if the mean line from the SPT results is transferred onto the undrained strength plot as in **Figure 63.5(c)**, it appears that the normal correlation does not work. In fact, the measured undrained strengths are remarkably high: they are consistent with a very low water content, which was measured, but this might simply mean that the samples had dried out on the way to the laboratory, though there was no reason to suspect this. **Figure 63.5(c)** also shows lines representing mean values through the data from other nearby sites, both for undrained shear strength and SPT results. The usual close correlation applies to these, and it is clear that the undrained strengths for the new site are remarkably high.

On the basis of these inconsistent data sets, what value should be used as the characteristic undrained strength? The values measured in the triaxial tests should not be ignored, but the SPT results and data from adjacent sites should also affect the decision. The characteristic value for these data is shown in **Figure 63.5(d)**. This is less than the initial assessments in **Figure 63.5(a)**, which were based on the triaxial results only, and is closer to a lower bound of this particular set of triaxial results.

Engineers often need to follow this sort of process when trying to interpret real data. It may be that statistical methods could trace a similar logical sequence. However, this would require quite advanced methods and any statistical approach that failed to take account of the diverse array of data, typically available, would be harmful to the design process.

63.3.2.1 Selection of characteristic groundwater parameters

General

A conservative estimate of the active and passive groundwater conditions should be taken when selecting the characteristic levels and groundwater pressure profiles on the active and passive sides of a retaining wall. The designer should check that the following have been considered:

- the proximity of sources of free water and the likelihood of such sources becoming available over the design life of the wall;
- the effects on the local hydrogeology of the site due to the construction of the wall, for example, the potential damming of natural groundwater flows or a long-term rise in aquifer groundwater levels;
- the effects of wall toe levels not reaching the target design levels due, for example, to obstructions or hard driving resistance;
- the effects of drainage or dewatering during construction and during the lifetime of the wall;
- changes to water pressures due to the growth or removal of vegetation;
- changes to water pressures due to long-term climatic variations.

Based on the above considerations, the designer should determine:

1. The water pressure and seepage forces that represent the most unfavourable values that could occur in extreme or accidental circumstances at each stage of the wall's construction sequence and throughout its design life. An example of an extreme or accidental event may be a burst water main in close proximity to the wall.
2. The water pressures and seepage forces that represent the most unfavourable values likely to occur in normal circumstances at each stage of the wall's construction sequence and throughout its design life. Extreme events such as a nearby burst water main may be excluded, unless the designer considers that such an event may reasonably occur in normal circumstances.

The groundwater pressure corresponding to (1) should be compared to the ULS while (2) should be compared to the SLS.

Undrained conditions

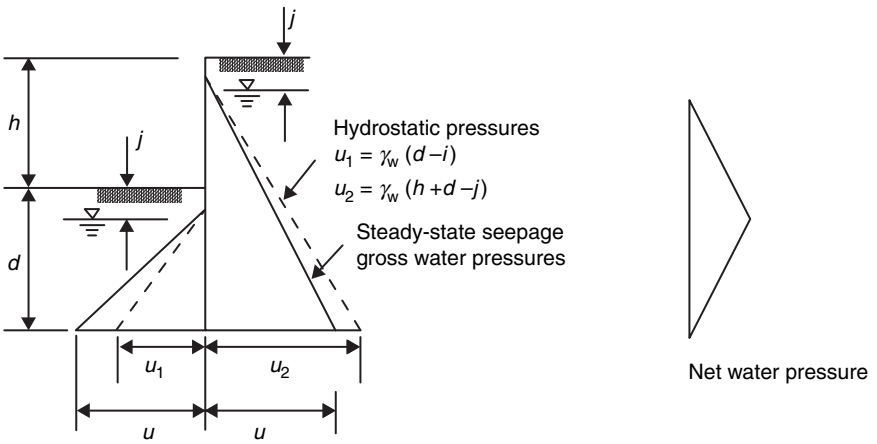
Where undrained conditions are considered to prevail during the construction of the wall, total stress considerations will apply. In such circumstances, there may be a tendency for tension cracks to develop in the retained soil. These tension cracks can be considered to have the potential to flood, depending upon the availability of water. Tension cracks may be less likely behind a propped wall compared with a cantilever wall. The depths of tension cracks and the groundwater pressure to assume are provided in CIRIA C580 (Gaba *et al*., 2003) and Chapter 64 *Geotechnical design of retaining walls*.

In the case of an embedded cantilever wall or where water is expected to be present, e.g. from water-bearing deposits overlying stiff clay, hydrostatic pressure should be used on the retained side of the wall.

CIRIA C580 (Gaba *et al*., 2003) proposes that where water is not expected, the total pressure acting on the retained side of the wall at any depth below the ground surface should be assumed to be not less than a minimum effective fluid pressure (MEFP) of $5z$ kN/m² (where z is the depth below the ground surface).

Drained conditions

Where the ground fabric and permeability indicate that drained conditions should be designed for, effective stress considerations will apply. The designer should evaluate the water pressure over the whole of the wall assuming steady-state conditions at relevant stages of construction and over the lifetime of the wall. Flownets are commonly used to establish the groundwater pressure distribution around the retaining wall. It should be noted that in reality, the ground is likely to be anisotropic with a non-uniform coefficient of permeability, which may greatly affect the pore water pressure distribution.



A commonly used simplified method of evaluating water pressure around an embedded retaining wall to a wide excavation in uniform isotropic conditions is shown in **Figure 63.6**.

This simplified method applies where the differential head of water across the wall dissipates uniformly along the length of the flow path adjacent to the wall and is sometimes referred to as linear seepage. This assumption tends to underestimate water pressures beneath narrow excavations. In general, the expressions in **Figure 63.6** should not be applied to excavations of widths that are less than four times the differential water head across the wall, BS 8002 (BSI, 1994). At greater excavation widths, the assumption of linear seepage provides a good approximation to the pore water pressure distribution around the wall.

In anisotropic ground conditions and in situations where the design of the wall is sensitive to small changes in earth and water pressures around the wall, water pressures should be evaluated by computer-based analytical methods or by flownets.

Mixed undrained and drained conditions

It is possible for the retained side of the wall to be considered drained (e.g. due to unloading laterally and the likelihood of open fissures allowing water into the clay and the potential for consequential softening or due to the presence of water-bearing silt and sand partings in the clay) while the restraining soil is considered to be undrained (e.g. due to an impermeable wall

= Assumption (1)
Uniform dissipation of differential head along flow path adjacent to the wall

$$u = \frac{2(d + h - j)(d - i)}{2d + h - i - j} \gamma_w$$

= Assumption (2)
Average hydrostatic pressure at wall toe

$$u = \frac{u_1 + u_2}{2} = \gamma_w \left\{ d + \left(\frac{h - i - j}{2} \right) \right\}$$

Figure 63.6 Uniform ground: simplifying assumptions for calculating water pressures for steady-state seepage conditions
Reproduced from Burland *et al.* (1981)

extending into impermeable ground thereby providing a cut-off to the groundwater recharge beneath the excavation on the restraining side). There is less likelihood of fissures opening and allowing water into the restraining clay due to its lateral confinement. In such circumstances, effective stress conditions may apply on the retained (active) side. Total stress conditions may apply in the restraining soil on the passive side and, possibly also, on the retained (active) side below the depth of the tension cracks.

The above is a very specific example used to highlight a scenario where mixed undrained and drained conditions may apply. This particular combination is quite often appropriate, though many other scenarios are possible.

The designer should carefully consider the likely ground behaviour on each side of the wall before finalising the design assumptions.

63.3.2.2 Other considerations

The designer should also include consideration of the following, prior to carrying out the retaining wall design:

- Adequate consideration of the dead and live loading that the retaining wall may be subjected to throughout the design life.
- Unplanned excavation on the passive side of the retaining wall. Generally assumed to be the lesser of 0.5 m or 10% of the total height retained for cantilever walls, or the height retained below the lowest support level for propped or anchored walls.
- Potential for softening of the soil on the passive side of the retaining wall.
- Effect of vertical forces applied to the wall through wall friction.

Further guidance on the selection of the above is given in CIRIA C580 (Gaba *et al.*, 2003) and Chapters 64 *Geotechnical design of retaining walls* to 67 *Retaining walls as part of complete underground structure*.

63.3.3 Temporary works design

The approach taken for temporary works design is a matter of risk assessment, management and mitigation. It is very important that the roles and responsibilities of each of the parties (client, owner, designer, contractor and sub-contractor) are clearly defined and fully understood by all parties in respect of the design and construction of the temporary (and permanent) works; also refer to Chapters 42 *Roles and responsibilities*, 78 *Procurement and specification* and 96 *Technical supervision of site works*.

The design of temporary works should be demonstrably robust. This robustness should be provided by identifying the hazards and risks and ensuring that these are adequately addressed by the temporary works design. The principal risks

lie in predicting ground behaviour and dealing with parameter uncertainty. For example:

- Will the ground respond in a drained or undrained manner, or a combination of both during construction?
- If undrained, will tension cracks develop? Are these likely to be dry or full of water?
- What groundwater regime will apply during construction?
- What provision should be made to allow for the deterioration in soil strength due to the installation of the wall and its support system and the disturbance due to excavation and partial drainage during the period of construction?
- What measures or controls will be applied to confirm that:
  - **(a)** The loading conditions assumed in design will not be exceeded?
  - **(b)** Unplanned excavation of the formation will not occur (see section 63.3.2.2)?
  - **(c)** The actual support (props, anchors, berms, etc.) to the wall will be as assumed in design?
  - **(d)** The actual wall performance (deflection, watertightness, etc.) will remain within pre-defined limits?

The assumptions made in temporary works design in respect of the above depend upon how the associated risks are mitigated during construction. Risk mitigation is undertaken through close control of the process of design and the construction of the temporary works on site. This requires an integrated interactive approach between design and construction on site with the ability to adapt the design quickly to suit changes in construction methods and *vice versa*. Appropriate contractual arrangements should be in place to permit this.

Special consideration should be given where there is uncertainty whether undrained or drained conditions may be assumed for the duration of the temporary works (see section 63.3.2.1 above). In terms of risk, three possible sets of ssumptions are possible for the design of temporary works in stiff clays:

- undrained conditions on both sides of the wall;
- mixed undrained and drained conditions;
- drained conditions on both sides of the wall with a steady-state groundwater regime.

The assumption of undrained conditions on both sides of the wall is associated with significant risk, while least risk is attached to the assumption of drained conditions. Further consideration of these assumptions is given in CIRIA C580 (Gaba *et al*., 2003).

63.4 Ground movements and their prediction

63.4.1 General

For the design and construction of retaining walls, it is inevitable that some movement will occur both in front and behind the retaining wall.

The amount of movement that is acceptable will depend upon the structures, utilities and infrastructure that are located within the vicinity of the new retaining structure and their tolerance to displacement.

Figure 63.7 shows the general type and form of movement that can be expected to occur.

Movements can be generally split into the following types:

- *Installation of the wall*: These could be due to a relaxation of the ground during the formation of piles or panels of an embedded retaining wall. Compression of the ground may occur, resulting in heave where sheet piles are driven into the ground. For embedded retaining walls, ground movements may occur due to the construction of the excavation because of the creation of the space where the gravity structure will be located or from settlements from loading the ground by the gravity structure.
- *Excavation related*: The excavation in front of a retaining wall will result in the retaining wall displacing laterally. This will lead to horizontal displacements and settlements behind the wall; see **Figures 63.8** and **63.9**.
- *Heave*: The removal of soil on the passive side of the wall will result in an unloading of the ground. This will lead to heave of the ground both on the passive and active sides of the retaining wall; see **Figure 63.8**.
- *Long term*: In fine-grained soils, the effects described above will result in long-term displacements arising from equalisation of the pore water pressures in the ground; see **Figure 63.8**.

It should be appreciated that during construction or installation of the wall, ground movements can also occur. These in general tend to be localised and aggravated by construction problems, for example, unacceptable vibration or overbreak. The removal of obstructions and the excavation of guide trenches before wall construction may also cause as much or more movement as wall installation itself. Further details of issues relating to construction may be found in Chapter 85 *Embedded walls*.

There are various techniques that can be used to assess the magnitude of ground deformation. The techniques broadly split into the categories of computational-based methods and physical models. For conventional design, computational

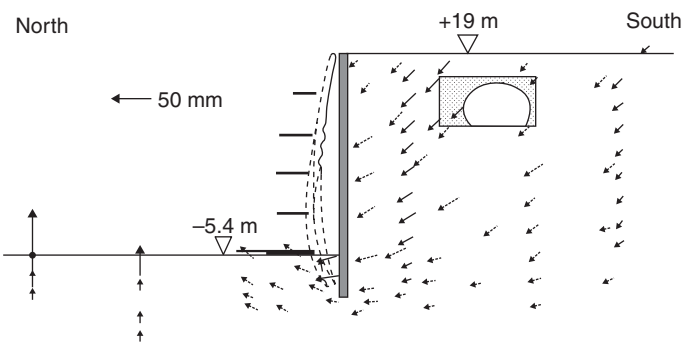


Figure 63.7 Typical ground movements around a deep excavation
Reproduced from Simpson (1992), all rights reserved

methods are generally used. Further details of these techniques are given in section 63.4.2.

Many of the methods described in this section consider only plane strain displacements (i.e. a 2D assumption). It should be realised that where retaining walls are used to form shafts or basements, the displacements will be significantly modified by the increased stiffness offered by the presence of corners around excavations. A basic consideration of how to account for these effects is given in CIRIA C580 (Gaba *et al*., 2003).

63.4.2 Calculation-based methods

63.4.2.1 Introduction

Calculation-based methods can be broadly split into empirical- and numerical-based methods.

If designing in accordance with Eurocodes, calculations are carried out using characteristic soil parameters selected by the designer. As discussed in section 63.3 above, any characteristic value should be a cautious estimate. As a consequence, calculation-based methods that involve the selection of characteristic soil parameters will also result in a conservative estimate of the magnitude of ground movements.

63.4.2.2 Empirical methods

Empirical methods rely on the collation of case history data to provide an estimation of ground movement. Numerous authors have provided empirical correlations for ground movements around retaining structures. In particular, the following references are often considered when calculating surface displacements: Clough and O'Rourke (1990), CIRIA C580 (Gaba *et al*., 2003), Moorman (2004) and Long (2001). Displacements are commonly calculated as a function of the retaining wall excavation depth and are grouped with respect to the stiffness of the excavation and ground conditions where they are carried out; see **Figure 63.10**.

CIRIA C580 (Gaba *et al*., 2003) also provides an empirical method for relating wall displacements from pseudo-finite element methods, for example, those calculated by programs such as FREW or WALLAP, to the ground surface displacement behind the retaining wall.

For use of these methods the case study database should be considered and compared with the particular conditions being analysed. Further assumption or correlations with case study movements are required if estimates of subsurface ground displacements are to be made without resorting to more rigorous methods of analysis.

63.4.2.3 Numerical methods

Numerical methods such as finite element or finite difference programs are commonly used for the design of retaining walls. The analysis methodology generally involves discretising the retaining wall and surrounding ground into elements within a mesh and specifying boundary conditions distant from the retaining wall. With the exception of discrete element analysis methods, the ground is modelled as a continuum. Further details on the use of numerical techniques may be found in Chapter 6 *Computer analysis principles in geotechnical engineering*. The primary reasons for using numerical methods include:

- They overcome the limitations and assumptions made by more simplistic analyses (for instance limit equilibrium or beam spring, pseudo-finite element programs).
- The use of numerical techniques can be readily extended to more complex problems (including berms).
- 3D analysis is available.
- The analysis can incorporate time-dependent consolidation.

Alongside this list of benefits, the following should also be borne in mind when considering numerical analysis:

- Application of the results of numerical analysis requires more knowledge and appropriate practical experience by the analyst.
- The active and passive limits are not easily computed.
- Data entry is more complex than other forms of computational analysis.
- Full numerical analyses carried out by a computer takes longer than limit equilibrium or pseudo-finite element of finite difference analyses.
- Interpretation of results takes longer and is often not as clearly understood.

63.5 Principles of building damage assessment

Further to carrying out an assessment of the magnitude of ground movements arising from retaining wall excavations it is important to assess whether the movements may have an impact upon adjacent structures and utilities. The principles of assessing the effect of ground movement on structures due to excavation is described in Chapter 26 *Building response to ground movements*.

It should be appreciated that lateral displacements and the resulting ground strains should also be considered as they may form a significant contribution to an affected structure's deformation. For many structures it should be appreciated that the interaction between the ground and structural deformation is complex. As a consequence either conservative assumptions or advanced forms of analysis may be required to adequately model this interaction.

Chapter 64

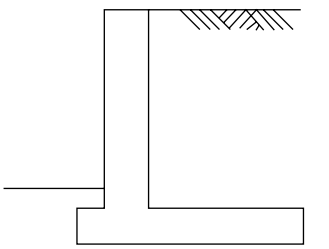
Geotechnical design of retaining walls

Adam Pickles Arup, London, UK

CONTENTS

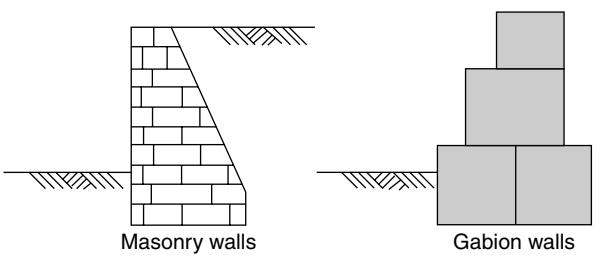
64.1	Introduction	981
64.2	Gravity walls	981
64.3	Reinforced soil walls	988
64.4	Embedded walls	988
64.5	References	999

This chapter outlines the design approach for retaining walls, following from the principles of retaining wall design outlined in Chapter 63 *Principles of retaining wall design*. The design basis is in accordance with BS EN 1997-1:2004, *Eurocode 7*. The mechanisms that typically require consideration in the design of gravity, reinforced soil and embedded retaining walls are identified and the design process for each type of wall is explained. Using the methods outlined in this chapter the reader will be able to size retaining walls to ensure adequate stability and calculate load effects for the structural design of the wall.



64.1 Introduction

This chapter outlines the design method for gravity retaining walls, embedded retaining walls and reinforced soil walls. The chapter develops the design concepts outlined in Chapter 63 *Principles of retaining wall design*, and identifies the limit states that should be typically considered when designing a retaining wall. The chapter describes how to apply the partial factors incorporated within BS EN 1997-1:2004 (British Standards Institute, 2004) to ensure a compliant design is achieved. Limit-equilibrium analyses that can be calculated by hand are described in addition to a design using more complex soil–structure interaction methods.



64.2 Gravity walls

64.2.1 Introduction

Gravity walls derive the majority of their stability from the self-weight of the wall, or soil placed on the toe or heel of the wall. This differs from an embedded wall, which derives significant support from the resistance of the ground in front of the wall for its stability. There are a variety of different types of gravity wall, as described in Chapter 62 *Types of retaining walls*, and the selection of a particular wall type will depend upon a variety of factors, as discussed in that chapter. There are broadly two types of gravity wall, one in which internal stability is provided by shear or bending in the structure, e.g. reinforced concrete stems, and the second type where gravity action and the self-weight of the wall provide stability, without mobilising tension in the structure, e.g. mass concrete or gabion walls. These are illustrated in **Figure 64.1**.

a) Internal stability maintained by structural stregth of reinforced concrete stem

b) Internal stability maintained by gravity action - no (or minimal) development of tension

Figure 64.1 Types of gravity wall: (a) internal stability maintained by structural strength of reinforced concrete stem wall; (b) internal stability maintained by gravity action – no (or minimal) development of tension

64.2.2 Limit states

BS EN 1997-1:2004 adopts the principle of a limit state design. The limit states relevant to gravity walls are discussed below. These are listed in Sections 9.2, 9.7 and 9.8 of BS EN 1997-1:2004.

64.2.2.1 Ultimate limit states (ULS)

BS EN 1997-1:2004 requires the following limit states to be considered for gravity retaining walls:

- bearing resistance failure of the soil below the base;
- failure by sliding at the base of the wall;
- failure by toppling of the wall;
- loss of overall stability;

- failure of a structural element such as a wall, anchor, wale or strut, or failure of the connection between such elements;
- combined failure of the ground and a structural element;
- movement of the retaining structure that may cause collapse or affect the appearance or efficient use of the structure, nearby structures or services that rely on it;
- unacceptable leakage through or beneath the wall;
- unacceptable transport of soil grains through or beneath the wall;
- unacceptable change to the flow of groundwater.

Some of these limit states are illustrated in **Figure 64.2**.

In addition to the limit states listed above, the designer should consider whether any additional limit states should be taken into account in respect of specific site conditions or other requirements not covered by this manual.

64.2.2.2 Serviceability limit states (SLS)

The following serviceability limit states should be considered:

- movement that may cause damage to structures or services, which rely on the support of the wall;
- excessive tilting, deflection or settlement of the wall. The acceptable values for these deformations should be assessed on a project-specific basis.

64.2.3 Factors of safety

The design approach outlined in this manual is based on BS EN 1997-1:2004 with partial factors being applied to characteristic values of material strengths, geometry and actions to give design values. This is a change from traditional practice for gravity-wall design where lumped factors of safety were typically applied to the different mechanisms analysed. In simple terms, the traditional methods used unfactored characteristic soil parameters and analyses were undertaken to assess factors of safety against overall stability, overturning about the toe of the wall, sliding along the base of the wall, and bearing capacity failure beneath the wall. Typical values of factors of safety adopted using such traditional design methods for designing permanent structures are given in **Table 64.1**.

Mechanism	Target factor of safety
Overall stability	1.3
Overturning	2.0
Sliding	1.5
Bearing capacity	3.0

Table 64.1 Traditional lumped factors of safety for gravity-wall design

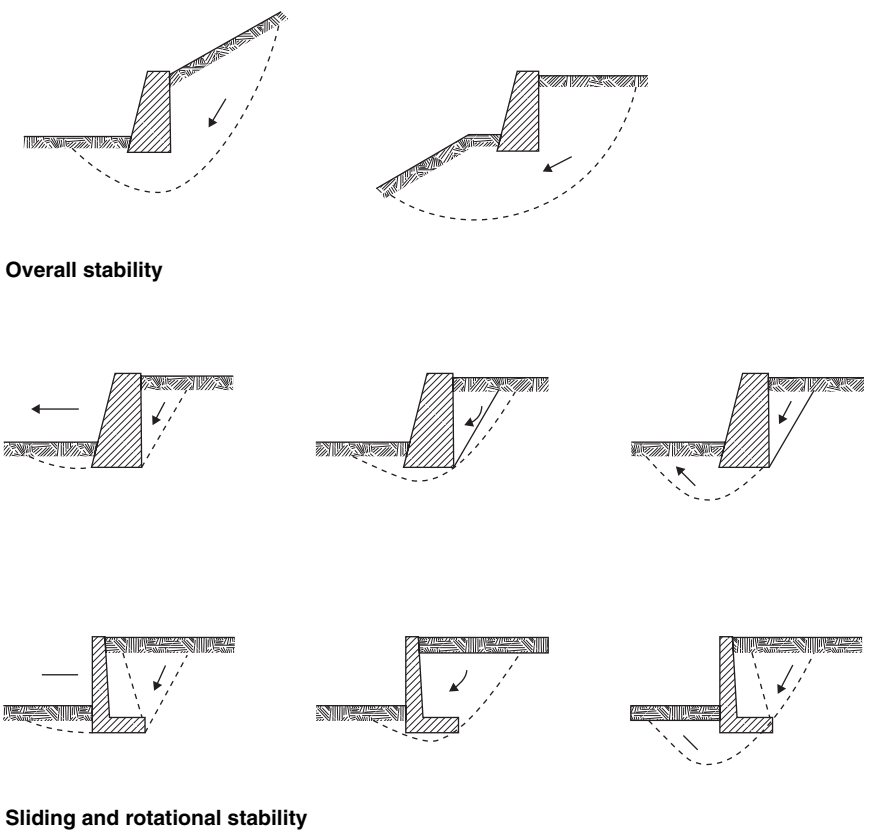


Figure 64.2 Gravity wall: ultimate limit states

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The partial factors required by BS EN 1997-1:2004 mean a different approach must be taken. Rather than seeking an overall lumped factor of safety, partial factors are applied to a number of different inputs, such as material strength, actions, wall geometry and water pressure. The size of the wall is then selected to ensure that the design actions, or action effects, are less than the design resistances for each of the limit states described above.

The design approach and values of partial factors to be used in design are stated in the relevant National Annex of BS EN 1997-1:2004. In the UK, Design Approach 1 is applicable for gravity walls. This approach comprises two combinations:

- Combination 1 (DA1-1): where the material partial factor is unity, and actions (or action effects) are factored by a value greater than 1;
- Combination 2 (DA1-2): where partial factors are applied to material strengths and variable actions, but the factor on the permanent actions (or action effects) is unity.

The reader should refer to the appropriate National Annex for confirmation of these partial factor values.

In addition it may be necessary to undertake an SLS analysis where all factors are unity. Traditionally, large lumped factors acted to reduce the proportion of strength mobilised, and hence control movement. The partial factors in BS EN 1997-1:2004, may lead to lower equivalent overall factors of safety and therefore there is potential for more movement. As a consequence an explicit check is needed for the SLS case.

64.2.4 Design situations, earth pressure, design geometry, groundwater conditions

64.2.4.1 Introduction

An illustration of the typical loads acting on a gravity retaining wall are summarised in **Figure 64.3**.

From a stability perspective, some actions tend to reduce the stability of the structure, whilst others tend to improve stability. The objective is to ensure that the design resistance exceeds the design action effects. The following considerations should be addressed:

- For *bearing capacity*: sum the vertical actions, horizontal actions and moments about the centre of the base, then undertake a check as a shallow footing – the design approach described in Chapter 63 *Principles of retaining wall design* should be followed.
- For *sliding*: calculate the net horizontal load and check that this is smaller than the sliding resistance. For free-draining granular soils, this is a function of the vertical load.

The traditional check on *overturning* is not generally necessary. If the wall was on the limit of toppling (or even past the limit of toppling), then the effective footing width from the bearing capacity calculation above would be very small or the line of action would fall outside the base of the wall. This would therefore be picked up as a bearing capacity failure. The only case where this may not be correct is for walls bearing on strong rock. In such cases the bearing capacity may be sufficient to resist very high load eccentricities and so overturning stability must be checked explicitly.

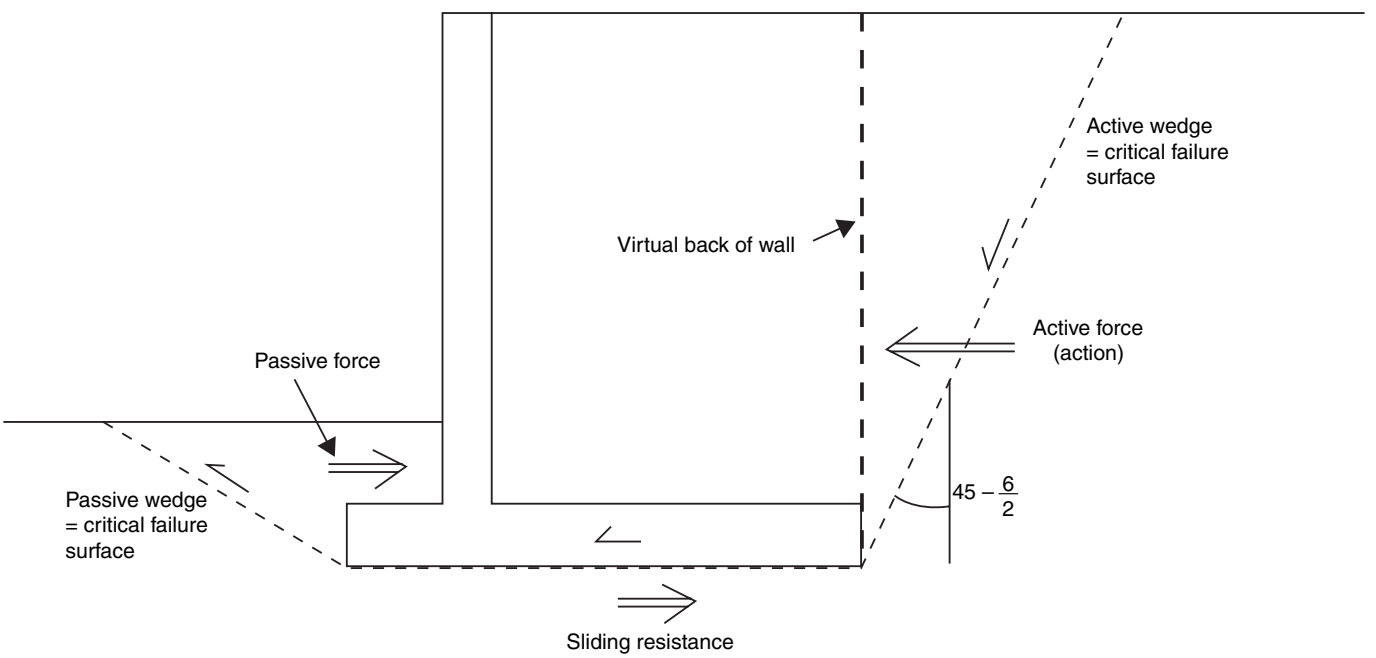

Figure 64.3 Idealised actions on a gravity wall

The sections below provide guidance on calculating the individual components of the load acting on a gravity wall.

64.2.4.2 Design situations

Before any analysis is undertaken, it is necessary to establish the appropriate design situations. Issues to consider include:

- *Design soil stratigraphy*: In variable ground conditions it may be necessary to consider more than one design soil stratigraphy. Each one would comprise a separate design situation.
- *Soil parameters*: Characteristic values should be assessed based on the approach outlined in Chapter 27 *Geotechnical parameters and safety factors*.
- *Time effects*: For example, whether the analysis will be short term (i.e. undrained parameters) or long term (i.e. drained parameters). If necessary both conditions may need to be checked as separate design situations.
- *Construction sequence*: It is necessary to ensure that all potentially critical stages are considered in the design.
- *Design geometry*: Where this varies for the structure, for example, because of changes in the overall retained height, consider how the wall will be divided up for design purposes and identify the critical section for each. Each geometry will then be considered as a separate design situation.
- *Imposed loading*: Are there any externally applied loads, such as traffic surcharges, impact loads or loads from adjacent structures that need to be considered in the analysis?

Whilst it may be necessary to calculate more than one design situation, by careful consideration of the relevant combinations that are likely to prove critical, it is possible that once a solution for the critical design situation has been determined, alternative situations may be confirmed as acceptable either by inspection, or through a reduced number of analyses and calculations.

64.2.4.3 Earth pressure

The principal actions on a gravity retaining wall are usually earth and water pressures. The earth pressure is derived from the self-weight of the soil and possibly from loads applied to the ground surface. In addition there may also be some direct loading of the wall, for example, from structures bearing onto the wall or from impact loads applied to parapets connected to the wall.

Typically, a gravity-wall analysis is carried out by assuming the limit-equilibrium earth pressure acts on the structure. It is relatively unusual for a gravity wall to be designed using a soil–structure interaction analysis. Whilst the general design principles outlined in this chapter may be applied to a soil–structure interaction analysis of a gravity wall, this section will primarily focus on the limit-equilibrium approach.

The first step in identifying the earth pressure acting on a wall is to select a virtual back (see **Figure 64.3**). Soil within this line is considered to act with the structural components of the wall as a rigid body. Normal stresses and shear stresses must then be evaluated along the virtual back. For many situations the virtual back is taken as a vertical line upwards from the heel of the wall. In this case it is assumed that a Rankine active wedge forms both within the soil mass over the heel of the wall and in the retained ground behind the virtual back. This means the force acting normal to the virtual back can be calculated using Rankine earth-pressure theory. Because the soil within the active wedge over the heel of the wall and in the retained fill are both moving downwards together, zero shear stress is mobilised along the virtual back (see **Figure 64.4**).

An alternative approach is to assume the virtual back lies on a plane joining the heel of the wall to the crest of the wall (see **Figure 64.5**).

For either of the above two cases, the active forces acting on the virtual back should then be evaluated for the chosen geometry, using either tabulated values of earth-pressure coefficients (e.g. Kerisel and Absi, 1990), the charts in BS EN 1997-1:2004 or the analytical method of calculating earth-pressure coefficients given in BS EN 1997-1:2004. The *design* material strength should be used in this calculation.

It should be noted that since DA1-1 and DA1-2 in BS EN 1997-1:2004 give different values for the partial factor on the material strength then the earth-pressure coefficients and hence the limiting earth pressures used for each design approach will also be different.

Where the base of the wall is founded below the ground level in front of the wall, passive earth pressures may be considered to act on the front of the wall. Careful consideration needs to be given as to the reliability of this pressure being mobilised. In order to form the wall base, the material in front of the wall is likely to have been excavated and then backfilled once the wall has been constructed. The quality of this material, and the level of compaction used to replace the material

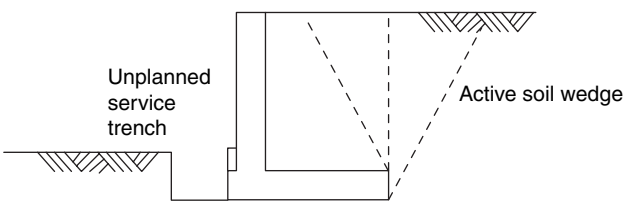

Figure 64.4 Rankine active wedge

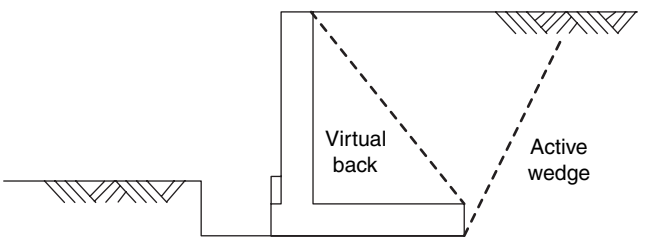

Figure 64.5 Inclined virtual back

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

may therefore influence the magnitude of passive resistance that can be mobilised and relied upon. The passive resistance may also be affected by unplanned excavation (see section 64.2.4.4 below). If there is any uncertainty regarding the reliability of the passive resistance, it is recommended that it be omitted from the analysis.

Where sliding is shown to be a critical factor in design, the stability of the wall may be improved by the construction of a shear key or the use of an inclined base. Further details regarding the inclusion of the effects of shear keys in a gravity-wall analysis can be found in *CIRIA C516* (Chapman *et al*., 2000).

As required by BS EN 1997-1:2004, it is important to ensure that the assumed earth pressures for a given limit state are compatible with the anticipated movements at that limit state. For geotechnical stability (i.e. sliding, toppling, bearing) it is reasonable to assume sufficient movement will occur to mobilise active earth pressures. However, for the structural design of the wall it is possible that the wall deformation under *in situ* conditions may be insufficient to mobilise active pressures. For structural design it will therefore often be appropriate to use the 'at-rest' earth pressures. BS EN 1997-1:2004 includes information on the magnitudes of any movement that are required to mobilise active and passive earth pressures and these are also discussed in Chapter 63 *Principles of retaining wall design*. The enhanced *in situ* pressures may also be applicable to the SLS case.

Since gravity walls typically retain placed fill, the *in situ* pressures must take into account the construction processes that formed the backfill. Typically some form of compaction will be used behind the wall to achieve the required backfill strength and to limit the potential for future settlement of the backfill. Compaction tends to lock in stresses in the ground, which can exceed the values calculated based on a typical *in situ* earth-pressure coefficient, K_0. The horizontal pressure acting along the back of the wall due to compaction is given in **Figure 64.6**.

The values of σ_{hrm}, h_c and z_{cr} can be determined as follows:

$$h_c = \frac{1}{K_0}\sqrt{\frac{2P}{\pi\gamma}} \qquad (64.1)$$

where P is the effective line load per metre of the roller, and γ is the density of the material undergoing compaction.

The maximum pressure σ'_{hrm} can be calculated from

$$\sigma'_{hrm} = \sqrt{\frac{2P\gamma}{\pi}} \qquad (64.2)$$

and this occurs below a depth of z_{cr} where

$$Z_{cr} = K_0\sqrt{\frac{2P}{\pi\gamma}}\ . \qquad (64.3)$$

64.2.4.4 Unplanned excavation

When assessing the geometry for a given design situation for a wall where the passive resistance of the ground is relied upon for stability, it is important to take into account the potential for unplanned excavation in front of the wall. BS EN 1997-1:2004 requires that for normal site controls, 10% of the retained height, up to a maximum of 0.5 m, should be assumed for an unplanned excavation.

64.2.4.5 Surcharges and direct loads

The design of a retaining wall must take into account that a surcharge may be applied to the ground retained by the wall. Such a surcharge may be derived, for example, from highway traffic in the permanent condition, plant loading during the construction phase or from the placement of stockpiled materials behind the wall. The effect of such surcharges must be incorporated into the assessment of the earth pressure acting on the wall.

BS 8002 (British Standards Institution, 1994b) has a requirement to consider a minimum 10 kPa surcharge behind a wall. Although this is not an explicit requirement in BS EN 1997-1:2004, for most walls some allowance should be made and a 10 kPa uniform distributed load is considered reasonable.

Typically such surcharges would be considered as a variable action. In these cases consideration should be given to whether the effect is beneficial to the stability of the wall. In particular if a live

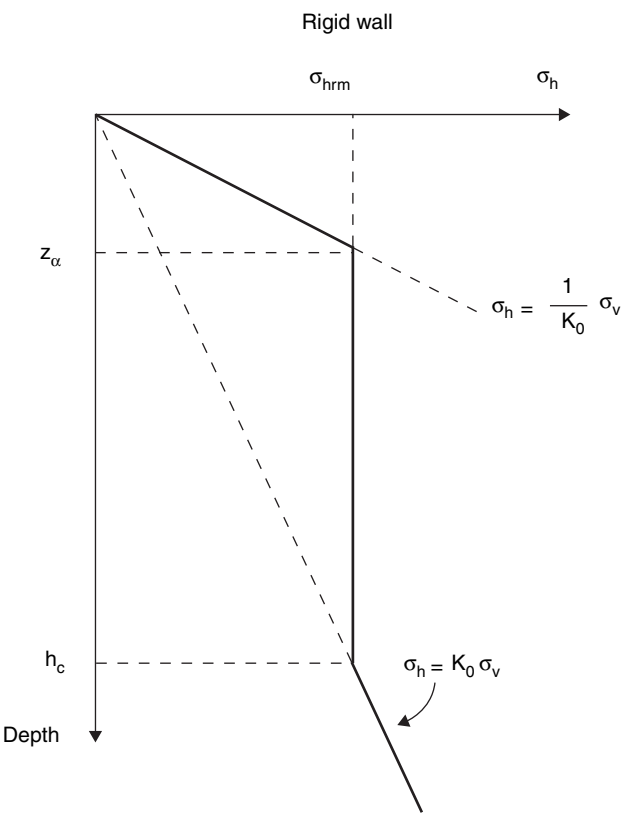

Figure 64.6 Calculation of compaction pressures

load surcharge acts on the soil directly over the heel of the wall, this would contribute additional load to resist overturning and sliding (for free-draining granular materials), which cannot be relied upon. However, for bearing capacity checks and the structural design of the wall, the additional vertical load from the surcharge over the heel may prove to be adverse. As a rule, live load surcharges are typically only applied to the ground outside the virtual back. In this way the destabilising effect of the load is considered, but no beneficial effects are relied upon; see **Figure 64.7**.

64.2.4.6 Water pressure

As is commonly the case for geotechnical design, water pressure can be a significant component of load on a gravity wall. Since gravity walls retain fill material, there is potential to install a drainage system behind the wall and hence control the water pressure. However, such a system would require ongoing maintenance to ensure that it continues to perform.

In the absence of a drainage system, BS EN 1997-1:2004 requires that the water level is assumed to be at the surface of the retained ground level for low permeability backfills. Consideration also needs to be given to the occurrence of seepage around a wall. In the absence of seepage analysis it may be appropriate to assume a linear variation in pore pressure across the base, from the pressure behind the wall to the pressure in front of the wall.

For the design groundwater conditions, the following should be determined:

1. Water pressure and seepage forces that represent the most unfavourable values that could occur in extreme or accidental circumstances at each stage of the wall's construction sequence and throughout its design life. An example of an extreme or accidental event may be a burst water main in close proximity to the wall.
2. Water pressures and seepage forces that represent the most unfavourable values likely to occur in normal circumstances at each stage of the wall's construction sequence and throughout its design life. Extreme events such as a nearby burst water main may be excluded, unless the designer considers that such an event may reasonably occur in normal circumstances.

Different approaches to groundwater are required for DA1-1 and DA1-2. In DA1-1 the actions of the water are factored by a value greater than unity, therefore it is recommended that water condition (2) is assumed, as the factor on the action of the water will give a margin of safety. For DA1-2, the design actions are derived from design material parameters, with a factor on permanent actions of unity. It is therefore recommended that the design water pressure is derived from a directly assessed design groundwater level, which is defined as (64.1) above.

64.2.4.7 Drainage systems and fill materials

There is a need to have consistency between the design groundwater assumptions and the specification of backfill or drainage. It is becoming more common to use site-won material. This may have lower strength and lower permeability than traditional backfill material so the designer needs to know in advance what is available. Without drainage, an assumption of hydrostatic conditions from the ground level is required by BS EN 1997-1:2004 for medium- and low-permeability soils.

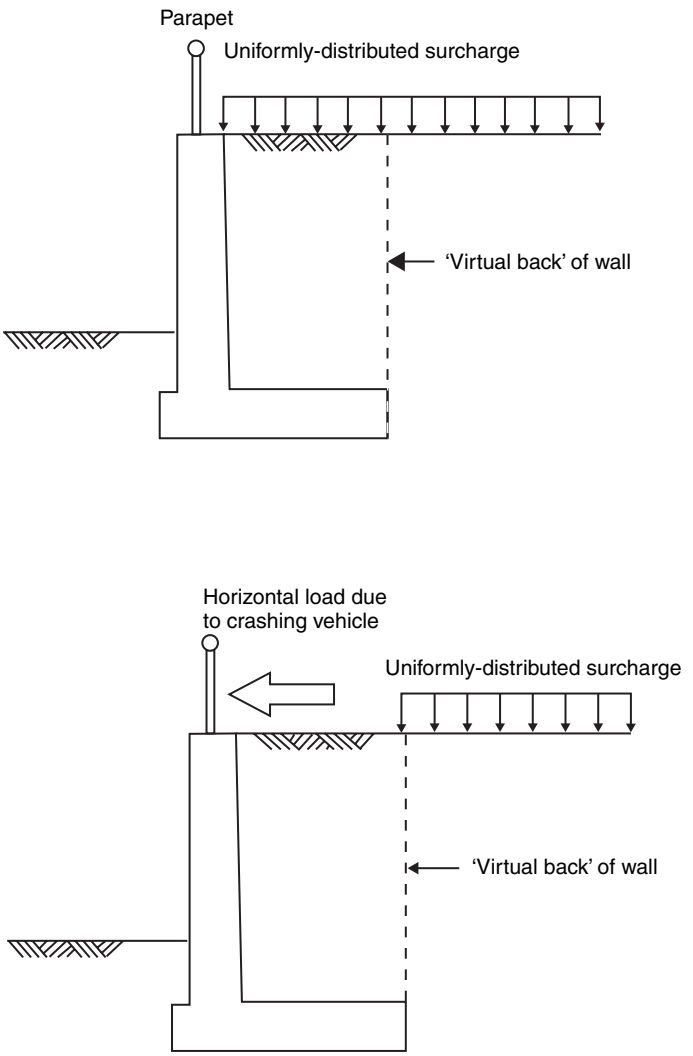

Figure 64.7 Surcharge assumptions for different design cases. (a) Load case 1: often critical for bearing pressure calculations and design for internal stability. (b) Load case 2: often critical for sliding stability and bearing pressure calculations

64.2.5 Design of structural elements

As noted above, it is necessary to ensure compatibility between the movement of the wall at a given limit state and the value of the earth pressure. This means that the magnitude of the pressure for structural strength design may be higher than for geotechnical stability. For reinforced-concrete walls, the load effects derived from the analysis are design effects to be used in the structural calculation.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

For mass gravity-type walls, e.g. mass concrete or gabion walls, it will be necessary to undertake checks at different points down the height of the wall to ensure that tension is not generated where it cannot be resisted, and that the shear forces do not exceed the sliding resistance, for example, along the boundary between two layers of gabion baskets.

64.2.6 Design method

The preceding sections outline how the various loads acting on a wall can be assessed. Once these actions have been identified, it is necessary to analyse the wall to verify that the limit states identified in section 64.2.2 above will be avoided. Typically this analysis is iterative, where an initial estimate of the wall geometry is made and stability against each failure mode is checked. The geometry of the wall may then be adjusted to optimise the solution while still ensuring stability. Such analysis and iteration may be calculated by hand, or calculated using proprietary software or a spreadsheet.

The design stages for a gravity wall are shown in the flowchart in **Figure 64.8** and described below.

(1) Confirm the relevant limit states for the problem, as identified in section 64.2.2. For serviceability limit states agree the deflection limits or other criteria that are to be adopted.

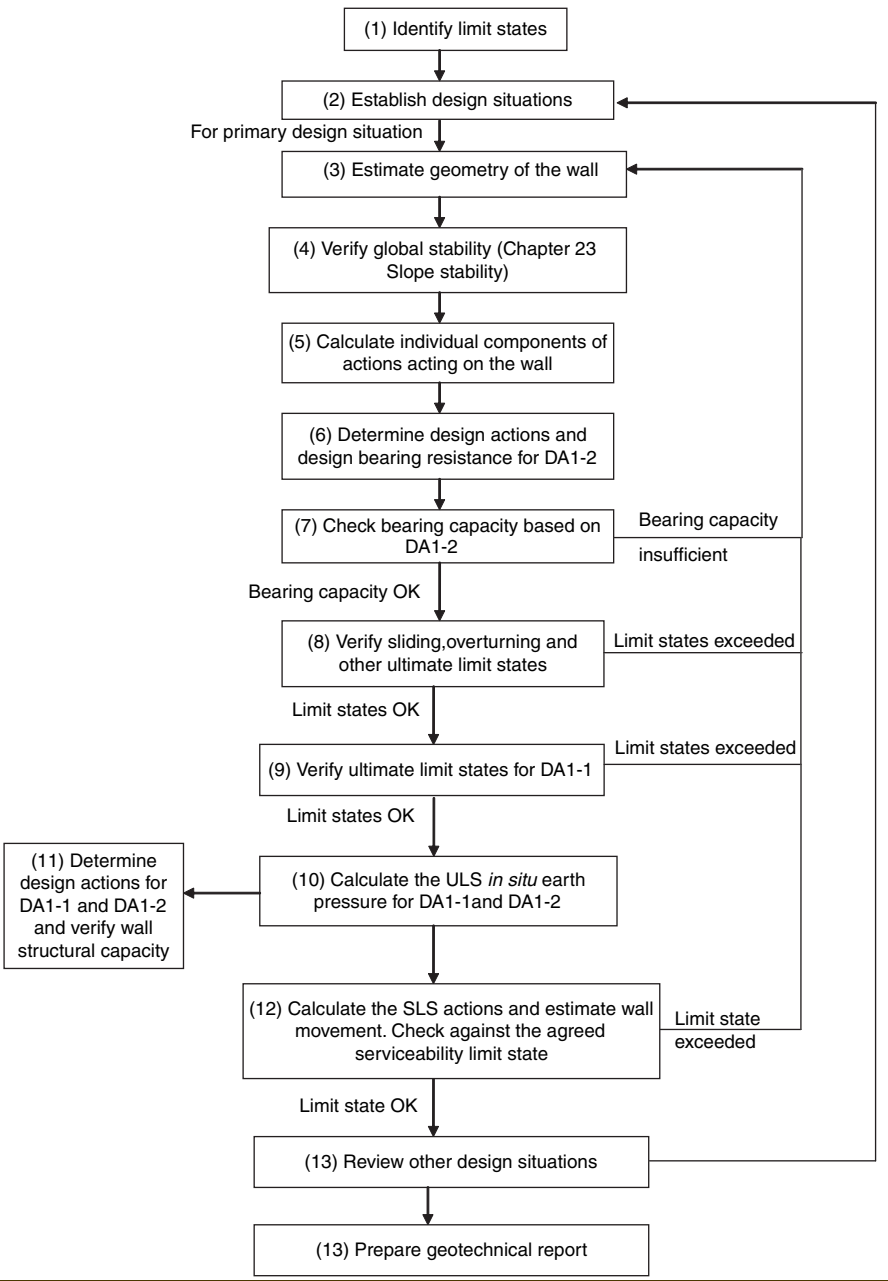

Figure 64.8 Gravity-wall design process

(2) Identify the design situations to be considered in the analyses, considering the issues described in section 64.4. Select an initial situation to analyse.

(3) For the selected design situation, estimate the initial geometry of the wall.

(4) Verify the global stability of the structure, in accordance with Chapter 23 *Slope stability.*

(5) Calculate the individual components of the actions acting on the wall for Design Approach 1 Combination 1 and 2, using the guidance of section 64.4.

(6) For Design Approach 1 Combination 2, apply the relevant partial factors to the characteristic actions to determine the design actions. On the basis of these design actions determine the design bearing resistance of the ground.

(7) Check whether the design actions exceed the design bearing resistance. If they do, return to step 3 and revise the wall geometry.

(8) Once sufficient bearing resistance has been demonstrated, verify that the sliding and overturning limit states are also acceptable. If not, return to step 3.

(9) Verify the geotechnical ultimate limit states for Design Approach 1 Combination 1. Return to step 3 if insufficient capacity is identified.

(10) Calculate the ULS *in situ* earth pressure acting on the wall, including the compaction pressure where appropriate, for DA1-1 and DA1-2.

(11) Determine the design actions on the wall for the structural design for DA1-1 and DA1-2. Verify the structural capacity of the wall is acceptable.

(12) Calculate the SLS *in situ* earth pressure acting on the wall, including the compaction pressure, where appropriate. Estimate the anticipated movement of the wall and check against the agreed serviceability limit state. If acceptable, the design situation has been verified as acceptable, otherwise return to step 3.

(13) Review other design situations: start at step 2 for each design situation.

(14) Prepare the geotechnical report, including details of maintenance requirements associated with any drainage systems included in the design.

When carrying out the different ULS checks, it is important to consider whether the actions are beneficial as this will influence the partial factor that is applied.

The procedure for verifying the bearing resistance should be undertaken in accordance with Chapter 53 *Shallow foundations*.

64.3 Reinforced soil walls

64.3.1 Introduction

Reinforced soil walls are essentially a specific type of gravity wall. Two different checks need to be made, one for external stability and the other for internal stability. The size of the block of reinforced soil is selected to provide overall stability, with the internal check being made to ensure that the reinforcement holds the block together. The external stability check should follow the procedure set out in section 64.2 above.

A discussion of the available types of soil reinforcement and a detailed explanation of the design of gravity walls is given in Chapter 73 *Design of soil reinforced slopes and structures* with a brief overview below.

It is noted that BS EN 1997-1:2004 is not applicable to reinforced soil walls and their design should be undertaken in accordance with the current British Standard BS 8006 (British Standards Institution, 1994a).

64.3.2 Design for external stability

As with any gravity wall, the overall block of reinforced soil must be selected to ensure the geotechnical limit states are met.

Slope stability, bearing capacity, sliding and overturning limit states must be checked.

For many projects it is common to design the soil block for external stability, which is typically presented as a minimum length of reinforcement.

64.3.3 Design for internal stability

Once the overall size of the reinforced soil block has been selected, the reinforcement must be designed. This typically includes parameters such as the gauge of reinforcement and the spacing of layers. On occasion it may also be necessary for the straps to be longer than the minimum required for external stability to ensure that pull-out failure is avoided.

There are a number of different proprietary soil reinforcement systems available, and whilst they generally work on the same principles, the detail of the design will vary. In general the design for internal stability must ensure that a soil block remains intact. Typically this requires checking the pull-out resistance and whether the reinforcement ruptures, which are described in Chapter 73 *Design of soil reinforced slopes and structures*.

Since the various systems differ, it is common for a specialist reinforced soil sub-contractor to undertake the detailed design.

64.4 Embedded walls

64.4.1 Introduction

As in Chapter 62 *Types of retaining walls*, an embedded retaining wall penetrates into the ground at its base to gain lateral support from the resistance of the ground in front of the lower part of the wall. This resistance may be used as the sole resistance to provide stability for the wall or it may act in conjunction with

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

anchorages, props or other sources of lateral support for stability. The structural strength of the wall in bending and shear is usually critical.

Unlike gravity walls, which support backfilled material, embedded walls will usually be installed into natural ground, which is then excavated in front of the wall. This means there is no control over the quality of the ground that the wall is supporting nor is there an opportunity to install drainage.

In general, embedded walls can be categorised as cantilever or propped. Whilst the overall principles for design are comparable between these two categories, there are differences in the specifics of the design approach and these are identified in the following sections.

64.4.2 Limit states

As with gravity walls, BS EN 1997-1:2004 adopts the principle of a limit state design. The limit states relevant to embedded walls are discussed below. These are listed in Sections 9.2, 9.7 and 9.8 of BS EN 1997-1:2004.

64.4.2.1 Ultimate limit states (ULS)

BS EN 1997-1:2004 lists the following ultimate limit states as relevant to embedded walls:

- loss of overall stability;
- failure by rotation or translation of the wall or parts thereof;
- failure of a structural element such as a wall, anchorage, wale or strut or failure of the connection between such elements;
- failure by lack of vertical equilibrium;
- combined failure in the ground and in the structural element;
- failure by hydraulic heave and piping;
- movement of the retaining structure, which may cause collapse or affect the appearance or efficient use of the structure or nearby structures or services, which rely on it;
- unacceptable leakage through or beneath the wall;
- unacceptable transport of soil particles through or beneath the wall;
- unacceptable change in the groundwater regime.

Some of these limit states are illustrated in **Figure 64.9**.

The design of an embedded wall must ensure that these limit states are avoided.

64.4.2.2 Serviceability limit states (SLS)

The primary serviceability limit state noted by BS EN 1997-1: 2004 for embedded walls is movement of the retaining structure, which may cause collapse or affect the appearance or efficient use of the structure or nearby structures or services, which rely on it. This may involve both lateral and vertical movement of either the wall or the soil around the wall.

64.4.3 Factors of safety – partial factors and lumped factors

As discussed in section 64.2.3 above, BS EN 1997-1:2004 adopts a partial factor approach to design. For embedded walls this concept has been in common use for a number of years, and should be readily adopted in design. There are, however, a number of traditional methods of embedded wall design that use a lumped factor approach. Typically these either sought a sufficiently large ratio of the restoring moment to the overturning moment in a rotational stability check, or applied a single factor to a measure of the passive resistance of the soil. *CIRIA C580* (Gaba *et al*., 2003) provides a detailed discussion of these approaches.

The ultimate limit states identified above typically relate to either the BS EN 1997-1:2004 GEO limit state ('failure or excessive deformation of the ground, in which the strength of soil or rock is significant in providing resistance') or STR ('internal failure or excessive deformation of the structure or structural elements in which the strength of structural materials is significant in providing resistance'). Partial factors to be used in the design of embedded walls are provided in BS EN 1997-1:2004 for these limit states. Design Approach 1 has been adopted in the UK: walls must be checked against both Combination 1 and Combination 2.

In Combination 2, factors greater than 1 are applied to the characteristic soil parameters to derive the design values to be used in the analysis. This is usually the critical case for stability and will establish the required wall geometry. The load effects in the wall from this analysis are used to check the structural capacity of the system, along with the output from Combination 1.

For the serviceability limit state check, partial factors of unity are used.

64.4.4 Design situations, design geometry, groundwater conditions

64.4.4.1 Introduction

The general aim of an embedded wall design is to select a wall length that is sufficient to ensure stability and to derive load effects so that the adequate structural performance of the wall and any support system can be ensured. In addition it is common that some form of movement analysis is undertaken to ensure that the structure meets the design performance requirements and to ensure nearby structures and utilities are not adversely affected.

The following sections outline the key considerations that the designer should address in designing an embedded retaining wall.

64.4.4.2 Design situations

Design situations are discussed in BS EN 1997-1:2004. When designing an embedded wall it is important to consider whether more than one design situation is applicable. For example,

where construction is staged, such as for multiple-propped walls, it is necessary to consider each stage of the construction sequence individually to ensure that the relevant limit states are avoided.

For each design situation, the designer must consider the following:

- *Design soil stratigraphy*: In variable ground conditions it may be necessary to consider more than one design soil stratigraphy. Each would comprise a separate design situation.
- *Soil parameters and ground model*: Characteristic soil parameters should be assessed based on the approach outlined in Chapter 27 *Geotechnical parameters and safety factors*. Walls are linear structures and therefore have the potential to encounter variations in the design stratigraphy and soil parameters. The designer must consider this variability and if necessary analyse the different ground models.
- *Time effects*: For example, whether the analysis will be short term (i.e. undrained parameters) or long term (i.e. drained parameters). If necessary both conditions may need to be checked as separate design situations.
- *Construction sequence*: It is necessary to ensure that all potentially critical stages are considered in the design.
- *Design geometry*: Where ground levels or retained heights vary along the length of the wall, it may be appropriate to divide the

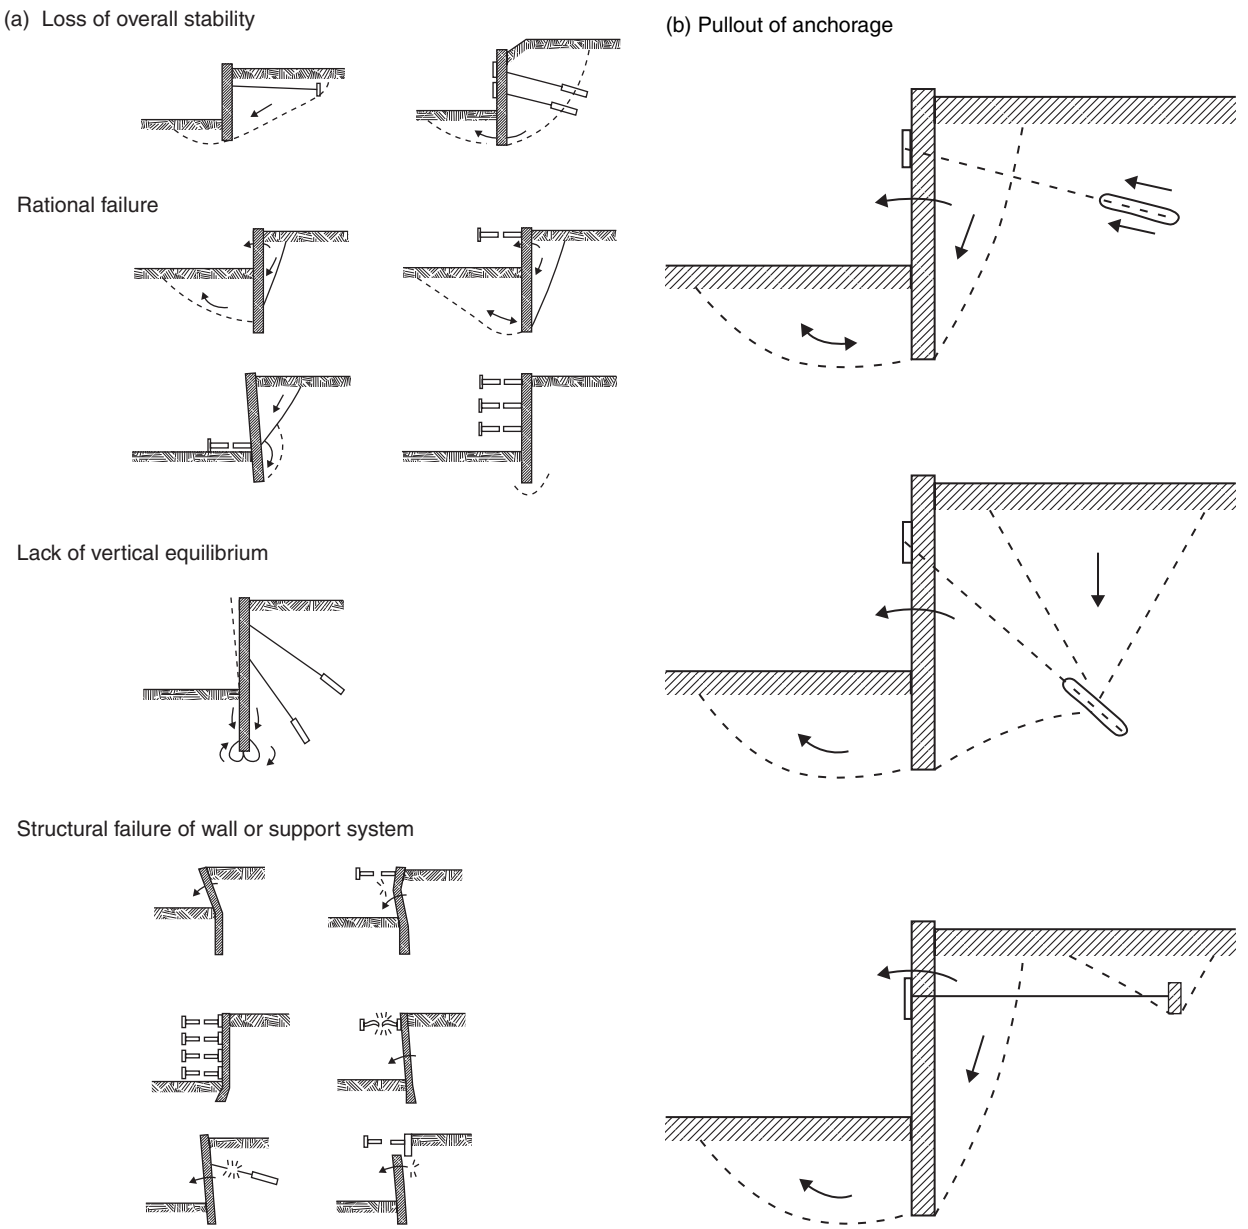

Figure 64.9 Ultimate limit state failure modes for embedded walls

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

wall into sections and select a representative geometry for each section. Each geometry will then be considered as a separate design situation.

- *Groundwater and drainage*: This is a key consideration when developing the design situations for a retaining wall. Depending upon the soil type, the construction sequence and the rate of construction, it may be necessary to analyse situations which consider that the ground is undrained in some cases and drained in others. This is discussed in detail in Chapter 63 *Principles of retaining wall design*.
- *Imposed loading*: Consider surcharges due to building loads or traffic and their effect.

Whilst it may be necessary to calculate for more than one design situation, by careful consideration of the relevant combinations that are likely to prove critical, it is possible that once a solution for the critical design situation has been determined, alternative situations may be confirmed as acceptable either by inspection, or through a reduced number of analyses and calculations.

64.4.5 Earth pressure

In order to verify the stability and movement of a wall, the earth pressure acting upon it must be calculated. There are two general analysis methods that are typically used to evaluate this pressure:

- limit equilibrium;
- soil–structure interaction.

Limit-equilibrium methods of calculation are based on conditions at collapse, when the full strength of the soil is mobilised around the retaining wall based on assumed failure mechanisms. Calculations are typically based on simple assumed linear lateral stress distributions, which represent a particular collapse mechanism. Collapse mechanisms are well developed for cantilever and single-propped walls, but less so for other forms of embedded retaining walls, such as multi-propped walls and walls propped significantly below the top. Limit-equilibrium analyses may be calculated using computer software or by hand.

Soil–structure interaction analyses require the use of specialist software. In such analyses the initial stresses in the ground are established, and the sequence of construction is modelled. At each stage, changes are made to the model to disrupt the equilibrium of the system, for example soil is excavated or a support removed, and the calculation models the deformation of the system and the mobilisation of stresses in the ground and the structure as the analysis attempts to restore equilibrium. These analyses therefore directly calculate the earth pressure that is generated around the wall and the associated wall and soil movement.

A discussion of the relative merits of limit-equilibrium and soil–structure interaction analyses are given in *CIRIA C580* (Gaba *et al.*, 2003).

64.4.5.1 Limit-equilibrium analysis

For a limit-equilibrium analysis, earth-pressure profiles are based on established mechanisms, and the selection of the appropriate earth-pressure distribution depends upon the design situation. The established mechanisms for two common situations: cantilever and propped walls are illustrated in **Figure 64.10**.

For the fixed-earth mechanism the wall is assumed to rotate about some pivot point in the ground. Above this point, the earth pressure on the retained side is assumed to be at the active limit and the earth pressure on the excavated side is assumed to be at the passive limit. To ensure rotational and lateral stability can be achieved, below the pivot point this is reversed so that

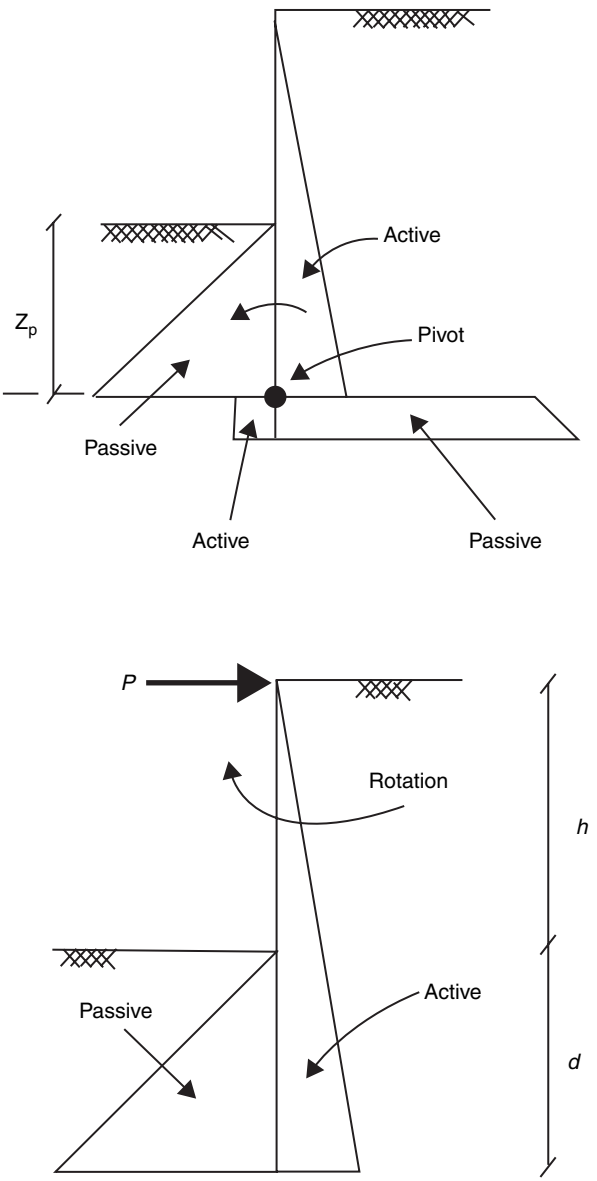

Figure 64.10 Limit-equilibrium earth-pressure distributions. (a) Fixed earth – cantilever. (b) Free earth – propped wall

on the retained side the pressure is at the passive limit and the pressure on the excavated side is at the active limit. The stability of the wall is verified by considering the moment equilibrium about the assumed pivot point, and the equilibrium of the assumed horizontal forces. To achieve equilibrium, an iterative calculation is required, where the toe and pivot points are varied until equilibrium is achieved. This process is best performed by specialist wall analysis software or a spreadsheet.

A simplification of the calculation is often adopted for hand calculations. In this case the length of wall below the pivot point is replaced by an assumed resultant force, R, as illustrated in **Figure 64.11**.

The depth to the pivot point, d_0, is then varied until moment equilibrium is achieved and the magnitude of the resultant, R, that is required for horizontal stability can be calculated. To ensure the wall is long enough to ensure stability, the toe of the wall is generally assumed to be 20% deeper than the pivot point, i.e. $1.2d_0$. It is recommended that this length of wall below the pivot point is sufficient to mobilise a reaction that is greater than the assumed resultant force, R.

The free-earth condition is simpler to assess as it is assumed that the wall rotates about the level of the prop. The earth pressure on the retained side is therefore assumed to be at the active limit and the earth pressure on the excavated side is assumed to be at the passive limit. To verify stability, moments are taken about the assumed pivot point and the toe of the wall varied until equilibrium is achieved. Any imbalance in the lateral pressure acting on the wall is taken up as a reaction in the prop.

For either mechanism, once the stability of the system has been verified, the earth pressure arising from that analysis is used to derive the action effects (e.g. bending moments and shear forces) in the wall.

Design values of soil parameters should be used when determining the values of the limiting earth-pressure coefficients that are inputs into the calculation. DA-1, Combination 1 and Combination 2, will therefore yield different results for the wall length, pivot points and prop forces. This is because the different partial factors on material properties and actions will lead to different limiting earth-pressure coefficients and imposed load effects. In terms of wall length, the longer wall from the two combinations should be adopted in the design.

The use of limit-equilibrium methods to derive design action effects where the length of the wall is fixed by criteria other than rotation or lateral stability, such as to achieve water cut-off or for vertical load capacity, requires further consideration. The toe level required for the limit-equilibrium mechanisms to achieve an equilibrium condition will be different to the wall toe level required to satisfy the other criteria. Load effects will therefore not be calculated for the full length of the wall. This may be overcome by deriving the equilibrium earth pressure and load effects in the wall based on the limit-equilibrium analysis, and then extrapolating the load effects down to the actual required toe level, as illustrated in **Figure 64.12**. This approach also applies to the SLS condition, where the toe level from the limit-equilibrium analysis will be shorter than from the ULS analysis, therefore the SLS load effects need extrapolating to the ULS toe level.

If this extrapolation of the load proves to be a critical consideration in the wall design, it may be appropriate to consider using soil–structure interaction methods as described below.

A further limitation of the limit-equilibrium method is the lack of arching or earth-pressure redistribution in the assumed earth-pressure profile. This is particularly relevant for a wall propped at or near the top where there is a risk of underestimating the prop loads. This is discussed further in section 64.4.7 below.

64.4.5.2 Soil–structure interaction analysis

As noted above, in a soil–structure interaction analysis, the earth pressure acting on a wall is calculated using computer

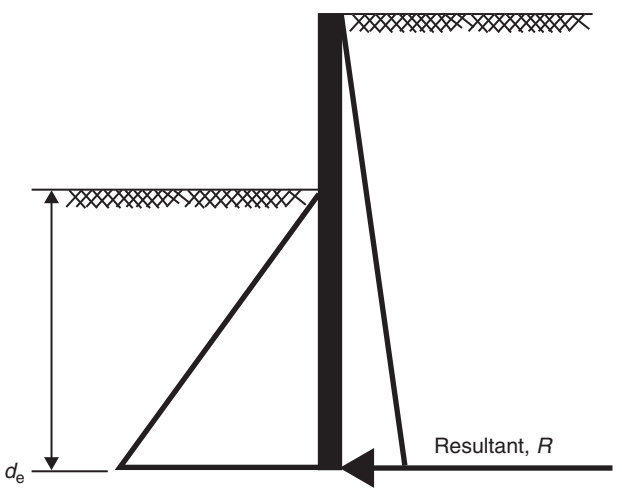

Figure 64.11 Simplification of the fixed-earth mechanism

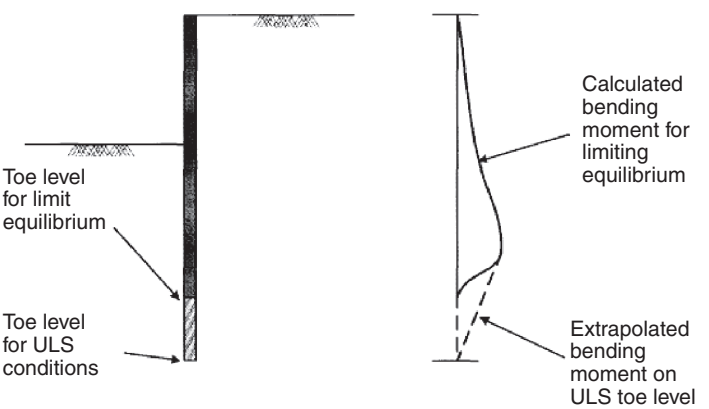

Figure 64.12 Extrapolation of load effects from limit-equilibrium analysis

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

software. A number of different methods of soil–structure interaction analysis are available:

- Sub-grade reaction (e.g. Geosolve WALLAP);
- Pseudo-finite element (e.g. Oasys FREW, Geosolve WALLAP);
- Finite element and finite difference (e.g. Plaxis, FLAC, Oasys SAFE).

This chapter does not go into the detailed theory behind the different methods and the method of software operation, as these are dependent upon the program used. However, the main considerations to be taken into account for a soil–structure interaction analysis are presented below.

Unlike a limit-equilibrium analysis, the *in situ* stresses are an important input for a soil–structure interaction analysis. Typically the software will require a value of the at-rest earth-pressure coefficient, K_o, for each soil layer.

One benefit of a soil–structure interaction analysis is the potential for modelling the sequence of construction. The sequence in which a wall is constructed will affect the earth pressure that is generated in the soil adjacent to the structure and therefore the action effects acting on the wall. The stages of the construction sequence that are to be modelled should therefore be established when the design situations are considered.

During analysis of the construction sequence, time effects can also be taken into account. This would include allowing fine-grained materials to behave in an undrained manner in the short term, but as drained materials in the longer term. Creep and corrosion of structural components may also be modelled and it is important that such effects are represented in the software after following the recommendations in the user manual.

It is important to read and understand the technical basis upon which any software carries out calculations to ensure that the correct assumptions and inputs are made for the analysis. It is also crucial that the output is checked carefully. With a complex analysis, it can be difficult to understand its theoretical basis and there is a danger that output is accepted without being critically reviewed. Before accepting the results of a soil–structure interaction analysis the user should consider whether the results are as expected – does the earth pressure look reasonable? How much of the soil is at the active or passive limit? Does the mode of deformation look reasonable? It is useful to relate the results back to a limit-equilibrium analysis of the same problem, where possible.

One particular difficulty with a soil–structure interaction analysis is the determination of the limiting stability, such as would be required when shortening a wall to find the minimum length that is stable. Whether or not an analysis converges will depend upon the number of iterations specified and the magnitude of any convergence tolerances specified in a particular program. Often an analysis may indicate that it has converged, which could lead the user into thinking that the wall is stable, however, if excessive deformation has occurred in order to reach convergence, it may be considered that the wall has actually failed, despite reaching convergence. Again this should be picked up when checking the detailed output of an analysis.

64.4.5.3 Other influences on earth pressure

The preceding sections outline the basic failure mechanisms assumed in limit-equilibrium analysis, and the general approach to soil–structure interaction analysis necessary to calculate the earth pressure acting on a wall. However, there are a number of additional factors that will influence the basic approach that need to be taken into account when assessing the actions acting on an embedded wall. These are discussed below.

64.4.5.4 Wall–soil friction

The interface friction angle between the soil and the wall structure will affect the limiting earth pressure that is mobilised adjacent to a wall. The magnitude of the soil–wall interface friction angle will depend upon the ground conditions and the wall type. The direction of the wall–soil interface friction angle will depend upon whether the wall is carrying a vertical load. For the conventional case, on the retained side the soil slumps downward relative to the wall, giving an upward reaction on the wall–soil interface, whereas on the excavated side the soil heaves upward relative to the wall giving a downward reaction. See **Figure 64.13**. Useful guidance on the use and interpretation of a soil–structure interaction analysis is given in Chapter 6 *Computer analysis principles in geotechnical engineering*.

If, however, the wall is carrying a vertical load, upward shear stresses need to be mobilised on the wall–soil interface in order to support the applied loads. Over the retained height of the wall it may be considered that the soil and wall move downwards together – generating no net friction at the interface. The resistance to the applied load therefore comes from the embedded portion. On the excavated side this corresponds to a reversal in the direction of the interface friction direction in relation to the conventional case. This is important as it can significantly reduce the limiting values of the passive resistance

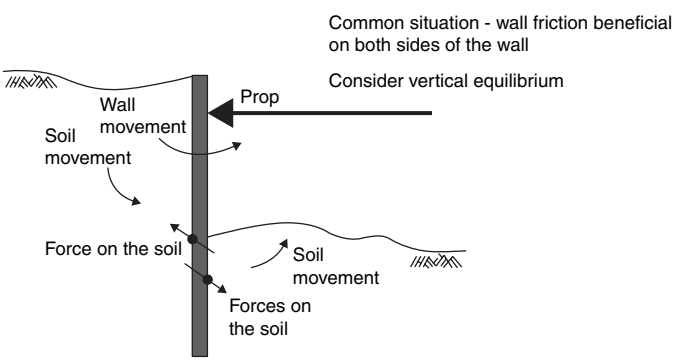

Figure 64.13 Common situation for wall friction

and may therefore increase the length of wall required for stability. Further details of walls carrying vertical loads are given in Chapter 62 *Types of retaining walls* as part of complete underground structures.

64.4.5.5 Passive softening

During excavation of the ground in front of a wall, the soil providing lateral stability for the wall is unloaded vertically. If this soil is undrained fine-grained material, there is a risk that the unloading will lead to a softening of the soil near the surface of the excavation as the excess pore pressure is dissipated. Any such softening will reduce the passive resistance available for wall stability and may therefore increase the required wall length. It is recommended that the value of the undrained shear strength at the surface of an excavation in fine-grained soils is taken as zero, rising to the design value of undrained shear strength at some depth, L, within the soil block, as illustrated in **Figure 64.14**. Where there is no potential for groundwater recharge this depth may be taken as 0.5 m. In other situations it may be taken as:

$$L = \sqrt{(12 c_v t)} \tag{64.4}$$

where recharge occurs at the excavation level but where there is no recharge within the soil. c_v is the coefficient of consolidation and t is the elapsed time.

Consideration should also be given to the potential effects of excavation unloading deeper in the soil mass.

64.4.5.6 Tension cracks

In fine-grained materials modelled with undrained shear strengths, there is a theoretical potential that on the retained side the active limit will be negative. Since soil cannot sustain tensile stresses, there is the potential for a crack to open up between the soil and the wall. In this zone the pressure upon the wall would be zero. Consideration must be given to such tension cracks becoming flooded with water, for example due to perched water on top of a clay layer. If a tension crack becomes flooded the pressure acting on the wall will be the hydrostatic pressure of the water in the crack. Even if there is no obvious source of water, it may not be appropriate to rely on a tension crack exerting zero pressure on the wall. In such cases it is common to limit the minimum pressure that is assumed to act on a wall to a minimum equivalent fluid pressure (MEFP). In dry conditions, the MEFP is typically taken as $5z$, where z is the depth below the retained ground surface. Water-filled tension cracks and the assumption of MEFP are illustrated along with passive softening of the ground in **Figure 64.14**.

64.4.5.7 Sloping ground

Sloping ground, either in front of or behind a wall, can significantly affect the pressure acting on the wall. BS EN 1997-1:2004 gives analytical and graphical methods for calculating the earth-pressure coefficients for sloping ground. A difficulty arises when the slope is uneven or of limited extent. In such situations, if approximating the profile to an infinite slope is unreasonably conservative, one of the following methods may be considered:

- Carry out a Coulomb wedge analysis to determine the active lateral thrust at different depths down the wall.
- Model the effect of the slope as a series of surcharges. It is noted that this method does not model the active thrust within the slope above the top of the wall. The active thrust should therefore be quantified separately and applied as an imposed force at the top of the wall.

64.4.5.8 Reverse passive

During excavation of the ground in front of a wall propped close to the top, the section of wall above the prop tends to rotate backwards into the retained soil. In a soil–structure interaction analysis this can mobilise an earth pressure up to the passive limit close to the top of the wall. In this zone, however, the soil is generally moving down relative to the wall (giving a negative value for the wall–soil interface friction, based on the standard sign convention for K_p), therefore it is important that the value of K_p applied over the soil zone near the top of the

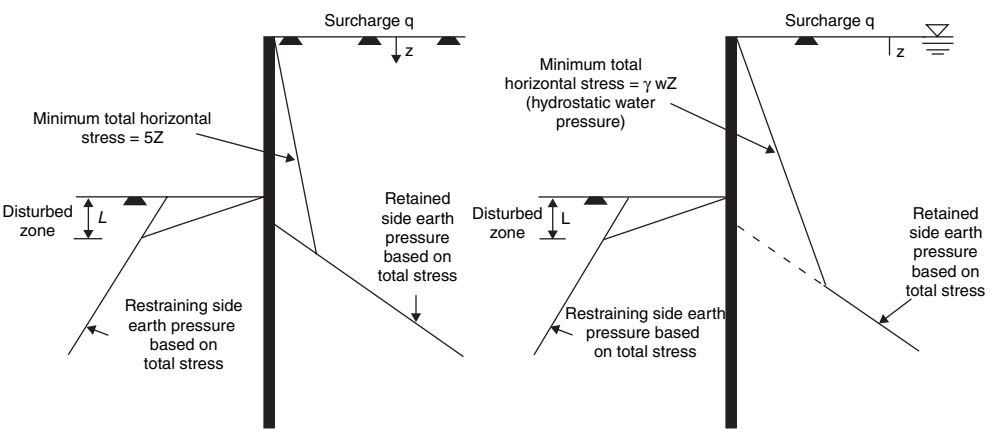

Figure 64.14 Passive softening and tension cracks. (a) Undrained conditions: dry tension cracks. (b) Undrained conditions: flooded tension cracks

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

wall takes this into account. It is generally found that a value of $K_p = 1$ is appropriate.

A limit-equilibrium analysis will not incorporate the reverse passive pressure near the top of the wall as the assumed pressure profile does not include it. The absence of this increased pressure is the main reason that limit-equilibrium analyses underestimate prop forces in a wall support system. A model factor should be applied to the calculated limit-equilibrium prop force to ensure the design is robust. Further details are given in section 64.4.7 below.

64.4.5.9 Multi-propped walls

Where walls are propped by more than one level of support, instability of the wall due to rotation or translation is not a concern, provided the structural design of the wall and the support system is adequate. However, to design the wall and the support system it is still necessary to calculate the earth pressure acting on the wall. Limit-equilibrium analysis is not particularly well suited to multi-propped situations, though some approaches are discussed in *CIRIA C580* (Gaba *et al*., 2003). In general, it is recommended that for multi-propped walls a soil–structure interaction analysis is undertaken, with the sequence of prop installation and excavation being modelled.

64.4.5.10 Wall and soil stiffness

Whilst not required for a limit-equilibrium analysis, wall and soil stiffness are important inputs in a soil–structure interaction analysis. It is important that the stiffness adopted is appropriate for the level of strain anticipated in the soil. Generally for retaining wall design this strain will be lower than for foundation design, therefore higher values of stiffness may be justified. In all cases the resulting wall and soil movements arising from the analysis should be verified against comparable experience, such as the wall and soil movement case histories presented in *CIRIA C580* (Gaba *et al*., 2003) or other technical papers, to ensure that the assumptions are reasonable.

Modelling wall and prop stiffnesses should take into account any time related effects. For example the bending stiffness of a reinforced-concrete wall is given as E_oI, where E_o is the short-term Young's modulus of the reinforced concrete and I is the second moment of area. However, as soon as a wall is loaded by bending, cracking will occur on the side of the wall that is in tension, which acts to reduce the stiffness of the wall that is bending. In the absence of a detailed calculation it is recommended that a value of $0.7E_oI$ is taken as the initial stiffness of the wall. In the long term, reinforced-concrete walls have the potential to creep due to strain at constant stress. Typically the long-term bending stiffness is taken as $0.5E_oI$.

In steel retaining walls, a reduction in stiffness may occur due to corrosion of the steel over the lifetime of the structure.

Modelling changes in wall stiffness between the short and long term needs to be appropriate to the software being used, and the user should consult the specific guidance for the software. In general, it is not acceptable to simply change the wall stiffness at any stage of the analysis.

64.4.5.11 Thermal effects

Temperature variations can lead to expansion and contraction of support systems, which may induce additional loads on the structure. In general this is more likely to be significant where the support system is exposed to atmospheric conditions, such as during construction, especially where temporary steel props are used. A method for calculating thermal effects on props is given in section 64.4.7 below.

Thermal effects may be significant for integral bridges (bridges without movement joints between the deck and the abutments). In these cases the abutment walls are subject to cyclic expansion and contraction that can lead to strain ratcheting – an effect that increases the earth pressure behind the wall. Specific guidance for the analysis and design of integral bridges is given in the *Design Manual for Roads and Bridges* (Highways Agency, 2000).

64.4.5.12 King post walls

King post walls are a specific type of embedded wall. It is generally assumed that retaining walls are a plane-strain problem and therefore the calculations are generally carried out on the basis of a 'unit length' of wall. King post walls, however, derive support from discrete elements embedded at a fixed spacing, s. Where s is less than three times the diameter of the support element, it may be appropriate to assume plane-strain conditions, however, for wider spaced supports a different approach is required, which is set out in *CIRIA C580* (Gaba *et al*., 2003) and summarised below.

The individual support elements should be designed individually to resist the calculated lateral loads. Full active conditions should be assumed behind the retaining wall. The passive resistance in front of the wall may be taken as follows (taken from Gaba *et al*., 2003; Equations (4.14) to (4.17)):

'The king posts should be designed as piles in lateral loading, with an ultimate net effective resisting force P'_a per metre length of

$$P'_a = K_p.b.p'_v/s \quad at\ embedment\ depths\ z \le 1.5b \qquad (64.5)$$

and

$$P'_a = K_p^2.b.p'_v/s \quad at\ embedment\ depths\ z \le 1.5b \qquad (64.6)$$

where b is the king post width, s is the spacing of the king posts ($s > 3b$), K_p is the passive earth-pressure coefficient ($K_p > 3$) defined as $(1 + \sin \varphi') / (1 - \sin \varphi')$, and p'_v is the effective overburden pressure at depth (Fleming *et al*., 1994).

The above expressions for P'_a are based on the work of Barton (1982) as reported by Fleming *et al*. (1994) and are considered applicable for K_p values of between 3.0 and 5.3 (i.e. $30° \le \varphi' \le 43°$).

In a total stress analysis, the ultimate net lateral resisting force per metre length P_u is given by Fleming *et al*. (1994) as:

$$P_u = \left[2 + \left(7z/3b\right)\right].s_u.b/s \quad at\ embedment\ depths\ z \le 3b \qquad (64.7)$$

and

$$P_u = 9.s_u.b/s \quad at\ embedment\ depths\ z \le 3b \qquad (64.8)$$

where b is the king post width, s is the spacing of the king posts ($s > 3b$), and s_u is the undrained shear strength at embedment depth z.'

This is illustrated in **Figure 64.15**.

64.4.5.13 Unplanned excavation

When assessing the geometry for a given design situation, it is important to take into account the possibility of an unplanned excavation in front of the wall. This is particularly critical for an embedded wall, where the passive resistance of the ground is necessary for stability. BS EN 1997-1:2004 requires that for normal site controls, 10% of the retained height, up to a maximum of 0.5 m, should be assumed for unplanned excavations.

64.4.5.14 Surcharges and direct loads

The design of a retaining wall should consider the possibility of surcharges being applied to the ground retained by the wall. Such surcharges may arise, for example, from traffic in the permanent condition, plant loading during the construction phase or from the placement of stockpiled materials behind the wall. The effect of such surcharges must be incorporated into the assessment of the earth pressure acting on the wall.

The method of modelling a surcharge will depend on how the wall is analysed. Where specialist software is used, the user manual should be consulted to ensure the surcharges are properly modelled. Uniformly and non-uniformly distributed loading, such as loading over a limited area, line load and point loads, can be modelled directly in a limit-equilibrium analysis. *CIRIA C580* (Gaba *et al*., 2003) gives different methods for determining the limiting lateral pressure due to non-uniformly distributed loads.

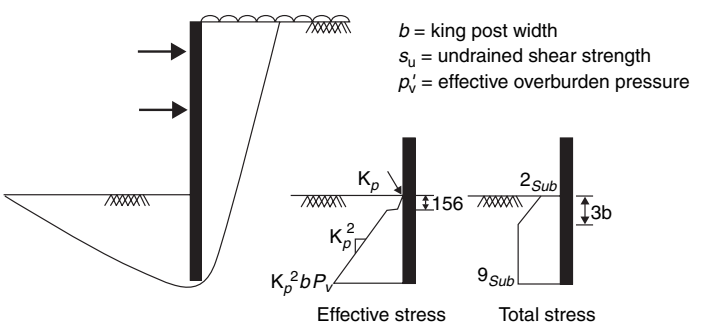

Figure 64.15 King post wall design. (a) Overall stability. (b) Lateral loading of individual king posts

BS 8002 (British Standards Institution, 1994b) has a requirement to consider a minimum 10 kPa surcharge behind a wall. Although this is not an explicit requirement in BS EN 1997-1:2004, for most walls some allowance should be made and 10 kPa is considered a reasonable value.

64.4.5.15 Groundwater

Understanding the groundwater conditions is crucial to embedded retaining wall design. Since the water pressure directly influences the effective stresses, and hence strength, of the ground, applying a partial factor on the water pressure may lead to unreasonable design situations. In order to ensure a margin of safety is achieved, it is recommended that a margin is applied to the groundwater levels upon which the pore pressures are based. The approach for selecting the groundwater level differs in DA1-1 and DA1-2. In DA1-1, the actions of water on the structure are factored by a value greater than unity. Whereas in DA1-2, the factor on permanent actions is unity. This means that for DA1-2, no factors are applied to the effect of water so it is recommended that a suitably cautious design water pressure is derived from a directly assessed design groundwater level, defined as:

> (1) Water pressure and seepage forces that represent the most unfavourable values, which could occur in extreme or accidental circumstances at each stage of the wall's construction sequence and throughout its design life. An example of an extreme or accidental event may be a burst water main in close proximity to the wall.

For DA1-1, a factor greater than unity is applied to water effects, so it is considered that a less cautious assessment of the groundwater level may be used than for DA1-2. The recommended approach is defined as:

> (2) Water pressures and seepage forces that represent the most unfavourable values likely to occur in normal circumstances at each stage of the wall's construction sequence and throughout its design life. Extreme events such as a nearby burst water main may be excluded, unless the designer considers that such an event may reasonably occur in normal circumstances.

When selecting the design groundwater levels, consideration must be given to any potential effect the construction of the embedded wall may have on the groundwater regime. For example, if the wall penetrates a layer of flowing groundwater, there may be a 'dam' effect that leads to a rise in groundwater levels adjacent to the wall. Conversely the installation of drainage within a basement may lead to a lowering of the equilibrium groundwater level. Such effects need to be considered in the design of the wall, and possible effects on adjacent structures must also be considered.

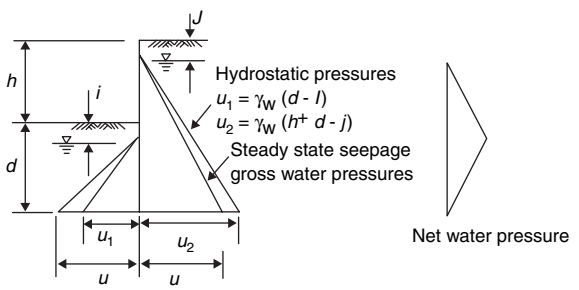
Where differing groundwater levels are identified on each side of a retaining wall, the potential for seepage around the wall must be investigated, as this will have an effect on the pore pressures assumed to act along the length of the wall. Where an impermeable wall penetrates an impermeable stratum, the assumption of unbalanced pore pressures at the toe of the wall

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

may be acceptable. However, in many situations, especially over the design lifetime of a structure, since the wall and the soil have a finite permeability there will be seepage around the wall and generation of non-hydrostatic pressure profiles.

In order to assess the pore pressures acting on the wall accurately, it may be necessary to undertake a seepage analysis. However, there is also a commonly adopted simplification to the seepage problem that has been developed on the basis of isotropic permeability and wide excavations. For this to be applied, the design must verify that these simplifying assumptions are reasonable. The method of calculating this simplified linear seepage profile is given in **Figure 64.16**. Further details of the effect of seepage on retaining wall design are discussed in *CIRIA Special Publication 95* (Williams and Waite, 1993).

64.4.6 Design of structural elements



The load effects from either the limit-equilibrium or soil–structure interaction analyses should be used in the structural design of a wall.

64.4.7 Design of propping systems

The design of propping systems is covered in Chapters 65 *Geotechnical design of retaining wall support systems* and 66 *Geotechnical design of ground anchors*. Careful consideration must be given to determining the design load effects that are to be used in the propping design. In general these will be derived from the reactions calculated in the retaining-wall analysis. However, there may be additional factors that need to be taken into account to ensure a robust solution is achieved.

64.4.7.1 Limit-equilibrium prop loads

As noted in section 64.4.5 above, the limit-equilibrium method for propped walls does not consider soil arching or redistribution of the earth pressure. This can lead to a significant underestimate of the prop loads that may be appropriate for use in design. Whilst this is conservative for the wall design, it is not conservative for prop design. *CIRIA C580* (Gaba *et al.*, 2003), therefore, recommends that a model factor of 1.85 be applied to the support reactions derived from a limit-equilibrium analysis to ensure a robust design is achieved.

= Assumption (1)
Uniform dissipation of differential head along flow path adjacent to the wall

$$u = \frac{2(d + h - j)(d - j)}{2d + h - i - j}$$

= Assumption (2)
Average hydrostatic pressure at wall toe

$$u = \frac{u_1 + u_2}{2} = \gamma_w \left| d + \left(\frac{h - i - j}{2} \right) \right|$$

Figure 64.16 Simplified approach for calculating the linear steady-state seepage water pressure

64.4.7.2 Distributed prop load method

A method for deriving design actions for a temporary prop design is the distributed prop load (DPL) method. This method is outlined in *CIRIA C517* (Twine and Roscoe, 1999) and is based on extensive field measurements of prop loads for flexible and stiff walls and for the range of ground conditions commonly encountered in the UK. Where the DPL method is adopted, the results should be compared against the findings of the wall analysis for the comparable temporary case. Where the prop loads differ between the two methods the designer should consider the reasons for the difference and adopt appropriate values in the design of the temporary props

64.4.7.3 Thermal effects

As noted in section 64.4.5 above, thermal effects can increase the design load effects for props and retaining walls. The effect on props due to thermal variations can be calculated as follows:

An increase or decrease in the temperature of a prop from its installation temperature will cause the prop to expand or contract according to the relationship:

$$\Delta L = \alpha . \Delta t . L \qquad (64.9)$$

where: ΔL = change in prop length

α = thermal coefficient of expansion for the prop material

Δt = change in prop temperature from the installation temperature

L = prop length

If the prop is restricted or prevented from expanding freely, an additional load is generated in the prop. The magnitude of this addition load is:

$$\Delta P_{temp} = \alpha . \Delta t . E . A . (\beta/100) \qquad (64.10)$$

where: E = Young's modulus of the prop material

A = cross-sectional area of the prop

β = percentage *degree of restraint* of the prop

(70% for stiff walls in stiff ground and 40% for flexible walls in stiff ground).

The designer should select the appropriate value of β to suit particular project circumstances. Values other than those generally

recommended above may be applied where the designer is confident that such values can be justified, e.g. on the basis of comparable experience.

64.4.8 Ground movement

Excavation in front of an embedded wall will lead to movement of the wall and the ground around the excavation. Where sensitive infrastructure or buildings are in close proximity to the wall, there is a risk of damage if movement is not limited. A check of the ground movement caused by the construction of an embedded wall is often required as part of the verification that SLS criteria have not been exceeded.

Methods for predicting ground movement are discussed in detail in Chapter 63 *Principles of retaining wall design*.

64.4.9 Design method

The preceding sections outlined how the various loads that may act on a wall can be assessed. Once these actions have been identified, it is necessary to analyse the wall to verify that the limit states identified in section 64.4.2 above will be avoided. For a soil–structure interaction analysis, an iterative approach is necessary, where an initial estimate of the wall geometry is made and stability against each failure mode is checked. The geometry of the wall may then be adjusted to optimise the solution while still ensuring stability. Such analysis and iteration is likely to require proprietary software.

This section outlines the stages in the design process for an embedded wall. These stages are illustrated by the flowchart in **Figure 64.17** and described below.

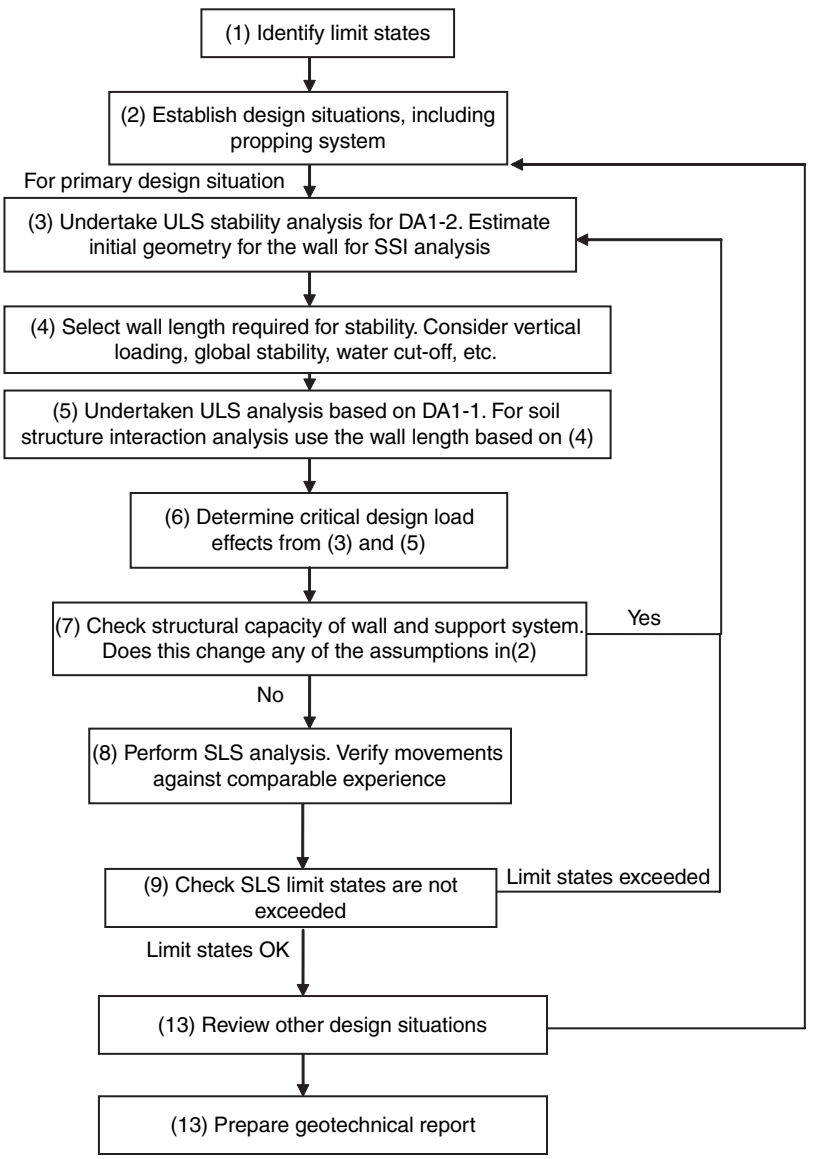


Figure 64.17 Embedded wall design process

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(1) Confirm the relevant limit states for the problem, as identified in section 64.4.2. For serviceability limit states agree the deflection limits or other criteria that are to be adopted.

(2) Identify the design situations to be considered in the analysis, considering the issues described in section 64.4.4, and make an assumption regarding the anticipated support system for the wall. Select an initial situation to analyse.

(3) Carry out a ULS analysis of the wall stability (Design Approach 1, Combination 2). For a soil–structure interaction analysis, an initial size for the wall must be assumed. In such cases it may often be appropriate to carry out a limit-equilibrium analysis to make an initial estimate of the required wall length.

(4) On the basis of (3), select the design length of the wall. For a soil–structure interaction analysis, step (3) may need to be iterated to optimise the solution. Consider whether other factors, such as global stability, vertical stability or water cut-off requirements will be critical for the wall length.

(5) Undertake a further ULS analysis (DA1-1) based on the geometry from (4).

(6) Consider the load effects from (3) and (5) and determine the design load effects in the wall and the support system.

(7) Undertake the structural design of the wall and support system. Consider whether this changes any of the initial assumptions (e.g. wall stiffness, support levels or support stiffness). If so, return to step (3) and re-analyse.

(8) Undertake SLS analysis to estimate wall movements. Validate against comparable experience or case history data, such as that presented in *CIRIA C580* (Gaba *et al.*, 2003).

(9) Check SLS limits are not exceeded. If they are, return to step (3).

(10) Review other design situations.

(11) Prepare the geotechnical report.

65.7	Other systems of wall support	1008
65.8	References	1009

As identified in Chapter 62 *Types of retaining walls*, embedded retaining walls gain lateral support from passive resistance of the soil in front of the embedded section of the wall, while gravity walls gain lateral support from passive resistance and friction of the soil on the underside of the wall. These walls may also rely on anchorages, props or other sources of additional lateral support for stability.

Many different forms of support systems are available with different properties; these vary from strength, stiffness and constraints to working conditions within the excavation. An understanding of these different properties as well as the site-specific constraints and characteristics is required to determine the most suitable support system for a project.

This chapter provides the reader with an overview of different methods of providing lateral support to both gravity and embedded retaining walls.

65.1 Introduction

Embedded retaining walls gain lateral support from passive resistance of the soil in front of the embedded section of the wall, while gravity walls gain lateral support from a combination of passive resistance and friction of the soil on the underside of the wall. Under many circumstances it is necessary to provide additional lateral support to the wall, to restrict the lateral movement of the wall, or to provide a more economical retaining wall solution.

This chapter presents the design and performance criteria to be considered by the designer as well as the advantages and disadvantages of adopting different methods of lateral support.

Key references for retaining wall support systems include:

65.2 Design requirements and performance criteria

Support to a retaining wall must be considered during all stages of the life of the retaining wall. In many cases, the temporary conditions during construction, which are dependent upon the sequence of construction adopted, can be more onerous than the permanent conditions and therefore critical for the design of the wall.

65.2.1 Temporary situations

Temporary situations predominantly occur during construction but can also relate to later activities such as major remedial or refurbishment works. It is very common for the stability of a basement embedded retaining wall to be dominated by the temporary condition, as the excavation reaches its maximum depth – but before the lowest permanent basement slab is constructed. Similarly the construction or maintenance of drainage in front of gravity retaining walls can be a dominant condition for stability.

65.2.2 Permanent situations

In the permanent situation or condition, retaining walls may be provided with any permanent support systems – such as slabs or permanent anchors – which will need to be designed to resist the lateral loading appropriate to the full design life of the wall.

65.2.3 Bottom-up/top-down construction sequences

For basement excavations using embedded retaining walls, two different sequences of construction may be adopted, as identified in Chapter 63 *Principles of retaining wall design*.

The *bottom-up construction sequence*, in its simplest form, consists of a cantilever retaining wall supporting the ground surrounding the excavation, followed by construction of the permanent works within the cantilever excavation. However there are many situations when additional temporary support, often in the form of temporary props or ground anchors, are utilised to supplement the earth pressures on the passive side of the wall during excavation. Following excavation, the permanent works are constructed within the excavation; the temporary support is subsequently removed once the permanent works are in place and to provide sufficient lateral restraint.

Top-down construction is defined by the use of the permanent internal structure of a basement to prop the retaining wall during excavation without the reliance on temporary propping

systems. To achieve this, the higher level slabs are constructed before the excavation progresses below the slab level and before casting the lower level slabs.

65.2.4 Control of ground movements

Ground movements result from both the installation of the retaining wall and the excavation. Control of ground movements is important in urban settings where buildings and infrastructure such as utilities are in close proximity to an excavation and will incur damage from ground movements. The magnitude of ground movements due to excavation in front of a retaining wall is dependent upon the stiffness of the wall and support systems. As such, the requirements for the control of ground movements may be critical in the selection and design of retaining wall support systems.

65.2.5 Accidental conditions

Accidental conditions, for example, leading to the loss of a support element such as a prop or anchor, should be considered in the design. The loss of one support element will shed loading into adjacent support elements. If these are not designed to resist this additional loading, they too may fail – leading to progressive loss of support elements and therefore excessive deflection if not progressive collapse of the retaining wall.

65.2.6 Design responsibility

The responsibility for the design of both the retaining wall and any lateral support will not always lie with the same party and therefore must be clearly defined. Situations where there is likely to be more than one design party involved include the following:

- *Temporary retaining wall* A temporary wall may be used to form an excavation, into which the permanent structure will be constructed. Performance criteria, such as the maximum wall deflection to ensure that the wall does not impinge on the permanent works, need to be clearly defined for the designer of the temporary wall. The temporary wall design will also need to consider the proposed construction sequencing to minimise constraints placed by the temporary works on the construction of the permanent works. The staging of the temporary works, for example the removal of temporary propping, can affect the permanent works. As such, the design of both the temporary and permanent works must fully account for any restrictions or reliance placed on one system by the other.
- *Permanent retaining wall with temporary support* For basement excavations it is not uncommon to utilise the permanent embedded retaining wall with temporary propping or anchoring during excavation and construction of the basement. The design loading acting on the retaining wall during construction will be very dependent on the strength, stiffness and sequence of installation and removal of the temporary support system. In this situation, the designer of the permanent wall will need to inform the designer of the temporary support system of the assumptions made regarding the strength, stiffness and staging of the temporary works in the design of the permanent works. If the temporary support designer is unable to satisfy these requirements, then the design of the permanent works, temporary works or construction staging will need to be modified to achieve a coordinated temporary and permanent works design solution.
- *Specialist lateral support* The permanent works designer may not possess the relevant specialist design skills for some of the methods of lateral support. Alternatively, a specialist contractor may provide additional value to the project by undertaking the design of the permanent lateral support to a wall. For this situation, key design assumptions of strength, stiffness, maximum wall deflection, construction staging and design life must be clearly communicated by the permanent works designer to the specialist designer to achieve a coordinated design solution.

65.3 Types of wall support systems

Many different forms of wall support systems can be used for retaining walls. Some of the more common types of wall support systems are briefly described below:

- *Cantilever* The retaining wall relies only on the passive ground resistance or sliding resistance of the wall and therefore has no additional wall support system.
- *Single support* A single level of support is provided to the retaining wall. The introduction of additional support will reduce the loading in the wall and therefore reduce its size, compared to a cantilever wall. It will also increase the stiffness of the excavation support system and therefore reduce ground movements behind the wall. As such, support is typically adopted either where the excavation depth is too deep for an economic cantilever wall with where a cantilever wall would result in unacceptably large wall deflections and associated ground movements, or where the introduction of support results in an overall saving for the project.
- *Multiple support* For deeper excavations, a single level of support is not sufficient to provide the strength and stiffness required to retain the ground behind the wall with acceptable wall deflections and associated ground movements; therefore several levels of support are required.
- *Circular construction* Retaining walls, constructed in a circular layout, derive support from hoop action due to the shape of the wall layout and excavation. For walls which provide a solid cross-section such as secant walls or diaphragm walls, support is likely to be provided by hoop action through the wall itself. In other situations, a continuous ring waling beam will be required to provide the hoop action.
- *Buttressed walls* A buttress is a local thickening of a gravity retaining wall. It acts to increase the stiffness of the wall and also to improve the resistance of the wall, particularly to overturning. Buttresses are more commonly provided to masonry walls and form an architectural feature to many historical masonry buildings and walls.
- *Temporary props* Props consist of steel sections, typically (but not always) orientated perpendicular to the line of a retaining wall. They provide lateral support by acting in compression, transmitting loading from the retaining wall on one side of the excavation onto a retaining wall on the opposite side, or onto another source of resistance.
- *Ties* Support to a retaining wall can also be provided by tying it back to another structure using a steel rod. The ties can be

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

connected back to an object such as a mass concrete block which relies on friction and passive resistance of the ground between the block and the wall to resist the tie force. They can also be connected back to embedded elements such as piles or other nearby embedded walls which utilise their stiffness and the passive resistance of the ground in front of the piles/embedded wall section to resist the tie loads.

- *Berms* The use of an earth berm in front of, and immediately adjacent to, a retaining wall reduces the effective depth of excavation felt by the retaining wall whilst allowing a deeper excavation within the centre of the site. Raking props from the top of the berm to a thrust block at the bottom of the excavation in the central area of the site can then be used to replace lateral support provided by the berm when excavation proceeds to full depth adjacent to the wall. Alternatively, removal of the berm down to the final excavation level and construction of the lowest slab level can be carried out in isolated sections or bays. Although there is a reduction in the lateral support provided to the retaining wall, arching in the soil and distribution of loading through the retaining wall capping beam reduces the loading and deflection that occurs on the short section or bay of wall.
- *Ground improvement* Strengthening or stiffening of the ground, particularly within the passive zone below the excavation level, can be utilised to provide support. Ground improvement methods include:
  - *Soil mixing, jet grouting or other strengthening measures* Such measures can be used to create a 'slab' of improved soil spanning between retaining walls (retaining an excavation) to provide enhanced passive restraint.
  - *Crosswalls* These are constructed using unreinforced slurry or diaphragm wall trenches and can enhance the passive strength and stiffness of the main retaining wall. Crosswalls provide enhanced passive performance at their locations, but little improvement between crosswalls. As such, they are most effectively used with diaphragm walls where a single crosswall can be provided for each diaphragm wall panel.
- *Ground anchorages* Anchors provide support to a retaining wall by transferring tension loading to a load bearing stratum behind the wall through friction over a grouted length of the anchor. Ground anchors are discussed further in Chapter 66 *Geotechnical design of ground anchors*.

65.4 Props

65.4.1 General

Temporary props are typically formed from steel sections but can also be formed from reinforced concrete. Ideally the props should be located at regular intervals along the length of the excavation using a waling beam to distribute the restraint between the individual props. Both the strength and stiffness of the propping system will be dependent on the properties of the waling beam, as well as the size and spacing of the props.

Temporary props will span across an excavation and provide a physical restriction on the working methods that can be adopted within the excavation. From program and ease of construction perspectives, there is a desire to have propping at larger intervals to minimise the restrictions on working methods. This desire needs to be balanced not only with the strength and stiffness of the propping system, but also with the practical issues related to installing and supporting large prop and waling sections.

65.4.2 Propping layout

The layout of propping will depend on the shape of the excavation (**Figure 65.1**). For long thin trough excavations, propping at regular intervals can be provided across the excavation. For rectangular basement excavation, propping will be required in two directions. This can be achieved using cross-bracing and diagonal propping in the corners.

Diagonal bracing can also be utilised to provide effective propping with an enlarged opening between props, which is often used as the location for mucking out of the excavation (**Figure 65.2**).

65.4.3 Inclined struts

Propping is typically installed horizontally. However, inclined struts can be used as raking props in conjunction with a berm solution, as described in section 65.3 above (**Figure 65.3**). They can also be used for unbalanced excavations where the excavation depth and loading is different on the opposite sides of an excavation.

65.4.4 Prop stiffness/pre-load/pre-stress

The stiffness of a propping system per metre length of wall is dependent on the Young's modulus of the propping member (E), the cross-sectional area of the member (A), the effective length of the prop (L), the angle of inclination of the prop from the horizontal (α) and the spacing of the individual props (s), and is given by:

$$k = EA\cos^2\alpha/Ls.$$

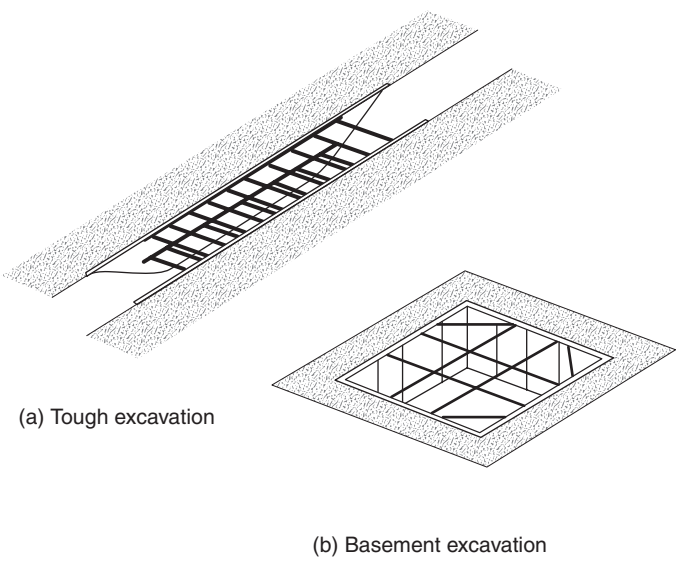

Figure 65.1 Typical excavations with temporary propping
Reproduced with permission from CIRIA C517, Twine and Roscoe (1999), www.ciria.org

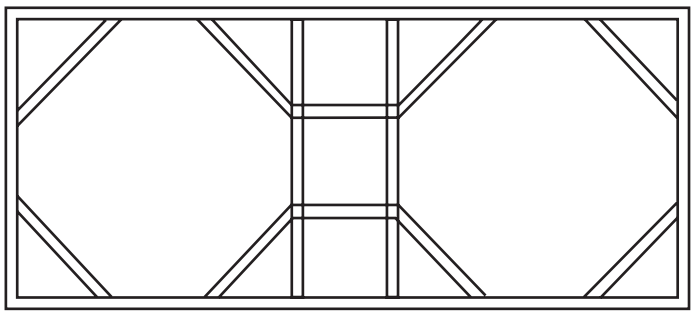

Figure 65.2 Use of diagonal bracing to provide enlarged opening for access
Reproduced with permission from CIRIA C517, Twine and Roscoe (1999), www.ciria.org

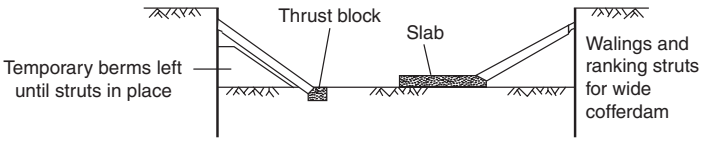

Figure 65.3 Use of inclined struts with temporary berm
Reproduced with permission from CIRIA C517, Twine and Roscoe (1999), www.ciria.org

For 'balanced' excavations, where excavation depth and loading on both ends of the prop are similar, L can be taken as the half of the excavation width. However for unbalanced or sway excavations, where the excavation depth and loading are much larger on one end of the prop, the length should be taken as the full excavation width.

Although this assessment of propping stiffness is commonly used, it is an approximation as it does not consider the influence of the waling beam on the effective stiffness of the propping system (**Figure 65.4**).

The application of pre-load or pre-stress into the propping system – typically around 10% of the design (working) load – can be used to take up the slack in the system. Higher preloading can be used to stiffen the support system to reduce wall deflections and hence movements behind the wall.

65.4.5 System stiffness

Available case history data indicate that the magnitude of horizontal wall deflection of embedded retaining walls is dependent on the effectiveness of the support system.

Clough *et al*. (1989) define system stiffness as $EI/(\gamma_w h^4)$, where I is the second moment of area of the wall section, γ_w is the bulk unit weight of water and h is the average vertical prop spacing of a multi-propped support system. Case history data indicate that wall deflections and associated ground movements are relatively insensitive to variation in wall thickness and stiffness, provided the overall system stiffness is not significantly reduced. Because of this, CIRIA C580 (Gaba *et al*., 2003) comments that economies in wall type and size can be achieved by adopting flexible walls (e.g. sheet pile walls) in stiff soils, without greatly increasing ground movements. Thus,

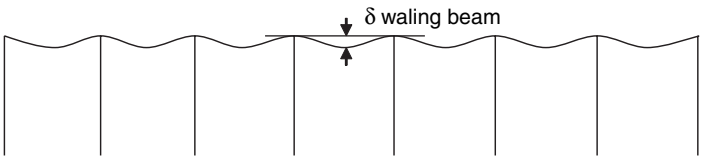

Figure 65.4 Waling beam deflection

in general, flexible walls with many props (smaller h) will give similar displacements to stiff walls with fewer props (larger h). However, it should be noted that the cost of additional propping should be offset against the cost benefit of using a more flexible wall. More extensive propping may be counterproductive, as it may slow the rate of construction and thereby increase ground movements.

65.4.6 Temperature effects

The change in length of a prop due to temperature effects depends upon the thermal coefficient of expansion (α), increase or decrease in the temperature of a prop from its installation temperature (Δt) and prop length (L):

$$\Delta L = \alpha \, \Delta t \, L.$$

In practice the waling beam, wall and retained ground at the end of the props, will restrict or prevent free expansion leading to an increase in loading within the props. The effects of temperature will be more significant for steel props in comparison to reinforced concrete due to higher values of coefficient of expansion in steel. Refer to CIRIA C517 (Twine and Roscoe, 1999) for further guidance. Thermal effects will be more pronounced for props in direct sunlight and less pronounced for more shaded lower levels of propping.

65.4.7 Accidental loading

The design of individual props should be robust and include consideration of accidental loading and the possible loss of a prop. The design needs to:

- incorporate the loss of a prop in the design of the wall and support systems; or
- provide adequate mitigation of the risk of accidental damage or loss of a prop through design changes and robust construction management strategy.

65.4.8 Buckling

Props are slender axially loaded elements. Therefore the design of props needs to consider buckling due to excessive or eccentric axial loading. For wider excavations or highly loaded props it may be necessary to provide mid-span restraint to the props. This can be provided using temporary king post piles within the centre of the excavation.

65.4.9 Determination of prop load for design

Refer to Chapter 64 *Geotechnical design of retaining walls* for the determination of serviceability limit state and ultimate

limit state prop loads using limit equilibrium and soils structure interaction methods.

Designers of temporary props may also make use of the distributed prop load (DPL) method presented in CIRIA C517 (Twine and Roscoe, 1999). The DPL method for calculating prop loads is based on the back analysis of field measurements of prop loads relating to 81 case histories, of which 60 are for flexible walls (steel sheet pile, king post walls) and 21 are for stiff walls (contiguous, secant, diaphragm walls). The case histories relate to excavation ranging in depth from 4 m to 27 m in stiff to very stiff clays, and 10 m to 20 m in coarse-grained soils.

Based on the case history data, a family of distributed prop load diagrams have been determined and are presented in CIRIA C517 (Twine and Roscoe, 1999) and summarised in CIRIA C580 (Gaba *et al*., 2003) (**Figure 65.5**). Further reference should be made to these publications for the details of the method as well as the considerations to be satisfied when using it.

65.4.10 Permanent structure propping

Permanent propping of embedded retaining walls is typically provided by permanent reinforced concrete slabs. Although the Young's modulus of reinforced concrete is lower than that of steel, the cross-sectional area of a solid slab is significantly higher than for temporary steel propping. Therefore, a reinforced concrete slab provides a stiffer support solution than temporary steel propping. This enhanced stiffness is one of the benefits of a top-down construction sequence to minimise wall deflections and hence ground movements.

The stiffness (k) of the slab to axial loading is dependent upon the Young's modulus of concrete (E), thickness of the slab (t) and effective length of the slab perpendicular to the wall (L):

$$k = Et/L.$$

As for the stiffness of temporary props, the effective length is dependent upon whether the excavation is balanced, or subject to sway loading, see section 65.4.4 above.

Large holes in the slab, for example for services, can locally influence the stiffness of the slab in supporting the retaining wall. The effect is most significant for holes adjacent to the retaining wall.

65.5 Tied systems

65.5.1 Ties and deadman anchors

Deadman anchors can be formed of either a plate section (e.g. sheet pile section) or a mass concrete block and provide restraint to a wall by means of passive resistance in front of the plate section or mass concrete block (**Figure 65.6**).

Where the passive soil zone in front of the anchor does not interfere with the active soil zone behind the main wall, the design of the main wall and the anchor can be undertaken independently of each other (**Figure 65.7**).

Ties can also be used to connect or tie a wall back to embedded elements for support; for example, raking tension piles (**Figure 65.8**). Embedded elements are able to gain passive resistance over a deeper extent than the plates or mass concrete plates used in deadman anchors. For raking elements, the resistance is provided by tension within the piles.

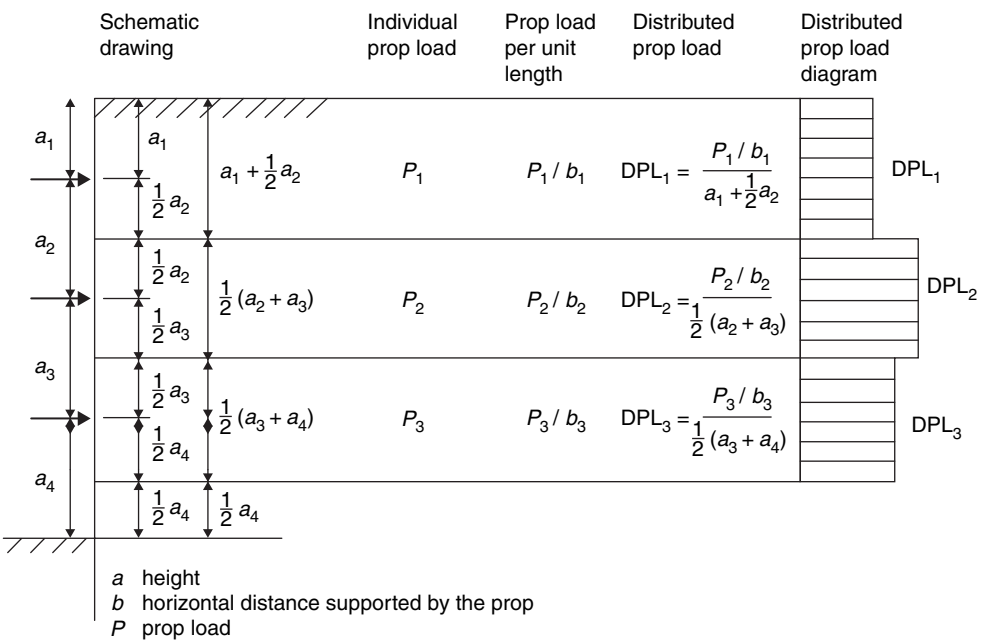

Figure 65.5 Method for calculating the distributed prop load. In order to compute prop loads from a distributed load diagram, the procedure is reversed

Reproduced with permission from CIRIA C517, Twine and Roscoe (1999), www.ciria.org

The effectiveness of a tied system will depend on the depth to which the ties and deadman anchors can be installed. This will be affected by practical considerations of excavation for the anchors. As such, tied systems are unlikely to be feasible where multiple levels of support are required; for instance, where the ground rises behind the retaining wall or where the groundwater level is high.

65.5.2 Earth-filled cofferdams

Earth-filled double-wall or cellular cofferdams are another form of tied structure. They are formed from two parallel lines of sheet pile walls connected to each other by means of waling beams and tie rods. The gap between the two lines of piling is backfilled with sand, gravel, broken rock or other coarse-grained material. Cellular cofferdams are formed by interlocking sheet pile sections to form cells which are then backfilled with coarse-grained material (**Figure 65.9**).

Earth-filled cofferdams are typically used in marine applications. The sheet piles are installed through the water and into the underlying ground before placing backfill between the rows or within the cells to above the surrounding water level. The cofferdams are designed to allow dewatering and excavation from within the area they enclose.

Further design consideration of tied systems including earth-filled cofferdams is given in BS8002 (1994), Piling Handbook (ArcellorMittal, 2008), Williams and Waite (1993) and for ground anchors, guidance is provided in Chapter 66 *Geotechnical design of ground anchors*.

65.6 Soil berms

Berms can be used to provide support to an embedded retaining wall by reducing the effective depth of the excavation.

The degree of support provided by a berm will depend on the ground conditions, the height of the berm (H), the width of the bench of the berm (B) and the angle of the berm slope (S) (**Figure 65.10**).

The slope of the berm will be governed by the soil and groundwater conditions, and for soils of low permeability, will depend on the duration for which the berm is to be relied upon

to support the wall. The height of the berm, bench width and also the slope of the berm will be influenced by the practical considerations of space and access. As such, the design of a berm will need to seek a balance between providing one of a suitably large size to provide meaningful support to the excavation, and yet be suitably small to minimise the restrictions on space and access within the excavation.

CIRIA C580 (Gaba *et al.*, 2003) comments that most methods of representing the effects of a berm in a limit equilibrium or soil-structure analysis, using sub-grade reaction and pseudo finite element methods, are semi-empirical and that this difficulty of analysis may explain why berms have often been used in conjunction with the observational method (Chapter 100 *Observational method*).

Several methods are commonly used to represent an earth berm in limit-equilibrium or soil-structure interaction analysis methods. CIRIA C580 (Gaba *et al.*, 2003) recommends the adoption of a raised effective formation level (after Fleming *et al.*, 1994) for routine analyses.

The raised effective formation level proposed by Fleming considers the berm as having a slope of 1:3 without any bench and with the full width of the berm. The effective formation level to be used in design analyses is determined as half of the reduced berm height which is equivalent to one sixth ($b/6$) of the full berm width. The benefits of berm structure beyond the assumed 1:3 berm profile and the effective formation level (shown as shaded in **Figure 65.11**) are incorporated into the analyses as a surcharge representing the weight of this additional berm structure applied at the effective formation level.

For information on other methods of modelling earth berms for consideration of wall stability or wall deflections, refer to CIRIA C580 (Gaba *et al.*, 2003, chapter 7).

65.7 Other systems of wall support

65.7.1 Circular construction

For circular excavations where the wall is not suitable to provide sufficient support through hoop action, support is typically provided in the form of a continuous ring beam. Due to the shape, a reinforced concrete ring beam is typically adopted.

For circular excavations, BS8002 (1994) identifies that earth pressures should be calculated as for straight-sided excavations; refer to Chapter 64 *Geotechnical design of retaining walls*.

In practice, the profile of the excavation and ring beam will deviate from a true circle and checks should be made for buckling in the ring beam with a radial waling load, W (kN/m), which is dependent upon the Young's modulus of the waling material, E (N/mm^2) and the moment of inertia about the x–x axis, I (cm^4) and the radius of the circular excavation, R (m), and is defined by:

$$W = 1.5\frac{EI}{R^3 \times 10^5}. \qquad \text{(BS 8002:1994, Equation 34.)}$$

65.7.2 Buttressed walls

The design of masonry walls to resist horizontal loading is covered by BS 5628 Parts 1 and 2. Buttresses act to improve the internal stability of the masonry wall structure as well as to increase the effective width of the wall footing (**Figure 65.12**). As such, they improve the ability of the walls to transmit horizontal pressures acting on the back of the wall down to the foundation level, where sliding resistance is provided through friction on the underside of the wall, and overturning resistance is provided through eccentric bearing resistance on the underside of the wall footing.

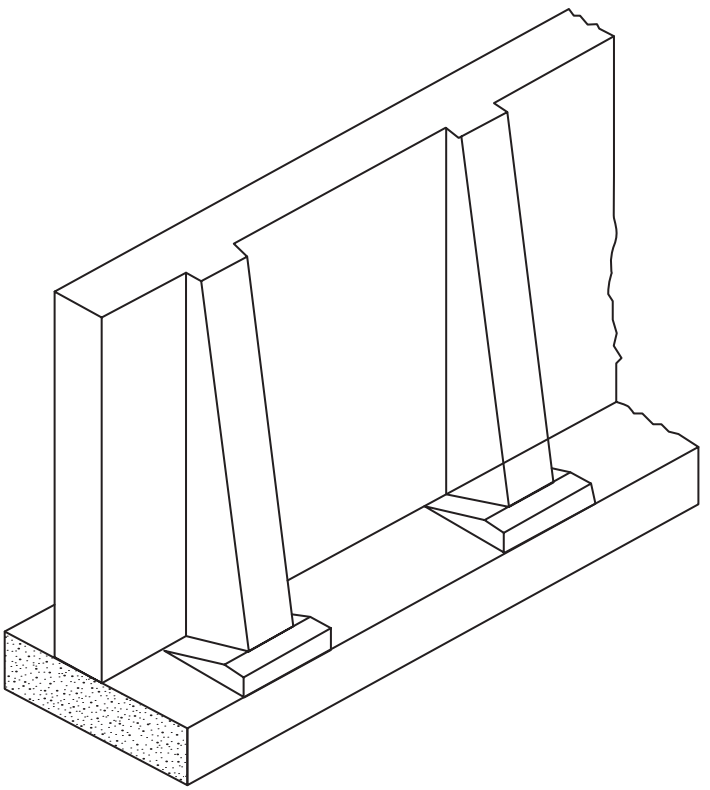

Figure 65.12 Buttressed masonry retaining wall on concrete footing
Reproduced with permission from BS 8002 © British Standards Institute (1994)

65.7.3 Ground improvement

Ground improvement methods such as soil mixing, jet grouting and crosswalls act by increasing the lateral support to an embedded retaining wall; they are more specialised than the

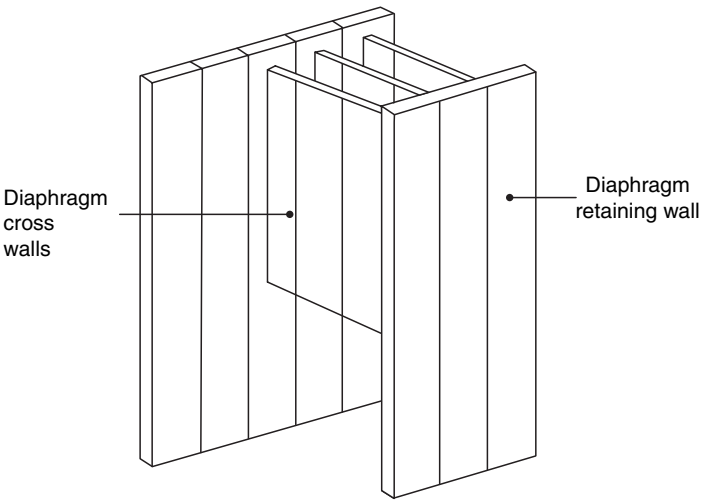

Figure 65.13 Use of crosswalls

other techniques discussed in this chapter (**Figure 65.13**). Such methods are generally only considered for excavation within soft soils where the benefit of improving the ground before excavation can outweigh the costs and time required for such ground improvement.

Guidance on the design and implementation of deep soil mixing and jet grouting is included in the following publications:

- CIRIA C573 (Mitchell and Jardine, 2002);
- EuroSoilStab Design Guide (2002);
- BS EN 14679 (2005a); and
- BS EN 12716 (2001).

Chapter 66

Geotechnical design of ground anchors

Michael Turner Applied Geotechnical Engineering Limited, Steeple Claydon, UK

CONTENTS

66.1	Introduction	1011
66.2	Review of design responsibilities	1014
66.3	The design of ground anchors for the support of retaining walls	1015
66.4	Detailed design of ground anchors	1017
66.5	References	1029

Ground anchors (also sometimes referred to as ground anchorages) are used to provide restraint to all forms of retaining structures, including embedded retaining walls, gravity walls (especially when such structures are being repaired, modified or upgraded) and some forms of hybrid wall, where additional lateral restraint is required.

In the wider civil engineering field, ground anchors are used to resist uplift, tension or other destabilising forces. These include structures subject to hydrostatic uplift or flotation such as dock structures or stormwater tanks and tension loads such as those exerted by transmission towers and masts, suspension bridges and tension roof structures. In addition, ground anchors are very commonly employed in the stabilisation of soil and rock slopes, landslides and cliff stabilisation works.

This chapter deals with the design of ground anchors as part of the restraint system to retaining walls.

It also covers general features concerning temporary and permanent anchors, load transfer mechanisms, tendon design and selection and overall stability considerations. These are applicable to ground-anchor design for other structural uses.

66.1 Introduction

This chapter should be read in conjunction with Chapter 89 *Ground anchors construction*, because the design aspects of ground anchors are intimately linked with their construction.

66.1.1 Definitions

66.1.1.1 BS EN 1537:2000

The execution standard for ground anchors, BS EN 1537:2000, defines an anchor as an installation capable of transmitting an applied tensile load to a load-bearing stratum. Such an anchor consists of an 'anchor head', a 'free anchor length' and a 'fixed anchor length', which is bonded to the ground by grout. The term 'ground' is taken to include both soil and rock. Ground anchors are normally pre-loaded to a predetermined service load. Such loads are applied to the anchor by tensioning the anchor tendon at the anchor head, usually by means of a hydraulic jack. The applied load is transferred from the anchor head, along the tendon, through the debonded free tendon length and into the ground through the fixed anchor zone.

The anchor head transfers the applied anchor force onto the structure, the fixed anchor length transfers the anchor force into the ground, and the free anchor length spans the gap between the anchor head and the fixed anchor length.

For reference, these terms are illustrated in **Figure 66.1**.

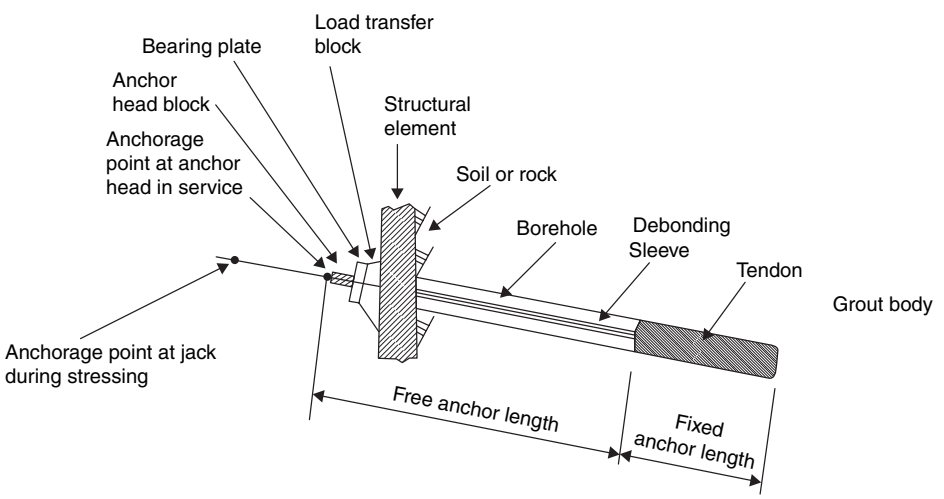

Figure 66.1 Sketch of a typical ground anchor
Reproduced with permission from BS EN 1537 © British Standards Institution 2000 (as published in CIRIA C580)

66.1.1.2 Temporary anchors

The execution standard defines a temporary anchor as one which is required to be in service for no more than two years and a permanent anchor as having a design life in excess of two years.

The execution standard requires that for a 'temporary' anchor the steel components of the anchor shall be provided with protection that will inhibit or prevent corrosion over a minimum design life of two years. To this end, the standard requires that as a minimum the exposed steel in the tendon bond length should be provided with a minimum grout cover of 10 mm from the borehole wall. In aggressive ground conditions, protection might need to be enhanced by use of a single corrugated-plastic duct.

EN1537 also draws attention to the fact that the least-protected zone of an anchorage defines the class of protection provided. Thus, attention to the anchor head and to joints and boundaries within the system are important, if not paramount, to the integrity of the anchor tendon in terms of assuring its level of corrosion protection. This requirement also applies to temporary anchors.

EN1537 also states that the two-year design life for a temporary anchor is mandatory. If the service life exceeds this, the anchor should be considered 'permanent'.

66.1.1.3 Permanent anchors

For a 'permanent' anchor EN1537 requires that corrosion protection to the steel tendon(s) should consist of at least a single continuous layer of corrosion protective material that will not degrade during the design life of the anchor. Acceptable systems within EN1537 (Cl. 6.9.3) are identified as those with:

(a) Two protective barriers to corrosion such that if one barrier is damaged during installation or anchor loading, the second barrier remains intact.

(b) A single protective barrier to corrosion, the integrity of which shall be proven by testing each anchor *in situ*. Such testing consists of some form of electrical resistance testing to demonstrate that the anchor tendon is electrically isolated from the ground and the structure.

(c) A corrosion protection system provided by a steel duct tube-a-manchette anchor.

(d) A corrosion protection system provided by a corrugated plastic duct tube-a-manchette anchor.

(e) A corrosion protection system provided by a steel duct compression tube anchor.

Examples of corrosion protection that may be considered to satisfy the above principles of protection for permanent anchors are described in Table 3 of EN1537.

66.1.2 Nomenclature

In the UK, currently the most common protective systems comply with Type (a) as described above. At the current time of writing, systems using Types (c) or (d) have also been used on some projects in the UK, but are less common.

Both EN1537 and the now partially superseded UK code BS8081 (BSI, 1989) pay attention to, and attempt to codify, the nomenclature of ground anchorages and techniques. In this regard, for example, **Figure 66.2(a)** illustrates the nomenclature and major features of a typical temporary anchor and **Figure 66.2(b)** shows a typical permanent anchor as described in (a) above.

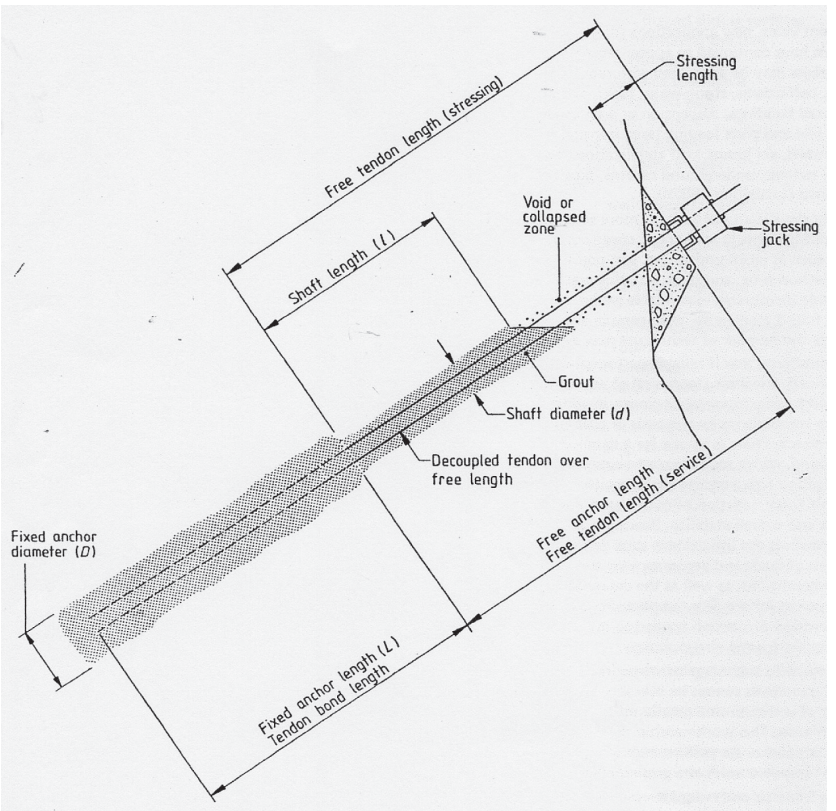
As illustrated in **Figure 66.2(b)**, a typical permanent anchor in the UK will consist of an encapsulated tendon bond length (which transfers the anchorage force into the fixed anchor length), a free tendon length and an anchor head. It will be noted that the fixed anchor length is not necessarily the same as either the tendon bond length or the encapsulation bond length. Correspondingly, the free anchor length is not necessarily the same as the free tendon length. This differentiation is intentional within EN1537 and BS8081, and allows flexibility of design by the designer.

In the case of a temporary anchor the tendon bond length and the fixed anchor length are usually, but not always, the same.

66.1.3 Classification of ground anchors

As detailed in Chapter 89 *Ground anchors construction* the sequence of constructing a ground anchor is usually:

- drill;
- install the tendon;
- place grout (extracting temporary drill casing if used).



Whilst it can be appreciated that the drilling method and technique can affect the magnitude of the grout-to-ground bond that can be mobilised, it is generally considered that the method of grouting has the most influence on the load-carrying capacity of a grout anchor (and similarly for micro-piles: as noted in FHWA, 1997, for example).

BS8081 (BSI, 1989) proposed a general classification of cement-grouted ground anchors into four groups, based primarily upon the type and pressure of the grouting. BS8081 termed these as Types A to D anchors, as described below and illustrated in **Figure 66.3**.

- Type A anchor: Grout is placed in the borehole under gravity head only, in straight-shafted boreholes, which may be temporarily lined or unlined, depending on hole stability.
- Type B anchor: Grout is injected into the borehole under low pressure, typically of less than 10 bar (1000 kN/m^2), using temporary or permanent casing, or an *in situ* packer at the top of the fixed anchor.
- Type C anchor: Grout is injected into the borehole under a high pressure, typically in excess of 20 bar (2000 kN/m^2) using a lining tube or *in situ* packer. Typically the injection process uses a tube-a-manchette system, or similar, which allows multiple phased injections if required.

Reproduced with permission from BS8081 © British Standards Institution 1989

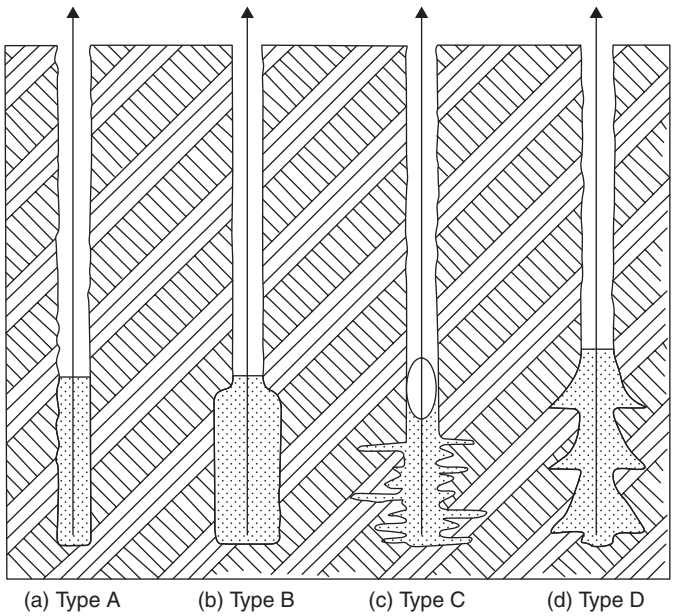

Figure 66.3 Classification of ground anchor Types A, B, C and D
Reproduced with permission from BS8081 © British Standards Institution 1989

- Type D anchor: Grout is placed under gravity head only, but the borehole is formed with a series of enlargement: either bells or under-reams.

Further reference to these four groups is made in Chapter 89 *Ground anchors construction*.

It is worth noting that European practice identifies two techniques of forming anchors that would fall into the category of Type C anchors. In French practice, these are termed, respectively, IGU techniques, where only a single 'global' high-pressure injection is undertaken through a non-reusable packer system, or IRS techniques, where repeated injections at specific horizons can be undertaken if necessary.

In addition since the publication of BS8081:1989 and EN1537:2000 there has been a rapid growth in hollow-core 'self-drilling' systems. With such systems the hollow bar is fitted with a drill bit and is used as both the drill rod and the anchor tendon. Grout is pumped down the hollow rods to exit out of the drill bit, either during or after drilling to the required depth. These can be equated to either BS8081 Type A or Type B anchors depending on their details of use.

66.2 Review of design responsibilities

EN1537 emphasises that the planning and design of ground anchors, together with their installation and testing, all require experience and knowledge of this specialised field. Additionally, in common with other such specialist operations, the technique requires skilled and qualified operatives and supervision in the field.

The design responsibilities for works involving the installation of ground anchors can often be spread among several parties, including the client, the overall project designer and specialist designers working for one or more of the contractors. It is important, therefore, that the responsibilities of all parties involved in the design, execution and maintenance of such ground anchors are properly identified and defined.

EN1537 includes a guide identifying an appropriate separation of 'design' and 'execution' activities, a copy of which is attached as **Table 66.1**.

From **Table 66.1**, the detailed 'design' of a ground anchor falls within the ambit of Activities 1 to 4 of the specialist execution activities. In addition, other aspects of anchor design are included within the overall design activities. In the context of anchors supporting a retaining wall, EN1537 identifies two different roles:

(a) The wall designer, who is responsible for the design of the retaining wall itself, and who would expect, or would be expected, to identify not only the requirement for ground anchors to support the structure, but also the details of individual anchor loads, their spacing and orientation, and their minimum length to ensure the stability of the structure (although, in practice, these design decisions might well be undertaken in conjunction with the anchor designer).

(b) The anchor designer, who is responsible for the selection and design of the anchor type and its component parts, and who is also responsible for the overall design of the ground anchor system, taking full account of the ground conditions anticipated at the site.

The following text centres upon the goals identified in (b) above. It should be borne in mind, however, that it is perfectly possible (and not unusual) for the wall designer to identify the magnitude of the horizontal restraint required to be provided to the wall, and its level or levels of action, leaving the anchor designer to determine the detail of individual anchor loads and their spacing and orientation. It should remain the wall designer's responsibility, however, to identify a minimum free anchor length or the extent of the zone beyond which the designed fixed anchor length must be placed, in order to ensure the stability of the structure. This is on the basis that only the wall designer is in a position to identify the full range and combination of forces and effects touching upon the design, construction and performance of the retaining structure.

The following text therefore assumes that the overall design activities 1 to 13 in **Table 66.1** are undertaken by the wall designer, albeit in possible conjunction with the anchor designer in an advisory or support capacity. The anchor designer in turn is responsible for specialist execution activities 1 to 4, where they affect 'design' matters. The assessment of site investigation data, for instance, is not limited to a 'design' issue, but is also a necessary part of the execution phase in determining the means to be adopted to install an anchor.

Overall design activities	Specialist execution activities
1. Provision of site investigation data for construction of ground anchors	1. Assessment of site investigation data with respect to design assumptions
2. Decision to use ground anchors, required trials and testing and provision of a specification	2. Selection of ground anchor components and details
3. Acquisition of legal authorisation and entitlement to encroach on third-party property	3. Determination of fixed anchor dimensions
4. Overall design of anchored structure, calculations of anchor force required. Definition of safety factors to be employed	4. Detailing of the corrosion protection system for the ground anchor
5. Definition of ground anchor life (permanent/temporary) and requirement for corrosion protection	5. Supply and installation of the ground anchor system
6. Specification of anchor spacing and orientation, anchor loads and overall stability requirements	6. Supply and installation of the ground anchor monitoring system
7. Specification of minimum distance from the structure to mid fixed length to ensure stability of the structure	7. Quality control of works
8. Specification of load transfer mechanism from the anchor to the structure	8. Execution and assessment of anchor tests
9. Specification of any sequence of anchor loading required of the structure and the appropriate load levels	9. Evaluation of on-site anchor tests
10. Specification of systems for monitoring ground-anchor behaviour and for interpretation of results	10. Maintenance of ground anchor as directed
11. Supervision of the works	
12. Specification of maintenance for ground anchors	
13. Instruction to all parties involved of key items in the design philosophy to which special attention should be directed	

Table 66.1 Design and execution activities

As examples of the above division of the duties undertaken by the various parties responsible for design, it is not uncommon in a project containing an anchored retaining wall that the design responsibilities are divided in one of the following ways:

(a) A project designer employed by either the client or the principal or main contractor will identify the need for such a retaining structure within the overall project scheme. A specialist foundation engineering contractor may be employed by the principal contractor, or directly by the client, to be responsible for the design and installation of the retaining wall, which would typically be an embedded retaining wall. The foundation engineering contractor may, in turn, sub-contract the design and execution of the ground anchors to a specialist geotechnical contractor, who may also design the anchors, or who may, in turn, employ a specialist consultant to design them on their behalf.

(b) Alternatively, the project designer may undertake the design and specification of the retaining wall, and also identify the need for ground anchors as part of the applied restraint to the wall at levels and spacings identified by the project designer. The construction of the retaining wall might be undertaken by a foundation engineering contractor to a specification prepared by the project designer, with the ground anchors being designed and installed by the foundation engineering contractor, or by an anchoring specialist. The anchors must provide the loadings specified by the project designer.

It will be appreciated that there are many such possible variations of the division of responsibility for the design and execution of the anchored structure, which underscores the necessity of ensuring that those responsibilities are clearly understood and accepted by all parties.

66.3 The design of ground anchors for the support of retaining walls

66.3.1 Introduction

As an essential precursor to design, a substantial retaining wall, requiring the use of ground anchors for support, should be accompanied by an adequate ground investigation.

It is often forgotten, or not recognised, that such ground anchors may extend beyond the confines or ownership of the site, and that in such circumstances any ground investigation should be expected to extend beyond the site boundaries. In addition, questions of wayleaves or permissions to install the anchors beyond the site boundary have to be addressed.

As a principle, any such site investigation should ideally extend beyond and below the anticipated limits of the anchors. Where this is not possible, or practicable, it should

be understood that the design involves additional risk by extrapolating geotechnical and geological data beyond known boundaries in order to formulate a predicted ground model.

Whilst the requirement for adequate ground information is similar in essence to the requirements that would be expected for the ground investigation for the design of the wall itself, it is not unusual in the design process that the need for a retaining structure is identified at some time before the requirement for ground anchors emerges. It might be only at this latter stage that the need for ground information at some distance behind the wall becomes clear, and this might have to be obtained as a second investigation phase.

The ground information should be sufficient to allow the anchor designer to understand the range, sequence and properties of the strata behind the retaining wall into which, or through which, the anchors will be installed. It should allow the anchor designer to illustrate this understanding with adequate and sufficient cross-sections through the wall and its attendant ground anchors. This appreciation of the 3D geological picture, including groundwater information, and the potential variation across the site, is vital to the successful design and execution of the anchors, as it is, indeed, for any other geotechnical design.

It also has to be appreciated, however, that the scope of the ground investigation may well depend to some extent upon the size and type of the project, and the practicalities of gaining access for an adequate investigation. It also may depend upon a degree of local knowledge and experience of ground conditions. It is possible and permissible, of course, to take an informed view of the degree of risk and uncertainty implied by the relative lack of ground information when undertaking design and construction. At the least, however, this must imply that the robustness of the ground model developed by the anchor designer must be adequate and flexible for the task in hand, and any potential shortcomings are sufficiently understood and capable of being addressed within the design and execution of the anchors.

66.3.2 Matters that have to be assessed at the design stage of the retaining wall.

In the context of the above discussion, it is probably useful at this stage to step back and review how these matters equate within the framework of the activities outlined in **Table 66.1**. With reference to the design activities, Activities 1 to 5 encompass both the site investigation phase and the design of the retaining wall, which will have led to the decision to use ground anchors, including decisions on their design life.

The next phase of the design, Activity 6, is to review the anticipated layout and 'sizing' of the anchor system in relation to the structural design of the wall and the ability of the ground within any potential fixed anchor length zone to transfer the projected design loads, and the ability of the wall to accept them. An example would be the consideration of whether it was preferable to use a large number of lower capacity anchors, or to adopt a smaller number of anchors with higher individual loads. As a guide, at this stage, for a typical 'average' embedded retaining wall, ground-anchor design working loads would typically be between 200 and 600 kN, with a mean typically in the range of 300 to 400 kN, and with horizontal and vertical anchor spacings of between 2.0 and 4.0 m. Designs requiring anchors outside this range would often be concerned with larger, deeper retaining walls and more arduous conditions.

Anchor inclinations typically vary between 20° and 45° below the horizontal, although inclinations outside these limits are not uncommon. Both the wall designer and the anchor designer need to bear in mind that the more steeply an anchor is inclined, the greater is the vertical component of the anchor force exerted on the wall. This can be particularly relevant for steel sheet piles, with their relatively low cross-sectional area.

It is not unusual for an anchored retaining wall to have corners or bends, to suit site constraints, ownership or the like. When corners become re-entrant (i.e. at an angle of greater than 180° relative to the site), there is an increasing tendency for anchors to clash with one another. A typical situation is illustrated in **Figure 66.4**. Measures have to be identified during design to ensure in such circumstances that anchors are positively designed to avoid intersecting one another, and that sufficient clearance is left between passing anchors. This usually has to be done by varying both the inclination and skew (horizontal angle to the wall) for some or all of the affected anchors. Even relatively simple intersection problems often become sufficiently complex that they are best solved by simple modelling of the layout, either by computer or by constructing a physical model.

After Activities 6 to 8, with adequate ground information in place, and ideas of anchor size having been developed, the detailed design of individual anchors can be undertaken.

66.3.3 Notes on the use of BS8081

It is intended that EN1537 should take precedence and eventually replace the UK ground anchorage code BS8081 from 2010. However, BS8081 contains much advice and guidance on best practice and the development and use of design parameters, particularly in terms of bond values for the various interfaces involved in ground-anchor design. Hence, for the purposes of this current document, BS8081 has been identified as a source reference for much of the basic design features of ground anchors. It should be understood, however, that where there is any potential conflict between any recommendations or advice within BS8081 and BS EN1997–1 (EC7–1) and EN1537, the latter two documents would normally take precedence. A feature of EN1537, in particular, is that many of its requirements are mandatory principles, *which have to be followed*, rather than recommendations or guidance.

66.4 Detailed design of ground anchors

66.4.1 Introduction

Four main components of design have to be considered by the anchor designer:

(1) load transfer into the ground;

(2) the type and strength of the tendon;

(3) the location of the fixed anchor zone, together with uplift or pull-out capacity;

(4) load transfer into the structure.

It can be seen that items (1) and (3) depend upon a knowledge of the characteristics of the ground, as revealed by the ground investigation.

66.4.1.1 Factors of safety

Ground-anchor design in the UK has traditionally been based on a global factor of safety or permissible stress.

The introduction of Eurocodes and, in particular, Eurocode EC7 (Geotechnical Design; BSI, 2004) requires design to be undertaken on a partial factor limit-state design basis. At the time of writing all of the 'wrinkles' associated with the adoption of this design philosophy have not been finally satisfactorily addressed and ironed out, particularly for ground-anchor design (see Bond and Harris, 2008, for example).

At present, the best advice would seem to be to retain the BS8081 recommendations for global factors of safety, as summarised in **Table 66.2**.

In such designs:

$$T_{\text{design}} = \frac{T_{\text{ult}}}{F}$$

where T_{design} is the design working load of the anchor, T_{ult} is the ultimate load capacity of the anchor by calculation or test and F is the 'global' factor of safety.

66.4.2 Load transfer into the ground

The load transfer between the ground anchor tendon and the soil or rock within which it is embedded depends upon the design of three boundaries:

- anchorage grout to ground (fixed anchor length);
- encapsulation to anchorage grout, if appropriate (encapsulation length);
- tendon to anchorage grout or encapsulation grout (tendon bond length).

66.4.2.1 Bond between anchorage grout and the ground (fixed anchor length)

General

The relationship between the design anchorage force, T_{design}, and the required fixed anchor length, L, is usually determined by a skin friction equation of the form:

$$T_{\text{design}} = \pi\, d\, L\, \tau_{\text{design}} \qquad (66.1)$$

where d is the diameter of the borehole and τ_{design} is the design value for the bond or skin friction at the grout–ground interface. It is not usual that an end-bearing component at the proximal end of the fixed anchor length, due for instance to a possible enlargement of the fixed anchor diameter by pressure grouting, is included in the design. However, some design techniques do attempt to take some account of this aspect, as will be discussed below. Under-reamed anchors in granular soils, however, usually take some account of such end-bearing.

Values for τ_{design} are derived from a wide variety of sources, such as pile-related bearing capacity formulae, back analysis of pull-out tests on specially constructed test anchors and the like.

With regards to design parameters, it is quite important to understand that ground anchors, together with, micropiles, 'conventional' piles, soil nails and other similar inserts, all have design and construction aspects in common. In particular, anchors and micropiles are usually quite similar dimensionally

Anchorage category	Minimum safety factor			
	Tendon	Ground–grout interface	Grout–tendon or grout–encapsulation interface	Proof load factor
Temporary anchorages where the service life is less than six months and a failure would have no serious consequences and would not endanger public safety, e.g. short-term pile test loading using anchorages as a reaction system	1.40	2.0	2.0	1.10
Temporary anchorages with a service life of say up to two years where, although the consequences of failure are quite serious, there is no danger to public safety without adequate warning, e.g. retaining wall tie-back	1.60	2.5 (1)	2.5 (1)	1.25
Permanent anchorages and temporary anchorages where corrosion risk is high or the consequences of failure are serious, e.g. main cables of a suspension bridge or as a reaction for lifting heavy structural members	2.00	3.0 (2)	3.0 (1)	1.50

[1] Minimum value of 2.0 may be used if full-scale field tests are available.

[2] May need to be raised to 4.0 to limit ground creep.

In current practice the safety factor of an anchorage is the ratio of the ultimate load to design load. This table defines minimum safety factors at all the major component interfaces of an anchorage system.
Minimum safety factors for the ground–grout interface generally lie between 2.5 and 4.0. However, it is permissible to vary these, should full-scale field tests (trial anchorage tests) provide sufficient additional information to permit a reduction.
The safety factors applied to the ground–grout interface are invariably higher compared with the tendon values, the additional magnitude representing a margin of uncertainty.

Table 66.2 Minimum safety factors recommended for design of individual anchors
Reproduced from BS8081 © British Standards Institution 1989

and in load capacity terms, and the design techniques and values obtained from field testing are often essentially interchangeable between the two, with appropriate allowances.

Similarly micropiles and conventional piles have common design and performance aspects. With regards to bond design, however, there are often considerable differences in size and construction technique that have to be factored into any comparisons on performance.

The load-carrying capacity of anchors in suitable soils or weak rocks can also be enhanced by under-reaming or by post-grouting techniques. In the latter technique, additional grout is injected into the fixed anchor length at high pressure after the initial anchorage grout has set.

In addition, higher anchor loads can often be developed using 'multi-stage' anchor tendons (also known by the proprietary name of Single Bore Multiple Anchors), a technique whereby a number of essentially single-strand anchors are placed within the same borehole. Each strand anchor is designed to transfer load over a separate section of the anchor hole. Hence, with such anchors, it can be seen that the free tendon length of each strand is different, as illustrated in **Figure 66.5**.

For further details on such techniques and systems, see Chapter 89 *Ground anchors construction*.

Guidance on fixed anchor length design

Fixed anchor length design generally focuses on three convenient 'groups' of anchoring material: granular soils, clayey soils and rocks. It will be realised that there can be some blurring of the boundaries between these idealised groups, as intact rocks weather towards 'soils', for instance.

As a general rule (e.g. BS8081) the fixed anchor length should be:

(a) A maximum of 10 m long (because of a trend of decreasing capacity per metre run, as discerned from back analyses of load testing). However, multi-stage anchors are able to employ longer load transfer lengths by means of 'stacking' fixed anchor lengths, as described below.

(b) Not less than 3.0 m; although for design working loads below 200 kN, a minimum fixed anchor length of 2.0 m may be acceptable in suitable circumstances.

Fixed anchor length design in granular soils

A typical design relationship based upon an expression developed by Littlejohn (1970) is shown in equation (66.2) below. Note that, contrary to equation (66.1) and its accompanying note, equation (66.2) does include consideration of an end-bearing component. This is discussed further in the accompanying text.

$$T_{ult} = A\overline{\sigma'_v}\pi kdL\tan\phi' + B\sigma'_h\frac{\pi}{4}[(kd)^2 - d^2] \qquad (66.2)$$

(shaft friction) + (end bearing)

where T_{ult} is the ultimate load holding capacity; L is the length of the load transfer length (fixed anchor length) within the

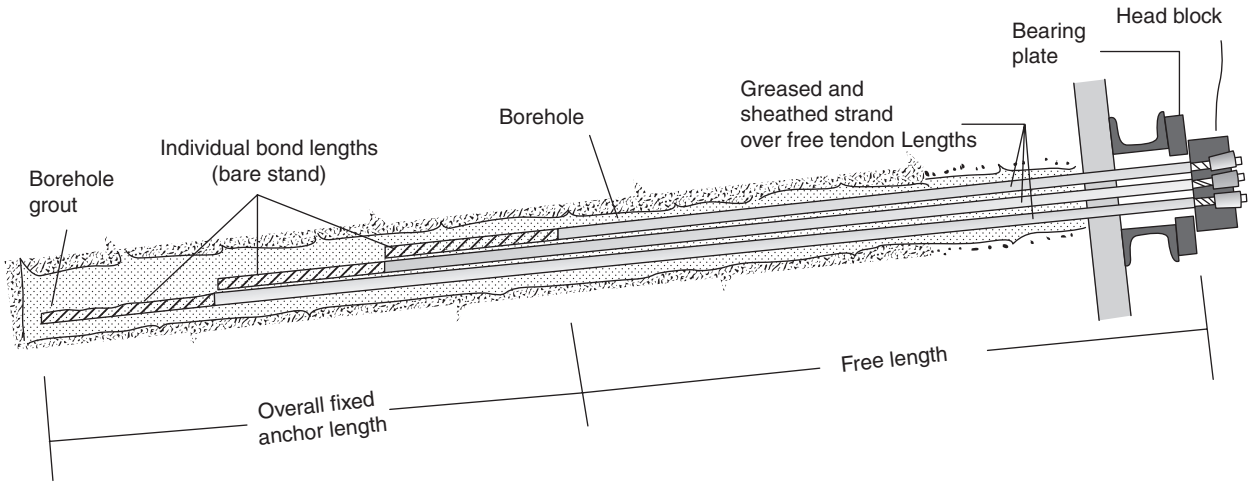

Figure 66.5 Characteristic features of a multi-stage ground anchor (temporary anchor shown)

stratum; d is the drillhole diameter; $\overline{\sigma'_v}$ is the average effective overburden pressure along the load transfer length; ϕ', is the angle of shearing resistance of the soil; A is a coefficient related to the contact pressure at the fixed anchor–soil interface and the average effective overburden pressure; k is a coefficient relating to the degree of enhancement of the diameter of the load transfer length from the grouting process and the penetration of the grout beyond the drillhole diameter; B is a bearing capacity factor; h is the depth of overburden to the top of the fixed anchor length; σ'_h is the effective overburden pressure at depth h.

This form of relationship is also described and discussed in BS8081 (Equation 3 of BS8081) and Littlejohn (1980).

Shaft friction

For BS8081 Type B anchors, values for k, the enhancement of the nominal drillhole diameter by penetration of the anchor grout into the surrounding ground, due to its fluidity and the pressure grouting process, have been determined by back analysis of pull-out tests. Derived values for k noted by Littlejohn (1980) were between 3 and 4 in coarse sands and gravels, perhaps 1.5 to 2 for medium dense sand and 1.2 to 1.5 for very dense sand.

Values for A depend to a large extent on the construction technique. Littlejohn (1980) derived values for A of 1.7 for compact sandy gravel ($\phi' = 40^o$) and $A = 1.4$ for compact dune sand ($\phi' = 35^o$). Other workers quoted in this reference derived similar values for A.

It can be seen that the product Ak derived from Littlejohn's work for compact sandy gravel is typically between 5.1 and 6.8. The same calculation for compact dune sand yields a range of between 1.7 and 2.1.

Littlejohn also quoted work in Sweden by Moller and Widing (1969), which reported on pull-out tests on ground anchors, where the authors had not tried to separate the varying influences of end-bearing and shaft friction (including enlargement or enhancement of the fixed anchor length). Moller and Widing's derived values for the product Ak (denoted in Littlejohn, 1980, as 'K_2') gave values varying between 4 and 9 in materials ranging from coarse silt and fine sand to sand and gravel, and with grout injection pressures of 3–6 bar. The lower values were for the finer-grained soils and the higher ones were obtained in coarser soils.

Back analysis by Turner (2010) of test anchors in coarse open gravels in Aberdeen produced similar values for K_2 of 9 or higher.

End bearing

With regard to the end-bearing component of equation (2), Littlejohn and his co-workers back-calculated values for the parameter B for compact sandy gravel as $B = 101$ and compact dune sand as $B = 31$. Further details can be obtained in the particular references cited above.

In practice, as noted earlier, the end-bearing component of equation (66.2) is usually ignored in design.

Summary

The above review suggests that load-carrying capacity in granular soils can typically be expressed by a relationship in the form of:

$$T_{ult} = K\pi dL\overline{\sigma'_y}\tan\phi' \qquad (66.3)$$

where 'K' is, effectively, the product of A (related to the increase of the radial effective stress around the fixed anchor length due to the grouting and installation process) and 'k' (a measure of the physical enhancement of the fixed anchor diameter by the pressure grouting process). It can be seen that this is very similar to the classic formula for calculating

the ultimate shaft friction of a pile in granular soils (see, for instance, Chapter 22 *Behaviour of single piles under vertical loads*).

In conventional pile design, typical values for K will vary between 0.7 and 0.9 for a bored pile, but there might also be a reduction in ϕ' to account for soil loosening. This range of K for bored piles can be compared with the much higher values obtained for ground anchors of between 4 and 9 by Moller and Wilding (1969) and 1.7 to 6.8 by Littlejohn (1980). (The higher Moller and Widing values might be explained because these results also include an element of the end-bearing component identified by Littlejohn.)

It can be envisaged therefore that the increase in K value exhibited by ground anchors in granular soils, compared with 'conventional' piles, can be attributed to:

(1) Scale differences between a typical pile diameter of perhaps 450 to 750 mm, compared with a ground anchor of 100 to 200 mm.

(2) Penetration of the fluid grout into the surrounding granular soil, so increasing the effective diameter of the fixed anchor length.

(3) The influence of grouting pressure on anchor capacity (by both permeation and by increasing the confining pressure around the fixed anchor length). The technique of pressure grouting includes, in order of increasing load capacity: grouting under hydrostatic head only (BS8081 Type A anchors), low-pressure grouting (less than hydro-fracture pressures) (BS8081 Type B anchors), or high-pressure post-grouted systems (using tube-a-manchette, or similar, techniques) (Type C anchors).

(4) The particle-size distribution of the granular strata: where coarser soils will, in general, permit a greater penetration of the anchor grout.

With respect to high-pressure post-grouted systems, empirical design curves for such techniques in sands and gravels were developed by Bustamante (1976) and Bustamante and Doix (1985) and are illustrated in **Figure 66.6**.

Fixed anchor length design in clayey soils

Straight-shafted anchors

A typical design relationship is expressed in the form of:

$$T_{ult} = \pi\, d\, L\, \alpha\, c_u \tag{66.4}$$

where c_u is the undrained shear strength; α is an adhesion factor; and d and L are as previously defined.

Again, it can be seen that this design approach is similar to that employed in bored-pile design practice.

As described in BS8081, design is almost always based upon undrained shear strength and total stress analysis rather than using the more fundamental concept of drained strength parameters and effective stress analysis. Drilling and grouting activities, usually using auger or water flush systems and fluid neat cement grouts, are difficult to model reliably using effective stress design. In addition, load-testing is of short duration

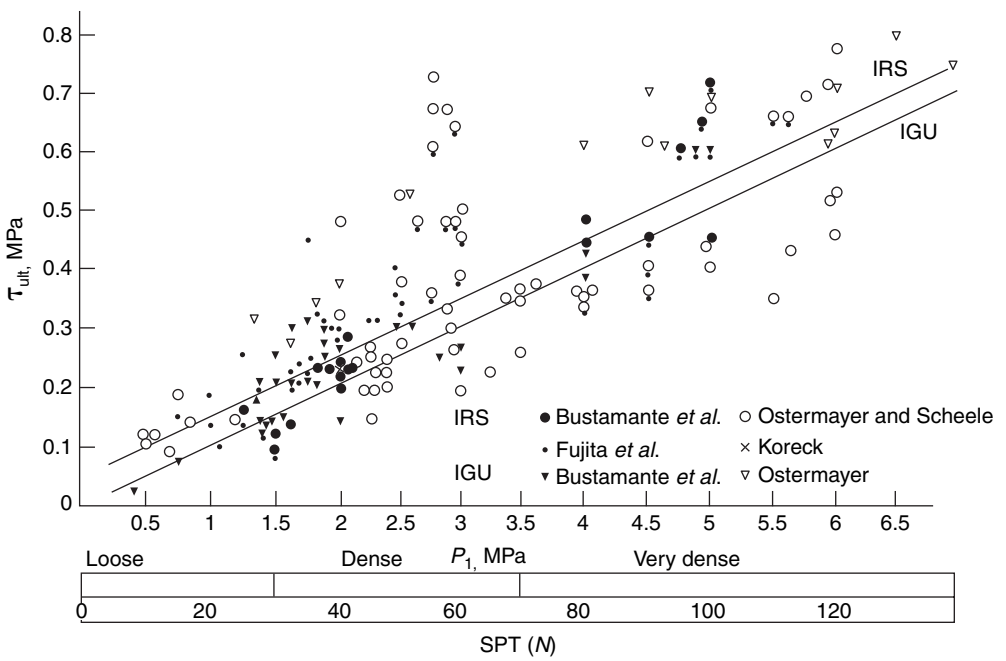

Figure 66.6 Empirical relationship for the determination of the ultimate skin friction for sand and gravel using IGU and IRP post-grouting techniques
Reproduced from Bustamante and Doix, 1985 (as published in FHWA, 1997)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

compared with the time for steady-state effective stress conditions to stabilise. Hence, the testing mode is more suited to a total stress approach.

It should be noted that increasingly in UK practice, anchor load testing involves not only investigating the ultimate 'short-term' load-holding capacity but also confirming acceptable creep values (see the Execution Standard EN 1537:2000 for more details).

For straight-shafted tremie grouted anchors with low or no pressure, quoted α values in BS8081 for stiff London Clay ($c_u > 90$ kPa) are typically around 0.3–0.35. For very stiff to hard Mercia Mudstone ($c_u = 287$ kPa) a design value of $\alpha = 0.45$ is suggested.

For multi-stage anchors, each strand is deemed to have its own short individual load transfer length within the overall fixed anchor length. Pull-out test data suggests this allows the use of markedly higher α values for design; values as high as 0.95 or 1.0 have been cited by Barley (1997).

Under-reamed anchors

Where anchors are constructed using multiple under-reaming techniques (BS8081 Type D anchors), as described in Chapter 89 *Ground anchors construction*, failure of the fixed anchor zone can be visualised as occurring through the outer edges of the bells within undisturbed material, together with the contribution from end-bearing and any non-under-reamed section of the shaft, as illustrated in **Figure 66.7**. A typical design relationship for such anchors would be of the form of:

$$T_{ult} = \pi\, DL\, c_u + \pi/4\, (D^2 - d^2)\, N_c\, c_{ub} + \pi\, dl\, c_a \qquad (66.5)$$

(side shear) + (end bearing) + (shaft resistance)

where D is the diameter of the under-ream (in metres); L is the length of the under-reamed section of the fixed anchor (in metres); c_u is the average undrained shear strength over the fixed anchor length (in kN/m^2); d is the diameter of the shaft (in metres); N_c is the bearing capacity factor (a value of 9 is commonly assumed); c_{ub} is the undrained shear strength at the proximal end of the fixed anchor (in kN m^2); l is the length of the shaft (in metres); c_a is the shaft adhesion (a value for c_a of 0.3 c_u to 0.35 c_u is commonly assumed, in kN/m^2).

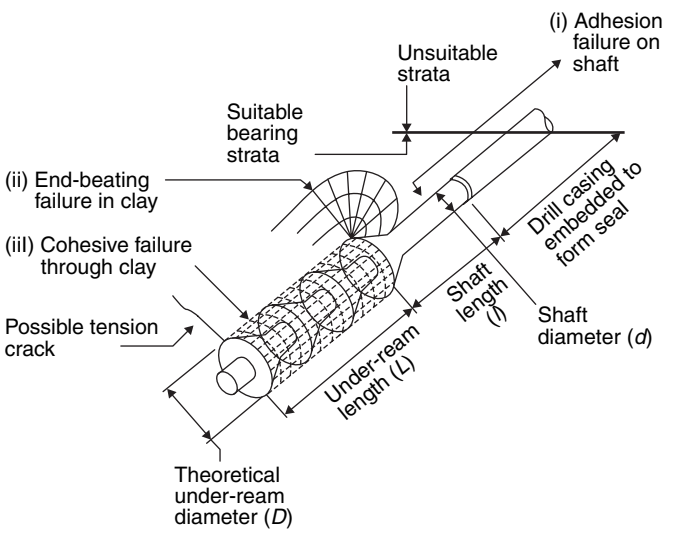

Figure 66.7 Diagram of multi-under-reamed ground anchor at ultimate capacity
Reproduced from Bassett, 1970 (as published in BS8081:1989)

It should be understood that l is the portion of the fixed anchor length at the proximal end of the under-reamed section. The contribution of this length is usually quite small, and is often ignored in practice.

Post-grouted anchors

For post-grouted (BS8081 Type C) anchors, additional grout is pumped under high, controlled pressures into the fixed anchor length using valved injection tubes, once the primary grout has achieved its initial set.

Load transfer design for such systems is based upon correlation with pull-out test data. This data effectively allows the estimation of an enhancement factor to the α value.

Design curves illustrating such relationships have been derived by Ostermayer (1974) as shown in **Figures 66.8** and **66.9** (from BS8081) and by Bustamante and Doix (1985) as in **Figure 66.10**.

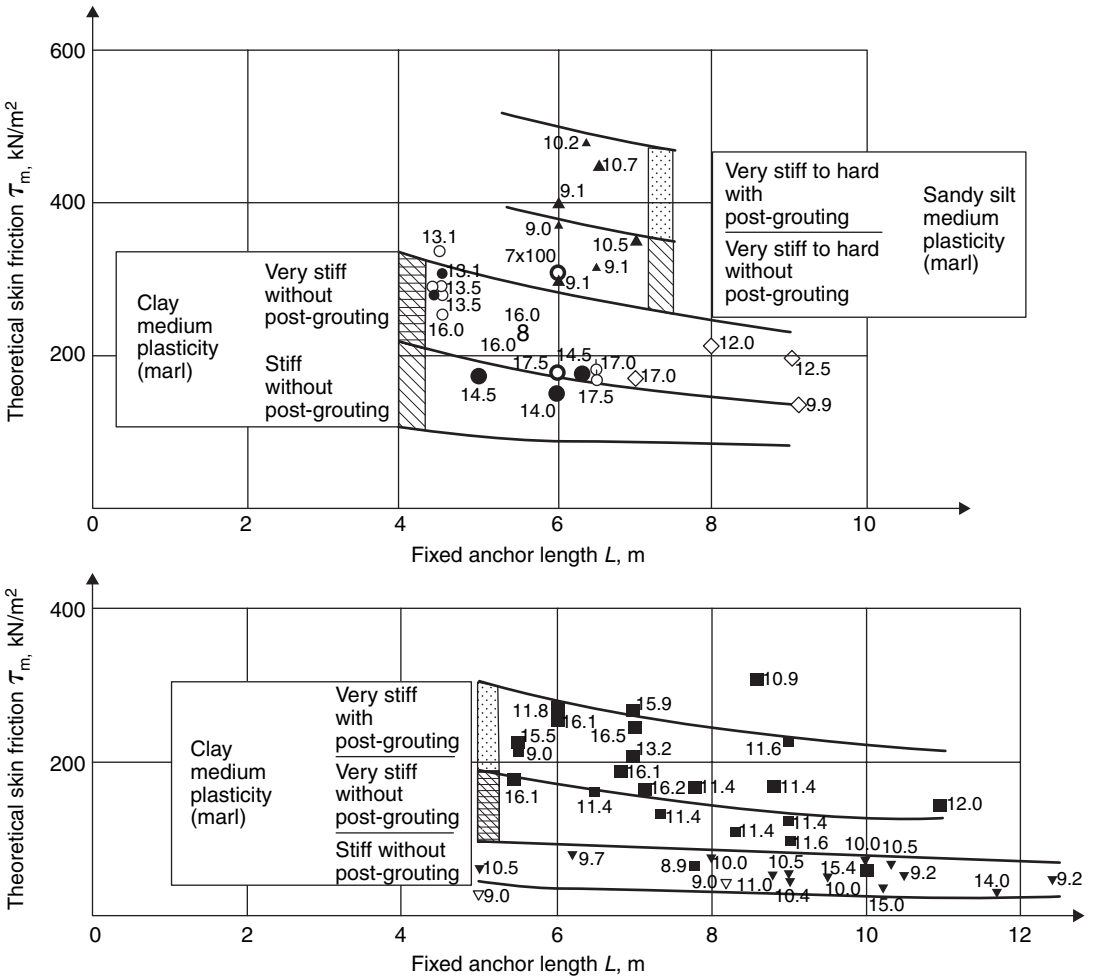
Tests undertaken by Jones and Turner (1980) indicated an equivalent increase in the 'α' value of between 2 and 3 times the 'normal' design value of 0.3.

Fixed anchor length design in rock

A typical design relationship is expressed in the form of:

$$T_{ult} = \pi\, d\, L\, \tau_{ult} \qquad (66.6)$$

where τ_{ult} is a value for the ultimate (or 'failure') bond stress to be used for design, based upon previous pull-out test data or established empirical relationships.

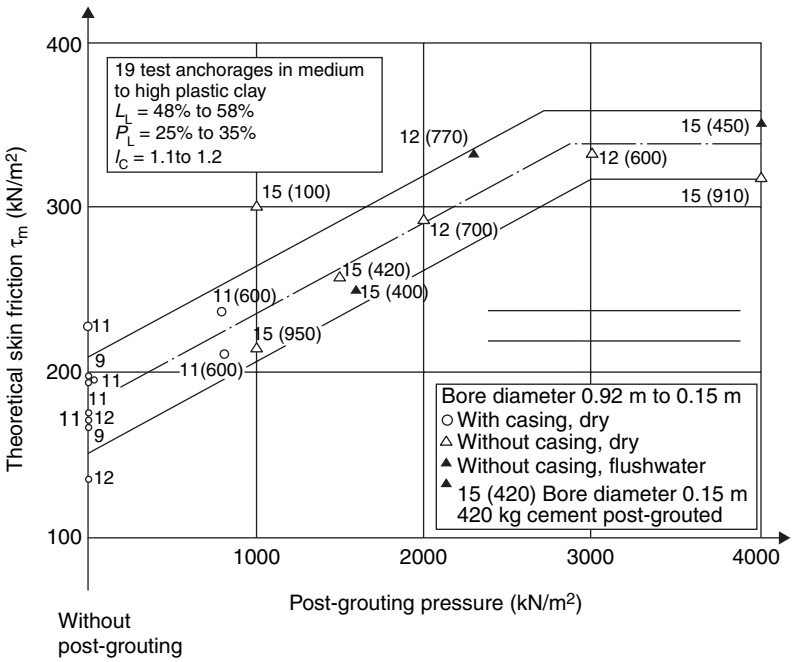


Established data may be site-specific or based upon tests in similar or related strata or conditions.

Most anchors installed in rock in the UK are straight-shafted, BS8081 Type A or B anchors (See Chapter 89 *Ground anchors construction*). Type C or D anchors have been less often used: mainly, as might be expected, in variable, low-strength or weathered rocks.

Almost all design bond-value data is empirical, based upon published case studies of field experience.

For strong intact rocks, an ultimate bond value equal to 10% of the unconfined compressive strength of the rock is often recommended. A maximum value of τ_{ult} of 4.0 N/mm^2 is usually recommended, based upon a typical design of the unconfined compressive strength for cement grout of 40 N/mm^2.



Tables 24 and 25 of BS8081 provide guidance on bond values, which have been utilised in design for a range of rock types and geological ages, mainly based upon field test data, or

Failure load was reached	Failure load was not reached	Post-grouting	Type of soil	L_L %	P_L %	I_c %

satisfactory performance. These are expressed in both τ_{ult} and τ_{design} values as available, since there is often surprisingly little published data on bond-failure values.

For chalk and weak mudrock, as well as sandstone and 'other' rock types, Barley (1988) has produced a wide-ranging review of rock anchor load test data. Of particular assistance in design are correlations of SPT *N* values against bond stress for the weaker rock types. These correlations are based upon the relationships suggested by Cole and Stroud (1977) and Stroud (1989) for 'extrapolated' SPT *N* values and unconfined compression strength for rocks.

Important information and parameters required from a site-specific ground investigation were identified by Turner (2007) as:

- rock type, with a brief general description;
- geological formation: indicating age and possibly identifying typical characteristics of the strata;

- weathering grade: based upon the UK Geological Society Engineering Group (GSEG) grades, which are incorporated into BS 5930:1981, the Code of Practice for Site Investigations;
- unconfined (uniaxial) compressive strength (UCS): based upon UK GSEG grades, subsequently adopted by BS 5930;
- total core recovery (TCR);
- rock quality designation (RQD).

This paper also included data from proving tests in rock on both ground anchors and micro-piles, which included as much of the above data as was available from each particular site. Based upon this data and other published information, it was suggested the following general conclusions could be drawn, with particular reference to the weaker, more weathered, or more fractured rocks:

- There was a tendency that RQD had to be below 25% before it noticeably affected bond values.
- The ultimate bond value in chalk anchors tended to show a correlation with the SPT *N* value. The typical range of suggested values varied between an ultimate bond value of 10 to 30 times the SPT *N* value (kN/m^2), with a median value of around 15 to 20.
- Barley (1988) developed a useful guide relationship between ultimate bond and SPT *N* value for mudrocks, with a lower limit value of the ultimate bond value = 5 x (SPT *N* value). Such rocks are often difficult to sample adequately in standard site investigations.
- (UCS) / 10 is often used as a rough guide to ultimate bond stress. The test data generally supported such a rough correlation, but it should be used with great care.
- One would expect a correlation of increasing hole diameter with decreasing ultimate bond stress, for the same rock type, but there was not enough data to confirm this expectation.
- As would be expected, the degree of weathering affected the ultimate bond value, so that the more variable or the greater the degree of weathering, the more variable will be the performance of the anchor (or micro-pile).

It can be seen, therefore, that fixed anchor design in rocks is more empirical, and to a large extent is very much driven by both the quality of the ground investigation and the local knowledge of the anchor designer or installation contractor.

66.4.2.2 Encapsulation to anchorage grout bond

The design of the corrugated plastic sheath forming this interface is typically required to be such that a mechanical interlock will be formed between the external and internal grout on either side of the boundary. BS8081 recommends a maximum ultimate bond stress of 3.0 N/mm^2 at this interface where cement grouts are used, assuming that the bond is uniform over the surface. Higher values can be adopted if adequately proven. Bond tests have confirmed this is a reasonable but conservative low bound, and in most cases this is not a critical interface in designs.

It has to be remembered that, where two concentric sheaths are used, the inner sheath will be the critical interface.

(It should also be noted that EN1537 requires an increased sheath thickness compared with BS8081 recommendations.)

66.4.2.3 Tendon to encapsulation grout or anchorage grout bond

For temporary anchors, where the steel tendon is embedded directly in the anchorage grout, the tendon bond length is usually the same as the fixed anchor length. The length necessary for the grout–ground bond is usually more than adequate to ensure against failure of the tendon–ground bond. In the case of permanent anchors using strands, however, the encapsulation length is often shorter than the fixed anchor length (because a shorter encapsulation length is more convenient for handling the tendon at installation). In such a case the tendon–grout interface can become critical.

BS8081 suggests that the value for the ultimate bond stress at this interface when using cement grout should be limited to 2.0 N/mm^2 for a clean pre-stressing strand or deformed bar, rising to 3.0 N/mm^2 for strands that have been locally noded (where the outer wires of each strand are unravelled and then rewound around small collars placed onto the kingwire at intervals to form small nodes). Tests described by Turner (1980) suggested that a value of 2.0 N/mm^2 for a plain strand was reasonable, but that deformed bars could develop in excess of the 5.0 N/mm^2 ultimate bond stress. The validity of the 50% increase in the bond value for noded strands to 3.0 N/mm^2 was considered to be more questionable, since tests indicated that such nodes would have to be at close centres to achieve the stated 50% increase in the bond value.

66.4.3 Tendon design

The great majority of anchors in the UK are constructed using tendons composed of one of the following materials:

- *Low-relaxation pre-stressing strands* A 15.2 mm diameter strand with a characteristic strength of 300 kN is the most common. Multiple strands are used for higher loads.
- *High-tensile steel bars of pre-stressing quality* Most often fully threaded bars are used, with diameters of between 15 and 75 mm, and characteristic strengths up to 4 500 kN. Larger, higher capacity bars are also available.
- *High-yield steel bars* Again, these are most often fully threaded, with diameters between 16 mm and 63.5 mm and characteristic strengths up to 2 200 kN.
- *High-yield steel hollow bars* These are usually fully threaded, with external diameters between 25 and 130 mm and characteristic strengths up to 2 310 kN.

When designing to BS8081 guidance, it is usual to use global factors of safety as in **Table 66.2** for both high-tensile (pre-stressing) and high-yield steels. When designing to EN1997 Eurocode-7 and BS EN1537 both these publications refer the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

designer to BS EN1992 Eurocode-2 The Design of Concrete Structures (BSI, 2004b).

66.4.4 The location of the fixed anchor zone (overall stability)

As noted in section 66.2 and **Table 66.1**, EN1537 implies that the responsibility for the specification of a minimum distance from the structure to the middle of the fixed length to ensure the stability of the structure lies with the wall designer. This is only part of the design. It has to be the responsibility of the anchor designer, in addition, to ensure that the anchors are deeply enough embedded beyond the zone identified by the wall designer to avoid an overall pull-out failure of the body of soil or rock surrounding the anchors.

The methodology generally adopted for such a design is to determine the location of a notional failure surface behind the wall that has an acceptable stability against general failure. The fixed anchor lengths of the ground anchors should then be located beyond this failure surface. In European practice it is not uncommon that the mid-point of the fixed anchor length is located on this surface. In UK practice it is more usual to locate the whole of the fixed anchor beyond this surface (e.g. Littlejohn *et al*., 1971).

Appendix D of BS8081 reviews several design methods for ensuring the overall stability of an anchored retaining wall, and an introduction to these is given below.

More general guidance on limit equilibrium methods of stability analysis are given in Chapter 23 *Slope stability* and Chapter 64 *Geotechnical design of retaining walls*.

