Contents

Volume I

Foreword and endorsement xi

Preface xiii

List of contributors xv

SECTION 1: Context 1
Section Editor: J. B. Burland and W. Powrie

Chapter 1: Introduction to Section 1 3
J. B. Burland and W. Powrie

Chapter 2: Foundations and other geotechnical elements in context – their role 5
J. B. Burland and T. Chapman

2.1 Geotechnical elements in the context of the rest of the whole structure 5
2.2 Key requirements for all geotechnical elements 6
2.3 Interaction with other professionals 6
2.4 Design lives for geotechnical elements 7
2.5 The geotechnical design and construction cycle 8
2.6 Common factors associated with geotechnical success 9
2.7 References 10

Chapter 3: A brief history of the development of geotechnical engineering 11
J. B. Burland

3.1 Introduction 11
3.2 Geotechnical engineering in the early 20th century 11
3.3 Terzaghi, father of geotechnical engineering 12
3.4 The impact of soil mechanics on structural and civil engineering 14
3.5 Conclusions 14
3.6 References 15

Chapter 4: The geotechnical triangle 17
J. B. Burland

4.1 Introduction 17
4.2 The ground profile 18
4.3 The measured or observed behaviour of the ground 18
4.4 Appropriate model 18
4.5 Empirical procedures and experience 19
4.6 Summary of the geotechnical triangle 19
4.7 Re-visiting the underground car park at the Palace of Westminster 19
4.8 Concluding remarks 26
4.9 References 26

Chapter 5: Structural and geotechnical modelling 27
J. B. Burland

5.1 Introduction 27
5.2 Structural modelling 27
5.3 Geotechnical modelling 29
5.4 Comparisons between structural and geotechnical modelling 30
5.5 Ground–structure interaction 31
5.6 Conclusions 33
5.7 References 33

Chapter 6: Computer analysis principles in geotechnical engineering 35
D. Potts and L. Zdravkovic

6.1 General 35
6.2 Theoretical classification of analysis methods 35
6.3 Closed form solutions 37
6.4 Classical methods of analysis 37
6.5 Numerical analysis 38
6.6 Overview of the finite element method 40
6.7 Element discretisation 40
6.8 Nonlinear finite element analysis 43
6.9 Modelling of structural members in plane strain analysis 50
6.10 Some pitfalls with the Mohr–Coulomb model 54
6.11 Summary 56
6.12 References 56

Chapter 7: Geotechnical risks and their context for the whole project 59
T. Chapman

7.1 Introduction 59
7.2 Motivation of developers 59
7.3 Government guidance on ‘optimism bias’ 61
7.4 Typical frequency and cost of ground-related problems 64
7.5 Expect the unexpected 65
7.6 Importance of site investigation 65
7.7 Costs and benefits of site investigation 67
7.8 Mitigation not contingency 68
7.9 Mitigation steps 68
7.10 Example 70
7.11 Conclusions 70
7.12 References 72

Chapter 8: Health and safety in geotechnical engineering 75
D. Ranner and T. Suckling

8.1 Introduction 75
8.2 An introduction to the legislation 75
8.3 Hazards 76
8.4 Risk assessment 79
8.5 References 80

Chapter 9: Foundation design decisions 83
A. S. O’Brien and J. B. Burland

9.1 Introduction 83

9.2 Foundation selection 83
9.3 A holistic approach to foundation engineering 87
9.4 Keeping the geotechnical triangle in balance – ground risk management 90
9.5 Foundation applications 96
9.6 Conclusions 103
9.7 References 104

Chapter 10: Codes and standards and their relevance **105**
T. Orr

10.1 Introduction 105
10.2 Statutory framework, objectives and status of codes and standards 105
10.3 Benefits of codes and standards 106
10.4 Development of codes and standards for geotechnical engineering 107
10.5 Why geotechnical and structural codes and standards differ 108
10.6 The geotechnical design triangle 111
10.7 Safety elements adopted in Eurocode 7 112
10.8 Relationship between the geotechnical design triangle and the geotechnical triangle 113
10.9 Codes and standards for geotechnical engineering 113
10.10 Conclusions 123
10.11 References 124

Chapter 11: Sustainable geotechnics **125**
H. Pantelidou, D. Nicholson and A. Gaba

11.1 Introduction 125
11.2 Sustainability objectives – background 125
11.3 Geotechnical sustainability themes 128
11.4 Sustainability in geotechnical practice 134
11.5 Summary 135
11.6 References 135

SECTION 2: Fundamental principles **137**
Section Editor: W. Powrie and J. B. Burland

Chapter 12: Introduction to Section 2 **139**
W. Powrie and J. B. Burland

Chapter 13: The ground profile and its genesis **141**
M. H. de Freitas

13.1 Overview 141
13.2 The ground profile 141
13.3 Importance of a profile 143
13.4 The formation of a profile 145
13.5 Investigating a profile 148
13.6 Joining profiles 150
13.7 Interpreting profiles 150
13.8 Conclusions 151
13.9 References 152

Chapter 14: Soils as particulate materials **153**
J. B. Burland

14.1 Introduction 153
14.2 Phase relationships 153
14.3 A simple base friction apparatus 154
14.4 Soil particles and their arrangements 156
14.5 The concept of effective stress in fully saturated soils 158
14.6 The mechanistic behaviour of unsaturated soils 160
14.7 Conclusions 161
14.8 References 161

Chapter 15: Groundwater profiles and effective stresses **163**
W. Powrie

15.1 Importance of pore pressure and effective stress profiles 163
15.2 Geostatic vertical total stress 163
15.3 Hydrostatic conditions for pore water pressures 163
15.4 Artesian conditions 164
15.5 Underdrainage 164
15.6 Conditions above the water table 165
15.7 *In-situ* horizontal effective stresses 165
15.8 Summary 165
15.9 References 166

Chapter 16: Groundwater flow **167**
W. Powrie

16.1 Darcy's Law 167
16.2 Hydraulic conductivity (permeability) 168
16.3 Calculation of simple flow regimes 169
16.4 More complex flow regimes 171
16.5 Groundwater control for stability of excavations 171
16.6 Transient flow 173
16.7 Summary 173
16.8 References 174

Chapter 17: Strength and deformation behaviour of soils **175**
J. B. Burland

17.1 Introduction 175
17.2 Analysis of stress 175
17.3 The drained strength of soils 177
17.4 The undrained strength of clay soils 181
17.5 The Mohr–Coulomb strength criterion 183
17.6 Choice of strength parameters for analysis and design 184
17.7 The compressibility of soils 184
17.8 The stress–strain behaviour of soils 186
17.9 Conclusions 191
17.10 References 193

Chapter 18: Rock behaviour **195**
D. J. Sanderson

18.1 Rocks 195
18.2 Classification of rocks 195
18.3 Rock composition 196
18.4 Porosity, saturation and unit weight 196
18.5 Stresses and loads 197
18.6 Rock rheology 197
18.7 Elasticity and rock stiffness 198
18.8 Poroelasticity 200
18.9 Failure and rock strength 200
18.10 Strength testing 202
18.11 Behaviour of discontinuities 203
18.12 Permeability 203
18.13 Fracture-controlled permeability 204
18.14 Rock mass characterisation 204
18.15 Rock tunnelling quality index, Q 205
18.16 Anisotropy 205
18.17 References 206

Chapter 19: Settlement and stress distributions **207**
J. B. Burland

19.1 Introduction 207
19.2 Total, undrained and consolidation settlement 207
19.3 Stress changes beneath loaded areas 208
19.4 Summary of methods of settlement prediction for clay soils 212
19.5 Elastic displacement theory 214
19.6 Theoretical accuracy of settlement predictions 216
19.7 Undrained settlement 218
19.8 Settlement on granular soils 218
19.9 Summary 219
19.10 References 220

Chapter 20: Earth pressure theory **221**
W. Powrie

20.1 Introduction 221
20.2 Simple active and passive limits 221
20.3 Effects of wall friction (adhesion) 224

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

20.4 In-service conditions 225
20.5 Summary 226
20.6 References 226

Chapter 21: Bearing capacity theory 227
W. Powrie

21.1 Introduction 227
21.2 Bearing capacity equation for vertical load – empirical adjustments for shape and depth 227
21.3 Inclined loading 228
21.4 Offset loading 229
21.5 Combined vertical, horizontal and moment (*V–H–M*) loading interaction diagram for a surface foundation 229
21.6 Summary 230
21.7 References 230

Chapter 22: Behaviour of single piles under vertical loads 231
J. B. Burland

22.1 Introduction 231
22.2 Basic load–settlement behaviour 231
22.3 Traditional approach to estimating the axial capacity of piles in clay 233
22.4 Shaft friction of piles in clay, in terms of effective stress 235
22.5 Piles in granular materials 241
22.6 Overall conclusions 244
22.7 References 245

Chapter 23: Slope stability 247
E. N. Bromhead

23.1 Factors affecting the stability and instability of natural and engineered slopes 247
23.2 Modes and types of failure commonly encountered 248
23.3 Methods of analysis for slopes, exploring their limitations of applicability 249
23.4 Rectification of unstable slopes 253
23.5 Factors of safety in slope engineering 255
23.6 Post-failure investigations 256
23.7 References 257

Chapter 24: Dynamic and seismic loading of soils 259
J. Priest

24.1 Introduction 259
24.2 Wave propagation in soil 260
24.3 Dynamic measurement techniques 261
24.4 Dynamic soil properties 262
24.5 Liquefaction of soils 266
24.6 Summary of key points 267
24.7 References 269

Chapter 25: The role of ground improvement 271
C. D. F. Rogers

25.1 Introduction 271
25.2 Understanding the ground 272
25.3 Removal of water 272
25.4 Improvement of soils by mechanical means 275
25.5 Improvement of soils by chemical means 277
25.6 References 280

Chapter 26: Building response to ground movements 281
J. B. Burland

26.1 Introduction 281
26.2 Definitions of ground and foundation movement 281
26.3 Classification of damage 282
26.4 Routine guides on limiting deformations of buildings 283
26.5 Concept of limiting tensile strain 284
26.6 Strains in simple rectangular beams 284
26.7 Ground movement due to tunnelling and excavation 287
26.8 Evaluation of risk of damage to buildings due to subsidence 292
26.9 Protective measures 294
26.10 Conclusions 295
26.11 References 295

Chapter 27: Geotechnical parameters and safety factors 297
J. B. Burland, T. Chapman, P. Morrison and S. Pennington

27.1 Introduction 297
27.2 Overall consideration of risk 299
27.3 Geotechnical parameters 300
27.4 Factors of safety, partial factors and design parameters 303
27.5 Concluding remark 306
27.6 References 306

SECTION 3: Problematic soils and their issues 309
Section Editor: I. Jefferson

Chapter 28: Introduction to Section 3 311
I. Jefferson

Chapter 29: Arid soils 313
A. C. D. Royal

29.1 Introduction 313
29.2 Arid climates 314
29.3 Geomorphology of arid soils and the effect of geomorphic processes on the geotechnical properties of arid soils 315
29.4 Aspects of the geotechnical behaviour of arid soils 329
29.5 Engineering in problematic arid soil conditions 333
29.6 Concluding comments 336
29.7 References 337

Chapter 30: Tropical soils 341
D. G. Toll

30.1 Introduction 341
30.2 Controls on the development of tropical soils 343
30.3 Engineering issues 347
30.4 Concluding remarks 358
30.5 References 359

Chapter 31: Glacial soils 363
B. Clarke

31.1 Introduction 363
31.2 Geological processes 363
31.3 Features of glacial soils 369
31.4 Geotechnical classification 373
31.5 Geotechnical properties 375
31.6 Routine investigations 383
31.7 Developing the ground model and design profile 383
31.8 Earthworks 386
31.9 Concluding comments 387
31.10 References 387

Chapter 32: Collapsible soils 391
I. Jefferson and C. D. F. Rogers

32.1 Introduction 391
32.2 Where are collapsible soils found? 392
32.3 What controls collapsible behaviour? 394
32.4 Investigation and assessment 398
32.5 Key engineering issues 403
32.6 Concluding remarks 407
32.7 References 407

Chapter 33: Expansive soils 413
L. D. Jones and I. Jefferson

33.1 What is an expansive soil? 413
33.2 Why are they problematic? 413
33.3 Where are expansive soils found? 414
33.4 Shrink–swell behaviour 416
33.5 Engineering issues 418
33.6 Conclusions 438
33.7 References 438

Chapter 34: Non-engineered fills 443
F. G. Bell, M. G. Culshaw and H. D. Skinner

34.1 Introduction 443
34.2 Problematic characteristics 443
34.3 Classification, mapping and description of artificial ground 444
34.4 Types of non-engineered fill 446
34.5 Conclusions 458
34.6 Acknowledgements 458
34.7 References 458

Chapter 35: Organics/peat soils 463
E. R. Farrell

35.1 Introduction 463
35.2 Nature of peats and organic soils 463
35.3 Characterisation of peats and organic soils 465
35.4 Compressibility of peats and organic soils 467
35.5 Shear strength of peats and organic soils 471
35.6 Critical design issues in peats and organic soils 473
35.7 Conclusions 476
35.8 References 477

Chapter 36: Mudrocks, clays and pyrite 481
M. A. Czerewko and J. C. Cripps

36.1 Introduction 481
36.2 Controls on mudrock behaviour 484
36.3 Engineering properties and performance 495
36.4 Engineering considerations 509
36.5 Conclusions 512
36.6 References and further reading 513

Chapter 37: Sulfate/acid soils 517
J. M. Reid

37.1 Introduction and key background information 517
37.2 Sulfur compounds in soils and rocks 518
37.3 Sampling and testing for sulfur compounds 523
37.4 Specific problems and how to assess them 526
37.5 Conclusions 531
37.6 References 531

Chapter 38: Soluble ground 533
T. Waltham

38.1 Introduction 533
38.2 Soluble ground and karst 533
38.3 Influences on the geohazard of limestone karst 534
38.4 Engineering works on soil-covered limestones 536
38.5 Engineering works on limestone bedrock 537
38.6 Ground investigation and assessment of karst 540
38.7 Geohazards on gypsum terrains 541
38.8 Geohazards in salt terrains 541
38.9 Karst geohazards on sabkha 543
38.10 Acknowledgements 544
38.11 References 544

SECTION 4: Site investigation 547
Section Editor: A. Bracegirdle

Chapter 39: Introduction to Section 4 549
A. Bracegirdle

Chapter 40: The ground as a hazard 551
J. A. Skipper

40.1 Introduction 551
40.2 Ground hazards in the UK 552
40.3 Predicting what the ground may have in store 553
40.4 Geological maps 553
40.5 Conclusions 554
40.6 References 554

Chapter 41: Man-made hazards and obstructions 555
J. Davis and C. Edmonds

41.1 Introduction 555
41.2 Mining 555
41.3 Contamination 562
41.4 Archaeology 562
41.5 Ordnance and unexploded ordnance (UXO) 563
41.6 Buried obstructions and structures 563
41.7 Services 564
41.8 References 564

Chapter 42: Roles and responsibilities 567
J. Cook

42.1 Introduction to site investigation guides 567
42.2 CDM regulations (2007), corporate manslaughter and health and safety 569
42.3 Corporate manslaughter 570
42.4 Health and safety 570
42.5 Conditions of engagement 570
42.6 When should a ground investigation be carried out? 571
42.7 Consultants and ground investigations 572
42.8 Underground services and utilities 574
42.9 Contamination 574
42.10 Footnote 575
42.11 Disclaimer 575
42.12 References 575

Chapter 43: Preliminary studies 577
V. Hope

43.1 Scope of this guidance 577
43.2 Why do a preliminary geotechnical study? 577
43.3 What goes into a preliminary geotechnical study? 578
43.4 Who should write a preliminary geotechnical study? 579
43.5 Who should read a preliminary study report? 579
43.6 How to get started: sources of information in the UK 579
43.7 Using the internet 581
43.8 The site walkover survey 581
43.9 Writing the report 582
43.10 Summary 582
43.11 References 582

Chapter 44: Planning, procurement and management 585
T. Chapman and A. Harwood

44.1 Overview 585
44.2 Planning the ground investigation 585
44.3 Procuring the site investigation 593
44.4 Managing the site investigation 598
44.5 References 600

Chapter 45: Geophysical exploration and remote sensing 601
J. M. Reynolds

45.1 Introduction 601
45.2 The role of geophysics 601
45.3 Surface geophysics 603
45.4 Potential field methods 604
45.5 Electrical methods 606
45.6 Electro magnetic (EM) methods 607
45.7 Seismic methods 609
45.8 Borehole geophysics 614
45.9 Remote sensing 614
45.10 References 618

Chapter 46: Ground exploration 619
J. Davis

46.1 Introduction 619
46.2 Techniques 619
46.3 Excavation techniques 619
46.4 Probing techniques 620
46.5 Drilling techniques 620
46.6 *In situ* testing in boreholes 623

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

46.7 Monitoring installations 624
46.8 Other considerations 626
46.9 Standards 626
46.10 References 627

Chapter 47: Field geotechnical testing 629
J. J. M. Powell and C. R. I. Clayton

47.1 Introduction 629
47.2 Penetration testing 630
47.3 Loading and shear tests 640
47.4 Groundwater testing 648
47.5 References 650

Chapter 48: Geo-environmental testing 653
N. Langdon, C. Lee and J. Strange

48.1 Introduction 653
48.2 Philosophy 653
48.3 Sampling 654
48.4 Testing methods 656
48.5 Data processing 659
48.6 Quality assurance 661
48.7 References 663

Chapter 49: Sampling and laboratory testing 667
C. S. Russell

49.1 Introduction 667
49.2 Construction design requirements for sampling and testing 667
49.3 The parameters and associated test types 668
49.4 Index tests 668
49.5 Strength 670
49.6 Stiffness 674
49.7 Compressibility 677
49.8 Permeability 679
49.9 Non-standard and dynamic tests 679
49.10 Test certificates and results 680
49.11 Sampling methods 681
49.12 Bulk samples 681
49.13 Block samples 682
49.14 Tube samples 682
49.15 Rotary core samples 684
49.16 Transport 685
49.17 The testing laboratory 685
49.18 References 686

Chapter 50: Geotechnical reporting 689
H. Scholes and P. Smith

50.1 Factual reporting 689
50.2 Electronic data 693
50.3 Interpretative reporting 695
50.4 Other geotechnical reports 695
50.5 Reporting production and timescale 696

Foreword and endorsement

The civil engineering sector represents some of the best professionalism, foresight and talent of any profession and this hard won reputation has been built up over decades. This ICE Manual series helps the profession maintain this position through the provision of coherent and authoritative frameworks for the modern civil engineer.

The importance of geotechnical engineering cannot be underestimated. It has a critical role to play in almost all major infrastructure projects being carried out across the world today.

The challenges are significant to deliver projects with the lowest carbon output and value for money. Promoting and developing our understanding of the impact of earth materials on engineering schemes will be crucial if we are to deliver safe, sustainable and economic answers to these challenges.

In bringing together often fragmented sources in a single document for civil engineers ICE Publishing is providing an excellent service for the professional and their projects in the interest of society. I commend the publication of this work and look forward to future editions.

Richard Coackley BSc CEng FICE CWEM FCIWEM
ICE President 2011-2012

It is several centuries since the *Magistri Ludi* were respected for understanding known science. It is several decades since individuals could be compared to the *Magistri* in the broad field of geotechnical engineering. So the *ICE Manual of Geotechnical Engineering*, as conceived here, has a dual function: to aid the specialist practitioners in areas where they are less experienced and to guide the non-specialists in their approach to problems. It fulfils this role commendably.

Rab Fernie Eur Ing BSc CEng FICE FIHT FGS
Chairman, British Geotechnical Association

Preface

We began to formulate the initial ideas for this Manual as early as 2006. It had become apparent to us that civil and structural engineers not specialising in geotechnics face a daunting knowledge gap when they come up against a geotechnical problem. Most civil engineers leave university with very little grounding in geotechnical engineering. They will have a fair grasp of applied mechanics (mainly aimed at structural engineering). They will have had a basic introduction to geology and they will have studied the elements of soil mechanics and rock mechanics. But a recent graduate usually lacks a coherent understanding of the approach to, and methods of, geotechnical engineering and how these differ from other more widely practised branches of engineering. A survey carried out by ICE Publishing showed that information tends to be obtained from a wide range of sources through word of mouth, the internet and various publications. For the young practitioner this leads to a fragmented approach. Much of the geotechnical material is written by specialists for specialists and its *ad hoc* application by a general practitioner is often inappropriate and can be extremely dangerous. We felt that it would be of great benefit to our profession to provide a single first-port-of-call authoritative reference source aimed at informing the less experienced engineer. To our delight this concept was endorsed by the ICE Best Practice Panel and the British Geotechnical Association and has offered a unique opportunity to provide authoritative guidance within a coherent framework of good geotechnical engineering.

This *ICE Manual of Geotechnical Engineering* has been a labour of love! The contribution of 99 contributors and 10 section editors has made it possible to distil a great deal of experience from the profession into the books you see here. Don't imagine this will cover everything that a geotechnical engineer will face in their career – but it provides a "starting point" from which to build experience whilst remaining grounded in robust fundamentals.

As mentioned previously, the Manual is aimed at people in the early stage of their careers who need a readily accessible source of information when working in new aspects of geotechnical engineering. However it is expected that it also should prove valuable to all geotechnical engineering professionals. The aim has been to produce a manual that addresses the practice of geotechnical engineering in the 21st century including contemporary procurement, process and design standards and procedures. The grouping of chapters has been carefully chosen to facilitate a multi-disciplinary and holistic approach to the solution of construction challenges. A key message is the importance of drawing on "well-winnowed experience" for the smooth and reliable execution of projects. Such experience is best gained by working closely with a suitably experienced design or construction team.

It is hoped that this Manual will help in the training and development of the next generation of geotechnical engineers and will act as a useful source of reference to those with more experience.

The Editors are grateful to all those contributors and section editors who have generously given so much of their time and knowledge in producing such a comprehensive book.

Section 1: Context

Section editor: **John B. Burland and William Powrie**

doi: 10.1680/moge.57074.0001

Chapter 1

Introduction to Section 1

John B. Burland Imperial College London, UK
William Powrie Imperial College London, UK

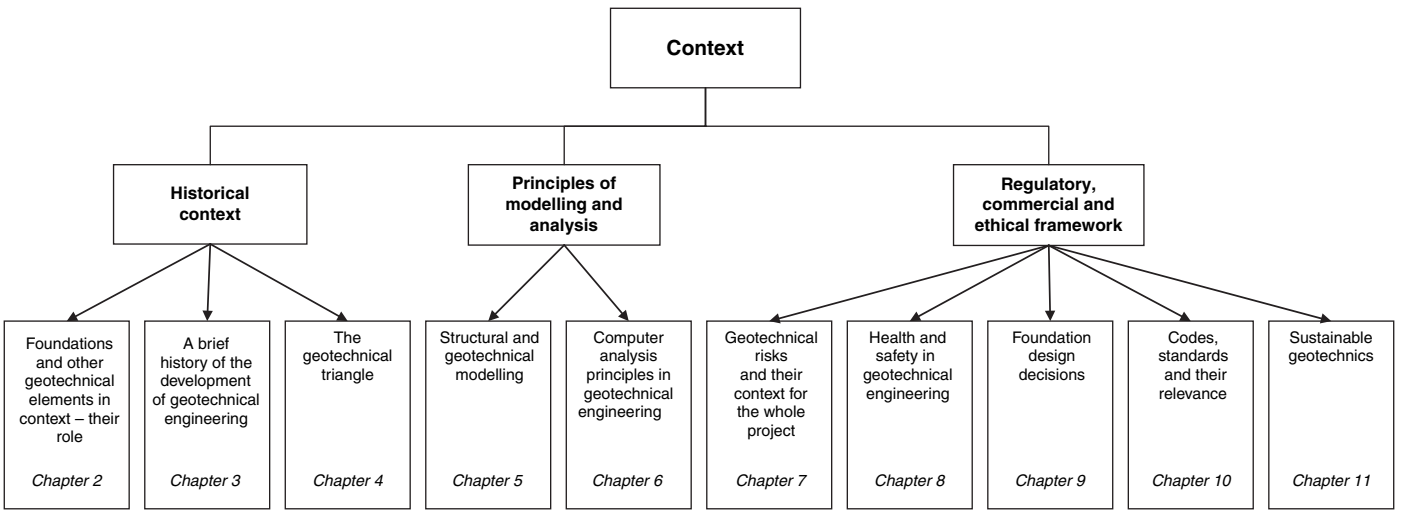

Figure 1.1 Layout of chapters in Section 1

Figure 1.1 outlines the layout and contents of Section 1 *Context*.

The first three parts of the section address the development of soil mechanics and geotechnical engineering as a distinct discipline over the past 80 years or so. Chapter 2 *Foundations and other geotechnical elements in context - their role* explains the importance of foundations and structures built in or of the ground within civil engineering and construction, and the need for a formal and holistic geotechnical engineering design process. Chapter 3 *A brief history of the development of geotechnical engineering* gives a history of the development of geotechnical engineering at the borderline between science and art, with the latter defined by Terzaghi in 1957 as a 'mental processes leading to satisfactory results without the assistance of step-for-step logical reasoning'. This is reflected in the 'geotechnical triangle', described in Chapter 4 *The geotechnical triangle*, which emphasises the essential elements of successful geotechnical engineering as understanding the ground, material properties and relevant precedence (well-winnowed experience), connected by an appropriate model for analysis.

Chapters 5 *Structural and geotechnical modelling* and 6 *Computer analysis principles in geotechnical engineering* address some important principles of modelling and analysis in geotechnical engineering. Particular attention is paid in Chapter 6 *Computer analysis principles in geotechnical engineering* to computer methods, for which it is essential that an engineer has a sound understanding of the basis of the method of analysis, the influence of the material properties used, and the shortcomings and limitations of the approach.

Finally, Chapters 7 *Geotechnical risks and their context for the whole project* to 11 *Sustainable geotechnics* discuss key aspects of the regulatory, commercial and ethical framework with which geotechnical engineering practice must comply, now and into the future. Chapter 9 *Foundation design decisions* emphasises that foundation engineering is a 'process' involving a number of interlinked operations, and design decisions need to take account of this. The other chapters address understanding and apportioning geotechnical risk within a whole project context (Chapter 7 *Geotechnical risks and their context for the whole project*); health and safety (Chapter 8 *Health and safety*

in geotechnical engineering); current standards and codes of practice (Chapter 10 *Codes, standards and their relevance*); and sustainability (Chapter 11 *Sustainable geotechnics*). These issues are especially important, given that the place occupied by geotechnical engineering at the borderline between science and art means that risks are often more difficult to foresee and quantify than other areas of civil engineering, and the discipline does not lend itself to highly detailed codes of practice.

2.7	References	10

The purpose of this chapter is to describe the basic principles of geotechnical design and construction in the context of the whole project. At a given site the ground conditions have resulted from millions of years of natural geological processes (which are seldom simple) and have sometimes been modified by humans, e.g. by mining or many other processes. As a consequence there are always inherent uncertainties and risks, and the art of geotechnical engineering is to make informed allowance for these, in both design and construction. The key requirements for all geotechnical elements of a project are described. Emphasis is placed on the importance of constructive and positive interaction with professionals engaged in the many other contributing disciplines. The design life of the geotechnical elements is considered and the important concept of the geotechnical design and construction cycle is introduced. Various managerial approaches to identifying the key elements of the complete design and construction process are described. The chapter concludes with a summary of the factors common to most geotechnical design and construction projects that are necessary for a successful outcome.

2.1 Geotechnical elements in the context of the rest of the whole structure

All built structures touch the ground in some way and hence all need some form of foundation. Other geotechnical elements include retaining walls and ground anchors. Sometimes they can be shallow, e.g. pad footings or gravity retaining walls; other times they are deep, such as piles or embedded retaining walls. Often they rely on geotechnical processes such as ground improvement to produce a geotechnical element.

All foundations and other geotechnical elements have a number of characteristics that distinguish them from other parts of the structures that they support:

- they tend to be amongst the most heavily loaded elements in any structure;
- their installation process is less amenable to factory-style production;
- their capacity is very dependent on the ground of the site, which is always characterised by few observations and tests, and is normally very heterogeneous and may contain hazards that are difficult to foresee;
- their capacity is strongly influenced by the method of construction and how well it is controlled.

Hence, the risk of failure tends to be significantly higher than that for other parts of the structure. The management of ground uncertainty is an important part of the design and construction process in order to produce elements that have the required degree of reliability.

A vital consideration in geotechnical design is the interaction of the structural element that is inserted into the ground with the ground itself – so-called 'soil–structure interaction'. Structural loads are applied to the element and the ground resists – generally either by friction along the element, or by bearing of the element against the ground. Both these resistances can occur vertically or horizontally, as shown in **Figure 2.1**. Normally ground stresses are maintained within failure limits, so the resulting displacements depend on the stiffness of both the element and the ground.

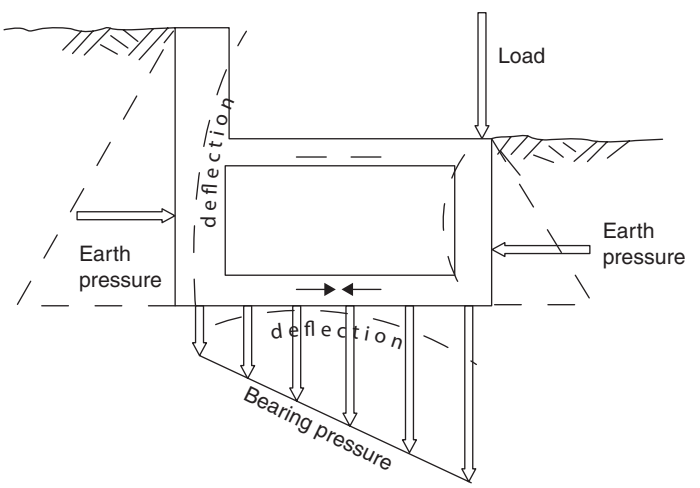

Figure 2.1 Soil–structure interaction

Loads can be imparted into foundations directly, as vertical or horizontal loads, or as imposed bending moments. They can also be imposed indirectly as displacements, which induce loads into the structural parts of the foundation. Eurocode 7 (BS EN 1997) (British Standards Institution, 2004, 2007b) treats these in a similar way by introducing the Newtonian concept of an 'action'.

Geotechnical elements are characterised by much higher degrees of uncertainty than other structural elements. The uncertainty is derived from the following:

- The inevitable significant assumptions and idealisations that underlie the overall geotechnical design.
- Natural variability in the ground being modelled, often manifested by vast scatter in data points on graphs.
- Inherent variability in the construction processes, and their control, that are used to install the geotechnical elements and foundations, which may also have a profound effect on their eventual performance in service.
- Usual variability in the applied loads transmitted through a normally highly structurally indeterminate construction meaning that the actual loads on each foundation may be very uncertain.
- There is always the possibility of the construction and performance being heavily influenced by an unexpected feature of a site, for example a major geological discontinuity such as a sinkhole or a fault. It is not unusual for major construction problems to arise owing to adverse groundwater conditions.

All of these uncertainties mean that engineers who presume that their calculations are precise and predictable are deluded and may expose themselves to much more onerous load combinations than they could imagine. The wise geotechnical engineer should be humble and make prudent allowances for uncertainty. This is explained in more detail in Chapter 7 *Geotechnical risks and their context for the whole project*.

2.2 Key requirements for all geotechnical elements

2.2.1 General

All foundations or other geotechnical elements must fulfil a number of essential criteria as listed below.

- They must not fail, or else the structure they support will also fail. In terms of limit state design, failure by any mode is termed reaching or exceeding an 'ultimate' limit state, and may involve failure of a structural element or rupture along a soil–structure or a soil–soil interface.
- They must not move excessively or else the structure they support may become impaired or fail to operate as intended. In terms of limit state design, excessive deflection involves breaching a 'serviceability' limit state.
- They must last for as long as intended. Unlike many other building elements, foundations are hugely difficult to upgrade or repair and so their longevity will often dictate the life of the structure that they support.

2.2.2 Ultimate limit state modes of failure

There is a range of ways in which geotechnical structures can fail an ultimate limit state, and these are shown in **Figure 2.2**.

2.2.3 Serviceability limit state and displacements

Failure of a serviceability limit state is usually less serious than failure of an ultimate limit state and is often repairable. It usually occurs when excessive displacements have taken place that impair the function of the structure. In addition to excessive movement, it also includes other forms of unacceptable tolerances, such as moisture penetration into basements. Examples are illustrated in **Figure 2.2**.

2.2.4 Design life and modes of deterioration

Design lives are covered in more detail in section 2.4. Other than failures of a limit state, the life of a structure can be reached when:

- it has become affected by material deterioration processes, such as corrosion of steel, carbonation of concrete or rotting or insect infestation of timber;
- it has been subjected to physical processes, such as repeated loading cycles causing fatigue, or excessive damage from impacts;
- it fails to meet new design or material standards and so offers a less than acceptable level of resistance against load, corrosion, etc.

2.3 Interaction with other professionals

2.3.1 General

The geotechnical engineer is seldom the professional solely in charge of a complete project – almost invariably the function sought of a new structure or facility goes beyond merely geotechnical considerations. Therefore, the role of a geotechnical engineer should be to support the wider design and construction process. He or she is likely to have most influence if the

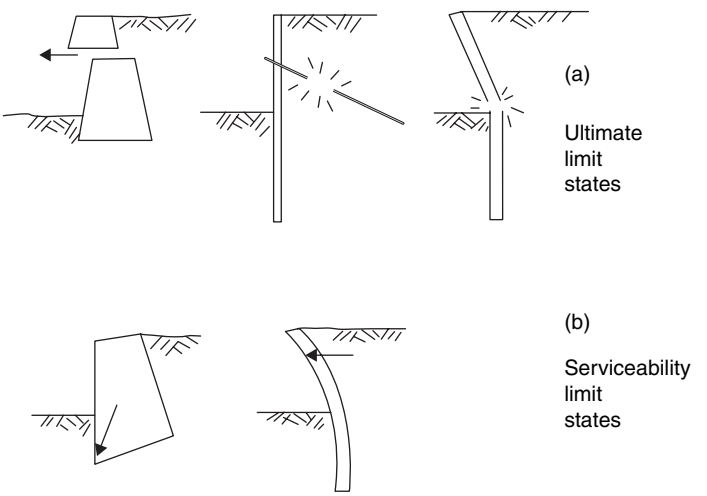

Figure 2.2 Limit state failures (BS EN 1997) (British Standards Institution, 2004, 2007b)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

input complements the work of other professionals rather than seeking to dominate or failing to engage.

2.3.2 General construction process

All project programmes involve controlled phases of input so that the optimum solution is devised with mutually consistent input from all members of the project team, through design procurement, implementation and commissioning. Once commissioned there is a need for maintenance, upgrades and repairs through the working life of the structure and finally decommissioning and sometimes re-use of the original elements in a fresh structure.

Client Best Practice Guide (Institution of Civil Engineers, 2009) provides a generalised approach for such inputs, based on the systems used for buildings (Royal Institute of British Architects, 2009) and the rail industry (Network Rail, 2010; previously known as *Guide to Railway Investment Projects*), as well as guidance from the UK's former Office of Government Commerce (OGC) (now part of the Cabinet Office Efficiency and Reform Group). More detail on these processes is given in section 2.5.

In the early stages, there will be little certainty about the optimum solution and many competing options will be considered and dismissed, often for reasons not obvious to individual members of the technical team. The design team can contribute best to this process if they understand the required function and client's business drivers for the new structure or facility.

The early stages are also the period when it is easiest for the project to take on board geotechnical constraints and design and construction requirements. Hence, the geotechnical engineer is likely to have most success in integrating these requirements into the rest of the structure if they are identified early on, although this will often be in advance of the acquisition of data and completion of analyses. Therefore, experienced geotechnical input is valuable in these early stages and will often lead to a better solution, simpler design and construction processes, and less costly subsequent geotechnical involvement.

The work of the geotechnical engineer is seldom complete in isolation. Normally there is much interaction with structural engineers. Sometimes the work of the geotechnical engineer is subsumed beneath that of the structural engineer. For simple structures, this may be appropriate and sufficient, but for more complex geotechnical structures, or where the ground conditions are complex, it is likely that the geotechnical engineer will be better able to explain the particular issues directly to other members of the design team.

2.4 Design lives for geotechnical elements

Relevant design lives for structures are defined in Eurocode 0 (BS EN 1990) *Basis of Structural Design* (British Standards Institution, 2005) and are generally distinguished according to whether the structure is a building or a piece of infrastructure. In its Table 2.1, it defines design life categories as follows:

- Category 1 – Temporary structures, not including structures or parts of structures that can be dismantled with a view to being re-used – 10 years.
- Category 2 – Replaceable structural parts, e.g. gantry girders, bearings – 10–25 years (The UK National Annex to BS EN 1990:2002 modifies this to 10–30 years).
- Category 3 – Agricultural and similar buildings – 15–30 years (modified in the UK to 15–25 years).
- Category 4 – Building structures and other common structures – 50 years.
- Category 5 – Monumental building structures, bridges and other civil engineering structures – 100 years (currently modified in the UK to 120 years to bring it into line with traditional Highways Agency bridge design life; it is possible that the UK may revert back to 100 years if the Highways Agency changes their guidance).

As foundations are difficult to repair or upgrade and as most structures last for longer than the period for which they were designed, allowing for a longer life is prudent.

Foundations are difficult and expensive to remove and so some consideration should be given to what will occur after the life expiry of the structure they support. This was addressed by the RuFUS (Reuse of Foundations on Urban Sites) project (see Butcher *et al*. (2006) and Chapman *et al*. (2007)). Where it is likely that a new structure with new foundations could become a major obstruction, the potential for future development of the site may be inhibited.

To prevent abandoned foundations from becoming an insidious form of ground contamination, the RuFUS project advocated that all foundations should be designed with the intention of allowing subsequent re-use. This mainly relates to the recording and saving of records so that the old foundations can be assessed by the future design team.

While most foundation and geotechnical elements are provided for 'permanent' elements that are required to persist for a normal structural life, sometimes foundations are required for shorter periods. These include:

- Interim structures, required for a significant life, perhaps 10 years.
- Contractor's 'temporary' works – structures that fulfil a temporary function during construction of a more significant structure, e.g. thrust blocks, crane bases. Sometimes a life of 1–2 years is specified. For these, Eurocode 7 Part 1 (BS EN 1997-1:2004; British Standards Institution, 2004) Clause 2.4.7.1 (5) states 'Less severe values than those recommended in Annex A [for partial factors] may be used for temporary structures or transient design situations, where the likely consequences justify it'.
- Demountable structures, such as scaffolding or temporary stands as may be required at sport or music venues, where a life of only perhaps weeks is required. The Institution of Structural Engineers (2007) guide, *Temporary Demountable Structures*, defines typical foundation concerns for such structures.

Design life can influence choice of factor of safety. However, it needs to be considered with the following points.

- The frequency with which the most onerous design load combination occurs – if it is very infrequent compared with the design life, some reduction in margin against failure may be possible.

This may occur with 1-in-100-year wind or flood events or with 1-in-475-year seismic events.

- The consequences of failure – where the consequences are mild and do not threaten safety, then a lower factor may be permissible provided the economic consequences are judged and agreed as acceptable.

The design life also to some extent governs the measures required to limit deterioration of the foundation materials. Conventional structural design codes such as Eurocodes 2 (BS EN 1992; British Standards Institution, 2006) and 3 (BS EN 1993; British Standards Institution, 2007a) contain implicit requirements to ensure longevity of foundations; principally, crack width criteria for reinforced concrete, intended to limit the intrusion of air and water which then can come into contact with the reinforcing steel, and whose effect can be exacerbated by the presence of chloride ions from salt. Where potential corrosion processes will be slow compared with the foundation design life, it may be possible to relax these structural requirements for structures intended to have short lives, provided that code non-compliance is acceptable to the owner and any approver.

Temporary structures may sometimes have less onerous movement limits. Their nature may mean that larger movements are easy to accommodate; for instance, in temporary stands where shims and jacks can be used to compensate for differential foundation movements or where there are no rigid finishes that make obvious the effects of differential settlements.

2.5 The geotechnical design and construction cycle

Geotechnical design should be carried out in conjunction with the design of the whole structure, as explained in section 2.1. Geotechnical design must always be carried out considering the source of the data and how the design will be implemented, with all three parts of this process being inextricably linked as illustrated in **Figure 2.3**.

2.5.1 Project phases

All construction projects go through a number of distinct phases:

- planning;
- development;
- implementation;
- operation;
- decommissioning.

A number of organisations have devised 'stages' (e.g. RIBA, 2009) or 'gateways' (Office of Government Commerce, UK) and have further sub-divided projects to suit these. Those work stages identified by RIBA (A to L, see **Figure 2.4**) as most commonly used in general design and construction are used here. Various stages/divisions are shown in **Figure 2.4**. The types of input needed at each stage are shown in **Figure 2.5**.

The modes of input needed at each stage are different. During the *planning* phase, input tends to be strategic and predominantly consultative – usually senior experienced input is needed to guide the project away from the more common pitfalls or significant hazards. By the end of this phase, the design should have progressed close to the stage of a single preferred option having been identified.

In the *development* phase, the design issues are resolved and all disciplines should produce a single coherent and coordinated output. In the latter stages, tender documents are produced which clearly describe the works to be undertaken on site. A design freeze is needed relatively early in this phase

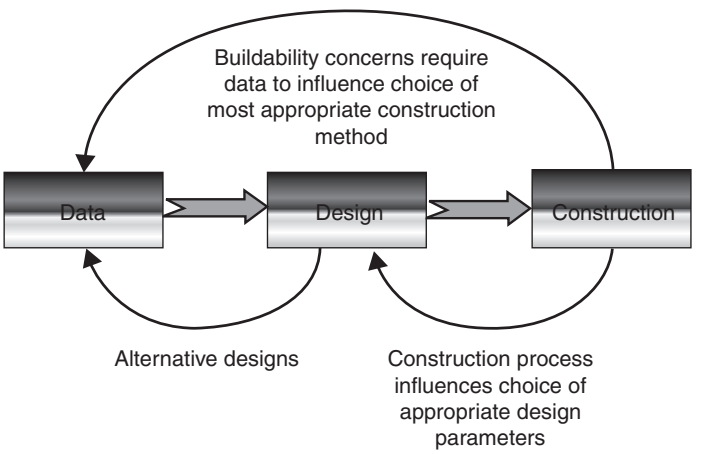

Figure 2.3 The geotechnical design and construction cycle

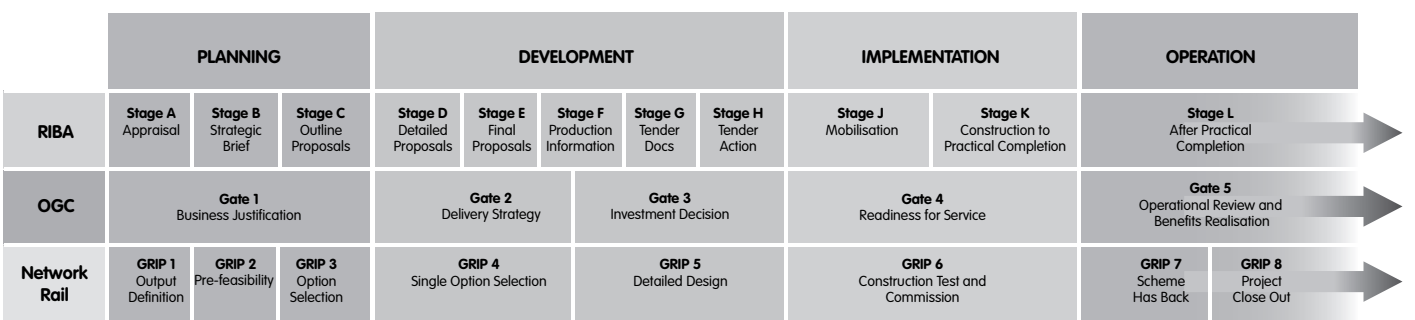

Figure 2.4 The work stages, *RIBA, OGC and NWR*
Reproduced from Institution of Civil Engineers (2009)

(end of RIBA Stage E 'final proposals') so that in subsequent stages coherent documents for tender and construction can be produced. The importance of a proper design freeze cannot be underestimated, as continued changes to the design jeopardise the production of an integrated and mutually consistent set of contract documents.

2.5.2 Importance of clarity in tender process

In RIBA stages F 'product information' to H 'tender action', the tender documents are produced and the contract is let. In these stages, the client becomes committed to investing in the whole of the project; therefore, at this stage clients need to be confident that:

- the investment decision criteria remain valid;
- they have funding;
- they are content that the project has been organised to run smoothly.

This is a key time for geotechnical input; many well-designed projects rush production of the tender documents and do not adequately communicate:

- the design intent and constraints;
- the inherent risks and means for allocating responsibility for those (including those under Construction (Design and Management) Regulations 2007).

2.5.3 Construction control

Unusual geotechnical construction processes need knowledgeable control, both for the contractor and for the client, the latter sometimes provided by a resident engineer or individual with similar technical understanding.

The observational method (see Nicholson *et al.*, 1999 (CIRIA R185) and Chapter 100 *Observational method*) can be an excellent way to build efficiently. Use of the observational method can be used to create something that conventional factors of safety may rule out. However, there must be well-founded evidence and experience that those factors would be inappropriately conservative. The observational method has been used most successfully for deep excavation in stiff clays where stability is controlled by slow dissipation of pore pressures, something that is difficult to rely on, but which can be monitored and managed by a well-trained and dedicated team.

2.6 Common factors associated with geotechnical success

The following factors are associated with successful projects and, conversely, absence of these factors is correlated with an increased frequency of failures.

- **Planning**
- good desk study to identify key hazards appropriate for the planned development – no skimping, e.g. historical map coverage extends back to first significant site occupation;
- gather constraint/hazard data early and present them clearly;
- address the likely construction issues in the ground investigation.
- **Development**
- beware trimming of important parts of the design service to save money, particularly the omission of knowledgeable input;
- choose foundation type to explicitly reduce risks, e.g. avoid bored piles in silty soil;

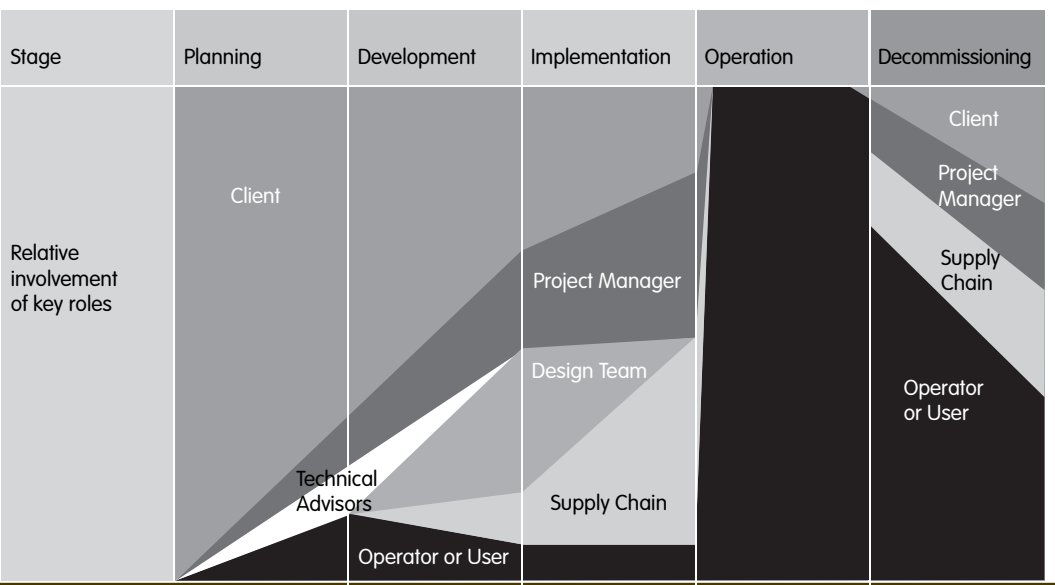

Figure 2.5 Input required at each stage of a project's lifecycle
Reproduced from Institution of Civil Engineers (2009) (after Martin Barnes)

- consider buildability as a critical element of the design process;
- ensure continuity of process ideally by the same capable individuals;
- be clear on responsibilities, especially at gaps where responsibilities are divided or can be confused;
- beware of designs based on optimistic assessment of parameters based on inappropriate extrapolation of test results;
- bring experience to bear early to identify the likely key design issues that affect other members of the design team, for instance space-proofing with the architect and structural engineer;
- watch water-proofing measures for basements, a frequent source of client disappointment;
- ensure designers understand key assumptions from the analysis process and that contractors understand key assumptions from the design process.
- **Implementation**
- produce clear specifications highlighting important issues and communicating the design intent.

In general, beware overconfidence and adopt humility – consider the occurrence of the unexpected and don't rely on everything happening as planned. There is the well known story told of the famous tunnelling engineer Sir Harold Harding who, on being informed of an overconfident young graduate in the design office, growled 'Bring him to me and I will put him down a big hole in the ground and teach him humility'.

Chapter 3

A brief history of the development of geotechnical engineering

John B. Burland Imperial College London, UK

CONTENTS

3.1	Introduction	11
3.2	Geotechnical engineering in the early 20th century	11
3.3	Terzaghi, father of geotechnical engineering	12
3.4	The impact of soil mechanics on structural and civil engineering	14
3.5	Conclusions	14
3.6	References	15

This chapter traces the development of the craft and science of foundation engineering from early history to the recent past. The story is told of how Terzaghi struggled to couple engineering geology with the science of soil mechanics so as to provide the necessary rigour for modern geotechnical modelling and analysis. These lessons from the past are very important and a major aim of this manual is to provide the framework and knowledge necessary for sound geotechnical design and construction.

3.1 Introduction

Foundation engineering is as old as the art of building and, like building, it developed largely on the basis of accumulated experience and empirical procedures. Because ground conditions vary so much from one locality to another, foundation practice varied widely. Moreover, the extrapolation of experience from one locality to another was fraught with uncertainty.

Parry (2004) describes how the ancient Egyptians learned from the foundation failure of the South Dahshur Pyramid. This was built during the reign of Pharaoh Snofru (2575–2551 BC) using a central core supported by a series of inclined buttress walls, as had become the tradition. The pyramid was founded on a clay layer. Large differential foundation movements resulted in significant structural distress in the tomb chambers and their access passages. As a result the pyramid was finished off so that the upper portions have a considerably reduced slope, giving rise to the structure being named the 'Bent Pyramid'. Abandoning the concept of buttress walls, future pyramids were built tier by tier, each tier consisting of a single layer of blocks of uniform thickness across the full width of the structure. Greater care was also taken in dressing and placing the blocks.

Kerisel (1987) describes how in Mesopotamia, over a period of three millennia, the art of building ziggurats was developed, in most cases on very weak alluvial soils. Because of the scarcity of stone these high massive structures were made of sun-baked bricks laid out in successive courses. As construction proceeded the underlying alluvium soon yielded under the weight causing the base to spread laterally. Work progressed very slowly with long pauses in between so that little by little the rate of settlement and spreading diminished. Eventually it was possible to build a small temple at the top (**Figure 3.1**). Around 2100 BC the Sumerians began to place thick layers of woven reeds between every six to eight courses of sun-dried brickwork. In this way the horizontal tensions caused by the tendency of the foundations to spread were resisted. As a result ziggurats could be built with nearly sheer sides and massive temples on top. This innovation is often cited as the earliest example of reinforced earth.

Two early examples of successful foundation engineering in China are given by Kerisel (1987). The elegant early 7th century Zhaozhou (otherwise known as Anji) Bridge (**Figures 3.2** and **3.3**) is founded on clay, which was treated by digging it out beneath the abutments and recompacting it in layers interspersed with compacted layers of broken bricks. The late 10th century 44 m high Pagoda of Longhua is founded on a thick layer of soft clay extending to a depth of about 30 m. The foundations are of brick laid on a wooden raft, which in turn rests on wooden piles driven at very close spacing – perhaps one of the earliest examples of a piled raft. The foundations remain unchanged since they were constructed over 1000 years ago.

3.2 Geotechnical engineering in the early 20th century

It is not widely appreciated what a parlous state ground engineering was in, prior to Terzaghi's contributions. Recently, as part of its centenary celebrations, the author was given the interesting task of tracing the development of foundation engineering over the last 100 years through the papers published in *The Structural Engineer* (Burland, 2008). Many of the early papers describe various techniques of foundation construction such as piles, sheet pile wall sections, coffer dams and caissons. But these papers make little reference to the mechanical properties of the ground and how its response can be assessed. For example Brooke-Bradley (1932–34) states that:

> If the bearing power of sub-soil should prove to be inadequate to carry the proposed loads, it must be artificially strengthened.

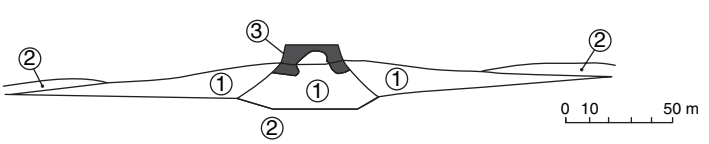

Figure 3.1 Construction of an early ziggurat. (1) Fill, (2) soft alluvium, (3) temenos – sacred enclosure
Reproduced from Kerisel (1987); Taylor & Francis Group

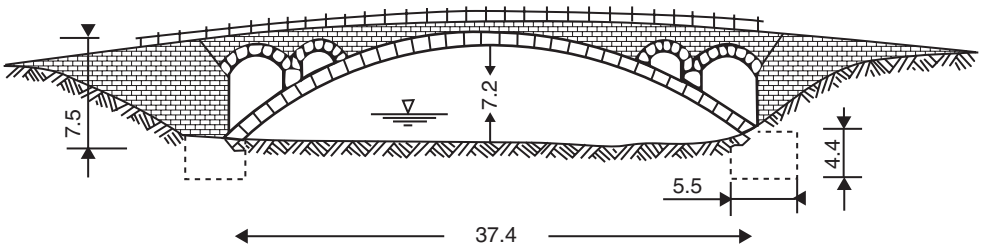

Figure 3.2 Zhaozhou Bridge – early 7th century
Reproduced from Kerisel (1987); Taylor & Francis Group

Figure 3.3 Zhaozhou Bridge

Methods of doing this are then described together with the various types of piles available for this purpose. Nowhere does one find how the 'bearing power' of the ground can be assessed in the first place. It is also stated that 'all settlement should be avoided if possible'; examples are given of damaging settlement but no guidance is given on how it could be estimated.

In the early issues of *The Structural Engineer* some space is given to the design and construction of retaining walls. In 1915 Wentworth-Shields wrote a paper on 'The stability of quay walls on earth foundations' (Wentworth-Shields, 1915). He opens with the following memorable statement:

> In spite of the large amount of experience which has been gained in the construction of quay walls, it is still one of the most difficult problems in engineering to design a wall on an earth foundation with confidence that it will be stable when completed. … Even if the designer of such a wall is assured that it will stand, he cannot with any confidence tell you what factor of safety it possesses.

In 1928 Moncrieff published a major paper in *The Structural Engineer* (Moncrieff, 1928) on earth pressure theories in relation to engineering practice. He summarises the various approaches to calculating earth pressures from Coulomb (1773) through to Bell (1915). At that time the angle of friction was generally equated with the angle of repose and Moncrieff refers to the difficulty of determining this angle for clayey soils. He cites a cutting in clay in which the side slopes varied from vertical to 1 vertical in 1½ horizontal while in places the clay was 'running down like porridge'.

It is all too clear from these early papers that, in spite of significant, even heroic, engineering achievements in the construction of major foundations, retaining structures, tunnels and dams, there was little understanding of the factors that control the mechanical behaviour of soil in terms of its strength and stiffness. Moreover, there is almost no reference to the influence of ground water on strength, stability or earth pressures. It is hardly surprising that there were frequent failures, particularly of slopes and retaining walls. This was the muddle that Terzaghi found when he first began to practise as a civil engineer.

3.3 Terzaghi, father of geotechnical engineering

Because of his work in developing the scientific and theoretical framework of soil mechanics and foundation engineering, Terzaghi is often regarded as essentially a theoretician. Nothing could be further from the truth. It is, therefore, worth reflecting on Terzaghi's struggles to develop the craft and the science of ground engineering for they have relevance in both the teaching and the practice of the discipline.

Goodman (1999) has written a most illuminating and thoroughly researched narrative of Terzaghi's life, *Engineer as Artist*. Terzaghi was born in Prague in 1883. He showed an early interest in geography, especially field exploration, and later astronomy. which evolved into a passion for mathematics. Later at school he was inspired by the natural sciences and performed brilliantly.

3.3.1 Terzaghi's education

He went on to read mechanical engineering at the Technical University of Graz. For a time he lost his way, engaging in drinking and duelling. He found the lectures were simply a set of prescriptions, which he claimed he could read for himself. Ferdinand Wittenbauer, a wise teacher, challenged Terzaghi to do better and go back to the original sources – in particular Lagrange's *Analytical Mechanics* (Lagrange, 2001).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Wittenbauer led Terzaghi gently on, guiding him not only into the excitement of scientific creativity but also in the very real social and cultural issues of the day. It was Wittenbauer who saved Terzaghi from being expelled after an over-exuberant student prank. Wittenbauer pointed out to the authorities that in the history of the university there had been only three expulsions: Tesla, who went on to revolutionise electrical technology, Riegler, who created the steam turbine, and a third who developed into a leading church architect. He went on to point out that the university was not good at choosing candidates for expulsion. Terzaghi was reprieved!

Though reading mechanical engineering, Terzaghi attended courses in geology. He was keen on climbing and it is related that he made every climbing expedition into a joyous adventure in field geology. During his compulsory year of military service he translated the *Outlines of Field-Geology* by Archibald Geikie (director of the British Geological Survey) into German. In a second edition, he actually extended it to a fuller coverage of karst features and the geomorphology of glaciated country, replacing the English examples with Austrian ones.

3.3.2 The switch to civil engineering

Terzaghi's interest in geology persuaded him that mechanical engineering was not for him. Switching to civil engineering, he returned to Graz for an extra year. He went to work for a firm specialising in hydroelectric power generation. Although his main activity was in the design of reinforced concrete, the planning of the structures was, of course, intimately involved with geology. But frequently he found the guidance of expert geologists unhelpful. He encountered many cases of failure. Significantly these were mainly due to the lack of ability to predict and control groundwater – piping failures were abundant. He also encountered many slope failures, bearing-capacity failures and structures undergoing excessive settlement.

3.3.3 Geology on its own

Recognising the difficulties that civil engineers experienced in dealing with the ground and also the obvious influence of geological factors, he concluded that it was necessary to collect as many case records as possible so as to correlate failures with geological conditions. It is well known that he then spent two intense years (1912–1914) in the western United States observing and recording. Two years that ended in disillusion and depression. The following quote from his presidential address to the 4th International Conference on Soil Mechanics and Foundation Engineering sums up his mood at that time (Terzaghi, 1957):

> At the end of the two years I took my bulky collection of data back to Europe, but when I started separating the wheat from the chaff I realised with dismay that there was practically no wheat. The net result of two years of hard labour was so disappointing that it was not even worth publishing it.

So much for geology on its own! So much for precedent and case histories on their own!

To quote Goodman (1999), the problem lay in the fact that:

> … the names geologists give to different rocks and sediments have developed mainly from a scientific curiosity about the geologic origin of these materials, whereas Terzaghi was aiming towards discerning the differences in their engineering properties.

This is still true today – the engineer needs to understand the key geotechnical properties that affect the response of the ground.

3.3.4 The birth of the science of soil mechanics

Shortly after his appointment to the Royal Ottoman Engineering University in Constantinople in 1916, Terzaghi began to search the literature for insights into the mechanical behaviour of the ground. He became increasingly frustrated. What he witnessed was a steady decline from 1880 in recorded observations and descriptions of behaviour. This was replaced by myriads of theories postulated and published without adequate supporting evidence. This experience must have been uppermost in his mind when, in his presidential address to the 1st International Conference on Soil Mechanics and Foundation Engineering, he stated the following (Terzaghi, 1936):

> In pure science a very sharp distinction is made between hypothesis, theories, and laws. The difference between these three categories resides exclusively in the weight of sustaining evidence. On the other hand, in foundation and earthwork engineering, everything is called a theory after it appears in print, and if the theory finds its way into a text book, many readers are inclined to consider it a law.

Thus, Terzaghi was emphasising the enormous importance of assembling and examining factual evidence to support empirical procedures. He also brings out the importance of instilling rigour. This is often equated with mathematics but there is at least as much rigour in observing and recording physical phenomena, developing logical argument and setting these out on paper clearly and precisely.

In 1918 Terzaghi began to carry out experiments on forces against retaining walls. He then moved on to piping phenomena and the flow beneath embankment dams. He used Forchheimer's flownet construction to analyse his observations and apply them in practice – methods that were themselves adapted from the flow of electricity. We see here the interplay between experiment and analytical modelling.

Over this period Terzaghi came to realise that geology could not become a reliable and helpful tool for engineers unless and until the mechanical behaviour of the ground could be quantified – this required systematic experimentation. On a day in March 1919, and on a single sheet of paper, he wrote down a list of experiments that would have to be performed.

Terzaghi then entered an intense period of experimental work in which he carried out oedometer (confined compression) tests and shear tests on clays and sands, thereby developing his physical understanding of the principle of effective stress

(the cornerstone of soil mechanics), excess pore water pressures and the time-rate of consolidation – this was the birth of soil mechanics. To make headway with modelling the consolidation phenomenon analytically he turned to the mathematics of heat conduction. Again we see here the interplay between experiment and analytical modelling. This intense period of experimental work and theoretical modelling culminated in the publication of his seminal book *Erdbaumechanik* (Terzaghi, 1925).

3.4 The impact of soil mechanics on structural and civil engineering

In 1933, a Soil Physics Section was established at the Building Research Station (BRS) in the UK, and Dr Leonard Cooling was put in charge of it. He set up the first proper soil mechanics laboratory in Britain, equipped with the apparatus necessary to classify soils, measure their basic mechanical properties and carry out sampling. By 1935 the first investigations of civil engineering problems had begun and the group moved to the Engineering Division of BRS and was renamed the Soil Mechanics Section. It was in August 1937 that the well-known Chingford embankment dam failure occurred and the team from BRS carried out the investigation. Terzaghi was called in to redesign the embankment, and the necessary testing and analysis was carried out at BRS. This gave great impetus to the acceptance of soil mechanics as a key discipline in civil engineering in the UK.

On 6 December 1934, Terzaghi delivered a lecture before the Institution of Structural Engineers in London with the title 'The actual factor of safety in foundations' (Terzaghi, 1935). He illustrated his lecture with a large number of case histories of measured distributions of settlement across buildings and their variation with time. He was able to explain the broad features of behaviour using the basic principles of soil mechanics and foundation analysis, demonstrating how vital it is to establish the soil profile with depth and across the plan area of the building. Even so, he showed that local variations in soil properties and stratification make it impossible to predict the settlement patterns with any precision. Without actually using the term, he drew attention to the important concept of ground–structure interaction, pointing out that the structure of a building should not be treated in isolation from its foundations. He even drew attention to the fact that reinforced concrete beams can yield plastically without impairing the stability or appearance of a frame building, provided the cracking is not excessive. It is of interest to note that, in their seminal paper on the allowable settlement of buildings, Skempton and MacDonald (1956) drew extensively on the case histories provided by Terzaghi in this lecture.

Towards the end of his lecture he made the following important assertion:

> Experience alone leads to a mass of incoherent facts. But theory alone is equally worthless in the field of foundation engineering, because there are too many factors whose relative importance can be learned only from experience.

On 2 May 1939, Terzaghi delivered the 45th James Forrest Lecture at the Institution of Civil Engineers, London with the title 'Soil mechanics – a new chapter in engineering science' (Terzaghi, 1939). The lecture summarised in simple terms the basic elements of the discipline of soil mechanics and its application to a number of engineering problems ranging from earth pressure against retaining walls and the failure of earth dams due to piping through to the phenomenon of consolidation and the settlement of foundations. Early in the lecture Terzaghi made the memorable statement that:

> … in engineering practice difficulties with soils are almost exclusively due, not to the soils themselves, but to the water contained in their voids. On a planet without any water there would be no need for soil mechanics.

He was a forceful and charismatic figure and this lecture made a very profound impact on the structural and civil engineers in the UK. The late Peter Dunican, past president of the Institution of Structural Engineers, attended as a young man and told the author of how Terzaghi had electrified the audience. Many leading geotechnical engineers, including the late Sir Alec Skempton, stress what a pivotal role this lecture played in the development of soil mechanics in the UK. As with his earlier lecture to the Institution of Structural Engineers, Terzaghi emphasised very strongly the importance of retaining a balance between theory and practice in soil mechanics. He stressed most strongly that precision of prediction was not possible due to the inherent variability of the ground and construction processes.

It is clear that Terzaghi is very much more than the father of the science of soil mechanics. His contribution was to place ground engineering on a rational basis, with geology as a key supporting discipline and soil mechanics providing the scientific framework for understanding the mechanical response of the ground. He is indeed the father of geotechnical engineering, which embraces engineering geology, soil mechanics and arguably rock mechanics as well.

3.5 Conclusions

Terzaghi's development of the science and art of geotechnical engineering grew out of his experiences as a civil engineer and his gradual realisation that the underlying principles governing the mechanical properties of soil were not understood. Although his contributions are often regarded as primarily theoretical, in reality this is anything but the case. A close study of his work reveals a brilliant and passionate engineer who at all times tried to maintain a balance between underlying theoretical principles, practical experience and the handling of the uncertainties that are always present when dealing with the ground in its natural state.

It is hoped that this chapter will provide a helpful summary that puts into context Terzaghi's struggles to provide a scientific and rigorous basis for geotechnical engineering. It demonstrates his grounding in geology; the importance of gaining an understanding of the mechanical behaviour of the ground and

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 3.4 Karl von Terzaghi
By kind permission of the Norwegian Geotechnical Institute

groundwater by means of experiment and testing; the need to develop an analytical framework for predictive purposes and, very importantly, the key role that experience plays and the importance of case histories. Time and time again he insisted that soil mechanics is not a precise science because of the inherent variability of the ground and the uncertainty of many factors associated with construction.

4.8	Concluding remarks	26
4.9	References	26

This chapter outlines a coherent approach to the key aspects of geotechnical engineering by making use of a simple aide-memoire termed the *geotechnical triangle.* The distinct and rigorous activities undertaken to obtain (1) the *ground profile*, (2) the *measured behaviour* of the ground and (3) an *appropriate model* are represented as the apexes of an equilateral triangle with empirical procedures and '*well-winnowed experience*' linked to all three at the centre of the triangle. The *ground profile* is placed at the top apex of the triangle because of its crucial importance and *experience* is located at the centre of the triangle because it is an essential aspect of all geotechnical engineering and relates to the other three activities. Each of the above activities has a distinct methodology, each has its own rigour and each is interlinked with the other. Successful ground engineering requires that each activity is properly considered so that a coherent approach is adopted and the triangle is 'kept in balance'. The application of the *geotechnical triangle* is illustrated by re-visiting the well-known case history of the underground car park at the Palace of Westminster in London.

4.1 Introduction

Geotechnics is a difficult subject and is regarded by many engineers as a kind of black art. The author used to think that this was due to the nature of the ground, which is a two- or even three-phase material. It is true that it is much more complex than the more classical structural materials of steel, concrete and even timber with which most engineers are familiar. As explained in Chapter 14 *Soils as particulate materials*, soil is a particulate material with little or no bonding between the particles. As a consequence:

- The stiffness and strength of a given soil is not fixed but depends on the confining pressure.
- When it is deformed, soil will tend to contract or dilate depending on how dense it is, and this can profoundly influence its properties.
- During shearing, the particles tend to change their orientation, which, in turn, has a big influence on the shearing resistance of the material.
- Most important of all – water pressures acting within the pores of the soil are just as important as the applied boundary stresses.

This complex particulate material has to be modelled as if it were a continuum but it is essential never to forget that in reality it is particulate.

Difficult as soil is as an engineering material, the problems confronted by the engineer in tackling a ground engineering problem are more subtle. Chapter 3 *History of geotechnical engineering* describes the struggles experienced by Terzaghi in establishing geotechnical engineering as a valid engineering discipline. After a careful study of the opinions expressed by Terzaghi and others, and from his own experience, the author came to the view that the main problem confronting the engineer is not so much the complex nature of soil as a material (difficult as that is) but a lack of appreciation of the number of aspects that have to be considered in tackling a ground engineering problem (Burland, 1987).

A close study of Terzaghi's struggles towards establishing the subject reveals that there are three distinct but interlinked aspects that have to be considered in tackling any ground engineering problem:

- the ground profile including groundwater conditions;
- the measured behaviour of the ground;
- the appropriate model for assessing and predicting performance.

All three of these aspects are supported by empirical procedures, judgement based on case histories and what the author has termed 'well-winnowed experience'.

The boundaries between these aspects often become confused. For example, it is frequently not clear whether a particular design approach is based on analysis or is mainly empirical. Moreover, one or more of the aspects is frequently completely neglected. The first three aspects may be depicted as forming the apexes of an equilateral triangle, with empiricism and experience occupying the centre and linked to the apexes as shown in **Figure 4.1**. This representation was originally developed as a teaching aid but it has since become apparent that it also provides a valuable aide-memoire for geotechnical practice.

Associated with each of the above aspects are distinct and rigorous activities and procedures, which are shown in **Figure 4.1** by the broken circles. Each activity is a major discipline in its own right. Successful ground engineering requires that all aspects of the geotechnical triangle should be considered. Excessive reliance on one aspect (e.g. computer modelling or empirical procedures) can be disastrous. The four aspects depicted in the geotechnical triangle and their associated

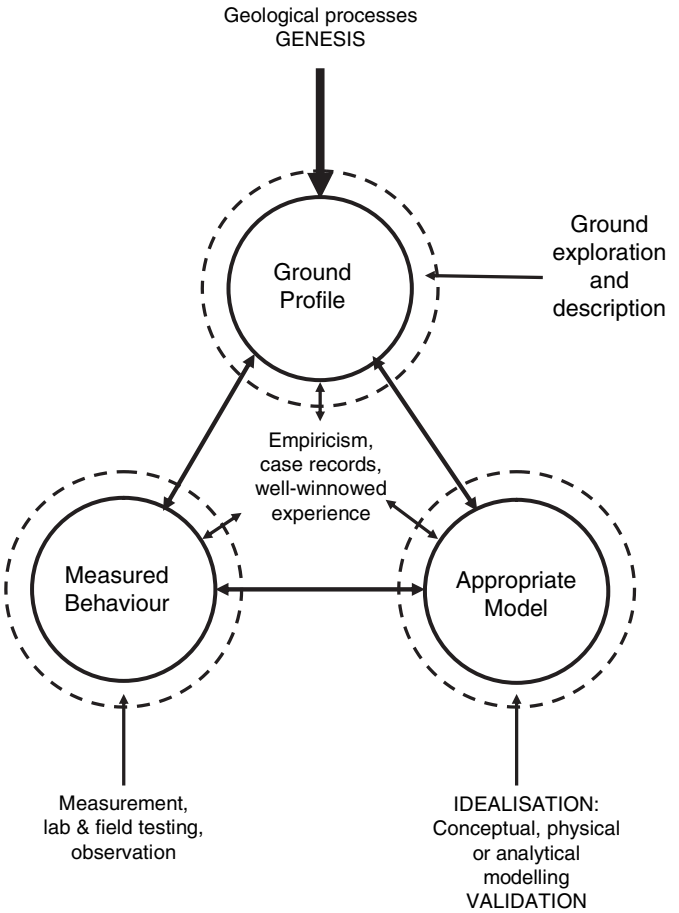

Figure 4.1 The geotechnical triangle. Each activity has its own distinct methodology and its own rigour

activities will now be briefly described. The order in which the activities are carried out will depend on the problem and may involve an iterative approach. For most problems the establishment of the ground profile is an early priority. It is also very important to establish at an early stage what experience is available for the problem being tackled and the ground conditions to be encountered.

4.2 The ground profile

Establishing the ground profile is a key outcome of the ground investigation as described in Chapter 13 *The ground profile and its genesis*. The ground profile is a description of the successive strata in simple engineering terms together with the groundwater conditions and the variations across the site. The importance of handling and describing the soil so as to establish the ground profile cannot be over-emphasised. Also it is vital to understand the geological processes and man-made activities that formed the ground profile, i.e. its genesis. The author believes that nine times out of ten, the key conceptual design decisions for a project can be made on the basis of a good description of the ground profile. Similarly, nine failures out of ten result from a lack of knowledge about the ground profile – often the groundwater conditions. The importance of the ground profile is emphasised by placing it at the top apex of the triangle.

Peck (1962) argued that the methodology of the engineering geologist in establishing the geological model for a site consists in making observations, organising and assembling these, formulating a hypothesis and then critically testing the hypothesis. However, the civil engineer, and in particular the structural engineer, is not usually trained in this methodology, which is at the heart of much geotechnical engineering.

4.3 The measured or observed behaviour of the ground

The activity associated with this aspect involves making measurements of the mechanical behaviour and interpreting the measurements. It includes laboratory and field testing, carrying out field observations of the ground and structural movements (e.g. back analysis of a landslip or of settlement observations) and measurements of groundwater pressures and flow. Rigorous methodologies and advanced instrumentation are often required for this work. The measurements require interpretation, which needs an appropriate analytical framework. A good basic understanding of the mechanical behaviour of soils and rocks is essential to these activities. Section 2 *Fundamental principles* of this manual provides a practical introduction to the fundamentals of soil and rock behaviour.

4.4 Appropriate model

When the author first put forward the original *soil mechanics triangle* in 1987 (now referred to as the geotechnical triangle), the term ‘applied mechanics’ was used for the bottom right-hand corner of the triangle. However, the term ‘appropriate model’ is a much better description of this aspect and its associated activities. The procedures involved in geotechnical and structural modelling are described in Chapter 5 *Structural and geotechnical modelling*.

Modelling is the process of:

- identifying what is to be modelled, e.g. the part of the structure, the particular type of behaviour or limit state;
- idealising or simplifying the geometry, material properties and loading;
- assembling these idealisations appropriately into a model, which is then amenable to analysis and, hence, can be used to predict responses.

The modelling process is not complete until the responses have been validated and assessed. The procedure may involve a number of iterations.

It is important to note that the process of modelling is very much more than simply carrying out an analysis. A model can be a very simple conceptual one, it can be a physical 1g model or a centrifuge model, or it can be a very sophisticated numerical model. By using the term ‘model’ we are emphasising the

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

idealisation process and demystifying the analytical process. The geotechnical triangle helps in this. It is also important to appreciate that a variety of models and idealisations will usually be needed for different aspects of a given project or structure.

4.5 Empirical procedures and experience

With materials as complex and varied as the ground, empiricism is inevitable and it is (and will always remain) an essential aspect of geotechnical engineering. That is why this aspect is placed at the centre of the triangle and is linked to the other three aspects. Many of our design and construction procedures are the product of what may be termed 'well-winnowed experience', that is, experience which results from a rigorous sifting of all the facts that relate to a particular empirical procedure or case history. The author chose the term having read Terzaghi's description of his attempts to 'separate the wheat from the chaff'' following his two years in the USA collecting case records (see Chapter 3 *History of geotechnical engineering*).

Empirical procedures are often regarded as somehow inferior to analytical procedures. The fact is that both have their essential place in geotechnical engineering and both need to be carried out with care and with understanding of their limitations.

4.6 Summary of the geotechnical triangle

In summary, depicted within the *geotechnical triangle* illustrated in **Figure 4.1** there are four key aspects of geotechnical engineering, each associated with distinct types of activity with different outputs. Each activity has a distinct methodology, each has its own rigour, and each is interlinked with the other. Terzaghi's approach to ground engineering reveals a coherence and integration, which is reflected in a 'balanced' geotechnical triangle. The geotechnical triangle provides a useful aide-memoire when tackling any ground engineering problem, whether it is in feasibility, design, construction, forensic investigation or teaching. It is possible to adapt the geotechnical triangle for particular applications. For example, in Chapter 9 *Different types of foundation applications* an adaptation is described for the vital task of verifying design assumptions when construction work has commenced and the influence of construction processes on the ground needs to be assessed.

4.7 Re-visiting the underground car park at the Palace of Westminster

Many of the above aspects can be illustrated by means of the well-known case history of the underground car park at the Palace of Westminster, London.

4.7.1 Background

This case history is described in detail by Burland and Hancock (1977). The site finally chosen for the 18.5-m-deep car park for the Members of Parliament was in New Palace Yard,

Figure 4.2 The site of the underground car park in New Palace Yard, Westminster

presenting major engineering challenges due to the proximity of the Big Ben Clock Tower, the Palace of Westminster and the 14th century Westminster Hall, as shown in **Figure 4.2**. The sensitive, load-bearing masonry construction of the buildings and their priceless historic value demanded a structural form and construction procedure for the car park which would result in minimum ground movements, both during construction and in the long term. The structural form chosen consisted of a reinforced-concrete diaphragm wall, strutted at all stages of excavation and construction by the permanent reinforced-concrete floors as shown in **Figure 4.3**. The columns are founded on under-reamed bored piles.

4.7.2 The importance of the ground profile

A preliminary site investigation had been carried out prior to the author's involvement in the project. The results showed that the top 10 m consisted of fill and soft alluvium, overlying medium-dense sand and gravel. London Clay extended from a depth of 10 m to 44 m, at which depth the Woolwich and Reading beds were encountered (now known as the Lambeth Group). A new site investigation was planned, aimed at ascertaining the detailed soil profile, its variation across the site and the groundwater conditions. Altogether 14 boreholes were sunk on the site. The author personally carried out a detailed visual examination on open drive samples from a number of the boreholes by splitting the samples longitudinally with a knife so as to overcome the smearing on the outside of the samples. Visual and tactile descriptions were carried out using a simple scheme described by Burland (1987), which is consistent with BS5930:1999, Code of Practice for Site Investigations. See Chapter 13 *The ground profile and*

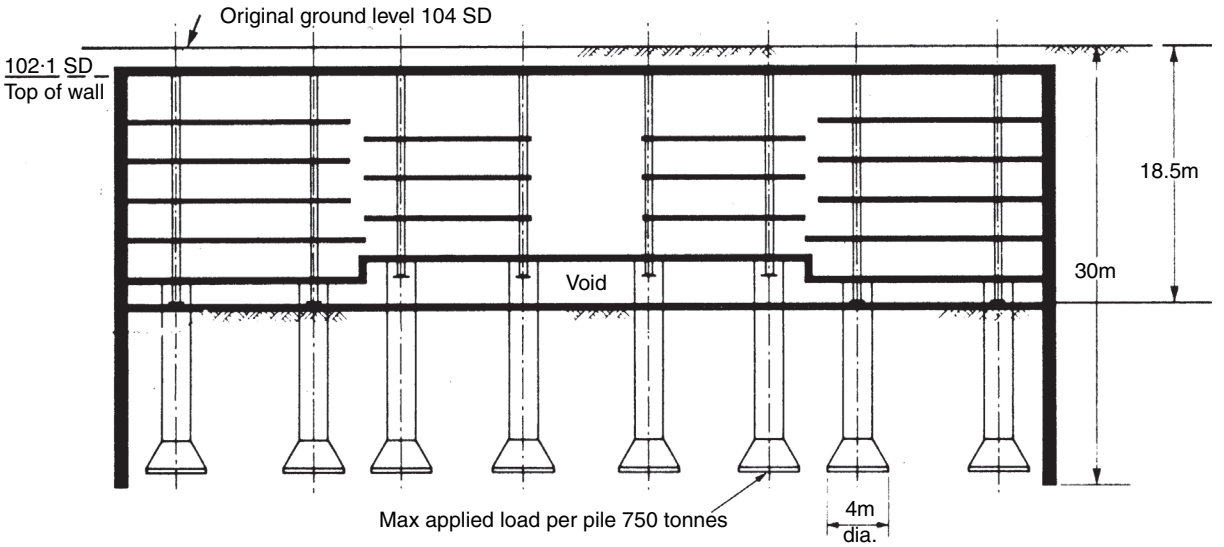

Figure 4.3 Section through underground car park in New Palace Yard

its genesis for more details of the information required in a description of the soil profile.

Good correlation of the various strata was found between the boreholes and the ground profile, as shown in **Figure 4.4**. A visual inspection revealed that immediately beneath the lowest level of the proposed car park, and extending from a depth of 19 m to 30 m, there exists a layer of London Clay containing partings of fine sand and silt up to 10 mm thick and at 50 mm spacing near the top of the layer. The frequency of the partings reduces with depth. This layer is immediately underlain by a 4 m thick layer of very stiff intact clay. Casagrande standpipes installed in most of the soil exploration boreholes showed that the groundwater pressures down to a depth of about 35 m were hydrostatic and in equilibrium with the water table in the overlying alluvium and gravel.

At the time, the finding of the layer containing silt and sand partings came as a surprise. Subsequently it has come to light that it had been encountered during tunnelling elsewhere in London and had caused problems of face instability. Recently, Standing and Burland (2006) encountered the same layer in nearby St James's Park in connection with the Jubilee Line Extension underground railway, where excessive volume losses were encountered during tunnelling. The discovery of this layer containing silt and sand partings had very important implications for the conceptual design of the retaining walls and the foundations. The relatively high horizontal permeability of this layer, coupled with hydrostatic water pressures in the surrounding ground, meant that high water pressures could develop beneath the excavation level, leading to hydraulic uplift and possible base failure. Moreover, seepage from the sand layers could have caused difficulties in the formation of the underreams of the bored piles. The development of high water pressures beneath the bottom of excavations due to the presence of water-bearing permeable strata is a well-known geotechnical hazard. Ward (1957) describes a case in which high water pressures in a stratum of laminated sand caused uplift at the bottom of a trench excavation in stiff clay. The problem was solved by the use of simple gravel-filled relief boreholes.

Various methods were considered for relieving the water pressures immediately beneath the final basement level of the car park, including the use of relief wells. Also detailed flownet calculations were carried out to assess the upward seepage gradients. However, there were considerable doubts about the short- and long-term effectiveness of relief wells. Moreover, the author was very unwilling to rely on a seepage analysis, knowing that even a small undetected permeable region could completely nullify the analysis. A robust solution was adopted, which involved taking the diaphragm retaining walls down into the intact clay layer at a depth of 30 m, thereby cutting off all horizontal seepage along the sand partings.

The choice and depth of the foundations was also profoundly influenced by the soil profile. The indications were that below a depth of 34 m (i.e. below the 4 m thick intact clay layer) there was the possibility of significant erosive seepage during excavation of the piles due to the silty nature of the clay at that depth. At a much shallower depth the significant reductions in effective stress immediately beneath the excavation would give rise to long-term reductions in stiffness and strength. With these considerations in mind, it was decided to use under-reamed bored piles founded on the intact clay layer at a depth of about 30 m, thereby making use of the higher shear strength beneath that level but avoiding difficulties due to seepage. A trial pile was constructed ahead of the main job in order to check on the groundwater and soil conditions and to evaluate the proposed foundation construction procedure. *In situ* inspection of the soil in the trial pile confirmed all the earlier deductions.

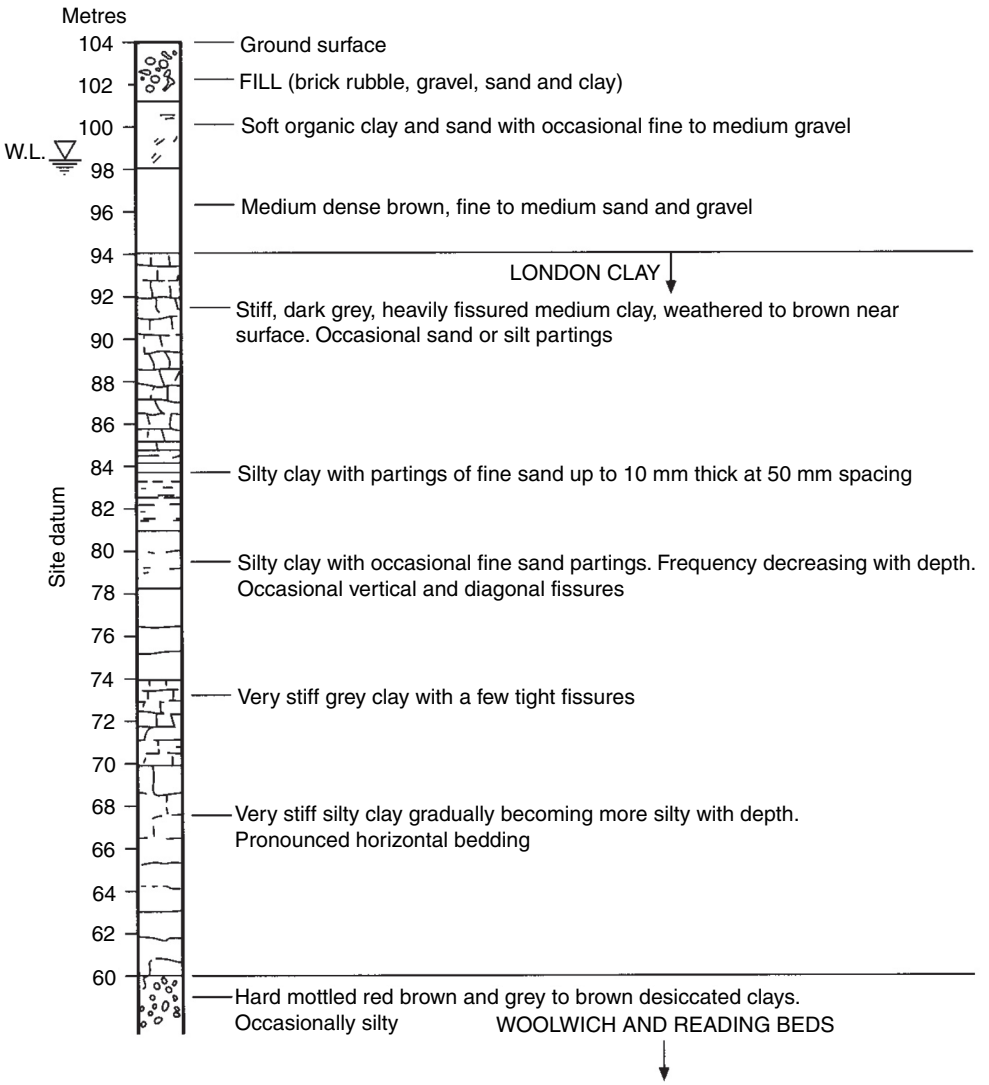

Figure 4.4 The ground profile at the Palace of Westminster

4.7.3 Modelling the ground movements

A major task in the design of the car park was to estimate the effects of the excavation on the surrounding buildings and on the structure itself. Accordingly a detailed finite element analysis was undertaken. The analysis was based on a number of idealisations and it is important to be absolutely clear about these.

Regarding the mechanical properties of the ground, the London Clay was assumed to behave as a linear elastic isotropic porous material having a stiffness that varies with depth. (See Chapter 17 *Strength and deformation behaviour of soils* for a discussion on the strength and deformation behaviour of soils.) This assumption was felt to be reasonable as the best research data available at the time suggested that at small strains, samples of London Clay tested in the laboratory exhibited linear behaviour. The variation of the undrained Young's modulus, E_u with depth used in the analysis is given by the line in **Figure 4.5**. The stiffness values for the London Clay and Woolwich and Reading beds were based on values obtained by back analysis of measurements of the movements of the retaining walls for the deep basement excavation for Britannic House in the City of London (Cole and Burland, 1972). Thus, the choice of stiffness values was based on previous relevant case histories and observations in the London area – a clear example of the application of 'well-winnowed experience'. The adopted values of E_u for the basement beds of the London Clay and the Woolwich and Reading beds are somewhat lower than those obtained at Britannic House. It was felt necessary to be conservative in view of the lack of knowledge about the Woolwich and Reading beds in the Westminster area. Nevertheless, it is worth noting that the values of E_u used in the analysis were three to five times larger than the values deduced from careful laboratory tests. The author would never have chosen such high values without the benefit of experience from the analysis of previous relevant case histories.

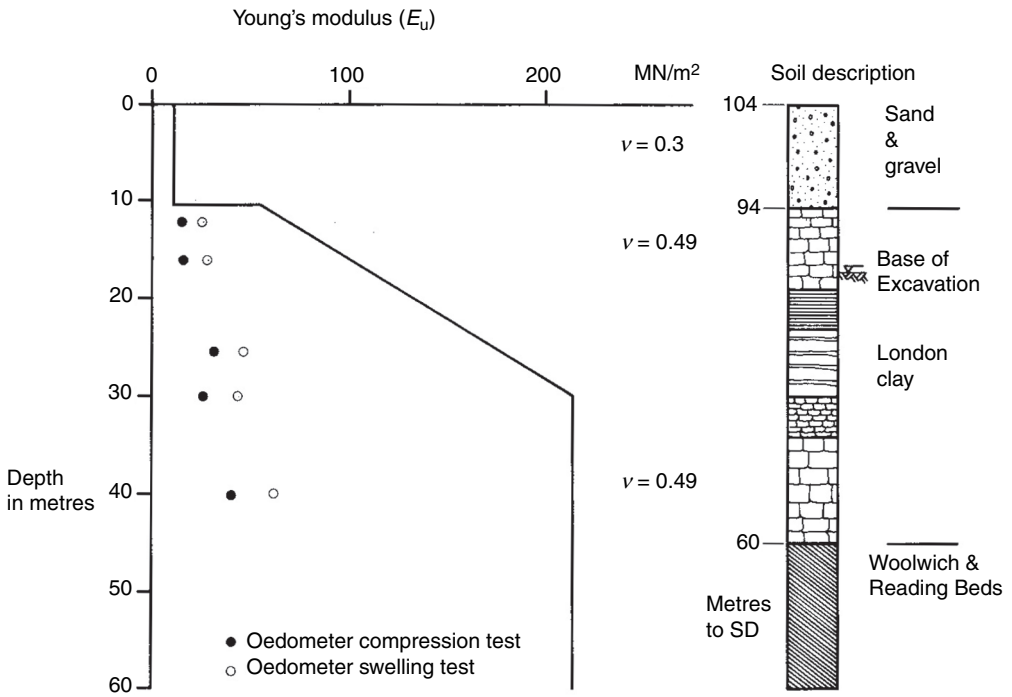

Figure 4.5 Values of undrained Young's modulus used in the finite element analysis

A key aspect of the modelling involved assessing the magnitude of the initial horizontal stresses in the clay, since these had to be progressively released during excavation. Once again the author made use of values deduced by others for various sites in London Clay. An assessment had to be made for the effects of erosion of the surface of the London Clay and the subsequent deposition of the gravel. This illustrates the importance of understanding the genesis of the ground profile – see section 4.2 above.

Even though the problem is highly three-dimensional, a plane strain analysis was adopted as being approximately representative of the centre of the north and south walls, respectively. The finite element mesh extended to the base of the Woolwich and Reading beds (60 m depth) and laterally to a distance of 80 m from the edge of the excavation.

Numerical analysis was carried out in a step-by-step process simulating the excavation and installation of the floor props at each stage, as described by Burland and Hancock (1977). **Figure 4.6** shows the predicted wall displacements at the various stages of excavation, the maximum inward displacement being about 22 mm. The predicted short-term horizontal and vertical movements of the ground surface outside the excavation are given in **Figure 4.7**. These predicted ground surface movements gave a maximum change of gradient of 1/800 and a maximum extension strain of 0.02%. These strains were felt to be unlikely to cause any significant damage to the surrounding buildings. Estimates were also made of the movements of the Clock Tower using an axisymmetric analysis, which was felt to be more appropriate for conditions close to the north-east corner of the car park. The Clock Tower was predicted to rotate away from the excavation by about 1/6000, while its foundations were predicted to move in towards the excavation by about 3 mm. The finite element model was also used to estimate the long-term movements and the swelling of the clay at the base of the excavation. On the basis of these calculations it was decided to use a suspended basement floor with a drained void beneath, rather than a solid slab, so that the clay could swell without interacting with the rest of the structure. It is very important to note that the predicted movements were published prior to work commencing on the project (Ward and Burland, 1973).

The numerical model was also used to estimate the vertical movement of the under-reamed piles during and subsequent to excavation. This information was used to assess the approximate magnitudes of the differential movements across the floor slabs and the associated bending and shear forces within them due to ground movements.

4.7.4 Field monitoring

In view of the depth of excavation, the close proximity of such priceless historic buildings and the sensitivity of the project, a very comprehensive programme of monitoring was undertaken during all phases of excavation and construction. Briefly, the monitoring can be considered under three broad headings: precision surface surveying, ground movements at depth and pore water pressures. Approximately 60 movement points were established by grouting Building Research Station (BRS)

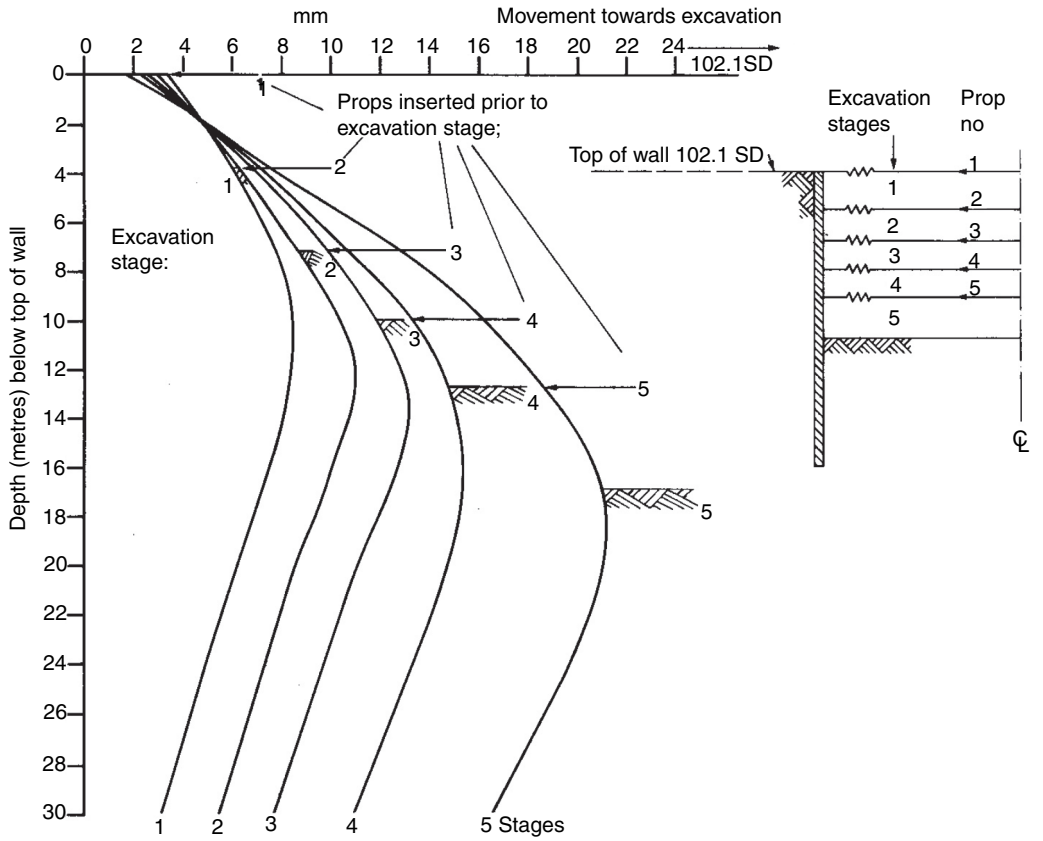

Figure 4.6 Predicted horizontal wall movements during excavation

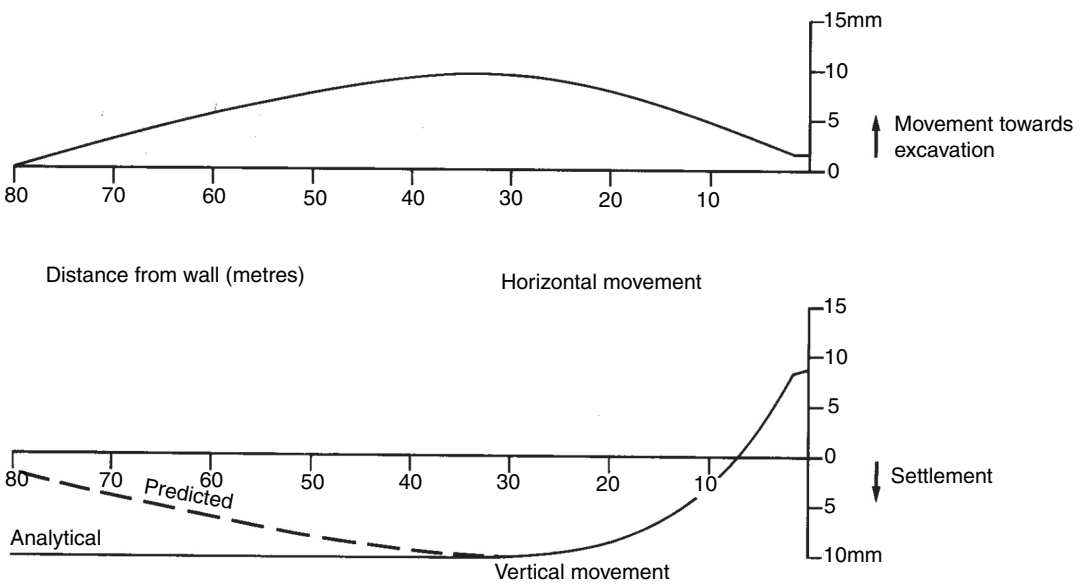

Figure 4.7 Predicted horizontal and vertical ground surface movements outside the excavation

levelling stations into the masonry of the surrounding buildings (Cheney, 1973). Precision settlement surveys were carried out continuously during construction. The frequency of observations was increased close to areas where construction activity was concentrated. Complete geodetic surveys in both plan and elevation were made at intervals of approximately two months over the construction period of about two years. Changes in the verticality of the Clock Tower were monitored daily by means of a Hilger and Watts 'autoplumb'.

The subsurface horizontal deflections of the diaphragm retaining walls were measured by means of inclinometers. Special demountable targets were fitted to the tops of the inclinometer tubes, and their positions were measured in plan and elevation at two-monthly intervals. An important aspect of the below-ground monitoring was to measure the heave at various depths during excavation as a check on the effectiveness of the design measures. Two magnet extensometers (Burland *et al.,* 1972) were installed at the centre of the excavation for this purpose.

A number of standpipes and pneumatic piezometers were installed within the area of the excavation and around its perimeter. They were to be used, in conjunction with the magnet extensometers, to check that hydraulic uplift was not developing. Unfortunately the pneumatic piezometers and many of the standpipes within the excavation were destroyed, but the standpipes outside the excavation all functioned satisfactorily.

4.7.5 Observed behaviour

Figure 4.8 shows the observed deflected shapes of the centre of the south diaphragm wall (inclinometer 8) at the various stages of excavation and support. These may be compared with the predicted behaviour given in **Figure 4.6**, where it is evident that the agreement is very satisfactory. The final predicted shape of the wall is shown as a broken line in **Figure 4.8(a)**. The major difference between the predicted and observed movement is the overestimation of the inward movement beneath the final excavation level. This is a direct result of the deliberate choice of conservative values of the undrained Young's modulus, E_u for the basement beds of the London Clay and the Woolwich and Reading beds.

A large range of deflected shapes were observed for the various wall panels. **Figure 4.8(b)** shows the two extreme cases given by inclinometers 3 and 10. The results demonstrate that, even for relatively uniform ground conditions, widely differing deflected shapes can be anticipated. These differences may be due in part to the precise manner in which the excavation was carried out at various locations. Nevertheless, the differences shown in **Figure 4.8(b)** are a salutary reminder that there are limits to the precision with which predictions can be made.

In **Figure 4.9** the measured total horizontal and vertical surface movements behind the south wall are compared with the predictions given in **Figure 4.7**. The predicted horizontal

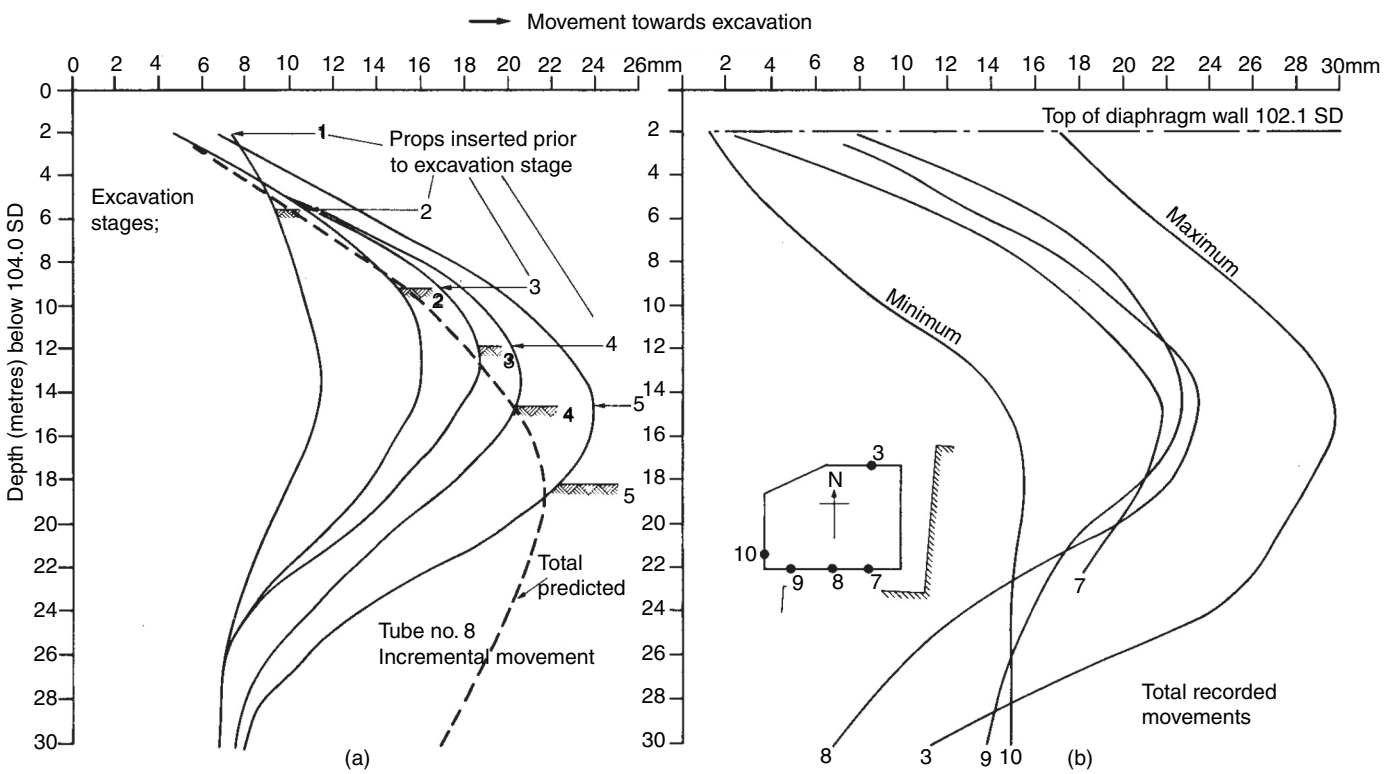

Figure 4.8 Observed movements of the diaphragm walls. (a) Inclinometer tube 8 at various stages of excavation. (b) Range of measured movements at end of excavation

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

movements are somewhat less than the observed values within 25 m of the wall, but further away the agreement is good. In general the overall form and magnitude of the prediction is reasonable. However, agreement between the observed and predicted vertical movements is not nearly as good. The upward displacement of the wall has been overestimated, while the maximum settlement has been underestimated. The 'settlement trough' is much nearer the wall than predicted. A consequence was that, whereas the Clock Tower was predicted to tilt away from the excavation by about 1/6000, it actually tilted towards the excavation by about 1/7000. The predicted and observed horizontal displacements were much more satisfactory, being 3 mm and 5 mm, respectively, towards the excavation.

In summary: The detailed ground profile together with experience of previous similar constructions led to the key conceptual design decisions – top-down construction to minimise ground movements, diaphragm walls cutting off horizontal seepage through the layer containing silt and sand partings, and founding the under-reamed piles in the intact clay layer. The stiffness parameters used in the finite element analysis were based on a back analysis of other deep excavations in the London area. Numerical modelling was used primarily to assess the movements in the surrounding Palace of Westminster but it was also used in the structural design of the diaphragm walls. The monitoring of the movements and groundwater pressures was carried out as a check that the behaviour was within acceptable limits. The car park was completed without significant damage to the surrounding buildings.

4.7.6 Subsequent refinements of the ground model

The difference between the predicted and measured vertical ground surface displacements just described proved very puzzling. However, shortly after the measurements were published by Burland and Hancock (1977), Simpson *et al.* (1979) showed that, by using a bilinear stress–strain law with a high initial stiffness, the agreement between observations and predictions could be greatly improved – particularly with respect to the vertical movements, as shown by the broken lines in **Figure 4.10**. At the same as this theoretical work was being carried out, laboratory studies began at Imperial College in which axial strains were measured locally on soil samples instead of between the end plattens, as was traditional. These measurements gave highly *nonlinear* stress–strain behaviour, with stiffnesses at small strains which were much larger than those inferred from traditional measurements. It now became clear that the pattern of ground surface movements observed at New Palace Yard, in which the vertical movements are concentrated

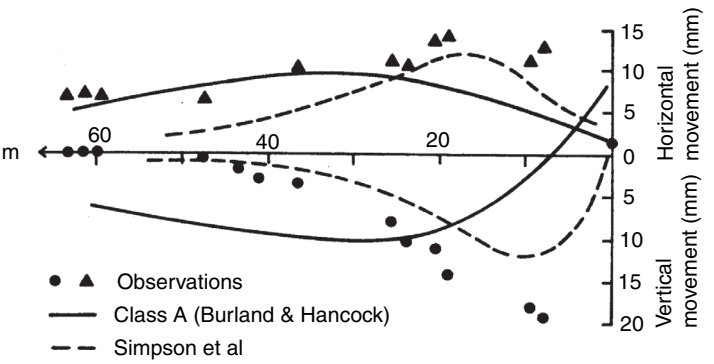

Figure 4.10 Improved predictions of the shape of the settlement trough (shown as a broken line) due to inclusion of small strain *nonlinearity* in the soil model

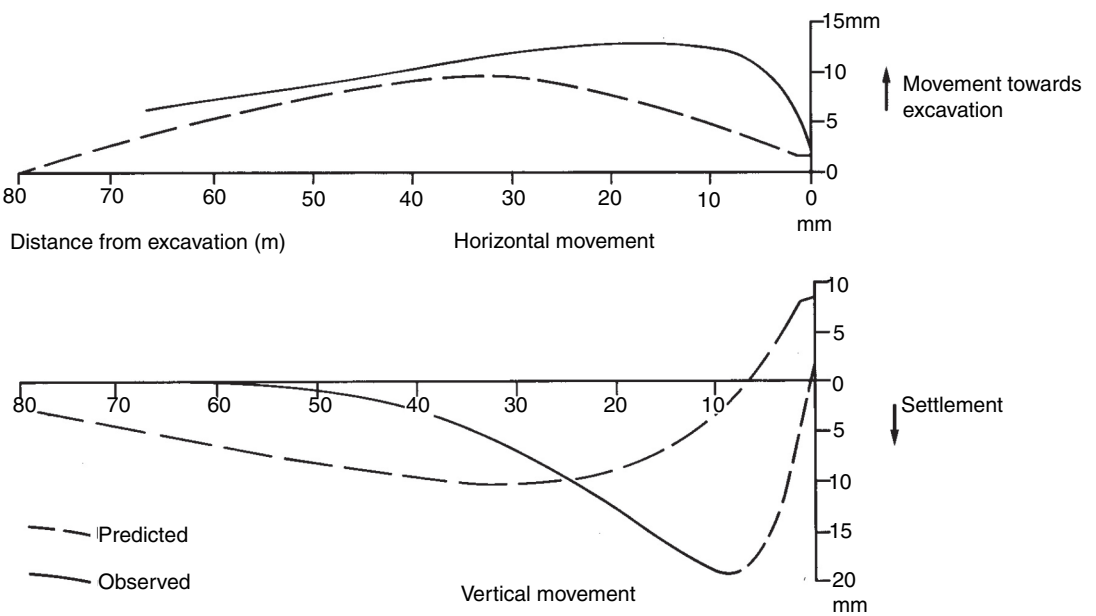

Figure 4.9 Comparison of predicted and measured ground surface movements away from the south wall

close to the edge of the excavation, is due to the *nonlinear* nature of the stress–strain behaviour of the soil.

This process of prior publication of predictions, though uncomfortable at the time, has proved highly beneficial as it caused the author to ponder long and hard as to the explanation for the discrepancies. Without such public disclosure it would have been all too tempting to quietly ignore the discrepancies and move on to other things. The work at New Palace Yard, and the measured response of the Clock Tower, has spawned a whole new important area of study of the behaviour of the ground at small strains – indeed whole international conferences are now devoted to the subject. These studies are proving very important for modelling the key mechanisms governing the interaction effects between ground and structure. Understanding these mechanisms is particularly important in the urban environment, where underground construction is a vital part of infrastructure development.

This case study is a clear demonstration of the importance of publishing well-documented case histories, as they serve to contribute to the profession's collective experience and can be used to calibrate new numerical modelling techniques for many years to come.

4.8 Concluding remarks

This chapter outlines a coherent approach to the key aspects of geotechnical engineering by making use of the *geotechnical triangle* (see **Figure 4.1**). The distinct and rigorous activities of (1) ground investigation, (2) measurement and observation and (3) appropriate modelling are represented as the apexes of the triangle with (4) 'well-winnowed experience' (an equally rigorous activity) linked to all three at the centre of the triangle.

The application of the geotechnical triangle has been illustrated by re-visiting the well-known case history of the underground car park at the Palace of` Westminster, London. A deep excavation was chosen as a case history since this type of problem demands all the traditional skills of the engineer including: reliance on observation and measurement; a deep understanding of both geotechnical and construction materials; the effects of groundwater and seepage; the development of appropriate conceptual and analytical models; and above all, judgment based on a knowledge of case histories and construction methods.

It should be noted that the key conceptual design decisions for the underground car park at Westminster were taken on the basis of a thorough knowledge of the ground profile obtained from the visual and tactile description of the soil samples and measurements of groundwater pressures from standpipes. The choice of stiffness properties for the London Clay was based on the careful and rigorous analysis of other appropriate case histories of deep excavations in the London area, illustrating the importance of case histories and 'well-winnowed experience'. The field measurements made during the excavation of the car park have proved most valuable in gaining an understanding of the influence of small-strain *nonlinear* behaviour of the ground. Even more importantly, these measurements have shown that precise prediction of behaviour is not possible and that successful design requires that inherent uncertainties of response must be taken into account.

During his career the author has encountered profound differences in the approaches taken by structural and geotechnical engineers, often leading to a lack of understanding and difficulties in communication. This chapter explores these differences and the reasons for them.

The term *modelling* is used extensively. It is defined as the process of idealising a structure and the underlying ground including the geometry, material properties and loading in order to make the problem amenable to analysis and, hence, assessment for fitness of purpose. It is demonstrated that traditional structural modelling is very different from geotechnical modelling and these differences need to be appreciated if ground–structure interaction problems are to be realistically modelled. It is concluded that concepts such as *ductility* and *robustness* underpin the success of both structural and geotechnical modelling and more explicit recognition of these is needed.

5.1 Introduction

There is always an interaction between a structure and its foundation … whether or not the designers allow for it. In some situations, the interaction can be minimised, e.g. by founding the building on rigid piles. Such an approach can be very costly and is often not feasible. If structure–ground interaction is to be taken into account, structural and geotechnical engineers themselves have to interact.

There have been many occasions when the author has both witnessed and experienced difficulties in communications between structural and geotechnical engineers and it has been a continuing source of interest to him as to why this should be so (Burland, 2006). It is a matter of outstanding importance because poor communication and lack of understanding can lead to poor engineering and even failures.

At the heart of the problem, there are differences in the day-to-day approach to *modelling* structural and geotechnical behaviour. By identifying these differences it is possible to move towards more integrated and realistic approaches to designing for ground–structure interactions.

The term *modelling* is used extensively in this chapter. It is intended to describe the process of idealising a real-life structure, foundations and ground (or parts of them) including the geometry, material behaviour and loading, in order to make them amenable to analysis, carrying out that analysis, reviewing it and then assessing the design for 'fitness for purpose'. Thus, the process of modelling entails very much more than the process of carrying out the analysis itself.

5.2 Structural modelling

The late Edmund Hambly, a most innovative structural engineer who obtained his PhD in soil mechanics, published a little book *Structural Analysis by Example* (Hambly, 1994). It was intended as a handbook for undergraduates and professionals who like to use physical reasoning and off-the-shelf computer modelling to understand structural form and behaviour. Fifty examples are given of structural problems of increasing complexity ranging from simple frames, through beams, columns and slabs, to shear lag and torsion, and then on to whole structures such as offshore platforms and spiral staircases. The book represents an admirable summary of the range of problems and types of analysis that a structural engineer encounters in day-to-day practice.

In terms of *modelling*, it is evident that the geometry of most structures is well defined and reasonably easy to idealise. Rather simple linear elastic material behaviour is usually assumed with a limiting stress imposed. The major idealisations in the modelling process are in the loading, although in Hambly's book this is specified, as is usually the case in codes of practice and standards. It is evident that the process of routine structural modelling mainly consists of idealising the structural form (often termed the 'conceptual model') and carrying out analysis – usually on the computer. Recently, the Institution of Structural Engineers (IStructE, 2002) and MacLeod (2005) set out more formal procedures for the structural modelling process.

5.2.1 Limitations to structural modelling

Using Hambly's book as an exemplar, it is evident that structural engineers think primarily in terms of the forces and stresses (or equivalent elastic displacements) that are the outputs from the structural models that they use in day-to-day practice. Yet most studies on real whole structures (especially buildings) show that the measured strains and displacements bear little resemblance to the calculated ones (Walley, 2001). Classic experiments on large-scale steel structures, carried out in the early 1930s under the direction of Lord Baker, revealed that the measured stresses

under working loads bore very little relation to the calculated values (Baker *et al.*, 1956). National Building Studies Research Paper No 28 records that the biggest change of strain in the steel beams of the Ministry of Defence building in Whitehall was caused by the shrinkage of the concrete after the floors had been cast – this was larger than that induced by the subsequent loading of the floors (Mainstone, 1960). In his own work, the author has found that the thermal and seasonal movements of buildings are often as large as the movements induced by tunnelling and yet these are overlooked when assessing the response of buildings to foundation movements (Burland *et al.*, 2001). These limitations have been appreciated for a long time but are easily forgotten. The fact is that the uncertainties of modelling real projects are dealt with in good practice not only by factors of safety, but also by incorporating appropriate levels of ductility and robustness.

5.2.2 Ductility and robustness

Ductility may be defined as *the ability to undergo inelastic deformations without significant loss of strength*, while robustness can be defined as *the ability to absorb damage without collapse*.

On page 1 of Hambly's book, reference is made to the *safe design theorem*, which, of course, derives from the lower bound theorem of plasticity. This theorem states that:

A structure should be able to carry its design loads safely if:

1. *The calculated system of forces is in equilibrium with the loads and reactions throughout the structure.*
2. *Each component has the strength to transmit its calculated force and the ductility to retain its strength while deforming.*
3. *The structure has sufficient stiffness to keep deflections small and to avoid buckling before design loads are reached.*

If the real structure deforms under load with a different flow of forces from that calculated, it should still be safe as long as the materials are ductile (like steel) and not brittle (like glass). The equilibrium check ensures that any underestimate of the force flowing through one part of the structure is balanced by an overestimate in the force in another part. Then ductility ensures that the component that is overstressed retains its strength while deforming, and sheds the excess force to the parts that have available capacity as a result of the equilibrium check. It is the ductility of structures that ensures the success of current design methods. This is frequently overlooked and, in the author's experience, many structural engineers still seem to believe that their structures behave as calculated – a belief that powerful computer programs and prescriptive codes of practice tend to reinforce. Both Heyman (2005) and Mann (2005) have written on this topic and stressed the need to ensure that the structural details are ductile – also a prerequisite for earthquake design. The inherent ductility and robustness of steel structures is well known and gave rise to modern methods of plastic analysis. Beeby (1997, 1999) summarised the developments in the understanding of ductility for traditional reinforced-concrete design and stressed the importance of designing for robustness.

It is important to note that the majority of structural failures result from defects at joints and connections (Chapman, 2001). Engineers do, of course, carry huge responsibility for ensuring that local instabilities cannot develop – particularly in temporary works and propping systems. For steel structures Burdekin (1999) drew attention to how important it is for designers to be aware of the factors that give rise to brittle fracture and fatigue.

5.2.3 The three- and four-legged stools (Hambly's paradox)

A simple but profound physical model can be used to illustrate what has been discussed so far. **Figure 5.1** shows two stools, one with three legs and one with four (Hambly, 1985). Imagine that each must support a milkmaid who weighs 60 kg, and who always sits with her centre of gravity directly over the middle of the stool. The problem is to determine how much load must be carried by each leg of the three-legged stool and the four-legged stool.

The three-legged stool is straightforward in that one third of the milkmaid's weight must go down each leg, i.e. 20 kg. For the four-legged stool the answer of 15 kg is wrong! Careful inspection of **Figure 5.1** shows that one of the four legs does not quite touch the ground, either because the leg is slightly short or because the ground is uneven; consequently the leg is not carrying any load. The opposite leg will also not be carrying any load because its load must balance that in the short leg when equilibrium of moments is considered about the diagonal through the other two legs. Thus, all of the weight is carried by two legs, i.e. 30 kg per leg, instead of being shared by the four legs. Hence, the paradox (Heyman, 1996) – the addition of a fourth leg to a three-legged stool can increase, rather than decrease, the force likely to be carried by each leg. So what load *should* the legs be designed to carry?

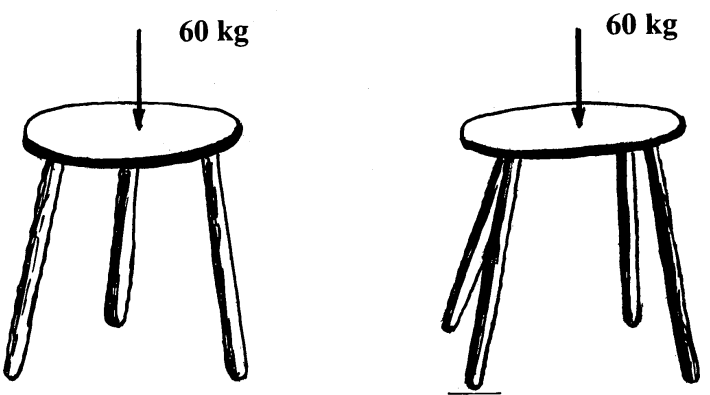

Figure 5.1 Three- and four-legged stools – Hambly's paradox

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

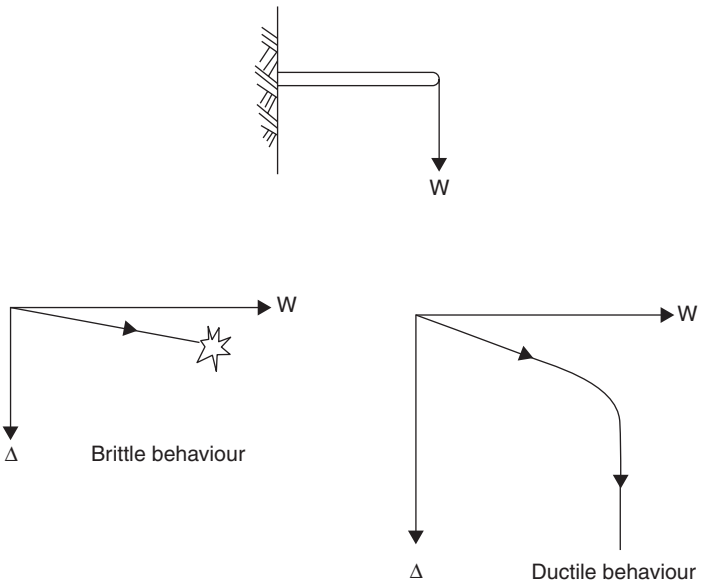

Figure 5.2 Brittle and ductile behaviour of stool leg

It is here that concepts of ductility and robustness come in and the illustrative model can be extended to include material properties. **Figure 5.2** shows the load-displacement properties of a leg, either when acting as a cantilever or in axial compression. In one case, very brittle behaviour is illustrated such that at a certain load the strength of the leg is lost completely, as it would be if it were made of glass. In the second case, the member exhibits ductile behaviour and retains its strength once yield has occurred.

If brittle material is used for the three-legged stool, then accidental overload, due perhaps to a very heavy milkmaid or the cow kicking out at the stool, can easily result in total collapse. Clearly high factors of safety are required to deal with this design. It may be decided to opt for four legs but this may be of little help. The design load for each leg would have to be 1.5 times higher than for the three-legged design. Moreover, accidental overload may cause loss of one member and there is then a risk of progressive collapse. In other words the structure is *fragile*.

If ductile properties are chosen, there is little likelihood of catastrophic collapse if one of the three legs is damaged. Moreover, with four legs there is scope for redistribution of the load once the carrying capacity of a leg is reached. Even accidental removal or serious damage to one member is unlikely to give rise to progressive collapse.

This simple example is very profound and can be extended to other aspects of structural behaviour and design including buckling and ground–structure interaction. Above all, it illustrates the importance of ductility, robustness and redundancy. It is useful to quote Heyman's (1996) conclusions to his study of Hambly's paradox:

> Hambly's four-legged stool stands, of course, for the general problem of design of any redundant structure. It has long been recognised that, in order to calculate the 'actual' state of a structure under specified loading, all three of the basic structural statements must be made – equilibrium, material properties and deformation (compatibility and boundary conditions). However, the calculations do not in fact lead to a description of the actual state. Boundary conditions are, in general, unknown and unknowable; an imperfection in assembly, or a small settlement of a footing, will lead to a state completely different from that calculated. This is not a fault of the calculations, whether elastic or not – it is a result of the behaviour of the real structure. … There is no correct solution to the equations, but one solution that will lead to the greatest economy in material. This is the solution sought by the simple plastic designer, and it is safe and valid provided that no instability is inherent in the structure.

The important message is that, in the process of structural modelling, the inherent uncertainties are such that the precise state of the structure cannot usually be calculated. The art of structural engineering is to use the process of modelling to produce a design that is robust enough to safely cope with the uncertainties, at reasonable cost, and that is fit for purpose. Difficulties arise in interacting with geotechnical engineers when the inherent uncertainties in the structural analysis are not recognised, i.e. when the output from a computer program is believed to represent the true state of a structure.

5.3 Geotechnical modelling

Soil mechanics is a difficult subject and is regarded by many structural engineers as a kind of black art. It is helpful to discuss the reasons for some of the difficulties.

One difficulty is that the soil, unlike concrete or steel, is a particulate material with little or no bonding between the particles. It is made up of an infinite variety of shapes and sizes of particles. This material is usually modelled as a continuum – but it is important never to forget that its properties are determined by its particulate nature.

Because soil is particulate, the water pressures acting within the soil pores are just as important as the stresses applied to its boundaries. This means that changes in the groundwater regime can be crucial in stabilising, or destabilising, a slope, retaining wall or foundation.

In summary, whereas the strength of structural materials, such as steel and concrete, is primarily cohesive and well defined, soil is primarily frictional, so that the confining pressure and pore water pressure determine its strength and stiffness.

5.3.1 The geotechnical triangle

But it is not just the complexity of soil as a material which causes difficulty. As pointed out in Chapter 4 *The geotechnical triangle* there are at least four distinct but interlinked aspects of any geotechnical problem:

- the ground profile – what is there and how it got there;
- the measured behaviour of the ground;

- prediction using appropriate models;
- empirical procedures; judgement based on precedent and 'well-winnowed experience'.

It is the author's experience that the major difficulty in soil mechanics lies, not so much in the complexity of the material as such, but in the fact that, all too often, the boundaries between the above four aspects become confused (Burland, 1987).

The first three of these may be depicted as forming the apexes of a triangle with empirical procedures occupying the centre as shown in **Figure 5.3**. Associated with each of these aspects is a distinct and rigorous activity or discipline.

Ground profile: This is the visual description in simple engineering terms of the successive strata making up the ground together with the groundwater conditions. The importance of handling and describing the soil so as to establish the ground profile cannot be over-emphasised. It is also important to understand how the ground got there and what might have happened to it during its formation – what is termed its *genesis*. As described in Chapter 13 *The ground profile and its genesis*, establishing the ground profile is a key outcome of carrying out a site investigation – often far more important than measuring the material properties.

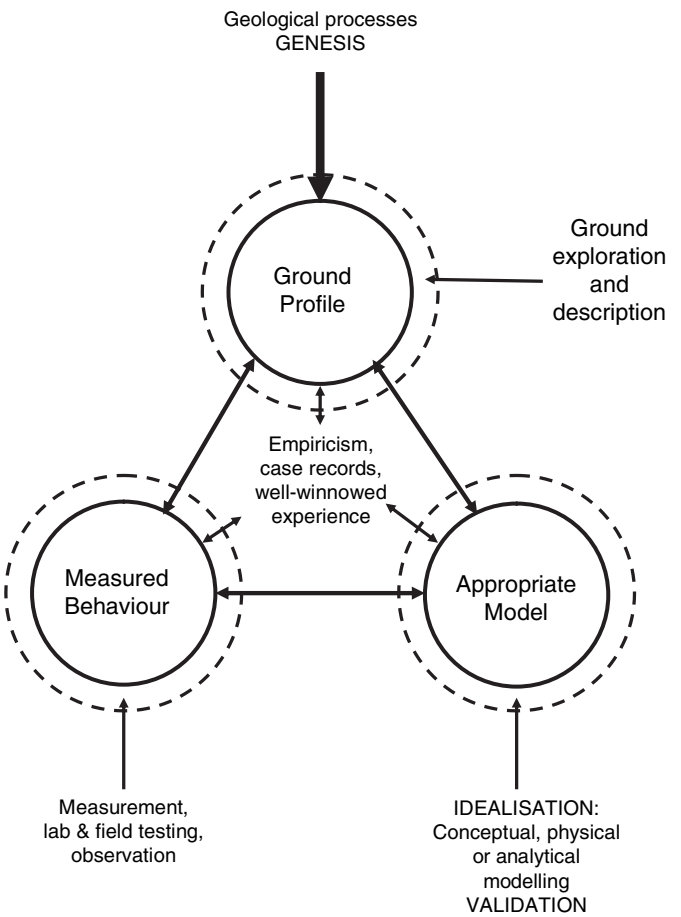

Figure 5.3 The geotechnical triangle. Each activity has its own distinct methodology and its own rigour

Behaviour of the ground: This is established from laboratory or *in situ* tests and usually requires very careful and experienced interpretation. The properties may also be inferred from field measurements of behaviour, e.g. the back analysis of a landslip or of settlement observations. Section 2 *Fundamental principles* of this manual provides a practical introduction to the fundamentals of soil and rock behaviour.

Appropriate modelling: This can be carried out at all sorts of levels. It may be purely conceptual and instinctive, it might be physical modelling or it can involve extremely sophisticated mathematical or numerical work. At whatever level, modelling first involves identifying what is to be modelled, and then follows a process of idealisation (to analyse is first to idealise), after which the analysis itself is undertaken. This should then be followed up by review and assessment – it often isn't! Frequently in soil mechanics, as in structural engineering, it is understanding the basic mechanisms of behaviour that is the key rather than the fine quantitative detail. It may be of interest to note that, whereas the success of much structural modelling relies on the *lower bound theorem of plasticity*, geotechnical modelling has traditionally made use of both the *lower* and *upper bound theorems of plasticity* for the study of limiting equilibrium using stress characteristics and slip-line fields. Thus, both disciplines are firmly grounded in plasticity. For both disciplines, if the material or structure is brittle in its response, extreme caution is required, as the lower and upper bound theorems no longer strictly apply.

Empirical procedures: With a material as complex as the ground, empiricism is inevitable and it is (and will always remain) an essential aspect of ground engineering. Many of our design and construction procedures are the product of what the author has termed *well-winnowed experience.*

Each activity in the geotechnical triangle has its own distinct methodology and rigour. Geotechnical modelling requires that each aspect be considered and that the geotechnical triangle remains 'in balance'. See Chapter 4 *The geotechnical triangle* for a more detailed discussion of the geotechnical triangle.

5.4 Comparisons between structural and geotechnical modelling

It is immediately obvious from the above that the processes of geotechnical modelling usually involve much greater explicit uncertainties and complexities in idealising both the geometry and the material properties than in structural modelling, where both of these are usually specified by the engineer.

In introducing the subject of soil–structure interaction to students, the author starts by asking them to imagine the utopian situation of having unlimited computational power in which, given the *geometry* of the problem, the *material properties* and the *loading*, any problem can be analysed. With this unlimited computational power, how much better would the results be?

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

As soon as the idealisations that are involved in most ground–structure interaction problems and the uncertainties of the boundary conditions are examined, it becomes obvious that the results will not be much better than they are today. Any design has to make allowance for these uncertainties.

5.4.1 The geotechnical triangle revisited

Hopefully, the above discussion will serve to help structural engineers to understand why the process of modelling geotechnical problems is inherently less certain than it appears to be for most structural problems. This is because much of the time the structural engineer is working with materials that are specified and manufactured under strict control. Usually the structural form can be idealised in a reasonably straightforward manner. The major uncertainties lie in the loading, in inevitable imperfections and in the connections. In geotechnical engineering, both the geometry (ground profile) and the properties (ground behaviour) of the 'structure' are laid down by nature and not specified. Precise analysis is usually not possible and the key requirement is to understand the dominant mechanisms of behaviour and their likely bounds.

Perhaps the differences between routine structural and geotechnical modelling can best be illustrated by comparing the approach of the structural engineer working on an existing building to that of the geotechnical engineer. In this situation the structural engineer is no longer able to specify the material and the structural form is often difficult to idealise (Burland, 2000). **Figure 5.4** shows an isometric of the West Tower of Ely Cathedral, which was strengthened during 1973 and 1974 as described by Heyman (1976). Also shown in **Figure 5.4** is the geotechnical triangle of **Figure 5.3** but with some descriptions changed to show the key activities undertaken by a structural engineer. For the *soil profile* at the top of the triangle, the *structure of the building and its materials* has been inserted. To establish these requires the most careful examination and investigation. As with the ground, small discontinuities and weaknesses can play a major role in determining the overall response. It is also vital to establish the way the building was constructed and the changes that have taken place historically – this might be called the *genesis of the building* and it is analogous to the geological processes that have formed the ground profile. At the bottom left of the triangle are the *properties* of the materials and the *observed behaviour* of the building. This aspect requires observation, field measurement, sampling and testing. At the bottom right of the triangle there is the need to develop *appropriate predictive models* that take account of the form and structure of the building, its history, its material properties and known behaviour – an almost identical requirement to that for the ground. There is a whole spectrum of models that can be developed, ranging from the intuitive and conceptual right through to highly sophisticated numerical models. The key is to appreciate the inevitable idealisations that have to be made and the limitations that they impose. Finally, as in ground engineering, well-winnowed experience is of supreme importance and well-documented case records are invaluable. It is of interest to note that, in developing his structural understanding of the behaviour of the West Tower of Ely Cathedral, Heyman (1976) drew extensively on the *safe design theorem* and did not attempt to model the 'actual' stress distributions within the structure.

It is evident from the foregoing that, even if engineers were in possession of unlimited analytical power, the uncertainties in both the ground and the structure are so great that precision in the prediction of behaviour would be unlikely to improve significantly. As in so many fields of engineering, modelling is only one of many tools required in designing for the soil–structure interaction. In most circumstances the real value of modelling will be in assisting the engineer to place bounds on the likely overall behaviour, in understanding the mechanisms of behaviour and in beneficially modifying that behaviour if necessary.

5.5 Ground–structure interaction

Both structural engineering and geotechnical engineering adopt a variety of procedures for modelling a wide range of problems. Section 2 *Fundamental principles* of this manual describes the basic approaches to a variety of geotechnical problems such as bearing capacity, settlement prediction, slope stability, etc. The book by Hambly (1994), mentioned previously, summarises the range of problems and types of analysis that a structural engineer encounters in day-to-day practice. Difficulties emerge when it is necessary to combine structural and geotechnical modelling.

Structural engineers are tempted to model the ground as a series of discrete springs since this allows conventional structural analysis software to be used. Sometimes sophisticated springs are used incorporating bilinear or nonlinear load-deflection characteristics to simulate the onset of plastic behaviour. Under certain circumstances it is reasonable to adopt springs to model the interaction with the ground (e.g. in some retaining-wall problems) but in the majority of situations their use is inappropriate and leads to very misleading results.

The simple case of a uniformly loaded flexible slab resting on clay can be used to illustrate the inappropriateness of adopting springs to model the ground – see **Figure 5.5(a)**. It is well known that for the majority of types of ground the slab will settle more in the middle than at the edges and settlement will also take place outside the loaded area, as shown in **Figure 5.5(b)**. Methods of calculating these settlements are described in Chapter 19 *Settlement and stress distributions*. If the soil is represented by a series of springs, then, as shown in **Figure 5.5(c)**, it is evident that the slab will settle uniformly and there will be no settlement outside the loaded area. Moreover, there is no simple standard way of calculating the appropriate spring stiffness from the measured compressibility or stiffness of the ground. Thus, the use of springs to represent the ground in this case will not be capable of capturing the differential settlements across a building founded on the slab or of simulating possible interaction effects with adjacent structures or services.

In cases where the ground–structure interaction is likely to be important it is essential that the structural engineer and geotechnical engineer interact so that an appropriate approach to modelling can be developed. It is hoped that this chapter will help each to understand the other so as to lead to positive and constructive interaction between them.

5.6 Conclusions

This chapter explores the differences in the philosophy of modelling and analysis between structural and geotechnical engineers. The idealisations that are involved in both disciplines are compared. It has been demonstrated that the approach that has to be adopted by a structural engineer working on an existing historic building is very similar to that of a geotechnical engineer working with the ground.

Superficially it might seem that the idealisations adopted by a structural engineer in routine practice are more certain than those that have to be adopted by a geotechnical engineer. However, on closer examination it has to be concluded that the calculation of the 'actual' state of a structure or building under a known set of loads is very uncertain.

The success of structural design calculations owes much to the inherent ductility of the structural elements, so that the *safe design theorem* applies. Geotechnical engineers, too, owe much to the plastic ductile behaviour of their materials and foundations for the success of their designs. In both cases it is vital to identify brittle behaviour as this invalidates the *safe design theorem* and can lead to progressive collapse.

Structural engineers tend to work and think in terms of forces and stresses. Geotechnical engineers are much more used to working with strain and deformation. This difference becomes particularly apparent for situations in which elements of the building or ground approach their maximum resistance. Structural engineers brought up on concepts of limiting stress find it difficult to accept behaviour that implies the full mobilisation of resistance (which is not the same as 'failure'). Reference to Hambly's three- and four-legged stool (*Hambly's paradox*) greatly aids in the understanding of the above ideas.

Of overriding importance is the need to gain a clear understanding of the mechanisms of behaviour of a soil–structure interaction system. If the analytical, computer or conceptual model does not capture the key mechanism, no amount of sophisticated computation will help solve the problem.

In summary, understanding and designing for the ground–structure interaction requires all the traditional skills of the engineer: reliance on observation and measurement; a deep understanding of materials, both ground and structural; the development of appropriate physical and analytical models to reveal the underlying mechanisms of behaviour; and *well-winnowed experience* based on a discerning knowledge of precedents and case histories.

6.1 General

Geotechnical analysis is part of the geotechnical design process, performed with the aim of assessing (i) the stability and serviceability of the new construction and (ii) the effects that the new construction imposes on existing adjacent structures and services. With respect to this, there are several forms of stability to be confirmed by geotechnical calculations. Firstly, it must be checked that the structure and its support system are stable as a whole, with no danger of promoting either local failure of the structure itself, or global failure involving the surrounding soil domain. Secondly, the loads on any structural elements must be calculated so that the structures can be designed to carry them safely. Finally, movements of both the structure and the ground must be evaluated, in particular if there are structures and services nearby. It may also be necessary to calculate any structural forces induced in the existing structures and services, to assess whether they can be safely sustained.

As part of the design process, it is necessary for an engineer to perform calculations to obtain estimates of the above quantities. Analysis provides the mathematical framework for such calculations. However, the usefulness of an analysis depends on its input. Only a simulation involving realistic material properties and loading conditions enables a proper understanding of the problem.

6.2 Theoretical classification of analysis methods

For the analysis of a geotechnical problem to be theoretically exact, it has to satisfy the following four requirements: equilibrium, compatibility, constitutive behaviour and boundary conditions.

6.2.1 Equilibrium

Equilibrium under static conditions implies that the applied external loads to the soil domain are fully counteracted by the internal stresses generated within the soil domain. External loads are any concentrated forces and distributed loads on the boundaries of the soil domain, as well as any body forces such as the soil's self-weight. In general three dimensional (3D) stress space the internal stresses have six components, three direct and three shear stresses, in the three coordinate directions. This theoretical requirement can be written in terms of the following equilibrium equations, for each of the coordinate directions:

$$\sum F_x = \frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} + \gamma = 0$$

$$\sum F_y = \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} = 0$$

$$\sum F_z = \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \sigma_z}{\partial z} = 0$$

where x, y and z are the coordinate directions; σ_x, σ_y and σ_z are the direct stresses in three coordinate directions; and τ_{xy}, τ_{xz} and τ_{yz} are the three shear stresses. The only external load in the above equation is the self-weight, γ, which is assumed to act in the x-direction.

6.2.2 Compatibility

Compatibility is a requirement related to the soil's deformations. If the applied loads do not result in rupture or overlapping of the soil, such deformations are considered to be compatible. Otherwise, they are non-compatible. Compatible deformations can be ensured by defining consistent strains. These strains are calculated from the displacements of the soil element, which

Method of analysis		Theoretical requirements: Equilibrium	Compatibility	Constitutive behaviour	Boundary conditions: Force	Displacement

have three components, u, v and w, in the three coordinate directions, x, y and z, respectively. They are:

$$\varepsilon_x = \frac{\partial u}{\partial x};\ \varepsilon_y = \frac{\partial v}{\partial y};\ \varepsilon_z = \frac{\partial w}{\partial z}$$

$$\gamma_{xy} = \frac{\partial v}{\partial y} + \frac{\partial u}{\partial y};\ \gamma_{yz} = \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y};\ \gamma_{xz} = \frac{\partial w}{\partial x} + \frac{\partial u}{\partial z}.$$

Similar to stresses, there are three direct strains, ε_x, ε_y and ε_z, and three shear strains, γ_{xy}, γ_{yz} and γ_{xz}.

6.2.3 Constitutive behaviour

For analysis purposes the behaviour of the soil, in terms of its load-deformation characteristics, is expressed through a set of constitutive equations. These provide a link between stresses and strains, and hence a link between equilibrium and compatibility. Depending on the stress–strain relationship, a soil can be characterised as one of the following: ductile, brittle, strain hardening or strain softening.

For calculation purposes the constitutive behaviour can be expressed in the following mathematical form:

$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \sigma_z \\ \tau_{xy} \\ \tau_{yz} \\ \tau_{xz} \end{Bmatrix} = \begin{bmatrix} D_{11} & D_{12} & D_{13} & D_{14} & D_{15} & D_{16} \\ D_{21} & D_{22} & D_{23} & D_{24} & D_{25} & D_{26} \\ D_{31} & D_{32} & D_{33} & D_{34} & D_{35} & D_{36} \\ D_{41} & D_{42} & D_{43} & D_{44} & D_{45} & D_{46} \\ D_{51} & D_{52} & D_{53} & D_{54} & D_{55} & D_{56} \\ D_{61} & D_{62} & D_{63} & D_{64} & D_{65} & D_{66} \end{bmatrix} \cdot \begin{Bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_z \\ \gamma_{xy} \\ \gamma_{yz} \\ \gamma_{xz} \end{Bmatrix}$$

or, more succinctly:

$$\{\boldsymbol{\sigma}\} = [\boldsymbol{D}] \cdot \{\boldsymbol{\varepsilon}\}$$

where D_{ij} (i=1,6; j=1,6) are the components of the constitutive matrix $[\boldsymbol{D}]$ and $\{\boldsymbol{\sigma}\}$ and $\{\boldsymbol{\varepsilon}\}$ are vectors of stress and strain components, respectively. The elements D_{ij} of the constitutive matrix represent soil properties (e.g. Young's modulus, Poisson's ratio, angle of shearing resistance) and depend on the complexity of soil behaviour and the constitutive model applied to simulate it.

6.2.4 Boundary conditions

Boundary conditions are any restrictions applied on the boundaries of the soil domain which have to be satisfied in order that equilibrium, compatibility and constitutive behaviour are not violated. They can be applied in terms of forces and displacements.

6.2.5 Categories of analysis methods

As stated at the beginning of this section, all four theoretical requirements have to be satisfied for the analysis solution to be exact. It is therefore useful to review the broad categories of analysis currently in use against these theoretical requirements.

Current methods of analysis can be grouped into the following categories: closed form, simple (or classical) and numerical analysis. The ability of each method to satisfy the fundamental theoretical requirements and provide design information are summarised in **Tables 6.1** and **6.2**.

Method of analysis		Design requirements: Stability	Movements	Adjacent structures
Closed form		✗	✓	✗
Limit equilibrium		✓	✗	✗
Stress field		✓	✗	✗
Limit analysis	LB (Lower bound)	✓	✗	✗
	UB (Upper bound)	✗	Crude estimate	✗
Beam-spring approach		✓	✗	✗
Full numerical analysis		✓	✓	✓

Table 6.2 Design requirements satisfied by various methods of analysis

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

6.3 Closed form solutions

A closed form solution is in many ways the ultimate method of analysis. If it is possible, for a particular geotechnical structure, to establish realistic constitutive models for material behaviour and appropriate boundary conditions, and to combine these with the equations of equilibrium and compatibility, then an exact solution can be obtained which satisfies all of the above theoretical requirements.

However, as soil is a highly complex multi-phase material which behaves nonlinearly when loaded, a closed form solution to realistic geotechnical problems is not normally possible. Closed form solutions are only possible for two very simple situations:

(i) The soil is an isotropic linear elastic material. The solution provides an estimate of movements and structural forces, but cannot be used for assessing stability. However, comparison with observed behaviour of geotechnical structures indicates that even the predictions of movement are often not realistic.

(ii) This situation involves elasto-plastic problems, where the geometry of the problem contains sufficient geometric symmetries such that it can be reduced to being essentially one dimensional. Examples of this are solutions for the expansion of spherical and infinitely long cylindrical cavities in an infinite elasto-plastic continuum.

6.4 Classical methods of analysis

Classical methods of analysis enable more realistic solutions to geotechnical problems; however, they also involve approximations. Whereas mathematics is still used to obtain a solution, one of the theoretical requirements may not be satisfied. Therefore, the solution is not exact in a theoretical sense. This approach was adopted by the pioneers of geotechnical engineering, when computer power was non-existent and it was therefore impossible to obtain a complete solution utilising purely manual calculations.

This group of analysis methods consists of the limit equilibrium, stress field and limit analysis methods. They consider only the ultimate limit states when the soil is at failure, but differ in the manner in which they arrive at a solution.

6.4.1 Limit equilibrium method

This method of analysis involves the following steps:

- An arbitrary failure surface is adopted for the problem, i.e. its position and shape, which can be either planar or curved, or a combination of both.
- The failure criterion is assumed to hold everywhere along the failure surface.
- Only the global equilibrium of the rigid blocks of soil between the failure surfaces and the boundaries of the problem is considered; external forces acting on the blocks include the self-weight; internal forces (stresses) are generated only along the failure surfaces.
- The internal stress distribution within the blocks of soil is not considered (i.e. they are assumed to be rigid).

The Coulomb wedge analysis for retaining walls and the method of slices for slopes are examples of limit equilibrium calculations. These calculations do not consider the compatibility requirement and it is therefore not possible to obtain any information about the possible movements of the soil.

6.4.2 Stress field method

As it can be seen in **Table 6.1**, the stress field method satisfies the same theoretical requirements as the limit equilibrium method of analysis and adopts the same assumption for soil behaviour (i.e. rigid with a failure criterion). However, there is an important difference in the assumptions of this method: while the limit equilibrium method assumes failure in the soil only along the failure surface, the stress field method assumes failure everywhere in the soil domain. Therefore, the equilibrium equations in the stress field method have to be written for an infinitesimal soil element in the form of partial differential equations. This complicates the solution process as it leads, when combined with the equations of the failure criterion, to a set of hyperbolic partial differential equations. These equations can only be solved analytically if the soil is assumed to be weightless. While a weightless soil is clearly unrealistic there are some scenarios where the soil's weight does not affect the solution and consequently analytical solutions are applicable. For example, appropriate analytical solutions are available for some boundary value problems where the soil behaves in an undrained manner with a Tresca (S_u) failure criterion (i.e. the bearing capacity of surface footings). For boundary value problems where weight is important and/or the soil behaves in a drained manner with a Mohr–Coulomb failure criterion, the governing partial differential equations must be solved using an approximate finite difference approach. Again, because compatibility is not considered, the method does not provide any information about ground movements and considers only the ultimate limit states (i.e. failure).

Examples of stress field solutions are the Rankine active and passive stress fields for earth pressure calculations and the earth pressure tables of Sokolovski (1960, 1965). The stress field method is also used for solving bearing capacity problems. The Prandtl (1920) and Hill (1950) stress fields for a rigid strip footing are examples. Computer programs are also available for performing stress field calculations for problems with complex geometries (Martin, 2005).

6.4.3 Limit analysis method

Limit analysis calculations provide bounds to the exact solution. The upper bound (UB) approach results in an unsafe estimate of the exact solution and arrives at the solution by ignoring equilibrium. The lower bound (LB) approach provides a safe estimate of the exact solution by ignoring the compatibility requirement. If the two solutions for the same problem are the same, then an exact solution to the problem is obtained.

In contrast to the limit equilibrium and stress field methods, the soil behaviour is assumed to be ideal elasto-plastic rather than rigid.

6.4.3.1 Safe theorem

If a statically admissible stress field covering the whole soil mass can be found, which nowhere violates the yield condition, then the loads in equilibrium with the stress field are on the safe side or equal to the true collapse loads.

This theorem is often referred to as the lower bound theorem. A statically admissible stress field consists of an equilibrium distribution of stress which balances the applied loads and body forces. As compatibility is not considered, an infinite number of stress fields can be postulated. The accuracy of the solution depends on how close the assumed stress field is to the real one for a given problem.

6.4.3.2 Unsafe theorem

An unsafe solution to the true collapse loads can be found by selecting any kinematically possible failure mechanism and performing a work rate calculation. The loads so determined are either on the unsafe side or equal to the true collapse loads.

This theorem is also known as the upper bound theorem. A kinematically possible failure mechanism is one that satisfies the compatibility requirements in the shear zones between blocks of soil in the assumed mechanism. Equilibrium of the work done by external and internal forces is then considered, instead of the equilibrium of the external and internal forces. Because the latter is not considered, an infinite number of failure mechanisms can be assumed. The accuracy of the solution depends on how close the assumed mechanism is to the real one in a given problem.

In practice it is often easier to postulate a realistic failure mechanism than an admissible stress field; consequently more use has historically been made of the unsafe theorem. It is rare to be able to obtain the same solution from both safe and unsafe calculations and when two such solutions are obtained, they usually provide differing answers which bracket the true solution – the true solution being that applicable to the ideal soil behaviour assumed to develop the limit theorems. To the authors' knowledge, there are only two geotechnical boundary value problems in which both safe and unsafe calculations have yielded the same result. One is the short term lateral load that can be sustained by an infinitely long cylindrical pile in an infinite clay deposit, and the other is the bearing capacity of surface strip footings.

Recently, considerable research effort has been expended in combining limit analysis with finite element techniques to develop an analysis tool that can deal with complex boundary value problems involving mixed soils (Sloan, 1988 a, b). Such a tool looks promising and should provide an alternative method for analysing ultimate limit states.

6.5 Numerical analysis

6.5.1 Beam-spring approach

This approach is used to investigate soil–structure interaction. For example, it can be used to study the behaviour of axially and laterally loaded piles, raft foundations, embedded retaining walls and tunnel linings. The major approximation is the assumed soil behaviour and two approaches are commonly used. The soil behaviour is either approximated by a set of unconnected vertical and horizontal springs (Borin, 1989), or by a set of linear elastic interaction factors (Pappin *et al*., 1985). Only a single structure can be accommodated in the analysis. Consequently, only a single pile or retaining wall can be analysed at a time. Further approximations must be introduced if more than one pile, retaining wall, or foundation, interact. Any structural support, such as props or anchors (retaining wall problems) is represented by simple springs (see **Figure 6.1**).

To enable limiting pressures to be obtained, for example on each side of a retaining wall, 'cut offs' are usually applied to the spring forces and interaction factors representing soil behaviour. These cut off pressures are usually obtained from one of the simple analysis procedures discussed above (e.g. limit equilibrium, stress fields or limit analysis). It is important to appreciate that these limiting pressures are not a direct result of the beam-spring calculation, but are obtained from separate approximate solutions and then imposed on the beam-spring calculation process.

Having reduced the boundary value problem to studying the behaviour of a single isolated structure (e.g. a pile, a footing, or

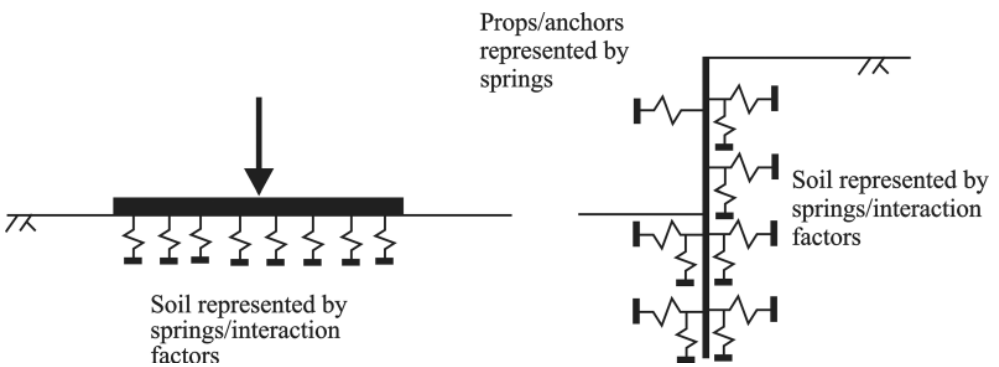

Figure 6.1 Examples of the beam-spring approach

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

a retaining wall) and made gross assumptions about soil behaviour, a complete theoretical solution to the problem is sought. Due to the complexities involved, this is usually achieved using a computer. The structural member (e.g. pile, footing, or retaining wall) is represented using either finite differences or finite elements and a solution that satisfies all the fundamental solution requirements is obtained by iteration.

Sometimes computer programs which perform such calculations are identified as finite difference or finite element programs. However, it must be noted that it is only the structural member that is represented in this manner and these programs should not be confused with those that involve full discretisation of both the soil and structural members by finite differences or finite elements, see section 6.5.2.

As solutions obtained in this way include limits to the earth pressures that can develop adjacent to the structure, they can provide information on local stability. This is often indicated by a failure of the program to converge. However, numerical instability may occur for other reasons and therefore a false impression of instability may be given. Solutions from these calculations include forces and movements of the structure. They do not provide information about global stability or movements in the adjacent soil. They do not consider adjacent structures.

It is difficult to select appropriate spring stiffness values and to simulate some support features. For example, when analysing a retaining wall it is difficult to account realistically for the effects of soil berms. Retaining wall programs using interaction factors to represent the soil can have problems in dealing with wall friction and often neglect shear stresses on the wall, or make further assumptions to deal with them. For the analysis of retaining walls, a single wall is considered in isolation and structural supports are represented by simple springs fixed at one end (grounded). It is therefore difficult to account for realistic interaction between structural components such as floor slabs and other retaining walls. This is particularly so if 'pin-jointed' or 'full moment' connections are appropriate. As only the soil acting on the wall is considered in the analysis, it is difficult to model realistically the behaviour of raking props and ground anchors which rely on resistance from soil remote from the wall.

6.5.2 Full numerical analysis

This category of analysis includes methods which attempt to satisfy all theoretical requirements, includes realistic soil constitutive models and incorporates boundary conditions that realistically simulate field conditions. Because of the complexities involved and the nonlinearities in soil behaviour, all methods are numerical in nature. The most widely used approaches are those based on finite difference and finite element methods. These methods essentially involve a computer simulation of the history of the boundary value problem from green field conditions, throughout the construction phase and into the long term.

The ability of full numerical analysis to accurately reflect field conditions essentially depends on (i) the ability of the constitutive model to represent real soil behaviour and (ii) the correctness of the boundary conditions imposed. The user has to define the appropriate geometry, construction procedure, soil parameters and boundary conditions. Structural members may be added and withdrawn during the numerical simulation to model field conditions. Retaining structures composed of several retaining walls interconnected by structural components can be considered and, because the soil mass is modelled in the analysis, the complex interaction between raking struts or ground anchors and the soil can be accounted for. The effect of time on the development of pore water pressures can also be simulated by including coupled consolidation. No postulated failure mechanism or mode of behaviour of the problem is required, as these are predicted by the analysis. The analysis allows the complete history of the boundary value problem to be predicted and a single analysis can provide information on all design requirements.

Potentially, the methods can solve full three dimensional problems and suffer none of the limitations discussed previously for the other methods. At present, the speed of computer hardware restricts analysis of most practical problems to two dimensional plane strain or axisymmetric sections. However, with the rapid development in computer hardware and its reduction in cost, the possibilities of full three dimensional simulations are imminent.

It is often claimed that these approaches have limitations. Usually these relate to the fact that detailed soils information or knowledge of the construction procedure is needed. In the authors' opinion, neither of these are limitations. If a numerical analysis is anticipated during the design stages of a project, it is then not difficult to ensure that the appropriate soil information is obtained from the site investigation. It is only if a numerical analysis is an afterthought, once the soil data has been obtained, that this may present difficulties. In this respect it is noted that site investigations are not always performed to an adequate standard to obtain certain parameters, and that not all parameters for advanced constitutive models can be directly obtained from the site investigation.

If the behaviour of the boundary value problem is not sensitive to the construction procedure, then any reasonable assumed procedure is adequate for the analysis. However, if the analysis is sensitive to the construction procedure then, clearly, this is important and it will be necessary to simulate the field conditions as closely as possible. Therefore, far from being a limitation, numerical analysis can indicate to the design engineer where, and by how much, the boundary value problem is likely to be influenced by the construction procedure. This will enable adequate provision to be made within the design.

Full numerical analyses are complex and should be performed by qualified and experienced staff. The operator must understand soil mechanics and, in particular, the constitutive models that the software uses, and be familiar with the software package to be employed for the analysis. Nonlinear numerical analysis is not straightforward and at present there are several algorithms (i.e. solution procedures) available for solving the nonlinear system of governing equations. Some are more accurate than others and

some are increment-size dependent. There are approximations within these algorithms and errors associated with discretisation. However, these can be controlled by the experienced user so that accurate predictions can be obtained.

Full numerical analysis can be used to predict the behaviour of complex field situations. It can also be used to investigate the fundamentals of soil–structure interaction and to calibrate some of the simple methods discussed above. However, as noted above, numerical analyses involve approximations and there are many pitfalls that can be encountered. Some of these approximations and pitfalls are considered below for the finite element method. However, it should be noted that similar considerations apply to finite difference approaches.

6.6 Overview of the finite element method

The finite element method involves the following steps.

(i) Element discretisation
This is the process of modelling the geometry of the problem under investigation by an assemblage of small regions, termed finite elements. These elements have nodes defined on the element boundaries, or within the element.

(ii) Primary variable approximation
A primary variable must be selected (e.g. displacements, stresses) and rules as to how it should vary over a finite element established. This variation is expressed in terms of nodal values. In geotechnical engineering, it is usual to adopt displacements as the primary variable.

(iii) Element equations
Use of an appropriate variational principle (e.g. minimum potential energy) to derive element equations:

$$[\boldsymbol{K}_E] \cdot \{\Delta \boldsymbol{d}_E\} = \{\Delta \boldsymbol{R}_E\}$$

where $[\boldsymbol{K}_E]$ is the element stiffness matrix, $\{\Delta \boldsymbol{d}_E\}$, is the vector of incremental element nodal displacements and $\{\Delta \boldsymbol{R}_E\}$ is the vector of incremental element nodal forces. It should be noted that the element stiffness matrix $[\boldsymbol{K}_E]$ is derived from the constitutive matrix $[D]$ discussed previously in section 6.2.3.

(iv) Global equations
Combine element equations to form global equations:

$$[\boldsymbol{K}_G] \cdot \{\Delta \boldsymbol{d}_G\} = \{\Delta \boldsymbol{R}_G\}$$

where $[\boldsymbol{K}_G]$ is the global stiffness matrix, $\{\Delta \boldsymbol{d}_G\}$ is the vector of all incremental nodal displacements and $\{\Delta \boldsymbol{R}_G\}$ is the vector of all incremental nodal forces.

(v) Boundary conditions
Formulate boundary conditions and modify the global equations. Loadings (e.g. line and point loads, pressures, body forces, construction and excavation) affect $\{\Delta \boldsymbol{R}_G\}$, while the prescribed displacements affect $\{\Delta \boldsymbol{d}_G\}$.

(vi) Solution of global equations
The above global equations are in the form of a large number of simultaneous equations. These are solved to obtain the displacements $\{\Delta \boldsymbol{d}_G\}$ at all the nodes. From these nodal displacements, secondary quantities – such as stresses and strains – are evaluated.

Several approximations are involved in the above process. Some of these are now considered in detail in the following sections.

6.7 Element discretisation

The geometry of the boundary value problem under investigation must be defined and quantified. Simplifications and approximations may be necessary during this process. For example, restraints on computational resources might impose that plane strain conditions have to be assumed. This geometry is then replaced by an equivalent finite element mesh which is composed of small regions called finite elements. For two dimensional problems, the finite elements are usually triangular or quadrilateral in shape, see **Figure 6.2**. Their geometry is specified in terms of the coordinates of key points on the elements called nodes. For elements with straight sides these nodes are usually located at the element corners. If the elements have curved sides then additional nodes, usually at the midpoint of each side, must be introduced. The set of elements in the complete mesh are connected together by the element sides and a number of nodes.

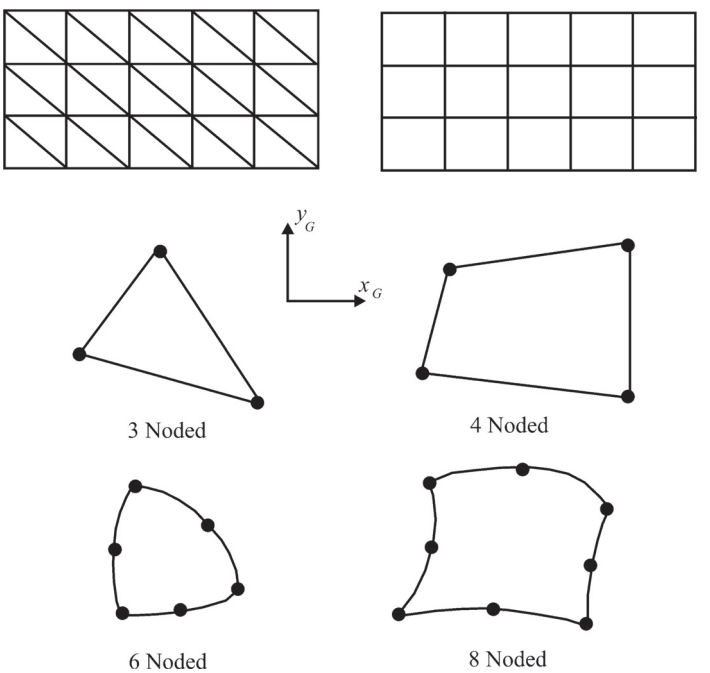

Figure 6.2 Typical 2D finite elements

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

When constructing the finite element mesh the following should be considered:

- The geometry of the boundary value problem must be approximated as accurately as possible.
- If there are curved boundaries or curved material interfaces, the higher order elements, with mid-side nodes should be used, see **Figure 6.3**.
- In many cases, geometric discontinuities suggest a natural form of subdivision. For example, discontinuities in boundary gradient, such as re-entrant corners or cracks, can be modelled by placing nodes at the discontinuity points. Interfaces between materials with different properties can be introduced by element sides, see **Figure 6.4**.
- Mesh design may also be influenced by the applied boundary conditions. If there are discontinuities in loading, or point loads, these may be introduced by placing nodes at the discontinuity points, see **Figure 6.5**.

In combination with the above factors, the size and the number of elements depend largely on the material behaviour which influences the final solution. For linear material behaviour, the procedure is relatively straightforward and only the zones where unknowns vary rapidly need special attention. In order to obtain accurate solutions, these zones require a refined mesh of smaller elements. The situation is more complex for general nonlinear material behaviour, since the final solution may depend, for example, on the previous loading history. For such problems, the mesh design must take into account the boundary conditions, the material properties and, in some cases, the geometry, all of which vary throughout the solution process.

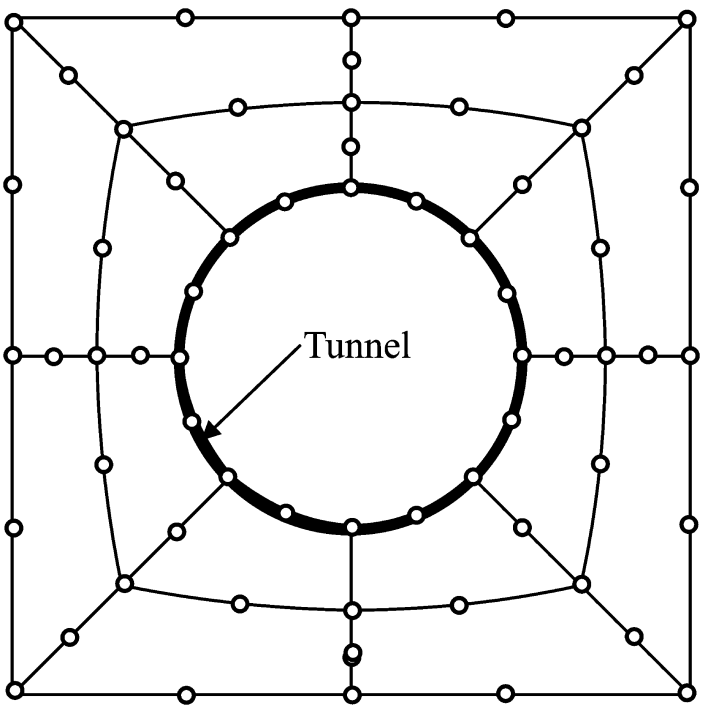

Figure 6.3 Use of higher order elements

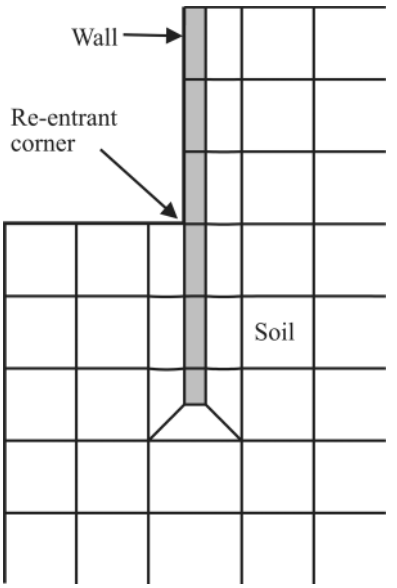

Figure 6.4 Effect of boundary conditions

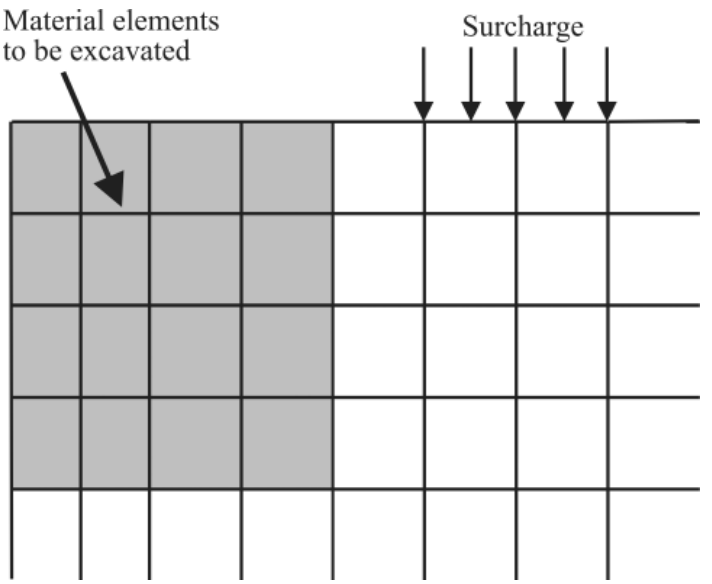

Figure 6.5 Geometric discontinuities

In all cases, a mesh of regularly shaped elements will give the best results. Elements with widely distorted geometries or long thin elements should be avoided.

To illustrate the error that can arise from the discretisation of the problem geometry into finite elements, the behaviour of smooth rigid strip and circular surface foundations under vertical loading will be considered. The soil is assumed to be linear elastic perfectly plastic, with a Tresca yield surface, with the following properties: Young's modulus, $E = 10\,000$ kPa, Poisson's ratio, $\mu = 0.45$ and undrained strength, $S_u = 100$ kPa.

Two alternative finite element meshes are shown in **Figures 6.6** and **6.7**. The mesh shown in **Figure 6.6** has 110 8-noded

isoparametric elements, whereas the mesh shown in **Figure 6.7** has only 35 8-noded elements. Both meshes have been used to perform plane strain (i.e. strip footing) and axisymmetric (circular footing) analyses, in which the foundation is displaced vertically downward to obtain the complete load–displacement curve. From a cursory glance at the two meshes, most users would probably conclude that the 110 element mesh was likely to produce the more accurate predictions due to its larger number of elements and their more even spatial distribution.

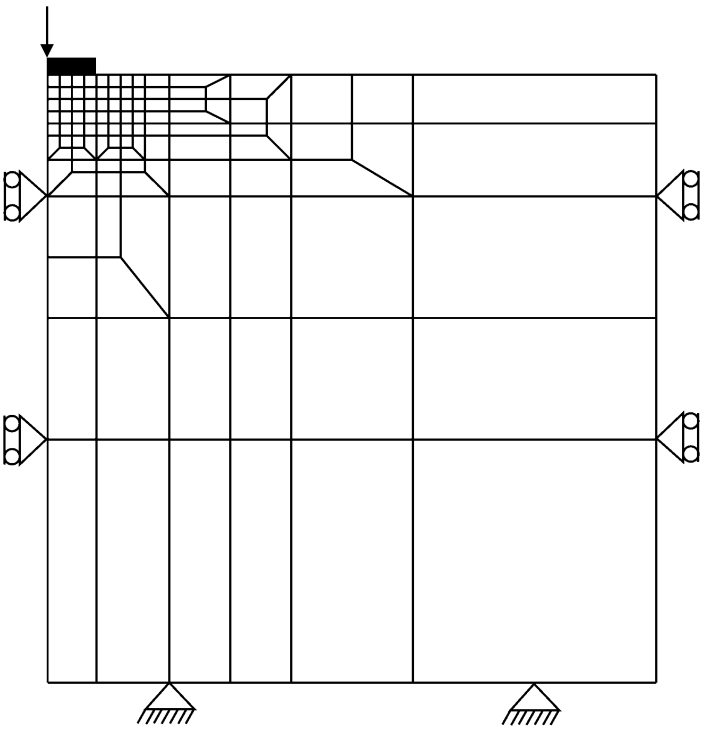

Figure 6.6 Smooth footing using a 110 element mesh

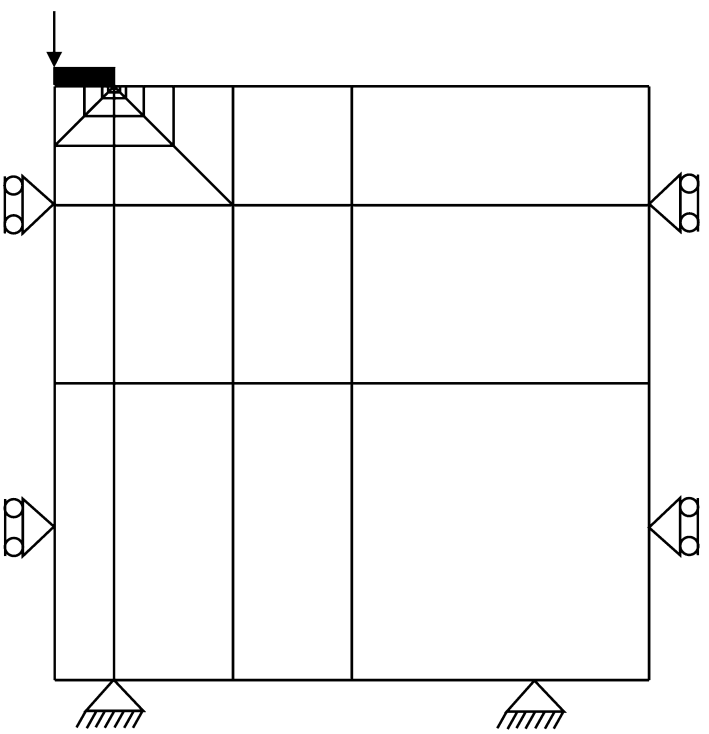

Figure 6.7 Smooth footing using a 35 element mesh

Although there is no analytical solution for the complete load–displacement curve for either the strip or the circular surface footings, there is an analytical solution for the ultimate load for the strip footing which gives $Q_{max} = q_f.2B$ per metre length, where $q_f = N_c S_u$, $N_c = (2 + \pi)$ and $2B$ is the width of the footing. Textbooks often quote an equivalent analytical solution for the circular footing of $Q = q_f.S_u.\pi R^2$, where $q_f = N_c S_u$, $N_c = 5.69$ and R is the radius of the footing. However, this solution is not strictly an analytical one, as it involves the numerical integration of some stress field equations. It is however thought to be reasonably accurate.

Results from finite element analysis using the meshes shown in **Figures 6.6** and **6.7** are presented in **Figure 6.8**. Also marked on this figure are the theoretical limit loads discussed above. Assuming that the theoretical limit loads are correct, then the analyses with the 110 element mesh overestimate the collapse loads by 3.8% for the strip footing, and 8.8% for the circular footing, respectively. However, the errors for the analyses performed using the 35 element mesh are much smaller: 0.5% for the strip and 2% for the circular footing. The reason for the relatively bad performance of the 110 element mesh can be seen in **Figure 6.9**, which shows vectors of incremental nodal displacements for the last increment of the 110 element strip footing analysis. Each vector indicates the magnitude (by its length) and direction (by its orientation) of the associated incremental nodal displacement. While the absolute magnitude of the incremental displacements is not important, the relative magnitude of each of the vectors and their orientation clearly indicates the mechanism of failure. Attention should, however, be focused on the corner of the footing where a rapid change in the direction of the incremental vectors is indicated. The direction changes by approximately 120° between the vector immediately below the corner of the footing and the adjacent node on the soil surface.

Such behaviour clearly indicates that under the corner of the footing there are large stress and strain gradients. In the 110 element mesh, the elements in the vicinity of this corner are too large and of insufficient number to accurately reproduce this concentration of behaviour. In comparison, the 35 element mesh – which has smaller elements and a graded mesh under the corner of the footing, see **Figure 6.10** – can accommodate this behaviour more easily and therefore produces more accurate solutions.

Clearly, it is important that smaller (and therefore more) elements are placed where there are rapid changes in stresses and strains, and therefore directions of movement. Some computer programs will automatically regenerate the finite element mesh to improve the accuracy of the solution. They work by first

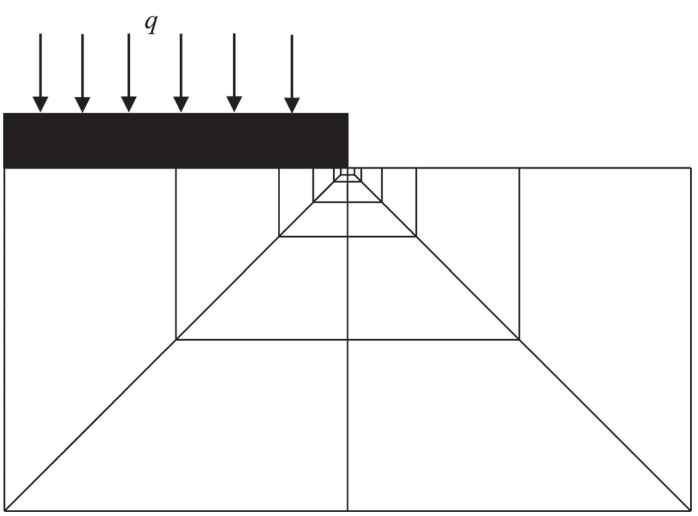

Figure 6.10 Detail from a 35 element mesh

performing a solution with a relatively even mesh. Based on the results of this analysis, a new mesh is generated with more elements in the zones of greatest stress and strain changes. The analysis is then repeated. In principle, this process of refinement could be repeated until the results were unaffected by further mesh refinement.

6.8 Nonlinear finite element analysis

If the soil is nonlinear elastic and/or elasto-plastic, the equivalent constitutive matrix is no longer constant, but varies with stress and/or strain. It therefore changes during a finite element analysis. Consequently, a solution strategy is required that can account for this changing material behaviour. This strategy is a key component of a nonlinear finite element analysis, as it can strongly influence the accuracy of the results and the computer resources required to obtain them.

As noted above, four basic solution requirements need to be satisfied: equilibrium, compatibility, constitutive behaviour and boundary conditions. Nonlinearity introduced by the constitutive behaviour causes the governing finite element equations to be reduced to the following incremental form:

$$\left[\boldsymbol{K}_G\right]^i \cdot \left\{\Delta \boldsymbol{d}_G\right\}^i = \left\{\Delta \boldsymbol{R}_G\right\}^i$$

where $[\boldsymbol{K}_G]^i$ is the incremental global system stiffness matrix, $\{\Delta \boldsymbol{d}_G\}^i$ is the vector of incremental nodal displacements, $\{\Delta \boldsymbol{R}_G\}^i$ is the vector of incremental nodal forces and i is the increment number. To obtain a solution to a boundary value problem, the change in boundary conditions is applied in a series of increments, and for each increment the above equation must be solved. The final solution is obtained by summing the results of each increment. Due to the nonlinear constitutive behaviour, the incremental global stiffness matrix $[\boldsymbol{K}_G]^i$ is dependent on the current stress and strain levels and is therefore not constant, but varies over an increment. Unless a very large number of small increments are used, this variation should be accounted for. Hence the solution of the above equation is not straightforward and different solution strategies exist. The objective of all such strategies is that the solution satisfies the four basic requirements listed above. Three different categories of solution algorithm, which are most popular in existing computer programs, are briefly considered below. For detailed information the reader is referred to Potts and Zdravkovic (1999).

6.8.1 Tangent stiffness method

The tangent stiffness method, sometimes called the variable stiffness method, is the simplest solution strategy. Using this approach, the incremental stiffness matrix $[\boldsymbol{K}_G]^i$ is assumed to be constant over each increment and is calculated using the current stress state at the beginning of each increment. This is equivalent to making a piecewise linear approximation to the nonlinear constitutive behaviour. To illustrate the application of this approach, the simple problem of a uniaxially loaded bar of nonlinear material is considered, see **Figure 6.11**. If this bar is loaded, the true load displacement response is shown in **Figure 6.12**. This might

represent the behaviour of a strain hardening plastic material which has a very small initial elastic domain.

In the tangent stiffness approach the applied load is split into a sequence of increments. In **Figure 6.12** three increments of load are shown, $\Delta \boldsymbol{R}_G{}^1$, $\Delta \boldsymbol{R}_G{}^2$ and $\Delta \boldsymbol{R}_G{}^3$. The analysis starts with the application of $\Delta \boldsymbol{R}_G{}^1$. The incremental global stiffness matrix $[\boldsymbol{K}_G]^1$ for this increment is evaluated based on the unstressed state of the bar corresponding to point **a**. For an elasto-plastic material this might be constructed using the elastic constitutive matrix. The first incremental equation is then solved to determine the nodal displacements $\{\Delta \boldsymbol{d}_G\}^1$. As the material stiffness is assumed to remain constant, the load–displacement curve follows the straight line **ab'** shown in **Figure 6.12**. In reality, the stiffness of the material does not remain constant during this loading increment and the true solution is represented by the curved path **ab**. There is therefore an error in the predicted displacement equal to the distance **b'b**, however in the tangent stiffness approach this error is neglected. The second increment of load, $\Delta \boldsymbol{R}_G{}^2$, is then applied, with the incremental global stiffness matrix $[\boldsymbol{K}_G]^2$ evaluated using the stresses and strains appropriate to the end of increment 1, i.e. point **b'** on **Figure 6.12**. Solving the incremental governing equation then gives the nodal displacements $\{\Delta \boldsymbol{d}_G\}^2$. The load–displacement curve follows the straight path **b'c'** on **Figure 6.12**. This deviates further from the true solution: the error in the displacements now being equal to the distance **c'c**. A similar procedure now occurs when $\Delta \boldsymbol{R}_G{}^3$ is applied. The stiffness matrix $[\boldsymbol{K}_G]^3$ is evaluated using the stresses and strains appropriate to the end of increment 2, i.e. point **c'** on **Figure 6.12**. The load–displacement curve moves to point **d'** and again drifts further from the true solution. Clearly, the accuracy of the solution depends on the size of the load increments. For example, if the increment size was reduced so that more increments were needed to reach the same accumulated load, the tangent stiffness solution would be nearer to the true solution.

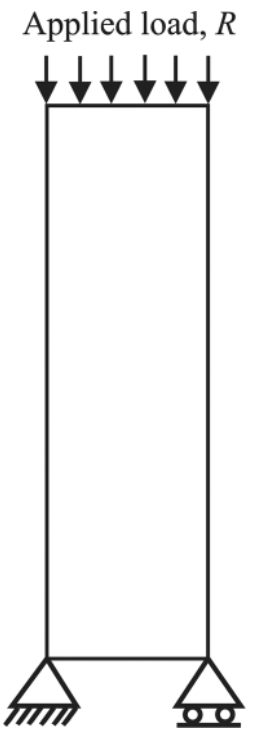

Figure 6.11 Uniaxially loaded bar

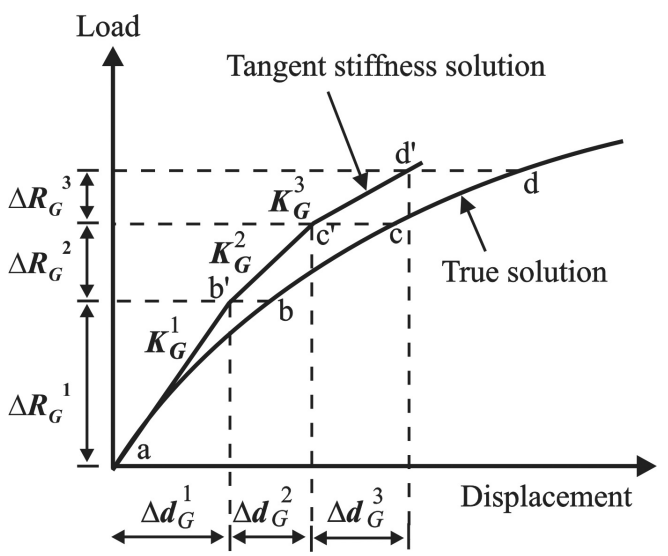

Figure 6.12 Application of the tangent stiffness algorithm

From the above simple example it may be concluded that in order to obtain accurate solutions to strongly nonlinear problems, many small solution increments are required. The results obtained using this method can drift from the true solution and the stresses can fail to satisfy the constitutive relations. Thus the basic solution requirements may not be fulfilled. It can be shown (Potts and Zdravkovic, 1999) that the magnitude of the error is problem-dependent and is affected by the degree of material nonlinearity, the geometry of the problem and the size of the solution increments used. Unfortunately, in general, it is impossible to predetermine the size of solution increment required to achieve an acceptable error.

The tangent stiffness method can give particularly inaccurate results when soil behaviour changes from elastic to plastic or vice versa. For instance, if an element is in an elastic state at the beginning of an increment, it is assumed to behave elastically over the whole increment. This is incorrect if, during the increment, the behaviour becomes plastic and results in an illegal stress state which violates the constitutive model. Such illegal stress states can also occur for plastic elements if the chosen increment size is too large – for example, a tensile stress state could be predicted for a constitutive model which cannot sustain tension. This can be a major problem with critical state type models, such as modified Cam Clay, which employ a v–ln p' relationship (v = specific volume, p' = mean effective stress), since a tensile value of p' cannot be accommodated. In this

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

case, either the analysis has to be aborted or the stress state has to be modified in some arbitrary way, which would cause the solution to violate the equilibrium condition and the constitutive model.

6.8.2 Visco-plastic method

This method uses the equations of visco-plastic behaviour and time as an artifice to calculate the behaviour of nonlinear, elasto-plastic, time-independent materials (Owen and Hinton, 1980; Zienkiewicz and Cormeau, 1974).

The method was originally developed for linear elastic visco-plastic (i.e. time dependent) material behaviour. Such a material can be represented by a network of the simple rheological units and is illustrated in **Figure 6.13**. Each unit consists of an elastic and a visco-plastic component connected in series. The elastic component is represented by a spring and the visco-plastic component by a slider and dashpot connected in parallel. If a load is applied to the network, one of two situations occurs in each individual unit. If the load is such that the induced stress in the unit does not cause yielding, the slider remains rigid and all the deformation occurs in the spring (elastic behaviour). Alternatively, if the induced stress causes yielding, the slider becomes free and the dashpot is activated. As the dashpot takes time to react, initially all the deformation occurs in the spring. However, with time, the dashpot moves. The rate of movement of the dashpot depends on the stress it supports and its viscosity. With time progressing, the dashpot moves at a decreasing rate, because some of the stress the unit is carrying is dissipated to adjacent units in the network, which as a result suffer further movements themselves (visco-plastic behaviour). Eventually, a stationary condition is reached where all the dashpots in the network stop moving and are no longer sustaining stresses. This occurs when the stress in each unit drops below the yield surface and the slider becomes rigid. The external load is now supported purely by the springs within the network; but, importantly, straining of the system has occurred not only due to compression or extension of the springs, but also due to movement of the dashpots. If the load was now removed, only the displacements (strains) occurring in the springs would be recoverable, the dashpot displacements (strains) being permanent.

Application to finite element analysis of elasto-plastic materials can be summarised as follows, using the example of a uniaxially loaded bar in **Figure 6.11**. On application of a solution increment, the system is assumed to instantaneously behave linear elastically (see **Figure 6.14**). If the resulting stress state lies within the yield surface, the incremental behaviour is elastic and the calculated displacements are correct. If the resulting stress state violates yield, the stress state can only be sustained momentarily and visco-plastic straining occurs. The magnitude of the visco-plastic strain rate is determined by the value of the yield function – which is a measure of the degree by which the current stress state exceeds the yield condition. The visco-plastic strains increase with time, causing the material to relax with a reduction in the yield function and hence a reduction in the visco-plastic strain rate. A marching technique is used to step forward in time until the visco-plastic strain rate is insignificant. At this point, the visco-plastic strain and the associated stress change are equal to the incremental plastic strain and the incremental stress change respectively.

In order to use the procedure described above, a suitable time step, Δt, must be selected. If Δt is small, many iterations are required to obtain an accurate solution. However, if Δt is too large, numerical instability can occur. The most economical choice for Δt is the largest value that can be tolerated without

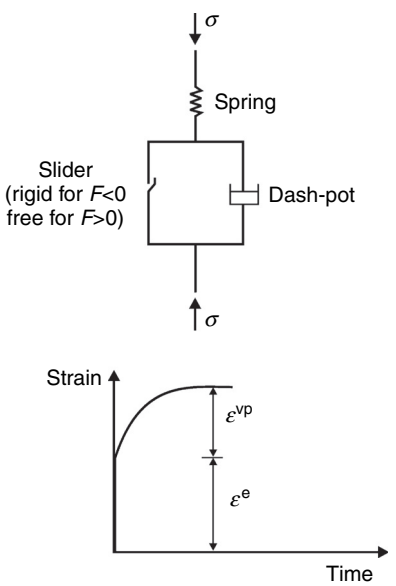

Figure 6.13 Rheological model for visco-plastic material

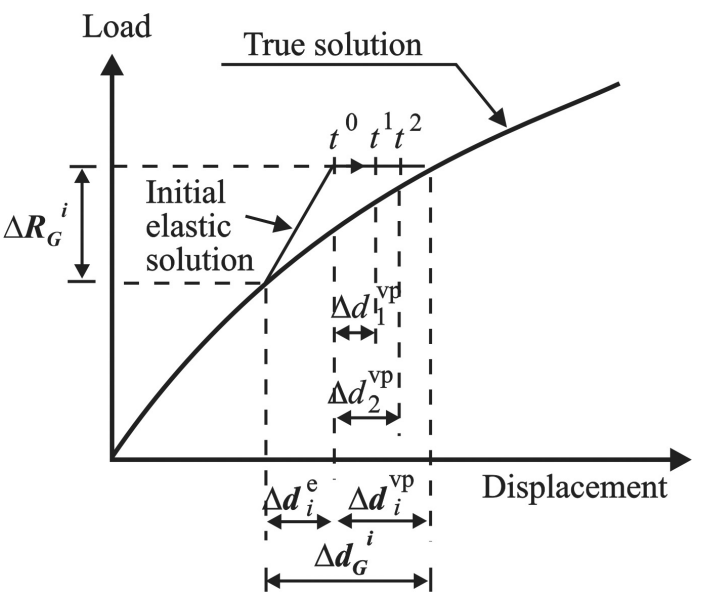

Figure 6.14 Application of the visco-plastic algorithm

causing such instability. For simple constitutive models, such as Tresca and Mohr–Coulomb, it can be shown that the value of the critical time step is dependent only on the elastic stiffness and strength parameters. As these parameters are constant, the critical time step has to be evaluated only once during an analysis. However, for more complex constitutive models, the critical time step is also dependent on the current state of stress and strain and therefore is not constant. It must therefore be continuously evaluated throughout the analyses.

Due to its simplicity, the visco-plastic algorithm has been widely used. However, in the authors' opinion, the method has severe limitations for geotechnical analysis. Firstly, the algorithm relies on the fact that for each increment the elastic parameters remain constant. The simple algorithm cannot accommodate elastic parameters that vary during the increment because, for such cases, it cannot determine the true elastic stress changes associated with the incremental elastic strains. The best that can be done is to use the elastic parameters associated with the accumulated stresses and strains at the beginning of the increment to calculate the elastic constitutive matrix, $[\boldsymbol{D}]$, and assume that this remains constant for the increment. Such a procedure only yields accurate results if the increments are small and/or the elastic nonlinearity is not great. Secondly, a more severe limitation of the method arises when the algorithm is used as an artifice to solve problems involving non-viscous material (i.e. elasto-plastic materials). Here, calculations to determine the plastic strains and elasto-plastic stress changes are evaluated at illegal stress states which lie outside the yield surface. This is theoretically incorrect and results in failure to satisfy the constitutive equations. The magnitude of the error depends on the constitutive model (see Potts and Zdravkovic, 1999).

6.8.3 Modified Newton–Raphson method

In both the tangent stiffness and visco-plastic algorithms, errors can arise because the constitutive behaviour is based on illegal stress states. The modified Newton–Raphson (MNR) algorithm attempts to rectify this problem by only evaluating the constitutive behaviour in, or very near to, legal stress space.

The MNR method uses an iterative technique to solve the system of equations. The first iteration is essentially the same as the tangent stiffness method. However, it is recognised that the solution is likely to be in error and the predicted incremental displacements are used to calculate the residual load, which is a measure of the error in the analysis. The system of equations is then solved again with this residual load, $\{\boldsymbol{\psi}\}$, forming the incremental right hand side vector. The system of equations can be then rewritten as:

$$[\boldsymbol{K}_G]^i \cdot (\{\Delta \boldsymbol{d}_G\}^i)^j = \{\boldsymbol{\psi}\}^j$$

The superscript j refers to the iteration number and $\{\boldsymbol{\psi}\}^0 = \{\Delta \boldsymbol{R}_G\}^i$. This process is repeated until the residual load is small. The incremental displacements are equal to the sum of the iterative displacements. This approach is illustrated in **Figure 6.15** for the simple problem of a uniaxially loaded bar

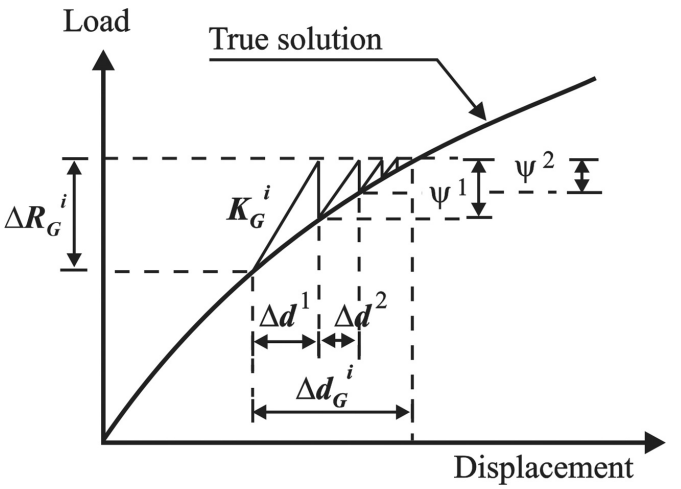

Figure 6.15 Application of the modified Newton–Raphson algorithm

of nonlinear material. In principle, the iterative scheme ensures that for each solution increment, the analysis satisfies all solution requirements.

A key step in this calculation process is determining the residual load vector. At the end of each iteration, the current estimate of the incremental displacements is calculated and used to evaluate the incremental strains at each integration point. The constitutive model is then integrated along the incremental strain paths to obtain an estimate of the stress changes. These stress changes are added to the stresses at the beginning of the increment and used to evaluate consistent equivalent nodal forces. The difference between these forces and the externally applied loads (from the boundary conditions) is the residual load vector. A difference arises because a constant incremental global stiffness matrix $[\boldsymbol{K}_G]^i$ is assumed over the increment. Due to the nonlinear material behaviour, $[\boldsymbol{K}_G]^i$ is not constant but varies with the incremental stress and strain changes.

Since the constitutive behaviour changes over the increment, care must be taken when integrating the constitutive equations to obtain the stress change. Methods of performing this integration are termed *stress point algorithms* and both explicit and implicit approaches have been proposed in various literature. There are many of these algorithms in use and, as they control the accuracy of the final solution, users must verify the approach used in their software (see Potts and Zdravkovic, 1999).

The process described above is called a Newton–Raphson scheme if the incremental global stiffness matrix $[\boldsymbol{K}_G]^i$ is recalculated and inverted for each iteration, based on the latest estimate of the stresses and strains obtained from the previous iteration. To reduce the amount of computation, the modified Newton–Raphson method only calculates and inverts the stiffness matrix at the beginning of the increment and uses it for all iterations within the increment. Sometimes the incremental global stiffness matrix is calculated using the elastic constitutive matrix, $[\boldsymbol{D}]$, rather than the elasto-plastic matrix, $[\boldsymbol{D}^{ep}]$.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Clearly there are several options here and many software packages allow the user to specify how the MNR algorithm should work. In addition, an acceleration technique is often applied during the iteration process (Thomas, 1984).

6.8.4 Comparison of the solution strategies

A qualitative comparison of the three solution strategies presented above suggests the following. The tangent stiffness method is the simplest, but its accuracy is influenced by increment size. The accuracy of the visco-plastic approach is also influenced by increment size (and by time step size) if complex constitutive models are used. The MNR method is potentially the most accurate and is likely to be the least sensitive to increment size. However, considering the computer resources required for each solution increment, the MNR method is likely to be the most expensive in terms of time required for an analysis; the tangent stiffness method is likely to be the cheapest and the visco-plastic method is probably somewhere in between. However, it may be possible to use larger and therefore fewer increments with the MNR method to obtain a similar accuracy. Thus, it is not obvious which solution strategy is the most economic for a particular solution accuracy.

To illustrate the difference between the solution strategies, two examples will be considered. Firstly, a smooth rigid strip footing subjected to vertical loading, as depicted in **Figure 6.16**, has been analysed. The soil has been modelled using a form of modified Cam Clay and has been assumed to behave undrained. The distribution of undrained strength with depth is shown in **Figure 6.16**. For further information on the constitutive model and the input parameters see Potts and Zdravkovic (1999). The finite element mesh is shown in **Figure 6.17**. Note that due to symmetry about the vertical line through the centre of the footing, only half of the problem needs to be considered in the finite element analysis. Plane strain conditions are assumed. Before loading the footing, the coefficient of earth pressure at rest, K_o, was assumed to be unity, and the vertical effective stress and pore water pressure were calculated using a saturated bulk unit weight of the soil of 20 kN/m^3 and a static water table at the ground surface. The footing was loaded by applying a series of equally sized increments of vertical displacement until the total displacement was 25 mm.

The load–displacement curves for the tangent stiffness, visco-plastic and MNR analyses are presented in **Figure 6.18**. For the MNR method, analyses were performed using 1, 2, 5, 10, 25, 50 and 500 increments to reach a footing settlement of 25 mm. With the exception of the analysis performed with only a single increment, all analyses gave very similar results and plot as a single curve (marked MNR on this figure). The MNR results are therefore insensitive to increment size and show a well defined collapse load of 2.8 kN/m.

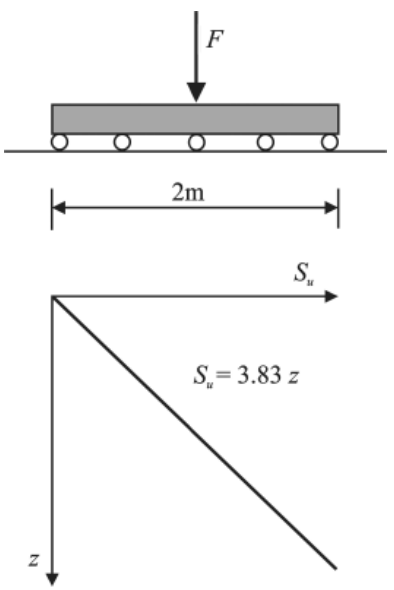

Figure 6.16 Geometry of footing

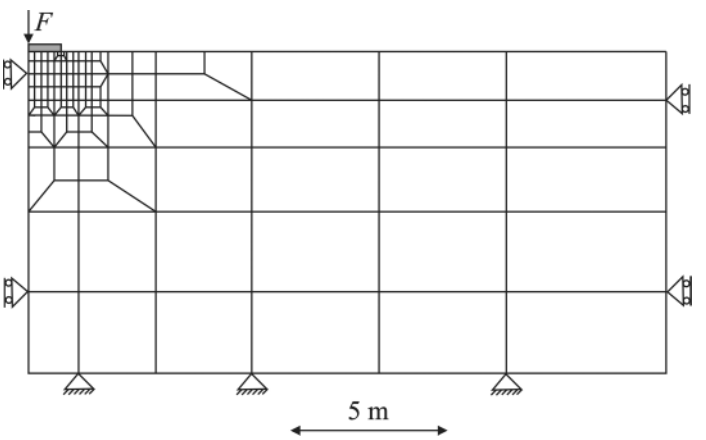

Figure 6.17 Finite element mesh for footing analyses

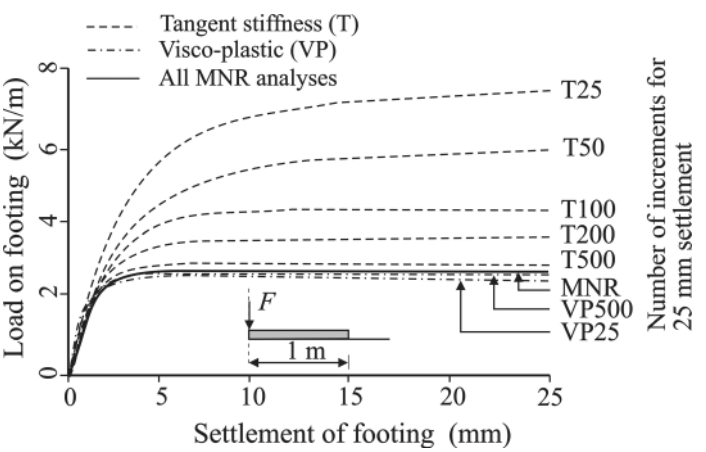

Figure 6.18 Footing load–displacement curves

For the tangent stiffness approach, analyses using 25, 50, 100, 200, 500 and 1000 increments have been carried out. Analyses with a smaller number of increments were also attempted, but illegal stresses (negative mean effective stresses, p') were predicted. As the constitutive model is not defined for such stresses, the analyses had to be aborted. Some finite element packages overcome this problem by arbitrarily resetting the offending negative p' values. There is no theoretical basis for this and it leads to violation of both the equilibrium and the constitutive conditions. Although such adjustments enable an analysis to be completed, the final solution is in error.

Results from the tangent stiffness analyses are shown in **Figure 6.18**. When plotted, the curve from the analysis with 1000 increments is indistinguishable from those of the MNR analyses. The tangent stiffness results are strongly influenced by increment size – the ultimate footing load decreasing from 7.5 to 2.8 kN/m as the applied displacement increment size reduces. There is also a tendency for the load–displacement curve to continue to rise and not to reach a well defined ultimate failure load for the analysis with large applied displacement increments. The results are unconservative, over predicting the ultimate footing load. There is also no indication from the shape of the tangent stiffness load–displacement curves as to whether the solution is accurate, since all the curves have similar shapes.

Visco-plastic analyses with 10, 25, 50, 100 and 500 increments were also performed. The 10 increment analysis had convergence problems in the iteration process; it would initially converge, but then diverge. Similar behaviour was encountered for analyses using still fewer increments. Results from the analyses with 25 and 500 increments are shown in **Figure 6.18**. The solutions are sensitive to increment size, but to a lesser degree than the tangent stiffness approach.

The load on the footing at a settlement of 25 mm is plotted against the number of increments, for tangent stiffness, visco-plastic and MNR analyses in **Figure 6.19**. The insensitivity of the MNR analyses to increment size is clearly shown. In these analyses the ultimate footing load only changed from 2.83 to 2.79 kN/m as the number of increments increased from 2 to 500. Even for the MNR analyses performed with a single increment; the resulting ultimate footing load of 3.13 kN/m is still reasonable and more accurate than the value of 3.67 kN/m obtained from the tangent stiffness analysis with 200 increments. Both the tangent stiffness and visco-plastic analyses produce ultimate failure loads which approach 2.79 kN/m as the number of increments increases. However, tangent stiffness analyses approach this value from above and therefore over predict, while visco-plastic analyses approach this value from below and so under predict. The CPU times and results for selected analyses are shown in **Table 6.3**. It should be noted that these analyses were completed many years ago, so the absolute time values are not indicative of analyses performed on modern computers. However the relative times are still valid.

The second example considers the mobilisation of the stresses in the soil immediately adjacent to a pile shaft during drained

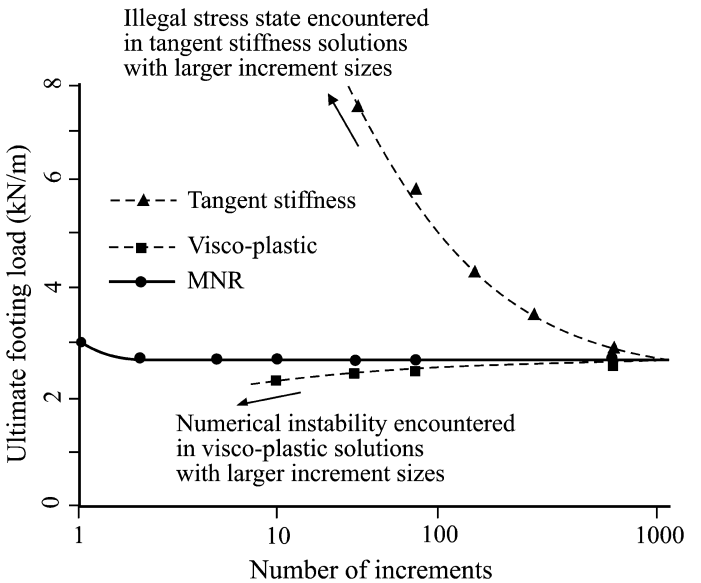

Figure 6.19 Ultimate footing load vs number of increments

Solution type	Number of increments	CPU times	Relative CPU times	Collapse load kN
MNR	10	15 345	1	2.82
Tangent stiffness	500	52 609	3.4	3.01
Tangent stiffness	1 000	111 780	7.3	2.82
Visco-plastic	25	70 957	4.6	2.60
Visco-plastic	500	1 404 136	91.5	2.75

Table 6.3 CPU times and failure loads for the footing analyses

loading. The behaviour of a segment of an incompressible 2 m diameter pile, well away from the influence of the soil surface and pile tip, is examined (see **Figure 6.20**). This boundary value problem has been discussed in detail by Potts and Martins (1982) and the alternative methods of representing the problem in finite element analysis have been explored by Gens and Potts (1984). The soil is assumed to be normally consolidated, with initial stresses $\sigma_v' = \sigma_h' = 200$ kPa. The parameters for the modified Cam Clay model are the same as those used for the footing problem and are discussed in detail in Potts and Zdravkovic (1999). Axisymmetric conditions are applicable to this problem and the finite element mesh is shown in **Figure 6.20**. Loading of the pile has been simulated in the finite element analyses by imposing a series of equally sized increments of vertical displacement to the pile shaft to give a total displacement of 100 mm. The soil was assumed to behave in a drained manner throughout.

Results from analyses using all three solution strategies and with varying numbers of increments are presented in **Figure 6.21** in the form of mobilised shaft resistance, τ, against vertical pile displacement. The MNR analyses, with 20 increments and above, plot as a single curve on this figure and are represented by the upper solid line. MNR analyses

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

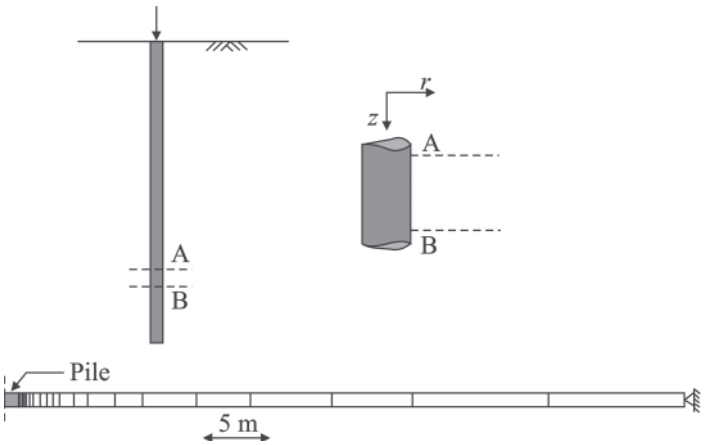

Figure 6.20 Geometry and finite element mesh for the pile problem

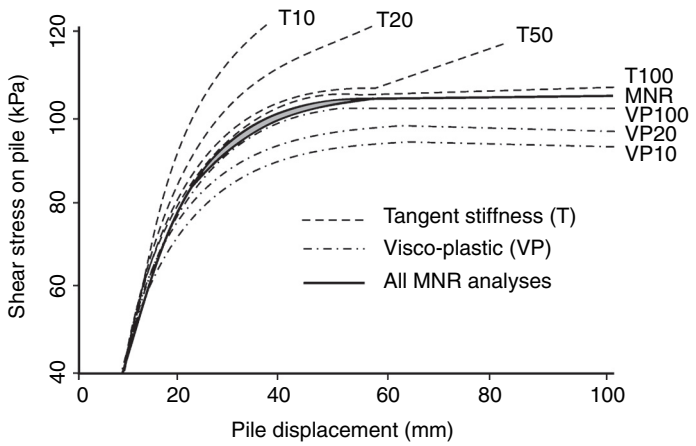

Figure 6.21 Mobilised pile shaft resistance vs pile displacement

with smaller numbers of increments (i.e. with larger applied displacement increments) showed minor differences with the above results between pile displacements of 25 and 55 mm. The MNR analysis with five increments is shown by the lower solid line in the figure. The spread of results between the MNR analyses with five and 20 increments is therefore given by the shaded band. Because this band is small it may be concluded that, as with the footing problem, the MNR results are insensitive to increment size.

Results from some of the tangent stiffness and visco-plastic analyses are also shown on **Figure 6.21**. If a large number of small increments of applied displacement are used, both these solution strategies give results which approach those of the MNR analyses. However, analyses using both these approaches are sensitive to increment size, and analyses with larger increments of applied displacement are inaccurate. The tangent stiffness over predicts and the visco-plastic under predicts the mobilised shaft resistance for any given pile displacement. The visco-plastic analyses predict that the mobilised pile shaft resistance increases to a peak value and then slowly reduces with further pile displacement. This behaviour is not predicted by the MNR analyses which show that once the maximum shaft resistance is mobilised, it remains constant. For the tangent stiffness analyses with less than 100 increments, the mobilised pile shaft resistance continually climbs and no peak value is reached.

Values of the mobilised pile shaft resistance, τ_f, at a pile displacement of 100 mm (the end point on the curves in **Figure 6.21**) are plotted against the number of increments used in **Figure 6.22**. As noted above, the MNR results are insensitive to increment size, with τ_f only increasing from 102.44 to 103.57 kPa as the number of increments increases from 1 to 500. The results from the tangent stiffness and visco-plastic analyses are much more dependent on the size of the applied displacement increment. Over 100 increments for the tangent stiffness and 500 increments for the visco-plastic analyses are needed to give reasonably accurate results. As the tangent stiffness and visco-plastic solutions approach those of the MNR when the applied displacement increment reduces, the 500 increment MNR analysis may be assumed to be 'correct'. The error in any analysis may therefore be expressed as:

$$\text{Error} = \frac{\tau_f - 103.6}{103.6}$$

where τ_f for the 500 increment MNR analysis equals 103.6 kPa. This error is plotted against CPU time in **Figure 6.23** for all analyses. The results clearly show that as well as being the least accurate, the visco-plastic analyses are also the most expensive in terms of CPU time consumed. As the MNR analyses give accurate solutions with small error values, typically less than 0.2%, the results plot along the CPU time axis in this figure. These CPU times compare favourably with those of the tangent stiffness analyses.

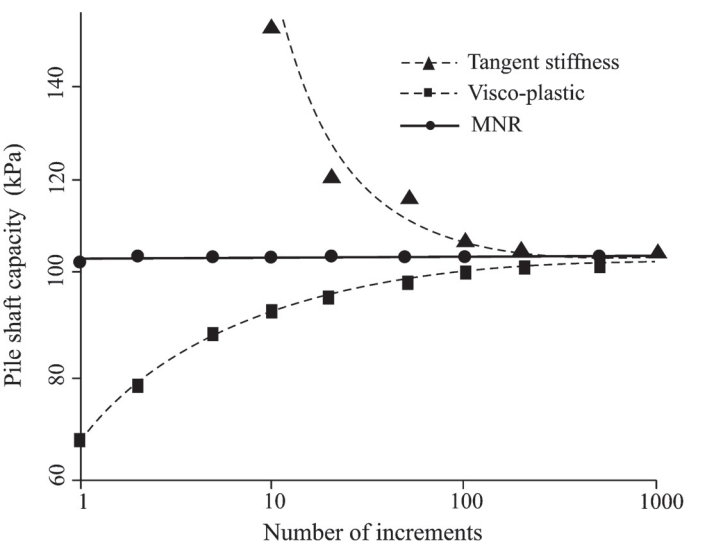

Figure 6.22 Pile capacity vs number of increments

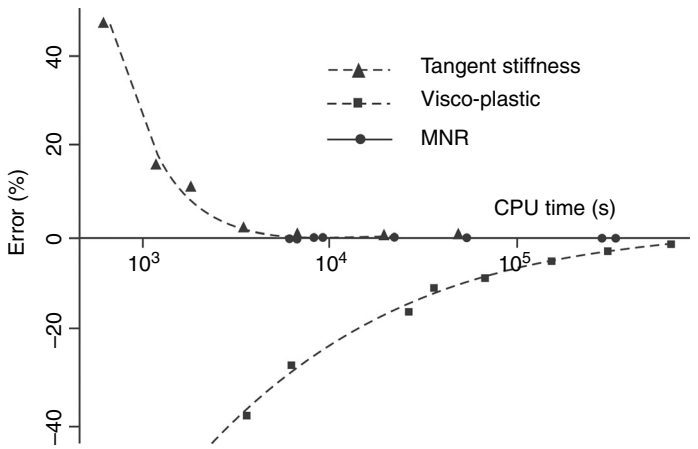

Figure 6.23 Error in pile analysis vs CPU time

The relatively bad performance of the visco-plastic strategy should be noted. This contrasts to its better performance for the footing problem. However, the footing problem involved undrained soil behaviour, whereas for the pile problem the soil is assumed to remain drained. Results from the analysis of a range of boundary value problems presented in Potts and Zdravkovic (1999) also indicate that the relative performance of the visco-plastic strategy is worse for drained than undrained sites. It may be concluded that for the analyses with the modified Cam Clay model, the visco-plastic approach is likely to be better behaved and less sensitive to the size of the solution increment when soil behaviour is undrained than when the soil is drained.

6.8.5 Comments

Results from the tangent stiffness analyses of both boundary value problems are strongly dependent on increment size. The error associated with the tangent stiffness analyses usually results in unconservative predictions of failure loads and displacements in most geotechnical problems. For the footing problem, large over predictions of failure loads are obtained, unless a very large number of increments (>1000) are employed. Inaccurate analyses based on too large an increment size produced ostensibly plausible load–displacement curves. Analytical solutions are not available for most problems requiring a finite element analysis. Therefore it is difficult to judge whether a tangent stiffness analysis is accurate on the basis of its results. Several analyses must be carried out using different increment sizes to establish the likely accuracy of any predictions. This could be a very costly exercise, especially if there was little experience in the problem being analysed and no indication of the optimum increment size.

Results from the visco-plastic analyses are also dependent on increment size. For boundary value problems involving undrained soil behaviour these analyses are more accurate than tangent stiffness analyses with the same increment size. However, if soil behaviour is drained, visco-plastic analyses are only accurate if many small solution increments are used. In general, the visco-plastic analyses use more computer resources than both the tangent stiffness and MNR approaches. For both the footing and pile problems, the visco-plastic analyses under predict failure loads if insufficient increments are used and are therefore conservative in this context.

Close inspection of the results from the visco-plastic and tangent stiffness analyses indicates that a major reason for their poor performance is their failure to satisfy the constitutive laws. This problem is largely eliminated in the MNR approach, where a much tighter constraint on the constitutive conditions is enforced.

The results from the MNR analyses are accurate and essentially independent of increment size. For the boundary value problems considered, the tangent stiffness method requires considerably more CPU time than the MNR method to obtain results of similar accuracy, in fact over seven times more for the foundation problem. Similar comparisons can be found between the MNR and visco-plastic solutions: the tangent stiffness or visco-plastic method with an optimum increment size is likely to require more computer resources than an MNR analysis of the same accuracy. Though it may be possible to obtain tangent stiffness or visco-plastic results using less computer resources than with the MNR approach, this is usually at the expense of the accuracy of the results. Alternatively, for a given amount of computing resources, an MNR analysis produces a more accurate solution than either the tangent stiffness or visco-plastic approaches.

The study has shown that the MNR method appears to be the most efficient strategy for obtaining an accurate solution to problems using critical state type constitutive models for soil behaviour. However, it should be noted that the MNR method is highly sensitive to the stress point algorithm (see section 6.8.3) that it uses, which is code-dependent. The large errors in the results from the tangent stiffness and visco-plastic algorithms in the present study emphasise the importance of checking the sensitivity of the results of any finite element analysis to increment size.

6.9 Modelling of structural members in plane strain analysis

While the main feature of many geotechnical problems might be adequately represented by a plane strain idealisation, other, smaller, components of the same problem might not be. For example, let us consider a typical urban excavation problem as shown in **Figure 6.24**. Here we have an embedded retaining wall, supported by ground anchors and a foundation slab tied down by tension piles. This could represent a cross-section of an excavation for a road. Let us now consider the structural members in turn.

6.9.1 Walls

If the wall is of the concrete diaphragm type, then it is best modelled using solid finite elements with the appropriate geometry and material properties. There is no serious modelling problem here as the wall satisfies the plane strain assumption. However,

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

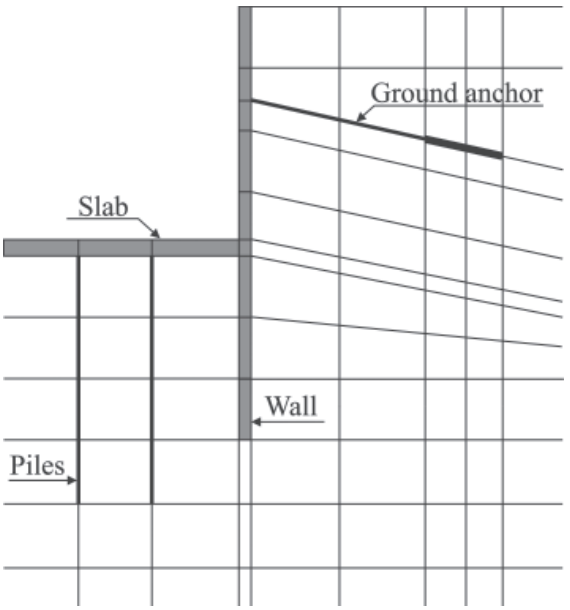

Figure 6.24 Typical urban excavation

if the wall is made from secant or contiguous concrete piles, steel sheet piles, or some combination of steel columns and sheeting, then the properties and geometry of the wall will vary in the out-of-plane direction and therefore will not satisfy the requirements of plane strain. Modelling of these components in a plane strain analysis will therefore involve some approximations. It is usually possible to estimate the average axial (EA) and bending stiffness (EI) per meter length of wall. If beam elements are used to model the wall, these parameters can be input directly as the material properties. However, if solid elements are to be used, then the EA and EI must be converted into an equivalent thickness t of the solid elements and an equivalent Young's modulus, E_{eq}. This is done by solving the following two simultaneous equations:

$$\text{EA:} \quad t \cdot E_{eq} = E \cdot A$$

$$\text{EI:} \quad \frac{E_{eq-t^3}}{12} = E \cdot I$$

where E is the Young's modulus of the wall, A is the cross-sectional area, and I the moment of inertia per meter length. It may also be necessary to calculate some form of average strength, but this will depend on the constitutive model employed to represent the wall. Clearly the above procedure only treats the wall in an approximate manner and it will not be possible to accurately estimate the details of the stress distribution within the separate components of the wall.

6.9.2 Piles

Modelling the piles below the base slab involves additional assumptions as the piles are not continuous in the out-of-plane direction, but are separated by relatively large expanses of soil. While it is again possible to estimate EA and EIs per unit length in the out-of-plane direction, and to calculate equivalent parameters as was shown for the wall above, modelling the piles with solid or beam elements implies that the soil is not able to freely move between the piles. This is because the piles are essentially modelled as a wall in the out-of-plane direction, see **Figure 6.25**. As a consequence, the lateral movements of the soil below the excavation will be restricted. It may therefore be more realistic to neglect the EI of the piles so that they provide no resistance to lateral soil movement. A spring or a series of membrane elements can then be used to represent the piles.

If a linear spring is used to represent the pile only, elastic behaviour of the pile can be represented. In addition, if the spring is connected between a node on the concrete slab and a node in the soil (i.e. nodes A and B in **Figure 6.26**), only forces at these two nodes will be accounted for. In other words, the pile and soil are not connected between A and B. It will then

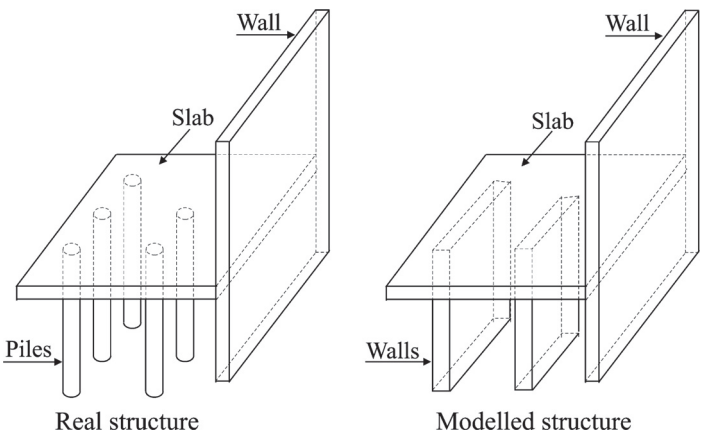

Figure 6.25 Comparison between real and simulated conditions for piles

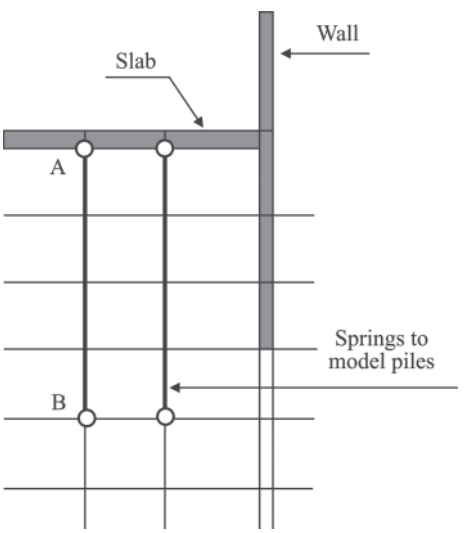

Figure 6.26 Springs used to model piles

not be possible to account for shaft friction nor to set a limit to the end bearing resistance of the pile (i.e. at node B).

If a series of membrane (or beam) elements are used to model the pile, then the pile will be connected to the soil along its shaft and consequently mobilisation of shaft resistance will be simulated to some limited extent (see **Figure 6.27**). However, the zero thickness of the elements in the plane of analysis implies that base resistance will be mobilised through a single node; it is therefore difficult to impose a limit to the end bearing resistance.

6.9.3 Ground anchors

The ground anchors located behind the wall comprise of two parts: the *fixed* and the *free* anchor lengths, see **Figure 6.28**. As with the piles, equivalent EA and EIs per unit length in the out-of-plane direction can be calculated for both components of a row of anchors. Account must be taken of the spacing of the anchors in the out-of-plane direction when calculating these equivalent values. Again, it is probably best to ignore the EI and model the two anchor components with either springs or membrane elements, or a combination of both (see **Figure 6.29**). The situation shown in **Figure 6.29(c)**, where a spring is used to model the free anchor length and a series of membrane elements the fixed length, is probably the more realistic approach. It is usual to neglect any shear stresses mobilised between the soil and the free anchor length. Consequently, the springs are connected to the wall at one end (point A in **Figure 6.29(c)** and the soil (and fixed anchor length) at the other (point C in the same figure). As with the piles, modelling the anchors in this way is rather crude as it is not possible to accurately account for the limiting end and shaft capacity of the fixed anchor length.

An alternative way of modelling the fixed anchor length is shown in **Figure 6.30** and involves the use of solid and interface elements. It is now possible to simulate the mobilisation of both shaft and end bearing resistance and to apply limits to these quantities. However, it is necessary to assign equivalent properties to the solid and interface elements to take account

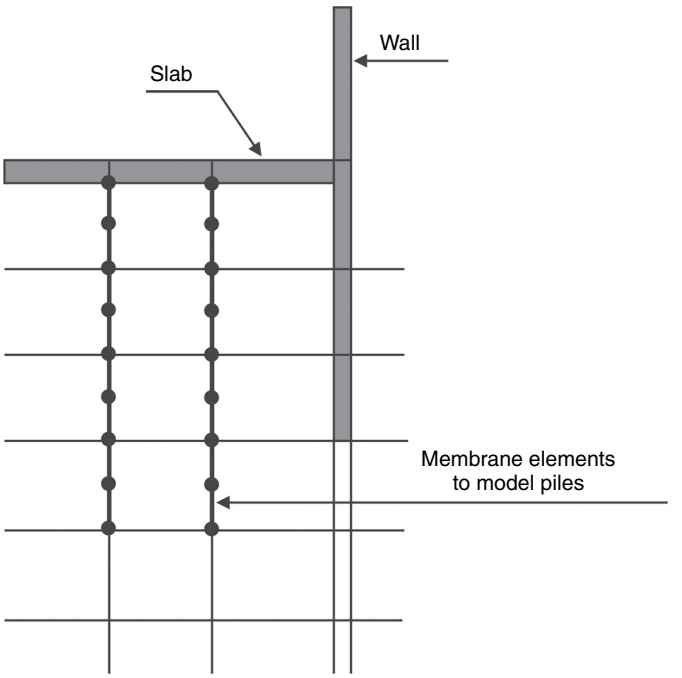

Figure 6.27 Membrane elements used to model piles

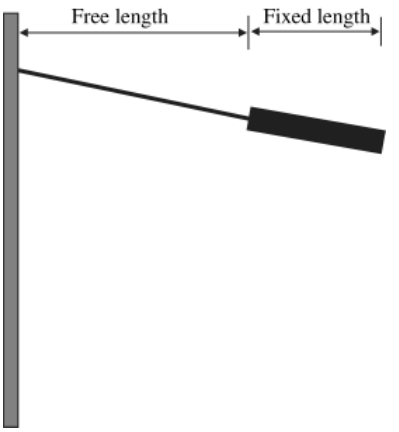

Figure 6.28 Ground anchor

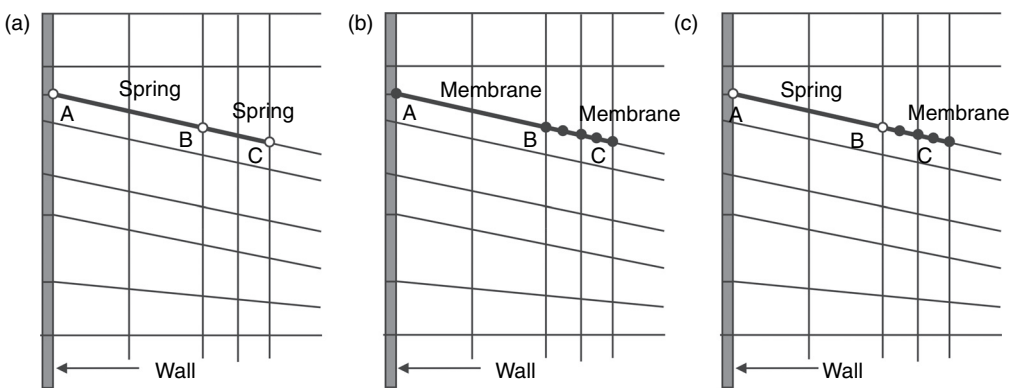

Figure 6.29 Modelling ground anchors using (a) springs, (b) membrane elements, and (c) a combination of spring and membrane elements

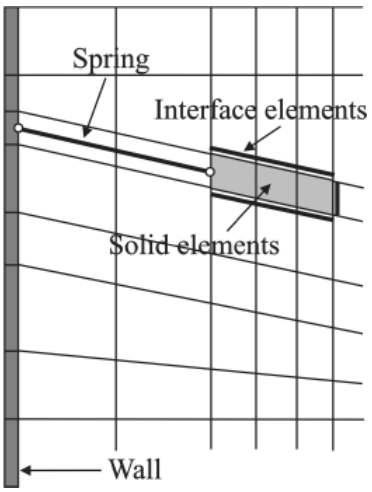

Figure 6.30 Modelling a ground anchor with solid elements

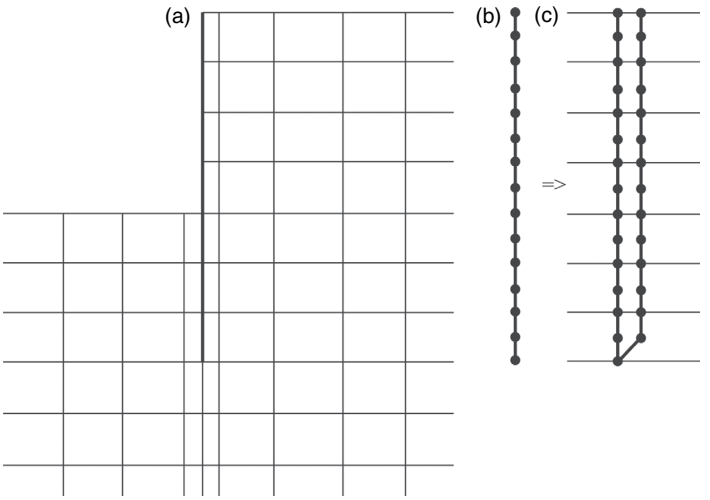

Figure 6.31 Dealing with impermeable line elements in consolidation problems (use of interface elements)

of the spacing of the anchors in the out-of-plane direction. This is often not straightforward. By assigning an equivalent Young's modulus to the solid elements, the fixed anchor length will have EI. This will limit soil movements perpendicular to the anchor. In reality, the soil will be able to deform between the anchors.

