta_{m2}l_{m_A})+$$
$$K_{tm_BC}l_{tm_BC}(Z_{m2}-Z_{m1}+2\beta_{t1}l_{tm_BC}+\beta_{m1}l_{m_BC}+\beta_{m2}l_{m_BC})+ \quad (6)$$
$$C_{s1}l_t(\dot{Z}_{w2}-\dot{Z}_{w1}+2\dot{\beta}_{t1}l_t)+K_{s1}l_t(Z_{w2}-Z_{w1}+2\beta_{t1}l_t)=0$$

Vertical motion of the rear bogie:

$$M_t\ddot{Z}_{t2}+C_{s1}(2\dot{Z}_{t2}-\dot{Z}_{w3}-\dot{Z}_{w4})+C_{s2}(\dot{Z}_{t2}-\dot{Z}_c+\dot{\beta}_c l_c)+K_{s1}(2Z_{t2}-Z_{w3}-Z_{w4})+$$
$$K_{s2}(Z_{t2}-Z_c+\beta_c l_c)+K_{tm_A}(2Z_{t2}-Z_{m3}-Z_{m4}-\beta_{m3}l_{m_A}+\beta_{m4}l_{m_A})+ \quad (7)$$
$$K_{tm_BC}(2Z_{t2}-Z_{m3}-Z_{m4}+\beta_{m3}l_{m_BC}-\beta_{m4}l_{m_BC})=M_t g$$

Pitch motion of the rear bogie:

$$J_t\ddot{\beta}_{t2}+K_{tm_A}l_{tm_A}(Z_{m4}-Z_{m3}+2\beta_{t2}l_{tm_A}-\beta_{m3}l_{m_A}-\beta_{m4}l_{m_A})+$$
$$K_{tm_BC}l_{tm_BC}(Z_{m4}-Z_{m3}+2\beta_{t2}l_{tm_BC}+\beta_{m3}l_{m_BC}+\beta_{m4}l_{m_BC})+ \quad (8)$$
$$C_{s1}l_t(\dot{Z}_{w4}-\dot{Z}_{w3}+2\dot{\beta}_{t2}l_t)+K_{s1}l_t(Z_{w4}-Z_{w3}+2\beta_{t2}l_t)=0$$

Vertical motion of the motor i ($i=1\sim4$):

$$M_m\ddot{Z}_{mi}+K_{mh}(Z_{mi}-Z_{hi}\pm\beta_{mi}l_{mh})+K_{tm_A}(Z_{mi}-Z_{tj}\pm\beta_{mi}l_{m_A}\mp\beta_{tj}l_{tm_A})+$$
$$K_{tm_BC}(Z_{mi}-Z_{tj}\mp\beta_{mi}l_{m_BC}\mp\beta_{tj}l_{tm_BC})=M_m g \quad (9)$$

Pitch motion of the motor i ($i=1\sim4$):

$$J_m\ddot{\beta}_{mi}+K_{mh}l_{mh}(\beta_{mi}l_{mh}\pm Z_{mi}\mp Z_{hi})+K_{tm_A}l_{m_A}(\beta_{mi}l_{m_A}-\beta_{tj}l_{tm_A}\pm Z_{mi}\mp Z_{tj})+$$
$$K_{tm_BC}l_{m_BC}(\beta_{mi}l_{m_BC}+\beta_{tj}l_{tm_BC}\mp Z_{mi}\pm Z_{tj})=T_{Li} \quad (10)$$

Vertical motion of the hollow-shaft i ($i=1\sim4$):

$$M_h\ddot{Z}_{hi}+K_{mh}(Z_{hi}-Z_{mi}\mp\beta_{mi}l_{mh})+K_{hw}(Z_{hi}-Z_{wi})=M_h g \quad (11)$$

Vertical motion of the wheelset i ($i=1\sim4$):

$$M_{\mathrm{w}}\ddot{Z}_{\mathrm{w}i}+C_{\mathrm{s1}}(\dot{Z}_{\mathrm{w}i}-\dot{Z}_{\mathrm{t}j}\mp\dot{\beta}_{\mathrm{t}j}l_{\mathrm{t}})+K_{\mathrm{s1}}(Z_{\mathrm{w}i}-Z_{\mathrm{t}j}\mp\beta_{\mathrm{t}j}l_{\mathrm{t}})+K_{\mathrm{hw}}(Z_{\mathrm{w}i}-Z_{\mathrm{h}j})+p_i=M_{\mathrm{w}}g+F_{0i}(t) \tag{12}$$

Where M_{c} and J_{c} are the carbody mass and moment of inertia; M_{t} and J_{t} are the bogie mass and moment of inertia; M_{m} is the motor mass; M_{h} is the hollow-shaft mass; M_{w} is the wheelset mass; C_{s1}, K_{s1} are the damping and stiffness of the primary suspension; C_{s2}, K_{s2} are the damping and stiffness of the secondary suspension; $K_{\mathrm{tm_A}}$ and $K_{\mathrm{tm_BC}}$ respectively are the equivalent stiffness of motor suspension at point A or point B/C; K_{mh} is the equivalent stiffness between the gearwheel and the hollow-shaft; K_{hw} is the equivalent stiffness between the hollow-shaft and the wheelset; l_{c} is the half-distance between the two bogies centers; l_{t} is half of the bogie fixed wheel base; $l_{\mathrm{m_A}}$ and $l_{\mathrm{m_BC}}$ respectively are the longitudinal distance from the centre of mass of the motor to the motor suspension point A or point B/C; $l_{\mathrm{tm_A}}$ and $l_{\mathrm{tm_BC}}$ respectively are the longitudinal distance from the motor suspension point A or point B/C to the centre of mass of the corresponding bogie; l_{mh} is the longitudinal distance from the centre of mass of the motor to the centre of mass of the hollow-shaft; p_i are the vertical loads between the wheels and the rails, and it can be calculated using Hertz non-linear contact theory; $F_{0i}(t)$ are the functions of wheel/rail excitation force.

In equations (9),(10) and (12), the subscript j ($j=1,2$) is the number of the bogie, when $i=1,2$, $j=1$ and when $i=3,4$, $j=2$; in equations (9)~(12), when $i=1,3$, the symbol $\pm$ and $\mp$ take the upper value and when $i=2,4$, $\pm$ and $\mp$ take the lower value.

In the equation (10), the T_{L} is the torque on the motor exerted by torsional vibration of the drive system through the gearbox, $T_{\mathrm{L}}=(c_1\Delta\dot{\theta}_1+k_1\Delta\theta_1)/R_{\mathrm{g}}$, where R_{g} is the gear ratio.

The slab track is modeled using the finite element method (ZHAO Huaiyun, 2007).(See the reference for more details of the method.)

2.3 Locomotive traction dynamic model and dynamic equations

The locomotive traction dynamic model shown in Figure3 and the locomotive traction can be represented by the following dynamic equation:

$$M\frac{dv_{\mathrm{tr}}}{dt}=F_{\mathrm{tr}}-R(v_{\mathrm{tr}})=\sum_{i=1}^{4}F_{\mathrm{ad}i}-R(v_{\mathrm{tr}}) \tag{13}$$

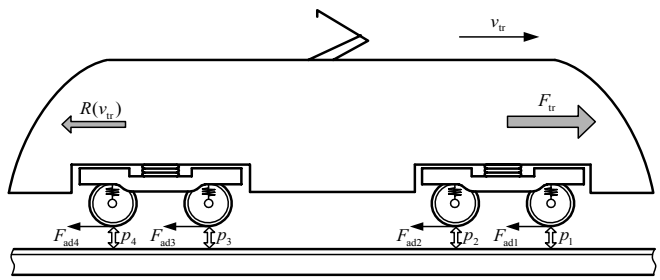

Figure 3. Locomotive traction dynamic model.

Where F_{tr} is the total traction force; F_{adi} are the adhesion forces, $F_{adi} = \mu \cdot p_i$, $T_{adi} = F_{adi} \cdot r_w$, $(i = 1 \sim 4)$; r_w is the wheel radius; μ is the adhesion coefficient; v_{tr} is the train speed (m/s); $R(v_{tr})$ is the running resistance, and the $R(v_{tr})$ can be described by the following expression according to TB/T1407-1998.

$$R(v_{tr}) = [1.02 + 0.0035 \times (3.6 \cdot v_{tr}) + 0.000426 \times (3.6 \cdot v_{tr})^2 \,] \times Mg / 1000$$

2.4 Adhesion coefficient and slip velocity

When the motor traction torque is added to the running wheelset, there is a tangent movement between the wheel and the track on their contact surface. The tangent velocity mentioned above is called slip velocity and can be defined as following:

$$v_{slip} = v_{wh} - v_{tr} = \theta_w \cdot r_w - v_{tr} \tag{14}$$

The adhesion coefficient is assumed to be as bellow (Yoshiki Ishikawa, 1997):

$$\mu(v_{slip}) = a \cdot \exp[-b \times (3.6 \cdot v_{slip})] - c \cdot \exp[-d \times (3.6 \cdot v_{slip})] \tag{15}$$

The values of the parameters *a, b, c* and *d* depend on the rail surface conditions between the wheel and the frictional surface. Table 1 gives the parameters used in this paper. Figure 4 illustrates $\mu(v_{slip})$.

Table 1. Parameters for adhesion coefficient in formula (15).

	a	*b*	*c*	*d*
Dry condition	0.53	0.12	0.53	2.40
Wet condition	0.60	0.20	0.60	0.65

3 SIMULATIONS FOR STICK-SLIP VIBRATION

Based on the models and equations in chapter 2, a simulation program is set up in MATLAB/SIMULINK, the scheme diagram is shown in Figure 5.

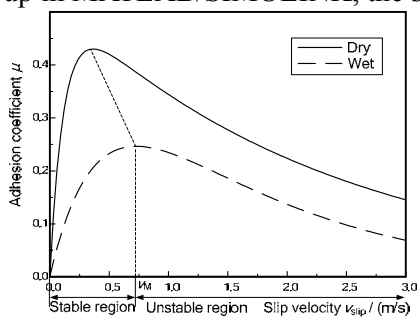

Figure 4. Adhesion coefficient curves in different track conditions.

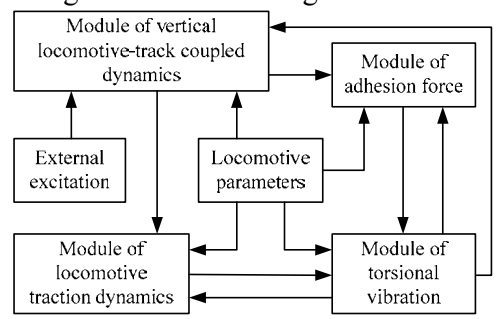

Figure 5. Scheme diagram for simulation.

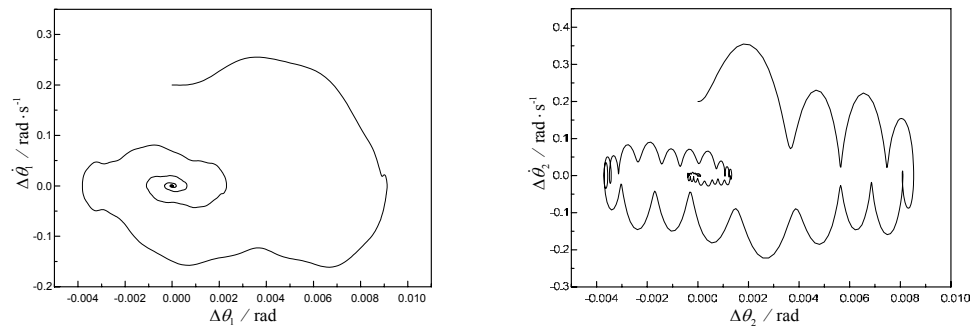
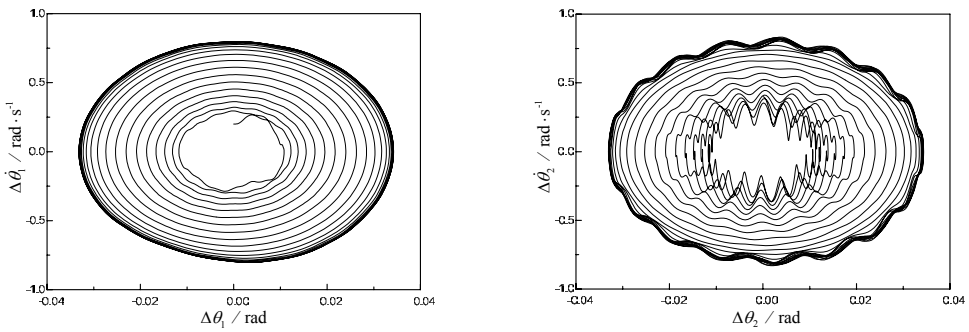
In this program, there are some modules: the module of locomotive traction dynamics and that of adhesion force can calculate the instantaneous slip velocity; the module of torsional vibration can calculate the drive system torsional dynamics and investigate the self-excited vibration by use of the phase plane method; the module of vertical locomotive-track coupled dynamics can calculate the locomotive vertical dynamics. In this paper, we mainly investigate the self-excited torsional vibration in the drive system; the effects of the self-excited vibration on the locomotive will be discussed in other papers. For the purpose of analyzing the self-excited vibration clearly, the wheel/rail excitation force is temporarily not considered in following calculations.

When the motor traction torque is at a low level, $v_{slip} < v_M$, the v_{slip} is located in the stable region (See Figure 4), where v_M is the slip velocity value corresponding to the maximum adhesion. Each phase trajectory of the hollow-shaft and wheelset (Shown in Figure 6) will be a curve which tends to the initial equalization point (0, 0), indicating that there are no self-excited vibrations occurring in the drive system. This is because the adhesion force between the wheel and the track acts as a positive damping when the slip velocity is located at the ascending slope of the adhesion coefficient curve (ZHENG Lianzhu, 1996), which constantly consumes energy, leaving the drive system in a steady state.



(a) Hollow-shaft (b) Wheelset

Figure 6. Phase diagrams of torsional vibrations when $v_{slip} < v_M$



(a) Hollow-shaft (b) Wheelset

Figure 7. Phase diagrams of torsional vibrations when $v_{slip} > v_M$

The slip velocity will increase with the increase of the motor output torque. When $v_{slip_0} > v_M$, the v_{slip_0} is located in the unstable region (See Figure 4), and each phase trajectory (Shown in Figure 7) will tend to a closed curve which is a limit cycle, indicating that a self-excited torsional vibration has occurred. The reason is that the adhesion force between the wheel and the track acts as a negative damping when the slip velocity is located at the descending slope of the adhesion coefficient curve (ZHENG Lianzhu, 1996), which provides energy to the system leading to the self-excited vibration and the phase trajectory will tend to the limit cycle.

4 CONCLUSIONS

In order to investigate the stick-slip vibration of the locomotive with the hollow-shaft drive system, a locomotive-track coupled dynamic model and a simulation program are established based on the theory of the vehicle-track coupled dynamics. Simulation results indicate that the stick-slip vibration will

occur when the slip velocity is located at the descending slope of the adhesion coefficient curve, and the drive system will be in steady state when the slip velocity is located at the ascending slope of the adhesion coefficient curve.

This simulation model could be used to forecast the self-excited torsional vibration of the locomotive drive system and the stability of the self-excited vibration. This model can lay a foundation for further research, such as adhesion control and locomotive dynamics considering the effect of drive system, etc.

ABSTRACT

Rubber tumbler locating nodes are widely used in railway vehicles as anti-vibration components involving both metal and rubber materials that last many years. It can well control vertical and lateral movements. Damage accumulation due to fatigue, significantly reduces the service life of the rubber tumbler locating nodes. Trains now travelling at higher speeds have led to a poor service environment. Many efforts have been made to optimize the design of rubber tumbler locating nodes. However, experimental methods are limited by costing a great amount of time and money to study the fatigue life of rubber tumbler locating nodes. It is essential to develop a new method to study rubber fatigue life. This paper proposes an effective fatigue life prediction approach for rubber tumbler locating nodes. A non-linear, multi-body model of a rail vehicle is combined with a finite element model of its bogie-frame. Loading histories at tumbler locating nodes were calculated and used as input of fatigue. Fatigue simulation was completed based on stress distribution and stress-time histories. It is shown that a quasi-static simulation for rubber tumbler locating nodes, using nonlinear software, can provide good indication for product design and failure analysis. It is also shown that this approach can be employed at a design stage for both metal and rubber fatigue evaluations.

1 INTRODUCTION

The ability of rubber nodes to control the vertical and horizontal moments has led to them being widely used in the railway vehicle industry. In recent years, the trend toward lighter vehicles and higher speeds has led to the the importance in studying the design and development of competitive vehicles. Because cumulative damage caused by fatigue can seriously reduce the rubber tumbler node service life, we have studied the performance of rubber tumbler node. Rubber tumbler nodes experiencing a sudden fatigue failure is often a threat to the vehicle suspension system. In more serious cases, it may even cause derailment accidentsleading to significant casualties and property losses. It is precisely these reasons that the domestic and foreign scholars have done significant research work in this field. Rubber tumbler nodes consist of metal plates bonded with rubber through a molding process resulting in its fatigue being more complex cthan metal fatigue. Because deformation of rubber materials shows strong similarities in geometry, physics, nonlinear and rubber components with the geometry of the complex, designers in the actual design process have no uniform method of calculation and design (Kim,1998;Oh,1980). In general, engineers have

two tools to assess fatigue toward rubber nodes: tests and simulations. Limited as they are, tests are not possible during the design phase of a new vehicle and require spending a great amount of time and money. With advances in computer technology, simulations based on FEA and multi-body dynamics offer a possibility to predict fatigue.

In this paper, the rigid-flexible coupling dynamic model has been modeled using the software SIMPACK. The fatigue load spectrum can be obtained through simulation with key parameters being studied to analyze the effects of fatigue. Some useful conclusions are drawn from the study. The fatigue design method in this paper can not only greatly shorten the development cycle of new products, but can also provide some guidance for the fatigue test and has a high practical value.

2 THE SIMULATION MODEL

The tumbler axle-box locating node in CRH2 was chosen as a basis for a case fatigue study consisting of rubber and metal.

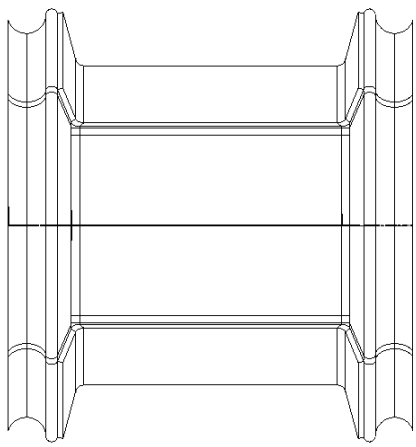

Fig. 1. the whole solid model.

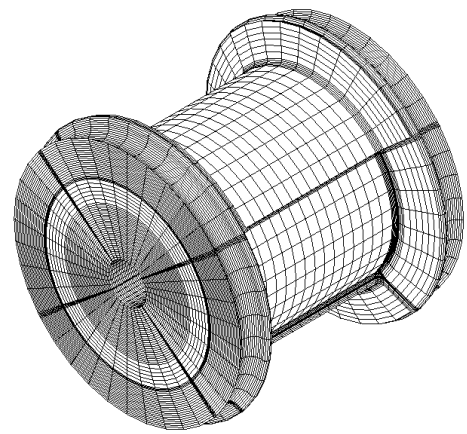

Fig. 2. the finite element model.

It is bonded with rubber and metal through a molding process displaying strong, non-linear mechanical properties. Because of the symmetry of the specimen, in this paper, only a quarter model of the specimen is established. Figure 2 shows the finite element model. The tumbler axle-box locating node is modeled by means of the commercial finite element software ANSYS, giving a model with approximately 23000 degrees of freedom. Solid186 elements represent the corrugated rubber and solid45 elements represent the corrugated metal.

2.1 MATERIALS PROPERTIES

The finite element analysis is used to study the stress distribution of the structure. In order to predict the stress, it is essential to select suitable material models and failure criteria. Rubber is a hyper-elastic material whose mechanical properties are affected not only by the external load but also by time and

temperature. In resent years, there are several hyper-elastic material models that are often used to describe rubber materials based on strain energy potential or strain energy density. The strain energy function can be expressed by the following polynomial series (Ogden,1984):

$$U = \sum_{i+j=1}^{N} C_{ij} \left(\overline{I}_1 - 3\right)^i \left(\overline{I}_2 - 3\right)^j + \sum_{i=1}^{N} \frac{1}{D_i} \left(J_{el} - 1\right)^{2i} \quad (1)$$

Where C_{ij} and D_{ij} are temperature dependent material parameters, J_{el} is the elastic volume strain, $\overline{I}_1$ and $\overline{I}_2$ are the strain are invariant. If $N = 1$, the polynomial formation will become the Mooney-Rivlin hyperelasticity model. The energy potential is as follows:

$$U = C_{10} \left(\overline{I} - 3_1\right) + C_{01} \left(\overline{I}_2 - 3\right) + \frac{1}{D_1} \left(J_{el} - 1\right)^2 \quad (2)$$

The Mooney-Rivlin form was used to model the rubber material. The material constants in Eq.(2) can be determined from experiments (Luo RK,2000; Luo RK,2001). The material constants in Eq.(2) may also be obtained from previously established databases of similar rubber material specimens. Calculating the fatigue life of tumbler axle-box locating nodes require material S-N curves. The curve indicates material failure at a constant dynamic amplitude under a certain number of cycles. S-N curves are generally carried out using the standard fatigue test specimen.

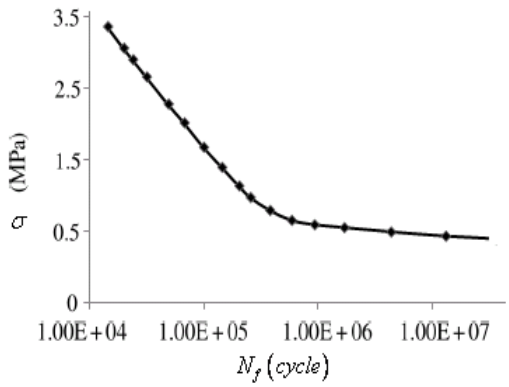

Fig. 3. rubber material S-N curve.

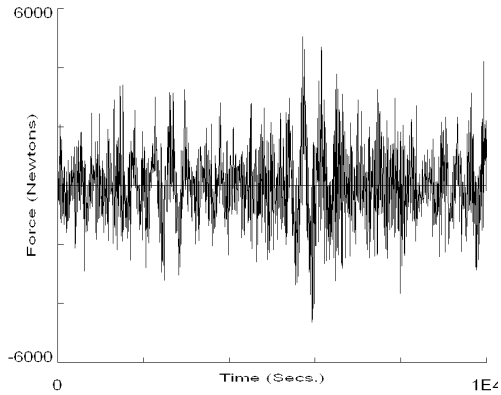

Fig. 4. fatigue load spectrum.

In this paper, material S-N curve is obtained by experiment, shown in Figure.3.

2.2 Fatigue load spectrum

In order to maintain fatigue analysis accuracy, the loading time histories must be able to reflect the actual work condition. In general, loading time histories are measurements of loading for a period of time which must be long enough to

ensure that the measurement reflects a typical duty cycle. However, experiments testing load spectrum require spending a great amount of time and money. In this paper, a rigid-flexible, multibody model of the vehicle including carbody, suspension, bogie and track was set up using the commercial software SIMPACK. The whole vehicle system has 60 degrees of freedom excluding the flexible degrees of freedom. The stress time histories, which indicate the critical locations, are extracted from the simulation results. The stress time histories for the critical locations are translated into input fatigue load spectrum through the rain-flow counting method. The rain-flow counting method, which is considered the non-linear relationship between material stress and material strain, was first introduced by Matsuiski and Endo and has a strong engineering practicability. Through these above processes, random fatigue load spectrum is obtained, shown in Fig.4.

3 NUMERICAL ANALYSIS

3.1 Stiffness Analysis

Rubber nodes are a typical rubber elastic structure working in a pre-stressed state. In this state, the performance of the tumbler axle-box locating node will become extremely complicated. The design of the structure must meet the matching requirements of stiffness making it essential to study the relationship between the performance and radial pre-displacementleading to conclusions that can help the engineering design.

3.1.1 Characteristics radial stiffness

This section studies the influence of pre-displacement on the radial stiffness is studied. According to the symmetry of model structure and load, a quarter model is set up to calculate the stiffness characteristics, which can greatly reduce the simulation time.

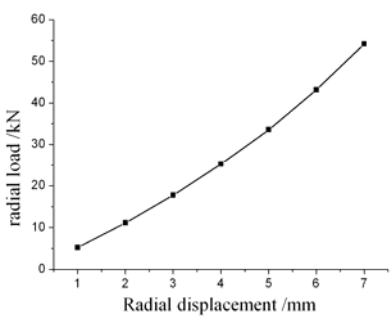

Fig. 5. load and displacement curve.

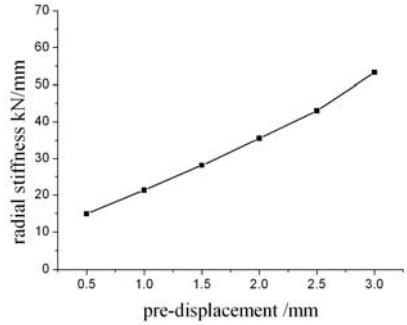

Fig. 6. stiffness and pre-displacement curve.

Fig.5 and Fig.6 show that the radial stiffness increases as the

pre-displacement increases. Radial non-linear properties of tumbler axle-box locating node show more strongly. At the same time, no matter how pre-displacement is applied, its performance often has a certain range of radial linear stiffness; however, when the pre-displacement increases, the scope of the linear stiffness becomes increasingly narrow.

3.1.2 Characteristics of Axial Stiffness

According to the present thesis, pre-displacement will affect axial stiffness. One simple explanation is that the pre-displacement will affect the internal stress distribution; however, the relationship between the axial stiffness and the pre-displacement needs to be studied more carefully. A set of numerical simulations of axial stiffness with different pre-displacements are used.

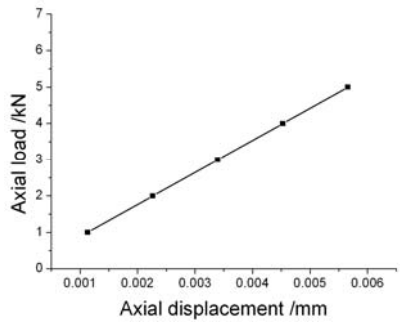

Fig. 7. load and displacement curve.

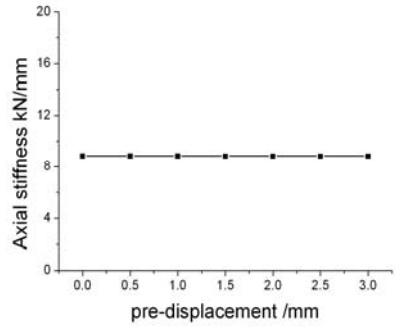

Fig. 8. axial stiffness and pre-displacement curve.

Fig.7 and Fig.8 show that the axial stiffness changes little as the pre-displacement increases. However, the axial stiffness maintains a downward trend, when increasing the pre-displacement and stability of tumbler axle-box locating nodes decreases. In order to improve product stability, it is agreed that the axial performance should stay at a flexible stage.

3.2 Fatigue Life Prediction

In this section, the influence of several factors on the fatigue damage of the tumbler axle-box locating node is studied, using the finite element software ANSYS (ANSYS, 2006).

The pre-displacement of the tumbler axle-box locating node will affect the fatigue damage so it is essential to carefully study the relationship between fatigue life and the stiffness. Some numerical simulations of the tumbler axle-box locating node with different stiffness are calculated.

Fig.9 and Fig.10 show the damage accumulation increase as the pre-displacement increases. In other words, the fatigue life decreases with increasing pre-displacement. The effect of pre-displacement is more significant at the small size pre-displacement stage.

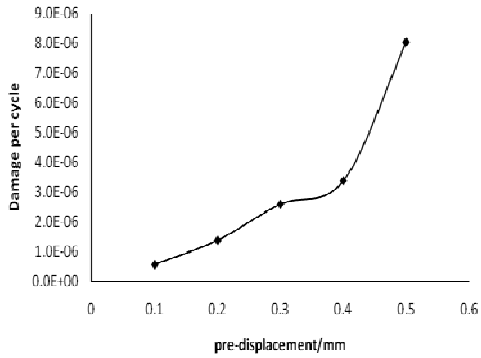

Fig. 9. relation between damage and pre-displacement.

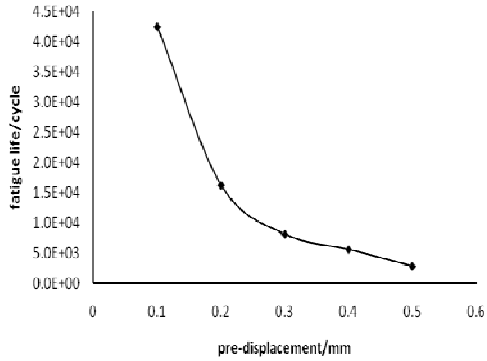

Fig. 10. relation between life and pre-displacement.

4 CONCLUSION

A rigid-flexible multibody model is set up in order to analyze fatigue life of tumbler axle-box locating node, a method used to study the effect of several parameters, namely pre-displacement, on fatigue damage. It is shown that this quasi-static simulation can provide an efficient method of predicting fatigue life of rubber material. Numerical simulation shows that stiffness and fatigue life are significantly affected by pre-displacements. So we should choose suitable pre-displacement in order to prolong life and good dynamic performance for rubber tumbler locating nodes.

ABSTRACT

Google Earth has masses of satellite image data, geographic information, and the functional KML interface. By employing these features, this paper realizes GPS serial-port communication, static and dynamic GPS accuracy analysis, GPS error offset, and GPS information publishing are more convenient and effective in offsetting the system error and improving GPS accuracy than traditional methods. Moreover, it brings a vivid and friendly presentation in publishing GPS information with supported satellite image data.

INTRODUCTION

In recent years, automobile and mobile telephones play significant roles in social activities (Colombo OL, Evans AG, 1998). To meet the sharply increasing needs for positioning, GPS (Global Positioning System) technology and applications are widely used in industriesthat improve economics of the society.

The essence of a GPS application is the displaying of the geographic location of a target, including obtaining and publishing information. It is important to check the accuracy of GPS sensors for the distinction among GPS sensors in production. Generally, it is necessary to access the longitude and latitude of a specific location to operate an experiment to verify GPS accuracy. Moreover, to improve the accuracy, differential GPS experiment requests even more specific spots, and GPS sensors have to be set in the exact places. For traditional information publishing, a visual representation of data and graphics is supported by GIS (Geographic Information System).

Though both methods mentioned are effective in obtaining and publishing GPS information, they have flaws. Traditional experiments verifying GPS accuracy request the exact location to place the sensor. Likewise, the existing methods for publishing GPS information demand support by a GIS map, which has to be formed in advance based on a massive data acquisition and is not always accurate enough for location verification. However, the emergence of Google Earth provides a high resolution remote sensing image, which is free and capable of meeting the needs for clearly spotting the target in most of the city. With the support of the Google Earth platform, an accurate location can be achieved, and

the combination of the vivid remote sensing image from Google Earth and graphics from the GIS offers a new option in research (MR Craymer, 1990).

APPLICATION REALITY OF GPS

Raw data parsing.

Almost all the datagram from GPS sensors are in accord with NMEA-0183 protocol, an international standard protocol formed by NMEA (National Marine Electronics Association). In this research, a portable MG/MGL-30 GPS receiver is chosen for its convenience of storing data, which transmits by simulating serial-port communication based on USB Communication Technology (Han S, 1997). Its communication configuration is shown in Table 1.

Table 1. Serial-port communication configuration settings.

Parameter configure	Baud rate	Data bit	parity checkout	Stop bit
value	4800	8	Null	1

NMEA-0183 has its grammar to parse every message. After setting the correct configuration in Table 1, raw data can be received. According to practical demand, it is necessary to parse the message with its beginning "$GPRMC," which is the briefest message to obtain time and geographic information. Thus, the flow chart below (see Figure 1) is designed to parse the "$GPRMC" message in order to store time and geographic data into a database.

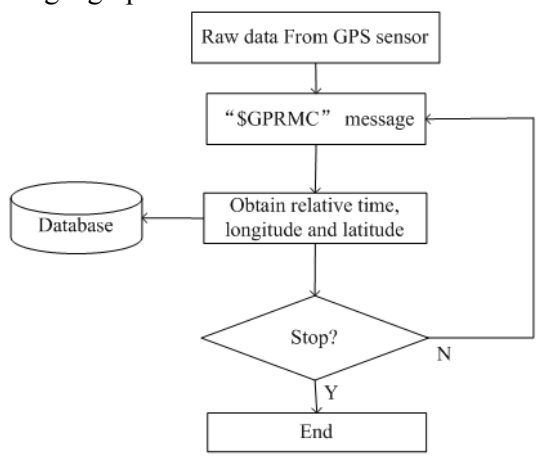

Figure 1. Flow chart of raw data parsing.

Static GPS Accuracy Analysis.

The accuracy of the location position sent by the GPS sensor is influenced by many factors, such as the available number of satellites, the specific satellites, and even the weather and circumstance. Besides the static accuracy, different GPS sensors cause different output delay. As a sequence, dynamic offset could bring considerable error. However, under a similar environment, a GPS sensor presents a stable accuracy.

After Data Extraction from GPS raw data, the relative time, longitude and latitude can be found in database. Then, this information is transferred into KML files so as to be imported into Google Earth software. Compared with the actual spot where the GPS sensor is placed, static offset can be calculated. The static accuracy analysis flow chart (see Figure 2) is below.

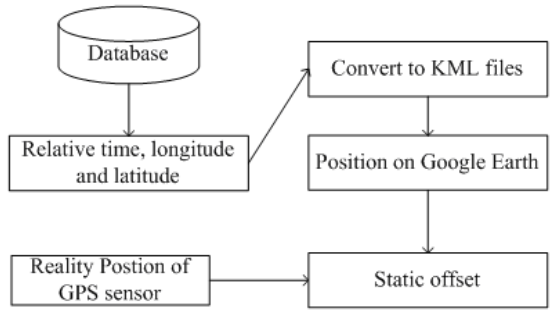

Figure 2. Flow chart of static GPS accuracy analysis.

An experiment has been done at the centre square of the School of Engineering (23°04'00"N 113°22'51"E), Sun Yat-sen University.

Environment: Sunny, Receiving 6-7 effective satellites, 5 minutes of experiment time, 1 time/s of sampling rate; Analysis: The static data of GPS, which distribute in a circle with 5 meter diameter, are shown in Figure 3.

Longitude offset: 00°00'08". Latitude offset: 00°00'24". Distance offset: 7.39m.

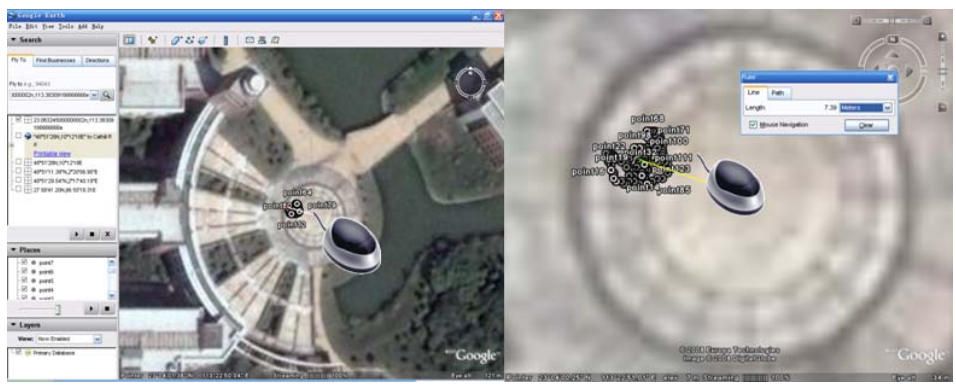

Figure 3. Experiment of static GPS accuracy analysis.

Dynamic GPS Accuracy Analysis.

Besides the static offset, dynamic error exists when it is operated in navigation, for the delay of output data. When a GPS device is mounted on a vehicle, a distance offset caused by a dynamic time delay can not be neglected. It seems difficult to find out the exact time delay directly. However, by taking advantage of a simple formulation “T= S/V”, a technique flow chart (see Figure 4) can be used to obtain time delay indirectly.

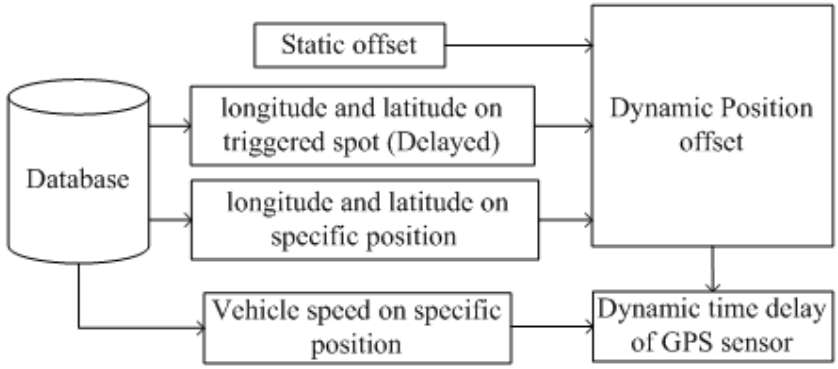

Figure 4. Flow chart of dynamic GPS accuracy analysis.

A dynamic experiment has been done on a laboratorial lane at the School of Engineering at Sun Yat-sen University (see Figure 5). When the vehicle, equipped with mounted a GPS sensor, passed the specific point, events were triggered: the time was marked down, longitude and latitude was stored, and the speed was recorded. Somehow triggered position is not exact the location of the specific point but the delayed one. After comparing it with the correct coordinates, the dynamic position offset could be obtained. Then, the dynamic time delay could be calculated with the vehicle speed.

As a result, an average speed of 38 km/h, caused a 16.5 meter dynamic offset, implying the GPS sensor had a time delay of about 1.5 seconds.

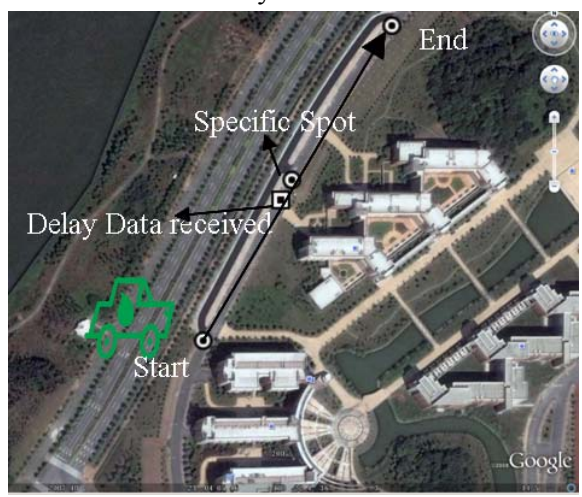

Figure 5. Experiment of dynamic GPS accuracy analysis.

KML Interface in Google Earth.

The layers of map data, landmarks, and other additional information of Google Earth are organized by KML (Keyhole Markup Language) or KMZ files. Google declared that the control of the KML would be open to public after the OOXML (Office Open XML file formats) from Microsoft became an international standard in April, 2008 (Google KML format, 2008). Then, the OGC has taken over the KML, and the KML used in Google Earth and Google Maps

also became an international standard (Google Earth. KML 2.1 Reference, 2007).

KML, which is proposed by Google, is a kind of language and file format based on XML (eXtensible Markup Language). It can be used to store various kinds of information, such as point, polyline and image, and can be used to display the information for the client of Google Earth. KML provides the interfaces for data cross operation, laying stress on the organization of data and the display styles of image and graphic to be loaded into Google Earth for display (Chen Ruixiang et al, 2007).

The GPS data must be transformed before being loaded into Google Earth. The format of the KML file used for the transformation of coordinates is shown by Fig. 6.

Realization Method of GPS Information Release.

The experimental technique proposed in this paper is an error-analysis technique of GPS data based on the Google Earth and is also a kind of method of GPS information release. It can be achieved in the field of vehicle navigation systems and positioning, and safety monitoring based on GPS. For instance, the vehicle navigation information can be sent wirelessly to the server. The server will then transform the GPS data into KML file, showing clients the position of the vehicle on Google Earth platform. As a result, the driver can obtain the real-time navigation information. Extending techniques like these can combine the aerial data from Google Earth, not only reflecting the real-time performance, but also making the information display direct and abundant (see Figure 7).

Figure 7. GPS Information Release.

CONCLUSION

This paper puts forward an experimental technique for dynamic-static error analysis of GPS based on the Google Earth platform. After acquiring and analyzing messages from the receiver, the positioning accuracy of GPS can be improved through reducing system error. It is more direct and rapid compared with the traditional technique. Meanwhile, the technique combined with the Google Earth is superior to the traditional method of information release in the field of GIS.

It is worth noting that the data of Google Earth is soured from aerial images and its error varies in different areas. Therefore, the "correct coordinate" used in this paper tends to adapt the display coordinate of the Google Earth software. And the system error of Google Earth is almost the same in a specific area so that the works can be achieved despite system error.

ABSTRACT

Based on the study of the 1/2 vehicle body of a semi-active suspension with fuzzy control, and taking into consideration such factors as engine and "passenger-seat" system, an automotive dynamic model of 1/4 vehicle body with 4-DOF is created. A parameters-self-tuning fuzzy PID controller is designed for the semi-active hydraulic suspension of the 1/4 vehicle body. The results of simulation by MATLAB/Simulink software show that the high-frequency constant engine excitation has little effect on acceleration of the vehicle seats, and the fuzzy PID controller is more self-adaptable than the fuzzy controller; therefore, ride comfort of the vehicle is better.

1 INTRODUCTION

The design of the automotive suspension system is an essential part concerning the study of automotive dynamics, which is of great importance in improving automotive performances, such as ride, comfort and handling stability. The spring constant and damping coefficient of the passive suspension system are not variable; therefore, it is hard to produce the shock-absorbing effect required by modern automobiles. The semi-active suspension system reduces the vibration of vehicle body and seats, with the spring constant and damping independently adjusted. Compared to active suspension system, it is simple in structure, hardly consumes the power from the system while in operation, and does not produce resonance of the unsprung mass. Its performance is almost equally effective as that of the active control. As a result, it will find a good application(Song et al, 2003).

Currently, many studies done on semi-active suspension systems are based mostly on the 1/4 vehicle body model with 2-DOF. In this type of model, consideration of the affects on ride comfort is only taken of the vehicle body, tire, suspension and road excitation, without considering the engine vibration and "passenger-seat" system. Therefore, it does not reflect the accurate load the vehicle body is subjected to and its dynamic model is confined to a certain degree. Based on our studies of the active and semi-active suspensions , we established

the 1/4 vehicle model of 4-DOF, with comprehensive consideration of many involved factors, such as vehicle body, tire, engine, seat, passenger and suspension, etc.

2 1/4 VEHICLE MODEL WITH 4-DOF

For the convenience of the study, and to be applicable to the real situation of a vehicle, the 1/4 vehicle body is simplified as a vibrating system, as shown in Figure 1, where m_1、m_2、m_3 and m_4 stand respectively for the unsprung mass, mass of the vehicle body, mass of the engine and mass of the passenger, z_1、z_2、z_3、z_4 respectively for their vertical displacement, k_1、k_2、k_3、k_4 respectively for the spring constants of the tire, the suspension, engine support and seat, and c_1、c_3、c_4 respectively for the damping coefficients of the tire, engine support and seat, A_s for the orifice area of the controllable throttle, z_0 for the excitation from the road surface, F for the exciting force of the engine.

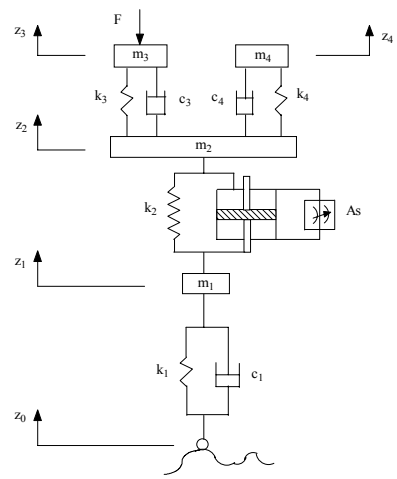

Figure 1. 1/4 vehicle model with 4-DOF.

According to Newton's second law, the dynamic equation of the 1/4 vehicle body with 4-DOF is:

$$\begin{cases} m_1\ddot{z}_1 = k_1(z_0 - z_1) + c_1(\dot{z}_0 - \dot{z}_1) - \left[k_2(z_1 - z_2) + f_d\right] \\ m_2\ddot{z}_2 = k_2(z_1 - z_2) + f_d - \left[k_3(z_2 - z_3) + c_3(\dot{z}_2 - \dot{z}_3) + k_4(z_2 - z_4) + c_4(\dot{z}_2 - \dot{z}_4)\right] \\ m_3\ddot{z}_3 = k_3(z_2 - z_3) + c_3(\dot{z}_2 - \dot{z}_3) - F \\ m_4\ddot{z}_4 = k_4(z_2 - z_4) + c_4(\dot{z}_2 - \dot{z}_4) \end{cases}$$

(1)

$$f_d = A_s(p_1 - p_2) = c(\dot{z}_1 - \dot{z}_2)$$

(2)

Replacing these physical variables in the system dynamic equation with state variables, let

$$x_1 = z_1,\ x_2 = z_2,\ x_3 = z_3,\ x_4 = z_4,\ x_5 = \dot{z}_1,\ x_6 = \dot{z}_2,\ x_7 = \dot{z}_3,\ x_8 = \dot{z}_4$$

$$\boldsymbol{X} = \{x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8\}^T \tag{3}$$

then the equation of the system state is

$$\dot{\boldsymbol{X}} = \boldsymbol{AX} + \boldsymbol{BU} + \boldsymbol{CF} \tag{4}$$

$$\boldsymbol{A} = \begin{Bmatrix} 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ -\frac{k_1+k_2}{m_1} & \frac{k_2}{m_1} & 0 & 0 & -\frac{c_1+c}{m_1} & \frac{c}{m_1} & 0 & 0 \\ \frac{k_2}{m_2} & -\frac{k_2+k_3+k_4}{m_2} & \frac{k_3}{m_2} & \frac{k_4}{m_2} & \frac{c}{m_2} & -\frac{c+c_3+c_4}{m_2} & \frac{c_3}{m_2} & \frac{c_4}{m_2} \\ 0 & \frac{k_3}{m_3} & -\frac{k_3}{m_3} & 0 & 0 & \frac{c_3}{m_3} & -\frac{c_3}{m_3} & 0 \\ 0 & \frac{k_4}{m_4} & 0 & -\frac{k_4}{m_4} & 0 & \frac{c_4}{m_4} & 0 & -\frac{c_4}{m_4} \end{Bmatrix}$$

$$\boldsymbol{B} = \begin{Bmatrix} 0 & 0 & 0 & 0 & \frac{k_1}{m_1} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{c_1}{m_1} & 0 & 0 & 0 \end{Bmatrix}^{\mathrm{T}}$$

$$\boldsymbol{C} = \begin{Bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & -\frac{1}{m_3} & 0 \end{Bmatrix}^{\mathrm{T}}$$

where, $\boldsymbol{U} = \{z_0, \dot{z}_0\}^{\mathrm{T}}$, p_1、p_2 stand respectively for the pressure exerted on the up-chamber and down-chamber of the hydraulic cylinder, c for the damping coefficient of the controllable damper

3 DESIGN OF THE SELF-ADAPTABILITY FUZZY PID CONTROL SYSTEM

The ride comfort of a vehicle is directly related to the control strategy of the semi-active suspension. The fuzzy control is of better robustness and can better overcome some uncertainties in the system; however, its control precision is low. The typical PID control is of simple structure, high precision, and has a good control performance for the linear system (Chen et al, 2008). The fuzzy PID control used in this study combines the fuzzy control and typical PID control, making the system faster, with better robustness and higher control precision.

Based on the 1/4 vehicle model with 4-DOF, the speed error of vehicle body e and its rate of change ec are used as the inputs of the fuzzy controller, and 3 gain parameters Δk_p、Δk_i and Δk_d of the PID controller as the outputs. The fuzzy PID controller can adjust online the three parameters according to the fuzzy control principle, and the damping force of the hydraulic damper is changed with the variation of the opening area of the throttle orifice under control so as to produce the damping force in accordance with the running conditions of motor

vehicle, thus achieving the control over the vibration of the vehicle body. The structural theory of the fuzzy PID control system over the 1/4 vehicle body with 4-DOF is shown as in Figure 2.

The basic universes of the input and output variables should respectively be determined according to the maximum value of the road disturbance and the

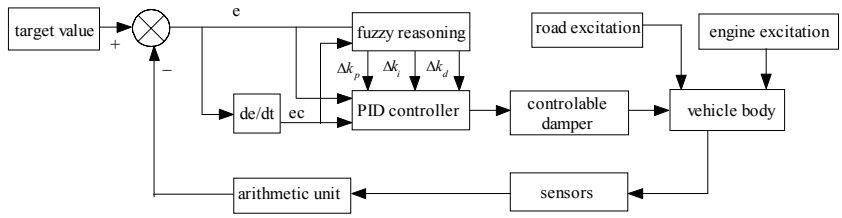

Figure 2. Block diagram of the fuzzy PID control system.

capacity
of maintaining a good performance of the suspensions while running on a rough road. Through the computer simulation of the road condition, the basic universes of the two input variables are taken as $e \in [-3,3]\,\mathrm{m/s}$ and $ec \in [-3,3]\,\mathrm{m/s^2}$, and their fuzzy sets are classified into (NB, NM, ZE, PM, PB). The basic universes of the output variables are $\Delta k_p \in [0,3]$、$\Delta k_i \in [0,3]$、$\Delta k_d \in [0,3]$, and their fuzzy sets are classified into (NB, NM, NS, ZE, PS, PM, PB). The membership functions of input and output variables are assumed to be triangular types.

The role of the proportional coefficient of the PID controller is to increase the response speed and precision of the system and the role of the integral coefficient is to eliminate the static error of the system. The role of the differential coefficient is to improve the dynamic property of the system. The rules of fuzzy control are designed according to the PID control rules and fuzzy control theory. The tuning rules of three parameters are performed as Table 1.

Table 1. Rule table of fuzzy control.

$\Delta k_p / \Delta k_i /$ Δk_d		EC				
		PB	PM	ZE	NM	NB
E	PB	NB/ZE/PB	NB/ZE/PS	NS/ZE/PM	ZE/ZE/PS	PS/ZE/PB
	PM	NB/NB/PB	NB/NM/PM	NS/ZE/PS	PS/PS/PS	PMPS/PM
	ZE	NM/NB/PS	NS/NM/PS	ZE/ZE/ZE	PM/PM/PS	PM/PS/ZE
	NM	ZE/NS/ZE	ZE/NS/NS	PS/ZE/NM	PB/PM/PM	PB/PB/PM
	NB	ZE/ZE/NS	ZE/ZE/NS	PS/ZE/NM	PB/ZE/PS	PB/ZE/PB

The output variables use the centre of gravity method for defuzzification. The

calculating formulas of on-line tuning PID parameters are:

$$\begin{aligned} k_p &= k'_p + \Delta k_p \\ k_i &= k'_i + \Delta k_i \\ k_d &= k'_d + \Delta k_d \end{aligned} \tag{5}$$

where k_p、k_i and k_d are the final control parameters at the PID control, and k'_p、k'_i and k'_d are the initial parameters at the PID control. After testing and adjustment, it is determined that $k'_p = 34$, $k'_i = 0.9$, $k'_d = 0.6$.