66.4.4.1 For c′=0 'granular' soils

The design methods used to determine the location of such an acceptably stable surface within granular soils vary from 'planar' wedge or 'sliding block' analysis techniques to conventional circular or non-circular stability analyses, as described below and, in detail, in Chapter 23 *Slope stability*. The methods are also reviewed in more detail in BS8081 and in Littlejohn (1970, 1972).

The planar wedge method is illustrated in **Figure 66.11**. It has been used for design in both granular and clayey soils, and for multiple rows of anchors. Values for the parameters 'β' and 'x' in this figure, which have been used in practice, are recorded (BS8081) as: varying between 27° and 45° to the vertical for β, with 'x' varying between zero and 6.0 m. However, it is commonly held (e.g. Hanna, 1982) that justification of the method is difficult because the mode of failure is unlikely to be planar.

A typical 'sliding block' analysis is illustrated in **Figure 66.12**. It is suitable for analysing a single row of anchors. The method illustrated is based upon that developed by Kranz (1953), and modified by Locher (1969) and Littlejohn (1970, 1977). Other methods are also described in BS8081.

As described by Littlejohn *et al.* (1971), the lateral earth pressure, P_n, on the vertical surface *b–c* drawn through the proximal end of the fixed anchor length is calculated using a 'nominal' friction angle ϕ'_n, which is less than the effective angle of internal friction of the soil such that

$$\tan \phi'_n = (\tan \phi'_d) / F \qquad (66.7)$$

where F is a safety factor, and ϕ'_d is the design value of the angle of internal friction of the soil.

The resultant R_n on the inclined sliding plane *c–d* will also be inclined at ϕ'_n to the normal to *c–d*.

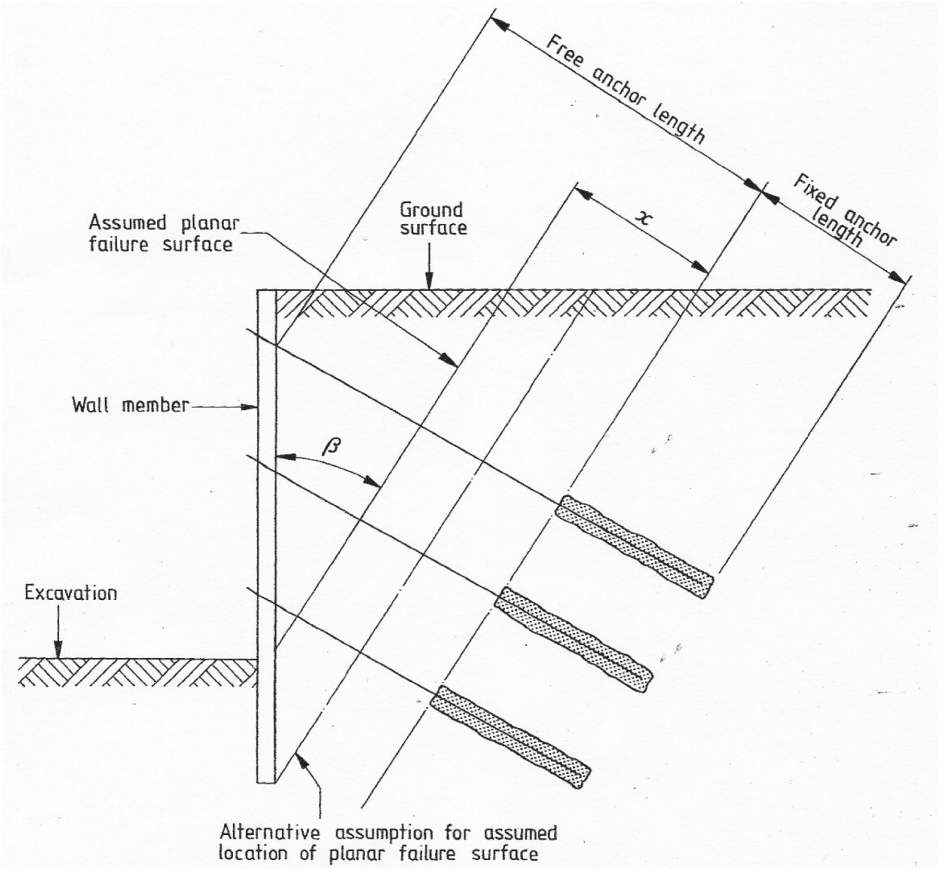
By iteration, when the disturbing and restoring forces are in equilibrium, by revising the geometry of the soil block *a–b–c–d*, then the desired safety factor has been achieved. The additional stabilising force due to the passive resistance at the toe of the wall is ignored in the calculation, which is a conservative assumption.

The dashed lines in **Figure 66.12** represent the typical shape of the failure curve, derived from experimental tests on plate or 'deadman' anchors. The polygon *a–b–c–d* is a simplification of this shape for calculation purposes.

It should be noted that both the above examples show the minimum distance to the proximal end of the fixed anchor length from the face of the wall as being at the boundary of the calculated 'failure' surface. As noted earlier, this is at variance with EN1537, which does suggest that the designer should specify the minimum distance to the mid-point of the fixed anchor length, as in **Table 66.1**. Hence, care should be taken to ensure that the wall designer and the anchor designer are in concert with their design approaches. As a general approach, it is recommended that the anchor designer locates the whole of the designed fixed anchor length beyond the design failure surface unless both designers agree that the EN1537 approach is appropriate.

It should also be noted that the anchors must also have a sufficient depth of vertical cover above the fixed anchor length to avoid localised passive failure of the soil, similar to the failure condition associated with shallow 'deadman' anchors. A typical rule of thumb cited by Littlejohn (1972), and based upon early experience of ground anchors in UK alluvial sands and gravels, suggests that a minimum depth of cover of 5 to 6 m is normally considered sufficient to guarantee a deep-seated failure condition at pull-out. It can be seen, also, that equation (66.3) for the calculation of the load capacity of an anchor is also sensitive to the overburden pressure around the fixed anchor length. Hence, by implication, it would be expected that the smaller the overburden pressure above a given fixed anchor length, the lower the capacity of the ground anchor. If there is any doubt about the performance of a near-surface anchor, its performance should be confirmed either by investigation or suitability testing to EN1537.

For multi-tied walls a circular-type of stability analysis is usually recommended to determine the location of the acceptably stable failure surface. This is because the shape of the sliding surface is not clear experimentally with multiple rows of anchors. Littlejohn *et al*. (1971) recommend a logarithmic



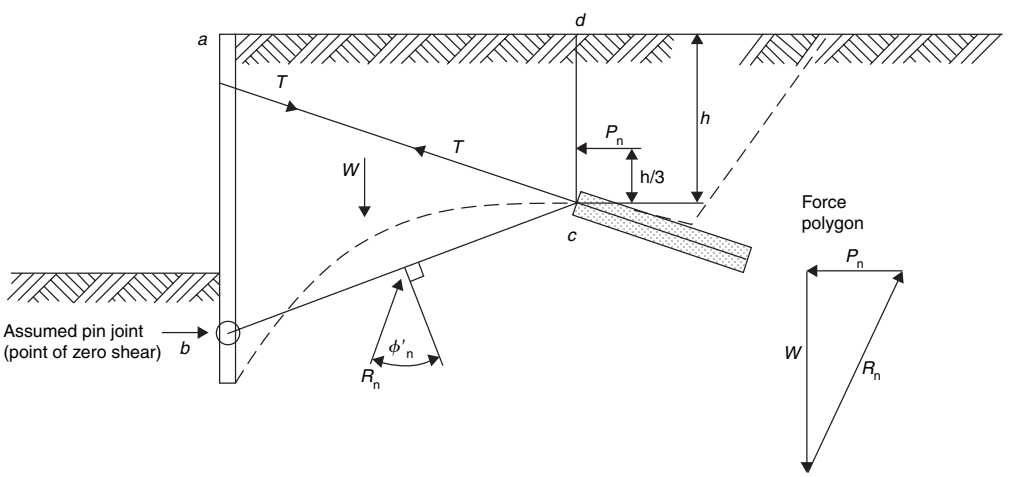


Figure 66.11 Typical planar wedge method of analysis

Factor of safety F is given by:

$$F = \frac{\tan \phi'_d}{\tan \phi'_n} \geq 1.5$$

where

ϕ'_n is nominal angle of shearing resistance in terms of effective stress (in degrees).

NOTE: If ϕ'_n has been correctly assumed, the weight W and the forces R_n, and P_n are in equilibrium. If this is not the case ϕ'_n has to be altered.

Figure 66.12 Typical sliding block method of analysis
Reproduced from Littlejohn (1972)

spiral method for defining this surface, as illustrated in **Figure 66.13**. The reason for this is that a log spiral has the property that the radius from the spiral centre to any point on the curve forms a constant angle ϕ_s with the line drawn normal to the curve. Hence, if a nominal friction angle, ϕ'_n, for the soil is selected for ϕ_s, then the line of action of the resulting forces on each part of the sliding surface will pass through the centre point of the spiral. Hence, none of the forces along the failure surface will create a moment around the centre point and they can be neglected when equating moments about this point.

In a similar manner to the sliding block method, the value for F is satisfied when the value for ϕ'_n is such that the moments of the remaining forces sum to zero, as shown in **Figure 66.13**.

It is again usual to ignore the stabilising effect of the passive resistance of the soil beyond the toe, so that when the moments W_s and W_o are equal, a conservative value is obtained of $F = \tan \phi'_d / \tan \phi'_n$.

The definition $F = \tan \phi'_d / \tan \phi'_n$ can be considered as a partial factor of safety against failure of the soil body. The chosen value of F used in practice can vary between 1.2 and 1.5 for a sliding block design, and ≥1 for a spiral-shaped sliding surface design. The higher value would be selected for more critical applications, or where conditions are less well defined.

All the analysis techniques illustrated in **Figures 66.11** to **66.13** make an underlying assumption that the pre-stress exerted by the post-tensioned anchors increases the shear strength of the soil sufficiently to ensure the potential failure plane is beyond the proximal end or the mid-point of the fixed anchor length, depending on the design philosophy noted above.

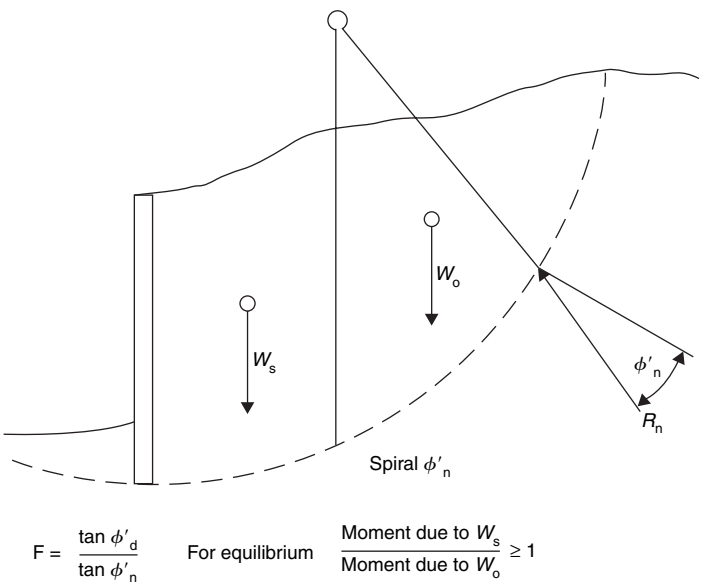

Figure 66.13 Typical stability analysis using a log spiral shaped sliding surface
Reproduced from Littlejohn, 1972

66.4.4.2 For clayey soils

For clayey soils a circular form of failure surface would normally be preferentially analysed, and, again, as a general recommendation, the whole of the fixed anchor length should be located beyond the failure surface with the required value for the factor of safety, unless the designers agree otherwise.

Reference has been made to the use of a planar wedge design method described above for granular soils, being used also for clayey soils, but this method has to be used with caution, and, also perhaps previous experience. It has been used successfully in the past on such projects as the Neasden Underpass in London (Sills *et al*., 1977).

Compared with the design assumptions for granular soils, it can be appreciated that anchor pre-stress will only slowly increase the shear stress of a clayey soil over time. It is usual for such soils, therefore, that a conventional analysis of the overall stability of the wall should be undertaken, ignoring the effect of the proposed ground anchors, and identifying the location of the failure surface that has an acceptable factor of safety, in a similar manner to that described above for granular soils. The fixed anchor lengths of the anchors should then be located beyond this calculated surface.

For mixed soil and rock conditions, where, typically, anchors might be located in a rock stratum beneath the overlying soils, as illustrated in **Figure 66.14**, it should be appreciated that rock anchors generally develop higher unit bond strengths than soil anchors. In some circumstances there could, therefore, be a risk of pull-out failure of a conical or wedge-shaped mass of rock by the tensile force imposed by the wall if the anchor is not embedded sufficiently deeply into the rock stratum. This possibility needs to be checked by the anchor designer.

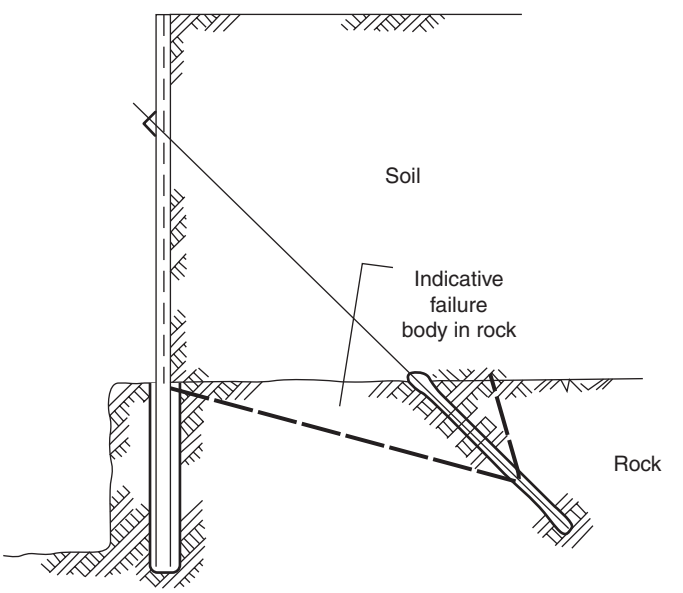

Figure 66.14 Indicative pull-out failure body within rock stratum

66.4.5 Load transfer into the structure

The head assembly for a ground anchor typically consists of a stressing head or anchor block onto (or into) which the tendon is anchored, and a bearing plate, which transfers the anchor force onto the structure. In the case of an embedded retaining wall the bearing plate can often bear onto steel or concrete waling beams to distribute the imposed anchor forces more evenly into the wall.

An important factor in such load transfer and distribution systems is that the vertical component of the anchor force has to be accommodated within the design.

In steel sheet piles and king-post walls, with steel waling beams, some form of angled bracket assembly must be provided. Typical solutions to this problem are illustrated in **Figure 66.15**.

In contiguous or secant piled walls, very often reinforced concrete walings or load transfer assemblies would typically be employed, as in **Figure 66.16**.

For diaphragm walls, a suitable angled pocket is usually cast into the wall panel, together with a guide tube through the wall section to locate the drill string clear of the reinforcement.

With particular reference to secant and diaphragm walls, it may be necessary to make provision for the anchor head system to withstand hydrostatic pressures. This is often more difficult to achieve than might be expected, and needs close attention to design, installation and construction procedures.

EN1537 (Section 6.3) outlines the design and tolerance requirements of the anchor head. One requirement is that the anchor head should be designed to tolerate an angular deviation of up to 3° from the axial direction of the tendon. Whilst this is a normal requirement for post-tensioning systems, it can cause difficulties with the protective systems for permanent ground anchors if attention is not paid to this detail. Specific requirements should be highlighted, discussed and clarified with the suppliers of such systems.

BS8081 makes specific reference to the design requirements of ground anchors in terms of the facility for the anchor to be re-stressed or even detensioned during its service life. It defines the requirements of 'normal', 're-stressable' and 'detensionable' anchor heads. These cases are not recognised by EN1537, which, effectively, leaves the decision to the knowledgeable designer. For reference, BS8081 identifies the following cases:

- A normal anchor head is designed to allow tensioning and overload testing of the anchor tendon during the acceptance test phase. Once the anchor has been accepted, the excess stressing tendon may be cut off and no further measurement or adjustment is possible.
- A re-stressable anchor head has all the properties of a normal head and, in addition, allows the load in the tendon to be checked during the life of the anchor and allows small losses of up to 10% of the working load to be recovered, normally by shimming or thread turning.

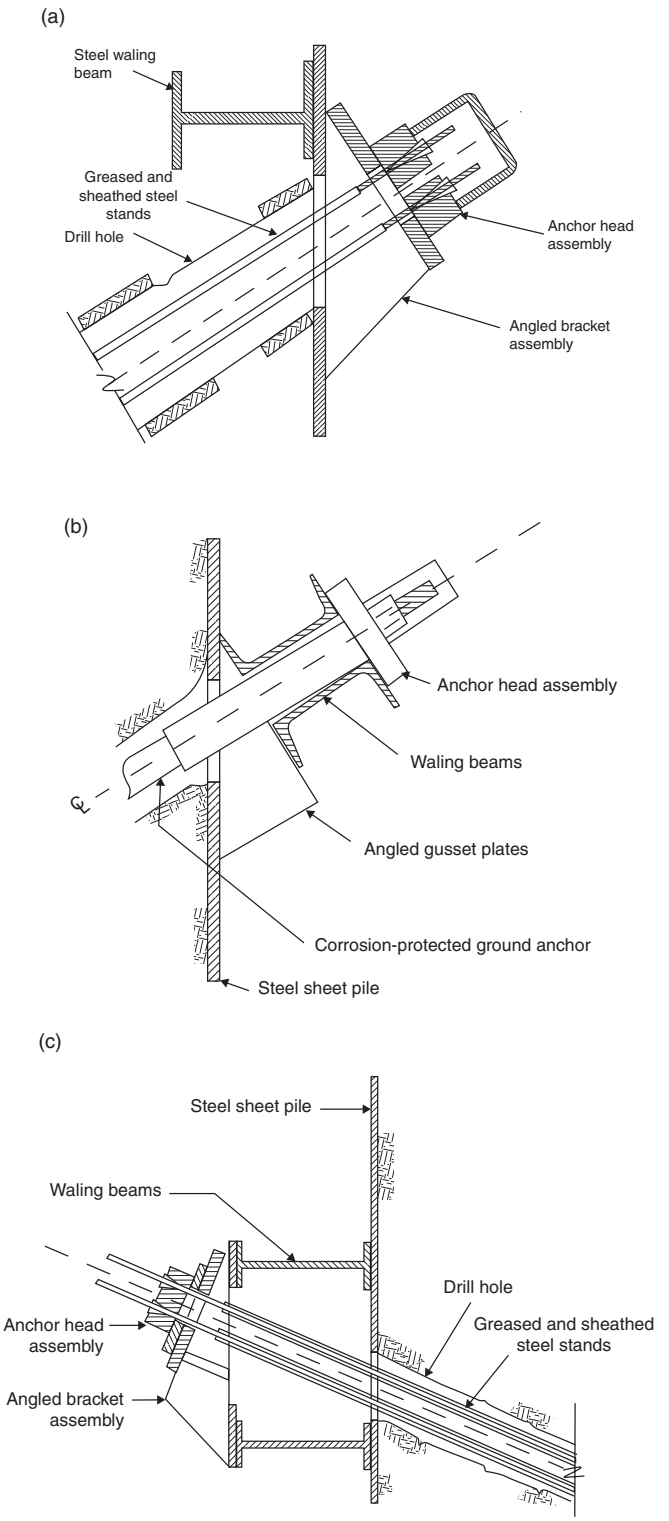

Figure 66.15 Typical use of ground anchors with steel walings. (a) Internal waling, with external angled bracket assembly; (b) external angled waling; (c) external waling with angle bracket assembly

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

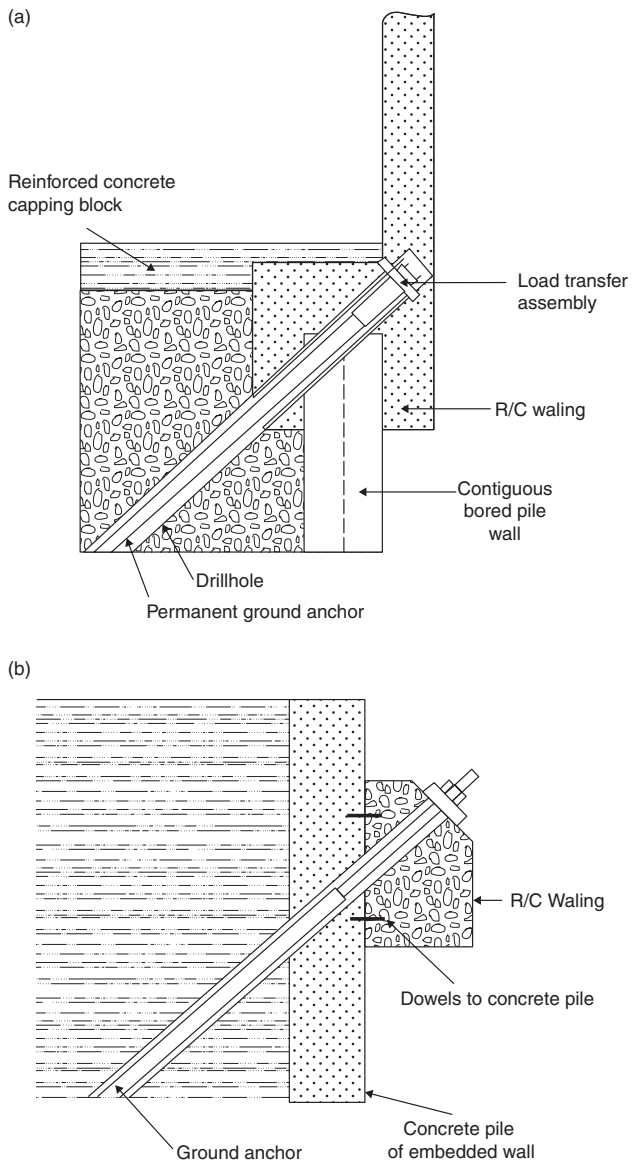

Figure 66.16 Typical use of ground anchors with reinforced concrete walings or load transfer assemblies

- A detensionable anchor head has all the properties of a re-stressable head and, in addition, allows the tendon to be detensioned in a controlled way at any time during the life of the structure.

It is important that the wall designer, as well as the anchor designer, is aware of these different facilities and is clear what level of 'adjustability' is required for their particular case.

BS8081 also suggests (at Clause 7.4.6) that a degree of redundancy should be allowed within the anchored system to a retaining wall. A structure should be designed so that, in the limit, any one anchorage can fail without the load on the other anchors exceeding the proof load to which they were initially tested.

66.4.6 Testing

The ground anchors supporting retaining walls should be subjected to the regime of investigation, suitability and acceptance testing recommended by BSEN1537, as outlined in Chapter 89 *Ground anchors construction*.

As part of the routine monitoring of the supported excavation, it is wise to consider monitoring loads in selected anchors, especially for deep, multi-tied excavations. It is important to confirm that the performance of a wall is maintained within its design envelope, and monitoring anchor loads is one part of this regime. Such load-checking can be undertaken using load cells or by routine check-lifting operations.

It is also not unknown for anchor loads to fall or fluctuate during the life of the structure, especially for sheet-piled walls where new fill has been placed behind the wall, in the construction of new river walls, for instance. Turner and Richards (2007) discuss load changes and lateral movements recorded in an anchored sheet pile wall constructed along the River Thames in 1979, where the site was redeveloped some twenty years later. Horizontal movements of the piled wall, supported by a single row of inclined ground anchors, were found to vary in a roughly cyclic manner between 25–30 mm over a year.

Chapter 67

Retaining walls as part of complete underground structure

Peter Ingram Arup, London, UK

CONTENTS

67.1	Introduction	1031
67.2	Interfaces with structural design and other disciplines	1031
67.3	Resistance to lateral actions	1033
67.4	Resistance to vertical actions	1034
67.5	Design of bored piles and barrettes to support/resist vertical loading beneath base slab	1036
67.6	References	1037

Retaining walls usually form part of an overall structure. They are often used both to create basement space and to act as part of the overall foundation system. As a geotechnical designer it is important not to lose sight of the fact that the function of the entire structure is the priority for the client, rather than the function of the walls and foundations alone.

This chapter is intended to highlight how, as part of designing an overall underground structure, it is necessary for the retaining wall designer to consider not only how the various elements forming the underground structure will interact and react as a whole structure, but also how the geotechnical design must be consistent with the work of other disciplines.

The following discussions provide the reader with a basic understanding of the issues relating to the holistic design of the whole basement/underground structure and interaction with other disciplines.

67.1 Introduction

This chapter provides a description of some of the wider issues which need consideration for holistic basement design in addition to basic retaining wall design calculations. The whole structure should be considered by designers before and during the design of the wall, as described in here and in Chapters 64 *Geotechnical design of retaining walls* to 66 *Geotechnical design of ground anchors*. Successful application of the concepts contained in this chapter can require a high degree of interaction between the various engineering disciplines involved in basement design.

67.2 Interfaces with structural design and other disciplines

Underground structures require input from a variety of disciplines, often with conflicting requirements. In order to safely design for the whole structure, it is important that the various engineering disciplines, and the architect, understand clearly the pinch points in each other's designs. For example, floor slab (e.g. propping) levels may be constrained by stair heights, and may therefore not be relocated to optimum levels to suit the geotechnical design. For small projects it is relatively easy to get a consensus as, typically, a small number of individuals are involved. For larger projects, this is most likely to be successfully achieved by:

- having the team in one location;
- regular multi-disciplinary design reviews;
- production of formal design guidance, setting out clearly how the different disciplines will design their respective elements of the structure, and how their design will interact with others.

The following sections deal principally with common design interfaces with the structural engineer.

67.2.1 Design life and durability

BS EN 1990: 2002 requires the designer to specify the design working life for the structure, and outlines indicative time periods for typical structures. *Building structures and other common structures* are to be designed for a suggested working life of 50 years, with *monumental building structures, bridges, and other civil engineering structures* having a suggested design working life of 100 years.

Durability in concrete structures is typically provided by three means:

(i) Having an appropriate concrete mix to take account of the method of placement, and exposure to aggressive ground conditions – determined with reference to BRE (2005).

(ii) Appropriate reinforcement detailing to limit cracking, usually incorporating a continuous layer of reinforcement in each face, for walls and slabs in contact with the ground.

(iii) Appropriate concrete cover to reinforcement in accordance with the requirements of BS EN 1992–1-1:2004.

67.2.2 Design philosophy for buried structures (crack width control, construction joints, watertightness, etc.)

Understanding the client's requirements for end use, and hence water tightness, is key to determining appropriate wall details.

BS 8102 (2009) defines grades of watertightness and methods of achieving them. **Table 67.1** is reproduced from the standard.

The previous edition of BS 8102 (1990) referred to grade 4 (or special) environments. The 2009 edition has not retained this grade, stating that the only difference between grades 3 and 4 is the performance level related to ventilation, dehumidification or air conditioning, and suggests referring to BS 5454

(2000) for recommendations for the storage and exhibition of archival documents. BS 8102 notes that the structural form for grade 4 could be the same or similar to grade 3.

The *Specification for Piling and Embedded Retaining Walls* (ICE, 2007) provides guidance on levels of acceptable wall seepage for the grades defined in BS 8102.

- *For grade 1 structures* Beading and limited damp patches are tolerable, but no weeping.
- *For grades 2, 3 (and 4) structures* Beading and limited damp patches are tolerable, but no weeping. Other components will be needed in addition to the retaining wall component to achieve the required watertightness of the whole system.

BS 8102 states that resistance to water ingress is usually provided by one or a combination of the following methods:

- *Type A (barrier) protection* Protection against water ingress which is dependent on a separate barrier system applied to the structure.
- *Type B (structurally integral) protection* Protection against water ingress which is provided by the structure.
- *Type C (drained) protection* Protection against water ingress into usable spaces which is provided by the incorporation of an appropriate internal water management (drainage) system.

Watertightness provided by the structure (types A and B) is affected by cracking, construction joints, differential movements, openings for services, etc., so design for an appropriate watertightness requires an understanding of how to control water ingress at these points.

BS EN 1992–1-1:2004 (BSI, 2004) provides requirements for crack control in reinforced concrete structures. Gaba *et al*. (2003) states that 'Cost savings are possible if a pragmatic approach is taken to crack width control'. Consideration of appropriate limits of cracking for buried retaining wall structures can lead to a significant reduction in the reinforcement required to control cracks. Useful guidance on this is given in IStructE (2004) and Gaba *et al*. (2003).

Grade	Example of use of structure	Performance level
1	Car parking; plant rooms (excluding electrical equipment); workshops	Some seepage and damp areas tolerable, dependent on the intended use
2	Plant rooms and workshops requiring a drier environment (than Grade 1); storage areas	No water penetration acceptable. Damp areas tolerable; ventilation might be required
3	Ventilated residential and commercial areas, including offices, restaurants, etc.; leisure centres	No water penetration acceptable. Ventilation, dehumidification or air conditioning necessary, appropriate to the intended use

Table 67.1 Grades of watertightness
Data taken from BS 8102:2009 (BSI, 2009)

In addition to consideration of appropriate limits on flexural cracking in the retaining wall section, and the cracking of wall structural elements, the following are the areas where particular care is required:

- Interfaces between structural wall elements and capping beams or slabs. These require careful detailing if water flow paths are to be restricted.
- Points of gross change in construction (e.g. where new and existing construction join) result in higher risk of entry for water.
- Discrete movement joints. These should be avoided where possible in the outer envelope of basements as they are a frequent point of weakness and leakage. Where such movement joints cannot be avoided they should be protected against water ingress.
- Construction joint spacing in water-resistant concrete should be determined in accordance with requirements to limit shrinkage and early age cracking.
- Applied barrier system waterproofing must be able to accommodate the predicted lateral wall movements following installation of the system.

Further discussion on watertightness of basement structures, and guidance for clients can be found in ICE (2009) *Reducing the Risk of Leaking Substructure – A Clients' Guide*.

67.2.3 Design codes and standards

Chapter 10 *Codes and standards and their relevance* provides a comprehensive list of the main codes and standards to be used in the UK for design. That chapter draws attention to the first point-of-call design guidance for underground structures in the UK, although these are likely to be broadly applicable to other geographic locations. The primary sources of geotechnical and structural design guidance for underground structures in the UK are shown in **Figure 67.1**.

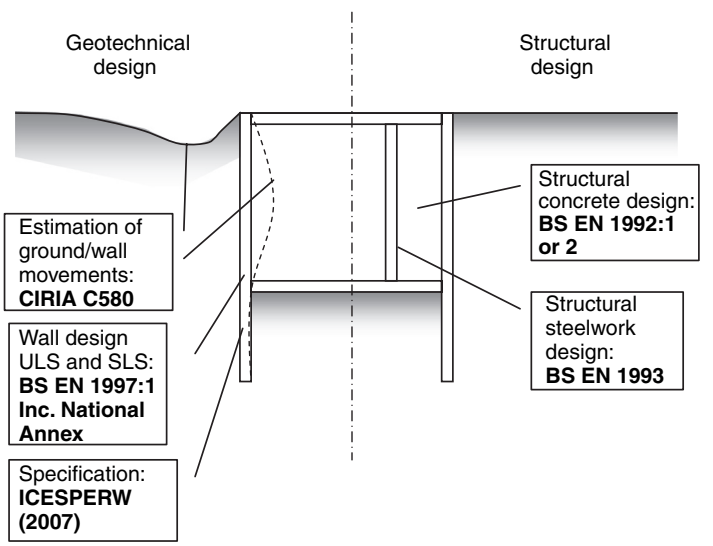

Figure 67.1 UK design guidance

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

In addition to the guidance highlighted in **Figure 67.1**, a series of execution standards are available to complement the Eurocodes. Most relevant to geotechnical construction of basements are:

- BS EN 1536: 2000 *Execution of Special Geotechnical Works – Bored Piles*;
- BS EN 1537: 2000 *Execution of Special Geotechnical Works – Ground Anchors*;
- BS EN 12063: 1999 *Execution of Special Geotechnical Works – Sheet Pile Walls*.

67.2.4 Load combinations (lateral and vertical)

BS EN 1997–1 Eurocode EC7 (2004) defines the following load factors for use in retaining wall design. Design is to be carried out using Design Approach 1 in the UK, using both Combination 1 and Combination 2 factors (**Figure 67.2**). Both of these load combinations are ultimate limit state (ULS) conditions. Serviceability must be considered separately.

67.3 Resistance to lateral actions

As part of the whole underground structure, the retaining wall needs to fulfil a variety of functions, and must:

- be able to resist lateral forces in bending or in overall horizontal stability, to provide an adequate factor of safety;
- be able to support the applied vertical loading at all stages of construction, and in the permanent condition, including the need to maintain a satisfactory factor of safety against flotation and soil heave;
- provide hydraulic cut-off and/or maintain satisfactory basal stability;
- be of sufficient stiffness to restrain ground movements outside of the structure to within tolerable limits.

67.3.1 Determination of retaining wall toe level for lateral stability and associated load effects

Chapter 64 *Geotechnical design of retaining walls* provides design guidance for considering retaining wall lateral stability and loading, highlighting the need for compatibility with the requirement for the wall to support vertical loading, and the importance of designing for both.

The design of underground structures requires a holistic and consistent approach to the design of the retaining walls, internal piles and base slabs. The following is a step-by-step approach to considering the interaction between the designs of the various elements:

(i) Determine magnitude of wall frictions for vertical/horizontal compatibility of wall movements.

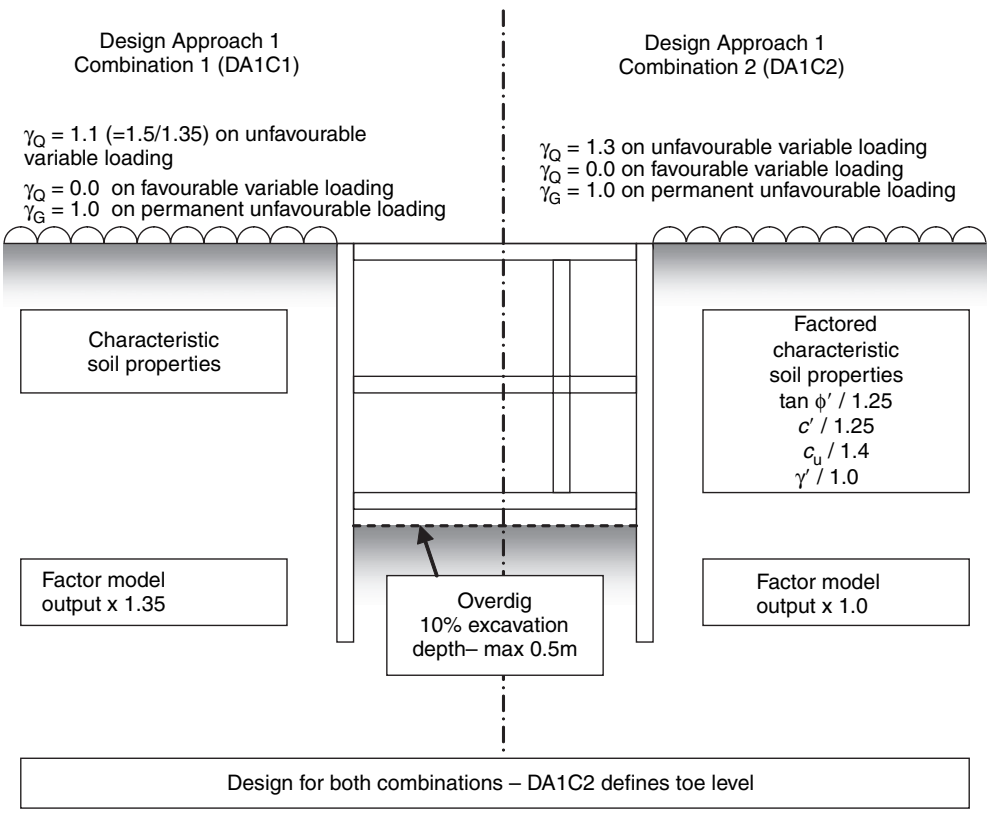

Figure 67.2 Design factors to BS EN 1997–1:2004, Eurocode EC7 (2004) . γ_Q partial factor for a variable action; γ_G partial factor for a permanent action; ϕ' effective angle of shearing resistance; c′ effective cohesion intercept; cu undrained shear strength; γ' effective unit weight

(ii) Analyse walls to determine minimum toe depth for lateral stability; see Chapter 64 *Geotechnical design of retaining walls.*

(iii) Consider the ability of walls to carry the vertical loads during excavation, and increase toe depth if necessary; see Chapter 64 *Geotechnical design of retaining walls.*

(iv) Determine additional foundation dimensions to carry vertical loading, e.g. pile foundations.

(v) Adopt design wall toe level and review the direction and magnitude of assumed wall friction and adhesion at soil/wall interface. Re-do lateral analyses, if appropriate, to confirm wall design toe level.

(vi) Consider vertical uplift forces (these can be reduced where deflection of the structure is acceptable).

(vii) Consider any heave void or under-slab drainage.

(viii) Increase foundation element/wall depths to ensure sufficient factor of safety against uplift, where necessary.

(ix) Consider the design of the base slab to accommodate any net uplift forces.

(x) Consider the base slab/piles/walls acting as an overall foundation system to resist vertical loads.

67.3.2 Accidental loading

Accidental loss of a temporary prop The designer should allow for the accidental loss of a temporary prop during construction which could happen for a variety of reasons; for instance, if something were dropped from a crane. The designer must ensure an adequate load factor, and deformations must remain within repairable limits. If the design is particularly sensitive to the loss of a temporary prop, the designer may opt to specify redundancy within the propping system to account for such an eventuality.

Loss of a permanent prop Most basement walls are unlikely to be able to survive this scenario without serious damage, and would most likely totally collapse. If this is recognised by the designer as a viable load case (for instance, in the design of metros which may be vulnerable to terrorist activity), then the designer needs to ensure that the slab/prop is structurally able to tolerate the foreseeable forces to which it may be subjected in such a scenario.

Flooding The designer should consider whether flooding is likely, to what extent, and for what duration. Flooding can increase loads on the structure in two main ways: (i) it may increase lateral water pressures behind the walls; and (ii) it may apply an additional surcharge on the slabs and the soil retained by the walls.

67.3.3 Out-of-balance forces

Underground structures are often subjected to out-of-balance lateral forces for a variety of reasons. It is important to consider the interaction of out-of-balance forces in design, rather than just designing the wall with the higher lateral forces and not considering how this will affect (or be affected by) the opposing wall.

Typical causes of permanent asymmetric loads are:

- ground or groundwater conditions, e.g. a sloping site, heavily variable stratigraphy, or a basement adjacent to water on one side;
- surcharges adjacent to the basement, e.g. from nearby structures, roads or railways;
- superstructure: varying building heights over the basement causing an imbalance in vertical loading of walls;
- substructure stiffness, e.g. different response of opposing walls formed in different manners;
- adjacent tunnels or other underground infrastructure;
- pressures from adjacent ground treatment works.

In addition, it is important that the designer considers temporary imbalances, for example:

- loading from adjacent construction plant;
- construction storage or stockpiles;
- asymmetrical construction sequences.

When the design is being carried out using finite element modelling (FEM), catering for these imbalances once they have been established is relatively straightforward. For underground structures subject to significant out-of-balance forces, FEM is likely to be the most expedient way of understanding and designing for these forces. It is common to design retaining walls using limit equilibrium or pseudo-finite element (PFE) analyses which consider a single wall only. For simpler force imbalances, it is possible to iterate between two separate PFE models, each representing opposite sides of the excavation, with the prop pre-stress forces adjusted at each iteration until deflection and prop force are balanced across the excavation.

67.4 Resistance to vertical actions

For a basement structure it is likely (and usually economical) that the retaining wall will be used to resist vertical loading. Vertical loading on the wall is likely to be different in the temporary and permanent condition. A typical basement structure carried out using a bottom-up methodology may be subject to the following variations in loading over its construction and use (**Figure 67.3**):

(i) Excavation of basement, using temporary props – walls lightly loaded.

(ii) Completion of substructure. Vertical downwards loads – increased from (i) due to the slabs – now supported by combination of walls and base slab bearing pressure. Uplift or heave forces on the structure to be resisted by a combination of structure dead weight and wall frictional resistance (or controlled by a heave void/drainage layer).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(iii) Completion of superstructure. Increased resistance to uplift/heave forces provided by superstructure weight. This also increases vertical downwards forces into walls/base slab.

(iv) Redevelopment of superstructure whilst re-using basement structure – similar to condition (ii).

The magnitude and direction of the vertical loading affects the direction of the friction forces acting on the wall, and hence the lateral pressure applied to the wall by the surrounding ground. The design of embedded retaining walls in the UK is often carried out using limit equilibrium or PFE computer programs such as STAWAL, FREW or WALLAP, where the designer must select the magnitude and direction of wall friction when determining active and passive earth pressure coefficients. It is therefore important to consider the variation of vertical loading in the temporary and permanent cases when determining appropriate wall frictions for use in lateral design.

67.4.1 Design of retaining walls to support/resist vertical loading

The design of embedded retaining walls in the UK is described in the previous paragraph. Typical directions of wall friction adopted for basement wall design are shown in **Figure 67.4**, which has been reproduced from CIRIA C580 (Gaba *et al*., 2003). These assumptions of wall friction are appropriate for excavations where vertical loading of the retaining wall is minor, such as in **Figure 67.5(a)**.

Diaphragm or piled retaining walls for deep excavations, particularly in the top-down method of construction or anchored walls, may be subject to significant vertical compressive loading during construction, in particular just prior to the casting of the base slab (**Figure 67.5(b)**). The designer must consider whether the magnitude of applied vertical loading is such that the assumed applied sense of the wall frictions reverses, as this will influence the applied horizontal pressures (see e.g. Ingram *et al*., 2009).

If the design is carried out using appropriate finite element analysis, then compatibility of friction assumptions can be modelled directly.

For excavations below the water table or in heaving soils, the retaining wall may become a tension element resisting the upward pressures acting on the underside of the base slab. Under these conditions, the friction directions shown in **Figure 67.6** may be applied.

The change in wall frictions caused by uplift conditions will reduce the passive resistance of the wall, increasing the

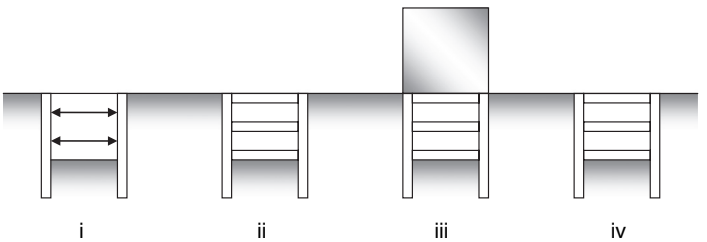

Figure 67.4 Typical construction conditions for basement wall loading

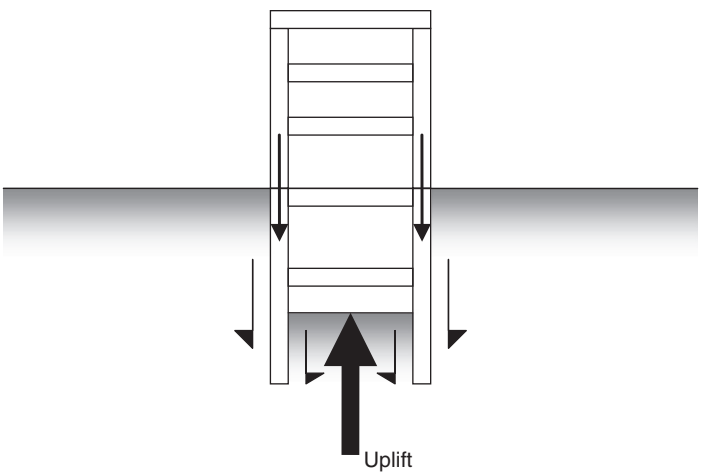

Figure 67.6 Possible wall frictions around excavations subject to long-term uplift

horizontal load in the slabs or props and modifying the bending moment and shear forces in the retaining wall. This should be considered as part of the wall design, but is often overlooked.

67.4.2 Flotation and heave

Uplift actions on underground structures can be caused by pore water pressure acting under the base slab and, in overconsolidated fine-grained soils, by soil heave pressure. The approach to dealing with the uplift pressures associated with these two phenomena should be considered early on in the design process. For both processes, it is possible to either resist or dissipate the forces on the substructure.

Flotation can be accommodated in design by either dissipating under-slab pore water pressures by under-slab drainage, or by resisting the imposed forces by a combination of the building weight and soil friction acting on the walls and any tension piles. Underdrainage can introduce other factors such as increased maintenance and operation costs, and may result in widespread settlement as a result of consolidation and/or loss of fines which could affect both the basement structure and adjacent third parties.

Possible methods of providing under-slab drainage are:

- a no-fines concrete drainage blanket beneath the base slab blinding;
- a series of shallow *French drains* beneath the base slab blinding;
- a number of passive wells, discharged by artesian pressure into the base slab drainage system;
- a number of active wells, discharged by pumping.

Soil heave pressure dissipates as upward movement is allowed (see **Figure 67.7**) and can therefore be accommodated in design by allowing the soil to move upwards. This can be achieved either by specifying a heave void or by allowing the structure to rise upward (which may not be appropriate from a serviceability perspective). If required, all or some of the heave pressure can be resisted using a combination of the building weight and soil friction acting on the walls and any tension piles.

It should be noted that where the designer opts to dissipate the uplift/heave forces using a drainage blanket or heave void, the effective stress under the base slab can be reduced, resulting in reduced vertical load capacity of the walls and piles.

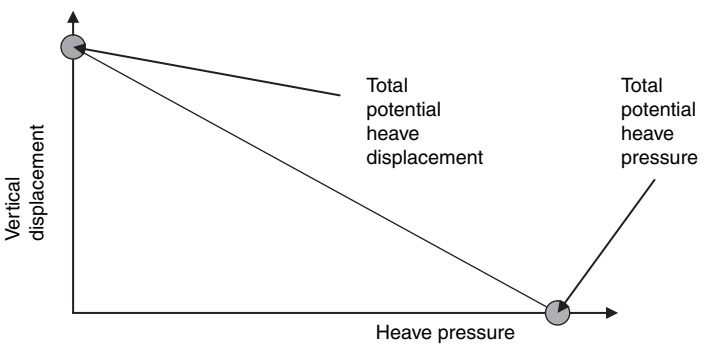

Figure 67.7 Dissipation of soil heave pressure with vertical displacement. Note: assumes linear elastic behaviour for simplicity

67.4.3 Design of ground-bearing base slab (for vertical downward loading and to resist heave and water pressures)

Aside from the geotechnical design of the base slab as a foundation, it is important to consider how it functions as part of the overall structure. The designer should consider the robustness of the whole structure, including connections. The base slab connects the walls to the ground below, and also to any additional piled foundations. Interaction of these various elements must be considered in design.

The base slab must be strong enough to resist the upwards flotation and heave forces, restrained by the self-weight of the box structure together with any tension forces mobilised through shaft friction in the piles and walls. It must also be able to distribute any concentrated applied loads to the supporting ground.

Provided that the appropriate overall ULS and serviceability limit state (SLS) considerations are satisfied, an economic foundation which just satisfies global resistance to uplift (or downwards) loading may well have individual pile or wall elements with a lower factor of safety.

The base slab must be strong enough to safely redistribute the loading in the scenario where the individual pile or wall elements only just achieve (or less obviously, achieve more than) their theoretical working load resistance. For example, piles that perform significantly in excess of predictions may settle less under applied loads, and therefore act as stiff points, potentially attracting further load. A robust consideration of the potential relative stiffnesses of the foundation system can be used to envelope the possible responses.

In addition to the strength of the base slab, the connection between the slab and the walls must be sufficiently strong to transfer all of the possible loads between the walls and the foundation structure.

67.5 Design of bored piles and barrettes to support/resist vertical loading beneath base slab

Where piles or barrettes are used as a foundation solution within a basement, their design has additional considerations compared to the design of piles with a cut-off level at or close to the ground surface. Excavation of the basement causes two phenomena which must be allowed for in pile design: (i) a reduction in overburden stress and hence ground strength; and (ii) heave-induced ground movements.

The change in the horizontal stress state ($\Delta\sigma'_h$) in the ground following a reduction in overburden stress can be calculated by considering an equation of the type:

$$\Delta\sigma'_h = \left(\frac{\nu}{1-\nu}\right)\Delta\sigma'_v$$

where ν is Poisson's ratio, and $\Delta\sigma'_v$ is the change in vertical effective stress due to excavation.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Piles beneath deep basements should be designed using effective stress parameters, as total stress design does not account for strength changes (unless, for example, c_u was measured after basement excavation). A detailed discussion of the effective stress approach to pile behaviour and design is given in Chapter 22 *Behaviour of single piles under vertical loads*.

Where piles are installed within a deep basement, pile reinforcement typically should extend full depth to resist heave forces. Consideration of the relative displacement and capacity of the pile shaft can be used to reduce the length of cages where the piles are not required to provide additional tensile capacity.

- Chapter 26 *Building response to ground movements*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles.* A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation.*

Section 7: Design of earthworks, slopes and pavements

Section editor: **Paul A. Nowak**

doi: 10.1680/moge.57098.1041

Chapter 68

Introduction to Section 7

Paul A. Nowak Atkins Ltd, Epsom, UK

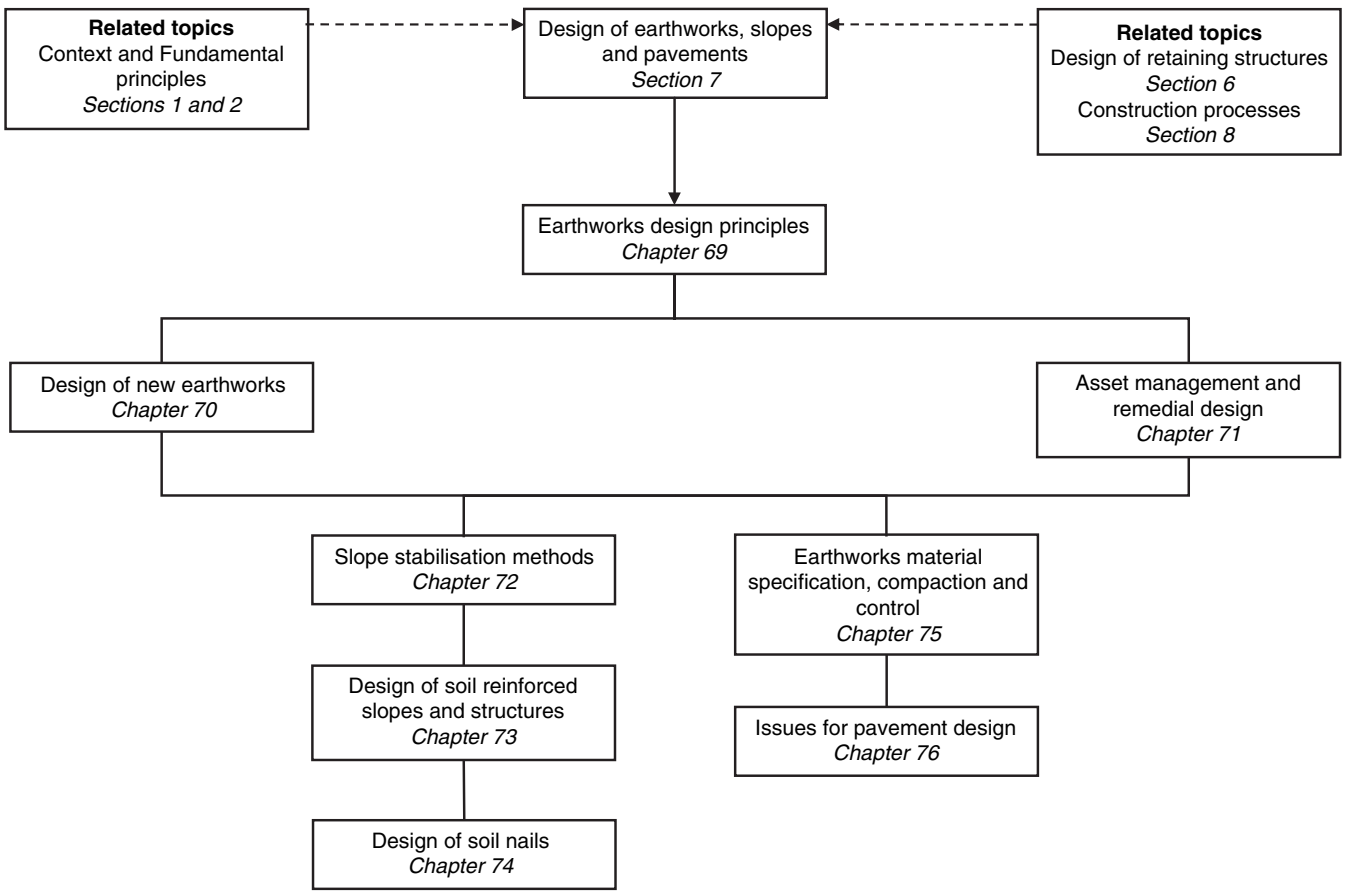

Figure 61.1 Relationships between the chapters in Section 7

Man has constructed earthworks in Europe since the Stone Age, but a major expansion of activity occurred in the nineteenth century with the development of the railways, in order to meet operational maximum gradient requirements.

The development of major road networks in the twentieth century continued this expansion and heralded the extensive use of earthworks plant and formal methods of compaction.

In both cases the earthworks were constructed to provide a balance between excavated and deposited material and to provide a stable platform on which the infrastructure can operate.

Current earthworks engineering can be considered to have three major streams:

- design and construction of new build routes;
- alteration or widening of existing earthworks;
- assessment and maintenance of existing assets.

The design of earthworks, although predominantly engineering, has always demanded a feel for material that is essentially heterogeneous and of varying properties, and the balance has changed over time. Much of earthworks construction occurred before the formal advent of soil mechanics theory in relation to earthworks engineering. Its development in the UK through the 1950s to the 1970s forms the basis of the concepts used in modern-day design. It grew in great part due to failures of constructed slopes on the railway network and slopes under construction on the trunk road network, and the need to understand failure mechanisms to prevent further earthworks failures.

This development was in parallel with that in the USA, which was driven mainly by failures of embankment dams such as Teton Dam.

Although the failure mechanisms were generally different in the UK (the presence of relict slip features in new build failures and pore water pressures in existing earthworks slopes) compared with the USA (internal erosion of embankment dam shoulders and core) the same theories were established which has allowed the development of more rigorous analysis as soil mechanics has evolved. It is interesting to note that, in both cases, the presence of water generally had a great influence on the instability.

Traditional earthworks design, where input assumptions have been tested against a varying final factor of safety against failure, have been replaced over the last 10 years by the design approach of Eurocode 7, the use of which was written into EU law in April 2010. This borrows the concept of partial factors on input parameters from structural engineering and represents a change in thinking, where the choice of input parameters demands more focus, although it does not detract from previous practice. Its introduction has provoked extensive use of this new approach but has not fully replaced the use of the final factor of safety approach.

Overall earthworks design usually considers ultimate limit state failure but, increasingly, in the assessment of existing assets, serviceability limit state behaviour is an important consideration, as 'failure' can be defined as loss of service through unacceptable movement of the earthworks formation.

Chapter 23 *Slope stability* of this manual provides an introduction to slope stability design. **Figure 68.1** outlines the layout and contents of Section 7 *Design of Earthworks, Slopes and Pavement.* This section covers the design of both unreinforced and reinforced earthworks, the assessment of existing assets, the specification of earthworks materials and consideration of pavement design.

The future holds an interesting mix of potential earthworks problems. New build schemes will demand a potentially differing approach from that of the maintenance and operation of existing, ageing assets and their potential replacement. The effects of climate change are likely to produce changes in rainfall pattern and a rise in sea levels. These effects are likely to generate the need for earthworks engineering in the provision of flood defence and sea erosion protection measures.

Chapter 69
Earthworks design principles

Paul A. Nowak Atkins Ltd, Epsom, UK

Earthworks, in the form of cuttings and embankments, have been constructed for some 4000 years. This chapter presents a brief history of development of analysis methods and the development of factors of safety to the current use of Eurocode 7.

CONTENTS

69.1	Historical perspective	1043
69.2	Fundamental requirements of earthworks	1043
69.3	Development of analysis methods	1044
69.4	Factors of safety and limit states	1044
69.5	References	1046

69.1 Historical perspective

The construction of earthworks in the UK can be traced back some 4000 years when earthworks took the form of buried mounds and mounded features such as Silbury Hill in Wiltshire (Charles, 2008).

The tradition was carried on by the Romans whose roads tended to follow natural contours but contributed with earthworks in the form of barriers like Hadrian's Wall to keep out invading tribes from the Empire.

The bulk movement and placing of earthworks coincided with the Industrial Revolution in the mid 18th century, initially in the construction of the canal network. This comprised the excavation of channels with gradients being overcome by the construction of locks – the most spectacular of which is probably the system on the Leeds–Liverpool Canal to take it over the Pennines.

The advent of the railways from the 1830s required the construction of cuttings and embankments as locomotives could not negotiate gradients of greater than 1 in 50. Initially, all bulk earthmoving was carried out using horse-drawn wagons with the materials being end tipped into embankments, then cut and placed at their angle of natural repose. This form of technology did not detract from large volumes of construction and Skempton (1995) reports the movement of two to three million cubic yards of material per year over the period 1834 to 1841. In the late 19th century, steam driven equipment was introduced but the method of placing of the fill was largely the same.

Embankment settlements could be large both during and subsequent to construction and were controlled by reballasting of the track and the imposition of speed restrictions. McGinnity and Russell (1995) describe London Clay embankment construction on London Underground in the late 19th and early 20th centuries, where settlement during construction was topped up with London Clay and steam locomotive ash.

The development of the roads network in the UK from the 1920s required earthworks gradients of less than 1 in 10 and coincided with large scale mechanisation of earthmoving plant in the United States. The development of mechanised plant allowed the control of fill quantity and the compaction of soil in layers for embankment construction.

69.2 Fundamental requirements of earthworks

The fundamental requirement of an earthwork is to form a stable foundation for the proposed end use over its design life. This usually represents minimal settlement for a road pavement or a railway track bed.

With respect to cuttings, the fundamental requirement is the stability of the cutting side slopes which, if they fail within the design life of the earthwork, may cause the deposition of debris at the toe of the cutting or failure of material at its base, causing damage to the road surface or railway track.

With respect to embankments, failure of side slopes is similarly important as loss of slope could result in undercutting of the asset that the embankment supports. Additionally, the settlement of the embankment over its design life, whilst not necessarily contributing to catastrophic failure, may result in the loss of service of the asset due to unacceptable differential movement. This is particularly the case with respect to railways, where differential settlement between the running rails is usually set at less than 5 mm. Acceptable differential settlement may also vary along the earthwork. The most critical area is usually where an earthwork adjoins a structure. The structure abutment is designed to minimise settlement of the overall structure which will be less than the likely settlement of the embankment adjoining the abutment. This can lead to eventual cracking of the road pavement or loss of horizontal rail alignment. In the short term, it can lead to a reduction in ride quality.

In planning earthworks for a linear transportation scheme, it is usual, where practicable, to endeavour to set the vertical alignment such that the scheme is 'in balance'. This means that the volume of material excavated from cuttings is nearly the same as that required to form embankments. The calculation of overall volume will take account of the amount of cut material that is unsuitable for use as embankment fill. This material is likely to have to be removed from the site. Common practice is now, however, to incorporate unacceptable material into landscape features, or to render it acceptable for use in the works by conditioning. This is dealt with in more detail in Chapter 75 *Earthworks material specification, compaction and control*. In calculating the overall volume of earthworks, bulking of the material from cutting to placing into embankment is sometimes considered. For most earthworks materials, the volume placed in embankments is up to 5% less than the

volume won from cuttings. This is due to the specification of formal compaction and the fact that mechanical placement and compaction in an embankment does not fully replicate the geological process under which the cut material was first deposited. The notable exception to this rule is unweathered chalk which shows up to 5% shrinkage in volume from cut to fill. This is due to the fact that the material occurs naturally with a high voids ratio and open jointing – which are destroyed by the compaction process.

It is common practice to ignore the volume increase due to bulking from cut to fill when calculating earthworks quantities, or to include it, but balance it with the volume of earthwork embankment lost due to settlement of the foundation material.

Overall guidance to the excavation of materials and their compaction into earthworks' embankments for highways schemes in the UK is given in document HA44/91(1995) produced by the Highways Agency.

69.3 Development of analysis methods

It should be noted that most of the earthworks built in the 19th and early 20th centuries were constructed when soil mechanics was in its infancy. Collin (1846) produced a slip circle stability analysis, but it was not until the work of Terzaghi (1925) on the influence of pore water pressure on the deformation and strength of soils, that stability and prediction of failure started to be understood.

In the 1930s the principle of effective stress for earthworks materials began to be understood and a move from empirical to numerate determination of slope stability began to be developed. Over time, a number of methods have been developed in order to ascertain the factor of safety of new and existing earthworks slopes. The rigour of the analysis was, however, was tied to the development of analysis technology and hence in the 1950s and 1960s (before the development of computer analysis programs) more traditional methods of mathematical computation were used. The main methods of analysis can be summarised as:

- infinite slope method;
- stability charts;
- limit equilibrium;
- numerical modelling;
- observation method.

The infinite slope method is a quick computational method developed for failures that occur at shallow depth in cuttings and embankments where the failure surface is assumed to be a plane parallel to the slope surface. The method is described in Skempton and DeLory (1952) and in Trenter (2001).

Stability charts like those by Taylor (1948) and Bishop and Morgenstern (1960) were developed from more rigorous analysis to produce a series of charts and tables where knowledge of shear strength, angle of friction and water conditions allowed a factor of safety to be computed for varying slope angle without further rigorous computation. These charts have been updated by Bond and Harris (2008) for use with Eurocode 7.

The limit equilibrium method was developed as the more rigorous analysis of a series of slices through the proposed slope where interaction between the slices was computed as the analysis method developed. Bishop (1955) developed the method for analysing circular potential failure surfaces. The method was developed by Morgenstern and Price (1965) and Janbu (1972) for analysing non-circular modes of failure.

Computational limitations in the 1950s and 1960s restricted the number of potential failure surfaces that could be practically analysed, and work carried out by Skempton (1964) and Chandler (1972), among others, tended to concentrate on back analysis of slope failures where the form of failure surface was already known. The advent of computer analysis in the 1980s has allowed these analysis methods to be applied to everyday earthworks analysis, with many failure surfaces analysed in the same computational run.

The development of finite element and finite difference analysis techniques in the 1990s has allowed more rigorous analysis of earthworks slopes to be computed from the limit equilibrium methods described above. These techniques model elements bounded by nodes and allow both ultimate failure conditions and movement of slopes, during their design life, to be determined.

The observational method of earthworks slope analysis, summarised by Nicholson, Tse and Penny (1999), represents an approach where design assumptions are reviewed during the construction and design life of an earthwork by use of instrumentation. The principles of the observational methods can be summarised as:

- Establishment of acceptable limits of behaviour.
- Assessment of the range of possible behaviour showing that there is an acceptable probability that the actual behaviour will be within acceptable limits. A plan of monitoring is devised which will determine whether actual behaviour lies within acceptable limits.
- The response time of the instrumentation and proposals for analysing the results shall be sufficiently rapid in relation to the possible evolution of a failure mechanism.
- Adoption of a plan of contingency actions which may be enacted if the monitoring reveals behaviour outside acceptable limits.

More information on the analysis and stability of natural and man-made earthworks can be found in Chapter 23 *Slope stability*.

69.4 Factors of safety and limit states

69.4.1 Factors of safety

Traditionally, the factor of safety against failure of an earthworks slope has been considered as a target 'lump' factor which should represent the minimum value that an analysis of failure can achieve.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Trenter (2001) comments that the chosen minimum factor of safety will depend on two sets of circumstances:

- technical assessment of the geotechnical data collected for a potential slip;
- judgement on the safety, environmental and economic costs of any failure.

BS6031 (1981) gives minimum factors of safety of 1.3–1.4 for first time failures, and 1.2 for failures involving ancient shear surfaces.

Trenter, considering environmental, economic and safety risks, suggests the minimum factors of safety for first time and reactivation failures of cuttings and embankments; these are summarised in **Table 69.1**.

The factors of safety for new dam construction are shown in **Table 69.2** (Johnston *et al*., 1999).

Other studies have considered a variable factor of safety for earthworks stability considering design soil parameters and groundwater/loading conditions. Egan (2005) considered the acceptable factors of safety for Network Rail earthworks shown in **Table 69.3**.

Perry *et al*. (2003) considered the variable minimum factors of safety for infrastructure embankments (see **Table 69.4**).

As can be seen from this table, the choice of minimum factor of safety lies with the designer and generally reflects the choice of design soil parameters, the application of loading and groundwater conditions, and the influence of failure on the infrastructure asset. These aspects are discussed in greater depth in Chapter 70 *Design of new earthworks*.

The implementation of BS EN 1997–1, Eurocode 7 (2004) introduces the concept of partial safety factors to input parameters, rather than the use of a final target 'lump' factor for the design of earthworks slopes.

The required condition to be met by the analysis is:

$$E_d \leq R_d$$

where E_d is the design value of the effect of actions, and R_d the design value of the resistance to an action.

The National Annex to BS EN 1997–1 for the UK (2006) adopts Design Approach 1 which requires the computation of two load combinations:

(i) Combination 1 = A1 + M1 + R1

(ii) Combination 2 = A2 + M2 + R1

where A = actions, M = materials, and R = resistance. The partial safety factors to be applied are given in **Table 69.5**.

Analysis to Eurocode 7 is usually reported as satisfying the condition above, i.e. $E_d \leq R_d$.

Bond and Harris (2008) introduce the concept of a degree of utilisation where the analysis result is reported as a percentage of the design value of the resistance to an action, rather than a factor of safety.

69.4.2 Limit states

The calculation of a satisfactory factor of safety against failure, or satisfactory achievement of design value of resistance to Eurocode 7, should result in a stability state where overall failure of the slope is unlikely to occur. This can be considered to be the ultimate limit state failure of the slope.

Conditions can, however, occur where the earthwork does not reach its ultimate failure state – movement occurs which affects its performance. This can be considered to be a serviceability limit state condition and is controlled by the

	Factor of safety (first time failure)	Factor of safety (reactivation failure)
Cuttings		
Permanent	1.30–1.50	1.10–1.30
Temporary	1.10–1.30	>1.0–1.20
Embankments		
Permanent	1.40–1.60	1.30–1.50
Temporary	1.20–1.40	1.10–1.30

Unconfined strength (q_u)	Y_{qu}	1.0	1.4
Weight density (Y)	Y_Y	1.0	1.0
Resistance		R1	R2
Earth resistance	Y_{Re}	1.0	1.0

Table 69.5 Partial safety factors for analysis to Eurocode 7

performance of the infrastructure that the earthwork supports. Common examples of this condition are:

- creep of cutting slopes, resulting in unacceptable movement of services, e.g. drainage, electricity or communications cables;
- settlement of embankment foundations or creep of embankment slopes, resulting in unacceptable deflections of railway tracks or highway surfacing/services.

BS6031 (2009) recommends that when considering deformation of earthworks, it is appreciated that they can undergo large deformations without detriment to their own serviceability, although the effect of deformations on shear strength may be sufficient to cause failures at ultimate limit state as shear surfaces develop. It is important to consider the effect of deformation of structures adjacent to or supported by earthworks, as these may control the overall earthworks design.

Deformation of earthworks over their design life can be determined by numerical methods of finite element or finite difference modelling outlined in section 69.2 above.

The design of earthworks needs to consider the interaction of a number of factors to understand their stability and performance over time. These include soil design parameters, groundwater conditions, external loading and the effects of vegetation. Additionally for embankment design the nature of fill material and the competence of the bearing stratum needs to be considered. This chapter introduces these concepts in the framework of design of cutting slopes and embankments.

An introduction to the mechanics of natural and earthworks slopes is presented in Chapter 23 *Slope stability* and an introduction to earthworks slopes can be found in Chapter 69 *Earthworks design principles*.

70.1 Failure modes

70.1.1 Introduction

The design of earthworks is predominantly driven by the possibility of failure of the completed earthworks slope. The failure of earthworks can generally be considered to fall into two categories:

- failure during or soon after construction;
- failure during operation through the design life of the earthwork.

Although a new earthwork would be analysed in the same way to take account of both types of failure the mechanisms of failure are fundamentally different as they are the result of a different set of circumstances.

Most modern earthworks are constructed to fulfil a 60-year design life (*design life = period without significant maintenance rather than failure after the period of the design life*) but throughout the UK infrastructure earthworks have been in place for up to 150 years with no significant signs of distress.

70.1.2 Types of slope failure

The main types of potential slope failure are summarised in **Table 70.1**. The failure mechanisms are shown in **Figure 70.1**.

The design against failure of a new earthworks slope is generally by limit equilibrium methods described in Chapter 69 *Earthworks design principles* and tends to concentrate on rotational circular failure, after Bishop, or rotational noncircular/translational failure, after Morgenstern and Price, as these are the analysis methods commonly available in computer analysis programs.

Compound failure, flow slides and slab slides are more difficult to predict as a failure mechanism for new earthworks. The analysis of compound failures tends to be the subject of back analysis of failed or partially failed slopes. The factor of safety against failure by flow slides and slab slides can, however, be evaluated by the infinite slope method or by limit equilibrium methods where shallow circular failures close to the slope surface are similar in shape to shallow flow slides.

Progressive failure is discussed further in section 70.1.4. It is difficult to analyse using limit equilibrium as the mechanism is strain-dependent and empirical adjustments are required to the measured or estimated material strength. It is more suited to finite element analysis methods which can be used to predict the behaviour of strain softening soils. It should be noted that calculation of progressive collapse has not predominantly been developed as a predictive failure tool but as a method of explaining the failure mechanism of failed slopes.

70.1.3 Failure during construction

The failure of earthworks slopes during, and within a short period after construction, are rare in modern earthworks but when they occur they can be attributed to a number of factors.

The failure of cutting slopes can usually be attributed to heterogeneity of the material in which the cutting has been formed such as:

- the presence of geological structures, bedding/laminations/fissures;
- the presence of zones of contrasting permeability, e.g. inter-bedded sands and clays;
- the presence of historical slip surfaces.

The presence of geological structures is more common in rock slopes but where they occur in soil slopes in the form of

Failure mode	Definition	Comments
Rotational slide	Rotation of mass of soil along curved surface	Not usually differentiated between both mechanisms
Circular slide	Rotational slide on a slip surface that is approximately circular	
Rotational non-circular	Rotational slide on a slip surface that is not wholly circular	
Translational	Movement of a shallow mass of soil in a plane roughly parallel to the slope due to a weakness on a plane	
Compound	Movement of soil mass that combines the characteristics of a rotational and translational slide	
Mud flow	Translational slide in saturated soil, caused by a sudden increase in pore pressure, in which the soil flows as a viscous liquid	
Debris slide	Translational slide of debris, forming a mantle on a slope or the disturbed material at the toe of a rotational slide when rainfall or surface water causes downward movement of debris	
Slab slide	Translational slide in which the sliding mass remains more or less intact	Usually occurs in weathered surface of a slope
Progressive failure	Brittle failure of a soil mass by development of a rupture surface which migrates causing failure before the surface fully develops	Not specifically covered by BS EN1997-1 (2004)

Table 70.1 Main types of failure of earthworks slopes

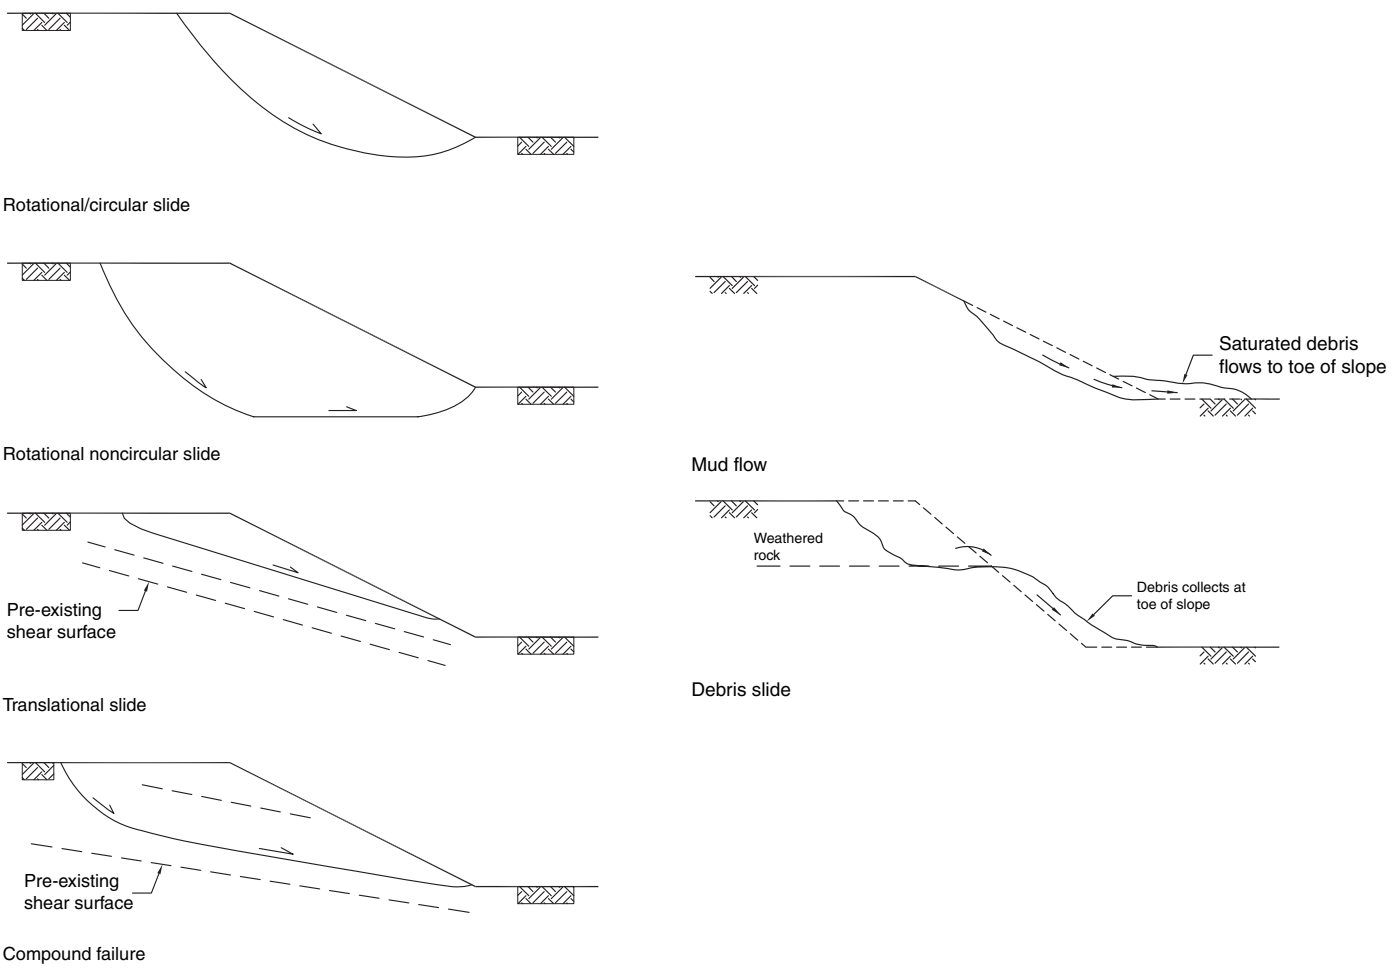

Figure 70.1 Types of failure of earthwork slopes

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

bedding or laminations these can form planes of preferential sliding if these surfaces are inclined detrimental to the inclination of the cut face.

The presence of fissures in cohesive materials can reduce material strength over time particularly in overconsolidated clays when pore pressures within a saturated soil mass readjust to new stress conditions.

The presence of zones of contrasting permeability can lead to large movements and slope failures on construction where the groundwater table is high in relation to depth of cutting. Where granular materials are inter-bedded with cohesive layers drainage is impaired and flow of groundwater is possible only through the day-lighting of the granular layers. The presence of groundwater in these layers considerably reduces their strength and flow can occur undermining the surrounding cohesive soils and causing instability of the slope.

The M3 motorway at junction 3 is underlain by Eocene Bracklesham Beds material comprising inter-bedded silty fine sands and clays. The final construction earthworks slopes were designed as 1V:3H. During construction in the 1970s failure of the slope occurred due to flow of groundwater and instability of the sand layers. Stable slopes were eventually formed at 1V:10H following the employment of extensive drainage measures.

The presence of historical slip surfaces is common in areas where cohesive strata are present which have been subject to peri-glacial activity and freeze–thaw action has caused the historical movement of material on shallow slope angles. The presence of the slip surfaces considerably reduces the material strength as described in section 70.2.2.

Failure of cutting slopes during construction occurred in Weald Clay on the A21 Sevenoaks bypass in the 1960s reported by Symons and Booth (1971) and in Gault Clay on the M25 motorway at Godstone in the 1970s. In both cases original cutting slopes were designed without taking reduced strength of relict slip surfaces into account. On the M25 motorway west of London shear surfaces were recognised in London Clay and Reading Beds material (Spink, 1991), and cutting slopes of 1V:6H were designed to prevent failure.

Hughes in Vasilikos (2009) reports a failure of a slope at Dromore on the M1 Belfast to Dublin motorway where a pre-existing shear zone in the Glacial Till caused failure of a 1V:2H cutting slope during a period of heavy rainfall.

The failure of embankments during construction can usually be attributed to:

- slope height, geometry and angle;
- foundation inadequacy;
- the presence of pre-existing shear surfaces in the embankment foundation material;
- change in the nature of embankment construction materials.

Failure due to slope geometry and angle are rare in current construction as adequate tools are available for the design of safe slope angles.

Similarly the adequacy of foundations can be controlled in order to prevent failure of the overall embankment slope and these are discussed further in section 70.2.6.

Historical failures of this type can be identified by lower slopes of low gradient, representing failures during construction. The 12-metre-high Roding Valley embankment on the London Underground Central Line was built in 1903 and comprises 4 metres of London Clay at the base at side slopes of 1V:6H overlain by 8 metres of ash. Contemporary accounts of its construction describe failure of the lower levels of embankment construction, sometimes overnight, due to failure of the underlying alluvial clay foundation.

Change in material type for embankment construction can present similar problems to those encountered in cuttings formed in inter-bedded materials described above but usually manifest themselves as shallow translational slides close to the surface of the embankment.

Construction of the M25 motorway between Egham and the M3 in Surrey in the 1970s comprised embankments up to 10 metres high built of Eocene Bagshot Beds silty fine sand. Some layers of the embankment material were laid at high moisture content which on further embankment loading caused build-up of pore pressure and subsequent loss of strength in these layers leading to sloughing of the embankment slopes with resulting regarding required. Similar failures were experienced during construction of the M65 motorway in Lancashire in the 1990s where an embankment 19 metres high was constructed of layered Glacial Till and fine-grained Glacial Sand.

70.1.4 Failure during operation

The failure of an earthworks slope during operation can be generally sub-divided into two modes:

- shallow failure by translation or shallow circular failure;
- deep failure, usually circular in nature by progressive collapse.

Shallow failures, particularly with respect to the UK highways network, have been studied over the last 20 years in an attempt to understand the mechanisms causing failure in order to minimise maintenance requirements over the design life of the earthwork.

Perry (1989) surveyed 570 km of the then constructed 2700 km of UK motorways. His study relates the angle of constructed slope for cuttings and embankments with the incidence of failure in particular geological strata. It presents a probabilistic and risk-management approach in which varying slope angles in the same material were examined for percentage of failure over the total lengths of earthwork. Stable slope angles were proposed for the various materials in cutting and embankment where incidence of failure was

recorded as less than 5% of total earthwork length. Perry concludes that the failure surface rarely exceeded a depth of 1.5 m with a minimum depth of 0.2 m and a maximum depth of 2.5 m.

Crabb and Atkinson (1991) studied failures in road embankments and cuttings in the south of England and recorded failures to 1–2 m below the slope surface. Reid and Clark (2000) observed similar depths of failure on slopes generally greater than 4.0 m in height. This concurs with the work of Perry where shallow failures were more critical in slopes greater than 5.0 m in height.

Investigation of these failures indicates that the most likely mechanism for failure is one of moisture content or pore pressure increase in the near surface of the embankment slope together with a potential reduction in strength properties of the near surface material. This increase is usually due to infiltration by surface water during and after precipitation and could generally be attributed to the lack or non-performance of slope drainage.

Regular inspection of earthworks of the UK major highway network over the last 15 years has revealed not only shallow failures as described by Perry but also signs of creep and tension cracking on existing slopes. Whilst these mechanisms may not pose an immediate danger to infrastructure users, any lack of maintenance or remediation may cause prolongation of the potential failures in surfaces with more significant volumes of failed material in the long term.

Perry *et al*. (2003b) record that operational serviceability failure of railway embankments is generally slow and insidious, associated with excessive movement rather than overall instability failure. Ultimate limit failure is less frequent but develops if serviceability failure is not addressed. Coppin and Richards (2007) report shallow embankment failures generally do not exceed 2.0 m in depth and are commonly translational although some shallow circular slips can occur.

Operational failure of embankment slopes can usually be attributed to:

- shrink–swell induced due to seasonal moisture changes and vegetation;
- deterioration of drainage;
- presence of water in the embankment over time (discussed further in section 70.2.3).

Work by Skempton after the Second World War on failures to London Underground cuttings, predominantly in London Clay, considered failure some time after construction. The failure mechanism and type was different to that described above, involving deep-seated circular failures which caused a significant hazard to the operation of the railway. Work by Potts (1997, 2000) has postulated a theory of 'progressive collapse' for these types of failure where the fissured, overconsolidated cohesive soil acts in a brittle failure mode with an increase in pore pressure along a failure surface propagating from the toe of the slope. Failure occurs when the strength of the soil on the remainder of the surface above which increased pore pressure is acting is less than the overall weight of material causing it to fail as shown in **Figure 70.2**.

Ellis and O'Brien (2007) have attempted to extend this work as a predictive tool for safe slope angle and slope height where progressive collapse will not occur. Their findings show that progressive failure is unlikely for cutting slopes in London Clay shallower than 1V:3H and less than 8 m in height. For steeper slopes or those greater than 8 m in height progressive collapse may occur up to 125 years after construction.

70.2 Typical design parameters

70.2.1 Derivation of design parameters

Traditionally, for slope stability analysis to a target factor of safety 'best estimate' or 'worst credible' parameters are usually chosen from a data set of laboratory or *in situ* test results or from back analysis of failed slopes.

Selection may be based on statistical analysis but is usually the result of engineering judgement. A typical example is shown in **Figure 70.3**.

The selection of best estimate or worst credible parameters will lead to a different target factor of safety being chosen as an acceptable minimum output from the analysis. From the discussion in Chapter 69 *Earthworks design principles* a value in the range 1.3–1.4 is usually considered acceptable where best estimate parameters are used. Where worst credible parameters are used a minimum value in the range 1.05–1.15 would be acceptable. Worst credible parameters can also be derived from the back analysis of failed slopes as these parameters equate to a factor of safety of just less than 1.0 immediately prior to the failure of the slope.

In deriving design values for slope analysis, the variation in parameters in relation to displacement should be considered as shown in **Figure 70.4**.

Values of c'_{pk}, φ'_{pk} reduce with greater displacement to c'_{cv}, φ'_{cv} and, in the case of cohesive soil where the plasticity index is greater than 25%, to c'_r, φ'_r when movement is sufficient to develop shear surfaces.

Best estimate parameters tend to equate to value between c'_{pk}, φ'_{pk} and c'_{cv}, φ'_{cv} whereas worst credible parameters tend to equate to c'_{cv}, φ'_{cv} or, in the case of cohesive soils with existing shear surfaces, c'_r, φ'_r.

The adoption of *Eurocode 7* (2004) introduces the concept of a set of characteristic values for analysis which are then factored prior to analysis as described in Chapter 69 *Earthworks design principles*.

Clause 2.4.5.2 (P) of BS EN1997-1 defines the characteristic value as 'a cautious estimate of the value affecting the occurrence of the limit state'. BS 6031 (2009) suggests

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

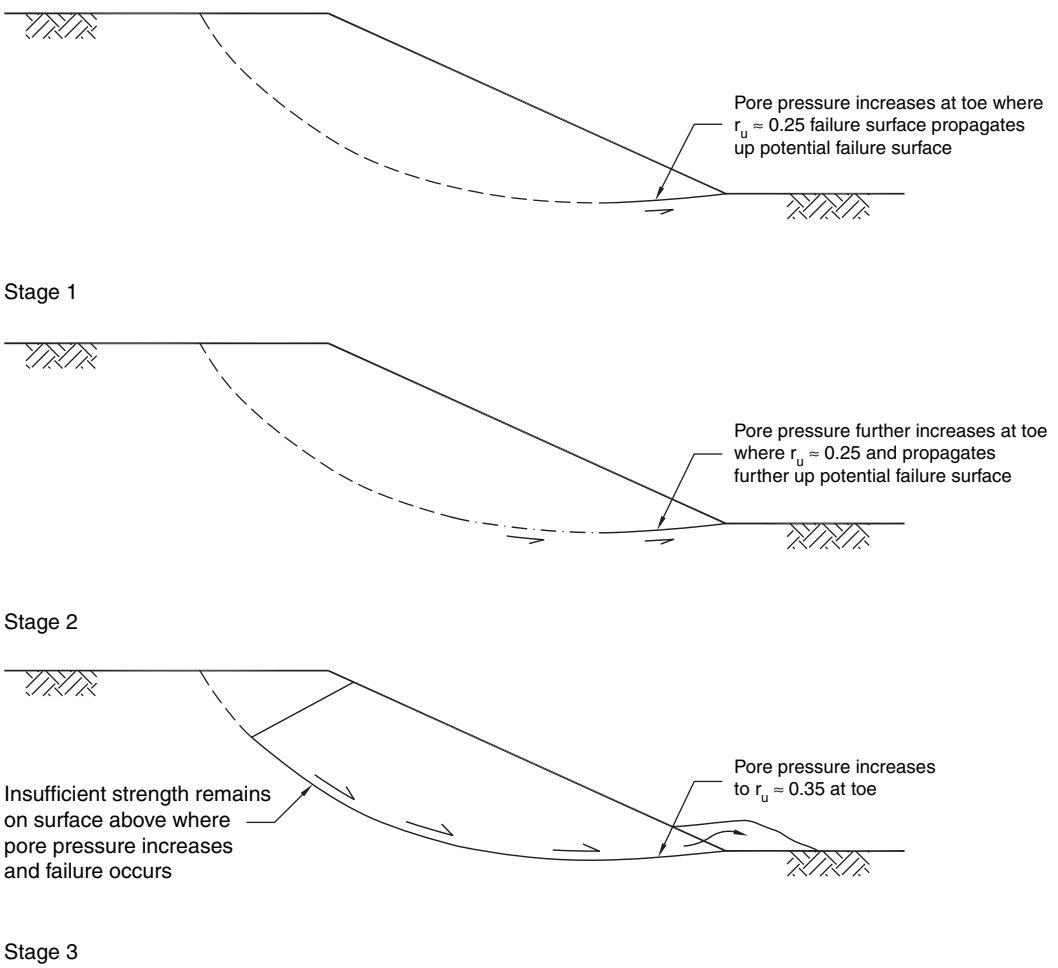

Figure 70.2 Simplified mechanism of progressive collapse

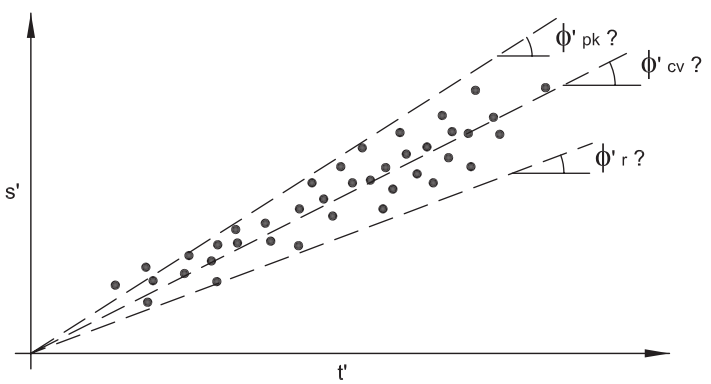

Figure 70.3 Possible selection of design parameters

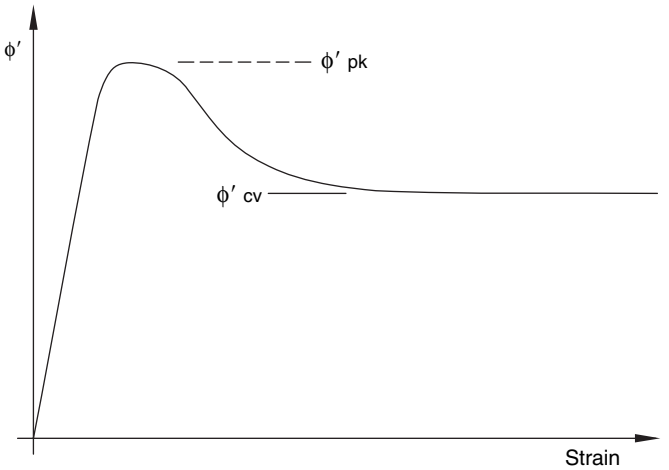
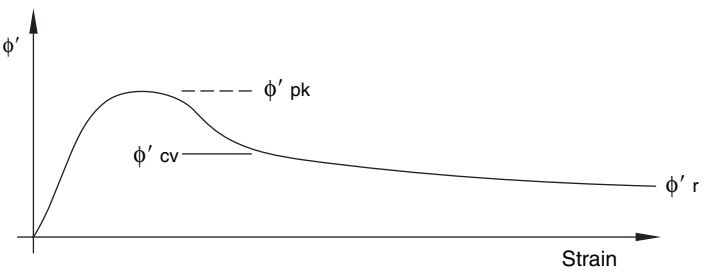


the factors affecting the choice of a characteristic design value are:

- geological, historical and other background data;
- the amount of measured data relating to the parameters under consideration;
- variability and degree of confidence in the measured data;
- extent of the zone of ground governing the limit state under consideration;
- ability of ground to transfer load from weak to strong zones;
- the consequences of failure at the limit state.



The characteristic value is, therefore, a choice through engineering judgement and although this is likely to equate to a value close to the best estimate value it may tend to worst credible if the consequences of failure are deemed to be exceptionally serious.

The choice of a value tending to worst credible must be viewed in the light of the likely failure mechanism and the fact that design values will have been assigned a subconscious partial safety factor prior to those applied through *Eurocode 7*.

It may be viewed as conservative to generally use lower design parameters for long-term stability of earthworks slopes when, as described in section 70.2.1, likely failure surfaces are shallow with no immediate effect on the overall failure of the earthwork immediately subsequent to failure.

(a) Grangular soils and cohesive soils for which Ip < 25%

(b) Cohesive soils for which Ip ≥ 25%

Figure 70.4 Variations of φ′ with displacement
Modified with permission from BS 6031 © British Standards Institution 2009

Bond and Harris (2008) equate characteristic design values to the 'moderately conservative' value used for design of retaining walls (Gaba *et al*. 2003). This equates to a low cautious average of the design data set. They state that 'The difference between CIRIA 104's moderately conservative value and Eurocode 7's cautious estimate is … merely one of semantics' (Bond and Harris, 2008: 139). This should be treated with caution in light of the discussion above.

Bond and Harris also introduce the theory of an upper and lower characteristic value from a data set. It is considered that the derivation of a characteristic value is unique to a set of ground conditions and the impact of failure of an earthwork as defined in BS 6031 and that a single set of values only should be derived.

70.2.2 Typical design parameters

Guidance on design values where no existing data are available, or where comparison of a data set with existing data and relationships is desirable, is available from a large number of sources some of which are described below.

For cohesive soils, BS 8002 (1994) presents a relationship between φ'_{cv} and plasticity index (Ip). Terzaghi *et al*. (1990) present a similar relationship between φ'_{pk} and Ip. These are presented in **Table 70.2**.

Skempton (1977) reports the following design values from testing and analysis of cutting slopes in London Clay.

$\varphi'_{pk} = 20°$, $c'_{pk} = 14$ kN/m^2, 38 mm samples;
$\varphi'_{pk} = 20°$, $c'_{pk} = 7$ kN/m^2, 250 mm samples;
$\varphi'_{cv} = 20°$, $c'_{cv} = 1$ kN/m^2, back analysis critical state;
$\varphi'_{r} = 13°$, $c'_{r} = 1$ kN/m^2.

It can be seen that φ'_{pk} and φ'_{cv} remain the same and that the difference in design value results from a reduction in cohesion (c'). Trenter (2001) recommends a similar variation in c' relationship with maximum c' of 2 kN/m^2 for fissured and structured overconsolidated clays and maximum c' of 10 kN/m^2 for non-structured clay.

Crabb and Atkinson (1991) report φ'_{cv} values from a study of shallow failures of embankments and cuttings in south-east England where failure was recorded at a depth of 1–2 m below slope surface. These are summarised in **Table 70.3**.

It should be noted that the results reported by Crabb and Atkinson do not entirely correlate with the results reported by Skempton or the Ip versus φ'_{cv} relationship in BS 8002. This indicates a scatter of results which is reported by Terzaghi *et al*. (1990). By way of illustration, **Table 70.4** presents a range of values reported for London Clay.

Soil design parameters, derived from previous analysis and testing, are available for selected strata in the literature listed in **Table 70.5**.

Undisturbed samples of granular soils are more difficult to obtain from ground investigation and design parameters tend to be taken from *in situ* testing, predominantly the standard penetration test (SPT) or cone penetration testing. Guidance on derivation of design parameters from *in situ* test results is

Lord *et al.* (2002)	Chalk

Table 70.5 Useful literature sources for design values of cohesive strata

provided in the literature from sources such as Clayton (1995) and Lunne *et al*. (2002). Design values can be derived from shear box testing (see **Figure 70.6**), but only if the *in situ* density of the material is replicated by the test.

The relationship between φ′ and SPT from commonly used relationships like Peck *et al*. (1974) will generally give φ′ values in the range 28° to 43°. These are usually acceptable for derivation of design values for cutting stability.

It should be noted, however, as described in section 70.1.3 above that the density of granular materials will be influenced by the presence of groundwater. This is particularly the case for silty fine-grained granular soils where removal of overburden below the groundwater table will effect considerable loosening of the soil structure. During the construction of the M25 motorway Bagshot Beds strata, comprising silty fine sand with an *in situ* SPT N-value of greater than 50, were seen to 'flow' when excavated below the water table. This is particular concern for the short-term stability of cutting faces in fine-grained granular soils before the groundwater table has reached its new equilibrium level subsequent to the formation of the cutting face and may require dewatering measures to be installed during construction to prevent short-term failure.

Where embankment construction comprises predominantly granular materials it is not normally common practice to test the density of the compacted material *in situ* and normally a conservative estimate of the φ' design value is taken. The London Underground Standard 1-054 gives a design value φ′ of 35° for granular embankments composed of well-graded sandy gravel of Alluvial Terrace gravel. The implementation by the Highways Agency in the UK of BA 42/96 (Highways Agency, 1996) for the design of backfill behind integral bridge abutments has focused the minds of materials engineers to provide a low φ′ material. Recent experience of shear box testing on well-graded granular materials for this purpose indicates that, when compacted to the required density, design φ'_{peak} is in the range 40° to 45°. The approach of BA42/96 has now been largely superseded by British Standard Document PD6694-1:2011 (BSI, 2011), which advocates the use of φ'_{max}, after Bolton (1986).

70.3 Pore pressures and groundwater

Pore pressures within an earthwork will vary with time and can influence the factor of safety against failure. This is shown in **Figure 70.5**. At a point A beneath an embankment foundation pore pressure increases initially on loading and then reduces as dissipation occurs over time increasing the factor of safety against failure over the design life of the earthwork. This is particularly marked in embankment foundations comprising cohesive materials. At points B and C, in the slope of an earthwork, pore pressure suctions act initially and dissipate with time resulting in a decrease in the factor of safety.

The consideration of groundwater in slope design is usually modelled as:

- adoption of a pore pressure ratio, r_u;
- modelling of a defined groundwater table.

The concept of r_u was developed in conjunction with the investigation of failures of existing earthworks slopes in order to simulate pore pressure conditions on a known failure surface by back analysis. Early soil mechanics, prior to the development of the computer, investigated conditions on a single or a small number of potential failure surfaces generally by hand calculation.

It must be borne in mind that the adoption of an r_u value is unique to a given failure surface and its use in computer analysis programs will generate a variable groundwater table with each potential failure surface generated. This can lead to conservative modelling of groundwater particularly when a free-draining material overlies a material of low permeability.

Exploratory hole data will usually allow the modelling of a defined groundwater table. The recorded groundwater level will, however, be influenced by the permeability of the soil. Whereas higher permeability sands and gravels are likely to indicate equilibrium groundwater level as flow into an exploratory hole during its construction the natural groundwater level in cohesive soils may not equilibrate for some time and accurate prediction will only be achieved from readings taken from piezometer installations.

In the modelling of the groundwater profile for long-term stability of earthworks slopes the effect of the earthworks construction should be considered with respect to long-term groundwater conditions.

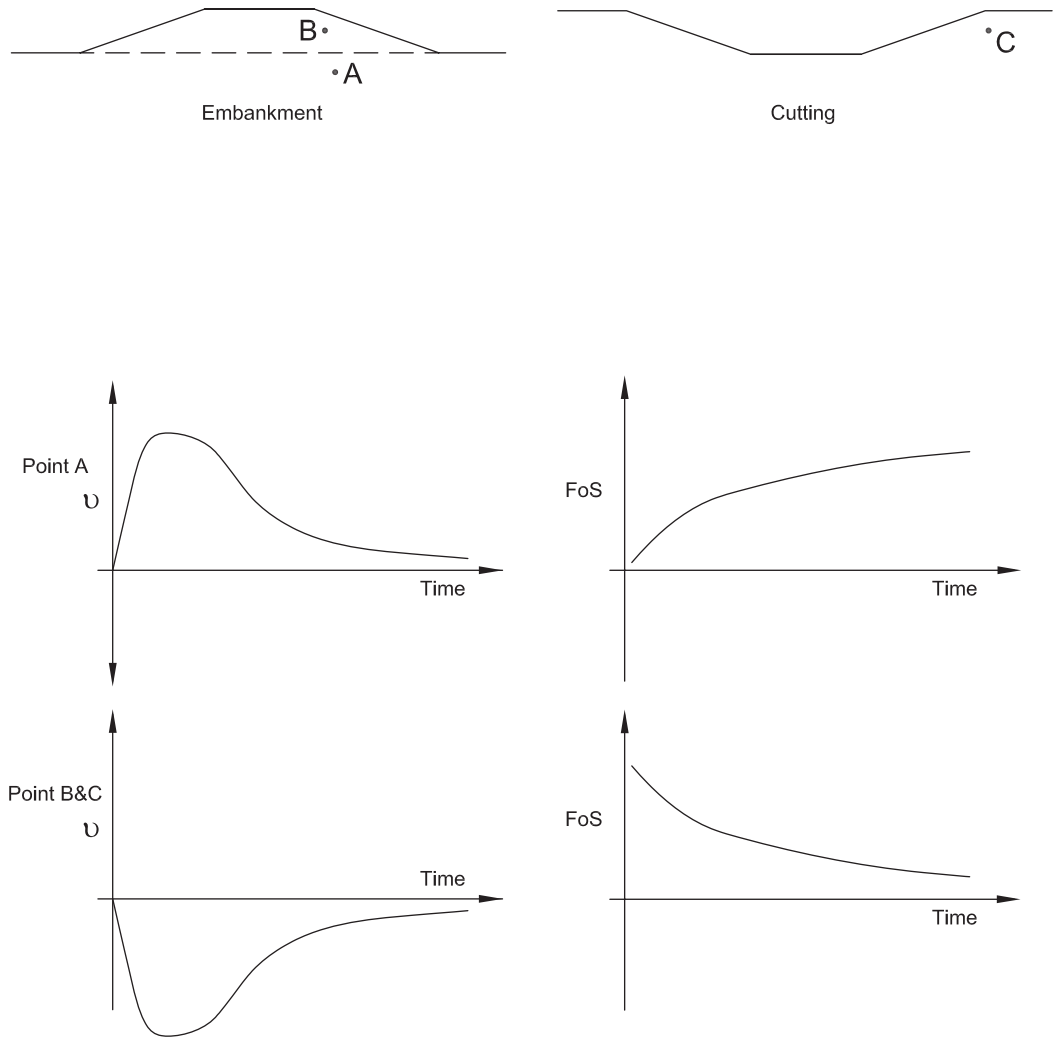

Figure 70.5 Change in pore pressure with time

Where cuttings are formed in materials where the original groundwater profile is above final finished road level this will be influenced by drainage installed at the base of the cutting to develop a revised profile over time depending on material permeability. This is illustrated in **Figure 70.6**.

Where the groundwater level is below the base of the cutting it is common to allow for a presence of groundwater in the cutting slope above the groundwater table. Farrar (1978) suggests a value of r_u in the range 0.1–0.3 should be used for slopes in cohesive materials. London Underground (2000) also suggest a similar approach for London Clay slopes with a base value of 0.25 within a range 0.15–0.35. The lower value is employed where slopes are underdrained and the higher value where no slope vegetation is present.

Groundwater conditions for embankment design differ from those in cuttings as the groundwater table will generally occur in natural ground below the embankment construction. It is usually accepted that some percolation of precipitation onto the embankment will occur over time and a nominal r_u value in the range 0.05–0.1 is adopted throughout the embankment material.

In adopting any groundwater conditions within the embankment the nature of the constructed embankment material and the likely infiltration of precipitation should be considered.

Where the embankment construction comprises granular material the permeability of the material is high and any percolating water will drain relatively easily. Where the embankment construction comprises cohesive material percolation will be slower but once saturated the embankment material will take much longer to drain.

When considering infiltration into an embankment its use should be taken into account. A highway embankment will be capped by an impermeable surfacing and possibly verge drainage which will preclude the infiltration of precipitation apart from on the shoulders of the embankment. A railway embankment is normally capped with permeable ballast to support the

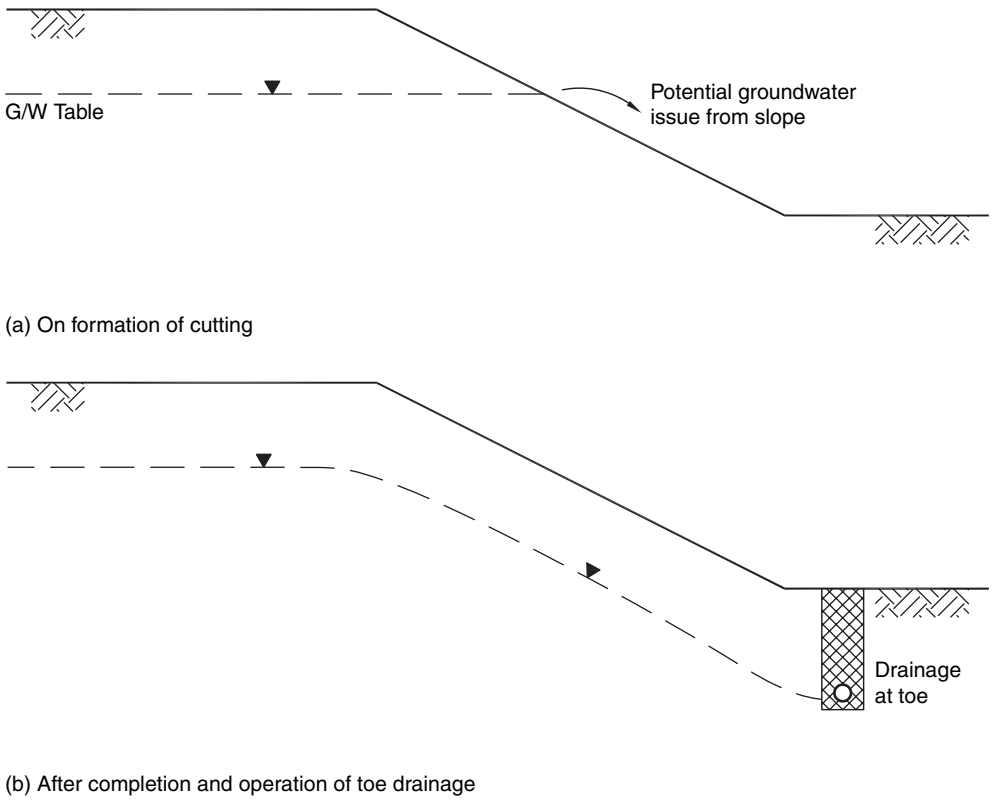

Figure 70.6 Influence of drainage of long-term groundwater level in cutting slope

tracks and, hence, infiltration can occur across the whole area of the embankment. This is shown in **Figure 70.7**.

It is common to simulate the increase of moisture content close to the slope surface, described in section 70.1.4 by an increase in r_u value in the upper 1.5–2.0 metres of the slope surface. A typical value of 0.2 is suggested by Jewell (1996) which is similar to the range 0.1–0.3 suggested by Farrar (1978).

Design of earthworks should consider the provision of drainage both to prevent the flow of surface water onto or below the newly formed earthwork and also to control the flow of groundwater.

The prevention of surface water flow is usually critical to cutting slopes. It takes the form of pre-earthworks drainage as it is usually constructed prior to the main earthwork slope and normally comprises the construction of a cut-off ditch at the crest of the cutting. This both collects run-off water from adjacent areas and can also collect any field drainage that may be intercepted as a result of the new cutting.

Pre-earthworks drainage in areas of embankment construction usually comprises measures to deal with existing watercourses and ditches in order that the earthwork can be constructed without detriment to the existing groundwater regime. This normally takes the form of new collector drains or culvert construction.

Interception of groundwater in a cutting face and its subsequent lowering may be critical to the short-term, construction, life of the earthwork or its long-term stability. Construction of permanent dewatering usually takes the form of gravel-filled trench drains in parallel or herring-bone pattern. Positive pumping from well points or deep wells is commonly employed for dewatering of temporary earthworks slopes and excavations. Long-term adoption of these measures is, however, normally impractical as a permanent measure due to the cost of operation and maintenance.

More details on the aspects of drainage and dewatering design are given in BS 6031 (2009), Hutchinson (1977), Preene *et al.* (2000) and Sommerville (1986).

Any drainage design should consider the discharge of collected water. This can be into existing watercourses or pipework, possibly through ponds or attenuation facilities. Alternatively a sustainable drainage system (SUDS) can be designed. Details of SUDS systems can be found in CIRIA Report C697 (Woods and Kellagher, 2007). In all cases, discharge should be agreed with the relevant authorities, for example the Environment Agency and water companies.

70.4 Loadings

Two types of loading should be considered in the design of earthworks slopes, namely:

- permanent loading;
- transient loading.

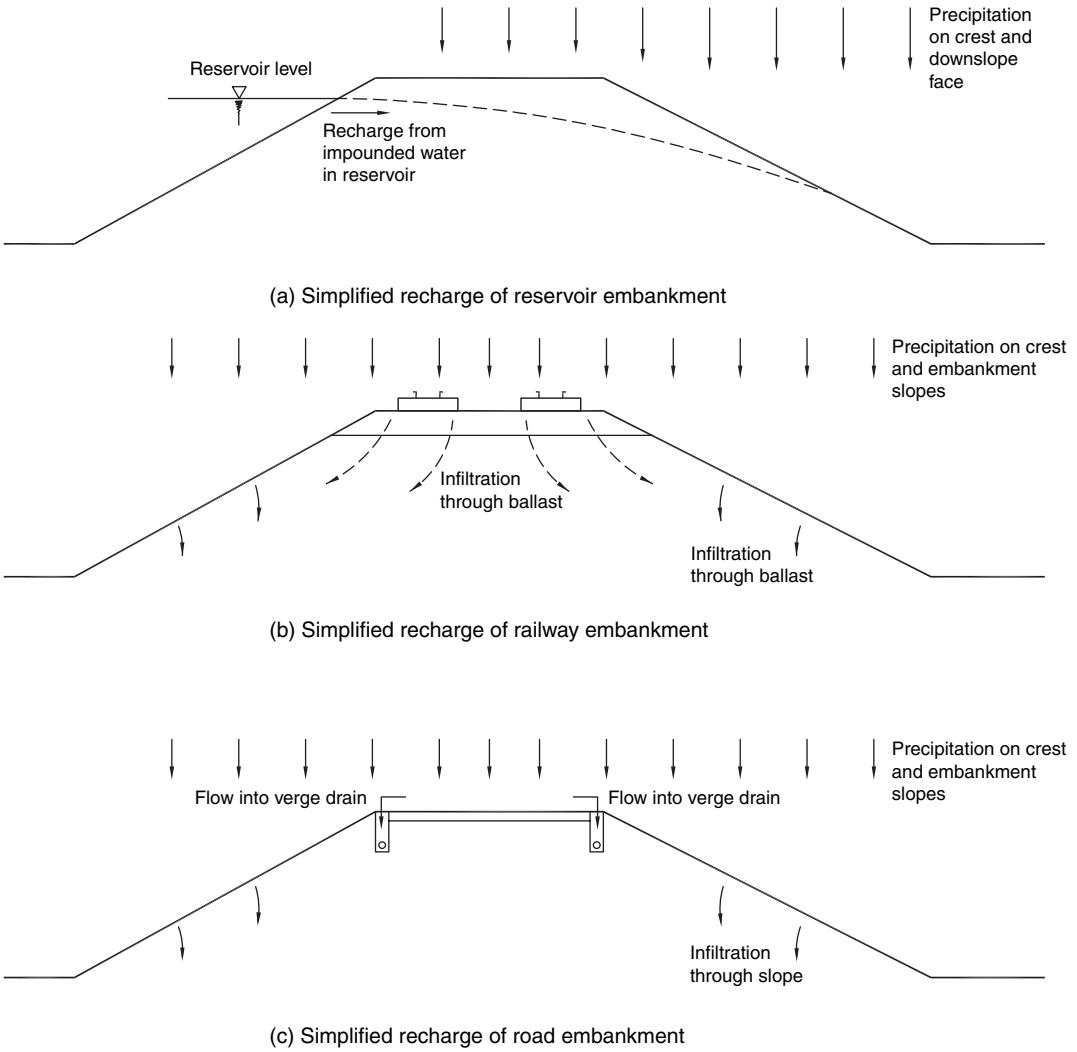

Figure 70.7 Recharge into different types of embankment

Permanent loading will be applied from buildings adjacent to cutting slopes and abutments of railway and highway structures that are constructed mid-height on the cutting slope.

Transient loads can be applied to earthworks in the form of:

- construction loads;
- stored materials/maintenance loads;
- road/rail loading on embankments.

It is usual to apply transient loads only where they contribute to the potential failure of an earthworks slope. Where transient loads may be of benefit to the stability of the slope they should be ignored.

Construction loads will influence the stability of a slope in the short term and are generally applied as a uniformly distributed load (UDL) at the top of cuttings and embankments. It is common practice to set loading from construction plant at 20 kN/m^2 for normal loading conditions. Where large items of construction plant are working at the top of an earthwork individual calculation of the applied load should be based on the weight of the plant from manufacturers' data. It should be borne in mind that large items of plant will generally operate on a construction mat comprised of granular material which will distribute the applied plant load as a UDL at the base of the mat but will also impart load in the short term.

Where materials may be stored or maintenance carried out to the earthwork over time it is usual to apply a 10 kN/m^2 UDL to take account of this eventuality. As stated above, this load would only be applied in areas where it may contribute to the failure of the slope, e.g. at the top of a cutting slope. The application of this transient load is not normally applied to cutting or embankment slope faces as significant maintenance activities or material storage is unlikely to occur at these locations.

Design of infrastructure earthworks require the application of traffic or rail loading to the top of embankment construction

Rail RL	30	London Underground and light rail
Rail RU	50	UK railway standard

Table 70.6 Design loads according to BS 5400 Part 2
Data taken from BS 5400 (2002), British Standards Institution

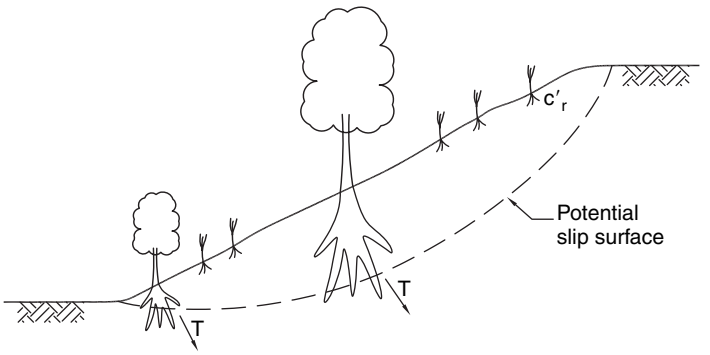
as detailed in **Table 70.6**. Information on road and rail loading is also contained in Eurocode 1 (2008, 20010).

In applying these loads for the calculation of stability of new earthworks the following should be noted:

- The loads are derived from British Standard BS 5400, Part 2 (2002), which is the design standard for steel, concrete and composite bridges, and from Eurocode 1. In the application of the loads to structures they are in direct contact with the structure and are applied to ensure that there is sufficient redundancy in the structure design.
- CIRIA Report C592 (Perry *et al.*, 2003b) comments that loading should be applied only to the worst credible analysis case and not to an analysis using moderately conservative values. The loadings above are transient and a cohesive soil is acting in its undrained condition during loading so applying load with drained strength parameters is only suitable for the worst credible case.
- BS 6031 (2009) comments that traffic loads are normally applied to the surface of an earthwork and usually contribute only a small proportion of the total earthwork load, thus may generally be ignored in settlement assessments unless there is a particular reason take them into account.

70.5 Vegetation

The effect of vegetation on long-term stability is not extensively considered in the design of new earthworks slopes. Perry *et al.* (2003a) detailed the main benefits of vegetated slopes as:



- control of erosion by shielding against the impact of rain, wind and water flow;
- enhancing shear strength through reinforcement by plant roots;
- removal of water by transpiration.

These are indicated in **Figure 70.8**.

Perry *et al.* indicate that most root reinforcement extends generally to 50 mm depth below slope surface with tree roots penetrating up to 3.0 m depth.

Norris *et al.* (2008) builds on the work of Greenwood (2004) and Norris and Greenwood (2006) in developing the concept of increase in soil cohesion due to root growth (c'_R). Typical values of c'_r from historical data after Norris *et al.* are summarised in **Table 70.7**.

A similar approach is developed by Coppin and Richards (2007) who indicate that an enhanced c′ value of up to 20 kN/m² can be taken in the upper surface of a slope where root structures penetrate.

C′r - Enhanced cohesion due to fine roots

T - Tensile force of roots acting on slip surface

Figure 70.8 Forces exerted on a slope by vegetation
Data taken from Norris et al. (2008)

	c'_r (kN/m²)	
Vegetation Type	Maximum	General range
Grasses and shrubs	60.0	2.0–6.0
Deciduous trees	63.0	3.0–10.0
Coniferous trees	94.3	3.0–6.0

Table 70.7 Shear strength contribution from vegetation
Data taken from Norris *et al.* (2008)

A practical observation of enhanced c′ due to plant growth is provided by the Longham Wood Cutting Trial in the Gault Clay on the A20 reported by Greenwood *et al.* (2001).

Norris *et al.* (2008) do not attribute any specific effect of vegetation on the groundwater table but note that pore water suctions can develop close to the surface of vegetated slopes. These can be evaluated by piezometers such as those developed by Ridley (2002).

The benefits of this suction are difficult to quantify on a definitive basis as they will vary with vegetation pattern and geology. They are likely to be beneficial to the stability of cutting slopes and the London Underground Standard for Earth Structures Assessment (2000) allows a reduction in design r_u of 0.05 where cutting slopes are vegetated. Vaughan *et al.* (2004) from work on London Underground embankment slopes report, however, that pore water suctions generate a seasonal pore water gradient through the embankment construction which can lead to seasonal shrink–swell movement in the form of creep. This movement can eventually lead to unacceptable movement of line-side services and London Underground have instituted a managed vegetation policy over the last few years to handle this problem. The difference between rail and highway embankments in the regime of potential recharge,

described in section 70.3 above should be noted, this problem being more likely on rail embankments.

70.6 Embankment construction

Embankment construction to the early twentieth century was carried out with no formal compaction with slopes generally formed at the angle of repose of the deposited material.

The mechanisation of earthmoving equipment, particularly in the United States in the 1920s and 1930s, created the need for control of earthworks compaction by a rapid means of determination. The work of Proctor (1933) developed the concept of 'optimum moisture content' and 'maximum dry density' for compacted material with laboratory testing carried out prior to placement being controlled on site by the use of moisture content determination. The use of optimum moisture content for control of compacted embankment fill is described more fully in Chapter 75 *Earthworks material specification, compaction and control*.

The Casagrande system of soil classification published in 1942 drew on the concept of Plasticity Index for cohesive soil. These classifications were developed in the UK for control of compacted earthworks material by the Road Research Laboratory leading to the development of the Department of Transport's *Specification for Highway Works* (Highways Agency, 2009). As the classifications were predominantly developed for quality control they do not translate directly into design values for earthworks materials but design values can be derived when the ranges of acceptability set are considered.

The control of moisture content for granular materials based on Optimum Moisture Content or cohesive materials based on plastic limit achieves a compacted density of greater than 90% of optimum and a measured density similar to that of the naturally occurring material from which they were derived. Hence, design values derived material from samples of natural material (as described in section 70.2 above) will be similar when compacted into earthworks embankments.

For most granular materials an acceptable moisture content of −3% to +2% of optimum achieves a compacted density of greater than 90% of optimum but this should be tested for all proposed materials. Care must be taken when specifying the upper limit for fine-grained granular materials particularly with a high silt content. These materials develop high pore pressures on compaction at moisture contents above optimum with a resulting loss of strength and limiting acceptable moisture content to optimum is sometimes necessary.

For cohesive materials the limiting of moisture content to limits around the plastic limit was not only to produce an acceptable compacted density but also to control the range of undrained shear strength of the placed material. Whyte (1982) showed that the shear strength of remoulded compacted clay is at 1.5 kN/m^2 at its liquid limit and between 100 and 130 kN/m^2 at its plastic limit (PL). The lower bound of moisture content for acceptability was set at PL -4% by the UK *Specification for Highway Works* and this reflects a maximum undrained shear strength of approximately 200 kN/m^2 at which normal compaction plant could achieve greater than 90% of maximum dry density.

Clayton (1979) notes that the purpose of the upper limit of moisture content was set to ensure embankment stability in the short term, keep self-settlement within acceptable limits and avoid problems due to loss of traffickability of earthmoving plant on the freshly placed fill. The latter is particularly important to the economics of earthmoving and Arrowsmith (1978) quoted minimum undrained shear strength of 35 kN/m^2 for caterpillar tractors and scrapers and 50 kN/m^2 for large rubber-tyred scrapers.

Dennehy (1978) relates remoulded undrained shear strength to tyre pressures of earthworks plant where he indicates a limiting rut depth of 275 mm for efficient plant working. This equates to a minimum shear strength in the range 40–60 kN m^2 for low tyre pressure plant and 60–80 kN/m^2 for high tyre pressure plant.

The Transport and Road Research Laboratory (Anon., 1975) record that for scrapers with a 16–18 m^3 struck capacity rut depth increased from 30 mm to 110 mm from a moisture content at plastic limit to one at 1.1× plastic limit. This reduced average speed from 15 km/h to 5 km/h and resulted in a 75% increase in earthworks costs. The depth of rutting of recently compacted material by plant tipping the layers above increases with moisture content and at undrained shear strength of less than 50 kN/m^2 it is likely that rutting could penetrate the previously compacted layer where compacted layer thickness is normally of the order of 250–300 mm. Further information is also provided by Farrar and Darley (1975).

The range of multiplier on plastic limit for upper bound acceptable moisture content varied with material, and usually Plasticity Index, but accepted limits were in the range PL × 1.1 and PL × 1.3. Arrowsmith (1978) presents a range between PL × 1.1 and PL × 1.2 for Glacial Clays in the north-west of England from which a value of PL × 1.2 was chosen to produce a minimum compacted remoulded shear strength of 70 kN/m^2.

The use of moisture content, with optimum moisture content or plasticity limit, as a compliance tool does, however, present a problem with respect to the reporting of results particularly for cohesive materials. To comply with BS 1377, samples have to be dried for 24 hours before a moisture content can be determined. In the case of cohesive samples the dried sample is used to determine plastic limit and a further 24 hours is required to determine the corresponding moisture content at plastic limit. This means that in excess of 48 hours could pass between sampling and determination of compliance or non-compliance over which time further earthworks layers will have been placed and remedial measures are difficult to effect if non-compliance is determined.

In order to overcome this time lag between sampling and confirmation of compliance Parsons (1976; Parsons and Boden, 1979) developed the moisture condition test. This uses

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

site-based laboratory compaction equipment to determine an immediate value which can be compared with a predetermined acceptability range from pre-earthworks testing. The pre-earthworks testing is accompanied by the determination of undrained shear strength, a correlation curve of the moisture condition value (MCV) against undrained shear strength can be plotted and MCV limits set based on the minimum and maximum compacted shear strength measured. This method was developed further by Parsons and Darley (1982) in relation to the operation of earthmoving plant.

It is usual to set the minimum MCV value at 8 which generally corresponds to a minimum undrained shear strength of 50 kN/m^2 for most cohesive materials. Correlation testing should, however, be undertaken on all materials prior to incorporation in embankment earthworks as the relationship between MCV and remoulded undrained shear strength is unique. On the M65 Blackburn bypass Glacial Till material achieved a minimum 50 kN/m^2 at MCV as low as 6.5.

The upper MCV limit is usually set at 16 but for most materials the equivalent remoulded shear strength is in excess of 300 kN/m^2 at this value. As stated above, minimum moisture content in terms of plastic limit was set to achieve a maximum remoulded shear strength of some 200 kN/m^2. Earthmoving plant has developed since this criterion was set and a remoulded shear strength of 250 kN/m^2 will still allow greater than 90% of maximum dry density to be achieved on compaction. This is likely to equate to an MCV value in the range 13–14 for most cohesive earthworks materials.

70.7 Embankment settlement and foundation treatment

70.7.1 Failure of embankment foundation

In considering the performance of new build embankments other factors apart from the stability of the embankment slopes should also be taken into account. These are:

- failure of the embankment foundation;
- settlement of the foundation material;
- self-settlement of the embankment fill.

The potential failure of embankment foundation by failure surfaces passing below the level of the embankment fill should be determined as part of the overall assessment of the stability of the embankment slopes. This failure mechanism is unlikely to occur where the embankment is underlain by granular material or overconsolidated clay. It is, however, a potential failure mechanism where the embankment is underlain by lightly and normally consolidated silts and clays or organic rich materials such as peat. These materials have lower strength properties in short-term undrained conditions rather than long-term drained conditions and failures have, historically, occurred during construction as mentioned in Chapter 69 *Earthworks design principles*. Analysis of the critical failure case should, therefore, consider undrained strength of these materials in slope stability analysis.

It is common where these materials are shallow, up to 2.0 m thickness, that they are removed and replaced with acceptable embankment fill, usually granular material, prior to the main embankment construction. Excavation to a greater depth can be considered if economically viable and there are no stability problems with short-term stability of the excavated slopes. This was the case on the N8 Fermoy byass in Ireland where 6.0 metres of soft material was removed prior to the construction of a 9.0-m-high embankment and replaced with Old Red Sandstone rockfill.

Where soft material cannot be wholly removed below embankment construction and the stability of the overall embankment slope is an issue a number of options are available to improve stability. The main options are:

- geogrids or geocells at the base of embankment construction;
- vibro stone columns or mix in place columns below embankment construction;
- vibro concrete columns or driven pre-cast piles.

The use of geogrids or geocells provides additional tensile strength along a potential failure plane in a manner similar to their use in steepened soil slopes. Design of this type of basal reinforcement is discussed in Chapter 73 *Design of soil reinforced slopes and structures*.

The use of vibro stone columns or soil mix columns produces a block of soil of greater strength than the existing ground and they are usually installed on a grid pattern over the footprint of the embankment. They perform, however, in different ways. Vibro stone columns introduce gravel size material as a column, usually up to 600 mm diameter, and displace the surrounding soft soil effecting a degree of compaction. The process produces a composite soil of bearing capacity up to 150 kN/m^2 but is generally limited to a depth of 10 m. Vibro stone columns are not very efficient in cohesive soil of undrained shear strength of less than 25 kN/m^2 as the untreated soil provides insufficient lateral restraint.

Soil mix columns introduce lime and cement into weak soils by initially mixing the column of soft soil then mixing in lime and/or cement by a dry mix process to produce a column of greater strength. The soil mix columns, normally up to 600 mm diameter, are usually installed as a series of rows. The use of soil mix columns is not as cost effective in soils of high organic content as the required cement content increases significantly.

Outside the UK jet grouting is more popular for treating weak soils. Columns of diameter up to 1.5 m can be formed to produce an overlapping grid of stiffened columns by a wet mix process.

A different mechanism of load transfer is employed if vibro concrete columns or driven pre-cast piles are used. These methods transfer the embankment load onto a stiffer stratum through end-bearing on the column or pile.

Vibro concrete columns are installed by the same process as that to install vibro stone columns, with the same depth

restrictions, but the vibrated material is a wet concrete mix. Most of the vibro concrete columns installed in the UK have been constructed to transfer load to either granular strata, weak rock, e.g. Chalk or Mercia Mudstone, or more competent bedrock.

Driven pre-cast piling is used particularly in treating ground on the approach to structures, the process for which is described in section 70.7.2 below. It was extensively used as a technique on the Channel Tunnel Rail Link in areas of soft sediments in the Thames Estuary. The same contract also experimented with screw piles, a product used extensively in Belgium (NCE; Anon., 2002), for the same purpose.

Typical load transfer mechanisms are shown in **Figure 70.9**.

70.7.2 Embankment foundation settlement

In addition to overall embankment failure settlement of the founding material should also be considered as part of new embankment design.

Settlement below embankment construction, like that below structural ground-bearing foundations, can be considered to comprise three phases:

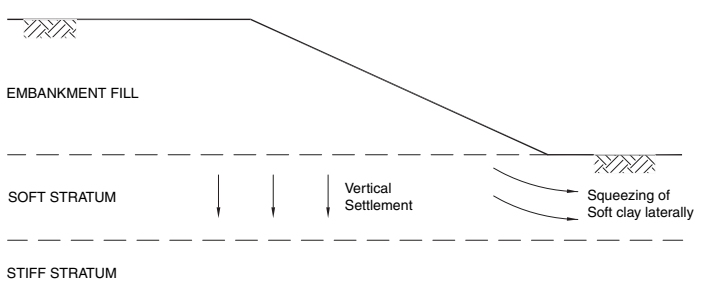
- immediate elastic settlement on loading;
- primary consolidation settlement;
- secondary consolidation settlement.

Settlement in granular materials below embankment construction with a permeability of greater than 1×10^{-5} m/s can be considered and calculated using elastic theory such as:

$$\Delta h = \Delta p \times I \times \frac{H}{E'} \qquad (70.1)$$

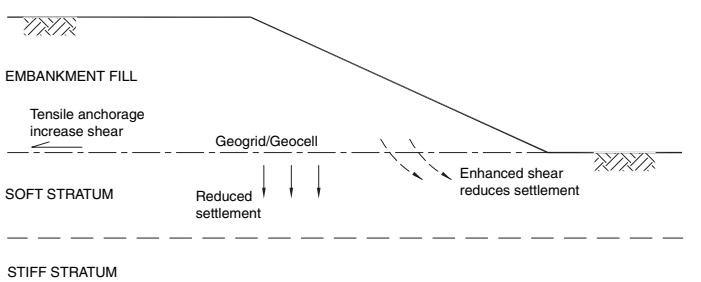
where: Δp = applied pressure (kN/m^2); I = influence factor taking account of depth below embankment foundation; H = thickness of layer in metres; E′ = long-term Young's modulus of soil (kN/m^2).

For cohesive soils settlement will occur on applied load as partly immediate elastic and partly primary consolidation. This is usually calculated using:



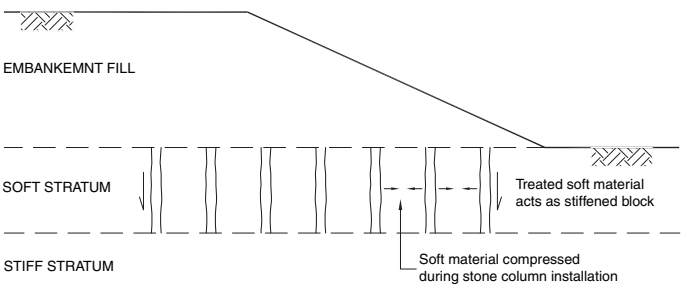
$$\Delta h = \delta p \times h \times m_v \text{ for over-consolidated soils} \qquad (70.2)$$

where: δp = applied pressure (kN/m^2); h = thickness of layer in metres; m_v = coefficient of compressibility (m^2/MN)
and for normally consolidated soils

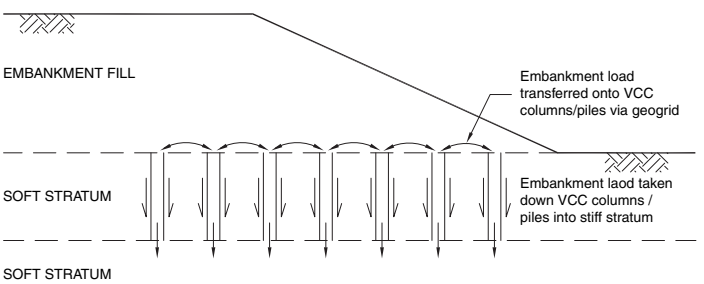


$$\Delta h = \frac{Cc}{1+e_o} \times H \times \log \frac{p_o + \Delta p}{p_c} \qquad (70.3)$$

where: Cc = compression index; e_o = initial void ratio; H = thickness of layer in metres; p_o = initial overburden pressure at centre of layer (kN/m^2); p_c = pre-consolidation pressure (kN/m^2); Δp = applied pressure (kN/m^2).



The parameters m_v, Cc, e_o and p_c can be usually obtained from the results of laboratory oedometer testing. m_v should be taken



(a) Behaviour of soft stratum without foundation treatment

(b) Foundation treatment with Geogrid/Geocell

(c) Foundation treatment with vibro stone columns

(d) Foundation treatment with vibro concrete column/driven pre-case piles

Figure 70.9 Embankment foundation treatment

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

in the range $p_o + \Delta p$ to obtain a realistic value with regard to embankment height. Cc is taken as the gradient of the straight portion of the consolidation curve and p_c taken from construction from the change of gradient of the consolidation curve.

The reduction in applied pressure in the soil beneath the embankment construction can be determined using elastic theory such as Boussinesq or Newmark (1942). The most appropriate is possibly that developed by Oesterberg and presented by Leroueil (1990).

It should be noted that the equations above calculate both immediate elastic and primary consolidation settlement. The proportion of each component will depend on the stress history of the cohesive soil. For an overconsolidated clay the two components are usually equal but for normally consolidated materials the proportion of primary consolidation is greater. Further guidance is provided by Padfield and Sharrock (1983).

The rate of primary consolidation settlement is governed by the Coefficient of Consolidation, C_v, which can be obtained from oedometer testing and is expressed as:

$$C_v = \frac{K}{m_v} \times \gamma_w \qquad (70.4)$$

where: k = coefficient of permeability (m/s); γ_w = unit weight of water.
C_v values from oedometer testing should be taken over a representative pressure range as for m_v.

The time over which primary consolidation occurs subsequent to embankment construction is expressed as:

$$t = T_v \times \frac{d^2}{C_v} \qquad (70.5)$$

where: Tv = time factor; d = length of drainage path (m).

The length of the drainage path is critical to the time required for primary consolidation to occur. If permeable materials such as granular strata both overlay and underlie the cohesive layer two-way vertical drainage can be considered and the length of the drainage path is halved with a subsequent reduction in the time over which primary consolidation is achieved.

In layered soils horizontal drainage should also be considered as although the drainage path to the sides of the embankment may be longer C_h may be considerably greater than C_v than the difference in the vertical and horizontal drainage paths.

In some cases, large consolidation settlements may be theoretically calculated but the length of the drainage path is such that these will be realised over a long period of time. This was the case for a 12-metre-high embankment construction for Heathrow Airport Terminal 5 spur which was underlain by up to 30 m of London Clay. Although 400 mm of total settlement was calculated the time to realise primary consolidation was over 200 years.

In soft compressible soils, where the pre-consolidation pressure is usually exceeded by the applied pressure from embankment loading, settlements will be large and normally unacceptable if the time for primary consolidation exceeds the construction period. A number of solutions are available to mitigate this situation, namely:

- use of lightweight fill;
- pre-loading or surcharging;
- drainage;
- structural elements.

The use of lightweight fill such as polystyrene, PFA or lightweight aggregate will reduce the initial applied load from embankment construction and, hence, the amount of settlement but will not influence the rate of consolidation.

Pre-loading, with embankment construction at the start of and prior to main construction works, will lengthen the period over which primary consolidation can occur. As the rate of consolidation settlement with time is hyperbolic this additional time may allow sufficient primary consolidation to occur such that any remaining subsequent to completion of construction will have minimal impact on the finished works.

The use of surcharge, where greater embankment height and, hence, load is applied, results in primary consolidation occurring in response to the greater applied load and a smaller percentage of total consolidation settlement is required over time to achieve an acceptable percentage under the original embankment loading.

Drainage usually comprises the construction of vertical drains either as vertical plastic strips or vertical sand drains. These are installed at close centres (1.0–2.5 m) in order to significantly reduce the drainage path and produce two-way drainage. A similar effect is produced by the use of vibro stone columns described in section 70.7.1 above.

Structural elements generally comprise driven pre-cast piles or vibro concrete columns and act in the same way as that described in section 70.7.1 by carrying the applied embankment load through the soft compressible stratum to a competent gearing stratum below.

The design of embankments on soft compressible soil next to structures should also take account of the influence of embankment loading on the structure abutments which are likely to be on piled foundations. Leroueil (1990) reports for an applied load greater than pre-consolidation pressure that horizontal movement is 20% of vertical deflection under load. This lateral squeezing of the soil will generate additional shear and bending moments which will have to be taken into account in the pile reinforcement in addition to the requirement from structural loading. An approach to calculate additional load on structural abutment foundations is presented by Springman and Bolton (1990).

One approach to reduce any additional lateral load is by reducing applied vertical load through use of lightweight aggregate. Another alternative is to support the earthworks

approach to the abutment on a structural platform using piles, vibro stone columns, vibro concrete columns or soil mix columns. This has the advantage of not only limiting settlement but also reducing lateral stress transferred from the soil below embankment construction onto abutment foundations. Driven pre-cast piles have been used extensively in this application and guidance on their use is given by Reid and Buchanan (1984). Structural support to the embankment construction behind a structure abutment also minimises the differential settlement between the earthwork and the structure which without treatment creates a hard spot requiring ongoing maintenance.

Embankment construction on soft compressible soils will also result in an increase in pore pressure if the drainage path is not sufficiently short that it can dissipate in a reasonable period subsequent to application of load.

In these conditions, where the drainage path is not reduced by the installation of vertical drainage described above, the increase in pore pressure can be such that failure of the soft material below the embankment can occur as the pore pressure is greater than the strength of the material.

In order to prevent failure it is usual to limit the construction rate in order that pore pressure can dissipate during embankment lifts. The build-up of pore pressure and its dissipation would usually be observed with a piezometer installed in the soft material below the embankment construction. Additionally, staged construction may be applied where hold periods are introduced subsequent to lifts of embankment construction. This allows pore pressure to dissipate prior to construction of the next lift. Examples of staged embankment construction are presented in Leroueil (1990).

The advent of PPP (public–private partnership) contracts with longer maintenance periods has demanded that the designer consider more closely the effects of secondary consolidation with time subsequent to embankment construction. Historically, secondary consolidation has been considered mainly in peat and organic soils where further breakdown and deterioration of the organic structure occurs subsequent to realisation of primary consolidation.

Secondary consolidation, which is load independent, can also occur in cohesive materials particularly normally and lightly overconsolidated clays where applied load is greater than the pre-consolidation pressure in the form of creep. For overconsolidated clays the pre-consolidation pressure is not usually exceeded and loading is applied on the shallow gradient of the consolidation curve with the result of very small settlements.

Secondary consolidation can be determined as:

$$p'_C = C_\alpha \times H \times \log\left(\frac{t_1}{t_0}\right) \qquad (70.6)$$

where: C_α = coefficient of secondary consolidation; H = thickness of layer (m); t_o = time for 95% primary consolidation; t_1 = time after start of embankment construction.

C_α can be derived from natural moisture content after the approach of Mesri (1973). It can also be derived as a ratio with Cc, compression index. Mesri and Feng (1991) and Mesri and Godlewski (1977) report Cc/C_α relationships in the range 0.024–0.055 and 0.025–0.085 respectively, the higher values being reported in peats and organic soils.

Andersen *et al.* (2004) report C_α values in the range 0.019–0.026 for alluvial silt and 0.055–0.108 for alluvial peat from back analysis.

The time to reach primary consolidation is important in the calculation of secondary settlement which may increase in the medium term if measures are taken during construction to accelerate primary consolidation. The use of vertical drainage will reduce the time to realisation of 95% primary consolidation settlement to, say, six months rather than five years without drainage. Although solving construction problems the onset of secondary consolidation occurs at an earlier stage in the maintenance period after construction rather than at a later stage and is of greater magnitude.

A method for reducing the amount, and onset, of secondary consolidation is the use of surcharge kept in place subsequent to achievement of the required amount of primary consolidation settlement within the construction period. This method is described by Mesri and Feng (1991) and Lambrechts *et al.* (2004).

70.7.3 Embankment self-settlement

The self-settlement of embankment fill, like that of the founding material, is dependent on fill type. Trenter (2001) reports the total self-weight settlement of fill can be calculated from:

$$p_i = 0.5 \times \frac{\gamma H}{D^*} \qquad (70.7)$$

where: γ = bulk density of fill material (kN/m^3); H = total height of embankment fill (m); D* = equivalent constrained modulus.

Charles (1993) gives values of D* for a 10 metre high embankment of 50 for well-compacted sandy gravel and 6 for low plasticity clay.

Charles (2008) reports settlements of less than 0.5% embankment height for well-graded granular embankments and less than 1% for clay embankments.

70.8 Instrumentation

Instrumentation is commonly used to confirm earthworks design assumptions and to monitor the performance of earthworks during construction. **Table 70.8** shows commonly used types of instrumentation.

Instrumentation can be installed during a ground investigation but its location should be considered as it may be destroyed by earthmoving plant during construction.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Instrumentation	Earthwork	Purpose
Piezometer	Cutting	Confirmation of *in situ* pore water pressure
	Embankment	Increase in pore pressure of founding material during construction
Inclinometer	Cutting	Movement of cutting slope
	Embankment	Movement of founding material beyond embankment toe
Settlement loop	Embankment	Settlement of founding material
Rod and plate	Embankment	Settlement of founding material
Survey monitoring	Both	Movement of earthwork during and after construction

Table 70.8 Commonly used instrumentation

The installation of embankment monitoring equipment is usually carried out as a pre-construction activity and, in the case of piezometers and rod and plate settlement gauges the reading tubes are extended as embankment construction proceeds. Survey monitoring has the disadvantage that survey stations cannot usually be installed until earthworks are complete and movement during construction may have been missed.

The use of piezometers should take cognizance of the time over which readings are required and the permeability of the stratum into which they are installed. Whereas a rapid response can be expected in granular materials the low permeability of cohesive materials is such that a period of time is required for the groundwater level in normal standpipe piezometers to stabilise. If readings are required rapidly after installation pneumatic or vibrating wire piezometers are preferable.

The observational method (Nicholson *et al*., 1999) is now commonly used to monitor existing assets, particularly in the railway environment, where instrumentation monitors the medium- and long-term performance of an earthwork, rather than employing immediate remediation, where initial analysis of stability indicates that the current factor of safety against failure is lower than would be normally acceptable.

The observational method is also used in earthworks construction. In this case a suitable contingency measure needs to be determined prior to construction to consider the situation where the installed instrumentation is showing the onset of potential failure. The contingency measure needs to be commensurate with the nature of the earthwork and the time for its instigation. An example is the temporary stockpiling of soil to act as a rapid toe-weight in the case of earthworks cutting failure.

Chapter 71

Earthworks asset management and remedial design

Brian T. McGinnity London Underground, London, UK
Nader Saffari London Underground, London, UK

CONTENTS

71.1	Introduction	1067
71.2	Stability and performance	1069
71.3	Earthwork condition appraisal, risk mitigation and control	1073
71.4	Maintenance and remedial works	1075
71.5	References	1085

Earthworks are the most common product of civil engineering activities and perform a crucial function in the efficient operation of civil infrastructure.

This chapter provides guidance on the asset management, stability, condition appraisal and stabilisation of existing earthworks.

71.1 Introduction

Asset management is a specialist field in its own right, and this section does not attempt to cover it in detail other than to comment on some of the principal considerations of asset management where they relate to earthworks and to guide the reader to other references where a wider or more detailed appreciation of the subject is required (Hooper *et al*., 2009).

The key texts on earthworks asset management to which reference should be made are Perry *et al*. (2003a) and Perry *et al*. (2003b). The recommendations of these CIRIA documents are relevant to all earthworks asset managers in the UK.

71.1.1 History

Embankments and cuttings form civil engineering structures known as earthworks or earth structures. They are the most common product of civil engineering activities. Little can be constructed without some excavation and transfer of soil or rock. The total length of embankments in the United Kingdom is considerably longer than that of bridges.

It was not until relatively recently that earthworks were designed. Earthworks for roads, canals and railways in the 18th and 19th centuries were built at slope angles that were based on experience and essentially by trial and error. If failure occurred, which it often did, the slope was slackened or other remedial works implemented (Skempton, 1996). These earthworks are generally operating at lower safety factors and steeper slopes than would be considered prudent today.

Before the 1930s nearly all embankments were constructed of relatively uncompacted material, as the process of compaction was poorly understood, and due to the lack of modern construction plant. Large settlement commonly occurred soon after construction. The legacy of these construction methods is reflected in the performance of these historic embankments and, hence, in the degree of current maintenance.

Since the 1930s the development of construction plant and a greater understanding of the discipline of geotechnical engineering have resulted in modern earthworks being better compacted and built at generally less steep slopes than historic earthworks. As a result modern earthworks in the UK suffer less from settlement due to their better compaction. However, slope failures still occur (Perry, 1989).

The deep-seated delayed failure of UK cutting slopes in stiff clays has been the subject of extensive study with a significant body of published research, e.g. Skempton (1964) and Potts *et al*. (1997).

71.1.2 Asset management systems

All earthworks should be managed by an appropriate asset management system to ensure that acceptable performance is achieved and that the earthworks do not present a risk to users.

Effective asset management allocates sufficient maintenance resources, within budgetary constraints, for efficient performance. Until fairly recently in the UK, a reactive approach to earthwork management has frequently prevailed but this is disruptive, inefficient and uneconomic, and inconsistent with long-term asset management objectives. Engineering performance has consequently suffered as a result. More recently there has been increasing trend to adopt a more proactive asset management approach. This requires the implementation of a reliable system of condition appraisal, maintenance and repair or renewal so that existing earthworks can be kept in good condition, avoiding service loss and minimising expensive unplanned works.

The nature of the asset management system will vary to reflect the use of the earthworks and the risks they pose. An asset management system should as a minimum include:

- an asset catalogue: an inventory and summary of condition;
- performance requirements, service level and required duty;
- an asset strategy and plan including consideration of whole-life costs and deterioration models;
- a risk register.

Typical performance requirements for earthworks include:

- safety and reliability;
- satisfying level of service and cost of service requirements;

- operational efficiency;
- satisfying statutory and regulatory obligations;
- value for money and business improvement;
- minimising environmental impact;
- maximising environmental value.

Figure 71.1 illustrates a typical earthworks asset management cycle, which follows a continuous process of condition appraisal, maintenance and improvement or repair, leading to a constant awareness of and improvement in asset condition and performance. An integral part of this process is the management of asset data and the provision of information links between condition appraisal and intervention planning.

An earthworks asset management system (EAMS) comprises a framework that provides asset life-cycle management from conception and design, construction, the work management required during the asset's operation and the planning for renewal, repair and replacement. An EAMS can support all condition appraisal and maintenance work management processes from the creation of work orders, through issuing of work, to the recording of work done. It can be a powerful support tool assisting asset managers to ensure the following:

- An earthwork's condition is improved to reduce the risk to safety and service loss.
- An earthwork achieves a life expectancy that meets the performance requirements.
- Asset management decisions are made on an economic whole-life basis.
- The knowledge and understanding of an earthwork is constantly improved.

The level of complexity and sophistication required of such a system will depend on the size and character of the earthwork asset base. Historically, earthworks management has relied upon written records, including card-indexing systems and files containing paper-based information. Although such systems may still be adequate for the management of very small numbers of assets, the demands of managing large numbers of earthworks and dealing with an ever increasing quantity of information mean that computer-based management systems, relying on electronic information storage and retrieval, offer definite advantages.

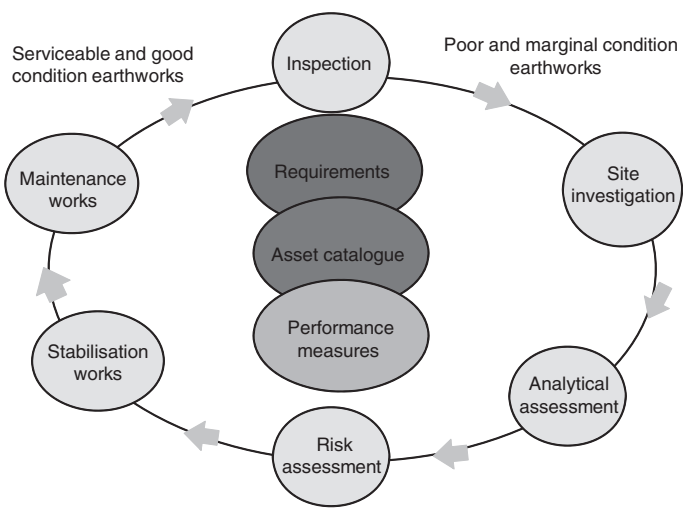

Figure 71.1 Earthwork asset management cycle

Like any other structure, earthworks will have a finite life before significant renewal or replacement works are required. This lifespan can be extended by systematic, continued maintenance and repair.

It is very common for earthwork assets to be in the operate-and-maintain phase of their life cycle, with no likelihood of closure or decommissioning. In the United Kingdom, much of the earthwork asset base has already been in service for longer than the design life of equivalent modern assets.

71.1.3 Whole-life asset management

Whole-life asset management balances maintenance, repair, refurbishment, renewal, replacement and upgrade activities to optimise the long-term value of an asset. The concept of whole-life costing is described by Perry *et al*. in CIRIA Report C592 (2003a). It can be a useful tool when comparing the capital cost of renewal schemes against longer term maintenance costs. Although whole-life asset management is a potentially useful tool it does have its limitations, particularly for existing earthworks that are expected to have very long service lives. These limitations should be understood and the process used with care to ensure sensible results. In practice it is difficult to set up a reliable model for the management of existing earthworks because the performance requirements, the availability of expenditure and an appropriate discount rate over the likely service life are very difficult to estimate. There is a risk that whole-life asset management models can become immensely complicated; however, if they are too simplistic this defeats the whole object of the exercise and their results may be misleading.

71.1.4 Risk assessment

The need for earthwork risk assessment arises principally in the United Kingdom to satisfy statutory safety obligations. The Management of Health and Safety at Work Regulations (1999a,b) impose a statutory duty on employers to conduct regular risk assessments.

The asset management of existing earthworks should follow the approach of reducing risk levels to 'as low as reasonably practicable' (ALARP), giving consideration to cost-benefit analysis of whether spending on remedial works will result in a cost benefit over a realistic maintenance period.

The ALARP principle allows that safety improvements should not be pursued at any cost, but only if the cost of averting a risk is not grossly disproportionate to the risk averted.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The risk assessment process, therefore, permits a logical analysis of the safety risks; how these can be mitigated or controlled; and the associated funding needs and financial forecasts. Minimal extension of the scope of the risk analysis can have secondary benefits, such as identifying the exposure to non-safety-related business risks and helping to formulate business cases and overall spending forecasts and plans. Risk assessment is, therefore, a tool that earthworks asset managers apply to ensure that safety objectives are met within a business framework, and that funds are justified and allocated in response to safety and business needs.

The management of risk should be a key aspect of earthwork repair or renewal projects as in all construction activity (Godfrey, 1996) and should include:

- programme, quality and financial risks to ensure the successful delivery of the project;
- health and safety and environmental risks to satisfy statutory requirements.

All UK earthwork repair or renewal projects will come under the requirements of the Construction (Design and Management) Regulations (2007), known as CDM. All those involved in design and construction activities associated with earthwork repair and renewal should consider the requirements of the project and seek to follow the 'spirit of CDM' to ensure the approach taken is appropriate for the project.

A project risk register (PRR) should be established and include all risks identified by those involved with the design and construction of earthworks, and those involved in repair and renewal.

71.1.5 Sustainability

Geotechnical engineers and earthworks asset managers need to consider not just the technical aspects of the work, but how it can be undertaken in a way that will enhance the environment and maximise sustainability, e.g. by maximising the use of existing fill materials in earthwork remedial works' design and construction, and with a sensitivity to the surrounding environment. The fact that many of the organisations responsible for earthworks have environmental policies and have set specific targets relating to environmental issues is testimony to their importance.

However, it should be appreciated that this is a rapidly developing field and further changes are likely. All those involved in earthworks asset management will need to be well informed and vigilant in understanding the consequences of changing legislation on environmental issues (also see Chapter 11 *Sustainable geotechnics*).

71.1.6 Earthwork asset interfaces

Earthworks can carry a number of different infrastructure elements such as structures, services, drainage or signage. It is important to coordinate all maintenance activities so that best use is made of time and that the works to all elements are integrated to prevent damage by piecemeal working. Asset managers should be kept informed of and approve all activities to be undertaken involving earthworks, as it is possible for overall performance to be adversely affected by the activities of others, e.g. an excavation for a service at the toe of the slope could trigger slope movement.

Conversely the designer should assess the potential impacts of earthwork repair or renewal on existing infrastructure. In all these cases earthwork activities can change the loading on the existing infrastructure or modify the surface water and groundwater flow paths, both of which could be detrimental to the stability of the adjacent assets and, therefore, require consideration within the design. Where the existing slope is identified as being of poor stability then the design of the temporary works will require special consideration to ensure that stability is maintained throughout construction.

71.2 Stability and performance

71.2.1 Mechanisms

71.2.1.1 Shallow instability

Shallow instability is usually confined to the sloping part of the cutting or embankment and the slip surface does not pass through the transport corridor (railway or highway) or the associated services usually located at the toe of the cuttings or on the crest of embankments. The failure surface is generally parallel to the slope surface and has typically a depth of between 1 and 1.5 m.

In granular materials this type of failure manifests itself as ravelling of material down the slope and collecting at the toe. In cuttings this will result in debris in the margins of the transport corridor at the toe and will require to be cleared through routine maintenance.

In cohesive soils this mechanism is generally controlled by the surface saturation within the zone of seasonal variation caused by exceptionally heavy rainfall, in particular following a prolonged dry season.

Vegetation on the slope surface generally has a positive effect on this type of instability through the reinforcement provided by the roots (Coppin and Richards, 2007) and the control of the pore pressures within the slope surface. In cohesive soils seasonal shrink and swell will cause surface cracking of the slope during the dry period leading to increased permeability.

71.2.1.2 Deep-seated instability

For deep-seated instability the slip surface is more extensive, covering the whole length of the slope and may pass through the soil layer beneath the embankment or cutting. The slip surface is generally deeper than 1–2 m and affects the transport corridor or the associated services located on the crest of embankments or the toe of cuttings. This type of failure, when it happens, is more disruptive and can have serious consequences.

For free-draining granular soils deep-seated instability is not a major concern and is generally easier to predict. The

instability in this type of material manifests itself as surface ravelling of materials downslope leading to maintenance problems.

Deep-seated instability in cohesive soils can be categorised as first-time slides and slides along old failure surfaces.

First-time slides

First-time slides happen to slopes that have not experienced previous slides and, hence, do not involve pre-existing shear surfaces. First-time slides have been studied extensively in particular in relation to cuttings in stiff clays (DeLory, 1957; Skempton, 1948, 1964, 1970, 1977; Chandler and Skempton, 1974; Chandler, 1984).

The results of these studies indicated that failure generally occurs many years or decades after construction due to a very slow rate of pore pressure equilibration (delayed failure). The results also indicated that the average strength at failure was considerably smaller than the peak strength measured in the laboratory but greater than the residual strength. The results of back analysis of long-term failures in five cuttings in brown weathered London Clay by Skempton (1977) indicated the following operating effective strength parameters at failure:

$$\phi' = 20°, \qquad c' = 1 \text{ kN/m}^2$$

with the average pore pressure ratio r_u typically ranging between 0.25 and 0.35.

The peak and residual strengths measured in the laboratory were:

$\phi'_p = 20°$, $c'_p = 7$ kN/m^2 (Sandroni, 1977)
$\phi'_r = 13°$, $c'_r = 1$ kN/m^2 (Skempton and Petley, 1967).

It is now well established that the most likely reason for the difference in the peak strength and the operating strength at failure is due to the mechanism of progressive failure (Potts, *et al*., 1997; Ellis and O'Brien, 2007).

The mechanisms of delayed failure and progressive failure referred to above are defined as follows.

Delayed failure

When a cutting is excavated in stiff overconsolidated clays of high plasticity due to unloading effects, the pore pressures in the soil are reduced sometimes even to negative values. With time these pore pressures will start to increase towards the long-term equilibrium values and the soil will start to swell. This process will lead to a reduction in the mean effective stress and the onset of delayed failure. The length of time to this failure will depend on the permeability of the soil and may take several decades (Vaughan and Walbancke, 1973; Potts *et al*., 1997).

Progressive failure

Progressive failure occurs as a result of the non-uniform development of strains along a failure surface leading to non-uniform mobilisation of shear strength. This phenomenon is specific to clays that exhibit highly brittle behaviour, defined as the magnitude of the drop from peak to residual strength (Vaughan, 1994; Potts *et al*., 1997; Ellis and O'Brien, 2007).

In a cutting formed in such a clay material, a non-uniform loading due to swelling of the soil near the toe will result in the mobilisation of the peak strength in an element of the soil whilst the other parts are still in the pre-peak state of stress. This is accompanied by the development of a slip surface at this location. With further increases in pore pressure the strength at this location is reduced from the peak towards the residual strength. Further increases in pore pressures will lead to the development of the rupture surface further into the slope. This will in turn lead to larger displacements and the final failure of the slope. At this time the strength along the rupture surface will be close to residual at some points, post peak at some other points and close to peak along the rest. Hence, the average strength of the soil along the failure surface will be somewhere between the peak and residual strength of the soil.

Slides along old failure surfaces

This type of failure is generally caused by slip along pre-existing shear surfaces or partially pre-sheared surfaces. These surfaces may have developed as the result of past instability, commonly, during construction or by landslides or other geological processes. Repair work does not always remove the shear surfaces fully. Shear surfaces are sometimes present within the softer alluvial deposits underlying embankments and, hence, may have been left in place.

The stability analysis for this type of failure is carried out using residual effective strength parameters or parameters close to residual strength where partially pre-sheared surfaces are suspected.

71.2.1.3 Seasonal shrink and swell

Seasonal shrink–swell movements occur in embankments and cuttings containing high-plasticity clay soils due to seasonal changes in the soil moisture content.

The seasonal movement is strongly influenced by the presence of high-water-demand mature trees, which leads to increased changes in the soil moisture content in the proximity of the trees. In the dry summer months due to lack of rainfall and the presence of mature vegetation, moisture is removed from the soil resulting in shrinkage. This causes shrinkage cracking. In the wet autumn and winter season the soil is re-charged with moisture. This wetting also combines with less demand for moisture from the trees leading to significant increases in the soil moisture content, which in turn causes swelling to occur. The resulting movements will influence the performance of the transport corridor located on the crest of an embankment and possibly at the toe of a cutting (**Figure 71.2**).

Shrinkage cracking of the soil in the dry periods leads to the formation of water pathways and increased permeability of the soil. This in turn leads to a more rapid inflow of water into the soil and a deeper penetration depth. This allows the

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

rainwater to reach significant depth in the following wet season, thus, increasing the zone of influence of shrink–swell effects.

In overconsolidated high-plasticity clays where increases in strain beyond the peak will result in a post-peak reduction in the shear strength, cycles of shrink–swell can lead to a loss of strength and onset of progressive failure.

The swelling of soils in the wet period is associated with upward and outward movements whereas the dry season is associated with mainly downward movement of the soil. This leads to a phenomenon called 'ratcheting' where the horizontal swelling that occurs in the wet periods does not fully recover in the dry summer months. Further information on seasonal shrink–swell movements and the effects of vegetation can be obtained from McGinnity *et al*. (1998), Kovacevic *et al*. (2001), Loveridge and Anderson (2007), Butcher and Pearson (2007), Take and Bolton (2004), Hudacsek and Bransby (2008) and Nyambayo *et al*. (2004).

Figure 71.2 Effect of trees on track deformation

71.2.1.4 Shoulder instability

Shoulder instability is a shallow type of instability that is more specific to embankments where, due to various factors described below, the shoulder of an embankment cannot provide the required support to the transport corridor on the crest (**Figure 71.11(a), (b)**). The main factors responsible for this type of instability are as follows:

- steep upper-slope angle, which can cause gradual ravelling of material down the slope leading to narrowing of the shoulder;
- dynamic loading of trains or road vehicles: this loading can travel laterally and mobilise the soil particles, and with time these soil particles will move down the slope under gravity;
- embankment material;
- fine granular materials such as ash are particularly prone to this type of instability; this type of material in a dry state can become very powdery and move under dynamic loading;
- seasonal effects.

71.2.1.5 Flooding and scour

Flooding and scour at the toe of the embankments can occur as the result of rivers or streams flowing parallel or through an embankment.

Increased water levels during wet seasons can cause flooding, resulting in increased water pressure at the toe of the embankment. This can result in reduced factors of safety against deep-seated failure leading potentially to the onset of instability, depending on the duration of flood.

Flooding can also cause scour erosion of the toe of the embankment, which again results in reduced factors of safety against deep-seated failure due to the reduced weight at the toe of the embankment (**Figures 71.3, 71.4**).

Figure 71.3 Scour erosion at the toe of a railway embankment

Figure 71.4 Concrete channels provide a more durable solution

Figure 71.5 A flow failure following a high-intensity rainfall event in Boston Manor (2006)
Reproduced with permission

The important factors to consider for the safe management of the slope are as follows:

- direction of flow of water in the river;
- extent of Environment Agency flood zone and capacity;
- topography and land use adjacent to the toe;
- presence, condition and capacity of drainage at the toe.

71.2.1.6 Flow failure

Flow failure is likely to occur in high-permeability granular materials as a result of rapid saturation caused by short but high-intensity rainfall or a storm event. The saturation is caused by infiltration of rain water into the slope surface but also, more significantly, from concentrated surface run-off in areas of poor drainage. Hence, this type of failure is much more likely to occur in cuttings where the topography, land use and poor drainage condition at the crest of the cutting allows a large volume of water to be directed towards the slope in a very short period of time. The high permeability of the soil within the cutting allows this water to be absorbed within the slope rapidly, leading to a mass flow of material.

From the above it can be seen that the key parameters for this type of failure to develop are:

- short-duration high-intensity rainfall event;
- high-permeability soil;
- slope geometry;
- topography;
- land use;
- vegetation;
- drainage.

Low-intensity long-duration rainfall events are unlikely to lead to a flow failure as, in a granular material, there will be adequate time for the excess water to drain. Flow failures are unlikely to develop in low-permeability soils where rapid saturation cannot take place. Finally, the right geometric and topographic conditions must exist to generate a concentrated flow of water. Hence, embankments are less likely to be at risk from this type of failure.

The consequences of this type of failure can be very significant. In a cutting a large volume of soil can flow onto the transport corridor at the toe of the cutting causing derailment of trains or accidents on the roads (**Figure 71.5**).

71.2.1.7 Frost shattering

Frost action can lead to gradual degradation of some rock cutting slopes, depending on the permeability, porosity and the joint system within the rock. Ice crystals that form within the pores and between the joints in a slope face induce strains, which result in splitting and shattering of the slope surface.

The volume change caused by the growth of ice crystals can result in an increase in the joint width and depth. Hence, a repeated freeze–thaw action can lead to an increase in the permeability of the rock mass, which in turn increases the depth of influence of the frost action.

One of the rock types particularly susceptible to frost action is chalk. Shattering or loosening of the surface of cutting slopes in chalk results in the generation of debris at the toe of the cutting, which affects the serviceability of the transport corridor located at the toe (Lord *et al*., 2002) (**Figure 71.6**).

Frost shattering can have more significant consequences in the transport corridor at the toe when loosening of the surface leads to destabilising of the vegetation and tree roots on the surface of the slope, which can fall onto the rail or road at the toe.

Figure 71.6 Frost shattering on a chalk railway cutting

Figure 71.7 Embankment failure as a result of increased pore pressures after a prolonged rainfall event (1994)

71.2.2 Limit states

71.2.2.1 Ultimate limit state

The ultimate limit state is reached when the disturbing forces acting on a slope exceed the resisting forces. Under this condition collapse, slope instability or other forms of structural failure will occur, which could significantly affect the safety of the services or the structures associated with the earthworks (Perry *et al.*, 2003a, 2003b).

For an embankment, an ultimate limit state failure will lead to significant disruption of the safe operation of the railway or highway transport running on the crest of the embankment (**Figure 71.7**).

In cuttings, the slope failure, depending on the size and extent of the rupture surface, may affect the operation and the safety of the transport infrastructure and the associated services running at the toe of the cutting. The failure could also affect the structures on the crest of the cutting such as buildings, roads, car parks and their associated services such as drains, cables, etc.

In order to prevent such a mode of failure, a margin of safety against the disturbing forces has to be introduced in the design and maintained during the life of the structure. For existing slopes this can be achieved by performing slope stability analysis. Where the stability of slopes is found to be marginal, remedial measures should be implemented to increase the margin against instability.

71.2.2.2 Serviceability limit state

A serviceability limit state is reached when deformation within an earthwork exceeds the desired or prescribed limits such that the structure can no longer perform its required functions satisfactorily.

Deformations within an embankment can affect the performance of the transport infrastructures running along the top leading to excessive settlement of roads or railway tracks or the associated services such as cable runs, signals, etc.

In cuttings, deformations within the slope can affect the buildings, roads, car parks, drains and other structures supported on the crest.

It is not common practice to carry out analysis of a slope to predict deformation. It is generally assumed that adequate factors of safety against deep-seated slope instability would ensure the satisfactory performance of the slope during its design life.

However, where required, numerical analysis can be carried out to estimate slope deformation. For existing slopes, however, any such analysis would need to model the loading history experienced by the slope since construction. The analysis would also require appropriate parameters such as strength, stiffness, permeability of the soil and the pore pressure regime within the slope in order to simulate the field conditions leading to realistic predictions.

The serviceability of slopes is affected by the following factors, some of which were discussed in the preceding sections:

- seasonal shrink–swell;
- vegetation;
- dynamic loading;
- animal burrowing;
- heavy rainfall;
- flooding;
- frost.

71.3 Earthwork condition appraisal, risk mitigation and control

71.3.1 Inspection

For an earthworks asset management system to be successfully delivered it is necessary to develop an appropriate earthwork inspection system. Its main purpose is to:

- appraise structural safety;
- detect incipient defects at an early stage and monitor the development of defects to determine the urgency for, and the nature of, corrective action;
- classify the condition of the earthworks according to a defined system;
- identify the need for preventative action.

The inspection approach varies between UK infrastructure asset owners: in all cases it involves an observation and recording of the earthwork condition at the time of the inspection.

The following factors should be considered in developing an inspection regime:

- defect definition, classification and condition rating system;
- inspection frequency;
- inspection types (cyclical or *ad hoc*);
- data-collection techniques;
- risk.

The frequency of cyclical inspections should be set considering the history and condition of the earthwork together with the likelihood and consequences of failure.

Where possible a record should be made of the drainage system as an integral part of the earthwork inspection process. The inspection should also establish the presence and overall condition of any additional stabilising structures (retaining walls, soil nails, etc.) within the earthwork. Some of the stabilising structures might require inspection by other disciplines and so harmonised inspection programmes should be considered.

The inspection should not only focus on the specific asset being inspected but should be watchful of nearby activities that may adversely affect the asset. The information collected from inspections should be used to identify defects and monitor the asset condition and degradation rate.

Remote inspection from airborne platforms is becoming an increasingly powerful tool to support traditional site inspection and aid strategic planning. It can offer a safer and more cost-effective method for identifying problem areas than visits conducted on foot. Duffell *et al*. (2005) described the use of airborne remote-sensing techniques to assist in prioritising detailed ground-based inspections of earthworks.

71.3.2 Analytical assessment

The objectives of an earthwork analytical assessment are more rigorous and detailed than an inspection and are to:

- provide data on and a detailed assessment of the condition of specific earthworks and to accurately quantify slope stability;
- provide evidence for a business case for works to improve performance of individual earthworks, based on ultimate and serviceability limit state criteria;
- identify those earthworks that need priority attention when formulating asset management plans;
- assess risks, plan maintenance budgets and programmes;
- anticipate future problems and identify a rate of deterioration;
- provide information for the design of any required stabilisation.

An earthwork assessment typically consists of the stages outlined below.

71.3.2.1 Desk study and walkover survey

A preliminary study includes a desk study, which reviews all relevant data obtained from inspection and maintenance records, and a detailed site inspection (walkover survey) to identify visually any areas of distress. In addition to geological and geotechnical data the desk study would also typically consider drainage, environmental, ecological and services information.

71.3.2.2 Ground investigation

A ground investigation considers instrumentation and monitoring, and includes exploration, sampling and laboratory testing.

71.3.2.3 Interpretation and stability analysis

Information obtained from the ground investigation and desk study, including any deformation data, must be interpreted to establish ground model and geotechnical parameters. Likely failure and deformation mechanisms must be considered and stability analysis performed.

71.3.2.4 Reporting and prioritisation

Results from the ground and desk study investigations and their interpretation, and the stability analysis are presented with an explanation of the condition and criticality of the earthworks. Recommendations and cost estimates for repair or renewal should be provided.

71.3.3 Earthwork risk mitigation and control

The principal responsibility of the asset manager is to ensure that earthworks are maintained in a condition such that the safety of users and the public is not compromised. Factors such as age, increased traffic loading, inadequate or poor maintenance and deferred repairs reduce the performance of earthworks and may ultimately compromise operational safety. Specific earthwork performance requirements are set by infrastructure owners, e.g. railway embankment deformation limits relate to maintaining track quality for a specified line speed.

When an earthwork experiences stability problems, it is often necessary to impose temporary restrictions on speed or loading, or close traffic lanes to maintain operational safety. When its structural capacity is inadequate and there is a risk of collapse, public safety is jeopardised and complete withdrawal of service may be necessary.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

If instability or other loss of functionality is predicted, the following options may be adopted in increasing order of impact:

- increased inspection frequency;
- monitoring;
- routine maintenance, e.g. unblocking drains;
- service restriction, either while mitigation is put in place or stabilisation is undertaken;
- renewal works;
- withdrawal from service.

71.3.4 Monitoring existing earthworks

The purpose of monitoring earthworks includes the following:

- mitigation of risk until repairs are implemented;
- determine the rate of movement and establish if it is constant, accelerating or decelerating;
- establish *in situ* pore water pressures and any variation over time;
- where movements have occurred, gather information on the depth, area and lateral extent;
- to establish the effects of construction adjacent to earthworks, both during construction and in the long term;
- to obtain quantitative performance data;
- to validate the output from analytical assessment, particularly where it is considered to have produced conservative results, and to confirm design assumptions.

The designer of the monitoring system should define the following aspects in advance of implementation of the scheme:

- objectives;
- techniques;
- required accuracy;
- frequency;
- trigger levels;
- data collection and reporting;
- action plans.

There is a vast range of instrumentation available and further guidance can be obtained from Dunnicliff (1998). Recent developments in this field include web-based, cable-free or fibre-optic systems, which offer remote, real-time monitoring that have the potential to be integrated to automate alert alarms. Owing to the rate of technological development in this field, discussions should always be held with specialist instrument manufacturers and installers.

In establishing trigger levels, the likely magnitude of normal baseline values should be established. For example, seasonal vertical movements of up to 50 mm have been recorded on some London Underground embankments due to the effects of vegetation on high-plasticity clay. Therefore, the monitoring system should be put in place sufficiently in advance of control periods so that the range and pattern of background movements can be established.

For new or modified earthworks, monitoring can aid in finalising the design either through the approach recommended in BS EN1997–1:2004 (British Standards Institution, 2004) or through observation itself (Nicholson *et al*., 1999).

71.4 Maintenance and remedial works

71.4.1 Preventative and corrective maintenance regimes

As discussed in section 71.1.2, maintenance forms a part of the asset management regime and is undertaken in order to maintain the assets in their current condition and to minimise asset deterioration and degradation. Preventative maintenance is carried out on a routine basis, e.g. through vegetation management and cleaning drainage systems. The frequency of preventative maintenance is governed by the severity of any potential problems and their consequences. Corrective maintenance is undertaken where defects are observed during inspection or site walkovers. Prioritisation based on risk is used to determine the maintenance programme. Maintenance for earthworks could include the following:

- vegetation management;
- debris clearance;
- drainage cleaning;
- animal burrows;
- erosion control measures;
- construction of a toe-retaining structure to capture debris;
- construction of a mesh and anchor system to contain and capture rock falls.

71.4.2 Repair and strengthening

Repair or strengthening is required in the following circumstances:

- where the earthworks can no longer provide the required function against the performance criteria;
- where the asset does not meet the minimum requirements of the standards set by the regulatory organisations;
- where a full or partial slope failure has occurred.

The aim of the remedial works is to improve the stability of the earthworks against the ultimate and serviceability limit states. However, during the design other safety and environmental features are considered and included in the remedial works in order to upgrade the asset to modern standards.

The performance criteria for remedial and strengthening design generally consist of the following:

- To improve the stability of the earthworks in order to meet the requirements for the minimum factor of safety against deep-seated instability.
- To improve the stability of the earthworks in order to meet the requirements for the minimum factor of safety against shallow instability.
- To limit the subsequent deformation such that the relevant maintenance target levels as defined in relevant stakeholder standards are not exceeded. For instance *LU Standard 1–159 Track Dimensions and Tolerances* (2011) requires the differential settlement of the outer rail to be limited to 1:500 along any 10 m length of track with a limit of 1:300 across the rails.
- To design remedial work such that it will have no detrimental effect on the stability of the existing structures within or adjacent to the earthworks.
- All permanent earthworks should achieve a specified design life that varies between 60 and 120 years depending on which design standards are being followed.

The stability of slopes can be improved by increasing restoring forces or reducing disturbing forces. The following options can be considered for the design of remedial works:

71.4.2.1 Cuttings

Re-grading

Cutting slopes can be stabilised by re-grading to a shallower angle provided sufficient room exists at the crest of the cutting.

In general this requires a significant amount of excavation and off-site disposal of large volumes of material. This option requires the complete removal of all vegetation and replacement after completion of construction. Earthworks of London Clay could also present difficult working conditions during wet periods.

Spaced bored piles

This solution consists of installing bored piles into the body of a slope in order to provide additional shear resistance against deep-seated instability. The piles are designed to penetrate the soil mass below the slip surface in order to provide adequate passive resistance. The piles can be between three and six diameters apart and the system relies on arching between the piles to support the soil mass in the active zone (Davies *et al*., 2003; Smethurst, 2003; Carder and Barker, 2005; Smethurst and Powrie, 2007).

The spacing of the spaced bored piles in the longitudinal direction is dependent on the ground conditions and individual pile capacity, and is selected so as to provide the required factor of safety against deep-seated instability. The selection of the pile diameter is affected by the sizes of the available piling rigs and the associated temporary works required. Safety issues associated with the construction of piles above an operational highway or railway are important when selecting the appropriate construction plant.

The location, pile diameter and spacing will need to be optimised in order to provide the most efficient system, as well as allowing for buildability issues such as the size of the piling rig, temporary works and the clearance from existing services and structures.

Construction of bored piles can be carried out using a mini-piling rig from a temporary bench excavated into the slope of the cutting or using a scaffolding platform. Small piling rigs, such as the TD610 for pile diameters up to 450 mm, can be used. Where the bending moment and shear forces require larger diameter piles, piling rigs such as the Klemm KR 709 or similar can be used. This type of rig has a larger size and weight and a higher mast when fully extended. Hence, the requirements for a suitable piling platform and the associated temporary works will need to be considered (**Figure 71.8**).

The advantages of this system are:

- relatively low cost;
- much of the vegetation on the upper slope can remain;
- minimised earthworks;
- access for plant and equipment;
- low environmental impact;
- ease of construction;
- design life.

Soil nailing

Soil nailing comprises the installation of nails into the body of the slope at shallow angles of between 10°–30° below the horizontal, penetrating the soil mass beyond the critical slip circle in the passive zone. Various types of soil nails are available and the choice is dependent on the particular application and the availability of space and access for installation plant, and the required design life and cost (Phear *et al*., 2005).

Hollow self-drilling soil nails are quick and easy to install in some granular soils. These are installed by simultaneous drilling and grouting, using a sacrificial bit attached to the advancing end of the hollow soil nail. Soil nailing a slope will require the complete removal of vegetation from the slope where nails are to be installed.

For sites where access is difficult, an abseiling technique can be adopted for installation of the nails. However, only a limited length of nails and depth of penetration can be achieved using this system. A soil-nailing scheme constructed under difficult access conditions using an abseiling rig is shown in **Figure 71.9**.

Design life and corrosion protection will significantly affect the financial viability of the scheme. A risk-based approach should be adopted where corrosion protection is related to the possibility of failure (Phear *et al*., 2005).

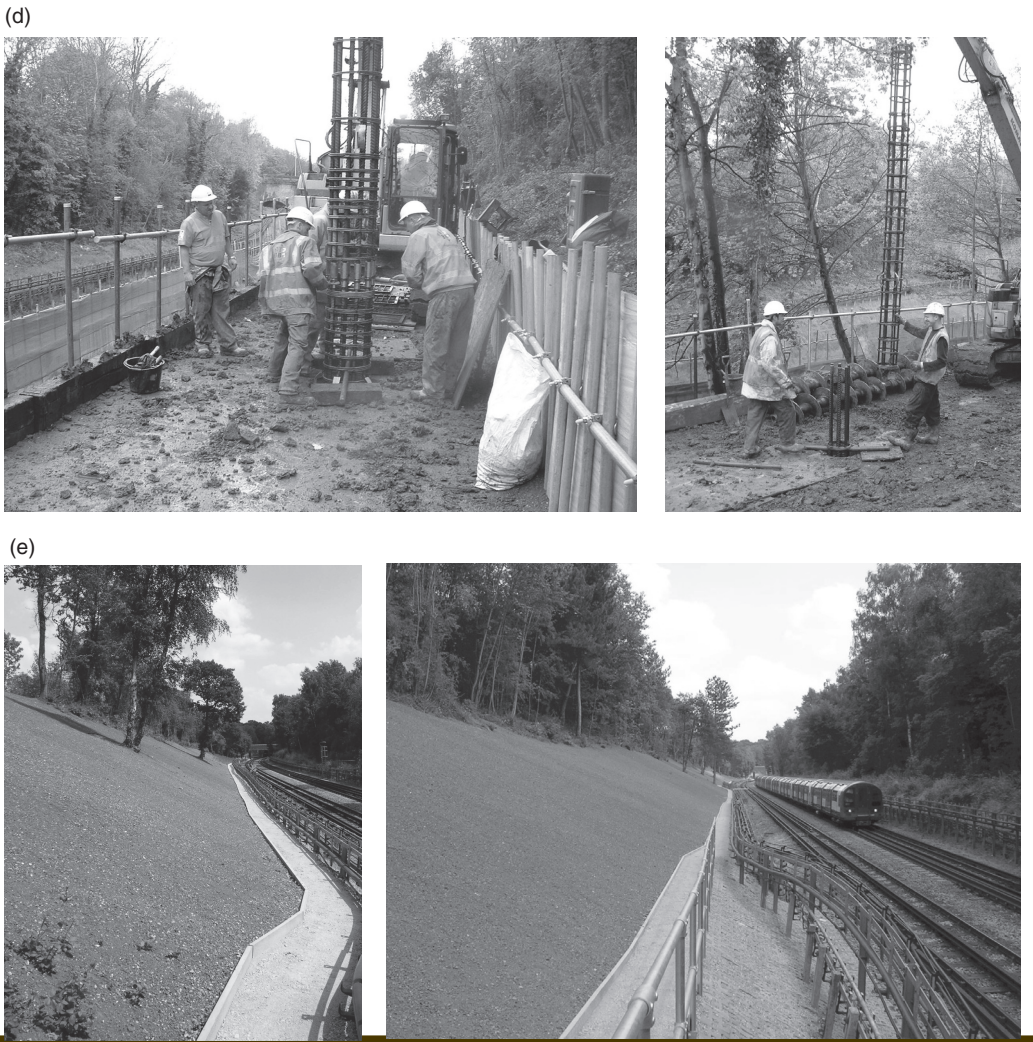

Figure 71.8 (d) lowering of the reinforcement cage; (e) slope after completion of construction

Toe retaining walls

Where space is available, the construction of a wall such as a mass-concrete gravity wall or a gabion wall at the toe of the cutting combined with backfilling with granular fill will provide additional weight at the toe to increase the factor of safety against deep-seated instability. The depth to the base of the wall should be designed such that the slip circles passing below the wall have the required factor of safety. This may require deep excavations at the toe, which may not be practical given the space constraints often existing at the toe.

Where excavation is impractical at the toe, a piled wall with a capping beam may provide a better solution.

Drainage

Where it has been established that the instability of a slope is due to excessive pore pressures within the slope, the installation of a drainage system to reduce the pore pressures may be a viable solution.

The following drainage systems may be considered:

- a cut-off drain at the crest in order to stop the flow of water into the slope;
- a counterfort drain in order to drain the body of the slope;
- a toe drain in order to keep the water level down at the toe;
- a combination of the above.

However, when designing a drainage system the following must be considered:

- need for reliable groundwater data;
- requirement for regular monitoring and maintenance of any slope drainage system in order to ensure continued operation during the intended design life;
- disposal of drainage discharge can require connection works to the existing track drainage;
- this solution may require to be combined with other remedial options in order to meet the factor of safety requirement.

71.4.2.2 Embankments

Re-grading

Embankment slopes can be stabilised by placing a berm against the slope and re-grading to a shallower angle, provided sufficient room exists at the toe.

The berm solution can be used to widen the crest and provide more support to the shoulder of the embankment. The re-graded embankment will typically have a uniform gradient. For embankment widening and re-grading, a Class 1A granular material is generally specified. Recycled material such as crushed concrete can be utilised for this purpose provided that chemical composition of the fill is found to be acceptable for the intended purpose.

This material will be benched into the existing slope, removing any existing local over-steepening or slope bulges. The fill will be placed and compacted in accordance with the contract specification. A layer of seeded topsoil is usually placed on top of the new fill to provide vegetation (**Figure 71.10**).

Figure 71.10 Re-grading of an embankment to increase stability, incorporating a walkway at the toe and crest

Ruglei™ verge protection system

In areas where the slopes of embankments have a satisfactory factor of safety against deep-seated and shallow slips but widening of the cess is required to provide a stable shoulder, the Ruglei verge protection system can be considered.

This system consists of an angular galvanised-steel mesh and a geogrid inset to contain and support the fill (coarse granular fill or ballast) that is required for the widening of the cess. Vertical and raked piles are used as necessary to stabilise the system. Driven, old rail sections or steel H-piles can be used as

vertical piles. The type, spacing and length of the vertical and raked piles depend on the slope geometry and ground conditions. The coarse granular fill or ballast provides a free-draining medium, which would also act as a natural barrier against vegetation. Hence, the lateral drainage of the track is improved and the application of weedkillers can largely be eliminated. A rapid rate of construction per shift can be achieved, in particular if rail sections are used as vertical dowels. This system is economical and is considered suitable for areas where the only requirement is to widen the cess and to provide shoulder stability (Saffari and Smith, 2005) (**Figure 71.11**).

Anchored bored-pile wall

For this option a system of embedded vertical small diameter (of the order of 300 mm) bored piles with raking piles and a capping beam can be used to improve the stability of slopes and/or provide support for the widening of the cess at the crest. The capping beam acts as a small retaining structure to support the widened cess. The vertical piles act as a foundation for the capping beam and the raking piles provide lateral stability. Alternatively, small-diameter driven piles could be used instead of bored piles. These piles can be installed from the toe of the embankment, thereby eliminating the need for a piling platform resulting in significant cost and time savings.

Toe wall

Where space at the toe of an embankment is too limited to re-grade the slope to stable angles, a combination of a wall at the toe of slope and re-grading by placing additional fill between the top of the toe wall and the edge of the widened crest can be used. Issues regarding the design and construction of this type of wall are generally similar to those for cuttings. Space at the toe of an embankment may be more readily available to accommodate a retaining wall compared to cuttings.

King-post wall

Where the factor of safety against deep-seated instability is satisfactory and the main problem is to provide a solution to mitigate shoulder instability and widen the shoulder, king-post walls can be used.

In principle a king-post retaining wall consists of embedded vertical structural members acting as king-posts with horizontal structural members spanning between them to form a retaining function. Backfilling with granular fill can be carried out behind the wall to provide the widened shoulder.

The vertical members can be bored or driven concrete or steel piles. Along the shoulder of an embankment space and access for construction is very limited and, hence, driven steel piles such as universal bearing piles using a track-mounted rig would provide a more practical solution. This arrangement eliminates the need for a piling platform and the associated temporary works. The horizontal members can be pre-cast concrete panels fitted between the flanges of the steel pile or against the web. An example of this type of wall is shown in **Figure 71.12**.

Sheet piling

Sheet piles can be installed at the toe or crest of an embankment slope to form a retaining wall. Backfilling behind the sheet piles will then be carried out to widen the shoulder and also increase the toe weight, which contributes to improving stability. The depth of the sheet piles will need to be designed to resist lateral loading as well as the rotational slope instability. A capping beam, steel or concrete, can be constructed to connect the sheet piles together. The sheet piles will need to be designed against corrosion to provide the required design life.

Installation of the sheet piles using a standard crane-mounted vibrating pile-driving method can be unsuitable at some sites, due to restrictions on the use of crane-mounted rigs and on lifting long sections of sheet piles adjacent to railways.

An alternative installation method using the proprietary Giken GRB non-staging system can be considered under these circumstances. This is a silent press method, using installed piles to provide reaction for a hydraulic pressing system. The piling press, power pack, pitching crane and pile transport equipment are all mounted on and travel along the installed piles; hence, no temporary access or staging is required. As the pile lifting equipment is clamped to the installed piles, there is a reduced risk to the railway from toppling plant. An example of this type of sheet piling is shown in **Figures 71.13** and **71.14**.

71.4.3 Remedial work design

For existing slopes, remedial work often needs to be carried out while the transport system running above or below the earthworks remains operational. Hence, the main challenges for existing slopes can be:

- very tight and limited space;
- limited access;
- safe operation of the railway, highway and associated services;
- environmental constraints.

Hence, innovative techniques are required in order to arrive at cost-effective, efficient and safe solutions for remedial work. Many innovative solutions such as the Ruglei shoulder protection system, Giken sheet piling, soil nailing and various types of piling have successfully been implemented. **Figure 71.15** shows the replacement of an old and worn out king-post wall in a difficult access area adjacent to a congested network of cables.

In some cases due to site and access constraints, a solution can only be achieved by providing protection rather than remediation. **Figure 71.16** shows the protection provided for the steep toe of a cutting, which could not otherwise be re-graded due to site constraints, by the placing Armortec revetment blocks.

71.4.4 Environmental considerations

Environmental factors could have an impact on the performance of an existing earthwork or on the maintenance or construction of the remedial works. Environmental factors could also affect the type of design solution adopted for the remedial works in order to comply with regulations.

These aspects, when identified, have the potential to significantly delay a project until approval from relevant authorities is obtained. Hence, a consideration of environmental aspects should be made from the start of any project in order to ensure that all risks are taken into account. An environmental risk assessment can be carried out at the start of a project and reviewed throughout the development of the project. A list of environmental factors that could have an effect on an earthwork is discussed below.

71.4.4.1 Vegetation

Performance

The effect of vegetation on the performance of earthworks has been discussed in the preceding sections. Whilst the presence of mature trees reduces the pore pressures within a slope leading to increased stability, on clay slopes it can cause seasonal swelling and shrinkage leading to serviceability problems.

The presence of vegetation may serve to reinforce and strengthen a slope through the root system. However, depending on the type of vegetation and the slope geometry, the root system may be quite shallow and ineffective and become unstable during storm events and fall onto the transport corridor below.