The above discussion indicates that while it is possible to approximate the wall behaviour in a realistic manner, much greater approximations are involved with the modelling of both the piles and ground anchors. This arises because these structural elements are not continuous in the out-of-plane direction.

6.9.4 Structural members in coupled analyses

A further pitfall can occur when using membrane or beam elements to model structural members in coupled consolidation analyses. The problem is best explained by considering the example of the retaining wall shown in **Figure 6.31**. The wall is modelled using beam elements and therefore shares a common set of nodes with both the elements in front of, and behind it, see **Figure 6.31(b)**. As the solid elements on either side of the wall have common nodes at the wall, the wall will be implicitly assumed to be permeable in a consolidation analysis. Water will therefore flow freely through the wall which may not be the desired outcome. If the wall is to be assumed impermeable, this can be achieved by placing interface elements along one side of the wall as shown in **Figure 6.31(c)**. If these elements are non-consolidating, they will provide an impermeable break between the solid elements on either side of the wall.

6.9.5 Structural connections

Potential problems can arise when modelling connections between different structural components, e.g. the connection between props and a retaining wall. Such connections can be modelled as *simple*, *pin-joined* or *full moment* connections. These conditions and the possible alternative ways that can be used to model them in plane strain analyses are shown in **Figures 6.32** to **6.34**. It is often all too easy to use the options given in **Figure 6.34** when in reality the connection is pin-jointed.

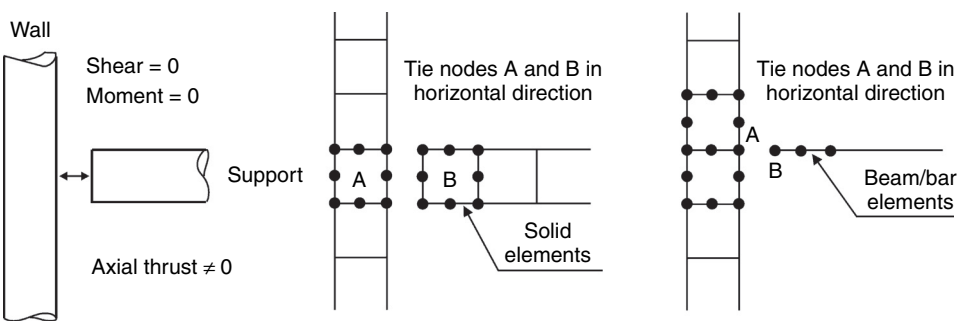

Figure 6.32 Simple connection between wall and beam

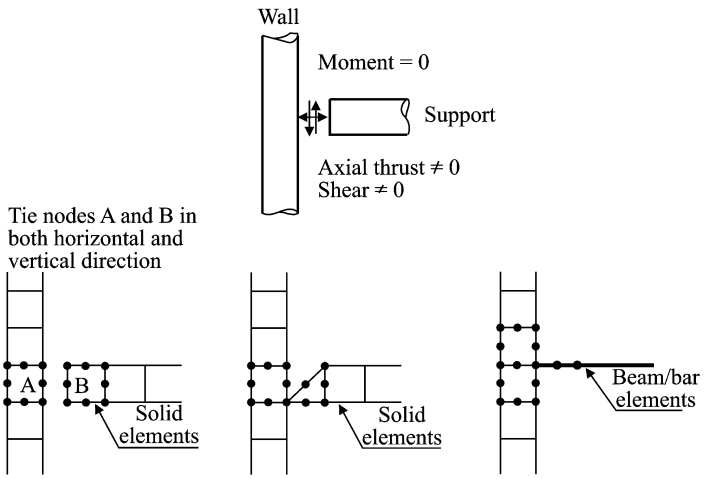

Figure 6.33 Pin-jointed connection between wall and prop

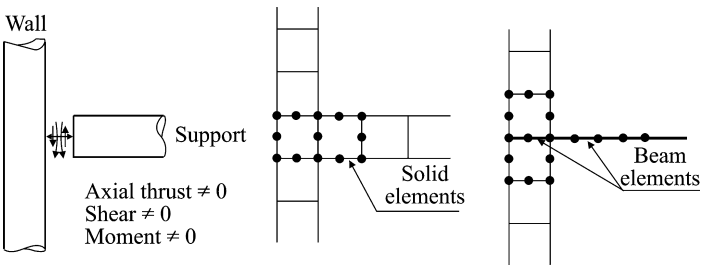

Figure 6.34 Full connection between wall and prop

6.9.6 Segmental tunnel linings

Many tunnel linings are constructed from segments. Between eight and 12 segments are usually required to form a complete circular ring, see **Figure 6.35(a)**. Sometimes the segments are bolted to each other and sometimes not. In either event, there is little bending resistance between the segments. It is often convenient to model the lining using beam or solid elements. However, if these elements are placed as a sequential ring (illustrated in **Figure 6.35(b)**), a full moment connection between the segments will be implied. If this is not what is required, then an alternative approach must be used. For example, special beam elements which represent the interface between the segments can be used. Each segment is modelled as a group of beam elements and these are then joined together by these small special beam elements; see **Figure 6.35(c)**.

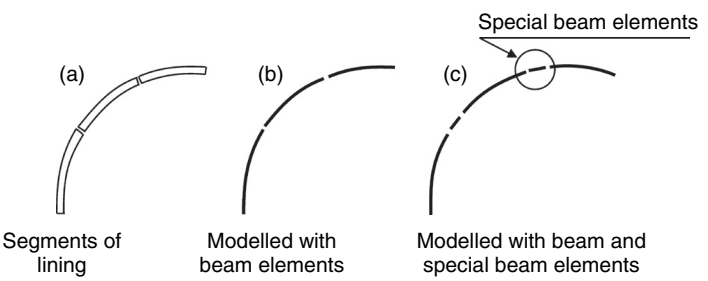

Figure 6.35 Modelling tunnel lining

6.10 Some pitfalls with the Mohr–Coulomb model

The Mohr–Coulomb constitutive model is the simplest representation of soil behaviour and forms part of most geotechnical software packages. It is also the most widely used constitutive model in geotechnical engineering practice. This is a linear elastic, perfectly plastic model, requiring only a few input parameters that can be obtained from standard laboratory testing, namely Young's modulus E and Poisson's ratio μ – to describe the elastic part of the model, cohesion c' and angle of shearing resistance ϕ' – to describe the plastic (failure) part of the model. If no other input parameter is required, this implies associated plasticity for the model and negative (dilative) plastic volumetric strains. Problems with such a formulation of the model are two-fold: (i) soil dilation is usually smaller than that implied by associated plasticity (i.e. angle of dilation $\nu = \phi'$); and (ii) once the soil starts to dilate, it will dilate forever, without reaching a limit load for volumetrically constrained problems.

6.10.1 Drained loading

An example of the performance of the Mohr–Coulomb model in drained conditions is given in **Figure 6.36**, which shows load–displacement curves for a vertically loaded pile, 1.0 m diameter and 20 m long, in a drained soil with $c' = 0$ and $\phi' = 25°$ (Potts and Zdravković, 2001). If the angle of dilation, ν, is equal to ϕ' (i.e. associated plasticity), the pile never reaches a limit load, no matter how far it is pushed into the ground. Even if the model has

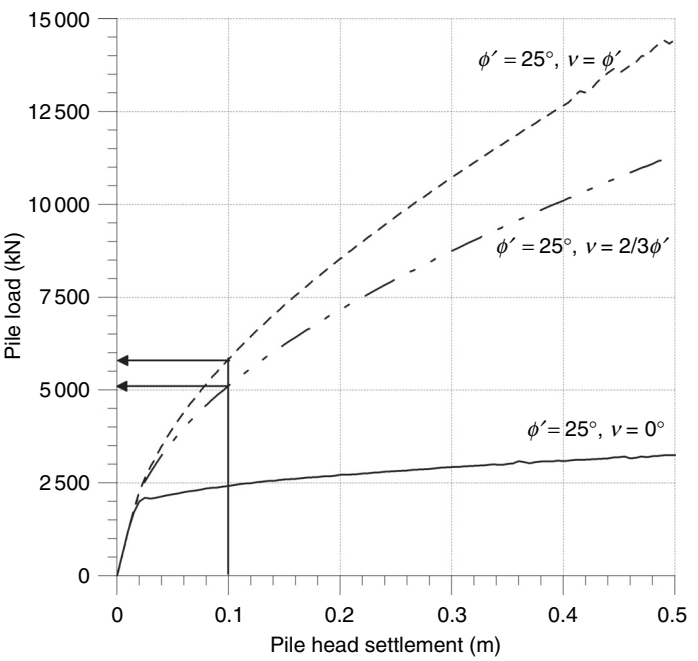

Figure 6.36 Load–displacement curves for vertically loaded pile

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the flexibility to input a value of ν smaller than ϕ', for any value of ν greater than zero, the model still does not predict a limit load. The magnitude of ν makes a difference only in the magnitude of the dilative volumetric plastic strains, which reduce with a reduction of ν and hence reduce the magnitude of the pile load for a particular displacement of the pile head. Consequently, a practical approach in determining a limit load from such analysis has been to arbitrarily adopt the load value that corresponds to the displacement equal to 10% of the pile diameter (0.1 m in this case). This can result in a significant overestimate in the load capacity of the pile in the case of associated plasticity, as soil dilation is generally over predicted. The pile can only reach a limit load if $\nu = 0$. This is a conservative prediction as most soils dilate to some extent, but it is at least a theoretically correct value obtained without any arbitrary decisions from the user.

6.10.2 Undrained loading

As noted above, the Mohr–Coulomb model can be used with a dilation angle ν ranging from 0 to ϕ'. This parameter controls the magnitude of the plastic dilation (plastic volume expansion) and remains constant once the soil is on the yield surface. This implies that the soil will continue to dilate indefinitely if shearing continues. Clearly such behaviour is not realistic as most soils will eventually reach a critical state condition, after which they will deform at constant volume if sheared any further. While such unrealistic behaviour does not have a great influence on boundary value problems which are unrestrained (i.e. the drained surface footing problem), it can have a major effect on problems which are constrained, as noted above, for the drained pile problem, due to the restrictions on volume change imposed by the boundary conditions. In particular, unexpected results can be obtained in undrained analysis in which there is a severe constraint imposed by the zero total volume change restriction associated with undrained soil behaviour. To illustrate this, two examples will now be presented.

The first example considers ideal (no end effects) undrained triaxial compression tests ($\Delta\sigma_v > 0$, $\Delta\sigma_h = 0$) on a linear elastic Mohr–Coulomb plastic soil with parameters $E' = 10\,000$ kPa, $\mu = 0.3$, $c' = 0$, $\varphi' = 24^o$. As there are no end effects, a single finite element is used to model the triaxial test with the appropriate boundary conditions. The samples were assumed to be initially isotopically consolidated with $p' = 200$ kPa and zero pore water pressure. A series of finite element runs were then made, each with a different angle of dilation, ν, in which the samples were sheared undrained. Undrained conditions were enforced by setting the bulk modulus of water to be 1000 times larger than the effective elastic bulk modulus of the soil skeleton, K', see Potts and Zdravkovic (1999). The results are plotted in **Figure 6.37**: (a) in the form of deviatoric stress (J) vs mean effective stress (p'), and (b) in the form of deviatoric stress (J) vs axial strain (ε_z). It can be seen that in terms of J vs p', all analyses follow the same stress path. However, the rate at which the stress state moves up the Mohr–Coulomb failure line differs for each analysis. This can be seen in **Figure 6.37(b)**. The analysis with zero plastic dilation, $\nu = 0$, remains at a constant J and p' when it reaches the failure line. However, all other analyses move up the failure line; those with the larger dilation moving up more rapidly. They continue to move up this failure line indefinitely with continued shearing. Consequently, the only analysis that indicates failure (i.e. a limiting value of J) is the analysis performed with zero plastic dilation.

The second example considers the undrained loading of a smooth rigid strip footing. The soil was assumed to have the same parameters as those used for the triaxial tests above. The initial stresses in the soil were calculated on the basis of a saturated bulk unit weight of 20 kN/m^3, a ground water table at the soil surface and a coefficient of earth pressure at rest $K_o = 1 - \sin \phi'$. The footing was loaded by applying increments of vertical displacement and undrained conditions were again enforced by setting the bulk modulus of the pore water to be 1000K'. The results

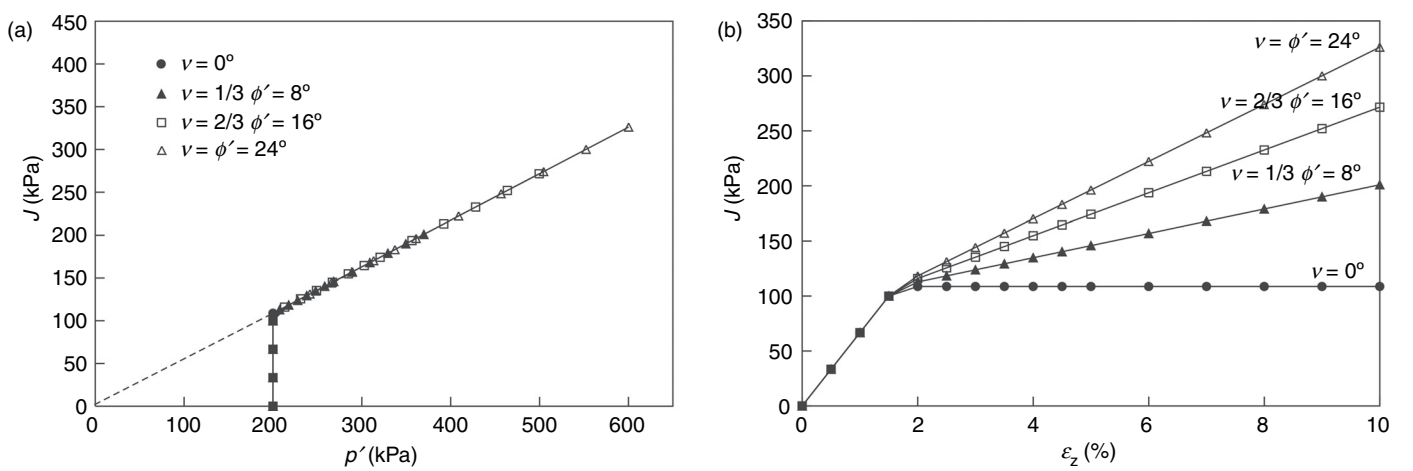

Figure 6.37 Prediction of (a) stress paths and (b) stress–strain curves in undrained triaxial compression using Mohr–Coulomb model with different angles of dilation

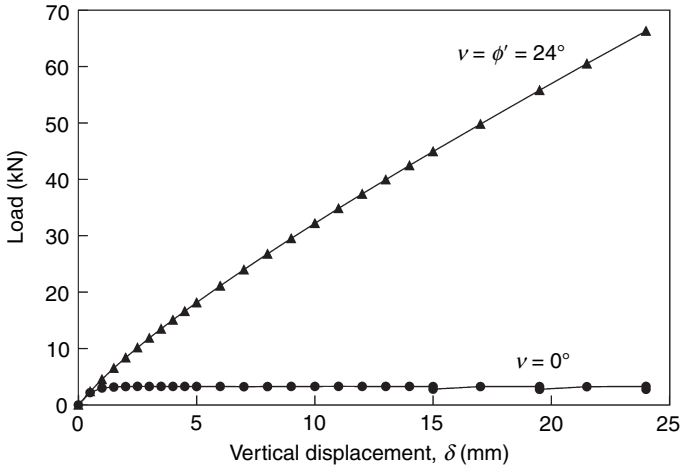

Figure 6.38 Load–displacement curves for a strip footing, using the Mohr–Coulomb model with different angles of dilation

of two analyses, one with $\nu = 0^{o}$ and the other with $\nu = \phi'$, are shown in **Figure 6.38**. The difference is quite staggering: while the analysis with $\nu = 0^{o}$ reaches a limit load, the analysis with $\nu = \varphi'$ shows a continuing increase in load with displacement. As with the triaxial tests, a limit load is only obtained if $\nu = 0^{o}$.

It can be concluded from these two examples that a limit load will only be obtained if $\nu = 0^{o}$. Consequently, great care must be exercised when using the Mohr–Coulomb model in undrained analysis. It could be argued that the model should not be used with $\nu > 0$ for such analysis. However, reality is not that simple and often a finite element analysis involves both an undrained and a drained phase (i.e. undrained excavation followed by drained dissipation). It may be then necessary to adjust the value of ν between the two phases of the analysis. Alternatively, a more complex constitutive model which better represents soil behaviour may have to be employed.

6.11 Summary

This chapter identifies the main design requirements for a geotechnical structure, for which calculations have to be performed in order to confirm the stability and safety of the design. These requirements are:

- local stability;
- overall stability;
- structural forces;
- ground movements.

Several methods of analysis are available for the above geotechnical calculations and they are classified into three main groups:

- closed form solutions;
- classical analysis (limit equilibrium, stress fields and limit analysis);
- numerical analysis (beam-spring approach and full numerical analysis).

In terms of satisfying the main theoretical requirements, it is important to note that:

- Closed form solutions are possible to obtain in some cases only if the soil is assumed to be linear elastic. However, this is a significant simplification of real soil behaviour and may result in the wrong predictions of ground movements. Additionally, these solutions cannot be used to assess stability of geotechnical structures.
- None of the classical methods of analysis satisfy all of the theoretical requirements; hence in general they do not produce an exact solution. An exception is when calculations using both the 'safe' and 'unsafe' theorems of limit analysis result in the same answer. However, such cases are rare.
- The beam-spring approach can analyse only one structural element with the soil represented by a number of springs. The main issue in this approach is to assign the appropriate spring stiffness.
- Full numerical analysis, in terms of finite elements or finite differences, is the ultimate analysis method which satisfies all theoretical requirements, discretises both the soil and the structure in the same way and can apply a constitutive behaviour which models the soil in a realistic manner.

However, it is important to recognise that full numerical analysis should not be performed blindly, without understanding the numerical methods (algorithms) and software used in the analysis. Some of the main causes of error in finite element analysis discussed in this chapter are:

- element discretisation (i.e. the type and size of finite element);
- choice of the nonlinear solver (i.e. solution of the system of nonlinear finite element equations);
- modelling of structural elements within the soil continuum;
- choice of appropriate constitutive models.

The number of potential errors increases as the analysis becomes more advanced – involving, for example, coupled problems (i.e. both mechanical behaviour and fluid flow, where the choice of correct permeability models and hydraulic boundary conditions becomes important), and soil dynamics and earthquake engineering problems (where appropriate constitutive models, boundary conditions and time integration schemes become important).

If all the above aspects of numerical analysis are applied properly, then it has an enormous potential to explain the engineering behaviour of geotechnical structures and produce an optimal and safe design.

Chapter 7

Geotechnical risks and their context for the whole project

Tim Chapman Arup, London, UK

This chapter provides an understanding of how project developers consider construction projects and their huge vulnerability to project delays, and when it can be profitable to proceed with a development. By example, it shows the proportion of geotechnical-related costs for a typical London office project and compares those costs to the tiny investments in geotechnical risk mitigation by desk study and ground investigation. It explains that geotechnical risks can be 'wildly random' instead of 'mildly random' and so the consequences of a problem can be hugely disproportionate to the initial cost. It compares typical frequencies of ground-related problems and finds that even the average cost of mildly random problems have consequences that far outweigh the very modest cost of a good ground investigation. It concludes that management of geotechnical risk by contingency is an approach fraught with peril and that management by mitigation is much more likely to produce the desired outcome.

7.1 Introduction

The aim of this chapter is to provide data to enable geotechnical engineers to communicate simply and clearly with their clients, and to persuade them of the merits of timely geotechnical investigations and other interventions.

It is well known that:

- construction problems occur too frequently;
- the consequential delays and their associated costs are huge;
- the problems could often have been avoided.

The aim of this chapter is to quantify (to some extent) the first and second two points, and to offer some potential solutions to the third.

This chapter considers financial risks only and not safety ones – it examines the overall design and construction process; safety risks are usually triggered by errors in discrete operations, such as a missing toe-board. Projects where the overall design and construction process is skimped may share characteristics with those that suffer the sorts of organisational breaches that lead to accidents. Delays due to injuries and scrutiny by the Health and Safety authorities can have a devastating effect on programme and out-turn costs, not to mention the human impact on all involved. Safety in geotechnical engineering is discussed in more detail in Chapter 8 *Health and safety in geotechnical engineering*.

7.2 Motivation of developers

> Heathrow's new terminal is on time and on budget. How odd.
> Headline in *The Economist*, 20 August 2005

To understand the critical issues that affect developments, it is worth examining the motives of developers, who fall into three categories:

- Commercial developers – who create developments essentially to make a profit; either speculatively where the eventual occupier is not yet known, or pre-let to a bespoke tenant.
- Self developers – where the intention of the development is to facilitate other operations such as building an office or a manufacturing function for a large company. Sometimes assistance from a commercial developer is sought on a consultancy basis.
- State developers – where the state creates the national infrastructure to allow the rest of the economy to function (e.g. roads, railways, schools and hospitals).

In each case, a rational cost benefit analysis can be carried out to decide whether a particular development should proceed.

To assist in understanding the sensitivity of commercial drivers on a development, it is helpful to study a hypothetical example. The example created by Chapman and Marcetteau (2004) has been altered and extended to show the main issues that influence the commercial success of a development.

The building under consideration is:

- A commercial office building in the City of London.
- Currently occupied by a 30-year-old building with a gross area of 16 000 m^2 (172 000 ft^2).
- Occupying a site which could be replaced by a new building with a gross area of about 20 000 m^2 (215 000 ft^2); with 85% efficiency the net lettable area would be 17 000 m^2 (183 000 ft^2). The site value, based on net lettable area, is estimated to be £376/ft^2 (a typical range would be £250–£500/ft^2) – so the land on which it is to be built would cost some £68.8 million.

The developer first needs to decide whether it is worth maintaining the existing asset, or proceeding with a new development. The type of development contemplated is shown in **Figure 7.1**, and its details are summarised in Appendix A of this chapter. The relative costs for the development are summarised in **Figure 7.2**. The basis for his choice to proceed with the development is given in **Table 7.1**. The new building will be attractive to a broader range of occupiers, including those able and willing to pay higher rents.

From the calculations in **Table 7.1**, proceeding with the development makes commercial sense, based on the increase in demand (and hence rent) for the newer and bigger building. The table omits the prospect of capital growth, which has also made property development a popular investment in good times. It also omits any requirement to provide affordable housing as a proportion of the extra space created, which can be a tax that inhibits new developments. **Table 7.2** shows a comparison of typical investment returns in 2001, given by RIBA (2003), showing why investment in property was favoured at that time.

By 2005 in a stronger property market, most income yields had remained the same but capital growth for equities had accelerated to 8% giving a total return of 11%, while capital growth for commercial property peaked at 11% giving a total return of 18%. Both had declined by early 2008, making the choice to invest in commercial property considerably more marginal. *The Economist* (Anon, 2008) reported that office rents in the city of London had risen by 22% from September 2006 to September 2007, and predicted that they may fall by 5% over the following year. At the time, it was predicted to lead to a fall in property value of up to 30% over the next three years, potentially the biggest collapse in commercial property prices since the Second World War. Of the speculative offices under construction now in the City of London, not all are forecast to find tenants in the short term. At the time of writing (2009), banks had become more cautious about lending to this sector and the drop in collateral prices is not encouraging further lending to developers for this purpose. By late 2009, with returns on all assets at long-term lows and liquidity re-entering the financial system, some signs of banking investment interest are returning. This has persisted with the start of a full recovery in London by mid 2011 but the property market elsewhere in the UK still in recession.

Figure 7.1 Typical new 6-storey London office development

A developer can make a simple profit by using his own funds for the whole development, as shown in **Table 7.3** (RIBA, 2003).

Developers can leverage their success by use of a bank loan, but it can also magnify failure. This is illustrated in a simplified form in **Table 7.4**.

Thus the developer can make a much greater profit by using a loan, but can also make a much greater loss if the project costs more than expected. Developers therefore crave certainty even above cheapness. Once a site has been bought (potentially with an outlay of over half the development cost) and demolished (so no further income will be received until the new building is occupied), the developer is very vulnerable. He is particularly vulnerable to any:

- Increase in costs – distorting the investment basis.
- Delay in completion – hence delaying the start of the income stream to pay for it. This is particularly painful when the development funds are borrowed and interest has to be found to be paid over the interim period until rental cash starts coming in.
- Increase in interest rates, particularly if unexpected.
- Reduction in standard of the completed building – making it less attractive to potential clients and hence lowering its rental value.

This is illustrated in **Figure 7.3**; this shows how rental rates need to develop rapidly to catch up with the mounting bank interest changes.

These calculations have been carried out for a City of London development, where demand generally tends to be strong and potential rental rises may offset extra costs due to any problems. In other locations, the calculations underpinning a new development are often more marginal and the prospect of a favourable rate rise is more remote.

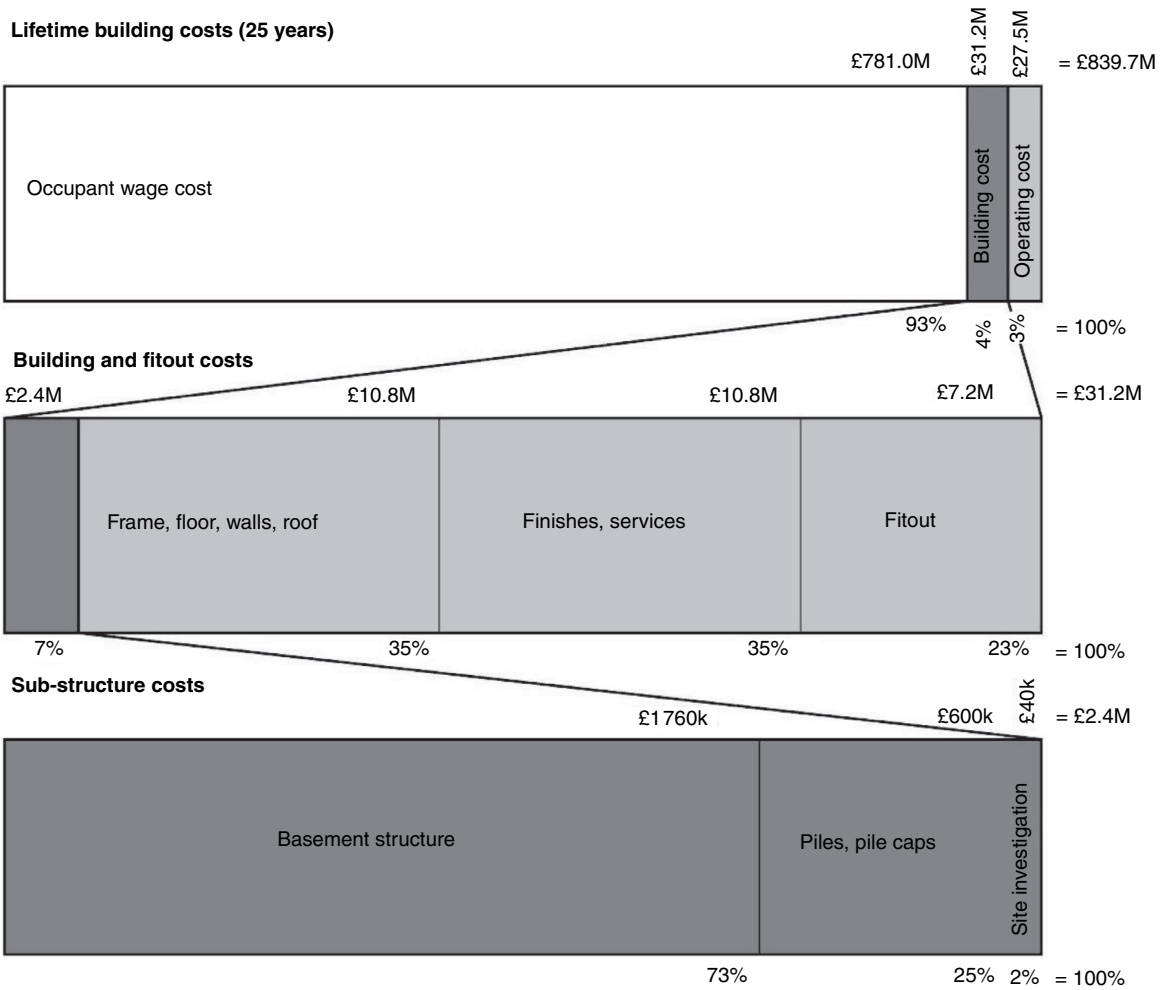

Figure 7.2 Breakdown of costs for a typical building

Reproduced from Chapman, 2008; all rights reserved

	No new development	New building
Annual rent per square foot (£)	39	55
Floor area	172 000 ft² (16 000m²)	215 000 ft² (20 000 m²)
Annual rent (£)	6.7 million	11.8 million
Payback period considered (years)	25	25 – 3 = 22 (3-year construction/rent-free period)
Total rent (£)	168.0 million	259.6 million
Less construction cost (£)	–	31.2 million
Net revenue (£)	168.0 million	228.4 million (i.e. 60.4 million extra)
Notes	Probably longer fallow periods between tenants; possibly shorter rental periods	Probably reduced maintenance and operating costs

Table 7.1 Comparison of value from new development to refurbishment of the old building

	Building society	Gilts (10 year bond)	Equities (FTSE 500)	Commercial property
Income	4%	5%	3%	7%
Capital	0%	0%	6%	3%
Total	4%	5%	9%	10%

Data taken from RIBA (2003)

7.3 Government guidance on 'optimism bias'

> 229 If a builder builds a house for someone, and does not construct it properly, and the house which he built falls in and kills its owner, then that builder shall be put to death.
>
> Hammurabi's Code of Laws 1700BC, Mesopotamia

The UK Government has studied the tendency of project costs and works durations to increase and has come up with advice in its Green Book (HM Treasury, 2003a) to redress the systematic optimism (which it terms 'optimism bias') that has historically afflicted the appraisal process for major projects.

Costs	£ million
1. Land, including fees and demolition	68.8
2. Design and construction costs	31.2
3. Leasing – at 20% of rent	2.0
4. Interest and financing	3.9
5. Void – 1 year rent free	11.8
Total cost	**117.7**
Value	
6. 215 000 ft² at £55/ft²	11.8/annum
7. Investment yield 7% (income from commercial property)	165.2
Dividing (7) by (6) gives a multiplier of 14	
Surplus	
8. Value less total cost (165.2–117.7)	47.5
Surplus as % of cost (47.5×100/117.7)	40%

Table 7.3 Overall consideration of costs and value for a new development
Data taken from RIBA (2003)

Costs (as % of cost of a successful project)	Successful project		A failure	
	Without a loan	With a loan	Without a loan	With a loan
Total cost	100	100	160	160
Loan		–70		–70
Developer's equity outlaid	100	30	160	90
Sale proceeds	140	140	140	140
Loan repayment		–70		–70
Outcome	140	70	140	70
Surplus at completion	40	40	–20	–20
Return on developer's equity (surplus/outlay)	40%	133%	–13%	–22%

Table 7.4 Illustration of the effect of a loan on project success or failure

It suggests that the two main causes for this bias in capital cost estimates are:

- poor definition of the scope and objectives of projects in the business case, due to poor identification of stakeholder requirements; and
- poor management of projects during implementation, so that schedules are not adhered to and risks are not mitigated.

In *Supplementary Green Book Guidance – Optimism Bias* (HM Treasury, 2003b) values are suggested for the extent of optimism bias typically found and are recommended for use unless robust evidence is available to support other values. The ranges are given in **Table 7.5**. These are based on various

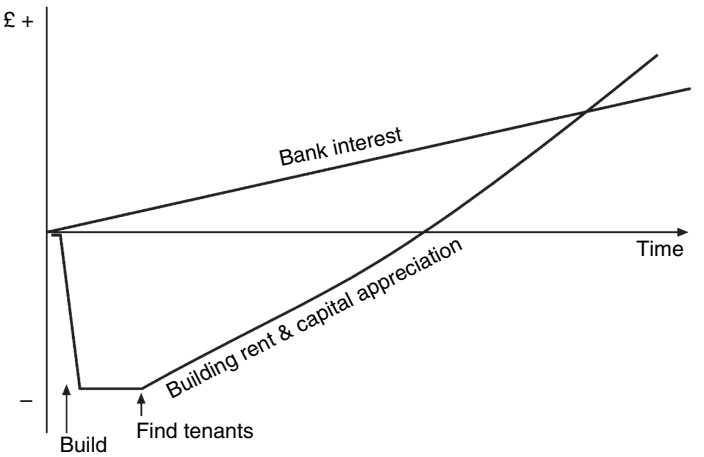

Figure 7.3 Comparison of building investment vs bank interest

contributory factors, listed in **Table 7.6**. Unfortunately, these contributory factors are not broken down into the project phase in which the problems occurred, so the proportion of problems originating in the ground is not discernible. **Table 7.7** shows an extract from the Supplementary Guidance illustrating the sorts of steps taken to mitigate risk for an example project.

From the guidance, it can be deduced that:

- Non-standard projects carry more risk, and non-standard building projects carry more risk than non-standard civil engineering projects. The reason for this is not obvious, but may be due to building projects involving a greater mix of different skills or perhaps because civil engineering projects procured by the state have more rigorous stage reviews and design checks (such as Category 3 checking).
- Building and civil engineering projects seem to be less risky than government projects to procure equipment, which includes software projects.
- Building projects' greatest failings have, as prime causes, inadequacy of the business case by the client and poor procurement, leading to disputes and claims (presumably due to poor specification).

		Non-standard buildings		Standard buildings		Non-standard civil engineering		Standard civil engineering

	Site characteristics	3	1	5	2		5	10	3
	Permits / consents / approvals	3	<1	9					
	Other (specify)	1	3						
External influences	Political	13				19			
	Economic		13		11	24	3		7
	Legislation / regulations	6	7	9	3		8		
	Technology	4	5			6	8		
	Other (specify)		2			<1	1		

* Indicative starting values – optimism bias profile for a project will change during its life cycle.
** Contributions from each area as a % of the recorded optimism bias. Rounding errors may result in the sum of values not adding up to 100%.

Table 7.6 Optimism bias upper bound guidance
Reproduced from HM Treasury (2003a) © Crown Copyright

Contributory factor	Project cost % contribution to optimism bias	Works duration % contribution to optimism bias	Example cost of risk management
Poor contractor capabilities	5	5	£0
Design complexity	3	2	£140 000
Inadequacy of the business case	23	22	£700 000
Poor project intelligence	6	5	£10 000
Site characteristics, e.g. ground investigation *	1	3	£40 000

* In the example, it is suggested that a Trust has owned a site for at least 20 years with a comprehensive site investigation carried out within the last 5 years, therefore only desk study and limited site investigation are needed.

Table 7.7 Main contributory factors to optimism bias for project cost and works duration for an example project given by HM Treasury
Reproduced from HM Treasury (2003b) © Crown Copyright

- Civil engineering projects suffer from environmental impact (presumably mitigation too late in the process), poor contractor capabilities and poor procurement leading to disputes and claims.

It is worth noting that better geotechnical design is an excellent way to mitigate the uncertainties that the allowance for optimism bias is meant to counter. By doing so, the allowance for optimism bias can be reduced – making the project more affordable. This service is of significant advantage to the project promoter.

7.4 Typical frequency and cost of ground-related problems

> When anyone asks me how I can best describe my experience in nearly forty years at sea, I merely say, uneventful. Of course there have been winter gales and storms and fog and the like but, in all my experience, I have never been in an accident … of any sort worth speaking about. I have seen but one vessel in distress in all my years at sea. I never saw a wreck and have never been wrecked nor was I ever in any predicament that threatened to end in disaster of any sort.
>
> Captain Edward John Smith, 1907
> (5 years before he became captain of the RMS Titanic for her maiden voyage.)

A review of 5 000 industrial buildings by the National Economic Development Office (NEDO, 1983) found 50% of the projects overran by at least a month. Study of a representative group of these projects showed that 37% of the overruns were due to ground problems. Of 8 000 commercial buildings, a third overran by more than a month and a further third by up to a month (NEDO, 1988). Half of a representative group of these had suffered delays due to unforeseen ground conditions. The National Audit Office (2001) reported little improvement by 2001: it cites an Office of Government Commerce study which found that 70% of a range of public projects were delivered late and 73% were over the tender price. Contemporary reports from the author's experience of legal disputes and the construction press suggest that incidences of unforeseen ground conditions still occur all too frequently. The UK airport operator BAA, quoted in an article in The Economist in 2005 (Anon, 2005), estimated the industry average for significant delays at 40% (with their own record at just under 20% due to their use of partnering and other ways of aligning their objectives with those of their project collaborators). These data are presented graphically in **Figure 7.4** – roughly one third of the projects studied were delayed by up to a month, and a further third suffered more serious delays. Where data on the cause are available, about a third to a half of delays were blamed on troublesome ground conditions. Thus significant delays due to ground conditions probably occur some 17–20% of the time. It is notable from **Figure 7.4** that the incidence of delays does not seem to have improved with time.

Van Staveren and Chapman (2007) examined figures on the financial impact of project failures, which were huge. In the Netherlands alone, failure figures are assessed between 5% and 13% of the yearly expenditure of the Dutch construction industry (for all failures, not just in the ground). As Dutch spending on construction totals some 70 billion euro per year, between 3.5 and 9 billion euro are spent to respond to failures (van Staveren, 2006). Chapman and Marcetteau (2004) showed that in the UK, about a third of construction projects are significantly delayed and of those, half of the delays are caused by problems in the ground. Applying this ratio to the overall Dutch construction failure rate would suggest that an average of some 2.5 billion euro are due to ground-related causes in the Netherlands, or probably equal to about 50 billion euro across the whole of the European Union; (the extrapolation is based on the size of the Dutch GDP in 2006 at US$613 billion to the whole of the European Union at US$13 600 billion; CIA factbook, 2007).

These ground-related problems often originate in an earlier phase than the phase in which they occur, as highlighted by Chowdhury and Flentje (2007), based on the extensive work of Sowers (1993). This latter study showed that in 57% of the projects studied, the geotechnical problems originated from flaws in the design phase and in 38% of the cases from the construction phase. However, these geotechnical problems actually materialised 41% of the time in the construction phase and 57% in the operational phase of the project.

An important part of the structural and geotechnical design processes should be for the whole project team to work together to reduce risks in the ground. Ground risks are one of the major causes of project delay and when they occur they are seldom resolved easily or quickly. As the installation of foundations

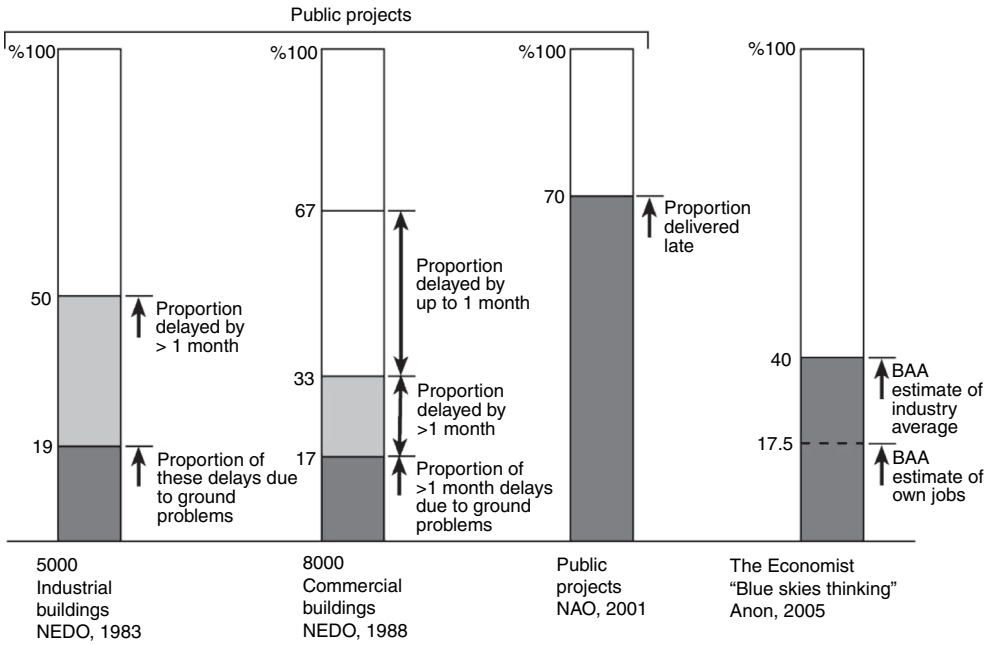

Figure 7.4 Typical UK delays for projects against time
The sources, shown below each project type, are all listed in the reference section of this chapter

and construction of basements are usually on the project's critical path, any delay affects all follow-on activities, and can impact directly on completion date.

7.5 Expect the unexpected

> … as we know, there are **known knowns**; there are things we know we know. We also know there are **known unknowns**; that is to say we know there are some things we do not know. But there are also **unknown unknowns** – the ones we don't know we don't know.
>
> Former U.S. Secretary of Defense, Donald Rumsfeld, explained a state of intelligence at a US Defense Department Briefing on February 12, 2002

To a large extent, this awareness of what might happen underpins successful geotechnical design. Managing risks for the 'unknown unknowns' is difficult as it is tricky to identify a likelihood and severity for unimagined events, which are not amenable to statistical understanding.

The concept of 'the 'Black Swan' was introduced by Nassim Nicholas Taleb (2007) – the name based on the unassailable belief by people in the Old World that all swans were white, confirmed by centuries of empirical evidence, until black swans were encountered in Australia in January 1697 (by Dutch explorer Willem de Vlamingh, http://birding.about.com/od/birdsswans/a/blackswan.htm). Taleb has created a whole theory based on the Black Swan, to which he attributes the following characteristics:

- as an outlier event, it lies outside the realm of regular expectations because no prior experience can point to the possibility;
- it has an extreme impact;
- despite being an outlier, once happened, human nature can concoct explanations for its occurrence – it is therefore obvious, but only with the benefit of hindsight.

Professor Taleb identifies many examples, ranging from the 9/11 events to the 'winner takes all' phenomenon for the wages of pop stars, footballers and artists. His thesis is that Black Swan events happen all too frequently and tend to dominate the success of many endeavours. He distinguishes between 'mild randomness' and 'wild randomness'. Dealing with ground risks is potentially a wildly random type of Black Swan because the consequences can be so severe, and so it is important that the possibility of unexpected events should not be discounted in geotechnical assessments.

It is possible by good planning to minimise the likelihood of a Black Swan. However, by the very nature of a Black Swan, their incidence can never be entirely eliminated. Those who manage complex geotechnical projects need to appreciate the possibility that they may be subject to Black Swans – a sense of humility is needed, plus an understanding of the range of catastrophic discoveries that can arise on any apparently innocuous site. Often Black Swans arise because engineers rely purely on previous experience and don't consider what might happen. This point is considered in greater detail in the example towards the end of this paper.

7.6 Importance of site investigation

> Without site investigation, ground is a hazard.
>
> Site Investigation Steering Group, 2003

As explained in Section 4 of this manual, site investigation consists of two main activities, as explained in BS5930 (BSI, 1999):

- Desk study, also known as *Preliminary Investigation* by Eurocode 7 (BSI, 2004) – the gathering of information about a site from documentary sources, made easier by free online aerial photography and other easily available resources, such as Envirocheck in the UK. A very valuable part of the desk study process is often to summarise all the ground-related hazards onto one site plan which can be used throughout the whole design and construction process. For larger (and more complex) sites, a geographic information system (GIS) can fulfil the same function.
- Ground investigation – the physical investigation of a site by boreholes and trial pits, with laboratory testing and reading of piezometers, to establish the ground and groundwater conditions. The ground investigation should be driven by the hazards identified in the desk study, together with an assessment as to how those hazards may affect the intended development proposals and construction processes.

In addition to normal geotechnical considerations like stratigraphy and stratum properties, it is important that the following aspects of a site are also investigated:

- potential presence of valuable archaeological remains;
- potential presence of contaminated ground or groundwater in the vicinity;
- potential presence of obstructions or other impediments to foundation installation, as well as neighbouring foundations, tunnels, etc.;
- buried cables and other services.

Often these man-made issues are a bigger risk for the project than normal geological variability. Desk studies that only consider, for instance, easily available mapping and not mapping data that go back to the start of the site's development, should be seen as potentially deficient.

The site investigation should also address constructability – it is therefore important that likely foundation types and processes needed on the site should be considered before the site investigation takes place. The risk of delay will be considerably increased if the contractors cannot derive useful information on the efficacy of installation for different types of foundation from the site investigation reports.

It is worth remembering that a site investigation is a careful but selective sampling of the ground, therefore the vast majority of the ground will not be encountered until main construction takes place. Using the soil volumes described in Appendix A of this chapter, a typical ground investigation will only recover some 0.03% of the soil beneath the site; only a fraction of that will be examined by a professional geologist or engineer.

The GeoQ process, introduced by van Staveren in 2006, is a formalisation of normal good geotechnical practice, emphasising the need for early data gathering. **Figure 7.5** shows a conventional contract, with the tendering stage between design and construction. A simplified example of applying the GeoQ steps, during a number of normal project stages, is shown in **Table 7.8**.

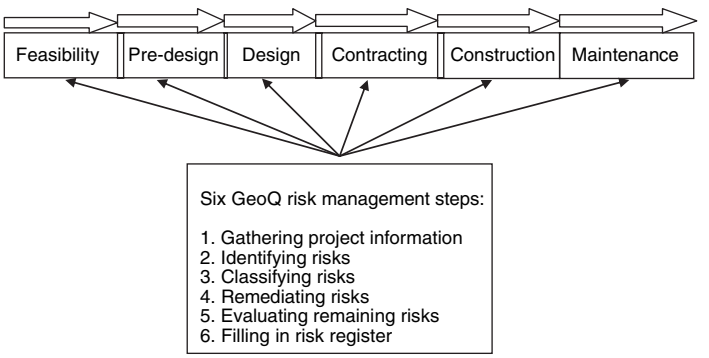

Figure 7.5 The GeoQ risk management model

GeoQ Step	Normal project stage	Typical example
1. Gathering project information	Desk study	Collecting historical and geological maps and other information
2. Risk identification		Discovery of old maps showing a filled-in watercourse crossing the site
3. Risk classification	Normally done during the **ground investigation** stage, when the magnitude and extent of the hazard can be quantified	Prove that channel is up to 10 m in depth and infilled with soft organic alluvium
4. Risk remediation	Normally done during **design**, when the development can protect itself against the main risks	Design of different foundations for that part of the site; inclusion of methane protection measures for basement
5. Risk evaluation	**Prior to tender**; collection of unmitigated risks so they can be managed and/or transferred to the contractor as part of the contract documents	Assess remaining extent of issues connected with channel
6. Risk mobilisation – Filling in the risk register		Highlight to contractor that his plant may get bogged down in alluvial formation; care of piling rig stability

Table 7.8 A simplified example of GeoQ steps during a few normal project stages

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

7.7 Costs and benefits of site investigation

> Quality is never an accident; it is always the result of intelligent effort.
>
> John Ruskin (1819–1900)

Geotechnical risks can be managed and mitigated. Sound geotechnical practices – for example hazard recognition and exploration by means of the desk study and ground investigation – can reduce risks substantially. The value of these investments needs to be seen in the context of the risks reduced.

For the building considered earlier and described in Appendix A of this chapter, a site investigation could consist of:

Desk study		£5 000
Ground investigation		
5 boreholes 20–40 m	£25 000	
10 trial pits	£5 000	
Contamination testing	£5 000	
Soils laboratory testing	£5 000	£40 000
		£45 000

This needs to be seen in the context of the £24 million building cost excluding fit-out costs (or £13.2 million structural cost or £2.4 million substructure cost). This site investigation is equal to 0.19% of the building cost, 0.34% of the structure cost, and 1.9% of the substructure cost. Compare this with Rowe's (1972) estimate for site investigations of between 0.05% and 0.22% of building cost.

The relative costs for delay can be compared to the savings that may have contributed to them. Using the statistics given earlier, it can be assumed that some 20% of projects are significantly delayed by ground conditions, by perhaps 1 month or more. From the perspective of the developer, the cost of 1 month's delay can be calculated as follows:

Land purchase cost	£68.8 million
Building cost (with fit-out)	£31.2 million
Total Cost	£100 million

Taking 7% annual return, the annual cost to service the loan is £7 million or £583 000 per month. If the delay prevents the occupier from working in the building then the costs will be much higher, as they will also have to include the lost productive effort of the people working there, which is assumed to exceed the cost of employing them – a further £31.25 million per year (equivalent to £2.6 million per month) or nearly five times more than the building finance costs.

Of course the loss of use of the building could be much higher as these figures do not include:

- missing the top of a property rental cycle, so that the achieved rent over subsequent years is less;
- missing an important season, such as Christmas for a shop or summer for a holiday facility;
- having to pay any dispute costs, which can be several times more than the original loss being argued over.

The developer's art involves predicting, potentially several years ahead, when there will be most demand for property and initiating the planning, design and construction process in sufficient time to provide property that meets the demand. This is illustrated in **Figure 7.6**. Thus, he is already vulnerable to uncertainties in the state of the property market when his facility is completed, as well as uncertainties in construction cost and programme.

If the developer skimps on the site investigation, a saving of half of the investigation cost might translate into £22 500 'saved' (but often a poorly thought-out site investigation makes very little saving).

Omitting dispute and occupier costs (as well as contractor liquidated damages), the delay costs for 1 month might be:

Client – delay interest		£583 000
Main contractor		
Establishment	£100 000	
Extra investigation	£30 000	
Redesign	£30 000	£160 000
		£743 000

There may also be increased construction costs due to a less efficient foundation design caused by the inadequate site investigation. As an example, the London District Surveyors Association (2000) allows a design basis for piles with a good site investigation that is 20% more efficient than one that is deficient. Thus a poor site investigation may result in piles that are some 20% less efficient, which may cost 10% more to construct. Thus for the example under consideration, the extra foundation costs may be £60 000 more, increasing the £743 000 to £803 000.

The extra 'average' cost for deficient ground investigation can be calculated as £209 000, spread over all developments. This figure includes an average extra delay cost due to unexpected ground conditions of £149 000 based on 20% of the calculated typical delay cost of £743 000, and an allowance for less efficient design of £60 000.

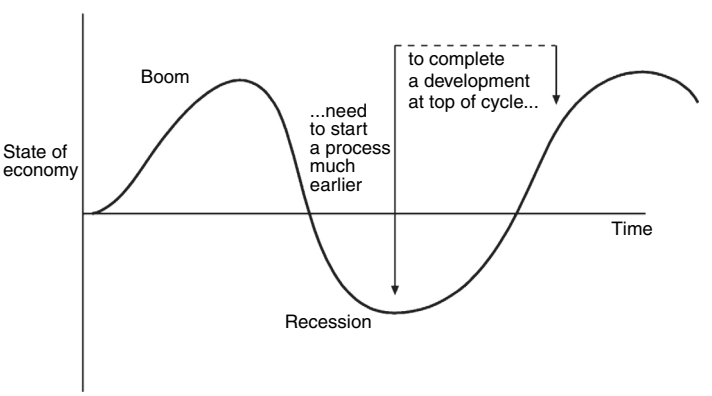

Figure 7.6 Graph showing how the start point of a development process is key to hitting the top of the economic cycle
Reproduced from Chapman, 2008; all rights reserved

Thus a saving of half of the site investigation budget of £22 500 would have to be balanced against a conservative estimate for a delay of more than £800 000 on the fifth of projects where the risks materialise, or an average extra cost over all projects of £209 000. In many cases, the consequences are much more severe than the fairly optimistic assumptions made in this illustration.

7.8 Mitigation not contingency

> It is unwise to pay too much, but worse to pay too little; when you pay too much, you lose a little money, that's all. When you pay too little, you sometimes lose everything, because the thing you bought was incapable of doing the things it was bought to do. The common law of business balance prohibits paying a little and getting a lot. It can't be done. If you deal with the lowest bidder, it is as well to add something for the risk you run. And if you do that, you will have enough to pay for something better. There is hardly anything in the world that someone can't make a little worse and sell a little cheaper – and people who consider price alone are this man's lawful prey.
>
> John Ruskin (1819–1900)

Often when faced with a low tender price, clients concentrate on the direct saving and not on the consequential losses to which they may be subjected. They may believe that a contingency will provide them with protection, rather than choosing to resolve the issues directly. This can be valid when the consequences are 'mildly random' but not when they may cause the sort of severe 'wildly random' impact on project finances that were illustrated earlier.

Many developers bear the financial risk themselves, and if things go wrong in a way that invalidates the assumptions in their financial model, they are left to sort out the consequences. The main problems are usually delays, resulting in late handover (delaying receipt of income streams), or higher costs. Often a disappointed developer will wish to recover losses from his design and construction team, for instance by liquidated damages for delay from the contractor, or via the designers' professional indemnity insurance policies. These are not reliable methods for recovering losses, and especially consequential losses. Better ways of covering risks are to insure them explicitly by project insurance that covers the whole team, or by latent defects insurance (LDI) that covers the final building (although LDI doesn't always cover consequential losses). While these insurance products encourage a shared approach to resolving problems, they don't let designers and constructors completely off the hook. For instance, the insurer may later decide to try to recover some of his losses (by a subrogated claim) if he suspects negligence was a cause.

LDI should not be seen as a solution by itself, in the same way that ever tighter liabilities on contractors and designers are unlikely to resolve a deteriorating position to the benefit of a developer. The best way to avoid the sort of issues that result in delays and losses is to avoid the problems in the first place. Thus spending more on proper investigation of ground issues is likely to be more fruitful than engaging lawyers to devise more onerous contracts to impose on project participants.

7.9 Mitigation steps

> The rain came down, the streams rose, and the winds blew and beat against that house; yet it did not fall, because it had its foundation on the rock. But everyone who hears these words of mine and does not put them into practice is like a foolish man who built his house on sand.
>
> Bible – Matthew 7: 25–26

The standard project work stages (based on RIBA's Outline Plan of Work – RIBA, 2007) are shown in **Table 7.9**, along with typical geotechnical design activities.

Timely intervention with appropriate advice at the best time is needed for all projects. Geotechnical advisors need to be aware of the timescale over which the rest of the project is being designed and the potential implications of late advice, particularly for more complex projects where there should be much early interaction with other parts of the design team, especially the structural designers.

Often geotechnical elements will present a major constraint on other parts of the development – for instance on a tight site, a complete retaining wall system might be up to 2 m wide (e.g. 0.15 m for guide wall, 0.9 m for hard/soft secant wall, 0.15 m for tolerances and protuberances to specification, reinforced concrete facing wall of 0.30 m, void of 0.15 m, blockwork wall of 0.15 m, giving a total thickness of 1.80 m), yet sometimes architects hope that a 0.3 m reinforced concrete wall (implicitly expecting an open-cut solution) will be possible. This will have severe implications for space planning around the complete perimeter of the building, and may have worse consequences if a parking layout has been derived for the smaller wall size. It is therefore important for the geotechnical team to make sure that their indicative solutions are provided early. So, for instance, not providing a retaining wall design until the results of some advanced laboratory tests are known (and hence relatively late in the overall design process) – while protecting the geotechnical designer from possibly having to change his solution – may cause consternation amongst the rest of the design team.

Whenever a test is carried out on a site, it carries the risk of not conforming to the specification. It is therefore wise to test earlier (and ideally off the project's critical path) instead of leaving important test results to be measured later and at a time when a non-conformance will bring greatest disruption. As examples:

- A geotechnical baseline report (GBR), as recommended by the British Tunnelling Society (2003), is a good way of ensuring clarity on risk sharing for all project types. Rather than giving comprehensive coverage of the ground conditions as in a geotechnical interpretative report, a GBR sets out the expected conditions simply, so that deviations from them are clear. It therefore seeks to provide clarity regarding when extra payment to a contractor is due, thereby reducing the likelihood of disputes.
- A ground investigation should concentrate on the greatest uncertainties usually revealed by the desk study. A ground investigation

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Project phase	RIBA work stage	Corresponding geotechnical activities
Preparation	A. Appraisal Identification of client's needs and objectives, business case and possible constraints on development Preparation of feasibility studies and assessment of options to enable the client to decide whether to proceed	■ Preliminary desk study, identifying major hazards that may profoundly affect development proposals
	B. Design brief Development of initial statement of requirements of the design brief by or on behalf of the client, confirming key requirements and constraints Identification of procurement method, procedures, organisational structure and range of consultants and others to be engaged for the project	■ Full desk study, identifying all key hazards
Design	C. Concept Implementation of design brief and preparation of additional data Preparation of concept design including outline proposals for structural and building services systems, outline specifications and preliminary cost plan Review of procurement route	■ Ground investigation ■ Geotechnical interpretative report ■ Initial designs for various options ■ Advice on preferred options ■ Agree requirement for site supervision
	D. Design development Development of concept design to include structural and building services systems, updated outline specifications and cost plan Completion of project brief Submit application for detailed planning permission	■ Design development ■ Detailed calculations for preferred option ■ Agree requirement for site supervision if design relies on it ■ Final calculation package and meet building control standards
	E. Technical design Preparation of technical design(s) and specifications, sufficient to coordinate components and elements of the project; confirm that they meet statutory standards and construction safety	■ Start on tender documents for initial comment ■ Construction design and management submission
Pre-construction	F. Production information F1. Preparation of detailed information for construction. Application for statutory approvals F2. Preparation of further information for construction required under the building contract. Review of information provided by specialists	
	G. Tender documentation Preparation and/or collation of tender documentation in sufficient detail to enable a tender or tenders to be obtained for the project	■ Complete tender documents ■ Identify preferred foundation contractors ■ Contractors to identify principal construction hazards
	H. Tender action Identification and evaluation of potential contractors and/or specialists for the project Obtaining and appraising tenders; submission of recommendation to the client	■ Tender reviews ■ Agreement to winning contractors – name, design, proposals, etc.
Construction	J. Mobilisation Letting the building contract, appointing the contractor Issuing of information to the contractor Arranging site handover to the contractor	■ Brief resident engineer (RE)
	K. Construction to practical completion Administration of the building contract to practical completion Provision to the contractor of further information as and when reasonably required Review of information provided by contractors and specialists	■ RE supervision ■ Act as geotechnical advisor to the contractor ■ Assist with claims ■ Piling close-out report

Table 7.9 (continued)

Use	L. Post-practical completion
	L1. Administration of the building contract after practical completion and making final inspections
	L2. Assisting building user during initial occupation period
	L3. Review of project performance in use

Table 7.9 RIBA work stages with normal corresponding geotechnical activities
Data taken from RIBA (2007) and ACE (2004)

based on a poor desk study will inevitably be hit-and-miss. Considering that less than 0.03% of the soil beneath is seen, it will tend to miss more than it hits. A good ground investigation will target the most likely hazards, which will often be the near-surface stratum boundaries as man's activities will tend to be more erratic (in most cases) than geological processes.

- The initial choice of foundations can have a profound effect on the processes that follow; piles in silty soils with a high water table tend to go wrong more frequently. Choosing shallow foundations on dense sandy silts above the water table can obviate the hazard. However, if piles have been selected, and particularly if they are specified with the design to be done by the piling contractor, then a shallow foundation solution is unlikely to be selected later.
- Early testing of a preliminary test pile provides confidence in both the constructability and capacity of a chosen pile type, leaving sufficient time for the design or pile choice to be amended if problems develop. The same principle applies to other forms of early testing; for instance, testing for the efficacy of a ground improvement method or for problems during trial boring or trial drives.
- Late working pile tests (pile testing during the works), in addition to obstructing progress, also raise the possibility of adverse results with no time to react. Completion of pile load testing after installation of all of the works piles means that every pile may need to be augmented if an unexpectedly low pile capacity is measured, which can be very difficult to resolve.
- As well as reducing risks, doing more pile tests before and fewer tests during works pile installation is often cheaper and causes less disruption to a construction programme.

The process should be to consider all risks from the outset, then mitigate them according to their likelihood and potential severity. Risks should be owned and managed by those best able to do so, not just delegated or passed on. The stages for doing so are summarised against RIBA workstages in **Table 7.9**.

7.10 Example

> He who has not first laid his foundations may be able with great ability to lay them afterwards, but they will be laid with trouble to the architect and danger to the building.
>
> Extract from *The Prince*, Niccolo Machiavelli (1469–1527)

For an example of how the occurrence and severity of a geotechnical Black Swan event can be mitigated by sound engineering processes for various levels of study and investigation by a design team, see **Table 7.10**.

In the case of poor investigation of the risks before starting, there would be no inkling of the possibility of a potentially catastrophic feature; the risk would initially be evaluated based on an expected range of mildly pessimistic assumptions. It is unlikely that any allowance would be made in the cost planning for such a catastrophic feature with potentially dire consequences. Its occurrence would cost heavily – it could have the potential to cause serious injuries to site workers, especially if the collapse was exacerbated by the large construction equipment used, the possible disposal of water, or by significant vibrations from construction plant. In the first case, there is also a possibility that the feature might not even be discovered during construction. Often such features can collapse subsequently, resulting in the closure of an operational building with huge financial costs – and possibly with a risk of injuries or fatalities.

7.11 Conclusions

> Everybody, sooner or later, sits down to a banquet of consequences.
>
> Robert Louis Stevenson (1850–1894)

A frequent cause of problems on projects is a failure to resolve issues at an early stage. There are many issues where the associated risk can be effectively mitigated during:

- initial data gathering;
- design;
- procurement of construction.

Many clients procure their design consultants on the assumption that all will provide design products of similar quality and that price should be a major basis for differentiating between them. For simpler projects with easily defined deliverables and where external influences are more easily controlled, price can be a valid comparator, especially if the design consultants have been pre-qualified for their skill and relevant abilities. For more complex projects, what matters most is the quality of the output, such as:

- collection of data into a very coherent and useful desk study report;
- consideration of buildability and ways to resolve such issues;
- better integration of temporary and permanent works solutions.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Site status – amount of investigatory work undertaken	Example of what might be known with the stated extent of investigation	Likely engineering approach given state of knowledge	Potential consequence if foundations were to be installed with state of knowledge	Rumsfeldian classification of feature when its presence was detected	Validity of approach
No desk study with hit-and-miss ground investigation	No knowledge of a large old mineshaft on the site	Evaluate site as normal	Major safety risk for site workers, e.g. collapse failure of a foundation during installation	Unknown unknown	Low known costs but high risk of subsequent failure. Also likely to have long dispute about costs and responsibility
Just a desk study, but no ground investigation	Knowledge there could possibly be a mineshaft somewhere on the site	Know of possible presence but not its poor condition	Feature's location and condition to be discovered so it is likely that there will be site delay while condition of feature is investigated	Known unknown	Possibly low known costs but still risk of significant delay and dispute
Desk study and ground investigation	Know there is an old mineshaft, its location and dimensions. Also know that its condition is poor and it is at risk of collapse	All aspects known – best foundation solution chosen at start; contractor knows how to cope with issue at tender time	Condition known in advance so low risk of extra direct costs or delay. Therefore unlikely to be a dispute	Known known	Potentially higher known costs but much lower risk. Development should be on time and to budget without debilitating row

Table 7.10 Illustration of risk mitigation and consequences

The mine shaft example in **Table 7.10** illustrates the very different consequences from various levels of preparation and study by the design team prior to the start on site.

If total design fees are 5% of the project cost, then an improvement in output quality with 20% more effort (more time or more experienced input) can translate into a 1% increase in project cost. Hopefully this will translate into much bigger savings in out-turn project cost in terms of:

- a lower incidence of hazards causing problems;
- a more deliverable programme;
- smarter ideas resulting in smaller capital cost.

For projects where viability is very tight, a greater investment up-front is even more important, otherwise the project is more likely to encounter unexpected events that will turn it into a financial failure. Perversely, it is often on such projects where most effort is made to minimise design costs that the likelihood of a Black Swan event occurring is inadvertently increased.

This chapter has sought to demonstrate:

- That while foundations are a relatively small part of the overall project cost (perhaps 7%), their problems can be responsible for half of significant project delays, occurring some 17–20% of the time.
- Typically only 0.05–0.22% of the project's building cost are spent investigating those risks, even though 'average' consequences are many times more.
- Developers' financial models are very vulnerable to unexpected shocks – such as project delays, especially when funded by loans, which is usually the case.
- Geotechnical uncertainties can be 'wildly random' rather than 'mildly random' – the effects of a problem can quickly magnify and be disproportionately expensive to solve. Therefore management by mitigation is far more effective than management by contingency.
- A coherent geotechnical risk reduction process can significantly reduce risks. A comprehensive desk study is one of the most cost-effective steps.
- The design, by admitting the possibility (or even probability) of some uncertainty, can go further in reducing the incidence of risk.
- Employment of experienced contractors who make proper allowance for uncertainty will generally provide a more reliable solution than a cheap solution by a less experienced contractor. Poor procurement and poor contractor capabilities were highlighted by the UK Treasury as major contributors to cost and programme overruns on government-funded projects.
- A testing strategy that confronts risks at an early stage by early testing, e.g. load testing of piles, and which reduces the incidence of unexpected or anomalous results during the main construction works will reduce programme vulnerability.
- Clarity of risk ownership with the best strategy being ownership of the risk by those best able to manage it – not just dumping of risks on those at the bottom of the supply chain. Early consideration and mitigation at the opportune time are better than late reaction to a deteriorating situation.
- Reliance on damages and negligence is not an effective way for developers to manage their risks with their constructors and designers – they will seldom recover all their consequential losses which will usually dwarf any direct losses.

- Only very seldom are ground engineering problems caused by gaps in engineering knowledge. Most problems are caused by a failure to apply known processes adequately.
- Communication and information sharing will often result in earlier identification of problems, enabling them to be solved earlier and more easily.

This chapter illustrates that there are no short cuts to gathering pertinent information, digesting it into a form that can be shared across the whole team and using it throughout the whole design and construction process. The main aim should therefore be for robust solutions and overall reliability. The reduction of ground risk needs better application of existing processes, not necessarily better science.

Appendix A
Example development

This example is an idealisation to provide indicative total costs for a typical building development. It is acknowledged that the total and relative costs will vary enormously for different developments. Assumptions are based on a site slightly smaller than 1 ha (1 hectare = 10 000 m^2) in a central area of London. As the site will accommodate 17 000 m^2 (183 000 ft^2) of net lettable area, the land price was set at £68.8 million (the site value, based on net lettable area is assumed to be £376/ft^2 – mid-way in the 2009 typical range of £250–500/ft^2). On the site is placed a 20 000 m^2 gross area high quality air conditioned office building, six storeys high with a single level basement for cycle and car parking and plant. The net lettable area is therefore 85% of gross floor area. A generous allowance of 17 m^2 per person gives a total building population of about 1 000. An average salary for the occupants of this building has been taken as £25 000 per annum. Employer's payroll costs are taken as an extra 25%, giving an average employee cost of £31 250. The total salary roll per year is therefore £31.25 million. Over a 25 year building life, the total employment cost will have been about £781 million (expressed in constant 2009 £).

A building cost has been calculated as typically £1 200/m^2, giving a total of £24 million. The costs have been apportioned as about 10% for substructure (foundations and basement), 45% for frame, floors, walls and roof, and 45% for finishes and services. Of the £2.4 million for substructure, it has been assumed that £600 000 went on piles and pile caps with the rest for the basement structure. Category A fit-out of the building has been assumed to cost some 30% of the total building cost (£7 million). The tenant's fit-out has been taken as £10/m^2 (£200 000), giving a total of about £7.2 million for fit-out. The total building costs for construction and fit-out are therefore £31.2 million, which equates to £1 560/m^2 or £145/ft^2. Professional fees are assumed to be included in the construction cost figures. The annual operating costs are assumed to be approximately £55/m^2 per year, giving a total of £1.1 million per year, or a total of £27.5 million over a 25 year design life. The site investigation costs have been taken as £5000 for a desk study and £40 000 for a ground investigation, including interpretation. These yield a total site investigation cost of £45 000. This represents about 0.19% of the building cost excluding fit-out (which was £24 million); this is typical for the site investigation proportion of structural costs which vary between 0.05% and 0.22% for building projects collected by Rowe in 1972.

Based on the hazards identified in the desk study, it has been assumed that a site less than 1 ha will need some 5 boreholes to depths ranging from 20 m to 40 m, 10 trial pits and associated testing for geotechnical properties and contamination, both on-site and in the laboratory. Assuming a site of 90 m × 90 m and considering the relevant soil depth that might influence the development down to 40 m, the total volume of soil for which geotechnical representation is needed is 324 000 m^3. The soil actually seen on site will be as follows:

- boreholes: $5 \times (0.15\,m)^2\ \pi/4 \times 30\,m$ average depth = 2.65 m^3
- trial pits: $10 \times 3\,m \times 1\,m \times 3\,m = 90\,m^3$.

This gives a total of around 93 m^3. The proportion of soil recovered by the ground investigation is therefore some 0.03% of the total. The proportion examined by a professional engineer or geologist will be a much smaller proportion again.

Chapter 8

Health and safety in geotechnical engineering

Delwynne Ranner Balfour Beatty Ground Engineering, Basingstoke, UK
Tony Suckling Balfour Beatty Ground Engineering, Basingstoke, UK

CONTENTS

8.1	Introduction	75
8.2	An introduction to the legislation	75
8.3	Hazards	76
8.4	Risk assessment	79
8.5	References	80

Construction is a dangerous occupation with on average 75 deaths and 3 330 major injuries reported every year in Great Britain. Safety is everyone's responsibility from client and designer to contractor and we must all work towards reducing the human cost of our profession. Every construction project is unique with a particular combination of contractors, subcontractors, processes, materials, hazards and risks. Maintaining safety is the primary focus of any site; there are legal obligations to be met by all directly involved in any project and all associated with it. It is the responsibility of all to identify risks and then to mitigate against them. Geotechnical engineering has its own specific hazards and risks. Safety on each and every project must be planned, continuously monitored and improved by competent personnel as part of the 'way we work' every day. Responsibility for safety cannot be delegated.

8.1 Introduction

Each and every construction project will have a unique combination of particular contractors, subcontractors, processes, materials, hazards and risks. Maintaining safety is the primary focus of any site, and if it isn't it should be. There are legal obligations to be met by all directly involved in any project and all associated with it. Clients must ensure that competent people are appointed to manage the project, designers must ensure that risks are identified and eliminated during the design phase, the principal contractor and contractors on site must manage and monitor the processes to ensure the work is completed safely. It is everyone's responsibility to identify risks and to mitigate against them. The accident record of the construction industry is improving, however in relation to most other industries construction remains dangerous with on average 75 deaths and 3 300 major injuries reported every year in Great Britain. Everyone, from the most senior to the most junior on any project, has the right to expect to work in a safe place and to return home at the end of the working day. Geotechnical engineering has its own specific hazards and risks, and these are generally described. Safety on each and every project must be planned, continuously monitored and improved by competent personnel as part of the 'way we work' everyday. Responsibility for safety cannot be delegated.

8.2 An introduction to the legislation

Health and safety has taken on great importance in the construction industry, partly due to increased health and safety legislation and partly due to pressure exerted on the industry because of its poor safety record. This chapter gives a brief overview of some of the liabilities under such legislation and is not intended to be a detailed reference on the subject. It should be noted that much of the legislation described applies only to England and Wales; however, the legislation applicable to Scotland and Northern Ireland is almost identical in most respects. For projects outside the United Kingdom different legislation will apply.

Most health and safety legislation is goal setting: the legislation describes broad principles which are expected to be achieved; the detail of how to achieve these principles is primarily left to the employer. Any breach of health and safety legislation is a criminal offence and as such both fines and/or imprisonment can be imposed, the levels of penalties are set out in the Health and Safety (Offences) Act 2008. Conviction can result in a criminal record. Health and safety law places a reverse burden of proof on any defendant. It is up to the defendant to demonstrate that they have complied with the legislation rather than the prosecutor having a responsibility to demonstrate that they have not.

The Health and Safety at Work Act 1974 (HSAWA) imposes duties on all parties (including the employer and the employee) with the purpose of ensuring the health and safety of people at work. The HSAWA is an enabling act which means there are many regulations, often accompanied by approved codes of practice (AcoPs) and guidance notes that take effect under the act. The HSAWA gives appointed inspectors wide reaching powers of investigation and enforcement, including the serving of improvement and prohibition notices.

The Management of Health and Safety at Work Regulations (Health and Safety Executive, 1999) places duties on employers and the self-employed in relation to others affected by their work. The main duties placed on employers are the assessment and reduction of risk, the need to establish emergency procedures, health surveillance, and to provide information and training for employees. The duties in respect of risk assessment in this legislation are the basis of all risk assessment in the workplace.

The Construction (Design and Management) Regulations (CDM) were first enacted in 1994 and were substantially revised in 2007 (Health and Safety Executive, 2007). The CDM places duties on everyone involved in construction works and is one of the most significant pieces of legislation governing

them. The 'duty holders' are divided into six key categories: client, CDM coordinator, designer, principal contractor, contractor and worker. Each of these duty holders have responsibilities if the project is 'notifiable' (notification to the Health and Safety Executive is required if the project is expected to last more than 30 days or 500 person days). However, one of the significant changes to the 2007 regulations was the imposition of duties on some duty holders when a project is classed as 'non-notifiable'. A summary of the main responsibilities of the duty holders is provided in **Table 8.1**.

CDM requires that anyone who wishes to appoint or engage someone to do a construction activity, or undertake design work, must be satisfied that the person they want to appoint has sufficient knowledge and experience to carry out the tasks. Accidents and major incidents often occur because the people carrying out potentially complex tasks have been appointed because they are the cheapest and can do the job the quickest. This is as true for geotechnical works as for any other construction activity. There have been many incidents where contractors have not understood the correct sequences (see Chapter 79 *Sequencing of geotechnical works*) or have not been experienced enough to undertake the job – thereby being ignorant of the hazards and risks involved. All persons have this duty; so a structural designer who needs to engage the services of a geotechnical engineer must ensure that the person is competent, and not appoint on cost alone.

A client should ultimately be satisfied that his whole design, procurement and implementation team is competent. He should therefore ensure that if members of the project team appoint sub-contractors, etc., they have rigorous procedures in place for assessing competencies.

Designers from all disciplines have a contribution to make in reducing and avoiding health and safety risks which are inherent in the construction process and subsequent work, e.g. maintenance and demolition. The most important contribution a designer can make to improve health and safety will often be at the concept and feasibility stages. For geotechnical works, maintenance and demolition are often ignored as being irrelevant but they should always be considered.

The main duty of designers of 'structures' is to assess the implications of their design on the health and safety of people affected by the building when in use and during maintenance of the 'structure'. This is a significant departure from previous safety legislation where most responsibility was placed on contractors. The definition of a 'structure' is wide-ranging and includes items such as tunnels, bridges, pipelines, drainage works, earthworks, lagoons, caissons and earth-retaining structures. It also refers to any formwork, scaffold or falsework which is designed to provide support or access during construction.

Once construction is complete, CDM requires the client to retain the health and safety file. This file is also commonly referred to as the operations and maintenance manual (O&M Manual), and the revision of the regulations in 2007 significantly reduced the amount of detail required in it. The focus of the O&M Manual is to provide information on the 'structure' relevant to the health and safety of those using, maintaining, repairing or renovating the structure. Information on the safe demolition of the 'structure' should also be included.

CDM (Health and Safety Executive, 2007) also made changes relating to the provision of welfare. The Construction (Health, Safety and Welfare) Regulations 1996 were revoked and their requirements included within CDM. Both the client and the principal contractor have responsibilities for ensuring that suitable welfare facilities are available prior to construction works starting.

It is important to note that there is no specific health and safety legislation for geotechnical engineering. British Standards such as BS 8008 (1996) *Safety Precautions in the Construction of Large Diameter Boreholes for Piling and Other Purposes* provide accepted standard practice; whilst they have no legal status they are often referred to in order to establish if legal duties have been adequately discharged. However, the specific requirements of geotechnical design and construction have to be considered within the legislative requirements for the whole industry.

Other legislation which may need to be considered includes, but is not limited to, the following:

- Control of Substances Hazardous to Health (COSHH) Regulations (1999)
- Manual Handling Operations Regulations (1992)
- The Provision and Use of Work Equipment Regulations (1998)
- The Lifting Operations and Lifting Equipment Regulations (1998)
- Personal Protective Equipment Regulations (1992)
- The Work at Height Regulations (2005)
- The Control of Vibration at Work Regulations (2005)
- The Control of Noise at Work Regulations (2005).

For more detailed information refer to the *ICE Manual of Health and Safety in Construction* (McAleenan and Oloke, 2010).

8.3 Hazards

A hazard can be described as the property of an item which has the potential to cause harm. This could apply to almost any item if used in a particular way; combining two or more items would give an infinite number of hazards which may need to be considered on any project.

Ground investigation works are hazardous as the personnel are often the first onto the site as part of the development. The principal contractor may not have been appointed at this stage, so the specialist ground investigation organisation will be required to perform his duties whilst on site. As these works are, by their very nature, an investigation, it should always be anticipated that there will be hazards which will not have been identified or even anticipated by the desk study. Also, if these works are to be undertaken inside an abandoned building, then consideration must be given to particular hazards

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

	All construction projects	Additional duties for notifiable projects
Clients	Check competence and resources of all appointees	Appoint CDM coordinator*
	Ensure there are suitable management arrangements for the project welfare facilities	Appoint principal contractor*
	Allow sufficient time and resources for all stages	Make sure that the construction phase does not start unless there are suitable welfare facilities and a construction phase plan is in place.
	Provide pre-construction information to designers and contractors	Provide information relating to the health and safety file to the CDM coordinator
		Retain and provide access to the health and safety file
CDM coordinators		Advise and assist the client with his/her duties
		Notify HSE
		Coordinate health and safety aspects of design work and cooperate with others involved with the project
		Facilitate good communication between client, designers and contractors
		Liaise with principal contractor regarding ongoing design
		Identify, collect and pass on pre-construction information
		Prepare/update health and safety file
Designers	Eliminate hazards and reduce risks during design	Check client is aware of duties and CDM coordinator has been appointed
	Provide information about remaining risks	Provide any information needed for the health and safety file
Principal contractors		Plan, manage and monitor construction phase in liaison with contractor
		Prepare, develop and implement a written plan and site rules. (Initial plan completed before the construction phase begins)
		Give contractors relevant parts of the plan
		Make sure suitable welfare facilities are provided from the start and maintained throughout the construction phase
		Check competence of all appointees
		Ensure all workers have site inductions and any further information and training needed for the work
		Consult with the workers
		Liaise with CDM coordinator regarding ongoing design
		Secure the site
Contractors	Plan, manage and monitor own work and that of workers	Check client is aware of duties and a CDM coordinator has been appointed and HSE notified before starting work
	Check competence of all their appointees and workers	Cooperate with principal contractor in planning and managing work, including reasonable directions and site rules
	Train own employees	Provide details to the principal contractor of any contractor whom he engages in connection with carrying out the work
	Provide information to their workers	Provide any information needed for the health and safety file
	Comply with the specific requirements in Part 4 of the Regulations	Inform principal contractor of problems with the plan
	Ensure there are adequate welfare facilities for their workers	Inform principal contractor of reportable accidents, diseases and dangerous occurrences
Workers	Check own competence	
	Cooperate with others and coordinate work so as to ensure the health and safety of construction workers and others who may be affected by the work	
	Report obvious risks	

* There must be a CDM coordinator and principal contractor until the end of the construction phase

Table 8.1 The main responsibilities of the duty holders
Reproduced from HSE (2007) © Crown Copyright

(e.g. asbestos) and a structural assessment must be undertaken prior to the ground investigation.

Most geotechnical works are specialist and are normally undertaken by specialist subcontractors. The subcontractor often undertakes both the design and the construction of their element of the works and so has the best understanding of the particular hazards and risks associated with the product or process. The principal contractor and the engineer are most likely to have the best understanding of the specific risks and hazards of the overall project. Therefore all parties must work together, both before and during the works, to identify the hazards and introduce appropriate mitigation or control measures.

A list of general hazard areas which must be considered on any construction project is provided below, with more detailed discussion of some of the hazards associated with geotechnical works provided in the clauses which follow. This list is not exhaustive and the unique combination of factors which go to make up any project means that each project must be reviewed on its own merits. Some areas for consideration are:

- Access and egress to the place of work for vehicles and pedestrians.
- The movement of vehicles on site, including the need to separate vehicles and pedestrians wherever practical.
- Protection of the public (almost every construction project will have some interaction with the public; consideration must be given as to how to ensure they remain safe and that the project inconveniences them as little as possible).
- Protection of the environment (watercourses, ground water, habitat, species, etc.).
- Provision of welfare for workers (this can be a particular challenge on geotechnical projects which may be small projects of a transient nature or large projects which stretch over many miles).
- The effects of weather (provision must be made for ensuring adequate lighting during winter months, workers must be able to dry wet clothes, the effect of wind speed on tall plant may need to be considered, and how to maintain safe ground conditions in heavy rain or snow).
- Site security (not only must provision be made to ensure that members of the public do not inadvertently access the works areas, but consideration should also be given to maintaining records of who is on site and what they are doing).
- Designing for safety (consideration must be given to designing out risks wherever practical; this should include any temporary works structures and geotechnical works in the temporary state).
- Emergency situations (consideration needs to be given to dealing with incidents on site such as the provision of first aiders, the location of the closest hospital and mechanisms for workers to report emergency situations).
- Management of works on site (including the programming of works to ensure that risks are minimised both from a design point of view and taking into account the physical working space).
- The elimination of the need to work at height, or the control of the risk of falling (this should include the risk of falling into excavations).
- Protection of workers' health (workers' short- and long-term health can be affected by a number of things such as noise, dust, biological hazards, manual labour and vibration. These hazards must be identified and controlled).

8.3.1 Shallow excavations

The stability of the sides of excavations depends on the ground conditions, including the effects of groundwater, as well as the depth of excavation and the surcharge placed on the sides of the excavation. It is important to note that stability is likely to decrease with time and can reduce very quickly by the introduction of water from precipitation or elsewhere. Unfortunately the number of people killed having been trapped in unsupported excavations remains constant year on year. Regulations do not specify any requirement for the support of excavations, other than that this should be reviewed by risk assessment. However, an assessment of stability should be based on sound engineering design principles and not judgement. Excavation stability must be assessed by a competent person taking into account items such as ground conditions, weather conditions, activities adjacent to the excavation and the movement of groundwater.

Consideration must also be given to access/egress to excavations (for people, plant, equipment and materials), maintaining the safety of the excavation with regards to water ingress, underfoot conditions and the possible build up of gases. Measures must be taken to ensure that people, equipment and/or vehicles do not fall into the excavation.

Care must also be taken to ensure that when an excavation has been completed it is backfilled with appropriate material and compacted where required. This is of particular importance where other activities will be using the area. Plant tracking over a poorly reinstated excavation is at significant risk of overturning. This not only applies to shallow excavations, but also to pile bores and deep urban excavations.

8.3.2 Piling works

Piling works use specialist plant which can weigh up to 140 tonnes, can be up to 30 m high, is front heavy, and the driver usually does not have full visibility around the machine. A safe exclusion zone must be maintained around the piling plant, the public must be protected from risk, and vehicle and plant movement around the piling plant must be properly controlled. Piling rigs require a significant amount of space to operate safely and the specialist contractor should be consulted as early as possible to ensure that the project is sequenced in a way which ensures that this space can be provided and maintained.

Three particular hazards associated with piling works are:

- Design, maintenance and repair of the working platform, see **Figure 8.1** and Chapter 81 *Types of bearing piles*. The platform must be adequate for the full duration of its use. Soft or hard areas beneath the platform, either existing before or created after construction of the platform, can cause rig instability.
- Failure of a pile load test reaction system, see **Figure 8.2**. Significant and real forces are applied through the test pile and

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 8.1 Photograph showing a piling rig which overturned due to the platform not having sufficient capacity to support the bearing pressure of the machine

Figure 8.2 Photograph showing a reaction test set-up which collapsed when a component part failed

reaction system, and each and every component must be designed and constructed rigorously.

- Site personnel getting caught up in rotating parts such as drill strings, augers or other rotating parts of the specialist machinery. The HSE has recently been very active in promoting fixed guarding around rotating parts and reliance on exclusions zones is no longer considered adequate. This has implications for the safe location of piles in restricted areas and when positioned within say 2 m of any physical barrier.

8.3.3 Deep urban excavations

Figure 8.3 shows an example of a congested city centre project which requires the excavation of a deep basement.

The particular hazards here include:

- The effect of works on adjacent structures.

Figure 8.3 A typical congested city centre project

- Sequencing of works is of particular concern where ground movement could occur as excavation of basement structures progresses.
- Protection to members of the public.
- Planning and sequencing the works to ensure that there is sufficient space for each of the contractors to work safely.
- Use of tower cranes. These have a unique set of hazards and must be appropriately planned, designed, registered, maintained and operated by competent persons.

8.3.4 Contaminated ground

Short- and long-term health problems can arise from contact with contaminated ground. Potentially dangerous substances need to be identified, the related risks assessed and safe systems of work put in place in accordance with the Control of Substances Hazardous to Health Regulations (COSHH).

In 1992, the British Drilling Association published *Guidance Notes for the Safe Drilling of Landfills and Contaminated Land*, and these were subsequently adopted by the Institution of Civil Engineers Site Investigation Steering Group and republished in 1993 as Part 4 of the publication *Site Investigation in Construction*. The British Drilling Association is currently producing an updated document called *A Guide to Safe Site Investigation*. Anyone involved with drilling into the ground, whether thought to be contaminated or not, should refer to such specialist documentation.

Guidance on the range of potential contaminants and the means of controlling the related risks is provided in HSG 66 (1991) – *Protection of Workers and the General Public during Development of Contaminated Land*. Specialist advice when dealing with contaminated land must be sought.

8.4 Risk assessment

Risk assessments are used as a means of documenting, defining and managing risk as a response to the Management of Health and Safety at Work Regulations. Risk identification and evaluation is the process of looking at the hazards identified,

calculating the severity of the outcome if their potentials were realised, and checking who might be affected. Risk control is ensuring that the hazard's potential cannot be realised. Therefore the risk assessment process, put simply, is figuring out how to keep people safe and then making a note of what has been decided, and why.

All geotechnical processes will have associated hazards and risks; these are identified and defined in the risk assessment form. Mitigation measures (controls) are introduced to hopefully eliminate the hazard. If complete elimination of the hazard is not possible then measures are introduced to reduce the risk of harm to an acceptable level. What defines an acceptable level of risk depends on a number of factors including the legislative requirements. Competent advice should be sought from geotechnical specialists when reviewing to check that proposed controls measures are adequate.

The best mechanisms are to avoid or eliminate hazards and risks; however if this is not possible then consideration must first be given to 'preventative' control measures. These are generally controls which work for a large number of people at the same time and do not require human input, e.g. using a fixed guard rail around an excavation. If preventative measures cannot be adopted then protective measures should be considered next. Protective measures will generally only work for one person at a time and will require the input of that person – for instance, he may be required to wear a safety harness to prevent a fall into an excavation. This whole process is documented in the risk assessment form. All control measures must be put in place, monitored and maintained, so that the risk to health and safety remains at a low level. Project-specific hazards and risks are dealt with as part of the same process.

The risk assessment process cannot be programmed to be undertaken at a particular point in a project, as the hazards and risks associated with a project will change on a daily basis. The process of identifying hazards, assessing risk and implementing appropriate controls is an ongoing one which should involve everyone who is associated with the project. Many hazards can be effectively eliminated and/or controlled long before the work on site starts, provided the right people, with the right skills, are involved in the planning process.

The other vital part of the risk assessment process is ensuring that the people who are going to do the work have the right information in order to keep themselves safe. Any significant risks on a project must be briefed to the workers. This is usually done in an induction. Inductions do not need to be long and complex; they should simply explain the key site risks and controls, the emergency procedures and the site rules.

Most construction companies have their own processes and procedures in relation to identifying and recording hazards and risks. Specialist geotechnical organisations are the same. These processes are usually based around the principles described in the Management of Health and Safety at Work Regulations and expanded on in the HSE's publication *Five Steps to Risk Assessment* (Health and Safety Executive, 2006) (INDG163).

CONTENTS

9.1	Introduction	83
9.2	Foundation selection	83
9.3	A holistic approach to foundation engineering	87
9.4	Keeping the geotechnical triangle in balance – ground risk management	90
9.5	Foundation applications	96
9.6	Conclusions	103
9.7	References	104

The objective of this chapter is to dispel the widely held view that foundation engineering is simply a matter of designing and then constructing a foundation to carry a given load. In practice, many key decisions have to be made in developing the conceptual design before detailed design calculations can be undertaken. An approach to tackling these key decisions is given. For foundations to be constructed economically and sustainably it is necessary for the geotechnical and structural engineer to work closely together from an early stage. Examples are given of the benefits associated with close cooperation across the design team. Great emphasis is placed on recognising that foundation engineering is a 'process' involving a number of interlinked operations. Success depends on the skill of the engineers and operators and the way these operations are monitored and modified as work progresses. The chapter contains a number of case histories describing problems that emerged during construction and how these were solved. They illustrate how important it is to keep the 'geotechnical triangle' in balance.

9.1 Introduction

In 1951 Professor Karl Terzaghi, in a lecture given at the Building Research Congress in London, said (Terzaghi, 1951):

> On account of the fact that there is no glory attached to the foundations and that the sources of success or failure are hidden deep in the ground, building foundations have always been treated as stepchildren and their acts of revenge for lack of attention can be very embarrassing.

The aim of this chapter is to describe the decisions and procedures that have to be undertaken in arriving at a foundation design and in successfully constructing the foundation and the structure it is intended to support. It is important to understand right from the start that foundation engineering is essentially a process. The process involves a number of interlinked operations, and success depends on the skill of the engineers and operators and the way these operations are monitored and modified as work progresses. Thus the design and construction of a foundation is critically dependent not only on the choice of foundation, but on numerous other factors including the ground and groundwater conditions and the way they are influenced by the construction method, the skill and experience of the contractor, the supervision and quality control of each operation and a clear understanding of the performance requirements of the structure resting on the foundations.

A number of case histories are included which are chosen to emphasise the importance of the geotechnical engineer, the contractor and the structural engineer working closely together to ensure that the process as a whole is successful.

9.2 Foundation selection

Many textbooks cover the topic of foundation design; however, the engineer reading these textbooks could be left with the impression that foundation design is solely concerned with the calculation of bearing capacity and settlement. In practice, many of the key decisions have been made before bearing-capacity and settlement calculations are carried out. A useful mnemonic for the foundation designer is the 'five S's':

- **Site:** What are the nature, topography and size of the site? Are there major constraints, e.g. limited headroom, major underground services? Are there settlement-sensitive structures adjacent to the site? What is the site history, e.g. is it underlain by historic mining, old buried foundations?
- **Soil:** What is the soil (or ground) profile and groundwater regime? This should be understood in the context of the local geology and hydrogeology. Do competent soils exist at shallow depth? Will groundwater seriously affect foundation construction?
- **Structure:** The size of structure, its structural form and layout, the type, magnitude and direction of applied loads, together with the allowable foundation movements, will be major factors in foundation selection.
- **Safety:** Numerous ground-related hazards may affect the site. These may be due to the intrinsic hazards associated with the soil/rock types which underlie the site and the way they may have been affected by post-depositional geological processes (such as landslips), or to human activities, such as historical industrial processes which have left a legacy of ground/groundwater contamination, or hazardous gases, or mining, quarrying or non-engineered materials (dumped fills or landfills) which are potentially unstable. Reference should be made to Chapters 8 *Health and safety in geotechnical engineering*, 40 *The Ground as a hazard* and 41 *Man-made hazards and obstructions* of this manual, in addition to guidance provided by the Health and Safety Executive, e.g. HS(G)66 (Health and Safety Executive, 1991), and CIRIA guides, e.g. CIRIA reports 132 (Steeds *et al.*, 1996) and 552 (Rudland *et al.*, 2001).
- **Sustainability:** This requires a consideration of environmental and social factors and the economic implications of different

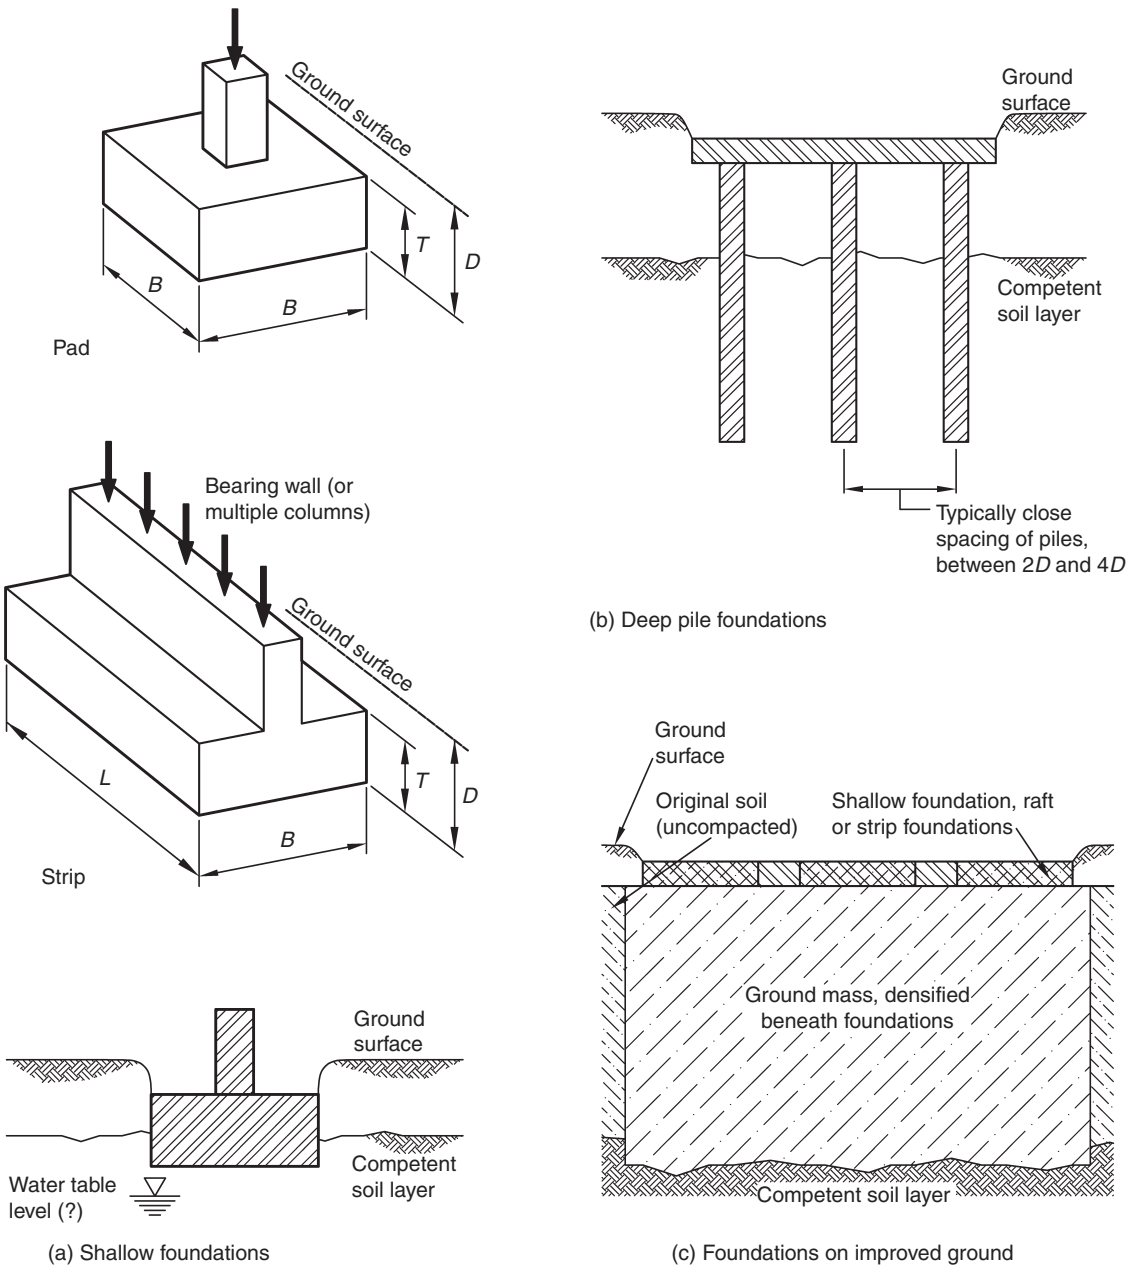

Figure 9.1 Foundation types

foundation options. The aim should be to minimise the environmental and social impact of foundation construction, providing the costs are reasonable. Environmental impacts include an assessment of embodied energy, and the carbon footprint of different options. Social factors would include potential disruptions to adjacent communities from construction traffic, noise, vibration, etc.

The above 'five S's' are discussed in more detail in Chapter 52 *Foundation types and conceptual design principles*. At the end of this chapter a case history is given, which provides a practical example of the factors which will influence foundation selection.

Foundation types are commonly classified into two types (**Figure 9.1**):

(i) *Shallow foundations* – these include: discrete pad footings which usually support a single superstructure column; strip footings which may support a wall; and raft foundations which support the entire superstructure. These are discussed in more detail in Chapter 53 *Shallow foundations*.

(ii) *Deep foundations* – most commonly these include piled foundations, either as single piles below superstructure

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

columns/piers (refer to Chapter 54 *Single piles*) or as several relatively closely spaced piles acting together as a pile group to support either the entire superstructure or heavily loaded parts of the structure (refer to Chapter 55 *Pile-group design*). More specialist deep foundations include deep shafts, caissons and barrettes.

It is also useful to consider a third generic foundation type (**Figure 9.1**):

(iii) *Hybrid foundations* – this type comprises elements which are common to both shallow and deep foundations. Examples include: deep ground improvement (to increase the bearing capacity and/or reduce the compressibility of soils below the structure), with shallow foundations constructed on the improved ground; piled rafts where the structure is supported by a raft and a few widely spaced piles. Chapter 59 *Design principles for ground improvement* discusses ground improvement design principles and Chapter 56 *Rafts and piled rafts* discusses piled rafts.

The ground profile and the allowable foundation movement are two key factors in selecting the most appropriate foundation type. If competent founding strata are close to the ground surface then shallow foundations should be considered, since they are usually relatively simple and cheap to construct. However, as foundation loads increase and/or allowable movements are reduced, then the use of piled foundations will become more appropriate. Often, the decision is fairly simple, for example, if there is a deep layer of heterogeneous Made Ground covering the project site, and the foundations are heavily loaded (say for a multi-storey public building or large bridge), then the use of piles will be obvious. However, if the proposed structure applies modest loads and is relatively tolerant of ground movement (say a steel frame single-storey warehouse), then it may be possible to found on the Made Ground (or non-engineered fill), especially if a deep-ground improvement technique can be used to strengthen/stiffen the Made Ground. The important topic of foundation engineering within non-engineered fills is considered in Chapter 58 *Building on fills*.

For some sites the foundation designer may be faced with a difficult decision in deciding upon the most appropriate foundation type. The 'five S's' will then need to be considered in great detail and the designer will have to juggle with a wide range of factors, such as ground strength/compressibility, allowable movement, available space for construction equipment, potential impacts on neighbours and the local community, and the ease, speed and safety of different construction options. Once the advantages/disadvantages are considered and balanced for each option, then a final selection of foundation types, and their dimensions, can be made. Some of the factors that will affect these decisions are subjective, and will be affected by perceptions of how to best minimise risks, especially during construction. This inevitably varies between individuals and organisations and will also reflect local construction practices (which vary markedly around the world). Common factors in properly understanding ground risks are:

(i) Understanding the site history and geology. This requires a comprehensive desk study to be carried out (refer to Chapter 43 *Preliminary studies*).

(ii) Understanding the site's groundwater regime and how it impacts upon the proposed construction and permanent works.

In the vast majority of cases when foundation problems occur it is because either (i) or (ii) above has not been properly understood by the foundation designer. A coherent approach to proper understanding of ground risk is provided by the 'geotechnical triangle' (introduced in Chapter 4 *The geotechnical triangle*), and practical examples are provided in section 9.4 of this chapter.

Figure 9.2 provides an example of the wide range of pad and pile sizes and shapes for the support of a nominal 9000 kN load on a deep layer of stiff overconsolidated clay. Although all the options are 'safe', in the sense that they all have an acceptable factor of safety against bearing-capacity failure, their expected settlement and the issues which need to be considered for construction all vary markedly. For example:

(i) Pad foundation: Is the expected settlement (at 100 mm) too large? If yes, can the pad be made larger, to reduce settlement to a tolerable amount? Is there sufficient space to form the pad? If the pad is excavated, will it undermine adjacent structures or slopes?

(ii) Pier foundations: If deep excavations are required, can an open excavation be formed (at a stable slope angle) or will temporary retaining walls be needed? Or will specialist caisson/shaft sinking methods be more appropriate? Again available space across the site will be a critical consideration. Will excavation need to be carried out below the water table? If the groundwater table is to be lowered to facilitate excavation, what settlement will be induced? What volume of water will be extracted and can it be disposed of?

(iii) Under-reamed piles: Will the ground be stable enough to form an under-ream? This will often depend on the detailed 'fabric' of the ground, together with the groundwater regime. Do silt/sand layers exist within the clay (which may lead to the under-ream becoming unstable prior to concreting), or is the clay uniform, and of low permeability?

(iv) Large diameter (1.2 or 1.5 m diameter) piles: These will require a large heavy piling rig to be mobilised to site, which will be expensive. Will a lot of large diameter piles be needed, or is this just for a few isolated foundations (hence the overall foundation requirements need to be considered for the whole project)? Are there significant weight restrictions for heavy plant, either due to weak surface soils, or weak bridges to gain entry into the site?

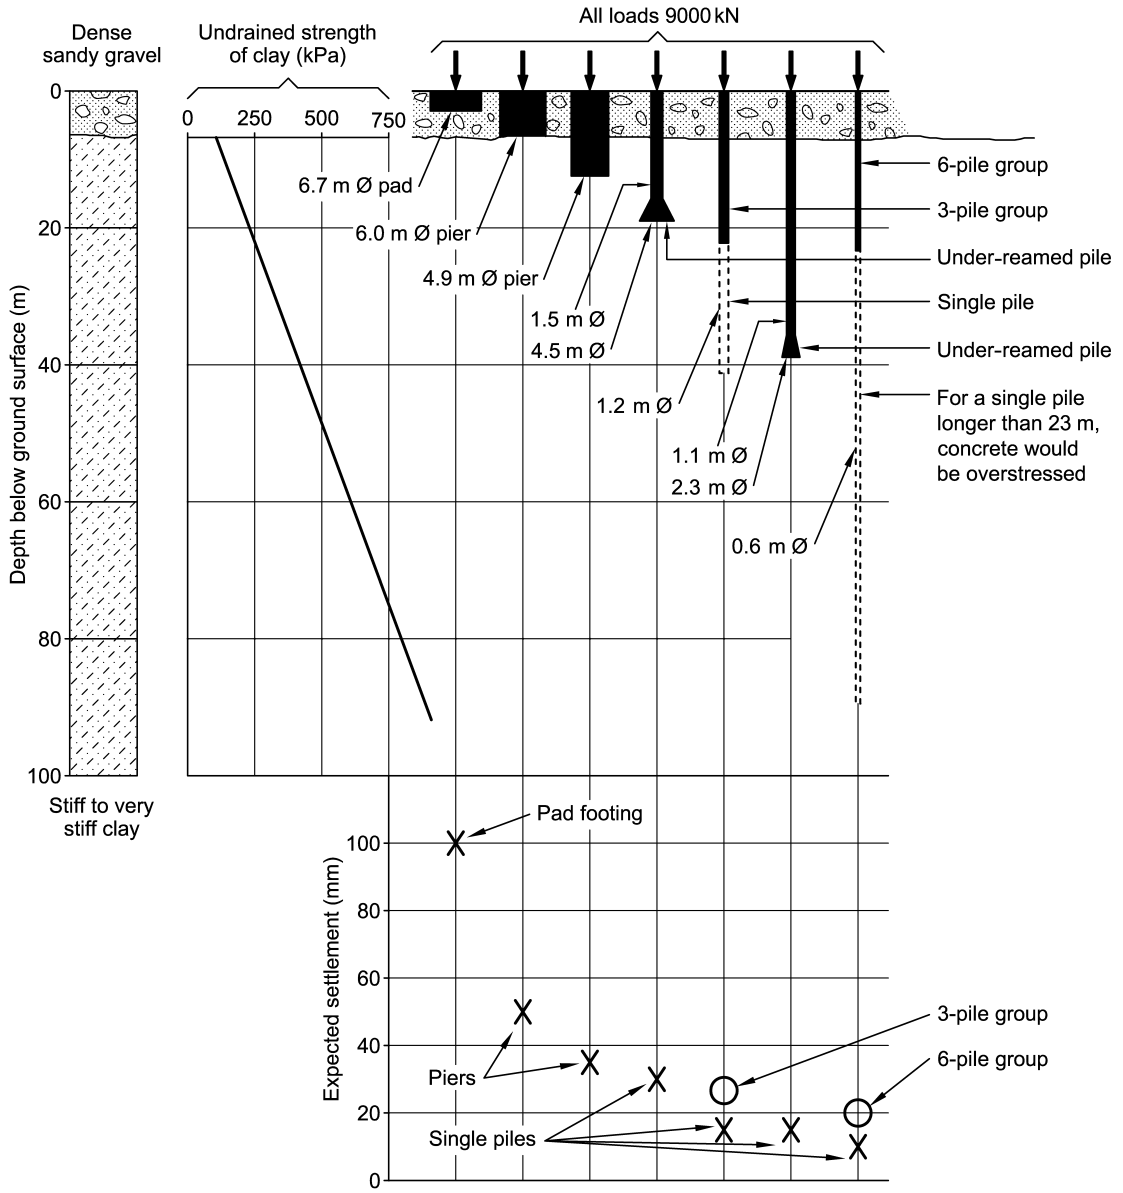

Figure 9.2 Methods of supporting a 9000 kN load
Reproduced from Cole (1988)

(v) Medium diameter (0.6 m diameter) piles: Is there sufficient headroom across the site to construct piles using conventional plant? For bored piles, will any temporary support be needed, e.g. temporary casing through surface gravels or support fluids at greater depth (if the clay is inter-bedded with silts/sands/gravels which lead to pile bore instability, especially if groundwater pressures are high)? Headroom and pile bore stability will also need to be considered for large diameter piles.

For smaller, and less powerful, piling rigs an important consideration will be the risk of hitting obstructions, for example, if old foundations are buried beneath the site, or if hard rock layers need to be penetrated. In these circumstances large diameter piles may be preferred.

Clearly when practical construction issues are being considered, early discussions with specialist contractors will be helpful. However, it is important for the foundation designer to develop a broad knowledge of construction issues, so that discussions with specialist contractors can be meaningful.

The predicted settlements for the different foundation types, shown in **Figure 9.2**, vary by an order of magnitude; hence an understanding of allowable foundation movement is clearly important when selecting the most appropriate and cost-effective foundation type. Often the limits set for allowable

total and differential settlement are arbitrary and overconservative. It is important for the foundation designer to have early discussions with the structural engineer on this matter. Usually total settlement is used as an indicator of what is 'allowable'; however, structural damage will be a function of *differential* rather than total settlement. It is also important to note that it is the differential settlement which occurs *after* the structure is built (and structural connections formed, and sensitive finishes completed) that will lead to damage to the structure. Hence, a considerable percentage of the total settlement that will occur during construction (due to the dead weight of the major structural elements) will be built out and have no impact on the risk of structural damage. This topic is considered in further detail in the context of foundation design, in Chapters 26 *Building response to ground movements* and 52 *Foundation types and conceptual design principles*. Finally, it should be noted that the main opportunity for economic foundation design is to set realistic (rather than overconservative) limits on allowable foundation movement, especially differential movements.

9.3 A holistic approach to foundation engineering

Most textbooks tend to focus on the behaviour of a foundation element (say a strip footing or a pile) acting in isolation. However, practical foundation engineering requires the foundation designer to consider the overall site redevelopment strategy, and in particular how different foundation types may be used in order to ensure the foundations are safe, simple and economic to construct.

Foundations are assemblages of different components, which may include various ancillary processes to facilitate design or construction (such as groundwater control, grouting, ground anchors, etc.) together with the use of retaining walls (either as temporary or permanent works). The interrelationship between foundation components, ancillary processes and assemblages is illustrated in **Figure 9.3**. A simple example would be the construction of a bridge abutment adjacent to a river bank (**Figure 9.4**):

(i) The *bridge abutment* is a composite structure. The stem of the inverted T retaining wall retains the approach embankment fill, and the base of the T acts as a pad footing to support the bridge deck and traffic loads. The settlement of the abutment is affected by the loads and settlement induced by the adjacent embankment, as well as those directly applied from the bridge.

(ii) *Temporary excavations* will be required for construction and may involve a combination of temporary sheet piling and/or groundwater control.

(iii) On the *adjacent river bank* the stability of the slope will need to be checked (under varying river levels), and the river

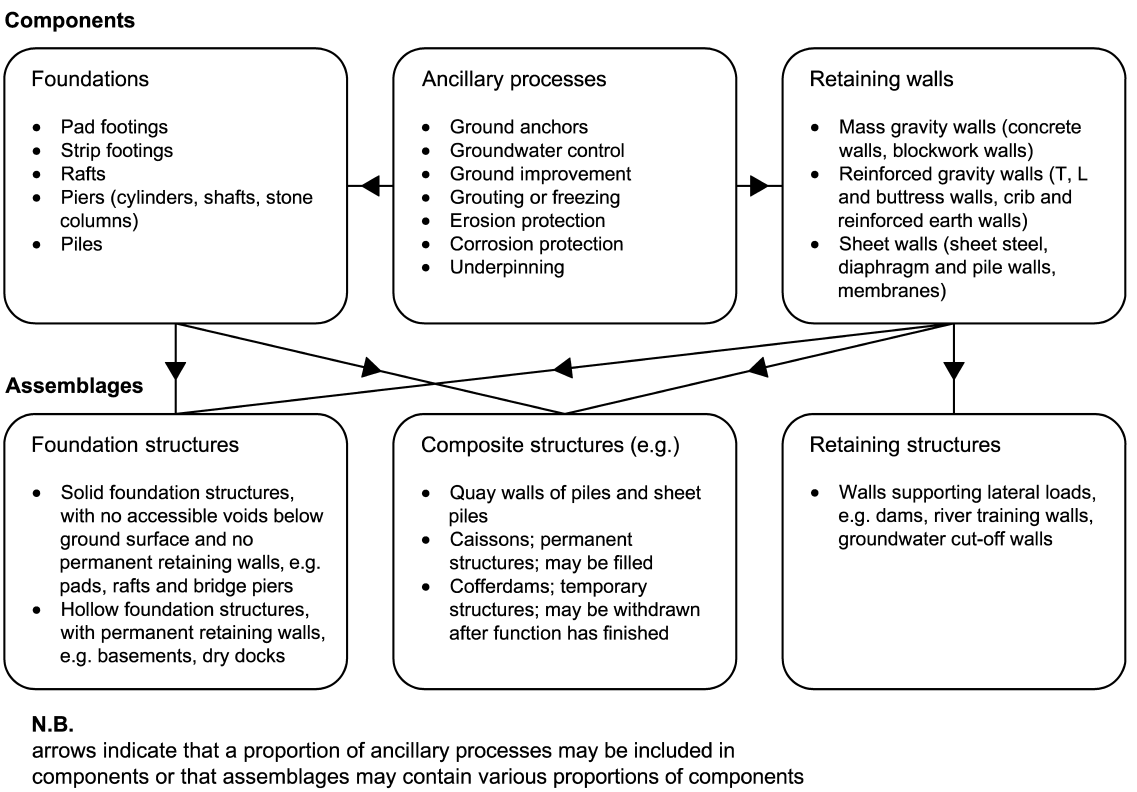

Figure 9.3 Relationships between components, ancillary processes and assemblages
Reproduced from Cole (1988)

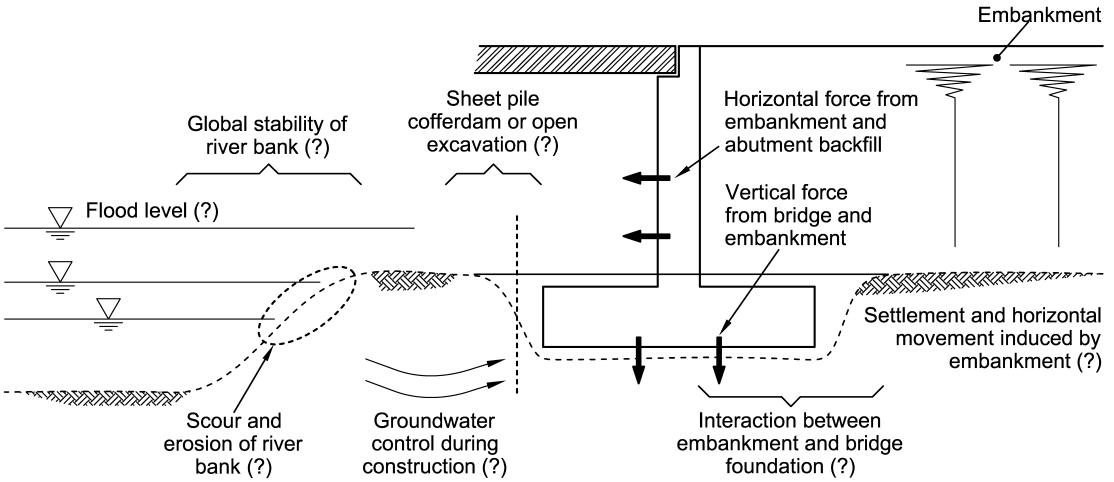

Figure 9.4 Foundation components, ancillary processes and assemblages: a bridge abutment adjacent to a river

bank will need erosion protection, so scour does not lead to the bridge abutment being eroded and undermined.

(iv) The interaction between the above elements also needs to be considered – for example, will the temporary excavation or temporary surcharge loads for the bridge abutment construction destabilise the river bank? Will the ground movements associated with the approach embankment adversely affect the bridge abutment?

Sometimes these different components of a project (say tasks (i), (ii) and (iii) above) are designed by different teams within an organisation, or by different organisations. It is important that potential interactions are considered by a single team and preferably this should be the lead project designer; otherwise serious problems can occur.

9.3.1 Examples of circumstances that influence foundation design

Because of the huge variety of ground and groundwater conditions which may be encountered and the widely different circumstances in which foundations are constructed, foundation design may involve a wide range of components, ancillary processes and assemblages. The main factors which influence those circumstances are: ground shape and location relative to other natural features (rivers, banks, slopes); adjacent site use and structures (surface and underground) and their sensitivity to ground movement/vibration; the site history; proposed superstructure requirements (allowable movements) and loads; the site geology and hydrogeology. A few practical examples are discussed below and illustrated in **Figures 9.5** and **9.6**:

(i) *Ground shape and location*. The overall shape of the ground (its geomorphology) both within and around the project site can have a major influence on foundation design and construction. A walkover survey by an experienced geomorphologist may allow the risk of, say, historic landslides being encountered to be assessed (Phipps, 2003; Fookes *et al*., 2007). Other examples are: sites in mining areas, which may be subject to subsidence and local instability; sites affected by large-scale erosion processes and/or flooding. The overall shape of the site may need to be changed to give a more satisfactory layout for the project development, for example by cutting and/or filling to form terraces, or to increase/decrease the overall site level. Although this may be necessary for the project, it may substantially increase the complexity of the foundation engineering because it will cause significant 'global' ground movements to develop (for example, settlement below deep areas of fill, or heave/swelling beneath deep excavations). If cut/fill is carried out on sites underlain by clays, these global ground movements may take several years to fully develop. Hence, additional forces (both vertical and horizontal) and ground movements would need to be considered in the design of individual foundation components. Chapter 57 *Global ground movements and their effects on piles* considers the effects of global ground movements on pile design.

(ii) *Site history and constraints*. Nowadays 'greenfield' sites, i.e. sites which have had no previous structures or industrial use, are increasingly rare. Obstructions, constraints and various hazards are commonly found on the site of a new project. Some sites may contain remains of archaeological value. Carrying out a comprehensive desk study at an early stage of the project is by far the best way of identifying these potential problems. Guidance on how to discover as much as possible about a site prior to carrying out ground investigation is given in Chapter 43 *Preliminary studies* of this manual. Some sites affected by industrial activities may be underlain by chemically contaminated materials (these may have originated at the site under consideration, or have 'leaked' in from neighbouring sites,

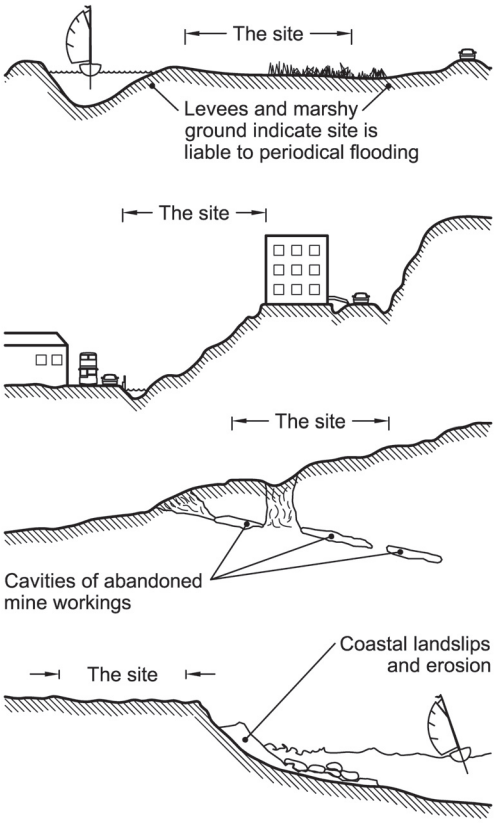

Figure 9.5 Influence of shape of ground on foundation design and construction
Reproduced from Cole (1988)

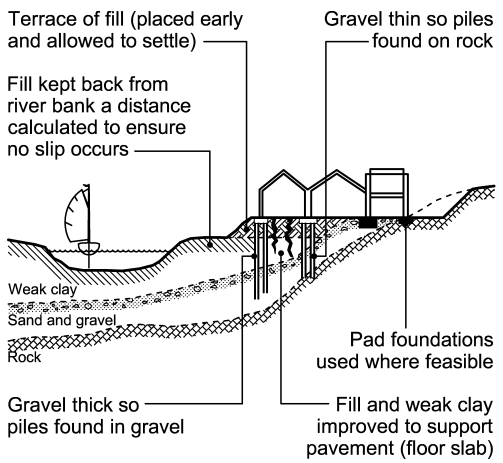

Figure 9.6 Example of how site re-levelling requires several foundation engineering activities
Reproduced from Cole (1988)

or have been spread across an area due to poorly controlled demolition). These contaminated materials may have impacted the soil or groundwater, or be in the form of noxious/explosive gases. If contaminated soils impact a site then the foundation designer will need to work closely with a contaminated land specialist and the relevant regulatory authorities, and it is likely to have a significant impact on foundation design/construction. Contaminated land guidance is given in a wide range of publications including those by the Department of the Environment, Environment Agency, etc. CIRIA reports, such as C552 (Rudland *et al*., 2001) provide a good introduction.

(iii) *Site geology and hydrogeology.* The composition and structure of the ground and the groundwater conditions, both now, during construction, and in the long term, during the design life of the structure, affect the choice of foundations. For example, consider the foundations for a multi-storey building. At one extreme, the site may be underlain by deep deposits of very soft alluvial clays/silts and peat, over an irregularly weathered and fractured rock mass affected by historic coal mining (a relevant case history is discussed in Chapter 52 *Foundation types and conceptual design principles*). The foundations may require numerous deep large diameter piles. Prior to piling, an ancillary process, involving grouting of the mineworkings, will be required to stabilise the site and avoid collapse of the mineworkings in the future. At the other extreme, a massive layer of a strong rock (say granite) with only a few widely spaced discontinuities may be encountered close to the ground surface. This rock could support the superstructure frame (columns/walls, etc.) with little enlargement to form the footings (this rock type would be stronger than the foundation concrete). Between these extremes lie a vast range of different combinations of ground conditions. Perhaps less obvious than the ground types which underlie the site are the potential influence of groundwater conditions on foundation engineering and how they may fluctuate seasonally and in the long term and how these may affect foundation behaviour. **Table 9.1** provides a check list of some groundwater-related factors which may affect foundation design, and an associated commentary. An additional challenge is how rapidly the groundwater regime will lead to changes in ground behaviour, for example softening of clays adjacent to an excavation. This rate of change is affected by the mass (or bulk) permeability of the ground. At one extreme are highly permeable soils, such as 'clean' gravels (i.e. with negligible silt/clay content) and at the other extreme are low permeability homogenous clays. This range covers a change in permeability of about seven orders of magnitude, between 10^{-3} m/s and 10^{-10} m/s. Most natural soils comprise varying amounts of clay, silt and sands; and the 'fabric', i.e. the arrangement of silt/sand layers/lenses within clays, or vice versa, has a major influence on the ground's mass permeability. Laboratory measurements of permeability are usually misleading, and *in situ* permeability testing is preferable (refer to CIRIA report C515 (Preene *et al*.,

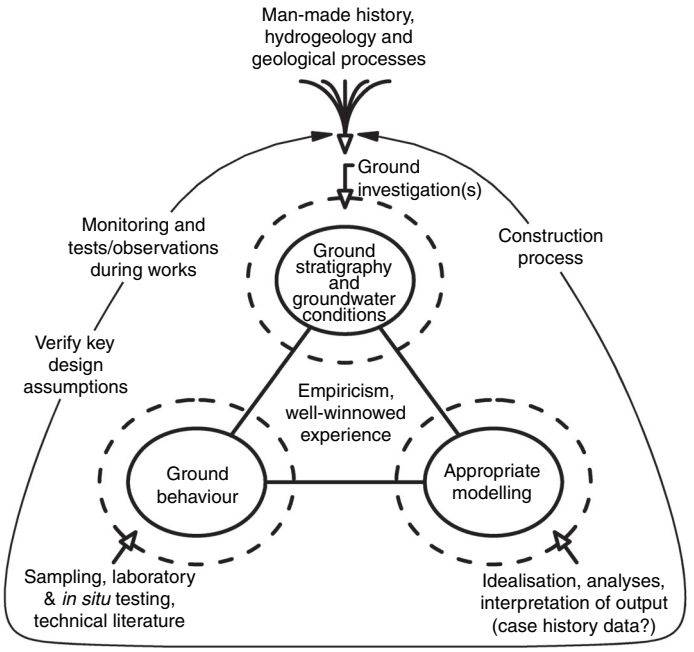
Swelling and softening of strata below excavation	For clays, as effective stresses reduce, the strength reduces and compressibility increases. In rocks, joints may open (or joint infill materials may soften), and overall rock mass strength/stiffness is reduced. Repeated wetting/drying of weak rocks may lead to breakdown of rock structure and large loss of strength.
Dewatering during construction and re-establishment after dewatering switched off	In clays/silts: dewatering of adjacent more permeable soils (such as sands/gravel) can lead to a reduction in pore water pressure in the clay/silt, leading to consolidation settlements. After dewatering is switched off, 'rebound' will occur, potentially leading to swelling (depending on foundation bearing pressure and net increase/decrease in effective stresses). In sands/gravel: dewatering may lead to a loss of fines and substantial differential settlement, and ultimately ground instability. Hence, appropriate filters and observations are essential to avoid loss of fines.
Excavation, basal instability	Due to excessive groundwater pressures or hydraulic gradients. Even if ground failure does not occur, there may be substantial loss of ground strength/stiffness.
Erosion and scour	Surface water flows may lead to undermining of shallow foundations, or loss of lateral support to shallow and deep foundations. Erosion protection essential in high risk situations. Silts and fine sands are especially vulnerable.
Frost action	Leads to volumetric expansion, due to ice lense formation and/or freezing of water in cracks. Local codes of practice usually specify minimum foundation depths to avoid adverse effects.
Groundwater level changes (low lying areas may be vulnerable to flooding)	Natural variations in groundwater table level may occur, or man-made changes may occur (e.g. due to burst water main). These may lead to uplift forces on foundations, and a requirement for anchors and/or drains/relief wells to avoid buoyancy failure.
Collapsible soils	These soils are either very loose unsaturated soils, or (more commonly in the UK) loose non-engineered fills. If these soils wet up due to a water table rise, then a large 'collapse'-type settlement may occur.
Expansive soils	Desiccated clays, located above the water table, will be prone to substantial swelling pressures and volumetric expansion (heave or swelling) if the clay wets up. High-plasticity clays are most vulnerable. In the UK, this problem is usually associated with vegetation effects and seasonal wetting/drying (see below).
Vegetation effects and seasonal wetting/drying	Large trees (especially high-water-demand varieties), together with high-plasticity clays, can induce substantial seasonal foundation movements due to winter wetting/summer drying of the clays. Chapter 53 discusses this problem in more detail. If trees have been removed, then the desiccated clay will slowly wet up over several years, as pore water pressures re-equilibrate, leading to large swelling and uplift forces on foundations.

Table 9.1 Groundwater-related issues which may affect foundation design and cause large foundation movements

2000)). It is important to note that the groundwater effects outlined in **Table 9.1** may lead to substantial foundation movements which are independent of the bearing pressures applied by the structure. These effects will often be overlooked by a structural or general civil engineer, and it is important for the geotechnical engineer to carefully consider groundwater-related effects and associated risks.

9.4 Keeping the geotechnical triangle in balance – ground risk management

9.4.1 Background



During the last 50 years or so, research developments in soil mechanics and the related engineering sciences have led to immense improvements in knowledge and understanding. Enormous developments in computer technology and numerical modelling enable engineers to analyse highly complex geotechnical problems, which would have been unthinkable a few decades ago. Alongside these theoretical and technical developments have been major improvements in practical construction techniques which enable a much wider range of ground conditions to be safely engineered and extremely large foundation loads to be resisted. Despite all these improvements, major geotechnical difficulties still regularly occur, causing costly delays to projects, and sometimes more severe failures which cause damage to adjacent infrastructure and injury or death to members of the public and construction workers. There are numerous reasons for these failures, including the fragmented nature of the industry, deficiencies in procurement of specialist services, and competitive and time-related pressures. At a technical level a major problem can be the lack of a coherent approach to geotechnical engineering and a systematic approach to ground risk management. In Chapter 4 *The geotechnical triangle* the geotechnical triangle has been described. The four main components of the geotechnical triangle (**Figure 9.7**) are:

(1) *Understanding the ground profile* (and the associated geological processes and man-made activities that formed the ground profile) *including groundwater conditions.*

(2) *The measured or observed mechanical behaviour of the ground* – this includes carrying out laboratory and field (or *in situ*) testing, and careful interpretation of the test data, in the context of the proposed foundation requirements.

(3) *Appropriate modelling* – this is much more than carrying out an analysis. It involves: idealisation, or simplification, of the real soil/structure; identifying and carrying out appropriate analyses; validation and assessment of the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

N.B.
This geotechnical triangle is modified via the outer circle for 'construction process'; this emphasises the importance of construction processes in foundation engineering, in the context of the potential impact of various processes on key design assumptions

Figure 9.7 The geotechnical triangle, foundation engineering applications

output. Several iterations may be needed, and a particularly difficult part of the process is selecting appropriate input parameters (based on (1) and (2)).

(4) *Empirical procedures and 'well winnowed' experience* – empiricism is an inevitable and essential aspect of geotechnical engineering. It is also important to understand the limitations of available empirical procedures. Experience is important in order to make the difficult judgements which are often required; however, the term 'well winnowed' emphasises the point that the experience needs to be founded on a proper understanding of the facts and key behavioural mechanisms associated with past activities and observations.

For practical applications of the 'geotechnical triangle' it has been helpful to consider a fifth component to the triangle (the 'outer loop' shown in **Figure 9.7**):

(5) *Construction processes and design verification* – the information which is available to the foundation designer is seldom perfect (for example, contradictory information about the site's history, variable data from ground investigations, etc.). Hence, several important assumptions often have to be made to develop a design. Therefore, it is important that these assumptions are verified during the construction process. There are a wide range of activities which may have to be carried out, and a few examples are provided in **Table 9.2**. At a basic level, it may be simply a visual check during construction that the geology of the founding stratum for, say, a shallow footing, and its strength, is the same as that assumed for design. For more demanding projects it may involve sophisticated tests of deep piles. Different organisations/design teams may be involved in the foundation engineering activities at different stages of the project. Throughout this process it is important that key assumptions are communicated to other parties, so that ultimately these assumptions can be checked when the foundations are being constructed.

All five components are important, and problems are likely to occur if one component is forgotten or poorly implemented and the triangle goes 'out of balance'. Outlined below are several short case histories, which briefly summarise some foundation engineering problems that have occurred on UK construction projects.

9.4.2 Shallow foundations, adjacent to a landslip

Figure 9.8 provides a plan and cross-section of the site. Shallow foundations, comprising pad and strip footings, were planned for an out-of-town retail development. A ground investigation had been carried out, which included five boreholes and several trial pits. These indicated a thin layer of Made Ground (typically less than 2 m thick) over rockhead which comprised strong limestone. In one corner of the site a shallow retaining wall (about 1.0 to 2.0 m high) was required to create extra space, in order to construct the shallow foundations. The low-height retaining wall was formed from proprietry pre-cast elements with a shallow foundation. Whilst the excavations were being carried out for the retaining wall and shallow foundations at the toe of the slope, a large landslip was triggered. This caused significant delay to the project and public concern, since the landslip caused the closure of a footpath and adjacent public areas. What had gone wrong?

(i) A geological desk study had not been carried out. The positioning of the boreholes and trial pits by the structural engineers had been based mainly on ease of access, rather than technical considerations.

(ii) Inspection of geological maps indicated that a fault passed through the site; unfortunately all the boreholes/trial pits were located on one side of the fault. On the other side of the fault, the ground conditions were quite different with inter-bedded mudstone and siltstone.

(iii) Based on a subsequent geomorphological inspection of the area, it was clear that the area to the west of the fault had suffered from past landslips, and the natural slope was at a factor of safety close to 1.0. Even quite minor excavations were sufficient to reactivate the landslip and cause further instability.

Foundation engineering issue	Possible tests/observations[1]
Confirm founding strata	Inspect excavated surface and compare with design assumptions, simple visual check. For layered strata and/or deep foundations, may need extra boreholes (continuous sampling), if GI boreholes too widely spaced.
Assess variability of strata	Usually simple *in situ* tests (static cone CPT, or dynamic probing) appropriate to check *relative* hardness or density of strata across site, if heterogeneous conditions expected.
Groundwater regime	Important if construction below water table required. Install piezometers in key strata. If dewatering necessary, large-scale pumping tests may be required, prior to works commencing.
Impact on adjacent structures	Precise levelling of affected structures from regular array of survey pins. Subsurface measurements may be needed in some circumstances, especially if lateral movements expected (inclinometers).
Foundation load-deformation	Large-scale load tests on key foundation elements, especially if sensitive to construction/installation, such as deep bored piles. Tests will be more complex if lateral load behaviour needs to be checked.
Deep ground improvement	Verification testing is usually critically important for controlling the effectiveness of the works. Type of test dependent on improvement mechanism, e.g. reinforcement, densification or providing increased cohesion, by addition of cementing agents, or reduction of permeability.

(1) The list is not intended to be comprehensive and merely highlights some common examples.

Table 9.2 Examples of verification tests/observations which may be required during foundation engineering

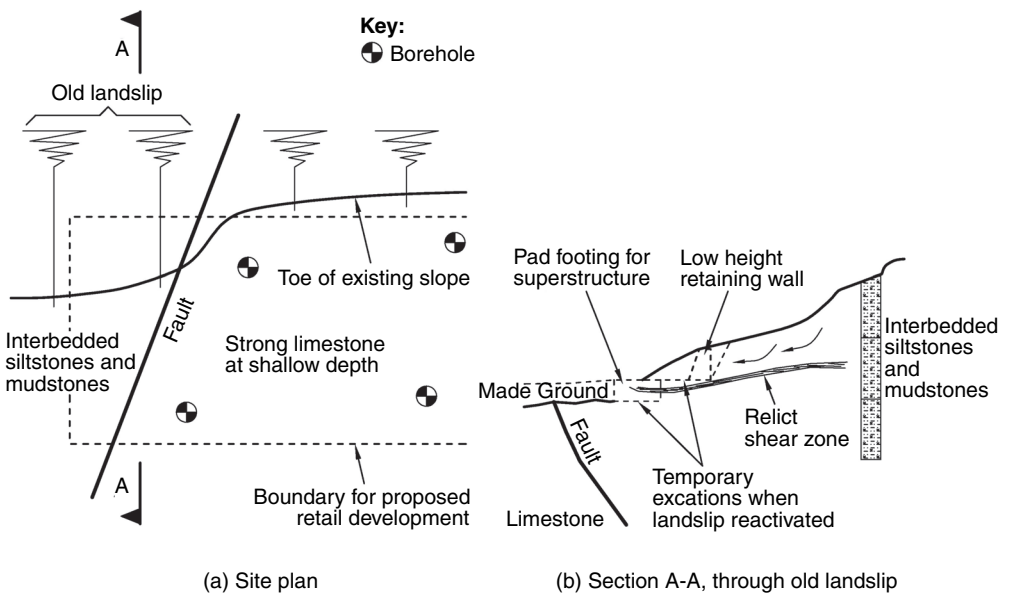


Figure 9.8 Shallow foundation adjacent to a landslip

This is a stark reminder that even simple foundation engineering needs to be done in a careful and systematic way. A desk study and an understanding of the site's geology is a fundamental requirement, and is essential in order to properly plan and design a ground investigation.

At this site, the first construction activity should have been to stabilise the landslip area. The landslip was stabilised by placing a temporary berm (at the landslip toe) and then installing a 'shear key' through the shear zone of the landslip. The shear key involved large diameter heavily reinforced bored piles, constructed as a contiguous embedded retaining wall. Following this the toe of the slope could be safely removed and excavations for the shallow foundations constructed.

9.4.3 Water treatment works, differential swelling

The design of a water treatment works required varying excavation and founding levels across the facility. The operation of the works meant that water levels in the various tanks would fluctuate over time. The construction of the works went well; however, just before the works opened, cracking of floor slabs was observed during commissioning tests. The cracks were monitored, and they became progressively worse over time.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

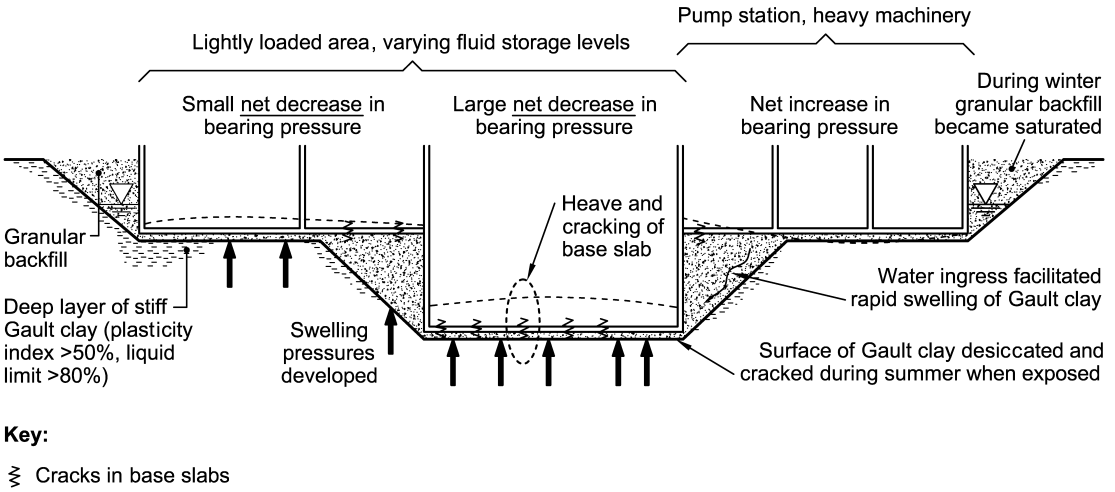

Figure 9.9 Water treatment works, differential swelling

At this stage, many of the areas which had suffered the worst damage were also relatively lightly loaded.

Figure 9.9 shows a cross-section through part of the works. The overall configuration of the sub-structure is quite complex, comprising an irregular array of reinforced concrete boxes of varying size. The site geology is quite simple, comprising a deep layer of heavily overconsolidated Gault clay. The site was in a semi-rural area and was a greenfield site. A simple open non-retained excavation was formed since there were no space constraints. The excavation was carried out during a relatively dry summer and there were no problems with ground or surface water. The concrete sub-structure 'boxes' were then built within the excavation and conventional granular backfill used (**Figure 9.9**).

When the cracking became apparent, survey points were fixed and monitored and these indicated differential vertical movements across the structure, and net upward, swelling, movement beneath the deepest part of the sub-structure. A standpipe piezometer in the backfill indicated about 1 m head of water. Subsequent analysis highlighted the following issues:

(i) Owing to the different founding levels, the different types of equipment, and water levels in certain parts of the works, the *net* change in bearing pressure is extremely variable, from small net *increases* in bearing pressure, to large net *decreases* in bearing pressure.

(ii) Because of the high plasticity index of the Gault clay and its high degree of overconsolidation, it is prone to significant long-term swelling, and if movement is restrained, large swelling pressures are developed against the structure in contact with the Gault clay.

(iii) The trigger for the swelling movements and structural damage was a readily available source of water. Over winter, rainwater seeped into the granular backfill, and along the (relatively poor and cracked) blinding concrete. During the summer period it is likely that desiccation cracking of the exposed Gault clay would have created a relatively high mass permeability, and allowed relatively quick infiltration of water into the clay.

(iv) The fundamental flaw, however, was the lack of awareness on the part of the designers that differential movements would develop, and the structural design was vulnerable to differential movement. The combination of relatively flexible slabs and stiff walls/columns meant that the sub-structure was particularly sensitive to differential movement.

(v) An important cause of the problem was poor communication between the geotechnical and structural engineers. The structural engineer asked the geotechnical engineer to provide 'allowable bearing pressures'. There was no discussion about the nature of the structure, or the variation in applied loads imposed on the foundations. As a result, the structural engineer did not realise there was a risk of swelling or differential movements across the structure. The geotechnical engineer did not realise there would be net unloading across large parts of the structure. This lack of communication led to the design of an intrinsically flawed foundation and structural design.

For this project the mechanical behaviour of the ground was not assessed *in the context* of the proposed foundation requirements. A more appropriate design would have created more uniform loading, or reduced the net unloading beneath the deepest part of the sub-structure, by reconfiguration of the plant layout, or if impractical, provided a structural design which would have minimised differential movement (e.g. a thicker, stronger raft) or allowed differential movement to occur without structural damage (provision of movement joints, rocker slabs, etc.).

9.4.4 Driven piling in mudstone, plugging of open-ended tubular piles

A highway bridge was to be constructed across a small river. The bridge and foundations were designed and let under a conventional ICE contract to a local civil engineering contractor. The foundations were bored pile groups constructed in the Coal Measures rocks, which comprised inter-bedded mudstone and sandstone. A high quality ground investigation was carried out; **Figure 9.10** summarises the ground conditions. The upper Coal Measures rocks were relatively poor quality, and predominantly comprised mudstones with an unconfined compressive strength of about 10 MN/m^2, and RQD values of between 0 and 10%, with frequent reference to open or clay-filled joints in the rock mass. The rock quality improved at depth, with more frequent layers of sandstone with unconfined compressive strengths of about 30 MN/m^2 and RQD values of between 30 and 60%. SPT

Sampling			Strata
Depth (m)	TCR	(RQD)	Description
10.40			
	75%	(0%)	Weak grey slightly carbonaceous SILTSTONE. Locally weathered to slightly sandy fine to coarse angular gravel. Discontinuities horizontal to subhorizontal very closely to closely spaced planar closed to slightly open (<3 mm) clean. At 9.80 m, clay smeared discontinuity. At 10.02 m, 10° clay smeared discontinuity. At 11.10 to 11.20 m, weathered to clayey fine to coarse angular gravel.

'N' values were typically in excess of 100; however, in these ground conditions the SPT was meaningless and of little value.

The contractor offered an alternative foundation design which comprised driven open-ended tubular piles. The driven piles were expected to be quicker to install, and provide equivalent overall performance (capacity and settlement) to the original foundation design. Pile driving proved to be difficult with some piles experiencing premature refusal during driving (probably due to local blocks of sandstone). The project specification required the contractor to carry out pile load tests on selected piles. These tests on working piles were meant to impose loads up to 1.5 times the working load with pile head settlement of less than 10 mm. Unexpectedly, at the working load the pile settlement was excessive and, for practical purposes, the pile had failed. Several other pile load tests were carried out and these also failed. A detailed review was carried out of both the pile installation and the pile design. A number of problems were apparent both in terms of pile construction and design. The pile design had assumed:

(i) The base of the tubular pile would 'plug', i.e. the end-bearing resistance would be mobilised over the full pile diameter. The end-bearing resistance was assumed equal to 4.5 times the unconfined compressive strength of the rock (i.e. equivalent to 9 times the undrained shear strength, as commonly assumed for clay).

(ii) The shaft resistance was based on a mobilised adhesion of twice the SPT 'N' value (i.e. in excess of 200 kN/m^2); the assumption that shaft shear resistance, $\tau = 2$ 'N' is commonly used when designing driven piles in sands and gravels.

Based on assumptions (i) and (ii) the geotechnical capacity of the pile was expected to be extremely high, and the factor of safety was expected to be well in excess of 3.0 at the working load. Unfortunately, as shown by the pile tests, the actual factor of safety was close to 1.0.

The above design assumptions were based on a published design guide for driven piles. However, the guidance and associated equations for calculating pile capacity were actually based on experience of driven piles in soils, not rocks. Hence, the design assumptions were inappropriate. A careful back analysis of the pile test data indicated:

(a) The open-ended tubular piles did not plug, i.e. end-bearing resistance was only mobilised across the annulus of the pile.

(b) Pile resistance was predominantly mobilised by shaft friction, both internally and externally; the average shaft adhesion varied between about 60 and 100 kN/m^2, with a median value of about 85 kN/m^2. The intense remoulding of the mudstone due to pile driving had effectively created a thin zone of very stiff clay along the sides of the steel pile.

The pile tubes had not been strengthened to facilitate hard driving (normally a tubular pile would have a specially designed thick-walled driving shoe, if hard driving was expected). The pile driving hammer was also of inadequate capacity. Hence, driving the piles deeper to the higher quality sandstone at depth was not a viable option. The most effective solution to these design and construction problems was therefore to drill out the materials inside the pile tubes and infill the void with concrete. This enabled the full end-bearing resistance to be mobilised.

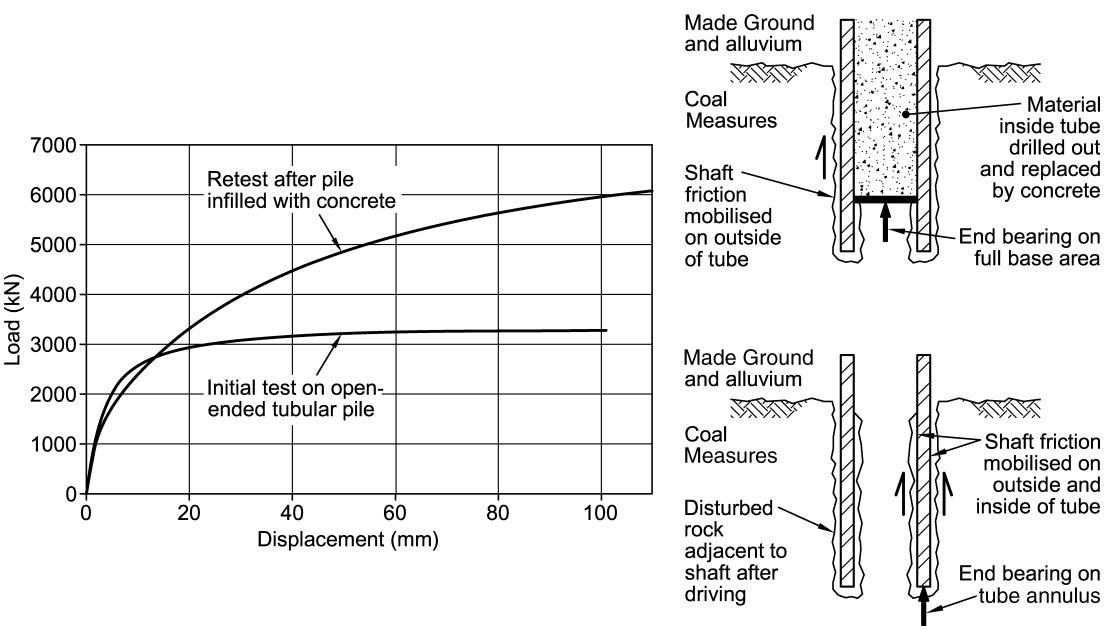

Figure 9.11 Driven tubular piles in mudstone, pile test data. Open-ended pile vs concrete-infilled pile

Subsequent pile load tests indicated that the modified piles had adequate capacity and settlement characteristics (**Figure 9.11**). Because of the fractured nature of the rock mass, the end-bearing resistance was between 1.5 and 2.5 times the unconfined compressive strength (i.e. 3 to 5 times S_u, considerably lower than soil mechanics theory would indicate).

This project experience clearly emphasises the need to understand the ground behaviour in the context of the proposed construction process (in this case the rock mass behaviour during pile driving, which is quite different from that of soil), and understand the limitations of empirically based design guidance. 'Well winnowed' experience was clearly *not* used either in terms of design or construction. When designing open-ended tubular piles, the end-bearing resistance of the pile annulus plus the internal shaft resistance should be compared against the bearing resistance across the full pile area, and the lesser of the two values should be used for design. In addition, the influence of the construction process, in this case the pile driving, on the mobilised shear resistance along the pile shaft was not appreciated. Estimating the capacity of driven tubular piles in weak rocks is actually quite challenging. Even if the design assumptions had been more appropriate, it would have been wise to carry out preliminary pile tests (to failure) on non-working piles, prior to the commencement of the main piling works. This would have significantly reduced the risk of unexpected pile failures, although the cost and duration of the piling works would have been increased.

9.4.5 The geotechnical triangle revisited

Reflecting upon the above case histories, the value of the geotechnical triangle can be appreciated. All aspects of the triangle should be considered and kept in balance, i.e. one element should not be given excessive attention whilst ignoring other aspects. There is a high risk of failures occurring if one or more aspects are forgotten.

Table 9.3 provides a commentary on the problems encountered in the above case histories in the context of the five aspects of the triangle. The errors and omissions which caused the foundation problems may seem obvious; however, all the engineers involved were experienced. In some cases, there was an assumption that because the engineering was perceived as 'simple and routine', short-cuts to normal good practice could be made without risk. Clearly, with the benefit of hindsight, the engineers involved would now have a different opinion!

9.5 Foundation applications

9.5.1 Introduction

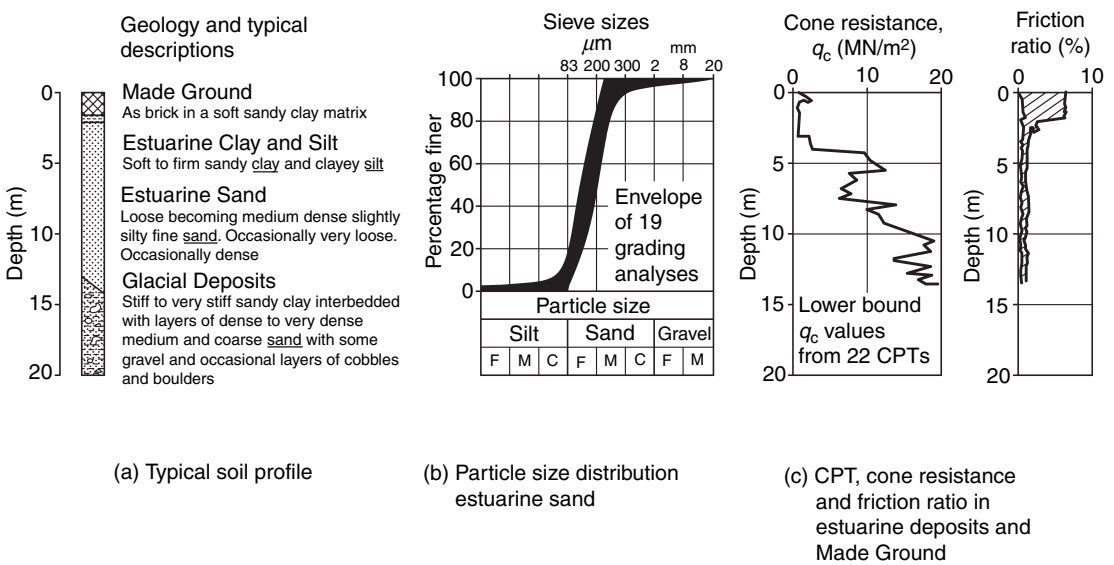
In this section two case histories are given which describe the foundation engineering for two very different projects. The first describes the selection of an appropriate foundation type for a multi-span bridge across an important railway line. The site was underlain by estuarine sands of variable density. The second discusses groundwater problems during construction of foundations for a building, which was underlain by chalk. Common to both case histories are the important observations and tests which were carried out during the construction works (i.e. the fifth key component of the geotechnical triangle), and the critical role that these played in successful completion of the works.

9.5.2 Vibrocompaction of estuarine sands

9.5.2.1 Site location and ground conditions

The site is located in North Wales, adjacent to the River Dee estuary. The project involved the construction of an access road into a new business park, which was to be located between an existing main road and the estuary. A bridge was required to carry the new road over a railway line which traverses the centre of the site. This railway line is a strategically important route connecting the UK network to the Irish Sea ferries. The bridge comprised a two-span deck, each span being about 30 m long. To attain adequate clearance to the railway, the approach embankments were relatively high at about 12 m. This case history is described in detail by O'Brien (1997).

The site is located on a flat estuarine plain and the geological sequence is shown in **Figure 9.12**. The groundwater table level was about 2.5–3.0 m beneath ground level, and pore water pressures varied hydrostatically with depth. Of concern, for bridge foundation design, was the variability in relative density of the estuarine sand. Although typically described as loose to medium dense, there were also very loose and dense layers. SPT 'N' values varied between 5 and 35, but the repeatability of the test was poor due to the difficultly of maintaining borehole base stability beneath the water table. CPT q_c values tended to increase with depth, although there was significant variability in the CPT q_c profiles.



9.5.2.2 Foundation selection

Several different foundation types were considered. The net increase in bearing pressure was about 300 kN/m^2. The bearing capacity of the sands was adequate, and the main concern was ensuring settlement, particularly differential settlement, was sufficiently low. For the multi-span bridge a limit on differential settlement of about 15 mm was targeted. Founding the bridge on shallow foundations, beneath the clay/silt capping layer, would have been feasible if the approach embankments (which imposed the majority of the bearing pressure) could have been constructed before placing the bridge deck. Unfortunately the bridge deck beams had to be placed within a narrow timeframe, when a track possession (for construction over the railway line) had been granted. This possession period was fixed and critical to the whole project, and all other activities had to be as flexible as possible. If the deck was placed before construction of the approach embankments, then differential settlement was expected to be higher than the 15 mm allowable (perhaps double this value, due to the variable density of the estuarine sands). The main foundation options are

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Case history	Ground profile and groundwater conditions	Ground behaviour	Appropriate modelling	Empiricism, case records, well-winnowed experience	Construction process test/observations and verifications
Shallow foundations, adjacent to landslip	No desk study. Geology *not* understood. Poor positioning of boreholes, relative to fault.	Since geology not understood, no awareness of adjacent landslip.	Global stability of site not assessed, only local stability of retaining walls/ foundations considered.	Geological maps and memoirs highlighted the risk of landslips in this area (but not reviewed by designers).	Because hazard not identified, construction process was inappropriate. Should have stabilised the slope ***prior*** to excavations.
Water treatment works, differential swelling	Geology and ground profile understood. Deep layer of Gault clay.	Poor communication between geotechnical and structural engineers. Hence, net unloading of O/C plastic clay not identified.	Only bearing capacity and settlement checks for net increases in bearing pressure. Consequences of swelling not assessed.	The swelling potential of high-plasticity overconsolidated clays, such as Gault clay, is well known. But poor communication meant that potential risk for this structure was not identified.	Since design was flawed, construction process, tests, etc. would not have mitigated the risk.
Driven piling in mudstone, plugging of tubular piles	Good desk study and high quality ground investigation carried out.	Appropriate testing and observations; ground behaviour was well established. But not understood by designer/contractor in the context of proposed construction, i.e. driven piling.	Poor modelling. Key assumptions were incorrect. Open-ended tubular piles were unlikely to plug.	Inappropriate design methods used (not relevant for weak rock). Poor construction methods (piles not strengthened for hard driving, underpowered piling hammer), so unable to drive to competent strata.	Pile tests on working piles identified problem, but too late, so overall project was delayed. Tests on preliminary piles would (technically) be preferable but cost/ time penalty.

Figure 9.12 Vibrocompaction of estuarine sands, ground conditions

summarised in **Table 9.4**. Pile integrity and durability was a particular concern, since previously the site had been used as a chemical works, and the ground conditions were aggressive to reinforced concrete. At the time the works were implemented (mid-1990s), CFA piling rigs were much less powerful than today. Large diameter (> 1.0 m) CFA rigs were not available, and installing heavy pile reinforcement, especially to accurate verticality tolerances, was judged to be impractical. Heavy pile reinforcement would have been required because the bridge abutment and embankment backfill imposed significant lateral loads onto the piles. Because of the reinforced concrete durability concerns, it would have been important to ensure the reinforcement had adequate concrete cover; hence accurate reinforcement installation was necessary. Driven piles would probably have caused damaging vibrations and settlement to the adjacent railway. Large diameter bored piles (due to the need to use bentonite slurry support) were expected to be very expensive. Vibrocompaction was believed to be the most appropriate foundation engineering option compared with the other available options. Deep ground improvement, using vibrocompaction, would increase the relative density of the sands, and in particular, eliminate the zones of loose sand that existed. This would enable simple foundations to be constructed on the improved ground, and reduce the risk of differential settlement. Vibrocompaction is discussed in more detail in Chapter 59 *Design principles for ground improvement*. The vibrocompaction method used at this site used a 'wet top feed' technique, which involves using a vibroflot (a large vibrating poker) to compact the ground. Water is used as a jetting medium to facilitate insertion of the vibroflot, and gravel is fed into the hole around the vibroflot from the ground surface and compacted by the vibroflot.

The ground conditions (fine estuarine sands, with a low silt/clay content) were believed to be ideal for vibrocompaction. Discussions with local contractors were held, but locally vibrocompaction was generally only carried out for lightly loaded industrial buildings founded on Made Ground. Typically, the performance criteria were less onerous, with net bearing pressures being of the order of 100–150 kN/m^2. Nevertheless, a review of the technical literature and discussions with specialist contractors indicated that vibrocompaction would be feasible, although possibly challenging. The specification was developed carefully, in order to control the anticipated project risks:

(i) A preliminary trial was required, using different compaction spacings, and compaction effectiveness was checked by carrying out CPT tests before and after compaction (during this trial, remote from the railway line, ground vibration and settlement were also monitored).

(ii) The specification was an 'end product' type: a target CPT cone resistance profile had to be met by the specialist ground improvement contractor (**Figure 9.13**).

(iii) A limit on allowable ground vibration and settlement at the railway line (based on discussions with the railway authorities) was stated. It was recognised that this constraint would prevent the use of the most powerful rigs for vibrocompaction, but lower-powered rigs could be used, and would still be able to densify the sands.

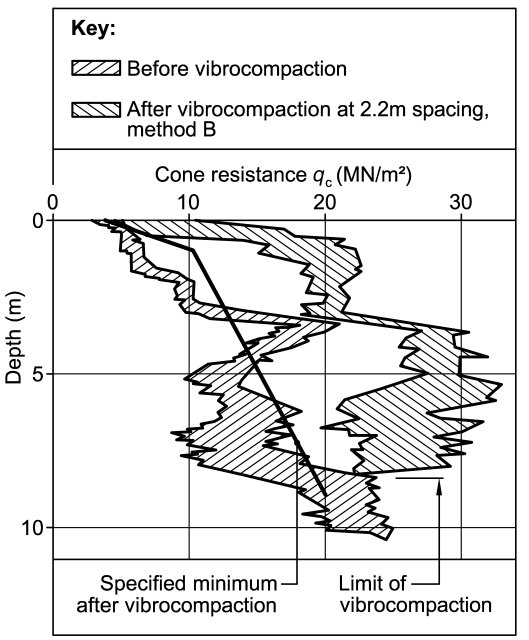

Figure 9.13 Vibrocompaction preliminary trial–influence of different compaction methods (method A vs method B)

Option	Potential advantages	Potential disadvantages
1. Driven piles	Suited to ground and groundwater conditions. Good vertical capacity.	Difficult driving due to dense sand layers. Large vibrations and damage to railway. Limited lateral/bending capacity unless raking.
2. CFA Piles	Low vibrations. Relatively inexpensive.	Inadequate lateral/bending capacity. Poor integrity/durability.
3. Large diameter bored piles	Good lateral/bending capacity. Low vibrations.	Need temporary casing and slurry support. Very expensive.
4. Vibrocompaction	Quick and inexpensive (less than 50% of 3). Suited to ground and groundwater conditions. Allows simple sub-structure.	Vibrations and possible damage to railway. Inadequate degree of improvement. Lack of precedent in UK for heavily loaded bridges.

Table 9.4 Case history: vibrocompaction of estuarine sands, advantages/disadvantages of different foundation options

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

9.5.2.3 Observations and tests during the works

The successful tenderer used a vibroflot with a power rating of 50–80 kW, and medium/coarse gravel was used as backfill at each compaction point. The initial trial using a compaction spacing of 2.6 m was very disappointing (refer to **Figure 9.13** (method A)), since the post-compaction cone resistance profile failed to meet the specification requirement. There were a range of possible reasons discussed by the designer and contractor (ground conditions different from expected? specified target cone resistance profile reasonable?), although the discussions quickly focused on how the vibroflot was being used by the rig operator. Method A involved: withdrawal of the vibroflot in 0.6–0.9 m depth increments, compaction duration per increment of 20–30 seconds, high water flow rates from side jets during withdrawal. This method had been used successfully to treat Made Ground, when the improvement mechanism was mainly 'reinforcement' by construction of relatively large diameter stone columns. In contrast, the prime requirement for this project was to densify the sands. An alternative construction method, 'method B', was proposed, which involved: withdrawal in 0.3 m depth increments, compaction continuing for a longer period until the power consumption peaked, and water flow during withdrawal kept to a minimum (to avoid washing out excessive quantities of sand). From **Figure 9.13** it can be seen that post-compaction CPT q_c tests showed that method B was far more effective than method A in terms of compacting the sands. Method B was used for the remainder of the trial (to check the influence of different compaction spacings on CPT cone resistance) and for the main works.

The measured ground vibrations were towards the lower bound of those reported in the literature (a resultant peak particle velocity of less than 15 mm/s) and ground surface settlements between 3 mm and 7 mm. Following completion of the trial the railway authorities were satisfied that vibrocompaction could take place up to 2 m from the railway.

For the main works a compaction spacing of 2.2 m was selected since at this spacing there was a negligible risk of the post-compaction CPT q_c values falling below the target profile. The plan area of compaction extended about 3 m beyond the bridge pad footings, with a minimum of one compaction point beyond the footing. The pad foundations were founded at about 2.5 m below ground level, to ensure the foundations were below a surface layer of silt and clay, and above the groundwater table level. Pre- and post-compaction CPT tests were carried out to verify that the vibrocompaction was adequate. CPT profiles for one of the bridge abutments are shown in **Figure 9.14**. The post-compaction CPT q_c values exceed the target profile by a comfortable margin, and are typically about two to three times higher than the pre-compaction values across the main depth of interest. The subsequent performance of the bridge foundations has been satisfactory. Based on the post-compaction CPT profiles, routine calculations indicated a settlement of about 15 mm, whilst more sophisticated analyses indicated a settlement of about 10 mm. Measured settlements

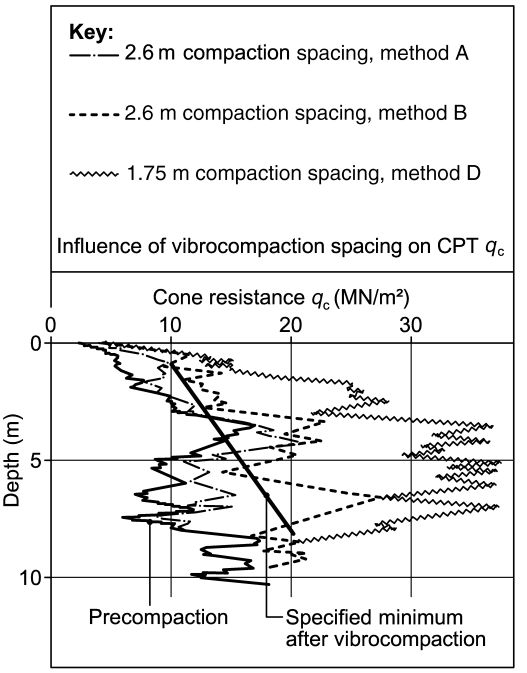

Figure 9.14 Vibrocompaction, before and after CPT tests, 2.2 m spacing, method B

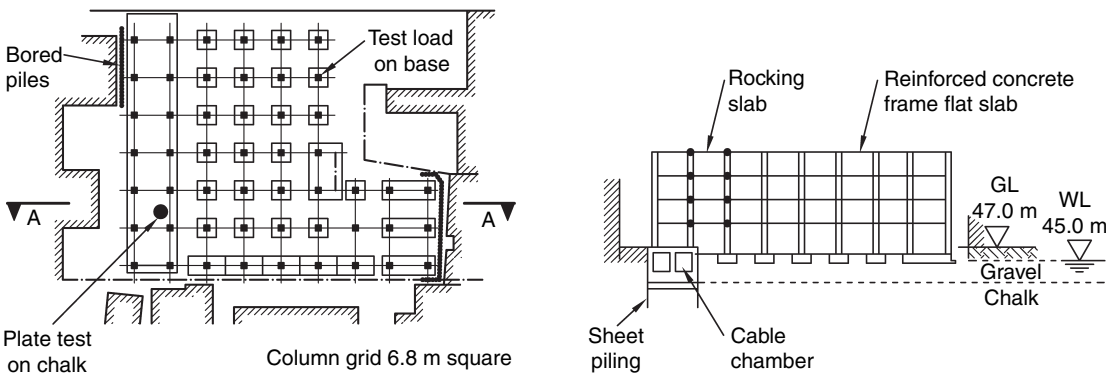
were between about 5 and 10 mm, with differential settlements of less than 5 mm. These were comfortably within the allowable limits for the bridge deck.

9.5.2.4 Concluding remarks

This case history describes some of the factors which need to be considered when deciding upon an appropriate type of foundation. The foundation type, deep ground improvement with shallow foundations, performed extremely well. However, successful use of the technique drew heavily on a balanced application of all five components of the geotechnical triangle. In particular, the fifth component, 'understanding the construction process and verifying the design assumptions', was important. The initial vibrocompaction method (method A) was inappropriate; observations and tests during a preliminary trial identified the problem and enabled a more effective construction method to be identified. This was critical for the successful completion of these works.

9.5.3 Shallow foundation on soft chalk



9.5.3.1 The ground conditions and construction problems

The construction of a telephone exchange in the centre of Salisbury came to an abrupt halt when unexpected ground conditions were encountered. Work was not to resume for some six months. The geological map shows the site to be covered by valley gravel overlying Upper Chalk. Four boreholes were sunk on the site using a shell and auger rig. The borehole logs showed the profile to consist of 0.9–1.4 m of Made Ground overlying 4.9–6.4 m of medium dense flint gravel with layers

of silty clay. All the boreholes were reported as entering hard fissured chalk below the flint gravel. The water table was about 2 m below ground level. This case history is discussed in detail by Burland *et al*. (1983).

The telephone exchange is a four-storey building of reinforced concrete flat slab construction. **Figure 9.15** shows a plan and cross-section through the building. Most of the structure to the east is founded on pad footings bearing on gravel with a pressure of about 200 kN/m^2. A notable feature is a chamber running along the western edge of the building. The base of the cable chamber was to be founded in chalk some 6.6 m below original ground surface at a gross bearing pressure of approximately 185 kN/m^2. The cable chamber was constructed in a coffer-dam 9 m wide and 47 m long. The coffer-dam was constructed mainly of sheet piles but in the north-west corner a contiguous bored pile retaining wall was used to minimise vibration alongside an existing building. **Figure 9.16** is a cross-section through the coffer-dam.

Work progressed smoothly until excavation within the coffer-dam penetrated the chalk. Thereafter progress was difficult. A close visual examination of the chalk in the base of the excavation revealed that, far from being hard and fissured, it was very soft, consisting of small angular pieces of chalk in a silt-like putty chalk matrix. At this stage two-thirds of the pad foundations had been completed. The coffer-dam area had been partially excavated. At the south end in the base of the excavation

(a) Site plan

(b) Section A-A

Figure 9.15 Shallow foundations on soft chalk; plan and cross-section through building

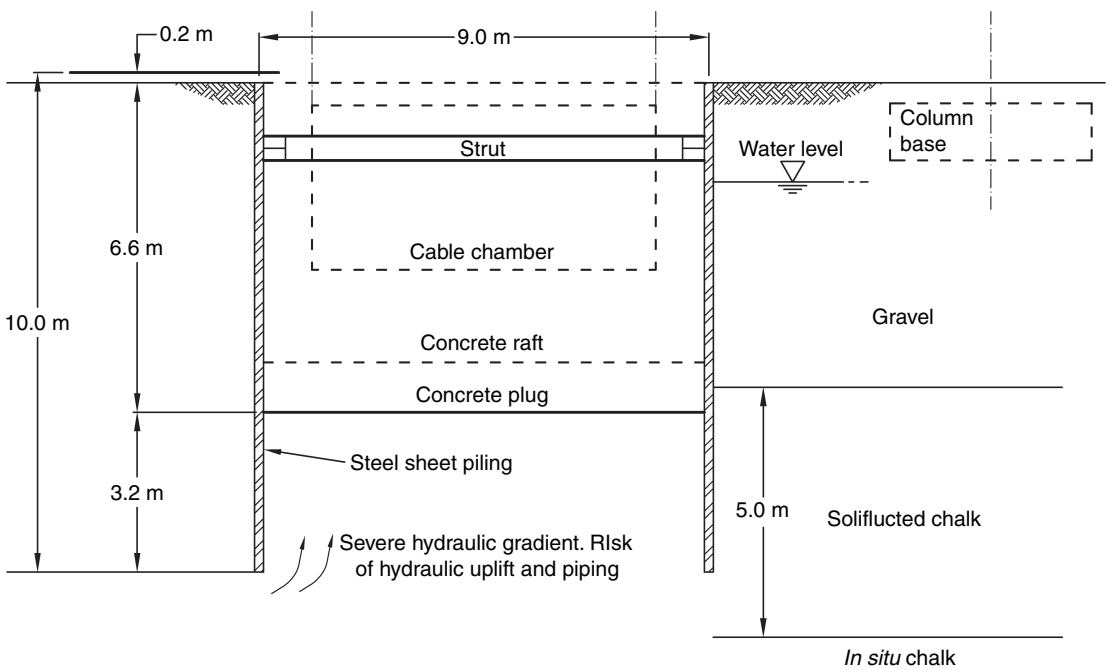


Figure 9.16 Shallow foundations on soft chalk; cross-section through coffer-dam

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the chalk had turned into a slurry, making it impossible to obtain a firm bottom. The coffer-dam was being kept partly free of water by pumping from two sumps, and a considerable quantity of water was flowing along the bottom of the coffer-dam.

Since the ground conditions within the excavation had proved to be so different from those assumed, the whole basis of the foundation design had to be questioned. In particular the use of pad footings and a raft foundation beneath the cable chamber were thrown into doubt. Before reaching any conclusions it was felt that a further site investigation should be carried out. The soil strata, as they affect the foundations, may be divided into three categories:

Medium dense sandy gravel – soil type G

This flint gravel contains very sandy pockets and also pockets or lenses of a more clayey nature. Near the bottom of the stratum there is an increasing proportion of cobble-size flints. At the base of the stratum is a layer of about 0.3 m thickness of gravel and sand-sized rounded particles of chalk.

Soliflucted chalk – soil type Ch 1

This stratum consists of fragments of hard white chalk in a soft matrix of remoulded chalk with flints. The matrix is mostly silt size but the materials exhibit cohesion and plasticity. Samples of the material broke open easily and were similar to soft or firm clayey silts in appearance and feel. During drilling the chalk was found to flow up into the borehole and the casing sank under its own weight. It appears therefore that the material is very sensitive and loses much of its strength when it is remoulded without drainage. The SPT values for this material are very low, ranging from 1 to 10 with an average of about 7.

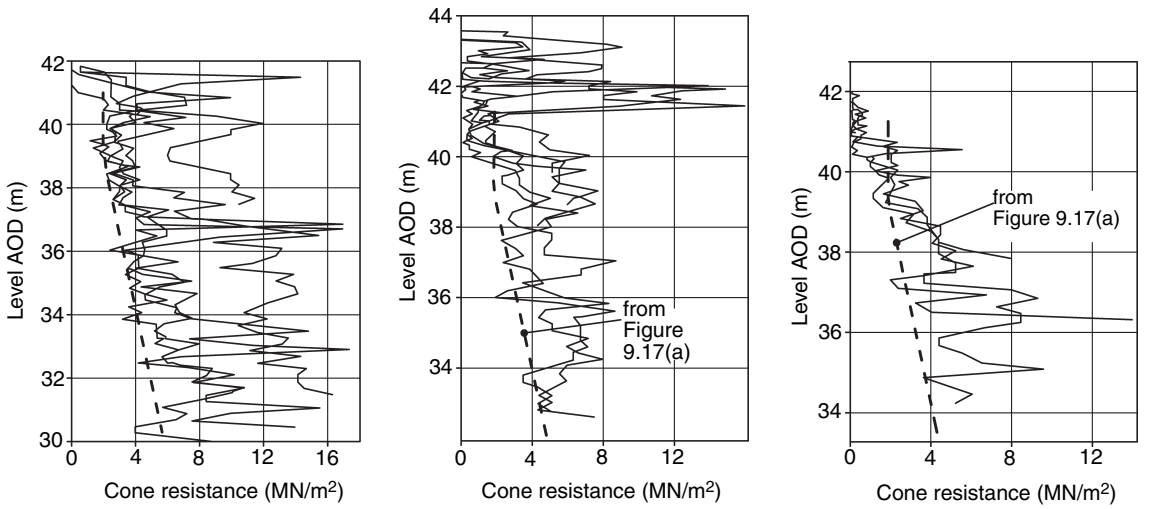
In situ chalk – soil type Ch 2

It proved difficult to accurately define the changeover between Ch 1 and Ch 2 chalk by examination of samples. There is, however, a noticeable increase in the SPT values when moving from Ch 1 into Ch 2 material. Moreover, on reaching the *in situ* chalk, the borehole casing stopped sinking. As a rough guide a level of about 35 m OD was taken as the change from Ch1 to Ch 2.

The soliflucted Ch 1 material had probably been redeposited, and it was felt that it would behave like a silt. Four 100-mm-diameter U100 samples of soliflucted chalk were selected for consolidated drained triaxial testing. The results of the tests gave $\Phi' = 40°$ and $c' = 0$. Values of m_v, measured during oedometer tests ranged from 0.04 to 0.11 m^2/MN. The measured permeability was about 4×10^{-8} m/s, which is consistent with a silt. Pumping tests in the underlying Ch 2 chalk gave a permeability of about 2×10^{-5} m/s, reflecting the fissured nature of the chalk. Hence, the natural chalk has a permeability which is about a thousand times higher than the overlying soliflucted chalk.

A simple calculation of vertical equilibrium of the chalk in the base of the coffer-dam (during the excavation stage) showed that the total vertical stress due to the chalk (at the sheet pile toe level) was about 69 kN/m^2, whereas the groundwater pressure at that level was 76 kN/m^2. There was therefore a high risk of failure by hydraulic uplift and piping in the base of the coffer-dam.

9.5.3.2 The pad footings



The first problem to deal with was the adequacy of the existing pad footings. Based on the ground investigation data for the soliflucted chalk, preliminary calculations indicated settlements of between 75 and 175 mm, which were deemed to be too large. An expensive solution was removal of the pads and installation of piles. Before taking this drastic action, an alternative means of assessing the pad footing settlement was required. Laboratory testing was believed to be unrealistic due to disturbance when sampling the chalk. *In situ* plate load tests would have been difficult below the water table. The simple and direct approach which was chosen was to load two of the existing pad footings up to the working load of 4000 kN (i.e. 400 tonnes) and measure the settlement. Although expensive, it was relatively quick, and all uncertainties (in terms of interpretation of alternative indirect methods) were eliminated.

The footings are 4.2 m square, 0.9 m thick, and founded at about 44.5 m OD. In order to measure soil deformation below the footing, holes were drilled through the pad: one hole to the gravel–chalk interface (about 3.5 m below founding level) and the other extended 8 m into the chalk. The holes were sleeved and rods embedded in mortar at the base of the hole. Precision levelling was used to measure the settlement of the rods and the four corners of the pad. The footing was loaded in 25 tonne increments up to 200 tonnes, and left for 42 hours. It was then loaded to 400 tonnes and left for 70 hours. Settlement was measured frequently throughout the test. Under full load the settlement was only 2.5 mm, with about one-third of this in the chalk. The time-dependent settlement was negligible. Because of these very small settlements, a second test was unnecessary. The full-scale test demonstrated unambiguously that the pad footings were more than adequate.

9.5.3.3 The cable chamber

In view of the very soft nature of the chalk it was felt that the stability of the sheet pile walls was marginal. Pumping was therefore stopped and the coffer-dam was allowed to flood. The next task was to investigate the chalk at the base of the coffer-dam and assess its degree of disturbance. It was felt that a simple method of doing this was to use a cone penetrometer. A number of tests carried out within the coffer-dam and outside it should provide a means of assessing the variability of conditions within the coffer-dam and the degree of disturbance in relation to the surrounding undisturbed chalk.

Eleven tests were carried out alongside the existing pad footings. The tests were made from the bottom of new boreholes drilled by shell and auger methods through the gravel and lined with rigid 74-mm-diameter UPVC pipe. The results of five

(a) Results of cone penetration tests alongside existing pad footings

(b) Results of cone penetration tests at north end of coffer-dam

(c) Results of cone penetration tests at south end of coffer-dam

Figure 9.17 Shallow foundations on soft chalk; cone penetration tests

typical tests are given in **Figure 9.17(a)**. As is to be expected the results show considerable scatter but there is a well-defined lower limit as shown by the broken line. Below a level of 39 m OD the penetration resistance increases steadily with depth.

Seventeen tests were carried out in the base of the coffer-dam from a rigid working platform spanning the excavation. At the north end of the coffer-dam the depth of excavation was approximately 3.5 m below original ground level and was still in the gravel. The results of five cone penetration tests are shown in **Figure 9.17(b)**. The gravel extends to approximately 41.5 m OD, which is confirmed by an adjacent borehole log. For comparison the broken line is taken from **Figure 9.17(a)**. It can be seen that the cone resistances lie well below the broken line down to about 40 m OD, below which there is reasonable agreement.

At the southern end of the coffer-dam, excavation was approximately 5 m below original ground level. **Figure 9.17(c)** shows the results of three cone penetration tests, and it can be seen that very low penetration resistances were encountered down to approximately 40.5 m OD. Below a level of about 38 m OD the results are in good agreement with those given in **Figure 9.17(a)**. The results of the cone penetration tests point strongly to the fact that the soliflucted chalk in the base of the coffer-dam had become loosened and disturbed by the upward flow of water causing piping. On the basis of the cone test results it was felt that it would be unwise to found the raft for the cable chamber above a level of 40.4 m OD.

Before reaching a final decision to found the cable chamber on a raft it was necessary to make an estimate of the settlement. A simple large-scale *in situ* loading test was devised. The aim of the test was to reproduce as realistically as possible the actual construction conditions. The test was sited at the southern end of the coffer-dam where the cone resistances were least. A 2 m square pit was excavated underwater to a level of 40.4 m OD (i.e. approximately 1.5 m below the existing bottom). A diver was used to guide and control the excavation. A 1.5-m-diameter concrete cylinder was then constructed and loaded by kentledge. There were a number of practical problems with carrying out this test; in particular, the cylinder was not vertical and tilted during loading. Nevertheless, load settlement measurements were made up to a load of 51 tonnes, and the test data showed two important features:

(i) up to working load, settlement was approximately proportional to load;

(ii) time-dependent settlement under constant load was very small.

Back analysis of the test, using linear elastic theory, allowed the settlement of the proposed cable chamber raft to be predicted; the results of these predictions are shown in **Table 9.5** for various construction stages. Construction up to ground floor level was to be carried out with groundwater pumping from wells in the natural (Ch 2) chalk. Dewatering would then be stopped leading to a decrease in *net* bearing pressure (and during the net decrease and subsequent increase in pressure, settlement was assumed to be zero until the previous maximum net pressure was exceeded). The total predicted measurable settlement is 62 mm. About half of this takes place during construction up to ground floor level. During superstructure construction the calculated settlement is 26 mm, with a further 10 mm due to live load. The large-scale test indicated that most of the settlement would be immediate. Hence, most of the settlement during superstructure construction would be 'built out'. Provision

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Construction stage	Bearing pressure (kN/m²)		Foundation settlement (mm)	
	Incremental	Net increase	Incremental	Total
Concrete plug	22	22	11*	–
Construction up to ground floor	52	74	26	26
Cease dewatering	–40	34	0	26
Construction to roof level	60	94	10	36
Internal walls and finishes	32	126	16	52
Live load	20	146	10	62

Note: * Not measurable

Table 9.5 Case history: Shallow foundations on soft chalk. Cable chamber, predicted settlements

was made for residual differential settlement between the cable chamber raft foundation and adjacent pad footings by incorporating 'rocker' slabs. These were omitted until *after* the superstructure was completed.

9.5.3.4 Cable chamber construction and foundation settlement

Concreting of the concrete plug in the bottom of the excavation was carried out under water in a series of transverse bays so as not to impair the stability of the coffer-dam. Before the concrete was placed, a layer of filter fabric was placed on the chalk type Ch 1 and covered with a layer, 100 mm thick, of coarse granular fill to form a drainage layer. Three 450-mm-diameter sleeves were cast in the plug through which sleeved wells were installed to a depth of 8 m below the excavation level and into chalk Ch 2. In addition two 75-mm-diameter pressure relief wells were installed through the plug in each bay and down into the chalk Ch 2. Pumping from the 8-m-deep wells using a 150-mm-diameter pump in each well lowered the water level to the level of the drainage layer beneath the concrete plug. Pumping continued until the raft and basement walls were complete, when the structure had sufficient weight to overcome buoyancy. Concrete for the complete raft was placed in a day.

The maximum settlement recorded for any of the pad footings was 5 mm and the average settlement was 2–3 mm. The time-dependent settlement was negligible. These results are in excellent agreement with the results of the full-scale loading test on one of the pad footings. The maximum settlement of the cable chamber near the south end was 15 mm, while near the north end it was 8 mm. Most of the settlement took place during the construction of the raft. Thereafter the settlements were small and very uniform, ranging from 3 to 5 mm.

9.5.3.5 Concluding remarks

It is evident from the measured settlements that the pad and raft foundations adopted for the telephone exchange were entirely satisfactory. Yet the decision to continue with these foundations was not an easy one. The top 5 m of chalk was very soft and all the available evidence pointed towards large settlements. It is very doubtful whether a traditional site investigation with sampling and laboratory testing would have resolved the issue because of the difficulty of obtaining representative undisturbed samples. In this case a direct approach to the problem was adopted by carrying out large-scale loading tests. The full-scale loading test on the pad footing was carried out quickly and simply and provided conclusive evidence of the adequacy of the pad foundations. The loading test in the coffer-dam was less satisfactory in that the results led to a significant overestimate of the settlements (62 mm predicted and 8–15 mm measured). Nevertheless, the large-scale test played a very important part in arriving at the final foundation solution.

This case history highlights the problems that can occur during construction, especially when the groundwater regime and groundwater effects during construction are not understood. Careful observations and tests during the works were of vital importance, in order to successfully complete the works. Construction of the cable chamber below the water table required a proper dewatering and depressurisation system to be installed. This was only switched off once the weight of the permanent works was sufficient to avoid buoyancy.

9.6 Conclusions

- A useful mnemonic for foundation design is the 'five S's': site, soil, structure, safety and sustainability.
- The ground profile and the allowable foundation movement are two key factors in selecting the most appropriate foundation type.
- Common factors in properly understanding ground risks are:
  - **(i)** understanding the site history and geology;
  - **(ii)** understanding the site's groundwater regime and how it impacts upon the proposed construction and permanent works.

In the vast majority of cases when foundation problems occur it is because either (i) or (ii) above has not been properly understood by the foundation designer. A coherent approach to proper understanding of ground risk is provided by the geotechnical triangle (introduced in Chapter 4 *The geotechnical triangle*).

- Often the limits set for allowable total and differential settlement are arbitrary and overconservative. It is important for the foundation designer to have early discussions with the structural engineer on this matter. Note that it is the *differential* settlement which occurs *after* the structure is built and finishes applied that has the potential to cause damage. The main opportunity for economic foundation design is to set realistic limits on allowable foundation movement, especially differential movements.
- The foundation engineering associated with a project can involve the assemblage of a number of components and a variety of processes. It is important that a holistic approach be adopted. When different components of a project are designed by different teams the potential interactions should be considered by a single team – preferably the lead project designer.
- Examples are given in the chapter illustrating the importance of keeping the geotechnical triangle 'in balance'. In addition to the four activities included in the triangle, it has been found helpful to consider a fifth aspect which involves *construction processes and design verification*. This aspect recognises the fact that foundation engineering is essentially a process requiring monitoring and verification of key design assumptions.

Geotechnical codes and standards represent standards of good practice. They serve as a means to achieve the safety levels required by society for geotechnical structures and as a means of communication, providing a common understanding between all those involved in a geotechnical project. Geotechnical codes and standards have moved from being prepared by committees of the engineering institutions to being prepared by technical committees of the European Committee for Standardisation (CEN, an acronym for Comité Européen de Normalisation) and from being based on the permissible stress method with overall factors of safety, to being based on the limit state design method with partial factors. The main components of a geotechnical design are the geometric data, the loads and geotechnical parameters, the verification method and the complex nature of geotechnical design situations. These design components are presented in the form of a geotechnical design triangle, the components of which are related to the aspects of the geotechnical triangle.

10.1 Introduction

As society grows more complex, with additional laws and regulations, and as people become more litigious, those involved in geotechnical engineering need to be confident that their designs are reliable and have the level of safety required by society. Reliable and safe geotechnical designs may be achieved through possessing a good understanding of soil behaviour, through adopting appropriate models for geotechnical design situations and, in view of the complex nature of soil, through taking appropriate account of previous comparable experience. Design codes of practice and standards aim to provide recommendations for good design practice, setting out the processes and procedures to achieve geotechnical designs that meet the requirements of society with regard to health and safety. In addition, they aim to provide designs that meet the requirements of the owners and users with regard to serviceability, i.e. with regard to acceptable settlements and deformations, and with regard to economy. As Simpson *et al*. (2009) noted, codes have a responsibility to balance economy with safety and serviceability in a world in which limitations of resources are increasingly recognised.

10.2 Statutory framework, objectives and status of codes and standards

The Building Regulations 2010, published by the UK Department for Communities and Local Government and made under the powers of the Building Act 1984, provide the statutory framework for buildings projects by setting out the functional requirements to ensure the health and safety of people in and around all types of buildings, as well as the requirements for energy conservation and the welfare and convenience of disabled persons. Practical guidance on ways to comply with the functional requirements of the Building Regulations is contained in Approved Documents, which are published in a number of parts by the National Building Specification (NBS) for the Department for Communities and Local Government. For example, Approved Document A (NBS 2006), which is concerned with structural safety, refers to two geotechnical British Standards, both published by the British Standards Institution, London (as are all the codes and standards referred to in this chapter and listed in the tables, except for the first codes of practice, CP 1, CP 2 and CP 4, as noted in section 10.4): BS 8002 *Code of Practice for Earth Retaining Structures* and BS 8004 *Code of Practice for Foundations*. These provide practical guidance for meeting the structural safety requirements of the Building Regulations. However, since the Eurocodes superseded these standards on 31 March 2010, prior to Approved Document A being revised, reference should now be made to BS EN 1997-1:2007 rather than to BS 8002 and BS 8004 as providing practical guidance on meeting the structural safety requirements of the Building Regulations. The prefix EN indicates that it is a European norm or standard.

It should be noted that the guidance given in the Approved Documents is not a set of statutory requirements and does not have to be followed. Compliance with the codes and standards referred to in the Approved Documents is just one way of fulfilling (i.e. being deemed to satisfy) the functional requirements in the Building Regulations. Hence, the referenced codes and

standards are not mandatory and alternative methods may be used, although the designer may need to prove that the alternative methods satisfy all the relevant functional requirements and that the resulting design still complies with the Building Regulations. There is a legal presumption that if a designer has followed the guidance in an Approved Document, this is evidence that the design has complied with the Building Regulations. The foreword to BS 5930:1981 *Code of Practice for Site Investigations* has the statement that '*compliance with this code of practice does not confer immunity from the relevant statutory and legal requirements*' and this statement is valid in the case of all the codes of practice referred to in the Approved Documents.

While the existing British codes of practice have been published with the objective (as noted in BS 5930:1981) to represent standards of good practice and have taken the form of recommendations, the objectives of the Eurocodes – including Eurocode 7 for geotechnical design (BS EN 1997-1:2007) – are broader. It is stated in the forewords to the Eurocodes that they are to serve as reference documents for the following purposes:

- as a means to prove compliance of building and civil engineering works with the essential requirements of Council Directive 89/106/EEC, particularly Essential Requirement N°1 – mechanical resistance and stability – and Essential Requirement N°2 – safety in case of fire;
- as a basis for specifying contracts for construction works and related engineering services;
- as a framework for drawing up harmonised technical specifications for construction.

With regard to those who use codes and standards in geotechnical engineering, Eurocode 7 makes the following important assumptions, which should not be overlooked:

(i) data required for design are collected, recorded and interpreted by appropriately qualified personnel;

(ii) structures are designed by appropriately qualified and experienced personnel;

(iii) adequate continuity and communication exist between the personnel involved in data collection, design and construction;

(iv) adequate supervision and quality control are provided in factories, in plants, and on site;

(v) execution is carried out according to the relevant standards and specifications by personnel having the appropriate skill and experience;

(vi) construction materials and products are used as specified in Eurocode 7, or in the relevant material or product specifications;

(vii) the structure will be adequately maintained to ensure its safety and serviceability for the designed service life;

(viii) the structure will be used for the purpose defined for the design.

Ensuring compliance with all of these assumptions is more important for ensuring the safety of geotechnical structures and reducing the risk of failure than is precision in the design calculations, or the values adopted for the safety factors. Regarding compliance with (i), (ii) and (v) above, Eurocode 7 does not define what is meant by people having appropriate qualifications, skill and experience. This will depend on the nature of the project and the ground conditions and has been left to national determination. A formal measure to address this issue has been undertaken by the Institution of Civil Engineers together with the Geological Society and the Institute of Materials, Minerals and Mining with the establishment in June 2011 of the UK Register of Ground Engineering Professionals (UK RoGEP). Details about the Register and how to become a registered ground engineering professional are given in document 3009(4) (ICE, 2011) prepared by the British Geotechnical Association under the auspices of the Ground Forum. The UK RoGEP provides external stakeholders, including clients and other professionals, with a means to identify individuals who are suitably qualified and competent in ground engineering.

10.3 Benefits of codes and standards

According to the British Standards Institution website (www.bsigroup.com), standards help to make life simpler and increase the reliability and effectiveness of the goods and services we use. Hence, in the case of geotechnical design, their benefits are that they establish the procedures and requirements, including the safety elements, for the design process to achieve the levels of safety, serviceability and economy required by society. Codes and standards are created by those involved in the industry and hence they bring together important collective understanding and relevant experience. Another benefit is that they provide a common reference and means of communication for all those involved in geotechnical projects: geotechnical designers, ground investigators, those working in geotechnical laboratories, structural engineers, contractors, clients, users, public authorities and regulators. Simpson *et al.* (2009) have elaborated on the communication aspect of codes and how they provide (i) a link between analysis and design, where analysis is a tool in the design process; and (ii) a link between the activities of the designer and the requirements of society regarding safety and serviceability.

In the case of the Eurocodes, the European Commission has published a document called Guidance Paper L (EC, 2003) in which the intended benefits and opportunities of the Eurocodes are listed as being to:

- provide common design criteria and methods to fulfil the specified requirements for mechanical resistance, stability and resistance to fire, including aspects of durability and economy;
- provide a common understanding regarding the design of structures between owners, operators and users, designers, contractors and manufacturers of construction products;
- facilitate the exchange of construction services between member states;

- facilitate the marketing and use of structural components and kits in member states;
- facilitate the marketing and use of materials and constituent products, the properties of which enter into design calculations, in member states;
- be a common basis for research and development in the construction sector;
- allow the preparation of common design aids and software;
- increase the competitiveness of the European civil engineering firms, contractors, designers and product manufacturers in their world-wide activities.

10.4 Development of codes and standards for geotechnical engineering

Codes of practice and standards are essentially two different types of document. A code of practice (CP) is defined by the British Standards Institution (BSI) in BS 0–2:2005: *A standard for standards* as a document which provides:

> recommendations for accepted good practice as followed by competent and conscientious practitioners, and which brings together the results of practical experience and acquired knowledge for ease of access and use of the information

while a standard is defined in BS 0–1:2005 as:

> a document, established by consensus and approved by a recognized body, that provides, for common and repeated use, rules, guidelines or characteristics for activities or their results, aimed at the achievement of the optimum degree of order in a given context.

Thus a code of practice is used for design as it aims to reach an acceptable technical level of quality and is expressed as functional requirements based on scientific/technical principles. It normally avoids standardising particular design methods or detailed construction procedures, leaving these choices to the designer (Krebs Ovesen and Orr, 1991). A standard, on the other hand, aims to achieve a certain degree of order in a given context through specifying particular methods or procedures to be used.

Examples of codes of practice in geotechnical engineering, as defined above, are the former BS codes for site investigations, earth-retaining structures and foundations, while examples of standards are the BS soil test standards which provide the specifications, i.e. the requirements and procedures, for the different tests for soils. Eurocode 7 is, by definition, a code of practice, since it provides recommendations for good practice as followed by competent practitioners. However, it is also a standard (according to the above definition) since it provides agreed rules aimed to achieve the optimum degree of order in geotechnical design expressed as a particular level of safety.

In recent years, since BSI has been publishing different types of document, including specifications, methods, guides, vocabularies and codes of practice, all with the same status and authority, it was decided to publish them all as standards. Hence, since the 1980s, BSI has published codes of practice as standards with the prefix BS for British Standard, although the term ‘code of practice’ has usually been retained in the title of the standard.

The first codes and standards for geotechnical engineering in the UK were prepared in the 1940s and 1950s by committees convened by the engineering institutions on behalf of the Codes and Practice Committee for Civil Engineering, Public Works, Building and Construction Work, under the aegis of the former Ministry of Works, for publication in the Civil Engineering and Public Works Series. These design codes of practice were based on the permissible-stress method with overall factors of safety. More details about the evolution of British codes of practice and standards have been provided by McWilliam (2002). He has reported on the issues that arose during the development of the codes of practice in relation to the traditional role of professional engineers, who regarded design rules as the individual choice for the engineer, and their developing relationships with government agencies and international trade.

Work on *Code of Practice no. 1 (CP 1): Site investigations* started in 1943 and was published by the Institution of Civil Engineers in 1950; *Code of Practice no. 2 (CP 2): Earth retaining structures* was published by the Institution of Structural Engineers in 1951; and *Code of Practice no. 4 (CP 4): Foundations* was published by the Ministry of Works in the late 1940s. The first standard for the testing of soils was published by BSI in 1948 as BS 1377: *Method of test for soil description and compaction*, which consisted of just one part when first published, but has since increased to nine parts. In 1949 the responsibility for the preparation and issue of the codes of practice of the Civil Engineering and Public Works Series in the UK was handed over to the following four professional engineering institutions: the Institution of Civil Engineers, the Institution of Municipal Engineers, the Institution of Water Engineers and the Institution of Structural Engineers.

In 1954, while the drafting of codes of practice remained with the professional engineering institutions, the responsibility for publishing the codes of practice was transferred from the engineering institutions to the British Standards Institution, where it has remained. Revised versions of CP 1 and CP 4 were published by BSI as CP 2001 in 1957 and CP 2004 in 1972, respectively. While they still had the phrase ‘code of practice’ in their titles, subsequent revisions of these codes of practice were published during the 1980s as British Standards with the prefix BS rather than CP. For example, the revised version of CP 2001 was published as BS 5930 in 1981 and the revised version of CP 2004 was published as BS 8004 in 1986. The first three revisions of BS 1377, in 1961, 1967 and 1975, were published as single documents. In the 1961 version, the title was changed to *Methods of Testing Soil for Civil Engineering*. The 1975 version was in metric form and included procedures for a greater range of soil tests. Subsequently, in 1990, the next revision and current version was published in nine separate parts with the slightly modified umbrella title *Method of Test for Soils for Civil Engineering Purposes*.

With the move towards harmonisation in Europe through the formation of the European Economic Community and then the European Union, the European Commission (EC) in 1975 initiated a programme to prepare the set of harmonised standards for the design of buildings and civil engineering works, known as the Structural Eurocodes. These standards are all based on the same limit state design method with partial factors. Thus they harmonise geotechnical design with structural design. In the case of geotechnical design, they have the additional advantage that, being based on the limit state design method, they provide a 'common language' for geotechnical design in the different countries in Europe. Until the publication of Eurocode 7, design codes and standards in Europe varied greatly. European harmonised standards are standards that are officially recognised by reference in the Official Journal of the European Union as meeting the essential requirements of a relevant European directive. In the case of the Eurocodes, the relevant directive is the Construction Products Directive 89/106/EEC (EC, 1989) of 21 December 1988 on the approximation of laws, regulations and administrative provisions of the member states relating to construction products. After 15 years' work on the Eurocodes, it was decided in 1990 to transfer this work from the EC to the CEN. The national standards organisations in Europe are members of CEN and hence BSI is the UK member of CEN. CEN has published Eurocode 7 as EN 1997.

Since the responsibility for establishing the required level of safety for structures in a particular country is a national responsibility; Eurocode 7 and each of the other Eurocodes is published with a National Annex. The National Annexes provide the values of the partial factors, referred to as Nationally Determined Parameters (NDPs), and other safety elements to be used with a particular Eurocode. The National Annexes also provide references to non-conflicting complementary information (NCCI) that may be used with the Eurocodes.

Each Eurocode has been prepared by a technical committee (TC) of CEN, TC 250 *Structural Eurocodes*. As well as preparing the Eurocodes for structural and geotechnical design, CEN has also in recent years been preparing, through its TCs, a large number of standards relating to other aspects of geotechnical engineering and many of these have now been published by CEN as ENs. Some standards relating to geotechnical engineering have also been prepared in recent years by technical committees of the International Standards Organization (ISO) and published as ISO standards, with the prefix ISO. In order to avoid duplication of work, it was decided in 1991, under the Vienna Agreement, that when CEN and ISO both required a standard in a particular area, they would cooperate in the preparation of the standard and exchange technical information. In practice, this has meant that there has been collaboration between CEN and ISO in the preparation of standards for geotechnical investigation and testing, most of these being prepared by CEN TC 341 *Geotechnical Investigation and Testing*, but with the standards for the identification and classification of soil and rock being prepared by ISO TC 182 *Geotechnics*.

As a member of CEN, BSI is obliged to adopt identical versions of all European Standards as British Standards, and to withdraw any national standards that might conflict with them. Hence, since the Eurocodes and other European standards have been approved and published by CEN as European Standards with the prefix EN, they have been adopted and published by BSI as British Standards with the prefix BS EN and the conflicting BS standards have been superseded. However, if BSI decides to keep an existing conflicting standard as a current document rather than withdraw it, this is achieved by changing its status from a standard, with the prefix BS, to a published document, with the prefix PD. This is a document that does not have the status of a standard but contains information that is useful for the industry. If ISO standards are adopted as British Standards, they are published by BSI with prefix BS ISO, unless they have been prepared by an ISO or CEN committee working under the Vienna Agreement, in which case they are published with the prefix BS EN ISO.

10.5 Why geotechnical and structural codes and standards differ

Geotechnical design codes and standards, such as Eurocode 7, differ in both structure and content from structural design codes. This is because soil has a number of special features which the materials used for structural design (e.g. steel) either do not have, or have only to a much lesser extent. The consequences for geotechnical design and Eurocode 7 of each of these special features of soil is explained in the following paragraphs and summarised in **Table 10.1**.

(a) *Soil as a natural material* The principal feature of soil which affects geotechnical design and causes geotechnical codes to differ from structural codes is that it is a natural material, unlike the materials used in structural design, such as concrete and steel, which are manufactured. The consequence of this is that the properties of the soil need to be determined as part of the geotechnical design process rather than being specified by the designer, as in the case of structural design. It is for this reason that Eurocode 7 has two parts, which cover all the components of geotechnical design. These are Part 1: *General rules*, with the principles and requirements for the geotechnical aspects of the design of buildings and civil engineering works, and Part 2: *Ground investigation and testing*, with the design requirements relating to the planning and reporting of ground investigations, the general requirements for a number of commonly used laboratory and field tests for soil, the interpretation of test results, and the derivation of geotechnical parameters and coefficients.

(b) *The two- or three-phase nature of soil* Soil consists of mineral particles which have shear strength, and water and air which have no shear strength. As a result, the principle

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Soil	Steel	Consequences for geotechnical design
(a) Natural material	Manufactured	Properties are determined, not specified, so ground investigation and testing are part of design process
(b) Two or three phases	Single phase	Need to consider water and water pressures as well as soil properties, and also short- and long-term behaviour
(c) Non-homogeneous and highly variable	Homogeneous	Characteristic value is not 5% fractile of test results and need to use comparable experience when selecting characteristic values. Also for redundant structures, stronger ground attracts load while weaker ground sheds load, so partial load factors close to unity are appropriate
(d) Frictional	Non-frictional	Loads affect resistances so need to take care factoring permanent loads, and hence partial factor of unity usually appropriate
(e) Ductile	Most manufactured materials are not as ductile as soil	Enables load redistribution in the ground and redundant structures, so that partial factors close to unity may be appropriate for structural loads
(f) Dilatant	Non-dilatant	Dilation on shearing and the magnitude of the shear strains need to be considered when deciding whether the peak, critical state or residual strength parameters are appropriate
(g) Compressible and with a low shear stiffness	Non-compressible	Design is often controlled by serviceability limit state, not by ultimate limit state
(h) Nonlinear with a complex stress–strain behaviour	Linear and simple	Serviceability limit state calculations usually difficult, so for simple situations, design may be carried out using ultimate limit state calculations

Table 10.1 Special features of soil compared with steel and consequences for geotechnical design

of effective stress needs to be taken into account in geotechnical design. This principle states that all effects of a change of stress on soil are due to changes in effective stress, where the effective stress is the total stress minus the pore water pressure – i.e. it implies that all changes of soil strength, compression and distortion are due to changes in the stresses acting on the soil particles, not due to changes in the pore water pressure. It is for this reason that the principle of effective stress is so fundamental to geotechnical design and why it is normally necessary in geotechnical design to determine the pore water pressures and understand how the pore water is behaving. Eurocode 7 takes account of this by constantly referring to the need in geotechnical design to consider pore water pressures and the effects of changes in pore water pressures, e.g. Paragraph 2.4.2(9)P. Furthermore, since changes in pore water pressure take time to occur in fine-grained, low permeability soils, and since the properties and behaviour of soils change with time as the pore water pressures dissipate, it is necessary in geotechnical design, as stated in Paragraph 2.2(1)P, to consider both short- and long-term design situations. This time-dependent behaviour is a unique feature of geotechnical engineering that does not occur in structural design. Further discussion of this behaviour is given in Chapter 17 *Strength and deformation behaviour of soils.*

(c) *The non-homogeneous and variable nature of soil* Soil is both non-homogeneous and variable and the volume of soil involved in any geotechnical design situation is usually very large compared with that which is sampled and tested. For these reasons, it is normally not appropriate to select the 5% fractile of the test results as the characteristic value for use in geotechnical designs (unlike when selecting material parameters for use in structural designs). According to Paragraph 2.5.4.2(2)P of Eurocode 7, the characteristic value of a geotechnical parameter shall be selected as a cautious estimate of the value affecting the occurrence of the limit state, which is often the mean of a range of values covering a large surface or volume of the ground. Although it is not anticipated that statistics will normally be employed in the selection of the characteristic value, Eurocode 7 states that a cautious estimate of the mean value is a selection of the mean value of the limited set of geotechnical parameter values, with a confidence level of 95%. It is important that the characteristic value should be selected not only on the basis of soil tests results, but also on the basis of experience of similar soil conditions and the behaviour of similar structures in such soil.

The greater inhomogeneity and variability of soil compared with manufactured materials not only affects the selection of characteristic values in geotechnical design, but also the values chosen for the partial material and load factors. Due to the greater variability of soil and the greater uncertainty concerning the soil parameter values compared with structural parameter values, larger partial material factor values are generally chosen for geotechnical design than for structural design, e.g. 1.25 on $\tan\phi'$ compared with 1.15 on the strength of steel, where ϕ' is the effective angle of friction. As a result of the greater variability of soil, in geotechnical design, there is often less uncertainty in the loads compared to the soil parameter

values, particularly when the loads are due to the self-weight of the soil, or compared with the uncertainty in the loads in structural design; for this reason, lower partial load factors are often chosen for geotechnical design. For example, 1.0 on permanent loads and 1.3 on variable loads compared wit the partial load factors of 1.35 and 1.5, respectively, chosen for structural design.

Another consequence of the non-homogeneous and variable nature of soil is that, in the case of redundant structures on soil, the loads from the structure will be redistributed from areas where the soil is weaker (hence less able to support the loads) to areas where the soil is stronger (better able to support the loads). This unplanned redistribution process is favourable with regard to the geotechnical design and hence justifies the choice of low partial load factors. However, in the case of structural design, the situation is different because manufactured materials are not normally non-homogeneous and variable, with weak and strong zones. Unplanned load redistribution in redundant structures is usually unfavourable rather than favourable and thus necessitates higher partial load factors than in geotechnical design.

(d) *The frictional nature of soil* Since soil is frictional, its strength is a function of the normal effective stress as well as the angle of friction. Thus it is necessary to be careful when factoring permanent loads in geotechnical design calculations, and to ensure that normal loads which are unfavourable (i.e. those tending to cause failure) but which are also contributing to the soil strength and resistance , through providing the normal stress on the failure surface, are not increased. It is for this reason that the partial factor of 1.0 mentioned in (c) above is normally used on permanent loads, including the self-weight of soil, in geotechnical design. Further discussion of the frictional nature of soil is given in Chapter 17 *Strength and deformation behaviour of soils.*

(e) *The ductile nature of soil* Soil is usually very ductile – it can undergo large deformations when sheared and still retain significant shear strength, even if, on shearing, it first reaches a peak strength and then reduces to a residual strength. Although some structural materials, such as steel, are ductile, the extent of their ductility is normally less than for soil and hence, unless special measures are included to improve the ductility, structures are not able to deform as much as soil before failing. A consequence of the ductile behaviour of soil is that when homogeneous soil supports a redundant structure, those areas that are more heavily loaded will yield, allowing load to be transferred through the structure from the more heavily loaded to the less heavily loaded areas. Hence, this ductile nature is beneficial for the geotechnical design. This is another reason why the partial factors on permanent and variable loads in geotechnical design are often less than those in structural design.

(f) *The dilatant behaviour of soil* Some soils, for example dense coarse-grained soils, dilate when sheared, exhibiting a peak angle of friction, ϕ'_p. After sufficient shearing, they reach the critical state or constant-volume angle of friction, ϕ'_{cv} when the soil is completely remoulded. In the case of other soils, for example clays, the soil particles may become aligned along the failure surface after large strains, with the result that a residual angle of friction is reached which is less than the critical state angle. Generally what is important in geotechnical design is the soil strength that is available to prevent failure occurring, rather than the strength after failure. Eurocode 7 states in Paragraph 2.4.3(2)P that the geotechnical parameter 'values obtained from test results and other data shall be interpreted appropriately for the limit state considered' and in Paragraph 2.4.3(4)P notes that 'account shall be taken of the possible differences between the ground properties and geotechnical parameters obtained from test results and those governing the behaviour of the geotechnical structure', giving soil and rock structure and brittleness as two of the factors that may cause these differences. Further discussion of the dilatant behaviour of soil is given in Chapter 17 *Strength and deformation behaviour of soils.*

Eurocode 7 generally does not state if the soil shear strength to be used in design calculations is the peak, critical state, or residual value. Paragraph 3.3.6(1)P notes that, when assessing the shear strength, the influence of features including the stress level, anisotropy of strength, strain rate effects, very large strains where these may occur in a design situation, pre-formed slip surfaces and degree of saturation, shall be considered. Since structures will generally be considered to have failed well before the deformations required to get to the critical state have been reached (geotechnical designs have traditionally been carried out using the peak strength), and since most field tests are correlated to the peak strength, this is the strength that is normally used in designs to Eurocode 7. This is indicated by Paragraph 6.5.3(5), which, referring to the strength used to determine the resistance to sliding, states that 'for large movements, the possible relevance of post-peak behaviour should be considered'. The only paragraphs in Eurocode 7 that refer to the use of a specific angle of friction are Paragraphs 6.5.3(10) and 9.5.1(3). Paragraph 6.5.3(10) states that 'the design (structure-ground interface) friction angle δ_d may be assumed equal to the design value of the effective critical state angle of shearing resistance, $\phi'_{cv,d}$, for cast *in situ* concrete foundations and equal to 2/3 $\phi'_{cv,d}$ for smooth pre-cast foundations'. Paragraph 9.5.1(3) states that 'A concrete wall or sheet pile wall supporting sand or gravel may be assumed to have a design wall–ground

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

interface parameter $\delta_d = k\phi_{cv,d}$. k, the wall-ground interface friction angle factor, should not exceed 2/3 for precast concrete or sheet piling'.

(g) *The compressible nature and low shear stiffness of soil* Since soil, particularly fine-grained soil, is compressible with a low shear stiffness, and is normally very much more compressible and less stiff than structural materials, it can undergo large deformations exceeding the limiting values for the structure. Hence the controlling criterion in many geotechnical design situations is limiting the deformations rather than preventing failure. Geotechnical designs are therefore often controlled by serviceability limit state considerations rather than by ultimate limit state requirements.

(h) *The nonlinear and complex stress strain behaviour of soil* The nonlinear and complex stress–strain behaviour of soil, and the difficulties in determining appropriate parameter values and modelling soil deformations, sometimes make it difficult to obtain reliable predictions of the ground deformations. Consequently for simple design situations, geotechnical designs may be carried out using ultimate limit state calculations with appropriate partial or overall safety factor values, chosen so as to limit the mobilised shear strength and hence the ground deformations. An example of this in Eurocode 7 is the application rule in Paragraph 6.6.2(16), which states that 'For conventional structures founded on clays, the ratio of the bearing capacity of the ground, at its initial undrained shear strength, to the applied serviceability loading should be calculated. If this ratio is less than 3, calculations of settlements should always be undertaken. If the ratio is less than 2, the calculations should take account of nonlinear stiffness effects in the ground'.

10.6 The geotechnical design triangle

Burland (1987) proposed that the teaching of soil mechanics should focus on four distinct aspects. He originally presented these four aspects as the soil mechanics triangle, a concept which he has developed and expanded into the geotechnical triangle shown in **Figure 10.1** and discussed in Chapter 4 *The geotechnical triangle*. The geotechnical triangle has the first three aspects at its apexes: the ground profile, the soil behaviour and an appropriate model. The fourth aspect: precedent, empiricism and well-winnowed experience, lies at its centre and is linked to the other three.

In a similar way, Orr (2008) has shown that the different components of geotechnical design can be formed into the geotechnical design triangle shown in **Figure 10.2**. The components of geotechnical design that form the apexes of the geotechnical design triangle are the geometrical data, the loads and geotechnical parameters, and the verification method. Linking these three components is the fourth component, the design

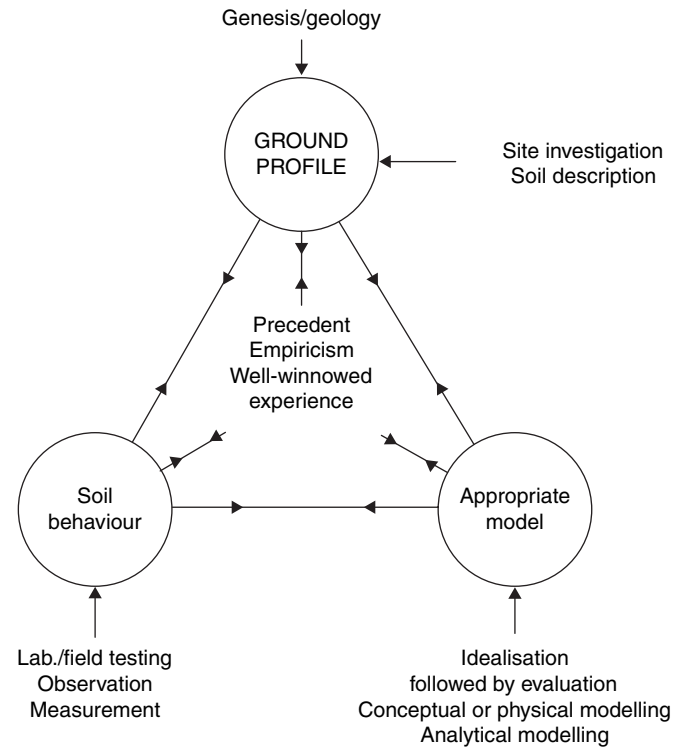

Figure 10.1 Geotechnical triangle

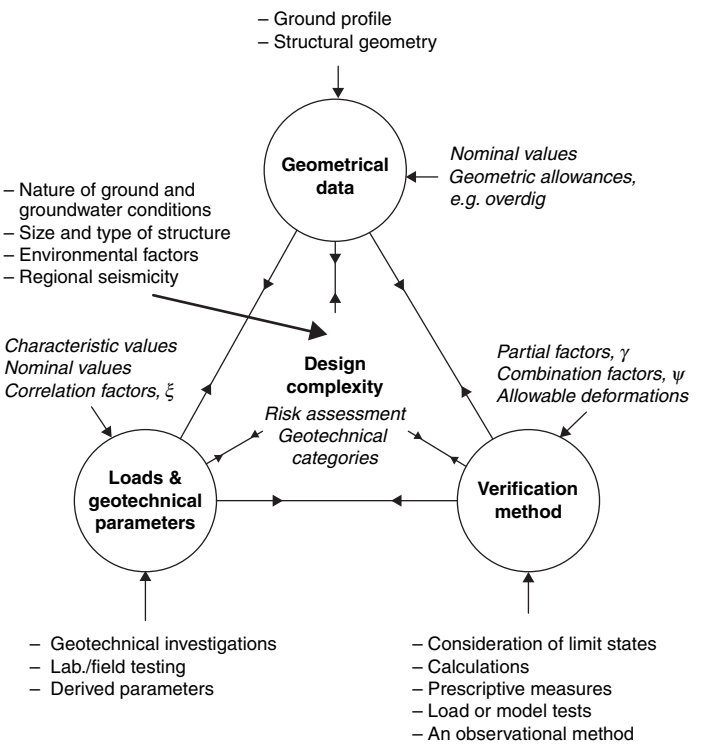

Figure 10.2 Geotechnical design triangle

complexity. How the design complexity affects the other geotechnical design components is an important design consideration and hence design complexity has been placed at the centre of the geotechnical design triangle, linked to each of the other three design components in the same way as precedent, empiricism and well-winnowed experience are linked to the components at the apexes of the geotechnical triangle.

The factors and design procedures involved in the four geotechnical design components are listed as bullet points in the geotechnical design triangle in **Figure 10.2**. The factors involved in the first component, the data describing the geometry of the design situation, include the level and slope of the ground surface, water levels, levels of interfaces between strata, excavation levels and the dimensions of the geotechnical structure. The loads involved in geotechnical designs are usually either provided by the structural designer or determined from the weight density (unit weight) of the soil, while the geotechnical parameters, such as the soil strength and stiffness, are determined as derived values from geotechnical investigations involving field and laboratory tests.

Regarding the verification method, with the introduction of Eurocode 7, the limit state design method has replaced the permissible-stress method for geotechnical design. This design method requires that all the relevant limit states are considered and shown to be sufficiently improbable. This should be achieved by adopting one or more of the following: the use of calculations, the adoption of prescriptive measures, loads or model tests, and an observational method. The factors that make up the fourth component, the design complexity, are the nature of the ground and the groundwater conditions, the nature of the structure, the nature of the surroundings, the environmental factors and, where relevant, the regional seismicity. Each of these factors and their level of complexity needs to be considered at the start of a geotechnical design as they will affect how each of the other three components is treated.

10.7 Safety elements adopted in Eurocode 7

In geotechnical designs to Eurocode 7, each component of the geotechnical design triangle is treated in an appropriate manner or with an appropriate safety element to ensure that the required level of safety is achieved. The treatment manner or safety elements adopted in the case of each component are explained in the following paragraphs and are shown in italics in **Figure 10.2**.

In the case of the geometrical data, the values used for design are measured or chosen nominal values. Where appropriate, geometrical allowances are included as the measures to ensure safety; examples of such allowances in BS EN 1997–1 are the overdig allowance in the design of retaining structures (Paragraph 9.3.2.2(2)) and the additional constructional tolerance on the foundation width in the case of spread foundations with highly eccentric loads (Paragraph 6.5.4(2)).

In the case of the loads and geotechnical parameters, the uncertainty and variability in these are taken into account and safety is achieved through the selection of suitably cautious values, which are known as characteristic values. Where sufficient statistical data are available, the characteristic value of a load is defined as the 95% fractile value of the load distribution, while in the case of a material parameter, it is defined as the 5% fractile value. However, often sufficient data are not available to obtain the characteristic value of a load statistically and hence a 'nominal' value is used instead. When combinations of loads are involved in a design situation, combination factors are applied to the characteristic loads to obtain 'representative' values of loads. These are the values to which the partial action (load) factors are applied to obtain the design values that are used in design calculations to Eurocode 7. Regarding the characteristic value of a geotechnical parameter, Paragraph 2.5.4.2(2)P of EN 1997–1 states that it 'shall be selected as a cautious estimate of the value affecting the occurrence of the limit state'. When the pile resistance is determined from pile load tests or profiles of field tests, BS EN 1997–1 provides correlation factors, ξ, that are applied to the test results or profiles to determine the characteristic pile resistance. The ξ values used to determine the characteristic pile resistance depend on the number of pile load tests or test profiles.

With regard to the verification method, the required level of safety when using the limit state design method in BS EN 1997–1 is achieved by applying appropriate partial factors to the loads and/or the geotechnical parameters values or resistances in the ultimate or serviceability limit state calculation models. Partial model factors may also be introduced to account for uncertainty in the calculation model, though this uncertainty is normally accounted for in the values chosen for the partial load and material factors. The values of the partial factors provided in the UK National Annex to EN 1997–1 are all for ultimate limit states, since the partial factors for serviceability limit states are all equal to unity.

The way that safety is introduced in BS EN 1997–1 with regard to the complexity of a design situation is by the requirement in Paragraph 2.1(8)P: that the complexity of each design situation shall be identified together with the associated risks so that minimum requirements for the extent and content of the geotechnical investigations, calculations and construction control checks can be established. When identifying and addressing the complexity of a design situation, it is important to take account of comparable experience, which is defined in Paragraph 1.5.2.2 as 'documented or other clearly established information related to the ground being considered in design, involving the same types of soil and rock and for which similar geotechnical behaviour is expected, and involving similar structures. Information gained locally is considered to be particularly relevant'. An example of a risk assessment procedure in BS EN 1997–1 to address the design complexity is the geotechnical categories given in Paragraph 2.1(10). These geotechnical categories are presented as an application rule, not as a principle, in BS EN 1997–1, and hence their use is optional for geotechnical designs carried out in the UK.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Soil mechanics aspects	Geotechnical design components	Treatment manner or safety elements
Ground profile	Geometrical data	Nominal values
– Genesis/geology	– Level and slope of ground surface	Foundation tolerance
– Site investigation	– Water levels	Overdig allowance
– Soil description	– Levels of strata interfaces	
	– Excavation levels	
	– Structural dimensions	
Soil behaviour	Loads and geotechnical parameters	Characteristic values
– Laboratory/field tests	– Geotechnical investigations	Nominal values
– Observation	– Field testing	Correlation factors, ξ
– Measurement	– Laboratory testing	
	– Derived parameters	
Appropriate model	Verification method	Partial factors, γ
– Idealisation followed by evaluation	– Consideration of all relevant limit states	Combination factors ,ψ
– Conceptual or physical modelling	Verification by	Design values
– Analytical modelling	– Calculations	Limiting movements
	– Prescriptive measures	
	– Load or model tests	
	– An observational method	
– Precedent	Design complexity	Risk assessment
– Empiricism	– Soil conditions	Geotechnical categories
– Well-winnowed experience	– Groundwater situation	Comparable experience
	– Influence of the environment	
	– Regional seismicity	
	– Nature of structure	
	– Nature of surroundings	

Table 10.2 Relationship between the geotechnical design components and soil mechanics aspects (continued overleaf)

10.8 Relationship between the geotechnical design triangle and the geotechnical triangle

The relationship between the four components of the geotechnical design triangle and the aspects of the geotechnical triangle is shown in **Table 10.2**. This table shows that the components of geotechnical design are related to and cover the same areas as Burland's aspects of soil mechanics. However, the safety elements of the geotechnical design components, which are a fundamental feature of geotechnical design, are not included in the four aspects of soil mechanics, which were identified as being essential for the understanding of soil behaviour.

With regard to complexity, Burland (2006) stated that he considered the main difficulty in soil mechanics was not so much in the complexity of the material as such, but in the fact that, all too often, the boundaries between the aspects become confused. He also noted the need for precedent, empiricism and well-winnowed experience to moderate and account for uncertainties in the aspects of soil mechanics. A similar situation exists in geotechnical design whereby it is not so much the complexity of the situation that affects the safety of a design, but the need to identify the uncertainties involved in each of the design components and adopt appropriate procedures for each component. This involves using comparable experience as defined in EN 1997–1. An important statement in BS EN 1997–1 related to ensuring safety in complex geotechnical design situations is Paragraph 2.4.1(2), which notes that 'knowledge of the ground conditions, which depend on the extent and quality of the geotechnical investigations, and the control of workmanship are usually more significant to fulfilling the fundamental requirements than is precision in the calculation models and partial factors'.

10.9 Codes and standards for geotechnical engineering

10.9.1 Groups of geotechnical codes and standards

The codes and standards in the UK for geotechnical engineering may be divided into four groups, presented in **Tables 10.3**, **10.4**, **10.5** and **10.6**: investigations and testing, geotechnical design, the execution of geotechnical work, and materials used in geotechnical engineering. These tables show the

prefixes and reference numbers of the standards, their titles, their abstract/descriptors/keywords and their status. Standards that have been published by BSI are shown in the tables with their date of publication after the reference number. Standards that are being or have been prepared by CEN or ISO, but have not yet been published by BSI, are shown with no date; the prefix it is anticipated they will have when they become British Standards is shown in brackets, e.g. (BS EN ISO).

10.9.2 Codes and standards for geotechnical investigation and testing

As shown in **Table 10.3**, the current British Standards for geotechnical investigations and testing are BS 5930: *Site investigations* and BS 1377: *Methods of Test for Soils for Civil Engineering Purposes*, which has nine parts covering laboratory and *in situ* tests. Since Parts 1 and 2 of Eurocode 7 have sections that cover the design aspects of site investigations, for example the planning and location of site investigations, these sections supersede those parts of BS 5930 which cover the same aspects and hence an amended version of BS 5930 was published by BSI in 2007 to avoid conflict with the two parts of BS EN 1997–1.

The ISO standards for the identification and classification of soil and rock are:

- 14688 *Identification and Classification of Soil* (2 parts);
- 14689 *Identification and Classification of Rock* (1 part).

These three parts have been published by CEN as EN ISO standards. Hence they have been published by BSI as the BS standards BS EN ISO 14688–1, BS EN ISO 14688–2 and BS EN ISO 14689–1 and have been introduced into UK practice. Since these new BS standards cover the identification and classification of soil and rock that was covered by BS 5930, they supersede those parts of BS 5930. Hence the amended version of BS 5930 issued in 2007 has been revised to remove soil and rock identification and classification to avoid conflict with these new BS standards.

CEN has prepared and is preparing, under the Vienna agreement, the following very comprehensive range of standards for geotechnical investigations and testing which will eventually supersede most parts of BS 5930 and BS 1377:

- 17892 *Laboratory Testing of Soil* (12 parts);
- 22282 *Geohydraulic Testing* (6 parts);
- 22475 *Sampling Methods and Groundwater Measurements* (3 parts);
- 22476 *Field Testing* (13 parts);
- 22477 *Testing of Geotechnical Structures* (7 parts).

All 12 parts of 17892 on laboratory testing have been published by CEN as Technical Specifications (TSs), where a TS is a CEN normative document in an area where the state of the art is not yet sufficiently developed to allow agreement as an EN but it may be adopted as a national standard. The only part of 17892 to be published so far by BSI is Part 6, which was published in 2010 as the Document for Development (DD) DD CEN ISO/TS 17892–6:2004: *Geotechnical investigation and testing. Laboratory testing of soils. Fall cone* – A DD is a provisional document that needs further information and experience of its practical application before BSI can decide to support its conversion into an international standard. BSI is working closely with CEN to convert the TSs of 17892 to ENs and publish them as BSs.

The six parts of 22282 on geohydraulic testing have been issued by CEN for formal vote and it is anticipated that they will be published by BSI as BS EN ISOs in 2012 and supersede parts of BS 5930.

Part 1 of EN 22475 on sampling and groundwater measurement has been published by CEN as TSs and by BSI as a BS, superseding parts of BS 5930. Parts 2 and 3 have been published by BSI as DDs.

Three EN standard parts for geotechnical field tests that have been adopted as BSs are Parts 2, 3 and 12 of BS EN ISO 22476, the standards for dynamic probing, the standard penetration test, and mechanical cone penetration test which supersede parts of Part 9 of BS 1377 on *in situ* tests, while Parts 1–8 of BS 1377 remain as British Standards. Parts 1, 4–11 and 13 of ISO 22476 are at different stages of development. Part 10 has been published by CEN as a TS, Part 11 has been published by BSI as a DD, Parts 1, 4, 5, 7 and 9 are expected to be published in 2012, while Parts 6, 8 and 13 are still under development.

All parts of ISO 22477 on the testing of geotechnical structures are still being developed.