4 TIME DOMAIN MODEL OF THE ROAD ROUGHNESS EXCITATION AND ENGINE EXCITATION

4.1 Time domain model of the road roughness excitation

The road power spectral density is used to describe the statistical characteristic of the road roughness, which is taken as the inputs causing vehicle vibration. The road displacement power spectral density recommended by GB7031-86 is in the following form (Yu, 2007)

$$G_q(n) = G_q(n_0)(\frac{n}{n_0})^{-W} \tag{6}$$

where n is the space frequency, n_0 is the referential space frequency. $G_q(n_0)$ is road roughness coefficient. W is the frequency index，taken as W=2. Considering the effect of the vehicle speed, the space spectral density can be converted into the time spectral density, and the result is

$$G_q(f) = G_q(n_0)n_0^2\frac{v}{f^2} \tag{7}$$

where f is the time frequency, v is the vehicle speed. Hence,

$$G_{\dot{q}}(f) = (2\pi f)^2 G_q(f) = 4\pi^2 n_0^2 G_q(n_0)v \tag{8}$$

$$G_{\ddot{q}}(f) = (2\pi f)^4 G_q(f) = 16\pi^4 n_0^4 G_q(n_0) f^2 v \tag{9}$$

It can be seen from the equation (8) that the road input speed power spectrum is a constant at the entire frequency range that is “white noise.” Therefore, the way to produce the random road roughness outline is to allow the white noise to pass a filter, and as a result, the road excitation exerted on wheel can be expressed by the differential equation

$$\dot{z}_0 = -2\pi f_0 z_0 + 2\pi n_0\sqrt{G_q(n_0)v}w(t) \tag{10}$$

where f_0 is the lower end frequency of road input, normally taken as 0.1Hz,

$w(t)$ is the white noise at mean value 0 and power 20dB.

Grade B and Grade C roads of China account for a large proportion; therefore, Grade C road is taken as the excitation input in this simulating test, hence road roughness coefficient is 128×10^{-6} m^2/m^{-1}. Figure 3 shows the excitation single to the vehicle when running at a speed of 25m/s.

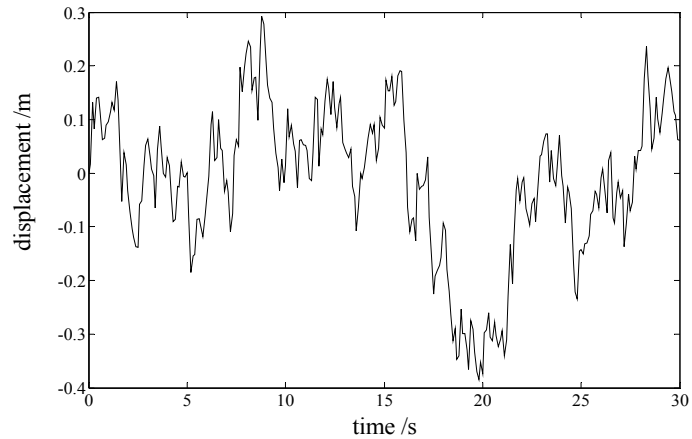

Figure 3. The C-grade road signal.

4.2 TIME DOMAIN MODEL OF ENGINE EXCITATION

The rotating speed of the engine is usually under 6000r/min, and its vibrating source is mainly the second-order mechanical vibration and therefore its frequency is normally under 200Hz. The engine vibration frequency is taken as 25 Hz in the simulating test, using $F = 200\sin 157t$ N sinusoidal to simulate the exciting force of the engine vibration.

5 ANALYSIS OF THE RESULT OF THE SIMULATING TEST

Use MATLAB/Simulink to do computer simulation of the model system. The vehicle model selected is the Red Flag CA 7460 automobile produced by the No 1 Changchun Automobile Works. Its structural parameters are shown as in Table 2.

Table 2. Structural parameters of the Red Flag CA7460.

m_1 / kg	m_3 / kg	k_1 / N· m^{-1}	k_3 / N· m^{-1}	c_1 /(N·s)·m^{-1}	c_3 /(N·s)·m^{-1}
150	120	800	10000	150	3000
m_2 / kg	m_4 / kg	k_2 / N· m^{-1}	k_4 /N· m^{-1}	c_2 /(N·s)·m^{-1}	c_4 /(N·s)·m^{-1}
1800	65	4000	500	2546	150

Table 3 shows the result of simulation of the semi-active suspensions using two different strategies of fuzzy control and fuzzy PID control. Figures 4 and 5 are the graphs of displacement and acceleration of the passenger and vehicle body with engine excitation under fuzzy PID control, while Figure 6 is the graph of acceleration of the passenger with and without engine excitation under fuzzy PID control. Figures 7, 8 and 9 are respectively the graphs of acceleration of passenger,

dynamic load of tire, and dynamic flexibility of suspension under fuzzy PID control and fuzzy control.

Table 3. RMS comparisons of the fuzzy and fuzzy PID control suspension

suspension		fuzzy control	fuzzy PID control
acceleration /m·s^{-2}	passenger	0.0438	0.0357
	vehicle body	0.0624	0.0470
dynamic load /N		69.505	54.575
dynamic flexibility /m		0.019	0.0108

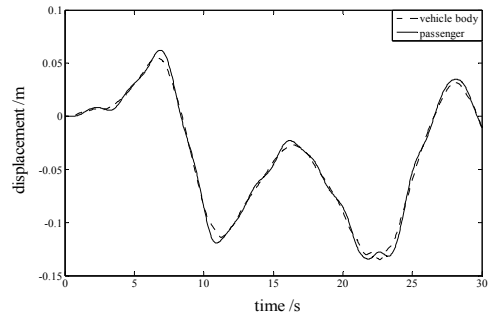

Figure 4. The displacement of passenger and vehicle body.

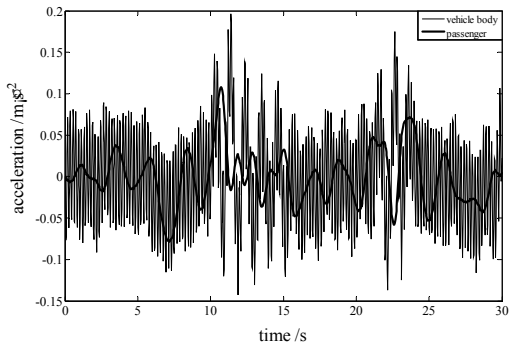

Figure 5. The acceleration of passenger and vehicle body.

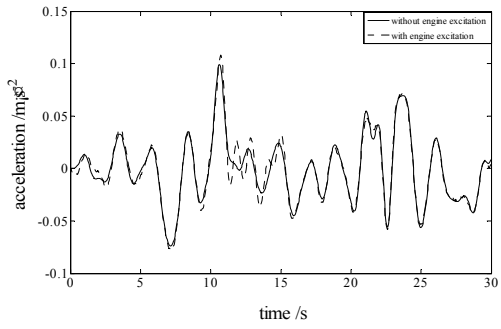

Figure 6. The acceleration of passenger with/without engine excitation.

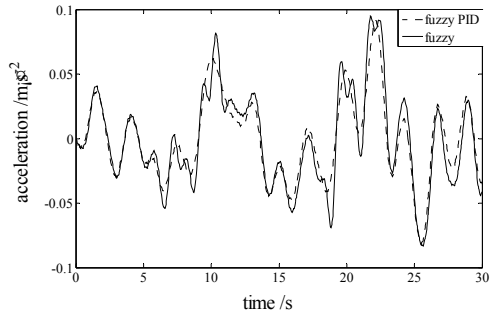

Figure 7. The acceleration of passenger under fuzzy PID/fuzzy control.

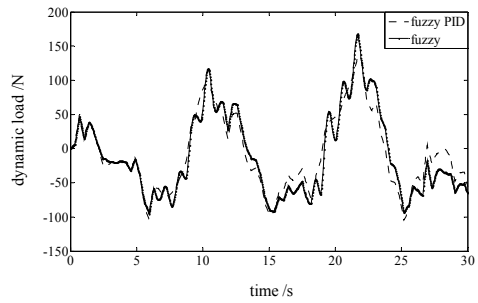

Figure 8. The dynamic load under fuzzy PID/fuzzy control/

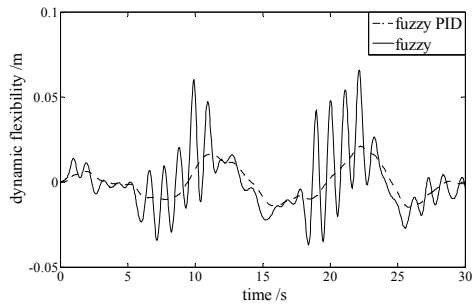

Figure 9. The dynamic flexibility under fuzzy PID/fuzzy control.

6 CONCLUSIONS

(1)The passenger vibration displacement is in perfect harmony with that of suspension, which shows the ride comfort is greatly improved.

(2)The connection between the seat and the suspension is simplified as the connection of the spring and damper. The peak value of its displacement is a bit higher than that of the rigid connection, but the peak value of its acceleration is reduced by 44.931%, which shows the structure of spring and damper is acceptable.

(3)The engine excitation is approximately a high-frequency constant, one compared with the road excitation, and when they both exert on the vehicle body, the RMS of passenger acceleration increases only by 2.61% more than the RMS without engine excitation.

(4)Compared to fuzzy control, fuzzy PID controller reduces the RMS of such

ride comfort values as dynamic load of tire, dynamic flexibility of suspension, etc, to 21.480% and 43.158% respectively, which shows the good self-adaptability of the fuzzy PID control system.

Study On Power Control Of Electric Power Steering System

Chunyan Mu[1], Jingnuo Yu[1], Wansheng Zhao[1], Jianxia Liu[1]

[1] Key Lab of Advanced Manufacturing & Automation Technology, Ludong University, P.O. Box 264025, Yantai Shandong Province, China; PH(+86)13220933388; email: muchunyan1@163.com

ABSTRACT

The method of the proportional control power is analyzed. The oscillations of an Electric Power Steering System are found. On these bases, the improvement measures of the power control carried on a differential calculus compensate is proposed. Proportional plus differential calculus control is designed. Analysis results show that the design of the proportional plus differential calculus control of the power control has a good function. The test shows that the control means is valid, and has a guiding significance to the development of electric power steering.

INTRODUCTION

An electric power steering system relies on electric motors to provide the impetus. EPS, compared with the traditional hydraulic power, to save fuel and improve stability, is beneficial to the environment (Man,H. L,2005). This paper studies the power control methods of an electric power steering system. Using proportional control methods with electrical power steering, the driver will feel a clear vibration in the steering wheel and reduced the stability. The adoption of proportional plus differential calculus control methods can significantly improve performance.

1 ELECTRIC POWER STEERING SYSTEM

When turning, the torque sensor detects steering shaft torque, the speed sensor signal detects the speed signal with the importation of ECU. ECU will process these signals to determine the size and power steering torque to the motor issue directive (Lin Yi,2003). Through deceleration, motor torque from the electromagnetic clutch decelerates to add twisting bodies, plus adjusts the car's steering bodies so that the steering force can adaptto easily provide different help at different speeds to ensure that vehicles in low- speed turns have flexiblity andhigh-speed turns are stable and reliable.

2 ELECTRIC POWER STEERING SYSTEM MATHEMATICAL MODEL

To analyze an electric power steering system power control, the impact of gear-suffered ground as input, the inhabitants applied steering wheel torque on the driver steering wheel as output, and the time-domain response characteristics of

motor steering system represent electric power steering power characteristics of the system. Figure 1 is a power function of the motor control block diagram. We hope that the system can guarantee flexibility in low-speed turning and stability and reliability inhigh-speed turning (Lin Yi ,2001).

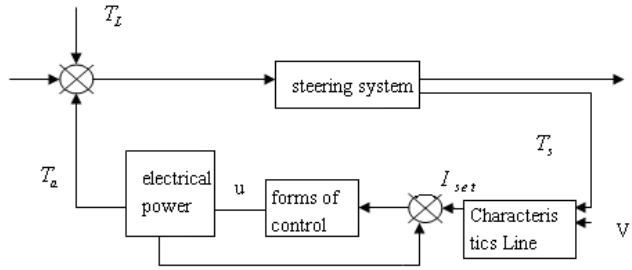

Figure1. Control system diagram.

The steering system dynamics analysis, gets the following equation:

$$T_S = K_s(\theta_h - \theta_c) \tag{1}$$

$$T_h - T_s = J_h \frac{d^2\theta_h}{dt^2} + B_h \frac{d\theta_h}{dt} \tag{2}$$

Where, T_h is imposed for the steering wheel on the steering torque; T_s is the torque sensor detecting the steering torque; K_s is the torque sensor stiffness; θ_h is fthe steering wheel angle; θ_c is equivalent for the front wheel to the steering axis angle; B_h is the steering shaft and bearings for the shift between the friction coefficient; J_h is the moment of inertia for the steering wheel.

For conditions in a tight corner, tire characteristics are linear, and steering resistance torque and the steering angle are in proportion.

That is:

$$T_L = K_c\theta_c \tag{3}$$

$$T_s - T_L = J_c \frac{d^2\theta_c}{dt^2} + B_c \frac{d\theta_c}{dt} \tag{4}$$

Where, T_L is equivalent to the shift shaft for steering resistance torque; K_c is equivalent to turning the front wheel axle cornering stiffness; J_c is the front wheel and steering mechanism to the steering column after the equivalent moment of inertia; B_c is the friction coefficient for the steering mechanism and front wheel equivalent to steering shaft .

The following formula helps determine motor on the steering system: (5)

$$T_m - \frac{T_a}{G} = J_m \frac{d^2\theta_m}{dt^2} + B_m \frac{d\theta_m}{dt} \tag{5}$$

$$T_m = K_T i_m \tag{6}$$

Where, T_m is the electric power generated by electromagnetic torque; G is electric power transmission ratio; T_a is power torque for the electrical power to the steering shaft; θ_m is electric Power Angle; i_m is motor power current; J_m is moment of inertia for power motor; B_m is the friction coefficient between the motor power shaft and the bearing; K_T is the coefficient for power motor electromagnetic torque.

The following formula determines motor current

$$u = Ri_m + L\frac{di_m}{dt} + K_E \frac{d\theta_m}{dt} \tag{7}$$

Where, u is motor armature control input voltage; K_E is the power motor counter electromotive force coefficient; R and L are motor power resistance and inductance respectively.

3 EPS MOTOR POWER CONTROL

3.1 PROPORTIONAL CONTROL MOTOR POWER

It can be assumed that the motor power control system is an ideal system when the relationship between the EPS motor power system dynamic performance and the proportional control is studied (Liu Zhao ,2003). Such an approach studies the transfer of function from the resistance torque input to maintain constant steering wheel angle of the steering wheel required torque. When the proportional control motor power and torque sensors detect volume proportionally, that is: $T_a = K_a T_s$, K_a is the power characteristic curve of the power coefficient. See Figure 2 showing EPS systems transfer function model structure.

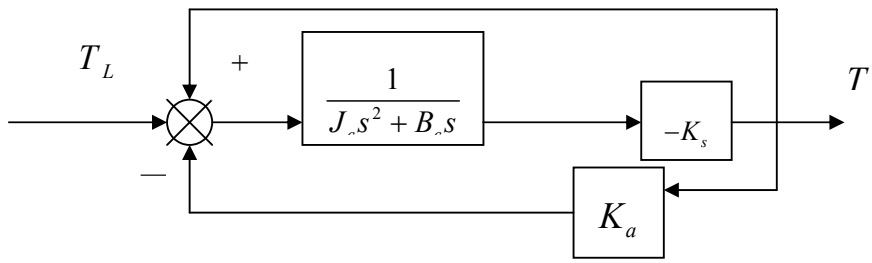

Figure 2. EPS system transfer function model structure diagram.

EPS system transfer function is:

$$G_{eps}(s) = \frac{T_h(s)}{T_L(s)} = \frac{K_s}{J_c s^2 + B_c s + K_s(K_a + 1)} \tag{8}$$

Oscillation frequency and damping coefficient are as follows:

$$\omega_n = [\frac{K_s(K_a+1)}{J_c}] \tag{9}$$

$$\xi = (B_c / J_c)/2\omega_n = \frac{B_c}{2K_s(K_a+1)} \tag{10}$$

This is a second-order system, with applications available at Matlab. Programming system unit impulse response curves are shown in Figure 3.1 where K_a is the smaller value of the response characteristic curves, 2 K_a is the larger value geting the response characteristic curves. From the figure, we can see that the damping ratio is too small, large amounts of overshoot, a strong tendency to respond to the oscillation, and poor stability. Unit pulse also caused a number of steering wheel torque oscillations leaving the system unstable.

When the power factor K_a increases, oscillation frequency will also increase while the damping coefficient will be reduced. This system tends to emphasize the dynamic characteristics and adjust over time, reducing the stability. Selection of a smaller power factor can increase the system damping, which is incentive to suppress high frequency interference from the roadwith the actual shift required in contradiction. Because at low speeds autos shift greater power torque, especially when turning in place, the need for greater torque reduces the proportion coefficient meaning the power torque reduces. Therefore, reducing the proportion coefficients will affect the electric power steering system performance.

Consequently, increasing the proportion of the relationship between power steering and torque should not satisfy the real needs and the need to improve the control algorithm.

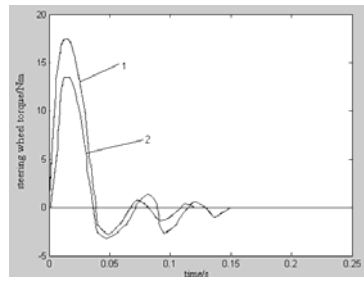

Figure3. Impulse response system.

3.2 PROPORTIONAL PLUS DIFFERENTIAL CALCULUS CONTROL OF MOTOR POWER

By the above analysis, system instability is due to the damping system being too small and the role on the steering gear on the input torque of the high frequency components of the oscillations caused by system. Therefore, if the system remained stable, need will increase system damping and differential control will increase in the original proportional control system.

The motor power using the torque sensor detection is proportional to the amount of torque, coupled with the differential signal, is directly proportional to the compensation items.

That is:

$$T_a = K_a T_s + \frac{K_d dT_s}{dt} \tag{11}$$

K_d is the torque differential coefficient. EPS system transfer function is:

$$G_{eps}(s) = \frac{T_h(s)}{T_L(s)} = \frac{K_s}{J_c s^2 + (B_c + K_s K_d)s + K_s(K_a + 1)} \tag{12}$$

System oscillation frequency is the same type (9), damping coefficient is increased, and the system dynamic performance has improved.

$$\xi = [(B_c + K_s K_d)/J_c]/2\omega_n \tag{13}$$

This system is still a second-order system. By changing the differential coefficient and adjusting the system damping coefficient, system transient stability can be improved and the system also has a strong oscillation suppression.

Application of Matlab programming is available to the system proportional plus differential calculus control, and the role of the steering wheel to shift gears on the flats in the time domain pulse response are shown in Figure 4.1 K_a is the smaller value of the response characteristic curves, 2 K_a is the larger values geting the response characteristic curves. And, Figure 4 comparing, to Figure 5, we can see that oscillation of the system has been significantly inhibited, and the system's response characteristics have markedly improved. The stability of this system has greatly improved and the peak has dropped vibrationrapid convergence. With proportional plus differential control, system transfer functions are always less than the original control system transfer function. That is, the steering wheel shimmy quickly disappears from the impact of the road.

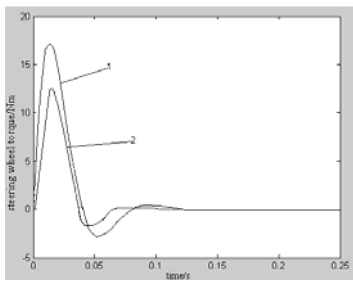

Figure 4. Impulse response system behind add a differential calculus.

4 ANALYSES OF TEST RESULTS

The different signals from the speed sensor and torque sensors in the bench test obtain the power effect. Figure 5 is in the test shows electric power steering system adopting proportional plus differential control of the test results. A

is the relationship of steering wheel torque and time, b is the relationship of the motor current and time. Motor current can better follow the changes in power characteristics which is consistent with previous simulation results. In this paper, the motor power control is effective.

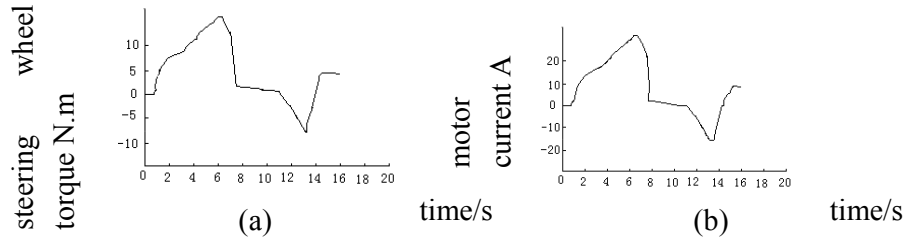

Figure 5. The test result of the comparison add a differential calculus control.

5 CONCLUDING REMARKS

Proportional plus differential control can achieve ideal power characteristics. The system resonance problem in the resonance region effectively eliminates high-frequency problems from the rack, gear, motor, and deceleration agencies inertia. The experimental results show that the control system is relatively stable, manipulative, and improves sensitive performance.

ABSTRACT

Presented is a model for the prediction of wheel/rail rolling noise generating of a high speed train running on slab track. Using vehicle-track coupled dynamics, the vertical wheel/rail force arises from the roughness excitation on the wheel and railhead running surfaces in time domain. Except for wheels as first rigid, the vertical velocity responses of rail as Timoshenko beam and slab as Euler beam are obtained. The wheel/rail force is transformed into frequency domain as an input of finite element vibration system of the wheels, and then the surface vibration velocities of the wheels are calculated. Based on the sound radiation theory, wheel/rail rolling noise of a train running on slab track is predicted. The results show that wheel/rail noises wayside are higher 5-6dB(A) than on ballasted tracks. Most noise emission energies accumulate in frequency range of 400-4000Hz. Wheel/rail equivalent sound pressure levels increase piecewise linearly as train speed increases.

INTRODUCTION

Compared to ballasted track, slab track has the advantage of structural stability, not easily deformed and requires little maintenance, so slab track has been widely applied to high speed railway all over the world today. In Japan, slab track covers about 90% of Northeast Shinkansen. In China, slab track has been successfully laid in some testing sections of Passenger Dedicated Line and the Beijing-Tianjin Inter-city Railway, and will be extended to newly-built high speed railway in future. But it is well known that slab track has higher environmental noise emissions than ballasted track. So, it is necessary to predict and control noise emission of a train running on slab track. The noise emissions caused by high speed trains are mainly composed of wheel/rail noises, aerodynamic noises, pantograph-catenary noises, etc. This paper investigates wheel/rail noise on slab track.

The first calculation model of wheel/rail rolling noise was presented by P.J. Remington in 1976. In this model, roughness of the wheel and rail running surfaces make the wheel and rail vibrate relative to one another, and these vibrations are transmitted through the structures and thereby radiating noise. This model was developed further and extended by Thompson (1993). Subsequent research funded by the European Rail Research Institute (ERRI) resulted in the implementation of the prediction model in a computer program, TWINS (Track-Wheel Interaction Noise Software) (Thompson 1996).

All the above models are limited to single wheel and single track, and simulated mainly in frequency domain, but the coupling of the wheels of the vehicle

and two rails of the track were neglected. Numerical calculation of high frequency vibration shows that the coupling influences between the two rails through the wheelset cross-admittances and the leading and trailing wheelsets through the rail cross-admittances are great, and cannot be ignored in the high frequency vibration analysis. A vertical model was originally developed by Xu to simulate wheel/rail rolling noise of slab track (Xu 2004). In Xu's model, full vehicles are considered and each rail in the track is modeled as a Timoshenko beam connecting with the discrete fasteners. The vertical vibrations of vehicle and track are simulated. In Xu's works on wheel/rail rolling noise, the vibrations of the wheel axle direction are ignored. It is also important that the axle vibrations of the wheel contribute to the total sound emission of the wheel. This paper attempts to overcome those shortcomings. In order to simulate precisely wheel/rail rolling noises of high speed trains running on slab track, a new model is developed based on the vehicle-track coupled dynamics and the sound radiation theory.

TRAIN-SLAB TRACK COUPLED SYSTEM

Train-track coupled model. A coupled train-slab track dynamic model is depicted in Figure 1. The train-slab track system consists of three subsystems: the vehicles, the track and wheel/rail contact. The interaction of the vehicles subsystem and the track subsystem is implemented by the wheel/rail contact. The passenger cars are considered and modeled as a full dynamic rigid multi-body system. It is equipped with a pair of two-axle bogies with double suspension systems. The wheelset and the bogie are connected by the primary suspension, while the carriage is supported on the bogie through the secondary suspension. It is noted that the car is assumed to move at a constant velocity, v.

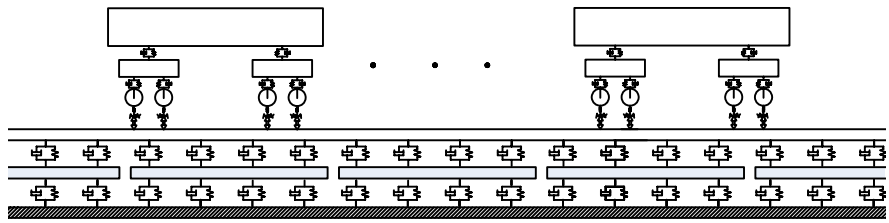

Figure 1. Coupling dynamic model of train-slab track interaction.

A rail in slab track is modeled as a Timoshenko beam connecting at the discrete fasteners. The slab is modeled as an Euler beam with two free ends. The rail pads and slab pads are modeled as spring-damping components. The normal wheel/rail contact force due to roughness excitation of wheel and rail surfaces is calculated using the Hertzian nonlinear contact theory in time domain. In order to simulate the coupled dynamic behavior of wheel/rail system, the passenger cars are assumed to be static with respect to the rail, while running surfaces roughness time historic values move backward. The vibration responses of the rail and the slab are obtained using the modal superposition principle (Zhai 2007). Except for the rail and the slab, the motion equations of the train/track system are second order ordinary differential equations. They are neglected in this paper for simplicity; see in references for details (ibid).

System excitation. In order to investigate high-frequency vibration and rolling noise of wheel/rail system, an expression about roughness (surface irregularity) had been presented by Sato (1977), and is described as follows:

$$S(\Omega) = \frac{A}{\Omega^3}\left(\mathrm{m}^2/\mathrm{rad/m}\right) \qquad (1)$$

Where, Ω is the wave number of roughness; A is the wheel/rail surface roughness coefficient; $S(\Omega)$ is the roughness spectrums. The wavelengths of roughness are between about 5 and 200mm. In the present model, the roughness is taken as an input which is normally assumed to be the same for wheel/rail rolling noise simulation and the roughness filter is considered. Using inverse FFT technique, the values of roughness time history are obtained and input into train-track coupled system to simulate wheel/rail high-frequency vibration (see Figure 2).

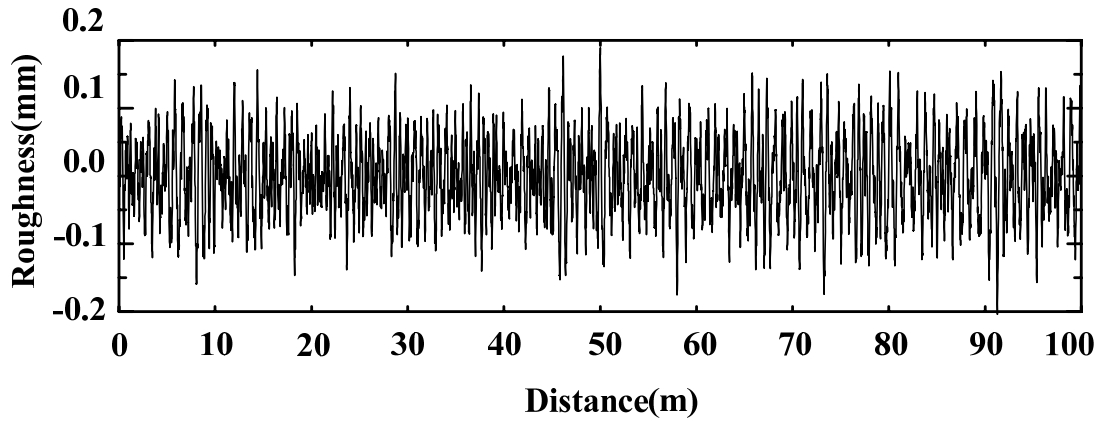

Figure 2. Time history values of roughness.

Solution of dynamic equations. To solve the motion equation of the system, the fast integration methods especially for large-scale dynamic problems in engineering are used to calculate (Zhai 1996). Wheel/rail contact forces are finally transformed into the frequency domain to calculate dynamic responses of the wheels using the finite element method.

MODEL OF WHEEL/RAIL NOISE EMISSION

Because wheel/rail noises are mainly caused by high frequency vibrations of wheel, rail and slab, the main radiating components are wheels, rails and slabs in wheel/rail system. While the vibrations of the carriages, bogies and ballasts take place in low frequency bands and barely contribute to wheel/rail noise, so noise radiations of these components are often ignored. The relationships between acoustic and vibration of wheel and rail have been investigated by Thompson (2002) and Wei (2006), respectively, while acoustic radiation property of railway slab fits to the one of thin plate. A short distance from the rail, wheel sound radiation is described as the summation of a serial of simple point sources, whereas rail and sleep sound radiation are viewed as the finite length line source passing observer point.

RESULTS AND DISCUSSION

Simulation of noise emission is assumed in free-field and takes into account reflections and absorption from the ground plane. Parameters of high-speed train and slab track can be found in the reference (Zhai 2007).

Model validation. In order to verify model validation, an observation point lies at 4.2m side of track center and 1.5m above of railhead. When a high-speed train travels on testing sections of the Passenger Dedicated Line in China at a speed of 200km/h, wheel/rail noise pressure levels are measured. Figure 3 illustrates that a comparison between theory prediction and field measurement for wheel/rail noise generating of a train running on slab track. It can be seen that the predicting values are in agreement with the measure results above those frequency bands of 500Hz, while there is a deviation on them below 500Hz. The causes are analyzed that an increase in train speed will give rise to the contribution of aerodynamic noise below 500Hz. However, wheel/ rail noise energies are predominantly distributed in frequency bands upon 500Hz. It is shown that the present model of predicting wheel/rail noise has satisfactory prediction accuracy.

Wheel/rail noise characters of train running on slab track. When a train runs on slab track at speed of 220km/h, sound pressure level of the observation point lies at 2m at the side of track center and 1.5m above of railhead is calculated. Figure 4 illustrates that some changes of wheel/rail noise frequency spectrums take place. It can be seen from Figure 4 that wheel/ rail noise on slab track is distributed mainly in the frequency range of 400-4000Hz, and the peak frequency of radiation noise is 1000Hz. It is also shown that rail noise occurs mainly in the middle and high frequency range of 500-4000Hz, that wheel noise is chiefly in the high frequency range of 1600-4000Hz, and that slab noise radiates in the frequency range of 125-500Hz. This makes clear that the peak frequency of rail, wheel and slab is 1000Hz, 2500Hz and 500Hz, respectively, which illustrate that the peak frequencies of rail, wheel and slab coincide with main frequencies of their vibrations.

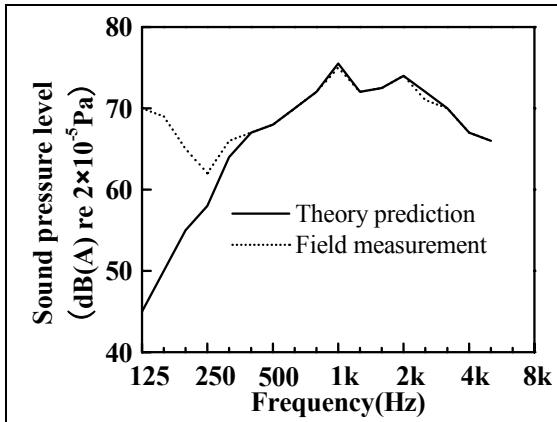

Figure 3. Wheel/rail noise frequency spectrums.

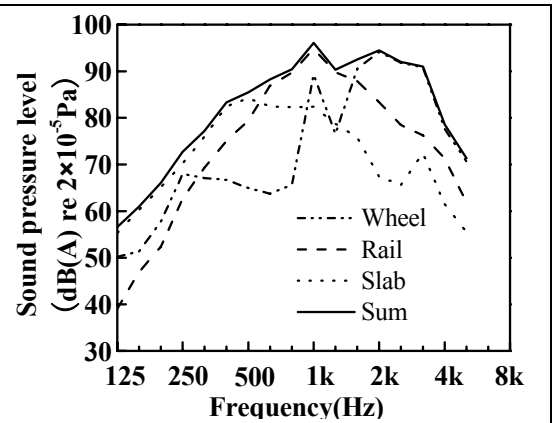

Figure 4. Wheel/rail rolling noise frequency spectrums on slab track.

When a train travels through observation point, the peak values of sound pressure level lie dead ahead of the observation point in full passing time. It can be

seen from Figure 5 that the fluctuation of sound pressure levels occurs the moment when one wheel of the vehicle travels through the observation point.

The influence of train speed on wheel/rail noise. Figure 6 shows the influence of train speed on wheel/rail equivalent sound pressure levels.

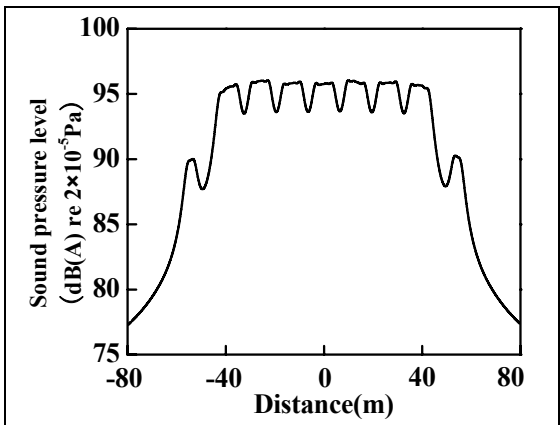

Figure 5. Wheel/rail rolling noise of a train in time domain.

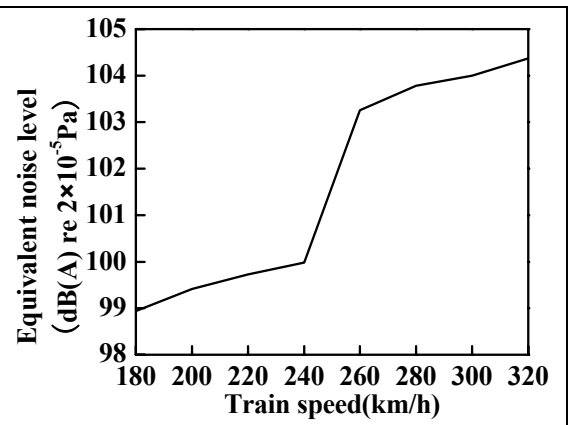

Figure 6. Changes of equivalent sound pressure level with train speed.

Figure 6 shows that wheel/rail equivalent sound pressure levels almost increases piecewise linearly as train speed increases. Sound pressure levels will increase sharply by 3.5dB(A) from 240km/h to 260km/h, while it increases slowly at the other speeds.

CONCLUSIONS

In our simulations, we may reach the following three conclusions for wheel/rail noise caused by high speed train running on slab track.

First, wheel/rail noises wayside are higher 6.2 dB(A) than on ballasted track. Second, most energies of noise emission are predominantly focused in the frequency range of about 400~4000Hz. Third, wheel/rail noise equivalent pressure levels increase picewise linearly as train speed increases.

Study of Influence of Subway Station Excavation on Existing Metro Deformation

LI Yun-Peng[1] and WANG Zhi-Yin[1]

[1]School of Mechanical and Electrical Engineering, China University of Petroleum, Beijing, 102249, China, email: liyp996@163.com

ABSTRACT

Based on the excavation engineering of the subway station across the existing metro tunnel and in situ monitoring displacements, the comprehensive mechanical parameters were obtained by the back analysis. According to the geological engineering conditions and the construction scheme, the numerical model of excavating subway station was established. The structural deformation, settlement and railway incline law of the existing metro caused by new subway station construction were given. The relation of the pipe tent supporting effectiveness to settlement was obtained, and the key excavation step of producing the maximum settlements was given. The evaluation and the prediction of the safety construction and the safety operation on existing subway track were made. The research results had been applied to the subway station across the existing metro tunnel. The obtained results may be referenced in the design and the construction of similar engineering.

INTRODUCTION

With the rapid development of urban rail, underground subway tunnels unavoidably traverse existing buildings, roads, railway tunnel and other existing structures. The research on urban subways, especially the design and construction technology of traversing the shallow tunnel structure, has a long history at home and abroad, and a lot of research results have been collected. For instance, settlement causes, initial supports and the application of grouting auxiliary construction were studied based on the monitoring settlement of Guangzhou metro line 2 (Zhong 2003). Subsidence control problems were researched according to the different requirements of ground settlement and building deformation (Zhong 2005). The basic laws of stratum movement caused by the shallow depth excavation method in weak watery stratum and controlling the large deformation technology were researched (Huang 2004). The control technology of large-span tunnel construction in metro station (Hu 2007); large deformation mechanism and large deformation control principle and technical measures were researched based on the experimental study on soil properties of strata (Lu 2003). And finally, using three-dimensional numerical simulation method, the various construction schemes were compared and simulated by considering the time-space effect and complex external environment factors, including high-rise buildings in flourishing city, ground with heavy traffic, underground pipe (Wu 2004), etc.

However, due to the complexity of the geological conditions in formation, especially the external environment condition of different engineering problems, merely copying existing methods and techniques would not be scientific. According to some subway station engineering across the existing metro line cited in this paper, the comprehensive mechanical parameters of influencing the deformation of soil layers are back analyzed based on the in-situ monitoring

displacements. Using numerical methods, the deformation behaviors of the existing subway structure and the surrounding rock (soil) in the process of traversing excavation are studied, a key step of excavating influence on the existing metro lines is found, and the safety operation of the existing metro lines is evaluated. These results can be supplied to similar engineering as references.

BACK ANALYSIS OF MECHANICAL PARAMETERS

The position and the structural plane layout of two subway stations are shown in Figures 1 and 2. The station structure has twin pillars, three islands, its total length is 208m, total width is 24m, and the width of platform is 14m. Existing tunnel structure is reinforced concrete square frame structure C30. There is a deformation joint every 18m (see Figure 2). The clear distance between the new station and the existing metro ring line is 1.98m. The new line will traverse under the existing line.

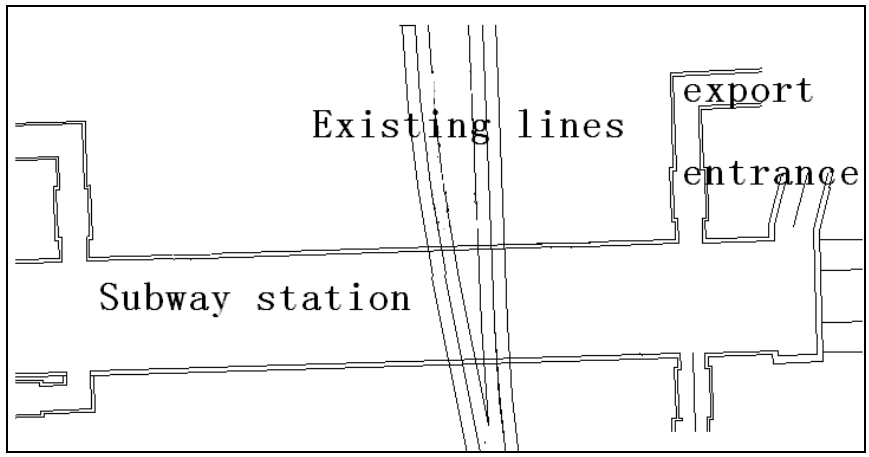

Figure 1. Position of subway station.

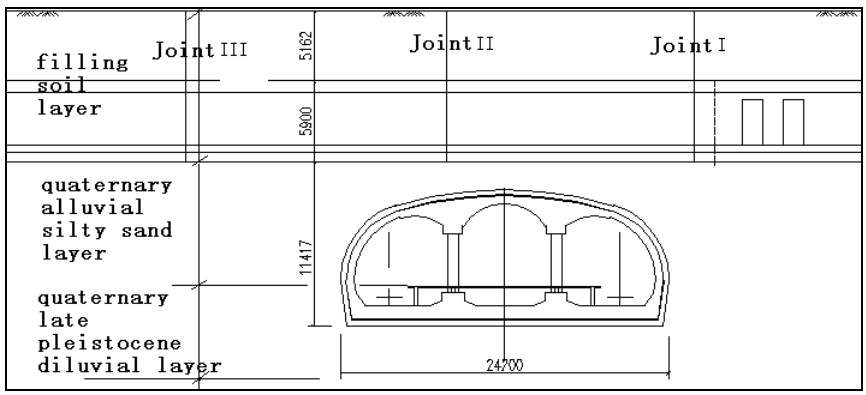

Figure 2. Elevation of metro lines.

It may be seen from the geological sections in the boring log that the formation materials around the new line can be sorted into three layers: earth-filling soil, quaternary alluvial silty sand, and quaternary late Pleistocene diluvial layer. From the in-situ construction data, the soil layers contain construction rubble and waste rock, leaving the mechanical parameters of the soil layers undetermined and fuzzy. In order to solve this problem, the back analysis method of parameters is adopted (Wang 1993, 2008).

According to the structure, construction situation, deformation laws and the corresponding construction characteristics within the intersection region of two subway lines, the back analysis model of the longitudinal section is selected, as shown in Figure 3.

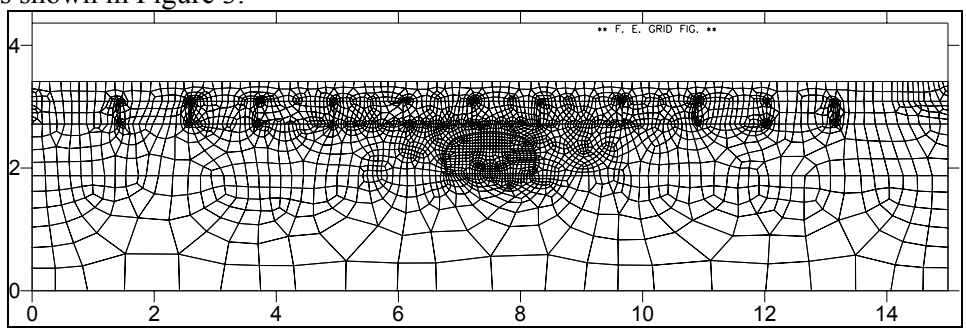

Figure 3. Finite element analysis model.

In order to reflect the rotation and settlement laws of the main structure in the longitudinal axis direction of existing line and the settlement features of expansion joints, taking the central axis of the new subway line as the symmetry axis of analyzing region, the distances from the left and the right boundaries to the symmetry axis are respectively around 120m along horizontal direction, and the upper boundary is the surface, and the lower boundary is 30m below the floor of new line along the vertical direction. The area contains the overburden soil of existing line, main structure, the corresponding soil layers around new station, etc. The fitting deformation points used by inversion are shown in Figure 4.

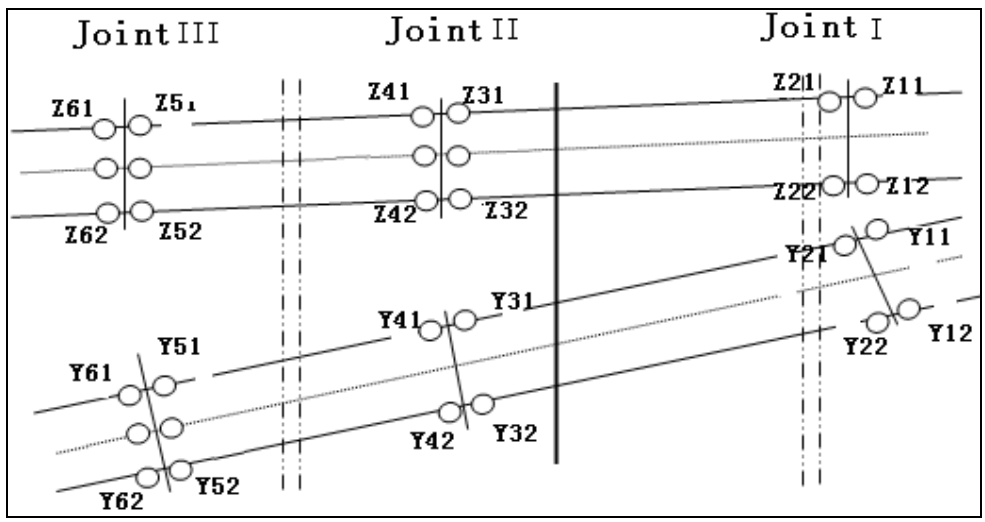

Figure 4. In-situ measuring points.

As mentioned above and seen in Figure 2, the concrete process is as follows: first, the soil formation is divided into three layers, namely, earth-fill, a quaternary alluvial silty sand layer and a quaternary late Pleistocene diluvial layer. The mechanical parameters of each layer take the weighted average values of corresponding soil and other materials as its initial analysis parameters. Then, the fitting inversion is carried out by using in-situ measured deformation at the special points, and the mechanical parameters of three soil layers are gradually

approached.

Through multiple fitting inversion, the comparisons of the longitudinal actual settlement curve of the structure with the inversion result are given in Figure 5 for both left and right lines respectively.

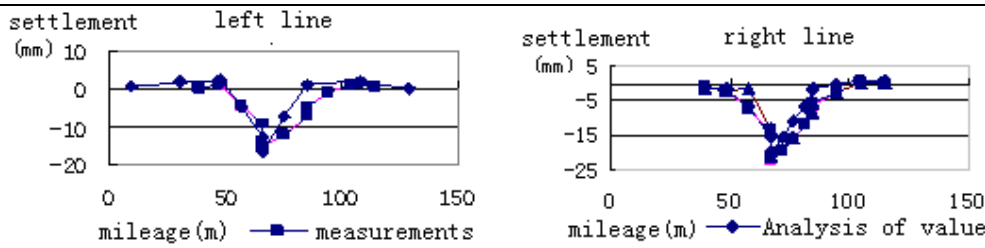

Figure 5. Comparison of settlement of structure with inversion results.

The fitting of three points at the deformation joint II in the left line and its left side is good from Figure 5, and the fitting of the points at two sides of joint II and a measuring point of joint I in the right line is better. Comparing the measured values with the calculated values of the corresponding points, the relative error in the structure at the left line 57m and 66m and the right line 67m is less.

Because the construction process and the subway structure are extremely complex, fitting only above three points is ideal. Through the above inversion and comprehensive analysis, the comprehensive mechanical parameters of soil around the subways are listed in Table 1.

Table 1. Mechanical parameters obtained by back analysis.

Soil layer	E/MPa	μ	C(MPa)	φ	γ(MPa/m^3)	Rt
upper	5.50	0.230	0.019	30	0.0160	0.000
middle	160.00	0.300	0.03	20	0.0195	0.000
lower	20.00-31.00	0.280	0.036	35	0.0200	0.001
C30	30000	0.167	2.000	49	0.0119	2.100

ANALYSIS OF DEFORMATION AND STRESS OF EXISTING LINE

Using the mechanical parameters obtained by inversion, both left and right line structure settlement laws and stress states caused by the new construction are simulated by finite element method.

The settlement results are shown in Figures 6 and 7. In Figure 6, for the left line the longitudinal settlement law of the structure varies with the excavation process of the new line station, and the structure settlement at joint II tends to the stable value after undergoing maximum settlement, and the structure settlement at the joint III undergoes the changing process of subsidence-upper expansion and tends finally to the stable value of upper expansion. The settlement laws of right line structure, as shown in Figure 7, are similar to those of the left line. In the whole construction process, the maximum settlements along existing left and right lines are 6.318cm and 6.473cm respectively, which both locate at the right side of joint II, and the stable settlement values are finally about 4.337cm and 4.997cm. The left and right line structures are expanded up at joint I and joint III to a certain extent, where the up-expanded maximum values on left and right lines are

1.220cm and 0.947cm respectively.

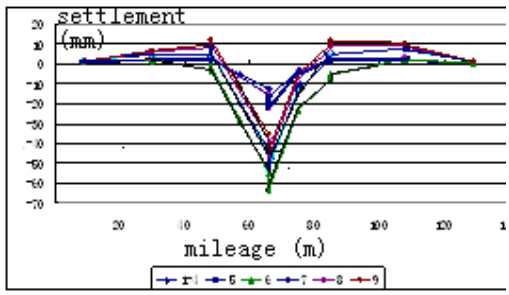

Figure 6. Settlement curves of left line.

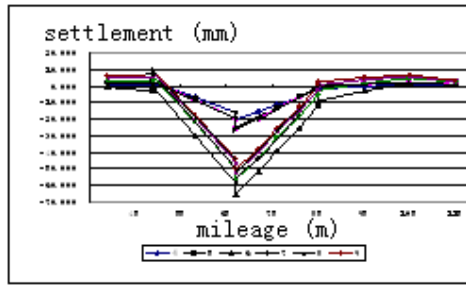

Figure 7. Settlement curves of right line

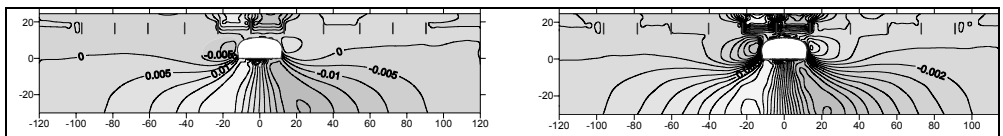
The displacement contours of longitudinal left and right sections of the existing subway are shown in Figure 8.

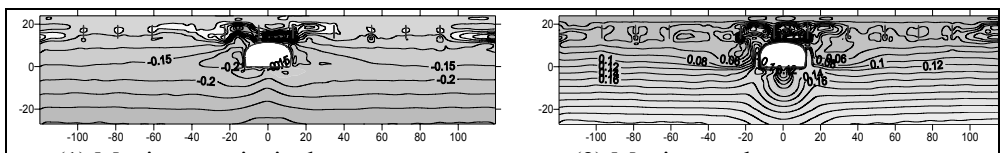


(1) left line (2) right line

Figure 8. Horizontal displacement contours.

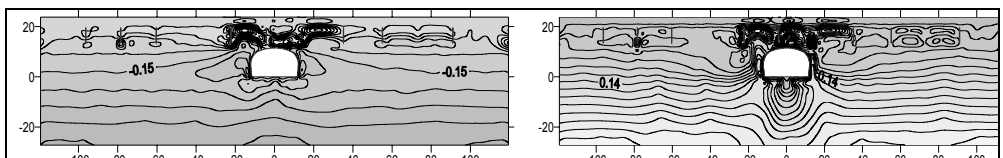
It is seen from the horizontal displacement contours of both left and right lines that the displacements of soil mass near the new subway tunnel vary greatly in each construction process and those near the existing line and deformation joints are less, which shows that the possibility of producing the longitudinal extruding deformation in existing line roadbed is less.

The principal stress and the maximum shear stress contours are shown in Figures 9 and 10. It is indicated from both these Figures that the stress concentration occurs mainly near the new subway tunnels and within the existing structure above the new subway tunnels. The tensile stress area appears in either left or right line existing structure and the region between the main structure and the station, and the area locates in the range from 50m to 60m along the transverse axis above new subway station.



(1) Maximum principal stress contour (2) Maximum shear stress contour

Figure 9. Stress contours of left line structure and soil mass around tunnel.



(1) Maximum principal stress contour (2) Maximum shear stress contour

Figure 10. Stress contours of right line structure and soil mass around tunnel.

The above stress and displacement contours are given under the condition that pilot pipes and supporting structure have 50% of the effectiveness. So, to improve the stress concentration, the tensile state and the displacement distribution etc, the supporting stiffness of the tube curtain and the related lining must be strengthened to ensure its effectiveness above 80-90%.

The stress distribution contour after excavating soil mass within the station section is shown in Figure 11.