Tree Preservation Order (TPO)

Trees which carry a tree preservation order cannot be removed from a construction site. There is usually an exclusion zone associated with these trees, which could be quite significant depending on the type and size of the trees and the root system. This can significantly affect the design of the remedial works in the vicinity of the tree. A preservation order on hedgerows on the crest of a cutting can significantly affect access to the cutting during construction. Hence, it is important that any

such orders are investigated at the start of a project in order to avoid any design changes and delays to the project.

Third Party

Vegetation and trees that may have a significant effect on the stability of a cutting or embankment could be located on third-party land. In this case the control of the vegetation may be outside the control owner of the infrastructure. Hence, caution must be applied during the design of the works regarding the long-term pore pressure regime within the structure.

71.4.4.2 Environment Agency (EA)

Streams and rivers located adjacent to an embankment or passing beneath it may be affected by construction activities. Drilling of exploratory holes for the design or drilling of piles may cause pollution in the river. Increasing an embankment's volume as the result of the construction of a berm may affect the EA flood capacity in the vicinity of a river. In this case, consultation with the EA during the design phase would be required. The design of a drainage scheme at the toe of an embankment may include a discharge of the collected water into the river. Prior approval from the EA would be required, including an outfall design that complies with EA requirements.

71.4.4.3 Ecological

For any investigation or remedial work, the following ecological aspects should be considered:

- nesting birds;
- badger setts;
- great crested newts;
- slow-worms.

An ecological survey would be required well in advance of the work so that appropriate mitigation measures are undertaken in order to comply with the relevant standards.

Earthworks slopes may require the use of structural solutions where geometric constraints or the proximity of settlement-sensitive structures prevent the design of a full height earthworks solution. Structural solutions may also be used for road widening where further land purchase is not possible, and for the stabilisation of existing earthworks slopes. This chapter introduces the major forms of structural slope solutions.

72.1 Introduction

Stabilised slopes incorporating structural components, nailing or reinforcing elements in new earthworks, are usually employed either:

- where long term performance of a conventional slope may impact adjacent structures e.g. adjacent buildings; or
- where geometric constraints do not allow the construction of a conventional slope that is stable over its design life.

Stabilised slopes are, however, common in stabilising existing assets and the widening of existing motorways where measures cannot extend outside the existing asset boundary.

The selection of a stabilisation method can depend on the balance of the capital expenditure to construct and maintain versus the adoption of a less expensive option that may require additional measures to be applied at a later date. This is usually the decision of the asset owner and can depend on the consequences of failure. A useful approach outlining responsibilities is given in Charles and Watts (2002).

This chapter describes briefly methods to stabilise slopes; they can be divided into:

- embedded solutions;
- gravity solutions;
- reinforced/nailed solutions;
- slope drainage.

In some cases, solutions comprise more than one of the above categories.

72.2 Embedded solutions

Embedded solutions generally comprise:

- concrete pile walls;
- sheet pile walls.

Concrete pile walls usually comprise bored cast *in situ* or continuous flight auger piles. Pile diameter and spacing will depend on the size of plant that requires access to the location and the requirements of the design with respect to bending moment and shear in the pile shaft.

Piled walls are usually designed in order that potential failure surfaces passing below the toe of the wall achieve a satisfactory factor of safety/degree of utilisation as described in Chapter 69 *Earthworks design principles*. Wall design should also consider the action of the piles to act as shear keys on potential failure surfaces passing through the wall, and should be designed as a conventional embedded retaining wall after Gaba *et al*. (2003).

Where the design of the wall cannot satisfy bending moment and shear requirements of the pile shaft, or deflection causing unsatisfactory settlement of the ground behind the wall, additional support can be considered. This would usually comprise (i) cantilever walls; (ii) ground anchors; (iii) raking piles; and (iv) tie bars; see **Figure 72.1**.

Ground anchors, installed at the head of the pile, apply a restraining force in an active manner directly after construction; the active load in the anchor being applied immediately after installation. The design of the anchor should be after BS 8081 (BSI, 1989).

Raking piles, installed in a similar manner to anchors, apply no initial restraining force and act passively whereby forward movement of the wall generates friction on the raking pile shaft. This initiates an anchoring action at the vertical pile head. The raking piles should be designed as conventional piles in tension.

Tie bars act in the same way as raking piles but can be post tensioned to act similarly to ground anchors. They require a restraint mechanism and are most practicably used in the stabilisation of existing earthworks embankments where there is a piled wall on the opposite side of the embankment. This solution has been employed in the stabilisation of London Underground embankments.

Sheet pile walls are designed in the same manner as bored pile walls, but may be precluded where vibration could affect adjacent structures if a driven method of installation is employed. This can be overcome by the use of a hydraulic jacking installation method. The use of a sheet pile solution for the remediation of a failed slope may be attractive as it can be implemented rapidly after the failure occurs.

Care should be taken in the design of sheet pile walls in that the design section chosen should be capable of being driven

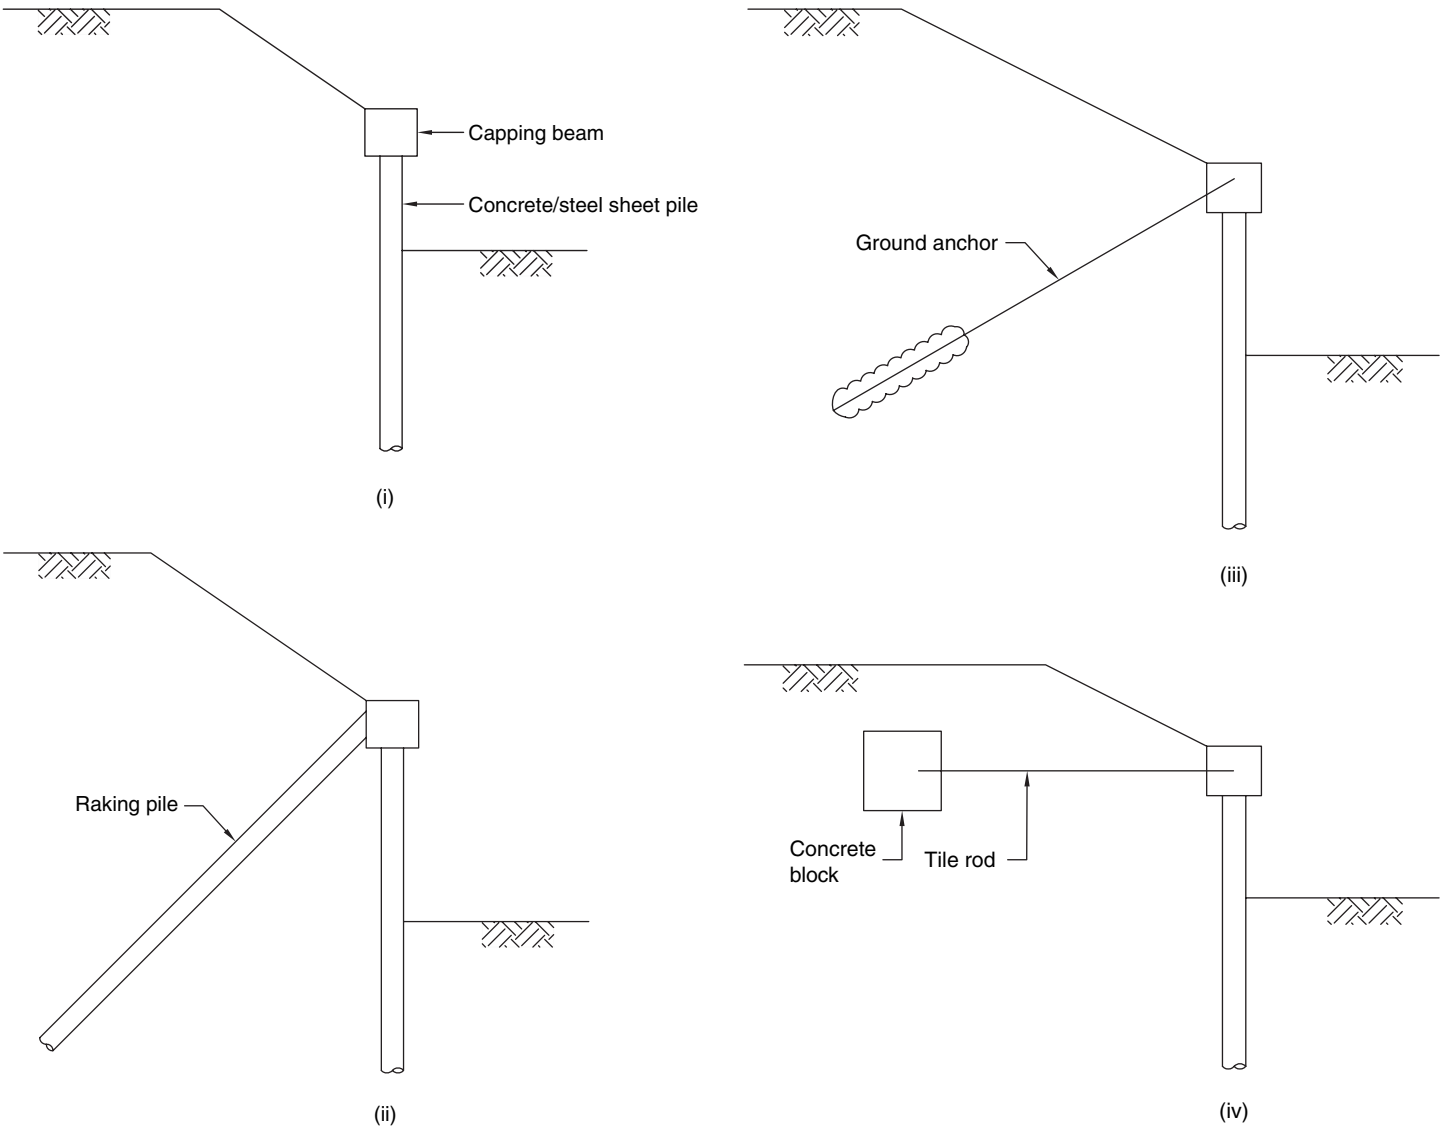

Figure 72.1 Typical embedded solutions: (i) cantilever wall; (ii) wall with ground anchor; (iii) wall with raking pile; (iv) wall with tie and deadman block

in the prevailing ground conditions. Guidance is given in Williams and Waite (1993).

Structural design of bored pile walls should be undertaken to BS EN 1992–1 (BSI, 2004a), BS8110–1 (BSI, 1997), BS8500 (BSI, 2006) or BS5400 (BSI, 2002). Structural design of steel sheet piles should be undertaken to BS EN 1993– 5 (BSI, 2007).

More advice on the design of embedded walls is given in Section 6 *Design of retaining structures*.

72.3 Gravity solutions

Gravity structures would usually comprise the following solutions: (i) reinforced concrete wall; (ii) gabion wall; (iii) dry block wall; (iv) crib wall; (v) reinforced soil wall; and (vi) reinforced earth wall. Typical solutions, without soil reinforcement, are illustrated in **Figure 72.2**.

The gravity structure performs under its own stability in terms of its resistance to sliding, overturning and bearing capacity failure. They can be designed in accordance with Chapman (2000). Reinforced earth and reinforced soil walls should be designed in accordance with BS 8006 (1995 and 2009b) as described in Chapter 73 *Design of soil reinforced slopes and structures*. More advice on the design of reinforced gravity walls is given in Section 6 *Design of retaining structures*.

In addition to the stability of the gravity structure, the designer should also consider the stability of the slope that it retains. It is common for walls greater than 3 m which retain a slope behind them to require embedment of the wall below

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

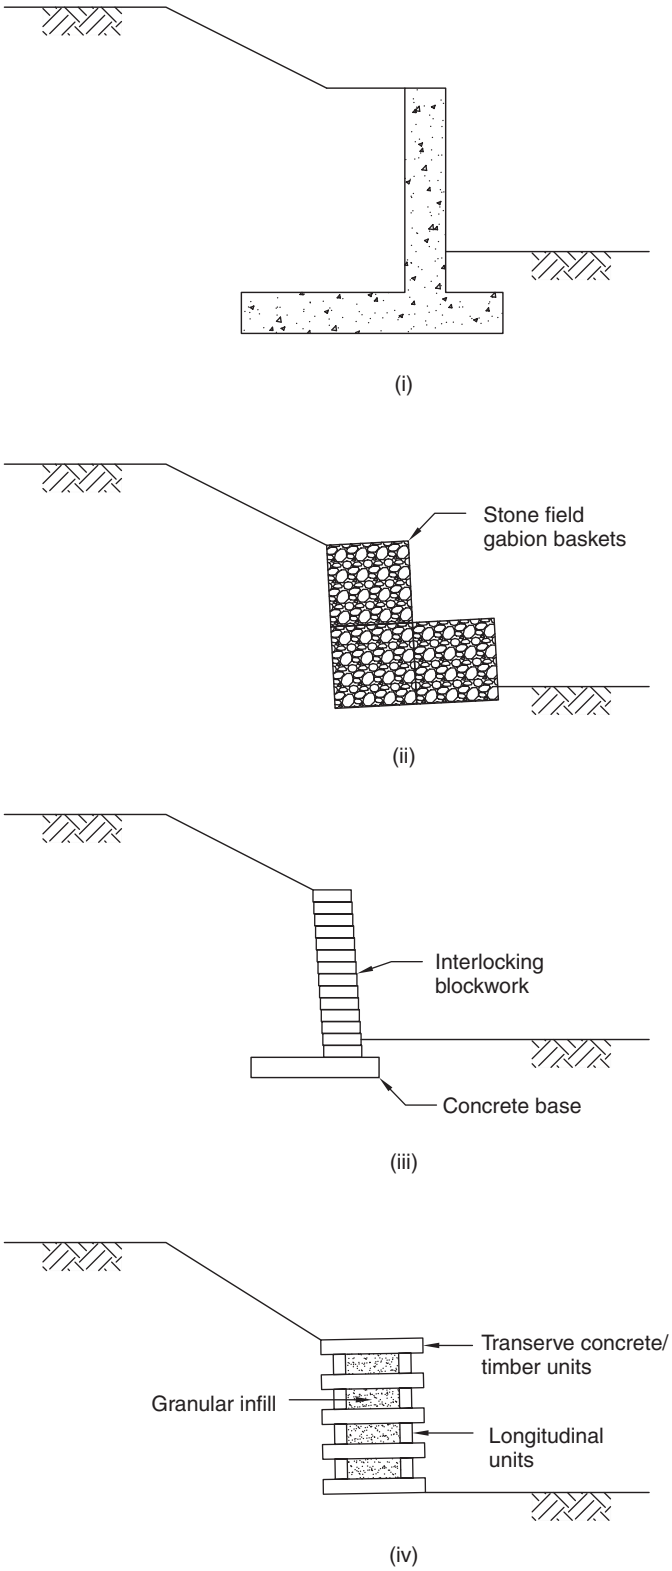

Figure 72.2 Typical gravity solutions: (i) reinforced concrete wall; (ii) gabion wall; (iii) dry block wall; (iv) crib wall

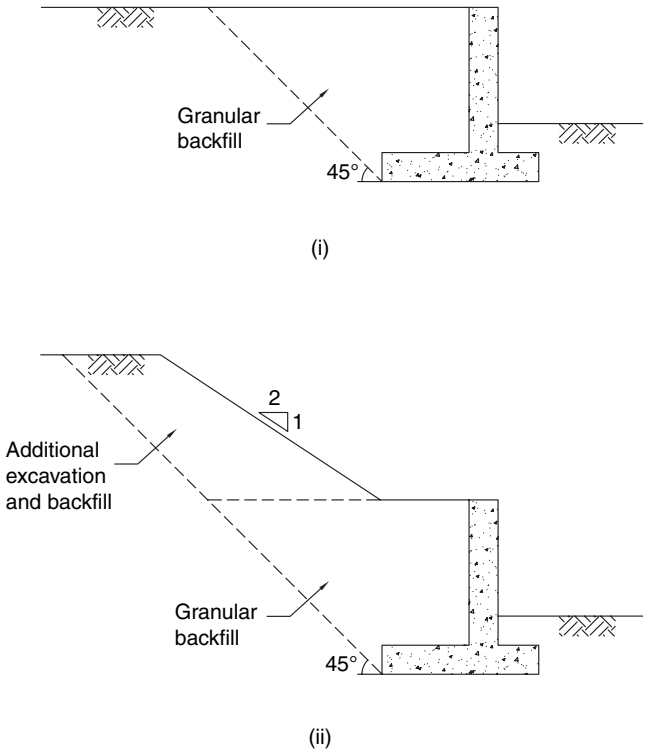

Figure 72.3 Effect of sloping ground on excavation and backfill volume: (i) gravity wall with horizontal ground behind; (ii) gravity wall with sloping ground behind

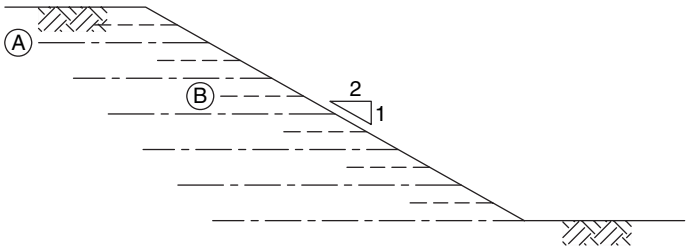
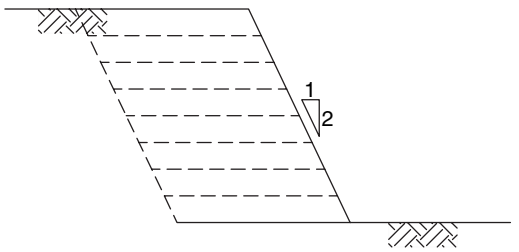


ground surface on the passive side in order to prevent overall failure of the composite slope and wall.

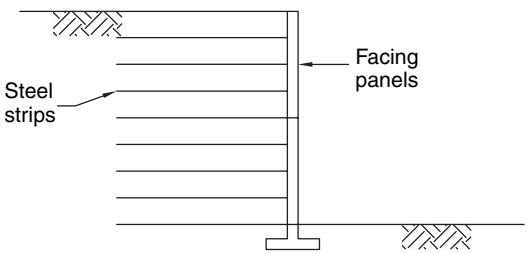
It is usual that gravity structures are designed with granular backfill in the area of the active wedge behind the wall. Care should be taken where a gravity structure is specified on existing or widened infrastructure, as it may result in significant excavation of the slope behind the wall as shown in **Figure 72.3**.

It is common that gravity structures, particularly masonry and brick walls, form part of an existing infrastructure asset. Where an assessment is required as part of an asset condition survey, this will be carried out to current best practice i.e. BS EN 1997 (BSI, 2004b) or, formerly, BS 8002 (BSI, 1994). It should be borne in mind, particularly with respect to railway infrastructure, that the structure may be up to 100 years old and would not have been constructed to current best practice. Assessment of the structure to BS EN 1997 or BS 8002 is likely to indicate failure of the structure or earthwork which shows no visible structural distress. In this case, the asset owner should be consulted and a sensible approach to the management of the asset agreed.

72.4 Reinforced/nailed solutions

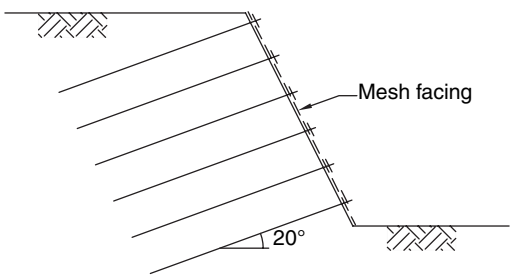


Reinforced or nailed slopes will generally comprise the use of geogrid reinforcement or a grid of soil nails to provide additional tensile strength along likely failure surfaces. Typical examples are shown in **Figure 72.4**.



(A) Primary reinforcement

(B) Secondary reinforcement to prevent local failure of face between primary grids



(i)

(ii)

(iv)

Figure 72.4 Typical reinforced/nailed solutions: (i) reinforced soil slope; (ii) reinforced soil block; (iii) reinforced earth slope; (iv) soil nail slope

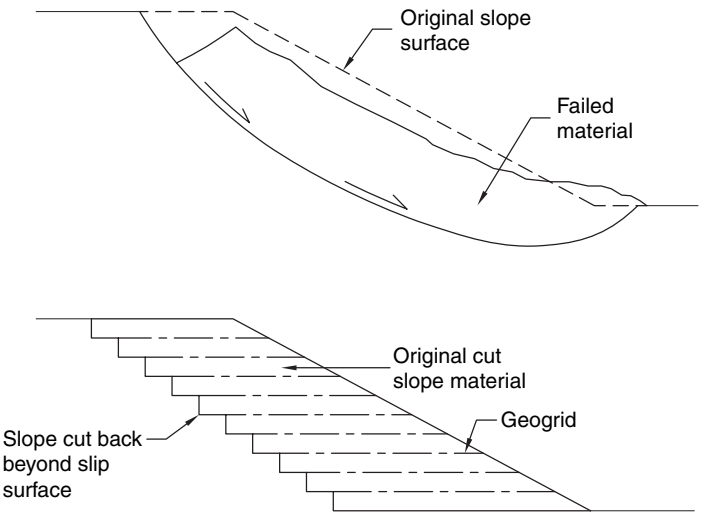

Figure 72.5 Repair of slope failure using geogrids

Design should be carried out in accordance with BS 8006 and further guidance is provided in Chapters 73 *Design of soil reinforced slopes and structures* and 74 *Design of soil nails*.

The use of soil reinforcement and nailing is not confined to steep-faced (approximately 60°) slopes; it can be applied to slopes of any angle where additional tensile strength of the reinforcement or nailing allows the adoption of a stable slope at a steeper angle than if no reinforcement were employed. On the Terminal 5 spur road project at Heathrow airport, geogrid reinforcement was employed to allow the use of 1V:2H slopes in London Clay embankments where geometric constraints prevented the adoption of 1V:4H slopes used for the majority of the embankment construction.

Geogrids have also been used to repair slope failures, particularly cutting slopes. They were extensively used on the M4 motorway in Berkshire in the 1970s and were also used in a London Clay cutting on London Underground at Hendon. The slipped material is excavated back beyond the slip surface, stockpiled and re-compacted with layers of geogrid to provide additional tensile strength to the original failed material as shown in **Figure 72.5**.

This solution may not always be practicable if there is insufficient facility to temporarily store the slipped material locally. If storage of excavated material is not available local to the failed area it is common practice for the slip repair to be effected using imported granular material.

72.5 Slope drainage

Stability of constructed slopes can be influenced by water either as groundwater (see Chapter 70 *Design of new earthworks*) or as precipitation.

The former may result in deep seated slope failure if uncontrolled and not in line with design assumptions, particularly in inter-bedded cohesive and non-cohesive strata; groundwater

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

flow in the non-cohesive strata causes softening of the surrounding cohesive material.

The ingress of precipitation can cause softening of the surface layers of cohesive earthworks, which leads to reduction in any effective cohesion in the slope material and the development of shallower failure surfaces. These are commonly seen on major road networks and require remediation.

It is common practice to counteract these problems with slope drainage, either as part of the original slope construction or as a remedial works measure.

Slope drainage usually takes the form of gravel-filled drains orthogonal to the slope (counterforts) or as a 'herring bone' pattern. The drains are commonly constructed with a carrier pipe and geotextile wrap to prevent the ingress of fine-grained material which would impact on their long-term performance.

Drains are usually spaced at intervals of between 5 and 10 m along the slope, depending on the composition of the slope material. Useful guidance on their design and the philosophy behind slope drainage is provided by Hutchinson (1977).

In designing slope drainage, a suitable outfall has to be considered to prevent ponding of drainage water which will occur at the base of the earthwork, potentially resulting in the softening of the toe and increasing the potential for failure in this area.

Slope drains can be connected to a drain constructed parallel to the toe of an embankment slope, or to verge drainage in a cutting. Outfall of the system can be by means of positive flow, such as an existing river course or existing public sewers, or to a sustainable drainage system (SUDS), Woods and Kellagher (2007).

Reinforced soil structures are composite constructions involving some form of reinforcement (usually geosynthetic or metallic), generally installed in horizontal layers within a soil mass. The reinforcement layers extend beyond the potential failure surface, absorb the tensile strains that would otherwise cause failure of the non-reinforced soil and redistribute them in the soil beyond the failure plane. This chapter aims to introduce the general concepts of soil reinforcement, the various materials and general principles involved in the design of reinforced soil structures. Reinforced soil walls and abutments, reinforced soil slopes and basal reinforcement are discussed.

73.1 Introduction and scope

The concept of reinforced soil structure consists of placing (typically horizontal) layered reinforcing elements with sufficient axial tensile stiffness within a soil mass to improve its tensile and shear capacities. This allows the construction of reinforced soil slopes and reinforced soil walls at significantly steeper angles – which would be unstable without the reinforcement. When used as basal reinforcement, this also allows the construction of embankments over poor ground or areas prone to subsidence that would otherwise fail without the reinforcement in their foundations.

The idea of introducing reinforcing elements to improve the strength of fill can be traced back to the earliest human times, when primitive people used sticks and branches for the reinforcement of mud dwellings. The earliest remaining example of reinforced fill is the Aqar Quf ziggurat built in modern Iraq by the Babylonians around 3000 BC, using clay bricks, reinforced with woven mats of reed laid horizontally on layers of sand and gravel, with plaited ropes of reed passing through the structure. Parts of the Great Wall of China built more than 2000 years ago also adopted a form of reinforced fill where tamarisk branches were used to reinforce a mixture of clay and gravel.

In the early 1960s, Henri Vidal introduced and developed the modern form of reinforced fill using flat metallic reinforced strips laid horizontally on a frictional fill. In the late 1960s and 1970s, extensive studies of reinforced soil structures sponsored by national bodies, notably the Laboratoire central des ponts et chaussées (LCPC) in France, led to a fuller understanding of the concepts involved and a better acceptance of the method. More or less simultaneously, advances in synthetic fabrics led to the development of geotextiles and geogrids. These new materials were soon put to good use in the construction of geosynthetic-reinforced soil structures and as basal reinforcements. It should be noted that reinforced soil is the general term for reinforcing elements placed within a soil mass and covers both metallic and polymeric reinforcement. The term 'reinforced earth' is the trademark for the Reinforced Earth Company – using its founder's (Henri Vidal) 'Terre Armée' concept.

This chapter introduces the various types of reinforcements and their properties, discusses the general principles of the reinforcement action and provides guidance for the design of reinforced soil structures. Reinforced soil walls and abutments, reinforced soil slopes and basal reinforcement are then covered in more detail. Particular forms of reinforcement such as anchored earth (Chapter 89 *Ground anchors construction*), soil nails (Chapter 74 *Design of soil nails*), and particular application of basal reinforcement such as load transfer platforms (Chapter 70 *Design of new earthworks*) are discussed elsewhere in this manual.

73.2 Reinforcement types and properties

73.2.1 Types of reinforcement

There are essentially two main types of reinforcement, defined by their extensibility.

- Extensible reinforcement: defined in BS 8006 (BSI, 1995) as reinforcement that sustains the design loads at strains greater than 1% and which are usually polymeric.
- Inextensible reinforcement: defined in BS 8006 as reinforcement that sustains the design loads at strains less than or equal to 1% and which are usually metallic.

The design life of the reinforcement can vary from a few months (e.g. basal reinforcement for embankment on soft ground) to up to 120 years (e.g. walls, abutments and slopes). The principal function of the reinforcement is to withstand tensile loads; the ability of the reinforcement to perform its primary function, both initially and throughout its design life, will largely depend on the material from which it is produced.

73.2.2 Properties of polymeric reinforcement

Polymeric reinforcement can take a variety of forms, such as grids, meshes, strips (commonly used to reinforce slopes and walls) and geotextile sheets (commonly used for basal reinforcement).

All polymers are essentially nonlinear viscoelastic materials, and as such are load rate dependent. In addition, polymers are subject to creep and their behaviour is therefore time dependent.

When subjected to a constant load, all materials will increase in strain over time. This phenomenon is known as creep and is significant in polymers at ambient temperatures. The tensile rupture strength of polymeric reinforcement will reduce over time, predominantly due to creep from an initial short-term ultimate tensile rupture strength (UTS) to a tensile creep rupture strength at the end of the selected design life. The propensity of polymeric reinforcement to creep will be primarily dependent on the particular polymer used to produce the geosynthetic reinforcement (e.g. polypropylenes tend to have a greater creep propensity than polyesters).

Isochronous curves plot the tensile load against the strain for a given time (during which the reinforcement has been subjected to the tensile force). The curves are derived from extensive testing and interpolations following guidelines in PD ISO/TR 20432 (BSI, 2007) and are unique to each proprietary geosynthetic reinforcement. The stress axis is generally normalised by expressing the tensile load as a percentage of the initial short-term UTS of the reinforcement.

These curves enable the designer to establish both the initial strains and post-construction strains for polymeric reinforcement at a given load/stress level; strains must remain below prescribed design limits. BS 8006 imposes varying serviceability limits on post-construction strain depending on the type of structure considered. Post-construction strains are limited to 0.5% for bridge abutments and retaining walls with permanent structural loads, and to 1.0% for retaining walls with no applied structural loading. For slopes where deformations are not critical, post-construction strains in the order of 5% may be acceptable. There usually is no limit on post-construction strain for basal reinforcement (used for embankment on soft ground) but there can be limits imposed when the basal reinforcement is used over areas prone to subsidence.

Additionally, the curves allow the designer to determine the variations of the reinforcement stiffness with time.

A typical set of isochronous curves are shown in **Figure 73.1**.

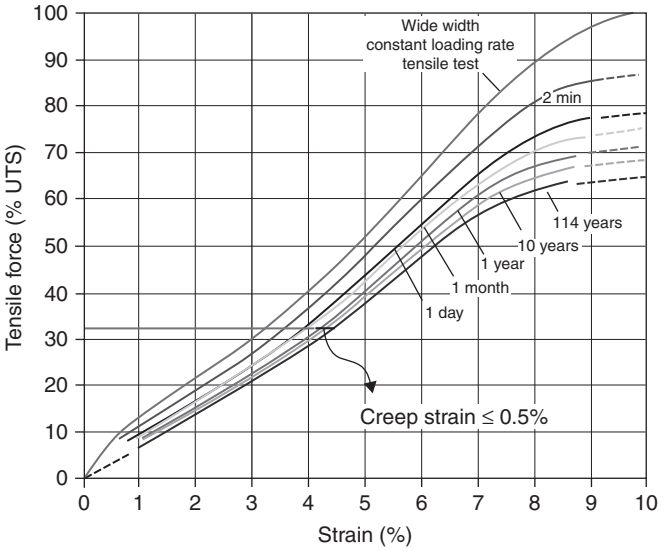

Figure 73.1 Typical isochronous curves for polyester-based reinforcement

73.2.3 Properties of metallic reinforcement

Metallic reinforcement can take a variety of forms, such as grids, meshes, strips, bars or rods (commonly used to reinforce walls and abutments).

Creep in metallic reinforcement is generally negligible in ambient temperatures. Metallic reinforcement can therefore be assumed to exhibit linear elastic behaviour to yield, independent of time. Hence, the tensile yield strength of metallic reinforcement will reduce over time, almost uniquely due to corrosion.

Corrosion in metallic reinforcement is essentially a process of oxidation; this forms a protective oxide layer which tends to retard further corrosion. The effects of corrosion are considered in design by allowing for a loss of the cross-sectional area of the reinforcement. BS 8006 provides guidance on the prescribed sacrificial thickness to allow for at the design stage, which varies depending on:

- particular metal or alloy and corrosion protection used;
- design service life of the reinforcement;
- corrosivity of the fill, soil or environment in which the reinforcement is placed (e.g. high acidity soil, which would be highly corrosive).

73.3 General principles of reinforcement action

73.3.1 Effects of introducing reinforcements in soil

When an inclined or vertical load (due to soil self-weight or surcharge) is applied to a soil, this will generate axial compressive strain in the soil and a corresponding lateral tensile strain. The maximum load that can be applied to a soil is limited by its internal shear strength. The introduction of reinforcement into the soil (of adequate stiffness) improves the shearing resistance of the soil (shear strength of reinforced soil = mobilised shearing in the soil + mobilised tensile force in the reinforcement) and has the effect of reducing both the axial compression and lateral deformations.

Deformation of the soil along a potential failure plane causes shear forces to develop in the soil and tensile forces to develop in the reinforcement intercepting the failure plane. The reinforcement

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

is most effective when placed in the direction in which the tensile/lateral strains develop. However, in most practical reinforced soil applications, the reinforcement is installed horizontally (with the exception of soil nails which are commonly inclined at an angle between 10 and 20° from the horizontal).

73.3.2 Strain compatibility

The relative magnitude of the shear force mobilised in the soil and the tensile force mobilised in the reinforcement will be a function of deformations and the relative stiffness properties of both soil and reinforcement (stiffer reinforcement will carry a higher percentage of the mobilised force). The magnitude of mobilised soil shearing resistance and the mobilised reinforcement strain need to be considered to provide equilibrium.

Inextensible (metallic) reinforcement will absorb, through frictional contact, the disturbing forces in the active zone at low soil deformations and transfer these forces beyond the failure plane. For more extensible polymeric reinforcements, the issue of strain compatibility becomes increasingly important – to ensure design reinforcement strain limits remain compatible with mobilised soil strains.

Figure 73.2 shows the mobilised shear resistance of a typical granular soil and the typical mobilised reinforcement force (time constant).

From the graph in **Figure 73.2(a)** it can be seen that as strains develop, the mobilised shear resistance in the soil increases (and the required reinforcement force to satisfy equilibrium decreases) up to a point where the mobilised shear strength reaches a maximum or peak strength ϕ'_p. Beyond this point (ϕ_m), increasing deformations result in reducing shear strength towards a minimum value ϕ'_{cv} (shear strength at constant volume) independent of strain, with a corresponding increase in the force required to satisfy equilibrium. At the same time, as strains develop, the force mobilised in the reinforcement corresponding to a specific loading period (t_d) and temperature (T_d) increases (**Figure 73.2(b)**).

Strains develop until a strain level is reached (in both the soil and the reinforcement) whereby the force mobilised in the reinforcement is that required to satisfy equilibrium (**Figure 73.3**).

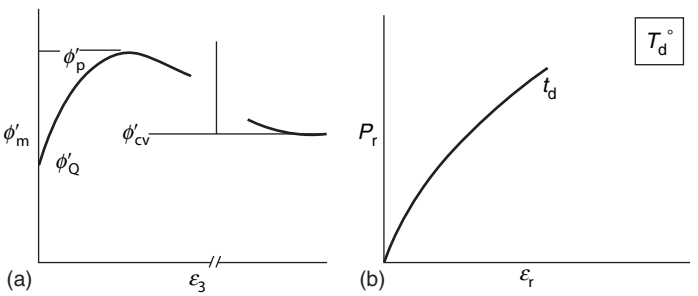

Figure 73.2 Relations for strain compatibility: (a) mobilised soil shearing resistance, (b) mobilised reinforcement force. P_r = mobilised reinforcement force; t_d = loading period; T_d = temperature; ε_3 = maximum tensile strain

Reproduced, with permission, from CIRIA SP123, Jewell (1996), www.ciria.org

At this point, further deformations will only occur as a result of additional loading, or through stress relaxation, or creep, of the reinforcement over time.

The stress–strain response of soil will vary depending on a number of factors including mineralogy and stress history; similarly, the stress–strain response of reinforcement will vary depending on a variety of factors including its form, manufacturing process and raw material. It is generally not practical to develop a set of compatibility curves for every soil type and proprietary reinforcement product available. BS 8006 provides practical recommendations for addressing strain compatibility by adopting certain values depending on the type of reinforced soil application. For example, ϕ'_p would be adopted for walls and steep slopes where mobilised strains and deformations are considered more critical to the overall performance, and ϕ'_{cv} for shallow slopes and basal reinforcement over soft soils where deformations are considered less critical.

73.3.3 Interaction between soil and reinforcement

Reinforcement develops a bond with the soil through either friction (for granular soils) or adhesion (for cohesive soils). There are two interaction modes:

- direct sliding, in which a block of soil slides over a layer of reinforcement;
- pull-out (bond), in which a layer of reinforcement pulls out of the soil after mobilising the maximum available bond stress.

73.3.3.1 Direct sliding

The sliding resistance of geotextile reinforcement is generated over the full plan area of contact. The sliding resistance of geogrids and strips is generated from both direct contact between the reinforcement and the soil, and from soil-to-soil contact through the apertures or adjacent to the reinforcement.

Modified direct shear tests are suitable for measuring the coefficient of direct sliding between soil and any type of reinforcement.

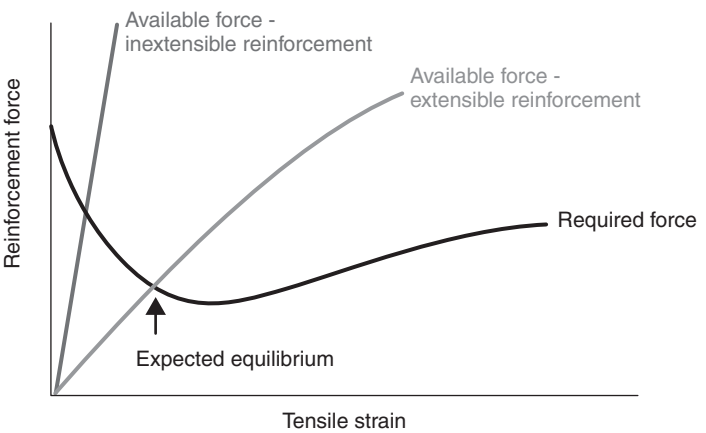

Figure 73.3 Typical compatibility curve for determining equilibrium in reinforced soil

Adapted, with permission, from CIRIA SP123, Jewell (1996), www.ciria.org

For cohesive foundation soils, subject to undrained loading, the bond stress developed between the soil and the reinforcement is directly related to the undrained shear strength of the soil by an adhesion factor, which will normally have a value less than unity.

73.3.3.2 Pull-out

The pull-out resistance of geotextile reinforcement is generated from surface shear over the full plan area. Geogrids develop pull-out resistance partly from surface shear and partly through bearing resistance from the transverse members of the geogrids. It is usually sufficient for the design to calculate the bond coefficient from theoretically derived values for these two components.

For narrow, rough, strip reinforcement embedded in dense cohesionless fill, the shear stresses developed during pull-out lead to dilatancy in the fill, which causes the vertical effective stress to locally rise above the overburden pressure. This gives rise to an enhanced pull-out resistance. It is generally recommended that field pull-out tests be carried out to verify the bond strength of these types of reinforcement.

Pull-out tests are relatively difficult to perform and can be significantly influenced by the boundary conditions of the test. They can, therefore, be unreliable.

73.4 General principles of design

The design of reinforced soil structures and slopes is not covered by the Eurocodes. In the UK, design of reinforced soil structures follows BS 8006 *Code of Practice for Strengthened/Reinforced Soils and Other Fills* (or HA68/94 *Design Methods for the Reinforcement of Highway Slopes by Reinforced Soil and Soil Nailing Techniques*; Highways Agency, 1994). BS 8006 follows a limit state approach and provides partial factors of safety calibrated for reinforced soil structure design through the assessment of historical data. It should be noted that the standard was first published in 1995 and that a new version has been published in 2010. The following text applies to both standards as there have been minimal changes between the two.

73.4.1 Limit state approach

Reinforced soil structures are designed against the occurrence of ultimate limit states (ULS) and serviceability limit states (SLS). ULSs are associated with collapse, rupture or major damage, and SLSs with excessive settlement or deformations.

73.4.2 Partial factors of safety approach

BS 8006 provides various partial factors of safety which are used to generate the overall safety of reinforced soil structures. Although BS 8006 does not specifically group them in this fashion, it is convenient to think of the partial factors of safety as being introduced to reduce material properties and resistances, and increase loads (a similar approach to that used in the Eurocodes).

A partial factor for ramification of internal failure (f_n) is also introduced to account for the ramifications (consequences) of internal failure. The value of f_n depends on the class of risk for the structure and introduces additional safety for structures where the consequences of failure are most onerous. This factor is applied both as an additional material factor and as an additional resistance factor on the reinforcement strength and fill reinforcement interactions, respectively.

73.4.2.1 Partial material factors

A partial material factor of safety on reinforcement (f_m) is applied on the reinforcement capacity to account for uncertainty on the reinforcement properties (manufacture and extrapolation of test data), susceptibility to damage during construction (e.g. due to shape and size of fill used) and environmental effects (e.g. temperature, exposure to ultraviolet radiation).

The partial factor for ramification of internal failure (f_n), as discussed above, is also applied to further reduce the reinforcement design strength and therefore acts as an additional material factor.

A partial material factor of safety is applied on soil strength parameters (f_{ms}) to account for uncertainty on the characteristic value of the soil parameters considered.

73.4.2.2 Partial load factors

Partial load factors are applied to increase the soil self-weight (f_{fs}), the external dead loads (f_f) and the external live loads (f_q). For walls and abutments, the worst load combination for the various design criteria must be identified and considered in the design.

BS 8006 uses high values for partial load factors on fill or soil self-weight, which is one of the parameters that is likely to be well known and not subject to large variations. However, it should be borne in mind that the values of partial factors of safety provided in BS 8006 have been specifically calibrated for reinforced soil structures. Even if the logic behind a particular partial factor looked at in isolation is not always apparent, the overall application of the full set of partial factors of safety leads to safe designs.

73.4.2.3 Partial resistance factors

For the internal failure mechanisms (i.e. within the soil/reinforcement block) involving fill/reinforcement interaction, a partial factor of safety on pull-out resistance (f_p) is applied to the resistance generated by fill/reinforcement interaction behind the potential failure surface, when this intersects a layer of reinforcement. A partial factor of safety on sliding resistance along reinforcement (f_s) is also applied to the resistance generated by fill/reinforcement interaction when the base of a potential failure surface coincides with a layer of reinforcement.

The partial factor for ramification of internal failure (f_n) is also applied to further reduce the fill/reinforcement resistances (pull-out and direct sliding) and therefore acts as an additional resistance factor.

For the external mechanisms (e.g. sliding or bearing capacity), a partial factor on sliding resistance along soil (f_s) is applied

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

to the resistance generated by soil/soil interaction on any horizontal plan, either within or at the base of the reinforced soil structure where there is soil to soil contact. A partial factor on bearing capacity resistance (f_{ms}) is also applied to the resistance generated by the ultimate bearing capacity. Please note that BS 8006 considers this partial factor of safety as a material factor (hence the notation f_{ms}) however, bearing capacity is not an intrinsic soil property and, therefore, in the following the partial factor on bearing capacity is considered as a resistance factor.

73.5 Reinforced soil walls and abutments

73.5.1 General

Reinforced soil walls and abutments are composite structures consisting of fill, reinforcement and a facing, as illustrated in **Figure 73.4**. Provided the reinforcement layout and properties are adequate to prevent an internal failure of the reinforced soil block, the block of reinforced soil retains the soil at its back as a mass gravity structure, and transmits and spreads the effects of surcharges and earth pressures over its wide base. Reinforced soil walls are cost-effective soil retaining structures that can tolerate large settlements. Reinforced soil structures with a face within 20° from the vertical can be analysed as reinforced soil walls.

73.5.2 Materials

73.5.2.1 Fill

Both the mechanical and chemical properties of the fill need to be assessed. Generally, frictional class 6I/6J fill of the *Specification for Highways Works* (Highways Agency, 1993) is used in the construction of reinforced soil walls and abutments. When steel metallic reinforcements are used, the electro-chemical properties of the fill also need to be considered.

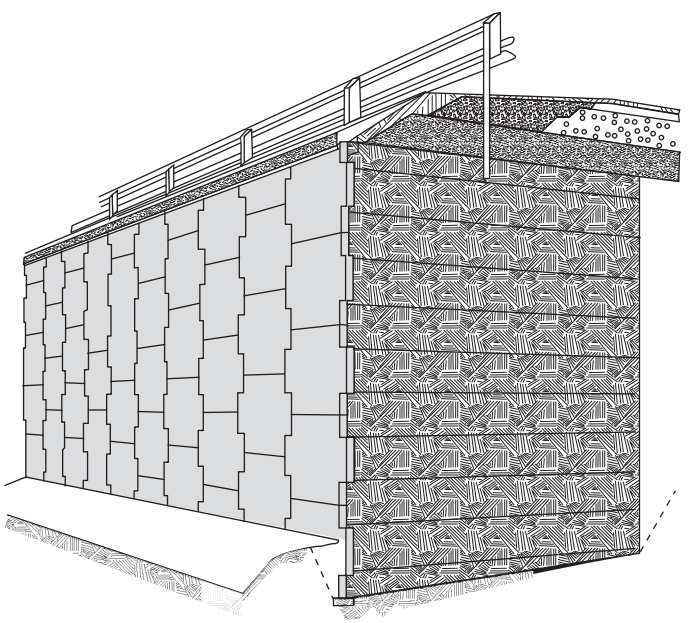

Figure 73.4 3D section through reinforced soil structure
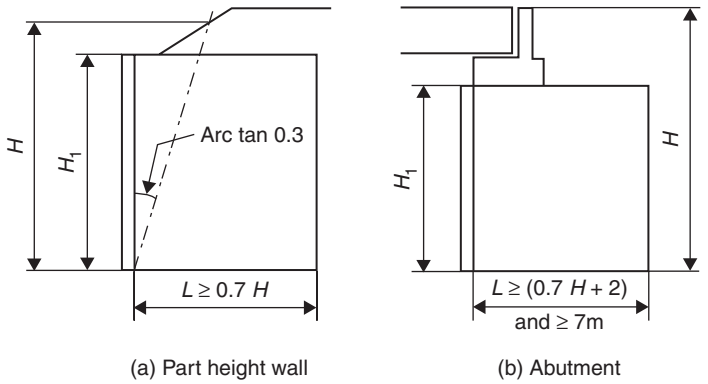
Courtesy of Terre Armée Internationale

Polymeric reinforcements are not influenced by electro-chemical properties, but the influence of chemicals on the proprietary polymeric reinforcements need to be assessed.

In certain circumstances, provided durability and compatibility with the reinforcement have been considered, cohesive fills, pulverised fuel ash, colliery spoil, argillaceous materials and chalk can be used (for details, refer to BS 8006, section 3). The selection and specification of fill for reinforced soil structure should be considered as early as possible in the project, and aspects such as sustainability, availability, impacts on design and costs should be borne in mind. The use of material other than class 6I/6J fill (provided durability and compatibility with the reinforcement have been considered) may lead to a design requiring longer, more closely spaced and stronger reinforcements, and to increased earthworks fill testing requirements during construction. However, the use of alternative material could also lead to a significant reduction in the quantities of selected fill to be imported – if site-won material can be re-used (thus reducing the quantity of material to be disposed of off-site). It could also reduce haulage costs if sources of acceptable fills are identified in the vicinity.

73.5.2.2 Reinforcement



The reinforcement in reinforced soil walls and abutments consists of either metallic strips or polymeric geogrids. The reinforcement properties and the principles of their interaction with the fill are discussed in sections 73.2 and 73.3 above.

73.5.2.3 Facing

The facing provides local support to the fill between reinforcement layers, prevention against weathering of the exposed soil and an aesthetically acceptable finish. Common facing types include full height panels, discrete panels, segmental blocks and wrap-arounds. They are constructed of concrete (reinforced or mass), steel, wood or polymers. Discrete panels (in hexagonal, square or cross patterns) are the most commonly used with metallic reinforcement, and segmental blocks are commonly used with polymeric reinforcements for permanent structures where a hard facing is acceptable. Wrap-arounds for polymeric reinforcement can provide a green finish but are more susceptible to ultraviolet degradation, accidental damage and vandalism. They are commonly used in temporary structures.

73.5.3 Common geometries and typical dimensions

Figure 73.5, in which L is the reinforcement length, illustrates common reinforced soil retaining wall and abutment geometries that can be used for assessing options at conceptual design stage and for preliminary sizing. These dimensions are given relative to the mechanical height H. For a wall, the mechanical height is derived as the vertical distance between the base of the reinforced soil block and the intersection of the finished profile and a line at 1V:0.3H from the front bottom corner of the reinforced soil block. For an abutment, H is the vertical height between the base of the reinforced soil block and the finished

(a) Part height wall (b) Abutment

Reproduced with permission from BS 8006–1 © British Standards Institution 2010

profile at the back of the abutment. Dimensions chosen for preliminary sizing may need amending following detailed design.

Other geometries including trapezoidal walls can be designed to suit particular site requirements.

73.5.4 Elements of design

The design of reinforced soil walls considers two distinct aspects.

- The external stability covers the design of the reinforced soil structure as a unit and follows the principles used for a general mass gravity retaining structure.
- The internal stability covers the internal mechanisms within the reinforced soil block and deals with considerations of stress distribution and reinforcement layout.

73.5.4.1 External stability

For external stability the following ULSs and SLSs should be considered:

- bearing and tilt failure – ULS;
- sliding – ULS;
- slip failure – ULS;
- settlement – SLS.

The factored applied bearing pressure at the base of the reinforced soil block (q_r) is derived using a Meyerhof distribution (equivalent rectangular distribution on a reduced area) as:

$$q_r = \frac{R_v}{L - 2e} \qquad (73.1)$$

where

R_v resultant of all factored vertical load components;
L reinforcement length at the base of the wall;
e eccentricity of resultant load R_v about the centre line of the base of width L.

The bearing capacity of the foundation soil derived using traditional bearing capacity equations must be greater than the applied bearing pressure (refer to Chapter 53 *Shallow foundations* for further details on bearing capacity).

At the base of the reinforced soil block, sliding should be checked either on a soil/soil interface or, if a layer of reinforcement is provided at the base of the reinforced soil structure, on a soil/reinforcement interface.

Any potential slip failure passing at the back of the reinforced soil structure should also be checked using traditional slope stability analysis software.

For the settlement check, both the settlement of the foundation soil and the internal settlement of the reinforced fill should be considered (refer to Chapter 70 *Design of new earthworks* for further details on fill self-settlement). However, when properly compacted, the selected fill used in reinforced soil walls and abutments will produce small internal settlements, and this component is often neglected.

In current UK practice, the internal stability of the reinforced structure is often designed by suppliers who do not generally assess the external stability. Instead, they provide target values for allowable bearing capacity of the foundation soil to prevent bearing capacity failure; target values for the shear strength of the foundation soil to prevent sliding; and SLS applied bearing pressures at the base of the reinforced soil block to allow an assessment of the settlements to be undertaken. It is critical to understand the limitations of such suppliers' designs and to ensure that:

- The external stability is adequately assessed, based on the actual ground investigation information and that, where required, ground improvement is applied to the foundation soil (or the geometry of the reinforced soil block is amended, or a combination of both) to ensure external stability is satisfied.
- The responsibilities of the various parties and the objectives/specification of the design are clearly defined (for most common applications, BS 8006 will provide a safe basis for design). Furthermore, notwithstanding the expertise of the suppliers, suppliers' designs should not be taken at face value.
- All other aspects such as drainage, services, fencing, aesthetics that could have an impact on the design are considered and communicated between the parties involved, to ensure an integrated overall design is achieved.

The court case that followed subsidence on a load transfer platform in Enniskillen, Northern Ireland (High Court of Justice in Northern Ireland, Queen's Bench Division, 2005), whilst not covering a reinforced soil wall or abutment, illustrates what can go wrong when the principles above are not followed.

73.5.4.2 Internal stability

Within the reinforced mass, there are two zones delimited by a potential failure surface. In the active zone (between the face of the wall and a potential failure surface) the fill sheds shear stress into the reinforcement and induces a tensile force in it. The reinforcement transfers this tensile force in the resistant

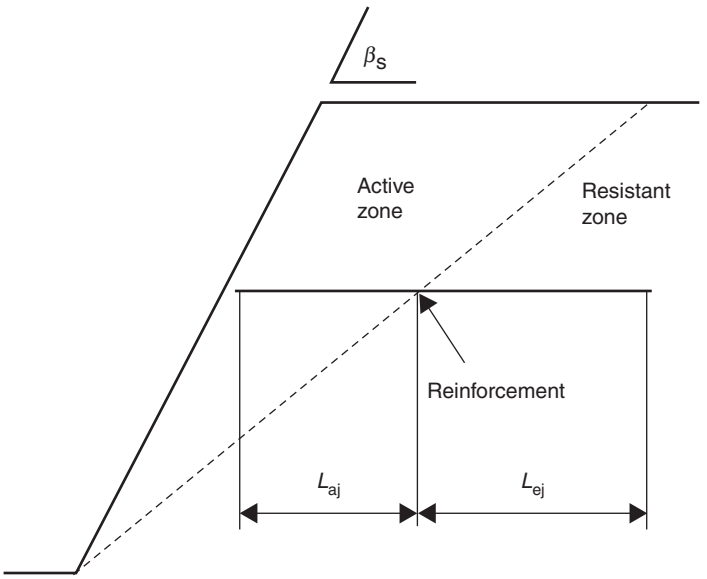

Figure 73.6 Internal stability of reinforced soil wall. L_{aj} = length of reinforcement within the active zone, L_{ej} = length of reinforcement within the resistant zone, β_s = slope angle

Reproduced with permission from BS 8006–1 © British Standards Institution 2010

zone (between the potential failure surface and the back of the wall) where the reinforcement sheds shear stress into the fill (**Figure 73.6**).

L_{aj} = length of reinforcement within the active zone.

L_{ej} = length of reinforcement within the resistant zone

β_s = slope angle

For the internal stability, the following ULSs and SLSs are considered:

- Local stability of a layer of reinforcement – ULS:
  - rupture of the reinforcement (or/and connection);
  - breakdown of the interaction between the fill and the reinforcement (pull-out or/and direct sliding);
- instability of a wedge of any size or shape assumed to behave as a rigid body – ULS;
- deformations – SLS.

Extensible reinforcements in which the design load is sustained at an axial tensile strain greater than 1% (polymeric reinforcement) are designed using the tie-back wedge method which is based on a theoretical approach.

Inextensible reinforcements in which the design load is sustained at an axial tensile strain less than 1% (metallic reinforcement) are designed using the coherent gravity method. This method is mainly empirical and is based on observations on instrumented reinforced soil structures.

Both methods follow broadly similar steps which are summarised below.

Tensile force in reinforcement

Both the tie-back wedge and the coherent gravity methods calculate the maximum factored tensile force in the *j*th layer of reinforcement T_j which is given as:

$$T_j = Tp_j + Ts_j + Tf_j \tag{73.2}$$

where:

Tp_j tensile force at *j*th layer of reinforcement generated by self-weight of fill, surcharge and retained backfill;

Ts_j tensile force at *j*th layer of reinforcement generated by vertical load applied to a strip;

Tf_j tensile force at *j*th layer of reinforcement generated by horizontal load applied to a strip.

The component due to the fill self-weight, surcharge and retained backfill is given as:

$$Tp_j = K\,\sigma v_j\,Sv_j \tag{73.3}$$

where:

K earth pressure coefficient. For extensible reinforcement (tie-back wedge method) active earth pressure coefficient K_a shall be used throughout the structure. For inextensible reinforcement (coherent gravity method) values varying between at rest earth K_0 at the top of the structure and active K_a lower down the structure shall be used.

σv_j vertical stress acting on the *j*th layer of reinforcement assuming the Meyerhof distribution. The derivation of σv_j varies slightly between the tie-back wedge and the coherent gravity method (refer to BS 8006 for details).

Sv_j Vertical spacing of the reinforcement at the *j*th level in the wall.

The component due to any vertical load applied to a strip is given as:

$$Ts_j = K\,\Delta\sigma v_j\,Sv_j \tag{73.4}$$

where $\Delta\sigma v_j$ is the increase in vertical stress generated by strip vertical loading at the level of the *j*th layer of reinforcement. The tie-back wedge method assumes a simple 2V:1H dispersion of the strip load through the reinforced fill. The coherent gravity considers the dispersal based on the Boussinesq equation for strips with an edge on the front face of the wall, and applies the principle of superposition to represent strip at a distance from the front face of the wall. The mathematics involved in the original coherent gravity method can be cumbersome and the 2010 revision of BS 8006 allows the use of the simple 2V:1H load dispersal assumption in conjunction with the coherent gravity method.

The component due to any horizontal load (F_L) applied to a strip is given as:

$$Tf_j = \alpha_j\,F_L\,Sv_j \tag{73.5}$$

where $\alpha_j\,F_L$ is the horizontal stress generated by strip horizontal loading at the level of the *j*th layer of reinforcement. The

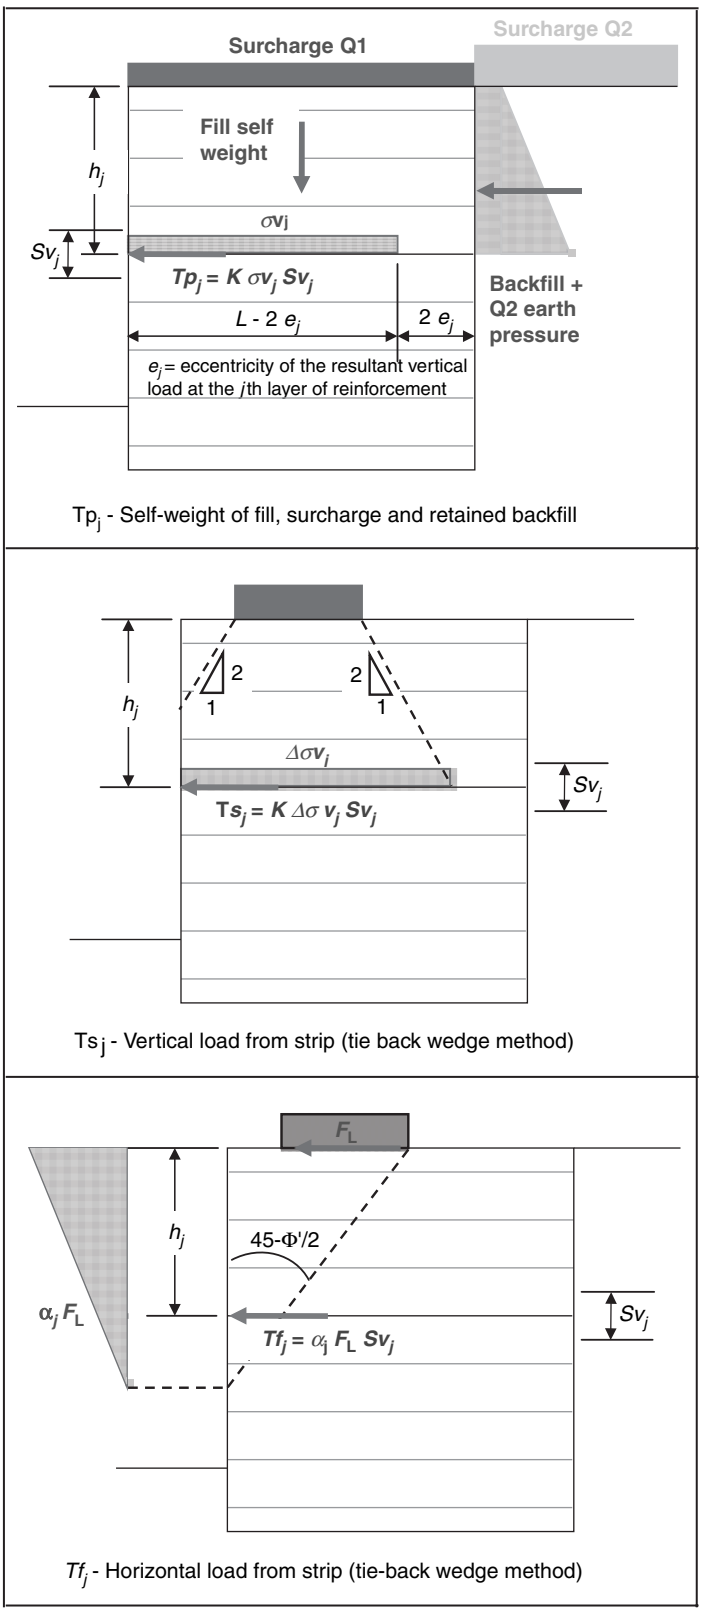

Figure 73.7 Tensile force in the *j*th layer of reinforcement

tie-back wedge method assumes a dispersion of the strip load at 45° + $\varphi'/2$ from the back of the strip through the reinforced fill. The coherent gravity assumes a dispersion of the strip load at 45° from the back of the strip through the reinforced fill.

The various components of the tensile force in the *j*th layer of reinforcement (for the tie-back wedge method) are illustrated in **Figure 73.7**.

Local stability checks

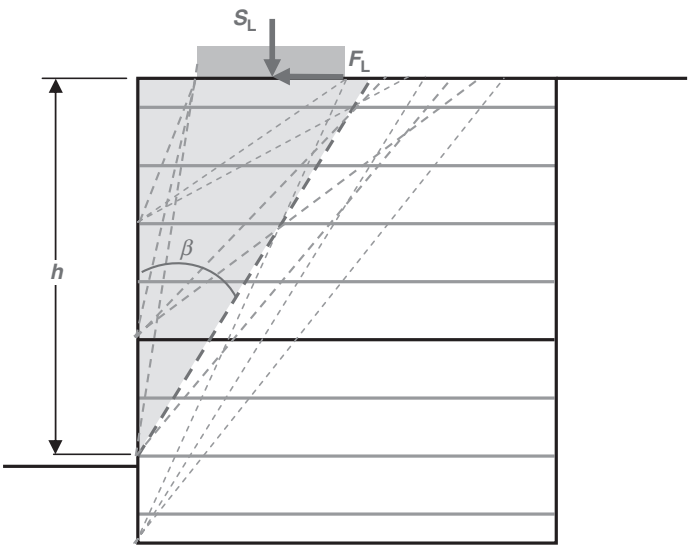
For each layer of reinforcement, check that the design tensile strength of the reinforcement is greater than the factored tensile force to prevent *rupture* of the reinforcement. Also, for each layer of reinforcement, check that the design adherence capacity of the reinforcement behind the failure wedge being considered is greater than the factored tensile force to prevent *pull-out* of the reinforcement.

For extensible polymeric reinforcement subject to creep the serviceability criterion is generally more critical than the ULS local stability check (see 'Serviceability' on page 1102 below).

Surface failure/lines of maximum tension

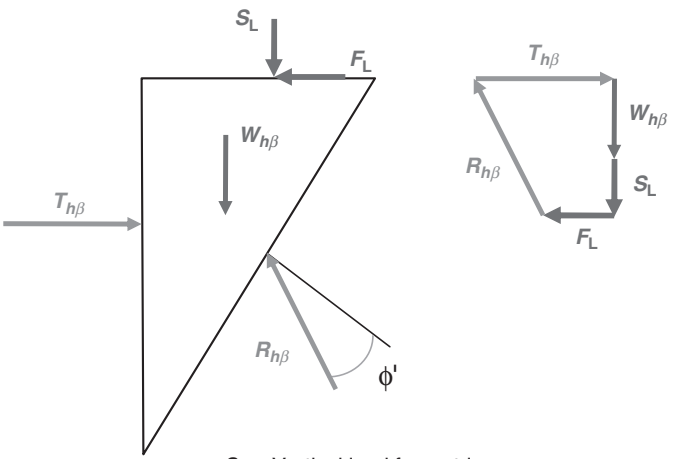
In the tie-back wedge method, the failure plane with the most tensile force needs to be determined by considering the stability of wedges, of any size or shape, assumed to behave as rigid bodies. The friction along the potential failure plane and the tensile resistance of reinforcement beyond the failure plane (rupture capacity or pull-out capacity, whichever is the smallest) must be greater than the disturbing applied loads.

In the coherent gravity method, results of monitoring installed along reinforcements have shown that the tensile force varies along the reinforcement. Lines of maximum tension are defined (the shape of the line considered depends on whether strip loadings are applied or not) and the tensile force in the reinforcement is calculated on these defined failure surfaces. Provided the local stability checks (rupture and pull-out) are satisfied on these defined failure surfaces, there is no requirement to carry any further wedge stability analysis (unless the geometry or loadings are unusual).



The failure plane in the tie-back wedge method and the lines of maximum tension in the coherent gravity method are illustrated in **Figure 73.8**.

Connections



The tensile force in the connection between the facing and the reinforcement depends on their properties. Unless the facing is stiff (e.g. full height panel with no movement capacity at connections), the tensile force in the connection will be less than the maximum tensile force calculated. However, the tensile force at connection is significant and the connection has to be designed to prevent rupture under this load throughout the design life. When metallic reinforcements are used, the connection generally involves a bolting arrangement that leads to the tensile capacity at the connection being less than that of the full bar – and this detail is particularly vulnerable to corrosion.

Facings

Finally, the facings are designed structurally to resist the connection tensile loads, any externally applied loads (e.g. impact loadings from traffic) and the effect of any construction tolerance. In the case of segmental block facings, sliding and movements between blocks and overtopping of the blocks above the uppermost layer of reinforcement must be checked.

Serviceability

Deformations post-construction can happen as the result of creep of polymeric reinforcement, where the tensile stiffness decreases with time from an initial short-term value. In order to limit movements due to creep, the capacity of the reinforcement should be considered in conjunction with a limiting post-construction value of strain (typically 0.5% for abutments and 1% for walls) at the end of the design life, using isochronous load strain curves. For metallic reinforcement, creep is negligible.

73.5.5 Construction

Factors affecting the construction of reinforced soil walls and abutments include:

- nature and properties of the soil at the base of the reinforced soil block;
- site controls and placement and compaction requirements for the specified fill;
- safe storage and handling of the reinforcement;
- facings;
- simplicity and robustness of the connection detail;
- requirements for drainage;
- site constraints;
- end use;
- erection rate.

Buildability is discussed in more detail in BS 8006 and in Chapter 86 *Soil reinforcement construction*. Recommended construction tolerances are also presented in BS 8006.

73.6 Reinforced soil slopes

73.6.1 General

Reinforced soil slopes are composite structures consisting of fill, reinforcement and facing. The front face is usually grassed up to provide a green slope finish. A distinction is made between 'shallow slopes' defined as no steeper than 45° from the horizontal, and 'steep slopes' defined as being between 45° and 70° from the horizontal.

73.6.2 Materials

73.6.2.1 Fill

Generally, frictional fill will be used as fill for reinforced soil slopes, but the range of fill that can be used is wider than for reinforced soil walls and abutments. As discussed in section 73.5.2.1 for reinforced soil walls and abutments, the selection and specification of fill for reinforced soil structure should be considered as early as possible in the project. Aspects such as sustainability, availability, impacts on design and costs should be borne in mind. Site-won material is often used as an economic and sustainable fill for reinforced soil slopes. Properties of particular significance are the drained shear strength parameters (φ' and occasionally c', although effective cohesion should be used with great care) which will govern the soil reinforcement pull-out capacity, and the maximum particle size which will govern the risk of mechanical damage during construction – and hence the reinforcement rupture capacity.

73.6.2.2 Reinforcement

For reinforced soil slopes, geogrids are predominantly used. The reinforcement properties and the principles of their interaction with the fill are discussed in sections 73.2 and 73.3 above.

73.6.2.3 Facing

For shallow slopes (no steeper than 45° from the horizontal) it is generally possible to place the fill without permanent or temporary supports. Intermediate short secondary geogrids are often placed between layers of main reinforcements to prevent small shallow seated failures in the front face. Some form of erosion mat is often provided to ensure that the topsoil placed does not erode in the short term, and to facilitate the establishment of vegetation. Health and safety issues associated with cutting grass on relatively steep slopes should be considered.

For steep slopes (steeper than 45° from the horizontal) the facing is generally built using either wrap-around or steel mesh. In a wrap-around detail, the reinforcing geogrid or geotextile is folded through 180° to form the face and is anchored back into the fill or connected to the next layer (up) of reinforcement. Temporary formwork is often required to allow placement and compaction of the fill. In a steel mesh facing arrangement, the reinforcing geogrid or geotextile can be connected directly to the steel mesh, or continued behind the face of the steel mesh and returned into the fill to allow for the future deterioration of the sacrificial steel facing. In both cases, topsoil is placed just behind the facing to facilitate the establishment of vegetation. In addition to health and safety issues associated with cutting grass on such steep slopes, the difficulties of establishing, irrigating and maintaining vegetation on them requires careful consideration.

Typical reinforced soil slope configurations are presented in **Figure 73.9**.

73.6.3 Elements of design

Similar to the design of reinforced soil walls and abutments, the design of reinforced soil slopes considers both external and internal stability. In current UK practice, the stability of reinforced soil slopes is often designed by suppliers who, unless they are provided with adequate information, tend to

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

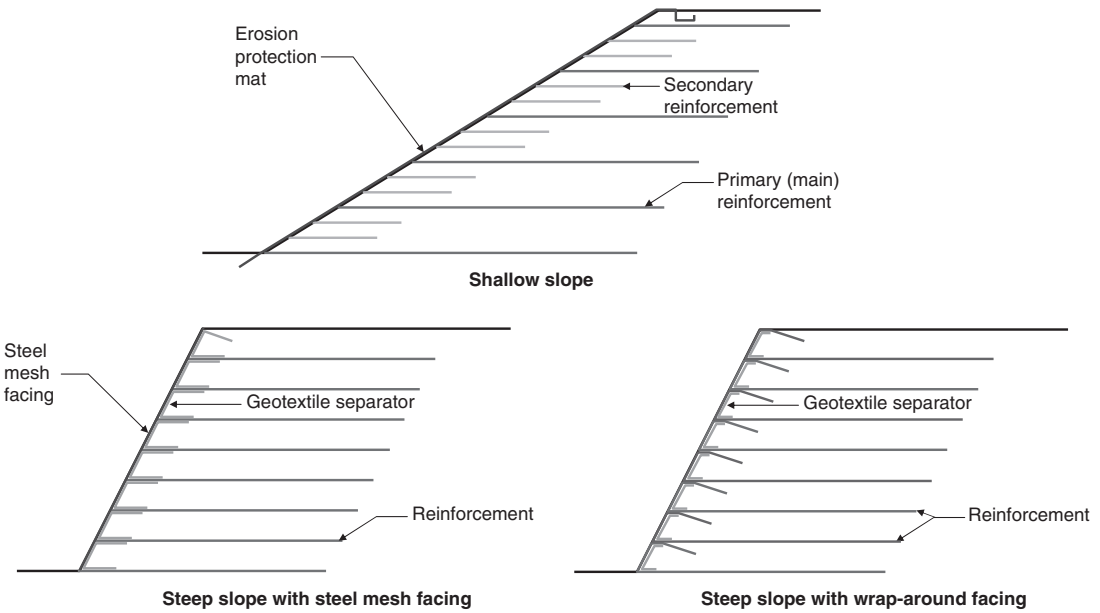

Figure 73.9 Typical reinforced soil slope configurations

concentrate on internal stability and the principles enounced in section 73.5.4.1 apply. In addition, compound stability, where the potential failure surface is partly within the reinforced soil zone and partly behind it, should also be considered.

73.6.3.1 External stability

For external stability the following ULSs and SLSs are considered:

- bearing and tilt failure – ULS;
- sliding – ULS;
- slip failure – ULS;
- settlement – SLS.

73.6.3.2 Internal stability

Similar to reinforced soil walls and abutments, a potential failure surface delimits an active zone and a restraint zone. For the internal stability, the following ULSs and SLSs are considered:

- local stability of a layer of reinforcement – ULS;
  - rupture of the reinforcement (or/and connection);
  - breakdown of the interaction between the fill and the reinforcement (pull-out or/and direct sliding);
- deformations – SLS.

Internal stability assessment is generally undertaken using one of many limit equilibrium methods available. The most commonly used are the two-part wedge mechanism and the method of slices, which are discussed below. Other methods, such as a non-circular analysis, a log spiral or a coherent gravity method, could be used.

Two-part wedge mechanism

The two-part wedge mechanism is an extension of the Coulomb wedge approach as illustrated in **Figure 73.10**. The mechanism may take any form (i.e. θ_1, θ_2 and X can vary) provided the mechanism outcrops at the toe of the slope and the inter-wedge boundary is vertical. By resolving the forces acting on the wedges (which requires assumptions on the inter-wedge boundary conditions), the out-of-balance force that needs to be taken by the reinforcement can be assessed for each mechanism. For each slope there is a unique critical two-part wedge mechanism for which the out-of-balance force that needs to be taken by the reinforcement is maximum. For more details on the two-part wedge mechanism, refer to HA68/94 (Highways Agency, 1994).

Considering the simple case of a slope with flat ground at the top and no surcharge, the maximum factored total force to be taken by the reinforcement T_{max} can be expressed as:

$$T_{max} = 0.5\, K\, \gamma\, H^2 \tag{73.6}$$

where:

K non-dimensional parameter equivalent (but not equal) to an earth pressure coefficient;

γ fill unit weight (kN m^{-3});

H fill height (m).

The factored tensile force in the jth layer of reinforcement T_j is given as:

$$Tj = K\, \gamma\, z_j\, Sv_j \tag{73.7}$$

where:

z_j depth below crest level to jth layer of reinforcement;

Sv_j vertical spacing at jth layer of reinforcement.

For each layer of reinforcement, a local stability check should be undertaken. The design tensile strength of the reinforcement should be greater than the factored tensile force to prevent *rupture* of the reinforcement. The design adherence capacity of the length of reinforcement (L_{ej}) behind the wedge considered should be greater than the factored tensile force to prevent *pull-out* of the reinforcement.

For each layer of reinforcement, the smallest of the design tensile strength and the design adherence capacity can be referred to as the design capacity of the *j*th layer of reinforcement: *Tdesj*. For the local stability check, it should be confirmed that for each layer of reinforcement:

$$Tdes_j \geq T_j \tag{73.8}$$

The overall reinforcement provided should be sufficient to prevent rupture of the two-part wedge mechanism, and it should be checked that:

$$\sum_{j=1}^{n} Tdes_j \geq T_{max} \tag{73.9}$$

Slice method for circular slip mechanism

The method of slices is traditionally used for unreinforced soil slopes and is adapted to take into account the effects of introducing the reinforcement layers. The additional restoring forces and moments provided by the reinforcing elements beyond the slip failure are considered in the calculations of the slope stability factor of safety. BS 8006 only considers moment equilibrium and suggests that inter-slice forces are ignored in the calculations. However, most current slope stability software allows for analyses using both force and moment equilibrium, and will consider some form of inter-slice interaction.

For each layer of reinforcement, a local stability check (**Figure 73.11**) should be undertaken and it should be verified that the design capacity of the reinforcing layer (either the pull-out resistance or the rupture strength of the reinforcement) is greater than the tensile load generated in the layer.

The overall reinforcement provided shall be sufficient to prevent slope failure and it shall be verified that:

$$F_{RS} + \sum_{j=1}^{n} Tdes_j \geq F_D \quad \text{(force equilibrium)} \tag{73.10}$$

$$M_{RS} + \sum_{j=1}^{n} \left(Tdes_j \times Y_j\right) \geq M_D \quad \text{(moment equilibrium)} \tag{73.11}$$

where

Y_j vertical distance from centre of rotation of slip to the reinforcement layer under consideration;

F_{RS} (M_{RS}) restoring force (moment) due to shear strength of soil;

F_D (M_D) disturbing force (moment) due to the weight of soil and surcharge.

73.6.3.3 Compound stability

Compound stability considers failure mechanisms where the potential failure surface is partly within the reinforced soil zone and partly behind it. The principles for analysing compound stability are similar to those for analysing internal stability.

73.7 Basal reinforcement

73.7.1 General

Reinforcement can be introduced at the base of embankments over poor ground to avoid ULS failure through shear in the foundation of the embankment and/or SLS failure through excessive deformations. It should be noted that BS 8006 still limits the applications of basal reinforcement to foundations for earthworks. The common applications are:

- Basal reinforcement over soft to very soft foundation soil to control initial ULS stability of the embankment without controlling the settlement.

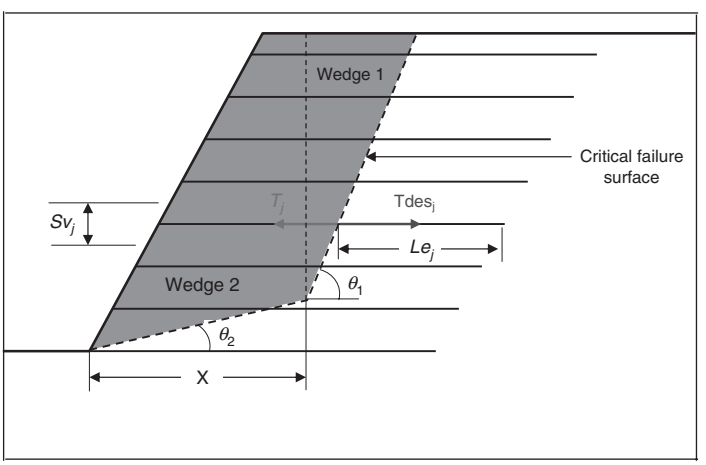

Figure 73.10 Two-part wedge mechanism

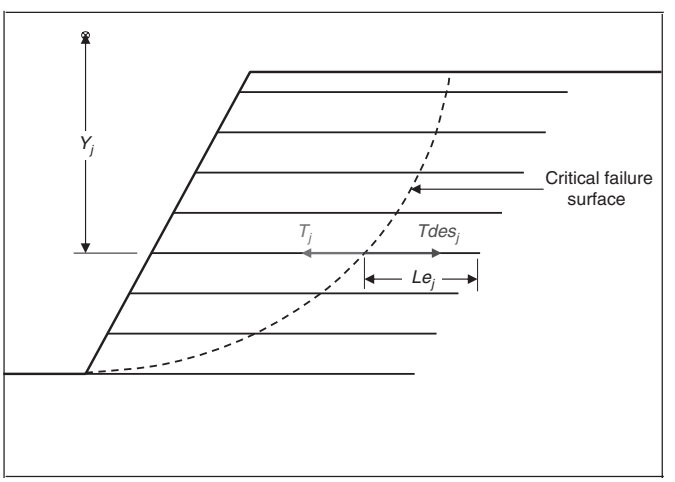

Figure 73.11 Circular slip failure mechanism

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- Basal reinforcement combined with another form of ground improvement technique over soft to very soft foundation soils (typically piled embankment with basal reinforcement acting as a load transfer platform) to control both the initial ULS stability and long-term SLS settlements of the embankment.
- Basal reinforcement over foundation soils prone to subsidence (e.g. mining) where the reinforcement is designed to span the void (ULS stability) and limit the deformations at the top of the embankment.

This chapter will focus solely on the first application of a simple basal reinforcement over soft to very soft foundation soil. For details of the other applications, refer to BS 8006.

The products used in basal reinforcement applications generally consist of geotextiles or geogrids, but products such as steel meshes are sometimes considered.

73.7.2 Basal reinforcement for an embankment on soft to very soft ground

When constructing an embankment on soft soil, shear failures are likely to develop through the foundation soil. The problem is always more acute in the short term (during construction) since soft soils will consolidate and strengthen over time due to the dissipation of the excess pore water pressures generated in the soil by the construction of the embankment. Once consolidation is complete, the basal reinforcement is often redundant. Basal reinforcement is often used in conjunction with other construction techniques (e.g. staged construction discussed in Chapter 70 *Design of new earthworks*) to limit the capacity required from the reinforcement. Strain compatibility between the reinforcement and the soft foundation soil should be satisfied in order to achieve a maximum bond coefficient. This is particularly the case when dealing with sensitive foundation soils that exhibit rapid strength loss post-peak, hence the strain in the reinforcement (SLS case) should not exceed the strain at which the peak shear strength is mobilised in the foundation soil (see section 73.3.2).

The ULS limit equilibrium mechanisms to consider are:

- deep-seated failure;
- lateral sliding;
- extrusion.

73.7.2.1 Deep-seated failure

The analysis of deep-seated failure is generally performed using the method of slices for a circular failure mechanism described in section 73.6.3 above. The reinforcement provided should have a sufficient design capacity *Tdes* (against rupture and pull-out beyond the failure mechanism) to provide moments and forces equilibrium. In the case of basal reinforcement, it is also necessary to ensure that the length of reinforcement within the failure surface mechanism is sufficient to prevent pull-out (**Figure 73.12**).

73.7.2.2 Lateral sliding

The reinforcement provided shall have a sufficient design capacity *Tdes* (against rupture and pull-out beyond the failure mechanism) to resist the outward thrust (active earth pressures)

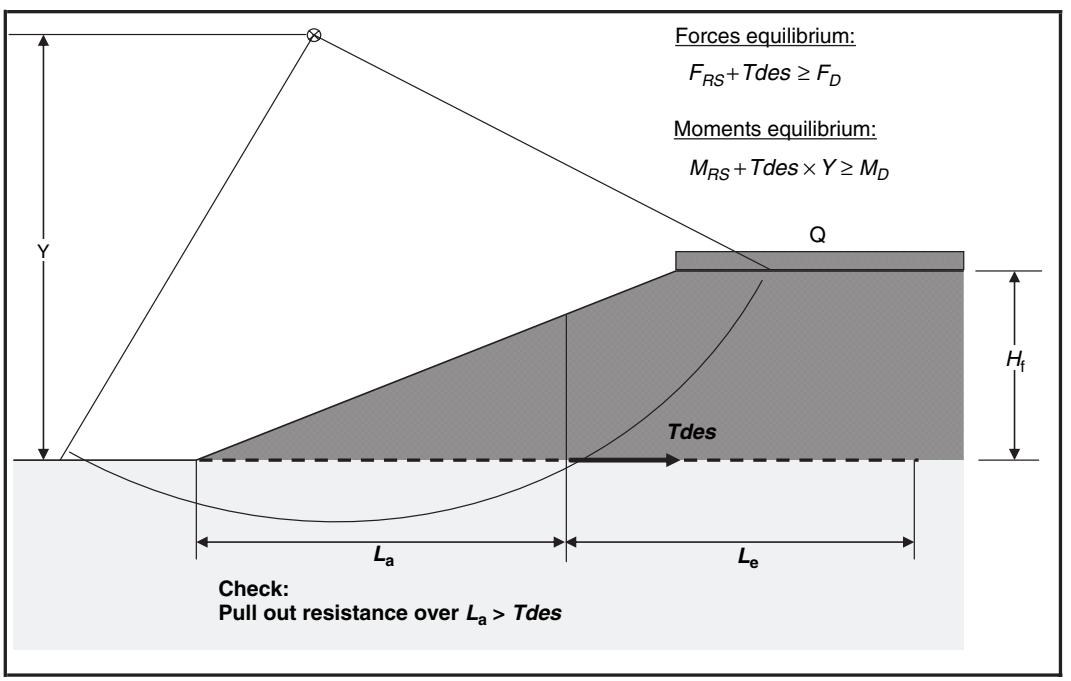

Figure 73.12 Basal reinforcement – deep-seated failure. Q = surcharge loading, H_f = height of embankment, L_a = length of reinforcement within active zone, L_e = length of reinforcement within resistant zone

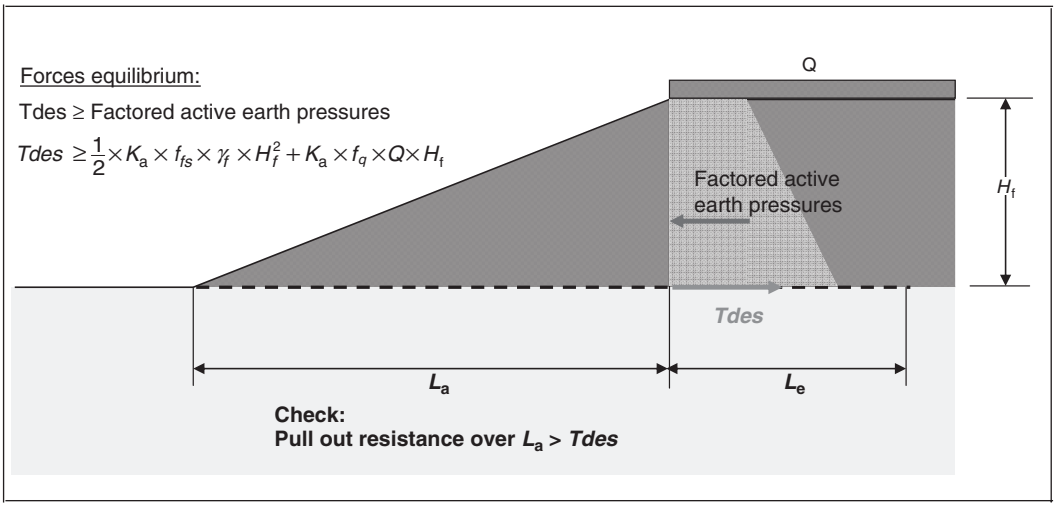

Figure 73.13 Basal reinforcement – lateral sliding. K_a = active earth pressure coefficient, γ_f = fill unit weight

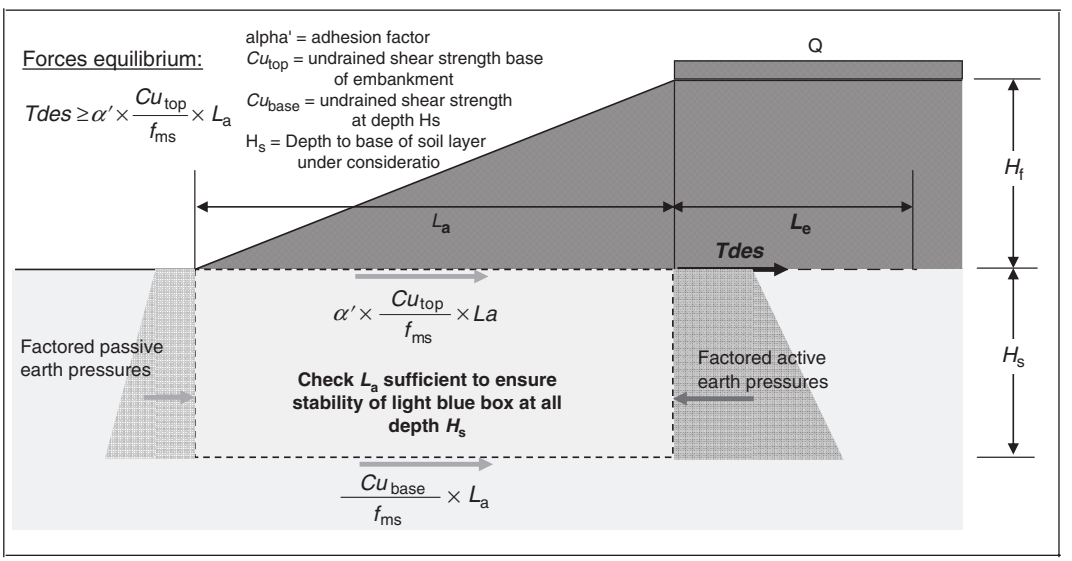

Figure 73.14 Basal reinforcement – extrusion. α' = adhesion factor, C_u top = undrained shear strength base of embankment, C_u base = undrained shear strength at depth H_s, H_s = depth to base of soil layer under consideration

from the embankment fill and any surcharge which is at a maximum at the top edge of the embankment slope. Again, it is also necessary to ensure that the length of reinforcement within the failure surface mechanism is sufficient to prevent pull-out (**Figure 73.13**).

73.7.2.3 Extrusion

Extrusion assumes the outward lateral displacement of a rectangular block of soft soil under the embankment fill. The reinforcement provided shall have a sufficient design capacity Tdes (against rupture and pull-out beyond the failure mechanism) to resist the tensile load generated by the outward foundation shear. In addition, it is also necessary to ensure that at any depth Hs within the reinforced soil, the rectangular block of soil is in equilibrium. The restoring forces are the adhesion along the base of the soil block, the adhesion between the reinforcement and the soil at the top of the block and the passive earth pressures on the outward side of the block (**Figure 73.14**).

Soil nails may be used to stabilise cuttings and embankments. The design of soil nails has to take account of the ground conditions and groundwater regime to allow the determination of the global and local stability of the strengthened slope. Various slope facings may be adopted for soil nailed slopes, ranging from a green finish to shotcrete

74.1 Introduction

Soil nailing is a method of ground reinforcement comprising the installation of steel or polymer bars sub-horizontally into a slope or wall. The nail head comprises a load plate, which is tightened against the slope facing. Soil nails are generally used to:

- stabilise new cuttings that are steeper than the soil properties allow;
- remediate existing embankments or cuttings that have failed or are under distress;
- strengthen retaining walls that have suffered excessive displacement;
- increase the stability of retaining walls or other structures that are to be subjected to greater loads than envisaged in the original design.

74.2 History and development of soil nailing techniques

Soil nailing was developed from similar techniques including rock bolting, multi-anchorage systems and reinforced soil. The first soil nailed wall was constructed in France in 1972. Research programmes on soil nailing were initially carried out in Germany and then in France through the Clouterre Project (Clouterre, 1991). The Clouterre Project, which published the Clouterre Recommendations (Clouterre, 1991), reported on large-scale experiments and their findings have been adopted in the design of soil nailing in numerous countries. The observations of the first full-scale experiment are shown in **Figure 74.1**. In this experiment, a low factor of safety was adopted, together with a method of saturating the soil behind the wall, so that the wall failed. Total failure of the structure did not occur due to the presence of the embedded shotcrete wall facing.

The third experimental test was carried out to demonstrate the effect of having nails that were too short. The results of this showed that failure of the wall was due to lack of adherence (see **Figure 74.2**).

In the UK, university research and research by the Transport Research Laboratory has led to increasing confidence in soil nailing as a technique and acceptance of soil nailing for major government infrastructure projects.

74.3 Suitability of ground conditions for soil nailing

A wide range of ground conditions are suitable for soil nailing including most clays (with the exception of soft clays), sands and mixed materials. However, appropriate face treatment will be required, for example to reduce the potential for surface failure due to surface run-off causing wash-out of unconsolidated materials. Problems can arise where there are elevated groundwater levels including perched water tables and spring lines. In these cases the design should pay close attention to the

incorporation of temporary and permanent drainage including slope drainage, toe drains and crest drains.

74.4 Types of soil nails

Soil nails are installed in cohesive or granular soils or in weak rocks using one of the following methods:

- Drilling of a sub-horizontal hole followed by the insertion of a steel or polymer bar and grouting of the hole using a tremie tube. Spacers are placed around the bars to ensure that the bar is centrally placed within the hole. This method is the most economic providing the ground conditions are suitable, e.g. within firm to stiff cohesive soils where there is no risk of collapse of the hole. However, care must be taken with this method when there is a delay between the drilling and grouting of a hole resulting in the undetected collapse and blockage of the hole leading to only partial grouting of the hole.
- Simultaneous drilling and grouting whereby a hollow high-yield steel bar is used as the drill rod with a sacrificial bit to form the hole by percussive drilling. During the drilling process the grout is passed down the annulus of the bar and the hole drilled to the required depth. Grouting continues until clean grout emerges at the surface. This method is very rapid and can be used in most types of soil. The grout supports the bore at all times, preventing collapse of the hole. The disadvantage of this method is that the spacers used around the bar cannot be too large otherwise the return of the grout to the surface during drilling may be restricted and, hence, the bar is unlikely to be absolutely central in the hole.
- Driving a soil nail into a slope using ballistic methods. This method is very rare and, therefore, is not discussed further.

74.5 Behaviour of soil nails

Soil nails are typically installed at 10° to 20° to the horizontal and are able to work in tension and shear. However, at the normal installation angles stated above, the shear component is negligible and usually neglected and, therefore, nails are normally designed to act in tension only. Hence, nails are designed to penetrate through the active zone of movement and sufficiently beyond any potential slip surface into the resistant soil zone. A suitable nail arrangement is adopted to form a stabilised reinforced block. Loads on soil nails can only be induced by movement of the slope or retaining wall, with the section of the nail furthest from the surface being the first to be stressed by the movement.

For steeper slopes a shotcrete facing incorporating one or two layers of mesh may be adopted.

74.6 Design

A geotechnical desk study would be carried out prior to any design to discover any existing ground data and also to inform the design of the ground investigation where insufficient information is available.

Following the ground investigation and any monitoring (of groundwater and movement) the geotechnical parameters are determined for each soil layer. Where a slope has failed or where monitoring by inclinometers, etc. has identified a failure surface, back analysis of the slope using a slope stability program may be used to estimate the soil parameters and groundwater condition that would produce an unfactored global factor of safety against instability of just less than 1.0, i.e. an unstable condition.

The design of soil nails is most frequently carried out using limit state design and a slope stability program, e.g. Slope/W (Geoslope International) or Talren (Terrasol) and by ensuring that the internal and external factors are checked. Alternatively, HA 68/94 (Highways Agency, 1994) can be used, which describes the two-part wedge method and may be appropriate under certain conditions. An example of a soil nail analysis is shown in **Figure 74.3**.

An initial soil nail array is chosen, i.e. the horizontal and vertical spacing and the length of the nails. For the initial array it is recommended that for slopes of 45° or less, an array of nails of 1.0 m vertical spacing and 1.5 m horizontal spacing is adopted. The length of the nails should be 1.0 to 1.5 times the height of the slope depending on the ground conditions. For slopes of more than 45° to 70° an initial array of nails of 0.5 m vertical spacing and 1.0 m horizontal spacing is recommended with similar nail lengths as above. It is recommended that the maximum depth of the top row of nails from the crest of the slope should not exceed 0.5 m to ensure that the potential for ravelling of the crest is reduced. Also the maximum height from the lowest row to the toe of the slope should also not exceed 0.5 m. A typical initial array for a nailed slope is shown in **Figure 74.4** and a typical nail head is shown in **Figure 74.5**.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The soil nail design is further refined by trial and error using the slope stability program with the geotechnical parameters and groundwater regime determined previously so that the most economic design is found. Initially it is recommended that the design is carried out to produce an overall factor of safety of 1.3. Once this initial design has been completed the analysis should be repeated using the specified partial factors on the soil parameters and external loads required by Eurocode 7 *Geotechnical Design* (British Standards Institution, 2004) or BS8006:1995 (British Standards Institution, 1995). Note that BS8006:1995 is being updated and the soil nailing part is to be issued as BS8006-2 *Code of Practice for Strengthened/Reinforced Soils and Other Fills. Part 2: Soil Nailing*. Further design advice can be found in *Soil Nailing – Best Practice Guidance, CIRIA Report C637* (CIRIA, 2005).

During the design process, due care should be taken of the site boundaries. If the soil nails pass beneath the site boundary into neighbouring properties, a wayleave will be required. However, it may be feasible to prevent the nails from passing beneath the ownership boundary by reducing the length of the upper nails, providing an adequate factor of safety is obtained, particularly in the upper section (see **Figure 74.6**).

Once the soil nail arrangement has been determined, the design of the load plate and surfacing is carried out. The load plates are used to apply a relatively low load to the slope surface and to hold the slope facing in place. The slope facing is required to stabilise the surface of the slope between the nails and to reduce the potential for any surface movement.

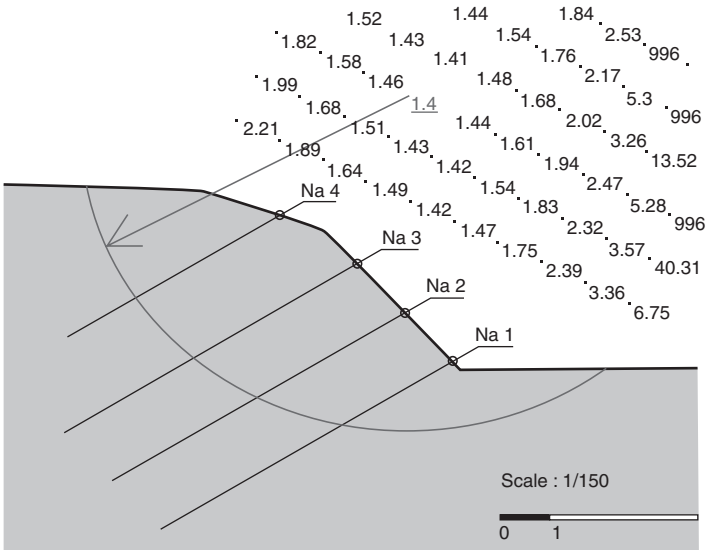

Figure 74.3 Typical soil nail analysis

74.6.1 Load plates

The design of the load plates should be such that bearing capacity failure of the slope surface does not occur during any future loading of the soil nails. There are a number of methods available to design the load plates, including that contained in Appendix E of HA 68/94 (Highways Agency, 1994). However, this method tends to overestimate the size of the plate as it does not take into account the slope facing itself. The section of the nail furthest from the slope surface tends to experience the highest load and the nail head itself may not experience the full load except in the unlikely event of approaching slope failure. The load transferred to the nail head generally increases as the slope angle increases, and the use of larger plates for shallower slopes, as in the Highways Agency guide, is likely to be conservative.

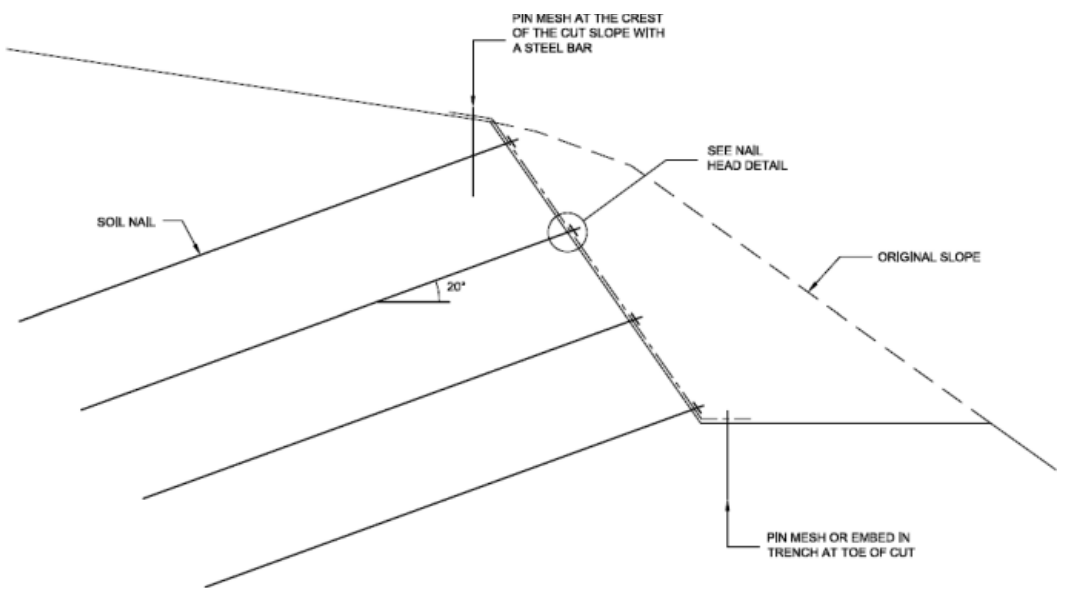

Figure 74.4 Typical soil nail array

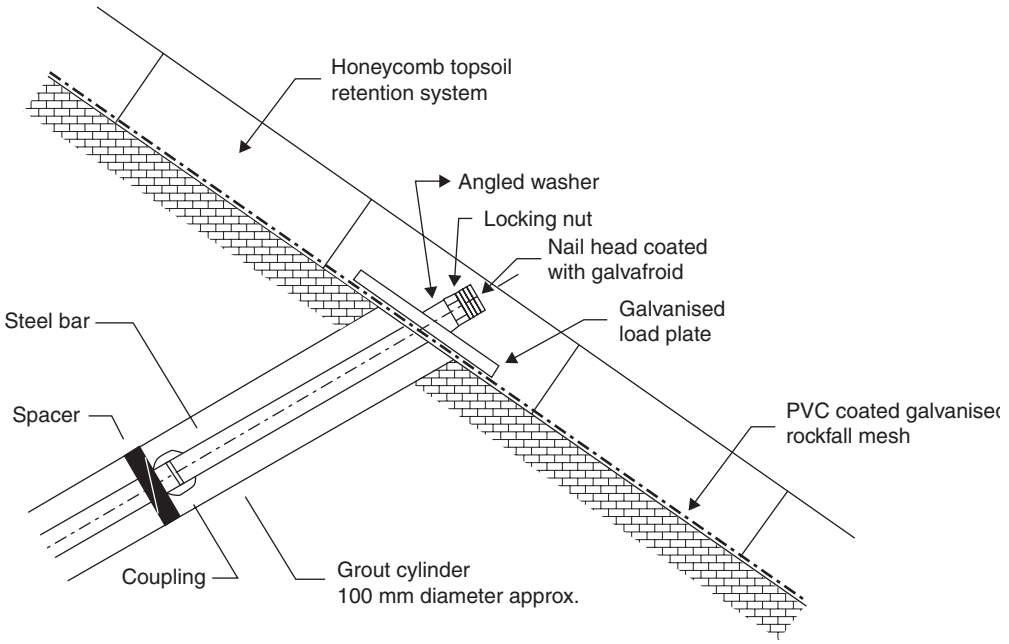

Figure 74.5 Typical soil nail head

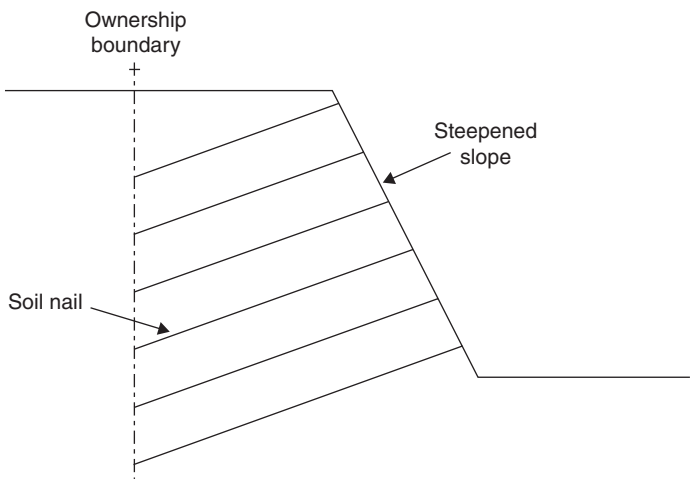

Figure 74.6 Design of soil nail array to prevent requirement for wayleave

Load plates may be mounted on the surface of the slope or cut into the slope. Generally plates of dimensions up to 300 × 300 mm are acceptable. The use of larger plates poses problems for installation due to the weight of the plates and there may be manual-handling issues.

74.6.2 Slope facing

There are no real guidelines for the design of slope facings; however, the following gives some practical advice.

For slope angles of ≤ 45°, a flexible form of surfacing can normally be adopted. This may comprise a rockfall mesh (normally PVC coated) or a geogrid, which is rolled down the slope over the nails. The nail load plates are then hand tightened against the mesh or geogrid. The slope may be covered in top soil for gradients up to 1:2 (vertical:horizontal) or hydroseeded for steeper slopes. However, where the slope is too steep and topsoil cannot be applied directly to the slope, and to prevent the potential hazard of the nail heads protruding from the slope, it is recommended that a cellular topsoil retention system is included in the design. This consists of a cellular geogrid, which is pinned to the slope. The cells are filled with seeded topsoil of sufficient depth to bury the nail heads.

For slope angles of more than 45 to 70°, a semi-rigid form of facing is generally acceptable. This type of facing may consist of two or more layers of rigid mesh or soil panels filled with topsoil or granular material, which are held on the slope by the nail heads; in the former the nail heads protrude from the slope and in the latter are concealed by the infill to the soil panels.

For slopes steeper than 70°, hard facings are generally adopted, which generally comprise sprayed concrete (shotcrete) incorporating one or two layers of mesh with the lowest layer of mesh held on the slope by the soil nail heads.

74.7 Construction

The construction of soil nailed slopes and walls are covered in Chapter 88 *Soil nailing construction*. However, generally these structures are constructed top down. Excavation is initially carried out over the top 1 m to 1.5 m to form a platform from which the nails can be installed. Alternatively the nails can be installed using long-reach plant from either the crest or toe of the slope. Once the first row of nails has been installed and the

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

grout has reached its required strength, excavation of the next 1 m depth of material is carried out and the second row of nails is installed. The process is then repeated until the whole excavation is complete. The required facing is then placed and the load plates tightened.

74.8 Drainage

Drainage is likely to be required behind any shotcrete facing and may include sub-horizontal drains inclined upwards (to prevent loss of material) using the same plant used to install the soil nails. These inclined drains would lead into a drainage system behind the shotcrete and eventually into a toe drain. Any drainage system concealed behind a hard facing must include a means of maintenance, e.g. access points where the inclined drains could be rodded.

For other forms of facing, drainage comprising gravel-filled trenches down the slope leading to toe drains may be utilised.

74.9 Corrosion of soil nails

The extent of corrosion protection required for soil nails depends on a number of factors including the specified design life, the aggressivity of the ground, the gradient of the nailed slope, the soil nail installation method and the thickness of the steel. The required design life for most soil nailed slopes is 60 years; however, where soil nails are incorporated into other structures, such as retaining walls etc., a design life of 120 years may be required. Guidance on the aggressivity of the ground is given in TRL Report 380 (Murray, 1993), which also recommends thicknesses for sacrificial steel that may be incorporated as a method of corrosion protection. This allows the diameter of the steel to be designed so as to give sufficient corrosion protection over the design life and also to provide sufficient structural strength.

For aggressive ground conditions, a further layer of protection may be provided, such as steel bars that are fully galvanised or epoxy coated by the manufacturer. Alternatively, a plastic duct may be placed within the upper part of the grout column around the steel bar, as the corrosion potential is likely to be greatest in the upper part of the installation, i.e. within the zone that is most likely to be subjected to seasonal variations in the groundwater level.

74.10 Testing soil nails

Soil nails are tested by sacrificial nail testing or production nail testing, as recommended by BS EN 14490:2010 (British Standards Institution, 2010).

Sacrificial nail testing is carried out in advance of the contract nails to prove the bond strength assumed in the design. Sacrificial testing involves a pull-out test in which the displacement of the nail head is measured over two load cycles. During sacrificial testing the nail may be taken to failure. Generally the top half of the nail is debonded to prevent any beneficial effect during testing. A minimum of three sacrificial tests on nails are normally carried out.

Production nail testing is dependent on the type of the soil nailed structure. For simple or conventional structures of Geotechnical Category 1 or 2 in accordance with Eurocode 7, BS EN 1997–1:2004 (British Standards Institution, 2010) and HD 22/08 *Managing Geotechnical Risk* (Highways Agency, 2008) it is recommended that 1.5% of the number of working nails is tested (or a minimum of three nails). For a more complex Category 3 structure, the guidance is that 2.5% of the number of working nails is tested (or a minimum of five nails).

74.11 Maintenance of soil nailed structures

Soil nailed structures generally require little maintenance. However, for more complex structures or where the consequences of failure of the structure would be catastrophic, it is recommended that sacrificial nails are installed adjacent to the structure, and these can be tested at intervals throughout the required design life. Where nail heads are visible, monitoring by precise surveying may be carried out. Other monitoring or observation that could be carried out includes visual inspection of the slope facing to check for any signs of bulging, inspection of any drainage installed that is a requirement of the design and observation of abnormal vegetation growth.

It is recommended this chapter is read in conjunction with

- Chapter 69 *Earthworks design principles*
- Chapter 72 *Slope stabilisation methods*
- Chapter 88 *Soil nailing construction*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 75

Earthworks material specification, compaction and control

Philip G. Dumelow Balfour Beatty, London, UK

This chapter describes how an effective earthworks specification can be produced for a project. It will define permitted material types, placement methods and appropriate means of control. The objective is earthworks which are safe during construction and use; durable and economically viable. Sustainable construction is a significant consideration.

doi: 10.1680/moge.57098.1115

75.1 The earthworks specification

75.1.1 Necessity and purpose

It is essential that a materials specification is produced for any earthworks contract, the core requirements being defined by the client. Whenever possible, all parties in the contract should be involved in preparing and developing the specification at the earliest stage. This will include the contractor and the designer, whether appointed by the client or the contractor.

The nature of certain contracts encourages such a collaborative approach:

- Design and Build (D&B)
- Design, Build, Fund and Operate (DBFO)
- Early Contractor Involvement (ECI).

Client, designer and contractor collaboration utilises the broadest possible experience and knowledge of materials, geotechnics and construction methods to guide how the specification is written. The purpose is to deliver a project built to best practice, economically and safely.

The completed specification will define:

- the client's core requirements for the works, e.g. levels, tolerances;
- methodologies for carrying out the works, e.g. excavating cuts, filling embankments and preparing formation;
- materials suitable for constructing the works, e.g. classes of material for specific purposes;
- material factors for physical, mechanical and chemical suitability, e.g. material parameters and limits for the required performance.

75.1.2 Current UK specifications

The earthworks specifications in widest use are produced by the Highways Agency (HA):

1. **Manual of Contract documents for Highway Works (MCHW)**
   - **Volume 1: Specification for Highway Works (SHW)**
   - **Series 600: Earthworks (Figure 75.1)**

Although this has been produced by the HA for their network of trunk roads and motorways, it is used by other clients. These include those in other infrastructures and disciplines. Use of the SHW is either in full or as the basis from which a specification is developed. Throughout this chapter, SHW and related HA publications will be used for reference; engineers working in other infrastructure disciplines must ascertain what specification is applicable to them.

The SHW has been developed from the Ministry of Transport 'Specification for Road and Bridge Works', in use from the 1960s to 1983, when it was replaced by the SHW. It is freely available, in all its parts, Series 000 to 3000 (generally incrementing by 100 for each series) plus appendices, as a download from the HA's web pages:

www.standardsforhighways.co.uk/

These web pages only hold the current documents.

The SHW refers to British Standards and the European Standards, BS EN, which replace them. These are not numbered the same as the superseded BS and the requirements are often very different. Prior to commencing any earthworks project and planning any of the works, an engineer must know which specifications and standards apply to the contract. These must be acquired and the requirements understood. Not to do so is inviting failure.

In addition, SHW references publications other than BS and BS EN; these are listed in Appendix F of SHW: 'Publications Referred to in the Specification'. It is the responsibility of the engineer to be in possession of the relevant publications.

Contract specific requirements are defined in the numbered appendices prepared by the specification's compilers.

Figure 75.2 Highways Agency NG 600 Series

Reproduced from Highways Agency, *Manual of Contract Documents for Highway Works*, Volume 2: *Notes for Guidance on the Specification for Highway Works*, Series NG 600. © Crown Copyright 2005

Accompanying and supporting the SHW are the HA publications:

2. **Manual of Contract documents for Highway Works (MCHW)**
   - **Volume 2: Notes for Guidance on the Specifications for Highway Works (NG)**
   - **Series 600: Earthworks (Figure 75.2)**

The clauses mirror those in SHW. The purpose of the NG is to assist in preparation of the contract; this includes commenting on the technical background underlying the SHW requirements and listing the appendices which must be produced for the contract (cf. 'Scope of the specification' below). Engineers commencing an earthworks contract must read the NG in conjunction with SHW for a full understanding of the specification.

3. **Design Manual for Roads and Bridges (DMRB)**
   - **Volume 4: Geotechnics and Drainage**
   - **Section 1: Earthworks**
   - **Part 1: HA 44/91 Design and Preparation of Contract Documents (Figure 75.3)**

This document gives guidance specifically directed to preparing the earthworks specification. This includes:

- cross-referencing the numbered appendices with the SHW Series 600 clauses;
- use of materials and construction methods;
- testing for acceptability.

Earthworks contracts in Scotland and Northern Ireland are subject to alternative clauses. These are included at the end of each series as 'National alterations of the overseeing organisation of Scotland/Northern Ireland'.

4. **Manual of Contract documents for Highway Works (MCHW)**
   - **Volume 1: Specification for Highway Works (SHW)**
   - **Series 100: Preliminaries**
   - **Series 500: Drainage and service ducts**

The engineer must be aware that other series within the SHW are related to earthworks activities, e.g. Series 500 specifies the requirements for drainage material.

The most significant of these is Series 100, clause 105. This requires the production of Appendix 1/5, which includes Table 1/5, defining the frequency at which all classes and types of material used in the works are to be sampled and tested. This includes all classes of earthworks materials.

75.1.3 Scope of the specification

The specification compilers will prepare the numbered appendices defining earthworks requirements for the contract. Sample appendices for an earthworks specification are listed in NG 600 Series (see **Table 75.1**). These inform the compiler what should be included in each appendix.

The specification compiler must also prepare an Appendix 1/5 and Table 1/5. Advice on test frequency is provided by Table 1/1 in SHW NG. Similarly to the overall specification, this compilation team should include client, designer and contractor to include the broadest knowledge and experience.

Some of the appendices are associated with tables with the same numbering. For site control of earthworks, the most important of these are:

- Table 6/1: Materials permitted in the works, acceptability limits, compaction method.
- Table 6/2: Grading limits for each material class.
- Table 6/4: Method compaction for earthworks materials: plant and methods.
- Table 1/5: Testing to be carried out by the contractor.

Extracts from a completed Table 6/1 are shown in **Figure 75.4(a)** and **4(b)**, and from Table 1/5 in **Figure 75.4(c)**.

The main material classes in Table 6/1 are shown in **Table 75.2**.

Each class may be sub-divided by a lettered suffix to describe differing material types (wet, dry, coarse, fine) or end use, especially for Class 6 materials. Class U1 material may be reverted to an acceptable class by treatment to modify its physical characteristics.

Class U2 is unacceptable due to chemical contamination. This class may also be sub-divided into material which can be treated to be acceptable and material which, either by the nature or concentration of contamination, must be removed from site to an appropriately licensed facility.

75.1.4 Key requirements for an effective specification

To produce the specification, the compilers must refer to and draw data and information from different sources. These will include:

- The client's core requirements:

  for an SHW type, this is SHW & NG 600 Series and DMRB, especially HA44/91.

- Ground investigations (GI) carried out for the project:

  both geotechnical assessment and acceptability classification of the material.

- Reports by other bodies:

  generally, these are by the Transport Research Laboratory (TRL) or the Building Research Establishment (BRE) for specific material types and conditions.

- Personal knowledge and experience:

  especially relevant if local materials merit specific consideration, including local knowledge of recycling and secondary materials sources.

The complete earthworks specification, whether using the format of SHW or any other, must deliver:

- clear, unambiguous statements on how the earthworks will be carried out;
- the means by which the works can be carried out safely;
- a durable end product to the client's satisfaction;
- characteristics and limits for the acceptability of materials, without overdesigning;
- methodologies for dealing effectively with specific materials and conditions;
- the most sustainable earthworks solution.

Correlation testing may be carried out on materials, relating fundamental properties with results from the site control tests.

App No.	Appendix title
6/1	Requirements for acceptability and testing, etc. of earthworks materials
6/2	Requirements for dealing with Class U1B and Class U2 unacceptable materials
6/3	Requirements for excavation, deposition, compaction (other than dynamic compaction)
6/4	Requirements for Class 3 material
6/5	Geotextiles used to separate earthworks materials
6/6	Fill to structures and fill above structural foundations
6/7	Sub-formation and capping and preparation and surface treatment of formation
6/8	Topsoiling
6/9	Earthwork environmental bunds, landscape areas, strengthened embankments
6/10	Ground anchorages, crib walling and gabions
6/11	Swallow holes and other naturally occurring cavities and disused mine workings
6/12	Instrumentation and monitoring
6/13	Ground improvement
6/14	Limiting values for pollution of controlled waters
6/15	Limiting values for harm to human health and the environment
1/5	Testing to be carried out by the contractor

Table 75.1 Numbered appendices required for an earthworks specification

Class	General material description	Typical use
1	Granular material	General fill
2	Cohesive material	General fill
3	Chalk	General fill
4	Various materials	Landscape fill
5	Topsoil	Topsoiling
6	Selected granular material	Specific uses, e.g. starter layer, backfill, capping
7	Selected cohesive materials	Specific uses, e.g. backfill, material for stabilisation
8	Class 1, 2 or 3 material	Lower trench fill
9	Lime or cement stabilised granular or cohesive material	Capping (synonymous with 'foundation' in pavement design)
U1	Any type of material	Materials physically unacceptable for the works
U2	Any type of material	Materials chemically unacceptable for the works

Table 75.2 The main material classes in Table 6/1 (Materials permitted in the works, acceptability limits, compaction method) of the Specification for Highway Works

From these derive the limits applicable to the test used for quality control of the project.

Sustainable earthworks must be a key consideration. This can be addressed by the specification compilers aiming to:

- minimise waste by balancing the cut with the embankment/landscape fill volumes;
- maximise the re-use of the excavated materials to minimise import;
- create opportunity for the optimum use of site-won material;
- utilise locally available recycled and secondary materials;
- improve poor quality materials by treatment (e.g. modification or geosynthetics);
- involve the contractor in additional GI and materials trials.

Additionally, specification compliers must ensure, when producing Table 6/1 and 1/5, that artificial constraints are not imposed. This can occur when:

- the contractor is not involved in specification compilation;
- the contractor is required to design part of the permanent works.

The specification must not unnecessarily restrict the materials allowed. The contractor may have experience of the successful use of alternatives which deliver the same performance. These may be more sustainable or economic or the methodology may have a programme benefit, yet their use is not permitted.

Amending the specification to permit materials not included in the specification takes time, resources and cost. Furthermore, there may be contractual implications. A 'Departure from Standards' may need to be formally requested through the design protocol. Engineers must be aware that adoption of a Departure may affect the ownership of risk associated with the material or method concerned.

75.1.5 Specifying test frequency

As referred to by item 8 in 'Control of earthworks' below, SHW NG advises on frequency of testing. For many materials – including most earthworks materials – the test frequency in NG Table 1/1 – Typical testing details – is only advisory. The reason for this is defined by the notes in the key at the foot of the table:

> Where materials are known to be marginal or if initial test results show them to be such, the frequency of testing should be increased. Conversely where material properties are consistently in excess of specified minimum requirements or well below specified maximum limits, then the frequency of testing should be reduced.

As discussed in 'Compliance testing of earthworks' below, it is essential that the specification compilers understand the:

- likelihood of the occurrence of non-conformance with specification;
- implications of non-conformance on the structural integrity of the works.

APPENDIX 1/5 TESTING TO BE CARRIED OUT BY THE CONTRACTOR

(c)

Clause	Work, Goods or Material		Test	Frequency of Testing	Test Certificate	Comments
Series 600						
601, 631 to 637 & 640	Acceptable material		For recycled aggregate, see sub-clauses 601.12 and 601.18. Cross-reference should be made to any requirements in Appendix 6/1			
	Class	General Description				
	1	General granular fill	Grading / uniformity coefficient	Twice a week	Required	
			MC (N)	2 per 1000m³ up to max of 5 per day per source		
			OMC (N)	Once per week per source		
		1C only	Los Angeles coefficient (N)	Weekly		
	2	General cohesive fill	Grading	Twice a week	Required	
			MC (N)	2 per 1000m³ up to max of 5 per day per source		
			PL/LL (N)	Weekly		
			MCV (N)	2 per 1000m³ up to max of 5 per day per source		
			Undrained shear strength – Hand Shear Vane	2 per 1000m³ up to max of of 5 per day per source		See Note 13 to Table 6/1
			Undrained shear strength of remoulded material (N)	2 per 5000m³ up to max of 2 per week per source		See Note 13 to Table 6/1
	2E	Reclaimed pulverised fuel ash cohesive material	MC (N)		Required	
			Bulk Density (N)	-		
	4	Fill to Landscape Areas	Grading	Daily	Required	
			MCV (N)	Daily		
	5	Topsoil	Grading	Daily	Required	

Figure 75.4 (Continued)

Two examples:

1. Primary aggregate Type I sub-base is supplied from a major quarry, subjected to a mature quality assurance system and CE marked.
2. 6N/6P backfill to a structure under a motorway is being supplied from multiple sources, processing to produce recycled aggregates.

In the first example, the likelihood of occasional non-conformance is low. In this situation, the deleterious effect on the works of, say, the product's grading analysis being 2% to 3% non-compliant on one of the coarser sieves is insignificant.

In the second example, it is not the author's intent to imply that the use of recycled aggregate is less suitable – quite the contrary, recycled and secondary aggregates should be used wherever possible for sustainable construction – but a specification compiler potentially in this situation must consider:

- multiple sources are being used;
- recycled material is produced from a variable feedstock;
- possible structural failure from frequent non-conformance;
- the nature and criticality of failure (e.g. slope instability, settlement).

Both compliant materials may be completely acceptable in performance terms and suitable for use at the locations. But, to manage risk effectively, it would be reasonable to expect material being used in example 2 to be sampled and tested more frequently than that in example 1.

75.2 Compaction

Compaction is the final action (other than trimming of the uppermost layer) in the sequence of earthworks events which commenced with excavation or import, followed by haulage to the point of deposition, tipping/discharge and spreading. Throughout these processes, the material has been disturbed and loosened, has high air voids and is mechanically unstable.

Compaction is achieved by the application of a force to the surface of the spread material. On major earthworks projects, this is usually in the form of a heavy roller, either towed or self-propelled and deadweight or vibratory. Where space is very restricted, or on small projects, point load plant may be used instead.

Compaction does not necessarily produce a 'dense' material; the term is subjective. The purpose of compaction is to produce a material which has, by packing the soil particles more closely together:

- air voids lower than a required maximum;

and/or

- dry density higher than a required minimum;
- predictable settlement and consolidation characteristics within prescribed limits;
- increased mechanical stability under load.

Further consequences may be, depending on the material type:

- increased impermeability;
- improved resistance to erosion;
- greater strength or stiffness.

75.2.1 The mechanics of compaction

75.2.1.1 Terminology

- moisture content: the mass of water in a soil as a percentage of the mass of dry soil;
- bulk density: the mass per unit volume of soil including water;
- dry density: the mass per unit volume of the soil excluding water, expressed by the equation:

$$\text{Dry density (Mg/m}^3) = \frac{[\text{Bulk density (Mg/m}^3) \times 100]}{[\text{Moisture content (\%)} + 100]} \quad (75.1)$$

Any earthworks material comprises solid particles, water and air voids. Compaction increases the packing of the solid particles and reduces air voids: water lubricates the soil particles and displaces air. From a dry condition, increasing water (or moisture) content increases the particle packing – measured as the dry density – and reduces air voids when a soil is compacted.

For any soil and applied compactive effort there is a condition when the water in the soil is just sufficient for the particle packing to be maximised and air voids minimised. This condition is the Maximum Dry Density (MDD). The water content at which MDD is achieved is Optimum Moisture Content (OMC).

At moisture contents below OMC, there is neither sufficient water to lubricate the particles for maximum density, nor to fill all the voids between the particles. Above OMC, water displaces the solid particles. As a result, dry density decreases and, with increasing moisture content, the material becomes increasingly unstable (e.g. deforming more under load).

The relationship between moisture content, dry density and air voids is demonstrated by drawing a compaction curve. This is from a series of tests measuring the dry density, at varying moisture contents, achieved by compacting each specimen in an identical manner, to the method defined in BS 1377 (see **Figure 75.5**).

MDD and OMC are a function of the compactive effort applied to any soil. Increasing the compactive effort raises MDD and lowers OMC. The compaction curve, whilst maintaining approximately the same shape, moves up and left. It does not approach the 0% air voids line more closely. A state in which air voids equal zero is not physically attainable with practical earthworks compaction methodologies.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

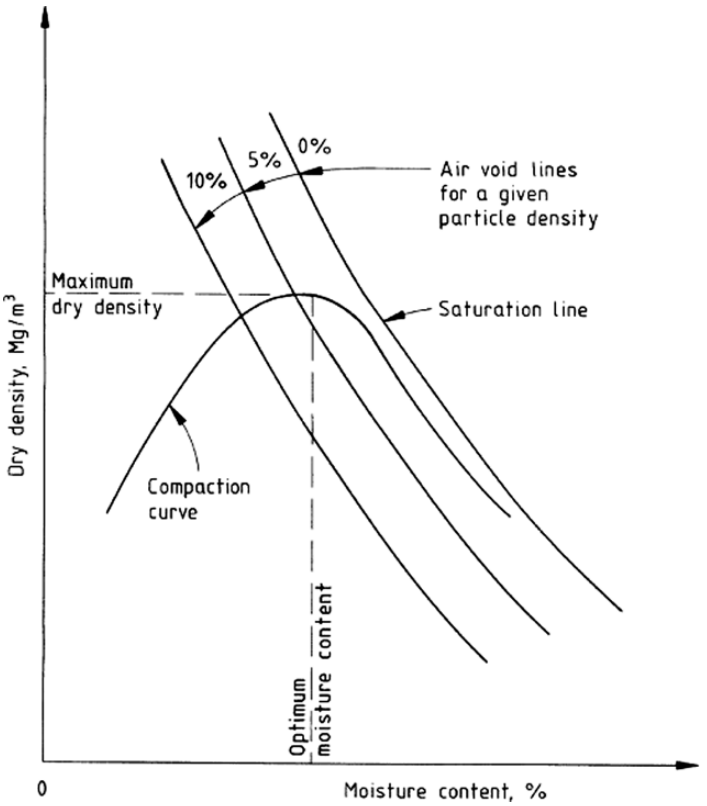

Figure 75.5 Dry density, moisture content and air voids relationship
Reproduced with permission from BS 1377–4. © British Standards Institution 1990

MDD, OMC and the shape of the curve are influenced by physical properties of the soil:

- particle shape;
- particle size;
- range of particle sizes.

Generally, angular or fine soils have a higher water demand than rounded or coarse soils. Well-graded materials, where particle size distribution is over a wide range of sizes, tend to have steeper curves than uniform materials, with particle sizes over a small range. It would appear from this that the permutations for OMC / MDD would be infinite; however, general ranges can be outlined for different material types:

Material	OMC range (%)
Clay	25–35
Silty, sandy clay	20–30
Pulverised fuel ash	15–25
Fine sand	10–20
Coarse sand	5–15
Sand and gravel	5–10
Crushed rock	5–10

The compaction curve is used by the specification compiler to set the moisture content acceptability limits for a soil type or class. The lower limit should ensure that air voids are less than the maximum acceptable for the design. The upper limit should be before increasing moisture causes any significant instability.

75.2.2 The compaction specification

The compaction specification must define the requirements for each class of material allowed in the project, as defined in Table 6/1.

75.2.2.1 Method compaction

For each type of compaction plant and the amount of compactive effort imparted (e.g. mass per metre width of roll), the requirements are defined for:

- the maximum thickness of the layer being compacted, when compaction is complete;
- the number of passes (roller) or applications (point load plant).

Table 6/4 lists the permitted permutations for each material class and Method number in Table 6/1 – see **Figure 75.6(a)** and **6(b)** for Methods 1 to 6 (Method 7 omitted). SHW permits plant and methods other than those in this table, if the effectiveness of the methodology is proven by site trials.

Method compaction is generally used for bulk earthworks operations. The methods specified in Table 6/4 assume a conservative approach and have been determined to deliver maximum air voids of between 5% and 10%, depending on the type of material and material class.

75.2.2.2 End Product compaction

The required level of compaction is specified. In earthworks this is usually a minimum *in situ* density, expressed as percentage of the MDD of that material. This percentage is 90% to 100%, depending on the material type and class. The MDD is obtained from the laboratory test defined in Table 6/1; either:

- BS 1377: Part 4 (2.5 kg rammer method) – usually used for cohesive materials; or
- BS 1377: Part 4 (vibrating hammer method) – usually used for granular materials; also imparts a greater compactive effort than the 2.5 kg rammer test.

The BS 1377: Part 4 (4.5 kg rammer method) test is not used by SHW Table 6/1.

The type of plant used, the thickness of the final compacted layer and the number of passes are not specified. Selection of these is the responsibility of the contractor carrying out the compaction operation, guided by the compaction plant manufacturer's recommendations.

Table 6/1 also defines the maximum and minimum moisture contents at which a material is acceptable to be placed in the works and compacted.

Table 6/4: method compaction for earthworks materials: plant and methods (method 1 to method 6) (this table is to be read in conjunction with sub-clause 612.10)

Dropping-weight compactor		Mass of rammer over 500 kg weight drop:													
	1	over 1 m up to 2 m	600	4	600	8	450	8	unsuitable		unsuitable		unsuitable	unsuitable	unsuitable
	2	over 2 m	600	2	600	8	unsuitable		unsuitable		unsuitable		unsuitable	unsuitable	unsuitable

Figure 75.6 (continued)

Recent changes to SHW have incorporated BS EN standards and greater emphasis on suppliers to provide conformity compliance control. Performance-based specifications allow a wider range of materials (e.g. recycled and secondary aggregates) to be more widely used.

75.3 Compaction plant

Many types and sizes of compaction plant are available. The Method Compaction options in Table 6/4 permit many of these for each material class, though experience has proved some to be more effective than others. For End Product compaction, not all of these are suitable for all materials, locations and conditions. Selection of plant for End Product compaction should be made with careful reference to the plant manufacturer's recommendations and, more importantly, an experienced earthworks manager.

The drum roller depicted in **Figure 75.7** is towed behind a tractor dozer, often the same plant used for spreading the tipped material. This plant can be obtained either as a deadweight roller or with a vibratory mechanism fitted.

This plant is normally deployed as the compaction plant where large volumes of Class 2 material (cohesive general fill) are to be placed and compacted to a Method Compaction specification.

As it is towed by a tracked machine, this plant can be used on a wide range of soft materials where a self-propelled roller might become bogged or cause rutting. A single drum roller, towed by a tractor, may have greater productivity than a self-propelled roller (see **Figure 75.8**), but is less manoeuvrable.

The self-propelled roller is effective in compacting most material types in many construction operations, including earthworks. The roller is normally fitted with a vibratory mechanism, which can be selected to work at various amplitudes and frequencies to suit the material. The manufacturer will provide data on the correct selection of these and an experienced earthworks manager should also be consulted.

Table 6/1 precludes the use of vibratory rollers on cohesive materials above a certain Liquid Limit. This plant may be operated as a deadweight roller to satisfy this requirement.

The driving wheels of this plant are pneumatic tyres with deep treads. These provide reasonable traction on soft cohesive materials. The self-propelled smooth drum roller is also available as a twin drum roller.

Available in deadweight or vibratory form, the tamping roller, commonly referred to as a sheepsfoot roller (**Figure 75.9**), is very effective at compacting high Plasticity Index clays. It can also be effective on sands and gravels, though usually those with a high silt and clay content. It is rarely used on granular fills, where a smooth drum vibratory roller is more effective.

A drawback of tamping rollers is the depressions left in the surface, which can trap water, leading to a softening of the material. If rain is expected, it is good practice to compact the surface with a smooth drum roller or, if this does not remove the depressions, blade off the surface and recompact with a smooth drum.

As with the drum roller, Table 6/1 precludes using this plant in vibratory mode on clays above a specific Liquid Limit to avoid damage to the structure of the clay.

The grid roller (**Figure 75.10**) is normally a towed item of plant. It can be obtained in a range of roll widths and masses. It is not usually available to operate as a vibratory action.

Grid rollers are particularly effective on coarse rockfill, e.g. starter layers to SHW Class 6B and 6C. They can be effective on sands and gravels, although other types of plant are more often used on this material.

Figure 75.7 Smooth single drum roller – towed

Figure 75.8 Smooth single drum roller – self-propelled
Courtesy of Balfour Beatty

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The roller depicted in **Figure 75.11** is also available as a heavier item of plant with wider drums. This is rarely used in major earthworks/bulk fill operations due to the lack of traction from two smooth drums.

The smaller unit pictured here is used where the area to be compacted precludes the use of larger plant. This will typically be used in small general fill activities, trench backfill and backfill to structures. The size of this plant restricts the permitted layer thickness, constraining productivity where large areas are to be compacted.

The self-propelled, pedestrian-controlled single and twin drum rollers depicted in **Figure 75.12** often have lifting hitches (visible in both **Figures 75.11** and **75.12**) for plant to be craned into otherwise inaccessible locations – e.g. for compacting backfill to structures, where they are widely used. However, the compactive effort of these items of plant is limited: care has to be taken to ensure that the limit for layer thickness is not exceeded. This plant is available as remote controlled, for compacting material in a trench without operator access.

Along with the vibro-tamper (not pictured), the vibrating plate and power rammer depicted in **Figure 75.13(a) and (b)** are the lightest items of compaction plant in use in UK construction. Use of these is generally confined to narrow, shallow, trench backfill.

Neither is recommended for compacting material to an End Product compaction specification.

Although a permitted option in Table 6/4, the pneumatic tyred roller (PTR) (**Figure 75.14**) is rarely encountered in UK earthworks. It is frequently used to compact cement or bituminous bound pavement layers, where the kneading action of the tyres is effective in compacting stiff materials.

75.4 Control of earthworks

Without a strategy to control an earthworks operation in place prior to the works commencing, non-conformances with the specification are inevitable. These may take the form of:

- unacceptable material placed in the works;
- the wrong class of material placed in the works;
- inadequate compaction.

Any of these occurring can result in some form of physical failure in the works. This might result in:

- physical injury to workforce or the public;
- prosecution;
- poor perception by the public of the works;
- deterioration in client–contractor relationship;
- damage to both client and contractor reputations;
- increased cost and delays.

Figure 75.14 Pneumatic tyred roller (PTR)
Courtesy of Balfour Beatty

Protocols and processes must be established. For the quality control of the earthworks, these must identify:

1. The client's Specific/Core Requirements.
2. Which specifications, and which revision of these, are relevant to the contract.
3. Whether the drawings have the right information, and there is no ambiguity.
4. Who contractually is responsible for risk.
5. Management and supervision.
6. A clearly defined chain of command from site operatives to the earthworks manager.
7. The need for a UKAS accredited site laboratory.
8. Inspection and test plans to comply with the client's requirements.
9. Additional testing requirements to manage specific risks.
10. Where Value Engineering could be used to benefit the project.
11. A system for rapidly reviewing test results to monitor for trends.
12. Transparency of test results between contractor, designer and client.
13. A system for reporting, addressing and closing non-conformances.
14. A no-blame culture, especially to allow early warnings to be acted upon.

Considering the above in detail:

1. **The client's specific/core requirements**
   A proposed method or material, an alternative to criteria here, may require a formal departure from standard to be approved by the client. All parties must be fully cognizant of how adopting such a departure alters the balance of risk ownership (see 4).

2. **Which specifications, and which revision of these, are relevant to the contract**
   Every engineer's office on a construction project should have a hard copy of the client's overall specification and the contract specific documents. These should be issued by one person on the contract – a document controller – responsible for ensuring all documents are kept up to date. This also applies to external specifications.

3. **Whether the drawings have the right information, and there is no ambiguity**
   Not simply a task delegated to the document controller, there should be a central register of dated current drawing revisions to which any engineer can refer to confirm the right one is being used.

4. **Who contractually is responsible for risk**
   A risk register compiled before the works commence must identify this issue. It must not be seen as a buck-passing exercise, but so that the parties responsible can be prepared and plan the mitigation.

5. **Management and supervision**
   A senior manager must be appointed to oversee the planning, management or coordination of the earthworks operations. On most projects, a works manager for earthworks will be appointed to supervise site operations.

6. **A clearly defined chain of command from site operatives to the earthworks manager**
   If an earthworks sub-contractor is used, this must include how its managers, staff and workforce collaborate with the main contractor. An organogram is essential. It should name staff and provide job titles for all parties, client, designer, contractor and sub-contractor. The inclusion of mobile phone numbers is useful, as are photos of staff at the start of a contract. The organogram should be displayed in a part of the office accessed by all personnel.

7. **The need for a UKAS accredited site laboratory**
   The specification will state whether or not this is a core requirement of the client. Most contracts require the contractor to carry out all earthworks testing; on any medium to large project adequate control is not feasible without a laboratory presence on site, if purely for reaction time to any situation.

8. **Inspection and test plans to comply with the client's requirement**
   SHW requires the production of Appendix 1/5: Testing to be carried out by the contractor. This includes tests to be carried out, at defined sampling rates, for the materials, including bulk earthworks, used in the project. The compilers take advice on test rates from SHW NG and HA44/91. It is strongly advised that, as with other parts of the earthworks specification, the contractor should contribute to the compilation of this appendix. This will draw on the broadest experience for the highest risk materials to be controlled and risk minimised.

9. **Additional testing requirements to manage specific risks**
   This is in addition to test rates defined in Appendix 1/5. Some materials can be realistically viewed as very low risk of non-conformance. These typically include processed and blended material imported from external quarries, covered by the supplier's Quality Plan and, often, EC certificated. The test regime for these need be no more than minimal. Other materials carry more risk of non-conformance. These include site-won materials where the deposit is known, from the GI, to be variable (including sands and gravels) and imported recycled material, due to the variation of feedstock. There must be a person appointed to know from where materials are sourced. This person, usually the site materials engineer, must be sufficiently experienced to assess the level of risk and how much the sampling rate should be increased above the minimum to mitigate this.

10. **Where value engineering could be used to benefit the project**
    This can be as simple as reviewing updates in specifications and standards and, where this offers a benefit to the project, for client, designer and contractor collaborating for their implementation. It can also be as complex as a major re-design of an element in the works. In any case, it is incumbent on all parties to encourage creative thought amongst staff.

11. **A system for rapidly reviewing test results to monitor for trends**
    A large earthworks project will generate a lot of test data, whether from a site or external laboratory. This is useless unless subjected to frequent, regular review. A UKAS accredited laboratory will, for each test carried out, produce a hard copy test report. This is a requirement of accreditation, but does not make review of multiple results realistic. A simple spreadsheet, on which earthworks testing – *in situ* and in laboratory – can be entered allows rapid review of all testing, for whichever material or property is filtered. Non-conformances can be quickly identified and, more importantly, trends identified, so early action can be taken to avoid non-conformance.

12. **Transparency of test results between contractor, designer and client**
    Having created a results database, it should be reviewed by all parties with a stakeholding in the success of the project. If a project has a local electronic network, it should be stored so that the client, client's agent, designer and contractor have open access to the data. Security measures must prevent alteration by those other than appointed persons.

13. **A system for reporting, addressing and closing non-conformances**
    A system should exist for openly addressing non-conformances to allow closure to the satisfaction of the client and designer. A non-conformance must be seen as an opportunity to improve, not as means to apportion blame for a failure. This can only work effectively in…

14. **A no-blame culture, especially to allow early warnings to be acted upon**

75.5 Compliance testing of earthworks

All testing, whether for compliance of the material or to measure the level of compaction, must have a minimum frequency specified as stated above. The frequency of testing must take into account all risks associated with the material:

- Likelihood of structural failure through non-conformance:

  some elements are critical, e.g. backfill to a structure under a motorway pavement.

- Potential variability of material composition:

  recycled aggregate will vary more than a quarry product from primary aggregate.

- Potential variability of material properties, e.g. moisture content:

  recycled aggregate is likely to be more variable than primary aggregate.

75.5.1 Material compliance

All earthworks materials, whether re-used, site-won or imported, must be used within the limits defined for various parameters by the client's specification and the designer's geotechnical design report. For projects using the SHW, these are specified in the 600 series and associated appendices and tables.

There is a wide range of physical, mechanical and chemical soil characteristics for which tests are carried out to ascertain compliance with specified suitability limits. It is outside the scope of this chapter to list all these, but **Table 75.3** gives tests which may be used to control the physical suitability of cohesive material for earthworks general fill – i.e. SHW Class 2.

75.5.1.1 Compaction compliance: Method Compaction

Although the tests quoted in **Table 75.4** may be carried out on Method Compaction earthworks, this is usually to confirm the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Test	Advantages of test	Constraints of test	Typical acceptable Limits
Moisture Condition Value (MCV)	Rapid – test takes about 15 min. Can be carried out on site.	Must be correlated against fundamental property tests to define limits. Not especially effective for granular soils, or very silty or sandy clays.	8–16
Hand Shear Vane (HSV)	Rapid – test takes 1 min. Can be carried out on site. Direct measure of cohesion/undrained shear strength C_u.	Not suitable for clay containing much sand or gravel.	>70 kPa
Plastic Limit (PL)	Used to define material properties at design stage – not often used for earthworks control.	Must be carried out in laboratory. Test can take 24 hrs from sampling to result.	See MC
Optimum Moisture Content (OMC)	Effective for granular soils, or very granular clays (e.g. Glacial Till) where MCV or HSV may not be suitable.	Must be carried out in laboratory. Test can take >48 hrs from sampling to result.	See MC
Quick undrained triaxial	Used to define material properties at design stage – rarely used for earthworks control. Direct measure of cohesion/undrained shear strength C_u.	Must be carried out in laboratory Test can take >48 hrs from sampling to result.	>70 kPa
Moisture Content (MC)	Fundamental soil property which should be measured for every soil sample taken. Can be rapid if microwave method used (correlated against oven dried).	Requires another test, e.g. OMC or PL, to provide control reference.	< PL x 1.2 >OMC-2 <OMC+3
Particle Size Distribution (PSD) – also known as Grading	Not frequently carried out on general fills (SHW Class 1 or 2) as other parameters of these materials affect suitability more. More often carried out on selected fills (SHW Class 6), where PSD has a greater effect on performance.	Generally, 48 hrs from sampling to result as two drying cycles are required for materials which have to be washed of clay and silt. A sample size of at least 80 kg is needed for material of 90 mm nominal size.	See SHW Table 6/2
California Bearing Ratio (CBR)	CBR is not a routine acceptability test, but engineers must be aware of the test. CBR is an empirical measure of material shear strength. It is used to design the thickness of the foundation layer of a pavement. It also identifies soft areas which require treatment (replacement or improvement) prior to placing the foundation. A rapid assessment of CBR can be made using a hand-held MEXE probe.		>2.5%
Falling/Light Weight deflectometer (FWD/LWD)	Like CBR, this is not a routine acceptability test but is used to measure the *in situ* stiffness of soils. This provides data for pavement foundation design and design verification testing.		–

Table 75.3 Tests which may be used to control the physical suitability of cohesive material for earthworks general fill (SHW Class 2)

conclusions of a geotechnical design, rather than as a control. The key control of Method Compaction is to ensure that the methodology is correctly carried out. This entails checking:

- that the method is suitable for the material class (SHW Table 6/4);
- that the type of compaction plant is suitable;
- the compactive effort (mass/m roll width etc.) of the plant.

This can be obtained by reference to the contract specification and to the plant manufacturer's performance data sheets.

In SHW, for each method and category of compactive effort, there are limits for the maximum thickness of compacted layer and minimum number of passes. These should be ascertained by direct measurement. Daily records must be kept of all observations and measurements.

75.5.1.2 Compaction compliance: End product compaction

Where a minimum level of compaction is specified for a material the compacted material must be tested *in situ* to ascertain compliance with the specification. It is strongly recommended that material is not overlaid with the next layer until it has been confirmed that the layer under test complies with the specification.

The test methods in regular use in the UK are listed in **Table 75.4**.

For each test method the moisture content of the soil must be determined in laboratory conditions to calculate the dry density. This is compared to the MDD obtained for that material (by the method specified) to be expressed as % of MDD.

Testing with a Nuclear Density Meter (NDM) has been used in the UK since at least the early 1980s and is a methodology

Test	Advantages of test	Constraints of test
Nuclear Density Meter (NDM)	Rapid – a result from a single test point takes less than a minute. Speed of test enables many test points to be taken. Suitable for most soil types, fine and coarse grained; unbound and hydraulically bound.	Significant administrative input required to manage issues of: Heath & safety Licensing Security. NDM apparatus requires regular correlation for each material against actual density. Moisture measurement by NDM is not reliable
Core cutter	Quick and simple to carry out on site. Can be rapid if microwave method used for MC (correlated against oven dried).	Not suitable for other than fine cohesive soils.
Sand Replacement Density	Suitable for coarse-grained soils.	Slow and labour-intensive.

Table 75.4 Compaction test methods in regular use in the UK

accepted by specifiers, designers and contractors. The technology is proven for bulk density measurement but not moisture measurement; dry density must be calculated from the moisture content, tested in the laboratory, of a soil sample from the NDM test location.

The legislation regarding the ownership and storage of NDM is extensive and it is not within the scope of this chapter to discuss this in detail. Anyone considering the acquisition of NDM is strongly recommended to seek the advice of a radiation protection adviser in the first instance, as soon as possible. Registration with the Environment Agency (EA) may take four months. NDM site testing may be carried out by a hired 3rd party operator registered with the EA; this is less onerous.

75.5.2 Selection of compliance parameters and limits

The specification compiler must select the test methods to be used on the project to control the earthworks. The compiler must take into account:

- suitability of the method for the materials to be encountered;
- urgency of the result to determine compliance with specification;
- avoiding conflicting parameters/limits.

Tables 75.3 and **75.4** provide guidance on the first two of these points. It is worth stressing the importance of selecting the most rapid method appropriate to the nature of the contract and earthworks: the triaxial test will certainly define whether a clay is a suitable fill or not; specifying it as the means to control the earthworks on a project where 1 000 000 m^3 of clay has to be moved in a season is not practical.

The MCV test was developed by TRL (then TRRL) in the 1970s as a rapid method of controlling earthworks for material acceptability. The method is ideal for medium to high plasticity 'heavy' clays, e.g. Lias, London, Gault; but can be effective on very silty or sandy clays if correlation testing against fundamental properties – e.g. shear strength – is carried out prior to the works commencing.

The Hand Shear Vane, when calibrated, is an effective method for cohesive materials of varying plasticity. It is less suitable if the clay is expected to include fractions larger than medium sand: coarser particles engaging with the vanes can produce erroneous results.

The third point needs careful consideration. In allowing more than one test method as a means of control, the specification compiler can introduce a paradox where a material tested to one method may comply but, tested to the other, may not. This may be a result of limit selection being imperfect, variation in the material from that used in correlation testing or just that natural material does not necessarily conform precisely to the models made for it.

In the example specification provided (**Figure 75.4(a)**), this possibility was addressed by a footnote to the table. This allowed earthworks control by Hand Shear Vane *or* MCV, so long as the Appendix 1/5 requirement for the minimum number of MCV was satisfied.

Selection of limits for a material must take account of:

- the material properties;
- results of any correlation testing;
- understanding how material will perform when subjected to the expected load;
- other physical conditions that may affect this performance;
- the acceptable level of risk/factors of safety.

Determining these limits is the role of geotechnical specialists of the designer and the client and, where possible, the contractor.

75.5.3 Dealing with non-conformance

This chapter has used 'non-conformance' and 'failure' as distinct and non-interchangeable terms. Non-conformance, where one or more of the tested properties of a material lies without

the specified limits, does not necessarily imply that the later, structural failure, is inevitable or even possible.

Whilst all non-conformances must be investigated, it must be noted that, in statistical analysis of a table of test results – the Normal Distribution Curve (Bell Graph) – a small number of 'defectives' are expected. About 4% of results of any test might be expected to be marginal non-conformances. It is not within the scope of this chapter to discuss how far outlying the specified limits constitutes a marginal non-conformance, or the statistical analysis of data.

When a test result lies outside the acceptable limits for that parameter, most quality control systems require the production of a Non-Conformance Report (NCR). This will describe the:

- material type and class (if appropriate);
- location used;
- specified limits;
- test result obtained.

This will allow the team assessing the NCR to make a judgement on the action required. This may vary and include:

- the criticality of the non-compliance, by severity and location;
- consideration that the factor of safety has not been affected and no action is necessary;
- resampling and retesting – the non-conformance may result from sampling bias;
- treatment to modify the characteristics of the material to comply with the specification;
- removal and replacement with compliant material.

As with all matters involving earthworks and the specification, the review of the NCR and the decision-making process should include client, designer and contractor. A solution that is without negative effect on the safety of the project, but is practical and commensurate with the situation is to be sought.

75.6 Managing and controlling specific materials

If not correctly managed, all materials may create problems for the earthworks operations. Some, in certain conditions, may be considered by the engineer as 'difficult', i.e. more prone to failure, even though there may have been no non-conformance with the specification.

75.6.1 Clay

Although not necessarily a difficult material to manage, working with clay merits consideration and planning that will benefit an engineer controlling earthworks.

Clay is moisture sensitive; more so with increasing silt content. Whilst light rainfall might not necessitate a temporary halt in earthworks, an experienced earthworks manager must be consulted on when work should cease. Continuing to traffic clay with earthworks plant, especially on narrow, channelled haul roads, during rainfall, has several negative effects:

- Safety. On clay, particularly firm-stiff high PI clays, light rain will reduce traction/grip for wheeled construction plant.
- Softening of acceptable material, so that it becomes unacceptable. This is increased by rutting.
- Rutting. Once started this can lead to a rapid deterioration of the material, as water is trapped in ruts, softening the clay and leading to deeper ruts (**Figure 75.17**).

Rutting is a serious problem, as trapped water will have to be drained away. On an embankment this may be done relatively easily, but in a cutting this may need pumping and long pipe runs. This has a negative effect on the programme and entails additional cost.

(a)

(b)

Figure 75.17 Earthworks after heavy rain: (a) not well drained; (b) rolled beforehand and well drained
Courtesy of Balfour Beatty

Planning, especially if rain is forecast, can mitigate or eliminate the effects of rain, mainly by managing the earthworks operations to create drainage paths:

- *Crossfall*. Manage deposition and compaction so that there is always a fall to the outer edge of the works.
- *Longitudinal fall*. In a fill, crossfall is easily created and is effective. In cuts there is no over-the-edge drainage. In this case, whilst a crossfall will take the water initially away from the works and haul road, drainage requires a longitudinal fall to the open end of the cutting. Care must be taken to ensure there is no accidental damming.
- *Grips*. Surface drainage channels to carry water away from low spots that will inevitably occur no matter how well the works are planned.
- *Proof rolling*. Although rolling is concurrent with deposition, with rainfall imminent additional attention should be taken to close the surface of the material, to prevent ponding. A smooth surface will also shed water along the crossfall faster.

  Any action to drain rainwater must take into account that a discharge off site may require licensing by the EA. A limit on suspended solids in any such discharge may be imposed.

Figure 75.18 Lime being added to saturated earthworks – the cloud is steam from the exothermic reaction between the quicklime and water, not lime dust
Courtesy of Balfour Beatty

Haul roads on clay must be maintained to avoid rutting. If ruts are allowed to develop, haulage times are increased, more fuel is burnt by the plant and in the worst cases, plant may become stuck and need pulling or pushing out. All these reduce the efficiency of the operation, increasing cost and adding delays. Rainwater ponding in ruts accelerates any deterioration.

Allowance must be made for a grader to trim the haul road so rutting does not develop. A roller may also be required.

Wet or soft unacceptable clay, either naturally occurring or through deterioration, can be reverted, but this needs planning and has programme and cost implications:

- *Natural drying*. Wet clay is excavated and loosely spread in windrows where sun and wind can effect natural drying. This process requires confidence for a prolonged spell of fair weather; it is not an option for winter. The process can take from a few days to a week or more, depending on the condition of the clay and the weather.
- *Lime modification*. Quicklime reduces moisture content by chemical combination and by the exothermic reaction evaporating some of the water. Quicklime is spread and rotavated into the clay. It should not be compacted immediately; the steam generated must be allowed channels to escape.

Lime modification must not be confused with stabilisation. Modification does not change the material from Class 7 to Class 9 and does not require the testing for those classes of material. However, the testing required for Class 2 must be carried out after treatment to confirm the material complies with the acceptability limits; further treatment is necessary if not.

Figure 75.19 Improvement with lime addition – dissipating steam
Courtesy of Balfour Beatty

Care should be taken if the clay is suspected to contain sulphate-bearing minerals such as Pyrite or Gypsum. Although modification uses a lower addition of quicklime (typically 1–2%) than stabilisation, there is still the potential for long-term, deleterious expansion from reaction with the sulphates.

The GI should be thoroughly assessed for:

- unacceptable clay, which the earthworks strategy may need to be modified;
- gypsum or pyrites described in the BH or TP logs;
- elevated sulphates;
- any testing carried out to TRL 447.

If there is any doubt, samples should be obtained from trial pits and tests 1, 2 and 4 in TRL Report 447 must be carried out. Advice should be sought from a geotechnical specialist to interpret the results.

The earthworks programme must be reviewed. Is there a programme-critical operation from late autumn to early spring when wetter weather is more likely and natural drying not feasible? Assessment and testing are required as above.

These processes take time and must be planned and undertaken well in advance of earthworks in that area of the project.

75.6.2 Silt

All the caveats for clay apply to silt, but more so. Silt is highly sensitive to variations in moisture content. As silt is more permeable than a clay, water can penetrate the material more readily.

If, during earthworks involving silt – or a very silty clay – it starts to rain, it is prudent to cease operations sooner than one would on clay. A small change in moisture content can render an acceptable fill material into slurry. Trafficking silt during rain will rapidly deteriorate the material to significant depths.

To revert unacceptable silt, lime modification can be used, but it is slightly less effective than with clay. As with clay, quicklime will reduce moisture by exothermic reaction with the free water. However, silt differs chemically from clay, and further reaction between the clay and the lime (as occurs in stabilisation) does not occur.

Natural revertion, by excavating and windrowing to dry, is just as effective for silt as it is for clay.

Draining the earthworks is even more important for silt than clay. It must be considered that silt erodes much more easily than clay and care must be taken to limit the fall of any grip to minimise this. Likewise, over-the-edge drainage of embankments must be carefully thought out to prevent the formation of deep washout rills in the batterslope and top of batter. Repairing these can be more problematic, and cost more, than the damage the drainage was intended to avoid.

Maintenance of haul roads over silt is critical to avoid rutting developing. Due to the sensitivity of the material, consideration must be made for providing a granular haul road to permit haulage in all weathers.

Haul roads can be formed from locally available material. Crushed rock, or crushed concrete/masonry is better than sand and gravel. This is due to the greater mechanical interlock of the particles providing more stability – less tendency to deformation – under the load of construction plant.

75.6.3 Fine, uniform sand

SHW Table 6/1 identifies this material as Class 1B. Two physical properties of this material characterise it:

- *Fineness*. Particle sizes are, typically, 100% <0.6 mm, 50% <0.3 mm, 10% <0.06 mm.
- *Uniformity*. The distribution of particles is over a small size range.

As a result of the effects of these characteristics, this material has:

- restricted acceptable moisture range;
- high mobility; readily moved by wind or water;
- increased risk of washout in heavy rain;
- poor traffickability by wheeled construction plant.

Techniques for managing this material generally require the close monitoring and control of moisture content:

- *Drier than OMC*. Water should be added during deposition. Water bowsers should be employed for this, and used during dry weather to prevent desiccation of the surface.
- *Wetter than OMC*. This material drains reasonably quickly. Only when excavation is below the water table is encountering this likely. If excavated and windrowed this material will drain and dry; it is important to monitor this to avoid overdrying.
- *Drainage runs*. Run-offs must be carefully planned to avoid significant falls and the risk of erosion.

- *Over-the edge drainage.* This is to be avoided, as the risk of washout is too great. To avoid the worst effects of run-off erosion, it may be better to allow rainwater to pond on the earthworks surface.

75.6.4 Chalk

Even the strongest, blockiest chalk can be reduced to a structureless mass by incorrect handling. Taking the right actions, most grades of chalk can be used in construction without increased risk:

- *Season.* Determined by the specification compilers in Appendix 6/4. This is decided by reference to rainfall and temperature records for the area and knowledge of the chalk. The usual period is March to November. However, if early spring is much wetter or colder than usual the start should be delayed.
- *Control*. Whilst Intact Dry Density and Chalk Crushing Value are used, the basic test for controlling chalk earthworks is the moisture content test. Microwave drying should be correlated to BS oven drying methods so rapid assessment can be made.
- *Excavation*. This – in fact, every part of the chalk operation – must be managed to retain as much of the chalk structure as possible. Chalk should only be excavated as a face. This should be as deep as possible; 5 m is the usual minimum, although site conditions and depth of cut may constrain this.
- *Haulage*. Chalk can lose about 2% moisture in haulage, in fair weather conditions and on an average haul distance. Chalk that is slightly wetter than the maximum limit may revert in haulage. This should be taken into account when the sampling and test plan is written.
- *Deposition.* Chalk should never be rehandled. It should be discharged from the dump truck at the point of final deposition. The lightest plant commensurate with efficiency should be used in spreading. Chalk should be spread in the thickest layer possible to maintain the structure; 0.5 m is not unreasonable.
- *Compaction*. SHW Table 6/4 permits light vibratory rollers. Unless the chalk is very strong it is normal practice to use deadweight rollers, again to minimise damage to the material. A rule-of-thumb guide is that, when the chalk starts to adhere to the drum, rolling should cease.

Any chalk fill must undergo a settlement period, before any pavement layers are added. This period is defined by the designer. It may be shortened by surcharging, which is removed prior to the addition of further layers of the permanent works.

75.6.5 Recycled and secondary materials

Engineers are likely to encounter recycled and secondary materials as fills and aggregates: there is a mature UK marketplace to supply these materials. Recycled and secondary aggregates are not interchangable terms. Neither are sourced from primary aggregate, i.e. naturally occuring sand and gravel (land or marine sourced) or crushed rock. Generally accepted definitions of each are:

> Secondary aggregate:
>
> produced as by-products of other processes.
>
> Recycled aggregate:
>
> produced from the processing of inorganic material used in a construction process.

Use of recycled and secondary aggregates is encouraged by government initiatives for sustainable construction. However, legislation and regulation require certain procedures to be carried out: there is a Duty of Care to ensure that contaminating substances, at concentrations liable to cause harm to human health or the environment, are not spread about.

The regulations covering the use of non-primary aggregates are still evolving. It would be unwise to provide definitive

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

instructions in this chapter; what is fact at the time of writing (February 2011) may easily be superseded a short time hence.

Recommendation can be given on sources of reference, the most significant of these being the Waste and Resources Action Programme – WRAP – which, in conjunction with the EA, has produced 'The Quality Protocol for the production of aggregates from inert waste'. Aggregates produced in accordance with this protocol are considered to be fully recovered and thus are not waste.

When recycled aggregates are not produced to the WRAP protocol, they are probably still considered to be waste by the regulators. Producers must then comply with the Environmental Permitting Regulations: a permit must be acquired from the EA, a process that may take many weeks to complete.

Potential users of recycled aggregate are strongly advised that, prior to importing any material to their works, they should ascertain that the supplier has produced the material in accordance with the WRAP protocol and can prove this and be subjected to audit by the purchaser. The supplier must provide test results which confirm the material complies with the protocol.

Contaminated Land: Applications In Real Environments (CL:AIRE) has, in conjunction with the EA, published "The Definition of Waste: Development Industry Code of Practice" Version 2 in March 2011. Anyone intending to re-use or recycle material is strongly recommended to acquire this freely downloadable document.

Consultation of the following is recommended to specification compilers and engineers:

- their in-house environmental nanager;
- external waste/environmental advisers;
- WRAP www.wrap.org.uk/index.html;
- CL:AIRE www.claire.co.uk/
- Environment Agency www.environment-agency.gov.uk/.

In addition to compliance with waste regulations, the use of non-primary materials may be restricted by the client's Core Requirements. The HA define their requirements for recycled aggregate in SHW clause 601.12 and Table 6/1 includes specific classes of material where recycled material is permitted.

In addition, HA DMRB Vol. 1, Sec. 1, Part 2: HD 35/04 'Conservation and the use of Secondary and Recycled Materials' provides detailed advice on using recycled materials to specifiers. Table 2.1 from this document is in part reproduced in **Table 75.5**.

It must be noted that clients other than HA may have significantly different requirements for using recycled aggregates. Before proceding, specifiers or users must ensure they understand what their client permits to be used and what may require a departure from standards, if this is possible.

Specification compilers and users should be aware that a client's Core Requirements may not include current industry best practice. For example, tyre bales are being increasingly used as lightweight embankment fill, but are not identified in **Table 75.5**.

Dicussion between client, designer/specifier and contractor is, as before in this chapter, strongly recommended to maximise the use of recycled and secondary material for sustainable construction.

75.6.6 Manufactured aggregate

The most likely material of the kind that will be encountered is lightweight aggregate. This is manufactured from sintered PFA or expanded clay and marketed under certain brand names. The materials are not included in the SHW. They are only likely to be used to resolve specific geotechnical problems and designers should seek advice from the manufacturers on the material properties and performance.

75.6.7 Peat

Although significant volumes of peat are uncommon in England and Wales, engineers expecting to work in Scotland and Ireland should be prepared to encounter this material. Peat characteristics are:

- Low cohesion/shear strength. Values of C_u are unlikely to exceed 10KPa.
- High moisture content. Values of >300% are common.
- High compressibility. When loaded, water is driven from the structure leading to a large volume change.
- Unpredictable settlement. Because peat is organic and not homogeneous, settlement is uneven over any unit of area. Actual settlement is very difficult to predict from laboratory testing.

Peat is not acceptable, in any condition, as general fill for an earthworks project. Classification of this material, according to SHW terminology, will always be Class U1. Neither is it suitable as a load-bearing material for an embankment. It must be dealt with or removed.

A strategy for dealing with peat first must consider how thick the layer is and, consequently, the volume to be removed. As it is not suitable even for landscaping, all the material may have to be removed from site. This may involve significant cost:

- there may not be a suitably licensed landfill locally;
- any landfill may have limits on the annual permitted intake of this material;
- it may attract the higher level of landfill tax, if this applies.

If peat is to be removed, it must be done with consideration for the stability of the remaining mass to each side of the excavation.

It may be preferable to leave the material in place. In this case the load of the overlying structure must be transferred to the underlying strata, usually by a piled raft. Any project encountering peat needs to be carefully planned in advance of the works.

Application and series ▶	Pipe bedding	Embankment and fill	Capping	Unbound mixtures for sub-base	Hydraulically bound mixtures for sub-base and base	Bitumen bound layers	Pq Concrete

KEY:

✓ Specific (permitted as a constituent if the material complies with the Specification (MCHW 1)) or
General Provision (permitted as a constituent if the material complies with the Specification (MCHW 1) requirements but not named within the Specification (MCHW 1)).

× Not permitted.

IMPORTANT NOTES:

1. Table 2.1 is for guidance only and reference must be made to the accompanying text and the Specification (MCHW 1). Materials indicated as complying with the Specification (MCHW 1) for a particular application may not necessarily comply with all the requirements of the series listed, only particular clauses. For example in the 600 series, Unburnt Colliery Spoil can satisfy the Specification (MCHW 1) as a general fill, but is excluded as a selected fill; and in Series 1000 recycled or secondary materials are not permitted within the running surface of PQ concrete. Reference should also be made to the Specification (MCHW 1) for any maximum constituent percentages of specific recycled or secondary aggregates. For example in the 1000 Series, the maximum by mass constituent of Recycled Asphalt is given under the limits for 'other material' (Table 10/2) within the Specification (MCHW 1).
2. There is no Specific or General Provision for the use of recycled glass as an aggregate in PQ concrete or Hydraulically Bound Mixtures due to the potential for deleterious alkali-silica reaction (ASR). However, its use may be permitted by the Overseeing Organisation if sufficient provisions to minimise the risk of deleterious ASR are included in the mixture design.
3. There is no Specific or General Provision for the use of steel slag as an aggregate in PQ concrete or Hydraulically Bound Mixtures due to the potential for volume instability. However, its use may be permitted by the Overseeing Organisation if sufficient assurance of volume stability is provided.

Table 75.5 Specification for Highway Works (MCHW 1): Application of Secondary and Recycled Aggregates

Reproduced from Highways Agency, ***Design Manual for Roads and Bridges***, HD 35/04. © Crown Copyright 2004

75.6.8 Topsoil

Topsoil is not used as a structural engineering soil. This is due to the organic content of the soil, which can create stability problems and, if used close to the surface, regrowth. However, topsoil is part of the earthworks and, as it is generally encountered as the first and final operations, must be considered and included in the programme.

75.6.8.1 Topsoil removal (topsoil strip)

- In cut or at grade areas: topsoil is removed before other earthworks can commence.
- In fill areas: topsoil may be removed or, when an embankment is above a minimum height, left in place. The advantages of this are:
- reduced disposal if there is a surplus of topsoil;
- reduced imported fill if there is a deficit of suitable material in the works;
- preservation of archaeology;
- programme and cost benefits.

The minimum height for this must be agreed between designer and contractor. Below this, topsoil must be removed.

Figure 75.22 Typical low-lying peat landscape
Courtesy of Balfour Beatty

Topsoil which will be re-used in the works must be stored in topsoil bunds. To avoid damage to the soil, there is a height restriction to these, which engineers must confirm with the designer before proceeding.

Topsoil strip is usually carried out by a scraper box towed behind a track-type tractor. This is effective if the topsoil bund is close to the area being stripped. However, if these are further away, stripping with a 360° excavator and haulage by articulated dump truck (ADT) is more efficient.

75.6.8.2 Topsoil replacement (re-soiling)

After completion of structural earthworks, topsoil is replaced where the contract requires. Areas to be re-soiled will include verges, batterslopes, landscaping and areas not otherwise overlaid by, for example, bound/block pavement, bound or unbound decorative finishes, surface treatments or over filter drains.

Topsoil is spread by a wheeled or tracked 360° excavator or a light track-type tractor. Topsoil is not compacted.

Engineers should note that SHW has different material classes for topsoil existing on site (5A) and imported topsoil (5B). Different parameters and limits may apply to each. Each of these classes may be sub-divided so the composition may varied to suit the ecology of a specific area.

It is recommended this chapter is read in conjunction with

- *Chapter 69 Earthworks design principles*
- *Chapter 78 Procurement and specification*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 76

Issues for pavement design

There have been significant developments in the design of pavements and trackbed for roads and railways in recent years. Latest design specifications take a more rational approach than the traditional recipe method based on experience, and offer potential rewards including the wider use of more sustainable marginal materials and reduction in construction thicknesses. Pavement design involves significant geotechnical engineering and the latest specifications place even greater importance on the assessment and selection of appropriate materials for the ground conditions present. This chapter gives a brief outline of good current design practice for UK roads and railways, and references are given to some of the key literature available for further reading. The focus is on the design methods developed for motorways and trunk roads (produced by the Highways Agency) and railways (Network Rail) as the majority of research carried out in the UK has been related to these. The importance of the assessment of the sub-grade and development of a design which suits the ground conditions present is emphasised.

76.1 Introduction

Transportation is a fundamental requirement of our lives and in the UK we are never far away from a road or railway. Considering this, it may seem surprising that pavement engineering, and pavement foundation design in particular, was relatively slow to develop as a technical aspect within civil engineering. Traditionally, pavements were built based on experience or precedent, and therefore construction has tended to be conservative or in some cases inadequate. Recent years have seen significant developments of a more theoretical framework for design. This approach has been driven largely by the change in the procurement method of many civil engineering projects towards public–private partnership, design and build, and design, finance and operate type contracts. These contracts, where the construction risk is transferred from the public to the private sector, have generated a greater desire for innovation to provide cost and environmental benefits by the use of alternative cheaper construction materials, and to minimise construction thicknesses whilst considering whole-life costing.

Pavement design practice involves several civil engineering disciplines including materials and structural engineering, hydraulics and geotechnics. The geotechnical engineer is required to assess the ground on which pavement will be constructed (sub-grade). The pavement engineer (for highways) or permanent-way engineer (for railways) will be required to determine requirements for the materials directly subject to traffic loading. The boundary between the responsibilities of the two disciplines varies in practice. Like building structures, the founding soil and the pavement foundation should be considered in unison (see Chapter 3 *A brief history of the development of geotechnical engineering*). Traditionally, for roads design, the boundary has been taken as the top of the capping; the geotechnical engineer is responsible for a suitable platform for the construction of the upper layers (Highways Agency, 2009b). The latest developments towards performance-based design have potentially changed the boundaries as the analytical design (which may be carried out by the pavement engineer) will require knowledge of the properties of each pavement layer. It is clear, however, that the geotechnical engineer's involvement should not be limited to the assessment of the sub-grade conditions. In particular, a geotechnical engineer is often best placed to judge the practicality of different foundation solutions – which is vital for successful construction. Design works best when the pavement engineer, geotechnical engineer, alignment engineer and drainage engineer work together to produce a suitable design solution.

This chapter concerns the design of pavement foundations. For the purpose of this chapter the term 'pavement foundation' is used to refer to the materials below the base course for roads (i.e. usually sub-base, capping and sub-grade) and materials below the sleepers for railways (i.e. usually the ballast, sub-grade and any intermediate layers). A variety of terminology is used to refer to the construction layers, with different terms being used for roads and railways. An attempt has been made to use consistent terminology: as examples, 'pavement foundation' is also used to mean 'trackbed', and 'trafficking' is used to refer to road or rail loading, as appropriate. The aim of this chapter is to provide an outline of good current design practice for UK roads and railways, and give references to some key texts for further information. It is not possible to provide a detailed description of pavement engineering theory and references are provided to some key literature. Pavement construction for other purposes, e.g. trams and airports, is not specifically discussed; however, many of the principles apply to any pavement foundations.

76.2 Purpose of pavement foundation

The basic terminology used for the various construction layers used in road and rail pavements is given in **Figures 76.1** and **76.2.**

Each pavement layer has different functions which are described in various sources (see Thom (2008) for roads and NR/SP/TRK/9039 (2005a); or Selig and Waters (1994) for railways). Trafficking applies a dynamic load to the pavement. This load will be distributed through the pavement to the pavement foundation. The fundamental roles of the pavement foundation are as follows:

- Provide a stable platform during construction to enable placement and compaction of the overlying pavement layers.
- Reduce the stress from traffic loading to an acceptable level for the sub-grade and prevent excessive deformation (in the short and long term).
- Maintain material properties under traffic loading. Worsening of material properties can occur either by attrition of the material particles or by migration of fines from adjacent layers.
- Resist lateral and longitudinal forces from traffic loading. This is most important for ballast which is required to maintain support to the sleepers.
- Allow drainage of water from the pavement layers to the drainage system. A separate but related topic is the drainage of the sub-grade which, in cuttings, is delivered by filter drains to avoid groundwater entering the pavement foundation.

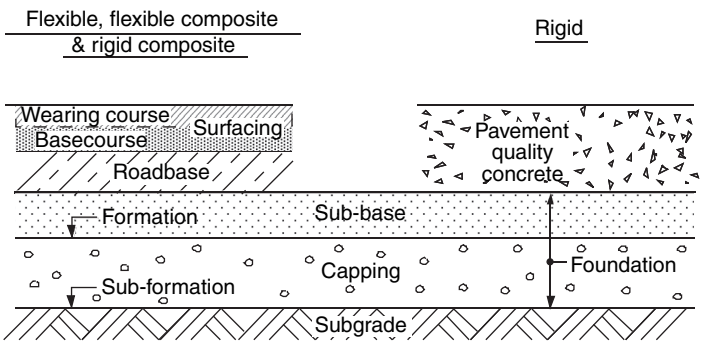

Figure 76.2 Road pavement layer terminology
Reproduced from The Highways Agency, *Design Manual for Roads and Bridges, HD 23/99* (Highways Agency, 1999) © Crown Copyright 1999

These functions are required both during construction and in service. For a pavement during construction, stresses in the foundation due to construction traffic are relatively high, although the number of stress repetitions is relatively low compared to in-service loading conditions. The extreme consequence of inadequate pavement foundations is rutting of the pavement and the underlying sub-grade. For the pavement foundation, rutting is more likely during construction and should be remedied appropriately (usually by excavation and replacement of the failed material), otherwise inadequate pavement performance is likely in the long term. Poor pavement

foundation performance commonly results in significantly higher long-term maintenance costs.

76.3 Pavement foundation theory

There is insufficient opportunity to explain the theory of pavement design in this chapter and sources such as Thom (2008) for roads and Selig and Waters (1994) for railways should be referred to for further detail. For road design, the Transport Research Laboratory (TRL) research of the 1960s to 1980s still provides much of the underlying logic that is followed today, therefore it is advisable to read TRL LR1132 (Powell *et al*., 1984) and refer to TRL LR889 (Black and Lister, 1979) for further details.

The upper bound layers (e.g. asphalt or concrete surfacing for a road, or the rails and sleepers of a railway) are designed to spread the traffic load, reducing it to a level that is tolerable for the pavement foundation. In turn, the foundation materials must be selected to perform under the design loading and reduce the stress passed to the sub-grade.

As described by Brown (1996), when a dynamic load is applied to an unbound material (soil), it will deform initially elastically (resilient deformation) and then plastically (permanent deformation), dependent on the stress path. The unloading action allows for only the elastic deformation to be recovered. The load cycles therefore cause an accumulation of permanent deformation, the magnitude of which depends on the size of the stresses applied, the number of load cycles and the stiffness and strength of the material. A typical shear stress–shear strain plot for an unbound material under dynamic loading is shown in **Figure 76.3**.

As shown in **Figure 76.4**, with increasing load applications at low levels of applied shear stress, the tendency is for plastic deformation to occur at an ever decreasing rate or actually cease altogether. At higher levels of shear stress, plastic deformation will increase at an increasing rate leading to large deformation or failure (Thom, 2008). The shear stress dividing these two conditions is called the threshold stress, which as a rough guide has been suggested as around half the undrained shear strength for a cohesive soil (Brown, 1996). The term 'shakedown limit' is also sometimes used in the available literature; it has a similar meaning to threshold stress but is arguably more complex.

The key point for the practising engineer is: if the stress applied remains below the threshold limit, then the effect of the applied stress will be to compact the soil rather than to soften it. Perhaps this logic is seen in nature by the evolution of chickens – whose feet are large enough to impart low stresses to the soil. Consequently, chickens stay clean even during rainy periods, and if you dig the ground below a chicken coop you will find the upper layer to be extremely compact.

The important parameters for pavement foundation design are therefore the elastic stiffness, some measure of plastic deformation and shear strength under repeated load. These parameters are difficult to determine in practice (and the ground will vary along the route, so many tests are required) which has led to significant simplifications in both the testing undertaken and the design.

76.4 Brief recent history of pavement foundation design

In the 1930s the California State Highways Department developed the California bearing ratio (CBR) as an index test for soils, specifically for the purpose of pavement design. The CBR test involves pushing a small plunger into soil at a constant rate and measuring the displacement. The CBR values obtained are a ratio determined by comparing the results to a 'standard' soil. The plunger penetration is due partly to elastic, plastic and shear deformation, and the CBR value obtained is an empirical value with no fundamental meaning. Despite these limitations, it has the advantages of using low-technology equipment, is quick to carry out and has become widely used. Various empirical design approaches have been developed around the world

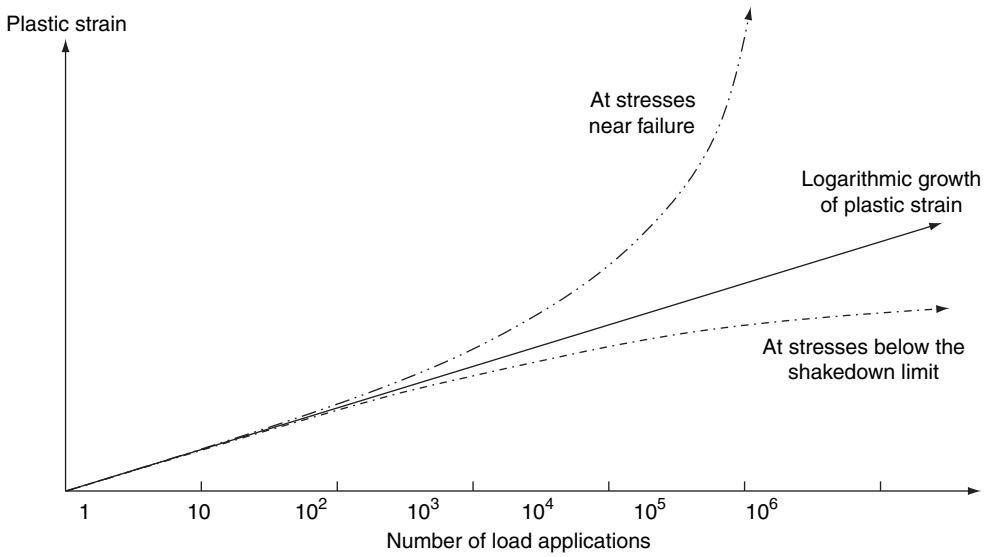

Figure 76.4 Plastic strain accumulation
Reproduced from Thom (2008)

to allow for local conditions using CBR values as a measure of stiffness and strength of a material.

The last few decades have brought important developments in the understanding of soil mechanics, testing procedures, materials research and design tools. There are now many possible test techniques which can help determine soil parameters and design can be undertaken analytically using computer models. However, the difficulty of determining the required soil parameters remains a problem; a practical testing technique has yet to be developed (see section 76.6 and Fleming *et al*., 2000). Design standards remain partially empirical and even though CBR testing is not actively encouraged by practitioners, designs standards still refer to CBR as an indirect measure of the stiffness of the sub-grade.

An underlying problem for pavement foundation design is that the stiffness of the soil prior to construction (i.e. during design) will in many soils be adversely affected by the construction process. The final stiffness of the soil will depend on many factors that the designer has only limited control over; these relate to the construction method employed, and how variations in ground and groundwater conditions are managed. Consequently, soil mechanics theory is only part of what goes into a pavement foundation design; potentially more important is engineering experience and for this reason the empirical CBR approach continues to have a place in practice.

76.5 Current design standards

Sections 76.2 and 76.3 describe how the pavement foundation must reduce the stress from traffic loading to an acceptable level (i.e. below the threshold stress) for the sub-grade. The design of the pavement foundation to perform this task is achieved by following industry standards and specifications, and more recently analytical design methods can also be used.

For UK roads and railways, several of the authorities responsible for the construction and maintenance of pavements have their own design standards. The two main standards are those produced by the Highways Agency and Network Rail, both of which are described in this section. Several local councils also have their own design standards for roads, which are mainly based on the now superseded Highways Agency HD 25/94 standard (Highways Agency, 2007) (or even its predecessor, Road Note 29), which is described below.

76.5.1 Highways Agency standards

The Highways Agency, responsible for motorways and trunk roads in England and Wales, present their design standards in their *Design Manual for Roads and Bridges*. This design standard is also used by Transport Scotland and the Northern Ireland Roads Service, who are responsible for motorways and trunk roads in their respective countries.

Until recently the Highways Agency design standard for pavement foundations was HD 25/94, which followed a method or recipe approach to ensure adequate performance. The standard was based on large-scale trials and long-term experience which is described in LR1132 (Powell *et al*. 1984). HD 25/94 included a table which relates the sub-grade design CBR value to the required thickness of sub-base and capping (see **Figure 76.5**). Options are given for a combined sub-base and capping layer, or a sub-base-only construction, i.e. a thinner but higher-quality foundation layer. The standard also provides good practical advice, such as restricting changes in foundation design along the route to prevent inconsistent ride quality. The standard was successfully used on many schemes; its main disadvantage is that no methodology was provided to allow for the different properties of foundation materials or traffic loading. An analytical approach which would take account of the

engineering properties of the proposed foundation materials would potentially allow a wider range of materials to be used – and foundation thicknesses to be reduced.

In response to this need, the Highways Agency has recently introduced a new standard: interim advice note (IAN) 73/06 (Highways Agency, 2006a). This standard superseded HD 25/94 in February 2006 and was revised in February 2009 and re-issued as revision 1. Further revisions may be undertaken prior to its implementation as a non-interim standard. As well as allowing analytical design for the pavement foundations, IAN 73/06 also links to new guidance from the Highways Agency on the design of the upper road layers in HD 26/06, which permits a thinning of the upper layers depending on the stiffness of the foundation (for classes 3 and 4). However, the old HD 25/94 and previous references remain of value for the design theory and for good practical advice.

IAN 73/06 specifies four permissible foundation classes, defined by their long-term minimum stiffness at the top of the foundation level (termed foundation surface modulus):

- class 1–50 MPa;
- class 2–100 MPa (see example below);
- class 3–200 MPa;
- class 4–400 MPa.

Class 1 is acceptable only for minor roads, class 2 usually represents a granular pavement foundation, whilst classes 3 and 4 represent lime- or cement-stabilised (stiffer) foundations.

The construction target values are different to the long-term values, and allow for subsequent confinement for granular materials, or curing rate and cracking in the case of bound materials.

The foundation surface modulus is not to be confused with the stiffness of an individual layer (termed layer modulus). The foundation surface modulus is a measure of the 'composite' behaviour under a 300-mm-diameter loaded plate, and is affected by the stiffness and thickness of the foundation layers and the underlying sub-grade. Hence an unbound sub-base foundation of sufficient thickness and with a layer modulus of 150 MPa overlying a sub-grade with a layer modulus of 50 MPa (approximate CBR of 5%) would provide a class 2 foundation with a foundation surface modulus of 100 MPa. The field target for stiffness testing is, in this case, 80 MPa.

Traditionally, before the introduction of IAN 73/06, for an unbound pavement foundation, the CBR at the top of the capping was assumed to be in excess of 15% and the CBR at the top of the sub-base was assumed to be in excess of 30%. These values corresponded to the CBR of these individual layers and should not be compared to the foundation surface modulus, which, as stated above, is a composite behaviour of the various layers under a 300 mm diameter loaded plate. If the individual

foundation layers were sufficiently thick (much thicker than in normal practice) then the loading from the plate would be distributed entirely within the individual foundation layer. In this case, the foundation surface modulus measured by the plate would be the same as the layer modulus of that layer measured using the same test method.

It is important to clarify that capping cannot easily be tested for CBR because of the cause of the coarse grading of most capping materials. Static plate load testing can be used to determine an equivalent CBR, but is rarely carried out. An alternative approach is to gain an indication of the CBR using dynamic cone penetrometer testing, although this may not be appropriate in some materials.

As a rough guide, a CBR of 15% for capping may correspond to a layer modulus of around 100 MPa, and a CBR of 30% may correspond to a layer modulus of around 150 MPa. However, a note of caution is required as correlation of CBR to stiffness is not well defined for higher stiffness materials. It is also of note that IAN 73/06 seems to suggest that capping may have a stiffness of only 75 MPa which may correspond to a CBR of less than 15% (depending on the correlation used). This does not correlate well with traditionally used values; however, it may reflect the intention that capping is a locally available lower-cost material and the IAN does give the option of carrying out a performance design using a higher stiffness. Experience shows that it is important that the material selected to use as a capping has a low fines content and is from a source that can deliver a layer of fill of reasonably consistent nature. If this is achieved, then the result should be a layer of stiffness suitable for a capping layer.

Two design processes are encompassed in IAN 73/06: a 'performance' approach and a more traditional 'restricted' approach. The restricted design involves determination of the pavement foundation thicknesses based on the sub-grade stiffness using a set of charts. The 'performance approach' design methodology is presented in the flow chart shown in **Figure 76.6**. This allows many more theoretical permutations and combinations of materials and design thickness than using the restricted method or the previous HD 25/94 standard.

For the performance design, the designer initially chooses appropriate layer stiffness values for the sub-grade and foundation layers, and determines the design based either on some charts provided for some limited design permutations or, more usually, from the equations provided with the aid of a computer model. The analytical model is based on multi-layer linear elastic analysis, which involves a number of simplifications and assumptions from the actual conditions which are described in Thom (2008). Testing and assessment of both the sub-grade and foundations materials are required to determine appropriate design stiffness values and the IAN gives some suggested test techniques.

After the design has been completed, a series of demonstration trials are required. The philosophy is that the demonstration trials are situated on various sub-grade conditions, which reflect the range of conditions that will be encountered. The trials are to be constructed using the methods and materials to be used in the main works. Testing and monitoring of the trials are carried out to validate the design, primarily relating to the density and stiffness of the placed layers, and satisfactory resistance to rutting under traffic loading. A key development in the new approach is inclusion within the trials and main works of the use of *in situ* dynamic plate tests (light-weight deflectometer and falling-weight deflectometer, described in section 76.6) to evaluate the 'as built' stiffness to prove compliance with the required foundation surface modulus for the intended foundation class. The foundation surface modulus values to be achieved during the trials and works are those expected in the short term and are not a direct method for determining the stiffness in the long term once the foundation is covered by the overlying pavement layers (Edwards and Fleming, 2009).

There has been a fair amount of debate on the benefits of IAN 73 and some merits and limitations are provided in Fleming *et al*. (2008). As stated above, the merits are the potential for the use of a wider range of materials – including the reuse of materials giving environmental and cost benefits. The demonstration trials and testing during the works also offer better assurance of performance. However, a number of limitations have been suggested, including very conservative thickness requirements for the 'restricted design' and extensive costly testing for the performance design approach, which for some designs would appear inappropriate. A fundamental assumption remains that short-term behaviour will represent long-term performance. Carrying out trials which represent all the appropriate sub-grade materials in all conditions which will influence performance (such as weather wetting/drying effects) in advance of the works, will often not be realistic and a degree of judgement will be required. Encountering alternative conditions on-site may require additional trials, which are likely to have a knock-on effect to the programme and to the cost.

Whilst the move to a more satisfactory analytical design-based method is welcome, significant development is required to develop a practical design approach. It should also not be forgotten that the most important factor in pavement foundation design (whichever approach is taken) is to undertake an appropriate assessment of the ground and groundwater conditions, and to develop a design which works for these conditions and the likely method of construction (see section 76.6 below). In this regard it is useful to refer to HA 44/91 *Earthworks – Design and Preparation of Contract Documents* (Highways Agency, 1991), because Chapter 10 provides some useful background on the design and specification of pavement foundations. HA 44/91 was produced prior to HD 25/94 and therefore some of the information has now been superseded. However, several of the key principles of pavement foundation design are explained briefly (with cross reference to LR1132) (Powell *et al*., 1984) and remain relevant, e.g. purpose of foundation layers (10.1 and 10.2) and discussion on sub-grade CBR values (10.9 to 10.23).

76.5.2 Network Rail standards

There are several different Network Rail standards which concern trackbed foundation design, the most relevant of which are given below:

- RT/CE/S/101 (1997) track design requirements;
- NR/SP/TRK/102 (2002) track construction standards;
- NR/SP/TRK/9039 (2005a) track design requirements;
- NR/SP/TRK/9006 (2005b) lineside drainage.