10.9.3 Codes and standards for geotechnical design

The British Standards concerned with geotechnical design are listed in **Table 10.4**. The first codes of practice listed in this table are those that were prepared and published by BSI prior to the publication of Eurocode 7:

- BS 6031 *Code of Practice for Earthworks*;
- BS 8002 *Code of Practice for Earth Retaining Structures*;
- BS 8004 *Code of Practice for Foundations*;
- BS 8006 *Code of Practice for Strengthened/Reinforced Soils and Other Fills*;
- BS 8081 *Code of Practice for Ground Anchorages*;
- BS 8103–1 *Code of Practice for Stability, Site Investigations, Foundations for Ground Floors for Housing*;
- CP 2012–1 *Code of Practice for Foundations for Machinery. Foundations for Reciprocating Machines.*

Since March 2010, the British Standard for geotechnical design is *Eurocode 7: Geotechnical design,* with its two parts:

- BS EN 1997–1 *Geotechnical Design: General Rules*;
- BS EN 1997–2 *Geotechnical Design: Ground Investigation and Testing*.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Reference	Title	Keywords/descriptors/abstract	Status
BS 5930:1999	Code of practice for site investigations	Site investigations, Soil surveys, Soil sampling, Soil testing, Groundwater, Rocks, Safety measures, Field testing, Excavations, Soil drilling, Aerial photography, Geological analysis, Sampling methods, Sampling equipment, Test specimens, Samples, Surveys, Geophysical measurement, Quality assurance, Reports, Classification systems, Density measurement	Amended in December 2007 to avoid conflict with newly introduced BS EN 1997–1 and retained as a normative reference
BS 1377–1: 1990	Methods of test for soils for civil engineering purposes – Part 1: General requirements and sample preparation	Soil sampling, Soil testing, Field testing, Sampling methods, Specimen preparation, Test equipment, Sampling equipment, Testing conditions, Laboratory testing, Soil-testing equipment	Current BS
BS 1377–2: 1990	Methods of test for soils for civil engineering purposes – Part 2: Classification tests	Soil classification tests, Water content determination, Test equipment, Specimen preparation, Liquid limit (soils), Soil-testing equipment, Testing conditions, Plastic limit (soils), Shrinkage tests, Density measurement, Relative density, Particle size distribution, Sedimentation techniques	Current BS
BS 1377–3: 1990	Methods of test for soils for civil engineering purposes – Part 3: Chemical and electro-chemical tests	Groundwater, Determination of content, Chemical analysis and testing, Organic matter determination, Specimen preparation, Ignition-loss tests, Sulfates, Gravimetric analysis, Carbonates, Volumetric analysis, Chlorides, Extraction methods of analysis, Solvent extraction methods, pH measurement, Electrical resistivity, Electrical measurement	Current BS
BS 1377–4: 1990	Methods of test for soils for civil engineering purposes – Part 4: Compaction related tests	Compaction tests, Soil compaction tests, Moisture measurement, Water content determination, Specimen preparation, Test equipment, Density measurement, Crushing tests, Impact testing, Compression testing, Soil bearing capacity, Penetration tests, Soaking tests	Current BS
BS 1377–5: 1990	Methods of test for soils for civil engineering purposes – Part 5: Compressibility, permeability and durability tests	Construction materials, Consolidation test (soils), Testing conditions, Compression testing, Calibration, Deformation, Mechanical testing, Specimen preparation, Test pressure, Swelling, Permeability measurement, Soil classification tests, Hydraulic tests, Sedimentation techniques, Frost susceptibility, Soil strength tests	Current BS
BS 1377–6: 1990	Methods of test for soils for civil engineering purposes – Part 6: Consolidation and permeability tests in hydraulic cells and with pore pressure measurement	Permeability measurement, Consolidation test (soils), Soils, Soil testing, Triaxial test (soils), Soil-testing equipment, Specimen preparation, Calibration, Testing conditions, Mathematical calculations, Reports, Soil strength tests, Test equipment, Construction	Current BS
BS 1377–7: 1990	Methods of test for soils for civil engineering purposes – Part 7: Shear strength tests (total stress)	Shear testing, Mechanical testing, Soil-testing equipment, Mathematical calculations, Specimen preparation, Testing conditions, Compression testing, Soil strength tests, Vane test, Triaxial test (soils)	Current BS
BS 1377–8: 1990	Methods of test for soils for civil engineering purposes – Part 8: Shear strength tests (effective stress)	Shear testing, Compression testing, Consolidation test (soils), Soil strength tests, Triaxial test (soils), Testing conditions, Test specimens	Current BS
BS 1377–9: 1990	Methods of test for soils for civil engineering purposes – Part 9: *In situ* tests	Field testing, Density measurement, Moisture measurement, Radiation measurement, Penetration tests, Soil strength tests, Soil bearing capacity, Vane test, Shear testing, Mechanical testing, Electrical testing	Partially superseded by BS EN ISO 22476–2 and 3
BS EN ISO 14688–1: 2002	Geotechnical investigation and testing. Identification and classification of soil – Part 1: Identification and description	The basic principles for the identification and classification of soils on the basis of those material and mass characteristics most commonly used for soils for engineering purposes. The general identification and description of soils is based on a flexible system for immediate (field) use by experienced persons, covering both material and mass characteristics by visual and manual techniques. Details are given of the individual characteristics for identifying soils and the descriptive terms in regular use, including those related to the results of tests from the field. Applicable to natural soils ***in situ,*** similar man-made materials ***in situ*** and soils redeposited by man	Introduced into UK practice in 2007 following amendment of BS 5930 published in 2007

Table 10.3 (continued)

BS EN ISO 14688–2: 2004	Geotechnical investigation and testing. Identification and classification of soil – Part 2: Principles for a classification	The basic principles for the identification and classification of soils on the basis of those material and mass characteristics most commonly used for soils for engineering purposes. The classification principles permit soils to be grouped into classes of similar composition and geotechnical properties, and with respect to their suitability for geotechnical engineering purposes. Applicable to natural soil and similar man-made material ***in situ*** and redeposited, but it is not a classification of soil by itself	Introduced into UK practice in 2007 following amendment of BS 5930 published in 2007
BS EN ISO 14689–1: 2003	Geotechnical investigation and testing. Identification and classification of rock. Identification and description	Identifies and describes rock material and mass on the basis of mineralogical composition, genetic aspects, structure, grain size, discontinuities and other parameters. It also provides rules for the description of various other characteristics as well as for their designation	Introduced into UK practice in 2007 following amendment of BS 5930 published in 2007
(BS EN ISO) 17892–1	Geotechnical investigation and testing – Laboratory testing of soil – Part 1: Determination of water content	This document specifies the laboratory determination of the water (moisture) content of a soil test specimen by oven-drying within the scope of the geotechnical investigations according to EN 1997–1 and 2	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will publish the EN as a BS
(BS EN ISO) 17892–2	Geotechnical investigation and testing – Laboratory testing of soil – Part 2: Determination of density of fine-grained soil	This document specifies methods of test for the determination of the bulk and dry density of intact soil or rock within the scope of the geotechnical investigations according to EN 1997–1 and EN 1997–2. This document describes three methods: (a) linear measurements method (b) immersion in water method (c) fluid displacement method	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will publish the EN as a BS
(BS EN ISO) 17892–3	Geotechnical investigation and testing – Laboratory testing of soil – Part 3: Determination of particle density – Pycnometer method	This document describes a test method for determining the particle density by the pycnometer method within the scope of the geotechnical investigations according to prEN 1997–1 and prEN 1997–2. The pycnometer method is based on the determination of the volume of a known mass of soil by the fluid displacement method	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will publish the EN as a BS
(BS EN ISO) 17892–4	Geotechnical investigation and testing – Laboratory testing of soil – Part 4: Determination of particle size distribution	This document describes methods for the determination of the particle size distribution of soil samples. The particle size distribution provides a description of soil, based on a subdivision in discrete classes of particle size. The size of each class can be determined by sieving and/or sedimentation	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will publish the EN as a BS
(BS EN ISO) 17892–5	Geotechnical investigation and testing – Laboratory testing of soil – Part 5: Incremental loading oedometer test	This document is intended for determination of the compression, swelling and consolidation properties of soils. The cylindrical test specimen is confined laterally, is subjected to discrete increments of vertical axial loading or unloading and is allowed to drain axially from the top and bottom surfaces	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will publish the EN as a BS
DD CEN ISO/ TS 17892–6: 2010	Geotechnical investigation and testing – Laboratory testing of soil – Part 6: Fall cone test	This DD specifies the laboratory determination of undrained shear strength of both undisturbed and remoulded specimens of saturated fine-grained cohesive soils by use of a fall-cone	Published by CEN as a TS in 2004 and published by BSI as a DD in 2010
(BS EN ISO) 17892–7	Geotechnical investigation and testing – Laboratory testing of soil – Part 7: Unconfined compression test on fine-grained soils	This document covers the determination of an approximate value of the unconfined compressive strength for a square or cylindrical water-saturated homogeneous specimen of undisturbed or remoulded cohesive soil of sufficiently low permeability to keep itself undrained during the time it takes to perform the test, within the scope of geotechnical investigations according to prEN 1997–1 and 2	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will publish the EN as a BS
(BS EN ISO) 17892–8	Geotechnical investigation and testing – Laboratory testing of soil – Part 8: Unconsolidated undrained triaxial test	This document describes the test method for the determination of the compressive strength of a cylindrical, water-saturated specimen of undisturbed or remoulded cohesive soil when first subjected to an isotropic stress without allowing any drainage from the specimen, and thereafter sheared under undrained conditions within the scope of the geotechnical investigations according to prEN 1997–1 and 2	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will published the EN as a BS

(BS EN ISO) 17892–9	Geotechnical investigation and testing – Laboratory testing of soil – Part 9: Consolidated trail compression tests on water-saturated soils	This document covers the determination of stress–strain relationships and effective stress paths for a cylindrical, water-saturated specimen of undisturbed, remoulded or reconstituted soil when subjected to an isotropic or an anisotropic stress under undrained or drained conditions and thereafter sheared under undrained or drained conditions within the scope of the geotechnical investigations according to prEN 1997–1 and 2	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will published the EN as a BS
(BS EN ISO) 17892–10	Geotechnical investigation and testing – Laboratory testing of soil – Part 10: Direct shear tests	This document specifies laboratory test methods to establish the effective shear strength parameter for soils within the scope of the geotechnical investigations according to prEN 1997–1 and 2	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will published the EN as a BS
(BS EN ISO) 17892–11	Geotechnical investigation and testing – Laboratory testing of soil – Part 11: Determination of permeability by constant and falling head	This document specifies laboratory test methods to establish the coefficient of permeability of water through water-saturated soils	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will published the EN as a BS
(BS EN ISO) 17892–12	Geotechnical investigation and testing – Laboratory testing of soil – Part 12: Determination of Atterberg limits	This document specifies methods of test for the determination of the Atterberg limits of a soil: the liquid limit, plastic limit and shrinkage limit. It also describes the determination of the liquid limit of a specimen of soil using the fall-cone method	Published by CEN as a TS but will not be published by BSI as a DD. BSI is working closely with CEN to convert the TS into an EN and will published the EN as a BS
(BS EN ISO) 22282–1	Geotechnical investigation and testing – Geohydraulic testing – Part 1: General rules	This document provides the general rules and principles for geohydraulic testing in soil and rock as part of a geotechnical investigation. It defines concepts and specifies requirements relating to permeability measurement in soil and rock	This has received a positive Formal Vote in CEN to be published as an EN. Subsequently it will be published by BSI as a BS
(BS EN ISO) 22282–2	Geotechnical investigation and testing – Geohydraulic testing – Part 2: Water permeability tests in a borehole using open systems	This document specifies requirements for determining the local permeability in soils and rocks above and below ground water level in an open hole by water permeability tests as part of a geotechnical investigation. It also includes requirements for estimating the permeability of unsaturated soils	This has received a positive Formal Vote in CEN to be published as an EN. Subsequently it will be published by BSI as a BS
(BS EN ISO) 22282–3	Geotechnical investigation and testing – Geohydraulic testing – Part 3: Water pressure tests in rock	This document deals with the requirements for water pressure tests (WPT) in boreholes drilled into rock to investigate the hydraulic properties of the rock mass, absorption capacity, tightness of the rock mass, effectiveness of grouting and geomechanical behaviour	This has received a positive Formal Vote in CEN to be published as an EN. Subsequently it will be published by BSI as a BS.
(BS EN ISO) 22282–4	Geotechnical investigation and testing – Geohydraulic testing – Part 4: Pumping tests	This document deals with requirements for pumping tests as part of a geotechnical investigation. It applies to pumping tests performed on aquifers whose permeability is such that pumping from a well can create a lowering of the piezometric head within hours or days, depending on the ground conditions and the purpose. It covers pumping tests carried out in soils and rock	This has received a positive Formal Vote in CEN to be published as an EN. Subsequently it will be published by BSI as a BS
(BS EN ISO) 22282–5	Geotechnical investigation and testing – Geohydraulic testing – Part 5: Infiltrometer tests	This document deals with requirements for infiltrometer tests as part of a ground investigation. The infiltrometer test is used to determine the infiltration capacity of the ground at the surface or shallow depth and the permeability coefficient. The principle of the test is based on the measurement of a surface vertical flow rate of water which infiltrates the soil under a positive hydraulic head	This has received a positive Formal Vote in CEN to be published as an EN. Subsequently it will be published by BSI as a BS
(BS EN ISO) 22282–6	Geotechnical investigation and testing – Geohydraulic testing – Part 6: Water permeability tests in a borehole using closed systems	This document specifies requirements for determination of the local permeability in soils and rocks above or below the ground water table in a closed system by the water permeability tests as part of a geotechnical investigation. The tests are used to determine the permeability coefficient k in low permeable soil and rock with k lower than 10^{-8} m/s. These can also be used to determine the transmissivity T and the storage coefficient S	This has received a positive Formal Vote in CEN to be published as an EN. Subsequently, it will be published by BSI as a BS

Table 10.3 (continued)

BS EN ISO 22475–1: 2006	Geotechnical investigation and testing. Sampling methods and groundwater measurements – Part 1: Technical principles for execution	Deals with the technical principles of sampling soil, rock and groundwater, and with groundwater measurements, in the context of geotechnical investigation and testing, as described in EN 1997–1 and EN 1997–2	Partially supersedes BS 5930:1999. Where conflict arises, BS EN ISO 22475–1:2006 should take precedence
BS 22475–2: 2011	Geotechnical investigation and testing. Sampling methods and groundwater measurements – Part 2: Qualification criteria for enterprises and personnel	This standard specifies the qualification criteria for an enterprise and for personnel performing sampling and groundwater measurement services, so that all have the appropriate experience, knowledge and qualifications as well as the correct equipment and groundwater measurements for the task to be carried out according to ISO 22475–1	Current BS
BS 22475–3: 2011	Geotechnical investigation and testing. Sampling methods and groundwater measurements – Part 3: Conformity assessment of enterprises and personnel by third party	This standard specifies the minimum criteria for external audit. It is applicable to the conformity assessment of enterprises and personnel performing specified parts of the sampling and groundwater measurements according to ISO 22475–1 and complying with the technical qualification criteria given in ISO/TS 22475–2 by third-party control	Current BS
(BS EN ISO) 22476–1	Geotechnical investigation and testing. Field testing – Part 1. Electrical cone and piezocone penetration tests	Geology, Penetration tests, Site investigations, Field testing	Publication expected 2012
BS EN ISO 22476–2: 2005	Geotechnical investigation and testing. Field testing – Part 2: Dynamic probing	This standard defines requirements for indirect investigations of soil by dynamic probing as part of geotechnical investigation and testing according to EN 1997–1 and 2	Current BS partially supersedes BS 5930:1999 and BS 1377–9:1990
BS EN ISO 22476–3: 2005	Geotechnical investigation and testing. Field testing – Part 3: Standard penetration test	This standard defines requirements for indirect investigations of soil by the standard penetration test as part of geotechnical investigation and testing according to EN 1997–1 and 2 to complement direct investigations	Current BS partially supersedes BS 5930:1999 and BS 1377–9:1990
(BS EN ISO) 22476–4	Geotechnical investigation and testing. Field testing. – Part 4: Ménard pressuremeter test	This document deals with field testing using the Ménard pressuremeter test as part of geotechnical investigation and testing	Publication expected 2012
(BS EN ISO) 22476–5	Geotechnical investigation and testing. Field testing. – Part 5: Flexible dilatometer test	This document deals with field testing using the flexible dilatometer as part of geotechnical investigation and testing	Publication expected 2012
(BS EN ISO) 22476–6	Geotechnical investigation and testing. Field testing. – Part 6: Self-boring pressuremeter test	No details available	Standard under development
(BS EN ISO) 22476–7	Geotechnical investigation and testing – Field testing – Part 7: Borehole jacking test	This document deals with field testing using the borehole jack test as part of geotechnical investigation and testing according to EN 1997–1 and 2	Publication expected 2012
(BS EN ISO) 22476–8	Geotechnical investigation and testing – Field testing – Part 8: Full displacement pressuremeter test	No details available	Standard under development
(BS EN ISO) 22476–9	Geotechnical investigation and testing – Field testing – Part 9: Field vane test	Soil mechanics, site investigations, field testing, soils, rocks, pressure testing, bore-holes	Publication expected 2012
CEN ISO/TS 22476–10: 2005	Geotechnical investigation and testing. Field testing – Part 10: Weight sounding test	This TS specifies laboratory test methods to establish the effective shear strength parameter for soils within the scope of the geotechnical investigations according to EN 1997–1 and 2. The test method consists of placing the test specimen in the direct shear device, applying a pre determined normal stress, providing for draining (and wetting if required) of the test specimen, or both, consolidating the specimen under normal stress, unlocking the frames that hold the specimen, and displacing one frame horizontally with respect to the other at a constant rate of shear deformation and measuring the shearing force and horizontal displacements as the specimen is sheared. Shearing is applied slowly enough to allow excess pore pressures to dissipate by drainage so that effective stresses are equal to total stresses. Direct shear tests are used in earthworks and foundation engineering for the determination of the effective shear strength of soils	Published by CEN as a TS but not published by BSI as a DD

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

DD CEN ISO/TS 22476–11: 2006	Geotechnical investigation and testing – Field testing – Part 11: Flat dilatometer test	Site investigations, Field testing, Soil testing, Soil mechanics, Soil profile, Penetration tests, Physical property measurement, Soil strength tests, Deformation, Construction operations, Dilatometry	Published by CEN as a TS and by BSI as a DD in 2006
BS EN ISO 22476–12: 2009	Geotechnical investigation and testing – Field testing – Part 12: Mechanical cone penetration test (CPTM)	Site investigations, Field testing, Soil testing, Soil mechanics, Soils, Soil profile, Penetration tests, Physical property measurement, Soil strength tests, Deformation, Soil-testing equipment	Current BS
(BS EN ISO) 22476–13	Geotechnical investigation and testing – Field testing – Part 13: Plate loading test	No details yet available	Standard under development
(BS EN ISO) 22477–1	Geotechnical investigation and testing – Testing of geotechnical structures – Part 1: Pile load test by static axially loaded compression test	No details yet available	Standard under development
(BS EN ISO) 22477–2	Geotechnical investigation and testing – Testing of geotechnical structures – Part 2: Pile load test by static axially loaded tension test	No details yet available	Standard under development
(BS EN ISO) 22477–3	Geotechnical investigation and testing – Testing of geotechnical structures – Part 3: Pile load test by static transversely loaded tension test	No details yet available	Standard under development
(BS EN ISO) 22477–4	Geotechnical investigation and testing – Testing of geotechnical structures – Part 4: Pile load test by dynamic axially loaded compression test	No details yet available	Standard under development
(BS EN ISO) 22477–5	Geotechnical investigation and testing – Testing of geotechnical structures – Part 5: Testing of anchorages	Soil mechanics, Testing, Structures, Load measurement, Anchorages, Temporary, Permanent, Design, Installation, Site investigations, Anchors, Tendons, Grouting, Corrosion protection, Corrosion-resistant materials, Sleeves (mechanical components), Inspection, Loading	Standard under development. Expected 2012
(BS EN ISO) 22477–6	Geotechnical investigation and testing – Testing of geotechnical structures – Part 6: Testing of nailing	No details yet available	Standard under development
(BS EN ISO) 22477–7	Geotechnical investigation and testing – Testing of geotechnical structures – Part 7: Testing of reinforced fill	No details yet available	Standard under development

Table 10.3 Codes and standards for geotechnical investigations and testing

Part 1 is intended to be applied to the geotechnical aspects of the design of buildings and civil engineering works and is concerned with the requirements for strength, stability, serviceability and durability of structures. Part 2 provides the requirements for the performance and evaluation of field and laboratory testing.

The UK National Annex to EN 1997–1 lists the following BSI publications as providing complementary, non-conflicting information: BS 1377, BS 5930, BS 6031, BS 8002, BS 8004, BS 8008, BS 8081 and PD 6694–1. PD 6694–1: *Recommendations for the Design of Structures Subject to Traffic Loading to BS EN 1997–1:2004*, was published by BSI in 2011 as a PD and and hence is not to be regarded as a British Standard. Another Eurocode part that is relevant to geotechnical design is Part 5 of EN 1993: *Design of steel structures: Piling.*

Many of the previous British Standards, such as BS 8002 and BS 8004, that have been superseded by EN 1997–1, were descriptive documents that have a broader scope than EN 1997, containing not only requirements for design aspects but also guidance on construction operations, construction materials, occupational safety and legislation, and including a bibliography as shown by the keywords for these standards in **Table 10.4**.

Reference	Title	Descriptors/scope	Comment
BS 6031:2009	Code of practice for earthworks	Earthworks, Land retention works, Construction engineering works, Design, Management, Risk assessment, Occupational safety, Site investigations, Soils, Classification systems, Soil mechanics, Structural design, Stability, Mathematical calculations, Design calculations, Shear strength, Embankments, Excavations, Trenches, Excavating, Landscaping, Drainage, Surface-water drainage, Groundwater drainage, Roads, Maintenance, Inspection, Construction equipment	Current BS, providing non-conflicting complementary information (NCCI) for BS EN 1997–1:2004 of August 2010
BS 8002:1994	Code of practice for earth-retaining structures	Retaining structures, Earthworks, Land retention works, Retaining walls, Design, Structural failure, Structural design, Loading, Foundations, Piles, Piling, Corrosion, Cofferdams, Embankments, Water retention and flow works, Maritime structures, Drainage, Bibliography	Superseded and withdrawn. Replaced by BS EN 1997–1:2004
BS 8004:1986	Code of practice for foundations	Design and construction of foundations for the normal range of buildings and engineering structures, excluding foundations for special structures. General design, shallow, deep and subaqueous foundations, cofferdams and caissons, pile foundations; guidance on geotechnical processes; also tide work, underwater concreting, diving and site preparation for foundation work. Durability of timber, metal and concrete structures. A special reference is made to safety precautions	Superseded and withdrawn. Replaced by BS EN 1997–1:2004
BS 8006–1:2010	Code of practice for strengthened/reinforced soils and other fills	Soil mechanics, Reinforced materials, Soils, Reinforcement, Reinforcing materials, Construction materials, Design, Plastic analysis, Structural design, Performance, Life (durability), Loading, Factor of safety, Stability, Dimensions, Embankments, Earth fills, Foundations, Walls, Retaining walls, Retaining structures, Earthworks, Land retention works, Maintenance, Soil testing, Soil strength tests, Tensile strength, Fasteners	Replaces BS 8006:1995 This standard should be read in conjunction with BS EN 1997–1:2004, UK National Annex (NA) to BS EN 1997–1:2004 and BS EN 14475:2006
BS 8081: 1989	Code of practice for ground anchorages	Anchorages, Structural members, Foundations, Structural design, Structural systems, Design, Construction systems, Wall anchors, Construction systems parts, Soils, Site investigations, Bolts, Rocks, Stress analysis, Corrosion, Corrosion protection, Tendons, Safety measures, Approval testing, Acceptance (approval), Maintenance, Grouting, Rock bolts	Current BS. Partially superseded by BS EN 1957, which is currently being revised
BS 8103–1:1995	Structural design of low-rise buildings – Part 1: Code of practice for stability, site investigation, foundations and ground floor slabs for housing	Buildings, Housing, Structural design, Design, Structural systems, Masonry work, Stability, Site investigations, Foundations, Strip foundations, Footings, Concretes, Slab floors, Dimensions, Shape, Wind loading, Loading, Walls, Load-bearing walls, Structural members	Current BS There is a project under way to revise this standard but a document has yet to be published
CP 2012–1:1974	Code of practice for Foundations for machinery. Foundations for reciprocating machines	Foundations, Structural systems, Structural design, Design, Site investigations, Vibration, Vibration control, Concretes, Dimensions, Fixing, Reinforced concrete, Pile foundations, Vibration dampers, Vibration measurement, Design calculations, Seatings, Construction operations, Grouting, Bibliography, Reciprocating parts	Current BS
BS EN ISO 13793:2001	Thermal performance of buildings. Thermal design of foundations to avoid frost heave	Buildings, Foundations, Thermal behaviour of structures, Thermal design of buildings, Ground movement, Climatic protection, Frost, Frost resistance, Thermal insulation, Thermal resistance, Slab floors, Suspended floors, Construction systems parts, Structural systems	Current BS
BS EN 1997–1:2004 + Corrigendum January 2010	Eurocode 7 Geotechnical design – Part 1: General rules	Soil mechanics, Structural systems, Buildings, Construction engineering works, Structural design, Construction operations, Foundations, Pile foundations, Retaining structures, Embankments, Subsoil, Anchorages, Mathematical calculations, Design calculations, Site investigations, Stability	Current BS The UK National Annex 2007 to BS EN 1997–1:2004 + Corrigendum No. 1 of 1 December 2007 are to be read with this standard

BS EN 1997–2:2007 + Corrigendum October 2010	Eurocode 7 Geotechnical design – Part 2: Ground investigation and testing	Soil mechanics, Structural systems, Buildings, Construction engineering works, Structural design, Site investigations, Soil testing, Soil sampling, Soils, Rocks, Ground water, Soil surveys, Laboratory testing, Field testing, Soil classification tests, Mechanical testing, Physical property measurement, Chemical analysis and testing	Current BS. The UK National Annex 2009 to BS EN 1997–2:2007 is to be read with this standard
BS EN 1993–5:2007 + Corrigendum August 2009	Eurocode 3 Design of steel structures – Part 5: Piling	Steels, Buildings, Structures, Structural systems, Construction engineering works, Structural design, Piling, Piles, Pile driving, Foundations, Sheet materials, Walls, Retaining walls, Anchorages, Mathematical calculations, Loading, Verification	Current BS. The UK National Annex 2009 to BS EN 1993–5:2007 is to be read with this standard
PD 6694–1: 2011	Recommendations for the design of structures subject to traffic loading to BS EN 1997–1:2004	Bridges, Construction engineering works, Traffic, Traffic control, Traffic flow, Spreaders, Foundations, Pile foundations, Retaining walls, Retaining structures	Current PD, not to be regarded as a British Standard

Table 10.4 Codes and standards for geotechnical design

In view of this, and in order not to lose this information, the existing BSs for geotechnical design either have been or will be revised to provide 'residual' documents with non-conflicting complementary information in support of BS EN 1997. Until such time as 'residual' documents are prepared, the Eurocode takes precedence.

The UK National Annex of EN 1997–1 notes that it does not cover the design and execution of reinforced soil structures. It states that, in the UK, the design and execution of reinforced fill structures and soil nailing should be carried out in accordance with BS 8006, BS EN 14475 and prEN 14490 (since superseded by BS EN 14490) and the partial factors set out in BS 8006 should not be replaced by similar factors from Eurocode 7. prEN is an acronym for pre-European norm, in other words, a Draft European Standard.

Another standard for geotechnical design published by BSI but prepared by ISO is BS EN ISO 13793 *Thermal Performance of Buildings. Design of Foundations to Avoid Frost Heave*. This is referred to in the application rule 6.4(3) of EN 1997–1.

10.9.4 Codes and standards for geotechnical construction

The British Standards concerned with the construction aspects of geotechnical engineering, or, to use the CEN terminology, the execution of geotechnical work, are listed in **Table 10.5**. The first standards listed in this table are those that have been prepared by BSI and not by CEN, namely:

- BS 8008 *Safety Precautions and Procedures for the Construction and Descent of Machine-bored Shafts for Piling and other Purposes*;
- BS 8102 *Code of Practice for Protection of Structures against Water from the Ground*.

CEN has recently prepared a comprehensive range of standards for the construction aspects of geotechnical engineering, all with the umbrella title *Execution of Special Geotechnical Works*. These standards cover more than the construction aspects covered by the superseded British Standards BS 8002 and 8004 and, except for the standard for soil nailing, have all been published by BSI as British Standards with the prefix BS EN. These 12 standards are:

- BS EN 1536 *Bored Piles*;
- BS EN 1537 *Ground Anchors*;
- BS EN 1538 *Diaphragm Walls*;
- BS EN 12063 *Sheet Pile Walls*;
- BS EN 12699 *Displacement Piles*;
- BS EN 12715 *Grouting*;
- BS EN 12716 *Jet Grouting*;
- BS EN 14199 *Micropiles*;
- BS EN 14475 *Reinforced Fill*;
- BS EN 14679 *Deep Mixing*;
- BS EN 14731 *Ground Treatment by Deep Vibration*;
- BS EN 15237 *Vertical Drainage.*

As noted in **Table 10.4**, BS EN 1537, covering the construction aspects of ground anchorages, partially replaces BS 8081; and BS EN 14475, covering the construction aspects of reinforced fill, partly replaces BS 8006. The execution standards EN 1536, EN 1537, EN 12063, EN 12699 and EN 14199 are referred to in principles and application rules in Sections 7 and 8 of EN 1997–1 on *Pile foundations and Anchorages*.

10.9.5 Codes and standards for geotechnical materials

Three CEN standards published by BSI that have been prepared for the specific use of certain materials in geotechnical engineering are listed in **Table 10.6** and are:

- BS EN 12794 *Precast Concrete Products*;
- BS EN ISO 13433 *Geosynthetics. Dynamic Perforation Test (Cone Drop Test)*;

Reference	Title	Abstract/Descriptors/Keywords	Comment
BS 8008:1996 + A1:2008	Safety precautions and procedures for the construction and descent of machine-bored shafts for piling and other purposes	Safety engineering, Occupational safety, Safety measures, Emergency measures, Accident prevention, Rescue, Rescue equipment, Underground, Lighting systems, Safety harnesses, Breathing apparatus, Construction equipment, Lifting equipment, Hoists, Passenger hoists, Air compressors, Personnel, Construction workers, Training, Communication equipment, Hazards, Working conditions (physical), Industrial accidents, Piling, Site investigations, Construction operations, Foundations, Pile foundations, Trenches, Access, Barriers, Guard rails, Restraint systems (protective), Hoisting cages, Dangerous materials, Toxic materials, Earthworks	Current BS. The status of this standard is 'Project Underway' which means that there is a project underway to revise it but a document has yet to be published
BS 8102:2009	Code of practice for protection of structures against water from the ground	Protection against water from the ground, Underground structures, Structural design, Buildings, Basements, Waterproofing materials, Waterproof materials, Vapour barriers, Ground-water drainage, Drainage, Grades (quality), Tanking, Site investigations, Render, Construction materials, Weather protection systems, Risk assessment	Current BS
BS EN 1536:2010	Execution of special geotechnical works – Bored piles	Piles, Foundations, Structural systems, Piling, Circular shape, Metal sections, Construction operations, Pile driving, Soil mechanics, Site investigations, Concretes, Grouting, Portland cement, Blast-furnace cement, Cements, Aggregates, Bentonite, Polymers, Steels, Design, Tolerances (measurement), Excavating, Excavations, Boring, Reinforcement, Loading, Records (documents)	Current BS
BS EN 1537:2000	Execution of special geotechnical works – Ground anchors	Soil mechanics, Anchorages, Temporary, Permanent, Design, Installation, Site investigations, Anchors, Tendons, Steels, Grouting, Corrosion protection, Corrosion-resistant materials, Sleeves (mechanical components), Approval testing, Inspection, Mechanical testing, Electrical testing, Electrical resistance, Resistance measurement, Loading, Technical data sheets, Records (documents)	Current BS. Has superseded parts of BS 8081:1989 dealing with anchorages. Currently being revised
BS EN 1538:2010	Execution of special geotechnical works – Diaphragm walls	Soil mechanics, Walls, Construction systems parts, Retaining walls, Concretes, Precast concrete, Reinforced materials, Slurries, Mortars, Bentonite, Suspensions (chemical), Design, Panels, Dimensional tolerances, Non-load-bearing walls, Construction operations, Excavating, Quality control, Technical documents, Technical data sheets	Current BS
BS EN 12063:1999	Execution of special geotechnical work – Sheet pile walls	Foundations, Pile foundations, Sheet-pile foundations, Structural members, Prefabricated parts, Walls, Permanent, Temporary, Construction systems parts, Anchorages, Steels, Wood, Information, Instructions for use, Site investigations, Design, Selection, Construction materials, Construction operations, Welding, Welded joints, Joints, Dimensions, Dimensional tolerances, Angles (geometry), Tolerances of position, Occupational safety, Safety measures, Excavating, Drainage, Performance testing, Records (documents), Storage, Lifting, Installation, Waterproof materials, Equations, Pressure measurement (fluids), Defects	Current BS
BS EN 12699:2001	Execution of special geotechnical work – Displacement piles	Piling, Soil mechanics, Structural systems, Excavations, Excavating, Piles, Steels, Cast iron, Concretes, Wood, Grouting, Site investigations, Design, Pile driving, Construction operations	Current BS
BS EN 12715:2000	Execution of special geotechnical work – Grouting	Soil mechanics, Grouting, Foundations, Site investigations, Design, Stabilised soils, Soils, Construction materials, Safety measures	Current BS
BS EN 12716:2001	Execution of special geotechnical works – Jet grouting	Soil mechanics, Grouting, Foundations, Site investigations, Design, Mechanical testing	Current BS
BS EN 14199:2005	Execution of special geotechnical works – Micropiles	Soil mechanics, Piles, Working load limit, Structures, Foundations, Transfer processes (physics), Loading, Structural design, Construction operations, Construction systems, Reinforcement, Soil settlement, Stability	Current BS

BS EN 14475:2006	Execution of special geotechnical works – Reinforced fill	Soil mechanics, Earthworks, Earth fills, Reinforced materials, Soils, Reinforcement, Reinforcing materials, Construction materials, Design, Structural design, Performance, Life (durability), Loading, Stability, Dimensions, Embankments, Foundations, Soil testing, Tensile strength, Retaining structures	Partially replaces BS 8006:1995
BS EN 14679:2005	Execution of special geotechnical works – Deep mixing	Structural systems, Construction operations, Soil mechanics, Excavations, Mixing, Slurries, Binding agents, Water, Particulate materials, Mixers, Deep foundations	Current BS
BS EN 14731:2005	Execution of special geotechnical works – Ground treatment by deep vibration	Soil mechanics, Construction operations, Compacting, Site investigations, Vibrators (compacting), Compacting equipment, Vibration, Foundations, Structural systems	Current BS
BS EN 14490:2010	Execution of special geotechnical works – Soil nailing	Soil mechanics, Stability, Earthworks, Land retention works, Excavations, Embankments, Tunnels, Stabilised soils, Reinforced materials, Reinforcement, Nailing, Reinforcing materials, Design, Construction operations, Loading, Structural design, Durability, Mechanical testing	Partially replaces BS 8006:1995. Supersedes the prEN version referred to in the UK NA to EN 1997–1 to be used with BS 8006
BS EN 15237:2007	Execution of special geotechnical works – Vertical drainage	Soil mechanics, Vertical drainage, Groundwater drainage, Surface-water drainage, Soils, Soil settlement, Soil improvement, Sand, Prefabricated parts, Geotextiles, Stability, Structural design, Inspection, Construction engineering works	Current BS

Table 10.5 Codes and standards for the execution of geotechnical work

Reference	Title	Abstract/descriptors/keywords	Comment
BS EN 12794:2005	Precast concrete products. Foundation piles	Concretes, Precast concrete, Reinforced concrete, Pile foundations, Pressurised concrete, Performance, Conformity, Marking, Testing conditions	Current BS
BS EN ISO 13433:2006	Geosynthetics. Dynamic perforation test (cone drop test)	Geosynthetic materials, Geotextiles, Textile testing, Fabric testing, Perforating tests, Impact testing, Penetration tests, Drop tests, Test specimens, Specimen preparation, Testing conditions, Test equipment	Current BS. Replaces BS EN 918:1996
BS EN ISO 13437:1998	Geotextiles and geotextile-related products. Method for installing and extracting samples in soil, and testing specimens in laboratory	Geotextiles, Textile products, Textiles, Textile testing, Fabric testing, Performance testing, Durability, Life (durability), Endurance testing, Environmental testing, Environment (working), Test specimens, Installation, Sampling methods, Mechanical testing, Testing conditions, Control samples, Specimen preparation, Visual inspection (testing), Forms (paper), Laboratory testing	Current BS
BS EN ISO 13438:2004	Geotextiles and geotextile-related products. Screening test method for determining the resistance to oxidation	Geotextiles, Textile products, Oxidation resistance, Polypropylene, Polyethylene, Chemical analysis and testing, Screening (sizing)	Current BS

Table 10.6 Codes and standards for materials used in geotechnical engineering

- BS EN ISO 13437 *Geotextiles and Geotextile Products. Method for Installing and Extracting Samples in Soil, and Testing Specimens in Laboratory*.

10.10 Conclusions

Geotechnical design in the UK has moved into a new era, dominated by codes and standards prepared by CEN and published by BSI. Those involved in geotechnical design need to know the new codes and standards, in particular Eurocode 7 and its associated standards, and how to apply them. The move from the traditional permissible-stress design method with overall factors of safety, to the limit state design method with partial factors, presents challenges and opportunities for the geotechnical designer. The special features of soil have influenced the codes and standards for geotechnical design, causing the geotechnical design components to differ from those for structural design. The components of geotechnical design, as embodied in Eurocode 7, are explained and have been presented in the form of the geotechnical design triangle. The geotechnical design triangle is presented as a concept to clarify and improve understanding of the geotechnical design process.

11.1	Introduction	125
11.2	Sustainability objectives – background	125
11.3	Geotechnical sustainability themes	128
11.4	Sustainability in geotechnical practice	134
11.5	Summary	135
11.6	References	135

Sustainability is undoubtedly the biggest challenge facing engineering in the 21st century. Natural resources are fast depleting, traditional energy production methods are becoming too expensive (post peak oil, etc.), water is turning into a precious and scarce commodity, climatic conditions are changing – threatening existing infrastructure and requiring mitigation measures. Geotechnical engineers need to demonstrate their capacity to make geotechnical practice sustainable and their ability to deliver developments which satisfy all three elements of sustainability: environmental conservation, social betterment and economic improvement.

This chapter discusses the relevance of the sustainability objectives to geotechnical engineering, and how geotechnical engineers may engage with the objectives during the design and construction process.

11.1 Introduction

Sustainability is potentially the widest ranging and most engaging issue for engineering development in the 21st century. Engineers have a key role to play in ensuring that present and future development is carried out according to sound sustainability principles.

According to the Brundtland (WCED, 1987) definition:

> Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs.

The emphasis of the Brundtland definition is that sustainable development must include all three elements – environmental, social and economic – also known as the 'triple bottom line'.

Sustainable engineering practice ultimately aims to ensure that the interface between the natural and engineered environment is harmonious and good design is an essential part of it.

Sustainability is a far-reaching subject, encompassing issues such as worldwide transport, economic and political stability, climate change and energy security, which cannot be fully addressed here. This chapter explores the sustainability framework for civil engineering and how it is interpreted in geotechnical engineering. The points discussed here are mainly UK-centric, focusing on the sustainability aspects that directly involve geotechnical engineering.

11.2 Sustainability objectives – background

Within the triple bottom line context, but more specifically focused on civil engineering and geotechnics, seven key sustainability objectives have been identified, as shown in **Table 11.1** (an evolution of the Buildings Sustainable Design Strategy (Arup, 2010)), setting the framework for sustainable development.

Triple bottom line sustainability objectives		Environmental	Social	Economic
1	Energy efficiency and carbon reduction	•	•	•
2	Materials and waste reduction	•	•	•
3	Maintained natural water cycle and enhanced aquatic environment	•	•	•
4	Climate change adaptation and resilience		•	•
5	Effective land use and management	•	•	•
6	Economic viability and whole-life cost		•	•
7	Positive contribution to society		•	

Table 11.1 Sustainability objectives in civil engineering and geotechnics

11.2.1 Energy efficiency and carbon reduction

Mackay (2008) gives three reasons why our addiction to fossil fuels is unsustainable:

> First, easily accessible fossil fuels will at some point run out, so we'll eventually have to get our energy from someplace else. Second, burning fossil fuels is having a measurable and very-probably dangerous effect on the climate. Avoiding dangerous climate change motivates an immediate change from our current use of fossil fuels. Third, even if we don't care about climate change, a drastic reduction in Britain's fossil fuel consumption would seem a wise move if we care about security of supply: continued rapid use of the North Sea oil and gas reserves will otherwise soon force fossil-addicted Britain to depend on imports.

Embodied energy (EE) and embodied carbon (ECO_2) are the two most commonly used indicators for quantifying the environmental impact of a structure. Hammond and Jones (2008) define EE as the total primary energy consumed during the lifetime of a product. Ideally, the boundaries would be set from the extraction of raw materials (including fuels) to the end of the product's lifetime (including energy from manufacturing and the manufacturing of capital equipment, transport, heating and lighting of factories). ECO_2 is an expression of the same environmental impact but in terms of CO_2 emitted in the environment rather than energy consumed.

Energy efficiency also has social implications; society will only be able to function with a continuity of energy supply. It also has economic consequences, as the cost of energy is likely to rise. Energy efficiency introduces the fundamental conundrum: build new (infra)structures with lower operational costs, or adapt existing (infra)structures and accept higher operational costs. New constructions often generate additional energy use, as in the case of a new highway.

11.2.2 Materials and waste reduction

Producing traditional construction materials (e.g. concrete and steel) is energy intensive and resource hungry. Natural resources are depleting and there is a need to find more sustainable ways of producing construction materials. The emphasis should be on re-using materials, recycling aggregates, incorporating cement replacement additives and returning to more sustainable forms of construction materials such as wood (from sustainably managed sources). Responsible sourcing of materials (RSM) is also an important consideration in construction, with both social and whole-life cost implications (BES 6001, 2009).

A significant by-product of the construction industry is waste. Waste generated by construction, demolition, excavation and refurbishment in the UK amounts to over 100 million tonnes per year, a third of the country's total waste production (DEFRA, 2007b). Reducing waste not only benefits the environment, but also makes good business sense. The true costs of waste are not just related to disposal. They include hidden costs such as the purchase of unused materials, handling and processing costs, management and time, lost revenues or potential business liabilities and risks (Foresight, 2009).

Tackling waste has many facets. DEFRA (2007a) introduced the inverted triangle of waste hierarchy: reduce, re-use, recycle – see **Figure 11.1**.

11.2.3 Maintained natural water cycle and enhanced aquatic environment

Water is one of the most important elements of the natural environment. It is a resource that may become less readily available. Water availability is unevenly distributed geographically; in some parts of the world significant investment in energy and infrastructure is required to transport it to where it is needed. Water pollution and shortage of water are key social (and economic) issues – as the recent problems in Northern Ireland (December 2010), Pakistan (August 2010) and Queensland flooding (January 2011) show.

The aquatic environment is a dynamic system and its equilibrium may be easily disrupted by artificial intervention with far-reaching, unanticipated consequences. Planning and managing what impact buildings and infrastructure have on the natural water cycle is paramount. Every engineering project should be actively dealing with:

- safeguarding and enhancing the quantity and quality of water resources in lakes, rivers and groundwater;
- minimising the project's impact on local water systems and their functions;
- minimising the project's impact on the wider water cycle and its dependants;
- valuing water appropriately in optimising project development, construction and operation choices.

The Environment Agency (2009) gives an overview of the existing pressures and future threats on the water environment and proposes a strategy to reduce pressures and improve resilience to climate change.

11.2.4 Climate change adaptation and resilience

Climate change is happening and is increasingly testing the robustness of existing infrastructure and building stock. Climate change adaptation (CCA) is the process of reducing vulnerability to the physical impacts of climate change, such as more severe weather, and long-term changes in temperature, rainfall and sea level rise. The role of CCA is to ensure robustness and longevity of a project under changing climatic conditions. Project design needs to take current climatic conditions and

future changes into consideration. Retrofitting existing infrastructure and building stock needs to take place to accommodate extreme weather events, sea level rise and other direct and indirect consequences of global warming.

The main impacts associated with climate change are likely to be:

- overheating: resulting from average and extreme summer temperatures, high solar irradiance;
- flood risk – coastal, fluvial (river) and pluvial (drainage): resulting from sea-level rise, increased rainfall and groundwater level fluctuation;
- water scarcity: resulting from changes in seasonal precipitation and drought risk, as well as areas with increasing demographics;
- structural failure: resulting from extreme storms;
- erosion and landslip: resulting from increased rainfall frequency and intensity;
- subsidence: resulting from changes in groundwater regime and rainfall;
- loss of green landscape and biodiversity: resulting from changes in seasonal precipitation and drought risk, change in the timing of the seasons and deforestation;
- air quality deterioration: resulting from increased sunshine hours, heat waves, wind speeds and direction, pollution.

Climate change scenarios (CCSs) provide quantitative information from climate models regarding future changes in different aspects of climate and sea-level rise under different scenarios for greenhouse gas emissions. They may be used as a basis for qualitative or quantitative CCA assessments and options appraisals. The UK currently has well developed scenarios issued by the UK Climate Impacts Programme (UKCIP) on behalf of the government. These scenarios are disseminated via the UKCIP website (www.ukcip.org.uk) and have been widely used for academic and commercial consultancy projects. Hacker *et al.* (2005) give helpful guidance on the use of the CCSs on designing a building; they are equally applicable to infrastructure designs.

11.2.5 Effective land use management

Population increase, combined with the legacy of uncontrolled historic industrial development, calls for a sustainable strategy for land use, balancing the needs for housing (and infrastructure), industry and agriculture. The Environment Agency (2005) has estimated that 300 000 hectares of land at over 325 000 sites in England and Wales are potentially affected by contamination from previous industrial land use. Over 250 new sites have been classified as contaminated each year since 2000. Remediation and re-development of brownfield sites with various levels of contamination should become a priority to reduce development on greenfield land, where appropriate and financially viable in whole-life cost terms.

More specifically, within an urban landscape where space and land availability are at a premium, pushing effective land use to its limits by seeking additional space underground in deep basements and tunnels is becoming the solution of choice. Moreover, enhancement or creation of agricultural land nearer the consumers (urban agriculture) may soon become a necessity, challenging the current boundaries between city and rural environments.

11.2.6 Economic viability and whole-life cost

The cost of construction (materials and labour) has been the traditional driver for the development of any civil engineering design and will always be one of the main decision factors for a project. It is the single, overarching indicator of value and benefit for any activity. However, cost should be considered in a holistic manner, taking into account the social and environmental impact relative to the economic impact during the operational life and beyond. Is the cheapest solution the most sustainable one, or is a cost premium sometimes necessary to minimise environmental and societal impacts?

Recent work in the US (Chester and Horvath, 2009) highlights the importance of a holistic approach to the provision of new transport and infrastructure. It puts into context the relative contribution (in carbon and energy terms) of the construction of infrastructure on which the transport operates. As an example, for a given road alignment, an optimised vertical profile which seeks to minimise changes in gradient and associated fuel consumption would yield substantial environmental benefits beyond the construction choices embedded in the construction of the road itself (O'Riordan *et al.*, 2011).

Economic viability must also address legacy issues including maintenance, change of use and decommissioning. It puts whole-life management at the heart of any sustainable engineering project, giving appropriate weight to financial, environmental and societal considerations. The aim is to produce:

- buildings and infrastructure which are fit for the intended purpose;
- durable, low maintenance buildings and infrastructure;
- an infrastructure flexible for successful adaptation beyond its design life;
- minimal social, environmental and economic impacts during construction and operation.

11.2.7 Positive contribution to society

Civil engineering can have a positive influence on people's lives, improving the local environment, economy, etc. However, projects can also have negative impacts to society and these must be explored.

Understanding the societal impacts of an engineering project requires an appreciation of who the stakeholders are and establishing whether the project objectives are consistent with their needs, interests and capacities. The social impact assessment on the various stakeholders, particularly vulnerable groups, includes a study of population characteristics, political,

social and community resources, community and institutional structures, as well as their cultural practices, beliefs and values systems.

Social risks that may affect the success of a project include community severance and displacement; nuisance to neighbours; loss of livelihood; impact on quality of life; loss of trust; loss of community stability; loss of historically and culturally significant places or artefacts.

A project can positively contribute to society by avoiding such risks and ensuring stakeholder satisfaction through early consultation and engagement at the masterplanning and design stages. Government bodies such as the Environment Agency, Olympic Delivery Authority and Transport for London *inter alia* are increasingly adopting policies and appraisal methodologies that encourage good practice approaches to social sustainability.

11.3 Geotechnical sustainability themes

How can geotechnical engineers adapt their traditional practices to this sustainability framework? They need to embrace a combination of imaginative creativity, holistic thinking and common sense. Geotechnical input can contribute to the sustainable design from early stages. The requirement for sustainable geotechnical development brings opportunities and endless new areas of growing interest and business, with sustainability focus for geotechnical engineers. Following the seven-point framework outlined in the previous section, the opportunities for geotechnical engineering contribution to sustainability are outlined below.

11.3.1 Energy and carbon

11.3.1.1 Environmental impact indicators

The first step in reducing the carbon footprint of geotechnical structures is to understand design and construction processes and quantify their energy consumption and contribution to carbon emissions in the environment.

There are established methodologies for assessing the EE and ECO_2 of a structure and these also apply to geotechnical structures. Comparing carbon emissions of different types of foundations, together with a comparison of their cost, can be an effective option selection tool for foundation design.

Appendix J of the NHBC guidance on piled foundations (NHBC, 2010) shows such a comparison for the foundation solution of a typical low rise building: it demonstrates that the traditionally favoured deep trench foundations have a significantly higher carbon footprint than the equivalent piled foundation option.

On a larger scale, Pantelidou *et al.* (2011) carried out a carbon emissions comparison of the various components of a new motorway. They estimated that earthworks (always a significant part of a linear infrastructure project) were only responsible for 6% of the total CO_2 emitted during construction, almost an order of magnitude less than the emissions attributed to the pavement construction (42% of the total emissions, **Figure 11.2**), thus identifying pavement construction as the big carbon emitter and where the focus for carbon reduction should be concentrated.

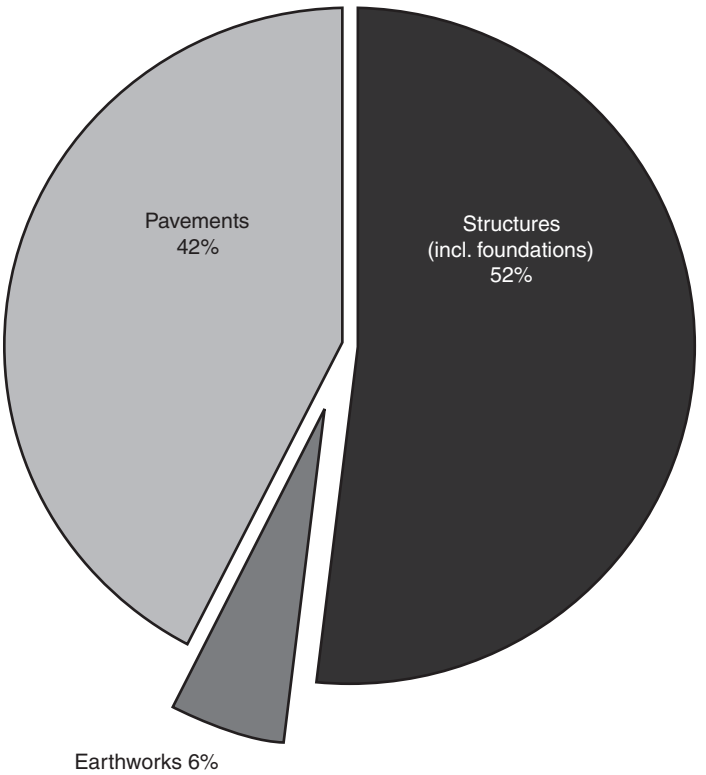

Figure 11.2 Construction and operational CO_2 emissions for a UK motorway project
Data taken from Pantelidou *et al.* (2011)

Within the context of whole-life assessment, construction emissions were compared with the vehicle emissions during the operational life of the motorway, suggesting that construction emissions are equivalent to the first four years of operation.

11.3.1.2 Ground energy

The need for alternative means of energy generation has provided new opportunities for geotechnical engineers. The ground is not only used for supporting the structure, but also for providing energy. Geothermal energy is heat stored in the earth's core. It originates from the radioactive decay of minerals and solar energy absorbed at the surface. The background to the development of geothermal energy is described by Dickenson and Fanelli (2004). Geothermal energy has three main uses: electricity generation, district heating and ground source heat pump (GSHP), described below.

1. *Electricity generation systems.* Conventional geothermal plants use water at temperatures greater than 180°C and binary power plants use water in the range 80–180°C. Electricity generation is mainly associated with the tectonic plate boundaries where fault lines and volcanic activity provide easy access to high temperature ground water in fractured permeable rock masses at relatively shallow depths,

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

say 1 km. Extraction and injection wells are used to circulate and reheat the water in the rock mass. Heat exchangers are used to transfer the heat to steam, which then powers electricity generators. The waste heat from the generators may also be used for district heating systems. Within the tectonic plates are areas of rock, e.g. granites, which are undergoing radioactive decay and generate heat. An example of this can be found at Cornwall's granite outcrop in the UK. In these areas, the rock mass permeability may be low and Enhanced (Engineered) Geothermal Systems (EGS) are used to hydraulically fracture and improve the rock mass permeability (Tester, 2007). These systems transfer the heat through heat exchanges to power electrical turbines. The EGSs are currently under development.

2. *District heating systems* use water in the range 30–120°C that is not hot enough to generate electricity, but can be used in a heating ring mains to supply neighbouring buildings. This geological source of heat can be used with boreholes to shallower depths because of the lower temperature requirements. Additional geological sources of heat for district heating are the deep aquifers capped with impermeable insulating layers. In the UK, the Southampton geothermal project is an example of this type of district heating system, using boreholes about 2 km deep (Southampton City Council, 2009).
3. *Ground source heat pump (GSHP) systems* use the low temperature (<30°C) zone to depths of less than 300 m, where the temperatures are controlled by solar energy as well as thermal gradient. In the UK, the average annual ground surface temperature is about 12°C with a thermal gradient of about 3°C per 100 m. The GSHP systems are used to increase the temperatures to between 30°C and 55°C for heating buildings and domestic hot water. Alternatively, the ground water can be used for directly cooling buildings or in conjunction with heat pumps (Banks, 2008). In many shallow systems, the ground is used as a thermal store with heat extracted during the winter and replenished during the summer. The GSHP systems can be classified as:

- *Closed systems* – horizontal loops, vertical boreholes where the heat transfer is by conduction. These systems can also be incorporated into piles, walls and tunnels (Brandl, 2006) and house foundations (NHBC, 2010).
- *Open systems* – ground water is pumped from wells, then through heat exchangers and returned to the ground via injection wells. In this case the circulating water transfers the heat to and from the surrounding ground. This process is known as advection.

11.3.1.3 Carbon capture and storage

It is recognised that we will continue to need fossil fuels as part of a diverse energy mix for some time, but the use of coal and gas must become cleaner. Carbon capture and storage (CCS) is an emerging combination of technologies which could reduce emissions from fossil fuel power stations by as much as 90% (IPCC, 2005).

Supercritical/dense phase CO_2 transportation via pipeline is likely to be preferred as it is relatively stable compared to liquid CO_2. CO_2 can be stored (long term) in geological formations (also known as geo-sequestration). There are three basic types of geological formations that are widespread and which have adequate CO_2 storage potential: deep aquifers, oil and gas reservoirs, and deep, unmineable coal seams. CCS provides new challenges and opportunities for geotechnical engineers, with skills required in areas such as geo-hazard assessment for site locations and engineering of deep underground storage.

11.3.2 Materials and waste

11.3.2.1 Lean design

Geotechnical engineering has evolved using appropriately applied conservatism to counteract the ground variability and uncertainty. A sustainable geotechnical design should aim to eliminate conservatism by optimising the interlinked components of geotechnics on Burland's triangle (Chapter 4 *The geotechnical triangle*): theoretical modelling, experimentation (ground investigation) and empiricism. An efficient geotechnical design makes optimum use of construction materials and hence reduces impact on natural resources – the waste prevention part at the top of the waste hierarchy inverted triangle of **Figure 11.1**.

11.3.2.2 Intelligent material choice

Consideration of the environmental impact and appropriate specification of the construction materials adopted for geotechnical structures is important: choosing between steel and concrete as a structural material, specifying a minimum requirement for recycled content of steel and steel reinforcement, encouraging use of recycled aggregates and cement replacement additives in concrete, and considering earthworks instead of structure.

11.3.2.3 Alternative materials

Twentieth century geotechnical structures employ hard engineering solutions (i.e. concrete and steel). More recently, new techniques and materials have found their way into geotechnics as alternative means of supporting a structure on the ground. This section aims to give a flavour of what are the sustainability implications on the choice of geotechnical materials, but is not intended as the definitive guide on material choice.

Ground improvement linked with reduced foundations' size, and soil reinforcement instead of retaining walls, are examples of 'doing geotechnics differently'. It is currently difficult to evaluate the pros and cons of available techniques, as there is no comprehensive environmental impact comparison between them. Geosynthetics may be good for stabilising fill, but making them out of plastic is resource depleting, energy intensive and environmentally polluting. Similarly, lime, cement or other stabilisation systems are ideal for allowing poor quality soils to

remain *in situ*, thereby avoiding their removal and landfill disposal, but produce high carbon emissions during manufacture (Hughes *et al.*, 2011). Until the benefits and drawbacks are systematically identified and quantified, geotechnical engineers will not be able to make sound, sustainable material choices.

The ever more popular use of tyre bales instead of lightweight fill would be a prime example of turning waste into a resource. Such an example is the lightweight embankment at Brodborough Lake for the A421 Improvement (Kidd *et al.*, 2009).

At Dartford Creek in East London, slope remediation was achieved by encouraging natural depositional processes by means of a soft engineering solution consisting of brushwood mattresses installed on the retreating slope (**Figure 11.3**). It was a revival of a medieval technique for controlling erosion, which was abandoned during Victorian times in favour of new technologies and engineering.

New technologies that can make a difference in dealing with geotechnical materials are always emerging. Accelerated Carbonation Technology (Carbon8, www.c8s.co.uk) may be one such example, where CO_2 becomes a resource instead of waste, with the potential of *in situ* soil improvement or production of alternative materials from waste.

11.3.2.4 Waste reduction

Geotechnical engineering produces its fair share of waste in the construction industry. Unsuitable soil, be it weak or contaminated, is often excavated and disposed into landfills. Reducing construction waste would require re-evaluating the need to excavate the material in the first place: can contamination be contained and treated *in situ*? Can the weak/unstable soil be improved *in situ*? Can waste material produced elsewhere be used as a resource on the project under consideration? For example, soil stabilisation may use by-products (ground granulated blastfurnace slag, pulverised fuel ash, furnace bottom ash) so, whilst the main process may produce CO_2, the use of waste in construction material blurs the boundaries between waste and material use. The earlier example of the tyre bales embankment is a similar case of turning waste into a resource. However, does using waste as a construction material make the preceding processes more acceptable, even if they are consumptive?

Help for using resources more efficiently and strategies and advice on reducing waste to landfill is available from Waste and Resources Action Programme (WRAP, www.wrap.org.uk/construction/).

Figure 11.3 Example of an alternative use of materials: brushwood mattresses for slope remediation at Dartford Creek
From Pantelidou and Short (2008)

11.3.3 Water

Water is an integral part of geotechnical engineering. Changes in groundwater result in ground movements and impact on geotechnical structures.

11.3.3.1 Impact on existing water environment

One of the main considerations for a geotechnical project should be its impact on existing water resources and their users. Water and groundwater at a project site is also part of a wider aquatic system and any changes to it will disturb the balance of that system. **Figure 11.4** shows a groundwater model for the Florence TAV Station, investigating the damming effects that the underground station box has on the regional groundwater flow, within the shallow unconfined sand aquifer, see Hocombe *et al*. (2007).

11.3.3.2 Sustainable drainage systems

To sustain balance in the natural water cycle, it is important to respect natural water processes. Providing large surface areas of hard covering inhibits natural water infiltration into the underlying aquifer.

According to CIRIA (www.ciria.org.uk/suds/) surface water drainage methods that take account of quantity, quality and amenity issues are collectively referred to as Sustainable Drainage Systems (SUDS). These systems are more sustainable than conventional drainage by trying to replicate the natural infiltration systems because they:

- manage runoff flowrates, reducing the impact of urbanisation on flooding;
- protect or enhance water quality;
- are sympathetic to the environmental setting and the needs of the local community;
- provide a habitat for wildlife in urban watercourses;
- encourage natural groundwater recharge (where appropriate).

11.3.3.3 Aquifer storage and recovery

Artificial recharge (AR) is a method of supplementing or replacing natural infiltration into an aquifer by storing water

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

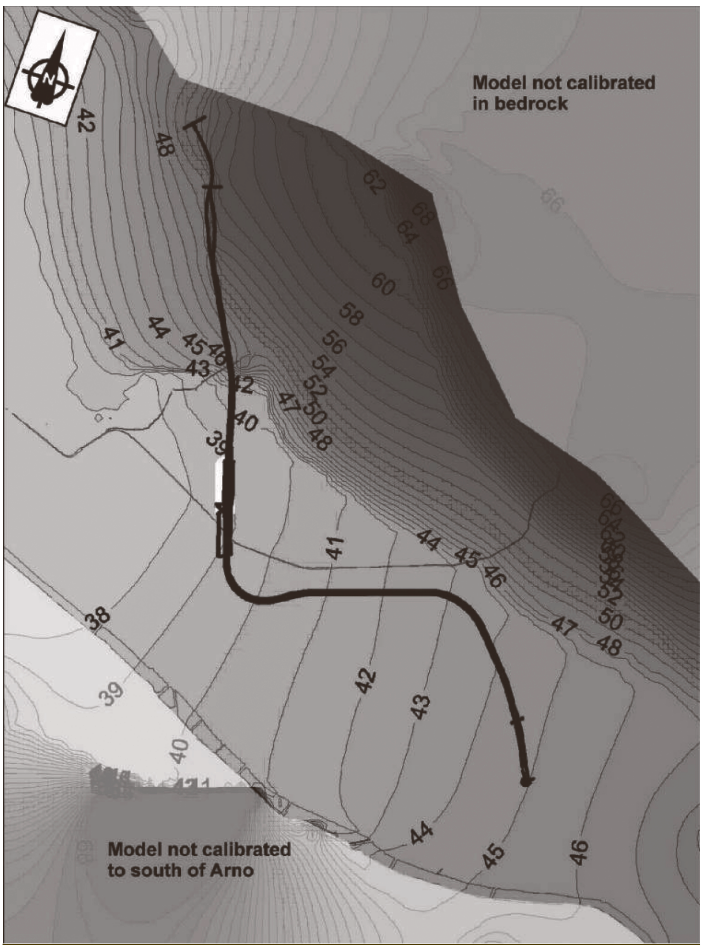

Figure 11.4 Groundwater modelling for the Florence TAV Station. Study of the damming effects of the station box within the shallow unconfined sand aquifer
Reproduced from Hocombe *et al.* (2007)

in an aquifer at times of surplus, for use at times of scarcity (Jones *et al.*, 1998). Aquifer storage and recovery has been proven to be a robust, cost effective and environmentally sustainable water resource management tool. The technique is well established in many parts of the world and for many companies it represents an integral component of their water resources strategy. In the UK, the benefits of aquifer storage recovery and aquifer recharge and recovery (ASR/ARR) are beginning to be realised, particularly by companies where resources are strongly influenced by peak demands. ASR should not be considered as a source of new water but represents a form of water conservation and efficiency. As a result the Environment Agency strongly supports the technique, since it maximises the use of existing licensed water with only marginal environmental impacts. ASR/ARR is consistent with the principles for proper management of water resources and can represent a Best Practical Environmental Option (BPEO).

11.3.3.4 Water in construction

Geotechnical construction invariably uses a considerable amount of water. Sustainable construction practices should aim to minimise water consumption by:

- optimising water usage during construction and operation – grey and black water re-use, recycling, low water use technologies;
- ensuring that the water quality for discharge is appropriate for the receiving aquatic environment.

11.3.3.5 Design for reduced operational energy

It is common practice designing sub-structure systems that rely on permanent dewatering for stability (e.g. numerous basements constructed in central London). Permanent dewatering requires energy consumed to pump water out of the system during the operational life of a structure. A sustainable alternative should be considered at design stage that eliminates the need for permanent pumping.

11.3.4 Climate change

Adaptation of buildings and infrastructure to climate change requires significant geotechnical input: highway and railway assets (embankments and cuttings) are vulnerable to climatic changes, be it from changes of groundwater regime and seasonal water fluctuation or from increase in frequency and magnitude of extreme rainfall events and surface runoffs, leading to surface erosion and eventually failure. Marine and freshwater flood defences are also vulnerable to weather extremes and climatic changes, including increased storm surges and magnitude of tidal ranges.

Figure 11.5 is taken from Shaw *et al.* (2007), a guide on climate change adaptation by design. It makes suggestions for timely monitoring and intervention for ground-related risks attributed to climate change. The main geotechnical requirements identified for climate change adaptation are:

- retrofitting/upgrading existing and construction of new flood defences, coastal and fluvial;
- slope reinforcement and stabilisation to resist increasing surface and ground water fluctuation;
- provision of sustainable water drainage and aquifer recharge schemes;
- retrofitting or replacement of foundations to compensate for increased ground movements due to changes in the groundwater regime.

Furthermore, prolonged dry weather may also become a frequent occurrence, even in the UK, which may create more widespread unsaturated ground conditions. Unsaturated soil mechanics may become more relevant to the geotechnics practice in the future.

Menu of strategies for managing high temperatures

The diagram summarises the range of actions and techniques available to increase adaptive capacity. Detail is given in the text on the proceeding pages.

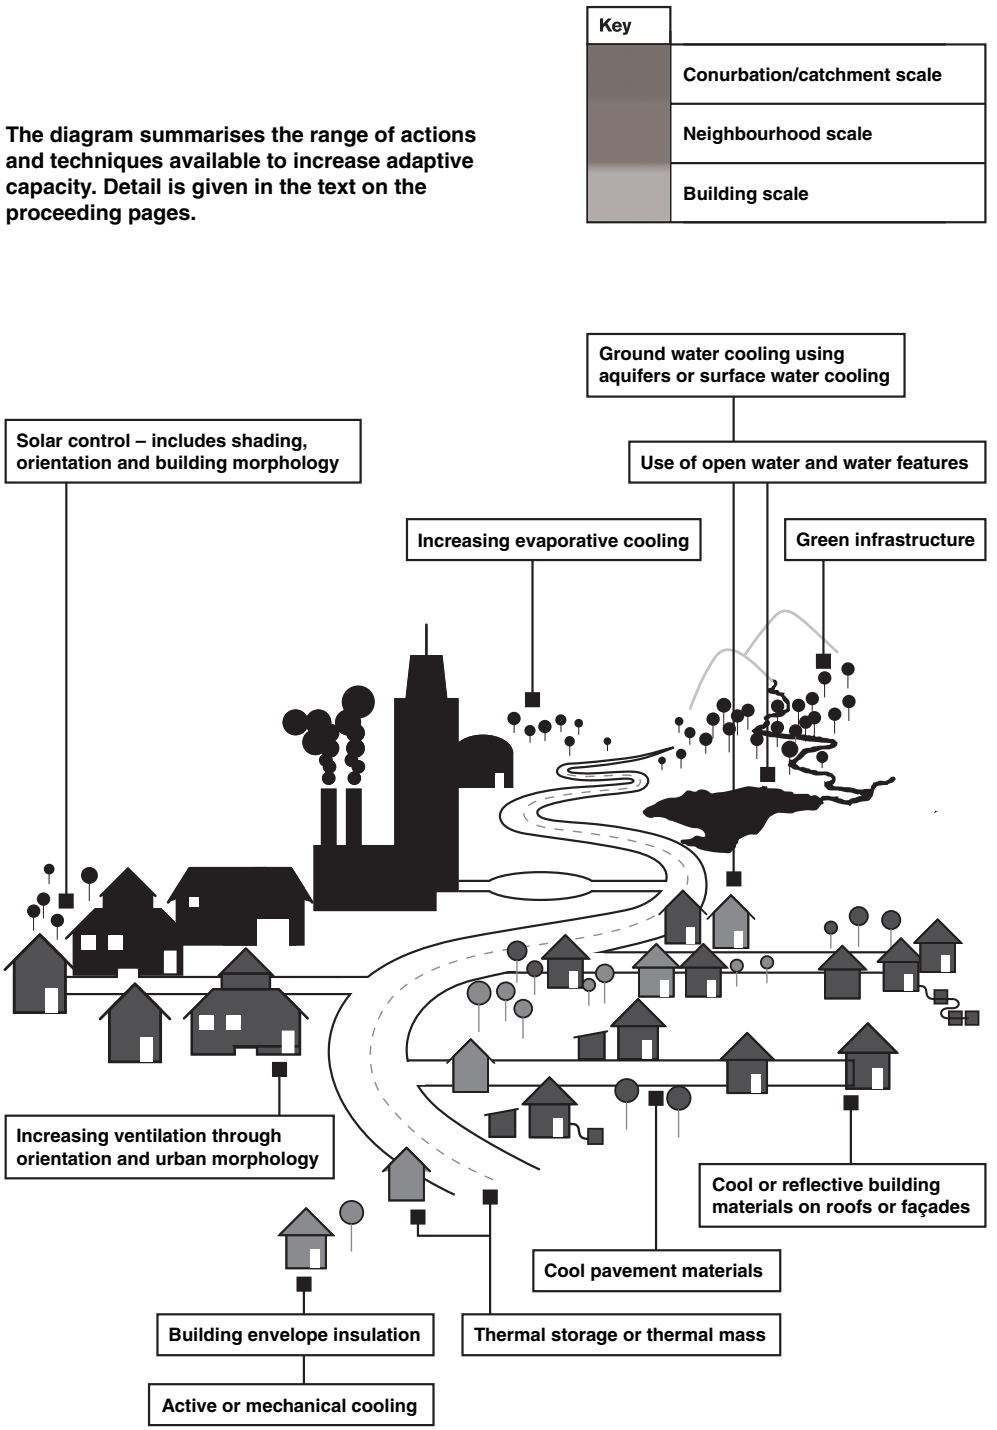

Figure 11.5 Strategies for managing ground conditions to increase adaptive capacity

Reproduced, with permission, from Shaw *et al*. (2007), Climate change adaptation by design: a guide for sustainable communities, Town and Country Planning Association © TCPA. Designed by thomas.matthews (www.thomasmatthews.com)

11.3.5 Effective land use

11.3.5.1 Contaminated land – remediation and containment

Brandl (2008) classified contaminated land remediation methods into three broad categories:

- *geotechnical methods:* including excavation, physical containment, groundwater control and soil treatment (e.g. soil mixing);
- *process-based methods:* using specific physical, chemical or biological processes to remove, immobilise, destroy or modify contaminants;
- *natural remediation methods:* using plants, natural fungi or natural groundwater processes to degrade contaminants.

The Geotechnical methods are more widely applicable and may combine with the process-based and natural remediation methods to a hybrid to achieve optimum remediation. Geotechnical engineers can address how contaminated land is treated (and how it came to be contaminated, in some cases).

CL:AIRE (www.claire.co.uk) are raising awareness of sustainable remediation technologies, with a variety of publications on geo-remediation topics.

11.3.5.2 Underground space in urban environment

In 2007, the world's urban population exceeded the rural population for the first time and the trend for migration from the countryside to the city is set to continue. Lack of urban space is an ever increasing challenge and discussions on strategic use of underground space for sustainable transportation and mobility in urban and rural areas are already taking place (COB, 2007). The ever increasing requirement for underground space presents opportunities to geotechnical engineers in particular, with underground expansion of transport corridors or provision of car parking and large retail and entertainment spaces. Tunnelling as well as multi-level basements require substantial geotechnical input. The technical challenges, substantial investment required and complex logistics involved in underground construction within the urban fabric have to be holistically considered for the successful development and long term viability of the underground urban space.

11.3.6 Whole-life management

Figure 11.6 schematically represents the stages involved in the life of a geotechnical structure. A life cycle assessment of the structure would include consideration of the impacts (environmental, social and economic) that each stage contributes.

Management of railway and highway earthworks and flood defences (river and coastal) assets should take on board whole-life management considerations. Advice can be found in Hooper *et al*. (2009).

Chapman *et al.* (2001) pointed out that the presence of old foundations in the ground is going to present an ever increasing problem and will ultimately inhibit future development on valuable urban sites. Re-using existing foundations makes financial and logistical sense, extending their usefulness beyond their intended life. Guidance on how to establish re-usability of existing foundations and incorporation into a new project is given by Butcher *et al.* (2006) and Chapman *et al.* (2007).

Design of new foundations should ideally take this a step further, by incorporating into their design the potential for re-use after decommissioning.

11.3.7 Societal contribution

Project involvement of geotechnical engineers is usually remote from early stakeholder engagement and social impact

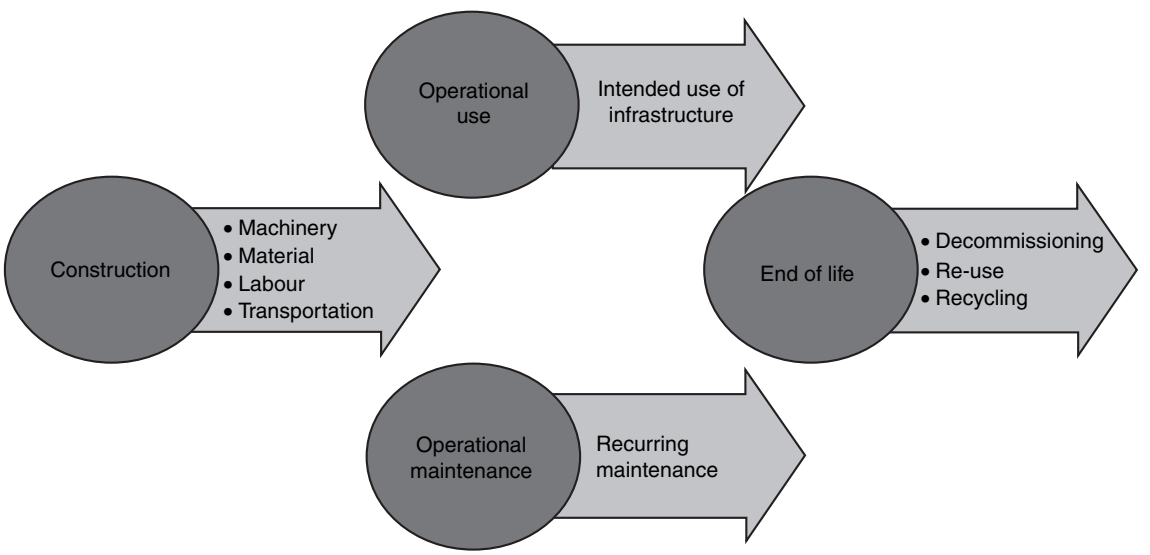

Figure 11.6 Stages involved in the life of a geotechnical structure

assessments. Nonetheless, positive contribution to society is within our brief and is our responsibility.

An integral part of the ground, especially in areas of rich cultural history, is archaeology. Archaeological resources are finite, non-renewable and increasingly dwindling as a result of inconsiderate development. Geotechnical desk studies and specifications must ensure early identification of archaeological issues related to a project. Geotechnical design and procurement should necessitate adoption of appropriate mitigation measures and programme allowances for implementation. Advice from and collaboration with archaeologists is essential for appropriate archaeological guidance, making archaeology an asset of a project rather than a hindrance.

Geotechnical construction may adversely affect the health and wellbeing of stakeholders (neighbours, labour, etc.). Noise, vibration and dust are common nuisances associated with piling and excavation works and must be minimised. This is strongly linked with the health and safety in construction issues discussed in detail in Chapter 8 *Health and safety in geotechnical engineering*.

11.4 Sustainability in geotechnical practice

The majority of the geotechnical sustainability themes discussed can be readily incorporated into current geotechnical practice. Some will need to be developed further; others will require familiarity to geotechnical engineers before they are fully endorsed. In any case, geotechnical engineering can make a big impact on the sustainability of the built environment.

An important issue is the timing of the sustainability considerations during the life of a project. **Figure 11.7** schematically represents the opportunities for adopting sustainable solutions rapidly diminishing as the planning and design progress. The biggest opportunities are given at the planning stage (e.g. the choice of the alignment of a highway); they reduce during design (optimisation of materials and structures) and become quite limited during construction (mainly focusing on energy efficiency of plant and process).

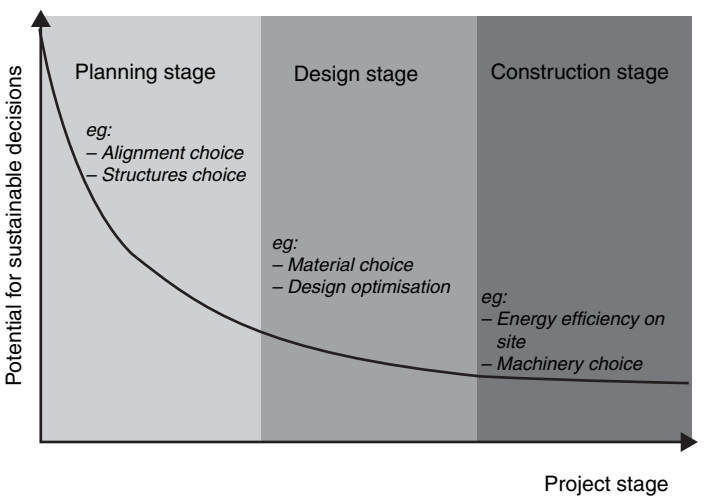

Figure 11.7 Opportunities for adoption of sustainable solutions during the life of a project

Geotechnical Engineers are specialists and as such are usually involved in a project after its design outline is fixed. A conscious shift of geotechnical involvement on earlier stages of the design process will have a positive contribution to the implementation of sustainability elements in the project outline.

The following explores the opportunities for applying the sustainability objectives within the traditional design and construction activities of a geotechnical engineer.

11.4.1 Desk study and ground investigation

A good quality geotechnical desk study for a project initiates prospects for sustainable intervention early on in the design process. A geotechnical desk study recognises key hazards (considered in Chapter 7 *Geotechnical risks and their context for the whole project*) at an early stage, thereby allowing the design to be adapted at optimum cost. It is also an excellent opportunity to identify information such as local sourcing of materials, site and project constraints and potential sustainability implications. It is the time to explore the potential for re-using existing foundations and outline the associated constraints, identify archaeological constraints and opportunities, carry out relevant geohazard assessments, and pull together all information that may assist in making the project more sustainable.

Based on the conclusions and recommendations of the desk study, a comprehensive site investigation should be designed, specified and executed to minimise the ground- and ground water-related uncertainties and inform an efficient geotechnical design.

Section 4 of this manual contains further details on site investigation.

11.4.2 Design

An efficient, lean geotechnical design is akin to a sustainable design. As an industry, geotechnical engineers should make every effort to understand the soil constitutive laws and improve the advanced design and modelling tools to enable design efficiency.

Innovation is an important ingredient of a sustainable design – lateral thinking (outside the box), considering new materials, turning waste to resource.

The design development of a project involves weighing up a number of design options, as discussed in Chapter 9 *Foundation design decisions*. Early geotechnical involvement in the design development can ensure early identification of the ground-related constraints and risks affecting the design solution.

Whole-life considerations should also be included in the design of a project, both financially and in terms of environmental impact.

Also see Sections 5, 6 and 7 of this manual for further detail on geotechnical design.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

11.4.3 Construction

Geotechnical construction aids sustainability by ensuring process efficiency and care for the neighbours and the environment through reduction and efficient management of waste, water and energy, local sourcing of materials and plant, and control of noise, vibration and dust.

11.4.4 Sustainability accreditation schemes

Measuring the social, environmental and economic impact of a structure is important, for comparison, accountability and improvement. Economic impact is usually well documented for any project, although whole-life costing is rarely considered. Environmental impact rating methods are used to assess design performance relative to a predetermined, industry recognised standard. The most commonly used schemes are BREEAM (www.breeam.org), LEED (www.usgbc.org) and GreenStar (www.gbca.org.au/green-star/) (applicable to Buildings) and CEEQUAL (www.ceequal.com) (applicable to infrastructure projects, see **Table 11.2**).

The above accreditation schemes generally address ground-related topics, although some give less emphasis to geotechnical issues than may be appropriate. For example, BREEAM are currently excluding foundations from their appraisal, although this is under development and will be included in their future issues.

There are also other tools that aim to support the decision-making process regarding sustainability issues and how they can be addressed at different spatial scales. Examples include SPeAR® (www.arup.com/environment/), IRM, LCA and Eco-footprinting. These methods do not specify a performance level to be achieved. Rather, they provide an approach to integrating sustainability into a development process and identifying outcomes and constraints. None of them is geotechnically specific, although geotechnical aspects are relevant to a greater or lesser extent.

	Section	Score weighting %	Geotechnical input
1	Project management	10.9	
2	Land use	7.9	•
3	Landscape	7.4	•
4	Ecology and biodiversity	8.8	
5	The historic environment	6.7	•

8	Material use	9.4	•
9	Waste management	8.4	•
10	Transport	8.1	
11	Effects on neighbours	7.0	•
12	Relations with the local community and other stakeholders	7.4	•

Table 11.2 CEEQUAL's 12 sections

11.5 Summary

This chapter provides a brief overview of the sustainability issues that concern engineering in general and geotechnics in particular. A framework of seven sustainability objectives is proposed: energy efficiency and carbon reduction, materials and waste reduction, maintained natural water cycle and enhanced aquatic environment, climate change adaptation and resilience, effective land use, economic viability and whole-life cost, and positive contribution to society. The geotechnical themes under each of the seven headings are discussed and constraints and opportunities for the geotechnical engineers indicated. The chapter concludes with suggestions on how sustainability elements can be incorporated in the current geotechnical practice: desk study and ground investigation, and design and construction, including reference to current sustainability accreditation schemes.

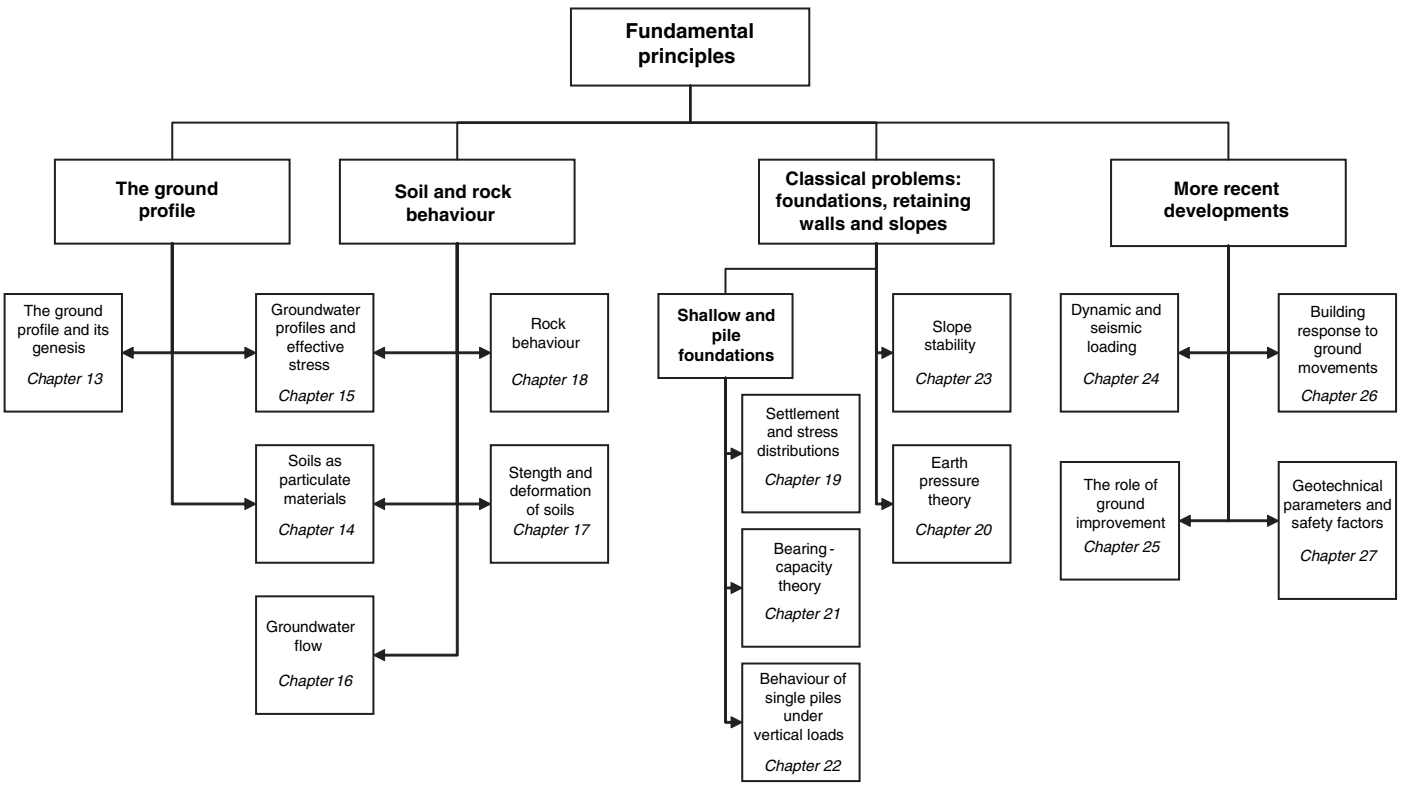

Figure 12.1 Layout of chapters in Section 2

Figure 12.1 outlines the layout and contents of Section 2 *Fundamental principles*.

Section 2 serves as an aide-memoire to the fundamental principles and theories underlying geotechnical engineering, from characterising the ground, through the behaviour of geomaterials, to the basic conceptual models used in the analysis and design of geotechnical engineering structures.

The first six chapters (Chapters 13 *The ground profile and its genesis* to 18 *Rock behaviour*) are concerned with characterising the ground and the fundamental aspects of material behaviour. Chapter 13 *The ground profile and its genesis* describes and discusses the development of the ground profile from a geological perspective, and how this knowledge may be used to inform the development of a conceptual ground model for use in geotechnical engineering. Chapter 14 *Soils as particulate materials* rehearses the factors that make soil, as a particulate material, fundamentally different from many other civil engineering materials such as steel and concrete.

Without groundwater, geotechnical engineering would be much simpler – but also less of a challenge and much less interesting. In many parts of the world, the soils of interest to the geotechnical engineer are saturated or nearly so; thus an

understanding of pore water pressures and groundwater flow is essential. Chapter 15 *Groundwater profiles and effective stresses* describes the estimation of pore water pressure and effective stress profiles in the ground, while Chapter 16 *Groundwater flow* discusses the calculation of flow rates and changes in pore water pressure induced by construction activities such as excavation. Chapters 17 *Strength and deformation behaviour of soils* and 18 *Rock behaviour* summarise the important aspects of soil behaviour and rock behaviour, and the conceptual and mathematical models commonly used to characterise and quantify them.

The next five chapters, Chapters 19 *Settlement and stress distributions* to 23 *Slope stability*, address the underlying theory applied to the three classic problems in geotechnical engineering: foundations (Chapters 19 *Settlement and stress distributions*, 21 *Bearing capacity theory* and 22 *Behaviour of single piles under vertical loads*), retaining structures (Chapter 20 *Earth pressure theory*) and slopes (Chapter 23 *Slope stability*).

The last four chapters, Chapters 24 *Dynamic and seismic loading of soils* to 27 *Geotechnical parameters and safety factors* address a range of topics representing arguably more recent developments in geotechnical engineering. The dynamic and seismic loading of soils (Chapter 24 *Dynamic and seismic loading of soils*) is generally considered more difficult than the static behaviour, but for certain applications and in many parts of the world cannot be ignored. Ground improvement (Chapter 25 *The role of ground improvement*) encompasses a number of techniques that geotechnical engineers use to improve certain properties of the ground. These often require an understanding of chemical or electro-chemical phenomena in addition to the more familiar mechanics, and given the uncertainties involved in applying these to the ground, they represent to many an area still closer to art than science. Understanding and predicting the response of buildings to ground movements (Chapter 26 *Building response to ground movements*) has become increasingly important as more and more ambitious construction projects involving open excavations and tunnels are undertaken in highly built-up areas. This need, combined with the development of computing power enabling complex and sophisticated, three-dimensional numerical analysis to be carried out, has driven a major area of advance in geotechnical knowledge and understanding in the last decade or so. Finally, Chapter 27 *Geotechnical parameters and safety factors* addresses the choice of design parameters and factors of safety. This is a topic of huge importance, about which there is a general lack of coherence and clarity in the geotechnical profession generally, partly because it is difficult to revise customs and codes of practice in a way that keeps pace with developments in geotechnical engineering knowledge and understanding.

Section 2 sets out to cover a huge range of soil and rock mechanics and geotechnical engineering knowledge. Inevitably, it can serve as no more than a reminder for those already familiar with a topic, or an introduction for those who are not. The following bibliography may be helpful to those wishing to find out more about any of the variety of subjects covered.

A ground profile, or vertical profile, is the starting place for developing an understanding of the ground for design and analyses. It is a record of the ground at depth and an interpretation of its formation up to the present. The correct identification of these materials and interpretation of their history indicates how ground is likely to respond to changes arising from either construction or natural processes such as rainfall and earthquakes. There is no guarantee that decisions based on a profile that is incorrect can be corrected by subsequent calculations, no matter how sophisticated they may be, because these calculations will be quantifying something that does not exist. Mistakes made with the ground profile delay works and even stop contracts; many result in claims. Profiles enable cross-sections to be constructed and these are the templates upon which all other geotechnical data should be superimposed. This is the only way a relationship can be obtained between geotechnical properties for the materials present and their geological history. Many case histories demonstrate this. Case histories are part of the inherited wisdom of geotechnical engineering and remove any excuse for either ignoring a ground profile or for obtaining one but failing to use it appropriately.

13.1 Overview

A ground profile, also called a vertical profile, describes the ground beneath a particular location. It lists the materials encountered with depth, as would be intersected by a borehole or trial pit, and then uses this and other data to interpret how the profile was formed and how it might behave in response to engineering within it. A ground profile therefore has two basic components: the vertical sequence and its interpretation. The vertical sequence usually starts at ground level and extends to whatever depth is deemed necessary for the geotechnical work for which it was requested. The age of the materials encountered increase with depth, so a profile represents the history of the ground, with the most recent part of that history being at ground level. The correct interpretation of the materials and history of a profile can indicate how the ground is likely to respond to engineering.

There are many forms of profile; all are crucial to decisions taken for geotechnical design, analyses and construction. If the description of the materials with depth is wrong or is missing important data, then decisions based on it will be wrong no matter how correct and accurate subsequent calculations may be. This is because these calculations will be quantifying something that does not exist. Mistakes made with the ground profile can be so seriously wrong that they may result in ground work being stopped and contracts being delayed, sometimes even being abandoned.

Having established the profile at one location it is usually necessary to compare it with profiles at other locations nearby, so that a series of profiles can be related to each other. There are hazards associated with such a seemingly simple task. The outcome of such comparisons is a depiction of the site geology in 3D. Rarely can this be done without considering how each profile has been formed, i.e. its genesis – analysis and construction come from understanding what has happened to the ground in the past.

Thus a ground profile is not just the sequence of soils and rocks but incorporates an understanding of what has happened to these during their formation and subsequent history to the present day. Aspects of this are explained because understanding the formation and history of a profile is one of the key tasks for an engineering geologist to complete. Working with appropriate material descriptions is critical, and using a scale appropriate for relating the ground to the intended engineering project is necessary. The sections, maps and 3D depictions so created become the basis upon which all other geotechnical data should be superimposed; only in this way can the distribution of geotechnical properties reflect the materials present and their geological history (de Freitas, 2009).

The acquisition and use of geotechnical data that has not been related to the materials and history to which it relates, is substandard geotechnical engineering; there are many case histories that demonstrate this. Case histories are part of the inherited wisdom of geotechnical engineering and they remove any excuse for either ignoring a ground profile, or for obtaining it but failing to use it appropriately.

13.2 The ground profile

A basement foundation, 10 m × 15 m to be placed at 7 m below ground level, has been investigated using 5 boreholes, each taken to a depth of 15 m and each used to recover a core of 100 mm diameter. If the core recovery is 100%, the volume of ground actually seen is less than 0.01% of the ground to be excavated and considerably less than that of the material relied upon to carry the foundation loads beneath the excavation for

the next 60 to 100 years. Thus the commercial investment that has facilitated this construction is based on virtually no knowledge. Such simple calculations demonstrate the value that must be placed on these tiny pieces of information and the need for this information to be gathered with care; this subject area is known as ground investigation. Retrieving a sample of ground and describing it so that it reflects the condition of the ground from which it came, are fundamental steps towards creating a ground profile; they require skill, knowledge and experience. However, such a log, by itself, is insufficient; its data has to be used for design and analyses, and the first step in using it this way is to generate a ground profile.

Two logs are shown in **Figure 13.1**, one from London and the other from Hong Kong; they illustrate that a description of a vertical sequence is the starting point for a ground profile. Note that they provide little direct information about either the origin or the history of the ground represented by the log; this comes later. Thus ground profiles require either logs of borehole cores or the boreholes themselves, or their equivalent from a quarry, or trial pit or other excavation. Such a profile refers to the ground beneath the point on the surface of the earth below which it is made, but may also be relevant to locations nearby if the ground does not vary significantly from place to place.

Such logs are used for many purposes, e.g. for the basic design of subsurface structures, for geotechnical analyses, for deciding methods of construction, for the installation of monitoring equipment, for the assessment of material volumes. Thus logs have to provide an accurate record of the ground as it exists, *in situ*. This can be considered the most basic of ground profiles.

Logs are the starting point for developing a fuller ground profile because the information they contain is used to understand how that sequence will respond to the particular changes that engineering work is likely to create. They also indicate aspects of the ground which should be studied further and how the data that arises should be used. These are two subjects that require care and attention, and improve with experience of the observer. Profiles that have to be created from the descriptions of others present different problems from those created by personal observation. The usefulness of a profile created from the records of others depends upon the extent to which those records are a relevant, complete and correct representation of the ground.

The most obvious characteristics to observe are the sequence that is present in the log and the materials it contains, as shown in **Figure 13.1**. The less obvious, yet sometimes crucial, characteristics to note are the fabric of the materials, the structure of their layers and the nature of their boundaries – their interfaces. Even more subtle is recognising what is missing; this is not usually

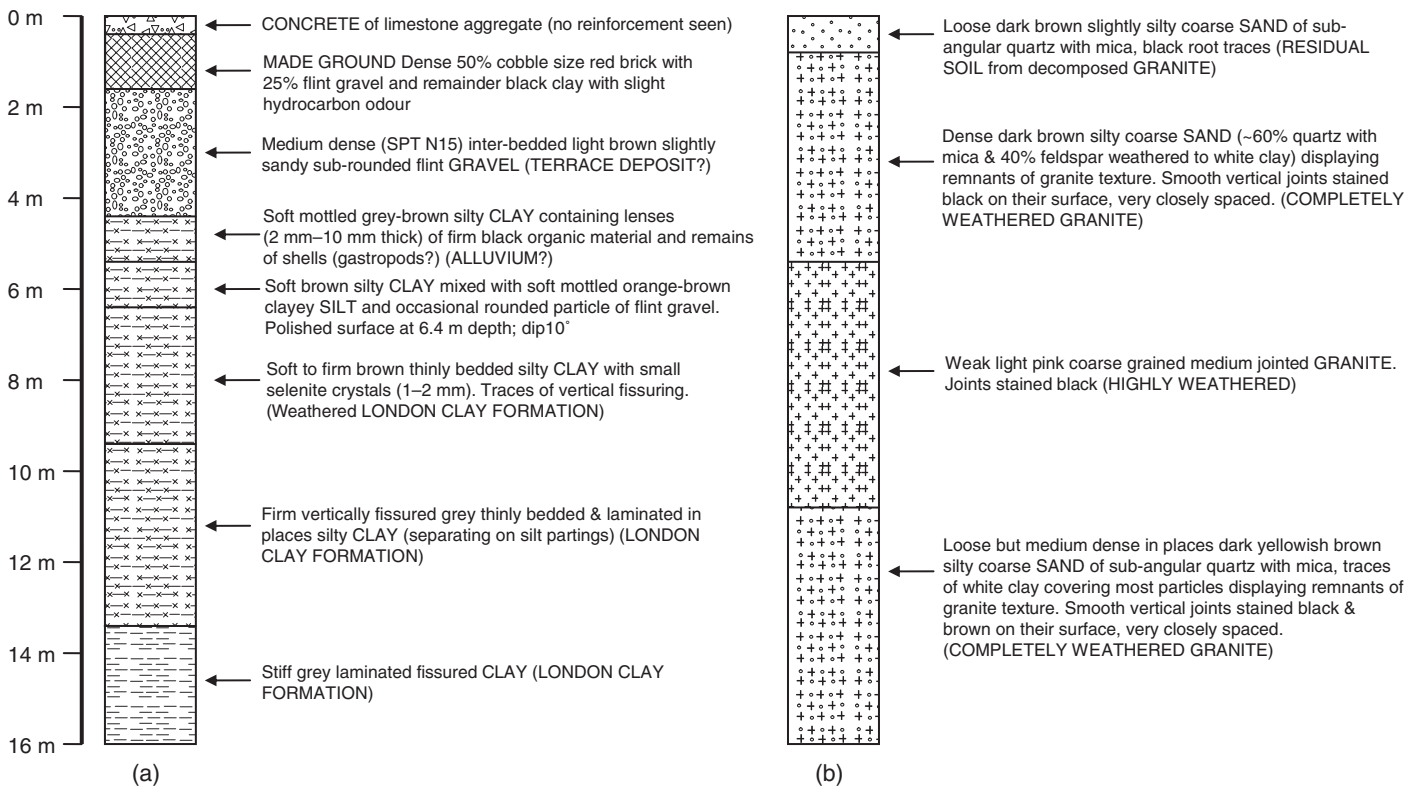

Figure 13.1 Borehole logs from (a) London and (b) Hong Kong illustrating vertical sequences formed mainly by sedimentation and *in situ* weathering of pre-existing granite. Details of recovery, water returns, etc., are omitted

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

a problem when a vertical exposure exists, as in the face of a quarry, cliff or trial pit, but becomes a key decision when using recovered samples, especially with borehole core where, during its recovery, material might be lost or its strength or consistency changed. All these aspects are static in character – they are either present or not present in the profile. However, an important component of most profiles is not static but dynamic; it can come and go. Liquids and gasses are the most obvious of these; the free face that exposes a profile and enables it to be observed in the side of a trial pit, shaft, quarry or cliff can affect the presence of liquids and gasses and their location in the ground.

Water will drain towards a free face if its level on the free face side is lower than that in the ground behind the face, so the level of water recorded on the free face may not be that further back in the ground. Air will replace the voids vacated by water and as this is rich in oxygen it will tend to chemically change the ground with which it comes into fresh contact. Black colours become yellowy brown, brown or even whitish, dark browns become light browns, solid wet surfaces become powdery and damp, or even dry. Other gasses such as methane, and other organic rich volatile material, all pertinent to the geotechnical character of the ground, may escape. All these are changes that occur with time but they need not be the only ones to occur. Any excavation, natural or man-made, removes the loads that were on the ground and the ground will respond to their loss and relax towards the free face that has been created. This relaxation can itself create many changes whose magnitude and extent depends on the time they have had to develop.

A good log is thus essential for developing a ground profile for use in design and analysis; some aspects of the ground can be captured by a photograph and it is always useful to obtain an image of the evidence used. Some aspects cannot be captured; they need to be deduced from considering what can be seen, what has changed and what has been lost. The geographical location of the profile also needs to be recorded (to the nearest decimetre) on the surface of the earth. The elevation of the datum from which the profile has been measured is also required, at least to the nearest decimetre, and if possible to the nearest centimetre. The age of the exposure or borehole core upon which the profile is to be based is also relevant and should be recorded, or if unknown, this should be noted. Finally, the profile needs a complete description. Should any one of these pieces of information be missing the profile is incomplete; that means the geotechnical engineering intended at the site will commence in ignorance of essential information. Its absence will call into question the geotechnical competence of those involved.

13.3 Importance of a profile

Section 1 of this manual has set geotechnical engineering in context; it is a branch of engineering that came from the need to engineer in soil and rock. Experience in this field is recorded as case history; it describes what happened in certain circumstances, even if the reason for the ground's response was not understood at the time. Geotechnical engineering requires knowledge of the ground and of its mechanics to be used in a relationship that is described by the geotechnical triangle. The ground profile forms the apex of the triangle and describes the material and its history to which the 'well-winnowed' case histories of the triangle refer. It is easy to appreciate why this is so. Ground has four attributes of direct relevance to geotechnical work: strength (the loads that can be carried), deformability (the deformations that the loads will generate), conductivity (the flows that will be permitted) and durability (the alterations that will occur as a result of changing the environment under which the ground existed before engineering began). All this information comes from a ground profile, either directly by testing and monitoring the ground, or indirectly by calculation and analogy. The success with which this is done is a function of the quality of the ground profile. A basic log is the minimum required; one that has been put into context and interpreted is better.

The profile illustrated in **Figure 13.2** comes from the investigations for the underground car park at the Palace of Westminster in London; otherwise known as the Houses of Parliament (Burland and Hancock, 1977). The site is adjacent to the bell tower of Big Ben and the north embankment of the River Thames. The works required an excavation to 20 m below ground level into the London Clay and the creation of a box supported on piles cast *in situ* under-reamed at their base. Diaphragm walls were considered for lateral support but their depth gave cause for concern once the ground profile for the site was properly studied. The core was carefully taken and logged in detail by splitting it along its length to reveal the fabric and grain size of the material. Thin layers of silt were found within the clay and these were identified as a serious potential hazard, because they could transmit water from the alluvium of the Thames, if hydraulically connected to it, possibly causing softening and erosion of the adjacent clay. Such silt layers were a source of drainage for the inter layers of clay, so facilitating consolidation; their presence would also jeopardise the efficiency of any under-ream executed within that zone. None of this was considered an acceptable risk adjacent to so important a national monument. The design was changed to deepen the diaphragm walls so as to cut off all water access through the 10 m of clay inter-bedded with silt, and the piles were lengthened so that their under-reamed base started below the 10 m section containing the silt horizons.

It is important to appreciate that it was the profile which made the case for design change self-evident and unquestionable; analyses of the changes followed but no calculation had been required to see the need to change the design. Interestingly, the problems arising from silts seem not to have been considered until the succession had been studied as a profile. Prior to that, emphasis had been placed on assessing strength; over 100 unconfined compression tests had already been conducted.

The profile in **Figure 13.3** comes from an area where soft marine sediments overlie very stiff clays that cover limestone bedrock. A linear excavation to bedrock for cut-and-cover tunnelling was required and needed diaphragm walling for permanent support. **Figure 13.3(a)** illustrates the character of the

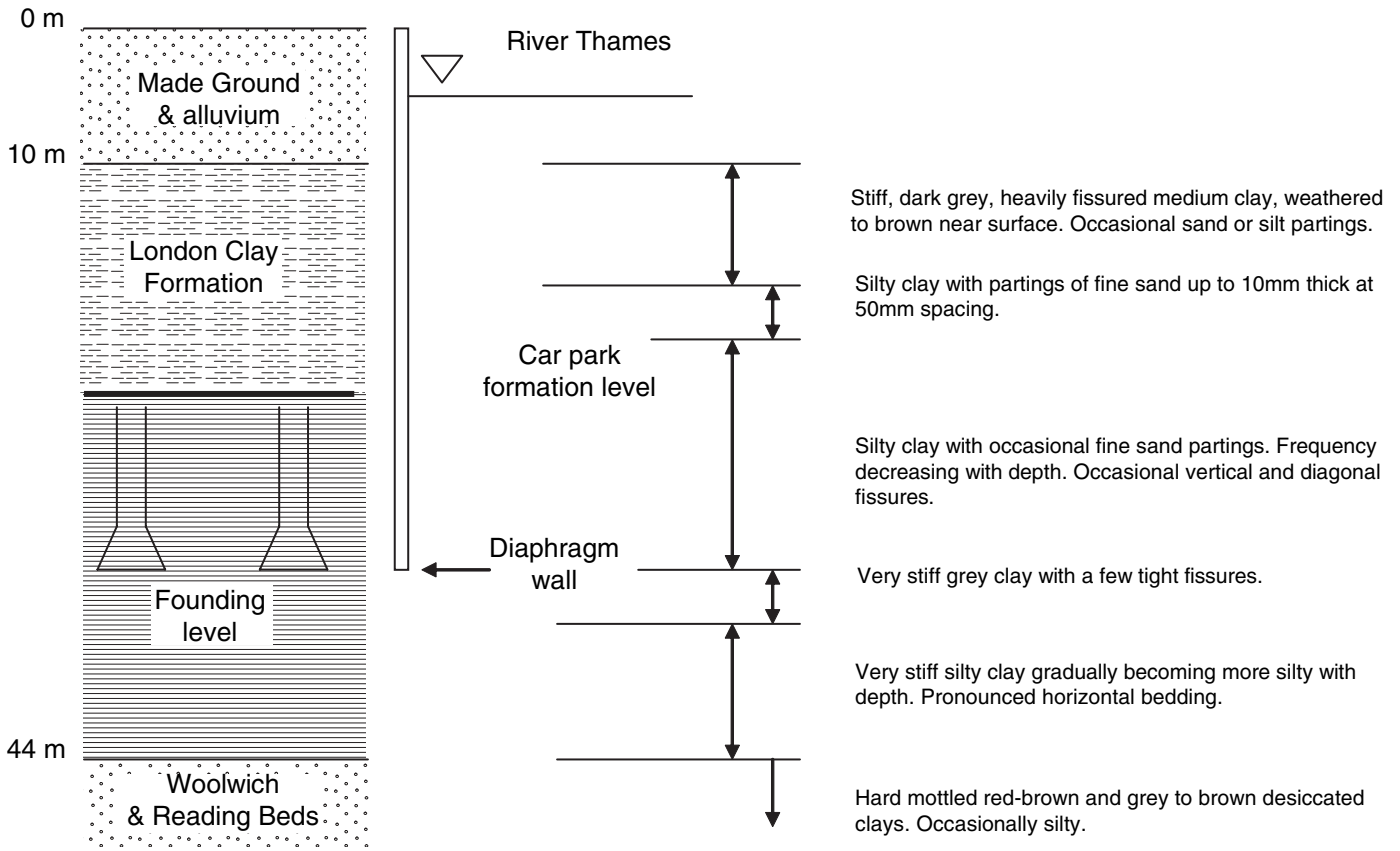

Figure 13.2 Portion of a log from the underground car park at the Palace of Westminster in London (Burland and Hancock, 1977)

ground and **Figure 13.3(b)** as it appeared in the borehole logs together with its description. The contractor had priced on the basis of the pictorial log and found that soil conditions terminated at higher levels, so upsetting both his progress and his contract price; delays followed and a claim resulted.

These examples highlight why the correct interpretation of a profile is important and illustrate some of the difficulties in creating one. In the case of the underground car park, the first mistake came from not appreciating the subtleties of geological nomenclature. 'London Clay' is short-hand for the name of a geological formation (the London Clay Formation) and not a lithology. A lithology is a sediment type whereas a formation is a deposit of a certain age usually named after the dominant lithology within it – clay, in this case. Other lithologies, notably silt, can also be present. Always ask: 'What is this material?' and request the answer in plain English, not in technical geological terms. For sediments and sedimentary rocks the description should be in terms of grain size, mineralogy and fabric; for igneous rocks it will be in terms of crystal size, mineralogy and fabric (sometimes called texture). Metamorphosed equivalents of these, created by the geological action of heat and pressure, can also be described in these terms, depending on whether they are now more like sedimentary or igneous rocks.

The second mistake followed from the first because the problem was perceived to be restricted to strength and deformation. Obviously strength and deformation were relevant but they were not the only issue of substance; much damage to both the ground and the surrounding structures could have resulted during excavation, long before the 'strength' of the ground in response to either lateral or vertical loads was mobilised. In other words, the design and an important part of the ground investigation to support it had missed a key component governing ground response to the engineering work. That is how the second profile caused problems for the excavation of diaphragm walls.

A number of contractors had declined to bid for this work sensing something was 'odd' about the site; the pictorial representation did not seem to reflect the written description. To understand the evidence it was necessary to appreciate the origins of the materials on site and their history. The limestone was of Carboniferous Age (~360 million years old) and much deformed by folding and faulting; further, there had been plenty of time and opportunity for dissolution and karst to develop within it. The clay above was hard, because it had been accumulated beneath a glacier, and contained large pieces of limestone picked up by glaciers as they travelled over the country. Glaciers had covered the area in the geologically

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

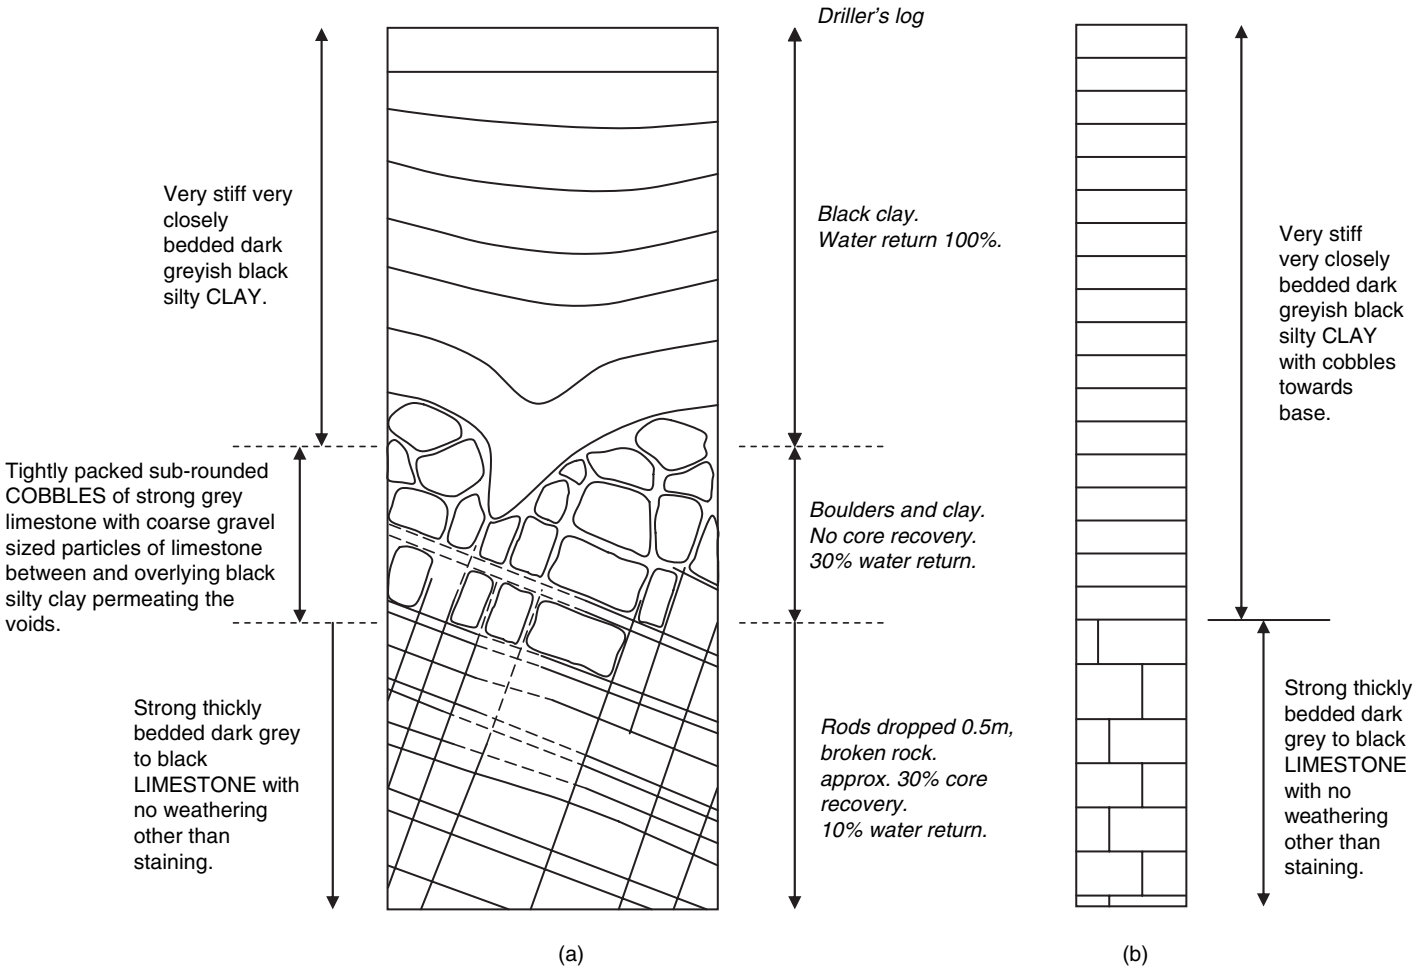

Figure 13.3 The borehole log of soft marine sediment over glacial deposits blanketing karstic limestone in Eire; (a) sketch of vertical profile as exposed by excavation and (b) as described by the driller and in the final logs

recent past (~10 000 years ago) and any debris they deposited or disturbance they created to the rock surface over which they travelled, would have filled karstic voids within the underlying limestone. None of this appears in the description; it has to be deduced from the profile and the geological history of the area. The problem here was that a zone of karstic rock with its voids infilled (as described above) had been recovered during the borehole investigation as loose debris with fragments of limestone, and interpreted as 'soil' above more solid bedrock. The cutters for the diaphragm walling machine encountered the top of the karstic limestone at depths where this so-called 'soil' had been expected.

These examples, two of many, illustrate that a ground profile is more than just the log of a borehole core or a trial pit, or a similar exposure. The observation and thought required to construct a profile comes from interpreting the factual records that such logs provide in terms of the response of that ground to the engineering within it; this brings such logs 'to life'. Thus, a qualitative ground profile leads to the quantitative means for predicting ground response to engineered change, viz mechanical properties and analyses; these are the two other points of the geotechnical triangle. Selecting the mechanical properties to be considered and the analyses to be used needs the direction and focus provided by a ground profile to ensure they address relevant behaviour. A ground profile can prevent serious mistakes being made in the quantitative aspect of the work.

13.4 The formation of a profile

Figure 13.4 illustrates four ways a ground profile can form. In **Figure 13.4(a)** layers of sediment have been deposited one on top of the other, and this would be the situation in many areas where sediments accumulate more quickly than they weather and erode. In **Figure 13.4(b)** weathering has changed the material near ground level so that the fresh parent material is now found at depth. This is commonly the case in regions where tropical weathering is either operating now or has operated in the past and alters material more quickly than it erodes. Such weathering can be well developed in crystalline materials, especially in granite and gabbro, where it can leave pseudomorphs of the original minerals. When that happens, shapes that were

clearly crystals of feldspar, amphibole and pyroxene originally are now found composed almost entirely of clay. Where these have remained undisturbed their structure and fabric remain intact and produce a zone of remarkable character known as a saprolite.

In many places a profile contains mixtures of weathered and unweathered material, because the rates of weathering, accumulation and erosion can change with time. Many of the profiles engineers will be dealing with in natural ground (as distinct from Made Ground) will extend from the present (at ground level) back to at least 10 000 years, to the start of the Pleistocene and the beginning of the Quaternary. Anyone working with Tertiary sediments is likely to encounter sediments whose ages can go back up to 65 million years and these would have experienced tropical conditions when the earth was a much warmer place than it is at present. Deep excavations near Aberdeen in Scotland (latitude ~57° N) penetrated stiff glacial clay that was laid down in the Pleistocene and now overlies much older granite that had been tropically weathered, probably during the Tertiary.

Figure 13.4(c) illustrates a variation of **Figure 13.4(b)**, as both are associated with the transport of material in a dissolved form. In **Figure 13.4(b)** the movement is predominantly downwards as infiltrating rainwater percolates through the profile carrying solids it has dissolved out of the profile – typical of weathering in wet climates. In **Figure 13.4(c)** dissolved solids in groundwater close to ground level are drawn up by evaporation and capillarity, and precipitate in the pores of material and at ground level as a mineral cement. This binds particles together and fills pores to produce a natural 'concrete' called a pedocrete; this is named after its predominant constituents, e.g. ferricrete also known as laterite (iron), calcrete also known as caliche (calcium), silcrete (silica), gypcrete (after gypsum; calcium and sulphur), alucrete also known as bauxite (alumina) and salcrete (after salt; sodium and chlorine). The durability they impart to the materials they indurate causes them to resist weathering and form a more durable crust to the landscape, hence they are also known as duricrusts. The layers beneath these crusts are often leached (weathered) and weaker than they were originally. Such weathering occurs in hot climates, especially in dry ones.

Figure 13.4(d) illustrates one of the consequences of disturbing the ground. In **Figure 13.4(d1)** the commonly occurring effects of overconsolidation are illustrated; fractures and bedding separation increase in number and become closer to each other towards ground level. This occurs when the ground has carried a greater effective stress than it does at present, the reduction normally being due to erosion over geological time and relaxation following the retreat of the glaciers at the end of the Ice Age. Vertical relaxation can also occur as a result of excavation, e.g. below open cast mines, quarries and deep foundations, and can start whilst these excavations are in progress. An example of relaxation associated with excavation is illustrated in **Figure 13.4(d2)**; in this case the collapse of a

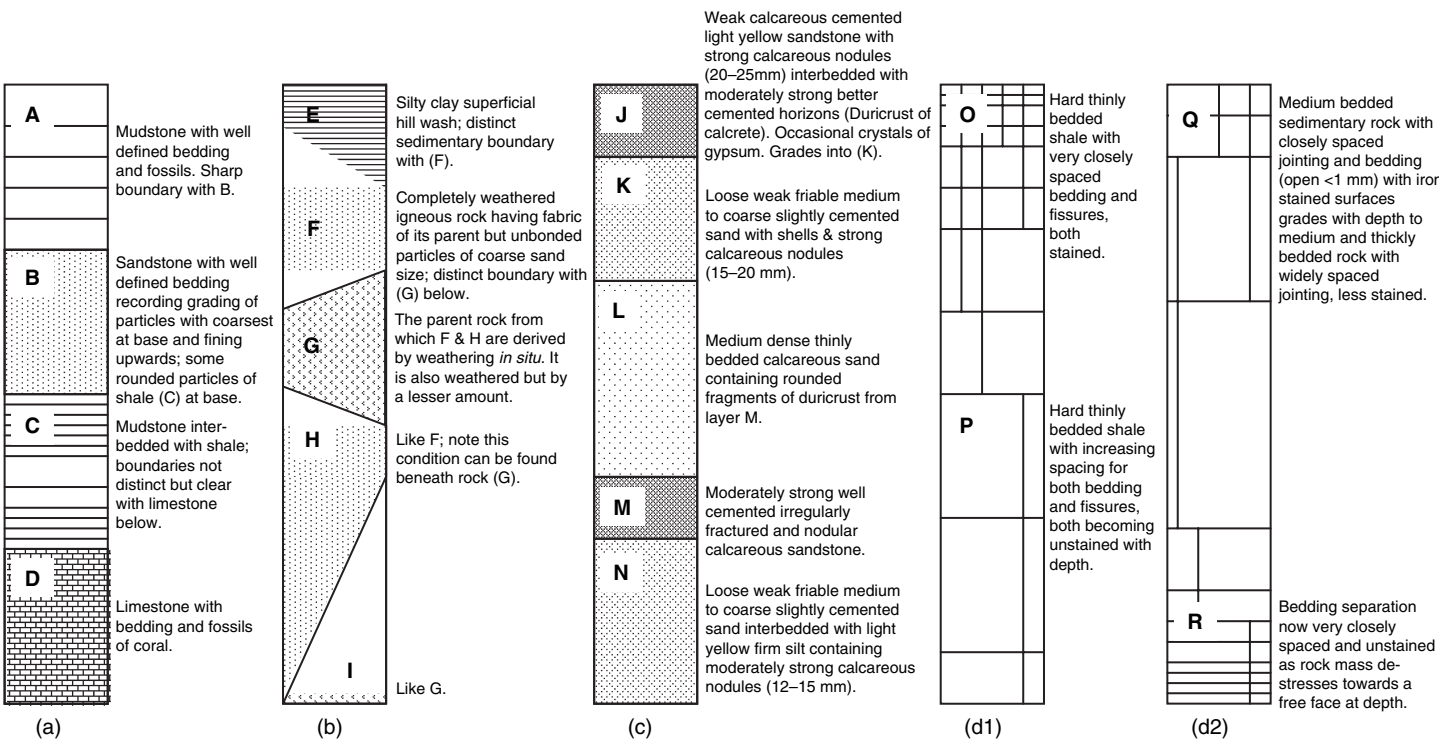

Figure 13.4 Examples of profile formation by (a) sedimentation, (b) weathering, (c) evaporation and (d) stress relief

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

mine below the base of the profile being studied. As layers of strata drop into the void at depth so bedding opens starting with the beds immediately above the void; the effect decreases with distance from the point of collapse. Thus the profile detects an increase in fractures per metre depth, interpreted (correctly) as a progressively deteriorating ground condition with depth – rather the opposite of what is normally encountered. Ground adjusting to the excavation of tunnels, shafts, inclines, basements and the like can create similar changes which increase in intensity approaching the boundary of the excavation.

Although profiles can form in a variety of ways, two features of their formation are unchanging and referred to in geology as the principles of superposition and uniformitarianism.

Any layer found above another is younger than the layer it covers – this is the principle of superposition: **Figure 13.5** illustrates how care needs to be taken even when applying this simplest of laws. Mass movement has transported clay of greater age (layer B) downhill over younger beds (layer A) to form the deposit (layer E); detailed analyses of the included particles, fossil content, and possibly carbon dating, of layer E all confirm the original age of the material making up the layer is greater than that of layer A. However the crucial point is that layer E came after layer A and is stratigraphically younger than layer A. To understand what has happened attention also needs to be directed to the different fabrics the layers may have and to the boundary between them as palaeo-shear surfaces can be expected beneath layer E. Such a situation is commonplace on many slopes and excavation across the junction between such layers can re-activate slope instability (Skempton and Weeks, 1976).

If the laws of physics and chemistry permit an action to occur naturally, then that action can be expected to have happened in the past. Thus, in **Figure 13.5**, the log of an excavation or borehole across layers E, A and B would be correctly interpreted as younger over older if the observer makes a connection between the properties of the profile and the presence of mass transport on the slope, i.e. landslides. This connection would be made because the interpreter either has experience with landslides or has read case histories describing them. In other words, actions experienced at present are usually relevant to interpreting similar actions that occurred in the past. This is the principle of uniformitarianism, often over simplified, as 'the present is the key to the past'.

The log of a vertical section or borehole records geological products as a sequence of materials arranged in layers and zones, with their depth, and by applying the principles of superposition and uniformitarianism this record of products can be used to reveal the likely processes that formed them. All this helps to secure a better understanding of the implications that the profile has for engineering work that is to come. It also means that care must be taken when investigating such profiles.

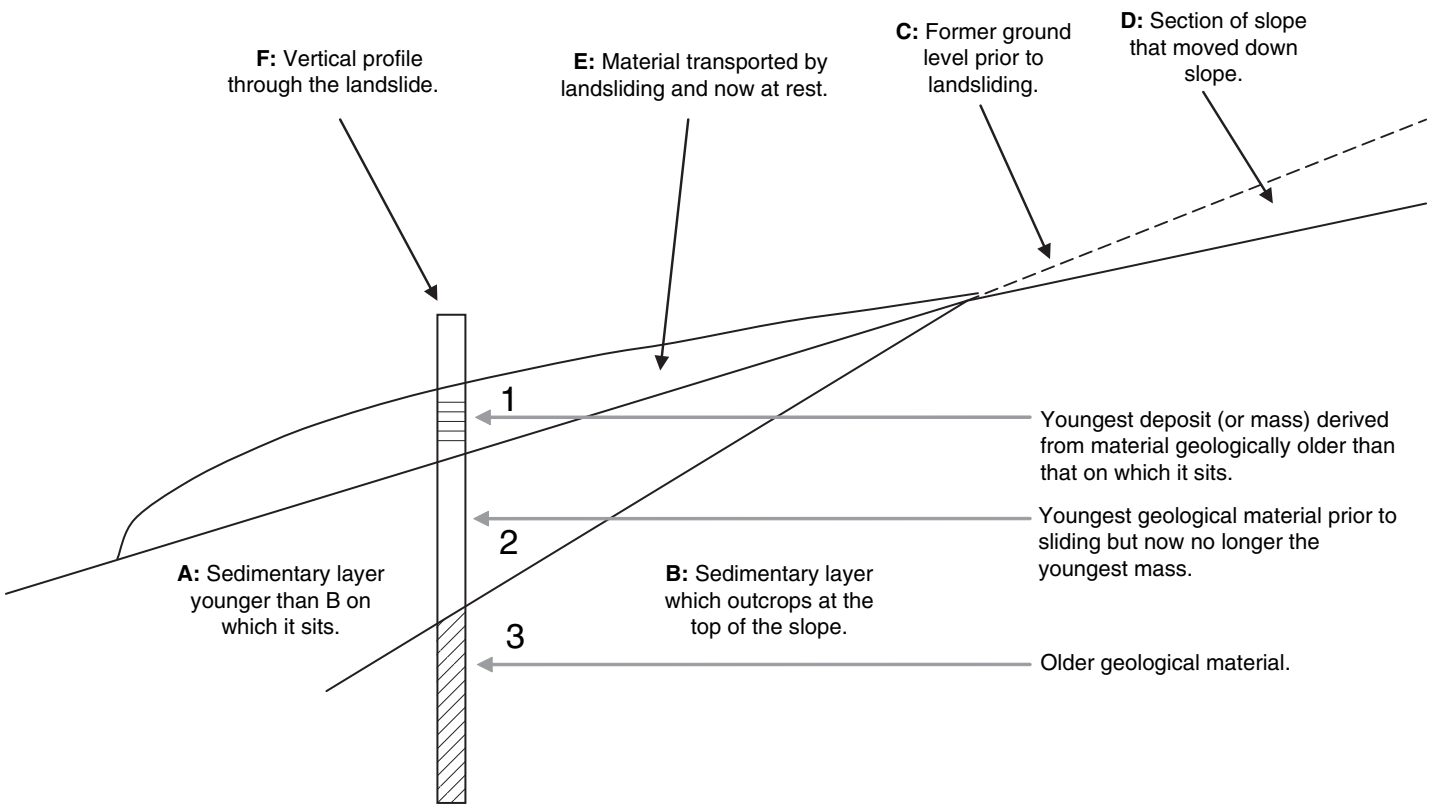

Figure 13.5 A profile from ground covered by landsliding

13.5 Investigating a profile

From what has been said about a ground profile in section 13.2 of this chapter it is evident that if resources and circumstances permit, it is best for the person who logs the ground to also provide the profile.

By far the greatest number of profiles will consist of natural geological sequences possibly covered by a thin layer of Made Ground; it is unlikely that at the start of an investigation the processes involved in forming these would be fully known. Thus any investigation into the ground and any description of it usually take place against this background of ignorance. The ground, even most Made Ground, is not a material manufactured to specification; there is no standard against which it can be compared; it is what it is and its investigation is assisted by considering as much of the ground as possible.

The easiest profile to investigate is one which is totally exposed, as in the face of a quarry or a trench. Compare that with a good quality borehole core from the same profile. The difference between these two pieces of evidence is that the quarry and trench enable the profile to be seen in context (ground to the left and right of it, and possibly below it too) whereas no such context exists for the borehole core, good though it may be.

There are three reasons why the context of information leading to a profile is important:

1. The first is that any investigation is limited; only when the ground is opened by excavation can it be properly seen. The unseen volume of ground that carries the reaction to applied loads can only be seen directly through small excavations such as boreholes, shafts and pits; thus their context is important.
2. The second reason is that the descriptions have, of necessity, to be idealised summations; every detail cannot be recorded. Seeing a profile in context makes a description easier because it helps the identification of significant features around which the idealisation and summation can be focused; thus it may be that the dominant feature is the stiffness and fissuring of clay rather than its silty laminations.
3. The third reason is that the scale used for recording has to be decided. Relevant features in a profile do not have to be large; Terzaghi records the importance of small-scale features to the stability of dams, in this case discontinuities measured in millimetres (Terzaghi, 1929). If recording had been at a scale of 1:1 the discontinuities would have been recorded on a pictorial log; however such a scale is impractical for most purposes. If the pictorial log reduces to 1:10 the fractures can barely be shown. Logs presented at around a 1:50 scale result in such small-scale features to be recorded entirely by words in the written description, supplemented by a good quality photograph, or image, of the core.

It is normal not to know the full context of a single ground profile and this should be remembered when interpreting the log of a succession. That is why it helps to refer to other related information, especially reports from a geological survey, geological maps, aerial photographs and historical land-use maps, and to visit the site and its surroundings. It also helps to have a number of profiles that are close to each other because they start to put each other into context. In addition to context there is the descriptive log upon which the profile is based and here there are rules and guidance from codes of good practice and norms. There is a tendency to believe that it is unnecessary to go beyond what a standard requires. That thinking is wrong – the standards outline the *minimum* that is required; sound guidance is provided by Norbury (2010). Man did not make the ground and often it is being described out of context; it is for this reason that Burland was instrumental in recommending the following descriptors (Anon, 1993) – some of which are used in standards – be given particular attention when logging for the purposes of creating a ground profile.

Moisture condition: this can be indicated using simple tactile descriptors such as *dry, moist* (i.e. neither wet nor dry), *slightly moist, moist, very moist,* and *wet* when water is visible. It is the state of the material as inspected and a condition that can change with time; it may be the only record of moisture content in a profile where samples are not sent to the laboratory for it to be measured. Many profiles penetrate partially saturated soils whose properties can change dramatically on wetting; clays that have shrunk can swell and sands that cohere through capillarity lose that bond when saturated.

Colour: this is the most obvious characteristic of sediments and rocks, regardless of their particle size. Although required for most standard descriptions, it is more than just an identifier because it is often related to moisture content and length of exposure to oxygen. In fissured and jointed materials the colour on the surface of these discontinuities can differ from that of the material they bound. In this way the relative ages of discontinuities can be determined, those *in situ* being stained and those formed later (e.g. by coring and/or stress relief) being less stained. A change in the colour of the sample between the field and the laboratory is the first sign that the sample has changed since its collection. Colour is not easily described; a colour chart designed for soil and rock description, such as the Munsell charts, should be used.

Consistency: this can be considered as a tactile assessment of hardness or density and thus reflects stiffness and strength. Such assessments are a normal requirement of standard descriptions and use such terms as *very soft*, *soft*, *firm*, *stiff* and *very stiff* in clayey plastic materials, to describe the ease with which material can be manipulated. It is important to handle a soil: to roll it in the fingers, squeeze it and push it to see how it holds together and whether it is on the wet or dry side of its plastic limit, and to record that for it may be the only record made if samples are not sent for testing. These simple tactile tests become even more important when dealing with silt contents that begin to alter the behaviour of the soil. The presence of silt can soon be detected by its grittiness and provided the sample has not been contaminated, this can be readily detected on the tongue and between

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the teeth. An alternative and safer method comes from the ease with which 'clay' can be brushed from hands and clothing. If your clothing can be cleaned under the blows of a good beating from your hands (which produce clouds of fine dust) then the 'clay' is largely silt. Failure to remove the soil this way suggests the presence of clay; see further comments under *Soil and rock type*. Silts and sands exhibit little in the way of plasticity and crumble under finger pressure; this has led to use of such terms as *loose* (easy to excavate or to penetrate), *dense* (difficult to do so) and *slightly cemented* (strong enough to be abraded). It is always worth attempting to test silts and sands this way as the origin of resistance within them may be no more than the capillary bond of water and easily lost with the addition of water; mineral cement provides something that can be much stronger as can fabric and not lost by the simple addition of water.

Although consistency is not a word associated with rock, weathered rock can share some of the characteristics described for soils, especially the silty-sandy soils. Weathered rock is by no means easy to describe and tends to grade from the surface of joint and bedding-bounded blocks to their interior. It is extremely valuable to describe the materials present, their locations and the volumetric percent they occupy within the mass. All this is best done qualitatively by careful observation, aided by picking and prodding the material (Martin and Hencher, 1986; Hencher and McNicholl, 1995; Norbury, 2010).

Structure: there are arbitrary divides between *structure*, *fabric* and *texture.* In geology these terms have been used synonymously; here *structure* will be used for features that extend for some distance within a mass and are easily visible to the naked eye. In profiles it is important to observe the structure of the mass – *bedding*, including *laminations*, *fissuring* (a term used for steeply inclined fractures in clayey soils), *jointing* (the term used for such fractures in rock) and *shear surfaces*, especially those from landsliding and faulting. Between these surfaces the material will possess a fabric, or texture, that will determine how the unjointed and unfissured material will behave. These elements of the mass and its materials become important when *in situ* properties are considered, as clearly seen when paper-thin shear surfaces govern the overall strength of a mass and reduce it to residual values. Structure is easy to describe using terms such as *thinly laminated* and *very thickly bedded* for the range of bedding and *extremely closely spaced* to *very widely spaced* for the range in fissures and joints.

Texture, or fabric, are much more difficult to describe yet they can largely control the behaviour of laboratory samples. Although there is no agreement on usage, it is helpful to think of fabric as being the spatial distribution of materials (like the pattern in a cloth woven from different threads) and texture to be the morphological result of their size and distribution (like the surface of such a woven material, which could be rough or smooth).

Small-scale features are significant (Rowe, 1972). They are often revealed by inclusions of different material (e.g. rounded chalk pellets and angular gravel-sized fragments of flint in a homogeneous matrix of putty-like chalk) and subtle changes in the roughness of a freshly formed surface produced by breaking the soil and allowing it to air dry. It is extremely difficult to describe much of what can be seen at this scale and use has to be made of concepts such as *structureless*, *heterogeneous*, and *mottled* (where colour and heterogeneity combine). Rarely can a description be considered complete and so the objective at this scale must be to record as much as can be seen with the vocabulary available, and support that with a scaled photograph. The difficulties here are well reflected in the problems associated with describing weathering (Anon, 1995). Sometimes clayey sediment separates easily on bedding, as partings, especially if it has traces of silt, and this should be noted.

Texture is something perceived on surfaces and should be considered because if the surfaces have formed by shearing they will almost certainly contain grooves and striations that betray *slickensides*; these indicate that their shear strength will be at a residual value in their direction of grooving. If surfaces are rough, their shear strength will be a function of friction and dilation in the direction of shear.

Soil and rock type: every description requires this and care must now be taken because the exercise of description slips into one of classification.

For soils, grain size and plasticity dominate the decision of what to call them; the former in materials where individual particles can be seen and the latter for materials where individual particles are indiscernible. The boundary between these two is where mistakes are easily made – in the silt/clay transition of the soil classification. Here tactile evidence is of great help; it is important to know whether silt is present in clay and a warning that laboratory tests may be needed to be certain what the soil should be called. A particularly sensitive tactile test requires a sample of the sediment to be placed in the palm of the hand and gradually dispersed with water until a paste is produced which can then be squeezed, by closing the palm, and relaxed by reopening the palm. The paste can behave in different ways depending on its silt content. If purely silt the paste, on opening the palm, will appear dry and possibly brittle, but tapping the palm will soon bring its free water to the surface as its brittleness melts away and it reverts to a paste again. All this reflects the response of pore water in the sample to dilation of its particles, and to capillary tensions between them; it indicates that the paste dilates readily, that its particles are larger than clay and permit the easy movement of water between them (unlike clay). In contrast, pure clay will produce a paste, which is still wet and creamy after the palm is squeezed and reopened. The name eventually given (*silt, clay, silty clay,* etc.) must conform to the specifications of the standards and codes that govern these things, and can normally only be achieved with the aid of laboratory tests.

For rocks the task is rather different. Rock names, unlike soil names, are traditionally based on their geological origin, petrological fabric and mineralogical composition e.g. granite, gabbro, limestone and sandstone. Their mechanical properties are linked to fabric and material, and as yet there are no rules that

can be used to relate rock names to their mechanical properties; the link for this is empirical. It is therefore important to name them correctly, as their name will be used to link into archives of behaviour for rocks of similar character. Serious difficulties for both description and naming arise when the rock is weathered; a working group that reviewed this cautioned that in every case the material should be described as well as possible but that a classification of weathering (grade 1, 2, 3, etc.) should only be used in cases where it can be applied unambiguously (Anon, 1995). Although some standards and codes may do things differently, the advice within the 1995 reference (*ibid*) is scientifically sound and worth recording as it can be applied to rocks in all climatic zones.

Origin: until now, the work of recording a profile has mainly involved description with some classification when dealing with soil and rock type, but to deduce the origin of a material is to venture into an interpretation, unless the material has been seen to form. The many ways in which geological materials may form can be grouped into two categories: either they were transported to where they are now – by wind, water or ice, or as a viscous flow driven by gravity, or by man – or they originated in place and are the remains, or residues, of what was there before. Geological experience is required to decide on origin especially as the materials within a profile may have formed in a number of ways. Section 13.4, The formation of a profile, introduces the four basic routes that can result in a profile, and any one route does not preclude the operation of another at a later date. Thus a saprolite that has formed in place may have its upper levels disturbed by hill wash and be covered by transported material that is later indurated to create a duricrust – the whole profile being subsequently disturbed by adjacent excavation which relaxes the ground. In other words, deducing the origin of a profile need not be straightforward.

Allocating a correct name to a material, particularly a stratigraphical name (e.g. Oxford Clay Formation) is helpful but not sufficient. It refers to the accumulation of the material at its *time zero* (when it was formed). However, the engineering behaviour of the profile will also reflect what has happened to it since then – and in geology *time zero* could be a long time ago.

Ground water: it is often not appreciated that this is truly an independent variable; its level can rise and fall for no ground-related reasons, but arising from infiltration, recharge and discharge. Its level is a fact in time and is important; it should be recorded both when encountered and not encountered. It may be that the descriptive log records no ground water and that standpipe and piezometric data needs to be obtained later to complete that record.

13.6 Joining profiles

Having obtained individual profiles from specific locations and in so doing acquired an insight into the character of the ground on site, it is necessary to use that knowledge to reveal what may lie elsewhere on site in locations that have not been investigated. Extrapolating the individual profiles laterally and possibly vertically (as results when they are joined to form vertical cross-sections) does this, and enables the tiny pieces of information they represent to be used to best advantage. However, there are three hazards associated with this exercise.

The first hazard when using extrapolation is quality: if the exercise uses data from different sources, e.g. logs from elsewhere and your own records, or a mixture of records from a variety of sources, then it is important to relate and calibrate the data so that like can be joined with like. Different schemes of logging or observers with different experiences might have been used. Similarly, descriptions might have been acquired at different times of the year when the profile may have exhibited seasonal changes linked to moisture content and water level. The second hazard is scale: it is necessary to consider the scale at which data has been recorded, as mentioned in section 13.5 above – to know what has been combined and is now presented as a 'homogeneous' unit. The third is origin: here, attempts at understanding the origins of a profile are rewarded because that knowledge constrains the data that can be joined. Units of different origin, even if they are at the same elevation, should not be joined. The fact that they cannot be joined suggests there is some other reason on site, perhaps not yet revealed, that prevents this, e.g. weathering, erosion, faulting, landsliding, subsidence.

Figure 13.6 illustrates a vertical section created from individual ground profiles. Three boreholes intersect firm, thinly-bedded clay that becomes soft towards ground level and stiff above a sand layer at depth. The only clear marker horizon is the clay–sand junction – and with no other information, that would be the only line on the section. However, when standard penetration test results obtained in the clay are plotted against the profile (**Figure 13.6a**), the change in consistency described qualitatively can be seen to have quantitative limits which divide the profile into three, so making four zones (**Figure 13.6b**). These can be detected across the site and, when used, show that although the site has horizontal strata there is superimposed upon this original structure a second profile that has sloping boundaries. Estimates of mechanical parameters and material response based on depth alone might therefore be in error. Such profiles can be generated by weathering and erosion.

13.7 Interpreting profiles

Interpretation is applied both consciously and subconsciously throughout the assembly of a profile; every description requires an interpretation to convert what is seen into a decision on what it is. Photographs involve no interpretation, but they have to be interpreted to help create a profile, and are often better if some thought is given to what is being recorded. Decisions are made about the material seen, the definition of its boundaries, its origins and its relationships with other profiles nearby. All this is a prerequisite to an interpretation of the response of the ground to engineering.

This interpretation might be possible without any further information, as was partly the case with the excavation at the

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

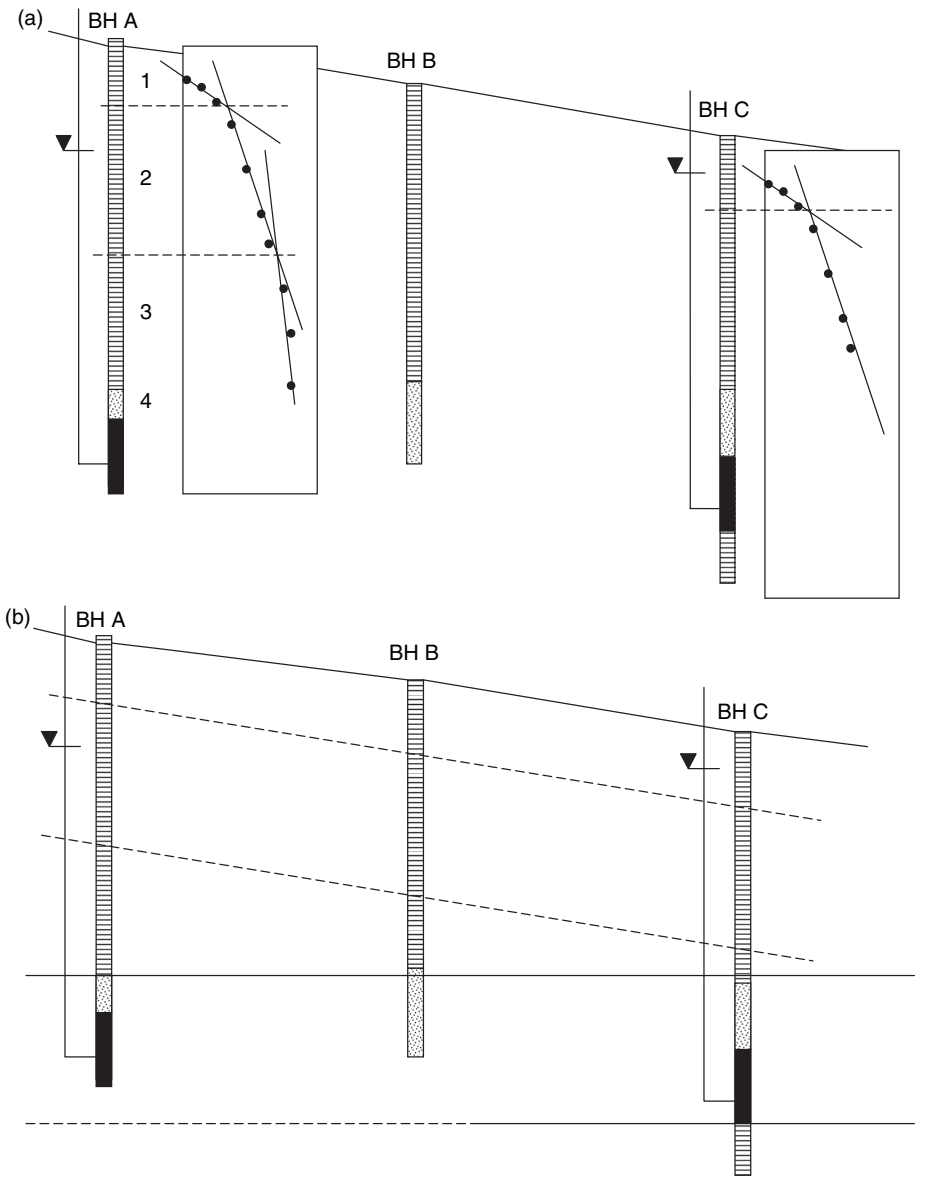

Figure 13.6 A vertical cross-section created by joining ground profiles

Palace of Westminster (**Figure 13.2**). However, in many cases there is other information of a more mechanical character that can be superimposed on the basic vertical cross-section(s) created from the individual profiles. Core recovery, fluid returns, water levels, penetration rates, borehole instability, *in situ* tests, laboratory tests, etc. can all be superimposed upon the vertical sections and profiles to assist their interpretation (**Figure 13.6**).

When using ground profiles it is helpful to consider the ground response that can be anticipated in terms of strength, deformability, permeability and durability, and to review the profile in relation to each, selecting whichever is pertinent to the work in mind; often this will be three of the four. From this will come an holistic view of the likely response of the ground: one that is qualitative but can be justified and its magnitude approximated to give sufficient focus to more quantitative methods for analyses that will have to idealise the ground for the practical purposes of calculation. In this way the basis for that idealisation is placed on reasoned judgement and good geotechnical practice.

13.8 Conclusions

1. A ground profile relies on an accurate and complete description of the ground, usually in the form of a log.
2. The primary purpose of that log is to describe the ground as it exists in the ground, *in situ*; it forms the most basic of ground profiles.

3. To that basic data should be added the observations and interpretations that put the log into context in terms of geological history, especially in terms of characters that are time dependent, such as ground water, gas, *in situ* stress and stress relief.
4. This allows some thought to be given to the history of the ground, from its formation to the present day, and especially over the past 10 000 years – essentially since the end of the Ice Age.
5. These data should then be considered at a scale that is appropriate for the engineering work to which they will be applied, and joined to give cross-sections from which a conceptual model of the ground can be gained.
6. Such a model enables the grouping of material, which will be allocated characteristic values, to be justified on the basis of available evidence, verified as the ground is exposed and adjusted as needs be, with the implications of such adjustments being fed directly into the mechanical properties of the ground and its analysis.
7. Ground profiles are therefore both the starting point for and the justification of quantitative analyses of the ground. Securing a good set of profiles is the best investment a ground investigation can make.

Soil is made up of countless particles of different shapes and sizes which are in frictional contact with each other and are acted on by gravity. This chapter illustrates the key features of mechanical behaviour that stem directly from the particulate nature of soils. A simple base friction apparatus is described that demonstrates some of these features. In particular the importance of self-weight and microfabric are illustrated, together with the phenomena of contractancy and dilatancy. The apparatus is used to study particle movements associated with active and passive earth pressures, settlement and bearing capacity. A simple mechanistic approach is presented to illustrate the importance of pore water pressure, leading to a demonstration of Terzaghi's effective stress principle. A similar mechanistic approach is used to introduce some key features of unsaturated soil behaviour.

14.1 Introduction

It was pointed out in the Introduction to Chapter 4 *The geotechnical triangle* that soil is a particulate material. Thus a sample of soil is made up of countless particles of a variety of shapes and sizes. The particles are in contact with each other, and the arrangement of particles is often referred to as the 'soil skeleton'. Loads are transmitted through this skeleton at points of contact between the particles. Frequently the contacts between the particles are essentially frictional. However, in many natural soils there is a small amount of bonding between the particles either due to cementation or physico-chemical effects (Mitchell, 1993). The presence of even a small amount of bonding between the particles can have an important influence on both the stiffness and strength of a soil.

The purpose of this chapter is to illustrate in a very simple mechanistic way the key principles governing the behaviour of particulate materials. In order to carry out calculations of ground displacement and stability it is necessary to idealise the soil as a continuum with certain stiffness and strength properties. The danger is that we get so used to thinking in terms of the stress–strain response of idealised continua (e.g. porous elastic materials or elastic–perfectly plastic materials) that we forget all too easily that the soil is actually particulate and its behaviour is controlled by this fact.

14.2 Phase relationships

Figure 14.1 illustrates an element of soil made up of a number of discrete particles. The spaces between the particles are referred to as the 'voids'. The voids may be filled with water or a mixture of water and air. Completely dry soils whose voids are filled with air are not often encountered in nature but can be reproduced in the laboratory.

The closeness of packing of the particles has a dominant influence on the mechanical behaviour of a soil. The more densely packed the particles the greater will be the stiffness and strength of the soil and the lower will be its permeability. A

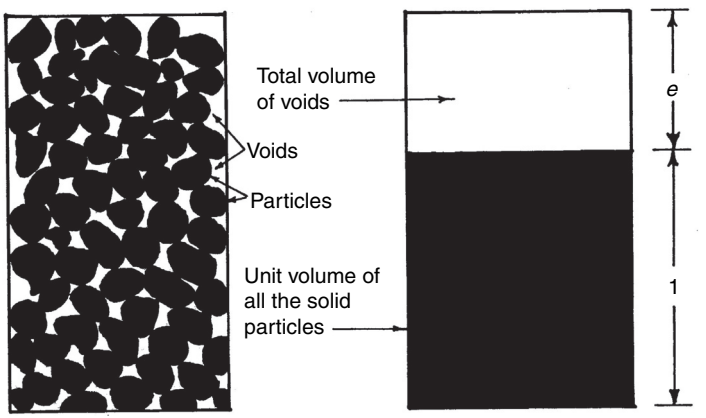

Figure 14.1 Soil is a particulate material. Void ratio e = volume of voids per unit/volume of solids

widely used measure of the 'closeness of packing' of the particles is the volume of the voids in an element of soil divided by the volume of all the particles (solids). This is termed the 'void ratio' of the soil and is denoted as e. Thus the void ratio e is the volume of the voids per unit volume of the solids – see **Figure 14.1**. Another less widely used measure of the closeness of packing of the particles is *porosity* (n), which is defined as the ratio of the volume of voids to the total volume of the soil element, so that, from **Figure 14.1**, $n = e/(1 + e)$. Because of its ease of determination, the closeness of pack of the particles in fully saturated soils (particularly clayey soils) is frequently specified in terms of the mass of water divided by the mass of the solids and is defined as the moisture content w. The various relationships between the volumes and masses of solids, voids, water and air are termed *phase relationships* and these can be found in any basic textbook on soil mechanics – e.g. Craig (2004) and Powrie (2004). These relationships are not complicated but remembering them can be tedious!

14.3 A simple base friction apparatus

It is possible to illustrate many of the basic mechanisms of behaviour of particulate materials using a simple physical model. **Figure 14.2** shows a photograph of what is termed a 'base friction apparatus'. It consists of a perspex base across which a standard acetate strip is drawn by means of a small variable speed electric motor. The arrow in **Figure 14.2** shows the direction of movement of the sheet. In this case the model particles consist of short lengths of copper tube of three different diameters. When the electric motor is switched on the acetate sheet carries the particles with it until they come up against a boundary, after which the acetate sheet 'drags' against each particle, simulating the force of gravity acting on it. The behaviour of the particles can be projected on to a vertical screen by means of an overhead projector so that they appear to be 'dragged' downwards under the action of gravity.

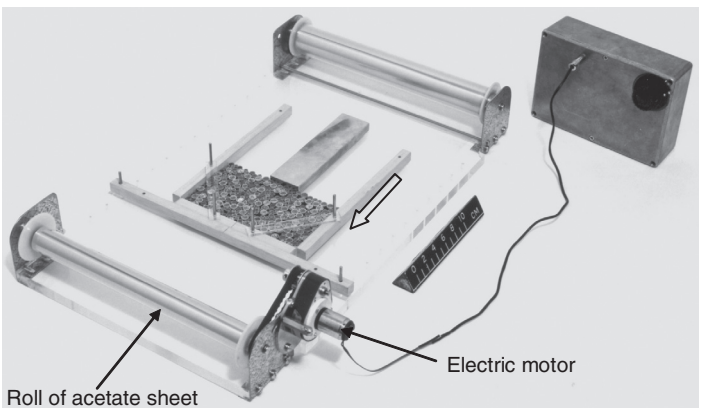

Figure 14.2 Base friction model (arrow shows direction of movement of acetate sheet)
Reproduced from Burland, 1987

The key feature of a base friction apparatus is that it simulates the forces of gravity which give rise to the all-important effects of self-weight. In soil mechanics, the self-weight of the material generates the confining pressures that govern its strength and stiffness, and it also provides the dominant stabilising and destabilising mechanisms for most stability problems.

14.3.1 The process of deposition

Figure 14.3 illustrates the process of vertical deposition of a dispersed suspension of particles acted on by gravity into a container with a horizontal base and vertical sides. **Figure 14.3(c)** shows the particle arrangements on completion of deposition and illustrates a number of important features. The small particles tend to form into clusters. There are a number of voids around which the particles tend to 'arch' so that beneath an arch the particles will not be transmitting much load. If a top plate is placed on the assemblage and gravity is 'switched off', then a gentle up and down movement of the whole assemblage shows that there are numerous 'loose' particles that are not transmitting any load, i.e. there are many more 'arches' than was at first apparent. The whole assemblage is clearly in a very loose state with a high void ratio.

Another key observation is that it is possible to trace numerous vertical and sub-vertical columns of particles showing well-defined preferred arrangements or 'structures'. Thus the particles have arranged themselves so as to resist the dominant vertical gravity forces and the assemblage is stiffer and stronger in the vertical direction than in the horizontal direction. In other words the assemblage has anisotropic properties which are inherent to the mode of deposition under the action of gravity.

The assemblage of particles shown in **Figure 14.3(c)** is termed 'normally consolidated' because the vertical stresses acting on it are those imposed as a result of deposition. If the vertical stresses are reduced subsequent to deposition the

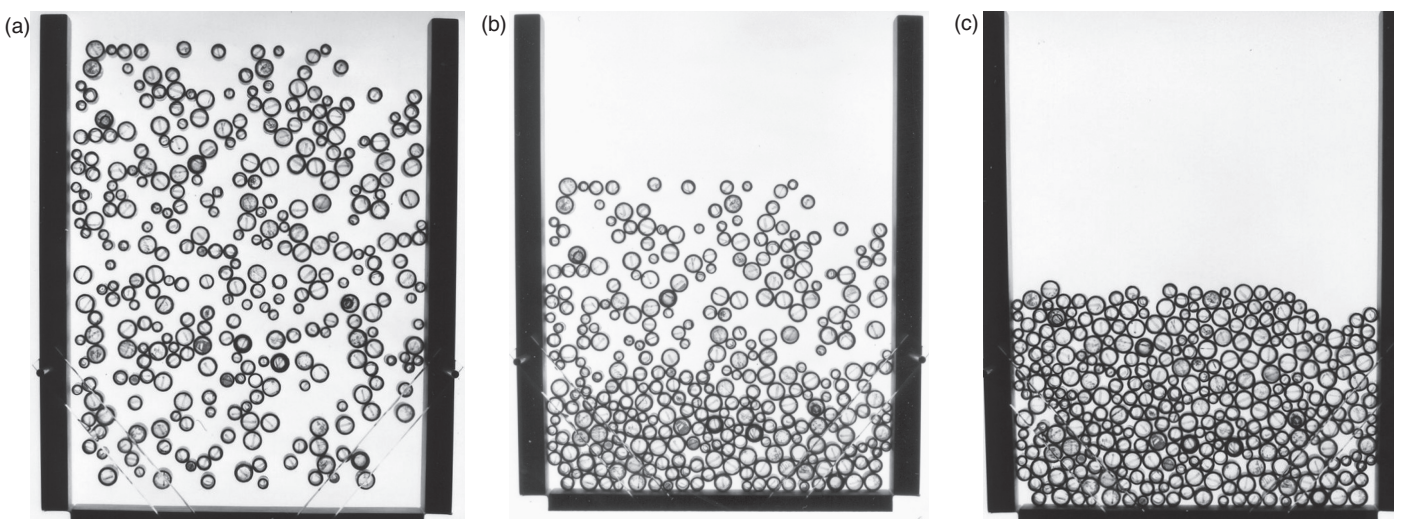

Figure 14.3 Successive stages of the deposition of an initially dispersed suspension of particles
Reproduced from Burland, 1987

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

material is defined as 'overconsolidated'. The 'overconsolidation ratio' is the maximum previous vertical stress divided by the present vertical stress. Normally consolidated soils are invariably in a loose state.

14.3.2 Contractant and dilatant behaviour

If a top plate is placed on the surface of the assemblage of particles, gravity is 'switched on' and the sides of the container are then slowly rotated by equal amounts in the same sense, then the assemblage will be deformed under what is termed 'simple shear'. During this process of shearing it will be observed that the various 'arches' of particles are broken down and the particles move to take on a closer packing, i.e. the void ratio *decreases*. This process of void ratio reduction during pure shearing is known as 'contractancy'.

The assemblage of particles can be compacted to a closer pack by 'switching on' gravity and tamping the top plate. If after compaction the assemblage is again subjected to simple shear it can then be observed that the particles ride over one another and the overall volume *increases*. This process of void ratio increase during pure shearing is known as 'dilatancy'.

The phenomenon of contractant and dilatant behaviour during shearing is almost unique to particulate materials and is an extremely important property having a profound influence on the shearing resistance of the material.

14.3.3 Active and passive earth pressures

The base friction apparatus can be used to illustrate the development of active and passive regions behind and in front of retaining walls. Refer to Chapter 20 *Earth pressure theory* which discusses active and passive earth pressures. **Figure 14.4(a)** shows what happens if gravity is 'switched on' and one of the sides is then rotated away from the retained assemblage of particles. It can be seen that the movement of the particles is confined to a relatively narrow wedge-shaped region close to the wall. This is known as the 'active' wedge. At a relatively small rotation the earth pressure reaches a steady minimum value termed the 'active earth pressure'.

Figure 14.4(b) illustrates the movement of the particles when the wall is rotated inwards towards the retained material. It can be seen that the region of movement of the particles extends much further than for the active wedge; it is known as the 'passive' region – in this case it is still wedge-shaped. Much larger rotations are required to fully mobilise full 'passive earth pressure' than for active conditions.

14.3.4 Foundation settlement and bearing capacity

The mechanisms involved in foundation settlement and bearing capacity can be studied by placing a thin rectangular strip of wood on the acetate sheet of the apparatus and then 'switching on' gravity. The foundation moves slowly down until it is in contact with the ground surface. By placing a relatively light weight on the wooden strip the frictional drag on the strip is increased (simulating a small increase in foundation loading)

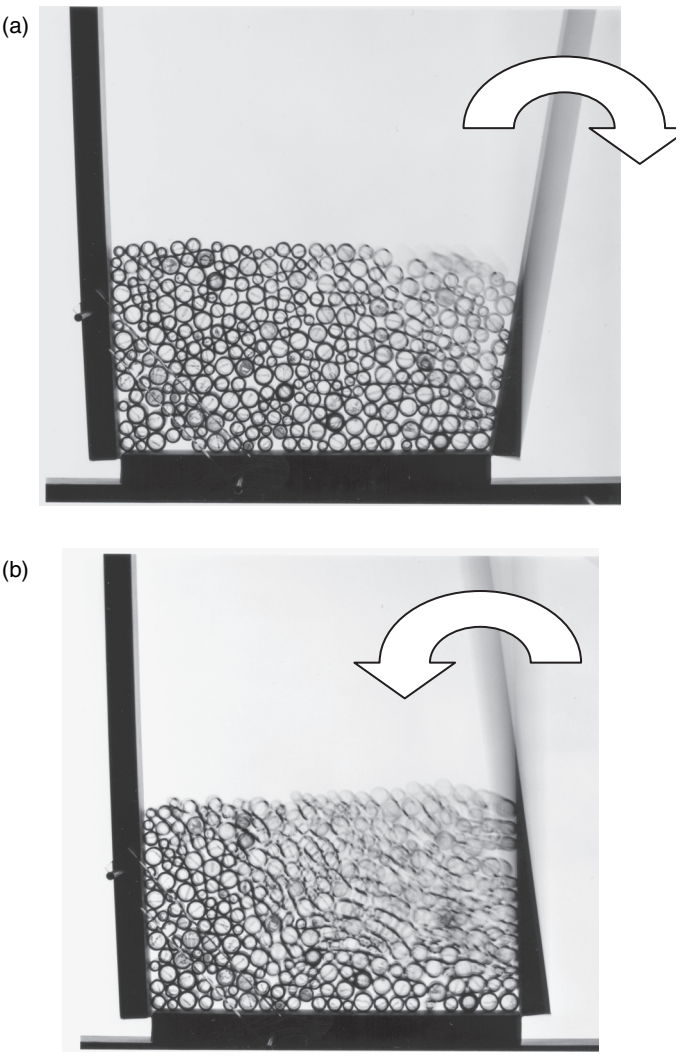

Figure 14.4 (a) Development of an active earth pressure region. (b) Development of a passive earth pressure region
Reproduced from Burland, 1987

and the foundation settles due to the compaction of some of the particles immediately beneath the foundation. The zone of compaction is confined to a depth equal to about half the width of the foundation.

The load can be increased further by replacing the wooden strip with a brass strip. When gravity is 'switched on' the foundation settles significantly and the zone of particle movement extends further beneath the foundation and outwards on either side as shown in **Figure 14.5**. The foundation has reached bearing-capacity failure and the shearing resistance of the assemblage of particles has been fully mobilised within the observed zone of movement. Further loading of the brass strip causes it to plunge and the zone of particle movement extends around the base and upwards to the surface alongside the strip. This behaviour is modelling the driving of a pile into granular material, and it is possible to visualise the development of high end resistances and also frictional resistance along the shaft of the pile.

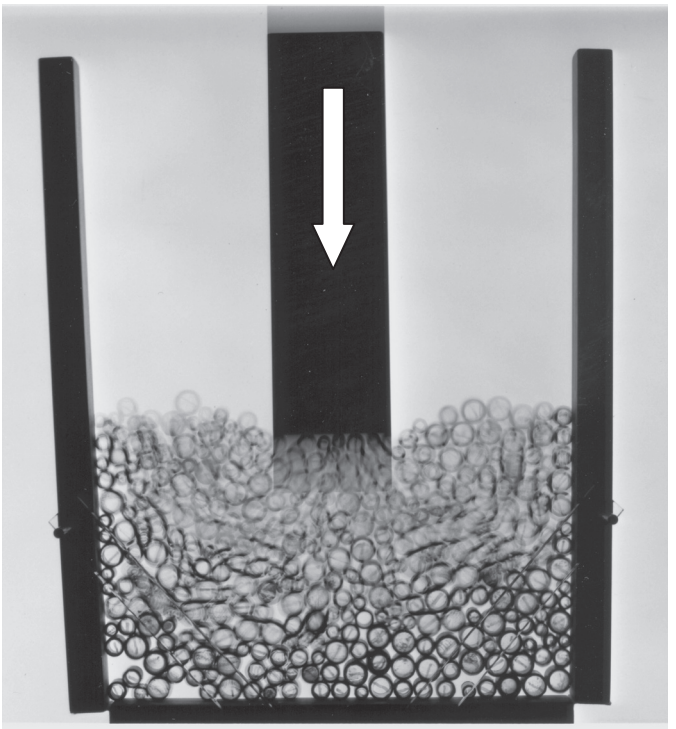

Figure 14.5 Development of bearing-capacity failure
Reproduced from Burland, 1987

The base friction apparatus can be used to illustrate mechanisms of ground behaviour for other geotechnical problems as well. For example it can be used to illustrate subsidence above tunnels and arching around them as they are excavated. Also it is possible to illustrate the mechanisms of deep-seated movement around propped excavations.

14.4 Soil particles and their arrangements

In the previous section we examined the mechanical response of a relatively simple assemblage of round particles of three different sizes. It was evident that, even with an assemblage composed of uniformly shaped and sized particles, relatively complex arrangements can occur. Most natural soils are made up of much more complex arrangements of particles.

14.4.1 Particle size

The range of sizes of particles that make up a soil is huge, varying from boulders, through gravels, sands and silts down to clay sizes. **Table 14.1** shows the approximate sizes of these particles and some important visual and tactile descriptions. **Table 14.2** illustrates the amazing range of sizes, numbers and surface areas of typical grains in a gram of soil. **Table 14.3** describes dimensions of three typical clay minerals. The engineering importance of grain size lies primarily in the drainage characteristics of the soil thereby influencing the permeability and rate at which the volume change and strength respond to changes in loading.

Very few soils in nature fall entirely within one grain size classification. Mostly soils are mixtures (e.g. silty clay; very sandy, fine to coarse gravel). The distribution of grain size in a soil is termed its 'grading'. Thus the 'soil type' is primarily based on grain size and grading. There is an unfortunate tendency in practice to refer to 'cohesive' and 'non-cohesive' soils to distinguish between soils with a high or a low clay content. This can be very misleading as many normally consolidated

Soil type		Size (mm)	Visual or tactile description
Boulders			**Visible to the naked eye**
Gravel	Coarse	>60	**Particle shape:**
	Medium	20	Angular; subangular; rounded; flat; elongated
	Fine	6	
Sand	Coarse	2	**Texture**: Rough; smooth; polished
	Medium	0.6	**Grading**: Well graded (wide range of sizes)
	Fine	0.2	Poorly (uniformly) graded
			Gap graded
Silt		0.01	**Not visible to naked eye**
			Gritty to hand or teeth
			Disintegrates quickly in water
			Exhibits dilatancy when squeezed in hand
Clay		0.002	Feels soapy when rubbed with water in hand
			Sticks to fingers and dries slowly
			When spread with knife leaves shiny surface
Organic soils			Contains substantial amounts of organic matter
Peats			Predominantly plant remains, dark brown or black
			Low bulk density

Table 14.1 Soil types

Particle	Diameter (mm)	Mass (g)	No. per gram	Surface area m^2/g
Boulder	75	590	1.7×10^{-3}	3×10^{-5}
Coarse sand	1	1.4×10^{-3}	720	2.3×10^{-3}
Fine sand	0.1	1.4×10^{-6}	7.2×10^{5}	2.3×10^{-2}
Medium silt	0.01	1.4×10^{-9}	7.2×10^{8}	0.23
Fine silt	0.002	5.6×10^{-12}	9×10^{11}	1.1

Table 14.2 Typical grain dimensions (assumed spherical)

Mineral	Width (mm)	Width/thickness	Surface area (m^2/gr)
Kaolinite	0.1–4.0	10:1	10
Illite	0.1–0.5	20:1	100
Smectite	0.1–0.5	100:1	1000

Table 14.3 Typical clay mineral dimension

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

clay soils do not exhibit cohesion and many granular soils can be bonded. Moreover, all soils that are sheared without allowing drainage exhibit undrained strength which is often treated as an equivalent cohesion in analysis. True cohesion in a soil is a very difficult property to determine and its precise definition is far from clear. It is much better simply to refer to 'clayey soils' and 'granular soils' without implying anything about their cohesion (sometimes the terms 'fine-grained' and 'coarse-grained' are used).

14.4.2 Particle shape

The particles used in the simple base friction model illustrated in section 14.3 of this chapter are circular in shape. Soil particles vary in shape. For granular soils (boulders down to silt-size particles) the variety of shapes may be embraced by the following descriptors: angular, sub-angular, rounded, flat, elongated – see **Table 14.1**. The texture of the particle surfaces also varies ranging from rough, through smooth, to polished. The shape and angularity of the particles have a profound influence on its shearing resistance. This was impressed firmly on the author when he went for a walk on Chesil Beach in Dorset. The beach is made up of smooth rounded gravel-sized particles – see **Figure 14.6**. As a consequence it is extremely difficult to walk on the beach because the grains move around so much underfoot!

Clay particles are generally much smaller than their granular counterparts and are usually plate-like in shape with plan dimensions much greater than the thickness. **Table 14.3** gives some typical dimensions of three common clay minerals: kaolinite, illite and smectite (montmorillonite). The clay content in a soil, together with stress history, has a dominant influence on its compressibility.

14.4.3 Fabric and micro-structure

The above sizes and shapes of particles combine to form a bewildering array of particle arrangements – termed the 'fabric' of the soil. **Figures 14.7** and **14.8** show, respectively, some typical

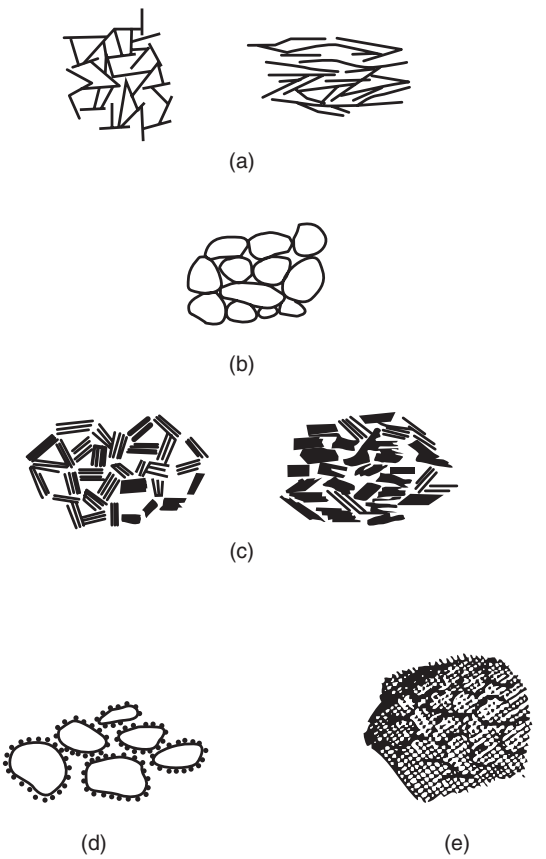

Figure 14.7 Schematic representation of elementary particle arrangements. (a) Individual clay platelet interaction. (b) Individual silt or sand particle interaction. (c) Clay platelet group interaction. (d) Clothed silt or sand particle interaction. (e) Partly discernible particle interaction

schematic representations of elementary particle arrangements and particle assemblages (Collins and McGown, 1974).

As mentioned previously, the particles of soil are usually in mechanical contact with each other, and resistance to sliding at the contact results from friction and interlocking. Frequently in natural soils the particles are lightly bonded at their grain contact points due to cementation or physico-chemical effects.

The term 'micro-structure' means the combination of 'fabric' (the arrangement of the particles) and interparticle 'bonding' (Mitchell, 1993).

14.4.4 Macro-structure

It is important to appreciate that many soils have discontinuities through the mass of the soil as a result of geological or man-made processes. For example joints and fissures can form due to deformations during deposition or tectonic activity. These give rise to important planes of weakness, particularly if clay particles on the joint surface have realigned themselves to give very low frictional resistance. Similarly, pre-existing shear planes can exist in clayey soils due to previous landslipping or geological processes. The weathering of rocks containing relic joints can also lead to important planes of weakness in the soil mass. The presence of such discontinuities can have a dominant influence on the strength of the ground.

Varying depositional environments can lead to alternating layers of clays and granular materials. These more permeable layers usually need to be taken into account in the design and construction of excavations, slopes and embankments. An example of this is given in Chapter 4 *The geotechnical triangle* where it is shown that the design of the underground car park at the Palace of Westminster was dominated by the discovery of thin silt and sand partings in the clay just beneath excavation level. It is also important to note that the presence of joints and fissures can profoundly influence the mass permeability of the ground, particularly if any bonding or cementation is present in the soil mass, because there will be a tendency for these discontinuities to remain open.

14.5 The concept of effective stress in fully saturated soils

Appreciation that soils are essentially particulate materials, albeit very complicated ones, leads to a simple mechanistic understanding of the underlying factors that govern the behaviour of fully saturated soils. **Figure 14.9** shows an element of

soil containing an aggregation of particles where the voids between the particles are full of water. The sides of the element are acted on by the stresses σ_v, σ_h and τ_{vh} as shown, and there is a positive pressure u acting in the water. The stresses acting on the boundaries of the element (called total stresses) are made up of two parts: (i) the water pressure u, which acts in the water and in the solids in every direction with equal intensity as shown, and (ii) the balances $(\sigma_v - u)$, $(\sigma_v - u)$, and τ_h which are carried by the soil skeleton. Terzaghi (1936) defined these balances $(\sigma - u)$ and τ as 'effective' stresses. He then stated his *effective stress principle*, which is that 'all measurable effects of a change of stress, such as compression, distortion and a change of shearing resistance, are exclusively due to changes in effective stress'. Thus the two variables, the total normal stress σ, and the pore pressure u, have been replaced by a single variable $\sigma' = (\sigma - u)$. This is a tremendous advantage when measuring the mechanical properties of a soil, as only the relevant effective stresses have to be applied and not the absolute values of the total stress and pore pressure. On the other hand the effective stress principle requires that, in carrying out a soil investigation, it is essential to know the *in situ* pore pressures as well as the total stresses acting on the soil.

It is important to note that the effective stress principle says nothing about the way that the effective stresses are transmitted through the soil skeleton, i.e. it gives no information about the stresses at the particle contact points. Thus an effective stress is *not* an inter-granular stress even though it is sometimes called that. The effective stress is simply that part of the total stress that is carried by the soil skeleton. Note that a shear stress is always an effective stress because water cannot carry shear.

The validity of Terzaghi's effective stress principle can be demonstrated mechanistically as follows. **Figure 14.10(a)** schematically illustrates an element of loose granular material which in **Figure 14.10(b)** is compressed by the application of an all-round stress σ with the pore pressure u held constant. At each grain contact point is acting a normal force P and a shear force T as illustrated in **Figure 14.10(b)**. In view of the large number of grain contact points for each grain, relative displacement between grains can only take place as a result of slip at the contact points. For a grain to be in equilibrium under its contact forces the ratio T/P must be less than or equal to μ at every contact point, where μ is the coefficient of friction of the material composing the grains.

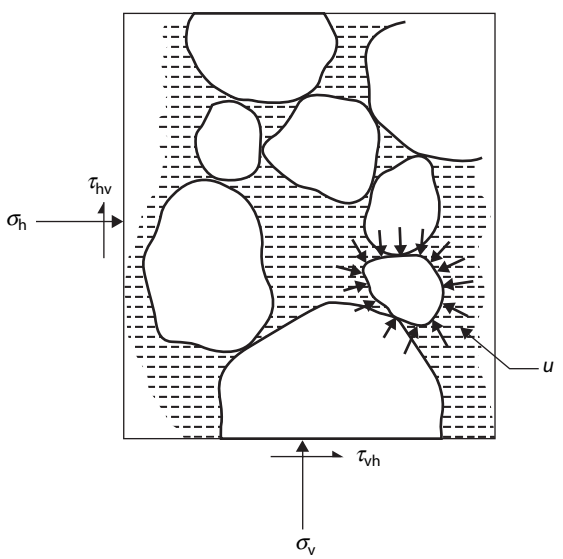

Figure 14.9 Mechanistic model of a loose granular material
Reproduced from Burland and Ridley, 1996

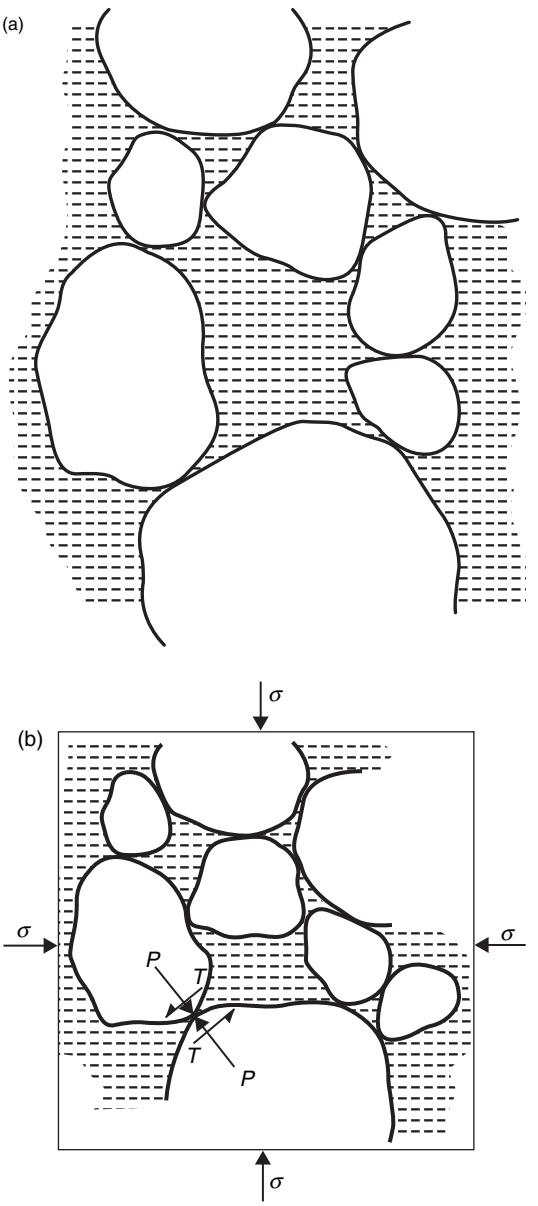

Figure 14.10 Mechanistic model of a loose granular material compressing under equal all-round effective stress. (a) uncompressed. (b) compressed
Reproduced from Burland and Ridley, 1996

An increase in all-round stress $\Delta\sigma$ at constant u will cause a small decrease in volume. This occurs as a result of grain slip at some contact points at which $T/P = \mu$ giving rise to a closer pack of the particles. Therefore an increment in all-round stress induces increases in shear force as well as normal force at the grain contact points. If, instead of an *increase* in total all-round stress σ, the pore pressure u is *decreased* by the same amount, the assemblage of grains would behave in exactly the same way. Clearly a decrease in u is equivalent to an increase in σ in its effects on the grain contact forces. This is a simple mechanistic demonstration of Terzaghi's principle of effective stress for fully saturated soils. It provides a clear demonstration that knowledge of the pore pressure in a soil is just as important as a knowledge of the applied stresses.

14.6 The mechanistic behaviour of unsaturated soils

When a soil is unsaturated the voids contain both air and water. If the air voids are continuous then the water tends to migrate towards the grain contact points due to surface tension effects. **Figure 14.11** shows two spherical particles in contact, with a lens of water around the contact point. It can be shown that surface tension within the curved surface of the water, called the meniscus, generates a compressive force F between the particles. This phenomenon is of profound importance to the behaviour of an unsaturated assemblage of particles. The pressure within the lens of water is less than atmospheric, i.e. the water pressure is negative and is often termed 'suction'.

14.6.1 The process of drying a soil

Figure 14.12 illustrates mechanistically the process of drying for a loose granular soil. In **Figure 14.12(a)** the assemblage of grains is fully saturated and the pore pressure is positive. Evaporation, or drying, then starts to take place, reducing the pore pressure. In **Figure 14.12(b)** the assemblage is still fully saturated but menisci have formed at the boundary. In this situation the pore pressure is less than atmospheric and the tension in the boundary menisci induces compression of the assemblage, resulting in some grain slip and a small reduction of volume.

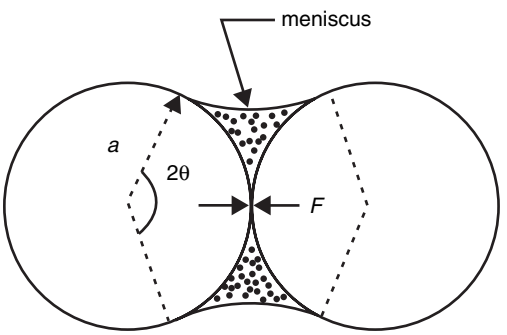

Figure 14.11 Inter-particle force due to surface tension
Reproduced from Burland and Ridley, 1996

At a limiting value of suction (known as the 'air entry value') air will enter the pores of the assemblage and the pore water will form lenses around the grain contact points as illustrated in **Figure 14.12(c)**. These water lenses will generate inter-particle contact forces which are essentially normal to the planes of contact. It is evident that the inter-particle forces generated in this way will tend to inhibit grain slip, thereby stabilising the aggregation of grains. We may think of the water at the grain contact points as acting rather like blobs of glue or bonds which increase both the stiffness and the strength of the soil. This is why a sand-castle constructed from damp sand is so much more stable than one constructed from either perfectly dry sand or very wet sand.

In clayey soils the process of drying can give rise to considerable shrinkage of the soil, often resulting in the formation of shrinkage cracks and fissures. Tree roots are a prime cause of drying out of soils in periods of drought, and in clayey soils the resulting shrinkage, and consequent subsidence of the foundations, can be very damaging to buildings.

14.6.2 The process of wetting up of a dry soil

In the previous section we saw that the process of drying an initially saturated granular soil stabilises the grain contact points and increases both the stiffness and strength. The converse is that if an initially dry soil is wetted up, the stabilising forces at the grain contact points are removed, resulting in a loss of strength and, for loose soils, a rapid reduction in volume. This process of rapid volume reduction during wetting

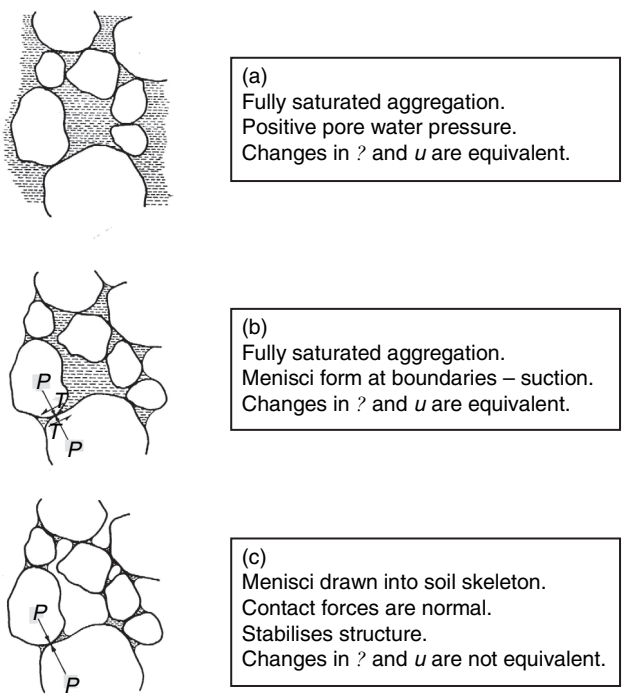

Figure 14.12 Mechanistic model showing the drying of a loose granular material
Reproduced from Burland and Ridley, 1996

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

is known as 'collapse of grain structure' or simply 'collapse'. The phenomenon of 'collapse' on wetting is well known for dry loose sandy soils in arid climates. This phenomenon is also well known for fill materials which have been inadequately compacted during placement and which subsequently wet up, often due to a rising groundwater table.

The wetting up of initially dry clay soils can also give rise to serious problems. Such soils are often fissured and cracked due to shrinkage. If water becomes available it can penetrate the clay rapidly through the cracks and cause the clay to swell, which can be very damaging to buildings founded on such soils. Also an excavation with steep sides in a dry clay soil may become unstable during heavy rain due to the rapid penetration of surface water down shrinkage cracks.

See Burland (1965) and Burland and Ridley (1996) for a detailed discussion of the mechanistic behaviour of unsaturated soils.

14.7 Conclusions

The key conclusions that can be drawn from this chapter are listed below. Some of them are oversimplified but they form a good basis for gaining an understanding of the complex behaviour of soils.

- All soils, even high plasticity clays, consist of countless particles of a variety of shapes and size. The spaces between the particles are referred to as the 'voids'. The void ratio is a measure of the closeness of pack of the particles and is an important parameter in determining the stiffness, strength and permeability of a soil.
- The particles are in contact with each other and may be thought of as forming the soil 'skeleton'. The arrangement of the particles is referred to as the 'microfabric'.
- The contacts between the particles are largely frictional but in most natural soils there is frequently a certain amount of bonding between the particles as well.
- A fundamental feature of the ground is that it has weight. The self-weight of the soil generates the confining pressures that govern its strength and stiffness. Moreover, the self-weight provides the dominant stabilising and destabilising mechanisms that operate in most stability problems.
- A simple base friction apparatus is described which simulates that action of gravity on the soil particles. The apparatus is used to introduce the formation of soil fabric during deposition. It is demonstrated that deposition under vertical gravity leads to preferred orientation of the particle arrangements and this leads to inherent anisotropy of the soil skeleton.
- When sheared, loosely packed particulate materials contract and densely packed particulate materials dilate. The base friction apparatus is used to illustrate these important phenomena.
- A number of standard soil mechanics problems are simulated in the base friction apparatus to illustrate the behaviour of particulate materials under gravity, including active and passive pressures, settlement and bearing capacity.
- The importance of particle grading, shape and fabric are discussed as well as the dominant influence that macro-structure can exert on the behaviour of a mass of soil.
- A simple mechanistic approach is presented to illustrate the importance of pore water pressure leading to the demonstration of Terzaghi's effective stress principle.
- This mechanistic approach is then used to illustrate some of the basic features that control the behaviour of unsaturated soils during the process of drying and wetting. In unsaturated soils the pore water forms lenses at particle contact points which provide an important stabilising effect on the aggregation of particles. During wetting up, this stabilising effect is reduced, leading to collapse of grain structure and reduction in strength.

Chapter 15

Groundwater profiles and effective stresses

William Powrie University of Southampton, UK

This chapter discusses the generation of profiles of effective stresses and pore water pressures within the ground for use in geotechnical engineering calculations. Total stresses and pore water pressures are usually calculated independently, with the effective stress given by the difference between them. The calculation of geostatic and hydrostatic vertical total stresses and pore water pressures arising from the self weight of the soil and the water, respectively, is described. Non-hydrostatic pore pressure profiles (corresponding to artesian conditions of higher pore pressures in an underlying aquifer) and underdrainage into an underlying, more permeable stratum, are discussed. Finally, the difficulties of estimating pore water pressures above the water table, and lateral soil stresses, are considered.

15.1 Importance of pore pressure and effective stress profiles

The nature of soil as a particulate material, generally with at least two phases present, was described in Chapter 14 *Soils as particulate materials*. If the soil is saturated, the two phases present are liquid (i.e. water in the pores) and solid (i.e. the soil grains). These two phases have very different stress–strain–strength responses – in particular, the pore water cannot carry any of the shear stress τ, but the presence of a pore water pressure u reduces the normal effective stress σ' to below the total stress σ and hence the ability of the soil skeleton to resist shear. According to Terzaghi's *principle of effective stress*:

$$\sigma' = \sigma - u \tag{15.1}$$

and the effective stress failure criterion for soils is:

$$\tau = \sigma' \tan \phi', \tag{15.2}$$

where ϕ' is the effective angle of shearing resistance or the effective angle of friction. Effective stresses, which govern the behaviour of all soils, cannot generally be calculated unless both the total stresses and pore water pressures are known. Thus in geotechnical engineering, it is essential to be able to define the distributions of vertical total stress and pore water pressure with depth as part of the initial ground model for the site.

15.2 Geostatic vertical total stress

It is usually relatively straightforward to estimate the profile of vertical total stress within the ground. Imagine a column of soil of unit weight γ, cross-sectional area A and height z. The force resulting from vertical total stress acting on the base, $\sigma_v(z)A$, must balance the total weight of the column, γAz, giving $\sigma_v(z) = \gamma z$. If the column of soil has a number of different layers having different unit weights, the calculation of vertical total stress must take this into account, so that more strictly,

$$\sigma_V(z) = \int_0^z \gamma(z)\,\mathrm{d}z. \tag{15.3}$$

Normally, equation (15.3) is discretised into finite layers and of course the effect of any surface surcharge q must be taken into account.

The resulting distribution of vertical total stress with depth corresponds to natural equilibrium conditions in the ground, and is often termed *geostatic*.

When applied to a body of soil, equation (15.3) gives the average total vertical stress over a cross-section. We have already seen in Chapter 13 *The ground profile and its genesis* how the stress distribution around a cavity such as a tunnel or a collapse (or, conversely, around a stiff inclusion) will be altered, and in Chapter 14 *Soils as particulate materials* that the structures set up during soil deposition may result in some contacts being relatively unstressed.

15.3 Hydrostatic conditions for pore water pressures

If the groundwater is static, the water pressure is unaffected by the presence of the soil skeleton as long as the pore network is continuous. Thus in the absence of groundwater flow, pore water pressures below the water table (defined as the level at which the pore water pressures are zero) can be calculated in a similar way to the total vertical stress, by considering a column of water of depth z below the water table. The pore water pressure would therefore be:

$$u(z) = \gamma_w z \tag{15.4}$$

where γ_w is the unit weight of water. These conditions, and the profile represented by equation (15.4), are known as *hydrostatic*.

(The reason that the presence of the soil grains makes no difference to the pressure in the pore water column is that each grain receives an upthrust equal to the weight of water displaced, while the residual weight of the soil grains, i.e. the actual weight minus the upthrust, is carried by contact forces between the grains.)

15.4 Artesian conditions

Most ground profiles will consist of a succession of strata of differing permeabilities (see Chapter 16 *Groundwater flow*). For example, two relatively high permeability strata through which water may flow relatively easily, may be separated by a low permeability stratum through which water flows only slowly and with difficulty. The relatively permeable strata are known as *aquifers*, and the relatively impermeable stratum is known as an *aquiclude*. It is quite possible for the water tables (or, more strictly, the *piezometric levels*) in the two aquifers to be different. In this case, vertical flow will occur through the separating aquiclude in response to the head difference across it (Chapter 16 *Groundwater flow*). In these circumstances, the upper aquifer is known as an *unconfined* or *water table aquifer* (because it is not overlain or confined by a low permeability layer); while the lower aquifer is termed *confined* (because it is).

A well known example of this is in the London basin, England, where a near-surface aquifer comprising alluvial sands and gravels (the Thames Gravels) is separated from the underlying chalk aquifer by the relatively impermeable London Clay. As the chalk is in hydraulic continuity with high ground to the north of London, the piezometric level within it is naturally higher than (i) ground level in the valley and (ii) the water table in the surface aquifer, which is hydraulically connected to the River Thames. The natural flow of groundwater will be upward through the London Clay, and the pore water pressures in this stratum will be greater than hydrostatic, relative to the upper surface of the clay (**Figure 15.1**, in which the upper aquifer is omitted for clarity). These conditions are known as *artesian*. A borehole drilled through the clay into the chalk would overflow: such a device is known as an *artesian well*. Originally, the fountains in Trafalgar Square, London, operated on this principle and did not need to be pumped.

The pore water pressure at the upper surface of the underlying aquifer cannot exceed the vertical total stress due to the weight of overlying stratum without the latter becoming unstable as the vertical effective stress is reduced to zero. Excessive pore water pressures at depth in nature may result in *boiling* or *piping* of water up through the overlying soil, or *quicksand* if the overlying material is more permeable. The creation of unstable uplift conditions by the removal of overlying material to form an excavation is discussed in Chapter 16 *Groundwater flow*. *Sub-artesian* conditions, in which the piezometric level in the underlying aquifer is above the water table in the overlying material (but below ground level), are probably more common than true artesian conditions.

15.5 Underdrainage

If the piezometric level in the underlying aquifer is below the water table in the upper aquifer, the direction of natural groundwater flow across the intervening aquiclude is reversed and is slowly downward. Pore pressures in the clay will be below the hydrostatic line drawn from its upper surface, as shown in **Figure 15.2**. This is known as *underdrainage*, and represents

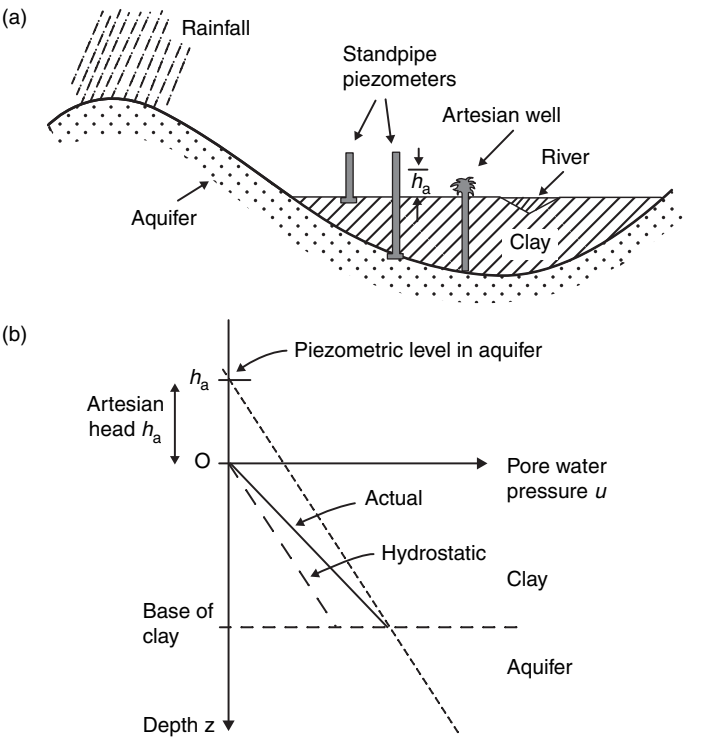

Figure 15.1 (a) Artesian groundwater conditions and (b) associated pore water pressures in the confining clay aquiclude

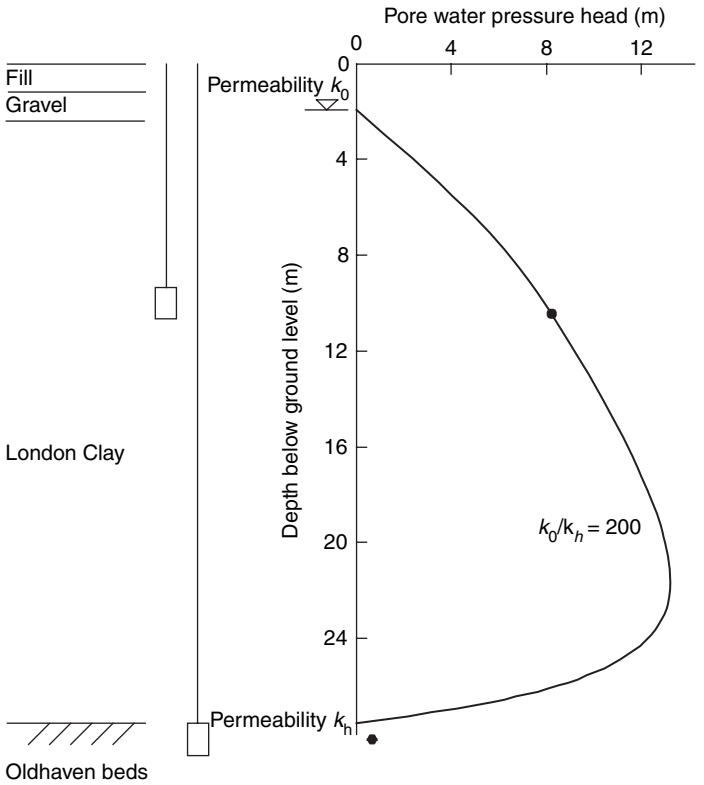

Figure 15.3 Variation of pore water pressure head with depth in a clay aquiclude in which the permeability decreases with depth
Modified from Vaughan (1994)

current conditions in London because the historic abstraction of groundwater by pumping from the chalk for industrial and domestic use has lowered the piezometric level within the chalk to below the water table in the alluvial gravels.

The water table in the upper aquifer is sometimes described as *perched*: this term is also applied to zones of higher pore water pressure resulting from extensive but discontinuous lenses of clay or other low permeability material.

It is important to realise that the simple linear distributions of pore water pressure with depth in the clay aquicludes indicated in **Figures 15.1(b)** and **15.2(b)** tacitly assume that the permeability of these layers is uniform with depth. For a clay, it is more likely that the permeability will decrease with vertical effective stress and hence with depth, giving an equilibrium pore pressure distribution more like the one shown in **Figure 15.3**.

15.6 Conditions above the water table

Above the water table in an unconfined aquifer, pore water will be retained in the soil by capillary action. Pore water pressures will fall with height above the water table (i.e. they will become negative) at the hydrostatic gradient, until a suction is reached at which sufficient air has entered the soil to disrupt the continuity of the water phase within the pores. This suction will depend on a variety of factors including the particle size and the particle size distribution, the density, and whether the soil is wetting or drying. Broadly, suction will increase dramatically with decreasing particle size. Thus gravel, with its large particle size, would become sufficiently unsaturated to disrupt the continuity of the liquid phase at a very low suction. A fine sand would hold a suction in the order of one to a few tens of kPa before becoming unsaturated; silt, several tens of kPa; and a clay, tens to a few hundred kPa. While soil suction can cause unwelcome and damaging shrinkage and settlements, in terms of the stability of a geotechnical structure (such as a slope) it is usually a good thing. However, because it is difficult to calculate and may be unreliable (for example, varying between seasons and with climate and vegetation cover), suctions are generally ignored in most engineering calculations and the pore pressures above the water table are often taken as zero. An exception may need to be made in the calculation of settlements when suctions can have a significant effect.

15.7 *In-situ* horizontal effective stresses

In-situ horizontal stresses are difficult to calculate, as they may lie anywhere between the active and passive limits for the soil, which is too wide a range to be useful (see Chapter 20 *Earth pressure theory*). One possibility is to calculate the horizontal effective stress using the theory of elasticity and the fact that during deposition of a soil, the lateral strains are zero. However, this requires estimates to be made of the elastic parameters. This is difficult for soils because of their dependence on stress history, stress state, stress path and stress change.

The most common approaches to estimating the *in-situ* horizontal stresses in a soil deposit are empirical. The *in-situ* horizontal effective stress is characterised by the earth pressure coefficient $K_0 = \sigma'_h / \sigma'_v$. For a normally consolidated soil (i.e. one that has not previously been subjected to a vertical effective stress greater than that which currently acts), Jaky's equation:

$$\frac{\sigma'_h}{\sigma'_v} = K_0 = (1 - \sin\phi') \tag{15.5}$$

is frequently used (Jaky, 1944).

For overconsolidated clays which have previously been subjected to a maximum vertical effective stress of $\sigma'_{v,max}$, some of the horizontal stress caused on first loading tends to remain 'locked in' on unloading, resulting in an increase in K_0. There are several empirical equations that can be used to capture this, for example Mayne and Kulhawy (1982) suggest

$$\frac{\sigma'_h}{\sigma'_v} = K_0 = (1 - \sin\varphi')(\mathrm{OCR})^{\sin\varphi'} \tag{15.6}$$

where OCR is the overconsolidation ratio, OCR = $\sigma'_{v,max} / \sigma'_{v,current}$.

15.8 Summary

- Profiles of pore water pressure and effective stress with depth are generally needed for use in geotechnical calculations.

- Vertical total stresses will normally increase geostatically with depth at a gradient equal to the bulk unit weight of the soil.
- If the groundwater is static, pore water pressures will increase hydrostatically with depth at a gradient equal to the unit weight of water, provided the water phase is continuous (e.g. the soil is saturated).
- Vertical effective stresses must be calculated by subtracting the pore water pressure from the vertical total stress.
- The horizontal effective stress profile may be estimated from the vertical effective stress profile, using an empirical relationship appropriate to the stress history of the deposit.

This chapter describes the fundamentals of steady-state groundwater flow in a saturated soil, based on Darcy's Law and the concept of soil permeability or hydraulic conductivity. Simple flow regimes including radial flow to single wells are described, and the use of plane flownets in plan and cross-section to calculate flowrates and pore water pressures is discussed. Flow in strata of anisotropic permeability and across a boundary between two soils having different permeabilities is briefly considered. The importance of controlling pore water pressures in the vicinity of an excavation is illustrated with reference to a case study, and some common methods of groundwater control are described. Finally, the concepts of transient flow and consolidation are summarised.

16.1 Darcy's Law

For almost all practical purposes, the flow of groundwater through a soil is governed by Darcy's Law,

$$q = Aki \tag{16.1}$$

where q is the volumetric flowrate in m^3/s; A is the gross area through which flow occurs (m^2); k is a parameter known as the *hydraulic conductivity* or the *permeability* (m/s), which is a measure of the ease with which water can flow through the soil; and i is the hydraulic gradient in the direction of flow being considered, which is defined as:

$$i = -\frac{\mathrm{d}h}{\mathrm{d}x}. \tag{16.2}$$

i.e. the rate of loss of total head, h (m), with distance x (m) along the direction of flow. The hydraulic gradient is therefore dimensionless. The head used is always the total head, measured above an arbitrary datum which, once chosen, remains fixed. In **Figure 16.1**, the total head for the point at the centre of the left-hand cross-section, A, above the datum indicated, is h_A. This is the level above datum to which water will rise in a standpipe piezometer with its tip at the point of interest A. Other types of head, which are not relevant for the purposes of Darcy's Law, are:

- *the elevational head*, i.e. the elevation of the point above the chosen datum, z_A;
- *the pressure head*, which is defined as the pore water pressure at the point of measurement divided by the unit weight of water, and is indicated by the height to which water in the piezometer rises above the measurement point – in the case of **Figure 16.1**, this would be $h_A - z_A$;
- *the velocity head*, defined as $v^2/2g$ where v is the velocity of groundwater flow, which is usually negligibly small in groundwater problems, and g is acceleration due to gravity.

Darcy's Law is illustrated schematically in **Figure 16.1**. This figure also shows the basis of the simplest form of hydraulic conductivity measurement, which involves subjecting a specimen of known cross-sectional area A to a known head drop h (from which the hydraulic gradient h/x may be calculated), and measuring the corresponding volumetric flowrate.

The main subtleties or potential pitfalls of Darcy's Law are that:

1. It applies only if the flow is laminar. However, unless the ground is very highly permeable, this will almost always be the case in groundwater applications.
2. The flowrate q may be divided by the cross-sectional area A to obtain an apparent, superficial or Darcy flow velocity $v_D = q/A$. This is not, however, the true average fluid flow velocity, because in reality flow takes place only through the soil pores. The pores occupy a proportion of the total area of nA, where n is the soil porosity defined as the volume of pores ÷

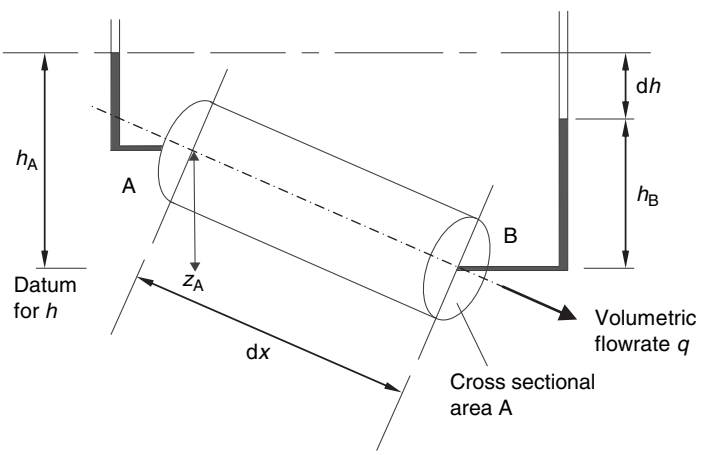

Figure 16.1 Schematic representation of hydraulic gradient and Darcy's Law

the total volume, or $n = e/(1 + e)$ where e is the void ratio. Thus the true average fluid flow velocity v_{true} is $(1 + e)/e$ times the superficial or Darcy flow velocity v_D,

$$v_{true} = \frac{(1+e)}{e} v_D \,. \tag{16.3}$$

3. The head loss h used in calculating the hydraulic gradient is in terms of total head, determined as the rise in water level above an arbitrary datum in an imaginary standpipe driven into the soil, with its tip at the point at which the head is to be measured.
4. The hydraulic conductivity depends on both the nature of the soil and the physical properties of the permeant fluid, in this case water.
5. Even in a uniform soil, the hydraulic conductivity depends hugely on the particle size ($k \propto D_{10}^2$) and to a lesser extent on the void ratio. In the ground it can vary massively from point to point because of natural inhomogeneities, and be strongly anisotropic (with horizontal k_h being much greater than vertical k_v) owing to soil fabric and structure. In finer grained and compressible materials such as clays and landfilled wastes, the hydraulic conductivity is especially likely to vary – often significantly – with stress and stress history, and hence with depth (Chapter 15 *Groundwater profiles and effective stresses*). In construction, what is usually sought is a reliable estimate of the effective bulk hydraulic conductivity of the volume of ground contributing to the flow of interest. This can be very difficult to estimate, even to within an order of magnitude, especially from small scale or laboratory element tests.
6. Darcy's Law forms the basis of nearly all groundwater flow calculations, whether they are carried out by hand or numerically. Darcy's Law can generally be applied to fissure flow in rocks (e.g. chalk) – in which case the hydraulic conductivity used is that representative of a volume of rock whose linear dimensions are large in relation to the typical fissure spacing.

Items (4), (5) and (6) are discussed in section 16.2.

16.2 Hydraulic conductivity (permeability)

The hydraulic conductivity, k, used in Darcy's Law depends on both the soil and the properties of the permeant fluid – in this case, water – according to the Equation (16.4):

$$k = \frac{K \gamma_f}{\eta_f} \tag{16.4}$$

where K (m^2) is the intrinsic permeability of the soil matrix, γ_f is the unit weight of the permeant fluid (kN/m^3), and η_f its dynamic viscosity (kNs/m^2). In geotechnical engineering, the hydraulic conductivity is often known simply as the permeability.

The practical implications of this are for the most part fairly limited. Obviously, the permeability will change if the permeant fluid is not water, but the dependence of the dynamic viscosity on temperature could also be significant in some cases (η_f reduces, and hence k increases by a factor of about 2 over a temperature rise from 20 to 60°C).

The hydraulic conductivity of a granular material is governed by the smallest 10% of the particles, and varies roughly with the square of the D_{10} particle size. Hazen's empirical formula:

$$k(\mathrm{m/s}) \approx 0.01\left[D_{10}(\mathrm{mm})\right]^2 \tag{16.5}$$

is often used to obtain a rough estimate of the hydraulic conductivity, even though it was originally intended for use only with clean filter sands. Thus the potential range of hydraulic conductivity even for uniform soils is very wide indeed, varying over perhaps ten orders of magnitude from 1 m/s for a clean, open gravel to 10^{-10} m/s for an unfissured clay (**Table 16.1**). This degree of variation is far greater than that of almost any other engineering parameter for natural materials – for example, the shear strength of a soft clay is a factor of about 10^5 less than that of high tensile steel.

Natural inhomogeneities such as lenses or zones of different materials (e.g. an infilled river channel) will cause the hydraulic conductivity in the ground to vary from point to point. Even in uniform soils, the *in situ* hydraulic conductivity may be anisotropic owing to the natural fabric or structure of the soil. In clays with no obvious layered structure, the hydraulic conductivity in the horizontal direction might be expected to be up to around ten times that in the vertical. If the soil displays an obvious layering, e.g. interlaminated bands of clay/silt and silt/sand, the ratio of horizontal to vertical hydraulic conductivity could easily be in the order of 10^2 or 10^3.

Some typical values of hydraulic conductivity are given in **Table 16.1**.

Indicative soil type	Degree of permeability	Typical hydraulic conductivity range m/s
Clean gravels	High	$>1\times10^{-3}$
Sand and gravel mixtures	Medium	1×10^{-3} to 1×10^{-5}
Very fine sands, silty sands	Low	1×10^{-4} to 1×10^{-7}
Silt and interlaminated silt/sand/clays	Very low	1×10^{-6} to 1×10^{-9}
Intact clays	Practically impermeable	$<1\times10^{-9}$

Table 16.1 Range of hydraulic conductivity for different soil and ground types
Data taken from Preene *et al.* (2000) (CIRIA C515)

In ground engineering, it is usual to use a fairly simple flow model based on a single value of hydraulic conductivity, at least in an initial calculation. It therefore becomes important that the value used is reasonably representative of the whole volume within which flow is taking place. Large scale, *in situ* tests that involve pumping on one or more wells, with an array of piezometers to monitor the resulting drawdown, are likely to give the most realistic estimates. Building a reliable picture from smaller scale tests can be difficult, not only because of the small volume of soil involved in the flow, but also because of the potential for disturbance during sample retrieval (for laboratory tests) or borehole installation (for rising or falling head tests in single boreholes). A review of the various methods of determining hydraulic conductivity for the purpose of large-scale groundwater control system design is given by Preene *et al.* (2000).

16.3 Calculation of simple flow regimes

Hand calculations based on Darcy's Law, combined with the condition of continuity of flow (i.e. the volumetric flow of water into an element of soil must be equal to the volumetric flow of water out, over a given increment of time, if the soil element is not changing in volume), can be carried out for simple flow regimes that are essentially two-dimensional in nature. Common situations include the following:

(i) Radial flow to a fully penetrating well in a confined aquifer (illustrated, with the terms defined, in **Figure 16.2**):

$$q = \frac{2\pi Dk(H-h)}{\ln\left(R_o / r_w\right)}. \qquad (16.6)$$

(ii) Radial flow to a fully penetrating well in an unconfined aquifer (illustrated in **Figure 16.3**):

$$q = \frac{\pi k\left(H^2 - h^2\right)}{\ln\left(R_o / r_w\right)}. \qquad (16.7)$$

Full details of the analyses leading to Equations (16.6) and (16.7) are given in Powrie (2004).

A large excavation of plan dimensions a (length) × b (breadth) surrounded by a ring of dewatering wells can be analysed approximately as a single well of equivalent radius r_e, provided that the aspect ratio of the excavation a/b is between 1 and 5, and the distance from the edge of the excavation to the recharge boundary, L_o, is greater than $3a$. The equivalent radius r_e is given by $(a + b)/\pi$, and the equivalent radius of influence R_o is $(L_o + a/2) \approx L_o$. Further details are given by Preene and Powrie (1992).

(iii) Plane flow: for excavations with close recharge boundaries, flowrates can be calculated by means of a flownet sketched within one half of the cross-sectional plane. The plane flownet is used to calculate the flowrate per metre run: this is then multiplied by the perimeter of the excavation to give the overall flowrate. If the excavation is long ($a/b > 10$) with close recharge boundaries ($L_o/a < 0.1$), plane flow to the long sides will dominate and end effects may be neglected. If the excavation is rectangular ($1 < a/b < 5$) with close recharge boundaries ($L_o/a < 0.3$), plane flow to the four sides dominates and corner effects may be neglected.

Plane flownet sketching is a useful and highly effective graphical technique for solving the Laplace Equation – governing the plane flow of groundwater through a soil of uniform or

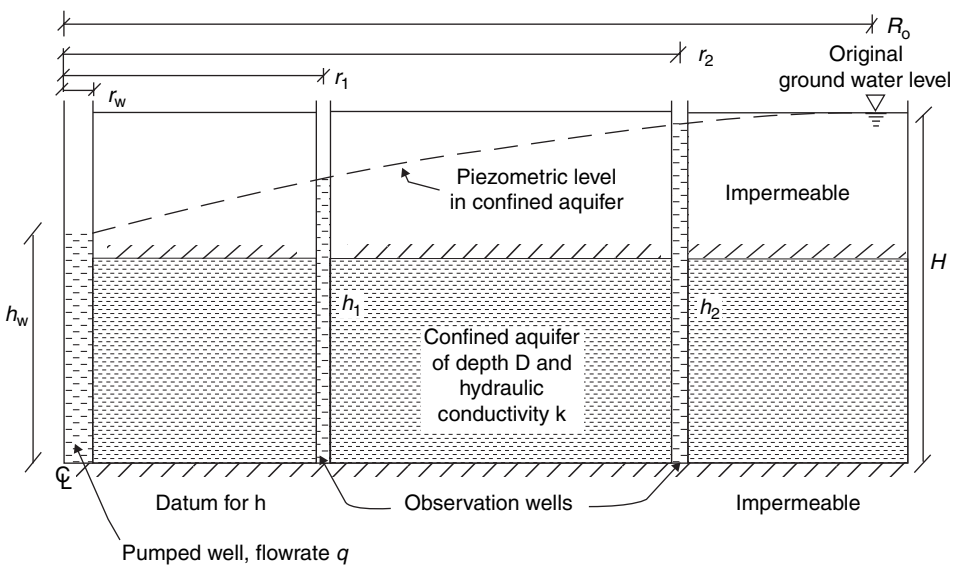

Figure 16.2 Radial flow to a fully penetrating well in a confined aquifer
Reproduced from Powrie (2004)

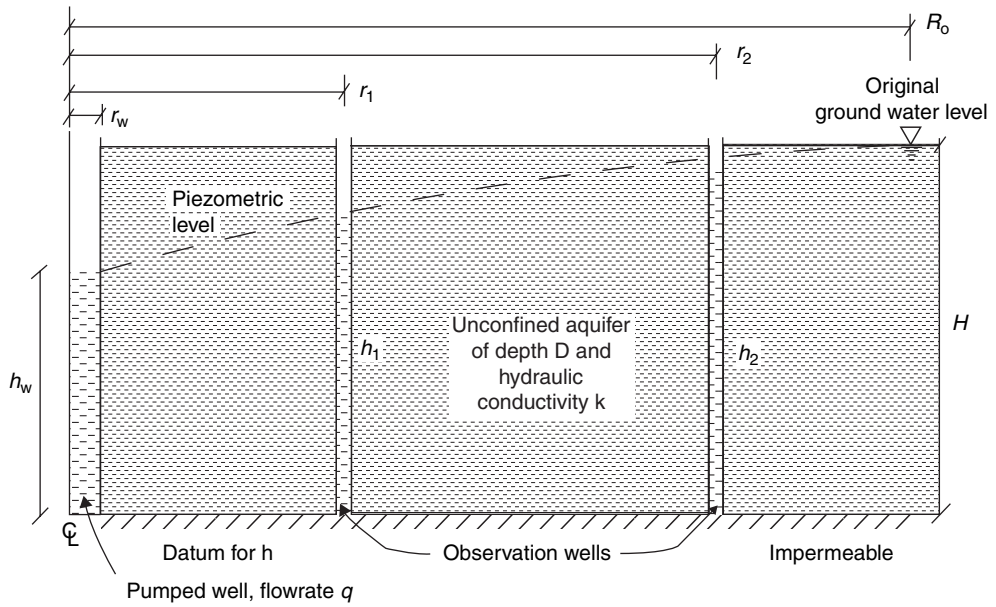

Figure 16.3 Radial flow to a fully penetrating well in an unconfined aquifer
Reproduced from Powrie (2004)

anisotropic hydraulic conductivity. The derivation of the equation, and a comprehensive introduction to flownet sketching, is given by Powrie (2004). In summary, plane flownet sketching involves determining the upper and lower equipotentials (i.e. lines of equal head) representing the source of water and the sink, and two bounding flowlines. The space so defined is then filled with a network of intermediate flowlines which intersect intermediate equipotentials at 90° to form elements known as 'curvilinear squares', whose length is equal to their breadth. (In practice, this means that a circle can be fitted inside each of them, although the circles will vary in diameter depending on the position of the element in the flownet.) In an unconfined aquifer, the need to determine the position of the top flowline (which represents the drawn down water table) as part of the general flownet sketching process represents a small additional complication. The flowrate per metre run is then calculated as:

$$q = kH \, N_F / N_H \qquad (16.8)$$

where H is the overall head drop between the upper and lower equipotentials (the source and the sink), N_F is the number of flowtubes (which is equal to the number of flowlines minus 1) and N_H is the number of equipotential drops (i.e. the number of equipotentials minus 1). A full description of the basic technique, which progresses by trial and error, is given by Powrie (2004).

An example of a plane flownet in the vertical plane is shown in **Figure 16.4**.

In cases where there is no similarity of vertical cross-sections and flow is primarily horizontal, flownets may be sketched in the horizontal plane as shown in **Figure 16.5**. The principles are the same, but the total flowrate is calculated by multiplying the flownet result (equation (16.8)) by the depth of the aquifer. An inherent assumption is that regions of vertical flow, for example up into the excavation, are small and do not significantly affect the basic premise of substantially horizontal flow.

Although the technique could be viewed as having been superseded by computer-based numerical methods, flownet sketching is quick and simple and has the great advantage of giving strong insights into the physicality of, and the main factors governing, the flow regime.

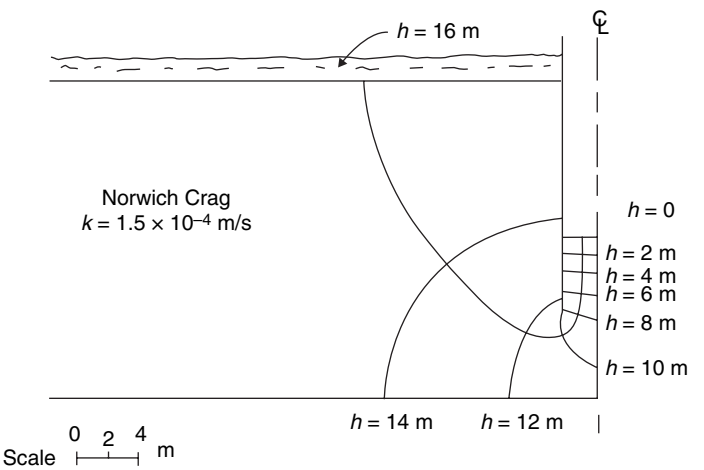

Figure 16.4 Example of a plane flownet in one half of the vertical cross-sectional plane for flow into a trench excavation
Reproduced from Powrie (2004)

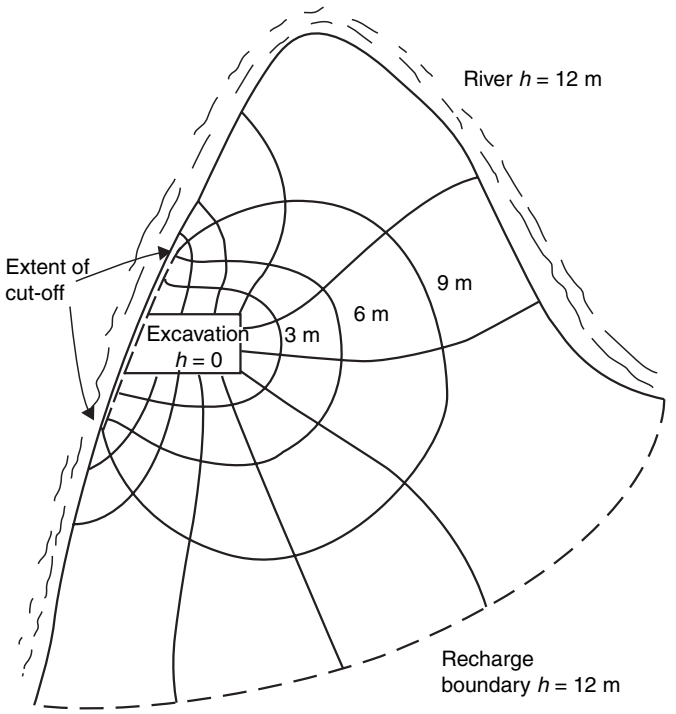

Figure 16.5 Example of a horizontal plane flownet, for flow to an excavation in a deep chalk aquifer on the Medway peninsula
Reproduced from Powrie (2004)

A finite difference solution to a plane flow problem can be obtained by establishing a grid of nodes and using Darcy's Law to write an expression for the flowrate into each node – in terms of the head difference between it and the adjacent nodes, the implied area of flow, and the soil hydraulic conductivity. At the steady state, the net flowrate into or out of each node is zero (except of course for the nodes on the constant head or equipotential boundaries). To obtain values of head that satisfy the condition of zero net flow into or out of each internal node, and give a sum of flowrates *into* the boundary nodes on the upper equipotential (the source) equal to the sum of the flowrates *out* of the boundary nodes on the lower equipotential (the sink), solution is by trial and error and is greatly facilitated by the use of a spreadsheet.

16.4 More complex flow regimes

Flownets can be sketched for anisotropic soils in the usual way, provided that the real geometry of the cross-section has first been 'transformed' to account for the difference between the vertical and the horizontal hydraulic conductivities. The true horizontal dimensions, x, must be multiplied by $\sqrt{(k_v / k_h)}$, where k_v and k_h are the hydraulic conductivities in the vertical and horizontal directions respectively. As k_v is usually less than k_h, this involves a shrinking of the horizontal distances on the transformed section. Equation (16.8) for the calculation of flowrates holds, except that the effective hydraulic conductivity of the transformed section, k_t, that must be used for this purpose is the geometric mean of k_v and k_h – in other words $\sqrt{(k_v k_h)}$. Derivations and further details are given in Powrie (2004).

Flownet sketching can also accommodate the presence of two or more strata of different hydraulic conductivities. If the ratio of hydraulic conductivities is in the order of hundreds, one will act as a reservoir compared with the other (i.e. any head drop within it will be negligible compared with that in the less permeable stratum), and this is the appropriate approximation to make. If the ratio of hydraulic conductivities is in the order of one to 100, the flownet should be sketched so that the flowlines deflect through an angle $(\beta_1 - \beta_2)$ as they pass from a soil with hydraulic conductivity k_1 into a soil with smaller hydraulic conductivity k_2, such that

$$\frac{\tan \beta_1}{\tan \beta_2} = \frac{k_1}{k_2}. \qquad (16.9)$$

This is analagous to the refraction of light as it passes between media of different optical densities. The derivation is given by Powrie (2004).

A comprehensive guide to flownet sketching for these more complex cases and even transient flow is given by Cedergren (1989), but given the ready availability of spreadsheets and low-cost personal computing it is probably easier to solve such problems using the finite difference approach and a spreadsheet, or one of the commercial computer programs available for modelling groundwater flow. The underlying principles, however, remain Darcy's Law and continuity of flow, and success still depends on understanding the physical constraints to the flow domain and the judicious selection of numerical values of soil hydraulic conductivity.

16.5 Groundwater control for stability of excavations

Whenever an excavation is made below the natural water table, at least in a non-clay soil, groundwater and pore water pressures must be controlled to prevent flooding and potential instability of the excavation. This can be achieved by physical means, e.g. grouting or a cut-off wall, pumping from dewatering wells placed in or around the excavation, or most usually a combination of both. Even when the sides of the excavation are supported by retaining walls, pumping may still be necessary to prevent instability of the base. Pumping will also often reduce the pore water pressures acting on the outside of the retaining walls, enabling them to be constructed more economically. In built-up areas, consideration should be given to mitigating the potential for settlement damage to buildings resulting from ground settlements associated with reducing the pore water pressures outside the excavation. Powrie and Roberts (1995) provide a case history on this subject.

As outlined earlier in this chapter, flow calculations are required (i) to estimate the likely flowrate that a dewatering

system will have to pump, and (ii) to calculate the reductions in pore water pressure that a dewatering system will achieve. The pore water pressures will feed in turn into calculations relating to the stability of sheet pile and other retaining walls, excavation side slopes and the excavation base. Most of these calculations are discussed elsewhere in this manual, but the importance of maintaining stability of the base will be discussed briefly here.

The base of an excavation will become unstable if the pore water pressures within a certain depth of the excavated surface become equal to the vertical total stress due to the weight of soil. The 'certain depth' will depend to some extent on the width of the excavation. If the sidewalls are of the embedded type, they will offer some additional frictional resistance to uplift, but the effect will diminish towards the centre of the excavation especially if the excavation is wide.. Ignoring any benefits of sidewall friction, it can easily be shown that instability or uplift will occur when the hydraulic gradient associated with upward flow to the base of the excavation is approximately 1, see Powrie (2004); or, when the pore water pressure on the base of a plug of low permeability soil exceeds the vertical total stress due to its weight.

The perils of ignoring the potential for unrelieved pore water pressures at depth to cause major damage, and possibly even loss of life, should not be underestimated and are illustrated by the case study summarised in **Figure 16.6**. This relates to an excavation for a pumping station near Weston-super-Mare which the contractor attempted to make without taking steps to reduce the pore water pressures in the underlying silty sand. As formation level was approached, the base became unstable and the excavation rapidly filled with water. This was quite predictable: at full depth, the pore water pressure at the point A on the base of the 6 m depth of soft clayey silt that remains below the excavation floor is 13 m × 10 kN/m^3 = 130 kPa, which is substantially in excess of the total vertical stress due to the weight of the clayey silt of 6 m × 18 kN/m^3 = 108 kPa. The remedial works necessitated by the failure were substantially more expensive than the cost of a pre-emptive groundwater control scheme, quite apart from the damage to plant and the potential for personal injury or even loss of life.

Methods of groundwater control by pumping are summarised in **Table 16.2**. Further details are given in Powrie (2004), Cashman and Preene (2001), Preene *et al.* (2000) and Powers (1992). The suitability of each method depends on the pumped flowrate, and hence the soil hydraulic conductivity and the drawdown, as shown schematically in **Figure 16.7**.

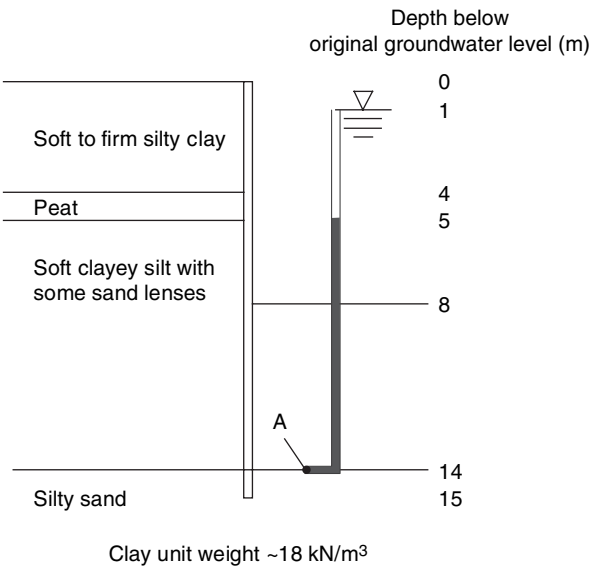

Figure 16.6 Case study demonstrating the importance of controlling pore water pressures to an adequate depth below the excavation floor

Method	Thumbnail description	Comments and case studies
Open sump	Literally an open sump into which groundwater is allowed to flow under gravity, and pumped away by a stand-alone diesel or electric site pump	Subject to limitations on space and accessibility, this method is generally only suitable for modest drawdowns (up to about 2 m) in well interlocked, open gravels
Vacuum wellpoints	Closely spaced small wells (typically in a line 1–3 m apart) approximately 50 mm diameter connected by risers to a common header main, pumped by a surface vacuum pump	Maximum drawdown (owing to limitations of vacuum lift) about 6 m, but can be used in multiple stages. Comfortable with flowrates typical of sandy soils
Deep wells	Large diameter wells (e.g. 200 mm diameter screens in 350 mm diameter bores) pumped individually by slimline electrical submersible pumps. Widely spaced so recovery of water table between wells is significant and well depth must allow for this	Can deal with higher flowrates and drawdowns than wellpoints. Restriction on depth of drawdown likely to be economic rather than physical. Vacuum can be applied via a separate system in lower permeability ground. Powrie and Roberts (1995); Bevan *et al.* (2010)
Ejectors (sometimes called eductors)	Nozzle and venturi devices installed at depth in deep but small diameter boreholes (minimum 50 mm), driven by high pressure water pumped from the surface	Will draw air as well as water so will create a vacuum automatically if the well is sealed. Particularly useful for lower permeability soils. Powrie and Roberts (1990); Roberts *et al.* (2007)

16.6 Transient flow

So far, we have considered steady-state flow, in which the volume of water flowing into a soil element in a given time is the same as the volume of water flowing out, i.e. there is no change in the volume of the soil element. This is not always the case; if the volume of the soil element is changing over time (for example in response to a change in the external loading regime), the flow into the element will be greater than the flow out if the soil volume is increasing (swelling), or less than the flow out if the soil volume is decreasing (compression). Non steady-state flow is known as *transient flow*, and the time-dependent process of volume change associated with it is known as *consolidation* (or possibly *swelling* if it is a volume increase).