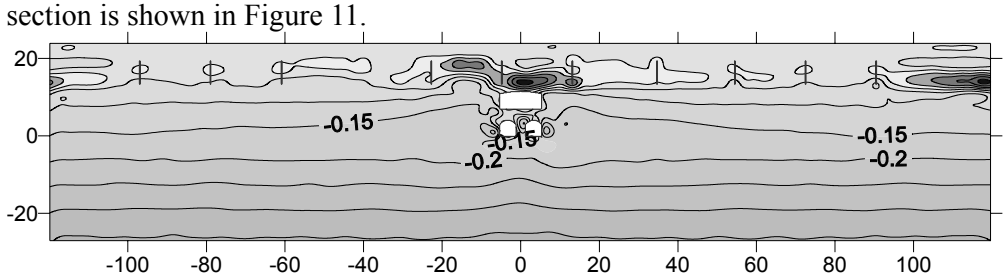


Figure 11. Maximum principal stress contour.

From Figure 11, the tensile stress appears in the connection soil layer of existing and new lines in the new station construction process, especially the serious stress concentration appeared in sandwich. Because the soil layer has no tensile strength, the layer is in tensile damage state and has fully lost its bearing capacity. The imbalance force resulted from tensile damage area is undertaken completely by the new line structure and the pilot pipes. In addition, the existing line structure is partly in tensile state, especially in the area above the new line, and the tensile area is very concentrated at concrete structure joints of existing lines. Although the maximum tensile stress in the area does not exceed the tensile strength of concrete, this will be a potential adverse factor for the existing concrete structure, and the unfavorable factor is in expanding and developing state.

From the plastic area seen in Figure 12, the deep plastic zone appears in soil mass around new line tunnel, the disturbance load within the area is basically undertaken by supporting structure.

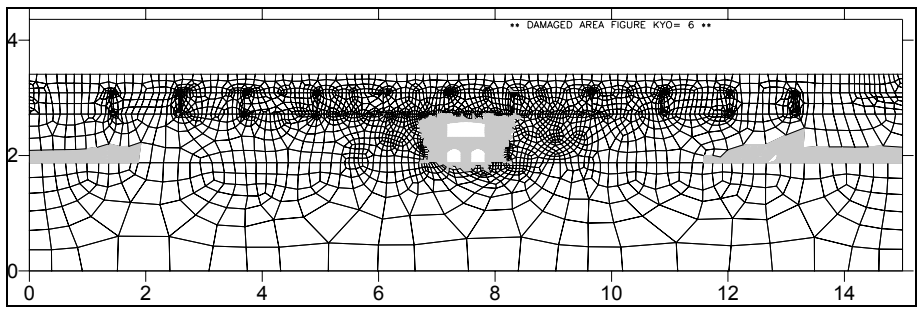

Figure 12. Plastic zone.

It can be seen from the above analysis that the new station construction across the existing lines is very insecure at present. So the strengthening support is suggested based on the current supporting structure, such as strengthening the pilot pipe tent supporting stiffness, whole section pre-grouting and rapidly setting initial support etc. to ensure the engineering safety and stability.

CONCLUSION

Firstly, by establishing the analyzing model of the subway station traversing the existing subway, the comprehensive mechanical parameters of soil around subway tunnels are obtained by the inversion, and the analyzing results are close to in-situ monitoring settlement values.

Secondly, it is shown from the study that there is different subsidence at the expansion joints in the process of construction, and it appears between the joint I and the joint III. The stress concentration area occurs mainly near the subway tunnel and within the existing line structure above the station. The tensile stress area appears in either left or right line existing structure and the region between the main structure and the station, and the area locates in the range from 50m to 60m along the transverse axis above the new subway station.

Lastly, the research indicated that strengthening the pilot pipe tent and supporting stiffness is an effective way of improving the settlement difference, stress concentration and tensile state and ensuring the safety construction of the subway station and the safety operation of the existing subway, and the supporting structures should be set up in time in the late construction process.

ABSTRACT

A train-ballastless slab track-subgrade vertical vibration mechanical model was put forward based on finite element method. Vibration equations were formulated by using the principle of total potential energy with stationary value in elastic system dynamics and the "set-in-right-position" rule for formulating matrixes. With the vibration mechanical model, influence of longitudinal connection mode of ballastless slab track on vertical vibration responses of train-ballastless slab track-subgrade system under the load case of track random irregularity was studied. The calculated results show that: longitudinal connection mode of ballastless slab track has little effect on vehicle vertical acceleration, rail vertical acceleration, wheel/rail vertical force and fastener vertical pressure force, but has significant influence on vibration characteristic of ballastless slab track structure. Continuous slab and concrete basement can decrease the vibration of ballastless slab track structure significantly.

INTRODUCTION

Ballastless track is a modern railway technology, and there are many merits for ballastless track compared to ballast track. For example, stability of track is increased, security of train operation is raised, and maintenance work of track is greatly reduced. With the development of ballastless track technology, it has been widely used in high speed railway in many foreign counties, such as Japan, Germany. In China, ballastless track has been successfully used in Beijing-Tianjin intercity high speed railway in 2008, and it will be widely used in many new-built high speed railways, such as Beijing-Shanghai, Wuhan-Guangzhou, Zhengzhou-Xi'an, Haerbin-Dalian railway line for passenger traffic.

There are two kinds of ballastless slab track. One is discontinuous ballastless slab track, and the other is longitudinal connected ballastless slab track. At present, although many researches has been made on vibration characteristic of train-ballastless slab track-subgrade system at home by Zhai W. M., Han W. J., Cai C. B., Wang Q. C.(1999), Cai C. B. (2007), Xiang J., He D., Zeng Q. Y. (2007), and Xuan Y., Wang L. (2005), and abroad by Verbic B. (1997), Esveld C. (2001), and Steenbergen, M.J.M.M., Metrikine, A.V., and Esveld, C. (2007), few studies have been made on the influence of longitudinal connection mode of ballastless slab track on vibration characteristic of ballastless slab track structure, especially on the dynamic stress of ballastless slab track structure.

In this paper, a dynamic model in which different longitudinal connection modes of ballastless slab track can be considered is established, and corresponding calculation program is developed based on MATLAB program language. With the established dynamic model, the influence of longitudinal connection mode of ballastless slab track on vibration characteristic of train-ballastless slab track-subgrade system is studied in detail.

DYNAMIC MODEL OF TRAIN-BALLASTLESS SLAB TRACK—SUBGRADE SYSTEM

Vehicle model**.** Each vehicle is consisted of 7 rigid bodies, and connected with each other by means of elastic and damping linear elements (see Figure 1). For car body and bogie, nodding and vertical motions are considered. For each wheel set, only vertical motion is considered. This results in a total of 10 degree of freedom for each vehicle.

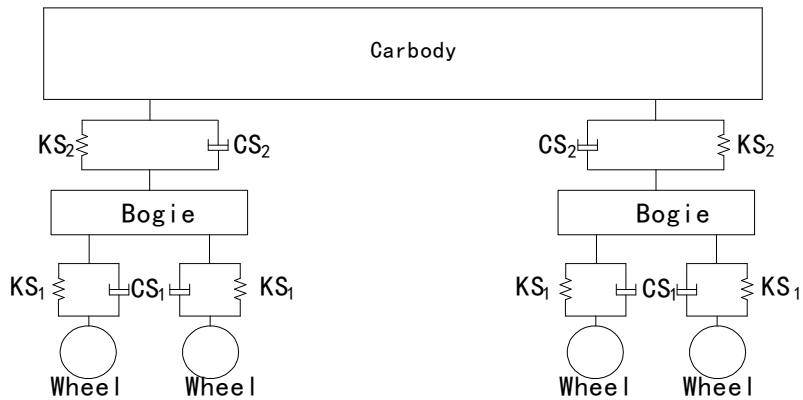

Figure 1. Vertical vibration mechanical model of vehicle.

Ballastless slab track model**.** Dynamic mechanical model of ballastless slab track on subgrade is shown in Figure 2. Rail, slab, concrete basement, longitudinal connections between slabs, longitudinal connections between concrete basements are modeled as beam element respectively. Fastener, CA mortar, and subgrade are modeled as linear spring-damping element respectively.

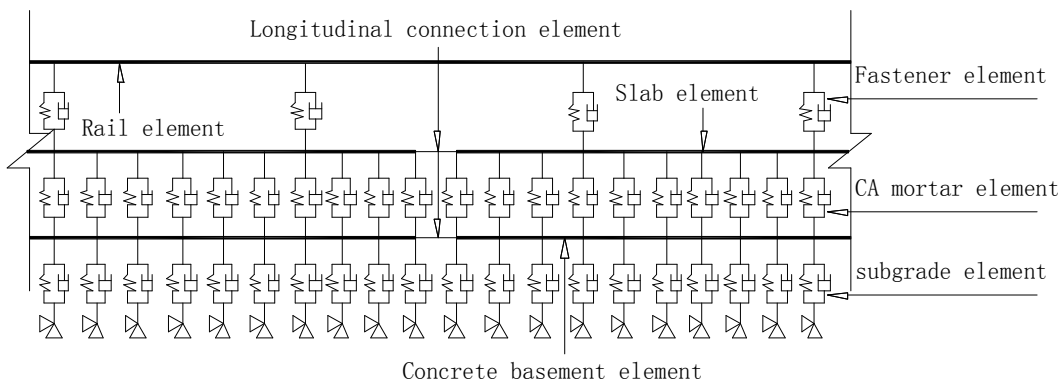

Figure 2. Dynamic mechanical model of ballastless slab track on subgrade.

The longitudinal discontinuity can be simulated by setting the stiffness of longitudinal connection element small enough. The longitudinal continuity can be simulated by setting the stiffness of longitudinal connection element equal to that of slab or concrete basement.

Track irregularity model and its numerical simulation**.** Germany's low disturbance track irregularity power spectrum, which is suitable for high speed railway allowable velocity above 250 km/h, is adopted in this paper. It is expressed as shown in Equation (1) Zhai W. M. (2002):

$$S(\Omega)=\frac{A_v\Omega_c^{\ 2}}{\left(\Omega^2+\Omega_r^{\ 2}\right)\left(\Omega^2+\Omega_c^{\ 2}\right)} \tag{1}$$

where: $S(\ )$ is power spectrum density; is spatial frequency; A_v is roughness constant, and the value is 4.032×10 $^{-7}$ m·rad; $_c$ and $_r$ are cutting off frequency, the values is 0.8246 rad/m and 0.0206 rad/m respectively.

Short wave-length has considerably important influence on ballastless track dynamic characteristic (Zhai W. M. (2002)). But Germany's low disturbance track irregularity power spectrum mainly describes medium and long wave-length track irregularity. Short wave-length track irregularity is added up to medium and long wave-length track irregularity in this paper, and its expression is shown as Equation (2)(Zhai W. M. (2002)):

$$S(f)=0.036f^{-3.15} \tag{2}$$

where: $S(f)$ is power spectrum density; f is spatial frequency.

By using numerical simulation method introduced by W. M. Zhai (2002), the amplitude and random phase can be firstly obtained according to track random irregularity power spectrum, and then track irregularity time domain simulation sample can be gained by inverse Fourier transform.

Wheel/rail interacting model**.** Vertical wheel/rail force can be calculated by Hertz nonlinear contact theory, and its expression is shown as Equation (3).

$$p_j(t)=\begin{cases}\dfrac{1}{G}\left[Z_w(j,t)-Z_r(j,t)-Z_0(t)\right] & wheel/rail \quad contact \\ 0 & wheel/rail \quad seperatoin\end{cases} \tag{3}$$

where: G is wheel/rail contact constant; $Z_w(j,t)$ is j-th wheel displacement at time t; $Z_r(j,t)$ is rail displacement under j-th wheel at time t; $Z_0(t)$ is track irregularity.

Establish and solution of equation set of system**.** Vehicle total potential energy includes inertia potential energy and gravitational potential energy of car body, bogie, and wheelset, and elastic strain energy and damping energy of suspension. Vehicle vibration equation set can be formulated by using the principle of total potential energy with stationary value in elastic system dynamics and the "set-in-right-position" rule for formulating matrixes. Ballastless slab track vibration equation set can be formulated by the same way.

Cross iterative method is used to solve the equation set of system based on wheel/rail interacting model (Lei 2002).

MECHANICAL MODEL VERIFICATION

Because we lack in-site measured data about ballalstless track, vehicle model, ballastless slab track model, and track irregularity models are verified respectively.

Vehicle model verification**.** In 1994, China's Academy of Railway Sciences measured the effect of wave length and wave amplitude on vehicle vibration acceleration on the Guangzhou-Shenzhen railway line. Vehicle vertical acceleration comparison between measured data and calculation data is show in Table 1. (For vehicle and track parameters see Zhai 2002.)

Table 1. Vehicle vertical acceleration comparison between measured data and calculation data.

Test conditions	Track irregularity	λ=10m a=10mm	λ=12m a=9mm	λ=12m a=9mm	λ=24m a=16mm	λ=24m a=20mm
	Vehicle velocity	160km/h	135km/h	150km/h	160km/h	160km/h
Measured data /g		0.12	0.06	0.08	0.12	0.13
Calculation data in this paper /g		0.104	0.078	0.085	0.096	0.120
Calculation data in Ref.8 /g		0.104	0.078	0.085	0.096	0.120

Ballastless slab track model verification**.** It is assumed there is sinusoidal force acting on rail node in the middle of slab. The load function is $F(t)=-100000\times\sin(2\pi vt/10)$, where v=83.33m/h(300 km/h). Slab is discontinuous, and concrete basement is continuous. Other calculation parameters are shown in Table 2. Calculation results by ANSYS and MATLAB program are shown in Figure 3 and 4.

Table 2. Calculation parameter of ballastless slab track.

Item		Unit	Value
Rail		kg/m	60
Vertical stiffness of fastener		kN/mm	35
Slab	Length	m	6.0
	Width	m	2.4
	Thickness	m	0.19
	Young's modulus	GPa	34.5
Concrete basement	Width	m	2.8
	Thickness	m	0.3
	Young's modulus	GPa	32.5
Young's modulus of CA mortar		MPa	400
Vertical stiffness of subgrade		MPa/m	190

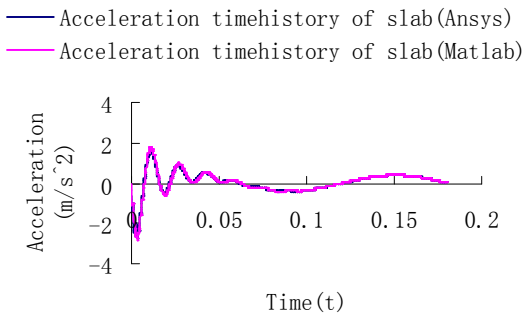

Figure 3. Comparison of time history of slab acceleration at load point position.

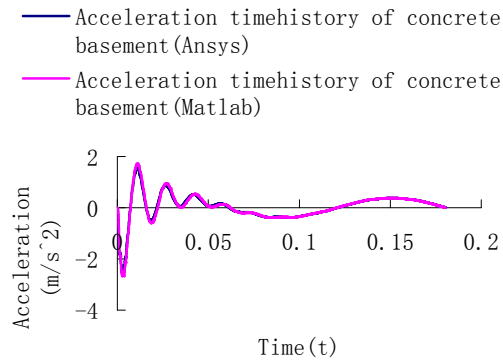

Figure 4. Comparison of time history of concrete basement acceleration at load point position.

Track irregularity model verification**.** Theoretical power spectral density is shown in Figure 5, simulation sample of theoretical power spectral density is shown in Figure 6, sample power spectral density is shown in Figure 7, the error between theoretical and sample power spectral density is shown in Figure 8. From Figure 8, we can see that the error between theoretical and sample power spectral density is very small, which proves the random irregularity simulation is correct.

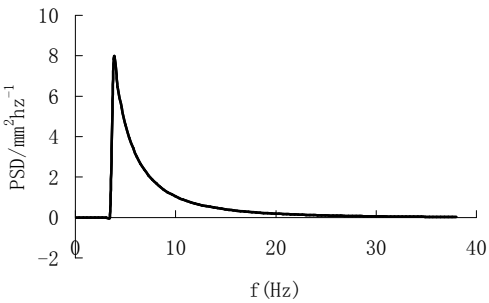

Figure 5. Theoretical power spectral density.

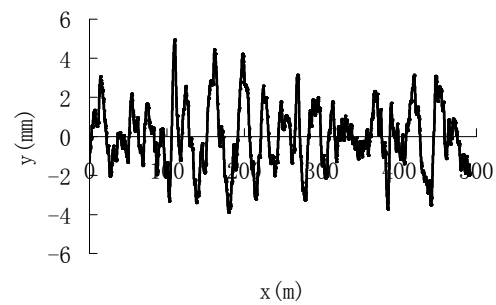

Figure 6. Simulation sample of theoretical power spectral density.

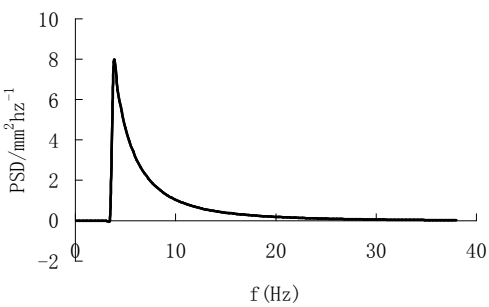

Figure 7. Sample power spectral density.

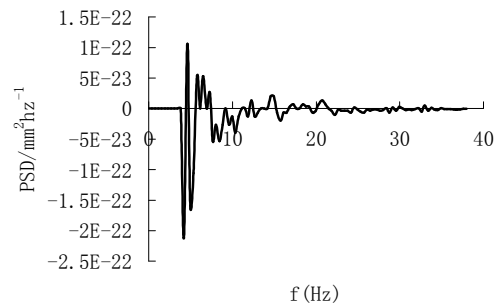

Figure 8. Error between theoretical and sample power spectral density.

INFLUENCE OF LONGITUDINAL CONNECTION MODE ON VIBRATION CHARACTERISTIC OF SYSTEM

Calculation condition. Take a high speed train formed with 4 trailers hauled by a motor car running at 300 km/h on ballastless slab track with different longitudinal connection modes as an example, to study the influence of longitudinal connection mode of ballastless slab track on vibration characteristic of train-ballastless slab track-subgrade system. (For parameters of train see Xuan Y., Wang L. (2005). The main parameters of track are shown in Table 2.) The following 4 load cases are calculated:

Load case 1: both slab and concrete basement are continuous.
Load case 2: slab is discontinuous and concrete basement is continuous.
Load case 3: both slab and concrete basement are discontinuous in the same section.
Load case 4: slab is discontinuous and concrete basement is discontinuous in the middle of slab.

Calculation Results. The effects of different longitudinal connection modes of ballastless slab track on vibration characteristic of train-ballastless slab track-subgrade system are shown in Table 3.

Table 3. Results comparison among different longitudinal connection modes.

Item	Load case 1	Load case 2	Load case 3	Load case 4
Max vertical acceleration of carbody (m/s^2)	0.397	0.397	0.396	0.397
Max vertical acceleration of rail (m/s^2)	1379.020	1376.397	1371.199	1372.617
Max vertical acceleration of slab (m/s^2)	87.969	131.400	127.764	130.100
Max vertical acceleration of concrete basement (m/s^2)	32.226	32.551	49.001	46.011
Max wheel/rail vertical force(kN)	159.694	159.594	159.182	158.877
Max dynamic vertical compressive force of fastener (kN)	38.214	38.198	37.970	38.155
Max dynamic vertical compressive stress of CA mortar (MPa)	0.072	0.102	0.082	0.102
Max dynamic bending stress of slab(MPa)	0.736	0.723	0.699	0.989
Max dynamic bending stress of concrete basement (MPa)	0.524	0.530	0.504	0.525
Max vertical compressive stress on surface of subgrade (MPa)	0.033	0.033	0.048	0.037

Calculation analysis. The effect of longitudinal connection mode of

ballastless slab track on vertical acceleration of car body, vertical acceleration of rail, wheel/rail vertical force, and vertical compressive force of fastener is no more than 1%. When slab is longitudinal continuous, maximum vertical acceleration of slab decreases about 33 percent. When concrete basement is continuous, maximum concrete basement vertical acceleration decreases about 34.2%. When slab and concrete basement are discontinuous in the same section (load case 3), maximum vertical compressive stress on surface of subgrade increases about 31.3%.

CONCLUSIONS

In this paper a general time varying coupling dynamic model is established, in which different longitudinal connection modes can be considered. Taking short, medium and long wave-length track irregularity into account, the influence of longitudinal connection mode of ballastless slab track on vibration characteristic of train-ballastless slab track-subgrade system is studied carefully. The results show that the effect of longitudinal connection mode of ballastless slab track on vertical acceleration of carbody, vertical acceleration of rail, wheel/rail vertical force, and vertical compressive force of fastener is very small, but the effect of longitudinal connection mode of ballastless slab track on ballastless slab track structure is considerable. On the whole, the dynamic characteristic of longitudinal continuous ballastless slab track is better than that of longitudinal discontinuous ballastless slab track.

Vehicle Semi-active Suspension System Simulation with Variable Structure Control Method

Li Zhongji[1] and Dai Huanyun[1]

[1]Traction Power State Key Laboratory, Southwest Jiaotong University, Chengdu 610031, China. email: lizhongjiqc@126.com

ABSTRACT

The semi-active suspension system is an effective method to improve riding comfortable. This paper considers variable structure control method with the simplified model for the design of a semi-active suspension system. Firstly, the dynamic model of a vehicle suspension system is built. Secondly, the damp controller with variable structure control method is designed based on that model. Then, the practical dynamic model is built using ADAMS/rail, and the model of the controller is obtained using Matlab/simulink. Finally, the vibration data of car body is obtained by co-simulation using ADAMS and Matlab. The result shows that the VSS (variable structure sliding mode control) controller can reduce the amplitude of car body vertical displacement and acceleration effectively.

INTRODUCTION

The vertical ride quality of railway vehicles could be improved by using the pneumatic active and semi active suspensions. At present, those style systems have been applied in the high-speed trains. The investigation, experiment and application show that the effect of active suspension is ideal. However, the cost of the active suspension system is extremely expensive and the construction is quite complex compared with the semi-active suspension system. Specifically, a power supply is needed in an active suspension system. It may, therefore, be difficult to obtain practical application. On the other hand, semi-active suspension does not need a power supply. More importantly, because there is no power input, the semi-active suspension system is stable and safe. Moreover, the construction of a semi-active suspension system is simple and the cost lower. Taking all this into consideration, semi-active suspension will have broad practicality in actual application.

As the key of semi-active suspension system research, the control policy is given more attention. Some of the commonly control policy include H_∞ control theory, fuzzy logic control, self-adaptation control, variable construction control and so on. But those modern control policies are mostly based on exact model of the practical system. The more exact the system model is, the more ideal the control effect is. Because the vehicle dynamic system has strong nonlinear and time-varying characteristic, the exact vehicle dynamic model would be very complex. Even, it is impossible to build the exact model sometimes. Therefore, according to the complex

model to design the controller, the controller will became more complicated, and the suspension system stability would be decreased. Because of that, it is necessary to simplify the vehicle dynamic model while designing the controller. But it come to the new problem that whether the controller designed base on the simplify model fit the practical system completely. In view of this, the variable structure controller was designed base on 3DOF simplify model in this paper, and the practical vehicle model was built by ADAMS/rail. The performance of VSS controller was verified by co-simulation with ADAMS and Matlab.

CONTROLLER DESIGN

System simplify model. The 3DOF vehicle dynamic model is build for designing the VSS controller. This model consists of two masses, m_b representing the quarter body mass and m_f representing the frame mass. The mass m_b is isolated from m_f by a spring k_b and damper C_b, along with a controllable damp. The controllable damp is represented by the control force u (Stutz, L.T. 2004). The mass m_f is connected to the wheel by a spring k_f and damper C_f. The body vertical displacement is x_b, the frame vertical displacement is x_f. The track disturbance is described by the elevation d and its time derivative. The model is depicted in Figure1.

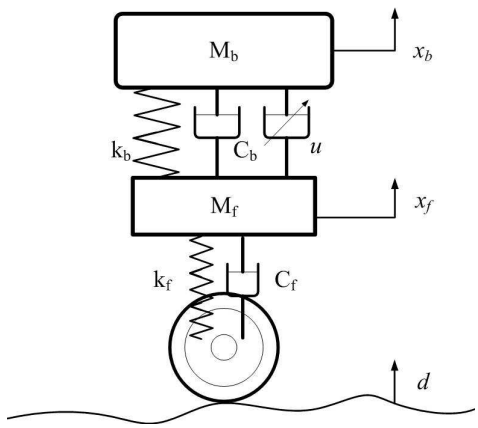

Figure 1. 3DOF vehicle model.

The dynamic behavior of the model is governed by the following equation

$$m_b \ddot{x}_b = -k_s (x_b - x_f) - (\dot{x}_b - \dot{x}_f) C_s + u \tag{1}$$

$$m_f \ddot{x}_f = -k_p (x_f - d) - C_p (\dot{x}_f - \dot{d}) + k_s (x_b - x_f) + C_s (\dot{x}_b - \dot{x}_f) - u \tag{2}$$

Using the following state variables:

$$x_1 = x_f \quad x_2 = x_b \quad x_3 = \dot{x}_f \quad x_4 = \dot{x}_b \tag{3}$$

$$\mathbf{x} = (x_1 \quad x_2 \quad x_3 \quad x_4)^T \tag{4}$$

The equation of motion can be written in state space as

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}u + \mathbf{E}d \tag{5}$$

where:

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\dfrac{k_b + k_f}{m_f} & \dfrac{k_b}{m_f} & -\dfrac{c_b + c_f}{m_f} & \dfrac{c_b}{m_f} \\ \dfrac{k_b}{m_b} & -\dfrac{k_b}{m_b} & \dfrac{c_b}{m_b} & -\dfrac{c_b}{m_b} \end{bmatrix} \quad \mathbf{B} = \begin{bmatrix} 0 \\ 0 \\ \dfrac{1}{m_f} \\ -\dfrac{1}{m_b} \end{bmatrix} \quad \mathbf{E} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ -\dfrac{1}{m_b} \end{bmatrix}$$

Sliding mode motion equation. Consider the following sliding surface

$$s = Cx \tag{6}$$

where C=(c_1,c_2,c_3,c_4), without loss of generality, from now on, one makes $c_4 = 1$, and others are constant.

Because **AB** is controllable, the system can be transformed to into skeleton type through nonsingular transformation (Gao W. 1996). Defining the transformation matrix as follows

$$\mathbf{T} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & \dfrac{m_b}{m_f} \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{7}$$

$$\bar{x} = \mathrm{T}x\,;\ \overline{\mathbf{B}} = \mathbf{TB}\,;\ \overline{\mathbf{A}} = \mathbf{TAT}^{-1} \tag{8}$$

The skeleton type equation is obtained, as following:

$$\begin{bmatrix} \dot{\bar{x}}_1 \\ \dot{\bar{x}}_2 \end{bmatrix} = \begin{bmatrix} \overline{\mathbf{A}}_{\mathbf{11}} & \overline{\mathbf{A}}_{\mathbf{12}} \\ \overline{\mathbf{A}}_{\mathbf{21}} & \overline{\mathbf{A}}_{\mathbf{22}} \end{bmatrix} \begin{bmatrix} \bar{x}_1 \\ \bar{x}_2 \end{bmatrix} + \begin{bmatrix} \mathbf{0} \\ \overline{\mathbf{B}}_{\mathbf{2}} \end{bmatrix} u \tag{9}$$

$$s = (\overline{C}_1, \overline{C}_2) \begin{bmatrix} \bar{x}_1 \\ \bar{x}_2 \end{bmatrix} \tag{10}$$

where:

$$\overline{\mathbf{A}}_{\mathbf{11}} = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ -\dfrac{k_f}{m_f} & 0 & -\dfrac{c_f}{m_f} \end{bmatrix} \quad \overline{\mathbf{A}}_{\mathbf{12}} = \begin{bmatrix} -\dfrac{m_b}{m_f} \\ 1 \\ \dfrac{c_b m_b}{m_f^2} \end{bmatrix} \quad \overline{\mathbf{A}}_{21} = \begin{bmatrix} \dfrac{k_b}{m_b} & -\dfrac{k_b}{m_b} & \dfrac{c_b}{m_b} \end{bmatrix} \tag{11}$$

To guarantee the existence of $(\overline{\mathbf{C}}_2\overline{\mathbf{B}}_2)^{-1}$, $\overline{\mathbf{C}}_2^{-1}$, the equation $m_f - m_b c_3 \neq 0$ must be satisfied. Therefore, the following equation can be written in sliding mode surface.

$$s = Cx = \overline{C}_1 \bar{x}_1 + \overline{C}_2 \bar{x}_2 = 0 \tag{12}$$

So that, the motion equation on sliding mode surface can be obtained:

$$\dot{\bar{x}}_1 = (\overline{\mathbf{A}}_{11} - \overline{A}_{12}\overline{C}_2^{-1}\overline{C}_1)\bar{x}_1 \tag{13}$$

The characteristic polynomial of this sliding mode motion equation can be written:

$$D(p) = -p^3 + \frac{m_f c_2 - c_f - m_b c_1}{m_f - m_b c_2} p^2 + \frac{c_2 c_f + k_2}{m_f - m_b c_2} p + \frac{k_2 c_2}{m_f - m_b c_2} \tag{14}$$

According the stable theory, require the following:

$$\begin{cases} c_2 > 0 \\ c_1 < \dfrac{m_f c_2 + c_2}{m_b} - \dfrac{k_f c_2}{(c_2 c_f + k_f) m_b} \end{cases} \tag{15}$$

Approach rate and controller. The condition of the sliding mode motion existence and accessibility can be expressed as $s\dot{s} < 0$. Introducing the approach rate limit the approach motion to improve the dynamic qualities in the normal motion stage. This paper selects the exponent approach rate.

$$\dot{s} = -\varepsilon \operatorname{sgn} s - ks \quad (\varepsilon、 k > 0) \tag{16}$$

Consider the following equation:

$$\dot{s} = C\dot{x} = C(\mathbf{A}\mathbf{x} + \mathbf{B}u + \mathbf{E}d) \tag{17}$$

The control force function is expressed as following:

$$u = -(CB)^{-1}(\varepsilon \operatorname{sgn} s + ks + CAx + CEd) \tag{18}$$

Since it is difficult to obtain the track irregularity, the track disturbance must be decoupled from u. So, $CE = c_3 k_f / m_2 = 0$, therefore $c_3 = 0$ (Zhao C, 2007). The control force can be written as follows:

$$u = -(CB)^{-1}(\varepsilon \operatorname{sgn} s + ks + CAx) \tag{19}$$

Constraint condition. Because the semi-active system attenuates vibration through damping force, the controllable damping force does only negative work. Introducing the constraint condition of semi-active suspension, the control force can be express as following:

$$u = \begin{cases} -(CB)^{-1}(\varepsilon \operatorname{sgn} s + ks + CAx + CEd) & \dot{x}_b(\dot{x}_b - \dot{x}_f) \geq 0 \\ 0 & \dot{x}_b(\dot{x}_b - \dot{x}_f) < 0 \end{cases} \tag{20}$$

CO-SIMULATION MODEL

The vehicle dynamic model of a certain style vehicle is created as Figure 2 (Wang, G. 2005). Base on the control force, the model of controller is constructed using Simulink. Finally, the co-simulation model is set up show as Figure 3. The co-simulation of the vehicle dynamic model and controller can be done using Simulink.

Then, the applicability and control performance of the VSS controller base on the 3DOF vehicle model for the practical vehicle are verified (Dong X, 2005).

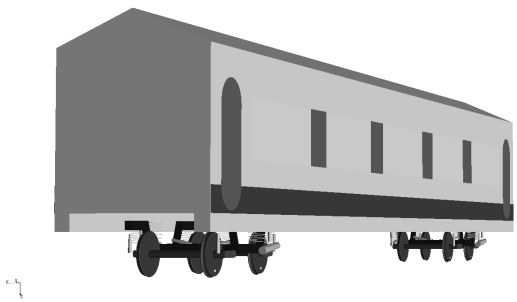

Figure 2. ADAMS vehicle model.

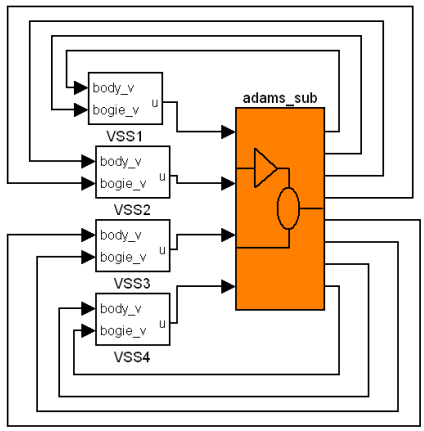

Figure 3. Co-simulation model.

SIMULATION AND RESULTS

According to the vehicle model which is built using ADMAS/rail, the parameter of simulation is presented in Table 1. The track disturbance adopt ORE low interfere spectrum.

Table1. Simulation Parameter

Parameter	Value	Parameter	Value
m_b/kg	32000/4	c_1	-30
m_f/kg	2615/2	c_2	30
k_b/(kN*sm^{-1})	430	c_3	0
k_f/(kN*sm^{-1})	1220*2	k	29
c_b/(kN*m^{-1})	20	ε	0.01
c_f/(kN*m^{-1})	4*2		

The car body displacement and velocity of the passive suspension system and semi-active suspension system are depicted in Figures 4 and 5.

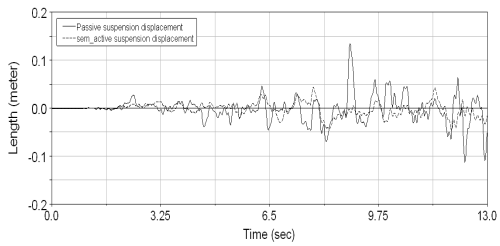

Figure 4. Displacement.

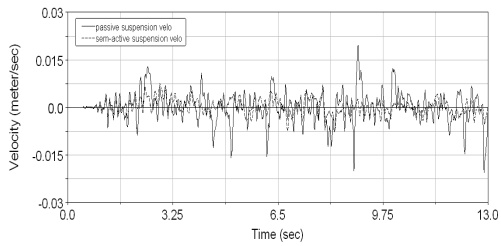

Figure 5. Velocity.

It is clear from Figure 4 that the semi-active suspension attenuates vibration

amplitude effectively. However, the amplitude is enlarged at 7.5 seconds and 11.5 seconds slightly, because the controller designed the base on simplified model does not fit the complex model completely. The car body acceleration of two suspension system is depicted in Figure 6.

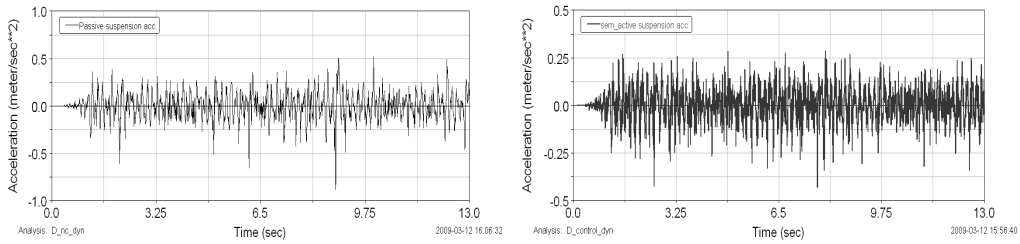

Figure 6. Acceleration of passive suspension and semi-active suspension.

Figure 7 is the acceleration frequency spectrum. The semi-active suspension system is also better than the passive one. From this it is clear that the low frequency vibration is isolated effectively.

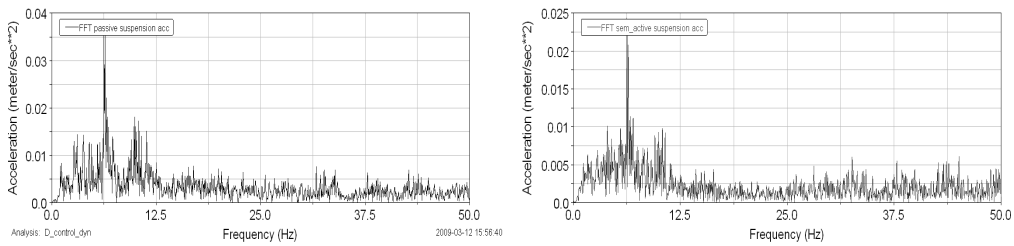

Figure 7. Acceleration frequency spectrum.

CONCLUSION

This paper considers the variable structure control with 3DOF vehicle model for design in a semi-active suspension system. Through the co-simulation, the effect of the VSS controller is studied for the practical complex model. The result shows that the isolating vibration effect of semi-active suspension system with VSS controller is better than the passive one. It is profitable to improve the riding comfort and security.

Structural Noise of Longitudinal Stiffened Concrete Cylindrical Shell

XIE Weiping[1] and SUN Liangming[1]

[1]School of Civil Engineering and Architecture, Wuhan University of Technology, Wuhan 430070, China; PH (86) 027-50247564; FAX (86) 027-87664561; email: wpxie@sina.com

ABSTRACT

Structural noise induced by urban viaduct box beam basically comes from the vibration responses with low frequency noises, which may adversely affect humans and the production of high-precision instruments. The mitigation of vibration induced noises becomes a hot, but practical, issue in the field of environmental protection. Aimed at the coupling effect between medium and structure, the characteristics of sound radiation of the longitudinal stiffened concrete cylindrical shell are investigated. Firstly, motion equations of infinite concrete cylindrical shell are established. Secondly, radial velocity of the shell in wave-number domain is obtained based on the wave-number domain approach and transfer matrix method. And then, the forecast model of pressure radiated by the shell is formulated according to the stationary phase method. The results show that longitudinal ribs can effectively reduce the vibration and noise of concrete cylindrical shell. These can provide foundation to the research of reducing vibration and noise of the pipeline structure in practical engineering and the theoretical research on structural noise of railway box beam in urban viaduct rail facilities.

INTRODUCTION

With the rapid development of urban rail industry, the vibration and noise pollution induced by traffic loads have attracted more and more attention in recent years. Structural noises induced by urban viaduct box beam basically comes from the vibration responses with low frequency noises, which may adversely affect humans, the production of high-precision instruments, and the basic operation of hospitals, academic institutions, etc. (Ngai and Ng 2002). The mitigation of vibration induced noises becomes a hot, but practical, issue in the field of environmental protection. The acoustic radiation caused by the vibration of box beam demonstrates the properties of fluid-structure coupling vibration, which is a leading topic in structural acoustics and noise control. The investigation on the acoustic radiation from the box beam based on analytical method or semi-analytical method are quite limited due to the complexity of the equation of motion induced by the curvature varying in the circumferential direction (Junger and Feit 1986).

Ngai (2002) states that the peak level of structure-borne noise is mainly caused by the vibration resonance of the concrete structure, and the frequency range of structure-borne noise generated from concrete box and railway viaduct is within the range from 20Hz to 120Hz. Burroughs (1984) investigated radiation acoustic

pressure in the far field of a fluid-loaded infinite circular cylindrical shell reinforced with doubly periodic ring supporters subjected to a point-driven force with the aiding of the Fourier Transform, modal expansion in circumferential direction and the impedance method. But the model was quite simple because only the radial interacting forces between the stiffeners and the shell were considered. Based on the Burroughs' model, Chen et al (2002) studied the acoustic radiation from the orthogonally stiffened circular cylindrical shells. Wu (2002) examined the double-layer structural-acoustic coupling problem for cylindrical shell through the combination of the wave-number domain approach and the boundary integral equation. Xie et al. (2008) investigated the acoustic properties of the concrete cylindrical shell with/without stiffened ring ribs based on the finite element method.

Present research mainly focuses on the properties of circular cylindrical shells in the fields of military and machine fabrication. Furthermore, the research on the fluid-structure coupling in civil engineering is reported only for experimental and numerical investigation on the circular cylindrical shells. To this end, this paper examines the properties of structural noise of longitudinal stiffened infinite concrete cylindrical shells. The observations made in this study can be provided as beneficial guidelines for the noise mitigation of pipeline structures and railway box beams of urban viaduct rail facilities.

THEORETICAL ANALYSIS OF COUPLING SYSTEM

The configuration of an example longitudinal stiffened infinite concrete cylindrical shell is displayed in Figure 1.

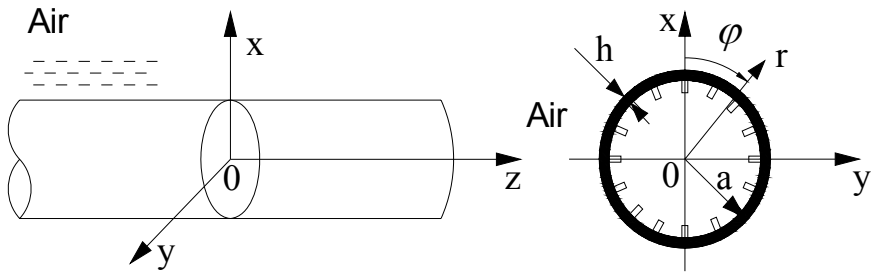

Figure 1. Longitudinal stiffened concrete cylindrical shell.

The exterior of the infinite concrete cylindrical shell is surrounded by air. The air is assumed to be compressible and inviscid. Therefore, only radial reaction on the shell can be observed. The mass density of the air is ρ_0 and the sound speed is c_0. The radius of the middle surface and the thickness are a and h respectively. Donnell's thin shell theory is utilized to describe the motion of the shell. The external excitation force is a point force towards the shell in the normal direction on shell outside surface. All of the loadings have a harmonic time dependence $e^{-i\omega t}$, where ω is the radian frequency, as an algebraic convenience, $e^{-i\omega t}$ is suppressed throughout. The observation point for the acoustic radiation is located in the far-field, such that $k_0 r >> 1$, where $k_0=\omega/c_0$ is the acoustic wave-number and r is the radial distance of the observation point from the z axis.

Following the classical assumption of Donnell, the equation of motion of the

shell can be expressed as:

$$[R]\cdot\begin{bmatrix} u_z(a,\varphi,z) \\ u_\varphi(a,\varphi,z) \\ u_r(a,\varphi,z) \end{bmatrix} = \frac{1-\mu^2}{E^* h}\begin{bmatrix} 0 \\ 0 \\ -p_l(a,\varphi,z) - F(a,\varphi,z) - p(a,\varphi,z) \end{bmatrix} \tag{1}$$

$$[R]=\begin{bmatrix} \frac{\partial^2}{\partial z^2}+\frac{1-\mu}{2a^2}\frac{\partial^2}{\partial\varphi^2}+\frac{\omega^2}{c_l^2} & \frac{1+\mu}{2a}\frac{\partial^2}{\partial z\partial\varphi} & \frac{\mu}{a}\frac{\partial}{\partial z} \\ \frac{1+\mu}{2a}\frac{\partial^2}{\partial z\partial\varphi} & \frac{1}{a^2}\frac{\partial^2}{\partial\varphi^2}+\frac{1-\mu}{2}\frac{\partial^2}{\partial z^2}+\frac{\omega^2}{c_l^2} & \frac{1}{a^2}\frac{\partial}{\partial\varphi} \\ \frac{\mu}{a}\frac{\partial}{\partial z} & \frac{1}{a^2}\frac{\partial}{\partial\varphi} & \frac{1}{a^2}+\beta a^2\nabla^4-\frac{\omega^2}{c_l^2} \end{bmatrix}$$

in which $u_z(a,\varphi,z)$, $u_\varphi(a,\varphi,z)$, and $u_r(a,\varphi,z)$ are the axial, circumferential and radial displacement at the cylinder's mid-surface, respectively. They are positive if they are in the positive direction of the coordinate axis. The mechanical excitation force is expressed as $F(a,\varphi,z)$. The acoustic pressure on the exterior surface of shell is $p(a,\varphi,z)$ and the reaction pressure due to the attachment of the axial ribs on the shell surface is $p_l(a,\varphi,z)$. ρ is the mass density of the shell; $E^*=E(1+i\eta)$ is the complex Young's modulus of the shell; μ is the Poisson's ratio of material; $\beta=h^2/12a^2$, $c_l=(E^*/\rho(1-\mu))^{0.5}$ is the longitudinal wave speed of the shell.

To define the Fourier Transform (FT) as:

$$\tilde{f}_n(r,\zeta)=\int_{-\infty}^{+\infty} f_n(r,z)e^{-iz\zeta}dz=\int_{-\infty}^{+\infty}(1/2\pi)\int_0^{2\pi} f(r,\varphi,z)e^{-in\varphi}d\varphi e^{-iz\zeta}dz \tag{2}$$

By using FT in the z direction and φ direction, the equation of motion of the shell in the wave-number domain can be written as:

$$\begin{bmatrix} \tilde{u}_{z,n}(a,\zeta) \\ \tilde{u}_{\varphi,n}(a,\zeta) \\ \tilde{u}_{r,n}(a,\zeta) \end{bmatrix} = \frac{1-\mu^2}{E^* h}\tilde{\Gamma}_n\begin{bmatrix} 0 \\ 0 \\ -\tilde{p}_{ln}(a,\zeta) - \tilde{F}_n(a,\zeta) - \tilde{p}_n(a,\zeta) \end{bmatrix} \tag{3}$$

where n denotes the order of FT in the φ direction; $\zeta=(k_0^2-\gamma_0^2)^{0.5}$ is the axial wave-number in the air; γ_0 is the radial wave-number in the exterior air. Therefore, the spectral radial velocity of the neutral surface of the shell is:

$$\tilde{\dot{u}}_{r,n}(a,\zeta)=i\omega[(\mu^2-1)/E^* h]\cdot\tilde{\Gamma}_{n3}^3\cdot[-\tilde{p}_{ln}(a,\zeta)-\tilde{F}_n(a,\zeta)-\tilde{p}_n(a,\zeta)] \tag{4}$$

Moreover, the spectral radial velocities among the inner surface, the neutral surface and the outer surface of the shell are identical. Based on the transfer matrix equation of the shell, the spectral radial velocity of the outer surface of the shell is:

$$\tilde{\dot{u}}_{r,n}(a,\zeta)=\tilde{F}(a,\zeta)/[-\tilde{Z}_{l,n}(a,\zeta)-\tilde{Z}_{s,n}(a,\zeta)-\tilde{Z}_{0,n}(a,\zeta)] \tag{5}$$

where the radial mechanical impedance is:

$$\tilde{Z}_{s,n}(a,\zeta)=E^* h/[i\omega(\mu^2-1)\tilde{\Gamma}_{n3}^3] \tag{6}$$

With harmonic time dependence, the acoustic pressure in the air surrounding the shell satisfies the following Helmholtz equation:

$$(\nabla^2+k_0^2)p(r,\varphi,z)=0 \tag{7}$$

The solution to Equation (7) in the wave-number domain is:

$$\tilde{p}_n(r,\zeta) = A_1(n,\zeta)J_{|n|}(\gamma_0 r) + A_2(n,\zeta)H_{|n|}(\gamma_0 r) \tag{8}$$

where $J_n()$ is the nth-order Bessel function and $H_n()$ is the nth-order Hankel function.

At the fluid-structure interface, the radial displacement of the air is equal to the radial displacement of the shell. From the momentum equation, it has:

$$\partial \tilde{p}_n(a,\zeta)/\partial r = i\omega\rho_0 \tilde{\dot{u}}_{r,n}(a,\zeta) \tag{9}$$

It is noted that the spectral radial velocity of the outer surface of the shell can be calculated when the exterior acoustical radiation impedance are determined. Based on the Sommerfield radiation condition, the exterior acoustical radiation impedance can be written as follows:

$$\tilde{Z}_{0,n}(a,\zeta) = i\omega\rho_0 H_{|n|}(\gamma_0 a)/(\gamma_0 H'_{|n|}(\gamma_0 a)) \tag{10}$$

The force on the shell surface exerted by axial ribs is given by:

$$p_l(a,\varphi,z) = \sum_{j=1}^{M} p_l^j(a,z) \sum_{n=-\infty}^{+\infty} \delta\{a[\phi - (\phi_j + 2\pi n)]\} \tag{11}$$

where $p_l^j(a,z)$ is the normal distributed force on the surface per unit length in the x direction, which is produced by the j-th axial rib, and the delta function has dimension [m^{-1}] in order to convert the force per unit length into the force per unit area on the cylinder; $\Phi_j=(2\pi/M)j$, M being the number of the axial ribs.

Here, the axial ribs are modeled as Euler beams, and the shear deformation and rotation inertia are neglected. On the basis of the continuity of the radial displacements between the shell surface and the FT, we have:

$$\tilde{p}_{\ln}(a,\zeta) = \frac{k^4 E_l I_l - \rho_l A_l \omega^2}{-2i\omega\pi a} \sum_{m=-\infty}^{+\infty} \sum_{j=1}^{M} e^{i(m-n)\phi_j} \tilde{\dot{u}}_{r,n}(a,\zeta) = Z_l \sum_{m=-\infty}^{+\infty} A_{nm} \tilde{\dot{u}}_{r,n}(a,\zeta) \tag{12}$$

where the cross-sectional area of the axial rib is A_l, the inertia moment is I_l, the material density is ρ_l, and Young's modulus is E_l. Because the n-order modal force of exterior shell by longitudinal ribs can not only determine by the n-order modal radial velocity, but also by the other order modal radial velocity. If longitudinal ribs are evenly arranged along the circumferential direction, circumferential modal coupling caused by them is a very weak coupling. The Equation (12) can be written as follows:

$$\tilde{p}_{\ln}(a,\zeta) = Z_l \cdot M \cdot \tilde{\dot{u}}_{r,n}(a,\zeta) \tag{13}$$

By applying the external force at the point (z_0,φ_0) from outside the shell, the expression for the external applied pressure is:

$$F(a,\varphi,z) = F_0 \delta(z - z_0)\delta(\varphi - \varphi_0)/a \tag{14}$$

where F_0 is the magnitude of the applied force. Taking the FT Equation (14) yields:

$$\tilde{F}_n(a,\zeta) = (1/2\pi)\int_0^{2\pi} e^{-in\varphi} \int_{-\infty}^{+\infty} F(a,\varphi,z) e^{-i\zeta z} dz d\varphi = (F_0/2\pi a) e^{-in\varphi_0 - i\zeta z_0} \tag{15}$$

Substituting Equations (10), (12), (15) into Equation (5) yields the spectral

radial velocity of the outer surface of the shell in the wave-number domain.

It should be noted that the crucial parts are the prediction of the acoustic radiation at far field. Let *(R, θ, ψ)* be the coordinates of an observation point *N* at the far field (see Figure 2), then according to the boundary integral equation and the stationary phase method, the far field acoustic pressure is expressed as:

$$p(R,\theta,\psi)=\frac{\rho_0 c_0 e^{jk_0 R}}{\pi R\sin\theta}\sum_{n=-\infty}^{\infty}\frac{(-i)^{|n|}}{H'_{|n|}(k_0 a\sin\theta)}\tilde{u}_{r,n}(a,k_0\cos\theta)e^{jn\psi} \tag{16}$$

where $\tilde{u}_{r,n}(a,k_0\cos\theta)$ is given by Equation (5), in which $\zeta=k_0 cos\theta$.

Thus, the far field acoustic pressure level is given by $L_p=20\lg[p(R,\theta,\psi)/p_{ref}]$, where $p_{ref}=2\times10^{-5}Pa$.

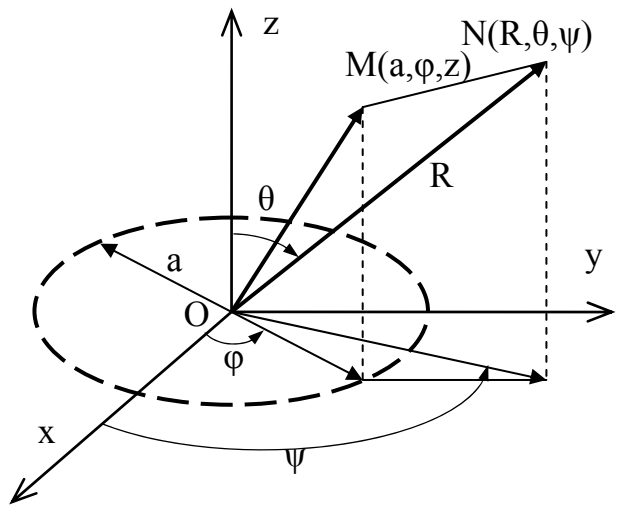

Figure 2. The source point and the observation point of geometry sketch map.