RT/CE/S/101 gives the minimum engineering requirements and principles for the design of track construction. It is a high-level specification which refers to other more detailed Network Rail standards. For the design of the trackbed foundation it

refers to RT/CE/C/039 (now superseded by NR/SP/TRK/9039) and for the design of the ballast it refers to NR/SP/TRK/102.

NR/SP/TRK/102 gives standards for new or re-laid track and includes details such as minimum ballast depths as well as specifications for rails and sleepers. Minimum ballast depths are given depending on the category of the track (based on train speed and track usage), rail and sleeper types, and range between 200 and 300 mm. This is based on experience and on minimum depths to allow maintenance, including tamping. For the design of the sub-grade and formation, the specification refers to RT/CE/C/039.

NR/SP/TRK/9039 gives recommendations for the design of trackbed treatments. It describes the various potential trackbed problems and suggests possible investigation techniques. Advice is provided on trackbed thickness and a chart illustrates the required thickness of trackbed layers, which varies depending on the undrained sub-grade modulus and railway type. This is based on a combination of empirical data and multi-layer elastic theory, and is in general agreement with German railway standards. Sketches of standard solutions are also provided for various criteria. The document states that its remit applies to track renewals and remodelling schemes, but not to new lines. It is not clear why this distinction is made since parts of the document (e.g. table 3) suggest that it may also apply to new track. Specification for new track design is not found elsewhere in Network Rail standards.

In practice, the Network Rail standards for trackbed design are likely to continue to develop and change with further research to encompass a broader range of design cases and ground conditions. At present, the designer needs to have a good understanding of the underlying theory and the research undertaken, particularly by British Rail in the 1950s to 1980s (as presented by Selig and Waters, 1994) in order to determine an overall design in conjunction with the advice given in the current standards.

76.6 Sub-grade assessment

The most important factor in pavement and track foundation design is to undertake an appropriate assessment of the sub-grade and groundwater conditions, and to develop a design which is appropriate for these conditions. For the purposes of the assessment, the sub-grade should be considered to be the layer or layers of ground below the foundation and not just the sub-formation surface on which the foundation will be founded. This is because the material properties of the sub-grade may change with depth and along the route, and in particular the stiffness may reduce. The depth of sub-grade which needs to be considered depends on the depth to which the majority of the stress from traffic will be dissipated during construction and in service. The influence of traffic-induced stress can extend to as much as 5 m below the bottom of the sleepers for railways (Brown, 1996). However, in the majority of circumstances, stress is usually considered to be distributed to around 1.5 m below the base of the foundation. This is supported by IAN73/06 (Highways Agency, 2006a), which suggests a rigid layer is modelled for analytical design 1.5 m below the foundation.

Unlike the other foundation layers, the sub-grade is variable and its performance is influenced by many factors. The factors that apply are site-specific but are likely to include some of the following, and ground investigations should be designed to address these issues:

- soil type, grading (especially for borderline cohesive/granular soils);
- variability within the soil type;
- permeability and stiffness;
- horizontal and vertical geological variability;
- soil fabric (e.g. lamination);
- likely presence of hard/soft spots;
- groundwater conditions and drainage (prior to excavation);
- conditions that encourage elevation of pore water pressures during construction (e.g. silts/fine sand or a thin clay layer over sand);
- topography – e.g. transition zones from cut to fill;
- construction procedures adopted and skill of the site foreman to implement these;
- construction season, timing of drainage installation, exposure time of sub-grade;
- quality control systems.

It is a common misconception that the sub-grade stiffness is the only factor which needs to be considered; it is just one item on a long list. To illustrate this issue, consider projects where the sub-grade consists of glacial till which typically comprises a sandy gravelly clay/silt with cobbles and boulders, and has a relatively low fines content. The sub-grade usually has a relatively high stiffness with design CBR values – typically varying between 3 and 6%. However, due to the grading of the material which includes a low, but dominant, fines fraction, the engineering properties of the material can be very sensitive to changes in moisture content. The permeability of the material can also be reasonably high. If groundwater is high (such as in cuttings) and is not adequately controlled, the sub-grade stiffness can deteriorate rapidly on excavation.

In determining the design sub-grade stiffness, consideration should be given to both the short-term (during construction) and long-term (in service) conditions. The stiffness of the sub-grade is dependent on the moisture content, particularly in fine-grained soils. If an excavation for a road pavement is undertaken during the summer in dry conditions, the stiffness recorded *in situ* may be high, but following construction of the road in service, the moisture content is likely to increase to the equilibrium moisture content – resulting in a reduction in stiffness. Conversely, construction in wet conditions in winter is likely to find lower initial stiffness sub-grade conditions during construction and these may then deteriorate to below equilibrium moisture content stiffness. In this case the material will never recover to a significantly higher stiffness in service.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

There are many possible exploratory and testing methods to investigate the sub-grade, many of which are discussed in Thom (2008), NR/SP/TRK/9039 and IAN73/06, and are not repeated here. As with all ground investigations, the methods should be designed specifically for the ground conditions present. Practical experience shows that it is better for the ground investigation to obtain a large number of relatively simple tests along the route (such as index properties, grading and a simple measure of shear strength) than simply to focus on a small number of advanced laboratory tests to determine stiffness.

Despite significant work carried out in recent years there is no one simple method to determine sub-grade stiffness, either *in situ* or in the laboratory. IAN73/06 suggests several testing methods and specifies the use of the falling-weight deflectometer (FWD) and/or the light-weight deflectometer (LWD) during construction for performance-based design. However, a review of a wide body of data from various LWD development trials on capping materials has shown that the stiffness values determined can vary significantly. This is complicated further by the large number of factors from the material properties and material states that can influence this variability (Lambert, 2007). Similar variability is typical for other *in situ* tests and laboratory testing. It is recommended that a range of testing is carried out to allow correlation between the various methods and a degree of engineering judgement, based on experience, is usually required to determine design stiffnesses.

The requirement to determine the long-term stiffness is also problematic. The long-term stiffness should be based on the equilibrium moisture content – which is the maximum moisture content that is likely to be present during the operation of the pavement. It is possible to undertake testing in the laboratory over a range of moisture contents to reflect the conditions which are likely to be experienced during construction and operation of the pavement. The equilibrium moisture content can also be determined from measurements on a suction plate (Black and Lister, 1979). However, this is not widely undertaken in practice due to uncertainty in the equilibrium moisture content and difficulties of the testing. As a worst case, testing can be carried out on saturated samples, with a common (but unsatisfactory) example being soaked CBR testing. However, this may be too severe and can result in very low results which may be unrealistic. In response to these difficulties, the Highways Agency have produced a table which provides an estimation of the sub-grade CBR value at equilibrium moisture content for various soils (see **Table 76.1**).

These estimates are mainly used for clay soils for which the estimated CBR depends on the plasticity index, the water table, the construction conditions and the thickness of the pavement. **Table 76.1** was originally published in LR1132 (Powell *et al*., 1984) and has been subsequently included in HD 25/94 and IAN73/06 revision 0. Only a brief extract is included in IAN73/06 revision 1, but reference is given to LR1132, which remains an important document for designers to understand the underlying logic and use of this table. The table is widely used in practice to estimate the long-term CBR values for clay sub-grades and has been found to give reasonable results. It

		High water table construction conditions						Low water table construction conditions					
	Plasticity index	Poor		Average		Good		Poor		Average		Good	
Soil	%	Thin	Thick	Thin	Thick	Thin	Thick	Thin	Thick	Thin	Thick	Thin	Thick
Heavy clay	70	1.5	2	2	2	2	2	1.5	2	2	2	2	2.5
	60	1.5	2	2	2	2	2.5	1.5	2	2	2	2	2.5
	50	1.5	2	2	2.5	2	2.5	2	2	2	2.5	2	2.5
	40	2	2.5	2.5	3	2.5	3	2.5	2.5	3	3	3	3.5
Silty clay	30	2.5	3.5	3	4	3.5	5	3	3.5	4	4	4	6
Sandy clay	20	2.5	4	4	5	4.5	7	3	4	5	6	6	8
	10	1.5	3.5	3	6	3.5	7	2.5	4	4.5	7	3	>8
Silt*	–	1	1	1	1	2	2	1	1	2	2	2	2
Sand (poorly graded)	–	20											
Sand (well graded)	–	40											
Sandy gravel (well graded)	–	60											

* Estimated, assuming some probability of material saturating.
Notes: 1. A high water table is 300 mm below formation or sub-formation.
2. A low water table is 1000 mm below formation or sub-formation.
3. A thick layered construction is a depth to sub-grade of 1200 mm.
4. A thin layered construction is a depth to sub-grade of 300 mm.

Table 76.1 Equilibrium sub-grade CBR estimation

needs to be used with caution as there are a number of complicating factors, as follows:

- Plasticity index is determined using samples of material with a grading of less than 425 μm. For well-graded soils which contain both a granular and cohesive fraction such as glacial till, the stiffness is affected by both fractions and the CBR values determined from **Table 76.1** may not be representative for material with a low-fines content.
- Plasticity index results are often variable and the designer must choose a representative value or range of values.
- For low-plasticity soils with a plasticity index of 5 to 10%, the designer must judge if the sub-grade will act as a silt (CBR of 1 to 2%) or a clay (CBR of 2.5 to 8%).
- It is also important to realise that if construction conditions are poor and groundwater is not controlled, the stiffness of fine-grained soil can easily fall below the values in **Table 76.1** and will not fully recover.
- The table also gives CBR values for granular materials which are relatively high and the actual stiffness will depend on the *in situ* density and pore water pressure. However, in practice, the requirement is simply to check if sub-grade remains above a CBR of 15%.

To obtain confirmation of the proposed design, a CBR investigation of an existing pavement of similar construction could be carried out. This approach is not often followed, and the few results obtained tend to show that the standard values are reasonable.

It is important for the designer to check that the original shear strength of the soil is sufficient to deliver the expected equilibrium moisture content CBR value, as construction will usually lead only to a softening below the undisturbed condition. In this regard, a commonly used approach is to apply an approximation for clay soils of CBR = C_u/23 (Black and Lister, 1979), where C_u is the undrained shear strength.

76.7 Other design issues

Once the ground conditions are confirmed, the majority of the design effort is often focused on providing a sufficient construction thickness to prevent (i) sub-grade strength failure; and (ii) excessive sub-grade deformation. Whilst these two failure mechanisms are obviously important, the design should also consider a range of issues as follows.

76.7.1 Materials

The design should carefully consider and specify the materials to be used in the pavement foundation. In particular, the materials specified should suit the ground and groundwater conditions present at the site. This is usually achieved by reference to material types given in standard specifications such as the *Manual of Contract Documents for Highways Works* (MCHW) (Highways Agency, 2009b) and further advice is given in BS 6031: *Code of Practice for Earthworks* (2009). The following examples illustrate a few of the most common issues to be considered.

IAN73/06 offers a reduction in foundation thickness, should a single sub-base layer be used rather than a two-layer sub-base on a capping due to the higher stiffness of the higher-quality sub-base layer. Contractors will generally prefer a sub-base-only solution based on an economic assessment of material costs. In practice, however, for many sites the use of capping is advisable to manage the sub-grade conditions as it is coarser and quicker to construct. This is particularly true where sub-grade conditions are susceptible to changes in moisture content and the capping provides a platform for the construction of the sub-base layer (which is finer and requires more precise construction). IAN73/06 also offers benefits from providing stiffer lime- or cement-stabilised foundations. In practice, it is important to consider whether the ground conditions are well suited to the use of thin sub-base only or stabilised foundation solutions and whether any additional measures (e.g. temporary drainage or modification of stabilisation mix) may be necessary to avoid problems with moisture-susceptible sub-grades.

IAN73/06 performance-based design, together with recent revisions of the MCHW, has opened up the possibility of a wide range of materials to be used in the foundation. This allows a greater potential for the re-use of locally available materials. The capping layer, in particular, is intended to be a locally available material, and the new specification provides greater potential for this to be realised.

The materials need to be selected to ensure that they do not deteriorate under trafficking. This is a common problem for railways, as the ballast is highly loaded due to its position directly under the sleeper, the heavy loading from trains, and mechanical maintenance. The ballast will break down with time and eventually become filled with fines. Once pore water pressures cannot dissipate under loading, track geometry will be affected and the occurrence of wet spots will become a common feature. This is described in NR/SP/TRK/9039 (2005a).

Geotextiles are often incorporated in pavement foundations. The Network Rail standards (see NR/SP/TRK/9039) specify the use of a separating geotextile or geocomposite where there are sub-grade erosion (pumping) issues, which may be used in conjunction with blanketing sand. The use of separating geotextiles is relatively uncommon for road pavements, as sub-grade pumping is usually less of an issue (due to the lower traffic loading and usually better drainage) although it may be considered for particular conditions. Geogrids may be incorporated in pavement foundations, particularly where the sub-grade has a very low stiffness.

Near-surface materials should not be susceptible to frost, and guidance on frost protection is given in IAN73/06. For routine cases, all material within 450 mm of the road surface should be non-frost-susceptible, although this may be reduced if the frost index is low. The frost index is a measure of the severity of a period of cold weather and provides a means of assessing likely penetration of frost into a road.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Environmental issues should be carefully considered when designing pavement foundations. Considering that some 25–30% of all materials extracted from the ground finish up in highways pavements (Thom, 2008), the environmental impact of pavements is clearly significant. Innovation to limit the environmental impact and reduce cost is a key aspect of design. The design life is an important consideration for the upper bound layers, but is not an easy consideration for pavement foundations. For these, it is usually desirable to use locally available materials to reduce transport costs during construction. Recycled materials are also often used, particularly for capping layers in road pavements, and the Highways Agency has made significant steps in recent years to encourage recycling (e.g. the addition of a wider range of recycled aggregates to table 6/1 of the MCHW, and IAN 73/06, which permits a wide range of construction materials).

76.7.2 Drainage

Adequate drainage is of vital importance to the performance of the pavement. IAN 73/06 gives some advice on drainage and states that it should be provided during both the construction and operation of the pavement.

During construction, the sub-grade should be protected to avoid deterioration due to surface water and groundwater. Failure to adopt suitable measures can result in the requirement for extensive additional excavation and replacement below sub-formation, which can significantly add to the construction costs. For moisture-susceptible sub-grades and cutting areas where groundwater is high, deep drainage is often required before the verge to draw down groundwater prior to excavation to sub-formation level. Additional drainage in the centre of the pavement or cross-drains may also be required is some cases. Open excavations may need to be limited, particularly in moisture-susceptible soils. If a drainage layer is present at the base of the pavement foundation, the sub-formation should be sloped so that water can be shed to the sides – to prevent ponding during construction, or entrapment of water in the completed pavement. If the upper pavement foundation layers are also intended to act as drainage layers (e.g. ballast or type 1 sub-base), their base may also need to be sloped.

Drainage during the operation of the pavement should be designed to maintain groundwater level below sub-formation level (earthworks drainage) and to drain water entering the pavement foundation by seepage through the upper pavement layers (pavement drainage). The pavement foundation layers should be constructed with a fall towards the drainage. This is a particularly important consideration for widening projects and a fall should be maintained through the existing and proposed pavement foundation layers to the drains. For these schemes, this can be the governing factor that determines the thickness of the pavement foundation layers.

76.8 Construction specification

The design needs to be adequately presented using drawings and/or a specification to allow construction. Unless the scheme is small and the ground conditions are very well understood, it is likely that the conditions in some areas of the site will be different to that indicated by the ground investigation information. This presents a risk of delays on-site whilst the design is amended, or the risk that the construction will be inadequate for the ground conditions present. This risk can be addressed by adopting a conservative design which will be adequate for most conditions likely to be present, preferably by providing flexibility in the design. The flexibility, where variable site conditions are encountered during construction (or limited pre-construction site data is available), is embodied in the 'observational approach' (Nicholson *et al.*, 1999). A similar methodology has been developed for a number of design-and-build schemes (Gilbert, 2004); it has proved appropriate for large highway foundation areas and allows swift construction. This was achieved by including full details of the design assumptions on the drawings and specification, including:

- pavement foundation layer specifications and thicknesses;
- design sub-grade CBR value or stiffness;
- design sub-grade ground conditions (e.g. clay, sand);
- design groundwater level, if relevant.

A defined regime was also specified, comprising site inspection coupled with rapid *in situ* testing methods to confirm the design assumptions and identify locations where the conditions differ from those expected. Clear procedures were also developed to enable changes to be made on-site, based on the actual conditions encountered. This allows the designer to make realistic predictions of a range of pavement foundation requirements. However, for this approach to work, trust and cooperation are required between all parties (client, contractor and designer) to allow the optimum foundation for the scheme to be built.

The approach given in IAN 73/06 performance-based design is similar to Gilbert's methodology in that the design assumptions must be clearly stated and rapid *in situ* testing methods are used during construction to confirm the design. The potential drawback is that there is no simple, quick procedure to enable changes to be made on-site based on the actual conditions encountered, and as stated in section 76.5.1, additional trials could be required which are likely to have a knock-on effect to programme and cost.

In addition to the issues mentioned above, the drawings and specification should address a number of other issues for the construction, some of which are listed below:

- permanent and temporary drainage;
- measures to protect the sub-grade during construction;
- transition zones, particularly cut/fill intersections, should be given special attention to avoid significant variations in pavement stiffness;
- consideration of consistent ride quality (i.e. minimise changes in foundation along the route).

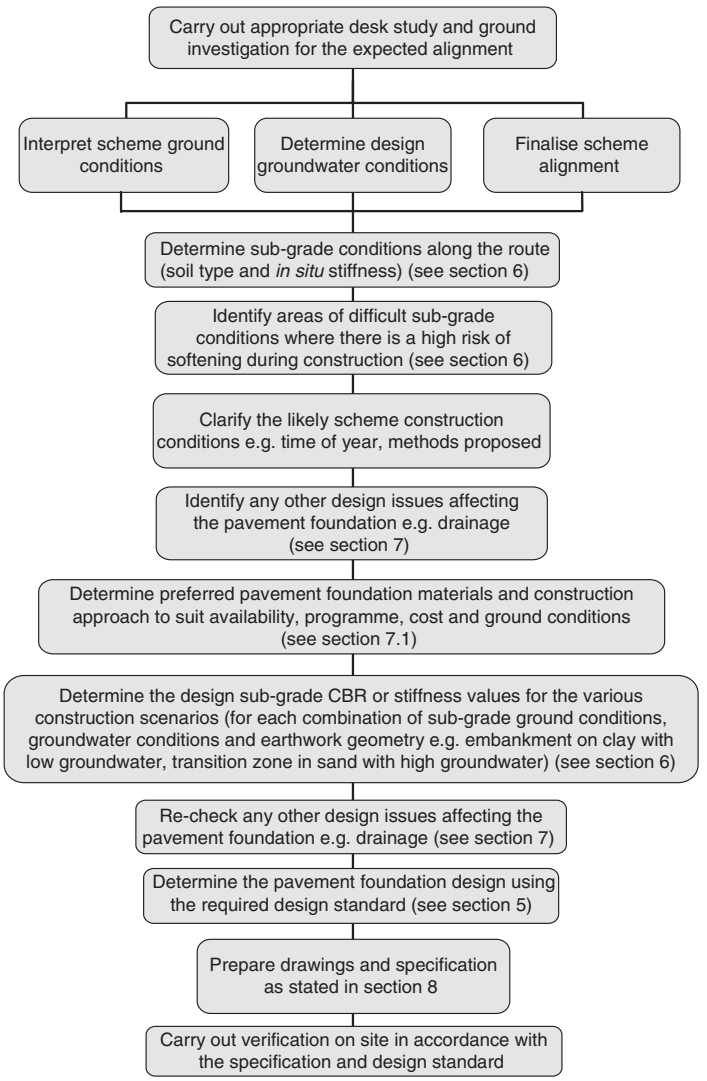

Figure 76.7 Pavement foundation design summary flow chart

76.9 Conclusion

A flow chart summarising the steps required in the design of pavement foundations, described in sections 76.5 to 76.8 above, is given in **Figure 76.7**.

There have been significant recent developments in pavement foundation design, particularly for roads. Whatever method is used for design, it should be remembered that the most important factor is to undertake an appropriate assessment of the sub-grade and groundwater conditions and to develop a design which works for these conditions.

Chapter 77

Introduction to Section 8

Tony P. Suckling Balfour Beatty Ground Engineering, Basingstoke, UK

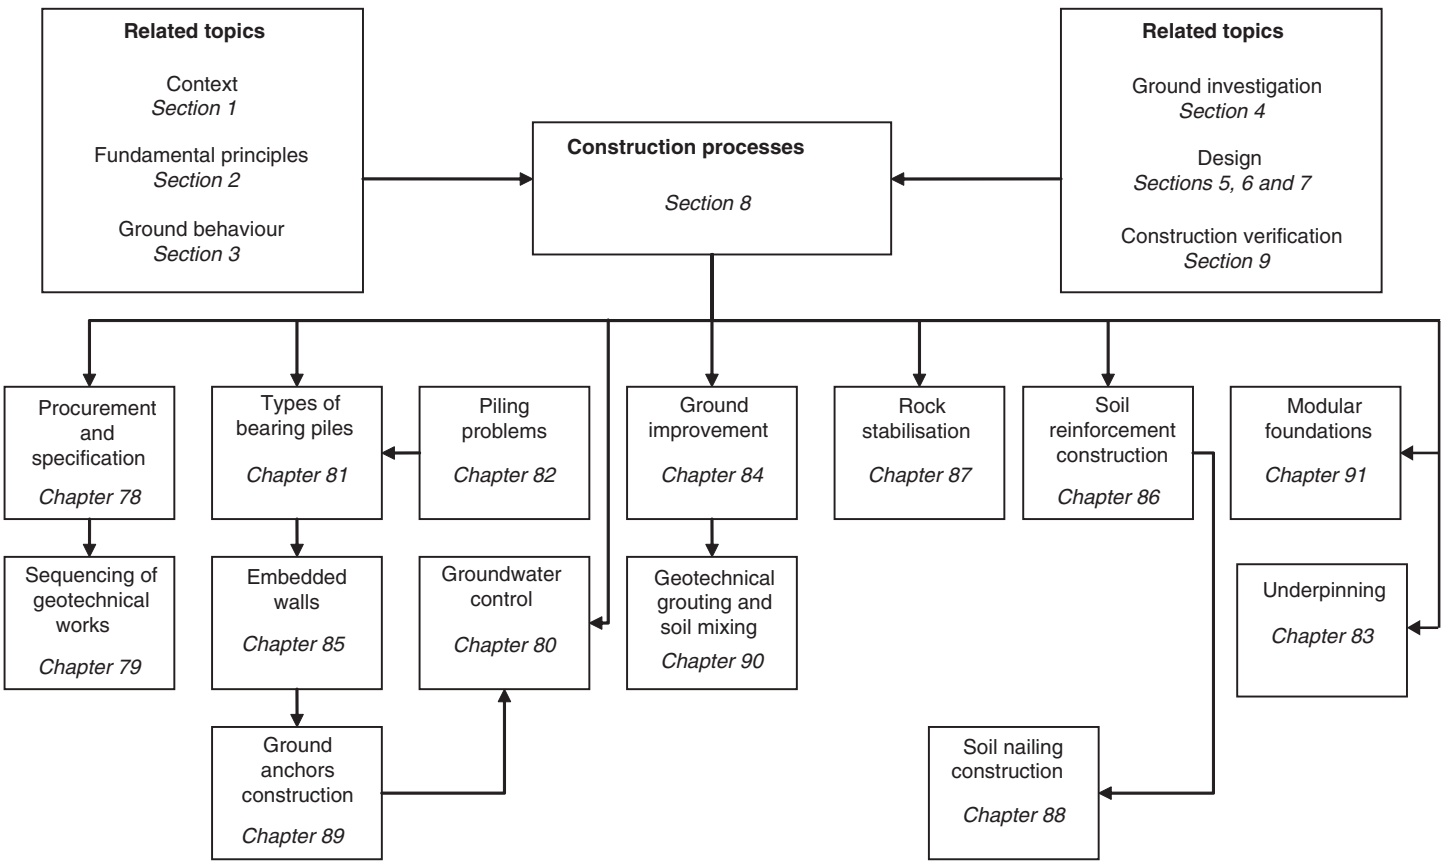

Figure 77.1 Layout of chapters in Section 8

Figure 77.1 outlines the layout and contents of Section 8 *Construction processes*.

Geotechnical engineering is different to most other forms of civil engineering in that it does not deal with man-made materials whose properties and behaviour can be reliably dictated and predicted. Man-made materials such as concrete and steel have been rigorously tested in the past and their engineering properties perfected away from the site environment. A concrete or steel member will perform the same way on different construction projects, provided the same materials are used and the same level of construction workmanship applied.

The ground is not normally man-made and so every construction project will have a unique set of ground conditions, including the groundwater regime. It is this unique combination of ground conditions and the applied load from buildings and structures, which makes geotechnical engineering so fascinating to those who work in the industry, and so frustrating to those who do not. It is no surprise that the biggest risks for new developments are often associated with the ground.

The physical characteristics of the ground need to be investigated for every new development. Geotechnical engineers use a combination of experience, empiricism and idealised engineering models to try to best predict the ground behaviour and its unique interaction with a new building or structure. This is as important for the practical aspects associated with construction as it is for design.

Ground behaviour is implicitly linked to the geotechnical construction process, for example a bored pile of a certain length will have a different load capacity to a driven pile of the same length. Consequently in geotechnical engineering

the design cannot and must not be divorced from the construction process. It is common in geotechnical engineering for specialist sub-contractors to offer both a design and construction service because of this. If the design is carried out by a party different from that undertaking the construction then the geotechnical designer must communicate the needs of the design to the contractor, and the contractor must communicate the construction process to the designer, so that both parties can ensure that design and construction are compatible with each other. This lack of compatibility is frequently the cause of disputes.

There are many different geotechnical construction processes, and even the same process can be undertaken in many different ways. Any process may be perfectly safe on one site, but have a very high level of risk on another. A process may also not be technically or practically possible in some ground conditions or site environments. It is recommended that during design development and the tender process for any new development, experienced geotechnical designers and experienced geotechnical contractors are brought together to ensure that the proposals are both viable and technically sound. It is essential that the final process is monitored during construction so that the impact on the design of any unforeseen changes in ground conditions can be appropriately managed.

For those who are not experienced in geotechnical engineering the best advice is to get yourself specialist advice. There are many geotechnical consultancies, specialist contractors and trade organisations available to provide expert advice and services. A failure to take specialist advice is fraught with danger due to the reasons described above. Beware of the World Wide Web; although there is a plethora of information available on the internet it should be used with caution due to the unique nature of every ground-engineering project.

Section 8 *Construction processes* describes the most common geotechnical processes in use today. Note that there are some very specialist processes, which are not covered here, for example ground freezing. The processes that are covered are introductions for the reader but they are absolutely not a replacement for specialist advice. This section does not consider design, which is covered in other sections. The exception is Chapter 80 *Groundwater control*, as the design of such systems is not described elsewhere in this manual.

78.1	Introduction	1161
78.2	Procurement	1161
78.3	Specifications	1163
78.4	Technical issues	1164
78.5	References	1165

Each construction project will have a unique set of ground conditions to be considered, and it is this unique combination of ground conditions and future applied loadings which presents the most risk for new developments. Consequently the procurement process which defines the scope of work, allocates responsibilities and risk, and chooses the contractor to do the work, is critically important. The specification which defines the minimum standard of the work is a key tool in ensuring a successful outcome. Tender documents and submissions need to be clear and non-contradictory, and the tender negotiation process must be managed to ensure that the chosen contractor has the necessary skills and tools to undertake the work in the prevailing ground conditions without unduly affecting the design. There are many forms of contract and sub-contract used in geotechnical construction, but none has been designed specifically for such specialist works. A common problem with geotechnical construction is identifying who is responsible at interfaces between different elements of work. Works at such interfaces must be clearly allocated in the contract documents, especially when one party will be relying upon another to supply a service. Enabling works can have a significant impact on geotechnical works.

78.1 Introduction

Each construction project will have a unique set of ground conditions to be considered, including the groundwater regime. It is this unique combination of ground conditions and future applied loadings (from the building or structure) which present the most risk for new developments. Consequently the procurement process which defines the scope of work, allocates responsibilities and risk, and chooses the contractor to do the work, is critically important. The specification which defines the minimum requirements for the work is a key tool in ensuring a successful outcome.

78.2 Procurement

Ground behaviour is implicitly linked to the geotechnical construction process being used. Consequently in geotechnical engineering, design cannot (and must not) be divorced from the construction process being used. Because of this, it is common in geotechnical engineering for specialist sub-contractors to offer both a design and construction service. If the design and the construction are being carried out by different parties, the geotechnical designer must communicate the needs of the design to the contractor, and the contractor must communicate the construction process being used to the designer. This is to ensure that design and construction are compatible with each other. Lack of compatibility and appropriate communication is frequently the cause of disputes.

There are various forms of procurement and employers have their own preferences. In general, the forms of procurement are:

- competitive tender – cheapest price;
- competitive tender – best value;
- preferred supplier;
- partnering arrangement.

After a competitive tender process, ‘cheapest price wins’ is the most common method of procurement in construction. However, most disputes over geotechnical works are associated with this method due to the inherent risks and uncertainties of working with the ground. Most experienced geotechnical engineers are not keen on this system; they can foresee that ground-related problems will necessarily increase their costs, and so are unlikely to offer the cheapest price and be successful.

The disadvantages of cheapest-price competitive tendering for geotechnical works can be overcome if the tenders are not assessed on cost alone. Other aspects to be considered may include construction experience in the appropriate ground conditions, design experience in the appropriate ground conditions, safety records, quality systems, plant reliability, and the ability to offer other solutions if unforeseen conditions were to arise. This is known as ‘best value’.

Some employers have their own preferred supply chain, which comprises organisations that meet criteria that they have decided are important. These criteria vary and may include safety records, quality assurance (see Chapter 93 *Quality assurance*), relevant experience, design capability and environmental systems. The scope of the works is identified and the preferred supplier provides the works. The costs for doing the work may be agreed by a competitive tendering process or by direct negotiation.

Larger employers who undertake construction works on a regular basis may enter into a partnering arrangement with a preferred supplier. Again, the scope of the works is identified and the preferred supplier provides the works. The costs for doing

the work are likely to have been agreed by negotiation and if the scope of the work changes, the cost implications and associated responsibilities will already have been identified in the arrangement. The advantage of this form of procurement is that the risks are normally identified and allocated early in the process.

Chapman (2008) states that geotechnical mitigation is better than the management of risks by contingency, and hence argues strongly against awarding a tender on cost rather than on the quality of the design and construction.

A modern approach for large projects has been to assess tenders on a declared split between cost and quality. This may be, say, 80% on cost and 20% on quality, but for complex projects it has been known to be 20% on cost and 80% on quality. However, this process of assessing the tenders is undermined if the assessment of quality is not considered in enough detail to prevent all the tenderers from gaining a similar score.

78.2.1 Tender process

The employer, i.e. the body that is funding the work, normally needs to appoint a professional team that comprises someone on their behalf to look after the technical aspects of the work (normally the engineer) and someone to look after the commercial aspects of the work (normally the quantity surveyor), as a minimum. A document describing the employer's requirements is produced and normally the engineer then designs the building or structure to meet these requirements.

Bills of quantities are then prepared, normally in conformity with a standard method of measurement, approved for use with the relevant form of contract. However, some of the provisions of these standard methods are not well suited to geotechnical processes and need to be amended. The type and number of amendments vary according to the specific requirements of the geotechnical work, the ground conditions, and for each type of construction process. Quantities of geotechnical work should always be billed as 'provisional' and measured and valued as 'executed', since it is only in exceptional circumstances that the ground is homogenous enough that the design quantities will be precise. There will normally be variations or additions to the design quantities, which should be anticipated and allowed for.

The employer's requirements: the bills of quantities, a description of the works (normally as drawings), a specification describing the minimum standard of work that will be acceptable, contract conditions and information on the expected ground conditions are then provided to prospective contractors with an invitation to tender.

The contractor will normally provide a tender, but it is often not fully in accordance with the original documents. Technically this counter-offer may be for a different standard of work, or a different construction process. Commercially, this counter-offer may be for a different level of risk or responsibility. Whatever the basis of the counter-offer, it is key that the professional team understands what is different, the reasons for the differences, and the impact these may have. The process of post-tender negotiation and agreement is especially important for geotechnical works as every project will be dealing with a unique set of ground conditions. If the professional team does not include a geotechnical advisor, as defined by the ICE site investigation steering group, then one should be considered.

78.2.2 Tender documents and submissions

A more detailed list of the documents which would normally form part of a contract is given below, but it is not intended to be comprehensive. This is to give the reader an indication of what is likely to be needed for complex geotechnical works where specialist advice must be taken.

The Form of Tender (a formal bid for the work) should include the period for which the tender is valid, who is engaged to supervise the works, and the results of any relevant on-site testing.

General and project-specific specifications should be provided, including either a tender schedule or the performance criteria which the design needs to achieve. If the contractor is required to design the works, this should be expressly stated.

Drawings should include details of underground services, existing structures and other known obstructions. Site-specific information and ground investigation data should include existing ground levels, ground levels at borehole and other test positions, and a drawing showing the positions of such boreholes relative to the outline location of the works.

The conditions of contract should also include the location of the site and access to it, any limitation on working hours, any special conditions limiting noise and vibration or other environmental constraints, any phasing of the works, and the available working and storage areas.

In the case of sub-contract documents, any known special conditions or restrictions should be described, and information on such matters as insurances, retention, liquidated damages, program requirements and bonds should be provided. The bill of quantities and the form of acceptance are also required.

The tender offer should include a method statement giving a description of the proposed type of equipment to be used for the execution of the works, the method of construction and any assumptions made. Also needed are an estimate of the time required for completion of the design, the period of notice required before commencement, and the contract period for working.

Part A of the Institution of Civil Engineers' *Specification for Piling and Embedded Retaining Walls* (ICE, 2007) gives details which are relevant to deep foundation works.

78.2.3 Common forms of contract

Contractors may be invited to tender to an employer using one of the established forms of contract, or a contract document drawn up especially for management-type contracts. There are four basic types of contractual arrangement under which construction work may be undertaken:

(i) Civil engineering works with an engineer responsible to an employer for design and supervision.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(ii) Building works with an architect responsible to an employer for design and supervision, advised by an engineer who may also be responsible to the employer for structural engineering elements of the works but who has no formal status under the conditions of contract. Under such a contract, it is desirable that the architect authorises an experienced geotechnical engineer to act as his representative in connection with the geotechnical works.

(iii) Building or civil engineering works with a contractor responsible to an employer for design and construction. The contractor may appoint an engineer to undertake the engineering duties appertaining to the geotechnical works, or may entrust those duties to a suitably qualified engineer of his own.

(iv) Building works with an architect responsible to an employer for design and supervision, but having no engineering advisor. The architect should consider the responsibilities which devolve upon him in these circumstances and should recognise that such an arrangement may not be in the best interests of either the employer or himself. This is not recommended for complex geotechnical works.

Part A of the *Specification for Piling and Embedded Retaining Walls* (ICE, 2007) gives further details relevant to deep foundation works.

78.2.4 Common forms of sub-contract

The use of specialist sub-contractors is very common for geotechnical works and such organisations often offer both a design and construction service. Sub-contract tenders for geotechnical works may be invited in the following ways:

(i) Tenders may be invited from specialist contractors for nomination as a sub-contractor; in such cases it is normal for a prime cost item to be included in the main contract bills of quantities. It is necessary to ensure that the specification and other relevant items from the sub-contract documents are included in the main contract tender documents – so that tenderers for the main contract are aware of, and can price for, their responsibilities to and their attendance on the sub-contractor. Equally, the sub-contract tender documents should include information regarding the form of the main contract, including the appendix to the contract, and sufficient detail to ensure that the sub-contractor is aware of their responsibilities and liabilities at the time of preparing the tender.

(ii) The geotechnical works may be measured and included in the bills of quantities for the main contract, and the document may stipulate that these works shall be executed by any one organisation from an approved list of contractors. The contractor may have the option of proposing further companies for approval.

(iii) The geotechnical works may be measured and included in the bills of quantities for the main contract, but without any list of approved sub-contractors. In such cases, the contractor will seek prices from their own selection of sub-contractors, for whom it is normal practice to seek approval before they are employed.

(iv) Following appointment, the contractor may be instructed to carry out additional works not included in the contract. Should this additional work include geotechnical work, tenders for such works will normally be invited from a list of companies agreed by the contractor and the engineer. It is most desirable that the tender document should be approved by the engineer before enquiries are issued.

With procedures (ii), (iii) and (iv), the selected sub-contractor is normally appointed as a domestic (direct) sub-contractor of the contractor.

Part A of the *Specification for Piling and Embedded Retaining Walls* (ICE, 2007) gives further details relevant to deep foundation works.

78.3 Specifications

78.3.1 Model specifications

There are many specifications published for use with specialist geotechnical works and most are updated on a regular basis; some examples follow.

78.3.1.1 Execution codes

BS EN 1536 *Execution of Special Geotechnical Work – Bored Piles* (BSI, 2000d)
BS EN 1537 *Execution of Special Geotechnical Work – Ground Anchors* (BSI, 2000b)
BS EN 1538 *Execution of Special Geotechnical Work – Diaphragm Walls* (BSI, 2000a)
BS EN 12063 *Execution of Special Geotechnical Work – Sheet Pile Walls* (BSI, 1999)
BS EN 12699 *Execution of Special Geotechnical Work – Displacement Piles* (BSI, 2001)
BS EN 12715 *Execution of Special Geotechnical Work – Grouting* (BSI, 2000c)
BS EN 14199 *Execution of Special Geotechnical Work – Micropiles* (BSI, 2005b)
BS EN 14731 *Execution of Special Geotechnical Work – Ground Treatment by Deep Vibration* (BSI, 2005a)

78.3.1.2 Specifications/codes of practice

American Petroleum Institute Specification for Line Pipes 5L (API, 2004)
BS EN 12794 Precast Concrete Products, Foundation Piles (BSI, 2005c)
BR 391 Specifying Vibro-Stone Columns (Building Research Establishment, 2000)
BR 458 Specifying Dynamic Compaction (Building Research Establishment, 2003a)

BR 470 Working Platforms for Tracked Plant (Building Research Establishment, 2004)
BRE 479 Timber Pile and Foundations (Building Research Establishment, 2003b)
ICE Specification for Piling and Embedded Retaining Walls ICE, 2007)
ICE Specification for Ground Treatment (ICE, 1987)

78.3.2 Design responsibility

The model specifications described above are written to be used in conjunction with all forms of contract. Hence they do not state who should have design responsibility and consequently this must be clearly stated in the contract documents.

In most cases, the engineer will design the superstructure and the part of the sub-structure which is above ground – which may include spread footings, pile caps and ground beams. A specialist sub-contractor or trade contractor will normally be asked to design the specialist geotechnical element of the works, such as the piling, ground treatment, grouting or embedded retaining wall. The engineer will nevertheless be expected to take overall responsibility for the sub-structure design and, in some cases, may be required to adopt any contractor design elements. Where the design roles are thus split, clear communication of all the design requirements is essential.

In certain circumstances the engineer may consider that it is preferable to design the complete foundation. This is usually in more complex circumstances, such as slope stabilisation, or where the geotechnical works will interact with other structures such as existing tunnels, or where it may be difficult to define the constraints adequately.

A good example is *Specification for Piling and Embedded Retaining Walls* (ICE, 2007) which requires an explicit award of responsibility for the design of the piles and foundation, and for the construction method.

78.4 Technical issues

78.4.1 Common engineer/main contractor issues

Below is a list of the issues that regularly cause dispute between the engineer and the main contractor. These are best prevented by early appointment of the contractor so that he can work with the engineer and influence the design during its development. In the absence of construction advice during the design process, the engineer may find that:

- his design is not practically buildable;
- his design is not safe to build;
- his design does not consider the latest technologies;
- instrumentation is not installed correctly or timely;
- monitoring of instrumentation is not carried out.

78.4.2 Common main contractor/sub-contractor issues

Below is a list of the issues that regularly cause dispute between main contractor and sub-contractor, and these are best prevented by early appointment of the sub-contractor and clear discussions regarding responsibilities and reliance:

- site not ready for sub-contractor upon arrival;
- working platform not adequate for the specialist plant;
- working platform not adequately maintained during the geotechnical works;
- below-ground obstructions either not removed, or removed causing disturbance to the ground or adjacent structures.

78.4.3 Common sub-contractor/sub-contractor issues

Below is a list of the issues that regularly cause dispute between the sub-contractors or trade contractors on a site. These are best prevented by getting the sub-contractors involved in the geotechnical work, or works associated with it, together soon after their appointments and discussing and agreeing interfaces and responsibilities. The contractor needs to appoint someone to manage these sub-contractors as they are likely to be relying on the services of others. Leaving sub-contractors working alone on a site is not acceptable, and disputes often arise when this happens. The list of issues is as follows:

- one sub-contractor is late, thereby delaying another sub-contractor;
- several sub-contractors need to use the same part of the site at the same time (including deliveries, use of tower cranes);
- one sub-contractor's design is not compatible with another's design;
- one sub-contractor's product is not compatible with another's product;
- when something goes wrong, all the sub-contractors blame each other and none can be proven to be responsible.

78.4.4 Preparation for construction

Specialist geotechnical works often require the use of specialist plant and the loadings these may apply to the ground may be considerable. The working platform is a key item of temporary works, and responsibility for its design, specification, construction, maintenance and repair must be clearly allocated. There have been fatal consequences from an inadequate working platform in the past. Guidance for piling platforms is provided in BRE report BR470 (Building Research Establishment, 2004).

Responsibility for identifying and removing obstructions in the ground needs careful consideration. Normally, shallow obstructions can be safely removed unless there are sensitive structures nearby. It may not be possible to remove deeper obstructions practically or safely, and hence these will have an impact on the design and construction of the geotechnical works. It may also not be possible to identify all obstructions in the ground, and the risks associated with these should be considered carefully.

Where obstructions have been removed from the ground, the geotechnical designer needs to take account of the methods used and any impact on their design or on adjacent structures both above and below ground. Backfilling of removed obstructions

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

needs to be a controlled procedure using materials and methods that do not unduly affect other works.

Unexploded ordnance in the ground is often a real hazard and should be investigated on most sites. Expert advice is provided in CIRIA report C681 (Construction Industry Research and Information Association, 2009).

To achieve the safety and technical requirements of geotechnical works, it is imperative that a sequence of working is agreed prior to commencement and is subsequently adhered to by all the organisations working on a project at the same time. When agreeing the sequencing, the role of the main/management contractor is crucial – they are likely to be the only party with an understanding of the overall construction sequence and the roles and responsibilities of each organisation on site. The main/management contractor needs to understand each organisation's ideal method of working to achieve their own particular safety and technical requirements. If, as is common, many organisations on a site interact with each other or are reliant on one another, the main/management contractor must help these organisations to modify their ideal method of working without compromising safety or technical requirements. Geotechnical design often requires a particular construction sequence to be followed or else the design is invalidated and the geotechnical works may not progress to plan; this would introduce another complication which would need to be managed by the main/management contractor.

79.1 Introduction

Every construction project will have a unique combination of particular contractors, sub-contractors, processes, products and materials on site. Geotechnical engineering is a specialist aspect of civil engineering and so is normally undertaken by specialist organisations. The geotechnical works need to be undertaken safely and achieve all the technical requirements. The safety of on-site personnel and the public is paramount, and the integrity of works by others (existing, new or proposed) must not be compromised.

It is common for the geotechnical works to be undertaken by one or more specialist organisations under the control of a main contractor or management contractor. This leads to two separate construction sequencing issues: the overall project construction sequence and the specific task construction sequence. To achieve the safety and technical requirements it is imperative that a sequence of working is agreed prior to commencement and then adhered to by all the organisations working on a project at the same time. When agreeing the sequencing, the role of the main contractor or management contractor is crucial – they will have responsibility for the overall project construction sequence. They are likely to be the only party on site with an understanding of the overall construction sequence and the roles and responsibilities of each organisation on the site. The main/management contractor needs to understand the ideal method of working for each of these organisations to achieve their own particular safety and technical requirements, and to investigate if any of the organisation's methods of working will impact on one another. If, as is common, many organisations on a site interact with each other or are reliant on one another, the main/management contractor must help these organisations to modify their ideal method of working without compromising safety or technical requirements.

Specific task construction sequences are generally better defined and controlled. In geotechnical works, each specific task sequence is generally the responsibility of one contractor who is experienced in the activity. Detailed method statements and risk assessments are carried out. It is hard to control the interaction and impact of specific task construction sequences on each other. A relatively minor change in the sequence of one task may have a significant impact on the overall process.

Geotechnical design often requires a particular construction sequence to be followed or else the design is invalidated and the geotechnical works may not progress to plan; this would introduce another complication which would need to be managed by the main/management contractor. The geotechnical designer needs to appreciate the constructability constraints in the design. If this is not the case and the contractor finds that the particular construction sequence cannot be followed due to practical or technical reasons, or due to safety concerns, then the work must cease and the sequence and design must be suitably modified before the works recommence.

79.2 Design construction sequence

Geotechnical design is dependent on a number of different factors; many of these are not exact and are based on the best available knowledge. Examples include assumptions about the ground conditions, the previous usage of the site, the groundwater regime and the type of construction methodology. It is important that all concerned understand any assumptions made in the design construction sequence, so that they are in a position to assess the impact of any changes during construction.

In order to accommodate unknowns or variables (due to the very nature of working with the ground), the geotechnical design would normally require one or more of the following to

be carried out on site: observations, monitoring, investigation, testing, and reported back to the designer to check the validity of the design. If the contractor chooses to deviate from the design construction sequence, either by choice or due to a lack of site control, it is likely that the design will be invalidated and the works will not progress to plan.

The geotechnical designer should have sufficient appreciation of the capabilities and limitations of the construction process, products and materials so that it is not unreasonable to expect the particular construction sequence assumed in the geotechnical design to be closely followed by the contractor. In reality, this can actually be difficult to achieve as many specialist geotechnical contractors use proprietary systems, and if the procurement process and contractual arrangements do not appoint the contractor before the design is finalised, then the design requirements may not be compatible with the contractor's capabilities or requirements. If the contractor finds that the particular construction sequence used in the design cannot be followed due to practical or technical reasons, or due to safety concerns, then the sequence and the design must be suitably modified before the works commence.

To best communicate the construction sequence between designer and contractor, a detailed drawing is recommended (see **Figure 79.1**). Geotechnical design is generally concerned with excavation into the ground or building on top of the ground. To this end, design construction sequences are generally two-dimensional drawings showing the maximum excavation or construction level for each phase. It is important not to overlook the plan constraints of the site works.

79.3 Site logistics

Site logistics are crucial in determining a successful construction project. There would be constraints on a very small site where plant movement is very limited, and on a large site where plant movement is a significant element in the programming of the project. The type of specialist plant available and how the plant can be moved may be an integral part of the overall solution. Contractors may organise work around available plant, which is difficult to plan during the design phase of contracts. However, it is important that allowance is made during design to cater for the most likely option. On particularly complex projects, advice should be taken from various specialist contractors to establish likely construction methodology.

Site logistics need to be planned to follow the specific design requirements of each element. For example, it is no use designing a complicated conveyor system to move spoil from a tunnel excavation if this does not fit around the propping system in the excavation at the tunnel portal.

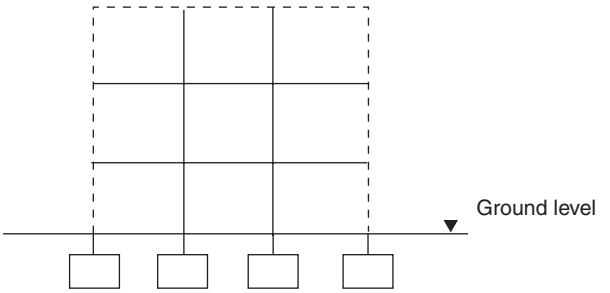
Specific task sequences have to fit within the overall project sequence. The site logistics for specific activities are easier to plan than those for the overall project. Specific activities generally lie with one contractor, who is fully aware of their own plant requirements and limitations. For example, following the construction of a section of retaining wall, excavation may be required to proceed as quickly as possible in front of the wall. One aspect to consider in how quickly this can happen is the movement of plant around the site. One contractor may be responsible for the wall construction and another for the excavation. The full sequence of working can only be developed when the plant and site logistics of each element are understood. If these logistics require a change to the designed sequence, it would necessitate a redesign and may impact many activities.

Minimum working areas must be defined for each contractor working on the site. In addition, access to each work site area has to be clearly agreed between all parties. Construction sites are, by definition, constantly changing and developing. It is important that drawings showing the working space requirements for each contractor are prepared and agreed by *all* parties involved. These will have to be prepared on a regular basis to reflect the changing nature of the site (see **Figure 79.2**). It is common for site logistics to be drawn in plan but the vertical excavation or construction should not be ignored in these drawings.

79.4 Safe construction

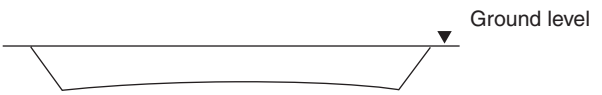
Health and safety in geotechnical engineering is described in Chapter 8 *Health and safety in geotechnical engineering*.

Generic and specific risks and hazards need to be identified for both the specific and project construction sequences. Each contractor is responsible for establishing the hazards and risks for the activities they are undertaking, and also for the residual risks they find on arrival, and those they hand on to any follow-on contractor.



Geotechnical works are increasingly being carried out on brownfield sites which have had one or more previous uses. Any construction sequence undertaken needs to take into account this previous usage.

Every contractor needs to assess the generic hazards and their control or mitigation measures for the specific characteristics of the site, and also to identify site-specific hazards and carry out a risk assessment for these, see **Table 79.1**.



Part of the site-specific risk assessment process is to identify if the proposed construction works or their sequence causes a hazard to others. It is common for the geotechnical works to be undertaken by one or more specialist organisations under the control of a main contractor or management contractor. To achieve the safety requirements it is imperative that a sequence of working is agreed to by all prior to commencement on site, and then adhered to by everyone working on a project at any one time. When agreeing this sequencing, the role of the main contractor or management contractor is crucial; they are likely to be the only party on site with an understanding of the overall construction sequence and the roles and responsibilities of each organisation on the site. The main/management contractor needs to understand the ideal method of working for each of these organisations and then to investigate if any of the organisation's methods of working will impact on one another. If, as is common, many organisations on a site interact with each other or are reliant on one another, the main/management

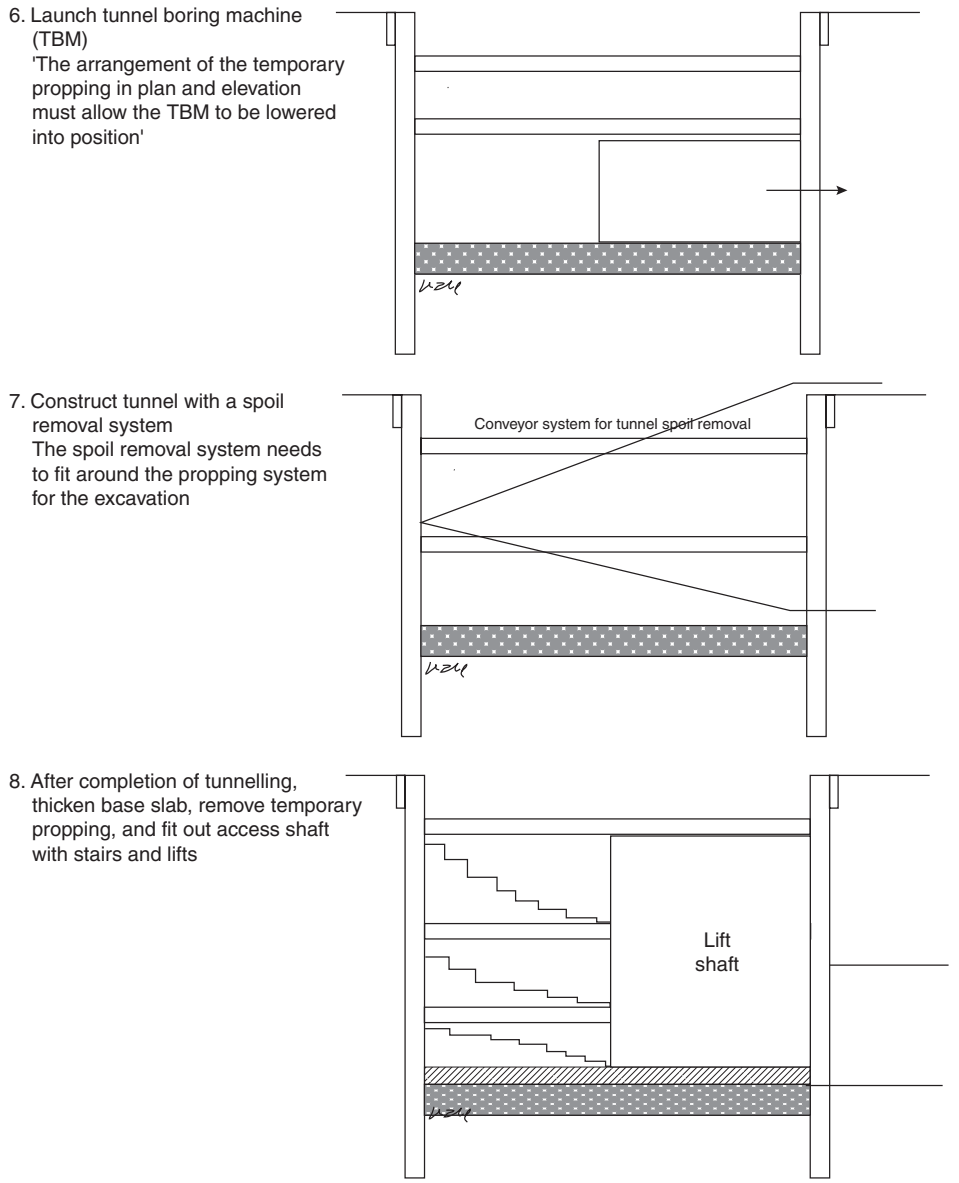

Figure 79.1 (Continued)

contractor must help these organisations to modify their ideal method of working to achieve a maximum level of safety.

79.5 Achieving the technical requirements

Geotechnical engineering is complex. The following technical requirements are often key components of the design and construction process:

- Installation method must not cause significant ground disturbance or movement and so invalidate the design (see **Figure 79.3**).
- Construction method must not be a nuisance, e.g. too noisy.
- Construction method must not cause damage to existing buildings or structures, either above or below ground, e.g. by causing too much vibration.
- Plant must not be too heavy or work in a way that could cause damage to underground structures or services, or to newly-constructed works.
- Sequencing of plant within temporary works needs to be carefully planned so that plant has sufficient and safe working areas, and temporary works continuously fulfill their function.
- Stockpiling of materials is done in a way that ground movements resulting from the applied surcharge to the ground do not damage existing buildings/structures or newly-constructed works.
- Construction method may cause softening or instability of the ground if work progresses too slowly.
- Construction method may cause premature failure of the ground if work progresses too fast.

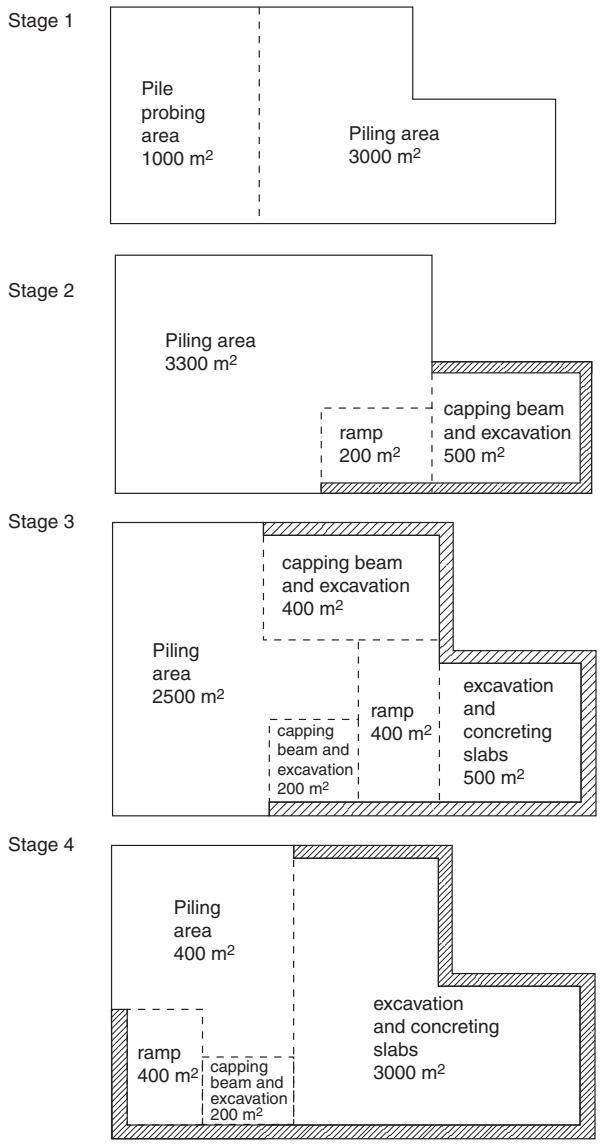

Figure 79.2 Example of typical working areas for a basement construction

- Follow-on works are planned in a way not to cause damage to the geotechnical works.

The relevance of each of these depends on the actual ground conditions, the geotechnical solution being adopted, the construction method being used and the design philosophy. Hence, geotechnical specialists are needed to assess each of these and communicate their findings to the professional team as an integral part of the design and construction process. The impact of one element of works on another, either generally or at interfaces, needs to be carefully considered.

79.5.1 Piling works

The following list is not exhaustive and there are many more examples of achieving the technical requirements for piles. Similar lists could be produced for all geotechnical processes.

- In ground conditions containing hard layers, the rotation of continuous flight augers (CFAs) can cause significant smearing of the bore, or induce ground movements invalidating the pile design.

Figure 79.3 Piles which have been affected by moving ground

Hazard	Likely consequences if hazard arises	Impact rating	Likelihood	Severity rating before mitigation (impact × likelihood)	Mitigation measures	Impact rating	Likelihood	Severity rating after mitigation (impact × likelihood)
	Risk of injury to either contractors' personnel	5	3	15		5	1	5
One contractor working in close proximity to another contractor	Risk of damage to plant	3	3	9	Provide barriers between work areas, exclusion zones within work areas and pedestrian access around the work areas	3	1	3
	Risk of damage to work done	3	3	9		3	1	3

Table 79.1 Example of how a generic risk assessment has been modified to take account of others on site concurrently. Ratings and likelihoods vary from 1 (low) to 5 (high)

- The driving of piles may be too noisy at the site boundary.
- Piles may be too close together: during construction of a new pile, a recently constructed one is damaged.
- Bearing pressures from piling plant on a working platform overlying a soft sub-grade may damage recently concreted piles.
- Piling plant working within temporary propping to basement walls has to be carefully designed and planned, with the props being removed and replaced in a controlled sequence.
- Stockpiling of fill material to form a piled embankment over soft clay is done in a limited way, so that ground movements resulting from the applied surcharge to the ground do not damage the piles.
- The time between boring and concreting a pile is to be minimised.
- Loading of a test pile in chalk should be undertaken in small increments.
- Trimming piles is to be carried out in a way so as not to cause damage to the piles.

79.6 Monitoring

It is often necessary for a geotechnical solution to be monitored during construction and maybe in the long term as well. The monitoring can be to confirm design assumptions or can be an integral part of the design, for example when filling for an embankment or when the observational method (see Chapter 100 *Observational method*) is being used.

The instrumentation should be installed prior to construction so that baseline readings can be established. The instruments and their cabling must be protected during construction, and the construction methods and sequencing should take this into consideration. Unfortunately this is often not the case.

79.7 Managing changes

Ground conditions are rarely homogeneous and are seldom investigated in enough detail prior to construction. Consequently it is common for the ground conditions to be slightly (or sometimes significantly) different to that expected. When this occurs, everyone involved comes under commercial pressure to provide an appropriate solution. In these circumstances, it is important to ensure that the changed sequencing of the geotechnical works still achieves the aforementioned safety and technical requirements.

It is common for an accident or technical problem to be related back to a change in circumstances on the site, which may be a change in ground conditions or in something else.

When on site, one should be aware that not everyone may actually follow the previously agreed method of working, either for good reason or for no reason at all.

There are always changes on site and it is difficult to ensure that all involved have reassessed their works and their impact on others. However, it is imperative to do so. A common problem occurs when a change is made to a specific task sequence, making it more efficient and cost effective. Checks may be made to show that the change in sequence has no impact on the design of that specific task. However, if this necessitates significant changes to the follow-on construction sequence (to ensure the design is valid) then the sequence should not be changed without the agreement of all the parties involved.

79.8 Common problems

Below are some specific problems that commonly occur on complex urban geotechnical projects.

(i) Poor quality material is used to backfill old foundations that have been removed, leading to excessive concrete overbreak on a new embedded wall installed along the line of the old foundations, which then has to be laboriously chiselled back to meet the requirements of the specification.

(ii) A ramp into an existing basement or excavation to allow a piling rig to access and egress to undertake piling from the base of the excavation normally needs to be at a slope of less than 1 in 10. Hence such a ramp needs to be over 100 m long for a 10 m deep excavation. It is often more practical to temporarily backfill an existing basement to allow new piling, but this may then require coring through any basement slab, or the breaking out of holes in the slab prior to backfilling.

(iii) Top-down basement construction can often be beneficial on congested sites, as one can then win back new laydown areas for materials and space for plant. For tall structures, top-down construction provides a shorter program; for smaller structures it may provide the only practical and safe method of construction.

It is recommended this chapter is read in conjunction with

- Chapter 8 *Health and safety in geotechnical engineering*
- Chapter 67 *Retaining walls as part of complete underground structure*
- Chapter 94 *Principles of geotechnical monitoring*
- Chapter 96 *Technical supervision of site works*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

80.8	References	1189

Groundwater control encompasses the range of temporary works techniques used to allow below-ground construction projects to be carried out in dry and stable conditions. Two principal approaches can be used: groundwater control by pumping (also known as construction dewatering), which involves pumping from an array of wells or sumps to lower groundwater levels in the vicinity of an excavation; or groundwater control by exclusion, which relies on low permeability cut-off walls around the excavation to prevent or reduce groundwater inflows.

80.1 Introduction

Groundwater control may be required as part of the temporary works for below-ground construction projects, in order to provide dry and stable working conditions. Groundwater control can be achieved by pumping (using a group of techniques known as construction dewatering). In this approach water is pumped from an array of wells or sumps, to lower groundwater levels in and around an excavation. Alternatively groundwater can be controlled by exclusion, where low permeability cut-off walls are installed around an excavation to prevent or reduce groundwater inflows.

80.2 Objectives of groundwater control

The occurrence and control of groundwater is fundamental to geotechnical engineering (see Chapter 16 *Groundwater flow*). Where groundwater is encountered during excavation, problems can occur either in terms of flooding of the excavation, or in the form of instability induced by its presence. Groundwater control can be defined as the range of activities used to allow construction work to proceed at depths below groundwater level.

The most obvious (but not necessarily the most important) objective of groundwater control is to prevent an excavation below the natural groundwater level from flooding. However, especially in fine-grained soils of low to moderate permeability (such as silts or silty sands) another objective is to avoid groundwater-induced instability of the excavation by controlling pore water pressures and hence effective stresses around the excavation. In these soils, the pore water pressures associated with even very small seepages into the excavation can cause serious instability. It is not always understood that in fine soils the objective of groundwater control is to control pore water pressures to ensure stability, and not to literally 'dewater' the soil.

Basic soil mechanics theory (see Chapter 15 *Groundwater profiles and effective stresses*) states that soil behaviour is controlled by the effective stress σ', which is related to total stress σ (due to external loads) and the pore water pressure u by Terzaghi's equation:

$$\sigma' = \sigma - u \tag{80.1}$$

The shear strength τ_f of a soil depends on the normal effective stress, according to the Mohr–Coulomb failure criterion:

$$\tau_f = \sigma' \tan \phi' \tag{80.2}$$

where τ' is the effective angle of soil friction. Equations (80.1) and (80.2) illustrate that a reduction in pore water pressure at constant effective stress (as may result from a drawdown in groundwater level) increases the normal effective stress and enhances the ability of the soil to resist shear, thus improving stability. Conversely, the positive pore water pressures associated with seepage into the excavation have a destabilising effect and result in slumping of side slopes and softening of the base as shown in **Figure 80.1(a)**. Base heave in an excavation can also occur due to unrelieved pore water pressures beneath very low-permeability layers below excavation formation level (**Figure 80.1(b)**). Both forms of instability can be avoided by the use of a suitable groundwater control system.

Groundwater control alone should not be expected to achieve a totally dry excavation. It can only do this in favourable ground conditions when used with an effective surface water control system. In other circumstances, groundwater control can give a stable and workably dry excavation, but some residual seepages may remain.

80.2.1 Permanent groundwater control

Although the predominant application of pumped groundwater control systems is as part of temporary works during construction, occasionally such systems are used on a 'permanent' basis for the entire design life of a structure. The most common application of permanent groundwater control is to reduce piezometric pressures below large underground structures. Their reduction will lessen the uplift buoyancy forces

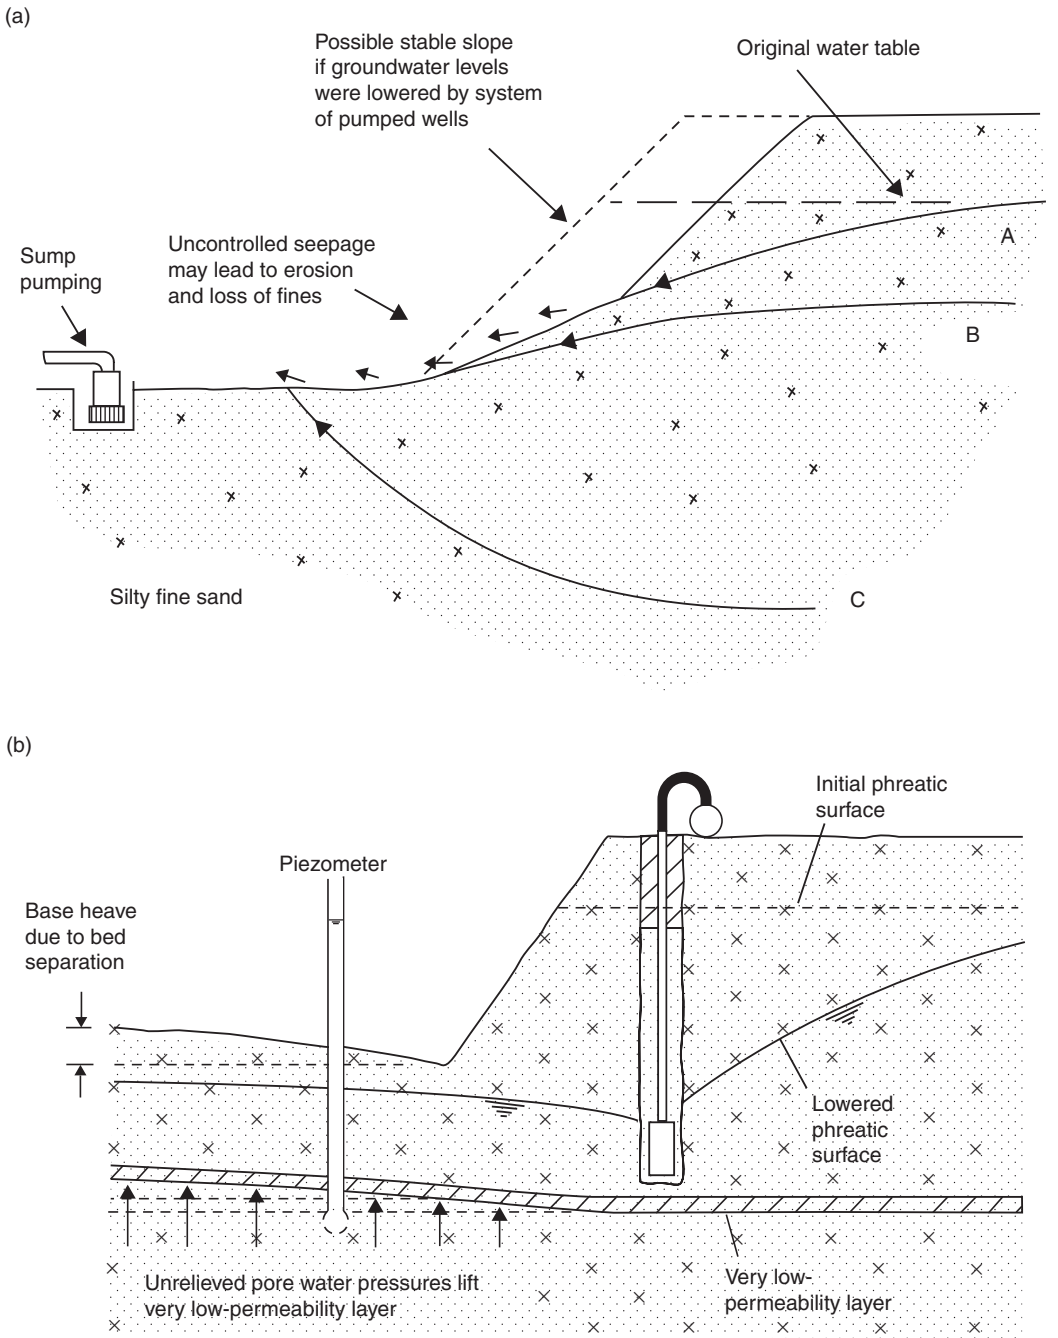

Figure 80.1 (a) Groundwater-induced instability of excavations; (b) Instability of base due to unrelieved pore water pressure
(a) Reproduced with permission from Cashman and Preene (2001) © Taylor & Francis Group; (b) Reproduced with permission from CIRIA C515, Preene *et al.* (2000), www.ciria.org

on the structure and may allow reduction in deadweight of the permanent structure. In such cases, the savings in capital cost of the structure may outweigh the costs of long-term operation of the pumping system (Whitaker, 2004).

80.2.2 Control of surface water

Groundwater control is separate from the control of surface water such as rainfall run-off. Many contractual disputes have arisen when a groundwater control system has been operating but puddles of water remain in the excavation. If layers of clay exist in the soil then these puddles may simply be ponded rainwater. Any excavation, including those above the water table, should have a system for surface water control, typically consisting of sump pumps and French drains. Surface water can come from a variety of sources, including rainfall, direct seepage from nearby rivers or lakes, leaking sewers and water mains

or the construction operations themselves. Whatever its source, surface water will need to be controlled to allow efficient construction operations. Guidance on surface water control can be found in Cashman and Preene (2001) and Powers *et al.* (2007).

80.3 Methods of groundwater control

The requirement to pump groundwater can be reduced or even avoided by installing a notionally impermeable physical cut-off wall or cofferdam around the excavation to exclude groundwater from it.

If an impermeable stratum exists at shallow depth beneath the excavation, then the wall may be able to penetrate down and into that stratum to create a full cut-off (**Figure 80.2(a)**). The only pumping requirement will be to drain the water trapped within the cut-off and to deal with leakages through the wall and through the impermeable stratum.

On the other hand, if an impermeable stratum does not exist at a convenient depth, only a partial cut-off (**Figure 80.2(b)**) can be formed. Groundwater will still enter the excavation, but the cut-off increases the seepage path length and reduces the flow rate compared to the case when there is no cut-off at all. The cut-off should be designed to be of adequate penetration to prevent piping failure of granular soils (see Chapter 16 *Groundwater flow*).

Alternatively, it may be possible to form a horizontal barrier or 'floor' to the cut-off structure to prevent vertical seepage (**Figure 80.2(c)**). The construction of horizontal barriers is relatively rare, but has been carried out using methods such as jet grouting (see Chapter 90 *Geotechnical grouting and soil mixing*) (Newman *et al*., 1994), and artificial ground-freezing techniques (Harris, 1995).

80.4 Groundwater control by exclusion

A wide range of methods can be used to exclude groundwater from excavations (Bell and Mitchell, 1986). Key attributes of more commonly used cut-off methods are described in **Table 80.1**. Some methods used to form groundwater cut-off barriers are described elsewhere in this book, including diaphragm walls, secant pile walls, sheet pile walls (Chapter 85 *Embedded walls*), permeation grouting, jet grouting (Chapter 90 *Geotechnical grouting and soil mixing*) and mix-in-place walls (Chapter 85 *Embedded walls* and Chapter 90 *Geotechnical grouting and soil mixing*).

Some of the methods are temporary. For example, the groundwater will thaw when artificial ground freezing is discontinued, or steel sheet piles can be extracted at the end of the job. These temporary methods should not have a significant effect on groundwater conditions at the site once the project is completed. However, methods which permanently affect soil permeability (e.g. grouting) can permanently alter groundwater flow regimes at the site – it is essential that the potential impact of this is assessed at design stage (see section 80.6.5).

Even when a cut-off is used, some pumping will be required to cope with:

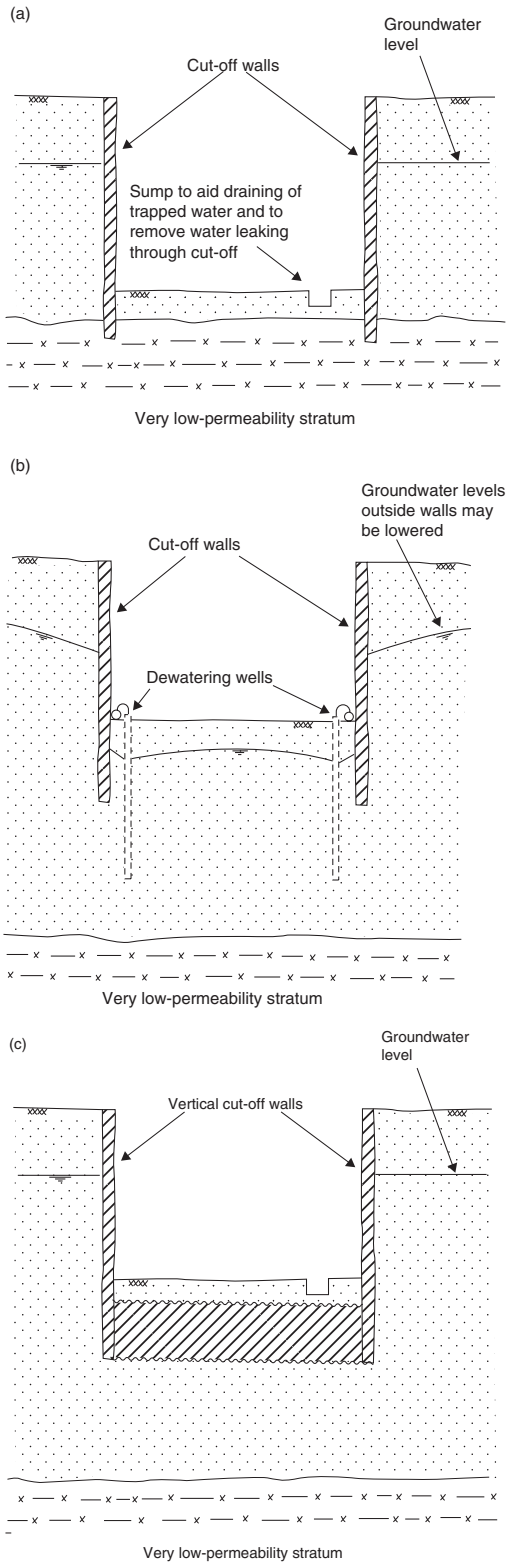

Figure 80.2 Physical cut-off walls (a) penetrating into very low permeability stratum; (b) used in combination with dewatering methods; (c) used with horizontal barrier to seal base

Method	Typical applications	Comments
Displacement barriers		
(1) Steel sheet-piling	Open excavations in most soils, but obstructions such as boulders may impede installation	Temporary or long-term. Rapid installation. Can support the sides of the excavation with suitable propping. Vibration and noise of driving may be unacceptable on some sites, but 'silent' methods are available
(2) Vibrated beam wall	Open excavations in silts and sands. Will not support the soil	A vibrating H-pile is driven into the ground and then removed. As it is removed, grout is injected through nozzles at the toe of the pile to form a thin, low-permeability membrane. Relatively cheap
Excavated barriers		
(3) Slurry trench cut-off wall using bentonite or native clay	Open excavations in silts, sands and gravels up to a permeability of about 5×10^{-3} m/s	The slurry trench forms a low-permeability curtain wall around the excavation. Quickly installed and relatively cheap, but cost increases rapidly with depth
(4) Structural concrete diaphragm walls	Side walls of excavations and shafts in most soils and weak rocks	Support the sides of the excavation and often form the sidewalls of the finished construction. Minimum noise and vibration
(5) Bored pile walls (secant and contiguous bored piles)	As (4)	As (4), but more likely to be economical for temporary works use. Sealing between contiguous piles can be difficult
Injection barriers		
(6) Jet grouting	Open excavations in most soils and very weak rocks	Typically forms a series of overlapping columns of soil/grout mixture
(7) Permeation grouting using cementitious grouts	Tunnels and shafts in gravels and coarse sands, and fissured rocks	The grout fills the pore spaces, preventing the flow of water through the soil. Equipment is simple and can be used in confined spaces
(8) Permeation grouting using chemical and solution (acrylic) grouts	Tunnels and shafts in medium sands (chemical grouts), fine sands and silts (resin grouts)	Materials (chemicals and resin) can be expensive. Silty soils are difficult and treatment may be incomplete, particularly if more permeable laminations or lenses are present
Other types		
(9) Artificial ground freezing using brine or liquid nitrogen	Tunnels and shafts. Will not work if groundwater flow velocities are excessive (>1 m/day or 10^{-5} m/s)	Temporary. A 'wall' of frozen ground (a freezewall) is formed, which can support the side of the shaft as well as excluding groundwater. Plant costs are relatively high. Liquid nitrogen is expensive but quick; brine is cheaper but slower
(10) Compressed air	Confined chambers such as tunnels, sealed shafts and caissons	Temporary. Increased air pressure (up to 3.5 bar) raises pore water pressure in the soil around the chamber, reducing the hydraulic gradient and limiting groundwater inflow. High running and set-up costs; potential health hazards to workers

Table 80.1 Physical cut-off techniques for exclusion of groundwater
Data taken from Preene *et al.* (2000)

- groundwater trapped within the cut-off area;
- rainfall and precipitation;
- seepage through the wall and through the ground.

It is important to recognise that most cut-off walls will leak. For the common example of steel sheet piles, clutches may leak and declutching of piles may occur in difficult driving conditions. The presence of cobbles and boulders will have a detrimental effect on the integrity of many cut-off methods.

Despite the potential problems, groundwater control by exclusion is widely used both in the UK and overseas. Perhaps one of the reasons is that, if carried out effectively and if ground conditions are favourable, an exclusion system can minimise or even eliminate any groundwater lowering outside the site area. This can be a very attractive outcome on projects where settlement of nearby structures or detrimental effects on other water users are of concern (see section 80.6.5).

80.5 Groundwater control by pumping

Groundwater control by pumping involves pumping groundwater from an array of wells or sumps with the aim of temporarily lowering groundwater levels to allow civil engineering projects to be constructed in stable conditions. Groundwater control by pumping is also known as *groundwater lowering*, *construction dewatering* or simply *dewatering*. The amount of lowering of the groundwater level is known as drawdown.

Table 80.2 lists the various techniques of pumped well groundwater control methods available. However, in the UK

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Method	Typical applications	Comments
Drainage pipes or ditches (e.g. French drains)	Control of surface water and shallow groundwater (including overbleed and perched water)	May obstruct construction traffic, and will not control groundwater at depth. Unlikely to be effective in reducing pore water pressures in fine-grained soils
Sump pumping	Shallow excavations in clean coarse soils, for control of groundwater and surface water	Cheap and simple. May not give sufficient drawdown to prevent seepage from emerging on the cut face of a slope, possibly leading to instability
Wellpoints	Generally shallow, open excavations in sandy gravels down to fine sands and possibly silty sands. Deeper excavations (requiring >5–6 m drawdown) will require multiple stages of wellpoints to be installed	Relatively cheap and flexible. Quick and easy to install in sands. Difficult to install in ground containing cobbles or boulders. Maximum drawdown is ~ 6 m for a single stage in sandy gravels and fine sands, but may only be ~ 4 m in silty sands
Horizontal wellpoints (machine laid)	Generally shallow trench or pipeline excavations or large open excavations in sands and possibly silty sands	Horizontal wellpointing is suitable for trench excavations outside urban areas, where very rapid installation is possible
Deep wells with electric submersible pumps	Deep excavations in sandy gravels to fine sands and water-bearing fissured rocks	No limit on drawdown. Expensive to install, but fewer wells may be required compared with most other methods. Close control can be exercised over well screen and filter
Shallow bored wells with suction pumps	Shallow excavations in sandy gravels to silty fine sands and water-bearing fissured rocks	Particularly suitable for coarse, high-permeability materials where flowrates are likely to be high. Closer control can be exercised over the well filter than with wellpoints
Passive relief wells and sand drains	Relief of pore water pressure in confined aquifers or sand lenses below the floor of the excavation	Cheap and simple. Create a vertical flowpath for water into the excavation; water must then be directed to a sump and pumped away
Ejector system	Excavations in silty fine sands, silts or laminated clays in which pore water pressure control is required	In practice, drawdowns generally limited to 30–50 m. Low energy efficiency, but this is not a problem if flowrates are low. In sealed wells a vacuum is applied to the soil, promoting drainage
Deep wells with electric submersible pumps and vacuum	Deep excavations in silty fine sands, where drainage from the soil into the well may be slow	No limit on drawdown. More expensive than ordinary deep wells because of the separate vacuum system. Number of wells may be dictated by the requirement to achieve an adequate drawdown between wells, rather than the flowrate, and an ejector system may be more economical
Collector wells	High-permeability sands and gravels	Each collector well is expensive to install, but relatively few wells may produce large flow rates and be able to dewater large areas
Artificial recharge	High-permeability soils and highly fissured rocks	Recharge systems are complex to operate and maintain. Recharge wells often suffer from clogging and may require periodic backflushing and cleaning
Electro-osmosis	Very low-permeability soils, e.g. clays	Only generally used for pore water pressure control when considered as an alternative to ground freezing. Installation and running costs are comparatively high

Table 80.2 Summary of principal pumped well groundwater control methods
Data taken from Preene *et al.* (2000)

the vast majority of projects are carried out using just four main conventional dewatering techniques:

- sump pumping;
- wellpoints;
- deep wells;
- ejector wells.

Each of the main pumping techniques will be described briefly in the following sections. **Figure 80.3** is a diagram which shows the range of application of each method relative to the two key parameters: drawdown required and soil permeability (the shaded areas show zones where more than one technique may be suitable).

A variation on groundwater control by pumping is 'passive drainage' where groundwater flow from an excavation or slope is facilitated by gravity flow, i.e. without the requirement for direct pumping. Indirect pumping of the water, after it has emerged from the ground, may be necessary to prevent the water causing problems elsewhere on site. Relief wells (see section 80.5.5.1) are a commonly used method of passive drainage.

An important distinction within the pumping methods is between open pumping and pre-drainage methods. Open pumping, most commonly carried out by sump pumping,

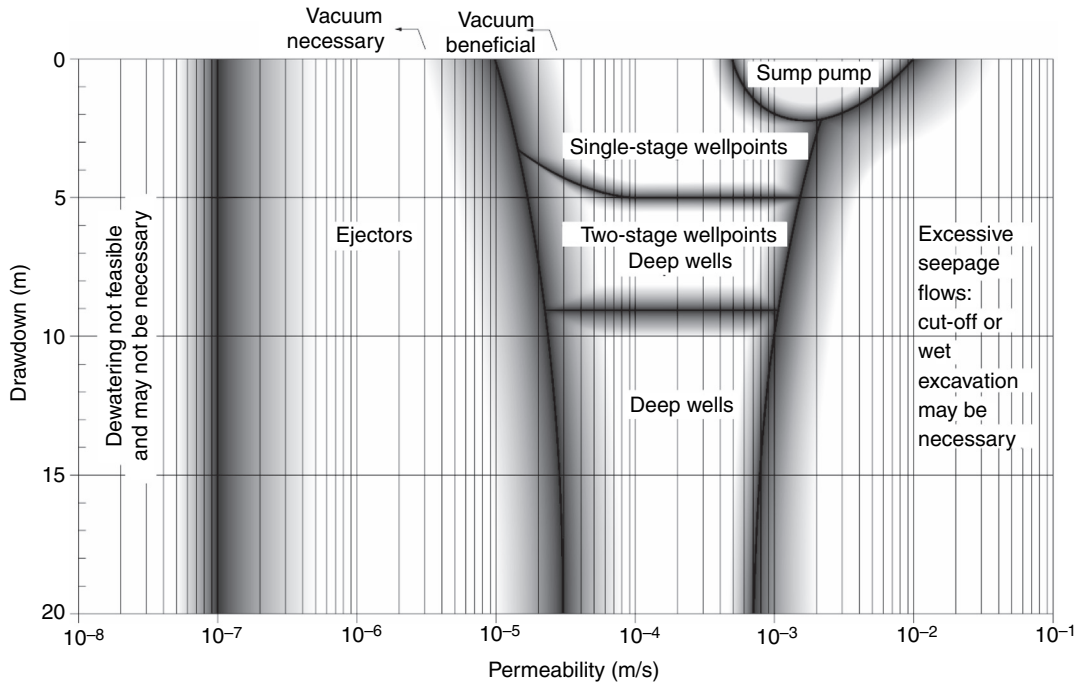

Figure 80.3 Range of application of pumped well groundwater control techniques
Reproduced with permission from CIRIA C515. Preene *et al.* (2000), www.ciria.org

involves removing water that has already entered the excavation by pumping from within it. While simple in practice, open pumping has the disadvantage that groundwater levels cannot be lowered in advance of excavation. Open pumping typically requires water to enter the excavation before it can be pumped away, and localised instability of the excavation may result.

In contrast, pre-drainage methods (which include wellpoints, deep wells and ejector wells) work on the principle of lowering groundwater levels in advance of excavation works. This group of methods has the advantage that groundwater can be managed so that water does not enter the excavation, reducing the risk of groundwater-induced instability.

80.5.1 Sump pumping

When sump pumping is implemented, water is allowed to enter the excavation where it is collected in drains and fed to special pits called sumps from where it is pumped away (**Figure 80.4**). The major limitations of sump pumping are that the sumps and collector drains take up space within the excavation, and it is not possible to lower groundwater levels much below formation level; the sump must be continually deepened as the excavation proceeds.

Under favourable conditions, sump-pumping systems can be a simple and cost-effective means of controlling groundwater inflows to an excavation. Under unfavourable conditions, a sump-pumping approach can result in delays, cost overruns and, occasionally, catastrophic failure. The primary limitation on sump pumping is the instability of the soil under the action of the seepage forces generated by the groundwater entering the excavation (**Figure 80.1**). This is commonly referred to as 'running sand conditions' or 'boiling' and can cause rapid loss of base and side slope stability, leading to a risk of undermining and settlement to adjacent structures.

The following attributes need to be taken into consideration when designing a sump:

- Depth: the sump should be deep enough to drain the excavation and drainage network, allowing for the pump intake level and some accumulation of sediment.
- Size: the sump should be substantially larger than the size of the pump to allow space for sediment and cleaning.
- Filter: the sump lining should be perforated or slotted, typically with a hole size or slot width of 10 to 15 mm. The sump should be surrounded with coarse gravel (20 to 40 mm).
- Access: good access is required to allow removal of the pumps for maintenance and cleaning of the sumps to remove any accumulation of sediment.

When carrying out sump-pumping operations, some of the sand and fines fraction in the soil will initially be removed in the immediate vicinity of the sump and drainage network. It is good practice to pass the discharge water through a settlement tank to allow the situation to be monitored and to remove the solids that settle readily prior to discharge. Settlement ponds or lagoons may be needed to remove any silt or clay fraction present to meet discharge consent requirements. If persistent movement of fines occurs, leading to ground loss and

settlement, or if an excavation shows signs of instability, sump pumping should be stopped and supplementary or other methods adopted. If the ground loss or instability is serious, it may be necessary to flood the excavation to maintain stability while the situation is reassessed.

80.5.2 Wellpoints

Wellpointing involves closely spaced, small-diameter shallow wells (known as wellpoints) in a ring around the excavation (**Figure 80.5**), or in lines alongside long trench excavations (**Figure 80.6**). The intention is to form a curtain of wellpoints around the excavation in order to intercept the groundwater. If a trench excavation is narrow and shallow, wellpoints may be required on one side of the trench only (single-sided system) but for wider or deeper trenches they will be required on both sides (double-sided system).

Wellpoints are typically installed at intervals of 1.5 to 3 m and linked via flexible 'swing' connectors to a 150 mm diameter header pipe laid alongside the excavation. The header acts as a manifold allowing one pump to act on many wellpoints

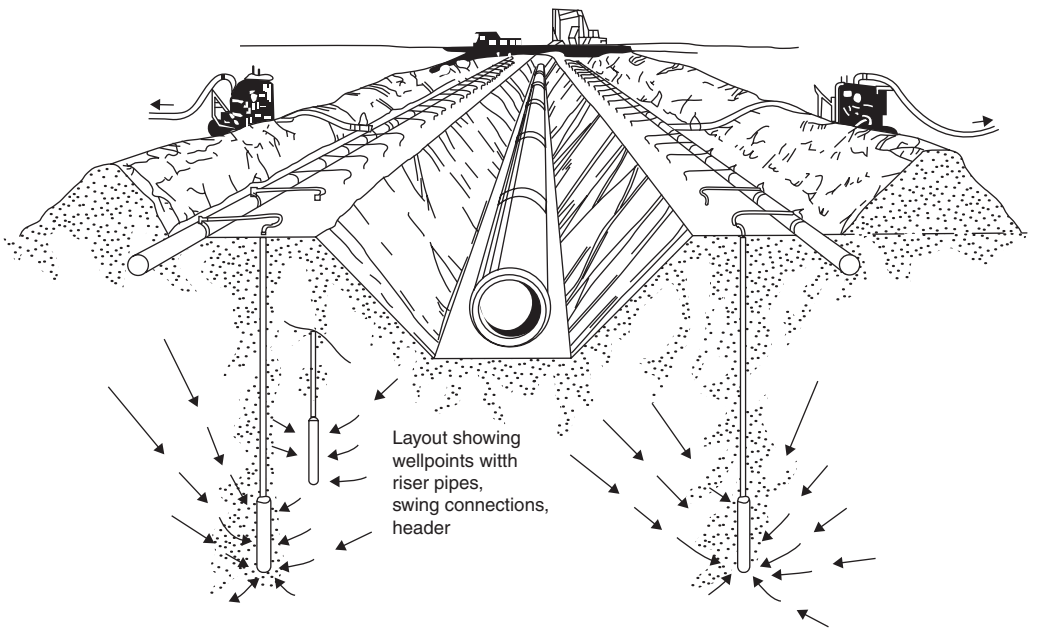

Figure 80.6 Progressive wellpoints for trench work
Reproduced with permission from CIRIA R113. Somerville (1986), www.ciria.org

(a 150 mm wellpoint pump can typically handle between 60 and 80 wellpoints). The wellpoint pump is located at ground level and applies a vacuum to the header pipe to draw groundwater up the wellpoints, along the header pipe to the pump from where the water is discharged. Pumps may be of a piston variety or may be a centrifugal pump with an ancillary vacuum pump.

Because the pump draws water up out of the wellpoints by suction, there is a practical limit to the drawdown that can be achieved using the wellpoint technique. The suction limit of the pump means that drawdowns of more than 5 or 6 m below the level of the pump and header pipe are rarely feasible. If greater drawdowns are required, a second stage of wellpoints can be installed at a lower level after the first stage has achieved its drawdown (**Figure 80.7**). Alternatively, the first-stage wellpoints and pump could be installed at a lower level after a site strip has been carried out. During operation, care must also be taken that the wellpoints are carefully adjusted or trimmed. Trimming is needed when wellpoints begin to pump excessive quantities of air when groundwater levels are drawn down to the top of the wellpoint screens. Trimming involves throttling the control valve on each wellpoint to reduce the air flow and avoid exceeding the pump's air-handling capacity. A poorly trimmed system will not achieve as much drawdown as a well-trimmed system.

Wellpoints typically consist of 38 mm diameter uPVC tubes with a 0.5 to 1 m long filter screen on the lower end. A steel jetting tube, washed into the ground by high-pressure water, is used to install the wellpoints. The hole around the wellpoint is backfilled with clean filter sand in a process known as sanding-in. The filter sand prevents fine particles being drawn into the wellpoints which could lead to clogging of the screens. Jetting is very quick in sands, but can be slow in gravels or

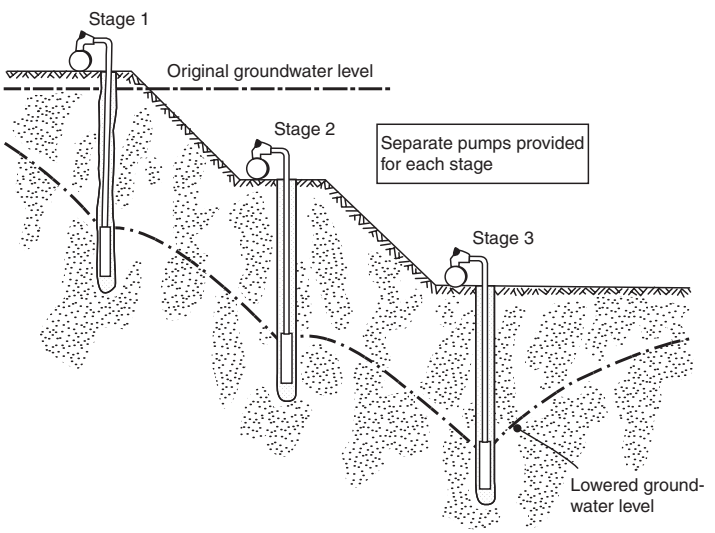

Figure 80.7 Multi-stage wellpoint system
Reproduced with permission from CIRIA R113. Somerville (1986), www.ciria.org

where cobbles are present. In addition to the high-pressure water supply, in difficult soils a 'hole puncher' with a hammer action can be used together with compressed air. Hydraulic augers are also sometimes used to penetrate stratums of stiff clay. Wellpoints are typically installed to 6 or 7 m below ground level, or occasionally deeper for pressure relief purposes.

For long, shallow trench excavations, horizontal perforated tubes are sometimes installed by a special trenching machine in a technique known as horizontal wellpoint dewatering (**Figure 80.8**). One end of the pipe is pumped on by a wellpoint pump every 100 m or so.

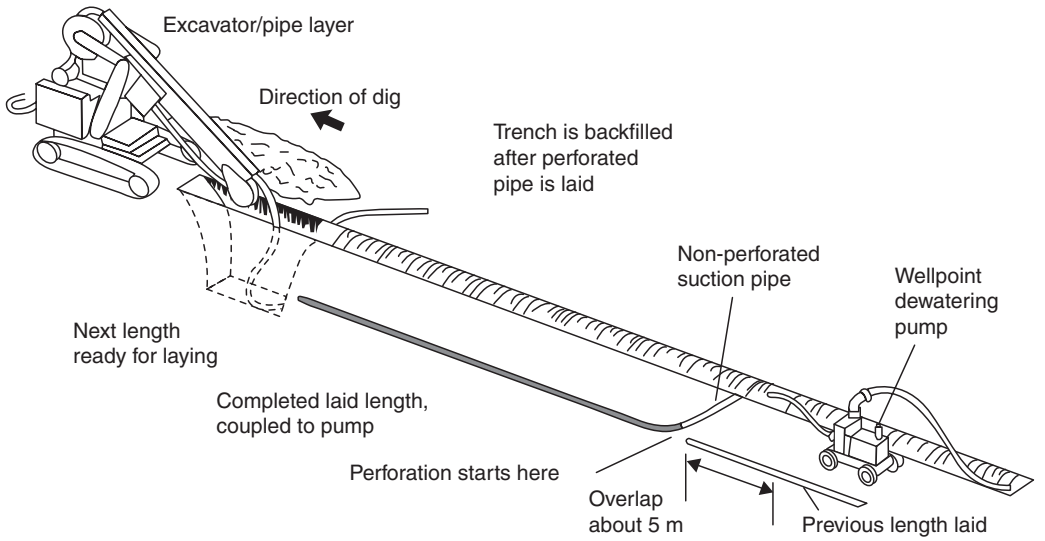

Figure 80.8 Horizontal wellpoint installation
Reproduced with permission from CIRIA C515. Preene *et al.* (2000), www.ciria.org

80.5.3 Deep wells with submersible pumps

A deep well system involves widely spaced deep wells around an excavation, each pumped by an electric submersible pump at depth. Because the submersible pump lifts the water from the base of the well there is no suction limit to the drawdown that can be achieved; theoretically, drawdown is limited only by the depth of the wells or by soil stratification. Unlike wellpointing, where the intention is to create a 'curtain' around the excavation, widely spaced deep wells rely on action at a distance. All the wells act together to cumulatively lower groundwater levels over a wide area.

A typical deep well (**Figure 80.9**) involves drilling a borehole (typically 250 to 350 mm diameter) to between 1.5 to 2 times the depth of the proposed excavation. A well liner (uPVC or HDPE tube) is then installed in the borehole. The lower section of the liner will be slotted or perforated to allow water to enter; this section is known as the well screen. The annulus between the borehole walls and the well screen is backfilled with filter gravel (known as the gravel pack). The annulus above the gravel pack may be filled with bentonite or grout to prevent surface water percolating down into the groundwater. The well itself may be drilled by a cable percussion rig or by a rotary drilling rig. Wells are typically installed at intervals of 15 to 60 m and are linked at ground level by electrical supply cables and water collection pipes.

For a deep well system, the most common layout is to space the wells evenly around the perimeter of the area where control of groundwater is required (**Figure 80.10**). The number of wells required for a scheme may be flexible. A few high-capacity wells or a greater number of smaller wells may give a similar extraction flow and drawdown. A few high-capacity wells may seem more cost-effective but, if there are uncertainties in the ground investigation information or a possibility of perched water, a larger number of smaller wells may result in better control of the groundwater. Also, a scheme with too few wells may be unacceptable if the stoppage of a single pump could cause flooding or even catastrophic failure. Standby electric power supply facilities can be readily provided, but standby pumping plant ready for immediate start-up is rarely supplied for economic reasons. Typically, the solution is to make sure that there is sufficient redundancy in the pumping capacity and that the system is not highly dependent on any one well. This can be a problem for schemes which comprise fewer than 3 or 4 wells. There have to be sufficient wells to draw the water table down. Keeping the groundwater level down may require a reduced flow rate compared with the initial period of pumping.

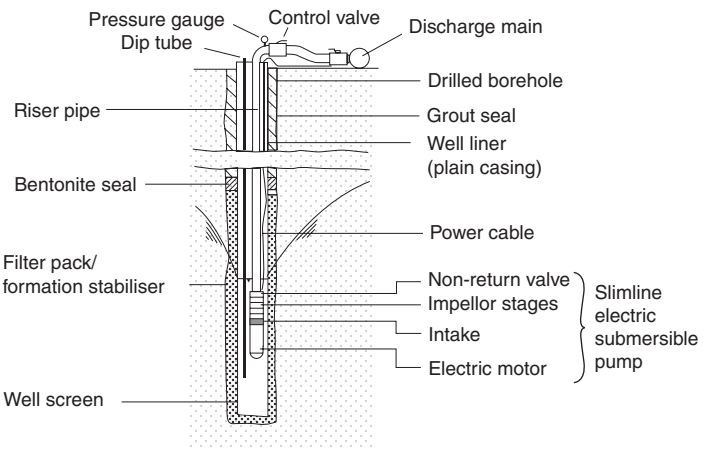

Figure 80.9 Typical deep well
Reproduced with permission from CIRIA C515. Preene *et al.* (2000), www.ciria.org

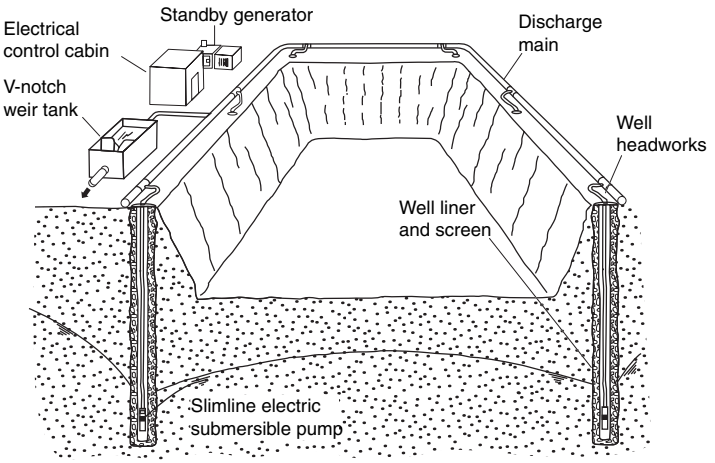

Figure 80.10 Deep well system
Reproduced with permission from CIRIA C515. Preene *et al.* (2000), www.ciria.org

One potential problem which can occur when deep wells are run for long periods is the build-up of a sticky red-brown gelatinous slime in the well and pump. This process is called biofouling and the slime is biomass produced by the iron-reducing aerobic bacteria *Gallionella*, which may occur naturally in groundwater. The lowering of the water level in the well provides the bacteria with an abundant source of oxygen. The *Gallionella* thrive in such conditions and adsorb soluble iron (Fe) present in the groundwater and excrete the resulting insoluble iron oxide and oxyhydroxide compounds. If the biomass is not removed, it can clog well screens and increase wear on pumps dramatically. Cleaning requires the pumps to be removed and washed down; the well can be cleaned by surging with compressed air. Other chemical and bacterial fouling problems can occur: calcium carbonate can leave a thick white paste in the wells, and anaerobic sulfate-reducing bacteria can create a black slime at the bottom of pumps, leading to acidic conditions which may eat into metal pump casings.

80.5.4 Ejector wells

Ejector well systems involve an array of wells around the excavation. Depending on ground conditions the ejector wells are sometimes closely spaced (like wellpoints) and sometimes more widely spaced (like deep wells). The principal distinguishing feature of ejector systems is the method of pumping. An ejector body is installed in each well containing a small-diameter nozzle and venturi. High-pressure water from supply pumps at ground level is supplied to the nozzle. The water passes through the nozzle at a high velocity (up to 30 m/s) creating a pressure drop and generating a vacuum of up to 0.95 bar at the ejector. This vacuum draws groundwater through the well screen to the ejector body, where it joins the supply stream of water and is piped back up to ground level. The water that comes out of the ejector is the supply water plus the groundwater; in simple terms you get more water out of an ejector than you put in. The water from the ejectors goes to a tank feeding the supply pumps and is recirculated to the ejectors (**Figure 80.11**). The excess water abstracted from the ground will start to fill up the tank and a V-notch weir is normally provided to allow the excess to overflow to a suitable disposal point. **Figure 80.11** shows that ejector systems have two header pipes: a supply header containing the high-pressure feed to each well, and a low-pressure return header to carry the recirculated water back to the supply pumps. The ejector body is fitted with a non-return valve which is intended to prevent high-pressure water being inadvertently injected into the ground.

Ejector wells are generally used only in lower-permeability soils such as silty sand or silts where groundwater flow rates are likely to be low. This is because commercially available ejector bodies have a relatively small pumping capacity. A typical ejector might be capable of pumping only 0.3 to 0.8 l/s of groundwater (the supply flow is in addition to this). Higher-capacity ejector bodies are theoretically possible, but are not available because of the low mechanical efficiency of ejectors. For every kilowatt of energy input into an ejector system, less than 25% is used to pump groundwater (the rest is used to circulate supply water and to overcome friction losses). This is a much lower efficiency than either deep wells or wellpoints, so for high groundwater flow rates, instead of designing larger ejectors, it is usually more economical to use deep wells or wellpoints.

A typical ejector well is similar to a deep well but, depending on the type of ejector used, can often be of smaller diameter. Single-pipe ejectors (where the supply and return flows are carried in concentric pipes) can fit down a 50 mm diameter well liner (**Figure 80.12(a)**). Twin-pipe ejectors (where the supply and return flows are carried in separate pipes) can generally fit down a 105 mm diameter liner (**Figure 80.12(b)**). In practice, for the supply pressures normally used of 100 to 160 psi (690 to 1 100 kPa), the drawdown achievable is limited to about 35 m below the level of the supply pump.

Like wellpoint and deep well systems, ejector wells are generally laid out in a ring configuration around the area to be dewatered. Spacing of ejector wells will be determined by the flow rate and capacity of the ejectors used. If the soil stratification indicates the possibility of perched water or overbleed seepage, the well spacing may have to be reduced. In practice, the intervals between ejector wells generally fall between those used for wellpoint systems (1.5 to 3 m) and those used for deep wells (10 m or more).

In a similar way to deep wells, ejector wells are prone to biofouling by bacterial action. Due to the smaller size of the flowpaths inside the ejector, where the biomass can build up, it is possible for an ejector body to become totally clogged up and cease functioning altogether. Regular monitoring of supply and return flow rates and drawdown levels should allow the problem to be identified at an early stage. The ejectors can be cleaned by compressed air surging in a similar way to deep wells.

80.5.5 Other groundwater pumping techniques

80.5.5.1 Relief wells

Relief wells (also known as pressure relief wells) can be used to prevent base heave of excavations (see Chapter 16 *Groundwater flow*), by allowing groundwater to flow upward from pressurised strata beneath an excavation (**Figure 80.13**). Relief wells are an alternative approach to pumped wells (typically located outside the excavation) and comprise a gravel-filled borehole (with or without a perforated liner) within the excavation. The relief well forms a vertical high-permeability pathway; as the excavation progresses groundwater will flow up the relief well into the excavation, thereby reducing pore water pressures below the base of the excavation, and improving base stability. The water entering the excavation is typically disposed of by sump pumping. A simple example of the application of relief wells is given in Ward (1957).

80.5.5.2 Collector wells

A collector well (sometimes known as a Ranney well after a proprietary system) typically comprises a vertical shaft (approximately 5 m in diameter), sunk as a caisson, from which small-diameter horizontal or sub-horizontal screened wells (termed

laterals) are drilled or jacked radially outward (**Figure 80.14**). Typically, a single duty pump is used to pump from the shaft, creating a pressure gradient along the laterals, causing them to discharge into the shaft.

The cost of installing collector wells can be large in comparison to other pumped groundwater control methods; for this reason, collector wells are rarely used in temporary groundwater control applications. Nevertheless, the technique has occasionally been used to lower groundwater levels (on a temporary or permanent basis) beneath areas where there is no surface access to drill conventional deep wells.

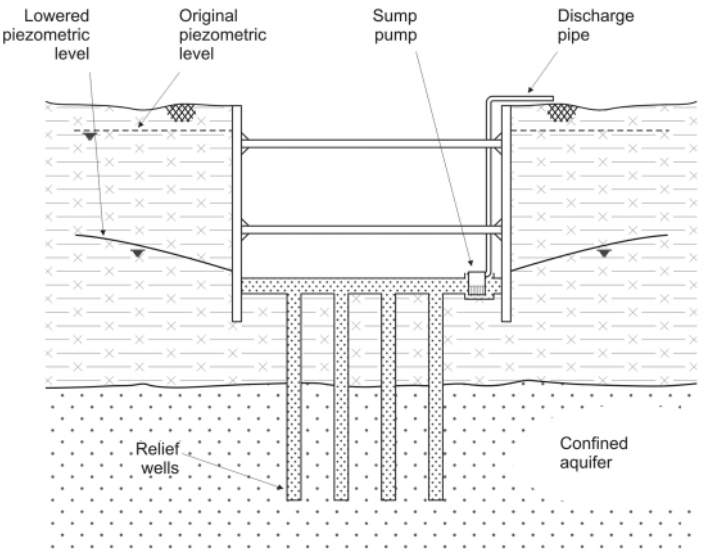

Figure 80.13 Relief well
Reproduced from Cashman and Preene (2001), with permission from Taylor & Francis Group

80.5.5.3 Artificial recharge systems

Artificial recharge involves injecting (or recharging) water into the ground in a controlled manner via recharge wells or recharge trenches. The intention is to mitigate the potential environmental impacts (including ground settlement) caused by pumping. Such systems need to be designed and operated with care as they must achieve their objective whilst retaining effective groundwater control in the excavation.

Water may be recharged via shallow recharge trenches, or via specially constructed recharge wells. Recharge trenches can be quick and cheap to install but, because of their shallow depth, are only suitable to recharge into unconfined aquifers with water tables near ground level. In contrast, recharge wells can be designed to inject water into specific aquifers, including (if appropriate) confined aquifers at depth beneath a site. A recharge well is essentially similar to a pumping well, but with the following features:

- The annulus around the well casing is typically sealed at the surface with a grout or concrete seal. This is to prevent injected water short-circuiting up to ground level via the filter pack.
- A downspout to prevent the recharge water from cascading into the well and becoming aerated. Aeration of the water may promote clogging processes in the well.
- Air vents to allow air to be purged from the system.
- Control valve and flow meter.

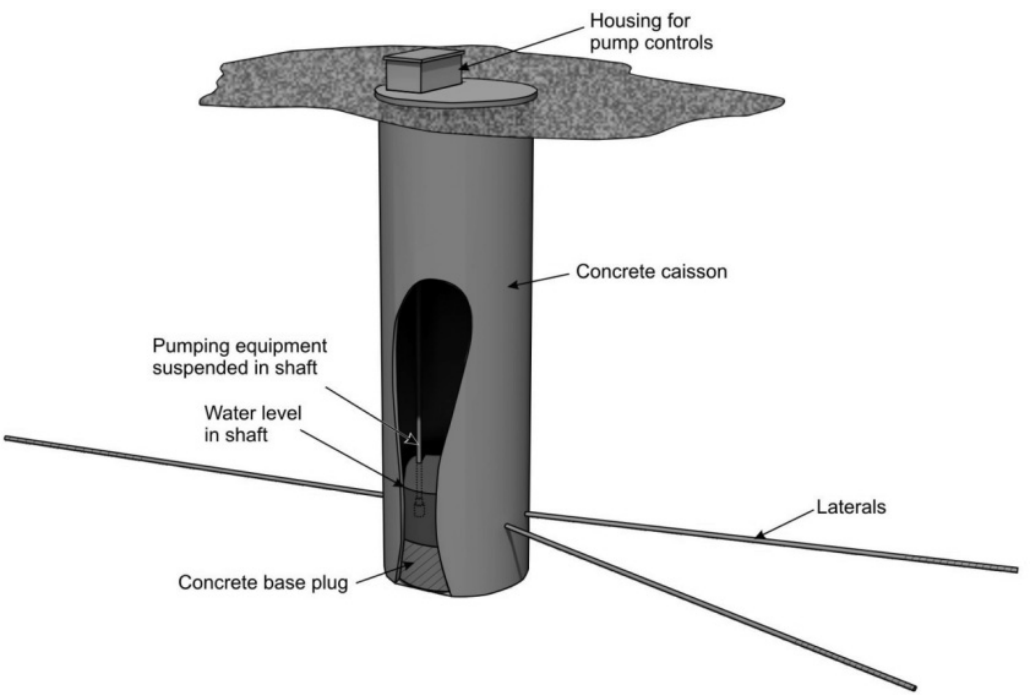

Figure 80.14 Collector well

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

A fundamental issue with the operation of artificial recharge systems (wells and trenches) is that they are very vulnerable to loss of performance due to clogging. Clogging may be caused by low levels of suspended solids (sand, silt or clay particles) in the recharge water, or by chemical or biological processes (such as the build-up of iron deposits or bacteriological slimes). It is normal to allow for regular cleaning of recharge wells by backflushing, and to allow for additional recharge capacity – which is necessary due to the long-term deterioration in performance of the wells. Further information on artificial recharge to mitigate the impacts of pumping can be found in Powers (1985). An example of the application of a recharge system is given by Powrie and Roberts (1995). Examples of the use of recharge trenches are given in Cliff and Smart (1998).

80.5.5.4 Electro-osmosis

Pumped groundwater control systems are often ineffective in very low-permeability soils such as silts and clays. This is because groundwater movement under the influence of hydraulic gradients caused by pumping will be excessively slow. In such circumstances, groundwater flow may be more rapid under the influence of electrical potential gradients created by the technique of electro-osmosis.

Electro-osmosis is a highly specialised technique, whereby a direct current is passed through the soil between an array of anodes and cathodes (**Figure 80.15**). The electrical potential gradient causes positively charged ions and water molecules around the soil particles to migrate from the anode to the cathode. The small volumes of water generated can be pumped away from the cathode by wellpoints or ejectors.

The main application of electro-osmosis is for the stabilisation of excavations in very soft silts or clays. Further information can be found in Casagrande (1952) and Casagrande *et al*. (1981).

80.5.5.5 Pumping and exclusion methods used in combination

Pumped groundwater control methods are sometimes used in combination. Common examples include:

- Pumping to dewater cofferdams – even where the soil stratification allows a cut-off wall to form a complete cofferdam to exclude groundwater (**Figure 80.2(a)**), some residual groundwater will remain trapped in the excavation. Groundwater pumping from within the excavation will be necessary to prevent this water from interfering with construction operations.
- Cut-off walls used to reduce pumped flow rates – in very high-permeability soils, pumped flow rates from excavations will be very large. It may be appropriate to use cut-off walls penetrating below excavation level (**Figure 80.2(b)**). If the abstraction points (wells or sumps) are located within the cut-off walls, the pumped flow rate will be reduced to some degree, potentially reducing pumping costs and making the pumped discharge easier to dispose of.
- Groundwater lowering to reduce loading on cut-off structures – where the sides of an excavation are supported by cut-off walls such as sheet piles or diaphragm walls, a significant proportion of the lateral loading on the walls may be due to external groundwater pressures (see Chapter 63 *Principles of retaining wall design*). In some circumstances, pumped dewatering wells are located outside the excavation to lower groundwater levels and reduce loading on the retaining structure. This can allow overall cost savings to be made by reducing the necessary wall stiffness and propping requirements (Roscoe and Twine, 2001).

80.6 Design issues

The design process needs to address hydrogeological factors in relation to the calculation of pumped flow rates, environmental

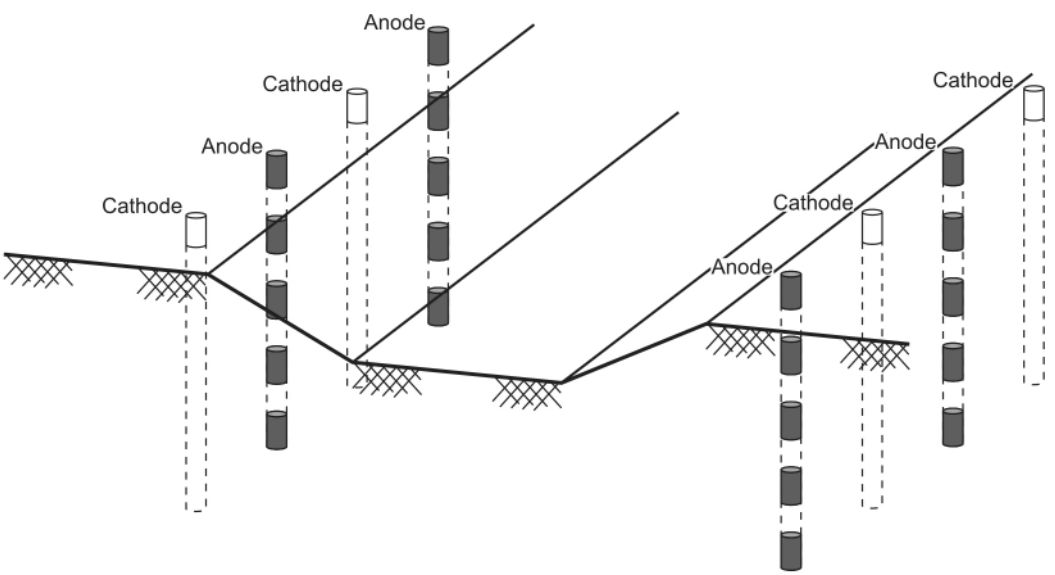

Figure 80.15 Electro-osmosis
Reproduced from Cashman and Preene (2001), with permission from Taylor & Francis Group

impacts, etc., but must also address the performance and selection of suitable technologies. In all but the simplest of groundwater control problems, the following steps should be followed as part of the design process:

(i) definition of problem and constraints;

(ii) development of hydrogeological conceptual model;

(iii) selection of method of groundwater control;

(iv) design calculations;

(v) assessment of environmental impacts;

(vi) review of design.

Each of these stages is briefly discussed in the following sections. On large and complex projects, the observational method is sometimes used (see Chapter 100 *Observational method*). Further details of design methods are given in Preene *et al.* (2000) and Cashman and Preene (2001).

80.6.1 Definition of problem and constraints

To allow a groundwater control system to be designed, three aspects must be addressed:

Define objectives of groundwater control The objectives must be established at the start. Is there a need to prevent inundation of excavations in permeable soils, or is pore water pressure control needed to ensure slope stability in fine-grained soils, or is there a need to reduce groundwater uplift pressures to prevent base heave in each of these? Such differing objectives may drive the design down different avenues.

Identify key constraints Groundwater control is not carried out in isolation; it must integrate with the rest of the construction project. Are there space and time constraints for the site works? Is the site in a sensitive environmental setting where prolonged pumping may cause problems (see section 80.6.5).

Gather and review available information It is important to collate information at an early stage to understand what is known about the site, and hence what is not known or is uncertain. Even if recent site investigations have been carried out, there may be uncertainty over the permeability of soil and rock at the site.

80.6.2 Hydrogeological conceptual model

A key stage in the design process is the development of the hydrogeological conceptual model relevant to the groundwater control problem, to provide the information necessary for design. If the conceptual model is a poor match for the actual conditions, any subsequent design work is likely to be of little value. If there is insufficient reliable data to formulate a convincing model, this could be a sign that further site investigation is needed. Some key factors in the conceptual model are outlined below.

80.6.2.1 Aquifer types and properties

The aquifer (water-bearing strata in which groundwater levels are to be lowered) must be defined and its nature identified. On major projects there may be a requirement to involve expert hydrogeologists to characterise groundwater conditions. Further details on the characteristics of aquifers can be found in hydrogeological texts such as Younger (2007).

80.6.2.2 System geometry

The depth and size of the excavation will have a key influence on the design of a groundwater control scheme. In particular, the depth of the deepest part of the excavation below groundwater level is a key parameter, which must be determined.

80.6.2.3 Soil permeability

The permeability of the aquifer is a critical parameter in the design of groundwater control systems, and must be assessed as part of the design process. Methods of estimation of permeability are described in Chapter 47 *Field geotechnical testing*. Permeability can be very difficult to determine accurately, either from laboratory or *in situ* tests; uncertainties in permeability can lead to major variations in calculated flow rates. It is often necessary to carry out sensitivity analyses to assess the impact of different permeability values on design.

80.6.2.4 Aquifer boundary conditions

Aquifers are rarely uniform and will typically have physical or hydraulic boundaries which influence their behaviour. Any significant boundary conditions need to be identified and accounted for in design. Examples of boundary conditions include low-permeability clay layers which may impede vertical water flow within sandy aquifers, or bodies of surface water (such as rivers, lakes or the sea) which may act as large local sources of water for an aquifer.

80.6.3 Selection of method of groundwater control

Correct selection of the method of groundwater control is essential for successful design. It is likely to be very expensive and disruptive to change methods and technologies at any stage after initial design.

A key step is to identify whether the most appropriate approach is groundwater control by pumping or by exclusion, or a combination of the two. This decision is likely to be influenced by a range of factors, including:

- technical issues such as order of magnitude of pumped flow rates, likely depth of cut-off to low-permeability layers (some scoping calculations may be needed at this stage);
- space or program issues for the main construction works;
- requirement to minimise external groundwater impacts (which would tend to favour exclusion options);
- availability of water disposal routes of adequate capacity (if no disposal routes are available, pumping options are unlikely to be feasible);
- cost and availability of experienced contractors for the various methods.

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

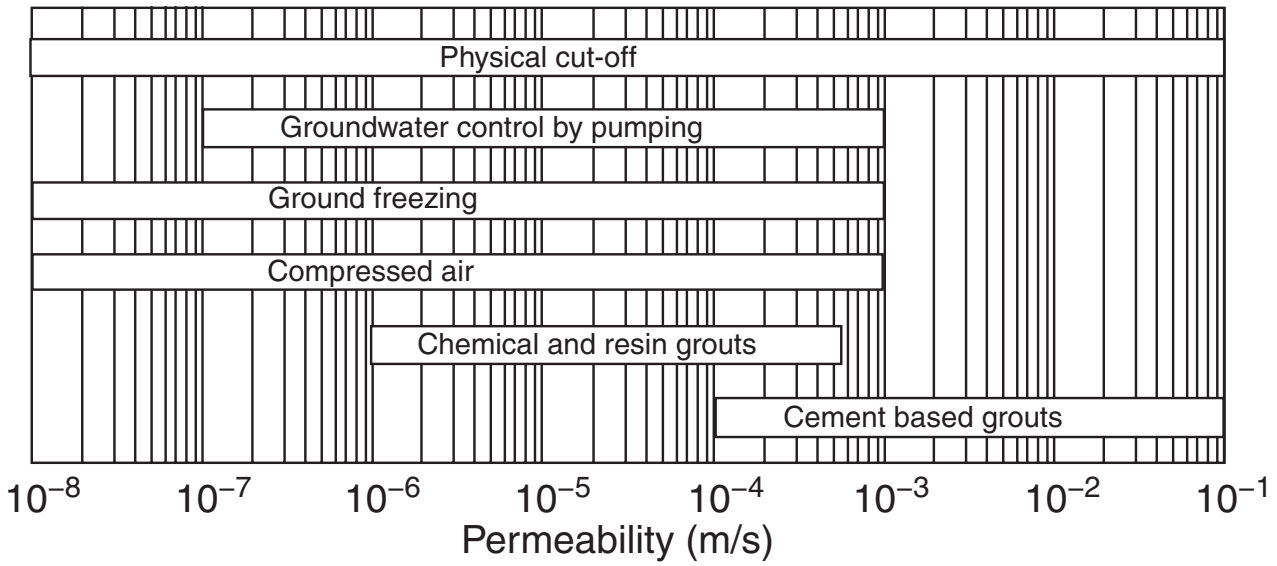

Figure 80.16 Approximate range of application of groundwater exclusion techniques in soils
Reproduced with permission from CIRIA C515. Preene *et al.* (2000), www.ciria.org

Once the method (exclusion or pumping) has been selected, the initial technology must be chosen. As the choice of technology will affect the design process, it must be selected early and then reviewed periodically during the design process to confirm it is appropriate. For groundwater control by pumping, initial technology selection can be made from **Figure 80.3**, which relates the range of application of pumped dewatering methods to the required drawdown and estimated soil or rock permeability. For groundwater control by exclusion, initial technology selection can be made from **Figure 80.16**, which relates cut-off methods to estimated soil or rock permeability.

80.6.4 Design calculations

Design calculations for pumped groundwater control systems are described in Preene *et al.* (2000) and Cashman and Preene (2001). In simple cases the design will be carried out using seepage calculations derived from classic Darcy's Law flow models; see Chapter 16 *Groundwater flow*, applied to appropriate boundary conditions. In more complex cases, numerical modelling may be used to model complex groundwater flow regimes. Occasionally the observational method (see Chapter 100 *Observational method*) may be used for groundwater control schemes. The observational method as applied to groundwater control by pumping is described in Roberts and Preene (1994).

80.6.5 Assessment of environmental impacts

Groundwater control has the potential to have measurable effects at considerable distances from the excavation which are dependent on the hydrogeological setting. These effects need to be assessed at design stage so that any necessary mitigation measures can be identified.

Pumping of groundwater can lower groundwater levels around a site. Occasionally, groundwater levels may be lowered by small amounts several hundred metres from the site. Cut-off walls installed as part of groundwater exclusion schemes may act as underground dams and may cause local changes in groundwater levels.

Table 80.3 summarises the range of potential impacts from groundwater control works. The more significant impacts include:

- reduction of yield from nearby water supply wells as a result of dewatering pumping;
- settlement of nearby structures as a result of effective stress increases caused by groundwater lowering (Preene, 2000);
- increased movement of contaminated or saline groundwater as a result of dewatering pumping;
- increases in groundwater level as a result of the installation of cut-off walls.

Guidance prepared by UK regulators is available (Boak *et al.*, 2007) on methodologies for hydrogeological impact appraisals (HIA) to be applied to dewatering abstractions. The HIA approach is often 'tiered' – with different levels of complexity of assessment, dependent on the nature of the project. Simple HIAs may be little more than a desk study to confirm there are no sensitive receptors nearby. However, a small number of large and complex projects may require extensive numerical modelling and field monitoring.

Further details of potential environmental impacts and associated mitigation measures related to groundwater control activities are given in Preene and Brassington (2003).

80.6.6 Review of design

It should be recognised that even when a thorough site investigation and design have been carried out, uncertainty may

Category	Potential impacts	Duration	Relevant construction activities
(1) Abstraction	Ground settlement Derogation of individual sources Effect on aquifer – groundwater levels Effect on aquifer – groundwater quality Depletion of groundwater-dependent features	Temporary	Dewatering of excavations and tunnels using wells, wellpoints and sumps Drainage of shallow excavations or waterlogged land by gravity flow
		Permanent	Permanent drainage of basements, tunnels, road and rail cuttings, both from pumping and from gravity flow
(2) Pathways for groundwater flow	Risk of pollution from near-surface activities Change in groundwater levels and quality	Temporary	Vertical pathways created by site investigation and dewatering boreholes, open excavations, trench drains, etc.
			Horizontal pathways created by trenches, tunnels and excavations
		Permanent	Vertical pathways created by inadequate backfilling, sealing of site investigation, dewatering boreholes, excavations, permanent foundations, piles and ground improvement processes
			Horizontal pathways created by trenches, tunnels and excavations
(3) Barriers to groundwater flow	Change in groundwater levels and quality	Temporary	Barriers created by temporary or removable physical cut-off walls such as sheet-piles or artificial ground freezing
		Permanent	Barriers created by permanent physical cut-off walls, or groups of piles forming part of the foundation or structure, or by linear constructions such as tunnels and pipelines
			Barriers created by reduction in aquifer hydraulic conductivity (e.g. by grouting or compaction)
(4) Discharge to groundwaters	Discharge of polluting substances from construction activities	Temporary	Leakage and run-off from construction activities (e.g. fuelling of plant)
			Artificial recharge (if used as part of the dewatering works)
		Permanent	Leakage and run-off from permanent structures Discharge via drainage soakaways
(5) Discharge to surface waters	Effect on surface waters due to discharge water chemistry, temperature or sediment load	Temporary	Discharge from dewatering systems
		Permanent	Discharge from permanent drainage systems

Table 80.3 Impacts on groundwater conditions from civil engineering works
Reproduced from Preene and Brassington (2003) from John Wiley & Sons Ltd

remain – perhaps in relation to values of soil permeability, or the magnitude of potential environmental impacts. It is important that a brief review is carried out at the end of the design process to consider if the remaining uncertainty is acceptable in the context of the proposed project. If necessary, the design may need to be revised, or additional ground investigation information gathered.

80.7 Regulatory issues

80.7.1 Abstraction licensing and discharge consents

In the UK, groundwater control by pumping is subject to specific Government legislation and is overseen by regulatory authorities. These authorities are: Environment Agency (EA, England and Wales); Scottish Environment Protection Agency (SEPA, Scotland); and Northern Ireland Environment Agency (NIEA, Northern Ireland). Publications are available which outline the regulatory approach (EA, 2008).

There are two facets to the legal requirements. The first deals with pumping of groundwater (termed abstraction) and is intended to make sure the regulators can control groundwater use so that groundwater control systems do not cause nearby groundwater users to lose their supplies. The second deals with disposal of groundwater (termed discharge) and is intended to ensure that the pumped water does not itself cause pollution. Up-to-date guidance on legal requirements can be found on the websites of the regulators.

80.7.2 Management of discharge water quality

Adequate management of the discharged water is essential for any groundwater control scheme. Discharge consents or permissions are required for all groundwater discharges.

Disposal options for discharge water include:

- To surface waters (e.g. river, water course, lake, sea). Consent is required from the regulators depending on the site location.

- To groundwater (e.g. via soakaways, recharge wells, or recharge trenches). Consent is required from the regulators depending on the site location.
- To an existing sewerage network. Permission is required from the sewer authority (e.g. water utilities or their agents).

Silt pollution caused by poorly managed pumped discharges from groundwater control operations is a common problem, typically resulting from poorly planned and executed sump pumping operations. It can harm the aquatic environment in several ways, including:

- injuring fish by its abrasive action;
- clogging the gills of fish, causing them to die by suffocation;
- destroying spawning sites and insect habitats on the river bed, removing the source of food for fish;
- coating the leaves of aquatic plants, limiting their growth.

The ideal way to manage suspended solids in discharges is to tackle the cause of the problem and to design and specify the groundwater control system with adequate filters to minimise sediment in the discharge water. Provided that suitable filters are installed, wellpoint, deep well and ejector well systems do not normally produce discharges with high sediment content, except during the initial periods of pumping and development when dirty water may be produced for short periods.

The method which most commonly produces sediment-laden water is sump pumping (section 80.5.1). Installation of adequate filters around sumps can be difficult and, as a result, clay, silt and sand-size particles can be drawn to the pump and entrained in the discharge water. Whenever sump pumping is carried out, arrangements should be made before final discharge to remove any suspended solids to below the maximum levels set in the discharge consent (by using, for example, appropriately designed and operated settlement tanks or ponds). If this is not possible, it may be necessary to change to another groundwater control method, such as wellpoints, with adequate filters.

CONTENTS

81.1	Introduction	1191
81.2	Bored piles	1192
81.3	Driven piles	1206
81.4	Micro-piles	1217
81.5	References	1222

Piles are slender, columnar foundation elements. They are most commonly designed, as discrete bearing piles, to transfer part or all of the vertical loading imposed by a structure through weak and compressible soils to competent and stable soils, or rock. This chapter describes the most commonly available types of bearing pile and discusses the methods of construction and the advantages and constraints of individual techniques. Other applications of piling are discussed in Chapters 83 *Underpinning* and 85 *Embedded walls*. Section 81.2 describes the plant and a range of methods used in the construction of bored piles, including rotary cast-in-place, continuous flight auger and displacement auger techniques. Brief discussion of some specialised techniques including under-reaming, base grouting, embedded columns and geothermal piles completes this section. Driven piling techniques including timber, segmental precast, prestressed precast and driven cast *in situ* concrete are described in section 81.3, along with steel H and box section piles and steel tube piles. A discussion of modern driven piling plant is set in a historical context. The impact of ground conditions, environmental aspects and particular construction issues such as drivability, installation control and the effects of pile driving on the ground are also discussed. Finally section 81.4 discusses the wide-ranging application of micro-piling techniques. Practical aspects of various construction methods are discussed, covering rotary case and auger, rotary duplex, rotary down-the-hole-hammer, rotary percussive, hollow-segmental-auger and driven micro-piling. The section is completed with discussions of the grouts used in micro-piling and the particular environmental, quality assurance and health and safety issues that apply.

81.1 Introduction

The use of piles as a foundation solution is in itself a key decision in the design process (see Section 5 *Design of foundations* of this manual). Once the use of piles has been identified, it is important to consider which forms of pile and methods of construction are most appropriate to the project. The selection of appropriate pile types should take place early in the foundation design if time is not to be lost pursuing uneconomical or impracticable solutions. The constraints of a particular project may dictate that only a narrow range of pile types is applicable, or may leave room for a wider choice of solution, which can then be based on more environmentally sustainable and economic grounds. The factors affecting the selection of pile type are many and varied, and are often interrelated. They include:

Performance	Environmental	Site constraints
• Bearing capacity	• Noise	• Restricted access
• Uplift capacity	• Vibration	• Restricted headroom
• Lateral load capacity	• Spoil disposal	• Restricted working hours
• Durability	• Contamination	
	• Carbon efficiency	• Existing assets and structures

Safety	Geotechnical
• Work next to operational railway	• Very weak strata (e.g. peat)
• Airside work at airports	• Deep unstable strata
• Work adjacent to sensitive assets	• Water-bearing strata
• Work on sloping sites	• Obstructions
	• Rock

These factors are commonly in conflict and a degree of engineering judgement is required to identify the most appropriate solution. A commercial and residential tower development, for instance, may call for relatively few piles with correspondingly high axial and lateral loading. On a site with reasonably open access large diameter bored piles (see section 81.2.1) would be suitable. On the other hand, if the site is subject to severe access, constraints and headroom limits, the installation of large diameter piles may be uneconomical or even impracticable. This may therefore dictate that a micro-piled solution (see section 81.4) is adopted. Such conflicts can have profound implications for the design of the sub-structure, and in some cases, the feasibility of development overall.

In another case, a relatively open site may be underlain by a significant volume of contaminated soil. Here the use of displacement piles (which avoid the need for off-site disposal of spoil) would present itself as an attractive solution. On a site where vibration is not an issue this might be most economically achieved with a driven form of pile (see section 81.3). However, adjacent to a vibration-sensitive installation, or in a residential location, a vibration-free displacement auger pile solution (see section 81.2.4) may be more appropriate.

In practice it is found that, however similar, no two projects are quite the same in regard to the founding solution. The piling solution for an extensive residential development, for example, may deploy a driven pile solution in the first instance. As the development grows and some sectors are populated, even though the performance requirements and ground conditions remain the same, later adjacent plots may require an

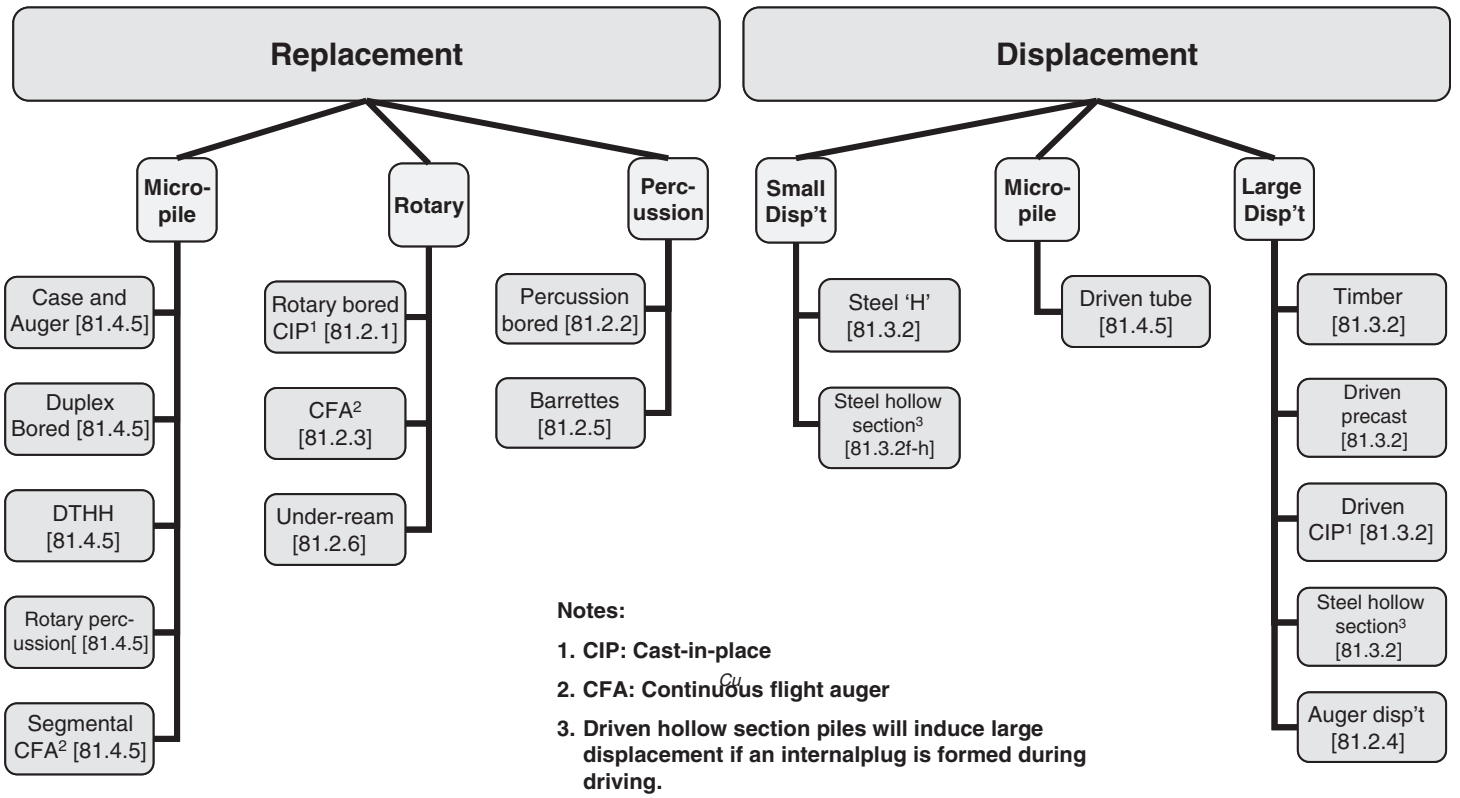

Figure 81.1 Broad classification of common bearing pile types (with reference to relevant sections of this chapter)

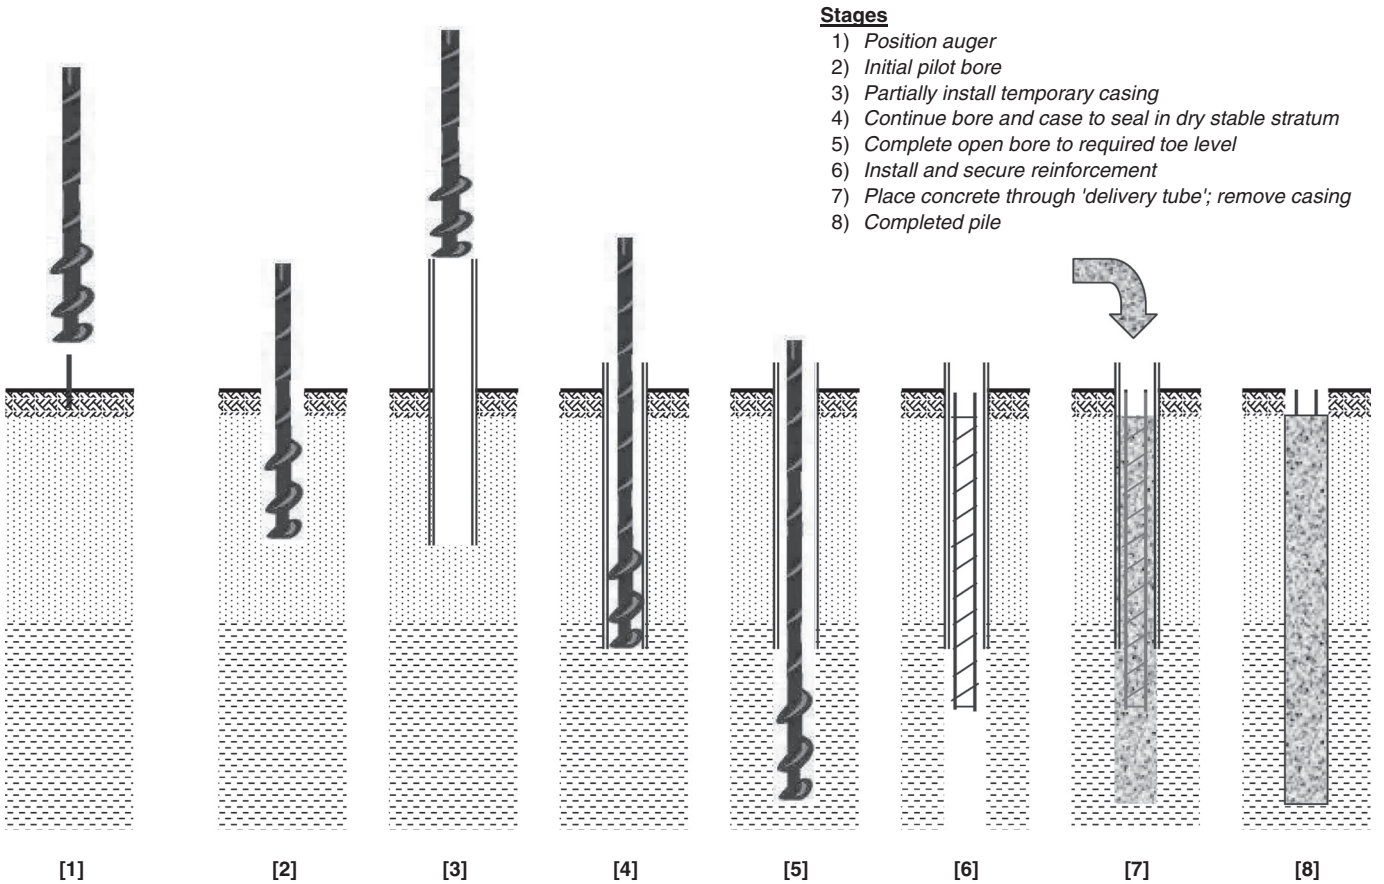
alternative solution such as CFA piling (see section 81.2.3) in order to keep vibration or noise to acceptable levels.

Figure 81.1 presents a simple classification of pile types, categorising each according to whether installation involves replacement or displacement of the soil (as originally proposed in BS 8004:1986 – now superseded). The figure includes references to the relevant sections in this chapter, where each pile type is briefly discussed.

81.2 Bored piles



Bored pile construction in the UK is generally carried out in accordance with the *Specification for piling and embedded retaining walls* (SPERW) (Institution of Civil Engineers, 2007) and is subject to the requirements of the European Execution Code, BS EN1536 (British Standards Institution, 1999). A bored pile is defined in BS EN1536 as 'a pile formed, with or without casing, by excavating or boring a hole in the ground and filling with plain or reinforced concrete'. This section describes the processes involved in constructing bored piles and gives illustrations of the plant most commonly used in the UK for this purpose. Some more specialised methods of construction are also discussed. Summaries of typical construction tolerances and the most commonly available pile sizes and depth ranges are given. The particular case of bored piles installed with micro-piling equipment is described in section 81.4.

Bearing piles are most commonly used to transfer structural loads through weaker near-surface soils, to more competent strata at depth. Unsupported bores and excavations through weak and unstable strata, such as very soft clays, highly organic soils, highly fractured rock or non-cohesive soils (silts, sands, gravel, especially if they are water-bearing), can result in uncontrolled inflows of soil and water. This may create unstable cavities outside of the pile shaft, undermine adjacent footings and pose a risk to the ultimate integrity of the concreted shaft (see Chapter 81 *Piling problems*). In unstable soils and beneath the water table it is therefore necessary provide a means of temporary or permanent support. The means of support may take the form of:

- temporary or permanent casings;
- drilling/stabilising fluid;
- soil-filled auger flights.

These stabilisation methods, coupled with the types of tools and processes used to excavate the piles, provide the key distinctions between the different forms of bored piles that are described below.

The majority of bored piles installed in the UK are constructed using either rotary bored and cased methods or continuous flight auger (CFA) techniques. Variations of these methods, such as tripod bored piles, circular clamshell grabs and down-the-hole hammer (DTHH) techniques, are also

Notes:
i Temporary casing may be installed in a single length (as shown) or segmentally as the bore proceeds.
ii Reinforcement generally extends beyond casing to prevent cage uplift during casing extraction.
iii Concrete 'delivery tube' should be long enough to direct concrete and avoid segregation by impact on steel (ICE SPERW B3.5.2.3).
iv Concrete should be cast to a level that ensures that a sound concrete connection can be made after trimming to the specified level (ICE SPERW Table B1.5).

Figure 81.2 Basic construction sequence for a rotary bored cast-in-place pile

sometimes used to suit particular sub-soil and environmental conditions. Increasing use is also being made of cast-in-place displacement piles, particularly to support relatively light structural loads. These distinct bored piling methods are discussed below. Heavy vertical loads, and particularly high lateral loads, may justify the use of barrettes, constructed using rectangular clamshell grabs and diaphragm walling techniques (see Chapter 85 *Embedded walls*). Chapters 79 *Sequencing of geotechnical works* and 82 *Piling problems* include discussion of the need for stable working platforms, the sequencing of pile installation and the problems that can arise during and following pile construction.

81.2.1 Rotary bored cast-in-place piles

The basic process of constructing a rotary bored cast-in-place pile is shown in **Figure 81.2**.

After setting the rig up over the pile location [1] an initial pilot hole is bored [2] using a short, flighted auger, mounted on a kelly bar. A temporary casing is then inserted [3] and the bore and casing are progressed together until a seal into a stable, dry stratum is achieved [4]. The bore is then completed to the required depth [5], the auger is withdrawn, and the reinforcement cage is lowered into position and secured [6]. Concrete is placed in the bore to the required level [7] and the temporary casing is withdrawn. Other types of bored cast-in-place pile generally follow this basic process but with variations to one or more aspects of construction to meet particular project-specific constraints.

The particular case of CFA piling is discussed in section 81.2.3 below.

81.2.1.1 Bored piling rigs

Bored piling rigs have developed considerably over the past 30 years in response to the changing and increasing demands made by the construction industry. The crane-mounted rigs that dominated rotary piling until the 1980s (**Figure 81.3(a)**) have

Figure 81.3 Rotary bored cast-in-place piling rigs: (a) crane-mounted rotary piling rig; (b) light–medium duty hydraulic rig; (c) heavy duty hydraulic rig
Photos courtesy of Cementation Skanska Ltd

Pile type	Rig characteristic	Range of diameters (mm)[1],[2]	Maximum depth (m)[1],[2]	Typical axial load range[3]
Rotary bored	Light rotary (< 35 t)	300–1200	18–35	< 5000 kN
	Medium rotary (40–80 t)	< 1800	40–60	< 20 MN
	Heavy rotary (> 100 t)	> 2400	< 90	> 30 MN
Percussion bored	Tripod	300–600	< 30	< 600 kN
CFA	Light CFA (< 35 t)	300–750	18–24	< 3000 kN
	Medium CFA (40–80 t)	450–1200	24–28	< 7500 kN
	Heavy CFA (> 100 t)	450–1200	< 32	< 10 MN
Cased-CFA	Twin-drive (> 100 t)	600–1200	casing: 18 m; bore: 25 m	< 10 MN
Auger displacement	Rotary (> 60 t)	400–600	25	< 2000 kN

Notes:
The above figures are given as a preliminary guide only. The advice of specialists should be sought before selecting the particular pile type, plant type and method of construction.
[1] Maximum achievable pile diameters and depths vary according to the plant manufacturer. Figures shown are for guidance only.
[2] In addition to the rig size and power, the available pile diameters and depths may also be limited by the ground conditions.
[3] Irrespective of pile diameter and depth, the achievable axial loads are dependent on ground conditions.

Table 81.1 Typical bored pile characteristics

been steadily replaced by purpose-built, self-erecting, vertically masted hydraulic units (**Figure 81.3(b)**). Simultaneously, as the demands of the commercial and infrastructure sectors have risen, increasingly powerful rigs have been developed, capable of installing large diameter piles to depths in excess of 60 m (**Figure 81.3(c)**). Tomlinson and Woodward (2008) provide a useful summary of the characteristics of self-erecting hydraulic rigs from various suppliers. Commonly available pile diameters and depths are listed in **Table 81.1**.

81.2.1.2 Excavation tools

A wide range of tools are available for use with rotary piling rigs to excavate pile shafts through the variable ground conditions found beneath UK sites (**Figure 81.4**). One or more of these tools may be used during the construction of an individual pile.

Augers are generally used to excavate soft ground (sands, clays, gravels, etc.) and some weak rocks (including chalk and marl). In hard ground a variety of chisels may also be deployed to break up the material at the base of the bore before removal

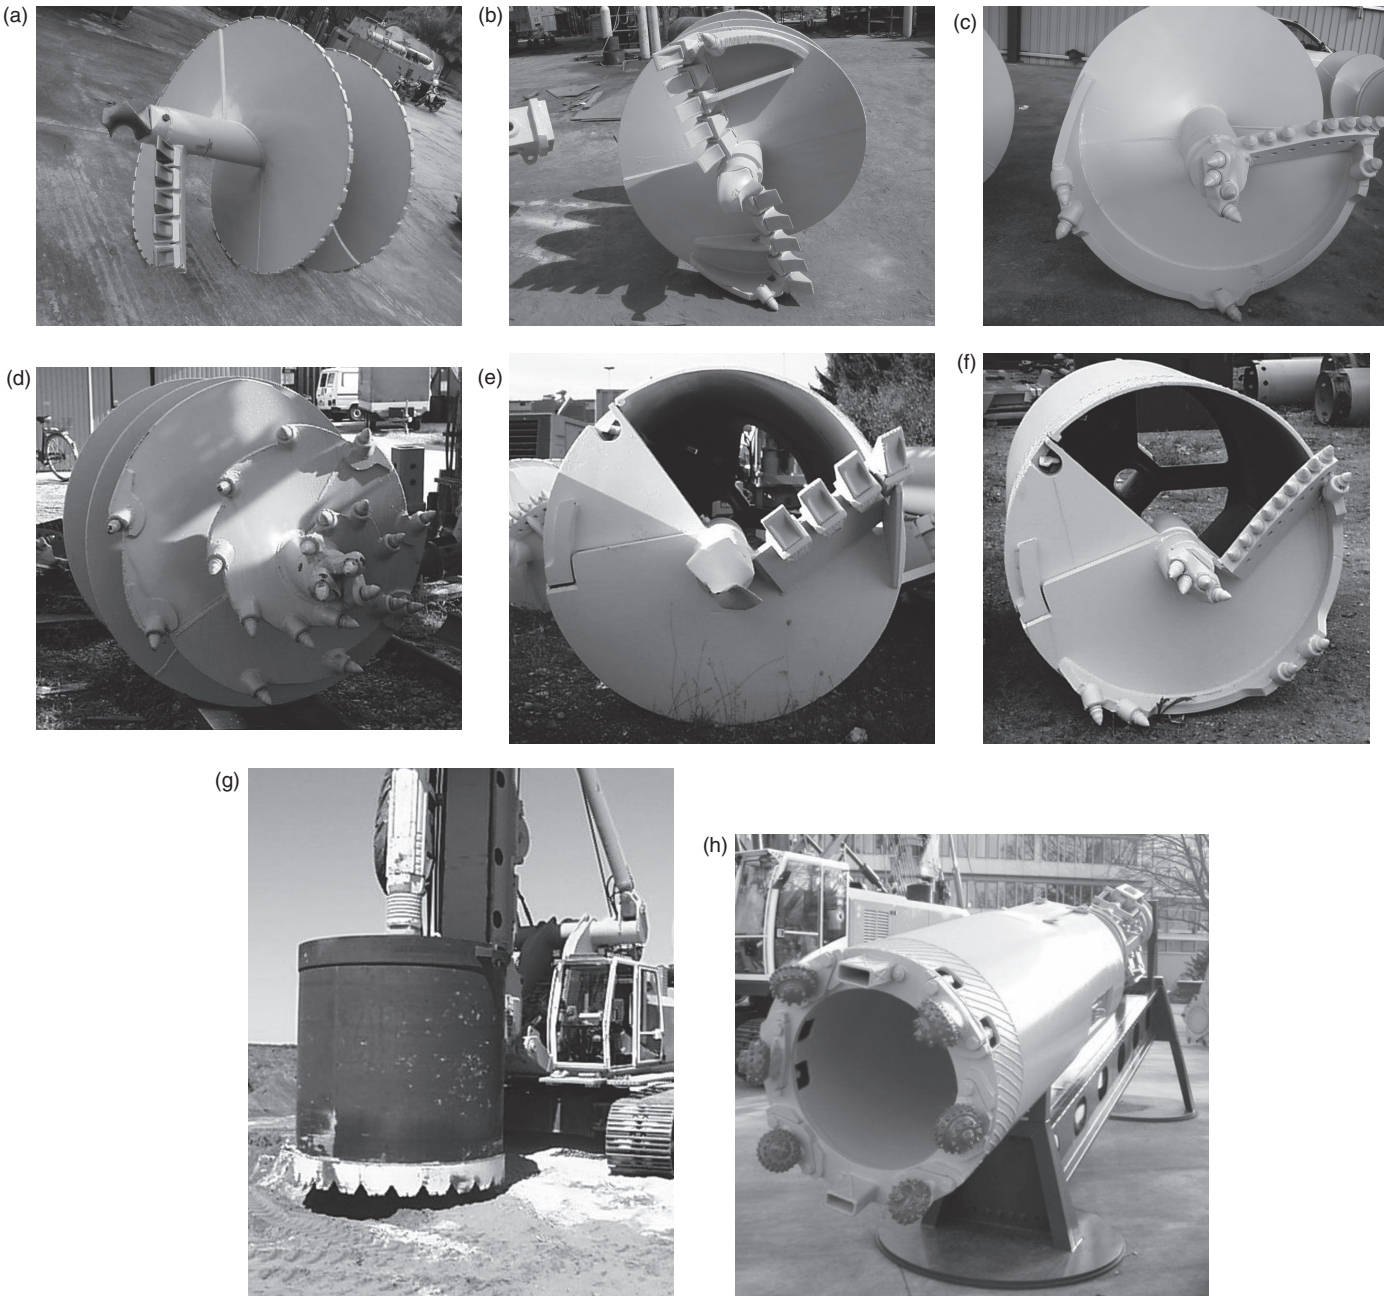


Figure 81.4 Rotary bored piling – excavation tools: (a) Single start soil auger; (b) double start soil auger; (c) single start rock auger; (d) single start progressive rock auger; (e) single cut digging bucket; (f) single start rock digging bucket; (g) large diameter coring barrel; and (h) heavy duty coring barrel with air flush

Photos courtesy of Bauer Equipment UK Ltd

by auger. Specially designed toothed augers can also be used to excavate stronger rocks, although production rates fall significantly at strengths above 10–15 MN/m^2, depending on the type of rig and tool design being used.

Drilling buckets are designed to recover materials that are not easily retained on an auger during retrieval from the bore. This can arise in water-bearing soils and fractured rocks. Specially designed buckets may be used when drilling under stabilising fluid, to minimise turbulence during insertion and retrieval of the tool, and avoid the resulting shaft and base instability. Where appropriate a drilling bucket may also be used to clean the base of the pile before concreting. Some caution is required in cohesive soils, however, since this can create a softened layer at the pile toe thereby diminishing the end-bearing response of the pile.

An alternative means of excavating pile shafts, not commonly used in the UK, is to employ a circular-section, clamshell grab or hammer grab. These tools are rope-suspended

from a tracked crane and can be combined with segmental casing techniques (see below) to excavate through most soils, and form sockets in weak rocks (using chisel attachments).

Harder and more massive rocks call for alternative methods:

- coring barrel;
- rock roller assemblies coupled with air flush or reverse-circulation systems to remove the cuttings (described in greater detail by Tomlinson and Woodward, 2008).

81.2.1.3 Casings

Temporary casings most commonly take the form of single-wall steel tubes, installed in one piece as illustrated in **Figure 81.5(a)**. These may be installed and removed from the bore using the piling rig or an attendant crane, with or without the assistance of a casing vibrator.

Where closer control of the boring process is required segmental casings may be used. These are stiff double-walled casings, typically 40–60 mm thick, mechanically jointed in 1–6 m lengths, with a cutting head at the leading edge (**Figures 81.5(b)–(c)**). Segmental casings can be installed to significant depths using the rotary drive of medium and heavy duty hydraulic rigs. Where greater installation/extraction capability is required, a casing oscillator (**Figure 81.5(e)**) or specially designed casing extractor may be used.

Segmental casings, installed as the bore proceeds, offer greater control over pile verticality and enable virtually

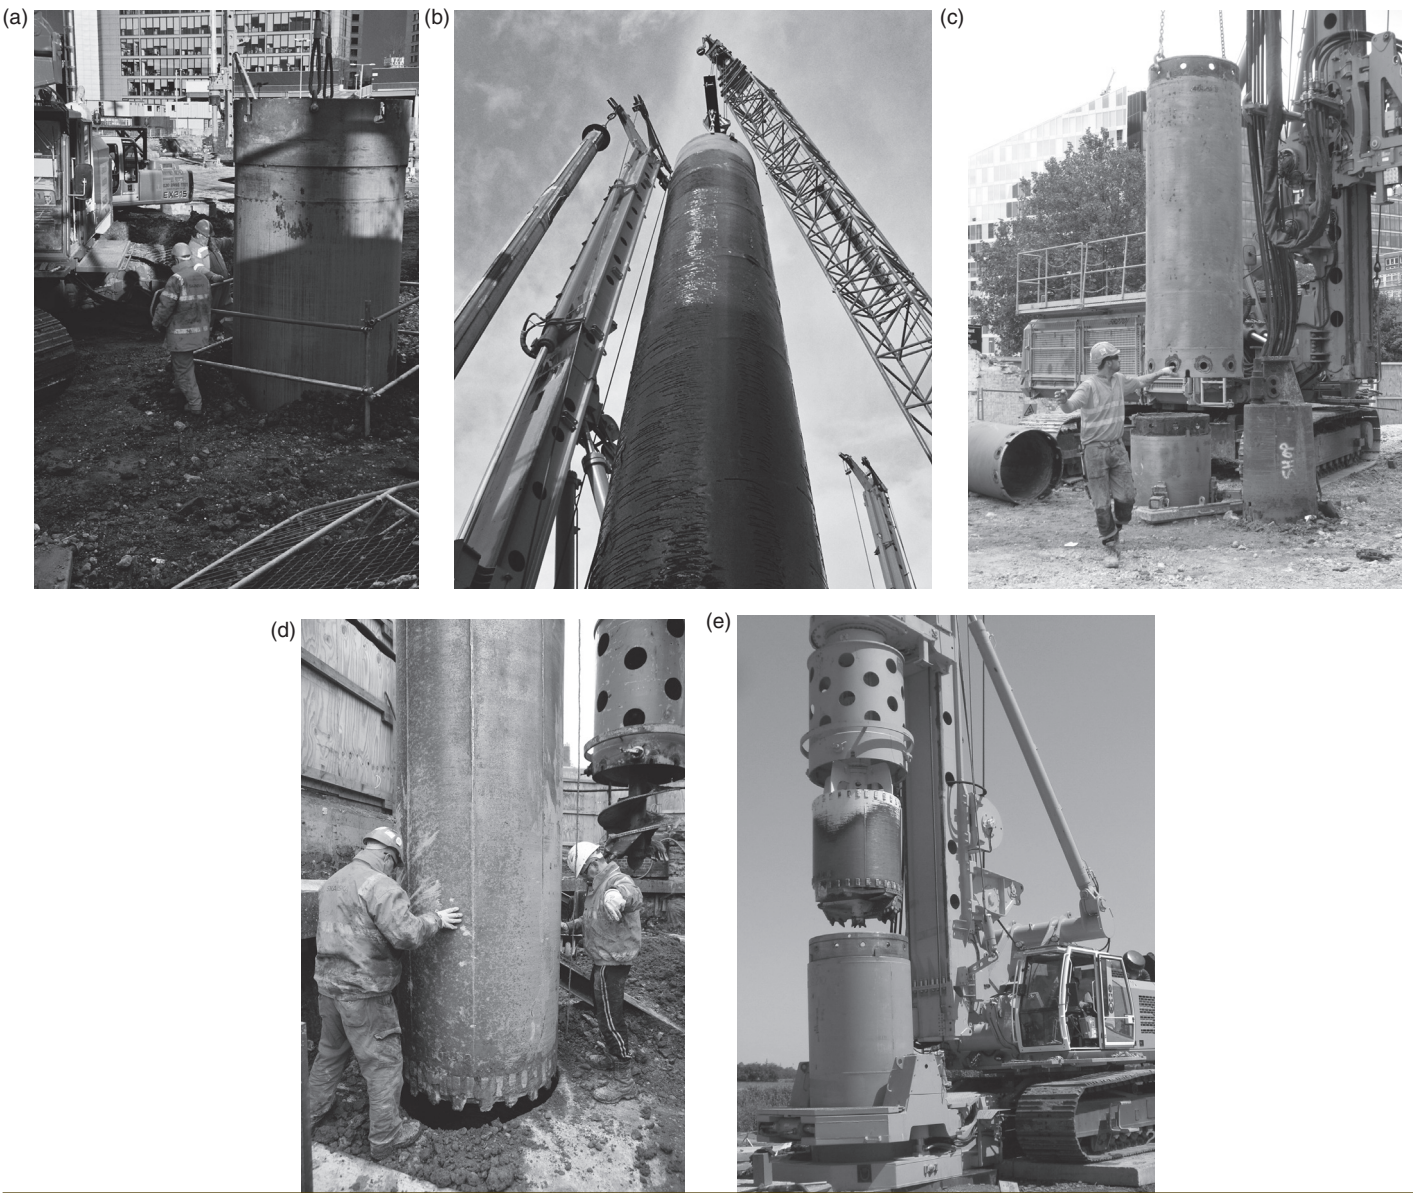

Figure 81.5 Rotary pile casings: (a) single wall temporary casing; (b) slip coated permanent lining; (c) segmental casing; (d) cutting head; (e) casing oscillator

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

continuous support of the bore through unstable deposits. With the right combination of power and cutting head, they can also be used in conjunction with heavy duty coring tools to overcome substantial obstructions (**Figure 81.6**), including, in some cases, old piles.

Drill casings can be left in place as permanent linings. These linings may be used to prevent washout of concrete fines by flowing groundwater or to support the concreted shaft in very soft soils. They may also be slip-coated to reduce negative skin friction or to reduce the load shed by the pile in the vicinity of sensitive structures such as tunnels and basement walls (**Figure 81.5(b)**). Lightweight permanent linings may alternatively be installed and cast within the pile bore, allowing recovery of the more expensive drill casings for reuse.

81.2.1.4 Stabilising fluids

Stabilising fluids are used to support pile bores where they pass through unstable soils at depths beyond the economical use of temporary casing. A typical pile construction sequence using stabilising fluid is shown in **Figure 81.7**. Stabilising fluids take the form of a bentonite clay suspension or a polymer fluid. The composition, properties and operation of bentonite and the various polymer fluids are distinct from one another and call for understanding and experience on the part of the practitioner. A few practical observations are made here:

- Drilling with fluid support is only feasible from a working level at least 1.5–2.0 m above the effective water table, since support of the bore wall is provided by maintaining a positive pressure differential between the fluid and the surrounding groundwater.
- Polymer fluids generally hold less detritus in suspension, for less time, than bentonite, making base cleaning more critical with polymer fluids.
- Polymer fluids suit smaller sites since they require less space for the mixing and treatment plant.
- Waste bentonite must be disposed of by tanker to licensed tips. Polymer fluids may be broken down to water and polymer, reducing the difficulty and cost of disposal.

More detailed accounts of the use of bentonite and polymer stabilising fluids may be found in Fleming *et al*. (2009).

81.2.1.5 Placing concrete

In a dry bore, SPERW (Institution of Civil Engineers, 2007) requires that concrete is placed, in a single continuous operation, via a hopper and sufficient rigid delivery tube to avoid a fall of more than 10 m within a reinforcement cage. This limits segregation of the mix caused by impact on the reinforcement during the fall. In a wet bore (filled with water or stabilising fluid) concrete must be placed with a full-length watertight tremie tube (**Figure 81.7**). The initial charge of concrete is separated from the fluid by a disposable plug to avoid segregation or contamination of the mix, and delivered to the pile toe via the tremie tip. This charge displaces the fluid upward, covering the pile base and engulfing the tip of the tremie. Further concrete is delivered through the tremie, which is progressively shortened as the concrete level rises, until the required concrete level is reached. The displaced fluid is pumped away at the pile head. Throughout this operation the fluid and concrete levels must be maintained to counteract the effects of any groundwater pressures along the pile shaft. The tremie tip must remain embedded between 3 m and 6 m into the rising concrete at all times.

81.2.2 Percussion bored cast-in-place piling

Tripod-mounted cable percussive boring equipment continues to be available for piling in the UK, although it is increasingly replaced by the growing capabilities of hydraulic micro-piling rigs. The method involves much manual handling of heavy tools and casings, and achieves relatively slow production. This makes it less attractive than other methods on both health-and-safety and commercial grounds. The boring tools, including clay cutters, 'shells' for sand and gravel, and chisels, are suspended by rope from the rig and sequentially lifted and dropped in the

Notes:
i Temporary casing may be installed in a single length (as shown) or segmentally as the bore proceeds.
ii Reinforcement generally extends beyond casing to prevent cage uplift during casing extraction.
iii Concrete should be delivered by tremie in a manner to fully displace, and avoid mixing with, the stabilising fluid (ICE SPERW - B3.5.2.4).
iv Concrete should be cast to a level that ensures that a sound concrete connection can be made after trimming to the specified level (ICE SPERW Table B1.5).

Figure 81.7 Typical construction sequence for bored cast-in-place pile under stabilising fluid

bore to cut or pump soils up from the base of the bore (**Figure 81.8**). The tool is raised and spoil is cut away or emptied out on the working platform for disposal. Considerable experience is needed to ensure that this process does not significantly soften or loosen the surrounding soils. Temporary casings, which are hammered or surged into place, are handled in short threaded sections, screwed together and installed as the bore proceeds. The reinforcement and concrete processes are similar to rotary piling except that concrete is commonly delivered by dumper, via a chute at the pile head, or by pump.

Tripod piling rigs are light and easily transported, and have been used for installing piles where access and headroom are limited (within basements and in the vaults beneath existing buildings, benched into sloping sites, etc.). Diameters up to 600 mm are possible and depths in excess of 30 m have been successfully achieved.

Earlier percussive processes, such as the Benoto method, Puller (2003), have been used to install larger diameter piles. These methods have died out in the UK, in the face of more economical techniques. In recent years however, down-the-hole hammers, more commonly used for small diameter mining applications, have become available in sizes suited to bored piling. Single-bit hammers up to 750 mm diameter are available. Larger diameters can be drilled using cluster drills (multiple hammer units). These units can be used in combination with cased rotary piling to form deep rock sockets (Fleming *et al.*, 2009). The technique requires large quantities of compressed air and casing for borehole stability. Hydraulically driven hammers are also becoming available. These can reduce the need for temporary casing.

81.2.3 Continuous flight auger (CFA)

The CFA process (**Figure 81.9**) allows economical and rapid pile construction in water-bearing strata, without the need for casing or stabilising fluid. It is suitable for constructing piles through sands, gravels, silts and clays, and for limited

(a)

(b)

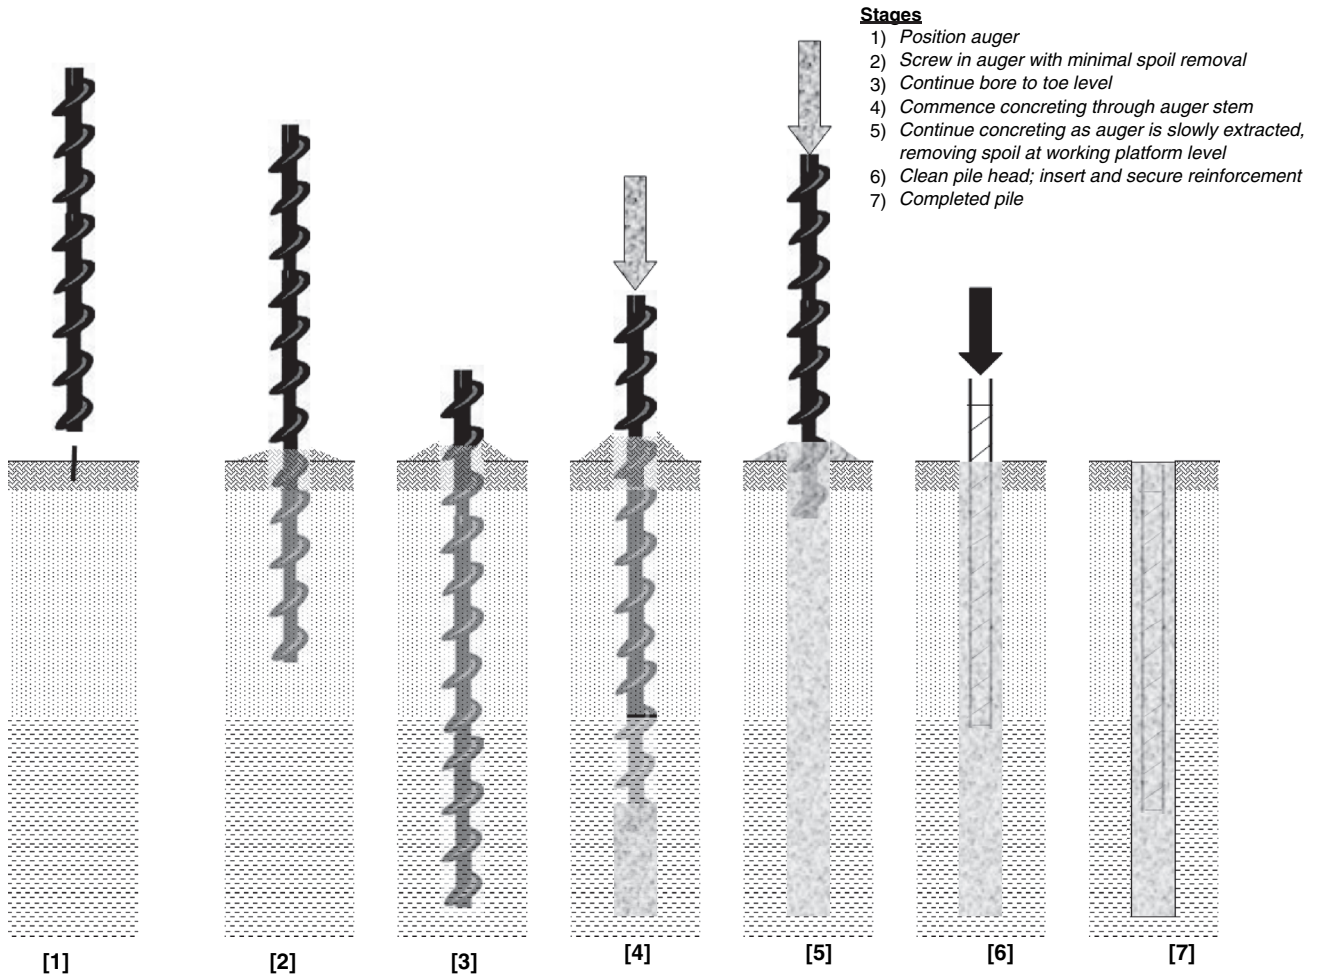
Figure 81.8 Percussion bored piles – tripod piling using: (a) 'shell' for boring in granular soils; (b) 'clay cutter' for boring in cohesive soils
Photos courtesy of Cementation Skanska Ltd

penetration of weak rocks. In comparison to rotary piling, greater power is required to drill in and extract the auger in a single pass. It is particularly important that the CFA piling equipment is sufficiently powerful to achieve the required pile depth without significant flighting of material from the bore (note: 'flighting' is the upward displacement of spoil along the auger flights to ground surface). The available depth and diameter range, and the ability to penetrate hard strata with CFA piling, are therefore more limited than with conventional rotary piling (**Table 81.1**). CFA piling is not appropriate in ground containing frequent and substantial obstructions, including old foundations and boulders, without due consideration in the foundation design.

After setting the rig up over the pile location [1] the hollow-stemmed, continuously flighted auger is drilled in a single stroke to the full pile depth [2]. The disturbed spoil remains on the flights at this stage [3]. Concrete, delivered by pump, is injected through the hollow stem of the auger to the base of the pile [4]. The auger, which is still rotating slowly, is lifted a short distance (< 100 mm) to allow entry of the concrete into the bore so that the initial charge engulfs the tip, and is then returned to the full bore depth. The spoil-laden auger, still rotating slowly, is then gradually retracted as further concrete is injected to form a continuous shaft [5]. Once the shaft is fully concreted to ground level the auger is withdrawn, the pile head is scraped clean and the reinforcement cage is inserted into the concrete [6] leaving the top of the steel at ground level [7].

81.2.3.1 CFA piling rigs

CFA piling became established in the UK piling market during the 1980s, coinciding with the development of purpose-built hydraulic piling rigs (**Figure 81.10**). Many hydraulic rigs are capable of modification to work in either rotary or CFA mode. The distinguishing features of CFA rigs are the single 'string' of continuously flighted auger, and the location of the drive table at the top of the auger.



Many CFA piling rigs are fitted with a winch-driven or hydraulic 'crowd' facility designed to increase the downward thrust of the auger whilst drilling through harder strata. Extraction capability is enhanced by providing a 'foot' at the base of the mast which bears on the working platform to stabilise the rig during withdrawal of the auger. Mechanical auger cleaners are fitted to CFA rigs to prevent spoil from rising with the auger string during extraction. The rising spoil would otherwise present a hazard to operatives working below, and potentially destabilise the rig.

81.2.3.2 Excavation tools

As the name implies the excavation tools are restricted to augers. In common with rotary piling, the lead augers are mounted with a wide range of cutting tools designed and arranged to suit the expected ground conditions (**Figure 81.11**). The various configurations of flat teeth, picks, bullet teeth, etc. are suitable for boring through most soils and into weak rocks. CFA piling is not generally capable of penetrating stronger rocks or hard obstructions.

81.2.3.3 Placing concrete

CFA piling relies on a steady delivery of concrete to the pile. Concrete is therefore often delivered to site by readymix wagon and held in an agitator ready for delivery by pump to the piling rig. Once the auger has been drilled to depth the pump lines and hollow stem are pre-charged with concrete. The auger, still rotating slowly, is lifted a short distance (< 100 mm) to allow entry of the concrete into the bore (via the hollow auger stem and an end

Notes:
i Pile boring and concreting stages should generally be subject to automatic real-time monitoring (ICE SPERW B4.4.8).
ii Concrete should be cast to the commencing surface level to allow removal of contamination before installing reinforcement.
iii Reinforcement cage must be robust enough to resist the stresses imposed by insertion through fresh concrete (ICE SPERW B4.4.7).

Figure 81.9 Basic construction sequence for a continuous flight auger pile

or side entry valve at the auger tip). The auger is returned to the full bore depth, so that the initial charge engulfs the tip, and then steadily extracted with the spoil as more concrete is delivered to fill the resulting pile shaft. It is essential that a positive pressure of concrete is maintained at the auger tip throughout the concreting process and that the auger tip remains embedded within the rising column of concrete. Failure to control and coordinate the delivery of concrete and extraction of auger can lead to pile integrity problems (see Chapter 81 *Piling problems*).

81.2.3.4 Rig instrumentation

During the early development of the CFA technique in the UK a number of projects encountered serious pile integrity problems; others suffered ground loss and an unexpected variability in load-bearing performance. These problems arose in part because the CFA process is largely hidden from the eye and cannot be directly verified. Fleming (1995) discussed these issues and highlighted the need for close control of the boring and concreting phases of pile construction. It is now a standard requirement (Institution of Civil Engineers, 2007) that automated instrumentation is provided to monitor critical parameters throughout pile construction.

Data from built-in instrumentation is displayed in real-time on a computer, mounted in the operator's cab. The data include critical boring and concreting parameters including auger depth and rates of rotation and penetration, applied torque, concrete pressure and rate of delivery (**Figure 81.12**). This enables the operator to control flighting of material and over-rotation during boring, and to prevent over/undersupply of concrete during auger extraction. The data also provide a permanent construction record for each pile. These detailed records, coupled with integrity test results (Chapter 97 *Pile integrity testing*), provide

Figure 81.10 CFA piling rig
Photo courtesy of Cementation Skanska Ltd

essential tools with which to assure the quality of the CFA operation.

81.2.3.5 Placing reinforcement

It is necessary to cast the pile to commencing level to allow removal of contaminated concrete before insertion of the reinforcement cage. Cages must be robust enough to tolerate insertion into wet concrete to the required depth without distortion. Insertion depths up to 12 m are common. Greater depths are feasible (depths over 20 m have been reported) but commonly require additional measures which can include careful cage detailing, special mix designs and using a cage vibrator. Particular caution is required when piling in dry, fine-grained silts and sands. These soils can draw moisture from the concrete, causing an early set, and thus prevent full insertion of the cage.

81.2.3.6 Cased CFA piling

Cased CFA piling combines the advantages of CFA piling with the additional capabilities of a cased system. The process is

Figure 81.11 CFA piling: typical lead auger and cleaner configuration
Photo courtesy of Cementation Skanska Ltd

the same as the CFA method except that a single length of thick-wall temporary casing is inserted and removed simultaneously with the auger. The casing has a cutting head and is counter-rotated against the auger, creating a higher torque to enable penetration into harder strata. The stiff temporary casing helps to prevent flighting of superficial deposits when drilling in hard strata, and provides greater verticality control. The system requires a very high-powered rig with either a single drive head coupled with a torque-multiplier or two independent rotary drive heads (**Figure 81.13**). The former system has a typical depth limit of 16–18 m, whilst with the latter, respective cased and bored depths of 21 m and 27 m are claimed. When using the twin-drive system it may be feasible to cast the piles with a cut-off level below commencing level, in the same way as cased rotary piles.

The simultaneous extraction of auger and casing results in spoil being discharged from a point high above the working platform. The additional weight of spoil and equipment at height can have a destabilising effect on the rig. Particular attention is therefore required in the design of the working platform and in assessing the rig stability during operation. The safe discharge of the spoil to platform level must be controlled by purpose-built chutes (**Figure 81.13**).

81.2.4 Cast-in-place displacement auger piling

Cast-in-place displacement auger piles are installed using high-torque rotary equipment with drilling tools designed to form the bore by displacement rather than removal of the soil.

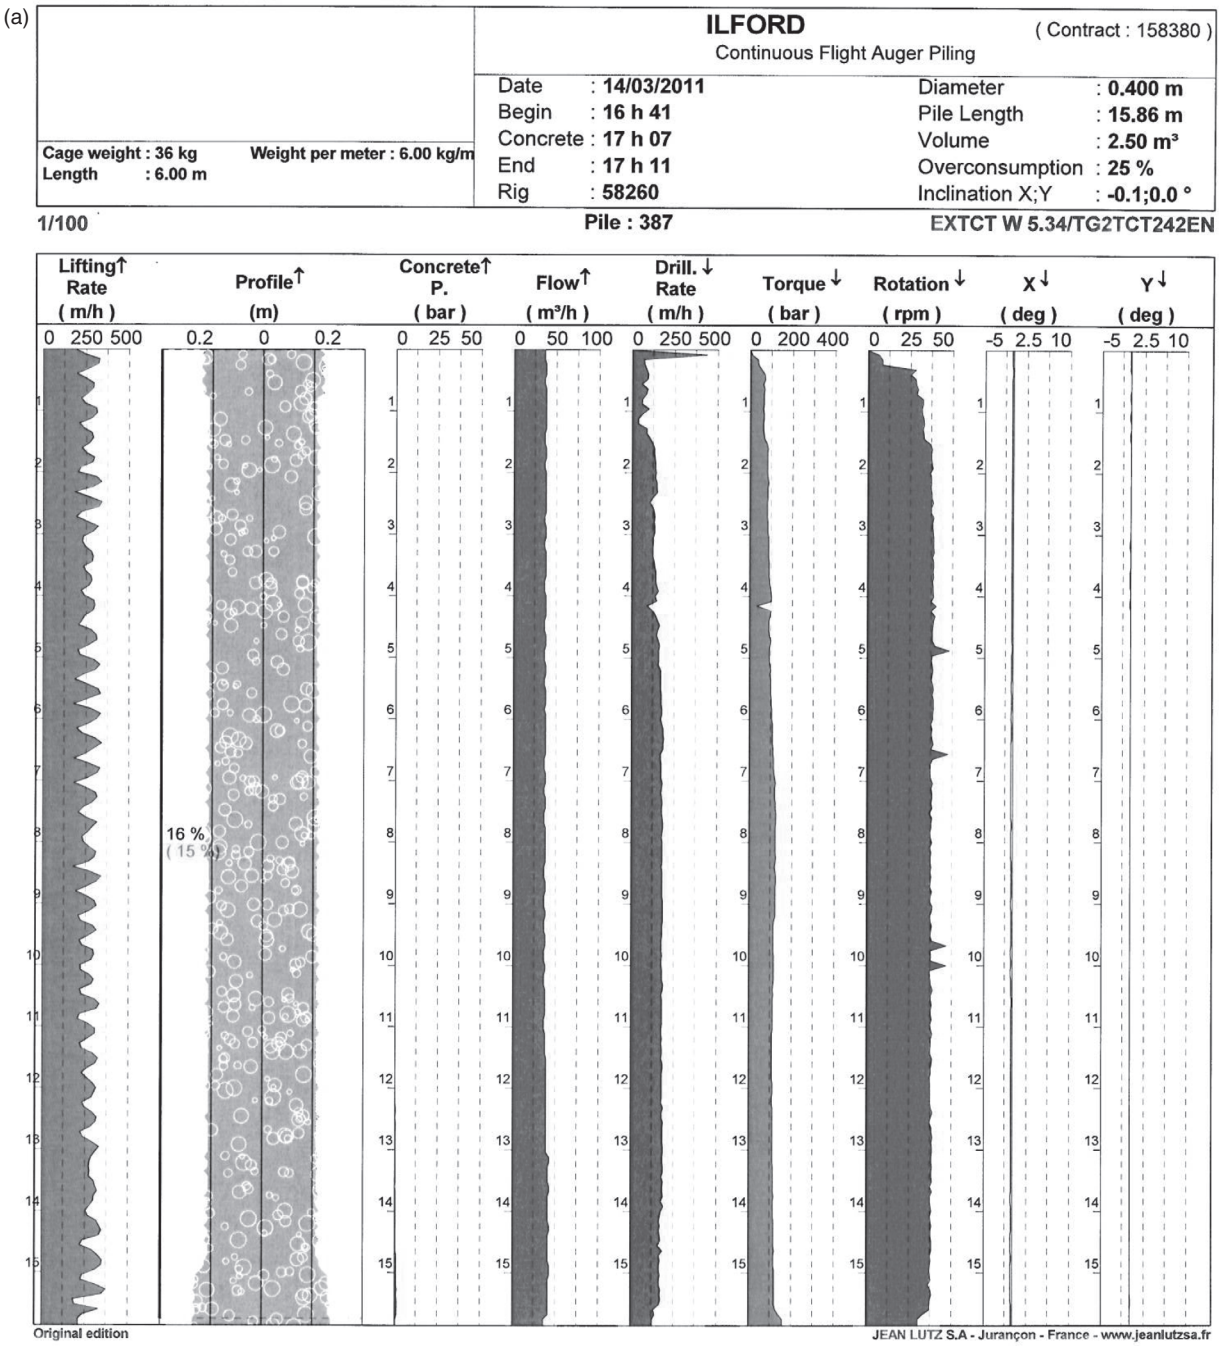


Figure 81.12 CFA piling rig instrumentation
Photo courtesy of Cementation Skanska Ltd

The system is relatively quiet and vibration-free, minimises the volume of spoil handling and concrete supply, and can improve the compaction of granular deposits. In the simplest form (e.g. the 'Omega' pile, Fundex system) a tapered or 'bullet'-headed auger is screwed into the ground, displacing the soil, and extracted as concrete is placed through the hollow stem, to leave a straight-shafted pile. A typical construction sequence is illustrated in **Figure 81.14**.

Alternative methods (e.g. Atlas pile, continuous helical displacement (CHD) pile and the 'Screwsol' system) employ a short, flighted, bullet-headed auger, screwed into the ground in one pass and carefully back-screwed along the same trajectory during concreting, to leave a screw-form pile (**Figure 81.15**). The construction of screw piles is subject to the requirements of the European Execution Code, BS EN12699:2001 (British Standard Institution, 2001).