For the effective stress to increase, the soil skeleton must compress: this requires water to flow from the pores, which cannot occur instantaneously because the rate of flow is limited by the hydraulic conductivity of the soil. Thus an increase in total stress results initially in an increase in the pore water pressure. The increase in pore water pressure causes local hydraulic gradients, in response to which water will flow out of the soil. As water flows from the pores, the pore water pressure falls back towards its equilibrium value, the soil compresses and the effective stress increases to make up for the reduction in pore water pressure. Eventually, the pore water pressures return to the initial equilibrium values, and transient flow stops. The soil has compressed, the effective stress has increased to mirror the increase in total stress, and consolidation is complete.

The rate of consolidation increases with the soil hydraulic conductivity k. The amount of compression associated with the eventual increase in effective stress decreases as the soil stiffness in compression, E'_o, increases. The parameters k and E'_o are combined to give the consolidation coefficient, c_v,

$$c_v = \frac{kE'_0}{\gamma_w} \qquad (16.10)$$

where γ_w is the unit weight of water. The consolidation coefficient c_v will obviously vary with soil stiffness and hydraulic conductivity, and hence with stress history, stress state and stress path. For stiff soils subjected to small changes in stress, it might be reasonable to assume an equivalent single value of c_v in analysis. However, for problems involving softer sediments and larger changes in stress, an approach which allows c_v to vary with both depth and stress will probably be required. The consolidation time also depends on the distance to the drainage boundary, d, and the flow geometry. For simple flow geometries approximating to one-dimensional flow, consolidation is usually considered to be substantially complete after a time t such that the dimensionless group T defined in Equation (16.11) is approximately equal to one:

$$T = \frac{c_v t}{d^2} = 1 \qquad (16.11)$$

In principle, all soils will undergo transient flow in response to a change in total stress or boundary pore water pressure. However, consolidation is normally only of practical importance in saturated, low permeability, fine grained soils. The reason for this, as illustrated in **Table 16.3**, is that sandy soils are so relatively stiff and more permeable that the timescale for transient flow is very short – perhaps a matter of minutes rather than months or even years.

It is important to realise that, while much practical soil mechanics theory is relatively straightforward, huge simplifications are involved both in idealising the complex behaviour of the soil and in choosing often a single value to characterise highly variable parameters such as hydraulic conductivity, soil stiffness and consolidation coefficient. This is why experience, judgement and a respect for reality are so important in translating theory into geotechnical engineering practice.

16.7 Summary

- The flow of water through the ground is governed by Darcy's Law, and controlled by a parameter known as the *hydraulic conductivity* or *permeability.*

- Hydraulic conductivity varies widely across the range of soils and can be difficult to determine with confidence, especially on the basis of tests involving small volumes of soil, owing to scale and fabric effects.
- Simple flow regimes can be analysed mathematically or by the use of plane flownet sketching.
- Anisotropy, and the deflection of flowlines as they pass between soil strata of differing hydraulic conductivity, can be taken into account if needed.
- Steps must be taken to lower groundwater levels and pore water pressures in the vicinity of an excavation below the natural water table, to prevent instability of the excavation sides or base. This is usually achieved by pumping from wells in a process known as construction detwatering.
- Transient flow occurs as a soil is changing in volume in response to a change in boundary stress. This leads to the process known as consolidation, which is usually only significant for low-permeability (clay) soils.

This chapter explains the basic strength and stiffness properties of soils by frequent reference to their particulate nature. The results of simple shear box tests on sand and clay are presented and compared with the Coulomb strength criterion – $\tau_f = c' + \sigma'_n \tan \varphi'$. It is demonstrated that the angle of shearing resistance φ' depends on a number of factors, including the effective confining pressure, the initial relative density and the stress history. The key roles played by contractancy and dilatancy in controlling undrained strength are explained. The phenomena of critical state strength and residual strength are described, and the extension of the Coulomb strength criterion to the widely used Mohr–Coulomb strength criterion is explained, together with its limitations. The latter part of the chapter deals with the deformation properties of soil and its behaviour under one-dimensional compression. The important influence of inter-particle bonding is introduced, leading onto the concept of yield. In geotechnical engineering, extensive use is made of elasticity in the solution of boundary value problems – such as the settlement of foundations. The behaviour of an ideal isotropic porous elastic material is explored in detail and compared with real soils. The important phenomenon of non-linear stress–strain behaviour is introduced briefly.

17.1 Introduction

This chapter deals exclusively with the behaviour of fully saturated soils. Discussion of the behaviour of unsaturated soils may be found in Chapters 14 *Soils as particulate materials*, 32 *Collapsible soils*, 33 *Expansive soils*, 30 *Tropical soils* and 29 *Arid soils*. As stressed in Chapter 14, a saturated soil of whatever type may be considered as a skeleton of solid particles in contact with each other and with the surrounding voids – which are filled with water. Nevertheless, for the purposes of analysis, it is necessary to idealise the soil as a continuum in which the sizes of the particles are neglected in relation to the sizes of the elements of soil that are being considered. It is essential in making this idealisation to remember that it is the particulate nature of soil that controls its behaviour.

Some of the key controlling features of a particulate material listed in the conclusions to Chapter 14 are:

(i) the effective stress is that part of the total stress that is transmitted through the particle contact points and controls soil behaviour;

(ii) the closeness of pack of the particles (i.e. the void ratio e) plays an important role in determining the stiffness, strength and permeability of a soil;

(iii) the self-weight of the soil generates the effective confining pressures that govern its strength and stiffness;

(iv) when sheared, loose soils tend to contract and dense soils tend to dilate;

(v) particle grading, shape and micro-fabric are important in determining soil properties;

(vi) the presence of discontinuities through the mass of the soil, such as shear and bedding planes, can exert a key influence on the behaviour of the mass.

The element of soil shown in **Figure 17.1(a)**, with a pore pressure u acting in the voids, is idealised as an element of continuum in **Figure 17.1(b)**. When considering the normal stress σ and shear stress τ acting on any arbitrary plane through the continuum, it is also necessary to consider the pore pressure u acting within the plane. Therefore the effective stresses acting on the plane are $\sigma' = (\sigma - u)$ and τ. In this chapter, strength and stiffness properties of soil are introduced and explained in simple mechanistic terms by referring to their particulate nature. References are given to aid more advanced study.

17.2 Analysis of stress

The analysis of stress is thoroughly covered by most textbooks on applied mechanics and strength of materials, and will be dealt with only briefly here. It is important to appreciate the sign conventions that are adopted in soil mechanics. In particular, compressive stress is taken as positive as tensile stresses seldom occur in practical problems. **Figure 17.2(a)** shows a two-dimensional element referred to Cartesian coordinates (x, z) acted on by compressive stresses σ'_x, σ'_z and τ_{xz} $(= \tau_{zx})$. A convenient sign convention is that, when standing at the origin and looking at the two nearest faces of the element, positive stress is in the direction of increasing x and increasing z. Thus the positive stress σ'_x is acting normal to the constant x-plane directed towards increasing x. Similarly the positive shear stress τ_{xz} is acting parallel to the constant x-plane directed towards increasing z. Note that for equilibrium, $\tau_{xz} = \tau_{zx}$, which satisfies the above

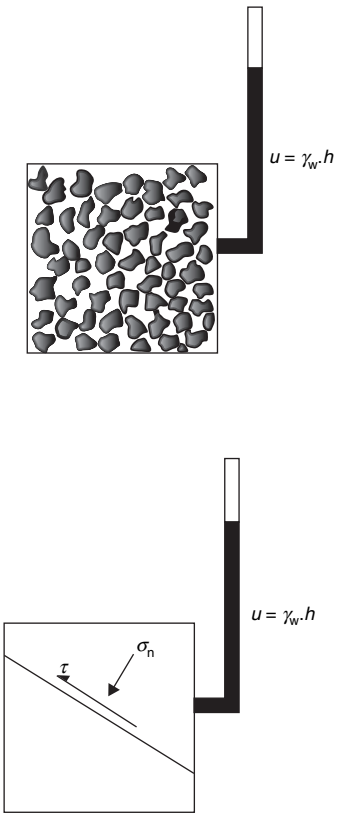

Figure 17.1 (a) An element of particulate material; (b) the element idealised as a continuum

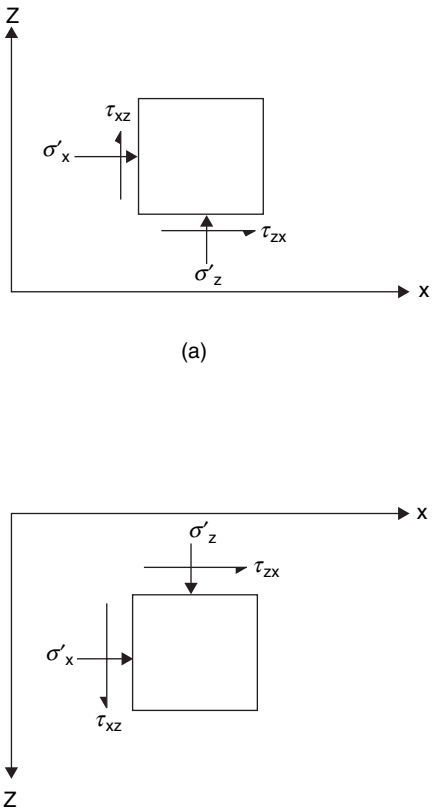

Figure 17.2 Sign convention for positive stresses (a) z positive upwards; (b) z positive downwards

sign convention. Also, for equilibrium, there are stresses acting on the other two faces in opposite directions from their counterparts. If z is taken as increasing downwards, which is common in geotechnical problems, then the direction of positive stresses acting on the element are as shown in **Figure 17.2(b)**.

17.2.1 Mohr's circle of stress

The stresses shown in **Figure 17.2** may be resolved to find the associated stresses acting on any plane through the element. The equations for such transformation of stress are given in most textbooks. In soil mechanics, extensive use is made of the well-known graphical procedure for transformation of stress by means of the Mohr's circle geometric construction – see, for example, Atkinson (1993). This is a very important tool in soil mechanics as it relates to the Mohr–Coulomb strength criterion which is universally used in soil mechanics. When using the Mohr's circle construction it is often not appreciated that it is necessary to make a small change to the sign convention for the shear stresses shown in **Figure 17.2**. For the geometric construction to work it is necessary to plot anti-clockwise shear stresses as positive and clockwise shear stresses as negative. Thus the shear stress τ_{zx} shown in **Figure 17.2(a)** is plotted as positive in a Mohr diagram, whereas the shear stress τ_{xz} is plotted as negative. It is important to stress that this sign convention only applies to Mohr's circles and not to stress analysis in general.

Figure 17.3(a) shows an element acted upon by major and minor principal stresses σ_I' and σ_{III}'. The stress state can be represented by a circle on a Mohr diagram of shear stress τ versus normal stress σ, as shown in **Figure 17.3(b)**. The points representing the major and minor principal stresses plot on the σ' axis since there are no shear stresses on the planes on which they act.

An important feature of a Mohr's circle is the pole (sometimes called the 'origin of planes'). If the pole can be located then the stresses acting on any plane can be found very simply. The pole is located by drawing a line parallel to the plane on which the stress acts through a known stress on the circle. Where the line intersects the circle again locates the pole. Thus, in **Figure 17.3(b)**, the line I–I is parallel to the principal plane on which σ_I' acts and passes through the point on the Mohr's circle representing σ_I'. Where this line intersects the circle again represents the pole.

Having found the pole, the stresses acting on any other plane may be found by drawing a line through the pole, parallel to the plane. Where the line intersects the circle again gives the required stress state. For the case shown in **Figure 17.3(b)**, the point E represents the stresses acting on the plane CD through the element. It can be seen that the shear stress is positive so

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

that the shear stresses acting on either side of the plane *CD* are in an anti-clockwise direction as shown.

17.3 The drained strength of soils

17.3.1 Coulomb's equation

In 1773 Coulomb read a paper to the French Royal Academy of Science with the title 'On the application of the rules of maximum and minimum to some statical problems, relevant to architecture' (Heyman, 1997). Besides dealing with the bending of beams and the stability of arches, Coulomb discussed the strength of masonry columns and pressures of 'fresh earth' against retaining walls. This was a most remarkable contribution which is still widely used in geotechnical practice.

For this work, Coulomb assumed that sliding takes place along an arbitrary plane on which the material has both friction and cohesion. By varying the orientation of the sliding plane he was able to work out the minimum value of the column load to give failure and the maximum thrust against a gravity-retaining wall. Although he never explicitly stated it as such, the strength criterion adopted by Coulomb, expressed in terms of effective stresses, is given by the equation:

$$\tau_f = c' + \sigma'_n \tan \phi' \qquad (17.1)$$

where τ_f, is the shear stress at failure on the plane and σ'_n is the effective stress normal to the plane.

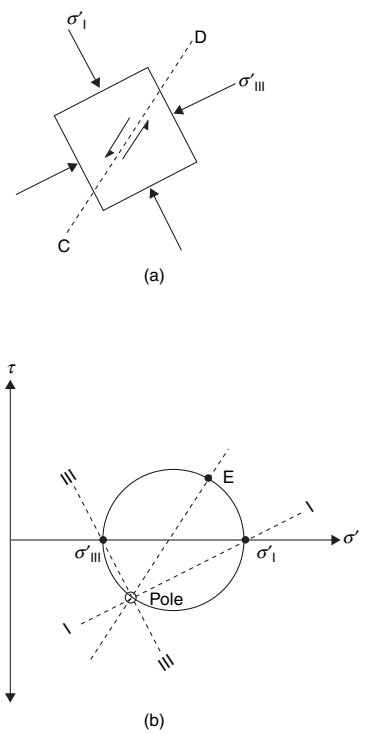

Figure 17.3 Application of Mohr's circle for the transformation of stress. For this construction anti-clockwise shear stresses are plotted as positive

Where c′ is the effective cohesion and φ' is the effective angle of shearing resistance (frequently referred to as the effective friction angle). However the author prefers the term 'effective angle of shearing resistance' as its value depends on other (more dominant) factors than inter-particle friction, such as particle shape and grading – see Chapter 14 *Soils as particulate materials*. Equation (17.1) is known as Coulomb's equation and it plots as two straight lines in a Mohr diagram as shown in **Figure 17.4** for positive and negative shear stress. In the following sections we will examine the results of laboratory tests using a simple shear box and compare them with the Coulomb equation.

17.3.2 Results of drained shear box tests on granular materials

For drained shearing, the shear stress is applied slowly so that the pore water can drain into or out of the soil sample as it dilates or contracts. Roscoe (1953), working at Cambridge University, developed a sophisticated shear box within which a soil sample is caused to deform uniformly in simple shear as shown in **Figure 17.5**. Drained tests were carried out on a variety of granular soils and clear patterns of behaviour emerged. **Figure 17.6** shows the results for some simple shear tests carried out on samples of sand at various initial relative densities ranging from very loose (best 1) to very dense (best 4). All the

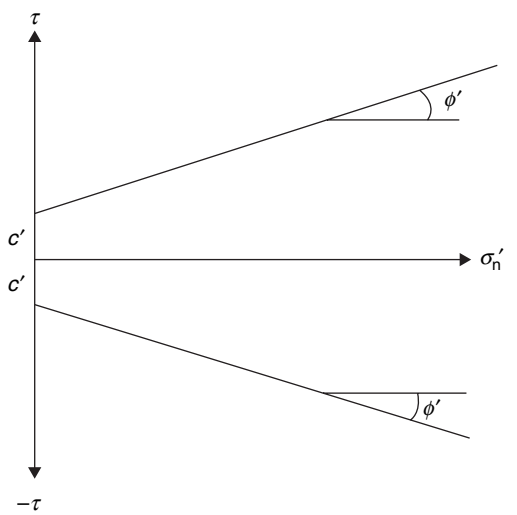

Figure 17.4 The Coulomb strength criterion

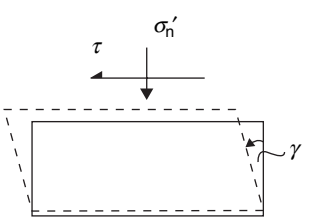

Figure 17.5 The mode of deformation of the Cambridge simple shear apparatus

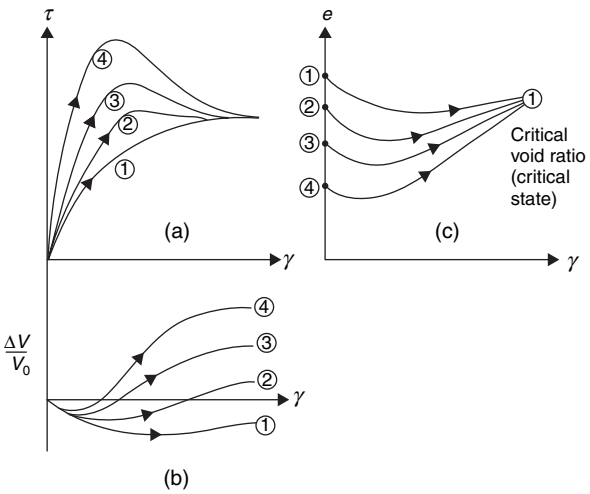

Figure 17.6 Results of drained tests on sand at various initial relative densities in the simple shear apparatus, carried out at the same value of σ'_n

tests were carried out at the same normal effective stress σ'_n. The results are plotted in **Figures 17.6(a–c)**.

Figure 17.6(a) shows graphs of shear stress τ against the shear strain γ. For the initially very loose sample it can be seen that the stress–strain curve rises at a decreasing rate until a maximum shear stress is reached, which then remains approximately constant as further deformation takes place. **Figure 17.6(b)** shows the corresponding volumetric strains during the test. It can be seen that as shearing commences the sample reduces in volume (contracts) initially, then increases very slightly and thereafter the volume remains constant for further deformation. Overall the sample can be seen to be contractant during shearing.

The above behaviour can be contrasted with that of an initially very dense sample. In **Figure 17.6(a)** it can be seen that the stress–strain curve rises steeply and reaches a maximum (peak) value, after which the strength reduces. Ultimately, with continued deformation, the shear stress reaches the same value of strength as the initially very loose sample. In **Figure 17.6(b)** it can be seen that after an initial small contraction, the very dense sample begins to dilate reaching a maximum rate of dilation at peak strength. Thereafter, the rate of dilation decreases until ultimately there is no further change in volume as shearing continues. Two samples of intermediate relative density show behaviour which lies between that of the initially very loose and very dense samples.

One of the key features of the Cambridge simple shear apparatus is that uniform deformations are imposed on the boundaries of the sample so that changes of void ratio can be measured throughout the test, right through to ultimate conditions at quite high shear strains. **Figure 17.6(c)** shows the changes of void ratio for each sample as the shear strains increase. The initially very loose sample starts at a high void ratio which reduces during most of the test. In contrast, the initially very dense sample starts at a low void ratio which then increases during the test. The important observation was made that all four samples ultimately ended up at the same void ratio, termed the 'critical void ratio'. It was further concluded that when a sample of soil reaches a condition in which it continues to shear at constant shear stress and constant void ratio, it has reached what is termed the 'critical state'.

All the tests described above were carried out at the same normal effective stress. **Figure 17.7** shows the results of tests at the four initial void ratios but with different values of vertical effective stress. The upper figure shows that the value of the critical void ratio reduces as the vertical effective stress increases, giving what has been termed the 'critical void ratio line'. In the lower figure, the peak strengths and ultimate strengths are plotted for each of the samples in a Mohr diagram. It can be seen that the ultimate strength line is straight and passes through the origin having a slope defined as φ'_{cs} – the critical state angle of shearing resistance. However the peak strength lines, particularly for the denser samples, are curved and lie above the critical state strength line. It can be shown that this upward displacement of the strength envelopes, together with their curvature, is due to the additional work done during shearing as a result of dilation.

The following broad conclusions can be drawn from these results:

(i) The effective confining pressure plays a dominant role in controlling the strength of a particulate material.

(ii) The initial density influences the peak strength. The greater the initial density, the steeper and more curved is the peak strength envelope in a Mohr diagram of τ versus σ'_n.

(iii) After a large shear strain, the shearing resistance of loose and dense samples under the same vertical effective stress converge to the same value. Similarly, the void ratios of each sample converge to the same value. This ultimate state is known as the 'critical state' in which a sample at a given value of vertical effective stress will continue to shear at constant shear stress and constant void ratio (i.e. at the critical state, the rate of dilation is zero).

(iv) On a Mohr diagram, the critical state strength line is straight and passes through the origin with an angle of shearing resistance φ'_{cs}.

(v) The initial density and the magnitude of σ'_n influence the amount of dilation during shear. The greater the initial density and the lower the magnitude of σ'_n, the greater is the dilation. It is noted that the maximum rate of dilation corresponds approximately to peak strength. The curvature of the strength envelope is related to the work done during dilation against the confining pressure.

(vi) At a given normal effective stress σ'_n, the peak strength τ_p is greater than the critical state strength τ_{cs}. The strength difference $(\tau_p - \tau_{cs})$ is due to the rate of dilation and is sometimes termed the 'enhanced strength'.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

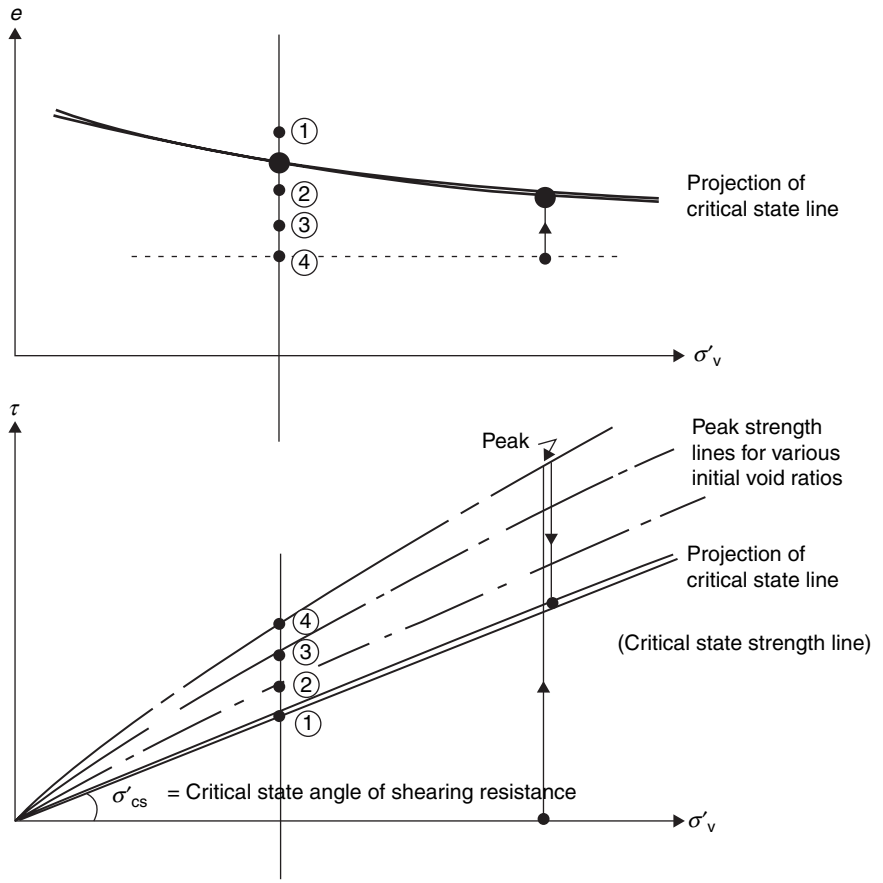

Figure 17.7 Results of drained tests on sand at various initial densities in the simple shear apparatus, carried out at various values of σ'_n

17.3.3 Results of drained shear box tests on clay soils

The basic strength properties of clay soils have been researched using samples that have first been formed with high moisture content and then consolidated to various values of effective normal stress in a shear box giving what is called 'the virgin compression line'. We describe such samples as remoulded or 'reconstituted'. **Figure 17.8(a)** shows the virgin compression line of void ratio e against σ'_v for a clay soil that has been formed in this way. At given values of effective normal stress σ'_v (points A and B), drained shear box tests are carried out. The behaviour is very similar to that of loose sand. **Figure 17.8(c)** shows the stress–strain curves of τ versus γ which rise at a decreasing rate until a maximum shear stress is reached, which then remains approximately constant as further deformation takes place (points A′ and B′). It can be seen from **Figure 17.8(c)** that as shearing commences, the samples contract at a rate that progressively decreases until at maximum strength there is no further volume reduction and void ratios remain constant (points A′ and B′ in **Figure 17.8(a)**). Thus the samples appear to reach a critical state condition. When plotted on a Mohr diagram of τ versus σ'_v, the strengths lie on a straight line through the origin, as shown in **Figure 17.8(b)**, having an angle of shearing resistance φ'_{cs} – the critical state strength line.

Overconsolidated reconstituted clay soils behave in a rather similar manner to dense sands. **Figure 17.9(a)** shows the relationship between void ratio e and σ'_v for a sample of reconstituted clay that has been consolidated to a high value of σ'_v (point B), after which the effective stress has been progressively decreased – causing the sample to swell and come to equilibrium at a much lower value of σ'_v (point C). If a drained shear box test is now carried out with σ'_v held constant, the stress–strain curve (see **Figure 17.9(c)**) will reach a peak value of τ at C′ which then gradually reduces as shearing continues. At the same time, the sample will tend to dilate so that the void ratio increases. When plotted on a Mohr diagram, the peak strength C′ lies above the corresponding critical state value and the strength envelope for the soil is curved as shown in **Figure 17.9(b)**.

17.3.4 Residual strength of clay soils

As described in section 17.3.2, for dense granular soils, tests show that after the strength reaches a peak value it gradually reduces to a steady state value corresponding to a critical state

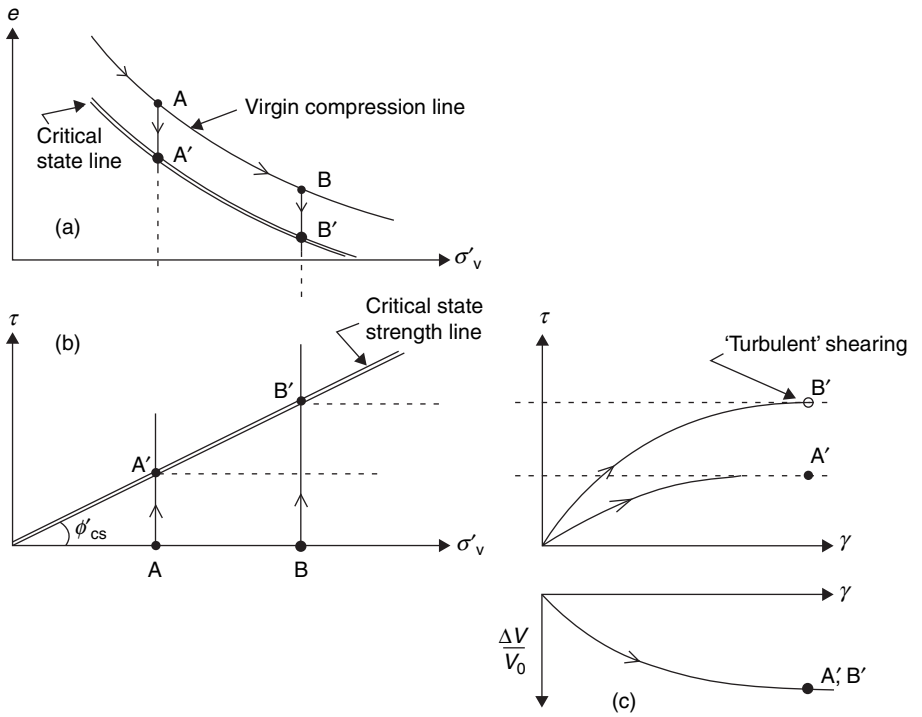

Figure 17.8 Results of drained simple shear tests on a reconstituted normally consolidated clay

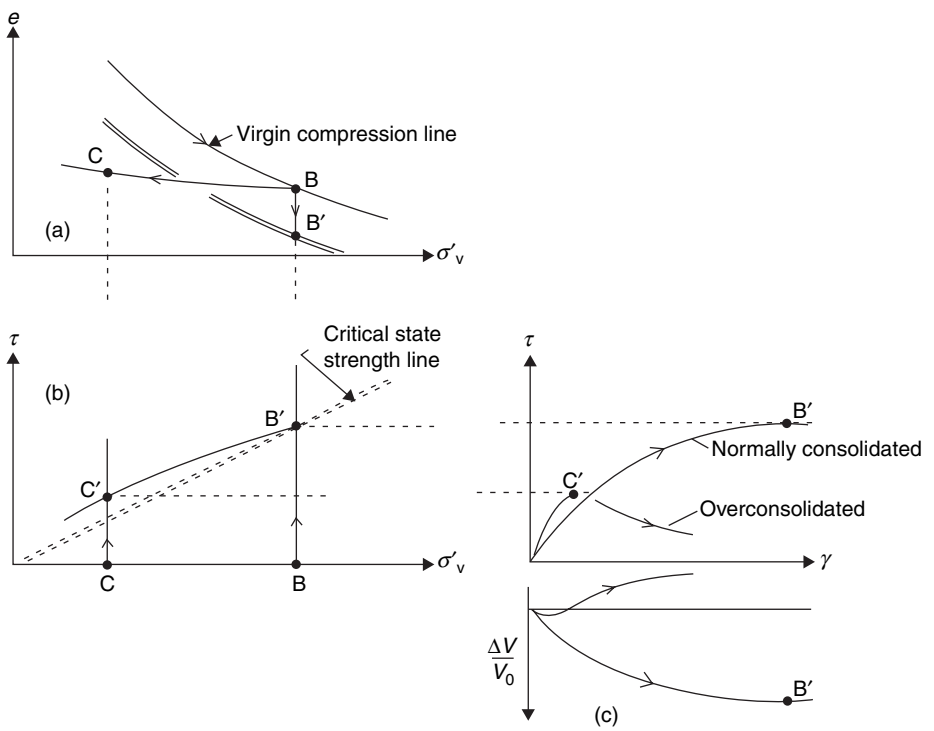

Figure 17.9 Results of drained simple shear tests on a reconstituted overconsolidated clay

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

condition. It is often assumed that overconsolidated clay soils behave in a similar way. However, the behaviour of clay soils is complicated by the fact that the shearing process can dramatically change the fabric (arrangement of the particles). Ring shear box tests on soils with a high clay content show that after peak strength is reached, the clay particles progressively align themselves in the zone of shearing until a polished shear surface is formed. In so doing, the strength steadily decreases with increasing displacement across the shear plane until the clay particles are fully aligned and a low 'residual strength' is reached – see **Figure 17.10**. Lupini *et al*. (1981) termed this 'sliding shearing'. They contrasted this with shearing at the critical state which they termed 'turbulent shearing' to convey the idea that during continued shearing at the critical state, the particles are tumbling over one another in a turbulent manner.

Figure 17.11 shows the comparison between the critical state angle of shearing resistance φ'_{cs} and the residual friction angle φ'_r for a sand–bentonite mixture in which the bentonite content was steadily increased. It can be seen that for a clay fraction of less than 20% there is little difference between φ'_{cs} and φ'_r. However, as the clay fraction increases the values of φ'_r become progressively less than φ'_{cs}. For an overconsolidated clay tested in a ring shear apparatus, the strength drops smoothly from peak to residual as shown in **Figure 17.10** and it is not possible to distinguish an obvious critical state strength. It seems that the simplest way of measuring the critical state strength is on normally consolidated reconstituted samples of the soil which contract during shearing.

17.3.5 The influence of bonding on the drained strength of clay soils

In the previous section, the influence of changes in microfabric on the drained shearing resistance of clay soils was described. Another important influence is the effect of inter-particle bonding which most natural clays exhibit to a greater or lesser extent. Bonding has the effect of increasing the strength and stiffness of the material. Tests on initially intact, natural, stiff, overconsolidated clays show that the breaking of the bonds results in a very rapid post-peak reduction of strength with the formation of well defined rupture surfaces – see **Figure 17.12**. The strength along the rupture surface, known as the post-rupture strength, has an effective angle of shearing resistance φ'_{pr}. This is remarkably similar to the critical state value for the reconstituted material, but often with a small effective cohesion c'. In view of the very brittle post-peak behaviour of such soils it would be unwise for the design to rely on strengths exceeding the post-rupture values.

17.4 The undrained strength of clay soils

When a shear stress is applied to a clayey soil of relatively low permeability, it takes a considerable time for the pore water to drain into or out of the pores. When shearing takes place with little or no drainage, the process is defined as 'undrained shearing', and the measured strength is defined as the 'undrained strength' S_u. The tendency for a soil to contract or dilate during drained shearing has a profound effect on the undrained strength of the material. This behaviour can be illustrated by considering elements of soil sheared undrained in a shear box, in which the applied normal stress σ_n is kept constant during the test.

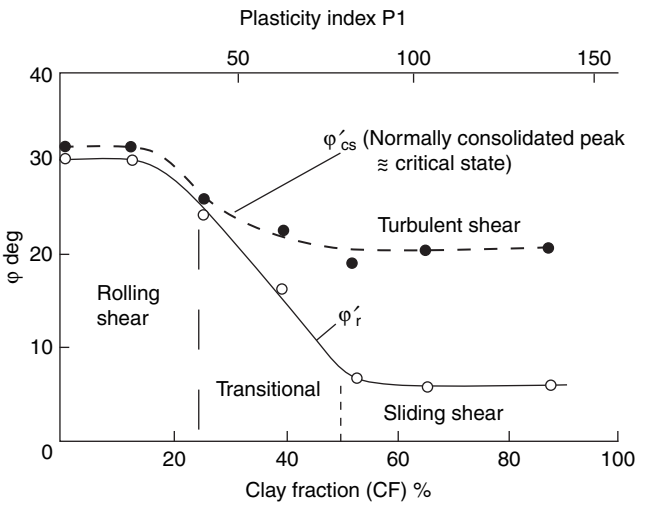

Figure 17.11 Ring shear tests on sand–bentonite mixtures. Normally consolidated at $\sigma' = 350$ kPa; PI/CF = 1.55
Data taken from Lupini *et al*. (1981)

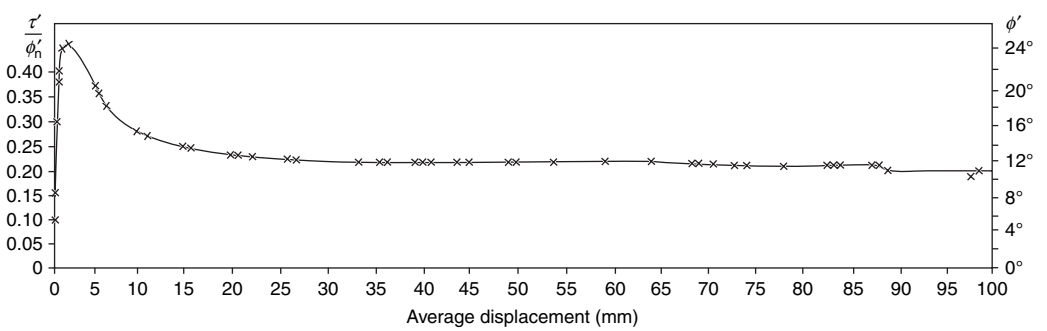

Figure 17.10 Results of drained ring-shear tests on an undisturbed sample of undisturbed Blue London Clay. Nominal normal stress $\sigma'_n = 207$ kPa; nominal shearing rate 0.0076 mm/min
Redrawn with data taken from Bishop *et al*. (1971)

For a loose (normally or lightly overconsolidated) sample, as τ is increased, the element will try to contract – but is prevented from doing so. As a consequence, stress is thrown onto the pore water so that the pore pressure u increases and, since σ_v is constant, σ'_v decreases. The resulting effective stress path and stress–strain behaviour are shown by the full lines in **Figure 17.13**. It can be seen that the undrained strength S_u (given by point A) is less than the corresponding drained strength (given by point B). If, at a given value of τ, drainage now takes place with τ and σ_v kept constant, the positive

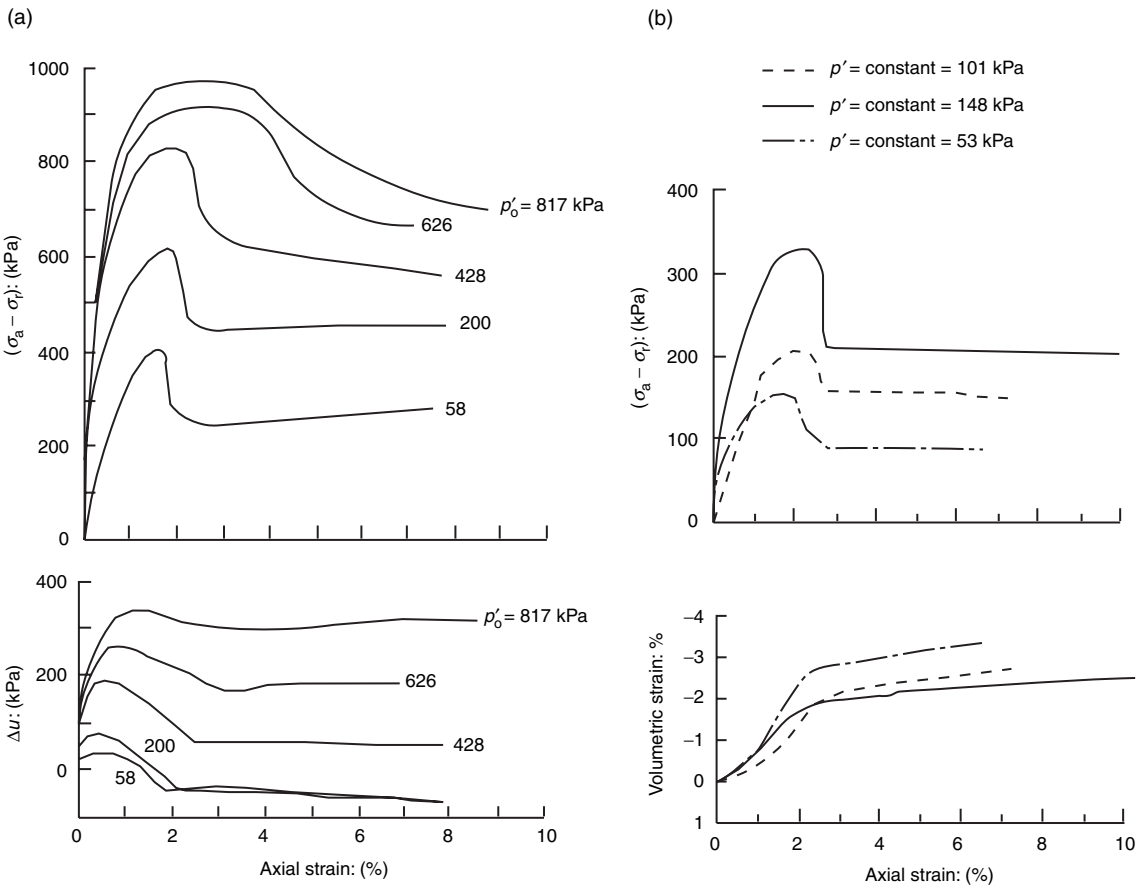

Figure 17.12 Results of (a) drained and (b) undrained triaxial tests on intact Vallerica Clay showing very brittle post-peak strength reductions
Reproduced from Burland *et al.* (1996)

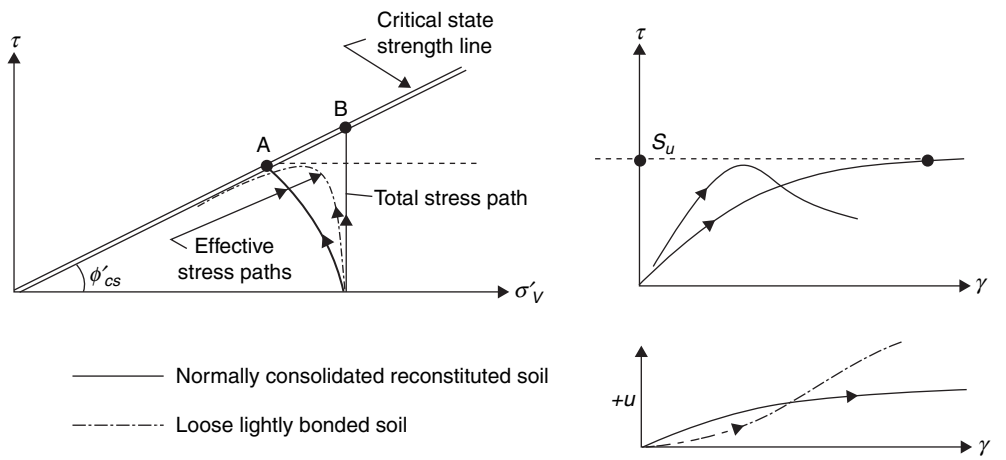

Figure 17.13 Undrained shearing of a normally consolidated clay

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

pore pressure dissipates, the volume decreases and the strength of the sample will increase. *Hence contractant soils tend to get stronger as they drain after the undrained application of a shear stress*.

For an initially dense (overconsolidated) sample, as τ is increased the element will try to dilate but is prevented from doing so. In contrast to the loose sample, the pore pressure u decreases as the soil tries to dilate and hence σ'_v increases. The resulting stress path and stress–strain behaviour are shown by the full lines in **Figure 17.14**. It can be seen that the undrained strength S_u (point A) is greater than the drained strength (point B). If, at a given value of τ, drainage now takes place with τ and σ_n kept constant, the negative pore pressure dissipates, the volume increases and the strength of the sample will decrease. Clearly if the drained strength is less than the applied shear stress τ, failure will occur as drainage is taking place. This is the cause of long-term (or delayed) slope failures in overconsolidated cut slopes – see Chapter 23 *Slope stability*. Hence dilatant soils tend to get weaker as they drain after the undrained application of a shear stress.

The chain-dotted lines in **Figure 17.13** represent the undrained behaviour of an initially very loose soil with some bonding between the particles. The material is highly contractive and positive pore pressures continue to develop after peak undrained strength is reached, and the bonds are progressively broken down. As a consequence, the strength reduces and the effective stress path continues to travel to the left moving down the critical state strength line. Hence loose soils, such as normally and lightly overconsolidated natural clays, can exhibit very brittle undrained shearing behaviour with significant loss of strength after the peak has been reached, particularly if they are lightly bonded or cemented.

The degradation of undrained strength upon remoulding is termed 'sensitivity' which is defined as the undrained strength of a clay divided by its remoulded strength at the same moisture content.

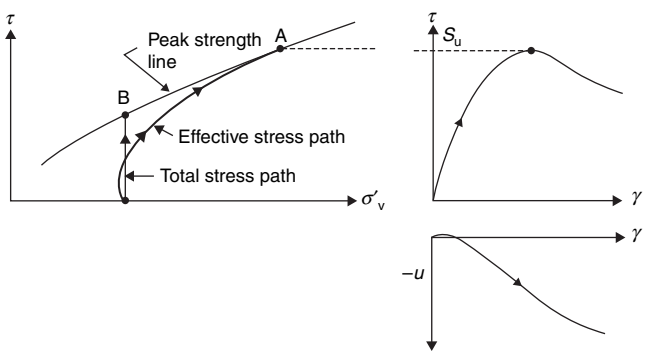

Figure 17.14 Undrained shearing of an overconsolidated clay

17.5 The Mohr–Coulomb strength criterion

So far we have only considered the strength of a mass of soil in terms of the classical Coulomb equation (17.1) applied to a shear box in which the normal effective stress σ'_n and the shear stress τ are known. This equation gives no information about the principal stresses or their orientation. Mohr showed that when a material fails according to the Coulomb criterion, the Mohr's circle of stress corresponding to the state of failure is tangential to the Coulomb strength line as shown in **Figure 17.15**.

Figure 17.16 shows the Mohr's circle of failure for a drained triaxial compression test for which the axial effective stress σ'_a is the major principal effective stress ($= \sigma'_I$) and the radial effective stress σ'_r is the minor principal effective stress ($= \sigma'_{III}$). From simple geometry, it can be shown that σ'_{III} is related to σ'_I by the expression:

$$\sigma'_{III} = \sigma'_I \tan^2(\pi/4 - \varphi'/2) - 2c' \tan(\pi/4 - \varphi'/2) \qquad (17.2)$$

which is known as the Mohr–Coulomb strength criterion.

In **Figure 17.16**, since σ'_a ($= \sigma'_I$) acts normal to a horizontal plane, the pole coincides with the σ'_{III} point as shown. The lines connecting the pole to the points of tangency of the Mohr's circle of failure are often termed 'stress characteristics'

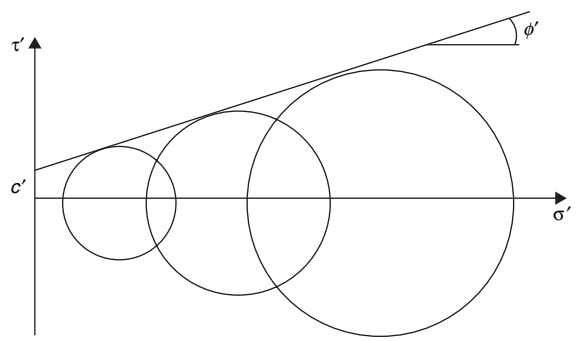

Figure 17.15 The Mohr–Coulomb strength criterion

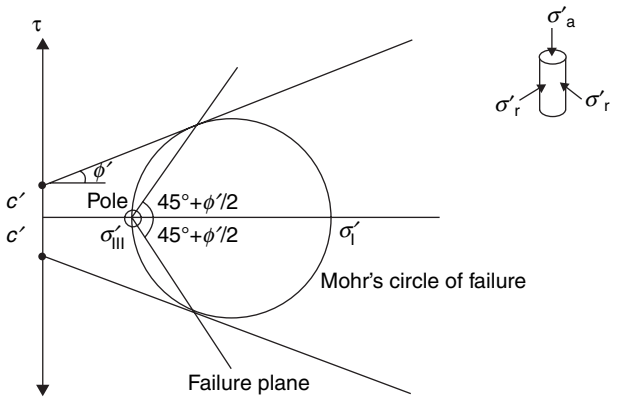

Figure 17.16 Failure in a triaxial compression test

or 'failure planes'. It can be seen that the failure planes make an angle of $\sigma'_n \pm (\pi/4 + \varphi'/2)$ to the major principal plane.

We saw that the measured strength envelope from a series of shear box tests is often curved. In this situation the Mohr's circles are still tangential to the envelope. By carrying out a number of drained or undrained triaxial tests with pore pressure measurements it is possible to construct the strength envelope by constructing the Mohr's circles of effective stress corresponding to failure. The best fit failure envelope is then sketched in tangential to these circles as shown in **Figure 17.17**. In this particular case, an effective cohesion intercept c' is indicated which will only exist if there is some inter-particle bonding at very low confining pressures.

17.6 Choice of strength parameters for analysis and design

In the previous sections we identified at least three common definitions of strength: peak strength, critical state strength and residual strength. Peak and critical state strength may be applied to either drained or undrained conditions. Residual strength is usually a drained condition.

We saw that the Coulomb equation is a simplification. Firstly, the peak value of φ' is not unique to a given soil, but depends on its initial void ratio or density. Secondly, the strength envelope is often curved and therefore does not strictly satisfy the Coulomb equation. As a consequence of these observations, which effective strength parameters to use in an analysis that makes use of the Mohr–Coulomb strength criterion is not straightforward. A simple practical approach is to choose a linear failure envelope defined by values of φ' and c' that are appropriate to the range of normal effective stresses encountered in the problem. In these circumstances it is important to appreciate that the chosen design value of c' is an analytical convenience rather than a true measure of the cohesion of the material.

The choice of a design value of undrained strength S_u is also not straightforward. The key point to remember about undrained strength is that it is not a unique quantity for a given deposit of soil or soil sample. Its value depends on at least three factors: (1) the rate at which the sample is tested (i.e. S_u is rate dependent – the higher the rate the greater the strength); (2) the undrained strength of most soils is anisotropic and depends on the orientation of the principal stresses; and (3) for stiff fissured clays, the undrained strength depends on the size of the sample being tested – the mean strength of 100 mm diameter samples of stiff fissured clays will usually be significantly lower than that of 35 mm diameter samples. The important subject of choice of strength parameters is covered in Chapter 27 *Geotechnical parameters and safety factors*.

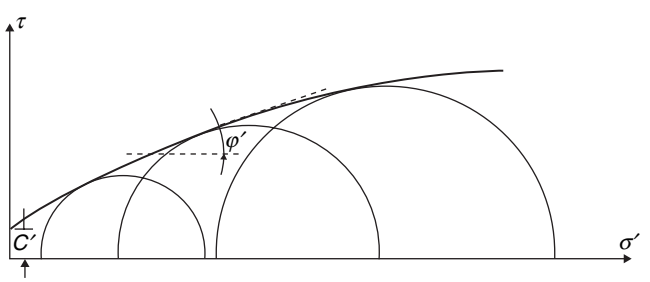

Figure 17.17 Curved strength envelope drawn tangential to Mohr's circles of failure

17.7 The compressibility of soils

We now move from discussing the strength of soils to their deformability. Because of their particulate nature, soils are compressible – especially clay soils. As discussed in Chapter 14 *Soils as particulate materials*, increases in all-round effective stress cause slip to take place between particles which then take on a closer pack and, as a consequence, water is squeezed out of the voids. The time taken for the water to be expelled is a function of the permeability and compressibility of the soil.

Perhaps the earliest, and still most widely used, apparatus for measuring the compressibility of soils is the oedometer, in which a sample of soil is compressed one-dimensionally as shown in **Figure 17.18**. Detailed descriptions of the test and its application are given in most textbooks – e.g. Craig (2004), Powrie (2004).

17.7.1 The coefficient of volume compressibility (mv)

We now consider the one-dimensional (confined) compression characteristics of an initially very loose sample of soil that is placed in an oedometer, subjected to a number of increments of increasing vertical effective stress with full drainage between increments, and then subsequently unloaded. **Figure 17.19(a)** shows a graph of void ratio e versus vertical effective stress σ'_v for the sample which is termed the 'virgin compression line'. It can be seen that this compression line ABC is concave upwards, showing that as σ'_v increases the soil becomes increasingly less compressible. The coefficient of volume compressibility m_v is defined as the increment in volumetric strain $\Delta V/V_0$ divided by the corresponding increment in vertical effective stress $\Delta\sigma'_v$. We consider a state B on the compression line for the sample corresponding to a void ratio e_0 and a vertical effective stress σ'_{v0}. An increment $\Delta\sigma'_v$ causes a decrease in void ratio Δe. Since the initial volume of the sample per unit volume of solid is $(1 + e_0)$ and the corresponding change of volume is equal to Δe, it follows that

$$m_v = \frac{\Delta e/(1+e_0)}{\Delta\sigma'_v}. \qquad (17.3)$$

Clearly m_v is not a constant, but it has to be determined for the appropriate stress range. It is usually expressed in the units m^2/MN – the inverse of stress.

17.7.2 Simple mechanistic explanation of compression and swelling

The soil sample is loaded to a vertical effective stress σ'_{vp} (point C in **Figure 17.19(a)**) and then unloaded in increments. It can be seen that the sample increases in volume as unloading

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

takes place. The unloading (or swelling) curve is much flatter than the initial compression line. A simple mechanistic explanation of this behaviour is that during initial loading, much of the volume reduction results from slip at the particle contact points as the particles take on a closer pack. On unloading, little 'reverse' slip occurs and much of the recovery results from elastic unloading of the particles and, in the case of clays, absorption of water into the clay particle lattice structure.

The sample is now re-loaded to an effective stress corresponding to point D which is greater than σ'_{vp}. Initially, the re-loading compression line lies a little above the unloading curve – until the stress approaches the maximum previous stress σ'_{vp} where it crosses the unloading curve and re-joins the virgin compression line. The simple mechanistic explanation of this behaviour is that initially, on re-loading, the material is responding approximately reversibly and the particles deform with little slip at the grain contact points. However, once the effective stress approaches the previous maximum value, slip at the contact point begins to re-commence and the re-loading compression line re-joins the original 'virgin compression line' as shown. Thus the maximum previous effective stress acts as a kind of 'pre-loading' such that, at lower stresses, the compressibility of the sample is much less than on first loading. Once the 'pre-loading' is exceeded, significant slip at the particle contact points re-commences. This concept of the onset of non-reversible particle contact slip is very important and is analogous to 'yield' of a ductile metal which signals the onset of irrecoverable (plastic) strains.

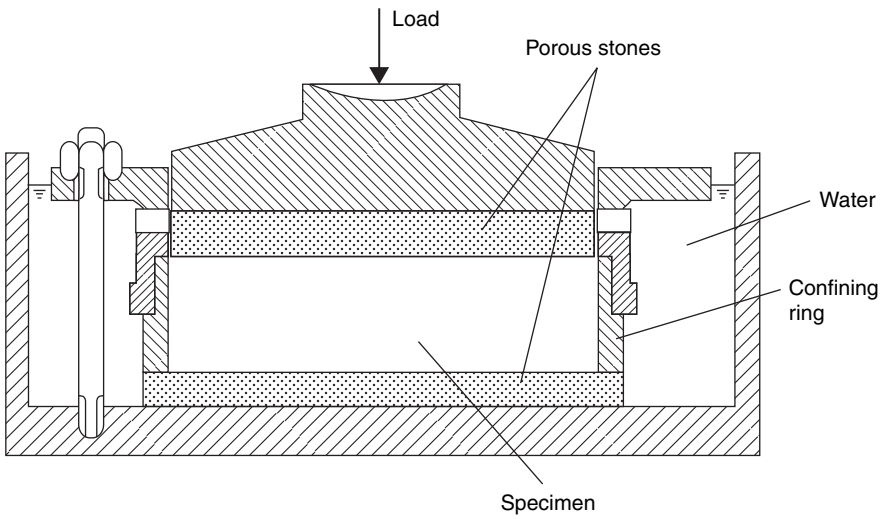

Figure 17.18 The oedometer

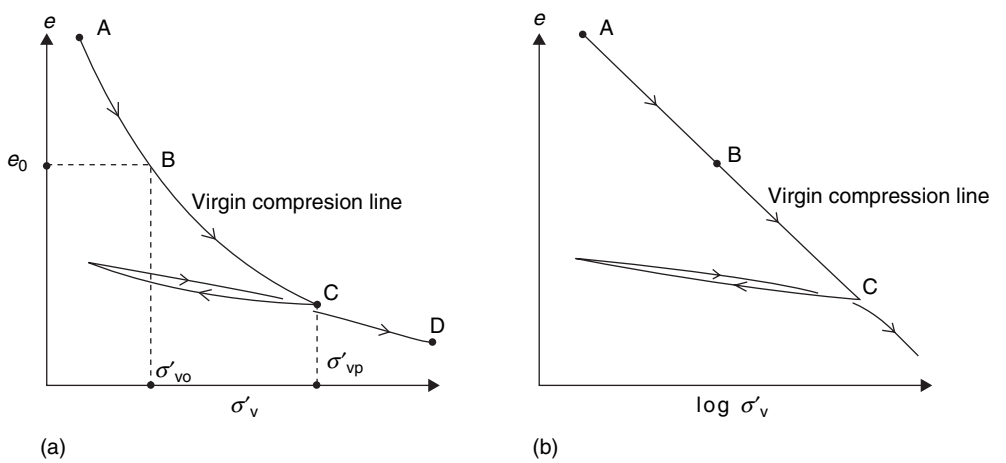

Figure 17.19 One-dimensional (confined) compression characteristics of an initially very loose soil subject to loading, unloading and re-loading; (a) σ'_v plotted to a natural scale; (b) σ'_v plotted to a logarithmic scale

17.7.3 The compression curve plotted on semi-logarithmic axes

It is common practice to plot the compression and swelling lines illustrated in **Figure 17.19(a)** using a log scale for the stress axis, as shown in **Figure 17.19(b)**. When plotted in this manner, the virgin compression and swelling lines approximate to straight lines. The slope of the virgin compression line in a semi-logarithmic plot is defined as the compression index, C_c, and for any two points on the approximately linear portion, it is given by:

$$C_c = \frac{e_0 - e_1}{\log(\sigma'_{v1} / \sigma'_{v2})}. \quad (17.4)$$

The slope of the unloading part of the $e - \log \sigma'_v$ plot is referred to as the swelling index C_s.

For the reloading line, the sharp downward curvature as it rejoins the virgin compression line has traditionally been used to determine the maximum past pressure σ'_{vp}. As will be explained in the following sections, some care is needed in interpreting oedometer curves in this way – as the sharp downward curvature also indicates the breaking of inter-particle bonds.

17.7.4 The influence of inter-particle bonding on compression and yield

Most natural soils have some inter-particle bonding (due to cementation or physico-chemical effects) which has an important influence on the compression characteristics. Physico-chemical bonds can develop over quite a short period of time in clay soils. Their influence was demonstrated by Leonards and Ramiah (1959) in some classic experiments, as reported by Burland (1990). A clay soil was reconstituted and compressed in an oedometer for which special precautions were taken to minimise wall friction. At a given value of vertical effective stress, the load was held constant for 12 weeks. After this ageing period, the loading process was then continued.

The results are illustrated schematically in **Figure 17.20** on a graph of e versus log σ'_v. As σ'_v was incremented daily, the soil compressed along the virgin compression line. At a stress σ'_{v0}, the load was maintained constant for 12 weeks, during which time some creep compression took place and the void ratio of the soil dropped below the virgin compression line. When loading was resumed, the resulting compression curve crossed to the right of the virgin compression line, then bent downwards sharply and rejoined the virgin compression line from above. Some additional tests were carried out in which creep was prevented during the ageing process. Once again, the subsequent compression line moved out to the right of the virgin compression line before bending down sharply and rejoining it as before. The downward 'kink' in the compression curve results from the breaking of the particle bonds and the onset of inter-particle slip. In the case of Leonards and Ramiah's experiments this 'kink' occurred at a stress equal to about 1.5 times the value of σ'_{v0}.

The important conclusion from the above work is that care is needed in adopting the classical interpretation of the point of maximum curvature of an oedometer compression curve as indicating the maximum past effective overburden pressure. What it actually indicates is the stress at which significant particle slip begins to take place, often due to the breaking of inter-particle bonds. For this reason, Burland (1990) recommended that this point be referred to as the vertical yield stress σ'_{vy} rather than the pre-consolidation pressure. The latter term should be reserved for situations in which the magnitude of such a pre-consolidation pressure can be established by geological means. It is the norm rather than the exception that normally consolidated natural clays have values of $\sigma'_{vy}/\sigma'_{v0}$ (termed the yield stress ratio) as high as 1.5. In cases where cementation has taken place, the yield stress ratio can be very much higher.

The accurate determination of σ'_{vy} is of great practical importance – if vertical effective stresses can be kept below this value, then settlements will generally be small. If, for soft clays, the vertical yield stress is exceeded, very large movements can take place. The vertical yield stress is also useful as an empirical indicator of undrained compressive strength S_{uc}. It has been found that the ratio S_{uc} / σ'_{vy} is roughly in the range 0.28–0.32 for a wide variety of natural clays (Burland, 1990).

Sometimes the use of an e versus log σ'_v plot can be misleading when attempting to evaluate σ'_{vy}. For example, a linear line on an e versus σ'_v plot becomes a convex upwards curve on an e versus log σ'_v plot. It is not unknown for such a line to be interpreted as exhibiting a pre-consolidation pressure or yield stress! A more reliable approach is to plot the data on double log axes as suggested by Butterfield (1979). **Figure 17.21** is taken from Butterfield (1979) who plotted $\ln(1 + e)$ versus log σ'_v for four sets of data given by Taylor (1948). It is evident that the double logarithmic plots give a clearer indication of the vertical yield stress than do the semi-logarithmic plots.

17.8 The stress–strain behaviour of soils

Section 17.3 began with a description of the most commonly used idealisation of the strength of soils *viz.* the Coulomb equation. Thereafter, the results of soil tests were examined to assess the equation's accuracy and limitations. A similar

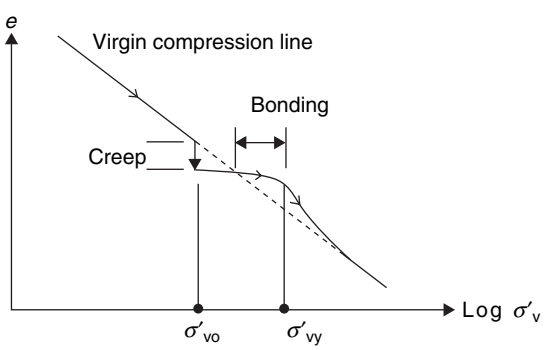

Figure 17.20 Influence of ageing and inter-particle bonding on the compression characteristics of a reconstituted normally consolidated clay

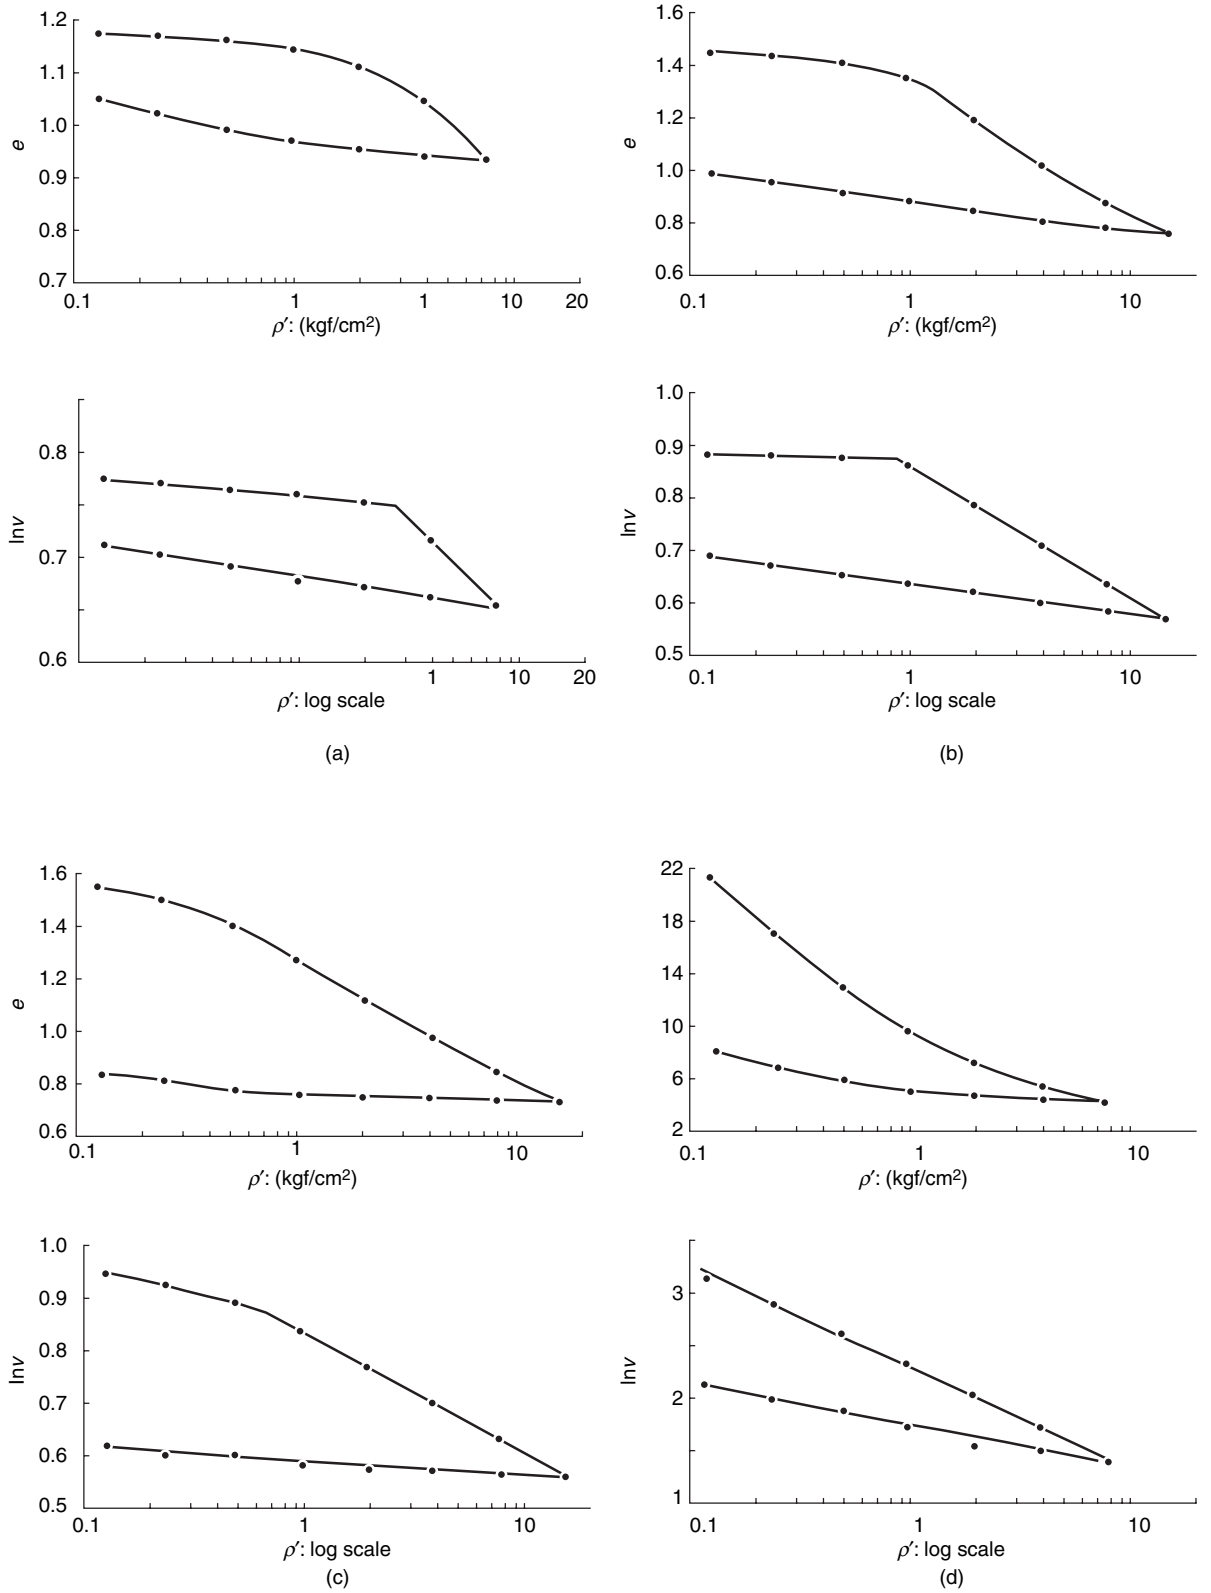

Figure 17.21 The use of double logarithmic plots to identify σ'_{vy} for various soils (a) Boston Blue Clay; (b) Chicago Clay; (c) Newfoundland silt; (d) Newfoundland peat

Reproduced from Butterfield (1979)

approach is adopted for the study of the stress–strain behaviour of soils. The most commonly used model of the stress–strain behaviour of soil is that of an ideal porous elastic solid.

17.8.1 Ideal isotropic porous elastic solid

A basic property of an elastic material is that when it is subjected to a closed cycle of stress, the deformations are reversible and fully recoverable. It is not necessary for the stress–strain behaviour to be linear. It is helpful to have a physical image of an isotropic porous elastic material: imagine a material which consists of very fine metal filings (elongated particles) arranged in a random manner and spot welded at their contact points (to ensure that the assemblage is elastic). The particles are so fine and the pores so small that the material has a low permeability. Hence, when loaded quickly, pore pressure changes can take place within the voids.

An isotropic elastic material is fully defined by two parameters. The most commonly used ones are Young's modulus E and Poisson's ratio υ. We are interested in the properties of the *skeleton* of this ideal soil. These are the properties that control its drained behaviour; we call them the 'effective' properties and denote them by a prime. The two most commonly used effective parameters are:

The effective Young's modulus E'

The effective Poisson's ratio υ'

The corresponding undrained parameters are denoted as E_u and υ_u.

17.8.2 The elastic equations

As is usually the case in soil mechanics, compressive stresses are taken as positive – so reductions in length or volume give rise to positive strains. In developing the elastic equations we deal with *stress changes* and their corresponding *strain changes*. Consider a vertical rectangular prism of isotropic porous elastic material as shown in **Figure 17.22**. An increment of principal vertical effective stress $\Delta\sigma'_1$ is applied allowing full drainage. The resulting increment in vertical strain $\Delta\varepsilon_1$ is $\Delta\sigma'_1/E'$. It also follows that the increments in horizontal strain are given by $\Delta\varepsilon_2 = \Delta\varepsilon_3 = -\upsilon'\Delta\sigma'_1/E'$.

Independent applications of $\Delta\sigma'_2$ and $\Delta\sigma'_3$ in the horizontal plane will cause increments of strain in the vertical direction as follows:

$$\Delta\varepsilon_1 = -\upsilon'\Delta\sigma'_2/E' \tag{17.5}$$

and

$$\Delta\varepsilon_1 = -\upsilon'\Delta\sigma'_3/E'. \tag{17.6}$$

By superposition, we find that for the general case of changes in all three principal effective stresses, the increment of vertical strain is given by

$$\Delta\varepsilon_1 = \{\Delta\sigma'_1 - \upsilon'\Delta\sigma'_2 - \upsilon'\Delta\sigma'_3\}/E'. \tag{17.7}$$

Similarly:

$$\Delta\varepsilon_2 = \{\Delta\sigma'_2 - \upsilon'\Delta\sigma'_1 - \upsilon'\Delta\sigma'_3\}/E' \tag{17.8}$$

and

$$\Delta\varepsilon_3 = \{\Delta\sigma'_3 - \upsilon'\Delta\sigma'_1 - \upsilon'\Delta\sigma'_2\}/E'. \tag{17.9}$$

These three simple equations can be used to derive a number of important properties for an ideal isotropic porous elastic material.

17.8.3 Volumetric strain

An increment in volumetric strain Δv $(= \Delta V/V_0)$ is equal to the sum of the three principal increments of strain (neglecting second-order terms). Adding equations (17.7)–(17. 9) gives

$$\Delta v = \frac{1-2\upsilon'}{E'}\{\Delta\sigma'_1 + \Delta\sigma'_2 + \Delta\sigma'_3\}. \tag{17.10}$$

Therefore,

$$\Delta v = \frac{3(1-2\upsilon')}{E'}\Delta p' = \frac{\Delta p'}{K'} \tag{17.11}$$

where $\Delta p' = (\Delta\sigma'_1 + \Delta\sigma'_2 + \Delta\sigma'_3)/3$, the effective mean normal stress and $K' = E'/3(1 - 2\upsilon')$, the effective bulk modulus.

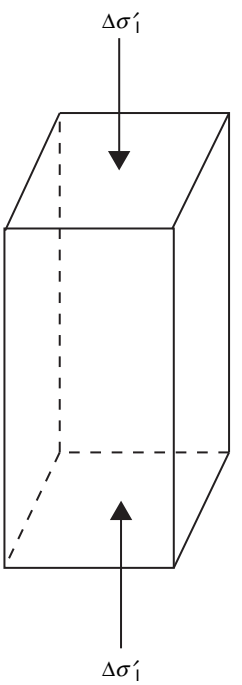

Figure 17.22 Element of porous isotropic elastic material subjected to an increment in vertical effective stress

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

It follows from equation (17.11) that if there is no volume change during the application of a general stress increment, then there will be no change in mean normal effective stress, i.e. if $\Delta v = 0$, then $\Delta p' = 0$, and vice versa. This result is an inevitable consequence of the idealisation of isotropic porous elastic behaviour. It has important consequences for undrained behaviour, as discussed later.

17.8.4 Shear strain

By definition, an increment in maximum shear strain $\Delta\gamma_{max} = \Delta\varepsilon_1 - \Delta\varepsilon_3$. Substituting from equations (17.7) and (17.9), and noting that $\Delta\tau_{max} = (\Delta\sigma'_1 - \Delta\sigma'_3)/2$, it follows that

$$\Delta\gamma_{max} = \frac{2(1+\upsilon')}{E'}\Delta\tau_{max} = \frac{\Delta\tau_{max}}{G'} \qquad (17.12)$$

where G' is the effective shear modulus $= E'/2(1+\upsilon')$. It follows from equation (17.12) that the application of an increment, in shear stress only, causes no volume change. Therefore this ideal material is non-dilatant. Moreover, we see that the effects of applying $\Delta p'$ and $\Delta\tau_{max}$ are entirely separate, in that the former only causes volume change and the latter only causes shear distortion. This is termed 'uncoupled' behaviour.

17.8.5 One-dimensional compression

We saw from section 17.7 that the coefficient of one-dimensional volume compressibility $m_v = \Delta v/\Delta\sigma'_v$ where $\Delta\varepsilon_2 = \Delta\varepsilon_3 = 0$. It can be shown from the elastic equations that

$$m_v = \frac{1 - \dfrac{2\upsilon'^2}{1-\upsilon'}}{E'}. \qquad (17.13)$$

It should also be noted that if $\Delta\varepsilon_3 = 0$ and $\Delta\sigma'_2 = \Delta\sigma'_3$ in equation (17.9),

$$\frac{\Delta\sigma'_3}{\Delta\sigma'_1} = \frac{\upsilon'}{1-\upsilon'} \qquad (17.14)$$

which gives the value of the coefficient of earth pressure at rest K_0 for the one-dimensional compression of an isotropic porous elastic material (See Chapter 15 *Groundwater profiles and effective stresses* for a discussion on the important topic of the coefficient of earth pressure at rest, K_0). The following limiting values of m_v from equation (17.13) should be noted:

- when $\upsilon' = 0$; $m_v = 1/E'$, i.e. m_v is the reciprocal of E';
- when $\upsilon' = 0.5$; $m_v = 0$, i.e. the material is incompressible.

17.8.6 The measurement of E′ and υ′ in an ideal drained triaxial test

For a standard drained triaxial test, increments of axial effective stress are applied without change in effective radial stress, i.e. $\Delta\sigma'_a = \Delta\sigma'_1 > 0$ and $\Delta\sigma'_r = \Delta\sigma'_3 = 0$. Both the axial strain $\Delta\varepsilon_a = \Delta\varepsilon_1$ and the volumetric strain $\Delta V/V_0$ are measured and plotted as shown in **Figure 17.23**.

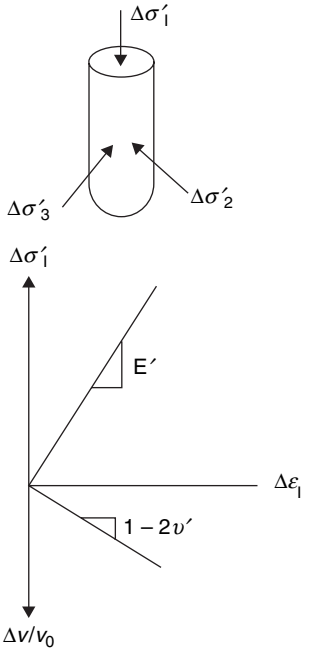

Figure 17.23 Determination of E' and υ' from a drained triaxial test on an ideal isotropic porous elastic material

From elastic equation (17.7):

$$E' = \Delta\sigma'_1/\Delta\varepsilon_1. \qquad (17.15)$$

By definition $\upsilon' = -\Delta\varepsilon_3/\Delta\varepsilon_1$ and $\Delta V/V_0 = \Delta\varepsilon_1 + 2\Delta\varepsilon_3$. Therefore

$$\Delta\varepsilon_3 = \frac{\left[\dfrac{\Delta V}{V_0} - \Delta\varepsilon_1\right]}{2}$$

and hence

$$\upsilon' = \frac{\left[1 - \dfrac{\Delta V/V_0}{\Delta\varepsilon_1}\right]}{2}. \qquad (17.16)$$

Note from **Figure 17.23** that the slope of the $\Delta\sigma'_1$ versus $\Delta\varepsilon_1$ line is equal to E' and the downward slope of the $\Delta V/V_0$ versus $\Delta\varepsilon_1$ line is equal to $(1–2\upsilon')$.

17.8.7 Ideal undrained triaxial test

For an undrained test, the pore water cannot drain out of or into the sample. Hence 'excess' pore pressures develop which can be positive or negative. Unless the pore pressures are measured, we only know the applied total stresses. The undrained Young's modulus E_u is given by:

$$E_u = \Delta\sigma_1/\Delta\varepsilon_1. \qquad (17.17)$$

As shown in the next section, the undrained Young's modulus is not usually equal to the drained Young's modulus E'. For an undrained test, full saturation is usually ensured so that there is no volume change – the water can be assumed to be incompressible. Hence υ_u (the undrained Poisson's ratio) is 0.5. When the excess pore pressure Δu is measured, as is usually the case for consolidated undrained tests, its value may be used to calculate the pore pressure coefficient A, which is referred to later.

17.8.8 Relationship between drained and undrained Young's modulus

Since water cannot carry shear, an increment in shear stress $\Delta\tau$ is an effective stress, irrespective of drainage. We have seen that for an ideal isotropic porous elastic material the application of $\Delta\tau_{max}$ will not cause any volume change in a drained test (or any pore pressure change in an undrained test). Hence the only deformation is a shear strain $\Delta\gamma_{max}$ which must be identical for both drained and undrained conditions. Hence the effective shear modulus G' is identical to the undrained shear modulus G_u. From equation (17.12) and its undrained equivalent:

$$G' = \frac{E'}{2(1+\upsilon')} = G_u = \frac{E_u}{2(1+\upsilon_u)}. \tag{17.18}$$

Setting $\upsilon_u = 0.5$ and solving for E_u:

$$E_u = \frac{3}{2(1+\upsilon')}E'. \tag{17.19}$$

This result is an inevitable consequence of the idealisation of isotropic elastic behaviour. It has particular significance when calculating undrained and drained settlements of foundations.

17.8.9 Pore pressure changes during undrained loading

We saw from equation (17.11) that, for an isotropic porous elastic material, if there is no volume change during general loading $(\Delta\sigma_1 + \Delta\sigma_2 + \Delta\sigma_3)/3$ there will be no change in mean normal effective stress p', i.e. $\Delta p' = 0 = (\Delta\sigma'_1 + \Delta\sigma'_2 + \Delta\sigma'_3)/3$.

Since, from the effective stress principle $\Delta\sigma'_1 = \Delta\sigma_1 - \Delta u$, etc., it follows that:

$$0 = (\Delta\sigma_1 - \Delta u + \Delta\sigma_2 - \Delta u + \Delta\sigma_3 - \Delta u)/3 \tag{17.20}$$

and

$$0 = \Delta p = \Delta u \tag{17.21}$$

i.e. during undrained loading of a fully saturated porous isotropic elastic material, $\Delta u = \Delta p$ (assuming the pore fluid to be incompressible in comparison with the skeleton). For an undrained triaxial compression test on a fully saturated sample of the ideal material in which both the axial and the radial total stresses are changed, we take $\Delta\sigma_a = \Delta\sigma_1$ and $\Delta\sigma_r = \Delta\sigma_2 = \Delta\sigma_3$. Hence from equation (17.21):

$$\Delta u = \Delta p = \frac{(\Delta\sigma_1 + 2\Delta\sigma_3)}{3} = \Delta\sigma_3 + \frac{(\Delta\sigma_1 - \Delta\sigma_3)}{3}. \tag{17.22}$$

Equation (17.22) is written in the form of Skempton's pore pressure equation:

$$\Delta u = B[\Delta\sigma_3 + A(\Delta\sigma_1 - \Delta\sigma_3)] \tag{17.23}$$

where A and B are experimentally determined coefficients. When the soil is fully saturated, $B = 1$. It can be seen by inspection of equations (17.22) and (17.23) that for an isotropic porous elastic soil, the value of A for an undrained triaxial test is fixed at 1/3. (It can be shown that under plain strain conditions the value of $A = 1/2$. Hence A is dependent on the total stress changes and is not a fundamental property, even for the ideal case of a porous isotropic elastic material.)

Further details on the determination and application of Skempton's pore pressure coefficients may be found in most basic soil mechanics textbooks, for example Craig (2004) and Powrie (2004). Note that the coefficient B can be measured by applying an increment of equal all-round stress $\Delta\sigma_3$ in an undrained triaxial test and measuring the change of pore pressure Δu. If B is less than unity then the sample is not fully saturated.

17.8.10 Summary of the properties of an ideal isotropic porous elastic material

Many soil mechanics problems are modelled using an ideal isotropic porous elastic material. We have shown in this section that this idealised material possesses some important and rather restrictive results which practising engineers should be aware of:

- Only changes in stress and strain are considered.
- Volume change only takes place if there is a change in mean normal effective stress, i.e. $\Delta v = \Delta p'/K'$.
- A change in shear stress only causes distortion and not volume change, i.e. $\Delta\gamma_{max} = \Delta\tau_{max}/G'$.
- The undrained Young's modulus E_u is uniquely related to the effective Young's modulus E' and the effective Poisson's ratio υ'.
- In undrained triaxial compression, the pore pressure coefficient $A = 1/3$.
- E' and υ' can be measured in the standard drained triaxial test.
- The one-dimensional volumetric compressibility m_v can be expressed in terms of E' and υ'.

17.8.11 The stress–strain behaviour of real soils

There are many useful solutions available for practical geotechnical problems based on ideal isotropic elastic materials – see, for example, Poulos and Davis (1974). In making use of such

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

solutions, the engineer has to make allowances for the fact that the stress–strain behaviour of real soils differs from that of the ideal isotropic elasticity in a number of ways. The three most obvious differences are non-linear behaviour, the dependence of stiffness on confining pressure, and the effects of anisotropy. All three stem directly from the particulate nature of soils.

It was shown in section 17.7 that the compressibility of a soil reduces with increasing pressure. Similarly, research has shown that, in the same way that strength is significantly dependent on the initial effective confining pressure p'_0, so is the stiffness – as shown in **Figure 17.24**. Since p'_0 increases with depth, it can be anticipated that the value of E' will usually increase with depth.

In Chapter 14 *Soils as particulate materials*, it was shown that the process of deposition of a sediment leads to preferred arrangements of the particles so that their stiffness and strength properties will be anisotropic. The geotechnical engineer needs to be aware of this departure from the ideal of isotropic behaviour. It is relatively straightforward to develop the elastic equations for a cross-anisotropic porous elastic material in which the properties in the horizontal direction differ from those in the vertical direction. For such a material, five elastic constants are required: E'_v, υ'_{vh}, E'_h, υ'_{hh} and G_{vh}. The determination of all these constants is far from straightforward experimentally and the application of a cross-anisotropic model should be carried out by an expert.

It is evident from the above that real soils depart from ideal isotropic elastic behaviour in a number of respects. The application of simple elastic theory can be very instructive in solving practical geotechnical problems. However, the key to its successful application is to understand clearly the properties of such a material and how the real material departs from these properties. The application of elastic theory to the calculation of foundation settlement and stress distributions is discussed in more detail in Chapter 19 *Settlement and stress distributions*.

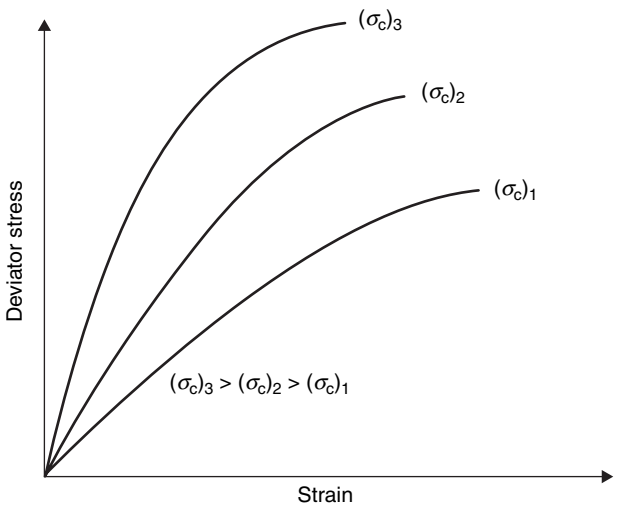

Figure 17.24 Influence of confining pressure on the drained stress–strain behaviour of soils

Most soils exhibit non-linear stress–strain behaviour of the form shown in **Figure 17.25**. A value of Young's modulus E' or E_u has to be selected which is appropriate for the range of stress changes involved. Frequently a value is chosen corresponding to about 0.1% axial strain. In sophisticated applications, numerical analysis is carried out using non-linear elastic formulations. The equations used are the same as those given in this chapter, but the elastic constants (E', G, K', etc.) are altered as the analysis progresses to reflect the reduction in stiffness of the soil as the strains increase. More advanced non-linear models make use of elastic–plastic formulations. A large number of non-linear constitutive models are available for undertaking the numerical analysis of geotechnical problems. When embarking on such complex analysis, it is important to remember that such models are idealisations and always carry with them a number of assumptions and limitations. Every effort should be made to understand these. For a detailed discussion of the benefits and limitations of the various soil models that are used in practice, reference should be made to Potts and Zdravković (1999). Non-linear analysis should only be undertaken with the advice and guidance of a specialist geotechnical engineer with expertise in numerical analysis.

17.9 Conclusions

The purpose of this chapter is to summarise the basic strength and stiffness properties of soils, emphasising the particulate nature of the material. In doing so, it has been necessary to relate the behaviour to simple idealised frameworks. Reference to the geotechnical triangle in Figure 4.1 of Chapter 4 *The geotechnical triangle* shows that there is a link between 'measured behaviour' in the bottom left-hand corner of the triangle and 'appropriate model' in the bottom right-hand corner. Simple models and idealisations are necessary to aid in prediction, but they need to be tempered with a clear understanding of real behaviour.

In the case of strength, the Coulomb criterion is universally used and the results of experiments on real soils have been compared with it. It is apparent that at least three measures of strength are used: peak strength, critical state strength and residual strength. In the case of peak strength, it has been shown that for dense or over-consolidated soils, the strength envelope is curved and depends on the initial relative density of the material. The engineer has to decide what measure of strength is relevant for a given problem and what values of φ' and c' to adopt in an analysis. This subject is covered in Chapter 27 *Geotechnical parameters and safety factors*; it is essential to have a clear understanding of the idealisations that are being made and their limitations.

Most clayey soils are very compressible compared with other structural materials and classical soil mechanics has focused particularly on the one-dimensional (confined) compressibility. In this chapter, discussion of the one-dimensional

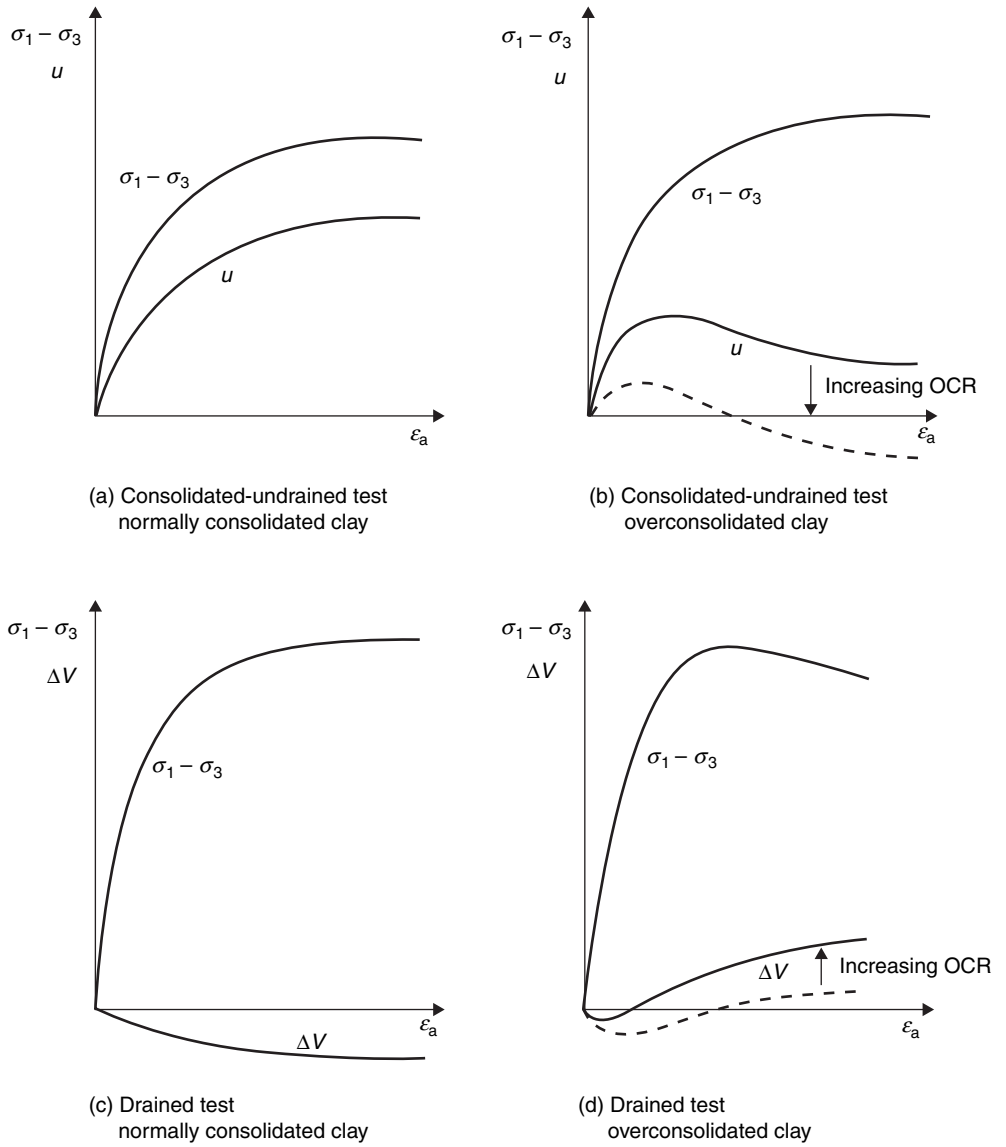

Figure 17.25 Typical stress–strain curves from consolidated undrained and drained triaxial tests

compressibility of soils follows traditional approaches. Particular emphasis is placed on the importance of inter-particle bonding which is present in most natural soils. In particular, the existence of the vertical yield pressure σ'_{vy} is introduced. This yield pressure represents the vertical effective stress at which the inter-particle bonds begin to break down and slip between the grains. In the past this pressure has been confused with the pre-consolidation pressure, but this can be misleading as most natural normally consolidated soils exhibit a value of σ'_{vy} which is greater than the effective overburden pressure σ'_{v0}. The ratio $\sigma'_{vy}/\sigma'_{v0}$ is known as the 'yield stress ratio'. A most useful empirical finding is that the undrained strength in triaxial compression S_{uc} is closely related to σ'_{vy} such that the ratio S_{uc}/σ'_{vy} usually lies roughly in the range 0.28–0.32.

Many practical solutions exist for deformation problems using simple isotropic elasticity. In this chapter, the properties of an ideal isotropic porous elastic material have been described in detail. This ideal behaviour has then been compared with the known stress–strain behaviour of real soils. It is hoped that this discussion will assist the engineer both in the choice of appropriate stiffness parameters and in assessing the limitations of predictions based on the simple elastic models. If a more complex analysis is required employing non-linear constitutive relations, it is important to remember that such models are idealisations and always carry with them a number of assumptions and limitations. Such an analysis should only be undertaken with the advice and guidance of a specialist geotechnical engineer with expertise in numerical analysis.

Rocks are naturally occurring, polycrystalline materials that play a wide range of roles in civil engineering. Their behaviour can be understood in terms of their intrinsic textures (grains, cement, voids and discontinuities) and through the application of standardised testing methods. Rocks and soils display a wide range of rheological properties, even under near-surface conditions. The void space in rocks is generally filled with water, at some pore pressure. For many engineering applications rocks may be considered as poroelastic, with a proportion of the applied load being supported by the pore pressure. Thus, their deformation is related to the effective stress (= total stress – pore pressure) as is generally found for soils. Rocks have a wide range of stiffness, strength and permeability, all of which will determine their suitability for different engineering applications. Most importantly, rocks are heterogeneous, displaying various forms of layering or grain fabrics, and are almost ubiquitously fractured. Thus the rock mass properties vary over a range of scales (heterogeneity) and orientations (anisotropy).

18.1 Rocks

Rocks are naturally occurring, polycrystalline materials that play a wide range of roles in civil engineering, ranging from their support for structures, to their use as construction materials.

All rocks can be considered as being made up of the following components (**Figure 18.1**):

Grains – discrete elements of either individual crystals or aggregates of crystals, usually having a distinct composition and shape;
Cement – usually crystalline material that binds the grains together;
Voids – spaces between grains, usually in the form of interconnected pores, often filled with water.
Discontinuities – macroscopic surfaces that separate the rock mass into blocks or layers. They may take the form of fractures (or joints), movement surfaces (faults), bedding planes or other surfaces. The discontinuities usually have markedly different physical properties from the rest of the rock material.

The composition and arrangement of these components gives rise to a variety of different rock types (that geologists describe with a bewildering range of names), which have a wide range of engineering properties. *The nature of the grains, cement, voids and discontinuities is important in evaluating the behaviour of rocks and rock masses.* Some understanding of the nature of rocks is necessary in order to discuss their physical behaviour.

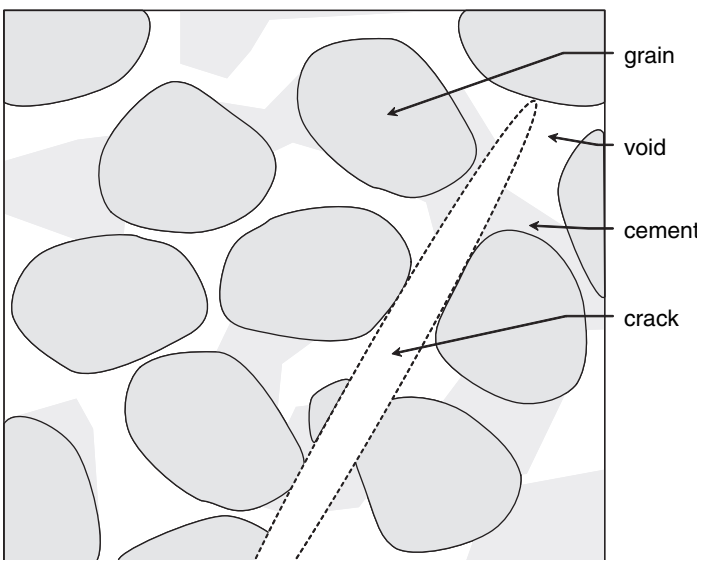

Figure 18.1 Diagrammatic representation of the components that make up a typical rock

18.2 Classification of rocks

Geologists recognise three broad categories of rocks, based on their mode of formation:

Sedimentary rocks – that form at or near the surface of the Earth from grains, usually eroded from previously formed

rock. The grains are then transported across the surface and deposited to form new ***sediments***. The main agents for these processes are water (in the form of rivers and seas), ice and wind. We can regard soils as a form of sediment.
Igneous rocks – that form by crystallisation of grains from molten rock either deep within the Earth (magma) or at the Earth's surface (lava).
Metamorphic rocks – that form deep within the Earth due to solid-state recrystallisation of other rock types.

Igneous and metamorphic rocks share many characteristics and consist of an interlocking aggregate of mineral grains, usually resulting in strong and stiff materials. The boundaries between grains are usually very narrow, with no cement, and it is the interlocking nature of these boundaries and the lattice-scale forces between grains that impart their strength. Void space is small, with the porosity (ratio of void space to total volume) generally being < 1%.

Sedimentary rocks on the other hand are generally formed as loose aggregates of grains, initially with a large amount of void space (porosities of 30% or greater). In the Earth, this porosity is usually saturated with water (and occasionally other fluids). The water may contain dissolved materials that can precipitate in the pore space to form cement.

At an initial stage, when porosities are high, the sediments resemble soils in their mechanical behaviour (see Chapter 17 *Strength and deformation behaviour of soils*). As the sediments are buried they experience elevated pressures and temperatures, leading to consolidation (usually by expulsion of water from the void space) and cementation. These processes essentially convert the 'soil' to rock. Near-surface chemical processes, generally termed diagenesis by geologists, accelerate the conversion of sediment to rock.

There is no clear boundary between rocks and soils, and many of the methods used to describe their behaviour are based on the same principles of continuum and granular mechanics. Both materials can exhibit considerable heterogeneity, often an important factor in assessing their engineering behaviour, but some important differences exist between the two.

Soils are essentially particulate (or granular) materials, with particle sizes that are usually many orders of magnitude less than the length scales of the imposed engineering loads. Thus they are generally treated as continuum materials, their micro-scale granularity being approximated by macroscopic parameters. On the other hand, the block sizes of rocks are often of a similar length scale to the applied loads and the discrete nature of rock masses is usually of greater importance in rocks than for soils (e.g. Hudson and Harrison, 1997).

Generally, both rocks and soils contain water, the void space often being saturated. Thus in both materials the effects of fluid pressure and the principles of effective stress are of great importance. However, the fundamental behaviour of soil changes dramatically with water content, changing from solid → plastic → liquid at the plastic and liquid limits, respectively. Rock properties are also affected by water, but not to anything like the same extent; for example, the strengths of dry and saturated rocks rarely differ by more than a factor of two.

18.3 Rock composition

An important distinction between the crystalline (igneous and metamorphic) and sedimentary rocks is the composition of the grains. The bulk composition of the Earth's crust is dominated by the elements silicon (Si) and oxygen (O) that readily combine to form the silica ion (SiO_4^{4-}). The next most abundant elements are the metals aluminium (Al), iron (Fe), magnesium (Mg), calcium (Ca), potassium (K) and sodium (Na), which form positively charged ions and combine with the SiO_4^{4-} to form a group of minerals known as rock-forming silicates. These include the common minerals quartz and feldspar, together with a complex array of other silicates (pyroxenes, amphiboles, micas, etc.). Most igneous and metamorphic rocks consist of a small number, typically three or four, of these rock-forming silicates, the composition of which depends on the chemistry of the patent magma or rock, and the pressure–temperature conditions under which the rock formed. The details of these minerals need not concern us here; what is important is that they generally have moderate to high strengths, contributing to the strength of igneous and metamorphic rocks.

Many of these rock-forming silicates weather on exposure to the Earth's surface, and are converted to various types of clay minerals and other salts; the latter often dissolve in water. An exception is the mineral quartz, which is highly resistant to weathering. Weathering leads to a reduction in strength of igneous and metamorphic rocks, and is facilitated by fracturing of the rock mass. Thus a key issue in the behaviour of such rocks is the rock mass quality.

Weathering leads to the development of sediment – hence, we would expect this to be composed mainly of quartz and clay minerals. Sediment is also generated by the precipitation of dissolved salts, either through evaporation (e.g. rock salt) or more commonly by biochemical action, mainly involving fixing of dissolved salts in the shells of invertebrate organisms. The nature of the sediment determines the type of sedimentary rock that is subsequently produced:

Quartz sand	→	sandstone
Clay minerals	→	claystone (also called mudstone or shale)
Calcite shells	→	limestone
Dissolved salts	→	rock salt (and other 'evaporates')
Organic matter	→	coal, oil, etc.

18.4 Porosity, saturation and unit weight

From the previous description of rock in terms of grains, cement and voids, we can consider the grains and cement together as a solid phase (**Figure 18.2**), with the voids being either liquid (pore water) and/or gas (air).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

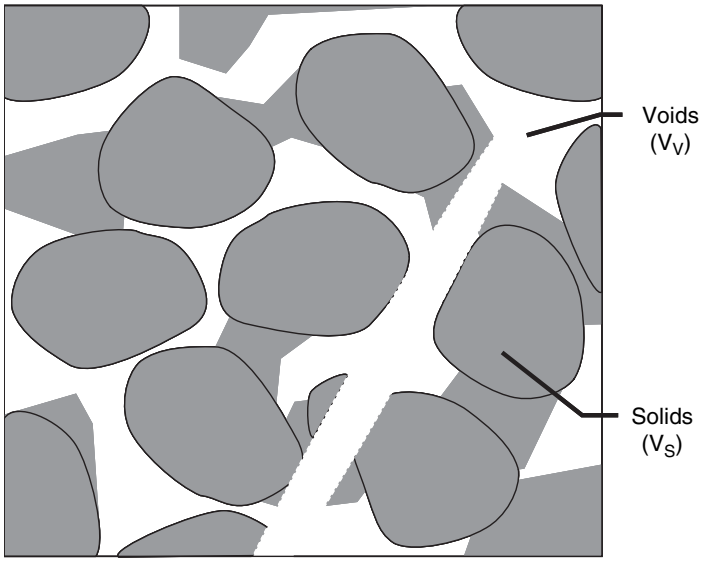

Figure 18.2 Rock components (as Figure 18.1) classified into solids (V_s) and voids (V_V)

The volume of the rock (V_R) is made up of solids (V_S) and voids (V_V), where $V_R = V_S + V_V$. The relative proportions of these define two parameters:

$$\textit{Porosity}\ (n) = V_V / V_R \text{ or } V_V / (V_S + V_V) \qquad (18.1a)$$

$$\textit{Voids ratio}\ (e) = V_V / V_S \qquad (18.1b)$$

where $$e = n / (1 + n) \text{ and } n = e / (1 + e). \qquad (18.1c)$$

Since the volume of voids can be filled with water and/or air: $V_V = V_W + V_A$, which we can express in terms of the **saturation** S, where:

$$S = V_W / V_V. \qquad (18.2)$$

Porosity, voids ratio and saturation are usually expressed as a fraction (0 – 1), but can be expressed as a percentage.

Knowing the densities (ρ) of the solid, water and air phases, and using g = 9.81, the weights of the phases may be calculated, where $W = \rho g$.

For example, $$\textit{unit weight}\ (\gamma) = (W_S + W_W + W_A) / (V_S + V_W + V_A) \qquad (18.3a)$$

$$\textit{unit dry weight}\ (\gamma_d) = W_S / (V_S + V_W + V_A). \qquad (18.3b)$$

These parameters are discussed more fully in Chapter 17 *Strength and deformation behaviour of soils*, but can provide a useful basis for characterising the multi-component nature of rocks and, hence, assessing rock behaviour. For example the uniaxial compressive strength (UCS) is related empirically to the porosity for different rock types, which provides a useful guide to rock strength in the absence of tests.

18.5 Stresses and loads

Stress exists throughout the Earth's crust and may be changed by surface and subsurface construction. There are four universal components responsible for this stress:

(1) The weight of the overlying column of rock, which is a relatively simple function of depth and rock density (unit weight), and is usually referred to as **overburden stress (σ_V)**.

(2) **Fluid (or pore) pressure (P)**, which arises from the fact that most rocks are basically two-phase materials consisting of mineral grains (which may or may not be cemented together) and fluid-filled pores and cracks.

(3) **Thermal stresses** arising from heating or cooling of rock, which tends to cause rocks to expand or contract.

(4) **Externally applied loads** that may be imposed by geological processes (tectonics, topography, etc.) or by construction.

These four components interact in different ways, but their combined effect is to act on or load materials to induce strain (change in shape and/or volume). In civil engineering we are mainly concerned with how the ground responds to externally applied loads, but we should not overlook the possible effects of other sources of stress.

Most rocks contain pores and cracks that are generally saturated by water. The externally applied loads create both a stress in the framework of grains and cement, and a pressure in the fluid, which we refer to as fluid pressure or pore presure. Terzaghi (1943) suggested that the applied loads may be supported by both the stress in the solids and the fluid pressure in the pores. At the grain boundaries, these two tractions oppose one another and create an **effective stress**, such that:

$$\text{Effective stress} = \text{Total stress} - \text{Pore pressure} \qquad (18.4a)$$

$$\sigma' = \sigma - P_f. \qquad (18.4b)$$

In a granular material, it is this effective stress that promotes deformation, with the relationship between effective stress and strain being determined by the rheology and properties of the material. The effective-stress principle is applied almost universally in soil mechanics and widely in rock mechanics. We will discuss this further in the section on poroelasticity (section 18.8).

18.6 Rock rheology

There are three basic responses of materials to applied stress that are easily recognised from plots of stress against strain or strain rate (**Figure 18.3**):

Elasticity – where the strain is linearly proportional to the stress (**Figure 18.3(a)**). This typifies the behaviour of solid materials and the ratio of stress to strain is referred to as the stiffness (Young's modulus, rigidity, etc.). In the ideal case, the

deformation is completely recovered on removal of the stress and the rock exhibits no significant change in structure. Many crystalline rocks approximate this behaviour and are fairly rigid, i.e. they exhibit a high stiffness, with Young's modulus being measured in GPa. This is one reason for their widespread use as construction materials.

Viscosity – is where the material flows and is the basic characteristic of liquids. In rock mechanics we often perform ***creep*** experiments where a sample is allowed to deform under a constant applied stress and the strain plotted against time, the slope being the strain rate (**Figure 18.3(c)**). If the strain rate is proportional to stress, the material exhibits linear or Newtonian viscosity, where the viscosity is the ratio of stress to strain rate. Some rocks exhibit Newtonian viscosity, but more generally the behaviour is more complex (nonlinear viscosity).

Yield – occurs when a material behaves elastically at low stress, but is ductile (i.e. flows) at higher stresses. The stress at which this transition takes place is the yield stress (**Figure 18.3(b)**). This behaviour is typical of plastic materials.

Rocks, in common with most other materials, exhibit all of these basic rheologies, the stiffness, viscosity and yield stress often being complex (nonlinear) and dependent on the temperature, confining pressure and strain-rate.

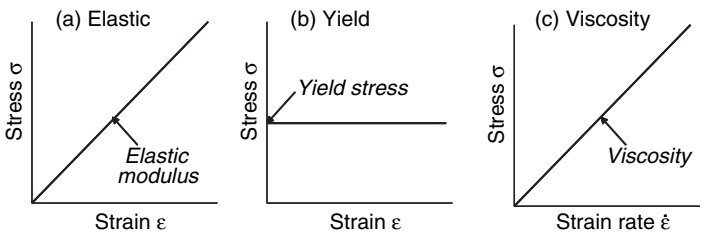

Figure 18.3 Idealised rheological behaviour showing (a) linear elasticity, (b) plastic yield and (c) Newtonian viscosity

It is useful, at least from a conceptual basis, to model rocks by combining the three basic rheological elements in various ways. For example, the stress–strain curves for rock (**Figure 18.4(a)**) at room temperature are elastic, whereas high confining pressures show a close correspondence to an elastic-plastic rheology. Confining pressure effectively inhibits failure and the rock exhibits a reasonably clearly defined yield stress at ~500 MPa (**Figure 18.4 (a)**). Yield stress and the stiffness decrease with increasing temperature (**Figure 18.4(b)**), as does the viscosity (not shown in **Figure 18.4**).

The rheology of a material is described by a ***constitutive law*** – an equation relating the deformation (strain) induced in the rock to the applied stress (or *vice versa*). We have encountered simple examples of these in the previous section. However, to define a constitutive law more rigorously we need to consider the relationships between different components of stress and strain. In general, the deformation can be described by a second-order strain tensor, ε_{ij}, which is related to the displacements (u):

$$\varepsilon_{ij} = \tfrac{1}{2}\left(\frac{\delta u_i}{\delta x_j} + \frac{\delta u_j}{\delta x_i}\right). \qquad (18.5)$$

Three commonly encountered deformation types (unconfined compression, simple shear and volumetric strain) are illustrated in **Figure 18.5**.

18.7 Elasticity and rock stiffness

For elastic behaviour, the relationship between stress and strain is linear and, for small deformations, can be described by a series of stiffness (or elastic) constants, defined by the ratio of different stress-to-strain components. The following elastic constants are widely used and relate to the three common deformation types (**Figure 18.5**) as follows:

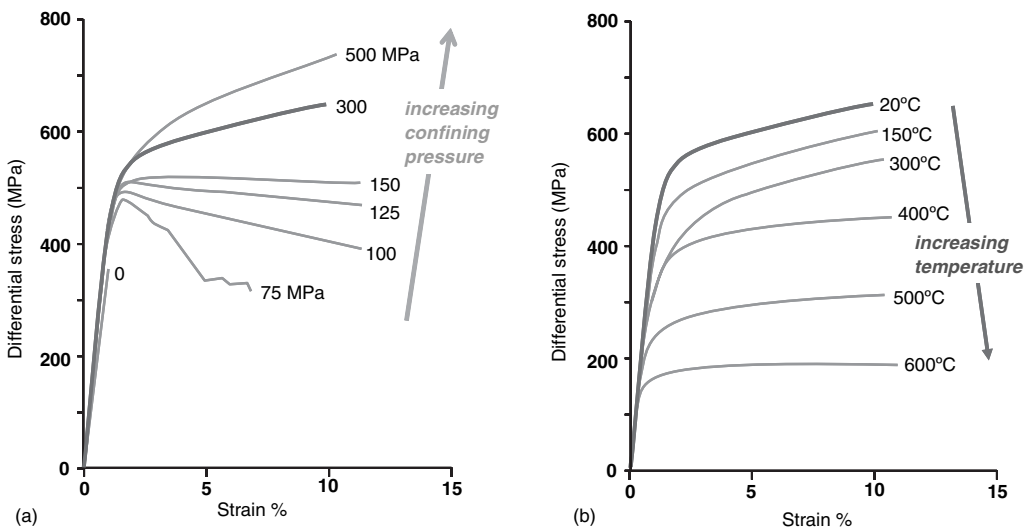

Figure 18.4 Stress–strain curves from triaxial tests on Solenhofen Limestone (after Heard, 1960). All tests at strain rate of 2×10^{-4} s^{-1}; (a) changing confining pressure at constant temperature of 25°C; (b) changing temperature at 300 MPa confining pressure

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Young's modulus (***E***) where $E = \sigma_{33} / \varepsilon_{33}$. This is the stiffness in unconfined (uniaxial) compression (**Figure 18.5(a)**), where σ_{33} is the only non-zero stress although there will be lateral strains in the other principal directions (i.e. $\varepsilon_{11} = \varepsilon_{22} \neq 0$).
Poisson's ratio (ν) where $\nu = -\varepsilon_{33} / \varepsilon_{11}$, is the ratio of lateral to axial strains in uniaxial compression.
Shear modulus (***G***) where $G = \frac{1}{2}(\sigma_{31} / \varepsilon_{31})$; it is easily determined from simple shear experiments (**Figure 18.5(b)**).
Bulk modulus (***K***) where $K = \sigma_{00} / \varepsilon_{00}$ and σ_{00} is the mean stress or uniform confining pressure (**Figure 18.5(c)**). The **compressibility** (c) is simply $1/K$.

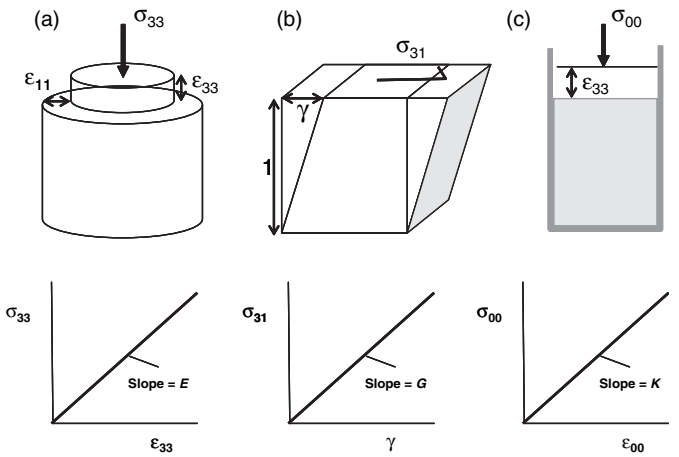

Figure 18.5 Three types of deformation involving different components of stress and strain and leading to different descriptions of rock stiffness

More generally the **constitutive equation** for linear elasticity is given by the equation:

$$\sigma_{ij} = \lambda \delta_{ij} \varepsilon_{00} + 2G \varepsilon_{ij} \tag{18.6}$$

where δ_{ij} is the Kronecker delta, which has a value 1 if i = j and 0 if i ≠ j. The term λ is a fifth elastic constant know as **Lame's constant** and, together with G, provides a more concise mathematical formulation of the constitutive equation in the theory of elasticity. The other, more practical stiffness constants can be related to λ and G, as follows

$$K = \lambda + 2G/3 \tag{18.7a}$$

$$E = (3\lambda + 2G) / (\lambda/G + 1) \tag{18.7b}$$

$$\nu = \lambda / [2(\lambda + G)]. \tag{18.7c}$$

Any two elastic constants can be used to define the material and, hence, all other constants (**Table 18.1**). The range of elastic properties in natural materials is very large, especially if we include water, as illustrated in **Table 18.2**.

The discussion of elasticity presented above assumes that rocks are homogeneous and isotropic. In reality a rock mass is inhomogeneous (properties vary with location) and anisotropic (properties vary with direction). A major contribution to anisotropy comes from the grain fabric due to depositional processes (commonly parallel to bedding) and ductile deformation. Fractures also contribute significantly to anisotropy, both on a macroscopic scale and due to microcracks (e.g. Goodman, 1989; Hudson and Harrison, 1997). This elastic anisotropy is

	Young's modulus E	Poisson's ratio ν	Bulk modulus K	Rigidity (Shear modulus) G	Lame constant λ
E, ν			$\frac{E}{3(1-2\nu)}$	$\frac{E}{2(1+\nu)}$	$\frac{E\nu}{(1+\nu)(1-2\nu)}$
E, G		$\frac{E}{2G}-1$	$\frac{EG}{3(3G-E)}$		$G\frac{E-2G}{3G-E}$
E, K		$\frac{3K-E}{6K}$		$\frac{3KE}{9K-E}$	$\frac{3K(3K-E)}{9K-E}$
ν, G	$2G(1+\nu)$		$\frac{2G(1+\nu)}{3(1-2\nu)}$		$\frac{2G\nu}{(1-2\nu)}$
ν, K	$3K(1-2\nu)$			$\frac{3K(1-2\nu)}{2(1+\nu)}$	$\frac{3K\nu}{(1-\nu)}$
ν, λ	$\frac{\lambda(1+\nu)(1-2\nu)}{\nu}$		$\frac{\lambda(1+\nu)}{3\nu}$	$\frac{\lambda(1-2\nu)}{2\nu}$	
K, G	$\frac{9KG}{(3K+G)}$	$\frac{3K-2G}{2(3K+G)}$			$K-\frac{2G}{3}$
λ, K	$9K\frac{K-\lambda}{3K-\lambda}$	$\frac{\lambda}{3K-\lambda}$		$3\frac{K-\lambda}{2}$	
λ, G	$G\frac{3\lambda+2G}{\lambda+G}$	$\frac{\lambda}{2(\lambda+G)}$	$\lambda+\frac{2G}{3}$		

Table 18.1 Conversion of elastic constants

	Crystalline rock	Soil	Water
Youngs's modulus (MPa)	4×10^4	$10^1 - 10^2$	0
Bulk modulus (MPa)	2×10^4	10^{-1}	2.2×10^3
Rigidity (MPa)	2×104	$10^1 - 10^2$	0
Yield stress (MPa)	$\sim 2 \times 10^2$	$10^{-3} - 10^{-1}$	0
Poisson's ratio	0.1 – 0.25	0.2 – 0.45	0.5
Viscosity (Pas)	$\sim 10^{19}$	$\sim 10^4$	10^{-4}

Table 18.2 Simplified material properties of rock, soil and water (liquid)

manifest in directional variation in seismic wave velocities, but discussion of this is beyond the scope of this study. We will return to anisotropy of rock mass strength in a later section.

18.8 Poroelasticity

Poroelasticity is an attempt to describe the deformation of a solid material with connected voids (pores) that are saturated in fluid, and is a useful description for many soils or rocks (e.g. Biot, 1941; Wang, 2000).

Consider a rock under an isotropic confining pressure σ_C, with pores that are subject to a fluid pressure P. The volumetric strain e will be affected by both pressures σ_C and P. We can conceptualise the material as comprising a solid 'framework' and a series of pores, shown schematically in **Figure 18.6(a)**. Based on the law of superposition, this stress system can be considered as the addition of (a) a confining stress (σ_C -P) acting on the outer boundary, with no pore pressure (**Figure 18.6(b)**), and (b) the pore pressure P acting on all boundaries (**Figure 18.6(c)**).

The total volumetric strain e_A is simply:

$$e_A = e_B + e_C \tag{18.8}$$

but:

$$e_B = 1/K\ [\sigma_C - P] \text{ and } e_C = 1/K_G\ [P] \tag{18.9}$$

where K and K_G are the bulk modulii of the rock and mineral grains, respectively.

Combining equations (18.8) and (18.9) and rearranging gives:

$$e_A = 1/K\ [\sigma_C - \alpha\ \Delta P]. \tag{18.10}$$

Thus, deformation is produced by an effective stress:

$$\sigma' = K\ e_A = \sigma_C - \alpha\ P \tag{18.11}$$

where $\alpha = (1 - K/K_G)$ is a dimensionless constant, usually referred to as the Biot constant. Note that equation (18.11) is identical to (18.4b), and hence Terzaghi's effective stress principle, for the case $\alpha = 1$.

For unconsolidated materials, where $K << K_G$, the Biot constant is $\alpha \approx 1$, as was originally proposed for soils (Terzaghi, 1943). For unfractured, crystalline rock the grain framework

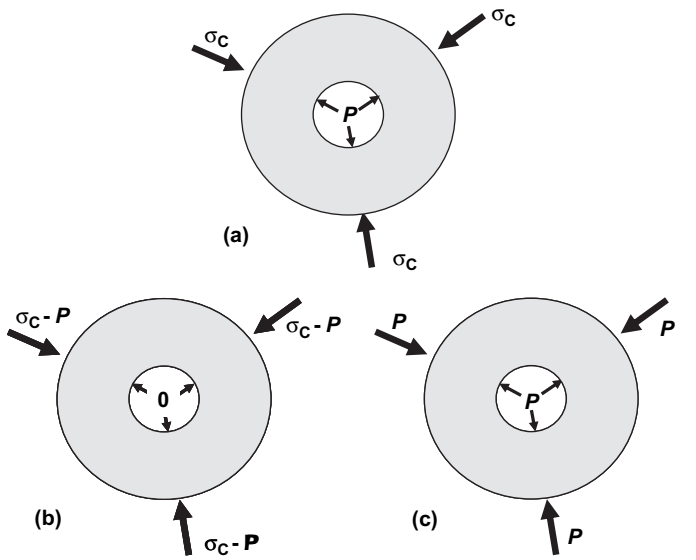

Figure 18.6 Decomposition of confining stress (σ_C) and pore pressure (P) – for explanation see text

may be stiffened by cement and/or interlocking grains, thus $K \rightarrow K_G$ and $\alpha \rightarrow 0$. Partially cemented sediments and fractured rock would be expected to have $0 < \alpha < 1$. For example, the bulk modulus for quartz is ~38 GPa, but that of sandstones is around 5–10 GPa; therefore we would expect $\alpha = 0.75$–0.9.

18.9 Failure and rock strength

In simple terms, we can recognise two broad types of failure in rocks:

(a) Brittle failure is where the rock undergoes some sort of fracture, usually accompanied by a volume increase (as cracks develop) and preceded by an essentially elastic behaviour of the rock mass.

(b) Ductile failure is where the rock undergoes some form of plastic yielding, usually accompanied by a volume decrease (collapse of pore structure) and preceded by some form of elastic compression or compaction.

Traditionally rock mechanics has focused on the brittle type of failure and soil mechanics on ductile yielding, but in reality both types of failure are seen in both rocks and soils.

The strength of a rock can be considered as the stress at which some sort of failure occurs. In rocks, strength is a complex concept and will depend not only on the properties of the rock components (grains, cement, voids and discontinuities) and their interactions, but on the type of failure and the conditions under which it occurs. Thus any specification of rock strength must include a careful description of the test conditions, or have been obtained under standard (i.e. pre-specified) conditions.

A simple view of rock failure is represented in **Figure 18.7**, which incorporates three widely recognised types of failure criteria.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

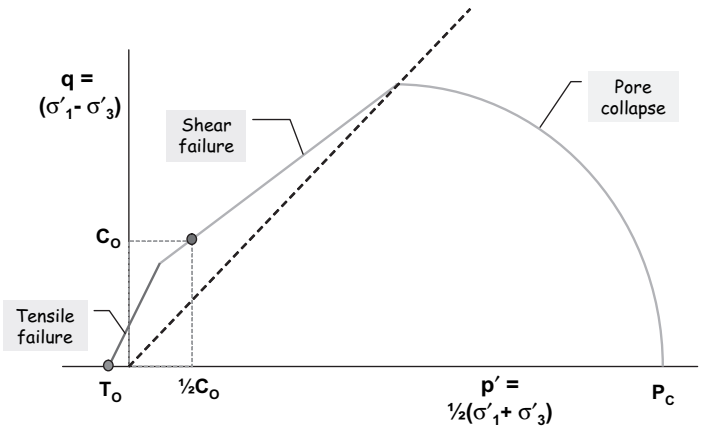

Figure 18.7 Plot of differential stress (q) against mean effective stress (p′) showing the three main types of failure mechanism T_O – tensile strength, C_O – uniaxial compressional stress (UCS), P_C – preconsolidation pressure

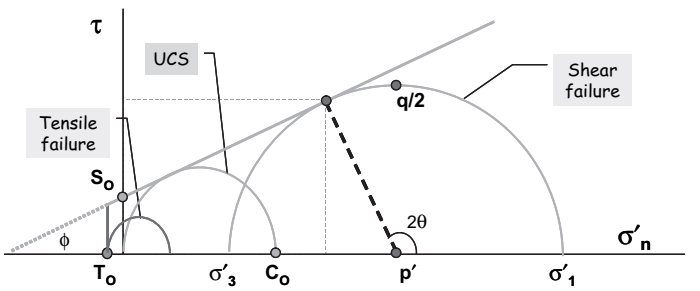

Figure 18.8 Mohr diagram (plot of shear stress, τ, against normal effective stress, σ'_n) showing conditions for tensile and shear failure T_O – tensile strength, C_O – uniaxial compressional stress (UCS), S_O – cohesion, φ – angle of friction, p' mean effective stress, $q/2$ – maximum shear stress = ½ (differential stress)

Tensile failure occurs when one of the principal effective stresses is negative (tensile) and cracks form normal to the minimum principal stress (σ_3), the magnitude of which is the tensile strength (T_O) i.e.

$$T_O = -\sigma_3. \tag{18.12}$$

The concept is simple, but direct tensile testing is difficult to achieve and interpret, and most tensile strengths are measured indirectly, e.g. from a Brazilian test. For most rocks tensile strengths are low, generally 0–30 MPa.

Following the work of Griffith (1921), we now appreciate that materials fail in tension due to the growth of micro-cracks. For a uniaxial remote tensile stress (σ_r), failure will occur when the stress concentration at the crack tip attains a critical value (K_C – the critical stress intensity factor or fracture toughness).

$$K = Y\,\sigma_r(\pi a)_{½} \tag{18.13}$$

where a is the half-length of the crack and Y is a factor (usually ~1) that depends on the geometry of the crack and sample.

Combining equations (18.12) and (18.13) and using $Y = 1$ gives:

$$T_O \approx K_C\,(\pi a)_{-½}. \tag{18.14}$$

Thus the tensile strength is a function of fracture toughness (a material property) and crack length (a textural property). The micro-cracks and other defects in an unfractured rock generally approximate to the size of the grains or pores (10^{-3} to 10^{-4} m) and K_C is in the range 0.3–3 MPa $m^{½}$. Thus, a tensile strength of 5–170 MPa would be expected for most rocks, as is observed.

Shear failure occurs on planes oblique to the principal stresses that, hence, experience a shear stress. A simple and widely used criterion was developed by Coulomb, which states that the shear stress (τ) must exceed a linear function of the normal stress (σ_n), such that:

$$\tau \geq S_O + \mu\,\sigma_n \tag{18.15}$$

where S_O is the cohesion – the shear stress required for failure in the absence of a normal stress, and μ is the coefficient of internal friction. This behaviour is analogous to frictional sliding (see section 18.11).

Coulomb failure is represented by a straight line on a plot of shear stress against normal stress – the Mohr diagram (**Figure 18.8**). Failure will occur on planes where 2θ is normal to the failure envelope, i.e. $2\theta = 90 + \varphi$, where φ is the angle of friction and $\mu = \tan(\varphi)$. For most rocks $\varphi = 20°–50°$, hence $\theta = 55°–70°$, with shear fractures forming at 20°–35° to the maximum compressive stress (σ_1) – a commonly observed orientation in tests and nature.

When triaxial test data are plotted on either the Mohr diagram or on a plot of σ_1 against σ_3 they tend to show a nonlinear relationship. Hoek (1968) originally proposed an empirical failure criterion for rocks, which was modified by Hoek and Brown (1980) to:

$$\sigma_1 = \sigma_3 + [m\,C_O\,\sigma_1 + s\,C_O^2]^{½} \tag{18.16}$$

where C_O is the uniaxial compressive strength, and the parameters m and s are chosen to best fit the data. For more discussion of this criterion see Chapter 49 *Sampling and laboratory testing*.

Tensile and shear failure both involve the development of cracks and are generally accompanied by small volume increases (dilatency). At high confining pressures, many porous rocks show a form of plastic yielding associated with localised **pore collapse** and compaction. This behaviour is typical of soils (Chapter 17 *Strength and deformation behaviour of soils*). This is shown schematically in **Figure 18.7** by the addition of an 'end cap' which meets the p′ axis at a pressure equivalent to the pre-consolidation pressure in soils. Stress paths, such as that produced by hydrostatic compression (q = 0), that lead to failure by pore collapse have a lower ratio of q/p than that for

shear failure. Such deformation is best analysed using the techniques of critical state soil mechanics (see Chapter 17 *Strength and deformation behaviour of soils*).

18.10 Strength testing

The field and laboratory testing of rock samples is described in detail elsewhere (Chapters 47 *Field geotechnical testing* and 49 *Sampling and laboratory testing*). Tests are usually performed on rock cylinders of standard shape and size, and some are briefly introduced below.

- **Uniaxial (unconfined) compressive test –** A simple and widely used test in which a cylinder or cube of rock is compressed between platens with no confining stress. The stress producing failure is the unconfined compressive strength (UCS).
- **Brazilian test** – A cylinder of rock is loaded between two platens transverse to its axis. This test is used to determine the tensile strength (T).
- **'Triaxial' test** – Axial compression (σ_1) of a cylinder under a radial confining stress ($\sigma_2 = \sigma_3$) – geometry similar to UCS. This test is usually run at several confining stresses and the failure envelope constructed, usually by plotting on a Mohr diagram (as in **Figure 18.8**).
- **Hydrostatic compression test** – This is usually carried out in a triaxial rig and involves increasing the confining pressure, in the absence of an axial load, until there is a volumetric collapse of the pore space. This is similar to the pre-consolidation pressure in soil mechanics and is used to define the plastic yield surface (**Figure 18.7**).
- **Shear tests** – The direct shear test involves a simple shear loading of a rectangular prismatic sample in a shear box. It is widely used to measure the shear strength (S_S) of soils, but is not suitable for anything but the weakest of rocks. A **torsional ring-shear test** has been developed that involves the twisting of a hollow disk between rigid end-disks to impart a shear on the specimen, which can be applied to a wider range of rock strengths.
- **Point load test** – This is a widely used test involving transverse loading of a cylinder of rock between two conical 'points' of standard shape (60º conical angle and tip radius of 5 mm). It can be performed with portable apparatus and applied to borehole core and irregular rock samples.

Other, field-based methods of measuring rock strength have been developed, which usually rely on an empirical calibration of some strength measure (usually UCS) to some physical response measured in the apparatus. A good example of this approach is the widely used **Schmidt hammer**, which measures the rebound of a spring-loaded rod propelled against a rock surface to estimate UCS. A **scratch test** determines the normal and tangential forces required to attain a constant depth of scratch on a rock surface, which can be related empirically to UCS.

A scheme for characterising rock strength based on simple field classification is outlined in **Table 18.3**. Essentially this is a subjective scheme based on the response of the rock to a series of simple physical tests using one's hand or a hammer. The scheme conforms broadly with the Working Party Report (Geological Society of London 1977) and found in Clayton *et al*. (1995) and Waltham (2009).

In terms of using these tests to describe rock behaviour it is important to remember that they are usually carried out on small pieces of the rock mass, typically at the cm-scale. Such tests may be useful in the characterisation of pieces of aggregate and building stone, but do not directly characterise the resultant structures (concrete, wall or foundation). Nor do the tests relate directly to the behaviour of the rock mass as a whole in groundworks, slopes, tunnels, etc. The following considerations are important in utilising laboratory estimates of rock strength.

- **Sampling –** Is the small specimen used in a test representative? All rocks are heterogeneous, usually at a wide range of scales – does the sampling capture this heterogeneity? This is particularly important in evaluating many sedimentary rock units that are made up of layers of different rock types and textures, with samples of a suitable size often being much easier to obtain from the thicker and stronger layers. These effects may be less of a problem in igneous and metamorphic rocks, although the fabrics in the latter produce anisotropy, which requires careful treatment (see section 18.16).

Description	UCS (MPa)	φ	Cohesion (MPa)	Field test	Rock type(s)
Very strong rock	300	50	20	repeated hammering to break	most igneous rocks
Strong rock	100	45	9	breaks with hammer	greywacke, quartzite, gneiss
Average rock	30	40	3.3	dented by hammer	sandstone, limestone
Moderately weak rock	10	35	1.35	cannot be broken by hand	shale, claystone
Weak rock	3	32	0.46	crumbles under hammer blows	soft chalk
Very stiff soil / Very weak rock	1	30	0.17	easily broken by hand	sand
Stiff soil	0.3	28	0.054	indented by finger nail	marl
Firm soil	0.1	25	0.020	moulded by fingers	clay
Soft soil	0.03	22	0.007	easily moulded by fingers	clay

Table 18.3 Field estimation of rock strength (UCS, internal friction angle for intact rock (φ) and cohesion)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- ***In situ* conditions** are difficult to replicate in a laboratory test for a number of reasons. Changes in boundary stress, and fluid pressure and saturation occur during the extraction, transport and storage of samples that can lead to permanent physical and chemical damage, which cannot be reversed under test conditions. This is common in soils and poorly consolidated rocks, but is less important in most rocks.
- Virtually all routine tests are on intact rock and *do not measure the contribution of the rock fractures.*

18.11 Behaviour of discontinuities

Discontinuities are macroscopic surfaces that separate the rock mass into blocks or layers. They include fractures (or joints), movement surfaces (faults) and bedding planes or other surfaces. The discontinuities usually have markedly different physical properties from the rest of the rock matrix and may fail in tension or shear.

Experiments of sliding on planar surfaces cut in rock show a simple linear relationship between the shear stress (τ) and normal effective stress (σ_n') at low normal stresses (**Figure 18.9**), such that:

$$\tau = \mu_S \, \sigma_n' \tag{18.17}$$

where μ_S is the coefficient of sliding friction. Byerlee (1978) proposed an average of $\mu_S = 0.85$, but at higher normal effective stresses ($\sigma_n > 200$ MPa), he found:

$$\tau \approx 100 + 0.65 \, \sigma_n' \text{ (MPa)}. \tag{18.18}$$

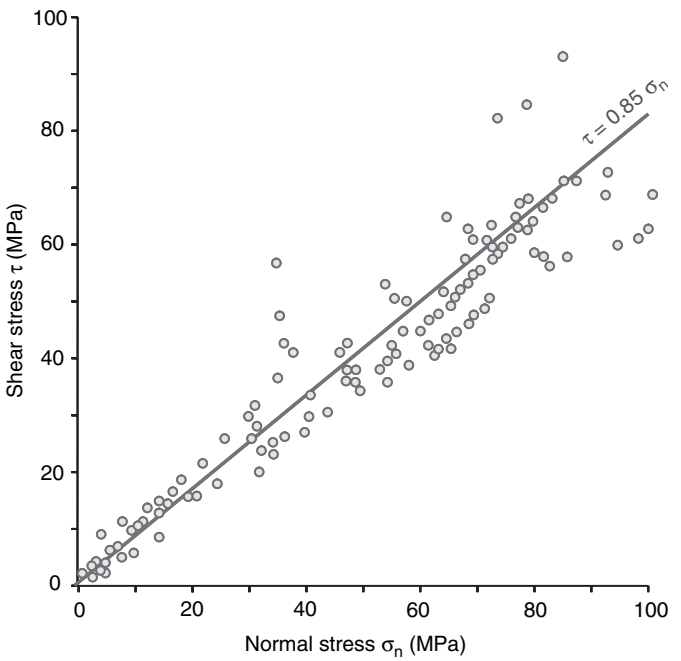

Figure 18.9 Data obtained by Byerlee (1978) for frictional sliding of planar rock surfaces at low normal stress

These results appear to be largely independent of rock type (at least for well consolidated and crystalline rocks). Based on Byerlee's results, it is widely assumed that cohesionless friction characterises many fractured rocks, with coefficients of sliding friction generally being between 0.65 and 0.85 – this has become known as 'Byerlee's Law'. The presence of weak material (e.g. clay fault gouge) in the fault plane can considerably reduce the coefficient of sliding friction. Water in the fractures mainly supports a pore pressure that controls the effective stress.

Since both shear and normal stress depend on the orientation of the surface in relation to the principal stress axes, failure by frictional sliding on rock fractures will be strongly controlled by the orientation of the fractures. If, however, sufficient variation in fracture orientation exists in a rock mass, then shear failure on optimally oriented fractures may be the dominant failure mechanism (e.g. Zhang and Sanderson, 2001).

18.12 Permeability

Rocks consist of solid phases (grains and cement) separated by voids. Flow of fluid between connected voids creates permeability in the porous medium. Flow is possible only through the connected void fraction, but for many rocks this is most of the void space. An exception is a rock such as pumice, which is a volcanic rock with isolated, unconnected gas bubbles; these make the rock light enough to float in water, but the rock is virtually impermeable – hence does not get 'waterlogged' and sink.

For most porous rocks, the flow is laminar (Reynolds number R_e<<1000) and the flow rate is linearly proportional to the pressure gradient. This was originally demonstrated by Henry Darcy in 1856, who showed that the flux (Q – m^3s^{-1}) of water in a pipe full of sand and subjected to a constant pressure drop (ΔP) or head (h) was proportional to its cross-sectional area (A) and inversely proportional to its length (L). Thus:

$$Q = -K_H \, A \, \Delta P / L. \tag{18.19}$$

The negative sign indicates that flow is from high to low pressure and the constant (K_H) is known as the hydraulic conductivity. K_H has SI units of ms^{-1} and depends on the nature of both the rock and the fluid.

$$K_H = k \, \rho \, g \, / \, \mu \tag{18.20}$$

where ρ and μ are the density and viscosity of the fluid, g is the gravitational acceleration and k the intrinsic permeability of the material. The intrinsic permeability has units m^2 with rocks typically having values in the range 10^{-18} to 10^{-10} m^2. The Darcy ($\approx 10^{-12}$ m^2) is often a more convenient unit as many rocks have permeabilities in the Darcy to milliDarcy range.

In civil engineering we are normally concerned only with groundwater, whose properties change relatively little. For water, at room temperature, $\rho g/\mu \approx 10^7$ in SI units; hence, $K_H \approx 10^7 \, k$. Again because of the low values K_H is often measured in

m/day or m/year. Another common practice in civil engineering is to refer to K_H as a 'coefficient of permeability' (or even just 'permeability'), a situation that can lead to confusion, and one that is both unnecessary and unhelpful.

A porous medium can be modelled as a system of pores, with porosity (n), connected by much finer tubes or throats of radius (r). Models can be used to relate the pore structure to the intrinsic permeability. For example, a simple model of a bundle of cylindrical tubes gives:

$$k \approx r^2 n / 8. \quad (18.21)$$

Thus for $r = 10^{-5}$ m and $n = 0.1$ this yields an intrinsic permeability of ~1 Darcy, equivalent to a hydraulic conductivity of a little less than 1 m/day.

The size and distribution of rock components (grains, voids, cement and fractures) have a major influence on the hydraulic conductivity of rocks.

18.13 Fracture-controlled permeability

Many rocks have very low porosities, such as most igneous and metamorphic rocks, and many cemented limestones. Others have very small grain size (and hence pore-throat radius), such as claystones, and this results in very low intrinsic permeability. Small specimens when tested in the laboratory confirm this. On the other hand when tested in the field, many of these rocks have permeability in the milliDarcy to Darcy range that can be attributed to flow in fractures. Thus it is the rock mass, rather than grain-scale, properties that control flow.

Fracture flow can be modelled by laminar flow between two parallel plates (**Figure 18.10(a)**) where:

$$Q = -(Wh^3/12) \cdot (\rho g/\mu)\, \Delta P/L. \quad (18.22)$$

This is the well-known 'cubic flow law'. Since the cross-sectional area A = Wh, it follows that the intrinsic permeability of the fracture is $k = h^2/12$; this would be the permeability of a layer assigned to model the fracture.

For a set of fractures oriented parallel to the pressure gradient (**Figure 18.10(b)**), with aperture (h) and density (d = number per unit length), then from equation (18.22), it is clear that the intrinsic permeability of the rock mass as a whole is proportional to the fracture density (d) and the cube of the fracture aperture (h) and is

$$k = d\, h^3 / 12 \quad (18.23)$$

since d has SI units m^{-1}, it follows that k has units m^2.

Fractures are an important component of the permeability of many rocks. A single fracture of aperture $h = 100$ microns (10^{-4} m) in a cubic metre, of rock (i.e. $d = 1$ m^{-1}) would provide a permeability of ~10^{-13} m^2 (or 100 milliDarcys), from equation (18.23). This is equivalent to the permeability of many sandstones used as oil or water reservoirs and would represent a hydraulic conductivity $K_H \approx 1$ m/day.

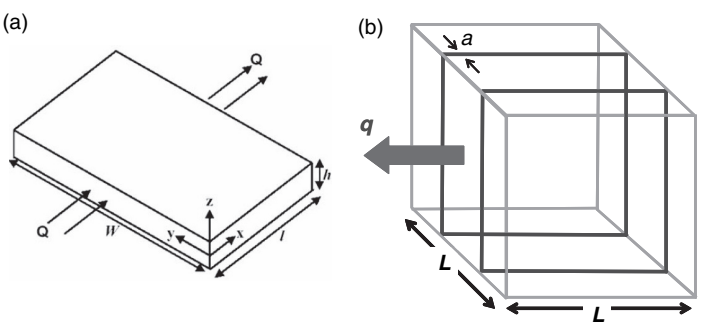

Figure 18.10 Flow of fluid through set of parallel fractures

18.14 Rock mass characterisation

Rock mass classification schemes have been around for over a century. They have generally been developed for assessment of behaviour in different engineering environments (tunneling, slope stability, etc.). Early schemes were simple and qualitative, e.g. Terzaghi (1946); more recent schemes use standardised measures and an algorithmic approach that can be implemented using spreadsheets.

Terzaghi's descriptions (simplified from his original paper) are:

- *Intact* rock contains no discontinuities and, hence, breaks across the rock matrix, either across grains or along grain boundaries.
- *Stratified* rock consists of layers separated by boundaries that may represent discontinuities across which the rock may have less resistance to separation and/or shear.
- *Moderately jointed* rock contains a network of joints that generally separate the rock into blocks, which interact along a large proportion of their surface and may be intimately interlocked.
- *Blocky and seamy* rock consists of grains and other rock fragments that are imperfectly interlocked and interact through small areas of contact.
- *Crushed* rock consists of small fragments and grains with no re-cementation that generally are surrounded by voids and interact at point contacts. The voids may be saturated with fluid.
- *Squeezing* rock flows into large voids (tunnel and other excavations) without perceptible volume increase. Such rocks typically have microscopic particles of mica or clay minerals with a low swelling capacity.
- *Swelling* rock flows into large voids on account of expansion. Such rocks contain clay minerals such as montmorillonite, with a high swelling capacity.

This scheme is entirely qualitative, but has the advantage of focusing attention on the main characteristic of the mass behaviour. It is rarely used in modern engineering design.

Rock quality designation (RQD) is a single parameter used widely to describe the degree of rock fracturing in borehole core and was developed by Deere *et al.* (1967). RQD is simply the percentage of intact core pieces longer than 0.1 m (4 inches) in the total length of core. The core should be at least

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

50 mm or 2 inches in diameter. RQD is dependent on the spacing and direction of fractures relative to the borehole axis, and should exclude any fractures induced by drilling or handling of the core.

RQD clearly depends on spacing of fractures – the inverse of the number of fractures per unit length (λ). For a negative exponential distribution of fracture, i.e. one obtained from random placement of fractures, Priest and Hudson (1976) showed that:

$$\text{RQD} = 100\, e^{-\lambda t}\,(1 + \lambda t) \qquad (18.22)$$

where t is the threshold length used to determine RQD. Using the conventional value t = 0.1 m, RQD varies between 5% and 95% in a range of 3 to 50 fractures/m and thus is insensitive to variations outside this range.

Rock mass rating (RMR) was designed for the estimation of rock strength (Bieniawski, 1973, 1989) and it uses six quantitative measures to classify a rock mass:

1. Uniaxial compressive strength of rock material
2. Rock quality designation (RQD)
3. Spacing of discontinuities
4. Condition of discontinuities
5. Groundwater conditions
6. Orientation of discontinuities.

Values of each of these measures are used to define 'ratings'. For measures 1–5 in the above list these ratings are numbers usually between 0 and 15–30, which sum to a total between 0 (good rock) and 100 (poor rock). The final factor (6) is expressed as a negative rating reflecting the favourable (low –ve value) or unfavourable (high –ve value) of the orientation of fractures to the structure (tunnel wall, slope, etc.). The magnitude of the –ve value also varies with the type of excavation, being greater for slopes than tunnels.

Factors 2 and 3 above are closely related, and together account for 40% of the RMR, indicating that the 'degree of fracturing' is a key factor in this rock mass classification. RMR also incorporates the condition of the fractures (alteration and water content as well as the strength of the rock matrix.

The classification system is generally applied to different regions within the rock mass, usually based on the distribution of different rock types and major discontinuities.

18.15 Rock tunnelling quality index, *Q*

This was developed by the Norwegian Geotechnical Institute for underground excavations (Barton *et al*., 1974) and is based on six quantitative measures:

1. RQD (as defined above)
2. Jn – the number of joint sets
3. Jr – the joint roughness number
4. Ja – the joint alteration number
5. Jw – the joint water reduction factor
6. SRF – a stress reduction factor.

These parameters are used to define three ratios:

1. RQD/Jn represents the structure of the rock mass. As RQD is assessed relative to a 10 cm length of intact core, the ratio is crudely related to the size of fracture blocks.
2. Jr/Ja is a ratio that accounts for the roughness and frictional characteristics of the fracture walls and/or filling materials.
3. Jw/SRF is a ratio that consists of two stress parameters and attempts to describe the *in situ* loading conditions within the rock mass. Jw is a measure of water pressure, which reduces the effective normal stress, hence the shear strength of fractures. SRF is a measure of the total stress or load applied to the rock mass, but also incorporates effects such as loosening due to excavation and squeezing loads in plastic materials.

For a simple introduction to the Q system see Waltham (2009, pp. 86–87).

Both the RMR and Q schemes use geological and engineering parameters to provide a quantitative assessment of rock mass quality. Many of the parameters used are similar, but the calculations and weightings differ. Both schemes consider the degree of fracturing and the conditions of the fractures (groundwater, roughness, alteration, etc.). A significant difference is that RMR uses compressive strength directly, whereas Q only considers this in relation to *in situ* stress (through the SRF parameter). The RMR also incorporates the orientation of the fractures relative to the structure. Some estimate of orientation can be incorporated into Q using guidelines presented by Barton *et al*. (1974).

Both the RMR and Q schemes are best implemented using standardised procedures, which can be easily and consistently executed using spreadsheets, and details of the precise implementation of the methods are not given here.

18.16 Anisotropy

As well as the presence of discontinuities, there are often marked differences in rock properties with orientation within the rock mass. The major causes of such anisotropy are related to depositional layering in sedimentary rocks and flow fabrics in metamorphic and some igneous rocks; generally the latter have the greatest homogeneity. The anisotropy of rocks can be of three fundamentally different types:

1. Intrinsic anisotropy at the grain-scale, caused primarily by the preferred orientation of mineral grains. The mineral lattice properties may be strongly isotropic, hence alignment produces a macroscopic anisotropy in the rock sample. Alternatively the mineral grains may have a shape fabric and, hence, even for isotropic minerals, the alignment of

grain boundaries produces anisotropy. Preferred orientation of micro-cracks can produce similar anisotropy.

2. Many rock masses consist of layers of different rock materials and these produce a composite material, whose properties are not simply the average of the two (or more) materials involved. An example of this sort would be thin clay layers in sandstones, where the lower stiffness, strength and permeability of the clay may dominate the physical behaviour of the material. In such cases there is usually a strong directional dependence on the material properties.
3. The presence of fractures (see section 18.11).

Recognition of one or other of these types of anisotropy necessitates careful design of procedures to characterise the material – sampling different layers, testing large representative samples, testing in different orientations, etc. Conversely, one must be very careful in applying test results to construction in such anisotropic and/or composite materials.

For example, anisotropy is a major consideration in many claystones (shales). Stiffness is generally greater for compression normal to layering. Strength (e.g. UCS) is generally greater for compression normal to layering, but for shear failure in fissile shales the strength may be less when loaded in directions oblique to layering.

19.9	Summary	219
19.10	References	220

This chapter describes the basic steps involved in calculating both the undrained and drained settlement of foundations on clay soils. It is demonstrated that the vertical stress changes beneath loaded areas, derived from simple elasticity, can be used with confidence for this purpose. In contrast, the changes in horizontal and shearing stresses are very sensitive to the assumed stress–strain behaviour and the theory of elasticity is much less reliable for calculating these. The four most common methods for calculating the final settlement are described. The somewhat surprising conclusion is reached that the simple one-dimensional method of analysis is even better than the more sophisticated methods, provided the appropriate soil stiffness parameters have been obtained. Settlements on granular soils are usually small and much of it takes place during construction. Numerous empirical methods have been proposed for predicting the settlement of foundations on granular materials, which lead to a wide range of estimates. A straightforward analysis of the measured settlements of over 200 records has led to a remarkably simple approach relating settlement to bearing pressure, breadth and average standard penetration test blow count, or cone resistance, over the depth of influence.

19.1 Introduction

This chapter describes in simple terms the most widely used methods of settlement analysis. These range from the simple classical one-dimensional (1D) method through to methods that make use of numerical methods of analysis. It is demonstrated that the simple traditional methods of analysis are usually adequate for practical purposes, provided that the appropriate soil stiffness parameters have been measured. Thus the main emphasis should be placed on high quality sampling and testing rather than sophisticated analysis. For granular soils, these procedures are not usually possible because of the difficulties of sampling them. Thus for granular soils a completely different approach is usually adopted.

19.2 Total, undrained and consolidation settlement

When a load is applied to a foundation and then kept constant, a time–settlement graph of the form shown in **Figure 19.1** is observed. Some settlement takes place almost immediately during loading. If the soil is saturated and of low permeability, there will be no time for drainage; this is termed the undrained (or immediate) settlement ρ_u.

As the excess pore water pressures (set up during loading) drain away under approximately constant load, consolidation (or time-dependent compression) of the soil takes place until all the excess pore water pressure has been dissipated. The settlement occurring during this process is termed the consolidation settlement and is termed ρ_c as shown in **Figure 19.1**.

For some soils, settlement continues after the excess pore water pressure has been dissipated due to creep of the soil skeleton. This is termed 'secondary' or 'creep' settlement and is termed ρ_s.

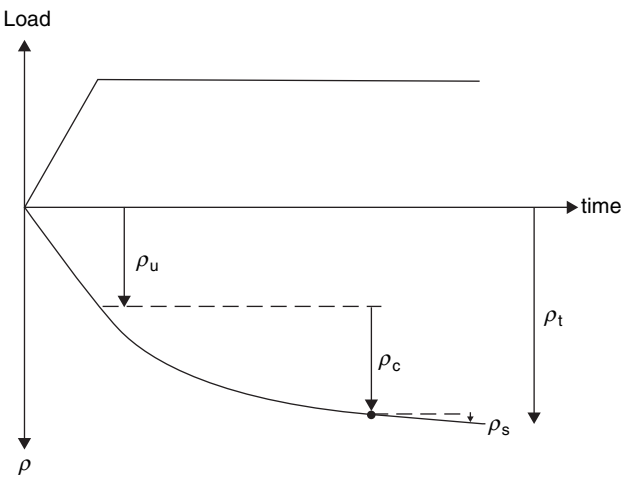

Figure 19.1 Idealised time–settlement curve for a foundation showing the undrained (ρ_u), consolidation (ρ_c) and secondary (ρ_s) components

Thus the total settlement ρ_t at a given time following completion of consolidation settlement is made up of three components:

$$\rho_t = \rho_u + \rho_c + \rho_s. \tag{19.1}$$

For rapidly draining or partly saturated soils, ρ_u and ρ_c may, for all practical purposes, be indistinguishable. Little attention will be devoted to ρ_s as it is not well understood and is frequently, though not invariably, small – see Simons and Menzies (2000) for a more detailed discussion on this topic.

Figure 19.2 shows schematically the ground surface movements that take place owing to (a) undrained settlement and (b)

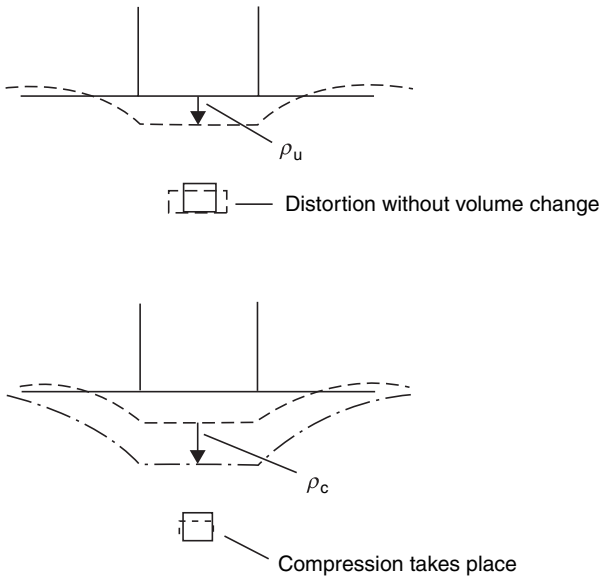

Figure 19.2 Schematic deformations of a soil element beneath a foundation during undrained loading and subsequent consolidation

subsequent consolidation settlement. The associated deformations of an element of soil beneath the centre line of the foundation are shown. It is evident that during undrained settlement only distortion without volume change occurs, whereas during consolidation, volume reduction of the soil skeleton takes place.

19.3 Stress changes beneath loaded areas

To carry out a settlement calculation it is necessary to derive the vertical strains ε_v at various depths beneath the foundation. The vertical compressions of the various layers of thickness Δz are then summed up over the depth of influence such that:

$$\rho = \sum \varepsilon_v \Delta z. \tag{19.2}$$

The calculation of ε_v at any depth requires knowledge of two things: (1) the stiffness or deformability of the soil at that depth, and (2) the stress changes at that depth induced by the loading of the foundation.

The theory of elasticity is invariably used for calculating the stress changes. Most textbooks outline methods of obtaining the vertical stress changes beneath simple loaded areas on an elastic, isotropic homogeneous half-space. For some particularly simple problems other stress changes, such as the principal stress changes or the horizontal stress changes, are given as well. All these results are obtained by integrating Boussinesq's famous solution for a point load on the surface and are often referred to as 'Boussinesq stresses'.

The chart given in **Figure 19.3** is the well-known one for deriving the vertical stress change at depth z beneath the corner of a rectangular uniformly loaded area. Superposition can be used to calculate the vertical stress change at any location

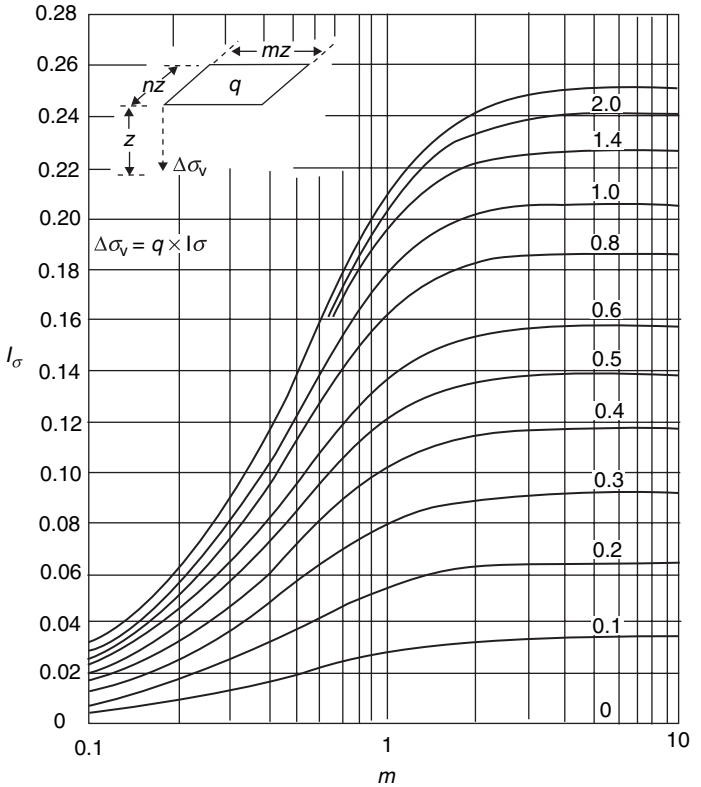

Figure 19.3 Vertical stress under the corner of a rectangular area carrying a uniform pressure

Reproduced from Simons and Menzies (2000); data originally taken from Fadum (1948)

beneath or outside the rectangle, as explained in most textbooks. The expressions for the vertical and horizontal stress changes beneath the centre of a uniformly loaded circular area of radius r are as follows:

$$\Delta\sigma_v = q\left\{1 - \left[\frac{1}{1+(r/z)^2}\right]^{3/2}\right\} \tag{19.3}$$

$$\Delta\sigma_h = \frac{q}{2}\left\{(1+2\nu) - \frac{2(1+\nu)}{[1+(r/z)^2]^{1/2}} + \frac{1}{[1+(r/z)^2]^{3/2}}\right\}, \tag{19.4}$$

where ν is Poisson's ratio. **Figure 19.4** is derived from equation (19.3) and shows the contours of increase in vertical stress Δq_v beneath a uniformly loaded circular area expressed as a proportion of the applied pressure at the surface Δq_s. The contour of $\Delta q_v/\Delta q_s = 0.1$ encloses what is termed the 'bulb of pressure' which is taken as an approximate but useful guide to the zone of influence beneath and around a loaded area. For a circular loaded area, the bulb of pressure is seen to extend to a depth of about twice its diameter. It is important to note that for an elastic homogeneous, isotropic half-space, the changes

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

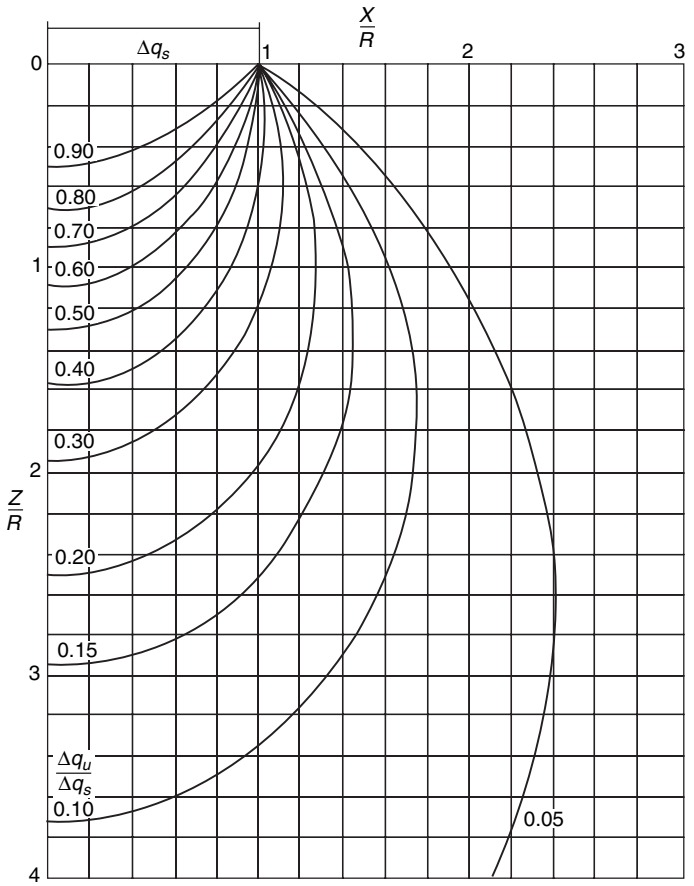

Figure 19.4 Vertical stress changes beneath a uniformly loaded circular area of radius *R*
Reproduced from Lamb and Whitman (1969) © John Wiley & Sons, Inc.

in vertical stress are always independent of Poisson's ratio υ. However for most problems, the other stresses are dependent on it. Poulos and Davis (1974) have assembled a very complete set of elastic solutions for a wide range of problems.

An obvious and important question that is not addressed in most textbooks is: how valid is it to use the Boussinesq theory to predict stress changes in soils beneath foundations? Most soils are patently not elastic, not isotropic and not homogeneous, so at face value the theoretical basis for calculating settlements looks pretty flimsy! As a result of recent analytical and numerical work using more 'soil-like' stress–strain properties, we are in a much better position to answer this question than we were a few years ago. In particular, the effects of nonlinearity, non-homogeneity and anisotropy have been studied.

19.3.1 Nonlinear stress–strain behaviour

A number of theoretical studies have been carried out to assess the influence of nonlinear behaviour on the stress changes beneath uniformly loaded areas. These studies have included elastic-perfectly plastic materials and continuously nonlinear stress–strain behaviour up to failure (see Burland *et al.*, 1977). All these studies have shown that the changes in vertical stress are remarkably similar to those given by the Boussinesq theory. However the other stresses, in particular the horizontal and shear stresses, depart significantly from Boussinesq. **Figure 19.5** shows the stress changes beneath the centre of a uniform circular surface load for an undrained nonlinear plastic material. It can be seen that the vertical stress changes are almost coincident with the Boussinesq values, but that the radial and deviator

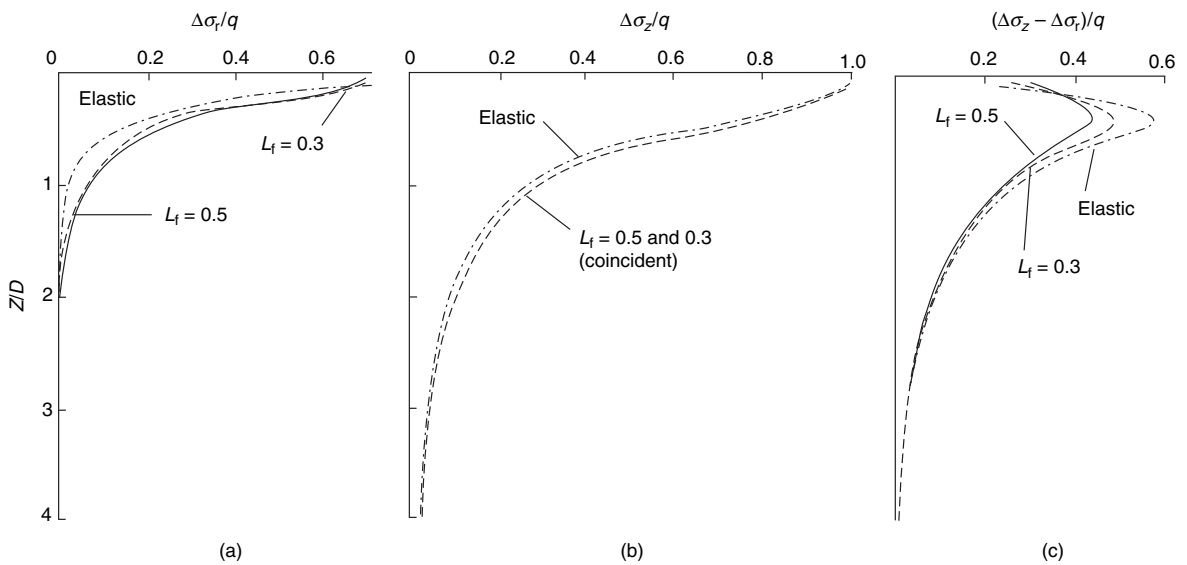

Figure 19.5 Distribution of stress increments beneath the centre of a flexible circular footing for various load factors *L*: (a) radial stress changes; (b) vertical stress changes; (c) deviator stress changes
Reproduced from Jardine *et al.* (1986)

stress changes differ significantly from the Boussinesq values and depend on the stress level.

19.3.2 Non-homogeneity

There is of course an infinite variety of types of non-homogeneity but it is instructive to examine some of the more common ones. One of the most common situations is where stiffness increases with depth, sometimes termed a Gibson soil. Since, for a given soil type, stiffness is approximately proportional to effective confining pressure, this is to be expected. **Figure 19.6** shows the distribution of vertical and horizontal stress changes beneath the centre of a uniform strip load on the surface of an elastic half-space, in which Young's modulus increases linearly with depth from zero at the surface (Gibson and Sills, 1971). The full lines give the Boussineq solution. Remarkably, for Poisson's ratio $\upsilon = 0.5$, the vertical and horizontal stress changes are identical to those given by Boussinesq. For $\upsilon < 0.5$ the vertical stress changes are only slightly larger than those given by Boussinesq, but the horizontal stress changes are much less – being very sensitive to the value of Poisson's ratio.

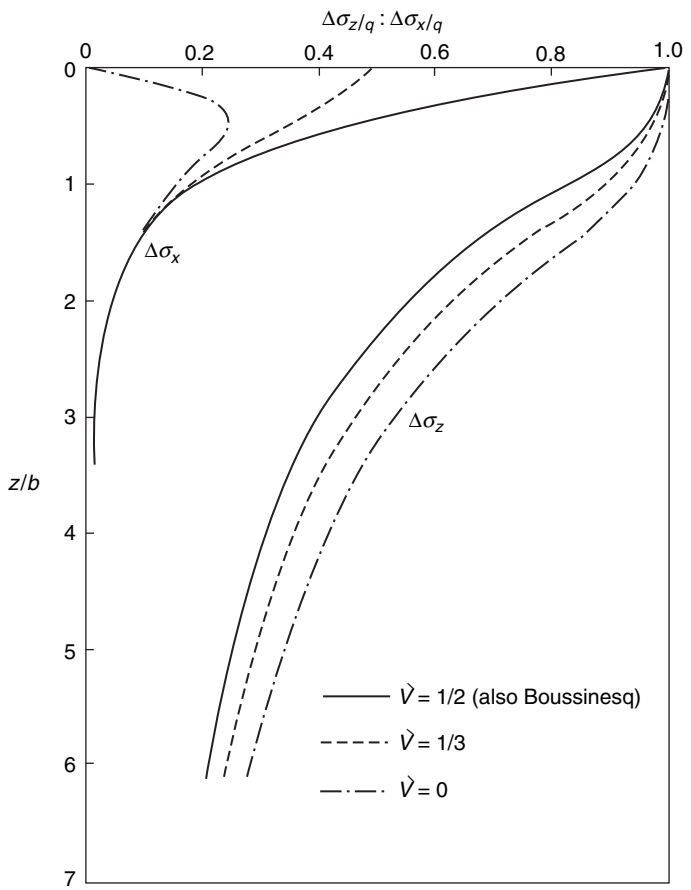

Figure 19.6 Stress changes beneath centre line of a uniform strip load on a Gibson half-space

Reproduced from Gibson and Sills (1971); all rights reserved

Another common form of non-homogeneity is that of a compressible layer of soil overlying rock. **Figure 19.7** shows the distribution of vertical stress change beneath the centre line of a uniform circular load resting on a compressible layer overlying a rigid layer. It can be seen that the vertical stress changes increase only slightly as the depth of the rigid layer decreases. It can be shown that the horizontal stress changes are very significantly affected by the depth of the rigid layer.

Unlike the previous two situations, the presence of a stiff layer overlying a soft layer has a significant effect on the vertical stress changes. **Figure 19.8** shows the vertical stress changes beneath the centre of a uniform circular load resting on a stiff layer overlying a more compressible layer. It can be seen that the presence of a stiff overlying layer significantly reduces the magnitudes of the vertical stress changes in comparison with the Boussinesq stresses. Thus the presence of a stiff overlying layer is very beneficial in reducing the stresses in an underlying softer material.

19.3.3 Anisotropy

In Chapter 14 *Soil as particulate materials* it was demonstrated that deposition under vertical gravity leads to preferred orientation of the particle arrangements, and this leads to inherent anisotropy of the soil skeleton. Hence anisotropy is a common feature of most soils. In Chapter 17 *Strength and deformation behaviour of soils* readers were introduced to the cross-anisotropic porous elastic model of soil in which the horizontal stiffness properties differ from the vertical ones. This model can be fully defined by the five parameters:

E'_v = effective Young's modulus in the vertical direction;

E'_h = effective Young's modulus in the horizontal direction;

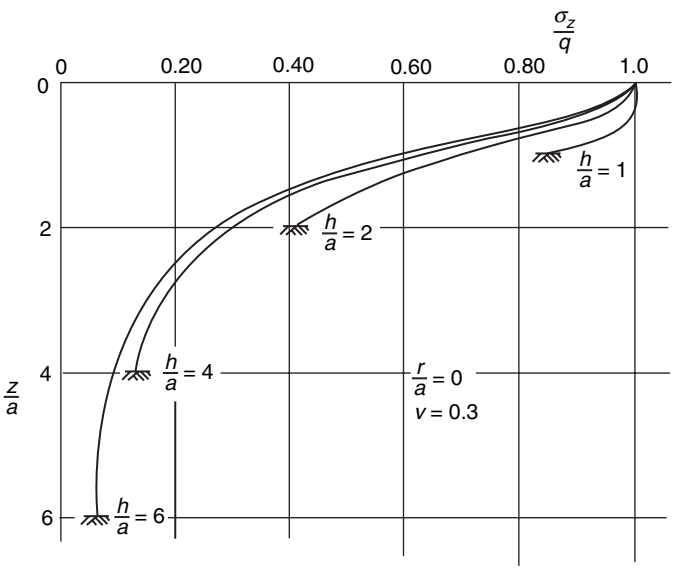

Figure 19.7 Vertical stress changes beneath the centre of a uniform circular load of radius *a* on a compressible layer of various thicknesses *h*

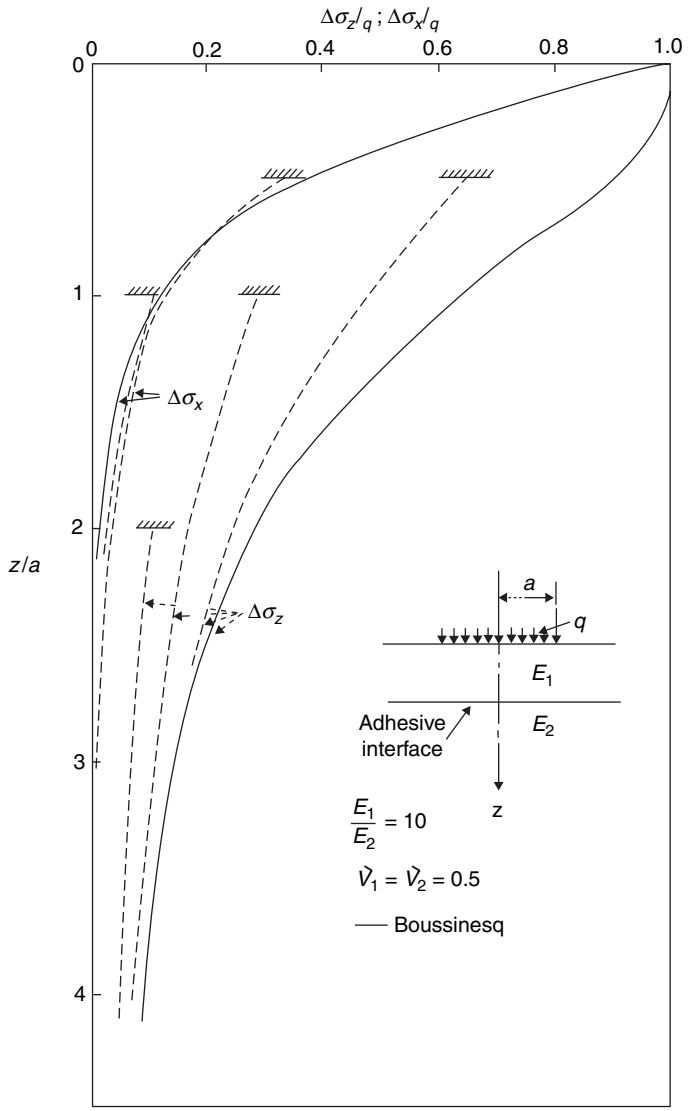

Figure 19.8 Influence of a stiff upper layer of various thicknesses on the vertical and horizontal stress changes beneath the centre of a uniformly loaded circular area
Reproduced from Burland *et al.* (1977)

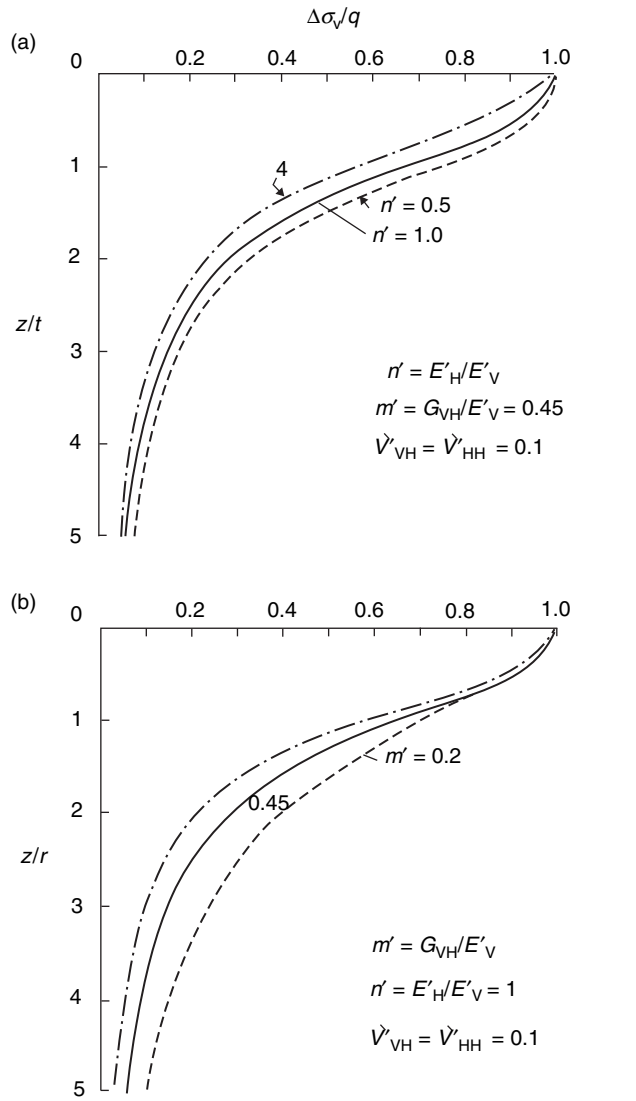

Figure 19.9 Influence of anisotropy on the vertical stress changes beneath the centre of a uniformly loaded circular area: (a) influence of change of E'_H; (b) influence of change of shear modulus G_{VH}

υ'_{vh} = effective Poisson's ratio for the effect of vertical stress change on horizontal strain;

υ'_{hh} = effective Poisson's ratio for the effect of horizontal stress change on orthogonal horizontal strain;

G'_{vh} = shear modulus in the vertical plane.

It is convenient to define the following ratios:

$$E'_h/E'_v = n' \text{ and } G'_{vh}/E'_v = m'.$$

Figure 19.9 shows the vertical stress changes beneath the centre of a uniform circular load on a porous elastic anisotropic soil for (a) varying n', with m, fixed at its equivalent isotropic value [= $0.5(1 + \upsilon'_{vh})$] and (b) varying m', with n, fixed at its isotropic value (=1). It can be seen from **Figure 19.9(a)** that the effect of varying n' has little effect on the vertical stress changes. However varying G'_{vh} (i.e. the value of m') has a much bigger effect.

19.3.4 Conclusions on stress changes

We can draw the following important conclusions from the examples given in this section:

- For many conditions which depart from the ideal of linear, isotropic, homogeneous elasticity, the Boussinesq theory gives very reasonable estimates of the changes in vertical stress beneath areas of known pressure distribution.

- Two exceptions to this are (1) for a stiff layer overlying a softer layer where large errors on the conservative side result from using Boussinesq; and (2) for anisotropic properties, whereas the vertical stress changes are relatively insensitive to the ratio $E'_h/E'_v = n'$ – they are much more sensitive to the ratio $G'_{vh}/E'_v = m'$. It is of interest to note that the static value of G'_{vh} is seldom measured in a routine manner because it is difficult to do so.
- In contrast to the vertical stress changes, the horizontal (and shear) stress changes are very sensitive to all the variables studied. Hence the Boussinesq equations are unlikely to give accurate estimates of these stress changes.

Although only a limited number of examples are given here, these conclusions are widely supported by numerous studies.

19.4 Summary of methods of settlement prediction for clay soils

This section gives a very brief résumé of the most commonly used methods of settlement prediction on soils that can be reasonably sampled and tested to give the deformation properties.

19.4.1 Conventional 1D method

This method was originally proposed by Terzaghi and was originally used for estimating the compression of a layer of clay situated at some depth. It later became used for thick layers of clay extending right to the surface. The procedure is as follows, referring to **Figure 19.10**:

(i) The compressible stratum is divided into a number of layers of thickness Δz (as shown at the bottom of **Figure 19.10**).

(ii) The initial vertical effective stress σ'_{vi} is calculated for the centre of each layer.

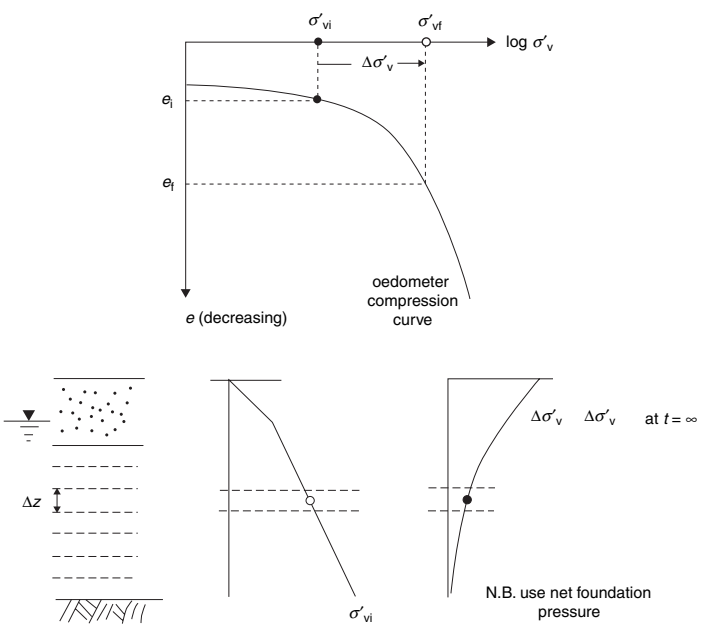

Figure 19.10 Classical one-dimensional method of settlement analysis

(iii) Using Boussinesq stresses, the increase in vertical stress $\Delta\sigma'_v$ is calculated for the centre of each layer. At the end of consolidation, when all excess pore water pressures have been dissipated, the stress increases will be effective stresses. Note that if the foundation is founded in an excavation, it is the *net* increase in vertical effective stress that gives rise to compression.

(iv) The vertical strain ε_v for each layer may be obtained directly from a plot of e versus σ'_v from one-dimensional (oedometer) compression tests (see top of **Figure 19.10**) such that:

$$\varepsilon_v = \frac{e_i - e_f}{1 + e_i} \qquad (= m_v \Delta\sigma'_v), \tag{19.5}$$

where the subscript 'i' refers to the initial value of e and the subscript 'f' refers to the final value of e. If quoted values of m_v are used, it is important to ensure that they have been measured over the appropriate stress range – see Chapter 17 *Strength and deformation behaviour of soils*. It should also be noted that in Equation (17.13) of that chapter, it was shown that m_v is related to the equivalent effective Young's modulus E' and Poisson's ratio υ' by the expression:

$$m_v = \{1 - \frac{2\upsilon'^2}{1 - \upsilon'}\}/E'. \tag{19.6}$$

(v) The compression of each layer = $\varepsilon_v \Delta z$ and, summing over the total thickness of the compressible stratum, the total 1D settlement is given by:

$$\rho_{1XD} = \sum \varepsilon_v \Delta z. \tag{19.7}$$

Note that Terzaghi assumed that ρ_{1D} is equal to the total settlement ρ_t. The accuracy of this assumption will be evaluated later in this chapter.

19.4.2 Skempton and Bjerrum method

In 1955, Skempton, Peck and MacDonald used the 1D method to calculate the total settlement of a number of buildings, but they recognised that the undrained settlement ρ_u could be a significant proportion of the total settlement ρ_t (see equation (19.1)). They used elastic displacement theory, described in section 19.5, to evaluate ρ_u. This led them to conclude that the consolidation settlement ρ_c is given by $\rho_c = \rho_{1XD} - \rho_u$. In the discussion of the above paper, various writers suggested that it was more logical to assume that $\rho_c = \rho_{1XD}$, so that

$$\rho_t = \rho_u + \rho_{1XD}. \tag{19.8}$$

With this background, Skempton and Bjerrum (1957) put forward their seminal method for calculating the consolidation settlement ρ_c. They argued that the consolidation settlement resulted from the dissipation of excess pore pressure Δu. The key assumption was made that consolidation takes place *one-dimensionally* so that the vertical consolidation strain ε_{vc} at a given depth is given by $\varepsilon_{vc} = \Delta u \,.\, m_v$ where Δu can be calculated

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

knowing the value of the pore pressure coefficient A (see equation (17.23) in Chapter 17 *Strength and deformation behaviour of soils*), $\Delta\sigma_v$ and $\Delta\sigma_h$. Hence the consolidation settlement ρ_c for the whole layer is obtained by summation:

$$\rho_c = \sum \Delta u . m_v \Delta z. \tag{19.9}$$

Skempton and Bjerrum defined a correction factor μ to be applied to ρ_{1XD} such that:

$$\rho_c = \mu . \rho_{1XD}.$$

Hence the total settlement is given by:

$$\rho_t = \rho_u + \mu\rho_{1XD}. \tag{19.10}$$

Simple elastic Boussinesq stresses were used to evaluate μ for a range of values of A and foundation geometries. The well-known Skempton and Bjerrum chart for values of μ is given in **Figure 19.11**.

It is important to note that the key assumption of the method is that consolidation takes place *one-dimensionally*. For soils which are approximately elastic in their response, this assumption can be significantly in error. Moreover, the values of μ are based on values of $\Delta\sigma_v$ and $\Delta\sigma_h$ obtained from isotropic, homogeneous, semi-infinite elastic theory. We have already seen that values of $\Delta\sigma_h$ obtained in this way are unreliable. Thus, although the method is widely used and taught, caution is needed in applying it.

19.4.3 Stress path method

Although attributed to Lambe (1964), the stress path method was suggested earlier by Skempton (1957) and developed by Davis and Poulos (1963). In essence, the method consists of the following:

(i) Take undisturbed samples from appropriate depths.

(ii) Set up each sample in the triaxial apparatus under the appropriate initial *in situ* effective stresses.

(iii) Without allowing drainage, apply the calculated values of $\Delta\sigma_v$ and $\Delta\sigma_h$. Measure the vertical strain and the excess pore pressure.

(iv) Then allow drainage to occur – if necessary, adjusting the applied stresses to the final calculated values. Measure the vertical strain and volume change.

(v) The measured strains for stages (iii) and (iv) are summed to obtain the undrained settlement and consolidation settlement.

The method appears to be logical but carries with it serious difficulties. The initial vertical and horizontal effective stresses must be known. A high degree of experimental skill

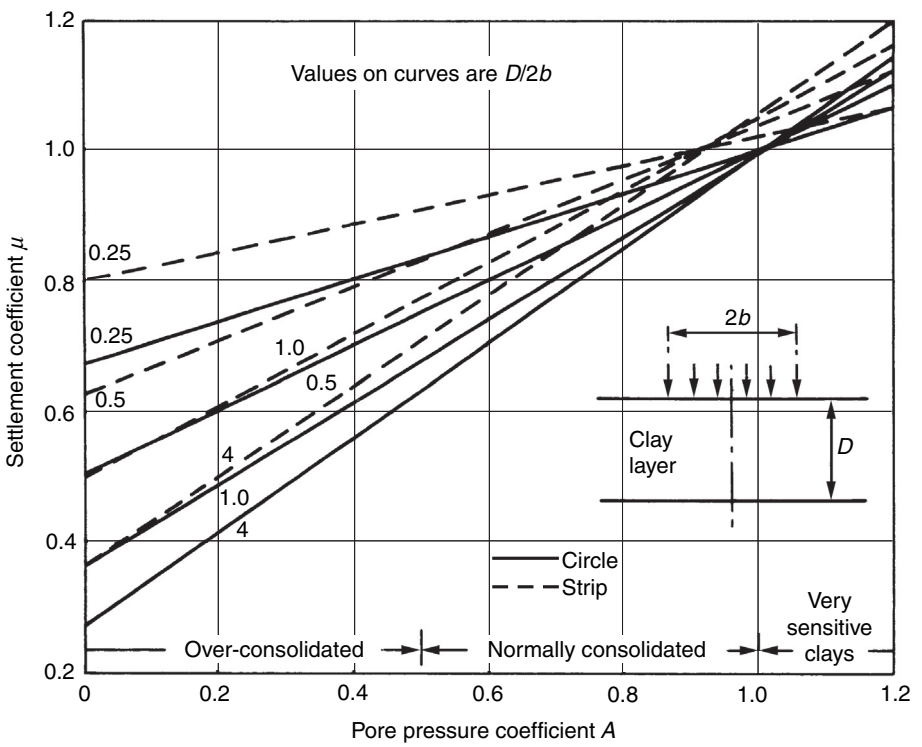

Figure 19.11 Skempton and Bjerrum's settlement coefficient μ for circular and strip foundations
Reproduced from Simons and Menzies (2000); data originally taken from Skempton and Bjerrum (1957)

is required. Isotropic, homogeneous elasticity is used to calculate the stress changes and uncertainties in the accuracy of $\Delta\sigma_h$ therefore exist. The testing is expensive and time-consuming, and a change in the foundation size or loading could render the whole testing program worthless.

A more realistic and flexible approach was suggested by Davis and Poulos (1963). Samples are subjected to appropriate stress levels and stress changes, and the associated equivalent elastic constants E_u, E', and υ' are deduced from the measured strains. The undrained and total settlements can then be obtained by calculating the corresponding equivalent elastic strains and summing them over the appropriate depth:

$$\rho = \sum \varepsilon_v . \Delta z = \sum \frac{1}{E}\{\Delta\sigma_v - \upsilon(\Delta\sigma_x + \Delta\sigma_y)\}.\Delta z. \qquad (19.11)$$

Alternatively, average values of E and υ can be used in conjunction with elastic displacement theory – see section 19.5.

19.4.4 Finite element method

In recent years, powerful numerical methods have become available which can be used for settlement prediction. Most finite element (FE) packages can handle non-homogeneous anisotropic elastic materials. Increasingly more can handle nonlinear stress–strain behaviour of varying complexity. It is perhaps a truism to say that the accuracy of the predictions depends on the quality of the input data. However, engineers are easily seduced by the apparent power and versatility of FE packages and forget, or are not aware of, the many idealisations and assumptions that are built into them.

It is important to examine some of the limitations of routine testing, however well conducted, in providing input data for a numerical analysis:

(i) For triaxial and oedometer tests, only axi-symmetric stress conditions can be applied i.e. σ_a and σ_r.

(ii) The principal stresses and stress changes remain vertical and horizontal.

(iii) Usually only the vertical stiffness E'_v and Poisson's ratio υ'_{vh} are determined.

(iv) Any nonlinear behaviour that is measured is strictly for the highly restricted stress conditions referred to in (ii) above.

(v) The *in situ* stresses and, in particular, stress history of the natural soil, is usually open to considerable speculation.

The above restrictions in the test data should be contrasted with the real situation in the ground:

(i) In real problems, axi-symmetric stress conditions almost never occur.

(ii) Rotations of principal stress directions take place during loading.

(iii) The stiffness both in direct loading and shear is almost certainly anisotropic and related in a complex way to the rotating stresses.

(iv) The previous stress history, and in particular whether the soil is in a loading or unloading cycle, profoundly affects the stress–strain behaviour.

In view of the above, any experimental data used in an FE analysis usually entails profound implicit idealisations.

19.4.5 Comments on methods of settlement prediction

It is evident from the methods presented above that the methods of settlement prediction have progressively become more sophisticated, moving from the classical 1D method through to numerical methods. This has been accompanied by the need for increasingly more soil parameters and more advanced testing. From a purely practical point of view, the engineer is entitled to ask whether such sophistication is necessary and whether greater accuracy is in fact achieved. This question is addressed in section 19.6 by comparing the various approximate methods with known rigorous solutions. First it is necessary to discuss briefly elastic displacement theory.

19.5 Elastic displacement theory

At the beginning of section 19.2, it was pointed out that a settlement calculation involves deriving the vertical strains ε_v at various depths beneath the foundation. For an ideal isotropic elastic material the vertical strain at any depth below a loaded area is given by

$$\varepsilon_v = \frac{1}{E}\left\{\Delta\sigma_v - \upsilon(\Delta\sigma_x + \Delta\sigma_y)\right\}. \qquad (19.12)$$

Note that the two horizontal stress changes and Poisson's ratio are involved.

Elastic displacement theory is based on integrating the vertical strains from $z = 0$ to infinity, such that

$$\rho = \int_0^\infty \varepsilon_v dz\,. \qquad (19.13)$$

Solutions for a wide range of problems are usually expressed in the form

$$\rho = \left\{\frac{qB}{E}(1-\upsilon^2)\right\} I_\rho\,, \qquad (19.14)$$

where:

q = average foundation pressure;

B = a characteristic dimension of the foundation (e.g. breadth);

$I\rho$ = a factor to take account of geometry, depth of founding, depth of rigid layer, etc.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Examples of some well known solutions are:

Settlement of the centre of a uniform circular load of diameter D:

$$\rho = \frac{qD}{E}(1-\upsilon^2)\,. \tag{19.15}$$

Settlement of the centre of a uniform circular load at great depth:

$$\rho = \frac{qD}{E}(1-\upsilon^2)\frac{1}{2}\,. \tag{19.16}$$

Settlement of a rigid circular load:

$$\rho = \frac{qD}{E}(1-\upsilon^2)\frac{\pi}{4}\,. \tag{19.17}$$

It is of interest to note that the settlement of a rigid circular load given by equation (19.17) is only very slightly less than the average settlement of a uniformly loaded (flexible) circular area (equation (19.15)). Thus, while stiffening a foundation significantly reduces the differential settlements, it has little effect on the average total settlements.

Numerous charts are available for calculating the settlement of various types of loaded area. For example, **Figure 19.12** is the well-known settlement chart for estimating the average undrained settlement of uniformly loaded rectangular areas at depth D with a rigid layer at a depth H beneath foundation level (Christian and Carrier, 1978). These charts are only for Poisson's ratio = 0.5 and are strictly only relevant for estimating undrained settlement.

In section 19.3 we saw that simple elastic theory gives a good estimate of the vertical stress changes for a range of soil-like properties and can therefore be used with considerable confidence. The same cannot generally be said of elastic displacement theory, which must be used with considerable caution. In particular, the calculation of the strains in equation (19.12)

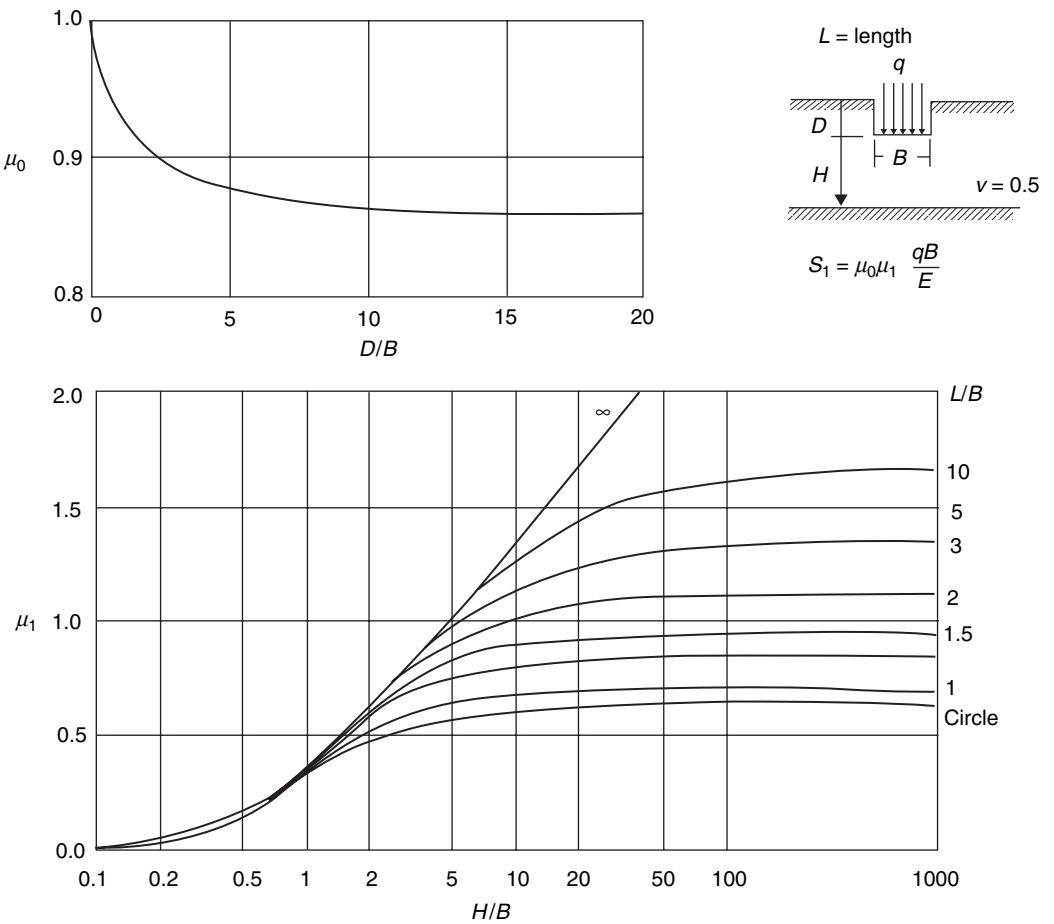

Figure 19.12 Average undrained settlement of uniformly loaded rectangular areas with a foundation depth D and a rigid layer at depth H beneath founding level

Reproduced from Christian and Carrier (1978) © Canadian Science Publishing or its licensors

involves horizontal stress changes which we have shown are very sensitive to many factors. Moreover the integration of the strains in equation (19.13) involves the assumption that the stiffness properties are constant with depth (homogeneity).

When using solutions based on elastic displacement theory, it is no easy matter to make allowance for the influence of such factors as anisotropy, non-homogeneity and nonlinearity of stress–strain behaviour. These influence the stress changes (in particular the horizontal ones) as well as the stiffness. However, when used with discrimination, elastic displacement theory can be very useful, particularly for estimating undrained settlements.

19.6 Theoretical accuracy of settlement predictions

In the past, the difficulty of assessing the accuracy of methods of settlement prediction was that the methods of testing were intimately linked with the analysis. This has meant that it has not been possible to isolate inaccuracies in sampling and testing from the limitations of the analysis.

With the advent of the FE method, it has been possible to obtain rigorous solutions using realistic soil-like constitutive relationships, and compare them with predictions based on the various current approximate methods of settlement prediction. The startling conclusion is reached that there is little to choose between the methods and that in most cases, the simple 1D method gives the best predictions of total settlement ρ_t. Hence all the effort should be devoted to measuring as accurately as possible the straightforward stiffness parameters such as m_v, E'_v and υ'. It is demonstrated that the vertical shear modulus G_{vh} is also a key parameter, but is very seldom determined from static tests.

The above important conclusions are briefly illustrated for a few cases in the following sections. The approach is to compare the rigorous solution with the predictions of the various methods.

19.6.1 Accuracy of the one-dimensional method for homogeneous isotropic elastic material

As explained in Chapter 17 *Strength and deformation behaviour of soils*, a homogeneous porous elastic material is completely defined by the two parameters E' and υ'. It was further shown in equation (17.13) of that chapter, and repeated as equation (19.6) above, that:

$$m_v = \{1 - \frac{2\upsilon'^2}{1-\upsilon'}\}/E' \quad .$$

For m_v constant with depth, equation (19.7) for the 1D settlement is given by:

$$\rho_{1XD} = m_v \int \Delta\sigma'_v dz \qquad (19.18)$$

where $\Delta\sigma'_v$ is obtained from Boussinesq stresses. For a uniform circular load of radius r, the values of $\Delta\sigma'_v$ are given by equation (19.3). It turns out that $\int\Delta\sigma'_v dz$ for this case is particularly simple and is equal to $2qr$. Hence equation (19.18) for the 1D settlement becomes:

$$\rho_{1XD} = 2.q.r.m_v = \frac{q.D}{E'}\left\{1 - \frac{2\upsilon'^2}{1-\upsilon'}\right\}. \qquad (19.19)$$

This is the analytical solution for the 1D settlement of the centre of a uniformly loaded circular load on an isotropic semi-infinite porous elastic material. But we know that the exact total settlement for this problem is given by equation (19.15), so:

$$\rho_{t(exact)} = \frac{qD}{E'}(1-\upsilon'^2) \quad . \qquad (19.20)$$

Hence the ratio of the one-dimensional settlement to the exact settlement, derived from equation (19.16) is:

$$\frac{\rho_{1XD}}{\rho_{t(exact)}} = \frac{1-2\upsilon'}{(1-\upsilon')^2}. \qquad (19.21)$$

Figure 19.13 shows a graph of equation (19.16). It can be seen that when $\upsilon' = 0$, the one-dimensional settlement is exactly equal to the total settlement. As υ' increases, the ratio $\rho_{1XD}/\rho_{t(exact)}$ decreases slowly at first, and then more rapidly until it equals zero when $\upsilon' = 0.5$. Most soils and weak rocks have values of $\upsilon' < 0.25$ over the range of working stress changes. It can therefore be concluded that ρ_{1XD} will usually be within 10% of the total settlement on the low side. If the compressible layer is of limited depth, the 1D settlement will be even closer to the exact total settlement.

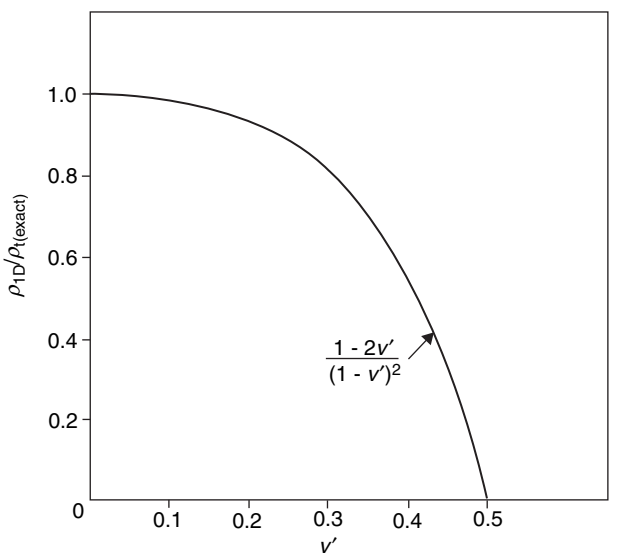

Figure 19.13 The influence of effective Poisson's ratio on the accuracy of the 1D method for a uniform circular load on an isotropic homogeneous elastic half-space

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

19.6.2 Accuracy of the one-dimensional method for homogeneous cross-anisotropic elastic material

In section 19.3.3, the five elastic constants that define a cross-anisotropic material were listed. It was pointed out in Chapter 17 *Strength and deformation behaviour of soils* that such a material is generally more representative of a stiff soil or a soft sedimentary rock than an isotropic elastic material. Using the example of a uniform circular load, we now compare the settlements predicted by the four methods described in section 19.4 with the solutions obtained by a rigorous FE analysis (for practical purposes we can assume that these solutions are exact).

It must be remembered that the engineer does not necessarily know that the material is anisotropic. It is assumed that the appropriate routine tests are carried out on vertical samples to measure parameters such as m_v, E', υ', E_u and A (the pore pressure parameter). Moreover, as is normal practice, Boussinesq stress changes are used in carrying out the settlement predictions.

Figure 19.14 shows graphs of $\rho_{(predicted)}/\rho_{t(exact)}$ versus the ratio $E'_h/E'_V = n'$ for the four methods of settlement prediction described in section 19.4. For the purposes of this analysis, the value of $G_{vh}/E'_V = 0.45$ was adopted (the isotropic value) and with $\upsilon'_{vh} = \upsilon'_{hh} = 0.1$. It is found that the solutions are insensitive to small changes in υ'.

The results for the 1D method are shown by the full line in **Figure 19.14**. It can be seen that for $n' < 1.2$, the exact total settlement is slightly underpredicted. As n' increases to 4, the method tends to overpredict slightly, reaching a maximum of about 6%. None of the other three methods give better predictions of the total settlement than the 1D method, despite its simplicity. The greatest discrepancy is given by the Skempton and Bjerrum method which for $n' > 4$ overpredicts the total settlement by 22%. Even the FE method, which makes use of the measured values of E' and υ', overpredicts the total settlement by as much as 20% for $n' > 4$.

19.6.3 Accuracy of the one-dimensional method for cross-anisotropic elastic material – stiffness increasing with depth

As explained in section 19.3.2, increasing stiffness with depth is one of the most common situations in soil mechanics – far more common than uniform stiffness with depth. If cross-anisotropy is also included, we are dealing with a very realistic and reasonably general condition that can be used for evaluating the accuracy of various prediction methods. Using methods identical to those described in section 19.6.2, the four common methods of settlement prediction are compared with exact values obtained using FE analysis. It is found that the one-dimensional method always gives predictions of the total settlement which are within 10% of the exact solution – significantly better than the other methods.

19.6.4 The influence of vertical shear modulus G_{VH}

For all of the above comparisons a value of $G_{VH}/E'_V = 0.45$ was used. This corresponds to the equivalent isotropic value given by $G = E'/2(1 + \nu')$ with $\upsilon' = 0.1$. The vertical shear modulus G_{VH} is an independent variable which is seldom measured other than by dynamic methods. In principle, there seems to be no reason why the value of G_{VH}/E'_V should not vary over quite wide limits. Rigorous FE analyses have been carried out for a uniform circular load varying the value of G_{VH}/E'_V and in **Figure 19.15** the results are compared with the 1D and the Skempton and Bjerrum

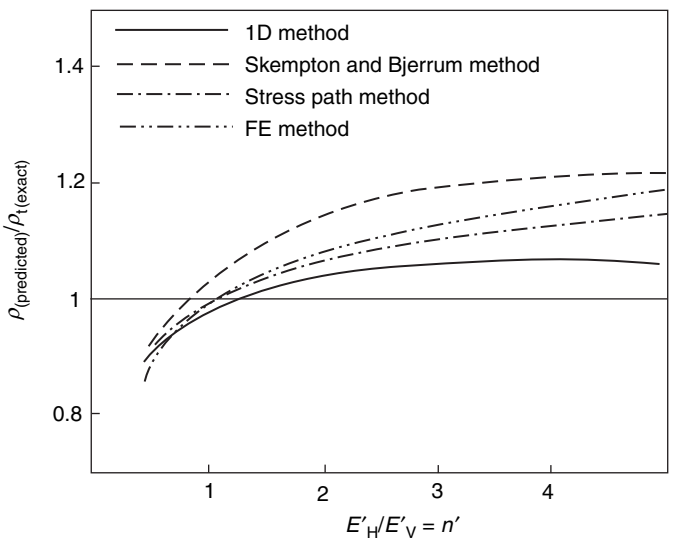

Figure 19.14 The accuracy of four methods of predicting the total settlement of the centre of a uniformly loaded circular area resting on a homogeneous, anisotropic elastic soil. All four methods make use of stiffness parameters obtained from oedometer or triaxial tests

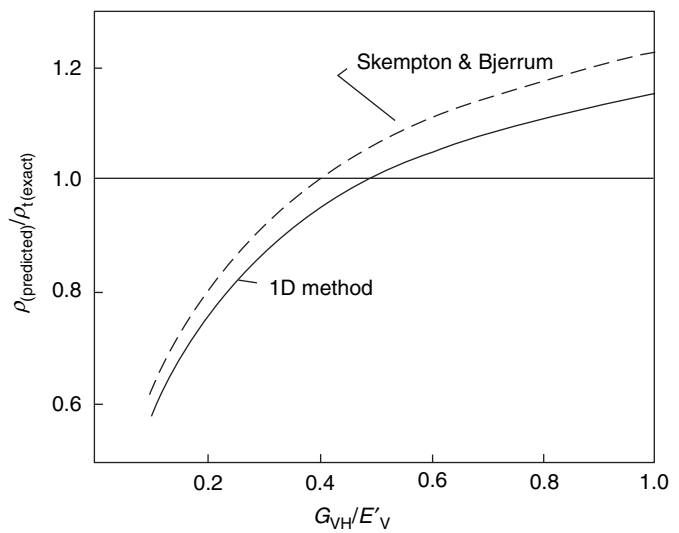

Figure 19.15 Results of rigorous finite element analyses, illustrating the important influence of the vertical shear modulus G_{VH} on settlement

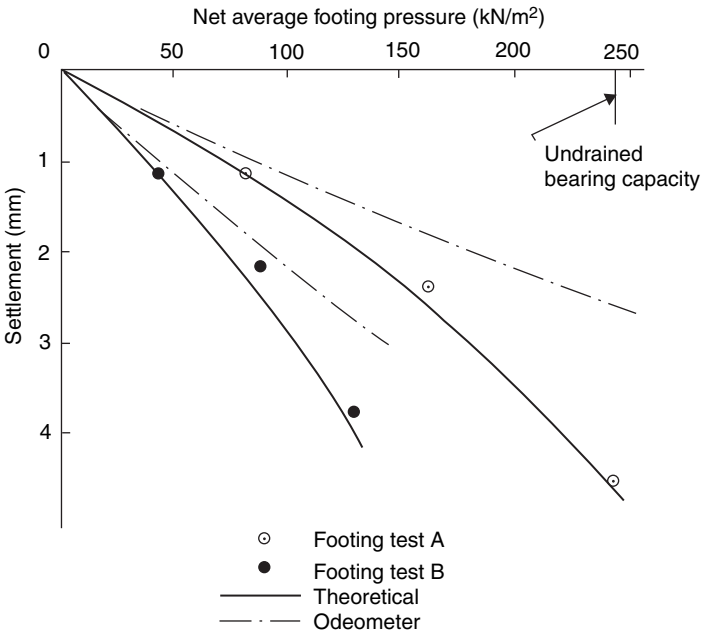

Figure 19.16 Observed consolidation settlements for two model footings on clay compared with predictions based on the 1D method and predictions using the modified Cam Clay model
Reproduced from Burland (1971)

methods, which cover the range given by all four methods. It can be seen that for values of $G_{VH}/E'_V > 0.45$ all of the methods underpredict the settlement whereas for values of $G_{VH}/E'_V < 0.45$, they overpredict. It is important to appreciate that the vertical shear modulus is a key parameter in determining the magnitude of settlement, yet it is seldom measured by static means and traditional methods of settlement prediction take no account of it.

19.6.5 Accuracy of the one-dimensional method for normally consolidated clay

In recent years, considerable developments have been made in developing mathematical models for the stress–strain behaviour of soft normally consolidated clays. A detailed discussion of these developments is outside the scope of this chapter. However, sufficient has been done to demonstrate that, for factors of safety on undrained bearing capacity greater than about three, the measured and theoretical values of the consolidation settlement ρ_c are only slightly larger than the one-dimensional settlement. **Figure 19.16** shows the results of two model footing tests on normally consolidated clays compared with the predictions of the one-dimensional method and the modified Cam Clay model for each model footing test (Burland, 1971). It can be seen that for bearing pressures up to about a third of the undrained bearing capacity, the measured settlements are only slightly larger than the predicted one-dimensional values.

19.7 Undrained settlement

The undrained settlement ρ_u is usually calculated by making use of elastic displacement theory (see section 19.5). Most available charts and formulae are based on homogeneous elastic theory and are therefore of limited value. Butler (1974) developed some useful charts for E_u increasing linearly with depth. A major problem in predicting undrained settlement is the accurate measurement and choice of appropriate values of E_u.

A simple pragmatic empirical approach is to estimate the undrained settlement as a proportion of the total settlement ρ_t. Simons and Som (1970) have reported on the settlement of twelve buildings on overconsolidated clays. They show that ρ_u/ρ_t varies from 0.3 to 0.8 with an average of 0.58. This figure is in agreement with elastic theory and many recent case histories.

For normally consolidated clays, Simons and Som (1970) reviewed nine case histories and show that ρ_u/ρ_t varies from 0.08 to 0.2 with an average of 0.16. Undoubtedly some consolidation would have taken place during construction and ρ_u/ρ_t will usually be less than 0.1.

19.8 Settlement on granular soils

Numerous methods of predicting settlement of foundations on sands and gravels have been published – many more than for clays. The reason lies in the difficulty of obtaining undisturbed samples for the laboratory determination of compressibility under appropriate conditions of stress and stress history. Hence resort has been made to the empirical interpretation of field *in situ* tests, such as standard penetration tests (SPTs) and cone penetration tests (CPTs). This extensive literature has been adequately covered by Sutherland (1974) and Simons and Menzies (2000). The latter authors apply the six most up-to-date methods to a simple illustrative example and show that the predictions differ by a factor of five, even when the representative values of the penetration results are given. Presumably the range would be even wider in practice where the engineer has, in addition, to interpret the penetration data.

The practical significance of the problem was put into perspective by Terzaghi (1956) when he stated that all buildings resting on sand, which were known to him, had settled less than 75 mm, whereas the settlement of buildings on clay foundations quite often exceeded 500 mm!

In view of the unsatisfactory state of the art, and mindful of Terzaghi's assertion, Burland *et al.* (1977) went back to the original databases on which the various empirical methods are based, to see whether a simpler picture emerges which is less dependent on quantitative correlations with erratic penetration tests.

Indeed, a much simpler picture does emerge as shown in **Figure 19.17** where measured settlement per unit pressure (ρ/q) is plotted against foundation breadth B. In each case, the sand is broadly classified as 'loose', 'medium dense' and 'dense', based on average SPT blow counts N. In this correlation no account has been taken of such factors as the water table, depth of loaded area and geometry. Reasonably well defined upper limits for dense, medium dense and loose sands are shown by the full, dotted and chain dotted lines respectively. When assessing the most probable settlement the engineer may

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

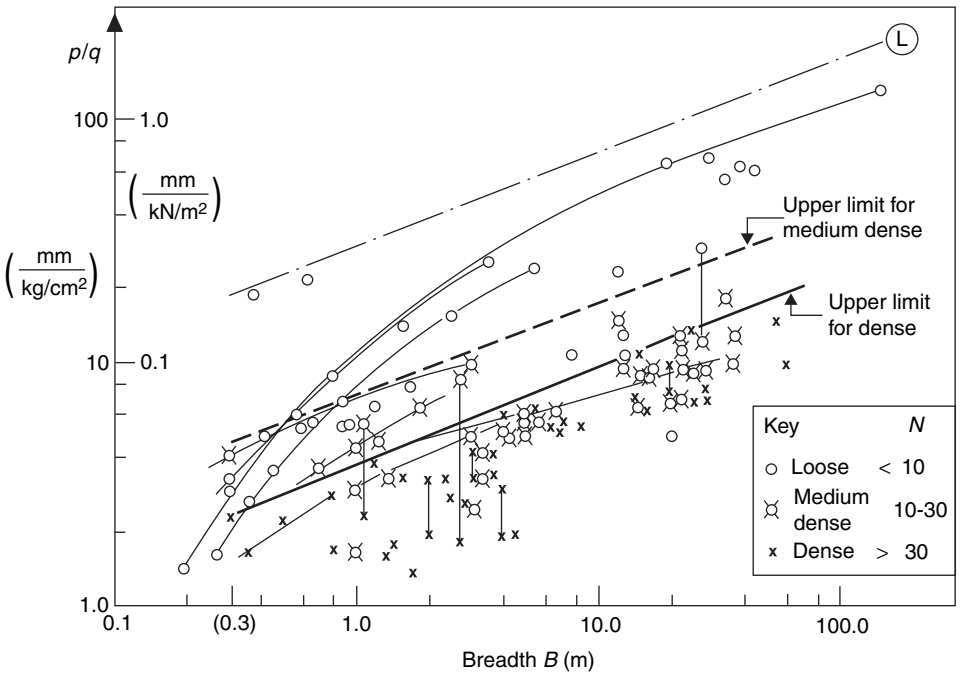

Figure 19.17 Measured settlement of foundations on sand of various relative densities
Reproduced from Burland *et al.* (1977)

elect to work to about 50% of the upper limit values. In most cases the maximum settlement would be unlikely to exceed about 75% of the upper limit. **Figure 19.17** is an example of an empirical approach in which, as far as possible, the measurements of foundation performance are allowed to speak for themselves with a minimum of indirect interpretation; see Chapter 4 *The geotechnical triangle*.

In **Figure 19.17**, the points which are connected by thin full lines are for different sizes of foundation at the same site. If plate loading tests are to be used to extrapolate to larger foundation dimensions, it is clear that the trends are not established at $B = 0.3$ m and that tests with $B = 1$ m are more likely to be successful.

Figure 19.17 is useful for making a preliminary assessment of the probable settlements on granular materials. Subsequent to the publication of this figure, Burland and Burbidge (1985) carried out a detailed statistical analysis of 200 case records of the settlement of foundations on sands and gravels. This resulted in a simple but more refined approach, which leads to an assessment of the likely range of settlements of a given foundation. It was also shown that time-dependent settlements can take place which, after 30 years, can reach 1.5 times the immediate settlements for static loads, and as high as 2.5 times for fluctuating loads. A brief summary of this more refined approach is given by Craig (2004). In concluding this section, it is appropriate to bear in mind the following remarks by Sutherland (1974):

> Before a designer becomes entangled in the details of predicting settlement (in sand) he must satisfy himself whether a real problem actually exists and ascertain what advantages and economies can result from refinements in settlement prediction.

19.9 Summary

- Vertical stress changes beneath loaded areas are insensitive to such factors as nonlinear stress–strain behaviour, anisotropy and increasing stiffness with depth. Therefore the Boussinesq equations can be used to calculate values of $\Delta\sigma_v$ with confidence.
- Two important limitations to the above are where a stiff layer overlies a soft layer and where the vertical shear modulus G_{vh} deviates significantly from the equivalent isotropic value. In the former case, the value of $\Delta\sigma_v$ will be overestimated by using Boussinesq.
- In contrast to the vertical stress changes, the horizontal stress changes are very sensitive to all the variables studied and are therefore likely to depart significantly from the Boussinesq theory.
- Elastic displacement theory is based on very restrictive idealisations and should be used with great caution.
- As methods of settlement prediction have become more complex, increasingly more sophisticated types of testing are required. The limitations and cost of laboratory testing must be recognised.
- A careful comparison between exact solutions and four common prediction methods covering a wide range of properties, shows that the simple classical 1D method is at least as good as any other method for calculating the total settlement ρ_t. For normally consolidated clays it appears that the 1D method gives a good estimate of the consolidation settlement ρ_c.

- For overconsolidated clays $\rho_u \approx 0.5\,\rho_t$ and $\rho_t \approx \rho_{1xd}$.
- For normally consolidated clays $\rho_u \approx 0.1\,\rho_t$ and $\rho_t \approx 1.1\,\rho_{1XD}$.
- A most important conclusion is that most effort must be directed towards the measurement of simple properties such as m_v and E'_v and their variation with depth. Errors in these are much more significant than differences in analytical methods.
- The settlement of foundations on granular soils will usually be small and much of it takes place during construction. Numerous empirical methods have been proposed for predicting the settlement of foundations on granular materials which lead to a wide range of estimates. A straightforward analysis of the measured settlements of over 200 records has led to a remarkably simple approach relating settlement to bearing pressure, breadth and average SPT blow count or cone resistance over the depth of influence.

This chapter describes the classical calculation of limiting lateral earth pressures for use in the analysis of retaining walls. The concept of simple active and passive zones of soil at failure is developed for total stress and effective stress failure criteria, for adhesionless and frictionless walls. The effects of dry and flooded tension cracks for the total stress (undrained) condition are considered. The way in which the simple active and passive zones can be modified to take account of the effects of wall adhesion or friction is described, and finally the possible in-service stresses acting on a retaining wall are discussed.

20.1 Introduction

The need to be able to calculate lateral earth pressures arises particularly in the design of vertical or near-vertical retaining walls. Owing to the difficulties of quantifying the detailed stress–strain behaviour of a soil, the approach to the calculation of lateral earth pressures in geotechnical engineering has traditionally been based on the concepts of plasticity. By considering the stress states of soil elements on the verge of failure, it is possible to deduce limits between which the lateral earth pressures must lie.

20.2 Simple active and passive limits

20.2.1 Mohr circle of stress

A state of plane stress within a soil (or indeed any solid material) can be characterised by means of the Mohr circle of stress, plotted on a diagram with axes representing the normal stress σ (in the x-direction) and the shear stress τ (in the y-direction). The Mohr circle shows how the combination of τ and σ on a given line within the plane varies with the orientation of that line. The Mohr circle is in effect a locus defining all possible combinations of τ and σ, acting on lines at different orientations, that make up a given state of stress within a plane. In the current context, the plane is usually the cross-sectional plane of a long retaining wall. The circle is symmetrical about the σ-axis: the two points at which it crosses the σ-axis represent *principal directions*, on which the shear stress τ is zero. The corresponding normal stresses are termed the *major* (greater) and *minor* (lesser) *principal stresses*. The stress state on a line at an angle θ anticlockwise from the line on which the major principal stress σ_1 acts is given by the point on the circle whose radius subtends an angle 2θ at the centre of the circle with the radius through the major principal stress point. This is illustrated in **Figure 20.1**. The angle 2θ between the radii corresponding to the major and the minor principal stresses is 180°, which means that in reality their

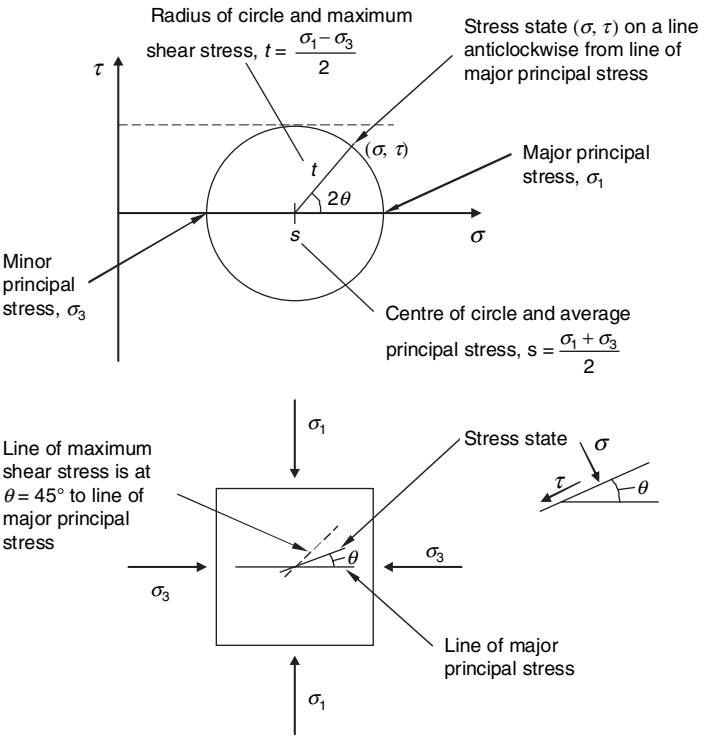

Figure 20.1 Mohr circle representation of the stress state within a principal plane

directions (or the directions of the lines on which they act) are at 90°.

In soils, the Mohr circle may be plotted in terms of either total stresses (σ, τ) or effective stresses (σ', τ), depending on the form of analysis being used.

20.2.2 Total stress failure criterion

If the soil is in a state of limiting equilibrium, there will be some orientation within the plane for which the combination

of stresses (σ, τ) or (σ', τ) lies on the line defining states of stress at failure, or the failure envelope. In soils, two alternative failure criteria or failure envelopes are used; the first is discussed here, the second in section 20.2.3 *Effective stress failure criterion*. In terms of total stresses, the first failure criterion specifies the maximum possible shear stress anywhere within the plane, τ_{max}, in terms of the undrained shear strength of the soil, c_u. This applies only to clay soils sheared rapidly to failure. The undrained shear strength c_u is not a soil property, but depends on the water content of the clay as sheared. The undrained shear strength failure criterion is written as

$$\tau_{max} = c_u \tag{20.1}$$

A Mohr circle of total stress which touches the undrained shear strength failure envelope is shown in **Figure 20.2**. Consideration of the geometry of the Mohr circle shows that the difference between the major and minor principal total stresses, $\sigma_1 - \sigma_3$, is equal to twice the radius of the circle, and the radius is equal to c_u. Thus at failure,

$$\sigma_1 - \sigma_3 = 2c_u \tag{20.2}$$

Assuming for the moment that the principal total stress directions are vertical and horizontal, there are two ways in which the soil could fail. In the first, the major principal total stress is vertical, and the minor principal total stress is horizontal. This could correspond to the withdrawal of lateral support at constant vertical stress until failure is reached. Such conditions might occur behind an embedded retaining wall, and are known as *active*. In active conditions, the horizontal total stress has fallen to its minimum possible value for a given vertical total stress. If the horizontal total stress were reduced any further (with the vertical total stress remaining constant), the Mohr circle of stress would expand beyond the failure envelope – which is not permissible. In active conditions, the (minimum) horizontal total stress is given by

$$\sigma_{h,min} = \sigma_v - 2c_u \tag{20.3}$$

In the second mode of failure, the major principal total stress is horizontal, and the minor principal total stress is vertical. This could correspond to an increase in lateral stress and a constant or possibly reducing vertical stress, as might occur in the soil in front of an embedded retaining wall. These conditions ($\sigma_h > \sigma_v$) are known as *passive*. In passive conditions, the horizontal total stress has increased to its maximum possible value for a given vertical total stress. If the horizontal total stress were increased any further, the Mohr circle of stress would expand beyond the failure envelope, which is again not permissible. In passive conditions, the (maximum) horizontal total stress is given by

$$\sigma_{h,max} = \sigma_v + 2c_u \tag{20.4}$$

As discussed in Chapter 15 *Groundwater profiles and effective stresses*, the vertical total stress is usually taken as $\int \gamma dz$ (= γz in a uniform soil), plus the effect of any surface surcharge q.

When calculating active earth pressures behind a retaining wall using equation (20.3), there are two important provisos. First, negative (tensile) stresses are not permitted, so a no-tension cut-off at $\sigma_h = 0$ comes into play where the uncritical application of equation (20.3) would otherwise give a negative value for $\sigma_{h,min}$ – equivalent to the development of a tension crack penetrating to a depth z_{tc} given by

$$\sigma_{h,min} = (q + \gamma z_{tc} - 2c_u) = 0$$

or

$$z_{tc} = \frac{(2c_u - q)}{\gamma} \tag{20.5}$$

which, in the absence of a surface surcharge, reduces to the more familiar $z_{tc} = 2c_u/\gamma$.

The second proviso is that if there is any possibility that the tension crack could flood, the total lateral stress acting on the soil in the active zone becomes equal to the hydrostatic pressure of water. A flooded tension crack may remain open to a greater depth, z_{ftc}, given by

$$\sigma_{h,min} = (q + \gamma z_{ftc} - 2c_u) = \gamma_w z_{ftc}$$

or

$$z_{ftc} = \frac{(2c_u - q)}{(\gamma - \gamma_w)} \tag{20.6}$$

where γ_w is the unit weight of water. As $\gamma_w \approx 0.5\gamma$, if $q = 0$ the depth to which a flooded tension crack may remain open

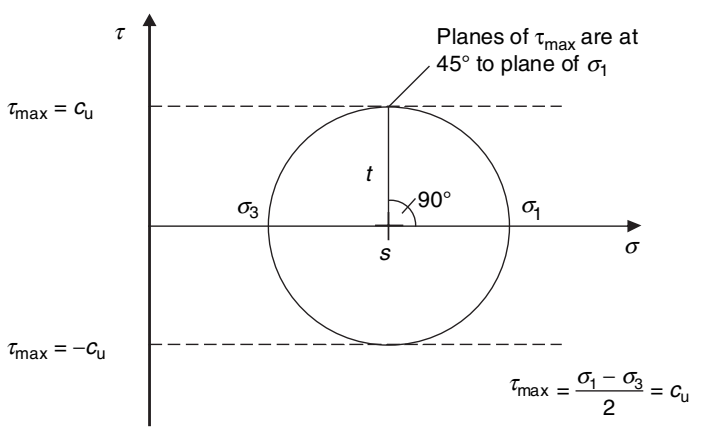

Figure 20.2 Mohr circle of total stress at failure for a clay soil obeying the undrained shear strength failure criterion, $\tau_{max} = c_u$

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(and, more importantly, hydrostatic pressures are exerted on the retaining wall), is $z_{ftc} \approx 4c_u/\gamma$. The tendency of the undrained shear strength c_u to increase with depth means that the depth z_{ftc} could well be more than twice the depth to which a dry tension crack can remain open.

20.2.3 Effective stress failure criterion

The second and more fundamental failure criterion is in terms of effective stresses, and specifies the maximum possible ratio of shear to normal effective stress anywhere within the plane, $(\tau/\sigma')_{max}$, in terms of the tangent of the effective angle of friction shearing resistance or friction of the soil, ϕ'. This applies to all soils at any time, but the pore water pressures must be known in order to calculate the normal effective stress. The critical state effective angle of shearing resistance or friction is a soil property, while the peak effective angle of shearing resistance is not. This is because the latter depends on the potential of the soil to dilate, which in turn depends on a combination of the relative density and the stress state, and must therefore be expected to vary with depth. The effective stress failure criterion is written as

$$\left(\frac{\tau}{\sigma'}\right)_{max} = \tan\phi' \tag{20.7}$$

A Mohr circle of effective stress which touches the effective stress failure envelope is shown in **Figure 20.3**. The radius t of the Mohr circle is equal to half the difference between the major and minor principal effective stresses:

$$t = \frac{(\sigma'_1 - \sigma'_3)}{2}$$

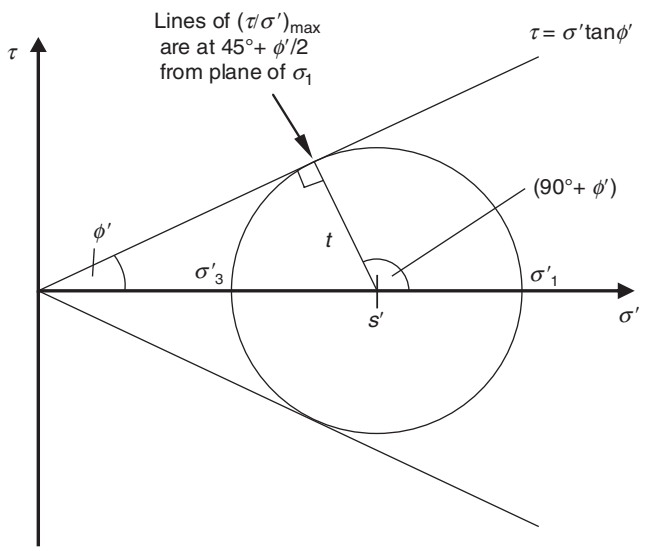

Figure 20.3 Mohr circle of effective stress at failure for a soil obeying the effective stress (frictional) failure criterion $(\tau/\sigma')_{max} = \tan\phi'$

while the distance of its centre from the origin, s', is given by half the sum of the principal effective stresses:

$$s' = \frac{(\sigma'_1 + \sigma'_3)}{2}$$

Further consideration of the Mohr circle geometry shows that $t = s' \sin\phi'$. Substitution of the expressions for t and s' in terms of the major and minor principal effective stresses σ'_1 and σ'_3 into this equation, followed by a little manipulation, gives the ratio of the major and minor principal total stresses σ'_1/σ'_3 at failure, as

$$\frac{\sigma'_1}{\sigma'_3} = \frac{(1+\sin\phi')}{(1-\sin\phi')} \tag{20.8}$$

Assuming again that the principal effective stress directions are vertical and horizontal, there are two ways in which the soil could fail. The first is again active, corresponding potentially to conditions behind a retaining wall with the major principal effective stress vertical and the minor principal effective stress horizontal. In active conditions, the (minimum) horizontal effective stress is given by

$$\sigma'_{h,min} = \frac{(1-\sin\phi')}{(1+\sin\phi')}\sigma'_v = K_a\sigma'_v \tag{20.9}$$

where K_a is the well-known active earth pressure coefficient. From equation (20.9), $K_a = (1 - \sin\phi')/(1 + \sin\phi')$ – this is sometimes written as the trigonometric identity $\tan^2(45° - \phi')$.