NUMERICAL INVESTIGATIONS

In this section, numerical results based on Equation (16) are presented for the far field acoustic pressure levels of the acoustic radiation from a longitudinal stiffened infinite concrete cylindrical shell immersed in air. It is demonstrated based on numerical observations that the effects of longitudinal ribs on the rule of infinite concrete cylindrical shell are important. The following parameters for the model are used in the calculations. $a=1m$, $h=0.05m$, $\mu=0.2$, $E=3.25\times10^{10}N/m^2$, $\rho=2550kg/m^3$, $\eta=0$, $(z_0,\varphi_0)=(0,0)$, $F_0=100N$, $\rho_0=1.21kg/m^3$, $c_0=343m/s$, $N_1(5m,\pi/2,0)$, $A_l=5.22\times10^{-3}m^2$, $I_l=3.28\times10^{-5}m^4$.

From Figure 3, it can be found that, the axial ribs have an evident effect on the acoustic radiation and vibration of the shell and the sound pressure levels (SPL) decrease.

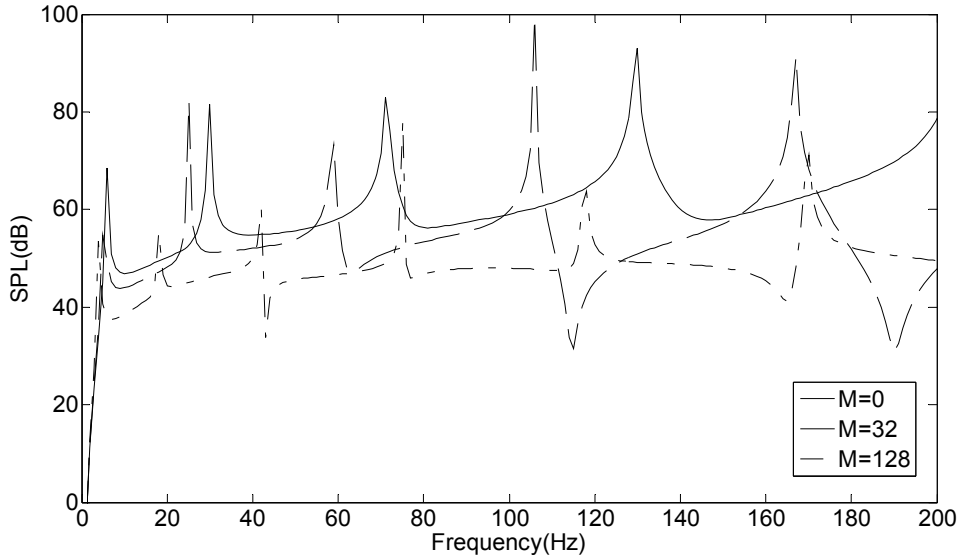

Figure 3. The curves of SPL and frequency with different ribs.

CONCLUSIONS

The analytical approach for rating noise effects of longitudinal stiffened infinite concrete cylindrical shell is actively investigated in this study. The key of computing the acoustic radiation from the infinite concrete cylindrical shell is the solution the equation of motion with fluid-structure coupling effects, the Helmholtz equation, the Sommerfield radiation condition and the coordination condition which is at the interface between air and concrete cylindrical shell. The predicting model of pressure radiated by the shell is deduced based on the wave-number domain approach and transfer matrix method. The results show that longitudinal ribs can effectively reduce the vibration and noise of concrete cylindrical shell. The observations made in this study can be provided as beneficial guidelines for the noise mitigation of pipeline structures and railway box beams of urban viaduct rail facilities.

ABSTRACT

Train rescheduling is the key work in railway operation. Due to its complexity, it is very difficult to achieve optimal results and the heuristic algorithms become the most popular and effective solving techniques. The paper presents a greedy algorithm for train rescheduling, in which conflicts are resolved respectively with the greedy principle. The algorithm has an excellent efficiency and enables dispatchers to take part in the optimization process more broadly. As a result, it can take more factors into account and make full use of experts' experience to make the solution more practical and efficient.

INTRODUCTION

Railways play a vital role in many countries, which has researchers focusing on train rescheduling a great deal of the time. Branch and bound algorithm is often applied to resolve the problem. The most recent research was done by Dessouky et al. (2006) and D'Ariano et al. (2007). There is, however, an unavoidable disadvantage in that the models are sometimes difficult to resolve, although powerful computers and programming software can resolve the problems. As a result, the application of the models must be limited to small-sized problems and sometimes "unimportant" factors have to be ignored. Furthermore, the experience of dispatchers can hardly be added into the models. All the above prevent the models from being applied in real-time operation. Since 2007, many heuristic algorithms have been developed to achieve satisfactory solutions, though not optimal, but are good enough.

Zhou (1994) used discrete event system (DES) to describe the railway system and presented an algorithm for train rescheduling based on DES firstly. Medanic and Dorfman (2001), (2002), (2004) researched greedy TAS algorithms based on DES with the objective of time or energy efficiency for single-track railway line. Cai et al. (1998) also developed a greedy heuristics algorithm for rapid scheduling of trains on a single line. The algorithm was so efficient that it could be used to tackle large numbers of trains. Cheng (1998) provided a hybrid simulation algorithm that tried to combine the advantage of event-driven and network simulation together to resolve each conflict more easily and effectively. Ismail (1999) provided an algorithm that handled immediate conflict according to dynamic priority of the trains. Adenso-Diaz (1999) presented a heuristic procedure to choose the most appropriate solution from solutions spaces. Jin ([2004) developed a non-delay dispatch algorithm with multiple objectives, which, in fact, is based on DES. In Dessouky's and D'Ariano's research,

some heuristic rules were added that greatly increased the efficiency of the algorithm in order to make it useful in real-time operation. All of the above research proved especially helpful for this paper.

MODELING PROBLEM

The most common objective is to minimize total weighted or unweighted delay time. Other possible objectives include the minimization of the total quantity of delayed trains and energy consumption, and so on.

In this study, we made the following assumptions and definitions:

1) The railway line in the paper has double tracks;

2) There are totally m stations ($s_1, s_2, \cdots, s_m$) in the problem ordered by inbound direction;

3) According to assumption 2, there are totally m-1 sections ($q_1, q_2, \cdots, q_{m-1}$) in the problem where s_i and s_{i+1} are the immediate stations of q_i.

Taking the minimization of overall weighted delay time as the optimizing objective, the model of the problem could be described as follows:

$$\min \sum_{i=1}^{n} \omega_i dt_i$$

Subject to:

$$(-1)^{d_{i,j}} \cdot t_{i,j+1}^{a} - (-1)^{d_{i,j}} \cdot t_{i,j}^{d} \geq (1 - d_{i,j}) \cdot r_{i,j}^{out,\min} + d_{i,j} \cdot r_{i,j}^{in,\min} \quad (1)$$

$$t_{i,j}^{a} \Theta t_{k,j}^{a} \geq I_{i,k}^{a,j} \quad (2)$$

$$t_{i,j}^{d} \Theta t_{k,j}^{d} \geq I_{i,k}^{d,j} \quad (3)$$

$$t_{i,j}^{d} - t_{i,j}^{a} \geq \tau_{i,j}^{s\min} \quad (4)$$

$$t_{i,j}^{d} \geq t_{i,j}^{*d} \quad (5)$$

$$\sum_{i=1}^{n} g_{i,j}^{s,t} \leq n_j^{gs} \quad (6)$$

$$C(t_{i,j}^{f}, {}^{d}_{i,j}, t_{k,j}^{wb}, t_{k,j}^{we}) \cdot O(g_{i,j}^{q}, G_k^{w}) < 1 \quad (7)$$

$$C(t_{i,j}^{f}, t_{i,j+1}^{d}, t_{k,j+1}^{f}, t_{k,j}^{d}) \cdot Q(g_{i,j}^{q}, g_{k,j}^{q}) \cdot D(d_{i,j}, d_{k,j}) < 1 \quad (8)$$

where :

ω_i, dt_i are the weight and overall delay time of train *i*;

$d_{i,j}$ is the direction of train *i* in section *j*, 0 is outbound and 1 is inbound;

$t_{i,j}^{a}, t_{i,j}^{d}$ are the arrival and departure time of train *i* in station *j*;

$t_{i,j}^{*a}, t_{i,j}^{*d}$ are original arrival and departure time of train *i* in station *j* ("original" in the paper refers to the data in last rescheduled plan or initial timetable if the last rescheduled plan doesn't exist) ;

$r_{i,j}^{in}, r_{i,j}^{in,\min}, r_{i,j}^{out}, r_{i,j}^{out,\min}$ are the standard and minimum running time of train i in section j inbound or outbound direction;

$I_{i,k}^{a,j}, I_{i,k}^{d,j}$ are arrival and departure headway interval between train i and k in section j;

Θ is defined as: $t_{i,j}^{d} \Theta t_{k,j}^{d} = \begin{cases} t_{i,j}^{d} - t_{k,j}^{d}, & t_{i,j}^{d} \geq t_{k,j}^{d} \\ \infty & t_{i,j}^{d} < t_{k,j}^{d} \end{cases}$

$\tau_{i,j}^{s\min}$ is the minimum dwell time of train i in station j;

n_j^{gs}, n_j^{gq} are siding quantity of station i and section i;

$g_{i,j}^{s,t}$ is a 0-1 value variable. 1 means train i occupies a siding in station j at t moment, otherwise 0;

$C(t_{i,j}^{a}, {}^{d}_{i,j}, t_{k,j}^{wb}, t_{k,j}^{we})$ is defined as: $C(t_{i,j}^{a}, t_{i,j}^{d}, t_{k,j}^{wb}, t_{k,j}^{we}) = \begin{cases} 1 & t_{i,j}^{d} \leq t_{k,j}^{wb} \quad or \quad t_{i,j}^{a} \geq t_{k,j}^{we} \\ 0 & otherwise \end{cases}$

where $t_{k,j}^{wb}, t_{k,j}^{we}$ are begin and end time of section blockage k in section j;

$O(g_{i,j}^{q,t}, G_k^{w})$ is defined as: $O(g_{i,j}^{q}, G_k^{w}) = \begin{cases} 1 & g_{i,j}^{q} \in G_k^{w} \\ 0 & g_{i,j}^{q} \notin G_k^{w} \end{cases}$, where $g_{i,j}^{q}$ is the track used by train i in section j; G_k^{w} is the set of track involved in window k;

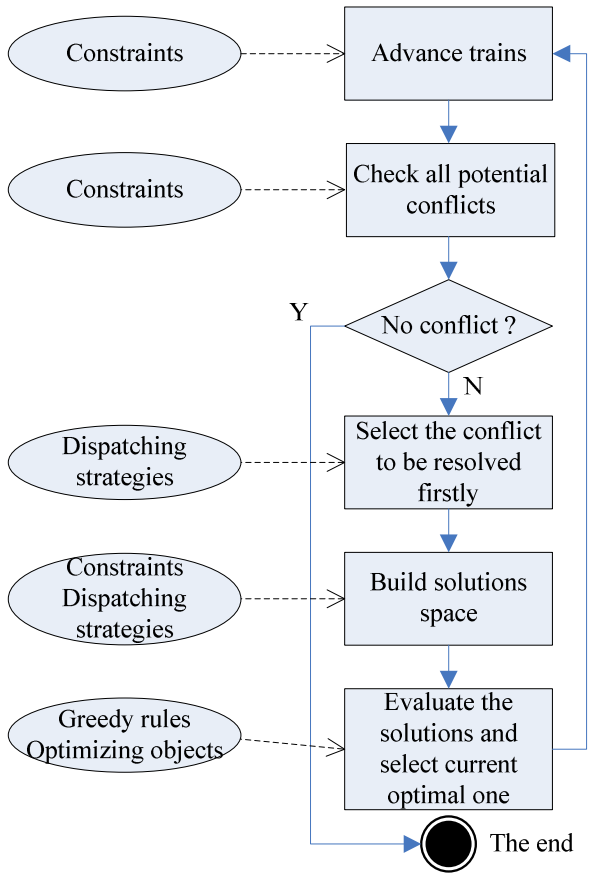
$Q(g_{i,j}^{q}, g_{k,j}^{q})$ is defined as: $Q(g_{i,j}^{q}, g_{k,j}^{q}) = \begin{cases} 1 & g_{i,j}^{q} = g_{k,j}^{q} \\ 0 & g_{i,j}^{q} \neq g_{k,j}^{q} \end{cases}$

$D(d_{i,j}, d_{k,j})$ is defined as: $D(d_{i,j}, d_{k,j}) = \begin{cases} 1 & d_{i,j} = 1 \quad and \quad d_{k,j} = 0 \\ 0 & otherwise \end{cases}$

GREEDY ALGORITHM

Main idea and process of the algorithm. There are usually over 100 pairs of trains in a dispatcher's territory with double tracks. As a result, the solution of the model above has obvious great complexity. It is generally impossible to get optimal solutions in a short time. Therefore, this paper presents a greedy algorithm for the problem. The main idea of the algorithm is to resolve only one conflict in each iteration and obtain the current optimal solution aiming at only the "current" conflict, until all conflicts are resolved. So that the optimization of the problem with large size is divided into a sequence of problems with small size and the solution can be gotten in a short time. Besides the objective and constraints described previously, the experience of experts can be introduced as dispatching strategies to enable the solutions more realistic and optimized. In addition, the algorithm is flexible and can be easily extended to deal with the new type of conflict, since each of the conflicts is resolved independently.

The process of the algorithm is shown as Figure 1.



1. Advance relative trains. The arrival and departure time of the delayed trains are recalculated from the changed location regardless the potential conflicts.
2. Detect potential conflicts according to the constraints described in the model. If no conflict exists, the process is accomplished and a new schedule is obtained.
3. Select the conflict that should be addressed firstly. In this step, some strategies such as "time priority" will be applied.
4. Build solutions space according to the constraints and dispatching strategies.
5. Evaluate each solution in solutions space and select the current optimal one. Then, turn to step 2 and a new iteration will begin.

Figure 1. Process of the algorithm.

Types of conflicts. Conflicts here refer to any events that make the current plan infeasible. In the real cases, conflicts usually interweave with each other especially in rush hours and it seems possible that each conflict involves several trains, which greatly increases the complexity of dispatching. Hence in this study, we assume that each conflict involves at most two trains. This means that conflicts occur either between two trains or between the train and other factors, such as section blockage. Therefore, a complicated conflict will be divided into several conflicts and each resolved separately. Six types of conflicts will be mentioned in the study:

- *Headway conflict*: headway interval between two trains is not enough. There are two subtypes: arrival headway conflict and departure headway conflict.
- *Facing in section conflict*: two trains meet in the same track in the section
- *Siding occupancy conflict*: two trains use the same siding at the same time while both/one of them must use it exclusively.
- *Route conflict*: two opposite routes are used at the same time.
- *Section blockage conflict*: the train runs through blocked area within the duration of section blockage.
- *Station blockage conflict*: the train uses the blocked device (siding, switch or

part of rail) of a station.

Train advancing. When abnormal events occur, the arrival and departure time of involved trains will have to be recalculated from the current station (if the delay occurred in station) or the next station (if the delay occurred in the section) mainly according to constraint 1, 4 and 5.

In some cases like Figure 2, some extra constraints could be added in order to improve the efficiency of the algorithm.

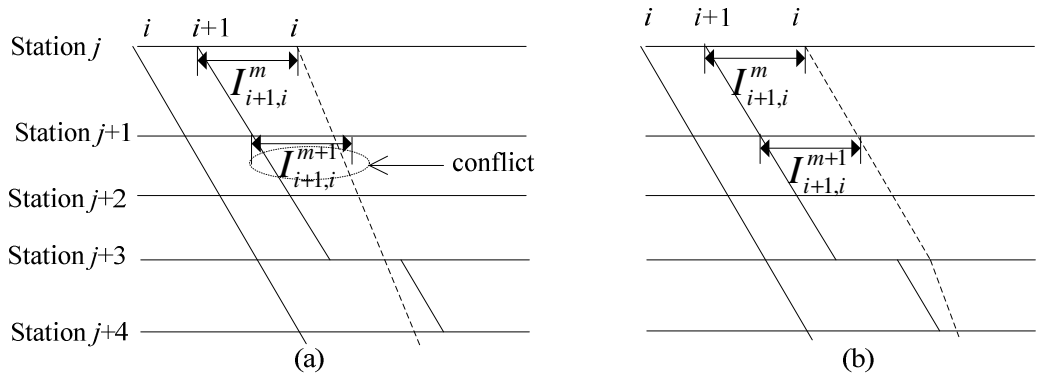


Figure 2. A case about train advancing.

In this case, train i and i+1 have a headway interval conflict in section j and the solution is to move train i behind of train i+1, shown as Figure 2(a). Since the minimum running time is used for train i, but train i+1 runs still by normal running time, the headway time between the two trains will become shorter and shorter. Since then, in a certain section, generally the section j+1, a new conflict occurs. According to previous solution, train i will be moved again. In the following iterations, similar situations will repeat again and again until train i+1 stops at a station. In fact, the following iterations can be avoided since it is always train i that is moved. Therefore, constraints 2 and 3 should be considered in this case and a new arrival time should be calculated as following from station j+1 to j+3 (station j+3 is the first station where train i+1 stops after station j) like Figure 2(b).

$$t^a_{i,j+1} = \max((1-d_{i,j}) \cdot r^{out,\min}_{i,j} + d_{i,j} \cdot r^{in,\min}_{i,j}, t^a_{i+1,j+1} + I^j_{i+1,j}) \quad (9)$$

Now there is no conflict from section j+1 to j+2 and much computation time is saved.

Approach to resolve the conflicts. The former four types of conflicts indicate that two trains want to occupy the same resource at the same time. The key to the solution is to determine which one should first use the resource and how to assign another resource or another time to the second train. Some strategies can help us in this process to determine the priority of the two trains directly. If none of the strategies can determine the final solution directly, a solutions space including two or

more possible solutions will be constructed and evaluated as follows:

Headway interval conflict. There are generally two possible solutions to this conflict: move train *i* while keeping train *k* unchanged or the contrary. The key to the approach is to reassign a new arrival or departure time to moved train.

Generally speaking, the moved train will arrive or depart as soon as the condition of headway interval can be fulfilled. Hence, if the current conflict is a departure headway interval conflict and occurs in station *j*, the solutions seem like Figure 3(a) and (b). In this case the new departure time of moved train (taking train *i* as example) is reassigned as: $t_{i,j}^{d} = t_{k,j}^{d} + I_{k,i}^{d,j}$. If the current conflict is an arrival headway interval conflict, the solutions have two possibilities, shown as Figure 3 (c) and (d). In the case of (c), the front train *i* is moved from station *j* and then the new departure time is: $t_{i,j}^{d} = t_{k,j}^{d} + I_{k,i}^{d,j}$. If train *k* is moved, the new arrival time in station *j*+1 will be reassigned as: $t_{k,j+1}^{a} = t_{i,j+1}^{a} + I_{i,k}^{a,j+1}$.

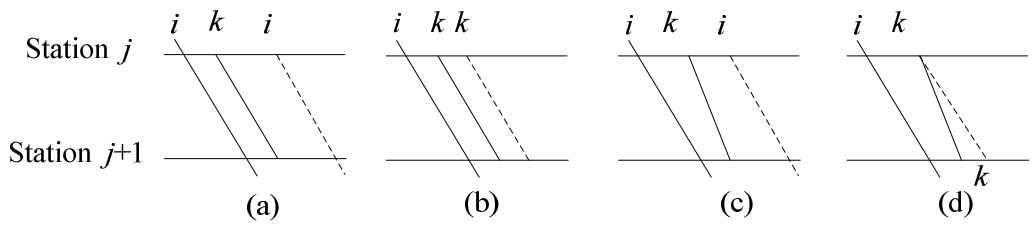

Figure 3. Approaches to resolve headway conflict.

Once a new departure or arrival time is changed, the moved train should be advanced from the station where change takes place to the destination of the train according to the method described in 3.3. Now overall weighted delay time of the two solutions in the solutions space can be calculated respectively according to the objective of the problem and the solution with less delay time will be the final solution for current conflict.

Facing in section conflict. The approach is similar to that described above. The difference lies in the determination of departure time of moved train. If outbound train *k* should be moved in station *j*+1, its departure time is changed to: $t_{k,j+1}^{d} = t_{i,j+1}^{d} + \tau_{j+1}^{ad}$, where τ_{j+1}^{ad} is the minimum interval between two trains needed by station operations.

Siding occupancy conflict. The main approach to resolve the conflict is to try to move each train to each siding of the station separately, and then evaluate the overall delay time of each solution and select the best one as the final solution of the conflict.

1) We assume that train *i* occupies the current siding, and train *k*

will be moved to another siding of the station *j* in turn. When train *k* is moved to siding *x*, the occupancy time slice of train *k* ($ts_{k,j}$) will be compared with the time slice of other trains that occupy siding *x* to calculate overlapped time of each two time slices. If $ts_{l,j}$ has the longest overlapped time with $ts_{k,j}$, train *l* and train *k* are the bottleneck of current operation and they will construct a solution. If none of the time slice have overlapped time with $ts_{k,j}$, train *k* will construct the solution itself.

2) If two trains construct the solution, the subsequent work is to postpone the later train to resolve the conflict between two trains. If train *l* is the later train, its earliest arrival time will be rearranged as $t_{l,j}^{a} = t_{k,j}^{d} + \tau_{j}^{o,\min} + \tau_{j}^{c,\min}$. Then train *l* should be re-advanced from station *j* and a solution is accomplished.

3) Continue the operations above, and finally *n* (*n* is the quantity of siding in the station) solutions will be obtained.

4) Assume that train *k* occupies the current siding and repeat operations above, and other *n* solutions will be obtained.

Now the solutions space has been constructed and the final work is to calculate overall delay time of each solution and select the one with least delay time as a final solution for this conflict.

Route conflict. The possible solutions include changing another route or even another siding and postpone arrival or departure time of one of the two trains. Since the duration of this conflict is usually pretty short and changing to another route will more likely lead to potential conflicts, we can just postpone the arrival or departure time of the train. Then the solutions space has also two solutions: to postpone train *i* or train *j*. Subsequent work is also to evaluate each solution and select one.

Section blockage conflict. The only solution for this conflict is to prevent the train from entering the blocked segment and postponing the departure time is the most common measure. In the algorithm, the departure time will be postponed to the end of blockage firstly. Some headway conflicts maybe occur after this operation. However, that is the work of next iteration and will not be considered here.

Station blockage conflict. If a siding is blocked, the resolving process is almost the same as with that of siding occupation conflict. The only difference is the blocked siding should not be considered. If other devices are blocked, the solution is to select another route for the train. At last, if there is no practicable route currently, the train has to be postponed in the previous station.

Tracing-back in the algorithm. If there are headway interval conflicts between train *i* and *k*, *k* and *m*, but no conflict between train *i* and *k*, shown in Figure 4(a). According to this algorithm, we should resolve the conflict between train *i* and *k* first, and get the new train diagram shown in Figure 4(b). Then, the conflict between *k* and *m* is handled and finally train *k* is moved. Now train *k* and *i* conflict again, and train *i* has to be moved second time. The final solution shown as Figure 4(c) is obtained. In this solution, train *i* is moved two times and becomes the last

train.

When we think over the whole process carefully, something unreasonable will be found. Train *i* moved firstly because the better solution is to keep train *k* unchanged. However, at the next step, train *k* is also moved. It means that the reason for the first movement of train *i* does not exist any longer and the first moving is unnecessary at that time. Thus, this solution is obviously not the result we need and some measures should be introduced into the algorithm to avoid this phenomenon in this situation.

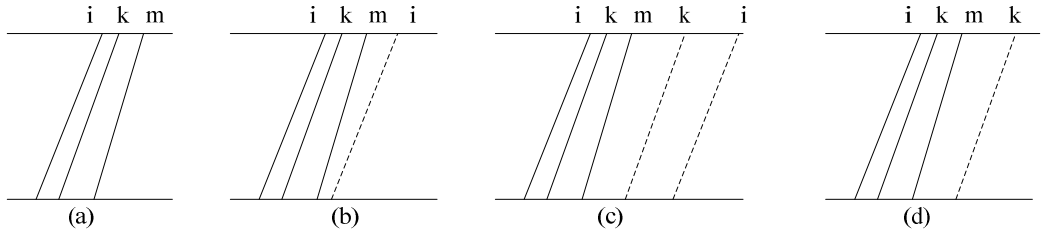

Figure 4. Example of rescheduling process.

Tracing-back in the algorithm is designed aiming at the circumstance described above. Firstly, when a train is moved, original information will be recorded in this train and the index information, generally the train ID, will be recorded in another train in the solution. Taking the instance above as an example, the information about train *i* will be recorded into a set of train *k* as $N_k^{move} = \{i\}$ when train *i* was moved in the first step. Then, in the following step, N_k^{move} will be checked once train *k* was determined to be moved. If the N_k^{move} is not null, the trains recorded in it will return back to their original status. The solution of the instance above is changed as Figure 4(d) when tracing-back is introduced.

Tracing-back should be introduced in handling not only headway interval conflicts, but also all the other types of conflicts. Once anything of the train, no matter arrival and departure time, route or siding, is determined to be changed in the process of rescheduling, the original information should be recorded in the train itself and the index of the train should be recorded in the other object (the other train or blockage). Once the latter is also changed (the train is moved or the blockage is canceled), the former will return back to its original status by the help of the information recorded previously.

In addition, the relative information in any train will be deleted when all the conflicts are resolved and current rescheduling is completed lest the information will influence next rescheduling.

EXAMPLES

We take Wu-guang line, a constructing passenger dedicated line (PDL) in China as the example which has double-track mainlines and 18 stations to test the algorithm. We construct a timetable that includes 115 pairs of high-speed trains (HS)

and 30 pairs of middle-speed trains (MS). The weight of HS and MS is 3 and 1 respectively. We set 4 scenarios in which delay rate and average delay time of HS and MS are: 1) 3%, 5 min, 5%, 5min; 2) 3%, 5 min, 10%, 10min; 3) 5%, 10 min, 10%, 15min; 4) 5%, 10 min, 20%, 15min.

Thirty experiments were made aiming at each scenario. The rescheduling result was shown in Table 1.

Table 1. Result of Rescheduling Test.

Scen-arios	Initially delayed trains				Finally delayed trains						WTDT	ASRT
	HS		MS		HS			MS				
	QDT	ADT	QDT	ADT	QDT	ADT	TDT	QDT	ADT	TDT		
1	3.6	5:20	1.7	4:57	1.9	1:56	3:45	1.8	16:45	29:27	40:42	0.68
					2.1	5:14	11:00	1.2	8:45	10:31	43:31	
2	3.6	5:20	3.4	10:00	3.1	1:56	6:04	3.5	17:04	59:27	1:17:39	0.8
					3.1	4:42	14:32	3.1	13:11	41:26	1:25:02	
3	5.9	09:46	3.2	15:01	7.5	03:31	26:26	5.4	17:02	1:32:36	2:51:54	2.93
					5.9	07:52	46:30	5.3	28:06	2:29:55	4:49:25	
4	5.9	10:02	6.5	14:59	9.1	03:15	29:43	7.7	19:30	2:30:10	3:59:19	3.5
					6.7	06:57	46:35	8.8	25:49	3:46:20	6:06:05	

* QDT: Quantity of Delayed Trains; ADT: Average Delay Time; TDT: Total Delay Time; WTDT: Weighted Total Delay Time; ASRT: Average System Running Time for each experiment (Seconds).

The data with gray background is the result of a typical class-based algorithm. According to this algorithm, when a conflict occurs between HS and MS, the HS will generally run firstly or the trains will run by their current orders. Furthermore, HS can also wait for MS under some special conditions.

As we can see from Table 1, WTDT of greedy algorithm are always better. The differences are remarkable especially in the scenarios with serious delay. On the other hand, the efficiency of the algorithm is quite high. Even in the scenario with serious delay, the rescheduling can also accomplished within several seconds. It is another outstanding advantage of the algorithm.

CONCLUSION

The greedy algorithm offers a quick method for train rescheduling. It can make full use of the experience of the experts and take more factors into account so as to make rescheduled plans more practicable. Furthermore, it is very simple to realize and it also can be extended easily to new networks. All the above make it suitable to real-time railway operation.

In the algorithm, all potential conflicts are ignored when we made the solutions space and evaluate the solutions. It is not doubtful that if the potential conflicts are taken into account, the quality of solutions will be better. The average

meeting and average overtaking delay models proposed by Petersen (1975) has given a good reason for the further study.

ABSTRACT

The regularity of track is a control factor which influences the safety of vehicles. For many foundation underpinning projects crossing existing rail transit tracks, the displacement of the underpinned foundation must be controlled within a reasonable range, which helps ensure the regularity of the track. Using the pile underpinning project of Tianjin-Binhai light railway as an example, this paper analyzes the impact on the regularity of track imposed by simulation calculation with software of ANSYS and Adams/Rail and test. The research results indicate: during underpinning, the change of static track regularity was lower than the controlled value of the criterion; the running safety indicators including the derailment coefficient (DC) and the reduction rate of wheel load (RRWL) were both under the limited value of norms. The underpinning of Tianjin-Binhai light railway bridge did not impose obvious impact on the regularity of the track, and the allowable displacement of underpinned pier is reasonable.

INTRODUCTION

With the popularizing of underpinning projects, pile underpinning technology has a rapid development in recent years. In 1930s, an engineer of Fondedile Company of Italy, proposed root piles at first (Lizzi, F. 1980). Then, Masuda et al. introduced a new method which can save construction period and cost by using some temporary structures, cast-in-situ diaphragm walls and piles, as elements of the new structures (Masuda et al. 1992). Ke et al. made model test and study of Shenzhen metro pile underpinning project which was considered as the highest load on single pile all over the world (Ke et al. 2003). Xiong et al.

carried out elastic and elasto-plastic analysis of reinforce concrete frame during underpinning construction using software-Ansys (Xiong et al. 2003). Lin, L. R. gave introduction to monitoring, recording, analysis and strain treatment during the positive dynamic replacement of railway bridge pile foundation which employed information technology (Lin, L. R. 2003). Li et al. analyzed the stress acting on rail located at beam gap when underpinning the bridge of railway or urban transit (Li et al. 2008).

The regularity of track is a control factor which influences the safety of vehicles. New track irregularity is produced during underpinning of rail transit tracks, which may bring a potential threat to the safety of the train when running. Based on simulation calculation and testing, this paper analyzes the impact of track regularity on the safety performance of vehicles during pile underpinning of the Tianjin-Binhai light railway. The results may be used as reference for future underpinning construction.

ENGINEERING SITUATION

The No.4 Road Tunnel of Central Avenue, New Coastal Region of Tianjin, crosses the viaduct of Jinbin Light Railway. In order to guarantee the safety of the viaduct, two piers should be underpinned. The cross-sectional diagram of pile underpinning is shown in Figure 1. The underpinned bridges are two linked 3-pan continuous beams; the A339 pier is designed as a braking pier, and the A340 is a linking beam. The underpinning structure is a 2-span rigid frame.

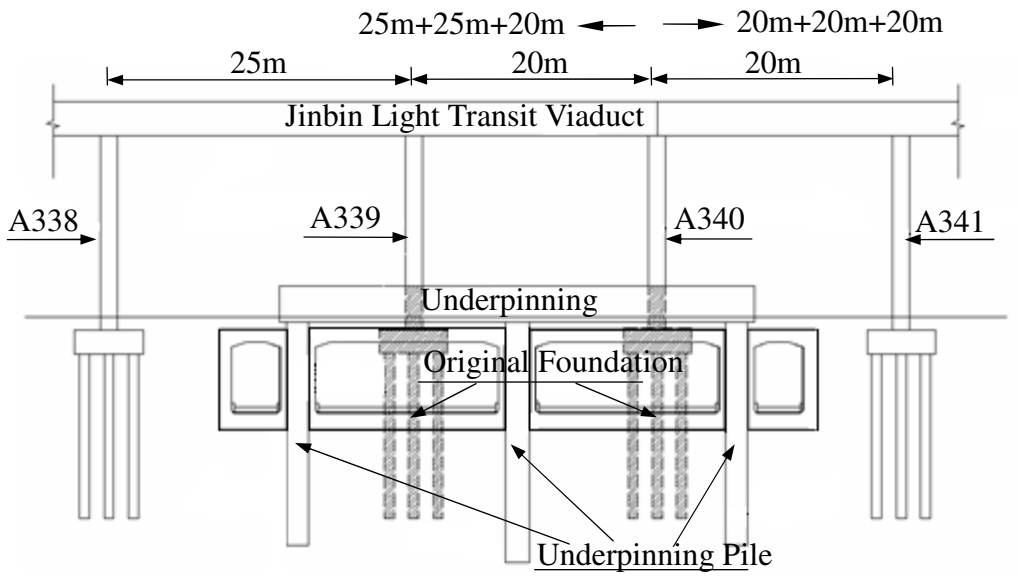

Figure 1. Pile underpinning cross-sectional diagram.

The section is located between Teda and Citizen Plaza Station. The line is in a transition curve whose length is 120 m, the radius of circular curve is 450 m, and the superelevation of the outer rail is 0.125m. Low Vibration Track is adopted with CHN60 rail and WJ-2 fastenings and the spacing of the elastic-bearing-block is 0.6m.

Jacks were installed on the top of the underpinning piles to bear the load of the underpinning beam during construction. During pre-jacking, arch camber occurred on the upper track, and settlement occurred when the state of the original foundation changed. Based on railway-related norms and the experience of Shenzhen Metro pile underpinning, the allowable vertical displacement of the underpinned pier is -3mm and 3mm (Yin et al. 2008). The settlement difference of adjacent piers should not exceed 5mm.

SIMULATION STUDY

Static simulation. Based on a discrete elastic support model，a finite element model for the track structure on the bridge was proposed by using finite element analysis code ANSYS. The model is shown in Figure 2. SOLID45 was used to build the box girder and support the rail bed; BEAM189 was used to build the rail; and COMBIN14 was used to build the series spring which is reduced by rail fastening and elastic shoe.

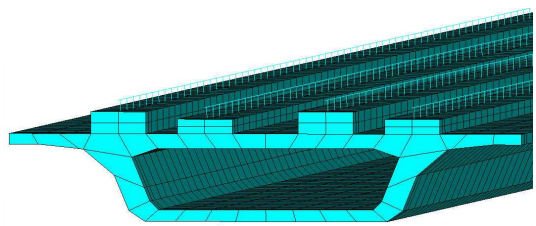

Figure 2. Finite element model of track structure on bridge.

Because A339 and A340 are both braking piers, they were simplified as fixed hinge supports. The others are simplified as movable hinge supports, including two non-braking piers (A338 and A341) and three linked piers (A337, A340 and A343). The constraint condition of the bridge model is shown as Figure 3. The rail was assumed as infinite long beam, and the effect of underpinning becomes small at the ends of the rail, so the ends were simplified as fixed supports.

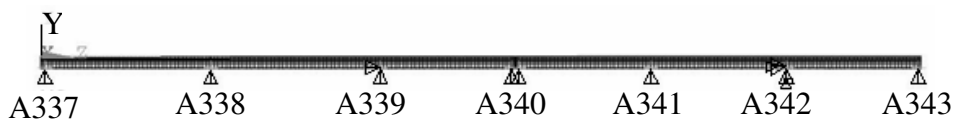

Figure 3. Constraint condition of bridge model.

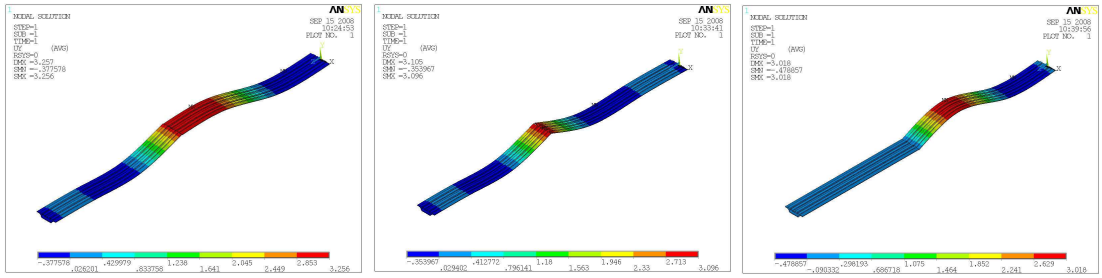
During the calculation of track deformation, the displacement of the pier was loaded on the bottom of the box girder. There were two types of jacking forms: uniform jacking and differences jacking. The former refers to applying the same load at A339 and A340; the latter refers to imposing different when the underpinned piers are different. The track deformations in different jacking cases are shown in Figure 4.

The results indicate: the maximum displacement occurred at the mid-span

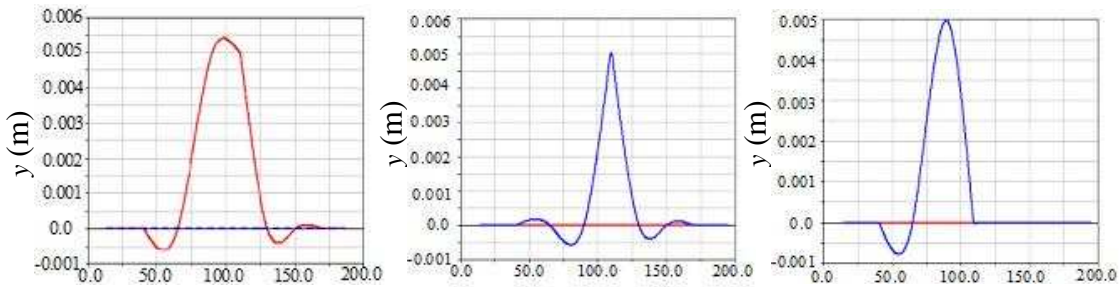
during uniformity jacking, and it was located close to the higher load during differences jacking. The result was consistent with the calculated result using structure mechanics.



(a) Both A339 and A340 are jacked. (b) Only A340 is jacked. (c) Only A339 is jacked.

Figure 4. Track deformations in different jacking cases.

The maximum displacement loads (5mm) were applied on the models in different cases, and the vertical irregularities (y) of track were carried out. The results are shown in Figure 5. According to the related provisions in TB10082-2005, the criteria for static vertical profile regularity are that 10m-bowstring versine should be less than 4mm.



(a) Both A339 and A340 are jacked.(b) Only A340 is jacked. (c) Only A339 is jacked.

Figure 5. Track irregularities in different jacking cases.

The results indicate: during underpinning, the change of static track regularity was within the allowable value of the criterion, so running simulation could be made.

Running simulation. Using Adams/Rail dynamic simulation software of vehicle-track, the vehicle-track model was built which is shown in Figure 6. The assumptions are that the track foundation is rigid, and the railway line adopts a cubic parabolic transition curve to link straight line and circular curve. The track was considered to have no irregularity before jacking, and the deformation of the track caused by jacking was considered as an additional irregularity during the calculation. The Benchmark vehicle-1 model was adopted, which is a general two-bogie coach model in Manchester Benchmarks.

Before introducing the additional irregularity to the track model, the vehicle was simulated running at different speeds. The variation curves of DC

and RRWL along with running distance are shown respectively in Figure 7 and in Figure 8. In the graphics, the negative value presents variations of the wheel running on the inner rail of curve.

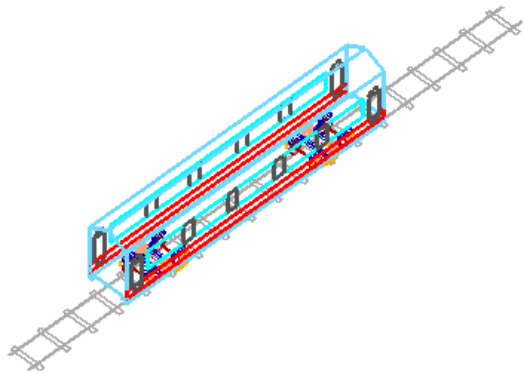


Figure 6. Dynamic simulation model of vehicle-track.

The results indicate: when the running speed was lower than the design speed (80 km/h), the DC and RRWL increased gradually with an increase in velocity. In the case when the vehicle ran at a lower speed, a surplus superelevation occurred, so the DC of the inner wheel was larger than that of the outer one, while it was contrary for the RRWL, viz, the RRWL of the inner wheel was smaller than that of the outer one. Moreover, the nearer the vehicle was to the circle curve from the transition curve, the higher the surplus superelevation, the DC of inner wheel and the RRWL of the outer wheel, until a constant one when the vehicle ran into the circular section entirely.

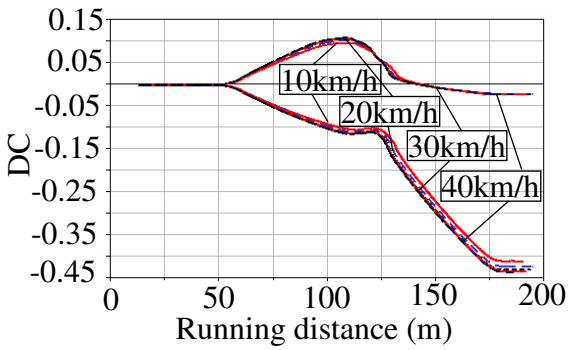

Figure 7. Variation of DC before jacking.

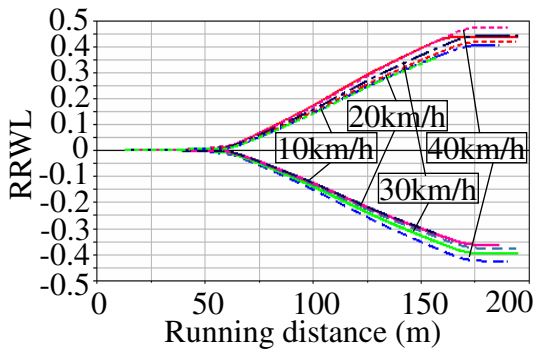

Figure 8. Variation of RRWL before jacking.

After introducing the possible additional-irregularity (as in Figure 5) to the track model, the DC and RRWL were calculated when the vehicle ran at 30 km/h. Simulations were conducted for three possible additional irregularities. Results from all three were similar and only the results from one test are shown in Figure 9 and in Figure 10 – both A339 and A340 were jacked up 5mm simultaneously.

The results indicate: when the vehicle ran at 30 km/h, the variation of DC and RRWL almost coincided with the values before jacking. The additional-irregularity would not impose obvious impact on the safe performance of a running vehicle.

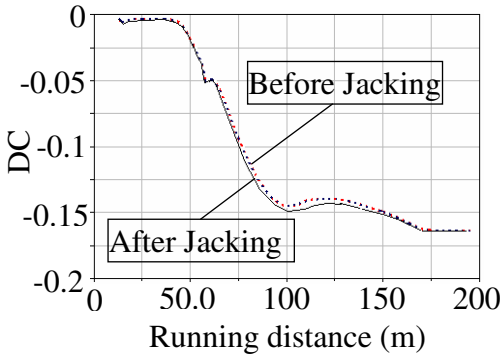

Figure 9. Comparison curve of DC.

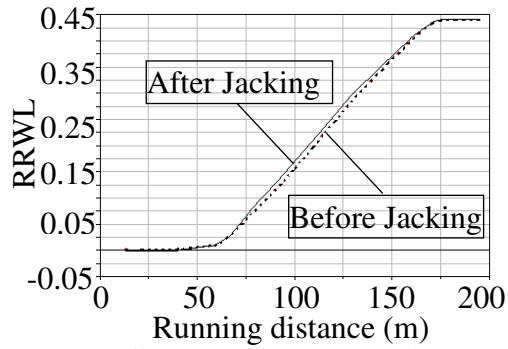

Figure 10. Comparison curve of RRWL.

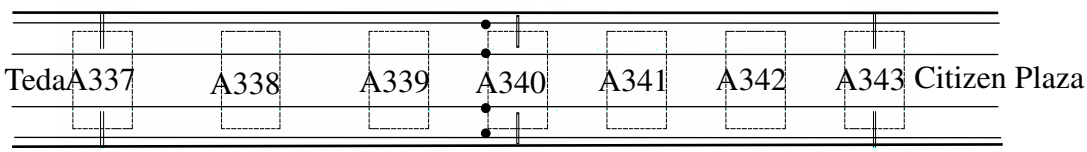
TEST STUDY

Description of the test. As shown in Figure 11, the strain gauges were installed at the beam gap where the dangerous cross-section A340 is located. Under dynamic load, wheel-rail vertical force P and lateral force Q were tested, and then safety performance indicators, including the DC Q/P and the RRWL $P/\overline{P}$, were derived. The safe running speed of the vehicle was selected before underpinning. The safety performance indicators under different conditions were tested during underpinning. Speed tests were carried out under increasing speed conditions and safety indicators were retested after underpinning.



• Strain gauge on rail

Figure 11. Dynamic test point layout.

Test method and criteria for safety evaluation. The "shearing method" was adopted for the test of wheel-rail vertical force P and lateral force Q. DASP2000 data acquisition system with 2048Hz sampling frequency was applied. Railway wheel-rail analysis software was used for the calculation of safety performance indicators. According to the related provisions in GB5599-85 and TB/T2360-93, the criteria for safety evaluation are as following: (1) The DC $Q/P \leq 0.7$; (2) The RRWL $P/\overline{P} \leq 0.6$.

Test results. The test results are listed as following:

(1) Before underpinning, the maximum testing values of DC and RRWL at different speeds are shown in Table 1. The relationship between the safety performance indicators and speed are shown in Figure 12 and in Figure 13. In the table and graphics, "Up" presents the up direction of the train running from Citizen Plaza to Teda, "Down" presents the negative direction; "Inner" presents the wheel on the inner rail of the curve, "Outer" presents the wheel on the outer rail of the curve.

The results indicate: when running speed v ≤ 40 km/h, the safety

performance indicators increased with the increase of speed generally with the exception of 20 km/h, where it decreased slightly.

Table 1. Maximum value of safety performance indicator at different speeds.

Velocity ($km \cdot h^{-1}$)	Q/P				$P/\overline{P}$	
	Up outer	Up inner	Down outer	Down inner	Up outer	Down outer
5	0.022	0.13	0.041	0.17	0.281	0.352
10	0.028	0.15	0.043	0.19	0.286	0.358
15	0.035	0.16	0.042	0.20	0.282	0.360
20	0.040	0.11	0.048	0.15	0.269	0.292
30	0.075	0.16	0.040	0.19	0.291	0.379

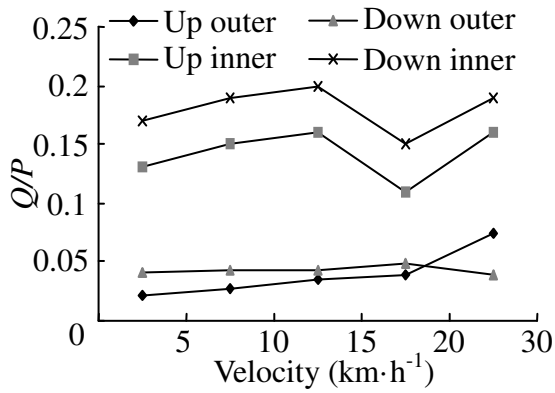


Figure 12. Relationship between Q/P and velocity before.

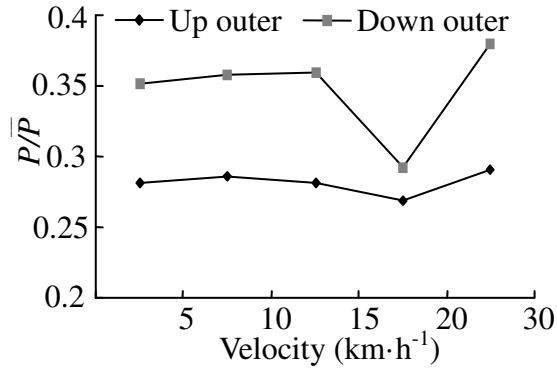

Figure 13. Relationship between $P/\overline{P}$ and velocity before underpinning.

(2) Considering the requirements of construction and operation, the running speed was limited at 10 km/h during construction. The maximum of safety performance indicators are shown in Table 2. The construction conditions are signed as "1" (before jacking), "2" (during underpinning), "3" (after cutting original piers) and "4" (after excavating foundation pit).

Table 2.Maximum of safety performance indicator at limited speed 10km/h.

Construction conditions	Q/P				$P/\overline{P}$	
	Up outer	Up inner	Down outer	Down inner	Up outer	Down outer
1	0.02	0.13	0.04	0.17	0.28	0.35
2	0.04	0.17	0.21	0.46	0.31	0.38
3	0.05	0.18	0.12	0.26	0.31	0.40
4	0.04	0.16	0.05	0.17	0.36	0.39

The results indicate: during the whole construction, the safety performance indicators did not vary obviously except the DC of the Down direction, which increased slightly.

(3) After having finished the underpinning construction, an increasing speed trial was done in order to improve the operation quality. The maximum test

results are shown in Table 3. The relationship between the safety performance indicators and speed are shown in Figure 14 and in Figure 15.

Table3. Maximum of safety performance indicator in speed increasing test.

Velocity ($km \cdot h^{-1}$)	Q/P				$P/\overline{P}$	
	Up outer	Up inner	Down outer	Down inner	Up outer	Down outer
20	0.02	0.16	0.04	0.19	0.31	0.36
50	0.05	0.20	0.06	0.20	0.27	0.29
70	0.05	0.17	0.08	0.12	0.24	0.16
80	0.06	0.15	0.09	0.14	0.23	0.17

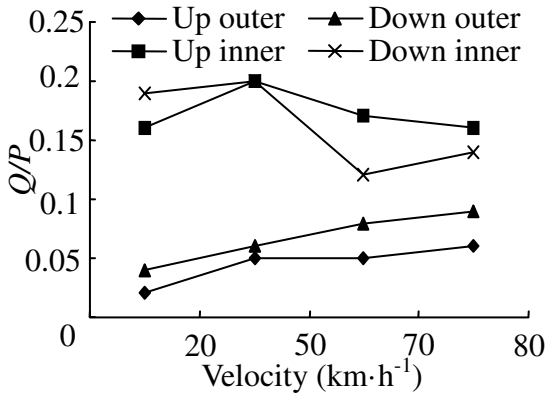

Figure 14. Relationship between Q/P and velocity before.

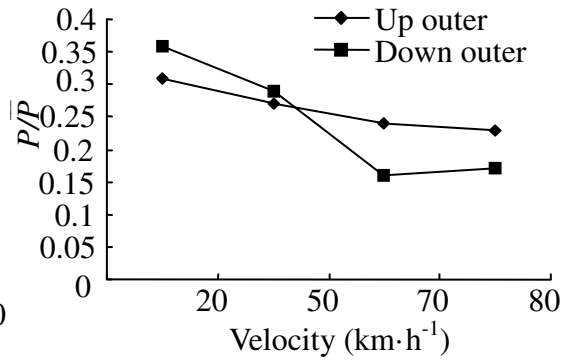

Figure 15. Relationship between $P/\overline{P}$ and velocity before.

The results indicate: as the speed increased to design speed, the DC of the outer wheel increased, while the DC of the inner wheel and the RRWL decreased.

CONCLUSIONS

Using the pile underpinning project of Tianjin-Binhai light railway as a research object, this paper analyzed the impact on the regularity of track from underpinning by simulation calculation and test study. Conclusions are as follows:

(1) During underpinning, the change of the static track regularity was within the allowable value of the criterion.

(2) The running safety indicators including the DC and RRWL are both under the limited value of norms. The simulation calculation and the test study had a similar variation law.

(3) The underpinning of Tianjin-Binhai light railway bridge would not impose an obvious impact on the regularity of the track, and the allowable displacement (Yin, 2008) of underpinned pier was reasonable.