(b)

Figure 81.12 (Continued)

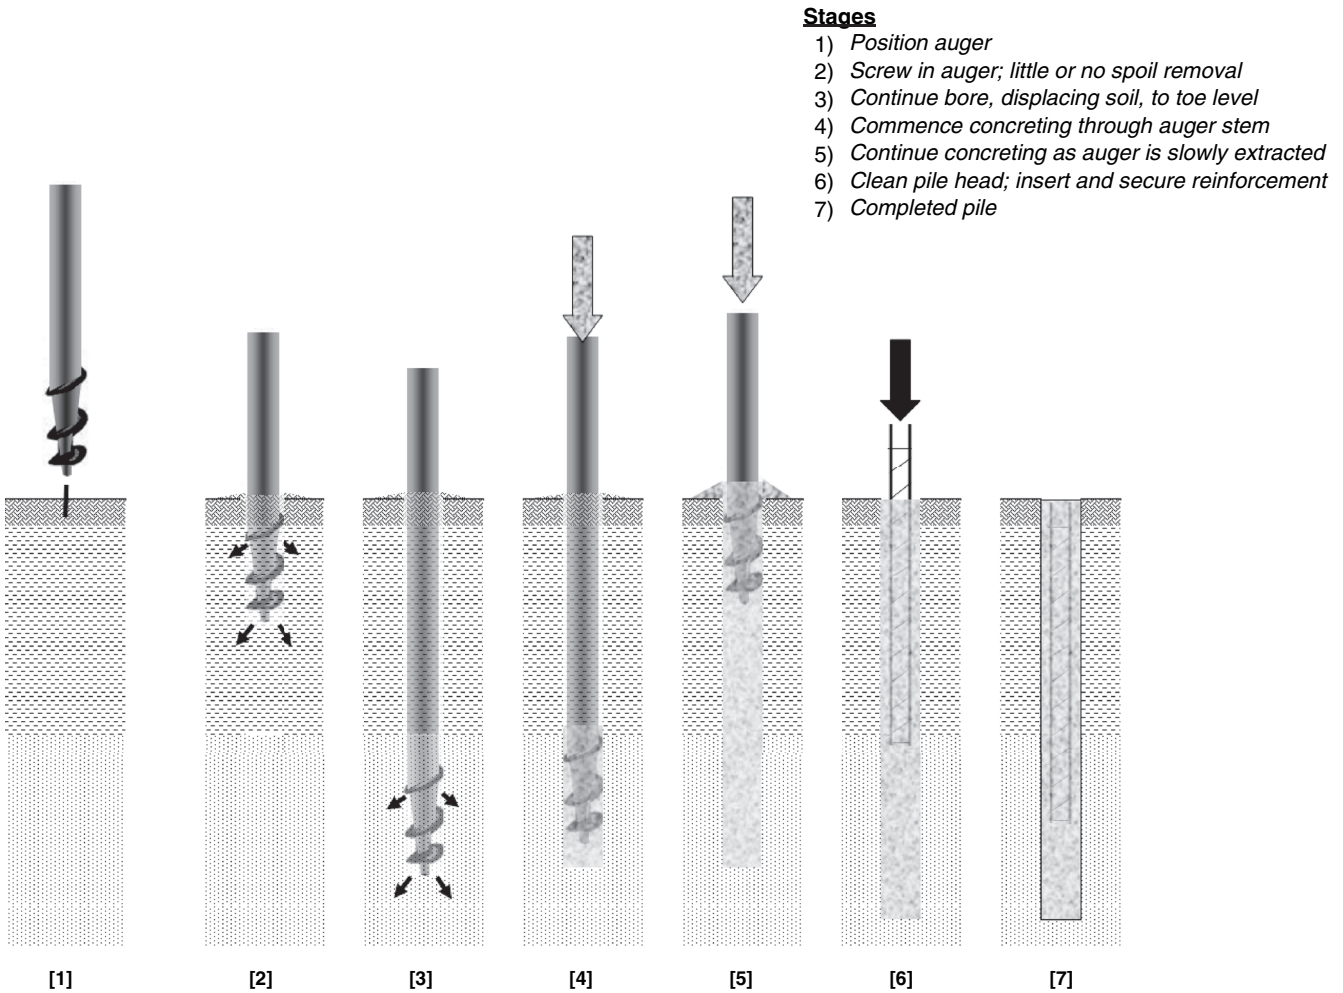
Figure 81.13 Cased-CFA piling rig
Photo courtesy of Cementation Skanska Ltd

All of these methods require comprehensive instrumentation to confirm successful construction of the pile at the required diameter. It is vital to confirm that each pile has reached the design bearing stratum and, in the case of screw-form piles, that the flights are robust enough to prevent premature failure. As with CFA piling the reinforcement is installed after completion of the concrete column to ground level.

When considering the use of this technique, it should be borne in mind that, in common with driven displacement piling, cast-in-place displacement piling is likely to cause heave of the surrounding ground.

81.2.5 Barrettes

Barrettes may be used to carry exceptionally large vertical loads and high lateral loads. They are constructed using diaphragm walling methods and equipment (Chapter 85 *Embedded walls*). They are most commonly rectangular but may take a variety of forms (**Figure 81.16**).



In soft ground, and some weak rocks, barrettes may be excavated using rope-suspended grabs. In stronger rocks, rock cutters or milling machines may be required, although deployment of such equipment is only occasionally economical compared to rotary piling.

81.2.6 Specialised techniques

81.2.6.1 Under-reaming

Under-reaming is an extension of the rotary piling technique which can significantly enhance the capacity of relatively slender and short piles. It is only practicable in stable and dry strata, typically stiff clays. After forming a straight-shafted bore to the required level a specialised under-reaming tool (**Figure 81.17**) is lowered in the closed position to the toe of the bore. As the tool is rotated the reaming arms are slowly opened to form the under-ream. Cuttings are removed by a collecting bucket at the bottom of the tool.

Under-reaming tools are designed to form a maximum under-ream diameter of approximately three times the pile shaft diameter, with a roof angle commonly limited to about 35° to vertical (Institution of Civil Engineers, 2007). Given the dependence of such piles on end-bearing it is essential that the drilling process is precisely controlled to ensure that no remoulded material or crumbs of soil remain on the base of the ream. This is usually proven by the use of CCTV, and testing or sampling apparatus mounted on the tool (for safety reasons physical descent and inspection is no longer an accepted process).

Notes: i Pile boring and concreting stages should generally be subject to automatic real-time monitoring (ICE SPERW B4.4.8).
ii Concrete should be cast to the commencing surface level to allow removal of contamination before installing reinforcement.
iii Reinforcement cage must be robust enough to resist the stresses imposed by insertion through fresh concrete (ICE SPERW B4.4.7).

Figure 81.14 Displacement auger piling – typical construction sequence.

81.2.6.2 Base grouting

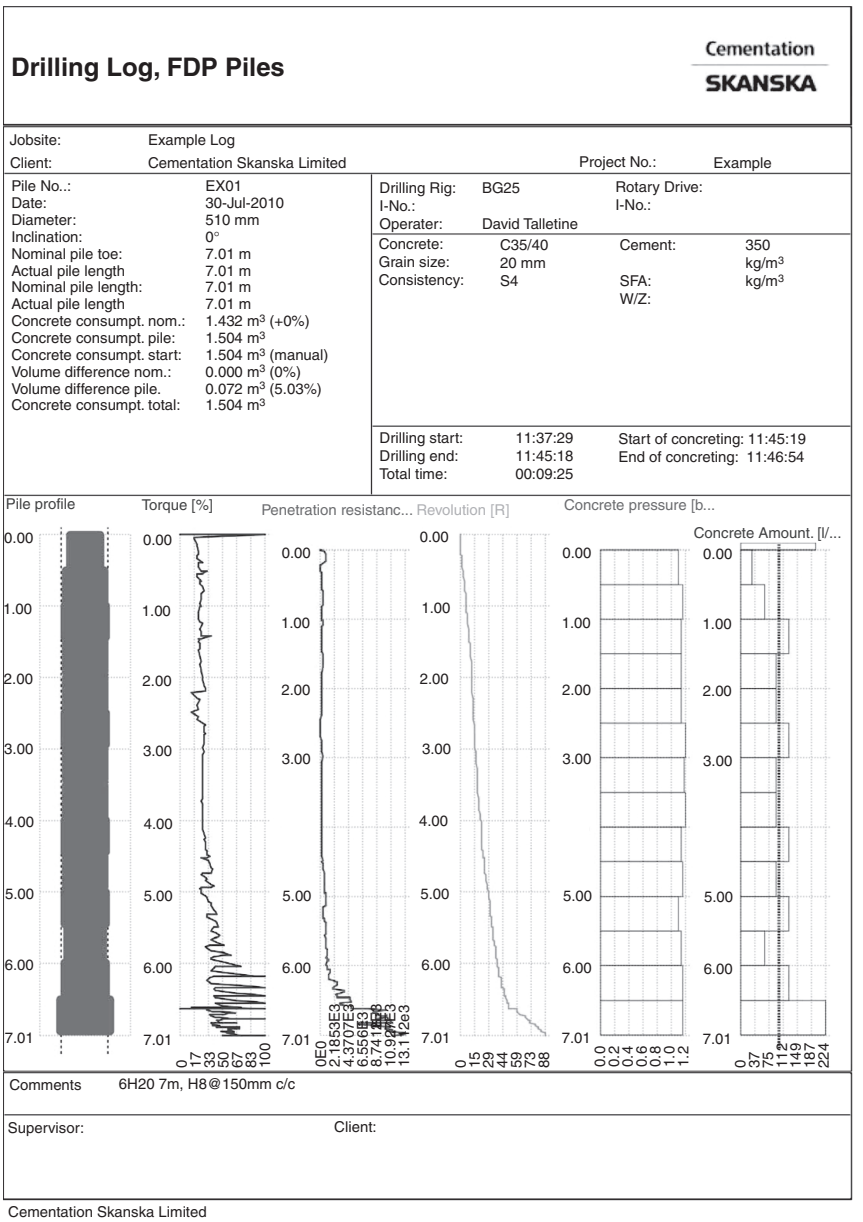
Base grouting is a secondary process applied to rotary piles. Its purpose is to mobilise very high base capacities in dense sands without excessive pile settlement. The effect is two-fold:

- consolidation of sand loosened by the pile bore;
- pre-compression of the shaft, reversing the direction of applied shaft friction.

This gives the pile a very stiff response under load, a necessary requirement for particularly tall structures, and can result in economies in the pile design (see Chapter 54 *Single piles*). Base grouting is generally only economical in large diameter piles and requires the pile to have sufficient shaft capacity to resist the uplift caused by grouting.

It is achieved by casting grout circuits into the pile. Each circuit comprises injection and exit tubes linked by a 'tube-à-manchette' (Chapter 86 *Soil reinforcement construction*) across the pile toe. The number of circuits depends on the pile diameter (**Figure 81.18**). After casting, and before the pile concrete gains significant strength, each circuit is pressurised with water to 'crack' the grout valves and the base concrete, in preparation for grouting. At a later stage cementitious grout is injected under pressure at the pile base in a controlled process that upwardly compresses the pile shaft. The effect of the grouting is confirmed by monitoring the pile head for uplift (a minimum of 1–2 mm is typically specified) or by instrumentation installed close to the toe of deeper piles, where the pile head may not respond.

81.2.6.3 Embedded columns



Embedded (plunge) column technology has been developed to enable accurate installation of permanent columns within

basements constructed using top-down techniques. The columns are embedded in large diameter rotary cast-in-place piles using specially designed placing equipment. These may be simple mechanically adjustable guides, or more sophisticated hydraulically operated frames that can install columns to tolerances consistent with BS EN1993 (British Standards Institution, 2005a) in dry or wet bores. **Figure 81.19** illustrates the typical embedded column installation sequence. The columns are generally rolled steel column sections, although other forms such as pre-cast concrete may be accommodated. After installation and removal of temporary casings the open bore around the column must be temporarily backfilled to stabilise the column and the surrounding ground and to prevent accidents.

81.2.6.4 Geothermal piles

Piled foundations are increasingly being used to exploit geothermal energy exchange between the supported structure and the ground. Coupled with heat exchanger technology, geothermal piles can be used to heat and cool buildings in an environmentally friendly manner. Flexible plastic pipework is incorporated in the reinforcement cages (**Figure 81.20**) of rotary cast-in-place piles or plunged into CFA piles. These pipes are connected via a manifold in the sub-structure to a heat pump,

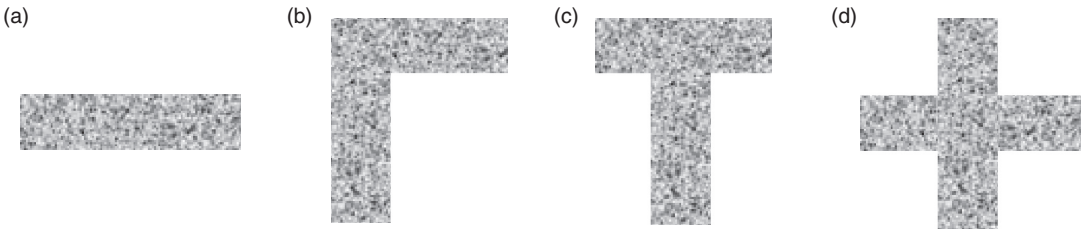

Figure 81.16 Typical forms of barrette

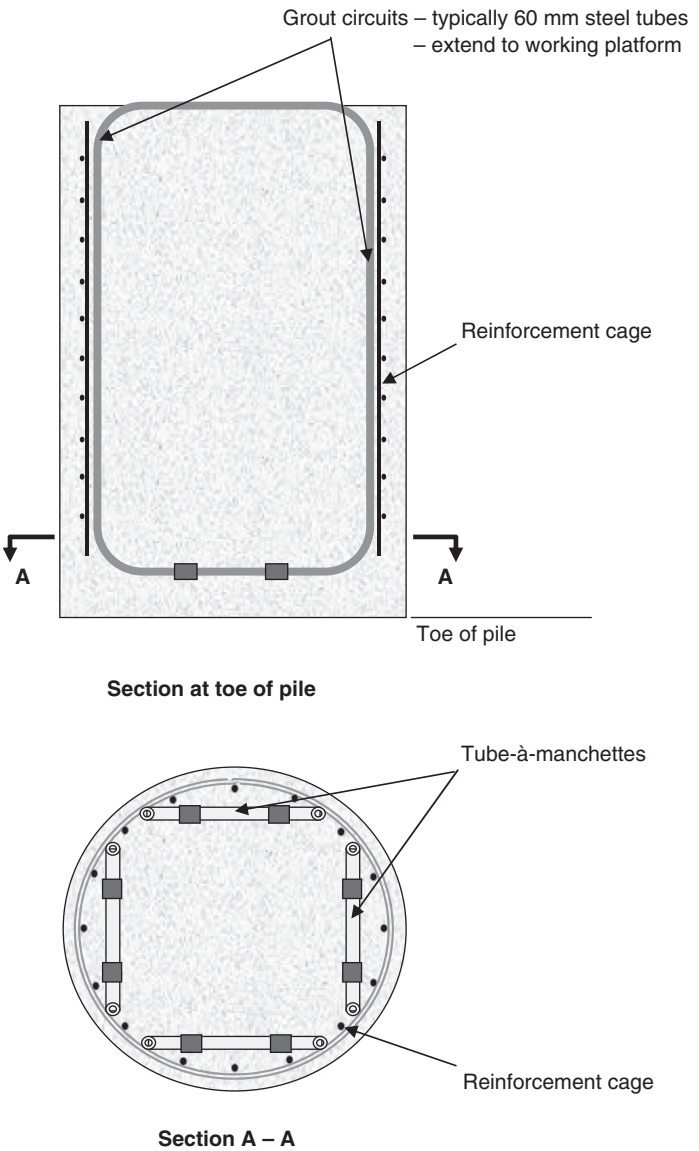

Figure 81.18 Typical base grouting circuit configuration

which allows a reversible exchange of energy between the structure and the ground (Bourne Webb *et al.*, 2009).

81.3 Driven piles

81.3.1 Introduction

Driven piles have historically been described by the means of installation or construction, driven into the ground using a piling hammer. A better term would be displacement piles, describing the manner in which the pile interacts with the soil during driving. The soil is displaced, predominantly in a lateral direction, rather than replaced as with a bored pile. A driven

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

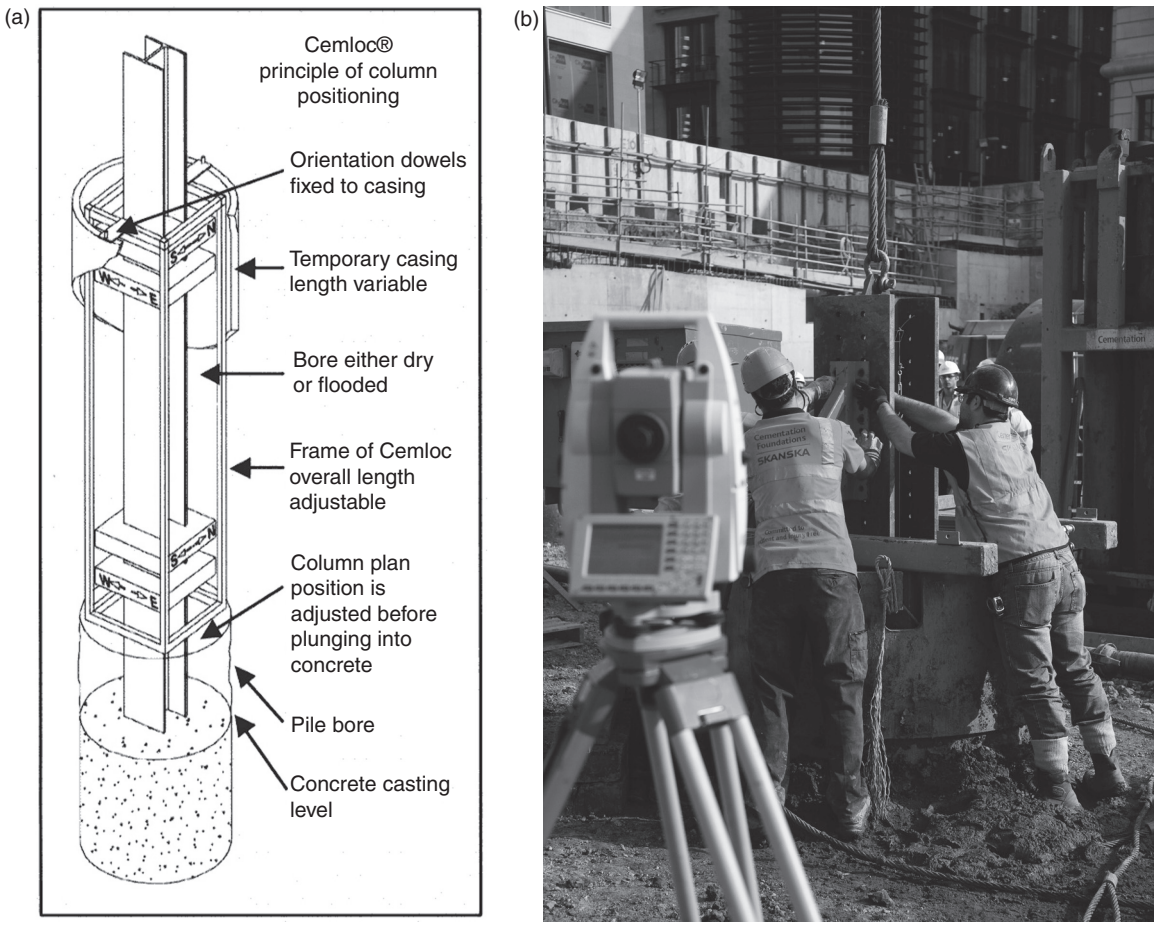

Figure 81.19 Plunge column piles: (a) plunge column installation; (b) precise installation of plunge column
Photos courtesy of Cementation Skanska Ltd

pile may be pre-formed or cast *in place*, and may be a large or small displacement type, as explained below.

In the UK driven piles are generally installed or constructed in accordance with the (Institution of Civil Engineers, 2007) SPERW and the process is subject to the requirements of the execution code for displacement piles BS EN12699:2001 (British Standards Institution, 2001; under systematic review by CEN TC288 at the time of publication).

81.3.2 Types of displacement pile used in the UK

(a) The concept of driving a pile for construction purposes is credited to a Neolithic tribe called the 'Swiss Lake Dwellers' who lived in what is now Switzerland about 6000 years ago. They used timber piles, not for supporting heavy loads as we do today, but for elevation to protect against attack from wild animals. The Romans built the first bridge across London's River Thames in the year AD 60 using timber piles. The modern age of wood-preserving began in England in 1832 with the concept of pressure injecting chemicals into wood.

In more recent times timber piles have been used almost exclusively in sea defence works (groynes), installed as the vertical posts supporting timber planks which act together to reduce longshore drift on beaches. Considerations of durability and drivability require that they are invariably produced from hardwood species, with section sizes of between 225 and 350 mm square.

It is necessary to protect the lower end of the timber pile with a pointed cast iron shoe, as shown in **Figure 81.21**, to aid penetration through the granular beach deposits without undue damage or deviation from plan position or vertical alignment. In order to prevent 'brooming' or splitting of the pile head a steel band is fitted (see **Figure 81.22**).

(b) Segmental pre-cast concrete piles were introduced in the 1970s into the UK from Scandinavia. These large displacement piles are now universally square in section and proprietary section sizes range from 150 mm to 400 mm square, with working loads usually in the range 200 kN to 1400 kN, although higher loads are achievable in favourable soil conditions.

Individual segment lengths normally range from 3 to 15 m, although some manufacturers are able to supply up to 17 m in single lengths. Where soil conditions require it the pile can be extended almost indefinitely (the longest to date in the UK is in excess of 70 m) using pile joints. BS EN12794 (British

Standards Institution, 2007) is the regulatory standard for both pile segments and pile joints, which are classified according to structural capability and robustness.

Piles are cast in moulds and removed to a storage area for curing the day after casting (see **Figure 81.23**). Once the required characteristic concrete strength has been reached, usually 8 to 10 days after casting, the piles can be delivered to site for installation.

All pile segments should be labelled to provide traceability (see **Figure 81.24**).

(c) Whilst segmental pre-cast concrete piles are generally reinforced with straight high-tensile main bars and a square helical binding, pre-stressed concrete piles manufactured using strand reinforcement have been used on sites where the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 81.23 Pre-cast concrete piles being removed from casting moulds

Figure 81.24 'CE' marked pre-cast concrete piles being installed on a power station project in Kent
Photo courtesy of Aarsleff Piling

quantity of piles justified setting up a casting facility on site. This type of pile permits longer segment lengths and is more popular in countries like the Netherlands where transporting long piles by road is easier than in the UK.

Where the piles are installed to a predetermined length in easy driving conditions, normal reinforcement can be incorporated into the head of the pile to provide bond steel into the pile cap (see **Figure 81.25**). Largely overtaken by the segmental pre-cast concrete pile, pre-stressed piles are now rarely encountered in the UK.

(d) Driven cast-in-place (DCIP) concrete piles are, as the term suggests, a large displacement pile formed in the ground using a temporary steel casing. The lower end of the casing is closed off during driving with an expendable steel shoe, and the casing is then driven to the design toe level, embedment or required resistance, generally with a hydraulic drop hammer striking the head of the casing.

Prior to placing high slump concrete, a steel reinforcing cage bound with circular helical wire is introduced into the casing. The casing is then withdrawn using either a vibrator or rapid blows of the piling hammer to assist with extraction and concrete compaction. The sequence of construction is illustrated in **Figure 81.26**.

Figure 81.25 Pre-stressed concrete piles with starter bars cast into the pile head

At all times it is necessary to maintain sufficient head of concrete in the casing to minimise the risk of 'necking' of the shaft, and piles must be cast above the water table and cut-off level, generally to piling platform level. These precautions are designed to prevent loss of pile section and/or washing out of fines from the concrete.

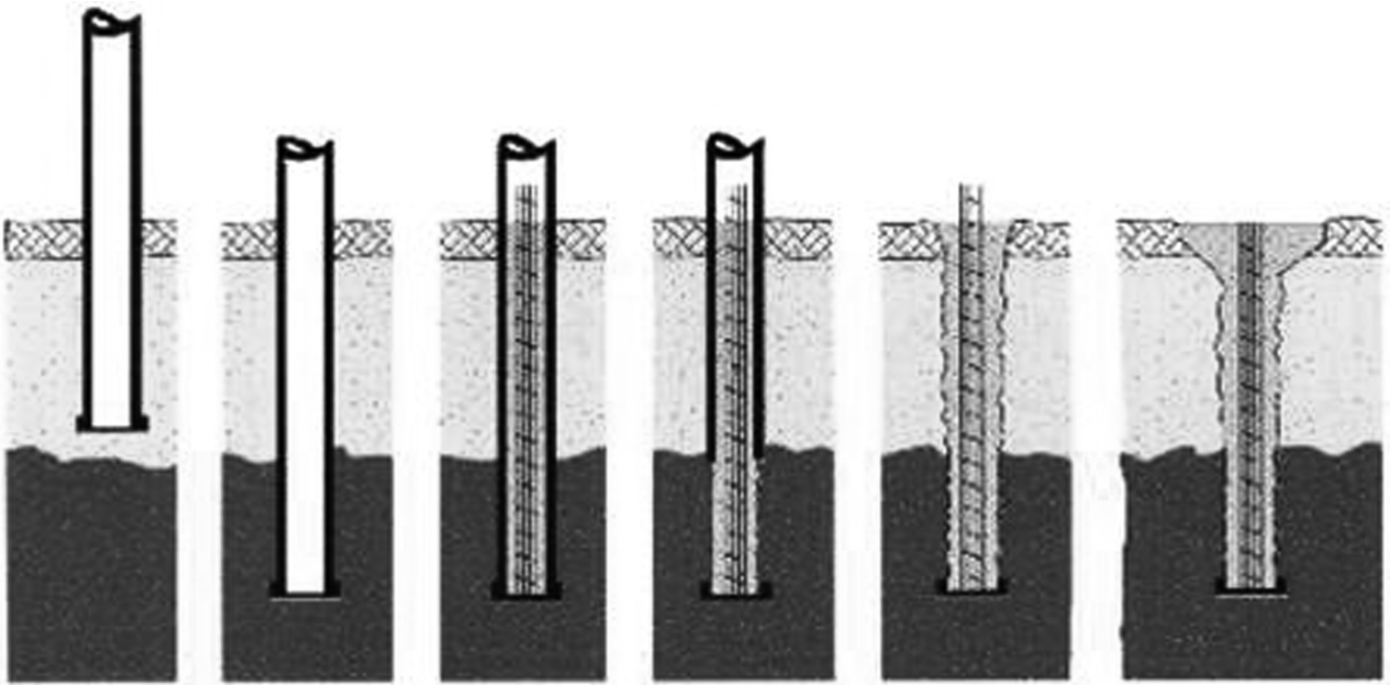

Figure 81.26 DCIP construction sequence (flared head shown at the right side of the schematic)
Photo courtesy of Cementation Skanska Ltd

DCIP piles are readily adaptable to changes in founding level and can incorporate flared heads as an extension of the shaft when used under concrete floor slabs or embankments.

Proprietary sizes range from 340 mm to 600 mm in diameter with safe working loads between 600 kN and 1500 kN depending on the ground conditions.

(e) Steel H piles take their name from the cross-section of the profile used. These may be universal column sections or universal bearing piles where the web and flanges are of the same dimensions and thickness. H piles are small displacement piles and are well suited to hard driving through ground where less robust piles might be damaged by artificial or natural obstructions.

They are able to resist higher levels of combined axial and lateral loads than the equivalent sizes of concrete pile and can be installed at a rake to enhance this capability further. This high combined load-bearing capacity, together with their low soil displacement characteristics, mean that they have been used frequently on highways projects, an example of which can be seen in **Figure 81.27**.

H piles can be delivered to site in single lengths of up to 30 metres, but this would require the use of very large rigs. Alternatively piles can be extended *in situ* by butt-welding, although this is time consuming and expensive.

Section sizes vary from 203 mm × 203 mm × 45 kg/m to 356 mm × 368 mm × 174 kg/m, capable of supporting maximum axial loads ranging from 600 kN to 2300 kN in compression when manufactured from high yield strength steel.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

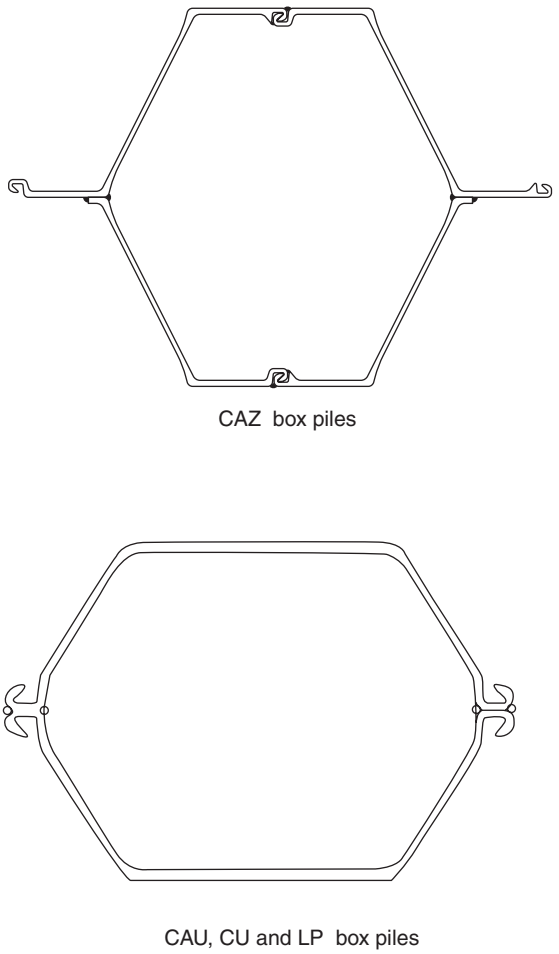

Figure 81.28 CAZ and CU steel box piles
Reproduced with permission from Arcelor Mittal; all rights reserved

(f) Steel box piles are formed by welding two U-section sheet piles or two pairs of Z-section sheet piles back to back, forming a symmetrical box profile (**Figure 81.28**). The clutches of the piles can be used to introduce the box piles into a line of sheet piling where high vertical and horizontal loads can be resisted without adversely affecting the appearance of the wall.

They can also be used as individual bearing piles in open jetty or marine dolphin construction as they have geometrical properties that permit long lengths with little or no lateral support.

They are generally driven open-ended and are, therefore, small displacement piles unless they plug with soil during driving (see the following section on large diameter steel tube piles for an explanation of plugging). They can be supplied in similar lengths to H piles and extended in the same way.

(g) Large diameter steel tube piles are commonly used in marine piling such as jetties, piers and mooring dolphins and utilise their high buckling strength as columns and energy-absorbing capacity in bending to resist loads where the piles project some distance above the sea-bed (**Figure 81.29**). Tubes

Figure 81.29 Pairs of 23 m long 610 mm diameter raking steel tube piles installed for a quay wall in Glasgow
Photo courtesy of Aarsleff Piling

with wall thicknesses greater than 10 mm are suitable for driving open-ended and so can be considered small displacement piles unless they plug with soil during driving.

Plugging is likely to occur once the cumulative shaft friction from the trapped soil on the inside of the tube wall exceeds the gross end-bearing resistance of the tube when considered as closed.

Large diameter steel tubes can also be driven with closed ends. These piles range in size from 273 mm to 2020 mm in diameter.

(h) Small diameter steel casings are an alternative to pre-cast concrete piles in situations where artificial or natural obstructions could deflect or damage the concrete pile. Commonly known as Aberdeen casings, they are a recycled product from the offshore oil industry, originally manufactured for use as drill casing.

Available as non-prime or second-hand material, they are manufactured to an American Petroleum Institute (API) specification with steel having yield strength of the order 550 to 600 N/mm^2. However, being uncertified material they are usually treated as being at least equivalent to grade S355JH. Independent batch testing of larger quantities can be arranged if deemed appropriate to particular project requirements.

Driven open-ended (and so qualifying as small displacement piles) their robust nature and drivability means that safe working loads of 400 kN to 1200 kN are achievable using the same installation equipment as is required for pre-cast concrete piling (see **Figure 81.30**).

Diameters range from 178 to 339 mm and stock lengths are in the range 11–14 m. The piles can be extended by driving the plain end of a second tube into the collar at the head of the first length driven (see **Figure 81.31** for detail of collar).

81.3.3 Types of displacement pile used outside the UK

(a) Within mainland Europe driven piling has generally been restricted to Scandinavia, the Netherlands and Belgium, together with Germany and Spain.

As stated in section 81.3.2(b) segmental pre-cast concrete piles originated in Scandinavia and are still widely used in those countries. They are often used as the upper part of a composite pile, with a timber shaft below the water table where the risk of timber decay is minimal. Segmental pre-cast concrete piles are also common in northern Germany and are now being regularly used in Poland and some former Eastern bloc countries.

In addition to installing (generally) pre-stressed concrete piles, contractors in the Netherlands and Belgium employ many variations on the DCIP piling technique, known locally as vibro-piling. In this context a Combi-pile, as the name suggests, involves the introduction of a pre-formed element as the shaft of the vibro-pile. In areas of deep compressible soil the annulus can be filled with bentonite to reduce downdrag, or otherwise filled with grout to improve positive shaft friction.

The term 'Combi-pile' is also used to describe tubular steel piles, usually driven open-ended to form the primary elements of an embedded steel pile wall. Clutches welded on either side of the tubular piles allow one or more sheet pile sections to form the secondary elements between the tubular piles.

In Belgium and Germany the Frankipile is still used regularly, having become practically obsolete in the UK. DCIP piles, including the Frankipile, are occasionally used in France and Italy but to a far lesser extent than bored or CFA piles.

In Spain driven pre-cast concrete piles, both segmental and pre-stressed, will be encountered on projects in the southern regions of the country.

In Germany and Switzerland small diameter ductile cast iron driven piles, installed with high-frequency hydraulic hammers, have established themselves as a low-vibration displacement piling system.

In a wider geographical context, small diameter steel 'pipe piles' are common in North America, along with proprietary systems such as the 'Tapertube' pile. Pre-cast concrete piles are also used but section sizes are larger than those generally encountered in the UK. In many areas of the Far East where deposits of soft compressible materials are encountered, pre-stressed spun concrete 'pipe piles' are commonplace.

81.3.4 Practically extinct types of driven pile (UK only)

Towards the end of the twentieth century the UK piling industry witnessed the decline and/or demise of two versatile driven piles, which lost their significant market share to faster and/or less labour-intensive methods. Improvements in integrity testing of piles and rig instrumentation, which boosted confidence in DCIP and continuous flight auger piles also contributed to the demise of the first of these to be discussed here.

(a) Developed and patented by Russian marine engineer Alexander Rottinoff, the West's shell pile was constructed using pre-cast, fibre-reinforced concrete tubes, 900 mm long, threaded on to a steel mandrel and driven into the ground with a solid concrete shoe placed at the bottom of the mandrel. The shells were held together with circular steel bands to prevent ingress of groundwater or silt and driven into the ground using a rope-operated drop hammer rig as shown in **Figure 81.32**.

Once the specified depth or resistance had been achieved the mandrel was withdrawn and concrete placed in the core, with a reinforcing cage to suit the diameter and loading conditions. Diameters ranged from 380 mm to 600 mm.

The same company also produced the West's segmental pile, an early form of solid pre-cast concrete pile 280 mm in diameter with 900 mm long segments being joined together during driving with a simple spigot and socket joint. On completion

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 81.32 Westpile 30RB based shell piling rig

of driving, a full-length single reinforcing bar was grouted into a central longitudinal hole. This system was only suitable for light loads in soft soil conditions and became obsolete on the introduction of West's Hardrive pre-cast concrete pile.

(b) The Frankipile, which is still used world wide, was first developed by the Belgian engineer Edgar Frankignoul, who registered an international patent for the system in 1902. It is a cast-in-place concrete pile with an enlarged base and a cylindrical shaft which can penetrate stiff soils and readily reach depths of 20 m.

The pile is constructed using a temporary steel casing and an internal drop hammer, the sequence being as illustrated in **Figure 81.33**. A plug of gravel is placed in the bottom of this tube and compacted by the hammer, which then enables the casing to penetrate the ground by virtue of the friction between the inner wall and the gravel plug.

On reaching the design depth, the casing is lifted slightly and the gravel plug broken out. Dry concrete is then introduced and expelled by the hammer to form an expanded base, thereby significantly improving the original bearing capacity of the founding stratum.

After inserting a reinforcing cage the pile shaft was traditionally formed in the same way using a semi-dry concrete, thus

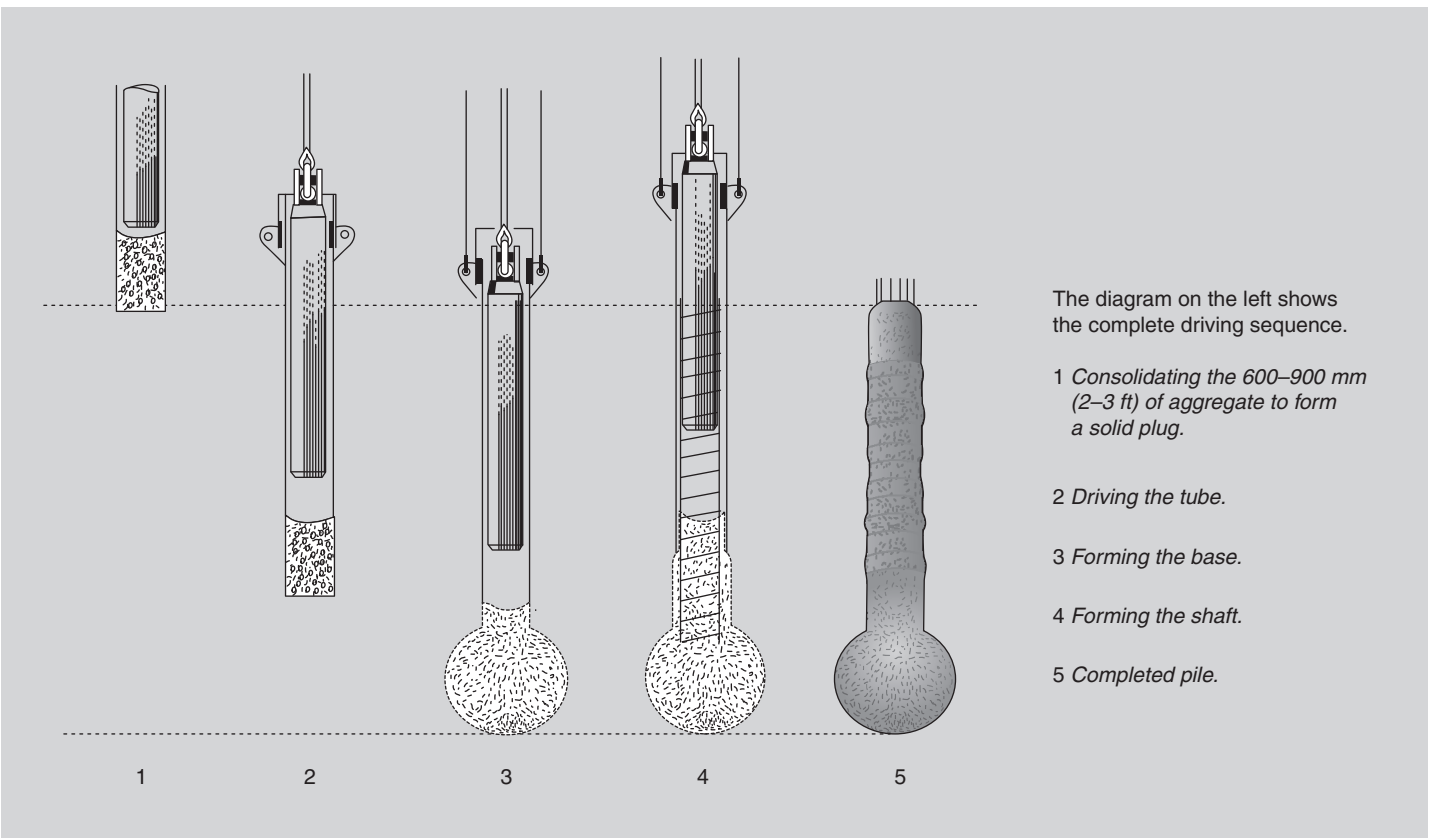

Figure 81.33 Frankipile construction sequence
Reproduced from FRANKI® pile, courtesy of Cementation Skanska Ltd

producing a pile with excellent end-bearing resistance and improved shaft resistance due to the ribbed profile caused by successive lifting of the tube and hammering out of the concrete.

Such a construction process is slow and labour-intensive, with production rates being only 20–25% of alternative driven cast-in-place or driven pre-cast concrete piles. The technique was modified in the mid 1970s by using high slump wet concrete to form the pile shaft, and where particular circumstances such as aggressive ground conditions require a protective coating, a pre-cast concrete pile can be used to form the shaft.

The application of the Franki system in the UK has decreased dramatically due to cost considerations, although this system is still an option when site conditions are suitable.

81.3.5 Driven piling plant

Driven piling frames provide a guide for the alignment of the pile and hammer during driving and usually have at least two winches. Early piling frames comprised open platforms on which were mounted the winches (often steam powered with a large boiler) and a vertical lattice or tubular mast that supported the piling leader used to guide the pile and hammer, as shown in **Figure 81.34**.

On land these frames usually moved on railway lines or by using a system of rollers; some Frankipile machines were able to 'walk' using an ingenious system of hydraulic jacks. These large frames provide the rigidity and stability needed to control the alignment of very large piles, and more recent versions can still be found working in marine applications. However, conditions on most onshore projects favour the use of smaller equipment.

Initially the move away from large fixed piling frames involved the use of hanging leaders suspended from the jib of a crawler crane. This type of rig was successfully used by West's Piling and Construction (later Westpile) for many years to install shell piles using a rope-operated drop hammer (see **Figure 81.32**) and the same type of equipment, modified by the addition of an adjustable foot boom and foot pad, was marketed by BSP International Foundations for the installation of steel piles using their own diesel hammers. At about the same time piling contractors such as Expanded Piling, Keller (then GKN) and Cementation adapted the BSP style of equipment to suit the rigours of DCIP piling, predominantly by strengthening the leaders. Typical examples of these largely obsolete piling rigs can be seen in **Figure 81.35**.

The arrival of pre-cast concrete piles in the 1970s from Scandinavia brought with it the compact fixed leader rig mounted on an Akermann hydraulic excavator, manufactured by Banut in Sweden. Although hanging leader rigs were used for some considerable time to install pre-cast concrete piles in the UK, the Banut rig allowed the development of a hydraulic piling hammer where the drop weight is lifted using a hydraulic ram instead of a rope and winch, the result of which is a better-controlled driving operation. Banut and Junttan (from Finland) have developed the fixed leader rigs to a level where they are suitable for all forms of driven piling, with only a few examples of hanging leader machines remaining in service. Junttan have further developed a hydraulic hammer with an accelerated fall which increases the efficiency rating of the hammer blow by up to 35%. A modern Junttan PM20 rig is illustrated in **Figure 81.36**. A Banut 700 rig is featured in **Figure 81.30** whilst a smaller Banut 500 rig can be seen in **Figure 81.37**.

Box piles and steel tube piles are generally installed using a combination of hydraulic/electric vibrator and/or hydraulic drop hammer suspended from a crawler crane, although fixed leader rigs can be used given satisfactory access and working space. Thin-walled steel tubes can be bottom-driven using an internal hammer falling on a plug of semi-dry concrete in the same manner as a Frankipile.

81.3.6 Suitable and unsuitable ground conditions

Driven concrete piles can be used in a wide range of ground conditions. Often considered to be only suited to end-bearing

Figure 81.34 Rail-mounted Frankipile rig *c.*1930

conditions in granular soils and weak rock, they can be used in cohesive soils provided that the limitations of driving stresses (for pre-cast concrete piles) and casing extraction forces (for DCIP piles) are considered. DCIP piles are not normally suitable for pile depths much in excess of 20 m because of the effort required to extract the casing. Boulders and massive obstructions will preclude the use of driven piles unless they can be economically removed prior to piling. Steel tube and H piles are particularly suited to hard driving situations or where small obstructions are anticipated. In the latter case it would be prudent to use Aberdeen casings as these are more readily available than ex-mill materials if additional piles are required. Durability in aggressive ground conditions will influence the choice of pile type and material. Steel tube piles can incorporate a sacrificial element of wall thickness, and both pre-cast concrete and steel piles can be given a protective coating to improve resistance to corrosion.

81.3.7 Environmental considerations

A common reaction to a proposal to use driven piling is that it will create undesirable levels of noise and vibration.

However, most construction processes create detectable levels of vibration and noise, and tolerance is greatly increased when the origin, likely levels and duration of noise or vibration are made known in advance and those affected are reassured that consideration has been given to these factors.

It may not be possible, for technical reasons, to replace driven piling by a 'quieter' piling technique. Even if it is feasible, the operation of the alternative method may prolong the piling duration, so that the overall disturbance to the community may not actually be reduced. Piling hammers are available that are completely shrouded (see **Figure 81.37**), and most hydraulic driven piling rigs can be adapted to prebore pile positions prior to driving to reduce the level of vibration (see **Figure 81.38**).

Factors affecting the acceptability of site noise include site location and layout, pre-existing ambient noise levels and the daily hours of work. In the case of both noise and vibration, measured levels will reduce with increasing distance from the source. Annex F of BS 5228-1 (British Standards Institution, 2009) gives guidance on predicting the expected levels of noise from construction sites and Annex E of BS 5228-2 (British Standards Institution, 2009) contains empirical expressions derived by Hiller and Crabb (TRL Report 429: 2000) for the prediction of vibration levels which take into account driving energy, soil conditions and distance between the source and the point of measurement.

Further considerations which play a part in the overall environmental impact of a piling scheme are traffic movements in and out of the site, the efficient use of natural materials, and the embodied energy/CO_2 emissions for the complete process.

A positive environmental consideration is that driven piling produces no spoil, making it particularly suitable for sites with contaminated Made Ground that would otherwise have to be disposed of safely and at great cost.

Extensive research at the University of Sheffield, the results of which have been endorsed by the Environment Agency, has concluded that solid square or circular piles pose no additional threat to an underlying aquifer when they are driven through contaminated ground that is separated from the aquifer by a clay layer.

81.3.8 Drivability

Given a set of foundation loads and a ground investigation report it is not that difficult to produce a piling layout with numbers, loads, section sizes, diameters and lengths. However, that piled foundation must be buildable, and in the case of driven piles, the lengths of piles calculated must be achievable using readily available equipment and without damaging the piles or driving equipment in the process.

This drivability assessment can be made based on experience, and a responsible piling specialist will always be prepared to comment on the viability of a scheme at an early stage of the design.

In addition to experience, computer software is available that can model the soil, pile and driving system to predict resistance to driving and stresses in the pile during installation.

81.3.9 Installation control

A driven pile provides valuable feedback on the strength of the ground through which it is being installed. This resistance to penetration will usually be recorded on the first piles driven (and thereafter at regular intervals) as the number of blows per unit of penetration (usually 250 mm in UK) for a given hammer weight and drop.

'Sets' will be recorded at varying intervals and at the end of drive, three consecutive sets will usually be recorded. The precise definition of set is the permanent downward displacement of the pile through the soil per hammer blow; however, measurements of set are generally recorded as the total movement for 10 successive blows. Set calculations provide a useful guide to the resistance that should be encountered for a given load-bearing capacity but should not be used in isolation. The relevant ground investigation information must also be reviewed to verify that the level at which the set is being achieved is reasonable.

Additional measurements of temporary compression (sometimes referred to as 'quake') of the pile and soil under individual hammer blows will also provide an indication of whether the pile toe is in competent material or is, for instance, sitting on a thin hard band underlain by weaker soil. Driven piles can be designed and installed to an embedded length in cohesive soils, in which case the set achieved is not necessarily indicative of bearing capacity, although comparing penetration records will highlight any potential variation in soil strengths and pile performance.

In weak rocks the depth of embedment will be as relevant as the set achieved, and in those materials prone to relaxation (such as Coal Measure Mudstones) it will generally be necessary to overdrive the pile to achieve a satisfactory outcome. Driven pre-formed piles have the advantage of permitting restrike sets to be measured at some time after installation to determine whether the ground is relaxing or conversely setting up and improving. These restrike measurements can be combined with dynamic load testing where appropriate.

81.3.10 Ground-related aspects of pile installation

As stated in section 81.3.1, driven piles displace soil as they are installed. Although the displacement is predominantly in a lateral direction, this can result in ground heaving upwards in closely spaced groups of piles. In the case of short piles end-bearing on rock, this can be enough to unseat the piles, but should be detectable by routine restrikes on pre-formed piles, and any risen piles can then be reseated by redriving. Ground heave can also affect the accuracy of setting out in large pile groups by moving marker pins. In the case of longer DCIP piles heave forces can compromise the integrity of freshly placed concrete if piles are installed consecutively too close together. In confined working areas such as inside coffer-dams or basements, ground displacement can have adverse effects on adjacent temporary or permanent structures.

Closely spaced DCIP piles should not be installed consecutively even where ground heave is not an issue. The driving of the casing can jeopardise the integrity of an adjacent pile shaft in which the concrete is still workable or not set. The minimum permissible spacing between adjacent piles formed in the same day will be a function of casing diameter and the soil strength. The sequencing of operations should, therefore, take account

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

of this risk, and plant movements should also be planned to avoid tracking over constructed piles.

Silty soils that are prone to dilation can give rise to 'false sets' where apparently high dynamic resistance does not result in the anticipated static resistance under a load test.

Driven piles installed through soft clays and silts can generate excess pore water pressures during driving, which will dissipate with time. As a result the ground will eventually reconsolidate (the same can happen if ground heave occurs) and induce an additional load on the shaft of the pile which should be accounted for in the pile design.

When pre-cast concrete piles are installed firstly through soft or loose materials and then require prolonged driving through more competent soil the pile will experience tensile forces caused by the stress wave travelling from the head of the pile to the toe and back to the head. In extreme cases these forces can be large enough to cause yielding of the main reinforcement in the pile. The computer software referred to in section 81.3.8 can be used to predict the tensile forces in the pile, and the hammer weight, fall height and main reinforcement in the pile can be adjusted to suit the anticipated conditions. Dynamic test measurements taken during installation can subsequently be used to verify the actual driving stresses in the pile.

Driven piles installed in cohesive soils will usually exhibit a degree of 'set-up' after a period of time has elapsed after installation, this effect being caused by the clay remoulding around the shaft as the excess pore water pressures created in the soil during driving dissipate. The same effect will also be found to occur in some grades of chalk. With pre-formed piles this effect can be demonstrated by the tightening of the set at restrike compared to that measured at the end of drive. In the case of DCIP piles restrike sets are not possible and in both cases load testing the pile too soon after installation will result in the pile underperforming compared to its long-term capability. However, as the ground may take several weeks to recover to a state where the pile performance can be optimised, considerations of programme rarely allow for this benefit to be maximised.

81.4 Micro-piles

81.4.1 Definition

Bored micro-piles are defined as bored piles with a shaft diameter no greater than 300 mm, and driven micro-piles are defined as driven thin-walled steel piles with a shaft diameter no greater than 150 mm.

81.4.2 History and introduction

Bored micro-piles were originally developed by Fernando Lizzi and Fondedile during the 1950s in Italy. Lizzi employed the Pali Radice ('root pile') micro-pile system for strengthening existing foundations which were settling or required upgrading (see **Figure 81.39**) (Lizzi, 1982). Bored micro-piles have become increasingly popular throughout Europe, North America and the rest of the world over the past five decades and they are now used in many different applications. Driven micro-piles were developed during the 1980s and they are primarily used to provide a low-cost foundation solution for the domestic building market. There are other types of micro-pile such as jacked, jet grouted and post-grouted micro-piles; however, they are less common and they are not covered here. The installation of micro-piles is labour-intensive, expensive and time consuming and they should only be used when the more conventional piling techniques have been discounted. However, when used correctly and in the right circumstances, they can bring real value to a project. There are a multitude of micro-pile types and this chapter can only provide a brief introduction to them. Specialist micro-pile advice should be sought when the preliminary micro-pile scheme has been decided.

81.4.3 Where to use bored micro-piles

Bored micro-piles are extremely versatile and they can be used in a wide variety of compression and tension loading applications:

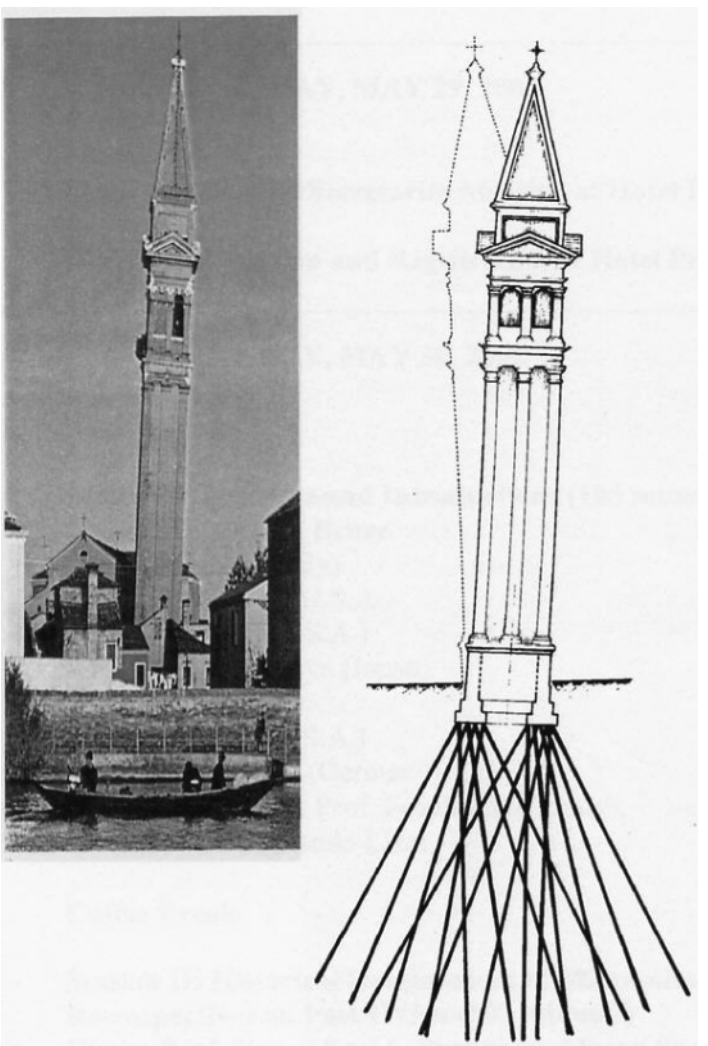

Figure 81.39 Burano Tower, Venice
Reproduced from Lizzi (1982)

- **Foundation upgrading and strengthening** – Pali Radice ('root pile') micro-piles are formed through existing foundations and develop an intimate bond with the structure; they found in competent ground at depth, thus providing the foundation with 'roots', hence their name.
- **Restricted access and working room** – There are a wide range of micro-pile drill rigs, from small 1 tonne rigs which can drive through doorways and work within 2 m of headroom (see **Figure 81.40**), through to larger 15 tonne rigs with 9 m+ high masts (see **Figure 81.41**). The capabilities, production rates and costs of these micro-pile rigs vary considerably.
- **Difficult ground and hard rock** – Bored micro-piles can be installed using an extensive range of drilling techniques to penetrate almost any ground conditions and/or obstructions, except possibly steel and strong timber, where high-speed coring techniques may need to be employed.

Figure 81.40 1.5 tonne drill rig (auger)

Figure 81.41 15 tonne drill rig (DTHH)

- **Permanent casings** – Bored micro-piles can install permanent steel casings through very soft ground or voids (e.g. caves or solution features) as part of the construction process.
- **Seismic loadings** – An increasingly important international use of bored micro-piles is their ability to be retrofitted to existing structures to upgrade their foundations to withstand seismic loadings.
- **Basement restraint** – Bored antiflotation tension micro-piles (ATMs) provide an efficient system of restraining large deep basements against hydrostatic uplift forces where there is reasonably competent ground at shallow depth. In addition, they can help reduce bending moments in basement slabs and thus reduce their thickness.

81.4.4 Where to use driven micro-piles

Driven micro-piles are less versatile and are generally used on new and existing (underpinning) housing projects where there is poor ground over firmer strata. Pile loadings are in the range of 100 kN to 300 kN. Driven micro-piles can be installed in restricted-access and low-headroom working locations using small drill rigs or even a hand-held grundomat hammer (see **Figure 81.42**).

Figure 81.42 Grundomat driven micro-pile

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

81.4.5 Types of micro-pile and drilling systems

There are a large range of micro-pile types and drilling systems to accommodate the wide range of working environments and ground conditions around the UK and the rest of the world:

- **Bored micro-piles** – There are four main types of bored micro-pile drilling systems (see **Figure 81.43**). These range in diameter from 100 mm to 300 mm with SWLs between 100 kN and 1500 kN (normally 300 kN to 700 kN). High-capacity micro-piles often require a full-depth large diameter central reinforcement bar to ensure adequate structural capacity. This central rebar is usually fully threaded (e.g. Dywidag GEWI or Macalloy Mac 500) to enable it to be connected together in sections using full-strength couplers for low headroom or deep pile applications. In addition, a steel head plate may also be required to facilitate an efficient force transference mechanism into the pile cap. If a steel head plate is used then this should be located in the middle of the pile cap and secured above and below with full-strength nuts. Bored micro-piles generate their geotechnical restraint primarily from shaft friction because the shaft area is considerably larger than the end-bearing area. They can provide high tension capacities as well as high compression capacities when they are founded deep into strong bedrock and incorporate a full-depth large diameter central rebar (e.g. 50 mm to 75 mm diameter). Micro-piles are bored using 0.5 m to 1.0 m lengths of drill rods/augers, depending upon the pile diameter and the headroom available, and can extend up to 50 m to 70 m deep. It is unusual for micro-piles to be deeper than 30 m and particular allowance should be made in the calculations for the elastic compression behaviour of the pile shaft if they are. Bored micro-piles can be installed vertically or at any rake up to 45°.
- **Rotary case and auger bored micro-piles** – These are the simplest and most popular form of rotary bored micro-piles, which are constructed by sealing temporary steel casing into competent strata and then dry open-hole auger drilling thereafter. The depth of the temporary casing varies according to the ground conditions. These micro-piles are popular in London where open-hole auger drilling in London Clay is possible. If ground water and/or obstructions are encountered then case and auger drilling may have to be stopped. The most popular temporary casing sizes range from 140 mm to 343 mm, with respective open-hole auger sizes from 102 mm to 305 mm. Whilst the largest 343 mm/305 mm diameter micro-pile is larger than the 300 mm diameter micro-pile limit, it is still often referred to as a micro-pile because it is installed using a micro-pile drill rig. Temporary casing depths should be limited to ~15 m wherever possible; however, this depth is dictated by the type and power of the drill rig and the ground conditions encountered.

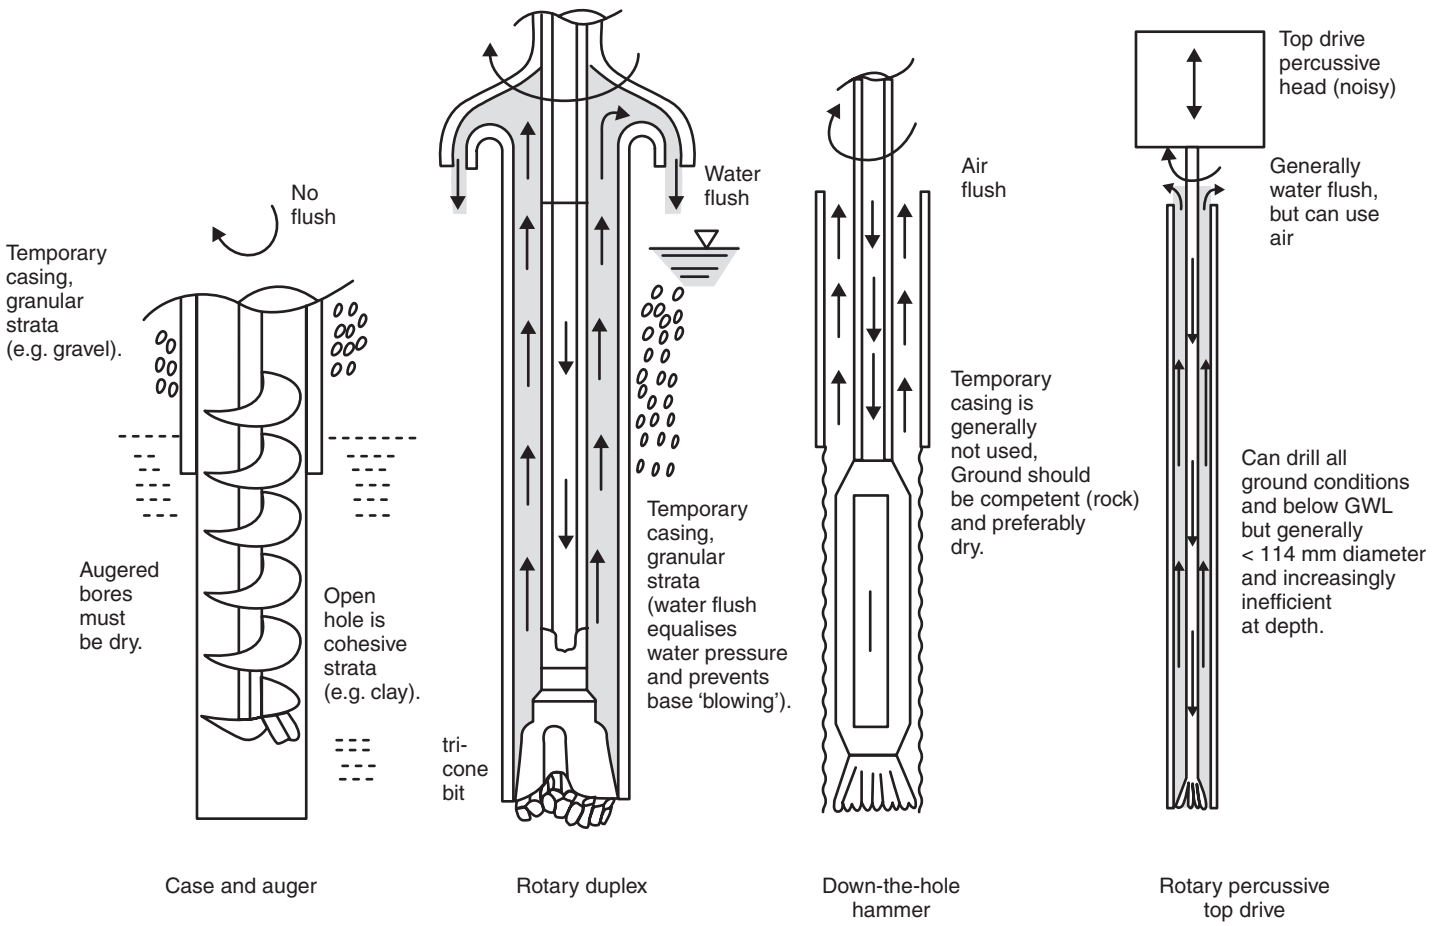

Figure 81.43 Bored micro-pile drilling systems

- **Rotary duplex bored micro-piles** – The rotary duplex drilling technique is useful in poor and/or granular strata with a high groundwater level, where there is a risk of bore hole or basal instability. The temporary casing and drill rod with tri-cone drill bit ('rock roller') are simultaneously rotary drilled into the ground using water flush. The drill water passes down the centre of the drill rods and up the inside of the temporary casing, before exiting through the duplex head. The hydrostatic forces therefore remain positive on the inside of the temporary steel casing, which will prevent 'blowing' conditions in the base. The most popular size is 220 mm diameter temporary casing with a 187 mm diameter tri-cone bit, although a variety of sizes down to 140 mm are available. A wide range of ground conditions can be drilled with this system, including weak rocks, which can be open hole drilled with a tri-cone bit below the temporary casing. However, penetration rates will become progressively slower in stronger rocks, leading to an increased risk of a 'smooth' bore, which can lead to lower grout-to-ground bond values. Large volumes of drilling water are required (~3 litres per second for a 220 mm diameter micro-pile) to ensure that there is sufficient uphole velocity to transport the drill cuttings out of the bore. An efficient drill water recirculation system is necessary, which may comprise sand bag bunds and recirculation/settling tanks. This type of micro-pile is becoming less common, due to the environmental implications of using and disposing of large volumes of drilling water. It is also possible to use air flush; however, this is not commonly undertaken, because of dust, lack of lubrication, bit wear and overheating problems.
- **Rotary down-the-hole hammer (DTHH) bored micro-piles** – This type of percussively drilled micro-pile has become increasingly popular in recent years, primarily due to the technological advancements in drilling equipment. Air-flushed DTHHs drill quickly through masonry, concrete and strong bedrock and typical sizes range from 100 mm to 300 mm diameter. There is also a water-flushed DTHH; however, this is expensive and not commonly used. Conventional DTHH micro-piles require temporary steel casing rotating into the ground until sealed into bedrock. The DTHH can then open-hole drill an efficient and 'rough' bore into the bedrock which can generate high bond values. DTHHs can drill strong bedrock quickly because the percussive hammer remains immediately behind the drill bit and it does not lose any energy as the bore gets deeper. However, there are risks with this type of micro-pile, primarily the failure to obtain an adequate casing seal into bedrock, which can lead to large volumes of air being pumped into the ground and causing problems, and borehole collapses behind the DTHH, which can lead to the loss of an expensive drilling system. DTHHs perform best in competent rocks (> 10 MPa) due to the percussive drilling action and the bore remaining stable and uniform; production rates are directly proportional to the pressure and volume of air provided. A 200 mm diameter DTHH requires a large, 750 cfm/170 psi, expensive-to-operate compressor; however, the equivalent micro-pile cost per metre will be considerably less than rotary drilling in rock. The air-flushed DTHHs require substantially dry bores; otherwise, large volumes of water will be blown into the air. In recent years DTHH overburden drilling systems (essentially a 'cased DTHH') have been developed, such as Odex, Symmetrix and Maxbit. These systems allow full-face DTHH percussive drilling with simultaneous advancement of the temporary steel casing to keep the bore open. Therefore, difficult granular strata with large boulders can be drilled efficiently using cased DTHH systems (see **Figure 81.44**).

Figure 81.44 Cased DTHH micro-piles

- **Rotary percussive micro-piles (including self-drilled hollow bar)** – These micro-piles are installed using top drive rotary percussive techniques and can achieve fast production rates. They generally require larger drill rigs to accommodate the heavy percussive drill heads ('drifter'), although smaller percussive heads are now appearing on ~5-tonne micro-pile rigs. The top drive percussive heads are noisy and the drill string loses energy into the ground as the bore extends deeper. There are two main types of rotary percussive micro-piles. The first is rotary percussive duplex drilled. This is similar to normal rotary duplex drilling, except that there is additional percussion which speeds up drilling through difficult ground containing cobbles and boulders. Unfortunately, large percussive drill heads are required to drive the heavy percussive drill casing/bit and therefore standard micro-pile sizes are 76 mm and 114 mm diameter. There is a 178 mm diameter system available but this requires an even larger, heavier and more powerful drifter, which requires a minimum 25 tonne base machine. The second system is the self-drilled hollow bar micro-pile, which is becoming very popular because of its rapid installation speed and the resultant low cost per metre. These micro-piles comprise a hollow reinforcement bar with an expendable drill bit which is percussively drilled into the ground using grout or water flush. It is preferable to use grout flush in difficult ground; however, if water flush is used during drilling to reduce grout waste, then it must be changed to grout flush immediately upon reaching the hole base.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Grouting must then be continued until there is a full column of clean grout around the hollow bar. It is important to keep the drill flush emitting from the bore at all times to ensure that there is a full column of grout upon completion. If drilling with grout, then the micro-pile is complete as soon as the required depth is reached, and the installation of the next micro-pile can then commence. Production rates of up to 400 m per shift can be achieved with this system. The drill flush keeps the bore open during installation and there is therefore no need for any temporary drill casing. This type of micro-pile can be installed into very difficult ground conditions, and typical sizes range from 75 mm to 150 mm. The main risks with this type of micro-pile are the hollow bar deflecting off a boulder and/or loss of flush. This system is also commonly used for soil nails and ground anchors (passive ties).

- **Hollow segmental auger (HSA) micro-piles (segmental CFA) –** This type of micro-pile is similar to a continuous flight auger (CFA) pile, except that the auger is segmental. Typical diameters are 300 mm and above, although the larger diameters are not strictly micro-piles. The hollow stem augers are rotated into the ground in nominal 1.0 m sections to the required depth and then sand cement grout is pumped down the central hollow stem while the auger is rotating slowly. This is continued until grout can be seen exiting around the augers at the surface. The augers are then carefully extracted whilst continuing to pump grout and maintaining a positive grout pressure. The grout level in the central stem should be visible at the surface as each section of auger is removed, and if not then it should be topped up as necessary. It is not possible to have a continuous monitoring record of the HSA micro-pile construction as with CFA piles; however, maintaining a positive head of grout at all times will ensure good pile integrity. HSA micro-piles are popular in granular strata with high groundwater levels because the augers provide temporary support to overcome borehole instability problems.
- **Driven micro-piles** – These are generally bottom-driven vertical 150 mm to 200 mm diameter thin-walled 'closed end' steel tubes with SWLs ranging from 100 kN to 300 kN. They are installed quickly and efficiently using a small drill rig with internal drop hammer on to a dry concrete plug with no spoil produced. Alternatively, smaller tubes can be driven into the ground via an internal air powered grundomat hammer, without any drill rig (see **Figure 81.42**). These micro-piles may have SWLs of up to 100 kN. The tubes can be driven in various lengths and welded together as the installation proceeds. The depth of the micro-piles is dictated by a predetermined 'set' and when this is reached the tube is filled with high slump concrete or grout and a central rebar if required.

81.4.6 Micro-pile drill rigs and coring

There is a wide range of micro-pile drill rigs and capabilities, from small ~1 tonne rigs with 2 m masts which can track through house doorways, through to 15 tonne rigs with 9 m+ masts. The smaller rigs have a more limited range of drilling techniques and are generally slower (and therefore they install more expensive micro-piles), whilst the larger rigs can use any drilling system and are faster. Careful thought should always be given to choosing the appropriate micro-pile rig and drilling system and the advice of specialist micro-pile contractors should be sought at an early stage. Micro-pile drill rigs have low rotation speeds and high torque and can rotary core drill though concrete, masonry and other obstructions with standard tungsten-tipped steel casing; however, coring rates can be slow. DTHHs can drill quickly through unreinforced mass concrete. If there are significant amounts of coring and steel reinforcement then consideration should be given to using a specialist coring company (which uses high rotation speed and low torque diamond-tipped coring barrels).

81.4.7 Micro-pile construction techniques

One of the key issues with micro-piles is to choose the most appropriate drilling technique to ensure that the micro-pile can be bored safely and efficiently to the required depth. Look at the borehole logs and take careful note of the stratum type, the groundwater regime, obstruction drilling and whether there are any cobbles or boulders. Micro-piles are normally formed with cementitious grout; however, readymixed concrete can be used with larger 300 mm diameter micro-piles in dry open bores (checked by shining a light down). If the micro-pile is 'wet' then a measured small diameter (25 mm or 38 mm diameter) plastic tremie pipe must be inserted completely to the base. The grout mix is generally a neat CEM1 mix or a 1:1 sand:CEM1 mix, with the neat mix used for the smaller diameters and the sanded mix more popular for the larger diameters. The sand should be a well-graded washed sharp concreting sand or similar (i.e. not a 'soft' sand) and it should preferably be used in 25 kg bags. Bulk sand can be used but it must be measured using calibrated containers on site (e.g. 6 level buckets = 100 kg). The grout is mixed in either a paddle mixer or a colloidal (high shear) mixer, which is more efficient and 'wets' more of the cement particles thus leading to a superior low bleed-higher-strength mix (see **Figure 81.45**). The correct amount of clean potable water should always be added first, followed by the CEM1 and finally the sand (if required). The standard cementitious grout mixes are detailed below:

- Neat CEM1 grout (this 0.40 water:cement ratio mix will produce 72 litres of grout)
  - 40 litres of clean potable water
  - 100 kg of CEM1
- 1:1 sand:CEM1 grout (this 0.45 water:cement ratio mix will produce 113 litres of grout)
  - 45 litres of clean potable water
  - 100 kg of CEM1
  - 100 kg of sharp sand

Both of these mixes will produce high quality cementitious grouts with unconfined compressive strengths of >40 MPa at 28 days. The CEM1 should preferably be grade 42N or 52N. There are a wide range of sands available and difficulties may be experienced adding the full 100 kg of some 'softer' sands. If this occurs, *do not add more water*, which would only weaken the final grout strength; it is better not to add all of the sand (but record the amount added). If higher grout strengths

Figure 81.45 Colloidal high shear grout mixer

Figure 81.46 Colcrete flowmeter

are necessary then plasticiser can be added and the amount of water reduced accordingly. Grout fluidity can be checked using the Colcrete Flowmeter Test if required (see **Figure 81.46**). This involves pouring 1 litre of grout into the cone and then releasing it and allowing it to flow along the level 'wetted' channel. A flowmeter reading of 375 mm (±50 mm) is normal for a 1:1 sand:cement grout and 450 mm (±50 mm) for a neat CEM1 grout. Micro-pile grouting should be carried out in a continuous operation by pumping clean grout into the base of the micro-pile until all the debris has been flushed out of the bore and a column of clean grout remains. The temporary casing can then be removed in sections, ensuring that the internal grout level is fully topped up to ground level each time. Finally, the clean reinforcement cage or bar should be carefully plunged into the grouted pile with appropriate centralisers (~3 m centres). If the micro-pile is very deep (or in dry sandstone, which may cause a flash set) and there is concern over inserting the reinforcement after grouting, then it can be installed first; however, this does increase the risk of smearing the rebar on the side of the bore. Upon completion of grouting the grout level should be carefully monitored for a minimum of one hour and topped up as necessary until it has completely stabilised. In granular strata it is common for the grout level to continue to drop as the pressure head forces the grout to permeate into the surrounding ground. Additional pressure of 3 to 4 bar (43 to 58 psi) can be applied during casing extraction using a pressure head coupling to further enhance grout take, effective pile diameter and micro-pile capacity.

81.4.8 Micro-pile environmental, quality assurance and health and safety issues

Micro-pile construction has several environmental issues which need to be carefully managed:

- disposal of water flush, which may have high silt contents and be harmful to fish;
- disposal of air flush, which will contain fine dust particles;
- noise suppression, especially from top drive rotary percussive drilling systems;
- disposal of grout overflush and washout.

Micro-pile quality assurance is similar to other piling techniques and requires the checking of the plan position, verticality, borehole depth, diameter and reinforcement. In addition, special care needs to be taken with site-mixed grout with regard to quantities of water, cement and sand. Grout cube sizes should be 100 mm × 100 mm × 100 mm.

Micro-pile construction is labour-intensive with several health and safety issues:

- manual lifting of casings, drill rods and reinforcement;
- slippage with water and grout flush;
- working near rotating augers (auger guarding during boring is now a statutory requirement);
- grout mixing on site;
- working in restricted and noisy locations.

82.4	Identifying and resolving problems	1233
82.5	References	1235

The successful installation of piles requires a good understanding of the potential problems that can arise, which are highly dependent on the type of piling and the ground conditions in which the pile is installed. These can affect the geotechnical behaviour of the piled foundation and its structural integrity, as well as its impact on the environment.

For bored piles, the different methods of boring, the type of drilling tool and the way the ground is supported will have different effects on the ground. The structural integrity is also affected by the way in which the concrete is placed, the detailing and installation of reinforcement, and the final trimming of pile heads.

Driven piles are either low or high displacement piles. Installation techniques vary from drop hammers and vibratory techniques to hydraulic press-in methods. The technique chosen and the amount of ground displacement can affect both the behaviour of the pile and its structural integrity. Installation aids such as jetting and pre-boring require careful control, and environmental effects such as noise and vibration also require particular consideration.

Guidance is provided on how problems are commonly identified, how they are assessed, and the ways in which they can be resolved.

82.1 Introduction

There are several key references that provide a comprehensive background to the potential problems that can arise in piling. The more common problems for driven and bored piles are described by Fleming *et al.* (2009) in their handbook *Piling Engineering*. Specific sections are also included covering driven cast *in situ* piles, continuous flight auger (CFA) piles, and cast *in situ* screw piles. Thorburn and Thorburn (1977) CIRIA report PG2 provides a review of piling problems associated with the construction of cast *in situ* concrete piles. Healy and Weltman (1980) CIRIA report PG8 provides a survey of the problems associated with the installation of displacement piles and although some of the techniques have changed, much of the guidance is still valid. Tomlinson (1994) describes the potential problems associated with piles in specific situations. These include piling for machinery foundations and underpinning, piling in mining subsidence areas, in frozen ground, for foundations for bridges on land and over water, foundations in cast and energy piles.

Specifications and codes are also an important source of information and many of the requirements contained in these documents have been incorporated as a result of problems that have been identified in piling projects. The ICE *Specification for Piling and Embedded Retaining Walls* (SPERW) (ICE, 2007) covers most of the common types of piling and includes guidance as well as specification clauses. The sections cover bearing piles and piles incorporated in retaining walls as contiguous piled walls, secant and sheet pile walls and king post walls. The Federation of Piling Specialists (FPS, 1999) have also provided a commentary on the ICE Specification (SPERW) but this relates to the 1996 edition which has been superseded by the 2007 edition (ICE, 2007). Nevertheless, the FPS commentary includes some useful guidance, some of which has been incorporated in the ICE (2007) specification guidance. Execution of bored piles is covered in BS EN 1536:2000 (BSI, 2000a) and execution of displacement piles in BS EN 12699:2001 (BSI, 2001). The different types of bored and driven piles and their methods of installation are also described in Chapter 81 *Types of bearing piles*.

Noise and vibration control in piling is comprehensively covered in BS5228 (2009). Part 1 (BSI, 2009a) covers noise, including methods of noise control, guidance on methods for predicting and measuring noise, and assessing its impact. Part 2 (BSI, 2009b) covers vibration and means of vibration control, as well as guidance on methods of measuring and assessing vibration. Measured levels of vibration for piling are included in an appendix.

The durability of steel piling is covered in EC3 Part 5 (BSI, 2007a) and in the *Piling Handbook* (ArcelorMittal, 2008), which also contains useful practical guidance on pile driving. It details corrosion performance of steel piles and describes protective measures that can be adopted to increase their effective life. The durability of bored piles is detailed in both EC2 Part 1 (BSI, 2004) and EN206 (BSI, 2000b), which describe the exposure classes affecting durability and the requirements for concrete cover to reinforcement.

Many of the common problems in piling can be avoided by selecting the right piling system for the site conditions, and then ensuring that the installation is properly controlled and executed. A comprehensive site investigation is an essential component in selecting the appropriate method and the Association of Geotechnical and Geoenvironmental Specialists (AGS, 2006) guidelines are a very useful starting point and aide-mémoire.

With a good understanding of the ground conditions and the risks that can arise with different pile systems, the designer can select an appropriate method and control measures that will ensure successful construction of the piles. This is all part of the pile design process which is described in Chapter 54 *Single piles*. The following sections cover the common problems that can arise with the installation of bored and driven piles.

82.2 Bored piles

82.2.1 Ground conditions

It is important to ensure that the equipment to be utilised for boring is adequate for the ground conditions. This may seem obvious but the greatest unknown is still the ground. There may be unproven obstructions, both natural and man-made, that could prevent a 'less heavy' item of plant from completing the boring. Delays may occur if break-out tools have to be mobilised to site. Sometimes, the specialist contractor may know if natural obstructions are likely in a given area. There is also the possibility that, due to some unforeseen ground condition, the piles may have to be re-designed utilising a differing pile diameter. Whilst this should not be anticipated by the specialist contractor, his plant should ideally be able to switch to the alternative geometry.

By far the most common problem is the poor understanding of the ground conditions, usually due to inadequate site investigation. When this occurs, the client usually ends up paying for the cost and time lost caused by the 'unknown' conditions. There is also the common problem of a varying depth of founding stratum. This is more acute for CFA piling as the boring is essentially blind. Probing using the piling auger is possible, but is only a crude identifier of such depths.

Boring tools should be checked to ensure that the design diameter is to be achieved. The ICE SPERW (ICE, 2007) recommends a tolerance of up to 5%. Depth indicators and other instrumentation should be regularly calibrated, particularly if drilling tools or auger strings are changed. Other issues that can be of concern are smear in clays and weak rocks, bores left open too long before concreting and bases not adequately cleaned. This list is not exhaustive.

82.2.2 Boring

The correct use of temporary casings is essential for the success of good pile construction. Casings should always be driven or screwed in advance of drilling tools through unstable soils so as to provide a safe working environment and avoid over-excavation. A basic problem is found when, due to variations in the depth of unstable soils, the casing lengths used are inadequate and attempts to push them further into the ground risk the safety of personnel working around the bore (a minimum of 1 m should be left above commencement level as a safety barrier). With the less frequent use of high speed rotation, the practice of 'mudding-in' has become less common and the prevalent method is to screw/crowd (i.e. push down) the casing, sometimes as the auger is rotating within the casing. Mudding-in had the inherent problem of creating a weak zone around the casing which, if adequate concrete head were not utilised during subsequent casing extraction during concreting, could lead to a reduction in the concrete cross-section (known as necking) as the ground slumped into the bore.

This phenomenon of necking can also occur when withdrawing temporary casings if there is insufficient head of concrete to resist the external groundwater pressure. This is illustrated in **Figure 82.1**. To avoid this, the ICE SPERW (ICE, 2007) has specified minimum casting levels for concrete which are included in **Table 82.1**. This type of problem is most acute with long casings. The fall in concrete within the casing must be carefully observed as the casing is extracted in order to top-up

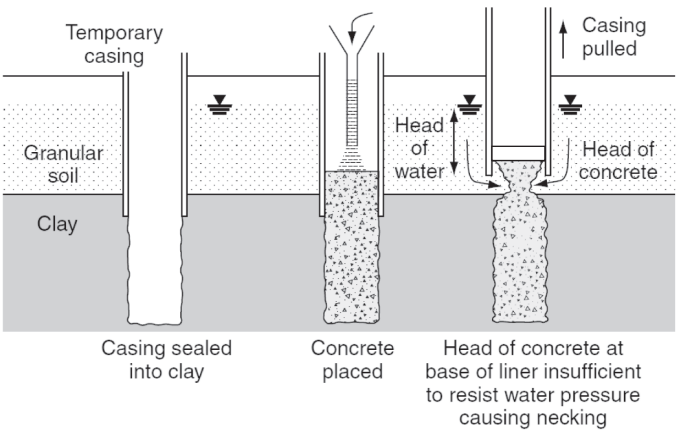

Figure 82.1 Necking in bored piles when the casing is pulled

Cut-off level below commencing surface, H[(1)] (m)	Casting tolerance above cut-off level (m)	Condition
0.15 to any depth	$0.3 + H/10$	Piles cast in dry bore within permanent casing or cut-off level in stable ground below base of casing
0.15–10.00	$0.3 + H/12 + C/8$	Piles cast in dry bore using temporary casing other than above
0.15–10.00	$1.0 + H/12 + C/8$ where C = length of temporary casing below the commencing surface	Piles or walls cast under water or support fluid[(2)]

[(1)]Beyond H = 10 m, the casting tolerance applying to H = 10 m shall apply.
[(2)]In cases where a pile is cast so that the cut-off level is within a permanent lining tube, or for a wall, the appropriate tolerance is given by deleting the casing term $C/8$.

Table 82.1 Concrete casting level tolerance above cut-off levels for specified conditions
Data taken from ICE (2007)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the bore to prevent such pressure differential affecting the concrete placement. Vibrating casings is an effective method for the larger diameter bores, but care must be exercised as above and disturbance to previously concreted piles or other structures prevented.

The sequence of bored pile construction, whether for discrete bearing piles or wall piles, and whether by conventional rotary bored piling or CFA methods, is of importance to pile integrity. The problems usually occur in weak or soft soils where the shear strength of the soils is inadequate to resist the lateral pressures of the fluid concrete. If the concrete is poured to a level significantly above groundwater level (and it is essential for all bored piles to be concreted to at least nominally 1 m above groundwater level), the excess hydrostatic pressure can be significantly greater than that in the ground.

During boring, the fluid concrete in an adjacent pile can be disturbed and flow laterally if the piles are close together and the ground between them insufficiently strong to resist the lateral pressures. During concreting, the pressurised column of fluid concrete could exceed the *in situ* pressures in a recently cast pile and cause ground movement towards the previously concreted pile – thus possibly causing a reduction in pile cross-sectional area. It is normal practice to leave at least three pile diameters spacing between successive piles in any one working day. When using CFA methodology which uses positive injection pressures to assist sound concrete placement, this spacing may have to be increased.

When boring into aquifers under drilling fluid or water, it is important to raise and lower drilling tools slowly to prevent suction or pressurisation destabilising the bore as shown in **Figure 82.2**. Drilling buckets should have a sufficient bypass for the fluid to pass through or around the bucket, such as the flat-sided bucket shown in **Figure 82.3**, in order to reduce the suction or pressurisation effects. Care must be taken to check the properties of the drilling fluid regularly. If the fluid density is too low this can lead to bore collapse; if the fluid is dense due to suspended solids it can lead to clean-up problems. Bores must be cleaned and the drilling fluid conditioned and re-circulated after boring and cleaning to ensure that no 'sludge' remains at the base which could lead to concreting problems and poor base loading of the pile. Sampling of the drilling fluid should be undertaken with special tools.

One of the most common problems encountered in CFA piling is the tendency to 'flight' material up the bore and cause over-excavation of the weaker soils. This is illustrated in **Figure 82.4**; guidance is given in ICE SPERW (ICE, 2007). Essentially, care has to be taken, particularly in silts and fine sands, to ensure an adequate rate of penetration of the auger versus the number of revolutions. Excessive rotation of the auger without penetration should not be permitted.

Auger displacement piles are a form of piling where the auger displaces the ground without removing spoil. There are two types of displacement piles: the helical (screw) and the soil displacement. For the screw displacement pile, the rate of

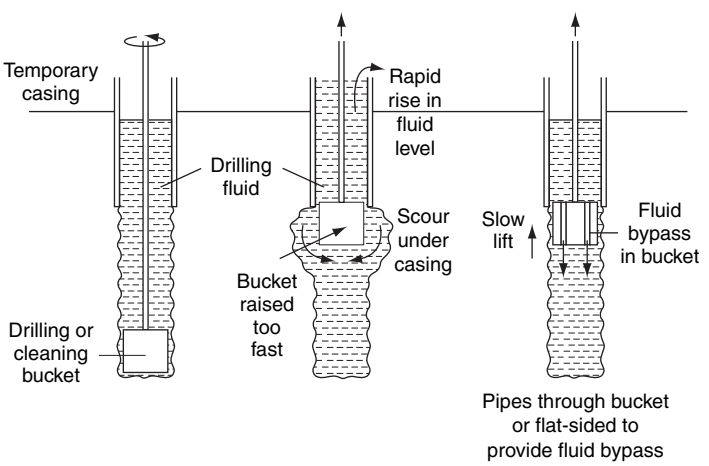

Figure 82.2 The effect of suction and scour on borehole stability when using drilling buckets

Figure 82.3 Flat-sided digging bucket to allow fluid to bypass
Courtesy of Balfour Beatty Ground Engineering

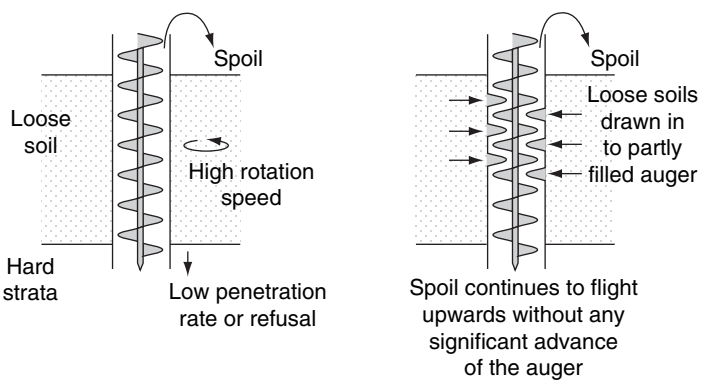

Figure 82.4 Flighting in CFA piles

penetration is controlled during insertion and removal of the auger to ensure that the auger follows the same path of flights – thus forming concrete ribs for the pile. Accurate monitoring and control of the rotation and penetration rate of the auger is essential to ensure integrity of the concrete ribs. For the soil displacement pile type, the soil is displaced without forming ribs. Substantial torque and crowd may be needed to ensure the auger penetrates the bearing stratum to a sufficient depth to achieve the required bearing capacity.

Other problems that may occur are discussed here. One problem is the meeting of natural or man-made obstructions. Even with the best desk study/collation of services information, the chances of hitting services are real. Smear to the bore walls, which can reduce the shaft friction, can occur in clays and weak mudstone due to over-rotation of the drilling tools. This is illustrated in **Figure 82.5** for a rotary bored pile shaft and in **Figure 82.6** for a CFA pile in mudstone which was deliberately over-rotated. If bores are left open too long, clays can soften and again result in lower shaft friction being mobilised. Pile end bearing can also be affected by allowing loose material to collect on the base. In a dry bore, a bladed auger or cleaning bucket is used to remove the loose debris. In piles that are bored under water or drilling fluid, suspended soil particles can settle onto the pile base and a cleaning bucket, air lift or submersible pump should be used to clean the base.

82.2.3 Concreting

Some of the problems associated with concrete placement have been noted in section 82.2.2, but this is by no means an exhaustive list. Since the most common method of concrete supply is via ready-mix suppliers, basic checks of the concrete delivery ticket, however mundane a process, can save problems with incorrect batching and distribution. The next most important check is of slump; as with all types of bored piling, high slump mixes are essential. Concrete that is too stiff is unsuitable for the self-compacting nature of the mixes employed and can cause blockages in tremie tubes and CFA delivery pipes. Placement pipes are desirable as they limit the segregation of concrete poured into bores, especially those that have pre-placed reinforcement cages. ICE SPERW (ICE, 2007) recommends the use of a rigid delivery pipe placed centrally in the bore to prevent the concrete hitting the reinforcement and so avoid segregation.

When concrete is placed inside a temporary casing, sufficient concrete needs to be provided to fill the extra volume created by the removal of the temporary casing. It is essential, especially for long casings, to monitor the internal concrete level and allow for topping up as casings are extracted.

There is the thorny subject for conventional bored piling of 'how wet can the bore be' before normal concrete placement has to be replaced by tremie placement. This is usually a problem encountered in otherwise dry cohesive ground, as the water table level in granular soils will normally be known before construction and the appropriate concrete placement method selected. Clearly, water entering the bore, whether from some way down the bore walls or from the base, influences the decision. On occasions where the amount of water entry is very minimal, it is impractical to use a tremie to place the concrete. In this situation it is quite adequate to either 'dry' the bore by the placement of dry cement or leave the final metres of boring until concrete is known to be ready on site for placement. If there is any doubt, the answer is to change concreting methodology and possibly pile design, so as to avoid the problem.

Whilst unlikely, the joints of tremie pipe assemblies can cause blockage if not adequately sealed due to the squeezing of water out of the fluid concrete by the excess pressure head in the pipe. Vigilance is important, particularly when removing and breaking such assemblies, and renewal of the rubber seal rings must be undertaken so as to prevent re-occurrence.

The removal of the tremie must be carefully controlled by logging the tremie depth as each volume of concrete is placed. Over-extraction of the tremie will cause a break in concrete quality in the bore with a zone of trapped detritus. To avoid over–extraction, ICE SPERW (2007) requires a minimum 3 m embedment for the tremie pipe in the concrete.

In CFA piling, a problem can occur either above or below the groundwater table due to the bleeding of water and possibly fines from the fluid concrete after placement. The problem is more prevalent above the groundwater table in dry granular soils and is caused by the squeezing of water/fines from the concrete due to the significantly higher pressure in the concrete versus the ground. Usually this problem can be foreseen and changes to concrete mix design (such as over-sanding and a higher dosage of plasticiser) are made. Problems also occur below the groundwater table for similar reasons but are not always evident before the commencement of work. Such problems are usually only detected when it becomes difficult or impossible to place reinforcement cages into the supposedly fluid concrete. The concrete in the affected depth zone will have lost its workability and present an obstruction to the smooth passage of the reinforcement cage. The remedy in these situations is to extract the reinforcement cage, re-bore, and re-concrete the bore so as to have workable concrete throughout the pile depth.

Another 'golden rule' is: 'once the concrete is placed, leave it alone'. That is to say, there is risk of contamination of the concrete in the bore if over-emphasis is made to clean up the top of the pile. However, with care, clean up and reduction of concrete level is achievable, even to the extent of preparing/casting pile caps integral with the piles.

82.2.4 Reinforcement

Congestion of reinforcement in heavy cages can lead to poor concrete placement with associated problems of design integrity of reinforcement bond. The problem is usually found when lapping multiple cages. BS EN1536 (BSI, 2000a) requires a minimum of 100 mm between main bars or 80 mm when using aggregate of 20 mm or less. On occasion it may be necessary to limit aggregate size to conform to these requirements, or use double circles of main reinforcement or bent bars to crank radially in the pile.

Poor handling and coupling of cages can be avoided by cage welding, which is now becoming more prevalent, or by using stiffeners, particularly for larger diameter cages. Pre-welded cages are usually more accurately produced than hand-tied cages and allow better matching of bars at laps. Correct lifting of cages should be observed to avoid collapse. Cages should be stored so as to remain essentially clean and must not become covered with mud or other debris.

Spacers to ensure adequate cover for the reinforcement to the bore walls do not always get the attention they deserve. After the expensive mobilisation of specialist equipment and manpower, procurement of high quality materials, do not allow the final product to be ruined for the sake of inadequate spacers – either by quality or number. Often the inadequacy of spacers only comes to light when the hardened pile is excavated or cut down – to reveal either no spacers, or bent or twisted ones that have allowed the cage to move eccentrically in the bore before the concrete has set and hence denigrate the finished product.

The level at which reinforcement is placed should be done with care so as to avoid subsequent problems with inadequate projection when follow-on trades take over the adoption of the piles into the works.

82.2.5 Ancillary works

After the completion of any one pile, the important thing is to ensure it is protected until the concrete has attained strength. Plant must not be allowed to travel near such piles as the fluid or partially set concrete cannot offer adequate passive resistance to the lateral pressures so induced (see **Figure 82.7**). This is often the reason for inadequate concrete cover or misaligned reinforcement cages. The clear identification of piles should also be a basic item of housekeeping on any site.

Other good housekeeping should include the removal of spoil and general area cleaning to create a safe working environment and prevent debris from entering the fluid concrete. This should be undertaken using appropriate reach plant, so as to avoid surcharging the piles.

Cutting down piles must be done with care. The use of laterally applied breakers, unless of a multi-circular configuration, must not be permitted. Ideally, proprietary multi-teeth breakers should be utilised. The removal of the top concrete core is assisted by the use of foam sleeves affixed to the reinforcement above cut-off level. FPS (2008) have produced a guidance note covering this topic and there is also a CIRIA (Cox, 2009) paper on the subject.

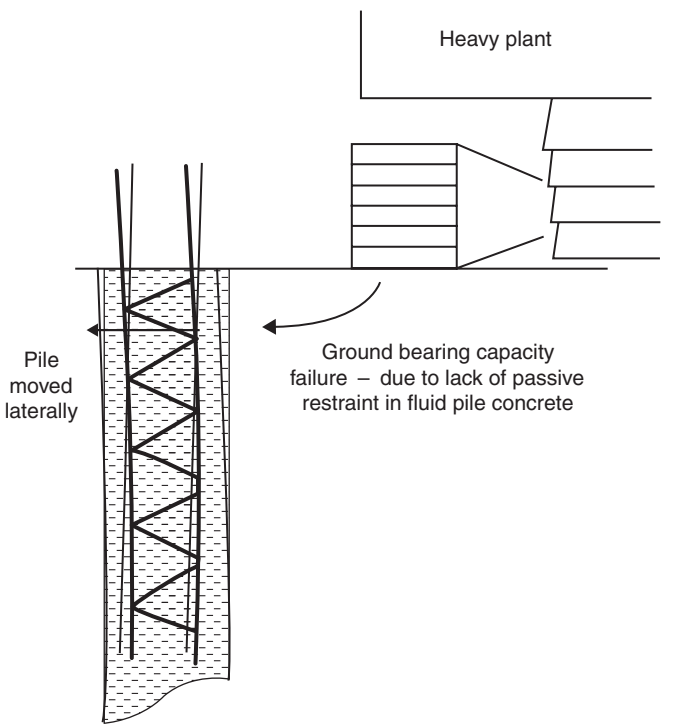

Figure 82.7 Damage to piles from nearby plant movement

82.2.6 Structural problems

Structural problems arise when reinforcement is placed at the incorrect level, or the cage becomes displaced due to poor use of spacers or mechanical displacement. The proving of concrete strength can be fraught with practical difficulties such as poor or dirty cube moulds, inadequate labelling, poor storage, curing tanks not being temperature controlled and poor off-site testing. Fortunately, the industry is moving to a self-certification system that is the province of the concrete supplier. The ready-mix industry has taken it upon itself to overcome the known shortcomings of this facet of construction and now collects samples from sites and produces records of the set concrete properties.

Pile eccentricity can cause problems, particularly if the designer has not taken account of the tolerance latitude that is permissible.

Figure 82.8 Ends of pre-cast piles, not cast square

82.3 Driven piles

82.3.1 Installation methods and ground conditions

BS EN 12699:2001 (BSI, 2001) covers the execution of concrete, steel, timber and cast iron displacement piles. Driven piles include low displacement piles such as open-ended steel tubes, steel sheets and steel H-sections, and high displacement piles such as pre-cast concrete sections, closed-ended steel tubes, timber piles and driven cast *in situ* concrete piles. Piles are installed by using drop hammers, vibratory techniques or by hydraulic press-in methods.

Hydraulically operated drop hammers are most commonly used to drive pre-cast concrete sections, and vibratory methods and drop hammers are both commonly used for steel piles. Hydraulic press-in methods are used to install steel sheets and some tube sections in areas where noise and vibration are to be avoided.

Adequate site investigation information is critical for making an assessment of driveability. The presence of obstructions and hard layers can affect driveability and additional measures such as jetting and pre-boring may be needed for the pile installation.

82.3.2 Pile manufacture

The manufacture of pre-cast concrete piles is covered by BS EN 12794:2007 (BSI, 2007b). The piles should be designed to withstand handling and driving stresses which are often considerably greater than the stresses they will experience in service. Pre-cast concrete piles are cast in moulds; the concrete strength needs to be sufficient for their removal from the moulds, handling and transportation, and then for final driving. The piles are cast in lengths that will subsequently be jointed on site. The ends of the sections therefore need to be cast square to the pile to ensure they fit tightly together and avoid eccentricity of loading (see **Figure 82.8**).

Steel and timber pile manufacture is unlikely to present any particular issues. Straightness of the section is important to avoid induced bending during driving.

82.3.3 Pile installation

Piles installed using drop hammer or vibratory techniques are held in leaders or guide frames to guide the hammer or vibrator, pitch the pile and hold the pile during the driving process. For hydraulic press-in methods, the hydraulic jaws clamp onto the pile to guide and feed the sections into the ground.

Over-driving, described by Healy and Weltman (1980), can often occur when attempting to drive piles to an unreasonable design depth. This can result in permanent damage to the pile head which is visible, or to the pile toe where it is unseen. In the case of toe damage, a pile may appear to be driving normally but the set may not build up as expected due to crushing or distortion of the pile toe. Where it is important to reach a particular depth, jetting or pre-boring should be considered.

Jetting and pre-boring need particular care to ensure that they do not cause disturbance to the ground that would affect adjacent structures such as utilities and buildings, or affect the performance of the piles. For jetting, a high pressure water jet is used to erode or loosen the soil at the pile tip. Water returns and pressures should be monitored to ensure the water is not finding an alternative flow path away from the pile tip. If the returns are blocked, pressure can rapidly build in the ground and cause heave. In pre-boring, an auger is used to loosen the soil prior to pile installation. Spoil removal should be limited to the minimum necessary to aid pile installation without affecting the geotechnical performance of the pile. Pile behaviour is best checked by dynamic or static test loading.

Damage during driving can occur, particularly at the pile head where the stresses are highest. For pre-cast concrete this will take the form of cracking and spalling of the concrete as shown in **Figure 82.9**, and on steel sections the pile head may bend or buckle. In order to prevent spalling, pre-cast concrete pile suppliers normally provide a protective steel band at the pile head and keep the concrete cover to a minimum whilst

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 82.9 Damaged pre-cast concrete pile head
Courtesy of Balfour Beatty Ground Engineering

still complying with durability requirements for protecting the reinforcement (Healy and Weltman, 1980 CIRIA report PG8). Damage can also occur within the pile due to tensile stresses. This can occur anywhere in the pile shaft when piles are driven using excessive hammer energy in soft ground and the damage is not noticed until harder driving occurs later towards the end of the drive. The cracking induced earlier in the pile shaft then leads to spalling and compressive failure at depth.

Pre-cast piles are usually reinforced to resist these driving stresses and breakages are relatively uncommon. They tend to happen when obstructions are encountered. Although piles are relatively slender, buckling is unlikely because of the restraint provided by the ground. Even soft ground will usually provide adequate support to prevent buckling during driving.

Where steel pile heads are damaged during installation, they can be cut back and extension pieces welded on. Requirements for structural welds can be difficult to achieve under site conditions and usually require verification testing which can delay the works. Procedures and testing requirements for both off-site and site welding are detailed in ICE SPERW (2007) and general guidance for arc welding is covered in BS EN 1011 Part 1 (BSI, 1998). Repairs to a concrete section can be made but delays are likely to be considerable due to the time required for the new section to cure.

Particular care is needed where driven piles are to be founded in a dense layer of variable thickness that is underlain by weaker material. Piles may punch through the dense layer in some locations before reaching the required set. In these circumstances, detailed site investigation information regarding the variability of strength and thickness of the founding stratum is critical. This information may need to be backed up by driveability trials, selecting areas close to boreholes where the founding stratum thickness and strength are the most critical.

During driving, steel tube piles can plug. This is where the soil inside the tube moves down instead of up as the pile continues to be driven. The mechanics of whether plugging is likely to occur have been investigated by White *et al.* (2002). They have shown how this affects the pile capacity and describe measures for reducing the effects by fitting a pile shoe. Piles can also be made to deliberately plug by welding an internal plate to prevent upward travel of soil inside the pile. Plugging in H-pile sections is very rare according to Biddle (1997) and should not be assumed unless it is demonstrated during driving.

Particular care is needed with founding driven piles onto buried inclined rock surfaces and rock head which contains boulders. These conditions can potentially deflect the pile off-line, inducing bending and damage to the pile and can lead to uncertainty in establishing a reliable set. Steep-sided rock faces, such as the edges of backfilled quarries, present a particular risk.

82.3.4 Final set

Driven piles are normally driven to a final set which is usually defined as the measured penetration for 10 blows. False sets can occur where there are obstructions or boulders in the ground, or where thin rock bands may overlie weaker layers. Trial drives at various locations around the site are a way of verifying consistent founding conditions and compatibility with the expected ground conditions and design. Pre-boring can be used where the pile driving is likely to be impeded by obstructions.

In very stiff clays and chalk the pile resistance can increase with time; this is known as set-up. A delay in the driving can then lead to extra energy being required to get the pile moving again. The increase in pore water pressure developed during driving reduces the ground resistance to driving. As this excess pressure dissipates, the resistance increases. This is beneficial to the long-term capacity but it is important not to test the pile too soon after installation – otherwise the pile capacity will be underestimated. If the problem is assessed as potentially significant, piezometers can be used to monitor the dissipation of the excess pore water pressures.

In dense silts and some weathered rocks, false sets can occur. This has been suggested to be the result of negative pore water pressures being induced by the pile driving. The dissipation of the negative pore water pressure can lead to a relaxation of the pile set. It is therefore necessary to carry out re-drive checks in these circumstances to check for any relaxation or reduction in pile resistance. The problem of relaxation can also occur in some mudstones where it has been suggested that the clay in the joints squeezes out or consolidates when load is applied after driving.

82.3.5 Downdrag

In soft clays and silts, the driving of displacement piles can cause excess pore pressures to develop which will dissipate over time. As the excess water dissipates, the soil will consolidate leading to an additional downdrag load developing in the pile. Pre-boring and sometimes slip coatings can be used to

reduce these effects. Generally, slip coatings have not proved very effective and their integrity after driving is uncertain. The additional downdrag load will usually be assessed and included as an additional load in the pile design. Downdrag loads can also occur in loose granular soils where the driving causes compaction of the soils.

82.3.6 Ground displacement

The process of driving a pile into the ground causes displacement of the ground which can lead to heave and lateral soil displacement in incompressible soils, or compaction and settlement in loose granular soils. The effects are greatest for high displacement piles in incompressible ground. In a confined situation such as a cofferdam, the cumulative effect of driving several piles can lead to increased ground displacement and lateral pressures. These can affect the cofferdam structure or make further driving of piles increasingly difficult as the ground tightens up. Use of low displacement piles, pre-boring and careful sequencing of the pile installation can all help to mitigate these effects. For large structures such as oil tanks, it is normal practice to drive piles from the centre working outwards. When working near to retaining walls, piles should be installed by working progressively away from the wall.

Preformed piles, such as pre-cast concrete and steel sections, can all be re-driven if there is a suspicion that they have been uplifted by driving adjacent piles. This is not the case for cast *in situ* driven piles, where an assessment would need to be made of any potential effect on performance.

82.3.7 Pile trimming

Poorly controlled pile trimming is probably the most common cause of damage to pre-cast concrete piles. *Breaking down of piles*, FPS (2008) provides guidance on various methods and states that heavy impact breakers should not be used on small diameter and lightly reinforced piles, or piles in soft ground. Cox (2009) also describes the different methods of pile trimming and the failure of the pile reinforcement that can occur with some systems. In particular, he notes the specific benefit of using debonding foam to avoid pile damage.

Trimming of steel piles should be carried out using a disc cutter or steel saw and not with burning equipment which will reduce the strength of the steel.

82.3.8 Jointing piles

Pre-cast concrete piles are usually supplied in sections which are connected by joints. There are two types of joints in general use. The first is a full strength mechanical joint which provides a compression, tension and moment connection. The second non-mechanical joint provides a compression connection only. Failure of joints is rare, but mechanical joints should be used where a lot of obstructions are known to be present.

For steel-cased piles, the problems of jointing casing lengths are associated with the practical aspects of site welding, including preparation and inspection. Again, the recommendations provided in SPERW (ICE, 2007) are highly relevant. Occasionally, threaded joints from second-hand or non-prime drill casing are employed as a means of avoiding the delays associated with welding. The casing sections are joined by driving the end of the casing with the male thread into the female internally-threaded collar. This provides an interference fit that is only suitable for compressive loads (and not tensile loads). For bottom-driven thin wall steel-cased piles, the casing sections are usually provided with simple interference fit spigot- and socket-type connections that can be jointed by tack welding. Alternatively, riveted connections can be used as a temporary expedient for the casing where the connection is only required to resist tension forces during driving. Thin-walled steel casings are also employed for Odex drilled-in piles, and in these cases tack welding is also satisfactory for jointing as the casings, left in permanently, are not considered structurally in the pile design process.

82.3.9 Noise and vibration

Noise is a potential problem for driven piling operations, particularly systems that are top-driven. Noise levels are generally less for bottom-driven methods where the hammer is contained within a driving tube or where vibratory methods are used. Consideration needs to be given to the proximity to noise- and vibration-sensitive areas. Measures can be taken to reduce the noise with acoustic shrouds and by restricting working hours. Alternatively, hydraulic push-in systems can be considered which have very low noise levels. Field measurements using this system have been compared to the existing recommended limits by White *et al.* (2002).

BS 5228 (2009) is the code of practice for noise and vibration control on construction sites and Part 1 (BSI, 2009a) covers noise. It provides guidance concerning methods of predicting and measuring noise, and assessing the impact on those exposed to it. Noise control from piling sites is specifically addressed in Section 8.5 and types of piling are discussed in Appendix H of the code. For top-driven systems, noise reduction can be achieved by introducing a non-metallic dolly (such as timber) between the hammer and the driving helmet. Acoustic shrouds have also been used to enclose the driving equipment. Data will normally be available from piling contractors for their particular system.

The driving of piles into the ground creates stress waves and vibrations that can affect the environment. The effects of vibration can be reduced by modifying the impact or frequency of the pile driving equipment. Vibratory piling methods also induce vibration in the ground. On some occasions, isolation trenches can prove useful in protecting neighbouring structures as they act as an inherent barrier to such ground-borne vibrations. However, 'freak' passages of vibration, possibly through susceptible strata, can also occur. As an alternative for steel piling, hydraulic push-in piling methods can be adopted which result in very low levels of ground vibration. White *et al.* (2002) have provided prediction curves showing that this system has

low vibration levels that enable it to be used much closer to residential buildings than impact or vibratory methods.

The level of vibration depends on the source and the distance from it. Even very low levels of vibration can be sensed by humans but much larger levels are necessary to cause damage to structures. BS 5228 (2009) is the code of practice for noise and vibration control on construction sites and Part 2 (BSI, 2009b) covers vibration. It provides guidance on methods of measuring vibration and assessing its impact on the environment. Annex C provides current measured vibration levels for piling and Annex D provides historic data.

The threshold of perception of vibration for humans occurs at very low levels of peak particle velocity (PPV) in the range 0.15–0.3 mm/s. The threshold criteria for damage to buildings occur at much higher levels and are presented in BS 7385–2 and are summarised in Annex B of BS 5228–2 (BSI, 2009b). These depend on the type of structure, the peak particle velocity of the vibration and the frequency range. In general, for reinforced or framed structures and industrial and heavy commercial buildings, the threshold level for cosmetic damage from transient vibration is 50 mm/s. For unreinforced or light framed and for residential or light commercial buildings the threshold is 50 mm/s for frequencies above 40 Hz, but reduces to 20 mm/s at 15 Hz and down to 15 mm/s at 4 Hz. Minor damage can occur at twice these values and major damage can occur to building structures at four times these values.

82.3.10 Durability

For concrete piles, the durability depends on the concrete quality and the concrete cover to the reinforcement. Healy and Weltman (1980) note that fine cracks of up to 0.2 mm in width may occur in high quality piles and these are not generally regarded as being of concern because they close up under the dead load from the structure. Larger cracks may occur as a result of improper handling, pitching or driving. The seriousness of excessive cracking depends on the aggressiveness of the ground into which the pile is being installed and the durability requirements. For concrete structures, these are covered in Eurocode 2 Part 1 (BSI, 2004).

Corrosion of steel piles is most likely to occur either in disturbed ground or in a marine environment. Corrosion rates for steel piling in natural environments are given in Eurocode 3 Part 5 (BSI, 2007a) as shown in **Table 82.2**. Various methods are available to combat corrosion and these are described by Fleming *et al.* (2009). Guidance is also provided by ArcelorMittal (2008) in their *Piling Handbook*.

82.4 Identifying and resolving problems

82.4.1 General guidance

The following sections describe the way in which piling problems are often identified, how they can be assessed, and the ways in which they can be resolved. Quality management systems and the process of identifying piling non-conformance are described in Chapter 93 *Quality assurance*. Problems often arise from the results of pile tests and useful guidance on pile testing and the interpretation and assessment of tests is provided in the *Handbook on Pile Testing* (FPS, 2006) and by Tomlinson (1994). Poulos (2005) also provides a range of case studies of piling problems and comments on the particular issues involved in investigating and analysing them.

82.4.2 Identification

There are a range of tests and records that can be used to identify potential problems. These include:

(i) Piling records – inconsistencies in ground conditions, driving records, out-of-position piles, uplift and lateral displacement, anomalies in concreting or reinforcement records.

(ii) Integrity tests – acoustic anomalies in integrity traces indicating the possibility of cracks, changes in section or inclusions in the pile. Guidance on different types of integrity tests and their interpretation is provided in Chapter 97 *Pile integrity testing* and by Turner (1997) in CIRIA Report 144.

(iii) Load tests – failure to meet the specified load/settlement behaviour, unexpected settlement behaviour indicating structural failure or low shaft resistance or a soft toe,

		Required design working life (years)				
Water	**Zone**	**5**	**25**	**50**	**75**	**100**
Common fresh water (river, ship, canal, etc.)	High attack (water line)	0.15	0.55	0.90	1.15	1.40
Very polluted fresh water (sewage, industrial effluent, etc.)	High attack (water line)	0.30	1.30	2.30	3.30	4.30
Sea water in temperate climate	High attack (low water and splash zones)	0.55	1.90	3.75	5.60	7.50
Sea water in temperate climate	Permanent immersion or in the intertidal zone	0.25	0.90	1.75	2.60	3.50

Notes
1. The highest corrosion rate is usually found in the splash zone or at the low water level in tidal waters. However in most cases, the highest bending stresses occur in the permanent immersion zone.
2. The values given for 5 and 25 years are based on measurement, the other values are extrapolated.

Table 82.2 Recommended values for the loss of thickness (mm) due to corrosion for piles and sheet piles in fresh water or in sea water
Data taken from BSI (2007a)

sometimes identified by using back analysis of load test results using methods such as those of Chin (1970) and Fleming (1992).

(iv) Materials tests – concrete cube tests not meeting the specified strength, failure of weld tests on steel connections.

(v) Inspection of trimmed piles – damaged pile head, weak concrete, buckled steel section.

(vi) Observations from the resident engineer or inspector staff detecting non-conformances with the specification that lead to further investigations that highlight problems.

Piling problems do not always arise from a non-conformance with the specification and may become apparent from observed inconsistencies. Sometimes the difficulty is to realise when there is a significant issue that needs further investigation. For example, a successful preliminary test on a bored pile in dry conditions in one part of a site may be found to be unrepresentative of wet conditions that become apparent in other areas. Another example is of driven piles which may all reach the required set but some are founded at a much higher level. Where this is unexpected and could affect the design, further investigation or testing may be needed.

82.4.3 Diagnosis

Test results should be viewed critically to ensure they are accurate and reliable, and they should be considered along with all the other information from pile records and knowledge of the site conditions. Further investigation may be necessary in the form of further testing or physical investigations before determining what remedial action, if any, is required. In some cases the test itself may be limited in what it can reveal.

For example, integrity testing in the form of sonic echo tests or cross-hole sonic testing relies on the interpretation of acoustic waves to identify potential anomalies in piles. Whilst these tests can indicate acoustic inconsistencies within the pile and between piles, this should be verified by physical investigation or load testing and a review of the pile records before deciding whether the anomalies are structurally significant. Similarly with load testing, unexpected pile load/settlement behaviour may be the result of variations in ground conditions or an inadequately performed test. Further evaluation and testing may be required to confirm the cause of poor or unexpected performance.

In some cases the anomalous test results may be the result of follow-on works where piles have been damaged by trimming or ground movements due to other works. It is therefore important that the testing is timely and carried out during the piling works or immediately on completion rather than at a later stage – otherwise the cause of the problem may be difficult to attribute to a specific contractor. It is advisable that testing is carried out as an ongoing process during the piling works so that potential problems can be identified during the work and remedial action taken whilst the works are in progress.

82.4.4 Resolving problems

Where tests or records indicate a potential problem with the piling, it is important to understand the impact of the problem for the structure. The issue may affect the durability or the structural performance.

In some cases, the problem may be easily accommodated by the structure without any remedial action, or with only minor remedial works. For example, with out-of-position piles, the pile reinforcement or the pile cap or ground beam arrangement may be sufficient to accommodate the eccentricity without any remedial action. Also, a pile load test that just exceeds the specified settlement limit may not be structurally significant; the structure may be able to accommodate slightly larger settlements than were originally specified without detriment to the overall structural performance. In these cases, whilst there may be a non-compliance with the specification, it is important not to overreact as it may be easily resolved by further assessment and analysis. It is not in the client's best interests to conduct a major investigation into apparent anomalies which may have no real significance for the structure.

Some problems may indicate a more fundamental issue with the piling which may affect the performance, safety and long-term durability of the structure. This will require a clearly defined strategy of investigation and assessment. The process should determine:

- the structural significance of the problem;
- whether other piles may be affected;
- any further testing that is considered necessary;
- remedial works if required.

The procedures for dealing with non-conformance should be defined in the contractor's quality plan. The actual procedure will depend on the contractual arrangements and whether the contractor's workmanship will be verified by an external party or whether the contractor will self-certify his work. The different quality management systems are described in Chapter 93 *Quality assurance*.

A significant area of misunderstanding can arise from the process of exploring the anomaly. Tests to verify that a pile can be safely incorporated into the works are conventionally paid for by the client (as the pile is ultimately acceptable), while tests that reveal defects that need remedying are paid for by the contractor. Payment for consequential costs is often contentious so it is in everyone's interest that the time for resolution is minimised.

The important underlying principle is that the lines of communication and project responsibilities should be clearly defined so that any non-conformance can be reported and remedial action proposed, assessed and approved as quickly as possible. Where this is likely to impact on cost, program or safety, the client needs to be kept informed of the solution.

Disclaimer

The example non-conformances included in this chapter are for illustrative purposes only and are not associated with, or reflective of the authors or their employers.

Association of Geotechnical and Geoenvironmental Specialists (AGS); www.ags.org.uk

It is recommended this chapter is read in conjunction with

- Chapter 96 *Technical supervision of site works*
- Chapter 97 *Pile integrity testing*
- Chapter 98 *Pile capacity testing*
- Chapter 101 *Close-out reports*
- Section 5 *Design of foundations*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 83
Underpinning

Tim Jolley Geostructural Solutions Ltd, Old Hatfield, UK

Before a final decision is made on the choice of underpinning for a particular application, there are several aspects to be considered. The various types of underpinning available are discussed in order to provoke thought on which type may be worth further consideration for the project at hand. Some factors are given which may influence the choice of underpinning to enable an informed decision to be made. Finally some specific points are covered in relation to groundwater, subsidence settlement, safety and the financial aspects of underpinning.

83.1 Introduction

83.1.1 Where underpinning is carried out and why

There are three main areas, namely:

(a) rectification of distress;

(b) extending foundations downwards to enable building and civil engineering works to be carried out;

(c) additional loading on an existing building.

83.1.2 Objective of the paper

Irrespective of the reason that underpinning is required, there are some common fundamental principles worthy of consideration prior to design or installation of an underpinning scheme. Some points are highlighted which may need to be borne in mind prior to embarking on an underpinning scheme whether it is at design stage or at construction stage. Information is therefore provided to provoke thought in order to facilitate correct decision-making at an early stage.

83.2 Types of underpinning

83.2.1 Mass concrete

Mass concrete underpinning is used as an extension of an existing masonry wall or footing. This may be necessary as a result of a requirement to lower the ground floor of a building where there is insufficient depth of existing foundation.

Another common use of mass concrete underpinning is to transfer the load of a building to stable ground as in the case of a building having suffered the effects of subsidence-related settlement. Where this is so, it is important to have sufficient information about the nature of the ground at an early stage in order to ascertain the likely depth at which stable ground will be found. This will enable a decision to be made on whether mass concrete underpinning is an appropriate solution in this case.

Where an existing building is being considered for the addition of further stories resulting in an increased loading on the foundations, mass concrete can be used to provide the required increase in bearing capacity of the soil upon which the building is founded. The proposed underpinning can be designed to increase the width of the existing footing or alternatively, to deepen the existing footings in order to found onto soil having greater bearing capacity.

If a new basement construction is proposed below or adjacent to an existing building, then mass concrete may be used to create a new wall to retain the soil behind. Generally a reinforced concrete lining wall is used in conjunction with the underpinning to provide permanent support. In order to maximise the space available in the proposed new basement room, the underpinning profile is often maintained in line with that of the existing walls. The underpinning profile is then widened at a point below the level of the new floor to achieve the same width as that of the original footing. In order to determine the degree of propping required in the temporary case, the proposed underpinning should be designed as a mass concrete gravity retaining wall. The proposed reinforced concrete lining wall will be designed to provide permanent restraint.

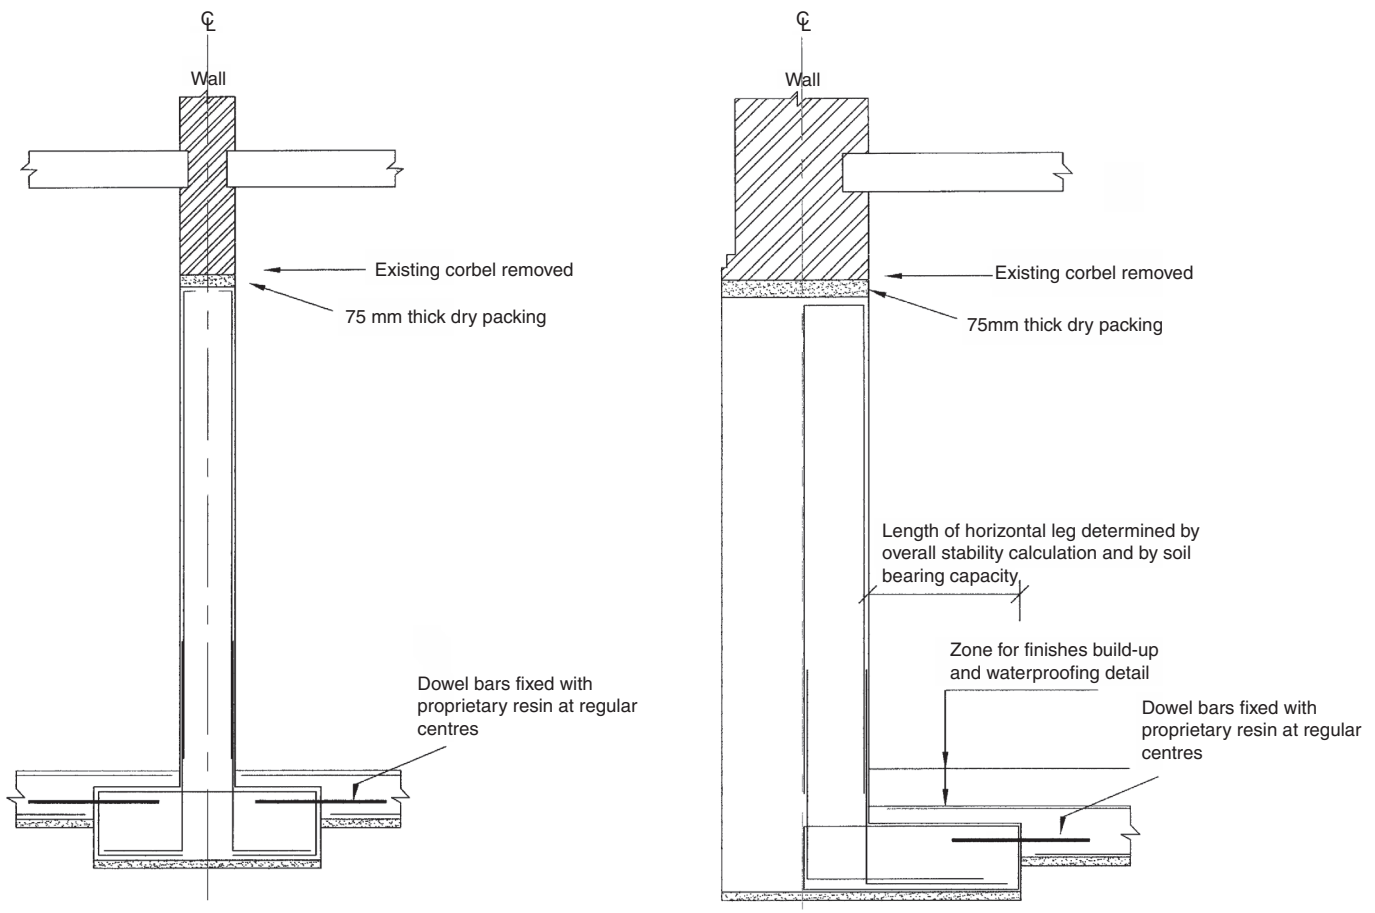
83.2.2 Hit and miss underpinning

Where appropriate, for reasons of economy, the mass concrete underpinning bases can be spaced apart in a ‘hit and miss’ pattern. As the loading from the structure above will now be concentrated onto a smaller area it is particularly important to check that the soil upon which the underpinning is founded does not become overstressed.

It is also important to consider the integrity of the structure which spans between the bases. In some cases it may be appropriate to introduce a lintel or series of lintels placed side by side to span between each adjacent base.

83.2.3 Reinforced concrete underpinning

Reinforced concrete underpinning bases are used most commonly when creating a new basement space below an existing building. They should be designed as a series of vertically spanning beams having a typical width of an individual underpinning base, say, 1.2 m. Continuity of reinforcement between the individual bases is therefore restricted to a series of dowel bars in order to ensure the new retaining wall acts as a homogeneous mass.



A reinforced wall is designed as the primary means of soil retention. In the permanent case, the wall will span as a beam between the various floor levels but in the temporary case, the underpinning may be required to resist the possibility of overturning and forward sliding. Depending on the circumstances surrounding each individual case, an 'L'-shaped underpinning profile may need to be adopted. The sectional dimensions of the horizontal leg will be determined from design analysis. Given the conditions in which underpinning bases are formed, it is advisable to provide a tolerance for construction of the base slab in relation to the horizontal leg. **Figure 83.1** shows a means of providing an economic design whilst allowing construction tolerance.

For reinforced concrete underpinning, the waterproofing is normally provided internally in the form of a cavity drain membrane or a flexible coating system. Waterproof concrete for construction of the reinforced underpinning bases can be considered but depending on the circumstances for a particular project, is sometimes found to be both impractical and uneconomical.

83.2.4 Piled underpinning

If an entire property is to be underpinned for reasons of subsidence-related settlement then a piled raft scheme should be considered. This is especially so if the ground conditions dictate that the depth of mass concrete underpinning is likely to be in excess of, say, 2.5 m. This figure is based largely on economic and practical considerations which are set out in section 83.10.

A system commonly used to underpin an entire building for subsidence-related settlement is formation of the raft by use of piles situated entirely within the building. A raft slab is formed to support the external walls by cantilevering out from piles placed just inside the building. In this way external drainage and other

(a) An internal wall

(b) A party wall

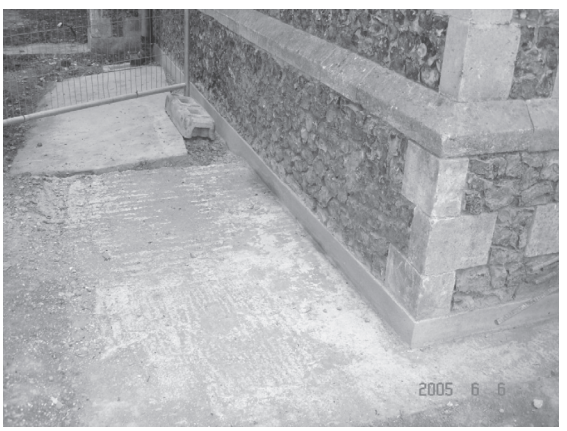
Figure 83.1 Underpinning detail for (a) an internal wall; (b) a party wall

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

services around the building are not affected by the piles. Internal walls are supported by piles placed either side. Sacrificial stools are used to temporarily prop the walls during installation of the reinforced concrete raft. Typically an entire building would be supported on a raft foundation formed from, say, three pours. In this way, stability to the building is ensured at all times.

For partial underpinning a 'needle pile' system can be used. A reinforced concrete beam is formed under the wall or preferably, within the depth of the existing foundation. If conditions permit, piles are placed each side of the wall at regular centres, say, 3.0 m with reinforced concrete needle beams to connect them together. **Figure 83.2** illustrates this technique, used at

Proposed beam spanning between needle



Stools placed in pairs and jacked into position

300mm diameter piles at needle locations

Completed beams and needles prior to dry packing

Finished works ready for landscaping

Figure 83.2 Piled underpinning, St John's Church, Wembley

St John's Church, Wembley. The brief was to underpin the external walls in order to overcome the effects of differential settlement caused by clay shrinkage within the prevailing London Clay soil. Sacrificial stools were used to form a reinforced concrete beam within the depth of the existing masonry structure, and needle beams connected through to bear on piles installed either side of the wall at regular centres.

When access to the interior of the building is not possible or is not preferred then a variation to the above described needle system can be used. Pairs of piles are placed on the external side of the building to act as a tension and compression couple.

Alternatively, a single pile can be used on the external side of the building. In this case, the pile is designed to support the vertical load but is combined with a design bending moment resulting from the lever arm between the pile centre and that of the wall. A reinforced concrete beam can be placed under the wall and extended at regular centres to form a series of pile caps. Depending on the loading conditions, the centre of the piles can be closed up so that the individual pile caps penetrate into the wall to form a series of castilations on a hit and miss basis.

A system of underpinning which avoids the requirement for a reinforced concrete beam using sacrificial stools is called 'Pali Radice' meaning 'root pile'. Typically a vertical pile is formed externally. This pile is coupled with another pile drilled at an angle through the existing foundation of the building. The two piles are designed to act in unison to support the building.

Irrespective of the type of piling used, it is always essential to ensure that there is sufficient bond between the old structure and the new pile to get the required load into the new pile. This is particularly important for the Pali Radice system as, unlike the other examples, there is no transition beam or slab to connect the existing structure to the piles. For the Pali Radice system each proposal would need to be assessed on its merits and a decision taken on whether sufficient bond can be achieved between the new pile and the old structure.

For the other cases it is important to maintain adequate load transfer from the pile into the slab or beam system. The steel reinforcement protruding from the pile should achieve a full bond into the reinforced concrete support system and where appropriate, a check should be made that the pile does not tend to punch through the slab through excessive load concentration.

83.2.5 Beam and pad underpinning

For subsidence-related underpinning the sacrificial stool system can be used to create a reinforced concrete beam below or within the depth of an existing foundation as described above. Isolated mass concrete pads are then formed at regular centres, say, 3.0 m. This form of underpinning is often more economic to build than the equivalent mass concrete system. This is especially so if, due to the prevailing ground conditions, the bases are anticipated to be formed at considerable depth.

Reference should be made to the comments in section 83.2.1 above in relation to the bearing capacity of the soil below the isolated underpinning bases.

83.2.6 Jacked underpinning

Where a building has settled differentially it is often possible to jack the structure back to eradicate or at least reduce the difference in levels. These are usually independent solutions appropriate to each case but as a general rule the principle involves forming a solid base from which to jack and to provide a 'cradle' under the building in order to contain it during the jacking operation. The cradle will then be used to support the building once the jacking is complete.

In the simple case where an extension has rotated downwards and away from the main building, it is important to provide a horizontal tie at foundation level. This is to allow the extension to rotate upwards during jacking but to prevent it from moving outwards at the base.

In all cases the jacking will only be effective if the existing cracks in the fabric of the structure are clear and free of previous repair or debris. If the building is allowed to 'pinch' on any material within the cracks then it cannot rotate back to its original position.

83.3 Factors influencing the choice of underpinning type

83.3.1 Reason for carrying out the underpinning works

Where the underpinning is not scheduled to be used to retain soil, for example, to counter the effect of subsidence settlement, then the choice of underpinning type can be determined by consideration of the most economical engineering solution given any access restrictions and taking in account the prevailing ground conditions. Where the underpinning is proposed to be used to retain soil then mass concrete or reinforced concrete bases become applicable. The use of mass concrete or reinforced concrete will then depend on such aspects of a project as the requirements for space creation, and the design conditions relating to the ability for the wall to act as an independent gravity retaining wall without an undue amount of propping.

83.3.2 Study of the site investigation

Save for the most basic of requirements an appropriate site investigation is essential in order to make an informed choice regarding the type and depth of underpinning. For example, clay soils may have suffered the effect of shrinkage through tree root activity. In certain circumstances, it is more economical to provide piled underpinning as an alternative to traditional underpinning. If the site investigation shows the soil to be desiccated to a depth in excess of 2.5–3.0 m, depending on the prevailing circumstances, it may well be more economical to consider a piled scheme.

If a clay soil is encountered then hand- or machine-excavated underpinning is relatively easily installed as the shoring can be safely placed at intervals leaving sections of exposed ground between the props. On the other hand, if loose uniformly graded sand is encountered then hand or machine excavation becomes much more difficult and therefore expensive as it is likely that a form of close boarded shoring will be required to make the excavation safe. For this form of shoring horizontal and vertical trench sheeting is often used to fully retain the soil.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The site investigation data should be used as a means to establish the founding depth of the proposed underpinning. In certain cases, for example, dense gravel over soft clay, the ground upon which the existing foundations are formed can have a higher bearing capacity than that of the ground below. This will influence the depth and width of mass or reinforced underpinning.

For ground conditions such as peat or where there is no stable ground to be encountered at reliable depth, a piled solution should be considered. Where the water table is above the proposed founding level for the underpinning, a piled solution should be considered wherever possible.

When commissioning a site investigation, prior knowledge should be gained of the type of ground likely to be encountered. This will enable an initial assessment to be made of the type of underpinning likely to be required. The investigation can then be commissioned to provide adequate information to enable a detailed and informed design to be carried out. A 5.0 m deep borehole may be sufficient for excavated underpinning but will be totally uninformative with respect to a piled solution. Standard penetration testing (SPT) should be undertaken in granular soils with U100 samples wherever possible in clay soils. The level and inflow rate of any water ingress should be noted and recorded. The final level of the water table should be noted and a piezometer should be installed in order to monitor any fluctuations in the level with time.

Soil suction tests should be undertaken when investigating the requirement for underpinning in the case of subsidence settlement. Specialist advice should be sought from an appropriate ground investigation company to ascertain the type and degree of testing to be carried out.

83.3.3 Settlement potential

In general a piled underpinning solution will perform with a lesser degree of potential settlement than an excavated solution. If, however, due to the required function of the underpinning, an excavated technique must be used, then the likely degree of settlement is an important factor for consideration.

It is possible to provide hydraulic jacking to alternate bases in order to pre-consolidate the soil as the bases are installed. In some cases, small diameter steel-cased piles can be placed in the excavated base prior to pouring concrete. This will create a load-sharing mechanism in order to minimise the effect of settlement.

If, for example, a dense granular soil underlies soft clays or loose granular materials, it may be effective to deepen the underpinning over and above the required depth in order to found on the material having a lesser potential for settlement.

In order to avoid the effect of multi-stage settlement at each phase of underpinning, single-stage underpinning should be considered wherever possible.

83.3.4 Gravity retaining wall design

For basement design the underpinning should be designed as a gravity retaining wall in terms of overall performance. A second analysis should then be undertaken to check its performance as a masonry wall or alternatively as a reinforced wall in bending and shear.

83.3.5 Party wall matters

If at all possible it is advisable to open discussion with party wall engineers at an early stage. This will minimise the risk of abortive design work and delay to the progress of the project as a whole. Reinforced concrete underpinning proposed along the party wall line may be considered as a ‘special foundation’ and can cause difficulty in achieving an award. The main principle, however, is not to encroach into the space below the plan area of the adjacent property and the choice of the underpinning system must reflect this requirement.

83.4 Bearing capacity of underpinning and adjacent footings

83.4.1 Bearing capacity theory

The shearing resistance of a foundation may be divided into three parts for ease of explanation (see **Figure 83.3**):

(a) frictional resistance resulting from the surcharge due to the depth of overburden;

(b) frictional resistance resulting from the weight of soil within the rupture zone BCD;

(c) cohesive resistance along the line ABC.

83.4.2 Excavation adjacent to an existing footing

Reference to **Figure 83.3** shows the effect of trench excavation to the level of an existing footing. As the depth of overburden has an influence on the bearing capacity of the soil below the existing foundation its removal can only serve to reduce the overall bearing capacity. This is especially so for granular soil as there is also no appreciable cohesive resistance along the rupture zone ABC shown in the diagram and the ground is much more reliant on the presence of an overburden to achieve adequate bearing capacity.

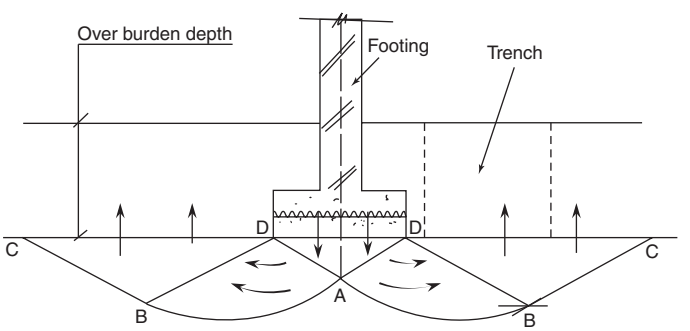


Figure 83.3 Failure of a foundation through inadequate shear resistance. Scott (1980)

83.4.3 Bearing capacity of the proposed underpinning

The mode of failure described above is a catastrophic collapse of the soil beneath the foundation through inadequate sheer strength. Failures of this type are not very common but when they do occur they lead to large distortions of the structure above. A more common mode of failure is through excessive settlement of the foundation.

For sands and gravels, the settlement takes place almost immediately and the cycle is usually complete by the end of the construction programme. This is because the settlement is caused through *compaction* of the soil through the increased load applied by the new foundation.

For clay soils the settlement is caused through *consolidation* rather than compaction. In this case, settlement occurs in diminishing amounts with time and can continue through the life of the structure. The settlement comes by consolidation of the particles in the tight soil matrix. This process is delayed, however, by gradual dissipation of the excess pore water pressure caused through loading the soil with the weight of the new foundation.

When underpinning in a clay soil it is therefore important to consider that the soil upon which the new foundation sits will settle with time by the process described above. It is advisable to leave a newly underpinned structure as long as possible to allow the greater part of the settlement process to take place before applying the final decorative finishes.

Any new foundation should have a calculable capacity and appropriate factor of safety. Wherever possible a site investigation should be carried out. Advice can be sought through the site investigation company on the most appropriate form of foundation to use along with information on allowable bearing capacity. It is of course necessary to brief the site investigation company beforehand on the information required for a particular project so that they may carry out the appropriate testing with samples gained at the time of the investigation.

83.5 Shoring

83.5.1 Types of shoring

Timber, steel or pre-cast concrete are often used. For a typical underpinning base the shoring supporting the face behind the wall will become sacrificial. For this reason, it is wise to use steel or concrete to support this face even if timber is used elsewhere.

83.5.2 Design of shoring

Safety for installation is a key factor in the design of shoring. Whilst pre-cast concrete planks or lintels are relatively low in cost and readily available, they are heavy to lift and are prone to progressive collapse when placed horizontally over the full height of an underpinning face. Steel trench sheets are equally robust but do not carry with them the same degree of safety concern.

For some soils, intermittent horizontal propping may be sufficient whilst for other soils, for example loose sand, full sheeting may be required. The size (and type) of props will be designed in accordance with the calculated soil pressure due to the overburden and any surcharging which may need to be taken into account. **Figure 83.4** shows an example of underpinning carried out in loose sands and gravels.

83.5.3 Minimising the risk of settlement

Any shoring technique will result in varying degrees of voiding behind the props due to lack of fit and local decay of the soil face prior to concreting. Consideration should be given to dry-packing behind the face of the shoring. For basement construction, the shoring to each underpinning base can be left in place prior to excavation of the entire basement. Depending

on the soil type retaining the shoring can be more effective in reducing the risk of settlement than backfilling each base, as the excavated material cannot always be readily compacted.

83.6 Underpinning in sands and gravel

Figure 83.4 shows the construction techniques used to create reinforced underpinning bases in a single stage to a depth of 6.0 m below ground level.

83.7 Dealing with groundwater

83.7.1 Pre-grouting

Figure 83.5 shows a technique for consolidating a granular soil prior to underpinning below the water table. The method relies on the interstices between the soil particles being capable of being filled with an injected material. In many cases, the interstices are too fine to permit cementitious grout to be used and therefore a chemical is required. Often a gel is used which is biodegradable so that the ground below adjacent properties is not affected in the long term.

This form of prevention for water ingress during underpinning is by no means guaranteed. The majority of injected material is excavated when carrying out the underpinning and therefore the most densely compacted areas are removed. The diagrams showing the angle of drilling indicate that the effectiveness of injection decreases with the distance from the drill location. This method of water prevention has been shown to be effective in certain locations but careful advice from specialist contractors should be sought if considering this method for a particular application.

83.7.2 Well pointing

The system typically comprises a series of perforated plastic tubes placed into boreholes and surrounded with granular soil with filter membrane. As water drains into the tubing it is pumped out thus lowering the water table locally. Depending on the soil type and the flow characteristics through it, the water table can be locally drawn down in order to permit the underpinning to be carried out in relatively dry conditions.

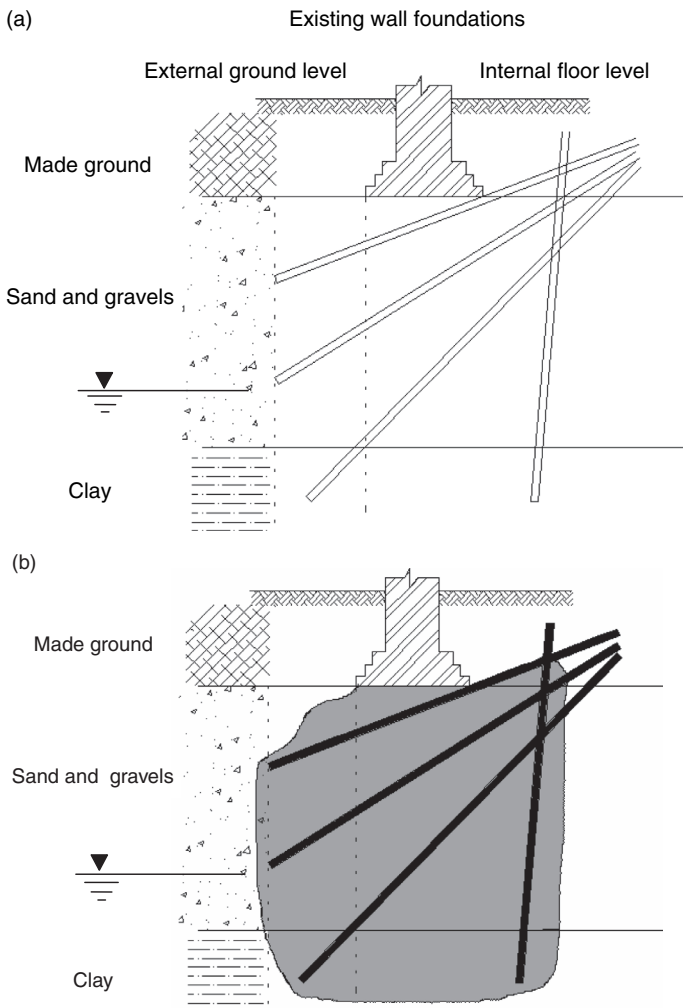

Figure 83.5 Illustration of pre-grouting technique

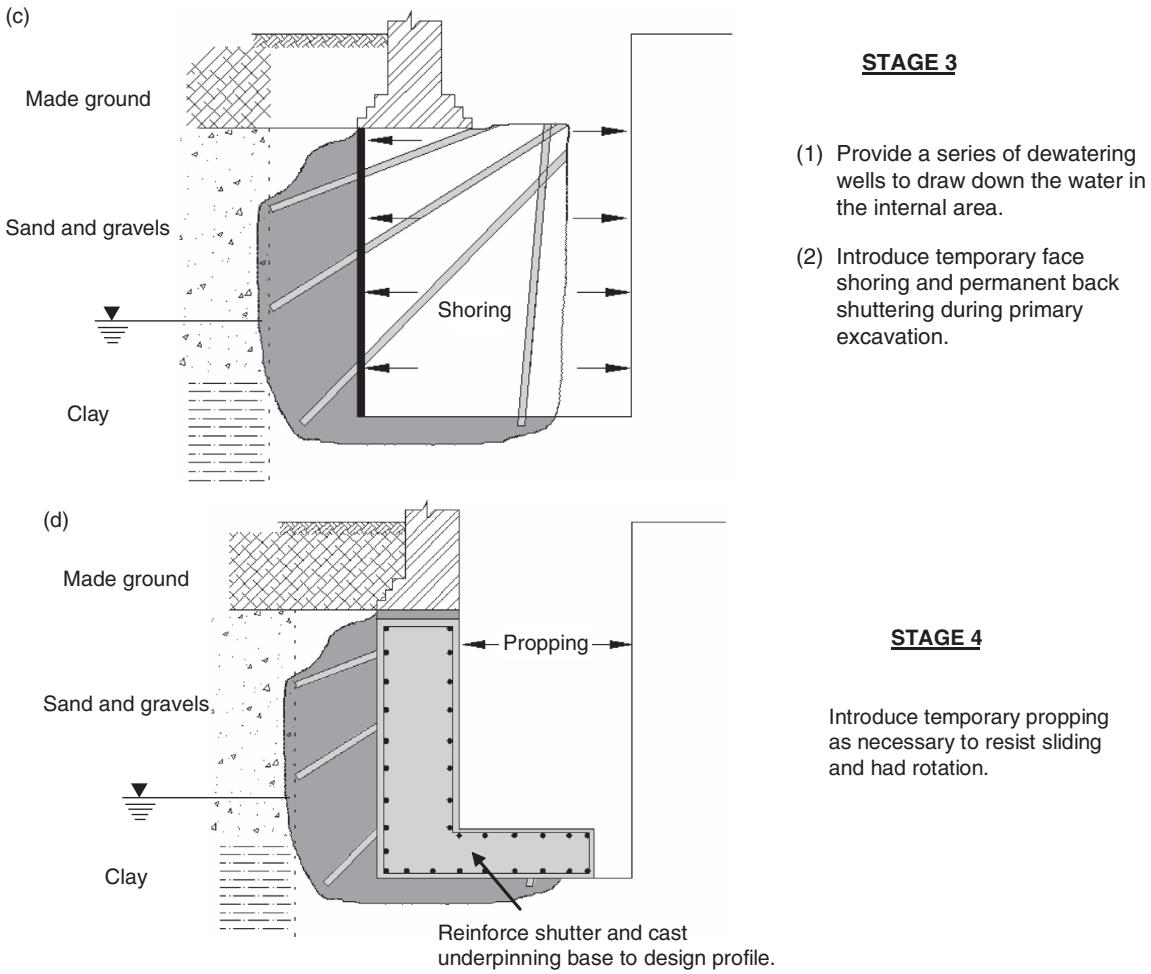

Figure 83.5 Continued

By changing the soil characteristics, lowering the water table can create a much increased possibility for settlement of the adjacent foundations. The movement of water through the ground can also cause settlement through migration of fines.

In the right circumstances however, local dewatering through well pointing can be a very effective way of enabling underpinning works to be carried out below the water table.

Consideration should be given to where the water is to be discharged. If it is to be discharged into the drains then permission should be sought from the local authority. Water which is discharged locally and allowed to soak into the ground will eventually find its way back into the system.

83.7.3 Local pumping

Depending on the nature of water inflow, local pumping can be used to enable an underpinning base to be formed in wet conditions. The use of local pumping should, however, be restricted to conditions which are safe in terms of the personnel involved in carrying out the work and in terms of potential settlement to the surrounding structures. If seepage is allowed to continue unabated during the progress of the works to install the base then fines can be drawn into the excavation. This will compromise both personnel safety and will increase the possibility of settlement occurring in the adjacent structures.

If the underpinning is required to penetrate the groundwater table then depending on the depth of penetration and the prevailing ground conditions local pumping can be effectively used. The point set out in section 83.7.2 above with regard to discharge of the pumped water is relevant here. For local pumping below the water table, it is usually difficult to control the amount of fines being pumped away along with the removal of water. The potential for settlement as a result of the pumping operation is correspondingly increased.

For both well pointing and local pumping the removal of fines within the soil will cause settlement to adjacent structures. The use of filters on the pumps is essential to minimise the possibility of this occurring.

83.8 Underpinning in relation to subsidence settlement

83.8.1 Choice of underpinning scheme

If the underpinning is not generally to be exposed or used as a soil retaining structure, the choice of underpinning is governed by the requirement to satisfy the design brief whilst achieving the best economy of construction. Whilst a performance specification or design brief can be developed by a consulting practice or surveyor, the actual choice of underpinning scheme may be left to the contractor's experience and specialist skills to conceive the best system in view of the prevailing ground conditions, access situation, safety aspects and overall economy.

83.8.2 ASUC

The Association of Specialist Underpinning Contractors (ASUC) is an organisation which has influence on activities related to subsidence settlement and other aspects of underpinning. Information concerning its initiatives and documentation can be found on the website www.asuc.org.uk.

83.8.3 Other subsidence-related stabilisation methods

In conjunction with underpinning works related to subsidence settlement, a programme of crack repair and refurbishment is usually undertaken. Crack repair can take the form of resin injection, 'brick stitching' by cutting out and replacement of the cracked bricks or insertion of steel reinforcing bars into the horizontal joints.

When the cause of the subsidence settlement is clearly defined by the presence of a tree or trees then, depending on the prevailing circumstances, these can be removed or pollarded. This can have the result of halting or even reversing the effects of subsidence settlement. A programme for tree removal/pollarding with subsequent monitoring is often undertaken prior to making a decision to carry out underpinning works.

If tree root activity is the cause of subsidence settlement, it is often important to implement and maintain a programme of continual tree maintenance to ensure that once the underpinning has been carried out, further settlement does not take place. Continual tree maintenance is carried out with the objective of containing the level of root activity to its current state. In this way, the shrinkable clay neither shrinks further nor recovers moisture with resultant ground heave.

83.8.4 Extent of underpinning

For subsidence-related underpinning, the question of whether to underpin at all or how much of the structure to underpin is always a difficult one. In order to find an appropriate solution it will usually be necessary to monitor the structure to establish the pattern of movement or indeed to establish whether the movement is still active and ongoing.

Study of the cracking pattern alone can be deceptive as it only indicates the degree of differential settlement. The whole structure could be settling but at different rates. Partially underpinning the worst area will serve to 'lock' this part of the building but then cracking may continue as the rest of the building settles further.

If, for economic reasons or for any other reason, it is not possible to underpin the whole of the property then appropriate measures should be taken to ensure that an adequate transition is made between the underpinned and non-underpinned structure. This will of course depend on the type of underpinning which has been chosen for the main structure. Typically this would involve stepped underpinning reducing the depth of the bases upwards towards the original foundation. To work effectively, however, each transition base should be separated from the adjacent one with polystyrene strips or similar in order to permit independent movement to take place. Otherwise the transition bases will tend to act as a corbel and therefore will not permit independent movement.

83.8.5 Contractual matters in relation to subsidence settlement

A contract in relation to subsidence settlement will probably contain clauses concerning the following points:

(i) A statement of the depth of underpinning/piling allowed and the practical/financial arrangements should the depth vary upwards or downwards.

(ii) For partial underpinning the extent of underpinning contained within the contract, a statement regarding any transition sections and arrangements concerning responsibility for the sections of the building not currently scheduled to be underpinned.

(iii) The extent of the design brief. Is the specialist contractor expected to design a total solution regarding the type and extent of underpinning required taking into account the damage which can be observed? Will the contractor take responsibility for variation of ground conditions? It will be necessary to accurately define the responsibility for both these questions.

(iv) An appropriate form of guarantee/warranty will usually be required. ASUC provide an insurance-backed guarantee, more details of which can be found on their website.

83.9 Safety aspects of underpinning

Underpinning works are considered by the Health and Safety Executive (HSE) as high risk and there is a requirement to produce method statements and risk assessments. Relatively recently the rule stating that excavations over 1.2 m deep required shoring was changed to include all excavations based on risk assessment.

The HSE publication HSG150 2006 contains a chapter on Groundworks. The publication warns of the danger of excavation in unsupported trenches and states the following:

341 Before digging any trenches, pits, tunnels, or other excavations, decide what temporary support will be required and plan the precautions that are going to be taken against:

- collapse of sides;
- people and vehicles falling into the excavations;
- materials falling onto people working in the excavation;
- undermining nearby structures;
- underground and overhead services; and
- the inflow of ground and serviced water.

Sections 338 to 381 provide information on safe practice with respect to the above subject headings.

Save for relatively shallow underpinning, the Confined Spaces Regulations (1997) will usually apply. As there is a risk of personnel falling into the excavations 'working at height' regulations apply especially with regard to the provision of handrails around all excavations irrespective of depth.

Under the current Construction (Design and Management) Regulations (CDM regulations), it is required that clients provide accurate information to enable the structural stability of the building and those adjacent to be assessed before work commences. A Health and Safety plan should be produced.

83.10 Financial aspects

As a general statement, deep hand-excavated underpinning is expensive and, where appropriate, consideration should be given to a piled scheme. Piles can be considered as a total solution in the case of Pali Radice or more often in conjunction with a reinforced concrete beam/slab arrangement.

Reinforced underpinning is of course relatively more expensive to install than a mass concrete equivalent but other considerations should be taken into account such as temporary works support and overall space creation. In general reinforced underpinning will occupy less space than the equivalent mass concrete system with reinforced lining walls.

In consideration of space creation construction, tolerance should be allowed in the calculation. Due to the nature of construction, it is difficult to achieve tight construction tolerance both in terms of verticality and precise formation level.

83.11 Conclusion

The process for finding the most appropriate form of underpinning to suit a particular set of circumstances is involved and can become complex. At all stages of the process specialist advice should be sought.

It is particularly important to produce a site investigation report which provides information in order to enable an informed and rational decision to be made on the correct type of underpinning to suit a particular set of circumstances. Advice from both specialist underpinning companies and site investigation companies should again be taken.

84.3	Vibro concrete columns	1259
84.4	Dynamic compaction	1261
84.5	References	1268

Ground improvement techniques can often be used as an economical alternative to piled and deep foundation solutions for a wide range of made ground, fill materials and natural soils to support houses, offices, industrial units, tanks, road embankments and similar low-rise developments. Techniques used include *in situ* compaction of clean sands using depth vibrators, adding stone or concrete during compaction to form vibro stone, or vibro concrete columns and dynamic compaction.

As the soil conditions have a large influence on the result, ground improvement techniques require an appropriate level of site and ground investigation to permit satisfactory geotechnical characterisation of the soil profile. Ground improvement also requires an appropriate level of understanding of where the differing techniques work and how to ensure correct and appropriate application. Quality control and monitoring procedures during execution of ground improvement techniques are essential to ensure successful implementation and performance.

Ground improvement techniques permit the adoption of relatively simple shallow foundations and groundbearing warehouse floor slabs. They can also provide significant sustainability advantages in comparison to more traditional deep foundation methods.

84.1 Introduction

Ground improvement involves the enhancement of ground properties, principally by strengthening or stiffening processes and compaction or densification mechanisms, to achieve a specific geotechnical performance.

Of the various ground improvement methods available, vibro techniques employing vibroflots (also referred to as vibrating pokers or depth vibrators) and dynamic methods incorporating the dropping of heavy steel tampers or weights on predetermined grid patterns, are the most commonly used. These form the main focus of discussion in this chapter.

It is important that ground engineering practitioners involved with the design, procurement and supervision of ground improvement techniques have an appropriate level of understanding of the various treatment methods being considered, the likely benefits, including selection of the most appropriate technique and any drawbacks or limitations of the technique selected for the prevailing combination of the ground conditions and applications being considered.

Choice of method will be influenced by the geotechnical requirements and engineering performance objectives of the ground improvement. Appropriate site supervision, quality control and monitoring procedures during execution of ground improvement techniques are essential to ensure successful implementation, as is an appropriate level of post-treatment testing to ensure satisfactory performance will be achieved.

Design principles for these techniques are covered elsewhere (Chapter 59 *Design principles for ground improvement*). Further guidance on these and a wider range of ground improvement techniques can be found in the referenced CIRIA Guides and Building Research Establishment (BRE) Specifications in this chapter. The ground improvement techniques of grouting and soil mixing are covered in Chapter 90 *Geotechnical grouting and soil mixing*.

Where any doubts or uncertainties exist specialist ground improvement contractors should always be consulted. Such advice is normally free of charge, although advance trials may sometimes be recommended.

84.2 Vibro techniques (vibrocompaction and vibro stone columns)

84.2.1 Introduction and history

The modern origins of vibro techniques were conceived in Germany in the mid-1930s. Vibrocompaction was the first technique to be developed, with its first application being for the *in situ* densification of loose sands for a government building in Berlin in 1937. Further development of the technique proceeded in parallel in Germany and the United States in the 1940s. The development of the vibro stone column method in the 1950s permitted the application of vibro techniques to a much wider range of soil types, most notably finer-grained soils (cohesive and mixed cohesive and granular soils), thus increasing the range of soils which could be treated by vibro techniques. Vibro stone column techniques were introduced into Great Britain and France in the late 1950s and have been used extensively worldwide.

84.2.2 Essential features of the vibroflot/vibrator equipment

The principal piece of equipment used to carry out vibro ground improvement techniques (whether for *in situ* densification or

construction of stone columns) is the vibroflot (also referred to as a vibrating poker or depth vibrator), which is either suspended from a crawler crane or mounted on a leader attached to a base machine, dependent upon the specific application. The essential features of the vibroflot are presented in **Figure 84.1**.

The vibroflot equipment comprises three main components – the vibrator head, the isolator and the extension tubes. The main component used to achieve compaction is the vibrator. Vibrations are produced close to the base or tip of the vibrator. These are induced by a series of rotating internal eccentric weights mounted on a shaft driven by an hydraulically or electrically powered motor located in the upper part of the vibrator casing. The rotating eccentric weights within the vibrator impart to the body of the vibrator a gyratory motion in a horizontal plane. Follower or extension tubes of similar or smaller diameter to the vibrator unit are attached to permit treatment of soils to varying depths. An elastic coupling isolates the vibration from the extension tubes and therefore prevents vibration travelling up the extension tubes to the supporting crane or base machines. Stabilising fins maintain stability of the vibroflot in the bore, by preventing rotation influenced by torque when the vibroflot is worked hard in the ground, which would otherwise lead to twisting or snagging of any external hydraulic or electric cables.

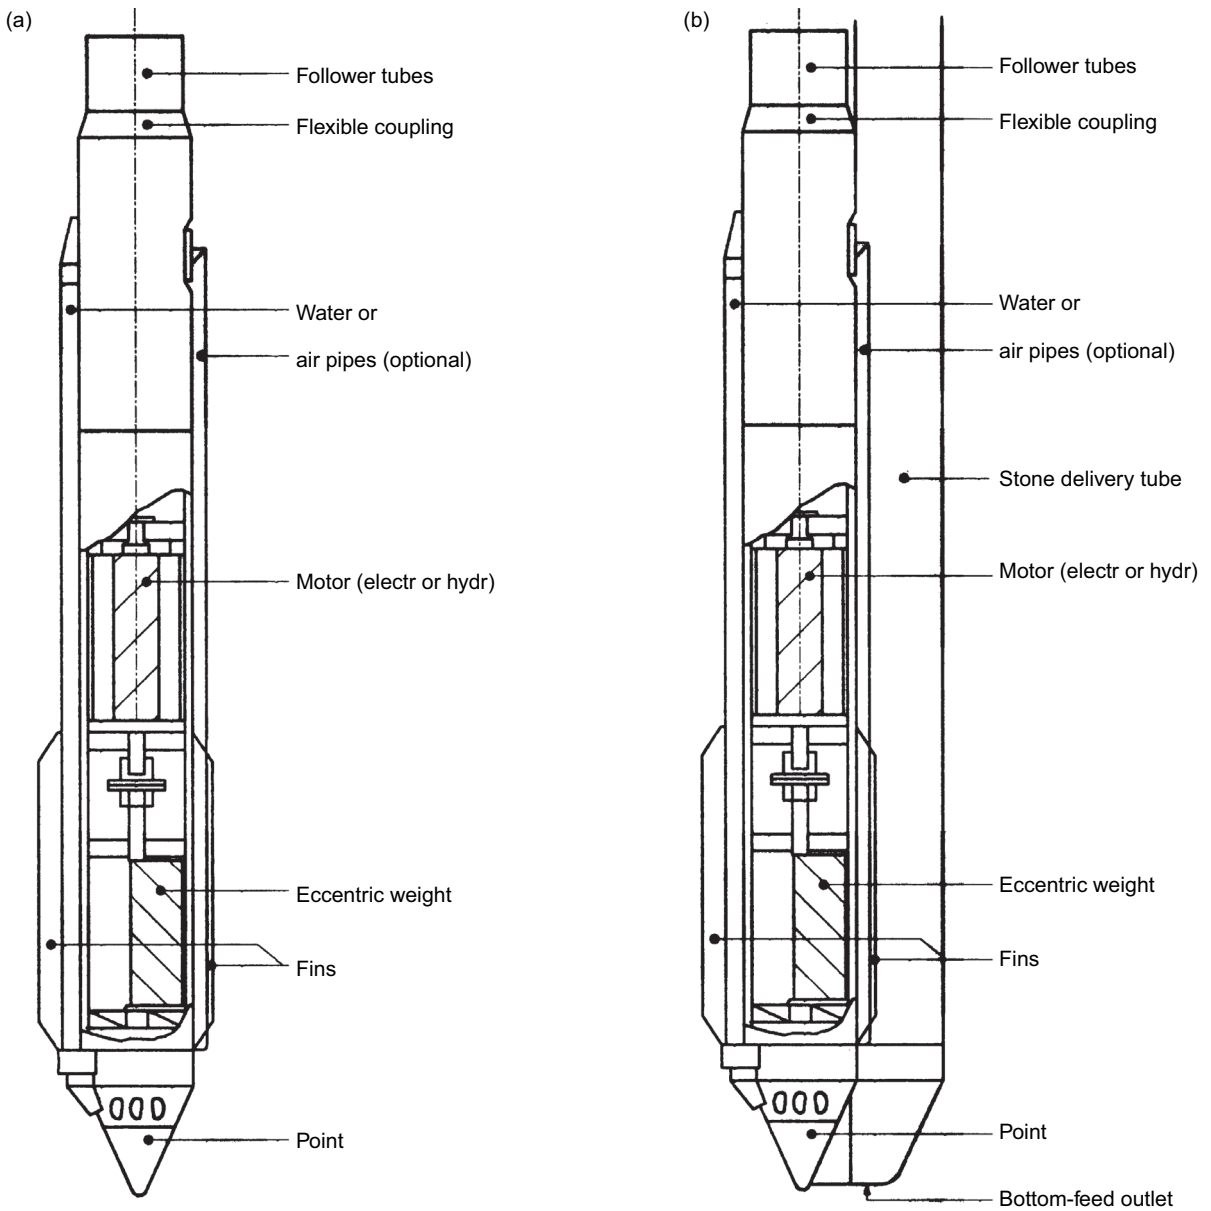

Figure 84.1 (a) Top-feed and (b) bottom-feed vibroflot (vibrating poker) units

Reproduced from Slocombe *et al.* (2000); all rights reserved

Whilst the basic components of the equipment have changed very little over the years, there have been significant developments in the reliability (with extended lifespans and reduced maintenance) and power ratings of the equipment with the objective of achieving greater efficiency in densification and stone column production.

84.2.3 Applicability of vibro techniques

The vibroflot may be used for both *in situ* compaction of cohesionless soils and for forming stone columns in fine-grained soils, as shown in **Figure 84.2**. The actual mechanism of improvement is a function of whether the soils are essentially granular (coarse-grained) or cohesive (fine-grained).

It is generally recognised that *in situ* vibro compaction is appropriate for granular soils with a total fines (particles finer than 0.06 mm) content of up to 15% of which the clay and fine silt content (particles smaller than 5 μm) should be less than 2% (Slocombe *et al.*, 2000).

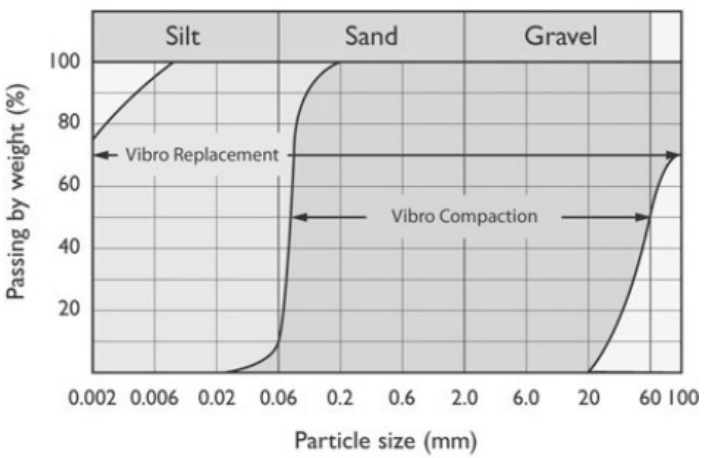

Figure 84.2 Range of soils treatable by vibrocompaction and vibro stone column techniques

84.2.3.1 Granular (coarse-grained) soils

The principle of vibro techniques in granular soils is based upon particles of coarse-grained (non-cohesive) soil being rearranged into a denser state by means of dominantly horizontal vibration from the vibroflot (vibrating poker). The resultant reduced void ratio and compressibility and corresponding increased angle of shearing resistance then permit the adoption of higher imposed design loadings at lesser settlement and increased seismic resistance.

84.2.3.2 Cohesive (fine-grained) soils

With fine-grained soils the cohesion between the soil particles dampens the vibrations and prevents rearrangement and compaction occurring. Improvement is achieved by 'reinforcing' the soil with relatively rigid stone columns. During the stone column construction the introduced coarse granular column material is pressed radially into the soil so that it is displaced beyond the diameter of the vibrator. The column of compacted dense granular material forms, together with the surrounding soil, a composite stone column – soil mass, with enhanced shear strength and bearing capacity, together with a corresponding reduction in settlements (attributed to the 'stiffening' effect of the stone columns). Stone columns in fine-grained soils also assist in the dissipation of excess pore water pressure under applied load or surcharge, which accelerates the consolidation process, together with providing enhanced slope stability parameters.

84.2.4 Vibrocompaction

For the vibrocompaction technique (**Figure 84.3**; see also **Figure 84.7(a)**) the vibroflot unit is positioned over the required compaction point, high pressure water jets in the vibrator nose cone are activated and the vibroflot is slowly lowered into the ground assisted by a combination of the weight of the vibroflot and the jetting action of the water jets. In the immediate

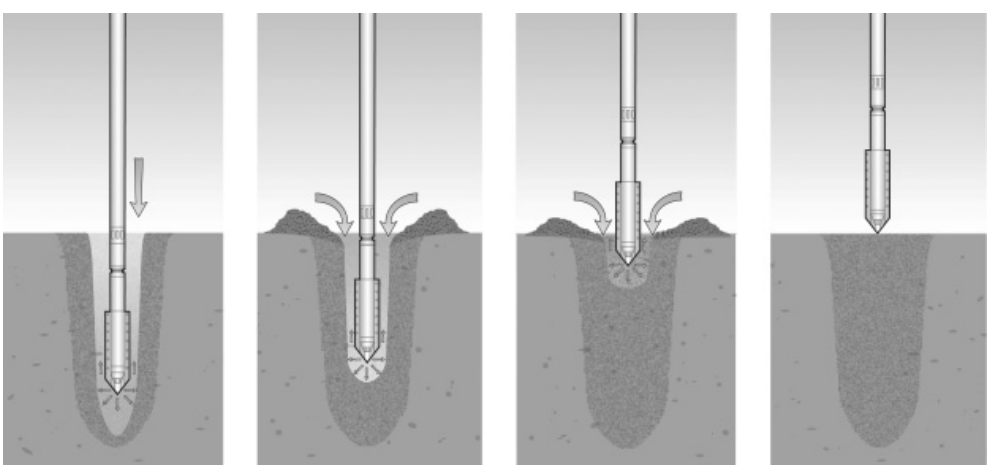

Figure 84.3 *In situ* vibrocompaction (sequence)

vicinity of the vibrator the saturated soil liquefies locally and temporarily under the influence of the vibrations. The vibroflot proceeds to sink rapidly into the soil under its own weight. When the required depth of penetration is reached, the vibrator is halted and the water supply reduced (or sometimes stopped). Under the action of the vibrations, the granular soil particles surrounding the vibrator are rearranged into a denser state. The effect of this compaction becomes visible at the ground surface in the form of a cone-shaped depression which is continually infilled with sand during the vibrocompaction process. When the required degree of compaction has been achieved (normally by monitoring the power consumption) at the depth of the vibrator, it is raised a short distance (typically 300–500 mm) from the base of the bore and the cycle repeated. Insertion of the vibroflot on a grid pattern will enable overlapping of the compacted cylinders and produce a homogeneous mass of compacted soil. Preliminary trials with pre- and post-treatment penetration testing may be employed to optimise the compaction spacings.

Sands of single-size grading or with a higher fines content are more difficult to compact than well-graded sands, as are sands that occur in relatively thin layers trapped between layers of clay and which require particular attention. Carbonate sands are susceptible to particle crushing and typically require closer grid spacings than silica sands.

84.2.5 Vibro stone column terminology and techniques

Terminology for vibro stone column techniques has not always been applied in a consistent manner and some attempt at addressing this can be found in BRE Document BR 391, *Specifying Vibro Stone Columns* (2000). This specification employs terms that reflect the fundamental principles of top-feed or bottom-feed to describe the method of stone aggregate supply, and wet or dry to describe the 'jetting' medium. This has given rise to the following terminology:

- dry top-feed technique;
- dry bottom-feed technique;
- wet top-feed technique.

The technique adopted is a function of ground conditions, bore stability and environmental constraints. Historically, literature has suggested that the dry top-feed technique should not be used in fine-grained soils with undrained shear strengths of less than 30 kN/m^2. For soils weaker than this, the dry bottom-feed technique (or historically the wet top-feed technique) has to be used. In terms of a lower-bound undrained shear strength, a value of 15 kN/m^2 has typically been used for vibro stone column applications. However, developments in vibroflot technology (together with monitoring and quality control systems) have allowed weaker soils to be treated in certain applications. Consideration also needs to be given to soil sensitivity when selecting the appropriate technique, as saturated sensitive soils can undergo significant remoulding when exposed to vibrations. For soft soils, settlement tends to be more of an issue than bearing capacity.

All three vibro stone column techniques described above use similar types of vibroflots, normally hydraulically or electrically driven, the main difference being the dry bottom-feed equipment which has a stone (aggregate) feed tube attached to the vibroflot to permit the stone aggregate to be introduced to the tip of the vibroflot without it having to be removed from the bore, thus overcoming any instability issues in weak ground or treatment to beneath the water table. The stone aggregate is typically handled by front end loaders with a side tip facility.

All the vibro stone column techniques are aimed at constructing well-compacted granular columns, typically of crushed stone or gravel aggregate in the void formed in the ground by the vibrating poker, thus improving bearing capacity and drainage while reducing total and differential settlements.

84.2.5.1 Dry top-feed technique

This technique can be used in a range of soil types, but relies on the bore remaining stable during column construction, with a general absence of groundwater within the treatment depth.

The vibroflot penetrates the soil by shearing and displacing the soil around it. Air flush via jets in the nose cone of the vibrator are used to overcome suction forces. Upon reaching the required depth the vibroflot is then completely withdrawn from the bore to facilitate introduction of granular backfill (aggregate) from the surface. Aggregate is tipped into the bore and the vibroflot then repenetrates to within a short distance of the original depth displacing the aggregate laterally and downwards, thus compacting it. The procedure is repeated in approximately 0.5 m lifts until the stone column construction is completed to the surface (**Figure 84.4**; see also **Figure 84.7(b)**). Stone column diameters of about 0.5–0.6 m are typically achieved, dependent upon soil properties.

84.2.5.2 Dry bottom-feed technique

This technique is used in weak soil profiles with a high water table where bore stability cannot be guaranteed during stone column construction with adoption of the conventional dry top-feed method.

The vibroflot penetrates the soil in the same manner as in the dry top-feed technique, the main difference being that the vibroflot has a stone tube (tremie pipe system) attached to it, allowing aggregate to be introduced to the tip of the vibroflot, without it having to be removed from the bore. Hence the vibroflot by remaining in the ground supports the potentially unstable bore. An airlock in the stone tube allows compressed air to assist discharge of aggregate. The vibroflot unit is mounted on leaders attached to a dedicated base machine which provides pulldown resistance during penetration of the vibroflot into the ground. During initial penetration the stone tube is charged with stone aggregate and when the required depth is reached the vibroflot is withdrawn a short distance from the base of the bore and a charge of stone aggregate is

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

discharged (with air pressure assistance) at the tip of the vibroflot, which is subsequently compacted on repenetration of the vibroflot. This cycle is repeated (in approximately 0.5 m lifts) until a compact stone column is constructed to the surface (**Figure 84.5**; see also **Figure 84.7(c)**).

84.2.5.3 Wet top-feed technique

This technique is employed in saturated fine-grained deposits and saturated granular soils deemed too silty for *in situ* vibrocompaction. The technique uses a similar technique to that used in vibrocompaction. When the required depth is reached, the vibroflot is sometimes surged up and down to flush out the bore. The vibroflot is then held a short distance off the bottom of the bore and the water pressure reduced sufficiently to allow a nominal outflow of water (and suspended fines) at the surface such that excess hydrostatic pressure and outward seepage forces support the uncased bore sufficiently long enough to form an annular space surrounding the vibroflot and permit construction of a stone column. A charge of aggregate is then introduced, while the vibroflot is still in the bore, down the annulus against the continuing low pressure upflow of water. This is subsequently compacted by repenetration of the vibroflot into the aggregate. The vibroflot is then lifted sufficiently to allow introduction of further charges of aggregate, which are then compacted and the cycle repeated until a continuous column of compacted stone is formed to the surface (**Figure 84.6**; see also **Figure 84.7(d)**).

The wet top-feed technique requires consideration of provision of water supply, drainage ditches, settlement lagoons and contamination of the site surface with fines as well as disposal of effluent.

Whilst the dry bottom-feed technique has largely superseded the wet top-feed technique on environmental grounds (there is a high water demand and effluent is generated), there are still certain ground types (where contamination is not an issue) where the wet technique may be more suitable and often necessary to achieve satisfactory results. In coastal or estuarine environments where soft clays and alluvial soils persist, the wet technique may be preferred, for example for bulk storage tanks or stockpiles of raw materials. The difference in construction

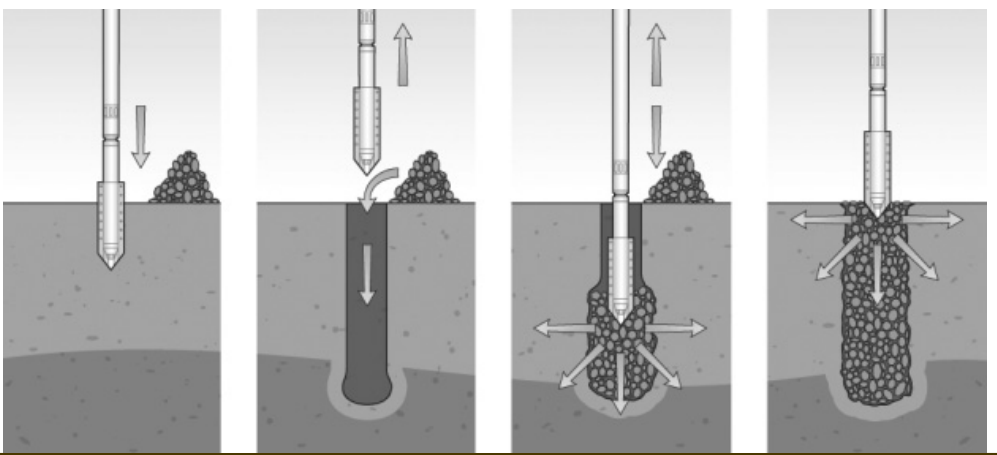

Figure 84.4 Installation sequence for dry top-feed vibro stone columns

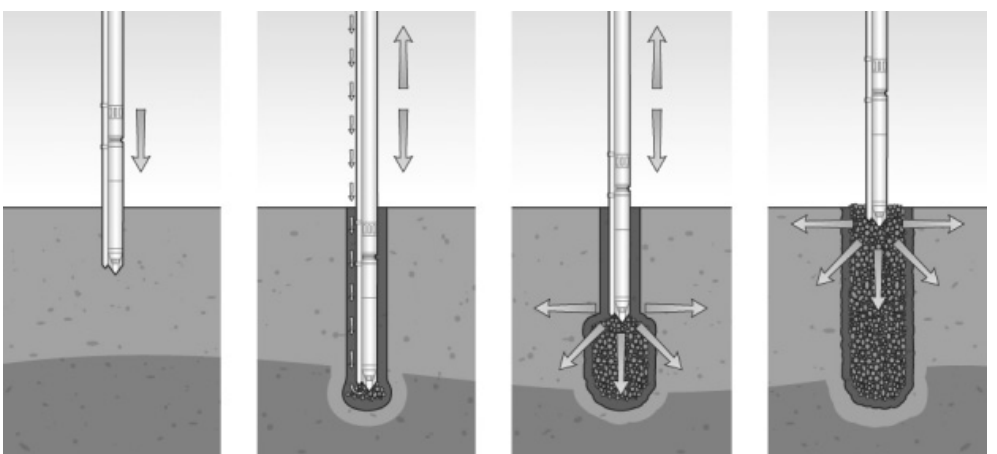

Figure 84.5 Installation sequence for dry bottom-feed vibro stone columns

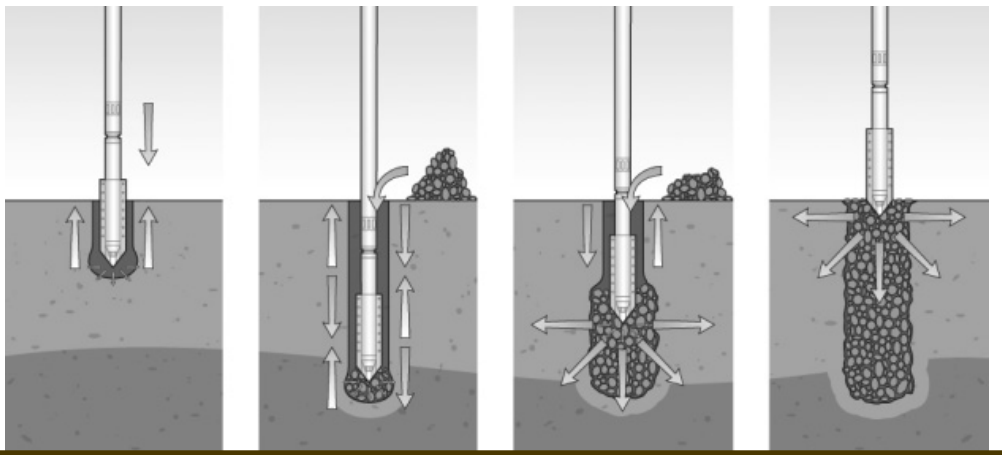

Figure 84.6 Installation sequence for wet top-feed vibro stone columns

technique between the wet method and dry methods typically results in the diameter of the stone column formed by the dry method being smaller than that formed by the wet method.

Vibro techniques are increasingly being used in near-shore marine applications, working off barges or pontoons, sometimes using larger cranes reaching out from existing quays.

84.2.6 Soil geotechnical properties and characterisation

Because of the large influence of the soil conditions on performance, ground improvement using vibro techniques requires a more extensive site and ground investigation programme compared with more conventional deep foundations solutions (Serridge, 2008). Site investigations are often designed to obtain soil parameters for deep foundation pile design. Ground improvement schemes then often require greater detail and laboratory testing on the near-surface soils than is provided. The most common types of ground-related problems encountered concern soil strata boundaries, i.e. geometry not as anticipated, and the geotechnical properties and characterisation of the soil profile. Site and ground investigation requirements for vibro techniques are dealt with elsewhere, e.g. BRE Report No. BR 391 *Specifying Vibro Stone Columns* (2000). In addition to satisfactory site geo-characterisation, important steps in achieving successful ground improvement implementation and performance include: an appropriate design and review process; consideration of the interfacing with other ground improvement techniques (or deep foundation techniques); preliminary trials (where applicable); monitoring; quality control and testing. Management of geotechnical risk is discussed by Clayton (2001).

84.2.7 Vibro stone column design

Within the UK design is typically based on Hughes and Withers (1974) for determination of stone column length and load-carrying capacity of an individual stone column. The guidance of Baumann and Bauer (1974) is frequently adopted for analysis of stress distribution between column and soil. Foundation settlement (without ground improvement) is first estimated using available geotechnical parameters and then applying appropriate settlement reduction factors (within the treated depth), according to Priebe (1995), to allow for the 'reinforcing' effect of the stone columns.

Although primarily applicable to embankment loadings over soft fine-grained/organic soils, it is important that secondary consolidation is considered as in some instances it may contribute to a significant part of the total settlement.

Some vibro design principles are provided in Chapter 59 *Design principles for ground improvement*.

84.2.8 Specifications

Within the UK the main specification documents and guidance notes covering vibro stone column techniques include:

- Institution of Civil Engineers (ICE) *Specification for Ground Treatment* (1987).
- Building Research Establishment (BRE) BR 391 *Specifying Vibro Stone Columns* (2000).
- Charles and Watts (2002) *Treated Ground – Engineering Properties and Performance*, CIRIA Report C572.
- BS EN 14731 *Ground Treatment by Deep Compaction* (BSI, 2005).
- NHBC Standards, Chapter 4.6 *Vibratory Ground Improvement Techniques* (2011).

84.2.9 Stone aggregate requirements

All the above-mentioned specifications convey a similar message with regard to stone aggregate requirements for vibro stone columns – that aggregate used in stone column construction should be sufficiently hard (i.e. must withstand the vibratory impact of the vibroflot); inert; free draining (typically with less than 5% fines); and of appropriate grading, shape and angularity to form dense granular columns with high angles of internal friction. Acceptable particle shapes for stone column material include rounded, angular and irregular. Unacceptable materials would be flaky and elongated.

Figure 84.7 (a) Vibrocompaction technique. (b) Dry top-feed technique. (c) Dry bottom-feed technique. (d) Wet top-feed technique
Courtesy of Keller (a, c) and Balfour Beatty Ground Engineering Ltd (b)

Historically a maximum Aggregate Crushing Value – ACV (BS 812 (BSI, 1990)) of 30 or a minimum Ten per cent Fines Value – TFV (BS 812 (BSI, 1990)) of between 50 and 100 kN (saturated) has been deemed appropriate for vibro stone column aggregate. For the more powerful and bottom-feed vibroflot units a minimum TFV of around 120 kN is typically required. However, with the advent of the new European Standards, the above test methods are no longer recognised and have been replaced by the Los Angeles Abrasion Value – LAA (BS EN 1097 (BSI, 1998)). Whilst no recognised correlation exists between ACV, TFV and LAA, an LAA value of between 30 and 40 is recognised within the industry as

Installation technique	Typical aggregate grading (mm)
Dry top-feed process	40–75
Wet top-feed process	25–75
Dry bottom-feed process	8–50

Table 84.1 Stone column aggregate grading for different vibro techniques
Data taken from BS EN14731:2005

being acceptable for use in vibro stone columns, dependent upon specific applications. Typical grading requirements for stone column aggregate as outlined in BS EN14731 *Ground Treatment by Deep Compaction* (BSI, 2005) are summarised in **Table 84.1**.

Smaller aggregate sizes are used in the bottom-feed delivery system to prevent blockages in the stone feed pipe. Rounded aggregates tend to flow better in the stone tube and it is imperative that the fines content is kept below 5%, also to prevent blockages.

Natural (primary) aggregate resources are not unlimited within the UK and their extraction causes increasingly unacceptable geo-environmental impacts. As part of achieving environmentally sustainable development within the ground improvement sector, there is an increasing desire to utilise recycled (and secondary) aggregates in vibro stone columns. However, where such materials are considered for use it is important that there are appropriate specifications and quality control/assurance procedures in place to ensure 'fitness-for-purpose'. Spent railway track ballast and crushed concrete currently have the greatest potential for this application in the UK and other materials have been investigated. Further information on these aspects can be found in Slocombe (2003b) and Serridge (2005) among others.

84.2.10 Environmental considerations

84.2.10.1 Noise and vibration

Whilst it is rare for noise issues to be a problem with vibro techniques, vibration levels need to be considered when working close to existing structures and services so that these are not adversely affected. The safe working distance will depend on a number of factors including type of ground, the vibroflot power rating, the nature and state of repair of the structure and also plant access, particularly if any basement structures are present. As a guide, minimum distances of 1–3 m are often appropriate. However, each situation must be assessed on its own merits and dilapidation or precondition surveys should be considered, in addition to appropriate risk assessments and vibration monitoring.

84.2.10.2 Contaminants

Appropriate risk assessment and precautions will be required on contaminated sites and to avoid exposure to the atmosphere of chemicals and materials such as asbestos.

84.2.10.3 Vibro concrete plugs

Penetrative ground improvement techniques such as vibro stone columns can generate potential pathways for contaminant migration on brownfield contaminated sites. This raises environmental concerns, particularly if sensitive groundwaters or underlying aquifers are present due to potential pollutant linkages (i.e. source–pathway–receptor linkages). An innovative approach to address this issue has been the development of 'vibro concrete plug' technology, incorporating the introduction of lean mix concrete into the basal section (toe) of the stone column, thereby isolating any pathways for downward migration of contamination via the stone columns. Further guidance on pollution prevention in this context can be found in Environment Agency Report NC/99/73 (2001). The above technology has also been utilised to bridge thin peaty deposits within the treated depth.

84.2.11 Monitoring, quality control and testing

Ground improvement exhibits a high frequency of highly ingenious equipment and solutions employed in difficult ground conditions. Close monitoring of ground response, quality control and testing throughout the duration of the vibro ground improvement works is therefore essential.

Bell (2004) describes an example of a range of quality (control) issues possibly arising from insufficient attention to construction detail on what he considers should have been a routine vibro stone column ground improvement project in mixed (heterogeneous) soils in the UK (**Figure 84.8**). Poor (discontinuous) column construction was attributed to the lack of constructing the columns in discrete lifts, each of which is required to be compacted to a predetermined limit such as target hydraulic pressure or ammeter reading, dependent upon whether the vibroflot is hydraulically or electrically driven. It is also indicated that accurate records of the amount of stone aggregate consumed by each column would have revealed the deficiencies of construction during installation.

The majority of vibro stone column projects in the UK involve the support of structures. Therefore, in addition to the monitoring and recording of installation parameters, some form of validation testing using load testing and/or penetration testing, dependent upon soil type, is normally required. Load tests typically include:

- short-term plate load tests;
- zone load tests or skip tests;
- embankment load tests (surcharge load tests).