The second failure mode is again passive, corresponding potentially to conditions in front of an embedded retaining wall, with the major principal total stress horizontal and the minor principal total stress vertical. In passive conditions, the (maximum) horizontal total stress is given by

$$\sigma'_{h,max} = \frac{(1+\sin\phi')}{(1-\sin\phi')}\sigma'_v = K_p\sigma'_v \tag{20.10}$$

where K_p is the passive earth pressure coefficient. From equation (20.10), $K_p = (1 + \sin\phi')/(1 - \sin\phi')$ – this is sometimes written as $\tan^2(45° + \phi')$.

As discussed in Chapter 15 *Groundwater profiles and effective stresses*, the vertical effective stress is usually taken as $\int\gamma\,dz - u$ ($= \gamma z - u$ in a uniform soil), plus the effect of any surface surcharge q.

Note that in the case of the total stress (undrained shear strength) failure criterion, a difference between the principal stresses is calculated, whereas the use of the effective stress (frictional) failure criterion leads to a ratio of principal effective stresses.

Of course, real walls are not frictionless, and the presence of a shear stress on the back or front of a retaining wall will invalidate the assumption that the principal stress directions are vertical and horizontal, at least adjacent to the retaining wall. This usually works to the designer's advantage in that wall friction or adhesion, provided it is in the right direction,

reduces the active stresses and increases the passive stresses. The calculation of earth pressures taking wall friction into account is discussed in section 20.3.

20.3 Effects of wall friction (adhesion)

It is relatively straightforward to calculate revised earth pressure parameters that take into account a known degree of soil/wall friction (in the case of an effective stress analysis) or undrained soil/wall adhesion (in the case of a total stress analysis). This is done by considering the effect on the average effective or total stress (s' or s) of the rotation in the direction of principal stresses that must occur between (i) a zone of soil near the free surface (within which the principal stresses are horizontal and vertical, as assumed in section 20.2 for the whole of the soil behind or in front of the retaining wall), and (ii) the soil adjacent to the wall (in which the presence of a shear stress on the vertical surface of the wall means that this cannot be a principal direction).

Details of this calculation may be found in Powrie (2004). In practice, it is usual to use the resulting general formulae, charts or tables based upon them, rather than deriving the required result from first principles every time. The key decisions facing the designer then concern the magnitude of the soil/wall adhesion or friction (usually expressed as a proportion of the design soil strength, c_u or ϕ'), and the direction in which the adhesion or friction acts.

A discussion on soil/wall friction is given in Powrie (2004). Eurocode 7 (EC7) (BSI, 1995) gives limiting values of soil/wall friction δ, where $\delta = \phi'_{crit}$ for rough (cast *in situ*) concrete, and $\delta = {}^2/_3\,\phi'_{crit}$ for smooth (precast) concrete or sheet piling supporting sand and gravel. EC7 (BSI, 1995) is silent with regard to values of soil/wall adhesion in an undrained analysis, but Gaba *et al.* (2003) recommend a maximum value of half the design undrained shear strength.

If the soil behind a retaining wall settles relative to the wall and the soil in front heaves, then the directions of soil/wall adhesion or friction act so as to reduce the active earth pressures and increase the passive. Both of these tend to enhance the stability of the wall. However, there are circumstances in which these conventional directions of relative soil/wall movement (and hence adhesion or friction) could be reversed. For example, if the wall carries a vertical load – such as the perimeter wall for a building basement – then the wall may settle relative to the retained soil and the direction of active side adhesion or friction will be reversed. Dewatering inside an excavation could cause relative settlement of the soil in front of the wall, but this is rather less likely.

For undrained conditions, a stress analysis taking into account the effects of a favourable soil/wall adhesion τ_w gives the following expressions for horizontal components of (i) the active stresses:

$$\sigma_{h,min} = \sigma_v - \tau_u\left(1 + \Delta + \cos\Delta\right) \tag{20.11}$$

and (ii), the passive stresses:

$$\sigma_{h,max} = \sigma_v + \tau_u\left(1 + \Delta + \cos\Delta\right) \tag{20.12}$$

where

$$\sin\Delta = \tau_w/\tau_u.$$

If $\tau_w = 0.5\tau_u$, the term in brackets in equations (20.11) and (20.12) becomes numerically equal to 2.39, compared with 2 in the case of the frictionless wall in section 20.2. The same comments regarding the possibility and depth of a dry or flooded tension crack behind the wall apply as in section 20.2. However, there is a minor intellectual complication concerning the depth below the bottom of the tension crack at which soil/wall adhesion starts to be mobilised.

The active and passive earth pressure coefficients, defined now as the horizontal component of the effective stress on the wall at depth z, $\sigma'_{h(z)}$, divided by the notional vertical effective stress at the same level, $(q + \int\gamma\,dz - u)$ where q is any surface surcharge, calculated in an effective stress analysis with an angle of soil/wall friction δ acting favourably are

$$K_a = \frac{\sigma'_{h(z)}}{\left(q + \int\gamma\,dz - u\right)} = \frac{\left[1 - \sin\varphi'\cos\left(\Delta - \delta\right)\right]}{\left[1 + \sin\varphi'\right]} e^{-\left[(\Delta-\delta)\tan\varphi'\right]} \tag{20.13}$$

and

$$K_p = \frac{\sigma'_{h(z)}}{\left(q + \int\gamma\,dz - u\right)} = \frac{\left[1 + \sin\varphi'\cos\left(\Delta + \delta\right)\right]}{\left[1 - \sin\varphi'\right]} e^{\left[(\Delta+\delta)\tan\varphi'\right]} \tag{20.14}$$

respectively, where $\sin\Delta = \sin\delta/\sin\varphi$.

Values of K_a and K_p for various effective friction angles ϕ' and relative soil/wall friction δ/ϕ' are given in **Tables 20.1** and **20.2** respectively. These, together with equations (20.13) and (20.14), are consistent with the equations and charts given in EC7 (BSI, 1995) and Gaba *et al.* (2003).

So far, no judgement has been made as to the value of soil strength used. If conditions at collapse are under investigation, then the soil strength used would be the best estimate of the soil and interface strengths relevant to that limit state. As discussed by Powrie (1996), for embedded retaining walls these may be the critical state soil strength, ϕ'_{crit}, with full wall friction, $\delta = \phi'_{crit}$. In design, an appropriate factor of safety would need to be applied to the soil and interface strengths, together with other measures including an unexpected surcharge on the retained side, an unexpected overdig in front of the wall, and the most onerous foreseeable pore water pressure conditions which might well (in the case of an undrained analysis) include a flooded tension crack between the wall and the retained soil.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The same techniques can also be used to calculate earth pressure differences and coefficients in cases where the backfill slopes, and/or the back of the wall is battered (see, for example, Powrie, 2004).

20.4 In-service conditions

Modern design codes including EC7 (BSI, 1995) generally require the designer of a retaining wall to guard against failure in the ground by carrying out an ultimate limit state (ULS) calculation with the actual soil strength reduced by a factor of safety or a strength mobilisation factor. (Certain other provisions also apply, such as an allowance for an unexpected surcharge load on the retained side, an unexpected overdig in front of the wall, and the most onerous foreseeable groundwater conditions.) The factored or 'design' strength, being lower than the estimated actual strength of the soil, will result

Table 20.2 Passive earth pressure coefficients K_p consistent with EC7 (BSI, 1995), calculated using equation (20.13) for various values of effective friction angle ϕ' and relative soil/wall friction δ/ϕ'
Data taken from Powrie (2004)

in increased active earth pressure coefficients, reduced passive earth pressure coefficients, and an increased depth of embedment in the case of an embedded retaining wall.

It will be possible to draw a free body diagram for the wall that is in equilibrium under the action of the factored active and passive lateral stresses. In fact, this is the basis on which the required depth of embedment (for an embedded wall) is calculated. However, the idealised earth pressures obtained from the limit equilibrium analysis with factored soil strengths are unlikely to correspond to those really acting on the wall, and they are likely to overestimate wall bending moments (but not prop loads). The reasons for this are varied and complex; for an embedded wall they may include:

- relative wall/soil flexibility, which will influence local strains and hence mobilised strengths along the depth of the wall (see Rowe, 1952);
- different relationships between wall movement and shear strain on either side of an embedded wall (see Bolton and Powrie, 1988);
- different rates of mobilisation of soil strength with strain or wall movement on either side of an embedded wall, arising from the different recent stress histories relative to the stress paths followed during excavation (see Powrie *et al*., 1998).

These effects are most likely to affect the linearity and magnitude of the lateral stresses with embedded walls propped at the crest, and multi-propped structures such as building basements. For these types of construction, a numerical soil-structure interaction analysis is likely to lead to some economies in design and specification (Gaba *et al.*, 2003).

Concern has also been expressed regarding the possibility of high lateral stresses on embedded *in situ* retaining walls in overconsolidated soils, as a result of the stress history of these deposits (a discussion of which is given in Powrie, 2004). However, field studies of these walls have generally produced no evidence for this (e.g. Richards *et al.*, 2007), probably as a result of the factors listed above, together with the effects of wall installation in reducing the lateral stresses prior to excavation in front of the wall to below the *in situ* values (Richards *et al.*, 2006). In many cases, the use of active earth pressure coefficients behind the wall based on the full soil strength and steady-state pore water pressures, will probably give a reasonable estimate of the bending moments likely to occur in service (Batten and Powrie, 2000; Powrie and Batten, 2000; Gaba *et al.*, 2003). However, this approach will tend to underestimate prop loads (Gaba *et al.*, 2003).

20.5 Summary

- Classical earth pressure theory is based on calculating limiting lateral earth pressures, corresponding to conditions of failure in the soil, and in its simplest form is applied to frictionless or adhesionless retaining walls.
- Active conditions correspond to failure with the major principal stress vertical, and represent the minimum possible lateral stress for a given vertical stress, and are usually associated with conditions behind a retaining wall. Passive conditions correspond to failure with the major principal stress horizontal, and represent the maximum possible lateral stress for a given vertical stress – usually associated with conditions in front of a retaining wall.
- Active and passive pressures can be calculated using either the total stress failure criterion (for clay soils, undrained) or the effective stress failure criterion. In the latter case, the pore water pressures must be considered explicitly as well.
- In an undrained calculation, consideration must be given to the possibility of a flooded tension crack developing between a retaining wall and the soil behind it.
- The simple expressions for active and passive lateral stresses developed for a frictionless or adhesionless wall are usually modified for use in practice to take account of the effects of wall friction or adhesion. However, consideration should then be given to the likely direction of relative soil/wall movement to ensure that wall adhesion or friction can be relied on.
- The in-service stresses acting on a retaining wall are likely to be different from those at failure in the ground, owing to the effects of wall flexibility and differential rates of mobilisation of soil strength (soil stiffness) behind and in front of the wall.

This chapter discusses the theory behind the well-known formulae for the bearing capacity of soils. Theoretical solutions for an infinitely long strip foundation on a weightless soil, with the soil above the founding plane acting simply as a surcharge, are presented for both total stress and effective stress failure criteria. The use of empirical adjustment factors to take account of foundation shape, depth and the self-weight of the soil below the founding plane is described. Finally, the effect on bearing capacity of an inclined and/or eccentric load is discussed.

21.1 Introduction

The bearing capacity of a foundation is one of the classical problems in geotechnical engineering. The solution for a long foundation on a soil obeying the undrained shear strength failure criterion $\tau_{max} = c_u$ was published by Prandtl (1920), in the context of the indentation of a metal by a flat die. The corresponding solution for a weightless soil of effective friction angle ϕ' obeying the effective stress (frictional) failure criterion $(\tau/\sigma')_{max} = \tan\phi'$ was given by Reissner (1924).

In the first case, the solution relates the difference between the vertical total stress on the foundation at failure, σ_f, and the vertical total stress in the ground on either side at the level of the bottom of the foundation (the *founding plane*), σ_o, to the undrained shear strength, c_u:

$$\frac{(\sigma_f - \sigma_o)}{c_u} = N_c = (2 + \pi) = 5.14 \qquad (21.1)$$

The ratio $(\sigma_f - \sigma_o)/c_u$ is known as a *bearing capacity factor* and is given the symbol N_c in an undrained (total stress) analysis. The side surcharge, σ_o, will usually arise because of the weight of the soil above the base of the foundation: $\sigma_o = \int \gamma dz = \gamma D$ for a foundation of depth D in a soil of uniform unit weight γ. The weight of the soil does not otherwise affect the calculation, because below the founding plane it adds equally to both σ_f and σ_o and therefore cancels itself out.

In the second case, the solution is in terms of the ratio of the vertical effective stress on the foundation at failure, σ'_f, and the vertical effective stress in the ground on either side at the level of the foundation base σ'_o:

$$\frac{\sigma'_f}{\sigma'_o} = N_q = K_p e^{(\pi \tan \phi')} \qquad (21.2)$$

where ϕ' is the effective angle of friction and $K_p = (1 + \sin\phi')/(1 - \sin\phi')$ is the passive earth pressure coefficient (see Chapter 20). In this case, the bearing capacity factor N_q is the ratio of the vertical effective stresses on the foundation and in the soil to either side, at the level of the foundation base. As before, the side surcharge σ'_o will usually arise because of the weight of the soil above the base of the foundation, $\sigma'_o = \int \gamma dz - u = (\gamma D - u)$ for a foundation of depth D in a soil of uniform unit weight γ, where u is the pore water pressure at the level of the base.

The undrained shear strength and effective stress failure criteria are discussed in Chapter 20 *Earth pressure theory*, and the analyses leading to equations (21.1) and (21.2) are given in full in, for example, Powrie (2004).

21.2 Bearing capacity equation for vertical load – empirical adjustments for shape and depth

The fact that the effective stress solution is developed for a weightless soil is, in practice, an important potential limitation in the use of equation (21.2). For every 10 kPa increase in the vertical effective stress σ'_o on either side of the foundation, the effective stress underneath the foundation, σ'_f, increases by N_q times this, – which for $\phi' = 30°$ could be 184 kPa (with $\phi' = 30°$, $N_q = 18.4$ according to equation (21.2)). Failure of the foundation will involve a mechanism extending to a depth approximately equal to the foundation width B below the founding plane. Thus the use of equation (21.2) on its own would significantly underestimate the true bearing capacity, because the increase in σ'_f with depth is neglected. The depth of soil below the founding plane that takes part in the eventual failure mechanism may be taken into account empirically by adding a further term to equation (21.2), known as the N_γ term, given by

$$N_\gamma \times (0.5\gamma B - \Delta u) \qquad (21.3)$$

where N_γ is a factor analogous to N_q, B is the foundation width, γ is the unit weight of the soil, Δu is the increase in pore water pressure between the founding plane and a depth of $0.5B$ below it, and $(0.5\gamma B - \Delta u)$ is then the increase in vertical effective stress over the same depth, in the soil on either side of the foundation. Thus equation (21.3) gives the bearing capacity of a surface footing for which the depth of embedment D (and

hence σ'_o) is zero. This is added to the basic equation (21.2) to estimate the bearing capacity of a long footing embedded to a depth D.

Two further problems with equations (21.1–21.3) are that in reality, (i) most foundations are not infinitely long and (ii) the strength of the soil on either side of the foundation above the founding plane, which is assumed in the analyses to act simply as a surcharge, will contribute to the bearing capacity of the foundation, especially as the depth of the founding plane D is increased. These are overcome by the use of empirical factors, usually based on the results of laboratory tests on model footings, to modify the basic theoretical equations.

In effective stress terms, the bearing capacity equation is written in the form

$$\sigma'_f = \left(N_q \times s_q \times d_q \times \sigma'_o\right) + \left[N_\gamma \times s_\gamma \times d_\gamma \times r_\gamma \times \left(0.5\gamma B - \Delta u\right)\right] \quad (21.4)$$

where, in addition to the symbols already defined,

- s_q and s_γ are shape factors, which account for the fact that the footing is not infinitely long;
- d_q and d_γ are depth factors, which account for the fact that in reality, the soil above the founding plane has some strength and therefore does more than act simply as a surcharge;
- r_γ is a reduction factor, to prevent the N_γ term increasing indefinitely with footing width B.

N_q, the basic bearing capacity factor, is generally taken as $K_p e^{\pi \tan\phi'}$ for a vertical load applied through the centre of the footing. Values of s_q, d_q, N_γ, s_γ, d_γ and r_γ suggested by Meyerhof (1963), Brinch Hansen (1970) and Bowles (1996) are given in **Table 21.1**.

For foundations on clay soils loaded quickly, the undrained bearing capacity equation may be written as

$$\left(\sigma_f - \sigma_o\right) = \left[N_c \times s_c \times d_c\right] \times c_u. \quad (21.5)$$

Parameter	Meyerhof (1963)	Brinch Hansen (1970)
Shape factor s_q	$1 + 0.1K_p(B/L)$	$1 + (B/L)\tan\phi'$
Depth factor d_q	$1 + 0.1\sqrt{(K_p)}(D/B)$	$1 + 2\tan\phi'(1 - \tan\phi')k$
$N\gamma$	$(N_q - 1)\tan(1.4\phi')$	$1.5(N_q - 1)\tan\phi'$
Shape factor s_γ	$= s_q$	$1 - 0.4(B/L)$
Depth factor d_γ	$= d_q$	1

Notes: Meyerhof's expressions apply for $\phi' > 10°$
$k = D/B$ if $D/B \le 1$; $k = \tan^{-1}(D/B)$ (in radian) if $D/B > 1$
$K_p = (1 + \sin\phi')/(1 - \sin\phi')$
$r_\gamma = 1 - 0.25\log_{10}(B/2)$ for $B \ge 2$ m (Bowles, 1996)
Foundation length L, breadth B and depth D

Table 21.1 Bearing capacity enhancement factors, effective stress failure criterion

Parameter	Skempton (1951)	Meyerhof (1963)
Shape factor s_c	$1 + 0.2(B/L)$	$1 + 0.2(B/L)$
Depth factor d_c	$1 + 0.23\sqrt{(D/B)}$, up to a maximum of 1.46 ($D/B = 4$)	$1 + 0.2(D/B)$

Note: Foundation length L, breadth B and depth D

Table 21.2 Bearing capacity enhancement factors, undrained shear strength failure criterion

For a vertical load acting at the centre of the foundation, the basic ϕ bearing capacity factor N_c is $(2 + \phi) = 5.14$, and s_c and d_c are enhancement factors accounting for the shape and depth of the footing respectively. In this case, there is no N_γ effect because the difference between the total stresses σ_f and σ_o is unaffected by the self-weight of the soil.

Values of s_c and d_c suggested by Skempton (1951) and Meyerhof (1963) are given in **Table 21.2**.

Brinch Hansen (1970) suggests an undrained bearing capacity equation of a slightly different form in which the enhancement factors are additive rather than multiplicative. He also gives adjustment factors that take account of inclined loads and founding planes.

Annex B of BSI (1995) gives equations of a similar form to (21.4) and (21.5), together with factors i_q and i_c intended to account for the effect of inclined loads but with the depth factors d_q and d_c omitted. However, a completely general bearing capacity equation in which parameter values are inserted to suit particular circumstances, can lead to confusion. In any case, inclined loads, non-horizontal footing bases and sloping ground on one or both sides of the footing can be taken into account analytically in the calculation of N_c or N_γ, as shown (for example) in Powrie (2004).

21.3 Inclined loading

The bearing capacity of a shallow foundation subjected to an inclined load acting through its centre can be investigated by modifying the stress analysis used to obtain the basic bearing capacity equations (21.1) and (21.2). An inclined load acting through the centre of the foundation may be split into its horizontal and vertical components, H and V.

For a foundation on a clay soil obeying the undrained shear strength (maximum shear stress) failure criterion, the loads are characterised by a normal stress $\sigma_f = V_f/B$ and a shear stress $\tau_f = H_f/B$, where B is the foundation width and V_f and H_f are the vertical and horizontal loads (in kN/m) at failure. The modified bearing capacity is then given by

$$\frac{\left(\sigma_f - \sigma_o\right)}{c_u} = N_c = \left(1 + \pi - \Delta + \cos\Delta\right) \quad (21.6)$$

where σ_o is the surcharge on either side of the foundation at the level of the founding plane, and $\Delta = \sin^{-1}(\tau_f/c_u)$.

For a foundation on soil obeying the effective stress (maximum stress ratio or frictional) failure criterion, the loads are

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

characterised by a normal effective stress σ'_f (= V_f/B, assuming that the pore water pressure on the base of the foundation is zero) and a shear stress τ_f (= H_f/B), where B is the foundation width and V_f and H_f are the vertical and horizontal loads (in kN/m) at failure. The modified bearing capacity is then given by

$$\frac{\sigma'_f}{\sigma'_o} = N_q = \frac{\left[1+\sin\phi'\cos(\Delta+\delta)\right]}{\left[1-\sin\phi'\right]} \times e^{(\pi-\Delta-\delta)\tan\phi'} \quad (21.7)$$

where σ'_o is the effective stress surcharge on either side of the foundation at the level of the founding plane, $\sin\Delta = \sin\delta/\sin\phi'$, and $\delta = \tan^{-1}(\tau_f/\sigma'_o)$.

21.4 Offset loading

A vertical load V acting at a distance e from the geometrical centre of the foundation is statically equivalent to a vertical load V acting through the centre, together with a moment of Ve about the centre. Foundations subjected to combined vertical and moment loading are considered in section 21.5.

Alternatively, a simple approach (suggested by Meyerhof, 1963) to calculate the bearing capacity of a long shallow foundation subjected to an offset or eccentric vertical load is to reduce the width of the foundation to $B' = (B - 2e)$ so that the load then acts through the geometric centre. If this reduced width is used with the limiting vertical stresses given by the appropriate equations presented in sections 21.1 and 21.2, a conservative (i.e. safe) estimate of the reduced load carrying capacity of the foundation will be obtained.

BSI (1995) requires that 'special precautions shall be taken where the eccentricity of loading exceeds 1/3 of the width of a rectangular footing or 0.6 of the radius of a circular footing', because this brings the point of application outside the equivalent of the 'middle third' of the foundation, leading to a tendency to tension or uplift at the edge away from the load.

21.5 Combined vertical, horizontal and moment (*V–H–M*) loading interaction diagram for a surface foundation

In general, a foundation may be subjected to a combination of vertical (V), horizontal (H) and moment (M) loads, either as a result of the application of an inclined point load offset from the centre of the footing (**Figure 21.1(a)**), or directly (**Figure 21.1(b)**). These are statically equivalent, with $V = R\cos\alpha$, $H = R\sin\alpha$ and $M = R\cos\alpha\, e$.

An alternative approach to calculating the bearing capacity of a surface footing subjected to simultaneous vertical, horizontal and moment loading is given by Butterfield and Gottardi (1994). On the basis of a large number of small-scale (model) tests, they showed that combinations of V, H and M at failure lay on a unique three-dimensional surface or failure envelope when plotted on a three-dimensional graph with axes V, H and M/B, where B is the breadth of the footing. The failure surface may be described as cigar-shaped, and is parabolic when viewed in either the V–H or the V–M/B plane (**Figure 21.2**).

Butterfield and Gottardi (1994) normalised their experimental values of V, H and M/B with respect to the vertical load V_{max} that would cause failure of the footing when acting on its own. For a foundation placed directly on the soil surface, the bearing capacity in symmetrical vertical loading σ'_f may be calculated using equation (21.4) with the surcharge on either side due to the weight of soil above the founding plane $\sigma'_o = 0$. The depth

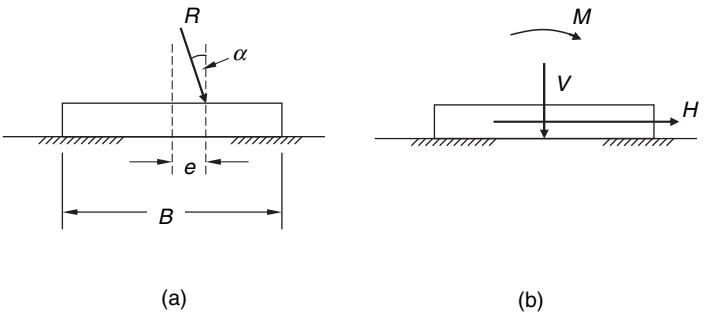

Figure 21.1 Statical equivalence of (a) an eccentric, inclined point load and (b) combined vertical, horizontal and moment loading through the centroid of a shallow foundation (Butterfield and Gottardi, 1994)

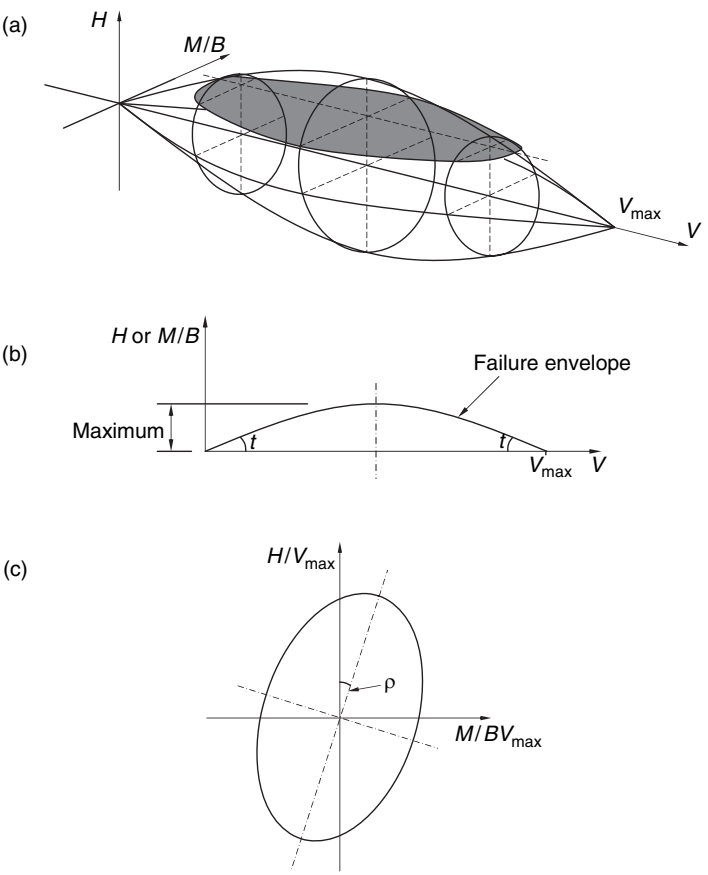

Figure 21.2 Failure envelopes for a shallow footing: (a) three-dimensional view in (*V–M/B–H*) space; (b) *H* or *M/B* against *V*; (c) normalised cross-section perpendicular to the *V* axis at $V = V_{max}/2$ (Parts (a) and (b) from Butterfield and Gottardi, 1994)

factor d_γ and the associated reduction factor r_γ are also omitted because the depth of burial of the foundation D is zero, giving

$$\sigma'_f\,(\text{kPa}) = N_\gamma \times s_\gamma \times (0.5_\gamma B - \Delta u). \tag{21.8}$$

If the foundation is of width B and length L, the vertical load at failure, acting through the centroid, is

$$V_{max}\,(\text{kN}) = \sigma'_f BL = N_\gamma s_\gamma (0.5\gamma B - \Delta u)BL. \tag{21.9}$$

The parabolas representing the projections of the three-dimensional failure surface in the V–H and V–M/B planes have equations

$$\frac{H}{t_h} = \frac{V(V_{max} - V)}{V_{max}} \tag{21.10a}$$

and

$$\left(\frac{M}{B}\right) \Big/ t_m = \frac{V(V_{max} - V)}{V_{max}} \tag{21.10b}$$

where t_h and t_m are the slopes of the parabolas at the origin in the V–H and V–M/B planes respectively (**Figure 21.2(b)**). For Butterfield and Gottardi's experiments, $H_{max} \approx V_{max}/8$ and $(M/B)_{max} \approx V_{max}/11$, corresponding to $t_h = 0.5$ and $t_m = 0.36$. H_{max} is defined at $M/B = 0$, $(M/B)_{max}$ is defined at $H = 0$, and both occur at $V = V_{max}/2$. Sections through the failure surface in the M/B–H plane (i.e. when viewed along the V axis) are ellipses, rotated through an angle ρ from the H axis towards the positive M/B axis (**Figure 21.2(c)**). The reason for this rotation is that the H and M/B loads can act either together or in opposition: if H and M/B act in the directions shown in **Figure 21.1**, the horizontal load at failure will be smaller than if either H or M/B is reversed.

The three-dimensional failure surface may be represented by an equation of the form

$$\left(\frac{H \Big/ V_{max}}{t_h}\right)^2 + \left(\frac{M \Big/ BV_{max}}{t_m}\right)^2 - \left(\frac{2C\dfrac{M}{BV_{max}}\dfrac{H}{V_{max}}}{t_h t_m}\right) = \left[\frac{V}{V_{max}}\left(1 - \frac{V}{V_{max}}\right)\right]^2 \tag{21.11}$$

where the constant C is a function of t_h, t_m and the inclination ρ to the H axis of the major axis of the cross-sectional ellipse. Data from three series of plane strain tests on foundations of different widths on different types and density of sand have a best fit failure surface represented by equation (21.11) with $t_h = 0.52$, $t_m = 0.35$, $\rho = 14°$ and C = 0.22.

The main practical implications of the above are:

- Surface footings are particularly vulnerable to horizontal and moment loading, with $H \approx V_{max}/8$ or $M/B \approx V_{max}/11$ being sufficient to cause failure. For this reason, foundations that are required to carry significant horizontal or moment loads are generally piled (see Chapter 22 *Behaviour of single piles under vertical loads*), or at least buried to some extent.
- The remoteness from the failure surface of a point on the (V–M/B–H) diagram representing a general load will depend on the load path followed to failure. Hence a factor of safety defined as a factor on the collapse load is likely to be ambiguous and potentially unsafe.
- If a surface footing is to be as safe as possible when subjected to a general load increment, the design vertical load should be about $V_{max}/2$.

It is difficult, if not impossible, to achieve a high factor of safety on load for a shallow foundation subjected to a load path that involves an increase in H or M coupled with a reduction in V. This is illustrated in an example given by Powrie (2004).

21.6 Summary

- Classical theory can be used to calculate the bearing capacity of an infinitely long strip foundation on a weightless soil, with the soil above the founding plane acting simply as a surcharge, for both total stress and effective stress failure criteria.
- Empirical adjustment factors are then applied to take account of foundation shape, depth and the self-weight of the soil below the founding plane.
- An inclined and/or eccentric load will affect the bearing capacity of a foundation: either a theoretical or an empirical approach can be used to take this into account, as appropriate.

This chapter concentrates on the prediction of the axial capacity of piles in clay and granular materials. It is stressed that piling is a geotechnical process, controlled by an operator, the outcome of which depends on numerous factors. It is therefore not reasonable to expect to be able to predict pile behaviour with great precision.

The fundamental mechanisms of load–settlement behaviour are described. The traditional approach to pile design in clay is presented using undrained strength as the controlling variable. The limitations of this approach are stressed and particular attention is drawn to the wide scatter of results on which design guidance is based. Because of these limitations, much of the chapter is devoted to the application of the effective stress method for pile shaft design. It is shown to give reasonable predictions of the shaft resistance of piles in soft clays with negative friction. The effective stress approach is also used in correlating the results of pile tests on overconsolidated clays. It is shown that these correlations are much better defined than by using undrained strength. The traditional approaches to the design of driven piles in granular soils are described.

22.1 Introduction

The installation of a pile is rather like other geotechnical processes, such as grouting and tunnelling. In essence, a geotechnical process is controlled by an operator or contractor and the outcome of the process depends on numerous factors – including the ground profile and groundwater conditions (see Chapter 13 *The ground profile and its genesis*), the type of pile (see Chapter 54 *Single piles*), the type of piling plant used, the skill and experience of the operator, and the supervision and quality control. Thus successful delivery of the project depends not only on the design and specification of the piles, but on the process of installation.

It is often said that there are as many theories of pile behaviour as there are piling engineers! What is abundantly clear as one studies the vast literature on the subject is that much of it is highly empirical. As pointed out in Chapter 4 *The geotechnical triangle*, empiricism is a key activity but it must be used rigorously with a clear understanding of the basis of the empiricism.

Even though piling engineering is operator-dependent and so inevitably empirical, nevertheless the behaviour of piles has been shown to depend on basic soil mechanics principles. Understanding these principles provides the key to understanding pile behaviour and the many factors that control it. The aim of this chapter is therefore to describe the basic soil mechanics principles that control the carrying capacity of piles.

This chapter does not cover the specialist subject of piles in rock. For an introduction to this topic the reader is referred to Fleming *et al.* (2009).

22.2 Basic load–settlement behaviour

Figure 22.1(a) shows a straight-shafted pile which has been installed in the ground in some manner and is then loaded by applying an axial load P to the top of the pile. This load is transmitted into the ground by the shaft resistance Q_s and the base resistance Q_b. For simplicity we will assume that the pile is rigid and does not compress under load.

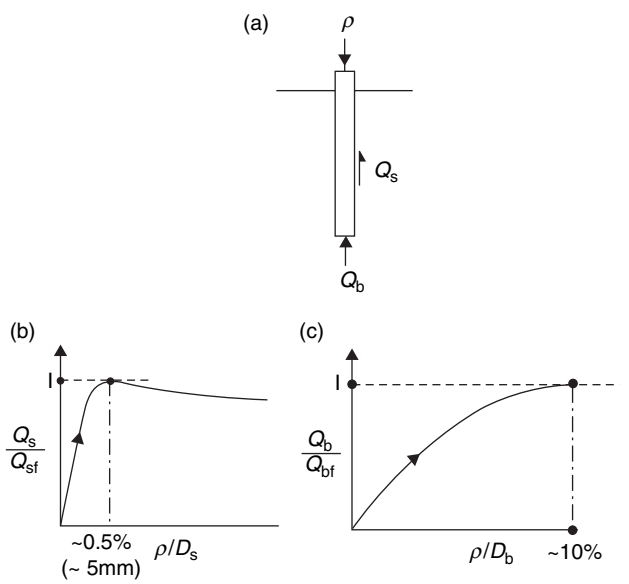

Figure 22.1 Contrasting development of shaft and base resistance with increasing settlement for straight-shafted pile in clay

As the applied load P is steadily increased, settlement ρ of the pile takes place. We will consider separately the development of the shaft resistance and the base resistance as the settlement increases.

22.2.1 Development of the shaft resistance

Figure 22.1(b) shows a graph of the development of the shaft resistance with increasing settlement. The axes are expressed non-dimensionally as Q_s/Q_{sf} versus ρ/D_s where Q_{sf} is the maximum shaft resistance and D_s is the diameter of the shaft. Numerous instrumented pile tests in a variety of ground types have shown that the shaft resistance is fully developed at small settlements. This settlement is usually about 0.5% of the shaft diameter or, alternatively, somewhere between 5 mm and 10 mm for routine pile diameters. Sometimes the shaft resistance reaches a maximum value and then slowly decreases with further settlement; on other occasions it may continue to increase slowly with increasing settlement. It is extremely unusual for the shaft resistance to reduce rapidly and by a large amount after the maximum value has been reached. In this sense, the shaft resistance usually exhibits ductile load–settlement behaviour.

22.2.2 Development of the base resistance

Figure 22.1(c) shows a graph of the development of the base (or end) resistance of a pile with increasing settlement. As for the shaft, the axes are expressed non-dimensionally as Q_b/Q_{bf} versus ρ/D_b, where Q_{bf} is the maximum base resistance and D_b is the diameter of the base. In contrast to the shaft resistance, the base resistance (both for bored and driven piles) requires much larger movements to develop fully – of the order of 10–20% of the base diameter.

22.2.3 Development of the combined resistance

The load–settlement behaviour of a pile is determined by the combined behaviour of the shaft and the base. **Figure 22.2(a)** shows the resultant load–settlement behaviour of a straight-shafted pile in clay, where the base only contributes a small proportion of the ultimate carrying capacity of the pile. The contributions of the shaft and base are shown as broken lines. Such a pile is often referred to as a *friction pile*. This behaviour can be contrasted with the load–settlement behaviour of a pile with an enlarged base, as shown in **Figure 22.2(b)**. In this case, the base makes a much larger contribution to the ultimate carrying capacity of the pile. For such piles, the shaft resistance is often fully developed under working load. Hence a pile with an enlarged base must settle more than a friction pile under working load if it is to operate efficiently.

In summary, it is important to have a clear appreciation of the two very different mechanisms of load transfer – the shaft resistance develops at relatively small settlements, whereas the base resistance requires much larger settlements to fully develop. It is also evident from **Figures 22.2 (a)** and **(b)** that the proportion of the applied load, carried by the shaft and the base, changes as the applied load increases. Thus, for a pile with an enlarged base, whereas under working load the shaft might carry (say) 80% of the applied load, at failure the shaft might only be carrying 20% of the applied load. Having a clear understanding of these two mechanisms of load transfer is very helpful when interpreting the results of pile loading tests.

22.2.4 Measured load–settlement behaviour of an under-reamed bored pile

Whitaker and Cooke (1966) carried out a seminal series of load tests on bored piles in London Clay at Wembley, in which the load carried by the base was measured by means of a sophisticated load cell. Knowing the applied and base loads at any stage of the test, it was possible to deduce the load carried by the shaft.

Figure 22.3 shows the results of one of Whitaker and Cooke's tests. In this case, the diameters of the shaft and base were 0.8 m and 1.7 m respectively and the depth of the pile was 12 m. For the first part of the test the loads on the pile were applied in increments, with the load at each stage being

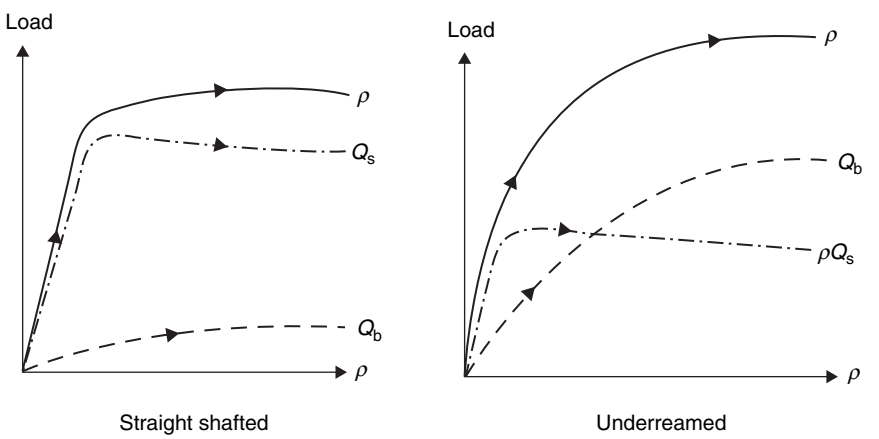

Figure 22.2 Contrasting load–settlement behaviour of (a) straight-shafted and (b) under-reamed piles in clay

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

maintained constant until settlement had practically ceased. In some cases the load was held constant for 30 or more days. The second part of the test consisted of carrying out a constant rate of penetration test on the pile so as to determine its ultimate carrying capacity. The full line in **Figure 22.3** shows the load–settlement behaviour of the pile as a whole. Note that, for clarity, the measurements made during the unload-reload cycle, that took place in changing from incremental loading to constant rate of penetration loading, have been omitted from the figure.

The broken line labelled 'Shaft' in **Figure 22.3** shows the measured load–settlement behaviour of the shaft. It is clear that the carrying capacity of the shaft is fully mobilised at very small settlements. The jagged 'saw tooth' shape of the load–settlement curve is of interest. When an additional increment of load is applied to the pile, the load carried by the shaft initially increases and then reduces as settlement takes place. The temporary increase of load carried by the shaft is a 'rate effect' due to the initial high rate of settlement with time (Burland and Twine, 1988). As the rate of settlement steadily reduces, so the load carried by the shaft reduces back to its previous value – with the reduction in shaft load being shed to the base. It can be seen that the equilibrium fully mobilised carrying capacity of the shaft remains remarkably constant with increasing settlement, confirming the ductile nature of the shaft behaviour as described in section 22.2.1. It is evident from **Figure 22.3** that the measured load–settlement behaviour of the base is dramatically different from that of the shaft, being much 'softer' and with full mobilisation taking place at significant settlements.

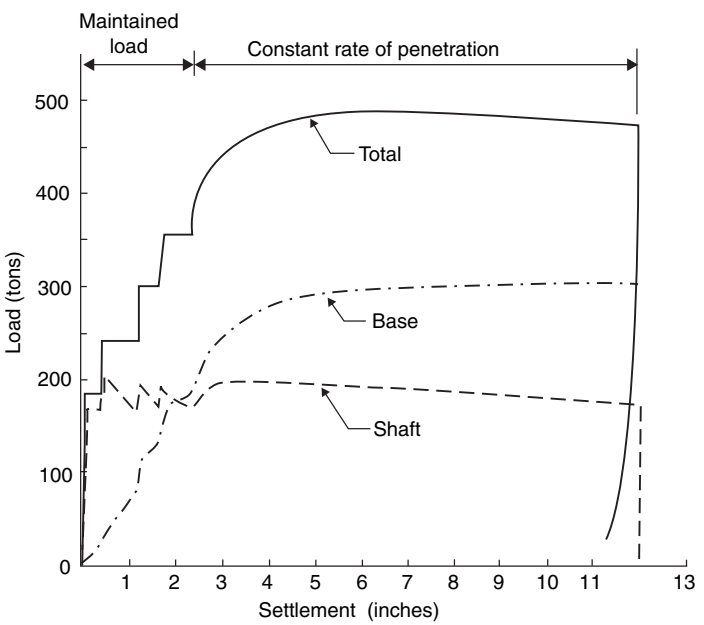

Figure 22.3 Measured load–settlement relationships for instrumented test on an under-reamed pile in London Clay
Reproduced from Whitaker and Cooke (1966)

It is important to note that for working loads in excess of about 170 tons, the pile will be operating with full mobilisation of the shaft-carrying capacity. There must be tens of thousands of large diameter bored piles operating satisfactorily in this way worldwide. As will be described in section 22.4, shaft resistance is essentially a frictional phenomenon, and as such is permanent and reliable – provided the effective stresses acting on the pile do not change significantly.

22.3 Traditional approach to estimating the axial capacity of piles in clay

It has become a well-established tradition to relate the carrying capacity of a pile in clay to undrained strength S_u. This is because undrained strength data are usually included with pile tests' results and it has proved very convenient to attempt to establish correlations between measured pile capacity and undrained strength. Unfortunately this empirical convenience is often overlooked and many piling engineers have come to regard the undrained strength as a fundamental controlling factor. In section 22.4 it is shown that this is not the case for shaft resistance. It is necessary to understand that undrained strength is not a straightforward parameter and this is discussed below.

22.3.1 Undrained strength of clay

The undrained strength of a soil depends on many factors, the following being the principal ones:

(i) *Stress path* For many soils, particularly normally or lightly overconsolidated clays, the undrained strength in plane strain or triaxial extension can differ significantly from the undrained strength measured in triaxial compression, S_{utc}. For soft clays, the strength in plane strain or triaxial extension can be less than the value in triaxial compression and may be as low as half this value.

(ii) *Orientation* The undrained strength usually depends on the orientation of the principal stresses, i.e. the undrained strength is anisotropic.

(iii) *Size* The undrained strength is often critically dependent on the volume of soil being tested. In stiff fissured clays, the undrained strength in the mass may be much less than the average strength of small samples due to the dominant influence of the presence of fissures.

(iv) *Rate* The undrained strength depends on the rate of testing. Usually, the slower the rate, the lower the strength.

(v) *Sample disturbance* This can be a major factor and can operate either way – sometimes reducing strength and sometimes increasing it. A particularly important problem occurs with stiff clays containing saturated silt or sand partings. The stress relief during sampling causes the samples to take up moisture from the partings and soften.

When the above factors are appreciated, it is obvious that different types of test and different sizes of samples give differing

values of S_u. In particular, the values of S_u derived from *in situ* tests such as vane, cone and pressuremeter, will frequently differ from the values measured in triaxial compression. For these reasons, when pile behaviour (in particular shaft resistance) is correlated with undrained strength, it is necessary to be absolutely clear as to how the strength was determined.

22.3.2 Ultimate capacity of whole pile

Figure 22.4 depicts a pile of weight W in a state of failure under a load P_f such that the total shaft resistance is Q_{sf} and the total base resistance is Q_{bf}. The average undrained strength over the length L of the pile is $\overline{S}_{u(shaft)}$ and the undrained strength appropriate to the base is $S_{u(base)}$. For the whole pile at failure:

$$P_f + W = Q_{bf} + Q_{sf} \ . \tag{22.1}$$

The base resistance can be derived from basic bearing capacity theory given in Chapter 21 *Bearing capacity theory* (equation (21.5)):

$$Q_{bf} = A_b[\{N_c \times s_c \times d_c\} \times S_{u(base)} + p_o] \tag{22.2}$$

where A_b is the area of the base and p_o is the overburden pressure (= $\gamma_{bulk}.L$). For a surface strip foundation, the basic bearing capacity factor N_c = 5.14, and for a deep circular or square foundation, the shape factor s_c = 1.2 and the depth factor d_c = 1.46. Hence equation (22.2) can be re-written:

$$Q_{bf} = A_b[9 \times S_{u(base)} + \gamma_{bulk}.L] \ . \tag{22.3}$$

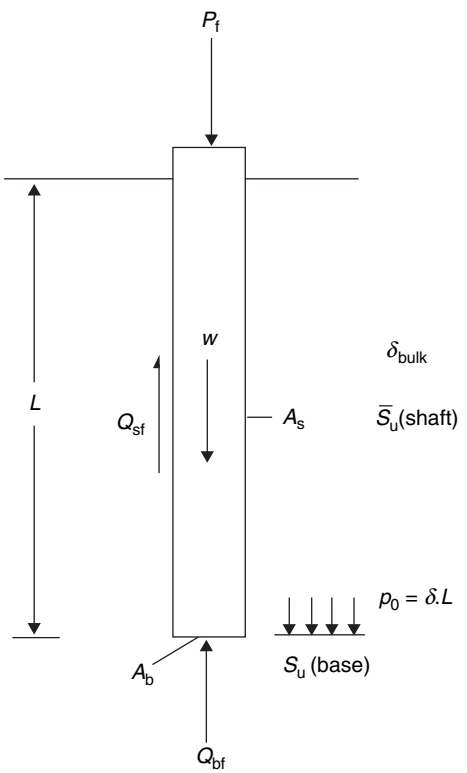

Figure 22.4 Ultimate capacity of a whole pile: a pile of weight W in a state of failure under a load P_f such that the total shaft resistance is Q_{sf} and the total base resistance is Q_{bf}

Undrained strength is used for assessing the base resistance of piles in clay because the undrained bearing capacity is usually much less than the drained bearing capacity, and the end resistance is at its lowest during the application of most of the working load.

For the shaft:

$$Q_{sf} = A_s \times \overline{\tau}_{sf} \tag{22.4}$$

where A_s is the surface area of the shaft and $\overline{\tau}_{sf}$ is the average shaft friction over the length of the shaft. Methods of estimating the value of $\overline{\tau}_{sf}$ are discussed later.

The ultimate capacity of the whole pile is obtained by substituting equations (22.3) and (22.4) into equation (22.1) as follows:

$$P_f + W = A_b[9 \times S_{u(base)} + \gamma_{bulk}.L] + A_s \times \overline{\tau}_{sf} \ . \tag{22.5}$$

The assumption is frequently made that the weight of the pile is equal to the weight of the soil it displaces, so that $W = A_b \times \gamma_{bulk} \times L$ and equation (22.5) simplifies to:

$$P_f = A_b \times 9 \times S_{u(base)} + A_s \times \overline{\tau}_{sf} \ . \tag{22.6}$$

For piles bearing on a strong stratum or with enlarged bases, much of the load at failure will be carried by the base. Hence care is needed in selecting the appropriate value of $S_{u(base)}$ to insert into equation (22.6). When the clay is fissured, the design strength should be close to the lower limit of the scatter of unconsolidated undrained triaxial compressive strengths (Burland, 1990).

22.3.3 Estimation of shaft resistance from undrained strength

Fleming *et al.* (2009) point out that most piles in clay develop a high proportion of their overall capacity along the shaft. Hence the reliable determination of the shaft friction is important. For reasons that were explained at the beginning of this section, it has become traditional to relate the average shaft friction $\overline{\tau}_{sf}$ to the average undrained strength $\overline{S}_{u(shaft)}$ over the length of the shaft such that:

$$\overline{\tau}_{sf} = \alpha \times \overline{S}_{u(shaft)} \ . \tag{22.7}$$

The factor α is known as the 'shaft adhesion factor' and is a purely empirical quantity which has been evaluated from the results of pile tests. It is not a constant but depends on a number of variables.

One of the most important considerations when adopting values of α in design is to be very clear about how the values of $\overline{S}_{u(shaft)}$ were determined in the original empirical correlation. This point can be illustrated by referring to the classic work of

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Skempton (1959) who analysed a number of load tests on cast *in situ* bored piles in London Clay and obtained an average value of $\alpha = 0.45$. He began his study by plotting the results of undrained triaxial tests on 1.5 inch (38 mm) diameter samples against depth, as shown in **Figure 22.5**. Each point represents the average of two to four samples at a given depth. Even so, it can be seen that there is a considerable scatter and this is common for London Clay, due largely to its fissured nature. Skempton drew a mean line through the strength results as shown by the full line. He used this basic line to obtain values of $\overline{S}_{u(shaft)}$ and $S_{u(base)}$ for each of the piles in the study. For each test pile, the value of Q_{bf} was estimated from bearing capacity theory and was subtracted from the measured ultimate load to obtain the value of Q_{sf} and hence the value of $\overline{\tau}_{sf}$ $(= Q_{sf}/A_s)$. **Figure 22.6** shows Skempton's plot of $\overline{\tau}_{sf}$ (y-axis) versus $\overline{S}_{u(shaft)}$ (x-axis). It can be seen that the points correspond to values of $\alpha (= \overline{\tau}_{sf}/\overline{S}_{u(shaft)})$ ranging between 0.3 and 0.6 with an average value of 0.45. Hence the recommended value of $\alpha = 0.45$ is based on two averaging processes of widely scattered data, firstly of the measured strength–depth results, and secondly of the correlation between $\overline{\tau}_{sf}$ and $\overline{S}_{u(shaft)}$.

In recent years, the practice has developed of measuring the undrained strength in triaxial compression using 98 mm rather than 38 mm diameter samples. It has been found that the average strength of 98 mm diameter samples of stiff fissured clay is significantly lower than for 38 mm diameter samples, because the larger samples contain more fissures (Marsland, 1974; Burland, 1990). Hence it is no longer appropriate to adopt a value of $\alpha = 0.45$; a higher value should be used to account for the lower average measured strengths.

Tomlinson (1995) has published design curves of α versus $\overline{S}_{u(shaft)}$ for driven piles in clay, based on the analysis of published and unpublished records of pile tests. In general, the suggested design values of α reduce from about 1 (at low undrained strengths) to as low as 0.25 (for strengths greater than about 150 kPa). The data points on which the suggested design curves are based are illustrated in **Figure 22.7** – which can be seen to show a very wide scatter (Tomlinson, 1971). Similarly, Weltman and Healy (1978) propose curves of α versus undrained strength for bored and driven piles in glacial till, based on data which shows a wide scatter. Hence great care is needed in the application of such design curves which should be regarded as indicative only.

In view of the uncertainties associated with the correlations between the shaft adhesion factor α and the average undrained strength, it is clearly advisable to carry out pile loading tests for specific projects. It is of course vital that the test piles are installed in the same way as the proposed working piles.

22.4 Shaft friction of piles in clay, in terms of effective stress

Section 22.3.3 describes the traditional approach of evaluating shaft friction as a proportion α of the average undrained strength $\overline{S}_{u(shaft)}$ over the length of the shaft. It was pointed out that the

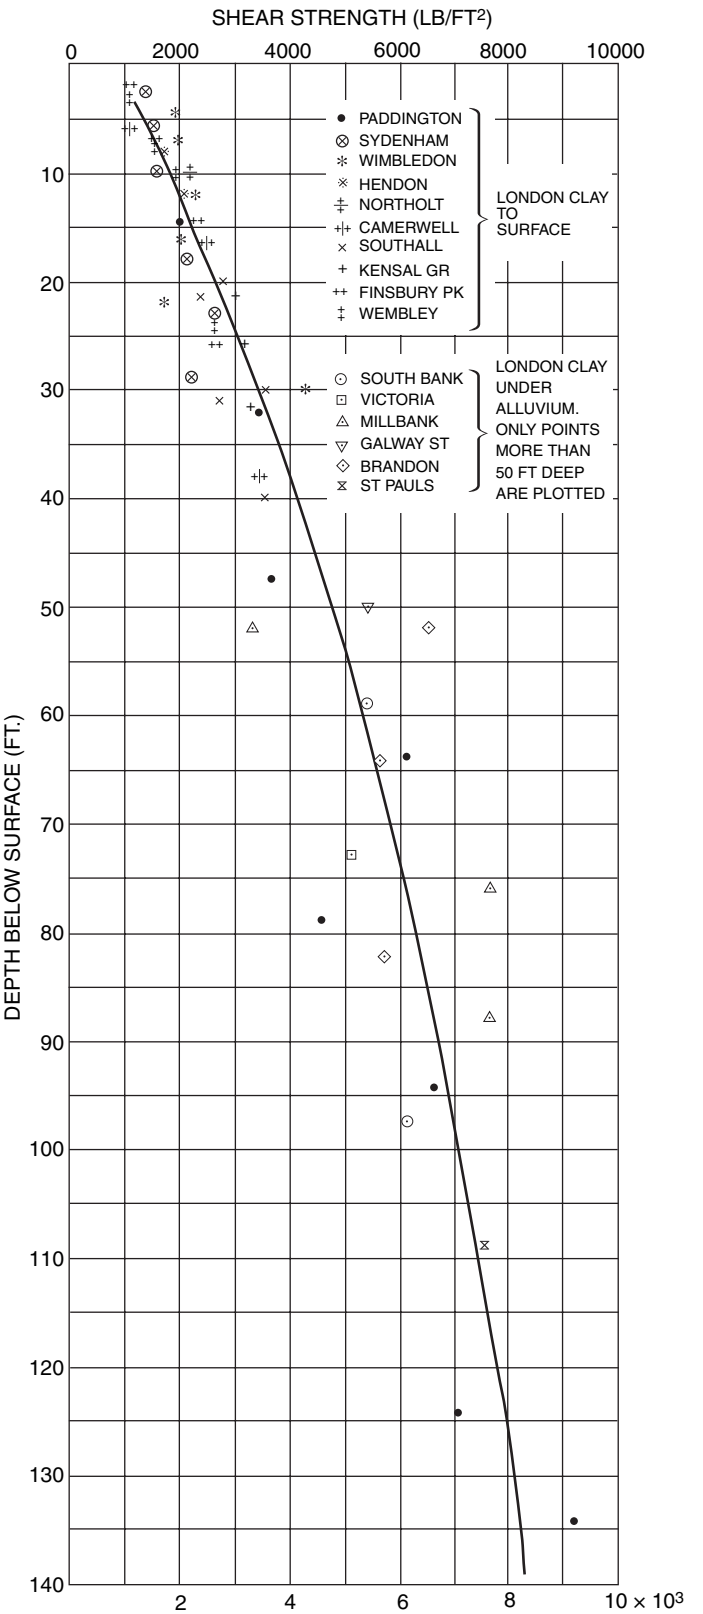

Figure 22.5 Values of average undrained strength S_u plotted against depth from various sites in London
Reproduced from Skempton (1959)

undrained strength does not have a unique value for a soil and is dependent on the test method and the quality of sampling. In stiff clays, the scatter of the undrained strength results can be very large due to the fissured nature of the clay. Examination of the pile test data on which suggested design values of α are based, shows that the scatter is also very large. In addition to these uncertainties, a major problem with the traditional approach to evaluating shaft friction is that it is wholly empirical; there is no fundamental underpinning theoretical framework as an aid to understanding the key factors controlling shaft friction. The effective stress approach also has its limitations but it is soundly based on fundamental soil mechanics principles.

22.4.1 Shaft friction in terms of the effective stress parameter β

The basis of the effective stress approach was first suggested by Johanneson and Bjerrum (1965) in relation to assessment of negative friction. Chandler (1968) suggested it could be

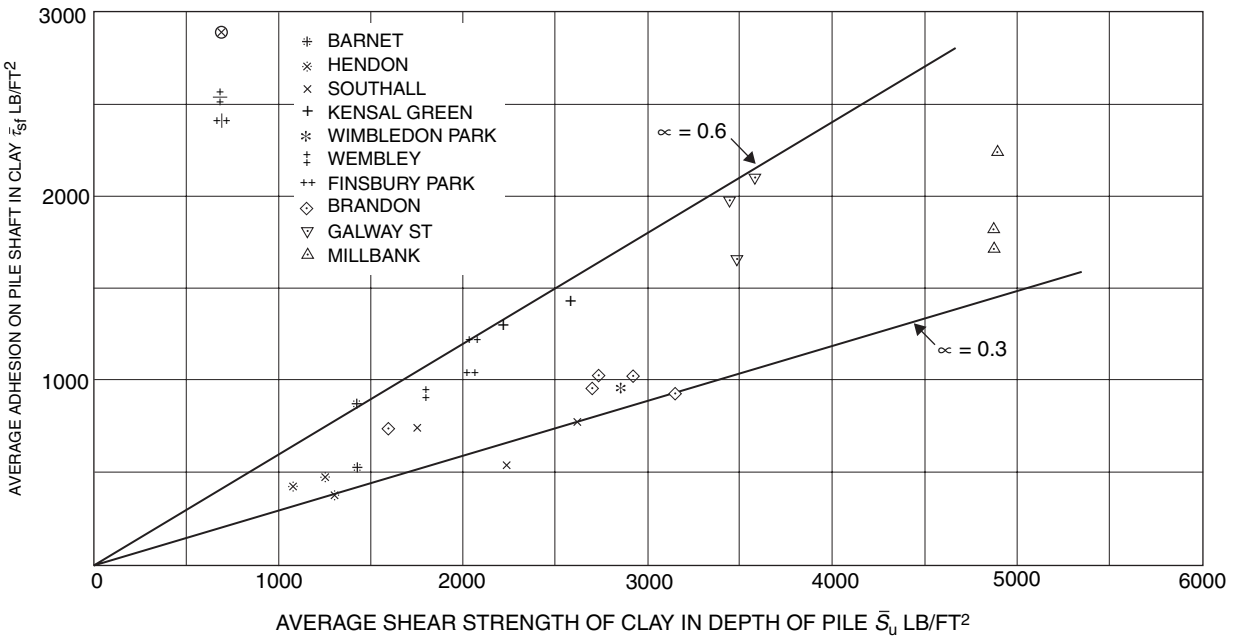

Figure 22.6 Range of measured α values for bored piles in London Clay
Reproduced from Skempton (1959)

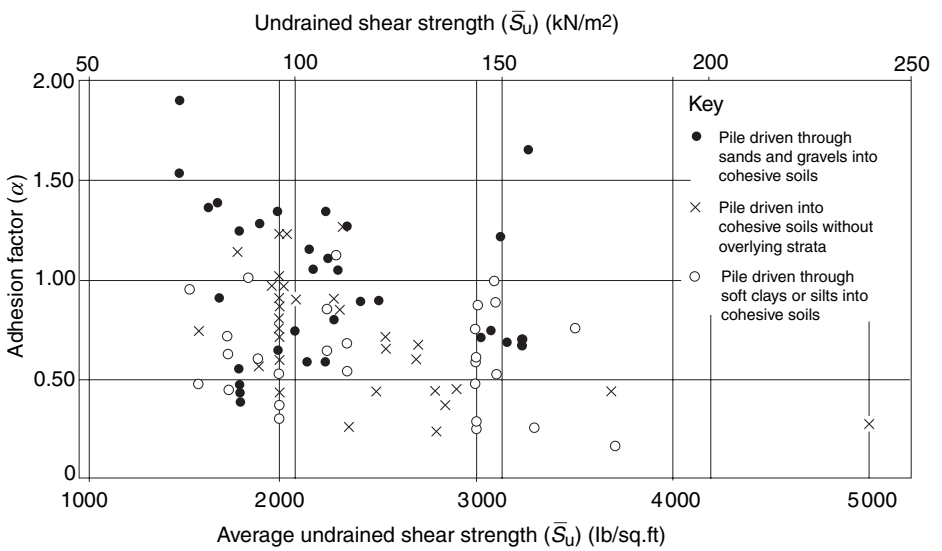

Figure 22.7 Relationship between adhesion factor α and average undrained strength over length of piles embedded in stiff to very stiff clays
Reproduced from Tomlinson (1971)

applied to the interpretation of the results of tests on bored piles in London Clay, and Burland (1973) applied it more generally. Other papers followed, notably by Meyerhof (1976) and Flaate and Selness (1977).

Research on instrumented piles (e.g. Lehane *et al.*, 1994) shows that limiting shaft friction is controlled by the simple Coulomb effective stress interface sliding law:

$$\tau_{sf} = \sigma'_{rf} \tan \delta'_f \tag{22.8}$$

where σ'_{rf} is the radial effective stress acting on the shaft at failure and δ'_f is the effective angle of interface friction at failure. Thus, the problem of evaluating shaft friction at any depth on a pile requires the determination of these two quantities.

The value of the radial effective stress at failure σ'_{rf} depends on the following factors, in approximate order of significance: (a) the vertical effective overburden stress σ'_v; (b) the overconsolidation history of the deposit which can be simplified to the evaluation of the overconsolidation ratio (OCR); (c) the effects of installing the pile; and (d) the change in σ'_r during loading. With regard to (c), it is normally assumed that any excess pore pressures set up during installation are completely dissipated. Regarding (d), it is reasonable to assume that loading takes place under fully drained conditions because the zone of major distortion adjacent to the pile is relatively thin and drainage will take place rapidly.

Because of the dominant influence of the effective self-weight of the surrounding ground and its ease and reliability of determination, the vertical effective overburden stress σ'_v can be incorporated into equation (22.8) as follows:

$$\frac{\tau_{sf}}{\sigma'_v} = \frac{\sigma'_{rf}}{\sigma'_v} \tan \delta'_f = K_{sf} \tan \delta'_f = \beta \tag{22.9}$$

where K_{sf} is the earth pressure coefficient on the shaft at failure. Burland (1973) pointed out that the parameter β can be obtained empirically by direct measurement of τ'_{sf} in pile tests (usually giving mean values $\bar{\beta}$). When determined in this way, β is analogous to the adhesion factor α in equation (22.7) but is much more rigorously defined, since σ'_v can be determined accurately and unambiguously, which we have seen is not the case for the undrained strength S_u. However, not only is β more rigorously defined empirically, but it can be evaluated by measuring δ'_f and determining K_{sf} from soil mechanics principles. Thus the parameter β is a much more clearly defined and fundamental parameter than α is.

22.4.2 Predicted shaft friction of an 'ideal' pile in normally consolidated clay

In this section we investigate the shaft resistance of an 'ideal' pile with a view to establishing a basic frame of reference for comparison with the measured behaviour of actual piles. An 'ideal' pile is one which has been installed in the ground without changing the *in situ* stresses. Moreover, it is assumed that shearing takes place through the remoulded ground next to the pile shaft so that $\delta'_f = \varphi'_{cv}$, the critical state angle of shearing resistance. Hence, for an 'ideal' pile equation (22.9) becomes:

$$\frac{\tau_{sf}}{\sigma'_v} = K_o \tan \varphi'_{cv} = \beta_{ideal} \tag{22.10}$$

where K_o is the earth pressure coefficient at rest – see Chapter 15 *Groundwater profiles and effective stresses*. For a normally consolidated clay, the value of K_o is accurately given by the Jaky expression $(1 - \sin \phi'_{cv})$. It follows that for a normally consolidated clay, equation (22.10) for an 'ideal' pile becomes:

$$\beta_{ideal} = (1 - \sin \varphi'_{cv}) \tan \varphi'_{cv} \ . \tag{22.11}$$

As shown in **Figure 22.8**, whereas K_o and $\tan \phi'_{cv}$ vary widely as ϕ'_{cv} changes, their product (β_{ideal}) changes very little, varying between 0.21 and 0.29 for the range of practical ϕ'_{cv} values. Equation (22.11) provides a basic framework for ideal pile behaviour in normally consolidated clays. Its validity can be tested against real pile behaviour and as a consequence it is possible to judge the extent to which the assumptions that $K_{sf} = K_o$ and $\delta'_{sf} = \phi'_{cv}$ need to be adjusted to account for the measured behaviour.

22.4.3 Comparison between measured and ideal values of β for normally consolidated clays

Burland (1973) compared this 'ideal' behaviour with careful experiments on some driven piles in two very different

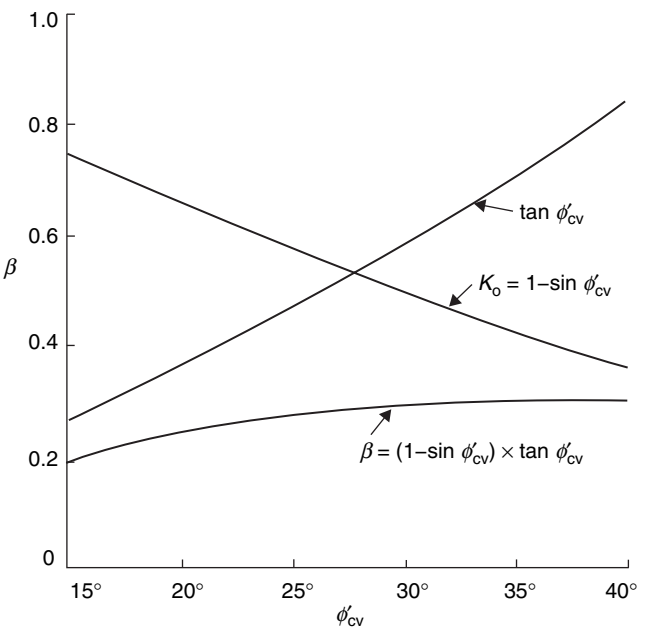

Figure 22.8 Relationship between the effective stress shaft friction parameter β and ϕ'_{cv}
Reproduced from Burland (1973); Emap

normally consolidated clays. **Figure 22.9** shows a plot of deduced average shaft friction $\overline{\tau}_{sf}$ versus average effective overburden pressure $\overline{\sigma}'_{vo}$. All except one of the results plotted in this figure are from tests described by Hutchinson and Jensen (1968) on a number of concrete, steel and timber piles driven into deep estuarine clay in the Port of Khorramshahr, Iran. The average liquid and plastic limits (*LL* and *PL*) for the clay are 48% and 23% respectively, and it has a sensitivity of between 2.5 and 3.0. The deduced values of α ranged from 0.43 to 0.79. It can be seen from **Figure 22.9** that the deduced average values of $\overline{\beta}$ lie between 0.25 and 0.4, with an average value of 0.32. Eide *et al.* (1961) published the results of some long-term tests on a timber pile driven into Drammen clay. The average liquid and plastic limits for this material are 35% and 15% respectively, and the clay has a sensitivity of between 4 and 8. The deduced value of α was 1.6. The black point in the figure corresponds to a deduced value of $\overline{\beta}$ equal to 0.32.

In spite of the clay at the two sites having very different properties and the deduced values of α for the two sites having extreme upper and lower limits for soft clay ranging from 1.6 to 0.42, the average values of $\overline{\beta}$ are the same. This average measured value of 0.32 is slightly larger than the average value for an 'ideal' pile of about 0.27 (corresponding to $\phi'_{cv} = 25°$ in equation (22.10)). Burland (1973) went on to examine a large number of results for driven piles in normally consolidated soils and found that the results lay between $\overline{\beta} = 0.25$ and 0.4. He suggested that a reasonable average design value would be 0.3, a little higher than the value of 0.27 given by an 'ideal' pile.

For a real pile driven into a normally consolidated sediment, it is reasonable to expect that the radial effective stresses would be somewhat larger than the 'at rest' pressures given by K_o, leading to somewhat higher measured values of $\overline{\beta}$. Hence, for the case of most normally consolidated clays, the simple ideal effective stress approach is seen to give very reasonable results. Results from fully instrumented tests on driven piles in a normally consolidated clayey silt give values of β of less than 0.2 (Burland, 1993). Such exceptionally low values are strongly suggestive of arching around the pile due to the highly contractive behaviour of the material.

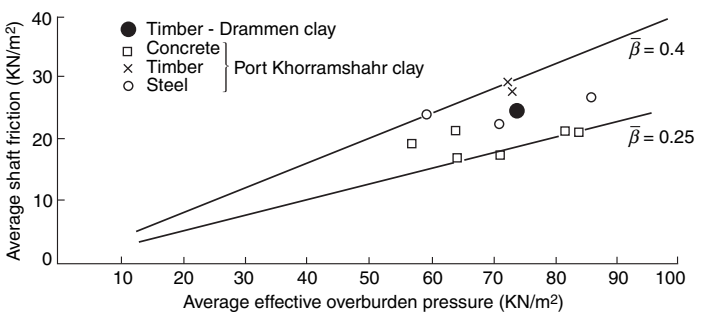

Figure 22.9 Comparison between results of pile tests on Port Khorramshahr clay (*LL* = 48; *PL* = 23; sensitivity = 2.5–3.0; α = 0.43–0.79) and Drammen clay (*LL* = 39; *PL* = 20; sensitivity = 4–8; α = 1.6)
Reproduced from Burland (*1973*); Emap

22.4.4 Negative friction on piles in soft clay

Negative friction, or 'downdrag' can occur on the shaft of a pile installed through a compressible layer of clay which undergoes consolidation. Such consolidation may result from the placing of fill on the surface, groundwater lowering, or even the dissipation of excess pore water pressures set up during pile driving. The consolidating layer exerts a downward drag on the pile and therefore the direction of shaft friction in the layer is reversed. Negative skin friction usually develops gradually as consolidation of the clay proceeds and the vertical and horizontal effective stresses increase with time due to the dissipation of pore water pressure.

Burland and Starke (1994) analysed ten case records in which negative friction had been measured. The results were analysed in terms of the effective shaft friction factor β. The causes of negative friction included surface surcharge, underdrainage and disturbance during pile driving. Both steel- and concrete-driven piles were considered, some of which were end bearing and others 'floating'. The period of measurement varied from a few months up to 17 years.

In spite of the wide range of conditions, average values of β for soft compressible sediments were found to lie within relatively narrow limits of 0.15 to 0.35. A careful study of the soil types revealed that for low plasticity marine clays the values of β were generally in the range 0.15 to 0.25, whereas for higher plasticity clays and silty clays β tended to lie between 0.2 and 0.35. It therefore appears that the values of β operating for negative friction are similar but somewhat lower than those associated with driven-friction piles in soft clays.

22.4.5 Predicted shaft friction of an 'ideal' pile in overconsolidated clay

There can be no doubt that the effective stress approach to shaft friction for piles in soft clays has major advantages over the traditional α approach with all its uncertainties. This is because the coefficient of earth pressure at rest K_o in equation (22.10) is well defined for normally consolidated clays. For overconsolidated clays, the determination of the *in situ* horizontal effective stresses requires very sophisticated *in situ* or laboratory testing, and the effective stress approach is therefore not nearly so straightforward. Nevertheless, establishing the behaviour of an 'ideal' pile in overconsolidated clay provides very useful insights into the factors controlling its behaviour.

As pointed out in Chapter 15 *Groundwater profiles and effective stresses*, for overconsolidated clays which have previously been subjected to a maximum vertical effective stress $\sigma'_{v,\,max}$, the horizontal effective stress caused on first loading tends to remain 'locked in' on unloading, resulting in an

increase in K_o. A widely used empirical equation for capturing this was developed by Mayne and Kulhawy (1982):

$$\frac{\sigma'_h}{\sigma'_v} = K_o = (1 - \sin\varphi'_{cv}) \times OCR^{\sin\varphi'_{cv}} \quad (22.12)$$

where OCR is the overconsolidation ratio (= $\sigma'_{v,max}/\sigma'_{v,current}$). Note that when OCR = 1, equation (22.12) reduces to the Jaky expression $K_o = (1 - \sin\phi'_{cv})$. Substituting equation (22.12) into equation (22.10):

$$\frac{\tau_{sf}}{\sigma'_v} = \beta_{ideal} = (1 - \sin\varphi'_{cv}) \times OCR^{\sin\varphi'_{cv}} \times \tan\varphi'_{cv} \ . \quad (22.13)$$

Hence it would seem appropriate to investigate the relationship between β and OCR. However, since the determination of OCR requires high quality sampling and oedometer testing, there is little available pile test data with which to test equation (22.13). What is needed is some simple indirect measure of OCR. It is well known (Jamiolkowski *et al.,* 1985) that the ratio (S_u/σ'_v) is related to OCR by an expression of the form:

$$S_{utc}/\sigma'_v = (S_{utc}/\sigma'_v)_{nc} \times OCR^m \ . \quad (22.14)$$

where S_{utc} is the undrained strength measured in an unconsolidated undrained triaxial compression test and $(S_{utc}/\sigma'_v)_{nc}$ refers to normally consolidated conditions where m is an empirical coefficient. Solving for OCR in equation (22.14) and substituting in equation (22.13) gives:

$$\beta_{ideal} = (1 - \sin\varphi'_{cv}) \times \tan\varphi'_{cv} \times \left[\frac{S_{utc}/\sigma'_v}{(S_{utc}/\sigma'_v)_{nc}}\right]^{\frac{\sin\varphi'_{cv}}{m}} \quad (22.15)$$

Although equation (22.15) looks rather complicated, it suggests that there should be a relationship between β_{ideal} and S_{utc}/σ'_v. To explore this relationship, equation (22.15) may be considerably simplified as follows.

The term $(1 - \sin\phi'_{cv}) \times \tan\varphi'_{cv}$ equals β_{ideal} for a normally consolidated clay, and we have seen that β_{ideal} changes very little with changes in ϕ'_{cv}. It is reasonable to set it equal to 0.27, corresponding to $\phi'_{cv} = 25°$. It is well known (Burland, 1990) that for normally consolidated natural clays the ratio $(S_{utc}/\sigma'_v)_{nc}$ is remarkably well defined, generally varying between about 0.28 and 0.32; a mean value of 0.3 can reasonably be adopted. A major uncertainty exists over the likely range of m and hence equation (22.15) can be simplified to:

$$\beta_{ideal} = 0.27\left[\frac{S_{utc}/\sigma'_v}{0.3}\right]^E \quad (22.16)$$

where E is an empirically determined exponent. This work suggests that there is likely to be a relationship between the effective shaft friction factor β and the undrained compressive strength normalised by the effective overburden pressure S_{utc}/σ'_v.

22.4.6 Measured values of β for driven piles in overconsolidated clays

Flaate and Selnes (1977) published the results of a number of pile tests on timber and concrete piles driven into normally and lightly overconsolidated clays. Semple and Rigden (1984) assembled an extensive database for piles driven into overconsolidated clays which formed the basis of guidance by the American Petroleum Institute for many years. After following the reasoning described in the previous section, Burland (1993) plotted these two sets of data on a graph of β versus S_{utc}/σ'_v and demonstrated that there is a very satisfactory correlation. Chow (1996) added significantly to these two databases and Patrizi and Burland (2001) showed that the effective shaft friction factor could be accurately represented by the expression:

$$\beta = 0.1 + 0.4(S_{utc}/\sigma'_v) \ . \quad (22.17)$$

The solid line in **Figure 22.10** shows the comparison between the results from the three databases and equation (22.17). The insert shows the data points for values of $S_{utc}/\sigma'_v < 1$ plotted to a larger scale. (It is of interest to note that the broken line plotted in this figure is given by equation (22.16) for an 'ideal' pile with the empirical exponent $E = 0.72$). The open points in **Figure 22.10** are for low plasticity clayey silts and it can be seen that there is a tendency for the values of β to be somewhat lower for these materials – a result referred to previously in sections 22.4.3 and 22.4.4.

It is necessary to mention that the values of S_{utc} are determined for intact samples of clay. If the clay is fissured, the values of undrained strength will not be representative of the intact material and are likely to be significantly lower than the intact strengths. When plotting results from tests, this leads to points lying significantly above the line given by equation (22.17) and when using this equation for predicting design values of β, they are likely to be significantly underestimated.

Patrizi and Burland (2001) demonstrated that the correlation between equation (22.17) and the results of the database is very good. An even better correlation can be obtained using the Imperial College Pile (ICP) design methods developed by Jardine *et al.* (2005), which are based on instrumented pile tests driven into both sands and clays. These approaches have been developed for the offshore industry and require advanced laboratory and *in situ* tests.

22.4.7 The effective stress behaviour of bored piles in stiff fissured clays

Burland (1973) developed the following expression for the average shaft friction $\overline{\tau}_{sf}$ for an 'ideal' pile in overconsolidated clay, which takes account of the variation of K_o with depth:

$$\overline{\tau}_{sf} = \frac{1}{L}\sum_0^L \sigma'_v \times K_o \times \tan\delta'_f \times \Delta L \quad (22.18)$$

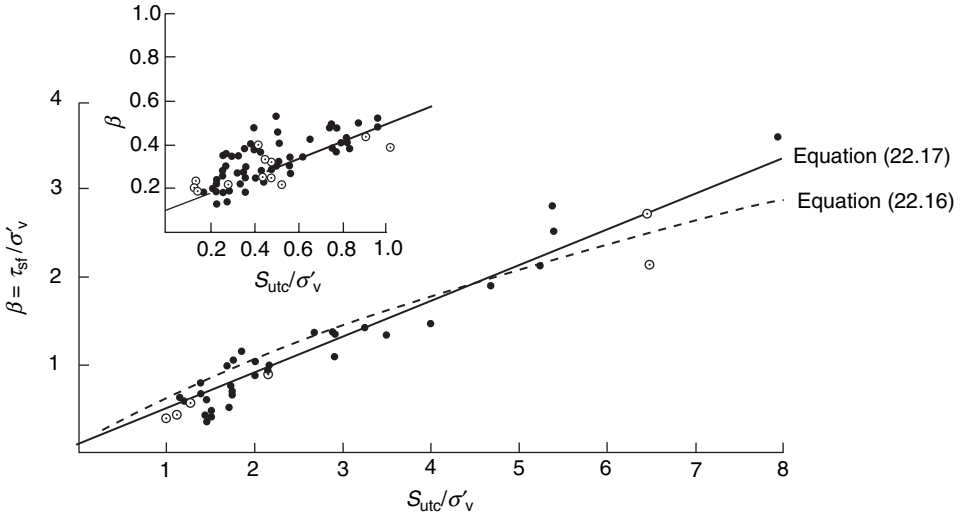

Figure 22.10 Driven piles in clay - relationship between the effective stress shaft friction parameter β and S_{utc}/σ'_v where S_{utc} is the *intact* unconsolidated undrained strength in triaxial compression. (This correlation is not appropriate for fissured clays for which S_{utc} is not representative of intact strength)

For London Clay, the variation of K_o with depth was determined by Skempton (1961) and Bishop *et al.* (1965) and an average distribution adopted. The assumption for an 'ideal' pile that $\delta'_f = \phi'_{cv} = 21.5^o$ was also made. **Figure 22.11** shows a plot of average shaft friction τ_{sf} versus average depth in clay. The full line was obtained from equation (22.18) and represents the predicted values of average shaft friction of 'ideal' piles in London Clay.

The open points plotted in **Figure 22.11** represent the average measured shaft friction deduced from maintained load tests on instrumented piles carried out at Wembley by Whitaker and Cooke (1966), previously referred to in section 22.2.4. It can be seen that, apart from one outlier, the results show relatively little scatter and give measured values of average shaft friction which are less than the 'ideal' values. Burland (1973) attributed this to the effect that the boring of the pile had on reducing the equilibrium value of the horizontal effective stress to below the 'at rest' K_o condition assumed for the 'ideal' pile.

Burland and Twine (1988) re-examined the Wembley data and concluded that the main reason for the measured values of $\overline{\tau}_{sf}$ being less than the 'ideal' values was that the angle of interface friction δ'_f was close to the residual angle of shearing resistance ϕ'_r, having values as low as 12°. Various causes for this were suggested – the two most probable being (i) the upward and downward passage of the auger causing a smooth surface of highly orientated clay particles; and (ii) thermal shortening of the shaft of only a few millimetres would be sufficient to induce a residual shear surface over much of the length of the pile. Burland and Twine also concluded that constant rate of penetration (CRP) testing must be interpreted with considerable caution, as current rates of testing can lead to a significant over-estimation of the shaft resistance under static load.

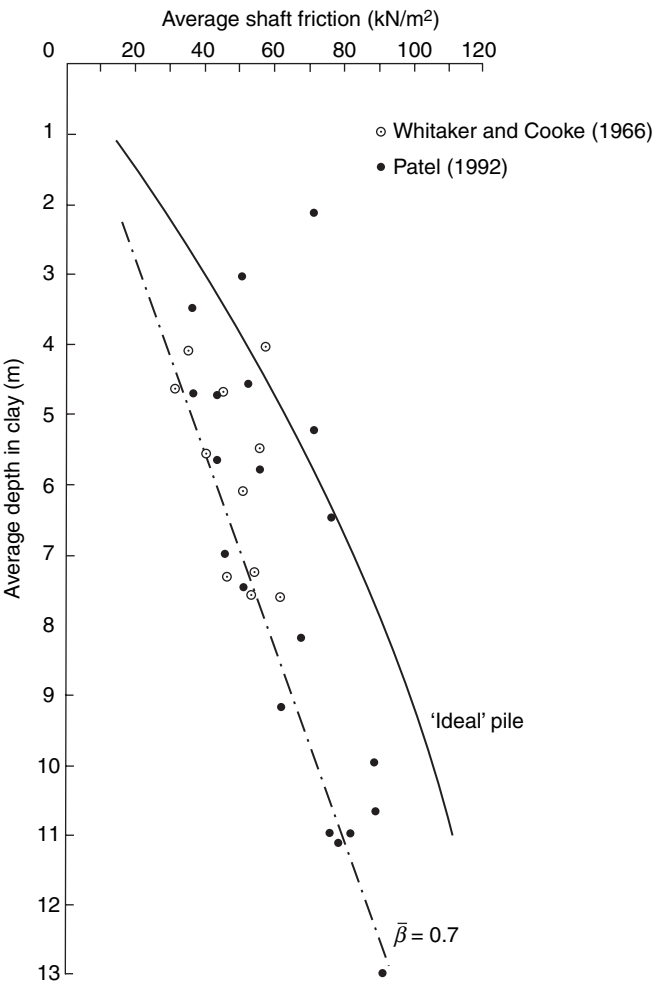

Figure 22.11 Relationship between measured average shaft friction and average depth in clay for bored piles in London Clay

Patel (1992) analysed a number of load tests on bored piles from 28 different sites in London. Maintained load tests were carried out at 16 of these sites and the shaft resistances were evaluated by subtracting the calculated base resistances from the ultimate resistance of the pile. The full points in **Figure 22.11** show the deduced values of $\bar{\tau}_{sf}$. Once again, apart from two outliers at shallow depth, the scatter is remarkably small. The chain dotted line representing a value of $\bar{\beta} = 0.7$ is close to the lower limit of the scatter and would be appropriate for design purposes for bored piles in London Clay (i.e. $\bar{\tau}_{sf} = 0.7 \times \bar{\sigma}'_v$). Patel (1992) also confirmed the conclusion of Burland and Twine (1988) that the use of CRP tests can overestimate the true values of shaft friction by up to 20% due to rate effects.

The use of **Figure 22.11** for assessing shaft friction in terms of effective stress for bored piles in London Clay offers a very simple and dependable method which is based on highly reliable load tests. It can provide a valuable check when using the traditional α method described in section 22.3.3, or when interpreting the results of pile tests. The approach is particularly appropriate for assessment of shaft resistance where long-term changes in effective stress will occur, as is the case beneath a deep excavation or where changes in ground water level are taking place. The traditional α method of assessing shaft friction is completely inappropriate for such conditions.

More generally, when analysing the results of pile tests in clay, it is worthwhile plotting the deduced values of $\bar{\tau}_{sf}$ against average depth in clay and evaluating the associated values of $\bar{\beta}\,(= \bar{\tau}_{sf}/\bar{\sigma}'_v)$. In this way, the basic data are allowed to speak for themselves without the confusion caused by correlating the results with average undrained strength and all the uncertainties that are associated with it. Bown and O'Brien (2008) have shown that when reliable methods are available for measuring σ'_{ho} (namely the *in situ* horizontal effective stress), equation (22.8) can be applied directly. They proposed that the average shaft friction of a bored pile in stiff plastic clay can be expressed as:

$$\bar{\tau}_{sf} = c.\bar{\sigma}'_{ho} \tan \delta'_f \qquad (22.19)$$

where c is a reduction factor for installation effects with values varying typically from 0.9 to 0.8, and decreasing with depth. For London Clay, a value of effective angle of interface friction $\delta'_f = 16^\circ$ was found to be appropriate.

22.5 Piles in granular materials

Piles in granular soils usually act primarily in end bearing and, unlike many piles in clay, shaft friction usually contributes only a small proportion of the load-carrying capacity. It is extremely difficult to obtain reasonably undisturbed samples of granular soils from boreholes. Moreover, the process of driving the pile will inevitably change the density of soil which will significantly affect the carrying capacity of both the base and the shaft. These facts, in addition to the inherent variability of granular deposits, make the prediction of pile behaviour by analytical methods both difficult and unreliable. It is therefore the usual practice to assess the ultimate bearing capacities of piles in these soils from the results of *in situ* tests.

Carrying capacity can be assessed on the basis of:

- bearing capacity theory aided by standard penetration tests (SPTs);
- cone penetrations tests (CPTs);
- pile driving formulae.

22.5.1 Bearing capacity theory

Equation (21.4) in Chapter 21 *Bearing capacity theory* gives the basic bearing capacity equation for a granular soil. For the tip of a pile the self-weight term involving N_γ becomes negligibly small. Moreover the shape and depth factors, s_q and d_q respectively, may be subsumed into the bearing capacity factor for surcharge N_q. Hence the ultimate base resistance of a pile in embedded a granular soil becomes:

$$q_{bf} = N_q \times \sigma'_v \,. \qquad (22.20)$$

A wide range of values for N_q are quoted in the literature, but perhaps the most generally accepted are those given by Berezantzev *et al.* (1961). **Figure 22.12** shows their proposed relationships between N_q (which include s_q and d_q) and the effective angle of shearing resistance ϕ' adapted by Tomlinson (1995). If the depths of penetration of the pile into the granular material are less than about five times the pile width, values of N_q corresponding to a surface footing should be used – see Chapter 21 *Bearing capacity theory*.

Evaluation of N_q in equation (22.20) requires knowledge of the effective angle of shearing resistance of the soil ϕ'. This is often done by making use of the well-known relationship

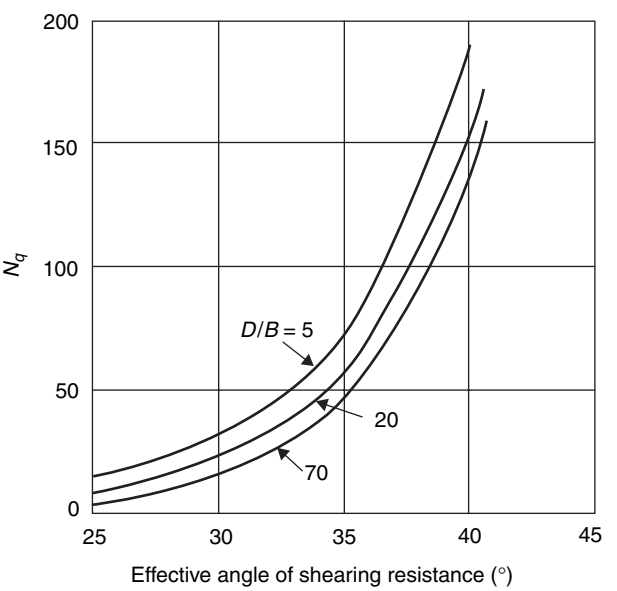

Figure 22.12 Relationship between N_q and ϕ'
Reproduced from Berezantsev *et al.* (1961); all rights reserved

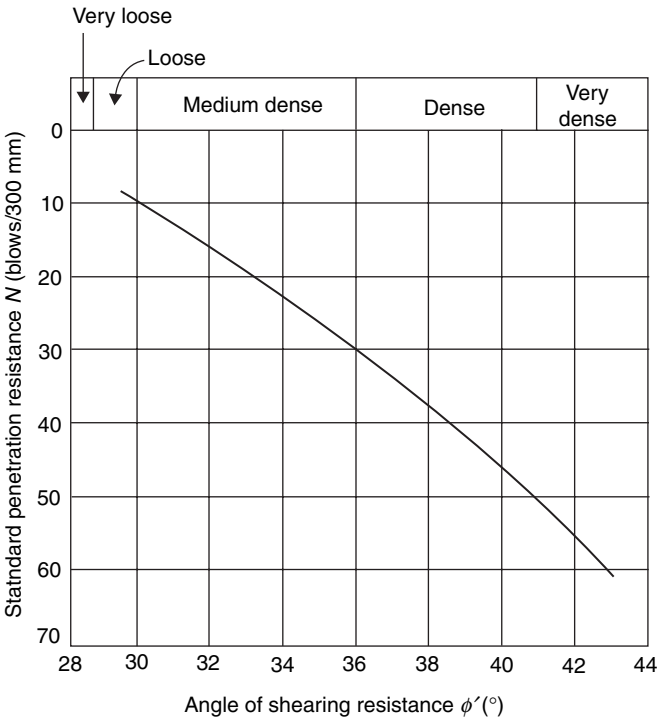

Figure 22.13 Relationship between SPT *N*-values and ϕ'
Reproduced from Peck *et al.* (1967); John Wiley & Sons, Inc.

between SPT *N*-value and ϕ' proposed by Peck *et al.* (1967), illustrated in **Figure 22.13**.

The expression for the ultimate shaft friction τ_{sf} is identical to equation (22.8) and can be re-written:

$$\tau_{sf} = \sigma'_v \times K_{sf} \times \tan \delta'_f \qquad (22.21)$$

where K_{sf} is the earth pressure coefficient against the pile shaft at failure and δ'_f is the angle of interface friction along the shaft.

There are various rules for evaluating δ'_f in equation (22.21). For a concrete or rough steel interface it appears that $\delta'_f \approx \phi'_{cv}$. For smoother interfaces, Jardine *et al.* (1992) conclude that δ'_f is a function of mean particle size (D_{50}) and varies from about 34° to 22° as D_{50} increases from 0.05 mm to 2.0 mm.

The evaluation of K_{sf} in equation (22.21) presents a real problem as it depends largely on the initial density of the soil, the pile installation method, and the volume of the displaced soil. Broms (1965) suggested the following values of K_{sf} in granular soils:

Type of pile	Loose	Dense
Steel	0.5	1.0
Concrete	1.0	2.0
Timber	1.5	3.0

Fleming *et al.* (2009) argue that the value of K_{sf} varies in a similar fashion to N_q and may be estimated from the expression

$$K_{sf} = N_q/50 \ . \qquad (22.22)$$

22.5.2 Methods based on static cone penetration tests

Methods based on CPTs are widely used for the design of offshore piles and their use on land is increasing. The electric cone provides a profile with depth of end resistance q_c and sleeve friction f_s which can be used for the design of driven piles. A brief description of the equipment is given by Simons *et al.* (2002).

Where the pile is deeply embedded in the granular layer, the tip of the cone may be regarded as a model of the base of the pile. Hence the base resistance of the pile q_{bf} is taken as equal to the cone resistance q_c. However the cone normally gives a fluctuating resistance with depth and requires careful interpretation. The currently accepted method of taking account of these fluctuations in deriving q_{bf} for a deeply embedded pile is given by Thorburn and Buchanan (1979) as follows:

$$q_{bf} = 0.25q_{co} + 0.25q_{c_1} + 0.5q_{c_2} \qquad (22.23)$$

where:

q_{co} = the average static cone resistance over a distance of two pile diameters below the pile base;

q_{c1} = the minimum cone resistance over the same distance below the pile base;

q_{c2} = the average of the minimum cone resistances over a distance above the pile base, neglecting any values greater than q_{c1}.

In situations where the cone resistance decreases to depths below the pile base greater than or equal to 3.5 pile diameters, the following expression gives a reasonable prediction of the ultimate base resistance:

$$q_{bf} = 0.5q_{cb} + 0.5q_{ca} \qquad (22.24)$$

where

q_{cb} is the average cone resistance over a distance below the pile base equivalent to 3.5 pile diameters and is determined from the following expression:

$$q_{cb} = \frac{q_{c1} + q_{c2} + q_{c3} + \ldots q_{cn}}{2n} + n.q_{cn} \ . \qquad (22.25)$$

q_{ca} is the average cone resistance over a distance above the pile base equivalent to 8 pile diameters, neglecting any values greater than q_{cn};

q_{c1}, q_{c2}, q_{c3}, … q_{cn}, are the cone resistances at regular intervals to a depth of 3.5 pile diameters below the pile base, q_{cn} being the lowest resistance at this depth.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

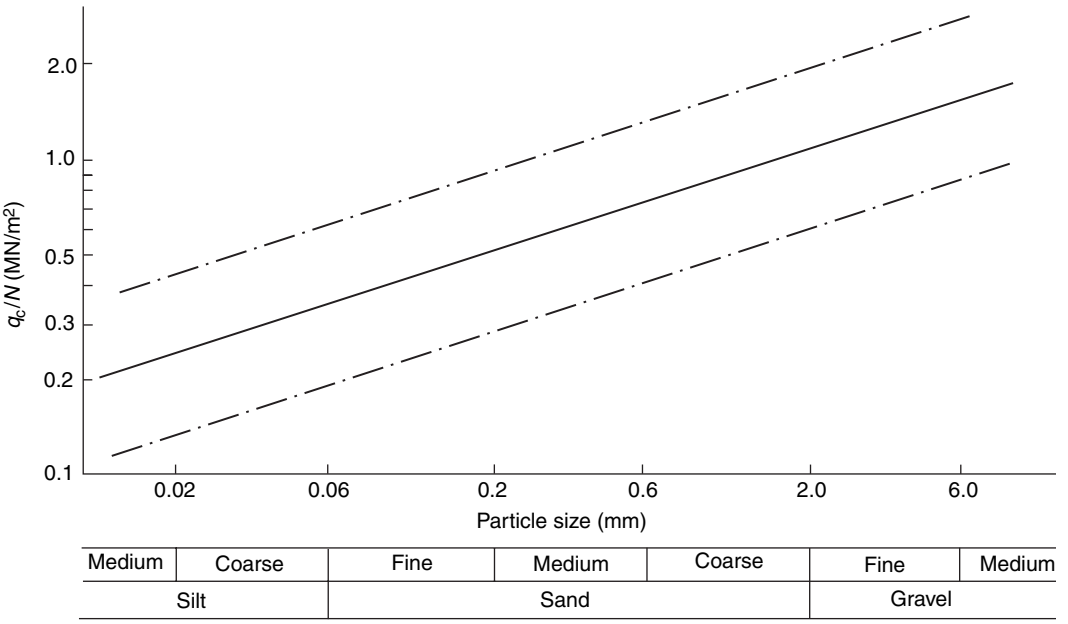

Figure 22.14 Relationship between q_c/N and grain size
Reproduced from Burland and Burbidge (1985)

The compressed rules given by Beringen *et al.* (1979) are broadly in agreement with the above.

De Beer *et al.* (1979) present some case histories of piles penetrating only a small distance into dense sands. They show that for small penetrations the end resistance of a pile can be significantly less than that given by the cone resistance. Various methods have been proposed to make allowance for this important scale effect. The method proposed by de Beer (1963) is widely used but is believed to be very conservative.

The results of CPTs are regularly used for predicting shaft friction τ_{sf}. This is usually taken as some fraction of the cone tip resistance q_c. Thorburn (1979) recommends that for sands $\overline{\tau}_{sf} = q_{c(ave)}/200$ where $q_{c(ave)}$ is the average point resistance over the embedded length of the pile. For silts, he recommends that $\overline{\tau}_{sf} = q_{c(ave)}/150$. For driven H-piles in granular materials, Meyerhof (1976) recommends $\overline{\tau}_{sf} = q_{c(ave)}/400$.

22.5.3 Methods based on standard penetration tests

In section 22.5.1, reference was made to the use of SPTs for evaluating the angle of shearing resistance ϕ' for use in the bearing capacity equation (22.20). Some approaches to pile design are based on direct empirical correlations between SPT blow count N and allowable end bearing and shaft friction – see, for example, GEO (1996) for bored piles in completely decomposed granite in Hong Kong. It is most important that the basis of the correlations is understood when using them, and that the piling method and ground conditions are appropriate.

When CPT tests are not available, a reasonable approach is to convert the SPT N values to equivalent cone resistance q_c using the graph in **Figure 22.14** (Burland and Burbidge, 1985). The methods outlined in section 22.5.2 can then be applied.

22.5.4 Pile driving formulae

Because of the uncertainties in predicting the carrying capacity of piles driven into granular materials, it has long been recognised that the driveability of a pile should provide a useful measure of its static carrying capacity. Moreover, in variable ground conditions, the driving record of each pile should be a good indicator of its quality. It is therefore not surprising that many attempts have been made to determine the relationship between the dynamic resistance of a pile during driving and the static load carrying capacity of the pile.

Whitaker (1975) has carried out a detailed review of a number of the better known pile driving formulae. The purpose of this section is to provide a brief introduction to the subject. Driving formulae assume an energy balance between the dynamic input energy (= $\eta.W.h$) of the hammer and the work (= $R(s+c/2)$) required to displace the pile permanently by a small amount s, where:

η = the efficiency of the hammer;

W = the weight of the hammer;

H = the drop height;

R = the pile resistance;

s = the permanent set of the pile;

c = the elastic, or recoverable movement of the pile.

Hence:

$$R = \frac{\eta.W.h}{(s + c/2)} . \qquad (22.26)$$

According to the widely used Hiley formula of 1925 the efficiency is given by:

$$\eta = \frac{k(W + e^2 W_p)}{W + W_p} \tag{22.27}$$

where

k = the output efficiency of the hammer;

W_p = the weight of the pile;

e = the coefficient of restitution between the hammer and the pile cushion.

Typical values of k and e are given by Whitaker (1975), and Fleming *et al.* (2009). In applying any pile driving formula, the fundamental assumption is made that the driving resistance R is equal to the ultimate static bearing capacity of the pile. This assumption can be significantly in error, particularly in clay soils, fine granular soils and cemented soils such as chalk. Whitaker (1975) and Tomlinson (1995) give valuable guidance on the practical application of pile driving formulae and more sophisticated forms of dynamic analysis.

22.5.5 Concluding remarks on piles in granular materials

The present state-of-the-art on the prediction of pile capacity in granular soils is such that pile loading tests should be carried out, if at all possible. Driving resistance records on all piles should be kept (blows per 0.2 m or 0.5 m penetration). These can be useful, particularly when correlated with loading tests at the site. Beware of pile heave due to adjacent pile driving – this is particularly important with saturated fine grained granular soils, i.e. silts. It may be necessary to re-drive some of the piles.

22.6 Overall conclusions

- The installation of a pile is a geotechnical process, controlled by an operator, the outcome of which depends on numerous factors. In these circumstances it is not reasonable to expect to be able to predict pile behaviour with great precision.
- Methods of prediction of pile behaviour are inevitably highly empirical. It is therefore important to seek to understand the basis of any empirical factor or correlation that is used, and the likely range of prediction.
- The load–settlement behaviour of a pile results from the summation of two very different mechanisms. The shaft resistance is essentially frictional and is fully mobilised at small settlements – typically about 0.5% of the shaft diameter or 5–10 mm. The behaviour of the shaft is usually ductile in the sense that little reduction in carrying capacity takes place, with continued settlement after full mobilisation. The full mobilisation of the base resistance requires much larger settlements than the shaft – typically 10–20% of the base diameter. Having a clear understanding of these two mechanisms of load transfer is very helpful when interpreting the results of pile loading tests.
- Basic undrained bearing capacity theory can be used to calculate the base resistance of a pile in clay. Usually the average undrained strengths from unconsolidated undrained triaxial compression tests (S_{uc}) are used for this purpose. In stiff fissured clays, for which the undrained strengths usually show considerable scatter, the *in situ* operational strength is close to the lower limit of the scatter and should be used for design purposes.
- Traditionally, the measured shaft friction τ_{sfh}' of piles in clay has been correlated with undrained strength (i.e. $\tau_{sf} = \alpha.S_u$) for the simple reason that undrained strength data are usually included with pile test results. This approach has serious limitations. It has been shown that the undrained strength of a particular soil is not a unique quantity and can show considerable scatter. The value of α has been shown to vary over wide limits. Frequently published design curves relating α to undrained strength do not include the enormous scatter on which they are based. It is essential that the engineer is fully aware of these limitations as they are frequently glossed over.
- It is because of these serious limitations that much of this chapter has been devoted to the determination of shaft friction in terms of effective stress. It is now clear beyond all reasonable doubt that shaft friction is controlled by the simple effective stress Coulomb sliding law given by equation (22.8). This equation can be normalised by the vertical effective stress and re-written as:

$$\frac{\tau_{sf}}{\sigma_v'} = \frac{\sigma_{rf}'}{\sigma_v'} \tan\delta_f' = K_{sf} \tan\delta_f' = \beta \,. \tag{22.28}$$

- The effective stress shaft friction parameter β can be obtained empirically from pile tests and is much more rigorously defined than α, since σ_v' can usually be accurately determined. The value of β can also be obtained from fundamental soil mechanics principles to give 'ideal' values, which can be used for judging the influence of various installation and operational processes.
- It has been shown that for driven piles in normally consolidated clays, measured values of $\overline{\beta}$ are well defined, lying between 0.25 to 0.4 – a little larger than the 'ideal' values.
- The effective stress approach is really the only viable approach to evaluating negative friction or 'down drag'. It has been shown that local values of β lie between 0.15 and 0.25 for low plasticity clays, whereas for high plasticity clays the values lie between 0.2 and 0.35.
- An approach is outlined for applying the effective stress method to overconsolidated clays when values of K_o are not known. It is shown that a theoretical relationship exists between β and S_{utc}/σ_v', where S_{utc} is the *intact* undrained strength in unconsolidated triaxial compression. Three large databases for driven piles in clay have been used to show that there exists a simple approximately linear relationship between β and S_{utc}/σ_v'.
- The effective stress method has been applied to bored piles in London Clay for which the distribution of K_o with depth is approximately known. The 'ideal' curve has been compared with a number of incremental load tests from various parts of London. The measured values are significantly less than the ideal values – the reason is believed to be that the angle of interface friction for traditional bored piles in London Clay operates close to residual

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

strength rather than critical state strength, which was assumed in the 'ideal' case.

- For bored piles in London Clay, the simple effective stress relationship $\bar{\tau}_{sf} = 0.7 \times \bar{\sigma}'_v$ is close to the lower limit of the scatter in **Figure 22.11** and is appropriate for design purposes. More generally, it is argued that there is a strong case for presenting the results of tests on bored piles in stiff clays in terms of average shaft resistance versus depth, with the appropriate values of $\bar{\beta}$ drawn in.
- Piles in granular material act primarily in end bearing. Because of the difficulty of obtaining undisturbed samples of granular soils, considerable reliance is placed on the use of *in situ* tests for evaluating the end and shaft resistance. The standard empirical methods of applying the results of CPTs and SPTs to pile design are described.
- A brief introduction is given to the application of pile driving formulae and their limitations.

Chapter 23
Slope stability

Edward N. Bromhead Kingston University, London, UK

This chapter explores the basics of slope stability and how relative stability is calculated using a limit equilibrium approach. It discusses the principles of slope stabilisation as they impact on the analysis required, and makes recommendations regarding the management of slope instability risks within the context primarily of the analysis.

23.1 Factors affecting the stability and instability of natural and engineered slopes

23.1.1 Introduction

It is customary to consider the problems of natural slopes as being distinct from those of engineered slopes, and in the latter to discriminate between cut (excavated) slopes and filled slopes, despite many of the technical issues being the same. Filled slopes give the engineer the option of controlling the material properties of the soils involved as well as controlling the shape of the resulting slope, whereas in both cut and natural slopes the geological succession and resulting properties are whatever nature presents. In cut slopes, one at least has the possibility of forming them to a desired shape, but in natural slopes, again, the engineer has often to deal with what is there.

Engineered slopes are created in connection with urban development, transportation routes, dams, mining and quarrying, municipal waste disposal and numerous other construction activities requiring the formation of excavations, and in building mounds. Where the available space does not permit stable slopes to be created, retaining structures are required (Section 6 of this manual).

Natural slopes present stability problems associated with contemporary coastal and river erosion; the erosion processes cause oversteepening. In addition, the range of processes that form hills and valleys commonly leave hill slopes in a state where they can be readily destabilised. For example, extremes of rainfall or modest earthworks may cause hitherto dormant soil masses that were at one time unstable to move again.

Many engineers would further distinguish between rock slopes and soil slopes, where in the former the behaviour is characterised largely by failure primarily along pre-existing discontinuities such as joints and faults, and much less so through the intact material and *vice versa*. However, many soil slopes fail along bedding, or weak layers constructed into a fill, so that such a distinction is somewhat arbitrary. The rest of this chapter deals primarily with soils.

23.1.2 Factors giving rise to slope failure

Factors giving rise to slope failure comprise external and internal geometric factors, intrinsic properties of the materials involved, the presence of discontinuities and other structural weaknesses (which may in part be due to geological causes and reflect the processes by which the soils were formed or emplaced), the presence of fluids (air and water) in the soil, and processes of weathering or ageing – some of which relate to long-term fluid pressure changes. Much of the loading in a soil comes from self-weight, but some slopes may be subjected to external loads from foundations and anchorages, and stresses induced dynamically, of which the most obvious is seismic shaking.

External geometric factors include its height and slope angle, and its shape, both in section and plan. Internal geometric factors include the disposition of different material types inside the slope. It is extremely common to find that failure in an engineered slope occurs because a weak layer was left in place in an embankment within its foundation, or in a cut slope within the body of the soil mass. Natural deposits, particularly of sedimentary origin, often contain strata which are weaker than the surrounding soils, and failures occur along such weaker layers.

23.1.3 The soil strength model

In the majority of slopes, the most significant loading comes from the self-weight of the soil mass, and therefore its density (unit weight γ, or *weight density* according to Eurocode 7) is a significant factor. It is convenient to model the resistance to shear s using a simple c–ϕ effective stress-based relationship:

$$s = c' + (\sigma - u)\tan\phi' \qquad (23.1)$$

as for a small range of stresses, and with appropriately selected parameters, this permits the analysis to consider the self-weight and pore fluid pressure effects in the soil (these are usually due to water, so the phrase *pore water pressure* is taken as equivalent in the following), both from steady and unsteady seepage, and caused or modified by undrained stress changes in the soil mass. Experience shows that laboratory measured peak parameters are often poor choices for c' and ϕ', and reduced φ'-values (largely based on empiricism or experience) may be required.

Soils vary so much in their composition that it is rarely possible to identify values for c' and ϕ' merely from a soil description, although some rules of thumb are useful. For example, in granular soils such as sands and gravels, ϕ' is almost invariably greater than 30° and increases with density and particle interlock, so that granular soils with angular particles and a range of particle sizes are normally much stronger than those with rounded, non-interlocking, similar-sized particles. Micaceous sands may not exhibit the interlock phenomenon, and may be weaker. Mineral cements such as iron compounds and calcite may further increase ϕ', but their effect is greatest on c', which would otherwise (in granular soils) be negligible. Cements are unreliable if present to a small degree – decalcification, for example, can occur with weak acids from vegetation or acid rain.

Clay soils commonly exhibit ϕ' in a range from just below 20° to about 25°. Factors that increase ϕ' are, again, the content of cementitious minerals and the type of clay minerals present (which may be apparent through their plasticity). Most clays lose significant amounts of strength when sheared, leading to the formation in the soil mass of slickensided shear surfaces. The amount of strength degradation or brittleness varies widely, and is usually highest where the soils contain smectites and lowest where they contain kaolinites. The strength along slickensided shear surfaces may also be represented by a c–ϕ, effective stress-based relationship, but using different c–ϕ values for the sheared or *residual strength* condition. This is denoted by a subscript 'r'. Commonly, illite clays exhibit ϕ'_r in the range 9–15°, but smectites may be much lower, down to around 4°. Effective residual cohesion is usually negligible.

Silty soils fall in between the two limits depending on whether they are devoid of, or rich in, clay.

The stability of a saturated clay mass is dominated not by the mean strength, but by the strength of the weakest path through the mass. Such weaker zones may be created at the time of deposition or placement of the soil and are often the result of having less effective cohesion. Therefore, notwithstanding the existence of effective cohesion in many clays (and it is almost invariably shown up in effective stress shear strength tests), stability analyses routinely employ little or no effective cohesion.

All assessments of stability using effective stress-based shear strength rely on the correctness of the pore water pressures used in the analyses. Soils with low densities, particularly organic soils such as peat and municipal solid waste, are extremely sensitive to fluctuations in the pore water pressure, as in equation (23.1) the direct stress σ (which arises out of self-weight) may not be much greater than the pore water pressure u.

23.1.4 Undrained strength

Under some loading conditions – notably the application of loads without change in the moisture content of the soil, and for clay fills that are placed in an unsaturated state – it may be convenient to employ an undrained strength soil model. Usually, this is nominally a c–ϕ model, but ϕ_u is commonly small or zero, and is ignored. Strictly, the undrained strength is s_u, but the term c_u is used and the two are interchangeable.

When using the undrained strength, pore pressure effects (some of which are highly complex) are lumped in with the other strength parameters, and the analysis is done as though the soil is devoid of pore pressures. Needless to say, that simplifies the analysis.

Undrained strengths in some saturated soils are subject to degradation upon remoulding or reworking. This is termed sensitivity. Unlike drained brittleness, which is a phenomenon of the soil particles, sensitivity is commonly a pore water pressure effect, although that in turn comes from disruption to the soil fabric. Unsaturated soils obtain much of their undrained strength from capillarity, and this may be lost upon soaking or saturation.

Slopes with clay soils or clay strata tend to fail in the clays, and subsequent to failure, slickensided shear surfaces are left in the ground. These surfaces dominate the subsequent behaviour and stability of the slope as a whole, although local slope facets may remain where the peak or unsheared strength continues to control local stability.

23.2 Modes and types of failure commonly encountered

There are a number of classification and descriptive schemes for slope failures (Cruden and Varnes, 1996; Dikau *et al.*, 1996). The critical distinction between slope deformation and slope failure is that in the latter a mass of soil or rock is detached from the parent mass and moves independently, whereas slope deformation is movement of a part of the parent mass with no, or incomplete, detachment. The detached mass may stay in contact as it moves, or may lose contact. If the moving mass breaks into a few pieces, and it loses contact (the pieces may bounce or roll, or simply free fall until impact), then it is usual to describe the slope failure as a *fall* (e.g. rock fall). Where a fall breaks up into many pieces during movement, the mass tends to hug the topographic surface and exhibit characteristics we associate with fluid flow, and it is then described as a *flow* (e.g. debris flow, mud flow).

Slides occur when one (or a few) discrete blocks of soil and rock stay in contact with, although are clearly detached from, the parent mass. Slides may also degenerate into flows if they break up into many parts that move independently.

From the perspective of engineered slopes, falls are most commonly experienced from rock slopes, and result from

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

weathering or water ingress into the slope – causing blocks to loosen and become detached along pre-existing discontinuities, with little or no failure through the intact rock mass. Falls of soil can, and do, occur from oversteepened temporary excavations such as trenches and pits.

Flows occur where the soil loses strength en masse. In loose granular soils, this can occur by vibration, rapid loading creating pore pressures, movement of water into or through the soil mass and deformation during sliding. Loose fills on sidelong ground are particularly susceptible to this mode of failure, as are soils placed hydraulically (e.g. from dredgings) where the failure may be termed liquefaction.

Slide failures are the most common type of failure, as they can occur on a range of slope angles including extremely low angled slopes, and are often the first stage of an event that turns into a flow or fall. Slide failures are particularly common where there is a pre-existing appropriately-orientated weakness in the slope. This can range from a fault, bedding or joints in a rock mass particularly where they dip out of the slope, to a weak (possibly organic) horizon in the foundation of an earth embankment. Such inappropriately orientated weaknesses are sometimes incorporated in earthworks by accident or neglect, including clay capping layers in municipal solid waste (MSW) facilities, or poorly prepared interfaces in clay fills.

Other modes of failure have been described in the relevant literature, but they occur chiefly in natural slopes, and are not commonly encountered.

23.3 Methods of analysis for slopes, exploring their limitations of applicability

23.3.1 Sliding analyses

Since many failures of slopes initiate with sliding, slope stability is usually assessed by means of a sliding model, employing a shear strength relationship of the type described above. The simplest of possible models employs a planar sliding surface, although this can be elaborated to cope with curved or compound (partly planar, partly curved) shapes, and is most often applied to a plane section through the slope. Occasionally, the three-dimensional shape of the slope and transverse curvature of potential sliding surfaces are taken into account. In rare cases, where the geology of a slope has demanded it, a kinked or dogleg section has been adopted. An analysis considering the collapse or ultimate limit state (giving rise to the epithet of 'limit equilibrium analysis') is usually sufficient for the analysis and design of routine engineered slopes and for the analysis of many natural slopes.

Continuum methods of analysis are used to explore the stress, strain and deformation conditions in slopes under their expected conditions of operation when the financial value of the slope itself (or the consequences of failure or underperformance) merits the additional costs of analysis and determination of parameters. Sometimes, such analyses are used to explore the conditions that led to failure in a *post hoc* or forensic investigation, as these methods must follow the correct stress path (or sequence of events).

Applied external forces such as live loads, anchors, etc., are simply in addition to, and often much less significant than, self-weight and pore pressure forces. More detailed treatment of the available methods is given by Bromhead (1992) and by Duncan and Wright (2005).

23.3.2 Planar sliding

Figure 23.1 shows a cross-section of a soil slope. If we consider the mass of soil of weight W above a planar surface A–A inclined at an angle to the horizontal of α, the component of this weight D acting down the plane A–A is:

$$D = W \sin \alpha \tag{23.2}$$

The component normal to the plane is $W \cos \alpha$, so that the maximum possible resistance R to sliding in the absence of water is

$$R = W \cos a \tan \phi' + c' A \tag{23.3}$$

where A is the area of contact between the block and the parent soil or rock mass. If there is a pore water pressure acting over the area of contact, then the force from the average pressure u multiplied by the area A must be taken into account, thus:

$$R = (W \cos a - uA) \tan \phi' + c' A = \tag{23.4}$$

Since the resistance is a reaction, and must therefore be equal to the applied force, we find that

$$D = W \sin \alpha = \frac{R}{F} = (W \cos \alpha - uA) \frac{\tan \phi'}{F} + \frac{c' A}{F} = \tag{23.5}$$

Note that if R is less than D, the mass of soil would accelerate under the unbalanced force $D-R$.

This equation could be used to determine the actual proportion of the shear strength parameters mobilised (i.e. to compute a factor of safety) or, by employing an inequality (<), to assure that the scenario is adequately stable when employing factored parameters.

23.3.3 Sliding on curved and compound surfaces

As soil slopes commonly fail on slip surfaces that combine curves and straights in a plane section, it is useful to consider the sliding mass to be made up from a series of vertical sided slices, each sliding down its own plane. (Non-vertical sided slices can also be employed, but vertical slices are much more common.) The precise number of slices is taken to ensure that the base of each is approximately planar. Since the above equation could be applied to each slice in turn to calculate a 'local' factor of safety, the factor of safety of the whole mass must lie between the maximum and minimum values so computed. Indeed, it is likely that the factor of safety of the whole is some sort of average of the individual values. An average would also take into account the tendency of some slices, if isolated, to

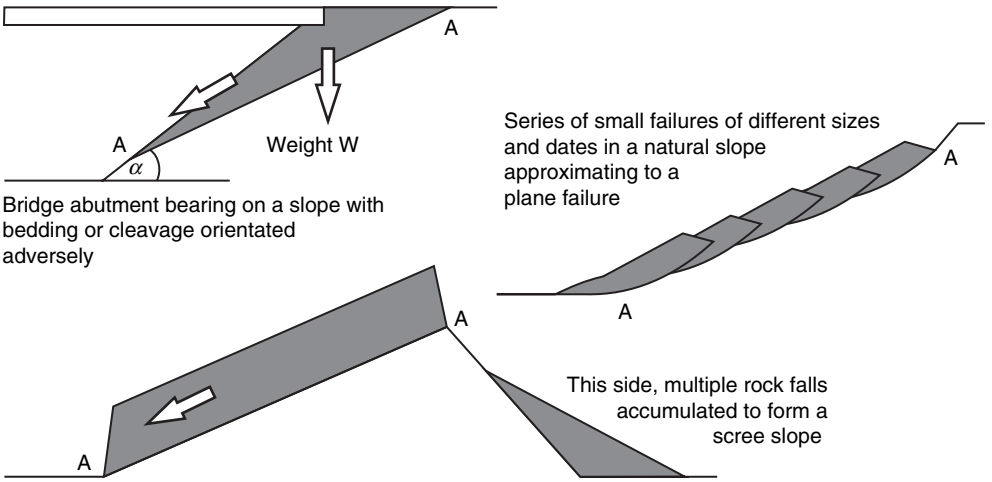

Figure 23.1 Examples of plane failure. The mass slides along plane A–A

slide in the opposite sense to the mass as a whole, especially in a toe zone that breaks out upwards.

A convenient averaging technique is to compute the sums of the driving (D) and resisting (R) terms, before dividing the latter by the former, since this takes into account implicitly the relative sizes and importance of the slices, and gives the overall factor of safety F as:

$$F = \frac{\sum_{i=1}^{n} \{(W\cos\alpha - uA)\tan\phi' + c'A\}_i}{\sum_{i=1}^{n} \{W\sin\alpha\}_i}. \qquad (23.6)$$

Note that this definition of F continues to be identical to the mobilisation factor on the shear strength parameters.

Consideration of the form of this equation shows that it reverts to the planar slide formula under the appropriate circumstances and is useful for shallow slip surfaces. However, if the slip surface is markedly curved, or descends deeply in the slope (especially when pore pressures are variable and high), the lack of computed interaction between the slices (i.e. the absence of inter-slice forces) makes the stress analysis change from merely approximate to highly dubious, and introduces errors which lead to a conservative estimate of F. Starting with an iterative procedure for dealing solely with the horizontal component of inter-slice forces published by Bishop (1955), efforts have been made to incorporate – as realistically as possible – the effects of inter-slice forces. One outcome of this is the publication of a multiplicity of named methods for the analysis of curved and compound sliding surfaces. Fortunately, provided that some attempts are made to model the inter-slice forces, the results do not appear to depend greatly on the precise technique used. Methods include using horizontal inter-slice forces (e.g. Bishop, 1955), inclined but parallel inter-slice forces (Spencer, 1967), and positioning the inter-slice force line of action at (say) 1/3 height on the slice. Morgenstern and Price (1965) introduced a procedure where the distribution of inter-slice forces is decided *a priori* by the analyst, but the precise magnitudes are determined during the equilibrium computation. This approach is followed by Sarma (1979).

The computational procedures almost always involve an iterative solution method (except where the soils are purely cohesive) once inter-slice forces are considered, however approximately. The analyst is usually faced with selecting one of a small range of options in whatever software he has, and does not have a free choice amongst the various methods available at large.

Since even Bishop's procedure is laborious to compute by hand, slope stability calculations became an early application for computers. To summarise, the essential differences between the methods lie in the treatment of inter-slice forces – and this choice is largely immaterial, and even the once-important issue of how long it took to produce results is of little significance, given the speed of modern computing hardware and software.

23.3.4 Slip circles

It is found that in many cases an arc of a circle (**Figure 23.2**) on the two-dimensional slope section provides an adequately good first approximation to the shape of a failure. Indeed, some case examples show that under particular combinations of conditions it can be a *good* approximation. These surfaces are called slip circles. Since all of the geometric factors can be calculated simply from the position of the centre of a slip circle together with its radius, the slip circle lends itself to repetitive analyses using many slip circles to find the one or ones with least factors of safety. Most analysis software uses a regular rectangular grid of centres together with multiple circles emanating from each centre. Refinements may include constraints on where the circles may intersect the slope, and grids of centres

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

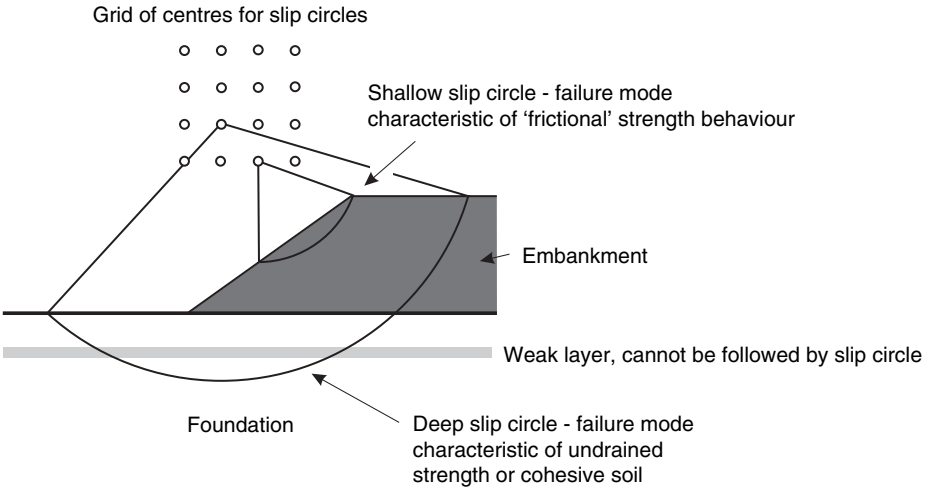

Figure 23.2 The slip circle, commonly employed where the critical clip surface is unknown

of various types and orientations. The particular method of indicating the critical slip circle (i.e. the one with the least factor of safety) and how it relates to other possible slip circles is not standardised, but depends in part on the imagination of the programmer and, to an extent, that of the analyst.

Stability analyses of slopes with soil strengths that are dominated by their angles of shearing resistance (ϕ') tend to indicate that shallow slip surfaces are the most critical. In the undrained case, and where strength is dominated by a cohesion parameter, the critical slip circles are deep, akin to foundation failures. A fundamental defect of the slip circle approach is that no circle can follow a thin stratum of weak soil (**Figures 23.2** and **23.3**), and where slip circles do indicate the weaker zones of a slope (low shear strength parameters, but also where high pore pressures exist) these zones are discoverable by visual inspection anyway. Since it is not possible to generate compound slip surfaces with quite the facility with which slip circles can be generated (from a grid of centres), it is useful to undertake a slip circle based analysis in the first instance, and use the most critical slip circles as a basis for extending into compound and other shapes to include the weak zones.

Many cases of slope failure in engineered slopes occur because at the time of construction a weak layer in an adverse orientation was incorporated into the fill or left in the embankment foundation. Similarly, in cuts and natural slopes, a weak horizon again provides a path for a failure surface. It is therefore essential in these cases not to rely simply on slip circle approaches.

23.3.5 Three-dimensional effects

Three dimensional analyses are rarely done in routine engineering earthworks design, simply because there is no 3D analogue of the slip circle search procedure. In forensic (post-failure) analyses, the 3D approach may convey some benefits. However, an alternative approach is to make 2D analyses and combine the results. This is often sufficient.

A determined analyst will find that 2D calculations often yield a lower factor of safety than the 3D calculation. This is sometimes the result of failing to consider adequately the variation in pore water pressure in the out-of-plane direction: field failures all have a three dimensional element.

23.3.6 Pore water pressure changes during the 'lifetime' of a slope

In the foundation of an earth fill, undrained loading usually gives rise to substantial pore pressures. Provided that failure does not occur, the dissipation of excess foundation pore pressures leads to a gain in foundation strength and therefore to increased stability with time, although the effect of pore pressure dissipation in the foundation decreases with time. In some cases, the migration of pore water laterally in horizontal layers of higher permeability may, early in the process, lead to a transfer of pressures from under the embankment crest where they do little harm, to the toe, where they do damage. The critical point for stability, therefore, in the lifetime of a filled slope on a weak foundation is either at the end of construction, or shortly thereafter if pore pressures do migrate out to the toe. Some benefit is obtained by filling slowly, or by allowing rest periods (often throughout the rainy season when fill cannot be placed) during which time the foundation consolidates and is therefore capable of bearing the following season's lift of fill.

In the case of a cut slope, the total stresses decrease during excavation, and the undrained pore pressure change in response decreases the pore pressure state over the lower part of the cut slope to a state of suction. Loss of this suction occurs with infiltration of water from the ground surface or from depth, and this leads to loss of strength and in some cases to delayed failure. The equilibration of pore pressures may take decades. The process is most marked in stiff clays.

Clay fills are inevitably placed incompletely saturated and manifest strength due to capillary effects in whatever pore water

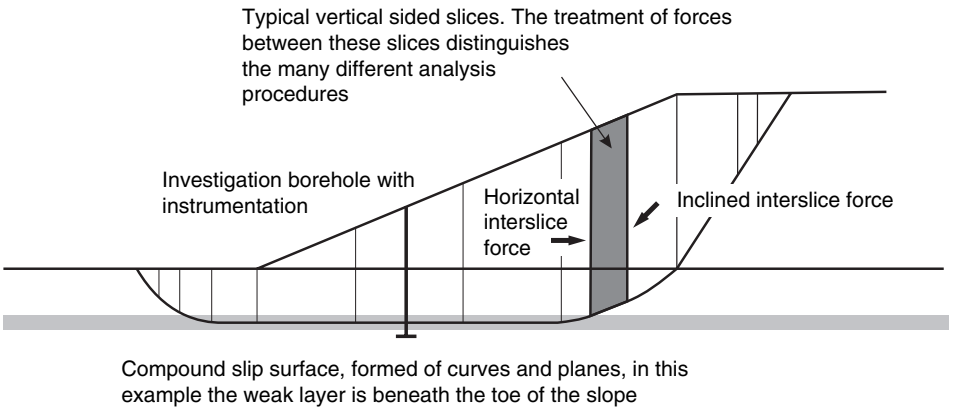

Figure 23.3 Compound failure with sub-horizontal bedding-controlled shear surface

there is. As in the case of a cut slope, loss of suction may occur due to water ingress, and this can, in clay fill slopes, also lead to delayed failure. However, suctions near the surface can be reinstated by dry weather, or by moisture abstraction through the roots of vegetation. The progress towards delayed failure is neither as certain nor as monotonic as the gain in strength of an embankment foundation as it consolidates. Although recent research work has been directed to understanding and quantifying these effects, they are not routinely considered in slope stability analyses, which proceed on the basis of pessimistically-assessed positive pore pressure conditions.

Partly submerged slopes gain support from the external water load, but lose strength as water enters the slope and exerts pore water pressures. These two effects act in opposite senses, and the result may increase or decrease the overall stability relative to the slope prior to submergence. In many cases, it is found that there is a particular water level termed the 'critical pool level' at which point the stability is least. Care on first impounding water-retaining earthworks is therefore called for. Stability is often severely affected if the support from the water is rapidly withdrawn ('rapid drawdown'), especially if there is insufficient time for water in the slope to flow out. This, as in all the cases of partly-submerged slopes, is modelled in slope stability analyses through the use of appropriate distributions of pore water pressures.

23.3.7 Seismic stability

During an earthquake, slopes may be accelerated and decelerated multiple times in a variety of directions, but usually for very short durations in each. A simple approach to dealing with this is to take the inertial forces as some fraction of gravity, and to apply the resulting forces in a standard slope stability analysis as a horizontal body force. In some cases, vertical body forces are applied in addition to weight. There may also be undrained pore pressure changes. Inevitably, slopes with a high static factor of safety and moderate to low inertial forces appear to perform well, and those with low initial stability or where the inertial forces exceed some threshold appear to be in line for failure. The body forces are calculated in the horizontal direction from $k_h W$, where k_h is the proportion of gravitational acceleration assumed to act horizontally.

An alternative procedure is to calculate the value of k_h that causes F to drop to one. This factor is termed k_{crit} or k_c. Then, whenever k_h exceeds k_c, the slope will begin to move. However, if the times involved are in milliseconds, the displacements per seismic pulse are tiny, although they increment pulse by pulse through each design model earthquake. We thus discover that $F < 1$ is not necessarily a disaster, provided that it occurs for a short time, and the soil properties are not left in a damaged state that will permit failure even when the shaking stops (e.g. via increased pore water pressures).

Slopes that continue to move after the earthquake vibrations have ceased are of course the primary concern. This may be the result of high earthquake-generated pore pressures. Loose fine granular soils and saturated cohesive soils with a porous fabric are most prone to loss of strength on shaking. Stiff clays form slip surfaces with diminished residual strength parameters, but this is often associated with dilation and lowered undrained pore pressures, and may not be significant.

23.3.8 Errors in slope stability analyses

Errors made in slope stability analyses are usually the result of:

(i) Incorrect assessment of design values for shear strength, including a failure to consider whether drained, consolidated drained, or consolidated undrained conditions are operating.

(ii) Incorrect assessment of pore water pressures in the ground.

(iii) Inadequate assessment of the effect of weak layers in the slope which may be present in the soil for stratigraphic reasons, or have been created by construction activities.

(iv) Selection of inadequate mobilisation factors in a particular case, especially where there is uncertainty surrounding the soil parameters and pore water pressures, but less obviously, where there is the risk of progressive failure.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The third item in this list sometimes manifests itself by a weak layer not having been recognised during investigation or construction, and also by the analyst not considering slippage along such weak layers. The use of slip circles alone may result in this situation arising in the analysis.

The technique most commonly employed in finding the critical (least safe) slip surface is a 'brute force' approach of analysing often thousands of slip circles. It is easy to forget that the critical surface may not be the arc of a circle.

Errors in the computation itself are much rarer than in the above technique, probably the result of the widespread deployment of quality-controlled computer software.

23.3.9 Continuum methods

Continuum methods (such as finite element and finite difference stress analyses) are occasionally employed in slope stability problems, but they need parameters that are more difficult to obtain, and an even more skilled analyst, so are expensive to apply in routine situations. They provide estimates of deformations, absent from a limit-equilibrium analysis (including the pattern of deformations) and they do not require analyst intervention to show the most probable mode of deformation leading to failure.

However, the problem of dealing with thin weak bands in the soil is perhaps more intractable than in limit equilibrium analyses.

23.4 Rectification of unstable slopes

23.4.1 Introduction

Unstable, or potentially unstable, slopes may pose threats to human interests and intervention of some sort is often called for. The baseline case is that nothing is done. Value judgements can then be made on the cost of intervention against the anticipated losses.

Slope stabilisation methods are described in Chapter 72 *Slope stabilisation methods* with the generalities of design in Section 7 of this manual as a whole; here, the analysis issues with those methods are discussed. Retaining structures in particular are described in Section 6 of this manual.

One form of intervention that may be highly successful is to ensure that no valuable assets lie in areas of high risk. Many of the best examples of the application of such controls are adjacent to the coast. They include prohibition of development via statutory ordinances, realignment inland of coastal roads, and in one celebrated case, the historic Belle Tout lighthouse at Beachy Head, East Sussex, was shifted bodily inland by about 50 m to protect it from coastal cliff erosion.

Where the commonest form of instability is that of small to moderate flows (e.g. debris flows in mountainous areas) or of occasional rock falls, assets may be protected by various forms of barrier and catch structures, or deflection barriers and channels. Barriers range from earth or rockfill bunds, through reinforced concrete walls, to steel or occasionally timber post walls. Catch structures may be bunded enclosures or fences and netting. Where the failures are frequent, the catch structures need periodic clearing to maintain their effectiveness, combined with some repairs (especially where a catch structure has been called upon to resist loading beyond its design envelope) to compensate for corrosion, rot, vandalism or changed environmental conditions.

The final alternative is to reduce the probability of failure by engineering works on the slope itself.

23.4.2 Earthworks solutions

Slopes may be reprofiled to an overall flatter gradient. Where the likely mode of failure is relatively shallow, this is the optimum expedient. However, there are numerous cases where grading to a flatter angle is not only useless, but may provoke failures. For example, a coastal slope with a large, pre-existing landslide may exhibit a coastal cliff with small failures. Flattening this cliff may solve the small-scale local stability problem, while at the same time destabilising the deeper slide system as it constitutes an unloading of the toe zone of the deep-seated slide. Many slopes with pre-existing adversely orientated weaknesses, or with pore water pressure conditions independent of the regraded slope facet, are subject to this effect.

Deeper-seated failure modes tend to be improved with the construction of toe weighting fills and berms. However, such earthworks may cause local slope stability issues if inappropriately founded, say for example, on weak compressible subsoils or on sidelong ground. Toe fills may not be fully mobilised to support a slope until movements have taken place and compressed the fill laterally. A further effect of some concern to geotechnical engineers is the problem that arises in slope stability analysis if the toe of a slip surface rises through a toe fill with a high angle of shearing resistance ϕ'. This tends to make the computed factor of safety excessively high as a result of the assumptions in the analysis method. Care is needed in interpretation of these results.

Unloading the head of a slip failure is a useful method of stabilising it, but at the risk of affecting the head scar of the failure, which may require more significant interventions to keep it stable.

In general terms, when attempting to stabilise a slip, fills are highly effective above parts of the slip surface where it rises to ground level at the toe, and cuts are highly effective where the slip surface is steeper than ϕ' (where the slip surface rises towards the head of the slope). In between these locations, the relative effectiveness of cuts and fills depends on the pore pressure response in the slope to stress change.

The analysis of the stabilisation solution is a re-run with the modified slope profile and soil properties.

23.4.3 Drainage solutions

Slope drainage systems fall naturally into two main groups: preventing water from penetrating the slope in the first instance, and removing it once it is there.

A good tree canopy is effective in controlling rainwater ingress, but deciduous trees lose this capability annually. In any case, the canopy is established slowly, and can be breached by the loss of

individual trees or wholesale felling. Creation of impermeable coverings inhibits the movement outwards of water already in the slope, and creates problems of peak discharge during heavy storms, as well as potential aesthetic issues. Very shallow drainage in a slope, such as ditch networks and land drains formed from clay pipes, tile drains and modern perforated plastic pipes, has the effect of controlling infiltration. Buried systems have the additional benefit of slowing down the release of captured water. Land drainage systems are easily blocked, and are difficult to maintain. When blocked, they back up water, overpressuring the drainage system and the soil, causing local failures.

Deep drainage systems may be installed to release pore pressures, such as undrained loading-induced pore pressures that are then unlikely to be replenished, or to control seepage-induced pore pressures that are continuously replenished. In the former case, filtration is unlikely to be of major significance, but in the latter case it is. Filters prevent loss of fines into and through the drainage system that would result in internal erosion in the soil, and possible blockages in the drainage system.

Pore pressures induced by undrained loading are most often associated with the construction of embankments over weak and deformable foundations, where the load from the embankment fill compresses the foundation. Release systems for these pore water pressures usually take the form of vertical filter-fabric wicks, or sand-filled drain wells, with hybrid systems sometimes employed. They may connect to permeable strata at depth, or to a collector drainage layer at their top, or both. Accelerated consolidation of the ground can be caused by applying suction, through the use of electrical systems, or where stability permits, by applying surcharge loads. Where the pore water pressures are induced in high fills, the drainage system may be laid at the time of construction. In this case, it is often a drainage layer formed from appropriately selected granular material with a high permeability. The cost of drainage layers in a very large earthwork can be high, and to minimise this, the layers are formed from a grid of interconnecting 'strips'. In earth dams, the drainage layers to control construction-induced pore pressures may form part of the permanent drainage system, in which case filters are obligatory. Filters may take the form of further granular layers or be made from thin sheets of manufactured and non-degradable fabric.

Permanent drainage systems may also be incorporated in a slope by drilling sub-horizontal or other drains. These are kept open in soils with perforated plastic (or other) liners. Filter protection of these employs proprietary systems of variable longevity, most of which prove difficult to maintain. Bored drains can be installed from the surface, or from shafts and tunnels, both of which operate as drains. Shafts collect water at their bases and ideally are interconnected by a tunnel or series of borings to permit the water to drain under gravity; if not, then pumps must be employed. These pumps are subject to breakdown, and have running and replacement costs.

The efflux from drainage systems may contain contaminants, requiring treatment before it can be discharged. These contaminants may include microbial contaminants (e.g. from MSW, or where septic tank foul drainage is employed locally), or mineral content such as the iron-rich oxygen demanding acid mine drainage water from underneath some types of mine waste tips. In some cases, discharge of water from a slope drainage system may not be permitted, or may be permitted only subject to severe constraints, by the appropriate local authority or environmental protection agency. Some forms of drainage water, most notably calcite-rich or iron-rich water can cause drain blockage due to precipitation, in the latter case assisted by bacteriological action.

Drainage trenches of several metres or more in depth are often employed to stabilise failures in cut slopes. Regardless of their depth, they can reduce pore water pressures. However, when they are deep enough to penetrate sheared surfaces or other zones of weakness, they also have a reinforcing or buttressing effect in the slope, in which case they are termed counterfort drains. Drainage trenches infilled with gravel and open to the surface may permit infiltration of water, and if the efflux is obstructed, they can operate in the opposite sense to which they were intended. Although drains may accelerate the equilibration of lowered excavation-induced pore pressures to their final state, that state is usually better for stability than if the drains were not there, and the net effect is beneficial overall.

Significant drainage actions lead to consolidation in the ground and surface deflections and strains. Drainage water collected in a pipework system has the capacity to do damage if it is released in the wrong place. Transporting drainage water across or through unstable slopes is not usually without risk of promoting failure should the drains leak.

Analysis of slope stability with drains is simply a question of modifying the pore pressures used in the analysis.

23.4.4 Anchorages and reinforcements

Active systems of restraint can be installed using pre-tensioned ground anchors. These employ cable anchorages running in boreholes through a slope into stable ground underneath where they are anchored, with tensioning loads applied at the ground surface. Pre-tensioned anchors may need periodic restressing if the ground consolidates, and in the case of some types of ground movement. They are highly susceptible to corrosion, and require elaborate protection systems. Furthermore, the existence of large cable tensions in ground anchors may give rise to long-term safety concerns, for example if they are forgotten and the site is redeveloped in ignorance. It is rarely possible to install pre-tensioned ground anchors in their mathematically optimum orientation and position (their length, access to anchor head positions for installation and restressing, etc., being key constraints). They are often installed to control ground movement in their vicinity even if they do not stabilise the slope as a whole. It is preferable to spread the load from anchors into the ground with individual pads, as this minimises the risk of progressive failure of the whole anchorage system (**Figure 23.4**).

Figure 23.6 Failed sheet pile retaining wall, originally installed in association with grading, drainage and sea defences, to stabilise compound slip with basal shear surface at approximately mid-slope height

Plastic and metal grids or strips can be incorporated into fill slopes to retain the face, where this is oversteep, or to prevent lateral spreading (sliding on sub-horizontal planes). They are also used to restrain the sliding tendency of the face of a fill on sidelong ground. Since the capacity and durability of these systems depends on their manufacturer, it is conventional to employ manufacturer-specific design tools and construction specifications. Reinforcement grids may be installed in multiple layers, but then care is needed to ensure that the layers do not slide over each other. Loads are induced in these reinforcement systems by deformations during construction, which makes them a passive system.

Passive restraints can be induced in other reinforcing elements in the slope and are usually inserted into drill holes. Where they are of comparatively small diameter and often low-angle they are called 'soil nails'. Soil nails are essentially small diameter steel-reinforced concrete 'piles', which act in tension. Piles may also be employed to reinforce the soil mass in a slope. They may take the form of dowels (rows or grids of medium diameter piles reinforced with traditional reinforcement cages of bars), or larger diameter piles reinforced with steel tubes (**Figure 23.5**), or structural steel I- or H-sections. Bored piling techniques are frequently preferred to driven piling techniques, as they prevent dynamic loading of the ground and employ larger sections than can conveniently be driven.

Trenches that go deep enough to penetrate sheared surfaces or other zones of weakness and which are subsequently filled with concrete or compacted rockfill provide shear keys. As noted above, if they are permeable, they can provide some drainage.

Sheet piles may prove effective to stabilise small slides, but they are intrinsically flexible, susceptible to corrosion, and come apart at the interlocks (**Figure 23.6**).

In analyses of slopes with reinforcing elements, the necessary forces and reactions can be considered in the equilibrium calculation. It is usually a serious error to incorporate soil zones with 'concrete' or 'steel' properties into a slope stability analysis dataset and then run slip surfaces through it.

23.5 Factors of safety in slope engineering

23.5.1 Risk

Risk is defined as the potential loss from a hazard. It is the product of the probability of the damaging occurrence (in a given place and timescale) multiplied by the consequences when it happens. *When* is used, not *if*, as any probability of failure other than zero implies that sooner or later it *will* happen. Those consequences are most easily expressed in financial terms, and reflect the number and value of elements at risk and

their vulnerability, or the proportion of their value lost in the damaging event(s). Fortunately, in the UK, fatalities and injuries from slope instability are comparatively rare. Apart from one small event, the entire record shows that financial effects far outweigh personal injury. This makes most risk analyses simply a matter of money. Other parts of the world are less fortunate and must find ways of dealing with the two aspects concurrently.

The entire gamut of engineering slope stabilisation measures deals with risk by reducing the probability of occurrence of damaging events (slope failures). Relocation of assets and control of access to sites reduces the number and value of elements at risk. Barriers and control structures may be seen as reducing the vulnerability of those elements. Hence, the treatment of slope instability (actual or potential) is a matter of risk reduction (Bromhead, 1997, 2005).

23.5.2 Factor of safety approach

In an ideal world, we might approach every slope with an intention to reduce the risk from failure to tolerable levels. In practice, engineering calculations rely on factors of safety, and these (as articulated above) represent a factoring down of shear strength parameters. Thus the traditional methods of slope stability engineering fit neatly with Eurocode 7's philosophy. The recommended factors in Eurocode 7 are believed to result (in most everyday practice) in tolerable levels of risk, provided that appropriate assessments of parameters and mechanisms are made in the first instance. There are almost certain to be cases where larger factors are required, for example where the consequences of failure are dire, or where uncertainties in soil behaviour or properties demand it. Natural slopes of large scale may require smaller factors of safety (or those recommended by Eurocode 7 may simply be unachievable) for an equivalent level of security. For example, residual strength on a very deep sheared surface is unlikely to be subject to further reduction, and this may not require factoring in the same way as the unsheared strength that may be sensitive or subject to degradation with strain. However, a highly sensitive soil may be subject to progressive failure at a mobilisation factor that is satisfactory where the subsoil is insensitive.

23.5.3 Serviceability limits

In the case of the routine design of earthworks of moderate height with conventional fills and placement methods, the Eurocode 7 factors also provide some control over deflections associated with the mobilisation of shear resistance in the ground (but not, of course, to consolidation settlement and related mechanisms). In these types of earthwork, adoption of lower factors of safety gives rise to ground deformations as shear strength is mobilised. The surface manifestations include toe bulging and cracking at the embankment crest. If the earthwork consolidates and gains strength, it may be possible to give the embankment a cosmetic 'makeover' without permanent impairment of its performance. However, such deformations are more commonly experienced as a precursor to collapse, probably because the soils involved are susceptible to progressive, brittle, failure and as a result, should be treated with caution. This is especially so if the embankment fill or subsoil is clayey and can develop slickensided shear surfaces at residual strength.

In-slope geotechnical instrumentation can detect the onset of ground deformations before they are apparent to the naked eye. Careful inspection and interpretation of geotechnical instrumentation readouts is therefore an essential adjunct to construction, especially of particularly high or steep earthworks, those on weak subsoils, and where the consequences of collapse are critical (from the perspective of collateral damage) and affect the construction programme.

23.6 Post-failure investigations

Post-failure investigations are conducted from a variety of motivations, from facilitating remediation through to attributing blame. In clay soils, an essential element of investigation is to ascertain the location of the basal shear surface of the slide. This may be done by visual examination of borehole samples, or, when the slide is still moving, by the use of appropriate instrumentation. Inferences on slip surface position and depth may be drawn from the surface morphology and surface deformations, but logged boreholes and instrumentation provide the best information. Shafts, adits and pits are used to expose shear surfaces *in situ*, but they are potentially hazardous, requiring proper support at all times, and they should only be entered by trained operatives acting within an appropriate safety plan.

Many failures occur under climate-driven or other transient pore water conditions; using post-failure instrumentation, it may still be not be possible to recover the situation.

In operation, failures in infrastructure earthworks and in both temporary and permanent slopes may prove disruptive and inconvenient to leave for later forensic investigation. It is therefore essential that proper investigations take place concurrently with the clear-up operations. During construction works, the costs of remediation of some slope failures may be significantly less than after completion of the works – as plant is on site and access is usually better. However, as failures are not normally contemplated at the design stage, it may be necessary to implement remedial works with additional care; they may well contain activities not catered for in the initial site health and safety plan.

It is sometimes the case that an engineer investigating a failed slope needs to form an opinion on the cause or causes of failure. In this situation, the failure is often the result of several preparatory factors, combined with a final trigger. It is naive to single out the final trigger as the causative factor. Instead, the individual preparatory factors should be investigated and ranked in decreasing order of impact on the slope. It is then usually clear that several factors in combination have led to the failure.

There are many circumstances where cyclic loads are applied to the soil, either by natural or manmade forces. Although the magnitudes of these dynamic loads are often much smaller than static loads, inertial forces may become important and must be considered in geotechnical design. This chapter introduces the reader to the dynamic loading of soils and the main characteristics that differentiate dynamic and static loading: loading frequency and loading cycles, and the strain dependent behaviour of soil. A variety of measurement techniques for characterising the dynamic response of the soil are available and these are outlined, differentiating those routinely employed during low and high strain cyclic loading, both in field measurements and laboratory testing. The theoretical response of the soil to cyclic loading is briefly examined and the main features highlighted. The factors that affect the dynamic soil behaviour are discussed, through the use of results from extensive laboratory testing in this area. The phenomenon of 'soil liquefaction' is also highlighted along with the factors that influence it.

24.1 Introduction

Traditional soil mechanics and geotechnical engineering design was predominantly concerned with soil strength and stiffness so that the design engineer could define the failure state of the soil and/or control excessive deformation of the soil/structure. In these circumstances, the loading is considered static and the strain imposed within the soil may vary from about 10^{-3} (in service) to a few percent (at failure).

There are however, many circumstances where cyclic (dynamic) loads are applied to the soil either by natural forces such as earthquakes (seismic), wind and water waves, or from manmade sources such as bomb blasts, traffic loads and machine foundations. The magnitudes of these dynamic loads are generally much smaller than most static loads and generate strains within the soil as low as 10^{-6}. However, during cyclic loading the soil is subject to inertial forces, which increase proportionally with the square of the loading frequency and may become important. It is therefore imperative for the design engineer to have an understanding of the dynamic behaviour of soils in circumstances where the soil may be subject to these loading events.

This chapter introduces the reader to the dynamic behaviour of soils and outlines some of its main features. References are given where more detailed information can be obtained if required.

24.1.1 Dynamic loading

Dynamic loading can be defined by two main characteristics, which are loading frequency and the number of load cycles (**Figure 24.1**). Generally, dynamic problems are where the cyclic load is applied at frequencies greater than around 1 Hz (1 cycle per second). Depending on the loading event, the number of cycles can vary from single loads, such as those generated by bombs or blasting, up to many thousands of cycles as in machine foundation vibration. Problems with dynamic load can be classified into three general areas based on the number of load cycles: (i) impulse load, such as bomb blasts where a single impulse of short duration occurs; (ii) vibration or wave propagation, generally applied to earthquake events and construction activities where a number of loading cycles occur (10–1000) at frequencies from 1–100 Hz; (iii) where the number of cycles is inordinately large, such as those associated with machine foundations and traffic loading (cars and trains). In this case the soil behaviour can be considered as potentially *fatigue* related.

24.1.2 Strain dependent behaviour of soils

Over recent years, it has been shown that the deformation behaviour of soils is heavily dependent on the level of shear

strain (γ) to which the soil is subjected. **Figure 24.2** shows the shear strain dependent behaviour of soils. It can be seen that for very small strains (10^{-6} to 10^{-4}) such as those induced by wave propagation and vibration, the soil response is elastic and recoverable (i.e. there is no permanent deformation). At these strains, both the number of loading cycles and the rate of loading have a negligible effect on the soil behaviour. At the intermediate strain range (10^{-4} to 10^{-2}) the soil is elastoplastic and irrecoverable permanent deformations occur, usually associated with cracks and differential settlement of structures supported on the soil. At these strains, the number of loading cycles and the rate of loading both have an effect. These strain levels are typical for a number of geotechnical structures such as retaining walls, tunnels and deep excavations (Mair, 1993). At higher strains the material exhibits failure, where the strains increase with no further increase in shear stress. These are typically associated with slope failure, compaction and liquefaction of non-clay soils.

Also listed in **Figure 24.2** are typical test methods employed for determining dynamic soil properties along with an estimate of the ranges of strain that can be generated. Generally there is little crossover between dynamic tests and those defined as static (less than 1 Hz frequency) with respect to the shear strain level applied. Thus, historical differences in stiffness – measured using dynamic and static tests – may result from the strain level induced in the soil. With field measurements using vibration or wave propagation techniques, large amounts of energy are required to generate strains in excess of 10^{-3} due to the inertial forces involved in mobilising the soil. Therefore, for tests at higher strains, low frequency repeated load tests (where inertial forces are negligible) are more commonly used. In these circumstances, the loading becomes a repetition of the static load (Ishihara, 1996). Large strain vibration tests are also difficult to achieve in the laboratory. Although sufficient energy may be available to induce large strains in a soil sample during vibration, the governing equations become invalid (see Richart *et al*., 1970). With repeat load tests at large strains, the determination of elastic constants is straightforward. It is important to specify the right test procedure to derive accurate parameters for use in the design process.

24.2 Wave propagation in soil

The tests highlighted in **Figure 24.2** can be broadly grouped into low and high strain measurements. At high strain, the stiffness and damping are calculated directly from the stresses and strains measured in the soil as would be done in a static test (see Chapter 49 *Sampling and laboratory testing*). Although recent advances in measuring small deformations in soils have allowed direct measurements of soil properties at small strains (Clayton and Heymann, 2001; Jardine *et al*., 1984; Xu *et al*., 2007), they are not routinely undertaken and so vibration/wave propagation techniques are typically employed for testing at small strains.

24.2.1 Wave velocity

Soil parameters are computed from wave propagation techniques based on the theoretical response of the soil during the propagation of a stress wave through it. There are a variety of waves that can propagate in an elastic material (see Richart *et al*. (1970) or Kramer (1996), for a detailed theoretical background to groundbourne wave propagation). For soils, three types of waves are readily encountered and are of importance. The first two are termed body waves, which are propagated

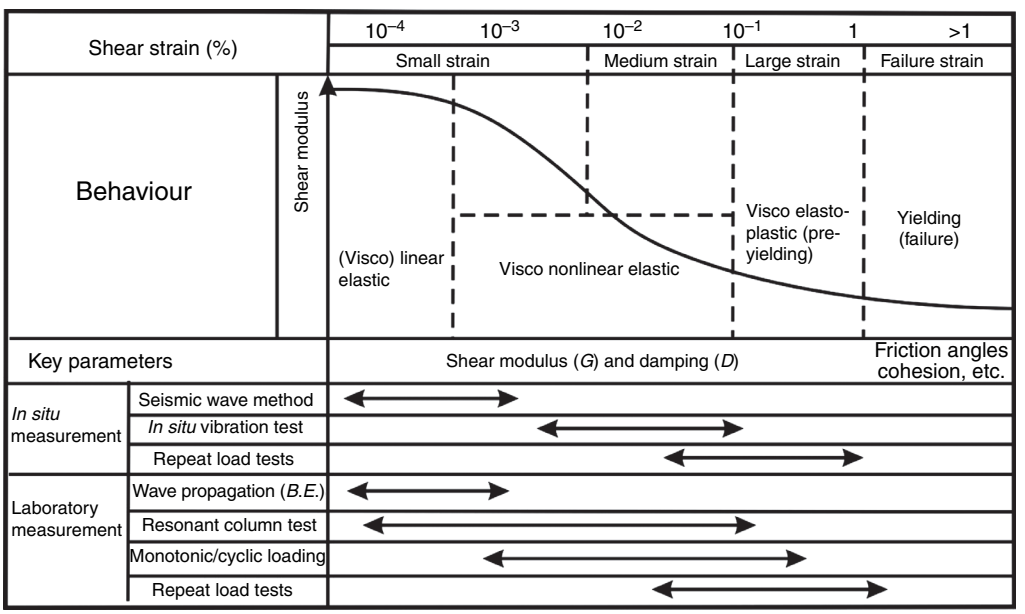

Figure 24.2 Strain dependent properties of soils. B.E. stands for Bender Element, which is a laboratory-based wave propagation technique
Modified with permission from Ishihara (1996) © Oxford University Press

within the soil and comprise the compressional wave (P-wave) and shear wave (S-wave). In relatively soft saturated near surface sediments (which is likely to be the case for a large number of geotechnical problems) the P-wave (V_p) is dominated by the bulk modulus of the pore fluid (the water is 'hard' compared to the soil) and the resultant V_p may be close to that of the pore fluid. If the soil is unsaturated, V_p can range from that of the soil matrix (with no pore fluid) to that for the saturated case. Therefore the use of V_p to determine the properties of soils is problematic, even with detailed knowledge of the hydrological regime, unless the bulk modulus of the soil is much greater than that of the pore fluid. However, pore fluids do not carry shear stresses, so the velocity of S-waves (V_s) is only influenced by the soil and not by the pore fluid. It can also be shown that during most dynamic loading events, it is cyclic changes in shear stresses that influence the behaviour of the soil. From the theory of propagating waves it can be shown that the wave velocity through the soil is related to the stiffness of the soil by

$$G = \rho V_s^2 \tag{24.1}$$

where G is the shear modulus of the soil, and ρ is the soil density.

Therefore changes in V_s within a soil can be used to determine the small strain stiffness, and measurement of S-waves is commonly employed to determine the dynamic behaviour of soils at small strains.

The third wave that is frequently encountered in soils is the Rayleigh wave, which travels along the ground surface. Rayleigh wave measurements have gained in importance in recent years since ground surface measurements can be readily and easily undertaken without the need for any intrusive investigations, such as those required for measuring P-waves or S-waves. There is no direct link between the velocity of Rayleigh waves (V_R) and soil stiffness (Young's modulus, E or G), however, it has been shown that for nearly all values of Poisson's ratio, $V_s \approx 1.09V_R$ (Richart *et al*., 1970). Therefore measurements of Rayleigh waves can give a good determination of shear wave velocities (Hiltunen and Woods, 1988) from which G can be derived.

24.2.2 Damping–wave attenuation

The theory of wave propagation is usually considered in terms of linear elastic materials, such that the waves would travel indefinitely without loss of strength (wave amplitude). However, in real soils the propagating waves are attenuated due to inherent material damping of the soil and geometric damping, where geometric damping relates to the loss of energy as the wavefront increases in length as it radiates out from the source. Material damping is associated with dissipation of energy during the passage of the stress wave as a result of friction, heat generation, etc. Thus, material damping is also a key parameter in determining the dynamic response of a soil.

24.3 Dynamic measurement techniques

As previously highlighted, the key parameters for understanding the dynamic behaviour of soils are shear modulus and damping. Although other parameters, such as Poisson's ratio and density, influence the dynamic behaviour of soils, these are generally secondary to stiffness and damping. A variety of field and laboratory techniques have been developed for measuring the shear modulus and damping, each with their own advantages and limitations. As the dynamic properties of soils are highly nonlinear with respect to strain, the choice of which technique (or range of techniques) to adopt needs to be carefully considered with respect to the existing stress conditions and those that may be imposed.

Detailed descriptions of soil investigation techniques and the data reduction methods employed to determine soil properties are given in Chapter 45 *Geophysical exploration and remote sensing* (field measurements) and Chapter 49 *Sampling and laboratory testing* (laboratory measurements). Section 24.4 lists the techniques relevant to determining dynamic soil properties.

24.3.1 Field measurement techniques

There are a number of well known advantages in performing dynamic field tests. These include: the ability to measure soil properties under *in situ* stress conditions; no sample disturbance to be accounted for during testing; the ability to survey large volumes of soil rather than using discrete locations (laboratory sampling). However, these must be considered in the light of certain disadvantages, such as working stress conditions cannot easily be applied to the soil; hydrological conditions cannot be controlled (pore water drainage); and for most tests, material properties are not measured directly but inferred (either theoretically or empirically).

24.3.1.1 Low strain tests

A number of low strain field measurement techniques can be used to measure dynamic soil properties and all measure the velocity of wave propagation in the soil. Those that determine soil properties from surface measurements include seismic reflection profiling and seismic refraction profiling – typically used to measure V_p, and continuous surface wave (CSW) or spectral analysis of surface waves (SASW) – used to measure V_R from which V_s is calculated. Those that determine soil properties from predrilled boreholes include seismic cross-hole and down-hole tests – which can be used to measure both V_p and V_s and respective damping parameters (with multiple receivers). The seismic cone is similar to the down-hole test but does not require a separate borehole since the cone is mechanically pushed into the ground.

24.3.1.2 High strain tests

For the majority of high strain field tests, the soil stiffness is usually obtained through empirical correlation with other non-related parameters from these tests. Such tests include the standard penetration test (SPT), the cone penetration test (CPT) and the dilatometer test (DMT) (see Chapter 47 *Field geotechnical testing*). The Ménard pressuremeter test (PMT) is the exception;

it can measure the soil stiffness directly through the stress–strain response of the soil.

24.3.2 Laboratory measurement techniques

In a similar manner to field measurement techniques, laboratory tests can be classified as either small or large strain tests. Also of importance in choosing a test method, is an understanding of the stress regime within the soil and the likely stresses that may be imposed, since each laboratory test can represent certain aspects of the required stress path.

24.3.2.1 Low strain tests

Advances in transducer accuracy and measurement techniques have allowed local strain measurements to be measured on samples under static loading. However, the most commonly used methods to determine small strain stiffness parameters are those relying on wave propagation. The three most popular methods are the *resonant column*, *ultrasonic pulse transmission* and *bender element* tests. These tests are generally considered to be non-destructive in that the soil remains unchanged during the dynamic test.

The resonant column is the most widely used test equipment and is routinely used to measure strain from 10^{-6} to 10^{-3}. Different modes of operation have allowed different soil parameters to be determined, such as G and E, as well as their respective damping (see Clayton *et al*., 2005). The resonant column works by vibrating the soil at its resonant frequency from which the wave propagation velocity can be derived. In contrast, the ultrasonic pulse transmission and bender element tests directly record the travel time of the generated wave between the source and the receiver. Typically the ultrasonic pulse transmission test will generate P-waves while the bender element test generates S-waves. For these two tests the strain imposed upon the soil is usually constant and of the order of 10^{-6}. Both these tests can be incorporated into conventional soil testing apparatus such as the conventional triaxial apparatus (Viggiani and Atkinson, 1995), the simple shear device, oedometers, etc.

24.3.2.2 High strain tests

For laboratory samples subject to high dynamic shear strains, the stiffness of soils is derived from the stresses and strains measured during a test. Soils tested in drained conditions are likely to exhibit changes in volumetric strain, while those tested in undrained conditions (where volumetric strains are prevented) exhibit changes in pore pressure (thereby changing the effective stress). Thus for high strain tests, measurements of pore pressure and/or volume change are required to determine soil stiffness and damping accurately.

A number of different devices are used to measure stiffness at high strains including the *cyclic triaxial*, the *cyclic direct simple shear* and the *cyclic torsional* tests. All tests measure the same basic parameters; however, there are differences between the tests which relate to how well they represent the shear stresses within the ground. Although the cyclic triaxial is the most commonly used apparatus for measuring the dynamic soil properties at high strain, it is the least accurate in reproducing the stress conditions that exist during dynamic loading. This is because the principal stresses are constrained to act in the vertical and horizontal directions. The cyclic direct simple shear test overcomes this shortfall by deforming the soil in a similar way to that during propagation of shear stress in the ground. However, shear stresses are only applied on the top and bottom surfaces of the sample. The cyclic torsional test overcomes these shortcomings and the stress conditions reproduce those under dynamic loading more closely.

24.4 Dynamic soil properties

24.4.1 Theoretical behaviour of soils

Complex geotechnical design problems focusing on soil–structure interactions can now be solved using a variety of numerical modelling techniques. In addition, advances in desktop computing power have allowed these problems to be routinely solved by most practising engineers if a model of the main characteristics of soil behaviour under cyclic loading is provided (see Chapter 6 *Computer analysis principles in geotechnical engineering*).

As discussed previously, at very small strains (10^{-6}) the behaviour of the soil is generally considered to be elastic in nature such that shear modulus is a key parameter. At intermediate strains, from 10^{-5} to 10^{-2}, the soil behaviour becomes elastoplastic with the shear modulus reducing with increasing strain. In addition, energy is dissipated during each cycle of stress due to slippage of particles at grain contacts. The energy loss (damping) is rate dependent and hysteretic in nature. Thus the dynamic behaviour of soils can be fairly accurately described using nonlinear viscoelastic theory (it should be noted that the material damping within the soil is not viscous in nature, but it is mathematically convenient to assume so; see Thomson (1988) for a mathematical derivation of viscous damping). The general hysteretic behaviour of a nonlinear-viscoelastic material during a stress cycle is illustrated in **Figure 24.3**. The stress–strain curve can be considered as being composed of two curves, (1) the backbone/skeleton curve which represents the montonic loading, and (2) the hysteretic loop. The shear modulus at small strains, G_{max} can be obtained from the initial gradient of the backbone curve, whilst the secant shear modulus at any given strain is given by

$$G = \frac{\tau_a}{\gamma_a} \tag{24.2}$$

where τ_a and γ_a are the shear stress and shear strain, respectively, at the given point in the loading cycle.

The inherent damping of the soil is related to the energy dissipated during a loading cycle and is defined by

$$D = \frac{1}{4\pi}\frac{\Delta W}{W} \tag{24.3}$$

where D is the damping ratio, W is the total stored energy (given by the area under the stress–strain curve) and ΔW is the energy loss per cycle.

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

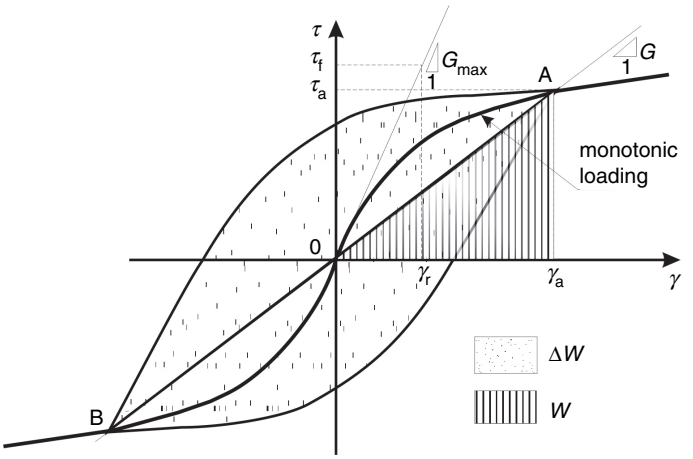

Figure 24.3 Stress–strain relationship for hysteretic soils

The two most popular constitutive models developed to describe the nonlinear stress–strain behaviour of soils are the two parameter hyperbolic model and the four parameter Ramberg–Osgood (R–O) model. The general features of both the hyperbolic and R–O models can be seen in **Figure 24.3**. For the hyperbolic model, the general forms of the equations are

$$\frac{G}{G_{max}} = \frac{1}{1 + \gamma_a / \gamma_r}, \tag{24.4}$$

$$G = \frac{\tau_a}{\gamma_a}. \tag{24.5}$$

where γ_r is a reference strain derived from the stress at failure from monotonic loading, τ_f, and assuming the soil behaves elastically.

For the R–O model, the general forms of the equations are

$$\frac{G}{G_{max}} = \frac{1}{1 + \alpha \left[\frac{G}{G_{max}} \frac{\gamma_a}{\gamma_r} \right]^{r-1}}, \tag{24.6}$$

$$\alpha = \frac{\gamma_f}{\gamma_r} - 1, \tag{24.7}$$

$$r = \frac{1 + \frac{\pi D_{min}}{2} \frac{1}{1 - G_f / G_{max}}}{1 - \frac{\pi D_{min}}{2} \frac{1}{1 - G_f / G_{max}}}, \tag{24.8}$$

$$G_f = \frac{\tau_f}{\gamma_f}, \tag{24.9}$$

where γ_f is the shear strain at failure derived from monotonic loading.

For the hyperbolic model both the initial shear modulus, G_{max}, and the shear strength, τ_f, are required, with the additional parameters α and r being required for the R–O model. These parameters are derived by fitting the respective models to experimental data.

24.4.2 Shear modulus and damping of soils

It has been previously highlighted that cyclic shear strain amplitude, γ_c, is a very important parameter for determining the dynamic behaviour of soils. Extensive laboratory testing undertaken to determine this behaviour has shown that shear modulus (G) and corresponding damping ratio of soils (D) are influenced by a range of parameters, such that

$$G; D = f(\gamma_c, \sigma'_0, e, N, Sr, \dot{\gamma}, OCR, C_m, t) \tag{24.10}$$

where γ_c = cyclic shear strain amplitude,

σ'_0 = mean effective principal stress,

e = void ratio,

N = number of loading cycles,

Sr = saturation ratio,

$\dot{\gamma}$ = strain rate (frequency of cyclic loading),

OCR = overconsolidation ratio,

m = grain characteristics – shape, size, mineralogy,

t = time of confinement under applied load.

When γ_c is around 10^{-6} it has been shown that for unconsolidated granular soils, such as sands, the dynamic behaviour is mostly independent of the variables considered above, apart from σ'_0 and e. For clayey materials, in addition to σ'_0 and e, other parameters such as OCR and t become important. At higher strains, both clay and non-clay soils are also affected by $\dot{\gamma}$ and N.

24.4.2.1 Small strain shear modulus, G_{max}

From testing of soils at very small strains (generally taken as $10^{-4}\%$), the shear modulus of soils has been found to be reasonably constant; and, for a given soil, a maximum. The value of shear modulus at these very small strains is therefore termed G_{max} or G_0. **Figure 24.4** shows the typical pattern of changes in shear modulus with isotropic stress for a range of dry granular materials. It can be seen that as σ'_0 increases, so does G_{max}. Empirically, a simple exponential relationship is found between G_{max} and σ'_0 of the form

$$G = A \sigma'^{b} \tag{24.11}$$

where A and b are constants (Hardin and Black, 1968; Hardin and Drnevich, 1972). By fitting equation (24.11) to the data in **Figure 24.5**, the b-value for the soil can be obtained (as highlighted in **Figure 24.5**). For non-clay soils the b-value is generally found to vary from 0.4 to 0.6. The b-value represents both

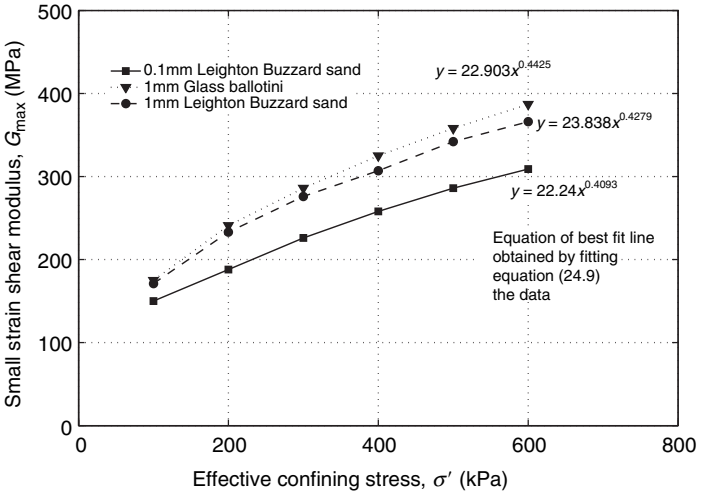

Figure 24.4 Influence of effective confining pressure (σ') on small strain shear modulus of a range of dry granular geomaterials
Data taken from Bui (2009)

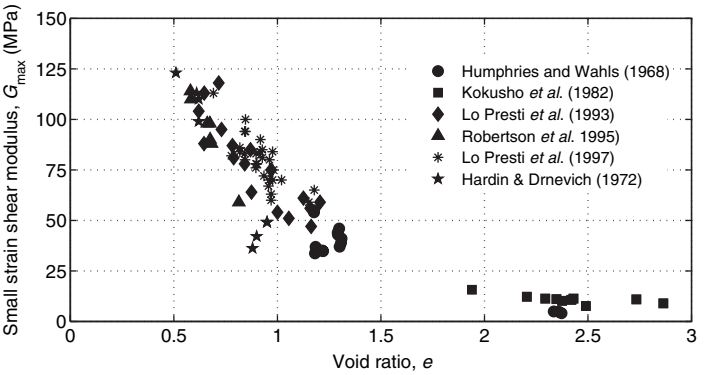

Figure 24.5 Changes in G_{max} with e for a range of soils. Data redrawn from review of literature conducted by Bui (2009)
Data obtained for samples subjected σ'_0 = 100 kPa

the nature of the contact stiffness and fabric change (Cascante *et al.*, 1998) during isotropic compression.

Based on Hertzian contact theory, the b-value for closely packed arrays of elastic spheres is 0.33 (Duffy and Mindlin, 1957), while a value of 0.5 is achieved for a random packing of elastic particles with non-spherical contacts (Goddard, 1990). Thus for non-clay soils, where changes in σ'_0 produce minor changes in fabric, aspects such as particle shape and size (which affect e) and the contact geometry influence the relationship between G_{max} and σ'_0. However, for clay soils where changes in σ'_0 can produce large changes in fabric (especially for soils with a high void ratio), the b-value may be appreciably higher than those for non-clay soils (Rampello *et al.*, 1997).

The influence of void ratio can be more clearly observed in **Figure 24.5**, which highlights changes in G_{max} with e for a range of geomaterials. It can be seen that as the void ratio reduces, G_{max} increases. For non-clay soils, the coordination number, N_c (the number of grain to grain contacts per grain), increases with reducing void ratio, leading to a reduction in average contact force under a given stress regime. Thus during dynamic loading, higher void ratio soils are likely to exhibit higher contact forces – giving rise to localized yielding at particle contacts, which reduces G_{max}. To account for the influence of void ratio on shear modulus, G is often normalized using a void ratio function, F(e) to eliminate the influence of void ratio. A number of empirically derived void ratio functions have been suggested, such as

$$F(e) = \frac{2.97 - e}{1 + e^2}, \text{ for values of } e \text{ between } 0.57 \text{ and } 0.98 \text{ (Hardin and Drnevich, 1972)} \quad (24.12)$$

$$F(e) = e^{-1.3}, \text{ for values of } e \text{ between } 0.81 \text{ and } 1.18 \text{ (Lo Presti } et\ al.\text{, 1997)}. \quad (24.13)$$

However, these functions are usually derived over a narrow void ratio range and there are no universal void ratio functions which can account for changes in G over the wide range of void ratios usually encountered.

Increasing OCR at a given value of σ'_0, primarily for clay soils, will increase G_{max}. This can be related to irrecoverable reduction in void ratio for a given soil as OCR increases, leading to increases in G_{max}. In addition, rearrangement of particle orientation inherently changes the structure of the soil causing an increase in G_{max} above that suggested by simply a reduction in void ratio (Kokusho *et al.*, 1982).

The influence of time on the measured shear modulus soils is related to the consolidation of the soil under applied stress (Humphries and Wahls, 1968), and can be characterized by two phases: (i) the initial phase which results from the primary consolidation of the soil, and (ii) a secondary phase which results from the long-term (creep) effects.

Figure 24.6 shows the effect of confinement time on G_{max} for a variety of soils. It can be seen that for clay soils both an initial phase and a secondary phase occur (**Figure 24.6(a)**), whilst for sands only a secondary phase is evident (**Figure 24.6(b)**). In addition, changes in G_{max} during the secondary phase for clay soils may be up to 15 times greater than that for sand. This observed behaviour has major implications for the testing of soils in the laboratory. For clay soils, testing must be conducted at the end of primary consolidation for each stress increment applied to the specimen. In addition, for all soils, testing must be conducted at equal intervals during the secondary phase for each sample.

24.4.2.2 Strain dependent shear modulus, G

As has been highlighted above, the dynamic behaviour of soils is highly nonlinear, and the material properties that are important such as shear modulus and damping change significantly with increasing strain during cyclic loading. Clays and sands have historically been treated individually. Seed and Idriss (1970) presented data from a wide range of test data compiled from the literature on a range of sands. They showed that when the ratio of G/G_{max} is plotted against strain, the results tended to

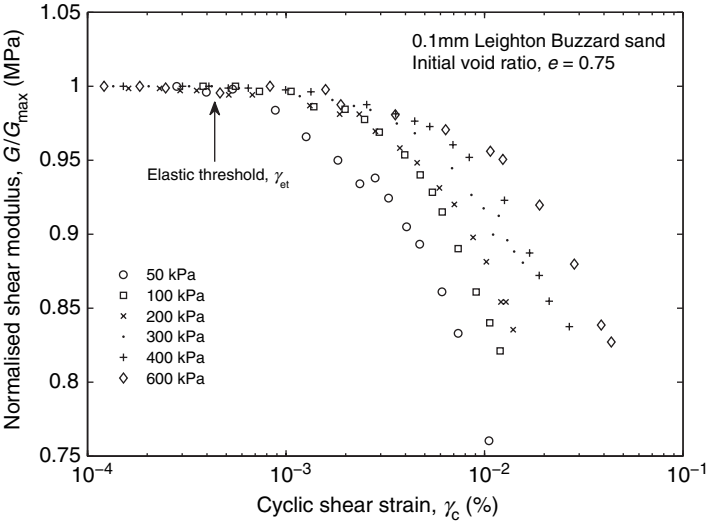

Figure 24.7 Changes in normalised shear modulus, G/G_{max}, as a function of applied cyclic shear strain at different effective confining pressures

fall within a narrow band for a given confining stress. **Figure 24.7** shows the results of resonant column tests conducted by the author using 0.1 mm diameter Leighton Buzzard sand. The results show a similar trend to that identified by Seed and Idriss (1970) and others. It can be observed that at a certain level of strain, the shear modulus starts to reduce with increasing strain. This point is referred to as the linear elastic threshold shear strain, γ_{et}. As for G_{max}, the shear modulus reduction curve is influenced by effective confining pressure. At higher confining pressures, γ_{et} increases, i.e. the linear elastic region occurs at higher strain and can be considered as shifting the whole curve to the right.

Recent research (Cho *et al.*, 2006; Bui, 2009) showed that soil attributes such as particle shape and surface roughness also influenced γ_{et}; Increased particle angularity and surface roughness increased γ_{et}, while more rounded particles such as glass ballotini gave a value of γ_{et} of around 10^{-6} (see **Figure 24.8**) such that there was little or no observable G_{max}. Vucetic and Dobry (1991) reviewed the results obtained for a broad range of materials, especially those for high plasticity clays. Their results, as presented in **Figure 24.9**, showed that γ_{et} was dependent on the plasticity of the soil and not its void ratio. They showed that as soil plasticity increased, γ_{et} increased. In addition it was shown that the influence of effective confining pressure was reduced as soil plasticity increased. It was also observed that there was a high degree of similarity between the curves for soils with a plasticity index (PI) of zero, and those obtained from Seed and Idriss (1970) on sands. Coarse gravels (Seed *et al.*, 1986) showed a similar response to sands, although the shear modulus reduction curve was slightly flatter.

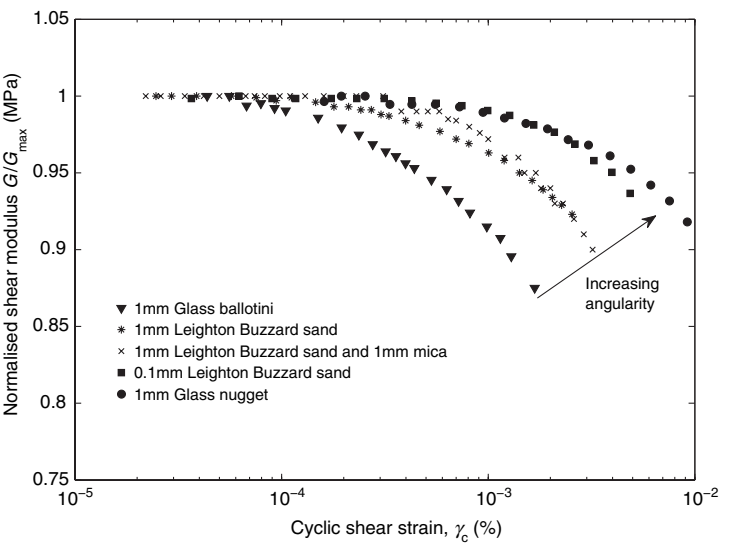

Figure 24.8 Changes in normalised shear modulus, G/G_{max}, as a function of applied cyclic shear strain at $\sigma'_0 = 100$ kPa for a range of geomaterials. Increasing particle angularity and surface roughness increase the elastic threshold strain, γ_{et}

24.4.2.3 Damping ratio

Theoretically, for soils subject to shear strain within the elastic region (~10^{-6}) no hysteretic energy is dissipated, since frictional losses through grain slippage and yielding are thought not to occur (Winkler *et al.*, 1979). However, even within the elastic limit a minimum value of damping is observable; this is often termed as D_{min} and may result from fluid squirt flow at grain contacts, or from Bauschinger effects (plastic yielding of individual grains at grain contacts. It is also important to realize that 'equipment damping – due to the apparatus' is also present when measuring material damping, and therefore careful calibration is required to remove this from the measured data (Priest *et al.*, 2006). This is important at low strains where the equipment damping may be the same order of magnitude as that of the material being tested.

Studies into the factors affecting damping ratio, D, are not as extensive as those for G. In equation (24.10), several factors were highlighted as having an effect on damping. It has been shown that D is strongly influenced by γ_c and σ'_0. **Figure 24.10** highlights the measured damping ratios as a function of both γ_c and σ'_0 for the same samples whose normalized shear modulus was presented in **Figure 24.7**. It can be seen that D reduces for increasing σ'_0 and increases for increasing γ_c. As σ'_0 increases, slippage at particle contacts is restricted thereby leading to a reduction in D, while at higher strains the shear stress at particle contacts is increased, leading to increased frictional losses. **Figure 24.11** highlights the influence of particle angularity on the measured damping ratio for a range of geomaterials. The results show that increased angularity leads to reduced damping for the range of geomaterials tested. γ_c and σ'_0 have major effects on D, but the time of confinement and e have only minor influences. The number of loading cycles is important at high strain amplitudes, but becomes less important as the induced strains become small.

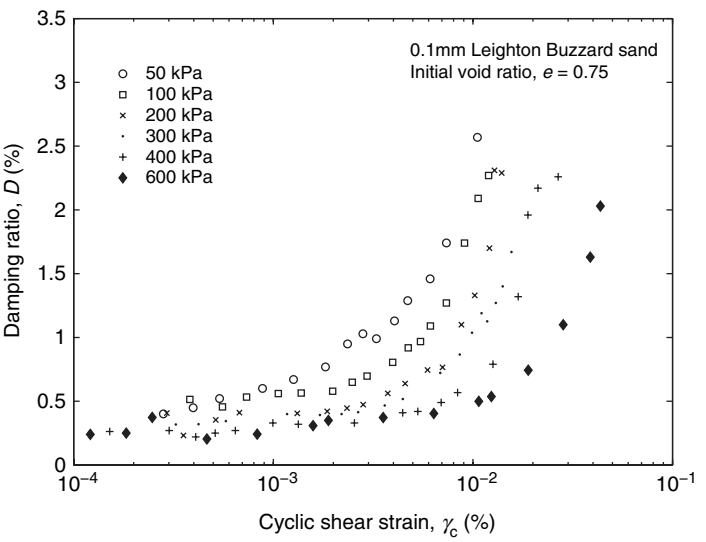

Figure 24.10 Influence of confining stress on the strain dependent damping ratio for Leighton Buzzard sand

24.5 Liquefaction of soils

The discussion above highlighted the nonlinear response of soils at strains from 10^{-6} to ~10^{-3}, where the deformation of the soil is negligible during cyclic loading. However, at higher strains, a phenomenon called soil liquefaction can occur in sands. During cyclic loading (such as that caused during an earthquake), frictional sliding and yielding occur at grain contacts. These lead to changes in soil volume, producing a build-up of pore pressure and subsequent reduction in effective stress, allowing large shear deformations to occur transforming the material from a solid to a liquefied state (Youd and Idriss, 2001). These shear deformations can be induced over short timescales and

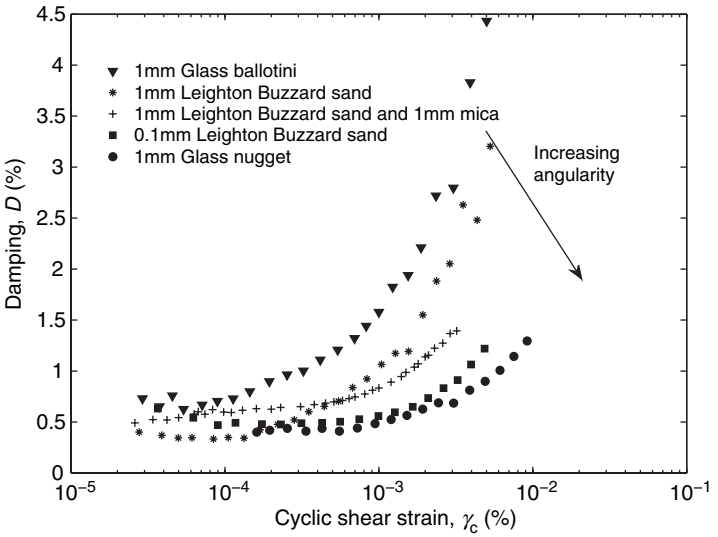

Figure 24.11 Influence of particle shape and roughness on the strain dependent damping ratio for a range of geomaterials at $\sigma'0 = 100$ kPa
Data taken from Bui (2009)

can lead to catastrophic failure of structures located on these soils (**Figure 24.12**). This dramatic change in behaviour is usually manifested in loose to moderately dense sands capped by impermeable layers, or in silty sands that have poor drainage properties; both prevent the high pore pressures induced in the sand from dissipating rapidly. For moderately dense to dense soils, liquefaction causes transient softening of the material and increases in shear strain. However, the tendency for dense soils to dilate during shearing inhibits major strength losses and restricts the development of large ground deformations. Although liquefaction has been predominantly reported in sands and silty sands, etc., significant ground deformations have also been induced in fine-grained clay soils. Boulanger and Idriss (2004) suggest that fine-grained soils can be classified as 'sand-like' (PI < 7) where the soil is liable to suffer liquefaction, or 'clay-like' (PI > 7) where the soil is liable to suffer cyclic failure. The terms 'liquefaction' and 'cyclic failure' do not imply strong differences in the observed stress–strain response of the soil during cyclic loading. They are used to identify soils where the mechanical behaviours are very different from each other and so require different procedures to be adopted to evaluate their seismic behaviours. A detailed discussion about the liquefaction or cyclic behaviour of fine-grained soils can be found in Boulanger and Idriss (2004).

The capacity of a soil to resist liquefaction is represented by the cyclic resistance ratio (*CRR*). From laboratory tests the *CRR* is defined as the point where the ratio of shear (τ) and mean effective (P′) stresses produces a 5% peak to peak amplitude shear strain, or when the buildup of pore pressure in the soil equals that of the mean effective stress. To constrain the tests, the number of load cycles to achieve liquefaction is required. An arbitrary value can be taken if relevant correction factors are applied, but given the number of significant cycles present in actual time histories, a value of 10–20 cycles is usually appropriate. **Figure 24.13** shows the typical response of saturated loose sand during cyclic loading. It can be seen that for each successive stress cycle a corresponding increase in pore pressure occurs. As the pore pressure increases and approaches that of the applied mean effective stress, large strains are manifested. Factors that influence the onset of liquefaction include initial confining stress, cyclic shear stress (intensity of shaking) and initial void ratio (relative density). In the application of constant shear stress, factors such as soil fabric are inherently important with regard to the pore pressure response. Therefore tests using constant shear strain amplitude are preferred for remolded sands, since the pore pressure response under constant strain is not significantly affected by the disturbance. **Figure 24.14** highlights the response from a cyclic triaxial test for medium dense sand with constant strain amplitude. As for constant shear stress test, pore pressure increases for each cycle with the shear stress reducing so as to maintain the constant shear strain amplitude. The stiffness response of the soil during constant strain amplitude can easily be incorporated into earthquake response programs.

Due to the inherent difficulty in obtaining undisturbed granular samples for testing and these soils being the most likely to liquefy, field tests are routinely carried out to assess liquefaction potential using techniques such as the SPT and the CPT, as well as measurement of shear wave velocity, V_s. Correlation curves have been developed over the years to relate test results to the *CRR*. Various corrections are required for these curves to take account of factors such as fines content, soil plasticity, soil type and overburden pressure, as well as test-specific correction factors. A detailed discussion of these can be found in Youd and Idriss (2001) and Idriss and Boulanger (2004).

24.6 Summary of key points

- The ground on which structures are founded can be subject to dynamic loads from both natural (earthquake, wave, water) and

man-made sources (vibrating machinery, traffic, bomb blasts), which generate strains in the soil (10^{-6}–10^{-2}) that are generally much lower than most static loads.

- Dynamic loading can be characterised by the frequency of the applied load (generally greater than 1 Hz) and the number of load cycles, which can vary from 1–2 (bomb blasts) up to many thousands (traffic loading and vibrating machinery).
- All soils exhibit nonlinear stress–strain behaviour where permanent, non-recoverable deformation of the soil occurs. At very low strains (10^{-6} to 10^{-4}) soil behaviour could be described as elastic, with recoverable deformations.
- Dynamic soil properties can be ascertained using field or laboratory techniques through either determining the velocity of wave propagation through the soil, or by direct measurement of the stress–strain response of the soil. The measurement techniques adopted will depend on what soil parameters are required and at what strains the measurements can be determined.
- The nonlinear behaviour of soils can be described using a number of nonlinear constitutive models, which can be adopted in numerical analysis. The key parameters for these models, such as very small strain shear modulus (G_{max}), and shear strength (τ_f) can be derived for experimental data.
- The shear modulus and damping in soils are influenced by a range of parameters, with the most important parameters being cyclic shear strain amplitude (γ_c), effective confining stress (σ') and void ratio (e). For clay soils both OCR and time of confinement (t) have also been shown to be important.
- At strains greater than 10^{-3}, frictional sliding and yielding at grain contacts can lead to changes in volume of the soil producing a build-up of pore pressures and subsequent reduction in effective stress, allowing large shear deformations to occur in the soil. This

behaviour is usually observed in loose to moderately loose sands and termed liquefaction. In dense sands, the tendency to dilate during shearing inhibits major strength loss.

- Fine-grained soils can be classified as having 'sand-like' behaviour and liable to liquefy, or exhibit 'clay-like' behaviour, where cyclic failure is likely to occur.

Chapter 25

The role of ground improvement

Chris D. F. Rogers University of Birmingham, UK

25.3	Removal of water	272
25.4	Improvement of soils by mechanical means	275
25.5	Improvement of soils by chemical means	277
25.6	References	280

Ground improvement can take many forms to cause temporary or permanent change, usually with some specific engineering purpose in mind. Common with all geotechnical design, specific engineering purposes (e.g. stable foundation) must be defined and the ground's current state in the zone of influence fully established. Analysis of the problem in light of this information usually yields a range of solutions, some of which might be altering the ground's properties. Techniques are available to strengthen or stiffen soft or weak ground, either by physically altering its structure or by changing the ground's chemical properties. Similarly, groundwater flow regimes can be altered to achieve greater stability or to stop flow of contaminants. Any analysis of ground treatment must therefore encompass the engineering purpose(s), the ground's current state and its potential to be altered, the proposed means of its alteration, and any side effects of treatment. Physical ground improvement includes application of static, vibrationary or dynamic loading; water can be drained using gravity, increased stresses or an electrical gradient; and chemicals can be introduced as solids or liquids. Hybrids of these processes and lateral-thinking approaches (e.g. ground freezing) complete a range of alternatives to 'structural' solutions and often provide more sustainable outcomes.

25.1 Introduction

Ground improvement covers any method by which the ground, whether natural or disturbed in some way by anthropogenic processes, has its performance for any specific (geotechnical) purpose enhanced. Typically the goal is strengthening and/or stiffening of soft or weak soil or fill, either temporarily or permanently, although other specific improvements (e.g. reduction or increase of hydraulic conductivity) might bring about the desired change or be the goal of the exercise. Equally the goal might be to make the properties worse (e.g. slurries introduced at the face of tunnelling machines to facilitate excavation and transportation of soil), while some techniques have unwanted side effects (e.g. vertical stone columns provide a route for venting gases), so the term 'improvement' should be treated with caution. Nevertheless it can be generally stated that a ground improvement process has some associated desired physical or chemical consequence, such as:

- settlements of overlying or embedded structures being reduced, speeded up, or rendered unimportant;
- the risk of failure being removed or reduced;
- the need for excessive or unnecessary use of natural resources (import of virgin material to a site) and/or waste generation (poor ground disposed of in landfill) being obviated;
- the movement of chemicals being enhanced (for extraction) or inhibited (for containment);
- the excavation of contaminated ground for treatment, thereby exposing it to the environment, being avoided.

Ground improvement for physical purposes is generally an alternative to structural solutions which either bypass the soils concerned (e.g. deep foundations) or act in spite of the soils concerned (e.g. rigid raft foundations). Ground improvement for chemical purposes might be used instead of permanent physical solutions (e.g. barriers to stop chemical contaminant migration), novel semi-permanent processes (e.g. permeable reactive barriers; see Boshoff and Bone, 2005) or costly temporary operations (such as pumping for groundwater lowering to generate an inward hydraulic gradient). Phear and Harris (2008) track developments in this subject.

There are very many reasons for undertaking some form of ground improvement. As with all engineering undertakings, the costs and benefits of the alternative engineering solutions must be examined, and this should be done using the broad three pillar (environmental, social and economic) or four pillar (adding natural resources, see Braithwaite, 2007) sustainability models (Fenner *et al.*, 2006). This is a most important aspect of an engineer's role due to the wider impact of geotechnical processes (Jowitt, 2004) – in the category of resource use falls energy (embodied and directly used) and hence CO_2 emissions, water, and similar concerns. The sustainability arguments are highly germane to ground improvement; if what is in place can be made adequate by some means, then the environmental and social (and resource) benefits are usually very substantial indeed, while economic benefits are also often favourable. The civil engineering industry has now moved to a state of global awareness that demands it goes beyond the traditional 'cost, quality and time' approach to engineering design. Ground improvement alternatives to 'structural' solutions represent an excellent example of how these considerations play out.

The aim of this chapter is to introduce the fundamental principles of ground improvement techniques, the detailed manifestations of which can be seen routinely in academic or professional journals. The scope of this chapter is limited to hydraulic, physical and chemical means of improvement. Soil reinforcement via the introduction of tensile elements

in the form of grids, strips, bars, fibres or similar is covered elsewhere (see Chapter 86 *Soil reinforcement construction*). Uncommon techniques, such as the thermal treatment of clays and the use of bitumen, fly ash or other 'non-standard' additives to improve soil properties, lie outside the scope of this manual. For a more complete review of ground treatment techniques, refer to Mitchell and Jardine (2002). Hereafter the term 'soil' will be used to represent undisturbed natural, disturbed natural and artificial ground (such as fills).

25.2 Understanding the ground

Common with all geotechnical design, the specific geotechnical engineering purposes for which the site is to be used must first be defined. These purposes in turn will define what is expected of the ground. So, for example, if the site in question is to house a multi-story building, the expectation of the ground is to provide a stable foundation, whereas if a river is to be protected from contamination migrating from an adjacent industrial site, the expectation of the ground is to provide a barrier to groundwater flow. In light of these expectations, the current state of the ground in the appropriate zone of influence (the influences of the stresses imposed by the building in the case of the foundation, or the potential routes through which the contamination might flow to the river) must then be established. Moreover, the future state of the ground for the design life of the expectation must equally be anticipated.

A useful tool for this analysis is presented by the 'Burland Triangle' (**Figure 25.1**), which provides a framework in which to explore whether the expectation can be met by the ground as it exists and is likely to continue to exist on the site in question. A site investigation will be conducted to establish the ground profile and provide clues to its geological history, and this provides the first pointer to the future likely state of the ground; for example, whether exposure might lead to further weathering of the natural soil and a change in its properties. If the building is to be founded on a clay soil at a certain depth below the ground surface, for example, then the net stress increase (maximum likely stress imposed by the building minus the stress relief due to excavation of soil above the foundation depth) must be determined, although of course it could be a stress reduction were it a lightweight structure founded at depth. The make up of the soil (see Chapter 14 *Soils as particulate materials*) will usually be established by the site investigation, while the properties of the soil (strength and deformation behaviour, see Chapter 17 *Strength and deformation behaviour of soils*) will likewise be established via laboratory testing; for a clay soil the deformation may take several years before it is complete.

Some form of modelling will determine whether, in general terms, the ground can fulfil the geotechnical expectation placed on it, taking cognisance of the ground properties, while an understanding of the geotechnical context of the wider area will provide clues as to whether the ground properties are likely to remain stable in the long term. Groundwater flow regimes (see Chapter 16 *Groundwater flow*) are important here, as they

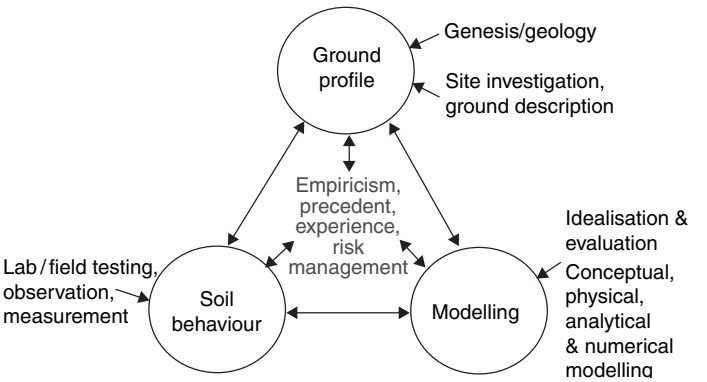

Figure 25.1 The 'Burland Triangle' for analysing the ground and how it might react for a geotechnical engineering purpose (Burland, 1987). Ground improvement processes can be analysed in the same manner

are for the second example of contaminant transport. Similarly, changes to the groundwater profile are important since they will alter the effective stress regimes operating on the site (see Chapter 15 *Groundwater profiles and effective stresses*), which in turn will alter the soil properties. The important point here is that sites are dynamic – the ground properties can change with time, and potential future changes must be accounted for in any geotechnical design, whether it is a conventional 'structural' solution (concrete foundation or cut-off wall) or a ground improvement process that is adopted. Analysis of the problem in the light of the totality of the above information will usually yield a range of solutions, some of which might be to alter the ground's properties. The remainder of this chapter is devoted to outlining the ways in which ground properties can be altered to obviate the need for more elaborate 'structural' solutions, and thereby provide additional weapons in the geotechnical engineer's arsenal.

25.3 Removal of water

25.3.1 Introduction

Water in soil is usually a nuisance (it gets in the way of construction operations) and, more importantly, the strength of a soil is usually very sensitive to both water content and water pressure (see Chapter 15 *Groundwater profiles and effective stresses*). Water is added to soil in certain situations (for example, to aid compaction of a granular soil or to weaken a clay soil to aid excavation) but on the whole, it is a hindrance. The problems posed by water in the context of ground improvement are generally that there is too much of it and/or it cannot escape quickly enough when additional, superimposed stresses are applied to the soil. Moreover, if water flows it can strengthen or weaken the soil according to the direction of flow and the pore water pressure distribution generated by the flow, which can be determined from a flownet (see Chapter 16 *Groundwater flow*). Only saturated soil (soil mineral particles and water) will be considered in terms of the need for water removal, which is the primary focus of the discussion hereafter. Natural groundwater

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

flow is excluded from this discussion, whereas techniques that induce the flow of water out of the soil are central to ground improvement.

From Terzaghi's law of effective stress

$$\sigma' = \sigma - u \quad \text{or more generally} \quad p' = p - u \qquad (25.1)$$

where σ' is the effective normal stress on any given plane in a soil mass, σ is the equivalent total normal stress, u is the pore water pressure, p' is the mean normal effective stress in three dimensions and p is the equivalent mean normal total stress (all measured in kPa). The parameter σ' (or p') is the factor which determines strength of the soil on any given plane (or in three dimensions). If the pore water pressure increases above its original level, σ' (or p') reduces, and *vice versa*.

Given that the pore water pressure increases linearly with depth below the groundwater table in the majority of cases (see **Figure 15.3**, Chapter 15 *Groundwater profiles and effective stresses* and associated text for exceptions to this rule) and water is held by capillary suction such that the suction (or negative pore water pressure) increases with height above the water table until the suction can no longer be maintained (which can be many metres in fine-grained soil having very small pores), one obvious means of ground improvement is to lower the groundwater table by some means of drainage. This principle stood the Romans in good stead when they were creating their roads, or (literally) their highways, in areas with a naturally high water table which adversely influenced the properties of fine-grained soil. Of course the same principle informs our current drainage specification for roads, railways, airport runways and other such traffic-carrying infrastructure. By digging deep ditches on either side of their roads, the Romans depressed the water table, thereby increasing the suction in the soil above the water table, or making u (the pore water pressure) more negative in equation (25.1). This in turn increased σ' (or p') and made the soil stronger (see **Figure 25.2**). Not only this, but by creating a cambered surface and paving it with stone flags, they minimised the possibility of water entering the road pavement structure from above and thereby maintained the suction regime. Drainage is therefore an assured means of ground improvement and is used widely: behind retaining walls, in slope faces and adjacent to dam cores, for example.

Fine-grained soil formation typically involves soil particles transported by water and settling in slow flowing conditions, such as in the base of lakes or the sea. The soil starts off as very wet indeed, but as more soil particles are progressively laid down above it, the soil densifies as water is progressively removed from the soil – it is squeezed out as the vertical (and hence mean normal) stress builds up by a process known as consolidation. The relationship between volume and mean normal effective stress is described by the normal consolidation line (NCL) and is shown using critical state theory terminology in **Figure 25.3**. A natural soil may undergo sequences of erosion and deposition, whereby the effective stress it experiences reduces and increases. One such sequence is shown in **Figure 25.3**, in which the soil is progressively consolidated as p' increases past points A and B until point C is reached. After this, p' reduces (due to erosion) until point D is reached. The degree to which the soil swells back relative to the projection of the critical state line (CSL) is important in determining the future response of the soil to applied stress regimes. The point on the NCL at which the soil at point D (and at any point on the Swellback Line, which is idealised as a straight line here for simplicity; in truth it is curved) has experienced its maximum p', is termed the *preconsolidation pressure*. If the soil at point D is thereafter reloaded, it will recompress and its state will move down the path of the recompression line

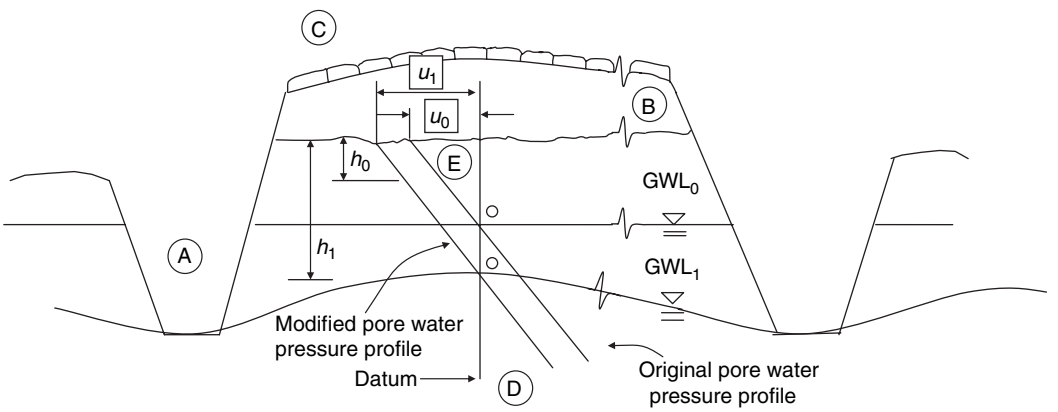

Figure 25.2 The effects on the strength of soil due to groundwater table lowering, as illustrated by a Roman road construction
A – Deep ditches on either side of road lower groundwater level (from GWL_0 to GWL_1)
B – Excavated soil creates highway
C – Stone flags on cambered surface limit surface water ingress
D – Pore water pressure increases linearly with depth below GWL
E – Suction, or negative pore water pressure, increases linearly with height h above GWL such that suction $u_1 > u_0$

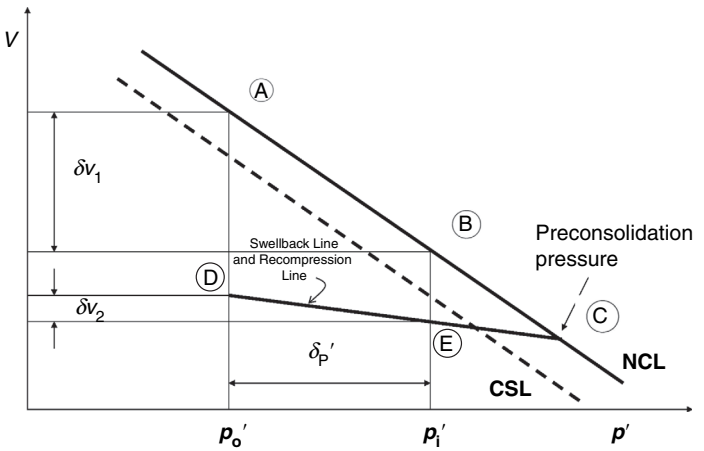

Figure 25.3 Graph of volume against mean normal effective stress

(idealised here as linear and coincident with the Swellback Line) to reach point C. It will then follow the NCL downwards once more.

In practice, if we encounter the soil at point D in equilibrium ($p' = p_0'$), and apply a superimposed stress to it of $\delta p'$, say due to a new building, according to the idealised graph the soil state would move to point E and the amount of volume change would be δv_2 once consolidation due to the imposed stress was complete, i.e. once water had been caused to flow out of the soil and a new equilibrium at $p' = p_1'$ had been reached. If, however, the soil encountered was at point A, also in equilibrium at $p' = p_0'$, and a similar stress of $\delta p'$ was imposed on it due to construction of the same building, then the far greater volume change of δv_1 would result once a new equilibrium at $p' = p_1'$ had been established as the soil state moved to point B; far more water would have been driven out of the soil to achieve this state. For practical purposes, therefore, it is desirable to ensure that the stresses imposed by construction activities remain below the preconsolidation pressure. One form of ground improvement is to create this situation, i.e. induce artificial overconsolidation.

The velocity (v in ms^{-1}) at which water flows through a saturated soil, which is a particulate material with interconnected pore spaces, is governed by the driving force (the hydraulic gradient, i, which is dimensionless) and the resistance to flow (the hydraulic conductivity, k in ms^{-1}) according to Darcy's Law:

$$v = ki. \tag{25.2}$$

When an increment of total stress (δp) is applied to a soil, this stress is instantaneously carried by the pore water and creates an excess pore water pressure of $\delta u = \delta p$. Water flows from high to low pressure and therefore away from this area of high pressure, thereby progressively reducing δu to zero, causing $\delta p'$ to rise progressively until it increases by δp. The driving force, i.e. the hydraulic gradient, is therefore due to the excess pore water pressure induced by the increment of stress (δp). In effect we have created a seepage problem, for which isochrones could be drawn to illustrate the direction of flow and progression of consolidation within the soil. In fine-grained soil, the rate of flow is small, with coefficients of hydraulic conductivity ranging from ~10^{-5} ms^{-1} for clean silts to ~10^{-11} ms^{-1} for heavy clay soils, while the distance that the water has to flow clearly governs the time required for consolidation to occur.

25.3.2 Pre-loading

Returning to the previous example illustrated in **Figure 25.3**, if we encounter a soil at point A and apply temporarily a stress equal to (applying $\delta p = \delta p'$ would take the state to point B) or greater than (say to point C) the stress subsequently to be imposed by the building, and were to allow the stress to remain in place for a sufficient length of time for consolidation of the soil to occur fully, i.e. for the water to flow out and equilibrium to be regained, then removal of the temporary stress and imposition of the new stress due to the building would cause only a small amount of volume change. Unloading (by removal of the temporary stress at points B or C) would cause the soil to swell, i.e. move upwards along parallel Swellback Lines, while the addition of the building would recompress the soil, i.e. move downwards along the relevant Recompression Line (being coincident with the Swellback Line). If this process of stress removal and replacement by the building were to take place quickly, and/or if the soil had a small coefficient of hydraulic conductivity (k), or the flow distance for the water to exit the soil is large, then the heave caused by the unloading and the compression caused by the building could be very small, and for buildings or foundations that are very sensitive to settlement, this process can be used to advantage to create negligible settlements.

This process is effective, especially for soils in which secondary compression (creep) is significant, but it is slow. One way to speed up the process is to increase the temporarily applied stress by increasing the driving force element. However, for thick soil deposits, especially where the direction of flow is upwards only (e.g. the soil overlies an impermeable rock), it can prove impractically slow; the rate of flow is proportional to the square of the drainage path. The temporary load can be earth or rubble fill, although water tanks or vacuum preloading (by pumping from beneath an impervious membrane) have been used. Placement of fill, ensuring continued drainage, is effected in layers as quickly as possible (staged loading is commonly needed to avoid overstressing the soft, weak soil being treated and avoiding failure); likewise, fill is removed as quickly as possible (staged removal is not necessary). The advantages are that this is a simple method that is easy to effect and certain to work, and is suitable for soils that undergo large volume decreases. It can, however, require a long time and much material, which has to be double handled.

25.3.3 Vertical drains

Although it adds to the cost and complicates the construction process somewhat, the time required for consolidation using

pre-loading can be greatly reduced by installing vertical drains. The rate of consolidation depends upon the length of the drainage path and the hydraulic conductivity of the soil associated with this path. In general, the water will flow vertically on loading to exit the soil and $k_{vertical}$, which is governed by the lowest coefficient of hydraulic conductivity of the substrata (e.g. interlayered fine sands, silts and clays in alluvium), will determine the rate of flow. By permitting horizontal drainage to vertical drains installed at predetermined intervals, not only is the length of the drainage path greatly reduced, but the rate of flow is governed by $k_{horizontal}$, rather than $k_{vertical}$. In general, the horizontal coefficient of hydraulic conductivity is far greater since it is the higher of the values of the substrata that dominate. For interlayered sands, silts and clays, this can mean a few orders of magnitude. This is why normally consolidated or lightly overconsolidated alluvial soils and stratified soils are most effectively improved using vertical drains. Types of vertical drains include sand-filled boreholes (though horizontal shearing would compromise their performance), sand-filled stockings that are inserted into vertical boreholes, and proprietary band drains consisting of a strong, flexible core (manufactured from polyethylene or similar) containing drainage channels and covered by a filter fabric. A horizontal free draining layer is constructed at the top of the vertical drains prior to application of the pre-load. Connection with an underlying permeable layer (e.g. sand or gravel) is also achieved where possible. Smearing of the borehole sides should be avoided so that horizontal drainage is not compromised (Hird and Moseley, 2000).

25.3.4 Electro-osmosis

When a voltage gradient is induced across a soil, the water in the pore structure of the soil moves from the anodes (often metal rods) to the cathodes (e.g. perforated metal pipes creating a series of filter wells), which are water abstraction points. The electro-osmotic flow of water through soil is expressed by:

$$v_e = k_e\, i_e \qquad (25.3)$$

where v_e is the electro-osmotic flow rate, k_e is the coefficient of electro-osmotic permeability (measured in m^2/Vs) and i_e is the potential gradient = V/L (where V is the potential difference and L is distance between the electrodes). This is analogous to Darcy's Law for hydraulic flow (equation (25.2)), yet there is a fundamental difference since k_e is commonly considered to be independent of the size of the pore spaces, while k is very strongly influenced by pore size. The technique is therefore most effective in fine-grained soils, in which k_e is typically 10^{-8} to 10^{-9} m^2/Vs (Mitchell and Soga, 2005, p. 275) whereas k can vary by orders of magnitude down to ~10^{-11} ms^{-1} (Mitchell, 1993, p. 270 provides example comparisons). Electro-osmotic flow is primarily caused by cations in the water surrounding negatively charged clay particle surfaces being transported towards the cathode drawing water (a polar molecule that is attached to the cations) with them. (Very occasionally, positively charged surfaces surrounded by anions will result in flow towards the anode.)

There are many phenomena acting (see Liaki *et al.*, 2008), and some can bring about additional improvements:

- Degradation of a metallic anode and transport of metal ions by electromigration can cause improvement of clay soils via cation exchange on the exchange sites of clay minerals.
- Transport of stabilising agents added as aqueous solutions (electrolytes) at the anode (anolyte) and cathode (catholyte) can result in stabilising reactions.
- Electrokinetic remediation can be used to draw contaminants to the electrodes where they can be removed, hence remediating chemically contaminated sites (Ottosen *et al*., 2008).

Electro-osmosis can be used for temporary dewatering in soils not readily treated by well pumping, or for permanent improvement, especially when accompanied by chemical changes. Moreover, it is fast and can be used in a confined area, though it remains little used in practice. The soil immediately adjacent to the anodes tends to dry out, causing increased resistance and current requirements, but can be countered by periodic short duration reversals of polarity or by an appropriate anolyte solution. Mitchell and Soga (2005) is a particularly helpful reference on the subject of ion movements.

25.3.5 Groundwater lowering

Well pumping is conceptually simple, being more of an accepted construction technique than a geotechnical process, and works best in soils with relatively high coefficients of hydraulic conductivity such as sands and gravels (see Chapter 80 *Groundwater control*).

25.4 Improvement of soils by mechanical means

25.4.1 Introduction

Compaction is widely used to increase the density of soils, and thereby increase their strength and stiffness, notably in road construction where surface compaction technology has reached a considerable level of sophistication. The principal goal is to cause the soil particles to pack together as closely as possible so as to minimise voids and to maximise 'particle interlock' – so that when the soil is sheared, the soil in the sheared region must dilate (i.e. particles must do work against the normal, or confining, force) as well as doing work against the frictional force. The types of rollers available include smooth-wheel dead weight rollers, vibrating rollers and sheepsfoot rollers (see Chapter 75 *Earthworks material specification, compaction and control*). Compaction technology has developed into deep compaction for more general ground improvement based on both vibratory and impact methods. Explosives have also been used to induce deep densification (Hausmann, 1990), but this approach lies outside the scope of the standard approaches and is not covered. A static form of compaction is achieved by pre-loading, which is covered in section 25.3.2.

25.4.2 Dynamic compaction

Compaction of soil by the repeated dropping of weights on the ground has been practiced for centuries with the aim of improving the bearing capacity. The extension of this technique to dynamic compaction, involving heavy weights and large drop heights, was used in the early 1970s to provide a stable foundation for structures of large plan area and for reclaimed land development. The principle of operation is simply based on the application of large vertical stresses to a considerable depth, thereby compressing the soil skeleton directly where the degree of saturation (S_r) is low (Gu and Lee, 2002). Where S_r is not low, high excess pore water pressures are generated; if they are sufficiently high they will cause failure and fissures (or cracks) to be created extending from the surface to significant depths. As the excess pore water pressures progressively dissipate, aided greatly by the fissures providing convenient drainage paths, the bearing capacity of the soil increases such that it exceeds the previous maximum value.

Dynamic compaction is effective in coarse-grained fills (including decomposed domestic waste and industrial fills) and soils, but relatively ineffective in soft clays and peats that absorb the applied energy. The weights, or pounders, typically have a mass of 10–20 tonnes (100–200 kN) and are typically dropped, using a crane, from heights of 10–20 m at wide intervals initially, the spacing being progressively reduced. Repeated application of the pounder causes craters, which are backfilled with coarse fill prior to the next series of load applications. The surface layers require rolling at the end of the process. It is a simple, rapid, relatively inexpensive method of treatment involving large equipment (though it cannot be used in confined spaces) and considerable ground vibration (hence it cannot be used adjacent to sensitive buildings or structures). A depth of compaction of 5–6 m can be easily achieved; a 'rule of thumb' for the treatment depth given by Hausmann (1990) is $0.5\sqrt{(WH)}$, where W is the mass of the weights, and H the height from which they are dropped. The same principle is adopted by *rapid impact compactors*, which were developed to provide a more controlled, rapid and thus readily applied form of the technique (see Serridge and Synac, 2006) and which typically deliver an energy input of around 8 tonne metres at a rate of 40 blows per minute. Guided or leader dynamic compaction rigs are also available.

25.4.3 Vibrocompaction

Vibrocompaction (sometimes termed vibroflotation) aims to cause deep densification, and hence strengthening and stiffening, of a specifically designed volume of ground by means of lateral vibration using a poker lowered by a crane. The poker contains an eccentric weight mounted on a vertical shaft which is rotated by a motor. The poker vibrates laterally thus compacting the ground while sinking to the design depth under its self weight. This is known as the 'dry method' of operation; the 'wet method' involves forcing water through the end of the poker while it is lowered into the ground, thereby producing what is stated to be a 'flushing effect'. The principles that underlie the standard compaction curve (described in section 25.5.2 and **Figure 25.4**) also apply here. A void is thus formed within an area of dense, compacted soil. The poker is withdrawn and a granular fill is dropped into the void and is compacted in 250–500 mm lifts by lowering the poker to refusal. The purpose of the granular fill is to compensate for the reduction in volume due to compaction of the existing soil. Vibrocompaction thus aims to create a uniformly dense, uniformly stiff block of soil onto which to locate some type of foundation. The size of each treated block of ground is designed to accommodate the bulb of pressure beneath the foundation, i.e. the plan area of the treated block is square for a pad foundation (using typically 4, 9, 16 or 25 insertions) and linear for a strip foundation. The poker typically compacts the soil to a radius of 1.0–2.0 m from the insertion point, the volume decrease being generally about 5–10%, and occasionally up to 15% (see Chapter 85 *Embedded walls*).

Loose natural soils and fills ranging from fine sand to coarse gravel are most effectively treated, while coarser material is difficult to penetrate unless it is well graded. A high fines content prevents rapid dissipation of the excess pore water pressures that are generated by vibration in soils with a high degree of saturation. It also serves to dampen the vibration, hence reducing the area of influence of compaction. Cohesionless soils with less than 15% fines are consequently commonly quoted as being suitable; see Slocombe *et al.* (2000). The technique has also been widely applied to fills consisting of brick rubble, ash and general demolition debris, the voids in these materials being broken down by regular insertion of the poker and granular fill forced into the remaining spaces.

25.4.4 Stone columns

The same equipment and construction methods are used as for vibrocompaction, although a single-sized crushed rock is used as the granular fill. The end result is a 0.9–1.2 m diameter column of dense stone within a less competent stratum – typically a saturated weak/compressible fine-grained soil, though stone columns can in principle be installed in any soil type. In this case, the vibration does not necessarily influence the soil between the columns significantly, especially when the soil has a high fines content and a high water content. This will lead to largely undrained shearing displacements since there is no time for the water to flow out of the soil (although any air within the soil voids would of course be compressed). The process of adding stone and compacting it using the poker, however, will inevitably cause stone to be forced sideways into the soil until it is resisted. Three zones of material might be considered once the process is complete: largely undisturbed soil that has undergone some displacement due to undrained shearing, a soil–stone intermediate zone, and the compacted stone column itself. This technique is sometimes known as vibroreplacement or vibrodisplacement.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The stone columns serve to reduce settlement of overlying foundations by acting as bearing piles and to strengthen the soil by virtue of zones of granular material having a much higher shear strength than the soil. It is also suggested that the stone columns act as vertical drains for the rapid dissipation of excess pore water pressures, although this remains a matter of debate associated with the degree to which the displaced soil fills the voids between the compacted stone. The depth of stone columns rarely exceeds 12 m, although lengths approaching 30 m have been recorded. The column fill typically consists of uniform 20–50 mm crushed stone, gravel or slag. Surface disturbance (due to a lack of confinement to resist the compaction energy) means that surface rolling is required after the columns have been formed (see Chapter 85 *Embedded walls*).

25.4.5 Micro-piles or root piles

Micro-piles were originally introduced for underpinning operations. They are now used for slope stability problems, retaining structures and underground construction. Micro-piles are constructed primarily to carry tensile and compressive forces and thereby increase the strength of soil for a particular purpose. They have only a limited degree of flexural (or bending) resistance and are therefore generally constructed at appropriate angles to carry direct forces. They can be used in most types of soil.

To create a micro-pile, a casing is jetted, driven or drilled to the desired depth, reinforcement is inserted into the casing and cement mortar is pumped in to fill the hole while the casing is withdrawn. In the case of root piles, the cement mortar is forced into the holes under higher pressure using a grouting technique so that it penetrates cracks or soft layers around the void. This creates a rough pile surface, thereby gaining maximum skin friction.

25.4.6 Soil nails, ground anchors and soil reinforcement

These techniques do not really lie under the heading of ground improvement and they are mentioned here only for completeness. Their purpose is to give the soil into which they are installed or buried an enhanced strength, either by providing tensile elements, increasing the mean normal effective stress, holding in place some form of structural facing to retain soil, or a mixture of all three. Soil nails are described in Chapters 72 *Slope stabilisation methods*, 73 *Design of soil reinforced slopes and structures*, 74 *Design of soil nails* and 88 *Soil nailing construction*. Ground anchors are described in Chapters 64 *Geotechnical design of retaining walls*, 87 *Rock stabilisation* and 89 *Ground anchors construction*. Soil reinforcement is described in Chapters 62 *Types of retaining walls*, 64 *Geotechnical design of retaining walls*, 72 *Slope stabilisation methods*, 73 *Design of soil reinforced slopes and structures* and 86 *Soil reinforcement construction*.

25.5 Improvement of soils by chemical means

25.5.1 Introduction

The addition of chemicals to clay soils to bring about improvements in strength, stiffness and volume stability (i.e. to inhibit shrinkage and swelling) or for other purposes, is hardly new – the Romans were adept at using the technique. The fact that lime has been used for this purpose in stabilising clays is equally unsurprising since limestone and shale (which is highly compressed clay) are the two primary ingredients of cement; cement factories being located where limestone and shale outcrop together. Other than the use of chemicals to dry very wet soils and make sites workable following heavy rain (quicklime is particularly effective for this), chemical soil stabilisation can be divided into two categories: (i) soil improvement as a result of the combined action of the soil constituents and the stabiliser to create a cemented product (as occurs by mixing lime and clay); and (ii) addition of a stabiliser that binds the soil particles together (as is the case with a sand-cement mix). The traditional manner of introducing the stabiliser is either as a powdered solid or a liquid suspension that is mixed with the soil at the surface, laid and compacted. However, more modern techniques have evolved to mix the stabilisers at depth or to pump stabilising solutions, such as cement grouts, into the ground. There are several applications (see for example Rogers *et al*., 1996) and while all have different requirements, the basic principles remain the same. Problems can be encountered when stabilising soils having a high plasticity index due to difficulties in achieving a thorough mix and ensuring a sufficiently large volume of stabiliser to chemically modify the clay minerals, leading to some concern over long-term softening due to water uptake.

25.5.2 Lime and cement stabilisation

Traditionally, lime has been used to improve the properties of clay soils by surface mixing, wetting where necessary, laying and compaction. Mixing lime with a clay soil alters its physical properties by fundamentally changing its nature as a result of cation exchange – a process termed *modification*. If sufficient lime has been added, and the modified material is compacted and allowed to cure for a significant period of time, the material cements by a process termed *stabilisation* (or *solidification*). The technique is most commonly used as a general ground improvement process, essentially to improve soft, weak clay soils, but it can also be used to treat contaminated soils.

Lime is a general term used to describe either quicklime (calcium oxide, CaO, created by heating hydrated lime to 450°C), hydrated lime (calcium hydroxide, $Ca(OH)_2$, which is formed when CaO comes into contact with water or water vapour) or lime slurry (a mixture of hydrated lime with water). Agricultural lime refers to calcium carbonate ($CaCO_3$), which is unreactive and will form if lime comes into contact with the atmosphere; carbonation must be avoided. In its simplest application, quicklime is used as a construction expediency to dry out sites that are unworkable due to water via a strongly exothermic reaction that turns CaO into $Ca(OH)_2$; dehydration taking place due to the reaction and to steam being released. Lime is simply spread evenly on the surface to effect this improvement, perhaps with some limited surface mixing.

Lime modification occurs as a result of cation exchange, the calcium ions exchanging with the cations on the clay mineral sites (usually monovalent sodium or potassium ions), which causes:

- a reduction in the thickness of the adsorbed water layer, and hence a reduced susceptibility of the clay to water;
- flocculation of the clay particles, due to greater electrical attraction (as the water layer has thinned);
- an increased internal angle of friction, i.e. greater shear strength;
- a textural change from a plastic clay to a friable material that appears granular in nature;
- a reduced plasticity as a result primarily of the plastic limit (PL) rising considerably.

To bring about this improvement the lime is spread evenly on the surface, mixed thoroughly with the clay to the required depth using a rotavator and allowed to mellow (or cure) for 24–72 hours. This timespan will ensure that all quicklime is fully hydrated (it hydrates via an expansive reaction and this must not be allowed to happen post-compaction), and that the cation exchange reactions are complete – the surface of the mixed material having been lightly rolled to seal it from rain and to inhibit carbonation. Lime modification can be achieved with the addition of a modest quantity of lime that is determined using the initial consumption of lime (ICL) test, which establishes the quantity of lime required to fully satisfy the cation exchange reactions. The ICL test is based on measuring pH changes in the soil, the ICL value being the lime addition that causes the pH to rise to 12.4 (or failing that, 12.3). This result can be confirmed by Atterberg limit tests of clay mixed with lime at different quantities.

To bring about the lime stabilisation reactions, sufficient additional lime is needed to raise the pH to a high level (>12). Also, once the cation exchange demand of the clay has been met, additional calcium ions are needed to react with constituents of the clay minerals (which are dissolved in the high pH environment) to achieve stabilisation via pozzolanic reactions (Boardman *et al.*, 2001). It is important that, as the reactions are taking place, there is a close proximity of the clay flocs so that the reaction products can bind the particles together in a coherent cemented mass. This process takes place in an environment that is free from chemical or organic contaminants that adversely affect the reaction processes. The reactions can be superficially stated as:

$$Ca^{2+} + OH^- + Al_2O_3 + H_2O \rightarrow \text{calcium aluminate hydrate gel}$$

$$Ca^{2+} + OH^- + SiO_2 + H_2O \rightarrow \text{calcium silicate hydrate gel}$$

and are the result of alumina (Al_2O_3) and silica (SiO_2) dissolving from the clay mineral under conditions of high pH. The two gels crystallise over time to yield strong, brittle bonds. This causes a considerable increase in strength and results in a material that is subject to brittle fracture (i.e. is non-plastic).

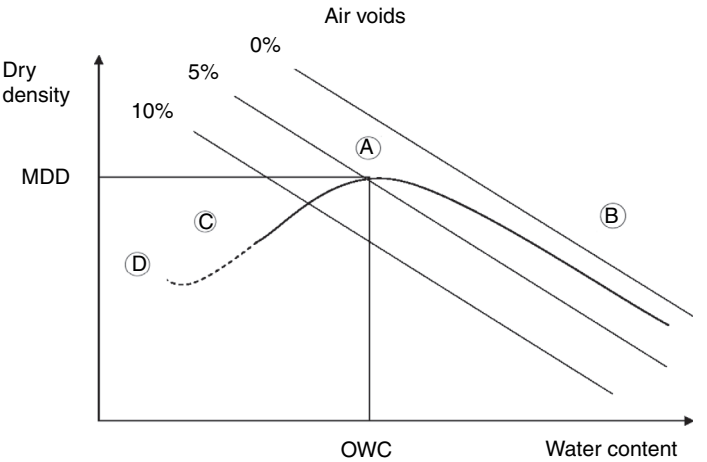

Figure 25.4 A standard compaction curve for fine-grained soil. Compaction seeks to maximise density and minimise air voids; for this application both of these compaction objectives are important
A – The maximum dry density (MDD) is achieved at the optimum water content (OWC) at which point the soil has minimum resistance to shear, hence densification
B – Additional water inhibits densification; undrained shearing occurs at progressively greater water content (hence lower dry densities)
C – As soil dries below OWC, suctions progressively increase thereby inhibiting shear under compaction stresses and the dry density falls
D – Where there is insufficient water, suction is lost and the dry density increases

The construction process is similar to that of modification, except that the mellowing process should not be as long (24 hours should be ample, and even this length of time has been considered to be detrimental to the long-term performance of the lime stabilised clay). The material should then be remixed, adding water if necessary to bring the water content up to the right level (between 0 and 2% above the optimum water content so that density is maximised while air voids are minimised, see **Figure 25.4**). It can then be placed and compacted in layers of appropriate thickness for the compaction energy applied, to ensure a density close to the maximum dry density throughout the full depth of the layer. The material should then be rolled with a smooth-wheeled roller if necessary to seal the surface while ensuring that there is a slight fall to avoid water ponding. Finally, it needs to be left to cure, free from frost and traffic until the reactions have advanced. The sulphate content must be sufficiently low (some specify <0.5%, others <1.0%) to avoid the creation of ettringite which forms via a highly expansive reaction, destroying the compacted state and compromising long-term strength. Organic material in the clay can be detrimental because it tends to be acidic, and hence lowers the pH, but more importantly calcium reacts preferentially with the organic material and thus less is available for the stabilisation reactions. The most assured method of design is to carry out laboratory trials of compacted mixes with different lime contents above the ICL value and allow them to cure for different periods before being tested for strength.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Cement stabilisation can be used in any soil (there is no requirement for the alumina and/or silica from the clay mineral). The principles behind the technique and the processes of design and construction are similar. A larger quantity of cement than lime is usually required to provide sufficient binding agent to create a matrix sufficient to encompass the soil particles. Cement contains a significant proportion of quicklime and, like lime stabilisation, the use of cement causes a large rise in pH. This effect can be reduced if a cement replacement material, such as ground granulated blast furnace slag (GGBFS), is used.