ABSTRACT

A new test system is put forward to understand the FSK modulated track signal parameters in real time. The system model and design is based on the spectrum correction method. Carrier frequency is firstly identified by energy distribution in the frequency domain. Then, the signal is filtered and zoomed within a specific range centering on carrier frequency to obtain the spectrum lines. The frequency, amplitude and phase of each spectrum line are corrected using the centrobaric correction method. Lastly, signal parameters were calculated according to spectrum symmetry. Virtual instrumentation techniques were adopted during system implementation and software realization. The programming methodology is described in detail. Trial tests show that the test system is efficient and easy to use; all of the requirements are satisfied.

INTRODUCTION

Track circuit plays an important role in the whole Automatic Train Control (ATC) system. It serves as the path through which an FSK modulated railway signal is transmitted continuously, carrying vital information about potential blocks ahead. Exposed to the harsh environment, such as rain, snow, rust, etc., track-bed conductivity is not stable, which causes track circuit malfunctions. Hence, the track circuit must be tested onboard in real time to ensure transmission reliability.

The major requirements for the onboard test system are described as follows.

Various Types of FSK Modulated Signals Must be Identified. There are two kinds of FSK modulated signals in the railway system -- the YiPin signal and the French UM71 signal. For YiPin signals, carrier frequencies are 550Hz and 750Hz for a down line, and 650Hz and 850Hz for an up line, the frequency deviation is 55Hz, and the modulating frequencies, which contain the vital information of the light mode ahead, are from 7 to 26Hz at the interval of 0.5Hz. For UM71signals, carrier frequencies are 1700Hz and 2300Hz for a down line, and 2000Hz and 2600Hz for an up line, frequency deviation is 11Hz,and the modulating frequencies are from 10.3 to 29Hz at the interval of 1.1Hz (Fei, X. K.,1993).

The test error requirement. Frequency resolution: Central frequency 0.2Hz, Modulating frequency 0.02Hz.

Amplitude error (absolute value) $\leq$ 2mV $\pm$ 2%*value indicated

Parameters must be tested in real time. Test results must be presented at an interval of less than 200ms so as to accord with the train speed at 250Km/h.

SPECTRUM CORRECTION ORIENTED PROGRAMMING METHODOLOGY

Energy Centrobaric Correction Method. During signal processing, only limited numbers of samples of the signal can be acquired. Thus, energy leakage happens. The method of centrobaric correction normally used in vibration analysis is migrated here. The method is based on the theory that most windowing functions such as Henning, Blackman, etc. when sampled, have an energy distribution centered on the zero in the frequency domain. Thus, the actual central frequency can be corrected with several spectrum lines around itself (Ding, K., and Xie, M., 1996).

Supposing the sample rate is fs, sample points for fft is N, the spectrum line number with maximum amplitude is m, the amplitude of the i_{th} line in the power spectrum is Y_i, then the actual central frequency x_0 can be obtained as shown in Equation (1).

$$x_0 = (\sum_{i=-n}^{n} Y_i(m+i)fs/N) / \sum_{i=-n}^{n} Y_i \qquad (1)$$

According to Parseval theory, the actual amplitude is obtained as shown in Equation (2):

$$A = \sqrt{k_t \sum_{i=-n}^{n} Y_i} \qquad (2)$$

where coefficient k_t can be calculated by numerical method.

The actual phase is shown as in equation (3).

$$\Phi_m = tg^{-1}(\frac{\mathrm{Im}}{R_m}) + (x_0 - mf_s/N)(f_s/N)\pi \qquad (3)$$

Programming Methodology. Railway signal is acquired continually by DAQ card at the sample rate of 9600S/s and sample duration of 1.28s. Analysis was done as follows:

Judging Carrier Frequency (F_c). Since the F_c of UM71 and YiPin signals are different, they can be identified by setting a frequency threshold. The frequency threshold must be selected between the maximum F_c of YiPin (850hz) and the maximum F_c of UM71 (1700hz).After judging the signal type, the actual F_c is roughly estimated based on the energy distribution in the frequency domain.

Spectrum preprocessing. Many noises are useless or irrelevant to the actual signal, preventing us from discerning the actual spectrum (Zhou, Q. S., Hou, F. Y. and Zhang, L. P., 2007). To avoid this, the signal required can be preprocessed to find a few lines around F_c which are high-valued relatively. Reduce the noises by discarding the minor-valued spectrum lines when there are several lines too close to each other.

Spectrum Correcting. Correct the spectrum lines obtained according to Equations (1), (2), and (3).

FSK Signal Parameter Calculation. Based on the result of spectrum correction, the parameters can be calculated based on the spectrum characteristics of

the FSK modulated signal. An FSK signal with a continuous phase modulated by a square wave is composed of many ingredients in the frequency domain. Suppose C_n is the n_{th} side frequency amplitude, then (Ding, K., 2008).

$$C_0 = (2A_0 / m\pi)\sin(m\pi / 2) \quad (4)$$

$$C_n = (2m / \pi(m^2 - n^2))\cos(m\pi / 2) \quad \text{n is odd} \quad (5)$$

$$C_n = (2m / (\pi(m^2 - n^2)))\sin(m\pi / 2) \quad \text{n is even} \quad (6)$$

For UM71signal, we adopt the F_c and the several lines nearest to the F_c

Rearrange the spectrum lines corrected by the amplitude. Find the very line around which the other pair of lines are symmetrically located and have similar amplitudes to each other. The corresponding frequency is the actual F_c .

Find the pair of lines within the specified restriction of the relative error in magnitude. Obtain the modulating frequency (F_m) according to this pair's relative position to F_c , as shown in Figure 1.

Based on the C_m and C_n , frequency deviation（ΔF）can be estimated by using the polynomial curve fit method.

Modulation index (m) can be gained as shown in Equation (7):

$$m = \Delta F / F_m \quad (7)$$

According to Equation (4), the amplitude of the signal (Amp) can be obtained as shown in Equation (8)

$$Amp = (C_0 m\pi / 2)\sin(m\pi / 2) \quad (8)$$

For YiPin signal, its spectrum features are: the spectrum line located on F_c is minimum, while most lines are scattered on the side frequencies.

Find enough pairs of lines, each of which are similar in value and located symmetrically. Then F_c can be estimated with the average frequency values of each pair of lines.

Based on the distance within each pair of lines, the modulating frequency (F_m) can obtained as shown in Figure 2.

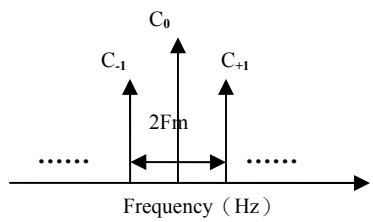

Figure 1. UM71 signal spectrum.

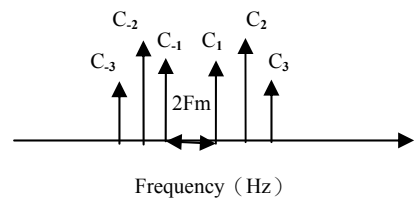

Figure 2. YiPin signal. spectrum

Suppose n1 and n2 are both the index of side frequencies, n1 ≠ n2, if n1 and n2 are both odd or even, then from Equations (5) and (6), m can be estimated in Equation (9):

$$m = \sqrt{(cn_1^2 - n_2^2)/(c-1)} \quad (9)$$

where, $c = C_{n1} / C_{n2}$.

So, m can be obtained by selecting the desired side frequency lines from the above pair of lines, and the amplitude of the signal can be estimated in Equation (5).

ΔF can be calculated as shown in Equation (10):

$$\Delta F = mF_m \quad (10)$$

SYSTEM CONFIGURATION AND SOFTWARE REALIZATION

System Configuration. The general architecture of the test system is shown as Figure 3, where the DAQ card is PXI 6221 multifunction DAQ card, and the software is LabWindows/CVI, a visualized virtual instrument developing environment (Liu, J. H., 2001; Ding, T. X., 2002).

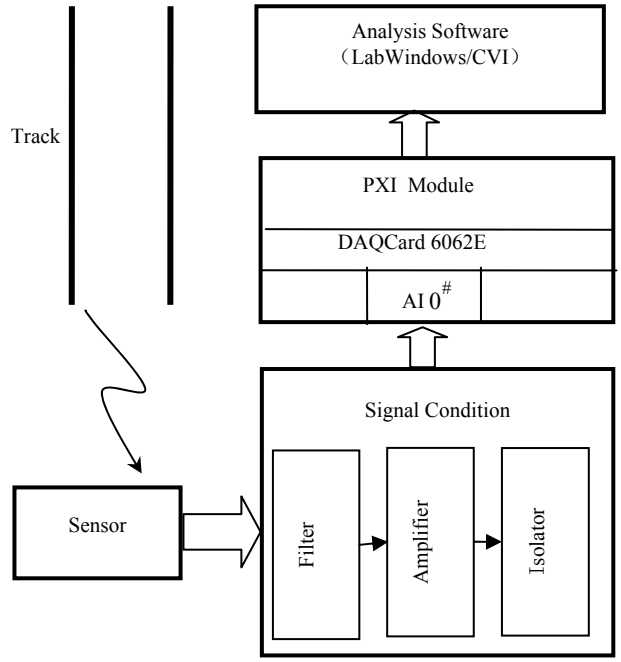

Figure 3.Railway signal parameter automatic onboard test system.

Software Realization. The main panel of the test system software is shown as Figure 4. The left area is for displaying the parameters of the track circuit signal acquired including the original signal in time domain, the original power spectrum and the zoom spectrum. The listboxes “Results in real time” in the upper right area are for displaying the results after spectrum correction, while the area named “FSK parameters” is for displaying the FSK modulated signal’s parameters.

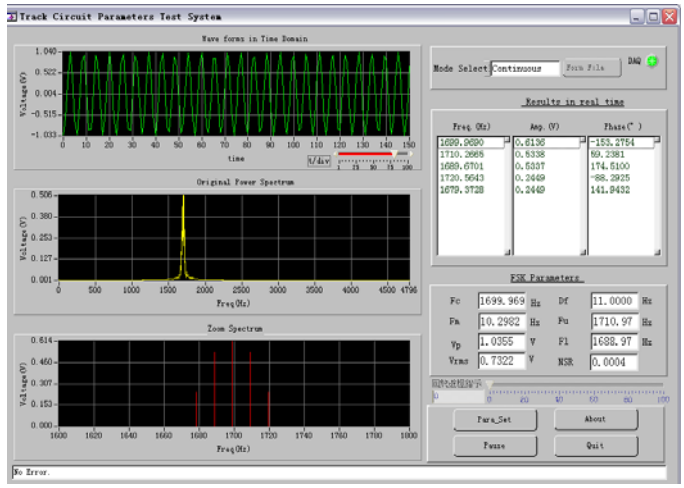

Figure 4. Railway signal parameter onboard test system software.

TESTING CASE EVALUATION

In the testing case, Monte Carlo simulation is used to generate simulated FSK modulated signal and white noise. The above mentioned algorithm is evaluated as follows.

Error Test for YiPin signals. The error test result is shown in Table 1. In this test, a pure YiPin signal was generated with an amplitude of 1V and an initial phase from 0 to 360 degrees at random and then processed. The sample rate is 9600 S/s, the sample duration is 1.28 seconds, samples for analysis is 4096, F_c is 550Hz. The table shows that: the maximum absolute error of F_c and amplitude are both within the error restriction.

Table 1. Error test result for YiPin signal

Modulating frequency（Hz）		7	9	13.5	17.5	20
Maxi-mum error of F_c	Hz	8.2e-2	5.5e-2	2.3e-1	1.3e-3	4.0e-6
	%	1.4e-2	1.0e-2	4.2e-2	2.4e-4	7.2e-7
Maxim-um error of amplitude	V	6.8e-3	1.8e-3	4.4e-3	6.7e-3	2.6e-3
	%	6.8e-1	1.8e-1	4.4e-1	6.7e-1	2.6e-1

Error Test for UM71 Signals. The error test result is shown in Table 2. In this test, a pure UM71 signal was generated with an amplitude of 1V and an initial phase from 0 to 360 degrees at random and then processed. The sample rate is 9600 S/s, the sample duration is 1.28 seconds, the samples for quantitative analysis is 4096, F_c is 1700Hz. The table shows that: the maximum absolute error of both F_c and amplitude are within the test error limit.

Trial tests show that:

As the quantity of samples for analysis decreases, the test error accelerates accordingly, yet at a very lower speed. Even when the number of samples for analysis is 512, the F_c can be judged.

Amplitude error can be reduced by enlarging the dynamic range of the AD converter. It has been verified that when the dynamic range is 200mV, amplitude error can be confined to 1mV.

Table 2. Error test result for UM71 signal

Modulating frequency（Hz）		10.3	13.6	16.9	20.2	29
Maxi-mum error of F_c	Hz	7.8e-3	7.4e-3	7.3e-3	7.7e-3	2.7e-2
	%	4.5e-4	4.3e-4	4.3e-4	4.5e-4	1.5e-3
Maxim-um error of amplitude	V	2.3e-4	5.0e-4	3.4e-4	4.8e-4	2.8e-4
	%	2.3e-2	5.0e-2	3.4e-2	4.8e-2	2.8e-2

CONCLUSION

(1) The spectrum correction oriented methodology is proposed to ensure railway signal parameters can be obtained with high precision in real time.

(2) The software is developed under a powerful visualized environment, i.e. LabWindows/CVI, which facilitates the programming realization, including friendly man-machine interface and visualized presentation of the measurement results.

ABSTRACT

The local and regional traffic problems of Harbin's Jingyu Street are analyzed. Because of the traffic, business functions are restricted. Two traffic modes are proposed: complete protection and restricted protection. Consideration must be given to the protection and redevelopment of Jingyu Street. Evaluation factors for traffic improvement schemes for a style protection district are discussed. These are based on three indexes: land zone, style protection, and traffic access degree. A fuzzy evaluation method to appraise schemes is presented which discusses experiences for protecting a traditional style protection district.

INTRODUCTION

Since early in the 20th century, there has been an increasing amount of attention devoted to the protection of urban historical and cultural heritage places all over the world. Since the reform and opening of our country, there has been rapid development of the urban economy and much new construction. Historical buildings and blocks have been destroyed to different degrees, and therefore, there is an increasingly urgent need to protect cultural and historical places.

Protection of historical and cultural legacy is done at different levels. It begins with the protection of landmarks, and then develops into protection at the city level and finally at the historical block level. Because of its values in the society, humanities and application, the protection of historical blocks become the most important in a multi-level protection system of historical and cultural heritage. Harbin is a national historical and cultural city and is facing the problem of protecting its historical blocks in the old region of the city. The problem of having modern traffic in historical blocks is becoming an urgent research subject

The traditional business style protection region of Jingyu Street, located in the Daowai district, is an important ingredient in Harbin's history and cultural protection blocks. With the acceleration of the urbanization process, traffic problems in protection blocks are emerging. As the process of land-use

replacement and building renovation in the old region occurs, it is important that planning efforts follow historical and cultural protection planning principles. This includes effectively organizing regional traffic and correctly locating and protecting the style of Jingyu Street.

PRESENT STATE

The style protection district of Jingyu Street covers an area of 53.11 hectares. Its functions include commercial, residential and transportation. The present state of the Jingyu Street protection district is divided into two categories according to different functions. The first category is mainly for commercial functions which has typical business streets, and where there is commercial retail, wholesale markets, as well as financial and business functions. Its traffic flow is a stream of commercial, passengers, and trucks. This category maintains a traditional street style, and Baroque architecture is distributed intensively and continuously on both sides of the street. The decorative style of the external walls is uniform and the aesthetic value is relatively high. Therefore, the historical and cultural conservation value is very important. The other category is mainly for residential functions, which has relatively developed business functions, but the scope of service is small.

PROTECTION LOCATING

The traditional style protection district of Daowai is the old region in Harbin. It has witnessed the effects of development due to the changes in the national economy and it has typical areas that combine Chinese and Western cultures. This region is the third largest traditional business district, following the business centers of Central Avenue and Qiulin. The protection and rejuvenation of this area will help fully exploit the functions of commercial, cultural, tourism, leisure and residential. By improving the infrastructure and the spatial environment, and by balancing the social, cultural, economic, and environmental benefits, it is possible to create a vibrant commercial, cultural, and tourist center that adapts to the requirements of modern life.

PLANNING PRINCIPLES

First, planning must be done according to the requirement of style protection, adaptation to local conditions, determining the planning standard for adjusting arterial roads, and adopting various treatment methods for different regions and protection hierarchies (Li 2006).

A second principle is to adjust the branch system according to bystreet theory and the spatial dimensions of the protection district

A third principle is the determination of the cross-sectional width that will satisfy style protection and preferably consider the relationships among traffic, public facilities, the urban landscape, and the ecological environment.

A fourth principle is to increase the branch system density in the commercial district and in dangerous rebuilding regions.

STUDY OF TRAFFIC MODES

According to the different protection aspects of Jingyu Street, this paper proposes two traffic modes. One is a completely protected traffic mode. This mode strengthens commercial functions, weakens both residential and motor vehicle traffic functions, and becomes a full-time commercial pedestrian street. The model applies to the first category protection area and mainly benefits booming commerce of the whole region. The other is a restricted protection traffic mode.

The commercial function is a key function in the model. The roads in the model are charged with motor vehicle traffic, and develop to time-limit commercial pedestrian streets (Li and Li 2006). The mode applies to the second category. At the same time, this model can also include streets that are restricted to pedestrian traffic at specific times, or at all times. This can be done for the traditional protection area of Jingyu Street by expanding the traffic capacities of the surrounding roads, which will enhance the commercial function

.

THE TRAFFIC IMPROVEMENT SCHEME

The key to accomplishing the above two traffic organizations are having a unified plan and managing the traditional style protection district. At the same time, it also key to excavate the road potentiality of the surrounding region, alleviating traffic pressures on Jingyu Street.

Firstly, the regional road network should be opened up to through traffic. Secondly, auxiliary lanes should be constructed on each side to further shunt traffic (Li 2006). Thirdly, the bystreet mechanism of the traditional style protection district should be applied to strengthen internal traffic connections. The traffic organizing methods of the traditional business street are that when pedestrian traffic volume is small, especially during off-peak hours, surrounding roads should be used to share traffic volume. When pedestrian traffic volume reaches a certain threshold, usually during the commercial peak hours, the street should be closed to vehicle traffic. To determine the specific scheme, it is important to consider the entire area of Jingyu Street and systematically consider the road network structure, the traffic organization, and so on.

Following the upper traffic organization principle and bystreet mechanism, this paper puts forth traffic organization strategies and schemes that are separate from the surrounding road network facilities, the static and dynamic traffic organization, the public transport organization, and the pedestrian traffic organization. The schemes are as follows:

The road network system structure is “three horizons, six verticals.” The three horizons are Beihuan Street., Jingyu Street, and Nanxun Street. The six verticals are Jingyang Street, First Street, Fifth Street, Seventh Street, Ninth Street, and Tenth Street. It is important to implement the following measures: rebuild Taigu Street; broaden the lanes from two lanes to four lanes; open up Binjiang Street; and, plan six lanes. To coordinate the relationship between the regional

protection and the sustainable transportation development, solve the bottleneck problems at the intersection of Seventh Street and Jingyu Street by using some traffic management tools, such as planning two one-way streets which include Seventh Street from south to north and Ninth Street from north to south.

According to "the norms on the protection of historical and cultural city planning" and combining with this specific situation, this paper puts forth the idea to open streets to full-time commercial pedestrian traffic in the part of the region which is surrounded by Jingyang Street, Shengping Street, Fifth Street, and Nanxun Street. At the same time, it is recommended that other areas of the protection district are restricted to commercial pedestrian traffic between 19:00 to 23:00. Also, building a branch system to strengthen the connections between east and west will help create a smooth and convenient shopping environment.

THE SELECTION PRINCIPLE OF EVALUATION FACTORS

Evaluation factors should be chosen that unify the characteristics of style protection, so both the shared characteristics and the differences can be identified

First, apply the dynamic principle. Consider the important characteristics of the study region, which are in accord with the new idea of applying protection knowledge. Choose characteristics that will be relevant under changing circumstances. Second, apply the universality principle. Ensure that the evaluation factors have common characteristics, that they are easy to grasp, and create a comparatively unified dimension in the process of evaluation. Third, apply the importance principle. Choose the factors that have the most effect. Fourth, apply the gathered principle. The evaluation factors should have gathered characteristics. Fifth, apply the comparative principle. The selected factors should rationally respond to various aspects of old city's historical and cultural protection district, and show differences when comparing them. Sixth, apply the irrelevance principle. The correlation of factors can affect objectivity and the accuracy of the evaluation.

EVALUATION FACTORS

Because of the restrictions of cultural relics, ancient trees, and protection bystreet mechanics (Eckholm 1998), the cultural protection district is not able to rebuild at large scales. Therefore, cultural protection factors (Zhang 2008) need to be added. The norm of historical and cultural protection city planning, which was announced in 2005, specifically defines that it should include improving residents' living environments and protecting district activities. An evaluation system for traffic improvement schemes for style protection districts uses three factors in the guidelines layer and ten evaluation factors in sub-layer and is illustrated in Figure 1.

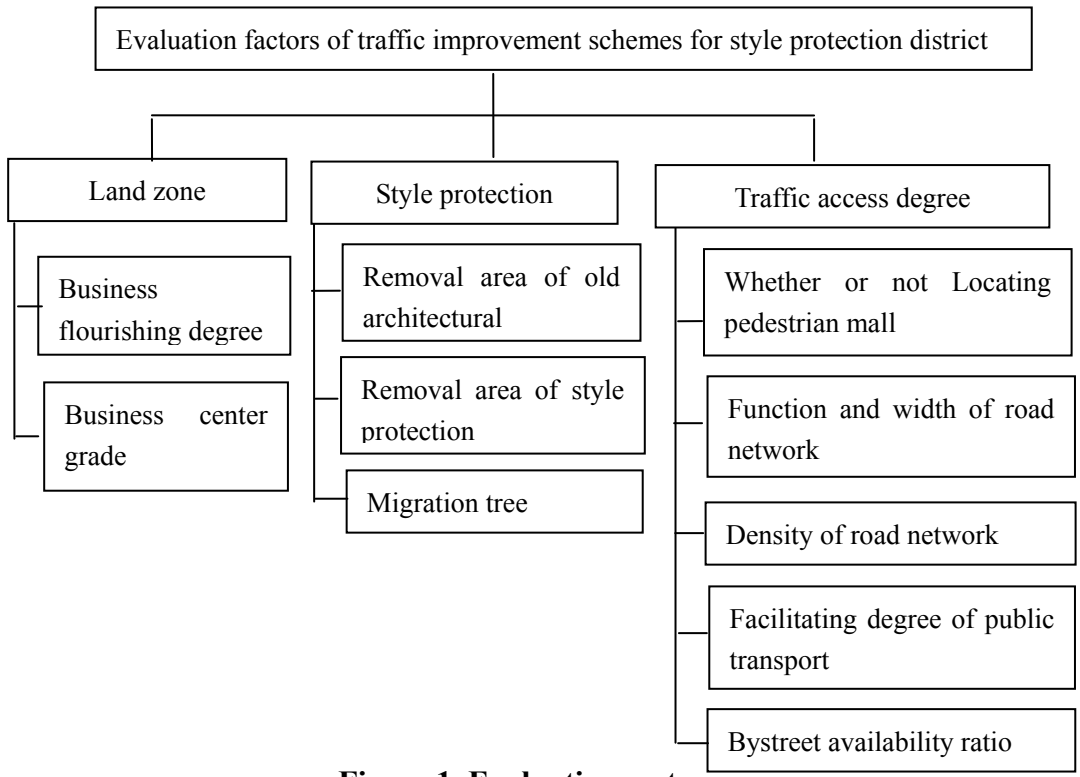

Figure 1. Evaluation system.

EVALUATION METHOD

At present, a commonly used evaluation method uses expert experience to determine a qualitative index and compares the options of the program. This method is simple and clear, and easy to program as a mathematical evaluation method. Moreover, the method is not completely divorced from the people's participation; the experience judgment is still present and by using mathematical evaluation tools, it is possible to break down complex issues and reduce the final evaluation effect of individual partial results. This method of evaluation is more objective and favors of program comparisons.

A fuzzy comprehensive evaluation method, the gray relational grade evaluation method, and AHP have been widely used in many industries (Zhang 2008). A fuzzy comprehensive evaluation is suitable for a multi-factor, multi-level, and multi-program evaluation and is also decision-making system. It is especially useful for system problems that have both qualitative and quantitative factors. This method can more easily carry out a comprehensive evaluation and yield the best solution for decision-making. A fuzzy comprehensive evaluation is based on a fuzzy mathematical approach to evaluation. The evaluation process uses a multi-level evaluation. It is a system that combines a number of factors or objects to give an overall evaluation. Therefore, the traffic organization program of a traditional style protection district such as that of Jingyu Street can be evaluated by a fuzzy comprehensive evaluation method using the three factors of land zone, style protection, and traffic access degree. Through experience

certificate, the evaluation results can scientifically reflect the advantages and disadvantages of various programs.

CONCLUSION

This paper studies the classification of the present state and the localization of a traditional style protection district, and analyzes current problems from the perspective of urban traffic. At the same time, this paper studies the impacts and constraints of regional traffic on the protection district, and puts forth two traffic modes: full protection and restricted protection. Moreover, this paper also proposes using a traffic improvement evaluation system based on land zone, style protection, and traffic access degree, and suggests applying a fuzzy comprehensive evaluation method to compare programs. The study objectives of the paper provide several lessons for protection and traffic improvement of a traditional style protection district.

ABSTRACT

Urban rail transit traction calculation plays an important role in the urban rail transit design. In this paper, the design objectives of this system are determined, which are to simulate the rail transit traction operation dynamically and real-time optimize the train operation through the dynamic combination of basic control strategies. Furthermore, the architecture and function of this system are analyzed and designed, and the system structure can be divided into four parts, including a basic data management subsystem, a traction automatic calculation subsystem, a human-computer interaction subsystem, and a data out subsystem. Moreover, the key technologies of the system are studied, including a multi-objective train operation model and traction calculation algorithm design. Finally, the system is proved to be effective by simulation train operation in Guangzhou Metro Line 3.

INTRODUCTION

With the growth of transportation demand and the rapid development of rail transit technology, urban rail transit has developed in many big or media-sized cities, and urban rail transit traction calculation can provide essential technical data for rail transit operation, important reference value in vehicle type selection, line design, signal equipment arrangement, etc. But present traction calculation software and algorithms are mostly based on railways, for example, traction calculation software developed by HE Hongyun (He 2000), a train operation simulation system developed by GUO Youmin (Guo,2002), a general-purposed simulation system on train movement developed by MAO Baohua (Mao 2000). Traction calculation software based on urban rail transit is quite rare. So, the development of traction calculation system suitable for the characteristics of urban rail transit is urgent.

1 SYSTEM STRUCTURE DESIGN

The functions of the system are determined through the analysis of current traction calculation software and the investigation of urban rail transit traction calculation software users, including designing a simple data management mode with certain compatibilities for using already existing data resources of other departures, realizing train automatic operation and the operation mode conversion between automatic control mode and manual control mode; completing perfect output function so that system data can be demonstrated intuitively by the way of graphs, animation, etc., and all data can be output by all kinds of standard output units. The architecture of urban rail transit traction calculation system is described in

Figure 1. On the whole, the system can be divided into four parts, including a basic data management subsystem, a traction automatic calculation subsystem, a human-computer interaction subsystem, and a data out subsystem.

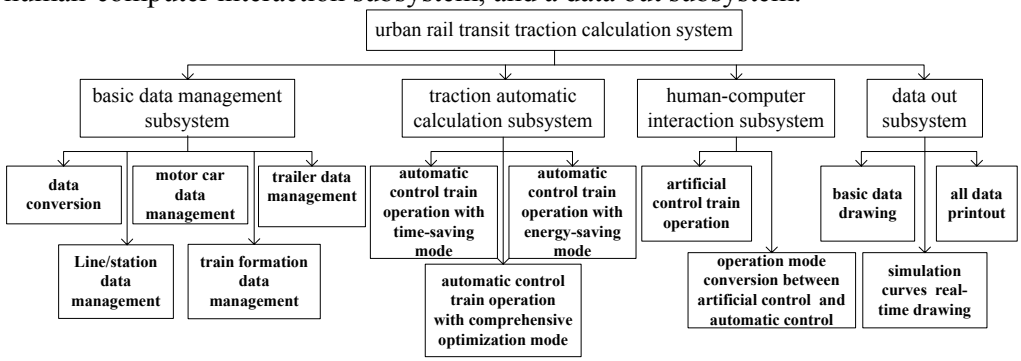

Figure 1: The architecture of urban rail transit traction calculation system.

1.1 Basic data management subsystem

The system includes four kinds of data: motor car data, trailer data, line and train data, and train formation data. The operation on basic data includes the addition, the deletion, the revision and the inquiry; uniformity of the data must be ensured in the operating process. Meanwhile, in order to use already existing data resources of other departures and improve the data input efficiency while decreasing error probability, a special-purpose data import subsystem is designed.

1.2 Traction automatic calculation subsystem

Three traction strategy modes are provided for automatic train control, including a time-saving mode, an energy-saving mode and a comprehensive optimization mode. Trains will realize automatic operation according to calculation parameters and a control mode selected by user, combined with practical operation situations such as vehicle characteristics, line conditions, and so forth.

1.3 Human-computer interaction subsystem

The user can use a mouse to control train operation by selecting the train running condition. The user can not only analog control whole course of train operation, but can also control train operation in the course of automatic operation at any time, moreover, the train can run back at any location and the running condition can be reselected at the location. Better operation effects are realized through the convenient conversion between automatic operation and artificial control, which gives full latitude to the experience of operators.

1.4 Data out subsystem

The basic data of a system such as speed restriction of a ramp, ramp profile, station location, and so forth can be draught, and in the course of train operation, speed-distance curve, time-distance curve, motor voltage-distance curve, motor current-distance curve, source current-distance curve can be real-time displayed by way of animation. All graphics and result reports can be output through all kinds of

standard output units.

2 MULTI-OBJECTIVE TRAIN OPERATION MODEL

According to the characteristics of urban rail transit, time-saving and energy-saving are determined as the control objectives of train operation; safety, accurate stopping, and such are determined as constraints. So, a multi-objective train operation model can be established as follows:

Objective of energy-saving: min $\alpha E = \alpha \sum E_i = \alpha \sum U_i I_i t_i$

Objective of time-saving: min $\beta t = \beta \sum t_i$

Constraints:

$$S(0) = S_b \qquad S(t) = S_e \qquad v(0) = v_b \qquad v(t) = v_e \qquad 0 \le v_i \le v_{max}$$

$$v_{max} = \min\{v_p, v_g, v_y\}$$

Where, α , β = the input parameters which will be explained in section 3.1; S_b= the starting position of train operation; S_e= ending position of train operation; v_b = starting speed, usually it is 0; v_e= ending speed, usually it is 0; v_i = speed of train at time i; v_p = speed restriction of ramp, it is a stage function of train operation position; v_g = design velocity of train (determined by the lower design velocity of motor car and trailer; v_y = operation speed restriction, including temporary speed restriction, etc., which is usually a constant.

Motion equation: $S_{i+1} = S_i + \frac{v_{i+1} + v_i}{2}\Delta t \qquad v_{i+1} = v_i + \Delta t F(v_i, f)$

Where Δt = time step for calculation, $F(v_i, f)$ = train operation acceleration at time i

Traction condition: $F_q(v_i, f) = \frac{f_{qy} - w_i}{(D+T)g}$ Coasting condition: $F_d(v_i, f) = \frac{-w_i}{(D+T)g}$

Braking condition: $F_z(v_i, f) = \frac{-f_{zd} - w_i}{(D+T)g}$

The control mode of nearly stepless traction is adopted in metro motor and light rail motor, so, the maximum tractive effort can be calculated according to speed, actual tractive effort can be obtained by interpolation method, as well as brake force.

$$f_{qy} = af_1(v) \qquad f_{zd} = bf_2(v)$$

where fq_y= train tractive effort, w_i= train running resistance, f_{zd}= train brake force, D= motor car weight , T= trailer weight , $f_1(v)$ = curve of traction characteristic, $f_2(v)$= braking curve, a= usage coefficient of tractive effort , b = usage coefficient of brake force.

Energy consumption for traction: $E_{i+1} = E_i + U_{qy}\left(I_{qy} + I_{zy}\right)\Delta t$

Energy consumption for breaking: $E_{i+1} = E_i + U_{zd}\left(I_{zd} + I_{zy}\right)\Delta t$

Where U_{qy}= traction voltage, I_q= traction current, I_{zy}= traction self-consumption current, U_{zd}= braking voltage, I_{zd}= braking current, I_{zy}= braking self-consumption current.

3 SYSTEM ALGORITHM DESIGN

3.1 The selection of coasting point

In the process of practical train operation, coasting is adopted according to the operation state, line situation and vehicle condition, etc. In many situations, coasting is adopted but the train speed is less than the restricted speed, so there is significant subjectivity in the selection of a coasting point. Several relatively simple cases are presented in Figure 2. If $\alpha = 0$, $\beta = 1$, a time-saving traction strategy is adopted, there is only "idle time" between traction condition and braking condition, shown as curve 1; if $\alpha = 1$, $\beta = 0$, an energy-saving traction strategy is adopted, a coasting condition is adopted until the speed decreases to the calculated speed, the coasting condition is furthest adopted, shown as curve 3; if $0 < \alpha < 1$, $0 < \beta < 1$, a comprehensive optimization traction strategy is adopted. Suppose the distance between a coasting point of a time-saving traction strategy and a coasting point of energy-saving traction strategy in traction curve is l, then, the coasting condition is adopted at the point $\frac{\beta}{\alpha+\beta}l$ apart from the coasting point of an energy-saving traction strategy until the coasting curve crosses with the back-stepping braking curve, following, and the braking condition is adopted, shown as curve 2.

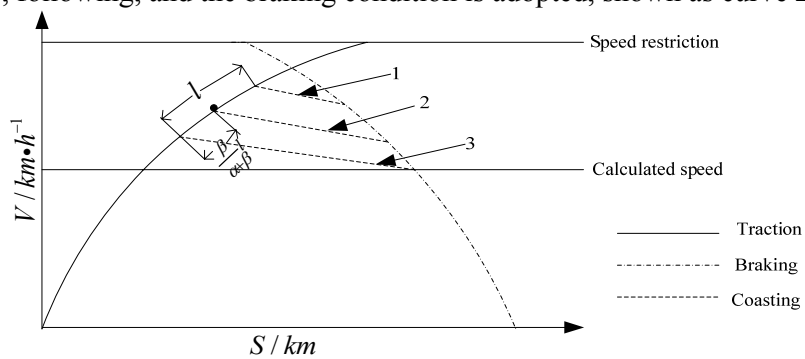

Figure 2: The selection of a coasting point.

3.2 Optimization algorithm of typical transition grade section

In the starting process, maximum tractive force should be adopted in train operation, either from the view of time-saving or from the view of energy-saving (Jin 1997); in the stopping process, based on the method of coasting point selection proposed above, a coasting condition should be adopted; after operation in coasting condition for a while, the braking condition should be adopted. So, the selection of an operation condition in the process of intermediate operation is emphasized in the algorithm. In the practical operation process, the combination of actual ramps is very complicated; control methods of train operation in typical ramps such as straight

ramps, long steep up-gradients, long steep down-gradients, and fragmentary ramps are analyzed as follows:

(1) Straight ramp. When operating on a straight ramp, according to a time-saving traction strategy, a train will run continuously around speed restrictions; according to an energy-saving traction strategy, a train will accelerate to its speed restriction, then a sawtooth operation mode is adopted, that is, the condition of traction—coasting—traction is adopted, and in turn, the operation speed fluctuates between speed restriction and calculated speed; according to a comprehensive optimization traction strategy, the coasting condition will be adopted when the speed of a train is close to speed restriction; coasting point and coasting distance are determined according to the method mentioned above and the parameters α,β input by users.

(2)Long steep up-gradient. When the train location is close to a long steep up-gradient, a traction condition will be adopted for a long time so that the train can run over the gradient by momentum. If the speed of train operation decreases when operating on a long steep up-gradient, traction will be adopted until the train runs over the ramp; if the speed of train operation accelerates continuously, a coasting condition will be adopted when the train operation speed is close to the speed restriction, and the coasting point and coasting distance are determined based on the parameters α,β input by users and the method mentioned above; then the traction condition is adopted, and the train condition of traction—coasting—traction is adopted in turn until the train runs over the ramp.

(3)Long steep down-gradient. When the train location is close to a long down-gradient, the coasting condition will be adopted for a long time in order to take full use of the ramp's potential energy. If operation speed is less than the speed restriction, a coasting condition is adopted until the train runs over the ramp; otherwise, a braking condition is adopted.

(4)Fragmentary ramp. When the train is operating on a fragmentary ramp, uniform motion should be kept; if the time for the conversion of operation condition is less than the specified time, target speed should be determined according to the line condition, and the train can run near the target speed by adopting the condition of coasting— traction — coasting in turn, giving consideration to both time-saving and energy-saving.

4 SYSTEM APPLICATION CASE

In order to prove the effectiveness of the algorithm, practical data of intervals between Eastern Guangzhou and Western Tiyu Road in Guangzhou Metro Line 3 are adopted for simulated train operation, and the main parameters are presented as follows:

(1)Line data: there are three stations between Eastern Guangzhou and Western Tiyu Road intervals, respectively, Eastern Guangzhou, Western Linhe, and Western Tiyu Road. The distance between Eastern Guangzhou and Western Linhe is 1107 meters, and the distance between Western Linhe and Western Tiyu Road is 1179.2 meters.

(2) Motor car data: Length is 60 meters, dead weight is 22 tons, passenger

capacity is 1950 persons, motor number is 1, gross weight is 158.5 tons, braking mode is electrically and pneumatically blended braking, power supply mode is pantograph, traction self-consumption current is 10A, coasting self-consumption current is 5A, braking self-consumption current is 10A, pantograph net voltage of traction condition, pantograph net voltage of coasting condition, pantograph net voltage of braking conditions are all 1500V.

(3)Calculated parameters: time step for calculation is 400ms, the time for the conversion of operation condition is 2s, error of speed restriction is 5km/h.

A simulation curve of train operation is shown in Figure 3, where ——represents the traction condition，---------- represents the coasting condition，---------- and represents the braking condition.

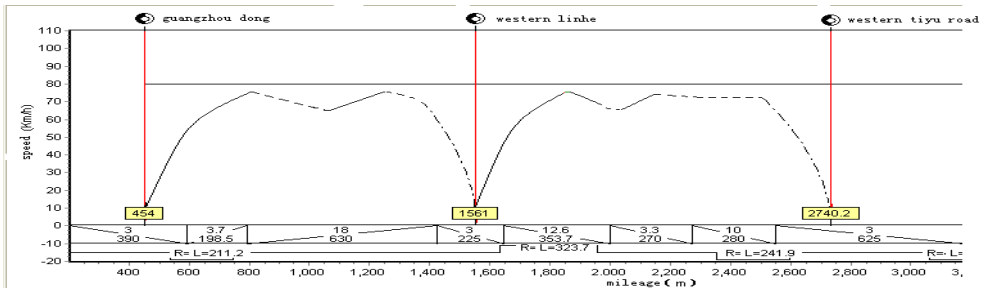

Figure 3 Simulation curve of train operation.

Table 1. Statistical results.

Interval	Distance between interval (m)	Total operation time (s)	Average speed(Km/h)	Traction time (s)	traction rate	energy consumption for traction (Kwh)	total energy consumption (Kwh)

5 CONCLUSION

Comprehensive optimization of train operation is very complicated. In this paper, an urban rail transit traction calculation system is established and the key technology comprehensive optimization traction strategy is analyzed. The system is proved to be effective by simulation train operation in the interval of Guangzhou metro line 3, therefore, it can be used in optimization of train operation and in comparison with operation control schemes under different operating conditions, etc.

ABSTRACT

In this paper, we define network characteristic indices from three aspects including topology, demand and operation, to investigate the characteristics of a rail transit network in Shanghai. First, we analyze the degree distribution, and show that the two stations with maximum degree are respectively the social and economic centers of the Pudong and the Puxi areas in Shanghai. Then, considering the demand and operation, we calculate the node closeness and weighted closeness of all the stations. Isoline analysis shows the concentric circle structure, whose centers represent the stations with better accessibility. Furthermore, considering the spatial locations of stations, we calculate weighted straightness for all stations, and use a new presentation to compare it with degree. The results show that the stations with high connectivity are still the hub stations. This research has theoretical significance in promoting the development of complex networks and guiding the planning practice of rail transit networks.

Key words: *rail transit, complex networks, network characteristic index, topology, demand and operation*

INTRODUCTION

In recent years, studies on complex networks have thrived. The development of transport networks represents a complex and dynamic process. However, most research that can be found about transport networks is centered on the topological study of railway, aviation, urban roads and public transport networks, and only a few on rail transit networks. Furthermore, transport networks are located in real space, where nodes and links occupy precise positions in Euclidian space, and links represent physical connections. It is insufficient to study the characteristics of transport networks using topology only. It is more realistic to also consider the spatial location of the nodes, as well as demand and operation when researching transport networks.

Nowadays, many urban rail transit lines are under construction in the metropolises of China. Since the Rail Transit Line 1 (South Section) opened to traffic in 1993, Shanghai, as China's economic and trade center, has formed a rail transit network that consists of Line 1, 2, 3, 4, 5, 6, 8 (Phase 1) and 9 (Phase 1).

By the end of 2007, the network had 148 operation stations and the operation mileage was 234km. The network pattern of '1 ring, 7 radials, 11 interchange stations' is formed and rated as No. 1 in size and dimensions among all the major cities in China. The rapid development of rail transit makes it increasingly important to urban transport.

This paper selects the indices commonly used in studies about complex networks. This paper also selects the indices which consider demand and operation to analyze the characteristics of the Shanghai rail transit network.

THE DEFINITION OF THE RAIL TRANSIT NETWORK

In network analysis, the actual network is usually abstracted as a planar graph: G= {V, E}, where V is a collection of nodes connected by links (edges) E. In this paper, the current rail transit network in Shanghai will be abstracted to planar graphs (see Figure 1). Nodes represent different stations in the network. Links represent actual operational rail transit lines. The length between nodes is the actual travel distance between different stations.

Figure 1 clearly shows the network pattern of '1 ring, 7 radials, and 11 interchange stations.' Particularly, '1 ring' refers to Line 4 -- the only ring line in the rail transit network of Shanghai. '7 radials' refers to the 7 radial lines of 1, 2, 3, 5, 6, 8, and 9. '11 interchange stations' refers to 4 stations intersected with 3 lines including the People's Square Station, the Century Avenue Station, the Zhongshan Park Station and the Shanghai Railway Station, as well as 7 other stations intersected with 2 lines. In addition, there are 9 common stations that belong to both Line 3 and Line 4.

Figure 1. Shanghai rail transit network pattern.

CHARACTERISTIC INDICES OF RAIL TRANSIT NETWORKS

Topological index. Degree represents the number of adjacent nodes connecting to a certain node. Normally, important nodes have more adjacent nodes - just like hub stations.

Indices considering demand and operation. Node closeness. Closeness measures the inverse of the average shortest path distance from node i to all other

nodes in a given network (Sabidussi, 1966). Considering the operation of the rail transit network, closeness is defined as:

$$C_i = (N-1) \Big/ \sum_{j \in N, j \neq i} T_{ij} \tag{1}$$

where T_{ij} represents the travel time using the shortest path.

Weighted closeness. Considering traffic demand, the peak-hour passenger flow of all the stations is selected as demand weight. The weighted closeness is calculated as follows:

$$C_i^w = \sum_{j \in N, j \neq i} \frac{W_j}{T_{ij}} \Big/ \sum_{j \in N, j \neq i} W_j \tag{2}$$

where W_j is the peak-hour passenger flow of station j. Higher C_i and C_i^w values represent better accessibility.

Indices considering spatial location of nodes. Weighted straightness. Latora and Marchiori (2001) proposed to measure the efficiency of spatial networks by comparing the length of the shortest paths between nodes with the crow-fly distance, which captures how much the travel paths deviate from crow-fly paths and considers the impact of spatial location of nodes on the network. Considering operation and demand, $T_{ij}^{crowfly}$ means crow-fly travel time. Thus, weighted straightness can be described as:

$$S_i^w = \sum_{j \in N, i \neq j} W_j \frac{T_{ij}^{crowfly}}{T_{ij}} \Big/ \sum_{j \in N, i \neq j} W_j \tag{3}$$

CALCULATIONS AND ANALYSIS

Degree. In network analysis, nodes with degree 1 usually are the terminal stations. Nodes with degree 2 occupy a higher portion of the whole network as illustrated in Figure 2. In the Shanghai rail transit network, the two stations with maximum degree 6 are People's Square Station and Century Avenue Station, which both are intersected with 3 lines. Actually, they are also social and economic activities of the Puxi and the Pudong areas in Shanghai.

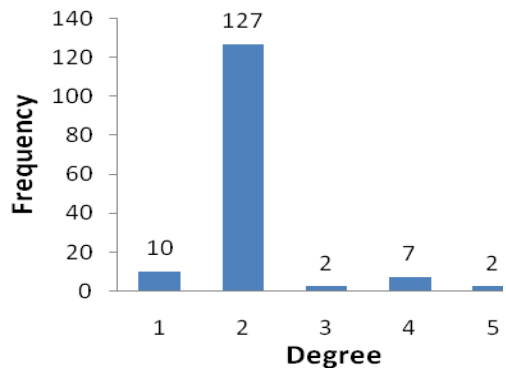

Figure 2. Degree distribution.

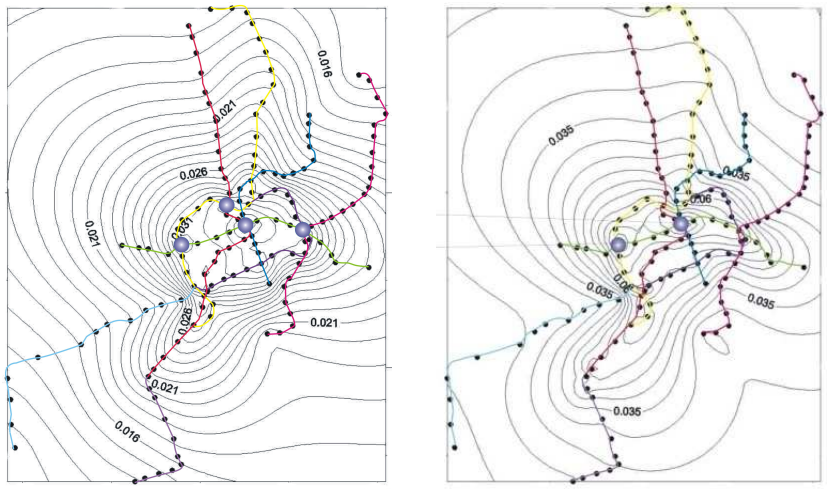
Node closeness and weighted closeness. Using Equation (1) and Equation (2), the node closeness and weighted closeness were calculated separately for the rail transit network of Shanghai. (Morning peak-hour passenger flow for all the stations was used as the demand weight for 7:00-9:00am, Thursday, April 21st 2008.) The results represent the accessibility of different stations. ***Isoline analysis*** shows that the spatial pattern is centered by one or several major stations, forming a concentric circle structure. These central stations have higher accessibility, which is defined as the closeness center (CC). As marked with "small ball" in Figure 3, the CCs of the spatial pattern of node closeness are located in People's Square Station, Shanghai Railway Station, Zhongshan Park Station and Century Avenue Station. The CCs of weighted closeness are People's Square Station and Zhongshan Park Station.



a）node closeness b) weighted closeness

Figure 3. Isoline analysis of spatial pattern of closeness.

The linear correlation analysis between node closeness and weighted closeness in 2008 (see Figure 4) proves that they are correlated. This indicates that stations with higher node closeness also had higher weighted closeness.

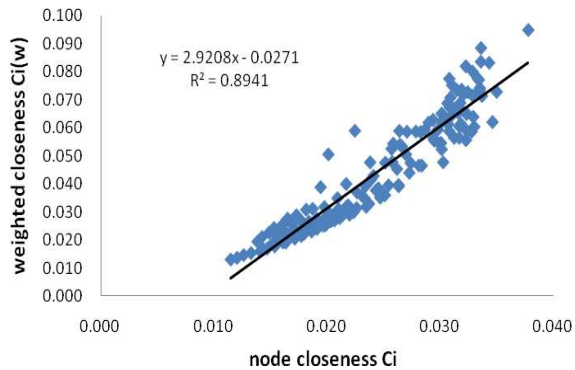


Figure 4. Linear correlation between C_i and C_i^w.

To further investigate the impact of demand on the node and weighted closeness, we ranked the passenger flow of the six stations in decreasing order

(see Table 1). We found that stations with higher closeness also had higher passenger flow. Moreover, these stations are intersected by 3 lines. However, Xinzhuang Station and Zhangjiang Hi-Tech Park Station, which were ranked No. 2 and No. 4 in passenger flow volume, both have lower closeness scores. This indicates that there is a mismatch between their demand and accessibility. Hence, it is necessary to improve the accessibility in future planning and construction efforts.

Table 1. The impact of passenger flow on closeness.

Rank	Station	Passenger flow (W_j)	Ci	Ci(w)	Number of lines
1	Shanghai Railway Station	23,864	0.035	0.073	3
2	XinZhuang	21,469	0.022	0.040	2
3	People's Square	18,087	0.038	0.095	3
4	Zhangjiang Hi-Tech Park	15,297	0.024	0.041	1
5	Century Avenue	13,998	0.033	0.077	3
6	Zhongshan Park	13,825	0.034	0.088	3

Comparison between degree and weighted straightness. In this section, we offer a special representation to investigate the relation between the degree and weighted closeness in the Shanghai rail transit network (Blumenfeld-Lieberthal, 2008). It is based on the assumption that connectivity of stations can be defined by its degree and weighted closeness, rather than by each of them alone. By examining the relations of these two indices, not only the ***connectivity level*** of various stations can be analyzed, but also the ***operational efficiency*** of the whole network can be measured. As illustrated in Figure 5, the graph is divided into 9 regions, of which Region A—D represents four different types of stations, and Region 1—5 represent intermediate situations of development between A—D.

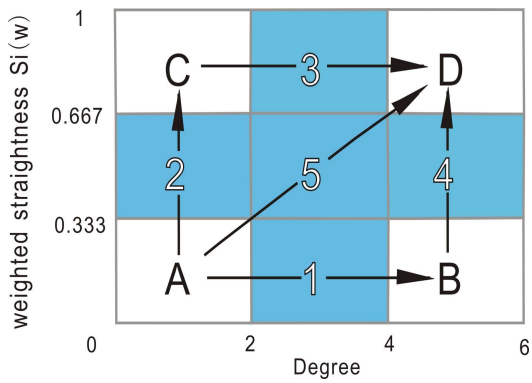

Figure 5. Regions division of degree vs. weighted straightness.

Region A: a low-importance station in a low-efficiency network. Stations in this region are typical of a low-connectivity network with unreasonable line settings.

Region B: a high-importance station in a low-efficiency network. Stations in this region are typical of hub stations in a low-connectivity network.

Region C: a low-importance station in a high-efficiency network. Although stations in this region have fewer adjacent stations, further degree gains would have been possible because of the reasonable line settings of the whole network.

Region D: a high-importance station in a high-efficiency network. Stations in this region are typical of hub stations in a high-connectivity network.

Applying this method to the Shanghai rail transit network, Figure 6 shows that most of the stations appear in Regions 2 and 5; fewer are located in Regions 3 and D; and, no stations appear in Regions 1, A, or B. This means that the rail transit network in Shanghai is still developing towards a better orientation. Besides, the 5 stations in Region D are all hub stations with a high connectivity level. They are the People's Square Station, the Shanghai Railway Station, the Zhongshan Park Station, the Century Avenue Station, and the Shanghai Indoor Stadium Station.