84.2.11.1 Short-term plate load tests

Plate load tests are normally of less than two hours' duration with plate diameter comparable to the design stone column diameter, normally standardised at around 600 mm. Loading is quickly applied to the test column to between 1.5 times and 3.0 times the design pressure over the plate area, using a crane or vibro rig as reaction. The tests are principally regarded as a

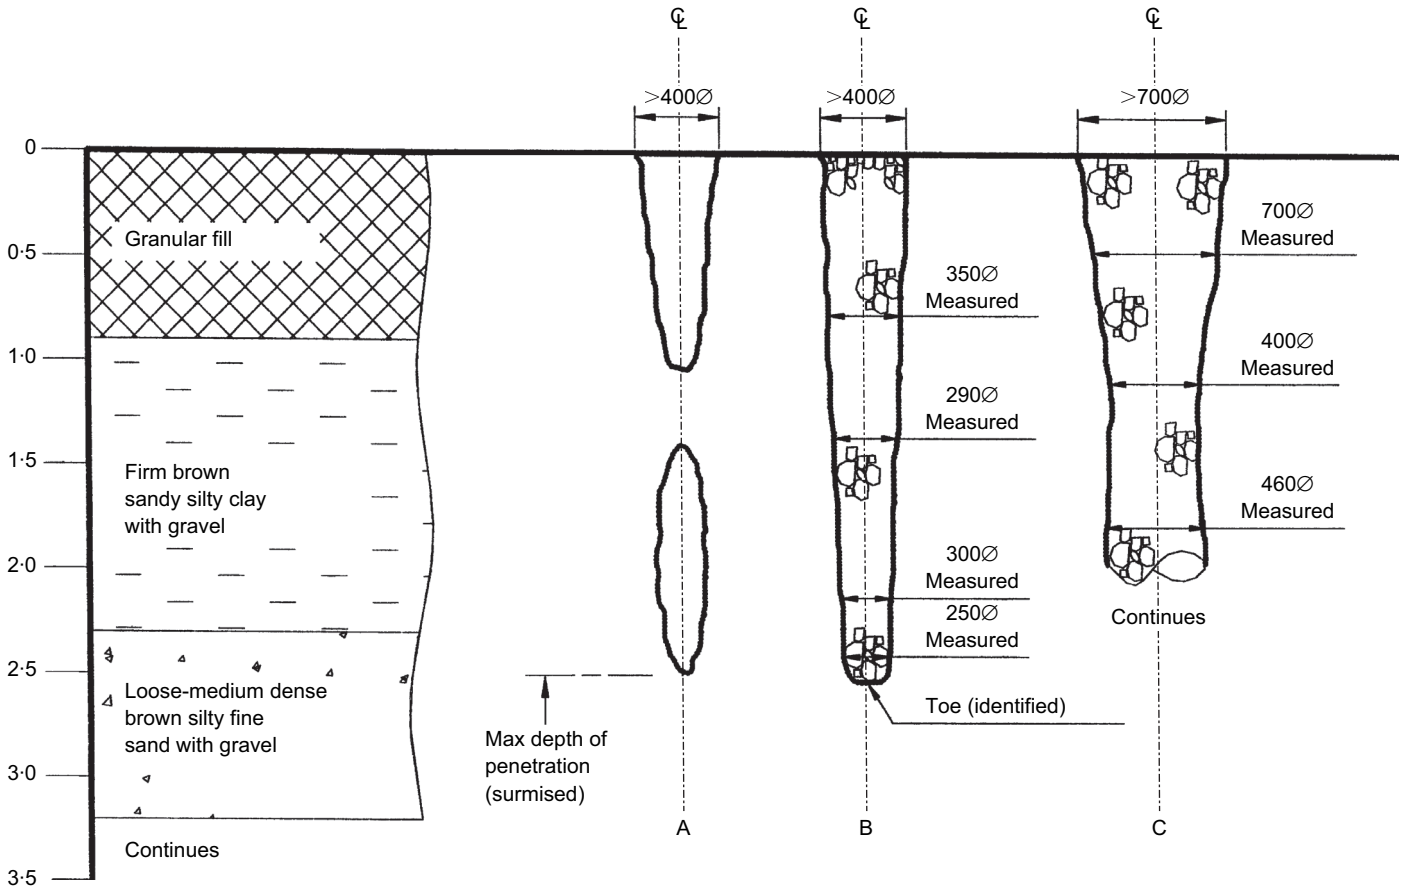

Figure 84.8 Example of poor quality control with vibro stone columns
Reproduced from Bell (2004); all rights reserved

quality control test to assess level of workmanship with regard to stone column installation.

84.2.11.2 Zone load tests or skip tests/dummy foundation tests

Zone load tests are normally of similar size to the project foundations and are performed over a group of columns – either by direct loading or against a system of grillage and kentledge for a period of between 24 hours and one week. These tests are more meaningful than the plate load tests since they apply load to the composite structure of both stone columns and soil but are far more expensive because of the cost of importing kentledge to site.

Skip tests/dummy foundation tests provide an intermediate test between zone load tests and plate load tests and may be more practical and economic on smaller projects (see BRE BR 391 *Specifying Vibro Stone Columns* (2000) and NHBC Standards, Chapter 4.6 *Vibratory Ground Improvement Techniques* (2011).

84.2.11.3 Embankment loading tests (surcharge load tests)

These tests can impose loads over a larger area for a longer period of time. They are particularly useful for road embankments on soft ground where time-dependent performance may be important (to ensure post-road construction settlements fall within acceptable limits). As with untreated soft soils, the rate of loading should be carefully controlled and monitored via appropriate field instrumentation. This facilitates better assessment of the performance of widespread loads. Where such tests are not possible, emphasis should be placed on monitoring and observing ground response to stone column installation and ensuring the design column diameters are achieved, supplemented by good quality control.

84.2.11.4 Penetration tests

In situ tests are typically employed to assess the technical success of *in situ* vibrocompaction and performance is measured by the level of densification achieved against a specified target. The densification can be readily checked using standard penetration tests (SPT) or cone penetration tests (CPT). Comparisons can be made between pre- and post-treatment tests and care should be taken to ensure the same techniques of testing are used in each situation. They are not normally employed on stone column projects, particularly where the soils contain a significant fines component.

With both load tests and penetration tests, it is important that there is an appropriate recovery period following completion of vibro ground improvement to allow a satisfactory level of pore water pressure dissipation in order to obtain meaningful results. A suitability rating for different testing methods for vibro techniques in presented in **Table 84.2**.

A modulus of sub-grade reaction or California Bearing Ratio – CBR (BS 1377–9 (BSI, 1990)) value may sometimes be specified for a groundbearing floor slab. It is important to recognise that whilst there may be some improvement in relative density between stone columns in granular soils, this will not be the case in cohesive soils (where the stone columns are acting as 'reinforcing elements'). In this instance the main objectives of stone columns are for control of total and differential settlements. Floor slab design would need to be based upon values obtained at sub-grade between stone columns.

Test method	Granular	Cohesive	Comments
McIntosh Probe	*	*	Pre-/post-treatment essential. Can locate obstructions prior to treatment.
Dynamic cone	**	*	Too insensitive to reveal clay fraction. Can locate dense layers and buried features.
Mechanical cone	***	*	Rarely used in UK.
Electric cone (CPT)	****	**	Particle size important. Can be affected by lateral earth pressures generated by treatment. Most appropriate test for seismic liquefaction evaluation.
Boreholes and SPT	***	**	Efficiency and repeatability of test important. Recovers samples (e.g. split spoon sampler).
Dilatometer	***	*	Rarely used.
Pressuremeter	***	*	Rarely used.
Small plate test	*	*	Does not adequately confine stone column. Limited stress depth. Affected by pore water pressures.
Large plate test	**	**	Better confining action.
Skip test	**	**	Can maintain test for extended period.
Zone loading test	****	****	Best test for realistic comparison with foundations.
Full-scale (e.g. surcharge load test)	*****	*****	Not commonly used. Tends to be confined to highway embankment projects.

* Least suitable ***** Most suitable

Table 84.2 Suitability rating for test methods applied to vibro techniques
Data taken from Moseley and Priebe (1993)

84.2.12 Practical issues

There are a number of practical issues to consider in the context of vibro stone column techniques. The more pertinent ones are discussed below.

84.2.12.1 Dealing with obstructions

Obstructions, dense granular made ground and remnant foundations can be an issue in terms of preventing vibroflot penetration and potential for forming hard spots. These should be suitably remediated (e.g. pre-loosening/excavation with removal and/or screening/crushing of oversize granular material before returning to excavation) and with provision of an appropriate cushion of granular material between underside of foundation or groundbearing floor slab and top of buried remnant foundation.

84.2.12.2 Working platforms and stabilised platforms

Provision of a safe granular working platform is essential for safe access and execution of vibro ground improvement. Stabilised platforms (lime/cement) can be used, but due consideration needs to be given to implications of 'spragging' of rig tracks and ponding of water in inclement weather, which may necessitate placement of a surface granular layer.

84.2.12.3 Pre-boring

Many historic heterogeneous fills in the UK are quite competent, particularly in their uppermost layers. This, together with placement of any engineered/stabilised upfill in advance of vibro ground improvement, can impede vibroflot penetration, necessitating the use of pre-boring. Arisings will be generated which then need to be dealt with.

84.2.12.4 Slopes and interceptor drains

For construction at the base of slopes, it is important that there is appropriate drainage at the toes to intercept water draining off the slope, to avoid any detrimental effects on the treated ground.

84.2.12.5 Lateral forces

Vibrocompaction and vibro stone column construction, as with driven piling, can generate lateral forces that can act on existing retaining structures, sheet piles and quay walls. Consideration of these effects requires specialist input.

84.2.12.6 Gas venting

On historic landfill sites, stone columns can actively vent any gases trapped in the fill. Therefore consideration of provision of gas venting measures may be required following appropriate risk assessment.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

84.2.12.7 Installation tolerances

Accepted positional tolerances for vibro stone columns are more flexible than for piles and are typically quoted as 150 mm.

84.2.13 Conditions where caution is to be exercised for vibro stone columns

There are recognised ground conditions within the ground improvement industry which are either deemed not suitable for vibro stone column techniques, or where caution should be exercised. Some of the more significant ones are discussed briefly below:

1. *Excessive degradable materials* – On sites where the made ground contains excessive quantities of degradable domestic refuse – this would decay with time and cause loss of support to the stone columns and hence settlement. Generally, where the degradable refuse content is less than about 10% (by volume) and fairly evenly distributed, sites can be considered for treatment, but the design approach has to be conservative and whether or not vibro is adopted is dependent upon the building, its function, and also the client's (performance) requirements.
2. *Non-engineered recent clay fills* – This is a situation where self-weight movement will not be complete. Whilst introduction of stone columns may well improve the situation it is very difficult to control self-weight movements. Typically, significant depths of clay fill (up to 5–8 m) should not be considered suitable for treatment if less than five to eight years old. Each site has to be judged on its own merits and with due consideration of settlement performance requirements.
3. *Opencast mineworkings* – A variant on the backfilled clay pit is the backfilled opencast mineworking, where in addition to differential settlement implications for structures spanning the pit edge or buried high wall, there is the issue of restoration of the groundwater table (inundation), the timing of which is totally unpredictable. When the groundwater does re-establish itself there is a breakdown of the clay fill and further settlement, which can be in excess of the self-weight movements. Vibro can be considered if careful attention is given to sealing the tops of the stone columns with clay immediately following their installation and during subsequent foundation excavation by concrete blinding, thus inhibiting surface water ingress due to, for example, heavy rain.
4. *Thick peat deposits* – Thin peat layers can be accommodated (see BRE BR 391 *Specifying Vibro Stone Columns* (2000)). Thickness, depth and lateral variations have to be considered very carefully in relation to the size of foundation and its loading. On some sites covered by up to 2.0 m of peat, the peat has been excavated along the lines of the foundation over a 2.0 to 3.0 m width and replaced with granular fill, vibratory stabilisation then being carried out in the normal way.

84.2.14 Design of foundations after vibro ground improvement

The bearing pressures achievable with vibro techniques are a function of the engineering properties of the soils prior to ground improvement. **Table 84.3** provides a guide as to what can be achieved in terms of load-bearing capacity and settlement performance for a range of soil types and applications after vibro ground improvement. Each site has to be assessed on its own merits.

Following adoption of vibro ground improvement techniques, conventional shallow pad/strip foundations and groundbearing floor slabs can be adopted. Because the stone columns are formed by working against the overburden pressure, the stone aggregate at the top of the constructed columns is not as compact as at depth. For this reason the main load-bearing foundations should be placed at a minimum depth of 600 mm below the level from which the ground improvement was carried out in order to fully realise the enhanced performance. In cohesive soils, in particular, there should be appropriate allowance for minimum top and bottom mesh reinforcement. Levelling off and proof rolling of the sub-grade following completion of vibro ground improvement is normally acceptable prior to construction of groundbearing floor slabs.

84.2.15 Case histories

84.2.15.1 Introduction

Vibro techniques have been applied successfully on many projects and there are many well-documented case histories in the literature. Cases of unsatisfactory performance in vibro ground improvement inevitably occur but are not commonplace. They are usually not well publicised, principally because of legal and contractual ramifications. Nevertheless, there is much to be learned from situations where problems have arisen. Examples of unsatisfactory performance include those relating to ground risk and insufficient site and ground investigation data; those relating to lack of understanding of vibro ground improvement techniques and their application; lack of appreciation of the

Soil type	Bearing pressure (kN/m^2)	Settlement range after treatment (mm)
Made Ground: (cohesive and mixed granular and cohesive)	100–165	5–25
Made Ground: (granular)	100–215	5–20
Natural Sands or Sands and Gravels	165–500	5–25
Soft Alluvial Clays	50–100	15–75

Table 84.3 Typical improvements achievable in terms of load bearing and settlement after vibratory stabilisation
Data taken from Slocombe (2001)

implications of changes in site levels; issues such as inundation; those relating to quality control and workmanship issues (see section 84.2.11); plus later drainage excavations undermining the constructed foundations on treated ground.

84.2.15.2 Successful case histories using vibro stone columns

Case study 1

For highway schemes, the approaches to bridges (or the transition between rigid bridge abutments and the consolidating soil behind the abutment) are a challenge for geotechnical engineers who are exploring cost-effective ground improvement solutions, to ensure a smooth settlement profile and vehicle ride quality and to reduce maintenance. Dependent upon the soil profile and geometry, this can be achieved in critical zones using a combination of ground improvement techniques such as vibro stone columns (VSC), vibro concrete columns (VCC) and vertical band drains (BD) and also addressing issues such as lateral loads on abutment piles due to lateral 'squeezing' of the soil during soil consolidation beneath embankments. One application (see Serridge and Synac, 2007) is summarised in **Figure 84.9**, where vibro stone columns have been used in conjunction with other ground improvement techniques to support highway embankments over soft ground.

A similar application using a combination of VSC and VCC is described by Cooper and Rose (1999), for a project in Bristol.

Case study 2

Long-term renewable energy targets have led to the construction of increasing numbers of wind farms and biomass power plants. Vibro stone columns have been used to support their foundations, one example being for a 44 MW annual power production plant in Scotland with output sufficient to supply 70 000 homes.

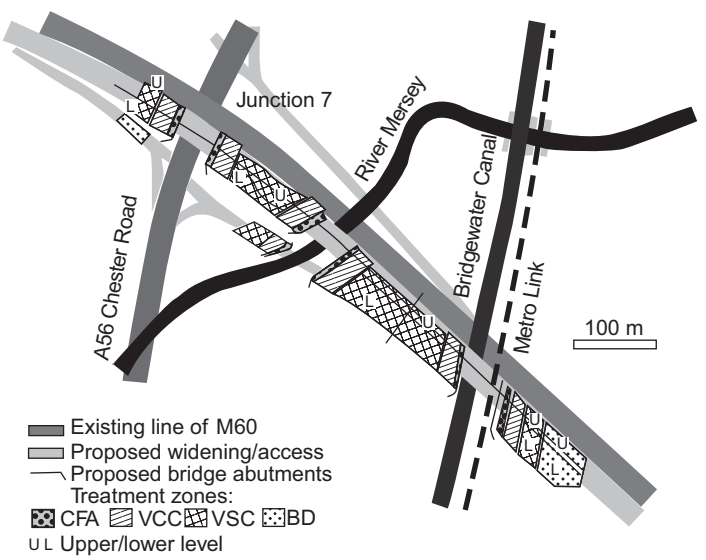

Figure 84.9 Ground improvement applications to support highway embankment construction over soft ground – M60 motorway widening, South Manchester

Reproduced from Serridge and Synac (2007); all rights reserved

The project involved a number of structures of various sizes and loadings, some also including heavy plant that was very sensitive to movement, particularly under the dynamic loadings during operation. Settlements were required to be limited to no greater than 20 mm under loadings of up to 250 kN/m^2. The near-surface ground conditions were highly variable comprising recent alluvial deposits, that were present in some areas but absent in others, variable depth of water table, then interbedded lenses and layers of saturated sands and silts, locally clays, all underlain by sandstone at depth. Some areas were considered suitable for dry top-feed vibro, some vibrocompaction without stone aggregate and others requiring bottom-feed treatment. The ground was so variable, however, that all treatment was performed using the dry bottom-feed technique to construct around 2000 stone columns to depths of up to 8 m. With such tightly specified post-treatment performance and variable soils additional design control checks were carried out using the monitoring systems on the bottom-feed installation rig to correlate the actual energy, depths of penetration and stone consumption as the work progressed. This effectively provided highly intensive investigation of the treatment areas, mapping areas to compare to soil properties reported in the site investigation.

One of the 'worst' areas was then subjected to a zone loading test on a 2.5 m × 2.5 m reinforced concrete base using an hydraulic jack reacting against kentledge blocks placed on grillage for maximum applied loading of 234 t or 1.5 times the design load. Settlements of 8 and 16 mm were respectively recorded at 1.0 and 1.5 times working load and were well within the specified 20 mm limit. The results are presented in **Figure 84.10**.

84.2.15.3 Case history of poor settlement performance

Wilde and Crook (1992) describe the settlement of a steel portal frame factory unit within the River Mersey floodplain in Warrington, Cheshire. The site was shown to be underlain by soft alluvial soils varying in thickness from 5 m to 10 m. Prior to implementation of vibro stone column ground improvement techniques, the site was brought up to the required plateau levels by addition of up to 1.5 m of upfill coincident with the maximum 10 m thickness of soft alluvial deposits. The subsequently installed vibro stone columns did not fully penetrate the soft alluvial soils and upon completion of ground improvement the factory unit was constructed on simple pad and strip footings and with adoption of a groundbearing floor slab. Subsequent monitoring of the portal frame structure showed that over a six-year period 120 mm of total settlement occurred, with maximum differential settlement of 100 mm along the length of the structure. It was estimated that there was probably another 50 mm of settlement during the construction period, but which was not recorded. Levelling of the floor slab revealed similar movements to those experienced by the main foundations.

It is clear that the majority of recorded settlement is attributed to the surcharge effect of the upfill associated with raising of site levels rather than the relatively small weight of the industrial unit. This brief example clearly demonstrates the need for careful consideration of changes in site levels in the context of vibro stone column techniques, when considering treatment to thick layers of soft soils.

This example illustrates some of the difficulties of defining unsatisfactory performance. The building in this instance performed satisfactorily despite the high total settlements and without apparent structural distress or serviceability problems and suggests that some settlement tolerances specified for low-rise lightweight buildings are unnecessarily stringent.

84.2.16 Conclusions

Vibro techniques are adaptable to a wide range of soil conditions and permit adoption of simple foundation solutions. Vibrocompaction will increase the density of clean sands (and mitigate liquefaction potential) and vibro stone columns will reinforce fine-grained soils. Both techniques will improve the bearing capacity of the ground and result in reduced total and differential settlements.

Vibro design relies heavily on good quality site and ground investigation data for accurate prediction of performance.

Good quality control procedures are necessary to ensure the successful implementation and performance of the vibro ground improvement techniques.

Where knowledge of a particular vibro technique is lacking, or there is uncertainty as to the applicability of vibro techniques to a specific set of site circumstances and performance requirements, then specialist advice should be sought to ensure appropriate vibro ground improvement selection and specification.

84.3 Vibro concrete columns

84.3.1 Introduction and history

Vibro concrete columns (VCCs) were first developed in Germany by injecting grout into already constructed stone columns. The aim was to overcome the lack of confining action to stone columns from very soft soils and peat. The grouting operation was then replaced by pumping suitable concrete directly down the bottom-feed delivery tubes, the first use being in the mid-1970s. VCCs were introduced into the UK in 1982.

84.3.2 VCC plant and equipment

VCCs are constructed using the specialist instrumented bottom-feed vibro stone column equipment and vibrators, but without the stone skip that normally runs up and down the leaders (see **Figure 84.11**). The concrete is then delivered to the top of the vibrator via an external pump.

84.3.3 VCC concrete, reinforcement and technique

In Germany both high and low slump concretes with high cement contents are used. However, in the UK the technique generally uses low slump concrete (typically less than around 60 mm) to be able to use vibration and ramming of their bases to densify basal granular soils to enhance end-bearing and generating enlarged 'end bulbs' for higher capacity at shorter length than for conventional pile design. Higher slumps have been used for some applications in the UK, depending upon site-specific circumstances. Once the end bulb is formed the vibrator is withdrawn at a controlled rate from the ground whilst maintaining positive pressure of concrete. The construction process also tends to be faster than normal piling when performed in suitable ground conditions.

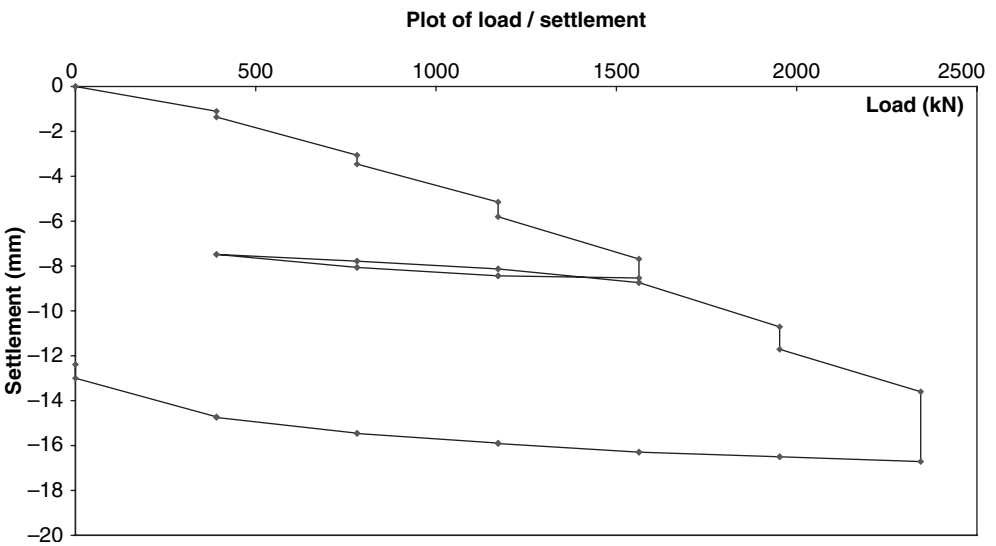

Figure 84.10 Zone load test on vibro stone columns for biomass plant
Data courtesy of Keller

Figure 84.11 Vibro concrete column equipment
Courtesy of Keller

VCCs are normally designed to support vertical axial loads. However, they are generally not constructed using reinforcement cages, sometimes simply with a central large section bar, sometimes with no reinforcement when beneath floor slab areas and road embankments, but normally with tie bars to tie into foundations. As a result individual VCCs have limited capacity to resist horizontal, shear and tension forces.

84.3.4 Applications and limitations

The VCC construction process allows a 'ground improvement' approach that is especially useful when considering the control of settlements of road embankments that are approaching piled bridges and in their superior settlement performance in comparison to vibro stone columns in very soft soils (see Maddison *et al.*, 1996; Cooper and Rose, 1999; Serridge, 2006). Enlarged heads are commonly constructed to assist in the transfer of embankment loadings via granular geogrid-reinforced load transfer platforms, as well as more efficient industrial floor slab design.

The construction of VCCs with end bulbs and tight interlock of concrete to soil can also prevent migration of contamination to underlying aquifers (see Environment Agency, 2001). Also, as the VCCs can develop safe loads of up to 600 kN with only short penetration of a sand/gravel stratum, they are useful where conventional piling would normally have to penetrate deeper. This shorter 'pile length' is particularly useful for the prevailing ground conditions to the east and west of London where there is generally a suitable layer of sand and gravel underlain by either London Clay or Chalk aquifer.

The system is relatively quiet with low vibration in comparison to driven piles and does not require the removal of spoil that would be required for continuous flight auger (CFA) piling.

As with all displacement piles care has to be exercised when installing VCCs at closer than about three times their diameter. It is also common practice to install single full-length central large section bars for spacings of up to about six times the VCC diameter (typically about 400–500 mm) to resist the effects of installing adjacent columns. Significantly larger diameters are generated in weak peat layers.

84.3.5 Site investigation (ground model)

The safe working capacities of VCCs are predominantly derived from end-bearing minus the assessed negative skin friction along the length of the pile shaft. As a result the depth to and penetration into suitable founding stratum has to be established over the extent of the proposed development. In addition, where VCCs are founded within granular soils that are underlain by cohesive strata, the capacity may have to be limited where the granular strata are relatively thin. Where there are thin clay layers within the granular founding strata the VCCs should be designed on the basis of a clay toe.

Such details are often best investigated by cone penetration tests (CPT) since these provide greater detail than standard penetration tests (SPT) in boreholes. It is relatively common for VCC quotations to include for the performance of one or two days of CPT investigation to better refine the VCC design.

The soil chemistry must also be investigated to provide suitable buried concrete design, as per conventional piles.

84.3.6 Monitoring and testing

The specialist VCC rigs include computer-generated instrumentation, comparable to CFA piling rigs, to provide continuous records of the depths, concrete pressures, extraction rates, etc. of every column. Static and dynamic loading tests are often performed to confirm capacity. However, integrity tests are difficult to interpret due to the sometimes irregular shape of the pile shaft, particularly in the presence of thick peat layers.

84.3.7 Concluding remarks

VCCs are effectively an alternative type of pile that is constructed using vibro equipment, often in conjunction with stone columns, for better settlement performance in softer and peaty soils. They are perhaps best considered as settlement reduction piles.

84.4 Dynamic compaction

84.4.1 Introduction

Dynamic compaction (DC) improves weak soils by *controlled* high energy tamping. The reaction of soils during dynamic compaction treatment varies with soil type and energy input. A comprehensive understanding of soil behaviour, combined with experience of the technique, is vital to successful improvement of the ground. Dynamic compaction is capable of achieving significant improvement to substantial depth, often with considerable economy when compared to other geotechnical solutions.

The principle of dropping heavy weights on the ground surface to improve soils at depth has attracted many claims for its earliest use. However, the advent of large crawler cranes led to the current high energy tamping levels first being performed on a regular basis in France in 1970 and subsequently in Britain in 1973 and in North America in 1975.

An extension of the concept of weights dropped onto the ground – rapid impact compaction (RIC) – was developed in the late 1970s for the rapid repair of explosion damage to military airfield runways using modified (BSP) hydraulic piling hammers acting on a steel foot that remains in contact with the ground and is now used for civilian applications.

84.4.2 Processes

The original concept for dynamic compaction was to collapse voids, particularly for the treatment of natural sands plus granular, mixed and cohesive made ground and fills. This was then extended to finer natural soils where the high impact energy effectively provided localised surcharge to squeeze water out of silts and clays, this being termed dynamic consolidation. Dynamic replacement was then developed to drive large diameter columns of coarse imported materials through soft near-surface soils, particularly for peat and sabkha strata.

The worldwide use of dynamic compaction has resulted in a large number of important terms, some of which can have different meanings to different nationalities or could be confused with other geotechnical descriptions. The following are the main terms that have been adopted in Britain (see Slocombe 2003a for fuller listing):

(a) 'Effective depth of treatment' is the maximum depth at which significant improvement is measurable.

(b) 'Drop energy' is the energy per blow, i.e. mass multiplied by drop height (tonne metres).

(c) 'Tamping pass' is the performance of each pattern of treatment over the whole treatment area.

(d) 'Total energy' is the summation of the energy of each tamping pass, i.e. number of drops multiplied by drop energy divided by respective grid areas (normally expressed in tonne metre/metre^2).

(e) 'Recovery' is the period of time allowed between tamping passes to permit the excess pore pressures to dissipate to a low enough level for the next pass.

(f) 'Induced settlement' is the average reduction in general site level as a result of the treatment.

84.4.3 Techniques

Dynamic compaction, whether to shallow or deep layers, improves the ground to the basal layers first and then progressively upwards to the shallower layers in a series of tamping passes (i.e. a bottom-up process) (see section 84.4.6). In contrast the rapid impact compaction (RIC) improves the soils by first creating a 'plug' or layer of denser ground and then progressively driving this plug/layer to greater depth (i.e. a top-down process). The response of the ground to these two approaches is fundamentally different. Whereas the relatively lower number of high energy impacts at wide grid centres of DC tends to initially bypass the upper layers and then, by subsequent progressive treatment builds up the strength of the near-surface soils, the higher number of lower energy impacts of the RIC requires consideration of the possible generation of pore water pressures that could inhibit the required ground improvement in finer-grained soils.

84.4.4 Plant and equipment

At first sight, the physical performance of dynamic compaction would appear to be simple, i.e. a crane of sufficient capacity to drop a suitable size of weight in virtual free fall from a certain drop height. Most contracts are performed with standard crawler cranes, albeit slightly modified for safety reasons and productivity, with a single lifting rope attached to the top of the weight (**Figure 84.12**). The operation must be performed safely and as a result the Health and Safety Executive in Britain requires that a crane should operate at not more than 80% of its safe working load.

Recent crane developments allow automation of the whole work cycle. This is controlled by a data processing unit which plots for each compaction point its location, number, weight size, drop height, number of blows and measurement of imprint achieved. Some cranes include the ability for synchronous operation of two winches to lift larger weights than the conventional crane rating.

The majority of DC contracts in Britain have utilised weights within the range of 6 to 20 tonnes dropped from heights of up to 20 m. The majority of UK work is now performed using 8 tonne weights dropped from heights of up to 12 m. Standard crawler cranes have also been used in America and Europe for weights of up to 33 tonnes and 30 m height. Specialist lifting frames with quick-release mechanisms have been utilised to drop weights of up to 170 tonnes in France.

Weights are typically constructed using toughened steel plate or box-steel and concrete. The effect of different sizes and shapes of the weight has also been extensively researched

with narrower weights being generally used for dynamic replacement columns. Treatment has also been performed below water using barge-mounted cranes and more streamlined weights with holes cut out to reduce water resistance and increase impact velocity on the sea bed.

Within the UK RIC typically employs a 7 tonne weight dropped repeatedly through a 1.2 m height onto a 1.5 m diameter steel articulated compaction foot which remains in contact with the ground (**Figure 84.13**). Whilst the energy per blow is not large (typically 8.4 tonne.metre), the equipment permits a large number of impacts to be applied at a rate of about 40 blows per minute. Weights ranging from 5 to 12 tonnes are used worldwide.

84.4.5 Applications and limitations

Dynamic compaction can be applied to many of the filled sites that are considered to be suitable for treatment by vibro methods, except where weak natural clays and silts are the main problem layer (see section 84.4.6.2). Many more UK sites are treated by vibro due to the noise and vibration generated by dynamic compaction and the ability of the dry vibro methods to permit closer follow-on operations. Dynamic compaction can, however, provide superior performance in comparison to vibro for treatment to younger deep made ground and in the presence of degradable constituents within landfills.

84.4.6 How dynamic compaction works

In contrast to having constructed a vibro stone or concrete column, the treatment at that location being then completed, dynamic compaction is generally performed as a series of tamping passes over the treatment area with different combinations of energy levels designed to achieve improvement to specific layers within the depth requiring improvement. The most common approach is to consider the ground in three layers. The first tamping pass is aimed at treating the deepest layer by adopting a relatively wide grid pattern and a suitable number of drops from the full-height capability of the crane. The middle layer is then treated by an intermediate grid, often the

Figure 84.12 Dynamic compaction equipment
Courtesy of Keller

Figure 84.13 Rapid impact compaction equipment
Courtesy of Balfour Beatty Ground Engineering Ltd

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

mid-point of the first pass or half the initial grid, with a lesser number of drops and reduced drop height. The surface layers then receive a continual (contiguous) tamp of a small number of drops from low height on a continuous pattern to compact the uppermost soil layers disturbed during the earlier higher energy tamping passes.

It is sometimes feasible to combine, and sometimes necessary to sub-divide, the three basic tamping passes for various reasons. The performance of increasing correctly controlled total energy input will normally lead to better engineering performance of the treated ground. This, however, is not a linear relationship and the post-treatment parameters are heavily dependent upon the characteristics of the soil. As a general rule similar total energies, whether per m^2 of area or m^3 of treatment depth, provide better performance to granular soils than mixed soils. Mixed soils are then better than cohesive with refuse-contaminated soils generally offering the least performance.

Some dynamic compaction design principles are provided in Chapter 59 *Design principles for ground improvement*.

For treatment using RIC the operator monitors and can record the number of impacts, the total energy input applied, the foot penetration per blow and the cumulative penetration. When a specified parameter is reached, for example, foot penetration or set per blow, the RIC equipment is moved and positioned at the next treatment point. This primary treatment pass is normally performed on a closely spaced grid pattern, typically 1.5 to 2.5 m. Additional offset and/or lower energy passes, or conventional proof roller compaction, are occasionally performed to achieve better coverage.

84.4.6.1 Granular soils

In dry granular materials, such as sand, gravel, ash, brick, rock, slag, etc., it is easy to understand how heavy tamping improves engineering properties. Physical displacement of particles and, to a lesser extent, low frequency excitation will reduce void ratio and increase relative density to provide improved load bearing and enhanced settlement characteristics.

When granular materials extend below the water table, a high proportion of the energy impulse is transferred to the pore water which, after a suitable number of surface impacts, eventually rises in pressure to sufficient level to induce liquefaction in a similar manner to vibrocompaction. Low frequency vibrations caused by further stress impulses will then reorganise the particles into a denser state.

Dissipation of the pore water pressures, in conjunction with the effective surcharge of the liquefied layer by the soils above, results in further increase in relative density over a relatively short period of time. This can vary from one to two days for well-graded sand and gravel, to one to two weeks for sandy silts. The testing program should therefore recognise the time-dependent response for soils that are normally considered to be free-draining.

Laboratory and *in situ* tests have consistently shown that in order to achieve maximum density, the lowest number of stress impulses to attain the required energy input will provide the optimum result. Saturated granular soils will normally require higher treatment energy overall, in a larger number of tamping passes, than if the soils were essentially dry.

When the individual sand particles are weak, such as the calcareous sands of the Middle East, 'sugar' sands of North America or the Thanet Sands of Britain, crushing tends to occur during the treatment. A similar response affects ash, clinker and weak aerated slags. When these soils are dry, the effect of such particle breakdown is not particularly significant. However, below the water table the higher proportion of fines developing with increasing energy input results in a rapid change from a granular to a pseudo-cohesive soil response.

In summary, excellent engineering performance can easily be achieved in dry granular soils using both DC and RIC equipment. However, care must be exercised for the treatment of granular soils with significant silt content, particularly below the water table.

84.4.6.2 Cohesive soils

The response of clays is more complex than that of granular soils. There is again the distinction between above and below the water table.

With conventional consolidation theory, a static surcharge loading will collapse voids within clay fills and expel water to induce consolidation and increase strength. In contrast, dynamic compaction applies a virtually instantaneous localised surcharge that collapses voids and transfers energy to the pore water. This creates zones of positive water pressure gradient which induce water to drain rapidly from the soils matrix. Consolidation can therefore occur more rapidly than would be the case with static loading. However, as with staged construction, the application of too high energy too soon can lead to problems.

Where the soils occur above the water table, the clays tend to be of relatively low moisture content, generally less than their plastic limit, where even a small reduction in water content can result in significant improvement in bearing capacity. Treatment is relatively straightforward and is mainly the collapse of voids to provide a more intact soil structure. However, care must be applied for the treatment to higher plasticity clays.

Where the clays occur below the water table, a much larger reduction in moisture content is generally required in the presence of a smaller available pore pressure gradient and a longer drainage path. These conditions can, if not properly controlled, result in localised failure of the clay matrix. Control is achieved by using greater numbers of tamping passes of lower energy input, requiring greatly extended contract periods in comparison to normal productivity.

To date, only nominal degrees of improvement have been achieved for thick layers of relatively weak saturated alluvial clays and silts, even with additional measures such as sand or wick drains. It is, however, more common in the UK to adopt vibro stone columns in such soils and then perform dynamic compaction to pre-load the ground (see Slocombe, 1989) with

the benefit of the stiffer columns also acting as drains to control excess pore water pressure.

It cannot be emphasised too strongly that the treatment of clayey made ground and fills together with natural clay soils requires experienced control on-site. Particular care has to be exercised in the timing of successive tamping passes to permit adequate recovery of pore pressures to avoid excessive remoulding of the soils. Efficient treatment is achieved by attempting to provide as much improvement as quickly as possible while recognising that the response of the soils will dictate the speed of the treatment operations.

In summary, dry cohesive made ground and fills respond well to dynamic compaction. Care must be exercised in the treatment of weak natural clayey soils or clayey made ground and fill below the water table, i.e. when saturated. The prior performance of vibro stone columns to both stiffen the ground and enhance drainage has been successfully combined with dynamic compaction to clayey soils.

84.4.6.3 Landfills

The capability of dynamic compaction to treat every square metre of road and parking areas is increasingly used in the development of former landfill sites where, depending on their age, the original degradable constituents have decayed to create extensive voids. It has also been performed to reduce ground levels to avoid costly removal to specialist tips to permit development at the desired site level.

As a general rule, the older the landfill the less the residual presence of matter susceptible to long-term decay and some older landfills, particularly those of high ash content, have been compacted to support structures that would normally be piled. However, the more recent landfills generally contain significant proportions of organic matter and structures would normally be piled.

There is as yet little documented proof that dynamically compacted landfill can affect the rate of decay of residual degradable constituents, although a paper by Sharma and Anirban (2007) clearly records far better post-treatment performance at creep rate of 2% per log cycle than for static surcharge over a monitoring period of about 15 years. As there will be ongoing decay, when this technique is combined with piled structures, increasing differential settlements will become apparent with time and a degree of maintenance may be required at some future time.

The principle of treatment to landfills is comparable to the treatment of mixed clayey made ground and fills but with generally higher energy input than for inert made ground and fills. This is to collapse near-surface voids and to 'overcompact' the remaining inert constituents. If a void then starts to develop due to localised long-term decay then the inert materials will tend to ravel into the void, bulk up and spread the void effect rather than have a localised sharp deformity in the finished surface. Geogrids have also been used for a number of sites where the movements of heavy goods vehicles were critical to the development operations.

84.4.7 Site investigation

As with vibro designs the extent of the site investigation should be appropriate to the type of development. For deep fill sites, desk studies to establish the locations of buried high walls plus age and degree of control of placement are essential data. Water contents for comparison with liquid and plastic limits should be performed for clayey constituents. Densities as revealed by SPTs and CPTs plus the basal soils, whether clay, sand and gravel or rock are also required. The presence of any overhead wires, buried services or nearby structures should also be established.

84.4.8 Depth of treatment

Menard and Broise (1976) originally proposed that the effective depth of treatment was related to the metric energy input expression of $(WH)^{0.5}$ where W is the weight in tonnes and H the drop height in metres. This has now been modified by a general factor of 0.5, reducing to 0.3 for heavier weights and greater drop heights. The range of treatment depths can also vary with initial strength, soil type and energy input as illustrated in **Figure 84.14**, as well as the depth to the groundwater table.

High-speed photography has shown typical impact speeds of about 35 and 50 mph for 8 and 12 tonne equipment to achieve effective depths of treatment of about 5 to 6 m and 6 to 8 m respectively. Within these depths, for similar volumetric energy input, the 12 tonne treatment will generally achieve better engineering performance than the 8 tonne weight, albeit at greater cost in view of the larger cranes required.

The shape of improvement in the ground tends to be similar to the Boussinesq distribution of stresses for a square foundation. Modification of energy levels for each tamping pass can be used to custom-design the treatment scheme to the specific soils profile and engineering requirements.

For rapid impact compaction, the BRE Report No 458 (2003) records depths of treatment of between about 2.0 and 4.0 m at total energy inputs ranging from 80 to 190 Tm/m^2 for granular fills and silty sands. Greater treatment depths using higher energy inputs in favourable conditions, together with a range of applications, have been reported by Serridge and Synac (2006).

84.4.9 Practical issues

There are a number of practical factors that must be taken into account when performing dynamic compaction contracts. The large crawler crane must be safely supported by a free-draining working surface, the thickness of which will depend upon the type of ground being treated. If the surface 1.0 m layer is basically granular, no imported working carpet is generally required. However, when working from a sandy surface, particularly during wet weather, fly-debris has been seen to be ejected through the air up to 60 m from the point of impact. If work is to be carried out near to roads, railways or property a movable screen is often used to intercept such fly-debris, albeit these affect the productivity. Alternatively, the programme should contain sufficient flexibility to permit treatment to be performed within,

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

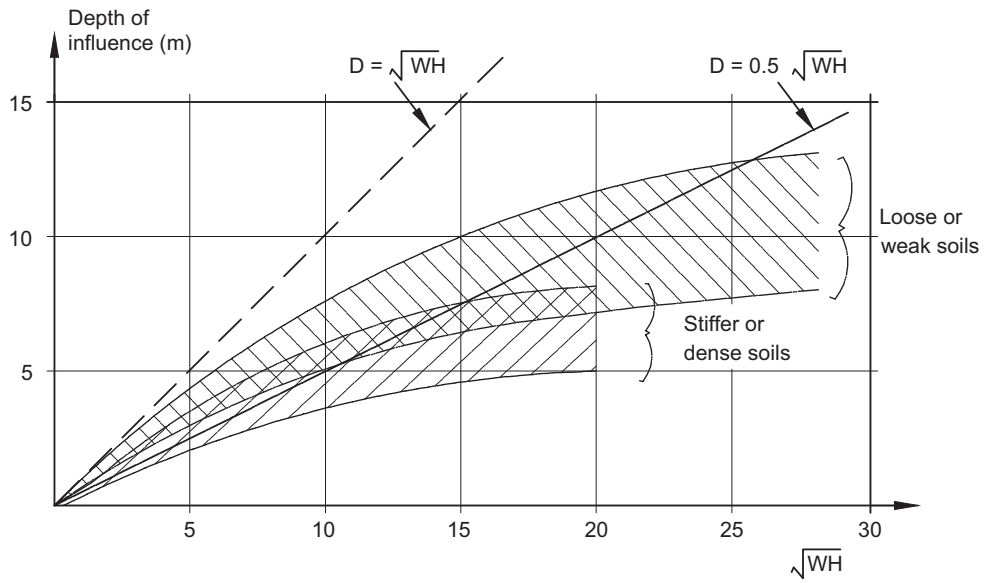

Figure 84.14 Depth of treatment

say, 50 m of such features only when the surface conditions permit its safe operation. As the RIC foot remains in contact with the ground there are no such issues with this equipment.

Where cohesive surface conditions exist, a free-draining granular working carpet is normally required. The thickness can be as little as 150 mm for light energy treatment in reasonably competent soils to up to 1.5 m when treating heavily voided refuse fills. Winter working will place more onerous requirements on the adequacy of the working surface. The general rule is to increase the depth of the granular working carpet by 25% in comparison to summer thickness. When working in arid climates there is often no need for any working surface, even for clayey soils.

The free-draining granular surface materials are also used to infill the localised deep imprints generated by the high impact energy treatment operations by blading in with a large dozer. Alternatively, suitable on-site granular materials, e.g. crushed concrete, can be placed directly into the imprints. In such cases it is useful to compare the imported quantities to the assessed volume of the directly infilled imprints.

As the performance of dynamic compaction tends to induce increases in water pressures, a pre-existing groundwater table within about 1.5 to 2.0 m of the working level can inhibit the productivity of the technique. In such cases bottom-feed vibro stone columns may be the preferred approach.

If more than one rig unit is to be used they should be separated by at least 30 m. Similarly, subsequent operations by the main contractor may have to be delayed until the treatment operations are sufficiently remote. Furthermore, whilst dynamic compaction can be performed over areas of vibro stone columns it has to be performed before any adjacent piling operations to avoid possibly damaging the constructed piles.

84.4.10 Environmental considerations

Dynamic compaction utilises large, highly visible equipment. The process creates noise and vibration, both of which must be considered in Britain under the Control of Pollution Act, 1974. The standards listed in the reference section provide further details (BS 5228–1 and 2: 2009; BS 7385 Part 1, 1990 and Part 2, 1993; BRE Digest 403, 1995).

Airborne noise levels are generated by a number of factors. Of these the point of impact is by far the highest noise level at typically 110 to 120 dB at source. However, its duration only occupies about 0.5% of the lifting cycle. The considerably lower noise values during lifting and idling when combined with the impact noise using the LAeq calculation method will normally meet most environmental limitations at distances of greater than 50 m from the treatment operations.

By far the most important consideration, however, is ground vibration. In addition to the magnitude of the vibration, the typical frequency of about 5–15 Hz is potentially damaging to structures and services, and particularly noticeable to human beings. It is suggested that there are three vibration levels that will influence the design of the treatment scheme. Guide values of resultant peak particle velocity at foundation level for buildings in good condition are:

Structural damage	40 mm/s
Minor architectural damage	15 mm/s
Annoyance to occupants	2.5 mm/s

Lower values must be adopted for buildings in poor condition or environmentally sensitive situations such as schools, hospitals and computer installations. Services and utilities

must be considered on an individual basis depending upon their age, condition and importance with values of 15–20 mm/s normally being considered acceptable, except for higher pressure gas mains.

The level of vibration transmitted through the ground is an imprecise science because of the variable nature of the characteristics of soils. Field measurements of vibrations at ground level have revealed a number of trends which are illustrated in **Figure 84.15**. The upper dynamic compaction limits tend to occur in the presence of granular or refuse-type soils with the lower limits in cohesive strata.

Careful assessment is required where the soil being treated is directly underlain by relatively dense sand, gravel or rock which will tend to transmit vibrations over larger than normal distances with comparatively little attenuation. Pre-existing dense surface or buried layers can have a similar effect of causing the transmission of higher than anticipated vibration levels.

As the RIC equipment is based on lower impact energy but greater numbers of drops this method has been employed as close as 10–15 m from an existing structure that was to be extended.

When vibrations become a problem the main methods of reducing their effect are to simply reduce the drop height, to reduce both the impact energy and penetration of the stress impulse that may have attained an underlying dense stratum, and/or to excavate a cut-off trench to sufficient depth to intercept the surface wave.

Human beings are particularly sensitive to vibrations and have a psychological reaction in believing that damage is caused even though the values are far below the well-established damage threshold levels. A public relations exercise can sometimes help to overcome concern amongst local residents. Building condition surveys prior to the commencement of treatment are often advisable.

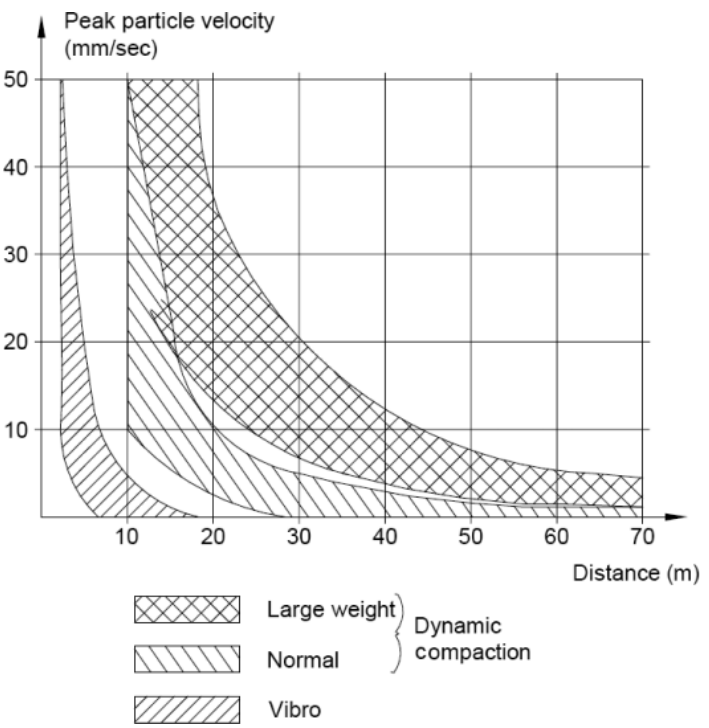

Figure 84.15 Vibrations

Dynamic compaction is a highly sustainable technique since it does not use cement or quarried stone, normally only requiring suitable inert free-draining granular waste as a working platform and to infill localised deep imprints. It is also an area treatment technique that permits changes in foundation layouts and localised loadings, for example mezzanine support foundations, anywhere within the treatment area. A number of dynamic compaction contracts have permitted the rebuilding of developments where fire destroyed the original by simply performing a number of loading tests upon the treated ground.

84.4.11 Monitoring and testing

Many contracts have simply involved the measurement of depth of first pass imprints and monitoring of site levels. Post-treatment *in situ* (SPT and CPT) and loading tests are also often performed in a similar manner to vibro testing (see section 84.2.11 and **Table 84.2**). In clayey soils, as with the performance of the treatment, it is essential that a sufficient recovery period be allowed to avoid ambiguous results.

It is common for dynamic compaction to be performed for sites underlain by coarse made ground or including obstructions that would cause penetration problems for vibro and piling methods or *in situ* testing. Surface loading tests only are more normally performed in this situation.

Tests normally reveal superior performance being achieved when treating granular materials in comparison to clayey soils.

84.4.12 Additional comments

The general densification and collapse of voids will induce general reduction in site levels, the settlement being dependent on the total energy input and the manner in which it is applied. A convenient simple approach is to adopt approximate percentages (see **Table 84.4**) of the target treatment depth for 8 tonne equipment (50 to 100 Tm/m^2) and 12 tonne (100 to 200 Tm/m^2), the total energies with the 12 tonne energy applying to greater depth of treatment.

Higher percentages can be induced. However, the increase in energy input will not be a linear relationship with induced

Soil type	% of treatment depth
Natural clays	1–3
Clay fills	3–5
Natural sands	3–10
Granular fills	5–15
Refuse and peat	7–20

Table 84.4 Guide to induced settlement

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

settlement as during the treatment the material becomes progressively stronger and there is less and less potential void reduction available. Care has to be exercised to avoid over-treatment and possible loss in strength in these situations. Also, many sites, especially refuse tips, tend to be capped by clay soils.

Loose materials will obviously be induced to settle more than denser soils. Ash and certain types of slag also tend to break down during treatment to produce induced movements towards the higher value for granular fills given above.

Many sites of former heavy industry are now being reclaimed in Britain. These often present the designer with the problems of deep made ground, uncontrolled fills and massive obstructions from old basements and foundations. Any technique that has to make a hole in the ground will experience difficulty in gaining adequate penetration and large excavations often have to be performed to remove the obstructions. However, with dynamic compaction such features can be left in place provided they occur at sufficient depth to avoid excessive differential performance. The sequence of operation would be for advance earthworks to remove all known features down to a specific level, then perform treatment and normal construction operations.

Brownfield sites with minor contamination are well suited to treatment since the technique does not create a bore that could permit the migration of leachate. However, care should be exercised to ensure that the impact energies do not shear any underlying clay layer that may prevent the downward migration of contaminants into an aquifer. Dynamic compaction can also be controlled to avoid exposure of hazardous material to the atmosphere while still compacting soils at depth in the presence of, say, asbestos contamination.

Sites of former quarries are prime situations for treatment in view of the potential for piles to glance off the buried sub-vertical face between made ground and rock, and the possibility of constructing piles to inadequate depth as a result of false readings from boulders or inaccurate historical information on the depth of the quarry.

An area of increasing importance is the treatment of partially saturated made ground and natural soils that are susceptible to collapse compression due to inundation for the first time. Dynamic compaction reduces such potential by generally reducing voids, inhibiting surface water from penetrating the ground and by creating a 'stiff crust' over the effect of deeper movements, should they occur.

84.4.13 Case histories

84.4.13.1 Case study 1

A former colliery site was to be developed for several very large industrial and retail units including three-storey offices. The existing fills and mounds of colliery spoil were first excavated and then re-compacted in layers to minimum 95% maximum dry density. However, better settlement performance of maximum 35 mm total and 1 in 1000 differential over 25 years was required irrespective of the depth of fill.

On the first phase of 92 000 m^2 development the depths of fill varied between about 5 and 8.5 m with one area being up to 12.5 m depth beneath the proposed levels. The deeper zone was treated from lower level during the filling operations and then from the final level using 12 tonne weights dropped from heights of up to 15 m.

The second phase of 45 000 m^2 was performed after the first phase had been constructed. This area was underlain by between about 1.5 and 5.5 m depth of fill and was also located near to an electricity sub-station. This work was performed using 8 tonne weights and drop heights of up to 12 m.

The two phases of treatment were performed using similar volumetric energy input (Tm/m^3) for the full depths of fill. They were then tested by zone loading tests on 2.0 × 2.0 m test bases to twice working load of 96 tonnes. In addition a number of tests were performed on conventionally compacted fills, i.e. untreated ground. Comparison of their results revealed equivalent moduli of:

Untreated	E = 16–18 MPa
8T DC	E = 30–50 MPa
12T DC	E = 50–60 MPa

84.4.13.2 Case study 2

Dynamic compaction was performed in several contracts to a large area of landfill that was to be developed to industrial and office use. The first contract was to the deepest and newest landfill, parts of the site being up to 11.5 m depth and being filled with predominantly paper and cardboard waste only the year before treatment. Groundwater was typically at about 2.0 m depth.

All structures were supported on driven piles founded in the underlying competent clays with dynamic compaction being performed for the roads, parking and service areas. Treatment was performed using 12 tonne weights with cranes operating from nominal 1.0 m thickness of free-draining working platform.

The treatment area extended near to existing industrial units where the landfill was much shallower. This required a reduction in drop heights, while still capable of improving the full landfill depth within agreed vibration limits. The site was also near to a local railway line where safety precautions were put in place.

Induced settlements of over 1.0 m were recorded within the deepest landfill area. Zone loading tests were performed to confirm that the required short-term performance had been achieved. The site was then monitored for six years with maximum settlement of 75 mm. This was assessed as being equivalent to rates of creep movements of about 1–1.5% per log cycle.

84.4.14 Concluding remarks

The dynamic compaction method is a powerful tool when applied to suitable sites. A large database has been collated over the years to define its limitations and, more importantly, capabilities which can be used with confidence. As with every specialist technique, the designer and contractor performing

this method of ground improvement must understand these capabilities and limitations. Such understanding can only be gained by experience.

It is recommended this chapter is read in conjunction with

- Chapter 25 *The role of ground improvement*
- Chapter 59 *Design principles for ground improvement*
- Chapter 100 *Observational method*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 85
Embedded walls

Robert Fernie Skanska UK Plc, Ricksmanworth, UK
David Puller Bachy Soletanche, Alton, UK
Alec Courts Volker Steel Foundations Ltd, Preston, UK

doi: 10.1680/moge.57098.1271

This chapter considers the various forms of embedded wall and in particular focuses upon the selection of and construction issues associated with the different types. It considers the economics of different wall types and gives guidance on issues such as adjacent structures, groundwater, temporary works ground conditions and construction methods. Systems covered include steel piled walls, concrete piled walls and diaphragm walling.

85.1 Introduction

The principal function of embedded walls is to safely enclose space within the ground to an agreed watertightness, although some embedded walls are used simply as groundwater or leachate barriers. The UK with its range of geology (and its industrial heritage) employs and has contributed to the development of almost all embedded wall types.

The choice of embedded walling type is dependent upon a number of factors including the following:

- ground;
- groundwater;
- proposed depth;
- site logistics;
- economy (including programme economy);
- wall finish and watertightness.

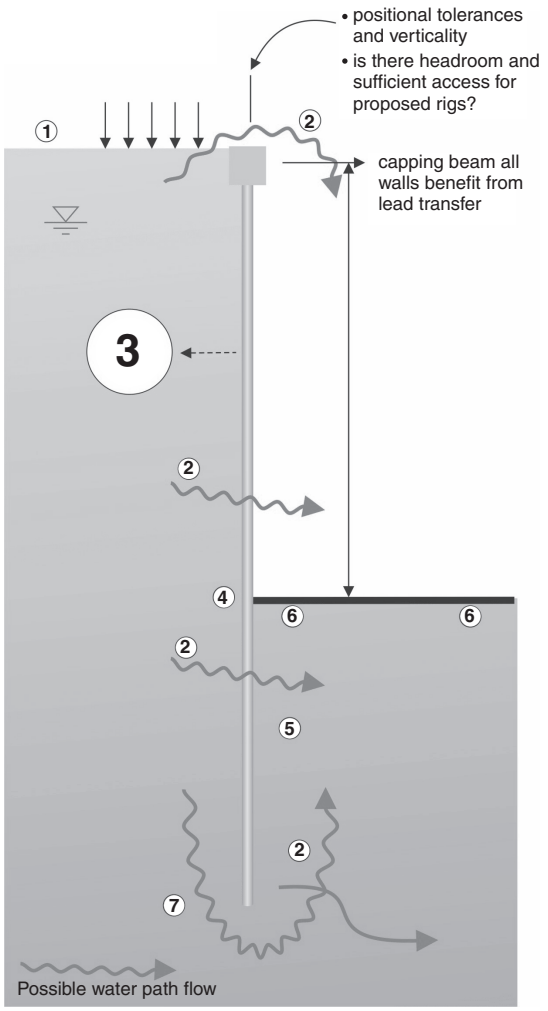
The 'generic' sketch (**Figure 85.1**) indicates the major issues that need to be considered when choosing a wall type (for further guidance, see C580; Fernie Suckling GE; Sperwall ICE).

Walls in the UK seldom fail structurally – a great deal of discussion, debate and hard finance is spent on their aesthetics above the dredge, their contribution to local ground deformation and the effect of their placement and exposure on adjacent structures and particularly their 'watertightness'.

It is often the issue of watertightness that governs the ultimate judgement of the success of the wall, yet to date no agreed qualitative method of assessing this issue exists between users and providers. The publication *Reducing the Risk of Leaking Substructure – A Client's Guide* and the further references within it, is recommended reading for those involved in any aspect of embedded walling.

If walls are judged post-construction on aesthetics and watertightness they appear to be procured almost purely on the basis of economics; **Figure 85.2** tries to indicate 'relative' costs for the various wall types and schematically illustrates where wall types are employed. The schematic indicates how difficult it is to generalise likely costs; at the polarised ends, small schemes for canals and temporary works for motorway cuttings are economically provided for by sheet pile walls but deep shafts in difficult ground require diaphragm walls.

This chapter covers embedded walling by considering the following wall types:



- diaphragm walls;
- piled walls;
- steel walls;
- hybrid and other walls.

Each section addresses the generic issues raised in **Figure 85.1** and indicates how the walls are constructed, the range of their application, their strengths and which particular interfaces need closest attention.

85.2 Diaphragm walls

Diaphragm walls are embedded concrete walls, usually reinforced, formed using the ground as a shutter. The process is illustrated in **Figure 85.3**. To ensure that the ground does not collapse the panel is supported by a fluid suspension – normally a bentonite or polymer suspension. Discrete 'panels' are excavated and supported by the fluid and at their ends by 'stop-ends'. The bentonite support fluid suspends materials not removed by the excavation and cutting process and it requires cleaning via a replacement or recycling process. Reinforcement cages are placed. The fluid suspension is then displaced by specially designed concrete mixes with sufficient consistency to flow to the panel extrados and 'scour off' any bentonite from any element (stop-ends, reinforcement, box-outs, etc.) within the panel.

As illustrated in **Figure 85.2** diaphragm walls tend to be used on larger, deeper walling contracts in more difficult ground – walls have been constructed to 150 m depth and also to 2.5 m thickness, although more commonly wall thicknesses of 800 mm, 1000 mm, 1200 mm and 1500 mm are used. They can be built in nearly all ground conditions, but special works may be necessary in very soft ground (Su < 20 kPa) and hard ground (lightly fissured rock with an unconfined compressive strength

Some Major Issues

① Do adjacent services or structures inhibit access or apply constraints?

② Groundwater leakage possible via paths shown. The greater the number of interfaces/joints, the greater the problem. Walls are often ultimately judged on perceived watertightness.

③ The ground is the major influence on the choice of wall type. Can you drive, bore, drill or jock in wall elements? Is the ground stable? A soil or rock or a melange.

④ How easily are joints effected? How necessary are walings, props, anchors, plates, head details and any connections?

⑤ Depth to dredge dictates whether can be cantilebered or whether it needs props or berms. Depth below dredge can depend on cut-off, bearing and hold down requirements as well as stability.

⑥ Ground at dredge critical to stability, movements, water considerations and connections from wall to base slab.

⑦ Can wall depth be acheived by 'standard' construction methods? Need toe be pinned/castellated/curtailed?

General

- How does temporary and permanent works interface and impact on the wall elements? Is this fully appreciated by all parties?
- Can predicted movement be accommodated or sensibly influenced?
- How important are finishes and aesthetics?

Figure 85.1 The major issues that need to be considered when choosing a wall type

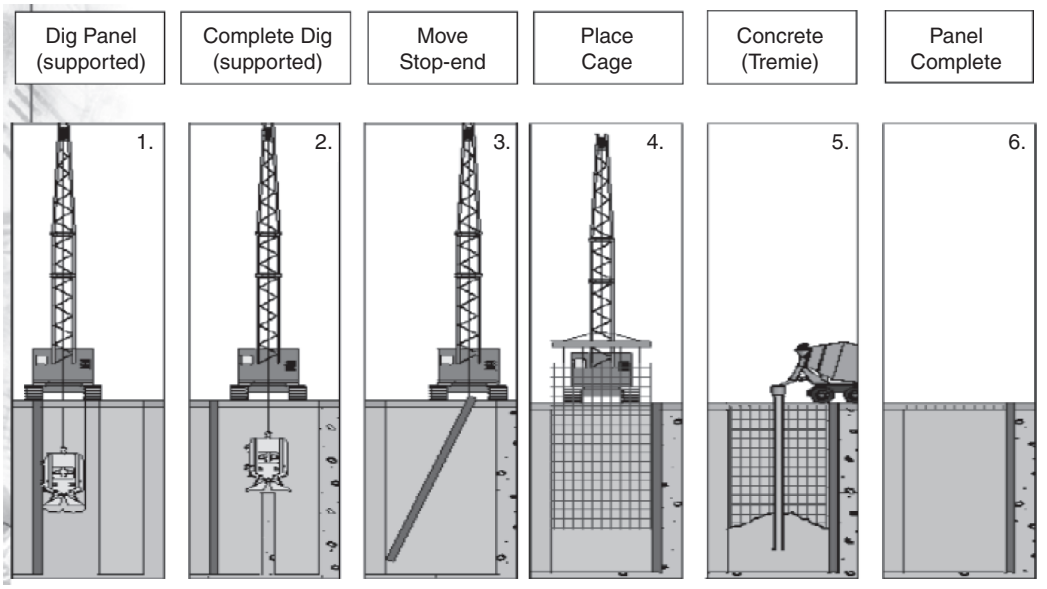

Figure 85.3 Diaphragm wall construction

greater than 20 MPa). Construction techniques can be readily configured to produce circular or near circular shafts of diameter greater than 8 m and panels in various shapes can efficiently carry large imposed loadings. Introduced to the UK in the 1970s by ICOS, diaphragm walling has grown with the tendency for deeper basements and deeper shafts. Extended motorway and metro troughs of up to 1 km in length, shafts 40 m in depth and basements 30 m in depth have been constructed in the UK in recent years. Since diaphragm wall panels are typically 6 m in length (range 2.8–7 m), they have fewer joints (which can also be fitted with water bars) than other embedded walls and are favoured in ground where the control of groundwater, seepage and damp is necessary. It must be noted, however, that no better than Grade 1 watertightness (see Chapter 64 *Geotechnical design of retaining walls*) should be assumed possible for any concrete embedded wall. In western Europe and its influence zones, diaphragm walling seldom provides structural continuity across panel joints. Such continuity is more common in the Far East at a considerable cost premium.

As with most embedded walling expertise, quality workmanship and close cooperation at the interfaces is necessary for successful construction. There is useful guidance in *BS EN1538 Diaphragm Walling*.

Excavation for diaphragm wall panels is usually carried out using grabs or hydromills (cutters or hydrofraise); see **Figure 85.4**. These are dedicated pieces of plant, which experienced diaphragm wall specialists are reluctant to modify since any change affects the process. Designers for economy are encouraged to work with what is available rather than what is optimum. Grab and cutter widths are typically 2.8 m. Grabs (cable or hydraulic) were used in early developments and were used particularly for softer cohesive ground. A typical excavation rate for a grab is 100 m^2/shift. Modern grabs are fitted with instrumentation so that depth and deviations can be monitored in real time and recorded (particularly where rotating head Kelly bars are fitted). Specification requirements of 1 in 75 verticality tolerance can be bettered using such techniques. Grabs are usually employed to start excavation works when mills are to be used.

Mills (cutters or hydrofraises) are hydraulically powered drum wheel excavators, which remove soil via slurry, which also acts as trench support. The process uses reverse circulation with the spoil transport medium in a continuous circuit abstracted by a mud pump, fed by pipework to a separation plant (desanders, desilters) where the solid materials are removed, to be pumped back to the panel again (see **Figure 85.5**). Developed initially for cohesionless soils and weak rocks, excavation rates were typically up to five times that of a grab. However, at this rate of excavation in a soft cohesive soil, it is difficult to provide an efficient cleaning or replacement cycle to remove the finely graded soil material from the support fluid. There has been much use of mills in recent times in stiffer, carbonated and overconsolidated clays and in stronger rocks. Verticality tolerances of better than 1 in 1000 have been achieved using mills but contractors tend to limit their contracted tolerances to 1 in 300. In addition, contracts usually allow for protrusions of not greater than 100 mm from the 'true wall face'. This criterion is based on the experience of many contracts but the truth is that it is controlled by the ground. In loose cohesionless or soft cohesive soils, the overbreak could be much greater, contrasting with overconsolidated clays where the finish can be smooth and dense.

With the correct tooth configuration on the cutter wheels, mills can cut into the 'green' concrete of an existing panel, forming a 'continuous' concrete member (still without rebar continuity). This can be particularly useful for deep shafts

(a)

(b)

Figure 85.5 (a) Desanding equipment and (b) cage lifting

(circular or ellipsoidal) where depth precludes the use of other methods of achieving good quality joints between panels. However, this form of overcut joint has been found to have rather dubious watertightness and, hence, its use should be restricted to structures where panels tend to be in hoop compression or where watertightness is not considered to be important. The choice between using a mill or a grab is usually a straightforward comparison between productivity and the difference in set-up costs (mills being more expensive), although site access, logistics, ground conditions and environmental considerations can be relevant.

Diaphragm-wall ancillary equipment includes heavy chisels to aid excavation through rock and boulders, brushes to clean panel joints, service cranes for cage installation and concreting and mud mixing and separation plants.

As noted, diaphragm walls are often employed where groundwater and soft soils are present and, hence, trench stability is critical. In these circumstances, stability is designed for by limiting panel length – thereby encouraging arching effects and by ensuring a positive head in the support fluid with respect to the groundwater level (usually not less than 2 m). This positive head has to be maintained throughout the process and is ensured by harnessing a reservoir or the containment effect of the guide walls. The panel size will also be important in terms of ground movement with larger panels tending to

develop larger ground movements; however, they can be easier and more efficient to prop. The converse is true of smaller panels, which have less inherent movement but greater difficulty in propping. Guide walls have several uses: they act as positional guides for the excavation tools, they indicate the positive fluid support level that must be maintained, they act as a reservoir for this level and they act as a support for (the often heavy) down-hole insertions such as stop-ends, tubes and reinforcement cages. Guide walls are seldom less than 1 m deep and 300 mm thick. Occasionally existing adjacent basement walls are employed as one side of a guide wall.

The specific gravity of freshly mixed bentonite slurry is about 1.02 to 1.04 and with water at 1.0 it is not surprising then that water has occasionally been used as a support medium. Bentonite has the added property of thixotropy and can form a filter cake on the trench wall in many soils, thus, enhancing panel stability by preventing side sloughing. Polymers, where the long polymeric chains clog up the ground pores, are fairly commonly used for bored pile support, but have not been used successfully in diaphragm walling in the UK. The science behind these polymers is only now being developed and the ENs recommend their use only after extensive exhaustive trials or direct comparable experience. Increasingly bentonite support fluids with polymer additives are being utilised.

Early diaphragm walling employed circular pipe stop-ends, which were extracted clear of the 'green' concrete as part of the panel formation process. Circular pipes gave way to 'organ pipe' stop-ends, which were still pulled some several hours after the last concreting. Where panels were very deep or working hours restrictive permanent steel (H-sections) or precast concrete stop-ends were employed.

Currently most practitioners use 'peel off' stop-ends. These are prised off the end of the hardened concrete panel once it has been exposed during excavation of the adjacent panel. They can incorporate a water stop, which will extend into adjacent panels. This system has greatly facilitated diaphragm wall programming. However, experience of successfully placing and removing such stop-ends is limited to about 50 m depth. Accurate and vertical placing of stop-ends is a vital part of the process and if high standards are not achieved then subsequent panel joints and exposed wall surfaces can be seriously compromised.

Diaphragm-wall tool sizes are such that multi-returns and complex wall shapes are not encouraged. Panel dimensions are dependent on plant size, and stability considerations both for the panel and for adjacent structures. The logistics are also important, since excavated panels soften, and common practice is usually to concrete quickly and handling much more than 200 m^3 to 300 m^3 of concrete within a normal working day is often difficult. However, panel volumes up to 1400 m^3 have been cast in the UK. Wherever possible, practitioners will promote simple rectangular panels, although corner panels must be accepted. T-, Z- and I-shaped panels can offer significant structural benefits in terms of stiffness and moment capacity but it must be recognised that they are more difficult to construct. Here, as in the case of corner panels, continuity of reinforcement across changes in panel direction should be avoided if at all possible. However, in the case of re-entrant corners, continuous cages may be necessary for structural reasons.

Two examples of diaphragm walls are shown in **Figure 85.6**.

The tendency for deeper walls, carrying bigger loads over larger spans is leading to heavier densities of reinforcement in diaphragm-wall panels. The need to incorporate connection box-outs and wall cut-outs can exacerbate problems. Panels have construction requirements (tremie space, clearance to stop-end and water-bars), which constrain reinforcement cages. These tendencies act against the need for open, accessible panel faces to facilitate concrete movement, to ensure penetration, to ensure scour of slurry or filter cake deposits and to ensure dense concrete cover. Although EN1538 indicates a minimum clear vertical bar space of 80 mm may be allowed in special cases, the authors of this chapter believe that 100 mm

(a)

(b)

Figure 85.6 (a) Deep shaft (France) and (b) 'peanut-shaped' (UK) diaphragm walls

should always be attempted. ICE (2007) C8.4.4 provides more detailed recommendations and differentiates between vertical and horizontal reinforcement. It is extremely important that discussions take place between the wall constructor and designer well in advance of cage fabrication (ideally prior to commencement of detailing) to ensure that buildability is not compromised.

The challenges faced by the constructor regarding the lifting and handling of reinforcement cages must not be overlooked. Issues such as transportation to site, safe lifting, on-site welding of reinforcement and cage splicing must all be discussed at an early stage and the appropriate risk assessments and temporary works design carried out.

All embedded concrete walls require special 'flowable' retarded concrete mixes, which can be placed reliably via tremie pipes and which self-compact without the need for vibrators or mechanical means. It should be noted that such concrete has evolved over decades to meet the specialist demands of deep-foundation contractors. The mixes are not the expensive 'self-compacting' mixes generally sold to the construction industry.

Diaphragm walls with their flat surfaces can easily be 'joined' or connected to adjacent structural elements (props, walers, beams, slabs). Box-outs in the form indicated are preferred in deep walling for such connections and these can be placed to within +150/–50 mm of the design elevation. Whereas simple pull-out bars will only provide very limited moment fixity and are used generally to aid transfer of shear, the use of couplers can provide a high degree of moment fixity. Alternatively, connection bars can be drilled and grouted into the wall face on exposure during bulk excavation. The joint between a diaphragm wall and the base slab (or roof slab in the case of cut-and-cover tunnels) is most likely to be subject to groundwater or water infiltration and needs particular and serious attention in its detailing.

Diaphragm walls may be lengthened (deepened) where necessary to increase the flow path beneath the toe of the wall or where they are employed as vertical load carrying elements as well as acting as retaining walls. It is not commonly required to reinforce walls below the depth required for embedded wall stability in such cases. There are also circumstances where the ground is too hard and works cannot be economically progressed to the required 'design' depth. Such cases are often resolved by taking a series of pins through the panel into the hard ground below, ensuring lateral support at the toe. This is usually foreseeable at the design stage and steel reservation tubes can be provided in the cage for this purpose as well as providing locations at which toe grouting can be carried out to significantly reduce rock permeability.

Diaphragm walling contracts need large dedicated plant, which usually necessitates sole occupancy of the site. Bentonite plant (silos, mud pumps and cleaning or desanding equipment) typically requires 150 m^2. As noted above, it is often the logistics of the mud plant that controls overall planning of the diaphragm walling activity.

Joints are inevitably 'leaky' and even with best practice can be areas where bentonite or ground inclusions are trapped. Contractors will make good areas with inclusions and will contract to exclude 'running leaks' – as stressed in the introduction this particular issue needs much upfront discussion and a clear understanding of what is likely to be achieved in a particular ground.

Diaphragm walling continues to be pushed to deeper and longer spans and to incorporate higher densities of reinforcement and ancillary inclusions (box-outs, soft eyes for tunnel connections, geothermal pipes, instrumentation tubes, sonic coring tubing, etc.). It is a technique that is likely to grow in application.

Another example of the construction of diaphragm walls is shown in **Figure 85.7**.

85.3 Secant pile walls

85.3.1 Description and use

Secant pile walls are formed from a series of intersecting bored cast *in situ* concrete piles. In most cases alternate 'male' (secondary) piles are reinforced to provide the structural capacity of the wall with the intervening 'female' (primary) piles acting as unreinforced barriers to groundwater flow (**Figure 85.8**). As well as providing retention of soil and groundwater pressures, secant walls can be used to carry superstructure loads. Considerable flexibility in plan shape is offered by secant pile walls (**Figure 85.9**), which leads to efficient use of the basement space. Hence, secant pile walls are a popular form of embedded retaining wall in building projects as well as civil engineering structures such as metro stations, underpasses, cut-and-cover tunnels and pumping stations. Circular and elliptical shafts (**Figure 85.10**) have also been constructed successfully using secant pile walls.

Constructed in the 1970s using mechanically configured rigs, walls were relatively expensive and slow to install. However, the advent of powerful hydraulic piling rigs increased both the range of application and the rates of production. By the mid-1980s, deep secant pile walls were being constructed as permanent walls. Later that decade hard-hard secant pile walls were constructed at a number of sites in the UK using the continuous flight auger (CFA) method. The most recent developments have seen the use of cased continuous flight augers, which are able to combine the benefits of high productivity through using a continuous flight auger with the tight construction tolerances obtained using temporary casing.

Some confusion exists in the terminology used to differentiate between the types of secant pile wall. The key constant in all walls is that the male piles are nearly always reinforced structural concrete and the variable is usually the strength of the female piles, which will typical vary as follows:

Hard/soft walls – this wall type is often used in temporary works or where the long-term durability of the female pile can be neglected as its function is taken over by some other form of construction such as an internal structural liner wall. Female

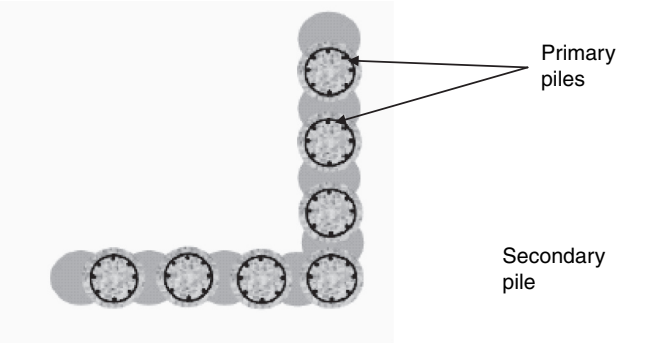

Figure 85.8 Primary–secondary pile sequence

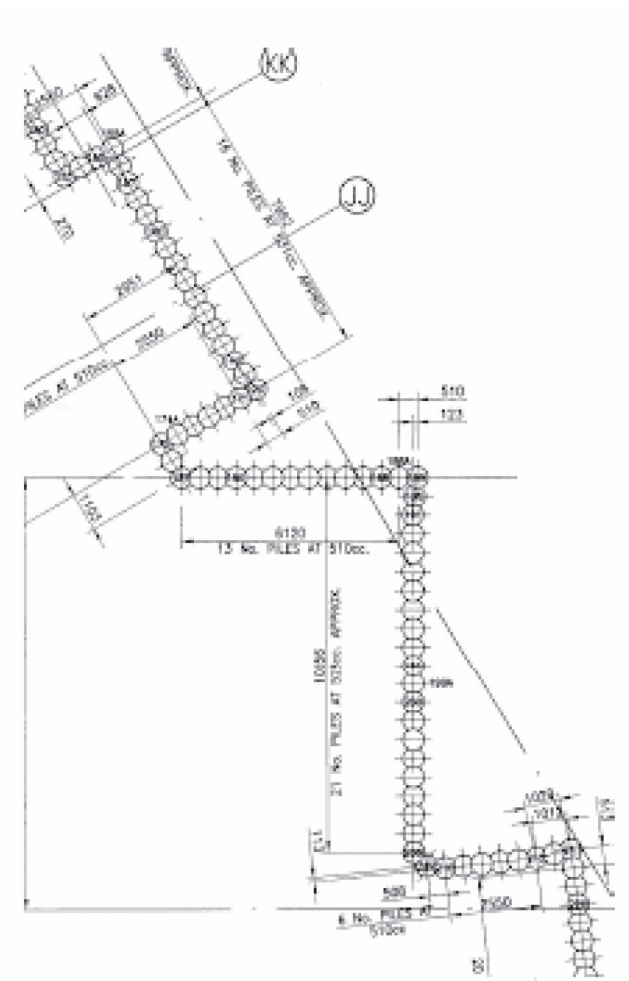

Figure 85.9 Flexibility in plan shape

piles are designed simply as short-term water blockers using a cement/bentonite mix or similar (**Figure 85.11**).

Hard/firm walls – this wall type is often used for basement walls for building projects and constructed usually using either the CFA or cased CFA technique. Female piles are designed to suit the design life of the structure but with a close eye on constructability. There is sometimes a perceived conflict here between the minimum cement requirements to ensure durability and the difficulty encountered when overcutting female piles of excessive strength. Female piles are often designed to achieve a strength of C8/10 at 56 days.

Hard/hard walls – these walls are usually constructed using segmental casing and intended to act as permanent works with

Table 85.1 Range of pile diameters

equal durability of both male and female piles. Female piles are usually unreinforced but are constructed with a full structural concrete mix typically either C28/35 or C32/40.

85.3.2 Range

The increased use of secant piles has been driven by the development of ever more powerful hydraulically powered rotary drilling rigs with torque in excess of 500 kN·m. However, the range of application varies significantly depending on the installation method.

It is difficult to provide hard and fast limits on the depth achievable with each technique since this is dependent on many factors including rig power, pile diameter and ground conditions. However, in general whilst it is possible to construct CFA piles to depths in excess of 25 m, cage depths are usually limited to about 18 m. Cased CFA pile depths are currently limited to about 18 m and cased secant piles are rarely constructed beyond 30 m depth. It is important to remember that the depth over which the piles will actually be secanted will be determined by tolerances and not by the depth that the piling rig can drill (see **Table 85.1**).

85.3.3 Installation and materials

Piles are constructed at a predetermined spacing designed to ensure that the piles will intersect over the required height of the wall allowing for the combined positional and verticality tolerances of both piles. The provision of reinforced concrete guide walls (**Figure 85.12**) is essential in order to maintain good positional tolerances at the piling platform level. The scalloped profile of the guide walls is usually achieved using special formwork or pods, which are adjusted to achieve the desired pile layout.

Female piles are constructed first at an initial spacing such that there is no risk of interference between recently constructed piles as a result of plant track or concreting pressures. For example, this may require a pile construction sequence of pile numbers 1, 5, 9, 13, 17 then 3, 7, 11, 15. For hard/hard and hard/firm walls, male piles are ideally constructed within three to seven days of construction of the adjacent female piles. This is particularly important for walls constructed using the CFA method where the excessive concrete strength of the female piles can cause severe verticality tolerance issues during male pile installation; male piles actually pop out of alignment at depth leading to watertightness and space-proofing problems. Care must be taken not to open up too much of the wall by constructing an excessive number of female piles without the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 85.12 Guide walls

Figure 85.13 Cased CFA wall piling with spoil management system

intervening male piles. In addition, in the case of phased construction it may prove necessary to install a gravel pile at the end of a phase by overcutting the last female pile whilst it is still green and backfilling it with gravel; the overcut can be achieved several weeks later if necessary as the phases of the works become joined.

The productivity of CFA and cased CFA rigs can exceed 10 piles per shift and, therefore, it is necessary for continuous sections of wall in excess of 50 m in length to be available for these rigs to work efficiently.

Whilst excavation of CFA piles takes place under the support of the soil on the flights of the auger, cased CFA utilises a stiff temporary casing to support the ground and overcut adjacent female piles. Air is supplied down to the auger tip by a nozzle in the concreting pipe via the hollow auger stem, to assist flighting of the drilling spoil up the auger. At the top, the spoil is directed into a series of telescopic muck bins, which transfer the drilling arisings safely to earth (**Figure 85.13**). The casing and continuous flight auger are powered independently by separate rotary drives.

The guidelines for the reinforcement of diaphragm walls cited in section 85.2 are in many areas equally applicable to secant pile walls. Particularly relevant is the observance of minimum clear bar spacings of 100 mm. Consideration to the pairing of bars should be given to ease congestion. Special attention should be paid to congestion at overlaps and the use of couplers may be required if there are two layers of reinforcement. Furthermore, the cranking of larger diameter bars, such as 40 mm or 50 mm, may not be feasible.

Additional cover (100 mm rather than 75 mm) may be provided in order to facilitate the installation of long reinforcement cages in CFA and cased CFA secant piles. The slight resulting loss of structural capacity is normally recouped by the improvements in productivity (or lack of re-drilled piles due to stuck cages).

Concreting of CFA pile walls follows similar practices to those required for deep CFA bearing piles. Special care should be paid to concrete workability and the longevity of fresh mix properties for cased secant piles to avoid common faults such as cage displacement, stuck temporary casings and damage to green concrete during casing removal.

85.3.4 Tolerances

There are a number of essential ingredients to achieve good construction tolerances in secant pile walling:

- design and construction of robust guide walls;
- selection of appropriate plant and experienced personnel;
- careful sequencing of the pile installation;
- appropriate materials, especially female pile concrete mix design;
- attention to detail in designing the pile layout.

Wall installation tolerances are heavily dependent on the construction method. *Specification for Piling and Embedded Retaining Walls* (ICE, 2007) gives some useful guidelines in Table C9.1. Section B9.4 of this specification gives further guidance on guide wall and reinforcement cage tolerances.

85.3.5 Interfaces

Unlike diaphragm walls, it is not possible to install slab connection reinforcement or box-outs in secant pile walls without excessive risk that they will not be located within the required tolerances. Reinforcement cages installed either by plunging into fresh concrete or by installing prior to concreting within a temporary casing will usually become significantly twisted out of position particularly at depth. As a result, it is usually preferable to achieve slab-to-pile connections by drilling and grouting in bars at the required level.

Figure 85.14 Hard/hard cased secant pile wall, Royal Opera House, London

Secant pile walls that are supported by temporary props will require waling beams, which must be properly packed to achieve contact between the waler and every pile to ensure effectiveness. In many cases temporary props are arranged to support the wall via a top capping beam, which may be required anyway, hence, saving the need for a temporary waling beam. When temporary anchors are used, the provision of a waling beam can be avoided if every female pile is restrained by an anchor using an anchor head block (**Figure 85.14**).

Waterproofing details for secant pile walls require particular attention given their geometrical shape at the slab-to-wall connections and also at the capping level. The provision of re-injectable trays for permanent structures can be beneficial provided access is available in the long term.

85.4 Contiguous pile walls

85.4.1 Description and use

Contiguous pile walls consist of a series of cast *in situ* bored piles, which do not intersect with each other. The gaps between the piles are usually sized so that, at a minimum, the piles do not clash at depth although they can be larger, dependent upon the ability of the ground to arch between the piles; typical gaps are around 100–200 mm but can be bigger.

These walls are designed to resist earth pressure but are generally not designed to be groundwater retaining, which means some form of drainage detail is necessary at the formation level of the proposed structure. For aesthetics, the walls are often faced with a variety of finishes, e.g. panels, tiles, bricks or blocks. To protect both the drains and facing from ground sloughing in the gap, it is good practice to infill this area with a free-draining material, such as no-fines concrete or a propriety geofabric or plastic drain.

Contiguous bored piled walls are most often employed in low-permeability ground. Despite being less structurally efficient than diaphragm walls and suffering from the interface problems common to secant pile walling, they can offer a very economical solution and walls have been constructed in a range of diameters typically 600 mm up to 2400 mm – see **Figure 85.15**.

Figure 85.15 Contiguous bored piled wall

85.5 Sheet pile walls

85.5.1 Description and use

Sheet pile walls consist of a series of interlocked steel sections, which when installed are capable of withstanding both horizontal and vertical loads. Historically sheet pile walls were utilised in temporary situations where, for example, support was required during an excavation, whilst the permanent works were constructed. Advances in both the manufacture of sheet piles and installation methods now mean that steel sheet piles are used as commonly in permanent retaining solutions as for temporary support measures. Common uses for sheet pile retaining walls include:

i. *Steel-intensive basements* – Sheet piles are used as the permanent retaining structure and can also carry the vertical perimeter structural loads. The exposed face of the wall is often left visible and in these cases the steel will generally be cleaned and painted to provide an aesthetically acceptable product (**Figure 85.16**). Further details on steel-intensive basements can be found in *Steel Intensive Basements* (Yanzio and Biddle, 2001).

ii. *Flood defence and quay walls* – Sheet pile walls are used in rivers, inland waterways, ports and harbours to provide both protection against flooding and berthing for vessels. As vessel size has increased over recent years there is a need for deeper berths. There are limits to the capacity of a standard sheet pile wall and as the retained height

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

increases it is more likely that the wall will be constructed as a combi-wall where stiffer primary elements are inserted between a number of sheet piles. This technique is covered in further detail in the next section.

iii. *Retaining walls* – Sheet piles are commonly used along highways and in other situations where slopes need to be supported. Generally the piles act in cantilever where there are lower retained heights. For higher walls, other methods can be incorporated into the wall construction to allow greater capacity. The wall can be anchored using soil or rock anchors, or if space is available in front of the wall then waling beams and props can be installed.

85.5.2 Plant

The plant and equipment used for the installation of sheet piles has developed significantly over the last 30 years. Panel driving was the most common method historically; however, this has largely been superseded by rig-mounted hydraulic vibrators and pressing techniques on a pitch-and-drive basis.

The power available in rig-based units has increased as has the size of the rig itself. A modern leader rig equipped with a vibratory hammer can now weigh in excess of 60 tonnes and be equipped with a hammer with a centrifugal force of 1400 kN; only 20 years ago a state-of-the-art rig would have weighed closer to 40 tonnes and its hammer would have had a maximum centrifugal force of approximately 600 kN. This has allowed the range of applications where sheet piles are the most suitable retaining solution to be extended, as heavier sections can be handled and driven in ever more difficult soils. The design of the vibrators has also changed during this period with most equipment now operating at higher frequencies, which means that any vibration imparted into the surrounding soils attenuates much more quickly, leading to less risk of damage to adjacent structures (**Figure 85.17**).

Figure 85.16 Basement construction utilising steel sheet piles and temporary propping

Where sensitive structures are present and noise and vibration needs to be limited, then there are now a range of hydraulic pile presses available, which either use the reaction supplied by previously installed piles or a large base machine to push the sheet pile into the ground. The use of these techniques is more sensitive to the soil type encountered but can be assisted in some circumstances by pre-boring to loosen the soils along the pile line or by water jetting during pile installation (**Figure 85.18**).

Where long sheet piles are required or very accurate installation tolerances need to be achieved, then conventional methods allied to panel-driving techniques will be most appropriate. With these methods, large crane-suspended vibrators and impact hammers can be used to impart high-driving forces into the sheet piles whilst controlling the position and alignment within a set of guides and piling gates.

85.5.3 Materials

Sheet pile walls can be manufactured in either cold-rolled or hot-rolled sections. The use of cold-rolled sections is generally limited to lightly loaded situations, as they are generally of a lighter section and do not interlock as tightly as hot-rolled sections.

Figure 85.17 Sheet pile installation utilising leader rig with hydraulic pile press

Figure 85.18 Kowan hydraulic pile press

The tolerances for the manufacture of cold-rolled sheet piles is covered in BS EN10249 (British Standards Institution, 1996b). The inherent limitations of cold-rolled piles mean that they are more susceptible to de-clutching if the pile is installed inaccurately or in denser more difficult soils. The manufacture of hot-rolled sheet piles is covered in BS EN10248 (British Standards Institution, 1996a). Hot-rolled sheet piling of non-alloy steels and the manufacture to tight tolerances is one of the main advances in pile manufacture in recent years. The provision of a tight interlock allows for their use in more heavily loaded situations with more difficult ground conditions. There are a large range of sheet piles available on the market in both U- and Z-shaped profiles. Profile selection depends upon the design requirements. However, from an installation point of view it is important that the design takes account of the driving conditions. It may be that a design and selected pile section can be completely sufficient for the permanent applied loads, but would fail during installation due to the temporary loads applied by driving. In these cases a heavier pile section would be selected to accommodate the driving forces. The driveability of a sheet pile section is related to its cross-section, stiffness, length, steel grade, quality and the chosen method of installation. Further details on the factors affecting driveability can be found in the *Piling Handbook* (ArcelorMittal, 2005), along with detailed product information regarding their manufactured sections.

85.5.4 Installation

The method of installation will vary depending upon the type of wall, the selection of pile section and physical site characteristics. However, the method will generally fall into one of the following categories:

85.5.4.1 Pitch-and-drive

This methodology utilises specialist equipment to pick up and pitch-and-drive single piles to the required depth. Originally this technique was limited to situations where the soil was loose and the piles short. In recent years the equipment has become more powerful and larger allowing the technique to be used on more complex sites with more difficult soils. Care needs to be taken to ensure that the piles remain vertical during installation as the lack of any guidance frame can allow the piles to lean in the direction of driving or rotate, particularly in stiffer soils or where driving longer piles.

85.5.4.2 Panel driving

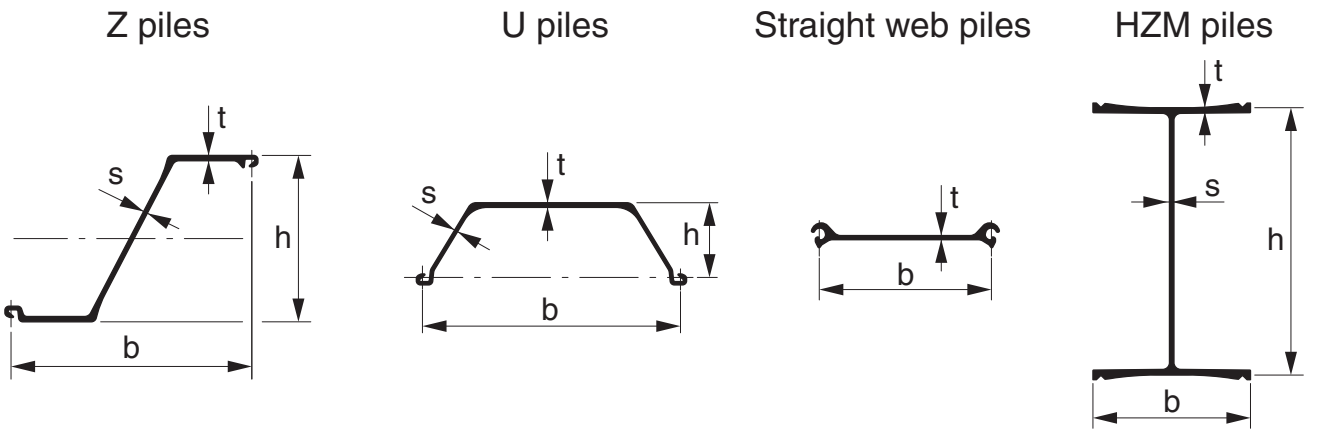
With this methodology a number of piles are inserted into a pre-constructed frame located along the required wall line. Three basic driving techniques are used:

85.5.4.3 Impact driving

The pile is repeatedly hit with a falling mass travelling over a controlled stroke length. The method can generate high levels of low-frequency vibrations and high-noise levels. The advantage is that, given a variety of hammer weights and stroke lengths, high levels of energy can be put into the piles overcoming most soil conditions.

85.5.4.4 Vibrodriving

Piles are installed using high-frequency vibration from sophisticated and powerful hammers, which can overcome most problematic soil types. However, the hammers are expensive to operate and repair compared with impact hammers.



85.5.4.5 Pressing

With pressing, installation in granular soils can be limited unless assisted by other methods such as water jetting or preboring. The major advantage is that equipment generates low levels of noise and vibration and can be used near to existing structures.

85.5.5 Tolerances

Installation tolerances have been established for many years and are summarised in a number of documents including the *Specification for Piling and Embedded Retaining Walls* (ICE, 2007), the *Piling Handbook* (ArcelorMittal, 2005) and in BS EN12063 (British Standards Institution, 1999). There is a movement within the piling industry to review these tolerances, as much tighter accuracy is now possible and can be offered where there is a structural need for piles to be installed to within say 25 mm of plan position as opposed to the standard specification of within 75 mm. As sheet piles are a manufactured product it is also important to consider manufacturing tolerances when installing a sheet pile wall (see **Figure 85.19**). For example it is not uncommon for a standard 600 mm wide U-section to actually measure 606 mm and as such be within the specified manufacturing tolerances. However, at site level this would mean that for every 100 piles one less pile would be installed than anticipated from the theoretical layout.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

85.5.6 Interfaces, joints and connections

One of the major benefits of utilising a sheet pile wall is that each element is manufactured in factory conditions and is supplied with a designed connection detail, which is capable of providing the full section modulus. This interlock is complemented by a series of special sections, such as 'corners and junctions', which allow a sheet pile wall to be installed in numerous configurations. Some of the more common corner products available are shown in **Figure 85.20**.

With all wall types the issue of watertightness is most critical at the location of joints and interfaces. For sheet pile walls where watertightness is important, a number of methods can be utilised to exclude or minimise water penetration. There are a number of clutch sealants on the market, which can be placed within the clutch prior to pile installation. However, these products usually provide resistance to prevent water ingress in a temporary situation. When permanent exclusion of water is required it is more common to weld the clutches after installation, during basement construction. This provides a permanent seal, which will not degrade with time. As the seal is created post installation, it can normally only be carried out over the exposed length of pile, from the surface level down to the formation level of the basement. This means that some sort of flange will need to be installed linking the sheet pile wall with the basement slab to ensure that water cannot penetrate through the base. As sheet pile walls are made from steel, there

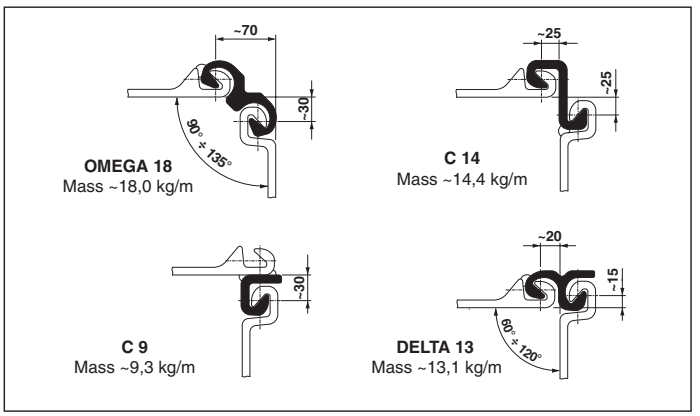

Figure 85.20 Range of corner profiles used to change wall direction

Figure 85.21 Detail of floor/wall connection in a permanent steel basement

are more possibilities for carrying out post-installation work to improve or maintain watertightness, such as welding at clutch locations or installing additional steel products over damaged joints. **Figure 85.21** shows a typical steel flange connection at the base of a permanent sheet-pile basement construction.

85.6 Combi steel walls

85.6.1 Description and use

Many of the issues relating to combi steel walls are closely related to the previous section on sheet pile walls. The main difference is that the design approach relies upon any load being retained on individual primary elements, which are separated by infill panels (secondary elements), usually consisting of steel sheet piles. As the retained height is generally larger, much larger plant and equipment are required to install the heavier sections. The table below gives some common configurations for various combi steel walls and is taken from Figures 85.1 to 85.5 of BS EN1993–5 (British Standards Institution, 2006), which details many of the requirements for combi steel piling.

Common uses for combi steel pile retaining walls include:

- deep steel-intensive basements and cofferdams;
- flood defences and quay walls;
- retaining walls.

85.6.2 Plant

Most combi steel walls will be installed using traditional crane-hung vibratory and impact hammers due to the size of the wall elements (**Figure 85.22**). As the elements are relatively large and, thus, heavy, greater amounts of energy are required to drive the piles to the required depth. A further advantage of using crane-hung equipment is that when working near water the heavy plant and equipment can be set back from the edge, which, therefore, minimises any surcharge loading on the unprotected slopes.

In some cases, such as deep basements within city centre locations, it may not be possible to use either vibro- or impact-driving methods due to existing structures. In recent years, pile-pressing methods have been developed to allow the installation of combi-walls with low levels of noise and no vibration. These techniques can be slower and, therefore, more expensive than traditional methods but have extended considerably the range of locations where combi steel walls can be utilised.

85.6.3 Materials

Most materials used will conform to relevant standards such as BS EN10248 (British Standards Institution, 1996a) for hot-rolled sheet piling. However, it is not unusual for primary elements, e.g. tubular steel piles, to be sourced on the open market and may be second-hand. If this is the case then it is essential that all materials used are certified and if necessary tested, to ensure that they comply with the design and project requirements.

85.6.4 Tolerances

Due to the greater retained heights leading the design towards a combi-wall solution, the weight and physical size of the wall elements will be much larger than for sheet pile walls. In order to ensure that the various elements are installed accurately it is generally found that the position and verticality will be controlled through the use of gates. These consist of a framework of temporary steelwork set at two levels, which ensures that the wall elements are installed accurately (**Figure 85.23**).

85.6.5 Interfaces, joints and connections

In order to join the various elements of a combi steel wall together, it is common that before delivery to site standard clutch profiles are welded to the primary elements. This allows them to be clutched directly to the steel sheet piles, which will act as the infill panels. See **Figure 85.20** for typical details of corner

and junction profiles, as detailed in the *Piling Handbook* (ArcelorMittal, 2005).

85.7 Soldier pile walls (king post or Berlin walling)

The soldier pile, usually a steel or concrete member, is driven or set in a pre-excavated hole at about 2–3 m centres.

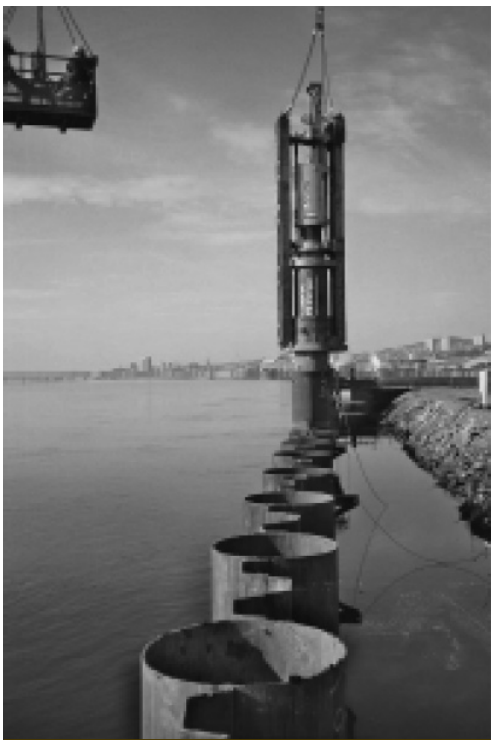

Figure 85.22 Driving of combi-wall elements using a hydraulic impact hammer

Excavation then proceeds at around 1 m 'steps' and horizontal sheetings or 'laggings' (timber, steel or concrete) are placed to restrain the ground between the soldier pile or king post. The system is illustrated in **Figure 85.24**.

The lagging encourages horizontal arching and the king posts carry the major thrust of the ground. By incorporating walings and tie backs, significant depths of excavation can be achieved. In very competent soil (stiff clays and soft rocks), lagging may not be necessary and simple local safety measures such as mesh pinning or guniting may be sufficient. The works are not considered permanent although the soldier piles may be incorporated into the final structure.

King post walls are most suited to competent ground, typically dense granular material (with lowered groundwater) and stiff to very stiff clays. Conventional soldier piles are not used in soft clays and loose granular material, which may run and contribute to loss of ground. Such works are comparatively cheap to construct in suitable ground. Of all the wall types, they are the most associated with 'failure' (usually excess deformation and local movement), probably caused by attempting to use them in the wrong conditions.

King post walls are not often employed in the UK (because of ground conditions) but are much employed in the USA, Asia and in central Europe. Local practices and useful semi-empirical processes and rules have evolved to suit local ground. Examples of such are:

- the German wedging practice, which encourages arching in poorer soils (**Figure 85.25**);
- the 'louvre' lagging gaps to permit back-packing of the ground in timber and concrete lagging practice (**Figure 85.26**);
- the empirical evolution of timber capacity to loading – illustrated for competent and difficult soils (**Table 85.2**).

The range of king post walling is typically up to three or four basements although in good conditions this is only constrained

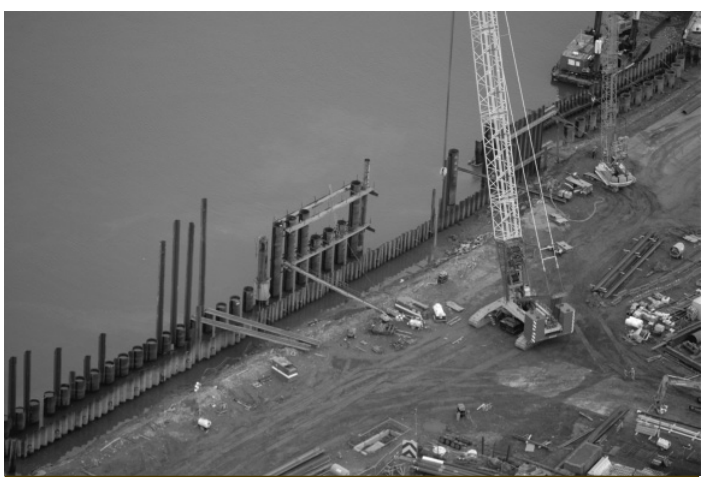

Figure 85.23 Typical combi-wall arrangement showing primary tubular piles and infill sheet pile elements

Figure 85.24 Typical soldier pile wall showing use of timber laggings

Clayey sands (loose) below water table	SC							

Note:
*For 'potentially dangerous soils', the use of lagging is questionable.

Table 85.2 Empirical lagging sizing

by the depth to which the structural king post itself can be sensibly placed or driven and the propping arrangements. Shallow walls may be able to cope with larger lagging spans. The arching effect means that a fairly modest lagging provision can be used at depth, provided the horizontal spans are not excessive, i.e. about 2 m.

Plant used for the king post or soldier pile is dependent upon the construction system but is similar to the driven or bored

pile techniques described above. Where bored piles are used, then below the dredge larger diameter piles can be employed to increase bending capacity with an appropriate steel or concrete soldier pile plunged (or placed) into the bored pile.

Soldier pile walls have only the king post as their embedded component. The majority of their exposed area is dependent on the excavation, lagging and packing process and this needs much care, discipline and good working practice and interface consideration in construction. Suitable local drainage arrangements and alert observational techniques are required for the successful completion of the system. Particular attention has to be paid if the works are adjacent to sensitive structures, since local 'blowouts', squeezing or runs can be catastrophic; this process is more prone to systemic failure than other walling types.

Despite having to cope with many significant interfaces, in the correct ground conditions and with careful processes, soldier pile walls (and their derivatives) can give very effective and economic solutions to earth-retaining problems.

85.8 Other wall types

Although categorised as 'other' wall types, the remaining types of embedded retaining wall are in essence variations or hybrids of those mentioned previously. They are generally used in niche markets in areas where local ground conditions are appropriately favourable.

Four such 'other walls' are identified – walls employing:

- concrete sheeting;
- soft walls with pre-cast walls or steel sheet insertions;
- unreinforced mix-in-place walls;
- firm walls with king posts.

a. Concrete sheeting is much less robust than its steel precursor but nevertheless can be competitive if used in deep soft soil deposits – such as the clays of Mexico City and deep soft marine alluvium. Other than specialist head protection, its process and provision follows very similar patterns to its steel counterpart. In the correct situations, it is a real and useful alternative and it can give, for example, more robust protection in the aerobic zone. It tends to be limited in depth because of joining and transportation issues for the pre-cast panels. It has been used to support dredge depths up to typically 5 m.

b. 'Soft' walls have steel sheeting or pre-cast concrete inserts. Normally when a trench with support fluid is constructed, the most economical solution is to move on to a full diaphragm wall. Occasionally (often because of space constraints), it is necessary to provide pre-cast solutions, which can take the form of concrete panels or sheet piles. This technique has been used successfully in Germany on sites where a deep cut-off is required.

Plant and construction techniques are identical to diaphragm techniques. The 'soft' mix, which surrounds the inserts, is often a cement bentonite, which can be removed from the front of the wall and which aids 'watertightness' at the joints.

c. Unreinforced mix-in-place walls are employed where the ground is suitably granular such that a reasonably consistent and homogeneous mixing of cement can guarantee a sensibly 'strong' compressive strength material. This can be employed, for example, in shafts. The walls will be relatively thick since they must act in compression, and relatively shallow (<10 m). The required plant is highly specialised for an effective mix-in-place (**Figure 85.27**). The technique is more often encountered in Asia and increasingly in the USA.

d. Reinforced mix-in-place or 'firm' walls, where the reinforcement is essentially a series of king posts, have grown in popularity in areas with suitable (again mainly granular) ground. Steel and concrete pre-cast sections carry the majority of the structural loading with the unreinforced mix-in-place material containing the ground between the soldiers. King posts are set at a spacing sufficiently close to encourage arching or to cope with the applied loading (**Figure 85.28**).

Unlike soldier pile walls, such walls are fully embedded, do restrain local ground movement and groundwater movement at the excavation stage. The containing mix-in-place material requires considerable attention to its process to ensure that the king posts can be accurately plunged, yet the mix will 'firm

Figure 85.27 Plant for mix-in-place walls

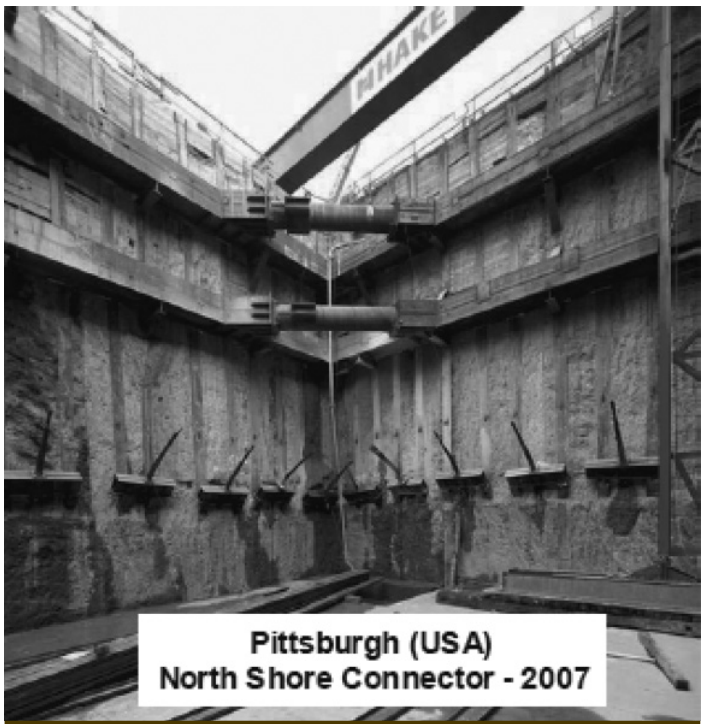

Figure 85.28 Reinforced mix-in-place or 'firm' walls

up' (in time) to sufficient strength to cope with local anomalies and flexure. Such walls are not encountered in the UK but are increasingly popular in Asia and the USA where ground conditions are suitable.

Plant for mix-in-place applications is continually developing and can vary from drumhead rollers to multi-armed auger systems.

86.5	References	1294

The process of construction of soil-reinforced structures is made up of many different operations. These include the assembly of all relevant information, planning, materials testing for validation purposes, delivery, acceptance and storage of materials, the construction itself, and maintenance requirements. The contractual links between the various parties to the project are also a very important consideration, as the construction process itself is often carried out by a separate contractor appointed just for that particular aspect of the works. The two main components of soil-reinforced structures are soil and reinforcement – hence the soil itself has a very important part to play in the success of the final result. The reinforcement materials should have had their assessment completed before the installation process commenced, whilst the combination of the elements can only be achieved in situ. The importance of placement and compaction of the soil materials in order to achieve the strength properties used in the design, and hence a strong, stable reinforced soil block, must be appreciated by the construction team.

86.1 Introduction

Soil-reinforced structures are composite structures which combine the properties of soil (earth) and soil-reinforcement materials. The applications can be divided into two main areas:

(i) *Vertical and near-vertical walls, and steep slopes* Walls and steep slopes are essentially soil-retaining structures. The composite material of soil and reinforcement is designed to have the mass and geometry necessary to prevent the retained unreinforced soil from failing. Vertical and near-vertical walls are generally faced with some form of hard facing material, whilst steep slopes are normally vegetated to provide a green and environmentally pleasing face. The function of the facing is essentially for erosion protection and aesthetics. In terms of the design, the contribution of the facing is relatively small, but the consequences of the facing not providing the appropriate protection could be quite severe. The importance of the soil element of the composite material must be appreciated and is dependent on the quality of the construction process.

(ii) *Embankment foundations* Embankment foundations applications are generally used when the existing soils beneath a proposed embankment, which is stable within itself, are not capable of supporting the new construction. Embankment foundation applications can range from relatively light reinforcement materials providing a working platform through to very robust, piled embankment solutions with very high-strength geotextile reinforcement sheet materials. There are two British Standard publications that are relevant to the construction phase of a project, BS EN 14475:2006 (BSI, 2006) and BS 8006–1:2010 (BSI, 2010).

The construction process can be divided into three distinct phases: pre-construction, construction and post-construction, which are discussed below.

86.2 Pre-construction

The gathering of information before construction commences is a very important part of the process and can be the key to avoiding problems later on. This is particularly important if the contractor who is actually carrying out the construction is outside the original contract team. Information regarding existing site conditions, services, and any restrictions that may apply to the work, should be supplied to that contractor at a very early stage. A comprehensive list of particular information is given in BSI (2006) but there are some areas that warrant additional emphasis.

86.2.1 Roles and responsibilities

The roles and responsibilities of all the parties involved in the reinforced soil construction should be defined very clearly at an early stage of the process. Good definition at this early stage can ensure that any problems that occur during the construction process are dealt with quickly and efficiently by the responsible party. Poor definition inevitably leads to confusion and a much slower response to a problem, which may have escalated in the interim. The split of the responsibilities between the engineer, the reinforced soil designer, the reinforcing material supplier, the main contractor and the reinforced soil sub-contractor could be quite complex, and the contractual links need to be well defined. In many cases one party will carry out a number of these tasks, but there could be situations where all the functions are separate.

86.2.1.1 Reporting channels

The arrangements for change management need to be understood by all parties to deal with any unforeseen circumstances in soil conditions, for example, and the inevitable alterations to geometry and detail that occur during the life of a project. The definition of the line of communication is vital to the smooth

running of the process for standard design-generated structures, and becomes even more important when the observational approach to design is adopted.

86.2.2 Site investigation

An adequate site investigation (see Section 4 *Site investigation*) should be carried out to determine the existing soil conditions and also the possibility of using existing soils in the reinforced soil structures. There may be situations where the reinforced soil contractor needs to design and install temporary works in order to carry out construction of the permanent works. In these cases, the contractor will require soil testing in order to be able to assess the suitability of fills and soil properties for the temporary works design (see Chapter 49 *Sampling and laboratory testing*).

If the reinforced soil contractor has some choice in the selection of the reinforcement material, then the chemical properties of the existing soils and the fill could be important in that selection process. Guidance on the suitable fill types and durability data for different materials is given in BSI (2006) and BSI (2010).

86.2.3 Planning

The reinforced soil element of a project may be very large – in some situations being the whole construction; in others it may be only a very small part of the complete project. It is very important, therefore, to plan for the reinforced soil construction and ensure that all the components are available in the right place at the right time.

86.2.3.1 Materials

The design and drawings for the reinforced soil element of the works will include material properties, and facing details if appropriate. There may be some element of selection that is available to the contractor in terms of the source of the fill material and the reinforcement materials. In some cases, the required facing appearance and the reinforcement type will be linked by a proprietary connection detail. Information on suitable fill types for particular applications is given in BSI (2006).

86.2.3.2 Material testing

The design will include the specified properties of the fill materials that have been used to derive the reinforcement layout. The actual fill to be used should be tested or verified in some other way to ensure that it satisfies the design value (see also Chapter 99 *Materials and material testing for foundations*).

The reinforcement materials are the subject of the Construction Products Directive (1988), and as such will have CE marking information to verify the properties – providing that the harmonised properties are relevant to the application for which the reinforcement is being used.

Once the fill material and the reinforcement have been selected, the interaction parameters between the two materials need to be determined to verify whether the design parameters are satisfied. More comprehensive details of the information that would be expected to be in a design output are given in BSI (2006).

86.3 Construction

86.3.1 Delivery and storage of materials

Identification of the different components involved in the construction, separation and isolation of apparently similar materials is very important in preventing mistakes. Facing components should be stored carefully as they are the face of the structure on completion. Some reinforcing materials may require specific storage conditions; details should be obtained from the material supplier.

86.3.2 Preparation of the foundation

The foundation level and extent will be indicated in the design and, as with any structure, the accuracy of the initial foundation layers is vital in the production of a serviceable end result. In situations where the foundation soils are soft, it is important to limit the disturbance that they have to endure during the construction process. The parameters used in the design (see Section 5 *Design of foundations*) will generally be those of the foundation soils in their pre-construction condition using the parameters from the ground investigation report (see Chapter 50 *Geotechnical reporting*) and hence any major disturbance of those soils will have a significant effect on the final result.

Notes on the installation of vertical drains and reinforcement over piled foundations are available in BSI (2006) and BSI (2010).

When hard facing materials are used in the construction of reinforced soil walls, there is generally a requirement for some form of levelling pad, concrete or sometimes gravel, on which to place the first face elements. This pad does not have a structural purpose but it does provide a firm surface from which the wall face rises. As with any engineering structure, errors in line or level at the foundation level will be very difficult, if not impossible, to rectify later.

Soft-faced walls and slopes, such as vegetated faces, do not generally require a levelling pad.

86.3.3 Installation of drainage

Drainage of structures is important from two points of view.

Firstly, there is a design aspect regarding the possible presence of water within or outside a structure. Water that is not allowed to drain away can have a significant effect, so if there is a possibility that the materials being used are not free-draining, then drainage layers should be included and linked into the drainage system on the site. Some particular fill materials such as pulverised fuel ash (PFA) require particular drainage arrangements to ensure isolation of the PFA block.

The second important reason for drainage provision is aesthetic. A number of facing block finishes have open joints and staining can occur if there is no drainage layer behind the block face to draw any water seepage down to the toe of the wall.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

86.3.4 Placement of facings

General information on the placement of facings is given in BSI (2006). It must be noted that whilst the facing does not have a true structural function, it does provide erosion protection and it is the visible result of the construction. The accuracy of placement of the facing and the care with which the fill is placed and compacted behind it define the quality of the final structure. A good understanding of these principles by the reinforced soil contractor's team will result in sound and serviceable structures.

The flexibility of modular block facings for reinforced soil walls enables complex geometric shapes to be constructed. Care should be taken to ensure that the heights of free-standing blocks without reinforcement are limited to those advised by the supplier or manufacturer. Exceeding the recommended heights can cause great difficulties in keeping the line of the wall within acceptable tolerances. Indicative tolerances are given in Annex C of BSI (2006); see **Figure 86.1**.

Lifting and placing of the larger panel facings is carried out using craneage, whereas the modular block facings can generally be manhandled. The limitations of block size and weight to comply with the Health and Safety requirements for manual lifting must always be observed.

86.3.5 Placement of fill materials

86.3.5.1 Walls and slopes

Whilst all the tasks that are involved in the construction of a reinforced soil structure are important to produce a satisfactory and pleasing result, the placement and compaction of the fill is probably the most important operation of the whole process. The development of a true composite mass of soil and reinforcement depends on the two materials being intimately related to each other by the appropriate mechanism. Strip-type reinforcement materials generally rely on a frictional interaction on the surface of the reinforcement, whilst grid-type materials interact through an interlocking of the soil particles into the geogrid apertures. Whichever mechanism is appropriate, it will only be mobilised effectively if the soil is placed and compacted to standard specification levels. The design of structures, vertical walls and steep slopes to BSI (2010) uses the peak friction angle for the reinforced fill and for the unreinforced backfill. The peak friction angle will only be achieved if the compaction of the soil is carried out to specification. The case study in **Box 86.1** shows how a well-compacted, good-quality fill material can produce a completely stable and durable soil/reinforcement composite mass even under severe circumstances. BSI (2006) gives a large amount of guidance on this aspect of the construction, recognising its importance. Particular care should be taken to follow the guidance regarding compaction close to the face; see **Figure 86.2**.

Incorrect operations in this area can cause face deformations which may be irretrievable and result in an unsatisfactory appearance.

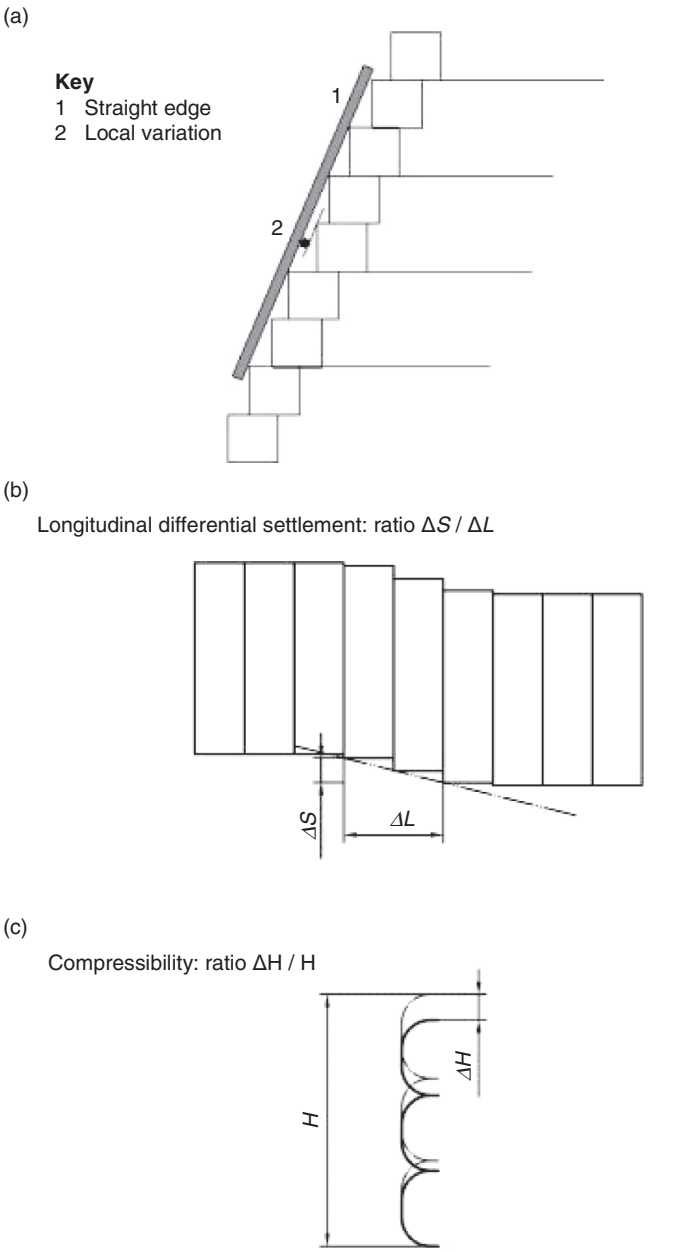

Figure 86.1 Indicative construction tolerances from BS EN 14475. (a) Cross-section through wall; (b) front elevation of wall; (c) cross-section through wall

Reproduced with permission from BS EN 14475, Annex C (2006) © British Standards Institution

86.3.5.2 Embankment foundations

BSI (2006) and BSI (2010) give good guidance on this quite specific application area. The reinforcement of embankment foundations generally involves the requirement to place fill over soft soils or piles which are hard points within a generally soft soil. Whilst the construction of walls and slopes can generally follow reasonably standard procedures, the construction sequence techniques have to be more site-specific. Placement of

Figure 86.2 Limitations of compaction plant close to structure face
Courtesy of Tensar International Ltd

relatively thin soil layers over a wide area and a gradual increase of load onto the foundation are general principles, but there will be many variations and these should be considered with care.

86.3.6 Placement of reinforcement

86.3.6.1 Walls and slopes

Guidance on reinforcement placement is generally available from the manufacturer or supplier, and BSI (2006) and BSI (2010) also give helpful information. The main points to bear in mind are that the reinforcement should not be damaged in the construction process and that any flexible reinforcements should be pulled tight, not tensioned, to ensure that any slack is removed from the system. Construction equipment should not run on the reinforcement, regardless of type – there should always be a layer of soil above the reinforcement before any trafficking is allowed whether by the compaction plant or other site equipment.

Connection of the reinforcement to the face unit is a critical aspect of reinforced soil structures and can be achieved in many ways. Steel strip reinforcement may be bolted to anchor plates embedded within the facing panel, while there are many proprietary fixing devices for the connection of geosynthetic reinforcement to modular block facing systems. Reference should be made to manufacturers' literature for full details.

Pulling the reinforcement tight minimises the possibility of post-construction face movement. This may happen if the face connection between the reinforcement and a facing block, or a joint between two pieces of reinforcement is left with slack. A typical example of removing the slack is shown in **Figure 86.5**.

Protection of the connections during the construction process, particularly the placing and compacting of the fill materials, is very important. The restrictions on compaction equipment weight and thickness of fill over the reinforcement layers must be followed. Long-term durability requirement of the connection should also be carefully implemented in accordance with the manufacturer's specification to avoid possible post-construction problems.

Box 86.1 Case study

A 19-m-high reinforced soil wall constructed in a very dry climate was subjected to a flash flood before the contractor had placed sufficient scour protection at the toe of the structure. Consequently, over a short length, the levelling pad was undermined and the facing blocks fell away from the reinforced soil block. **Figure 86.3** illustrates a flash flood that occurred later at the site.

Figure 86.3 Example of severe flood water flow
Courtesy of Tensar International Ltd

However, the fill material was of very good quality and the contractor was careful to ensure that the compaction matched the specification required, with the result that the main structural element, the reinforced soil composite block, remained completely serviceable throughout this very severe encounter. During the face reconstruction, the reinforced soil block did not require any treatment and the road remained open and serviceable with no signs of cracking or damage. **Figure 86.4** illustrates the stable reinforced soil block.

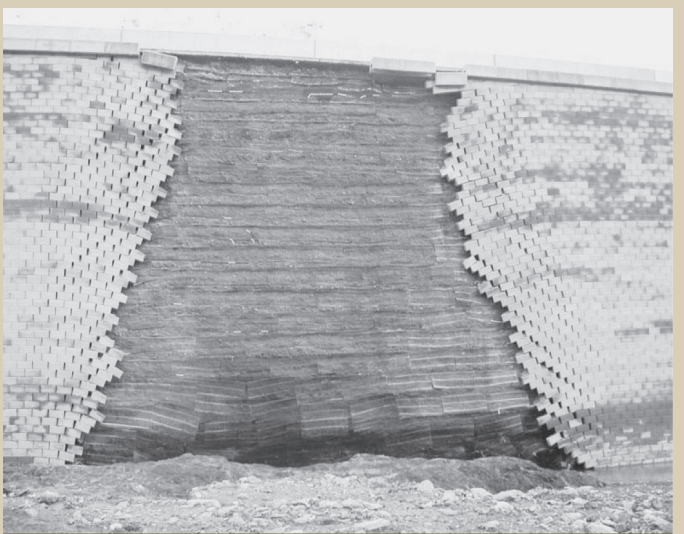

Figure 86.4 Result of lack of scour protection, stable reinforced soil block after critical event

86.3.6.2 Embankment foundations

The principles of reinforcement placement in embankment foundations are essentially the same as for walls and slopes, except there will not be a face against which to take any slack out of the system. Joints or overlaps will probably be required and these are the areas that require the most care. Working below water brings its own special requirements when using materials which actually float; weighting down may be required.

86.3.7 Vegetation

A very common facing for steep slopes is vegetation, where the nutrient soil for the vegetation is placed behind some sort of open facing and the vegetation grows through to provide a soft face to the structure. There is a very comprehensive section on vegetation in the revised BSI (2010) but the main requirements for survival of the face are water and nutrients in the face soil. Selection of the type of vegetation is also quite critical in ensuring survival – naturally growing local vegetation probably has the best chance of successful development. Special drought-resistant plant species have also been developed for particularly difficult situations.

Timing of the introduction of vegetation is a planning issue and careful thought can improve its establishment.

86.3.8 Monitoring and supervision

86.3.8.1 Walls and slopes

The construction of reinforced soil walls and slopes is a relatively straightforward operation using well-accepted engineering earthworks principles. The main areas of interest – the supervising and monitoring of the construction – can be summarised as:

(i) Compaction of the fill. Ensuring and verifying that the compaction meets the specification is of major importance with regard to the development of the design soil properties and the true composite block performance.

(ii) Diligent observation of the line of any facing during construction will ensure an early warning of any tendency to veer out of tolerance.

(iii) Monitoring any reinforcement connection details, reinforcement to face or reinforcement to reinforcement, and ensuring that any slack is taken out, particularly of flexible reinforcement materials, will benefit the final appearance.

86.3.8.2 Embankment foundations

The construction of reinforced embankment foundation projects is not as formalised as for walls and slopes, and each project will have its own specific characteristics. A construction sequence, specific to the project, should be part of the design and any monitoring and supervision requirements will be specified in that document. General earthworks principles will, of course, still apply.

86.4 Post-construction

86.4.1 Records

Records of weather conditions, etc., during reinforced soil construction should be the same as those conventionally kept on construction sites. A particularly important area of record keeping is the location of the reinforced soil structure itself. The fact that a structure is constructed of reinforced soil may not be obvious; a concrete-faced wall may look the same as a reinforced concrete wall, and hence an indication that soil reinforcement is present is important in the event of further construction in the future.

86.4.2 Maintenance

In general, reinforced soil structures are low-maintenance. The usual requirements of ensuring that drainage is maintained, etc., still apply and in extreme conditions can be very important. Maintenance of vegetated faces is an area that may need some consideration in terms of irrigation and plant species selection.

Chapter 87

Rock stabilisation

Richard Nicholson CAN Geotechnical Ltd, Chesterfield, UK

CONTENTS

87.1	Introduction	1295
87.2	Management solutions	1296
87.3	Engineered solutions	1297
87.4	Maintenance requirements	1301
87.5	References	1302

Rock faces can be natural or man-made features of the landscape that can arouse significant local or national interest. A designer needs to be sensitive to the position and location of a rock face and give careful consideration to the likelihood and consequences of a failure. This is likely to determine the conceptual approach to any stabilisation works. Risk mitigation measures can comprise a management approach where failure of the rock face is permitted, but the consequences of a rockfall are managed. This can be achieved through the installation of warning systems, rockfall netting or catch fences. Alternatively, an engineered solution can be sought, typically comprising the removal of the hazard or a reduction in the likelihood of a rockfall. Examples of remedial works adopting this approach would include scaling, installation of ground anchors or the application of sprayed concrete.

Installation and subsequent maintenance of any remedial works should be undertaken by a specialist with experience of working in potentially exposed locations on an unstable rock face. Careful consideration needs to be given to access requirements and the safety of the workforce and third parties. It is, therefore, essential that a full risk assessment is undertaken at the design stage and reviewed throughout construction.

87.1 Introduction

87.1.1 Principles

Rock faces can form naturally or as a result of construction activities. The stabilisation of rock faces can, therefore, be undertaken on existing rock slopes or newly formed faces, either during or after their excavation. Both landowners and employers owe a duty of care to ensure that the safety of the site user is not compromised.

In situ rock is unlike the majority of materials encountered by engineers. Rock can be highly variable within a short distance and usually only the front face is visible. When working with *in situ* rock it is critical to have a clear understanding of the geological context and the engineering characteristics of the rock mass, as well as the forces that are acting upon it. The design process is likely to require an inspection of the exposed face and an intrusive ground investigation to obtain an understanding of not only the engineering properties of the rock but also the quality of the rock mass as a whole. The design of stabilisation measures may, therefore, need to be undertaken by a specialist.

When selecting the design approach to be adopted, the designer will need to consider both the likelihood and consequences of a failure of the rock face. The land use both at the toe and crest of the face is likely to determine whether risk mitigation measures comprise a management approach, where failure of the rock face is permitted, or whether a fully engineered solution is required.

87.1.2 Access considerations

The design of any remedial measures will need to give careful consideration to access requirements, both for construction and subsequent maintenance of the works (see **Figure 87.1**). Newly cut faces can be stabilised during excavation in a top-down manner as long as there is a clear understanding of the scope of the whole works.

Existing rock faces in remote locations may be difficult to access from the nearest highway. Alternatively some rock faces will preclude working from the toe or crest (e.g. due to the presence of infrastructure or water). The inherent nature of existing steep and irregular rock faces may also preclude the use of traditional plant and scaffolding. Consideration may need to be given to employing a contractor specialising in difficult access techniques. This will typically involve specialist plant reaching up from the toe, or reaching down from the crest of the rock face. Alternatively, equipment may be suspended by steel cables attached to a temporary access system located behind the crest and winched into position on the face.

Personnel undertaking the works must, therefore, not only be competent in undertaking the specified work tasks but also

Figure 87.1 Different access solutions
© CAN Geotechnical Ltd

be competent in accessing the work site. Rope access methods in accordance with BS 7985 (British Standards Institution, 2009) have become increasingly accepted as offering a safe, cost-effective access solution.

87.1.3 Safety considerations

Given the inherent nature of rock stabilisation works they are often undertaken on faces that pose a risk of injury due to rockfall. In assessing the stability of the face careful consideration must be given to the safety of the workforce, other contractors and members of the public. The works should be planned such that a safe working environment can be provided at all times. Consideration may therefore need to be given to the implementation of the following mitigation measures:

- temporary works including removal of loose rock or strapping of blocks;
- implementation of an inspection and monitoring regime during the works;
- a method of working such that construction is undertaken in a controlled, systematic manner (e.g. top-down);
- installation of quarantine areas at the toe or crest to protect the workforce and third parties.

It is, therefore, critical that a full risk assessment is undertaken at the design stage and reviewed throughout the construction stage. It is also important that only competent contractors are employed, with a proven track record for the safe delivery of rock stabilisation works.

87.1.4 Environmental considerations

Existing rock faces are natural features of the landscape that often arouse significant local or national interest from various organisations. When designing or undertaking any stabilisation works, due regard for the conservation, recreation and access requirements for the rock face and the surrounding area should be given. Environmental considerations may include:

- setting and location;
- fauna and flora;
- geological interest;
- historical interest;
- recreational amenity (walking, climbing).

Each of the above may affect the design approach and the scope of works or the time of year in which the works are undertaken. In addition, the rock face or the surrounding area may have statutory protection (e.g. RIGS, SSSI) and consultation with regulatory bodies will be required.

87.2 Management solutions

Risk mitigation measures can comprise a management approach where failure of the rock face is permitted, but the consequences of rockfall are managed to minimise the effect of a failure.

87.2.1 Warning systems

Warning systems can be quick and easy to install and provide a reactive solution whilst permanent works are designed, or alternatively can be installed as part of the ongoing management regime for the site.

Warning systems might be simple signage to warn site users in areas of known rockfall (e.g. as typically seen on highways). More sophisticated warning systems include the regular inspection or monitoring of rock faces where the consequences of a failure may be considered more significant (e.g. as used on railway cuttings). This may include the installation of simple trip wires or instrumentation such as load sensors that can be monitored remotely by data logger and modem. If agreed trigger values are reached then alarms can be activated and appropriate action taken.

87.2.2 Rockfall netting

Rockfall netting is a cost-effective method of controlling the fall of rock debris and discrete blocks (see **Figure 87.2**). There are several products readily available including polymer geogrids and PVC-coated double-twist steel mesh. The netting is typically hung as a drapery with rock allowed to fall to the toe of the face.

Consideration must be given to the typical block size, mass and trajectory to ensure that rockfall will be contained by the netting. It is important to realise that the netting will only be as effective as the weakest component within the system. The netting must, therefore, be secured to a robust anchor system installed behind the crest. This typically comprises a crest cable fixed to rock bolts with a bond length within competent rock. Should soil materials be present at the crest then driven earth anchors are often used to provide the necessary restraint.

Adjacent rolls of netting must be securely connected by tie wire or steel hog rings fixed along the seam, or selvedge wire, at regular centres. This join is often the weakest component of

Figure 87.2 Typical rockfall netting installation
© CAN Geotechnical Ltd

the system. Steel cables can be woven or fixed to the selvedge to act as reinforcing elements.

Consideration needs to be given to the proximity of infrastructure to the rock face, as accumulations of trapped debris may extend well beyond the toe of the face. Careful detailing of the toe fixings is also important to ensure that rock debris can be easily and safely released for periodic uplift and clearance.

87.2.3 Catch fences and ditches

Where there is room at the toe of a rock face, consideration can be given to the construction of catch ditches or bunds. Simple earthwork solutions can be cost effective, particularly where the height or condition of a face would require extensive remedial measures to be installed. Bunds are typically used in working quarries where the location of rock faces can be temporary and earth-moving plant is readily available.

Ditches and bunds can be constructed in combination where there are soil materials at the toe of the face (e.g. a scree slope). Ditches can be lined with uniformly graded aggregate to dissipate the impact energy from falling rocks, to reduce the bounce height and to further mitigate the risks associated with rockfall. Bunds can also take the form of walls (typically gabion structures) as often seen in alpine areas to contain or divert debris flows away from infrastructure.

Catch fences may be often installed where trajectory analysis suggests that bounce heights would require substantial bunds or ditches (see **Figure 87.3**). Catch fences can be sacrificial, designed to slow the speed and reduce the kinetic energy of a falling rock, or permanent being designed to withstand repeated impacts. The location, height and capacity of a fence are critical to contain rockfall. Rigorous trajectory analysis should be undertaken, utilising one of the software products that are widely available. Catch fences can be cantilevered from the face (e.g. above a tunnel portal) or free-standing structures located downslope from the toe of the rock face, often on scree slopes or areas of unconsolidated ground.

Various proprietary products are available, typically tested and certified from 100 to 5000 kJ. Whilst the fence and individual components are likely to have been subjected to rigorous testing within a controlled environment, considerable uncertainty may exist in relation to the foundation detail for the fence posts. The foundations may comprise concrete pads with compression or tension piles securing the fence to the underlying competent strata. Additional raking and lateral anchors may also be required to secure stay and end fence cables, depending on whether the fence is a dynamic or static system.

Figure 87.4 summarises the typical management solutions.

87.2.4 Case study – Merstham cutting

Failure of a steep-sided chalk cutting near Merstham, south London, resulted in the reactive installation of remedial works. The cutting is located on the northern approach to the South Downs tunnel on the London to Brighton railway. The first phase of works comprised the installation of rockfall netting

Figure 87.3 Construction of a 3000 kJ catch fence in Gibraltar
© CAN Geotechnical Ltd

over approximately 40 000 m^2 to provide an effective containment system (see **Figure 87.5**). This netting was installed, predominantly with the line open to trains, within a six-week period. A second phase comprised the construction of an additional king post wall at the toe of the cutting towards the tunnel portal utilising temporary possessions of the railway.

87.3 Engineered solutions

Engineered solutions typically comprise the removal of the hazard or reducing the likelihood of rockfall. Stabilisation of the rock face is often achieved by reducing pore water pressures or changing the force regime acting on the face (e.g. by the provision of structural support or re-profiling the face).

87.3.1 Scaling, block removal and re-profiling

Scaling comprises the removal of rock debris and loose blocks from the face utilising light hand tools (see **Figure 87.6**). Care should be taken not to dislodge material that could result in the stability of the face being compromised. It should also be noted that scaling is a palliative treatment, often being undertaken at the commencement of works to mitigate against the short-term risk of a rockfall.

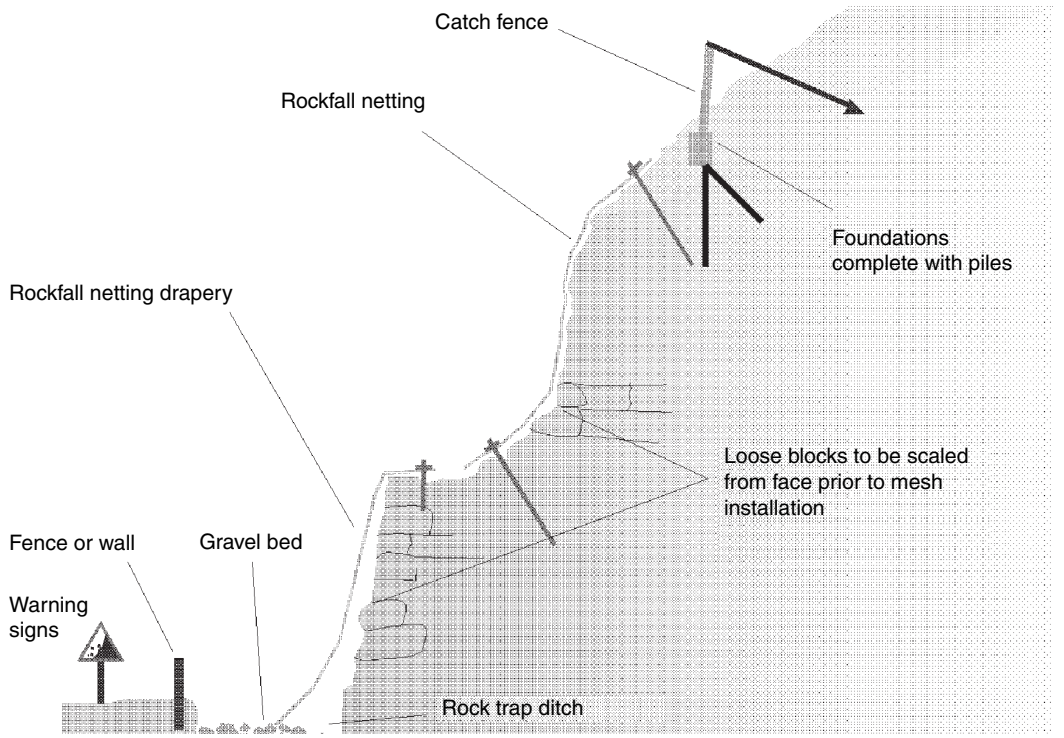

Figure 87.4 Summary of typical management solutions
Reproduced from Fookes and Sweeney (1976) © The Geological Society

(a)

(b)

Figure 87.5 Installation of rockfall netting
© CAN Geotechnical Ltd

Block removal is the controlled dislodgement of discrete blocks, often by the application of pneumatic or hydraulic breakers or jacks. Expansive grouts and gas systems can also be used to break rocks.

Where there is available land at the crest, wholesale re-profiling of the rock face to a stable angle will provide a long-term, low-maintenance solution. However, consideration needs to be given to the method of excavation as blasting can dilate joints resulting in further instability. Alternatively benches can be formed to reduce the face height, contain rockfalls or provide access to undertake further remedial work.

87.3.2 Ground anchors

Further details of ground anchors are provided within Chapter 89 *Ground anchors construction*; however, they are also included within this section for completeness (see **Figure 87.7**).

Significant rock features can be restrained by the introduction of reinforcing elements. Monobar or multi-strand ground

Figure 87.6 Controlled lowering of a block
© CAN Geotechnical Ltd

anchors are installed into pre-drilled large diameter holes. Substantial compressive loads can then be applied to ensure the stability of the rock mass.

A ground anchor can, therefore, be considered as an installation capable of transmitting an applied tensile load to a load-bearing stratum and comprises an anchor head, free length and bond length.

Given the high-capacity, safety-critical nature of ground anchors they are manufactured to a specific requirement for corrosion protection, in accordance with BS EN1537 (British Standards Institution, 2000). Care must be taken to ensure that the integrity of this corrosion protection is not compromised during anchor installation. Rigorous testing and commissioning of the anchor must also be undertaken to demonstrate the efficacy of the installation.

Low-capacity ground anchors that are not safety critical are often referred to as rock bolts. They are available in a range of materials (stainless steel, glass-reinforced plastic, epoxy-coated or galvanised high-yield steel) and can be grout or resin bonded. In addition, dowels are passive installations relying primarily on the shear-strength characteristics of the bar being used. They are often installed into small diameter drill-holes and resin bonded.

Ground conditions will determine the method of drilling and the need for any additional ground improvement or grouting to ensure the integrity of the anchor bond.

87.3.3 Surface protection

Often the stability of a rock face can be compromised by the effects of ongoing weathering, particularly where the rock mass is weak or fissile. Protection of the face can be afforded by the provision of 'soft' or 'hard' facing systems.

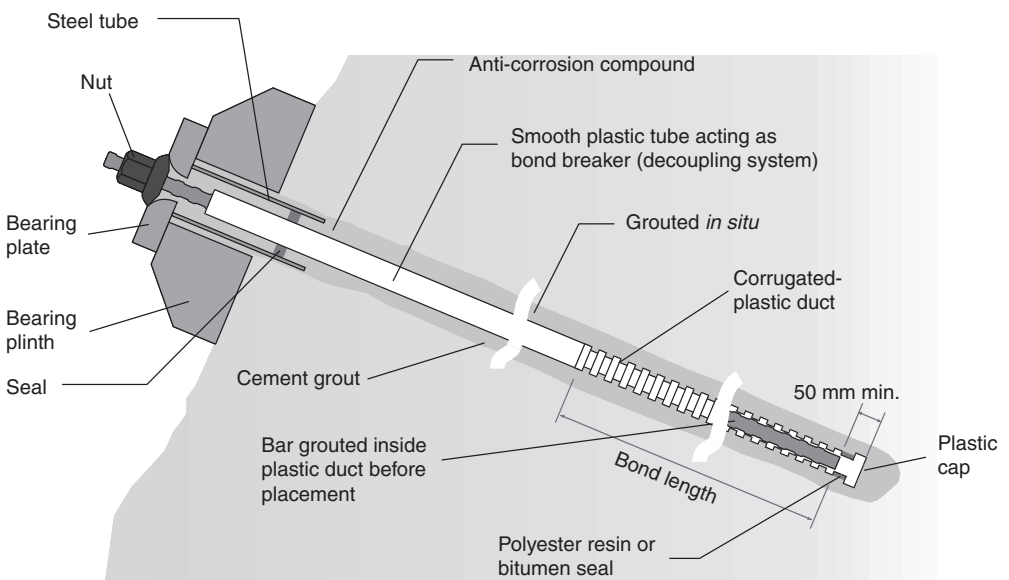

Figure 87.7 Ground anchor detail
© CAN Geotechnical Ltd

Soft facing systems typically comprise rockfall netting, which can be tensioned using an array of pre-installed rock bolts. The rock bolts are installed within surface hollows so that the netting will be tight against the rock face. This method of installation may, therefore, be appropriate for the stabilisation of the near surface materials, and can in turn encourage indigenous vegetation to become established. This can provide an aesthetically pleasing finish; however it should also be noted that vegetation may become a maintenance liability.

Hard facing systems typically comprise concrete pneumatically sprayed to suit the profile of the rock face. The concrete can comprise 'wet' or 'dry' mix and may be reinforced with glass fibres or steel staples. The mix can also include pigment in an attempt to complement the rock face. Weepholes or drainage membranes should be provided to alleviate any build-up of groundwater. Careful detailing of the tie-in detail is also required to avoid delamination or spalling of the finished concrete. Sprayed concrete is particularly effective where preferential weathering of a weak bed within the face has resulted in the undercutting of more competent strata above.

87.3.4 Dentition and buttressing

Sprayed concrete can also be installed in conjunction with steel reinforcement (either fixed *in situ* or weldmesh) to provide structural support to the face (see **Figure 87.8**). Care must be taken to remove any loose material from the surface to be treated and depth gauge markers should be used to ensure that the required depth of concrete is applied to both the face and reinforcement.

For larger structures, cast *in situ* buttresses can be constructed. These will typically be tied back into the rock face by ground anchors with the head blocks either concealed within the fabric of the structure or exposed on the front face. Buttresses can be faced with locally won masonry to provide a sympathetic finish.

Crib walls, pier and beam structures and Reno mattresses can also be used to provide toe support or protection of the rock face.

87.3.5 Drainage

The provision of effective drainage is often overlooked for rock faces. Groundwater can be the controlling factor in rock stability, particularly where there are inter-bedded or steeply dipping strata, or where out-dipping clay seams are present. An understanding of the hydrogeological characteristics of the rock mass should, therefore, be obtained if the implementation of an effective drainage regime is being considered as a stabilisation solution.

Adits have long been used for the deep drainage of mines and rock faces. Face drainage such as the installation of inclined drains can also reduce groundwater levels, particularly within cuttings. Cut-off or interceptor drains can be installed behind the crest of the rock face to divert surface run-off away from the rock face. This will reduce potential infiltration of joints and the consequent build-up of pore water pressures behind the face.

Figure 87.9 summarises the typical engineered solutions.

87.3.6 Case study – Camp Bay, Gibraltar

A 15 000 m^3 failure of the former sea cliff above the main beach area in Gibraltar resulted in the multi-phased stabilisation of a 100-m-high rock face. The works comprised the installation of over 250 rock anchors. Typically, these were 100 tonne, multi-strand rock anchors up to 38 m in length. The fault-brecciated, karstic limestone resulted in the need to pre-grout the drill holes and undertake rigorous testing of all installed anchors. Other

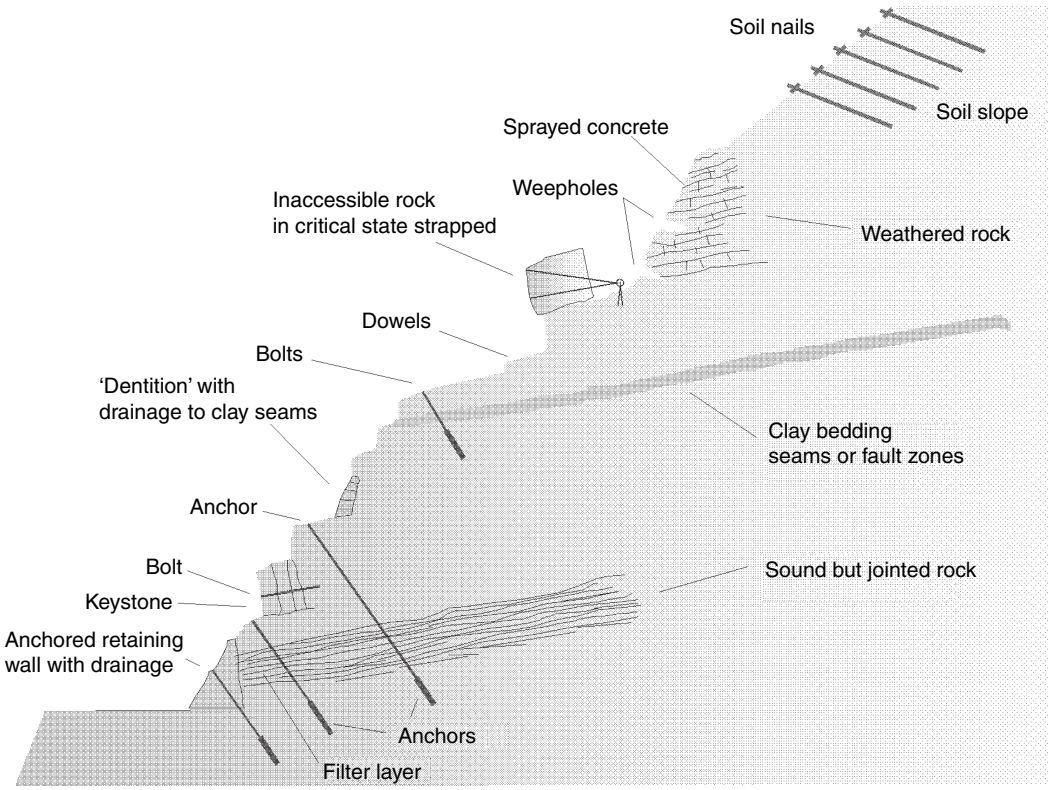

Figure 87.9 Summary of typical engineered solutions
Reproduced from Fookes and Sweeney (1976) © The Geological Society

engineered solutions included the construction of cast *in situ* buttresses, application of sprayed concrete and the installation of rock bolts, dowels and rockfall netting. The works required bespoke drill rigs to facilitate both down-the-hole (DTH) and drifter drilling in sub-vertical locations (see **Figure 87.10**).

87.4 Maintenance requirements

As part of the management of any asset, a maintenance regime should be developed that is specific to the installed stabilisation works. However, in general rock stabilisation works typically require minimal maintenance.

87.4.1 Inspection

It is prudent to instigate a monitoring and inspection regime to ensure that any issues are identified at an early stage. Annual inspections should be undertaken by maintenance staff and comprise a visual inspection from the toe and crest of the rock face. Principal inspections should be undertaken one year following completion of the works and then at three to five year intervals by a geotechnical specialist. These inspections may entail tactile inspection of the rock face and the installed works.

The inspections should identify any significant changes or defects in the face and installed works compared to the as-built photographs and drawings. A written record and appropriate photographs of the inspection and findings should be made and kept in a health and safety or operation and maintenance file.

Figure 87.10 DTH drilling for 100 tonne-capacity multi-strand anchors in Gibraltar
© CAN Geotechnical Ltd

87.4.2 Scaling and rock removal

During a principal inspection, the opportunity should be taken to scale the rock face, removing any rock debris that may have the potential to cause harm to people or infrastructure below.

Rock traps and rockfall netting should be cleared of any arisings to avoid accumulation of rock debris that may damage netting or negate the benefit of the rock ditch.

87.4.3 Vegetation control

Trees and vegetation (including creepers such as ivy) should in general be prevented from becoming established on the face or crest, because roots have detrimental effects on the rock face and vegetation can conceal hazards. Vegetation should be removed and any stumps or roots injected with systemic herbicide.

Where it is desired that vegetation does become established, there needs to be careful consideration of the aspect and drainage of the rock face. Only very shallow-rooted and drought-tolerant species should be promoted.

Shrubs (particularly prickly species such as hawthorn and blackthorn) should be encouraged at the toe of the face as they will deter access to the toe of the face and also act as a catch system for any spalling debris weathering from the face.

87.4.4 Stabilisation works

The maintenance regime should be bespoke to the works installed, with a checklist to ensure a systematic record of repairs is kept. The list below is generic covering typical areas of maintenance only and is not intended for site use:

- Catch fences and rockfall netting should be inspected for signs of impact damage to posts, fraying of cables or damage to the netting.
- Ground anchors should be inspected for signs of corrosion and the tightness of anchor nuts and plates checked. Anchor caps, if installed, should be re-greased and new gaskets fitted. Periodic lift-off tests should also be undertaken on anchors to monitor the residual load applied.
- Condition of sprayed concrete should be monitored so that any damage (concrete spalling or cracking) can be repaired.
- Inclined drains should be flushed and weepholes rodded to ensure that they are free flowing.

Soil nailing is now an established method of providing efficient slope stabilisation and structural retaining wall stability. Soil nails are utilised on a wide range of slope geometries and in variable ground conditions; this has resulted in the development of a variety of innovative materials and construction methods.

The technique involves the installation of a reinforcement bar within a drilled hole which can be grouted before, during or after the reinforcement is inserted. The soil nails are usually arranged on regular grid spacing depending on ground conditions and slope geometry. The surface of the slope is also usually covered with either a hard or flexible facing with a head plate being fixed to the nail reinforcement and bearing on the facing. Soil nail projects also involve the excavation or preparation of the slope face, construction of crest and toe drainage. Quality control includes the load testing of nails.

88.1 Introduction

The soil nail technique may be used to improve the stability of a recently cut slope, an existing unstable slope subject to landslips or a retaining wall formed before or during the excavation process. Soil nails are installed within the soil of the slope providing reinforcement to resist destabilising forces. This chapter outlines the various stages and methods which are required in order to construct a soil nail scheme. The design of soil nails is covered in Chapter 74 *Design of soil nails*.

Detailed planning of the scheme is required to ensure a safe and economical site and construction sequence is established using the appropriate plant. Following the provision of suitable access, the slope needs to be carefully prepared before the nails are installed. Soil nails consist of slender reinforced elements, usually steel bars, and cement grout which are installed on a regular grid within the slope. There are various techniques available for the drilling of the nails, placing of reinforcement and grouting which depend on slope geometry, access and ground conditions. The slope to be treated generally requires a surface facing medium to be placed and the construction of drainage for which there are also several possible solutions. The load testing of the soil nails forms part of the quality control and design verification and requires careful on-site practice.

CIRIA have published a comprehensive report, *Soil Nailing: Best Practice Guidance* (C637) (Phear *et al.*, 2005), which provides detailed information on the design, construction, testing and maintenance of soil nailed walls and slopes and can be read in conjunction with this chapter.

88.2 Planning

88.2.1 Health and safety

Soil nailed slopes tend to have all the ingredients for a hazardous activity: working at height, slippery slopes, manual handling, haul roads close to the face and rotating drill strings. It is essential that the planning phase considers all the concurrent activities and how they impact on one another. Invariably, several different trades are involved and so coordination is required.

On new slopes it is typical for the site/haul road to pass along the face of the works. The drilling rig, and any mobile elevated working platforms (MEWPs), will be positioned close to passing site traffic with potential for clashes. On road widening schemes this is exacerbated by public traffic alongside generating noise and distractions. Adequate separation and management of site traffic is required and personnel must be segregated from the movements as much as possible.

Cut slopes will vary widely but often present wet slippery surfaces that lie between 30 and 60 degrees from horizontal. These are sources of considerable risk if access to nail positions and the crest are not planned adequately. There may be several phases of access required to any one part of the slope. If the slope is excavated in a top-down manner access is required near the crest to install the top row of nails and again at intermediate rows, etc. Then to test sample nails access may be required at random. To fit the facing access will be required from behind/above the crest, down the face and finally, to fit the face plates and tighten them up access will again be required. On each occasion the means of access, the slope surface and the type of work changes. Preparation is vital to ensure these activities are well managed.

One good solution to provide efficient safe access is to use the soil nailing machine to place anchorage points along the crest to which a wire rope can be strung. The operatives can then attach themselves to this with fall-arrest lanyards. Possibly the most overlooked risk is of personnel slipping down the cut face and impaling on the protruding nails.

Where existing faces are to be strengthened or oversteepened similar risks are likely to be present but less severe. Nevertheless, each activity needs to be considered.

88.2.2 Access

Soil nailing is usually best suited to a sequence of tasks from one end of the slope to the other. Consequently, access along the slope should be continuous and have regard for the constraints (if any) imposed by the designers. For instance, it may only be permissible to excavate for one row of nails at a time, which requires a considerable length of site accessible for one shift of work. To allow for curing and the next level of excavation up to three days' production may need to be available along the length of the slope. Therefore, the sequencing, access and deliveries need to be considered to allow efficient working.

Access up the face of the slope is typically achieved using MEWPs. These are currently available with up to 23 m reach and have become the standard tool where the benches are deep or to gain access for the 'finishing' activities once the slope is cut (**Figure 88.1**).

In the case of a high slope where benches are not being cut it may be necessary to resort to specialist drilling equipment that can access the face from the toe. An extreme example is shown in **Figure 88.2**.

Consideration must be given to the means of access for fitting plates, meshing or similar surface covering and testing. Modern test frames need to be located on the slope surface with independent reference beams and access for the technician. The selection of the location of load test and access to it should be planned early. See section 88.9.

88.2.3 Rig types

There are numerous types of rig that can be used for soil nailing, which include:

- tracked hydraulic drilling/mini-piling machines;
- excavator-based drill masts;
- telehandler mounted drill masts;
- hand-held drills;
- air-powered drills – sometimes used with rope access systems.

Provided a hole can be formed that is suitably accurate and straight any drilling machine that can reach will do. Holes can be drilled with purely rotary methods (tri-cone rollers, drag bits or similar) or augered. Where harder ground is encountered percussion is frequently used where the impact energy and a flushing medium are used to penetrate. This is the most common style of drilling for self-drilled hollow bars.

The decisions on type of drilling and type of reinforcement are linked and are sensitive to cost and programme. Occasionally access constraints will also determine the selection. The relatively high cost of self-drilling hollow bars has to outweigh the cost of installing solid bars in pre-drilled holes. With the former, the hole is drilled with the bar that will form the soil nail. On reaching depth it is left in the hole and grouted. Therefore, the speed at which these holes can be drilled is high – typically 180 to 220 linear metres per shift. In the case where the hole is pre-drilled the drilling tools have to reach depth and then be removed before the reinforcing bar is positioned. The extra time is the key factor but the stability of the hole can present a risk. All of the above will influence the choice of drill rigs and equipment.

88.2.4 Working platforms

The working surfaces for new slopes in cuttings tend to be the most difficult to manage. Because the benches cut to provide access to the soil nail entry positions are also the working platforms for the rigs – and are temporary – they can be a source of problems. Trafficking and uncontrolled surface water will soon cause deterioration that poses risks and can adversely affect the quality of the product.

The activities of other trades near the slope have to be allowed for in terms of access and impact on the slope. For instance,

Figure 88.1 Example of long reach personnel access

Figure 88.2 Example of long reach personnel access

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

if the temporary slope is only stable over a specific height the excavation of a trench along the toe to provide for services would not be acceptable. It is quite common for communications cables and drainage to run parallel to the toe of the slope and also for gantry positions to require special consideration.

88.2.5 Sequencing

This issue has been referred to above with regard to safety considerations. Each project will need to be considered separately as there are no 'fixed' approaches. When there are repeat visits to a section of slope it can protract the period before the slope is completed. This is particularly true for slopes where the nail installation is followed by acceptance testing, mesh, soil retention geofabrics, topsoiling and then final geofabric covering. In such circumstances the overall stability of the slope and the risk of surface erosion need to be considered. A temporary cover may be beneficial but is obviously extra work.

The application of a mesh, where required, on the surface is a key step. The mesh has to be in place before the nail heads are fitted so therefore, the period between the nails being drilled and the mesh placed can be a 'hold point' preventing further benching.

88.2.6 Spoil/drill arisings

There tends to be little spoil from the drilling of soil nails unless formed in soft clays. Typically bores will be 100–150 mm in diameter and so produce a small volume of waste.

When liquid flush is used to drill the holes there can be a continuous flow from the top of the hole and that requires control and disposal or recycling. In some cases that flush will be grout but frequently it is water. Either way, the final grouting of the hole will cause overspill and so needs to be cleaned off the slope. Such waste needs to be segregated as it is not inert.

88.2.7 Environmental considerations

Most soil nail applications are carried out on slopes with freshly cut faces. Vegetation clearance and reptile control would normally all be in place in advance. Some slopes though may need enhanced stabilisation and so trees, shrubs and surface vegetation remain. Each case needs to be considered on merit to minimise environmental impact and consideration should be given to the aesthetics of the end product.

The issue of spoil from the drilling and grouting is described in section 88.2.6 above.

Some fibrous geofabrics – coir matting in particular – are easily set alight. This can be accidental, deliberate vandalism or inadvertent when cutting the protruding bars from the finished slope. In hot dry periods this has to be considered as it will result in damage to the other facing materials.

88.2.8 Pre-construction approvals

The nature of soil nailing projects means that often any preliminary test is difficult. This may be because the access is not available, the slope can't be cut or even the site is not available. However, the nature of this type of work means that early agreement as to the size, length and construction method is a significant advantage that will avoid delays and aborted work when the main phase starts.

Refer to section 88.10.1 for details of preliminary testing.

88.3 Slope/site preparation

The site access roads, working platform and slope face should be planned in consultation with the soil nail contractor and designer and then constructed and maintained to provide a safe and efficient site for the installation of soil nails.

88.3.1 Topographic accuracy

An accurate topographic survey will be required for both the soil nail designer, setting out engineer and for the soil nail and facing installation contractor. The survey should detail both the overall slope geometry and any localised variations as these can affect nail design, spacing, the setting out and difficulties in placing head facing materials.

88.3.2 Haul roads/platforms

Haul roads to the site should be designed and prepared to allow the safe passage to and from the slope for all the relevant plant that is required to excavate the slope and install the soil nails. The haul roads may have to be frequently moved due to the excavation and construction sequences.

Working platforms should be designed and constructed to ensure the safe operation of the rigs during nail installation. Soil nail rigs can vary in weight from 4 tonnes to 40 tonnes for long-reach machines. It is therefore recommended that platforms are designed, constructed and maintained in line with BR470 *Working Platforms for Tracked Plant* guidelines (Skinner, 2004). The working platforms should be placed to ensure that the rigs provided can reach all the soil nail positions and allow access for nail testing.

Soil nails can also be installed using rope access techniques where the slope topography and access dictates. Consultation with at least one of the several specialist companies that undertake this type of work is recommended during the planning phase.

88.3.3 Slope surface preparation

The method of slope surface preparation depends on whether or not the slope is to be excavated and cut to a steeper angle or whether the existing slope is just to be soil nailed at its existing angle.

Where an existing slope is heavily vegetated and impedes the safe and efficient installation of the soil nails and slope facing, the vegetation should be removed. It should be noted that on some slopes the vegetation is providing a beneficial effect on the stability of the slope and consideration should be given to ensure its removal will not cause instability.

Following removal of the vegetation the slope should be reinstated to provide a uniform surface suitable for the placing

of the facing and head plates. Excavated slopes should be cut as uniformly as possible in order to reduce problems with the placing of facing and head plates. Any very loose material or surface anomalies should be removed.

Guidelines for the excavation tolerances of the slope surface are available and given in CIRIA Report C637 (Phear *et al.*, 2005).

88.3.4 Setting out

Sufficient data for the level and position of the soil nail heads, angle and length of the soil nails should be provided by the soil nail designer to enable accurate setting out and construction. The entry position of the soil nail should be marked accurately using a steel pin in the slope. The slope topography can vary significantly compared to the theoretical design profile: in these cases the setting out of the nails can be difficult and the designer should be consulted to ensure any variations satisfy the design requirements.

88.3.5 Services/land drains

A full survey to establish the existence of services and land drains should be undertaken before the commencement of the works. This is to ensure both the safety of personnel and that the services or drains are not damaged during excavation, drilling or filled with grout up during the works.

88.4 Drilling

The tolerances for setting up and drilling soil nail bores is set out in *Soil Nailing: Best Practice Guidance*, Section 10.6 (Phear *et al.*, 2005). Recommendations given there are summarised below:

- slope face angle deviation = ±2.5°;
- localised tolerance of the slope face = +150 mm/−300 mm;
- positional tolerance at the installation ground surface: ±100 mm horizontally and vertically;
- orientation at the head of the completed soil nail: ±5°;
- orientation of the soil nail along its length: ±2°.

Care is needed in applying these tolerances. Unduly stringent demands can significantly affect the costs and programme but do not provide any benefits to the client. For instance, the accuracy of the cut face in a new slope may not need to be so tightly specified if the design is not too sensitive to local variation and the nail head plate/washer assembly is designed to cope with some variability. Conversely, if a flat sprayed concrete finish is required a variation in the face of up to 450 mm would consume a lot of material. What is essential is that each aspect is considered in the context of the project and specified accordingly.

Aligned to the issue of setting up rigs is the risk of deflection. Thin self-drill bars can readily be deflected on boulders or tree roots and so may not be appropriate if such a deflection were to endanger services or other features. Casings or stiffer bars would have to be used to mitigate the risk.

88.4.1 Open holes (unsupported)

In stable clayey soils, weak rock or similar the bores can usually be formed by drilling rotary techniques or augers. The hole would be drilled to depth, cleaned out and the drill string withdrawn. The bar can then be placed in the hole with requisite centralisers and couplers and finally the hole grouted to the top (see C637, Section 4.0). Alternatively, the bore can be filled with grout first and the bar plunged into it. This is the preferred method if there is any risk of instability.

88.4.2 Cased holes (temporarily supported)

Casing is often used where there is a risk of unstable ground interfering with the installation of the reinforcement (and occasionally where extra accuracy is required). The casing is advanced to the required depth which may only be part way down the hole. The bore is drilled to depth and then the installation of the steel is undertaken as described above. However, the casing then needs to be removed using the drill rig and so productivity is adversely effected. In this instance it would be preferable to grout the bore, remove the casing and thereby release the rig to drill another hole while installing the steel bar.

88.4.3 Drilling with fluids

Some ground will lend itself to drilling using a fluid to support the bore instead of using a casing. The fluid supports the bore's sides but also clears the arisings by flushing them to the surface. The choice of fluid is usually either neat grout or water. Occasionally a polymer may be added. Whatever the fluid it must not be detrimental to the bond of the grout to the ground. That applies equally to some clay soils. If flushed with water they can cause smearing to the sides and prevent a good bond.

88.4.4 Self-drill hollow bars

Usually drilled with grout or water flush the hollow bars form the reinforcement as well as the drill tool. Each bar is drilled into the hole and the subsequent bar added using an external coupler. Drill bits can be attached to cater for a variety of soil types and are available in different diameters. The bar diameter and wall thickness (therefore torsion capacity) limits the size of bit that can be used in any one ground condition. On reaching depth the drill string should be surged up and down the hole a few times to ensure a clear bore. The drill bit is sacrificial in this operation which can prove a costly element, especially in hard ground where tungsten-tipped bits are required.

88.5 Placing the soil nail reinforcement

The essential element for a soil nail is the reinforcing bar. It provides the tension capacity in the ground by countering the strain along its length and by resisting the loads on the head plates. To do this over the design life the grout/bar/soil bond must be effective and the bar must survive any corrosion.

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The head plate and the connection details must be equally resilient.

It is essential that the bore is clean and free of debris and water. The grout, however placed, must form a constant column in the ground completely surrounding the bar. It is not actually critical that the bar lie on the axis of the bore but it must be surrounded by a sufficient thickness of good grout to provide a bond to the soil and in most cases corrosion protection. For example, a plain bar will have been designed to have a thick grout cover (40 mm or so), whereas galvanised or stainless steel nails may not rely at all on the grout for corrosion protection. They still need the bond provided by the grout but not its protection. Refer to Chapter 74 *Design of soil nails*, on design.

Given the variables described above judgement can be made on which elements of the quality are critical and which are not. If it is essential to maintain the bar on the axis of the hole adequate centralisers must be provided at appropriate intervals. In the case of self-drilled hollow bars it can be difficult to achieve a consistent result due to the methods normally used. A series of radial splines arranged around a circular collar are typically used at each coupling. These are loose fitting and allow the bar to rotate inside the collar. When drilling down the centralisers are pushed up against the coupler. However, on completion of the drilling any surging of the bar to flush the hole or any particularly soft areas may allow the centralisers to move and or dig in thus compromising the grout cover. Consequently consideration needs to be given to the finished product and whether the method of installation is entirely appropriate.

Where bars are not self-drilled the centralising can be more controlled and is generally more reliable.

In the event that bars have been specifically coated for their durability care must be taken not to damage that protection system during installation.

88.6 Grouting

In almost all cases soil nails are grouted with a conventional neat Portland cement. The characteristic strength rarely needs to exceed a UCS of 30 N/mm^2 because soil nails are usually used in weak ground. The composition can vary but a water/cement ratio between 0.4 and 0.5 is commonly used for the final article. Frequently though, while drilling, a 'lighter' grout mix will be used to support the bores and flush the arisings effectively.

In particularly aggressive ground other cement types may need to be considered.

The mixing of the grout is important. A properly blended grout needs to be mixed in a high-shear mixer for about three minutes before use. Other types of mixer, such as those that mix dry cement immediately before pumping, must be verified before use to ensure thorough blending is achieved. This can be done by passing the mix over a fine mesh filter and looking for 'lumps' of dry cement.

Bleed, the loss of excess water, has the potential to be a significant problem. When grout bleeds the particles of cement settle, the free water separates and there is a loss of volume. The problem is not at the surface where the effects can be seen (column of grout recedes and may crack on the surface) but below ground where the effects cannot be seen. The results of excessive bleed will include the loss of grout cover, deterioration of its durability and at worst loss of cross-section. Regular bleed testing should be an integral part of the quality control on a project.

The portion of the hole immediately behind the head plate is often the main cause of concern. The grout may settle or shrink at the face while curing. This can be due to bleed as described but also filtration into the host ground. The grout surface is usually sub-horizontal in its liquid form and so a separate operation is required to top up the grout to form a surface parallel with the ground surface (see **Figure 88.3**). In this location the plate and grout need to be in close contact and the bar must be adequately protected against near-surface moisture that would readily corrode an unprotected bar. Obviously, as discussed above, the degree to which this issue becomes critical depends on the environment, the protection system and the design life.

88.7 Completion/finishing

The issue of the final preparation of the grout column near the surface has been covered above.

The head plates form an integral part of the soil nail and so need to be placed and positioned properly to work well. There are few problems with plates (provided the protection is not compromised) but frequently the slope surface is not trimmed well enough to permit a flush fitting of the plates. This is particularly true where weak rock or mixed ground cause an uneven surface to be cut. In such instances the plate is only in partial contact and may put the bar into bending. Hemispherical nuts and tapered washers can provide some flexibility but it is limited. Where necessary the face should be levelled after trimming and patched to provide a suitable bearing surface for the

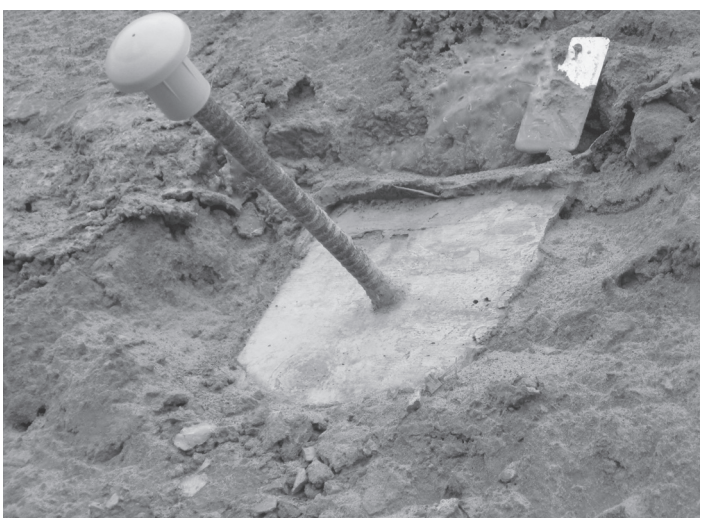

Figure 88.3 Finished grout around a plain solid bar nail

plates. In the worst cases this could require small shutters to hold grout on the slope.

88.8 Slope facing

Slope facing is required to provide resistance to any localised failure or ravelling between the soil nails and also to provide additional bearing support for the nail head plates. In addition slope facing can provide topsoil retention and promote vegetation growth. The slope facing should be specified by the soil nail designer. Various types of facing and methods of installation are available and are dependent on the site topography and design requirements.

88.8.1 Types

The three main categories of slope facing are:

- **Flexible structural facings** – These generally comprise of a metallic mesh which may be coated for corrosion protection and also may incorporate fibrous matting to assist in the growth of vegetation (see **Figure 88.4**).
- **Hard structural facings** – Hard facings comprise reinforced concrete which can be formed using pre-cast panels or more often utilising the sprayed concrete method into which the soil nail heads are embedded or fixed on the external face (**Figure 88.5**). Hard facings may also be adopted to prevent soil erosion or for purely aesthetic reasons. These may consist of solutions such as timber crib walls or stone-filled gabion-like baskets.
- **Soft facings** – The most common forms of soft facings are coir mats or geotextiles which promote the growth of vegetation and help to prevent soil erosion. In addition, the use of cellular topsoil retention facings is becoming frequent as they have the aesthetic benefit of completely covering the nail head plates and providing a good depth of topsoil to promote vegetation.

88.8.2 Installation and joining details

88.8.2.1 Flexible structural facings

The most widely used flexible structural facings consist of a coated wire mesh. The mesh is placed following the installation of the soil nail bar reinforcement and grouting. The mesh is usually supplied rolled and is installed in a top-down sequence. It should be initially fixed at the crest of the slope above the top row of nails and then rolled vertically down the slope. The mesh is fixed to the slope using galvanised hooked pins at regular grid spacings. At the top of the slope it is good practice to provide sufficient facing so it can be anchored above the crest of the slope. The spacing of the pins and pin length (400 to 600 mm long) should be specified by the designer or specialist contractor and will depend on slope geometry and soil conditions in the near surface and are installed by hand. The soil nail head plates will then be placed over the mesh on to the nail reinforcement and secured by a locking nut. This helps to fix the mesh.

Where the slope is to be cut top-down in staged excavations it may be necessary to install the facing in the same sequence

(a)

(b)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

also leaving the roll of mesh securely fastened above the next row of nails to be installed.

At joints to adjacent strips of mesh a suitable overlap should be provided and the meshes joined using ties or clips to provide a structural join.

The use of MEWPs can simplify the procedure and provide a safe access platform for the personnel installing the meshing and head plates (see **Figure 88.1**)

88.8.2.2 Sprayed concrete

Sprayed concrete involves the placing of fresh concrete on a slope surface using a high-pressure spraying technique. The slope surface is first cut to the required angle and this should be cut as accurately as possible as filling voids with sprayed concrete can be uneconomical. Following installation of the soil nails the facing material, usually steel mesh, is placed against the slope surface ensuring spacers are placed at sufficient intervals to provide the required cover. The soil nail head plates can be installed before or after the sprayed concrete is placed depending on whether they are to be incorporated into the concrete or left exposed on the surface.

Concrete is then sprayed onto the surface around and through the reinforcement and head plates (**Figure 88.6**). Depending on the thickness of the concrete facing specified this can be done in one or more layers. Sprayed concrete can either be placed using wet or dry mix methods. It is recommended that a specialist sprayed concrete contractor is consulted during both the design and planning stages to ensure a practical solution is specified.

Sprayed concrete is generally used on steeper or even vertical cuttings (**Figure 88.5**). The stability of the slope is therefore often more critical and the sequencing of the excavation, nailing and sprayed concrete should therefore be given careful consideration. It may be necessary to cut the slope in discrete panels on a hit and miss basis and install the soil nails and sprayed concrete before excavating the adjacent section. In this case an allowance for the lapping of the sprayed concrete reinforcement should also be made.

88.8.2.3 Facings

Various facings can be installed in conjunction with soil nails including timber crib walls, modular blocks and gabion basket facings and these will be constructed following the completion of the excavation and soil nails. The facing is normally connected to the soil nails and is installed from the base of the slope. Specialist suppliers and contractors will provide facing materials, guidance on installation and design and if required full construction for these types of facings (**Figure 88.7a** and **88.7b**)

Figure 88.6 Applying sprayed concrete to vertical face (note the double mesh and drainage holes)

(a)

(b)

Courtesy of Phi Group

88.8.2.4 Soft facings

Soft facings are installed in a similar manner to the flexible facings as described in section 88.8.2.1.

88.8.3 Soil retention systems

Cellular soil retention systems are installed following the completion of the soil nail head plates and may be placed over flexible structural facings. They are fixed to the slope using steel pins in a similar fashion to the facing (**Figure 88.8**). Alternatively a narrow steel mesh cage, or soil panel, can be used to contain the topsoil. Topsoil can then be placed by normal excavators before *hydro seeding*.

88.8.4 Vegetation: hydro seeding

Hydro seeding (the placement of a seeded solution by spraying) is generally carried out by specialist landscaping companies. This operation should be carried out following the placing of all the slope facings and topsoil if required.

88.9 Drainage

The stability of a slope is usually highly dependent on the groundwater levels within the slope strata and it is therefore essential that any drainage systems specified are constructed properly to ensure they are fully operational.

88.9.1 Crest and toe drainage

If crest or toe drainage channels or trenches are specified they are usually installed using standard excavation and drainage methods. There are, however, increased risks working above and below a slope whilst excavating and precautions should be taken to ensure the slope stability is not compromised.

88.9.2 Slope surface drainage

For most soil nail schemes the slope surface drainage occurs naturally through any meshing and vegetation. Where an impermeable hard facing such as sprayed concrete is specified drainage measures can consist of weep holes and/or a drainage fabric placed between the facing and soil on the slope. Weep holes can be formed using plastic pipe and a filter membrane and fixed to the mesh before sprayed concrete is placed. Weep holes can also be drilled through the sprayed concrete after it has been constructed and hardened.

The drainage fabric should be placed and pinned to the slope surface before the placing of any mesh reinforcement and sprayed concrete.

88.9.3 Horizontal or subsurface drainage

The design of the slope may also require the installation of horizontal drains which can assist in the control of groundwater pressures. The drains usually consist of a slotted uPVC pipe with a geotextile membrane which is placed inside a pre-drilled bore. The drains should be inclined 5° to 10° upward to allow the water to drain to the slope face. The drains can be installed by the same rigs and personnel as the soil nails especially for cut slopes where the excavation is undertaken in stages (**Figure 88.9**).

A recent innovation by Ischebeck™ involves the use of a horizontal drain installed using self-drilling hollow techniques and a permeable grout mix.

88.10 Testing

Soil nail performance can be affected by variations in ground conditions and soil nail installation methods. Soil nail testing is therefore required to verify that the nail–grout–ground interaction performance is in accordance with the design assumptions.

88.10.1 Preliminary and acceptance testing

The type, frequency, location and loading schedule of the load test should be specified by the soil nail designer (see Chapter 74 *Design of soil nails*). Guidance on this can also be found in Section 11.3 of CIRIA 637.

Preliminary soil nail tests are carried out in advance of the main works usually on sacrificial nails installed using the same technique as the proposed working test nails. Depending on the site conditions and topography it may be necessary and more efficient to undertake vertical nail tests which can still demonstrate the nail–ground bond in the same strata as the working nails.

Acceptance or working nail tests are undertaken on production or working nails which form part of the permanent works. These tests are carried out during or after the main working nails are installed using similar testing methods as for the preliminary nails.

88.10.2 Reaction system

A suitable reaction frame should be provided to transfer the stressing loads into the slope or ground adjacent to the nail. The actual detail of the reaction frame will depend on the slope topography, ground conditions and test load to be applied. These should be considered carefully for each project. A typical beam test set up is shown in **Figure 88.10**.

The reaction system design should take into account the test load and condition of the slope surface. It is essential to ensure the reaction system is safely secured to the slope.

88.10.3 Monitoring

The extension of the soil nail during the load test should be accurately monitored. The actual method of measuring the extension will vary depending on the load test location and the topography of the slope (**Figure 88.11**). Ideally a displacement (dial) gauge or transducer should be placed on the exposed soil nail bar end and supported on a frame which is not subject to movement from the stressing operation or other factors (see **Figure 88.11**).

The stressing load should be measured using a calibrated pressure gauge connected to the jack.

88.10.4 Free length formation

The designer may specify that the soil nail to be tested should be de-bonded over part of its upper length in order to prove the nail capacity in a certain strata or level in the resistant zone. The de-bonding can be carried out using a plastic sheathing between couplers which should be sealed against grout intrusion.

88.10.5 Approvals

For preliminary tests sufficient time must be allowed in the construction programme for the contractor and nail designer to be able to review the soil nail testing and make any required changes to the design before the main works commence. The working test results should be reported, reviewed and approved as soon as practically possible after the tests so any consequential actions can be implemented minimising possible delays and costs.

Chapter 89

Ground anchors construction

John Judge Tata Steel Projects, York, UK

Ground anchors are an important geotechnical component in the resisting of destabilising forces in structures and slopes. The construction process is of fundamental importance in the performance of the ground anchors and the industry offers many contractor-designed systems. The history and experience of anchoring contractors is critical in terms of the use of drilling and grouting systems and their effect on the surrounding ground conditions. The long-term corrosion resistance of the anchor system is important, together with the long-term monitoring and maintenance of the anchor heads.

89.1 Introduction

Ground anchors are tensile members that allow load transfer from a structural face to a discrete zone of ground. The particular ground where the load transfer is carried has been previously examined and defined through good ground investigation and survey works, and targeted as part of the preliminary anchor design process. This transfer of load to a particular stratum of ground makes the ground anchor approach different from systems such as the rock bolt, soil nail and tension micropile (where load is generally carried along the full length of the structural member).

Ground anchors can be installed for loads from 10 kN to in excess of 5000 kN. However the normal range of loads tends to be 100–1000 kN for permanent systems. The ground anchor is commonly used to support retaining structures, resist anti-flotation and earthquake loads, and for slope stability schemes. The ground anchor is also used to improve rock face stability with similar techniques used for soil nail installation (see Chapter 88 *Soil nailing construction*). The design of these systems is closely linked to the construction process, hence good understanding is required between the designer, contractor and specialist anchor contractor when using this system within a project design.

This chapter reviews the following aspects of ground anchors:

- applications of ground anchors;
- types of ground anchors;
- ground anchor tendons;
- construction methods in various ground types: cohesive and granular materials, and weak and strong rock;
- ground anchor testing and long-term maintenance of anchor systems.

89.2 Applications of ground anchors

Ground anchors in the United Kingdom are generally installed based upon the requirements of BS 8081:1989 *Code of Practice for Ground Anchorages* (BSI, 1989). However the BS EN1537: 2000 *Execution of Special Geotechnical Work* (BSI, 2000). *Ground Anchors* also reviews construction practice.

Ground anchors (or anchorages) consist of an anchor head, free anchor length and fixed length (see **Figure 89.1**). Each part requires a detailed design based upon the structure type and the expected ground conditions (see Chapter 66 *Geotechnical design of ground anchors*). The design of the fixed anchor length (bonded length) where the load transfer occurs has a particularly important link to the construction process.

One of the key aspects of ground anchor design is that specialist ground anchorage contractors must be consulted at an early stage to advise on construction issues and how they can influence the proposed design. In addition, where specialist ground anchorage contractors are proposed, the design engineer and main contractor must be satisfied with the experience of the installer. Failure to follow this approach may lead to construction and performance problems with the ground anchors.

The design of fixed lengths is summarised within BS 8081: 1989 (BSI, 1989) and is covered in detail in Chapter 66 *Geotechnical design of ground anchors*, and is based upon the construction process. This is summarised as follows:

Type A anchor	Straight-shafted anchors where uniform bond stress is developed
Type B anchor	Low-pressure grouted anchors where enhancement of the ground strength occurs; increase in diameter of fixed lengths achieved through permeation and compaction of the granular material
Type C anchor	High-pressure grouted anchors (tube à manchette systems) where the ground is hydro-fractured causing grout rooting into the ground
Type D anchor	Under-reamed (or multi-bell) systems where the fixed length drill diameter is enlarged through a system of bells

The construction of the ground anchor involves one or more of the above processes and these are referenced throughout this chapter.

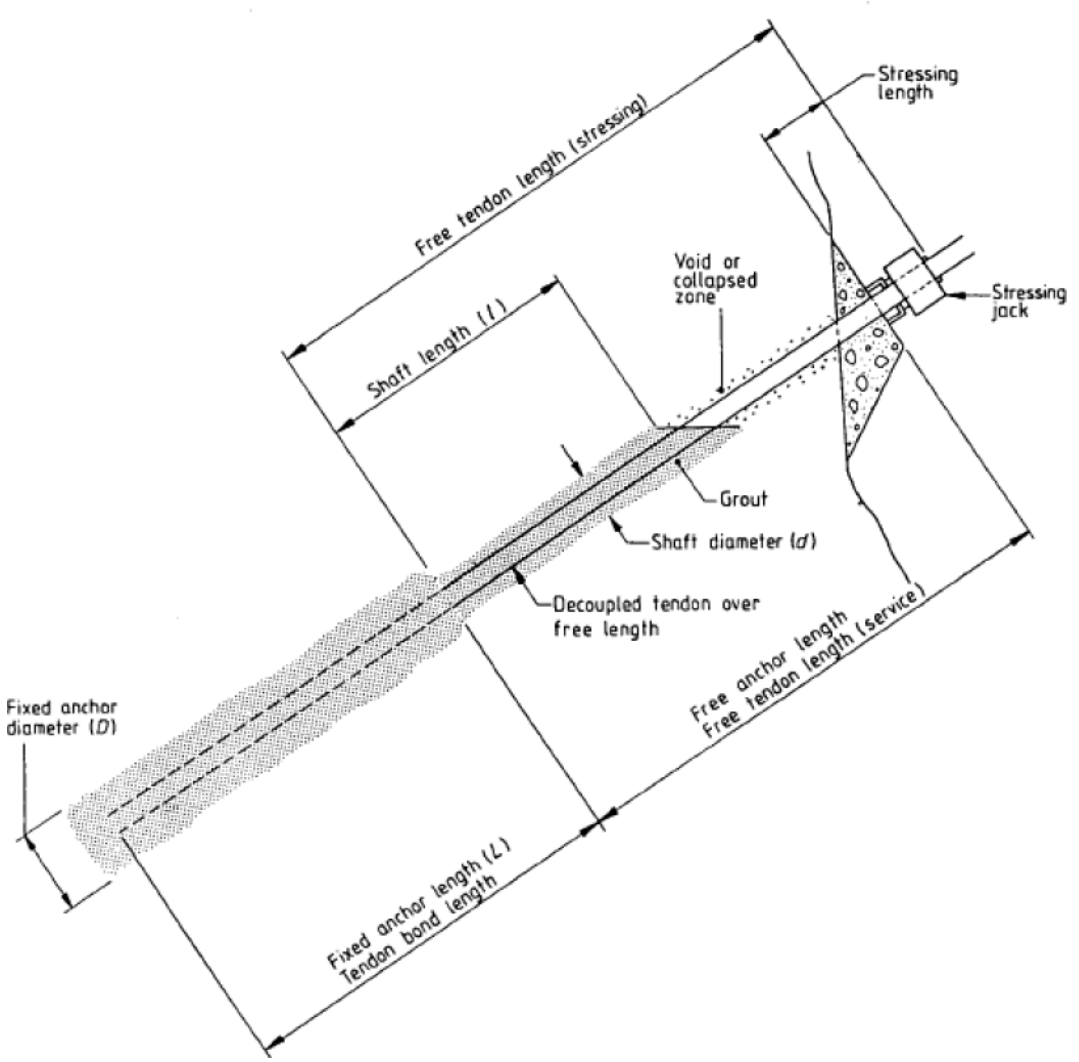

Figure 89.1 Ground anchor nomenclature for a grouted anchor
Reproduced with permission from BS 8081 © British Standards Institution (1989)

89.3 Types of ground anchors

Ground anchors can be divided into either mechanical or grouted-type installations.