25.5.3 Lime, lime-cement and cement columns

The modern techniques of lime column construction have been developed in Sweden and Japan, although there is now a far greater use of cement only and lime-cement mixes rather than lime only. This technique, commonly referred to as 'deep mixing', has generally only been carried out in soft/weak soils due to the difficulty of operating the mixing plant in stiff/strong soils. The principles listed above remain valid for the deeper process, notably the need for sufficient water for the reactions to take place, the mixing to be achieved thoroughly and the resulting material to be adequately densified. The mixing takes place with a purpose-designed tool that is augered into the ground; the densification occurs by counter-rotation of this tool such that there is downward pressure on the mixed material as the tool is withdrawn. The correct water content can be achieved by the inclusion of quicklime in a powder mix (nowadays consisting primarily of cement to guarantee the reaction products) to dry out wet soils, or, by using a cement slurry in cases where additional water is needed (see Chapters 84 *Ground improvement*).

25.5.4 Lime piles

An alternative stabilisation technique, commonly restricted to clay slope stabilisation, is to create lime piles, which are columns of compacted quicklime. The quicklime hydrates via the exothermic hydration reaction causing water content reduction and immediately reducing the pore water pressure and creating suctions; these have been found to arrest slope movement (Rogers *et al*., 2000a). The lime hydration releases calcium and hydroxide ions into the ground and they migrate from the quicklime pile into the surrounding soil, which is thus stabilised, to a distance that is dependent on the water content of the soil and the reactivity of the clay (Rogers and Glendinning, 1996). This distance is usually a few tens of millimetres, although clay cracking due to the rapid dehydration causes fissures that radiate from the pile and these provide conduits along which the lime migrates and stabilises the clay further away from the pile. The process can be enhanced by the inclusion of different additives, GGBFS being particularly effective (Rogers *et al*., 2000b).

25.5.5 Lime slurry pressure injection

Lime slurry pressure injection is another alternative that borders on the use of cement grout, but remains distinct since the aim of the process is to cause chemical changes in the clay soils into which the slurry is injected. A lime-water mix is injected at different depths into the clay on a grid pattern with the aim of creating an approximately uniform distribution of slurry. Migration of ions into the soil adjacent to the slurry seams results in the classical lime stabilisation reactions occurring. The technique has been used for clay embankment stabilisation in the USA, but has been little used in the UK and requires further research before its efficacy can be proved.

25.5.6 Grouting

Grouting has been practised for roughly 100 years and can be effected in many ways. The aim is generally to strengthen the soil by introducing a cementitious grout and/or by causing densification as a result of introducing the grout, or to prevent the flow of water by filling the voids in the soil. Essentially a fluid is injected into the soil and hardens at some later stage. The 'split spacing' method of group injection is generally used, whereby pre-determined quantities of grout are injected through holes spaced at two or three times the final spacing, the hole spacing gradually being reduced. The voids become progressively smaller and the ground progressively tighter. Grouting is covered in Chapters 84 *Ground improvement*, and 90 *Geotechnical grouting and soil mixing*, and so will be covered only briefly here.

25.5.6.1 Permeation grouting

Permeation grouting refers to the process in which no volume change or soil structure change occurs as the grout permeates the soil via the pore spaces. Once the grout is in position it hardens with time to strengthen the soil. Particulate grouts can be used where the soil is relatively coarse grained. Chemical grouts can penetrate smaller voids (medium silts or coarser), but are unsuitable for soils having more than 15% fines. Electrochemical injection can be used in silts and silty clays.

25.5.6.2 Displacement grouting

Displacement grouting refers to the process by which high viscosity grouts are pumped into the soil under high pressures with the aim of causing lateral or radial compaction of the soil. The grout usually consists of mixtures of cement, soil and/or clay, and water. Either spherical bulbs of grout are formed at the end of the grout pipe or columns of grout are formed by withdrawing the pipe. The process was first developed in the 1940s in France, but was of limited use until more recently developed pumping capabilities enabled the method to be more effective. The technique is applicable to soils which are readily compactable.

25.5.6.3 Jet grouting

Jet grouting is a variation that was introduced in Japan in the 1970s, the technique being based on the use of high speed water jets. The native soil is either mixed with a stabiliser (grout) *in situ* or, in the case of poor soils, the soil can be removed and grout columns formed in their place.

25.5.7 Artificial ground freezing

Artificial ground freezing is a construction expedient only. It is a temporary measure used to stabilise an area or zone of saturated soil while a particular construction operation is performed. It is a potentially dangerous construction process (significant precautions are necessary) and an expensive last resort, but it is a useful technique in certain cases.

The water within a soil mass is frozen by installing closely spaced freezing pipes through which a continuous supply of coolant is passed. The frozen soil has a greatly increased bearing capacity, a far higher strength and a permeability approaching zero. Excavation (for tunnels, underpinning, etc.) can proceed in safety once the ground is frozen.

Freezing causes a volume increase that is dependent on the water content of the soil, though a significant heave of the soil can be expected and this can cause problems similar to those of expansive clays if precautions are not taken. Conversely, adverse settlements occur during thaw and these too can create unwanted side effects. Sands and gravels are little affected because they are free draining, whereas movement can be large in silts and clays.

Ground movements affecting buildings can result from the loads applied by the building itself to the subsoil or from a variety of external causes including swelling or shrinkage of the subsoil, subsidence due to tunnelling or mining, and groundwater lowering. This chapter summarises an approach to assessing the response of buildings to ground movement and draws together in a coherent way a number of related studies including definitions of foundation movements, the description and classification of damage, and the factors controlling limiting distortions of buildings. The latter part of the chapter is devoted to applying the above principles to the important problem of assessing the impacts on buildings of subsidence induced by tunnelling. Methods of mitigating these impacts are described.

26.1 Introduction

Ground movements affecting buildings can result from the loads applied by the building itself to the subsoil or from external causes such as swelling or shrinkage of the subsoil, subsidence due to tunnelling or mining, and groundwater lowering. Whatever the cause of the ground movements they are likely to have an impact on the building and its function. In almost all cases, it is the differential movements (both vertical and horizontal) that are of importance – these can lead to tilting, distortion and possible damage to the building.

Compared with the literature on the prediction of ground movements, the question of allowable ground movements and their influence on the performance and serviceability of structures has received relatively little attention. Burland and Wroth (1974) listed some possible reasons for this:

(i) Serviceability is very subjective and depends both on the function of the building and the reactions of the users.

(ii) Buildings vary so much one from another, both in broad concept and in detail, that it is very difficult to lay down general guidelines as to allowable movements.

(iii) Buildings, including foundations, seldom perform as designed because construction materials display different properties from those assumed in design. Moreover, a 'total' analysis including the ground and the cladding would be impossibly complex and would still contain a number of questionable assumptions.

(iv) As well as depending on loading and settlement, movements in buildings can be attributed to a number of factors such as creep, shrinkage and temperature. As yet, there is little quantitative understanding of these factors and there is a lack of careful measurements of the performance of actual buildings.

There is tendency amongst foundation engineers, indeed structural engineers as well, to believe that the movements of the foundations are the major cause of distress in buildings, and that by controlling these the satisfactory performance of the building is guaranteed. At a conference on *Design for movement in buildings* hosted by The Concrete Society in 1969, many cases were quoted of damage to finishes which resulted from movements of the structural members rather than the foundations. Another aspect of the problem which engineers may overlook is that a certain amount of cracking is unavoidable if the building is to be economic (Peck, Deere and Capacete, 1956). It is said that it is impossible to build a structure that does not crack due to shrinkage, creep, etc. Little (1969) has estimated that in the case of one particular type of building, the cost of preventing any cracking could exceed 10% of the total building cost.

This chapter outlines the fundamental principles associated with assessing the response of buildings to ground movement. Two key aspects are: (i) the importance of clear definitions of ground and foundation movement; and (ii) the objective description and classification of building damage. These are required for an objective approach to the assessment of impacts of ground movement on buildings and are discussed in the following two sections.

26.2 Definitions of ground and foundation movement

A study of the literature reveals a wide variety of confusing symbols and terminology describing foundation movements.

Burland and Wroth (1974) proposed a consistent set of definitions based on the displacements (either measured or calculated) of a number of discrete points on the foundations of a building. Care was taken to ensure that the terms did not prejudice any conclusions about the distortions of the superstructure itself, since these depend on a large number of additional factors. The definitions appear to have been widely accepted and are illustrated in **Figure 26.1**. A few points to note are as follows:

(i) *Rotation* (or slope θ) is the change in gradient of a line joining two reference points (e.g. A, B in **Figure 26.1(a)**).

(ii) The *angular strain* α is shown in **Figure 26.1(a)**. It is positive for upward concavity (sagging) and negative for downward concavity (hogging).

(iii) *Relative deflection* Δ is the displacement of a point relative to the line connecting two reference points on either side (see **Figure 26.1(b)**). The sign convention is as for (ii).

(iv) *Deflection ratio* (sagging ratio or hogging ratio) is denoted by Δ/L where L is the distance between the two reference points defining Δ. The sign convention is as for (ii).

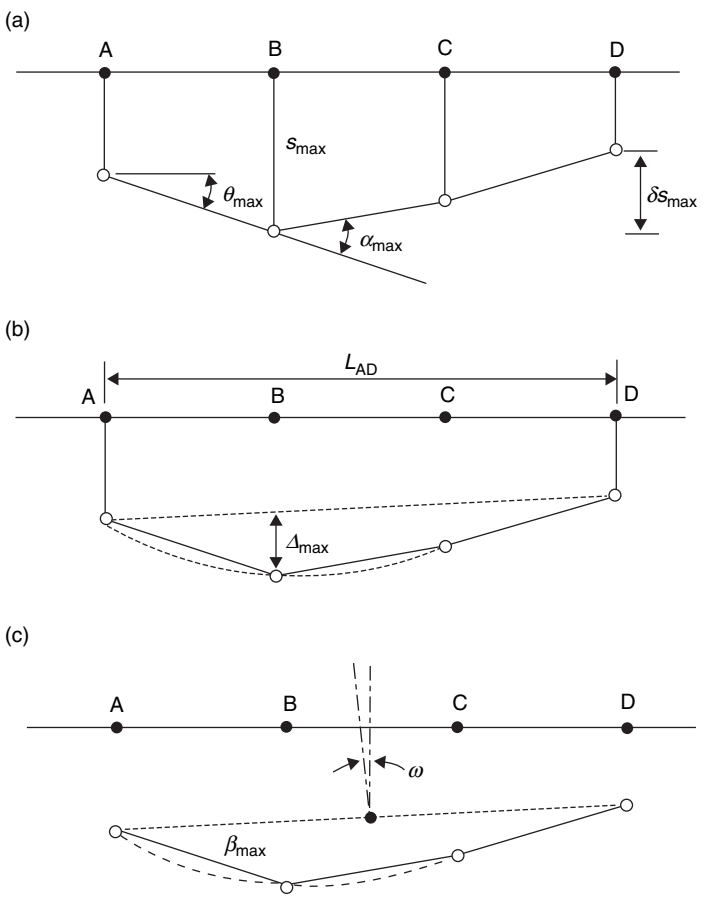

Figure 26.1 Definitions of ground and foundation movement: (a) rotation or slope θ and angular strain α; (b) relative deflection Δ and defection ratio Δ/L; (c) tilt ω and relative rotation β

Reproduced from Burland (1997); all rights reserved

(v) *Tilt* ω describes the rigid body rotation of the structure or a well defined part of it – see **Figure 26.1(c)**.

(vi) *Relative rotation* (angular distortion) β is the rotation of the line joining two points, relative to the tilt ω – see **Figure 26.1(c)**. It is not always straightforward to identify the tilt and the evaluation of β can sometimes be difficult. It is also very important not to confuse relative rotation β with angular strain α. For these reasons, Burland and Wroth (1974) preferred the use of Δ/L as a measure of building distortion.

(vii) *Average horizontal strain* ε_h is defined as the change of length δL over the length L. In soil mechanics it is customary to take a reduction of length (compression) as positive.

The above definitions only apply to in-plane deformations and no attempt has been made to define three-dimensional behaviour.

26.3 Classification of damage

26.3.1 Introduction

Assessment of the degree of building damage can be a highly subjective, and often emotive, matter. It may be conditioned by a number of factors such as local experience, the attitude of insurers, the cautious approach of a professional engineer or surveyor who might be concerned about litigation, market value, and 'saleability' of the property. In the absence of objective guidelines based on experience, extreme attitudes and unrealistic expectations towards building performance can develop. It is worth stressing that most buildings experience a certain amount of cracking, often unrelated to foundation movement, which can be dealt with during routine maintenance and decoration.

Clearly, if an assessment of the risk of damage due to ground movement is to be made, the *classification* of damage is a key issue. In the UK, the development of an objective system of classifying damage is proving to be very beneficial in creating realistic attitudes towards building damage, and also in providing logical and objective criteria for designing for movement in buildings and other structures. This classification system will now be described.

26.3.2 Categories of damage

Three broad categories of building damage can be considered. These affect: (i) visual appearance or 'aesthetics'; (ii) serviceability or function; and (iii) stability. As foundation movements increase, damage to a building will progress successively from (i) through to (iii).

It is only a short step from the above three broad categories of damage to the six (more detailed) classifications given in **Table 26.1**. Normally, categories 0, 1 and 2 relate to aesthetic damage, 3 and 4 relate to serviceability damage, and 5 represents damage affecting stability. It was first put forward by Burland *et al.* (1977) who drew on the work of Jennings and Kerrich (1962), the UK National Coal Board (1975) and MacLeod and Littlejohn (1974). Since then the classification

has been adopted with only slight modifications by BRE (1981) and the Institution of Structural Engineers, London (1978 and 1994).

The system of damage classification in **Table 26.1** is based on 'ease of repair' of the visible damage. Thus, in order to classify visible damage it is necessary, when carrying out the survey, to assess what type of work would be required to repair the damage both externally and internally. The following important points should be noted:

(i) The classification relates only to the visible damage at a given time and not to its cause or possible progression which are separate issues.

(ii) The strong temptation to classify the damage solely on crack width must be resisted. It is the ease of repair which is the key factor in determining the category of damage.

(iii) The classification was developed for brickwork, blockwork and stone masonry. It can be adapted for other forms of cladding. It is not intended to apply to reinforced concrete structural elements.

(iv) More stringent criteria may be necessary where damage may lead to corrosion, penetration or leakage of harmful liquids and gases or structural failure.

Besides defining numerical categories of damage, **Table 26.1** also describes the 'normal degree of severity' associated with each category. These descriptions of severity relate to standard domestic and office buildings and serve as a guide to building owners and occupiers. In special circumstances, such as for a building with valuable or sensitive finishes, these descriptions of severity of damage may not be appropriate.

26.3.3 The division between categories 2 and 3 damage

The dividing line between categories 2 and 3 damage is particularly important. Studies of many case records show that damage up to category 2 can result from a variety of causes, either from within the structure itself (e.g. shrinkage or thermal effects) or be associated with the ground. Identification of the cause of damage is usually very difficult as it frequently results from a combination of causes. If the damage exceeds category 2, the cause is usually much easier to identify and it is frequently associated with ground movement. Thus the division between categories 2 and 3 damage represents an important threshold which will be referred to later.

26.4 Routine guides on limiting deformations of buildings

Perhaps the two best known studies leading to recommendations on allowable deformations of buildings are those of Skempton and MacDonald (1956) and Polshin and Tokar (1957). Skempton and MacDonald summarised settlement and damage observations on 98 buildings, 40 of which showed signs of damage. The study was limited to traditional steel and reinforced concrete frame buildings and to a few load-bearing wall buildings.

Category of damage	Normal degree of severity	Description of typical damage Ease of repair is underlined *Note*: Crack width is only one factor in assessing category of damage and should not be used on its own as a direct measure of it
0	Negligible	Hairline cracks less than about 0.1 mm
1	Very slight	Fine cracks which are easily treated during normal decoration. Damage generally restricted to internal wall finishes. Close inspection may reveal some cracks in external brickwork or masonry. Typical crack widths up to approximately 1 mm
2	Slight	Cracks easily filled. Re-decoration probably required. Recurrent cracks can be masked by suitable linings. Cracks may be visible externally and some repointing may be required to ensure weathertightness. Doors and windows may stick slightly. Typical crack widths 2–3 mm but may be up to approximately 5 mm locally
3	Moderate	The cracks require some opening up and can be patched by a mason. Repointing of external brickwork and possibly a small amount of brickwork to be replaced. Doors and windows sticking. Service pipes may fracture. Weathertightness often impaired. Typical crack widths are approximately 5–15 mm or several closely spaced cracks > 3 mm
4	Severe	Extensive repair work involving breaking-out and replacing sections of walls, especially over doors and windows. Windows and door frames distorted, floor sloping noticeably[1]. Walls leaning[1] or bulging noticeably, some loss of bearing in beams. Service pipes disrupted. Typical crack widths are 15–25 mm, depending on the number of cracks
5	Very severe	This requires a major repair job involving partial or complete rebuilding. Beams lose bearing, walls lean badly and require shoring. Windows broken with distortion. Danger of instability. Typical crack widths are > 25 mm, depending on the number of cracks

[1] *Note*: Local deviation of slope, from the horizontal or vertical, of more than 1/100 will normally be clearly visible. Overall deviations in excess of 1/150 are undesirable.

Table 26.1 Classification of visible damage to walls with particular reference to ease of repair of plaster and brickwork or masonry

As their measure of building distortion, they used the ratio of the differential settlement δ and the distance l between two points after eliminating the influence of tilt of the building. They defined the ratio δ/l as the 'angular distortion' which corresponds to the 'relative rotation' β defined in section 26.2. It was concluded that the limiting value of β to cause cracking in walls and partitions is 1/300 and that values of β greater than 1/150 will cause structural damage. It was recommended that values of β greater than 1/500 should be avoided. Subsequently, Bjerrum (1963) supplemented these recommendations by relating the magnitude of β to various types of impacts and structures. It is important to appreciate that Skempton and MacDonald's conclusions relate to traditional frame buildings and that the evidence relating to load-bearing walls was not reliable. Also, no classification of damage was used other than 'architectural', 'functional' and 'structural'. The limitations of the data and the tentative nature of the conclusions were emphasised by Skempton and MacDonald in their paper, but these qualifications are seldom emphasised in textbooks and design recommendations.

Polshin and Tokar (1957) discussed the question of allowable deformations and settlements, and defined three criteria: relative rotation β; deflection ratio Δ/L; and average settlement. The limiting values of these, adopted by the 1955 Building Code of the USSR, were then listed. It is of particular interest to note that frame structures were treated separately from continuous load-bearing walls. Recommended maximum relative rotations vary from 1/500 for steel and concrete frame infilled structures to 1/200, where there is no infill and no danger of damage to cladding.

Much stricter criteria were laid down for load-bearing brick walls. For L/H ratios (where L is the length and H the height) of less than 3, the maximum values of Δ/L are 0.3×10^{-3} for sand and 0.4×10^{-3} for soft clay. For L/H ratios greater than 5, the corresponding maximum values of Δ/L are 0.5×10^{-3} and 0.7×10^{-3} respectively. In their paper, Polshin and Tokar (1957) introduced two important variables: (i) the L/H ratio of the building or wall; and (ii) the concept of limiting tensile strain before cracking. Using a limiting tensile strain of 0.05%, the limiting relationship between L/H and Δ/L was presented and was shown to be in good agreement with a number of cracked and uncracked brick buildings. The above recommendations for load-bearing masonry walls are based on a requirement for no cracking; if adhered to, the degree of damage would be unlikely to exceed category 1 (very slight) in **Table 26.1**.

The reader is referred to Chapter 52 *Foundation types and conceptual design principles* for a more detailed discussion on routine guides to allowable building movements.

26.5 Concept of limiting tensile strain

26.5.1 Onset of visible cracking

Cracking in masonry walls and finishes usually, but not always, result from tensile strain. Following the work of Polshin and Tokar (1957), Burland and Wroth (1974) investigated the idea that tensile strain might be a fundamental parameter in determining the onset of cracking. A study of the results from numerous large scale tests on masonry panels and walls carried out at the UK Building Research Establishment (BRE) showed that, for a given material, the onset of visible cracking is associated with a reasonably well defined value of average tensile strain which is not sensitive to the mode of deformation. They defined this as the critical tensile strain ε_{crit} which is measured over a gauge length of a metre or more.

Burland and Wroth (1974) made the following important observations:

(i) The average values of ε_{crit} at which visible cracking occurs are very similar for a variety of types of brickwork and blockwork and are in the range 0.05–0.1%.

(ii) For reinforced concrete beams the onset of visible cracking occurs at lower values of tensile strain in the range 0.03–0.05%.

(iii) The above values of ε_{crit} are much larger than the local tensile strains corresponding to tensile failure.

(iv) The onset of visible cracking does not necessarily represent a limit of serviceability. Provided the cracking is controlled, it may be acceptable to allow deformations well beyond the initiation of visible cracking.

Burland and Wroth (1974) showed how the concept of critical tensile strain could be used in conjunction with simple elastic beams to develop deflection criteria for the onset of visible damage. This work will be discussed in more detail later.

26.5.2 Limiting tensile strain – a serviceability parameter

Burland *et al.* (1977) replaced the concept of *critical tensile strain* with that of *limiting tensile strain* (ε_{lim}). The importance of this development is that ε_{lim} can be used as a serviceability parameter which can be varied to take account of differing materials and serviceability limit states.

Boscardin and Cording (1989) developed this concept of differing levels of tensile strain. Seventeen case records of damage due to excavation-induced subsidence were analysed. A variety of building types were involved and they showed that the categories of damage given in **Table 26.1** could be broadly related to ranges of ε_{lim}. These ranges are tabulated in **Table 26.2**, which is important as it provides the link between estimated building deformations and the possible severity of damage.

26.6 Strains in simple rectangular beams

This section describes how Burland and Wroth (1974) and Burland *et al.* (1977) used the concept of limiting tensile strain to study the onset of cracking in simple weightless elastic beams undergoing sagging and hogging modes of deformation. This simple approach gives considerable insight into the mechanisms controlling cracking. Moreover, it is shown that the criteria for initial cracking of simple beams are in very good

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Category of damage	Normal degree of severity	Limiting tensile strain (ε_{lim}) (%)
0	Negligible	0–0.05
1	Very slight	0.05–0.075
2	Slight	0.075–0.15
3	Moderate1	0.15–0.3
4–5	Severe to very severe	> 0.3

[1] *Note*: Boscardin and Cording (1989) describe the damage corresponding to ε_{lim} in the range 0.15–0.3% as 'moderate to severe'. However, none of the cases quoted by them exhibit severe damage for this range of strains. There is therefore no evidence to suggest that tensile strains up to 0.3% will result in severe damage.

Table 26.2 Relationship between category of damage and limiting tensile strain (ε_{lim})
Data taken from Boscardin and Cording (1989)

agreement with the case records of damaged and undamaged buildings undergoing settlement. Therefore, in many circumstances, it is both reasonable and instructive to represent the facade of a building by means of a simple rectangular beam.

26.6.1 The relationship between limiting values of Δ/L and limiting tensile strain

The approach adopted by Burland and Wroth (1974) is illustrated in **Figure 26.2**, where the building is represented by a rectangular beam of length L and height H. The problem is to calculate the tensile strains in the beam for a given deflected shape of the building foundations and hence obtain the sagging or hogging ratio Δ/L at which cracking is initiated. It is immediately obvious that little can be said about the distribution of strains within the beam unless we know its *mode* of deformation. Two extreme modes are: (i) bending only about a neutral axis at the centre (**Figure 26.2(d)**); and (ii) shearing only (**Figure 26.2(e)**). In the case of bending only, the maximum tensile strain occurs in the top fibre and that is where cracking will initiate as shown. In the case of shear only, the maximum tensile strains are inclined at 45°, giving rise to diagonal cracking. In general, both modes of deformation will occur simultaneously and it is necessary to calculate both bending and diagonal tensile strains to ascertain which type is limiting.

The expression for the total mid-span deflection Δ of a centrally loaded beam having both bending and shear stiffness, is given by Timoshenko (1957) as:

$$\Delta = \frac{PL^3}{48EI}\left(1+\frac{18EI}{L^2HG}\right) \tag{26.1}$$

where E is Young's modulus, G is the shear modulus, I is the second moment of area and P is the point load. Equation (26.1) can be re-written in terms of the deflection ratio Δ/L and the maximum extreme fibre strain $\varepsilon_{b\,max}$ as follows:

$$\frac{\Delta}{L} = \left(\frac{L}{12t}+\frac{3I}{2tLH}\frac{E}{G}\right)\varepsilon_{b\,max} \tag{26.2}$$

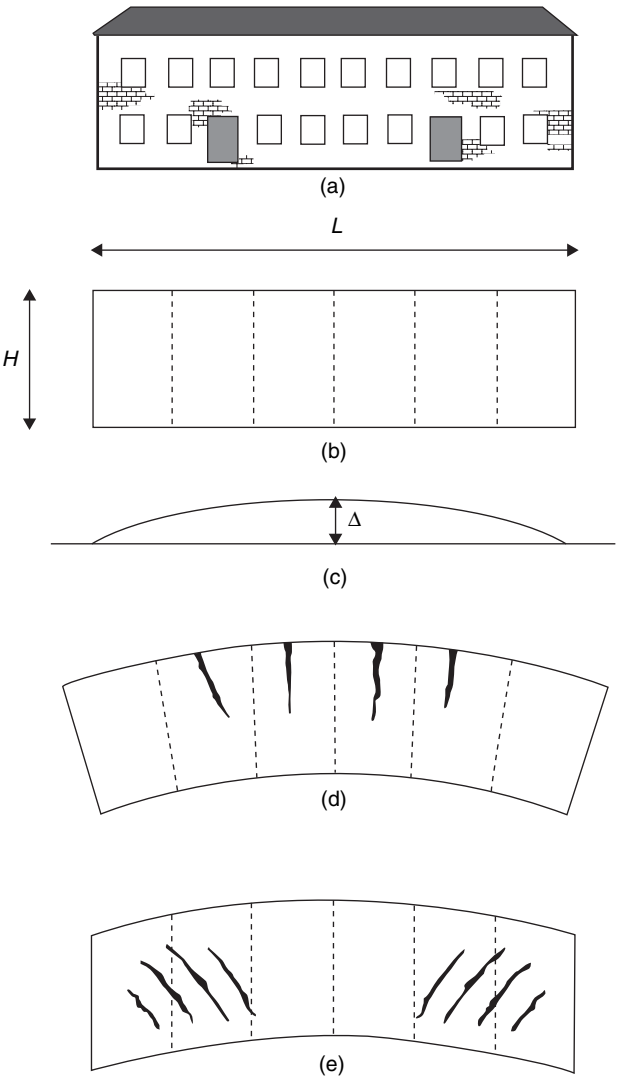

Figure 26.2 Cracking of a simple beam in bending and in shear: (a) actual building; (b) equivalent deep beam; (c) deflected shape of foundation; (d) bending deformation; (e) shear deformation
Reproduced from Burland (1997); all rights reserved

where t is the distance of the neutral axis from the edge of the beam in tension. Similarly for the maximum diagonal strain $\varepsilon_{d\,max}$ equation (26.1) becomes:

$$\frac{\Delta}{L} = \left(1+\frac{HL^2}{18I}\frac{G}{E}\right)\varepsilon_{d\,max}. \tag{26.3}$$

Similar expressions are obtained for the case of a uniformly distributed load with the diagonal strains calculated at the quarter points of the span (i.e. at $L/4$ and $3L/4$). Burland and Wroth (1974) drew the important conclusion that the maximum tensile strains are much more sensitive to the value of Δ/L than to the precise distribution of loading.

By setting $\varepsilon_{max} = \varepsilon_{lim}$, equations (26.2) and (26.3) define the limiting values of Δ/L for the deflection of simple beams.

It is evident that, for a given value of ε_{lim}, the limiting value of Δ/L (whichever is the lowest in equations (26.2) and (26.3)) depends on L/H, E/G and the position of the neutral axis. For an isotropic beam ($E/G \approx 2.5$) with a neutral axis in the middle, the limiting relationship between $\Delta/L.\varepsilon_{lim}$. and L/H is given by curve (1) in **Figure 26.3**. For a beam which has relatively low stiffness in shear ($E/G = 12.5$), the limiting relationship is given by curve (2). A particularly important case is that of a beam which is relatively flexible in bending, and is subjected to hogging such that its neutral axis is at the bottom. Curve (3) shows the limiting relationship for such a beam having $E/G = 0.5$. These curves serve to illustrate that even for simple beams, the limiting values of Δ/L causing cracking can vary over wide limits.

26.6.2 Limiting values of Δ/L for very slight damage

Burland and Wroth (1974) carried out a preliminary survey of data for cracking of infill frames and masonry walls. They concluded that the range of values of average tensile strain at which the onset of visible cracking for a variety of common building materials was remarkably small. For brickwork and blockwork set in cement mortar ε_{lim} lies in the range 0.05–0.1%, while for reinforced concrete having a wide range of strengths, the values lie in the range of about 0.03–0.05%.

In order to assess the potential value of the limiting tensile strain approach in estimating the onset of visible cracking in buildings, Burland and Wroth compared the limiting criteria obtained from the analysis of simple beams with observations of the behaviour of a number of buildings – many of them of modern construction. For this comparison, a value of $\varepsilon_{lim} = 0.075\%$ was used. As can be seen from **Table 26.2**, this value corresponds to the threshold between category 1 (very slight) and category 2 (slight) damage. The buildings were classified as frame, load-bearing walls undergoing sagging, and load-bearing walls undergoing hogging. **Figures 26.4(a)**, **(b)** and **(c)** show the comparison with curves (2), (1) and (3) respectively from **Figure 26.3**, with $\varepsilon_{lim} = 0.075\%$. Also shown is the criterion of limiting relative rotation $\beta = 1/300$ proposed by Skempton and MacDonald (1956) and the limiting relationship proposed by Polshin and Tokar (1957) for load-bearing walls. In spite of its simplicity, the analysis reflects the major trends in the observations. In particular, the prediction is borne out that load-bearing walls, especially when subjected to hogging, are more susceptible to damage than frame buildings which are relatively flexible in shear.

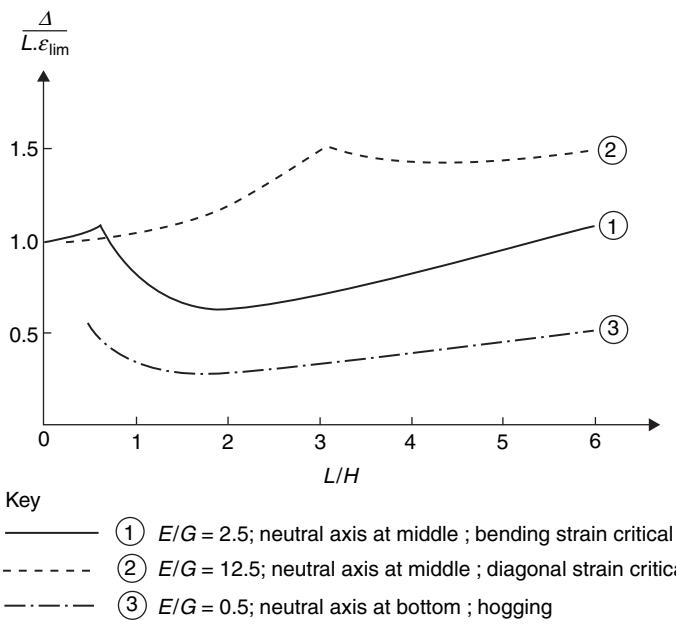

Figure 26.3 The influence of *E/G* and mode of deformation on the cracking of a simple rectangular beam

26.6.3 The relationship between Δ/L and levels of damage

At this point it is necessary to emphasise that limiting tensile strain is not a fundamental material property like tensile strength. It should be regarded as a measure of serviceability (as set out in **Table 26.2**) which aids the engineer in deciding whether a building is likely to develop visible cracks, their severity, and where the critical locations might be. Equations (26.2) and (26.3) can be used in this way to assess what levels of damage might be expected for a given (perhaps calculated) value of Δ/L.

The advantages of this approach over traditional empirical rules limiting deformations are:

(i) It can be applied to complex structures employing well established stress analysis techniques.

(ii) It makes explicit the fact that damage can be controlled by paying attention to the modes of deformation within the building structure and its finishes.

(iii) The limiting values can be varied to take account of differing materials and serviceability limit states, e.g. the use of soft bricks and lime mortar can substantially reduce cracking as it raises the value of ε_{lim}.

It is also important to appreciate that the onset of visible cracking does not necessarily represent a limit of serviceability. Provided cracking is controlled, it may be acceptable to allow deformations to continue well beyond the initiation of cracking. Cases where the propagation of initial cracks may be fairly well controlled are framed structures with panel walls, and also reinforced load-bearing structures. Unreinforced load-bearing walls undergoing sagging under the restraining action of the foundations may also fall into this category. An important mode of deformation where uncontrolled cracking can occur is that of hogging of unreinforced free-standing load-bearing walls. Once a crack forms at the top of the wall there is nothing to stop it propagating downwards. Low-rise houses with shallow

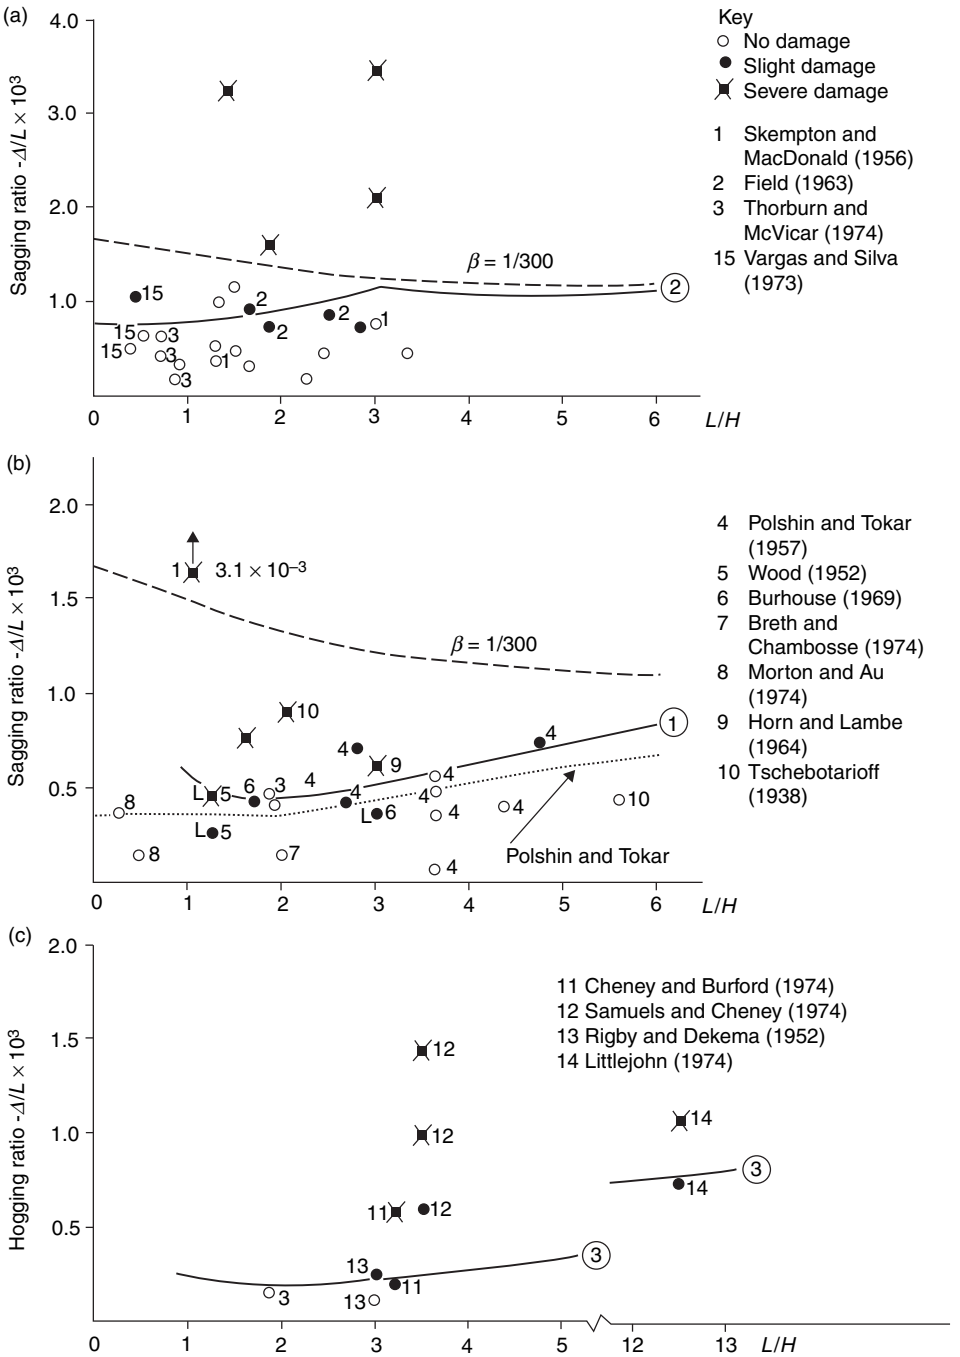

Figure 26.4 Relationship between Δ/L and L/H for buildings showing various degrees of damage: (a) frame buildings; (b) loadbearing walls; (c) hogging of loadbearing walls

foundations on swelling or shrinking clays are particularly prone to this form of damage.

The remainder of this chapter is devoted to applying the principles set out above to the important case of assessing the impacts on buildings of subsidence induced by tunnelling and excavations.

26.7 Ground movement due to tunnelling and excavation

26.7.1 Introduction

In recent years, assessment of the environmental impact of major construction projects has become a normal and required procedure. The construction of tunnels in urban areas, while

having many long-term environmental benefits, can also create significant environmental impacts. During construction, such impacts would include construction traffic, noise, vibration and dust as well as temporary restrictions on access to certain roads and other public areas. Longer term impacts would include land and building acquisition, traffic and ventilation noise and vibration levels, and other impacts such as pollution, ground water changes and effects on ecology.

An environmental impact which is causing increasing public awareness and concern is that of subsidence and its effects on structures and services due to tunnelling and deep excavations. Construction of tunnels and deep excavations is inevitably accompanied by ground movements. It is necessary, both for engineering design and for planning and consultation, to develop rational procedures for assessing the risks of damage. Coupled with such assessments is, of course, the requirement for effective protective measures which can be deployed when predicted levels of damage are judged to be unacceptable.

The following section summarises the approach that was originally developed in the 1990s for assessing the risks of subsidence damage for the London Underground Jubilee Line Extension project, which involved tunnelling under densely developed areas of central London. The experience gained from this project has been summarised in a two volume book (Burland *et al*., 2001a and 2001b). The approach to assessing the risks of subsidence damage, which is presented here, draws on the results of the studies described previously, including the description and classification of damage and limiting distortions of brickwork and masonry walls.

The construction of tunnels or surface excavations will inevitably be accompanied by movement of the ground around them. At the ground surface, these movements manifest in what is called a 'settlement trough'. **Figure 26.5** shows diagrammatically the surface settlement trough above an advancing tunnel. For greenfield sites, the shape of this trough transverse to the axis of the tunnel approximates closely to a normal Gaussian distribution curve – an idealisation which has considerable mathematical advantages.

26.7.2 Settlements caused by tunnel excavation

Figure 26.6 shows such an idealised transverse settlement trough. Attewell *et al*. (1986) and Rankin (1988) have summarised the current widely used empirical approach to the prediction of immediate surface and near-surface ground displacements. The settlement s is given by:

$$s = s_{max} \exp\left(\frac{-y^2}{2i^2}\right) \tag{26.4}$$

where s_{max} is the maximum settlement and i is the value of y at the point of inflection. It has been found that, for most

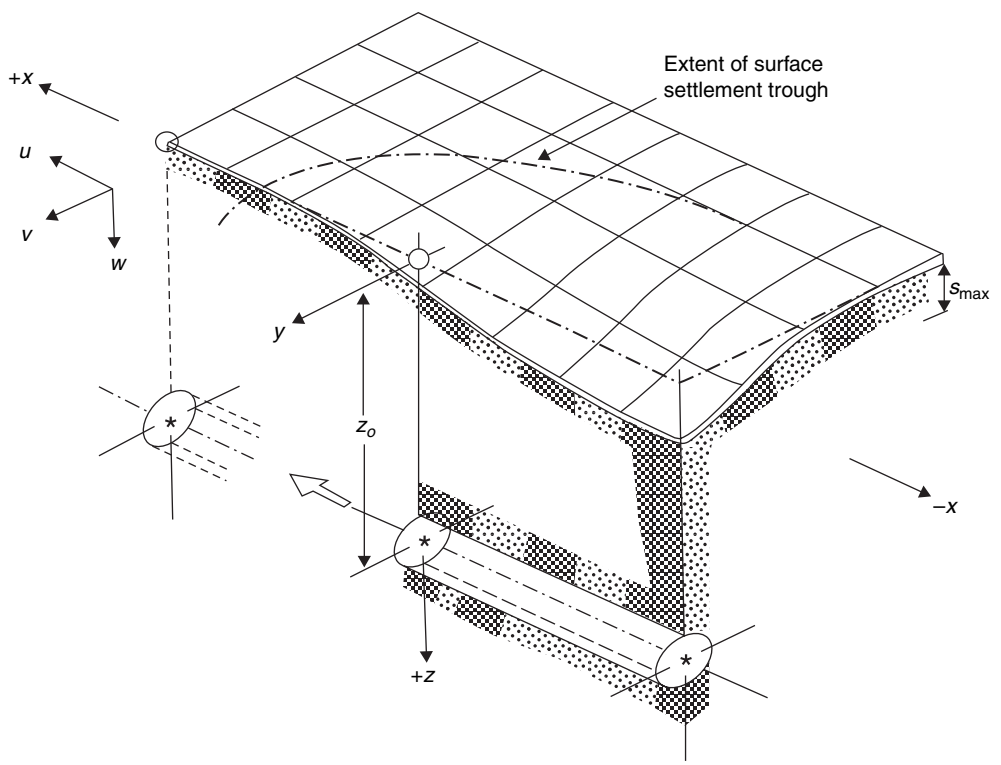

Figure 26.5 Settlement trough above an advancing tunnel

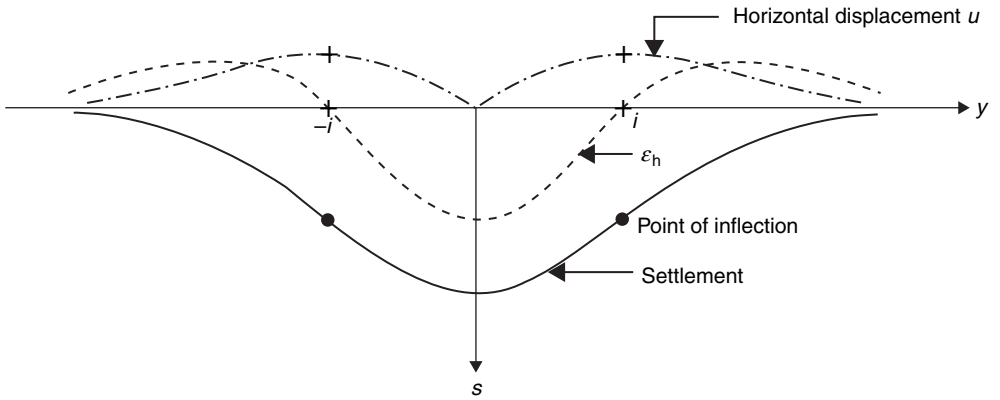

Figure 26.6 Transverse settlement trough and horizontal displacement profiles

purposes, i can be related to the depth of the tunnel axis z_o by the linear expression:

$$i = K z_o. \tag{26.5}$$

The trough width parameter K depends on the soil type. It varies from 0.2 to 0.3 for granular soils, 0.4 to 0.5 for stiff clays, to as high as 0.7 for soft silty clays. As a general rule, the width of the surface settlement trough is about three times the depth of the tunnel for tunnels in clay strata. It is important to note that, although the value of K for *surface* settlements is approximately constant for various depths of tunnel in the same ground, Mair *et al.* (1993) have shown that its value increases with depth for *subsurface* settlements.

The immediate settlements caused by tunnelling are usually characterised by the 'volume loss' V_L which is the volume of the surface settlement trough per unit length V_s expressed as a percentage of the notional excavated volume of the tunnel.

Integration of equation (26.4) gives:

$$V_s = \sqrt{2\pi}\, i\, s_{\max} \tag{26.6}$$

so that:

$$V_L = \frac{3.192\, i\, s_{\max}}{D^2} \tag{26.7}$$

where D is the diameter of the tunnel. Combining equations (26.4), (26.5) and (26.7) gives the surface settlement s at any distance y from the centreline:

$$s = \left(\frac{0.313 V_L D^2}{K z_o}\right) \exp\left(\frac{-y^2}{2K^2 z_o^2}\right). \tag{26.8}$$

26.7.3 Horizontal displacements due to tunnelling

Building damage can also result from horizontal tensile strain, and therefore predictions of horizontal movement are required. Unlike settlements, there are few case histories where horizontal movements have been measured. The data that do exist show reasonable agreement with the assumption of O'Reilly and New (1982) that the resultant vectors of ground movement are directed towards the tunnel axis. It follows that the horizontal displacement u can be related to the settlement s by the expression:

$$u = \frac{s.y}{z_o}. \tag{26.9}$$

Equation (26.9) is easily differentiated to give the horizontal strain ε_h at any location on the ground surface.

Figure 26.6 shows the relation between the settlement trough, the horizontal displacements and the horizontal strains occurring at ground level. In the region $-i < y < i$, the horizontal strains are compressive. At the points of inflection the horizontal displacements are a maximum and $\varepsilon_h = 0$. For $y > |i|$ the horizontal strains are tensile.

26.7.4 Assessment of surface displacements due to tunnelling

The above empirical equations provide a simple means for estimating the near-surface displacements due to tunnelling, assuming greenfield conditions, i.e. ignoring the presence of any building or structure.

A key parameter in this assessment is the volume loss V_L. This results from a variety of effects which include movement of ground into the face of the tunnel and radial movement towards the tunnel axis due to reductions in supporting pressures. The magnitude of V_L is critically dependent on the type of ground, the ground water conditions, the tunnelling method, the length of time in providing positive support, and the quality of supervision and control. The selection of an appropriate value of V_L for design requires experience and is greatly aided by well documented case histories in similar conditions.

A number of other assumptions are involved in the prediction of ground displacements due to tunnelling. For example,

in ground containing layers of clay and granular soils, there is uncertainty about the value of the trough width parameter K. When two or more tunnels are to be constructed in close proximity, the assumption is usually made that the estimated ground movements for each tunnel acting independently can be superimposed. In some circumstances this assumption may underestimate the movements and allowance needs to be made for this.

It is clear from the above that, even for greenfield conditions, precise prediction of ground movements due to tunnelling is not realistic. However, it is possible to make reasonable estimates of the likely range of movements provided tunnelling is carried out under the control of suitably qualified and experienced engineers.

26.7.5 Ground movements due to deep excavations

Ground movements around deep excavations are critically dependent both on the ground conditions (e.g. stratigraphy, groundwater conditions, deformation and strength properties) and the method of construction (e.g. sequence of excavation, sequence of propping, rigidity of retaining wall and supports). In general, open excavations and those supported by cantilever retaining walls give rise to larger ground movements than strutted excavations and those constructed by top-down methods. In the urban situation, the latter are clearly to be preferred if building damage is to be minimised.

The calculation of ground movements is not straightforward and much experience is required to make any sensible use of complex analyses. It is therefore essential that optimum use is made of previous experience and case histories in similar conditions. Peck (1969) presented a comprehensive survey of vertical movements around deep excavations which was updated by Clough and O'Rourke (1990). Burland *et al.* (1979) summarised the results of over ten years of research into the movements of ground around deep excavations in London Clay. The Norwegian Geotechnical Institute have published a number of case histories of excavations in soft clay in the Oslo area (e.g. Karlsrud and Myrvoll (1976)). For well-supported excavations in stiff clays, Peck's settlement envelopes are generally very conservative as settlements rarely exceed 0.15% of the depth of excavation. However, movements can extend to 3 or 4 times the excavation depth behind the basement wall. Horizontal movements are generally of similar magnitude and distribution to vertical movements, but may be much larger for open and cantilever excavations in stiff clays.

Advanced methods of numerical analysis, based on the finite element method, are widely used for prediction of ground movements around deep excavations. Such analyses can simulate the construction process, modelling the various stages of excavation and support conditions. However, comparison with field observations shows that successful prediction requires high quality soil samples with the measurement of small-strain stiffness properties using local strain transducers mounted on the sides of the samples (Jardine *et al.*, 1984).

As for tunnelling, it is essential that deep excavation work be carried out under the close supervision of an experienced engineer. Unless positive support is provided rapidly and groundwater is properly controlled, large unexpected ground movements can develop.

26.7.6 The influence of horizontal strain

It was shown in section 26.7.3 that ground surface movements associated with tunnelling and excavation not only involve sagging and hogging profiles, but significant horizontal strains as well – see **Figure 26.6**. Boscardin and Cording (1989) included the influence of horizontal extension strain ε_h in equations (26.2) and (26.3) by using simple superposition; i.e. it is assumed that the deflected beam is subjected to uniform extension over its full depth. The resultant extreme fibre strain ε_{br} is given by:

$$\varepsilon_{br} = \varepsilon_{b\,max} + \varepsilon_h \tag{26.10}$$

where $\varepsilon_{b\,max}$ is obtained from equation (26.2). In the shearing region of the beam, the resultant diagonal tensile strain ε_{dr} can be evaluated using the Mohr's circle of strain. The value of ε_{dr} is then given by:

$$\varepsilon_{dr} = \varepsilon_h\left(\frac{1-\nu}{2}\right) + \sqrt{\varepsilon_h^2\left(\frac{1+\nu}{2}\right)^2 + \varepsilon_{d\,max}^2} \tag{26.11}$$

where $\varepsilon_{d\,max}$ is obtained from equation (26.3) and ν is Poisson's ratio. The maximum tensile strain is the greater of ε_{br} and ε_{dr}. Thus, for a beam of length L and height H, it is a straightforward matter to calculate the maximum value of tensile strain ε_{max} for a given value of Δ/L, and ε_h, in terms of t, E/G and ν. This value of ε_{max} can then be used in conjunction with **Table 26.2** to assess the potential associated damage.

The physical implications of equations (26.2), (26.3), (26.10) and (26.11) can be illustrated by considering the previous case of the isotropic beam undergoing hogging, with its neutral axis at the bottom edge and $\nu = 0.3$. By combining equations (26.2) and (26.10), the influence of ε_h on the limiting values of Δ/L can be examined for bending strains only by setting $\varepsilon_{bmax} = \varepsilon_{lim}$. **Figure 26.7(a)** shows the normalised relationship between Δ/L and ε_h. For $\varepsilon_h = 0$, the limiting values of Δ/L are the same as given in **Figure 26.3** for various values of L/H. It can be seen that as ε_h increases towards the value of ε_{lim}, the limiting values of Δ/L for a given L/H reduce linearly, becoming zero when $\varepsilon_h = \varepsilon_{lim}$.

Similarly, **Figure 26.7(b)** has been derived from equations (26.3) and (26.11) for the diagonal strains only. Once again, for $\varepsilon_h = 0$ the limiting values of Δ/L are recovered from **Figure 26.3**. As ε_h increases, the limiting values of Δ/L decrease non-linearly at an increasing rate towards zero. It is of interest to note that the values of Δ/L are not very sensitive to the values of L/H between 0 and 1.5.

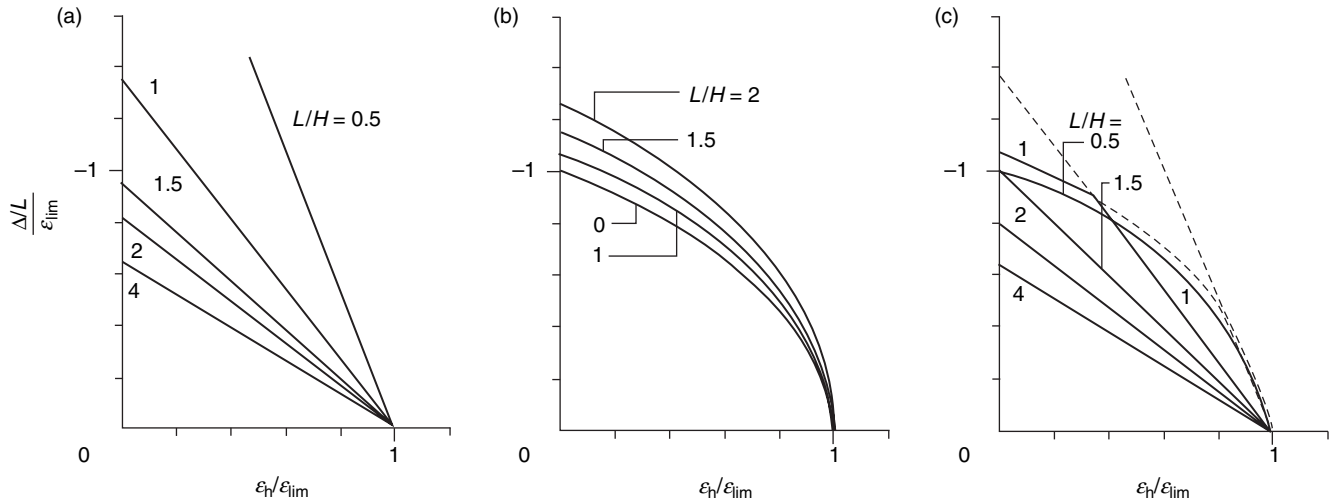

Figure 26.7 Influence of horizontal strain on $(\Delta/L)/\varepsilon_{lim}$ for (a) bending strain controlling; (b) diagonal strain controlling; and (c) limiting combinations of (a) and (b). Note that $E/G = 2.5$ and the mode of deformation is hogging

Reproduced from Burland (1997); all rights reserved

Figures 26.7(a) and **(b)** can be combined to give the resultant normalised limiting relationships between Δ/L and ε_h for various values of L/H, as shown in **Figure 26.7(c)**. It can be seen that, for $L/H > 1.5$, the bending strains always control. Also, for lower values of L/H, as ε_h increases, the controlling strain changes from diagonal to bending. It must be emphasised that **Figure 26.7** relates to the specific case of hogging with the neutral axis at the lower face and with $E/G = 2.5$.

By adopting the values of ε_{lim} associated with the various categories of damage given in **Table 26.2**, **Figure 26.7(c)** can be developed into an interaction diagram showing the relationship between Δ/L and ε_h for a particular value of L/H. **Figure 26.8** shows such a diagram for $L/H = 1$.

There are similarities between **Figure 26.8** and the well-known Boscardin and Cording (1989) chart of angular distortion β versus ε_h. The latter chart has the following limitations:

(i) it only relates to $L/H = 1$;

(ii) maximum bending strains ε_{bmax} are ignored;

(iii) β was assumed to be proportional to Δ/L whereas Burland *et al.* (2004) have shown that the relationship is in fact very sensitive to the load distribution and to the value of E/G;

(iv) as mentioned in section 26.2, the evaluation of β is not always straightforward.

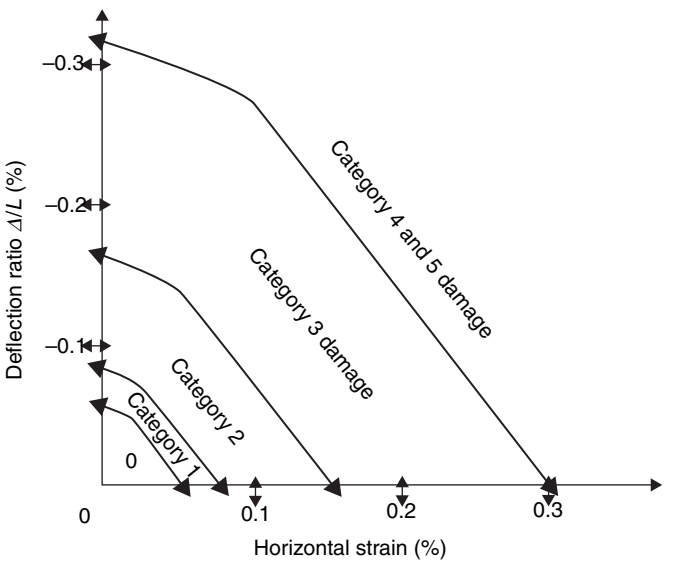

Figure 26.8 Relationship of damage category to deflection ratio and horizontal strain for hogging ($L/H = 1$, $E/G = 2.5$)

26.7.7 Relevant building dimensions

An important consideration is the definition of the relevant height and length of the building. A typical case of a building affected by a single tunnel settlement trough is shown in **Figure 26.9**. The height H is taken as the height from foundation level to the eaves. The roof is usually ignored. It is assumed that a building can be considered separately either side of a point of inflexion, i.e. points of inflexion of the settlement profile (at foundation level) will be used to partition the building. The length of building is not considered beyond the practical limit of the settlement trough, which for a single tunnel can be taken as $2.5i$ (where $s/s_{max} = 0.044$). In a calculation of building strain, the building span length is required; it is defined as the length of building in a hogging or sagging zone (shown as L_h or L_s in **Figure 26.9**) and limited by a point of inflexion or extent of settlement trough.

26.8 Evaluation of risk of damage to buildings due to subsidence

The various concepts discussed in the previous sections can be combined to develop a rational approach to the assessment of risk of damage to buildings due to tunnelling and excavation. The following broadly describes the approach that was adopted during the planning and enquiry stages of the Jubilee Line Extension underground railway in London, and which is now widely used internationally with minor variations (Burland, 1997).

26.8.1 Level of risk

The term 'the level of risk', or simply 'the risk', of damage refers to the *possible degree of damage* as defined in **Table 26.1**. Most buildings are considered to be at low risk if the predicted degree of damage falls into the first three categories 0 to 2 (i.e. negligible to slight). At these degrees of damage, structural integrity is not at risk and damage can be readily and economically repaired. It will be recalled from section 26.3.3 that the threshold between categories 2 and 3 damage is a particularly important one. A major objective of design and construction is to maintain the level of risk below this threshold for all buildings. It should be noted that special consideration has to be given to buildings judged to be of particular sensitivity, such as those in poor condition, containing sensitive equipment, or of particular historical or architectural significance.

Because of the large number of buildings that are usually involved, the method of assessing risk is a staged process as follows: preliminary assessment; second stage assessment; detailed evaluation. These three stages will now be described briefly.

26.8.2 Preliminary assessment

So as to avoid a large number of complex and unnecessary calculations, a very simple and conservative approach is adopted for the preliminary assessment. It is based on a consideration of both maximum slope and maximum settlement of the ground surface at the location of each building. According to Rankin (1988), a building experiencing a maximum slope θ of 1/500 and a settlement of less than 10 mm has negligible risk of any damage. By drawing contours of ground surface settlement along the route of the proposed tunnel and its associated excavations, it is possible to eliminate all buildings having negligible risk. This approach is conservative because it uses ground surface displacements rather than foundation level ones. It also neglects any interaction between the stiffness of the buildings and the ground. For particularly sensitive buildings it may be necessary to adopt more stringent slope and settlement criteria.

26.8.3 Second stage assessment

The preliminary assessment described above is based on the slope and settlement of the ground surface and provides a conservative initial basis for identifying those buildings along the route requiring further study. The second stage assessment makes use of the work described in the previous sections of this chapter. In this approach, the façade of a building is represented by a simple beam whose foundations are assumed to follow the displacements of the ground in accordance with the greenfield site assumption mentioned in section 26.7. The maximum resultant tensile strains are calculated from the pairs of equations (26.2), (26.10) and (26.3), (26.11). The corresponding potential category of damage, or level of risk, is then obtained from **Table 26.2**.

The above approach, though considerably more detailed than the preliminary assessment, is usually still very conservative. Thus the derived categories of damage refer only to *possible* degrees of damage. In the majority of cases, the likely *actual* damage will be less than the assessed category because in calculating the tensile strains, the building is assumed to have no stiffness – so that it conforms to the greenfield site subsidence trough. In practice, however, the inherent stiffness of the building will be such that its foundations will interact with the supporting ground and tend to reduce both the deflection ratio and the horizontal strains.

Potts and Addenbrooke (1996; 1997) carried out a parametric study of the influence of building stiffness on ground movements induced by tunnelling using finite element methods, incorporating a non-linear elastic-plastic soil model. The building was represented by an equivalent beam having axial and bending stiffness EA and EI (where E is the Young's modulus, A the cross-sectional area and I the moment of inertia of

the beam). The relative axial stiffness α^* and bending stiffness ρ^* are defined as:

$$\alpha^* = EA/E_sH \text{ and } \rho^* = EI/E_sH^4 \quad (26.12)$$

where H is the half-width of the beam (=B/2) and E_s is a representative soil stiffness.

Figure 26.10 shows the influence of relative bending stiffness on the settlement profile for a 20 m deep tunnel excavated beneath a 60 m wide building with zero eccentricity. **Figure 26.11** shows the modification factors MDR that are applied to the green field site deflection ratios (Δ/L) for sagging and hogging modes of deformation at different e/B ratios, where e is the eccentricity of the tunnel centreline. It can be seen that, for hogging in particular, the building changes from relatively very flexible to relatively very stiff over quite a small range in relative bending stiffness.

Potts and Addenbrooke's assessment of the influence of global stiffness of a building is a most valuable addition to the existing methodology for assessing the risk of damage. The results can be used to make more realistic assessments of relative deflection, and hence average strains within a building.

Reproduced from Potts and Addenbrooke (1997)

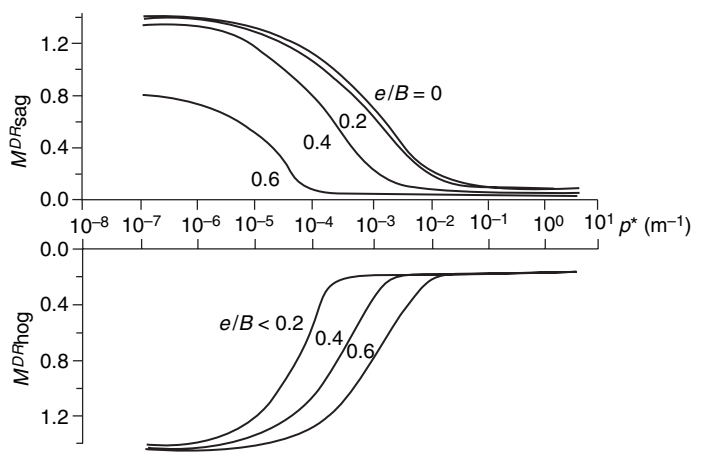

Figure 26.11 Bending stiffness modification factors
Reproduced from Potts and Addenbrooke (1997)

26.8.4 Detailed evaluation

Detailed evaluation is carried out on those buildings that, as a result of the second stage assessment, are classified as being at risk of category 3 damage, or above (see **Table 26.1**). The approach is a refinement of the second stage assessment in which the particular features of the building and the tunnelling and/or excavation scheme are considered in detail. Because each case is different and has to be treated on its own merits, it is not possible to lay down detailed guidelines and procedures. Factors that are taken more closely into account are discussed below.

26.8.4.1 Tunnelling and excavation

The sequence and method of tunnel and excavation construction should be given detailed consideration, with a view to reducing volume loss and minimising ground movements as far as is practical.

26.8.4.2 Structural continuity

Buildings possessing structural continuity, such as those of steel and concrete frame construction, are less likely to suffer damage than those without it, such as load-bearing masonry and brick buildings.

26.8.4.3 Foundations

Buildings on continuous foundations such as strip footings and rafts are less prone to damaging differential movements (both vertical and horizontal) than those on separate individual foundations, or where there is a mixture of foundations (e.g. piles and spread footings).

26.8.4.4 Orientation of the building

Buildings oriented at a significant skew to the axis of a tunnel may be subjected to warping or twisting effects. These may be accentuated if the tunnel axis passes close to the corner of the building.

26.8.4.5 Soil/structure interaction

The predicted greenfield displacements will be modified by the stiffness of the building. The detailed analysis of this problem is exceedingly complex and resort is usually made to simplified procedures – some of which are described in the report published by The Institution of Structural Engineers (1989). The beneficial effects of building stiffness can be considerable, as demonstrated by some measurements on the Mansion House in the City of London during tunnelling

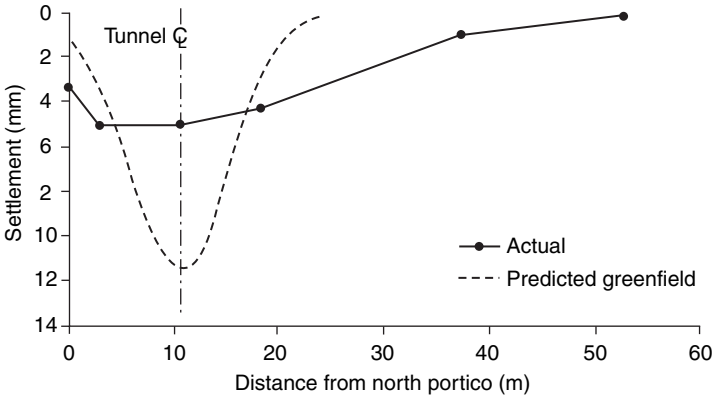

Figure 26.12 Comparison of observed and greenfield site settlements of the Mansion House, London, from driving a 3.05 m diameter tunnel at 15 m depth
Reproduced from Frischman *et al.* (1994)

beneath and nearby – see **Figure 26.12** from a paper by Frischman *et al.* (1994).

26.8.4.6 Previous movements

The building may have experienced movements due to a variety of causes such as construction settlement, ground water lowering and nearby previous construction activity. It is important that these effects be assessed as they may reduce the tolerance of the building to future movements. If the building is already cracked, an assessment should be made as to whether the tunnelling-induced movement will focus on these cracks. Sometimes this can be an advantage, as other parts of the building are then at less risk of damage.

As many factors are not amenable to precise calculations, the final assessment of possible degree of damage requires engineering judgement based on informed interpretation of available information and empirical guidelines. Because of the inherently conservative assumptions used in the second stage assessment, the detailed evaluation will usually result in a reduction in the possible degree of damage. Following the detailed evaluation, consideration is given as to whether protective measures need to be adopted. These will usually only be required for buildings remaining in damage categories 3 or above (see **Table 26.1**).

26.9 Protective measures

Before considering near-surface measures, consideration should be given to measures that can be applied from within the tunnel to reduce the volume loss. There are a variety of such measures, for instance increasing support at or near the face, reducing the time to provide such support, the use of forepoling, soil nailing in the tunnel face and the use of a pilot tunnel. These approaches tackle the root cause of the problem and may prove much less costly and disruptive than near-surface measures.

If, for a particular building, tunnelling protective measures are considered either technically ineffective or too expensive, then it will be necessary to consider applying protective measures near the surface or to the building itself. However, it must be emphasised that such measures are generally disruptive and can have a significant environmental impact. The main forms of protective measures currently available fall into the following six broad groups.

26.9.1 Strengthening of the ground

This can be achieved by means of grout injection (cement or chemical) or by ground freezing. It is normally undertaken in granular water-bearing soils. Its primary purpose is to provide a layer of increased stiffness below foundation level or to prevent loss of ground at the tunnel face during excavation.

26.9.2 Strengthening of the building

Strengthening measures are occasionally undertaken in order that the building may safely sustain the additional stresses or accommodate deformations induced by ground movements. Such measures include the use of tie rods and temporary or permanent propping. Caution is needed when adopting such an approach as the work can be very intrusive and may lead to greater impacts than simply allowing some cracking to take place which can subsequently be repaired.

26.9.3 Structural jacking

In some special situations (e.g. sensitive equipment) it may be possible to insert jacks and use them to compensate for tunnelling-induced settlement as it takes place.

26.9.4 Underpinning

There may be circumstances in which the introduction of an alternative foundation system can be used to eliminate or minimize differential movements caused by tunnelling. However, because the ground movements are usually deep-seated, such an approach may not be possible. If the existing foundations are inadequate or in a poor condition, underpinning may be used to strengthen them and provide a more robust and stiffer support system.

26.9.5 Installation of a physical barrier

Occasionally, consideration has been given to the installation of a physical barrier between the building foundation and the tunnel. This might take the form of a slurry trench wall or a row of secant bored piles. Such a barrier is not structurally connected to the building's foundation and therefore does not provide direct load transfer. The intention is to modify the shape of the settlement trough and reduce ground displacements adjacent to and beneath the building.

26.9.6 Compensation grouting

Compensation grouting is the controlled injection of grout between the tunnel and the building foundations in response to observations of ground and building movements during tunnelling. As its name implies, the purpose is to compensate for ground loss. The technique requires detailed instrumentation

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

to monitor the movements of the ground and the building. Experience of compensation grouting is reported by, amongst others, Harris *et al.* (1994) and Harris (2001). The technique was successfully used on the Jubilee Line Extension Project in London for the protection of many historic buildings, including the Big Ben clock tower at the Palace of Westminster (Harris *et al.*, 1999). More recently, Mair (2008) described the successful application of compensation grouting in granular soils and the innovative application of directional drilling for installation of the grout tubes.

It cannot be emphasised too strongly that all of the above measures are expensive and disruptive, and should not be regarded as a substitute for good quality tunnelling and excavation practice aimed at minimising settlement.

26.10 Conclusions

Damage due to foundation movements is only one aspect of the wider problem of serviceability of buildings. The problem of coping with differential settlement, as with creep, shrinkage and structural deflection, may frequently be solved by designing the building, and in particular the cladding and partitions, to accommodate movement rather than resist it. Successful and economic design and construction of the total structure requires cooperation between the geotechnical engineer, the structural engineer and the architect from the earliest stages of planning.

In this chapter, clear definitions have been given of foundation movement; it is vital that these are understood and used. Also, a widely accepted classification of damage based on ease of repair is described. These two aspects form the basis of a coherent and objective approach to assessing limiting distortions of buildings. The concept of limiting tensile strain as a serviceability parameter is introduced as a means of gaining insight into some of the factors influencing limiting distortions in buildings.

The latter part of the chapter summarises briefly a rational and coherent approach to the assessment of risk of damage to buildings due to tunnelling and excavation. A three-stage approach is recommended for assessing the potential for damage due to subsidence. The first two stages neglect the stiffness of the building in assessing the magnitude of the induced strains within it. The assessments are therefore very conservative. The advantages of this staged approach are that it is simple to use and the buildings which require detailed analysis are identified without recourse to a large amount of unproductive complex analysis.

A wide variety of protective and mitigation measures are described to minimise impacts of ground movement. In general, it is much better to control ground movements by controlling the tunnelling operation (so as to minimise ground loss) than to embark on expensive building protective measures which can themselves be disruptive and damaging.

A key aspect of geotechnical design involves the choice of appropriate parameters for characterising the ground. This chapter describes how the engineer should set about this important aspect of design. Great emphasis is placed on the fact that the selection of the appropriate geotechnical design parameters must be undertaken in the context of overall considerations of risk. A number of examples are given to illustrate how the characteristic values and design values of various geotechnical parameters are selected for a variety of problems. Much of the discussion relates to the requirements of Eurocode 7 but reference is also made to other more traditional approaches.

27.1 Introduction

27.1.1 The design process

This chapter presents the process that should be followed for choosing the appropriate geotechnical parameter for a particular safety factor regime – the two should always be chosen in tandem. The chapter generally follows the approach proposed by Part 1 of Eurocode 7 (BS EN1997-1:2004). Other design codes are also referenced to illustrate how different approaches to design can be used to achieve a similar result. Eurocode design is based on a cautious estimate of the parameters which are used along with partial factors to calculate design values. These design values are then used to assess whether a limit state is being satisfied (e.g. the design axial load on a pile is less than the design resistance to axial load of the pile).

The choice of geotechnical parameters and partial factors is a balance between economy and reliability. (Design to the Eurocode uses partial factors rather than factors of safety. Within geotechnical design to Eurocode 7 partial factors are applied to both material strengths (or resistances in piles) and applied actions, so as to factor each element in the design according to the degree of uncertainty to which the parameter/action is known and according to the implication of variation in the parameter's/action's value.) A cautious approach is generally safer and the resulting structure will be more robust with a much lower risk of under-performing than if a less cautious approach is taken. However, few clients are prepared to pay for an excessive level of redundancy resulting in design being the art of making elements safe and functional as well as economical. In geotechnical design especially, where the risk of failure is very real and the ability to predict failure accurately is not easy, the art of design is to select a design basis that is robust, but not excessively so.

Design is usually carried out within the constraints of a code, e.g. Eurocode 7. The preparation of a code allows the experience of others to be encapsulated in a concise manner. As such the choice of appropriate ground parameters must be compatible with the intent of the code writers for the values of partial factors that are to be used. Further, the choice of geotechnical parameters must be made in the context of the complete structural design being embarked upon. In order for geotechnical parameters to be identified and assessed through the design and construction process the following actions are recommended (see **Table 27.1**).

In addition to the actions detailed in **Table 27.1**, the following considerations are important in ensuring good design:

- Consideration of how a design can be robust to accommodate unforeseen or unexpected loading events, this consideration is important to both ground and structural elements.
- Utilisation of a procurement processes in which the allocation of risk is carried out appropriately and which rewards experienced contractors who make proper allowance for those risks for which they are responsible. To deal with unexpected conditions the contract should place an onus on the contractor to identify such conditions at as early a stage as possible and should thereafter allow for reasonable compensation (time/money).

The confidence that errors in design or construction have been avoided can always be increased by additional third-party checking, both of the design process (such as Category 3 checks proposed by the Highways Agency standards) or on construction sites (such as independent supervision, full-time on-site auditing of the processes and verification of records). These factors are explored by Chapman and Marcetteau (2004).

The management of temporary works risks during construction can include use of the Observational Method – this permits the adoption of less pessimistic parameters and replaces the otherwise lost confidence by more robust management processes, supported by construction monitoring and a set of

Action	Output (Eurocode 7)
■ A well-planned desk study should be carried out, this may include a site walkover (recommended) as well as a preliminary site investigation – see section 27.4.	Desk Study Report with preliminary Ground Model
■ Carrying out a well-planned ground investigation(s) that responds to the risks identified in the desk study. Interpretation of the findings of the investigation allowing for sufficient time to monitor groundwater and environmental gasses to be completed. Part 2 of Eurocode 7 'Ground investigation and testing' (BS EN 1997–2:2007) give suggested scopes, etc.	Factual and Ground Investigation Report with refined Ground Model
■ Use of experienced and knowledgeable designers who take part in a coherent design process using proven models which include consideration of geotechnical, structural and performance requirements	Geotechnical Design Report with recommendations for construction and monitoring
■ Clear design documentation (Geotechnical Design Report) must state the assumptions made in the design in a clear manner to allow the professional involved during the construction (execution in Eurocode terminology) phase to assess ground conditions against the design assumptions. Re-evaluation of the geotechnical parameters/conditions may be necessary at any stage of design and construction. In the design of geotechnical elements it is important for the design to anticipate the construction processes to be used, as those processes may affect the magnitude of the design parameter that is used – for instance different methods of piling cause different values of skin friction.	
■ Where appropriate, testing of trial constructions (e.g. preliminary test piles) may be necessary to validate the design models and geotechnical parameters adopted. Testing samples of the works (e.g. working pile load tests) may also be necessary to verify that the constructed elements do not differ from the trial constructions or design intent.	Refinement of Geotechnical Design Report.

Table 27.1 Recommended actions for identifying and assessing geotechnical parameters

feasible predetermined contingency measures. This is covered by Nicholson *et al*. (1999).

Within the stricture of modern design codes there is limited opportunity for waiver from the partial factors (or factors of safety) stated in design codes. It is only for design of the most basic of structures that design based on comparable experience is permissible. (It is noted that for structures of high importance, such as hospitals in earthquake regions, there is a logical need for increased safety in these structures due to the consequences of failure being so great.) As such it is vitally important that the choice of ground parameter values is appropriate to the level of safety provided for in the code's stated partial factors; the designer must maintain control of the design process by informed choice of the geotechnical parameter to use within a framework of partial factors.

27.1.2 Design codes

In design to Eurocode 7 the value of the partial factors (e.g. in the UK NA to BS EN 1997-1:2004) is based on the assumption that the designer will adopt a ground parameter value that is a cautious estimate of the parameter's value relevant to the limit stage being considered (Clause 2.4.5.2 of BS EN1997-1:2004). Failure to adopt a cautious estimate of the ground strength would result in a potentially unsafe construction. In contrast to a cautious estimate approach, the LDSA note for pile design in London (LDSA, 2009) stipulates that the undrained strength of London Clay should be taken as an average value (and not a cautious estimate). Such an approach is reasonable based on the great knowledge from long history of pile testing to failure in the area and due to the size of factor of safety applied to pile resistance; the combination of mean ground strength and factor of safety combine to provide a level of confidence deemed reasonable. Both of these approaches, Eurocode 7 and the LDSA, and many others, are valid when applied consistently across a design; they must not, however, be mixed.

The list of codes in **Table 27.2**, including Eurocode 7 and the LDSA note, shows how the degree of conservatism used in the geotechnical parameter is balanced by the value of the partial factor on the geotechnical parameter. The methods are all different but aim at achieving similar end constructions.

Mean value (LDSA guidelines)	High value of partial factor/factor safety
Moderately conservative line or conservative best estimate (CIRIA R185 *The Observational Method in Ground Engineering*)	
Representative line or conservative estimate (BS8002 'Code of Practice for earth retaining structures')	Median values of partial factor/ factor safety
Characteristic line or a cautious estimate (Eurocode 7)	
Worst case line or a realistic worst value (CIRIA C580 *Embedded Retaining Walls – Guidance for Economic Design*)	Low value of partial factor/factor safety

Table 27.2 Code comparison

27.2 Overall consideration of risk

27.2.1 An example

When considering the choices for partial factors and ground parameters it is necessary to consider the overall risk regime. Eurocode 7 Part 1, Clause 2.1, introduces the concept of safety categories for design, where Category 1 is for small and relatively simple structures with negligible risk, Category 2 is for normal structures and Category 3 is for special structures where the consequences of failure are worse than normal.

Some of these concepts are illustrated in **Figure 27.1**.

The idealised example of a 'Project' in **Figure 27.1** is provided to highlight the need to design not only for the 'Project' but also for the surrounding context of the project. It is suggested that the design of the foundations for the project building need have no more than typical safety requirements (as supplied by the combination of caution in choice of geotechnical parameters and partial factors) on the assumption that local failure of the building is not anticipated to impact on the nuclear power plant below. However, the design of the retaining wall above the nuclear plant will need to have enhanced safety due to the consequences of its failure. This enhanced safety would logically include larger partial factors on the building loads from the 'Project' than would be used to design the building itself.

Considering the retaining wall, the design for the retaining wall supporting the building will be subservient to the design of the wall protecting the nuclear plant. The implication of this is that the combination of geotechnical parameter and partial factor used to design the wall to protect the plant will be the controlling feature and will result in lower design soil strength than would be used for design of the 'Project' foundations (same ground different levels of safety).

In section 27.2.2 below the concept of risk category is presented; in this context the 'Project' could be a category 2 structure, while the wall should be a category 3 structure. It must be recognised that the stability of the building depends crucially on that for the retaining wall, so the building designer should be satisfied that the retaining wall is sufficiently stable, and has a design life commensurate with that intended for the building.

As a parting comment on this example, what category would be placed on assessment of the slope uphill of the project building? If a slope failure could impact on the nuclear plant then its category would be 3, if not, then 2.

27.2.2 Risk factors

The factors which may affect the level of caution are summarised in **Table 27.3**.

Precautionary measures to reduce the risk for geotechnical elements can be applied by some of the following ways:

- robust design processes including ground investigations;
- checks on design;
- checks on construction;
- some redundancy in the structures (e.g. many piles per column).

27.2.3 Geotechnical categories to Eurocode 7

The concept of geotechnical category to take account of risk as presented in Eurocode 7, Part 1, as introduced in the preceding section is useful in defining the level of caution that is

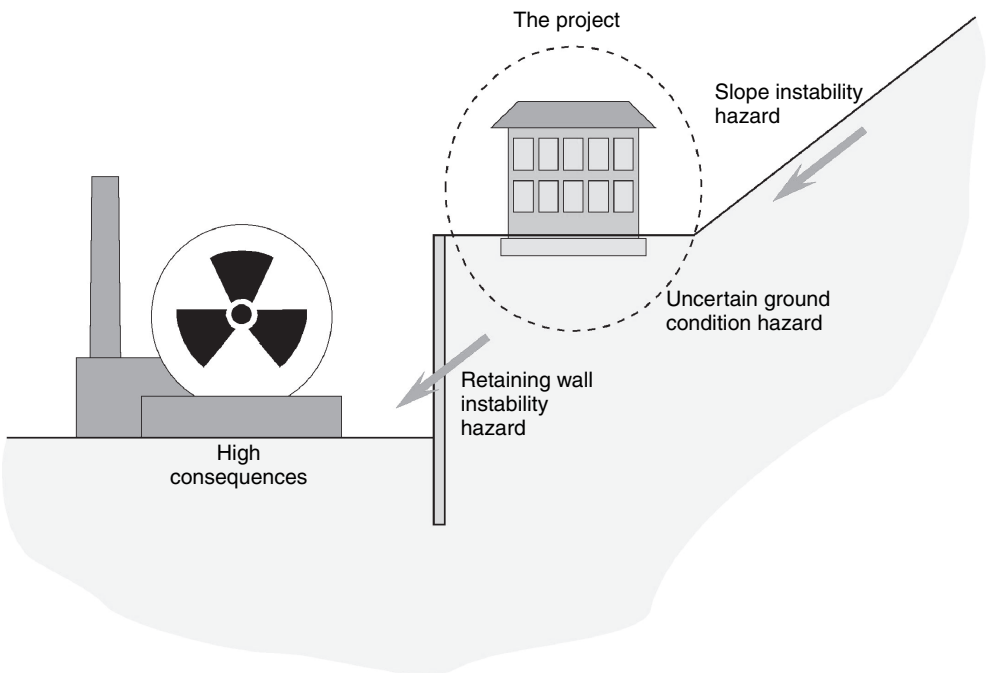

Figure 27.1 The context of a design problem

appropriate when considering the design of a structure. These geotechnical categories are summarised in **Table 27.4**.

An analogous assessment of risk is presented in the Eurocode (BS EN1990:2002+A1:2005).

27.3 Geotechnical parameters

27.3.1 General

Geotechnical conditions are represented in design by series of geotechnical parameters which are used to characterise the complex properties of the ground and groundwater such that they can be modelled for the purposes of that design. Geotechnical parameters can be measured directly or obtained through the use of correlation, theory and empiricism or they can be sourced from published data; it is often best to obtain geotechnical parameters by more than one way to allow confidence in the variability of the parameter to be developed.

In everyday usage, the terms 'geotechnical parameters' and 'design parameters' are often used interchangeably. However, in the context of this chapter and in the Eurocodes, a design value is the particular value of a geotechnical parameter selected for a specific design purpose. The numeric value of the design value will vary depending on the limit state being considered as a function of the particular level of safety required in the specific calculation being carried out and the manner in which safety is achieved in the calculation (factoring of actions or factoring of resistances or a combination of both). For ultimate limit state calculations the design parameter is typically the factored version of the geotechnical parameter. For serviceability limit state the design and geotechnical parameters are typically equal. In all cases the partial factor is applied to adjust the geotechnical parameter detrimentally. Sometimes an upper value of a parameter may result in a less safe condition than a lower one – hence just picking a lowerbound value is not always appropriate without understanding the calculation to be carried out. This may mean that it is necessary to increase the 'Cautious upper' estimate of the geotechnical upwards rather than downwards to obtain a design line to use in ultimate limit state assessments.

In certain circumstances, rather than determining a unique value of a geotechnical parameter or a design parameter it may be appropriate to consider a range of parameters to see how these influence the design being carried out; such a situation may be applicable to ground strength but is more typically applicable to ground stiffness. The estimate may have varying levels of caution depending on the limit state being considered and this should accommodate the balance between caution in choice of parameter and caution inherent in the magnitude of factor of safety or partial factor being applied.

A geotechnical parameter is the culmination of an interpretation process in which geotechnical data are critically examined through a process which considers code requirements and issues such as:

- Ground model
  - geological history;
  - uncertainty with respect to the ground conditions;

Factors due to the supported structure	Factors due to the project or its situation
Structural form very vulnerable to damage or collapse, e.g. statically determinate.	Difficult or complex ground, or poorly understood ground conditions.
Columns supported by single piles.	High or very variable groundwater conditions and groundwater flows.
High economic consequences of failure, e.g. the structure is vital to the cash flow or financial well-being of a major organisation.	Seismic conditions or ground otherwise unstable, e.g. on a hillside suspected as prone to failure.
High safety consequences of a failure, e.g. risk that many people may be injured or killed by a geotechnical failure, such as a concert hall or sports stadium.	High live loads give a greater level of uncertainty of the maximum load likely to be applied. Cyclic loading resulting in large settlement.
High safety consequences of a failure, due to the processes carried out within, such as a chemical production or electricity generation from nuclear power.	Ground conditions where accurate prediction is difficult. Complex ground, or poorly understood ground conditions; attention to settlement at working loads and how these vary over time.
Monitoring and maintenance regimes important.	
Choice of foundations which are unproven in the circumstances or where comparable experience suggested a high rate of defects.	Appointment of an inexperienced or poorly equipped foundation contractor.

Table 27.3 Consideration of risk

	Category 1	Category 2	Category 3
Risk level	Negligible	Not exceptional	Abnormal
Groundwater level	Construction above the water table only	Construction above or below the water table	Construction above or below the water table
Ground	Straightforward with good record of performance for type of structure proposed	Routine	Exceptionally difficult
Type of analysis	Qualitative	Quantitative	Special (quantitative)
Typical structures	Small and relatively simple	Normal spread footings, piles, rafts, retaining walls, etc.	Large or unusual; or in highly seismic areas, etc.

Table 27.4 Geotechnical categories
Data taken from BS EN1997-1:2004

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- scope of ground investigation – is it adequately thorough?
- groundwater conditions and variation with time;
- treatment of anomalous data;
- anisotropic or heterogeneous ground;
- brittle or strain softening ground.

- Risks associated with proposed structure and design simplifications:
  - type and complexity of the intended structure;
  - required design life;
  - geotechnical design models;
  - scale/rate/strain effects;
  - comparable experience.
- Construction related factors:
  - anticipated construction methods and workmanship;
  - adjacent site activities.
- Social considerations:
  - level of acceptable risk/importance of the intended structure.

27.3.2 Eurocode 7

Eurocode 7 uses four terms when referring to geotechnical data:

- raw data;
- derived values;
- characteristic values;
- design values.

Raw data are, as the name suggests, data collected in their most basic format, for example, standard penetration test (SPT) N values.

Derived values are ground properties interpreted from raw data directly or indirectly (e.g. correlation, theory and empiricism), and from other sources such as published data. An example of an indirectly derived ground property could be undrained shear strength based upon SPT data.

Characteristic values are the basic form of geotechnical parameters used in design and are defined in Eurocode 7 as 'a cautious estimate of the value affecting the occurrence of the limit state'. They are selected from derived values.

Design values are characteristic values that have been modified by a partial factor determined according to the limit state being considered and the design approach being adopted. It is noted that in some instances (e.g. when dealing with water pressures) design values may also be selected directly without the use of partial factors.

27.3.3 Traditional codes

Traditional codes such as British Standards are typically based on working stress design approaches (with global factors of safety rather than partial factors) though some are based on limit state design principles. They are not as explicit with their definitions of geotechnical data as Eurocode 7 is, however, they do have similar terms to the Eurocode 7 characteristic value as previously mentioned in section 27.1.2 above.

27.3.4 Considerations for parameter choice

27.3.4.1 General

The partial factors in Eurocode 7 are based on a geotechnical parameter being a cautious estimate of the value controlling the limit state. Within Eurocode 7 this value of the geotechnical parameter is called a 'characteristic value'. Clearly this cautious estimate of the geotechnical parameter implies a value that is offset from what is deduced to be the most probable value by a margin to provide a level of caution.

Choosing a characteristic value is not about putting a line through a set of data. It is about understanding the issues that lead to the choice. Once these are understood, the selection of a characteristic value or line should be straightforward, and whilst it could be curved, straight, stepped, constant with depth or increasing with depth, an overly complex line is generally not necessary or helpful. An overly complex choice more frequently leads to errors in calculations.

Whilst the use of statistical methods to determine a characteristic line, by attributing a statistical definition to the characteristic value, has been promoted by various authors, they are often a trap. It should be kept in mind that the ground is not a well-behaved material (e.g. concrete), data sets are often small, not of normal distribution, and they can contain significant scatter – not an ideal situation for the application of rigorous statistical approaches.

Rather than try to describe how a characteristic line could be selected, it seems more appropriate to communicate the idea via an example. The following example provides a simple illustration of how such an assessment could be made in the context of Eurocode 7.

27.3.4.2 Illustrative considerations for shallow foundations

For shallow foundations, design parameters are very dependent on the construction process and in particular, the preparation of the bearing surface. They also typically engage far less ground than, for example, a pile, and can be affected by localised changes in ground properties or by non-typical soils such as sensitive clays, loose wet sands or collapsible soils. Sometimes those more onerous conditions may lurk just below the exposed formation and may not be observed in the formation preparation. Geotechnical parameters need to be selected with these issues in mind.

27.3.4.3 Illustrative considerations for piled foundations

For piles, design parameters are very dependent on the construction processes used to form the piles and the clear separation of design and construction responsibilities is not as simple as in other branches of engineering. For instance, if a pile fails is it because the geotechnical parameters were too optimistic for the

likely construction methods, or because the construction methods failed to live up to the standards expected by the designer?

Geotechnical parameters need to be selected in full cognizance of:

- the likely construction methods;
- the range of results of load tests carried out for the particular pile type and ground conditions;
- the specification to be employed, to ensure that processes known to be detrimental are not used, or where it would be impractical for them not to be used, that the design parameters are reduced accordingly.

Furthermore, the detailed choice of construction methodology needs to be made in full cognizance of the design assumptions and parameters.

27.3.4.4 Illustrative considerations for slopes

For slope stability, it is often a thin layer of soil that is most critical for the stability of a slope. For example, the back analysis of the failure at the Carsington dam by Potts *et al.* (1990) showed that a thin layer of soil had been neglected in the analyses. Furthermore, understanding the groundwater regime is equally important and in particular, accidental events such as burst water pipes should not be forgotten.

The selection of design parameters is absolutely critical for slopes and it may be that just one data point (perhaps an outlier) is most representative for the behaviour of the overall slope.

For slopes, too often a computer is used to plot results of several drained triaxial tests, and the choice of what should be characteristic values for effective cohesion (c′) and effective

Box 27.1 Case study 1

This example is one of a pile embedded in a stiff clay formation which is subjected to a fixed lateral displacement at the top of the pile 1 m above ground level as shown in **Figure 27.2**.

The undrained shear strength, measured on 100 mm diameter samples tested in quick undrained triaxial compression, with depth is shown in **Figure 27.3**.

The measurement of undrained shear strength has been carried out by means of undrained triaxial compression tests. The clay stratum was logged as being uniform with the exception of a sand layer at 16.5 m depth. Prior to lines being *drawn* on the data it is necessary to review the data to isolate any results that are not representative of the ground. Notes are provided in **Figure 27.3** for three of the data points which are considered to be atypical of the *in situ* state. The high value at approximately 6.5 m depth is noted in the laboratory test log as having dried out; such data may be excluded from further assessments. The two data points at 16 to 17 m depth appear to be soft and coincide with a sand layer; it is likely that sand and water from the sand layer have been included in the samples obtained allowing the clay to swell within the sample tube prior to testing. While the measurement of undrained strength is therefore not representative of *in situ* conditions the observation that the sand layer may have implications for pile construction should be carried through to the design process. The end product of this review is that three data points have been removed from the ground data prior to assessing the characteristic strength of the clay.

It is usual to assume that a characteristic design line (cautious estimate) through the data would be in keeping with the 'Cautious lower' line. By adopting this line the strength of the soil will be towards a lower bound. However when considering the limit state relevant to the structural design of the pile adopting this line as the characteristic property of the ground will likely underestimate the bending moment and shear force in the pile as it would result in a low assessment of mobilised resistance of the ground to pile head movement (δh). Hence for this particular design case the correct characteristic design line through the undrained shear strength data will be the 'Cautious upper' line as only this will provide the appropriate resistance to the pile head movement for carrying forward to structural design of the pile.

The lines shown for the 'Cautious lower' and 'Cautious upper' are open to debate and discussion and tweaking. For the data set used the lines are close to being parallel; this is clearly not a requirement and the splay from the average line should be a function of the scatter in the data and the confidence that the designer has in the data.

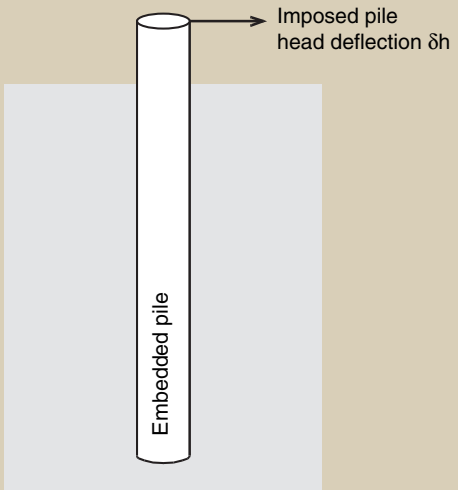

Figure 27.2 Laterally loaded pile

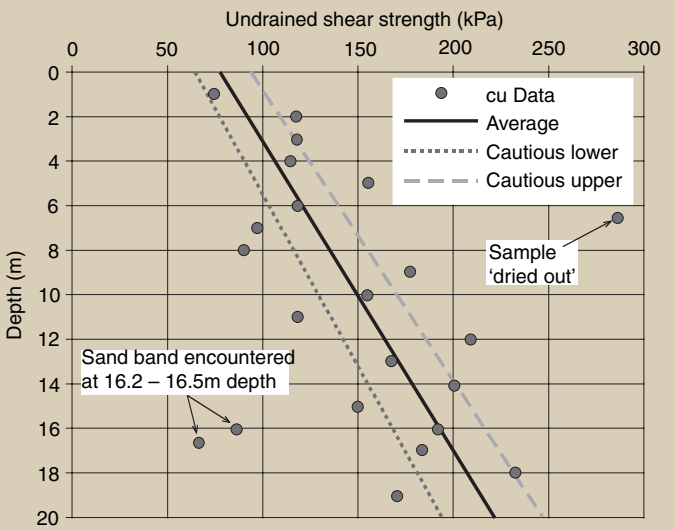

Figure 27.3 Selection of characteristic line

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

angle of internal friction (φ') is not made with sufficient understanding of the true soil behaviour. c′ is unlikely to persist for shallow cut slopes as it will be lost due to weathering and φ' should be chosen over a stress range that is representative of that which will occur in practice.

Box 27.2 Case study 2

An example of how the construction process can lead to problems is seen in CFA piles. A good CFA pile may corkscrew its way into the ground, thereby creating a pile with a ribbed shape. This creates a high capacity pile with a shaft resistance which obtains its resistance from a failure interface between soil and soil rather than a failure interface which is between remoulded soil and smooth concrete. Continued auger rotation during the construction process can, however, quite quickly remove the beneficial ribs by a low rate of penetration per revolution. Hence parameters derived from a test on a very well-constructed pile may not apply to a pile built by the same equipment but with less control, or where circumstances have led to greater auger rotations.

An example of how design parameters could be too optimistic is illustrated by shaft-grouting. For a shaft-grouted pile, it is sometimes difficult to discern what has been improved – has the interface been made rougher, has the pile diameter increased or have the horizontal soil stresses been increased? Learning lessons from load tests requires an understanding of the physical processes in order to decide which parameters have been improved.

27.3.4.5 Illustrative considerations for retaining walls

For retaining walls, critical geotechnical parameter choices can include:

- appropriate selection of water pressures and cognizance of the effect of seepage throughout construction stages, and design life;
- allowance for locked-in earth pressures caused by compaction plant or integral bridges;
- knowing when undrained behaviour can be relied upon;
- allowing for construction mistakes such as overdig.

27.4 Factors of safety, partial factors and design parameters

27.4.1 General

Geotechnical design falls into two main categories: design against failure and design against unacceptable movement. In limit state design theory, these two concepts are known as breaching an ultimate limit state and breaching a serviceability limit state.

In many instances the historical choice of the value of a factor of safety allowed for settlements or lateral movements

Box 27.3 Case study 3

In the following example a situation is described along with discussion of how a designer may accommodate the ground conditions in the calculation process.

Situation: Open cut excavation in a stiff high plasticity clay stratum (see **Figure 27.4**).

Context: Long-term design case critical.

Consideration: Case history records of open excavations in stiff overconsolidated high plasticity clays exhibit progressive failure whereby a range of mobilised strengths (c′, φ') values are mobilised at different parts of the resulting failure mechanism.

- What design parameters should be used in design (long-term conditions)? How is progressive failure accommodated?
- Measurements of shear strength parameters may be made in the laboratory (triaxial, shear box, ring shear, etc). These typically return values of peak resistance and may also show strength reduction with increasing shear strain. How can these results be carried into the analysis of slope stability?
- One option would be to incorporate in a sophisticated numerical analysis model of the slope and ground a soil model which fully accounted for the strain softening of the ground – in this manner a geotechnical parameter model could be populated with appropriately cautious ground parameters. In subsequent calculations partial factors can then be applied to achieve the appropriate level of risk. This is not a standard approach and not one advocated for general design.
- An alternative solution would be to look at the worst possible strength parameters (e.g. residual strength) that are considered possible and to use them with reduced partial factors, possible equal to unity, to provide an equally coherent design approach.
- A third approach would be to use case history data from similar slopes to derive 'safe' parameters to bring forward into the design process. Clearly for this approach to be valid a large set of data for slopes with age similar to the design life of the project slope would be necessary; extrapolation for time-dependent failure is not viable.
- Adjustments will be necessary to any design input to allow for environmental changes in the future that are not replicated by past experience (e.g. global warming and associated changes in precipitation and temperature variations).
- Clearly, consideration of strength parameters is only one part of the stability assessment. Equally important is the consideration of water pressures in the slope. Such considerations need to look at anisotropy of permeability and recharge boundaries. Any drainage provisions that are put in place will need to be maintained if they are to be relied upon in design (it is sometimes the case that drainage provisions are assumed to fail due to risk of not carrying out maintenance).

In this example three possible approaches to the slope stability are proposed. They are quite different in approach (cautious estimate of strength to worst possible estimate of strength) but by using an appropriate value of partial factor in each case the design can be shown to be coherent. As always, water pressures need to be chosen correctly.

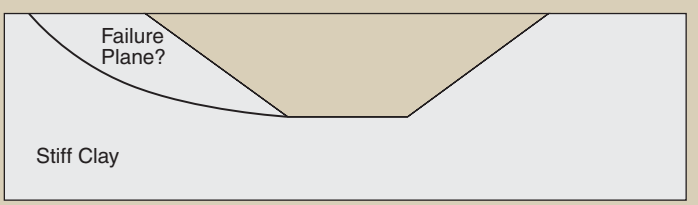

Figure 27.4 Open cut excavation

of a structure that were acceptable for typical performance requirements. Use of such all-encompassing factors of safety is acceptable (even in Eurocode, for example, Geotechnical Category 1) where there is well-established experience allowing 'rules of thumb' to be used. Where such rules do not exist, or where they are not suitable for the level of rigour required, then the designer must assess serviceability explicitly.

In other situations the factor of safety has simply been a factor to create a margin against a real failure, such as rupture, or constant movement. Given the provenance of historic factors it is necessary for the designer to be aware of the implications in choosing a particular value to ensure that the resulting performance is satisfactory in terms of serviceability and ultimate limit states for the particular design being undertaken.

Often geotechnical factors are composite and are created so as to be sufficiently high to prevent both ultimate and serviceability failure. This is one reason why geotechnical factors are sometimes higher than in other branches of engineering. Another is that ground engineering is an inexact subject and utilises materials with wide natural variation and hence the extent of uncertainty in any parameter is much larger than for manufactured materials.

27.4.2 Eurocode basis

The Eurocode use of partial factors is significantly different from a factor of safety approach, in that they are written in terms of limit state principles rather than those of working stress design. The creation of Eurocode 7 brings geotechnical engineers into line with the longer established structural engineering limit state approach to design which will hopefully lead to a more efficient and robust design process and better understanding between geotechnical and structural engineers.

In limit state design the designer is obliged to think about the problem at hand in terms of a particular limit mode and level of risk. Safety is applied in the form of partial factors on individual parameters in a way that more rigorously takes account of uncertainty compared with the lumped factor of safety approach. However, caution should be exercised given the complexity of design to Eurocode 7. There is a risk that the more intricate design concepts and processes will cloud the designer's mind.

The Eurocodes divide limit state design into ultimate limit states and serviceability limit states:

- Ultimate limit states (ULS) are those concerned with collapse and safety; they are not intended to be realistic in terms of the day-to-day

Box 27.4 Case study 4

In the following example a situation is described along with discussion of how a designer may accommodate the ground conditions in the calculation process.

Situation: Basement formed in a retained excavation in stiff clay with layers of water-bearing sand (see **Figure 27.5**).

Context: Design for short- and long-term conditions.

Consideration: The presence of water-bearing sand layers suggests that the overall behaviour of the ground to a retained excavation will be dominated by the presence of the sand layers.

What design parameters should be used in temporary and permanent design?

- Typically in stiff clay undrained parameters are assumed for temporary works design. This is possible due to the drainage path length preventing all but the exposed formation from swelling. However, in this situation, what impact do the sand layers have? The designer must assess the effect that these layers have on the rate that the clay layers can swell and thus the length of time that the undrained strength can be relied upon. Is the geotechnical parameter a drained or undrained parameter? Caution would indicate a drained parameter in the absence of other case histories or additional data.
- The presence of a sand layer close to the toe of the wall requires consideration of uplift of the soil below the excavation. Could the base of the excavation 'blow'? Has the GI investigated both water levels and also supply rate to allow such a design decision to be made? What design conditions should be attributed to the sand layer (permeability and recharge potential)?
- The assumption of the retaining wall forming a cut-off below formation level cannot be taken for granted without careful construction and trial dewatering. If the wall is not continuous then pore pressure in the upper sand band may be recharged through the retaining wall and cause loss of passive resistance in the zone immediately below formation level (this is the zone that controls retaining wall movement the most). What design assumptions are made to the retaining wall, and how can these be validated?

While design parameters are usually considered in terms of strength and stiffness, in this case in order for these to be useful they need to be understood in the context of permeability of the ground, the anisotropy of the ground and the boundary conditions. It is as important to make cautious assessment of these other factors as it is to strength and stiffness.

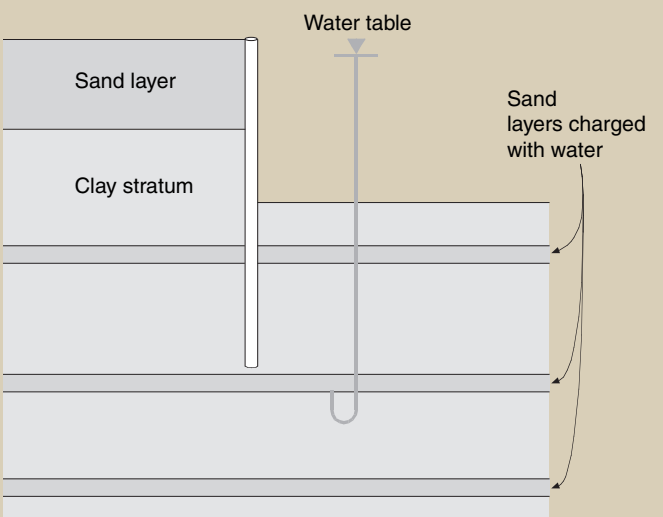

Figure 27.5 Retaining wall in layered soil

performance of a structure. Accidental cases are also covered by the ULS condition.

- Serviceability limit states (SLS) are those concerned with the day-to-day requirements for a structure such as comfort of people and cracking.

In order to verify that potential limit states will not occur, Eurocodes typically adopt the method of partial factors to achieve a suitable level of safety. Eurocode 7 goes one step further to define the following ways by which limit states may be verified:

- by prescriptive methods ('rules of thumb');
- using calculation methods;
- through models and load tests;
- by observational methods.

In the partial factor method, actions, materials, resistances and geometry are factored using prescribed, partial (γ) and combination (ψ) factors. The majority of factors contained within the Eurocodes have been determined by calibration to well-established experience so a design undertaken using them should be similar to conventional designs undertaken with a single lumped factor of safety. Some factors have, however, been determined in a probabilistic manner from laboratory and field data.

27.4.3 Traditional code basis

Traditional British Standards for geotechnical design (note: the Eurocodes are British Standards) are generally now withdrawn and replaced by Eurocode 7 in the UK. However, the traditional standards often remain as non-contradictory-complementary-information (NCCI) referenced in the Eurocodes. This means that the information within them can be used in conjunction with Eurocodes provided it does not contradict the Eurocodes. A further point to note is that Eurocode 7 is currently only compulsory for public sector projects.

The traditional approach to factors of safety can be illustrated as follows:

> BS 8004, Clause 7.3.8: 'In general, an appropriate factor of safety for a single pile would be between two and three. Low values within this range may be applied where the ultimate bearing capacity has been determined by a sufficient number of loading tests or where they may be justified by local experience; higher values should be used when there is less certainty of the value of the ultimate bearing capacity.'

In addition to the traditional codes, some cities adopt their own building codes. One example is the London District Surveyors Association (LDSA 2009) guidance notes for pile design. These 'local' codes can take precedence over the Eurocodes in the appropriate locations.

27.4.4 Consideration of safety

27.4.4.1 General

Historically, factors of safety in geotechnical engineering have incorporated both ULS and SLS considerations without being explicit about these limit states. For foundations, as per Eurocode, it is better practice for these to be considered

Box 27.5 Case study 5

For design against failure the factor of safety has historically been defined as the ratio of resisting actions to disturbing actions. The units of these actions can be force, moment or indeed pressure or stress depending on the calculation being carried out. In order to best understand the factor of safety, the following example is presented.

In **Figure 27.6** the factor of safety for the gravity wall in sliding is:

FOS = $\Sigma_{resisting} / \Sigma_{disturbing} = (P_{P1} + T_{S1}) / P_{A1}$. (Typically a value of 2 would be required.)

Where all actions are based on unfactored parameters rather than factored parameters.

It is noted that the 'resisting actions' should be taken as the sum of all resisting actions and the 'disturbing actions' the sum of all disturbing actions. When calculating a bulked factor of safety it is not admissible to consider the net disturbing or restoring action as part of the calculation.

With the introduction of limit state design, the term 'factor of safety' has been dispensed with and the level of safety is now accommodated through independent partial factors on actions, materials, geometry and resistances to arrive at design values. The resulting verification of safety for a particular ultimate limit state calculation becomes:

Design value of the effect of actions (E_d) ≤ Design value of the resistance (R_d).

Considering the loading conditions in **Figure 27.6** and using Eurocode 7 calculations requirements for the GEO/STR condition of the Ultimate Limit State (Design Approach 1 Combination 2 as per the UK NA to 1997-1:2004), all actions and material strength parameters attract unique partial factors. Safety is introduced by reducing the soil parameters by a partial factor which increases P_{A1} and reduces both T_{S1} and P_{P1} as well as increasing the detrimental influence of transient surcharge loading. Verification that the limit state has not been exceeded can be achieved by showing that the design value of P_{A1} is ≤ the sum of the design values of P_{P1} and T_{S1} where the design values of all three forces are based on factored soil parameters and surcharge loading.

Note: for Design Approach 1, Combination 2 of BS EN 1997-1:2004 the partial factors that must be applied are as follows: $\gamma_{\varphi'} = 1.25$ (applied to tan φ'); and $\gamma_c' = 1.25$; $\gamma_{cu} = 1.4$.

For all permanent loads $\gamma_G = 1.0$, while for variable loads only unfavourable loads are considered and for these $\gamma_{Q;unfav} = 1.3$ ($\gamma_{Q;fav} = 0.0$).

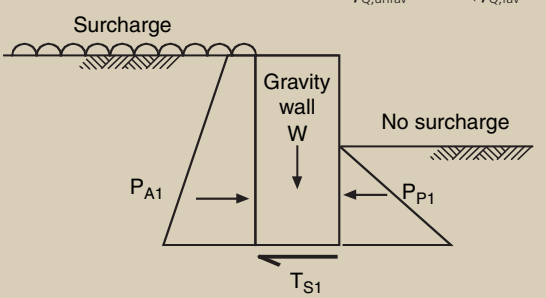

Figure 27.6 Factor of safety against sliding

separately. Factors just providing a margin against failure can be lower than those seeking to control movements, for instance.

27.4.4.2 Illustrative considerations for shallow foundations

For shallow foundations designed to Eurocode 7, the design bearing resistance is calculated using ground parameters modified by partial factor. This design bearing resistance is then compared with the design effect of actions which are also factored (note: in traditional design the ultimate bearing resistance would be factored and referred to as the safe bearing pressure).

The values of the partial factors for the two main Eurocode 7 ULS design situations for foundation design, namely GEO and STR, vary as to where partial factors are applied. For GEO the ground strength values are factored leaving density or surcharge effects largely unfactored or with small partial factors while for STR the actions or effects of the actions are factored (e.g. surcharge loading and calculated shear stress or bending moment in an element). By splitting into these two design cases it is possible to be confident of the geotechnical stability (usually this would be assessed first) and then the structural forces (usually calculated after the geotechnical stability is addressed).

Settlements (SLS) are considered separately and computed using partial factors of unity for the stresses imposed. They are compared to the values of settlement that it is thought that the structure of the function in the structure can withstand. If the calculated settlement is too high then the design is modified (note: in traditional design the safe bearing resistance would be reduced to an allowable bearing pressure if settlements controlled the design).

27.4.4.3 Illustrative considerations for piled foundations

In traditional design for piles, two criteria are often applied:

- An overall factor on the combined shaft and base resistances, giving a margin against failure.
- A reduced factor on the stiffer and normally more reliable shaft capacity alone, to limit movements to the stiffer part of the pile load/settlement curve, giving control on movements of the supported structure.

There are cases when this approach can be too conservative, such as when the pile base performance is known to be both stiff and reliable; in these cases the factor on shaft capacity is not used.

Under Eurocode 7, the capacity and settlement of a pile are usually dealt with separately; the design resistance being calculated by modifying the characteristic resistance by partial factors. However, where serviceability is not considered explicitly, an alternative set of partial factors on resistance are used.

For temporary works, sometimes lower safety factors are considered. However, their use is only appropriate where the higher resulting risks can be accommodated and where larger displacements are acceptable.

27.4.4.4 Illustrative considerations for slopes

For slope stability, overall moment and vertical stability are the key ultimate limit state concerns. Serviceability is generally related to the effect that slope displacement has on surrounding structures rather than internal displacements, unless there are aesthetic constraints to consider.

27.4.4.5 Illustrative considerations for retaining walls

For retaining walls, the geotechnical modes of failure are more varied and typically require separate calculations, for example, rotation about the top, rotation about the base, vertical displacement and horizontal displacement. Whilst safety is typically accommodated in partial factors on actions and ground parameters, geometrical variation and progressive failure checks are also important.

Serviceability is typically addressed in terms of lateral movement and the effect this has on supported structures, although excessive displacement of a wall into a basement, for example, may impact upon its amenity despite it not causing problems for structures that it supports.

27.5 Concluding remark

Geotechnical parameters and safety factors must be viewed holistically: the manner by which one is chosen needs to mirror the level of risk in the other. Beyond ground strength and designing against failure, the assessment of soil structure interaction, movement and performance of structures associated with the ground elements need also to be assessed with an understanding of the level of certainty in the design parameters.

Section 3: Problematic soils and their issues

Section editor: **Ian Jefferson**

doi: 10.1680/moge.57074.0311

Chapter 28

Introduction to Section 3

Ian Jefferson University of Birmingham, UK

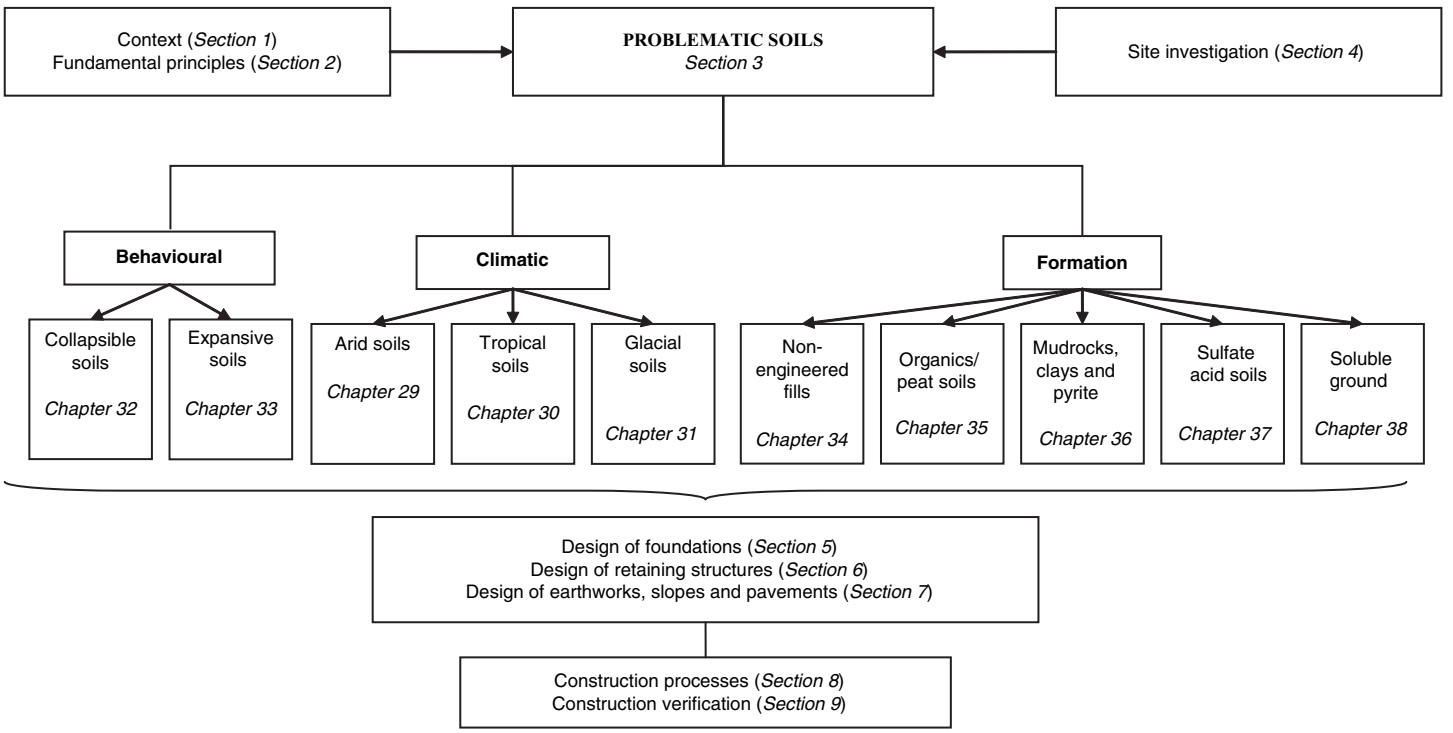

Figure 28.1 Layout of chapters in Section 3

Many soils can prove problematic to geotechnical engineering. Problematic characteristics include significant volume change, a distinct lack of strength, or soils that are potentially corrosive. This creates difficulties across built and urban environments and continues to cause billions of pounds of financial loss annually across the world: costs that often exceed those associated with earthquakes, floods, hurricanes and tornadoes combined.

The degree to which a soil is problematic to engineering is a function of:

(1) the nature of the soil itself (mineralogy, micro-fabric and geotechnical and other properties);

(2) the geological processes that caused it to be formed (whether fluvial, glacial, aeolian, or others);

(3) the processes that are acting on it currently (weathering, erosion and human activity).

However, problematic soils are also profoundly influenced by the climatic regime in which they were developed. This, creates many types of problematic soils and a number of key challenges when dealing with them. Nevertheless, these can be overcome by paying careful attention to:

- recognition (through geology and geomorphology);

- classification and assessment (through correlations, laboratory and field testing);
- evaluation (via use of appropriate models – empirical, analytical or numerical);
- treatment by application of suitable and appropriately targeted engineering solutions.

Thus problematic soils can be engineered effectively through observation, understanding and technological development, allowing soils that are considered problematical to be assessed in a rational manner using the approaches detailed throughout this manual. This will overcome what Leroueil (2001) considered as problematic engineering, designs, specifications or use of technologies that occur through a lack of appropriate or detailed understanding of the situation in hand. We are moving to ever-better understanding of soil behaviour; however, as Vaughan (1999) suggests, many of our geotechnical materials seem unusual or 'problematic' because their behaviour does not fit the classic theories of soil mechanics. Thus, modification of basic soil mechanics is needed to incorporate problematic soils. However, as yet this has not been fully accomplished and many soils continue to cause problems globally.

Section 3 *Problematic soils and their issues* covers the main problematic soils/ground encountered globally. These have been grouped to reflect the main process in their formation (see **Figure 28.1**):

(1) Behavioural:

- Chapter 32 *Collapsible soils*
- Chapter 33 *Expansive soils*

(2) Climatic:

- Chapter 29 *Arid soils*
- Chapter 30 *Tropical soils*
- Chapter 31 *Glacial soils*

(3) Formation:

- Chapter 34 *Non-engineered fills*
- Chapter 35 *Organics/peat soils*
- Chapter 36 *Mudrocks, clays and pyrite*
- Chapter 37 *Sulfate acid soils*
- Chapter 38 *Soluble ground*

These soil types or formations, which continually cause significant challenges, are associated with many of the difficulties experienced with problematic ground, both across the UK and throughout the world. Moreover, these constitute the problematic soils/ground commonly encountered in geotechnical engineering.While this does not represent all possible types of problematic soils, the approaches highlighted throughout Section 3 *Problematic soils and their issues* provide a useful benchmark from which all problematic soils can be dealt with.

The ultimate aims of this section are therefore to:

- highlight the importance of understanding geological and geomorphological aspects associated with problematic soils;
- identify methods to assess and evaluate problematic soils and their behaviour, and
- present methods to treat and engineer problematic soils effectively.

Overall this Section provides a sound basis of engineering in problematic soils and thus aims to help prevent many of the costly mistakes that continue to plague engineers dealing them.

Arid soil forms when more water evaporates than enters the ground from precipitation. It is this process that generates specific problematic soils occurring at specific locations on the Earth's surface. Arid soils present a number of challenges to engineers due to the highly variable nature of their engineering properties associated with active and ancient geomorphic processes; the considerable diurnal temperature ranges experienced, potentially resulting in accelerated disintegration of soil and rock formations as well as man-made structures; lithification processes can result in cementation of the soil particles, making excavation problematic; and various problematic behaviour occurs in arid conditions, such as soils with significant shrink–swell or collapsing potentials, or aggressive salt environments. Key to understanding how arid soils behave and how these soils can be engineered is achieved through an appreciation of the geomorphology of their formation. Associated with these processes are soils that can be cemented or uncemented, whilst being unsaturated. Once geomorphologic effects are understood, appropriate engineering assessment and mitigation can be applied. A number of other logistical challenges also occur with arid environments owing to the limited availability of suitable water sources for construction; only through careful planning can these problems be avoided.

29.1 Introduction

Arid soils can be described as those soils that are conditioned by an arid climate; such climates occur when the potential annual evaporation exceeds annual precipitation and a soil moisture deficit is the result (Atkinson, 1994). Overall, it is estimated that a third of the Earth's land mass currently experiences arid conditions (Warren, 1994a) yet only approximately 25% of the soils found in hyper-arid and arid regions comprises active sand dunes (see **Figure 29.1**) (Warren, 1994b). Arid conditions can be found in both hot and cold locations on the Earth, e.g. arid soils can comprise hot desert soils such as the Sahara, cold desert soils such as the Gobi, even locations within the polar regions are considered arid.

In addition, movements of the tectonic plates result in soils and rock previously formed in arid conditions being found in temperate climates (such as the dune-bedded sandstones, **Figure 29.2**, in the UK's midlands), and soils not commonly associated with arid conditions being found in modern-day arid environments.

Arid soils present a number of challenges to engineers owing to:

- the highly variable nature of their engineering properties associated with active and ancient geomorphic processes;
- the considerable diurnal temperature ranges experienced, potentially resulting in accelerated disintegration of soil and rock formations as well as man-made structures;
- lithification processes, which can result in cementation of the soil particles, making excavation problematic;

- various problematic soils, which occur in arid conditions, such as those with significant shrink–swell or collapse potentials (see Section 3 *Problematic soils and their issues* of this manual for related chapters).

Arid conditions can mean there is a limited availability of water for construction, potentially affecting the suitability of geotechnical processes during construction. This may necessitate the use of locally sourced water, which can contain high concentrations of dissolved salts and will affect construction activities such as the casting of concretes. Limited availability of water can create logistical problems, which must be surmounted if the project is to be completed on time, or it can raise the cost of the project.

The mechanics describing the behaviour of arid soils are not unique to these deposits; soils not currently experiencing arid conditions may still be unsaturated, cemented, prone to shrink-swell or be metastable, although the effects of these mechanisms can be pronounced in arid deposits. However, the climatic and geomorphologic processes that shape arid soils must be considered in order to understand the nature and engineering behaviour of soils in arid regions. This chapter will, therefore, give the key aspects of soil mechanics and geotechnical engineering associated with arid soils along with a description of climatic and geomorphologic processes that shape arid soil conditions (and are likely to continue affecting a site after the completion of a construction project).

29.2 Arid climates

Arid climates form when more water evaporates and transpirates than enters the ground from precipitation. It is this process that generates specific problematic soils occurring at specific locations on the Earth's surface, therefore this section briefly introduces:

- the development of arid conditions in hot and cold regions;
- the characterisation of arid regions into hyper-arid, arid and semi-arid zones.

29.2.1 Development of arid conditions

Arid conditions develop through the global circulation patterns (or macroclimate) of the atmosphere, the location of the land in relation to the sea and the prevailing winds. This is governed by a number of complex processes driven by differences in air temperature and pressure across the globe and the rotation of the Earth. The distribution of arid environments around the world is shown in **Figure 29.3**.

The equatorial regions of the Earth experience the greatest concentration of solar radiation and the poles the least; this imbalance creates a number of convection currents within the macroclimate on either side of the equator (see Wallen and Stockholm, 1966, for further details). The associated climate and atmospheric patterns are the principle reasons why the majority of hot arid conditions are located around the 30° line of latitude on either side of the equator (see **Figure 29.3**).

Cold arid landscapes tend to form because of their location within a land mass in relation to the sea and the prevailing winds (Bell, 1998; Wallen and Stockholm, 1966; **Figure 29.3**); the further from the sea the more likely the water transported in the atmosphere has already precipitated, leaving the air relatively dry (see Lee and Fookes, 2005a, for more details). Topographic structures, such as mountain ranges, can also interrupt the transport of water from sea to land by inducing precipitation

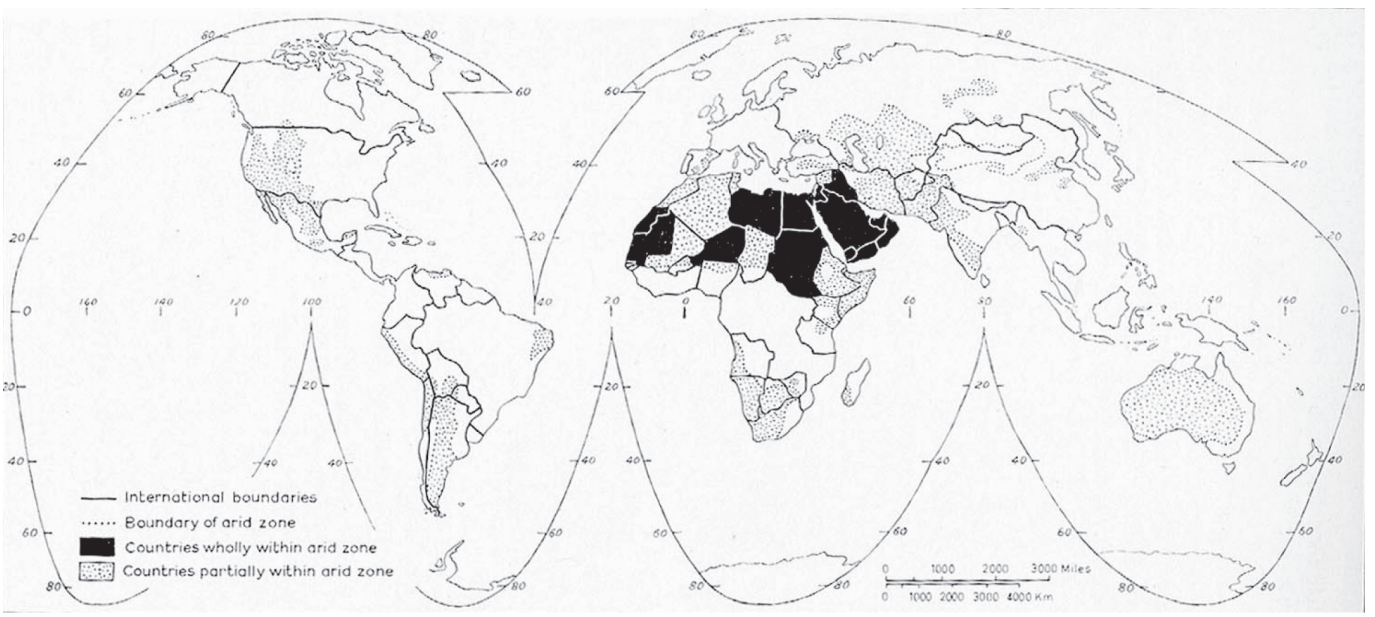

Figure 29.3 The distribution of arid environments

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

on the topographic structure and leaving the air flowing into the lands behind relatively dry (Bell, 1998; Wallen and Stockholm, 1966).

Cold sea currents that approach the surface and flow near to land (such as the Humboldt Current, situated off Chile's coast) can exacerbate the effect of atmospheric circulation on an arid environment by creating stable and cool air conditions at sea, making precipitation unlikely to occur (although fog and clouds can still form) (Wallen and Stockholm, 1966). The Atacama Desert, Chile, is considered one of the driest places on Earth due to the combined effects of the atmospheric circulation, the presence of a topographical structure along the coastline and the Humboldt Current (Wallen and Stockholm, 1966; Lee and Fookes, 2005a); Lee and Fookes (2005a) give data indicating that the Atacama Desert receives a mean annual precipitation of less than 0.3 mm.

29.2.2 Precipitation in arid environments

Arid environments are not necessarily under constant drought conditions; although there are locations in hyper-arid regions that may be in drought for years, if precipitation occurs at all. However, by definition, arid environments do experience a moisture deficit. Regions can be classified as arid (or subdivided into hyper-arid and arid, depending on the classification system used), sub-humid (where the magnitude of the deficit is low) or semi-arid (transitional tracts of land between arid and sub-humid lands); see **Figure 29.4**.

Lee and Fookes (2005a) give a simple relationship between mean annual precipitation and annual potential evapotranspiration (the combination of water vapour entering the atmosphere via evaporation and transpiration, Fetter, 2001), see **Table 29.1**, to determine the aridity of a region. Calculation of the annual potential evapotranspiration for a region can be determined using a number of approaches, although the Penman equation (not considered here) is considered the most suitable (see Lee and Fookes, 2005b, and Wallen and Stockholm, 1966, for further details). Deriving the annual potential evapotranspiration requires the quantification of a number of environmental parameters and Wallen and Stockholm (1966) give an alternative method (developed by Köppen) that relates aridity to mean annual precipitation and mean annual temperature (for a winter, summer or undefined season); see **Table 29.1**.

Figure 29.4 Semi-arid desert conditions in Botswana during the summer 'wet season'; note the profusion of green vegetation indicating the occurrence of recent rains
Image courtesy of Mrs Jackson-Royal

Arid regions can be described as having wet and dry seasons, although such an approach is more applicable to semi-arid regions than arid or hyper-arid regions. The duration of the wet season can be very short. Predicting actual precipitation patterns in hyper-arid and arid conditions can be very difficult as the annual precipitation can vary considerably, whereas semi-arid regions can experience more predictable conditions (Bell, 1998; Lee and Fookes, 2005b). Taking the mean precipitation over a reasonable time frame will result in the values quoted in the literature, though the annual precipitation will vary considerably throughout this period; some years very little precipitation, if any, will occur whilst in other years far greater amounts will be recorded (Lee and Fookes, 2005b). Lee and Fookes (2005b) give further details of the distribution of arid regions, including indications of aridity, periods of drought and associated temperature and the occurrence of wet and dry seasons.

Precipitation, when it occurs, can take the form of short-lived very heavy storms known as convection-cell cloudbursts. These storms can occur as infrequently as once in a decade or even once in a century in certain arid environments (Hills *et al*., 1966). However, they are very intense events and they can cause significant changes to localised topography and can damage earthworks (as illustrated in the subsequent sections of this chapter).

29.3 Geomorphology of arid soils and the effect of geomorphic processes on the geotechnical properties of arid soils

An overview of the geomorphology of arid soils has been included in this chapter as the geomorphic processes active in arid regions are fundamentally related to the geotechnical properties of the soils found within those areas. Failure to understand the geomorphic processes, which have acted upon, and will continue to act upon, the arid soils found on site, will limit the ability to successfully engineer those soils. Therefore, this section of the chapter considers:

- the commonly encountered types of arid regions and the associated ground conditions;
- erosion and deposition processes within arid regions (alluvial, chemical, fluvial and mechanical) and the potential effect these process have upon construction processes;

Humidity province	Characteristic vegetation[1]	*P*/ETP[2]	Summer[3]	Winter[3]	Undefined season[3]
Sub-humid zone	Grassland	0.50–0.75	-	-	-
Semi-arid zone	Steppe	0.20–0.50	$P \leq 20T$	$P \leq 20(T + 14)$	$P \leq 20(T + 7)$
Arid zone	Desert	0.03–0.20	$P \leq 10T$	$P \leq 10(T + 14)$	$P \leq 10(T + 7)$
Hyper-arid zone	Desert	<0.03	-	-	-

Where P is the annual precipitation (mm), ETP is the annual potential evapotranspiration and T is the annual mean temperature (°C)
1. Lee and Fookes (2005a)
2. Lee and Fookes (2005b)
3. Hills *et al.* (1966)

Table 29.1 Methods to determine if arid conditions apply for a given region
Data taken from Lee and Fookes (2005a, b) and Hills *et al.* (1966)

- landforms that are found in arid regions and their potential for use as aggregates;
- the formation of duricrusts and cemented soils and the problems these present to construction;
- the formation of hammada, dunes and other aeolian features, the conditions associated with these landforms and the geohazards these landforms present when undertaking construction;
- the formation of fans, wadis and other fluvial landforms, the conditions associated with these landforms and the geohazards these landforms present when undertaking construction;
- the formation of salinas, sabkhas and playas, the conditions associated with these landforms and the geohazards these landforms present when undertaking construction;
- considerations when undertaking site investigations in arid environments and potential sources of aggregates.

The geomorphic processes affecting arid environments are similar to those affecting other regions; arid environments are not governed by special circumstances (Hills *et al.*, 1966). However, the lack of vegetation and the aridity of the ground conditions makes aeolian erosion more prominent in arid regions than in other regions: aeolian deposits can be prone to collapse (as described in detail in Section 3 *Problematic soils and their issues* of this manual), affecting the design of structures built in such conditions. Stabilisation may be necessary before constructing on these deposits. Aeolian deposits can also be extremely mobile, potentially swamping a site and making it unfit for purpose. Arid conditions can also experience extreme changes in diurnal temperature, resulting in both increased rates of mechanical and chemical weathering of soils and man-made structures, such as concrete, and can significantly reduce the engineering life of a structure. Certain geomorphic processes will only occur infrequently, such as fluvial erosion, yet can have a pronounced effect upon conditions on site.

29.3.1 Landforms within arid environments

There are two distinct types of arid region: shields and basins (or plains) (Lee and Fookes, 2005b), with four distinct zones (from a geomorphologic viewpoint) that control the topography within an arid region: uplands, foot-slopes, plains and base level plains (Lee and Fookes 2005b). Each of these zones exhibits different geotechnical problems as a direct result of their geomorphologic environments. Shields are defined as a 'major structural unit of the Earth's crust, consisting of large mass of Precambrian rocks, both metamorphic and igneous, which have remained unaffected by later mountain building' (Whitten and Brooks, 1973, p. 411). Such features are remarkably stable geological formations having survived intact since the Precambrian eon (Precambrian rocks were formed at least 570 million years ago and can be billions of years old). Therefore, many shield deserts do not contain active volcanoes (although there are examples of recently active volcanoes in arid regions of America; Hills *et al.*, 1966) and many of the topographic features within a shield that were created by tectonic actions in a previous age have been affected by hundreds of millions of years of geomorphic processes (i.e. mountain ranges become reduced to hills by weathering and erosion). A shield may be overlain by younger rock formations, or soil, that will erode preferentially to the shield. Conversely a basin (defined as a 'depression of large size, may be of structural or erosional origin'; Whitten and Brooks, 1973, p. 49) will act as a sink for debris eroded from higher ground via fluvial and aeolian actions and will contain soils with a considerable range of particle sizes. A basin may have dunes.

29.3.1.1 Uplands and foot-slopes

Uplands are regions of hills, plateaus and canyons, characterised as having flat tops with scarps and ramparts (**Figure 29.5**). The topography of upland regions (with the exception of the ramparts) tends to be denuded of soil deposits by fluvial and aeolian processes leaving barren rock or boulder fields (Lee and Fookes, 2005b). The topography of upland regions is shaped by mechanical, chemical and thermal weathering and eroded by fluvial and aeolian action (and is also weathered by these processes), with weaker rock formations eroding preferentially to harder ones. This creates the prominent flat-topped, steeply sided features synonymous with arid environments (Monument Valley in the USA being a prime example).

Foot-slopes (**Figure 29.6**) are transitional regions between uplands and a basin. Gently dipping plateaus that form between

two regions are known as piedmonts. Eroded materials from uplands are deposited, by fluvial and aeolian actions, within a piedmont to form transitionary topographic structures such as alluvial fans and pediment slopes, which can exhibit a significant potential for collapse.

The same geomorphic processes that created deposits on foot-slopes will also erode them, transporting the eroded material into a basin. Whilst chemical, mechanical and thermal weathering occurs in these regions, aeolian and fluvial processes dominate the shaping of the topography in foot-slope environments. The actual geomorphologic processes involved are not universally agreed. However, from a geotechnical engineering viewpoint, piedmonts can be valuable sources of readily available aggregates and other resources for construction projects (Lee and Fookes, 2005b), as illustrated in section 29.3.7.5.

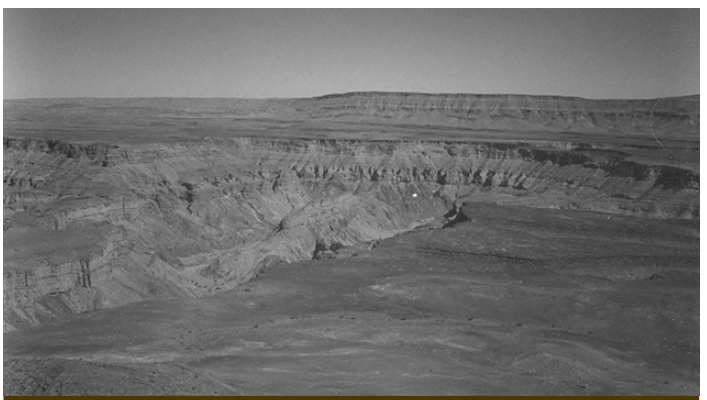

Figure 29.5 Fish River Canyon, Namibia; note the flat and barren tops, steep scarps, establishment of ramparts at the base of the scarps and the development of a mesa and a butte (centre) within the canyon

29.3.1.2 Plains and base level plains

The topography of plains tends to be dominated by the deposition and continued transport of previously weathered and eroded materials from uplands and foot-slopes. Aeolian and fluvial transport mechanisms dominate the changing topography of these regions, creating dunes and wadis, for example, and segregating the transported particles with respect to size and density depending on the location of the source material and the orientation of weathering process. Base level plains are naturally occurring depressions within a basin and they are also affected by aeolian and fluvial actions (akin to plains), although the groundwater level can be relatively near the surface. The proximity of groundwater, the moisture deficit experienced by the soils in the vadose zone and the chemistry of the pore water can result in an accumulation of salts within the vadose zone. These highly salty conditions can accelerate the weathering of soil and rock deposits within base level plains and can cause damage to man-made structures.

Whilst upland features such as scarps and inselbergs (Ayers Rock being a prime example, Hills *et al*., 1966) can be ancient, features such as pediment slopes, fans and dunes (**Figure 29.6**) are thought to be products of the Quaternary and are likely to be reshaped by future geomorphic processes (Lee and Fookes, 2005b). The lack of vegetation and predominantly dry surface soil result in coarse-grained soils being readily eroded by

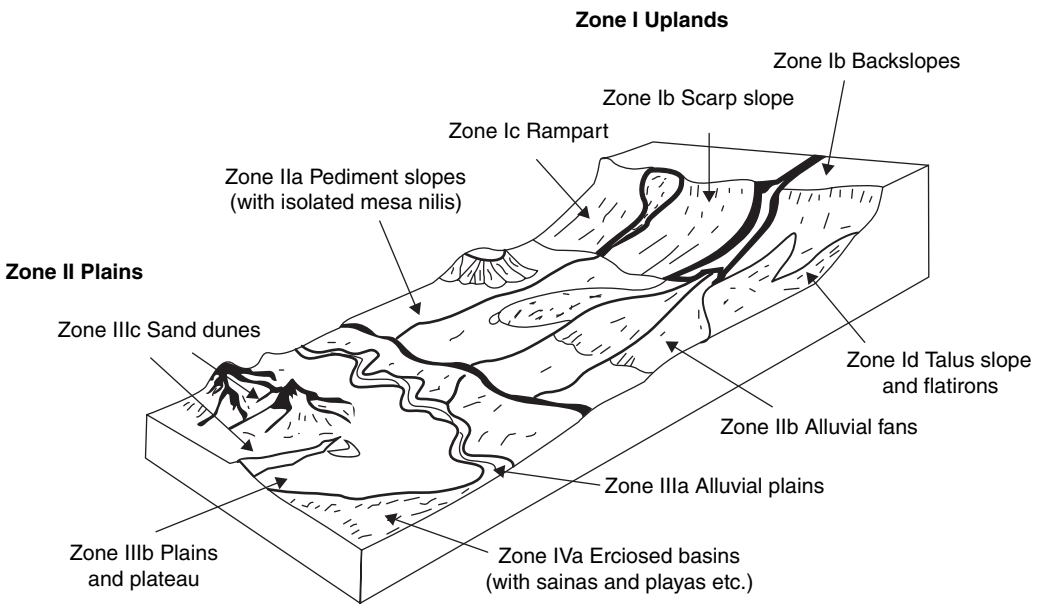

Figure 29.6 Illustration of hot desert topography
Reproduced from Lee and Fookes (2005b) Whittles Publishing

geomorphic processes; phreatic surfaces can be found in arid environments although the depth of the water table can vary considerably and can be very deep; Lee and Fookes (2005b) cite an example of a phreatic surface being 50 m below the ground surface in the Sahara, and this is echoed by Blight (1994) who cites similar groundwater levels in semi-arid conditions in southern Africa. The geomorphic processes that dominate arid environments include aeolian and fluvial erosion as well as chemical, mechanical and thermal weathering.

The transitional, and desiccated, nature of superficial deposits within arid landscapes, along with the bedrock being very close to the surface in upland areas, can prove to be a significant resource of aggregates for construction purposes, as illustrated in section 29.3.7.5.

29.3.2 Development of arid soils through weathering

Weathering by aeolian, chemical, fluvial, mechanical and thermal processes occurs in arid environments. These processes produce a complex array of landforms and associated ground conditions, many of which present a number of significant challenges to geotechnical engineers. An understanding of this behaviour is essential. Further details and other useful references can be found in Fookes *et al*. (2005b).

29.3.2.1 Mechanical weathering processes in arid environments

The process of eroding an upland is relatively slow; Lee and Fookes (2005b) cite rates for a scarp to recede as being of the order of millimetres per year. The resilience of upland formations is related to the nature of the upper layers of the topography, with rocks such as sandstone, or cemented soils (known as a duricrust), forming barriers that resist the erosive processes. These layers are called capping layers and they can slowly be eroded at the scarp by mechanical weathering. If the formations of uplands are jointed then a capping layer may be undermined by block-by-block failure (Lee and Fookes, 2005b; Howard and Selby, 2009); if the formations below the capping layer are susceptible to erosion by water (if they contain smectites, gypsum, etc.) then these formations can soften when inundated by water, resulting in the collapse of the capping layer blocks above (Howard and Selby, 2009). The capping layer may also be weathered if the rock underlying the capping layer is permeable. Water seeping through this rock may weaken it; eventually voids will form within the underlying rock and ultimately lead to collapse of the weakened capping layer above (Lee and Fookes, 2005b).

Mechanically weathered material will fall from the scarp and accumulate on the ramparts where it continues to weather, forming a debris slope (known as a talus slope). Talus (commonly known as scree) will form at or near the angle of repose; it can form metastable collapsible materials, and in response to changes in environmental conditions can collapse down the slope. Thus, talus slopes are dangerous places for construction and may require treatment to prevent slips causing disruption. Degradation of a scarp can result in a gradual reduction in the scarp angle (and height), producing smoother slopes, with the upland eventually being reduced to piedmont slopes (see Lee and Fookes, 2005b, for details).

Cyclic changes in climate experienced by the uplands, alternating from wet to dry, can result in the development of flatirons (wedge-shaped features, which can be of considerable size, that have detached from the rampart and slipped down the talus slope; for more information see Howard and Selby, 2009) within a talus slope. Repeated wedge failure, instigated by weakening of internal boundaries (joints, slip surfaces, dipping rock boundaries, etc.), with a change in climate (from dry to wet), may result in rapid degradation of a scarp and result in a number of flatirons being created on the ramparts.

29.3.2.2 Acceleration of mechanical weathering processes with changes in temperature

The mechanical weathering of arid landscapes, and man-made structures within these arid environments, can be accelerated by changes in temperature. Arid environments experience considerable changes in temperature throughout the year and more importantly diurnally, for example when working on a site in a hot arid region during the summer, the daily temperature would change from low twenties (°C), or less, in the early morning to the high forties (°C), or greater, in a matter of hours; therefore, the acceleration in weathering can be considerable. Rapid changes in temperature can result in the degradation of man-made structures; this is particularly true for composite structures containing materials with different thermal expansion coefficients (such as reinforced concrete), as differential expansion and contraction induce stresses within the material. The material need not be composite to experience such weathering, differential heating and cooling rates (i.e. the outer face compared to the core) can equally result in increased rates of weathering; the outer layers of the material can spall via a process known as exfoliation. Hills *et al*. (1966) suggest that this method of weathering can be very slow and that unconfined rocks, free to expand and contract, do not readily fail via exfoliation. However, rocks, or structures, that are partially buried in a different medium will experience differential rates of change in temperature (the surface exposed to the ambient temperature will expand or contract at a greater rate than the buried surface), the differential movements within the rock will result in additional stresses developing and lead to accelerated rates of weathering.

29.3.3 Degradation of arid environments and man-made structures through chemical weathering

Diurnal changes in temperature can cause chemical weathering of rocks, and man-made structures, via the precipitation of salts within the joints or pores of the rock or soil, or by chemical attack, as illustrated in **Figure 29.7**.

Miscible salts are often found naturally occurring in soils and sedimentary rocks, either as crystals or dissolved salts within the pore water. Vertical seepage of groundwater, induced by

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

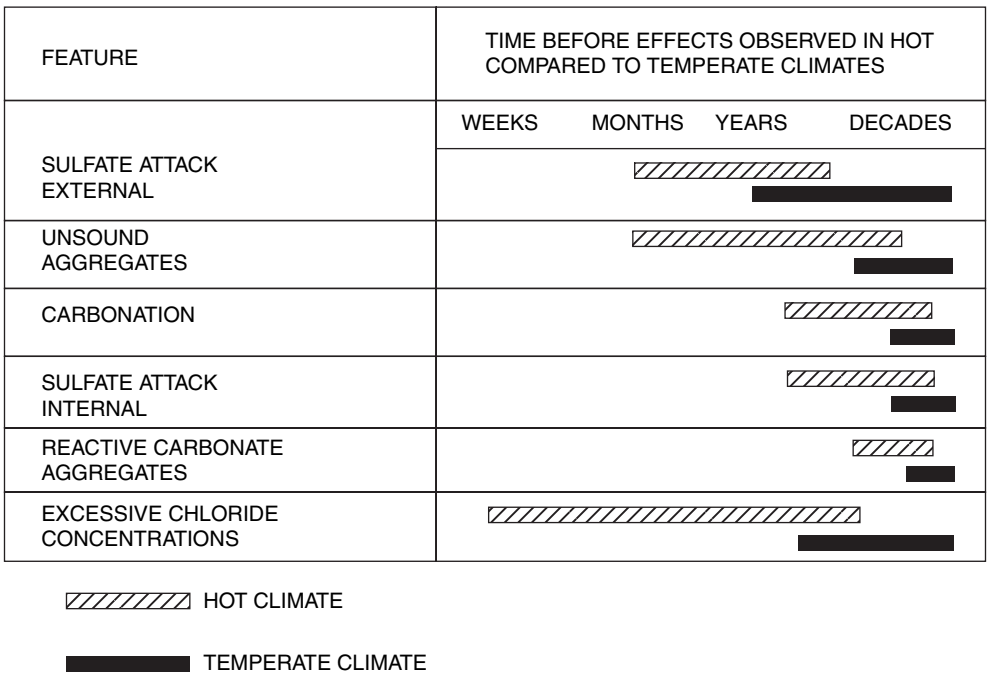

Figure 29.7 Deterioration of concrete due to environmental factors over time
Reproduced from Khan (1982), with permission from Elsevier

suction within the vadose zone, will transport dissolved compounds upwards. If the groundwater table is sufficiently close to the ground level, and suction due to capillarity acts on the groundwater, then the transport of water vertically upwards (see section 29.4.6 for more information) will increase the concentration of soluble compounds within the pores of the near-surface layers of soil.

The concentration at which water can no longer support additional quantities of miscible compounds is known as the saturation concentration. The solubility of a compound is related to a number of parameters including temperature (for more information please refer to Fetter, 1999) (**Figure 29.8**); thus, diurnal changes in temperature can be sufficient to result in a reduction in the saturation concentration and the precipitation of compounds above this threshold, resulting in crystal growth and pressures being exerted on the soil/rock fabric. If the ambient temperature is sufficiently high, evapotranspiration can dry out the pores causing the precipitation of all salts previously dissolved in the pore water. However, Goudie (1994) states that it is not necessary for pores to dry out before the precipitation of miscible compounds is an issue for naturally occurring rock, soil and man-made structures alike. Diurnal changes in temperature will result in cycles of precipitation and dissolution, and this is sufficient to weather the host material. Man-made structures can be particularly at risk with concretes spalling and steel reinforcing experiencing accelerated rates of corrosion. Al-Amoudi *et al*. (1995) suggest there is also the potential for solutes to enter placed fills, such as the layers of a highway, via capillarity and this can result in damage occurring to these structures with time.

Changes in environmental conditions, including a change in temperature, a change in the concentration of dissolved salts, a change in the volume of pore water, can result in the precipitation of compounds out of solution. The volume of a solid form of a salt is likely to be greater than that for the compound when dissolved in water, particularly if the compound hydrates on precipitation, applying a pressure in the pore or fissure and causing degradation of the soil or rock structure.

Bell (1998) gives crystallisation pressures for various salts: gypsum ($CaSO_4.2H_2O$) at 100 MPa, kieserite ($MgSO_4.H_2O$) at 100 MPa and halite (NaCl) at 200 MPa, and cites a study illustrating that the salts Na_2SO_4 and $MgSO_4$ caused a far more pronounced degradation of sandstone cubes that were exposed to solutions containing them, and that a mixture of salts within a solution can be far more destructive than when present individually. The pressures exerted by precipitation of miscible compounds can be considerable and man-made structures are equally at risk of degradation via this process (Goudie, 1994). Thus, detailed investigation is necessary before undertaking construction in highly salty ground conditions to ascertain the likely effect the salts will have on the engineering life of the structure. Ground conditions with high concentrations of salts can cause physical weathering of man-made structures (due to the expansion of precipitated crystals within pore spaces, cracks, etc.) and chemical weathering (such as the accelerated corrosion of steel reinforcing) (Goudie, 1994).

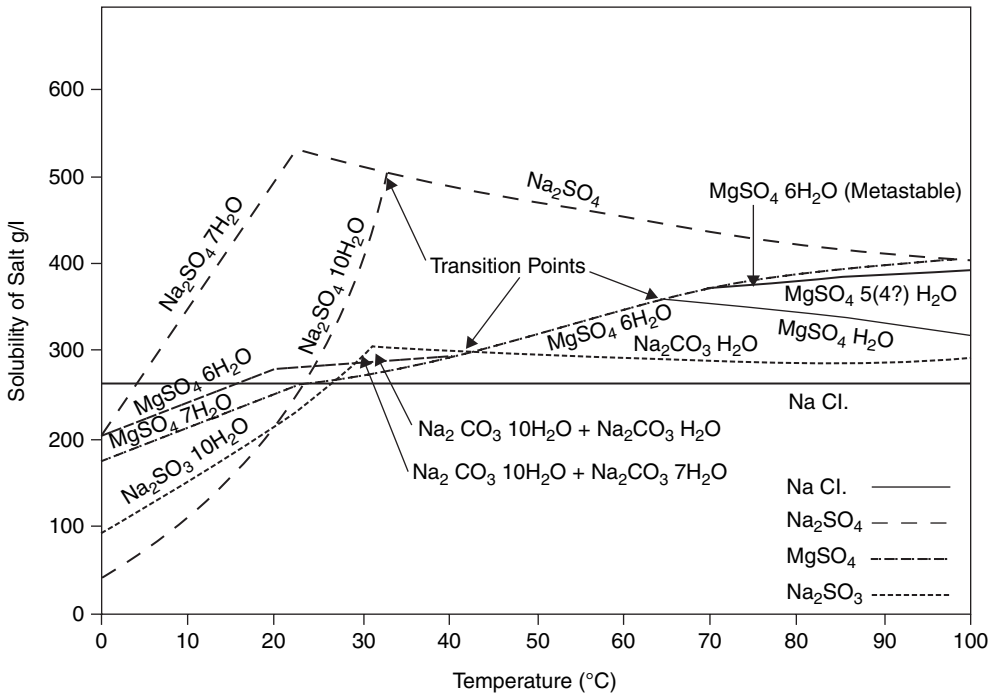

Figure 29.8 Temperature/solubility relationship for some common salts
Reproduced from Obika *et al.* (1989) © The Geological Society

The saturation concentration for a compound is also related to the presence of other compounds dissolved within the pore water. Pore water can only undergo a finite degree of restructuring to accommodate miscible compounds; thus, if more than one compound is present the saturation concentration for each will be reduced and the concentrations of salts precipitated out of solution will be greater than predicted by summing the saturation concentrations for each compound present. This situation is colloquially known as 'salt-out'. Understanding how dissolved compounds will behave within a pore is vital if the design of a proposed foundation is to include protection against this type of weathering. Numerical or analytical modelling, based on the Gibbs free energy, can be used to predict solubility, which can also be modelled within a laboratory using batch tests (Fetter, 1999).

29.3.4 Chemical bonding of soil creating duricrusts and cemented soils

Duricrusts (defined as 'a layer of strongly cemented material occurring in unconsolidated sediments, often found a short distance below the surface; usually formed as a result of water action; the cementing material may be calcareous, siliceous or ferruginous', Whitten and Brooks, 1973, p. 222) are cemented soils, and often form below ground and are exposed by erosion. Duricrusts are commonly a few hundred millimetres thick (300–500 mm), although the development of multiple crusts can result in significant duricrust thicknesses (3–5 m) (Lee and Fookes, 2005b), and are common in arid conditions (and other environments); for example calcrete duricrusts are estimated to cover 13% of the Earth's land mass (Dixon and McLaren, 2009).

The cementation process stabilises the soil and makes duricrusts resilient to weathering and provides strengths greater than those associated with unaffected soils. The types of duricrust commonly encountered in arid conditions include: aluminous, calcareous, gypseous and siliceous duricrusts; siliceous and aluminous duricrusts are considered to be stronger than calcareous duricrusts (Hills *et al.*, 1966; Dixon and McLaren, 2009) although any of the duricrust formations found in arid conditions can prove to be very difficult to excavate. Excavation of a duricrust may necessitate drill and blast techniques or powerful plant (Lee and Fookes, 2005b). Once through the duricrust, the subsequent strata may require less effort to excavate. Therefore, not only do duricrusts create rock structures resilient to erosion, they can also create problematic conditions for construction and must not be underestimated when planning.

The formation of lightly cemented soil also occurs in arid environments, whilst not producing materials as resilient to erosion as the heavily cemented duricrusts, there may be an increase in stiffness and they may be self-supporting when excavated (the sides of an excavation in cemented, desiccated sands may not collapse with time if the degree of cementation is sufficient to resist movement). The soils may be cemented by precipitation of salts via the same mechanisms creating duricrusts (Dixon and McLaren, 2009) or they may be cemented via clay bridging, although soils cemented by clay structures are considered weaker than those chemically stabilised.

29.3.5 Fluvial erosion, the effect of flooding and the creation of challenging engineering environments including salinas, playas and sabkhas

The majority of watercourses found in arid regions are ephemeral: they only contain water directly after a storm, and the water rapidly evaporates or permeates the soil leaving the watercourse dry once more. The drainage path of the water from a storm will dictate how it interacts with the surrounding environment (**Figure 29.9**); flood water will readily migrate across rocky piedmont slopes to wadi drainage channels, forming ephemeral streams; conversely flood water entering tracts of loose sandy soil will rapidly diminish due to infiltration of the water into the soil and ephemeral streams are unlikely to form.

Lee and Fookes (2005b) cite a study indicating that 90% of the erosion on a site over a ten-year period occurred over five days involving seven storms. This is because the intensity of convective cell storms, which take place over a relatively short time frame, results in large volumes of water migrating through previously established drainage networks (or creates new networks when draining). The velocity of this water is sufficient to transport significant quantities of sediment as it migrates through the drainage pathways, creating new topographic features as the sediment is deposited (for more information, refer to Parsons and Abrahams, 2009). The infrequent storms encountered in arid conditions can also damage earthworks (particularly during construction when the earthworks and their drainage provision are incomplete); discharging water can erode the surface of an earthwork; and water permeating into an earthwork can reduce suction within the soil, thus, reducing the stiffness of the soil and inducing ground movement. The former can result in damage to the earthwork, necessitating remedial measures to reinstate the earthwork, and any ground movement can cause serviceability issues or the failure of structures on the earthwork, again necessitating remedial action. Puttock *et al.* (2011) describe a construction project in Morocco that experienced storms during the construction of an earthwork. **Figure 29.10** illustrates a drainage channel neighbouring the construction site in flood, this occurred after a storm, and jeopardised a section of the newly compacted earthwork.

There is often a lack of flood risk assessment for sites within arid environments and such an assessment should have been included during the planning stages for this project, as a matter of course, if potential flood risks were to be properly managed.

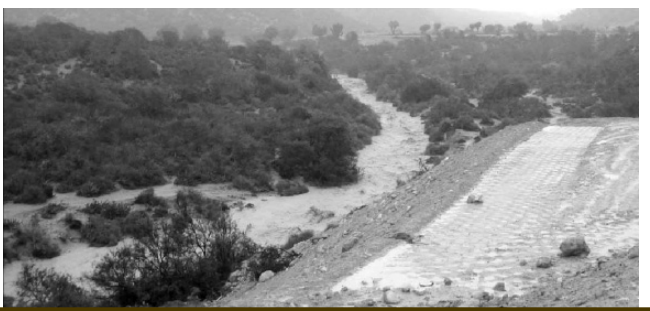

Figure 29.10 Ephemeral drainage channel in flood after a storm; note the proximity of the drainage channel to the newly placed earthwork places the earthwork at risk

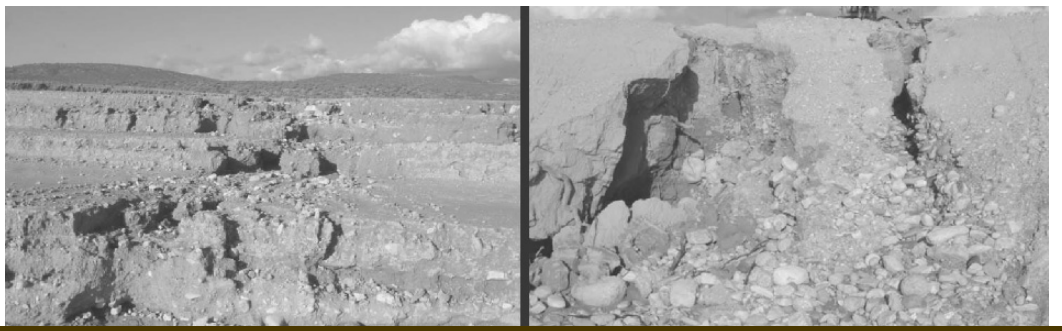

Figure 29.11 Damage to compacted earthwork
(left) Reproduced from Truslove (2010); (right) reproduced from Puttock *et al*. (2011). All rights reserved

Whilst the occurrence of a flood might be significantly lower in arid environments, the potential damage arising from such an event could still be significant. This requires suitable drainage provision for the placed earthwork. If storm water collects on the surface of an earthwork until it reaches a drainage pathway and then dissipates, damage to the earthwork will occur (**Figure 29.11**), requiring remedial measures to reinstate it to a functional condition.

29.3.5.1 Sediment transport and deposition

When precipitation falls on uplands, where the upper surfaces are commonly barren or comprise boulder fields, the water will rapidly drain through a discrete network of drainage pathways, via gullies, into the plains below. The limited nature of the drainage channels and gullies eroded into uplands creates locations for the repeated deposition of eroded materials around the base of the uplands. The materials deposited within these regions can vary greatly but can prove an excellent source of aggregates for the construction industry (Lee and Fookes, 2005b).

29.3.5.2 Alluvial fans

Sediment load is a function of velocity and as this decreases the water will start to deposit sediment, resulting in poorly graded fan-shaped deposits. These fan deposits (alluvial fans) are prominent features on piedmont slopes. Repeated storms will create newly deposited alluvial fans, with the flood water flowing through preferential pathways within previously established fans; the flood water will erode sections of a previously created fan, depositing it further away from the uplands and creating distinctive 'lobe' shapes within the fan. Alluvial fans can cover significant tracts of land; Hill *et al*. (1966) reported the extent of an alluvial fan in the Atacama Desert as stretching 60 km from the upland source. Further details can be found in Blair and McPherson (2009).

29.3.5.3 Wadis

Wadis (valleys with intermittent streams) are ephemeral in nature and form braided streams. Whitten and Brooks (1973, p. 62) define these as 'a stream consisting of interwoven channels, constantly shifting through islands of alluvium and sandbanks; the banks are comprised of soft sediments (often self-deposited), which are easily eroded; the stream beds are wider and shallower than where meander occurs, and are more liable to flood, which in itself helps the constant shifting, widening process'. This creates new alluvium deposits along the river valley in what can seem like haphazard locations (when compared to deposition sites of meandering watercourses). Thus, subsequent patchy lavers of poorly graded, loose alluvium deposits (overlying previously deposited alluvium) can be encountered when working in these conditions. Loose deposits can be eroded and redeposited in subsequent storms; thus, the topography of wadis are transitory. These conditions can also be dangerous places to work during the 'rainy' season when flash floods can occur very quickly and with little warning (Waltham, 2009).

29.3.5.4 Sabkhas, salinas and playas

Fine-grained particles are the sediment likely to settle out of suspension last, and so they can be transported considerable distances by flood water. In base level plains the flood water will pond to form ephemeral lakes. As the lakes recede, silts and clays settle out and form a crust (an example of a crust formed as lake water evaporated can be seen in **Figure 29.12**, although this was not formed by receding flood water but due to changes in river pathways that previously fed the lake). These clay or silt crusts will accumulate with subsequent floods, forming additional layers and will thicken the crust (Lee and Fookes, 2005b). These layers may be interspersed (or overlain) by layers of sand, deposited by aeolian action between periods of flooding, or contain evaporites (in the case of sabkhas and salinas). The surfaces of these crusts can be resilient to settlement induced by light loading or inundation of water during flooding, and Al-Amoudi and Abduljawad (1995) suggest that (in the case of sabkha deposits) this is due to the desiccated and cemented nature of the crusts.

If the crusts form on plains adjacent to the sea then sabkhas or salt playa can form (see **Figure 29.13**). Sabkhas experience

Figure 29.12 Nxai Pan in Botswana, one of a series of salt pans created with the drying of a major lake (Makgadikgadi) due to regional changes in river pathways in southern Africa (caused by tectonic uplift)
© A. Royal

coastal flooding and are likely to have a water table close to the surface. The salt concentrations accumulated within these crusts can be extremely high (**Table 29.2**).

Salt playas can also have high salt concentrations (although not the same magnitude as sabkha) due to the precipitation of salt with the silts and clays as the flood water recedes (Lee and Fookes, 2005b). Sabkhas and salt playas may experience a degree of cementation with the precipitation of solutes from the pore water. Such precipitation can also lead to the creation of gypsum, and other evaporite lenses, developing within these landforms (Al-Amoudi and Abduljawad, 1995) – see also Chapters 37 *Sulfate acid soils* and 38 *Soluble ground* of this manual.

However, the soil below the crust can be metastable, it might contain minerals susceptible to dissolution (e.g. gypsum and halite), and it might be very soft, and, hence, potentially susceptible to ground movement once the upper surface of the crust is compromised (Al-Amoudi and Abduljawad, 1995).

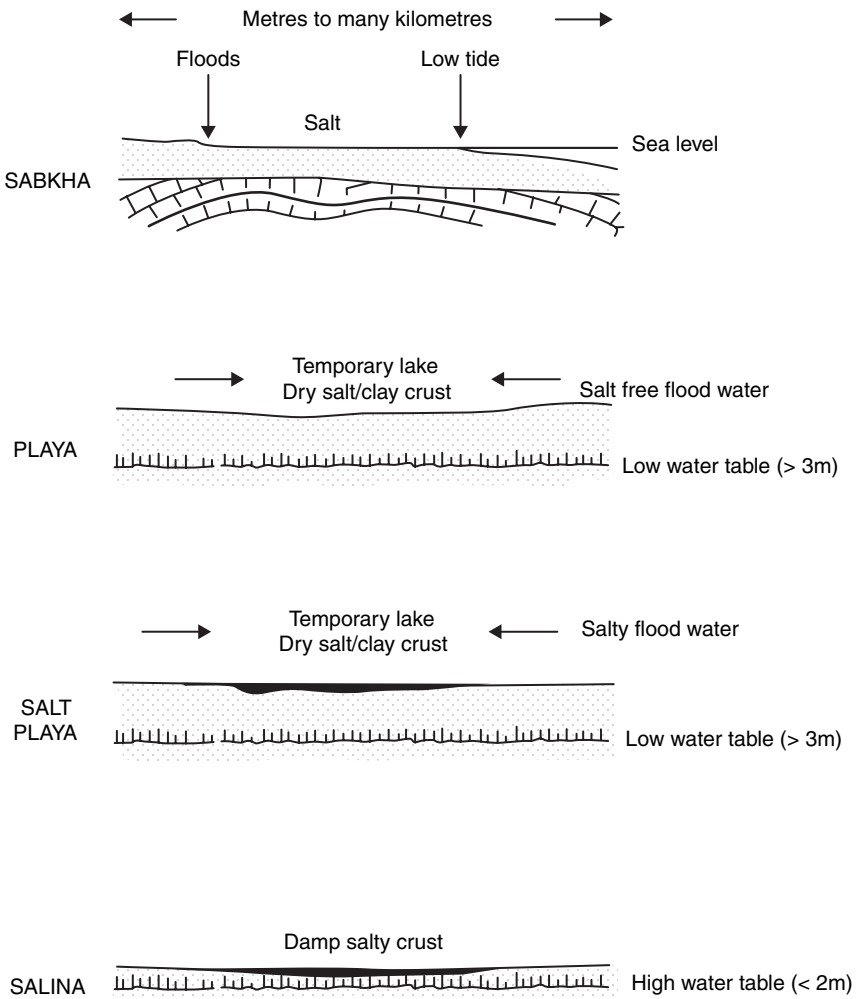

Figure 29.13 Idealised cross-sections through a sabkha, playa, salt playa and salina
Lee and Fookes (2005b), reproduced from Fookes (1976)

Ion (mg/l)	Open sea	Coastal seawater, Arabian Gulf	Sabkha water
Ca	420	420	1250
Mg	1320	1550	4000
Na	10700	20650	30000
K	380	650	1300
SO_4	2700	3300	9950
Cl	19300	35000	56600
HCO_3	75	170	150

Table 29.2 Typical compositions of seawater and sabkha water (in mg/l)
Data taken from Fookes *et al.* (1985)

The properties of sabkha soil can also change with the season; with once trafficable surfaces becoming impassable during the wet season as the cementing salts dissolve (Shehata and Amin, 1997). Sabkhas also formed during the Quaternary (Al-Amoudi and Abduljawad, 1995), leaving deposits along what formally was the coastline. However, the sea level has fluctuated since the Quaternary and many of the sabkhas created via this mechanism have been reworked, by action of the sea, to form carbonate sands and silts as well as bioclastic sands (Al-Amoudi and Abduljawad, 1995).

Care must be taken when constructing on these topographic features; the high concentration of salts within these crusts makes them problematic when coupled with the potential for flooding (Millington, 1994). Construction in such environments requires consideration of the stiffness of the underlying soil (particularly for salinas), as the density of these soils can be low (Al-Amoundi, 1994). Other issues include the collapse potential and the highly salty nature of the upper layers of the soil. Buried man-made structures within these landforms, e.g. concrete foundations or steel pipes, can experience accelerated weathering due to the high salt content within the soil (Shehata and Amin, 1997). Using materials from these areas for construction processes is not recommended (see section 29.3.7.5 for further details).

Silt or clay crusts formed by freshwater flooding are known as playas or salinas, with the difference in behaviour being dictated by the proximity of the water table to the ground surface. In base level plains the groundwater table can be relatively close to the surface, and suction within the vadose zone can result in a significant capillary rise, e.g. over 10 m in clays and between 1 to 10 m in silts (Bell 1998). If the playa is susceptible to the movement of water via capillarity then it is called a salina and salts are transported towards the surface (Lee and Fookes, 2005b). The increase in salt concentration within the salina, akin to sabkha and salt playa, can also make construction difficult. If the movement of groundwater intersects with the ground surface then the surface layers of the salina can be damp (**Figure 29.13**), with soft material directly below.

29.3.6 Aeolian erosion and the creation of challenging engineering environments including collapsible soils, hammadas and sand dunes

Arid soils are more susceptible to aeolian erosion than soils found in other regions due to climatic conditions and the resulting lack of vegetation. Aeolian erosion has two principal forms: firstly, the wind can transport soil particles from one location to another; the ability of the wind to transport soil particles is related to a number of factors including wind speed and particle type (e.g. size, shape, specific gravity), and secondly, soil transported by the wind can be used to scour existing topographic features (akin to the sea using transported sediment to erode the base of cliff faces). The scouring power of wind should not be underestimated and has negative connotations when working on site (for more information, see Parsons and Abrahams, 2009).

The mode of aeolian transport is dependent upon the size, shape and density of the soil particles (for given wind and topographic conditions). Very fine materials (less than 20 μm) will stay in suspension for a long time, their transport can last for several days and particles can be transported thousands of kilometres (Nickling and McKenna Neuman, 2009). Larger fine-grained materials (less than 70 μm but greater than 20 μm) are too heavy to stay in suspension for a long time, transport will last a few minutes to hours, and the particles can be transported tens of kilometres (Nickling and McKenna Neuman, 2009). Granular material is too heavy to transport via suspension and instead can be transported by saltation or rolling. Saltation describes the process where particles (up to 500 μm) move through the air in a cycle of collection, transportation and deposition via short elliptical paths. Larger particles will roll along the surface of the ground under the force of the wind; however, there is a point where the particles become too large to be transported by aeolian action.

The segregation of particles by size, shape and density, due to aeolian erosion, will result in a grading of particles within a basin relative to the dominant wind direction and source of material. The loss of transportable particles via aeolian action will result in a gradual lowering of the ground surface and at the same time an accumulation of particles too large to transport via aeolian action. Eventually the particles too large to be transported by the wind will cover the ground surface and prevent further erosion through aeolian action. The ground surface is then known as a hammada (see Stalker, 1999, for further details). These are resilient surfaces that can be beneficial to construction; the surface can be trafficable without the need for much preceding ground improvement, but once the surface is broken the affected area will once again be susceptible to aeolian erosion.

The movement of sand-sized particles – not necessarily quartz: the particles can be clay aggregations, salt crystals, non-quartz particles (Warren, 1994b) – via aeolian action can lead to the creation of dunes at the windward or leeward face of a topographic feature, whether naturally occurring or man-made, or where two or more winds converge (Lee and Fookes, 2005b). The type of dune formed (see Stalker, 1999, for details

of common dune types) is dependent upon a number of factors including the volume of sand transported and the consistency of the direction of the wind, with wind consistency being considered of primary importance (Lancaster, 2009). The particle diameter size range commonly found in a dune is 0.1–0.7 mm, with median grain diameters between 0.2 mm and 0.4 mm. A dune is considered to be poorly graded (Lee and Fookes, 2005b).

The processes that create dunes can cause them to migrate across the surface of an arid region, and they are then known as active dunes. Sands accumulate on the slip face, which causes the crest of the dune to move with time and, hence, the location of the slip face. The migratory rates of dunes (see Warren, 1994b, for details of the rates of movement with height) are inversely related to the dune height, and are a function of the cross-section and bulk density of the dune as well as the aeolian transport rate of the sand (Lee and Fookes, 2005b). Dunes can form across vast areas (known as dune fields or sand seas; sand seas being far larger than dune fields). For example, it is considered that about four-fifths of arid lands are barren rock or boulder fields (Bell, 1998) and that less than 25% of arid and hyper-arid regions are covered in active dunes (Warren, 1994b), yet Hills *et al*. (1966) cite an uninterrupted sand sea in the Sahara covering a surface area greater than France. In such places the dunes can achieve considerable heights; Lee and Fookes (2005b) describe extreme transverse dunes in the Sahara reaching 240 m.

The transition from arid to semi-arid conditions can result in a stabilisation of the dunes as increased precipitation levels results in increased coverage of vegetation. Dunes can also be stabilised with the cementation of the sand particles, via the development of salt crystals, or the weathering of the non-quartz particles within the dune (Warren, 1994b). Lancaster (2009) gives the geographic locations of dune fields and sand seas across the world and the activity of their dunes.

The aeolian erosion of arid soils is likely to occur during and after construction and this must be taken into account during the planning stage of any construction project. Aeolian deposits can affect structures (blocking doorways and in extreme cases burying houses; see Shehata and Amin, 1997), can affect construction processes (e.g. engine filters readily become blocked with fine materials, prevent setting out using optical devices) and can create logistical problems (e.g. see **Figure 29.14**) where loose material can be problematic to negotiate, particularly large vehicles not equipped with caterpillar tracks, such as articulated lorries. Measures can be established to protect a site against the build-up of wind-transported soils, such as using porous fences as sand traps, illustrated in **Figure 29.15**, although the land required to protect a site can be considerable.

Aeolian erosion denudes landscapes of the finer-grained particles, and creates transitory features such as dunes. However,

particle-laden winds (transporting particles with sizes in the range 60 μm to 2000 μm) also act as a geomorphologic process on rock formations, scouring them (akin to commercial sand-blasting, if not as intensive) and further shaping the topography of the uplands and foot-slopes; this process is slow and continuous. Laity (2009) quotes abrasion rates of the order of magnitude of 0.01 mm/year to 1.63 mm/year (abrasion can be far greater in places like Antarctica, where wind speeds can be considerable, although this is not considered here). A variety of different rock formations (Bell, 1998) are created depending on the type of rock, rock strength and the alignment of the layers of rock.

29.3.7 Undertaking site investigations in arid areas and classifying arid soils

Soil classification for geotechnical engineering applications should provide sufficient information so that the design and construction phases of a project are cost effective whilst minimising the risks of failure. However, to ignore the very nature of arid soils courts failure of the project (during or after construction) via potentially unexpected means (Smalley *et al.*, 1994). Whilst construction projects often do not have sufficient resources to fully classify the properties of a soil found on site (in terms of mineralogy, formation, etc.), it is recommended that the classification process is extended beyond the scope of a laboratory study to determine the geotechnical parameters of the soil and to consider textural (e.g. fabric and soil structure) aspects of the soil (Rogers *et al.*, 1994).

In arid conditions, soils are often unsaturated, can contain high salt concentrations and, due to the geomorphologic process that created them, can be loose, metastable and, therefore, collapsible, or expansive (see Chapters 32 *Collapsible soils* and 31 *Expansive soils* for further details). **Figure 29.16** can be used to help to identify soils that may experience changes in volume. Laboratory testing to identify physical parameters will not identify the risks posed to the foundation of a structure through chemical or physical weathering induced by high salt concentrations below the ground surface, or failure of the foundation via collapse (or expansion) of the soil skeleton upon wetting. Moreover, a perfectly serviceable structure could become expensive to maintain due to the continued accumulation of windblown deposits.

29.3.7.1 Guidance for site investigation in arid soils

The soil or rock formations encountered will depend on the location (as illustrated in section 29.3.1); soils found on uplands or foot-slopes will vary considerably from those in the plains and this must be considered when developing a site investigation strategy. Any deposits investigated are likely to be heterogeneous in nature due to the geomorphic processes that created them, so engineering parameters derived from a limited number of borehole samples or laboratory-derived data may be unreliable. Furthermore, any deposits encountered are likely to be unsaturated (unless within a base level plain, where the phreatic surface can be relatively close to the surface), could be dry, and are possibly metastable (e.g. talus slopes, aeolian deposits such as loess) making the collection of undisturbed samples effectively impossible. Therefore, any site investigation should be underpinned by a preliminary desk study to highlight the types of soil that may be encountered and identify the types of tests required to characterise the soils on site.

However, care is needed when using standards, e.g. British or European standards, as these may not be best suited to arid soil conditions (for tropical soil see Chapter 30 *Tropical*

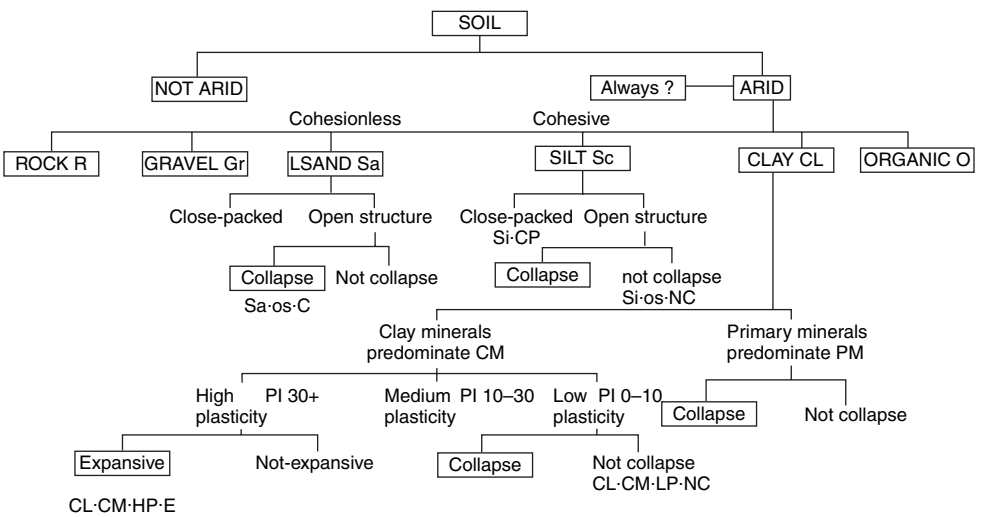

Figure 29.16 Proposed decision tree to indicate volume change problems . Si·CP, silt – close packed; Si·os·NC, silt – open structure – not collapse; Sa·os·C, sand – open structure – collapse; Sa·os·NC, sand – open structure – not collapse; Cl·CM·LP·NC, clay – clay minerals dominate – low plasticity – not collapse; Cl·CM·HP·E, clay – clay minerals dominate – high plasticity – expansive

soils). For example Puttock *et al*. (2011) constructed earthworks in an arid environment and found success when combining French standards (*Technical Guideline on Embankment and Capping Layer Construction*; LCPC and SETRA, 1992), which they suggest are more suited to arid conditions than British standards, with practices taken from British standards (end performance specifications and placed soil investigation techniques).

29.3.7.2 *In situ* testing

In situ testing can determine geotechnical data or classify soil properties and can complement data obtained from laboratory tests (such as characterising and index testing, physical testing: including swelling and the collapse potential of reformed samples). *In situ* testing may disturb the soil but in loose, unsaturated, granular deposits (or those with collapse potential) this is likely to be less than the disturbance from extracting samples for laboratory analysis; British and European standards provide guidance on the suitability of various drilling methods in given soil conditions and describe the quality of the samples likely to be obtained (see section 29.7.2 British Standards). Guidelines for the application of various *in situ* geotechnical tests can be found in for example BS2247 (parts 1 to 12) (British Standards Institution, 2009).

An illustration of potential issues can be found in Livneh *et al*. (1998), who undertook a site investigation for a proposed runway in arid ground conditions containing gypsum. The ground conditions included sandy soils containing clays and gravels with silt and clay lenses and gypsum-rich lenses interspersed between the sandy soils; the authors suggest that the site could be characterised as a sabkha. The gypsum formed through precipitation of soluble minerals with changes in groundwater conditions and concern was raised over the performance of the ground if the gypsum was wetted during loading. Various *in situ* tests were undertaken including dynamic cone penetrometer testing, density determination and loss of weight with wetting of the gypsum-bearing deposits. It was found that low *in situ* density values, coupled with the potential for dissolution of the gypsum, were the parameters that dictated the pavement design for the runway. Livneh *et al*. (1998) carried out the following laboratory tests on samples taken from the site: plasticity index testing, dry density, California bearing ratio (CBR), unconfined compressive strength (UCS) and analysis of pore water chemistry, to supplement the information gathered from *in situ* testing.

Various *in situ* tests to evaluate the collapse and swell potential are discussed in Chapters 32 *Collapsible soils* and 33 *Expansive soils*, respectively, and details of the various control, interpretation and assessment issues are given in these chapters.

29.3.7.3 Laboratory testing

Care must be taken when investigating some arid soils in the laboratory, notably those that are metastable or those that contain high solutes such as sabkhas. Laboratory tests for collapsible soils and expansive soils can be found in Chapters 32 *Collapsible soils* and 33 *Expansive soils*, respectively.

An example of an arid soil that requires careful handling in the laboratory is described in a study by Aiban *et al*. (2006). The sabkha soil investigated was found to exhibit different behaviour depending on the water used in the laboratory tests. For this soil, **Figure 29.17** shows the differences in the particle-size distribution and **Table 29.3** gives the plasticity index for this sabkha soil when prepared with distilled water or sabkha brine.

These differences are believed to be related to the difference in the salt concentration between the soil and the water used; distilled water only contains minute concentrations of the solutes in the soil so a proportion of the crystalline salts cementing the soil would precipitate into solution. This change in the salt concentration within the soil changed the physical properties of the soil. Thus, it is important that any liquid used in a soil investigation is similar to the liquid that will be used on site.

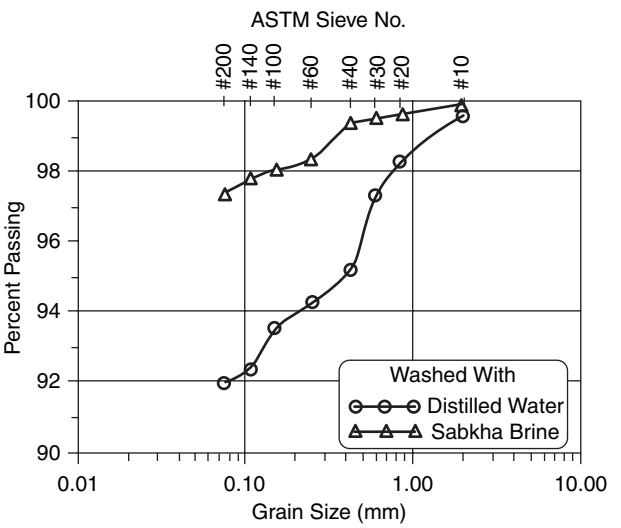

Figure 29.17 Grain-size distributions of a sabkha soil using either distilled water or sabkha brine to wash the soil
Reproduced from Aiban *et al*. (2006), with permission from Elsevier

Property particle-size range (passing ASTM sieve 200)		Value more than 50%
Liquid limit (LL)	Distilled water	42.5
	Sabkha brine	33.0
Plastic limit (PL)	Distilled water	26.3
	Sabkha brine	20.4
Plasticity index (PI)	Distilled water	16.2
	Sabkha brine	12.6

Table 29.3 Difference in plasticity index with the solution used to investigate a sabkha soil (Aiban *et al*., 2006)

29.3.7.4 Geophysical investigation of arid soils

Geophysical testing can be successfully used in arid ground conditions, it can be non-disruptive and it can cover significant tracts of land. Geophysical testing augments information derived from traditional borehole or trial-pit surveys. Guidance on the use of geophysical techniques in site investigations can be found in the *Geological Society's Engineering Geology Special Publication 19* (McDowell *et al*., 2002); although not written specifically for arid ground conditions this guide does introduce the geophysical techniques commonly associated with site investigations.

Shao *et al*. (2009) investigated the use of polarimetric synthetic aperture radar (SAR) to detect subsurface hyper-saline deposits in arid conditions and found promising results. Ray and Murray (1994) report on research into the use of airborne SAR, AVIRIS (Airborne Visible/infra-red Imaging Spectrometer) and thermal imaging to investigate the nature of surface sand deposits in an arid region within the USA and found that mobile sand deposits could be distinguished from fixed deposits using these techniques. The ability to detect mobile deposits stems from the difference in particle-size distribution (active soils tend to comprise a greater proportion of particles in the saltation range and also tend to be poorly graded) and the relative density of active and fixed sand deposits (Ray and Murray, 1994). The ability to detect certain problematic soil deposits geophysically provides an opportunity to optimise any additional investigation and provides the means of identifying geotechnical processes that will have to be undertaken before construction can continue.

29.3.7.5 Material resources for construction projects in arid environments

Various landforms within uplands, foot-slopes and plains (see section 29.3.1) are potentially sources of aggregates. **Table 29.4** indicates potential locations for sourcing aggregates and suggests potential applications within construction processes for these materials. Lee and Fookes (2005b) recommend alluvial deposits (fans and wadi channels) when sourcing aggregates; it is suggested that dune deposits can be used but with caution as the particle grading often encountered in dunes can be too fine to be readily applicable. It is recommended that deposits containing high concentrations of salts should be avoided (or treated to remove the salts). Lee and Fookes (2005b) also suggest that care should be taken when sourcing aggregates

Feature	Aggregate type	Nature of material	Engineering properties of fills	Potential volume
Bedrock mountains	Crushed rock suitable for all types of aggregate	Angular, clean and rough texture	Depends on rock type and processing. Good fills	Very extensive
Duricrust	Road base and sub-base	Often contains salts. Needs crushing and processing	May be self-cementing with time. Quite good rockfill	Often only small deposits of good quality
Upper alluvial fan deposits	Concrete and can be crushed for road base	When crushed and screened angular and clean. Otherwise sometimes dirty and often rounded	Good compaction as fill	Often very extensive but good quality material may be found only in small deposits
Middle alluvial fan deposits	May make road base	Often high fines content	Often good compaction as fill. Good bearing	Small to extensive
Lower alluvial fan deposits	Generally not useful	High fines content. Needs processing	Poor bearing and as fill	Small to extensive
Other piedmont plain alluvium	Variable, locally good concrete aggregate	Dirty, rounded and well graded. May contain salts	Good bearing capacity (dense sediments) and as fill. Locally poor due to clay and silt layers	Very extensive but good quality material in small deposits
Old river deposits	Concrete	Variable	Difficult to locate in field	Often deposits patchy and thin
Dunes	Generally not good	Usually too fine and rounded	Fills of poor compaction	Locally extensive
Interdunes	Fine aggregate	Coarse to fine, angular. Needs processing	Fills of poor compaction	Very localised
Salt playas and sabkhas	Not suitable	Very salty and aggressive	Poor. Special random fill.	Locally extensive
Coastal dunes	Generally not suitable	Generally too fine and rounded	Special fills often poor compaction	Sometimes extensive
Storm beach	Fine aggregate may be sharp or salty	Sufficiently coarse for concrete sand. Clean after processing	Random fill	Sometimes extensive
Foreshore	Generally not suitable	Fine, rounded sand	Salt contaminated, but might make random fill	Locally extensive

Table 29.4 Landforms and aggregate potential
Reproduced from Lee and Fookes (2005b); data taken from Fookes and Higginbottom (1980) and Cooke *et al*. (1982)

as cemented deposits are likely to require processing before being suitable.

The availability of water for construction projects in arid regions must be considered, as this can severely affect the processes being undertaken. Arid regions are often located in developing countries (Wallen and Stockholm, 1966), which have, potentially, limited infrastructure away from urban centres, and the climatic and geomorphologic processes affecting the site must be understood. Thus, water may have to be brought to a site, or groundwater must be extracted (if the phreatic surface is sufficiently close to the surface to make this option economically viable); groundwater can contain significant concentrations of dissolved minerals, which can have a detrimental effect on construction (casting of concrete, etc.) and these factors should be considered by a site investigation.

29.4 Aspects of the geotechnical behaviour of arid soils

When engineering a site in an arid environment it is vital to understand how the aridity will affect the work and what geomorphologic processes will (more than likely) continue to act on the site once construction is complete. This section contains a description of generalised aspects of the geotechnical behaviour of arid soils, and, therefore, considers:

- generalised aspects of the geotechnical behaviour of arid soils;
- various aspects that should be considered when dealing with arid soils including: the generalised behaviour of unsaturated soils; the development of suction within the soil; the relationship between total stress, effective stress, pore water pressure and pore air pressure; and how the shear and volume change behaviour can be evaluated;
- the behaviour of expansive and collapsible soils in arid regions and the effects of cemented soils, together with how such soils can be treated.

29.4.1 Generalised aspects of the geotechnical behaviour of arid soils

Arid soils, by definition, have a moisture deficit, which is likely to result in unsaturated conditions being prevalent (in the surface layers of the soil at least, as is the case in base level plains). This is not to suggest that groundwater cannot exist in arid locations, but it may be at a significant depth below the ground surface. The resulting suction may lead to an increase in effective stress of the unsaturated soil and can induce groundwater flow vertically upwards from the phreatic surface to the vadose zone. Both phenomena can have a marked impact on the behaviour of arid soils.

The suction in an arid soil is a function of the interaction between water and air within the pores. In simple terms, suction forms due to the creation of menisci within the pores because of surface tension between the pore water and pore air (Fleureau and Taibi, 1994) as the pore water preferentially lines the surfaces of particles before filling the pore space. However, in soils containing a distribution of pore sizes, some of the pores may fill completely with fluid (known as bulk water) whilst others remain unsaturated (containing meniscus water), resulting in a heterogeneous distribution of suction within the soil (Wheeler *et al*., 2003). Thus, the effective stress of the unsaturated soil is a function of the suction within the soil (see section 29.4.2), which in turn is a function of the fabric of the soil. Therefore, a change to the structure of the soil (such as could occur when obtaining samples for laboratory investigation), for a constant water content, will result in a different effective stress of the soil (Wheeler *et al*., 2003).

Suction within a soil may be described as matrix suction (a function of the relationship between pore water and pore air pressure) or total suction (which incorporates suction due to osmotic pressure within the soil in addition to matrix suction), although at high suction (1500 kPa and greater) total suction and matrix suction are considered to be the same (Fredlund and Xing, 1994). The relationship between the suction experienced within a soil and the water content is illustrated by a soil–water characterisation curve (Fredlund and Rahardjo, 1993a, 1993b); see **Figure 29.18**. The nature of these curves is determined by soil parameters such as the pore size distribution, the minimum radius of the pores as well as the stress history and the plasticity of the soil (Fredlund and Xing, 1994).

In arid environments, soils can be uncemented (with particles free of any cementing bonding material) or cemented. Various aspects of their behaviour including suction must be considered. These will be considered in turn, highlighting key features pertinent to arid soils. However, only brief details

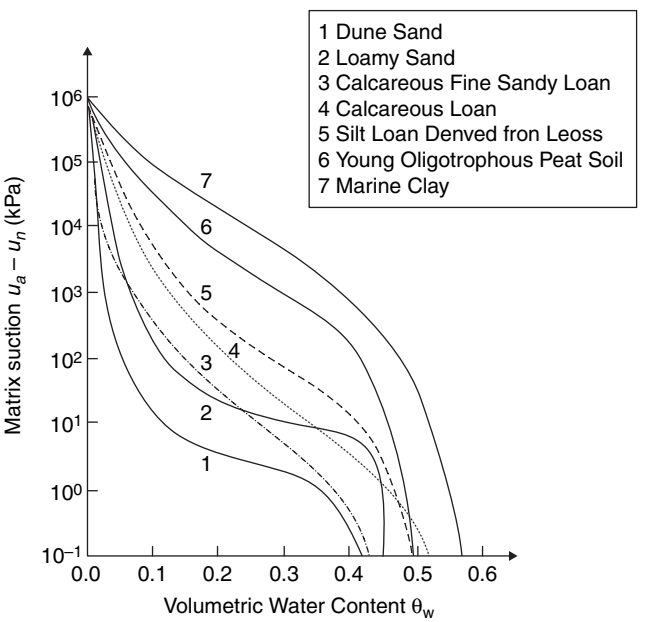

Figure 29.18 Typical soil–water characterisation curves for various soils Mitchell and Soga (2005)
Reproduced from Koorevaar *et al*. (1993), with permission from Elsevier

are provided and further details can be found in Fredlund and Rahardjo (1993a).

29.4.2 Engineering behaviour of unsaturated, uncemented arid soils

If a soil is uncemented and has reached the air entry point, the relationship between stress and pore water pressure must be modified to consider the effect of suction in the soil on the effective stress, and, hence, the shear strength, of the soil. At this point effective stress is a function of total stress, pore water pressure and pore air pressure (μ_a), which control the engineering response of an uncemented arid soil.

The shear strength of uncemented unsaturated arid soils may be determined using Equation (29.1) below (in which stress is σ, net stress is $\sigma - \mu_a$, effective stress is σ', shear strength is τ, angle of friction is φ', matrix suction is $\mu_a - \mu_w$ and cohesion is c'), although this may overestimate the shear strength, particularly at low suction. Instead of combining the net stress and the matrix suction to form the shear strength, which is affected by the angle of shearing resistance, an alternative relationship can be derived if the shear strength is considered to be a function of both the net stress and the matrix suction. This relationship for shear strength is given in Equation (29.2), where a and b are parameters for net stress and matrix suction, respectively. Using two angles of shearing resistance allows for the reduction in the effect of suction on shear strength, given by Equation (29.3), where ϕ^b is the angle of shearing resistance with respect to matrix suction. The angle of shearing resistance with respect to matrix suction is equal to the angle at high suction but can be reduced by an increase in saturation (Rassam and Williams, 1999).

$$\tau = c' + \left(\left(\sigma - \mu_a\right) + \left(\mu_a - \mu_w\right)\right)\tan\phi' \qquad (29.1)$$

$$\tau \propto a\left(\sigma - \mu_a\right) + b\left(\mu_a - \mu_w\right) \qquad (29.2)$$

$$\tau = c' + \left(\sigma - \mu_a\right)\tan\phi' + \left(\mu_a - \mu_w\right)\tan\phi^b . \qquad (29.3)$$

The compressibility and volume change behaviour for uncemented unsaturated soils have been studied using various models (e.g. the Barcelona model) developed by Alonso and Gens (1994). These allow net stress, deviatoric stress and volumetric strains to be assessed together for the soils. This suggests that matrix suction improves the ability of a soil to resist movement, even after the soil experiences plastic deformation. If suction within the soil dissipates then a new stress path will develop within the soil; this stress path results in the soils exceeding the pre-consolidation pressure and the soil will yield without an increase in external load (Alonso and Gens, 1994). The dissipation of suction results in a softening of the soil and an associated deformation.

Whilst an uncemented, unsaturated soil experiences elastic deformation with the dissipation of suction, i.e. the pre-consolidation pressure has not been reached, the soil will expand when water enters its pores (Alonso and Gens, 1994). Once the pre-consolidation pressure is reached the sample will yield and experience plastic (i.e. unrecoverable) deformation and the soil will compress. Even though suction continues to dissipate, the soil will not expand due to restructuring of the soil fabric on yielding (Alonso and Gens, 1994).

Restructuring of the soil fabric at the microscale in response to the dissipation of suction can result in disruption to the soil packing on the macroscale (Alonso and Gens, 1994). Thus, the overall effect may soften the soil and the actual pre-consolidation pressure may be less than predicted from the results of small-scale experiments. Softening may also occur if a soil experiences shearing. As the soil deforms under shear, the menisci within the pores may fail, and until the menisci reform the soil will experience a decrease in suction and as a result it will soften (Mitchell and Soga, 2005).

29.4.3 Relationship between net stress, volumetric strain and suction for collapsible and expansive arid soils

By studying the behaviour of soil samples taken from a site, Blight (1994) was able to describe the relationship between net stress, suction and volumetric strain for expansive and collapsing soils. In this section, drawing from the work of Blight (1994), a brief description of the relationship between net stress, volumetric strain and suction for collapsible and expansive soils is given. More details are given in Chapters 32 *Collapsible soils* and 31 *Expansive soils*, respectively.

An expansive soil with a low load will experience an increase in volumetric strain with the dissipation of suction and the associated increase in water content until the suction has fully dissipated and then the soil will experience additional swelling under saturated conditions (**Figure 29.19**). The dissipation of suction and the increase in volumetric strain may result in the expansive soil becoming unstable and at a critical level of suction the structure will become unable to support itself and will collapse. Once the soil structure has collapsed, additional expansion can occur with a continued reduction in suction. The load experienced by the soil will dictate the degree of volumetric strain experienced by the unsaturated expansive soil. Once suction has dissipated the soil may experience swelling or shrinking with a change in total stress.

Blight (1994) investigated the behaviour of a clayey silt sample using an oedometer at the natural water content of the soil and under saturated conditions. An oedometer was chosen because it allows a load to be applied to the soil sample, which was then inundated with water to simulate conditions likely to occur within the field, thus, allowing the degree of settlement for the soil to be predicted. The saturated soil sample in this investigation initially experienced heave under light consolidating pressure before yielding and suffering plastic deformation (see **Figure 29.20**). The unsaturated sample did not experience heave on loading and yielded at a greater pre-consolidation pressure

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

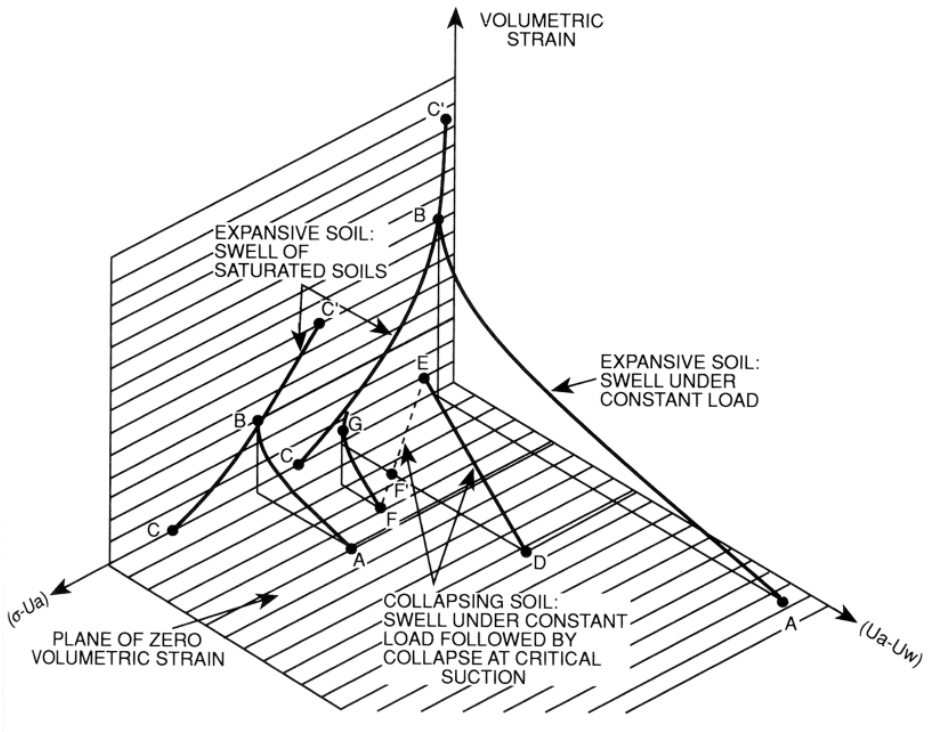

Figure 29.19 Figure 29.19 Three-dimensional stress--strain diagrams for partially saturated soil for the swell of a partially saturated soil under constant isotropic load
Reproduced from Blight (1994)

and, having yielded, was initially stiffer than the saturated sample (**Figure 29.20**). This is not a constant relationship, the soil particles within both the saturated and unsaturated samples will be forced together as the void ratio is reduced with increasing consolidating pressure, resulting in the samples becoming stiffer.

Thus, it is clear that actual deformations experienced by an unsaturated soil on site due to changes in loading can be very difficult to predict and it is recommended that laboratory or field trials are undertaken to determine the behaviour of the soil. Blight (1994) states that arid soils can be particularly problematic, due to the geomorphologic processes that formed them, as they can be prone to both expansion and collapse (echoed by Wheeler, 1994). Thus, some form of experimental investigation is considered fundamental if the behaviour of a soil is to be understood; oedometer testing is a popular laboratory method and plate loading has successfully been used in the field to describe the behaviour of arid soils (as illustrated in section 29.5).

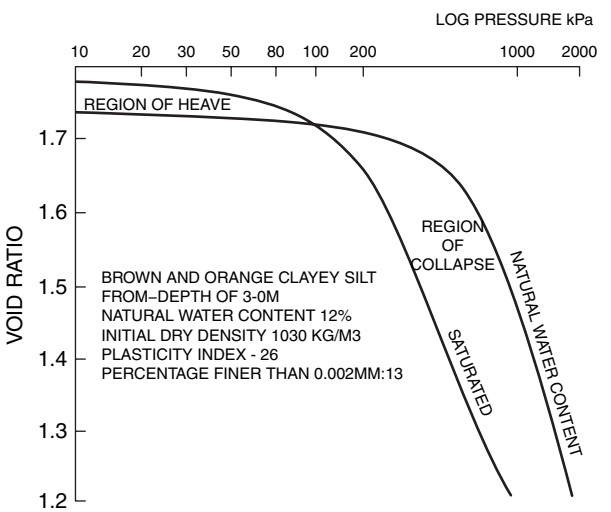

Figure 29.20 Behaviour of clayey silt at natural water content and after saturation
Reproduced from Blight (1994)

29.4.4 Cemented soils in arid conditions

Light cementation of soils (as opposed to the degree of cementation required to create a duricrust) is common in arid environments (see section 29.3.4 above) and will affect how a soil behaves on loading. Cemented soils may have increased tensile strength and may remain stable even after excavation; **Figure 29.21** shows aeolian sand deposits in a semi-arid environment during the wet season. The soil is stable after excavation due to cementation of the soil grains.

Care should be taken when assuming that the walls of an excavation will remain stable due to cementation; localised loading may still cause the sides of an excavation to deform

and ultimately fail. Cementation of the particles will result in an increase in the shear strength, increased elastic deformation during loading (**Figure 29.22**) and an increased yield stress. However, once the cemented soil yields, the residual strength of the uncemented soil and lightly cemented soils (assuming all other parameters are the same) are similar. This is because the crystals bonding the particles within the cemented soil together are relatively brittle and will shear at low strains (Mitchell and Soga, 2005). Once the cementation is disrupted the shear strength reduces and becomes a function of the behaviour of the soil particles, following the behaviour of uncemented soils.

Figure 29.21 Excavation with sides of stable cemented sand (aeolian deposits) during the wet season in semi-arid conditions

29.4.5 Sabkha soils

Sabkha soils are heterogeneous in nature, may be cemented, may be metastable and may contain high salt concentrations. Much like other metastable deposits, changes in water content can induce collapse in sabkha soils. The dramatic effect of water on sabkha soil was demonstrated by Aiban *et al.* (2006), who showed how the CBR for unsoaked specimens was around 50% at the maximum dry density, compared to around 5% when soaked at the same density. This difference in behaviour is due to dissolution of the cementing salts.

Sabkha soils are considered to be metastable; once the strength of the salts cementing the particles is exceeded (or the influence of the cementing salts is reduced as dissolution occurs with changes in the pore water) then there can be rapid rearrangements of the particles within the soil resulting in compression. This behaviour is not universally encountered in laboratory investigations of the collapse potential of metastable sabkha samples; soils loaded and inundated with water do not always collapse. Al-Amoudi and Abduljawad (1995) suggest that this is a function of the volume of water introduced into the sample, with an equilibrium forming between the concentration of salts in the water and the cemented soil. They used a modified oedometer that applied a constant head of water across the sample and allowed fluid to flow through the soil whilst it experienced loading. The modified oedometer test exhibited collapse compression and lower resulting void ratios under a load, whereas a sample in a traditional oedometer test did not collapse.

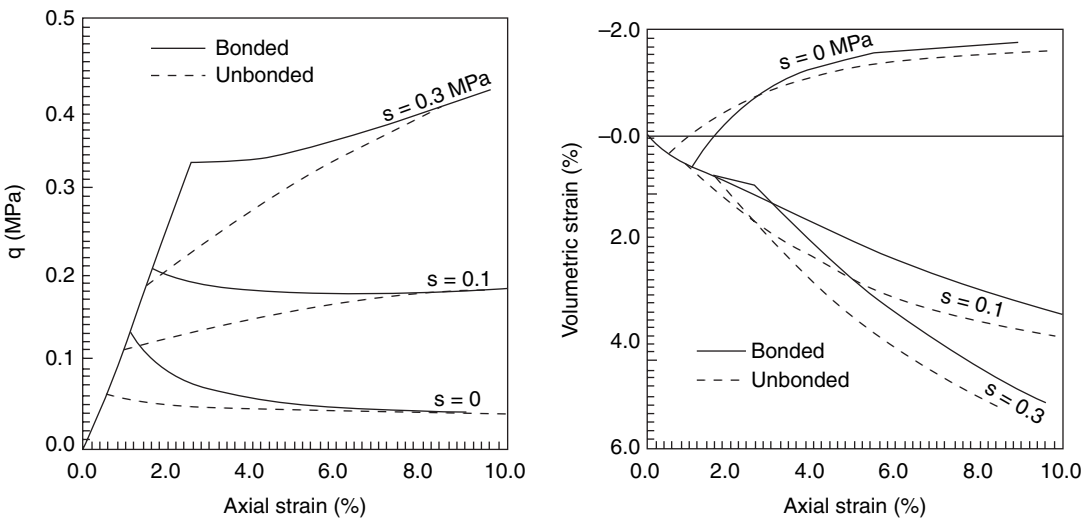

Figure 29.22 Simulated triaxial tests on unsaturated cemented and uncemented soils; (left) shear stress shear strain relationship and (right) volumetric response
Reproduced from Alonso and Gens (1994)

Al-Amoudi and Abduljawad (1995) suggested two simple equations that can be used to predict if the magnitude of the collapse in the oedometer signals problematic soil conditions on site. In Equations (29.4) and (29.5), i_{c1} and i_{c2} are the collapse potentials, Δe_c is the reduction in the void ratio on wetting, e_0 is the initial void ratio and e_1 is the void ratio at the beginning of saturation:

$$i_{c1} = \left(\frac{\Delta e_c}{1+e_1}\right) \times 100 \tag{29.4}$$

$$i_{c2} = \left(\frac{\Delta e_c}{1+e_0}\right) \times 100. \tag{29.5}$$

Equation (29.4) gives the change at the commencement of flooding and Equation (29.5) the collapse potential at the commencement of the consolidation test. Al-Amoudi and Abduljawad (1995) cite findings by Jennings and Knight (1975) that relates the collapse potential to the severity of the problem (see Chapter 32 *Collapsible soils* for further details).

29.4.6 Hydraulic conductivity and groundwater flow in unsaturated soils

Darcy's Law can be applied to unsaturated soils with modification. Mitchell and Soga (2005) give a relationship for the vertical seepage velocity in unsaturated soils, Equation (29.6), where $k(S)$ is the saturation-dependent hydraulic conductivity, ψ is the matrix suction and $\delta z/\delta x$ a gravitational vector measured upwards in the direction of z, for flow in direction i. This equation can be incorporated into a mass conservation equation to give Equation (29.7), which predicts changes in flow for changes in saturation and suction. Here, η is the porosity and $k(\psi)$ is the matrix suction-dependent hydraulic conductivity, derived from $k(S)$ using the soil–water characterisation curve.

$$v_i = -k(s)\left(\frac{\delta\psi}{\delta x_i} + \frac{\delta z}{\delta x_i}\right) \tag{29.6}$$

$$\eta = \left(\frac{\delta S}{\delta\psi}\frac{\delta\psi}{\delta t}\right) = \frac{\delta}{\delta x_i}\left[k(\psi)\left(\frac{\delta\psi}{\delta x_i} + \frac{\delta z}{\delta x_i}\right)\right], \tag{29.7}$$

in which vertical seepage velocity is v_i, matrix suction equivalent head is ψ, saturation is S, time is t, hydraulic conductivity is k, acceleration due to gravity is g.

This solution is valid provided that there are no changes in the soil structure or loss of water from the system (i.e. no loss of water due to biological activity, etc.). The transitional nature of the groundwater flow in unsaturated media, with changing permeability, degree of saturation and suction with flow and time, lends itself to numerical solutions (Mitchell and Soga, 2005).

Measurement of the hydraulic conductivity in unsaturated soils can be problematic due to the dependent relationship between the hydraulic conductivity, saturation and the matrix suction. The soil–water characterisation curve of a soil may be used to derive the hydraulic conductivity; an alternative approach is to use the apparent permeability (see Mitchell and Soga, 2005, for further details). The apparent permeability (k_r) and the saturated hydraulic conductivity (k_s), or the intrinsic permeability (K), may be used to estimate the hydraulic conductivity for an unsaturated soil, Equation (29.8), where ρ_{pf} and η_{pf} are the density and dynamic viscosity of the permeating fluid, respectively. The intrinsic permeability is defined by Equation (29.9), where e is the void ratio, k_0 is a pore shape factor, T is a tortuosity factor and S_0 is the wetted surface area per unit volume of particles.

$$k = k_r K \frac{\rho_{pf} g}{\eta_{pf}} = k_r k_s \tag{29.8}$$

$$K = \frac{1}{k_0 T^2 S_0^2}\left(\frac{e^3}{1+e}\right). \tag{29.9}$$

Lee and Fookes (2005b) suggest that in arid conditions the fines content can reach 30% without having a significant effect on the ability of the soil to drain.

29.5 Engineering in problematic arid soil conditions

The creation of metastable, expansive and chemically aggressive (from the viewpoint of the durability of man-made structures) soil deposits within arid regions results in a number of geohazards, which must be addressed by the geotechnical engineer. Therefore, this section introduces case studies of various ground conditions encountered in arid regions, including:

- foundations in expansive, desiccated or collapsible soils;
- foundations in chemically stabilised soil or rock formations;
- compaction of placed fill;
- stabilisation of sabkha soils.

Chapters 32 *Collapsible soils* and 33 *Expansive soils* describe the behaviour of collapsible soils and expansive soils, with more detailed explanations of structure–ground interactions. This section provides an overview of problems encountered when dealing with soil deposits in arid environments with the aim of highlighting areas that may necessitate the attention of the geotechnical engineer during design and construction.

29.5.1 Geohazards encountered in desiccated, expansive and collapsible soils

29.5.1.1 Examples of foundation behaviour in expansive soils

A detailed review of foundations suitable for arid soils that exhibit expansive behaviour can be found in Chapter 33 *Expansive soils*. That chapter deals with assessment and the foundation or remediation options available to deal with such

soils. The key aspect is the implication of the unsaturated state due to the arid environment, which dictates the nature of the problem and the responses needed.

For example, Kropp (2010) reviewed changes in the foundation design for domestic dwellings on expansive soils in the San Francisco Bay Area. Here, the preference in the local community is for grassed or planted gardens and watering is common. It was suggested that homeowners regularly overwatered the ground, to the point where the mass of water penetrating the ground exceeded that exiting the ground via evapotranspiration, and this change in localised groundwater conditions results in considerable, and potentially differential, ground movement; movement which strip footings were ill-suited to resist.

Nusier and Alawneh (2002) report on the distress caused to a single-storey concrete building with a mat foundation (a reinforced concrete slab) constructed on expansive clay in Jordan. The shallow foundation experienced differential ground movement as the ground under most of the house heaved, yet one corner of the building settled (due to the desiccating action of a tree); the mat was not sufficiently rigid to withstand these movements, the concrete foundation walls were not reinforced and the building suffered significant cracking. It was suggested that the soil under the building heaved due to a thermal gradient existing across the soil below the building and the soil surrounding the building directly exposed to sunlight, resulting in the migration of water from the surrounding area towards the ground below the house. Nusier and Alawneh (2002) concluded that had the foundation been deeper, to a depth where the pressure from the building acting on the soil equalled, or exceeded, that of the pressure from the expanding soil, then the situation could have been avoided. Instead, the building was repaired by installing a reinforced concrete skeleton to the outside of the building and a ring beam to the mat. This intervention cost approximately 25% of the original cost of constructing the building, highlighting the need to understand the probable behaviour of the ground before undertaking construction.

When a desiccated clayey soil experiences infiltration of water during, and directly after, a storm (or because of a leaking utility) the soil fabric will undergo restructuring as it swells. This phenomenon can be pronounced if the soil comprises a significant fraction of clays, or an active clay mineral such as smectite. The seasonal cycle of desiccation/wetting may also cause problems with deep foundations. Blight (1994) reports that pile tests in soil conditions in southern Africa indicate that soil shrinks away from the surface of a pile as it dries in the dry season; clearly this has significant implications when designing a deep foundation if there is a considerable reduction in the skin friction acting on a pile.

Various improvement approaches can be used to treat expansive arid soils (see Chapter 33 *Expansive soils*). For example Rao *et al*. (2001) investigated the performance of lime-stabilised expansive-clay compacted samples exposed to repeated cycles of wetting and drying. Samples were created with lesser and greater amounts of lime than the initial consumption of lime (ICL) value of the soil and were then exposed to several wetting and drying cycles. Both the wetting and drying phases each took 48 hours to complete. It was noted that repeated cycles of wetting and drying had a detrimental effect upon the lime-stabilised soil, in particular for samples with lime contents slightly above or below the ICL. Increasing the number of wetting and drying cycles resulted in:

- more clay detected in the stabilised samples, which Rao *et al*. (2001) suggest is illustrative of the decaying stabilisation of the clay soil;
- a higher liquid limit;
- a lower plastic limit;
- a lower shrinkage limit.

29.5.1.2 An example of foundation behaviour in a collapsible soil

A detailed review of how to deal with foundations in arid soils that exhibit collapsible behaviour can be found in Chapter 32 *Collapsible soils*. That chapter deals with assessment and the foundation or remediation options available to deal with such soils. The key aspect, as with expansive arid soils, is the implication of the unsaturated state due to the arid environment, which dictates the nature of the problem and the responses required.

Loess, a collapsible arid soil, is often considered to be a problematic soil readily collapsing after inundation by water or an increase in load. However, loess often initially experiences a small degree of settlement before experiencing heave, particular at low applied pressures (see section 29.4.3 and **Figure 29.20**). For example, during a plate-loading test, Komornik (1994) applied cycles of loading and unloading to a plate in a loess soil, at the natural water content and after wetting the soil. Wetting resulted in collapse, leading to large unrecoverable deformations. The difference between the behaviour of the soil at the natural water content and the soil after wetting illustrates the necessity of designing a foundation carefully if swelling or collapse potential is considered a possibility, and also the necessity of protecting the location from possible inundation during storms in order to prevent movement of the foundation after completion of construction.

A range of treatment and improvement approaches can be employed to mitigate the behaviour of collapsible arid soils (e.g. dynamic compaction, cement stabilisation) and further discussion can be found in Chapter 32 *Collapsible soils*.

29.5.2 Compaction of fill

In an arid environment, where water is not generally plentiful, applying too little water to the soil (or, in a hot arid environment, applying the desired amount and losing a proportion to evaporation) may result in the development of suction within the soil as it is compacted. The suction will resist the compactive effort and the net effect is a low-density fill, which may experience undesirable levels of settlement. It has been suggested that in

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

such circumstances compacting the soil when it is dry might be more appropriate (Newill and O'Connell, 1994). Of course, dry compaction will produce fills with a high volume of air voids and measures must be taken to ensure that subsequent ingress of water is prevented or the fill may undergo restructuring of its fabric, causing the fill to deform or collapse.

In large construction projects, the volume of water required can be significant, which can create logistical problems when working in arid conditions. For example, Newill and O'Connell (1994) investigated the construction of a major road in an arid environment and estimated that the water required to create one kilometre of the road could be as much as 2800 m^3 and equated to approximately 20% of the total construction cost in sourcing and transporting the water to site. This value, by far, exceeds the cost of water for construction in tropical or temperate climates. It must also be considered that arid conditions are often located in developing countries (White, 1966), and the infrastructure can be, at best, extremely limited outside urban areas. Due to the potential lack of infrastructure in rural areas, the source of water may be from boreholes and it is unlikely that any treatment will be applied to the extracted water before it is used for construction. Therefore, the extracted water can potentially contain significant concentrations of salts, salts that will remain within the fill and can have a detrimental effect on the man-made structures placed upon it.

In addition, not all construction projects in developing countries boast the resources necessary to surmount the logistical problems of sourcing sufficient water for a project. For example, whilst working on a site in arid conditions a sister site (approximately 100 km away) faced significant problems when it was announced that the local village borehole was at risk of running dry and a moratorium was placed on the use of water for anything other than critical functions (which did not include construction). In order to continue construction, and ensure that the workforce had water for drinking and washing, 5 m^3 of water was transported by bowser daily. This placed a strain on the efficiencies of both sites and it was difficult to justify the use of water when compacting fills, when other more critical functions (drinking, washing, casting concrete, etc.) took precedence. Eventually it was decided that in order to meet the specifications (end-product specifications were being used) water would have to be used during compaction and the programmes for both sites overran.

When compacting soils in arid environments, particularly for significant geotechnical structures such as roads or embankments, the processes applied are likely to be governed by a framework or standard. Truslove (2010) and Puttock *et al*. (2011), by considering suitable earthwork specifications in arid environments, reviewed a number of standards used in various countries with arid lands. Truslove (2010) concluded that currently there are standards that permit the use of compaction of dry fill in rural areas (such as Kenya), whereas other standards refer to an end-product specification (minimum acceptable dry density, etc.) and do not necessarily comment on the amount of water used. Kropp *et al*. (1994) investigated a compacted fill that had suffered excessive deformation; the soil was a granular material that contained clay and had been compacted to a density greater than the minimum required in the end-product specification, although with a water content less than the optimum (up to 7% less). It was concluded that wetting had induced collapse and that, perhaps, the standard should also impose conditions on the water content of the compacted fill to try to avoid this scenario. Truslove (2010) cites studies that suggest that consideration must be given to the nature of the soil underlying the compacted fill and that care should be taken when selecting the water content of the fill as there is the potential for water to migrate from the fill into the underlying soil, which could induce structural changes within the underlying soil, jeopardising the performance of the fill above.

Sahu (2001) investigated the performance of six regionally sourced soils, from locations in Botswana, when mixed with fly ash with the aim of producing a range of materials that could be used as base courses in highway construction. The six soils ranged from Kalahari sand, calcrete, silts (of various plasticities) and silty sands as well as an expansive clay soil. Various proportions of fly ash were mixed with the soils, and the mixtures were hydrated and left to cure. With the exception of the expansive clay, the inclusion of fly ash lowered the maximum dry densities. However, the inclusion of the fly ash did increase the CBR for the soils containing silts and the calcite; therefore it was suggested that this made these soils suitable for use in highway construction. The inclusion of fly ash in the Kalahari sands and the expansive clays did not have a noticeable impact on the CBR and these were deemed unsuitable for highway construction.

29.5.3 Stabilisation of sabkha soils

Al-Amoudi *et al*. (1995) cites instances where geotechnical improvement techniques such as dynamic compaction, stone columns, densification piles and the creation of drainage have all successfully been used to improve the physical properties of these notoriously weak materials. Al-Amoudi *et al*. (1995) quotes unconfined strengths of around 20 kPa and SPT N ranges of 0 to 8 for these types of formations of sabkha soils, although a value of 30 kPa can be achieved at depth (Shehata and Amin, 1997).

Alternative ground-improvement materials, such as the use of filler particles (limestone dust or marl), to reduce the void ratio of the soil and potentially increase the UCS, have been trialled with sabkha soils (Al-Amoudi *et al*., 1995). The limestone dust (a by-product of an industry local to the study) and marl increased the maximum dry density of the sabkha soil, with the limestone dust reducing the optimum water content and the marl increasing the optimum water content. However, varying the content of limestone dust or marl did not noticeably change the UCS of the sabkha soil, suggesting that the incorporation of these materials can reduce the volume of voids of the compacted sabkha soil but not have a noticeable increase on its strength.

Cement and lime have also been investigated and found to be beneficial as stabilising agents for sabkhas soils (**Figure 29.23**), although there are concerns with the long-term durability of the stabilised materials (Al-Amoudi *et al*., 1995).

Damage to the base and sub-base courses of highways due to movement in the underlying sabkha sub-grades has resulted in investigations into the use of geotextiles between the road foundation and the sub-grade (Abduljawad *et al*., 1994; Aiban *et al*., 2006). Static and dynamic testing of dry and wet sabkha soils, underlying various geotextiles and sub-base materials in a laboratory, illustrated that geotextiles could increase the load required to induce deformation within the soil. **Table 29.5** illustrates the force required to induce a 30 mm deformation at the load plate on the soil for soaked and 'as moulded' conditions with and without a geotextile.

29.6 Concluding comments

Arid soils form in environments where evapotranspiration rates exceed rainfall. Arid soils cover about a third of the Earth's land mass and occur in hot and cold arid regions. However,

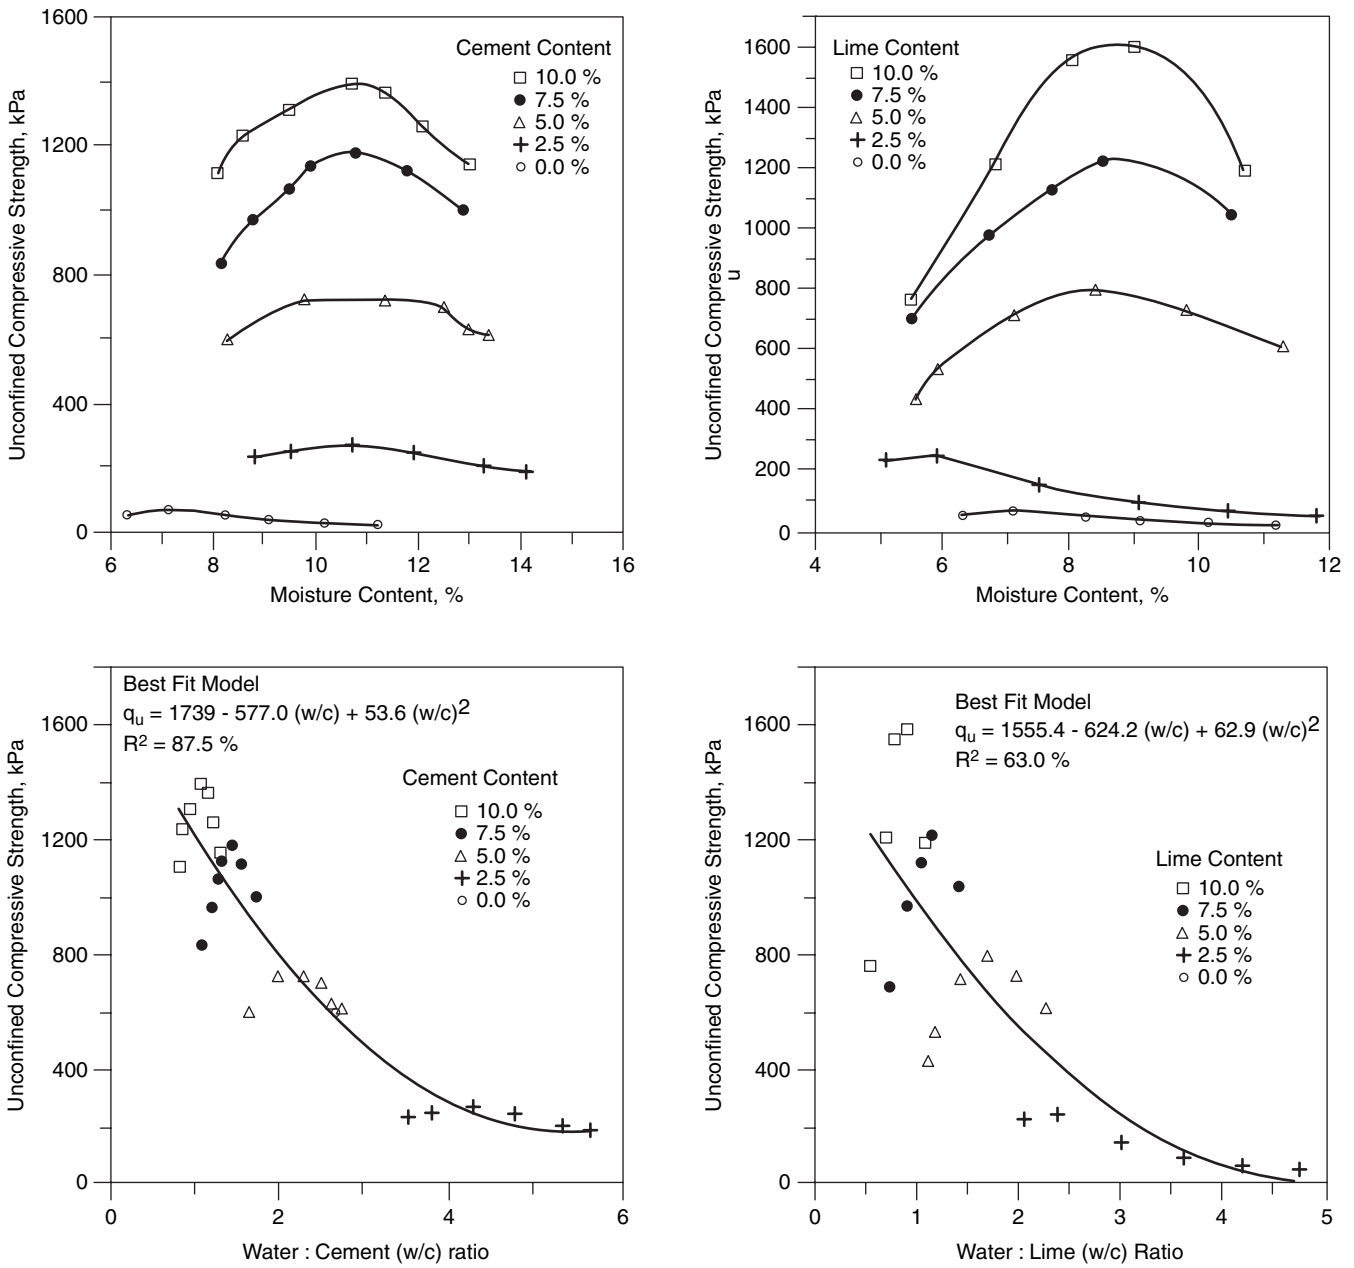

Figure 29.23 Stabilisation of a sabkha soil with cement (top left) and lime (top right). Illustration of the relationship between the UCS and the water/cement ratio (bottom left) or the water/lime ratio (bottom right)

SG300H65D	23.5	As moulded

Table 29.5 Loads required to achieve a deformation of 30 mm at the load plate on a sub-base overlying a sabkha sub-grade, with or without a geotextile, in soaked and 'as moulded' conditions (Aiban *et al.*, 2006)

soils formed under arid climates can also be found in temperate regions due to ancient geological processes.