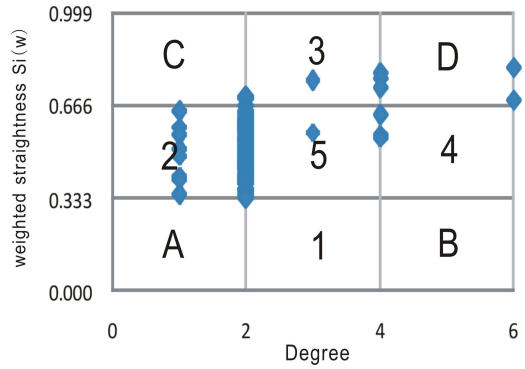

Figure 6. Degree vs. weighed straightness.

CONCLUSIONS

This paper selected the indices of topology, demand, and operation, and used these three aspects to analyze the characteristics of the current rail transit network in Shanghai.

(1) Degree was selected as a topological index. The analysis showed that the two stations with maximum degree 6 are the People's Square Station and the Century Avenue Station, which are also the centers of social and economic activities of the Puxi and the Pudong areas in Shanghai.

(2) Considering demand and operation, the spatial pattern of the node closeness and weighted closeness both showed concentric circle structures. Stations with better closeness (better accessibility) were focused on the 4 stations that intersected with 3 lines. Furthermore, the node closeness and weighted closeness (using passenger flow as the weighting factor) showed linear correlation with each other. For stations with lower closeness and higher passenger flow, future planning and construction should consider improving the accessibility of these stations.

(3) With further consideration of the spatial location of stations, weighted

straightness was defined. By comparing it with degree, we classified different types of stations by their stages of connectivity. The results show that high-connectivity stations are also the hub stations.

Future research will further investigate the correlation among network expansion, land development, and traffic demand, and try to grasp the relationship between transport and land use from the growth perspective of complex networks.

ABSTRACT

A section was selected to carry out both dynamic and static tests in order to assess the operation adaptability of existing line speed increases to 200 km/h and to put forward corresponding railway maintenance technology. It assessed the 200km/h EMUs operation safety on existing reform line, and analyzed operation adaptabilities of special sections, such as at the transition between road and bridge, R = 2200m curve and rail welded joints, etc. The results show that for a railway line with a speed increase to 200km/h, a roadbed-bridge transition section should be set up to reduce the additional dynamic impact caused by the changes in track stiffness. It is appropriate to increase the speed of 2200m radius curve to 180km/h, and its speed should be increased accordingly with the speed of freight trains. For a railway line of mixed passenger and freight traffic with speeds up to 200~250km/h, welding joint irregularity should be strictly controlled, and a timely polishing should be arranged when the irregularity is over 0.3mm. Based on the challenges for the China railway and the in-depth analysis of foreign high-speed railway maintenance characteristics, this proposes a maintenance technology system of raising the speed reform railway line by focusing on 4 aspects: the maintenance system, the track management standards, the track detection mode, and maintenance operations.

INTRODUCTION

To realize train speeds of 200km/h or more, two methods are mostly used: 1) construct a dedicated high speed passenger line, which separates passengers and freight transportation; the highest speed can reach 350km/h, such as in France and Japan; and 2) transform the equipment on existing lines, mix passengers and freight transportation; the highest speed can reach 250km/h, such as in Germany and England. On April 18, 2007, the China railway implemented the sixth speed increase: 200 – 250km/h for EMUs, 80 – 120km/hr for 5000t freight trains and double-decker container trucks running on existing reform lines; the railway speed increased to 200km/h along 6003km, of which there are 846km with a speed over 250km/h. This change means China has stepped into world's advanced class (Xi, 2006). In order to assess the operation adaptability of the existing line speed increases to 200 km/h and put forward the corresponding track maintenance

technology, Infrastructure Equipment Test Center of China Railway, Southwest Jiaotong University and Tsinghua University together carried out a study on "Adaptability Assessment and Maintenance Technology Research of Existing Railway Line Speed Increases to 200 km/h."

INTEGRATED ASSESSMENT OF REFORMED RAILWAY OPERATION ADAPTABILITY

A section was selected to carry out dynamic and static tests to assess the 200km/h EMUs running safety on the existing reformed line, and to analyze the operation adaptability of several special sections, such as at the transition between road and bridge, R = 2200m curve and rail welded joints, etc. The track dynamic and static regularities of the reformed track were tested also.

Transition of road and bridge. The track stiffness at the transition between the road and the bridge changes gradually with less additional dynamic impact. Dynamic performance is obviously better than that of the existing bridgehead line (Zhang, 2007). For 200km/h EMUs, the track integral stiffness at the transition between the road and the bridge is 83% of that on the bridge. The additional dynamic coefficient is 5%, and the maximum dynamic irregularity is only 0.1mm. This ensures the safety and comfort of EMUs running at 250km/h. Track stiffness changes abruptly on the existing bridgehead line, and the additional dynamic impact is big. At 195km/h EMUs, the track integral stiffness at the railroad outside bridge is 39% of that on the bridge. The additional dynamic coefficient is 20%, and the maximum dynamic irregularity is 0.7mm. Therefore, a transition between the rail and the bridge should be set up for railway lines with speed increases up to 200km/h so as to decrease the additional dynamic impact caused by stiffness changes. Test results are shown in Table 1.

Table 1. Dynamic test results of transition of road and bridge.

Measuring point	Vehicle	Velocity	Maximal Rail Vertical force (KN)	Maximal rail vertical force variational value(KN)	Additional dynamic coefficient	Maximal Rail Vertical displacement (mm)	Maximal rail vertical displacement variational value(mm)	Vertical displacement variation	Track dynamic stiffness on bridge (KN/mm)	Track dynamic stiffness of transition section (KN/mm)	Track Entire Stiffness ratio
Transition between road and bridge	EMUs	240	86.8	4.3	5%	0.843	0.115	14%	121	101	83%
	passenger train (locomotive)	131.2	162.8	16.36	11%	1.388	0.244	18%	143	111	78%
	Double-decker container truck	119.2	173.46	22.04	15%	1.672	0.473	28%	132	99	75%
	The indicators ratio between EMUs and passenger train		0.53			0.61					
	The indicators ratio between EMUs and double-decker container truck		0.5			0.5					
Existing Bridgehead line	EMUs	195	92.9	15.2	20%	1.203	0.711	59%	175	68	39%
	passenger train (locomotive)	121.6	177.49	16.67	10%	2.041	0.868	43%	147	80	54%
	passenger train (locomotive)		0.52			0.59					

Curve R=2200m. When EMUs pass a curve (R=2200m, superelevation 90mm, maximal deficient superelevation 125mm) at the speed of 200km/h or less, test results show that running stability indexes are all within the allowable safety limits and the dynamic impact is less than that of ordinary trains. See Figure 1. The speed difference between passenger and freight trains and freight train density are comparatively large (MORPRC 2007), so for a curve where R = 2200m, it is

better to increase speed to less than 180km/h which considers passenger comfort and curve maintenance. The speed should be increased with the velocity of freight trains.

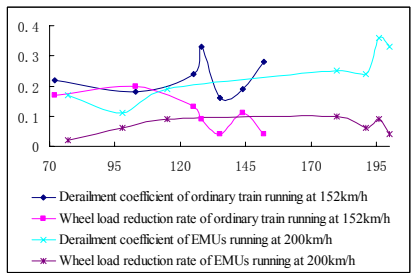

Figure 1. Test results comparison on curve.

Rail Welded Joints. The dynamic impact of EMUs on rail welded joints is comparatively little. For rail welded joints with an irregularity value of 0.25mm, when the EMUs pass at speeds of 240km/h, the wheel-rail vertical force and the acceleration of the rail are both 50% of that of a passenger train running at 120km/h. The impact of the irregularities of rail welded joints on the dynamic performance of the EMUs increases with the increase of speed. For rail welded joints with irregularity values of 0.25mm, when EMUs run respectively at 200km/h and 240km/h, the wheel-rail vertical force of the latter is 2% larger than that of the former, while acceleration is increased 18%. The impact of the irregularity of the rail welded joints on ordinary train dynamic performance increases significantly with the increase of the irregularity of the joints. When EMUs runs at 240km/h and passenger trains and double-decker container trucks run at 120km/h, the wheel-rail vertical force and acceleration of rail welded joints with 0.47mm irregularity are respectively increased by 11% - 18% and 21% - 100% as compared with rail welded joints with 0.25mm irregularity. The impact of the irregularity of rail welded joints on the dynamic performance of 25T axle load double-decker container trucks is comparatively severe. For rail welded joints with a 0.25mm irregularity value, and when a double-decker container truck runs at 120km/h, its acceleration (109.2g) is 1.7 times as large as that of a passenger train(65.30g) running at 120km/h. It is 3.2 times as large as that of EMUs (33.89g) running at 240km/h. The wheel-rail vertical force of rail welded joints with a 0.31mm and 0.25mm irregularity value is slightly different from those of neighboring other rail test points, around 5%. Thus, as for railway lines of mixed passenger and freight transport increase speeds up to 200 – 25km/h, the irregularity values of rail welded joints should be strictly controlled. When it is over 0.3mm, the rail will need grinding.

Safety of EMUs. Three EMUs dynamic performance tests were carried out on Jiao-Ji railway. The test results of frame transversal acceleration show that there is no transversal instability. Maximal lateral wheelset force is less than the operation limits (MORPRC 2005). The derailment coefficient was over 0.8 only once. The maximal wheel load reduction rates are generally less than 0.80; only

a few of which are over 0.80 and they are all single peak unloading. No two peaks appear successively over 0.80. Maximal average values of both transversal and vertical stability of the tested vehicle are less than 2.50, reaching the superior grade. The reformed test section satisfies the safety and comfort requirements of EMUs running between 200～250km/h.

Track Irregularity Spectrum. The track quality of Jiao-Ji railway has greatly improved since its electrification innovation reform in July, 2005. Due to two years of fine maintenance, from between February 2006 to June 2007, the average TQI decreased from 10.16 to 6.93, which is a 32% reduction. The track irregularity spectrum is almost lower than the German Low Interference Spectrum; i.e. the irregularity spectrum of a partial wave band is slightly higher, but none is higher than High Interference Spectrum. See Figure 2. Between July 2006 and June 2007, there were no grade IV over limits, and grade III over limits were within 0 -- 10. Until the sixth raising the speed reform, each dynamic quality index remained stable and the track quality satisfies the criterion of speed increases between 200 -- 250km/h.

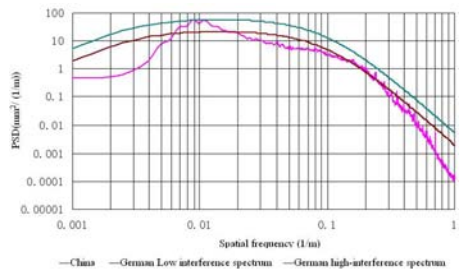

Figure 2. Horizontal irregularity spectrum of Jiao-Ji line.

CHALLENGES FOR RAISING SPEED RAILWAY MAINTENANCE IN CHINA

The integrated assessment of operation adaptability deepens the understanding of the challenges for raising the speed railway line maintenance in China:

(1) To realize high railway regularity based on the operation mode of high speed, high density, big axle weight, and mixed passenger and freight transport.

(2) To improve safety and comfort based on the status of the existing line raising speed reform, but the existing raising speed reform criterion is comparatively low, such as less curve radius, weak roadbed and the stiffness of existing bridgehead line changes dramatically, etc.

(3) To ensure the operation safety under the condition of mixed passenger and freight transport and setting up type V “skylight” for construction operation.

STUDY OF RAISING SPEED RAILWAY MAINTENANCE TECHNOLOGY

Characteristics of Overseas Railway Maintenance and Management.

(1) Advanced concept of design and construction. Make overall plans of

new railway construction and maintenance operation; consider less track maintenance while designing a new line so as to pursue optimized economic benefits. Attach importance to the quality of constructing new lines and strictly control the track starting irregularity. Adopt the principle of equipment first, decrease the influence of artificial factors, i.e., replace personal judgment and operation with equipment. Suit the fixture by mobile equipment to improve the train performance and lighten train axle load and unsprung mass so as to decrease the impact of the train on the track.

(2) Scientific track management. Stipulate integrated criteria for track condition evaluation and management; establish an investigation system with advanced survey techniques, reasonable investigation cycle and dynamic constant velocity testing first with static testing second; predict and control the change of infrastructure equipment scientifically to guide the maintenance. Thoroughly implement guiding ideology of preventive maintenance; rely on an advanced railway information management system, set up "skylight" by adopting a large track maintenance machine according to absolute reference to carry out rail grinding; realize "Equipment Status Repair", efficiently eliminate rail long wave irregularity and rail surface short wave irregularity; improve maintenance precision and track durability so as to extend the track maintenance cycle. See Figure 3 for track irregularity change trends in Germany.

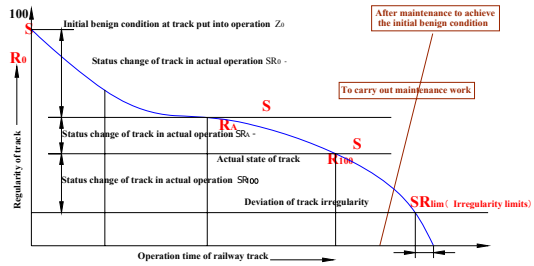

Figure 3.Track irregularity change trends in Germany.

(3) Strict safety management. Establish a disaster prevention and safety monitoring system for high speed railway; carry out complete, accurate and real-time safety controls so as to prevent a sudden disastrous attack (Yu, 2004).

Raising Speed Railway Maintenance for China. Based on integrated assessment results of raising speed railway operation adaptability and in-depth analysis of foreign high speed railway maintenance and management characteristics, this paper put forth a maintenance technology system for raising the railway line speed to 200km/h.

(1) Track maintenance system. Separate systems for management and detection should be put into practice. Establish a detection and monitoring center, which manages the equipment detection, measuring, data analysis, rail flaw inspection, scheduling and computation uniformly.

(2) Track quality management criteria. Complete track quality evaluation criteria are put forward here, including management standards for track dynamic irregularity, track static geometry size allowable errors, and track surface short

wave irregularity. The management standards for track dynamic irregularity contain part irregularity (peak value management), entire irregularity (average value management) and wheel-rail force assessment. See Table 2 for tolerance values for track part dynamic irregularity at different levels. All tolerance levels are divided into four levels: Level I: maintenance standard, level II: comfort standard, level III: temporary repair standard, and level IV: speed limit standard.

Table 2. Dynamic quality tolerance of track.

Items			200km/h≤v≤250km/h			
			I	II	III	IV
Gauge(mm)			+4 -3	+6 -4	+8 -6	+12 -8
Cross-level(mm)			5	8	10	13
Track twist irregularity (gauge length 2.5m)（mm）			4	6	8	10
Comfort indexes	Wave length 1.5～42m	Rail vertical irregularity (mm)	5	8	11	14
		Rail alignment (mm)	5	7	8	10
	Constant velocity detection	Car body vertical acceleration（g）	0.10	0.15	0.20	0.25
		Car body transversal acceleration（g）	0.06	0.10	0.15	0.20
	Wave length 1.5～70m	Rail vertical irregularity (mm)	6	10	15	
		Rail alignment(mm)	6	8	12	
Gauge change rate(gauge length 2.5m)（‰）			1.0	1.2		
Curvature change rate (gauge length 18m)（1/m2×10-6）			1.2	1.5		
Car body transversal acceleration change rate (gauge length 18m)（m/s3）			0.8			

(3) Railway track inspection. It is necessary to adopt a new inspection mode for raising railway speed, which includes dynamic constant velocity detecting first, with static testing second, advanced detection techniques, reasonable inspection cycle, and fast data processing.

(4) Maintenance and repair work. The guiding ideology of preventive maintenance should be implemented, adopt advanced track management technology and equipment status repair regulations to improve maintenance precision, reliability, and achieve the comfort standards.

In detail, six aspects of transformation are needed: (A) Put preventive maintenance into full practice, and track maintenance target switches from safety management to comfort management; (B) Use large railway track maintenance machinery by adopting an absolute reference measurement system; Track maintenance changes from improving track status to completely renewing design, geometry, and shape; (C) Emphasize rail regularity, change from ballast tamping first to reducing ballast tamping by rail grinding; (D) Adopt advanced track management technology, change from traditional experience management to digital, information and customization management; (E) Attach great importance to safety of type V “skylight” operations; as for quality check after construction, it should change gradually from static inspection to dynamic inspection confirmation; (F) Spare no effort to establish a cubic safety barrier for raising speed lines, change from ordinary open railway to raising speed fully-closed railway line.

CONCLUSIONS

(1) Transition between road and bridge should be set up for speeds up to 200km/h so as to reduce the additional dynamic impact caused by track stiffness changes; make overall plan of EMUs comfort and curve maintenance, for

R=2200m curve, it is better to limit speed to not more than 180km/h, moreover, it should be increased with the speed increase of freight train; for raising the speed of mixed passenger and freight transport, the rail welded joints irregularity should be strictly controlled, and the rail needs grinding when it is over 0.3mm.

(2) Raising the railway speed should be based on the principle of preventive maintenance, and it should rely on advanced management technology, and realize comfort target management through equipment status repair.

(3) More research should be carried out soon to determine the mode at which large railway track maintenance machinery works by adopting an absolute reference measurement system in China. Meanwhile, problems such as decreasing additional dynamic impacts caused by track stiffness changes and improving railway dynamic regularity, and tracking integral stiffness proper matching of existing bridgehead railway line, etc., are also urgent research tasks.

ABSTRACT

Whether the type of high-speed railway transition curves is suitable or not affects a train's running stability and passengers' comfort directly. The lateral change of acceleration (LCA) plays an important role in determining the transition curve parameters. Based on vehicle movement dynamics, the motions with positive or negative acceleration are taken into account to deduce the equation of lateral change of the vehicle acceleration. The LCA of several common transition curves were compared in five different motion models. The results show that the LCA which considers motion with positive or negative acceleration can be used for the optimization of high-speed railway transition curves as a theoretical basis.

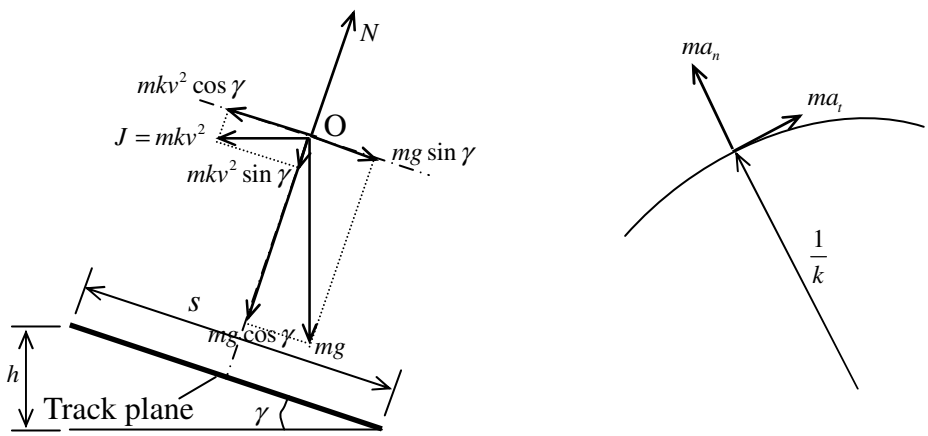
INTRODUCTION

As train speed increases, to ensure that vehicles run safely and are stable, higher requirements on track geometry should be met. Transition curves are normally inserted between straight lines and circular curves in order to make the train pass smoothly from a straight line to a circular curve or from a circular curve to a straight line. Studies on transition curves have been carried out for about 100 years and much information can be found in the literature (Baykal, O. and Tari, E. 1998; Baykal, O. and Tari, E. 2005; Lipicnik, M. 1998; Wang, X. W. 1997; Zhou, X. Z. 1996; Zhu, W. S. 1997). However, there is still much dispute about the selection of transition curve shapes (Wang, X. W. 1997; Zhu, W. S. 1997). Several transition curves are used in the world at present, such as cubic parabola (CP), half-wave-length sinusoidal (HS) and sinusoidal (SI). However, only CP and HS are used in wheel-rail high-speed railway (Liu, X. and Liu, Z. J. 2004). The LCA

plays an important role in determining the transition curve parameters. Based on the vehicle movement dynamics, and assuming that the conditions of the vehicle and the track are sound, simplifying the vehicle as a particle, and taking into account of the motions with positive or negative acceleration, the equation of the lateral change of the vehicle acceleration is deduced in this paper. Additionally, the values of LCA for several familiar transition curves such as CP, HS, and SI are compared.

DEDUCTION OF LCA FUNCTION

Forces acting on a vehicle that is moving on curve are the gravitational force (mg), the centrifugal force ($\boldsymbol{J}=mkv^2$), the reaction force of the track ($\boldsymbol{N}$), and the motor or resistance force (ma_t). See Figure 1(a) and (b). According to Figure 1(a), the gravitational force (mg)/the centrifugal force ($\boldsymbol{J}=mkv^2$) can be divided into two: $mg\cos$ /$mkv^2\sin$ and $mg\sin$ /$mkv^2\cos$ perpendicular and parallel to the track plane, respectively. The component $mg\cos$ and $mkv^2\sin$ are balanced with the reaction of the track plane (N) and becomes effective in only the vertical change of acceleration. The $mg\sin$ and $mkv^2\cos$ are the forces which form the LCA.



(a) Cross section **(b) Plane view**

Figure 1. Forces acting on a vehicle moving on curve.

From Figure 1(a)

$$\boldsymbol{a}_n = (kv^2\cos\gamma - g\sin\gamma)\ \mathbf{n} \tag{1}$$

can be derived, where $\boldsymbol{a}_n$ is the acceleration along the direction of the curve normal on an inclined track plane (m/s^2); k is the curvature of orbiting curve defined on a horizontal plane (m^{-1}); v is the vehicle velocity; is the bank angle; g is the gravitational acceleration (9.81 m/s^2); and $\mathbf{n}$ is the unit vector along the curve normal.

The tangential acceleration caused by the motor or the resistance force is

$$\boldsymbol{a}_t = \frac{dv}{dT}\ \mathbf{t} \tag{2}$$

where $\mathbf{t}$ is the unit vector along the direction of the tangent of the curve; T is time

(s), and the resultant acceleration of the motion is

$$\boldsymbol{a} = \frac{dv}{dT}\,\mathbf{t} + (kv^2\cos\gamma - g\sin\gamma)\,\mathbf{n} = \frac{dv}{dT}\,\mathbf{t} + \left(kv^2\sqrt{s^2-h^2}\,/\,s - gh/s\right)\mathbf{n} \tag{3}$$

where s is the distance between the centers of the rails (1.5 m); and h is cant (m). In the case where the velocity (v) is constant (a_t=0) along the transition curve and the bank angle (<<1) is small, Equation (3) which is a common function of the lateral acceleration,.can be simplified as

$$a = kv^2 - gh/s \tag{4}$$

where $v = v(l)$ is a function of the velocity related to the track; $k = k(l)$ is a function of the curvature related to the track; and $h = h(l)$ is a function of cant related to the track. The derivative of Equation (3) with respect to the track is

$$\frac{d\boldsymbol{a}}{dl} = \frac{dv}{dT}\frac{d\mathbf{t}}{dl} + \frac{d\left(kv^2\sqrt{s^2-h^2}\,/\,s - gh/s\right)}{dl}\,\mathbf{n} \tag{5}$$

where

$$\frac{d\mathbf{t}}{dl} = k_e\,\mathbf{n} \qquad \text{(O. Baykal 1996)} \tag{6}$$

k_e is the curvature of the orbiting curve defined on the inclined plane of the track; and l is the horizontal distance measured along the transition curve. Since the curvature of the orbital curve is defined on a horizontal plane, as a rule it should be traced on to the inclined plane, such as

$$k_e = k\cos\gamma = \frac{\sqrt{s^2-h^2}}{s}k\,. \tag{7}$$

Introducing (6) and (7) into (5) and multiplying both sides by **n**

$$\frac{d\boldsymbol{a}}{dl}\mathbf{n} = \left(k\frac{dv}{dT} + v^2\frac{dk}{dl} + 2kv\frac{dv}{dl}\right)\frac{\sqrt{s^2-h^2}}{s} - \left(kv^2\frac{h}{s\sqrt{s^2-h^2}} + \frac{g}{s}\right)\frac{dh}{dl} \tag{8}$$

can be obtained. In addition, the following can be written

$$\frac{d\boldsymbol{a}}{dT} = \frac{d\boldsymbol{a}}{dl}\frac{dl}{dT} = v\,\frac{d\boldsymbol{a}}{dl} \tag{9}$$

$$\frac{dv}{dl} = \frac{dv}{dT}\frac{dT}{dl} = \frac{1}{v}\frac{dv}{dT} = \frac{a_t}{v}\,. \tag{10}$$

Introducing (9) and (10) into (8), the equation of the LCA can be derived as follows:

$$f = \frac{d\boldsymbol{a}}{dT}\mathbf{n} = v\left[\left(3ka_t + v^2\frac{dk}{dl}\right)\frac{\sqrt{s^2-h^2}}{s} - \left(kv^2\frac{h}{s\sqrt{s^2-h^2}} + \frac{g}{s}\right)\frac{dh}{dl}\right]\,. \tag{11}$$

Equation (11) can also be written as follows:

$$f = \frac{d\boldsymbol{a}}{dT}\mathbf{n} = v\left[\left(3ka_t + v^2\frac{dk}{dl}\right)\cos\gamma - \frac{kv^2\tan\gamma + g}{s}\frac{dh}{dl}\right]\,. \tag{12}$$

LCA FUNCTIONS OF TRANSITION CURVES

Characteristics of transition curves. The characteristics of CP, HS, and SI are listed in Table 1 where h_0 is maximum cant; R is the radius of a circular curve; and L is the total horizontal length of a transition curve.

Table 1. Characteristics of transition curves.

Characteristics	CP	HS	SI
k	$\frac{l}{RL}$	$\frac{1}{2R}\left[1-\cos\left(\frac{\pi l}{L}\right)\right]$	$\frac{1}{R}\left[\frac{l}{L}-\frac{1}{2\pi}\sin\left(\frac{2\pi l}{L}\right)\right]$
h	$\frac{h_0 l}{L}$	$\frac{h_0}{2}\left[1-\cos\left(\frac{\pi l}{L}\right)\right]$	$h_0\left[\frac{l}{L}-\frac{1}{2\pi}\sin\left(\frac{2\pi l}{L}\right)\right]$

LCA function of CP, HS and SI. Taking vehicle passes from a straight line to circular curve for example, the function of the LCA of the transition curves are derived from Equation (11) by taking into consideration the characteristics in Table 1 as follows:

LCA function of the CP:

$$f=\frac{v}{RLs}\left(3a_{\mathrm{t}}lA+Av^2-Rgh_0-\frac{v^2h_0^2l^2}{LA}\right) \tag{13}$$

where $A=\sqrt{s^2-\left(\frac{h_0 l}{L}\right)^2}$.

LCA function of the HS:

$$f=\frac{v}{4RLs}\left\{3a_{\mathrm{t}}LBC+\left[\frac{2\pi v^2(2s^2-h_0^2B^2)}{C}-2\pi Rgh_0\right]\sin\left(\frac{\pi l}{L}\right)\right\} \tag{14}$$

where $B=1-\cos\left(\frac{\pi l}{L}\right)$, $C=\sqrt{4s^2-(h_0B)^2}$.

LCA function of the SI:

$$f=\frac{v}{RLs}\left\{3a_{\mathrm{t}}LDE+\left[\frac{2v^2(s^2-2h_0^2D^2)}{E}-2Rgh_0\right]\sin^2\left(\frac{\pi l}{L}\right)\right\} \tag{15}$$

where $D=\frac{l}{L}-\frac{1}{2\pi}\sin\left(\frac{2\pi l}{L}\right)$, $E=\sqrt{s^2-(h_0D)^2}$.

CALCULATING

Five different motion models are established by taking into account

motions with positive or negative acceleration.

Calculation parameters. The line is flat; the radius of the circular curve R=5000 m; the length of the transition curve L=300 m; the length of the circular curve L_0=600 m; and the maximum cant h_0=0.055 m.

Model 1-Motion model with constant velocity. In this model, velocity (v=300 km/h) is assumed to be constant (a_t=0) along the total curve. To compare the curves, the graphs of the LCA of the curves for model 1 are illustrated in Figure 3 by introducing the calculation parameters into Equations (13), (14) and (15).

Model 2 and 3-Motion model with constant acceleration. The acceleration is assumed to be constant (a_t=constant) along the total curve. The following equations of velocity and acceleration are valid (where the velocity is v_0 at ZH (l=0) and v_e at HZ (l=2L+L_0) in Figure 2).

$$a_{\mathrm{t}} = \frac{v_{\mathrm{e}}^2 - v_0^2}{2\left(2L + L_0\right)}; \qquad v = \sqrt{v_0^2 + 2a_{\mathrm{t}} l} \tag{16}$$

According to Equation (16), the motion with positive acceleration is valid for v_0 (v_0=150 km/h) < v_e (v_e=300 km/h) (model 2), and the motion with negative acceleration is valid for v_0 (v_0=300 km/h) > v_e (v_e=150 km/h) (model 3). To compare the curves, the diagram of the LCA of the curves for model 2 and model 3 are illustrated in Figure 4 and in Figure 5 by introducing Equation (16) and the calculation parameters into Equations (13), (14) and (15).

Model 4 and 5 Motion model with variable accelerations. The velocities at ZH, M (l=L+L_0/2), and HZ are assumed as v_0, v_c and v_e, respectively. The velocity and the acceleration equations are given for two sections, ZH-M, M-HZ, and are valid as

$$a_{t,1} = \frac{v_c^2 - v_0^2}{2\left(L + L_0/2\right)}; \qquad v_1 = \sqrt{v_0^2 + 2a_{t,1} l}\ ; \qquad (0 \le l \le L + L_0/2) \tag{17a}$$

$$a_{t,2} = \frac{v_e^2 - v_c^2}{2\left(L + L_0/2\right)}; \quad v_2 = \sqrt{v_c^2 + 2a_{t,2}\left(l - L - L_0/2\right)}; \quad (L + L_0/2 \le l \le 2L + L_0) \tag{17b}$$

where a_{t1} (a_{t2}) and v_1 (v_2) is the acceleration and velocity of the former (latter) section, respectively.

According to Equation (17), the motion with negative acceleration - positive acceleration is valid for v_0 (v_0=150 km/h) < v_c (v_c=300 km/h) > v_e (v_e=150 km/h) (model 4), and the motion with positive acceleration - negative acceleration is valid for v_0 (v_0=300 km/h) > v_c (v_c=150 km/h) < v_e (v_e=300 km/h) (model 5). To compare the curves, the diagram of the LCA of the curves for model 4 and model 5 are illustrated in Figure 6 and Figure 7 by introducing Equation (17) and the calculation parameters into Equations (13), (14), and (15).

COMPARISONS

The continuity of the LCA function is the most important criterion in the comparison of transition curves for several reasons: because discontinuities in the form of jumps affect travel comfort on railways; it changes the geometry of the rails; and more importantly, it causes wear on wheels and rails in railways. The comparisons of the LCA of CP, SI, and HS transition curves with each other using five different motion models as follows:

(1) We can see from Figures 3-7 that the CP has discontinuities at 4, 3, 3, 3 and 5 points, respectively; the HS and SI do not have any discontinuities in the

form of a jump in Figures 3-5, and in Figures 6 and 7 there are discontinuities at one point only. Therefore, according to the criterion the HS and SI are better than the CP.

(2) There are magnitudes of discontinuities in the form of jumps on the diagrams of the LCA. The jumps of the function of the LCA at point ZH, HY, M, YH and HZ and the sums of absolute values of the jumps are given as the criterion listed in Table 2. From Figures 3-7 and Table 2 we can see that the maximum sums of jumps of the transition curves with five different motion models are 1.0032, 0.4584, 0.4584, 0.5883 and 0.8868 m/s^3 for CP. We can also see that the jumps of HS are the same as that for SI. Therefore, according to the criterion, the HS and SI are better than the CP, especially in models 4 and 5.

(3) To better compare the LCA of transition curves, the absolute maximum values of the function of the LCA are given as one of the criteria and are listed in the last column of Table 2. We can see from Figures 3-7 and from Table2 the largest absolute values of the function of the LCA are 0.2508, 0.3937 and 0.5013 m/s^3 for CP, HS and SI, therefore the HS is better than the others.

Table 2. Discontinuities of LCA in the form of jumps (m/s^3).

Point number		Discontinuity Magnitude ZH	HY	M	YH	HZ	Sum of jumps	Maximum
Model 1	CP	0.2508	0.2508	0	-0.250	-0.250	1.003	0.2508

CONCLUSION

In this paper, the function of the LCA is obtained by taken into account the motions with positive or negative acceleration based on vehicle movement dynamics. And, Equation (11) is suitable for the optimization of transition curves. However, this article is only a theoretical derivation and useful for comparison purposes. It is necessary to conduct further research and do simulation analyses by using vehicle-track coupling dynamics theory.

By comparing several types of transition curves, we can see that the HS curve is superior to the other two. Due to a lack of construction and maintenance experience about the HS and SI curves, most countries still choose the CP as railway transition curves if a long enough long transition curve can be ensured. In order to improve passengers' comfort, we suggest that the HS curve should be used when the length of the transition curve is constrained by the surroundings, especially at both ends of the station area where there are changes in vehicle acceleration.

ABSTRACT

In view of the actual disability and inaccuracy of evaluating railway vehicle bogie stiffness parameters, a more reasonable design scheme about novel bogie dynamic testing system is discussed. The system can satisfy dynamic testing and static testing of stiffness parameters about the whole vehicle bogie and the unattached bogie. Some testing models are given based on the technical features of the system. Testing models such as the H-type bogie of the CRH3 high-speed multiple unit, were investigated. In addition, an optimized neural network PID controller was researched. Results show that the manufacture of a novel bogie dynamic testing system can measure bogie stiffness parameters accurately. The foundation for the application and popularization of a novel bogie parameter testing system has been established.

INTRODUCTION

In order to improve the technical content about high-speed trains and heavy-haul trains, railway manufacturers need to research multifunctional parameter test equipment urgently. The bogie, which is the unique running mechanism of railway vehicles, is the structural parameter and the important factor that affects running security, stabilization, and high effectiveness, etc. Therefore, the need to conduct research for a multifunctional parameter test system of bogie is significant (P.R.China Ministry of Railways, 2003; Broom, M. L., 1990). Although there are massive correlation studies of bogies abroad and in China, as well as the fact that some test equipment has been developed, it is difficult to test the whole vehicle bogie and meet requirements of primary spring and secondary spring for vertical stiffness, transverse stiffness, longitudinal stiffness, and rotary stiffness (Eikhoff, B. M., 1995). Hence, the successful development of a dynamic testing system of bogie is significant for the quality control, product development, and for shortening the development cycle, etc.

THE SYSTEM COMPOSITION

Composition of a bogie dynamic test system such as is shown in Figure 1, the anti-thrust gantry system can be used to test vertical stiffness of a bogie dynamically. It includes two vertical cylinders and two position adjusting motors. The two vertical cylinders can load in both synchronous and asynchronous manners and have the following parameters: the maximum loads are 200KN, the loading waveform uses a sine wave, the maximum amplitude is ±6mm, the maximum dynamic loading frequency is 5Hz, and the two motors can be used to adjust the position of two vertical cylinders in the X-direction for different types of bogies. The anti-thrust

gantry system, which includes the bogie anti-thrust location screw and the vehicle body anti-thrust location screw, can be used in the process of testing.

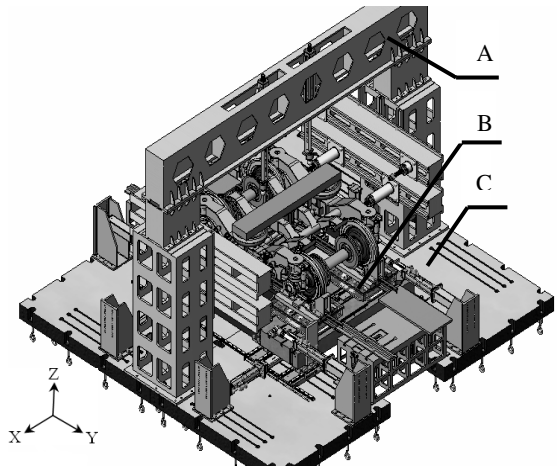

Figure 1. Novel bogie stiffness test system (A. Anti-thrust gantry system B. Cross slipway force system C. Foundation Platform).

It is worthwhile to note that while testing, the whole vehicle needs to remove the anti-thrust gantry system except for the vehicle body anti-thrust location screw. The cross slipway force application system can be used to test vertical stiffness, transverse stiffness, longitudinal stiffness, flexural stiffness, rotary stiffness, shear stiffness, and wrap stiffness, etc. Besides that, it includes a wheel-set clamp device and a guidance orbit device for the positioning function. The hydraulic system uses an optimized neural network PID controller (force-closed feedback control) to control servovalves. The industrial computer can be used to collect, treat and analyze signals of sensors which include force, displacement and angle to complete the testing, recording, and displaying of the parameters and the curve to be measured.

Considering that every single wheel will bear a different force in a different direction, there are four 3-D force sensors under each respective wheel. All hydraulic cylinders use ball-ends and hinges to ensure freedom of cross slipway.

PARAMETERS TEST MODEL

The test of bogie stiffness includes collecting collect force, moment, linear displacement and angular displacement mainly, fix frame in the testing process, meanwhile, load to wheelset slowly and periodically, neglect all inertial mass (Ji, Q. 2005). The system can simulate the forced state of a bogie and draw a curve in the process when the system working. The method and model of testing in this full-text are based on the simplified bogie model that was proposed by Wickens (a British railway expert in the 1960s) (Wickens, A. H. 1965). Using the test models in this paper, we take the H-type bogie of CRH3 multiple unit as an example. Due to the restriction on the length of this paper, the author analyzed some models and methods partially. Other testing models and testing methods are homologous, according to

the parameters of bogie stiffness. It is worth pointing out that the frame must be fixed in the testing process.

DYNAMIC TEST MODEL OF BOGIE VERTICAL STIFFNESS

Locate frame via the four bogie anti-thrust location screws. Next, locate wheel-sets via the four wheel-set location and clamp devices, where the four wheel-set location and clamp devices have been installed on the cross slipway. In addition, a force sensor has been installed at the front-end of every single hydraulic cylinder to constitute a force-closed feedback control. To avoid measurement error caused by the lateral force of a bar in the cylinder, every single force sensor is connected with the supporting body by means of a . The dynamic model can be expressed using the following equations:

$$\begin{cases} m_1\ddot{Z}_{1i} + C_{Z_{1i}}\dot{Z}_{1i} + K_{Z1i}Z_{1i} = F_{Z1i}I(t), (i = 1,2,3,4) \\ m_2\ddot{Z}_{2j} + C_{Z_{2j}}\dot{Z}_{2j} + K_{Z2j}Z_{2j} = F_{Z2j}I(t), (j = 1,2) \end{cases} \quad (1)$$

Equation (1): Z_{1i} -dynamic displacement between frame and axle boxes; Z_{2j} - dynamic displacement between frame and bolster; $C_{Z_{1i}}, C_{Z_{2j}}$ -suspension damping coefficient of primary and secondary; t -time variable (forced); m_1, m_2 -weight on spring; $F_{Z1i}I(t)$ -vertical measured value of 3-D force sensor; $F_{Z2j}I(t)$ -force of two vertical cylinders; $I(t)$ -unit step function.Using $I(t)$ can test vertical stiffness dynamic and instantaneous, let $\delta_{1i} = [Z_{1i}(\infty) - Z_{1i}(0)]$, let $\delta_{2j} = [Z_{2j}(\infty) - Z_{2j}(0)]$; $Z_{1i}(\infty), Z_{2j}(\infty)$ - steady state terminal value of the dynamic displacement in primary and secondary; $Z_{1i}(0), Z_{2j}(0)$ -steady state initial value of the dynamic displacement in primary and secondary.

PRIMARY VERTICAL STIFFNESS OF BOGIE

The force of the vertical hydraulic system needs to transfer downward, which passes through a secondary suspension (air spring), a primary suspension, a vertical hydraulic shock absorber, an axle box, a wheel flange, and a tread, etc. In case the force of the four wheels is unequal, the testing process needs to realize nearby wheels. Measurements are made of the displacement by using the grating displacement transducers of the magnetic base mode, the contact of four grating displacement transducers are rebound, one end is absorbed to the frame, the other end is supported on the axle box. The primary stiffness values are calculated by means of measured values of the four grating displacement transducers and the four 3-D force sensors in the vertical direction, such as is shown in Figure 2. The calculation formula is as follows:

$$K_{Z1i} = F_{Z1i}I(t) / \delta_{1i}, (i = 1,2,3,4) \quad (2)$$

where K_{Z1i} is the primary vertical stiffness of the bogie, and i is one of the four wheels.

SECONDARY VERTICAL STIFFNESS OF BOGIE

The testing process of the secondary vertical stiffness needs to use the nearby bolster and the displacement sensor as in the previous section 2.1.1. However, the

connect type is different. The one end is absorbed to the frame and the other end is supported on the bolster. The secondary stiffness values are calculated by means of a measured value of the four grating displacement transducers and the two force sensors that are installed at the front-end of the vertical hydraulic cylinder, such as is shown in Figure 3. The calculation formula is as follows:

$$K_{Z2j} = F_{Z2j} I(t) / \delta_{2j}, (j = 1, 2) \quad (3)$$

where K_{Z1i} is the secondary vertical stiffness of bogie, and j is one of the two air springs.

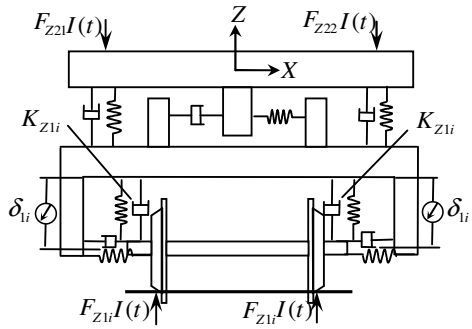

Figure 2. Test of primary vertical stiffness.

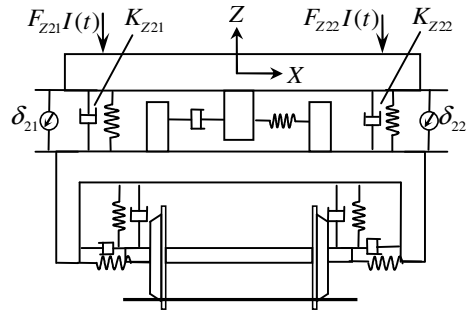

Figure 3. Test of secondary vertical stiffness.

STATIC TEST MODEL OF BOGIE IN XOY PLANE

The stiffness parameters in the XOY plane include primary transverse stiffness, primary longitudinal stiffness, and primary rotary stiffness, etc. These parameters can be measured on a dual cross slipway based on the design features, so it is necessary to conduct movement analyses.

MOVEMENT TENDENCY ANALYSIS OF DUAL CROSS SLIPWAY

The cross slipway force system includes six hydraulic cylinders and the dual cross slipway can move in different directions, as shown in Figure 4. This can test transverse stiffness, longitudinal stiffness, rotary stiffness, shear stiffness, and wrap stiffness, etc. The author has introduced test methods and test models of transverse stiffness and rotary stiffness in this paper.

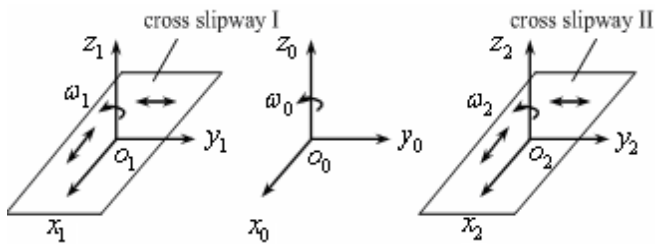

Figure 4. Movement tendency of dual cross slipway.

PRIMARY TRANSVERSE STIFFNESS OF BOGIE

With the two transverse hydraulic cylinders loading synchronously, the 3-D sensors measure the transverse force of the wheel-sets. The four displacement sensors measure the transverse displacement of the wheel-sets that are relative to the

frame. The sensor is the same as that discussed in section 2.1.1, whose one end is absorbed to the frame. The other end is supported on the axle box. The primary transverse stiffness is measured by the four displacement sensors and the 3-D force sensors, such as is shown in Figure 5. The calculation of the formula is as follows:

$$K_{Yi} = F_{Yi} / Y_i , \quad (i = 1,2,3,4) \qquad (4)$$

where K_{Yi} is the primary transverse stiffness of the bogie, F_{Yi} is the transverse measured value of every single 3-D force sensor; and Y_i is the transverse measured value of every single displacement sensor.

ROTARY STIFFNESS OF BOGIE

With the four longitudinal hydraulic cylinders loading respectively, the 3-D sensors measure the transverse force and the longitudinal force of the wheel-set. The angle sensors measure the angle of the wheel-set that is relative to the foundation platform. The rotary stiffness is the measured value of the angle and the 3-D force sensors, such as is shown in Figure 6. The calculation of the formula is as follows:

$$K_\tau = (*F \times L) / \varepsilon \qquad (5)$$

Where $*F$ is the resultant force of the four longitudinal hydraulic cylinders; L is the distance between the two longitudinal hydraulic cylinders; ε is the rotation angle of the cross slipway; M , M' is the torque reaction of the wheel-set; and, ψ is the angle of the frame ($\psi = 0$).

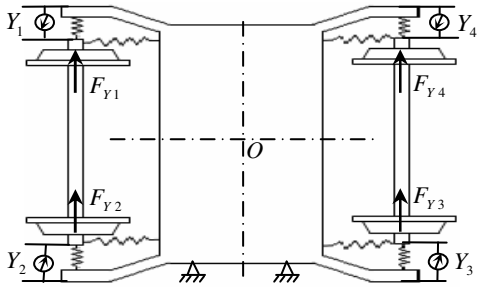

Figure 5. Primary transverse stiffness test.

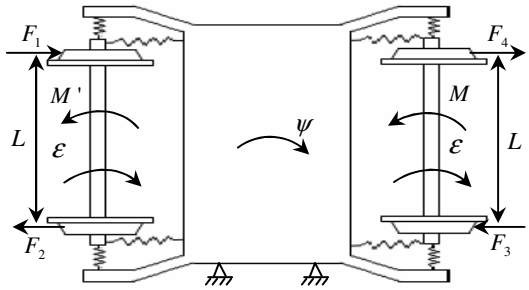

Figure 6. Rotary stiffness test.

OPTIMAL CONTROL MODEL OF NEURAL NETWORK-PID

The accuracy of the testing results about bogie stiffness except the test models and test method mentioned in previous paper, the control accuracy of electro-hydraulic servo system is essential too. In order to reduce the error that is caused by step mutation and external disturbance effectively, an optimized neural network PID controller should be used in the electro-hydraulic servo system; the controller should include a PID controller, a NNI (neural network identification), and a NNC (neural network controller), such as is shown in Figure 7. Firstly, the NNI identifies the 'servo mechanism,' while the accuracy of the identification is up to the requirement, it will transfer the weight to the NNC, and then finds the control parameters which can meet the control requirement via the optimization algorithm and transmit these parameters to the controller. After that, the system by means of the controller which controls the 'servo mechanism', the NNI transmits the optimal estimation of the 'servo mechanism' to the NNC and itself, which is used to regulate

the weight. Via the tonsure algorithm of the neural network, the K_P, K_I, K_D is controlled to reach the optimal performance index.

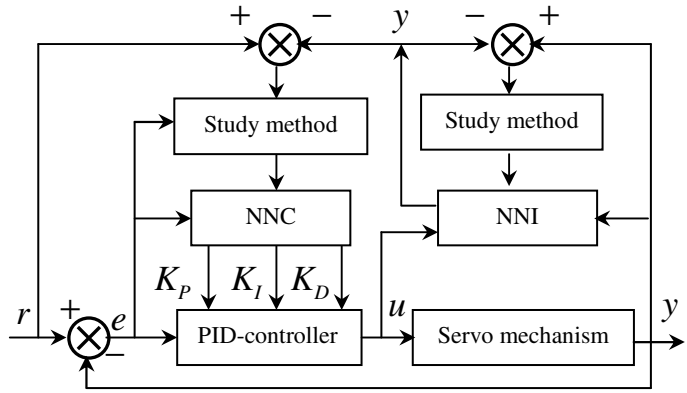

Figure7. NN-PID controller frame.

EXPERIMENTAL VERIFICATION

Because the bogie stiffness is unknown and nonlinear, the author made a pertinent simulation verification based on the models and methods of the previous paper. Due to the restriction on the length of this paper, the author introduced the main control parameters and control results. Figure 8 shows the dynamic simulation results of the system about the sine wave tracking. Among them $K_p = 20.75$, $K_i = 12.68$, $K_d = 0.26$, $\alpha = 0.6$, where α is the inertia coefficient $(0 < \alpha < 1)$), and $\eta = 0.65$ (η is the learning efficiency), $-1 < f(*) < 1$, $-1 < g(*) < 1$. Other training parameter settings are based on control requirements. Figure 9 is the corrected static simulation result. Among them $K_p = 500, K_i = 0, K_d = 0.21$. It is easy to see that the optimized neural network PID controller possesses accurate control precision by comparing Figure 8 and Figure 9. The system can meet the dynamic testing requirement and static testing about bogie stiffness.

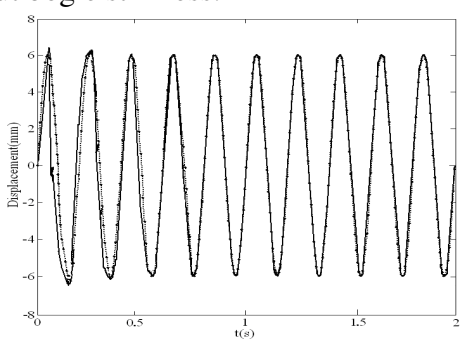

Figure 8. The control result of sine wave tracking.

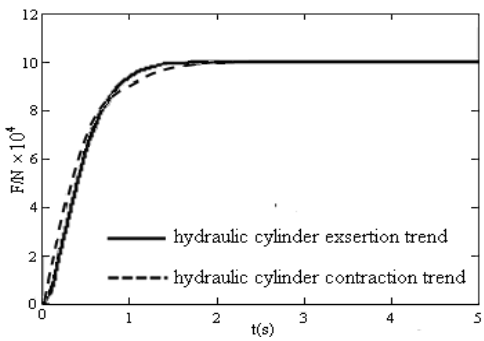

Figure 9. The response curve of time domain characteristics.

CONCLUSION

The novel dynamic testing system of bogies takes the actual situation of railroad cars as the research object, and via reasonable design about structure can test

the main kinetic parameters of bogies objectively and accurately. The system can also actualize testing of stiffness parameters about the whole vehicle bogie and the unattached bogie. We have achieved the goal of multiple test items at one test bench. Detailed research has been introduced about test model, the test method, and the control model in this paper. The successful development of a dynamic testing system about bogies has very wide application prospects, which is significant for accelerating the update of railway vehicles.

ABSTRACT

Increasingly, urban rail transit has become the focus of Social Economic Development. This is encouraging comprehensive evaluations of urban rail transit which will enhance operation efficiency. This paper sets up an analysis model of an urban rail transit arrangement based on the application of the Delphi and Analytical Hierarchy Process (AHP) and analyzes the shortcomings of AHP. Furthermore, this paper proposes a design of a more comprehensive and more scientific evaluation index system of urban rail transit performance assessment. The proposed system calculates every index weight using the weighting method -- G_1 – which is based on the differential principle. It appraises comprehensive performance using a fuzzy comprehensive evaluation method. Verification of the proposed system was done by conducting an experiment using the Shanghai rail transit systems to measure its performance status. Results provide the theoretical foundation for the development and correction of the Shanghai urban rail transit system

INTRODUCTION

The development of urban modernization has created a need to improve the situation of urban transit congestion, and the fast collection and distribution of passenger flow. Urban rail transit saves parking expenses, reduces traffic accidents, increases car-free mobility, improves people's living standards, and promotes economic development. Urban rail transit plays a very important role (Litman 2004, 2003).