89.3.1 Mechanical ground anchors

Mechanical anchors are generally used for low capacity anchors. The resistance is generated by driving in the anchor tendon to depth and forming a load transfer mechanism with a plate system; two examples are the Platipus system (see **Figure 89.2**) and the Duckbill system.

The advantage of these systems is fast installation, no requirement for curing of grout and instant load application. However the design method for these systems is semi-empirical with the load capacity based upon the expected ground conditions and the structural loads required by the designer. These systems are suitable for small-scale installations such as masonry wall repair, foundation anchors and slope support.

However, caution needs to be exercised with these systems as confirmation of acceptance does not conform to BS 8081:1989 (BSI, 1989) in terms of testing and corrosion protection requirements. The use of such systems in permanent works therefore needs careful consideration with regard to the long-term performance and the factor of safety involved. Typical systems are designed for working loads of 10–120 kN; however, it is rare that these are tested to the full three times working load required by Table 2 of BS 8081: 1989 (BSI, 1989). Actual factors of safety on the system would therefore require preliminary tests on site to give confirmation of the levels of safety achieved.

Mechanical anchors are generally driven into the ground to the required length using pneumatic hammer systems. Due to this method of installation, they are particularly susceptible to obstructions within the ground. The key difference with other geotechnical products is that the only section of the ground anchor that can be shortened is the fixed anchor length

(following detailed site trials). The ground anchor must achieve the free length detailed by the designer to maintain overall stability of the structure (see Appendix D of BS 8081:1989; BSI, 1989). Hence, if obstructions are encountered, pre-drilling works may be required to allow installation. Due to these problems, these systems tend to be installed in relatively low strength fine-grained soils of a homogenous nature. It is important that specialist suppliers and installers of these systems are consulted if this method is to be employed.

89.3.2 Drilled and grouted ground anchors

Drilled and grouted ground anchors are generally the most common form of ground anchor installation for large civil engineering projects. These systems allow the designer to use developments in drilling technology as well as specialist grouting techniques. Both these areas of construction have a significant influence on the load carrying capacity of the ground anchor in its final condition (and to achieve the factors of safety required by the Design Codes).

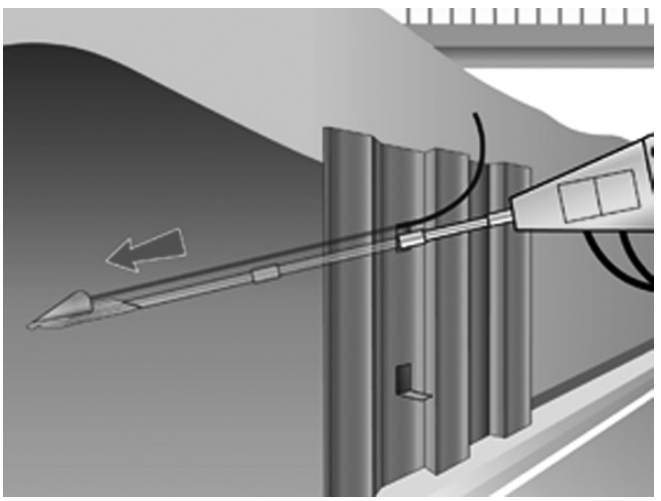

Figure 89.2 Platipus mechanical anchor system
Courtesy of Platipus Anchors Ltd

The drilled and grouted system generally involves the formation of the anchor borehole using the following: open hole drilling techniques, rotary duplex cased systems, rotary percussive cased systems, or down-the-hole hammer systems. Significant variation and overlap of these systems can be used and the type of drilling system generally depends on the type and strength of ground expected over the anchor length. These systems are explored further within this chapter in relation to different types of ground encountered.

On completion of the borehole, an anchor tendon is installed to the base of the borehole and grout introduced using a tremie system. This allows full grouting of the borehole and prevents the occurrence of voids within the anchor bore, which could lead to failure of the anchor. Where temporary casing has been utilised, this is gradually withdrawn whilst continually topping up the grout level.

Based upon the tendon arrangement, and the drilling and grouting methods, a number of ground anchor systems have been provided by specialist contractors and suppliers. Examples of these types of developments are single-bore multiple anchor (SBMA) systems, multi-stage multi-bell/under-reamed ground anchors and tube à manchettes. All these systems allow modification and efficiencies in the load transfer mechanism compared to conventional anchors, and in particular allow high anchor loads to be obtained in poor ground conditions.

89.4 Ground anchor tendons

The anchor tendon generally consists of either a high strength steel bar or woven wire pre-stressing strands (see **Figure 89.3**). The tendon system is factory fabricated to avoid contamination of the units on site. This is especially important with regard to the corrosion protection system (for permanent anchors) and the greasing and free movement over the anchor free length.

Figure 89.3 Factory fabricated double plastic corrosion protected ground anchors
Courtesy of Keller Geotechnique

Figure 89.4 Storage frame
Courtesy of Keller Geotechnique

The factory-fabricated anchor tendon is delivered to site in a secure storage system to allow installation (see **Figure 89.4**). Any corrosion damage to the anchor tendon during transportation or installation could affect its long-term performance.

89.5 Construction methods in various ground types

89.5.1 Construction issues and risks

The key area to consider in ground anchor construction is the effect the installation method will have on the load carrying capacity of the ground anchor. The preference with most ground anchors is to use a construction method that allows formation of the fixed length to the diameter of the borehole. Although enlargement of the fixed length (by techniques such as grout enhancement or under-reaming) is accepted, great control of these processes is required.

Where ground conditions are such that actual grout loss can occur, this can be detrimental to the construction and performance of the ground anchor. Grout loss should be carefully considered within materials such as chalk (where solution features are expected) and Coal Measures (due to past mining activity and fissured bedrock). Methods to deal with this problem include the use of thixotropic grouts or pre-grouting works prior to construction, i.e. a two stage process.

The effect of the flushing medium on the ground and the knock-on effect on the load transfer mechanism can also be detrimental. Careful consideration of the flushing medium and its control is required – not only from a design point of view, but also from an environmental and control perspective. In certain situations, poor control of flushing systems can cause severe effects on adjacent structures and ground types.

Careful consideration is required regarding the tolerances and location of as-built anchors. Ground anchor construction is now routinely used in areas where retaining walls support structures that are supported on piles. The ground anchor system can be designed to pass between piles and be installed at inclinations (both vertical and horizontal) that pass with safe clearance to the deep foundations. Tolerances quoted by BS 8081:1989 (BSI, 1989) are:

- entry point ±75 mm;
- alignment at entry point ±2.5°;
- borehole deviation during construction 1 in 30.

These tolerances are generally achievable, but can often be improved to allow greater control of anchor location. The location of as-built anchors is also important in terms of construction design and management (CDM) requirements, and for future construction works causing disturbance and possible failure of the ground anchors. This has been especially common in the Docklands area of London where new developments utilising piling techniques have had to be carefully monitored in relation to the effect on existing ground anchors to the river walls. Where concern is raised regarding anchor location and possible interference, accurate borehole alignment monitoring techniques can be used as part of the construction works. A precise understanding of the accuracy of these techniques is fundamental in the choice of system and data management.

89.5.2 Construction of fixed anchor lengths within clays

Ground anchor construction in clays should be viewed with some caution, and detailed assessment of strength development with depth should be carefully considered at the design stage. Design of fixed lengths within clay deposits tend to start with the Type A anchor system approach. This is very common within over-consolidated clays such as London Clay, Oxford Clay and Gault Clay found in the southeast of the United Kingdom.

To support loads in excess of 100 kN, the clay needs to be of firm (but heading towards stiff) consistency (BS 5930:1999). Clay strengths less than 75 kN/m^2 should be treated with caution in terms of anchor design and construction, although some success has been achieved in softer soils with membrane expansion-type anchors. The limitations on fixed anchor lengths due to the effect of progressive de-bonding mean that they are generally limited to less than 10 m. This limits the load carrying capacity of the ground anchor, hence the development of the under-reamed system. Littlejohn (1977) details the under-reamed anchor (or multi-bell) system which gives a load carrying capacity of up to five times more.

Even with this increase, under-reamed anchors have limited use outside of the London area. This is due to the requirement of careful quality control of the under-ream and demonstration of good construction. The influence of granular material within clays or low strength clays can cause instability of the bore during construction. However, the system should not be discounted as it has major advantages where issues with land take and boundary constraints on anchor length exist.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

One system that has allowed higher capacities to be achieved with clay deposits is the SBMA system (Barley, 1997). This system allows the fixed length construction to exceed the maximum of 10 m used by single encapsulated lengths, and hence fully utilise the increase in strength with depth of clay deposits. The disadvantage of this system in clays is the large anchor lengths and the effects on boundary constraints. A schematic of the differences between conventional and SBMA fixed length load distribution is shown in **Figure 89.5**. Another similar system is the DYWIDAG (acronym for Dyckerhoff & Widmann AG) multi-stage anchor tendon.

The most common form of anchor construction in clay is the use of auger drilling systems (see **Figure 89.6**) where the drill string helical causes the material to pass to the surface for disposal. This system is quick and allows the borehole to be constructed with minimal use of temporary casing. However, problems can develop where groundwater is encountered within clays, an example being mudstone bands in London Clay. The drilling system does not allow for removal of the water and this can create a slurry which can rapidly reduce the clay strength and grout ground bond stress properties. This can also prevent installation of the ground anchor as the borehole cannot be cleaned to allow anchor tendon installation.

For clays that can contain granular material and possible groundwater, rotary duplex or rotary percussive systems are often employed (see **Figure 89.7**). These are commonly used in the boulder clays and glacial tills encountered within the northeast of the United Kingdom where full length casing can be employed, together with a water flush to maintain stability of the borehole. Water-flushed drilling techniques ensure that a positive hydrostatic head is maintained within the bore which will prevent 'blowing' conditions.

For applications where drilled and grouted anchors do not achieve the required factors of safety on working load

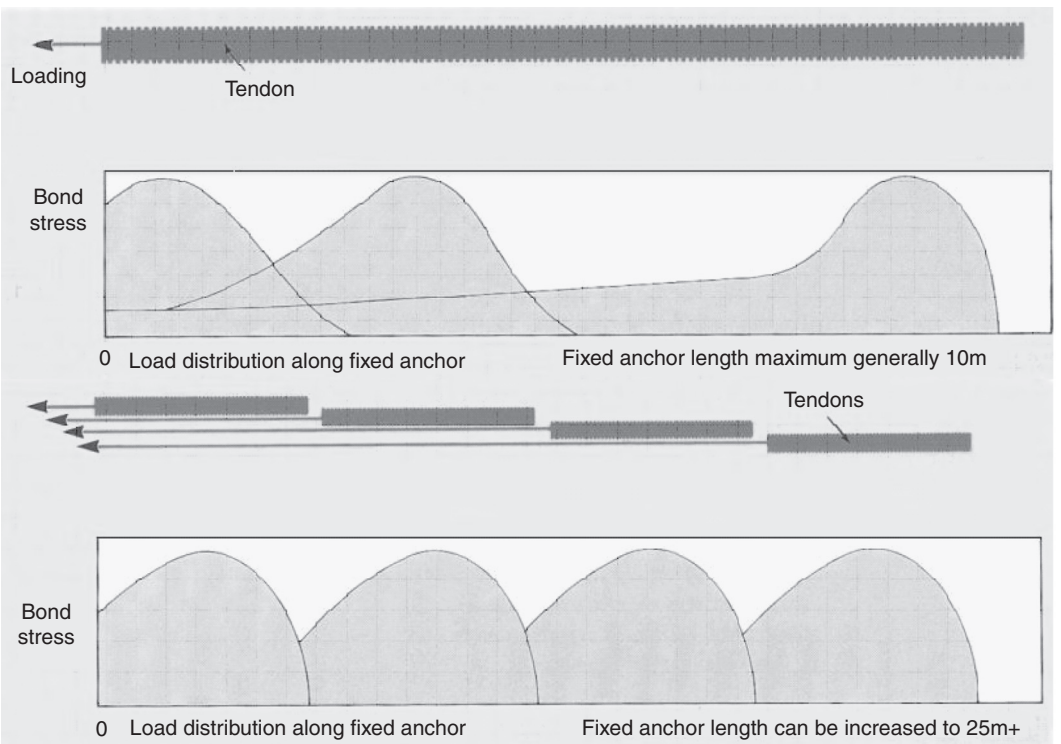

Figure 89.5 Load transfer of conventional and SBMA systems
Courtesy of A. D. Barley/Geoserve Global Ltd

requirements, high pressure grouting techniques have been used. This involves the use of tube à manchette systems with high pressure grouting, using packers. This system can cause hydro-fracture of the clay and allow some grout penetration into the clay (see **Figure 89.8**).

89.5.3 Construction of fixed anchor lengths within sands and gravels

The construction of fixed anchor lengths within sands and gravels are almost all exclusively based upon low pressure grouting techniques (Type B anchors). Low pressure grouting of the high strength grout uses the fully cased system to increase the borehole diameter of fixed lengths through permeation and compaction of the granular material (see **Figure 89.9**). With limitations of fixed lengths of 7–8 m due to progressive de-bonding, permanent anchor loads of 350–450 kN can be achieved within marine sands commonly found within the United Kingdom in coastal areas. However, for coarser deposits which are proven to be predominantly gravels (e.g. terrace gravel), permanent anchor loads of 600–800 kN can be achieved. Utilisation of the SBMA system allows these loads to be exceeded for permanent anchors with working loads of up to 1200 kN – achieved in the Cotton Beds of Great Yarmouth.

The key installation method for ground anchors within granular materials is to have the casing closely follow the drill bit, with a good control on the flush system. The use of water flush is common as this minimises disturbance to the material, and is a safe flushing system in terms of re-circulation (with the use of Siltbuster technology). However, careful monitoring is required to stop 'water jetting' where the soils are loosened and allowed to collapse – creating loose zones. This can cause settlement of the ground surface and affect adjacent structures. The use of air flush is not recommended in granular soils due to the aggressive nature of the flush and the migration of the air through the ground – which again may affect adjacent structures.

Ground anchor construction within alluvial and marine sand deposits generally involve river wall and harbour wall support. Typical installation plant used is illustrated in **Figure 89.10**.

89.5.4 Construction of fixed anchor lengths within chalk

The United Kingdom contains large areas of chalk where major infrastructure works have been carried out. This generally is around the southeast of England, Norwich and Humberside. Anchoring in chalk carries a greater degree of risk compared to other soils due to the high variation in weathering, and the strength and presence of solution-related features (causing excessive grout take).

Barley *et al.* (1992) reviewed works completed at Castle Mall in Norwich where pre-grouting works were carried out using a sand cement grout prior to re-drilling and anchor installation. Grout volumes of three to seven times the theoretical borehole volume were recorded for the test anchors using this technique, due to the existence of solution features. Careful

drilling and pre-grouting is required within the chalk as the use of water flush can trigger ground subsidence from collapse of the solution feature.

Construction methods used within chalk are generally end-of-casing grouting techniques (Type B), utilising rotary duplex or rotary percussive drilling methods. The use of these techniques, the structure of the chalk and the increased grout take cause expansion of the fixed length diameter (see **Figure 89.11**).

89.5.5 Construction of fixed anchor lengths within rock

Ground anchors are commonly associated with rock anchors used within rock cutting support or anti-flotation anchors. The question 'when is a soil classified as a rock?' is very much open to debate, especially in ground anchor construction. This is always a borderline discussion in terms of chalk type, based upon the weathering profile of the material. Ground anchors within the United Kingdom can be sub-divided by its strength and geological history.

Problems of anchor construction within weak bedrock in the United Kingdom generally revolves around mudstones and siltstones such as Coal Measure deposits, Mercia Mudstones and Lias Clay deposits, which tend to cross the country from the Severn Estuary to the north of England. For very weak mudstones, the drilling process can have a major impact on the bond stress properties of the material, hence caution should be taken with regard to over-estimated designs. It is recommended that very weak mudstones are designed based upon a clay soil approach.

Because of the unpredictable nature of weak rocks, the use of water, air or auger drilling techniques should be carefully considered regarding the effect they have on the structure and bond properties of the rock type. Auger drilling can create a smear effect on the ground interface (especially in mudstones) which can rapidly reduce load carrying capacity of the ground anchor. Air flush can cause migration along open fractures and affect adjacent structures. The use of air can also cause disintegration of the bedrock, reducing bond stress properties.

Water flush drilling can cause localised softening, especially where boreholes are left open for a period of time. The use of anchor contractor experience and trial anchor testing are important parts in demonstrating constructability in weak rocks.

One major problem with forming ground anchors within weak, weathered rock, is the inter-bedded nature with stronger, more competent materials. This is especially common with Coal Measures where bands of strong sandstone can be encountered. Also, the Mercia Mudstones can be inter-bedded with strong bands of limestone. The drilling system in these conditions is generally chosen for the strongest element, hence when anchors are formed within these materials, variation in the positioning of the fixed length in the rock type can be a problem. In these materials, careful review of construction methods compared to design is required. Detailed review of testing within mudstones is covered by Barley (1988).

For stronger, more competent bedrock, i.e. igneous deposits in Scotland, Wales and southeast England, limestone, Sherwood Sandstone and metamorphic rocks, down-the-hole hammer systems are generally used to form the anchor boreholes. These systems are efficient because the energy of the drill is directly applied at the drill bit (and not at the drill head, as with rotary percussive drilling). This is especially important in drilling strong rocks as the rate of penetration is quicker than 'top' drive systems.

Down-the-hole hammer systems use air flush to return the drill spoil to the surface, hence the calculation of uplift velocity compared to depth drilled is extremely important. These drilling systems rely on air compressors to have the capacity to return the spoil, so the diameter of hole compared to the rod size needs careful review. If the air gap between the rods and the hole diameter is too great, the returns will not be expelled at the surface and will affect the ground anchor construction. These systems have one key problem compared to water flush systems – control of the spoil is difficult due to the airborne nature of the returns. Head collecting systems or reverse circulation systems can be used to control the material. Symmetrix and MaxBit down-the-hole hammer overburden drilling systems are becoming increasingly popular due to their speed and ability to bore through difficult ground.

Drilling within igneous deposits that have a high quartz content can cause extreme wear on the drill bits, which is accelerated when drilling in rock that contains saline ground water. Careful review of these systems is required. Large high capacity ground anchors are used within dam construction and dock wall remediation where earthquake loading is required; such systems are very common as these structures are often constructed on bedrock (see **Figure 89.12**). High tolerances of construction are required for these structures, and hammer and rod systems can be flexible in their nature (similar to auger drilling). In these situations, the hammer is often connected to a strong casing member over the initial 10 m to give a stiff drill string. Using this method can give a high degree of drilling accuracy and tolerance. These techniques are reviewed in Cavill (1997) and Shields (1997). Centralising rods can also be used, but again, trial drilling and measurement should be carried out to confirm that the tolerances can be achieved as required by the designer.

89.6 Ground anchor testing and maintenance

Ground anchors are probably the most tested component in geotechnical works. Many ground anchors that are installed are active (carry pre-stress load). Some ground anchors are considered passive – where a nominal load is introduced, based upon the use of a torque wrench or jack system. These passive anchors are always bar systems and are often used to resist hydrostatic uplift forces.

Ground anchor testing is covered in some detail by BS 8081:1989 (BSI, 1989) and BS EN 1537:2000 (BSI, 2000) and the reader is directed to these references. The testing regime is covered by preliminary trial anchor tests, on-site acceptance tests and suitability tests. The anchor testing and lock-off is the most important part of the anchor commissioning process. The designer and contractor should make sure any specialist ground anchor contractor has the necessary experience and history of installing ground anchors. Indeed, if there is concern of the contractor's experience, a contract should be let on a preliminary trial anchor program to confirm the contractor's competency and design proposals.

Anchor testing is generally carried out using a mono- or multi-jack system (see **Figure 89.13**), hence proper quality control and calibration certificates for the jacks are of paramount importance. Also, the necessary access is required for the stressing crews in terms of anchor locations and temporary platforms, as the stressing jacks can be large and heavy.

One of the most important areas of ground anchor construction, which is commonly overlooked, is the long-term maintenance of the anchors. These tendons are often critical in terms of the performance of the structure, hence it is important to include a long-term maintenance program for the duration of the design life. Strong evidence exists that long-term anchor failure and/or poor performance is due to problems at the anchor head, hence load checks and visual inspection by an anchor specialist is very important. Some engineers consider the use of load cells for

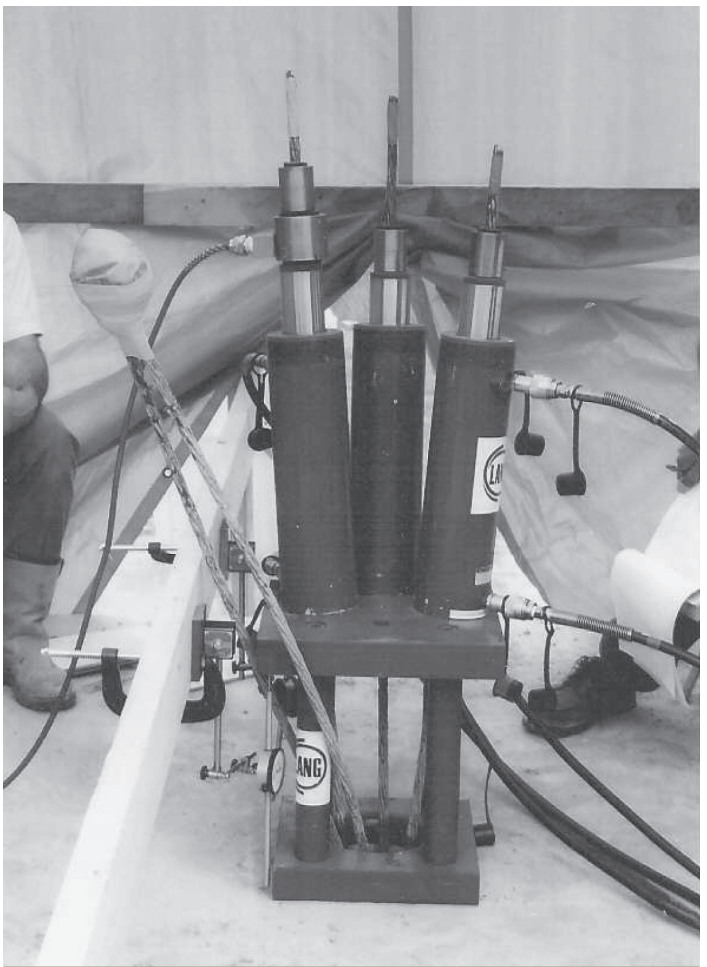

Figure 89.13 Hydraulic multi-jack system for SBMA tendons
Courtesy of A.D. Barley/Geoserve Global Ltd

long-term monitoring (BD90/64) as an option, as remote data collection becomes more popular. However, caution should be exercised as load cells can have long-term performance issues and the use of load cells enlarges the anchor head. Their use does not review the state of the anchor locking system and corrosion protection compound in the anchor head. Therefore a proper anchor maintenance program must be considered when designing and constructing ground anchors.

Grouting and soil mixing are a range of processes that involve the injection of wet or dry materials into the ground to provide improved engineering properties. Common aims are to increase strength or stiffness or to reduce permeability within the mass of ground treated. The simplest process in concept is the permeation of the pore spaces with a fluid grout which then sets, and provides the desired properties. Soilfracture and compaction grouting methods overcome some of the limitations of permeation and employ displacement to insert volumes of grout into the ground. Compaction grouting can be used to densify cohesionless soils, and soilfracture can be used to improve cohesive soils by consolidation. Both compaction and soilfracture processes can be used to arrest or even control ground movements. Jet grouting employs erosion and mixing using high energy jets, to attack a wide-ranging set of soils and applications. Soil mixing employs powerful mixing tools to mix soils with grouts or dry binders *in situ*. A range of shapes and applications are in use. Finally verification to ensure that the intended performance is achieved is necessary, and the main methods are briefly described.

90.1 Introduction and background

This chapter covers methods using the injection or mixing of wet or dry materials to improve the performance of the ground. Mechanical improvement employing deep vibratory and dynamic compaction methods are covered separately in Chapter 84 *Ground improvement*.

Geotechnical grouting is the controlled injection of a fluid grout mix into soil or rock. The grout is typically designed to harden with time to secure improvement in the strength, stiffness or watertightness of the ground so that temporary construction or permanent specified performance can be realised. Special applications of grouting include the restoration of levels to badly settled foundations and the control of ground movements caused by underground works such as tunnelling.

Soil mixing, as the term implies, is a related set of processes whereby the ground is improved by mixing grouts in the ground, so forming a new material which hardens to deliver the desired properties.

Success in these processes depends on four crucial and related issues:

- the type, state, properties, profile and variability of the soil or rock to be treated;
- the formulation of the grout and its preparation;
- the method for placing or injecting the grout in the ground;
- the intended properties or performance required of the treated ground and how these will be verified.

These will determine the selection of which process to use; the level of improvement possible; and the costs.

Early attempts at direct injection of simple cement grouts into the ground were often hampered by failure to permeate the ground, leading to an appreciation of the limits of this grout type for permeation, and the development of silicates and more complex chemical formulations to extend the range of soils treatable, but with significant limitations.

Subsequent grouting development concentrated more on the means of delivery of simple cementitious grouts. This has opened up the range of soils and processes available, and has considerably broadened the range of applications. By the early 1990s jet grouting, compaction grouting, soilfracture grouting and soil mixing methods were all being widely and successfully applied in addition to permeation grouting (e.g. see Bell, 1994; Rawlings *et al*., 2000). Since then there has been increased use of soil mixing, and continued development of the other grouting methods particularly in relation to electronic monitoring and control of the processes on site.

Today, many of the processes require only fairly simple grouts consisting of suspensions of water and cement, or microfine cement, with the water : cement ratio being a key variable. Additives can be used to modify either the temporary fluid grout behaviour such as longer gel times, or hardened properties such as unconfined compressive strength. Reactive additives such as PFA, Bentonite, Lime, GGBS (blast-furnace slag) or Gypsum may be included in the grout mix. Indeed some of these materials are sometimes used without cement. Inert materials such as sand, rock flour or talc can be added as fillers. Chemical solutions and emulsions may also be used as grouts. Silicates are used for permeating finer-grained sands, and epoxies are sometimes used in sealing, e.g. fine rock fissures.

Figure 90.1 shows the main methods and their usual ranges of application in soils as a function of grain size. However, this figure does not allow for the effects of layered soils, highly

variable or mixed-grain soils, and the soil strength, density or stiffness, and is for general guidance only.

A summary of the key physical effects and property changes of the various grouting and soil mixing processes is included in **Table 90.1**.

The methods are extensively used to solve a range of geotechnical and foundation problems. All have been used for improving foundation-bearing capacity and for reducing total or differential settlements. Permeation, jet grouting and soil mixing have been applied in forming barriers to minimise the flow of water or waterborne pollution. Soilfracture and compaction grouting have been used to minimise foundation movement or surface displacements caused by adjacent excavations or tunnelling, and for re-levelling previously tilted or distorted foundations. However, matching the problem to be solved with the appropriate technique requires careful consideration.

It can be seen from the above that grouting and soil mixing are a range of processes, which depend on the ground profile, the type of grout selected, the method employed and the end objective. They do not produce homogeneous volumes of improved ground, but depend instead on the mass properties produced, with necessary variations in properties within the mass. This reality must be accepted in design and verification approaches to ensure technical and economic success.

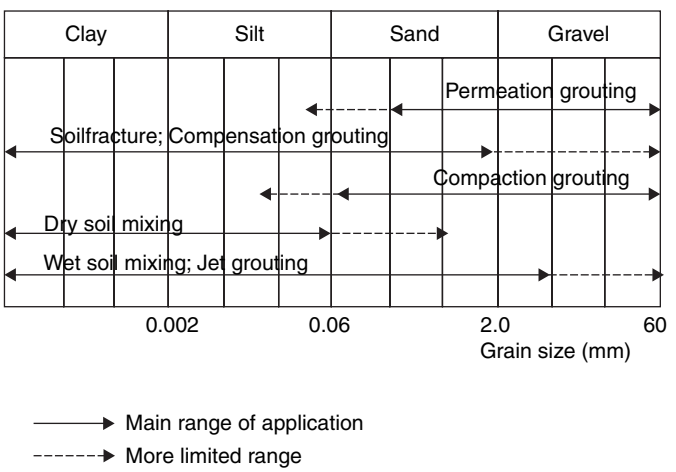

Figure 90.1 Grouting processes applicability according to grain size

It is important to ensure, early in project planning, that the ground investigation is designed to include relevant ground properties for the prospective approaches. Pre-contract or preliminary trials may be necessary to optimise the approach, or in some cases to confirm the viability of the process. Use of an observational approach, requiring changes to the quantities or injection parameters as the project proceeds, has also been found to be helpful for difficult sites. However, a detailed consideration of the limitations and considerations in grouting and soil mixing is beyond the scope of the present chapter, and those requiring further information should refer to the references and reading lists, notably CIRIA reports C572 (Charles and Watts, 2002), C573 (Mitchell and Jardine, 2002) and C514 (Rawlings *et al*., 2000). Specialist advice needs to be sought in all cases.

90.2 Permeation grouting in soils

Permeation grouting is achieved by grouting to partially fill the pores in cohesionless soils, largely displacing the water or air that is present naturally in these spaces, and without altering the structure of the ground. Groutability is a key issue, ensuring that permeation is possible in the target soil or rock mass. In soil it is influenced by the grout type and grain size distribution, and the soil permeability, grain size and grading, fines content and variability.

Soil pore size is theoretically more relevant than grain size, but establishing the pore size, shape and distribution, even in cohesionless soils is difficult. An additional issue is that small grout particles become wedged together to form a filter cake thus effectively preventing further penetration. Groutability based on soil and grout particle gradings can be developed, and a rough guide for acceptability is given by Mitchell and Katti (1981) as:

$$D_{15(soil)}/D_{85(grout)} > 24$$
$$\text{or} \quad D_{10(soil)}/D_{95(grout)} > 1$$

where the D values relate to the percentages passing a given size. This kind of approach is useful in a general sense, but care is needed as grout particles flocculate after hydration so changing the apparent particle sizes. Decisions about groutability are usually taken on the basis of experience coupled with detailed information on the variability and true grading range of the soils being considered. It should be appreciated that many

Method	Major physical effect	Key properties for application
Permeation grouting	Infills voids and fissures with grout	Reduces permeability; increases strength or stiffness
Soilfracture grouting	Opens network of fissures using grout	Increases strength or stiffness; controls ground movement
Compaction grouting	Forces a body of grout into the ground	Increases density; controls ground movement
Jet grouting	Erodes the ground, replaces with grout	Increases strength or stiffness; reduces permeability
Wet soil mixing	Mixes grout with the ground *in situ*	Increases strength or stiffness; reduces permeability
Dry soil mixing	Mixes dry binders with the ground *in situ*	Increases strength or stiffness

Table 90.1 Summary of physical effect and properties for application

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

ground investigation sampling methods may not recover all of the fines in cohesionless soils, and this may distort the view taken on groutability or variability of the ground. Advice on the number and quality of samples for grading, and the interpretation of gradings, and similar care with rock discontinuity assessment, must be sought as part of the early planning process. Greenwood (1994) provides a more detailed consideration of the issue.

Generally, experience indicates that low-pressure permeation grouting using simple cement grouts is usually limited at best to gravels containing perhaps some coarse sands, or to fissures > *c*. 0.2 mm in rock. With microfine or ultrafine cements (more finely ground cements) and/or silicates, described below, it is possible to extend permeation into the coarse sands and even fine to medium sands with silicates.

Key properties of simple cement grouts as a function of water/cement ratio are shown in **Figure 90.2**.

Sandy cohesionless soils may be treated using sodium silicate – the process developed in 1926 by Dr Hugo Joosten using a two-stage approach to combine waterglass and calcium chloride to form precipitate silicates *in situ*. By the late 1950s a single-shot approach was developed by mixing an organic hardener and waterglass before injection, which then gels after predetermined periods in the ground. This principle remains applicable in soil permeation, and various proprietary reagents are available as hardeners, with widely differing properties and durability.

Other single fluid low-viscosity chemical grouts capable of penetrating finer-grained soils such as silts have also been developed, but these are expensive, and the strength, stiffness and durability often more limited than with simple cements. Several are also highly toxic leading to restrictions or bans on their use, and are not considered further here as they now see little use and are for very specialist applications only.

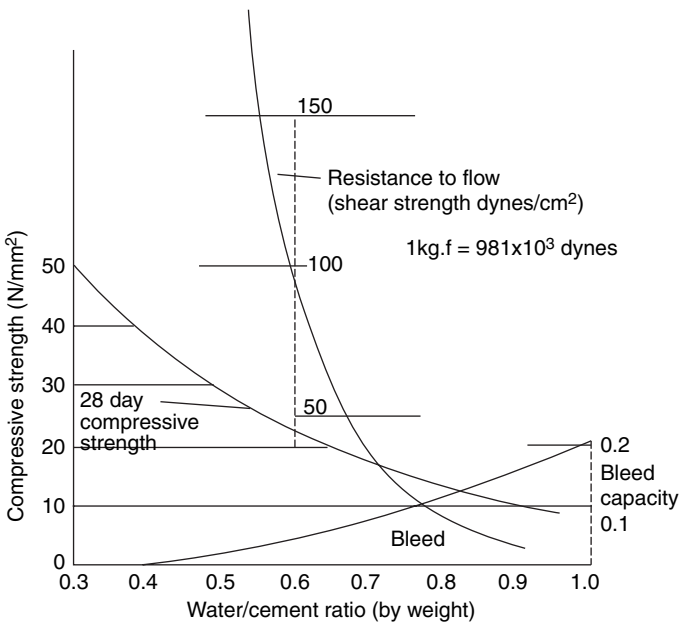

Figure 90.2 Properties of simple cement grouts
Reproduced from Littlejohn (1982)

The mass properties of permeated ground are quite different from the neat grout properties, and **Table 90.2** provides an indication of the strength and permeability limits expected. The expected properties of treated ground depend on the grout type, the grading and state of the ground and the details of the permeation grouting method employed. Considerable variation, particularly in strength and stiffness, is normal.

Equipment employed in permeation grouting is wide-ranging and to some extent dependent on the grout selected and the method of injection. Drilling boreholes is the normal precedent to grouting, necessary in order to get access to the ground to be grouted. A description of drilling processes is beyond the scope of this chapter (see Warner, 2004 and the suggested reading list). Only relatively small diameter holes are needed, less than 100 mm diameter, and while vertical holes with long masts in open sites are cheapest, inclined holes, including drilling from shafts, galleries and tight corners are perfectly feasible if the application demands it.

For low-cost treatment in highly porous ground, grouting can be performed directly from the end of borehole casings or lances or through slotted pipes installed in the boreholes. High pressures are not effective due to grout surfacing, and control of permeation is relatively crude. However, such methods can be relevant for improving marginal situations in open ground, and particularly for temporary works.

Soil grouting was considerably improved with the invention of the Tube à manchette pipe by Ischy in 1933, or TaM pipe (**Figure 90.3**). These pipes, typically 25 mm to 50 mm o.d. are installed in lengths which screw together in a borehole to attain the depths required, and are grouted in place using a relatively weak sleeve grout. Grout ports closed with cylindrical rubber seals are spaced at regular intervals, ranging from 250 to 500 mm. A packer placed inside the pipe isolates one set of ports at a time, and grout can be injected into the surrounding ground, after it expands the surrounding seal and breaks the sleeve grout.

The TaM pipe method provides much more control for permeation and related forms of soil grouting because the injection position can be selected, repeated injections from any port location can be made, and grout pressure or volume can be measured or controlled. The TaM method is now almost invariably used in all but the least demanding soil permeation applications. Borehole spacings for TaM installation depend on the grout and permeability of the soil, and the application, but range typically from 0.6 m to 2 m.

	Cements	Microfine	Silicates
Unconfined compression strength UCS (N/mm²):	< 15	< 10	< 7
Coefficient of permeability k (m/s)	> 10^{-6}	> 10^{-7}	> 10^{-7}

Table 90.2 Properties of cohesionless soils treated by permeation grouting

Permeation grouting is a flexible process because discrete layers or zones of soil can usually be treated, even when beneath buildings and structures as only small diameter drilling is needed to reach them, and the shape of the treated volume can be made flexible to suit. Minimal spoil is generated, and ground movements likewise, if the grouting is properly selected, specified and executed (Greenwood, 1994).

Major applications are as follows:

- underpinning foundations;
- sealing cracks, joints and other rock discontinuities;
- temporary support for excavations, shafts or tunnel construction;
- temporary cutoffs;
- reducing permeability below dams;
- improving stability of retained ground;
- support for services, such as pipelines on poor ground.

Perhaps the major use of permeation grouting worldwide is to reduce soil or rock permeability. Many dams have cut-offs formed in this way (**Figure 90.4**). Another very broad range of applications concerns the provision of temporary stability to facilitate the construction of tunnels, shafts and excavations. Underpinning has also been a key use of permeation, where ground conditions allow (e.g. **Figure 90.5**).

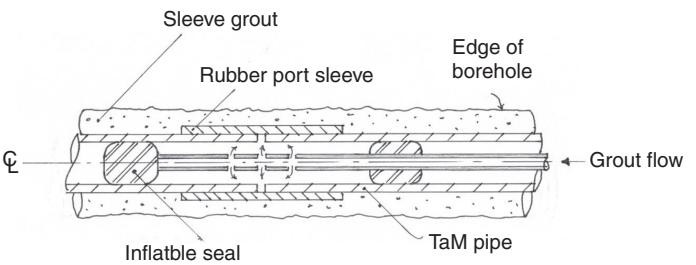

Figure 90.3 Principle of operation of Tube à manchette pipe

90.2.1 Permeation grouting in rock

Permeation grouting in rock is usually applied to infill the discontinuities in otherwise sound rock. It is mainly used for sealing, or less frequently for strength or stiffness, in fissured or jointed rock: for example cut-off curtains or blankets beneath dams; sealing rock near nuclear installations; to enable tunnel construction or for permanent improvement around or near tunnels. Site investigation needs to identify the volume and size of the rock fissures and voids so cores and *in situ* tests will be needed to properly explore the rock mass.

Grout hole diameters are small, typically 35–75 mm, and spacings typically 1–2 m with opportunity for infill holes if needed. For curtain grouting the holes may be spaced in two or more rows, depending on the specification and rock openness, to improve the effective thickness of the curtain. The rock is often grouted within the bores in stage lengths of 3–5 m. Each stage is isolated by down-the-hole packers which seal the upper and lower boundaries of the stage. Depending on the rock mass state, grouting may proceed from the top (descending stage) or from the base of the borehole (ascending stage).

Seepage through grouted rock can be determined using the Lugeon unit (1 Lugeon is the volume of water (litres) lost per metre length of hole per minute at 10 bars pressure). However, this does not necessarily relate well to groutability, so the GIN (grouting intensity number) method has been developed, which

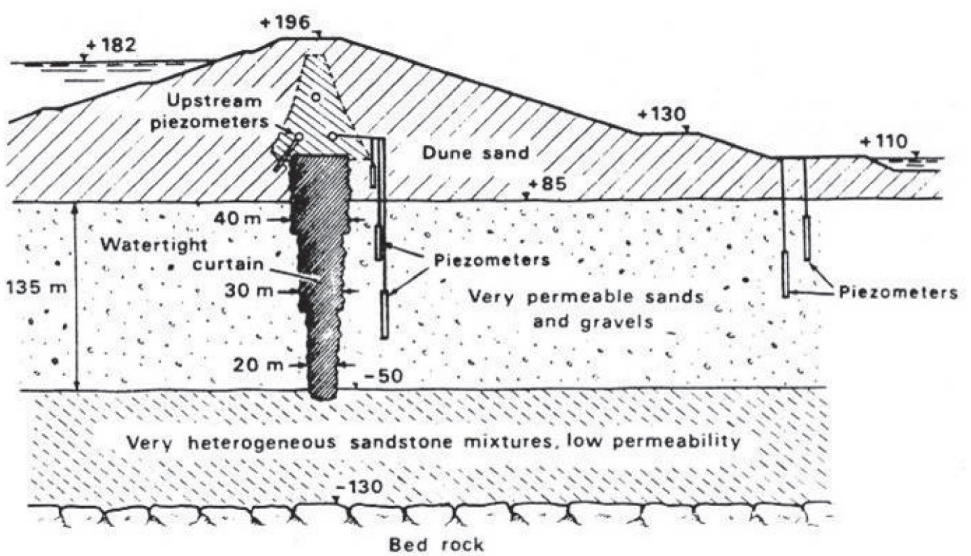

Figure 90.4 Grout curtain for high Aswan Dam
Reproduced from Littlejohn (1983)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

avoids the need for Lugeon testing, and is increasingly being used in the USA, Europe and the UK. The method was introduced by Lombardi and Deere (1993), and is described in Warner (2004).

Cavities in rock are also frequently backfilled with grouts, particularly in areas of old underground mineworkings in the UK. Low-cost grouts are used to fill old shafts and working tunnels to prevent migration of voids to the surface and thus prevent or minimise any consequent surface subsidence. Methods are described in CIRIA SP32 (Healy and Head, 2002) and on the websites of the specialist contractors.

90.3 Soilfracture and compensation grouting

Fracture grouting, or soilfrac grouting, employs a similar equipment and approach as permeation grouting in soils but uses higher pressures to deliberately cause 'hydrofracture' which opens up a network of fissures in the ground, thus enabling the injection of grout. This widens the range of soils applicable, and enables treatment to extend even into the clay range. Significant control issues in regard to pressures and volumes injected, and the nature of the grout itself, are needed. Compensation grouting is a particular application of fracture grouting which enables the control of ground movements to compensate for deformations arising from construction.

Fracture grouting was often correctly seen as an undesirable effect of overpressuring in soil permeation grouting, but was first developed in France as a positive measure and is thus sometimes referred to as 'claquage' grouting. Controlled hydrofracture is achieved by injecting high-viscosity grout under high pressures so inducing cracks in the ground which are opened up by the flowing grout in them. By repeated injections of relatively small amounts of grout a network of veins and lamellae form a dendritic structure in the ground (**Figure 90.6**). Steel TaM pipes are often used to ensure the repeatability of the injections, especially for compensation grouting applications which can go on for many months and sometimes years. Grouts employed are commonly cements but often contain additives to assist in achieving early strength or other required characteristics.

It is important with hydrofracture grouting that experienced specialists are employed who understand the process well, as uncontrolled hydrofracture at best will be ineffective and at worst can create deleterious effects for the ground and may cause grout to travel into such structures as drains, sewerage systems or basements, creating blockages or damage.

The technique can be applied in mixed and cohesive soils for straightforward ground improvement for foundations, although applications are limited due to time and cost. Generally the process causes consolidation or tightening between the grout veins, and stiffness increases of between two and five are typically possible.

However, perhaps of more interest is that, particularly in cohesive or more dense granular ground, the volume of the soil mass has to increase to accommodate a significant proportion of the extra volume of the injected grout. Consequently a powerful application is to employ the technique to arrest excessive total or differential settlement beneath existing buildings and structures.

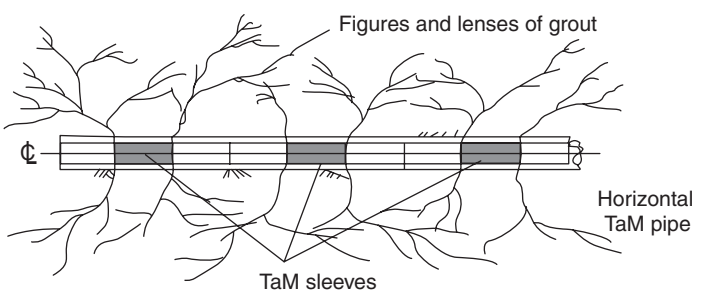

Figure 90.6 Formation of dendrictic structure of grout inclusions using soilfracture grouting

In such cases it is advantageous to have the pipes drilled in at low angles to the horizontal or even from specially constructed shafts in order to get the array of pipes installed. Since the movements induced in the ground are locally very small and are attenuated over a larger area when transmitted underneath a foundation, the technique is kind to the structure when properly managed. In any case the existing state of the structure and its foundations, and any adjacent structures or buried services, must be well understood prior to design and grouting operations.

The volume increase caused by soilfracture, if injection persists, can migrate to the surface as heave. This effect, when controlled by the layout of the TaM pipes, the grout type, and the sequence and intensity of injection, can be used not only to arrest settlement, but to take the process further in order to relevel previously settled buildings and foundations – a major application of the technique (e.g. **Figure 90.7**).

This application was first employed in Germany, and not only led to high accuracy in many cases, but also to the development and application of soilfracture grouting to compensate in real time for ground loss (Raabe and Esters, 1990). This takes concepts of re-levelling even further and attempts to balance the ground loss arising from tunnelling with the volume increases in the ground caused by the soilfracturing grout injection. Basic principles of compensation grouting are outlined in **Figure 90.8**.

The technique has been applied in the UK where it is known as compensation grouting, and the first major applications were in connection with protection of many key structures during construction of the running tunnels for several of the Jubilee Line Extension contracts in London (Linney and Essler, 1994), and is now a common technique across Europe and further afield (Moseley and Kirsch, 2004; Mair, 2008).

90.4 Compaction grouting

Developed in the USA in the late 1950s, compaction grouting is now used extensively there, and has been adopted in the UK (e.g. see Crockford and Bell, 1996) and increasingly in Europe and Asia. It offers a very different approach from permeation or soilfracture. The method employs low slump mortar-like grout (slump typically 25–75 mm but can be more), which is forced into the ground under high pressures to form bulb-shaped masses. These can be employed to compact loose granular soils, or can be used to displace cohesive and mixed soils in order to create heave, close voids or control ground movements during construction. (It should be noted that in the USA recent terminology distinguishes between 'compaction grouting', used only in applications to compact soils, and other applications of the technique, referred to as 'low mobility grouting'. In Europe all applications come under the 'compaction grouting' umbrella.)

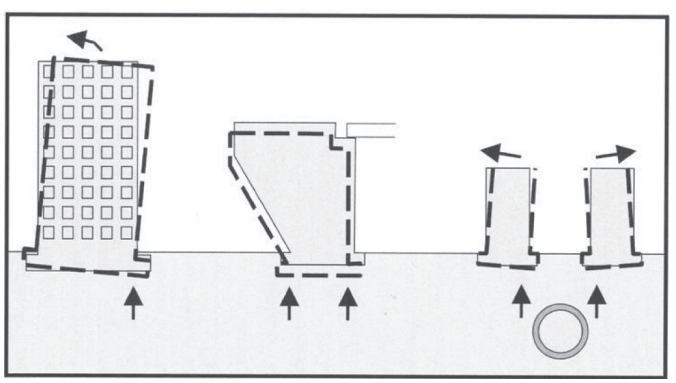

Figure 90.7 Applications for soilfracture grouting
Modified from Raabe and Esters (1990)

A key requirement of the grout mix is that it does not permeate or mix with the soil, or cause hydrofracture as a fluid, but remains a plastic growing mass during injection, with enough internal friction to allow flow but not so much that segregation or filter blocking occurs. Mixes consist of a wide range of aggregate sizes, often a silty sand, with silt sizes accounting for 10–25% of the total by weight, with cement or cement substitutes such as fly ash. Further details are included in Rubright and Bandimere (2004) and Warner (2004). The grout is often batch-mixed on site in simple pugmills, or is supplied from readymix plants. More expensive continuous batching set-ups can be effective for large or high-volume demand sites.

Generally the grout bulbs are formed from the end of casings installed in boreholes or pipes of about 50 mm to 100 mm max dia. driven directly. Gaining access under structures can be facilitated by the use of inclined borings. A typical set-up for ground improvement using compaction grouting is shown in **Figure 90.9**. Typical pressures needed are often in the 40–60 bar range, and concrete pumps with capabilities of 80 bar or more are typically specified. Pressures at which further grout intrusion refuses are not usually obtained before surface heave is reached, which is helpful for applications in which surface movements are required.

Lateral spacings between the pipes, forming the bulbs upstage or downstage, the vertical spacing between bulbs, and the order in which adjacent casings are injected are interrelated and depend on the objective of the process, the ground conditions and the site environment. Spacings between pipes vary for compaction purposes from about 1 m where overburden pressures are low, to about 4.5 m or so where deeper layers at 10 m or more are being addressed.

To enable efficient compaction, pipes are often installed in primary and secondary grid arrangements. Upstage grouting is the most common and least costly approach, with each bulb injected at intervals as the pipe is withdrawn from the maximum required depth. Downstage grouting can be useful where compaction is needed only at shallow depths to provide some near-surface confinement for subsequent grouting beneath. Compaction grouting applications usually proceed by injecting target volumes, to ensure relatively even distributions of grout in the ground. Experience indicates grout takes

of 3–12% of ground volume, more frequently at the upper end, are needed to achieve intended levels of densification or movement in non-voided soils.

Compaction grouting can be used as a ground improvement technique to densify loose natural or voided filled ground (e.g. **Figure 90.9**) to be employed as bearing material for new or adjacent construction; or to deal with features such as loose material in chalk cavities. The latter is not uncommon in southern England and compaction grouting has been used for several foundations for structures and the preparation of waste disposal sites, as well as remedial works beneath existing buildings. It has also been applied in the densification of potentially liquefiable zones for earthquake protection, and has been applied retrospectively to provide seismic protection

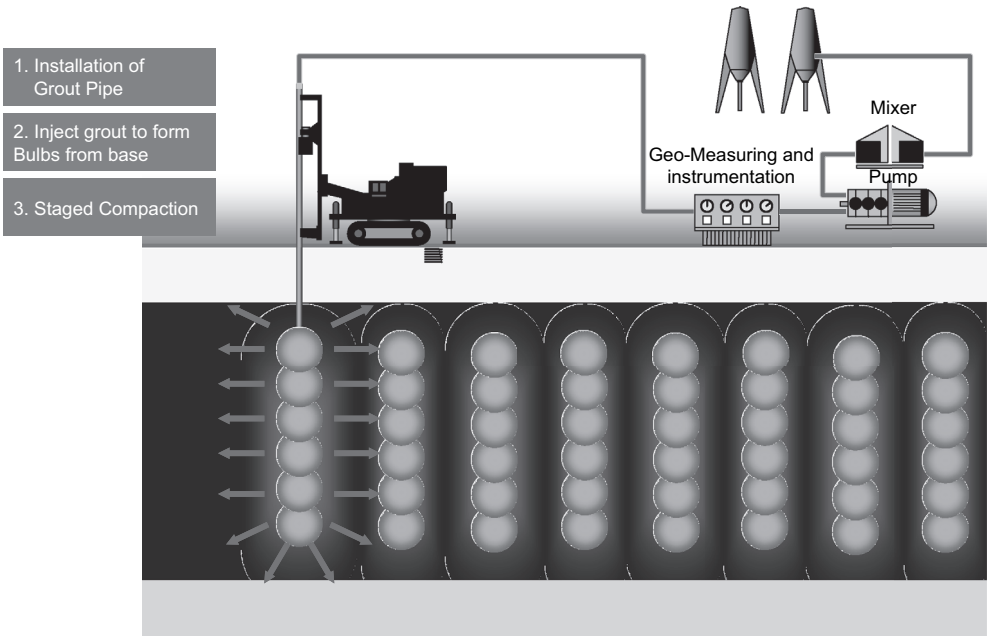

Figure 90.9 Equipment and procedure for ground improvement using compaction grouting

for pre-existing structures. Warner (2004) and Moseley and Kirsch (2004) provide many examples.

However, because it can create heave, like soilfracture grouting, a key application area is in re-levelling structures (**Figure 90.10**) and to compensate for ground movements caused by tunnel or other excavations. Indeed the first compensation grouting in the USA employed compaction grouting and predates the use of soilfracture grouting in Europe for the same purpose (Baker *et al*., 1983)

90.5 Jet grouting

Jet grouting uses erosion to enable grouting to proceed across a very wide range of soil types. High-pressure jets of water or grout break down the soil structure, and remove varying proportions of the resultant soil particles. The grout replaces the eroded material and becomes mixed with the residue, which can be a very small proportion depending on the method employed and its ability in discharging spoil to the surface.

There are now several forms of jet grouting in use, and the majority stem from three basic variants: single, double or triple systems (**Figure 90.11**). Examples of the drilling equipment and high-pressure pumps required are shown in **Figure 90.12**. Compact crawler rotary drills with rotary heads are most often used to reach the zone identified for treatment by jet grouting. Where possible, long masts should be used to enable the jet grouting for each element to be completed in one lift, so avoiding costly re-entry and joints in the treatment. The erosive pumps (grout for the single and double, and water for triple) need to operate consistently at high pressures of up to 600 bar or more. Grout is usually mixed and batched on site and held in tanks before injection.

In all cases the work commences by drilling a small borehole of *c*. 100 mm diameter to take the hollow jetting rods containing the relevant jetting fluids to the maximum treatment depth. A column is formed by simultaneously withdrawing and rotating the rods at constant predetermined rates, while the erosive jets cut the ground and the grout is placed with predetermined volumetric injection rates. In some cases panels of grout are formed as this geometry can be useful in sealing applications. The jetting parameters, i.e. lift and rotation speeds, fluid flows and pressures, are always monitored very closely and in many cases are controlled automatically to ensure highest quality. Columns are the most commonly required shape, and are usually intersected to form a treated mass of ground with properties determined in part by the nature of the ground being eroded, as well as the injected grout. Some examples of column and panel arrangements for various applications are shown in **Figures 90.13**, **90.14** and **90.15**. The grout mix is typically a simple water/cement grout, sometimes with additives such as bentonite. It must be free from impurities and sufficiently fluid to flow easily through the jetting nozzles.

The single and double systems use a grout jet to erode and place the grout, shrouded in the case of the double system to improve efficiency. The triple system employs an efficient air-shrouded water jet for erosion and the grout is separately placed below the erosive jet. Precutting using water or air–water jets may be useful in stiffer cohesive layers or with very mixed soils, to improve the efficiency and uniformity of the final column.

It is important to ensure the spoil has an unhindered passage to the surface to prevent excess ground pressure, which can result in unwanted heave at the surface. Similarly, planned and efficient spoil handling and disposal, possibly by recycling, will be necessary. In many applications, notably underpinning, a thorough survey of the existing structural integrity of any structures likely to be influenced will be needed. Monitoring of structural movements and ground heave will be necessary, and proficient real time systems of communication established between the monitoring and the jetting process and personnel.

Since jet grouting can erode large volumes of soil, attention also needs to be paid to temporary stability, the gain of grout

strength with time, and the sequence of forming interlocking columns. Diameters of up to 5 m or more are possible with higher-energy air-shrouded grout jet systems using double opposed nozzles (i.e. the 'superjet' process) and these can be very efficient in such applications as forming basal cut-off slabs in basements and excavations. However, large diameters are not always appropriate or economic depending on the application, for example beneath adjacent sensitive structures which may have limited ability to span large unsupported volumes of ground in the temporary condition. Column diameters in most UK applications tend to be much less than 3 m. Erodability of the soils being treated is also highly relevant to the diameters that can realistically be achieved, and variation in soil type or state in the treatment zone must be understood in advance to ensure success.

Table 90.3 provides a rough guide to the range of mass properties expected, but actual properties will depend on the ground properties and variability, the process and jetting parameters used, and the properties of the grout injected.

Jet grouting has the ability to treat discrete layers in the ground, along with other forms of grouting, but is able to treat a wider range of soil and rock and has additional advantages in that the geometry can be more flexible, the properties more predictable and able to meet demanding specifications, with good performances available in a wide range of soils. Indeed jet grouting enjoys wide application also due to its flexibility of geometry in the ground, and the broad range of ground conditions treatable.

A key further advantage is the intimate contact which jet grouting can make with overlying structural foundations, or with sealing sheet piles, particularly with the double and triple systems as the erosive jet cleans existing structural surfaces prior to the grout being placed (see **Figure 90.13**). This makes jet grouting suitable, with appropriate consideration, for sealing and underpinning applications. It can also be used in weak rock, in cleaning out softer zones in weathered rock, in debris-filled fault zones, fractures, fissures or joints.

Underpinning of existing buildings needed for new adjacent construction is one of the most common applications of jet grouting. This is frequently done in conjunction with basement construction, as the jet grouted mass not only provides support of the foundations of the existing building, but also support for the excavation and formation of the new basement, which can be taken close to the existing building line thus saving space over other methods. It has been used frequently in many cities around the world including London. Typical arrangements for jet grouting underpinning are shown in **Figure 90.14**.

As well as underpinning, jet grouting has been widely used in both permanent and temporary cases for providing basal seals and plugs and in forming new cut-offs or extending or remediating existing cut-offs beneath dams and other water-retaining structures. Due to its capacity to be bonded to existing structures *in situ* it has been used to seal leaking coffer-dams and shafts. It is

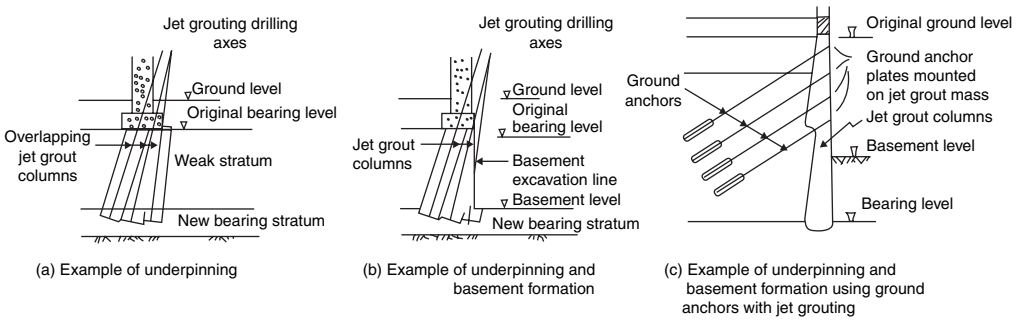

Figure 90.14 Examples of underpinning and basement formation using jet grouting

also used directly and indirectly to provide support, for example improving the capacity of existing foundations and abutments. It is also extensively employed in creating temporary stability for tunnel construction or for break-in/break-out blocks. Some examples of such applications are included in **Figure 90.15**.

Figure 90.16 shows a sheet-piled excavation supported by a jet grout base plug. After driving piles to support the eventual structure, the base plug is formed using interlocking jet grout columns, drilling from the surface and jetting only over the depth range needed for the plug. Sheet piles to support the sides of the excavation are then driven, and a structural high-level propping system installed during initial excavation. Further excavation proceeds to final excavation level with no need to install further support as the jet grout seals against water ingress, stabilises against heave and acts as a basal prop. This approach to constructing excavations, with some variations in sequencing of the elements illustrating the flexibility of jet grout construction, is widely applied and has been employed on several projects in the UK.

90.6 Soil mixing

Deep soil mixing has developed in two major ways. Dry soil mixing uses dry powders, often cement or lime-cement, which is usually blown with compressed air into the mixing train, and the soil moisture is sufficient for the properties of the mix. Dry soil mixing was developed in Sweden in the 1960s to address the compressible soft soils found there. The method, initially employing lime binders, is now widespread in Finland and Norway as well as Sweden, and more recently in other parts of Europe including the UK and the USA. Cement and cement-lime binders are now more common.

In contrast, wet soil mixing uses wet grout, usually a cement suspension, prepared and mixed at the surface, before being pumped into the ground through the mixing tool for subsequent mixing in with the soil. Water in the grout mix and water in the ground contribute to the final mix. Wet soil mixing was introduced in the USA in the 1950s, and has been developed steadily since the 1970s notably in Japan with depths of 50 m or more having been treated, and with some very sophisticated equipment developed for near and offshore work. The method is now well accepted in the USA and the Far East as well as Japan, and is increasingly being employed across Europe, notably in Poland.

Soil mixing is being applied in a wide range of applications, often using columns to provide an improved mass of ground similar to jet grouting. Soil mixing needs to be performed from the surface in each case, lacking some of the flexibility of jet grouting, but is nevertheless usually competitive due to its generally lower cost per cubic metre. Applications of soil mixing include:

- improvement of bearing capacity;
- reduction of total or differential settlement;
- improvement of slope stability;
- support in temporary or permanent case for excavations or tunnels;
- reduction of earth pressures behind retaining structures;
- cut-off barriers (reduction of permeability);
- immobilisation or confinement of *in situ* soil contaminants;
- improvement of seismic (liquefaction) resistance in new and retrofit construction.

A more complete description of the methods may be found in Topolnicki (2004, 2009), and in the proceedings from two recent international conferences at Stockholm in 2005 and Okinawa in 2009 (see references below).

90.6.1 Dry soil mixing

Dry soil mixing is typically applied to soft soils in which the natural moisture content is close to or above the liquid limit. It is increasingly being used for more organic soils and even some peats. Typical dosage rates are 75–200 kg cement per m^3 of natural soil, or more for very soft or organic soils but depend on the soil and binder types, the intended performance of the mixed soils, and the capability of the equipment. Undrained shear strengths attainable are up to 1000 kPa or better at 28 days in inorganic silts, but are typically much lower, and especially so in the case of organic clays and peats.

In any case, it is normal to conduct pre-contract laboratory mixing tests with a range of prospective binder dosages on representative soil samples, to confirm the expected level of improvement. Often, and in particular where experience with

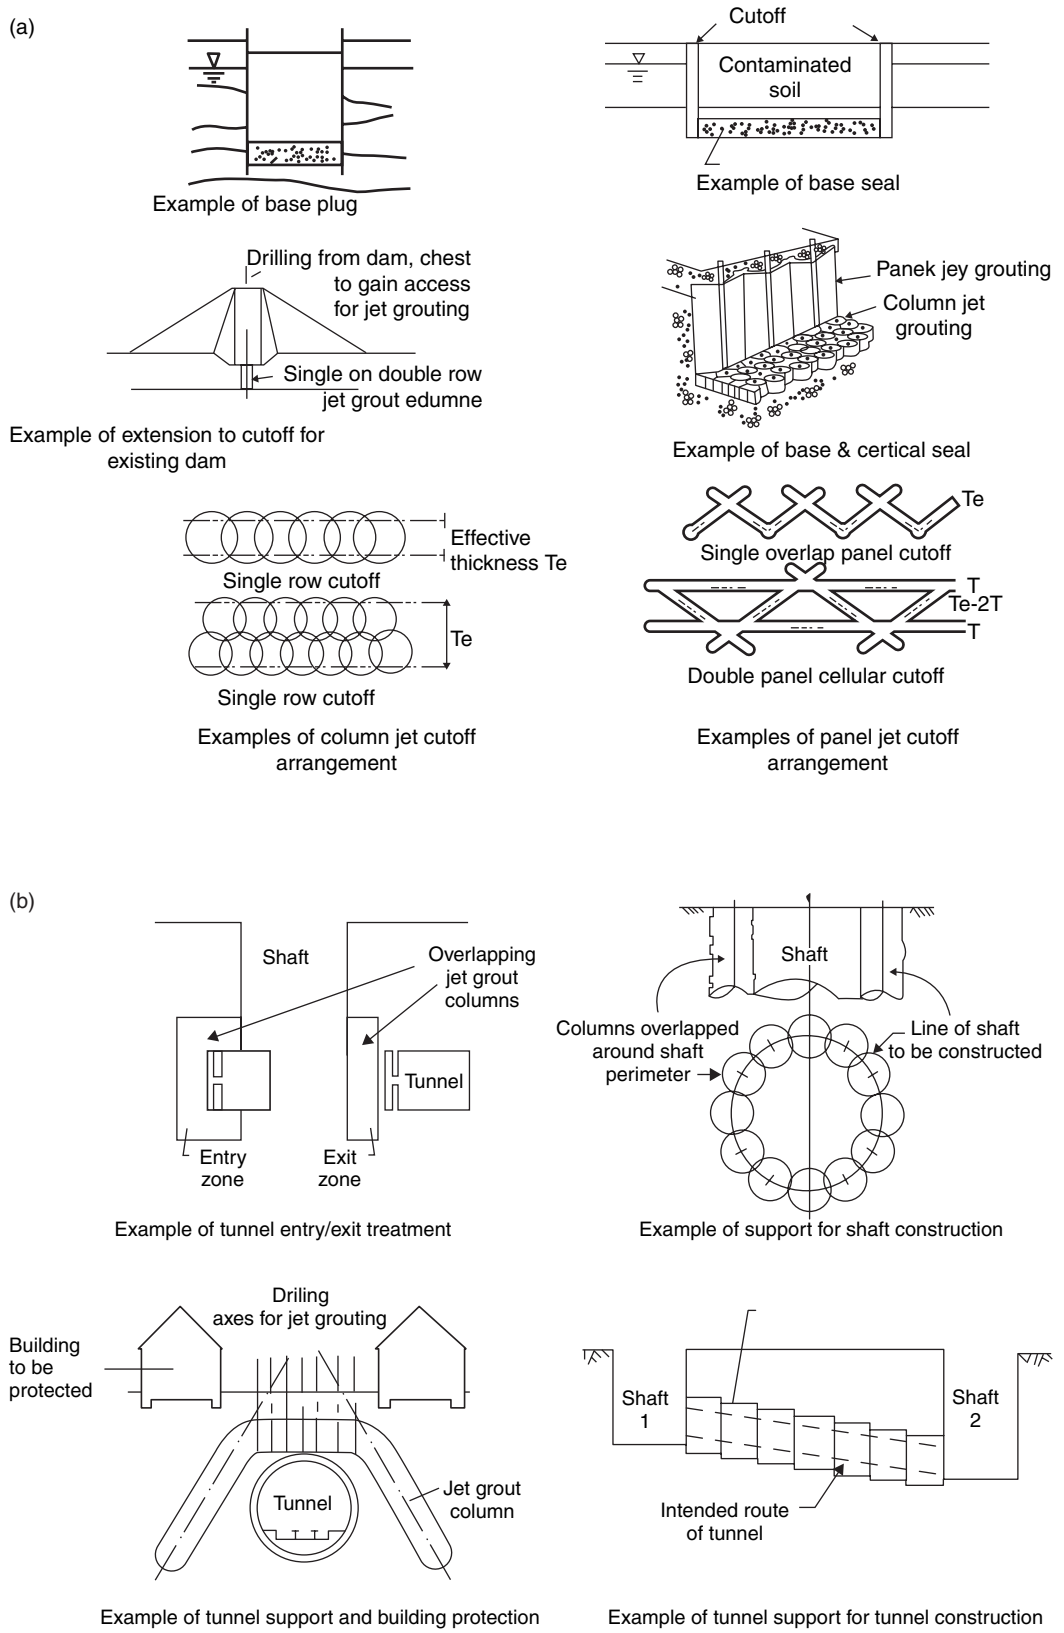

Figure 90.15 Some examples of jet grouting (a) in sealing applications; (b) for shafts and tunnels (Bell, 1993)

(a)

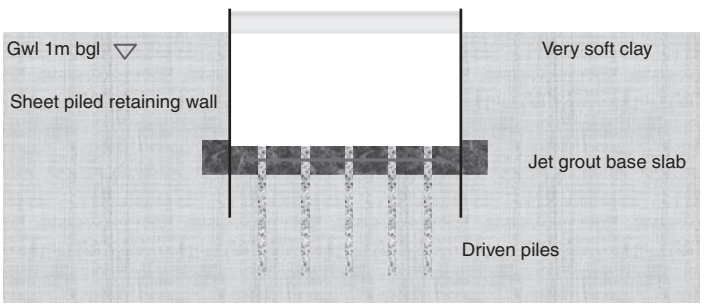

Figure 90.16 Jet grouted base slab
Courtesy of Keller Ground Engineering

the soil type or area is minimal, it will be necessary to conduct preliminary site trials as well, as laboratory mixing can never be truly representative of the ground profile or the mixing efficiencies achieved in the field.

The mass of ground to be improved is often formed using columns of mixed soil, most designed to interlock. After the initial set of the columns a small surcharge can be applied to optimise the settlement performance in embankment and foundation applications. Mixing tools to form columns range in size from 500–1000 mm diameter, and commonly 600–800 mm diameter, to suit the binder injection equipment. Most designs employ vertical columns, with construction tolerances of up to 1 in 100, but small inclinations of up to 10V:1H may also be used especially beneath embankments.

Equipment (**Figure 90.17**) consists of a relatively lightweight hydraulic base machine of up to 40 tonnes or so, with wide tracks to assist with operating on working platforms formed over soft ground. The machine operates in tandem with a self-propelled binder delivery unit, a pressurised air vessel known as a 'shuttle'. The base machine rotates a Kelly bar with a mixing tool attached to its base, into the ground to the desired depth. It is then withdrawn at a steady rate and the tool rotated at a high rate, typically 150–200 rpm, as the binder is injected using compressed air, so forming the mixed column. Columns

Figure 90.17 Dry soil mixing equipment: dry binder shuttle and mixing machine
Courtesy of Keller Ground Engineering

can be constructed to about 20 m depth or beyond, given due consideration of machine stability and enhanced air pressure. Dosage rates can be modified to some extent during withdrawal to suit significantly differing layers in the ground. However, the horizons of such layers must be well established in advance of construction using, for example, CPT equipment, as the dry soil mixing process is not intended for ground investigation. Binder wastage is under 5% in most cases.

It is important to ensure even distribution and mixing of the binder into the ground. The shape, numbers of blades and nozzle spacing on the tool are set to optimise binder injection across the diameter of the column. Distribution with depth is dependent on steady binder delivery and tool rotation and withdrawal, and it is common to automatically measure the binder delivery, and show this against depth and tool parameters, and to display this information in the cab of the mixing machine. Some machines are now using such information to not only measure, but also control binder delivery, thus improving the quality of the mixing and minimising waste.

A useful broad indication of mixing efficiency is provided by the blade rotation number (BRN), defined as the total number of mixing blades passing during mixing over a 1 m depth interval for a single shaft, whence:

$$BRN = (NR)/V$$

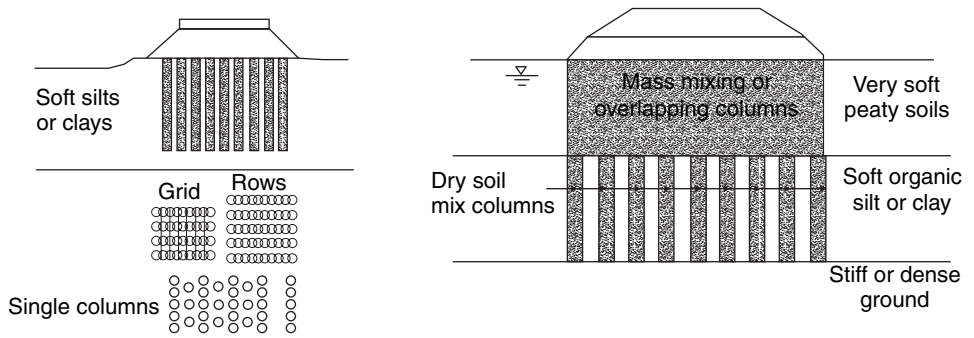
Where N = nr of blades
R = rpm of tool
V = withdrawal velocity (m/min)

Experience from Sweden indicates that BRN values for adequate dry mixing in normal soft soils range from 220 upwards, and in practice is often 300 or more.

At relatively shallow depths, typically 3–5 m in depth, mass mixing rather than column mixing may be used. Here, tools

rotating in a horizontal axis, or larger than normal vertical axis tools, are mounted on the booms of basic hydraulic diggers. These are used to form large volumes of improved ground relatively quickly, by repeated mixing within designated zones. Care is needed with site control to ensure appropriate binder distribution and mixing, as there is no means of accurately measuring binder dosage due to the large overlaps used. However, provided the applications for mass mixing, such as highway sub-grades, are carefully selected to match this approach it can represent a cost-effective solution.

Like jet grouting, blocks of treated ground can be formed by interlocking dry soil mixed columns together to attack a wide range of geotechnical problems. Dry soil mixing has extensively been applied to support road and rail embankments over soft ground (see **Figure 90.18**). It has also been employed beneath housing and other structures; to provide side and base support to excavations; to buttress retaining walls; and in shaft and tunnel construction.



90.6.2 Wet soil mixing

Wet soil mixing differs from dry soil mixing, not only in that wet grout is injected, but in that the equipment, range of applications and soil types treatable are very much broader. Columns can be formed using single vertical axis systems, or with double, triple or more axes constructing interlocking columns in one cycle (**Figure 90.19**). The multi-axis systems tend to be more efficient when constructing linear structures in the ground such as cut-off walls or long earth-retaining structures. Single-axis soil mixing is used to construct columns typically of 600–2500 mm diameter and multi-axis systems have a wide range of geometry, with nominal diameters again of 600 mm and greater. Japanese development has gone even further and large multi-axis mixing machines are available for working off barges to depths of 60 m or more from sea level.

The key equipment for wet soil mixing consists of silos for storage of the cement and other materials needed, high shear mixers, water supply and pumps capable of delivering sufficient slurry grout to ensure that each cycle of mixing in the ground is not held up – for quality as well as production reasons. The grout is pumped through delivery lines into the hollow drilling stem and thence through ports placed in the mixing tool at its end. The stem or Kelly bar is normally mounted on the masts or leaders of cranes, and rotated using high torque heads. The base machines tend to be heavier than with dry soil mixing reflecting the wider range of soil types and larger column diameters, and multi-axis approaches that are employed, and additional consideration for good working platforms needs to be made. Mixing tools vary widely in design depending mainly on the soil type being treated, most with multi-level blades.

Construction for single axis and many multi-axis cycles commences with penetration to the maximum treatment depth, and unlike dry mixing, grout is usually injected both during this phase and the withdrawal phase. The wet grout assists penetration in drier cohesive soils and in sandy and mixed soils, and in the uniformity of the mixing. Penetration speeds and withdrawal speeds normally are different, as are the injection rates during penetration and withdrawal. Some approaches employ a further complete cycle or partial repenetration to ensure a higher mixing efficiency. Rotation rates are lower than for dry soil mixing, but the BRN, described above, has been found to be helpful also for wet soil mixing. Topolnicki (2009) showed that the BRN should exceed 430 for a reasonable consistency in relation to the variation in strength of the mixed ground in single-axis mixing using cement grout in clay soils. It is expected this should also apply for multi-axis methods. In practice most wet mixing approaches in cohesive soils provide at least this level of BRN. Different considerations apply for wet soil mixing in cohesionless soils such as sands, and lower BRN values may apply.

As with dry soil mixing, electronic measurement and reporting is commonplace, and is also now increasingly being used to control the mixing cycles. The reporting and control provide confidence in the dosage rates with depth, and assist in minimising variability and waste.

Example of column arrangements

Example of mass and single column arrangements

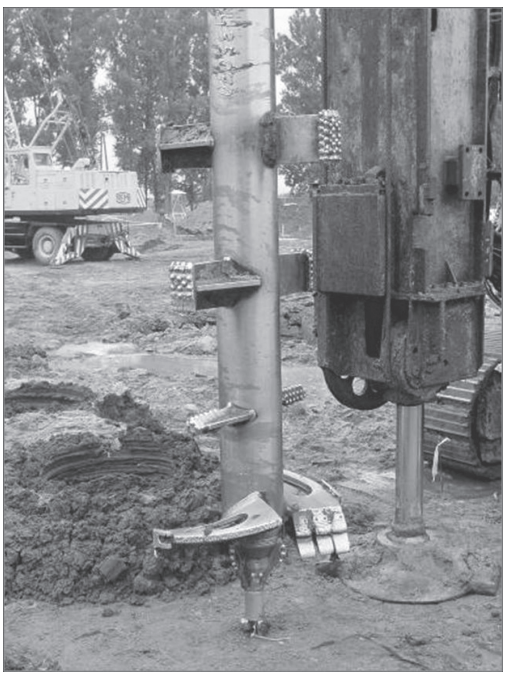


Figure 90.18 Methods for supporting embankments on soft ground using dry soil mixing

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Dosage rates vary typically from 100 to 350 kg cement or more per cubic metre of natural soil, with the higher dosage rates used in the softer and more organic soils, or where very high strengths are required by the particular application (see **Table 90.4**). Stiffness in the form of elastic modulus is less often required, but where measured is typically in the range of 75 to 100 × UCS (Filz, 2009). Mass coefficient of permeability, k, may be as low as 10^{-8} m/s or better where the grout mix, method and application demand, as shown below, but can be at least one or two orders of magnitude higher.

Wet soil mixing, like jet grouting, has found applications in a broad range of geotechnical problems. Given that relatively high strengths and consistency can be achieved, wet soil mixing can be used to provide foundations not only for embankments and the like, but also for relatively large loaded structures (see **Figure 90.20**). Wet mixed columns can be arranged to form gravity walls or alternatively slimmer forms can be reinforced with H section steel beams or the like, to provide additional bending capacity and stiffness and an excellent example is shown in **Figure 90.21**. Likewise in suitable ground conditions wet soil mixing can provide low permeability and has been used to provide new or remedial cut-off elements for dams and other barriers to water or contaminated flows. Triple-axis mixing is often more efficient than single-axis for this range of applications.

90.6.3 Soil mixing using trench cutting

Another approach to soil mixing has been provided by the recent development of equipment which enables mixing of wet grout whilst cutting trench structures in the ground. Originally developed and used in Japan there are now several approaches available and in use in Japan, in the USA and across Europe. The major applications are in forming linear *in situ* structures such as cut-off barriers and retaining walls. Reinforcement in the form of steel sections can be used to provide additional structural strength where needed. Advantages of these systems, given the right conditions, are a reduction in the number of joints over competing methods, less waste for any required wall thickness as overlap is minimised, so leading to reduced costs and improved quality. Wet grout mixes are generally used, with similar mix proportions and final *in situ* mixed characteristics as with other methods of wet soil mixing.

The TRD equipment (**Figure 90.22**) consists of a large machine of about 100 tonnes and 8 m tall and effectively enables cutting and mixing by means of a chainsaw concept. An initial starter trench is formed into which a post is assembled and lowered into the ground to the required depth. Depths of 30 m or more have been treated. The post holds the cutting chain and injection proceeds as the machine crawls forward cutting a full depth face and providing a uniform mix in place material. Joints in the soil mixed trench material only occur if production is stopped, for example if only day shifts are being used. In this way joints are few and the system is particularly efficient for long cut-off barriers.

The CSM (cutter soil mixing) method (Stoetzer *et al.*, 2006) is increasingly being used world-wide. It uses combination cutter wheel arrangements attached to Kelly bars or suspended from ropes (**Figure 90.23**) to form panels up to 2.8 m in length or greater. An advantage of the method is that both fresh-in-fresh and fresh-to-hard panel construction joints can

Figure 90.22 TRD cutter soil mixing machine
Courtesy of Hayward Baker

be facilitated. Depths up to 55 m or so can be achieved with the rope suspended CSM. In relatively uniform soils, or for retaining structures up to about 20 m deep, mixing is conducted during cutting (penetration) and withdrawal. For deeper cut-off walls and for less uniform soils a two-phase approach is adopted using bentonite for temporary trench support during cutting. As with conventional diaphragm wall construction, the bentonite slurry is recirculated and cleaned by passing through de-sanding equipment. Grout is injected during the withdrawal phase and mixed with remaining soils.

90.7 Verification for grouting and soil mixing

It is important to verify the mass properties of the grouted or mixed ground in some way to ensure that the treatment has delivered the intended specification.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

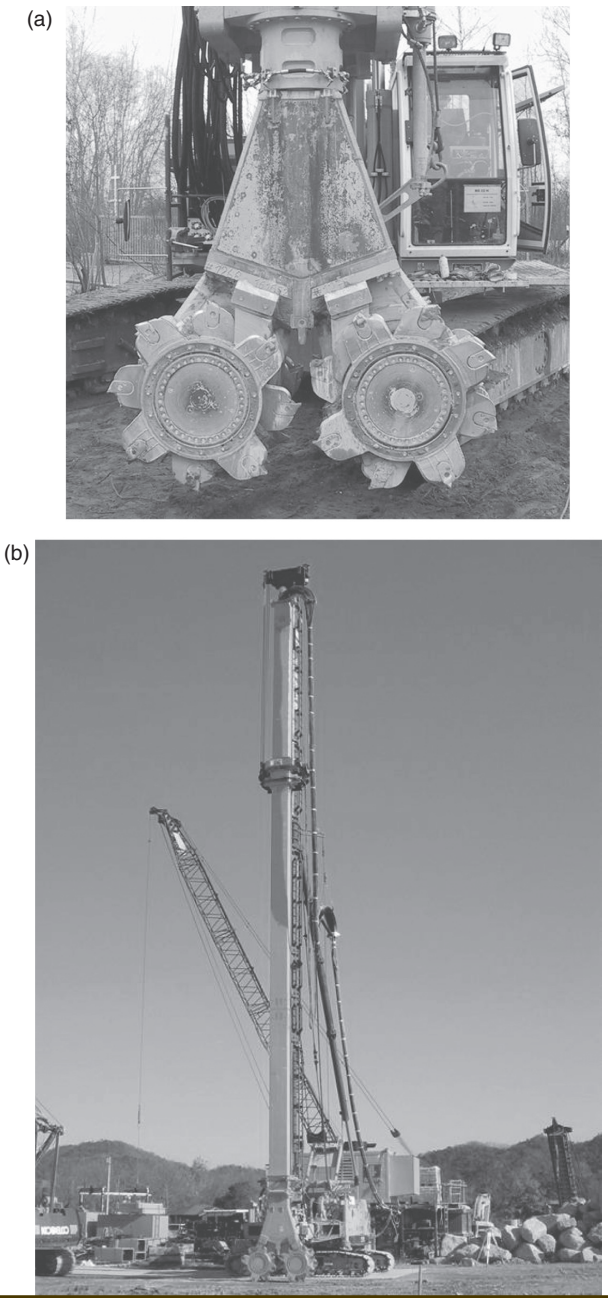

Figure 90.23 (a) Mixing wheels and housing; (b) Kelly guided CSM unit
Reproduced from Stoetzer *et al*. (2006)

Verification in fact commences with the careful execution of the work within the specified tolerances to an appropriate level of quality control. Further verification using field trials, laboratory or *in situ* tests or some other means is usually necessary. Attention should be paid to guidance available in the CIRIA reports C572 (Charles and Watts, 2002), C573 (Mitchell and Jardine, 2002) and C514 (Rawlings *et al*., 2000), and the European execution codes listed below. As with the processes themselves it is essential that advice from experienced specialists is taken.

Considerable care is needed in the selection, execution and interpretation of these tests, and all parties to the work need to be clear on the verification strategy and the interpretation of the results before testing commences. It is clearly wise to select a verification programme which has had a proven track record. **Table 90.5** indicates the main means of verifying treatment, but the reader should be aware that there are several other means, some specific to individual processes, which may be particularly relevant to their project.

Pre-contract trials at full scale are often useful, and sometimes essential, in order to establish the properties or even the viability of the prospective process. In jet grouting, for example, evidence of the diameters and associated properties may require the formation of full-scale test columns, which can then be examined in detail to provide confidence in conditions for which previous experience is small or unavailable (**Figure 90.24**).

For both dry and wet soil mixing, laboratory trial mixes are particularly useful, but cannot directly take account of variability in the ground, and lab mixing efficiencies will inevitably be different from *in situ* mixing. Careful interpretation of such tests is therefore necessary.

Tests on cores, or more rarely on block samples, recovered from the treated zone are often considered and can be good guides to performance. However, low sample disturbance, accuracy in aligning the coring tool, and high core recovery to properly represent the mass properties are needed. Realism in assessing the prospects of achieving good-quality cores, together with the employment of specialist crews experienced in verification coring, is essential to achieve a successful outcome. In wet soil mixing and in jet grouting, triple tube coring methods have shown good efficiency where the treated mass is suitable.

Another option possible in some situations for soil mixing and jet grouting consists of the recovery of 'wet' samples soon after completion of the process and before setting takes place. These samples can be placed in cylindrical or other approved moulds and tested at the specified time intervals.

A range of tests carried out from within boreholes can be conducted. Again it is important to ensure the positional tolerance of these, and take account of the possible effects of disturbance on the properties being measured. They are particularly helpful in measuring permeability as some feel for the mass behaviour is gained. Other common *in situ* tests such as SPT or CPT are commonly considered for verification tests. It should be appreciated, nevertheless, that these were developed for soil investigation and they can be unpredictable in assessing the properties of what in effect are artificial cemented materials produced by one of a range of grouting and soil mixing processes. The author is aware of sites for which the CPT grossly underpredicted the apparent *in situ* shear strength of cement bentonite injections, jet grouted columns and soil mixed masses, by comparison with tests on cores and wet samples. These systems can therefore only be recommended when there exists a good body of relevant information for the processes

	Permeation	Jet grouting	Soil fracture	Compaction	Dry soil mixing	Wet soil mixing

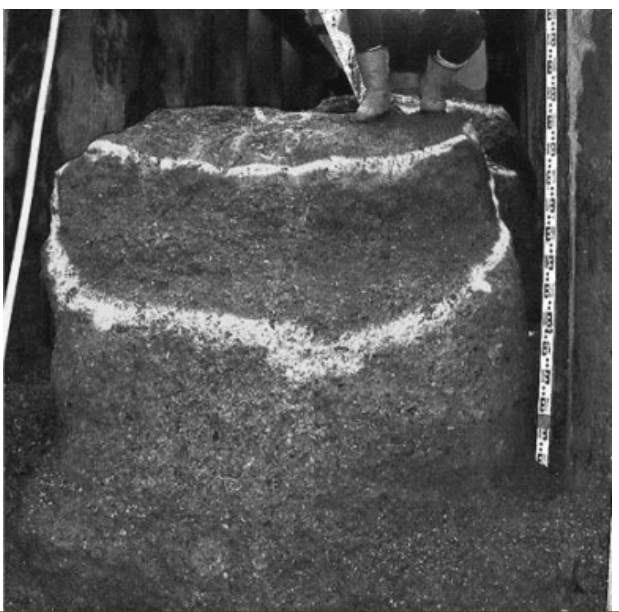

Figure 90.24 Example of jet grouted column formed as part of a pre-contract trial

and specific soils to be treated, or where sufficient pre-contract trials are specified in order to calibrate such tests with the required properties.

Finally, testing at or near full scale can be a powerful means of verifying the performance of the treated mass. However, this is often expensive and can suffer from lack of coverage of the whole volume of treatment. In assessing permeation, for example, such as for cut-off walls, piezometers suitably placed either side at the key levels can be used to check the overall cut-off performance. However, the timescales involved in assessment may be considerable and well beyond the construction programme. Similarly, foundation settlement under load can be assessed to some extent by full-scale loading on the improved ground, although usually needing further interpretation to cover the likely timescales and loading complexities imposed during the design life of the structure being supported.

The introduction of the *Code for Sustainable Homes* (DCLG, 2009) has seen an increase in the use of modular off-site foundation systems. This is particularly noted in the case of house foundations and other lightly loaded structures. The benefits of using modular foundations are only just being realised and as the trend for 'off-site superstructure fabrication' continues to progress, the use of such sustainable options will increase. The emphasis of many of the leading ground engineering specialists has therefore been to explore and develop new systems that assist building contractors to achieve a higher code rating than would be realised by using traditional 'dig and dump' foundations.

91.1 Introduction

Structures that utilise a form of modular foundation have been with us for decades. The British landscape is peppered with excellent examples of just how forward-thinking our ancestors were. Sustainability was not high on their agenda. They had not heard of lean construction, Egan, or Latham, and they did not appreciate the effects of global warming and the lasting legacy of their actions. They built foundations for the structures like the ones shown in **Figures 91.1** and **91.2** because they had practical reasons to do so.

The methods they employed depended on the skills and equipment of the time, but were always tried and tested techniques. The drivers for their construction were purely practical. In the case of **Figure 91.1**, the requirement was to store grain off the floor in a dry environment away from rodents and other vermin, and in the case of **Figure 91.2** the need was to live above water. They were not designed using mathematical formulae and did not employ the concepts of soil mechanics or geotechnical engineering. They were built using techniques passed down from generation to generation and, more importantly, the methods they employed worked.

As engineers we seek to improve on the 'traditional' methods employed by our ancestors. The Egan report *Rethinking Construction* (Construction Task Force, 1998) brought to the attention of the construction industry the concept of 'lean construction'. One of the cornerstones of this concept is the use of modularisation, off-site techniques and 'just-in-time' delivery. The concept was not really new to the foundations industry – it had been installing pre-cast driven piles (a factory-produced product delivered 'just in time') for decades and had been fabricating pre-cast concrete walls and foundation beams since the early 1930s. Many of these early modular buildings still survive and are in good serviceable condition (BRE, 1984). However, the principles behind *Rethinking Construction* require the piling and foundations industry to take a more holistic view and move towards the use of a truly modular foundation. Generally,

© Mikhail Nekrasov

this is not a practical solution – for instance, in the case of rotary bored or driven cast *in situ* piles. However, in the particular case of house foundations and lightly loaded structures, there have been recent (contractor-led) developments towards the use of modular off-site foundation *systems*.

91.2 Modular foundations

We can define a *module* as being 'a separable component, frequently one that is interchangeable with others, for assembly into units of differing size, complexity or function', and *modular* as being 'composed of standardised units or sections for easy construction or flexible arrangement'. What is therefore meant by a modular foundation? The historic 16th-century grain store foundation shown in **Figure 91.1** provides us with an excellent example of how a simple practical design concept of the past can be translated into modern concepts. The foundation *system* is modular; the staddle stones provided the support mechanism in a similar way to a foundation system patented some 450 years later.

Perhaps the most well-known example of a modular foundation is the pre-cast pile (**Figure 91.3**), a concrete unit manufactured in a factory environment and delivered to site, where it is subsequently driven into the ground. Individual pre-cast concrete sections (modules) can be joined together during the driving process and the final length of pile is therefore determined during the actual installation process. In the strictest sense the system is truly modular. A more in-depth review of modular piling systems is covered elsewhere in this publication: Chapter 81 *Types of bearing piles* provides further information on the construction of these and other displacement pile types; Chapter 82 *Piling problems* outlines some of the commoner problems that may be encountered; and finally, suitable design methods are discussed in Chapter 54 *Single piles*.

In house building, the trend for 'off-site superstructure fabrication' continues to progress. There is now a diversity of approaches based on steel or concrete systems, as well as timber frame or panels. Timber-framed buildings had a bad press in the 1980s due to poor construction and maintenance issues, but they have recently made a comeback due to better product quality control and their green credentials. The influx of light steel and other panel systems from the Continent has huge implications for traditional cladding and roofing products, as well as site practices. This applies across the whole housing and offices sector. It is only in recent years that the foundation sub-structure has moved into an off-site environment. Designs based on modular foundation units (fabricated in a factory environment and assembled on site) have been around for many years, but it is only recently that they have been viewed in a more holistic way – the sub-structure becoming an integral part of the superstructure design.

91.3 Off-site manufactured solutions – the rationale

There is now strong evidence that our climate is changing and our planet is warming up (Stern, 2007). The 24 million homes in the UK account for over a quarter of the UK's carbon usage emissions (DCLG, 2007). As responsible contractors/engineers, the need to change our approach to construction has never been greater. The standards set out in the *Code for Sustainable Homes* (DCLG, 2009) (an environmental assessment method to measure the sustainability of new homes) will need to be achieved if we are to protect our future. We need a revolution in the way we build new homes – both to cut our carbon emissions and to respond to our changing climate – and we need that revolution to begin with this generation of designers, engineers and builders. Chapter 11 *Sustainable geotechnics* provides a holistic overview of sustainable geotechnics and also contains some excellent references which outline the subject in greater detail.

Homes account for around 27% of UK's carbon emissions (compared to air travel, which currently contributes 3% of the global carbon emissions, and cement production which contributes 2%). The emphasis of many of our leading ground engineering specialists has therefore been to explore and develop new systems that assist building contractors to achieve a higher code rating than would be realised by using traditional 'dig and dump' foundations. The contributing issues that modular foundations can affect in respect of the *Code for Sustainable Homes* are detailed in **Table 91.1**.

Several proprietary examples of modular foundation systems are currently marketed in the UK and all offer differing but significant advantages to prospective developers. The most efficient modular foundation systems provide major sustainable benefits (NHBC Foundation, 2010). To give an example,

Categories	Issues
Energy and CO_2 emissions	Building fabric
Materials	Environmental impact of materials
Responsible sourcing of materials – building elements	
Surface water run-off	Flood risk
Waste	Construction waste management
Pollution	Global warming potential of insulates
Health and well-being	Sound insulation
Management	Considerate constructors scheme
Construction site impacts	
Ecology	Protection of ecological features

Table 91.1 Contributing factors for modular foundations to Code for Sustainable Homes (DCLG, 2009)

Figure 91.4 Factory construction of foundation components
Courtesy of Roger Bullivant Ltd, all rights reserved

consider the following: 'traditional' trench-fill foundations for an average house (having a footprint of 80 m^2) will release 45 tonnes of CO_2 into the atmosphere. A modern composite reinforced concrete and galvanised steel foundation system will release 11 tonnes, a reduction of 75%. Even greater percentage reductions are calculated for water and raw materials usage (Arup, 2009).

Given the major impact that construction (and house building in particular) has on the environment, these long-term benefits could have significant implications for the building industry as a whole. However, they are only just starting to be realised in the UK. To a large extent, it is future legislation that is currently driving the use of such systems by national house builders; however, small-scale developers and individual self-builders are the ones who seem to be eager to embrace modular building techniques. They are pushing the boundaries by increasingly using these systems for bespoke one-off developments (www1, 2010).

Most modular foundation systems require no trench excavation, thus avoiding the hazardous practice of working in excavated ground. Components are manufactured off-site (**Figure 91.4**) and installed on-site (**Figure 91.5**) with a significant time saving on traditional house foundation construction methods. These advantages are more pronounced when the systems are installed in large volumes.

Significantly, most of these patented proprietary systems have been developed by specialist geotechnical contractors rather than general building contractors. The most common types are detailed below.

91.4 Pre-cast concrete systems

Modular pre-cast concrete foundation systems have been used successfully for many years, particularly in the housing sector where they form one of the larger component sub-assemblies for either conventionally built or modern methods of construction (MMC) dwellings. A variety of proprietary pre-cast suspended flooring systems are available found on either

Figure 91.5 Pre-cast concrete beams for modular foundation system
Courtesy of Roger Bullivant Ltd, all rights reserved

conventional strip or trench fill foundations for good ground conditions, or on piled supports in poorer ground. The more common types of system are:

(i) *Beam and block*, which is suitable for use at both ground and upper floors and is used in conjunction with standard format building blocks to provide a fast and cost-effective floor deck.

(ii) *Insulated beam and block*, which utilises pre-stressed beams in conjunction with expanded polystyrene blocks to provide inherent thermal insulation for ground floors.

(iii) *Hollowcore*, comprising pre-stressed and reinforced hollow-cored slab elements which easily accommodate the longest spans for domestic applications.

(iv) *Lattice girder*, which is a pre-cast concrete permanent formwork used in conjunction with a composite concrete topping. These floor types easily satisfy the requirements of *Part L* of the Building Regulations (BRE, 2006).

91.4.1 Composite reinforced concrete and galvanised steel

This type of foundation system is a lightweight, modular, composite, fully insulated foundation and ground floor system which will support any low-rise building in all ground conditions at an affordable cost and with significant environmental benefits. The system comprises fibre-reinforced high-strength screed on expanded polystyrene insulation which is incorporated into galvanised steel channel section floor beams. This floor is placed on composite reinforced concrete and galvanised steel primary support beams (**Figure 91.6**). Manufactured predominantly off-site in a factory environment, the system is assembled on-site, by hand, and is connected together with an appropriate amount of reinforced steel and fibre-reinforced *in situ* concrete (**Figure 91.7**).

The modular system is value-engineered to eliminate waste. It contributes to the sustainable design in new construction by substantially reducing the use of natural resources and subsequently the embodied carbon footprint of the building when compared to more traditional foundations. These types of modular foundation system generally have A+ ratings in the BRE green guide (BRE and Oxford Brookes University, 2009). Three types of floor can be used, depending on the level of code requirement. These deal with the Current Building Regulations (as at 2011), a floor to Code 3 (requiring the home to be 25% more energy efficient than one built to the 2006

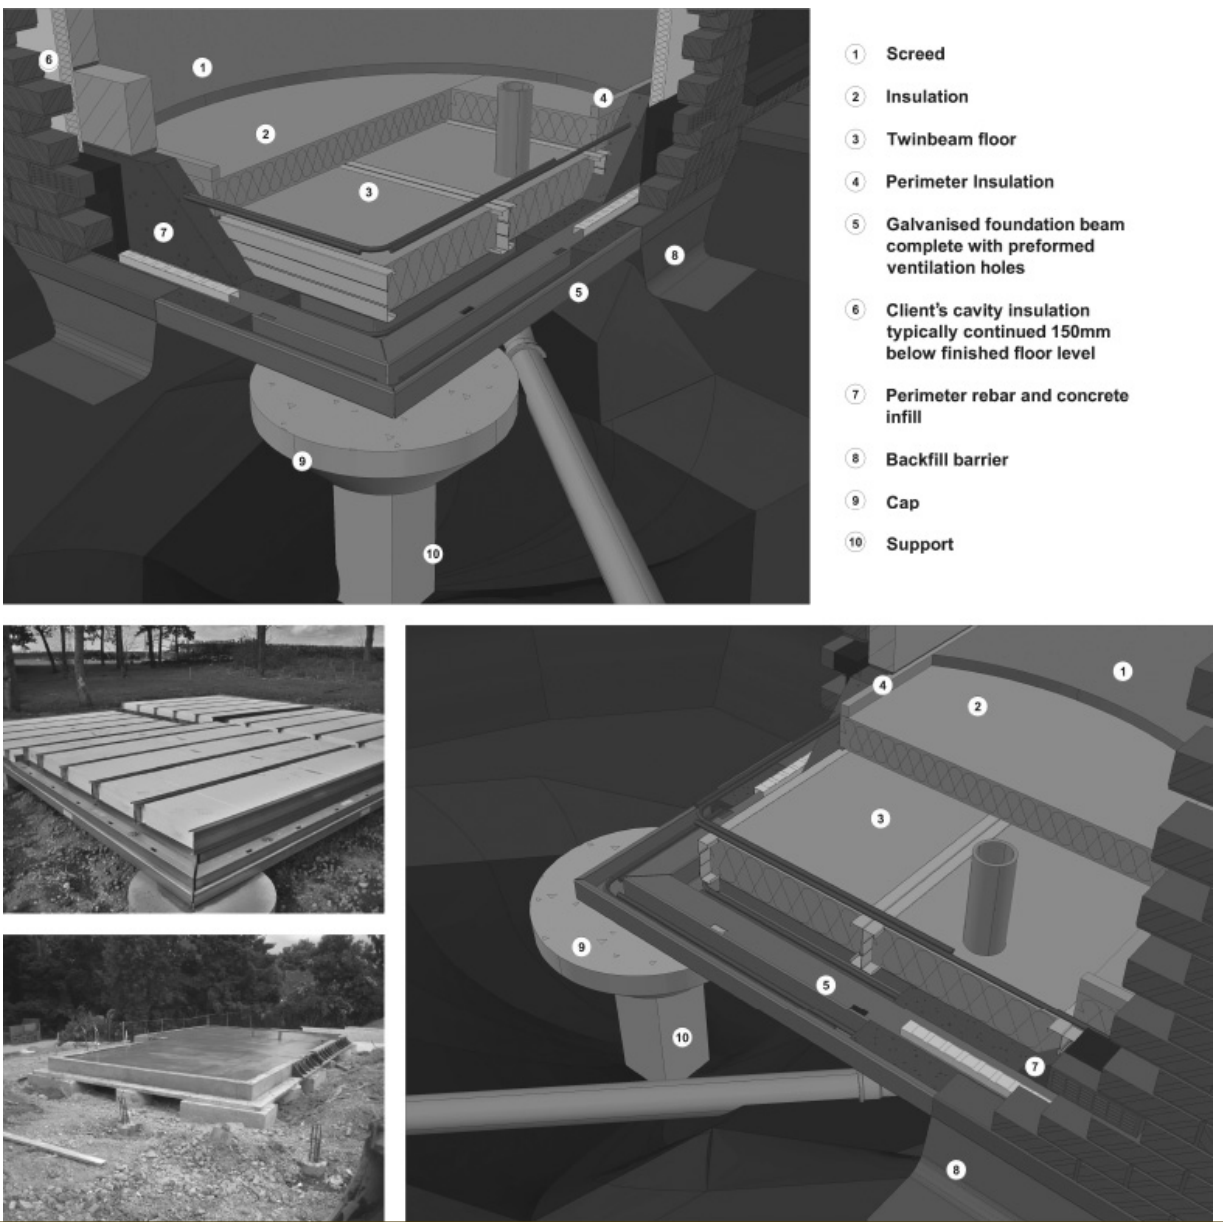

Figure 91.6 Composite foundation floor sections

Building Regulations Standards) or a floor to Code 6 (the code requiring the home to be completely zero carbon by 2013). The manually assembled construction process eliminates the requirement for heavy plant, which significantly improves on-site health and safety. Each of the modular units weighs less than 25 kg, meaning that they satisfy the safety requirements for manual handling.

These types of composite modular system are 'flexible', in that they can accommodate superstructure designs based on the following forms of construction: timber frame, traditional masonry, structural insulated panel (SIP), lightweight steel, composite concrete panels, and insulated concrete formwork (ICF). The last two forms of construction require major modifications to the foundation system, which may prove uneconomical.

As with any foundation system, the site-specific geotechnical conditions will dictate the support to be used and it is therefore a fundamental requirement that a sufficient ground investigation is provided at design stage. There are a range of support products and techniques available to suit most modular foundation systems, such as pads, piers, displacement cones, vibro-concrete columns or piles. Although these systems have been developed with low-rise, domestic-type construction in mind, they can be adapted to suit other building categories by increasing the number of supports, limiting the floor and ground beam spans, as well as increasing the ground beam capacity.

91.4.1.1 Case study 1 – Bucks Green, West Sussex

On this small housing development, the client was determined to construct five detached dwellings to a very high standard and planned to achieve the highest possible rating with regard to the *Code for Sustainable Homes*.

The underlying geology of the sloping site, in West Sussex, was Weald Clay with a high plasticity index, necessitating the use of anti-heave precautions in the piles and below the pile caps, as well as a 250 mm void beneath the floor slab. A total of 178 (300 mm diameter) continuous flight auger (CFA) piles, drilled to a depth of 8 m, were required to support the dwellings (**Figure 91.8**).

To assist in achieving the desired rating, the client selected a composite reinforced concrete and galvanised steel system as the most appropriate floor system. The floor was designed to include under-floor heating throughout the ground floor to provide a U-value of 0.12 w/m^{2}K (a U-value is the measure of heat loss through an element expressed as watts per square metre for every degree Kelvin difference in heat either side of the element).

The standard foundation was modified at the design stage to accept brick plinths and a bespoke timber frame. The system proved to be flexible enough to include a 1.5 m level change between one of the dwellings and an attached garage; the level change was required due to the nature of the sloping site.

Many modular foundation systems also contribute greatly to the thermal efficiency of a building. A U-value of up to 0.12 W/m^{2}K can be achieved from the floor construction. As a comparison, values currently achieved with traditional block and beam floors are in the region of 0.18 W/m^{2}K.

91.4.2 Reinforced concrete piled raft

The Housedeck® foundation system is a form of piled raft and offers similar benefits over traditional foundations. The system in its basic form is shown in **Figures 91.9** and **91.10**.

There are many variations available; for example, a void can be incorporated to overcome the potential problem of clay heave. Apart from speed of installation, Housedeck® is particularly useful where trees are located adjacent to the development. The system can guarantee that the piles and construction will not sever crucial life-supporting roots. This is achieved by hand augering at pile locations and then moving the piles to avoid any roots that would otherwise be damaged by the piling

Figure 91.9 Reinforced concrete piled raft foundation – Housedeck®

process. Geotextile membranes and lightweight rigs are also used wherever possible to avoid crushing the roots.

Proprietary systems in themselves offer greater comfort to the customer as they are often subject to a quality management system.

91.4.2.1 Case study 2 – Waltham Abbey, Essex

The project involved the design and construction of a reinforced concrete raft foundation system for 48 no. residential units, incorporating two- and two-and-a-half-storey houses/apartments (**Figure 91.10**). The ground conditions of the site

Figure 91.11 Post-tensioned concrete modular foundation – Smartfoot®
Courtesy of Van Elle Ltd, all rights reserved

comprised Made Ground composed of stiff fissured clay up to 2.7 m in depth; alluvium, a soft grey silty clay down to 4.0 m; loose to medium dense well-graded sand and gravels (Kempton Park Gravels) 7.0 to 7.5 m below existing ground level; and London Clay, stiff to very stiff fissured clays with medium to high shrinkability. The piling contractor undertook the design and construction of the piling platform in accordance with construction design and management (CDM) regulations and the Federation of Piling Specialists recommendations, and then designed and constructed 460 no. 300 mm diameter continuous flight auger piles to depths varying from 9.0 to 14.0 m. In this particular example, the specialist sub-contractor also designed and constructed the 2 240 m^2 of suspended reinforced concrete slabs which, because of the shrinkable clay strata, had to incorporate a full 225 mm void to overcome potential heave.

91.4.3 Post-tensioned concrete modular systems

A post-tensioned pre-cast concrete modular foundation system offers similar benefits to the systems already outlined above for a wide range of structures varying from traditional build, modular structures, housing, hotels, prisons and schools (**Figure 91.11**).

Like the preceding modular systems, this type of foundation provides many benefits over traditional strip or trench-fill foundations. It is cost-effective and fast (up to 400 m of beam can be installed in one day), and can be installed to high tolerances (±3 mm). The system is suited to traditional and modular type construction and can be installed with or without piles.

91.4.3.1 Case study 3 – Houghton-le-Spring, Sunderland

The client wanted to develop a site of affordable housing for the local community. Due to the nature of the project, the development had to be both time- and cost-efficient – the developer wanted the houses up as soon as possible. In view of the client's overriding need for the foundations to be installed in the shortest

Figure 91.12 Post-tensioned concrete modular foundation system, Houghton-le-Spring, Sunderland
Courtesy of Van Elle Ltd, all rights reserved

possible time and at the most affordable cost, the project was therefore scoped using a post-tensioned pre-cast modular foundations system and concrete pre-cast driven piles (**Figure 91.12**). There were 58 plots on the site and 600 no. 200 mm × 200 mm piles, and around 2 500 m of ground beams were installed. The job was completed within eight weeks. The scope of works turned out to be a great example of off-site construction methods. Both the piles and ground beams were manufactured off-site to site-specific designs. What followed was a clean site, accurate installation and fast completion, proving all of the benefits provided by the use of a modular foundation system.

91.5 Modular retaining structures

A retaining structure or retaining wall is used to provide lateral support for a soil mass and may be used to carry vertical load, for example bridge abutments or basement walls. The varieties of structural arrangement that may serve as a retaining wall are almost unlimited. Their classification is based on their method of achieving stability; the most common are the gravity wall, cantilever wall, counterfort wall, buttress wall, diaphragm wall, sheet pile wall and reinforced earth wall (Clayton *et al.*, 1993). For a more in-depth review of retaining walls, reference should also be made to Chapter 62 *Types of retaining walls* and Chapter 64 *Geotechnical design of retaining walls* and to Chapter 67 *Retaining walls as part of complete underground structure* as part of complete underground structure.

The use of modularisation is beneficial in many retaining structures, both in terms of cost and productivity. For these reasons, the use of repeating modular units to form structural retaining systems has long been favoured by foundation specialists. Gravity walls, for example, which rely on their own weight and rigidity for stability, can be constructed using smaller interlocking modular units. Examples include gabion walls, crib walls and pre-cast reinforced concrete walls. Gabions are rectangular baskets made from galvanised steel mesh or woven strips filled with stone rubble or cobbles. They are aesthetically pleasing and provide a quick method of installing free-draining wall units. Crib walls are formed with interlocking pre-cast concrete units (or timber). Stretchers run parallel to the wall face and headers are laid perpendicular to the stretchers. The space formed by the 'cribs' is then filled with free-draining material such as rock, cobble or gravel. RC walls are the commonest modern form of gravity wall and are suitable for walls up to 6 m in height.

Interlocking sheet piles are commonly used for embedded retaining walls, both for temporary works and permanent structures. A factory-produced product, these steel (or plastic) 'modules' are designed to provide the maximum strength and durability at the lowest possible weight. The design of the sheet pile section interlocks facilitates pitching and driving, and results in a continuous wall with a series of closely fitting joints (ArcelorMittal, 2008). Steel sheet piling has traditionally been used for river control and flood defence structures, and is a tried and tested material for the construction of quay walls for ports and harbours. It is also an ideal material for constructing basement-retaining walls as it requires minimal construction width. One example where steel sheet piling has been found to be particularly effective is for the creation of underground car parks (SCI, 2001). The reader is directed to the following references which provide further detail on many aspects of the use of modular foundations.

Chapter 92

Introduction to Section 9

Michael Devriendt Arup, London, UK
Michael Brown University of Dundee, UK

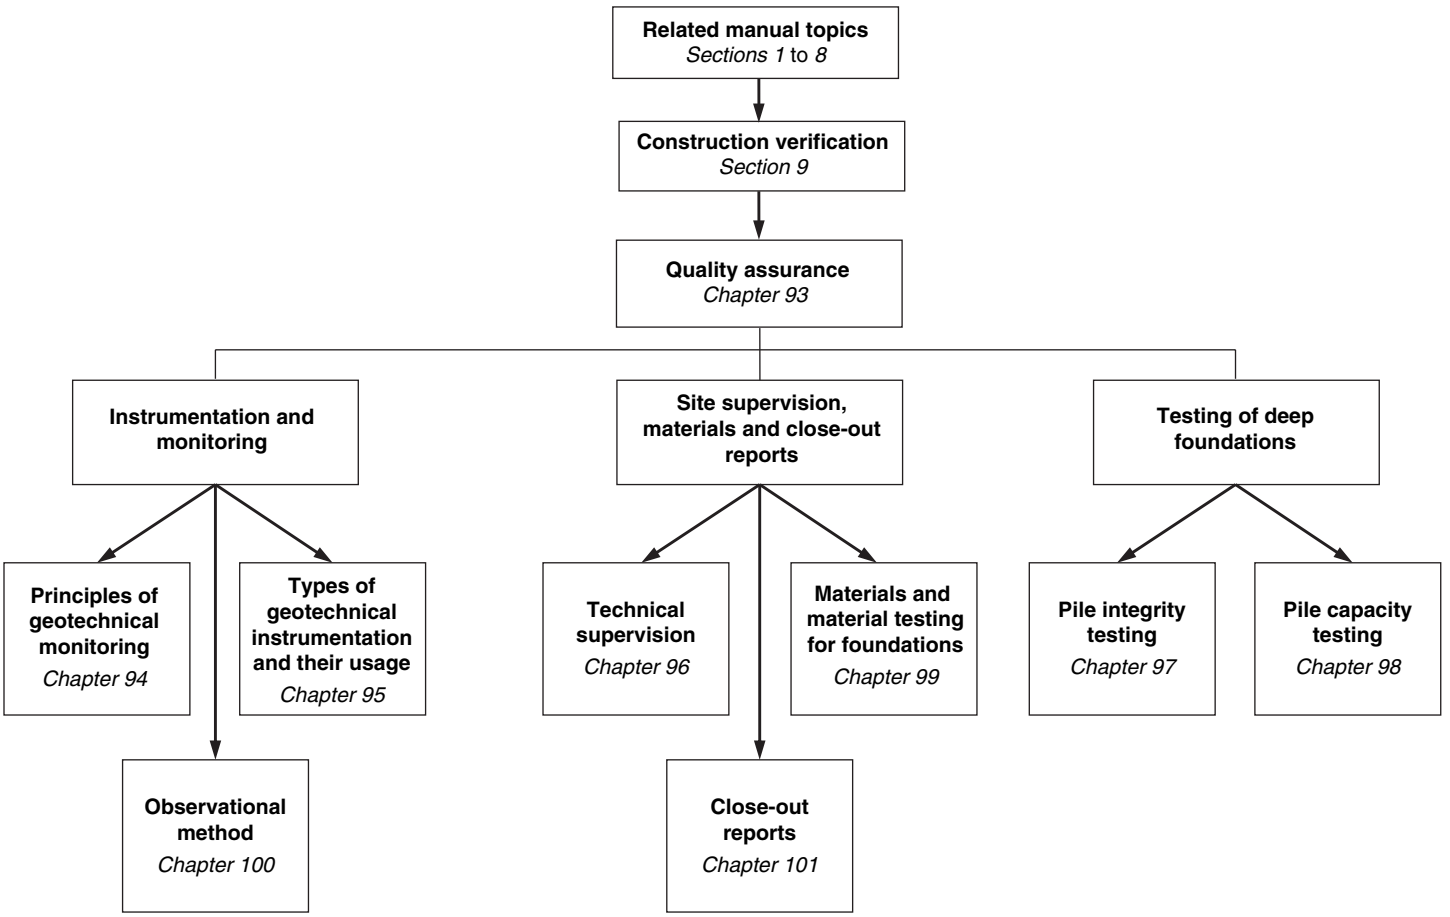

Figure 92.1 Layout of chapters in Section 9

Construction verification can be described as the process of providing test or monitoring results to contribute towards design or management of the works, or to confirm that construction work is being carried out in accordance with the proposed design, specification and appropriate standards.

In no other area of construction is the inter-relationship between design and construction so pronounced. Ground is inherently variable so the main construction material can never be known in advance with enough precision. Additionally, design parameters are often dependent on the methods of construction, so can be easily invalidated by minor changes in technique or in soils encountered. Hence construction verification has a much higher significance in geotechnical design than it does in most other areas of construction. Additionally, there is much to be learnt from observing construction and most innovations in geotechnical engineering have their roots in watching and understanding construction taking place. Hence there is a long-term virtuous circle in improving the links between construction and design. Designers must understand how geotechnical works will be enacted and constructors must understand the significance of the design assumptions underpinning the methods they are using.

This section is composed of nine chapters (see **Figure 92.1**) and begins with Chapter 93 on quality assurance (QA) which outlines the processes and management systems that may be put in place to ensure a minimum quality of the final construction product. One of the most important elements of a QA process is construction verification which is particularly important for geotechnical works as completed elements are usually buried and difficult to inspect subsequently. They are

also amongst the most heavily loaded structural elements and their construction is invariably on the project's critical path. This results in a need for early identification and remediation of non-conformances.

The remaining chapters in the section can then be divided into three general themes:

Instrumentation and monitoring

- Chapter 94 *Principles of geotechnical monitoring*
- Chapter 95 *Types of geotechnical instrumentation and their usage*
- Chapter 100 *Observational method*

Construction verification and close-out reports

- Chapter 96 *Technical supervision of site works*
- Chapter 99 *Materials and material testing for foundations*
- Chapter 101 *Close-out reports*

Testing of deep foundations

- Chapter 97 *Pile integrity testing*
- Chapter 98 *Pile capacity testing*

Geotechnical monitoring provides confirmation that works are being carried out in a safe, controlled and efficient manner. By setting pre-agreed limits, monitoring also provides information on when and how contingency measures should be adopted. Comparisons of the monitoring data can also be made with design calculations or results can be back analysed to improve calculations on future projects with the potential for significant cost savings. Although monitoring may be viewed as being beneficial, it is important that systems are installed with a clear objective and a plan of how the measured data will be implemented. Monitoring is also very useful for avoiding claims from third parties on the effects of construction on them and their activities – movement, noise and vibration monitoring can be particularly valuable for refuting claims which could otherwise result in long and costly legal procedures.

Site supervision, close-out reports and materials testing provide confidence that the site works are being carried out and documented in an appropriate manner. Improvements in data recording, management and storage have increased the importance of these subjects, particularly when modifications are carried out to existing structures or where sites are redeveloped. For example, there has been more interest recently in the re-use of foundation elements, especially deep foundations in congested urban environments. Knowledge captured as part of the original construction (as covered in all of the chapters in this section) will form a valuable source of data for future construction teams which may be faced with a new set of challenges.

The testing of deep foundations allows efficiencies to be made in the design of foundations and can confirm that the piles have been constructed in accordance with the design intent. Deep foundation testing has seen recent changes in techniques (e.g. automated static testing, rapid load testing) as well as new applications through the re-use of piles. This means that the engineer needs to decide:

- when testing is necessary;
- how many piles to test;
- the most appropriate techniques to use;
- how to assess and interpret the findings of testing.

The publishing and dissemination of pile test data is also invaluable for improving the collective knowledge for the design and construction of piles in similar materials in the future.

All of the chapters covered in this section contribute significantly towards the centre of the geotechnical triangle (Burland, 1987 and Chapter 4 *The geotechnical triangle*). The geotechnical triangle is used as a framework for geotechnical engineering; its centre focuses on:

- *establishing precedent* E.g. the use of instrumentation, monitoring and the observational methods for new construction techniques, or where ground conditions are unfamiliar or have uncertain behaviour, or are difficult;
- *the use of empiricism* E.g. pile capacity testing to refine design assumptions and increase efficiency;
- *forming well-winnowed experience* E.g. technical site supervision, selection of appropriate materials and dealing with non-conformances.

The range of subject matter in this section has been chosen to assist an engineer in making appropriate decisions to manage and verify construction processes. It is important, however, to realise that such techniques are only one component in the overall strategy to successfully complete a set of foundations or other geotechnical works. Construction verification must also consider the influence of the ground profile, soil behaviour and the need for an appropriate model to compare experience with. In this respect, the following quote from Terzaghi (1935) summarises the importance of having knowledge from both theory and experience: 'Experience alone leads to a mass of incoherent facts. But theory alone is equally worthless in the field of foundation engineering, because there are too many factors whose relative importance can be learned only from experience.'

As a profession, we can collectively make improvements to existing knowledge by utilising the best practice, some of which is contained in this section. This will enable improvements and efficiencies to be made on current and future projects.

Quality assurance is an essential part of the design and construction process and provides confidence to the other parties to the contract that the end product will be built to at least a minimum standard. The specification defines this minimum standard – in geotechnical engineering there are many different model specifications available to suit different construction processes. An additional complementary project-specific specification is needed considering the unique nature of the project and its ground conditions. Workmanship is verified either by a resident engineer, or similar, or by the contractor undertaking self-certification. A key component of quality assurance is the identification and reparation, if necessary, of non-conformances. If any workmanship is thought to be faulty, or if there is a failure, then a forensic investigation will need to be carried out. The records produced by the quality assurance procedure provide factual data for use as part of this investigation.

93.1 Introduction

Geotechnical works are often supplied by different parties undertaking the choice of the type, design, procurement and construction of the works. However, all of these are inter-dependent and a failure in one will likely lead to a failure of the whole works.

Quality assurance (QA) is the management system that will ensure that all key parts of the geotechnical design and construction process are undertaken consistently in order to provide at least a minimum standard. Certification of the QA system by an accredited independent body is the evidence that clients, consultants or contractors can rely upon so that each party does not need to audit the other organisations.

A designer will use quality control (QC) systems to ensure that the design and checking process is undertaken to meet the QA requirements. The contractor will use QC systems to ensure that the construction is in accordance with the specification and design. Dependent upon the contractual arrangements on any particular project, the contractor will either have his workmanship verified by an external party, such as a resident engineer (RE), or will be required to self-certify his own work.

Identifying and rectifying non-conformant work is a key part of the QA process. For geotechnical work, it is paramount that a thorough forensic investigation is carried out at the earliest opportunity so that these issues are closed out early on in the construction process.

93.2 Quality management systems

For background information on quality management systems refer to ISO 9001, ISO 14001 and OHSAS 18001.

Both the design and construction of geotechnical work need to produce an end product that meets three key criteria:

(i) to have an adequate safety margin against failure;

(ii) to have acceptable displacements over the likely range of applied loads;

(iii) to be durable for the stated design life.

For UK design work, *British Standards* and *Codes of Practice* define methods of achieving these criteria. Execution codes, as listed in Chapter 78 *Procurement and specification*, also provide recommendations to help the designer achieve the criteria.

For geotechnical work it is essential that the method of construction is compatible with the design, and that the workmanship meets at least the minimum requirements of the design. The contractor will use QC systems to ensure that these are achieved. QC systems are important in all aspects of construction, but are especially so in geotechnical work as there may be variation in the ground conditions not shown by a site investigation – which only provides information from a limited and discrete number of locations. Many geotechnical processes, such as piling, have to be carried out without necessarily having the knowledge of specific ground information at the particular location. Consequently, continuous monitoring of these processes is a key aspect of the QA management system.

93.3 Geotechnical specifications

The specification defines the minimum standard of work necessary to meet the requirements of the design and of the employer. Because there are many geotechnical processes and solutions, there are many model specifications available; some of these are listed in Chapter 78 *Procurement and specification*.

Model specifications should be used because these have been written by experts in the field and will have been subjected to critical scrutiny by the geotechnical community. However, geotechnical processes can be undertaken with variations and so systems and methods may vary from those stated in a model specification. Such variations in the method of construction or equipment must be clearly identified in the

specialist sub-contractor's method statement and be compatible with the design.

Geotechnical engineering is a very innovative part of the construction industry and both design methods and construction processes are improving all the time. This means that model specifications, if not recently updated, can become outdated and may even be contradictory to current practice. It is essential that experienced geotechnical engineers are used to assess any proposals that would vary the requirements of these specifications.

In addition to model specifications, a project-specific specification is very important for geotechnical work because ground conditions are unique for any site. The particular aspects which may affect the geotechnical work need to be stated so that all concerned can be informed. Project-specific specifications should include all available factual information on the ground conditions, including the groundwater conditions. Clause B1.2 of the *ICE Specification for Piling and Embedded Retaining Walls* (2007) is a good example of what needs to be included in a project-specific specification.

93.4 Role of the resident engineer

The detailed responsibilities of the RE on any site will probably not be defined in the contract documents. Normally the role of the RE is to supervise the works on behalf of the employer and to make sure that the employer's project is delivered as intended, see Chapter 96 *Technical supervision of site works*. If the engineer is also the designer of the geotechnical work, then the RE will also be supervising the works to ensure that the standard of construction is in accordance with the design and specification requirements.

To save costs, it has become common for there to be no RE at all, or for the RE to be on site on a part-time basis with no formal power under the contract. This is not recommended except for the most straightforward of geotechnical work. Geotechnical engineering requires experience of a wide range of ground conditions and of complex construction processes, and it can only be of benefit to the project, and ultimately the employer, to have an RE present. It is preferable that the RE supervising geotechnical work should be a geotechnical engineer experienced in the prevailing ground conditions and construction process being used. There are many specialist geotechnical consultancies that can provide this service if the employer's professional team does not have the appropriate experience.

93.5 Self-certification

Most geotechnical work is carried out on a design and construct basis by specialist organisations that are often contracted to self-certify their work and provide a warranty for it. Self-certification by the trade contractor or specialist sub-contractor requires them to apply the QA processes on site in relation to their own works. If a project is self-certified there may not necessarily be an RE on site; if there is, they will have little or no contractual responsibility for the self-certified works. The process is often associated with the use of the new engineering contract (NEC), especially on large civil engineering projects, although the NEC itself does not impose self-certification, nor does it actually impose QA. Consequently, any requirement for self-certification will either be defined in specific contract amendment clauses ('Z' clauses in NEC), the *project specification* or in *works information*.

Self-certification by the contractor reduces the burden on the employer and the professional team, particularly where new technologies are involved. If the process is carried out efficiently, the specialist contractor is best placed to coordinate the construction and the checking of the construction process. Any faults or non-conformances should be found and dealt with at the earliest opportunity, minimising the cost of rectification and any consequences.

93.5.1 The self-certification process

The fundamental requirements of the self-certification process are that every part of the construction process should be monitored for compliance and performance. The basic questions are:

(i) Does the work satisfy the specification?

(ii) Is the work being implemented as planned?

(iii) Are the construction and design requirements being met?

The contractor's staff on site should be competent to self-check their own work and supervisory staff made responsible for review and inspection.

The employer will need to approve the contractor's quality management system and will monitor that it is being applied correctly, and carry out spot checks on finished work. Under NEC option 3 (target cost), non-conformances identified by the contractor are paid for by the employer. However, if they are not identified by the contractor but found subsequently, the contractor pays – which provides an incentive to the contractor to ensure that their quality control is applied consistently. If the process is to be carried out with confidence, the contractor must set out in his quality management system a detailed description of how the construction standards will be monitored, checked and maintained, at all times.

Clause 40.3 in the NEC describes how self-certification works best:

> The contractor and the supervisor each notifies the other of each of his tests and inspections before it starts and afterwards notifies the other of its results. The contractor notifies the supervisor in time for a test or inspection to be arranged and done before doing work which would obstruct the test or inspection. The supervisor may watch any test done by the contractor.

The Construction (Design and Management) Regulations 2007 (CDM) require the contractor to:

> Plan, manage and monitor construction work carried out by him or under his control in a way which ensures that, so far as is reasonably practicable, it is carried out without risks to health and safety.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

These CDM requirements must be satisfied in addition to any self-certification requirements, including monitoring and testing.

The records that need to be kept and submitted as part of the self-certification process need to be very detailed, and are likely to be incorporated into the contractor's method statements. The contractor's quality management system needs to define who will be responsible for the implementation of each element of the works, who will be responsible for independent inspection and, if appropriate, who will be responsible for auditing the whole process.

An important part of the self-certification process is the ability to react quickly to any revealed non-conformances. The processes and responsibilities for dealing with these situations should also be defined by the contractor's quality management system.

93.6 Finding non-conformances

Undetected problems with work carried out in the ground can have severe consequences later on, including major financial implications for all involved. For example, a defective pile can normally be easily replaced during the piling works, but once the sub-structure and superstructure are in place it can be very difficult to do so. (Also refer to Chapter 82 *Piling problems*.)

The methods for finding non-conformances vary depending on the construction process, but would normally involve a combination of some or all of the following: design review, observation, measurement, testing and investigation. The most common non-conformances in geotechnical work are described below.

93.6.1 Concrete in the ground

Concrete placed in the ground is particularly at risk from expensive investigation and remedial measures if the concrete test results subsequently prove to be unacceptable. The first point to consider is the source of the concrete. Ready mixed concrete is often delivered to the site, but on larger projects the concrete may be batched and mixed on site. The quality scheme for ready mixed concrete (QSRMC) certification for the batching plant should be checked, along with the date of certification and any changes that may have been made at the batching plant since then.

The strength of blended mixed concretes can be particularly sensitive to weighing accuracy. These are mixes which use either pulverised fuel ash (PFA) or ground granulated blast furnace slag (GGBFS) as partial replacement for the cement content. The higher the cement replacement ratio, i.e. the less cement the mix contains, the more sensitive the ultimate mix strength becomes to the batch weight of the cement.

Different types of concrete have different characteristic rates of gain of strength that are well documented; they can be used to assess the likely 28 or 56 day strength from earlier testing. Careful tabulation, analysis and plotting of early age (3 or 7 day) testing maximises the chance of early identification of any problematic concrete. The presence of low strength concrete may affect its durability, the protection of reinforcement and the structural capacity of the element.

It is always advisable to review the early cube strength test results in order to check for any indications that the specified strength may not be achieved. If low strength concrete results occur, with a knowledge of the typical rate of gain of strength characteristics of the particular type of mix, it may be possible to predict whether or not the required strength will be achieved – even if at a later date than specified. Alternatively, cores can be taken and tested to establish the actual *in situ* strength of the concrete.

93.6.2 Pile load testing

One risk associated with load testing is that in certain ground conditions, the ultimate load capacity may increase with time (see Chapter 98 *Pile capacity testing*). Consequently, testing foundation elements such as piles too early may result in underestimating their load capacity, even if the concrete strength has developed sufficiently to carry the load. If early testing of a pile, typically 7 to 14 days after installation, does not verify the required load capacity, re-testing at a later date may show some improvement. This behaviour can affect the performance of bored and driven displacement piles in fine-grained soils and rocks.

If load testing cannot verify the required pile load capacity, the most common solution is to down-rate capacity and install additional piles which may require modifications to the sub-structure.

93.6.3 Integrity testing of piles

There are two basic types of integrity testing for piles, see Chapter 97 *Pile integrity testing*. The sonic echo method is usually restricted to small to medium diameter piles due to the limited energy that can be imparted with a small hammer. The potential difficulty with this testing is that although the measurement of the response to the applied impulse is common to all practitioners, the signal processing that is applied to produce the test response can vary. This may result in testing by one organisation showing an anomaly in a pile, whereas testing by another may not show the anomaly. Integrity problems are least likely to occur in relatively uniform ground conditions and are most likely to occur in highly variable ground conditions.

Reported anomalies can also result from reflections at the bottom of a reinforcement cage or from a bulge in the concrete in soft ground, as well as from defects such as cracks and necking of the concrete section.

If integrity testing does indicate an anomaly and retesting is carried out, the reported results should include the recorded data, i.e. before processing, so that it is available for an independent re-analysis. Ultimately it is often necessary to excavate out around the pile to investigate the true nature of a reported anomaly (see **Figure 93.1**). Small diameter piles are particularly

Figure 93.1 Temporary casing withdrawn from pile after initial setting of the concrete

susceptible to lateral impact or ground-induced loading, e.g. from a truck, piling rig or crane passing by too close. These piles need to be protected from such events either by increasing reinforcement provision (using high visibility marking on any protruding reinforcement), or by fencing off completed areas. Trimming piles can also induce pile damage which will not be identified by integrity testing, if the testing takes place before the pile is trimmed down to its cut-off level.

For cross-hole sonic logging (see Chapter 97 *Pile integrity testing*), apparent anomalies can occur if the tubes are locally debonded from the adjacent concrete, or if there is a small volume of no-fines concrete close to the tube.

93.6.4 Retaining wall deflections

Retaining wall deflections are often specified as a means of controlling a wide range of performances, as they are relatively simple to measure. However, care should be taken to specify deflections that are appropriate to the required performance and that should realistically be achieved, to ensure that economy in design is maintained. Any behaviour which is not 'as predicted' must be observed and promptly reported to experienced geotechnical engineers.

93.6.5 Prop loads

In major excavations it is becoming more common to monitor the loads in props, the largest of which may carry loads of several hundred tonnes. Monitoring of the loads, which may include an initial pre-stress load, should be carried out from installation, and the measured loads compared with the predicted ones for each relevant stage in the construction. If the monitoring shows that there are early signs that the prop load is increasing faster than predicted, this may indicate not only that the final load in the prop may exceed the allowable value, but also that the loads on the supported wall are higher than anticipated – which may result in overstressing of the wall itself.

The first thing to establish is whether the prop overload is indicating that the total load from the wall may have been underestimated, or the distribution of load from the wall to the prop(s) is not as predicted. Increased loads are often due to temperature effects or to construction imperfections, or they may indicate a departure from the design construction sequence or a change in the construction itself.

In order to be able to redesign the construction process, the design must be reassessed and parameters and loadings reviewed and adjusted until the design model predicts the measured prop load(s) and the observed wall deflection. Then, using the revised parameters and loading, additional props and/or berms can be considered in a revised design and construction sequence.

93.6.6 Lack of cover to reinforcement

The three main reasons for a pile, barrette or diaphragm wall panel losing cover to the reinforcement cage are:

Concrete If the concrete mix is too stiff to flow and fill the annulus outside the reinforcement, then the thickness of the concrete cover is likely to be variable, and typically be thinnest in front of the reinforcing bars.

Reinforcement spacing The specification should state the minimum spacing for both vertical and horizontal reinforcement so that there is adequate space for the concrete to flow in between the reinforcement and completely fill the annulus beyond it. The execution codes BS EN 1536 and BS EN 1538 give the minimum reinforcement spacing for various types of piles and for diaphragm walls.

Tremie concreting Control of the flow of fresh concrete into a pile, barrette or diaphragm wall panel is essential in order to ensure that no segregation of the concrete takes place, and that old hardening and stiffening concrete is not continually pushed vertically upwards where it could impede the flow of the fresh concrete around and to the outside of the reinforcement. The specification combined with the contractor's method statement should describe the acceptable procedures for placing concrete by tremie pipes.

Remedial measures can include breaking of exposed concrete back to the reinforcement and then re-concreting the surface to make good the cover. The difficulty with this method is that if the cover has been compromised on the exposed face of an element, it is also likely to be compromised on unseen

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

and relatively inaccessible faces cast against the ground. In extreme cases, measures such as jet grouting adjacent to the ground face may be required.

93.6.7 Water ingress

The specification should set out the minimum standard for water ingress into any excavation below the water table (see **Figure 93.2**) and how this is to be measured, although this may be modified to suit particular usage requirements. If water ingress does not satisfy the specified requirements, then it is most common to resort either to grouting of the ground (by drilling from an exposed face) or, in some situations, to drilling from the ground surface.

There are two types of risk associated with this particular problem. Firstly, there is an inevitable delay while remedial grouting takes place. Secondly, and potentially more serious, water flow may have an impact on the integrity of the wall itself or induce ground settlements that may cause damage to adjacent structures.

93.7 Forensic investigations

The definition of a failure is 'an unacceptable difference between expected and observed performance' (Leonards, 1982). When geotechnical failures occur, they are often a surprise event and can happen very quickly. Having said that, it is also common to find that there were earlier warning signs that were either unseen, or seen but unheeded. It is common to find that when first called upon to investigate a failure, there is a lack of relevant information.

Figure 93.2 Example of a damp water patch

Forensic engineering is becoming increasingly important since foundation and other geotechnical failures can lead to litigation and possibly criminal action. The causes of a failure may be complex, but it is important to be able to explain the failure in simple terms to those charged with resolving any contractual or legal matters arising from the failure.

Failures can occur, for example, due a fundamental flaw in the design assumptions, or due to a small defective detail. There is no unique recipe for failure and no definitive exhaustive checklist of possible causes.

Attention to any possible warning signs may give some advance notice of an impending failure, may save money and ultimately may save lives. Simple signs, such cracking of concrete sections, cracks around bolted or welded connections in steel structures, or unexpected deflections, should be noted and reported to experienced engineers, and reacted to promptly. To ignore any such signs may lead to expensive or even fatal consequences.

93.7.1 The process

Following a failure, information gathering is often a cyclical process. Initial documents provided are reviewed, collated and assessed. This invariably leads to requests for other documents that were mentioned but not provided, or there may be existing documents that have not yet been referred to. Much of the documentation presented may ultimately prove to be irrelevant, but everything should be considered. Small pieces of information contained in large documents can turn out to be vital.

It is necessary to be completely methodical with all the information provided, which should be catalogued and arranged chronologically. The precise order and timing of events leading up to a failure is often important.

Cross-checking information is always an important part of the forensic process. For example, do the 'as constructed' records agree with the approved design and construction sequence? Is the ground investigation data (including field and laboratory test results) as would be expected, taking into account the local geology? Are any materials tests consistent within themselves, e.g. are variations in concrete strength reflected in variations of the measured concrete density?

When reviewing the information, note all the important points as they are found. It is frustrating to remember seeing something important, but not being able to remember which document/page/line it came from.

93.7.2 Design

It is often the case that the fundamental cause of a failure is that the geotechnical or structural behaviour assumed for design purposes is not appropriate and does not reflect reality.

The following quotations from eminent geotechnical practitioners relate specifically to the topic of geotechnical design, and have much to commend them:

'Simple calculations based on a sound conception are far more meaningful than elaborate calculations which ignore controlling factors.' *Ralph B Peck*, 1973

'Recent examples of inappropriate analysis … suggest modern engineers could benefit from a wider appreciation of elementary principles.' *Sir Alan Muir Wood*, 2004

'I express much concern over the extent to which engineers, presented with a technical problem, tend to fly directly to numerical solutions without pausing to understand the physical basis of the problem. Too often, the numerical model does not address the actual conditions, or provides output in a form that confuses rather than informs. Almost universally, the apparent precision of a solution bears no relationship to the uncertainty of the data. The ability to make a first estimate on the basis of a sketch and the formulation of equations for simple analysis continues to provide an essential tool to avoid expensive errors and misunderstandings. ' *Sir Alan Muir Wood*, 2004

When considering the design of the elements relevant to a failure, some basic questions need to be asked:

(i) Does the analytical model represent the likely actual mechanical behaviour of the construction in the ground?

(ii) How were the design parameters derived, and are they representative of the physical behaviour of the structure and the ground?

(iii) Have design parameters been used that are appropriate to the particular situation? Short- and long-term parameters, small and high strain parameters: were they appropriate to the structural mode in compression, tension, shear and bending?

Finally, does the end result of the analysis appear reasonable? The use of simplistic hand calculations to check the outcome is invaluable – it is too easy for the effect of a slipped decimal place to become lost in a complex numerical model analysis.

At the same time as considering the design, construction and workmanship must also be investigated. The construction records must be checked to confirm that the correct sequence was followed. Webcams that continuously monitor and record site activities have been found to be invaluable when checking against contractor's records.

Test results and monitoring records need to be interrogated for clues regarding the possible causes of failure.

Observations can take many forms, from anecdotal evidence to measurements of deflections, monitored stresses and strains. Some of this evidence may prove to be correct and true, some may prove to be untrue, and for some it may not be possible to verify either way. As with ground investigation information, the task of forensic investigation is to attempt to identify what is reliable, and why this should be so. Conversely, it must also attempt to identify what is not reliable, and for what reasons.

Having considered all the available evidence, one or more hypotheses must be formulated and tested for consistency with the observed behaviour. It is important to consider that there may be more than one explanation for what has occurred. All possibilities should be considered, and rejected only when they have been thoroughly examined. It is never sufficient to consider just one explanation and look no further, even if that one explanation happens to be consistent with the observed behaviour.

93.7.3 Reporting

Forensic investigation usually has two functions: (i) to find a solution to a problem; (ii) to document the investigation, the findings and the conclusions. If there has been a significant problem resulting in a dispute, then the matter may be resolved directly under the project contract, or indirectly by such means as set out in the contract. Resolution may involve adjudication, mediation, arbitration or ultimately, litigation. In case the matter eventually has to be resolved by litigation, great care should be taken when reporting on a forensic investigation to ensure the accuracy and validity of all statements made.

If it is possible that a report may be used in litigation, then Civil Procedure Rules Part 35 (CPR35) *Experts and Assessors*, and the accompanying *Practice Direction*, include the requirements for expert evidence to be given in a written report. It is important to distinguish between the evidence considered (the input data), the assessment of the evidence and opinions expressed, and the conclusions reached, and present a report with clearly-defined sections dealing with all aspects required by CPR35. Thus the forensic report should be clearly divided into the following sections:

- evidence;
- assessment of the evidence;
- opinions and conclusions.

Most reports on a forensic investigation will be read by people who will be less qualified than the author. It is therefore helpful to minimise the use of technical terminology and to add explanations where necessary. Judgements may be made based on the report, so it has to be easily understood by the reader. A style that works well is to minimise the content of the main body of the report so that it is easy to read and absorb, and to use appendices for reference information. Conclusions should be as succinct as possible.

A one page summary is a useful inclusion in a report on a forensic investigation, both for the author and the reader. For the author it ensures that the essence of the problem and the conclusions are presented logically, and for the reader it provides an easily absorbable overview.

93.8 Conclusions

QA is the management system that will ensure that all key parts of the geotechnical design and construction process are

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

undertaken consistently in order to provide at least a minimum standard. A designer will use QC systems to ensure that the design and checking process is undertaken to meet the QA requirements. The contractor will use QC systems to ensure that the construction is in accordance with the specification and design.

Dependent upon the contractual arrangements on any particular project, the contractor will either have his workmanship verified by an external party such as an RE, or will be required to self-certify his own work.

Identifying and rectifying non-conformant work is a key part of the QA process. For geotechnical work it is paramount that a thorough forensic investigation is carried out at the earliest opportunity so that these issues are closed out early on in the construction process.

Disclaimer

The example non-conformances included in this chapter are for illustrative purposes only and are not associated with, or reflective of, the authors or their employers.

Almost every construction project involving soil or rock runs some risk of encountering surprises, in particular 'unforeseen ground conditions'. Compared with other branches of civil engineering where there is greater control over the materials used, monitoring is vital to the practice of geotechnical design and construction. For this reason geotechnical engineers, unlike their colleagues in many other fields, must have more than a casual knowledge of geotechnical monitoring and instrumentation: it is an essential working tool.

The benefits of geotechnical monitoring are outlined in this chapter. These are followed by a systematic approach to planning monitoring programmes using geotechnical instrumentation, an example of systematic planning and general guidelines on the execution of monitoring programmes.

94.1 Introduction

Every geotechnical design has to cater for some uncertainty and every construction project involving soil or rock runs some risk of encountering surprises. These circumstances are the inevitable result of working with materials that are a product of nature, created by processes that seldom result in uniform conditions. The limitation of ground investigation procedures to detect all significant properties and conditions of natural materials in advance, requires the designer to make assumptions that may not reflect the overall ground conditions. The construction constructor may choose equipment and construction procedures without full knowledge of what might be encountered. Despite the limitations of not being able to explore every point within a site, geotechnical monitoring, including quantitative measurements obtained by field instrumentation, provides the means by which the geotechnical engineer can design a project to be safe and efficient, and the constructor can execute the work with safety and economy. Thus, geotechnical monitoring is vital to the practice of geotechnical design and construction. For this reason, geotechnical engineers frequently need a comprehensive knowledge of geotechnical monitoring and instrumentation.

Geotechnical monitoring is not merely the selection of instruments but a comprehensive step-by-step engineering process, beginning with a definition of the objective(s) and ending with implementation of contingency measures if the data warrant. Each step is critical to the success (or failure) of the monitoring programme, and the monitoring process involves combining the capabilities of instruments and people.

Peck (1984) states 'The legitimate uses of instrumentation are so many, and the questions that instruments and observation can answer so vital, that we should not risk discrediting their value by using them improperly or unnecessarily.'

Clauses 4.5, 11.7, 12.7 and Annex J in Eurocode 7, Part 1 (EN 1997–1:2004) provide guidelines on geotechnical monitoring.

The benefits of geotechnical monitoring are outlined in the following sections. These are followed by a systematic approach to planning monitoring programmes using geotechnical instrumentation, an example of systematic planning, and general guidelines on the execution of monitoring programmes.

Instruments that are used for geotechnical monitoring are described in Chapter 95 *Types of geotechnical instrumentation and their usage.*

Primary sources of text for this chapter have been Dunnicliff (1988, 1993), Dunnicliff (1998) and, with permission from the American Society of Civil Engineers (ASCE), Marr (2007).

94.2 Benefits of geotechnical monitoring

The following are the principal technical reasons for recommending a geotechnical monitoring programme for a project:

1. Minimising damage to adjacent structures.
2. Implementing the observational method.
3. Revealing unknowns.
4. Assessing a contractor's construction methods.
5. Devising remedial measures to address problems.
6. Improving performance.
7. Documenting performance for assessment of damages.
8. Showing that everything is satisfactory and as expected.
9. Warning of impending failure.
10. Advancing the state-of-knowledge.

Each of these is discussed next in the context of today's practice of geotechnical engineering. In general, a common feature of these technical reasons is that monitoring programmes save money.

94.2.1 Minimising damage to adjacent structures

Geotechnical construction may affect adjacent property with undesirable results, such as expensive repairs, bad relations and protracted litigation. Geotechnical monitoring can be used to warn of unacceptable movements of adjacent property. By doing this, the costs required to repair the damages are likely to be avoided. **Figure 94.1** shows a motorised total station for monitoring any movement of structures whilst tunneling beneath a road.

94.2.2 Implementing the observational method

The complete application of the observational method (see also Chapter 100 *Observational method*) embodies the following steps (Peck, 1969):

1. Exploration sufficient to establish at least the general nature, pattern and properties of the deposits, but not necessarily in detail.
2. Assessment of the most probable conditions and the most unfavourable conceivable deviations from these conditions.
3. Establishment of the design based on a working hypothesis of behaviour anticipated under the most probable conditions.
4. Selection of quantities to be observed as construction proceeds and calculation of their anticipated values on the basis of the working hypothesis.
5. Calculation of values of the same quantities under the most unfavourable conditions compatible with the available data concerning the sub-surface conditions.
6. Selection in advance of a course of action or modification of design for every foreseeable significant deviation of the observational findings from those predicted on the basis of the working hypothesis.
7. Measurement of quantities to be observed and evaluation of actual conditions.
8. Modification of design to suit actual conditions.

Figure 94.1 Motorised total station for monitoring any movement of structures

Photograph courtesy of SolData; all rights reserved

The degree to which all these steps can be followed depends on the nature and complexity of the work, but it is clear that in all cases a geotechnical monitoring programme is essential.

For example, it is possible to build an embankment over a soft soil stratum by constructing it in stages. Placed all at once, the embankment might cause foundation failure. Placing the embankment in stages at suitable time intervals allows the soft soil to strengthen by consolidating between each stage. Instruments to measure settlements and pore water pressures can be used to determine when enough consolidation of the clay has occurred, so that the next stage of fill can safely be added. A balance is usually sought between adding the next stage as quickly as possible to minimise construction time – but not so fast as to cause foundation failure. This example is described in more detail in section 94.4.

Section 2.7 in EN 1997–1 (2004) indicates that it is appropriate to apply the observational method when prediction of geotechnical behaviour is difficult. It includes: requirements to be met before construction is started; requirements to be met during construction; assessment of the results of monitoring; replacement of monitoring equipment.

94.2.3 Revealing unknowns

Using procedures which reveal unknown conditions and engage remedial work as early as possible will lead to the lowest project cost. A good geotechnical monitoring programme is vital to this approach. The alternative of delay, denial and blame almost always costs more.

94.2.4 Assessing a contractor's construction methods

The outcome of some geotechnical projects depends on the construction methods used and the ability of the construction contractor. Geotechnical monitoring is used to determine whether these meet the specified performance requirements.

94.2.5 Devising remedial methods to address problems

When problems occur in geotechnical construction, the cause must be identified as far as possible, and remedied. Finding the best remedy requires an understanding of what went wrong. Data from geotechnical monitoring can help engineers determine what caused the problem. A remedial action can then be devised that focuses on the specific cause rather than addressing several potential causes in the light of uncertainty. **Figure 94.2** shows an unstable slope that is being monitored with sub-surface

Figure 94.2 Instruments in an unstable slope

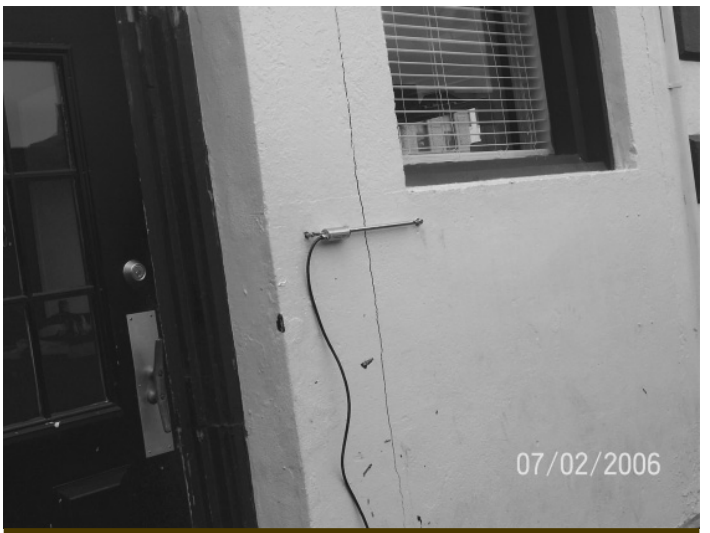

Figure 94.3 Vibrating wire crack gauge on the side of a building

deformation gauges to determine the depth of the failure surface so that an appropriate remedial action can be implemented.

94.2.6 Improving performance

Modern concepts of business management stress continual improvement and the need for measurements to gauge success. A common saying in business practice is 'that which is measured improves, while things not measured eventually fail'. The mere process of measuring performance coupled with normal human behaviour leads to improved performance.

94.2.7 Documenting performance for assessment of damages

Damage claims by third parties represent one of the substantial risks encountered in geotechnical projects. Claims sometimes include charges for damage unrelated to the construction in question. Others may be inflated, such as a claim for structural damage when only minor architectural damage has occurred.

Data from geotechnical monitoring can help establish the validity of such claims, thereby satisfying stakeholders and regulators, and reducing litigation. For example, if instrumentation shows that an adjacent building has not moved during construction, it becomes more difficult for the owner to claim that cracks in the building resulted from the construction activity. **Figure 94.3** shows a vibrating wire crack gauge on the side of a building to determine whether nearby construction is causing changes in crack width.

94.2.8 Showing that everything is satisfactory and as expected

Increasingly we use geotechnical monitoring programmes to demonstrate that the actual performance is within the bounds anticipated by the designers. The presumption is that there will be no surprises or unexpected consequences to the overall cost and schedule, and that unexpected behaviour can be identified early enough to maintain control of the project cost and schedule.

Data from a geotechnical monitoring programme help maintain the various parties' confidence in the performance of the work, thus allowing them to focus on other issues. Increasingly, project owners desire performance monitoring systems that are comprehensive and robust, but with instant reporting as simple as a green light to indicate that everything is progressing acceptably.

Figure 94.4 shows a tied-back retaining wall instrumented with load cells on some of the tiebacks to monitor any changes in load.

94.2.9 Warning of impending failure

Geotechnical structures can fail with catastrophic consequences to life and property. Such failures may be the result of excessive loads, design errors, construction deficiencies, unknown or unexpected conditions, deterioration, operational errors or intentional action. Geotechnical monitoring has been widely used to detect the onset of failure in dams, slopes, embankments and excavations. **Figure 94.5** shows vibrating wire strain gauges mounted on a pipe strut across an internally braced excavation to warn of excessive load in the strut. In practice, monitoring of a single strut in this way is insufficient – a significant number of struts need to be monitored to provide representative data.

94.2.10 Advancing the state-of-knowledge

Many of the advances in understanding ground and structural response in geotechnical engineering have their roots in data from geotechnical monitoring of full-scale projects. The data give us insight into how the ground/structure is responding to construction and about causal relationships. A significant amount of geotechnical instrumentation is currently used and has been used historically as part of a research effort to improve our state-of-knowledge. Much of this has been paid for by governmental agencies with a mission to improve practice. **Figure 94.6** shows a long-stroke vibrating wire strain

Figure 94.4 Load cells on tie-back anchors

Figure 94.5 Vibrating wire strain gauges mounted on a pipe strut across an internally braced excavation

gauge mounted on a geotextile for advancing the state-of-knowledge about geotextile performance.

94.2.11 An overview of the above ten benefits of geotechnical monitoring

Ten principal technical reasons (or benefits) for recommending a geotechnical monitoring programme for a project have been identified and discussed in the context of today's practice of geotechnical engineering. As stated earlier, a common feature of these technical reasons is that monitoring programmes generally save money. It is probable that the first reason, minimising damage to adjacent structures, is the most common of these. However, it is strongly recommended that designers of construction projects should study the other nine potential reasons in the context of the project specifics, and endeavour to persuade their clients to adopt geotechnical monitoring if it can be shown that there is a clear technical or financial benefit.

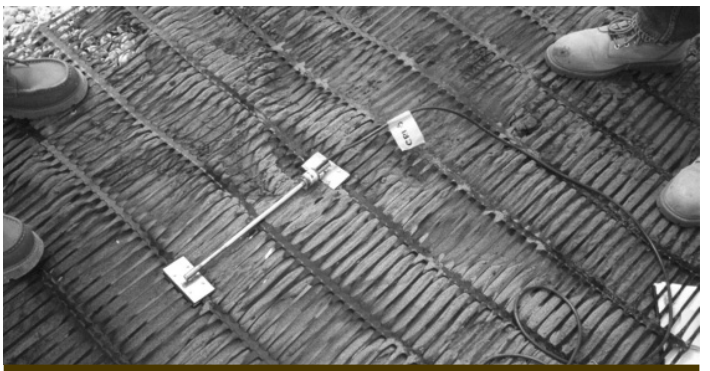

Figure 94.6 Long-stroke vibrating wire strain gauge mounted on a geotextile

94.3 Systematic approach to planning monitoring programmes using geotechnical instrumentation

Planning a monitoring programme using geotechnical instrumentation should begin with defining the objective and end with planning how the measurement data will be implemented. Planning should proceed through the steps listed in **Table 94.1** and outlined below. More detail is given in Dunnicliff (1988, 1993). All of these planning steps should, if possible, be completed before geotechnical monitoring work commences in the field.

94.3.1 Step 1. Define the project conditions

The person responsible for planning a monitoring programme must become very familiar with the project type and layout, sub-surface stratigraphy and engineering properties of sub-surface materials, groundwater conditions, status of nearby structures or other facilities, environmental conditions and the planned construction method.

94.3.2 Step 2. Predict mechanisms that control behaviour

Prior to developing a monitoring programme, one or more working hypotheses must be developed for mechanisms that are likely to control behaviour.

94.3.3 Step 3. Define the geotechnical questions that need to be answered

Every instrument on a project should be selected and placed to assist in answering a specific question: if there is no

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Step	Task
1	Define the project conditions
2	Predict mechanisms that control behaviour
3	Define the geotechnical questions that need to be answered
4	Identify, analyse, allocate and plan for control of risks
5	Select the parameters to be monitored
6	Predict magnitudes of change
7	Devise remedial action
8	Assign tasks for the construction phase
9	Select instruments
10	Select instrument locations
11	Plan documentation of factors that may influence measured data
12	Establish procedures for ensuring data correctness
13	List the specific purpose of each instrument
14	Prepare budget
15	Prepare instrumentation system design report
16	Plan installation
17	Plan regular calibration and maintenance
18	Plan data collection and data management
19	Prepare contract documents
20	Update budget

Table 94.1 Steps in systematic approach to planning monitoring programmes using geotechnical instrumentation

question, there should be no instrumentation. This is the first golden rule.

94.3.4 Step 4. Identify, analyse, allocate and plan for control of risks

All risks associated with construction should be identified, and each 'geotechnical question' should be prioritised based on risk. Responsibility for each risk may be allocated to a single party or to more than one party. Risk responsibility allocation should be included in the construction contract documents.

Risk analysis embodies a wide range of scientific theories and engineering analyses to identify potential sources of risk, determine the probability of occurrence for each source, and estimate the consequences from each source of risk. Total risk is the summation of the probability of each source of risk occurring multiplied by the consequences of that occurrence. Risk can be decreased by actions that reduce the probability of a source of risk or its adverse consequences occurring.

Van Staveren (2006) provides comprehensive guidance on identification, analysis, allocation and planning for control of risks, and Marr (2007) provides an approximate method for quantifying the benefits that have been described above, based on concepts of decision theory and risk analysis. Risks are also discussed in Chapter 7 *Geotechnical risks and their context for the whole project.*

94.3.5 Step 5. Select the parameters to be monitored

Typical geotechnical parameters include:

- pore water pressure;
- deformation;
- tilt;
- total stress;
- load and strain in structural members;
- temperature.

The question: 'which parameters are most relevant?' should be answered.

Clauses 4.4, 11.7, 12.7 and Annex J in EN 1997–1 (2004) includes guidance on selecting the parameters to be monitored.

94.3.6 Step 6. Predict magnitudes of change

Manufacturers of geotechnical instruments will define their range and accuracy. In order that appropriate instruments are selected, there must be a prediction of the maximum change that might occur, hence determining the needed range. For the same reason, the needed accuracy must also be determined.

If measurements are for construction control or safety purposes, a predetermination should be made of numerical values that indicate the need for decisive mitigation measures. These values are often referred to as trigger levels. The concept of green, amber and red trigger levels is useful:

- green indicates that all is well;
- amber indicates the need for cautionary measures including an increase in monitoring frequency;
- red indicates the need for timely remedial actions and being prepared to implement them quickly.

The following are guidelines for selection of trigger levels:

- Early trigger levels can be based on calculated changes, whereas later levels can be based on (unrelated) tolerable changes.
- Trigger levels must recognise the changes that occur from causes other than construction.
- Trigger levels should be several times larger than the accuracy of measured changes (those last four words are very carefully chosen).

94.3.7 Step 7. Devise remedial action

Inherent in the use of instrumentation for construction purposes is the absolute necessity for deciding, in advance, a positive means for dealing with any problem that may be disclosed by the results of the observations. If the observations should demonstrate that remedial action is needed, that action must be based on appropriate, previously anticipated plans. Arrangements should be made to determine how all parties will be forewarned of the planned remedial actions.

94.3.8 Step 8. Assign tasks for the construction phase

The second golden rule (remember that the first golden rule has been given in Step 3 above) is: *Tasks should be assigned to the people who have the greatest motivation to achieve high quality data.* Many geotechnical monitoring programmes have been unsuccessful because planners of the programmes have assigned key tasks to people who have inadequate motivation. Hence this step is of the utmost importance, and is covered in some detail in this section.

The tasks include:

1. buying instruments;
2. installing instruments;
3. collecting data;
4. interpreting data;
5. implementing actions resulting from the data;

and it is crucial to ensure that these tasks are assigned to the people who are most likely to maximise quality.

Clearly data interpretation should be the responsibility of the people who initiated the monitoring programme. Implementation should be by construction personnel.

If principal construction contractors, temporary works contractors, specialist geotechnical sub-contractors or design/build contractors have initiated the monitoring programme, clearly they have the greatest motivation and tasks 1, 2 and 3 should be assigned to them. However, if the programme has been initiated by the designer of the project, there are four reasons for not assigning tasks 1, 2 and 3 to the principal construction contractor:

A. Principal construction contractors may not have enough motivation to ensure quality. Use of the conventional lowest tender procedure, whereby these tasks are included as items in the principal construction contactor's contract, has often led to poor quality data.

B. Monitoring cannot start until after the award of the principal construction contract, hence adequate pre-construction (baseline) data are usually unavailable. Structures move and groundwater regimes often change from season to season, and geotechnical monitoring data cannot be interpreted correctly if baseline data are not established. Whenever practicable, it is highly preferable to establish at least one year of baseline data.

C. It costs the project owner more. Potential monitoring sub-contractors give prices to principal construction contractors prior to the latter tendering. After contract award, there is normally a bargaining process, and the project owner pays £1 for work that costs the principal contractor 85 or 90 pence.

D. For multi-principal contract projects, there would be one monitoring sub-contractor for each principal construction contract.

The following assignments are recommended for tasks 1, 2 and 3:

- *Pre-construction baseline data*: specialist firm under contract with the project owner, using a qualifications-based selection procedure.
- *During construction, outside principal construction contractor's work area*: same as above.
- *During construction, within principal construction contractor's work area*
  - owner's representative, with assistance from principal construction contractor for access as necessary; or
  - specialist firm, as a nominated (assigned) specialist sub-contractor, selected using a qualifications-based procedure, with instruments selected on the basis of proven performance; or
  - principal construction contractor, with partnering and rigorous and *enforced* specifications.

For further information on assignment of tasks and for details of the above recommendations, see Dail and Volterra (2009), Dunnicliff (2009), Dunnicliff and Powderham (2001a, 2001b) and Klingler (2001).

Additional information on writing specifications is given in Chapter 78 *Procurement and specification*.

94.3.9 Step 9. Select instruments

The preceding eight steps should be completed before instruments are selected. When selecting instruments, the overriding desirable feature is *reliability*. Selection of instruments and readout equipment depends directly on the methods used for data collection – see section 94.5.5 for general guidelines. The scale of the geotechnical monitoring programme should match the identified risks and the scale and complexity of the geotechnical questions.

Details of some instruments, together with their applications, are given in Chapter 95 *Types of geotechnical instrumentation and their usage.*

The lowest cost of an instrument should never be allowed to dominate the selection. The least expensive instrument is not likely to result in minimising project cost. In evaluating the economics of alternative instruments, the overall cost of procuring, calibration, installation, maintenance, monitoring and data processing should be compared.

94.3.10 Step 10. Select instrument locations

A practical approach to selecting instrument locations entails three steps:

1. Establish the zones where the risk is highest. Instrument these thoroughly.
2. Zones are identified (normally cross-sections) where predicted behaviour is considered representative of behaviour as a whole. These cross-sections are regarded as *primary instrumented sections*, and instruments are located to

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

provide comprehensive information on ground/structural responses and construction performance.

3. Because unknown factors may cause poorer performance at other locations, instrumentation should be installed at a number of *secondary instrumented sections*, to serve as indices of comparative behaviour. Instruments at these secondary sections should be as simple as the requirements allow and be installed at the primary sections so that comparisons can be made. If, in fact, the behaviour at a secondary section appears to be significantly different from the behaviour at the primary sections, additional instrumentation may be installed at the secondary section as construction progresses.

When selecting locations it should be recognised that some instruments will probably cease to function when data are still required, hence some duplication may be needed. Some limited duplication of measurements leads to increased confidence in data, especially in areas of uncertainty or greatest change.

94.3.11 Step 11. Plan documentation of factors that may influence measured data

Measurements by themselves are rarely sufficient to provide useful conclusions. Geotechnical monitoring normally involves relating measurements to causes, and therefore records and diaries must be maintained of all factors that might cause changes in the measured parameters, including construction details and progress.

94.3.12 Step 12. Establish procedures for ensuring data correctness

Personnel responsible for geotechnical monitoring must be able to answer the question: *Are the data realistic?* The ability to answer depends on availability of good evidence, for which planning is required. In critical situations, duplicate instruments can be used. A backup system is often useful and will frequently provide an answer even when its accuracy is significantly less than that of the primary system.

94.3.13 Step 13. List the specific purpose of each instrument

At this point in the planning, it is wise to question whether all planned instruments are justified. Each planned instrument should be numbered and its purpose listed. If no viable specific purpose can be found for a planned instrument, it should be deleted.

94.3.14 Step 14. Prepare budget

Even though the planning steps are not complete, a budget should be prepared at this stage for all tasks that are included in section 94.5 to ensure that sufficient funds are available. A frequent error in budget preparation is to underestimate the duration of the project and the total costs for data collection and interpretation. If insufficient funds are available, the monitoring programme may have to be curtailed or more funds obtained.

94.3.15 Step 15. Prepare instrumentation system design report

This report should summarise the results of planning steps 1–14. It should then be reviewed by others to ensure that everything is consistent, that the plan is a good one and that it covers the needs of the project.

94.3.16 Step 16. Plan installation

Installation procedures should be planned well in advance of scheduled installation dates. Written step-by-step procedures should be prepared, making use of the manufacturer's instruction manual and the designer's knowledge of specific site geotechnical conditions. The written procedures should include a detailed listing of required materials and tools, and installation record sheets should be prepared for documenting factors that may influence measured data. Installation plans should be coordinated with the construction contractor and arrangements made for access and protection from damage of installed instruments. An installation schedule should be prepared, consistent with the construction schedule.

94.3.17 Step 17. Plan regular calibration and maintenance

Calibration and maintenance should be planned well before field work starts; calibrations are described in section 94.5.2. Maintenance planning should include readout units, field terminals and embedded components.

94.3.18 Step 18. Plan data collection and data management

Written procedures for data collection and data management should be prepared well before field work starts. These are significant tasks, and the effort required for them should not be underestimated. Guidelines are given by Dunnicliff (1988, 1993) and in section 94.5.5.

At this stage in the planning, a verification should be made to ensure that field staff are appropriately trained, remedial actions have been planned, personnel responsible for interpretation of monitoring data have the contractual authority to signal remedial action, communication channels between design and construction personnel are open, and that arrangements have been made to forewarn all parties of the planned remedial actions.

94.3.19 Step 19. Prepare contract documents

Any necessary contract documents should be prepared, to match the decisions made during step 8.

94.3.20 Step 20. Update budget

With planning complete, the budget for all tasks listed in planning step 8 should be updated in light of all planning steps.

94.3.21 An overview of the most common failures in implementing a systematic approach to planning monitoring programmes

All the above 20 steps are important. In the experience of the authors, the following steps are the most crucial:

- Step 3. Define the geotechnical questions that need to be answered. As indicated above, every instrument on a project should be selected and placed to assist in answering a specific question: if there is no question, there should be no instrumentation. This is the first golden rule, and is commonly ignored.
- Step 4. Identify, analyse, allocate and plan for control of risks. When a risk analysis is made, it is often not comprehensive enough, and risk responsibility allocation is commonly not adequately covered in the construction contract documents.
- Step 7. Devise remedial action. All too often instrumentation programmes are planned without ensuring that viable remedial actions are available in the event that trigger levels are reached.
- Step 8. Assign tasks for the construction phase. As indicated above, the second golden rule is that tasks should be assigned to the people who have the greatest motivation to achieve high quality data. Many geotechnical monitoring programmes have been unsuccessful because planners of the programmes have assigned key tasks to people who have inadequate motivation.

Singling out these four steps in this overview in no way implies that the other 16 steps are unimportant.

94.4 Example of a systematic approach to planning a monitoring programme: using geotechnical instrumentation for an embankment on soft ground

In this example, the geotechnical questions are associated only with the soft ground below the embankment, and not with the embankment itself. Only selected planning steps are included in the example (i.e. not all the 20 steps that have been detailed in the previous section). Ladd (1991) presents valuable guidelines for geotechnical monitoring of embankments on soft ground.

Examples of steps 3, 5 and 9 for ten additional project types are given in Chapter 95 *Types of geotechnical instrumentation and their usage*. These additional project types are:

- internally braced excavations;
- externally braced excavations;
- clay embankments;
- cut slopes in soil;
- landslides in soil;
- cut slopes in rock;
- landslides in rock;
- tunnels;
- driven piles;
- bored piles.

94.4.1 Step 1. Define the project conditions

- **Figure 94.7** illustrates the project conditions for this example of planning.
- The embankment is wide compared with the thickness of the very soft clay layer.
- Staged construction and vertical drains are planned so that the roadway on top of the embankment can be completed as soon as possible.
- **Figure 94.8** shows the installation of vertical drains through very soft clay.
- There are some silt layers in very soft clay.
- Initial groundwater conditions are hydrostatic.
- There are no nearby structures.
- The predicted total vertical compression of the clay is 15% strain.

94.4.2 Step 2. Predict mechanisms that control behaviour

- Settlement (consolidation of very soft clay).

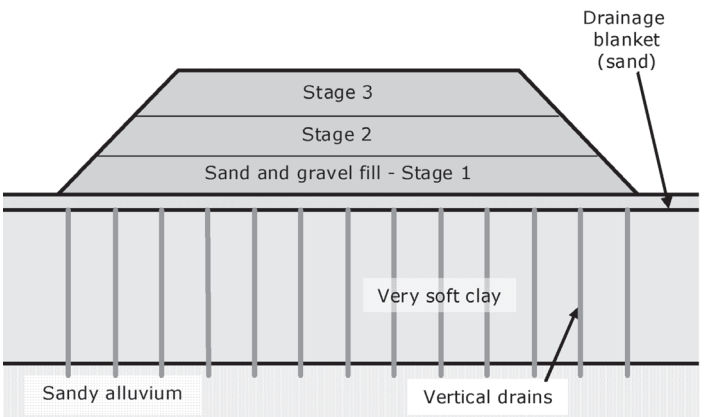

Figure 94.7 Project conditions for an embankment on soft ground

Figure 94.8 Installation of vertical drains through soft clay

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- Lateral bulging displacements of the clay, causing heave either side of the embankment.
- A rotational slide, causing failure.

94.4.3 Step 3. Define the geotechnical questions that need to be answered

(See Chapter 95 *Types of geotechnical instrumentation and their usage*.)

- What are the initial site conditions in the soft ground?
- Is the embankment stable in the short term?
- So that decisions can be made as to when to place the next stage of fill, what is the progress of consolidation and associated gain of strength of the soft ground?

94.4.4 Step 4. Identify, analyse, allocate and plan for control of risks

- Risks are that (i) an embankment failure may occur and (ii) the completion of the roadway is delayed.
- The project owner's construction manager will be on site to make decisions about placing subsequent stages of fill, and the project owner accepts responsibility for risks (i) and (ii) above.
- Strength gain will occur more slowly than predicted, thereby slowing construction, delaying completion and creating a possibility for the construction contractor to submit a claim for extra money.

94.4.5 Step 5. Select the parameters to be monitored

(See Table 95.3.)

- Pore water pressure in the clay.
- Vertical deformation.
- Horizontal deformation.

94.4.6 Step 6. Predict magnitudes of change

- Pore water pressure in the clay:
  - range – initial pressure plus additional pressure caused by the weight of the embankment;
  - accuracy – consider the time plot that shows dissipation of pore water pressure under a single stage of fill, and the need to extrapolate from that to decide when the next stage can be placed.
- Vertical deformation:
  - range – as the predicted vertical compression is given as 15%, surface settlement can be calculated;
  - accuracy – same logic as for pore water pressure.
- Horizontal deformation:
  - range – base this on an estimate of the maximum deformation that could occur;
  - accuracy – no general recommendation can be given, as required accuracy depends on project details.
- Trigger levels need to be determined.

94.4.7 Step 7. Devise remedial action

- Remove fill.
- Place a berm at the toe of the embankment.

94.4.8 Step 8. Assign tasks for the construction phase

- The monitoring programme has been initiated by the project designers.
- Responsibility for pre-construction baseline data is assigned to a specialist firm under contract with the project owner, selected using a qualifications-based procedure.
- During construction, the tasks of buying and installing instruments and for collecting data are assigned to a nominated specialist sub-contractor, selected using a qualifications-based procedure. Instruments are selected on the basis of proven performance.
- The project designers are responsible for interpreting monitoring data.
- The construction contractor is responsible for implementing actions resulting from the data.

94.4.9 Step 9. Select instruments

(See Table 95.3.)

- Pore water pressure in the clay:
  - vibrating wire piezometers.
- Vertical deformation:
  - surface monuments with surveying;
  - probe extensometers – probably magnet/reed switch type.
- Horizontal deformation:
  - surface monuments with surveying;
  - inclinometers.

94.4.10 Step 10. Select instrument locations

- This would depend on the length of the new roadway.
- Perhaps a minimum of three primary instrumented sections and three times as many secondary instrumented sections.
- Within each of these sections decisions would have to be made regarding the position of instruments (e.g. piezometers midway between vertical drains.

94.4.11 Step 11. Plan recording of factors that may influence measured data

- Fill level.
- Weather, e.g. amount of precipitation, sun, wind.
- Temperature.
- Barometric pressure (if vibrating wire piezometers have been selected).
- Visual observations of unexpected or unusual behaviour.

94.4.12 Step 12. Establish procedures for ensuring data correctness

- Visual observations.
- Consistency among instruments for monitoring the same parameter.
- Consistency between pore pressure dissipation data and vertical compression data.
- Consistency of reaction of instruments to a new lift of fill.
- Study of repeatability, over both short and longer term.

- Measured pore water pressures, under no load change, should extrapolate to initial pressures.
- Regular calibrations of readout units and survey equipment.

94.5 General guidelines on execution of monitoring programmes

94.5.1 Introduction

This section includes general guidelines for the following tasks:

- calibration;
- installation;
- maintenance;
- data collection;
- processing and presentation of monitoring data;
- interpretation of monitoring data;
- reporting of conclusions;
- implementation.

Additional guidelines are given by Dunnicliff (1988, 1993).

94.5.2 Calibration

An instrument reading is only useful if the correct calibration is applied. Changes in calibration factors occur due to wear and tear, misuse, creep, moisture ingress and corrosion. If these changes are not accounted for, the entire monitoring programme can become worthless or lead to wrong conclusions and costly recommendations. To maximise their effectiveness, all instruments must be calibrated and checked properly.

Instrument calibrations and/or function checks are generally required at the following stages:

- Calibrations prior to shipment. These are the responsibility of the manufacturer, and are referred to as *factory calibrations*. Calibration certificates should be provided to the user. **Figure 94.9** shows factory calibrations of transducers for vibrating wire piezometers.
- Function checks by the user before installation. These are referred to as *pre-installation acceptance tests*, their purpose being to verify that no damage has occurred during transit. Manufacturers will provide guidelines on what checks should be made.
- Function checks after installation. These are referred to as *post-installation acceptance tests*. Try to apply/identify some known change to test whether the instrument continues to function as expected.
- Calibrations during service life. Calibrations or function checks of instruments and readout units are required during service life. These calibrations are usually performed by personnel responsible for data collection.

94.5.3 Installation

Each instrument must be installed before its planned finish date. The schedule will be based on the need to establish pre-construction (baseline) conditions, construction activity, availability of installation personnel, instrument delivery dates and other relevant factors.

Figure 94.9 Factory calibration of transducers for vibrating wire piezometers
Courtesy of Geokon Inc., Lebanon, New Hampshire, USA

Figures 94.10–94.12 show installations of a borehole extensometer, inclinometer casing, and electrical resistance strain gauges, respectively.

Surface exposures of instruments should usually be protected with robust cover plates, welded, bolted or otherwise attached to the surface. Exposed tubes and cables are extremely vulnerable to damage and should usually be protected by conduit or armouring. **Figure 94.13** shows precast concrete pipe segments used as surface protection for borehole instruments.

The presence of a measuring instrument should cause minimum alteration to the value of the parameter being measured. If the instrument alters the value significantly, it is said to have *poor conformance*.

As indicated in step 17, installation record sheets should be prepared during the planning phase and completed during the installation. These records serve two purposes. Firstly, when installation personnel are required to enter data/information in the blank spaces on a field form, they are more likely to follow the installation procedure with care. Secondly, 'as-built' data are required both for record purposes and for use during evaluation of data. These records form an important part of any quality assurance programme.

On completion of installation, an installation report should be produced to provide a complete compilation of information needed by personnel responsible for data collection, processing, presentation and interpretation. The installation report should contain as-built information, descriptions of instruments and readout units, results for calibrations and checks, details of installation procedures, initial readings and a copy of each installation record sheet.

94.5.4 Maintenance

Regular maintenance required during service life is usually performed by personnel responsible for data collection.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 94.10 Installation of borehole extensometer above future tunnel

Figure 94.11 Installation of inclinometer casing

They should always be on the lookout for damage, potential for damage, and deterioration or malfunction.

94.5.5 Data collection

There are three primary means of collecting data:

- Manual reading involves people going to the instrument readout location and using some device to read the instrument. The reading is manually recorded on paper or perhaps in an electronic device. This approach may be the most cost effective when readings are required less than once per week and the distance to the instrument is not too far, and the readout location can be safely reached. Instruments for manual readings do not have to be electronic and may be of low cost and easy to maintain. **Figure 94.14** shows the manual reading of piezometric level in an open standpipe piezometer.
- Data loggers with periodic manual data download may be used when the reading interval is less than one week or it is difficult to get to the instrument location and there is no immediate need to know the readings. Readings are stored in the memory of the data logger, where they are periodically downloaded manually to a portable electronic device for transport back to the office. Someone travels

Figure 94.12 Installation of electrical resistance strain gauges on segment of cast iron tunnel lining

to the data logger once per week or month or quarter to collect data recorded since the last visit. This approach requires the use of electronic instruments that are read by the data logger. Hardware for this approach may cost more than for the manual reading approach but the cost of collecting data may be less, and more frequent readings can be obtained for essentially no added cost.

- Data loggers with remote data access are used when there is an immediate need for the instrument readings and when reading frequency is more than once per day. In this approach, the data logger is connected to a remote computer system by landline or mobile phone modem, satellite modem, radio or the internet. These systems allow users to see data within seconds of when it is recorded. They also allow alarm systems to be set up that can inform project staff whenever an instrument indicates a value that exceeds a pre-established trigger level. An example of such a data logger, with solar panels for battery charging, is shown in **Figure 94.15**.

Figure 94.13 Borehole instruments protected from damage by precast concrete pipe segments

Figure 94.14 Manual reading of piezometric level in an open standpipe piezometer

Each of these approaches has its advantages and limitations which directly influence how data are collected, reduced and communicated – hence the importance of selecting the data collection approach during the planning phases of the monitoring programme.

The frequency of data collection should be related to construction activity, to the rate at which the readings are changing, and to the requirements of data interpretation. Clause 4.5 in EN 1997–1 (2004) includes guidance on the duration of monitoring.

When construction commences and approaches the instrument location, readings should be taken frequently; for example, once a week, once a day, once a shift or even more frequently in relation to construction activity (such as before and after each blast, during pile driving, or during the placement or removal of a preload). It is often wise to increase the frequency

Figure 94.15 Data logger with remote data access for monitoring lateral movement of a lock wall

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

of readings during heavy precipitation. As construction activity moves away from the instrument location or ceases altogether, and when readings have stabilised, the frequency may then be decreased. It is generally advisable to continue the monitoring effort until near completion of all construction activities because some effects of construction take time to fully develop and there may be activities by others that affect your project.

94.5.6 Processing and presentation of monitoring data

The first aim of data processing and presentation is to provide a rapid assessment of data in order to detect changes that require immediate action. The second aim is to summarise and present the data in order to show trends and to compare observed with predicted performance so that any necessary action can be taken.

After calculations have been made, graphs of data should always be prepared. Various types of graphs are described by Dunnicliff (1988, 1993):

- graphs to assist with data screening;
- graphs of data versus time. An example of this type of graph is shown in **Figure 94.16**;
- graphs for comparing observed and predicted behaviour;
- graphs for comparison of measurements with construction events. **Figure 94.16** includes construction events on the time axis;
- graphs to examine 'cause and effect' relationships. **Figure 94.17** is an example of this type of graph, showing load as 'cause' and displacement as 'effect' during a pile load test;
- summary graphs.

Increasingly project management staff want to know the status of the monitoring programme without being involved with the details, unless unacceptable values are imminent. A one-page summary report of important information is useful for this purpose.

94.5.7 Interpretation of monitoring data

Many monitoring programmes have failed because the collected data were never used. If there is a clear sense of purpose for a monitoring programme, the method of data interpretation will be guided by that sense of purpose.

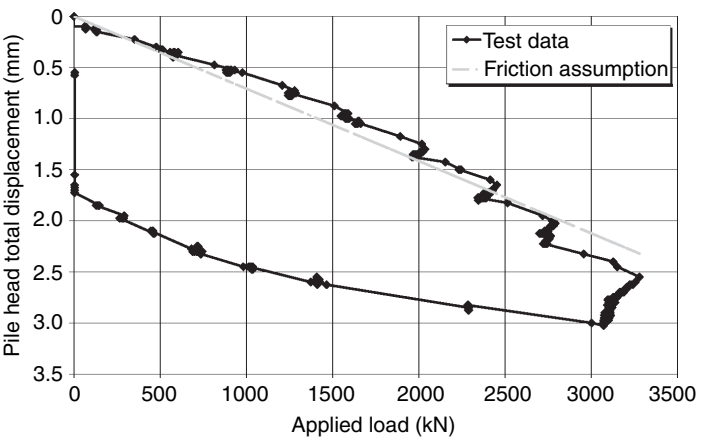

Figure 94.17 Graph of pile load test data

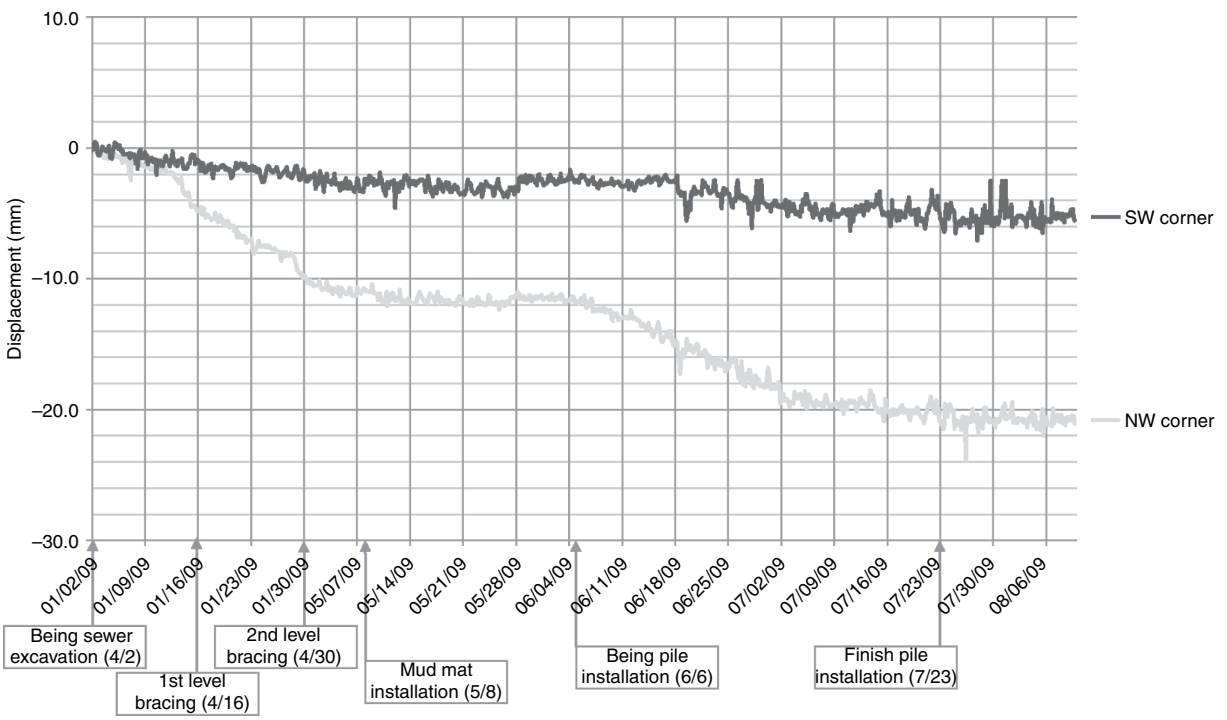

Figure 94.16 Graph of building settlement adjacent to excavation versus time

The first data interpretation step should be to provide a rapid assessment of data in order to detect changes that require immediate action. The essence of subsequent data interpretation steps is to correlate the instrument readings with other factors (cause and effect relationships) and to evaluate the deviation of the readings from the predicted behaviour.

Trigger levels (see section 94.3.6) should be watched very closely when interpreting monitoring data. Don't ignore changes during the green trigger level period by simply waiting for the green flag to change to amber. Trends during the green period can give useful forewarning.

Interpretation is an ongoing process. Interpretations should be made as frequently as change is expected; those from early data will usually be revised or refined as more data become available, and as a clearer understanding of real behaviour is developed.

An open communication channel should be maintained between design and construction personnel, so that discussions can be held between design engineers (who raised the questions that caused the instrumentation to be used), field engineers (who provide the data) and construction or operations personnel (who use the data). It is important to establish at the start of the project the channel of communications for transmitting reports and alarm messages.

Clause 4.5 in EN 1997–1 (2004) includes guidance on evaluation of monitoring data.

94.5.8 Reporting of conclusions

After each set of data has been interpreted, conclusions should be reported in the form of an interim monitoring report and submitted to personnel responsible for implementation of contingency measures. These interim reports may be daily, weekly or monthly, depending on the specific needs of the project.

94.5.9 Implementation

Implementation includes carrying out all the steps described above. For the geotechnical monitoring to be effective, there must be actions that implement the data in order to manage risk. These actions include:

- execute remedial actions where required;
- revise design as necessary;
- change contractor's construction methods;
- evaluate measured effects on remaining work;
- synthesise lessons learned and modify standard procedures where required.

94.6 Summary

Ten principal technical reasons for recommending a geotechnical monitoring programme for a project have been outlined. Each of these has been discussed in the context of today's practice of geotechnical engineering. In general, a common feature of these technical reasons is that monitoring programmes save money.

There is a tendency among some users of instrumentation to proceed in an illogical manner, often first selecting an instrument, making measurements and then wondering what to do with the resulting data. Planning a monitoring programme using geotechnical instrumentation should begin with defining the objective and end with planning how the measurement data will be implemented. Twenty steps in a systematic planning process have been outlined, and an example has been given.

Finally, guidance is given for maximising the quality of field tasks associated with monitoring programmes.