Arid soils present a number of challenges to engineers owing to:

- the highly variable nature of their engineering properties associated with active and ancient geomorphic processes;
- the considerable diurnal temperature ranges experienced, potentially resulting in accelerated disintegration of soil and rock formations as well as man-made structures;
- lithification processes, which can result in cementation of the soil particles, making excavation problematic;
- various problematic soils, which occur in arid conditions, such as those with significant shrink–swell or collapsing potentials, or aggressive salt environments.

Key to understanding how arid soils behave and how these soils can be engineered is achieved through an appreciation of how geomorphology controls their formation. Associated with these processes are soils that can be cemented or uncemented, whilst being unsaturated. Once the geomorphologic effects are understood, the appropriate engineering assessments and mitigation can be applied. A number of logistical challenges associated with water also occur in arid environments: limited availability (resulting in the use of groundwater with high salt concentrations in construction processes, or having to bowse water from external locations to the site); or poor management (for example through lack of appreciation of the significant impact of flash flooding on the erosion of natural, or man-made, soil formations, or the impact of water containing high salt concentrations on construction processes such as the casting of concrete).

30.5	References	359

Tropical soils are formed primarily by *in situ* weathering processes, and hence are residual soils. Terminology for tropical soils is confused and many classification schemes exist, based on either pedological, geochemical or engineering criteria. For classification schemes to be useful they need to include the effects of disintegration due to weathering, mineralogy (particularly the 'unusual' clay minerals that are particular to tropical soils), cementation and structure. Tropical residual soils are highly structured materials, both at macro and micro levels. The micro-structure is produced by leaching out of minerals during weathering, leaving an open structure. Tropical soils are also likely to be cemented soils due to deposition of minerals either during or after weathering. The highly structured nature of tropical soils, combined with the fact, they often exist in an unsaturated state, makes them difficult to deal with as engineering materials. However, they often have good engineering properties. Nevertheless, some tropical soils can be problematic, demonstrating collapse or shrink–swell movements. Ground investigation for tropical soils poses some difficulties due to their heterogeneous nature. Sampling of tropical soils so that the original structure is maintained can be a major challenge, and hence there is a strong emphasis on *in situ* testing methods.

30.1 Introduction

Tropical soils are formed primarily by *in situ* weathering processes, and hence are *residual soils*. The climatic conditions in tropical regions, with high temperatures and high levels of precipitation, lead to stronger chemical weathering of primary minerals and a greater penetration of weathering than occurs in other regions of the Earth (**Figure 30.1**).

The weathering process propagates from the Earth's surface and is controlled primarily by water movement within the joints of the parent rock. Weathering starts on the joint surfaces and progressively penetrates into the rock mass. The direction of propagation of a weathered profile will be dictated by the direction of the joints, so while there is likely to be a vertical component, weathering can also progress horizontally or at other inclinations.

Weathering is usually defined by the degree of decomposition/disintegration of the rock to form soil. This is rated as Grade I (*fresh rock*) through to Grade VI (*residual soil*), where the rock has fully decomposed to form soil. This weathering scale will be discussed in more detail below. The upper three grades, VI (*residual soil*), V (*completely weathered*) and IV (*highly weathered*), represent a material where more than 50% of the rock has decomposed to form soil; the term *tropical residual soil* is used to describe these upper three weathering grades that are dominated by soil material (note the distinction between ***tropical*** *residual soil*, which incorporates all three weathering grades IV, V and VI, and *residual soil,* which only describes Grade VI). The term *saprolite* is used to describe completely and highly weathered material, i.e. a soil which

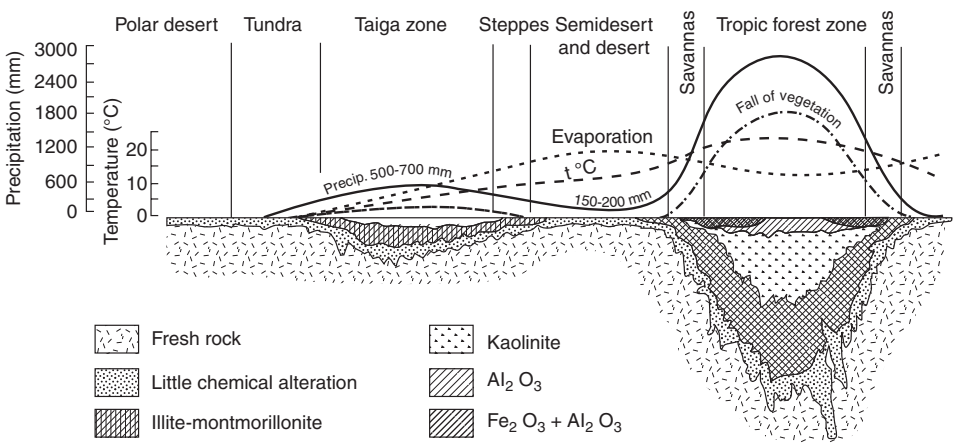

Figure 30.1 Depth of residual soil development related to climatic factors. Weathering may penetrate to greater than 30 m in tropical regions
Reproduced from Strakhov (1967)

still contains some unweathered rock, but does not incorporate the fully decomposed Grade VI.

The particle size distribution (grading) of tropical soils can be highly variable. Early stages of weathering are likely to produce coarser-grained soils. Large boulder- or cobble-sized fragments of unweathered material may still survive as corestones. Stronger chemical weathering will cause minerals such as feldspar and mica to decompose to form clay minerals, so the resulting residual soil may be more fine-grained. The resulting grain size distribution after weathering will depend on the parent rock. For instance, acidic igneous rocks (e.g. granite) contain a high proportion of silica that will resist weathering, so the resulting soil will contain sand-sized silica particles. **Table 30.1** shows the types of residual soil resulting from different parent rocks.

A common feature of many tropical soils is the presence of iron or aluminium oxides, often referred to as sesquioxides (Fe_2O_3 or Al_2O_3). This produces the reddish coloration common to many tropical soils. Iron and aluminium oxides released by weathering are not dissolved as in more acidic environments and remain *in situ*. Iron oxide is crystallised as haematite when the soil is seasonally desiccated, or as goethite in a constantly humid environment; haematite gives the soil a red colour, goethite a brown or ochreous colour. Gibbsite is the main aluminium oxide formed. During the weathering process, silica and bases (K, Na, Ca, Mg) are lost in solution or incorporated into clay minerals.

The term *laterite* has been used to describe a wide range of red soils, and the term has become almost meaningless in an engineering sense. It was used originally to describe a red clay which hardened irrecoverably on exposure to air, but has subsequently been used to describe almost any soil with reddish coloration. The term *laterite* will be used here to refer to a soil with a high degree of iron cementing and the term *red tropical soil* will be used for a soil that has red coloration but without significant cementing.

The weathering process can be divided into three stages based on the mineralogical and geochemical changes (Duchaufour, 1982). These stages are based on the dominant clay minerals that are produced by weathering:

(1) fersiallitisation (smectite clays dominant);

(2) ferrugination (kaolinite and smectites);

(3) ferrallitisation (kaolinite and gibbsite).

As weathering proceeds (ferrugination–ferrallitisation) there is a decrease in concentration of silica and bases and an increase in concentration of iron and aluminium oxides. The resulting soil at the final stage of weathering (ferrallitic soil) is clay-rich and also rich in sesquioxides.

The iron, in the presence of negatively charged clay particles, may be present in the reduced form as ferrous oxide (FeO). Ferrous (Fe^{2+}) iron is soluble and highly mobile, whereas ferric (Fe^{3+}) iron is virtually insoluble. If oxidising conditions become present (such as exposure to air in an excavation or by lowering of the groundwater table) the soluble ferrous iron is precipitated as ferric oxides (Fe_2O_3) such as goethite or limonite. This results in an indurated soil, i.e. a soil that becomes harder through cementation. Alternating reduction and oxidation due to fluctuating groundwater levels in the geological past leads to the development of concretionary or nodular laterites.

Indurated, rock-like *duricrusts* can be formed by cementing of tropical soils by a number of chemicals. Iron and aluminium oxides or silica released during weathering, or calcium carbonate, can be moved laterally or vertically through the soil profile by groundwater flow and may accumulate sufficiently in some horizons for crystallisation to occur, resulting in duricrust formation.

Terminology for tropical soils is confused and many classification schemes exist, based on either pedological, geochemical or engineering criteria. The classification given by Duchaufour (1982), based on weathering stages, has been adopted as the basis of a Working Party Report by the Geological Society (Anon., 1990), later published by Fookes (1997). However, it will be argued that there are other factors, such as weathering grade, degree of cementation and mass structure, that are equally important.

Tropical residual soils are often highly structured materials, both at macro and micro levels. The micro-structure is produced by leaching out of minerals during weathering, leaving an open structure, combined with the effects of secondary cementing by minerals deposited during or after weathering has taken place. The cementing (bonding) can maintain the fabric of the soil in a metastable state, i.e. such a loose structure could not exist if the bonding was not present to support it. **Figure 30.2** shows a typical example of the micro-structure of a residual soil from Singapore. The open fabric can be clearly seen as well as a variation in the degree of cementing within the soil.

Parent rock	Residual soil type	Relative susceptibility to tropical weathering
Calcareous rock (limestone, dolomite)	Gravel in clayey or silty matrix	1 (most vulnerable)
Basic igneous rock (gabbro, dolerite, basalt)	Clay (often grading into sandy clay with depth)	2
Acid crystalline rock (granite, gneiss)	Clayey sand or sandy clay (often micaceous)	3
Argillaceous sedimentary rock (mudstone, shale)	Silt or silty clay	4
Arenaceous sedimentary or metamorphic rock (sandstone, quartzite)	Sand (clayey sand in the case of residual arkose or feldspathic sandstone)	5 (least vulnerable)

Table 30.1 Types of residual soil from different parent rocks
Data taken from Brink *et al.* (1982)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Tropical soils have a reputation for being 'problematic'. This is because they do not conform to the widely used classification systems that have been developed for temperate sedimentary soils to identify likely engineering behaviour. They are also difficult to investigate, as attempts to sample or test them can destroy the cementing and structure that supports them. This chapter will identify the problems in classifying and investigating tropical soils, and identify schemes and methods that are appropriate for tropical soils.

Of course, some tropical soils can be highly problematic. Residual soils can exist in a loose, structured state and can collapse on loading, or due to wetting, leading to sudden settlements. Other problematic types of tropical soil contain highly expansive smectite clays, resulting in significant heave or shrinkage as wetting or drying occurs. These aspects of behaviour of tropical soils will be considered in a range of applications: foundations, slopes and highways.

30.2 Controls on the development of tropical soils

30.2.1 Weathering processes

One of the most important factors in the engineering behaviour of tropical soils is the degree of weathering. Little (1969) first proposed a six-grade classification for tropical residual soils. This has become the well-established scheme for identifying the degree of rock weathering used in the Geological Society Working Party Report on Core Logging (Anon., 1970) and the Working Party Report on Rock Mass Description (Anon.,

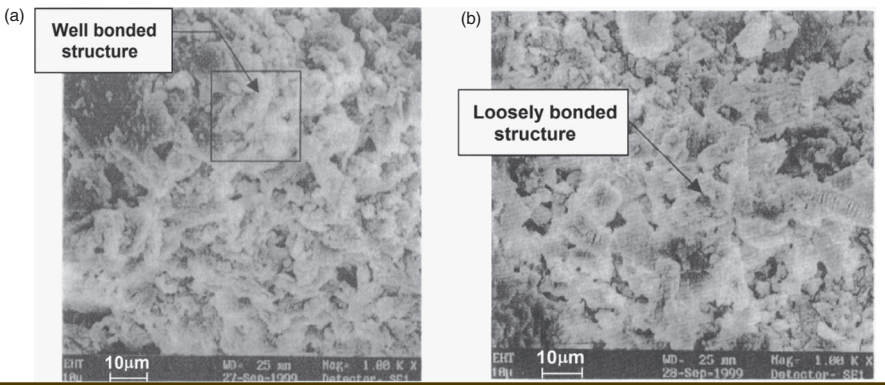

Figure 30.2 Scanning electron microscope images showing the micro-structure of a tropical residual soil from Singapore: (a) well bonded with strong cementing; (b) looser structure
Reproduced from Aung *et al.* (2000)

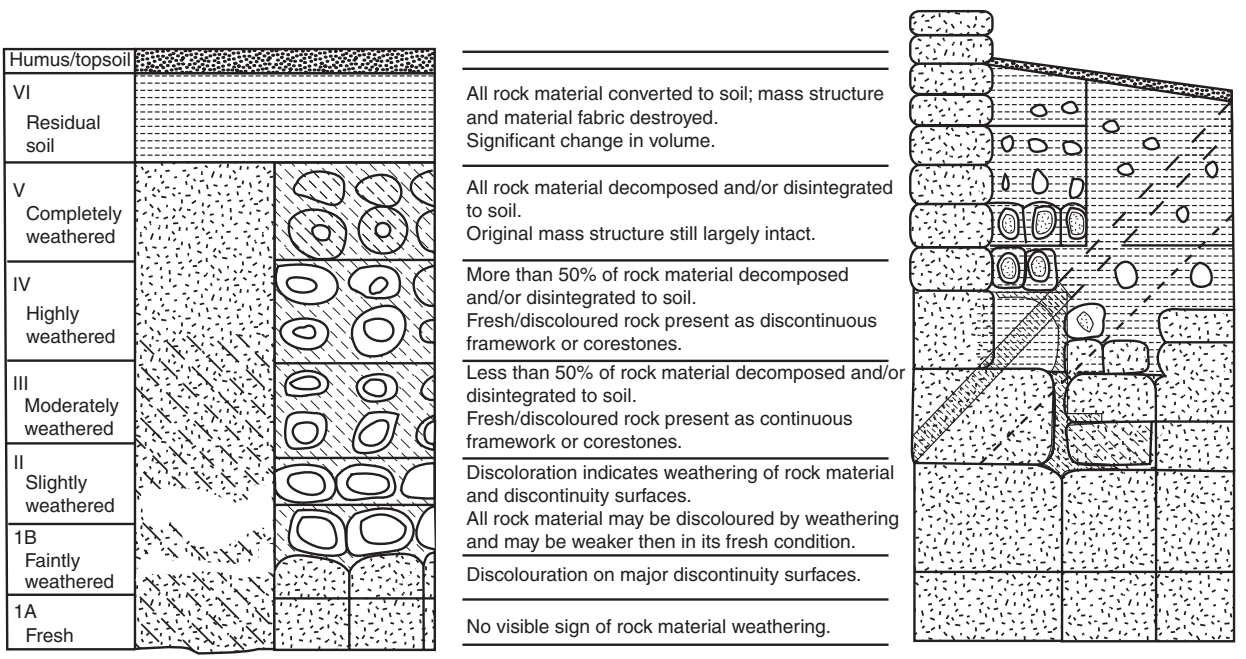

Figure 30.3 Schematic diagrams of typical weathering profiles
Reproduced from Anon. (1990) © The Geological Society

1977). This was the scheme used in ISRM (1978), whereby the relative percentages of 'rock' that has decomposed/disintegrated to form 'soil' are used to define the weathering grade. **Figure 30.3** shows a useful diagrammatic representation of the scheme.

British Standard BS 5930 (British Standard Institution, 1999) provided an alternative method to characterise the degree of weathering by identifying weathering grades based on three approaches, as shown in **Figure 30.4**. However, the British Standard was superseded by Eurocode documents for soil

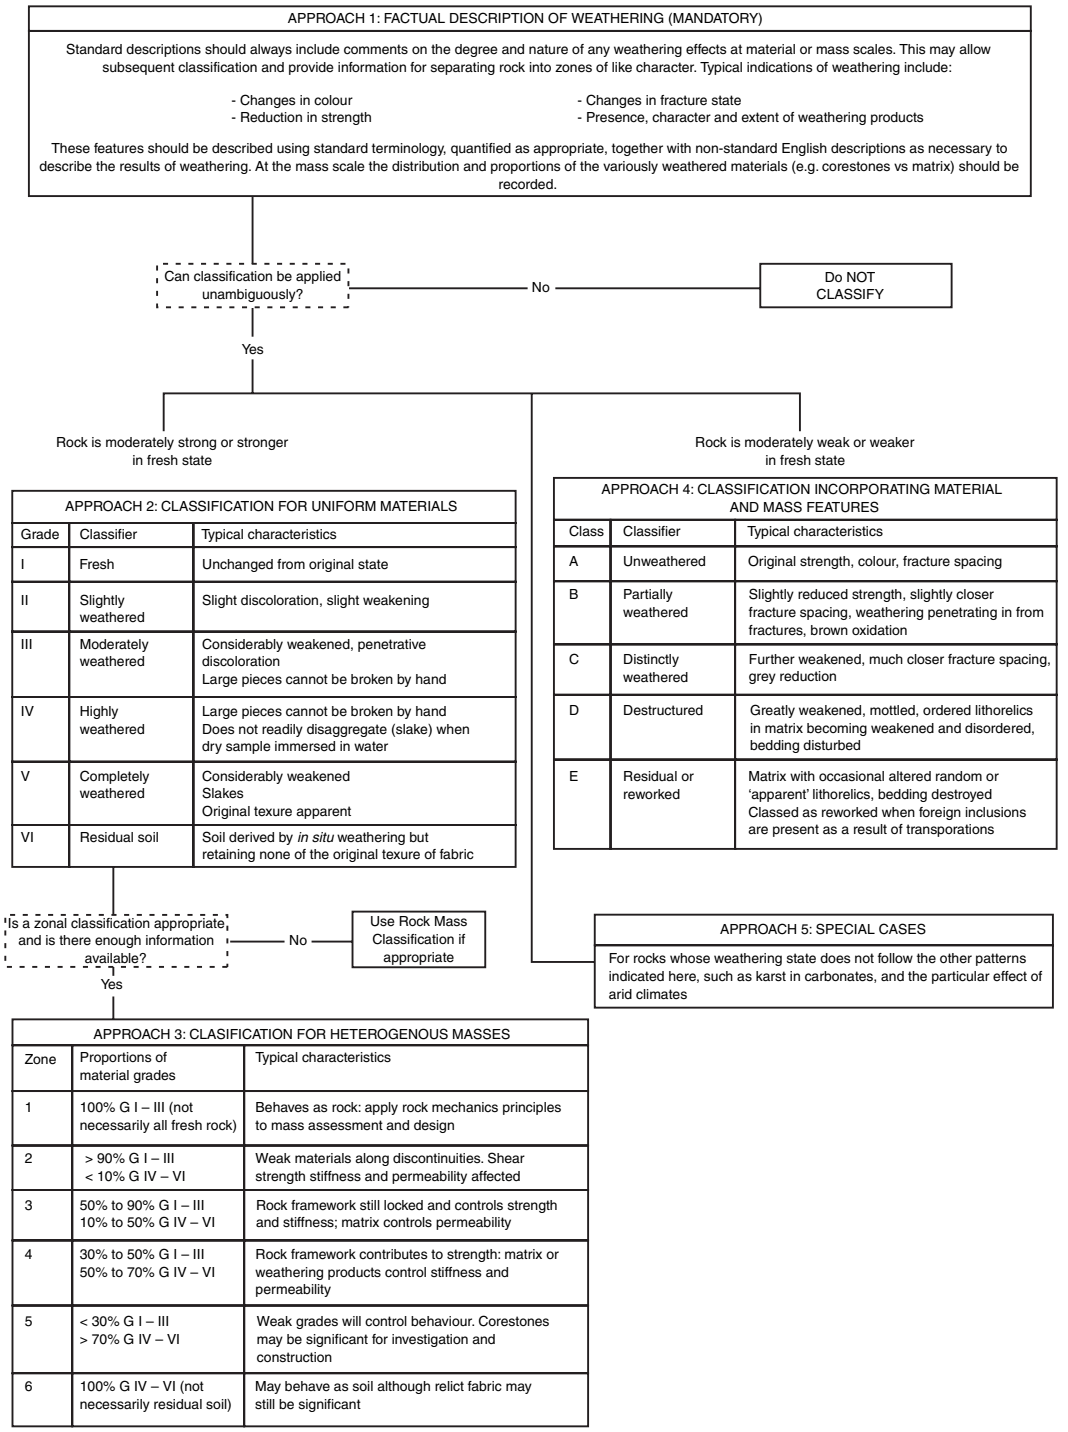

Figure 30.4 Description and classification of weathered rock for engineering purposes
Reproduced with permission from BS 5930 © British Standards Institution 1999

and rock description in April 2010. EN 14689-1:2003 (British Standard Institution, 2003) for rock description returned to the scheme illustrated in **Figure 30.3**. Hencher (2008) saw this transition from the BS approach to the EN definitions as a retrograde step. As will be discussed later, in section 30.3.2, a full classification of tropical soils must include more than just the weathering grade, and should also incorporate mineralogy, secondary cementation and structure.

As has been noted, Duchaufour (1982) identified three phases of development in the weathering process, based in changes in mineralogy and geochemistry, as opposed to the degree of decomposition/disintegration:

(1) fersiallitisation;

(2) ferrugination;

(3) ferrallitisation.

As weathering proceeds (fersiallitisation–ferrugination–ferrallitisation) there are changes in mineralogical composition, in particular the formation of clay minerals. This is associated with a decrease in concentration of silica and bases (K, Na, Ca, Mg) and an increase in concentration of iron and aluminium oxides. Fersiallitic soils are dominated by 2:1 clay minerals (smectites). The main clay mineral present in ferruginous soils is kaolinite (1:1) although some smectite may be present. Ferrallitic soils are dominated by kaolinite and gibbsite (aluminium oxide).

Clay minerals are alumina-silicates that are made up of sheets comprising either silica tetrahedrons (tetrahedral sheets) or alumina octahedrons (octahedral sheets). 1:1 clay minerals are made up of alternating tetrahedral and octahedral sheets. The adjacent layers are closely bonded together, preventing water molecules from penetrating between the sheets. This makes them relatively low-activity minerals (i.e. low shrinkage/swelling). 2:1 clay minerals have one octahedral sheet sandwiched between two tetrahedral sheets. Adjacent layers are not held together strongly, thus allowing water molecules to penetrate between sheets, resulting in high-activity minerals (i.e. high shrinkage/swelling).

Duchaufour's stages of weathering are shown in **Table 30.2**, together with comparisons with other pedological schemes and commonly used geotechnical descriptive terms. Duchaufour's scheme was adopted by a Geological Society Working Party Report on Tropical Soils (Anon., 1990; Fookes, 1997) for its classification of tropical soils, as will be discussed in section 30.3.2.

30.2.2 Parent rock

The type of residual soil will depend on the parent rock. Some typical examples of residual soil types are given in **Table 30.1**. Also shown are the relative susceptibilities to weathering in a tropical environment (Brink *et al.*, 1982).

30.2.3 Climate

The stage of weathering which is achieved is controlled by the climate. The effect of climate on the weathering products is shown in **Table 30.3**.

Reference	Rainfall (mm per annum)	Clay mineral type
Pedro (1968)	< 500	Montmorillonite
	500–1200/1500	Kaolinite dominant
	> 1500	Gibbsite and kaolinite
Sanches Furtado (1968)	800–1000	Kaolinite and montmorillonite
	1000–1200	Kaolinite dominant
	1200–1500	Kaolinite and gibbsite

Table 30.3 Climate and weathering products
Data taken from McFarlane (1976)

Pedological classifications			Common geotechnical terminology	Colour	Mineralogy
Duchaufour	USA	FAO/ UNESCO			
VERTISOL (fersiallitic)	Vertisol	Vertisol	Black Cotton soil	Black, brown, grey	Smectites (montmorillonite), kaolinite
ANDOSOL (fersiallitic)	Inceptisol	Andosol	Halloysite/ Allophane soil	Red, yellow, purple	Kaolinite (halloysite), allophane
FERRUGINOUS	Alfisol	Nitosol, alfisol, lixisol	Red tropical soil	Red, yellow, purple	Kaolinite, hydrated iron oxide (haematite, goethite), hydrated aluminium oxide (gibbsite)
FERRISOL (transitional)	Ultisol	Ferralsol	Lateritic soil, latosol	Red, yellow, purple	Kaolinite, Hydrated iron oxide (haematite, hoethite), hydrated aluminium oxide (gibbsite)
FERRALLITIC	Oxisol	Plinthisol	Plinthite, laterite	Red, yellow, purple	Kaolinite, Hydrated iron oxide (haematite, goethite), hydrated aluminium oxide (gibbsite)

Table 30.2 Terminology for tropical soils

The phases of weathering defined by Duchaufour (1982) can also be related to climate. In Mediterranean or sub-tropical climates with a marked dry season, stage 1 (fersiallitisation) is rarely exceeded. In a dry tropical climate development stops at stage 2 (ferrugination). Only in humid equatorial climates is stage 3 (ferrallitisation) reached (see **Table 30.4**).

The world distributions of the major types of tropical residual soils are shown in **Figure 30.5**. Fookes (1997) notes that these broad classes of soils extend beyond the tropics in favourable conditions. Examples are ferrallitic soils on high-rainfall sub-tropical continental east coasts, and fersiallitic soils in west coast/Mediterranean and continental interiors in mid-latitudes.

The development of duricrusts (rock-like cemented/indurated soils) is also highly dependent on climatic conditions. Ackroyd (1967) presents possible conditions under which the different stages of concretionary material develop in ferricrete (or laterite) (**Table 30.5**). The climate is categorised using the Thornthwaite moisture index (Thornthwaite and Mather, 1954). This provides a way of defining climatic conditions based on the difference between the precipitation and evapotranspiration expressed as a ratio to the potential evapotranspiration. A negative value indicates a dry environment and positive values indicate more humid environments.

Phase	Soil type	Zone	Mean annual temperature (°C)	Annual rainfall (m)	Dry season
1	Fersiallitic	Mediteranean, subtropical	13–20	0.5–1.0	Yes
2	Ferruginous Ferrisols (transitional)	Subtropical	20–25	1.0–1.5	Sometimes
3	Ferrallitic	Tropical	> 25	> 1.5	No

Table 30.4 Summary of Duchaufour's residual soil phases in relation to climate factors
Data taken from Anon (1990)

However, McFarlane (1976) points out that the conditions for development of concretions are not the conditions under which the laterite minerals initially form. McFarlane identified a model of laterite formation based on a fluctuating groundwater table in an overall downward flow environment. A cycle of development may result, where the original lateritic deposit is weathered, producing iron and aluminium oxides that are mobilised and recrystallised elsewhere to form a new laterite deposit.

30.2.4 Relief and drainage

Relief and drainage have major effects on the stages of weathering. Idealised soil profiles (catenas) are shown for three rock types in **Figure 30.6**. However, these simple catenary sequences will be modified by the drainage conditions. If the base of the slope is poorly drained, then fersiallitic soils will develop even on acid crystalline rocks. Equally if drainage conditions are good then ferrallitic soils may develop on basic rocks.

30.2.5 Secondary cementation

Many tropical soils are bonded due to the presence of chemical cementing agents. These chemicals may develop by pedogenic processes induced by the accumulation of iron or aluminium oxides (as they are released during weathering) or the movement of leached silica, aluminium and iron oxides, gypsum or carbonates by groundwater flow. These minerals may accumulate sufficiently in some horizons for crystallisation to occur.

The resulting harder varieties of pedogenic materials such as calcrete, silcrete, ferricrete and alucrete are known as duricrusts or pedocretes. The cementing agents for each type of duricrust are identified in **Table 30.6**.

Netterberg (1971) categorised calcretes into calcified material, powder calcrete, nodular calcrete and hardpan calcrete, and showed that the engineering properties were highly dependent on the type of calcrete. Charman (1988) adopted a similar classification scheme for laterite (or ferricrete) (**Table 30.7**).

Different stages of laterisation are reflected in the silica/alumina ratio (SiO_2/Al_2O_3) (Desai, 1985). Typical values are given in **Table 30.8**.

	Annual rainfall (mm)		
	750–1000	1000–1500	1500–2000
Thornthwaite moisture index	–40 to –20	–20 to 0	0 to +30
Length of dry season (months)	7	6	5
Type of product	Rock laterite or cuirasse	Hard concretionary gravels	Minimum requirements for concretions to develop

Table 30.5 Possible conditions for development of concretionary laterite

30.3 Engineering issues

30.3.1 Investigation

Ground investigation for tropical soils poses some difficulties due to the heterogeneous nature of tropical residual soils. The soil properties will be dependent on the degree of weathering, which varies within the weathered mass; there can often be 'corestones' of relatively unweathered rock (which can be of cobble or boulder size) contained within a matrix of more

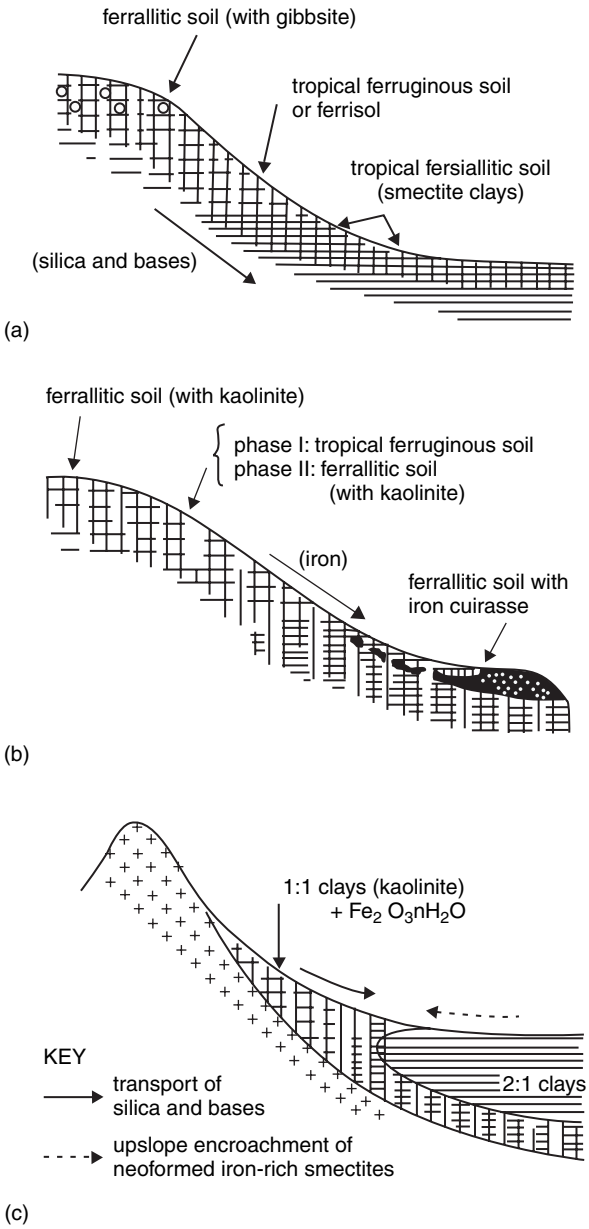

Figure 30.6 Simple soil catenas for different rock types: (a) basic volcanic rocks in a humid tropical climate; (b) acid crystalline rocks in a humid tropical climate; (c) around inselbergs in the tropics (Inselbergs are prominent steep-sided hills of resistant igneous rock rising out of a flat plain)
Reproduced from Fookes (1997) (from Duchaufour, 1982)

weathered material. The original rock mass structure, such as joint sets, will be represented in relict form in the tropical residual soil and can represent planes of weakness (Irfan and Woods, 1988; Au, 1996).

The overall degree of weathering will vary from the highest degree of weathering near the ground surface to less weathered and possibly fresh rock deeper within the ground mass. However, the changes between grades of weathering will be progressive; there are unlikely to be sharp distinctions between layers of different weathered materials, so identification of boundaries between weathering grades can be highly subjective.

In addition to this, the degree of secondary cementing can be highly variable, both in terms of the amount of the cementing minerals (e.g. iron oxides) and the strength of the cemented bonds. The 'structured' nature of tropical soils (Vaughan, 1985a) makes them particularly sensitive to disturbance during sampling and testing.

Duricrust	Cementing mineral
Silcrete	Silica
Calcrete	Calcium or magnesium carbonate
Gypcrete	Calcium sulphate dihydrate
Alucrete (bauxite)	Hydrated aluminium oxides
Ferricrete (laterite)	Hydrated iron oxides

Table 30.6 Duricrusts and their cementing minerals

Sampling of residual soils so that the original structure is maintained can be a major challenge. Driven or pushed samplers are likely to cause significant breakdown of the structure, resulting in samples that no longer represent the *in situ* conditions. Large block samples, trimmed by hand, may be the only way to get satisfactory samples. Details of sampling procedures are outlined in Fookes (1997).

There has been success with using rotary coring techniques, using triple-tube core barrels and air foam flush to recover good quality samples (Phillipson and Brand, 1985; Phillipson and Chipp, 1982). Mazier core barrels (73 mm diameter) are commonly used, as are Treifus triple-tube barrels (63 mm diameter). Plastic lining tubes should be used to protect the core on extrusion. Water drilling flush should not be used, as the flushing medium can cause erosion of the core or result in changes in water content. Even compressed air flush can potentially change the suctions in samples (Richards, 1985).

Due to the difficulties in recovering high-quality, undisturbed samples, there has been a strong emphasis on *in situ* testing to determine the engineering properties of tropical soils. Pressuremeter and plate load tests are suitable tests for assessing *in situ* properties. Standard penetration testing (SPT) is also widely used. Cone penetration testing (CPT) and vane testing are unlikely to be suitable for weathered profiles containing significant amounts of rock material, as penetration of

Age	Recommended name	Characteristic	Equivalent terms in the literature
Immature (young)	PLINTHITE	Soil fabric containing significant amount of lateritic material. Hydrated oxides present at expense of some soil material. Unhardened, no nodules present but may be slight evidence of concretionary development	Plinthite Laterite Lateritic clay
	NODULAR LATERITE	Distinct hard concretionary nodules present as separate particles	Lateritic gravel Ironstone Pisolitic gravel Concretionary gravel
	HONEYCOMB LATERITE	Concretions have coalesced to form a porous structure which may be filled with soil material	Vesicular laterite Pisolitic ironstone Vermicular ironstone Cellular ironstone Spaced pisolitic laterite
Mature (old)	HARDPAN LATERITE	Indurated laterite layer, massive and tough	Ferricrete Ironstone Laterite crust Vermiform laterite Packed pisolitic laterite
	SECONDARY LATERITE	May be nodular, honeycomb or hardpan, but is the result of erosion of pre-existing layer and may display brecciated appearance	

Table 30.7 Classification of laterite
Data taken from Charman (1988)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the testing device will be restricted. However, these techniques may be suitable for Grade VI residual soils.

The pressuremeter has been used for the investigation of properties of tropical soils (e.g. Schnaid and Mantaras, 2003). However, as Schnaid and Huat (2012) note, the pressuremeter response curve will be dependent on a combination of *in situ* horizontal stress, soil stiffness and strength parameters, and these parameters will reduce with destructuration at high shear strains. Schnaid and Huat suggest that, in residual soils, the pressuremeter should be viewed as a 'trial' boundary value problem against which a theoretical pressure-expansion curve predicted using a set of independently measured parameters can be compared to field pressuremeter tests. A good comparison between a number of observed and predicted curves can give confidence that the selected parameters used in the prediction are sensible, and can therefore be adopted in design. An example of a pressuremeter test carried out in a Brazilian residual soil reported by Schnaid and Mantaras (2003) is compared against a numerical simulation in **Figure 30.7** and shows that good agreement can be achieved.

Stage of laterisation	SiO_2/Al_2O_3
Unlaterised soil	> 2
Lateritic soil	1.3–2
Laterite	< 1.3

Table 30.8 Typical values for silica/alumina ratio
Data taken from Desai (1985)

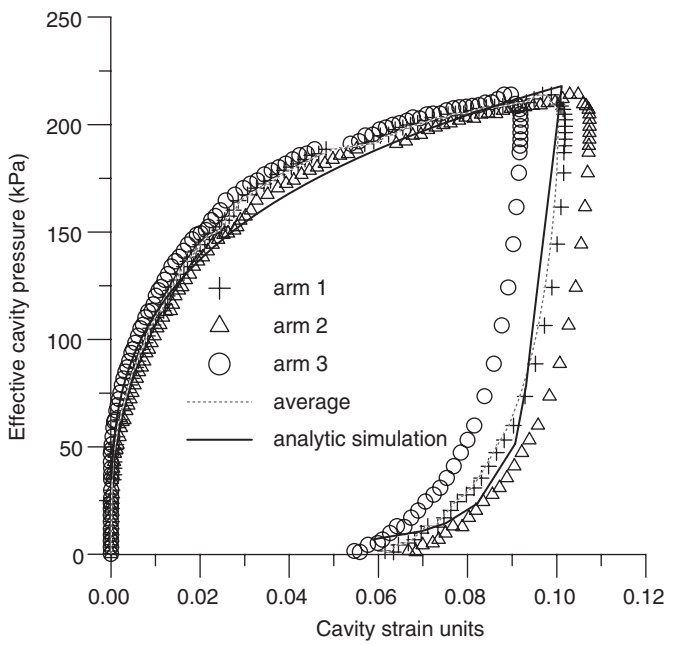

Figure 30.7 An example of a pressuremeter test carried out in saprolite from Brazil compared to an analytical simulation
Data taken from Schnaid and Mantaras (2003)

Plate load testing is a popular option for assessing tropical soils as it has the advantage of testing a larger volume of material, thereby giving a measure of the mass behaviour of a heterogeneous soil. Procedures for performing such tests are described by Barksdale and Blight (1997). The results can be used primarily to estimate the stiffness or compressibility of the soil. The interpretation of the results may be complicated by the structured nature of the soils and unsaturated state, as both factors will influence the initial soil stiffness and the yield stress observed. Schnaid and Huat (2012) suggest that interpretation of test data may require sophisticated numerical analysis with appropriate constitutive models, rather than the conventional interpretation methods commonly used to estimate the elastic modulus.

Standard penetration tests are widely used around the world for assessing the relative density and hence the angle of shear resistance of soils, based on empirical correlations. It has to be recognised that such correlations have usually been established from databases of tests on sedimentary soils. They are unlikely to be appropriate for tropical residual soils as they take no account of any cementing/bonding that influences the strength of the soil. Local relationships may need to be determined for a particular tropical soil that take account of the cementing and local variability.

Schnaid *et al*. (2004) have suggested that cementation of residual soils can be observed by considering the ratio of the elastic stiffness to ultimate strength, G_0/N_{60}, where G_0 is the shear modulus at very small strains and N_{60} is the SPT test value standardised to a reference value of 60% of the potential energy of the SPT hammer. They plotted this ratio against $(N_1)_{60}$, where the N_{60} value is normalised to take account of the vertical effective stress and hence should give a closer indication of relative density of the deposit. They found that the bonded structure has a marked effect for residual soils, producing values of normalised stiffness (G_0/N_{60}) that are considerably higher than those observed in fresh uncemented materials.

30.3.2 Classification

The search for an appropriate scheme for classifying tropical soils has occupied engineering geologists, geotechnical engineers, pedologists and soil scientists for many years. A proliferation of such schemes exist: the Geological Society Working Party Report on Tropical Soils (Anon., 1990; Fookes, 1997) tabulates over 20 different schemes developed between 1951 and 1986, each with a different end use in mind. Although a number of well-developed pedological schemes exist, they are not always relevant for classifying tropical soils for engineering use. Leong and Rahardjo (1998) conclude that, in spite of the efforts to develop classification schemes by geologists, pedologists and engineers, no suitable classification system exists for the study of residual soils.

The Geological Society Working Party Report on Tropical Soils (Anon., 1990; Fookes, 1997) represents the most complete attempt to produce a useful classification scheme for tropical soils. The Working Party opted for a purely pedogenic

classification scheme based on the work of Duchaufour (1982) (**Table 30.2**).

Another major work on residual soils (Blight, 1997) proposes a rather different classification scheme (Wesley and Irfan, 1997). They identify the factors influencing residual soil behaviour as:

- physical composition (e.g. percentage of unweathered rock, particle size distribution, etc.);
- mineralogical composition;
- macro-structure (layering, discontinuities, fissures, pores, etc. discernible to the naked eye);
- micro-structure (fabric, inter-particle bonding or cementation, aggregation, etc.).

To take these factors into account they suggest grouping soils into three types (**Table 30.9**).

According to Wesley and Irfan, Group A (which is not strongly influenced by particular clay minerals) is typical of many tropical soil profiles. The group is further sub-divided by structure components (macro-structure dominated, micro-structure dominated or soils not significantly influenced by either). They suggest that the engineering properties of Group B (which includes vertisols) will be very similar to transported soils with the same clay mineralogy. Group C, which is dominated by minerals only found in tropical soils (halloysite, allophane and aluminium and iron sesquioxides) is sub-divided according to the minerals present.

A way to incorporate these different aspects is proposed by the author of this chapter, where the four factors of disintegration, mineralogy, cementation and structure (DMCS) are encoded on a six-point scale for each factor. It is suggested that the four factors are depicted as shown in **Figure 30.8** using the scales listed in **Table 30.10**. A higher number in each category indicates a more problematic material.

Major division		Sub-group
Group A	Soils without a strong mineralogical influence	(a) Strong macro-structure influence
		(b) Strong micro-structure influence
		(c) Little or no structure influence
Group B	Soils with a strong mineralogical influence derived from clay minerals also commonly found in transported soils	(a) Montmorillonite (smectite group)
		(b) Other minerals
Group C	Soils with a strong mineralogical influence deriving from clay minerals only found in residual soils	(a) Allophane sub-group
		(b) Halloysite sub-group
		(c) Sesquioxide sub-group (gibbsite, goethite, haematite)

Table 30.9 Classification of residual soils
Data taken from Wesley and Irfan (1997)

It has to be recognised that there will be cross-linkages between the different categories; for example a material that is fresh rock (D = 1) but has no secondary cementing (C = 6) will not be a problematic material, even though the cementing category has a high score. Similarly, a residual soil (D = 6) that has hardpan cementing (D = 1) will not be problematic, as the cementing will overcome the decomposition due to weathering and result in a strong rock-like soil.

30.3.3 Characteristics and typical engineering properties

The stages of weathering result in different clay mineralogies, and these are reflected in the cation exchange capacity (CEC) of the clay fraction (Anon., 1990). Typical values are given in **Table 30.11**.

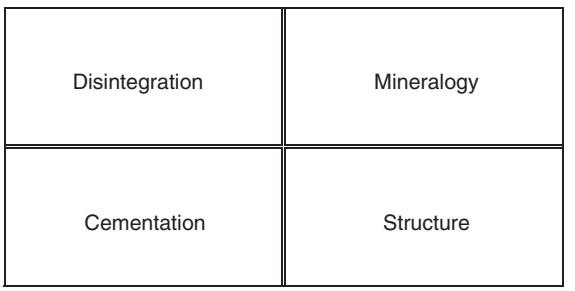

Figure 30.8 DMCS classification scheme

Grade	Disintegration	Grade	Mineralogy[1]
6	Residual soil	6	Smectite (vertisol)
5	Completely weathered	5	Smectite/kaolin (ferruginous)
4	Highly weathered	4	Allophane/halloysite (andosol)
3	Moderately weathered	3	Kaolinite (siallitic)
2	Slightly weathered	2	Kaolinite (ferrisol)
1	Fresh/faintly weathered	1	Kaolinite/gibbsite (ferrallitic)
Grade	**Cementation[2]**	**Grade**	**Structure spacing**
6	No cementing agents present	6	Very small (less than 60 mm)
5	No evident cementing effect	5	Small (60 mm to 200 mm)
4	Weakly cemented	4	Medium (200 mm to 600 mm)
3	Nodular	3	Large (600 mm to 2 m)
2	Honeycomb	2	Very large (greater than 2 m)
1	Hardpan	1	No evident macro-structure

[1] These are ranked in order of engineering behaviour rather than stages of weathering.

[2] This is a measure of secondary cementing of the weathered material, not the initial cementation of the parent rock.

Table 30.10 Proposed classification of tropical residual soils

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Fersiallitic soils can comprise vertisols or andosols that form at the early stage of weathering. Vertisols commonly occur in areas of impeded drainage such as on valley floors. They are often black or dark brown in colour and contain smectite clay minerals. They often exhibit excessive shrinkage and swelling properties and present major engineering problems.

Andosols are fersiallitic soils that develop from volcanic parent rocks and contain amorphous allophane or halloysite. They frequently exist in an extremely loose state, and can have water contents of around 200%. Nevertheless, these high water contents do not reflect in their engineering behaviour since they generally have low compressibility and high angles of shearing resistance (Wesley 1973, 1977).

The latter stages of weathering (ferruginous, ferrisols, ferralitic) usually result in soils with red coloration, reflecting higher iron and aluminium sesquioxide contents. They generally contain low-activity kaolinite minerals, and do not usually present major engineering problems. However, they may perform quite differently from temperate sedimentary soils, and hence the application of standard classification systems can lead to difficulties.

Stage of weathering	Cation exchange capacity (mEq/100 g)
Fersiallitic soil	> 25 (typically 50)
Ferruginous soil	16–25
Ferrallitic soil	< 16

Table 30.11 Typical values for cation exchange capacity of the clay fraction
Data taken from Anon. (1990)

Ferruginous soils (red tropical soils) have red coloration but do not contain high iron oxide contents. Ferrisols (lateritic soils) have higher iron contents, and contain granular nodules (pisoliths) of iron cemented material. Ferricrete (laterite cuirasse or carapace) is an indurated deposit, heavily cemented with iron oxides, and can behave like weak rock.

The effect of secondary cementation is to improve the engineering properties. **Figure 30.9** shows the variation of void ratio, compressibility and strength properties (c' and ϕ') in a weathering profile. In the Grade VI residual soil, the void ratio will be high due to leaching out of minerals and the resulting structured form of the soil. This open structure results in high compressibility and low strength properties.

Figure 30.9 shows the effect that secondary cementing by sesquioxides (laterisation) can have on the residual soil near the ground surface. This results in an upper profile with variations in the degree of cementing, from a concretionary or partly cemented layer to a fully cemented layer at the surface. The presence of the sesquioxides partially fills voids and reduces

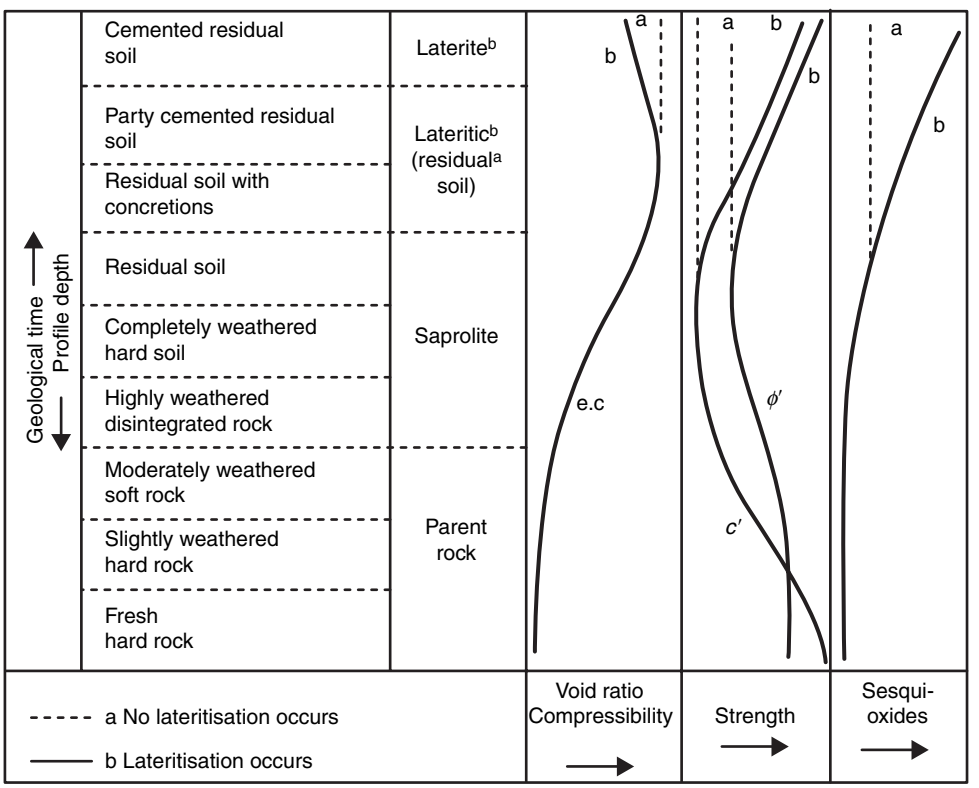

Figure 30.9 Changes in compressibility and strength in a weathering profile
Reproduced from Blight (1997), Taylor & Francis Group (adapted from Tuncer and Lohnes, 1977 and Sueoka, 1988)

the compressibility. Secondary cementing also produces major improvements in strength properties.

The permeability of tropical residual soils is controlled to a large extent by the macro-structure provided by relict joints etc. The more mature residual soils (Grade VI) may have lower permeability (**Table 30.12**), as the weathering will modify the macro-fabric and reduce the dominance of relict joints, as well as producing more clay minerals. However, materials that have been laterised can have higher permeability due to the open micro-structure and vesicular nature of the more cemented materials.

30.3.4 Problematic behaviour

Geotechnical classification schemes such as the Unified Soil Classification Scheme (USCS), which are widely used for temperate sedimentary soils, have severe limitations when applied to tropical soils. This gives tropical soils a reputation for being 'problematic' as they do not conform to these simple classification systems. However, many tropical soils, particularly the 'red' soils, can be good engineering materials and are often not problematic.

That is not to say that all tropical soils are problem-free. Some residual soils can exist in a loose state. Some ferruginous soils (Red Coffee soils) may exist with densities as low as 0.6 Mg/m^3, i.e. less than the density of water. This loose structure may be sustained by an unsaturated state, where suctions give strength to clay 'bridges', supporting the coarser particles and maintaining a low density. If the soil is wetted, so that the strength of the clay bridges is lost, the soil may collapse. Cementing agents may also maintain a loose metastable structure. If the soil is loaded beyond the yield strength of the bonding material, this can also lead to collapse. More information is provided in Chapter 32 *Collapsible soils*.

A further factor to be aware of is that the particles themselves may be crushable; this may be due to a loss of intrinsic strength as a result of chemical attack during weathering, or it may be that the coarse-grained size fraction is in fact made up of finer particles that are held together by secondary cementing or by a clay matrix. When subjected to high stresses the particles may start to crush, resulting in additional volumetric compressions (Lee and Coop, 1995).

Zone	Relative permeability
Organic topsoils	Medium to high
Mature residual soil and/or colluvium	Low (generally medium or high in lateritic soils if pores or cavities present)
Young residual or saprolitic soil	Medium
Saprolite	High
Weathered rock	Medium to High
Sound rock	Low to medium

Table 30.12 Permeability of weathering profiles in igneous and metamorphic rocks
Data taken from Deere and Patton (1971)

Another major problematic type of tropical soil is vertisols, as they contain smectite clays and can be highly expansive. Information on dealing with such swelling/shrinking soils is discussed in Chapter 33 *Expansive soils*.

Other problematic aspects of tropical soils are identified below. In many cases, the soils are not problematic *per se*, but problems result from inappropriate use of classification systems that were designed for temperate soils and are not applicable to tropical soils.

30.3.4.1 Presence of 'unusual' clay minerals

Some clay minerals found in tropical soils (halloysite and allophane) exist in non-platey forms. These are unlike the common clay minerals found in temperate soils (kaolinite, illite, montmorillonite), which are generally platey in nature. The engineering behaviour of allophanous or halloysitic soils is often very different from what would be predicted by schemes like the USCS (Wesley, 1973, 1977).

Allophane is amorphous (or is poorly structured) and can hold significant amounts of water within the amorphous mineral. On drying it appears that allophane forms a more ordered structure, completely changing the nature of the soil. An allophanous clay can change in behaviour to appear like a sand after drying.

Halloysite is a member of the kaolinite family but has a tubular habit. Water can be held within the 'tubes', where it does not contribute to the engineering behaviour. Halloysite exists in two forms: hydrated halloysite and metahalloysite containing no water of crystallisation. In metahalloysite the 'tubes' may split or become partially unrolled. The transition takes place if the moisture content reduces below about 10% or the relative humidity drops below about 40% (Newill, 1961). The change is irreversible.

Because of the ability of allophane and halloysite to hold water that does not contribute to the engineering behaviour, they are often classified as troublesome soils (since they have high natural water contents and liquid limits) (Wesley, 1973). However, they generally have very good engineering properties (Wesley, 1977). They show high angles of shearing resistance (compared to kaolinite or montmorillonite). Also, since they are not platey in form, they do not show a significant reduction in angle of shearing resistance due to clay particle alignment. Therefore, residual angles of shearing resistance are also high.

30.3.4.2 Presence of cementing agents

Many tropical soils are structured due to the presence of cementing agents that produce a physical bonding between soil particles. Schemes like the USCS are based on measurements on remoulded (or destructured) soil (Atterberg limits and particle size determination) and therefore cannot take account of soil structure. This is a severe limitation even for many temperate soils, but can be particularly limiting for tropical soils.

Under tropical weathering conditions iron and aluminium oxides are released and are not dissolved (as would occur in more acidic environments), so remain *in situ*. The presence

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

of iron and aluminium oxides significantly affects the behaviour of tropical soils. Newill (1961) demonstrated that these oxides can suppress the plasticity of tropical clay soils, since on removal of the iron oxides the liquid limit was found to increase. This is the case if the oxides have an aggregating effect on the clay minerals. However, it is also possible for the oxides to contribute to plasticity, as was found by Townsend *et al.* (1971). If the oxides are present as amorphous colloids they can have a large water retention capability due to their large specific surface, and will then contribute to plasticity.

30.3.4.3 Difficulties in determining Atterberg limits

Atterberg limit determinations on tropical soils are sensitive to the methods of preparation (e.g. Moh and Mazhar, 1969). Different degrees of pre-test drying (e.g. oven dried, air dried or tested from natural moisture content) can produce very significant differences in the Atterberg limits (Anon., 1990; Fookes, 1997). In addition the amount of mixing of the soil during test preparation can also change the index properties significantly (Newill, 1961).

A comparison of the effects of different degrees of pre-test drying on the Atterberg limits is shown in **Table 30.13**. It should be noted that these changes are irreversible, and a permanent change in plasticity is produced by drying. To overcome problems relating to pre-test preparation, Charman (1988) suggests a procedure for testing the susceptibility to the method of preparation. This involves testing at different drying temperatures and different periods of mixing. If sufficient time is not available for such a detailed test programme, the best solution is to test the material without drying below the natural moisture content with a standard mixing time of five minutes.

30.3.4.4 Difficulties in determining particle size distributions

Like Atterberg limits, the measurement of clay content can also be affected by pre-test drying, since the drying process causes the clay particles to aggregate (Newill, 1961). These aggregations are only partially disaggregated by standard dispersion techniques, and clay fractions are often underestimated. For example, a red clay from Sasumua, Kenya showed a clay fraction of 79% when testing at natural moisture content, but this reduced to an apparent value of 47% after oven drying (Terzaghi, 1958). Another problem is that the coarse fraction of red soils often consists of weakly cemented particles which readily break down and change grading during sieving or compaction (Gidigasu, 1972; Omotosho and Akinmusuru, 1992).

30.3.4.5 Unsaturated state

Many tropical soils exist in an unsaturated state, since evapotranspiration is greater than precipitation. Water tables are often greater than 5 m deep, in many cases considerably deeper. The strength of these soils will be very dependent on moisture conditions.

Soil suction is made up of two components: *matric suction* and *osmotic suction* (also called *solute suction*). The sum is known as the *total suction*. Matric suction is due to surface tension forces at the interfaces (menisci) between the water and the gas (usually air) phases present in unsaturated soils (the surface tension effect is sometimes referred to as capillarity). Osmotic suctions are due to the presence of dissolved salts within the pore water.

In much of the soil science literature, suction is expressed in pF units, i.e. the logarithm (to base 10) of the suction expressed in centimetres of water (Schofield, 1935). For engineering applications, it is generally more convenient to use conventional stress units. The relationship to convert from pF units to kPa is given by:

$$\text{suction (kPa)} = 9.81 \times 10^{\text{pF}-2}. \qquad (30.1)$$

The suction scale (showing both kPa and pF units) with some points of reference and indications of the moisture condition of a soil are shown in **Figure 30.10**.

The maximum suction that can be sustained within the pores of a soil will depend on the pore size. In a clean sandy soil, where pore sizes will be of the order of 0.1 mm or larger, the maximum suctions will be very small (typically < 5 kPa). In clean silty materials, where pore sizes might be of the order of 0.01 mm, the maximum suctions are likely to be less than 100 kPa. However, in clayey soils, where pore sizes can be less than 0.001 mm, high suctions greater than 1000 kPa can be sustained. This explains why clean sandy soils have no strength when they dry out (they lose the suction 'bonds' that hold them together as they cannot sustain high suctions). However, clayey soils can become very strong when they dry out, due to the high suctions that are maintained in the fine pores of the soil. The suctions pull the soil particles together and give the soil considerable strength in a dry state.

	At natural moisture content			Air dried			Oven dried (105°C)		
Location	LL	PL	PI	LL	PL	PI	LL	PL	PI
Costa Rica	81	29	52				56	19	37
Dominica	93	56	37	71	43	28			
Kenya (red clay)	101	70	31	77	61	16	65	47	18
Kenya (lateritic gravel)	56	26	30	46	26	20	39	25	14

Table 30.13 Effect of drying on classification tests on red soils

Suction (kPa)	Suction (pF)	Reference points	Moisture condition
1 000 000	7	Oven dry	Dry
100 000	6		
10 000	5		
1 000	4	Wilting point for plants Plastic limit	Moist

1	1		
0.1	0	Liquid limit saturated	

Figure 30.10 The suction scale

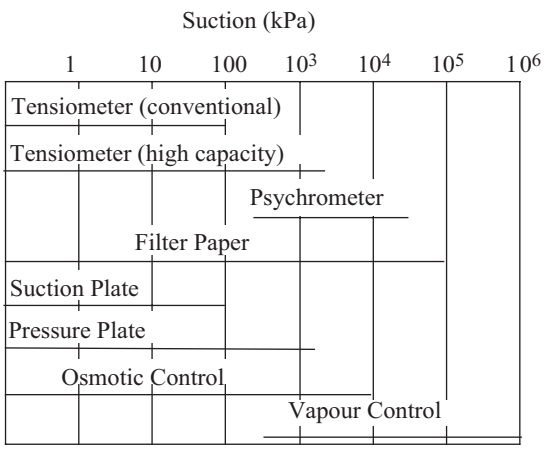

Figure 30.11 Ranges for which suction measuring/controlling devices are suitable

There are a number of different techniques for suction measurement and control. Their suitability varies according to the range of suctions operating. An indication of appropriate ranges is shown in **Figure 30.11**. It is generally necessary to use a variety of techniques in order to cover the entire suction scale.

As a soil dries out (or wets up) the suction within the soil will change. The relationship between water content and suction is known as the soil water retention curve (SWRC) (also called the soil water characteristic curve, SWCC). Although water contents

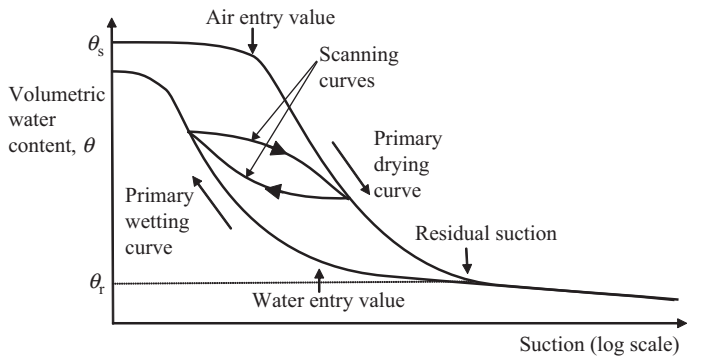

Figure 30.12 Typical soil water retention curve

are usually defined gravimetrically (i.e. by weight) in geotechnical engineering, soil water retention curves are often expressed in terms of volumetric water content, θ, or degree of saturation, S_r versus suction. **Figure 30.12** shows a typical SWRC.

If the soil starts from a saturated state and is then subject to drying, it will follow the *primary drying curve*. At a value of suction known as the *residual suction* (with a corresponding residual water content, θ_r) the SWRC may flatten, and much smaller changes in volumetric water content result from an increase in suction. To achieve zero water content (equivalent to an oven-dried condition) requires a suction of the order of 1 GPa (pF 7) (Fredlund and Xing, 1994). On wetting from an oven-dried state, the soil will follow the *primary wetting curve*. The primary drying and wetting curves define an envelope of possible states within which the soil can exist. If drying is halted part way down the primary drying curve and wetting is started, the soil will follow an intermediate *scanning curve*, which is flatter than the primary wetting curve, until the primary wetting curve is reached. Therefore, different suctions can exist at a given water content depending on the pathway followed.

The most commonly used approach to interpreting shear strength behaviour in unsaturated soils is to adopt an extended version of the traditional Mohr–Coulomb approach. This extension to unsaturated soils was put forward by Fredlund *et al.* (1978). It involves two separate angles of shearing resistance, to represent the contribution to strength from the net stress (total stress referenced to the pore air pressure) and matric suction (the pore water pressure referenced to the pore air pressure), giving the shear strength equation as

$$\tau = c' + (\sigma - u_a) \tan \phi^a + (u_a - u_w) \tan \phi^b, \qquad (30.2)$$

where

τ is shear strength;

c' is the effective cohesion intercept (many tropical soils demonstrate a true cohesion intercept at zero effective stress due to their bonded structure);

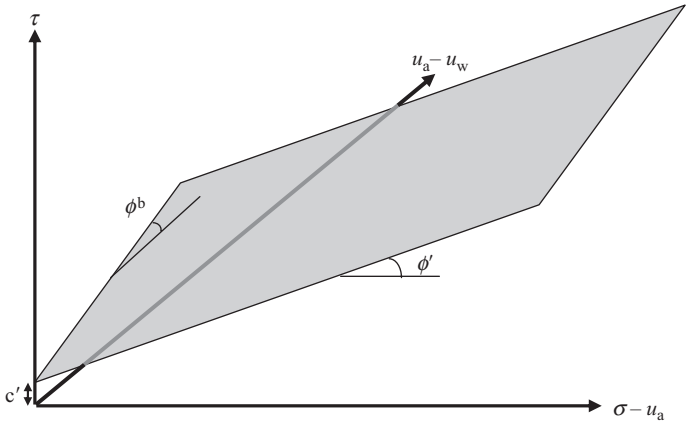

Figure 30.13 The extended Mohr–Coulomb failure envelope

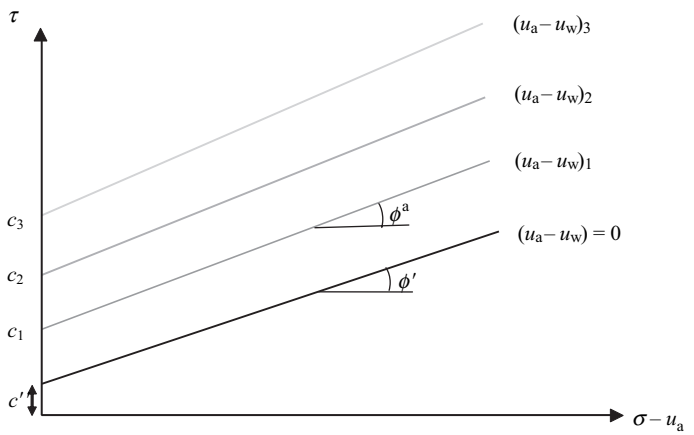

Figure 30.14 The extended Mohr–Coulomb failure envelope in net stress space

ϕ^a is the angle of shearing resistance for changes in net stress $(\sigma - u_a)$;

ϕ^b is the angle of shearing resistance for changes in matrix suction $(u_a - u_w)$.

This separates the effects of net stress $(\sigma - u_a)$ and suction $(u_a - u_w)$ and treats them differently by having two angles of shearing resistance relating to the two components of stress. The extended Mohr–Coulomb failure surface is shown in three dimensions in **Figure 30.13**. The surface is shown by views in the net stress plane in **Figure 30.14** and in the suction plane in **Figure 30.15**.

Figure 30.14 shows that the strength envelope increases as the suction increases. This can be represented as an increase in the total cohesion, c where:

$$c = c' + (u_a - u_w) \tan\phi^b \qquad (30.3)$$

Figure 30.15 shows the increase in total cohesion, c, as the suction increases. The slope of the graph is defined by ϕ^b. The

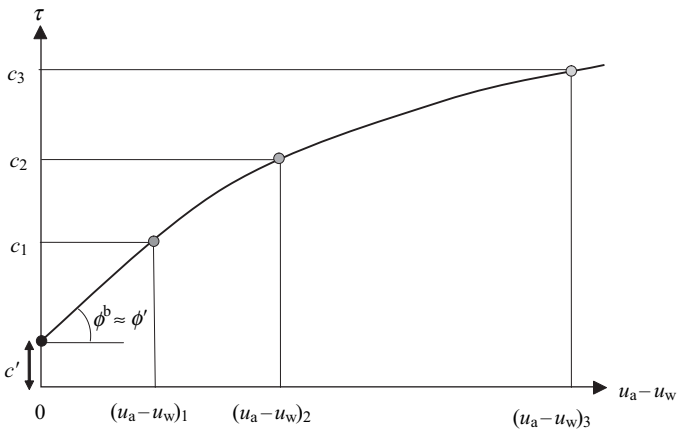

Figure 30.15 The extended Mohr–Coulomb failure envelope in matric suction space

relationship between τ and $(u_a - u_w)$ has been found to be non-linear by Escario and Saez (1986) and Fredlund *et al.* (1987). Below the air entry value (when the soil remains saturated) ϕ^b is equal to ϕ', but at higher suctions the value of ϕ^b reduces (**Figure 30.15**). The tangent value may fall to zero at high suctions, implying no further increase in strength at higher suctions.

A more complete model of unsaturated soil behaviour is that proposed by Alonso *et al.* (1990) and now known as the Barcelona Basic Model. This extends the Modified Cam Clay model to the unsaturated state, and provides the coupling between volumetric and deviatoric behaviour that is essential for a complete understanding of soil behaviour. It introduces the concept of a loading-collapse (LC) surface that defines yielding due either to external loading (total stresses) or wetting (loss of suction).

If the role of suction in an unsaturated soil is not recognised, then test results can be incorrectly interpreted. For instance, the compressibility of an unsaturated soil may be observed to be low at the water content at which the specimen is tested, as a result of the presence of a significant suction. However, the same soil could have much higher compressibility if the soil is wetted and loses the suction. Similarly, an apparent cohesion intercept observed in strength tests may be largely due to suction rather than being a true 'cohesive' contribution to strength from bonding. Again, this component of strength will reduce (and may even be lost entirely) if the soil is wetted.

30.3.5 Foundations

Problems with shallow foundations on tropical residual soils are usually associated either with collapse problems on loose, metastable soils or shrink–swell movements on expansive vertisols.

Collapse settlements can result from overstressing the cemented micro-structure of tropical soils. The compressibility may be low if the stresses applied do not exceed the yield strength of the cementing material. However, if the foundation is loaded beyond this stress, large and rapid settlements can take place.

Collapse settlements of foundations can also occur due to wetting. Some ferruginous soils (Red Coffee soils) may exist with densities as low as 0.6 Mg/m^3, i.e. less than the density of water. This loose structure is often maintained by bridges of clay minerals which support the sand- or silt-sized particles. The strength of these bridges is controlled by suction, and if the soil wets up or becomes flooded, there is a rapid collapse of the loose structure, resulting in large surface settlements.

A build-up in moisture under a pad or raft foundation can occur due to cutting off evaporation and changes in the temperature regime due to construction of a covered area (e.g. a concrete foundation). However, wetting up can also be caused by simpler means, such as the construction of soakaways for buildings, or leaking services, resulting in loss of strength and failure of the foundation.

If shallow foundations are constructed on vertisols, the likely problem will be seasonal movements as water contents change beneath the foundation due to wetting and drying. Foundation heave will be observed in wet season conditions, and settlements will be induced by shrinkage in dry season conditions. The zone of variation of water content will affect the edges of the foundation, while the central area of a large raft may not be affected. This results in differential movements that can be severely deleterious to the foundation and the overlying structure.

Methods to deal with foundation construction on expansive soils are:

30.3.5.1 Removal and replacement

Remove expansive material and replace with non-expansive soils. Generally the expansive layer extends to depths too great to economically allow complete removal and replacement. It must then be determined what depth of excavation and fill will be necessary to prevent excessive heave.

30.3.5.2 Remoulding and compaction

The swell potential of expansive soils can be reduced by decreasing the dry density. Compaction at low densities and at water contents wet of optimum will reduce the swell potential. However, the bearing capacity of the soil at the lower density may not be adequate. Some soils have such a high potential for volume change that compaction control does not significantly reduce swell potential.

30.3.5.3 Surcharge loading

If the surcharge load applied is greater than the swelling pressure then heave can be prevented. For example, a swell pressure of 25 kPa can be controlled by 1.5 m of fill and a concrete foundation. However, swelling pressures are often too high (~400 kPa) for this to be a realistic option.

30.3.5.4 Pre-wetting

This is based on the assumption that increasing the water content will cause heave prior to construction. If the high water content is maintained, there will be no appreciable volume change to damage the structure. However, the procedure has many drawbacks. Expansive soils are normally clays with low permeability, and the time required for adequate wetting may be years. Also, the increase in water content will reduce the strength of the soil and cause reductions in bearing capacity.

30.3.5.5 Moisture control by horizontal and vertical barriers

Soil expansion problems are primarily the result of fluctuations in water content. Non-uniform heave is the major cause of damage, as opposed to total heave. If changes in water content can be made to occur slowly and if the water content distribution can be made uniform, differential heave can be minimised. Moisture barriers do not prevent the heave taking place but have the effect of slowing the rate of heave and providing a more uniform moisture distribution.

Horizontal barriers installed around a building can limit the migration of moisture into the covered area. Concrete aprons, or paved areas for car parking can achieve this. The width of the barrier should be sufficient to extend the 'edge distance', i.e. the distance measured inward from the slab edge over which the soil moisture varies enough to cause soil movement (Post-Tensioning Institute, 1980).

30.3.6 Slopes

Many of the landslides which occur in the saprolitic zone of tropical residual soils are directly or indirectly controlled by relict discontinuities (Brand, 1985; Nieble *et al.*, 1985; Dobie, 1987; Irfan *et al.*, 1987; Irfan and Woods, 1988). Many types of mineral infillings and coatings may be present along relict discontinuities as a result of weathering processes, including clay minerals. Some discontinuities may be polished or slickensided as a result of internal deformation in the slopes (Irfan, 1998). These infilled or polished surfaces may have low residual angles of shearing resistance, providing a plane of weakness, so that failure is constrained to occur on these relict surfaces.

Landslides are often triggered by rainfall, particularly in tropical climatic regions, where rain storms can be very intense. Major landslides occur all too often, but minor landslides occur even more frequently. Although minor landslides may not lead to loss of human life, they still have economic and social impact.

A clear linkage has been established between landslide occurrence and high rainfall in tropical regions of the world. This has been confirmed by studies in Brazil (Wolle and Hachich, 1989), Puerto Rico (Sowers, 1971), Fiji (Vaughan, 1985b), Hong Kong (Brand, 1984; Au, 1998), Japan (Yoshida *et al.*, 1991), Nigeria (Adegoke-Anthony and Agada, 1982), Papua New Guinea (Murray and Olsen, 1988), Singapore (Pitts, 1985; Tan *et al.*, 1987; Chatterjea, 1994; Rahardjo *et al.*, 1998; Toll, 2001), South Africa (van Schalkwyk and Thomas, 1991) and Thailand (Jotisankasa *et al.*, 2008).

Soil slopes in tropical regions are normally unsaturated during the dry season, and the groundwater table may often be at

depths of more than 10 m for most of the year. When the soil is unsaturated, suction or negative pore water pressure provides additional strength to the soil, hence stabilising the slope. This additional strength may disappear during an intense rainstorm when the soil becomes saturated and pore water pressure becomes zero.

Figure 30.16 shows rainfall data for a large number of landslides in Singapore (Toll, 2001). It shows the rainfall on the day of the landslide (*triggering* rainfall) plotted against the rainfall in the five-day period preceding it (*antecedent* rainfall). It can be seen that it is usually not a single rain storm that produces failure; rather it is a build-up of pore water pressure over a number of days due to the antecedent rainfall followed by a storm that finally triggers the landslide event. However, there are occasions where a single storm is big enough to produce a failure even when there has been no significant antecedent rainfall in the preceding days.

It is important when studying climate effects on slopes that we do not always assume that rainfall will produce a rise in water table level. Infiltration of rainfall at the surface can produce significant changes in pore water pressure without a change in water table (although a perched water table may be induced at the surface) (Toll, 2006).

30.3.7 Highways

Traditionally, materials used in the construction of road bases have been clean graded aggregates, generally obtained from crushed rock. However, in tropical climatic zones, good quality rock for crushing is often unavailable because of the extensive weathering that occurs in the tropics. Even when it is available, the costs of processing and transporting the material can make this an uneconomical option. Therefore naturally occurring materials such as lateritic gravels or calcretes are widely used for construction of roads with low traffic volumes. These natural materials generally contain a greater amount of fines, and the fines have higher plasticity, than is accepted by many existing specifications for construction materials. Details of materials which have been successfully used as road base construction materials in the tropics are given by Lionjanga *et al*. (1987), Grace and Toll (1989), Gidigasu (1991), Metcalf (1991), Netterberg (1994) and Gourley and Greening (1997).

Because naturally occurring gravels have greater quantities of fines it means that soil suction and fabric are major factors controlling their behaviour. The presence of around 10% clay in a lateritic gravel was sufficient to provide a matrix with small pore sizes which could sustain significant suctions (Toll, 1991). Yong *et al.* (1982) similarly report that a small clay fraction had an important effect in influencing the suction characteristics of a weathered granite. Therefore, the effects of suction should not be overlooked in granular materials if they contain small amounts of clay. Provided the fines are well distributed, it will be possible to develop high suction throughout the soil. The matrix of fines will then act as a binder which can hold the granular material together, thus imparting overall high strength and stiffness.

The ability to maintain soil suction, and hence maintain good performance, is highly dependent on the avoidance of wetting up of the road base material, particularly in unsurfaced roads. In cases where the water table is close to the surface, the benefits of suction cannot be relied upon, and conventional specifications using good quality aggregates must be adopted. For cases where the water table is more than 5 m below the

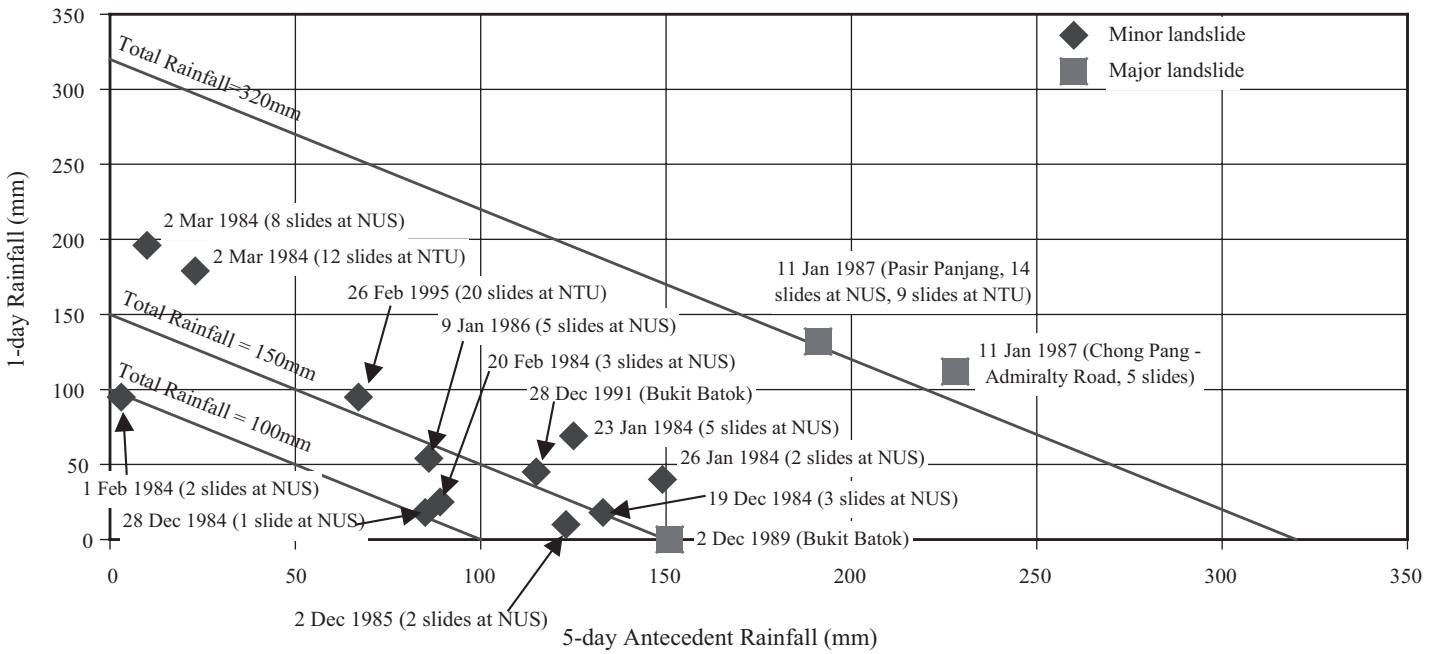

Figure 30.16 Rainfall events leading to landslides in Singapore

ground surface, reliance can be placed on suction, provided drainage measures ensure that water will not pond on the road surface. A bituminous surface is beneficial in preventing direct infiltration into the road base material.

Trial constructions in Kenya of low-volume roads surfaced with a sprayed bituminous seal coat compared lateritic gravel with conventional crushed stone for the road base (Grace and Toll, 1989). It was found that the lateritic gravel sections showed better performance. This was because failures of the bituminous surface coat allowed water to penetrate and spread within the high-permeability crushed stone base, softening the sub-grade and causing large areas of cracking. On the laterite sections, a small pothole formed where the bituminous surface coat failed, but it did not spread, due to the low permeability of the road base material. Any water accumulating in the pothole during a rain storm evaporated during drying periods. Therefore, the laterite sections performed better than the 'higher quality' construction methods.

Toll (1991) argues that a good material for a road base in a sub-tropical or tropical climate will have sufficient fines to allow significant suctions to develop and also produce low permeability. A small amount of clay can be beneficial in this. However, the fines content should not be so great as to suppress the dilatent tendency of the granular fraction or to significantly reduce the angle of shearing resistance. Also, any clay present should have low activity in order to restrict shrinkage and swelling. The fines should be well distributed throughout the fabric if they are to support high suctions and provide a strong binder, holding the granular fraction together. This also produces low permeability.

Charman (1988) provides comparisons between specifications for natural gravels for road bases used around the world. More recently, Paige-Green (2007) gives recommended material specifications for unsealed rural roads (**Table 30.14**) based on experience in southern Africa. This is based on distinguishing between materials that will become slippery, erode, ravel or form corrugations (**Figure 30.17**).

Paige-Green suggests a minimum value of soaked CBR (at 95% modified AASHTO compaction) of 15%. This is even lower than the *minimum* value of 20% suggested by Grace (1991) for bituminous sealed roads, combined with an *average* value of soaked CBR of 40%. Gourley and Greening (1997) suggest a minimum soaked CBR of 45% (at 100% modified AASHTO compaction) for sealed roads carrying less than 0.01 million equivalent standard axles (ESA), but a higher requirement of 55–80% for more highly trafficked roads carrying 0.5 million ESAs (the lower limit for road base CBR of 55% is for a weak sub-grade with CBR = 3–4% and the higher limit of 80% for a strong sub-grade with CBR > 30%).

30.4 Concluding remarks

Tropical soils pose many challenges for geotechnical engineers. They are highly structured at both micro and macro levels. They are often cemented due to deposition of minerals either during or after weathering has taken place. They can be highly heterogeneous. A major difficulty is that traditional classification systems that have been developed for temperate sedimentary soils cannot be used to infer likely engineering behaviour for tropical soils. Simple classification tests, such as Atterberg limits, cannot be easily determined, due to the presence of unusual clay minerals, such as halloysite and allophone, or due to the effects of iron or aluminium sesquioxides.

Tropical soils are often thought of as problematic soils, largely due to the difficulty in classifying them. However, many tropical soils, particularly the 'red' soils, often have good engineering properties, such as low compressibility and high strength. The cemented structure can enhance their strength.

Nevertheless, some tropical soils do demonstrate problematic behaviour. Examples are those that exist in a loose, metastable state that can collapse when loaded, or when subject to wetting. Other problematic tropical soils are vertisols that contain active smectite clay minerals that demonstrate excessive shrink–swell behaviour when subject to drying and wetting.

Property	Value
Maximum size (mm)	37.5
Maximum oversize index (I_o)[1]	5%
Shrinkage product (S_p)[2]	100–365 (maximum of 240 preferable)
Grading coefficient (G_c)[3]	16–34
Soaked CBR (at 95% modified AASHTO compaction)	> 15%
Treton impact value (%)	20–65

[1] I_o, the oversize index, is the percentage retained on 37.5 mm sieve
[2] S_p = linear shrinkage × (% passing 0.425 mm sieve)
[3] G_c = ((% passing 26.5 mm – % passing 2.0 mm) × (% passing 4.75 mm))/100

A large volume of geological literature exists on glacial soils, which are common throughout the world's temperate zone. In the UK they account for some 60% of all soils and globally 10%. There is little published information on geotechnical characteristics despite the number of ground investigations. Glacial soils can vary from deformed basal layers that retain many of the original features of those layers to unsorted mixtures of gravel, sands, silts and clays to laminated clays. They can be deposited through a process of pressure and shear beneath a glacier as it advances, or be deposited when the ice melts. This creates a spatially variable soil which contains features that impact on the mass behaviour and lead to wide variation in results from a single source of glacial soil, making the selection of design parameters difficult. Routine sampling may not pick up these features. Tills are deposited in such a way that their characteristics do not necessarily conform to soil mechanics theory and empirical relationships created from studies of gravitationally compacted soils. Hence developing the ground model depends on knowledge of the genetic classification, creating a regional database to enhance data from new investigations, tests on reconstituted tills and a consistent framework to evaluate the mechanical characteristics.

31.1 Introduction

Glacial soils are a hazard. The modes of deposition result in spatially variable soils, which are difficult to classify and characterise. Inadequate ground investigation and lack of understanding of the impact of processes on the geotechnical behaviour leads to claims and even failures. Yet a large volume of literature exists on Quaternary (glacial) geology (Hughes *et al.*, 1998) and glacial soils are common throughout the world's temperate zone. In the UK they account for some 60% of the soils (**Figure 31.1**) and globally 10%. A more detailed map and GIS database related to features formed during the last glacial event in the UK (the Devensian) are provided by Clark *et al.* (2004). The majority of this literature, which is often contradictory, focuses on geological aspects of glacial till (or till). Although a large number of ground investigations have been carried out in glacial terrains in the UK, only a fraction of the information they revealed is available to the geotechnical profession (Trenter, 1999). Hence the issues highlighted in **Table 31.1**.

Glacial soils include those that are deposited under water (glaciolacustrine and glaciofluvial soils) resulting in consolidation processes that fit with soil mechanics theory developed for gravitationally compacted or sedimented soils. However, the deposition of the majority of glacial soils (tills) is a complex process as a result of periods of glaciation, pore water regimes and source materials leading to spatially variable, unsorted mixes of boulders, gravel, sands, silt and clay which can include lenses and layers of sand and gravel and laminated clay. This clay can include rock flour and clay particles. There is evidence that these tills do not conform to classic theories of soil mechanics (Clarke *et al.*, 1997; Hughes *et al.*, 1998) which means the application of empirical and theoretical rules based on observations of sedimented soils is inappropriate. They can be difficult to sample and the inclusion of gravel and sand lenses can produce a range of stiffness, strength and permeability with depth. Quality sampling is usually restricted to clay matrix-dominant till which is free of cobbles. Any gravel or fissures, which is usual, may affect the sampling, and lead to a wide range of test results for a given property, making it difficult to select design parameters unless there is a clear set of rules to take into account the natural variability and the impact the fabric, composition and the sampling process have upon the derived parameters.

In conclusion, till may have been gravitationally compacted, sheared, possibly reworked and weathered. Till can contain a range of particle sizes from clays to boulders and can vary from clay matrix-dominant till that contains discrete granular particles to clast-dominated tills, which contain some fines. Tills can be fissured and laminated. The implication for the construction industry is that till is a challenging material as it is difficult to predict the characteristics of a particular till. This chapter focuses on tills, though reference is made to other glacial soils to help understand the formation of tills.

31.2 Geological processes

The movement of a glacier or ice sheet across the underlying soil or rock either deforms that material creating a deformation till, or erodes it, moves it to a new location and deposits it either as a lodgement or melt-out till or as a water-lain deposit (**Figure 31.2**). These processes create a range of different debris formations (see **Table 31.2**), which leads to a genetic classification based on those processes (**Table 31.3**). The erosion and transportation processes, for example, result in a breakdown of the material due to crushing, fracturing and abrasion, which may be assisted by freezing of the ground at the base of the

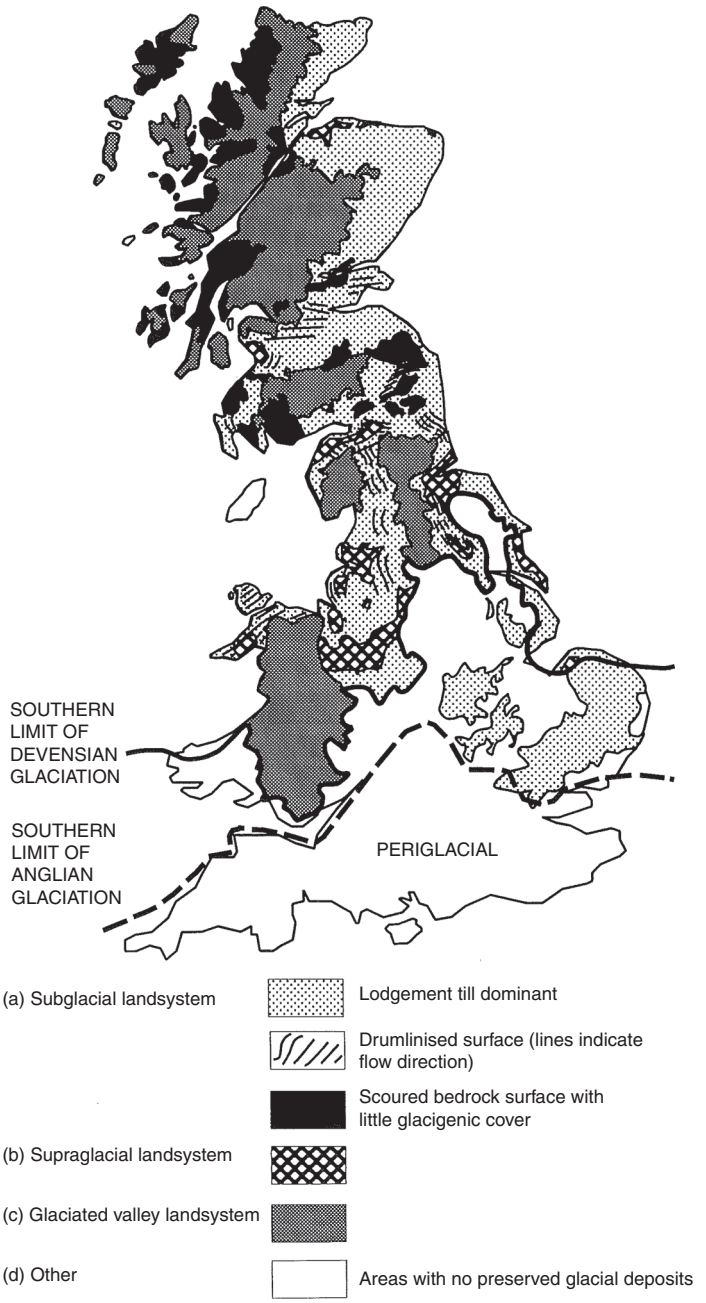

Figure 31.1 Distribution of glacial soils in the UK
Reproduced from Eyles and Dearman (1981), with kind permission from Springer Science+Business Media

glacier. This leads to a homogenised diamicton, which is the geological term used to describe a poorly sorted sediment. If a glacier is moving across soil and that soil is not frozen, then sub-glacial deformation can occur. Hence it is possible to find glacio-tectonic features, such as faults and folds (**Figure 31.3**), in glacial soils. Further deformation results in the folded material breaking up, leading to pockets of original layers known as boudins within the till matrix. Glacial soils produced from ice sheets are all derived from the base of the ice sheet. Glacial soils produced from valley glaciers can include supraglacial debris that falls from the valley sides. Glacial debris is classed as sub-glacial (base of the glacier), supraglacial (surface of the glacier) or englacial (within the glacier). Supraglacial and englacial materials may not be modified by the movement of the ice; basal materials are modified because of abrasion and crushing. Debris can move between these three zones depending on the physical processes that take place within the glacier as it moves and as the temperature changes. The debris (**Figure 31.4**) can be spread into place beneath a glacier (e.g. lodgement and deformation tills); deposited beneath a glacier as the glacier melts (e.g. melt-out till); deposited within a melt-water lake (e.g. laminated clays); or deposited from melt-water streams (e.g. sands and gravels). Glacial deposits are divided into those that are typically sorted or structured deposits from melt water; and directly deposited non-sorted deposits. This simple classification can be misleading because directly deposited glacial soils can contain layers, lenses or pockets of stratified water-lain deposits if the glacier has passed over a deformable bed composed of water-lain deposits, which may or may not be a glacial deposit.

It must be noted that glaciers can move considerable distances and advance and re-advance during cold periods and retreat (or melt) during warm periods. It is estimated that the UK experienced up to 16 periods of glaciation during the Pleistocene era (approximately the last two million years) (DoE, 1994). The consequence of this is that glacial soils may have moved several times and been deposited in different forms. This contributes to the complex deposits of spatially variable glacial soils. It also implies that a simple classification of glacial soils may not be possible.

Consider a glacier moving across a rock surface (**Figure 31.5**). The rock is eroded creating a mixture of boulders, gravels, sands and rock flour. This material may be moved a short distance and be deposited at the base of the glacier. As the glacier continues to advance abrasion of the sub-glacial layer continues, leading to an unsorted mix which, when deposited, is known as lodgement till. Some of the sub-glacial material will migrate into the glacier. This can either be deposited as melt-out till or melt-water deposits as the glacier retreats. The next time the glacier advances it advances over till. Initially the till will deform, the amount of deformation depending on the distance moved, the pressures and the temperature profile. This till now becomes deformation till, using the definition that it is a sub-glacial material that has not moved very far before being deposited. Therefore a deformation till could contain traces of previous glacial deposits (**Figures 31.3** and **31.5**). Further movement can increase the amount of abrasion and crushing, leading to a lodgement till. This is why it is not unexpected to find lenses of water-lain deposits of laminated clays and sands and gravels within what appears to be a till. It explains why rock particles can be found many miles from their original source and still be intact and why rock particles from one source can be widely distributed. It also shows why

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Construction process	Hazard	Description
Investigation	Strength	Some tills are so strong that it is difficult to obtain undisturbed samples. The fabric of till can have a significant effect on the strength determined from routine tests. Empirical correlations developed for stiff clays may not apply to basal tills. Boreholes may not be positioned to pass through zones of weaker materials.
	Permeability	*In situ* permeability is often greater than that measured in the laboratory because of fissures and laminations.
	Boulders	This could lead to false identification of rock head from borehole records.
	Laminated clay	It will be difficult to identify whether this is a pocket or layer of laminated clay from borehole records.
	Sand and gravel	It will be difficult to identify whether this is a pocket or layer of sand and gravel from borehole records.
Excavation	Strength	Some glacial soils, particularly basal tills, are very dense and hence difficult to excavate; explosives and road picks have been used. Basal tills can contain pockets of more ductile soil which can influence the stability of excavations.
	Boulders	Some glacial soils may contain boulders which can vary in size up to rafts of rock. These could be an issue for excavations for piles, tunnels or diaphragm walls.
	Boulder beds	These can occur between different layers of tills or within melt-out tills and basal till. Their presence will impact on any form of excavation.
	Laminated clay	Deformation till formed from glaciolacustrine deposits can include pockets and lenses or layers of laminated clays. These may be softer than the surrounding till, leading to instability.
	Sand and gravel	Glaciolacustrine deposits and deformation till formed from glaciolacustrine deposits can include pockets and lenses or layers of sands and gravels. These could be water-bearing and, if connected to an aquifer or source of water, lead to flooding.
	Fissures	Many basal tills are fissured as a result of depositional processes. This can lead to block failure and the development of shear zones.
Design	Strength	The *in situ* undrained shear strength of some basal tills exceeds that measured in the laboratory. This leads to overdesigned foundations.
	Stiffness	The stiffness of some basal tills is such that settlement calculations overpredict the amount of settlement. The stiffness of some tills is such that the pore water response is lower than expected.
	Boulders	These are more of an issue for excavation, but the presence of a boulder could lead to an unsafe estimate of performance of a test pile.
	Boulder beds	This could lead to differential movements of a group of end-bearing piles.
	Laminated clay	Pockets of laminated clay could lead to differential movement of a group of piles. Laminated clay beneath the base of piles could lead to excessive settlement. Laminated clay over the pile length could reduce the capacity. Laminated clay layers could trigger slope failures in the longer term.
	Sand and gravel	Pockets of sand and gravel could lead to differential movement of a group of piles.

Table 31.1 Examples of construction problems associated with glacial soils

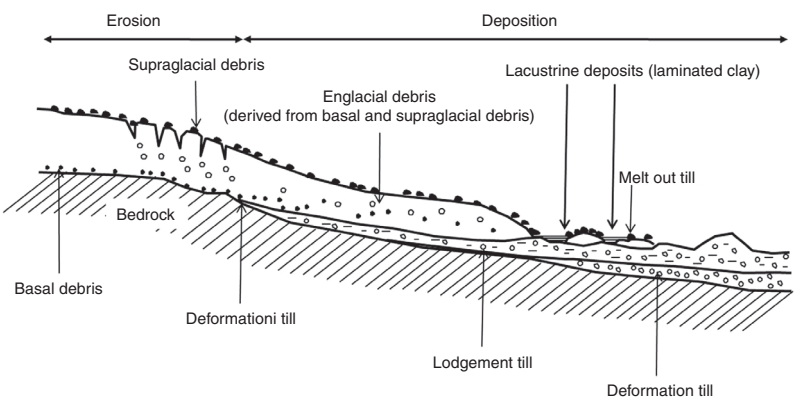

Figure 31.2 The formation of glacial soils
Reproduced from Hambrey (1994); UCL Press

Type of debris	Deposition Environment	Type of glacial soil	Description
Supraglacial			Debris that is carried on the surface of a glacier; derived from rock falls and, possibly, from the glacier bed
Englacial			Debris that is found within a glacier either derived from supraglacial or sub-glacial material
Sub-Glacial			Debris that is deposited from the base of a glacier
	Glacioterrestial		Basal deposits on land
		Melt-out till	Deposited by melting of stagnant or slowly moving debris-rich glacier ice without subsequent transport or deformation
		Flow till	Deposits that flow from the margin of a glacier
		Lodgement till	Deposited by spreading under pressure glacial debris from a sliding glacier bed
		Deformation till	Sediment which has been disaggregated and (possibly) homogenised by shearing in the subglacial deformed layer
	Glaciofluvial		Sand and gravel deposited from water from a melting glacier
		Ice marginal	Adjacent to the glacier
		Proglacial	Deposited in front of or just beyond the outer limits of a glacier or ice sheet
		Sub-glacial	Deposited beneath the glacier
	Glaciolacustrine		Laminated clays found in ice dammed lakes
		Ice contact	Deposited adjacent to the ice margin
		Distal	Deposited some distance from the glacier
	Glaciomarine		Glacial deposits found within a marine environment
		Fjord	Deposited within a fjord
		Continental	Deposited on the continental shelf
		Waterlain	Deposited by water
		Proximal	Deposited near to the glacier
		Distal	Deposited some distance from the glacier

Table 31.2 Key descriptions of glacial materials

it is difficult to be certain that an unsorted soil of glacial origin can be classified as a lodgement till.

There is a genetic classification of tills (**Figure 31.4** and **Table 31.3**) based on those produced after one cycle of advance and retreat of a glacier. This classification may not apply in practice because of the cycles of advance and retreat of glaciers leading to glacial deposits being transported and deposited several times. In addition to the glacial action, post-glacial processes can also alter the properties of glacial soils both between movements of a glacier and since the last glaciation. This adds a further complication when interpreting glacial soil profiles. For example, in northern England it is not uncommon to find three layers of glacial soil: an upper and lower red till separated by a thin layer of sand and gravel or laminated clay from a lower grey till (**Figure 31.6**). It is commonly stated that this succession was originally deposited as a grey lodgement till by a single ice sheet advance, and that the reddish colour of the upper till is solely due to post-glacial weathering (Eyles and Sladen, 1981; Lunn, 1995). There are, however, some aspects of the composition of the glacial succession that do not seem to be adequately explained by this single deposit and weathering concept. These include the red (upper) till generally having a much lower stone content (gravel, cobbles, boulders) than the grey (lower) till (Beaumont, 1968) and the frequency and extent of the sand/gravel laminated clay layers, which in some cases are well over a square kilometre in area, are very probably pro-glacial (glaciolacustrine/glaciofluvial) deposits and therefore indicate that the ice front was receding and releasing debris-laden melt water before the area was again overlain by later ice and ice-transported deposits (Hughes *et al.*, 1998). This demonstrates the difficulty of producing a simple geotechnical model from a complex deposition process which is not fully understood; although a number of geological and hydrogeological domains are distinguishable based on field characteristics (e.g. McMillan *et al.*, 2000 for further details).

The consequences of a failure to understand the geological model can be dramatic, as highlighted in **Table 31.1**. The sample descriptions leading to the soil classification do not

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Criterion	Lodgement till	Melt-out till	Flow till	Deformation till
Deposition	Deposited by plastering of glacial debris from the sliding base of a moving glacier, by pressure melting and/or other mechanical processes (Hambrey, 1994)	Deposited by a slow release of glacial debris from ice, neither sliding nor deforming internally (Dreimanis, 1988)	Deposition accomplished by gravitational slope processes and may occur supraglacially, sub-glacially or at the ice-margin (Dreimanis, 1988)	Comprises rock or unconsolidated sediment detached by the glacier from its source; primary sedimentary structures distorted or destroyed and some foreign material admixed (Elson, 1988)
Position and sequence	Lodged over older glacial sediments or on bedrock	Usually deposited during glacial retreat	Most commonly the uppermost glacigenic deposit	Formed and deposited sub-glacially, often where the glacier moves upslope
Basal contact	Lodgement and melt-out tills formed and deposited at glacial base. Contact with the substratum (bedrock or unconsolidated sediments) generally erosional and sharp Glacial erosion-marks and clast alignment have same orientation. Supraglacial melt-out tills may have variable basal contact		Variable basal contact but seldom conformable over longer distances. Tills may fill shallow channels or depressions	Variable basal contact
Landforms	Mainly ground moraines, drumlins, flutes and other sub-glacial landforms	Those ice-marginal landforms where glacier ice stagnated	Associated with most ice-marginal landforms	Landforms rarely diagnostic
Thickness	Typically one to a few metres thick but may attain substantial thickness in the English lowlands; relative lateral consistency	Single units usually a few centimetres to a few metres thick. Units may stack to much greater accumulated thickness	Very variable. Individual flows usually a few tens of centimetres to metres thick. Units may stack to accumulated thickness of many metres	Varies up to many metres depending upon nature of glacier bed
Structure	Usually massive but may contain various consistently oriented macro- and microstructures. Sub-horizontal jointing common and vertical and transverse joints may also be present. Orientation of deformation structures related to stress applied by moving glacier and may be laterally consistent	Either massive, or with faint structures partially preserved from debris stratification in basal debris-rich ice. Loss of volume with melting leads to draping of sorted sediments over large clasts	Either massive or displaying various flow structures depending on type of flow and water content	Primary structure may be preserved but usually deformed, especially in upper part of the sequence which may blend into other massive tills
Grain size composition	Abrasion in traction zone during lodgement produces silt-size particles typical of lodgement tills. Most have relatively consistent grain-size composition except for the basal part which may contain boulders of local glacier bed	Winnowing of silt and clay-size particles occurs during melt-out. Some particle size variability inherited from debris bands in ice. Supraglacial melt-out tills of valley glaciers contain characteristic coarse-grained debris	Usually diamicton with polymodal particle size distribution. Some particle size redistribution and sorting may occur during flow. Inverse or normal grading may develop	Deformation tills derived from weak rocks contain clasts separated by minor amounts of finer matrix. Clast size reflects bedding thickness of original material
Lithology of clasts and matrix	Lithological composition often more consistent than other tills. Composition of matrix particularly uniform. Materials of local derivation increase in abundance towards basal contact	Supraglacial melt-out till more variable in composition with increased possibility of exotic material	Lithological composition generally same as source material. May include incorporated glacier bed or exotic materials depending on debris source, transport and deposition	Deformation tills generally have same lithological composition as underlying sediments. Occasional erratics present particularly in upper part of the sequence

Table 31.3 (continued)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Criterion	Lodgement till	Melt-out till	Flow till	Deformation till
Clast shapes and their surface marks	Sub-angular to sub-rounded clasts. Bullet-shaped, faceted, crushed, sheared and streaked-out clasts more common in lodgement than other tills. Lodged clasts striated parallel to direction of the lodging movement	Variable degree of roundness but angular clasts occur where supraglacial melt-out debris is englacially or supraglacially derived	If present, soft sediment clasts may be rounded or deformed by shear. More resistant rock clasts will retain their original shape	Clast shape and surface marks generally inherited from original material and not diagnostic. Clasts generally transported passively and not significantly modified
Fabric	Strong macro fabric with clast long axes parallel to local direction of movement. Transverse orientation possible, associated with folding and shearing	Fabric inherited from glacier transport. Melt-out process may weaken fabric, particularly micro-fabric	Fabric may be random or strongly developed and parallel or transverse to flow direction. Fabric may vary laterally over short distances	Preferred orientation rare and generally reflects shearing deformation
Consolidation	Consolidation process depends on pore pressure regime, temperature profile and permeability of glacier bed. Tills can be 'lightly overconsolidated' to 'heavily overconsolidated'	Lightly overconsolidated	Usually normally consolidated	Variably consolidated
Density	Very dense, often in excess of gravitationally compacted stiff clays due to combination of normal and shear stress during deposition	Bulk density lower and more variable than lodgement till	Density lower than lodgement tills and typical of normally consolidated deposits	Spatially variable densities due to presence of lower density pockets of material and dilatency during deformation
Strength	Very strong due to high densities. Strengths can approach those of weak rock in some cases	Strength lower and more variable than lodgement till	Strengths typical of normally consolidated deposits	Spatially variable strength due to presence of lower density pockets of material and dilatency during deformation
Permeability	Highly impermeable if a clay matrix-dominant till	Permeability variable due to mix of particle sizes	Relatively permeable compared to clay matrix-dominant lodgement tills	Spatially variable strength due to presence of lower density pockets of material and dilatency during deformation

necessarily describe the macro and micro behaviour of the soil mass. Laminated lenses or layers may trigger failures in excavated slopes; lenses of sand and gravels can lead to local collapses in excavations and, importantly, in open hole excavations; layers of water-bearing sand and gravel can flood excavations; boulders can impede piling and tunnelling operations; failure to correctly identify rock head can affect the design and construction of end-bearing piles and tunnels along the rock head elevation.

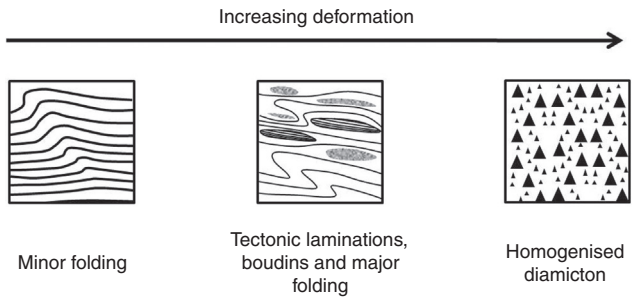

Figure 31.3 Glaciotectonic features found in deformation tills

31.3 Features of glacial soils

A genetic classification of glacial soils is based on the deposition process (**Figure 31.4**). The source of glacial material controls the lithology of the particles and, possibly, the grain size distribution and particle morphology (e.g. Benn and Evans, 1998). The mode of transport effects the abrasion process and hence the morphology, grain size distribution, fabric and structure. The deposition process affects the geological and geotechnical profile. Lawson (1981) defined till as a sediment deposited directly by glaciers which is a primary deposit including lodgement till, deformation till, communition

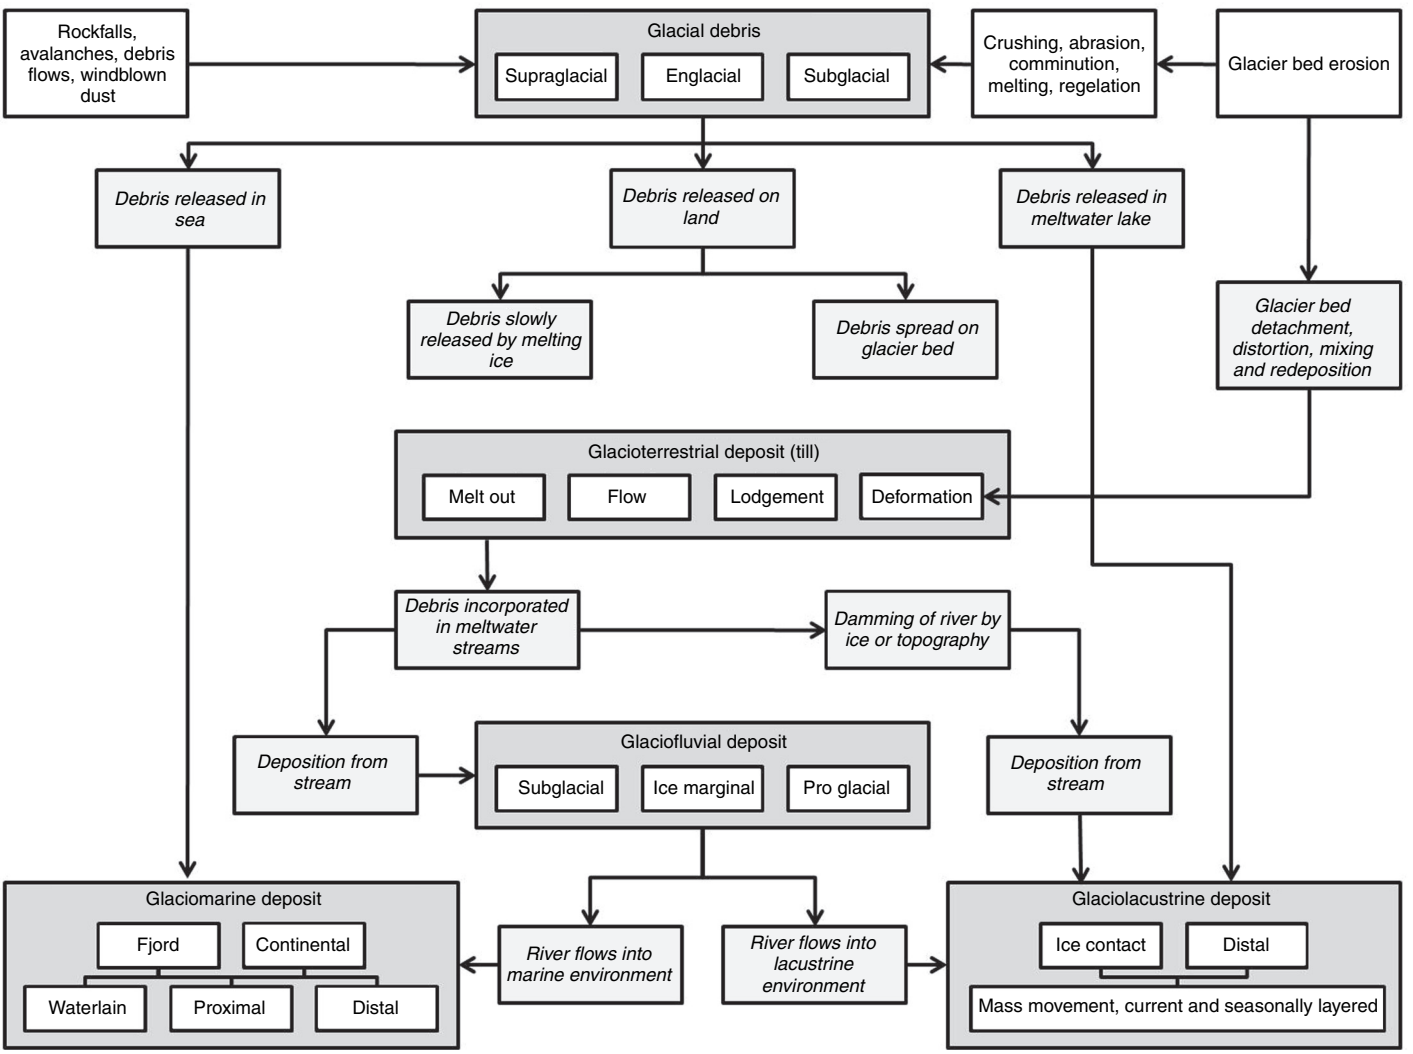

Figure 31.4 The transport and deposition processes for glacial soils leading to a genetic classification. Table 31.2 lists definitions of the key terms
Reproduced with permission from CIRIA C504, Trenter (1999), www.ciria.org

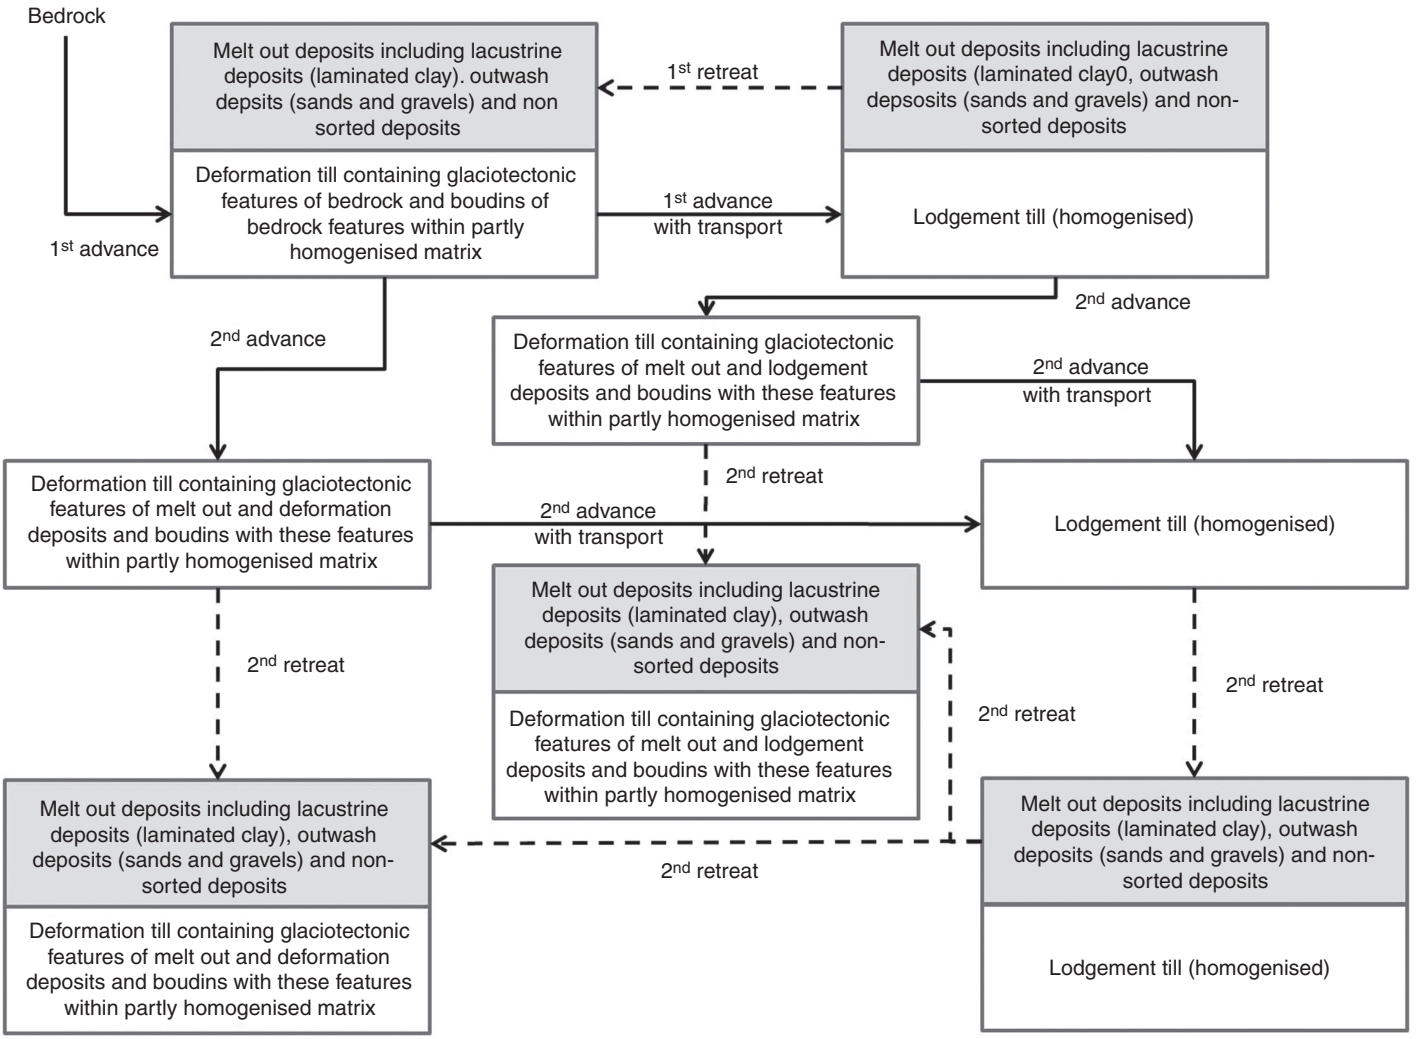

Figure 31.5 The processes at the base of a glacier showing how reworking of a glacial landscape can incorporate features of glacial soils in subsequent glacial deposits

till (formed by sub-glacial grinding or crushing) and melt-out till. There are a number of types of failures of tills which occur because of their fabric (**Table 31.1**). In this case fabric refers to depositional and post-depositional processes (Trenter, 1999) which create the clasts, layers, lenses, fissures, cracks and joints found in tills. The risks associated with these features can be substantially reduced by building up a ground model of local glacial geology from other investigations and observations of excavations. Fookes (1997) describes the total geological model, which is based on the principle that you start by creating a geological model of the site from known regional and local information, and that preliminary model drives the design of the ground investigation which is designed to confirm the model, fill in the gaps in the model and produce data to characterise the ground and produce design parameters.

31.3.1 Deformation till

Deformation till is formed of soil, which may or may not be glacial in origin. Ice moving across this soil will start to deform the soil, initially leading to glaciotectonic features of faults and folds, sometimes separately referred to as glaciotectonite. As the ice continues to move, these features will be further distorted. Folded material (**Figures 31.3** and **31.5**) will become detached to create pockets of material within the till. These, known as boudins, will become increasingly drawn out, forming tectonic laminations and eventually homogeneous till.

Deformation tills that have been deposited by a glacier passing over rock head will contain intact rock fragments, which can be extensive, leading to the possibility that rock head may be incorrectly identified. The lateral extent of rock encountered in a borehole is unknown, but observations from excavations indicate that the pieces of rock can vary in size from

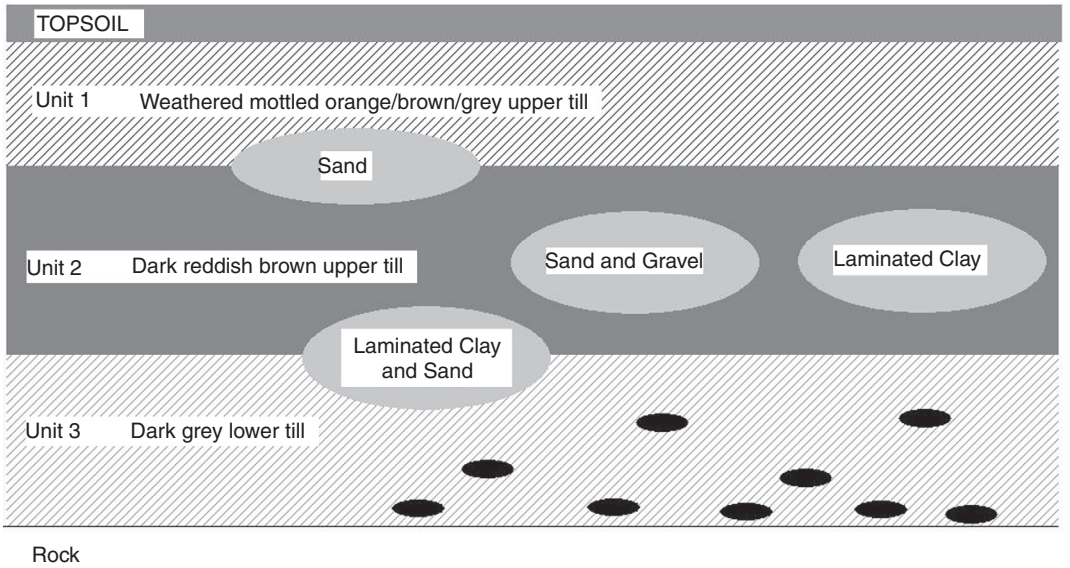

Figure 31.6 A tripartite succession found in the north of England showing three units of till separated by thin layers of laminated clays and sands and gravels
Reproduced from Clarke *et al.* (2008)

boulders to extensive rafts of rock. Therefore it is important to prove rock head. These boulders and rafts of rock can present problems during excavation. It is very difficult to indicate how many boulders will be present from borehole records. It is prudent to assume that till contains boulders even if none are encountered in the boreholes.

Deformation tills that have been deposited by a glacier passing over glacial soils will contain remnants of those soils often within a matrix of gravel, sands, silts clay and rock flour. These could include intact rock fragments, lodgement till, melt-water tills including laminated clays, and lenses of sands and gravels. It may be difficult to identify whether they are isolated pockets of these materials or layers of materials. It is prudent to assume that glacial soils can contain pockets and lenses of more ductile material. Laminated clay pockets could lead to zones of weakness and potential failure, especially in excavations (see **Table 31.1**). Sand and gravel lenses could be water-bearing and, if interconnected, lead to potential flooding of excavations. These features are common, suggesting many tills are deformation tills derived from melt-out, deformation and lodgement tills.

Many basal tills (or sub-glacial tills) are deformation tills (e.g. Bennett and Glasser, 1996). Indeed the deformation process could be responsible for many of the hazards listed in **Table 31.1**. The fact that these tills are created from underlying soil, which may have been deposited by a previous glaciation, means that the composition of the till is the same as the underlying soil. This may make it difficult to identify the base of a deformation till. The till could contain glaciotectonic features, rafts of intact soil or rock that have not been subject to abrasion and a range of particle sizes and pockets of intact, possibly distorted, material such as laminated clay as well as sands and gravels.

Thus samples may not be representative of the soil mass, leading to uncertainty over the 3D geological model. There could be unidentified zones of weakness (e.g. laminated clay lenses) or misinterpreted zones of weakness. For example, failures in excavations in till have been triggered by lenses of laminated clay – especially where they dipped into the excavation. There could be water-bearing layers. For example, a piling contractor took the view that the soil description referred to a clay and therefore open boreholes could be used. Unfortunately one borehole encountered a sand layer which proved to be continuous across the site and possibly connected to a nearby river. This led to all boreholes being fully cased. Proving rock head is critical, especially when considering end bearing piles or tunnelling operations.

31.3.2 Lodgement till

This is a sub-glacial or basal till, which is deposited as ice advances because the frictional resistance between the till and the bed is greater than the shear introduced by the moving ice. There are two theories of deposition: one related to effective stress at the bed of the glacier (Boulton, 1974) and the other (Hallett, 1979) in which the contact pressure between the glacial soil and bed is independent of the effective stress. In the effective-stress model, the stress is created by the weight of ice and the water pressure. The stress will depend on the temperature at the base of the glacier and the hydrological characteristics of the bed. The effective stress will increase as the permeability of the bed below a warm-based glacier increases. This means abrasion will increase if the debris continues to

move. However, the friction between the debris and the bed will also increase, which could lead to the deposition of the debris due to lodgement. If the bed is less permeable, then the effective stress will not be as great. If the bed of the glacier is frozen, the effective and total stress will be similar. The debris can be deposited at any time, depending on the friction.

The alternative view (Hallett, 1979) is that the debris is carried by the ice. Abrasion occurs as the debris moves across the bed. The debris will be deposited as the ice slows down or melts. Both of these theories are correct at some time as they depend on the depth of ice, the speed of ice movement and the temperature profile (**Figure 31.7**).

Lodgement tills are generally a very dense mixture of sands, silts and clays or rock flour and could be considered a relatively uniform deposit. Often they are a clay matrix till containing gravel, which typically has rounded edges, striated faces and is aligned with the direction of flow. The particle size distribution can be uniform or gap graded. Shear planes are evident.

Lodgement tills are difficult to sample because of their density and presence of gravel. Thick-walled sampling tubes are commonly use, which can lead to sample disturbance. For the same reasons it is difficult to sub-sample these tills, hence strength tests are usually based on 100 mm samples. *In situ* strength can exceed laboratory-measured strengths. This has affected tunnelling operations because the assumed strength was less than the *in situ* strength. These tills are described as clays and therefore there is an assumption that they have an undrained shear strength. Designs based on that strength are often conservative because the mobilised strength is much greater. These tills have been highly remoulded and can include shear planes, which means that their expected behaviour based on classic soil mechanics theories and the interpretation of standard laboratory tests is not experienced. The tills are denser, stronger and stiffer *in situ* than predicted from routine site investigations. This does lead to conservative designs, but given the uncertainties over the 3D model from a site investigation that is acceptable unless use can be made of regional knowledge.

31.3.3 Sub-glacial melt-out till

This till comprises debris deposited as a glacier melts primarily due to geothermal heat. There may also be sediment flow features. A key difference between this till and lodgement till is that this till is likely to be less dense as the till was lowered into place rather than spread into place. These tills are characterised by their variability leading to difficulty in selecting characteristic design parameters.

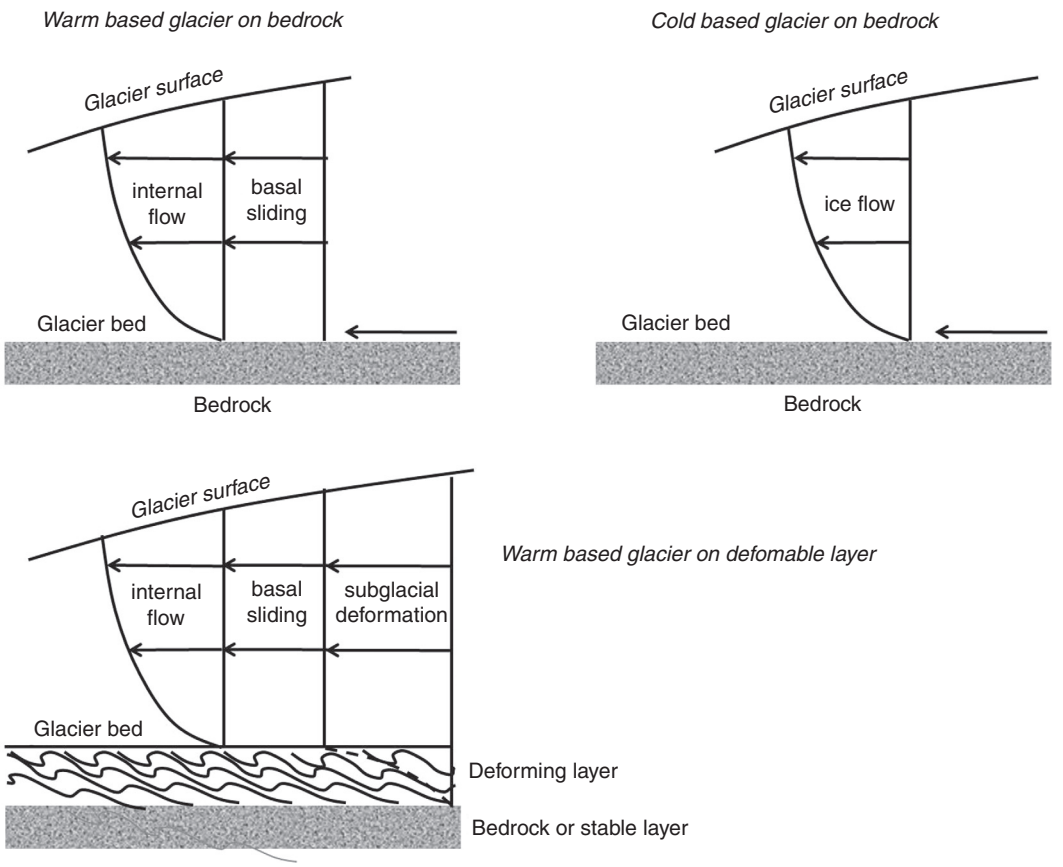

Figure 31.7 The relationship between the temperature profile and type of bed and the effect that they can have on the depositional process. The contours within the ice mass refer to the relative deformation of the ice
Reproduced from Boulton (1976); The Royal Society of Canada

31.3.4 Supraglacial melt-out till

This till is formed as the surface of a glacier melts. It is typically a loose, coarse, angular deposit that has been reworked because of movements of debris associated with flow and topography. As the ice melts releasing the supraglacial and englacial debris, the debris can insulate the underlying ice leading to an irregular topography. In this case, the debris will eventually be deposited as an ablation till creating a landform of moraines (mounds or ridges) of various types including lateral moraines formed at the margin of the ice, hummocky moraines deposited as the ice retreats and end moraines formed at the front of a glacier. If the debris layer is thin, then the ice melts uniformly leaving a thin layer of coarse material. These layers could include outwash sediments. The total extent of supraglacial till is significantly less than that of sub-glacial tills because it is deposited only when the ice melts.

31.3.5 Macro features of tills

The periods of glaciation sometimes lead to layers of different tills separated by a thin layer of sands and gravels or laminated clay. The upper tills are variously described as a distinctly different lodgement till to the lower layer or a weathered version of the lower layer. They are often of a different colour, supporting the weathering hypothesis, though the alternative is that the source of the till is different.

Deformation and lodgement tills often contain shear planes (e.g. Boulton, 1970) with associated conjugate shears because of the shearing that takes place as the tills are moved. These planes can lead to local failures and block failures in excavations. Both deformation and lodgement tills are very dense and brittle. It is difficult to recreate this density in soil mechanics laboratories due to the shearing process linked to the pressure of the weight of ice. The shearing process also means that these tills are highly remoulded implying there is little loss of strength on excavation. It is not unusual to find natural slopes in tills of 45º (Vaughan, 1994) even though the laboratory tests indicate lower strengths and hence lower slopes. The pockets and lenses within a till are likely to be less dense and more ductile.

Laminated clays, a feature of glacial lakes, are generally composed of thin alternative layers of clay and silt creating a highly anisotropic material in terms of stiffness, strength and permeability. Layers of laminated clays are often found in basal tills. It is not uncommon for failures to occur in excavations of these basal tills if laminated clays are present.

31.4 Geotechnical classification

As with all soils the geological processes govern the geotechnical properties. Water-lain glacial soils produced at the end of the glacial period and not subject to further glacial erosion will behave in a similar manner to other water-lain soils. However, the process of deposition may create an anisotropic structure (e.g. laminated clay) or a spatially variable structure (e.g. outwash deposits primarily of coarser materials). Supraglacial tills are gravitationally deposited but not through water. Therefore they could have similar properties, but not features, to water-lain deposits.

Sub-glacial or basal tills (i.e. deformation and lodgement) are either deformed or 'smeared' into place under great pressure due to the weight of ice. These are the predominant till types. For example, Eyles (1979) suggested that Icelandic glaciers produce between 1% and 7% of supraglacial till compared to basal till. This may take place under frozen or unfrozen conditions. In either case it should result in a very dense material. This density is not just a result of pressure but is a result of a combination of pressure and shear. Basal tills include those that are essentially deformed bed layers, which are likely to contain glaciotectonic features such as faults and folds with pre-existing features being readily identified (see **Figure 31.3**). These dense tills can contain pockets of less dense material. These pockets of material retain their density because of the fact that the till was frozen or unfrozen. If unfrozen the density of the surrounding till was such that excess pore waters could not dissipate. This can also occur because the structural form of the inclusion meant that the surrounding till provided a structural seal to the pocket of material. These pockets of less dense material, often remnants of melt-out tills, can be a hazard (see **Table 31.1**).

Sub-glacial tills may be classed as lodgement tills based on their fabric but in fact because of the periods of glaciation many could be considered deformation tills: i.e. tills that retain much of the original features of the bed, having been transported a short distance with little abrasion. Therefore the genetic classification may not be the best indicator of geotechnical properties. Meer *et al*. (2003) came to the conclusion that there is only one type of basal till, deformation till, since all basal tills contain deformation features.

It is possible to create a classification of glacial soils based on their geotechnical performance. This classification combines the genetic classification with observations of glacial soils to highlight the features that will impact on the interpretation of ground investigation and the behaviour of the tills during construction and in service.

McGown and Derbyshire (1977) suggested that it is more appropriate to use a classification that is based on superimposing the dominant soil fraction on the genetic scheme (**Table 31.4**). The classification suggests that the dominant soil fraction and the type of till govern the relative value of the engineering properties. This qualitative assessment shows that the density and compressibility decrease as the dominant soil fraction size increases; i.e. a clay matrix lodgement till is likely to be the densest and stiffest of the tills. This is not surprising given the amount of shearing and abrasion that takes place during transportation. A feature of all these tills is the fact they can be lightly or normally consolidated despite the pressures involved during deposition and the relief of those pressures due to ice melt. The link between consolidation theory and the mechanical characteristics of soils developed for gravitationally sedimented soils

Till	Dominant soil fraction	Fabric features	Relative scales (1 (low) to 9 (high)) Density	Compressibility	Permeability	Anisotropy
Lodgement till	G	MACRO: Interlayering of glaciofluvials, joints, fissures, contortions. Consistent preferred clast orientation.	4–7	1	5–6	7
	W	MESO: Fissuring. Contortion. Moderate to very high consistency of preferred orientation of clasts.	5–8	2	2–3	
	Mg	MICRO: Moderate to high degree of parallelism of fines in sympathy with clast surfaces	6–8	2	4–5	
	Mc		6–8	3	2	
Melt-out till	G	MACRO: Occasional interlayering with glaciofluvials. Clast preferred orientation often retained from englacial state.	2–4	2–4	7–9	3–5
	W	MESO: Moderate to high preservation of preferred clast orientation from englacial state, especially in sub-glacial type.	2–6	3–5	4–5	
	Mg	MICRO: Open to moderately closed arrangements of fines with many englacial arrangements retained, especially in sub-glacial type.	2–6	3–6	5–8	
	Mc		2–7	4–7	3–4	
Flow till	G	MACRO: Inter layering with glaciofluvials common. Segregation, contortions, layering and fissuring in upper section and nose of flow.	3	2	7	7
	W	MESO: Aligned low angle orientation of clasts conforming to flow direction rather than ice direction.	4	2–4	4	
	Mg	MICRO: Rather compact parallel arrangement of fines related to flow rather than direction of ice movement.	5	2–4	6	
	Mc		5	2–5	3	
Deformation till	G	TOTAL FABRIC: Deformed bedrock and soil (including previous glacial deposits) structures related to ice movement direction.	5–8	1–3	2–8	3–7
	W					
	Mg					
	Mc

Mg = Granular matrix till
W = Well graded till
Mc = Cohesive matrix till

Table 31.4 Characteristics and geotechnical properties of glacial tills
Data taken from McGown and Derbyshire (1977)

does not apply to tills. This means that very strong, stiff glacial soils are not necessarily heavily overconsolidated. In fact the behaviour of till often depends on the relationship between the fabric and the geotechnical structure, with the fabric having a significant impact on the performance of the geotechnical structure (see **Table 31.1**).

Consider an element of basal till. The total vertical stress on the element is equal to the pressure of the ice plus the pressure due to the overlying till. When the glacier retreats (melts) the total stress reduces to the pressure due to the overlying till. The pore water will depend on whether the basal till was frozen or unfrozen and the hydrological characteristics of the bed of the glacier. **Table 31.5** shows the possible pore water regimes. If

Bed of glacier	Base of till	Underlying soil/rock	Pore pressure**	Degree of overconsolidation
Frozen	Frozen*	Aquifer	No excess	Heavy
Frozen	Frozen*	No aquifer	Excess	Normal
Unfrozen	Frozen*	Aquifer		Heavy
Unfrozen	Frozen*	No aquifer		Normal
Unfrozen	Unfrozen	Aquifer	No excess	Heavy
Unfrozen	Unfrozen	No aquifer	Excess	Normal

*pore pressures generated as ice melts
**the total stress is equal to the pressure due to the weight of ice

Table 31.5 Pore water pressure regimes within till during deposition

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the bed is frozen, then the pore water pressure is zero. As the glacier melts pore water pressure will be generated due to the weight of till as the bed melts. The total stress reduces as the weight of ice reduces. Therefore the degree of consolidation is low. In the case of a bed that is not frozen and the bed acts as an aquifer, the degree of consolidation is high because the effective stress reduces due to the weight of ice. It is possible, therefore, for a till to be 'normally consolidated' or 'heavily overconsolidated' depending upon the pore water regime and underlying geological conditions.

The shearing, abrasion and crushing processes further complicate the stress regime. The concept of overconsolidation ratio (i.e. the ratio of the maximum past effective stress to the current effective stress) applied to gravitationally compacted sediments can be applied to tills but since the maximum stress, related to the thickness of ice, is unknown and the deposition process introduces shear the concept of the degree of consolidation as an indication of soil properties is not valid and therefore characteristics cannot be deduced from stress history. Indeed density and the dominant matrix may be a better indication of likely behaviour.

31.5 Geotechnical properties

31.5.1 Classification data

It is important with glacial soils to link the geological characteristics with the geotechnical classification to ensure that the soils are correctly identified and the appropriate properties assigned. For example, a liquid and plastic limit test on laminated clay formed of clay layers separated by silt layers will produce very different results from tests on the two layers forming the laminated clay. The test may suggest a silty clay when in fact it is a laminated clay. Indeed in this extreme case liquid and plastic limit tests may not be appropriate. Linking empirical relationships developed for gravitationally compacted soils between liquid and plastic limit test results and mechanical properties is not advisable for tills.

Boulton and Paul (1976) showed that the plasticity indices for tills cluster around the T-line, a line parallel to the Cassagrande A-line. This may be due to the fact that the finer particles in tills comprise rock flour rather than clay minerals. This applies to many tills (**Figure 31.8**), which shows that tills vary from CL to CI in general. The limit tests are only carried out on the finer particles and therefore are only relevant to clay matrix dominated tills. Therefore one technique to identify tills is to assess the properties of the matrix. A clay matrix-dominant till is defined as well-graded till with a fines content of between 15% and 45% (McGown and Derbyshire, 1977). Barnes (1987) and Winter *et al.* (1998) showed that the matrix dry density reduced markedly when the stone content exceeded 40–50%. At that point a glacial soil is considered a granular soil and has the characteristics of such soils. Gens and Hight (1979) reported that tests on reconstituted soils are unaffected by the gravel content if the gravel content is less than 15%. Thus the grading curve is a useful indicator of characteristic behaviour.

Limit tests can be used to assess whether a till is weathered, since the weathering process increases the clay content due to the formation of clay minerals. It also increases the water content. Limit tests on weathered till still cluster around the T-line. Therefore it would be expected to find the limit test results to migrate down the T-line with depth because the amount of weathering reduces.

31.5.2 Particle size distribution

The wearing down of particles due to abrasion and crushing during the transportation process results in a broad range of particle sizes. The percentage of fine particles increases with distance from source. A feature of lodgement tills is that the distribution of particle sizes has fractal characteristics; i.e. the numbers of grains at each size when plotted on a double logarithmic plot are linearly related (**Figure 31.9**). Theoretically the slope of the line would be 2.58 (Sammis *et al.*, 1987) if the particles were produced solely by fracturing. In practice the slope is greater (Hooke and Iverson, 1995).

The particle size distribution in glacial soils can vary from pure clay to pure gravel. However, the majority of lodgement and deformation tills are clay matrix-dominant tills which sit between a silty clay (e.g. London Clay) and a sandy gravel (e.g. Thames Gravel) in terms of their grading (**Figure 31.10**). Note that boulders will not have been included in the grading curves, so the curves are not necessarily a true representation of the soil. The chart distinguishes between fine soils and sands, gravels and cobbles. Fine soils include clays, silts and rock flour, the rock flour being derived from the abrasive processes during deposition. Rock flour is clay and silt size but is neither clay nor silt; it is formed of particles of rock.

Clay-dominant sub-glacial tills are generally well graded. **Figure 31.11** shows a ternary diagram for the percentages of fines, sands and gravel (**Figure 31.11a**) and clay, silt and coarse particles (**Figure 31.11b**). Note that cobbles are removed either in the sampling process or in preparing the specimen. The gradings confirm that the tills are dominated by fine-grained particles. The averages show that the tills are distinctly different, as can be seen from **Table 31.3**.

31.5.3 Mechanical characteristics

31.5.3.1 Undrained shear strength

Sampling clay basal tills is difficult because of the stone content and the strength of the till. This leads to significant scatter in the results of strength and stiffness tests. It is for that reason that tests are often carried out on U100 samples, providing a single value of strength at the depth of the sample. It has been practice to carry out multi-stage tests on a single 100 mm sample (Anderson, 1974). The sample is taken to failure in the first stage. The same sample is taken to failure a second and third time at different confining pressures, with shear taking place on the

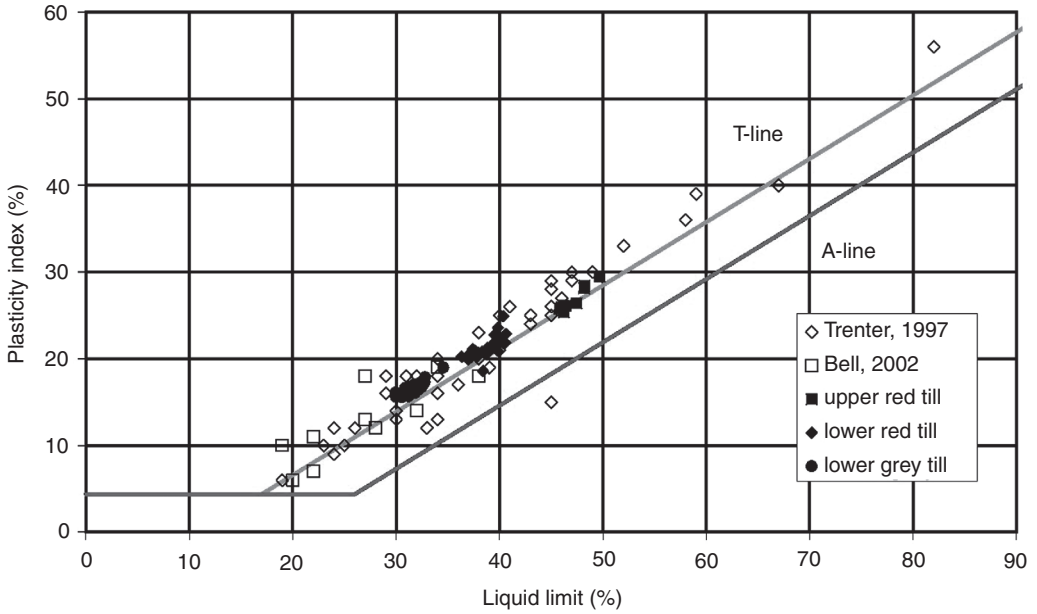

Figure 31.8 Typical Atterberg limits of glacial basal tills showing the tendency to cluster around the T-line

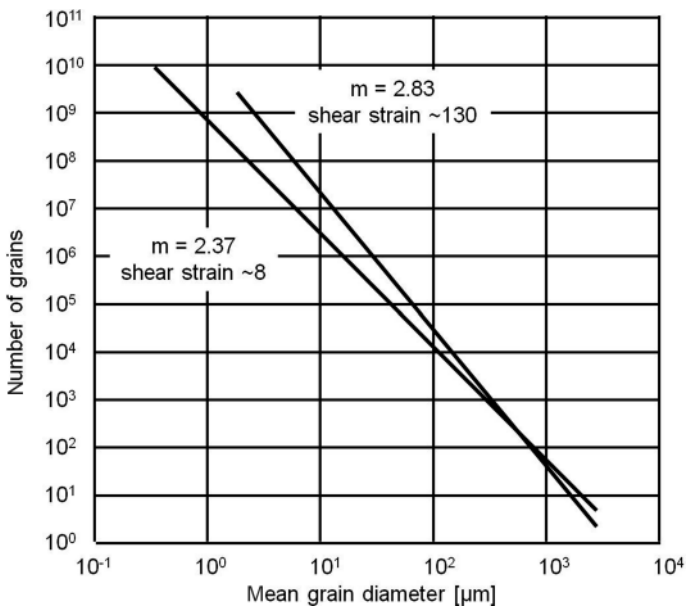

Figure 31.9 The fractal characteristic of lodgement tills
Reproduced from Iverson *et al.* (1996); International Glaciology Society

predetermined plane. Given the density of the till it is likely that it will exhibit brittle behaviour during the first stage, thus creating a predetermined failure plane for the subsequent stages. The implication is that the derived shear strength from a multi-stage test does not have any meaning. However, given the difficulty of preparing sub-samples from 100 mm diameter samples of basal tills because of the particle size distribution, in particular the gravel content, it is normal to test 100 mm samples. Given that there will be only one strength test from each sample it is prudent to increase the number of samples tested for strength. Much of the sample still exists after the strength test, so it is possible to use that sample for classification tests.

The measured undrained shear strength of clay matrix-dominant tills is very dependent on the fabric and method of sampling. The density of the till means that sample distortion using driven tubes is inevitable. Stones affect both the sampling and mode of failure. Fissures affect the mode of failure (**Figure 31.12**). McGown *et al.* (1977) suggested that a representative undrained strength can be obtained only from samples larger than those normally taken in ground investigations. This questions the value of U100 samples from ground investigations. Hence profiles of undrained shear strength in till are likely to show much scatter (**Figure 31.13**). McGown *et al.* (1977) used the fact that the relationship between intact strength and strength of fissured soil varied with sample size, leading to the conclusion that the representative strength is typically 0.75 of the average strength measured using U100 samples of fissured till.

In some cases, because of the composition and strength, it is difficult to obtain undisturbed specimens. Therefore an alternative method is used to indirectly measure undrained shear strength. For example, undrained strengths of some Irish tills (Farrell and Wall, 1990) are estimated from correlations between SPT blow counts and tests on remoulded specimens. A value of 6 ($s_u = 6N$) for Irish tills (Orr, 1993) is commonly used, but note that the correlation was based on tests on remoulded specimens. This empirical method is commonly used for gravitationally compacted soils. Stroud (1975) presented a correlation between undrained shear strength and blow count based on plasticity index for fissured clays. This

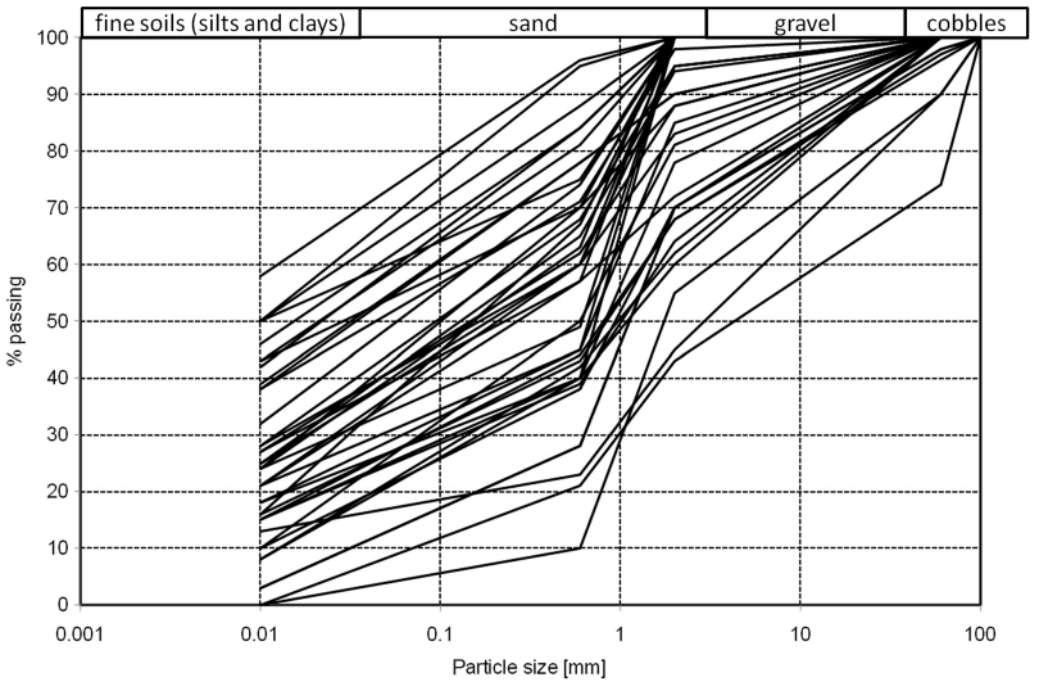

Figure 31.10 The grading of glacial tills; the data come from various sources from across the UK including those summarised by Trenter (1999)

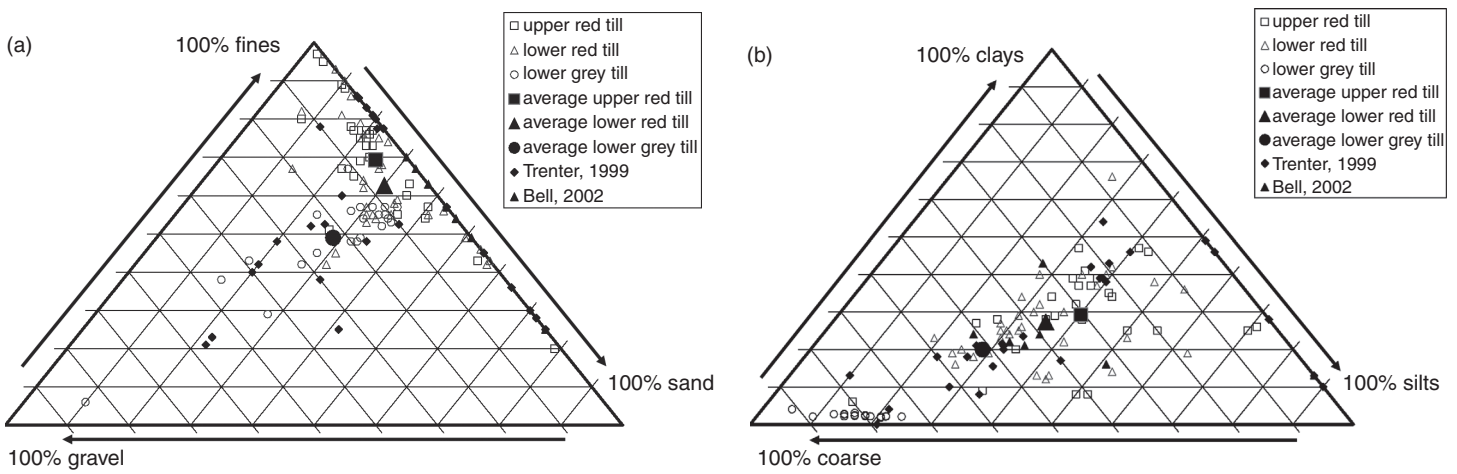

Figure 31.11 A ternary plot of a number of glacial basal tills showing (a) the relationship between fine and coarse particles and (b) between the fine particles

correlation used uncorrected values of SPT blow count. Ground investigations carried out in accordance with Eurocode 7 will provide corrected values.

Many tills are fissured so the correlation may apply to tills, but there is evidence that shear strengths estimated from SPT results using the Stroud correlation are significantly less than the *in situ* strength, suggesting the correlation factor is too low. This could be because the correlation has not been developed for such dense clays or it could be because the stiffness of these tills makes them behave in a partially drained manner. It is assumed that the clay tills can be considered as undrained clays when loaded because they are considered relatively impermeable. However, they are very stiff. This means that pore pressures generated during rapid loading (as in an undrained test) may be less than expected, since some of the load will be taken by the soil skeleton as water is compressible in reality. Further, *in situ* the pore pressures may dissipate more quickly than expected because the coefficient of consolidation is high. The coefficient of consolidation is the ratio of the stiffness to permeability. Given that the permeability of the basal till is similar to other clays but the stiffness can be much greater, the coefficient of consolidation is often much greater than that of sedimented

clays. Thus the dissipation of pore pressures could be much quicker than observed in sedimented clays. This may account for the apparently high undrained strengths in basal tills; in practice they are behaving in a partially drained manner.

The data used by Stroud, which covered plasticity indices between 15% and 65%, showed that the ratio between undrained shear strength and the SPT blow count varies between 7 and 4.1. **Figure 31.14** shows data from a site in northern England in which results of triaxial tests on undisturbed specimens are plotted against depth together with values of strength derived from SPT N values. There is evidence from piling contractors that quoted correlations between undrained shear strength and blow count are too low. This suggests that earthworks calculations should be based on a factor of 6 since the till is remoulded during construction, whereas foundation design calculations

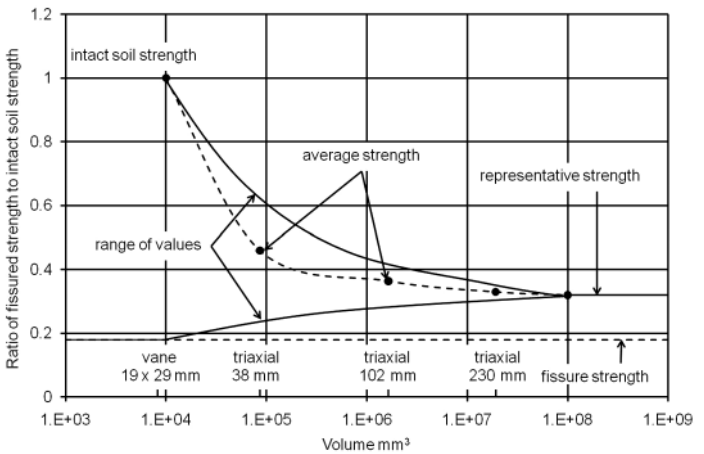

Figure 31.12 The effect of fissures on the strength of glacial till showing the ratio of strength of fissured strength to intact strength against the size of the sample expressed in terms of volume

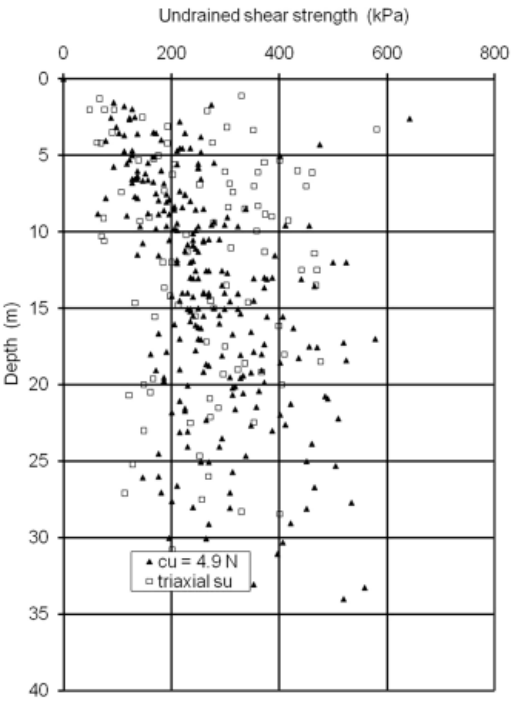

Figure 31.14 The relationship between SPT blow count and the triaxial undrained shear strength of some tills in northern England

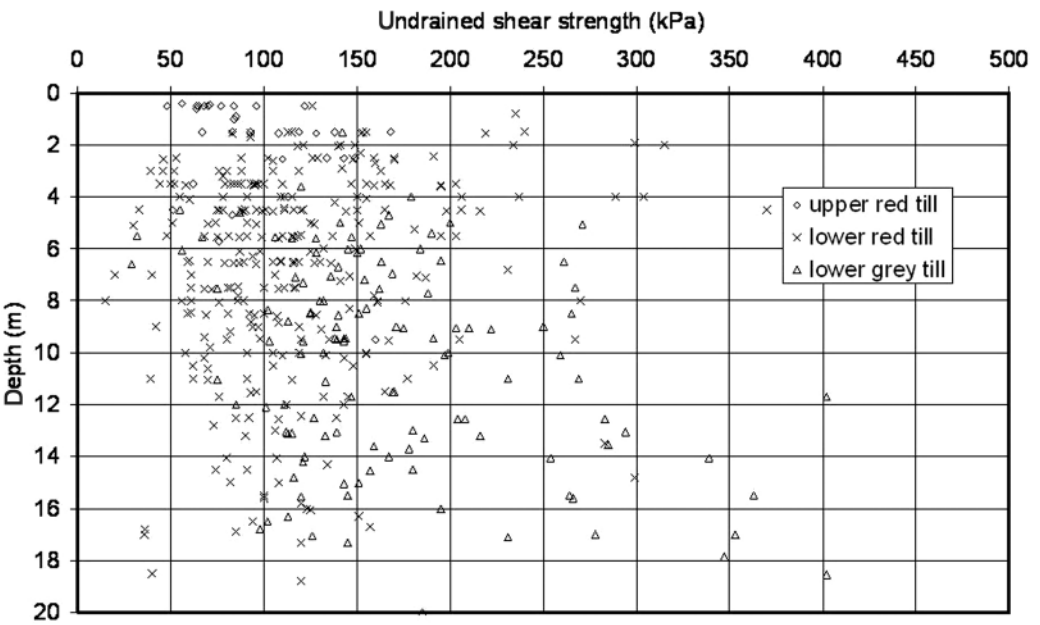

Figure 31.13 A typical profile of undrained shear strength of basal till highlighting the scatter in the data and the difficulty in selecting a characteristic value of strength (the upper and lower tills refer to the tripartite succession in northern England)

could be based on 9, since the *in situ* strength is mobilised during foundation loading. Note that sometimes 9 may be considered too low, but this should be challenged unless there is evidence from the investigation that supports this view.

The consequence of this response of basal clay tills is that foundations are often overdesigned and excavation techniques inappropriate. This reinforces the need for pile tests to assess the actual performance rather than the predicted performance.

31.5.3.2 Effective strength parameters

As with undrained shear strength, the fabric and composition of glacial soils have an effect on the interpreted values of c′ and ø′ It is important to stress that c′ and ø′ are based on the assumption that there is a linear relationship between confining pressure and deviator stress independent of the level of confining pressure and, for a given soil, independent of the variation in fabric between specimens. In tills, the latter assumption is invalid, resulting in a wide variation in values of c′ and ø′ for tills, even if they are from the same till deposit. Increasing the density of a till increases its strength and there is an optimum fines content for a maximum strength. Thus, density is an indication of strength. Hence, when interpreting laboratory test results, it is useful to disregard low values of strength from high density samples because the fabric may have been the dominant factor in determining the strength; i.e. failure may have been triggered by gravel inclusions or shear planes. This emphasises the need for quality descriptions of the samples tested and for caution when selecting characteristic strengths from a limited number of tests. The fabric may be the dominant factor that influences the mass behaviour and not the material strength.

There have been attempts to relate ø′ with PI (**Figure 31.15**), percentage fines and density (**Figure 31.16**) for clay matrix-dominant tills. It is clear that such relationships exist but they may not be appropriate for till because of the effects of fabric and sampling.

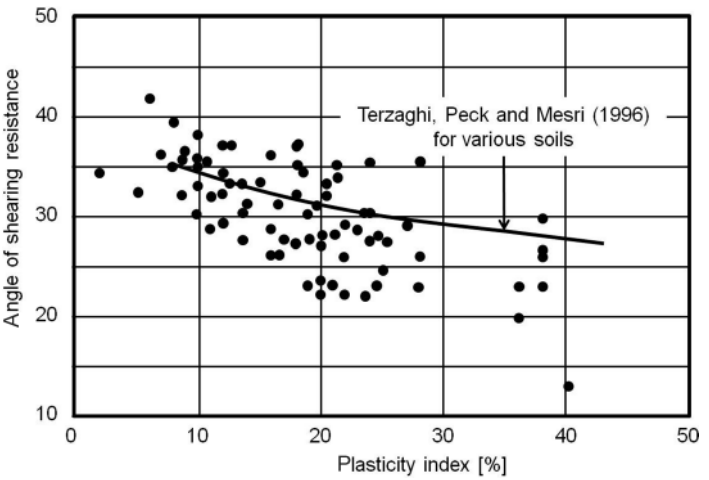

Figure 31.15 Relationship between angle of shearing resistance and plasticity index for a number of basal tills

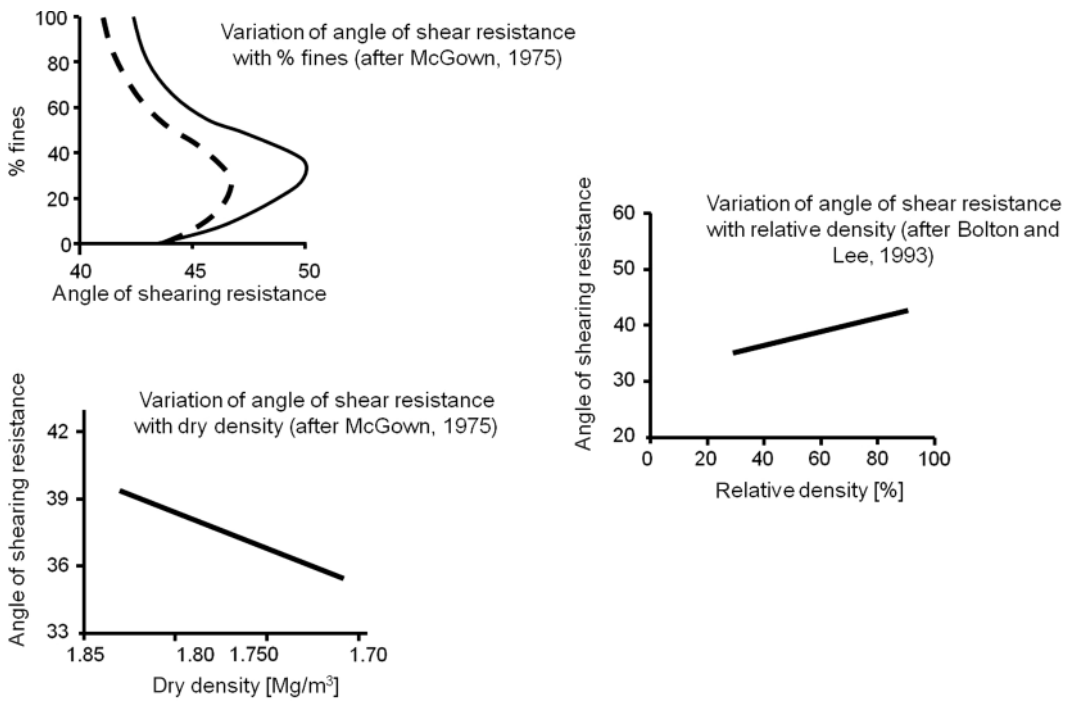

Figure 31.16 Relationship between percentage fines, density and angle of shearing resistance
Reproduced with permission from CIRIA C504 Trenter, (1999), www.ciria.org

There are two approaches that could be used to evaluate a characteristic strength. In both cases (**Figure 31.17**) the samples have to be grouped together according to their description and classification data, noting that two tills from the same site can have the same description but different liquid limits. This is because the source of the tills may be different resulting in different particle compositions. The first approach is to plot the deviator stress and mean stress for all samples on the same graph and identify the failure envelope from these data (**Figure 31.18**). Spurious data points related to density and fabric should be given a lower weighting. This gives the characteristic value of strength provided sufficient samples are tested.

The alternative way of producing a characteristic strength, especially when there are a limited number of samples, is to test reconstituted glacial till (Burland, 1990) with all coarse material removed. In this case, the laboratory prepared specimens are gravitationally compacted to as high a density as possible, ideally using a hydraulic press. The density will still be less than the *in situ* density so the test results could be considered a lower bound value. Basal tills were spread into place under vertical loads of up to 10 000 kPa; typical laboratory tests use pressures of up to 700 kPa. The scatter due to fabric is removed when testing reconstituted till (**Figure 31.19**) but the interpreted value of strength lies below the values obtained from tests on intact samples.

Note, however, in both cases the strength of the glacial till mass may be dominated by lenses or pockets of laminated clay and sand and gravel.

31.5.3.3 Stiffness

Stiffness of soils is notoriously difficult to measure, is test dependent and depends on the quality of the soil being tested. In tills this is further compounded by the fact that the tills are spatially variable to such an extent that measurements

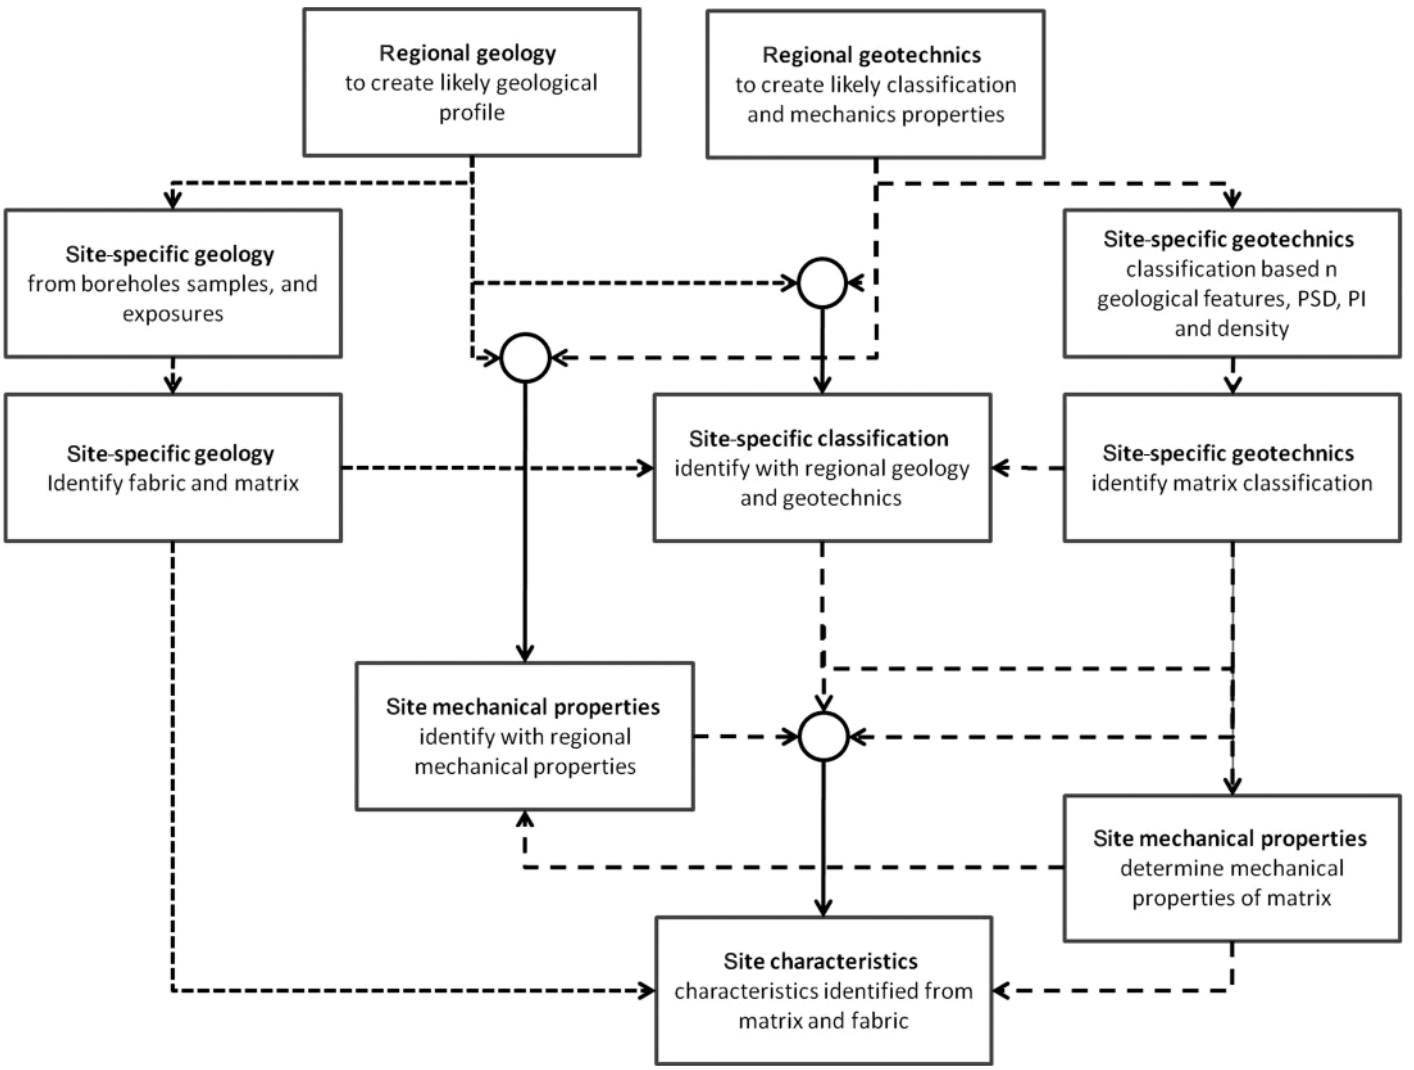

Figure 31.17 A flow chart for the assessment of soil characteristics; in particular the strength of the till

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

of the stiffness of elements of tills may not be representative of the mass stiffness. The comments on the impact of fabric and sample size on strength apply to measurements of stiffness.

No matter which method is used it is important to test a quality element of till. This means high quality samples such as wireline and block samples from matrix dominated till, which are only possible on major projects because of the cost. In general, U100-driven tube samples will be available. In that case it may be prudent to determine stiffness from tests on reconstituted till though, as with strength, the value obtained will be less than the *in situ* value. However, as **Figure 31.20** shows, results (the shaded area) can be obtained from intact samples of matrix dominated tills.

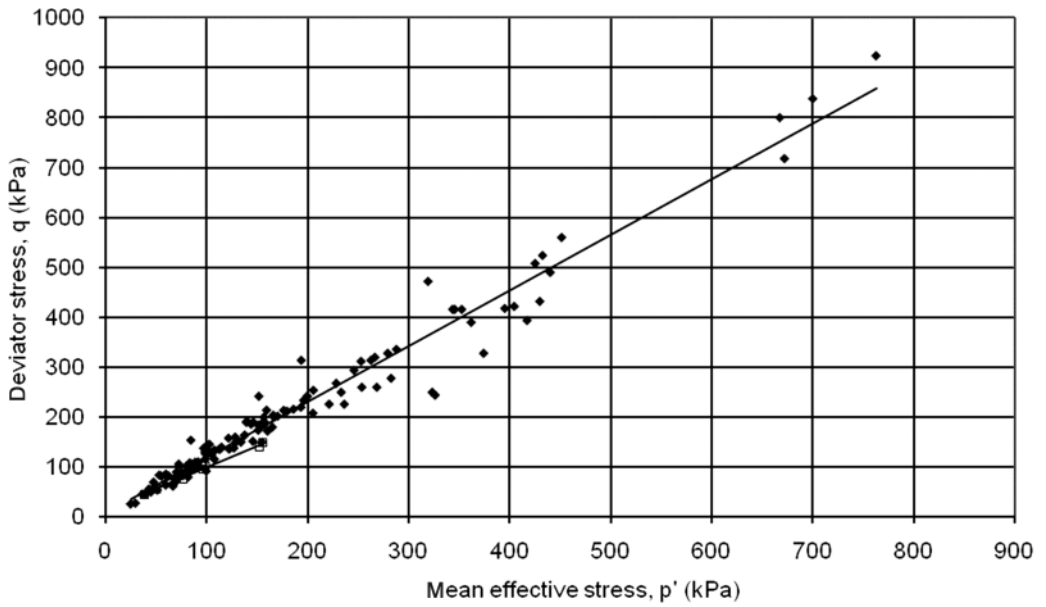

Figure 31.18 Characteristic strength derived from tests on individual specimens. The ranges of cohesion (0 kPa to 27 kPa) and angles of friction (15° to 34°) were reduced to characteristic values of cohesion of 2.5 kPa and angle of friction of 31°; the two trend lines refer to the best fit to the data from 0 to 100 kPa (p') and 0 to 800 kPa

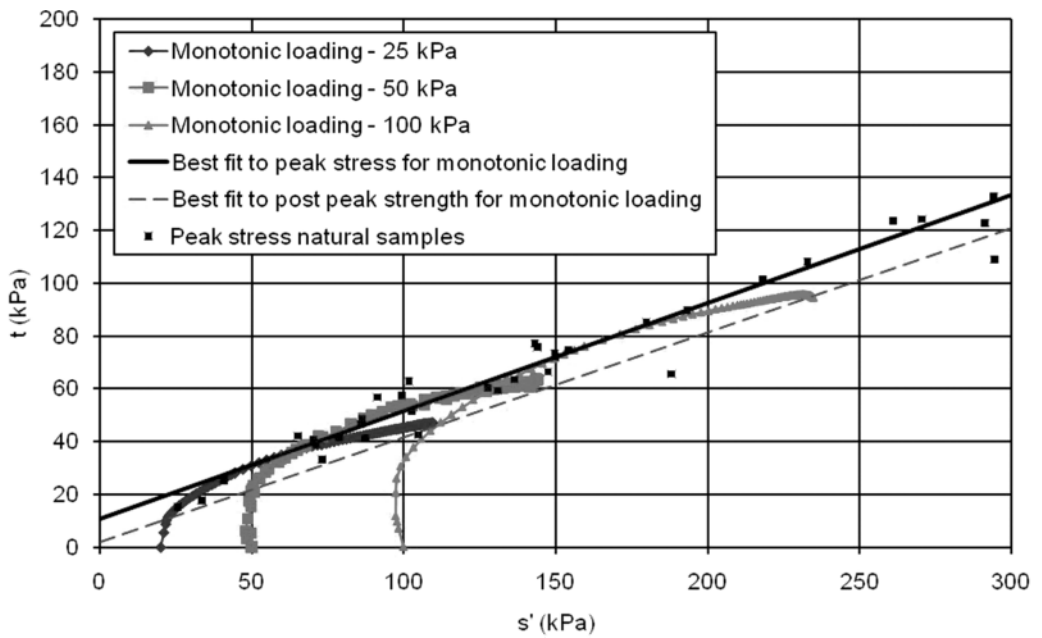

Figure 31.19 Comparison between tests on reconstituted tills and tests on intact specimens showing that the strength of the reconstituted till lies below that of the natural tills

It is possible to measure stiffness *in situ* (e.g. pressuremeter, plate and cone). In these cases the installation of the measuring device inevitably disturbs the till, leading to an underestimate of the *in situ* stiffness, leading in turn to the use of empirical correlations. Non-destructive geophysical methods can be used to obtain the maximum shear modulus (G_{max}) with some degree of accuracy. The shear modulus strain degradation curve obtained from quality tests on elements of till can then be normalised to G_{max}. These techniques are expensive and may be used on large projects, but a combination of geophysical tests and tests on reconstituted samples of till may be the best combination to determine the stiffness characteristics of till.

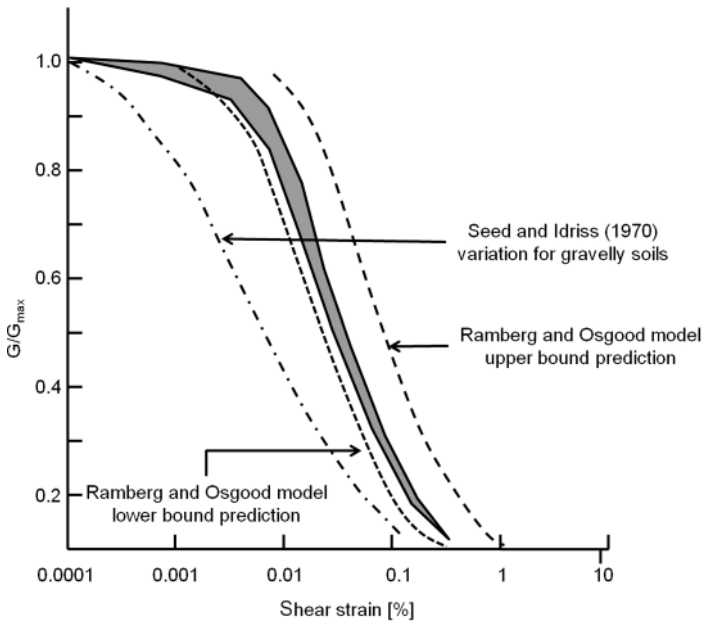

Figure 31.20 Degradation of stiffness from resonant column tests on samples of glacial till
Reproduced from Chegini and Trenter (1996)

31.5.4 Hydraulic conductivity

The *in situ* hydraulic conductivity of glacial soils will be dominated by the fabric and structure of the soil; hence, correctly describing the till and identifying its features are critical. The presence of fissures in clay tills and the laminations in glaciolacustrine deposits imply that the *in situ* hydraulic conductivity may be several orders of magnitude greater than that of the intact matrix. The implication is that the hydraulic conductivity measured in the laboratory will depend on sample size and orientation as well as density and grading, but *in situ* the fabric may be the dominant factor. Hence, as with strength, scatter in values of hydraulic conductivity is expected and a representative value may be difficult to obtain from laboratory tests. Lloyd (1983) suggested that the permeability of clay matrix-dominant tills would be between 10^{-11} and 10^{-8} m/s; and if fissured between 10^{-10} and 10^{-7} m/s. It is possible to determine the intrinsic value of hydraulic conductivity from reconstituted till (**Figure 31.21**). In practice, if the hydrological characteristics are critical, then it is best to undertake *in situ* borehole tests using a test pocket that is sufficiently long enough to take into account the representative fabric and features of the till. This means that it is important to establish a quality 3D geological model that adequately describes those features which could influence the mass hydrological characteristics.

31.6 Routine investigations

Much of the development work on exploratory boreholes in UK site investigation practice took place in the south-east of England (e.g. Cooling and Smith, 1936; Cooling, 1942) where soft alluvial clays, stiff clays, and sands and gravels are found. They evolved from well-boring techniques that fixed the diameter of the boreholes and sampling devices which led to the U100 sampling tube and the Standard Penetration Test (SPT), both of which had their origins in American 'dry' sampling techniques. This then fixed the size of the test specimens.

The subject of soil mechanics was being developed at the same time as the site operations and this led to the introduction of the oedometer, triaxial and shear box tests. The testing techniques have essentially remained the same since then. While the techniques have proved successful in areas in which clays and sands are the predominant soil type, they are not necessarily the best for other areas where heterogeneous mixtures of soil particles are more commonly found. For example, it is difficult to select design parameters from standard tests on tills because of the difficulties in sampling and testing these soils using standard equipment. It may be possible to develop other techniques, but they could not be used in practice because parameters are test dependent and confidence in design methods is based on standard tests.

Table 31.6 lists the sampling methods suggested by Trenter (1999) giving an indication of the quality of the sample. The U100 driven tube is the most common method of sampling matrix-dominant tills in the UK. The quality of the sample will depend on the amount and size of gravel and cobbles present, the strength of the matrix and the presence of shear planes. A detailed description of those samples tested is required to help evaluate the significance of the results of the tests. For example, the failure of a sample in a triaxial test may be a result of the fabric and not the strength of the matrix.

31.7 Developing the ground model and design profile

31.7.1 The ground model

Figure 31.14 highlights the difficulty in assigning characteristic values to this spatially variable soil. Clarke *et al.* (2008) have suggested that it is possible to use a regional database to create characteristic values. In that way data from a new site can be compared to the regional database and, if found to be statistically aligned with that database, then the characteristic values for the region can be used.

Box plots (**Figure 31.22**) are a visual means of assessing the normality of the data. From an engineering point of view the differences in Atterberg limits between the sites are not significant, hence the regional values have been identified. This approach can also be applied to water content and density.

Schneider (1999) suggested that the characteristic value for a new investigation is simply the mean less half the standard deviation, since the regional coefficient of variation is likely to be unknown. **Table 31.7** shows that this can lead to a characteristic value with about 70% of the results exceeding that value; i.e. it is an overcautious estimate of the mean.

The first step in establishing the characteristic values from a new site is to determine whether the soils are tills. This could be proven from the geological description, Atterberg limits

Glacial soil type (typical description)	Equipment/method of sampling	Comment
Matrix-dominant (sandy clay with gravel)	U100 driven tube	Generally suitable depending upon the amount and size of gravel and cobbles present; maintain frequent checks for circularity of sampler; change cutting shoes regularly and keep inside of sampler lightly oiled
	Block	Suitable: adjust block size to cope with largest particles present
	Rotary core double tube plus liner	Suitable for strata definition but swelling on contact with flushing medium may preclude use for laboratory test purposes
	Wireline	Generally suitable. Note that the bit is not routinely brought to the surface to permit inspection for wear, as with the conventional system
Clast-dominant (clayey sandy gravel with occasional cobbles)	U100 driven tube	Generally unsuitable because of the gravel content: the sample will be disturbed; using double tubes may make it possible to recover a (disturbed) sample sufficient for lithological description
	Block	Depends upon amount and plasticity of matrix: where sufficient to form a coherent block during excavation, the procedure may be used; adjust block size to cope with largest particles present
	Rotary core double tube plus liner	Sometimes suitable for strata definition but core retention may be difficult; bit wear may be high; usually unsuitable for laboratory test purposes
	Wireline	May be suitable, depending on amount, nature and angularity of the particles. Note that the bit is not routinely brought to the surface to permit inspection for wear, as with the conventional system

Data taken from Clarke *et al.* (2008)

and grading curves. If this combination indicates that the soils are likely to be typical of the region, then Bayesian statistics can be used to determine the characteristic values. An example is given in **Table 31.7**, which shows the values based on the data set and on *a priori* knowledge of the regional data set. This leads to less cautious design parameters and hence a more economical, design. The Bayesian low mean or high mean is used depending on the worst condition being assessed.

31.7.2 Intrinsic properties

Design parameters can be selected using a deterministic model based on empirical or theoretical relationships or a stochastic

model based on a statistical analysis of the data or a combination of these. The former includes relationships between the Atterberg limits and undrained shear strength of remoulded clays (e.g. Wroth and Wood, 1976; Carrier and Beckman, 1984); *in situ* strengths of normally consolidated clays, density and Atterberg limits (e.g. Skempton, 1957); and overconsolidated soils and Atterberg limits (e.g. Yilmaz, 2000). Given the spatial variability of tills it is recommended that a consistent framework for the interpretation of design parameters is used which is based on a geotechnical model that encompasses a study of the deposition and post-depositional processes, soil mechanics theory and experimental data, including tests on reconstituted tills.

Burland (1990) suggested that the compressibility and strength of reconstituted clay could provide a consistent framework for the interpretation of properties of natural clay. Reconstituted clay is a natural clay mixed with water such that the water content is at about 1.25 w_L; the true liquid limit. The properties of this slurry are inherent to the material but independent of its natural state. In the case of a clay matrix-dominant till the slurry should be made from the clay matrix. This is not practical given the difficulty of separating out the fine particles. However, removing all particles exceeding 2 mm produces a soil that is essentially the matrix of the till.

This framework is shown in **Figure 31.23** in which the average shear strength for three tills is plotted against the void index, I_v:

$$I_v = \left(\frac{e - e^*_{100}}{C_c^*} \right) \tag{31.1}$$

where e^*_{100} is the void ratio at a vertical effective stress of 100 kPa on the intrinsic compression line and C_c^* is the slope of the intrinsic compression line (ICL). SCL is the sedimentation compression line, which is the compression line for natural or intact soils. Burland (1990) suggested that these two intrinsic properties are empirically related to the void ratio at the liquid limit, e_L:

$$e^*_{100} = 0.114 + 0.581 e_L \tag{31.2}$$

$$C_c^* = 0.256 e_L - 0.04 \tag{31.3}$$

The intrinsic compression line represents the compression curve for reconstituted clays; the intrinsic strength line, ISuL, represents the strength of reconstituted soils (Chandler, 2000). **Figure 31.23** shows that results of tests on reconstituted tills (Clarke *et al.*, 1998) fit to the ISuL which suggests that this framework can be used to characterise the tills.

The majority of the data from tests on samples of natural tills lie to the left of the ISuL. Two of the tills lie about the trend line for the regional database. The scatter in the data reflects the nature of till but a combination of the geological history, description and the classification characteristics suggests that the tills are the same and part of the regional database. The third till lies about a separate but parallel regional trend. The fact that the data points lie to the left of the ISuL confirms that they are overconsolidated. The single till on the lower trend line is there because the pre-consonsolidation pressure exceeded that of the other two tills. The slope of the lines is such that the average void ratio is very nearly constant, which

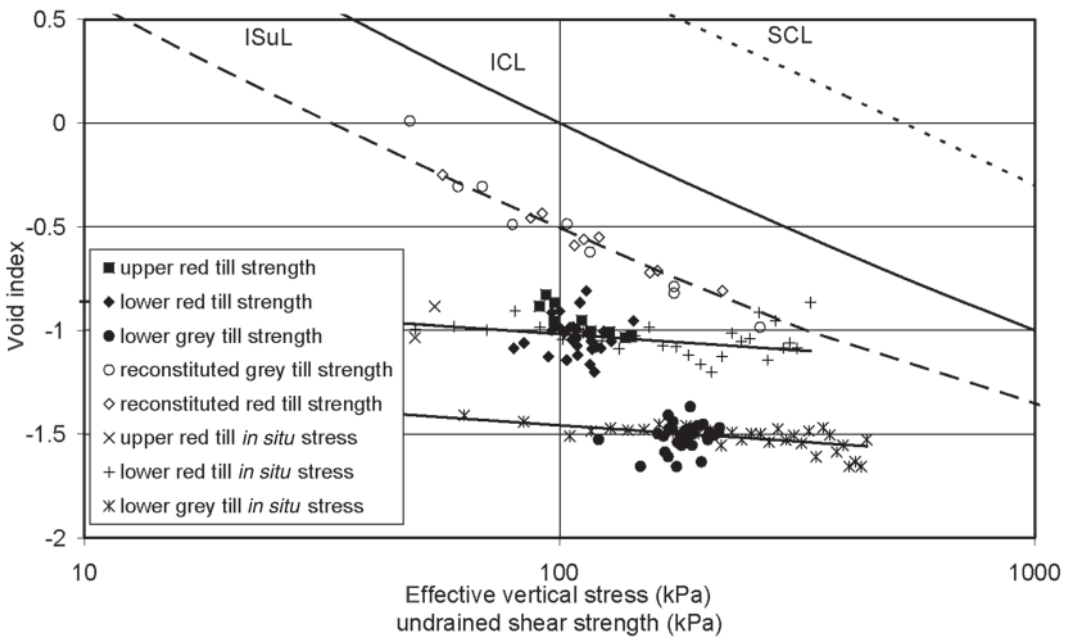

Figure 31.23 The properties of three basal tills using the intrinsic framework proposed by Burland (1990) and Chandler (2000)

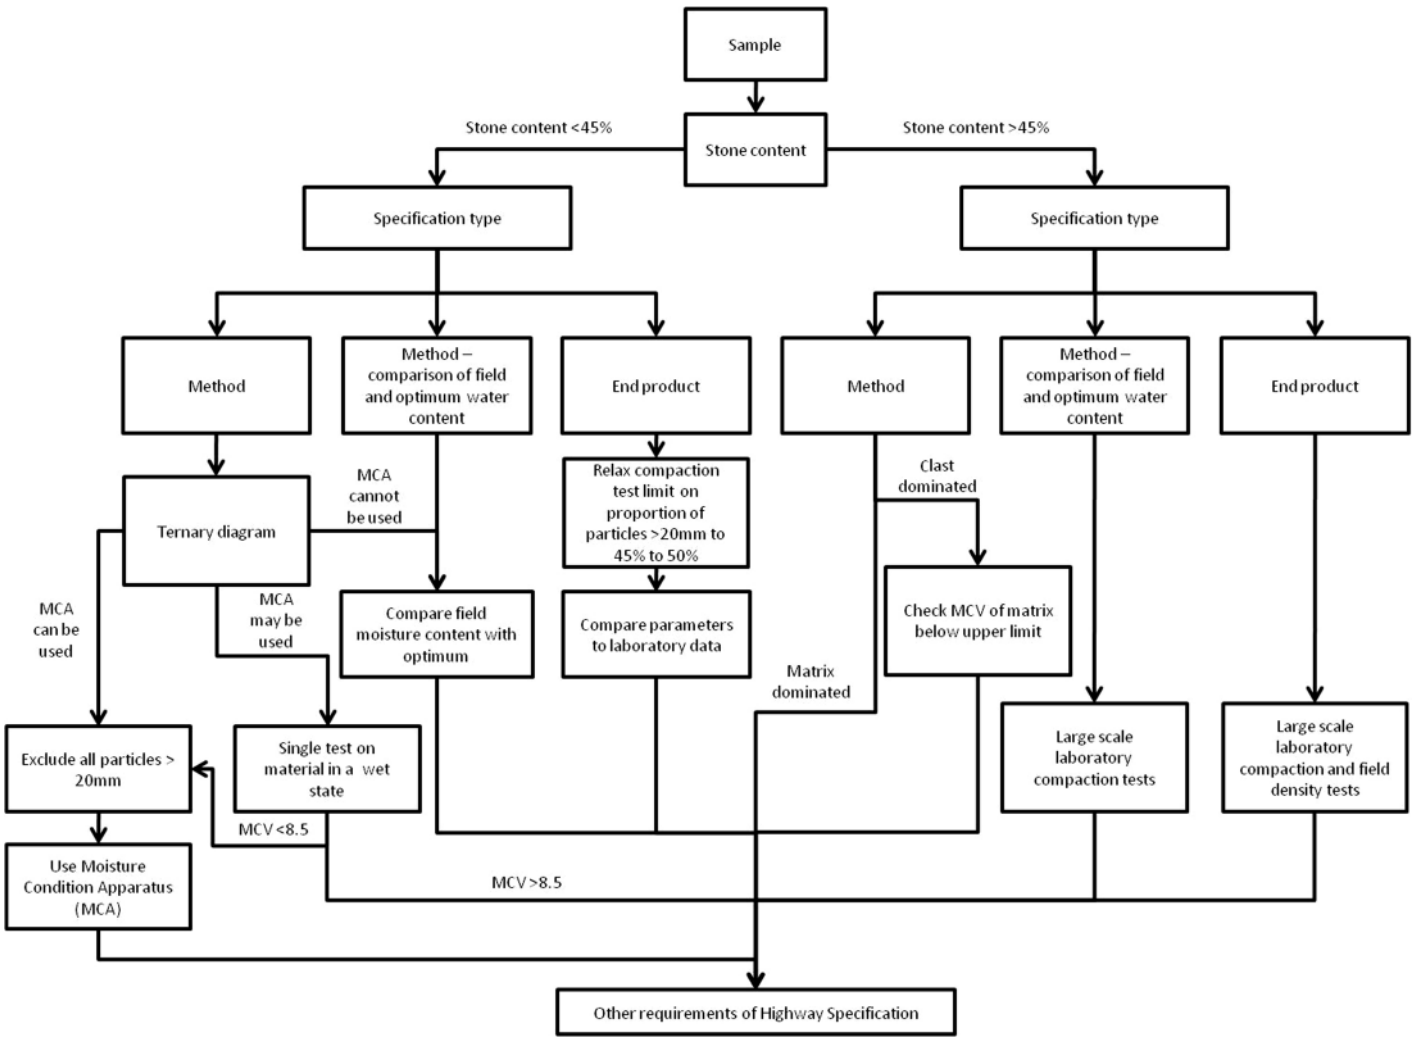

Figure 31.24 Flow chart for the acceptability of tills for earthworks
Reproduced from Winter *et al*. (1998) © The Geological Society

implies that the characteristic shear strength profile could be considered to be vertical.

31.8 Earthworks

The previous sections have focused on the selection of design parameters for excavations, foundations and retaining structures. Till is also used as a construction material for earthworks and landfills. In these cases it is necessary to prove that the material can be compacted to the correct density, the compacted material is strong enough to resist failure in the design of embankments and, for landfill liners, it is ductile enough to remain relatively impermeable when subject to deformation.

It is most likely that a matrix dominated till could be used for landfill construction including liners. The acceptable criteria are likely to be based on a 5–10% air voids line. Tills have a variable mean particle density (PD) which implies, in practice, that it is possible for site tests to plot above the 0% air voids line, because of the high PD particles in the sample. It is unlikely that the water content of the till will be altered so it is important to determine the hydraulic conductivity, strength and ductility of the till at that water content. Typically a strength of 50 kPa is required (Terraconsult, 2010) to allow clay to be compacted. The maximum hydraulic conductivity is 10^{-9}m/sec. A reduction in water content increases the strength, making it more difficult to compact and possibly producing a brittle material that will fracture on straining, leading to an unacceptable increase in hydraulic conductivity. Further details of the testing regime can be found in the Environment Agency's guide to landfill design (Terraconsult, 2010).

The thickness of a compacted layer specified by the Highways Agency is 300 mm, which means that all particles in excess of 125 mm have to be removed. Thus it is still possible to use matrix-dominant and clast-dominated tills. However, there is a limit to the size of particles in the control tests (e.g. compaction and moisture condition value). Stones (20 mm to 37.5 mm) and cobbles have to be removed before testing. If the stone

Property	'Minimum' requirement	Test
Permeability/hydraulic conductivity	Depends on Environmental Permit	BS 1377:1990, Part 6: Method 6
Remoulded undrained shear strength	Typically ≥ 50 kPa or other site-specifically defined value	BS 1377:1990, Part 7: Method 8
Plasticity index (Ip)	10% ≤ IP ≤ 65%	BS 1377:1990, Part 2: Methods 4.3 and 5.3
Liquid limit	≤ 90%	
Percentage fines	<0.063 mm (63 μm) ≥ 20 % but with a minimum clay content (particles < 2 μm) of 8 %.	BS 1377:1990, Part 2: Methods 9.2, and 9.5
Percentage gravel	> 5 mm ≤ 30%	
Maximum particle (stone) size	2/3rd compacted layer thickness	Typically 125 mm but must not prejudice the liner, for instance by larger particles sticking together to form larger lumps

Table 31.8 Properties of tills for landfill liners
Data taken from Terraconsult (2010)

content is small, i.e. they are discrete elements in the sample, then it is possible to test the matrix (Winter *et al.*, 1998). This is the case for up to 50% stone content. Above that the stones govern the behaviour. An increase in stone content increases the maximum dry density and lowers the optimum water content but this is not important since the stone of high density and low water content is replaced by a low density high water content, matrix. **Figure 31.24** shows the method of selecting tills for earthworks. Note that if those earthworks include landfill liners then there are further limits indicated in **Table 31.8**.

31.9 Concluding comments

Glacial soils are a hazard but, through a strategic approach to the ground investigation linked to an understanding of the impact the geological processes have upon the geotechnical behaviour, it is possible to mitigate against the risk. There are two extremes. The first is to base the design parameters on the properties of the dominant material; the second is to base the design on the zones of weakness. The former can lead to local failure; the latter to overdesign. Therefore, investing in the ground investigation to establish the extent of the zones of weakness and taking sufficient samples to establish the characteristic values is prudent. This should be carried out with a thorough understanding of the ground model developed from previous investigations and observations of exposures of glacial soil.

32.4	Investigation and assessment	398
32.5	Key engineering issues	403
32.6	Concluding remarks	407
32.7	References	407

Collapsible soils present significant geotechnical and structural engineering challenges the world over. They can be found in many forms – either naturally occurring or formed through human activities. However, an essential prerequisite is that an open metastable structure develops through various bonding mechanisms. Bonds can be generated via capillary forces (suctions) and/or through cementing materials such as clay or salts. Collapse occurs when net stresses (via loading or saturation) exceed the yield strength of these bonding materials. Collapse is most commonly triggered by inundation through a range of different water sources, although the impact varies with different sources yielding different amounts of collapse. To engineer in and mitigate the effects of collapsible soils, it is essential to recognise their existence, which may not be easy, and to gather vital geologic and geomorphologic information. Collapsibility should be confirmed through direct response to wetting/loading tests using laboratory and field methods. The key challenge faced with collapsible soils is the spatial extent and the degree of wetting that will take place. Care is needed to ensure that appropriate and realistic assessments are undertaken. Ultimately, if treated using one of a suite of the possible improvement techniques available, then the potential for collapse can be eliminated effectively.

32.1 Introduction

Collapsible soils are extremely common and can be formed naturally owing to various geologic and geomorphologic processes, or be the result of human activity. These processes, although different in nature, allow the development of an open metastable structure: the essential prerequisite to the formation of a collapsible deposit (Dudley, 1970). Volume changes that occur are more sudden than those experienced through consolidation processes and typically occur in material that is non-plastic or of very low plasticity, confined and initially dry (Houston *et al.*, 2001).

Although collapsible soils are found only in arid regions, arid environments tend to favour their formation. Naturally occurring collapsible soils are formed typically from debris flow (e.g. alluvial fan materials), as wind-blown sediments (e.g. loess), as cemented high salt content metastable soils (e.g. sabkha, see Chapter 29 *Arid soils*), and as tropical residual soil (see Chapter 30 *Tropical soils*). In addition, collapsible soils can be formed artificially through poor compaction control or where compaction is dry of optimum (e.g. non-engineered fill, see Chapter 34 *Non-engineered fills*), or as waste materials (e.g. fly ash beds, Madhyannapu *et al.*, 2006). However formed, common to almost all collapsible soils are both low densities and a relatively stiff and strong state when dry (as illustrated in **Figure 32.1**). Notable exceptions to this are post-glacial sensitive 'quick' clay soils found mainly in Canada, Alaska and Scandinavia, but these are arguably a special case, being geographically centred and in a saturated collapsible state. An additional exception is saturated slide material such as saturated sands that has been allowed to flow on slopes that have experienced liquefaction (Nieuwenhuis and de Groot, 1995).

Collapsible soils can be defined as soils in which the major structural units are initially arranged in an open metastable packing through a suite of different bonding mechanisms. If the soil is loaded beyond the yield strength of the bonding material, collapse will occur – this results in a rearrangement of particles to form a denser stable configuration (see **Figure 32.2**). Thus the collapse itself is controlled both microscopically and macroscopically. An appreciation of both these elements is essential if the true nature of collapse, and therefore its effective remediation, are to be fully understood.

Collapse is often triggered by a combination of increased stress (load) and the addition of water leading to increased

Figure 32.1 Example of loess in its pre-collapsed state exhibiting its relatively stiff soft rock state when dry, allowing the formation of man-made caves, Slovakia

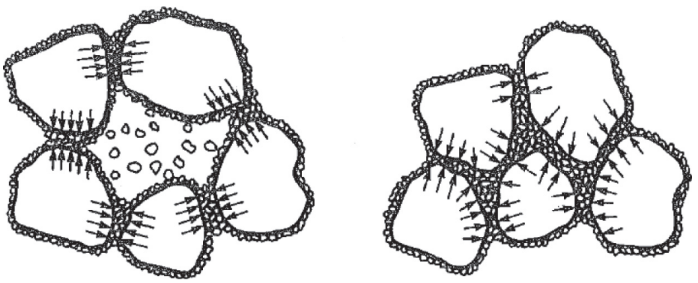

Figure 32.2 An illustration of collapse through inundation

degrees of saturation. However, collapse is most often triggered by an increase in water content. There are a variety of sources of water ingress that can initiate collapse, many associated with urban environments. These include landscape irrigation, broken water or sewer pipes, run-off or poor drainage control, groundwater recharge, or water content changes through capillary rise.

An example of the effects of urbanisation and associated landscaping was illustrated by a commercial building in New Mexico. After winning the city's most beautiful lawn and landscaping award, achieved through heavy watering, the building suffered US$ 500 000 foundation damage owing to soil collapse (Houston *et al.*, 2001). The result of infiltration with water results in a relatively sudden volume compression, and is often associated with loss of strength. This can clearly have important geotechnical consequences, including loss of serviceability resulting in expensive remediation or, on occasion, complete failure. This was illustrated by the structural failures caused by damage to foundations on collapsible soils in Egypt (Sakr *et al.*, 2008), and the collapse problems caused by hydrogeological changes associated with the construction of a dam in Brazil (Vilar and Rodrigues, 2011).

Other reported problems have occurred in embankment bases (Thorel *et al.*, 2011), dam embankments (Peterson and Iverson, 1953), road embankments (Knight and Dehlen, 1963) and fill (Charles and Watts, 2001). It can be particularly problematical when collapse causes damage to historic buildings (Herle *et al.*, 2009), e.g. the cracking that developed in the wall of a 15th century pagoda in Lanzhou, China, after the introduction of an irrigation scheme (see **Figure 32.3**).

From this it is clear that, given the correct depositional environment, collapse has the potential to occur in any soil. In fact, given the correct stress environment, a collapsible soil may exhibit expansive behaviour (Derbyshire and Mellors, 1988; Barksdale and Blight, 1997; see also section 32.3.3 below). It is therefore necessary to understand the process of collapse if problems associated with collapsible soils are to be avoided or mitigated. As collapse is for the most part triggered by increases in water content, problems are often

Figure 32.3 Collapse-induced cracking in a 15th century pagoda
Reproduced from Billard *et al.* (2000); John Wiley & Sons, Inc.

encountered in urban and built environments and so the impact occurs where it has potential to cause the most harm. This can be particularly problematical as in many parts of the world collapsible soils exist in areas of high seismic actively (Houston *et al.*, 2003). The consequences can be catastrophic, e.g. the Haiyuan earthquake in which induced loess landslides in 1920 killed over 200 000 people (Derbyshire *et al.*, 2000; Zhang and Wang, 2007). Moreover, the potential for collapse will remain until full collapse has been induced either naturally through flooding and/or loading (earthquakes), or artificially by human activity. Human activity can be either accidental via poor drainage control, or deliberate through ground improvement, e.g. dynamic compaction.

32.2 Where are collapsible soils found?

Rogers (1995), Lin (1995), Bell and de Bruyn (1997) and Houston *et al.* (2001, 2003) discuss in detail the various forms of collapsible soils found worldwide. Collapse occurs because

soil has certain inherent properties. Typical features that are found with most collapsible soils include:

- an open metastable structure;
- a high voids ratio and low dry density;
- a high porosity;
- a geologically young or recently altered deposit;
- a deposit of high sensitivity;
- a soil with inherent low interparticle bond strength.

Thus many soils can and will exhibit collapsible behaviour. This is illustrated in **Figure 32.4** along with the various formation processes that can yield a collapsible soil.

Collapsible soils include naturally occurring soil formations, such as tropical residual soils, loess and quick clays, and anthropogenic soils such as uncompacted or poorly compacted fill. However, any compacted soil can exhibit collapse if the confining pressure is high enough (see section 32.3.3 below). Further details of tropical and anthropogenic soil collapse can be found in Chapters 30 *Tropical soils* and 34 *Non-engineered fills* respectively. Additional information on the collapse behaviour of residual soils is also provided by Barksdale and Blight (1997) and Roa and Revansiddappa (2002). Examples include decomposed gneiss (Feda, 1966), decomposed granites (Brink and Kanty, 1961) and granitic gneiss (Pereira and Fredlund, 2000).

Other soils exhibiting collapse include collapsible gravels (Rollins *et al.*, 1994), granitic sands in South Africa (Jennings and Knight, 1975), collapsible sands of the southern African east coast (Rust *et al.*, 2005) and quick clays (Bell, 2000). Loess is probably the most commonly encountered naturally occurring collapsible soil, covering some 10% of the worlds landmass (Jefferson *et al.*, 2001). Many of the practices and engineering approaches used to deal with collapsible soils stem from the treatment of loess soils.

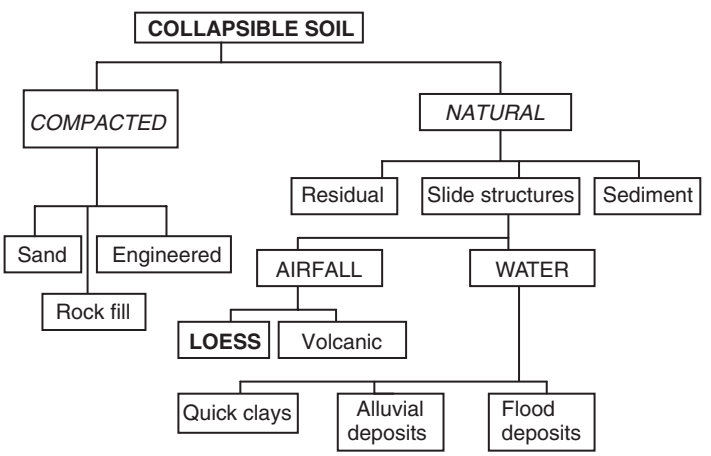

Figure 32.4 Classification of collapsible soils (Rogers, 1995)

32.2.1 Wind-blown soils – collapsible loess soils

Loess consists essentially of silt-sized (typically 20–30 μm) primary quartz particles that form as a result of high energy earth-surface processes such as glacial grinding or cold climate weathering (Rogers *et al.*, 1994). These particles are transported from the source by rivers. Subsequent flooding by these rivers allows the quartz silt particles to be deposited on flood plains (Smalley *et al.*, 2007). On drying out, these particles are detached and transported by the prevailing winds until deposition leeward at distances ranging from tens to hundreds of kilometres. Cementing materials are often added after deposition or dissolved and re-precipitated at particle contacts (Houston *et al.*, 2001). This process has resulted in the almost continuous deposit draped over the landscape from the North China plain to southeast England (where it is generally referred to as 'brickearth') – see **Figure 32.5**.

It is possible to isolate five major loess regions worldwide: North America, South America, Europe (including western Russia), central Asia and China (Smalley *et al.*, 2007). These loess regions often underlie highly populated areas and major infrastructure links, making them vulnerable to soil collapse. The areas of most widespread concern are concentrated in eastern Europe, Russia and, to a growing extent, China (see Derbyshire *et al.*, 1995, 2000), although potentially serious problems of collapse exist wherever loess is found.

Figure 32.5 indicates the approximate distribution of loess/brickearth greater than 0.3 m in thickness in the UK. Significant thicknesses (greater than 1 m) are restricted to north and east Kent (see Fookes and Best, 1969; Derbyshire and Mellors, 1988), south Essex (see Northmore *et al.*, 1996) and the Sussex coastal plains. In Essex, deposits of up to 8 m have been found, although thicknesses of 4 m or so are

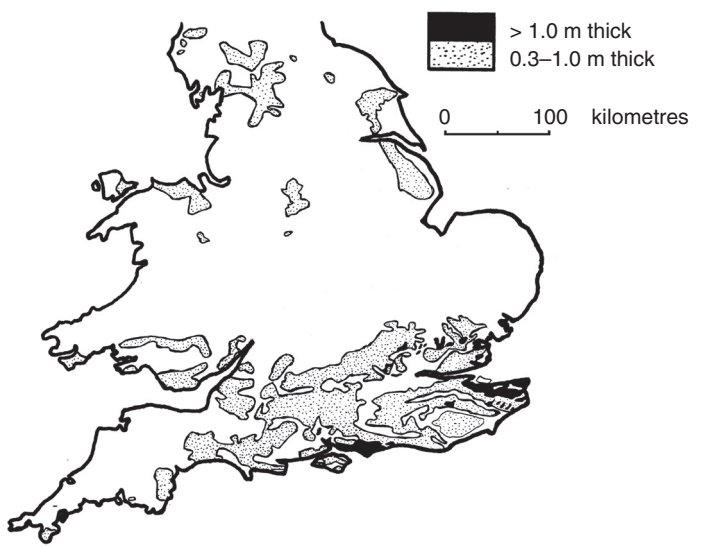

Figure 32.5 Distribution of 'brickearth' (loess) deposits in southern England and Wales
Modified from Catt (1985); Allen & Unwin (as reproduced in Jefferson *et al.*, 2001)

more typical (Northmore *et al.*, 1996). However, substantial deposits can reach tens and even hundreds of metres thickness worldwide (see Smalley *et al.*, 2007 for further details).

Regional trends in loess occur in the type of deposit found around the world and these can be determined through textural and mineralogical distinctions. However, there is generally a progressive decrease in modal size with distance from its source material – suggesting that sorting of loess material occurs with wind direction during deposition (Catt, 1985).

Originally, loessic deposits would have been more extensive but they have been removed by post-depositional erosion, colluviation, deforestation/agriculture and resource stripping activities (Catt, 1977). As a result, modern loess deposits are often only found overlying relatively permeable strata.

32.2.2 Other collapsible deposits

As discussed in sections 32.2 and 32.3, many soils exhibit collapsibility. Apart from those already highlighted above, a number of water-sediment deposits exhibit collapse potential. Two main groups exist: alluvial deposits and quick clays. Alluvial deposits reported to cause collapse problems include alluvial fans, alluvial flood plain deposits and mud flow deposits, with several case histories of collapse problems in alluvial fan deposits being provided by Rollins *et al.* (1994).

By comparison, saturated quick clay has become unstable owing to its post-glacial depositional environments, allowing an open structure to form via slow sedimentation under shallow marine conditions (Rogers, 1995; Locat, 1995). The resulting open fabrics are maintained by small amounts of carbonate cementation of clay minerals, with salt leaching often having occurred. Quick clays typically have liquidity indices greater than 1, with liquid limits often less than 40% (Bell, 2000). When disturbed, the particles in quick clays are remoulded into closely packed configurations. As the water content remains unchanged during the collapse process, quick clays become oversaturated and may flow as a viscous liquid. This can have devastating effects as witnessed by the 1978 landslide in Rissa, Norway, where, after the initial landslide, a series of minor slides developed which eventually covered an area of 3 300 000 m^2; or more recently by the large landslide in Leda clay in Ontario, Canada in 1993 (see Bell (2000) for further discussion).

32.3 What controls collapsible behaviour?

Collapsibility occurs owing to the various geomorphologic and geologic processes as well as human activities during soil formation. The key to this is understanding the nature and processes that take place during provenance (P), transportation (T) and deposition (D) of the soil particles: it is the PTD sequence of a deposit that produces an open metastable collapsible structure of relatively high void ratio (Sun, 2002; Jefferson *et al.*, 2003b; Smalley *et al.*, 2007). The PTD approach conceptualises the processes of soil genesis, subsequent transportation and ultimate disposition, so elucidating how these influence the engineering behaviour of the final deposit.

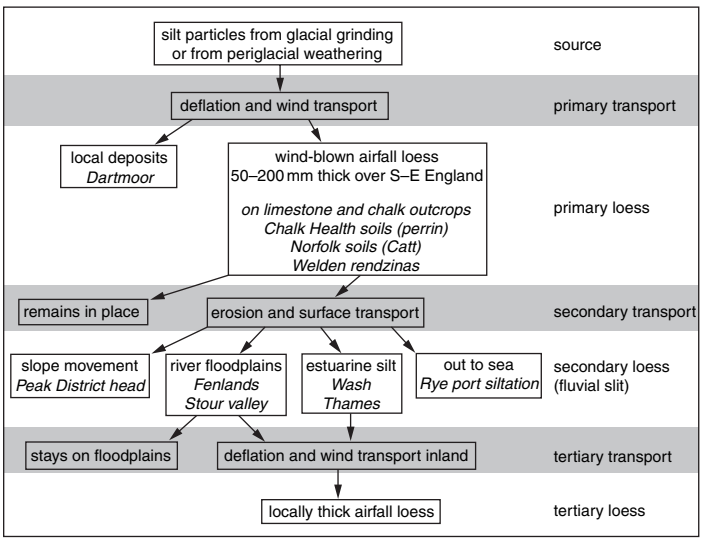

Figure 32.6 A PTD geomorphological model of loess in southern Britain. Note: Norfolk soils (Catt *et al.*, 1971); Chalk Heath soils (Perrin, 1956)
Reproduced from Jefferson *et al.* (2003b); East Midlands Geological Society

However, some deposits have been through secondary or tertiary PTD sequences, often reducing or even eliminating collapse potential. An example to illustrate this is given in **Figure 32.6**, based on a PTD model of loess found in southern Britain, with further details discussed by Pye and Sherwin (1999) and Derbyshire and Meng (2005).

Wind-blown collapsible soils such as loess often consist of different zones of variable collapsibility, both laterally and with depth, as a result of their geomorphology. The prevailing wind direction generates zones of material laterally changing in nature from sandy loess through to clayey loess deposits; see **Figure 32.7**. It should be noted that the terms clayey, silty and sandy loess are defined by particle size analysis (see Holtz and Gibbs, 1952). In turn, the degree of saturation and potential collapsibility often follows similar trends. For example, the loess in Bulgaria (**Figure 32.7**) exhibits an increase in saturation as the modal size reduces (Jefferson *et al.*, 2002). The thicknesses of loess formed often follow the same pattern – with the greatest thicknesses occurring nearest to the source material.

In addition, deposits such as loess have been formed over many thousands of years and during this time climactic conditions have varied considerably. As a result, the loess soil sequence has alternating layers of loess (formed during cold periods) and clay-rich palaeosols (formed during warm periods) – see **Figure 32.8** for illustration.

The alternating nature of loess formation significantly influences the engineering behaviour and ultimately the nature of collapse, and the location (depth) where collapse occurs. This will dictate the nature of the infiltration patterns of water into the soil and as a result can yield collapse in unexpected locations. Moreover, this can influence the

effectiveness of any ground improvement approach used to remove collapsibility.

As a result of the various geomorphologic processes involved in the formation of loess, these deposits typically have three zones of relative collapsibility:

- Zone 1: a zone at depth of collapsed material due to overburden pressure.
- Zone 2: a collapsible zone.
- Zone 3: a surface crust (which requires additional load to cause collapse). This has led countries with extensive loess deposits (including Eastern Europe and the former Soviet Union) to develop classification schemes related to the collapse of loaded foundations (see **Figure 32.8**). Two types of collapsibility occur in such schemes:

  Type I mainly loaded collapsibility (collapse deformation under overburden pressure of $\delta_n < 5$ cm); and

  Type II mainly unloaded collapsibility ($\delta_n > 5$ cm, where δ_n is the collapse deformation).

Type I loess is usually of small thickness (shown in **Figure 32.8**) and contains one or two palaeosols (PS), together with an associated carbonate zone (Cz). Collapse occurs after the foundation stress exceeds a certain critical stress, which can be determined by laboratory tests or tests in the field (see section 20.4 below).

Type II loess has greater thickness – up to 50 m or more. **Figure 32.8** shows a typical case of a Danubian terrace with a deposition of loess of about 20 m. In this case, three loess horizons (L_1, L_2 and L_3) are separated by two palaeosols (PS_1 and PS_2). In the Type II loess, three zones can be distinguished:

(i) upper zone A – no unloaded collapsibility but with potential loaded collapsibility;

(ii) middle zone B – unloaded collapsibility; and

(iii) lower zone C – uncollapsible (or collapsed).

Loess in zone C has previously collapsed under overburden pressure. Loess in zone A has had no unloaded collapsibility, since here the overburden pressure is small (i.e. it will not collapse under self-weight). However, it can be collapsible under additional load. In zone B, unloaded collapsibility occurs – it often contains thicker loess horizons with lower density and

higher porosity, n (i.e. $n > 50\%$), and it has a higher silt content than in zone C.

Further details of the different geomorphologic processes that generate collapsibility are given in Chapters 30 *Tropical soils* and 29 *Arid soils*, and an excellent treatment of the broader subject is provided by Fookes *et al.* (2005).

32.3.1 Bonding mechanisms and fabric

For collapse to occur, an open structure with relatively large voids must exist together with a source of strength to hold soil particles in position, resisting shearing forces associated with the current stress environment. To achieve this, bonding between particles or grains of sufficient strength must occur which, when weakened by the addition of water and/or an additional load, allows particles to slide over one another – resulting in collapse. There are generally considered to be three main bonding mechanisms present in collapsible soils (Barden *et al.*, 1973; Clemence and Finbarr, 1981; Rogers, 1995), namely:

(i) capillary or matric suction forces (see **Figure 32.9(a)**);

(ii) clay and silt particles at coarser particle contacts (see **Figure 32.9(b-d)**);

(iii) cementing agents, such as carbonates or oxides (see **Figure 32.9(e)**).

The fabric of a collapsible soil takes the form of a loose skeleton built of grains (generally quartz in the case of loess) and micro-aggregations (in the case of loess assemblages of clay or clay and silty-clay particles, see **Figure 32.10**). In some soils, such as loess, carbonate diagenesis may strengthen the meniscus clay bridges between silt grains and further influence collapse potential. Recent observations by Milodowski *et al.* (2012) suggest that there are three variants of the clay bridges: (1) simple clay meniscus films, (2) clay films developed on a scaffold of an earlier meniscus of fibrous calcite and (3) clay films permeated or encrusted by microcrystalline calcite and/or dolomite. Hence the strength can vary both laterally and vertically over relatively short distances. This, together with the durability of the cementing material, needs to be taken into account for engineering purposes.

It should be noted that the microfabric of loess soils that have experienced reworking (cf. **Figure 32.6**) are often anisotropic and as a result exhibit much reduced collapsibility (Pye and Sherwin, 1999). In addition, as with other collapsible soils, domains of pelletised material can form and be arranged in a loose framework. Further details are given in Klukanova and Frankovska (1995), Jefferson *et al.* (2003b) and Milodowski *et al.* (2012). Derbyshire and Meng (2005) provide further discussion of fabrics associated with loess soils in China.

Other collapsible soils, such as quick clay, have essentially the same open metastable fabric, but are generated under different geomorphologic conditions. Further details are provided by Locat (1995), Bentley and Roberts (1995) and Bell (2000); see also section 32.2.2 above. Further details related to other collapsible deposits are given elsewhere in this manual (see Chapters 34 *Non-engineered fills* and 30 *Tropical soils*).

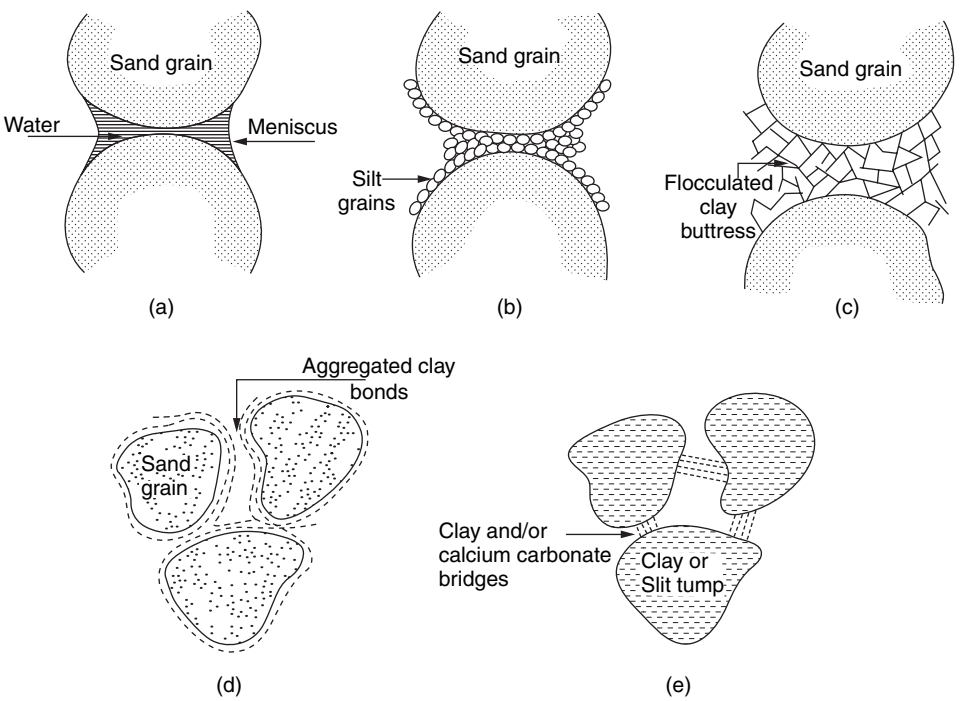

Figure 32.9 Typical bonding arrangement formed in collapsible soils

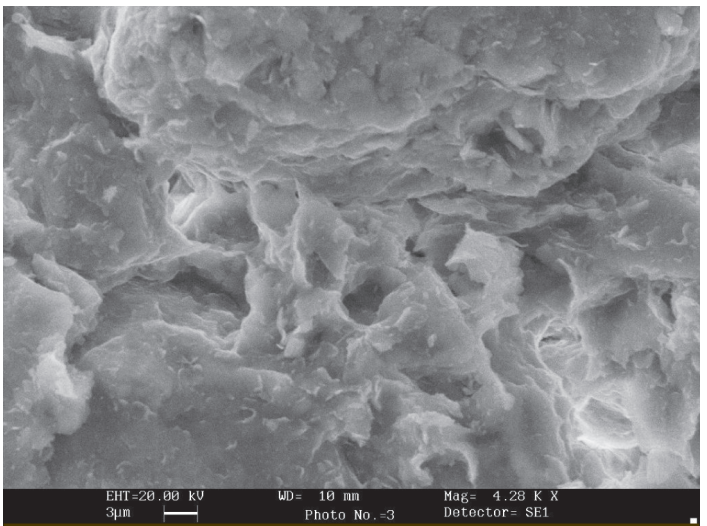

Figure 32.10 Scanning electron micrograph of bonded quartz particles in Brickearth (loess) from Ockley brickworks, Sittingbourne, Kent

Reproduced from Jefferson *et al.* (2001); all rights reserved

It should be noted that although fabric is widely recognised as important in explaining collapse behaviour, it lacks a simple quantitative descriptor (Alonso, 1993 as cited by Pereira and Fredlund, 2000).

32.3.2 Mechanisms of collapse

Collapse in cemented soils typically involves the destruction of all three bonding types. In contrast, collapse, in uncemented dry soils is solely due to the destruction of capillary forces. The strength derived from suction and cementing can be characterised in similar ways. However, on wetting suction will be lost, whereas chemical bonding is likely to be less affected by a change in suction. However, salt and clay bonds that occur at particle contacts will tend to be removed or weakened after inundation and hence collapse occurs.

Petrographic evidence indicates that collapse in cemented loess soils occurs in three stages after inundation (Klukanova and Frankovska, 1995; Milodowski *et al.*, 2012):

Stage 1 Dispersion and disruption of clay bridges or buttresses between loosely packed silt grains, leading to initial rapid collapse of inter-ped matrix.

Stage 2 Load taken up via contact between adjacent compact silt peds, which rearrange into a closer packing.

Stage 3 With increased loading, progressive deformation and shearing of peds occur, resulting in further collapse as peds disaggregate and silt particles collapse into now-unsupported inter-ped areas.

Similar observations concerning the collapse process in compacted soils have been made by Pereira and Fredlund (2000), who suggest:

Phase 1 (Pre-collapse): High matric suction generates a metastable structure that suffers small volume deformations with decreased suction. No particle slippage occurs and structure remains intact.

Phase 2 (Collapse): Intermediate matric suction and a significant decrease in volume occur, altering the structure through bond breakage.

Phase 3 (Post-collapse): Saturation is approached and no further decrease in volume (or reductions in matric suction) will occur.

Pereira and Fredlund (2000) further observed that as the net confining pressure increases, the wetting-induced collapse becomes greater and the matric suction associated with phases 1 and 3 will be higher.

During the collapse process, the nature of pores also changes. Studies on loess have shown that most of the macropores (100–500 µm) are typically destroyed, leaving smaller intergrain and interaggregate pores (8–100 µm) (Osopov and Sokolov, 1995). Similar observations with respect to collapse mechanisms were made by Klukanova and Frankovska (1995) and Feda (1995), and more recently on residual soils by Roa and Revansiddappa (2002).

Cerato *et al.* (2009) observed that compacted soils with a greater number of smaller clods showed greater collapse, with collapse largely dependent on the interaggregate and intra-aggregate pore distribution. Moreover, when clods are in a drier than optimum water content, stronger state, higher yield stresses result and the overall soil structure is less prone to collapse. In some fill materials the parent material may also lose some strength, or aggregates within the fill may soften as its water content increases – resulting in a possible collapse (Lawton *et al.*, 1992; Charles and Watts, 2001; Charles and Skinner, 2001).

For uncemented soil, collapse is related to the destruction of capillary (matric suction) forces, with water infiltration producing wetting fronts. The volume change associated with collapse is confined to the wetted zone (Fredlund and Gan, 1995). As matric suction can be visualised as isochrones (akin to excess pore water pressures seen in consolidation) analysis can be undertaken in much the same way. Further details of this, including experimental observations, are provided by Fredlund and Gan (1995). Collapse deformations that occur owing to suction reductions have been found to depend mainly on soil density and the stress state under which collapse occurs (Sun *et al.*, 2007).

Pereira and Fredlund (2000) highlighted key features in the collapse of compacted soils:

- For any type of soil compacted dry of optimum water content, collapse can occur.
- High microforces of shear strength exist through bonding, chiefly via capillary action.
- Compressibility gradually increases and shear strength gradually decreases in collapsible soils during saturation.

- Soil collapse progresses with increasing degree of saturation. However, above a critical degree of saturation, no further collapse occurs.
- Collapse is associated with localised shear failure (see further discussion in section 32.4.5 below).
- During wetting-induced collapse under constant load and anisotropic oedometer conditions, horizontal stresses increase.
- For a given mean normal total stress under triaxial conditions, the magnitude of axial collapse increases and radial collapse decreases with increased stress ratio.

Fill collapse potential is thus controlled by placement conditions, water content history and stress history. Further discussion on this subject and of other poorly compacted materials is provided by Charles and Skinner (2001), Charles and Watts (2001), and elsewhere in this manual; see Chapter 34 *Non-engineered fills*.

32.3.3 Modelling approaches – collapse prediction

Most collapsible soils exist in a partially saturated state. The suctions that develop are made up of two components: matric suction and osmotic suction, the sum of which is known as total suction. Discussion of these aspects and their implications is presented in Chapter 30 *Tropical soils* and a detailed treatment is also provided by Fredlund and Rahardjo (1993) and Fredlund (2006).

This approach has important limitations and a more complete model has been developed by Alonso *et al.* (1990). Their approach extended the Modified Cam Clay model to unsaturated soils and introduced the loading–collapse (LC) surface to define yielding due to either external loading (total stress) or saturation (loss of suction). Experimental evidence for this has been presented by a number of authors, e.g. Jotisankasa *et al.* (2009). The LC model further demonstrated the stress path dependency of collapse and explains why, under lower net stress, water inundation may cause swelling and at higher net stresses, collapse occurs. Therefore any modelling approaches used should treat soils as potentially expansive or collapsible in the same framework. However, it should be noted that collapse, unlike swelling, is an irreversible process.

The effects of bonding and bond yield strength are important aspects in many collapsible soils. Further details are discussed by Leroueil and Vaughan (1990), Maâtouk *et al.* (1995), Malandraki and Toll (1996) and Cuccovillo and Coop (1999).

Reviews of the constitutive models used to assess partially saturated soils are provided by D'Onza *et al.* (2011) and Sheng (2011), with discussion on their limitations provided by Zhang and Li (2011). Overall, constitutive models for partially saturated soils deal with the mechanical stress–strain and hydraulic suction–saturation relationships.

Constitutive models have allowed a number of numerical approaches to be developed. However, these often need a range of parameters for analysis and so may not be cost-effective for many projects. However, this can be mitigated to some degree using approaches developed by Nobar and Duncan (1972) and Farias *et al.* (1998) that utilise, for example, stress–strain curves for dry and saturated behaviour. A similar approach has been advocated by Charles and Skinner (2001) and Skinner (2001) when dealing with fill. In addition, discrete element methods (DEMs) are allowing micromechanical aspects of collapsible soils to be examined (see Liu and Sun, 2002, for further details).