Zadeh, L. A. established a fuzzy mathematical method in the 1960s. Fuzzy synthesis assessment is based on fuzzy mathematics and is a method which fixes the quantities of some factors within a fuzzy margin (Pengfei 2007). At present, research about fuzzy mathematical methods is being done around the world; Xiang, H. of Chongqing Jiaotong University proposed a fuzzy mathematical method and applied it to the assessment of traffic flow forecasting. Li, C., of Nanjing University of Aeronautics and Astronautics proposed a fuzzy mathematical model and applied it to evaluating the synthesis of the competitive capacity of enterprises. Jiang, F., of Hehai University researched the performance evaluation of supply chain management using a fuzzy synthetic evaluation. A proposed method was applied to the risk assessment of

transporting hazardous chemical materials by Guo, P., of Nanjing University of Technology. However, assessing urban rail transit performance based on FCE-AHP has not been studied so far. This reasonable and scientific evaluation method combines quantitative description and qualitative analysis to evaluate the performance of an urban rail transit system. Based on fuzzy evaluation theory, a comprehensive evaluation method for evaluating urban rail transit performance is proposed in this paper, which combines objectivity and subjectivity, static and dynamic analyses, and uses quantitative analysis as the main one.

ESTABLISHMENT OF FCE—AHP MATHEMATICAL MODEL

Shortcomings of Analytic Hierarchy Process. The Analytic Hierarchy Process (AHP) (Wu 2002) is a qualitative and quantitative method of system analysis that was developed by T. L. Saaty, a famous American operations research specialist in the 1970s. By using five steps such as confirm the problem, establish the structural model, build a judgment matrix, create a hierarchy for single ranking and general ranking, AHP calculates the combined weight of interactive influencing factors on the general goal. It draws a comprehensive evaluation value based on different feasible schemes. And, it provides the theoretical foundation for an optimal plan. Establishment of the judgment matrix is the key of the AHP. Whether the judgment matrix is reasonable or not can influence the results of the AHP. Much recent research suggests that there are some shortcomings in AHP (Zhang 2000). It is difficult to check the consistency of the judgment matrix. It is necessary to get the biggest characteristic root $_{max}$ for a consistent test, and observing whether $_{max}$ is equal to n. If $_{max}$=n, it is consistent. When the order is larger, the workload of calculating $_{max}$ is great. When it is not consistent, it is necessary to adjust the elements of the judgment matrix to make it consistent. Only after multiple adjustments and tests is consistency achieved. If is often impossible to achieve this and apply the method in practice. The concept of a fuzzy matrix can solve these problems.

Establishment of FCE—AHP Mathematical Model and Factor Set. It is necessary to introduce the definition and character of the fuzzy matrix for the best analysis. In the analytic hierarchy process, comparing judgments between two factors about which is more relevant offers the following quantitative expression, that is:

Definition: if matrix $A=(a_{ij})n\times n$ can satisfy $0\leqslant a_{ij}\leqslant 1$, ($i$=1,2,…,n; j=1,2,…,n), then call A fuzzy matrix (Xu 1988).

According to the investigation result of urban rail transit, this paper initially constructs the comprehensive evaluation system of urban rail transit operation performance using the Delphi method and the AHP method. Through 2-4 consultations, which are based on optimization theory, an evaluation index set is defined according to the 7±2 psychological extreme limit concept (Cai 2004). Using the function and characteristics of rail transit, this paper eventually constructs an evaluation index system of rail transit performance in accordance with three main factors (rail network structure, operation management level, and

passenger service performance), and corresponding twenty one sub-factors such as the total length of the rail network, the daily total of passengers, operation cost, passenger ticket price etc. (Xi 2008; Ji 2004; Du 2003). (See Figure 1.)

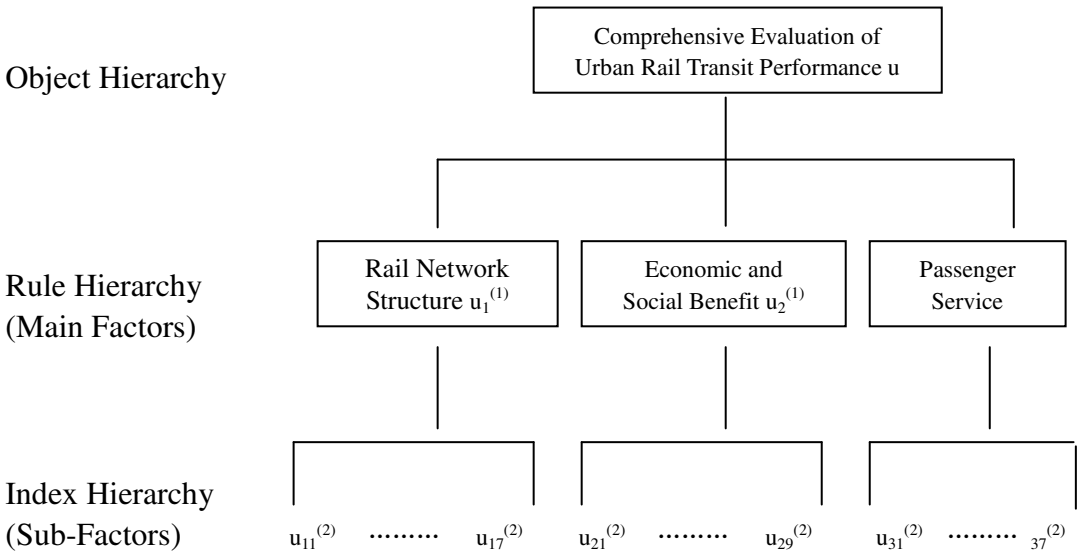

Figure 1. Comprehensive Evaluation Index System of Urban Rail Transit Performance.

The rail network structure $u_1^{(1)}$ (weight, $_1$=0.3125): mainly includes the total length of the rail network $u_{11}^{(2)}$ (ω_{11}=0.1736), the density of the center area rail network $u_{12}^{(2)}$ (ω_{12}=0.1364), a non-linear coefficient $u_{13}^{(2)}$ (ω_{13}=0.0968), transfer joint numbers $u_{14}^{(2)}$ (ω_{14}=0.2211), the rate of covering the center region areas $u_{15}^{(2)}$ (ω_{15}=0.1035), the cohesion number of large passenger flow distributed points $u_{16}^{(2)}$ (ω_{16}=0.0829), and the daily total of passengers $u_{17}^{(2)}$ (ω_{17}=0.1967).

The economic and social benefit $u_2^{(1)}$ (weight, $_2$=0.4613): mainly includes the investment cost $u_{21}^{(2)}$ (ω_{21}=0.0981), operation costs $u_{22}^{(2)}$ (ω_{22}=0.1034), operational revenue $u_{23}^{(2)}$ (ω_{23}=0.0897), the influence on economic development $u_{24}^{(2)}$ (ω_{24}=0.1327), the increase in residents' quality of life $u_{25}^{(2)}$ (ω_{25}=0.1068), resource consumption $u_{26}^{(2)}$ (ω_{26}=0.1201), the environmental capacity $u_{27}^{(2)}$ (ω_{27}=0.1132), the requirement rate of travel-time $u_{28}^{(2)}$ (ω_{28}=0.1097), and the prourban rail transition of transit trip $u_{29}^{(2)}$ (ω_{29}=0.1263).

The passenger service performance $u_3^{(1)}$(weight, $_3$=0.2262): mainly includes the running speed(ω_{31}=0.1727), service frequency $u_{32}^{(2)}$ (ω_{32}=0.1196), the punctuality rate $u_{33}^{(2)}$ (ω_{33}=0.0825), circumstances inside the vehicle and comfort $u_{34}^{(2)}$ (ω_{34}=0.1637), service attitude $u_{35}^{(2)}$ (ω_{35}=0.1290), passenger ticket price $u_{36}^{(2)}$ (ω_{36}=0.1892), and the price of the completed facility $u_{37}^{(2)}$ (ω_{37}=0.1433).

ESTABLISHMENT OF THE WEIGHT SET AND THE EVALUATION SET (THE REMARK SET)

The Determination Method of Weight. The value of the index weight is determined by a statistical analysis method and by an expert evaluation method

(Ahamed, T., 2000). The author determines the weight using a subjective weighting method based on the differential principle—G_1. The specialists on urban rail transit evaluate the rule hierarchy (i.e., the main factors) and index the hierarchy (the sub-factors) for standardization.

Establishment of the Weight Set. The weight of every sub-factor $_{ij}$ (i=1,2,⋯,m; j=1,2,⋯ ,n) is defined by membership degree of the sub-factors to the main factors, then weight sets of sub-factors $_i$={ $_{i1}$, $_{i2}$,⋯; $_{in}$}, among them, $_{ij}\geqslant 0$

and $\sum_{j=1}^{n}$ $_{ij}$ = 1 (Zou, K., 1990).

According to the degree of influence of the main factors to the urban rail transit performance of the object hierarchy $u_i^{(1)}$ (i=1,2,⋯ ,n) , all of the main factors are calculated by adding the proper weights $_i$ (i=1,2,⋯ ,n). We get the weighted set of main factors = ($_1$, $_2$, $_3$).

Define the Remark Set. The remark set V=(v_1 ,v_2 ,⋯,v_m), v_t(t=1,2,⋯,m) shows remarks from high to low at all levels. This paper adopts the 5-grade scoring system. For example, when m=5, that is V=very good; good; general; poor; poorest (Wangqing, W., 2007).

Define Ratings and Scale Score of Factors. According to the actual situation, this paper determines ratings, remarks, and scale scores of factors. In this paper we use 5-point scales, H=excellent; good; middling; general; no. The corresponding scale scores are 0.9; 0.8; 0.6; 0.4; 0 (Yan, B. 2007).

FUZZY COMPREHENSIVE EVALUATION OF URBAN RAIL TRANSIT PERFORMANCE

A fuzzy comprehensive evaluation (FCE) is a multi-layer comprehensive evaluation starting at the bottom and proceeding layer by layer, resulting in an objective hierarchy. An evaluation index of the k-th layer is the membership degree of the k-1 layer. In this paper the second-level comprehensive evaluation is completed from sub-factor to multi-layer and the like may be deduced by analogy.

If $\tilde{R}_1$, $\tilde{R}_2$, and $\tilde{R}_3$ are single factor evaluation matrixes of $u_1^{(1)}$, $u_2^{(1)}$, $u_3^{(1)}$ respectively, single factor assessment results are obtained by the following fuzzy transformation.

$$\tilde{B}=\omega.\tilde{R}=\tilde{A}_1\circ\begin{pmatrix}\omega_1.\tilde{R}_1\\ \omega_2.\tilde{R}_2\\ \omega_3.\tilde{R}_3\end{pmatrix}$$

Mathematic Model of Urban Rail Transit Performance Evaluation. Comprehensive evaluation $\tilde{B}$ is a fuzzy set from the remark set, that is, $\tilde{B}=\omega\circ\tilde{R}$.

"∘" is called the operator, such as the main factor determination model $(\wedge, \vee)$,the main factor outstanding model $(\cdot, \vee)$, the weighted mean model $(\cdot, \oplus)$ etc. (Liu 2000). These are necessary for an assessment of urban rail transit although each factors' effect on the system and its weight values are different. When the operator is adopted in the compound operation of fuzzy matrixes, the operation itself must consider the weight contributions of all of the factors, including influence on the urban rail transit system, and the weighted mean model is adopted. Models of a comprehensive evaluation are as follows:

The first level evaluation model: $\tilde{B}_i = \bar{\omega}_i . \tilde{R}_i$

The second level evaluation model: $\tilde{B} = \bar{\omega} . \tilde{B}_i$

Fuzzy Evaluation Example Analysis. The first level comprehensive evaluation. Currently, there are 5 urban rail transit lines operating in Shanghai, which have 94 stations and covers 144.6km. The average passenger volume is 180,000 person-time/day, and the maximum is 243,000 person-time/day. The Shanghai traffic mileage and average passenger volume is the largest rail system in China. The fuzzy comprehensive evaluation method is used to do a qualitative analysis of the performance evaluation of Shanghai's urban rail transit system.

The result of the first level comprehensive evaluation: $u_{11}=0.318\times 0.9+0.613\times 0.8+0.069\times 0.6+0\times 0.4=0.8180$, is good. Similarly obtain other u_{ij} and evaluations.

The final evaluation space divided $(u_i^{(1)}, V, \tilde{R}_i)$ has been evaluated. $\tilde{R}_i$ is a single evaluation matrix of sub-factor sets $u_i^{(1)}$.

$\tilde{B}_1 = \bar{\omega}_1 . \tilde{R}_1 = (0.1736 \quad 0.1364 \quad 0.0968 \quad 0.2211 \quad 0.1035 \quad 0.0829 \quad 0.1967)$.

$$\begin{pmatrix} 0.318 & 0.613 & 0.069 & 0 \\ 0.354 & 0.459 & 0.178 & 0.077 \\ 0.363 & 0.496 & 0.085 & 0.056 \\ 0.449 & 0.370 & 0.094 & 0.087 \\ 0.264 & 0.493 & 0.168 & 0.075 \\ 0.277 & 0.333 & 0.306 & 0.084 \end{pmatrix}$$

$$\begin{matrix} 1 & 0 & 0 & 0 \end{matrix}$$

$= (0.485 \quad 0.377 \quad 0.108 \quad 0.050)$

$u_1=0.485\times 0.9+0.377\times 0.8+0.108\times 0.6+0.050\times 0.4=0.8229$

We believe that the rail network structure evaluation $u_1=0.8229$ is good. Similarly, other factors influencing urban rail transit $\tilde{B}_i$ and u_i are obtained, $\tilde{B}_2 = (0.436 \quad 0.257 \quad 0.273 \quad 0.040)$, $\tilde{B}_3 = (0.279 \quad 0.357 \quad 0.321 \quad 0.043)$; the economic and social benefit $u_2=0.436\times 0.9+0.257\times 0.8+0.273\times 0.6+0.040\times 0.4=0.7778$ is middling; and passenger service performance evaluation $u_3=0.279\times 0.9+0.357\times 0.8+0.321\times 0.6+0.043\times 0.4=0.7465$ is middling.

The second level fuzzy comprehensive evaluation. The second grade comprehensive evaluation is an analysis of the sub-factors. The single factor evaluation matrix is constructed from the result of the first level comprehensive evaluation $\tilde{B}_i$.

$$\tilde{B} = \bar{\omega} \cdot \tilde{B}_i = (0.3125 \quad 0.4613 \quad 0.2262) \cdot \begin{bmatrix} 0.485 & 0.377 & 0.108 & 0.050 \\ 0.436 & 0.257 & 0.273 & 0.040 \\ 0.279 & 0.357 & 0.321 & 0.043 \end{bmatrix}$$

$$= (0.4158 \quad 0.3171 \quad 0.2323 \quad 0.0438)$$

$u = 0.4158 \times 0.9 + 0.3171 \times 0.8 + 0.2323 \times 0.6 + 0.0438 \times 0.4 = 0.7795$. The result of the evaluation is middling.

The results of the first level comprehensive evaluation shows that transfer joint numbers $u_{14}=0.6891$ and the requirement rate of travel-time $u_{28}=0.6953$ are the lowest, while their combined weight numbers of the index are correspondingly higher. Because of limited regional land resources in Shanghai, traffic capacity has always been a bottleneck problem in the city. This question warrants careful consideration. The total length of the rail network $u_{11}=0.9$, and the increase in residents' quality of life $u_{25}=0.9$ are the highest numbers. The results show that the total length of the rail network of the Shanghai urban rail transit system is at the national forefront, residents' quality of life has risen significantly in recent years. We can see that the evaluation results coincide with the actual situation of Shanghai.

The general comprehensive evaluation results show that the rail network structure is $u_1=0.8229$ and the evaluation is good; the economic and social benefit is $u_2=0.7778$ and the evaluation is middling; passenger service performance is $u_3=0.7465$ and the evaluation is middling. The general evaluation result of Shanghai's urban rail transit performance is $u=0.7795$ and the evaluation is middling. This means that Shanghai's urban rail transit system still needs further development and improvements.

CONCLUSIONS

This paper adopts a fuzzy comprehensive evaluation method to evaluate the performance of urban rail transit and convert a qualitative appraisal into quantitative results. Practical applications truly reflect the present situation of urban rail transit in Shanghai. By careful analysis of the evaluation results, the crux of the problems and the weak points of rail transit management can be identified. Some concrete and effective measures for rectifying the above mentioned evaluation results are put forth to solve problems in the development of rail transit promptly and to improve the level of rail transit management.

Based on the evaluation of urban rail transit performance, the main conclusions are as follows: 1) Urban rail transit performance evaluation is a multi-attribute fuzzy comprehensive evaluation. The key to effective evaluations is to establish an evaluation system. This paper establishes an analytic hierarchical

model of rail transit performance using the Delphi and AHP method, and constructs a comprehensive evaluation index system of performance. 2) The method calculates every index weight using the G_l weighting method, which is based on the differential principle. 3) The verification of the method was done by conducting an experimental evaluation of the actual urban rail transit system in Shanghai. A fuzzy comprehensive evaluation was used. Results provide a theoretical foundation for the development and correction of Shanghai's urban rail transit system.

ABSTRACT

Based on the parametric variational principle (PVP), the wheel/rail relation problem is analyzed in this paper with the help of the elastic-plastic contact model and the FE parametric quadratic programming method. The precise computational models are constructed according to the contact between the wheel tread and the rail top. The influence of functionally gradient material on wheel-rail contact performance is also investigated. Analysis of the results shows that the maximum stress on rails made of functionally gradient material is smaller than those made of homogeneous material when the wheel-rail contact is loaded.

INTRODUCTION

Currently, there is a world trend for developing high speed trains and heavy haulage. The problems of wheel-rail performance are becoming more serious, and include problems such as rail corrugation resulting from wheel-rail wear, rail fatigue strength caused by rolling contact, derailment, and so on. Large economic losses in international railway transport services are produced due to these problems every year. The damage to China's railways is about 8 billion RMB every year.

Functionally gradient materials are new materials developed in the 21st Century and used in many fields, such as spaceflight, aircraft, chemical engineering, bioengineering, and so on (Williamson, 1993; Tanigawa, 1995; Yang, 2003). They are widely used because of their wear-resistant, thermophilic and corrosion-resistant properties (Koizumi, 1993). Applying functionally gradient materials at the contact surface between wheel and rail could decelerate wheel-rail wear. In this paper, wheel-rail contact is calculated under different load cases when wear-resistant gradient material is used. An FE parametric quadratic programming method and the substructure technique that is developed in this paper is used to calculate results.

COMPUTATIONAL THEORY

In this paper, an FE parametric quadratic programming method is used to solve the elastic-plastic contact problem of wheel-rail. This method is based on the PVP which was put forth in 1985 by Professor Zhong Wanxie, who is a member of the Chinese Academy. This method is very efficient at solving undetermined boundary problems in mathematical physics (Zhong, 1997).

The basic equations of elastic-plastic contact mechanical boundary problem in domain $\Omega = \Omega(1) + \Omega(2)$ are:

1. Equilibrium equation

$$A^{(\nabla)} d\sigma + db = 0 \tag{1}$$

2. Strain-displacement relations

$$d\varepsilon = L^{(\nabla)} du \tag{2}$$

3. Boundary conditions

On the force-prescribed boundary S_p

$$n d\sigma = d\bar{p} \tag{3}$$

On the displacement-prescribed boundary S_u

$$du = d\bar{u} \tag{4}$$

The boundary conditions on the possible contact boundary S_c is determined by state equations of the contact system, i.e.,

$$\begin{cases} f(du_c, \tilde{\lambda}) + \tilde{\nu} = 0 \\ \tilde{\nu}^T \tilde{\lambda} = 0, \tilde{\nu}, \tilde{\lambda} \geq 0 \end{cases} \tag{5}$$

4. Constitutive relations

$$\begin{cases} f(d\varepsilon, \lambda) + \nu = 0 \\ \nu^T \lambda = 0, \quad \nu, \lambda \geq 0 \end{cases} \tag{6}$$

The PVP of elastic-plastic contact problems can be described as follows: among the admissible displacement incremental fields, which satisfy the strain-displacement relations (2) and geometrical boundary conditions (4), the exact solution renders the index of the total potential of the elastic-plastic contact system as follows:

$$\begin{aligned} \Pi\left[\lambda(\cdot), \tilde{\lambda}(\cdot)\right] = & \int_\Omega \left[\frac{1}{2} d\varepsilon^T D d\varepsilon - \lambda^T R d\varepsilon - db^T du \right] d\Omega \\ & + \int_{S_c} \left[\frac{1}{2} d\varepsilon_c^T D_c d\varepsilon_c - \tilde{\lambda}^T \tilde{R} d\varepsilon_c \right] dS - \int_{S_p} d\bar{p}^T du dS \end{aligned} \tag{11}$$

Minimum values under control of state equations (5) and (6), where $d\sigma$, db, $d\varepsilon$ and du are stresses, body forces, strains and displacement increments, respectively; $d\bar{p}$ and $d\bar{u}$ are prescribed surface tractions and prescribed displacement increments; λ and $\tilde{\lambda}$ are variables which do not join variation and according to their physical meaning they are flow and slip parameters; $R = \left(\frac{\partial g}{\partial \sigma} \right) D$, $\tilde{R} = \left(\frac{\partial g}{\partial p_c} \right) D_c$.

It can be proved that the PVP may be changed into a quadratic programming problem through derivation. A normal quadratic programming problem is a convex programming problem; it has a mature solution method (e.g., Lemke algorithm), and can ensure a highly efficient computation.

THE COMPUTATIONAL MODEL OF WHEEL-RAIL

The computational model is constructed according to actual sizes of diesel locomotive wheel sets and 60kg/m standard rail. Only half of a wheel set and one side rail are used owing to symmetrical structure and loads. Besides the wheel set and the rail, the model also includes the sleepers and ballast.

The computational mesh of wheel-rail contact system is shown in Figure 1.

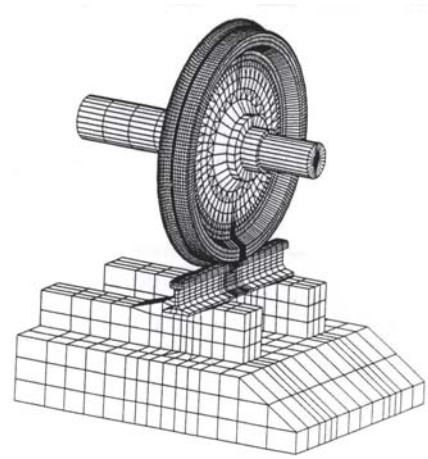

Figure 1. The computational mesh of wheel-rail contact.

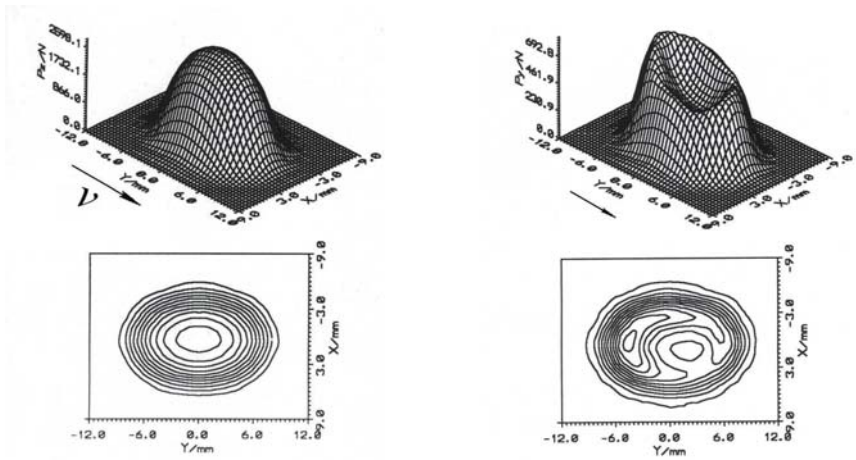
In order to investigate the influence that the composition of the material has on the stress distribution of the structure, the mesh must be divided very fine. This reduces the computational efficiency and makes it difficult to analyze the gradient material. To solve this problem, a multi-level and multi-branch substructure method is used for the model and the mesh of the substructures containing the gradient material mesh is very fine.

A hardened layer with a thickness of only a few millimeters on the contact surface is produced, although the heat treatment is performed and wear-resistant material is used on the detail. In order to analyze the influence of the material gradient change on stress distribution in the structure under contact loads, only a thin part including the contact spot is computed. One-point contact between the wheel and the rail is computed and the wheel-rail internal contact force is used as the applied load (Zhang, 2004). The contact forces between the wheel and rail are shown in Figure.2.



(a) Normal forces (b) Longitudinal friction forces

Figure 2. The computed forces of the wheel-rail contact model.

The functionally gradient material is applied on top of the top of the rail with a layer thickness of 2mm. Furthermore, both the wheel and the rail are made of low carbon steel with an elastic module of 200 -- 400 GPa. The distribution law of elastic module is linear, i.e., 400 GPa on the surface and 200 GPa at a depth of 2mm. In

addition, an isotropic structure is analyzed using the same model and the elastic module is 200 GPa.

THE COMPARISON OF STRESS STATES FOR TWO MATERIALS UNDER SINGLE AXLE LOAD

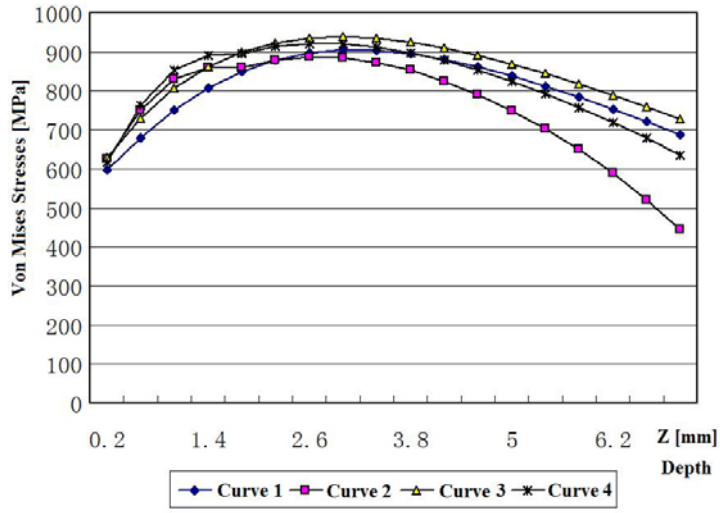
Computational results state that the stress distribution law under the wheel-rail contact force produced by a single axle load is close to that of Hertz's hypothesis, i.e., the stress distribution is symmetrical along longitudinal and lateral center lines. The maximum von Mises stresses of two materials are all located 2.4 mm from the contact spot center. Their values are 908.48 MPa and 887.24 MPa, respectively. The maximum von Mises stresses for isotropic material at depths of 0.8, 2.4, 4.0, and 5.6 mm from the contact surface are 829.86, 908.48, 884.70, and 792.39 MPa, respectively. Those stresses for gradient material at the same depths are 870.16, 887.24, 834.08, and 668.24 MPa. The stresses of the gradient layer are a little larger than those of the isotropic material and the stresses of the lower gradient layer are smaller than those of the isotropic material.

THE COMPARISON OF STRESS STATES FOR TWO MATERIALS UNDER A COMBINED AXLE LOAD AND DRIVING TORQUE

The maximum von Mises stresses for the isotropic material under the wheel-rail contact force produced by the combined axle load and driving torque at depths of 0.8, 2.4, 4.0, and 5.6mm from the contact surface are 882.47, 943.99, 924.70, and 849.75 MPa respectively. Those stresses for the gradient material at the same depths are 903.40, 921.72, 888.20, and 781.01 MPa, respectively. Results are similar to the case of a single axle load. The stresses of the gradient layer are a little larger than those of the isotropic material and the stresses of the lower gradient layer are smaller than those of the isotropic material.

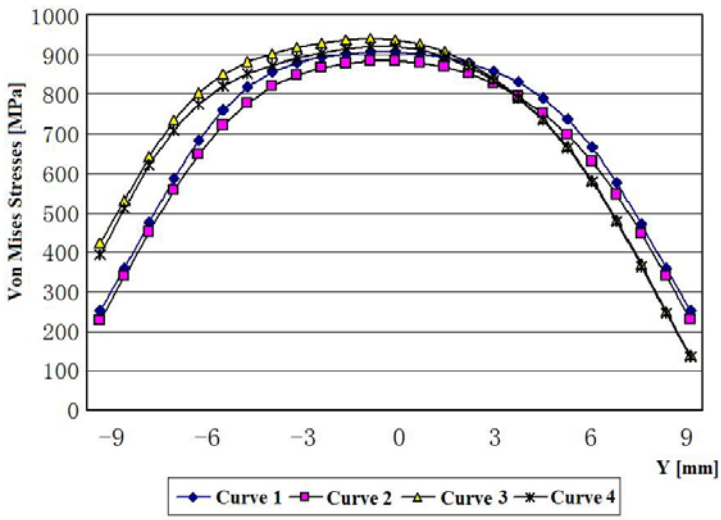
Since there are larger tangential forces at the contact spot, the wheel-rail stress distribution is complicated. The stress level in the contact layer between the wheel and the rail is increased and the high-stress area is larger than at the single axle load area obviously. The maximum von Mises stresses of the two materials are 943.99 MPa and 921.72 MPa respectively and are located at a depth of 3.2 mm in the rear of the contact spot center. This is the result of a combined effect of the normal force and the longitudinal tangential force at the contact spot.

The stress curves of the above-mentioned four models at different depths under the center of the contact spot are shown in Figure 3. The stress curves of the four models in the longitudinal direction at a 3 mm depth under the contact spot are shown in Figure 4. It can be seen that the distribution level of stress changes at a 3 mm depth when the wheel passes the rail.



Curve1: for isotropic material under single axle load
Curve2: for gradient material under single axle load
Curve3: for isotropic material under the combined axle load and driving torque
Curve4: for gradient material under the combined axle load and driving torque

Figure 3. The comparison of stress distribution along the depth under the contact spot center.



Curve1: for isotropic material under single axle load
Curve2: for gradient material under single axle load
Curve3: for isotropic material under the combined axle load and driving torque
Curve4: for gradient material under the combined axle load and driving torque

Figure 4. The stress curves of different models in longitudinal direction at a 3 mm depth under the contact spot.

Figures 3 and 4 show that the stresses at the center of contact spot under the combined axle load and driving torque are larger than those under the single axle load

at every depth. The stresses of the gradient layer are larger than those of the isotropic material, and the stresses out of the gradient layer in the gradient material are smaller than those at the same location in the isotropic material. But the total stresses in the gradient material are smaller than those in the isotropic material and thus the gradient material can decrease the maximum stresses at the wheel-rail contact surface.

CONCLUSION

The problem of the wheel-rail relation is an elastic-plastic frictional contact problem. The computations performed in this paper show that using an FE parametric quadratic programming method and derived from the parametric variational principle can solve various complicated wheel-rail contact problems successfully.

The shape of the contact spot and the distribution of the adhesion and creep regions can be precisely determined by using the FE parametric quadratic programming method. Under a single axle load, the contact spot is an oval, which entirely coincides with Hertz's hypothesis. Under the combined conditions of axle load and driving torque, the contact spot is also an oval.

The maximum stress on the rail of gradient material will be smaller than that of isotropic material under wheel-rail contact load, i.e., in the case of equal stresses, the carrying capacity of gradient material rail is high and gradient material rail can bear the heavy load.

ACKNOWLEDGEMENTS

This work was supported by the Natural Science Foundation Committee of China that grants the research project (50605003, 50875218). It is also supported by Liaoning BaiQianWan Talents Program and the Department of Education of Liaoning Province.

ABSTRACT

The rapid development of rail transit inevitably needs large capital investments. As a huge investment in urban infrastructure projects, financing is the key to the implementation of the construction. In this paper, the Business Investing and Financing Model (BIFM) of a Rail Transit Project is proposed which includes not only the project construction but also the land development along the rail transit line. Its aim is to attract private capital injection through the interests in the land development. At the same time, the calculation method of the impact area of the rail transit's development interests is amended for reasonable providing land development area to investors. Finally, using the Changsha City Rail Transit Line2 (CCRTL2) as an example, the investing and financing strategy is analyzed. The result shows that the model can reduce the pressures of government from financing and can increase the social benefits at the same time.

INTRODUCTION

According to the "Analysis and Investment Consulting Report on China Urban Rail Transit and Equipment Industry, 2008", in China, more than 10 cities have rail transit projects in operation at present, such as Beijing, Shanghai, Tianjin, Guangzhou, etc. As urban infrastructure projects with huge investments, financing is the key to the implementation of the construction.

There is much research on the investing and financing of rail transit at home and abroad, such as Jie-fen Zheng (2002), Tsinghua University, Wang Hao (2002), Beijing Mass Transit Railway Corporation, and so on. All consider that rail transit projects should be given adequate operating concessions for land development, commerce, advertising and so on, in order to create basic commercialization operating conditions and attract a wide range of investors. On the basis of that, Zhou Jun (2002) analyses the corridor-effect of rail transit on the calculation of development interests of rail transit. Xia-Fei Ye (2002) from Tongji University has studied methods for calculating the rail transit development interest along the track based on the value of the assets in the outskirts of the city and has put forward the

basic ways and means to restore rail transit development interests. However, the gradient effect factors of the corridor-effect are difficult to determine; Ye's calculation is based on the scope of 2km around the railway stations. According to the rail transit planning and design, the distance between two closed mass transit stations is 1 to 2 km. If a 2km distance is used, the benefits calculated can include the effectiveness of another station, so it has some error when calculating the investing and financing benefit of the rail transit. In this paper, a Marketization Investment and Financing Model (MIFM) of urban rail transit based on land revaluation is proposed. The impact area of the rail transit is analyzed reasonably as well as the development interests of the rail transit, and the investing and financing strategies of the rail transit are discussed.

ANALYSIS OF THE DEVELOPMENT INTERESTS IMPACT AREA (DIIA) OF RAIL TRANSIT

For the development interests impact area of the rail transit, there is a low-cost function method (such as Jean-Jacques Filleul 2002; Enrico 2006). According to Ye (2002), the typical model can be changed as:

$$\Delta P_i = a_1 \cdot \ln x_{i1} + a_2 \cdot \ln x_{i2} + a_3 \quad (1)$$

Where: ΔP_i is the land price gap (RMB / m^2); x_{i1} is the distance(m) between the nearest subway station from the block i and the central area (CBD); x_{i2} is the travel distance (m) from the center of the plot to the closest rail station; a_1, a_2 and a_3 are the parameters . It can be seen that ΔP_i is an interval of [0, 1]. For instance, the price gap of land for commerce and office surrounding Hong Kong's MTR is [0, 0.51] and [0, 0.59] respectively.

Because the impact on the land price at the edge of the impact area may be smaller than the impact of other public facilities in the vicinity, the price gap should be in a certain range. Namely,

$$\Delta P_i = a_1 \cdot \ln x_{i1} + a_2 \cdot \ln x_{i2} + a_3 \geq p_i \quad (2)$$

When Equation (2) is met, take the value of x_{i2}, as the radius of the impact areas, while $\Delta P_i = p_i$ (p_i is a given value, depending on the nature of the rail station). As a result, the shape of the region may not be regular round.

DESIGN AND ANALYSIS OF RAIL TRANSIT PROJECT BUSINESS FINANCING MODEL

The Business Investing and Financing Model of Rail Transit project is a Market-oriented Investing and Financing Model (MIFM) for profit. (See Figure 1.)

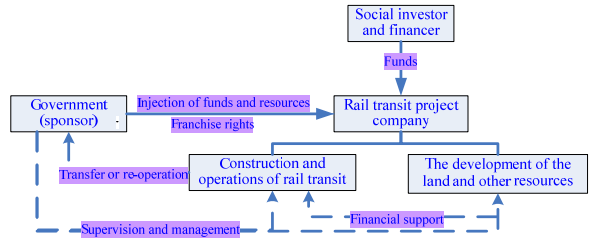

Figure 1. Market-oriented investing and financing process map.

Because the nature of the land varies by section along the rail transit, a reasonable and comprehensive development approach should be undertaken. According to the main industries of each node district, some corresponding markets in the vicinity of the station are set up properly. In the outer suburbs with small populations, the development of logistics types of industries is suitable, as well as the development of various large-capacity and high-tech parts and accessories production industries, machinery industries and farm produce processing industries. The specific models follow.

(1) Ground resource development model (GRDM)

Land resources along the rail transit line on the outskirts are the most important resources for rail transit firms. The local government may consider selling some land to the rail transit company at low-cost or provide it for free according to the specific conditions of some sections.

(2) Underground resources development model (URDM)

With the ground space limited and price question, some bigger entertainment leisure facilities are shifted into the underground spaces. Using the underground space effectively and saving the aboveground space can satisfy different consumer's multi-level expense requirements, and make the service industry stronger in the node district and provide more employment opportunities and tax revenues.

(3) Diversified development model (DDM)

Recently, the rail transit company adopted the DDM where the operating revenue is taken as the principal part, and the real estate industry, the logistics, retail business, travel and tourism and hotel services, etc., were taken as supplements. This and changed the situation so that operation income is not their only income.

The essence of MIFM is that the public welfare and business of the project is clearly defined before the investment is made in the projects, and the loss of rail transit operation is no longer subsidized by the government. The MIFM has a little difference with a PPP (public-private partnership) model with respect to the development of land. The former is that the government hands over the land along the rail transit line to the investors for development. The project company and the government sign a franchise contract, and control the rights of the land in the development interests impact area of the rail transit. The government assesses the enterprises by some indexes provided by the project company which may include the quality of services and their effectiveness status.

The comparison of MIFM and the traditional PPP model are shown in Table 1.

Table 1. Comparison of MIFM and the traditional PPP model.

		MIFM	Traditional PPP model
Investors		Government, Private investors	Government, Bank loans, Private investors
Advantages	Government	Enough Finance, land development well and social benefits increasing	Enough finance
	Private investors	Signed a franchise contract, Control right of the land along, Capital return quickly and Profit space large	Signed a franchise contract
Disadvantages	Government	Land revenue cut a little	Finance pressure and land development slower
	Private investors	Huge finance and With risk in finance return if operation improper	Little Profit space

CASE ANALYSIS

The total investment of CCRTL2 project. CCRTL2 (which includes line 1A and 2A) consists of 36,848 km and needs about 16.676 billion ￥ gross investment. The 1A line needs about 12.873 billion￥ investment. According to the needs of the construction period, the 1A line will be finished by 2013 and the 2A line completion is set for 2017 (TJJT, 2008).

Determine the development interest's impact area of rail transit. In this paper, sections of the CCRTL2 are used to perform a sample analysis of the impact area. These sections include Huangxing road (HXR) station, Furong Road (FRR) station, Jiefang Road (JFR) station and Railway (RW) station. (See Figure 2.) The CBD of Changsha City is located in the region between the Wuyi Road and the Jiefang Road. For the sake of convenience, the CBD is considered as the mid-point of the region.

According to reference [4], the land characteristics surrounding the blocks and the distances to the FRR station are given. According to Equation (2), the development interest's impact area of the four stations can be drawn as shown in Figure 3.

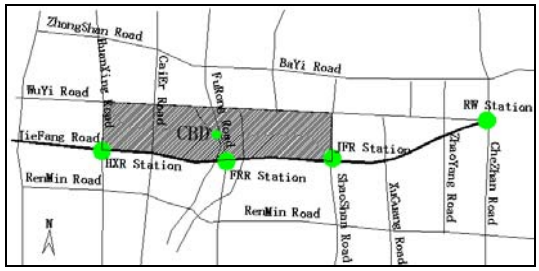

Figure 2. Parts of Changsha metro line 2.

Figure 3. Impact area of four-set.

According to Zhang, et al., 2005, the value of the parameters in Equation (2) are: $a_1 = 919.9$, $a_2 = -379.3$, $a_3 = 1274.9$;

According to the history variance of the three types of land price growth rate (commercial, residential, office), there is $p_{commerce} = 0.03$, $p_{resident} = 0.02$, and $p_{office} = 0.01$.

Table 2 shows the impact area and the land revaluation of the four stations.

Table 2. The land revaluation along Rail Transit (4.488 km)

The Type of Land	Commercial	Residential	Office	Total
Area（m^2）	977,061	1,072,312	191,082	2,240,445
The revaluation of land (100million RMB）	30.87	11.47	1.89	44.23

The proportion of investing and financing. The construction funds for the project are divided into project capital and debt. The government's special funds and the city land revenue constitute the project capital, which is 40% of the total funds; the debt comes from financing, 60% of the total funds (see Table 2).

As shown in Table 2, the total revaluation of CCRTL2 is about 363 billion RMB. If the benefit to the rail transit company is twice their cost, we can attract about 180billion RMB as social investment. So, the private investment (10 billion RMB) of CCRTL2 is guaranteed.

According to the "Study on economic and social development in Changsha City, 2008," from 2008 to 2017, the Changsha City local fiscal revenue is expected to reach 467.200 billion RMB. If 10% will be used for rail transit construction, 4.6 billion of special funds are guaranteed. According to the "Report on National Economic and Social Development of Changsha city, 2006," Changsha City collected 1.796 billion RMB of land deed taxes in 2005. Assuming Changsha City lands maintain a stable situation, and assuming a 2% growth rate, the governors can collect 17.735 billion RMB of the city's land revenue between 2008 and 2017. The 2.0703 billion for the construction of rail transit is feasible.

Table 3. The proportion of the investing and financing.

Types	Special	Land revenue	Private investment	Total
Financing (100million￥)	46	20.703	100.054	166.757
Proportion	27.59%	12.41%	60.00%	100%

Comparison with a traditional investing and financing model. The traditional investing and financing (CRSDG co., LTP 2008) is shown in Table 4.

Table 4. The proportion of the traditional investing and financing.

Types	Special	Land revenue	Bank loans	Equipment leasing	Long-term debt	Total
Financing (100million￥)	46.88	24.83	55.03	23.346	16.68	166.76
Proportion	28.11%	14.89%	33.00%	14.00%	10.00%	100%

According to the traditional model, the government needs to give subsidies to rail transit—about 5.0 billion RMB/year. Therefore, the additional cost to the government reaches 100 billion in the next 20years. So, adding the 5 billion repayment, the total additional cost to the government is more than 105 billion RMB/20years.

However, the MIFM shows that the government lost 19.07 billion RMB for the construction and operation of the rail transit project. By comparing to the traditional investing and financing model, the former will save about 80 billion in costs, if the rail transit ticket sales aren't considered. Besides, the social benefits will be unimaginable, if the land development and the construction of the rail transit are combined perfectly. It is very clear which strategy for investing in rail transit the government should choose.

CONCLUSIONS

The investing and financing strategies of urban rail transit projects can determine the success or failure of a project. The MIFM, which is based on land revaluation, is a cooperative method according to investors "expertise" and reasonably allocates the work. Firstly, the impact area of the development interest of the rail transit is calculated, and then the rail transit companies comprehensively develop the rail transit and the land. It is a deviation from the traditional PPP model. However, this model increases the difficulty of determining the cost of the work at the pre-construction stage. How to form a series of legal documents so as to carefully balance the interests of all parties needs to be solved for similar construction projects in the future.

ABSTRACT

This paper summarizes the background information for the establishment of the Integrated Data Platform for Railway Maintenance (IDPFRM). It analyzes the spatial characteristics, the subject characteristics and the time characteristics of Fundamental Data for Railway Maintenance (FDFRM) generally. Then it proposes the thoughts of integrating the FDFRM based on these characteristics. It proposes to construct the IDPFRM through regarding the spatial location as ligament, the single facility as the center, and the maintenance management flow as the master line. Finally, it gives an application example of the IDPFRM in Kunming Railway Bureau.

1. INTRODUCTION

The goal of constructing the Chinese digital railway was envisioned in "Railway Informationization Overall Plan" (MOR, P.R.China, 2005). Its fundamental purpose is to integrate the massive, static or dynamic, multi-resolution, three-dimensional data of railway departments of transportation (locomotive, maintenance, communication and signaling, vehicle, operation management, etc.), according to the unified geographic coordinates, and to construct the fundamental database of the railway.

It is necessary to establish the unified countrywide database of the transportation facilities, the technical state of the facilities, study the technology of synthetically inspection, state estimation, reinforcement and reconstruction about the track, roadbed, bridge and tunnel of the speedup lines, study the regularity of rail wear and defects, and to install the preventive maintenance technical system for the speedup lines (MOR, P.R.China, 2007).

At present, there are many problems about the data management in the

railway maintenance departments, such as decentralized data, non-uniform data standards, and so on. It led to the fact that the current information systems are unable to support the above requirements (Gao, Y. F. etc, 2006).

Therefore, finding ways to collect and integrate the various data resources in track maintenance departments according to the uniform data standard and to install the IDPFRM accordingly have become an extremely urgent research topic.

About the data platform, a 3-tier service architecture of the application service sharing platform for China railway geographic information system has been put forward. The system can provide 5 kinds of data services: access, analysis, visualization, metadata and application integration (Jia, L.M., etc, 2003). A scheme for constituting a synthetic information platform for inspection data, as well as the detailed descriptions of the methods to collect, store, and manage the different track inspection data has been given (Liu J., etc, 2006).

The authors will analyze the characteristics of the FDFRM and propose motions of integrating the FDFRM by constructing the IDPFRM.

2. BASIC CHARACTERISTICS OF THE FDFRM

Although the fundamental data produced in the track departments has decentralized sources and too many categories, its basic characteristics may be induced into the following:

(1) Spatial characteristics. Spatial characteristics refer to the geometry characteristics of the space object, such as position, shape, and size, as well as the topological relations with its neighboring objects.

The fundamental data of the railway track departments is extremely spatially characteristic. According to the preliminary analysis about the data structure of the PWMIS which is widely used in the railway track departments at present, over 95% of the data records have the fields with space position attribute “the central kilometrage”, “the beginning kilometrage”, “the end kilometrage” and so on. For example, in the curve table of PWMIS, “the beginning kilometrage” expresses the beginning of a curve, and “the end kilometrage” expresses the end of a curve (see Table 1). These two fields reflect the curve space position information. But the radius field and the super elevation field reflect the curve’s own geometric characteristics. In the bridge table, “the central kilometrage” expresses the central point of a bridge (see Table 2).

Table 1. Data structure of curve data table in PWMIS (part).

LINE_ CODE	BEGIN_KILO-METRAGE	END_KILO-METRAGE	CURVE_ HAND	RADIUS
0954	302.31449	302.63857	LEFT	1400.0
0954	304.26343	305.01648	RIGHT	600.0
0954	305.06381	305.48275	LEFT	600.0
0954	305.53302	305.91298	RIGHT	800.0

Table 2. Data structure of bridge data table in PWMIS (part).

LINE_ CODE	LINE_NAME	BRIDGE_CODE	CENTTAL_KILOMETRAGE	BRIDGE_ LENGTH
0954	NANJIANG	277	304.085	15.40
0954	NANJIANG	278	304.963	117.30
0954	NANJIANG	279	305.942	6.50
0954	NANJIANG	280	306.010	12.50

Remembering the position of a space object, human beings are not generally prone to memorize its space coordinates, but to determine the space position relations with the neighboring objects with which they are more familiar. The relations are generally called the topological relations. For example, the relations between a curve and two stations (which two stations is the curve between?), the relations between a curve and a tunnel (whether the curve is located in a certain tunnel), the relations between a curve and a bridge (whether the curve is located on a certain bridge). The second curve of Table 1 and the second bridge in Table 2 have the intersecting relations on the space position (see Figure 1). These relations reflect how the curve facilities relate to other facilities.

Figure 1. A bridge on Nanjiang Line.

(2) Subject characteristics. The subject characteristics refer to the other characteristics of the spatial phenomenon beside the time characteristic and the spatial characteristic. For example, a certain region has the characteristics of annual rainfall, land cover type, population density, air pollution degree and so on.

The subject characteristic of the railway facilities data has not only too many data types, but also a huge amount of records. The chief data characteristics of the track facilities are listed below:

A) Fundamental data of the facilities produced in the designing and producing stage, such as specification, model, and material.
B) Inspection data produced by the process of the facilities being used. It includes dynamical and static inspection data. The dynamic inspections include the inspection by track inspection cars, locomotive-mounted dynamic inspection instrument, portable inspection instrument, managers on trains, and rail detector cars. The static inspections include the manual line inspection, track instrument inspection, and line patrolling.
C) The facilities' flaw data produced in the process of the facilities being used.
D) The maintenance data produced in the process of the facilities being used. The track maintenance must take one of the three different repair methods of major repair, medium maintenance, and maintenance, according to different line condition. The maintenance is an operation for eliminating the common line defects or the planned preventive work between two repairs of major or medium maintenance. The Line maintenance may divide into synthetical maintenance, daily maintenance and temporarily repair according to its work pattern (MOR, P.R.China, 2006).
E) The train load data produced in the process of the facilities being used. It includes the information of gross train weight, the speed, the rolling stock type, the axis weight and so on when the train passes the facilities.
F) Management data produced in the process of the facilities being used. It includes the facilities' ownership units, the principals, the data's collecting persons, inputting persons, renewal frequency, and management standards.

(3) Time characteristics. The spatial data or the subject data is always collected or computed at some specific time or in some time span. The time characteristics of basic data of track facilities are the key aspect for tracing the reasons for facilities' failures and forecasting the trend of the facilities' changing states.

3. CONSTRUCTION OF THE IDPFRM

The important foundation of the track maintenance informationization is to manage the FDFRM with multi-sources, different structures massive amounts, to

construct the IDPFRM. These data resources are the enterprise assets that the track maintenance departments hold, with equal importance to the materiality assets. To achieve this goal, we study how to make the data coding standard, dictionary standard, quality specification and so on, and how to establish the data interface program with PWMIS, TMIS and the inspection devices that the Chinese railways commonly use, such as track inspecting cars, track static intelligent inspection instrument, a train-mounted track inspection tester, etc., and to construct the integrated track facilities database in Railway Bureau using the ETL pattern (Inmon W. H., 2005), which will lay the foundation for data mining of a track's state. A description about the data collecting process is given (see Figure 2).

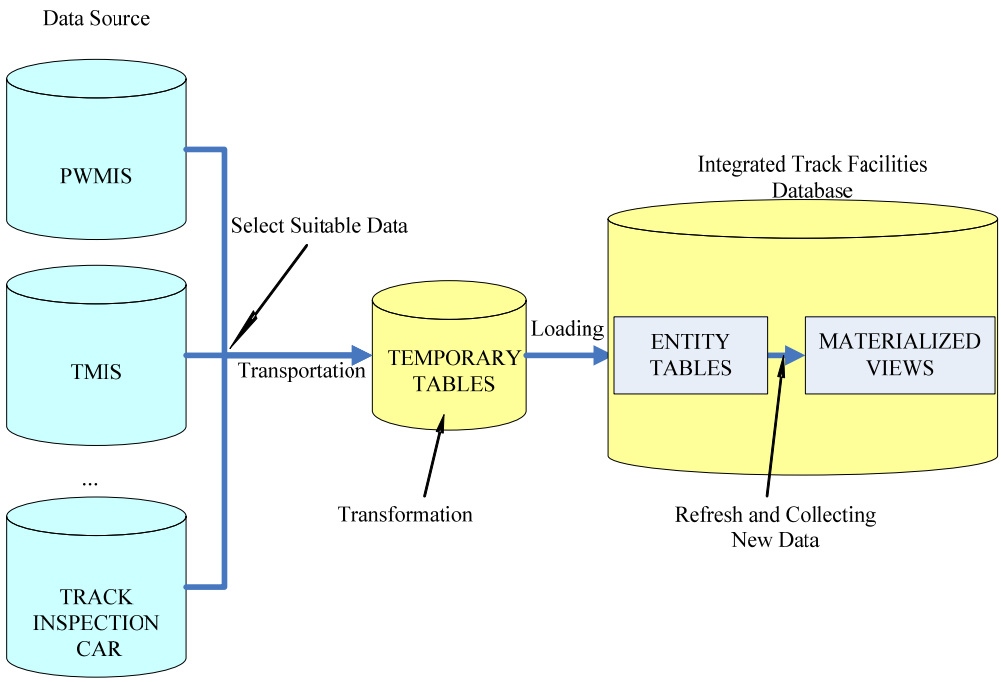

Figure 2. Data Gathering Process in Integrated Track Facilities Database.