32.4 Investigation and assessment

In order to provide an economical and efficient engineering solution four basic steps must be undertaken when dealing with collapsible soils (after Popescu, 1986):

(i) identification – determine whether a collapsible soils exists;

(ii) classification – if a collapsible soils exists, how significant is it?

(iii) quantification – assess the degree of collapse that will occur;

(iv) evaluation – assess the design options.

However, one of the greatest problems with collapsible soils is that their existence and the extent of their collapse potential are often not recognised prior to construction (Houston *et al.*, 2001). Thus it is essential to first identify a collapsible soil and then to estimate its collapse potential, particularly (but not exclusively) on sites containing water-sensitive soils.

Engineers often mistake, or simply do not recognise the presence of, a collapsible soil. Current standards relating to soil field descriptions, used by engineers, tend to group all fine materials together (e.g. silts and clays) under a common descriptor, which does not help in this regard. Whilst there are practical reasons for this, such groupings potentially reduce the ability of engineers to identify and assess whether a soil is collapsible. Moreover, even though a considerable database of knowledge exists globally, much of this work tends to be lost owing to use of formats and terms unfamiliar to engineers or simply suffers from language barriers (Jefferson *et al.*, 2003a).

Popescu (1986), Houston and Houston (1997) and Houston *et al.* (2001) provide excellent overviews of the key aspects associated with the identification and characterisation of collapsible soils. When characterising a collapsible soil, Houston *et al.* (2001) suggest the following stages be undertaken:

(i) reconnaissance;

(ii) use of indirect correlations;

(iii) laboratory testing;

(iv) field testing.

These aspects are, in general, common to the investigation of expansive soils and reference to discussions in Chapter 33 *Expansive soils* would be useful.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

32.4.1 Reconnaissance

Using reconnaissance to gather useful geologic and geomorphologic information can be useful in anticipating collapse by providing clues on what to look out for. The first step is to understand geologic and geomorphologic settings (see section 32.3 above). For example, Lin (1995) found that there was a strong correlation between geomorphologic information and collapsibility. It may be that the underlying assumption should be that a deposit is collapsible until confirmed otherwise – as in the case of Beckwith (1995), who recommends that alluvial fans should all be assumed to be collapsible. Charles and Watts (2001) make a similar suggestion when dealing with partially saturated fill – until there is adequate evidence to the contrary. Further clues to the likelihood of collapsible soils can be gained from prior history and environmental factors.

Lin (1995) highlighted how collapse of loess soils was influence by age, overburden pressure, and the degree of saturation and suction, illustrating the difficulties associated with determining whether or not a soil is collapsible. Popescu (1992) highlighted other aspects that need to be considered when assessing the collapsibility of soils. These include:

(i) Internal factors

- mineralogy of particles;
- shape and distribution of particles;
- nature of interparticle bonding/cementing;
- soil structure;
- initial dry density (which is often low);
- initial water content.

(ii) External factors

- availability and nature of water;
- applied pressure;
- time permitted for water percolation to occur;
- stress history;
- climate.

Thus a detailed programme of classification and quantification is necessary to fully assess collapse potential across a site.

Details of reconnaissance and its role in site investigations are dealt with elsewhere in the manual – see Chapter 45 *Geophysical exploration and remote sensing*. Further information can also be found in Fookes *et al*. (2005).

32.4.2 Indirect correlations

Various collapse coefficients related to loess have been produced, which include ever more parameters, e.g. Basma and Tuncer (1992) and Fujun *et al*. (1998). However, these are unnecessarily complex and the traditional collapse potential, for example the one described by Gibbs and Bara (1962), is better owing to its relative simplicity.

Many criteria and correlations have been proposed in the assessment of collapse potential based on soil properties such as natural water content, void ratio or index properties (see Rogers *et al.*, 1994; Northmore *et al*., 1996; Bell, 2000). However, these can be misleading as they are often based on remoulded and approximate soil properties; therefore, inappropriate evaluation can thus occur (Northmore *et al.*, 1996). Many of the correlations available have met with only moderate success owing to their weak correlations and considerable scatter (Houston *et al.*, 2001). Thus, it is more efficient and economical to use either laboratory or field tests when assessing collapse potential. This has the added advantage of providing not only identification, but also assessment data.

32.4.3 Laboratory testing

The most effective method to access collapsibility is through collapse tests. The actual collapse potential is traditionally measured using double and single oedometer tests (Jennings and Knight, 1975), which have been subsequently modified by Houston *et al.* (1988). The amount of collapse strain produced when the test specimen is flooded under a given pressure indicates a sample's susceptibility to collapse.

Figure 32.11 illustrates a typical response (Houston *et al.*, 1988), where a seating stress of 5 kPa has been used to establish an initial state. Any compression under this stress is attributed to sample disturbance. The initial compression curve A–B–C represents the response of the soil at its *in situ* water content. Pressure is applied until the stress on the sample is equal to (or greater than) that expected in the field. At this point, the sample is inundated and compression measured (C–D in **Figure 32.11**), after which further loading is undertaken, corresponding to line D–E. This equates to the three phases of collapse described by Pereira and Fredlund (2000).

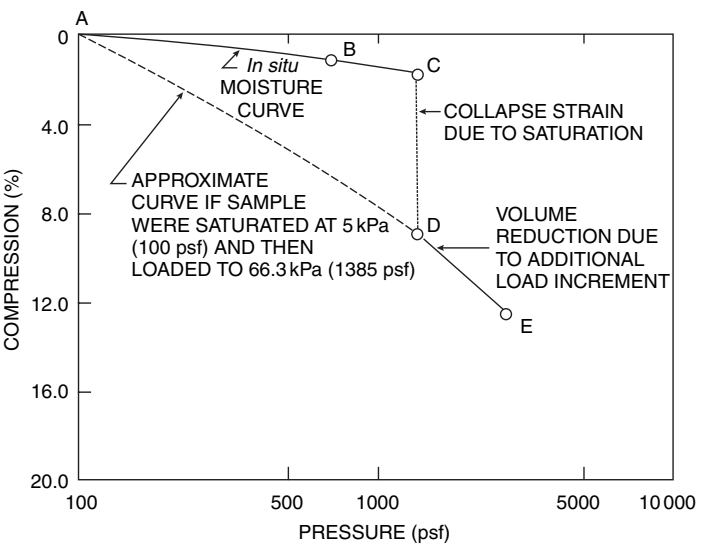

Figure 32.11 Compression curves for modified Jennings and Knight oedometer test (N.B. 1 pound per square foot (psf) = 0.0479 kPa)
Reproduced from Houston *et al.* (1988), with kind permission from ASCE

The amount of collapse of a layer is found by multiplying the thickness of the layer by the collapse strain, using values corresponding to the final stress at the midpoint of the zone in question. Further details are provided by Houston *et al.* (1988), who note that collapse strains vary both laterally and with depth, so requiring integration of strains along a vertical column of zones to estimate surface settlements.

The double oedometer test uses two near-identical specimens of soil and incremental stress increases are applied to one specimen in its natural state and to the other specimen that has been immediately saturated at under a seating stress of typically 5 kPa. Based on the double oedometer test, the degree of collapsibility can be assessed and used to provide an indication of the potential severity of collapse. **Table 32.1** provides details presented by Jennings and Knight (1975), which indicate a 1% collapse can be regarded as metastable. However, this cut-off varies across the world, with values of 1.5% taken in China (Lin and Wang, 1988) and values in excess of 2% in the USA used to indicate soils susceptible to collapse (Lutenegger and Hallberg, 1988).

Collapsible fill identification is often best achieved by testing samples at various water contents and dry densities over the range of stress levels expected (Houston *et al.*, 2001; Charles and Skinner, 2001).

Although only approximate, double oedometer tests do give a repeatable and reproducible qualitative indication of collapse. Often it is the collapsibility risk that is more important to assess than the actual amount of collapse that will occur. However, traditional oedometer tests suffer from sample disturbance effects and often reach saturations not commonly encountered in the field (Rust *et al.*, 2005). The extent of sampling effects has been debated, as have the relative merits of the use of block and tube sampling when testing collapsible soils (see Houston *et al*., 1988; Day, 1990; Houston and El-Ehwany, 1991; Neely, 2010). Northmore *et al.* (1996) observed that, upon flooding in the oedometer, certain specimens of brickearth became saturated almost instantaneously with a rapid intake of water into the pore space.

Thus, at best, traditional oedometer collapse tests should be considered as index tests; for full collapse evaluation, a field trial should be conducted. When estimating collapse settlements, significant suctions may remain after wetting and soil will remain only partially collapsed (see section 32.5.1 for further discussion). This must therefore be accounted for in any assessments.

Collapse (%)	Severity of problem
0–1	No problem
1–5	Moderate trouble
5–10	Trouble
10–20	Severe trouble
>20	Very severe trouble

Table 32.1 Collapse percentage (defined as $\Delta e/(1+e)$, where e is the void ratio) as an indication of potential severity
Data taken from Jennings and Knight (1975)

Other test methods have been employed to characterise collapsibility; these include suction-monitored oedometers (e.g. Dineen and Burland, 1995; Jotisankasa *et al.*, 2007; Vilar and Rodrigues, 2011), Rowe cells (Blanchfield and Anderson, 2000) and triaxial collapse tests (e.g. Lawton *et al.*, 1991; Pereira and Fredlund, 2000; Rust *et al.*, 2005). Further details are provided by Fredlund and Rahardjo (1993) and Rampino *et al.* (2000). Tarantino *et al.* (2011) provide a review of techniques used for measuring and controlling suctions, whilst Fredlund and Houston (2009) discuss protocols for the assessment of unsaturated soil properties in geotechnical practice. Vilar and Rodrigues (2011) provide a useful example of suction measurement in the assessment of collapse. Further details are presented in Chapter 30 *Tropical soils*.

32.4.4 Field testing

Field methods have traditionally used plate loading tests (Reznik, 1991, 1995; Rollins *et al.*, 1994) and more recently, pressuremeter tests to determine collapse potential (Smith and Rollins, 1997; Schnaid *et al.*, 2004). Francisca (2007) provides details of the use of standard penetration tests (SPTs) to evaluate the constrained modulus and collapsibility of loess in Argentina, with higher N values being recorded in soils of a lower collapse potential. However, care is needed to ensure uniformity of stress state in the collapse region. This is often the main disadvantage with *in situ* collapse tests and has led a number of researchers to develop more sensitive test methodologies.

For example, Handy (1995) devised a stepped blade method to evaluate lateral stress changes. Methods to determine response to wetting were developed by Houston *et al.* (1995b) (the downhole plate test) and Mahmoud *et al.* (1995) (the box plate load test). A brief but useful overview of interpretation and comparison of collapse measurement techniques, including their relative merits, is provided by Houston *et al.* (1995a). These include minimal sample disturbance, large soil volumes tested and degree of wetting likely to be similar to the prototype.

Houston *et al.* (2001) present field investigations of the collapse potential of a low plasticity silt using an *in situ* test apparatus (see **Figure 32.12(a)**). Boxes of concrete or steel were lowered onto a concrete pad and filled with soil, the base of the foundation was inundated with water and movements were recorded (see also Mahmoud *et al.*, 1995). The relationship between partial collapse, matrix suction and degree of saturation (**Figure 32.12(b)**) highlights the importance of understanding the likely changes in water content of the soil surrounding a structure – something which Houston *et al.* (2001) suggests can be very difficult to predict accurately.

Houston *et al.* (2001) also provide a comparison between collapse predicted for a soil investigated using *in situ* methods (not the same tests as presented in **Figure 32.12**) and laboratory methods (**Figure 32.13**), and suggest that there are difficulties involved with the *in situ* approach. The load applied can

be controlled but the region affected by wetting and the degree of wetting can be very difficult to control.

Smith and Rollins (1997) investigated the use of a borehole pressuremeter to investigate the collapse potential of an arid soil. Once at the desired depth within the borehole, the pressuremeter expands radially to apply a pressure to the annulus of the borehole and measures the dry modulus of the soil (E_D). A set volume of water is discharged through the pressuremeter into the surrounding soil; the modulus during collapse (E_C) and wet modulus (E_W) post-collapse are then measured (see **Figure 32.14**). Smith and Rollins (1997) suggest that the moduli ratios E_C/E_D and E_W/E_D can be used to predict the collapsibility of a potentially collapsible soil (**Table 32.2**).

With recent improvements in technology, geophysical approaches have been advanced as a method to determine collapse potential (Evans *et al.*, 2004; Rodrigues *et al.*, 2006). The power of geophysical approaches to assess when a collapsible zone is present and its extent across a site was illustrated by Northmore *et al.* (2008), see **Figure 32.15**.

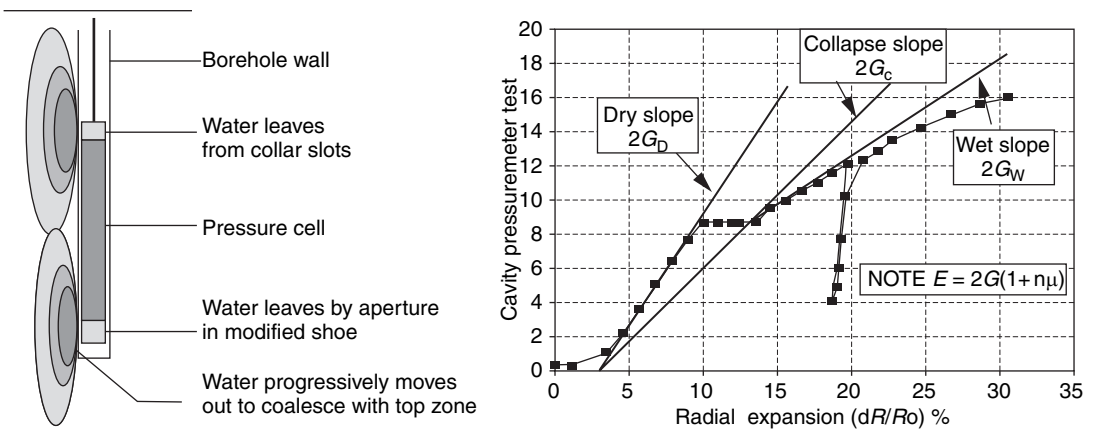

Figure 32.14 Illustration of pressuremeter (water only illustrated on left hand for clarity) and determination of the dry, collapsible and wet moduli, where *G* is shear modulus and μ is Poisson ratio

Reproduced from Smith and Rollins (1997); ASTM

Northmore *et al*. (2008) illustrated how depth and lateral extent of both collapsible and a non-collapsible loessic brickearth could be ascertained using a suite of different geophysical approaches, including electromagnetic (EM31 and EM34), electrical resistivity and shear wave profiles. Further details are provided by Gunn *et al.* (2006) for shear wave measurements and Jackson *et al.* (2006) for resistivity measurements. However, it is vital that adequate calibration is undertaken through laboratory testing. For this, traditional double oedometer and Panda probe profiling are used, where the Panda probe is a lightweight dynamic cone penetrometer which allows detailed physical soundings down to around 5 m to be taken (Langton, 1999). Once achieved, a full assessment of the presence of a potentially collapsible soil across the site can be made.

An important aspect with any field evaluation is the number of tests needed to adequately characterise the collapse potential of a loess soil. Houston *et al.* (2001) discuss statistical approaches developed to evaluate the minimum number of tests required to satisfactorily characterise a site and its collapse potential.

Criteria			Collapse potential
E_C/E_D		E_W/E_D	
≈1	and	≈1	Not collapsible
<1		≈1	Moderate collapse
≈1		<1	Moderate collapse
<1		<1	Possible severe collapse

Table 32.2 Use of modulus ratios to predict collapsibility of potentially collapsible soil
Data taken from Smith and Rollins (1997)

32.4.5 Assessment of wetting

The most challenging task for improving collapsible soils is the assessment of wetting extent and degree of potential future wetting. This is particularly true in arid or semi-arid environments where collapsible soils have not been wetted to any significant depth. However, even with collapsible deposits found in more humid environments, the deposits are often situated where significant wetting at depth has not occurred, or only part saturation has taken place, rendering the deposit still partially collapsible (Northmore *et al.*, 1996; Charles and Watts, 2001).

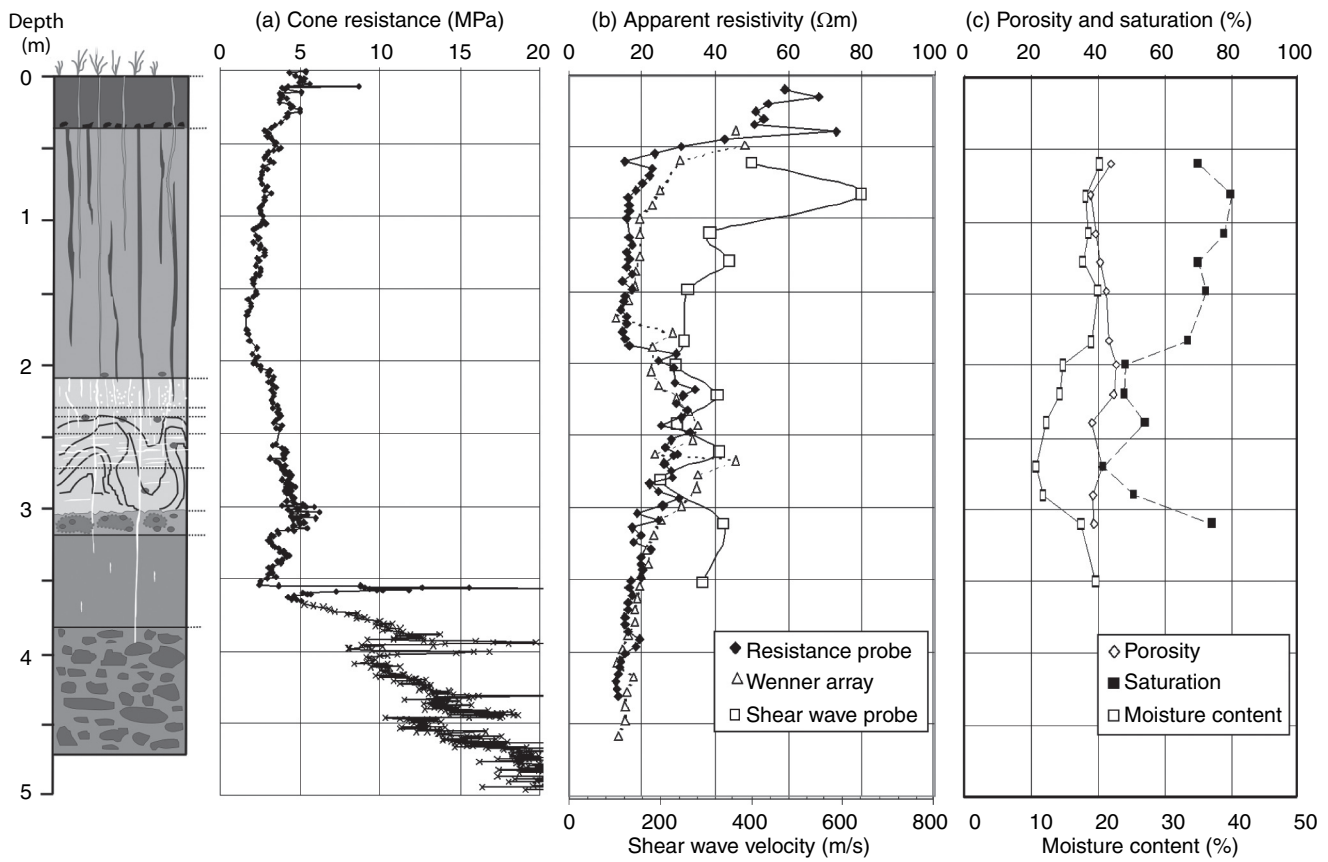

Figure 32.15 Profile through collapsible (~2–3 m) and non-collapsible (~0.5–2 m) brickearth – with collapsible deposits existing between 2 to 3 m, correlating to a drop in the degree of saturation
Reproduced from Northmore *et al.* (2008) all rights reserved

In general, detrimental effects of collapse occur in the zones both under foundations and within the probable wetting front (Houston *et al.*, 1988). Ponding tests may be used which can give an indication of depth and lateral extent of water migration, from which the best foundation option can be determined. El-Ehwany and Houston (1990) present results from laboratory infiltration wetting fronts and, by comparing these with observed rates, predict the depth of wetting versus time. They then describe how this information can be used to predict collapse settlements, taking account of partial wetting.

Clearly an assessment of the extent and degree of wetting is essential to determine collapse potential and the scope and requirements for any treatment processes. Many practitioners tend to be conservative and assume the degree of wetting equates to 100%, particularly if the collapsible zone is near to the surface and does not extend too deeply (Houston and Houston, 1997). Full wetting of a collapsible soil would only be expected with rising ground water. However, this is not often the case, and saturation only usually reaches between 35 and 60%, particularly when downward infiltration occurs. Hence the additional costs associated with such a conservative assumption may not be warranted (Houston *et al.*, 2001). El-Ehwany and Houston (1990) found that 50% saturation produces 85% of full collapse, agreeing approximately with the observations presented in **Figure 32.12 (b)**. They suggest that full collapse is achieved at between 65 and 70% saturation. Lawton *et al.* (1992) and others have shown that partial saturation will first trigger partial collapse, with full collapse occurring at saturation values as low as 60% – a figure that Bally (1988) agrees with. However, Osopov and Sokolov (1995) considered that full collapsibility would be realised only when saturation exceeded 80%.

This has implications for the prediction of collapse settlement, based on laboratory tests, which overestimate collapse strain and generally produce a greater degree of saturation than is achieved in the field; estimates put the overestimation at around 10% (El-Ehwany and Houston, 1990). However, this is not particularly large given the nature and accuracy of settlement predictions in general.

Wetting effects can be modelled using unsaturated stress state variables: net normal stress ($\sigma - u_a$) and matric suction ($u_a - u_w$) – further details can be found in Fredlund and Rahardjo (1993). The matric suction changes during wetting can be indicated by soil–water characteristic curves (SWCCs); further details are discussed in Chapter 30 *Tropical soils*. Houston *et al.* (2001) provide a range of SWCCs for collapsible loess soils from around the world. Further details of the evaluation of wetting using suction measurements have been discussed by Walsh *et al.* (1993).

All collapsible soils will experience partial collapse under partial wetting conditions. However, the shape and position of the partial collapse curve depend on the soil type, fines content and type of bonding present. Overall, it is clear that assessment of the extent and degree of wetting is the most difficult part of collapsibility evaluation.

32.5 Key engineering issues

32.5.1 Foundation options

Four basic approaches exist when dealing with design solutions in collapsible soils (Popescu, 1992):

(i) Use very stiff raft foundations and a rigid superstructure to minimise the effects of differential settlements (e.g. **Figure 32.16**). This tends to be expensive and not universally successful.

(ii) Ensure sufficient flexibility of the foundation and superstructure to accommodate ground movements without damage. This approach may be more applicable to smaller, lower cost buildings. Alternatively, a split rigid building can be flexibly connected.

(iii) Bypass the collapsible layer by use of piles.

(iv) Control or alter ground conditions through one or more of the various improvement techniques available (see section 32.5.5 and Chapter 25 *The role of ground improvement*).

Where the thickness of collapsible soil is relatively small, foundation recommendations are straightforward: the foundation level should be set below the collapsible soil layer. If this is not the case, then some form of pre-treatment is necessary to remove collapse potential.

If the collapsible layer is deep or is of significant thickness below the surface, pile foundations are used. However, Grigoryan (1997) has reported several cases where piles used in collapsible soils have experienced loss of bearing capacity and excessive settlements immediately after inundation through negative skin friction effects. In addition, the presence of a collapsible layer may adversely affect the performance of piles during the life of a building.

Kakoli (2011) provides one of the few detailed reviews and assessments of piles used in collapsible soils, drawing mainly on the work of Grigoryan and Grigoryan (1975). They suggested that in collapsible soils, negative skin friction exists for a few hours but disappears after pile settlement. Chen *et al.* (2008) present load tests for piles in collapsible soils subjected to inundation. They measured negative skin friction across five sites in China, finding values of negative skin friction between

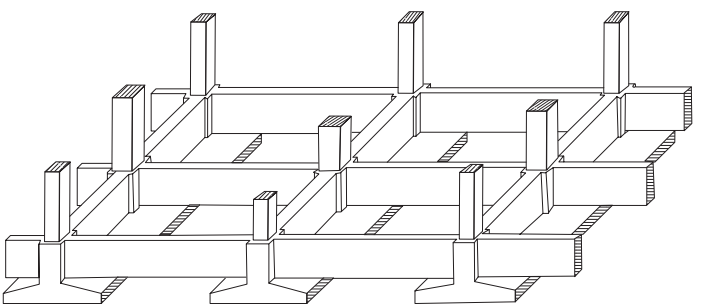

Figure 32.16 Continuous footing design for collapsible soils
Reproduced from Zeevaert (1972); Van Nostrand Reinhold Co.

around 20 and nearly 60 kPa. Kakoli (2011) presents numerical works (using PLAXIS) in the assessment of the effects of inundation on the performance of piles in collapsible soils, achieving results comparable with those presented by Chen *et al.* (2008). He further demonstrates how the effects of inundation increase collapse potential. Further details of the general behaviour of piles in collapsible soils are provided by Redolfi and Mazo (1992).

Often less expensive foundation options can be employed: Bally (1988) and Poposecu (1992) provide some examples of foundation practice in collapsible soils and Jefferson *et al.* (2005) illustrate this with a case study from Bulgaria.

32.5.2 Transport and utility infrastructure

As with foundations, transport infrastructure (roads and railways) can experience problems due to collapse. Particular problems for roads are the non-uniform collapse and non-uniform wetting of sub-grades that occur along the length of a road. These cause rough, wavy surfaces and have the potential to result in many miles of extensive damage to road structures (Houston, 1988). The potential damage to railways is more severe owing to their intolerance of longitudinal differential settlement, and the same is true for pipelines unless they are sufficiently flexible to permit longitudinal differential or lateral movements. Moreover if water pipelines or sewers suffer fracture due to differential movement, water leakage can exacerbate the collapse phenomena. Damage can also occur to associated structural and geotechnical assets, including bridges, slopes and cuttings.

Stress applied to sub-grade from highways has two components: overburden stress and imposed traffic loading (determined using common pavement analytical tools). It is likely that once wetting has occurred, short duration loading from heavy lorries would be sufficient to cause full collapse. It should be noted that collapse strains can occur at any depth at which significant wetting occurs (see section 32.4.5, above), regardless of the relative balance between overburden and imposed loads. Clearly changes in soil type along the length of a highway are important and routine non-destructive tests such as the falling weight deflectometer are useful here (Houston *et al*., 2002).

Drainage management is of particular concern, as most collapsible soils have higher permeabilities and suctions than road foundation materials. In addition, the pavement interrupts evaporation and changes water content regimes relative to the surrounding land. Hence significant risks of wetting collapsible soil sub-grades exist; the extent and depth of wetting is controlled by the sources of water, for example rising groundwater or surface ponding from poor drainage.

The approaches discussed above in section 32.4 and below in section 32.5.5 essentially apply to roads built on collapsible soils. Further details specific to roads are provided by Houston (1988) and Houston *et al.* (2002). Examples of parameters used in pavement design associated with collapsible soils are provided by Cameron and Nuntasarn (2006) and Roohnavaz *et al*. (2011).

32.5.3 Dynamic behaviour

Collapsible soils are particularly susceptible to liquefaction and dynamic settlement owing to their highly contractive nature during shearing. This can result in devastating consequences, with the Haiyuan landslide being a prime example (see Zhang and Wang, 2007). However, detection of the liquefaction and dynamic settlement potential of collapsible soils is difficult as they often have sufficient cementing when dry to prevent significant deformations during dynamic or earthquake loading (Houston *et al*., 2001). If, however, they become wetted, these bonds weaken and their liquefaction and dynamic settlement potential can significantly increase. Post-wetting behaviour is therefore of particular importance in earthquake-prone regions, especially if collapse is triggered by rising groundwater (Houston *et al.*, 2003). Moreover, these soils often have insufficient fines to render them non-liquefiable if saturated. Hence compressions induced upon wetted collapse may be inadequate to mitigate liquefaction and dynamic settlement potential (Houston *et al.*, 2001).

Houston *et al.* (2003) provide a brief overview of research that examines dynamic behaviour of collapsible soils. Their results show how cyclic stress ratios (CSRs) are strongly dependent on the degree of saturation (see **Figure 32.17**). Here, failure is taken to occur at CSR causing 10% strain. Cyclic stress ratios can be defined as the ratio of maximum shear stress (related to the cyclic shear stress amplitude of the earthquake) to vertical effective stress.

Liquefaction in loess soils is complicated by their microstructural aspects and so the process is generally less well understood than liquefaction in sands (see Hwang *et al.*, 2000; Wang *et al.,* 2004). However, improvement approaches that have proved successful in reducing liquefaction potential include dynamic compaction, use of compaction piles and methods that alter the soil's structure such as grouting (Wang *et al.*, 2004) – see section 32.5.5 for more details.

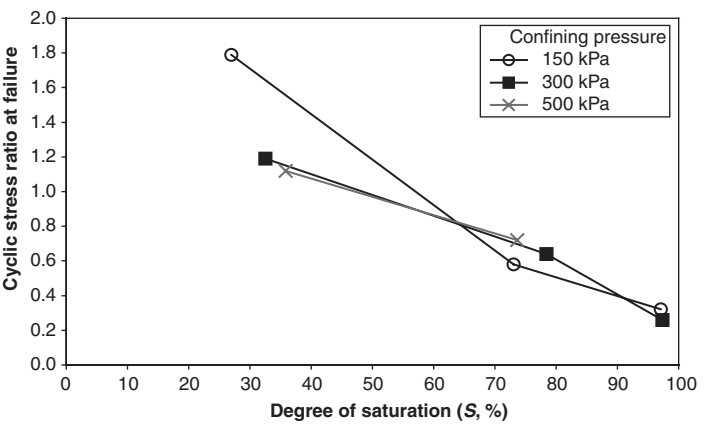

Figure 32.17 Variation of cyclic stress ratio at failure with degree of saturation
Reproduced from Houston *et al.* (2003)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Wang *et al.* (1998, 2004) provide details of lessons learnt when dealing with earthquake-induced problems in loess soils through the use of dynamic triaxial tests and resonant column tests. Key earthquake-induced problems are seismically induced landslides (e.g. the 1920 Haiyuan landslide – Zhang and Wang, 2007); seismically induced subsidence, and liquefaction. Similar problems can occur in other collapsible soils due to earthquakes, for instance seismically induced landslides triggered in quick clays (Stark and Contreras, 1998).

32.5.4 Slope stability

Slope stability issues related to collapsible soils are a problem associated extensively with loess soils, although other collapsible deposits such as quick clay can exhibit significant problems, e.g. the Rissa landslide (see section 32.2.2 above), with further details discussed by Bell (2000).

However loess regions, such as the loess mantled mountainous region of Gansu in China, have suffered more than 40 000 large scale landslides over the last century (Meng and Derbyshire, 1998). Landslides in this region are caused by seismic shocks and severe summer monsoonal rains. As a consequence of this rainfall, loess karst and sinkholes features are additional hazards.

Landslides in loess are very diverse owing to a broad range of conditions in which they occur (Derbyshire and Meng, 2005). The principal types of landslide in loess are shown in **Figure 32.18** with detailed descriptions given in Meng and Derbyshire (1998) and Meng *et al.* (2000b). It should be noted that Tan-ta are small adjustment failures, generally less than 10 m in diameter and at a depth of a few metres, occurring predominately on steep slopes in loess. After initiation of the slide, rapid disintegration takes place, often with high sliding velocities (Meng *et al*., 2000b).

The considerable experience from China had led to success with a number of control measures. These include:

- landscaping, e.g. stepped slopes;
- retaining structures, e.g. retaining walls, underground drainage trenches and retaining piles.

Using these methods, most shallow and moderately deep landslides can be treated. Often a combination of approaches has proved to be best; for instance, using a combined structure of retaining walls and drainage ditches. However, terrace landslides can prove difficult to handle and often require a horizontal drainage borehole to alleviate groundwater pressures. Because of these pressures loess liquefaction, induced by slight slope displacement, can threaten whole slope stability.

Further details are provided by Meng and Derbyshire (1998) and Meng *et al.* (2000a), including details of successful treatment for landslide control. In addition, Dijkstra *et al.* (2000a) provide a detailed account of laboratory and *in situ* strength measurements with respect to slope stability in loess; details of modelling of landslides are presented by Dijkstra *et al.* (2000b).

32.5.5 Improvement and remediation

A wide variety of improvement processes exist for collapsible soils. Some of the more exotic ones have only been tried at an experimental stage. Evstatiev (1988), Houston *et al*. (2001)

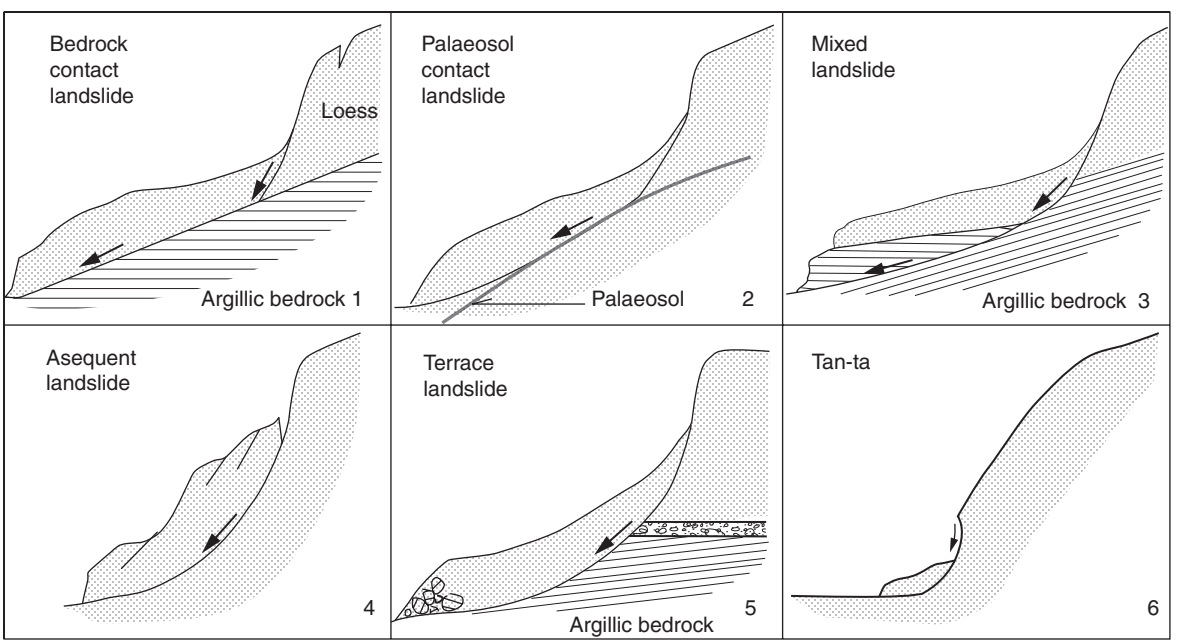

Figure 32.18 Principal types of loess landslides
Reproduced from Meng and Derbyshire (1998) © The Geological Society of London

and Jefferson *et al*. (2005) provide excellent overviews of a range of possible treatment techniques used to improve collapsible loess soils.

Ultimately the best technique depends on several factors (after Houston *et al.*, 2001):

(i) when the collapsible loess soil was discovered;

(ii) how stress is to be applied to the soil;

(iii) depth and extent of the collapsible zone;

(iv) sources of wetting;

(v) costs.

Details are provided throughout the literature, in particular the experience from Eastern Europe, especially Russia, e.g. Abelev (1975), Lutenegger (1986), Ryzhov (1989), Evstatiev (1995) and Evstatiev *et al.* (2002). Deng (1991), Wang (1991), Zhong (1991), Zhai *et al.* (1991), Fujun *et al.* (1998) and Gao *et al*. (2004), amongst others, allow insights into treatment techniques commonly employed in China, while researchers such as Clemence and Finbarr (1981), Rollins and Rogers (1994), Rollins and Kim (1994), Pengelly *et al.* (1997), Houston and Houston (1997), Rollins *et al*. (1998), Houston *et al.* (2001) and Rollins and Kim (2011) provide reviews of ground improvement approaches used to treat collapsible soils in North America. Rollins and Rogers (1994) provide an overview of the various advantages and limitations of a number of different possible treatment methods to reduce/eliminate collapsibility.

Table 32.3 provides an overview of techniques that can be used to treat loess ground and reduce/remove its collapse potential.

It is very common to find bands of clayey material (palaeosol) within some collapsible soils, such as loess deposits. However, it still uncertain what role these bands play in the overall behaviour of the loess mass. It is likely that they will act as planes of weakness. What is certain, though, is that the presence of these bands will influence the effectiveness of any method used to treat a collapsible soil. These bands will affect the transmission of compaction energy and the route taken by stabilising fluids through the soil.

Post-construction treatment typically involves some form of chemical stabilisation – typically grouting – or alternatively some form of underpinning, both of which can prove expensive. The following methods have been used in cases where collapsing loess has damaged existing buildings: silicate grout injection (silicatisation), jet-grouting, underpinning by root piles (pali radici), squeeze grouting (injection by 'tube à manchettes') and stabilisation by in-depth heating.

An alternative proposed by Houston *et al*. (2001) involves controlled differential wetting via separately controllable trenches built around the foundation slab. This approach has been used to tilt a structure in a controlled way. Initial trials demonstrated that, firstly, it was possible to re-level the foundation thereby eliminating any future collapse potential, and, secondly, its control was relatively straightforward by allowing site owners to control flow rates from each trench. However,

Depth (m)	Treatment method	Comments
0–1.5	Surface compaction via vibratory rollers, light tampers	Economical, but requires careful site control, e.g. limits on water content
	Pre-wetting (inundation)	Can effectively treat thicker deposits but needs large volumes of water and time
	Vibrofloatation	Needs careful site control
1.5–10	Vibrocompaction (stone columns, concrete columns, encased stone columns)	Cheaper than conventional piles but requires careful site control and assessment. If uncased, stone columns may fail with loss of lateral support on collapse
	Dynamic compaction; rapid impact compaction	Simple and easily understood but requires care with water content and vibrations produced
	Explosions	Safety issues need to be addressed
	Compaction pile	Needs careful site control
	Grouting	Flexible but may adversely affect the environment
	Ponding/inundation/pre-wetting	Difficult to control effectiveness of compression produced
	Soil mixing lime/cement	Convenient and gains strength with time. Various environmental and safety aspects, and the chemical controls on reactions need to be assessed
	Heat treatment	Expensive
	Chemical methods	Flexible; relatively expensive
>10	As for 1.5–10 m, some techniques may have a limited effect	(See above)
	Pile foundations	High bearing capacity but expensive

Table 32.3 Methods of treating collapsible loess ground
Reproduced from Jefferson *et al.* (2005), with permission from Elsevier

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

as yet there are few directly relevant precedents, which limit its take-up.

A number of case studies illustrate how collapsibility has been successfully treated and details of these are provided by Evans and Bell (1981), Jefferson *et al*. (2005) and Rollins and Kim (2011).

32.6 Concluding remarks

Collapsible soils are found throughout the world and are formed through various geomorphologic and geologic processes. These can be natural (through fluvial or aeolian processes) or man-made (via poor compaction). Whatever the processes involved, the key prerequisite is that an open metastable structure develops through bonding mechanisms generated via capillary forces (suctions) and/or through cementing materials such as clay or salts. Collapse occurs when net stresses (via loading or saturation) exceed the yield strength of the bonding material. Inundation is by far the most common cause of collapse and can be triggered through a range of different water sources. Different sources yield different amounts of collapse.

Thus a detailed knowledge of macroscopic and microscopic characteristics is vital to engineer these materials effectively and safely. Failure to recognise and deal with collapsible soils can have a significant impact on the built and urban environments – with catastrophic effects and potential loss of life. To engineer effectively in collapsible soils it is essential to recognise their existence, for which key geologic and geomorphologic information is vital. However, collapsibility should be confirmed through direct response to wetting/loading tests using laboratory and field methods. The key challenge with collapsible soils is to predict the extent and degree of wetting that will take place. Care is needed to ensure that appropriate and realistic assessments are undertaken, followed by treatment through a suite of the possible improvement techniques available. The collapsible potential can then be eliminated effectively.

Expansive soils present significant geotechnical and structural engineering challenges the world over, with costs associated with expansive behaviour estimated to run into several billion pounds annually. Expansive soils are those which experience significant volume changes associated with changes in water content. These volume changes can either be in the form of swell or shrinkage, and are sometimes known as swell–shrink soils. Key aspects that need identification when dealing with expansive soils include soil properties, suction/water conditions, temporal and spatial water content variations that may be generated, for example, by trees, and the geometry/stiffness of foundations and associated structures. Expansive soils can be found both in humid environments where expansive problems occur with soils of high plasticity index, and in arid/semi-arid soils where soils of even moderate expansiveness can cause significant damage. This chapter reviews the nature and extent of expansive soils, highlighting key engineering issues. These include methods to investigate expansive behaviour both in the field and the laboratory, and the associated empirical and analytical tools to evaluate expansive behaviour. Design options for pre- and post-construction are highlighted for both foundations and pavements, together with methods to ameliorate potentially damaging expansive behaviour.

33.1 What is an expansive soil?

Essentially, expansive soil is one that changes in volume in relation to changes in water content. The focus here is on soils that exhibit significant swell potential and, in addition, shrinkage potential. There are a number of cases where expansion can occur because of chemically induced changes (e.g. swelling of lime-treated sulfate soils). However, many soils that exhibit swelling and shrinking behaviour contain expansive clay minerals, such as smectite, that absorb water. The more of this clay a soil contains, the higher its swell potential and the more water it can absorb. As a result, these materials swell and thus increase in volume when they become wet, and shrink when they dry. The more water they absorb, the more their volume increases – for the most expansive clays expansions of 10% are not uncommon (Chen, 1988; Nelson and Miller, 1992). It should be noted that other soils exhibit volume change characteristics with changes in water content, e.g. collapsible soils, and these are dealt with in Chapter 32 *Collapsible soils*.

The amount by which the ground can shrink and/or swell is determined by the water content in the near-surface zone. Significant activity usually occurs to about 3 m depth, unless this zone is extended by the presence of tree roots (Driscoll, 1983; Biddle, 1998). Fine-grained clay-rich soils can absorb large quantities of water after rainfall, becoming sticky and heavy. Conversely, they can also become very hard when dry, resulting in shrinking and cracking of the ground. This hardening and softening is known as 'shrink–swell' behaviour. The effects of significant changes in water content on soils with a high shrink–swell potential can be severe on supporting structures.

Swelling and shrinkage are not fully reversible processes (Holtz and Kovacs, 1981). The process of shrinkage causes cracks which, on re-wetting, do not close up perfectly and hence cause the soil to bulk out slightly, and also allow enhanced access to water for the swelling process. In geological timescales, shrinkage cracks may become in-filled with sediment, thus imparting heterogeneity to the soil. When material falls into cracks, the soil is unable to move back – resulting in enhanced swelling pressures.

The primary problem with expansive soils is that deformations are significantly greater than those that can be predicted using classical elastic and plastic theory. As a result, a number of different approaches have been developed to predict and engineer expansive soils, and these are highlighted throughout this chapter.

33.2 Why are they problematic?

Many towns, cities, transport routes and buildings are founded on clay-rich soils and rocks. The clays within these materials may be a significant hazard to engineering construction due to their ability to shrink or swell with changes in water content. Changing water content may be due to seasonal variations (often related to rainfall and the evapotranspiration of vegetation), or be brought about by local site changes such as leakage from water supply pipes or drains, changes to surface drainage and landscaping (including paving), or following the planting, removal or severe pruning of trees or hedges, as man is unable to supply water to desiccated soil as efficiently as a tree originally extracted it through its root system (Cheney, 1988). During a long dry period or drought, a persistent water deficit may develop causing the soil to dry out to a greater

depth than normal, leading to long-term subsidence. This is why expansive problems are often found in arid environments (see Chapter 29 *Arid soils*). As this water deficit dissipates it is possible that long-term heave may occur.

In the UK, the effects of shrinkage and swelling were first recognised by geotechnical specialists following the dry summer of 1947, and since then the cost of damage due to the shrinking and swelling of clay soils in the UK has risen dramatically. After the drought of 1975/76, insurance claims came to over £50 million. In 1991, after the preceding drought, claims peaked at over £500 million. Over the past 10 years the adverse effects of shrink–swell behaviour have cost the economy an estimated £3 billion, making it the most damaging geohazard in Britain today. The Association of British Insurers has estimated that the average cost of shrink–swell related subsidence to the insurance industry stands at over £400 million annually (Driscoll and Crilly, 2000). In the US, the estimated damage to buildings and infrastructure exceeds $15 billion annually. The American Society of Civil Engineers estimates that one in four homes have some damage caused by expansive soils. In a typical year, expansive soils cause a greater financial loss to property owners than earthquakes, floods, hurricanes and tornadoes combined (Nelson and Miller, 1992).

Swelling pressures can cause heaving, or lifting, of structures whilst shrinkage can cause differential settlement. Failure results when the volume changes are unevenly distributed beneath the foundation. For example, water content changes in the soil around the edge of a building can cause swelling pressure beneath the perimeter of the building, while the water content of the soil beneath the centre remains constant. This results in a failure known as 'end lift' (**Figure 33.1**). The opposite of this is 'centre lift', where swelling is focused beneath the centre of the structure or where shrinkage takes place under the edges.

Figure 33.1 Structural damage to house caused by 'end lift'
© Peter Kelsey & Partners

Damage to foundations in expansive soils commonly results from tree growth. This occurs in two principal ways: (i) physical disturbance of the ground, and (ii) shrinkage of the ground by removal of water. Physical disturbance of the ground caused by root growth is often seen as damage to pavements and broken walls. An example of vegetation-induced shrinkage causing differential settlement of building foundations is provided in **Figure 33.2**. Vegetation-induced changes to water profiles can also have a significant impact on other underground features, including utilities. Clayton *et al*. (2010), reporting monitoring data over a two-year period of pipes in London Clay, found significant ground movements (both vertical and horizontal) of the order of 3–6 mm/m length of pipe, which generated significant tensile stresses when in the vicinity of trees. Such tree-induced movement has the potential to be a significant contributor to failure of old pipes located in clay soils near deciduous trees (Clayton *et al*., 2010). Further details are discussed in section 33.5.4.5.

33.3 Where are expansive soils found?

In the UK, towns and cities built on clay-rich soils most susceptible to shrink–swell behaviour are found mainly in the southeast of the country (**Figure 33.3**). In the southeast, many of the clay formations are too young to have been changed into stronger mudstones, leaving them still able to absorb and lose moisture. Clay rocks elsewhere in the country are older and

Figure 33.2 Example of differential settlement due to influence of trees

have been hardened by processes resulting from deep burial and are less able to absorb water. Some areas (e.g. around The Wash, northwest of Peterborough – see **Figure 33.3**) are deeply buried beneath other (superficial) soils that are not susceptible to shrink–swell behaviour. However, other superficial deposits such as alluvium, peat and laminated clays can also be susceptible to soil subsidence and heave (e.g. in the Vale of York, east of Leeds – see **Figure 33.3**).

Expansive soils are found throughout many regions of the world, particularly in arid and semi-arid regions, as well as

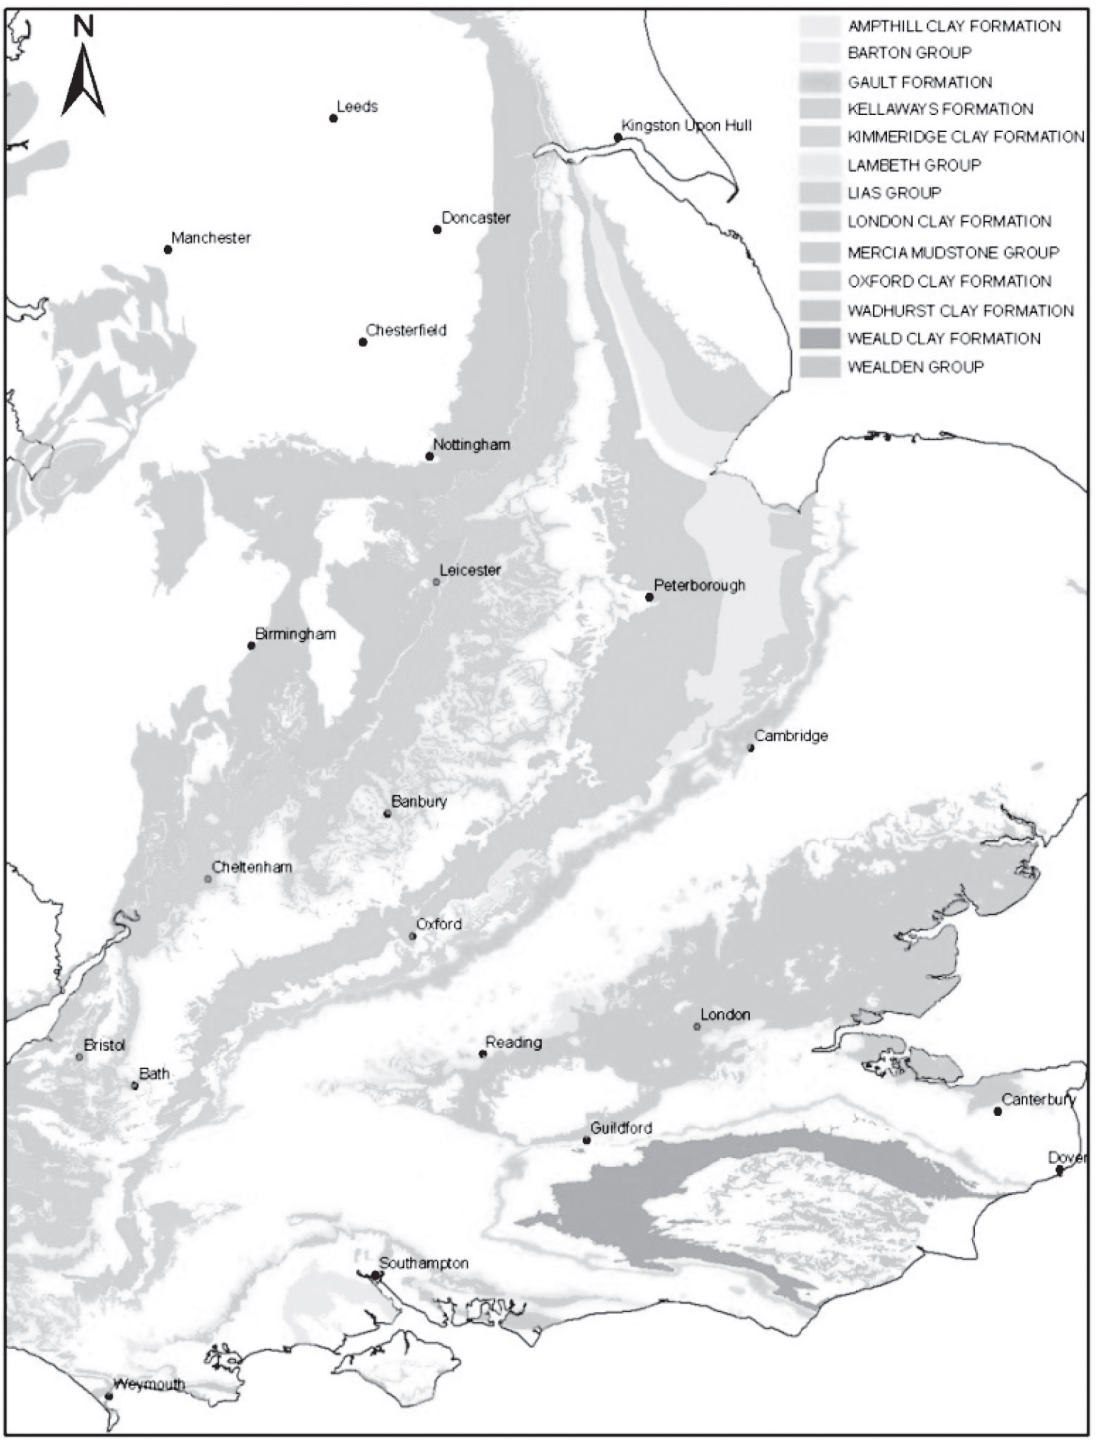

Figure 33.3 Distribution of UK clay-rich soil formations. A colour version of this figure is available online

those where wet conditions occur after prolonged periods of drought. Their distribution is dependent on geology (parent material), climate, hydrology, geomorphology and vegetation.

The literature is full of studies from all over the world, concerned with problems associated with expansive clays (e.g. Simmons, 1991; Fredlund and Rahardjo, 1993; Stavridakis, 2006; Hyndman and Hyndman, 2009). Expansive soils incur major construction costs around the world, with notable examples found in the USA, Australia, India and South Africa, to name but a few. In these countries, or significant areas of them, the evaporation rate is higher than the annual rainfall so there is usually a moisture deficiency in the soil. Subsequently, when it rains, the ground swells and so increases the potential for heave to occur. In semi-arid regions a pattern of short periods of rainfall followed by long dry periods (drought) can develop, resulting in seasonal cycles of swelling and shrinkage.

Due to the global distribution of expansive soils, many different ways to tackle the problem have been developed and these can vary considerably (Radevsky, 2001). The methods to deal with the problem of expansive soils differ in many ways and depend not only on technical developments, but also on the legal framework and regulations of a country, insurance policies and the attitude of insurers, experience of the engineers and other specialists dealing with the problem, and importantly the sensitivity of the owner of the property affected. In the UK in particular, there is high sensitivity to relative small cracks (see section 33.5.3, below). A summary of these issues is provided by Radevsky (2001) in his review of how different countries deal with expansive soil problems, and a detailed informative study from Arizona, USA has more recently been presented by Houston *et al*. (2011). The latter study demonstrated how the source of problems from expansive soils often stems from poor drainage, construction problems, homeowner activity and its adverse effects, and landscaping through the use of vegetation, or a combination of these. These aspects may cause more expansive soil problems than landscape type itself.

Overall, in humid climates, problems with expansive soils tend to be limited to those soils containing higher plasticity index (I_p) clays. However, in arid/semi-arid climates, soils that exhibit even moderate expansiveness can cause distress to residential property. This stems directly from their relatively high suction and the larger changes in water content that result when water levels change.

33.4 Shrink–swell behaviour

Excluding deep underground excavations (e.g. tunnels), shrinkage and swelling effects are restricted to the near-surface zone. Significant activity usually occurs to about 3 m depth, but this can vary depending on climatic conditions. The shrink–swell potential of expansive soils is determined by its initial water content, void ratio, internal structure and vertical stresses, as well as the type and amount of clay minerals in the soil (Bell and Culshaw, 2001). These minerals determine the natural expansiveness of the soil, and include smectite, montmorillonite, nontronite, vermiculite, illite and chlorite. Generally, the more of these minerals that are present in the soil, the greater the expansive potential. However, these expansive effects may become diluted by the presence of other non-swelling minerals such as quartz and carbonate (Kemp *et al*., 2005).

The key aspect of expansive soils behaviour is the soil vulnerability of water-induced volume change. When soils with a high expansive potential are present, they will usually not cause a problem as long as their water content remains relatively constant. This is largely controlled by (Houston *et al*., 2011):

- soil properties, e.g. mineralogy;
- suction and water conditions;
- water content variations, both temporally and spatially;
- geometry and stiffness of a structure, in particular its foundation.

In a partially saturated soil, changes in water content, or suction (increasing strength of the soil due to negative pore water pressures), significantly increase the chances of damage occurring. Changes in soil suction occur due to water movement through the soil due to evaporation, transpiration or recharge, which are often significantly influenced by interaction with trees through response to dry/wet periods of weather (Biddle, 2001). In a fully saturated soil, the shrink–swell behaviour is controlled by the clay mineralogy.

33.4.1 Mineralogical aspect of expansive soils

Clay particles are very small and their shape is determined by the arrangement of the thin crystal lattice layers that they form, along with many other elements which can become incorporated into the clay mineral structure (hydrogen, sodium, calcium, magnesium, sulfur). The presence and abundance of these dissolved ions can have a large impact on the behaviour of the clay minerals. In an expansive clay, the molecular structure and arrangement of these clay crystal sheets have a particular affinity to attract and hold water molecules between the crystalline layers in a strongly bonded ‘sandwich’. Because of the electrical dipole structure of water molecules, they have an electro-chemical attraction to the microscopic clay sheets. The mechanism by which these molecules become attached to each other is called adsorption. The clay mineral montmorillonite, part of the smectite family, can adsorb very large amounts of water molecules between its clay sheets, and therefore has a large shrink–swell potential. For further details of mineralogy of clay minerals and their influence of engineering properties of soils, see Mitchell and Soga (2005).

When potentially expansive soils become saturated, more water molecules are absorbed between the clay sheets, causing the bulk volume of the soil to increase, or swell. This same process weakens the inter-clay bonds and causes a reduction in the strength of the soil. When water is removed, by evaporation or gravitational forces, the water between the clay sheets is released, causing the overall volume of the soil to decrease, or shrink. As this occurs, features such as voids or desiccation cracks can develop.

Potentially expansive soils are initially identified by undertaking particle size analyses to determine the percentage of fine particles in a sample. Clay-sized particles are considered to be less than 2 μm (although this value varies slightly throughout the world), but the difference between clays and silts is more to do with origin and particle shape. Silt particles (generally comprising quartz particles) are products of mechanical erosion, whereas clay particles are products of chemical weathering and are characterised by their sheet structure and composition.

33.4.2 Changes to effective stress and role of suctions

Following any reduction in *total* stress, deformations will take place in the ground. A distinction can be made between (i) an immediate, but time-dependent elastic rebound, and (ii) swelling due to effective stress changes. In soils, as in rocks, rebound can be an important deformation process which encourages stress relief fractures and zones of secondary permeability which can localise delayed swelling. The amount of deformation depends on the undrained stiffness of the soil, which is equivalent to the modulus of elasticity for the soil, as reflected by its Young's modulus and Poisson's ratio. Subsequent swelling requires an *effective* stress decrease, and a movement of fluid into a geological formation or soil. The magnitude of strains associated with these processes depends on the drained stiffness, the extent of the stress change, the resulting water pressures in the soil or rock, and the new boundary conditions. The rate of volume change depends on the compressibility, expansibility and hydraulic conductivity of the sediment and surrounding materials. In stiff homogeneous materials with a low hydraulic conductivity, several decades may be necessary to complete the process.

Accurate laboratory measurements of the controlling elastic properties at small strains in both rebound and swelling (i.e. before yield takes place) are difficult, largely because of sampling disturbance (Burland, 1989). Further discussion of these difficulties, states of stress, and the other important concepts of consolidation/swelling in soils are treated in detail by many standard soil engineering texts (Powrie, 2004; Atkinson, 2007) – see also Section 2 *Fundamental principles* of this manual.

Shrinkage by evaporation is similarly accompanied by a reduction in water pressure and development of negative capillary pressures. Deformation follows the same principles of effective stress. However Bishop *et al*. (1975) have shown by laboratory studies that the degree of saturation of unconfined dried clay samples at a given water content was less than for a similar sample consolidated in a triaxial test to the same water content, i.e. there was some intake of air which affected both the modulus and strength of the soil. This process leads to a void ratio which is higher than for a clay consolidated to the same water content by simply increasing the confining load. Such a soil thus becomes inherently unstable and, if re-wetted, may collapse. Subsequent laboratory tests on partially saturated soils have shown that depending on their *in situ* stress conditions and fabric, some samples may also first swell and then collapse (Alonso *et al*., 1990). The processes of shrinkage due to evaporation have also been reviewed in detail using effective stress concepts by Sridharan and Venkatappa (1971).

33.4.3 Seasonal variations in water content

The seasonal volumetric behaviour of a desiccated soil is complex and this increases with severity of the shrinkage phenomena. This is reflected by the vertical *in situ* suction profile, water content profile and the degree of saturation (see **Figure 33.4**).

The relative values of suction depend on the composition of the soil, particularly its particle size and clay mineral content. The hydraulic conductivity of a soil may also vary both seasonally and over longer timescales. Secondary permeabilities can be induced through fabric changes, tension cracking and shallow shear failure during the swelling and shrinkage process which may influence subsequent moisture movements. For example, Scott *et al*. (1986) have shown in a microfabric study of clay soils that compression (swelling) cracks tended to run parallel to ground contours and dip into the slope at around 60º, and could usually be distinguished from shrinkage cracks which were randomly distributed. In the London Clay soils studied, for example, they found that the ratio between shrinkage and swelling discontinuities was about 2:1. Although not discussed, it seems likely that the nature and distribution of

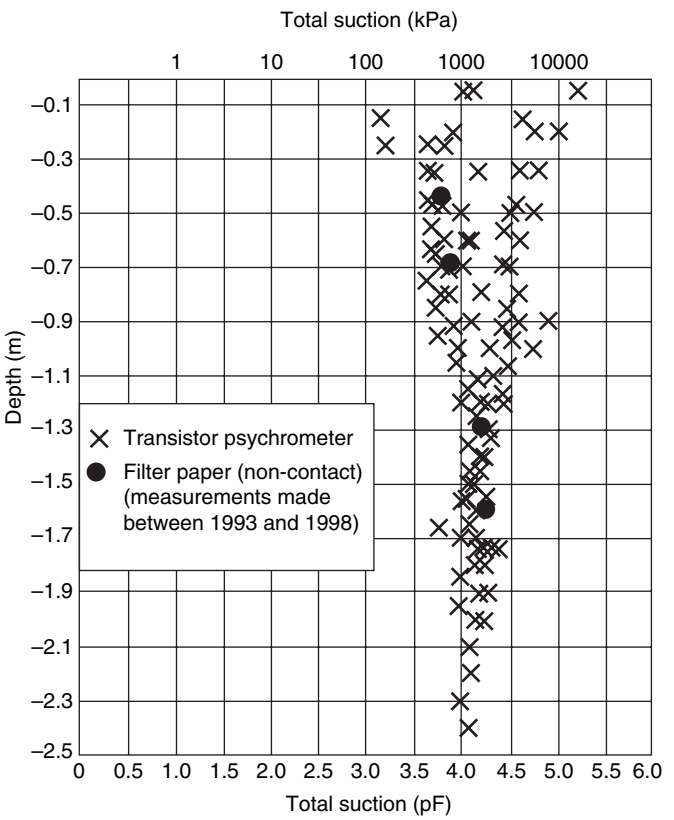

Figure 33.4 Examples of total suction profile
Reproduced from Fityus *et al*. (2004), with kind permission from ASCE

these discontinuities will also influence bulk volumetric seasonal strains.

Expansive soil problems typically occur due to water content changes in the upper few metres, with deep-seated heave being rare (Nelson and Miller, 1992). The water content in these upper layers is significantly influenced by climatic and environmental factors and is generally termed the zone of seasonal fluctuations, or active zone, as shown in **Figure 33.5**.

In the active zone, negative pore water pressures exist. However, if excess water is added to the surface or if evapotranspiration is eliminated, then water contents increase and heave will occur. Migration of water through the zone is also influenced by temperature, as shown in **Figure 33.5**, with further details provided by Nelson *et al*. (2001). Thus it is important to determine the depth of the active zone during a site investigation. This can vary significantly with different climatic conditions – it may be 5–6 m in some countries, but typically in the UK it is 1.5–2 m (Biddle, 2001). If the drying is greater than the rehydration, then the depth of this zone will increase, with 3–4 m having been observed in some cases in London Clay (Biddle, 2001). These effects are likely to become more significant with climate change.

The term 'active zone' can have different meanings. Nelson *et al*. (2001) provide four definitions for clarity:

1. *Active zone* The zone of soil that contributes to soil expansion at any particular time.
2. *Zone of seasonal moisture fluctuation* The zone in which water content changes due to climatic changes at the ground surface.
3. *Depth of wetting* The depth that water contents have reached owing to the introduction of water from external sources.
4. *Depth of potential heave* The depth at which the overburden vertical stress equals or exceeds the swelling pressure of the soil. This is the maximum depth of the active zone.

The depth of wetting is particularly important as it is used to estimate heave by integrating the strain produced over the zone in which water contents change (Walsh *et al*., 2009). Details of how this can be achieved and the relative merits of regional and site-specific approaches are considered in detail for a post-development profile by Walsh *et al*. (2009), with further discussion presented by Nelson *et al*. (2011); Aguirre (2011); and Walsh *et al*. (2011).

33.5 Engineering issues

As has been previously stated, many towns, cities, transport routes, services and buildings are founded on expansive soils. These may be solid (bedrock) geological strata in a weathered or unweathered condition, or superficial (drift) geological strata such as glacial or alluvial material, also in a weathered or unweathered condition. These materials constitute a significant

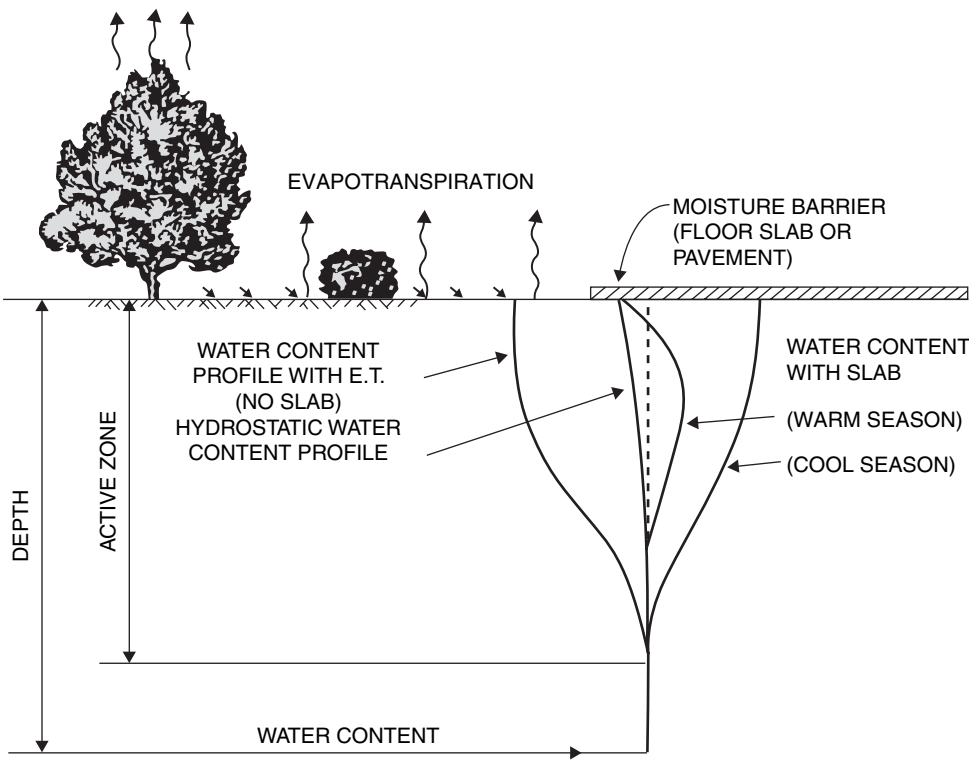

Figure 33.5 Water content profiles in the active zone
Reproduced from Nelson and Miller (1992); John Wiley & Sons, Inc

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

hazard to engineering construction in terms of their ability to swell or shrink, usually caused by seasonal changes in moisture content. Superimposed on these widespread climatic influences are local ones, such as tree roots and leakage from water supply pipes and drains. The swelling of shrinkable clay soils after trees have been removed can produce either very large uplifts or very large pressures (if confined), and the ground's recovery can continue over a period of many years (Cheney, 1988). It is the differential, rather than the total, movement of the foundation, or superstructure, that causes major structural damage. The structures most affected by expansive soils include the foundations and walls of residential and other low-rise buildings, pipelines, pylons, pavements and shallow services. Frequently, these structures only receive a cursory site investigation, if any. It is usually sometime after construction that problems come to light. Damage can occur within a few months of construction, develop slowly over a period of 3–5 years, or remain hidden until something happens that changes the water content of the soil.

Houston *et al*. (2011) examined the type of wetting that occurs in response to irrigation patterns. They observed that deeper wetting was common with irrigation of heavily turfed areas, and that if ponding of water occurred at the surface, there was more likely to be greater distress to buildings through differential movements. Walsh *et al*. (2009) also note that when heave is deep seated, differential movements are less significant than when the source of heave is at shallower depths.

The structures most susceptible to damage caused by expansive soils are usually lightweight in construction. Houses, pavements and shallow services are especially vulnerable because they are less able to suppress differential movements than heavier multi-story structures. For more information about design parameters and construction techniques for housing and pavements, reference should be made to:

- *NHBC Standards: Building near trees* (NHBC, 2011a)
- *Preventing foundation failures in new dwellings* (NHBC, 1988)
- *Planning Policy Guidance Note 14: Development on unstable land: Annex 2: subsidence and planning* (DTLR, 2002)
- *BRE Digests 240– 242: Low-rise buildings on shrinkable clay soils* (BRE, 1993a)
- *BRE Digest 298: The influence of trees on house foundations in clay soils* (BRE, 1999)
- *BRE Digest 412: The significance of desiccation* (BRE, 1996)
- *Criteria for selection and design of residential slabs-on-ground* (BRAB, 1968)
- *Evaluation and control of expansive soils* (TRB, 1985).

In many respects, engineering in expansive soils is still based on experience and soil characterisation, and so is often perceived as difficult and expensive (especially for lightweight structures). Engineers use local knowledge and empirically derived procedures, although considerable research has been done on expansive soils – for instance, the database on performance (Houston *et al*., 2011). However, through careful consideration of key aspects associated with expansive soils, problems and difficulties can be dealt with in a cost effective way.

Two major factors must be identified in the characterisation of a site where a potentially expansive soil exists:

- the properties of the soil (e.g. mineralogy, soil water chemistry, suction, soils fabric);
- environmental conditions that can contribute to changes in water content of the soil, e.g. water conditions and their variations (climate, drainage, vegetation, permeability, temperature), and stress conditions (history and *in situ* conditions, loading and soil profile).

Normal non-expansive site investigations are often not adequate and a more extensive examination is required to provide sufficient information. This may involve specialist test programs, even for relatively lightweight structures (Nelson and Miller, 1992). Although there are a number of methods available to identify expansive soils, each with their relative merits, there are no universally reliable ones. Moreover, expansiveness has no direct measure and so it is necessary to make comparisons, measured under known conditions, as a means to express expansive behaviour (Gourley *et al*., 1993). However, the stages of investigation needed for expansive soils follow those used for any site (see Section 4 *Site investigation* for further details).

33.5.1 Investigation and assessment

It is important to recognise the existence, and understand the potential problems, of expansive soils early on during site investigation and laboratory testing, to ensure that the correct design strategy is adopted before costly remedial measures are required. It is equally important that investigations determine the extent of the active zone.

Despite the proliferation of test methods for determining shrinkage or swelling properties, they are rarely employed in the course of routine site investigations in the UK. Further details of tests commonly employed around the world are given by Chen (1988) and Nelson and Miller (1992). This means that few datasets are available for databasing the directly measured shrink–swell properties of the major clay formations, and reliance has to be placed on estimates based on index parameters, such as liquid limit, plasticity index and density (Reeve *et al*., 1980; Holtz and Kovacs, 1981; Oloo *et al*., 1987). Such empirical correlations may be based on a small dataset, using a specific test method, and at only a small number of sites. Variation of the test method would probably lead to errors in the correlation. The reason for the lack of direct shrink–swell test data is that few engineering applications have a perceived requirement for these data for design or construction.

33.5.1.1 Site investigation

A key difficulty with expansive soils is that they often exhibit significant variability from one location to another (i.e. spatial variability). These proper, adequate, site investigations in areas of potentially expansive soil are often worth the cost. Essential

to the investigation of any expansive soils is a good knowledge of local geology: the use of maps provides a framework for this. These maps are particularly useful when constructing transportation networks. In some countries such as the US, mapping includes identification of expansive soil potential (Nelson and Miller, 1992). As with any site investigation, field observations and reconnaissance can provide valuable data of the extent and nature of expansive soils and their associated problems. Some key features may be observed locally and important observations include:

1. *Soil characteristics*
   - spacing and width of wide or deep shrinkage cracks;
   - high dry strength and low wet strength – high plasticity soil;
   - stickiness and low trafficability when wet;
   - shear surfaces have glazed or shiny appearance.
2. *Geology and topography*
   - undulating topography;
   - evidence of low permeability by surface drainage and infiltration features.
3. *Environmental conditions*
   - vegetation type;
   - climate.

Sampling in expansive soils is generally done in the same way as for conventional soils, with care taken to minimise disturbances through, for example, water content changes or poor control during transportation. Further details are provided in Section 4 *Site investigation* of this manual, and an overview of practices specifically used for expansive soils in other countries is provided by Chen (1988) and Nelson and Miller (1992). However, the depth and frequency of sampling may need to be increased in expansive areas due to their high spatial variability.

33.5.1.2 *In situ* testing

A suite of different field tests can be used to evaluate expansive soils and these include:

- soil suction measurements using thermocouple psychrometers, tensiometers or filter paper methods;
- *in situ* density and moisture tests;
- settlement and heave monitoring;
- piezometers or observations wells;
- penetration resistance;
- pressuremeters and dilatometers;
- geophysical methods.

Expansive soils can be tested in the field using methods that rely on empirical correlation such as the standard penetration test (SPT) or the cone penetration test (CPT) to infer soil strength parameters (Clayton *et al*., 1995). Initial effective stresses can be estimated using a psychrometer (Fredlund and Rahardjo, 1993) or a suction probe (Gourley *et al*., 1994) which will measure the soil suction. The undrained shear strength of the soil can be determined using a shear vane (Bjerrum, 1967). The stiffness parameters of the soil can be determined using a plate loading test (BSI, 1999), along with its strength and compressibility. Other tests include the pressuremeter and the dilatometer (ASTM, 2010) which measure strength, stiffness and compressibility parameters.

Seismic test apparatus uses the transmission of elastic waves through the ground in order to determine its density and elastic properties (see Chapter 45 *Geophysical exploration and remote sensing*). Electrical resistivity methods have also shown promise as a method to determine swell pressure and shrinkage of expansive soils. Resistivity was found to increase as both swell pressure and shrinkage increased (Zha *et al*., 2006). More recently, Jones *et al*. (2009) successfully monitored tree-induced subsidence in London Clay using electrical resistivity imaging.

Monitoring should also be considered and a number of approaches can be used which are common with non-expansive soils. Key methods are: settlement and heave monitoring for volume change, and piezometers for pore water changes. Monitoring of water content profiles over several wet and dry seasons are used to establish the extent of the active zone (Nelson *et al*., 2001). In cases where the soil is not uniform or several strata exist, a correction can be applied using the liquidity index. Nelson and Miller (1992) provide an example of this calculation.

Examples of monitoring associated with expansive soils are provided throughout literature. Examples include Fityus *et al*. (2004), where a site near Newcastle, Australia, was instrumented, and soil water and suction profiles together with ground movements were determined over a period (1993–2000). In addition, the work of the BRE at their London Clay site near Chattenden, Kent, provides details of similar monitoring regimes over a number of years (Crilly and Driscoll, 2000; Driscoll and Chown, 2001). Stable benchmarks are important for any monitoring in expansive soils, and design details and installation instructions are given in many papers, e.g. Chao *et al*. (2006).

Further details can be found in Sections 4 *Site investigation* and 9 *Construction verification* of this manual. For specific discussions in the context of expansive soils, see Chen (1988), and Nelson and Miller (1992).

33.5.1.3 Laboratory testing

Considerable research work has been carried out on behalf of the oil and mining industries, especially in the US, on the swelling behaviour of ‘compact’ clays and mudrocks, in particular clay shales. Swelling pressure has caused damage in tunnels (Madsen, 1979), as is the case – usually at great depths – in the mining industry. In the oil industry, the swelling of shales and ‘compact’ clays in borehole and well linings has been a topic of interest. Laboratory test methods developed

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

differ considerably from those applied by the civil engineering industry, and tend to duplicate the particular phenomena causing problems. For example, the moisture activity index test (Huang *et al*., 1986) duplicates changes in relative humidity in the air passing through mine tunnels, and consequent swelling of the tunnel lining. However, the confined swelling pressure test is relatively universal. As shrinkage is a near-surface phenomenon in the UK, much work has been done by the soil survey and agricultural organisations. Reeve *et al*. (1980) describe the determination of shrinkage potential for a variety of soils classified on a pedological basis.

For geotechnical purposes, a suite of different tests can be used to identify expansive soils and include Atterberg limits, shrinkage limits, mineralogical tests such as X-ray diffraction, swell tests and suction measurements (see Nelson and Miller, 1992 for further details). Undisturbed samples are normally used for one-dimensional response to wetting tests. However, it should be noted that when conducting swell tests in the laboratory, it is important to distinguish between swelling in compacted, undisturbed and reconstituted samples, which occurs due to significant differences in their respective fabrics.

Swell–shrink tests

Swelling tests may be broadly divided into those tests attempting to measure the deformation or strain resulting from swelling, and those which attempt to measure the stress, or pressure, required to prevent deformation due to swelling. These two types are referred to here as swelling strain and swelling pressure tests, respectively. Swelling strain tests may be linear, i.e. one-dimensional (1D) or volumetric, i.e. three-dimensional (3D). Swelling pressure tests are almost always one-dimensional and traditionally used oedometer-type testing arrangements (Fityus *et al*., 2005). However, shrinkage tests deal solely with the measurement of shrinkage strain in either 1D or 3D.

Standards do exist for shrink–swell tests but these do not cover all the methods in use internationally. Like many 'index'-type soils tests, some shrink–swell tests are based on practical needs and tend to be rather crude and unreliable. Whilst measurement of water content is easily achieved with some accuracy, the measurement of the volume change of a clay soil specimen is not, particularly in the case of shrinkage. Solutions to this problem have been found by the measurement of volume change in only one dimension, or by immersion of the specimen in a non-penetrating liquid such as mercury. However, the use of mercury in this way is far from ideal. Measurement of volume change in the case of swelling, where the specimen is assumed to be saturated, is only slightly less problematic. In this case, dimensional changes are required to be made whilst the specimen is immersed in water. This introduces the problem of either immersed displacement transducers or sealed joints for non-immersed transducers.

Nelson and Miller (1992) provide a detailed account of various swell and heave tests (with the oedometer being the most commonly used) which are often developed based on geographic regions with specific expansive soil problems. However, they can be considered applicable in general situations (Fityus *et al*., 2005). These tests determine the applied stress required to prevent swelling strain when a specimen is subjected to flooding. The ability to do this is enhanced by computer control, or by at least some form of feedback control. The determination of swelling pressure should not be confused with the determination of rebound strain under consolidation stresses in the oedometer test. In the latter case, the slope of the rebound part of the familiar voids ratio versus applied stress (e–log p') curve is referred to as the swelling index (C_s); that is the rebound or decompressional equivalent of the compression index (C_c). It is common, however, for measured swell potential to be low to medium when soil units across a region have high potential; this is the result of natural soil variability (Houston *et al*., 2011).

Mineralogical testing

In addition to the traditional approaches used, several parameters have been investigated which are either wholly or largely dependent on clay mineralogy. These are surface area (Farrar and Coleman, 1967), dielectric dispersion (Basu and Arulanandan, 1974), and disjoining pressure (Derjaguin and Churaev, 1987). The factors affecting swelling of very compact or heavily overconsolidated clays and clay shales may differ from those affecting normally consolidated or weathered clays. Physicochemical and diagenetic bonding forces probably dominate in these materials, whereas capillary forces are negligible. It is likely that the distance between clay platelets, the ionic concentration of pore fluids, and fluids used in laboratory tests relative to the clay mineral activity of such materials, are the key factors in swelling. Traditional concepts of Darcian permeability and pore water pressure are thrown into doubt in these compact clays and clay shales. Diffusion may be the principal mode of fluid movement in these very low permeability clays.

Use index tests

The volume change potential (VCP) (also known as the potential volume change, PVC) of a soil is the relative change in volume to be expected with changes in soil water content, and is reflected by shrinking and swelling of the ground; in other words, the extent to which the soil shrinks as it dries out, or swells when it gets wet. However, despite the various test methods available for determining these two phenomena, e.g. BS 1377, 1990: Part 2, Tests 6.3 and 6.4 *Shrinkage Limit* and Test 6.5 *Linear Shrinkage* and Part 5, Test 4 *Swelling Pressure* (BSI, 1990), they are rarely employed in the course of routine site investigations in the UK. Hence few data are available for databasing the directly measured shrink–swell properties of the major clay formations. Consequently, reliance is placed on estimates based on index parameters, namely, liquid limit, plastic limit, plasticity index, and density (Reeve *et al.*, 1980; Holtz and Kovacs, 1981; and Oloo *et al.*, 1987). No consideration has been given to the saturation state of the soil and therefore to the effective stress or pore water pressures within it.

The most widely used parameter for determining the shrinkage and swelling potential of a soil is the plasticity index (I_p). Such plasticity parameters, being based on remoulded specimens, cannot precisely predict the shrink–swell behaviour of an *in situ* soil. However, they do follow properly laid down procedures, being performed under reproducible conditions to internationally recognised standards (Jones, 1999). A 'modified plasticity index' (I'_p) is proposed in the Building Research Establishment Digest 240 (BRE, 1993a) for use where the particle size data, specifically the fraction passing through a 425 μm sieve, is known or can be assumed as 100% passing (**Table 33.1**).

The modified I'_p takes into account the whole sample and not just the fines fraction; it therefore gives a better indication of the 'real' plasticity value of an engineering soil and eliminates discrepancies due to particle size, for example in glacial till. This compares with a classification produced by the National House-Building Council which forms the basis of the NHBC 'foundation depth' tables (**Table 33.2**), which uses the same modified I'_p approach as presented in **Table 33.1**.

The concept of 'effective plasticity index' has been described (BRAB, 1968) to deal with multi-layered soils of different plasticity index.

Ultimately, swelling and shrinkage *potential* may be considered to be the ultimate capability of a soil to swell and shrink, but this potential is not necessarily realised in a given moisture change situation. These do not therefore represent the fundamental properties of a soil. However, potential may be described differently. For example, swelling potential is described by Basu and Arulanandan (1974) as 'the ability and degree to which swelling is realised under given conditions'. So there is already some confusion in terminology. Oloo *et al*. (1987) differentiate between intrinsic expansiveness (swell) and heave. They define intrinsic expansiveness as that property which 'relates change in water content, and thus change in volume, to the suction change' of a clay soil. Thus a soil of high intrinsic expansiveness will exhibit a large water content or volume change compared with one of low intrinsic expansiveness for a given suction change – all other things being equal. Oloo *et al*. (1987) state that no procedure has been developed to measure this property. Swell is defined as 'a measure of the volume strain, or axial strain, in a soil under a particular set of stress and suction conditions'. Heave is defined as 'the displacement of a point in the soil due to suction and stress changes interacting with the intrinsic expansiveness'. Heave is not a soil property.

Overall, there are many methods of testing for the shrinkage and swelling properties of clay soils. These methods are covered in detail in Jones (1999), where the pros and cons of each method are discussed and the reasons for the selection and rejection of methods is determined. Further evaluation of these tests is also provided by Fityus *et al*. (2005).

I'_p (%)	Volume change potential
> 60	Very high
40–60	High
20–40	Medium
< 20	Low

Note: $I'_p = I_p \times (\%<425\,\mu m) / 100\%$

Table 33.1 Classification for shrink–swell clay soils
Data taken from BRE (1993a)

I'_p (%)	Volume change potential
> 40	High
20–40	Medium
10–20	Low

Data taken from NHBC (2011a)

33.5.2 Shrink/swell predictions

Common to all geotechnical predictions of volume change is the need to define initial and final *in situ* stress state conditions. In addition this requires characterisation of the stress–strain behaviour of each soil profile. Initial stress states and constitutive properties can be evaluated using a suite of approaches (highlighted by many texts, e.g. Fredlund and Rahardjo,1993; Powrie, 2004) but it is the final stress condition that must usually be assumed. Guidelines are presented by Nelson and Miller (1992), with calculations based on knowledge of effective overburden stress (i.e. the increment of stress due to applied load and soil suction). However, each situation requires engineering judgement and consideration of environmental conditions.

Details of constitutive relationships for expansive soils have been reviewed and a useful description of these is given by Nelson and Miller (1992). These include unsaturated soil models dealing with matric and osmotic suctions. A detailed account of this, the theoretical basic, associated models used to predict partially saturated soils behaviour, together with test methods used to determine key soil parameters, is provided in Fredlund and Rahardjo (1993) and Fredlund (2006).

Overall prediction methods can be grouped into three broad categories: theoretical, semiempirical and empirical. They all rely on testing methods; particular care must be taken with empirical methods which are only valid within the bounds of the soil type, environment and engineering application for which they were developed.

A number of heave predictions are available that are based on oedometer or suction tests, and Nelson and Miller (1992) provide a detailed account of these, together with examples of associated predictions. For example Nelson *et al*. (2010) provide an illustration using free-field heave predictions and their use in foundation design, as well as methods for prediction heave rates.

33.5.2.1 Oedometer-based methods

Oedometer-based tests include one-dimensional and double oedometer tests (developed by Jennings and Knight, 1957).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Double oedometer tests consist of two near-identical undisturbed samples, one loaded at its natural water content and the other inundated under a small load and then loaded under saturated conditions. The use of the oedometer has distinct advantages due to familiarity amongst geotechnical engineers.

Tests can be conducted as free swell tests where swelling is allowed to occur at a pre-determined pressure after water is added. The swell pressure is then defined as the pressure required to recompress the swollen sample to its pre-swollen volume. These tests, however, suffer the limitation that volume change can occur and that hysteresis is incorporated into the estimation of the *in situ* state. An alternative approach that overcomes these problems involves inundating a sample placed in the oedometer and preventing it from swelling. The swell pressure is then the maximum applied stress required to achieve a constant volume. Typical results from these tests are shown in **Figure 33.6**, with σ'_0 representing the stress when inundation occurred and σ'_s representing the stress equated to swelling pressure.

The constant volume test may overcome the difficulties of the free swell test, but as a result is more vulnerable to sample disturbance. To account for sample disturbance, Rao *et al*. (1988) and Fredlund and Rahardjo (1993) suggest simplifications to facilitate predictions using parameters measured by constant volume oedometer tests (pressures increase during swelling to maintain constant volume) using established techniques. This is illustrated in **Figure 33.7**.

Fityus *et al*. (2005) questioned this approach and considered that specialist apparatus not normally used in standard geotechnical engineering testing laboratories is needed to achieve meaningful results. However, not all authors agree, with Nelson and Miller (1992) believing good quality data and predictions can be obtained with such an approach. Moreover, a number of disadvantages exist, as tests where the specimen is fully wetted are conservative, as full saturation is not often reached in the field (Houston *et al*., 2011). Thus, swell tests based on submerged samples at the level of stress of interest will overpredict heave. The effect of partial wetting may be as important as the depth to which wetting has occurred (Fredlund *et al*., 2006).

33.5.2.2 Suction-based tests

Suction tests are used to predict soil response in much the same manner as with saturated effective stress changes. Various methods have been developed, e.g. the US Army Corps of Engineers Waterways Experiment Station (WES) method or the clod method, details of which (including advantages and limitations) can be found in Nelson and Miller (1992). Fredlund and Hung (2001) have subsequently developed suction-based predictions to evaluate volume changes from both environmental and vegetation changes – and they provide useful outline example calculations.

Nelson and Miller (1992) suggest that with careful sampling and testing it is possible to predict heave within a few centimetres. However, it is essential that the testing is conducted within the expected stress range in the field. Furthermore, experimental studies involving direct measurement of partially saturated properties is expensive and often time-consuming. For example, Chandler *et al*. (1992) provide details of suction measurements using the filter paper method, highlighting the need for careful calibration as results can be affected by temperature fluctuations, particle entrainment in the filter paper during testing, and hysteresis effects. Such approaches have a number of advantages as a means to estimate soil suction and hence suction profiles (see **Figure 33.4**).

For this reason, increasingly numerical and semiempirical methods use the soil–water characteristic curves (SWCCs) (Puppala *et al*., 2006). The SWCCs describe the relationship

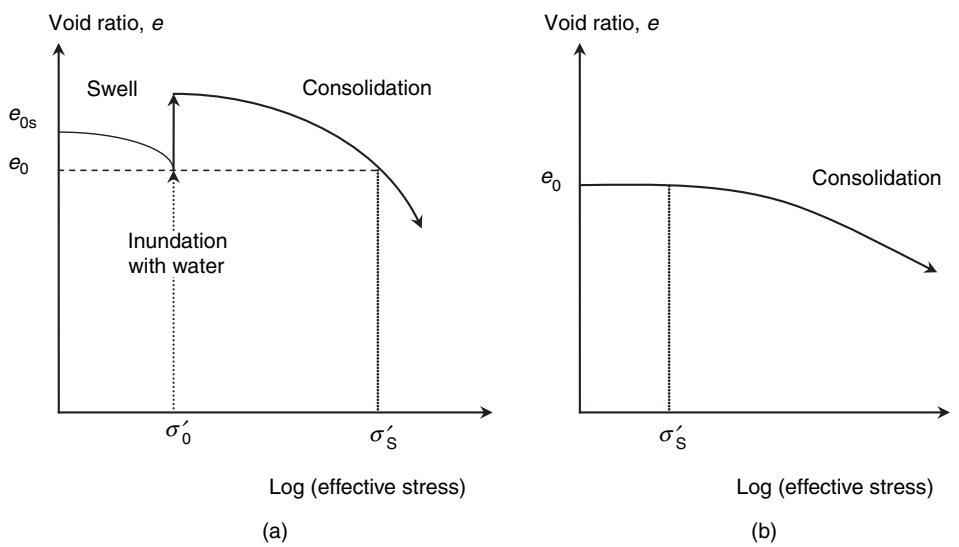

Figure 33.6 Typical oedometer swell test curves: (a) an illustration of a free swell test result; (b) an illustration of constant volume test results

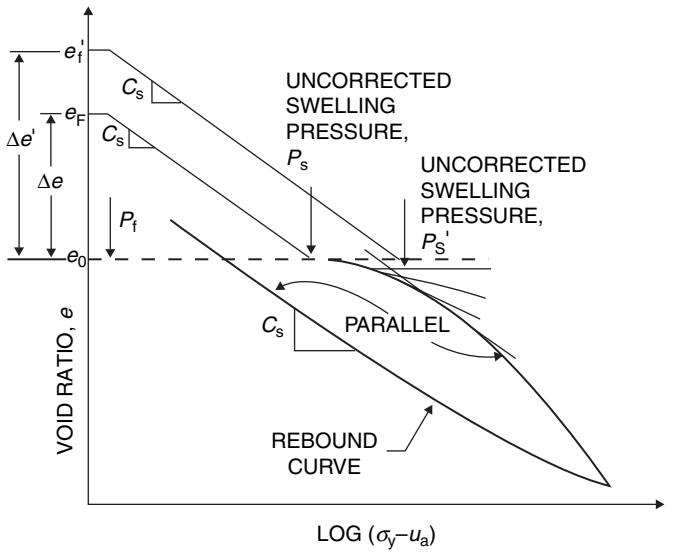

Figure 33.7 One-dimensional oedometer test results showing effect of sampling disturbance. Note: C_s is swell index; ($\sigma_y - u_a$) is overburden pressure; P_f is final stress state; e_f is final void ratio, and e_f' is final void ratio corresponding to corrected swell pressure, P_s'
Reproduced from Rao *et al.* (1988), with kind permission from ASCE

between water content (either gravimetric or volumetric) and soil suction. Alternatively, they can be used to describe the relationship between the degree of saturation and soil suction. A more detailed discussion and examples of typical SWCCs are also provided in Chapter 30 *Tropical soils*.

Only a limited number of investigations have been undertaken on expansive soils with Ng *et al*. (2000), Likos *et al*. (2003) and Miao *et al*. (2006) providing some example of these. Puppala *et al*. (2006) details SWCCs for both treated and untreated expansive soils. Further details of this are provided by Fredlund and Rahardjo (1993) with Nelson and Miller (1992) providing details in the context of expansive soils. However, it should be noted that suction measurements are subject to errors that can be substantial (Walsh *et al*. 2009).

Empirically-based methods are still common in geotechnical engineering (Houston *et al*., 2011). Heave is often estimated by the integration of strain over the zone in which the water contents change. However, uncertainty occurs and arises from three sources (Walsh *et al*., 2009):

1. the depth over which the wetting will occur;
2. the swell properties of the soil;
3. the initial and final suction over the depth of wetting.

Furthermore, care is needed with all models used, as small changes in input parameters can lead to significant changes in an estimated soil response. The real challenge is, therefore, to understand the relationship between soil–water stress level and volume changes, coupled with a prediction of the actual depth and degree of wetting that will occur in the field. Both are related to soil properties and control of site water (Houston *et al*., 2011).

Houston *et al*. (2011) compared predictions from a number of forensic studies from field and laboratory investigations in arid/semi-arid areas to those undertaken using numerical approaches (in this case, the simple 1D and 2D unsaturated flow model), with details of site drainage and landscape practices also considered. Comparisons were made after one year; they concluded that drainage conditions were the more important factor in the prediction of foundation problems. This study revealed that the effects of poor drainage and roof run-off ponding near a structure is the worst case scenario. Uncontrolled drainage and water ponding near foundations led to significant suction reduction to greater depths (0.8 m was found after one year), resulting in differential soil swell and foundation movement (see **Figure 33.8**).

33.5.2.3 Numerical approaches

1D simulations also dominate numerical studies, as unsaturated flow solutions are sensitive to accurate and detailed simulation of surface flux conditions, thus requiring an extremely tight mesh and time steps (Houston *et al*., 2011). This may result in very lengthy run times of several months, even for 1D assessments (Dye *et al*., 2011). However, Xiao *et al*. (2011) demonstrated how numerical simulations could be used to assess pile–soil interactions, providing an effective way to undertake sensitivity analysis, but noted that many parameters are needed when undertaking numerical assessments.

33.5.3 Characterisation

Many attempts have been made to find a universally applicable system for the classification of shrinking and swelling in order to characterise an expansive soil. Some have even attempted to produce a unified swelling potential index using commonly used indices (e.g. Sridharan and Prakash, 2000; Kariuki and van der Meer, 2004; Yilmaz, 2006) or from specific surface areas (Yukselen-Aksoy and Kaya, 2010), but these are yet to be adopted. Examples of various schemes commonly used around the world are illustrated in **Figure 33.9**. The various schemes that have been developed lack standard definitions of swell potential, since both sample conditions and testing factors vary over a wide range of values (Nelson and Miller, 1992).

33.5.3.1 Classification schemes

Most classification schemes give a qualitative expansion rating, e.g. high or critical. The different classification schemes can be categorised into four groups, depending on which method they employ to determine their results. These are:

1. free swell (see Holtz and Gibbs, 1956);
2. heave potential (see Vijayvergiya and Sullivan, 1974; Snethen *et al*., 1977);
3. degree of expansiveness (see US Federal Housing Administration (FHA), 1965; Chen, 1988);
4. shrinkage potential (see Altmeyer, 1956; Holtz and Kovacs, 1981).

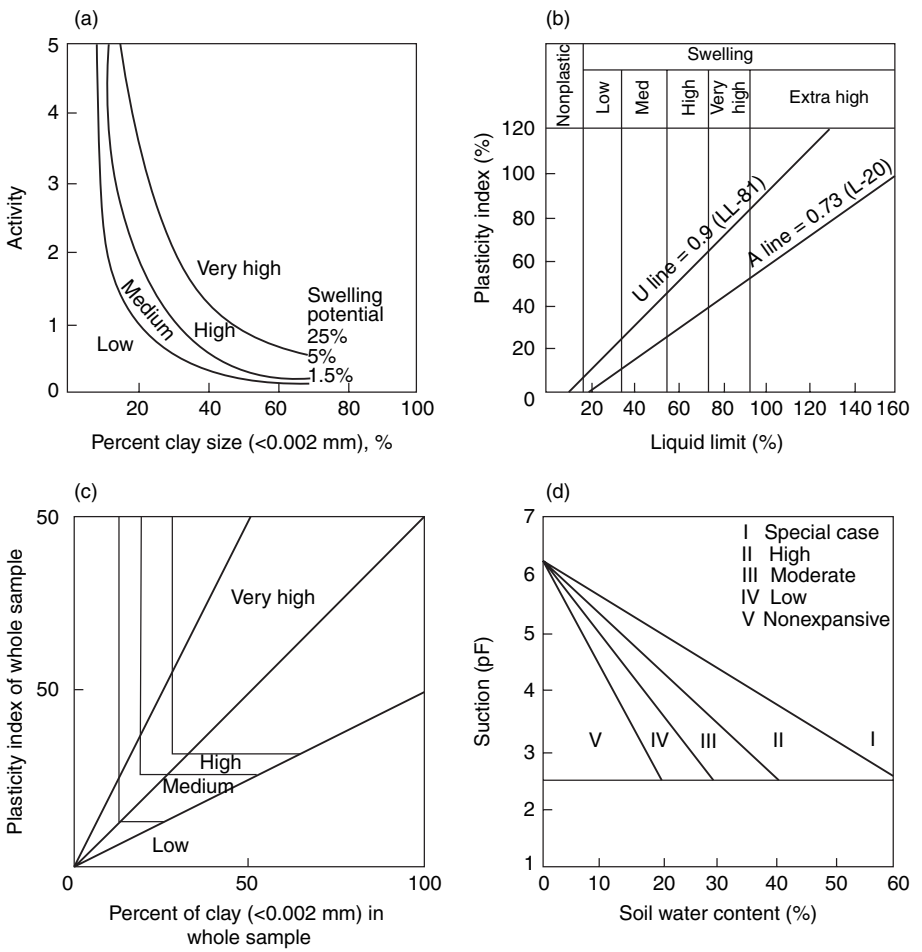

Figure 33.9 Commonly used criteria for determining swell potential from across the world
Reproduced from Yilmaz (2006), with permission from Elsevier

Since liquid limit and swelling of clays both depend on the amount of water a clay tries to imbibe, it is not surprising that they are related. Chen (1988) suggested that a relationship between the swelling potential of clay and its plasticity index can be established. While it may be true that high swelling soil will manifest high index properties, the converse is not always true.

Other classification schemes relate to expansion potential, based on the Skempton 'activity' plot (Skempton, 1953) and its development by Williams and Donaldson (1980) from Van der Merwe (1964). Details are described in Taylor and Smith (1986) with respect to various UK clay mudstone formations.

A host of schemes have been put forward for estimating shrink–swell, particularly in the US (see Chen, 1988; Nelson and Miller, 1992), most of which use swelling and suction as their basis (Snethen, 1984). Sarman *et al*. (1994) concluded that swelling was not related solely to clay mineral type, but also to pore-morphology. It was found that samples showing high swelling had a large pore volume combined with a high percentage of small-sized pores. The high swelling was attributed to the samples' ability to absorb and adsorb water. It was found that correlations between swelling and other parameters were unsuccessful.

With all classification schemes only indications of expansion are obtained with, in reality, field conditions varying considerably. Such ratings can be of little use unless the user is familiar with the soil type and the test conditions used to develop the ratings. Ratings themselves may be misleading and can, if used with design options outside the region where the rating was established, cause significant difficulties (Nelson and Miller, 1992). Classifications, therefore, should only be considered to provide an indication of potential expansive problems, and further testing is needed. If such schemes are used as a basis of design, the result is either over-conservative solutions or inadequate construction (Nelson and Miller, 1992).

33.5.3.2 UK approach

Whilst much study has been carried out worldwide to infer swelling and shrinkage behaviour from soil index properties such as plasticity (see section 33.5.1.1.3), few direct data are available in UK geotechnical databases (Hobbs *et al*., 1998). Two schemes that are commonly used within the UK are based on the BRE and NHBC schemes.

Volume change potential has more recently been defined for overconsolidated clays in terms of a modified plasticity index term (I'_p) by Building Research Establishment Digest 240 (BRE, 1993a) – see **Table 33.1**. This classification aims to eliminate discrepancies due to particle size.

High shrinkage potential soils may not behave very differently from low shrinkage ones, because environmental conditions in the UK do not allow full potential to be realised (Reeve *et al*., 1980). The National House-Building Council (NHBC, 2011a) classified volume change potential as shown in **Table 33.2**. This classification forms the basis of the NHBC's 'foundation depth' tables.

Since a set of soil properties will often not fit neatly into one category, the determination of shrinkage potential requires some judgement. The BRE (1993a) suggests that plasticity index and clay fraction can be used to indicate the potential of a soil to shrink, or swell, as follows:

Plasticity index (%)	Clay fraction (<0.002 mm)	Shrinkage potential
>35	>95	Very high
22–48	60–95	High
12–32	30–60	Medium
<18	<30	Low

The overlap of categories reflects the fact that figures were obtained from multiple sources.

33.5.3.3 National versus regional characteristics

A meaningful assessment of the shrink–swell potential of soil in the UK requires a considerable amount of high quality and well-distributed spatial data of a consistent standard. The British Geological Survey's *National Geotechnical Properties Database* (Self *et al*., 2008) contains a large body of index test data. At the time of writing, the database contained data from more than 80 000 boreholes, comprising nearly 320 000 geotechnical samples, with 100 000 containing relevant plasticity data.

The British Geological Survey (BGS) GeoSure *National Ground Stability Data* provides geological information about potential ground movement or subsidence, including the GeoSure shrink–swell dataset (Booth *et al*., 2011). It should be noted that this assessment does not quantify the shrink–swell behaviour of a soil at a particular site; it indicates the potential for such a hazard to be present with regard to the behaviour of the underlying geological unit throughout its outcrop.

The VCP of a soil provides the relative change in volume to be expected with changes in soil water content. This was calculated from the I'_p values and a classification made based on the *upper quartile* value (**Table 33.3**). This is based on the BRE (1993a) scheme shown in **Table 33.1**. In this way, a VCP was assigned to each of the geological units and a map of shrink–swell potential built (**Figure 33.10**).

Looking at clays on a national scale can give a good indication of the potential problems associated with them and provide

Classification	I'_p (%)	VCP
A	< 1	Non-plastic
B	1–20	Low
C	20–40	Medium
D	40–60	High
E	> 60	Very high

Table 33.3 Classification of VCP

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

initial information regarding planning decisions. However, no two clay soils are the same in terms of their behaviour or their shrink–swell potential. Therefore, it is useful to look at a particular clay formation on a more regional basis. For illustration, the London Clay formation will be used.

The London Clay formation is of major importance in the fields of geotechnical engineering and engineering geology. This is because it has hosted a large proportion of sub-surface engineering works in London over the last 150 years. It has also been the subject of internationally recognised research in soil mechanics

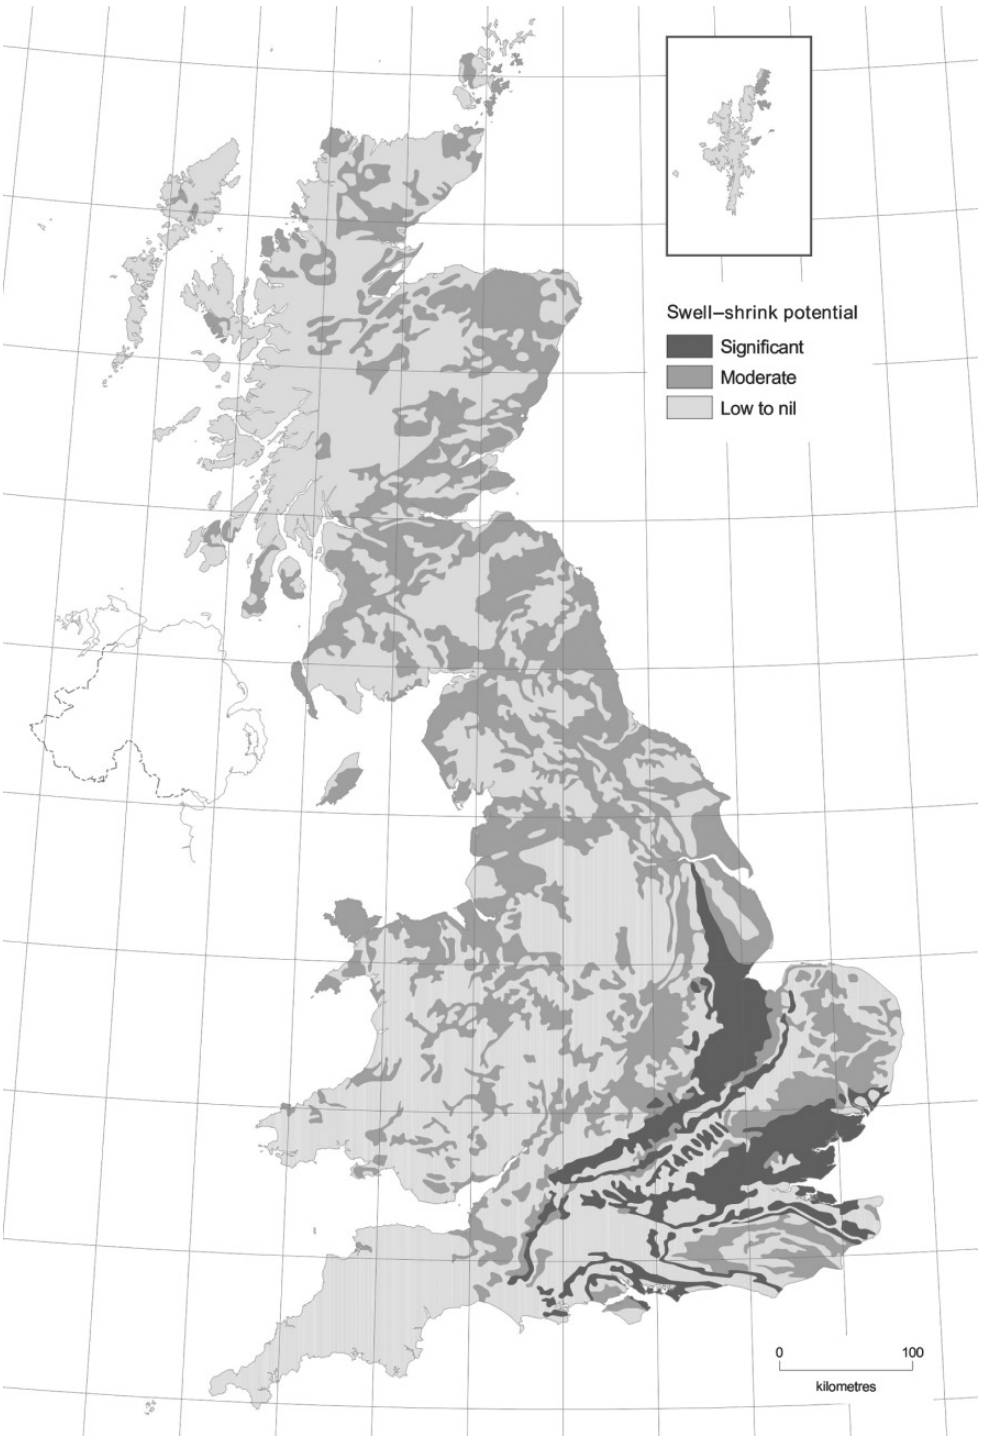

Figure 33.10 Shrink–swell potential map, based on VCP
Reproduced from Jackson (2004) © NERC, with permission from the British Geological Survey

over the last 50 years (Skempton and DeLory, 1957; Chandler and Apted, 1988 and Takahashi *et al*., 2005). The London Clay is subject to shrinkage and swelling behaviour, which has resulted in a long history of foundation damage within the outcrop.

Jones and Terrington (2011) follow the methodology described in Diaz Doce *et al*. (2011) using 11 366 samples across the London Clay outcrop, splitting it into four distinct areas based on geographical location, plasticity values and depth of overlying sediment. In this way, a more detailed assessment of the outcrop could be carried out, and a 3D model providing a seamless interpolation of the VCP of the London Clay was created. This model gives a visualisation of the I'_p values, allowing them to be examined at a variety of depths relative to ground level (**Figure 33.11**). This type of analysis indicates that 3D modelling methods have considerable potential for predicting the spatial variation of VCP within expansive clay soils, so long as they have large enough data sets.

33.5.4 Specific problems with expansive soils

The principal adverse effects of the swell–shrink process arise when either swelling pressures result in heaving (or lifting) of structures, or shrinkage leads to differential settlement. As a result, a number of mitigation and design options exist either in the form of specific foundation types, or through the use of a range of different ground improvement techniques. Excellent reviews of the full range of these are provided by both Chen (1988) and Nelson and Miller (1992), together with details provided by NHBC (2011a). A summary is provided in the following sections (33.5.4.1–33.5.4.4) highlighting the key features associated with these options. In addition, discussion of some of the key issues faced in the UK is provided (see section 33.5.4.5) where impact of vegetation is often the major cause of soil–structure problems faced by expansive soils.

33.5.4.1 Foundation options in expansive soils

A large number of factors influence foundation types and design methods (see Section 5 *Design of foundations*); these include climatic, financial and legal aspects, as well as technical issues. Importantly, swell–shrink behaviour often does not manifest itself for several months and so design alternatives must take account of this. Other issues, such as financial considerations, can place strain on this and so early communication with all relevant stakeholders is essential. Higher initial costs are often offset many times over by a reduction in post-construction maintenance costs when dealing with expansive soils (Nelson and Miller, 1992).

Foundation alternatives when dealing with potentially expansive soils follow three options:

1. use of structural alternatives, e.g. stiffened raft;
2. use of ground improvement techniques;
3. a combination of (1) and (2).

As with any foundation option, the main aim is to minimise the effects of movement, principally differential. Two strategies are used when dealing with expansive soils:

- isolate structure from soil movements;
- design a foundation stiff enough to resist movements.

The major types of foundations used in expansive soils from around the world are pier and beam or pile and beam systems, reinforced rafts and modified continuous perimeter spread footings. These are summarised in **Table 33.4**; further details are provided by Chen (1988), Nelson and Miller (1992) and NHBC (2011a, 2011b, 2011c), and are discussed further below. It should be noted that terminology used to describe the foundation types listed in this table vary across the world with, for example, slab-on-grade used in the US for raft foundations.

Pier and beam; pile and beam foundations

These foundations consist of a ground beam to support structural loads, transferring the load to the piers or piles. A void is provided between the pier/pile and the ground beam to isolate the structure and prevent uplift from swelling. NHBC (2011a) provides guidance on minimum void dimensions. Floors are then constructed as floating slabs. The piers/piles are reinforced (with reinforcement taken over the whole length to avoid tensile failures) using concrete shafts with or without bell bottoms, steel piles (driven or pushed), or helical piles whose aim is to transfer loads to stable strata. Under-reamed bottoms and helical piers/piles can be effective in soils with a high swell potential, overcoming the impractical length that would otherwise be required with straight shaft piers/piles, or where there is a possibility of a loss of skin friction due to rising groundwater levels. If a stable non-expansive stratum occurs near the surface, the piers/piles can be designed as rigid anchoring members. If, however, the depth of potential swell is high, the piers/piles should be designed as elastic members in an elastic medium. **Figure 33.12** illustrates a typical pier and beam foundation from US practice. Very similar arrangements are used in the UK and are illustrated in NHBC (2011a, Figures 10 and 11, therein).

Design and construction procedures for each of these systems are provided in detail (including sample design calculations) by Chen (1988) and Nelson and Miller (1992). Additional discussion and example design calculations are provided by Nelson *et al*. (2007). It is important to ensure sufficient anchorage below the active zone. Pier/pile diameters are kept small (typically 300–450 mm). Any smaller, and problems will result in poor concrete placement and associated defects, e.g. void spaces. Another problem that can occur is 'mushrooming' near the top of the pier/pile, which provides an additional area for uplift forces to act upon. To avoid this, cylindrical cardboard forms are often employed and removed after the beam is cast to prevent a means to transmit swell pressures. The size of this void space depends on the magnitude of potential swell, with 150–300 mm often being used. In the upper active zone, shafts should be treated to reduce skin friction and hence minimise uplift forces. It is important that any chosen approach does not provide potential pathways to allow water to ingress to deeper layers, as this will cause deep-seated swelling.

Stiffened rafts

Stiffened slabs are either reinforced or post-tensioned systems, the latter being common in countries like the US. Design procedures consist of determining bending moments, shear, and deflections, associated with structural and swell pressure loads. The general layout used is illustrated in **Figure 33.13**, which shows examples used commonly in the US. Similar approaches are used in the UK and are presented in NHBC (2011a; 2011b).

Designs are modelled on the soil–structure interaction at the base of the slab, by considering the slab as a loaded plate or beam resting on an elastic medium. Essentially, two extremes exist – the first where a ground profile develops assuming a

Foundation type	Design philosophy	Advantages	Disadvantages
Pier and beam; pile and beam	Isolate structure from expansive movement by counteracting swell with anchoring to stable strata	Can be used in a wide variety of soils; reliable for soils of high swell potential	Relatively complex design and construction processes requiring specialist contractors
Raft; stiffened raft	Provides a rigid foundation to protect structure from differential settlements	Reliable for soils of moderate swell potential; no specialist equipment needed in construction	Only works for relatively simple building layout; requires full construction quality control
Modified continuous perimeter footing; deep trench fill foundations	Same as raft or stiffened raft foundation – includes stiffened perimeter beams	Simple construction with no specialist equipment needed	Ineffective in highly expansive soils or within the zone of influence of trees

Table 33.4 Foundation types used in expansive soils

Reproduced from Nelson and Miller (1992); John Wiley & Sons, Inc

weightless slab, and the second where a slab of infinite stiffness is placed on the swelling soil. In reality, slabs exhibit some flexibility and so the actual heave produced by swelling soils lies somewhere between these two extremes. These modes of movement are illustrated in **Figure 33.14**.

Several design approaches have been developed, each using a range of different combinations of soil and structural design parameters. A detailed account of these is provided by Nelson and Miller (1992) with additional discussion provided by Houston *et al*. (2011).

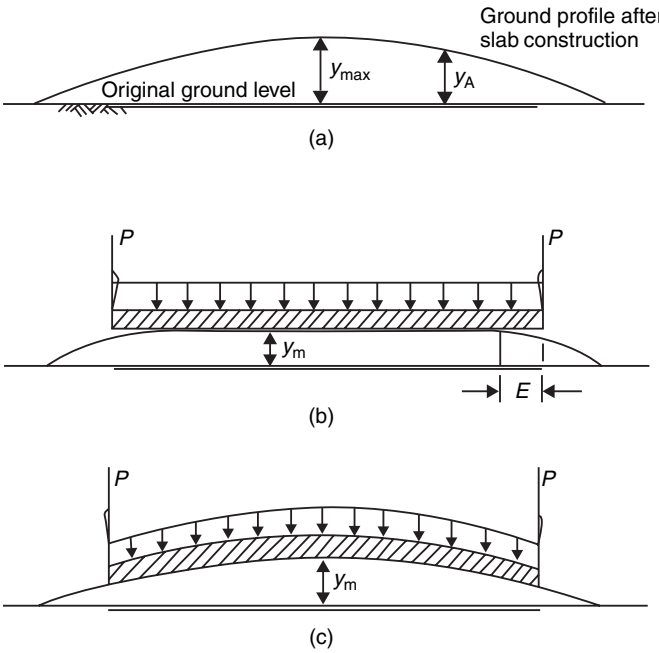

Figure 33.14 Profiles after construction for various stiffness of raft: (a) with no load applied; (b) with infinitely stiff slab; (c) with flexible slab. Notes: y_{max} = maximum heave, no foundation present – the free field heave; y_m = maximum differential heave; E = distance from outer edge to point where swelling soil contacts foundation; P = loading; y_A = height of free field heave along ground profile
Reproduced from Nelson and Miller (1992); John Wiley & Sons, Inc

The primarily geotechnical information required includes size, shape and properties of the distorted soil surface that develop below the slab. These depend on a number of factors including heave, soil stiffness, initial water content, water distribution, climate, post-construction time, loading, and slab rigidity. It should be noted that the slab, through its elimination of evapotranspiration (see **Figure 33.5**), promotes the greatest increase in water content near to the centre of the slab – and hence to where long-term distortion is most severe. However, the maximum differential heave (y_m in **Figure 33.14**) has been found to vary between 33 and 100% of total maximum heave (Nelson and Miller, 1992). On occasion, edge heave can occur when the exterior of a structure experiences increases in water content before the interior.

Modified continuous perimeter footing

Shallow footing should be avoided where expansive soils are found. However, where they are used, a number of approaches can be employed to minimise the effects of swelling/shrinkage. Modifications include:

- narrowing footing width;
- providing void spaces within support beam/wall to concentrate loads at isolated points;
- increasing perimeter reinforcement – taking this into the floor slab stiffening foundations.

The use of narrow spread footing in expansive soils should be restricted to soils exhibiting 1% swell potential and very low swell pressures (Nelson and Miller 1992).

NHBC (2011a) suggested that strip and trench fill foundations can be used when placed in a non-expansive layer that overlies expansive soils, provided that:

- soil is consistent across the site;
- the depth of non-expansive material is greater than ¾ of the equivalent foundation depth, assuming all soil is expansive (guidance provided within NHBC, 2011a);
- the thickness of the non-expansive soil below the foundation is at least equal to the foundation width.

Case studies

Chen (1988) provides a series of case study examples of foundations and problems that arise when dealing with expansive soils, including distress caused by the following: pier/pile uplift, improper pier/pile design and construction, heaving of a pad and floor slab, heaving of a continuous floor, and a rising water table. Further reviews of issues related to other foundation types, for example the use of post-tensioned stiffened raft foundations, are discussed by Houston *et al.* (2011). Other useful case studies are provided by Simmons (1991) and Kropp (2011). It is clear that a number of foundation failures occur and these can be summarised as follows:

1. *Changes in water content*
   - chiefly high water tables;
   - poor drainage under foundations;
   - leaks due to sewer failure or poorly managed runoff;
   - irrigation and garden watering.
2. *Poor construction practice*
   - insufficient edge beam stiffness;
   - inadequate slab thickness;
   - inadequate anchorage from piers;
   - pier length inadequate or ‘mushrooming’ of piers/piles resulting in uplift as swelling occurs;
   - lack of reinforcement making structure intolerant to movements;
   - inadequate void space.
3. *Lack of appreciation of soil profile*
   - underlying geology contains inclined bedding of bedrock, causing swell to be both vertical and horizontal;
   - uncontrolled fill placement;
   - areas of extensive depth of expansive soil, so drilled pier and beam foundation may not be practical and a more flexible system should be used.

When assessing failure from swell–shrink behaviour it is important to isolate structural defects from foundation movement, as both can cause cracking distress in buildings (Chen, 1988). Useful reviews of geotechnical practice in relation to expansive soils have been provided by Lawson (2006) for Texas, Kropp (2011) for the San Francisco Bay Area, and Houston *et al*. (2011) for Arizona. Although these are US-based, there are many lessons that geotechnical engineers can learn from these studies. Ewing (2011) provides an interesting case from Jackson, Mississippi, USA, of a series of repairs over a 30-year period to a house (on the US's register of historic places) built on 1.5 m of non-expansive soils overlying expansive clay some 8 m thick.

33.5.4.2 Pavement and expansive soils

Pavements are particularly vulnerable to expansive soil damage, with estimates suggesting that they are associated with approximately half of the overall costs from expansive soils (Chen 1988). Their inherent vulnerability stems from their reasonably lightweight nature, extended over a relatively large area. For example, Cameron (2006) describes problems with railways built on expansive soils where poor drainage exists, and Zheng *et al*. (2009) provide details (from China) of highway sub-grade construction on embankments and in slopes. Damage to pavements on expansive soils comes in four major forms:

- severe unevenness along significant lengths – cracks may or may not be visible (particularly important for airport runways);
- longitudinal cracking;
- lateral cracking, developed from significant localised deformations;
- localised pavement failure associated with disintegration of the surface.

Pavement design is essentially the same as that used for foundations. However a number of different approaches are required as pavements cannot be isolated from the soils and it is impractical to make pavements stiff enough to avoid differential movements. Therefore it is often more economic to treat sub-grade soils (see section 33.5.4.3 below for further details). Pavement designs are based on either flexible or rigid pavement systems; these procedures are discussed in Section 7 *Design of earthworks, slopes and pavements* and Chapter 76 *Issues for pavement design* of this manual. However, when dealing with expansive soils a number of approaches should be considered:

1. choose an alternative route and avoid expansive soil;
2. remove and replace expansive soil with a non-expansive alternative;
3. design for low strength and allow regular maintenance;
4. physically alter expansive soils through disturbance and re-compaction;
5. stabilise through chemical additives, such as lime treatment;
6. control water content changes – although very difficult over the life of a pavement. Techniques include pre-wetting, membranes, deep drains, slurry injection treatment.

Nelson and Miller (1992) provide further details on testing undertaken to mitigate expansive soil behaviour for pavement construction. Cameron (2006) has advocated the use of trees as they can be beneficial in semi-arid environments to manage poorly-drained areas under railways. However, this needs careful management and may require several years to be fully effective.

33.5.4.3 Treatment of expansive soils

Essentially, treatment of expansive soils can be grouped into two categories:

1. soil stabilisation – remove/replace; remould and compact; pre-wet, and chemical/cement stabilisation;
2. water content control methods – horizontal barriers (membranes, asphalt and rigid barriers); vertical barriers; electrochemical soil treatment, and heat treatment.

A detailed account of the various treatment approaches is provided by Chen (1988) and Nelson and Miller (1992), with a detailed review of stabilisation over the last 60 years provided by Petry and Little (2002). As with any treatment approach, it is essential to undertake appropriate site investigations and evaluations (see Section 6 *Design of retaining structures* and section 33.5.1 above). Special consideration should be given to the following: depth of the active zone, potential for volume change, soil chemistry, water variations within the soil, permeability, uniformity of the soils, and project requirements. An overview of each of the two categories of treatments applied to expansive soils is provided below, with **Table 33.5** providing brief details of soil stabilisation approaches.

In a recent survey, Houston *et al*. (2011) found that many geotechnical and structural engineers considered chemical stabilisation approaches, such as the use of lime, as ineffective for pre-treatment of expansive soils for foundations. Preference is typically given for use of either pier/pile and beam foundations, or stiffened raft foundations. This is not true for pavements, where lime and other chemical stabilisation approaches are commonly used worldwide. The various stabilisers can be grouped into three categories (Petry and Little, 2002):

- traditional stabilisers – lime and cement;
- by-product stabilisers – cement/lime kiln dust and fly ash;
- non-traditional stabilisers – e.g. sulfonated oils, potassium compounds, ammonium compounds and polymers.

Further details of these can be found in Petry and Little (2002). However, as with any soil treated with lime, care is needed to assess chemical as well as physical soil properties to prevent swelling from adverse chemical reactions (Petry and Little, 2002). For example, Madhyannapu *et al*. (2010) provide details

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

of quality control when stabilising expansive sub-soils using deep soil mixing, demonstrating the use of non-destructive tests based on seismic methods.

Chemical stabilisation can be used to provide a cushion immediately below foundations placed on expansive soils, e.g. for pavements (Ramana and Praveen, 2008). Swell mitigation has also been achieved by mixing non-swelling material e.g. sand (Hudyma and Avar, 2006) or granulated tyre rubber (Patil *et al*., 2011) into expansive soils to dilute swell potential.

In some cases surcharging may be used, but this is only effective with soils of low to moderate swelling pressures. This requires enough surcharge load (see the first row in **Table 33.5**) to counteract expected swell pressures. This method is therefore only used for soil of low swell pressure and with structures that can tolerate heave. Examples include secondary highway systems, or where high foundation pressures occur. Pre-wetting – due to its uncertainties – can only be used with caution, with both Chen (1988) and Nelson and Miller (1992) indicating that it is unlikely to play an important role in the construction of foundations on expansive soils.

Fluctuations in water content are one of the primary causes of swell–shrink problems, with non-uniform heave occurring due to non-uniformity of water content, soil properties, or both. Thus, if water content fluctuations can be minimised over time, then swell–shrink problems can be mitigated. Moreover, if water content changes can be slowed down and water distributions in expansive soils made uniform, then differential movements can also be reduced. In essence, this is the aim of the introduction of moisture/water barriers. These act to:

1. move the edge effects away from the foundation/pavement and so minimise seasonal fluctuation effects;
2. lengthen the time for water content changes to occur – due to longer migration paths under foundations.

Barrier techniques comprise:

- horizontal barriers – using membranes, bituminous membranes or concrete;
- vertical barriers – polyethylene, concrete, impervious semi-hardening slurries.

Improvement approach	Outline of approach	Advantages	Disadvantages
Removal and replacement	Expansive soil removed and replaced by non-expansive fill to a depth necessary to prevent excessive heave. Depth governed by weight needed to prevent uplift and mitigate differential movement. Chen (1988) suggests a minimum of 1–1.3 m	Non-expansive fill can achieve increase bearing capacities; simple and easy to undertake; often quicker than alternatives	Preferable to use impervious fill to prevent water ingress which can be expensive; thickness required may be impractical; failure can occur during construction due to water ingress
Remoulding and compaction	Less expansion observed for soil compacted at low densities above OWC[1] than those at high densities and below OWC (see **Figure 31.15**). Standard compaction methods and control can be used to achieve target densities	Uses clay on site, eliminating cost of imported fill; can achieve a relatively impermeable fill, minimising water ingress; swell potential reduced without introducing excess water	Low density compaction may be detrimental to bearing capacity; may not be effective for soil of high swell potential; requires close and careful quality control
Pre-wetting or ponding	Water content increased to promote heave prior to construction. Dykes or berms used to impound water in flooded area. Alternatively, trenches and vertical drains can be used to speed infiltration of water into soil	Has been used successfully when soils have sufficiently high permeabilities to allow relatively quick water ingress, e.g. with fissure clays	May require several years to achieve adequate wetting; loss of strength and failure can occur; ingress limited to a depth less than the active zone; water redistribution can occur – causing heave after construction
Chemical stabilisation	Lime (3–8% by weight) common with cements (2–6% by weight) sometimes used, and salts, fly ash and organic compounds less commonly used. Generally lime mixed into surface (~300 mm), sealed, cured and then compacted. Lime may also be injected in slurry form. Lime generally best when dealing with highly plastic clays	All fine-grained soils can be treated by chemical stabilisers; effective in reducing plasticity and swell potential of an expansive soil	Soil chemistry may be detrimental to chemical treatment; health and safety need careful consideration as chemical stabilisers carry potential risks; environmental risks may also occur – e.g. quick lime is particularly reactive; curing inhibited in colder temperatures

[1] OWC – optimum water content, as determined by standard proctor test BS1377 (BSI, 1990).

Table 33.5 Soil stabilisation approaches applied to expansive soils
Data taken from Nelson and Miller (1992)

Detailed accounts of these are provided in both Chen (1988) and in Nelson and Miller (1992). In addition, electrochemical soil treatment approaches are being developed that utilise electrical current to inject stabilising agents into the soils. Further details are provided by Barker *et al*. (2004). As well as barrier methods, water management can be employed with restrictions applied to avoid irrigation within certain distances of the structure. However, monitoring is needed to ensure compliance with these restrictions.

33.5.4.4 Remedial options

Expansive soils cause significant damage to buildings, as discussed throughout this chapter, and so remedial action is required to repair any damage. However, it is important to establish a number of factors before embarking on a remedial plan. Key questions that should be considered are (after Nelson and Miller, 1992):

- Are remedial measures needed – is damage severe enough to warrant treatment?
- Is continued movement anticipated and so would it be better to wait?
- Who will pay?
- What criteria should be selected?
- How has the damage been caused and what is its extent?
- What remedial measures are applicable?
- Are there any residual risks post remediation?

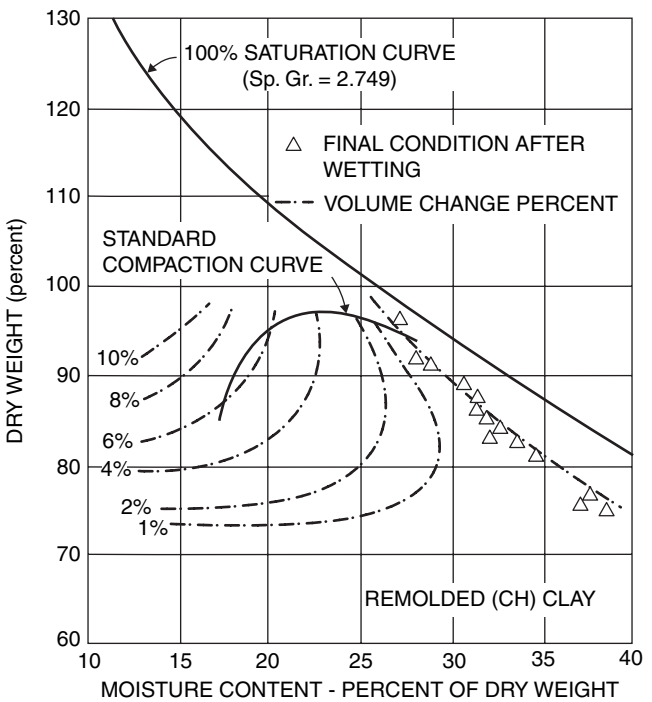

Figure 33.15 Percentage expansion for various placement conditions (c.f. Table 33.5)
Reproduced from Holtz (1995) all rights reserved

Clearly, to select an appropriate remedial measure, an adequate forensic site investigation is required. Key information required includes the cause and extent of the damage, the soil profile (as it is often difficult to determine whether settlement/heave is the cause of structural distress), and the soil's expansive potential. Other necessary information has already been discussed in section 33.5.1 above. Failure to carry out an adequate site investigation can lead to false diagnoses and inappropriate remedial measures employed. Further details are provided by Nelson and Miller (1992) as well as BRE Digests 251 (1995a), 298 (1999), 361 (1991), 412 (1996) and 471 (2002).

The following are examples of remedial measures employed for foundations:

- repair and replace structural elements or correct improper design features;
- underpin;
- provide structural adjustments of additional structural supports e.g. post tensioning;
- stiffen foundations;
- provide drainage control;
- stabilise water contents of foundation soils;
- install moisture barriers to control water content fluctuations.

Full underpinning of an operational structure is often impractical (and increasingly seen as unnecessary) and it is more common for underpinning work to be applied only to key parts of the foundations (Buzzi *et al*., 2010). Moreover, localised application of underpinning to deal with differential settlements may not improve the overall performance of the foundation (Walsh and Cameron, 1997). Thus any localised treatment must be designed to take account of all factors, otherwise there is a danger of exacerbating the problems due to the inherent natural spatial variability of expansive soils. Recently, underpinning using expanded polyurethane resin has met with some success, because resin can be injected using small diameter tubes directly where it is needed (Buzzi *et al*., 2010). However, due to concerns about its long-term stability and the possibility that swelling in injected soils could be exacerbated if all the cracks were filled, its adoption has been slow. However, a detailed experimental study (Buzzi *et al*., 2010) concluded that resin injected expansive soils did not exhibit enhanced swelling as a number of cracks remained unfilled, providing swell relief. Problems with lateral swelling can sometimes be accommodated by cracking within the soil matrix. However, if no cracks are present, problems can occur – particularly with retaining structures. Expanded polystyrene geofoam has demonstrated some success with dealing with lateral expansion, and has been shown to reduce the subsequent impact of vertical swelling (Ikizler *et al*., 2008).

With respect to pavements, distress can be considered as one of four possible types of damage, as highlighted in section 33.5.4.2 above. Most common remedial measures are

either removal and replacement, or construction of overlays. Whichever method is used, care is needed to ensure that the causes of the original distress are dealt with.

Many of the pre-construction approaches can also be used for post-construction treatments; for pavements these include moisture barriers, removal, replacement and compaction, and drainage control.

33.5.4.5 Domestic dwelling and vegetation

Tree roots will grow in the direction of least resistance and where they have the best access to water, air and nutrients (Roberts, 1976). The actual pattern of root growth depends upon, amongst other factors, the type of tree, the depth to the water table, and local ground conditions. Trees will tend to maintain a compact root system. However, when trees become very large, or where trees are under stress, they can send root systems far from the trunk. There is some published guidance on 'safe planting distances' that can be used by the insurance industry to inform householders of the potential impacts of different tree species on their properties. Further details are also given in NHBC (2011a).

Paving of previously open areas of land, such as the building of patios and driveways, can cause major disruption to the soil–water system. If the paving cuts off infiltration, many trees will send their roots deeper into the ground or further from the trunk in order to source water. The movement of these tree roots will cause disturbance of the ground and will lead to the removal of water from a larger area around the tree. Problems occur when houses are situated within the zone of influence of a tree (**Figure 33.16**).

If an impermeable method of paving is used, it may prevent water from penetrating into the ground. This can affect

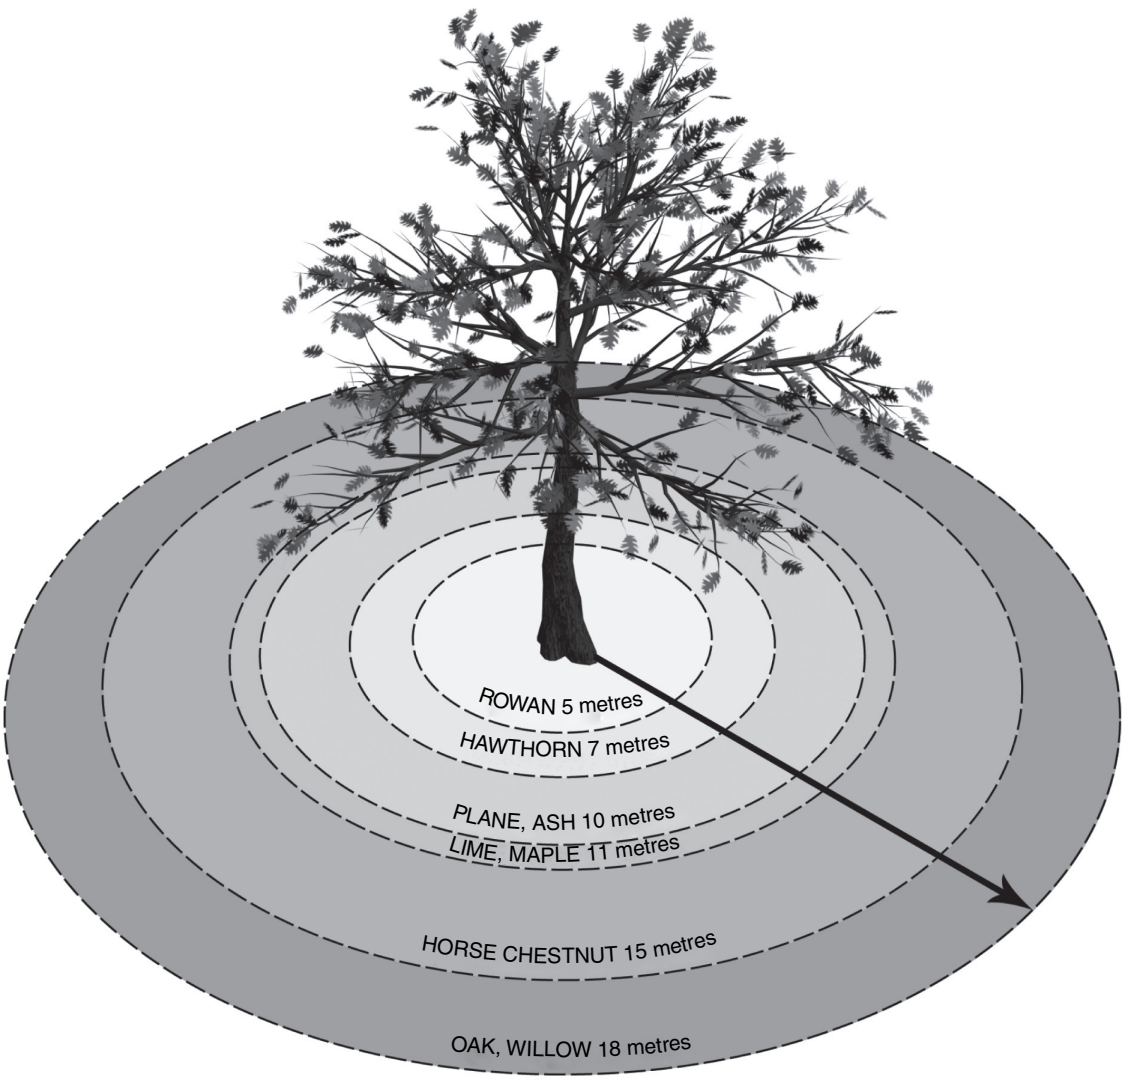

Figure 33.16 The zone of influence of some common UK trees
Reproduced from Jones *et al.* (2006) © NERC, with permission from The British Geological Survey

the shrink–swell behaviour of the ground and also the growing patterns of nearby trees. A well-designed impermeable paving system, in good condition, may actually reduce the amount of shrink–swell activity in the ground immediately below it. Paving moderates variations in water content of the soil and thus the range of shrink–swell behaviour. However, if the paving seal is broken, water can suddenly enter the system, causing swelling of the ground.

Different problems are faced when considering the distinctly separate areas of designing new build structures and remediating existing damaged buildings. New build guidelines for domestic dwellings recognise the need for thorough ground investigations to design systems to cope with the hazards presented by existing trees or their recent removal. Reference should be made to National House Building Council (NHBC) Standards Chapter 4.2 *Building Near Trees* (NHBC, 2011a) and the *Efficient Design of Piled Foundations for Low-Rise Housing – Design Guide* (NHBC, 2010). In the case of existing dwellings, a range of reports and digests are available (e.g. BRE Digests 298, 1999; 412, 1996) and *A Good Technical Practice Guide* provided by Driscoll and Skinner (2007).

Essentially, foundations should make allowances for trees in expansive (swell–shrink) soils and should take account of (NHBC, 2011a):

- shrinkage/heave linked to changes in water content;
- soil classification;
- water demand of trees (this is species-dependent);
- tree height;
- climate.

In the case of existing structures, the main cause of distress results from the effects of differential settlement, where different parts of the building move by varying amounts due to variations in the properties of the underlying soil. Equal or proportionate movements across the plan area of a building, though significant in terms of vertical movement, may result in little structural damage (IStructE, 1994). However, in the UK this is rare; by far the most overwhelming cause of damage to property results from the desiccation of clay subsoil which consequently causes differential settlements/movements, often stemming from the abstraction of water by the roots of nearby vegetation.

If vegetation is involved, it produces a characteristic seasonal pattern of foundation movement: subsidence in the summer, reaching a maximum around September, followed by upward recovery in the winter (see **Figure 33.17**). If subsidence followed by recovery is occurring, there is no need to try to demonstrate shrinkable clay or desiccation. No other cause produces a similar pattern – soil drying by vegetation must be involved (unless the foundations are less than 300 mm). Furthermore, there is no need to demonstrate the full cycle as it is sufficient to confirm movement is consistent with this pattern. Monitoring upward recovery in the winter is particularly valuable in this case. Further details are given by Crilly and Driscoll (2000) and Driscoll and Chown (2001), drawn from a test site in Chattenden, Kent, set in expansive London Clay (see **Figure 33.17**). In addition, both articles provide details of instrumented piles, discussing design implications.

Level monitoring can demonstrate this pattern. BRE Digest 344 (1995b) makes recommendations for the taking of measurements of the 'out-of-level' of a course of masonry or of the damp-proof course, which can be used to estimate the amount of differential settlement or heave that has already taken place. BRE Digest 386 (1993b) discusses precise levelling techniques and equipment which can monitor vertical movements with an accuracy consistently better than ±0.5 mm. Precise levelling can be conducted easily, quickly and accurately and so provides one of the most effective ways to distinguish between potential causes of foundation movement (Biddle, 2001).

The choice of mitigation should be proportionate to the problem and specific to the true area of the affected structure. It is important not to become distracted by extraneous but nevertheless interesting features.

Biddle (2001) suggests one of four remedial options to deal with the adverse actions of trees:

1. fell the offending tree to eliminate all future drying;
2. prune the tree to reduce drying and the amplitude of seasonal movement;
3. control the root spread to prevent drying under foundations;
4. provide supplementary watering to prevent soil from drying.

Biddle (2001) states that it is now recognised that in most situations, underpinning is unnecessary and that foundations can be stabilised by appropriate tree management – usually by felling the offending tree or by carrying out heavy crown reduction. Site investigations should reflect this change and be aimed at providing the information to allow appropriate decisions on tree management. In particular:

- confirmation that vegetation-related subsidence is involved;
- identification of which tree(s) or shrub(s) are involved;
- assessment of the risk of heave if a tree is felled or managed;
- identification of the need for any other site investigations;
- if the tree warrants retention, assessment of whether partial underpinning would be sufficient;
- confirmation that vegetation management has been effective in stabilising the foundations;
- provision of information within an acceptable timescale.

Trees are often pruned to reduce their water use and therefore their influence on the surrounding soil. However, unless the trees are thereafter subjected to a frequent and ongoing regime of management, the problems will very quickly return. Whilst

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

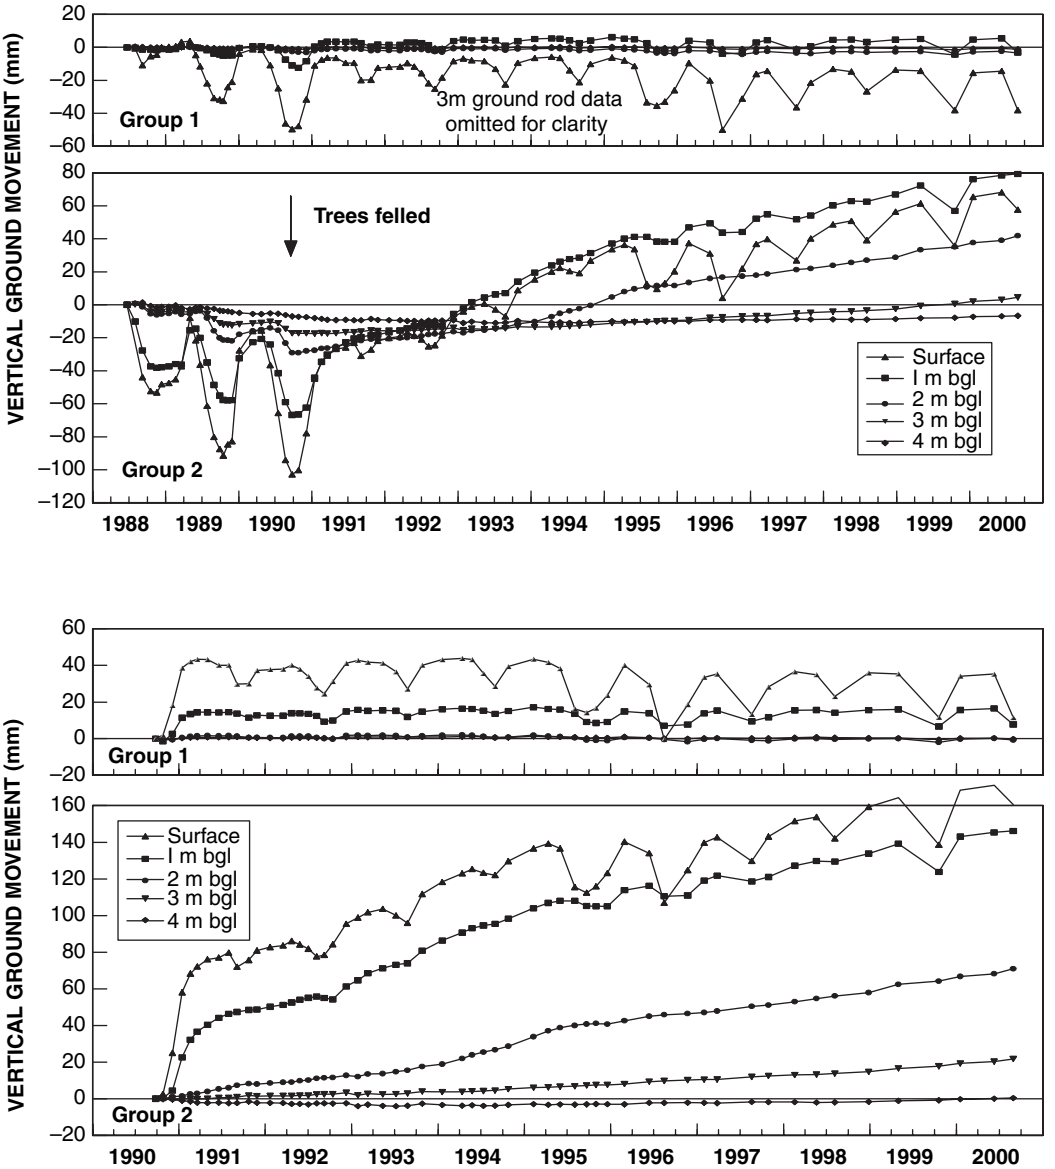

Figure 33.17 Examples of ground movements due to seasonal fluctuations at Chattenden. The upper plot shows results obtained since the first movements in June 1988. The lower plot shows an enlarged scale with results obtained since the trees were felled – group 1 is remote from tree and group 2 near to trees

tree removal will ultimately provide an absolute solution in the majority of cases, there are situations where this is not an option (e.g. protected trees, adverse risk of heave, incomplete evidence in contentious issues, and physical proximity of trees).

In the past, an obvious and often knee-jerk solution has been to provide significant and often disproportionate support to the structure through foundation strengthening schemes, incorporating various forms of underpinning. This approach is often ecologically, financially and technically incongruent with the problems faced. Alternatively, various forms of physical barriers can be used, constructed from, for example, *in situ* concrete. However, such barriers often prove ineffective over time. Barriers are currently being developed that incorporate a bioroot barrier, which is a mechanically-bonded geocomposite consisting of a copper-foil firmly embedded between two layers of geotextile. Such biobarriers are now being used specifically in arboriculture and for Japanese knotweed control where a permeable barrier is required. They act as signal barriers by diverting root growth (both biologically and physically) without making any attempt to physically restrain their progress.

Alternative remediation by supplementary watering is usually considered impractical due to the quantities required by the tree. This approach can suffer from the unavailability of water precisely when it is needed – due to prevailing drought conditions.

If a mature tree is felled, a building may incur heaving on a dry clay soil. Unfortunately, the evidence is rarely obvious; however, clues to look out for include:

- the house is new – less than 20 years old;
- there is expansive soil present;
- the crack pattern might appear a bit odd – wider at the bottom than at the top, with no obvious cause; and
- cracks continue to open, even in the wet months.

Heave problems can be costly and always require thorough investigation involving soil sampling, precise levels and aerial photographs. Heave is a threat but rarely a reality where established existing properties are involved, and the structure predates the planting of the tree.

Ultimately, if the offending tree can be accurately targeted and dealt with rapidly before the next growing season, the extent of any damage and need for remedial work will be kept to a minimum (Biddle, 2001).

33.6 Conclusions

Expansive soils are one of the most significant ground-related hazards found globally, costing billions of pounds annually. They are found throughout the world – commonly in arid/semi-arid regions – where their high suctions and potential for large water content changes can cause significant volume changes. In humid regions, such as the UK, problematic expansive behaviour generally occurs in clays of high plasticity index. Either way, expansive soils have the potential to demonstrate significant volume changes in direct response to changes in water content. This can be induced through water ingress, through modification to water conditions, or via the action of external influences such as trees.

To understand, and hence engineer expansive soils in an effective way, it is necessary to understand soil properties, suction/water conditions, water content variations (temporal and spatial), and the geometry/stiffness of foundations and associated structures. This chapter provides an overview of these features and includes methods to investigate expansive behaviour both in the field and in the laboratory, together with associated empirical and analytical tools to evaluate it. Following this design, options for pre- and post-construction are highlighted for both foundations and pavements, together with methods to ameliorate potentially damaging expansive behaviour, including dealing with the impact of trees.

34.7	References	458

The term 'fill' (or 'made ground') is used to describe material that has been deposited by human processes. The material could be natural, or have been altered artificially prior to deposition. Fill is either engineered or non-engineered depending on whether any specific treatment during deposition takes place. As a result, a number of engineering challenges may exist and will require different remediation approaches to improve and mitigate problematical behaviour.

Non-engineered fill may consist of domestic waste, building waste, slag, mining and quarry waste, industrial waste and soil waste. However, methodologies for the classification and description of fills are not fully developed or standardised nationally or internationally. This affects the way in which fills are presented on geological maps, though standardisation in the UK is becoming established.

Non-engineered fills may settle variably, have poor bearing capacity and may suffer significant movements due to causes other than the imposed loading. Other problems associated with some wastes include contamination, spontaneous combustion and the emission of gas. The extent to which non-engineered fill will be suitable as a foundation material depends largely on its age, composition, uniformity, properties and the method by which the material was placed.

34.1 Introduction

The term 'fill' refers to material that has been deposited artificially as, for instance, in an excavation or as ground made by human activity. Collectively, these deposits, together with unfilled excavations, are sometimes termed 'artificial ground' with reference to their geographical distribution and method of placement, rather than their composition (for example, see Ford *et al.*, 2006). Non-engineered fill, as opposed to engineered fill, is material that has not been subject to some degree of controlled placement to ensure that the geotechnical properties of the finally placed material comply with a predetermined design. It is dumped, with little control, in deep lifts so that it is typically poorly compacted and, so, is likely to be in a loose state with varying geotechnical properties, both laterally and with depth. Terminology, in practice, can be confusing, as Norbury (2010) has pointed out, in that engineered fill is often referred to as 'fill' while non-engineered fill is referred to as 'made ground'. This usage does not coincide with that of the British Geological Survey (BGS) in mapping artificial ground (see section 34.3.1).

Due to the shortage of prime land for development in urban areas, artificial ground, of necessity, is being, and increasingly will be, used for building purposes (Charles, 2008). However, non-engineered fill is derived from a wide variety of materials including domestic refuse, ashes, slag, clinker, building waste, chemical waste, mining and quarry waste, as well as different types of soils. These materials, by their very nature, exhibit significant variability, both physically and chemically. Thus, the extent to which an existing non-engineered fill may be suitable as a foundation material depends largely on its composition and uniformity; its engineering behaviour is influenced by its method of placement and subsequent history. In the past, the control exercised in placing many fills was frequently insufficient to ensure appropriate engineering properties (hence the term 'non-engineered'). Consequently, non-engineered fills may have variable settlement characteristics (**Figure 34.1**) or poor bearing capacity, and may be compositionally variable over short distances and suffer significant movements due to causes other than the imposed loading. Other problems can include contamination, spontaneous combustion and the emission of gas, depending on the nature of the fill material. In addition, time-related changes in volume and composition are likely to take place or may be triggered by any stress or environmental changes.

This chapter first discusses the generic characteristics of non-engineered fills that cause their problematic properties and their often unpredictable engineering behaviour, which can yield significant problems for geotechnical engineers. An overview of how non-engineered fills are classified (as 'artificial ground'), mapped and described is followed by a discussion of the nature, properties and behaviour of a range of non-engineered fills. Chapter 58 *Building on fills* gives specific details of building and foundation aspects for fill materials.

34.2 Problematic characteristics

Fills exhibit a range of engineering properties quite as wide as that of natural soils. The behaviour of natural soils and rocks is strongly influenced by their structure and fabric. Although soil structure arises from many different causes, its effect on

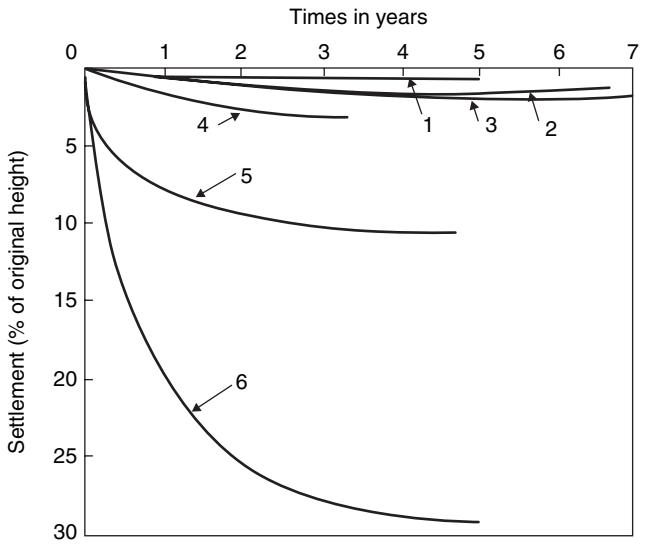

Figure 34.1 Observations of the settlement of various types of fill due to consolidation under its own weight. 1. Well-graded sand, well compacted. 2. Rockfill, medium state of compaction. 3. Clay or chalk, lightly compacted. 4. Sand, uncompacted. 5. Clay, uncompacted. 6. Mixed refuse, well compacted

Reproduced from Meyerhof (1951); Institution of Structural Engineers

behaviour is similar. As strength increases, the stress domain over which a soil exhibits stiffer behaviour is enlarged. In fills formed from natural soils, such structure will have been largely destroyed during excavation and placement, with little opportunity for it to be reinstated. Consequently, fill behaviour may be inferior to that of apparently similar natural soils.

Variability cannot be overemphasised. Whether between areas of infilled ground and natural ground, or between different areas of fill, variability can result in differential settlement or structural loading that is unacceptable. All analyses of fill must address the likely variations in properties and behaviour. Where fill density and history can be estimated, tests on representative, recompacted samples may give an indication of fill behaviour. The engineering behaviour of the material should be identified within the required context: for example, load-carrying capacity, volume changes in response to load or other factors, or strength. In addition, the potential for the generation of deleterious substances should be identified.

It is helpful to compare and contrast the properties of fills with the properties of natural soil, with the following factors in mind that will affect their engineering behaviour:

- Nature of the material: a fill may be composed of the same type of material as a natural soil (such as clay, sand or rock) or it could be composed of a range of other materials (such as wastes from chemical and industrial processes). The nature of the material will indicate the underlying best-case strength and stiffness behaviour and will affect the potential for any change in density, whether by mechanical, hydrological, biological or chemical causes.
- Method of deposition: a fill may have been deposited in a manner that is quite similar to the deposition of some natural soils (for example sedimentation under water) or it may have been deposited in a quite different manner (such as compaction). The method of placement and any subsequent activities will affect the density, water content and variability. Generally, like natural materials, a higher density at a lower moisture content is likely to demonstrate better engineering behaviour, although care should be taken where cementation or other 'metastable' conditions may occur.
- Age: many fills have been placed quite recently and the deposits are much younger than natural soils. Often, younger deposits are still undergoing movements arising from their placement or material type. In addition, changes in composition may be anticipated; for some fills that may mean poorer behaviour should be anticipated – for example, the ash content of more recent domestic refuse is lower, and the accompanying behaviour poorer, than older deposits.

See section 34.7.1, Further reading, and Chapter 58 *Building on fills* for more information.

34.3 Classification, mapping and description of artificial ground

34.3.1 Classification

Geotechnical engineers have typically divided 'fills' into those that are engineered and those that are not. However, when carrying out a site investigation on existing artificial ground it is not usually easy to make this distinction. Traditionally, geological surveyors have ignored artificial ground when creating a geological map. Engineering geologists, too, have paid little attention to the mapping of these deposits. For example, a report by the Geological Society Engineering Group Working Party on engineering geological mapping (Knill *et al*., 1970) only recognised 'made ground', 'spoil tip (made ground above natural surface level)' and 'backfilled opencast site or excavation'. However, the increased demand for land in urban areas has resulted in pressure to re-develop brownfield sites, including artificial ground. In turn, this has encouraged mapping geologists and engineering geologists to include these deposits on their maps. However, the simple mapping of artificial ground without systematically distinguishing between different categories does not meet the needs of developers and geotechnical engineers for more detailed information. In the last decade, a simple classification of artificial deposits has been used on geological maps in the UK. Ford *et al*. (2006) have extended the classification of Rosenbaum *et al*. (2003) and identified five principal classes of artificial ground (**Figure 34.2**):

1. *Made ground* is where material has been placed upon the pre-existing ground surface. Most engineered fill would fall into this class.
2. *Worked ground* is where there have been excavations into the pre-existing ground surface.
3. *Infilled ground* is a combination of one or more phases of excavation involving the extraction of material (worked ground) and one or more phases of deposition of material on the excavated surface or made ground (Price *et al*., 2011).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

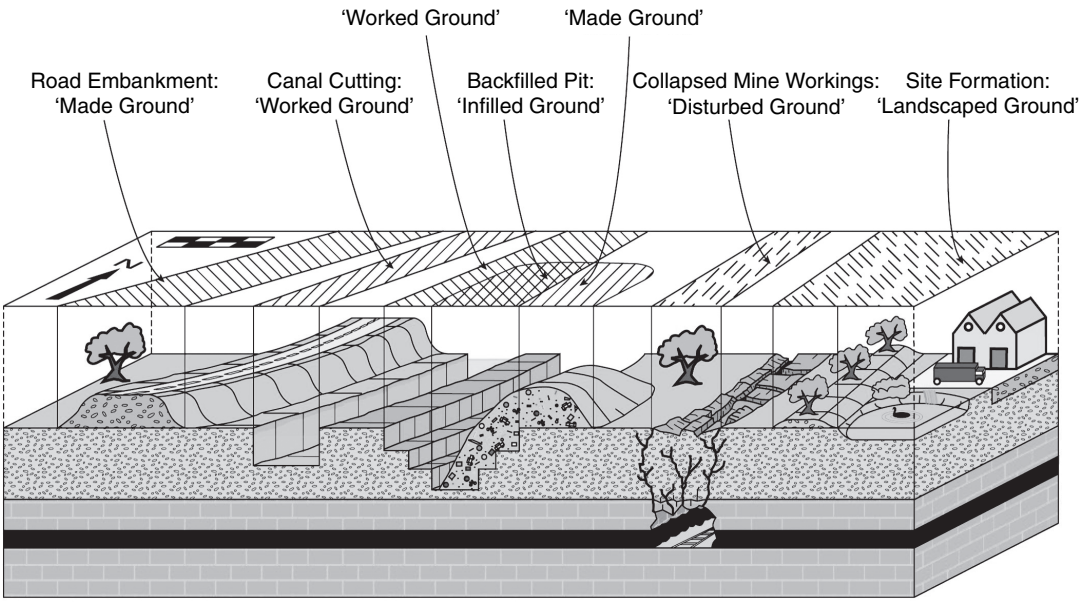

Figure 34.2 The main types of artificial ground and the way in which they are depicted on geological maps in the UK
Reproduced from Price *et al.* (2011); The Royal Society

4. *Disturbed ground* is where there has been surface or near-surface disturbance so that ill-defined excavations, areas of subsidence, spoil and other irregular features are associated in a complex way with each other: areas around mines often fall into this category.
5. *Landscaped ground* is where the original surface has been extensively remodelled, but where it is impractical or impossible to separately delineate areas of worked and made ground.

For each of the classes 1, 2 and 4, a three-tier hierarchy (class, type, unit) provides a flexible and logical sub-division into an increasingly descriptive set of lithostratigraphical categories for mapping purposes. The structure allows the user to select an appropriate level of detail according to available requirements, whilst providing a structure that is readily amenable to digital recording. Examples of the classification hierarchy are shown in **Figure 34.3**.

The typical usage is intended to be intuitive. The unit level gives the highest level of detail, allowing specific types of artificial ground to be recorded. This level of detail is suitable for mapping at 1:10 000 scale, which is the scale of most geological maps in the UK. Should a confident unit-level classification be impossible due to insufficient data or time, then a classification at the type level can be considered. The range of type-level categories provides a non-specific set of parent classes that retain a moderate level of detail. Class-level corresponds to the level of detail currently available on 1:50 000 scale geological maps published in the UK in the last 20 years or so. This is a very general classification level and specific observations and significant information may be lost through generalisation.

For landscaped ground, the classification is not sub-divided beyond type level. This is intended to avoid duplication of information that is available from other UK sources (for example, Ordnance Survey topographical maps and the National Land Use Database, which provides a comprehensive, consistent and up-to-date record of previously developed land in England that may be available for development).

34.3.2 Mapping

The mapping of artificial ground utilises the same principles as for superficial deposits and, to a lesser extent, bedrock. Mapping considers *morphology* (the shape of the ground), *origin* and *genesis* (the 'process' that has formed the deposit), *age* (important where several generations of deposits are present) and *lithology* (the composition of the materials themselves). This can be illustrated by comparing the way in which a railway embankment (class – made ground; type – embankment; unit – railway embankment) and an esker (an embankment-like natural deposit formed as a glacier retreats) are mapped. The two have similar morphologies, though an esker may well be more sinuous. Their genesis is clearly different: eskers are formed as glaciers retreat while railway embankments are formed during the construction of railway systems. Eskers have ages of thousands of years, while railway embankments are less than 200 years old. Eskers are composed largely of sand and gravel while railway embankments can be composed of a variety of materials, both natural and artificial, which have experienced varying degrees of engineering (usually compaction).

34.3.3 Description

The Geological Society Engineering Group Working Party reports on core logging and on engineering geological mapping (Knill *et al.*, 1970; Geological Society Engineering Group Working Party, 1972) do not refer to how fill materials should be described. However, the International Association of Engineering Geology's Commission on Engineering Geological Mapping has produced a brief guide to the mass characteristics of non-engineered fill that should be described (IAEG Commission, 1981):

- mode of origin, including method of placement;
- presence of larger objects;
- voids;
- chemical and organic matter;
- toxic materials including gases;
- age.

In terms of non-engineered fills, Norbury (2010) has suggested a more detailed approach. First, a sample of non-engineered fill material is divided into the very coarse, gravel and fine fractions. The proportion of each is determined and how the material is likely to behave in different situations (for example, in the sides of an excavation or in a spoil heap) is assessed. The material is then described in terms of its composition identifying the following:

a) natural soil materials;

b) artificial materials such as:

- asphalt;
- concrete;
- masonry, blockwork and brickwork;
- glass, metal, plastics;
- wood, paper;
- burnt products such as slag, clinker and ash including evidence by strong colours;
- large objects and obstructions, which may be critical to piling operations;
- hollow objects, compressible and collapsible objects or voids, which could be important for ground stability;
- chemical wastes and dangerous or hazardous materials;
- decomposable materials with a note of the degree of decomposition.

The proportions of each are also determined.

Norbury (2010) suggested that further information should be provided where possible covering:

- any dating for papers or other artefacts;
- signs of current or recent heat or combustion;
- smells or odours;
- layers and their inclination as a guide to the method of placement;
- origin of materials, if identifiable.

34.4 Types of non-engineered fill

Non-engineered fills generally are associated with the backfilling of opencast mineral extraction sites, disposal of waste and

with derelict land. Although a modern waste disposal site is engineered so that its construction should minimise the production of leachate and its infiltration into the ground, as well as dealing with any landfill gas produced, it is not necessarily designed to support the subsequent erection of buildings.

34.4.1 Filled opencast sites

34.4.1.1 Working of opencast sites

Stratified mineral deposits that occur at, or near, the surface, such as coal or sedimentary iron ore in relatively flat terrain, are generally mined by strip or opencast mining. A deposit will either be horizontal or gently dipping. In Britain, opencast coal mining involves the exploitation of shallow seams at sites normally from 10 to 800 ha in area. This usually involves creating a box-cut (an initial, trench-like excavation) to reveal the coal. The opencast working of coal involves its excavation to maximum depths of around 100 m below the surface with stripping ratios (the ratio of the amount of overburden or non-coal material to the amount of coal recovered) of up to 25:1. Hence, opencast mining has been a major producer of deep fills, the geotechnical properties of which are of notable importance if, after restoration, they are to be considered for building development. In this context, the major factor according to Charles (2008) is the possibility of long-term settlement of the backfill.

An opencast area will be worked on a broad front with face lengths of 3 to 5 km not being uncommon. Once the coal has been extracted, the box-cut is filled with overburden from the next cut. Draglines may be used for overburden (primarily sandstone and mudrock) removal along with face shovels and dump trucks, and scrapers. The topsoil is removed separately by scraper and placed in dumps around the site for use in subsequent restoration. Similarly, the subsoil is stripped and stored temporarily in separate dumps about the site, again for restoration purposes. Face shovels are used to excavate the initial box-cut and for subsequent forward reduction of overburden. The material from the box-cut is placed above ground in a suitable position in relation to filling the excavation so that later re-handling is minimised. Draglines excavate the lower seams in a progressive strip cut behind the face shovels. Drilling and blasting is carried out where necessary. Because of the short lifespan of spoil heaps, they can often be maintained at their natural angle of repose.

Restoration can begin before a site is closed; indeed, this usually is the more convenient method. Hence, worked-out areas behind the excavation front are filled with rock waste. This means that the final contours can be designed with less spoil movement than if the two operations were undertaken separately. Furthermore, more soil for spreading can be conserved when restoration and coal working are carried out simultaneously. Because of high stripping ratios (often 15:1 to 25:1), there is usually enough spoil to more or less fill an excavation. Once the spoil has been re-graded, it is covered with topsoil. The restored land is generally used for agriculture or forestry but it can be used for country parks, golf courses, housing or light industrial estates with suitable engineering.

34.4.1.2 Properties and engineering behaviour

The properties of some backfills of opencast mines were given by Charles and Watts (2001) and have been summarised by Charles (2008); see **Table 34.1**. However, many fills are heterogeneous and may contain large boulders of mudstone, siltstone or sandstone so the geotechnical properties quoted should be regarded as indicative values, at best. Hence, field measurements taken at opencast sites are of special value in understanding the geotechnical behaviour of a backfill. Instrumentation and monitoring of a fill is carried out once filling is finished (see Chapter 58 *Building on fills* for further details).

The water table at many opencast sites is lowered by pumping to provide dry working conditions in the pit. If, when worked out, a site is to be restored for agricultural use or for

(a) Coarse backfills

Location	Fill type	Silt and clay %	Dry density (ρd) Mg/m³	Particle density (ρs) Mg/m³	Moisture content (w) %	Porosity (n) %	Air voids (V_a) %
Horsley	Mudstone and sandstone	10	1.70	2.54	7	33	21
Blindwells	Mudstone and sandstone	20	1.56	2.45	7	38	23
Tamworth	Clay with shale fragments	45	1.78	2.62	9	32	16

(b) Clay backfills

Location	Moisture content (w) %		Plastic limit (w_P) %	Liquid limit (w_L) %	Undrained shear strength (w_u) kPa
	Mean	Range			
Ilkeston	19	12–25	23	41	150
Corby	18	7–28	17	28	100

forestry, then this takes place without control of compaction. However, if a site is to be built over, then settlement is likely to be a problem without proper compaction. In particular, significant settlements of opencast backfill can occur when the partially saturated material becomes saturated by rising groundwater after pumping has ceased. For example, Charles *et al.* (1993) referred to an opencast site in Northumberland, where the waste was backfilled without any systematic compaction. They recorded that when the water table rose some 0.33 m into the fill, settlement occurred where the fill was 63 m in depth.

Settlement due to wetting collapse is more significant than that due to the self-weight of the backfill, which can give rise to difficulties in settlement prediction (Blanchfield and Anderson, 2000). Therefore, if a site is to be built on after restoration, then ideally the waste should be compacted properly. However, the subsequent development of a site will frequently be some time after an opencast area has been worked out and backfilled. As a consequence, such areas require investigation prior to any building development to determine the moisture condition of the backfill material and to determine how much it has been compacted (if at all) (Occupational Health and Safety Information Service, 1983). Consequently, Charles (1993) recommended that if an opencast site is to be built over but the backfill was not properly compacted, then collapse compression could be realised prior to development by inundation. Indeed, Charles and Skinner (2001) maintained that the susceptibility to collapse compression on inundation often represents a notable hazard when construction is to take place on fill. Most types of partially saturated fill, which are in a sufficiently loose or dry state, are susceptible to collapse compression over a wide range of applied loads when first inundated. Inundation can result from the downward percolation of water infiltrating from the surface or can be due to rising groundwater levels after pumping has ceased. Collapse compression can cause serious damage to any buildings placed upon such fills. However, in many instances flooding is difficult to carry out in a controlled and effective way. Alternatively, the ground could be pre-loaded or subjected to deep compaction by either vibrocompaction or dynamic compaction, or the structures could be designed to accommodate any subsequent ground movements. However, placing vibro stone columns in opencast backfill, according to Charles and Watts (2001), might provide a means of allowing surface water into the fill and thereby cause collapse compression.

Alternatively, where backfilled opencast coal workings exceed 30 m in depth, because greater settlements may occur, Kilkenny (1968) recommended that the minimum time that should elapse before development takes place should be 12 years after restoration is complete. He noted that the settlement of opencast backfill appeared to be complete within 5 to 10 years after the operation. For example, comprehensive observations of the opencast restored area at Chibburn, Northumberland, which was 23 to 38 m in depth, revealed that the ultimate settlement amounted to approximately 1.2% of the fill thickness and that some 50% of the settlement was complete after 2 years and 75% within 5 years. In shallow opencast fills, that is, up to 20 m in depth, settlements of up to 75 mm have been observed. Greater settlement may occur if there is movement of groundwater through a permeable fill, including a rising water table as noted above, as a result of the breakdown of point-to-point contacts in the shale or sandstone components of the fill. In such circumstances settlement may continue over a greater length of time than noted by Kilkenny.

Restoration of other opencast mineral workings can be dealt with in a similar way to those for coal. Another mineral that has been extracted on a large scale by opencast mining was sedimentary iron ore; for example, this was worked near Scunthorpe, Lincolnshire, and near Corby in Northamptonshire. In the latter area Penman and Godwin (1975) noted that the maximum rates of settlement occurred immediately after the construction of two storey semi-detached houses on an old opencast site that had been backfilled. Settlement decreased to small rates after about 4 years. They suggested that two of the causes of settlement in this fill were creep, which is proportional to log time, and partial inundation. Similar conclusions were reached by Sowers *et al.* (1965). The houses at Corby were constructed 12 years after the fill was placed. The amount of damage that they suffered was relatively small and was attributable to differential settlement; it was not related to the type of foundation structure used. These were either strip footings or reinforced-concrete rafts with edge beams.

34.4.2 Domestic waste disposal or sanitary landfill

With increasing industrialisation, technical development and economic growth, the quantity of waste produced by society has increased immensely. In addition, in developed countries the nature and composition of waste has evolved over the decades, reflecting industrial and domestic practices. For example, in Britain, domestic waste has changed significantly since the 1950s, from largely ashes with little putrescible content of relatively high density to low density, highly putrescible waste. Although domestic waste is disposed of in a number of ways, quantitatively the most important method is placement in a landfill. In England in 2003–2004, for example, of approximately 25.2 million tonnes of domestic solid waste produced about 72% was disposed of in landfills (Parliamentary Office of Science and Technology, 2005). However, by 2007–2008, the amount recycled had increased to 35% (Office of National Statistics, 2009). Landfill is controlled through the European Landfill Directive (Council of the European Union, 1999), implemented in the UK through the Landfill (England and Wales) Regulations 2002 and the Landfill (Scotland) Regulations 2003. Since the introduction of these regulations, the amount of waste sent to landfill has reduced significantly. Increasingly, waste materials from different sectors (e.g. construction or household) are recycled. However, geotechnical engineers commonly encounter historical landfill sites, which, depending on their time of operation, will exhibit significantly different physical and chemical characteristics. Moreover, landfills are active sites with a

number of time-dependent changes occurring throughout its life. The Environment Agency has published a series of guides covering waste acceptance; monitoring of landfill leachate, groundwater and surface water; landfill engineering; landfill gas; and landfill permitting and surrender (www.environment-agency.gov.uk/business/sectors/108918.aspx).

34.4.2.1 Composition

Waste disposal or sanitary landfills are usually very mixed in composition (**Table 34.2**) and suffer from continuing organic decomposition and physicochemical breakdown. They can consist of a heterogeneous collection of almost anything: waste food, garden rubbish, paper, plastic, glass, rubber, cloth, ashes, building waste, metals, etc. In future, recycling is likely to change the character of waste. Nonetheless, matter exists in the gaseous, liquid and solid states in landfills and all landfills comprise a delicate and shifting balance between the three states. Any assessment of the state of a landfill and its environment must take into consideration the substances present in it, and their mobility now and in the future. Much of the material of which a landfill is composed is capable of reacting with water to give a liquid rich in organic matter, mineral salts and bacteria, commonly known as leachate. Leachate is formed when rainfall infiltrates into a landfill and dissolves the soluble fraction of the waste and from soluble products formed as a result of chemical and biochemical processes occurring within the decaying waste. Methane and carbon dioxide are the primary gases produced in landfills together with traces of organic gases, carbon monoxide and hydrogen sulfide. The concentration of methane can range from 20% to 65%, carbon dioxide from 15% to 40%, while other gases typically make up <1% (Wilson *et al.*, 2007). In very general terms, gas production is likely to have reduced to a very low level after about 50–60 years (Nastev 1998). Gases are produced in the breakdown process and accumulations of gas in pockets in fills have led to explosions, for example, following the escape of methane at Loscoe in Derbyshire (Williams and Aitkenhead, 1991). Some materials such as ashes and industrial waste may contain sulfate and other products that are potentially deleterious to concrete.

Material	Characteristics as fill
Garbage: food, waste	Wet. Ferments and decays readily. Compressible, weak.
Paper, cloth	Dry to damp. Decays and burns. Compressible.
Garden refuse	Damp. Ferments, decays, burns. Compressible.
Plastic	Dry. Decay resistant, may burn. Compressible.
Hollow metal, e.g. drums	Dry. Corrodible and crushable.
Massive metal	Dry. Slightly corrodible. Rigid.
Rubber, e.g. tyres	Dry. Resilient, burns, decay resistant. Compressible.
Glass	Dry. Decay resistant. Crushable and compressible.
Demolition timber	Dry. Decays and burns. Crushable.
Building rubble	Damp. Decay resistant. Crushable and erodible.
Ashes, clinker and chemical wastes	Damp. Compressible, active chemically and partially soluble.

Table 34.2 Municipal waste materials incorporated in fills

34.4.2.2 Landfill design

The design of a landfill site is influenced by the physical and biochemical properties of the waste and the need to control leachate production. Post-closure settlement of sites is taken into account at a very early stage in the design of a landfill. Indeed, modern landfill disposal facilities require detailed investigations to ensure that appropriate design and safety precautions are undertaken. Furthermore, legislation generally requires that those responsible for waste disposal facilities guarantee that sites are suitably contained so as to prevent harm to the environment (for further details see the Environment Agency's website). Geological and hydrogeological conditions must be taken into account when selecting a landfill site (Proske *et al.*, 2005). However, the selection also involves economic and social factors. It should be noted, also, that the methods used to contain landfill have changed considerably. It was not until the late 1970s and early 1980s that landfill liners were used; prior to this leachate and gas control was through dilute-and-disperse techniques. Since then, landfill liner and capping construction have become ever more sophisticated, with double lining systems now being used, combining clay (or a suitable substitute using bentonite enriched sands or clays, or engineered spoil material, such as colliery spoil) and plastic HDPE (high-density polyethylene) liners. Included in a lining system there will also be a series of leachate and gas collection layers and protection media, so that liners are complex engineered inclusions within a landfill matrix. Great care is needed to avoid compromising the lining system during investigation or ground treatment (for example, through piling), otherwise pollution linkages will be generated allowing possible migration to a number of sensitive receptors. **Figure 34.4** shows the early stages of construction of a cell within a landfill site.

However, it is vital that monitoring continues during and after the construction of a landfill, particularly with regard to leachate and gas emissions. Boreholes through the base of a leachate-containing landfill to check what is happening should only be used if precautions are taken to avoid leakage. Geophysical methods are being used increasingly for this purpose (for example, see Kuras *et al.*, 2006).

At the present time there is no standard rule as to how waste should be dumped or compacted. Nonetheless, compaction is important since it reduces settlement and hydraulic conductivity, while increasing shear strength and bearing capacity. Moreover, the smaller the quantity of air trapped within landfill waste, the lower the potential for spontaneous combustion. Modern well-designed landfills usually possess a cellular structure, as well

Figure 34.4 Early stages in the construction of a landfill cell in north-east England. The liner and a high permeability drainage layer are being placed
© Paul Nathanail, with permission

Figure 34.5 Cellular structure of landfill near Kansas City, USA

as a lining and a cover, that is, the waste is contained within a series of cells formed of clay (see **Figure 34.5**). However, certain leachates have been troublesome for some clay liners. Those consisting of organic solvents and those containing high levels of dissolved salts can give rise to cracking and the development of pipes in clay. However, clays can be treated with special polymers to reduce their sensitivity to potential contaminants. Uneven settlement of a landfill can cause fractures within the cover, which allow water to percolate into the fill. If conventional compaction techniques are used they do not always achieve effective results, especially with non-uniform waste. An additional complication is the time dependency of waste degradation, resulting in further settlement and the potential for cracking of capping layers.

34.4.2.3 Geotechnical properties

Waste materials in landfills have very variable properties with dry densities varying from 0.16 to 0.35 Mg/m^3 when tipped; after compaction the density may exceed 0.60 Mg/m^3. The moisture content ranges from 10% to 50%, the average specific gravity of the solids varies from 1.7 to 2.5, and the low bearing capacities are 19 to 34 kPa. Baling or shredding the waste materials before deposition improves their *in situ* properties but at greatly increased cost. Further details of typical engineering properties of landfill are given by Dixon *et al.* (1998).

34.4.2.4 Decomposition

Initially, the decomposition of organic waste is aerobic. Once decomposition starts, the oxygen in the waste is rapidly exhausted and so the waste becomes anaerobic. There are basically two processes for the anaerobic decomposition of organic waste. Initially, complex organic materials are broken down into simpler organic substances, which are typified by various acids and alcohols. Any nitrogen present in the original organic material tends to be converted into ammonium ions that are readily soluble and may give rise to significant quantities of ammonia in the leachate. The reducing environment converts oxidised ions such as those in ferric salts to the ferrous state. Ferrous salts are more soluble and, therefore, iron is leached from the landfill. The sulfate in the landfill may be reduced biochemically to sulfide. Although this may lead to the production of small quantities of hydrogen sulfide, the sulfide tends to remain in the landfill as highly insoluble metal sulfides. In a young landfill the dissolved salt content may exceed 10 000 mg per litre, with relatively high concentrations of sodium, calcium, chloride, sulfate and iron, whereas as the landfill ages the concentration of such inorganic materials usually decreases. Also, suspended particles may be present in the leachate due to the washout of fine material from the landfill.

The second stage of anaerobic decomposition involves the formation of methane. In other words, methanogenic bacteria use the end-products of the first stage of anaerobic decomposition to produce methane and carbon dioxide. Methanogenic bacteria prefer neutral conditions, so that excessive acid formation in the first stage will inhibit their activity.

As a landfill ages, because much of the readily biodegradable material has been broken down, the organic content of the leachate decreases. The acids associated with older landfills are not readily biodegradable. Consequently, the biochemical oxygen demand (BOD) in the leachate changes with time, increasing to a peak as the microbial activity increases. This peak is reached between six months and 2.5 years after tipping.

Methane production can constitute a dangerous hazard because methane is combustible and in certain concentrations in air is explosive (5–15% by volume in air), as well as asphyxiating. In many instances, landfill gas is able to disperse safely into the atmosphere from the surface of a landfill. However, when a landfill is completely covered with a soil capping of low permeability to limit leachate generation, the potential for the

gas to migrate along unknown pathways increases and there are cases of hazards arising from methane migration. Furthermore, there are unfortunately cases on record of explosions occurring in buildings due to the ignition of accumulated methane derived from landfills near to, or on, which they were built (Williams and Aitkenhead, 1991).

The source of gas should be identified so that remedial action can be taken. Generally, the connection between a source of methane and the location where it is detected can be verified by detecting a component of the gas that is specific to the source or by establishing the existence of a migration pathway from the source to the location where the gas is detected. Identification of the source can involve a drilling programme and analysis of the gas recovered. For instance, in a case referred to by Raybould and Anderson (1987), distinction had to be made between household gas and gas from sewers, old coal mines and a landfill before remedial action could be taken to eliminate the gas hazard affecting several houses. Proper closure of a landfill site can require gas management by passive venting, power operated venting or the use of an impermeable barrier. Measures to prevent migration of the gas include impermeable barriers (clay, bentonite, geomembranes or cement) and gas venting. Venting either wastes the gas into the atmosphere or facilitates its collection for utilisation. Where atmospheric venting is insufficient to control the discharge of gas, an active or forced venting system is used. Further details on the investigation of gas hazard in landfills and of remedial measures are given by Wilson *et al.* (2007) and references therein.

Other hazardous situations can occur due to microbial activity in a landfill, which generates heat. Hence, the temperature in a landfill rises during biodegradation to between 24 °C and 45 °C, although temperatures of up to 70 °C have been recorded. In some cases landfills have caught fire, increasing the risk still further, though the risk is relatively low; Roche (1996) reported fire problems in around 1 in 600 landfill sites in England and Wales compared with surface water pollution, groundwater pollution and gas migration, each affecting about 1 in 60 sites. A fire at the Lean Quarry landfill site near Liskeard in southeast Cornwall in June 2010 took over 12 hours to extinguish. A fire in January 2011 at the Kerdiffstown landfill near Naas in Ireland burned for several weeks.

34.4.2.5 Settlement

McDougall *et al*. (2004) noted that settlements associated with landfills are likely to be large and irregular. According to Sowers (1973) the mechanisms responsible for the settlement of waste disposal fills include mechanical distortion, bending, crushing and reorientation of materials, which cause a reduction in the void ratio; ravelling (that is, the transfer of fines into the voids); physicochemical and biochemical changes such as corrosion, combustion and fermentation; and the interactions of these various mechanisms. The initial mechanical settlement of waste disposal fills is rapid and is due to a reduction in the initial void ratio. It takes place with no build-up of pore water pressure. This primary compression takes place within a few days of further material being placed on top (Powrie *et al.*, 1998). Settlement continues due to a combination of secondary compression (that is, material disturbance) and physicochemical and biochemical action, and Sowers showed that the settlement log-time relationship is more or less linear. The rate of settlement produced by ravelling and combustion is erratic. Hence, the ultimate settlement is related to the initial void ratio and the environmental conditions favourable to deterioration, decay, ravelling and combustion.

The prediction of the settlement at a landfill site is a vital element for effective design, particularly in relation to post-closure settlement during site redevelopment. However, a determination of the amount and rate of settlement of a landfill is not a simple task. Secondary settlement of between 15% and 50% of the original fill thickness has been suggested (Powrie *et al.*, 1998) while Ling *et al.* (1998) gave figures of 30–40% for overall settlement. The heterogeneous nature of the materials involved, the fact that different materials may have been disposed of in different places and at different times, means that traditional soil mechanics for settlement prediction is generally unsatisfactory. Not only would settlement, especially large differential settlement, adversely affect any future construction on such a site but it may damage the cover system or lining, for example, geomembrane linings may be torn. Accordingly, Ling *et al.* (1998) reviewed the various empirical methods of estimating the settlement of landfills and then proposed a further method for evaluating the amount and rate of settlement. Watts and Charles (1999) also discussed the settlement characteristics of landfills and suggested various ground improvement techniques that could be used; these are discussed in Chapter 84 G*round improvement*.

34.4.2.6 Stabilisation

The stabilisation of soft landfills can be realised by mixing with soil, fly ash, incinerator residue, lime or cement. When a minimum unconfined compressive strength of 24 kPa occurs due, for example, to irregularities in mixing at the site, a geosynthetic material (for example, a geoweb) should be used to span such areas and should be securely anchored in a trench at the perimeter of the site. A geomembrane should be placed over the geoweb to provide a secondary seal protecting against the infiltration of surface liquids. Clay soil above the geomembrane acts as a seal but it must be as thin as possible so as not to overload the geoweb and geomembrane.

34.4.3 Coarse colliery discard

Spoil heaps associated with coal mines are ugly blemishes on the landscape and have a blighting effect on the environment (see **Figure 34.6**). In the past, these had the potential for catastrophic failure with devastating consequences (for example, the Aberfan failure in October 1966). Spoil heaps consist of coarse discard, that is, run-of-mine material that reflects the various rock types (mudrock, siltstone and sandstone) that are extracted during mining operations. Coarse discard also contains varying

Figure 34.6 (a) Spoil tips (one of which has been 'landscaped') at International Colliery, Blaengarw, Garw Valley, South Wales; (b) Spoil tip at the abandoned Greenside lead mine tip in the Glenridding Valley, Cumbria, England

amounts of coaly material that has not been separated by the preparation process. Obviously, the characteristics of coarse colliery discard differ according to the nature of the spoil. The method of tipping also influences the character of a coarse discard. In addition, some spoil heaps, particularly those with relatively high coal contents, may be burnt, or still be burning, and this affects their mineralogical composition.

34.4.3.1 Composition and properties

In Britain illites and mixed-layer clays are the principal components of unburned spoil in English and Welsh tips (Taylor, 1975). Although kaolinite is a common constituent in Northumberland and Durham, it averages only 10.5% of the discard of other areas. Quartz exceeds the organic carbon or coal content, but the latter is significant in that it acts as the major diluent, that is, the clay mineral content tends to decrease as the carbon content increases. Sulfates, feldspars, calcite and other materials average less than 2%.

The chemical composition of spoil material reflects the mineralogical composition. Free silica may be present in concentrations up to 80% and above, and combined silica in the form of clay minerals may range up to 60%. Concentrations of aluminium oxide may be between a few per cent and 40% or so. Calcium, magnesium, iron, sodium, potassium and titanium oxides may be present in concentrations of a few per cent. Lower amounts of manganese and phosphorus also may be present, with copper, nickel, lead and zinc in trace amounts. The sulfur content of fresh spoils is often less than 1% and occurs as organic sulfur in coal, and in pyrite. Pyrite is an unstable mineral, breaking down quickly under the influence of weathering (see also Chapter 36 *Mudrocks, clays and pyrite*). The primary oxidation products of pyrite are ferrous and ferric sulfates and sulfuric acid. A chemical attack by sulfate on concrete can lead to its deterioration. The oxidation of pyrite within spoil heap waste is governed by the access of air, which, in turn, depends upon the particle-size distribution, water saturation, and the degree of compaction. However, any highly acidic oxidation products, which may form, will be neutralised by alkaline materials in the waste material. Charles and Watts (2001) noted that pyrite in some shales has led to expansion through slow oxidation.

The moisture content of spoil increases with increasing content of fines. It also is influenced by the permeability of the material, the topography and climatic conditions. Generally, it falls within the range 5% to 15% (**Table 34.3**).

The range of specific gravity values depends on the relative proportions of coal, shale, mudstone and sandstone in the waste and tends to vary between 1.7 and 2.7. The proportion of coal is of particular importance: the higher the coal content, the lower the specific gravity. The bulk density of the material in spoil heaps shows a wide variation, with most material falling within the range 1.5 to 2.5 Mg/m^3. Low densities are mainly a function of low specific gravity. The bulk density tends to increase with increasing clay content.

The argillaceous content influences the grading of the spoil, although most spoil material is essentially granular (**Table 34.3**). In fact, as far as the particle-size distribution of a coarse discard is concerned there is a wide variation; often most material may fall within the sand range but significant proportions in the gravel and cobble ranges may also be present. Indeed, at placement a coarse discard very often consists mainly of gravel to cobble-sized particles but subsequent breakdown on weathering reduces the particle size. Once buried within a spoil heap, particles of a coarse discard undergo little further reduction in size. Hence, older and surface samples of spoil contain a higher proportion of fines than those obtained from depth.

The liquid and plastic limits can provide a rough guide to the engineering characteristics of a soil. However, for a coarse discard they are only representative of that fraction passing the 425-μm-BS sieve, which frequently is less than 40% of the sample concerned. Nevertheless, the results of consistency tests indicate a low to medium plasticity, whilst in certain

instances spoil has proved to be virtually non-plastic (**Figure 34.7**). Plasticity increases with increasing clay content.

34.4.3.2 Weathering

The most significant change in the character of a coarse colliery discard due to weathering is the reduction of particle size. The extent to which breakdown occurs depends upon the type of parent material involved and the effects of air, water and handling between mining and placing on the spoil heap. After a few months of weathering the debris from sandstones and siltstones usually consists of larger than cobble-sized particles. After that, the degradation to component grains takes place at a slow rate. However, mudstones, shales and seatearth exhibit rapid disintegration to gravel-sized particles. Although a coarse discard may reach its final level of degradation within a matter of months, with the degradation of many mudstones and shales taking place within days, once it is buried within a spoil heap it suffers little change. When spoil material is burnt, it becomes much more stable with respect to weathering.

Taylor and Smith (1986) stated that mudrock breakdown resulted from either mechanical (air breakage) or physicochemical mechanisms. Seedsman (1993) divided physicochemical swelling into crystalline and osmotic swelling. The former involves an increase in the volume of the clay mineral by adsorption of water at its surface. The latter involves the addition of water into the interlayer space of the clay mineral in response to chemical conditions and a consequent increase in volume. Taylor (1988) maintained that the disintegration of British Coal Measures mudrocks (which form a significant part of colliery waste) takes place as a consequence of air breakage after a sufficient number of cycles of wetting and drying.

In other words, if mudrocks undergo desiccation, then air is drawn into the outer pores and capillaries as high suction pressure develops. Then, on saturation, the entrapped air is pressurised as water is drawn into the rock by capillarity. Such slaking, therefore, causes the fabric of the rock to be stressed. The size of the pores is more important than the volume of the pores, for the development of capillary pressure. Capillary pressure is proportional to surface tension. Previously, however, Badger *et al.* (1956) had contended that air breakage occurred only in Coal Measures shales that were mechanically weak, whilst the presence of dispersed colloidal material appeared to be a general cause of disintegration. They also found that the variation in the disintegration of different shales in water was usually not connected with the total amount of clay colloid or the variation in the types of clay mineral present. Rather, it was controlled by the type of exchangeable cations attached to the clay particles and the accessibility of the latter to attack by water, which, in turn, depended on the porosity of the shale. Air breakage could assist this process by presenting new surfaces of shale to water. Subsequently, Dick and Shakoor (1992) maintained that the influence of clay minerals on slaking diminishes in those mudrocks that contain less than 50% of clay-sized particles and that micro-fractures are the dominant lithological characteristic controlling durability. In such cases, slaking is initiated along micro-fractures. Moon and Beattie (1995), in a study of Coal Measures mudrocks from Waikato, New Zealand, found that the proportion of clay mineral present in the mudrock had the greatest influence on durability. Further details of mudrocks are given in Chapter 36 *Mudrocks, clays and pyrite*.

Intra-particle swelling was considered by Taylor and Spears (1970) to have a major effect on the durability of mudrocks from Coal Measures in Britain that contained significant amounts of expandable mixed-layer clay minerals. Moreover, they suggested that those mudrocks that exhibited the greater breakdown were found to contain a higher exchangeable Na ion content in the mixed-layer clay. In fact, the presence of expandable mixed-layer clay is thought to be one of the factors promoting the breakdown of argillaceous rocks, particularly if Na^+ is a prominent interlayer cation. Present evidence nevertheless suggests that in England, colliery spoils with high exchangeable Na^+ levels are uncommon. Sodium may be replaced by Ca^{2+} and Mg^{2+} cations originating from sulfates and carbonates in the waste but dilution by more inert rock types is possibly the most usual reason for the generally low levels of sodium. Moreover, after going through the preparation process and after exposure as a new surface layer of a spoil heap prior to burial, the disintegration of the mudrock and shale material will have been largely achieved. However, it appears that the low shear strength of certain fine-grained English spoils is associated with comparatively high exchangeable Na^+ levels.

34.4.3.3 Spontaneous combustion

Spontaneous combustion of carbonaceous material, frequently aggravated by the oxidation of pyrite, is the most common cause of burning spoil. It can be regarded as an atmospheric oxidation (exothermic) process in which self-heating occurs. Coal and carbonaceous materials may be oxidised in the presence of air at ordinary temperatures, below their ignition point. Generally, lower rank coals (that is, coals with a lower carbon content) are more reactive and accordingly more susceptible to self-heating than coals of higher rank. Spoil heaps that have been subject to spontaneous combustion are made up of a mixture of burnt, partially burnt and unburned material. Therefore, the characteristics of the spoil are more variable.

The oxidation of pyrite at ambient temperature in moist air leads to the formation of ferric and ferrous sulfate, and sulfuric acid (see Chapter 37 *Sulfate acid soils*). This reaction also is exothermic. When present in sufficient amounts, and especially when finely divided, pyrite associated with 'coaly' material increases the likelihood of spontaneous combustion (Michalski *et al.*, 1990). When heated, the oxidation of pyrite and organic sulfur in the coal generates sulfur dioxide. If there is not enough air for complete oxidation, then hydrogen sulfide is formed, which is a highly toxic gas.

The moisture content and grading of spoil are also important factors in spontaneous combustion. At relatively low temperatures an increase in free moisture increases the rate of spontaneous heating. Oxidation generally takes place very slowly at ambient temperatures but as the temperature rises, oxidation increases rapidly. In material of large size the movement of air can cause heat to be dissipated whilst in fine material the air remains stagnant, which means that burning ceases when the oxygen is consumed. Accordingly, ideal conditions for spontaneous combustion exist when the grading is intermediate between these two extremes and hot spots may develop under such conditions. These hot spots may have temperatures around 600 °C or occasionally up to 900 °C (Bell, 1996). Furthermore, the rate of oxidation generally increases as the specific surface of the particles increases.

Spontaneous combustion may give rise to subsurface cavities in spoil heaps, the roofs of which may be incapable of supporting a person. Burnt ashes may also cover zones that are red hot to appreciable depths. Thomson (1973) recommended that during restoration of a spoil heap, a probe or crane with a drop-weight could be used to prove areas of doubtful safety that are burning or underlain by cavities. Badly fissured areas should be avoided and workers should wear lifelines if they walk over areas not proved safe. Any area that is suspected of having cavities should be excavated by a dragline or drag scraper rather than allowing plant to move over suspect ground. An example of an exposed cavity in an Indian spoil tip is shown in **Figure 34.8**.

When steam comes in contact with red-hot carbonaceous material, water gas (carbon monoxide and hydrogen) is formed, and when the latter is mixed with air, over a wide range of concentrations, it is potentially explosive. If a cloud of coal dust forms near burning spoil when reworking a heap, then it can ignite and explode. Damping with a spray may prove useful in the latter case.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Noxious gases are emitted from burning spoil. These include carbon monoxide, carbon dioxide, sulfur dioxide and, less frequently, hydrogen sulfide. Each may be dangerous if inhaled at sufficiently high concentrations, which may be present at fires on spoil heaps (**Table 34.4**). The rate of production of these gases may be accelerated by disturbing burning spoil through excavating or reshaping. Carbon monoxide is the most dangerous gas since it cannot be detected by taste, smell or irritation and may be present in potentially lethal concentrations. By contrast, sulfur gases are readily detectable and are usually not present in high concentrations. Even so, when diluted they may still cause distress to someone with a respiratory ailment. Nonetheless, sulfur gases are mainly a nuisance rather than a threat to life. In certain situations a gas monitoring programme may be required. Where danger areas are identified, personnel should wear breathing apparatus.

Burning spoil material may represent a notable problem when reclaiming old tips (**Figure 34.9**). Spontaneous combustion of coal in colliery spoil can be averted if the coal occurs in an oxygen-deficient atmosphere that is humid enough with excess moisture to dissipate any heating that develops. Cook (1990), for example, described shrouding a burning spoil heap with a cover of compacted discard to smother the existing burning material and prevent further spontaneous combustion. Thomson (1973) also recommended blanketing and compaction, as well as digging out, trenching, injection with non-combustible material and water, and water spraying as methods

Gas	Concentration by volume in air (parts per million)	Effect
Carbon monoxide	100	Threshold Limit Value (TLV) under which it is believed nearly all workers may be repeatedly exposed day after day without adverse effect
	200	Headache after about 7 hours if resting or after 2 hours if working
	400	Headache and discomfort, with possibility of collapse, after 2 hours at rest or 45 minutes exertion
	1 200	Palpitation after 30 minutes at rest or 10 minutes exertion
	2 000	Unconsciousness after 30 minutes at rest or 10 minutes exertion
Carbon dioxide	5 000	TLV. Lung ventilation slightly increased
	50 000	Breathing is laboured
	90 000	Depression of breathing commences
Hydrogen sulfide	10	TLV
	100	Irritation to eyes and throat: headache
	200	Maximum concentration tolerable for 1 hour
	1 000	Immediate unconsciousness
Sulfur dioxide	1–5	Can be detected by taste at the lower level and by smell at the upper level
	5	TLV. Onset of irritation to the nose and throat
	20	Irritation to the eyes
	400	Immediately dangerous to life

Notes
1. Some gases have a synergistic effect, that is, they augment the effects of others and cause a lowering of the concentration at which the symptoms shown in the above table occur. Further, a gas which is not, itself, toxic may increase the toxicity of a toxic gas, for example, by increasing the rate of respiration; strenuous work will have a similar effect.
2. Of the gases listed, carbon monoxide is the only one likely to prove a danger to life, as it is the commonest. The others become intolerably unpleasant at concentrations far below the danger level.

by which spontaneous combustion in spoil material may be controlled. Bell (1996) described the injection of a curtain wall of pulverised fuel ash, extending to the original ground level, as a means of dealing with hot spots.

34.4.3.4 Restoration

The configuration of a spoil heap depends upon the type of equipment used in its construction and the sequence of tipping the waste. The shape, aspect and height of a spoil heap affect the intensity of exposure, the amount of surface erosion that occurs, the moisture content in its surface layers and its stability. Although the mineralogical composition of coarse discards from different mines varies, pyrite frequently occurs in shales and coaly material is present in spoil heaps. When pyrite weathers it promotes acidic conditions in the weathered material. Such conditions do not aid the growth of vegetation. Indeed, some spoils may contain elements that are toxic to plant life. Furthermore, the uppermost slopes of a spoil heap are frequently devoid of near-surface moisture. To support vegetation a spoil heap should have a stable surface in which roots can become established, must be non-toxic and contain an adequate and available supply of nutrients. Hence, spoil heaps are often barren of vegetation.

The restoration of a spoil heap will require large-scale earthmoving. The restored land may be used for agriculture, for public amenities such as golf courses, or for buildings. Since restoration invariably involves spreading the waste over a larger area, this may mean that additional land beyond the site boundary has to be purchased. Where a spoil heap is very close to a disused colliery, spoil may be spread over the latter area. This involves the burial or removal of derelict colliery buildings and sometimes old mine shafts or shallow old workings may have to be treated (Johnson and James, 1990). Watercourses may have to be diverted, as may services, notably roads.

The landscaping of spoil heaps is frequently carried out to allow them to be used for agriculture or forestry. This type of restoration is generally less critical than when structures are to be erected on the site, since bearing capacities are not as important and steeper surface gradients are acceptable. Most spoil heaps offer no special handling problems other than the cost of regrading and possibly the provision of adjacent land, so that the gradients on the existing site can be reduced by the transfer of spoil to the adjacent land. However, as noted, some spoil heaps present problems due to spontaneous combustion.

The surface treatments of spoil heaps vary according to the chemical and physical nature of the spoil, and the climatic conditions. The preparation of the surface of a spoil heap also depends upon the use to which it is to be put subsequently. Where it is intended to sow grass or plant trees, the surface layer should not be compacted. Drainage plays an important part in the restoration of a spoil heap and during landscaping there should be erosion control. If the spoil is acidic, then it can be neutralised by liming. The chemical composition influences the choice of fertiliser used and, in some instances, spoil can be seeded without the addition of top soil, if suitably fertilised. More commonly top soil is added prior to seeding or planting.

34.4.3.5 Acid mine drainage

Acid mine drainage (AMD) or acid rock drainage (ARD) may be associated with a coarse colliery discard since the coaly material and mudrock are likely to contain sulfide minerals, notably pyrite (Geldenhuis and Bell, 1998). Such drainage results from the natural oxidation of sulfide minerals in the waste when it is exposed to air and water. It is a consequence of the oxidation of sulfur in the mineral to a higher state of oxidation and, if aqueous iron is present and unstable, the precipitation of ferric iron with hydroxide occurs. Acid mine drainage can also be associated with opencast workings as well as underground workings, tailings ponds or mineral stockpiles (Brodie *et al.*, 1989). If acid mine drainage is not controlled it can pose a threat to the environment since acid generation can lead to elevated levels of heavy metals and sulfate in surface water or groundwater, which will obviously have a detrimental effect on water quality (see Coal Authority website: http://coal.decc.gov.uk/en/coal/cms/environment/about_m_water/about_m_water.aspx). Acid generation tends to occur in the surface layers of spoil heaps where air and water come into contact with sulfide minerals. Methods for remediating AMD have been reviewed by Johnson and Hallberg (2005). Broadly, there are three main types. Active

methods require the pumping of the mine water and treatment with chemical reagents such as hydrogen peroxide or caustic soda. Passive methods use natural systems such as reed beds to improve water quality and do not use pumping; the water from the mine is allowed to flow under gravity. Hybrid active and passive schemes may utilise pumping and some chemical treatment at the start of the process before water flows into reed bed systems (Coal Authority website: http://coal.decc.gov.uk/en/coal/cms/environment/treat_types/treat_types.aspx). Around 50 abandoned coal mines have been treated in Britain, mostly using passive systems. For the Wheal Jane tin mine in Cornwall, Whitehead and Prior (2005) described a passive treatment system developed as part of a research project. Three separate systems were installed, each with aerobic reed beds, anaerobic cells and rock filters. The three systems differed in the method used to raise the pH of the mine water entering them. The Coal Authority website (see above) briefly describes the treatment approaches used at a number of former coal mining sites.

34.4.4 Other types of fill

34.4.4.1 Pulverised fuel ash (PFA)

Pulverised fuel ash (PFA) is waste that is produced by coal-fired power stations and is defined as the solid material extracted by electrostatic or mechanical means from the furnace flue gases (Winter and Clarke, 2002). Charles and Watts (2001) pointed out that most of the PFA is metal oxides along with some trace constituents and pozzolanic materials. About 80% of the ash from a coal-fired power station is PFA and the remaining 20% is furnace bottom ash. After extraction, the PFA is referred to as fresh PFA and can be conditioned with an optimum amount of water to produce conditioned ash. Conditioning PFA allows it to be transported more easily and reduces the problem of dust. When PFA is stored as conditioned ash it is called stockpiled ash.

When PFA is disposed of as waste, it is usually mixed with water so that it can be transported as slurry to a lagoon, for example. It can be disposed of in this manner in old clay pits. This ash can be subsequently retrieved as stockpiled ash. The water in the lagoon can be decanted when the ash has settled out of the slurry. Developments on PFA lagoons are rare but some are mentioned by Charles and Watts (2001). One is the Metro Centre at Gateshead and another is housing in Peterborough. They also referred to an oil tank being constructed on a 5 m thickness of lagoon PFA in Denmark.

According to Yang *et al.* (1993), the properties of fresh pulverised fuel ash are governed by the type and chemical composition of the coal used, the source of the coal, the degree of pulverisation, the efficiency of combustion, the variation in firing conditions and the extraction process. Consequently, the character of PFA does vary. In fact, it is not only variable between sources but also on a day-to-day basis from a single source. Nonetheless, the particles of PFA are primarily of coarse silt to fine-sand size and are more or less spherical in shape. Their specific gravity ranges from around 1.90 to 2.72, depending on their source and they are non-plastic. Ash may exhibit 'cohesive' properties although Yang *et al.* (1993) noted that such properties might be attributable to the suction forces that develop during compaction of the ash. Hence, they may dissipate with time or when inundated, so leading to loss of strength. Some ashes are self-hardening because of the presence of cementitious material such as free lime or calcium sulfate compounds. In addition to Yang *et al.* (1993), reviews of the engineering properties of PFA can be found in Sutherland *et al.* (1968), Gray and Kin (1972) and Leonards and Bailey (1982). PFA has a number of other civil engineering applications, for example as a cement replacement or additive.

Most PFA is used for land-reclamation projects or for general and structural fills (for example, embankments, foundation fills or fills behind retaining walls). Pulverised fuel ash has frequently been used for the construction of road embankments. For instance, Ekins *et al.* (1993) mentioned the use of lightweight PFA in the construction of the Western Approach Road, Southampton. Pulverised fuel ash is also used as fill behind the abutments of road bridges. The use of PFA as a structural fill for the foundations of a precipitator at a power generating station in Indianapolis, Indiana, was described by Leonards and Bailey (1982). In addition, a notable quantity of PFA is used in the manufacture of cement as some types of PFA are pozzolanic. The pozzolanic activity is attributable to the reaction of the fine glass (mullite) particles with free lime in the presence of water.

Conditioned PFA can be used as high-quality selected fill, either as fill to structures and reinforced earth or for stabilisation with cement to form capping. Enough water must be added to the PFA so that it is suitable for compaction. Winter and Clarke (2002) indicated that the optimum moisture content of conditioned ash is around 25% but that it may be as high as 35% or more. They further noted that the optimum moisture content of some conditioned ash from Scotland may be as low as 18% whereas that of lagoon ash may be as high as 28%. They quoted maximum dry densities varying from 1.0 to 1.65 Mg/m^3.

34.4.4.2 Industrial waste

There are many types of industrial waste, such as chemical wastes and wastes from ore smelting. Not only may industrial fills be very heterogeneous and poorly compacted but they may be chemically problematic in that the ground may be aggressive. Industrial wastes can take a number of forms such as smelter slag, various types of residues and sludge. Furthermore, industrial wastes are commonly associated with derelict sites. Such sites represent a wasted resource and are normally located within urban areas so that their rehabilitation is highly desirable. Mabey (1991) reviewed the position of derelict land in Britain, noting that in 1988 there were some 40 500 ha of derelict land. Of the land attributable to industrial dereliction, 94% was considered to need remediation. More recently, there has been great emphasis on the reclamation of derelict land but national statistics seem

to show that there may be nearly 80 000 ha in this condition in Britain. According to the National Land Use Database, the amount of derelict land in England has remained fairly constant in recent years falling from about 66 000 ha in 2002 to nearly 62 000 ha in 2009. In Scotland, there were just over 8 000 ha of derelict land in 2010 (Anon., 2011).

Unfortunately, many industrial wastes have been contaminated to a greater or lesser extent (Bell *et al.*, 2000). Contaminated land may also emit gases or may be a fire hazard. Details of such hazards should be determined during a site investigation (British Standards Institution, 2011). Site hazards result in constraints on the freedom of action, necessitate stringent safety requirements, may involve time-consuming and costly working procedures, and affect the type of development. For instance, Leach and Goodyear (1991) noted that constraints might mean that the development plan has to be changed so that the more sensitive land uses are located in areas of reduced hazard. Alternatively, where notable hazards exist, then a change to a less sensitive end use may be advisable. There are a number of general references that provide further information on how to deal with and remediate hazards from contaminated land; for example, Nathanail and Bardos (2004) and Bardos *et al.* (2007). Bunce and Braithwaite (2001) described the remediation of an 80 ha site at Pride Park, Derby. The land had been used for gravel extraction, waste disposal, railway works and a gas and coke plant. The site was heavily contaminated and for the worst areas a bentonite containment wall was constructed to prevent contaminant migration. Water collecting within the wall was pumped out using 18 abstraction wells, treated and finally discharged into the River Derwent. About 75% of the site was usable as a result of the remedial work.

Some industrial wastes, notably those that are non-contaminated, can be used as bulk fill for land-reclamation schemes. Indeed, derelict sites often require varying amounts of filling, levelling and regrading. Fill should be obtained, if possible, from the site. Furthermore, some industrial wastes can be used as raw materials; for example, blast furnace slag can be used for road aggregate.

34.4.4.3 Building waste

Building waste is associated with demolition work and mainly includes concrete and brick rubble. In addition, timber, steel reinforcement, glass, plaster, stone, slate and tiles are likely to be included in building waste to a greater or lesser extent so that it is essentially heterogeneous in composition. Some of these materials are unsuitable for use as fill. For example, Reid and Buchanan (1987) mentioned that the derelict Queen's Dock in Glasgow had been filled with 1.3 million m^3 of demolition rubble from old buildings in the vicinity, degradable material such as timber having been removed. Similarly, Hartley (1991) referred to the use of old foundation material that was crushed and used as fill at a site in Middlesbrough. Building wastes are usually poorly compacted and may contain gypsum products. The latter could be a source of sulfate, which could attack concrete. Again building wastes like industrial waste may be contaminated and, therefore, appropriate assessment will be needed (see discussion above). However, it is increasingly the case that building waste following demolition is separated, crushed and graded (where appropriate) and recycled.

34.5 Conclusions

The reclamation of derelict land is an important aspect of government policy. More recently there has been an emphasis on siting new building developments on brownfield rather than greenfield sites and many of these brownfield sites are covered in substantial depths of fill. Thus, the subject of building on fill has acquired considerable prominence in recent years. The geotechnical problems in achieving safe and economic developments on filled ground are substantial.

Therefore, it is important to understand both the distribution of different types of fill and their likely behaviour. It has been shown that the engineering behaviour of a fill is strongly influenced by its composition, method of deposition and subsequent stress history. These factors control the key aspects in successfully reusing areas underlain by non-engineered fill. It is important, therefore, to assess the variability of a fill (in terms of composition and physical, mechanical and chemical properties), and to assess how the behaviour of a fill may change over time. In particular, a fill may be subject to significant volume change on loading. This can be caused by a number of factors including the original loading as the fill was deposited (often over wide areas), changes in water content influenced by variable permeability, swelling and shrinkage of clay fills, collapse compression, biodegradation and chemical reactions.

Past (largely) industrial land use indicates the likely nature of non-engineered fills encountered. The principal types of fill include filled opencast sites (widely distributed in coalfield areas), domestic waste and sanitary landfill (widely distributed in former quarries and other excavations in urban, peri-urban and rural areas), colliery discard (found close to former coal mines), pulverised fuel ash (both as a waste and used for land reclamation), industrial wastes (which can be both physically and chemically variable) and building wastes (often found in central urban areas).

Chapter 54 *Single piles* describes the requirements for building on fills in further detail, with reference to the investigation and prediction of behaviour.

Extensive deposits of peat and organic soils can be found in Great Britain, Ireland and worldwide. Their engineering behaviour depends on their morphology, which must be reflected in the description and classification of soil and in turn must be included in the interpretation of geotechnical parameters. Water content is the most important index test and can be used to estimate engineering properties of virgin peat. Other indices are loss-on-ignition and the degree of decomposition scale. Secondary compression dominates when estimating settlements of peat; generally this occurs during the primary consolidation (hydrodynamic) phase and after dissipation of excess pore pressure. Sophisticated soil models reflect this continuous secondary compression, although these are not readily used for routine design. Surcharging of peat is effective in reducing long-term creep movements under embankments. Permeability of peat decreases with compression and affects consolidation behaviour.

Determining effective stress parameters of fibrous peats depends on the type of test and the orientation of the sample. Fibres affect *in situ* test methods to determine undrained shear strength, particularly the *in situ* vane which gives s_u values that depend on the size of the vane used. Laboratory tests also recorded relatively high s_u/σ_v ratios.

Design issues include design and construction approaches for roads, structures, slopes, canals and dykes founded in or with peats and organic soils.

35.1 Introduction

Peats and organic soils would generally be considered 'problematic' in a geotechnical context because of their high compressibility, creep behaviour, low bulk density and generally low undrained shear strength. The high compressibility and creep behaviour have given rise to large settlements under structures and to undulating roads that become a hazard to traffic. Regionally, for example, changes in the hydrogeological regime have resulted in settlements of several metres and large bogslides have wiped out villages in Ireland with many fatalities. Historically, dykes and canals have been constructed on or with peat, which leaves a legacy of high-risk structures within our society. The engineering behaviour of peat and organic soils is therefore an important aspect of geotechnical engineering, both in the design of structures on peat and organic soils and in the assessment of existing structures on these soils.

The percentage of land covered by peat is about 33.5% in Finland, 18% in Canada, about 17% in the Republic of Ireland and Sweden, 13.7% in Indonesia, 12.4% in Northern Ireland, 10.4% in Scotland and 6.3% across the United Kingdom as a whole (Hobbs, 1986). Large tracts of peatlands are also to be found in Russia and the USA. A variety of terms in the English language are used to describe the areas within which peats and organic soils are formed, such as swamp, boglands, moor, fen and muskeg. However, 'mire' is the internationally accepted term to cover all of these ecosystems (Gore, 1983). This chapter mainly discusses the particular properties of peats; however, there is obviously a transition in the behaviour from highly organic soils, which would have many similar properties to peats, to soils with low organic content, which would have similar behaviour to mineral soils.

35.2 Nature of peats and organic soils

Peat and organic soils include a wide range of soils with different morphologies and characteristics that impact on their engineering behaviour. The organic content can come from plants or animals, but most of this chapter will relate to the organics from plant debris. Peat itself is formed from the accumulation of the remains of dead vegetation in various stages of decomposition, and this accumulation can build up where there is a reservoir of water to promote growth and to preserve the remains. However, there are a variety of conditions where this can occur. For example, raised bogs obtain their nutrients from rainwater, which results in a particular type of vegetation growth, and are made up almost entirely of organic material, whereas other bogs are fed from surface and groundwater flow that inevitably includes some inorganic particles, which are generally referred to as mineral particles in this context.

The remains of plants that make up peats and organic soils have an open cellular structure which gives rise to their high compressibility and high moisture contents. The open structure of a peat fibre can be appreciated from the electron microscope image of a typical stem shown in **Figure 35.1**. The cell structure can thus deform when transferring inter-particle forces. Water is held in three forms: (i) free water in large cavities; (ii) capillary water in the narrower cavities; (iii) water bound physically, colloidally and osmotically (MacFarland and Radforth, 1964). There is also the reinforcing effect of the fibres, which can significantly affect the ability of peats to resist load. These

Figure 35.1 Electron microscope image of Balltdermot peat

differences from clays and sands should, in theory, make many of the traditional methods of analysis inapplicable. However, many of the correlations between various properties and behavioural parameters are little different from those of clay soils except in regard to its strength (Hobbs, 1986).

The decomposition of the plant remains can have a significant effect on the characteristics of a peat, and this is normally termed the degree of humification in geotechnical engineering. Plant remains are broken down by soil microflora, bacteria and by fungi and in non-acidic soils earthworms can contribute to the breakdown (Hobbs, 1986). The initial process is aerobic where the plant matter is broken down to give off gas and water. Immersion in water dramatically reduces the availability of oxygen, thus reducing not only the aerobic microflora but encouraging the anaerobic species with different and less rapid metabolic activity. The partially decayed vegetation matter can thus accumulate as peat. The upper active layer with undecayed fibrous plants is called the acrotelm (generally100–600 mm thick), with the lower layer being called the catotelm. Initially the decomposition of the cellulose structure affects the plant leaves but this process can develop to the stems and roots of the plants, and eventually to completed decomposition into an amorphous-granular material consisting of mainly gelatinous organic acids, which have a sponge-like structure (Landva and Pheeney, 1980). However, the complete breakdown of the plant remains is rare in the UK and Ireland. The rate of decay generally increases with an increase in temperature and with pH. This process of plant degradation is not uniform and therefore can exacerbate the natural non-uniformity of peatlands. The nature of peat can also be affected by historic fires, anthropogenic effects, previous landslides and other external factors.

Mires can be broadly separated into fen and bog, with bog being sub-divided into raised bog (over fen bog) and blanket bog. Raised bogs are formed over what was originally a fen bog and include a transitional stage, which must be considered when making an engineering assessment. The separation between fen and bogs lies in the origin and chemistry of their water supplies. Moore and Bellamy (1974) and Hobbs (1986) illustrate the different formation environments in which mires are formed.

Fens are predominantly fed by groundwater or flowing water sources, and generally are neutral to alkaline, although there are also acidic fens. The alkaline environment increases the rate of decay and hence can result in a greater degree of humification than in raised bogs. Fens form in a variety of wetlands, from water-filled depressions to river banks and lake shores, and can support a variety of vegetation growth, depending on their water sources and genesis. Floating bogs can form by vegetation growth from the side of a lake, leaving clear water between the base of the peat and the lake bottom.

Bogs are formed in ombrotropic (rain-fed) conditions and are acidic. Raised bogs start off by organic growth on or from the banks of lakes, i.e. fen peat, which expands to encompass the lake, at which stage the landscape would commonly be referred to as a fen (Hobbs, 1986). These fen peats would frequently be formed over the original very soft lake-bed deposits, where these exist, which can be the critical feature in the selection of appropriate design/construction options on these deposits. Where the conditions are appropriate, there is a transitional stage where the upward growth is such that the plants come to rely more on rainfall for nutrients rather than on the natural groundwater and eventually a mounded mass of organic material is formed, which obtains its entire nutrient from rainwater; at this stage it is called a raised bog. Sphagnum moss and cotton grass tussocks are common forms of vegetation.

Blanket bogs are a form of raised bog with rainwater as the principal source of nutrients but which form directly on the original soil rather than on a lake. They typically form on the side of mountains in the colder and temperate regions of the Earth where there is an excess of precipitation over evaporation. Given that these are generally on sloping ground, the nature of the original ground on which they are formed and the hydrogeological conditions can be important considerations when assessing the slope stability of the mass, together with the characteristics of the peat itself. Features of some of these blanket bogs are the presence of subterranean pipes or channels which have developed over time and also, in some locations, the presence of a hardpan layer in mineral soils close to the base of the peat, which was formed by the accumulation of leached minerals from the peat. Donnelly (2008) documents the presence of soil pipes of up to 1.5 m in diameter on parts of the Pennine moors and of pseudo-sinkholes caused by their collapse.

Layers of marl can be associated with peat deposits in calcareous regions. These layers form due to photo-reduction of dissolved carbon dioxide by submerged green plants.

Peats have also been deposited in estuarine and coastal environments and are sometimes buried under mineral soils

due to change in the depositional conditions. For example, Kidson and Heyworth (1976) have shown that large areas of Somerset, known as the Levels, are underlain by considerable thickness of Quaternary sands, gravels, clays and peats which were formed within the contemporary tidal-range, the sedimentation being influenced by rise in sea level over the last 9000 years.

35.3 Characterisation of peats and organic soils

35.3.1 Classification systems

There are a number of classification systems for peat deposits in existence, most of which have a botanical basis suitable for agriculture and ecology but these are generally too elaborate for engineering applications. An example of a comprehensive classification system is given in Clymo (1983). Engineering classification systems have been proposed by von Post (1922), Radforth (1969) in Canada, Landva *et al*. (1983), Hobbs (1986, 1987), and by others. The von Post system, which was developed for horticultural, agricultural and forestry use, includes a simple 'squeeze' test as a means of assessing the degree of decomposition of peats, which has been incorporated into many of the other classification systems, albeit with some modification.

The important characteristics to be identified in any engineering classification system are the type of peat, the structure, the degree of decomposition and the amount of mineral particles present. The *in situ* colour description can be useful; however, a characteristic of organic soils is the rapid change in colour on exposure to air due to oxidation which can make colour descriptions from recovered samples problematical.

The Eurocode system references two standards which cover the identification and classification of soils, namely EN ISO 14688-1:2002 (*Identification and Description*) and EN ISO 14688-2:2004 (*Principles of Classification*). EN ISO 14688-1:2002 defines organic matter as consisting of plant and/or animal organic materials, and the conversion of products of those materials, e.g. humus (see **Table 35.1**). BS 5930:1999 (BSI, 1999) has description categories of fibrous, pseudo-fibrous and amorphous peat. Gygttja is a particular Scandinavian term which is applied to organic bottom deposits in lakes or the sea. The degree of decomposition of a peat in EN ISO 14688–1:2002 is assessed on the basis of a simple squeeze test (see **Table 35.2**), which is a simplification of the von Post system where the degree of decomposition (H_n) is measured on a scale from one to ten, a modification of which has been incorporated into the ASTM standards (see **Table 35.3**). The von Post system is commonly used where a detailed description of peats is required.

Term	Description
Fibrous peat	Fibrous structure, easily recognisable plant structure, retains some strength
Pseudo-fibrous peat	Recognisable plant structure, no strength of apparent plant material
Amorphous peat	No visible plant structure, mushy consistency
Gyttja	Decomposed plant and animal remains; may contain inorganic constituents
Humus	Plant remains, living organisms and their excretions, together with inorganic constituents, form the topsoil

Table 35.1 Identification and description of organic soil
Data taken from EN ISO 14688-1:2002

Term	Decomposition	Remains	Squeeze
Fibrous	None	Clearly recognisable	Only water No solids
Pseudo-fibrous	Moderate	Recognisable	Turbid water <50% solids
Amorphous	Full	Not recognisable	Paste >50% solids

Table 35.2 Degree of decomposition of wet peat as determined by squeezing
Data taken from EN ISO 14688-1:2002

Degree of humification	Nature of material extruded on squeezing	Nature of plant structure in residue
H1	Clear, colourless water; no organic solids squeezed out	Unaltered, fibrous, undecomposed
H2	Yellowish water; no organic solids squeezed out	Almost unaltered, fibrous
H3	Brown, turbid water; no organic solids squeezed out	Easily identifiable
H4	Dark brown, turbid water; no organic solids squeezed out	Visibly altered but identifiable
H5	Turbid water and some organic solids squeezed out	Recognisable but vague, difficult to identify
H6	Turbid water; ½ of sample squeezed out	Indistinct, pasty
H7	Very turbid water, ½ of sample squeezed out	Faintly recognisable; few remains identifiable, mostly amorphous
H8	Thick and pasty; 2/3 of sample squeezed out	Very indistinct
H9	No free water; nearly all of sample squeezed out	No identifiable remains
H10	No free water; all of sample squeezed out	Completely amorphous

Table 35.3 Degree of humification or decomposition, ASTM D5715-00
Based on von Post (1922)

Soil	Organic content (≤2mm)% dry mass
Low organic	2 to 6
Medium organic	6 to 20
High organic	>20

Table 35.4 Classification of soils with organic constituents
Data taken from EN ISO 14688-2:2004

EN ISO 14688-2:2004 (*Principles of Classification*) classifies a soil with more than 20% organics as high-organic soil (see **Table 35.4**); however, there is no particular definition of when an organic soil becomes a peat or when a clayey peat becomes a peaty clay or how the organic content is determined. BS 5930:1999 (BSI, 1999) gives a classification system for soils where the organic content is the secondary constituent but does not classify a peat. ASTM classifies a peat as having less than 25% ash content, which is equivalent to an organic content in excess of 75%.

35.3.2 Index tests

The water content (w) is the most important property when dealing with peat and organic soils, as it is a simple test to which many of the engineering properties can be related. Consequently, w can be used to quantify variations in the peat and organic soil deposits. There is evidence that there may be charring of certain types of peat when the water content is determined at the normal 105–110°C and MacFarlane and Allen (1964) suggest that a temperature of 85°C may be appropriate if combustion of material or oxidation of the peat is to be avoided. However, Hobbs (1986) considers that the normal 105°C is acceptable for engineering purposes and this would be consistent with the findings of O'Kelly (2005) and with general practice.

The organic content is a very useful index test and is normally taken as being equal to the loss-on-ignition (N). This index test quantifies the amount of organics present and also has the very useful relationship between the average specific gravity of the particles (G_{Save}) given as Equation (35.1) (Skempton and Petley, 1970). This equation is based on the specific gravity of the cellulose being about 1.4 and of the mineral particles being about 2.7. This specific gravity can be used to estimate the bulk density using Equation (35.2); however, it should be noted that the degree of saturation S_r can be less than 100% in some peats due to its gas content.

$$\frac{1}{G_{s_{ave}}} = \frac{N}{1.4} + \frac{(1-N)}{2.7} \tag{35.1}$$

$$\rho = \frac{G_{save}\rho_w(1+w)}{1+\frac{wG_{save}}{S_r}} \tag{35.2}$$

The loss-on-ignition (N) is determined on a specimen initially dried at 50°C and fired in a muffle furnace at 440°C ± 40°C as recommended in BS 1377:Pt3:1990 (BSI, 1990). Clay minerals present lose fixed water at temperatures in excess of 450°C causing an error in the ignition loss. The ASTM uses the ash content (D), rather than the organic content, where D = 1 – N, and includes two tests for its determination, one for a firing temperature of 440°C (initially dried at 105°C) until it is completely ashed and the other for 750°C. Some researchers have found that fresh plant roots are not removed at temperatures below 900°C. Hobbs (1987) summarises the correction factors to be applied to the loss-on-ignition value determined at temperatures above 450°C to account for the water loss from minerals. BS 1377:Pt.3:1990 (BSI, 1990) also includes a chemical titration test (Walkley and Black method), which is generally used only for soils with low organic content.

The liquid limit (w_L), which can be a useful indicator to the morphology of the peat and its degree of decomposition, can generally be carried out on peats with a degree of decomposition greater than H_3 on the von Post scale (von Post scale given in **Table 35.3**). The structure of the peat/organic soil generally has to be broken down to a suitable size using a mechanical device, thus not only breaking down the structure but also some of the decomposed material (Hobbs, 1986). Hanrahan *et al.* (1967) found the w_L value to be sensitive to the chemistry of the water, therefore water from its natural source should be used. Bog peats (w_l = 800 to 1500%) typically have higher w_L than fen peats (w_L = 200 to 600%). Hobbs (1986) showed, by observing the decomposition of a cauliflower, that both the liquid limit and the water content decreased with the degree of decomposition, and considered that the water content (natural) was equal to about $1.38w_L$ and $0.875w_L$ for bog and fen peat, respectively. The plastic limit can only be carried out on peats with some clay particles, and consequently is generally of little interest to bog peats. The addition of organic content to a mineral soil can alter its liquid and plastic limit significantly, not only because it introduces an additional material, but also because the organic particles, which are negatively charged, may be strongly adsorbed on the mineral surfaces, with the effect that the properties of both materials are altered (Mitchell and Soga, 2005). It also means that the classification of an organic soil based on organic content alone would not be expected to capture all the significant geotechnical features of a soil.