Although the data categories of the integrated track facilities' databases that are shown in Figure 2 differ from each other, they have close relationships in time and space, according to characteristics described in the above section. They can be collected and integrated from the following aspects according to these relations.

(1) Information integration by regarding the spatial position as the ligament. All track data is assigned a certain kilometrage in the unified one-dimensional coordinate system (kilometrage), and all related data are gathered with kilometrage as the ligament. It provides the foundation for analyzing the track facilities' state evolution regularity based on time and space.

(2) Track facilities' centered information integration. Except for being

assigned a certain kilometrage, the track data is assigned the code of the facility it belongs to, for the convenience of data integration with the facilities as the ligament. It provides the foundation for analyzing a single facility's state evolution regularity.

(3) Information integration with the track maintenance management process as the master line. All track data is assigned to the step of the track maintenance management process that their source belongs to, for the convenience of data integration with the process as the ligament. It provides the foundation for realizing the track facilities closed-loop management of "inspection → state analysis → prediction → repairing → evaluating→ inspection".

4. AN APPLICATION EXAMPLE OF THE IDPFRM

An application system had been developed for rail track safety and maintenance in Kunming Railway Bureau in 2008, which was based on the IDPFRM, and the rail track facilities' data was fully considered. The system has worked uninterrupted for one year, and the information integration with space, facilities and work flow has been achieved. We can perform the following innovations for track safety and maintenance with the system.

(1) The dynamic and static track quality index (TQIs) computation, single item computation, TQI history changing regularity of the line with arbitrary length.
(2) Track geometric size changing regularity analysis and forecast the data of track inspection cars.
(3) Redrawing waves and contrasting analyses of many kinds of inspection data at one kilometrage (or same facility, especially essential key facilities, such as rail switches, curves, welded joints, joints between line and bridge, and so on).
(4) Maintenance plans made based on track's state changing regularly.
(5) Construction of facilities' trouble database based on the IDPFRM.
(6) Flow designing with "defects" as the master line, and the "defects" tracing management.
(7) Realization of the closed loop management of track maintenance.

These innovations will change the maintenance idea of the traditional "repairing after limits have been exceeded", "repairing after trouble has taken place", and "periodically repairing," to the idea of "selective maintenance", mainly by "preventive maintenance". They will sustain the decision making.

5. CONCLUSION

Analyzing the characteristics of the FDFRM is of great importance to the establishment of the IDPFRM, which will carry out the information integration of

the space position, facilities, and maintenance management processes, and will bring many innovations in the track maintenance management.

ABSTRACT

A new track structure calculation model is proposed with the characteristics of track noncontinuous supports and rail 3-dimension. Track structure responses at different high frequencies are obtained using Harmonic Response Analysis. The new model can better describe the response of track structure to high-frequency excitations. It excels the traditional beam model in calculation precision and applicable range. Rail foot and rail head vibration response in response to high-frequency excitations and their corresponding vibration distributions are studied, and track structure high-frequency vibration impedance characteristic is determined. Also, vertical vibration propagation decay rates are calculated. It is shown that rail cross-section vibrates mainly as a whole below 1000Hz; but produces deformation when vibratess at high frequencies.

1. INTRODUCTION

Noise pollution produced by high-speed trains has become a prominent problem in the development of high-speed railway system. It has attracted extensive attention from various government agencies and research institutes. Wheel-rail noise is one of the most important parts of railway noise, and high-frequency vibration is the main source of wheel-rail noise. In order to reduce the wheel-rail noise, it is critical to study high-frequency track vibration characteristics [P. J. Remington. (1987)]. The rail is effectively an infinite structure. Timoshenko beam and Eular beam models are often used to simulate the rail in previous studies. These studies are limited to modeling continuously supported beam (D. J. Thompson. 1993) and periodically supported beam (M. A. HEl CKL. 1992). Also, the traditional models did not consider the deformation of track cross-section for high-frequency excitation very well. A more precise model and calculation method are established in this paper to analyse the track structure vibration characteristics.

2. THE ANALYSIS METHOD OF VIBRATION CHARACTERISTICS

Any sustained cyclic load will produce a sustained cyclic response (a harmonic response) in a structural system. Through the harmonic (or sinusoidal) excitation, the amplitude ratio and phase difference between excitation and

response can be employed directly to determine the system impedance:

$$Z_j = F_j / V_j \tag{1}$$

Where: *Z_j represents the vibration impedance of structure. F_j and V_j represent the excitation and response, respectively.*

Sinusoidal force can be expressed as a plural:

$$f(t) = Fe^{i(\omega t+\varphi_1)} \tag{2}$$

Where: *F represents the amplitude of excitation force; ω denotes frequency; t is time; and φ_1 is phase angle of force*

The corresponding displacement, velocity, and acceleration can also be expressed as plural too:

$$x = Xe^{i(\omega t+\varphi_2)}, \dot{x} = i\omega Xe^{i(\omega t+\varphi_2)}, \ddot{x} = -\omega^2 Xe^{i(\omega t+\varphi_2)} \tag{3}$$

Where: *X represents for the amplitude of sinusoidal displacement response amplitude; φ_2 is phase angle of response.*

Equation (1) can be rewritten as:

$$Z_j = \frac{Fe^{i(\omega t+\varphi_1)}}{Ve^{i(\omega t+\varphi_2)}} = \frac{F}{V}e^{i(\varphi_1-\varphi_2)} \tag{4}$$

Where: *V denotes the amplitude of response*

Harmonic response analysis makes it possible to predict the sustained dynamic behavior of structures in Finite Element Method. The idea is to calculate the structure's responses at different frequencies and to obtain a mapping between response quantities (usually displacements) and frequency [ANSYS, Inc. (2005)].

Consider the equation of motion for a structural system:

$$[M]\{\ddot{x}\} + [C]\{\dot{x}\} + [K]\{x\} = \{F^a\} \tag{5}$$

where: *[M] represents structural mass matrix; [C]: structural damping matrix; [K]: structural stiffness matrix; {x} : nodal displacement vector; and {F_a}: applied load vector*

As mentioned above, all points in the structure are moving at the same known frequency, however, not necessarily in phase. Also, it is known that the presence of damping causes phase shifts. Therefore, the displacements may be defined as:

$$\{x\} = \{x_{\max}e^{i\phi}\}e^{i\Omega t} \tag{6}$$

where: *x_{max} : maximum displacement; Ω:imposed circular frequency (radians/time); Φ : displacement phase shift (radians)*

Note that x_{max} and Φ may be different at each degree of freedom (DOF).

The use of complex notation allows a compact and efficient description and solution of the problem. Equation (6) can be rewritten as:

$$\{x\} = \{x_1\} + i\{x_2\}e^{i\Omega t} \tag{7}$$

Where: *{x1}: real displacement vector; {x2}: imaginary displacement vector*

The force vector can be specified analogously to the displacement:

$$\{F\} = \{(F_1)\} + i\{F_2\})e^{i\Omega t} \tag{8}$$

where: *Ω represent force phase shift; {F1} represent real force vector; {F1} represent imaginary force vector.*

Substituting equations (7) and (8) into equation (5), The dependence on time ($e^{i\Omega t}$) is the same on both sides of the equation and may therefore be removed, then the follow equation can be get:

$$([K] - \Omega^2[M] + i\Omega[C])(\{x_1\} + i\{x_2\}) = \{F1\} + i\{F2\} \tag{9}$$

The response can be obtained by the solution to equation (9).

3. The track structure model

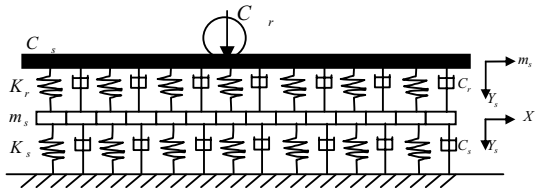

Figure 1. Two degrees of freedom vibration system with sleeper quality model.

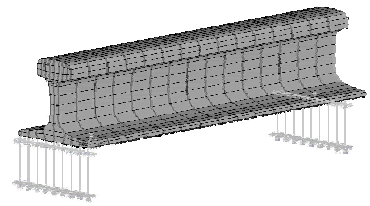

Figure 2. Three-dimensional track structure model.

Two DOF vibration system with sleeper quality model is established in reference [LIU linya. (2004)]. Rail vibration mechanical analysis model is shown in Figure 1. For further optimization of the model, the rail is simulated with three-dimensional solid element shown in Figure 2. In this model, spring-damper combination and mass element are employed to describe the rail support and sleeper, respectively.

4. THE VIBRATION CHARACTERISTICS OF TRACK STRUCTURE

4.1 Track vibration impedance

Based on the model described in Section 3, track responses are calculated. Track parameters are selected from reference [LIU Linya.(2006)]. Figure 3 gives

impedance amplitude and phase angle of rail head and rail foot when excited in the head centerline of rail at mid-span. Figure 4 shows the same value when excited in the head centerline of rail at sleeper supporting point.

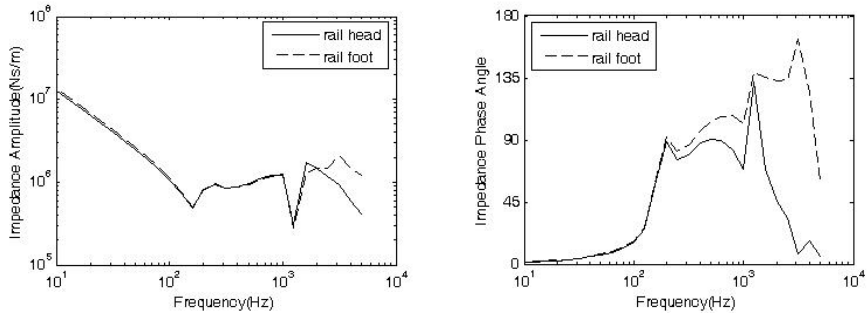

Figure 3. Impedance of track structure when excited in the head centerline of rail at mid-span.

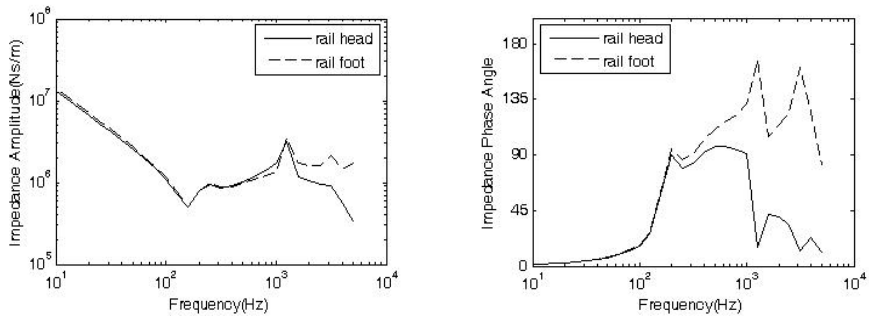

Figure 4. Impedance of track structure when excited in the head centerline of rail at sleeper supporting point.

Both Figures 3 and 4 show that vibration impedance amplitudes of rail head and rail foot are very close when the frequency is lower than 1000Hz. This similarity indicates that rail vibrates mainly as a whole. In the high-frequency part, rail impedance amplitudes of rail head and rail foot are significantly different, which shows that rail cross-section produces deformation vibration at high frequencies.

The traditional models can not effectively reflect the rail cross-section deformation at high frequencies. Thus they cannot precisely simulate the track structure vibration at high frequencies. The model introduced in this paper can describe the deformation very well, thus providing better calculation precision than the beam model.

Comparison between Figures 3 and 4 shows that the track structure vibration characteristics are very similar when excited at mid-span and sleeper supporting point at low frequencies (less than 1000Hz). However, the vibration difference between excitations at mid-span and sleeper supporting point become very large at high frequencies. Particularly, when excited at mid-span there is a resonance point at about 1250Hz. At around the same frequency, there is also an anti-resonance point when excitated at sleeper supporting point.

4.2 Track vibration distribution

Figure 5 gives the typical vibration distributions along the track direction. Some vibration rules can be drawn:

Below 125Hz, vibration distributes with half-wavelength around 4 spans and attenuates in the track length direction rapidly.

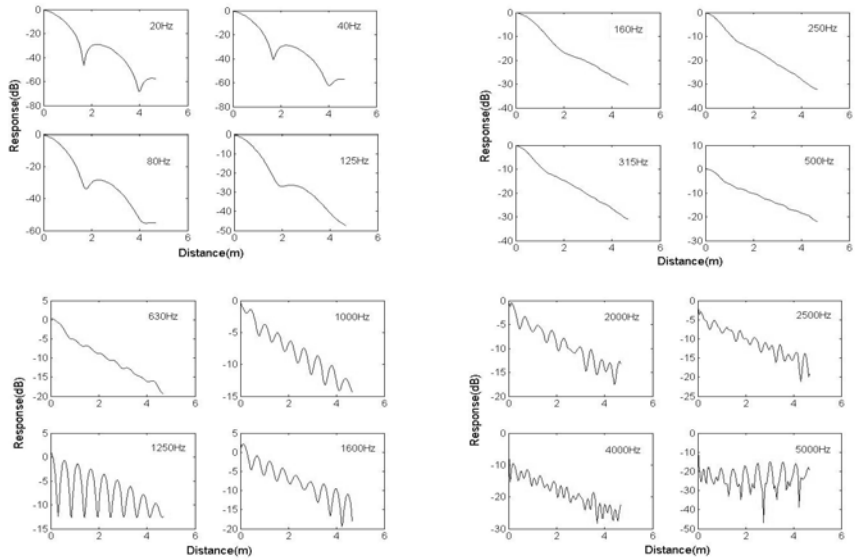

Figure 5. Vibration distribution along the track direction.

Between 160Hz and 500Hz, track vibration attenuates linearly with respect to the track length.

Ranging from 630Hz to 1600Hz, track vibrates in pinned-pinned mode with a span length of half-wavelength especially for 1000Hz.

4.3 Track vibration propagation decay rate

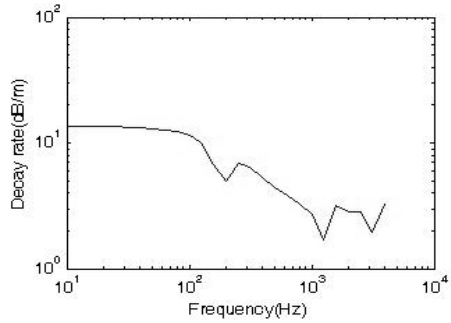

Figure 6. Vibration propagation decay rate.

As illustrated in Figure 5, the track vibration attenuation along the track direction is directly related to frequency. The propagating wave decay rate is obtained [C.J.C. Jones. (2006)] and shown in Figure 8.

It can be seen from Figure 8 that vibration attenuates rapidly at low frequencies; and track structure has comparatively longer transmission distance at

high frequencies.

5. CONCLUSIONS

Based on a three-dimensional track structure vibration model, harmonic response analysis is employed to investigate the vibration characteristics of track structure. This three-dimensional model can better describe the rail cross-section deformation at high frequencies, therefore producing better calculation precision at high frequencies compared to the traditional beam model. Impedances of different exciting and pick-up points are obtained by calculating the track structure. In addition, some interesting rules of track structure vibration at high frequencies are observed:

1. Rail cross-section vibrates mainly as a whole below 1000Hz; At high frequencies, rail cross-section produces deformation when vibrates.
2. Track vibrates in a pinned-pinned mode with a span length of half-wavelength for 1000 Hz.
3. Vibration attenuates rapidly at low frequencies; track structure has comparatively longer transmission distance at high frequencies.

ABSTRACT

This paper presents a study of the ground subsidence law caused by tunnel excavation with EPB shield machine, in which a Metro site was selected for data collection. With the data measured in field and tools of general FEM program ABAQUS, three-dimensional finite element model was established and a simulation study was conducted to analyze the construction progress under influences of all possible factors. Major regional and sub-regional factors influencing the ground subsidence were estimated, and the terrain types affecting vertical surface during construction and the amount of ground subsidence in various stages of construction are analyzed. Based on comprehensive understanding of these influencing factors, the prediction model for estimating ground deformation was studied. With the actual values of stratum and construction parameters as well as other relevant data for samples, the established model was applied to forecast the ground deformation and verification the availability and satisfactory results were produced.

1 INTRODUCTION

Construction method for shield tunneling has the virtue of less traffic impact, less excavated earth, short construction period, so it is more and more applied in urban metro construction. But, during construction, this method inevitably caused stratum loss and ground subsidence. When the stratum deformation is out of range, it will

endanger adjacent buildings, urban roads, underground utilities and other a series of geotechnical problems.

Study methods on ground subsidence induced by shield tunneling at home and abroad may come down to: theory and empirical formula method, numerical simulation, model experiment and so on. In this paper, use FEM program ABAQUS to simulate the excavation processes and analyze the ground subsidence law induced by shield tunneling in sandy stratum.

2 INFLUENCING FACTORS ANALYSIS OF GROUND SUBSIDENCE BY SHIELD TUNNELING

Synthesizing home and abroad successful experiences, it can thus be concluded that the stratum loss give major cause for ground subsidence. The subsidence mainly appears on the period of construction. The reason is found expression in over-excavation, unmatched propulsion parameter, insufficient grout or grouting untimely, gesture adjustment and so on. Besides, some factors such as planning, design, local geological conditions can also cause ground subsidence, which happen during construction and long time after construction.

3 MEASURE AND ADVANCING FACTOR

3.1 Project description

Tunnel interval is simple cavity and simple line circle section, whose diameter is 6m, the thickness of lining is 0.3m. The maximal buried depth of the tunnel top is 13.723m, and the minimum is 7.86m, the buried depth of the measured district is 11m, and the stratums are made of expanding granular, such as clay, silt, medium sand, grit, gravelly sand and pebble. The pressure in soil store is 0.18Mpa, the advance rate is 3~4m/min, two grouting hole work at the same time and the pressure is 0.4 Mpa, the amount of grout is $4m^3$.

3.2 Scope of measure and disposition

Measure the horizontal and vertical displacement, there is a measure section per 20m in range of 100m while shield is departure and lifted out, and per 50m in other districts. Concrete factory is as shown in Figure1. The range of 50m before cutter head and 20m after shield tail is considered in this paper.

Ground subsidence observation spot should penetrate road structural layer, and fit in natural soil. The style of the measured spot is shown in Figure 2.

3.3 Analysis of measured results

Taking the section where spot Y4 locates for example, the data is as indicated in Figure2 and Figure3. From Figure2, the conclusion that the subsidence rise and maximize near by spot Y4 can be drawn. After that, the subsidences tend to decrease and uplift begins to emerge. The subsidence shows over-excavated and uplift shows that grouting takes effect, so grouting in time is necessary.

See Figure3, the subsidence of spot Y3 (20m after shield tail) is stable. The uplift and subsidence of spot Y4 and Y5 is also stable before 20m, and make small changes after 20m. But, the uplift and subsidence of spot Y6 and Y7 make big changes; it shows that the thrust of jack and over-excavated play a part. So, measuring range, from 20m after shield tail to 50m before 50m before cutter head, is reasonable.

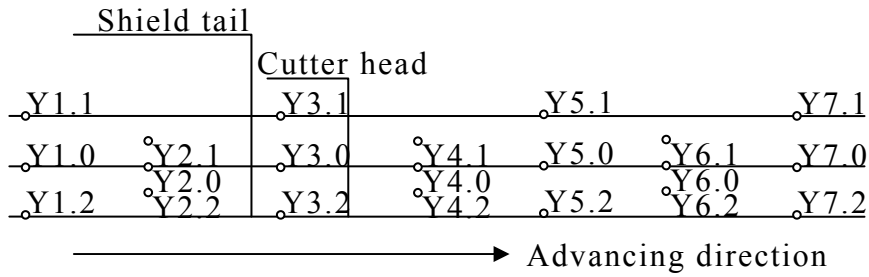

Figure1. Measure site (part).

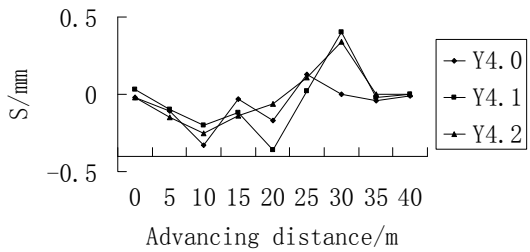

Figure 2 Lateral measured data.

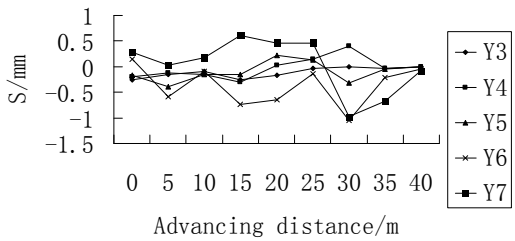

Figure 3 Longitudinal measured data.

4 FINITE ELEMENT MODELS

4.1 Calculation hypothesis

Simplify tunnel lining as homogeneous and linear elasticity material. Time effect is without consideration and only space deformation is considered. The ground surface and solum of soil is homogeneous and flat bedded. Constitutive model of the soil body is Drucker-Prager model, which combine ABAQUS/Explicit destruction model to define stiffness reduction, removing element and so on. Physics mechanics index of earth is shown as Table1.

4.2 Finite element model

On the basis of the width estimation formula from Peck sedimentation tank and solum condition on site, estimate Section size of the model: 60m width, 50m height and 100m length. The top surface is free, the bottom is two-way restraint, the left and right is horizontal restraint and the front and back is also horizontal restraint. The boundaries except the top use infinite element. The solum is simulated by solid elements, which is C3D8R. The tunnel lining is simulated by skin elements, which is applicable to three-dimensional model and can superiorly model the weighted conditions of linings. The excavated step is 1.2m length. As aforesaid, the finite element model is build as below. See Figure 4.

Table 1 Physics mechanics index.

Depth of Stratum (m)	Geotechnical name	Volume weight Γ (kN/m^3)	Cohesion C(kPa)	Internal frictional angle standard φ_k (°)	Coefficient of compressibility α(1/MPa)	Modulus of compression $Es_{0.1}$(MPa)
4.7	Silty clay	18.9	34.0	11.3	0.281	6.65
5.8	Silty fine sand	17.1	9.8	29.8	0.132	12.57
8.4	Medium rough sand	17.7	1.7	33.9	0.132	12.39
5.1	Silty fine sand	19.0	1.5	34.0	0.132	11.99
8.6	Gravelly sand	19.9	1.7	41.8	0.103	14.77

4.3 Computation simulation

Use the ADD technology to activate part lining element, and REMOVE technology to remove excavated soil element. The analysis step is set up as below.

(1) Initial geostatic stress equilibrium: Use step GEOSTATIC to simulate Initial stress field.

(2)The first step is tunnel excavation (release part load). The process of simulating tunnel to be excavated is not absolute stress relaxation. On condition of initial geostatic, diminish modulus of elasticity to soften soil to be excavated. Put it this way to diminish supporting force of country rock, and amount to once stress relaxation. Use command TEMPERATURE to change modulus of elasticity and release 60% geostatic stress.

(3) Assemble lining: Use commands REMOVE to remove lining elements before excavation, and activate a lining (1.2m width) after excavation.

(4) Release remnant stress: Remove the first part soil to release 40% stress.

Repeat step (2)~(4) to excavate to be finished. Only thirty lining(that is 36m width) is simulated in this paper because of the computer' s work. By this time, the ground subsidence is basically stable and can satisfy the analysis required. The part result is shown in Figure 5.

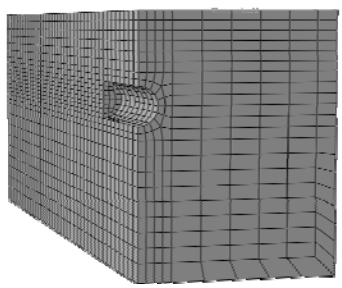

Figure4. Finite element model

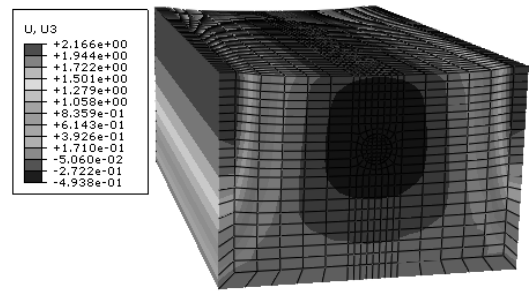

Figure5. Initial geostatic stress equilibrium.

5 CONTRAST OF MEASURED AND SIMULATED RESULT

5.1 Lateral subsidence

The contrast data come from 15m before cutter head to 15m after shield tail. Take points Y4 (Y4.0, Y4.1 and Y4.2) for example and the data comes from 20m before section where Y4 locates. The measured and simulated result of the lateral subsidence is as shown Figure 6. See it from the Figure6 that the measured subsidence increase and then decrease up to uplift, but the simulated can't reflect the increasing part. That is because that the stress relaxation of the model differ from over-excavated solum, and this is a problem to be solved in follow-up work.

5.2 Longitudinal subsidence

Take the three point Y3.0, Y4.0 and Y5.0 right above the tunnel axes for example and inspect changing situation of their ground subsidence during excavation. Because the interval of measured section is longer (20m) and the simulated and calculated model is only 36m length, so the overall changing situation of the longitudinal subsidence cannot be made known.

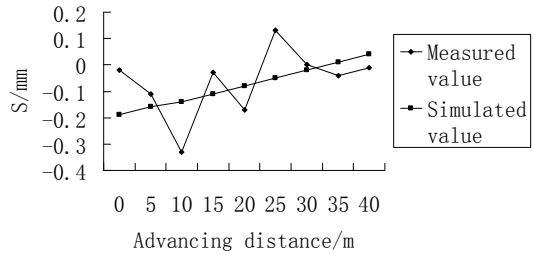

Figure 6. Measured value Compared to simulated value.

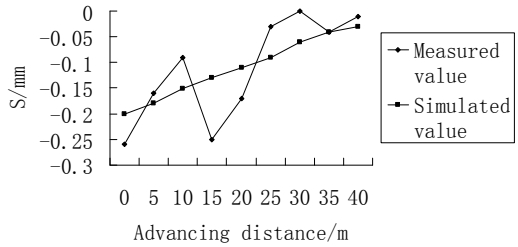

Figure7. 20m far from shield tail (Y3section).

Part match Results are shown in Figure 7 to Figure 8. It can be see that the trend is basically same and the model on the whole can reflect the change law of subsidence.

6 CONCLUSIONS

The measure data make known the ground subsidence law of sandy stratum. Establish three dimensional finite element model by software ABAQUS to simulate the subsidence, and result is as follows.

(1) The simulated value of ground subsidence is approximate to measured value after contrasting and analyzing the value, and the simulation can better give expression to lateral ground subsidence law.

(2)Three-dimensional numerical method can effectively simulate dynamic construction and the change of ground subsidence. Consequently, the simulation results are more accurate and open up a new way to forecast the subsidence cause by excavation.

(3)The three dimensional finite element model established by ABAQUS can superiorly simulate kinds of materials, such as soil, lining, and grout. The stress and deformation, excavation and timbering can all be simulated. The infinite elements of boundaries preferably correspond with Actual projects. The results provide a foundation of next steps, that is, advancing parameter and seepage flow coupling.

Study on the Carrying Capability of Preplanned Regional Earthquake Evacuation Corridor Based on Macro-Simulation
Analysis on Standards Used in Traffic Impact Study

Cao, Liping
Dynamic Response of Saturated Asphalt Pavement Based on Three Dimensional Finite Element Simulation
Permanent Deformation Characteristic of Asphalt Mixture Considering Pavement Temperature Distribution

Cao, W. S.
A Study of Vehicle and Materials Depot Location Problems for Winter Road Maintenance

Cao, Xiaodong
Analysis of the Competitive Strategy of the Core Enterprises in Virtual Intermodal Freight-Transportation Enterprise

Cao, Xintao
An EEG Predictor of Driving Fatigue

Cao, Yi
Vehicle Dynamics Model in Two-Dimension Collision Accident
Vehicle Trajectory Model in Two-Dimension Collision Accidents

Cen, Guo-ping
Performance of Pavement Plate Reinforced with Modified Unsaturated Polyester Fiberglass Reinforced Plastic

Chai, Gan
A Multi-Objective Decision Model of Traffic Rescue Service Site Location on Road

Chai, X.
Research on Simulation of Train Tracing Operation Based CBTC

Chang, A.
Link Average Speed of Traffic Flow Estimation Method Based on Floating Car

Chang, Chun-qing
Viscoelastic Mechanical Properties of Crumb Rubber Modified Asphalt Mixture

Chang, Liang
The Numerical Analysis of Sound and Vibration from a Tire by FEM and BEM

Chang, M. F.
Study on Permanent Deformation Characteristics of Asphalt Pavement Based on Discrete Element Method
Mechanism of Rutting Formation in Long and Steep Climbing Sections of Asphalt Pavement

Chang, Qing
An Improved Ant Colony Algorithm for the Shortest Path Problem in Time-Dependent Networks
Optimal Dynamic Substitution Policy for Components in an Assemble-to-Order

System
Coordination Policies of Supply Chain Where Deterioration Begins at a Random Time Point

Chang, Yun-tao
Analysis and Evaluation of Expressway Planning Schemes Based on Integrated Macro and Micro Simulation
Evaluation of Traffic Impact on Land Development Projects Based on Matter-Element Analysis

Chang, Zhenwen
The Analysis of Traffic Flow State on Foggy Expressway Based on Fuzzy Clustering

Chao, Huanhuan
Empirical Correlation Analysis of Parking Arrival and Departure Rates for Urban Parking Facilities

Chen, A. R.
Flutter Derivatives Identification of Aeroelastic Model of Hangzhou Bay Bridge

Chen, Bin
Risk Evaluation Model for Construction of a Logistics Park Based on Principal Component Analysis

Chen, Dafei
Analyzing the Motivation of Queue-Jumping Driving-Action on Transportation Systems by Prospect Theory

Chen, Dingjun
An Improved Ant Colony Algorithm for Placing-In and Taking-Out of Wagons in Branch-Shaped Sidings

Chen, Gangliang
Multi-Section Short-Term Traffic Flow Prediction Based on Multi-Dimensional Time Series

Chen, Hanzhen
Research on the Crashworthiness of Two-Layer Thin-Walled Structures

Chen, Hong
The Evaluation of Micro-Benefit on Highway Construction Investments
An Active Parking Guidance Information System Based on Dynamic Agent Negotiation

Chen, Hongyun

Evaluating the Impacts of Ramp Configurations and Influential Factors on Freeway Exit Ramps

Chen, J.
Optimal Setting of the VMS's Future Range Based on the Characteristics of Driving Speed

Chen, Ji-hong
A Nonlinear Model for Decision-Making for Container Slot Chartering and Allocation under Liner Shipping Alliance

Chen, Jian
Design of 3D Virtual Simulation and Evaluation System for Road Traffic Signs

Chen, Juan
The Application of the Maximal Coverage and Partial Coverage Model in the Shelter Location Problem

Chen, Jun
Empirical Correlation Analysis of Parking Arrival and Departure Rates for Urban Parking Facilities
The Attitude and Psychological Demand Related Determinants of Public Transport Use

Chen, Lijun
Structure System Model of Modern Logistics

Chen, Minglan
Investment and Financing Influence Analysis and Countermeasures for Highway Construction in the Period of China's 11th Five-Year Plan

Chen, Nianhe
A Study on Cable-Removing Scheme of the Cable-Stay System of the Zhijing River Bridge

Chen, Ningning
Adaptive Control Method of Multi-Phase Intersection Based on Traffic Status Identification

Chen, Rong
Adaptability Assessment and Maintenance Technology Research of Existing Railway Line Speed Increases to 200 km/h

Chen, Rui-Xiang
Application Research of GPS Based on Google Earth Platform

Chen, S.
Influence of Crack Size of Old Concrete Pavement Slab on Structure Stress of Asphalt Overlay

Chen, Shijun
Vibration Characteristics of Permafrost Embankment Induced by Passing Trains in Qinghai-Tibet Railway in Winter

Chen, Shuanfa
An Evaluation of the Effectiveness of Geo-Textile-Binder-Aggregate System for Surface Treatment of Distressed Asphalt Pavement

Chen, Sili
Study on Experiment of Concrete Mixed with II Degree Flyash under the Corrosion of Freeze Thawing

Chen, Suping
A Comprehensive Bus Line Evaluation Method Based on Fuzzy C-Means Clustering Algorithm

Chen, T.
Research on Optimization of Crew Scheduling of the Passenger Dedicated Line Based on a Genetic Ant Colony Algorithm

Chen, Tao
A Traffic Accident Reconstruction Study on Continuous Collision of Three Cars
Study and Implementation on JPEG Image Enhancement System of Tire Mark

Chen, Tianhong
Stability and Reinforcement Methods of a High Slope at the Hang-Yong Natural Gas Pipeline in China

Chen, Wanji
A Speed Limit Model of Vehicle for Urban Road Hazmat Transportation

Chen, X.
Study on the Rules of Crash Distribution
Evaluating the Equity Impacts of Rural Road Investment Projects on Household Welfare Based on a Quantile Regression Approach: Evidence from Fujian Province

Chen, Xi
Finite Element Analysis on Shear-Lag Effect in Curved Continuous Box Girder with Corrugated Steel Webs

Chen, Xiang

A Study of the Fuzzy PID Control Over the Hydraulic Semi-Active Suspension in Consideration of Automotive Engine and Passenger-Seat System

Chen, Xiao

Damage Model Analysis of SBS Modified Asphalt Mixture

Chen, Xiaohong

The Analysis of Traffic Landscape from Users' Perspective: The Case of the Zhangjiang Tram

Investigation of Relationship between Level of Service and Safety

Investigation of the Relationship between Red-Light-Running Frequencies and Intersection Features

Chen, Xiaoping

Adaptability Assessment and Maintenance Technology Research of Existing Railway Line Speed Increases to 200 km/h

Chen, Xin-dong

A Calculation Method for the Information Utility of Traffic Guide Signs

Chen, Xiqun

Evaluation and Optimization of Public Transport Subsidies for Alternative Energy

Chen, Xuewu

Study on the Relationship of Traffic Flow Complexity and Traffic Conflict on Urban Road

The Key Technology of "One Road One Line with Straight Driving" Public Transportation System

Assessing Performance of Public Transit Network Using Network-Based Accessibility Measures

The Study on Design Method of Vehicle Intake Silencer Based on Three-Dimension/One-Dimension Models Coupling

Li, Jiang
Study on Accident Reconstruction Model Based on Reverse-Reasoning Method

Li, Jianglong
Observation and Theoretical Analysis of the Temperature Field on the Cross Section of Concrete Filled Steel Tubes Arch Bridge Rib

Li, Jie
Information Needs of Urban Transit Travelers—The Case of Wuhan, China
Study on Different Residual and Weight Coefficient in Model Updating of Bridge Structure

Li, Ke-ping
Impact Analysis on Countdown Device on Transit Priority Signal Control

Li, Keping
The Comparison of Three Getting Signal Control Delay Video Methods at Signalized Intersection
A Manual Calibration Method for Simulation of a Freeway Weave Section

Li, L.
Traffic Signal Control Optimization of Urban Arterials Based on a Method of Main Intersection Control Strategies
Study on Shear Properties for Adherence of New and Old Concrete and Its Practical Calculation

Li, Li-hui
Study on Asphalt Treated Permeable Base in Permafrost Regions

Li, Li
Node-Importance-Degree-Based Logistics Node Analysis

Li, Lilan
Research on the Bicycle Capacity of Signalized Intersection Based on Fluid Diffusion Characteristics
Gray-Periodic Extensional Combinatorial Model for Road Traffic Accidents in Cold Regions

Li, Lin-bo
Study on the Location Parking Index Based on Function Division of Parking Space

Li, Linbo
The Analysis of Transportation Demand Generation Mechanisms of the Urban Agglomerations in China

Li, Ling-jie
A Study on Signal Timing Optimization of Individual Intersections Based on an Ant Colony Algorithm

Li, M.
Analysis of the Influence of Emergent Incident on Expressways by Simulation
Research on Calculation of Important Parameters of Freeway Financial Post-Evaluation

Li, Maosheng
Optimization Theory of Regulation on Rural Transit Market Based on Rule of Transport Equality
Analyzing the Motivation of Queue-Jumping Driving-Action on Transportation Systems by Prospect Theory

Li, Mingshui
A Study on Spatial Correlation and Power Spectrum of Natural Wind at Xihoumen Bridge

Li, Musong
Test and Analysis of Rail Break Emergency Treatment Device for Railway Switches
Impact on Regularity of Track from Pile Underpinning of Light Railway Bridge
Analysis on Mechanical Performances of High-Speed Railway Transition Curves

Li, Na
The Analysis of Traffic Landscape from Users' Perspective: The Case of the Zhangjiang Tram

Li, Peng-fei
Research on Urban Public Transit Dispatching System Based on Real-Time Prediction and Game Theory

Li, Pengfei
Influencing Factor Analyses of Section Types on Vehicle-Bridge Interaction of Concrete Box Girder with Corrugated Steel Webs

Li, Ping
The Application of Anti-Rutting Agent on Improving the High-Temperature Stability of Asphalt Pavement

Li, Q. Q.
Urban Road Travel Speed Estimation Based on Low Sampling Floating Car Data

Li, Q.
Mixed Traffic Micro-Simulation of Urban Branch Roads
An Interval-Varying Floating Car Data Clustering Approach Based on Self-Organizing Maps
Simulation Study on a Freeway Climbing Lane
Evaluation of Supervision Engineer's Control over Investment Based on AHP

Li, Qiang
Efficient Link Travel Time Estimation for Signalized Link by Small Size Probe Reports
Experimental Tests and Finite Element Modeling of Shrinkage Behavior in Cement Stabilized Aggregate Base

Li, Rongda
Research on Application of Externally Prestressing for Simple-Continuous Bridge

Li, Rui
The Prediction of Urban Bus Travel Time

Li, S.
Research on Urban Intersection Vehicle Emission Reduction Based on Microcosmic Simulation

Li, Shiwu
A Time-Varying Route Optimization Model for Urban Hazmat Transportation
A Speed Limit Model of Vehicle for Urban Road Hazmat Transportation
Application of Locating Technology in the Highway Emergency Response System

Li, Shuang
Basic Study on Fractal Characteristic of Pore Structure in Cement Mortar

Li, W.
Mixed Traffic Micro-Simulation of Urban Branch Roads
Track Access Technology of Traffic Accident Vehicles Based on Video

Li, Wei-sheng
Performance Model for Pavement Maintenance of Expressway in Northwest of China

Li, Wen-quan
A Reserve Capacity Model of Optimal Traffic Lane Allocating
Research on Conversion Coefficients between Bicycle, Electric Bicycle, and Pedestrian on Urban Road Intersection

Li, Wenquan
Conventional Bus Stop Capacity in Peak
Estimation of Original-Destination Matrices for Public Traffic Passenger Flow
The Prediction of Urban Bus Travel Time

Li, X.
Study on Burner Type Diesel Particulate Filter System Using Compressed Air from Turbocharger
Research on Numerical Simulation of Pollutant Dispersion at Expressway Toll Plazas Based on Multi-Influencing Factors

Li, Xi-ying
A Retrograde Vehicle Detection Method Based on the Optical Flow Field

Li, Xiamiao
Analysis of the Competitive Strategy of the Core Enterprises in Virtual Intermodal

Freight-Transportation Enterprise

Li, Xiangguo

Test and Analysis of Rail Break Emergency Treatment Device for Railway Switches

Bridge Damage Assessment by Dynamic Response in Time Domain

Impact on Regularity of Track from Pile Underpinning of Light Railway Bridge

Analysis on Mechanical Performances of High-Speed Railway Transition Curves

Li, Xiaowei

Plastic Behavior for Compaction Pile with Hole Expanded by Blasting or Tamping Techniques

Li, Xin-kai

Gradually Rolling Prediction of the Use-Level of Road Network Based on BP Neural Network

Li, Xinkai

The Analysis of Dowel and Tie Bars Effects on Curling Up in Concrete Pavement Slabs

Experimental Analysis of Interface Bond Performance of UTW

Li, Xuefu

Construction Control of Cable-Stayed Bridges Based on ANN and GA Hybrid Algorithm

Li, Y.

Evaluating the Equity Impacts of Rural Road Investment Projects on Household Welfare Based on a Quantile Regression Approach: Evidence from Fujian Province

Li, Yajun

Analyzing the Effects of the Growth of Maritime Industries on the Regional Economy with Dynamic Inverse Matrix

Li, Yan

An Improved A* Algorithm for the Intelligent Transportation System

Observation and Theoretical Analysis of the Temperature Field on the Cross Section of Concrete Filled Steel Tubes Arch Bridge Rib

Li, Yang

Analysis of Runway Incursion in Civil Airport Based on Bayesian Network

A Safety Protection Technology System on Highway Roadside in China

An Active Parking Guidance Information System Based on Dynamic Agent Negotiation

Li, Yanwei
An Analytical Method for Predicting the Service Life of Bridge Structures

Li, Ying-Hong
Vehicle Tracking from Videos Based on Mean Shift Algorithm
Vehicle Detection from Videos Containing Complex Background Based on Bayesian Statistical Modeling

Li, Ying
Technical Efficiency of Container Terminals in China Using a Multi-Activity Data Envelopment Analysis Model

Li, Yu-ming
Study on the Control Strategy of Gas Injection of Gas Engines

Li, Yun-peng
Study on Safety Stability of Excavating Shallow Depth Neighborhood Tunnel in Traversing Construction
Study of Influence of Subway Station Excavation on Existing Metro Deformation

Li, Yunfeng
Application of High Performance Concrete Mixed with Steel Slag Powder in Concrete Pavements

Li, Z.
Frequency Optimization Model for a Public Traffic Scheduling System

Li, Zaixin
Experimental Tests and Finite Element Modeling of Shrinkage Behavior in Cement Stabilized Aggregate Base

Li, Zheng-Xi
Vehicle Tracking from Videos Based on Mean Shift Algorithm

Li, Zhenxia
Research on Rapid Curing Technology of Lime-Flyash-Cement Stabilized Macadam

Li, Zhijie
Study on the Carrying Capability of Preplanned Regional Earthquake Evacuation Corridor Based on Macro-Simulation

Li, Zhixia
Dilemma Zone Modeling Using Yellow-Onset Vehicular Trajectory Data

Li, Zhongji

Vehicle Semi-Active Suspension System Simulation with Variable Structure Control Method

Li, Zhonglong
Design and Validation of Wireless Dynamic Testing System for Bridge Based on the 941B Type Vibration Sensor

Li, Zimu
Transit Network Optimization Method Based on BRT Attracting Region: A Case Study of Changzhou

Lian, Yuchao
Research on the Mechanism for Preventing Reflective Cracks in Old Cement Concrete Pavement Reconstruction

Liang, Dui-dui
Analysis and Evaluation of Expressway Planning Schemes Based on Integrated Macro and Micro Simulation
Evaluation of Traffic Impact on Land Development Projects Based on Matter-Element Analysis

Liang, Shihua
Dynamic Effects of Moving Vehicular Loads on Continuously Reinforced Concrete Pavements on Winkler Foundation

Liang, Xuerong
The Analysis of the Correlation between International Roughness Index and Body Ride Comfort

Liang, Yanping
Research on Vehicle Information Extraction from High-Resolution Satellite Images

Liang, Ying-hui
Study on Fuzzy Neural Network Model of Vehicle-Bicycle Conflicts at Grade Intersection Based on Failure Tree Analysis
Study and Simulation of Behavioral Decision-Making Model of Through Bicycles Passing Vehicles at Signalized Intersection

Liang, Yubao
Discussion on Methods of Traffic Routes' Alignment Survey and Application of Principle of Least Squares

Liang, Z.
Highway Traffic Parameters Estimation by Using Cell Dwell Time

Liao, Haili
A Study on Spatial Correlation and Power Spectrum of Natural Wind at Xihoumen Bridge

Liao, Xiaobo
Dynamic Alliance of Road Logistics Enterprise Based on Ant Colony Algorithm

Lin, Cheng
Simulation of Turning Stability Control for Two-Motor-Drive Electric Vehicles

Lin, Ciyun
Dynamic Model of Transit Signal Priority on Colored Time Petri Net

Lin, Hangfei
Investigation of Relationship between Level of Service and Safety
Side Road Traffic Considered in Transit Signal Priority Control

Lin, Huigang
Research on Taboo Simulated Annealing Combinatorial Optimization Algorithm of Location Routing Problem with Pickups and Deliveries

Lin, Li-Xia
A Safety Evaluation Method of Existing Flexible Suspension Bridge with Double Cable

Lin, Lifan
A Study on the Location Selection of Public Traffic Transfer Hub Based on Improved Particle Swarm Algorithm

Lin, Tao
Algorithm of PFE and Its Application in Shenzhen Urban Transport Simulation System

Lin, Y.
A Route-Based Model for Determining Interconnection of Isolated Traffic Signals
Research on Dynamic Measuring System and Model of Novel High Speed Railway Vehicle Bogie

Lin, Yu
Locating Emergency Response Facilities for Hazardous Materials Transportation with Probabilistic Response Time

Ling, Ling-yong
Study on the Control Strategy of Gas Injection of Gas Engines

Ling, X. Z.
Shake Table Test on Seismic Response of Non-Free Liquefiable Site

Ling, Xianzhang
Case Studies for Shaking Table Tests on Seismic Soil-Pile Group-Bridge Structure Interaction in Liquefiable Ground
CT Scan on Frozen Roadbed Soil under Dynamic Triaxial Test Condition of Beilu River Section, Qinghai-Tibet Railway of China
Freeze-Thaw Stability of Slopes in Seasonally Frozen Regions of the Northeast China
Stability and Reinforcement Methods of a High Slope at the Hang-Yong Natural Gas Pipeline in China
Stability of Slope with the Weak Structural Plane Based on 2-D Nonlinear Finite Element Method
Vibration Characteristics of Permafrost Embankment Induced by Passing Trains in Qinghai-Tibet Railway in Winter
A New Cellular Automaton Traffic Flow Model for an Off-Ramp Junction of a Chinese Urban Expressway

Liu, B.
Research on the Competitiveness of China’s Ports
Mixed Traffic Micro-Simulation of Urban Branch Roads
Track Access Technology of Traffic Accident Vehicles Based on Video
Traffic Signal Control Optimization of Urban Arterials Based on a Method of Main Intersection Control Strategies

Liu, Baodong
Influencing Factor Analyses of Section Types on Vehicle-Bridge Interaction of Concrete Box Girder with Corrugated Steel Webs

Liu, Bin
The Application of TUXEDO Middleware in a Network-Based Train Working Diagram Compilation System

Liu, Bing
Enhancing Immersion through Adjusting Parameters of Vehicle Driving Simulator
Design Theory for Speed Control by Using Constant Edge Rate
The Reasonable Distance of Unsignalized Crosswalks Based on Traffic Flow, Stability, and Efficiency

Liu, Bo
Influence Factors Analysis of Buffeting Response of Self-Anchored Cable-Stayed

Suspension Bridge

Liu, Bohang
Reinforcement Learning Control for On-Ramp Metering Based on Traffic Simulation

Liu, C.
Research on the Competitiveness of China's Ports

Liu, Cong-hong
Study on the Green Traffic Planning System of New Rural Communities

Liu, D.
Detecting the Type of Multi-Fractality in Traffic Time Series

Liu, Dapeng
Analysis of the Competitive Strategy of the Core Enterprises in Virtual Intermodal Freight-Transportation Enterprise

Liu, Dewu
Risk Evaluation Model for Construction of a Logistics Park Based on Principal Component Analysis

Liu, Dong
Traffic Safety Evaluation of the 30 Provincial Capital in China Based on Principal Component Analysis

Liu, Fang
Investment and Financing Influence Analysis and Countermeasures for Highway Construction in the Period of China's 11th Five-Year Plan

Liu, G.
A Study of Vehicle and Materials Depot Location Problems for Winter Road Maintenance
A Study of Transit Evacuation Route Planning Based on Time-Expanded Network

Liu, Ganbin
Dynamic Effects of Moving Vehicular Loads on Continuously Reinforced Concrete Pavements on Winkler Foundation

Liu, Gui-wei
Mechanical Characteristics of Reinforced Gravity Oblique High U-Shaped Abutment

Liu, Han-bing
Experimental Research on the Mechanical Parameter of Fly Ash Soil
Sensitivity Analysis of the Dynamical Parameters on Road Materials

Liu, Han-Qing
The Application of Anti-Rutting Agent on Improving the High-Temperature Stability of Asphalt Pavement

Liu, Hao-zue
Risk Evaluation for Highway Transportation of "Toxic Gas" Hazardous Materials—Based on a Back Propogation (BP) Neural Network

Liu, Haopeng
Study of Hydrodynamic Pressure on the Cylindrical Pile-Cap Pier in Deep Water Subjected to Seismic Action

Liu, Hongbo
Study on the System Design and Optimal Models of Urban Rail Transit Traction Calculation System

Liu, Hongqi
Evaluation Study of the Median Markings in Undivided Highway Tunnels
Driving Simulation Study on Traffic Flow Characteristics on the Climbing Lane on a Two-Lane Rural Road

Liu, J.
Car-Following Criteria at a Signalized Intersection in Beijing

Liu, Jian-Yi
Choice of Reasonable Longitudinal Gradient at Alignments of Mountain Highways Based on Driver's Physiological Reactions
Impacts of Road Sight Distance on Safe Driving Conditions

Liu, Jiangtao
Modeling Passenger Choice Behavior in Chinese Multi-Airport Regions

Liu, Jianxia
Study on Power Control of Electric Power Steering System

Liu, Jianxin
Simulation and Analysis for Stick-Slip Vibration of Locomotive with Hollow-Shaft Drive System

Liu, Jianyi
Equilibrium Model of Trip Modes in Road Traffic and Orientation of Charge Policy
Optimization of Regional Traffic Structure from the Perspective of Sustainable Development

Liu, Jike
Parameter Sensitivity Analysis of Accident Reconstruction Model Based on Orthogonal Design

Liu, Jin-guang
The Research of Signal Phase Sequences Based on the Conglomeration of Pedestrians and Bicycles

Liu, Jing
Expressway Data De-Noised Approach Based on Wavelet Analysis

Liu, Jun
An Analytical Method for Predicting the Service Life of Bridge Structures

Liu, Kai-zheng
Risk Evaluation for Highway Transportation of "Toxic Gas" Hazardous Materials—Based on a Back Propogation (BP) Neural Network

Liu, Kai
A Google-Map Integrated Web-Based Stated Preference Survey for Modeling Personal Mobility

Liu, Kening
Study on Pedestrian Safety and Countermeasures in Crosswalks around Campus—Case Study at Ludong University in Yantai

Liu, Lan
Research on the Crashworthiness Optimization of Curved-Road Concrete Barriers

Liu, Lihua
Nonparametric Analysis of Timely Distribution of Traffic Crash

Liu, Linya
Track Structure Vibration Characteristic Analysis Based on FEM 3D Model

Liu, Ming
A Study on Spatial Correlation and Power Spectrum of Natural Wind at Xihoumen Bridge

Liu, Peng
Simulation of Turning Stability Control for Two-Motor-Drive Electric Vehicles

Liu, Qin
Study on a Passageway Location Model on Underground Expressway

Liu, Qing

A Study on Vehicle Trip Distribution Forecasting Based on BP Neural Network

Liu, Ruifen