95.1 Introduction

In the first part of this chapter, instruments for the monitoring of groundwater pressure, deformation, load and strain in structural members and total stress are described, together with a brief explanation of how they work, schematic diagrams of selected instruments and other important issues. Applications for the instruments are included. During the past ten years there has been an increasing trend towards the development and acceptance of instruments that allow for wireless data transmission, thereby reducing costs of data transmission and collection, and reducing the potential for damage to electrical cables.

In the second part of this chapter, the general role of instrumentation is given for various types of projects. This is followed by tabular listings of possible 'geotechnical questions that need to be answered' (see Chapter 94 *Principles of geotechnical monitoring*) that may lead to the use of instrumentation, with summaries to indicate some of the types of instruments that can be considered for helping to provide answers to these geotechnical questions.

When references are cited, priority is given to those that are available online. A significant part of the contents of this chapter is based on Dunnicliff (1988, 1993) and Dunnicliff (1998).

Associated Chapter 94 *Principles of geotechnical monitoring* includes the benefits of geotechnical monitoring, a systematic approach to planning monitoring programmes using geotechnical instrumentation, and general guidelines on the execution of monitoring programmes.

95.2 Instruments for monitoring groundwater pressure

95.2.1 Introduction

In this chapter the term 'piezometer' is used to indicate a device that is sealed within the ground so that it responds only to groundwater pressure around itself and not to groundwater pressures at other elevations. Piezometers are used to monitor positive (and sometimes negative) pore water pressure in soil and joint water pressure in rock. An observation well is a different type of instrument: it has no subsurface seals, and creates a vertical connection between strata.

Applications for piezometers fall into three general categories:

- First, for monitoring the pattern of water flow; second, to provide an index of soil or rock mass strength and third, for measuring groundwater pressure at an installed response zone elevation. Examples in the first category include monitoring subsurface water flow during large-scale pumping tests to determine permeability *in situ*, and monitoring the long-term seepage pattern in slopes.
- Monitoring pore water pressure (positive or negative) or joint water pressure allows an estimate of effective stress to be made and thus an assessment of strength. Examples include assessing the strength along a potential failure plane behind a cut slope in soil or rock, and monitoring of pore water pressure to control staged construction over soft clay foundations.
- When readings are taken from a number of different instruments with response zones at different elevations, a piezometric profile can be inferred. This is of significance for geotechnical design.

95.2.2 Observation wells

As shown in **Figure 95.1**, an observation well consists of a perforated section of pipe attached to a riser pipe, installed in a sand- or gravel-filled borehole. Typical diameters are: pipe 25–50 mm; borehole 75–250 mm. The surface seal, with cement mortar or other material, is needed to prevent surface run-off from entering the borehole, and a vent is required in the pipe cap so that water is free to flow through the wellpoint. The elevation of the water surface in the observation well is determined by sounding with an electrical probe attached to a graduated cable (sometimes an integral survey tape and cable), commonly referred to as a dipmeter. When the probe reaches the water surface in the riser pipe, an electrical circuit is completed and this is indicated by a light or buzzer in the read-out unit.

Appropriate applications for observation wells are very limited. In current practice they are frequently installed in boreholes during the site investigation phase of a project, ostensibly to define initial groundwater pressures and seasonal fluctuations. However, because observation wells create a vertical connection between strata, their *only* valid application is in continuously permeable ground in which groundwater pressure increases uniformly with depth. This condition can rarely be assumed. Here is a specific caution with respect to specifying observation wells with screens bridging between 'contaminated' and inert strata separated by relatively impermeable strata – this provides a preferential route for contaminant flow, hence is improper practice.

95.2.3 Open standpipe piezometers

The components are identical in principle to components of an observation well, with the addition of a subsurface seal, so that the instrument responds only to groundwater pressure around the filter element and not to groundwater pressures at other elevations. **Figure 95.2** shows an installation in a borehole. Typical diameters of standpipe and borehole are the same as for observation wells. The piezometer is sometimes referred to as a Casagrande piezometer (Casagrande, 1949). Traditionally, following Casagrande's installation procedure, a seal of bentonite chips or pellets was installed between the sand and the special grout. However, this is no longer necessary (Dunnicliff, 2008). The special grout (Mikkelsen, 2002; Contreras *et al.*, 2008) can be tremied directly onto the sand filter. To avoid

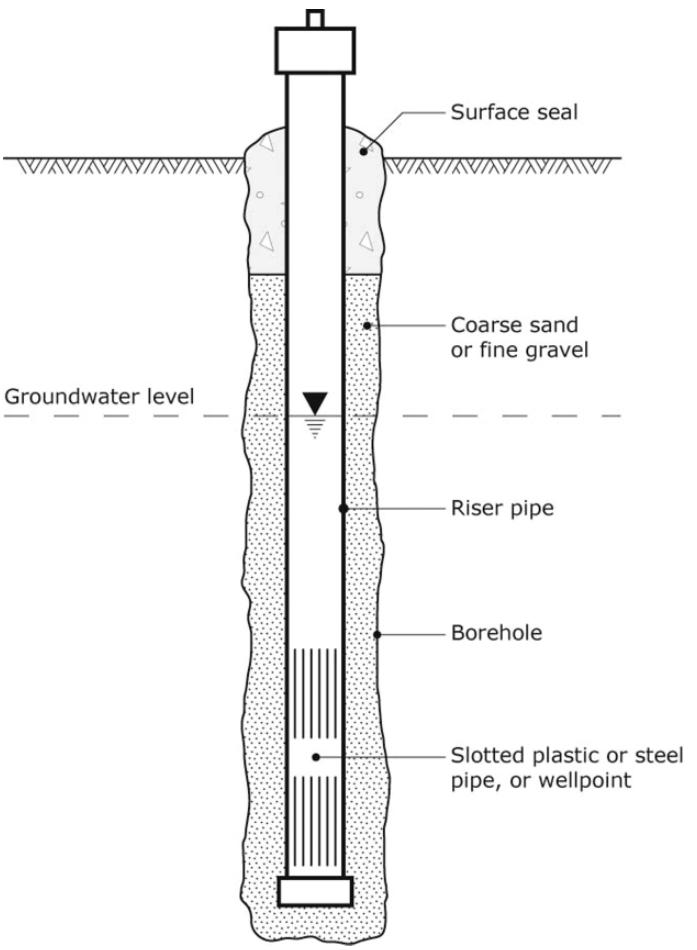

Figure 95.1 Schematic of observation well

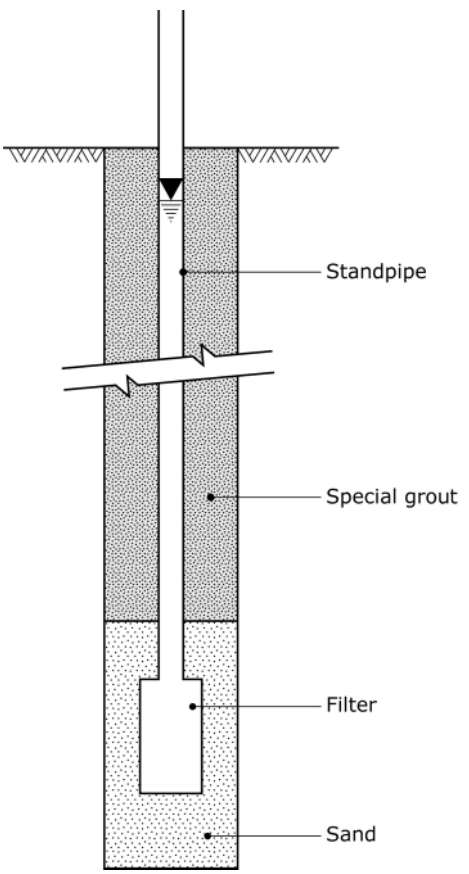

Figure 95.2 Schematic of open standpipe piezometer installed in a borehole

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

jetting of the sand, the bottom of the grout pipe should be plugged and the grout pipe should have side-discharge holes with either grouting under gravity or pumping very slowly.

As for observation wells, the elevation of the water surface in the standpipe is determined by sounding with an electrical probe.

Open standpipe piezometers have a long successful performance record, and can be converted to remote-reading piezometers by insertion of pressure transducers. However, they have a long time lag (response time), are subject to damage by construction equipment and by vertical compression of soil around the standpipe, and have freezing problems if the piezometric level rises above frost line.

95.2.4 Vibrating wire piezometers

As shown in **Figure 95.3**, the piezometer has a metallic diaphragm separating the pore water from the measuring system. A tensioned wire is attached to the mid-point of the diaphragm such that deflection of the diaphragm causes changes in wire tension. As with a piano string, the frequency of vibration varies with the tension in the wire. The wire is plucked magnetically by an electrical coil attached near the wire at its mid-point, and either this same coil or a second coil is used to measure the frequency of vibration by using a frequency counter. The manufacturer supplies a calibration between frequency and pressure. In the figure P is the current pore water pressure, K is a constant that is provided by the manufacturer, f_o is the pre-installation frequency of vibration and f is the current frequency of vibration. Vibrating wire piezometers respond to changes of atmospheric pressure so that, if these changes need to be removed from monitored data, atmospheric pressure must be monitored separately. Attempts to circumvent this issue by using 'vented' piezometers have generally been unsuccessful, as the small diameter vent tube usually does not allow for pressure equalisation.

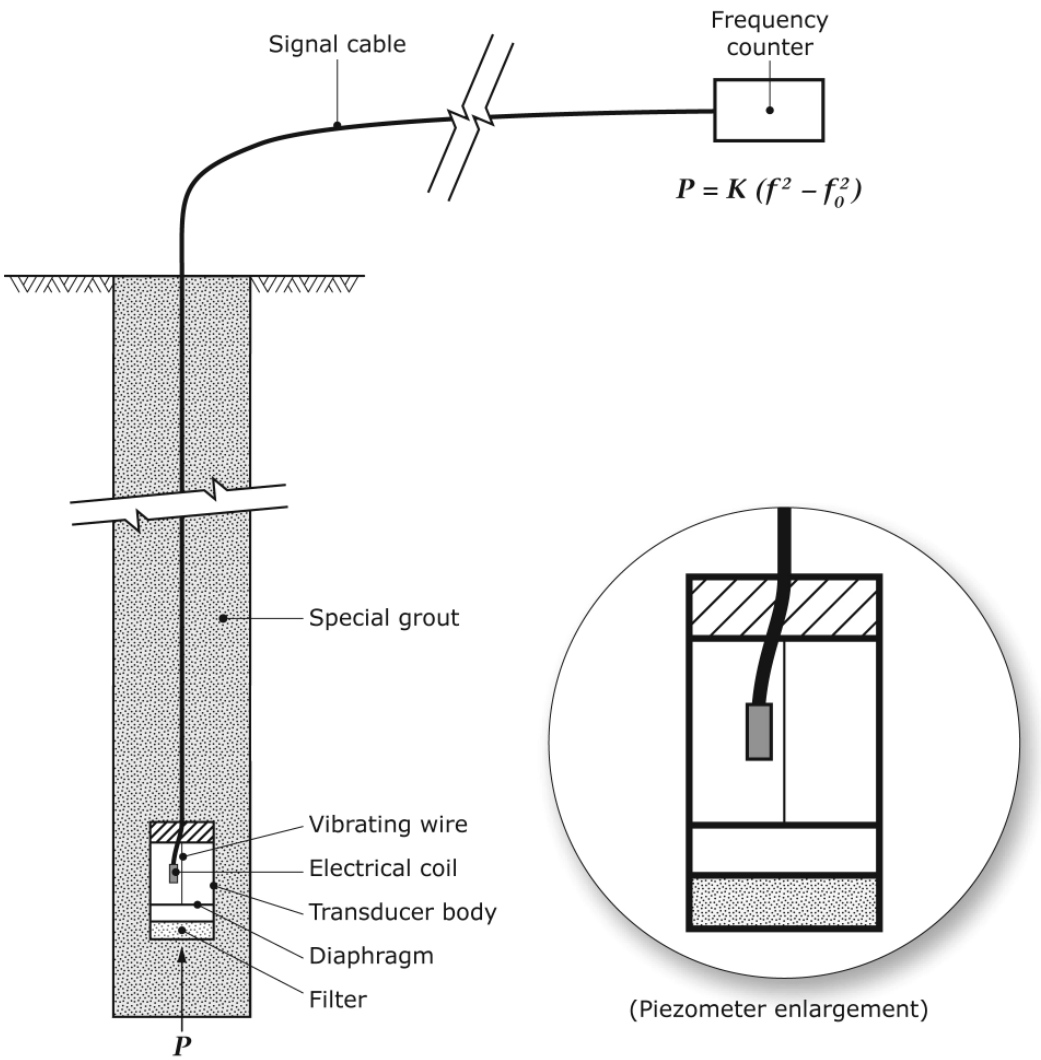

Figure 95.3 Schematic of vibrating wire piezometer installed in a borehole by the fully grouted method

Figure 95.3 shows the piezometer installed by the 'fully grouted method' (Contreras *et al*., 2008; Weber, 2009). As mentioned above, following Casagrande's installation procedure for open standpipe piezometers (Casagrande, 1949), a seal of bentonite chips or pellets used to be installed between the sand and the special grout. Several decades ago Vaughan (1969) showed that it is acceptable to use the fully grouted method, but few practitioners adopted the procedure. It is not necessary to use sand and bentonite chips or pellets (Contreras *et al*., 2008). Dunnicliff (2008) summarises some world-wide experiences with the fully grouted method, providing contact information for eight practitioners who have adopted the method as their standard procedure. Typical borehole diameter is 100–150 mm.

Wireless data transmission is available for vibrating wire piezometers. They are also manufactured for installation in soft soils by the push-in method.

Vibrating wire piezometers are very often the instruments of choice for monitoring groundwater pressure. They are easy to read and to datalog, have a short time lag, cause minimum interference to construction, and lead wire effects are minimal. They have long-term stability and can be used with long signal cables. However, lightning protection is required in locations where electrical storms occur.

95.2.5 Pneumatic piezometers

Figure 95.4 shows the basic arrangement of a pneumatic piezometer. An increasing gas pressure is applied to the inlet tube and, while the gas pressure is less than the pore water pressure, it merely builds up in the inlet tube. When the gas pressure exceeds the pore water pressure, the diaphragm deflects, allowing gas to circulate behind the diaphragm into the outlet tube, and flow is recognised either by noting a peak on the

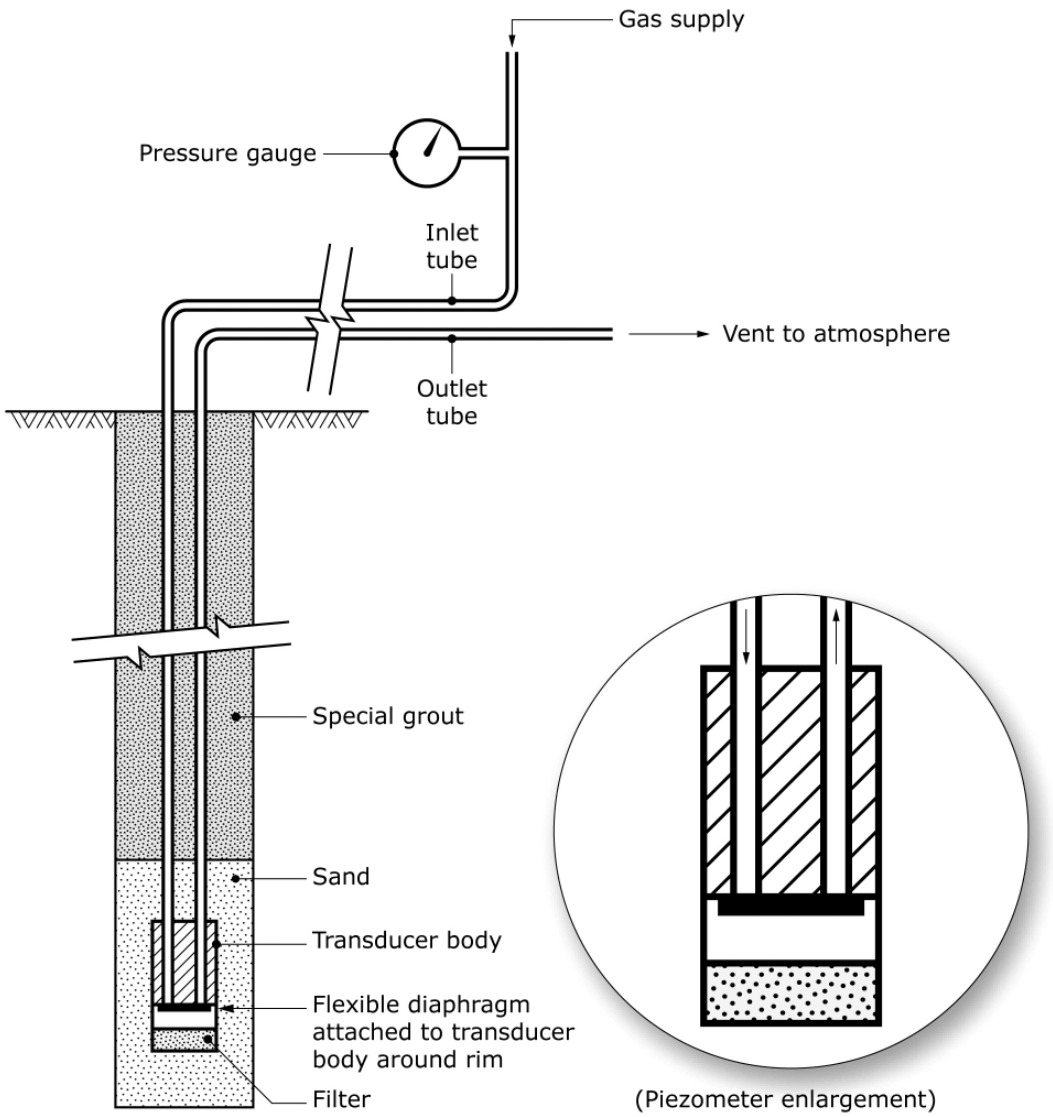

Figure 95.4 Schematic of pneumatic piezometer installed in a borehole

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

pressure gauge, or by hearing the gas flow emerging from the outlet tube. The gas supply is then shut off at the inlet valve, and any excess pressure in the tubes bleeds away, such that the diaphragm returns to its original position when the pressure in the inlet tube equals the pore water pressure. This pressure is read on a Bourdon tube or electrical pressure gauge. As for vibrating wire piezometers, pneumatic piezometers respond to changes of atmospheric pressure so that, if these changes need to be removed from monitored data, atmospheric pressure must be monitored separately. As for open standpipe piezometers, there is no need for a bentonite chip or pellet seal between the sand and special grout. The fully grouted method is not recommended for installation of pneumatic piezometers. Typical borehole diameter is 100–150 mm.

Pneumatic piezometers are also manufactured for installation in soft soils by the push-in method.

As for vibrating wire piezometers, they have a short time lag and cause minimum interference to construction. There is no need for lightning protection, but they cannot readily be datalogged and readings are somewhat operator-dependent.

95.2.6 Twin-tube hydraulic piezometers

Twin-tube hydraulic piezometers were developed for installation in the foundations and fill during construction of embankment dams. Each consists of a porous filter element connected to two plastic tubes, with a Bourdon tube pressure gauge or pressure transducer on the end of each tube. The tubes are filled with de-aired water and piezometric elevation is determined from the pressure readings. When used in the unsaturated cores of embankment dams attention must be paid to many details to ensure that pore water pressure (as opposed to pore gas pressure) is measured, and that the tubes remain continuously filled with water (Dunnicliff, 1988, 1993).

95.2.7 Flushable piezometers for measuring negative pore water pressures

Flushable piezometers (Ridley, 2003; Ridley *et al.*, 2003) have been developed primarily for measuring negative pore water pressures. Appropriate applications are slopes and excavations in clays. Negative pore water pressures will transmit tension to the water in a piezometer. This is likely to lead to the formation of air in a piezometer and eventually it can become dry. If air is present in a piezometer it may not record the correct pore water pressures. Therefore the air must be removed and replaced with fresh de-aired water.

Twin-tube hydraulic piezometers are inherently flushable, but suffer from the principal disadvantage that the hydraulic tubes that are used for flushing water through them have to be laid horizontally to maximise the range of negative pore water pressures that can be recorded and to avoid air becoming trapped within the tubes. The flushable piezometer shown in **Figure 95.5** overcomes this problem by incorporating a hydraulically operated shuttle valve that enables the piezometers to be installed in boreholes, typically 70 mm diameter. The valve is used to isolate the sensor from the flushing tubes, thereby enabling the piezometers to measure positive pore water pressures and negative pore water pressures to approximately –95 kPa, irrespective of the depth of installation. Using

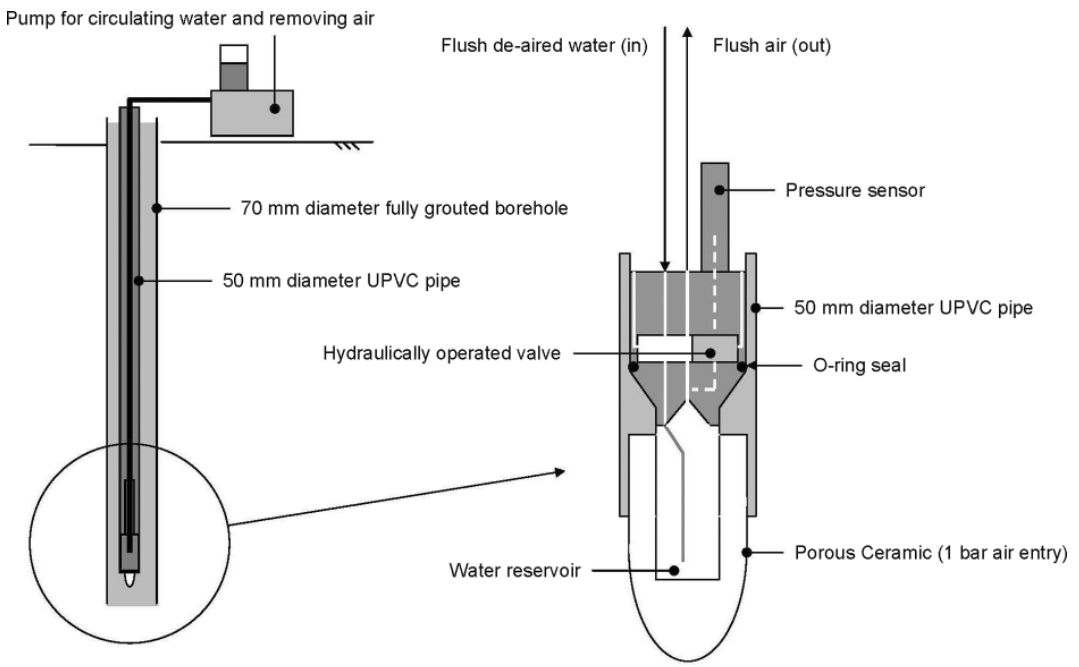

Figure 95.5 Schematic of flushable piezometer
Courtesy of Geotechnical Observations Ltd, Weybridge, Surrey

a high air entry porous filter also inhibits the formation of air in the piezometer, and adopting the fully grouted method of installation allows hydraulic continuity to be maintained between the pore water and the water in the piezometer.

95.2.8 Fibre-optic piezometers

Fibre-optic piezometers are recent developments (Glišić and Inaudi, 2007; Inaudi and Glišić, 2007a). They are categorised as 'Fabry-Peŕot interferometric point sensors', and consist of a capillary glass tube containing two partially mirrored optical fibres facing each other, but leaving an air cavity of a few microns between them. When light is coupled into one of the fibres, a back-reflected interference signal is obtained, due to the reflection of the incoming light on the two mirrors. When packaged as a pressure transducer this signal is processed to indicate pressure.

95.3 Instruments for monitoring deformation

95.3.1 Surveying methods

Surveying methods are used to monitor the magnitude and rate of horizontal and vertical deformations of structures, the ground surface, and accessible parts of subsurface instruments in a wide variety of construction situations. In general, whenever geotechnical instruments are used to monitor deformation, surveying methods are also used to relate measurements to a reference datum: a benchmark for vertical deformation monitoring or a horizontal control station for horizontal deformation monitoring.

Surveyors who work on construction sites often have little experience with the accuracies required for deformation monitoring, and a well-trained survey crew is essential when maximum accuracy is required. Measurement accuracy is controlled by the choice and quality of surveying technique and by characteristics of reference data and measuring points (Cheney, 1973). Survey instrument technology is well established, and most reputable manufacturers include a statement of accuracy in their instrument specifications, which can be relied on if the instrument is calibrated and operated in accordance with instructions.

A detailed discussion of surveying methods is beyond the scope of this chapter, and readers should make use of information provided by manufacturers of surveying equipment. However, there is a current trend to make wide use of both manual and motorised (robotic) total stations (Cook, 2006; Beth 2007; Kontogianni, 2007; Hope and Chaqui, 2008; Marr, 2008; Volterra, 2008). Total stations are survey instruments combining a theodolite and electronic distance measurement. Targets are mounted at the locations of interest and their deformation is monitored in 3D space. When a motor is added to the theodolite and automatic target recognition included, monitoring can be achieved automatically and remotely.

95.3.2 Probe extensometers

Probe extensometers are defined in this chapter as devices for monitoring the changing distance between two or more points along a common axis, by passing a probe through a pipe. Measuring points along the pipe are identified by the probe, and the distance between points is determined by measurements of probe position. Typical applications of probe extensometers are monitoring vertical strain within embankments or embankment foundations, and settlement alongside excavations and above tunnels.

Various types of transducers are used in probe extensometers, including induction coils and magnet/reed switch transducers. A magnet/reed switch transducer is an on/off position detector, arranged to indicate when the reed switch is in a certain position with respect to a magnet. The switch contacts are normally open and one of the reeds must be magnetically susceptible. When the switch enters a sufficiently strong magnetic field, the reed contacts snap closed and remain closed as long as they stay in the magnetic field. The closed contacts actuate a buzzer or indicator light in a portable read-out unit (Burland *et al*., 1972). A schematic of a borehole installation is shown in **Figure 95.6**.

The spider magnets shown in **Figure 95.6** are suitable for installation in soft ground. The three springs above the magnets and the three below are held back while being lowered into the borehole, and tripped once at the required depth. To ensure that a spider magnet moves the same as the ground around it, the stiffness of the six springs should be such that a force of at least 20 N is required to move a 200-mm-long

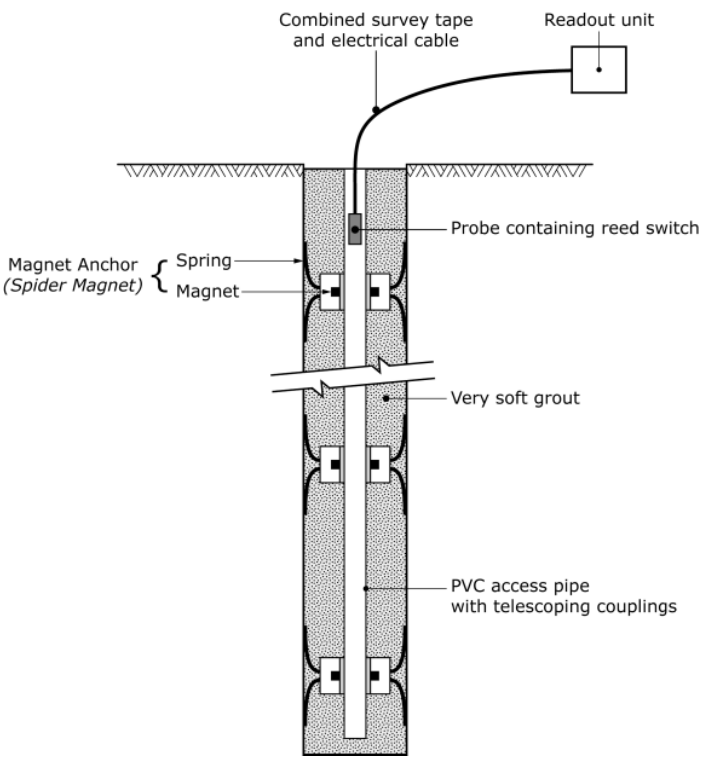

Figure 95.6 Schematic of probe extensometer with magnet/reed switch transducer

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

spring from its extended position to the longitudinal axis of the magnet housing. The tip-to-tip diameter of the springs, when in their extended positions should be at least 220 mm. For installation in stiff ground it is preferable to have only the three upper springs and to push them (no holding back) to the required depth with an insertion pipe that surrounds the access pipe, followed by an upward pull to ensure that they 'bite' into the ground. A bayonet disconnect between the bottom of the insertion pipe and the magnet housing allows removal of the insertion pipe.

The diameter of the access pipe is typically 33 mm, and the borehole diameter typically 65–225 mm. A telescoping access pipe is needed when the predicted vertical strain is greater than about 1%.

Some users have installed this instrument surrounding inclinometer casing, hoping to be able to monitor deformation in 3D. However, because the criteria for grout properties are different – high compressibility for vertical deformation data and significantly less compressibility for horizontal deformation data – data have often been unsatisfactory.

95.3.3 Fixed borehole extensometers

Fixed borehole extensometers are defined in this chapter as devices installed in boreholes in soil or rock for monitoring the changing distance between two or more points along the axis of a borehole, without use of a movable probe. When the location of a measurement point is determined with respect to a fixed reference datum, the devices also provide absolute deformation data. The operating principle is shown in **Figure 95.7**. Typical applications are monitoring deformations around underground excavation in rock and behind the faces of excavated slopes.

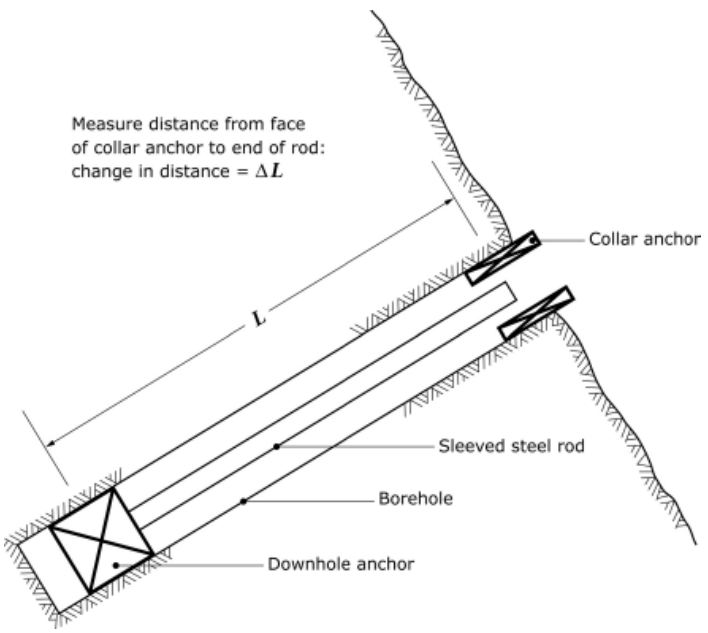

Figure 95.7 Operating principle of fixed borehole extensometer

The distance from the face of the collar anchor to the end of the rod is measured using either a mechanical or an electrical transducer. The device shown is a single-point borehole extensometer (SPBX), but several down-hole anchors can be located in a single borehole, each with an attached rod from the down-hole anchor to the collar anchor, to create a multi-point borehole extensometer (MPBX). The normal maximum number of anchors and rods for an MPBX is eight, and typical borehole diameter is 150 mm.

Many types of fixed borehole extensometers are available, the primary variables being choices of anchor type, SPBX or MPBX, transducer type, and extensometer head. Wireless data transmission is available for fixed borehole extensometers.

95.3.4 Tiltmeters

Tiltmeters are used to monitor the change in inclination (rotation) of points on or in the ground or a structure. A tiltmeter consists of a gravity-sensing transducer within an appropriate housing, either fixed-in-place or arranged as a portable device by mating with reference points permanently attached to the surface of the ground or structure. Various types of transducers are used in tiltmeters, including force balance servo-accelerometers, electrolytic levels (electrolevels), vibrating wire transducers and micro-electrical mechanical systems (MEMS). Wireless data transmission is available for tiltmeters.

Force balance servo-accelerometers are most familiar to users of instrumentation as the transducers in inclinometers. The transducer is based on a flexure-suspended proof mass which is deflected as the component of gravity changes with tilt angle.

An electrolytic level consists of a sealed glass vial similar to the vial on a conventional spirit level, partly filled with a conductive liquid. Electrical conductors inserted through the vial enable tilt to be monitored remotely. Although an inexpensive and often-used transducer, problems have often been experienced with temperature sensitivity.

A vibrating wire transducer consists of a pendulous mass which is supported by a vibrating wire strain gauge and an elastic hinge.

MEMS (Sellers and Taylor, 2008; Sheahan *et al.*, 2008) have recently become available as tilt transducers for the geotechnical instrumentation community. They are the integration of mechanical elements, sensors, actuators and electronics on a common silicon substrate through microfabrication technology. There are numerous types of MEMS, a large and rapidly growing high technology area. Similar to the force balance servo-accelerometer, a MEMS tilt sensor is based on a flexure-suspended proof mass which is deflected as the component of gravity changes with tilt angle. A position sensor senses this movement by differential capacitance sensors of high sensitivity. The proof mass, flexible mounting, position sensor and supporting electronics are all constructed from a single wafer of non-metallic material, usually silicon.

95.3.5 Inclinometers

Inclinometers are devices for monitoring horizontal deformation below the ground surface. Typical applications include determining the zone of landslide movement, monitoring the extent and rate of horizontal movement of embankments on soft ground and alongside open cut excavations, and monitoring the deflection of bulkheads, piles or retaining walls.

Inclinometers have four major components. First, a permanently installed guide casing, usually made of plastic or fibreglass, installed in a near-vertical alignment. The guide casing has tracking grooves for controlling orientation of the probe. Second, a portable probe containing two tilt transducers mounted 90 degrees apart for monitoring horizontal deformations in two directions. Third, a portable read-out unit for power supply and indication of probe inclination. Fourth, a graduated electrical cable linking the probe to the read-out unit.

Figure 95.8 shows the normal principle of inclinometer operation. After installation of the casing, the probe is lowered to the bottom and an inclination reading is made. Additional readings are made as the probe is raised incrementally to the top of the casing, providing data for determination of initial casing alignment. The differences between these initial readings and a subsequent set define any change in alignment. Provided that the lower end of the casing is fixed from translation by installing it in material such as bedrock that will not move laterally, these differences allow calculation of absolute horizontal deformation at any point along the casing.

Standard inclinometer casing diameters are 70 mm and 85 mm.

Most commercially available inclinometers make use of a force balance servo-accelerometer transducer but recently MEMS transducers have become available. Most have portable read-out units that store data on on-board memory.

Inclinometer casings can also be installed horizontally such that vertical deformation data are monitored, for example below embankments on soft ground.

Valuable guidelines on inclinometer data analysis are given by Mikkelsen (2003).

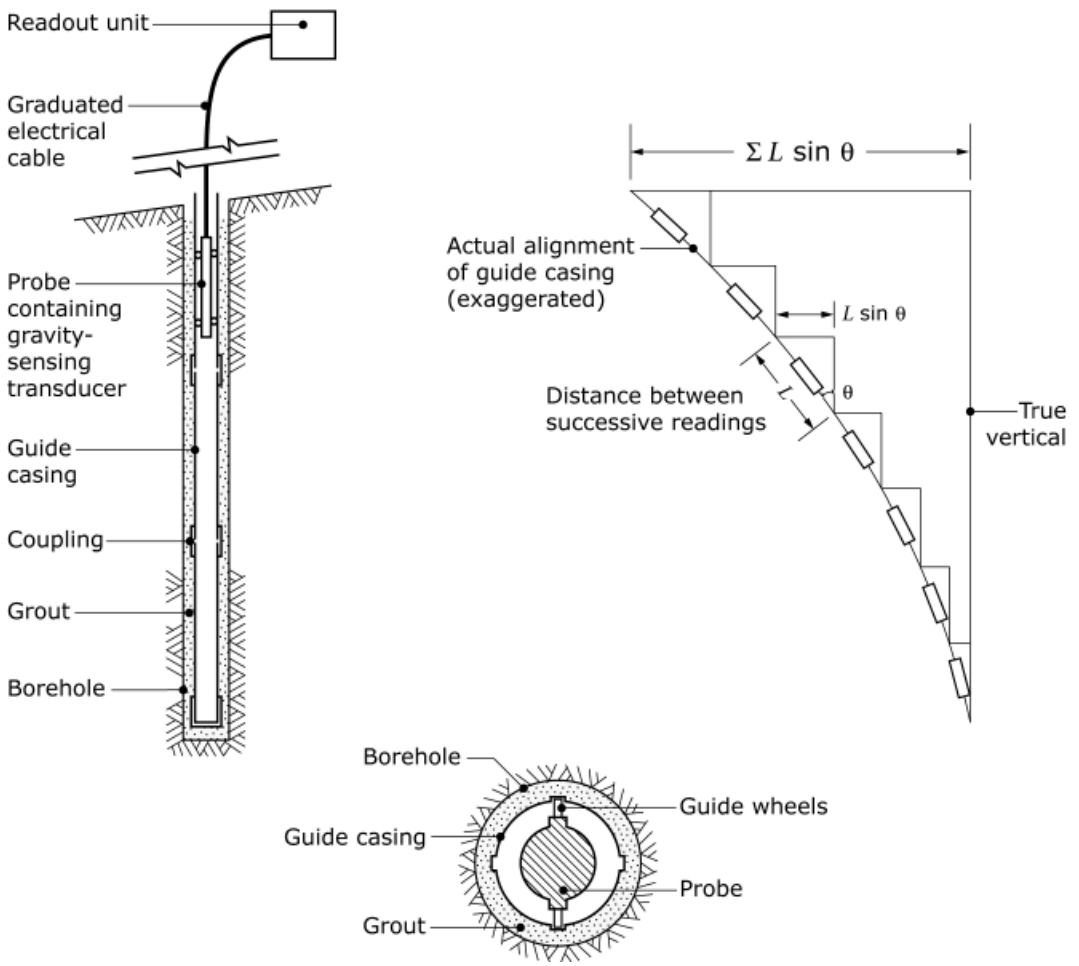

Figure 95.8 Principle of inclinometer operation

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

95.3.6 In-place inclinometers

In-place inclinometers are typically used for monitoring subsurface deformations around excavations or within slopes, when rapid or automatic monitoring is required.

An in-place inclinometer is generally designed to operate in a near-vertical borehole and provides essentially the same data as a conventional inclinometer. The device, shown schematically in **Figure 95.9**, consists of a series of tilt transducers joined by articulated rods. The transducers are the same as used in tiltmeters – force balance servo-accelerometers, electrolytic levels (electrolevels), vibrating wire transducers and MEMS. Uniaxial or biaxial transducers can be used. The transducers are positioned at intervals along the borehole axis and can be concentrated in zones of expected movement. Movement data are calculated using the same methods as for conventional inclinometers. Wireless data transmission is available for in-place inclinometers.

In-place inclinometers can be used effectively in combination with a conventional inclinometer. An in-place version can first be installed to define the location of any horizontal deformation, with minimal labour costs for reading. If deformation occurs, the in-place system can be removed and the moving zone monitored with a conventional inclinometer. Alternatively, a conventional inclinometer can be used first to indicate any deformation and an in-place version later installed across a critical deforming zone to minimise subsequent effort and perhaps to provide an alarm trigger.

A recent development, the ShapeAccelArray, or SAA (Abdoun and Bennett, 2008; Barendse, 2008; Mikkelsen and Dunnicliff, 2008; www.measurand.com), consists of a series of 300-mm-long rigid segments connected by composite joints that prevent torsion but allow flexibility of segments in two degrees of freedom. MEMS transducers are contained in each segment, such that when installed in a vertical borehole, horizontal deformation data are obtained in real time. The instrument is typically installed within a 25 mm pipe and, in contrast to inclinometers and conventional in-place inclinometers, tracking grooves are not required for controlling orientation. The SAA can also be installed horizontally to monitor vertical deformation.

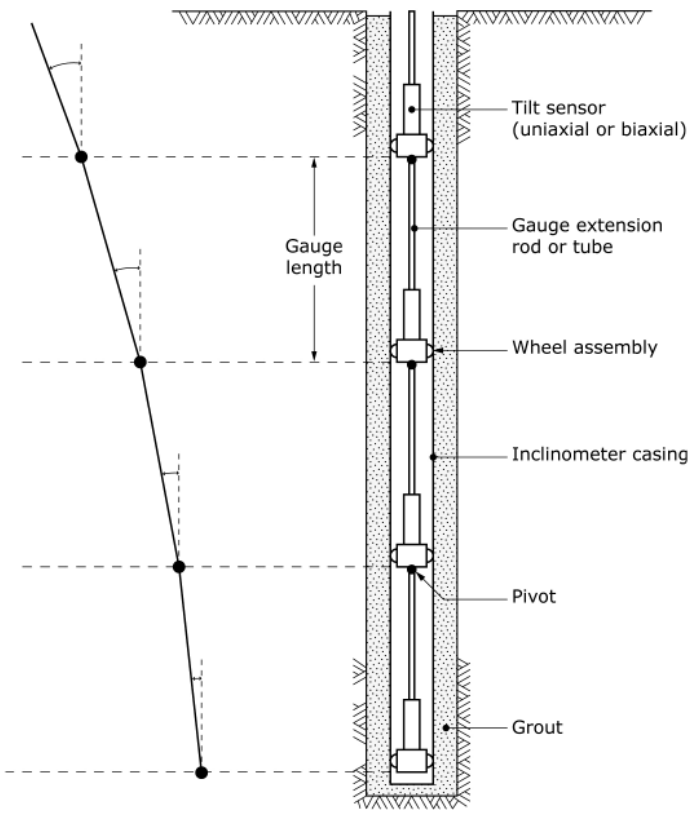

Figure 95.9 Schematic of in-place inclinometer

95.3.7 Liquid level gauges

Liquid level gauges are defined in this chapter as instruments that incorporate a liquid-filled tube or pipe for determination of relative vertical deformation. Relative elevation is determined either from the equivalence of liquid level in a manometer or from the pressure transmitted by the liquid.

The primary application for liquid level gauges is monitoring settlements within embankments or embankment foundations. They allow installation to be made without frequent interruption to normal fill placement and compaction, and minimising the potential for instrument damage. Most liquid level gauges also allow measurements to be taken at a central reading location. The gauges only provide a means of measuring *relative* elevations between two or more points. If *absolute* settlement or heave is required, as is usually the case, data must be referenced to a benchmark. If one end of the gauge cannot be mounted directly on a benchmark, a surveying method will normally be used, and accuracy may be dependent on accuracy of the surveying method.

The most common type of liquid level gauge is shown in **Figure 95.10**. The pressure transducer is usually a vibrating wire transducer. The upper surface of the liquid column is at a known elevation at the read-out location, therefore relative elevation of the transducer and reservoir can be determined from the pressure measurement and liquid density. **Figure 95.10** shows only one liquid-filled tube, but in practice it is preferable to have two tubes so that flushing is possible and independent measurements can be made on each tube as a check. The greatest potential source of error is discontinuity of liquid caused by the presence of gas, and this is a frequent problem despite use of de-aired liquid. A much better arrangement is shown in **Figure 95.11** (McRae, 2000; www.geokon.com). Sufficient backpressure is applied to force any gas into solution, and any increase in backpressure will not change the transducer reading.

The same arrangement can be packaged as a probe that is pulled along a buried pipe, thereby providing vertical deformation data at any point along the pipe. This is called a full-profile liquid level gauge.

Various liquid level gauges (sometimes called liquid levelling systems) are available with interconnected sensors, for

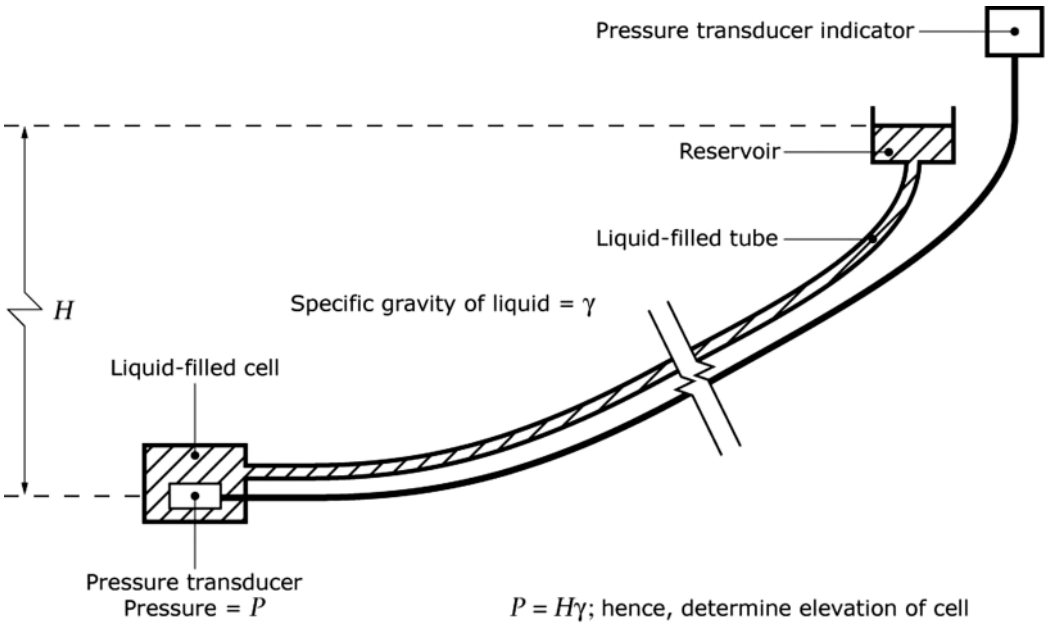

Figure 95.10 Schematic of liquid level gauge

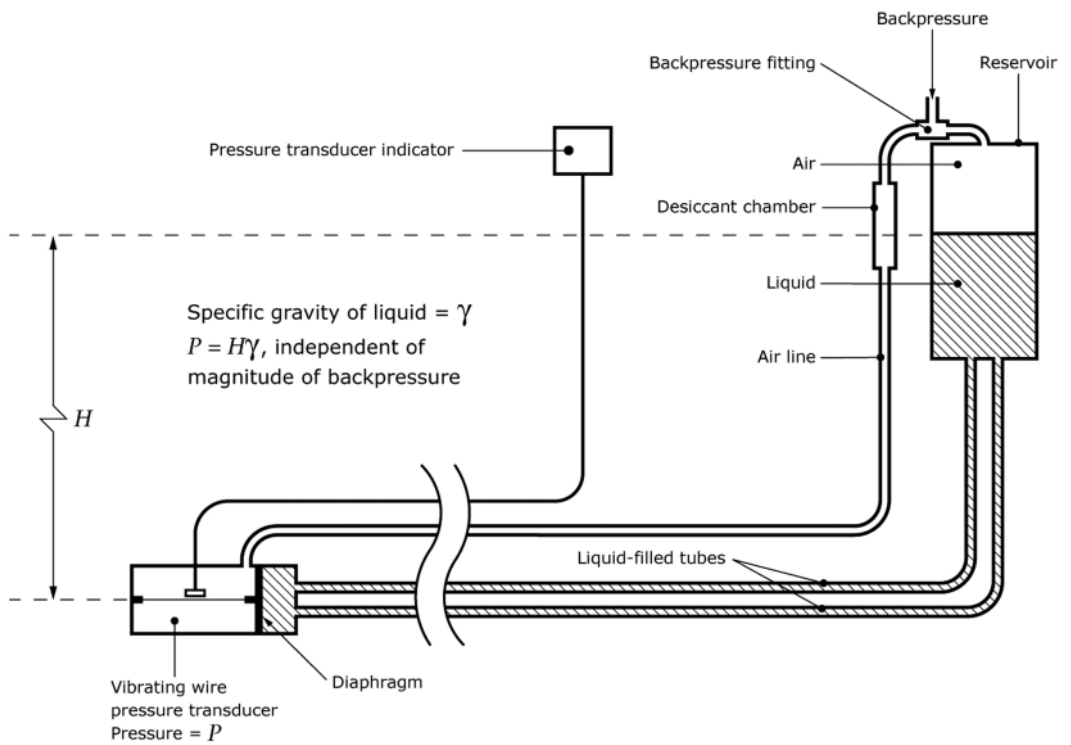

Figure 95.11 Schematic of closed loop liquid level gauge
Courtesy of Geokon, Inc., Lebanon, NH, USA

monitoring settlement at a series of locations. The sensors are connected together with both a liquid-filled tube and a tube for equalising air pressure. However, the small diameter of the liquid-level tube normally results in discontinuities in the liquid and a consequent major maintenance effort.

95.3.8 Crack gauges

Crack gauges (sometimes called jointmeters) are typically used for monitoring tension cracks behind slopes and for monitoring cracks in concrete or other structures, or joints or faults in rock. There are numerous versions, including portable or

fixed-in-place mechanical gauges, and portable or fixed-in-place gauges that incorporate a locally or remotely read displacement transducer. Wireless data transmission is available for crack gauges with electrical transducers.

95.3.9 Convergence gauges

Convergence gauges have typically been used for monitoring convergence across braced excavations and tunnels. While they are still used for these applications today, in most cases the measurements are now made by using total stations.

A typical convergence gauge, often called a tape extensometer, has a spring to control tension in the tape, and each end of the tape is attached to an anchor installed at an end of the span to be monitored. After attachment of the extensometer to the anchors and standardising the tension, readings of distance are made by adding the dial indicator reading to the tape reading.

95.3.10 Settlement platforms

Settlement platforms are typically used for monitoring settlement below embankments on soft ground. A settlement platform consists of a square plate of steel, wood or concrete placed on the original ground surface, to which a riser pipe is attached. Optical levelling measurements to the top of the riser pipe provide a record of plate elevations. The riser pipe is extended as embankment filling proceeds.

95.3.11 Fibre-optic instruments

Fibre-optic instruments for monitoring deformation are recent developments. The basic principle is given in the earlier section on fibre-optic piezometers. The signal is processed to indicate deformation. Glišić and Inaudi (2007) and Inaudi and Glišić (2007a) describe four types of fibre-optic sensing techniques: Fabry-Peŕot interferometric point sensors for monitoring distance across a discontinuity such as a crack, fibre Bragg Grating sensors that allow deformation measurements at multiple points along a single fibre line, SOFO interferometric sensors that are used for integrating deformation measurement over a long measurement base, and distributed fibre-optic sensors that are able to sense deformation at any point along a single fibre line. Inaudi and Glišić (2007b) describe the fourth technique in more detail. This last technique has very high potential for monitoring deformation over large areas, such as on slopes.

95.3.12 Time domain reflectometry

Time domain reflectometry (TDR) (O'Connor and Dowding, 1999) is a remote sensing electrical technique, similar in concept to radar along a cable. A voltage pulse, produced by a TDR pulser, travels along a two-conductor coaxial metallic cable until it is partially reflected by deformation of the cable. The distance to the deformation can be calculated knowing the propagation velocity of the signal in the cable and the time of travel of the voltage pulse from the disruption to the cable tester. TDR is used for monitoring unstable slopes, and for other applications for which an inclinometer might be considered – this application is described by Dowding *et al*. (2003). O'Connor (2008) describes geotechnical alarm systems based on TDR technology, and Lin (2009) presents some details of various types of measurements. Wireless data transmission is available for TDR.

95.3.13 Global positioning system

The global positioning system (GPS) consists of three parts: satellites, a ground control network, and user equipment. Radio signals are used in an interferometric mode. Two or more GPS receivers simultaneously receive signals from the same set of satellites, and the resulting observations are subsequently processed to obtain the inter-station difference in position. If one of the receivers is placed at a known position, the three-dimensional position of the second receiver may be determined, and the number of stations determined simultaneously is limited only by the number of receivers available. GPS is proving to be very useful for long-term performance monitoring of dams and other large structures (Rutledge and Meyerholtz, 2005).

95.3.14 Acoustic emission monitoring

Acoustic emission (AE) is a non-destructive technique for providing an early warning of failures. The primary application is for monitoring slopes in soil and rock. AE is a natural phenomenon that occurs when a solid is subjected to stress. This stress, from an external source, causes a sudden release of sound waves resulting in microseismic activity, which can be detected by transducers. Within a slope the stress induced by destabilising forces causes a re-arrangement of particles along developing shear surfaces. This inter-particle friction results in the release of AE, and is an indication of straining within a soil body.

Although historically used as a qualitative monitoring technique, Spriggs and Dixon (2005) describe a quantitative approach to using AE data as an early warning system.

95.4 Instruments for monitoring load and strain in structural members

95.4.1 Introduction

Instruments for measuring load and strain in structures fall into two groups: load cells and strain gauges. In each case, the transducers are used to measure small extensions and compressions. Load cells are interposed in the structure in such a way that structural forces pass through the cells, and strain gauges are attached directly to the surface of the structure or are embedded within the structure to sense the extensions and compressions in the structure itself.

Typical load cell applications include load testing of driven and bored piles, tiebacks and rockbolts, and long-term performance monitoring of tiebacks and end-anchored rockbolts. Calibrated hydraulic jacks are designed for application of load, and not for measurement of load. When used for load measurement in the field, errors caused by friction between the cylinder and the piston can cause underestimates of load of up to 20%.

Strain gauges are used where load cells cannot be interposed in the structure for reasons of geometry, capacity or economy and where load and stress can be calculated with adequate accuracy from knowledge of the relationship between strain and stress. Strain gauges are used, for example, to determine temporary or permanent stresses or loads in struts across braced excavations, in rockbolts, retaining walls, diaphragm walls and deep foundations.

95.4.2 Load cells

Most load cells have either electrical resistance strain gauge or vibrating wire transducers. As shown in **Figure 95.12** a cell with electrical resistance strain gauge transducers consists of a cylinder of steel or aluminum alloy, with electrical resistance strain gauges bonded to the outer periphery of the cylinder at its mid-section. Several strain gauges are used at regular intervals around the periphery, thereby reducing errors that result from load misalignment and off-centre loading. However, in all cases adequately thick bearing plates should be used at both ends of the cell, ground flat, smooth and parallel. Typical thicknesses are 38, 63 and 76 mm for cell capacities of 0.7, 1.8 and 2.2 MN respectively.

In most vibrating wire load cells, deformation of the load-bearing member is measured by using three or more vibrating wire transducers, and outputs from each transducer must be measured separately and averaged. The arrangement is similar to the electrical resistance load cell shown in **Figure 95.12**, but with vibrating wire transducers instead of bonded resistance strain gauges. However, the vibrating wire strain gauges are installed at a diameter mid-way between the inside and outside diameters of the cylindrical load-bearing member, thereby minimising errors caused by size mismatch between the cell and adjacent components. Wireless data transmission is available for load cells.

Load cells with outside diameters ranging from 80 to 320 mm are available, the size depending on the load range.

Sellers (1994) reports on tests made to examine the error caused by a size mismatch between electrical resistance load cells and adjacent hydraulic jacks. If the hydraulic jack is larger than the load cell there is a tendency for it to try to wrap the intervening bearing plate around the load cell and to bend the cylinder walls inward. If the hydraulic jack is smaller than the load cell it will try to push the intervening bearing plate through the hole in the load cell and to bend the cylinder

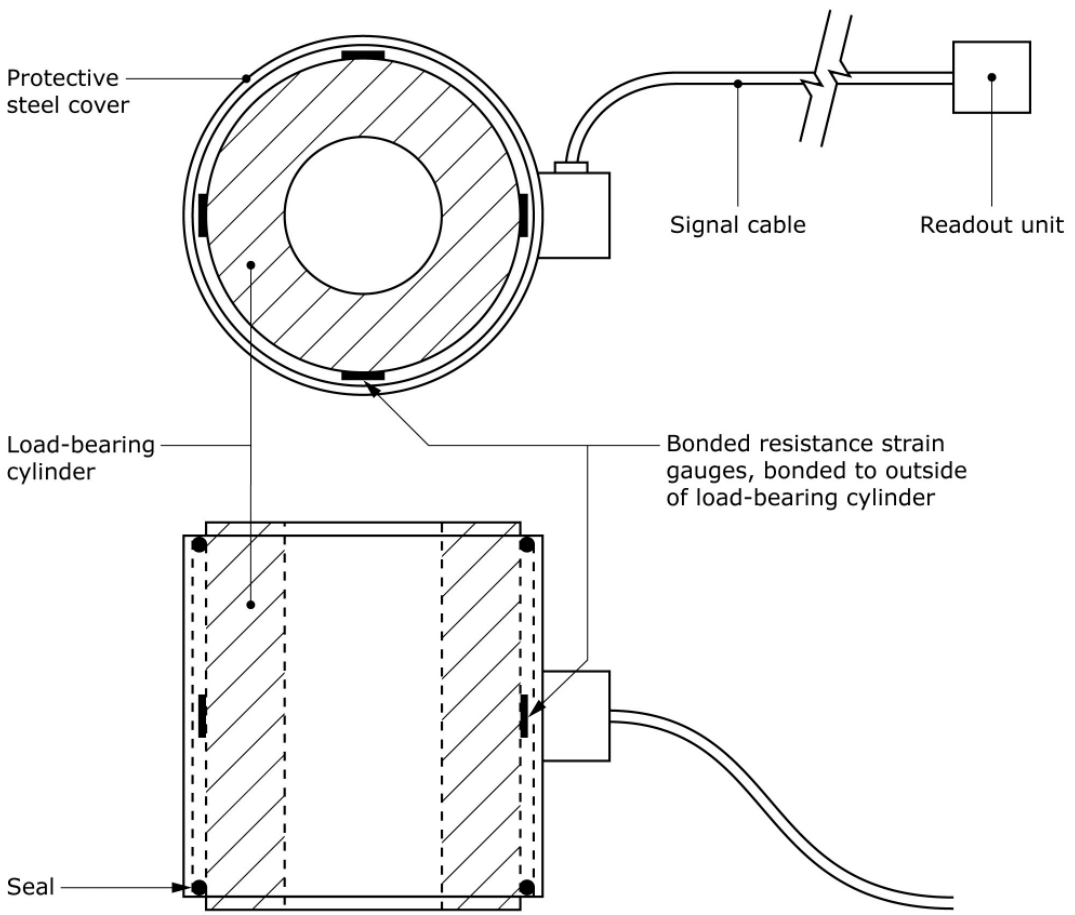

Figure 95.12 Schematic of load cell with electrical resistance transducers

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

walls outward. Sellers reports on errors of up to 8%. Dunnicliff (1995) reports on tests made by Sellers, subsequent to the tests referred to above, to examine the errors caused by a size mismatch between vibrating wire load cells and adjacent hydraulic jacks, where maximum errors were only 1%. In summary, it appears that cells with vibrating wire transducers are preferable to cells with electrical resistance strain gauge transducers.

Calibrated hydraulic jacks are used for the application of load to rockbolts, tieback anchors, piles, struts across braced excavations, and other structural elements. However, reliance on the measured pressure in the jack fluid as the sole method for load determination can often lead to significant inaccuracies. Off-centre and/or misaligned loading causes friction between the piston and cylinder, so use of the hydraulic pressure as an indication of load will indicate that the load is more than it truly is, i.e. a measurement on the unsafe side. Good practice when load testing piles and tiebacks includes use of a load cell in series with the hydraulic jack.

95.4.3 Surface-mounted strain gauges

Historically, three types of strain gauges have been used for measurements on structural surfaces: mechanical, electrical resistance and vibrating wire, but most applications today make use of vibrating wire gauges. The recent development of fibre-optic instruments provides a fourth method.

A schematic of a surface-mounted vibrating wire gauge is shown in **Figure 95.13**. The operating principle is described above in the section on vibrating wire piezometers. The gauge is available in the two basic configurations: typically 100–200 mm long for installation by arc welding and typically 50 mm long for installation by spot welding. When compared with the arc-welded gauge, advantages of the spot-welded gauge are small size, an installation procedure not requiring arc welding, and minimum errors that result from bending of the structure because of the close proximity between the vibrating wire and the structure surface. However, if adequate space is available, the larger arc-welded version is generally preferred. Wireless data transmission is available for these gauges.

Fibre-optic gauges are described above for monitoring deformation, and references are given. When used for monitoring strain all the same four techniques are applicable. Bennett (2008) describes some applications for the fourth technique, distributed fibre-optic sensors, for monitoring strain in piles and tunnels.

Strain data are rarely of interest; the data are merely a step in the determination of stress. When making measurements on steel, for which the modulus is of course known, strict attention must be made to the influence of temperature (Boone and Crawford, 2000; Druss, 2000; Boone and Bidhendi, 2001; Hashash and Marulanda, 2003; Daigle, 2005; Osborne and Tan, 2009).

Stress determination in concrete is by no means straightforward, and accurate results should not be expected. Strain in concrete can be caused by several factors other than stress change, and a strain gauge responds to all causes of strain. Strain other than that caused by stress may be due to creep (strain under constant stress), shrinkage and swelling (moisture content change), temperature change, and the progress of autogenous volume change (dimensional change that is self-generated and not due to temperature, moisture change or stress); other strain may also occur as concrete cures. Strain due to creep is generally more extensive in highly stressed pre-stressed concrete than in conventional reinforced concrete; therefore, for structural members such as pre-stressed concrete piles, creep strains are particularly significant. A special effort must therefore be made to determine the relationship between strain and stress, as described by Dunnicliff (1988, 1993) and Acerbis *et al*. (2011).

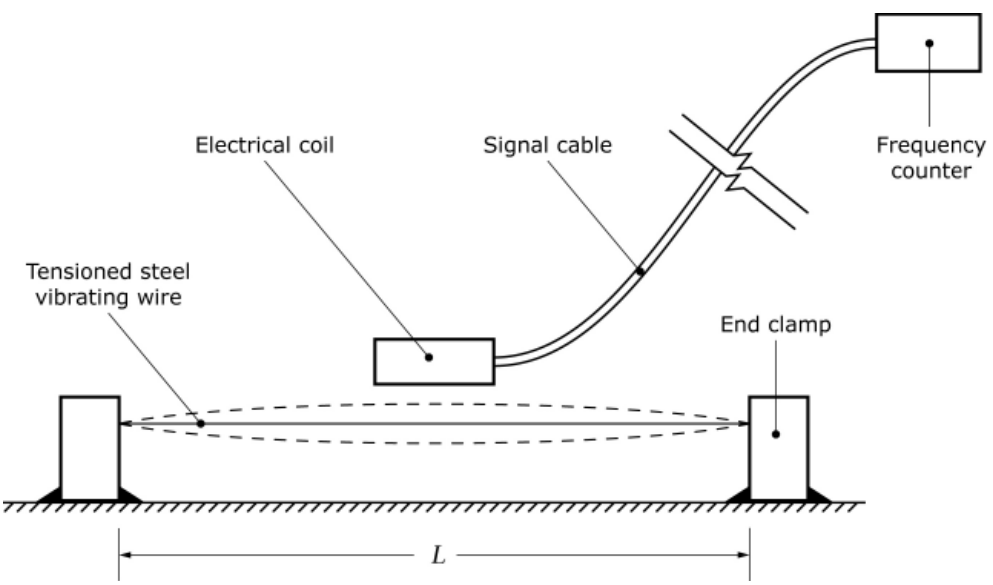

Figure 95.13 Schematic of surface-mounted vibrating wire strain gauge

95.4.4 Embedment strain gauges

The primary application for embedment strain gauges is measurement of strain in concrete. Typical applications are driven concrete piles, bored piles, diaphragm walls, concrete tunnel linings and concrete dams. As for surface-mounted versions, vibrating wire gauges are used in most applications today, although the recent development of fibre-optic gauges holds promise.

There are two basic types of vibrating wire gauge. The first is similar to the arrangement shown in **Figure 95.13**, with circular end flanges instead of the end blocks, typically 100–200 mm long. Most gauges are supplied with a preset tension, which can be specified by the user. The second type consists of a vibrating wire transducer mounted in the central portion of a length of steel bar, such as reinforcing steel. The use of a length of steel bar, embedded in concrete to measure strain, is sometimes referred to as a sister bar, or a rebar strain meter. **Figure 95.14** shows a sister bar.

The first type cannot be installed without protection prior to concreting, because of the likely damage when the concrete is vibrated. It must therefore be encapsulated in a briquette of fine-aggregate concrete, and the briquette must not be more than 24 hours old at the time that the primary concrete is placed – if it is older than this there will be an inclusion effect that will distort the gauge reading. The second type can be installed directly in concrete without protection, and is therefore preferred if sufficient space is available.

As for gauges surface-mounted on concrete, a special effort must be made to determine the relationship between strain and stress, as described by Dunnicliff (1988, 1993) and Acerbis *et al*. (2011).

95.5 Instruments for monitoring total stress

95.5.1 Introduction

Total stress measurements in soil fall into two basic categories: measurements within a soil mass and measurements at the face of a structural element. Instruments are referred to as earth pressure cells, soil stress cells and soil pressure cells, and in this chapter the terms ‘embedment earth pressure cells’ and ‘contact earth pressure cells’ will be used for the two basic categories.

Embedment earth pressure cells are installed within fill, for example, to determine the distribution, magnitude and direction of total stress within an embankment. Applications for contact earth pressure cells include measurement of total stress against retaining walls, culverts, piles and diaphragm walls.

The primary reasons for use of earth pressure cells are to confirm design assumptions and to provide information for the improvement of future designs; they are less commonly used for construction control or other reasons. When concerned with stresses acting on a structure during construction or after construction is complete, it is usually preferable to isolate a portion of the structure and to determine stresses by use of load cells and strain gauges within the structure. For example, this approach has been used successfully in the determination of earth pressures in braced excavation from measurements of support loads.

95.5.2 Embedment earth pressure cells

Attempts to measure total stress within a soil mass are plagued by errors because both the presence of the cell and the installation method generally create significant changes in the free-field stress. Therefore it is usually impossible to measure total stress with great accuracy, and realistic applications are rare.

Most available embedment earth pressure cells are of the type shown in **Figure 95.15**. A cell consists of two circular or rectangular steel plates, welded together around their periphery, with liquid filling the intervening cavity and a length of high-pressure steel tubing connecting the cavity to a nearby pressure transducer. Total stress acting on the outside of the cell is balanced by an equal pressure induced in the internal liquid. It is essential that the cell is filled with de-aired liquid and that no gas bubbles are trapped within the cavity during filling. Typical cell diameter is 200 mm, but larger diameter cells are available.

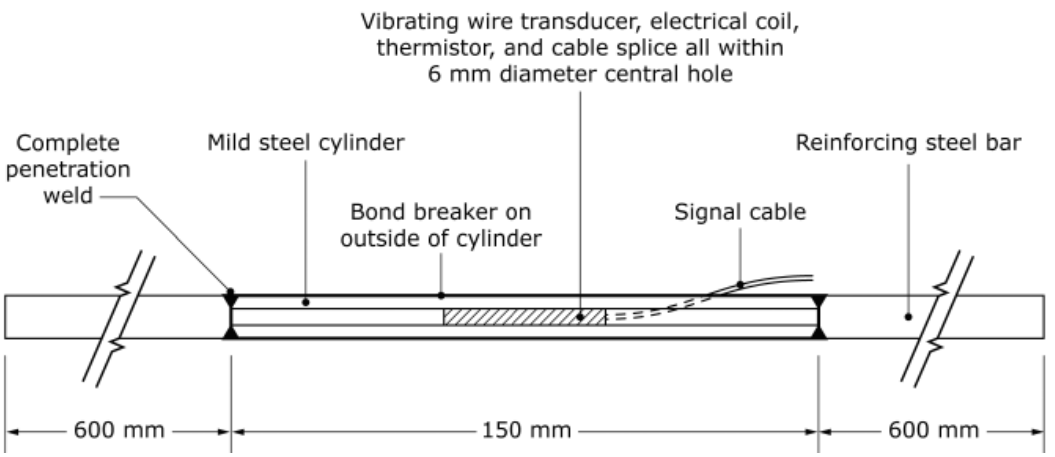

Figure 95.14 Schematic of sister bar with vibrating wire transducer

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

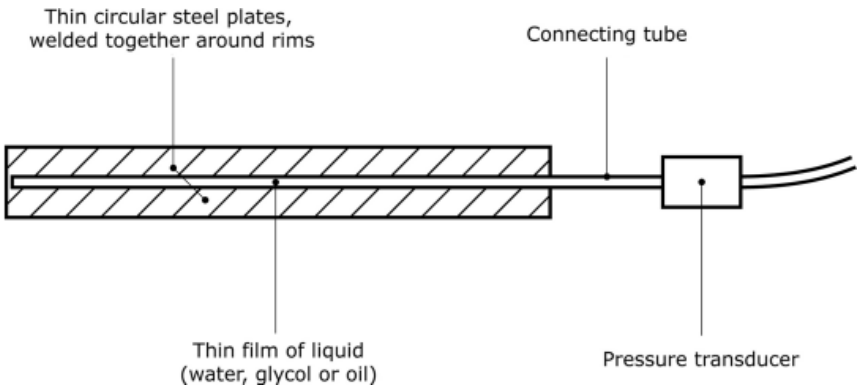

Figure 95.15 Schematic of embedment earth pressure cell

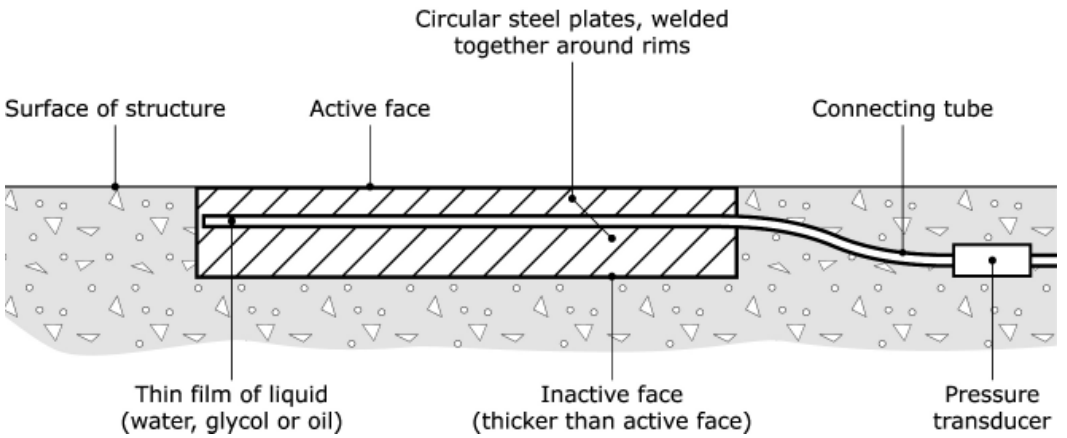

Figure 95.16 Schematic of contact earth pressure cell

95.5.3 Contact earth pressure cells

Measurements of total stress against a structure are not plagued by so many of the errors associated with measurements within a soil mass, and it is possible to measure total stress at the face of a structural element with greater accuracy than within a soil mass.

Figure 95.16 shows a typical contact earth pressure cell. This is similar to the embedment cell shown in **Figure 95.15**, with one of the active faces replaced by a thick inactive face. Cell diameters are the same as for embedment cells.

95.6 General role of instrumentation, and summaries of instruments to be considered for helping to provide answers to various geotechnical questions

95.6.1 Introduction

Instrumentation that may be considered for various types of construction projects is described in the following sections. For each type of construction project the general role of geotechnical instrumentation is given. This is followed by a tabular listing of the possible geotechnical questions that may lead to the use of instrumentation, indicating some of the types of instruments can be considered for helping to provide answers to those questions. It is recognised that there may be additional geotechnical questions and also additional instruments that are not described in this chapter.

The sequence of geotechnical questions is intended to match the time sequence in which the question may be addressed during the design, construction and performance process, and does not indicate any rating of importance.

The suggestions for types of instruments are not intended to be dogmatic, because the selection always depends on issues specific to each project, and is influenced by the personal experience of the person making the selection. In the tables some of the most likely instruments to consider are listed, with other possible types in brackets.

95.6.2 Internally braced excavations

95.6.2.1 General role of instrumentation

The design of internally braced (strutted) excavations is based for the most part on empirical procedures and past

experience. The consequences of poor performance can be severe and may on occasion be catastrophic. A monitoring programme may not be required if the design is very conservative, if there is previous experience with design and construction of similar facilities under similar conditions, or if the consequences of poor performance will not be severe. However, under other circumstances a monitoring programme will normally be required to demonstrate that the excavation is stable and that nearby structures are not affected adversely. Depending on the specific needs of each case, the monitoring programme may apply to the wall and struts, to the ground beneath or surrounding the excavation and/or to adjacent structures or utilities.

95.6.2.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.1 lists the possible geotechnical questions that may lead to the use of instrumentation for internally braced excavations, together with possible instruments that can be considered for helping to provide answers to those questions.

Some geotechnical questions	Measurement	Some instruments to consider
What are the initial site conditions?	Groundwater pressure	Open standpipe piezometers
		Vibrating wire piezometers installed by the fully grouted method
		(Pneumatic piezometers)
	Vertical deformation	Surveying methods
	Widths of cracks in structures	Crack gauges
Are the struts being installed correctly?	Load in struts	Calibrated hydraulic jacks
Is the excavation stable, and are nearby structures being affected adversely by ground movements?	Settlement of ground surface, structures and top of supporting wall	Surveying methods
	Horizontal deformation of ground surface, structures, and exposed part of supporting wall	Surveying methods
		(Convergence gauges)
	Change in width of cracks in structures and utilities	Crack gauges
	Subsurface horizontal deformation of ground	Inclinometers
		In-place inclinometers
		(Fixed borehole extensometers)
		(Fibre-optic instruments)
	Subsurface settlement of ground and utilities	Probe extensometers
		(Fixed borehole extensometers)
	Load in struts	Surface-mounted strain gauges
	Groundwater pressure	Open standpipe piezometers
		Vibrating wire piezometers installed by the fully grouted method
		(Pneumatic piezometers)
	Base heave	Probe extensometers
Is an individual strut being overloaded?	Load in strut	Surface-mounted strain gauges
Is the groundwater table being lowered?	Groundwater pressure	Open standpipe piezometers
		Vibrating wire piezometers installed by the fully grouted method
		(Pneumatic piezometers)
Is excessive base heave occurring?	Base heave	Probe extensometers
	Subsurface horizontal deformation	Inclinometers
		In-place inclinometers

Table 95.1 Some instruments to consider for monitoring internally braced excavations

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

95.6.3 Externally braced excavations

95.6.3.1 General role of instrumentation

The general role of instrumentation for externally braced excavations is the same as for internally braced excavations. However, it is possible to make regular visual inspections of internal bracing, but external bracing cannot be *seen*. Although confidence in the performance of an externally braced excavation is increased by conducting a proof test on every tieback anchor, if an anchor subsequently fails, the failure may be progressive and catastrophic. In general, therefore, instrumentation plays a role in three phases of external bracing that are not applicable to internal bracing: testing of *test anchors* during the design phase or at the start of construction, as input to design of the project anchors; *performance* and *proof testing* of anchors during construction; and subsequent *monitoring* of selected representative anchors. The third phase may be omitted if a conservative design has been used.

95.6.3.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.2 lists the possible geotechnical questions that may lead to the use of instrumentation for externally braced excavations, together with possible instruments that can be considered for helping to provide answers to those questions.

95.6.4 Embankments on soft ground

95.6.4.1 General role of instrumentation

This section relates to the use of geotechnical instrumentation where all the geotechnical questions are associated with the soft ground itself, and not with the embankment.

In many cases, selection of soil parameters for the foundation soil is reliably conservative. The embankment is therefore designed with confidence that performance will be satisfactory, and 'comfortable' factors of safety are used. In such cases, many projects will proceed without the use of instrumentation. However, some uncertainties always exist. Where design uncertainties are great, factors of safety small, or the consequences of poor performance severe, a prudent designer will include a performance monitoring programme in the design.

In spite of a long record of embankment construction throughout the history of civil engineering, embankments that are designed with a factor of safety greater than unity fail embarrassingly often. On the other hand, some test embankments that are designed to fail intentionally, never do. Thus, it is not surprising that instrumentation plays a significant role in design and construction of embankments on soft ground.

The most frequent uses of instrumentation for embankments on soft ground are to monitor the progress of consolidation and to determine whether the embankment is stable. If the calculated factor of safety is likely to approach unity, instrumentation will generally be installed to provide a warning of any instability, thereby allowing remedial measures to be implemented before critical situations arise.

Chapter 70 *Design of new earthworks* provides additional information on embankments on soft ground.

95.6.4.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.3 lists the possible geotechnical questions that may lead to the use of instrumentation for embankments on soft

Some geotechnical questions	Measurement	Some instruments to consider
What are the initial site conditions?	As in **Table 95.1**	As in **Table 95.1**
What is a suitable design for tieback anchors (by constructing and testing *test anchors*)?	Load in tieback	Load cells
	Deformation at head	Dial indicators
	Load transfer in grouted zone	Surface-mounted strain gauges
Are the tiebacks being installed correctly (by *performance* and *proof testing*)?	Load in tieback	Calibrated hydraulic jacks (Load cell)
	Deformation at head	Dial indicators
Is the excavation stable, and are nearby structures being affected adversely by ground movement?	As in **Table 95.1**, except for load in struts	As in **Table 95.1**, except for load in struts
	Load in tieback	Load cells (Calibrated hydraulic jacks and load cells: *lift-off tests*) Surface-mounted strain gauges
Is the groundwater table being lowered?	As in **Table 95.1**	As in **Table 95.1**
Is excessive bottom heave occurring?	As in **Table 95.1**	As in **Table 95.1**

Table 95.2 Some instruments to consider for monitoring externally braced excavations

Some geotechnical questions	Measurement	Some instruments to consider
What are the initial site conditions in the soft ground?	Pore water pressure	Vibrating wire piezometers installed by the fully grouted method

Table 95.3 Some instruments to consider for monitoring embankments on soft ground

ground, together with possible instruments that can be considered for helping to provide answers to those questions.

95.6.5 Clay embankments

95.6.5.1 General role of instrumentation

This section relates to the use of geotechnical instrumentation where the primary geotechnical questions are associated with the embankment, and not necessarily with the ground below the embankment.

All clay embankments begin life with negative pore water pressures, which should provide enhanced stability. Increases of the pore water pressure in the fill could lead to the development of instability. In most cases such failures will occur shortly after construction. Longer-term failures can occur in embankments that have an otherwise stable geometry, caused by progressive deformations induced by shrinkage and swelling that result from the presence of vegetation. It is these that give most cause for concern. Seasonal variations of pore water pressure giving rise to shrinkage and swelling also cause problems with the serviceability of clay embankments, particularly where they carry railway infrastructure. Identifying the presence of seasonal pore water pressure changes or shrinkage and swelling is therefore an important factor in determining the need for further assessment.

Once identified, the magnitude of the stress changes can be used in an analysis of the embankment, to determine if a failure surface is likely to develop. However, it is important to recognise that the analysis will be imprecise in its ability to predict the timing of a failure because the seasonal changes will not be consistent from year to year, and the history of stress changes will be unknown. Therefore long-term monitoring of the pore water pressures is likely to be required and suitable instrumentation should be selected. Inclinometers can be used to detect acceleration in the movement along discontinuities near the toe of the embankment, but these measurements must also be long-term.

Ultimate stability will be influenced by the underlying foundation. Low permeability soils could prolong the increase of pore water pressures within the embankment during extreme environmental conditions. Higher permeability soils will provide underdrainage and help to maintain lower pore water pressures within the embankment. Deep open standpipe piezometers are therefore useful for identifying the underlying groundwater regime.

95.6.5.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.4 lists the possible geotechnical questions that may lead to the use of instrumentation for clay embankments,

Some geotechnical questions	Measurement	Some instruments to consider
Is the embankment stable?	Negative pore water pressure	Flushable piezometers
	Horizontal deformation	Surveying methods
		Inclinometers
		(In-place inclinometers)
What is the underlying drainage condition?	Pore water pressure	Open standpipe piezometers
Is there any shrink swell?	Pore water pressure	Flushable piezometers
	Horizontal deformation	Inclinometers
		(In-place inclinometers)
	Vertical deformation	Probe extensometers
		Surveying methods

Table 95.4 Some instruments to consider for monitoring clay embankments

together with possible instruments that can be considered for helping to provide answers to those questions.

95.6.6 Embankment dams

95.6.6.1 General role of instrumentation

The main purpose of instrumentation installed within an embankment dam is to study whether or not the dam is behaving according to design predictions. This general statement can be subdivided into two categories: first, the study of special problems at individual sites that are related to special foundation conditions or uncommon design features and second, the study of behaviour when there are no such special problems.

When instrumentation is used for studying special problems that are related to special foundation conditions or uncommon design features, the design of the monitoring programme is tuned directly for the special conditions and features and, because the designers of the dam know the weaknesses of the particular site and the sensitive features of the design, they must play a leading role in the choice of type and location of instruments.

The practice of placing instruments routinely in embankment dams where there is no special problem to be studied, for example, a conventional dam of moderate height on a good foundation, has seen several ups and downs in the last fifty years. In the 1960s, many important dams were constructed with essentially no internal instruments. Each failure or major problem tends to be widely publicised, and dam engineers feel pressure to install instruments routinely for their own protection, even if they do not believe it absolutely necessary.

Peck (1985) comments:

> Instrumentation, vital for obtaining quantitative answers to significant questions, is too often misused, especially in earth and rockfill dams. In some countries regulations concerning the safety of dams demand the incorporation of inclinometers, settlement indicators, and piezometers in the cores of virtually all new dams, but for what purpose? Not for research, because the patterns of deformation and pore pressure development for ordinary geometries and materials are now well known and can be predicted by calculation. Only under unusual circumstances can it be said that design assumptions in these regards require verification. Yet, installation of instruments, even under the best of circumstances, introduces inhomogeneities into the cores, and occasionally is the direct cause of such local defects as sinkholes. The potential weakness introduced by an installation should be balanced against the potential benefit from the observations. In contrast to those located in cores, piezometers in foundation materials near the downstream toes detect upward seepage pressures that cannot be predicted reliably, and can thus give timely warning if measures are needed to ensure safety. There is a danger that instrumentation may be discredited because of indiscriminate use. Of all the internal instruments in embankment dams, piezometers are by far the most common, and an installation consisting only of piezometers can serve two purposes. First, piezometers in a clay core indicate rates of dissipation of pore water pressure and the approach of equilibrium conditions after impounding. Second, piezometers may be appropriate where it is desired to avoid criticism when designing a dam of conventional design and moderate height on a good foundation.

Although written in 1985, these comments are still applicable today.

Peck (2006) puts instrumentation into perspective: 'Monitoring of every dam is mandatory, because dams change with age and may develop defects. There is no substitute for systematic and intelligent surveillance. But monitoring and surveillance are not synonymous with instrumentation.'

95.6.6.2 Instruments to be considered for helping to provide answers to various geotechnical questions

Among the possible geotechnical questions are:

- What are the initial site conditions?
- Is performance satisfactory during construction?
- Is performance satisfactory during first filling?
- Is performance satisfactory during drawdown?
- Is long-term performance satisfactory?

The types of instruments to be considered for helping to provide answers to these questions are too numerous to be tabulated here, and readers are referred to Dunnicliff (1988, 1993). The most important methods for addressing the last question are visual observations of the entire structure by appropriately trained people and monitoring of leakage emerging downstream by using leakage weirs. Monitoring methods that have been developed or improved since the above reference was written, and which may be applicable for addressing the last question, include global positioning systems, distributed fibre-optic sensing and robotic total stations for monitoring deformation. Distributed fibre-optic sensors also have large potential for monitoring the temperature of seepage water (Inaudi and Glišić, 2007b), thereby indicating areas where water flow is concentrated.

95.6.7 Cut slopes in soil

95.6.7.1 General role of instrumentation

It is imperative that, prior to planning an instrumentation programme for a cut slope in soil, an engineer first develop one or more working hypotheses for a potential behaviour mechanism. The hypotheses must be based on a comprehensive knowledge of the locations and properties of stratigraphic discontinuities.

Instrumentation can be used to define the groundwater regime prior to excavating a slope. Results of measurements during excavation can be used as a basis for modification of the designed slope angle. Measurements of ground movement and positive or negative groundwater pressure can assist in documenting whether or not performance during and after excavation is in accordance with predicted behaviour. Measurements can also be used to document whether short- and long-term surface and/or subsurface drainage measures are performing effectively. If evidence of instability appears during or after construction, instrumentation plays a role in defining the characteristics of the instability, thus permitting selection of an appropriate remedy.

A very important subset is the case of a cut slope in clay. Here negative pore water pressures generated during excavation can give rise to temporary stability, the lifetime of which will be related to the height of the slope and the slope angle. Therefore monitoring the negative pore water pressures is an effective way of assessing the stability of a cut slope in clay. In some instances the stability may be maintained for long enough to undertake temporary works within the excavation and thereby save on expensive stabilisation measures.

Chapter 72 *Slope stabilisation methods* provides additional information on cut slopes in soil.

95.6.7.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.5 lists the possible geotechnical questions that may lead to the use of instrumentation for cut slopes in soil, together with possible instruments that can be considered for helping to provide answers to those questions.

95.6.8 Landslides in soil

95.6.8.1 General role of instrumentation

If there is evidence of slope instability, its characteristics must be defined so that any necessary remedial measures may be taken. The question *how much ground is moving?* can be answered by use of instrumentation. The question *why is the ground moving?* will not be answered by instrumentation alone: the answer of course also requires a complete geotechnical investigation and analysis. Instrumentation also plays a role in monitoring the long-term stability of the slope after remedial measures have been taken.

Chapter 72 *Slope stabilisation methods* provides additional information on landslides in soil.

95.6.8.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.6 lists the possible geotechnical questions that may lead to the use of instrumentation for landslides in soil, together with possible instruments that can be considered for helping to provide answers to those questions.

95.6.9 Cut slopes in rock

95.6.9.1 General role of instrumentation

The general role of instrumentation is identical to the role for cut slopes in soil, as discussed above. However, when planning to monitor the stability of rock slopes, it is important to recognise that if the slope is subject to a brittle failure mode, movement will be sudden. In such cases, geotechnical instrumentation may not be appropriate to forewarn of instability. It may be more appropriate to develop an area-wide correlation between rainfall intensity and slope instability, and to use rainfall measurements to warn of potential problems.

Chapters 72 *Slope stabilisation methods* and 87 *Rock stabilisation* provide additional information on cut slopes in rock.

95.6.9.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.7 lists the possible geotechnical questions that may lead to the use of instrumentation for cut slopes in rock, together with possible instruments that can be considered for helping to provide answers to those questions.

95.6.10 Landslides in rock

95.6.10.1 General role of instrumentation

The general role of instrumentation is identical to the role for landslides in soil, as discussed above.

95.6.11 Tunnels

95.6.11.1 General role of instrumentation

The consequence of poor performance of a tunnel can be severe and may on occasion be catastrophic. A monitoring programme may not be required if the design is very conservative, if there is previous experience with design and construction of similar facilities under similar conditions, or if the consequences of poor performance will not be severe. However, under other circumstances a monitoring programme will normally be required to demonstrate that the tunnel is stable and that nearby structures are not affected adversely.

95.6.11.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.9 lists the possible geotechnical questions that may lead to the use of instrumentation for tunnels, together with possible instruments that can be considered for helping to provide answers to those questions.

Table 95.6 Some instruments to consider for monitoring landslides in soil

95.6.12 Driven piles

95.6.12.1 General role of instrumentation

The subsurface length of a driven pile cannot usually be inspected after driving; thus, its physical condition and alignment are unknown. Subsurface geotechnical conditions are rarely known with certainty, and therefore the design of driven piles involves assumptions and uncertainties that are often addressed by conducting instrumented full-scale tests. Tests may examine the behaviour of the pile under load applied to the pile head or under load caused by settlement of soil with respect to the pile.

Defects in piles can be created during driving, and inspection procedures are available for examining the condition and alignment after driving. Certain types of driven pile cause large displacements and changes of pore water pressure in the surrounding soil, and these may in turn have a detrimental effect on neighbouring piles or on the stability of the site as a whole. Instrumentation can be used to quantify the consequences of pile driving and thus to assist in planning any necessary action.

The following chapters provide additional information on driven piles: Chapter 54 *Single piles*, 55 *Pile-group design*, 81 *Types of bearing piles* and 82 *Piling problems.*

95.6.12.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.10 lists the possible geotechnical questions that may lead to the use of instrumentation for driven piles, together with possible instruments that can be considered for helping to provide answers to those questions.

95.6.13 Bored piles

95.6.13.1 General role of instrumentation

Many uncertainties exist during design of bored piles, and instrumentation plays a role in determining the load–movement relationship by conducting load tests. Concrete integrity is often uncertain during construction, particularly when bored piles are constructed in granular soils below the water table or in softer, squeezing clays, when concrete slump is inadequate, or when concrete placement practices are inferior. Instrumentation can be used to examine the integrity of the concrete. For piles cast under support fluid, concrete integrity at the pile toe is particularly important.

95.6.13.2 Summary of instruments to be considered for helping to provide answers to various geotechnical questions

Table 95.11 lists the possible geotechnical questions that may lead to the use of instrumentation for bored piles, together with possible instruments that can be considered for helping to provide answers to those questions.

It is recommended this chapter is read in conjunction with

- Chapter 100 *Observational method*
- Section 8 *Construction processes*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation.*

Chapter 96

Technical supervision of site works

96.9	References	1418

This chapter explains the need for geotechnical site supervision and the general tasks expected of an engineer responsible for supervising site work. It explains how an engineer's site role can vary depending on the contract form and procurement route and gives guidance to help an engineer prepare for and carry out a technical site role. Particular attention is paid to the documentation process and typical engineer's responsibilities – in general, to health and safety and for the main types of geotechnical site supervision.

Box 96.1 Note on terminology

The titles in this section are used in their general sense, not as contractual terms. Particularly, the term 'resident engineer' (RE) is used to describe the general role of an engineer responsible for independent overviewing of site works.

96.1 Introduction

Fundamentally, all branches of civil engineering culminate in construction. For this reason it is likely that every civil engineer will spend at least some part of his or her career involved in site work. Perhaps more than any other engineering discipline, the role of site supervision in geotechnical engineering is essential to understanding the predesign ground conditions and later verifying construction quality prior to the works being covered.

In the early stages of a project, investigation of the ground and groundwater conditions is required to develop the geological model and parameters for use in design. This work will normally be carried out by a specialist contractor; however, the engineer who also attends the site works will gain firsthand knowledge of the ground conditions over and above that which can be gained through study of logs and laboratory test data alone. The engineer will also gain a thorough appreciation of the site constraints and key ground risks which can then be addressed in his or her design.

Site supervision during the construction phase is usually focused on monitoring the quality and progress of the works and ensuring that the contractor's working methods are in line with the design assumptions. Unlike most other forms of construction, for the majority of geotechnical works it is either very difficult or impossible to check the construction works once completed as they are usually buried in the ground. Problems with geotechnical construction are likely to come to light at a much later stage in the project, for example in the form of cracking in a building with poorly constructed foundations where the defects will only become apparent upon construction of most of the building (and therefore application of most of the load). Investigation of problems and the subsequent remedial works are usually expensive and time consuming, resulting in claims, disputes and general dissatisfaction. While the presence of an engineer on site can never guarantee that all defects are eliminated, their role during construction works can provide a valuable check on workmanship. For the client, the costs involved in correcting defects are usually disproportionately expensive compared to the cost of providing site supervision.

For the engineer, site work can be a very enjoyable and rewarding experience. An engineer that has spent time on site will generally have a better understanding of construction practicalities and the difficulties encountered by contractors. This knowledge of buildability will be invaluable to the engineer throughout the design process and should result in more workable designs and better construction details.

However, site supervision can also be a difficult experience if the resident engineer (RE) is not suitably prepared and supported throughout the site works. For all but the largest projects, the RE may be the only person from their organisation on site and in this case regular communication with the office-based team becomes critical. It is important that the design team provide adequate training and a thorough briefing to the RE before commencement of the site role and that they continue to do so throughout the site works. Additionally, it is important to recognise that supervision of site works requires a different skills set to that developed in the design office, with much more emphasis needed on communication, prompt decision-making and pragmatism.

This chapter aims to give guidance to engineers new to site work on:

- how to prepare for a site role (section 96.3);
- what to expect while on site including common difficulties and guidance for dealing with them (section 96.4);
- the engineer's responsibilities with respect to health and safety law (section 96.5);
- various types of geotechnical site work (sections 96.6: Site investigation, 96.7: Piling and 96.8: Earthworks).

It should also act as an *aide-mémoire* to the more experienced engineer who is preparing to send a junior engineer to site.

It is recognised that today's engineering site roles can vary greatly from a site engineer acting as conduit between design team and site, to an engineer working directly for the client or even a contractor. This chapter specifically provides guidance to engineers responsible for independently reviewing contractor's work. However, much of the guidance applies equally to other engineering site roles. The chapter primarily refers to technical supervision and ensuring technical compliance. It is not intended to give a detailed description of site roles that primarily involve contract administration.

96.2 Reasons for supervision of geotechnical works

96.2.1 General

Supervision of site works should be common practice in geotechnical engineering. It is usually required to ensure that the planned works are carried out in accordance with the contract and as an independent check on the quality of workmanship.

Site supervision is particularly important in geotechnics as in most cases the works are covered and are neither visible nor accessible for checking post-construction. For example, where the design of bored piles relies on a dry pile shaft with a base free from debris it is important to observe the works and to visually check the pile bore prior to concreting (**Figure 96.1**). If the pile does not perform as designed it will be very difficult to check these details retrospectively. Supervision therefore becomes a key quality control and risk management tool that can be used to help eliminate the need for remedial works and their associated disproportionately high costs (refer to Chapter 7 *Geotechnical risks and their context for whole project*).

The provision of site supervision is often a contractual requirement of the engineer. Even if it is not, the engineer generally has a duty to advise the client on the appropriate level of supervision for a particular project. This advice should include the level of expertise and skills of the supervisor and the proportion of time that should be spent on site. It should be based on professional judgement and knowledge of the project and should take account of:

- the complexity of the project;
- the degree to which the design is dependent on good workmanship;

Figure 96.1 Inspecting a pile bore before concreting
© Arup/Daniel Clements; all rights reserved

- the extent of work that will be covered up post-construction (and subsequently neither visible nor accessible for checking) and the time frame for it;
- the degree of completeness of the design;
- the method of procurement and the responsibility of the contractor;
- the level of experience of the contractor;
- the engineer's responsibilities as defined in their terms of appointment.

These recommendations should always be provided in writing to the client and the final agreed brief clearly documented.

96.2.2 Core aims of supervision

Regardless of the particular project, most supervisory roles will endeavour to meet one or more of the following core aims.

96.2.2.1 Provide an independent check on quality

The contractor will generally have a duty to ensure their workmanship is of the required quality. To demonstrate this, the contractor should put in place their own quality assurance procedures which will normally involve checking by members of their site team. However, it can be reassuring for the client to have an independent check on the quality of the contractor's work, particularly if the work is unusual or if the contractor is relatively inexperienced. The presence of the engineer should never relieve the contractor of their contractual obligations but a second set of eyes can assist with identifying potential quality issues early and agreeing methods for their resolution. Additionally, the engineer is less likely to be influenced by other external factors such as programme deadlines and can therefore ensure that these factors do not adversely influence the quality of the work.

For the particular case of site investigation work, the engineer will normally need to rely on the results of the investigation in later design work. Observation of the work can identify any problems that may affect the soil parameters (for example

a sticking catch on a standard penetration test (SPT) hammer invalidating the use of correlations with SPT 'N' values) and will give confidence that the related design is based on reliable data. Doubts as to the quality of the data may necessitate an overconservative approach, which will have a knock-on effect on the efficiency of the design and therefore project costs. If the engineer is unaware of problems with the data then this could equally result in an unconservative design and, in an extreme case, potential failures.

96.2.2.2 Ensure compliance with technical requirements

Technical requirements for site works will be communicated to the contractor through the contract documents and will normally comprise a specification and drawings. Through preparation of these documents the engineer should have identified any key design assumptions that could be affected by the contractor's working method, for example, the soil properties required from the fill material in an earthworks operation and the associated method and type of compaction plant.

The contractor will be responsible for ensuring that their work meets the specified technical requirements and should do so through agreed method statements, rigorous checking and record keeping. Again, the presence of an independent resident engineer will provide a check that the technical requirements are being met and that the contractor is working in accordance with their method statements. Problems can, in this way, be identified early, remediated and repeat occurrences eliminated rather than being left to manifest themselves later on in the project when their cause will be more difficult to determine and their resolution could have a major impact on the project.

96.2.2.3 Ensure design-related issues are raised and resolved promptly

Where observations give cause for concern, the RE will be responsible for ensuring that problems are raised promptly by the contractor through the predefined formal channels (usually non-conformance reports). The RE can then liaise with the design team to ensure that responses to the non-conformances and suggested resolutions are tackled and reported back to the construction team in a timely manner. This aspect of the role becomes particularly important towards the end of the site works as it is ideally required that any identified problems are resolved and remediated before the contractor leaves site.

96.2.2.4 Provide communication link between design and construction team

A defining factor of many successful civil engineering projects is clear and timely communication between all of the project parties and particularly the design and construction teams. Part of the RE's role will be to assist the contractor in understanding the contract documents and design intentions and providing clarification where there are questions or conflicts within the documents.

Through review of the contractor's method statements, the RE can help to identify issues and conflicts early to allow optimal time for their resolution. The RE can also provide regular updates to the design team, which can help them to plan and prioritise their activities to meet changing site requirements.

96.2.2.5 Contract administration

For some projects the RE will also be responsible for administration of the construction contract, but this will depend on the form of contract and procurement route used for the particular project. For example, civil engineering projects which use ICE conditions of contract will be administered by the engineer whereas building projects using JCT contract forms will normally be administered by an architect or project manager. For many site investigation projects the engineer will be called upon to provide both a technical and contract administration role on site.

The engineer's duties relating to contract administration should be established and agreed early on in the project.

96.2.3 Additional benefits of site supervision

In addition to carrying out a key project role, the engineer's site experience should improve their skills as a designer.

Through observation of the construction process the engineer will be able to understand which elements of their design work well and which cause practical problems for the contractor. This should help to develop a pragmatic approach and result in the production of more effective and buildable designs in the future. For example, by witnessing the reinforcement cages of bored piles being spliced together on site the engineer will appreciate how the design should consider the density and thickness of the bars to facilitate buildability.

Observation of the number of interrelated activities on site should give the engineer an appreciation of the complexity of coordinating site work which should help with the design of future projects in early feasibility and concept stages (**Figure 96.2**). It will also help in discussions with contractors on future projects.

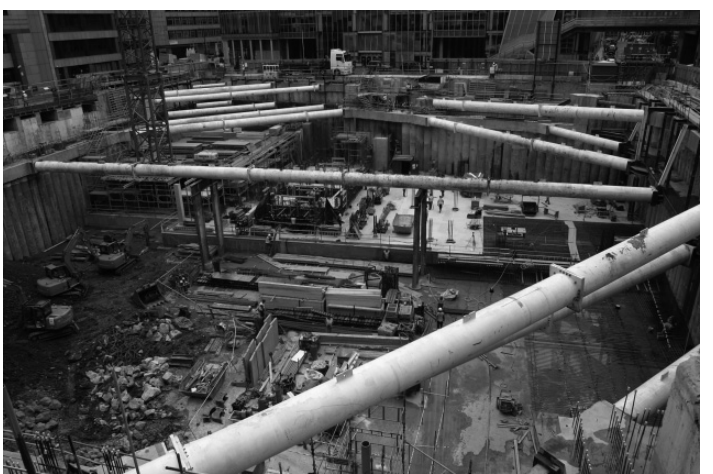

Figure 96.2 Deep basement construction involves a number of interrelated activities

© Arup; all rights reserved

Through working with the contractor to identify and resolve problems, the engineer will gain valuable experience that should allow those same problems to be eliminated from future designs but also to resolve other problems more quickly and effectively in the future.

Box 96.2 Key points: site supervision

- Site supervision is a key quality control and risk management tool that can be used to help eliminate the need for remedial works.
- The core aims of site supervision are to:
  - provide an independent check on quality;
  - ensure compliance with technical requirements;
  - ensure design-related issues are raised and resolved promptly;
  - provide communication link between design and construction team; and
  - contract administration.
- An engineer's site experience should improve their skills as a designer.

96.3 Preparing for a site role

96.3.1 Importance of preparation

Every site and site role is different and therefore requires a tailored approach based on a clear understanding of the project parties, the procurement route and contract conditions and the particular technical requirements. It is therefore essential that the RE prepares thoroughly for each and every site role so that they can, from the outset, operate effectively with all project parties to fulfil their supervisory obligations.

The first few weeks of site work can often be the most challenging as several project parties, who have not usually worked together before, start to establish working processes and relationships. The RE's time will be filled with carrying out initial site inspections and answering technical queries from the construction team. It is important that the RE has a thorough understanding of the technical requirements of the work so that they can set a clear expectation for the contractor. Once established, this should allow the contractor to settle quickly into a routine and will help to ensure the smooth running of the project.

In addition to setting the technical expectation, it is also essential that the RE establishes clear lines of communication with the various project parties. In order to do this the RE needs to understand the roles and responsibilities of the individuals working on the project and ensure that they in return are clear on those of the RE.

The amount of work required when preparing for a site role should not be underestimated, particularly where the RE is new to the project or to site work in general. It is the responsibility of the design team to ensure that the RE is suitably experienced in the type of fieldwork they are about to supervise or is trained and briefed before starting a site role and always remains well supported throughout. The benefits of this preparation will be felt by all involved in the project.

96.3.2 Defining roles and responsibilities

The roles and responsibilities of the RE should be agreed with the client well in advance of the start of site works. These should be recorded in a clear written statement of brief that is incorporated into the design team's contract.

For some construction contract forms such as the Institution of Civil Engineers 7th edition, the engineer is a named party with specific contractual duties clearly defined in the contract. Other contract forms may refer instead to a supervising officer or contract administrator and may not define the role of the engineer specifically. Under these types of arrangement the role of the contract administrator may be carried out by another project party (for example the architect, project manager or construction manager) and the engineer will usually act as a technical adviser to the contract administrator. In this instance the engineer's role will not be clearly defined in the main contract and it will be necessary for the design team to agree the extent of the technical supervision role (refer to Chapter 78 *Procurement and specification*).

The RE's brief will need to be tailored to suit the procurement route and contract form but should typically describe the following:

- the anticipated duration of the site work and the level of attendance (full time, part time, occasional visits);
- the elements of work that the RE will be responsible for witnessing and those for which the RE will not be responsible;
- the checks that are to be made and the records that must be kept;
- the format, frequency and distribution for progress reports;
- the RE's duties in relation to ensuring that the contractor is carrying out their role satisfactorily;
- the extent of the RE's authority including details of any limitations under the contract;
- the project change management system;
- the procedure for issuing instructions;
- the procedure for responding to requests for information and nonconformance reports;
- the interfaces and lines of communication with other members of the team.

Preparation of this brief will be a useful prompt in defining the boundaries between the RE's responsibilities and those of other project team members. Through the brief it is likely that areas of conflict or split responsibility will be identified and early preparation should enable resolution of areas of conflict prior to start of work on site.

96.3.3 Understanding the construction team

For the RE to operate effectively in the site environment it is important that a good knowledge of the various project parties and their organisation is gained. To develop this understanding it can be useful to draw an organogram of the project team

clearly indicating the lines of communication between the various project parties and summarising their main responsibilities (**Figure 96.3**). This could prove a very simple task, for example where the construction work is procured via a traditional route with the client separately appointing an architect, engineer and main contractor. Or, it could be a more complicated arrangement where there are many more contracts and parties involved in the construction works.

Having established the general project organisation, the RE should be able to identify named individuals with authority to take project decisions, issue instructions and tackle problems. The RE should be able to identify who to communicate with on a day-to-day basis and can then confirm this with the project team.

A major part of the RE's role will normally be to ensure that the contractor fulfils their obligations under the contract. These should be set out clearly in the contract documents for the construction works, which the RE should review and check for compatibility with their own duties.

If, following this assessment of the various site parties' responsibilities, there remain any uncertainties or conflicts, the RE should proactively raise these issues with the project team and ensure that they are resolved prior to start of the site role.

96.3.4 Preparatory work

The RE should be thoroughly briefed on the organisational and technical aspects of the site role by a senior member of the design team (section 96.3.2).

Additionally the design team and RE should gather together a set of base information to refer to while on site. This should include the items in **Checklist 96.1**.

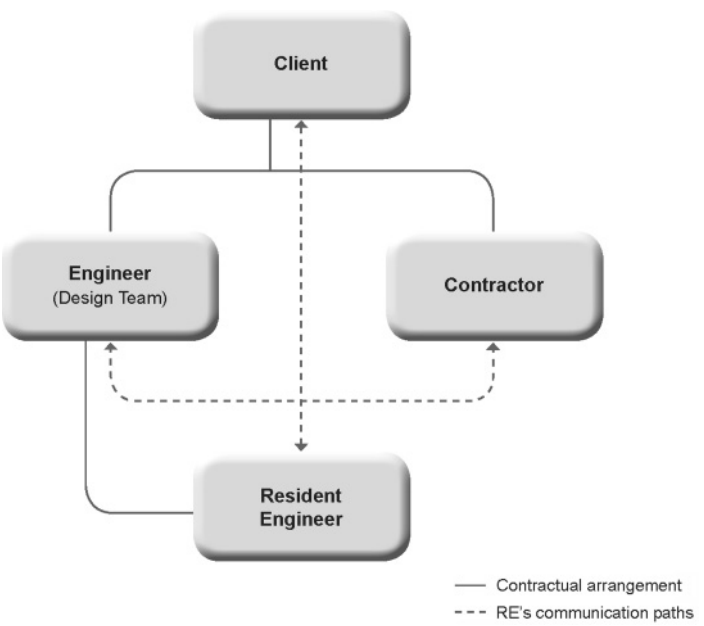

Figure 96.3 Typical lines of communication for a resident engineer under a traditional project arrangement

Generally it is advantageous for the RE to have had some experience of carrying out the design before going to site. However, this is not always possible and therefore the RE should have a good knowledge of the design prior to arriving on site. This will allow the RE to understand the criticality of certain aspects of the design and also reduce their dependence on the design team to resolve technical queries.

It is advisable to involve the RE in the initial review and checking of the contractor's method statements, which will occur prior to start of site work. This will allow the RE to beome familiarised with the site work and to identify the major issues in advance of start of the works. It will also allow the RE to be introduced to the key site parties so that they are already a familiar face before arriving on site.

The RE should insist that the contractor prepares the information required by the contract documents well in advance of the start of site works. These will generally include the items in **Checklist 96.2**.

The RE should ensure that information received is complete, and that their comments are issued promptly and addressed by the contractor.

Checklist 96.1 Preparatory documents

- ✓ The written statement of brief including the schedule of RE duties
- ✓ An overview of the project
- ✓ The design basis and, if appropriate, calculations
- ✓ Identification of critical elements of design that require particular checking procedures
- ✓ Specifications for the elements of the work for which the RE is responsible
- ✓ Construction drawings
- ✓ Proforma check sheets for each element of the work that requires inspection
- ✓ Method statements, inspection and test plans and fabrication drawings prepared by the contractor and agreed with the project team
- ✓ The project programme
- ✓ Health and safety documentation and records of briefings (refer to section 96.5)
- ✓ Copies of relevant codes of practice, handbooks and guidance notes
- ✓ Contact details for key project individuals

Checklist 96.2 Initial information prepared by contractor

- ✓ Programme and sequence of work
- ✓ Site organisation chart
- ✓ Method statements
- ✓ Inspection and testing plan
- ✓ Typical proforma sheets for inspection requests, contractor's submissions, requests for information, non-conformance reports

Box 96.3 Key points: preparatory work

- Thorough preparation is essential to a successful site role.
- A clear brief and schedule of duties will help the RE understand their site role.
- The RE should undertake appropriate training prior to start on site.
- The RE needs to understand the roles and responsibilities of others working on the project and know who to communicate with on a day-to-day basis.
- The RE should ideally be involved in the project for some time prior to the start of a site role and have experience of the type of works they will be responsible for.

96.4 Managing the site works

96.4.1 Setting up on site

The RE should aim to arrive on site slightly in advance of the start of site works to allow time to get organised before the works begin in earnest. This time should be occupied with setting up on site and making contact with key site individuals. Importantly, the RE should check that all health and safety requirements are in place and, if this is not the case, these should be addressed as a priority (section 96.5).

The contractor will normally be required to provide office space for the RE. This may be separate from or (as is becoming more common) contained within the contractor's own site office. The contract documents should contain a list of the facilities the contractor must provide, but these will normally include:

- electric power;
- lighting;
- air conditioner/heater;
- desk with lockable drawers;
- chair;
- filing cabinet and/or bookshelves.

The contractor is also legally obliged to provide adequate welfare provisions. If reasonable welfare facilities are not provided then the contractor should rectify this immediately.

The RE will normally be responsible for arranging provision of other facilities that are needed, for example a laptop, printer and phone, internet access and personal protective equipment (PPE). The RE should also ensure that the relevant project documents and reference material are taken to site so that they are instantly accessible (section 96.3.4 and summarised in **Figure 96.4**).

96.4.2 Documentation and record keeping

The importance of clearly documented, timely and well-organised site records must not be underestimated. Comprehensive and accurate site records can contribute significantly to the smooth running of a project and can be used to demonstrate that the RE is carrying out their role effectively. Good record keeping can also become critically important in the event of claims, particularly when these are raised long after the project has been completed. For example, if a pile integrity test is undertaken many days after a pile has been completed and shows the pile to have inclusions then detailed site records will be essential in understanding the cause of the problem and informing the subsequent investigation and remedial works design.

The volume of records that will be generated for even a short site role can be significant. For this reason, it is imperative that the RE is well organised and establishes a workable system that allows information to be stored neatly and in such a way that it can be found again quickly. Some projects may have clearly defined processes for doing this but if not, the RE should choose a method that suits the particular project and their style of working.

The RE will normally be responsible for both keeping and maintaining their own records and for collating and commenting on those produced by the contractor. **Figure 96.4** provides a schedule of the typical records that should be collated by the RE before, during and at the end of the site works in addition to the parties that would normally prepare the records. Possibly the RE's most important record is their diary. This should be written daily and should include the information listed in **Figure 96.4**.

Project changes can often be the cause of confusion and problems on site, particularly if these need to be justified retrospectively. It is essential the RE clarifies the project change procedure prior to starting the works and follows it precisely should a change be needed. On some projects the change procedure will be clearly defined; however, on other projects it can be useful for the RE to prompt the site and design teams to clarify the change procedure, prior to the site works commencing. For example, if during a site investigation it is necessary to introduce an additional borehole to provide clarity on conflicting information, the RE should follow the project change procedure and clearly state the reason for the addition so that payment can be easily certified later in the work when the contractor submits the application for payment.

96.4.3 Inspection and checking

Probably the most important aspect of the RE's role is the witnessing and selective checking of the contractor's work. The RE should ensure that checks are carried out rigorously and that each check is recorded by the contractor and separately by the RE using the pre-agreed proforma check sheets. It is important not to get behind on this paperwork as it can be difficult or impossible to fill out check sheets even a short time after the check has been carried out.

The contractor should normally be present at the time the RE carries out their checks. If the RE is unhappy with any element of the check they should raise it with the contractor immediately to give the latter an opportunity to rectify the problem before the work is completed. In the unlikely instance that the contractor refuses to rectify the defect then the RE

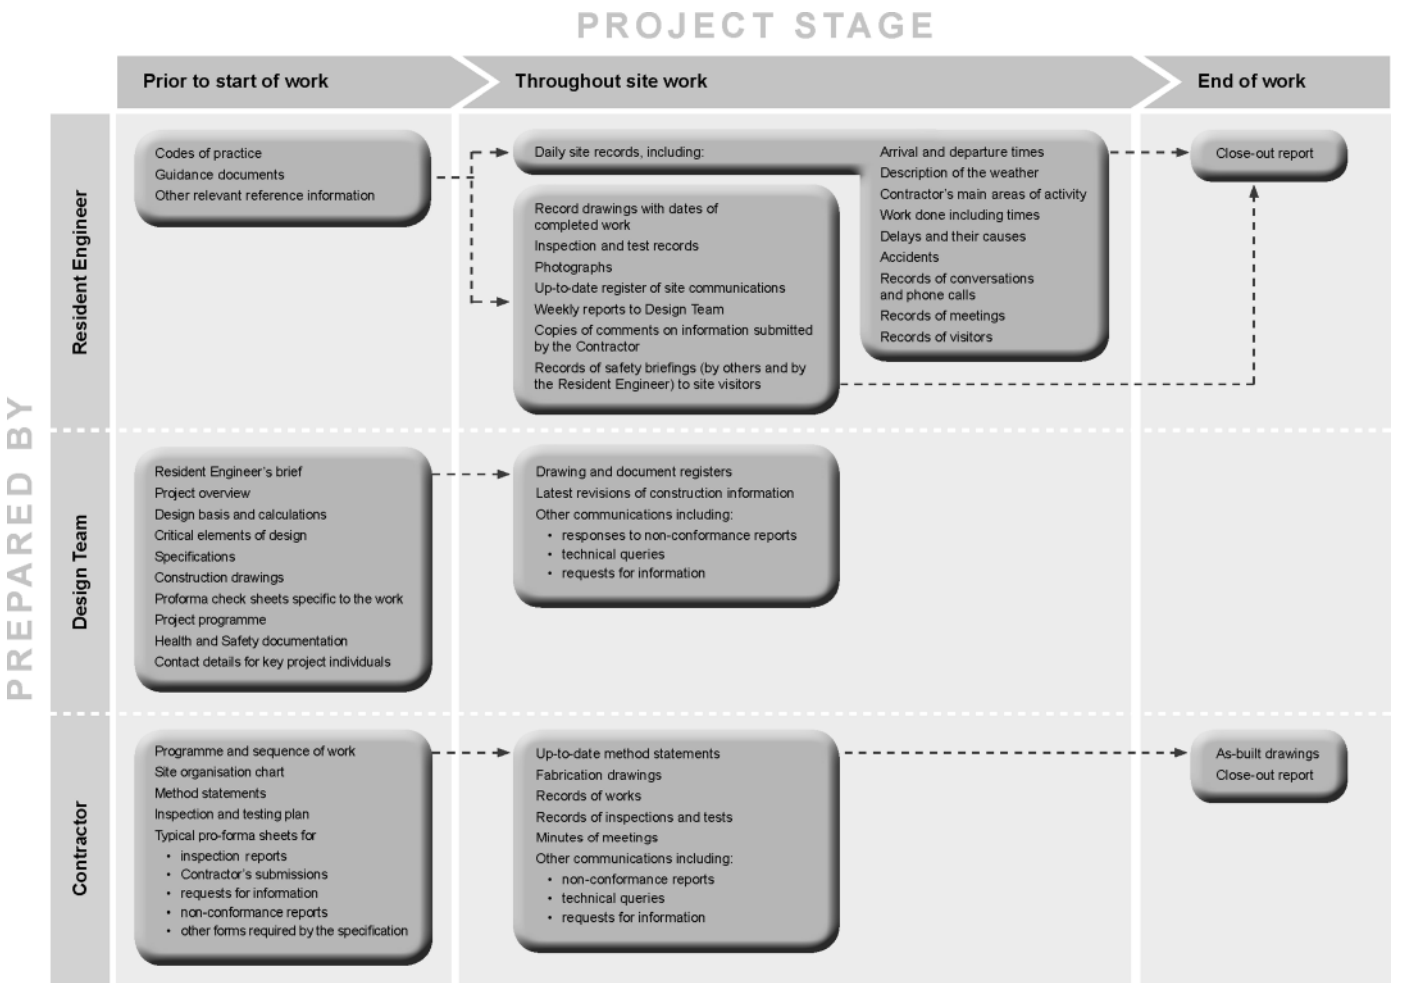

Figure 96.4 Schedule of site work documentation to be collated by the resident engineer

should make the contractor aware of the consequences of not rectifying the defect and then follow up this conversation in writing as soon as possible after the event.

The contractor will normally provide their own records of the works, copies of which should be sent to the RE in addition to the contract administrator. The RE should check the contractor's records for compatibility with their own and raise any concerns or incompatibilities with the contractor and the project team. In advance of start of site works the RE should obtain proforma check sheets from the contractor to check that these cover the elements required by the contract documents.

Precise details of the checks to be made, their frequency and the records to be taken will depend on the nature of the work being inspected and the RE's brief.

96.4.4 Communication

This will depend upon the form of procurement and the construction contract. However, the following sections contain general advice that can be modified to suit the particular project requirements.

96.4.4.1 Communicating with the contractor

The RE's most frequent contact will be with the contractor. Communication with the contractor will range from verbal discussions to formal written site instructions and, at first, it may be difficult to judge the most appropriate means of communication for a given situation.

The RE's first aim should be to establish a good working relationship with the contractor's staff. In doing this the RE must recognise that the contractor's staff will be working to time and cost deadlines; that their jobs may depend on the project's progress and profitability, and that in these circumstances the contractor may seek cost-driven, rather than quality-driven, solutions. However, while the RE should acknowledge that the contractor is in business to make a profit they should also be clear that the contractor is obliged to work within the contract terms.

In all of their site dealings, the RE should aim to adopt a fair, firm and consistent approach. Where the RE observes something going wrong they should raise the issue as early as possible and should not wait until it is completed and they are

formally invited to inspect it. The RE should try not to reverse earlier decisions or to find further faults in work that they have already accepted. In this way the RE will gain increasing respect and authority on site.

It is usual for the RE to have daily discussions with the contractor and these discussions should be summarised in the RE's site diary. If the discussions are informal, such as comments during site inspections or suggestions for improved working, then it should not be necessary to record and circulate them more formally provided the contractor acts on them. The RE should give comments only to pre-identified individuals on the contractor's team and not directly to the contractor's site operatives, or to their sub-contractors.

Where discussions are more formal the RE should send a written record to the contractor's team and distribute it to other affected site parties. These communications should use a pre-agreed form such as a site memo. Examples of when a written record may be required are: when the contractor has not responded to the RE's verbal comments during inspections; when safety matters are ignored; and when requesting written information such as method statements.

Site instructions should be reserved for formal contractual matters such as: issuing sketches and information for construction; instructing the contractor to rectify breaches of the specification; or dealing with safety issues (when the initial correspondence has not received a response); or for requiring the contractor to issue remedial work proposals. Remember that site instructions usually need confirming by the party acting as contract administrator. To aid the understanding of all parties involved, the RE should clearly state the reason for the issue of an instruction as this information can be of use later. If the RE is uncertain whether a site instruction is warranted, they should discuss the matter with their design team.

It is important to recognise that there is no such thing as a 'verbal instruction'. Any instruction given by the RE must be confirmed in writing so that it is on record.

The contractor will send the RE many communications including method statements, requests for inspection, requests for information, site memos and non-conformance reports. The RE should insist that all requests are in writing and that they follow the agreed site procedures. The RE will normally be contractually obliged to respond to each communication within a defined time period and should ensure that this period is known and adhered to. All responses should be in writing. In instances where a large number of requests are received, the RE may find it useful to set up a register to keep a check on which have been answered. The RE will need to liaise well with other members of the design team to seek input where required and ensure a coordinated response.

96.4.4.2 Communicating with the design team

For the benefit of all, the RE will need to keep in close contact with their design team. The RE should speak regularly to a designated member of the design team to give details of site progress, to pass on queries and to receive information. In the early days of a project it is a good idea to make contact at least once a day, even if there is little to report. The RE should make a brief note in their diary to record these communications.

It is a good idea for members of the design team to visit the site, especially at the beginning of the works. This will provide support to the RE and will give the design team an appreciation of the site conditions.

The RE should also provide written summaries of site events. The format and frequency of reporting should be agreed in advance with the design team. For most projects a weekly report summarising the following issues should be sufficient:

- project progress against programmed progress;
- major problems and delays;
- technical issues encountered and their resolution;
- instructions issued;
- communications received and responses outstanding;
- test results received;
- non-conformances identified.

The RE should ensure that the design team is clear on the information that is required on site and that a designated person is responsible for ensuring that the RE is supplied with the latest versions of specifications and drawings in a timely manner. Additionally, the design team will be responsible for keeping the RE apprised of project changes that could affect their work. Increasingly, web-based systems are being used to manage this documentation process and the RE must have the means to access such systems efficiently while on site and be provided notification of new uploads.

The RE should not be afraid to ask the design team for advice, especially in the early days on site. As the RE becomes more familiar with site work, they will become more confident and independent; however, they should recognise that in unfamiliar or unusual situations they should seek clarification from the design team.

96.4.4.3 Communicating with other parties

Depending on their particular brief, the RE may be required to interface with other site parties such as contract administrators, project managers, quantity surveyors, clerks of works, etc. The level and form of communication will vary from project to project and should be clearly defined prior to the start of site work.

While the RE should always be reasonably helpful and informative, it is important to ensure that the level of communication provided is appropriate to the role and authority of the party. Particularly, the RE should only accept instructions from parties that have authority to issue them.

Much of the communication with other site parties will be verbal but should always be recorded in site diaries or by more formal means if deemed necessary.

96.4.5 Site meetings

The contract administrator should arrange regular site meetings with the contractor, to review progress and discuss problems. These should be attended by the RE and representatives of the client and design team should also be invited.

A typical agenda for the meeting should as a minimum include:

- progress against programme and issues delaying progress;
- design-related issues;
- status of requests for information;
- status of non-conformance reports;
- problems encountered and means for resolution;
- health and safety issues;
- proposed works before the next meeting;
- any other business.

Minutes should be prepared for all meetings and these should be distributed to the attendees as soon as possible and certainly before the time of the next meeting. The RE should thoroughly review all minutes to ensure that they are a fair representation of the meeting. Any issues with the minutes should be raised at the start of the next meeting, or earlier if the need dictates. The RE should ensure that action items identified in the minutes are dealt with promptly.

In advance of the meeting the RE should make a note of points they wish to raise such as quality of work, matters of safety, and information required from the contractor. The RE should also take some time before the meeting to brief the design team representative on current topics.

96.4.6 Dealing with problems

In spite of the RE's best efforts, there will be times when problems arise and the RE will need to deal with these as proactively as possible.

To get an unwilling contractor to improve quality or correct mistakes is one of the hardest jobs on site. It is therefore wise to try to avoid head-on confrontation. The RE should initially try to avoid defective work by making the required standard clear the first time that any particular element is constructed or each time a new team arrives on site.

The RE's aim should be to establish a good working relationship with the contractor. If things are wrong or done poorly, the RE should explain the technical reasons behind the requirements. The RE should raise issues as soon as possible to give the contractor opportunity to correct problems quickly.

If the contractor does not act on initial verbal warnings, the RE must write a site memo to the contractor recording their verbal comments and requesting action is taken. This in itself is often enough to resolve issues. It also provides a written record of the request and the date of it, for future reference. The RE should be careful not to tell the contractor how to correct the fault; it is better to ask for their proposals.

Sometimes the contractor will fail to act on the RE's request. If the RE is satisfied that they have given the contractor reasonable opportunity to correct the issue then the RE should not be afraid take further action. In the case of an unresponsive individual within the contractor's organisation, the RE could contact one of their superiors or, in the case of the contractor's organisation generally being unresponsive the RE should contact the contract administrator or project manager. In either case the RE should record their concerns in writing and make reference to previous discussions and written communication. The RE should set out the reasons for their concern and the consequences of not resolving the issue promptly (for example repeating the faulty work).

Obviously such drastic measures should not be taken for something trivial. The RE will need to judge the severity of the fault initially and may need to seek the advice of the design team. If the defective work has since been covered the RE will need to be able to support their claim rigorously particularly if it contradicts the contractor's own records. In such circumstances, clear record photographs can be very convincing evidence of whether the alleged fault ever existed and the degree of its severity.

With one exception, the RE should never issue a stop-work instruction without first consulting the design team and the project manager or contract administrator. It is a very serious step leading to a difficult contractual situation. The one exception would be when there is immediate danger to human life (for example, an unsupported and unstable excavation) but even then it is vital that the design team and project manager are informed immediately.

Refer to Chapter 93 *Quality assurance* for more detailed information on avoiding defective work.

Box 96.4 Key points: managing the site works

- Preparing clearly documented, timely and well-organised site records is an essential part of the RE's duties.
- Numerous records will need to be produced by the RE and other site parties (refer to **Figure 96.4**).
- The RE needs to be clear on the project change procedure and follow it precisely should a change be needed.
- The RE must ensure that inspections and checks are carried out thoroughly and recorded using the pre-agreed forms.
- The RE should communicate in a clear and timely manner with the site teams and should vary the form of communication for each particular situation.
- The RE should not be afraid to ask their team for advice, especially in the early days on site.
- Regular site meetings provide an essential forum for discussing issues relating to the site works.
- When problems arise, the RE will need to deal with them proactively, raising issues as soon as possible to give the contractor the opportunity to correct problems quickly.

96.5 Health and safety responsibilities

96.5.1 The law

Health and safety practice in the UK is primarily governed by the Health and Safety at Work Act 1974 (HSAWA). This Act outlines the general duties imposed upon employers and other professionals to safeguard the health, safety and welfare at work of their employees and others who might be affected by their activities.

Implementation of the Act is through Regulations. These are in turn supplemented by Approved Codes of Practices, which contain detailed provisions and give practical guidance. Numerous regulations exist governing all aspects of construction work with those that are most commonly used listed below:

- The Construction (Design & Management) Regulations 2007 ('The CDM Regulations');
- Managing Health and Safety in Construction. Construction (Design and Management) Regulations 2007. Approved Code of Practice;
- Reporting of Injuries Diseases and Dangerous Occurrences Regulations (RIDDOR) 1995;
- Control of Substances Hazardous to Health Regulations (COSHH) 1999;
- Lifting Operating and Lifting Equipment Regulations (LOLER) 1998;
- Provision and Use of Work Equipment Regulations (PUWER) 1998.

Before embarking on a site role, the RE should ensure that they are familiar with the duties imposed by the Act and also the principal sets of Regulations under the Act.

Refer to Chapter 8 *Health and safety in geotechnical engineering* for more detailed information on health and safety law and its application to geotechnical engineering.

96.5.2 Personal safety

While the contractor is legally responsible for the safe execution of the works and supervision of the workforce, the RE also has a duty to take reasonable care of their own safety. Health and safety should form an essential part of the engineer's preparation for site works and will probably comprise a mix of formal training, briefings and reading of literature, as described in **Checklist 96.3**.

The RE should keep up to date with changes to the site health and safety procedures throughout the site works and should seek to contribute proactively to the management of health and safety on site.

During the site works the RE should ensure that they wear appropriate personal protective equipment at all times and do not take unnecessary risks. If the RE is asked to undertake work that they do not consider safe, for example to enter an unsupported excavation, then the RE should insist the contractor rectifies the problem before carrying out the work.

Checklist 96.3 Preparatory health and safety requirements

✓	Appropriate general training in site safety including a general briefing from their own employer
✓	Health and safety certification required by the contractor (for example a Construction Skills Certification Scheme card)
✓	Briefing on the risks associated with the particular site and construction works by both their own team and the contractor
✓	Access to and understanding of the necessary health and safety documentation including the construction phase plan, designer's risk assessments and contractor's risk assessments

In the event that the RE is injured, they should report the injury to the site team and to their design team immediately. As a minimum, the injury should be reported in the site accident book with further reporting to the HSE if warranted by the nature of the injury.

96.5.3 Safety of others

Under the Health and Safety at Work Act the RE has a duty to 'take reasonable care for the health and safety of themselves and of other persons who may be affected by their acts or omissions at work'. The RE should raise any observations relating to unsafe working practice promptly with the contractor. If these are not addressed in good time, the RE should refer the observations to a higher level within the contractor's and/or their own organisation as appropriate.

During their time on site the RE will receive visitors and they will need to take responsibility for ensuring their health and safety while on site. The RE should carry out a site-specific risk assessment for each visitor and provide a briefing before the site visit. The contractor should always be notified before the RE receives visitors on site and may require visitors to also attend a safety briefing given by the contractor.

Box 96.5 Key points: health and safety responsibility

- Before embarking on a site role, the RE should ensure that they are familiar with the duties imposed by the HSAWA and also the principal sets of Regulations under the Act (for example CDM).
- The RE has a duty to take reasonable care of their own safety. They must ensure that they have:
  - received appropriate training;
  - received site specific safety briefings;
  - are familiar with the key site safety documents including the construction phase plan and risk assessments.
- The RE also has a duty to take reasonable care for the health and safety of others.

96.6 Supervision of site investigation works

Site investigation works aim to provide information on the ground and groundwater conditions. Design of and methods for site investigation are discussed in detail in Section 4 *Site investigation* of this manual.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Each site investigation will be bespoke, designed to target the issues relating to the particular site and the proposed development. However, the engineer can never really know what the site investigation will reveal and on some sites the results can show ground conditions significantly different to those expected.

The RE for site investigation works therefore needs to be prepared to respond to the findings of the investigation as they are observed, check that they align with the anticipated results and if not, adjust the investigative works to ensure that information suitable to the needs of the project is obtained. In order to do this the RE needs to fully understand the overall aims of the site investigation and the specific aim of each exploratory hole.

The RE needs to collate and assess the results of the exploratory hole information as they are produced and be prepared to instruct changes to respond to unexpected results. In doing so the RE also needs to be aware of the cost implications of the changes they instruct. Where these are large, the RE should get written agreement of the change and the cost implication from the contractor and the contract administrator before the change is implemented.

Sometimes the contractor will suggest alternative ways for progressing holes or carrying out tests. The RE should be open to alternatives but should always question the need to depart from the specification and ensure that the proposed new method will produce data of the same or better quality than the specified method.

A site investigation is only of use to a project if the data obtained are of good quality and sufficient quantity of information is obtained. The RE should be familiar with the codes and standards governing the site investigation operations. Documents relevant to most site investigations in the UK are listed below; however, the RE should be aware of other codes or guidance documents relating to more unusual site investigations or works in other countries.

- British Standard 5930 + A2:2010: *Code of Practice for Site Investigations*;
- British Standard EN1997-2:2007: *Eurocode 7. Geotechnical design. Ground Investigation and Testing*;
- NA to BS EN1997-2:2007: *UK National Annex to Eurocode 7. Geotechnical Design. Ground Investigation and Testing*;
- *Site Investigation in Construction Series, Documents 1 to 4*.

The RE should observe the works carefully to ensure that they are confident that these standards are being achieved by the contractor (refer to Chapter 13 *The ground profile and its genesis* and Section 4 *Site investigation* of this manual). The RE should also check early on that the specified sampling and testing frequencies are being achieved.

There will often be significant pressure for the RE to supervise the site works in a part-time capacity. In this instance the RE needs to time site visits carefully to ensure that they are present at the most critical times. This will vary from site to site but as a general rule the RE should be present to agree all exploratory hole locations and to observe the early works to gain confidence in the capability of the contractor. Where numerous crews are working on the site, the RE should ensure they observe the early works of each crew to check for

Figure 96.5 Cable percussive drilling rig in use

Figure 96.6 Logging core recovered from rotary boreholes
© Arup; all rights reserved

variations in quality and working practices. If the RE is on site as a person who will later prepare the geotechnical interpretative report (as is preferable), then they also need to observe and understand the nature of the soils exposed and should time their site visits so that soils from each stratum are observed.

Because site investigations often occur in the early stages of a project and because the site teams are normally relatively small, welfare provisions and security for site investigations can often be less well established than for other construction works. The RE should nevertheless ensure that adequate welfare, security and health and safety provisions are made on site and should insist that inadequate conditions are rectified immediately.

Box 96.6 Key points: supervision of site investigation works

The RE should:

- observe the works carefully to ensure that the required quality and quantity of data are being achieved in line with the specification and relevant codes of practice;
- check the findings of the site investigation throughout the field-work and adjust the scope of work if the ground conditions are shown to be significantly different to what was expected;
- ensure they are on site at critical times, if their role is part time.

96.7 Supervision of piling works

The precise nature of the RE's supervision activities will depend on the type of piling being witnessed and the design requirements. Sections 5 *Design of foundations* and 8 *Construction processes* of this manual describe the many types of piling that are commonly used in geotechnical engineering today. Additionally, a list of codes and guidance documents is provided below:

- BS EN1997-1:2004: *Eurocode 7. Geotechnical Design. General Rules*.
- NA to BS EN1997-1:2004: *UK National Annex to Eurocode 7. Geotechnical Design. General Rules*.
- BS EN1536: *Execution of Special Geotechnical Work. Bored Piles*.
- BS EN1583: *Execution of Special Geotechnical Work. Diaphragm Walls*.
- BS EN12063: *Execution of Special Geotechnical Work. Sheet Pile Walls*.
- BS EN14199: *Execution of Special Geotechnical Works. Micropiles*.
- BS EN12699: *Execution of Special Geotechnical Works. Displacement Piles*.
- Tomlinson and Woodward (2009).
- Various CIRIA guides, see CIRIA website www.ciria.org.

The RE should be clear on the level of checking required, the construction details to be checked and the criteria for acceptance. This will depend largely on the design. For example, if single piles are used to support critical elements of structure then it would be expected that every such pile is rigorously checked due to the serious consequences of failure of a defective pile. However, it may be acceptable to check a proportion of piles for a design using pile groups to support a structure due to the inherent redundancy in the pile group. The complexity of the construction technique and relative experience of the contractor will also be factors, for example more rigorous checking of new or complex piling methods would be expected over proven and relatively straightforward piling methods.

It is also important that the RE is familiar with the practical elements of the piling technique before they take sole responsibility for the site supervision. Ideally this would be achieved by visiting another site using the same piling technique and assisting the RE there. Otherwise an experienced engineer should initially accompany the RE to site to assist in understanding the piling process and gaining confidence in the checking procedure.

The RE should ensure that they clearly understand the contractor's piling method and also the consequences of varying that method on the pile design.

There will be times on site when circumstances beyond the contractor's control disrupt the piling works, for example breakdown of plant, unforeseen ground conditions or severe weather. At such times, the contractor and the RE will come under pressure to resolve the situation as quickly as possible and with minimal effect on the pile design. It is therefore useful for the RE in conjunction with the contractor to consider the possible situations where things could go wrong and plan their actions in advance.

Where the piling works are repetitive, it is even more important than usual for the RE to establish the required quality standard at the start of the works. The RE also needs to ensure that standards are maintained throughout the work, particularly on long projects where personnel may change over the course of the contract. The RE will often be a young face on site compared to the site operatives and should recognise that these people can be very knowledgeable. The RE should consider their suggestions carefully but should also be aware that just because the crew have 'always done it like that' does not mean that it is the right solution for the project.

Figure 96.7 Typical bored piling site in Central London

© Arup; all rights reserved

On piling projects, particularly those with high pile production rates, it can be tempting for the RE and contractor to fall behind with their record keeping. It is important that the RE does not let this happen and insists on records being produced in the timeframes specified in the contract.

Timely and accurate production of close-out reports are increasingly important on piling projects (refer to Chapter 101 *Close-out reports*). Close-out reports should be comprehensive and detail not only the as-built pile details but also record any problems encountered during the works and the chosen resolution. This will aid the re-use of the piles in the future and the RE should not consider their duties fulfilled on site until these have been completed.

Box 96.7 Key points: supervision of piling works

The RE should:

- be familiar with the practical elements of the piling technique (through previous experience or visits to other sites using the same technique);
- be clear on the level of checking required, construction details to be checked and the criteria for acceptance;
- keep up to date with records, especially if production rates are high;
- have considered the possible situations where things can go wrong and (with the contractor) plan their actions in advance;
- ensure that standards are maintained throughout the work, particularly on long projects where personnel may change over the course of the contract.

96.8 Supervision of earthworks

Earthworks construction projects can range from the very small (excavation of pad foundations for a low-level building) to the very large (major road infrastructure construction). However, the level of supervision required should be decided upon based on the complexity of the project as well as its scale.

For detailed information on design of earthworks, refer to Section 7 *Design of earthworks, slopes and pavements* of this manual. Additionally, a list of codes and guidance documents is provided below:

- BS EN1997-1:2004: *Eurocode 7. Geotechnical Design. General Rules*.
- NA to BS EN1997-1:2004: *UK National Annex to Eurocode 7. Geotechnical Design. General Rules*.
- BS 6031: *Code of Practice for Earthworks*.
- Various CIRIA guides, see CIRIA website www.ciria.org.

It is important that the RE understands the intended use of the earthworks structure as this will influence the level of inspection and the decisions they are required to make. For example, criteria for a structure required to carry heavy loads or plant with strict movement tolerances will be much more stringent than for a non-structural fill providing a platform for soft landscaping.

Prior to the site works commencing it is important to pre-classify the materials on site through site investigation (refer to section 96.6 above and Section 4 *Site investigation* of this manual). This allows the design and site teams to identify the appropriate type of plant to use for excavation, the angle of slopes that can be achieved and for filling the level of compaction that can be achieved. In addition the RE should make themselves familiar with the types of compaction plant that may be suitable for the material on site and how they function.

With the exception of the smallest earthworks projects, it is usually only possible to inspect a selection of the works. It is important that the RE ensures that the required frequency of testing (either *in situ* or laboratory-based) is obtained and that the samples are representative of the site as a whole and not, for example, just a limited area of the site or soil type. It is normally preferable for the RE to choose the testing locations to ensure these are independent of the contractor and focused on the key activities. Alternatively the contractor may propose a sampling and testing schedule for agreement with the RE. In addition procedures for dealing with contaminated material should be agreed prior to testing in case any such material is encountered during the works.

Where testing of the samples is required, the RE must ensure that the laboratories have achieved the specified certification for the particular tests that have been carried out. This is particularly important for site-based laboratories. For off-site laboratories it is important to ensure that samples are stored and transported in such a way as to have minimal effect on their behaviour.

Detailed daily recording of the weather is essential to earthworks operations as this could affect the performance of the soils used. Additionally, the possible effects of inclement weather on the performance of the materials should be considered by the design team and understood by both the RE and the contractor. The RE should be aware of the contractual implications of inclement weather and if it is counted as 'extraordinary', in which case the client could be liable for any costs incurred or if it is within the contractor's liability.

Where earthworks are inspected, the RE should keep good quality annotated photographic records complemented by

Figure 96.8 Typical earthworks site
© Arup; all rights reserved

detailed descriptions of the works they have observed and the type and location of compliance testing. The contractor will often have to produce a validation report at the end of the works, which the RE may be asked to comment on. The RE should ensure that the contractor is providing elements of this report throughout the site works to prevent problems occurring at the end of the works if the information is inconsistent or incomplete. The RE should also produce a comprehensive and timely close-out report (refer to Chapter 101 *Close-out reports*) to summarise the works and to collate their independent records.

Box 96.8 Key points: supervision of earthworks

The RE should:

- understand the intended use of the earthworks and how that influences their supervisory role;
- have a thorough understanding of the site investigation and therefore the site soils;
- ensure that the sampling frequency and quality of testing are achieved and that samples are representative of the site as a whole;
- keep detailed records of the weather and understand how conditions could affect the performance of the soils;
- keep good quality annotated photographic records.

A pile integrity test is defined as a non-destructive test (NDT) which examines the response of a pile to some form of indirect physical scanning technique; such a test may employ acoustic shock waves, electrical energy, nuclear radiation or other input to excite the pile (CIRIA 144, 1997). Analysis of the response of the pile may allow an interpretation of the 'integrity' of construction of the pile body, typified by the homogeneity of the construction concrete or the uniformity of its external shape. Such tests are commonly used as part of a pre-planned quality control programme, as a retrospective testing programme, or as an aid to the evaluation of existing foundations.

The most common non-destructive pile testing techniques are described with particular reference to low-strain integrity tests and cross-hole sonic logging. Guidance is given on the analysis, interpretation and reporting of the results of such tests, including computer-aided signal matching and modelling techniques to enhance the interpretation of the signal responses obtained.

Parallel seismic testing and high-strain integrity testing are also reviewed. The former is commonly used for retrospective testing of foundation piles when they are to be re-used and the latter is a by-product of dynamic load testing.

97.1 Introduction

CIRIA Report 144 (CIRIA 144, 1997) defines a pile integrity test as a non-destructive test (NDT) which examines the response of a pile to some form of indirect physical scanning technique. Integrity testing is most commonly used as part of a pre-planned quality control programme for a particular site. It can also be used as part of a retrospective testing programme, where a problem has become apparent during or subsequent to the construction of the piled foundations. It can also be used as an aid to the evaluation of existing foundations: where they might be required to be re-used as part of a new development for example.

Non-destructive, or integrity testing of foundation piles has become routine on most UK construction sites, but is often considered something of a 'black art' by many engineers and industry professionals. Such tests employ indirect testing techniques to examine the structure of the pile. These techniques include the use of acoustic shock waves from a hammer blow; ultrasonic pulses; electrical resistivity; nuclear radiation such as gamma or neutron scanning; or other input to excite the pile. The response of the pile allows interpretation to be made and conclusions to be drawn on the 'integrity' of construction of the pile body, typically related to its internal construction or the uniformity of its external shape.

Pile integrity testing and its principal methods have evolved since their introduction in the 1970s to become an important part of the quality control process. They can provide additional information on the as-built construction of piles, as well as enabling further evaluation of piling systems. Recent advances in computer technology have provided convenient solutions for compact and portable site acquisition equipment, and developments of sophisticated analysis programs have led to their widespread use by the construction industry.

This chapter will provide an insight into the main pile testing methods currently in use, together with background theory and guidelines on the choice of the most appropriate method. Specifying the most appropriate test is not universally understood and the test method applied is often driven by varying factors. A wider understanding is therefore essential, and all engineers with responsibility in this area should have a working knowledge of the appropriateness of the various test methods, their limitations and the interpretation of the data obtained from such tests.

The main test techniques currently in use in the UK, which will be discussed in this chapter, can be identified as:

- low-strain integrity testing;
- cross-hole sonic logging;
- parallel seismic testing;
- high-strain dynamic testing.

Electrical and nuclear, or radiometric, tests are not commonly used in general site practice. Further information on these and other test techniques can be found in Fleming *et al*. (2009) and CIRIA 144 (1997).

The principal features of these four main test techniques can be summarised as follows:

(a) *Low-strain integrity testing* is the examination of the response of the pile to an external impulsive force: usually imparted by striking the head of the pile with a light,

hand-held hammer, generally fitted with a hard plastic tip. The shock wave from the hammer blow travels down the pile. Part or all of the energy from this blow may be reflected or affected by a change in pile properties: the pile toe being an obvious source of such an effect. An analysis of the response of the pile (measured by a receiving sensor at the pile head) to both the initial blow and any returning reflections from depth allows inferences or conclusions to be drawn on the properties of the buried pile.

(b) *Cross-hole sonic logging (CSL)* is the examination of the response of the pile to a sonic or ultrasonic pulse travelling between a number of vertical ducts cast into the pile concrete. A signal transmitter or emitter is lowered to the bottom of one duct, and a receiver is lowered to the bottom of an adjacent duct. Both transducer and receiver are then raised in tandem at a predetermined rate. Changes in the characteristics of the pile or its constituent materials can affect the travel time or quality of the signal arriving at the receiver.

(c) *Parallel seismic testing* is a method of estimating the acoustic length of a pile where no direct access can be gained to the pile head (a pile within an existing foundation for example). A vertical tube, such as a borehole casing, is driven or bored into the ground alongside the pile. A sensor is lowered sequentially down the tube while the foundation above the pile is struck with a small hand-held hammer. The transit time of the shock wave to travel through the pile and the intervening ground to the sensor is measured. Once the sensor passes the end of the pile, the shock wave must pass through an increasing distance of soil to reach the sensor and the transit time will increase markedly.

(d) *High-strain integrity testing* is an ancillary use of dynamic pile testing systems such as those as described in Chapter 98 *Pile capacity testing*. The test involves striking the pile with a large falling weight, such as a piling hammer. Sensors attached to the pile measure the impulsive force imparted into the pile by the falling weight and the resulting acceleration and velocity of the pile as it is driven downwards. Analysis of the signals from these sensors can allow the identification of pile damage such as a broken pile.

97.2 The history and development of non-destructive pile testing

97.2.1 Low-strain integrity testing

Most of the integrity testing of piles in the UK involves measuring the acoustic properties of the pile by striking it or causing some other acoustic vibration within it. This mechanical impulse generates 'shock' or 'acoustic' waves, which travel along or through the pile at a velocity determined by the characteristics of the pile material. The transmission of such waves through the pile is most readily represented or analysed by stress-wave propagation theory using the principles of one-dimensional wave mechanics in elastic rods.

During the 1960s low-strain integrity testing research was pursued in France by Paquet, working at the Centre Experimental de Recherché et d'Etudes du Batiment et des Travaux Publics (CEBTP). This centred upon the response of a pile to an external impulse in both the time ('sonic echo') and frequency ('vibrational') domains. This work led to the conclusion by CEBTP (Paquet, 1968) that there were limitations to the time-based 'echo' methods and that the assessment of piles by the 'vibration method' was preferable, particularly when defects in the upper few metres of the pile were of concern. These developments are discussed in detail in Hertlein and Davis (2006). Contemporary technology made practical on-site application of the theories discussed in the paper difficult to apply, and it was not until the early 1970s that appropriate equipment became commercially available.

At that time, Davis and Dunn (1974) described the application, theory and interpretation of results gathered by the frequency-based vibration method, using an electrodynamic vibrator or 'shaker' attached to the pile head and measuring the response of the pile to the spectrum of vibration frequencies. The significant downside to the method at this time was the extensive pile head preparation necessary to perform the test and the cumbersome equipment required.

Over the same period research was also being undertaken at Institute TNO in the Netherlands, and Case Western University in Texas, for example. These projects were generally focused on pile driving analysis using the wave equation (Smith, 1960). These researchers also investigated the use of the wave equation to examine pile integrity based upon 'low-strain' test techniques using a small hand-held test hammer. These forms of analysis therefore concentrated upon time-based 'sonic echo'-type techniques.

During the early 1980s the CEBTP 'vibration' test method was further developed by substituting the vibrator with a broad spectrum load cell which was struck with a small hand-held hammer to generate the necessary range of frequencies to accommodate the test. This was further developed into an integrated hammer which incorporated the load cell (Stain, 1982). After 1982, the test method was characterised by CEBTP as the Transient Dynamic Response (TDR) method. Other specialists use terms such as the impulse response method. In the following text such tests are described under the generic name of frequency response tests.

Parallel developments in the 1980s by both research and commercial organisations saw the development from analogue to digital processing, recording and analytical techniques, and, by the mid-1990s site equipment had become truly portable, being both compact and battery powered. Such systems can store several hundred pile records and, if necessary, download them via a modem link to an office base for speedier processing and report production. Advances in software and analysis programming with the advent of greater computing power

have also enabled result simulation and modelling techniques to be used to aid result interpretation, as described later.

97.2.2 Cross-hole sonic logging and parallel seismic testing

The history of the development of cross-hole sonic logging (CSL) and the parallel seismic test broadly follows a similar path to low-strain integrity testing, as outlined above. Cross-hole sonic logging, in particular, was developed by CEBTP in the late 1960s (Paquet, 1969) to counter one of the flaws with low-strain integrity testing, which was that the response of the pile to the pile head excitation is depth-limited. Cross-hole logging utilises sonic transmitter and receiver probes which are lowered down ducts within the pile and allow the construction characteristics of the pile to be examined at depth.

Parallel seismic testing (Paquet and Briard, 1976) utilises a duct placed outside a previously constructed pile (which might have been already incorporated into the as-built structure, for example) to examine the length or characteristics of the pile.

As with low-strain testing, the use of these systems was limited by the technology available at that time. Advances in portable computers throughout the 1980s and the introduction of improved analysis equipment saw widespread use of CSL on major projects in Europe, the Far East and Africa.

97.3 A Review of defects in piles in the context of NDT

97.3.1 Introduction

The foundation system is selected by the designer of the piles and/or the overall scheme designer from a range of possible alternatives to suit the ground conditions and the imposed structural loads. In selecting the system both parties need to consider the means by which the as-constructed works are checked against the design intentions and assumptions. Ideally, these design and performance requirements should be outlined within the project specification.

To a large extent, each pile is unique and, because it is buried in the ground, it cannot be examined in the same way as the structure it supports. Additionally, the foundation system cannot normally be subjected to pre-loading to confirm its adequacy before being put into service (except in a case such as a storage tank or silo). Hence, the evaluation of the foundation pile system usually requires inference and extrapolation from a combination of direct and indirect testing and, if necessary, the targeted examination of individual piles. It should be understood that a key point in any such evaluation process is the accurate recording of construction information for each pile, usually by the pile installer. Guidance on essential construction records are listed, for example, in the ICE SPERW document (ICE, 2007).

NDT is therefore undertaken as part of the contractual evaluation system, to provide additional information on aspects of the pile construction, as an aid to the evaluation of the foundation system.

97.3.2 An overview of pile defects and NDT

Problems that may arise in the construction of various types of pile are reviewed in Chapter 82 *Piling problems*. In the context of the use of NDT, the features arising from the problems, or potential problems, identified in Chapter 82 *Piling problems* fall into four general categories (CIRIA 144, 1997). These are identified as:

Type A. Changes to the intended shape of the pile body itself.

Type B. Total rupture of the pile, in the form of a transverse crack or break across the body of the pile.

Type C. Changes in the internal properties of the pile.

Type D. Features that affect the interaction of the pile with its environment and, consequently, its ability to transfer the design load into the surrounding soil or rock.

Type A features are usually associated with some aspect of the pile-forming process, either in the pile construction or post-construction phase. Features that affect the shape of the pile body were generally identified by CIRIA 144 (1997) by the terms necks, waists, bulbs, expansions, steps or bites, as illustrated in **Figure 97.1**.

Type B features are linked to the action of unplanned external tensile or lateral forces acting upon the hardened pile material, before (as in the case of pre-formed or precast piles), during or after installation. The effect of such an external force is typically to produce a transverse fracture perpendicular or at an acute angle to the long axis of the

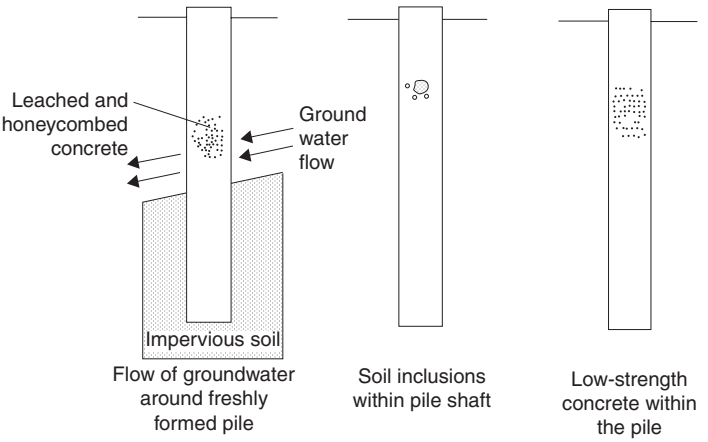

Figure 97.3 Typical type 'C' features within a pile
Reproduced with permission from CIRIA R144 (1997), www.ciria.org

pile, as illustrated in **Figure 97.2**. Transverse cracks can also be formed by shrinkage of the concrete or by the effects of ground heave.

Type C features might be caused by faulty concrete or concreting processes, or the use of sub-standard materials. They therefore reflect internal changes in the properties of the pile, as illustrated in **Figure 97.3**. The changes in properties, such as concrete strength, could be gradational or sharp. Other examples are where some of the pile concrete is contaminated by suspended spoil (e.g. piles formed under bentonite) or variations in concrete cover to steel reinforcement.

Type D features include poor toe conditions and softened or degraded bore sides due to relaxation or water ingress. Type D features are therefore typically associated with deficiencies in the pile construction process at the boring or drilling stage, prior to concreting, or, in the case of driven piles, with pile heave in congested groups, or with relaxation effects after driving. Such factors can therefore directly affect the load-carrying capacity of the pile.

It is important to understand, however, that these 'features' are not necessarily defects: in the sense that a 'defect' might be considered to be something that would significantly affect the short- or long-term performances or the load-carrying capacity of the pile. The identification of a particular feature is not a judgement of whether a pile is defective, sub-standard or non-compliant. Further evaluation and, possibly, further investigation may need to be undertaken to determine whether the feature is an unacceptable 'defect'.

CIRIA 144 (1997) proposed the terms 'anomaly' and 'defect' where an anomaly was an irregular or unexpected response that might or might not represent a real feature of the pile shaft. In contrast, a defect was categorised as a feature in the pile that was not in accordance with its specified construction, and which might or might not affect the ability of the pile to perform as required.

In terms of the latter Amir (2001) proposed further that a defect which was not significant in terms of its effect on pile capacity or durability should be termed a 'flaw', reserving the term 'defect' for a feature that would affect the bearing capacity or likely durability of the pile. A 'defect' would require engineering evaluation: perhaps the pile could be accepted at a reduced capacity for instance.

Integrity testing therefore inherently requires a step-by-step process leading from the identification of a 'feature' or an 'anomaly' by the test to the evaluation of its significance and the decision on any further action required.

Section 97.4.6, below, discusses in more detail these analytical and interpretative processes associated with the evaluation of such 'features'.

It is important that the method of testing and evaluation should be chosen with reference to the pile type and construction method, pile layout, piling programme, subsoil conditions and level of site control, both during and after pile installation, to ensure it is suited to the detection of the type of fault which could exist.

A further point to understand is that, in general, non-destructive tests are better at highlighting sharp changes in pile properties, as opposed to gradational ones. Hence in **Figure 97.1** small changes such as 'waists' or 'expansions' or gradual changes in pile diameter, rather than 'steps', would typically be difficult or impossible to identify in practice.

97.4 Low-strain integrity testing

97.4.1 Time-based analysis

The general arrangements for a time-based integrity test are illustrated in **Figure 97.4**. These tests are often known as 'echo' or 'sonic echo' (time domain) tests.

To understand the essence of the test technique it is helpful to initially consider the case of a perfect free pile (i.e. a pile which has no lateral soil restraint or base support) of length L. In this case, the toe of the pile is said to be a 'free' end, as

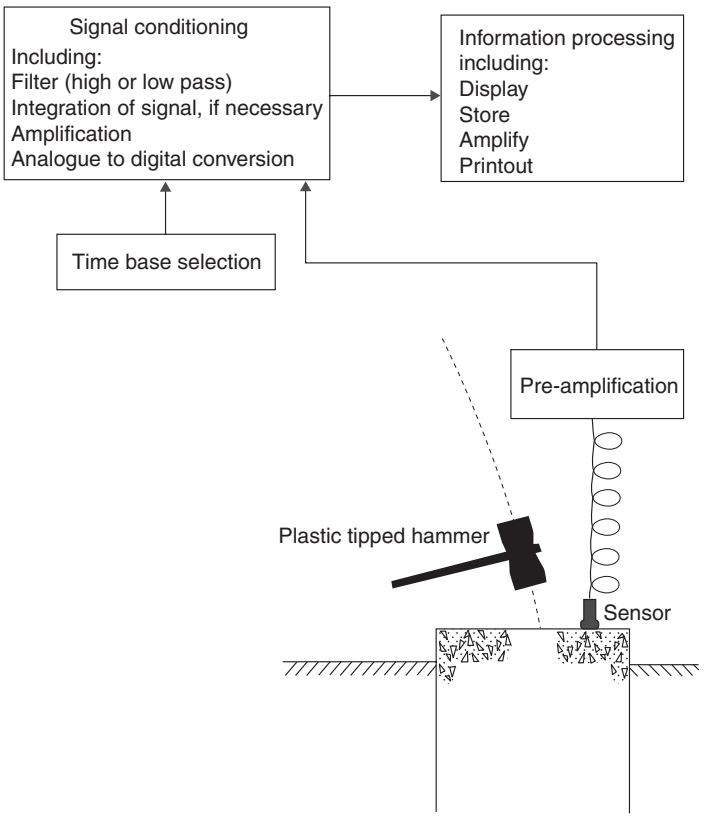

Figure 97.4 Schematic of a typical time-based 'sonic echo' test layout
Reproduced with permission from CIRIA R144 (1997), www.ciria.org

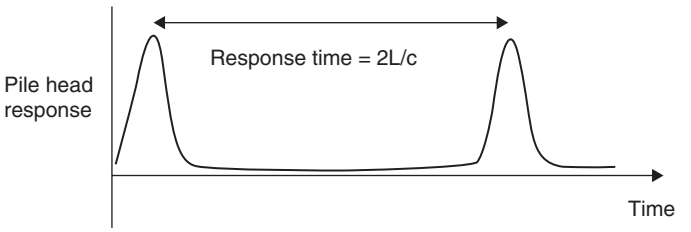

Figure 97.5 Graphical representation of hammer blow and 'echo' reflection observed at the pile head from a 'free' end at the pile toe

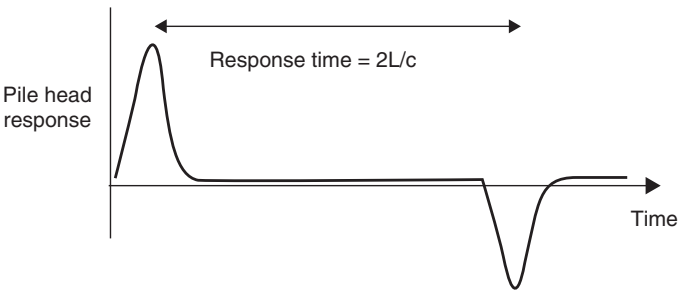

Figure 97.6 Hammer blow and 'echo' reflection observed at the pile head from a 'fixed' end at the pile toe, showing an upward-travelling compression wave, with its polarity opposite to the downward-travelling wave

it is free to move downwards in response to the downward-travelling stress wave from the hammer blow. Applying a short duration impact to the pile head, such as a blow from a hand-held hammer, causes a compression wave to propagate down the pile in the form of a longitudinal or bar wave (commonly termed a stress wave). Upon reaching the pile toe the wave reflects back to the pile head as a tension wave. The fundamental propagation velocity, c, for longitudinal waves is given by one dimensional wave theory as:

$$c = \sqrt{E/\rho} \qquad (97.1)$$

where E = material Young's modulus
and ρ = material density.
It can be seen that the time, t, taken for this wave to propagate from the pile head to the pile toe and back up to the head will given by:

$$t = 2L/c. \qquad (97.2)$$

This is illustrated in **Figure 97.5**, where the first peak is generated by the hammer blow and the second peak is the reflection or 'echo' of the wave returning from the 'free end' at the pile toe. It should be noted that on most of the illustrations of time-based (sonic echo) testing in this chapter the intial hammer blow is represented as an upward peak on the signal response graph. It will be realised that it could equally be represented as a downward-facing peak, and hence all other peaks or troughs will be similarly reversed, and other figures show this mode. Commercially available testing systems usually adopt one or the other method of data presentation.

Now consider the case of a similar pile, without skin friction but this time supported on an infinitely rigid base. The applied compression wave from the hammer blow upon reaching the supported base reflects in the form of a compression wave but one with an opposite polarity to the downward travelling wave as shown in **Figure 97.6**.

In practice, of course, the pile will be embedded in the ground. This has the effect of dissipating the energy from the stress wave as it propagates down the pile shaft. The degree of signal attenuation is a function of the pile diameter, the pile length and the stiffness of the surrounding soils. Generally speaking, piles with a length to diameter ratio in excess of 30:1, embedded in stiff to very stiff clays exhibit 100% signal attenuation: so that, effectively no return signal reflected from the pile toe reaches the pile head. Hence, in such a situation, it can be seen that the test may be of diminishing use in identifying the location of the toe of the pile, if this was of concern to the engineer. However, it must be appreciated that the test will still have application in examining the upper section of such a pile.

The attenuation of the low-strain integrity test signal from longer piles was also the reason that cross-hole sonic logging was developed (see section 97.4.5).

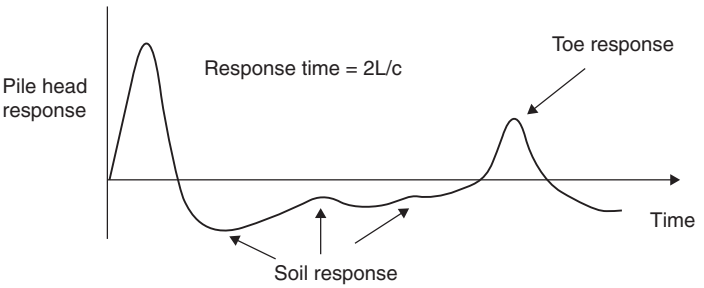

Figure 97.7 Pile head response in multiple soil horizons

Velocity of plane wave propagation in concrete	3500–4000 m/s
Density/unit weight of concrete	23–24 kN/m³
Young's modulus of concrete	approximately 38 GN/m²
Soil shear wave velocity	100–300 m/s
Soil density/unit weight	16–21 kN/m³

Table 97.1 Typical values of material properties

Changes in soil characteristics along the shaft will also generate partial reflections of the downward-travelling stress wave. At each of these soil horizons, a proportion of the stress wave will be reflected back to the pile head, the remaining portion continuing to the pile toe. Multiple soil horizons along the shaft can therefore have a major effect on the theoretical pile response, so that interpretation of the return signal becomes more complex, as shown in **Figure 97.7**.

Inevitably, the resultant response from an embedded pile is often not as straightforward to interpret as the theory may suggest. A more detailed explanation of wave propagation in piles is given in CIRA Report 144 (1997).

97.4.2 Typical pile and soil properties

As discussed in 97.4.1 above, in order to evaluate the response of a pile to a low-strain integrity test impact it is necessary to consider the properties of both the material from which the pile is constructed and the soil surrounding the shaft. It can be appreciated that a sound pile shaft constructed in a very stiff soil, or socketed into rock, would produce a response significantly different to a pile floating in space with no skin friction or base support. The stiffness of the soil surrounding the embedded pile contributes to damping of the stress wave as it propagates down the shaft. This damping factor was first recognised by Briard (1970) and can be measured by the attenuation of the response from the pile base. Typical values of material properties are as shown in **Table 97.1**

97.4.3 Pile impedance

Any changes in pile properties along the shaft will also generate partial reflections of the stress wave as it passes the boundary at which the change occurs. Such property changes within the pile are defined by a parameter termed the impedance, Z, of the pile. The value of Z at any given location along the shaft is given by:

$$Z = \rho \,.\, c \,.\, A. \qquad (97.3)$$

An increase in pile impedance, such as an increase in the cross-sectional area, A, of the pile, will generate a compression wave at the level of the change. This will propagate back up to the pile head and produce a pile head response in the *opposite* direction to the hammer impact response: in a similar manner to the rigid toe reflection illustrated in **Figure 97.6**. Conversely, a reduction in pile impedance, such as a reduction in cross-sectional area, or a reduction in the density of the concrete forming the pile, will generate a tension wave: producing a response at the pile head in the same direction as the hammer impact response, in a similar manner to the 'free end' toe reflection in **Figure 97.5**.

It can be seen, therefore, that the reflection of the signal from the toe of the pile, and its interpretation as either a free end or a fixed end effect, would also be produced by other features within the pile, such as a change of section, for example. Typical features which might be expected to produce a free end response are illustrated in **Figure 97.8(a)**. Similarly, features which would be expected to produce fixed end responses are illustrated in **Figure 97.8(b)**.

In addition, the impedance change associated with a particular feature might only cause a partial reflection of the downward-travelling stress wave from the initial hammer blow on the pile head, while the remainder of the signal continues downwards towards the toe of the pile. An example of such a feature might be a bulge or a neck in the pile section. It will be appreciated that, in such a case, the part of the signal that reaches the pile toe and is reflected back towards the pile head will again suffer partial reflections, and hence attenuation or degradation, as it passes through the feature, so that it might be barely detectable at the pile head. The practical significance of such partial reflections is that the pile head response becomes more complex as a consequence of the effect of more than one impedance change upon the transmitted and reflected stress waves. **Figure 97.8(c)** illustrates the effect of the possible 'combined' response of piles with a neck or a bulb feature within the pile section. In addition, **Figure 97.8(d)** illustrates the effect of the attenuation of the signal response as a result of soil skin friction upon the pile. At the limit, for a long pile embedded in a stiff soil, no toe reflection would return to the sensor at the pile head, and only the initial impulse from the hammer blow would be recorded, as illustrated in **Figure 97.8(e)**.

It will be appreciated that a relatively small impedance change would only reflect a small percentage of the downward-travelling wave, so that most of the signal would continue downward towards the pile toe. As the impedance change becomes greater, an increasing proportion of the downward-travelling wave would be reflected. Ellway (1987) suggested

that when the ratio Z_1/Z_2 or Z_2/Z_1 is greater than 4 the downward-travelling wave will be effectively completely reflected at the interface between Z_1 and Z_2, so that no return signal would be received from below this level.

97.4.4 Frequency-based analysis

Initially, as discussed in section 97.2.1, for the 'vibration' test method employed by Paquet (1968) and Davis and Dunn (1974), the pile head was subjected to a cyclically varying excitation force using an electro-dynamic 'shaker' attached to the pile head. By this means the pile head force was applied in discrete frequency steps, gradually sweeping through a frequency range from 0–1000 Hz. By applying this vibration at constant amplitude and force F_o and observing the maximum velocity V_o at the head of the pile within this frequency range it will be seen that the discrete frequencies at which resonance occurs are equally spaced along the frequency spectrum. The first resonating peak

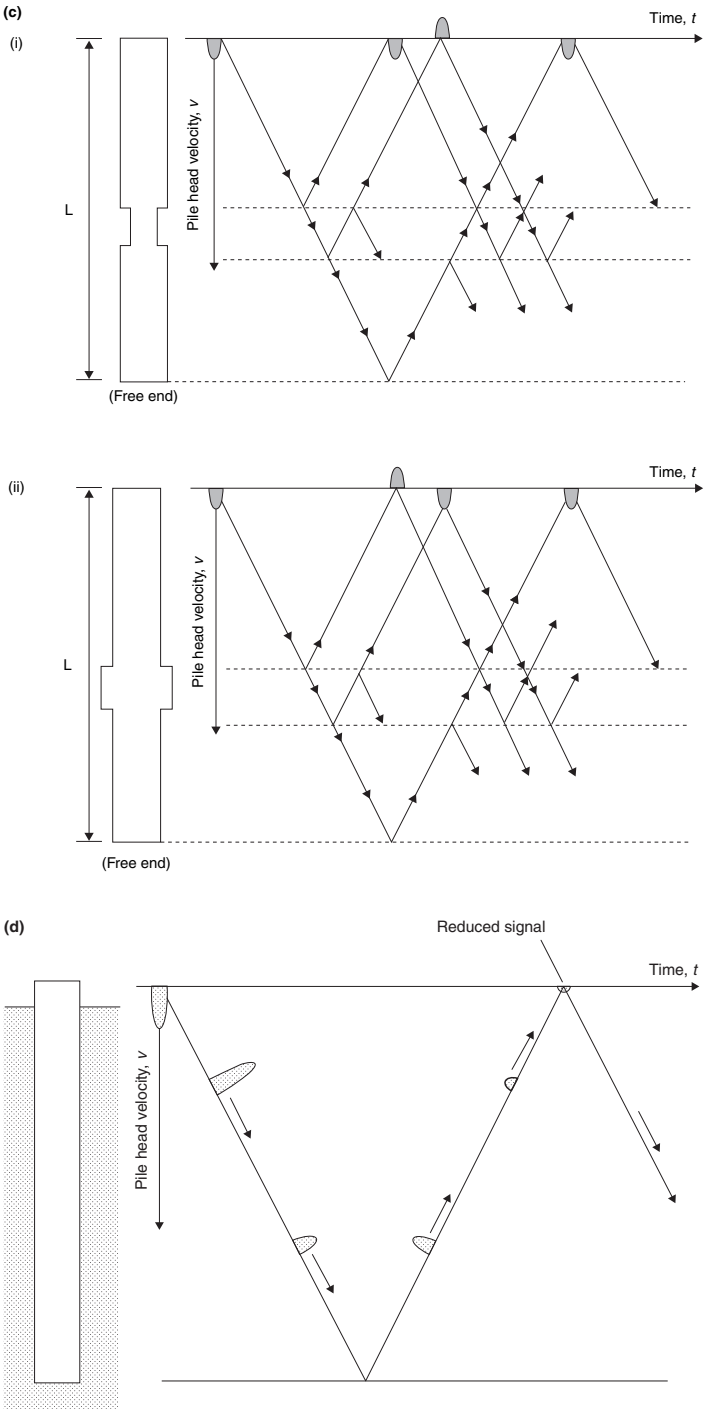

Figure 97.8 (c) Typical 'combined' responses for time-based tests:

in the series is the natural frequency of the pile and subsequent peaks are harmonics of the natural frequency.

As described earlier, later developments utilised a load cell attached to the pile head, which was then struck with a small hand-held hammer fitted with a suitable impact head capable of generating the same bandwidth of frequencies used for the vibration tests. Current systems use a hammer incorporating the load cell as a single complete unit.

The current frequency-based test techniques are commonly known as 'impulse' response and by such proprietary names as Transient Dynamic Response (TDR) methods. Within this text they will be described under the generic term of 'frequency response' tests.

An important difference between the current time- and frequency-based techniques is that the latter always measures the force applied to the pile head by the hand-held test hammer. A schematic of the general arangement of this test method is shown in **Figure 97.9**.

This method can best be understood by referring back to the original 'vibration' test technique using an electro-dynamic shaker. For any discrete frequency of excitation generated at the pile head, the returning wave and consequential pile head velocity will be the vector sum of the phase of the returning wave and the original input wave. For example, if the returning wave is in phase with the input wave then the pile head velocity will be at a maximum; if out of phase by 180 degrees the resultant pile head velocity will be at a minimum.

From standard wave theory relating to vibrations in long slender rods, the distance between resonating peaks, Δf, is given by:

$$\Delta f = c / 2L \tag{97.4}$$

where c is the velocity of plane wave propagation along the pile and L is the length of the pile.

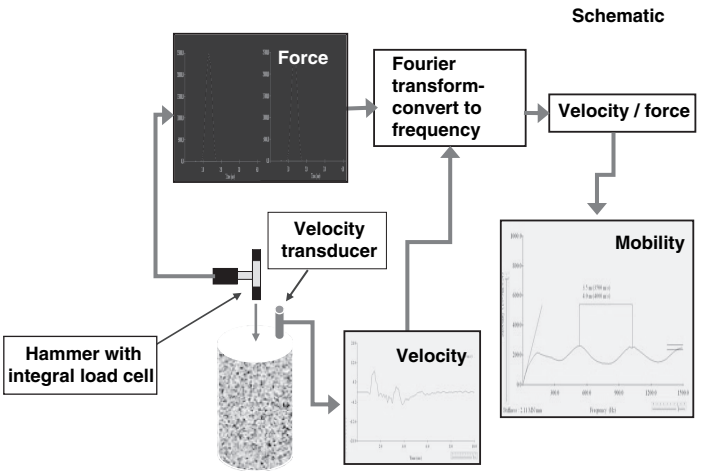

Figure 97.9 Schematic of general arrangements for the frequency response method
Courtesy of Testconsult Limited

To 'normalise' the response from the pile impact and produce a unique pile signature the output from the pile head velocity transducer (V_o) is divided by the input force (F_o), where V_o / F_o is the mobility, M_o (also termed the mechanical admittance), of the pile at the particular frequency. The units for mobility are therefore m/s/N. The pile head response is thus plotted in terms of pile head mobility versus frequency.

In the case where the elastic base is infinitely rigid (see section 97.4.1 above), the lowest frequency of resonance has a value of *c/4L* as shown in **Figure 97.10(a)**.

By contrast, when a pile rests on an infinitely compressible base, resonance first occurs at a very low frequency (**Figure 97.10(b)**). When the base is an elastic one of normal compressibility the lowest frequency of resonance lies in an intermediate position between that of the rigid and infinitely compressible bases as shown in **Figure 97.10(c)**.

In a similar manner to that described above for time-based analyses, a free or fixed end effect could also be produced by other features within the pile: such as a reduction or increase of the pile section, for example, or a broken or cracked pile.

As described by Ellway (1987), the sharpness of the pile shaft resonances depends upon the relative amount of the energy of the stress wave that is either transmitted or dissipated each time it is reflected from a boundary layer, such as the pile toe. A short pile in free air would have little energy loss, and would be expected to exhibit the sharp resonant peaks illustrated in **Figures 97.10(a)** to **97.10(c)**. However, where a pile is embedded within a soil then the propagation of the stress wave will be dissipated, or *damped* by the soil. The idealised signal response curve of **Figure 97.10** would therefore be modified to the form shown in **Figure 97.11(a)**. This form is typical of most frequency response signal curves met in practice.

In an exactly similar way to the 'echo' test, if the soil was sufficiently stiff, all of the stress wave would be attenuated and no

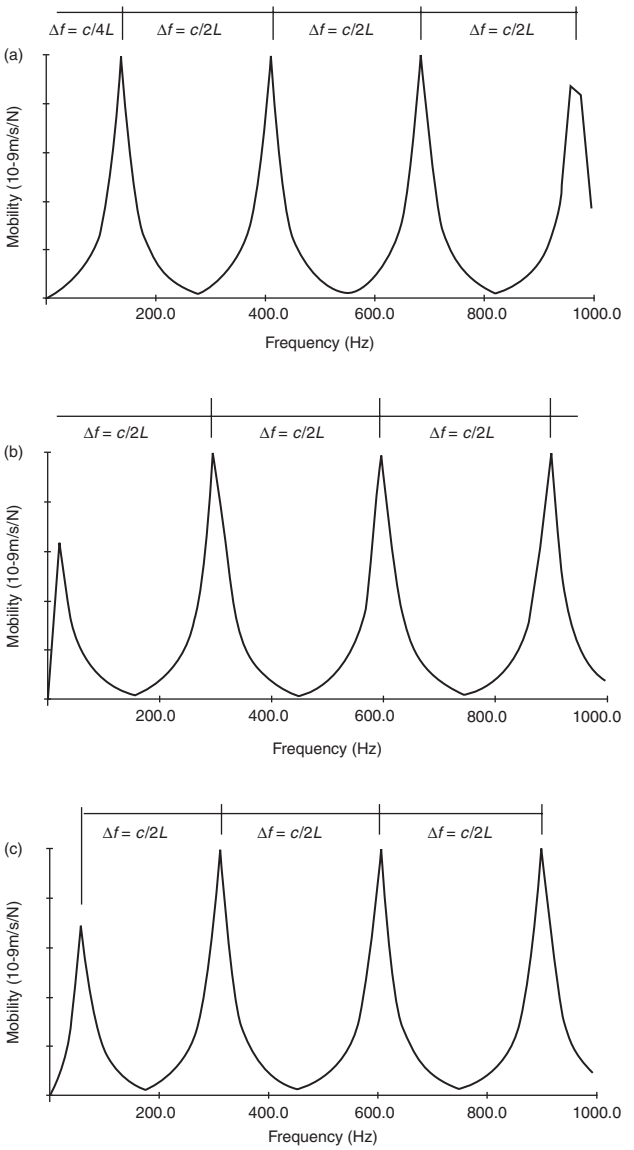

Figure 97.10 Pile with (a) rigid base support; (b) no base support; (c) normal base support

reflection would be received from the toe of the pile by the sensor at the pile head. Hence, no resonances or frequency peaks will be registered, and the signal response will tend towards a single value of mobility, as illustrated in **Figure 97.11(b)**.

The stress wave can be attenuated not only by the surrounding soil, but also by a very long pile, where the wave has to travel through the pile to the toe, before returning to the sensor at the pile head. It can be seen that an infinitely long pile of uniform cross-section would produce no reflection from the toe, and there would be no intermediate impedance changes to cause reflections of the signal. Thus the frequency response curve of a very long pile would therefore also tend to that illustrated in **Figure 97.11(b)**, and the value of the mobility would

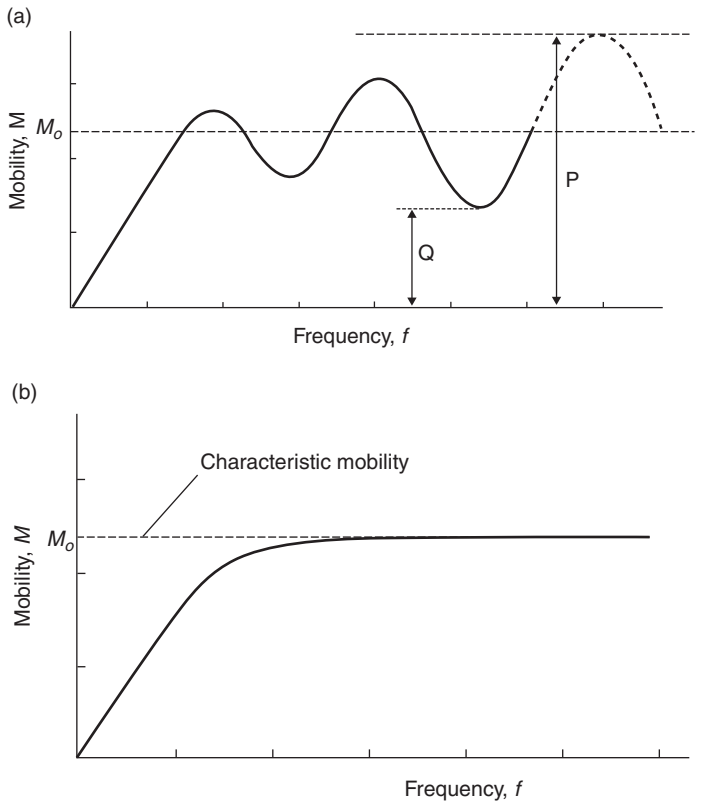

Figure 97.11 (a) Effect of soil damping on signal response curve; (b) Idealised frequency response curve for an infinitely long pile
Reproduced with permission from CIRIA R144 (1997), www.ciria.org

reach a constant value. This value is termed the characteristic mobility, M_o, of the pile, and is given by:

$$M_o = L / \rho\, c\, A. \qquad (97.5)$$

The characteristic mobility, M_o, for a particular pile therefore depends only upon its internal properties, and is a unique calculable value. The calculated theoretical value of M_o for a pile tested in the field is often annotated onto commercial signal response curves as an aid to interpretation and comparison.

From a consideration of Equation (97.5), it can be seen that a test value of M_o greater than its theoretical value could be caused by one or more of the pile parameters σ, c or A being lower than its design or intended value. Conversely, a lower value of M_o would imply σ, c or A being greater than their design value: a larger diameter pile, for example.

The above text and figures also clarify that the attenuation of the frequency response curve can be the result of either a shorter pile embedded within a stiffer soil, or a longer pile in a weaker soil. In both cases, the difference in amplitude between maxima and minima (indicated by P and Q in **Figure 97.11(a)**) is reduced, so that the response curve gradually approaches the value of the characteristic mobility of the pile.

In addition, the initial straight line portion of the mobility versus frequency curve is a measure of the *dynamic stiffness*, E, of the pile head. E would be expected to be a specific value for a group or 'class' of piles on a site having the same cross-sectional area, length and unit weight, installed into the same soil stratum. Hence, a pile with a lower dynamic stiffness than its fellows might be considered for further examination or test. Further description of this feature is given in Hertlein and Davis (2006) and CIRIA 144 (1997).

97.4.4.1 Pile impedance and partial reflection

In a similar manner to analysis in the time domain discussed in sections 97.4.2 and 97.4.3, it would be expected that an intermediate feature in the pile, such as a reduction or increase in diameter, which caused only a partial reflection of the stress wave, would be identifiable by its characteristic resonant frequency in addition to the frequency peaks due to, say, the toe of the pile. Hence, the two signals might be superimposed onto the response registered for the pile. This is illustrated in **Figure 97.12**, taken from CIRIA 144 (1997), after Ellway (1987). Ellway noted that the reflection coefficient (the proportion of the signal either reflected or transmitted) across the change of impedance (shown as a bulb in **Figure 97.12**) is also governed by the frequency of the vibration wave. In general, this coefficient increases with frequency, so that a greater proportion of the vibration energy is reflected from the change in impedance interface at higher frequencies. Thus, as seen in **Figure 97.12**, at lower frequencies the full length of the pile can be discerned. At higher frequencies the intermediate impedance change becomes increasingly discernible. Ellway suggested that, for this reason, a frequency-based test should examine the response of the pile over a minimum frequency range of 0–2500 Hz.

Figure 97.13 further illustrates the return signal from a pile with a major impedance change at shallow depth. Section 97.4.5 discusses the interpretation of site data in further detail.

97.4.5 Features detected by low-strain integrity tests

97.4.5.1 Features detected using time-based sonic echo test methods

Figure 97.14 illustrates a typical response from a pile with a previously placed 'neck' defect (from a test site at Blyth, in north-east England, as described by Lilley *et al.* (1987). The first upwards peak is from the hammer impact and the second from the reflection or 'echo' from a change in pile or soil impedance. As the echo is of positive polarity (relative to the hammer impact peak) we know that the returning wave is a tension wave and is therefore a result of a reduction in impedance due to a change in pile or soil properties. The magnitude of the reflection would suggest a shaft feature rather than a soil feature and this is most likely to take the form of a reduction in section or 'necking' of the pile shaft.

The separation of the two peaks is 1.4 ms, which, based upon a wave speed within the concrete pile of between 3500

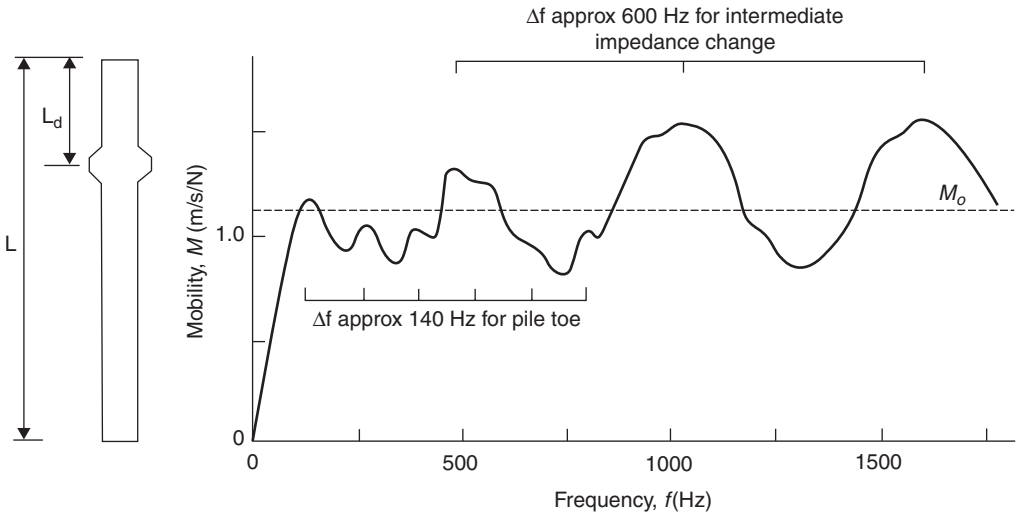

Figure 97.12 Frequency response test, illustrating the effect of an intermediate impedance change

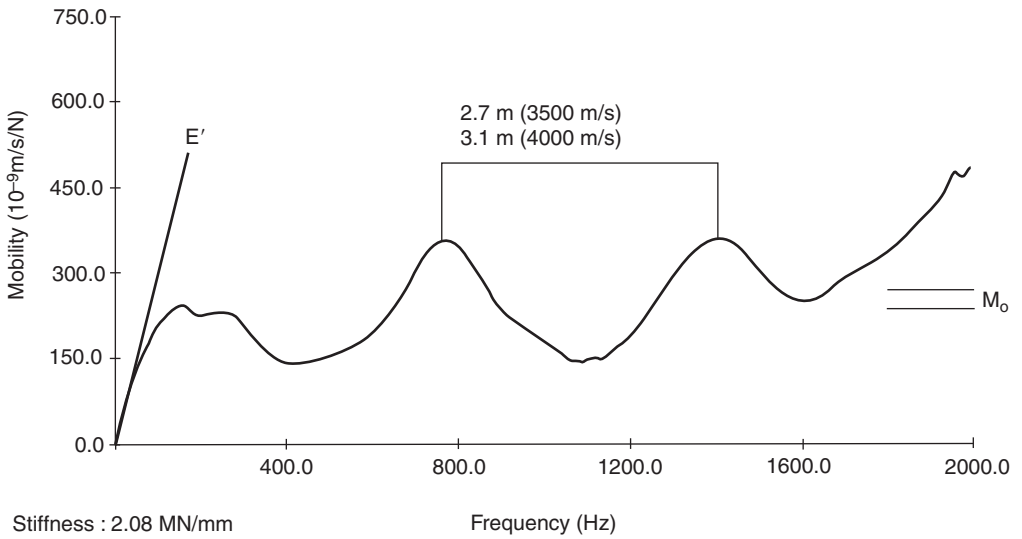

Figure 97.13 Typical site trace of a frequency response test on a pile with a neck defect, showing interpretation of pile head dynamic stiffness, *E′*, and characteristic mobility, M_o
Courtesy of Testconsult Limited

and 4000 m/s, is equivalent to a depth of 2.4–2.8 m below pile head level. The signal response may also suggest an increase in impedance very shortly after (probably as the pile returns to normal section).

There is no obvious toe reflection from the pile, which was recorded as 11.3 m long and installed within very stiff to hard Glacial Till (Boulder Clay). Again, based on a wave speed of between 3500 and 4000 m/s the pile toe would be expected on the signal trace at around 5.5 to 6.5 m/s from the hammer peak. The toe is not clearly discernible because of attenuation of the signal by the strong soil.

Caution should always be taken with this type of result as the reduction in pile impedance suggested may also be associated with an oversize pile section reducing to nominal diameter at the indicated depth. If this is suspected then reference should be made to pile construction records, concrete volume and geotechnical conditions.

The normal course of action with this pile result (once reference to construction records has eliminated an oversize upper section) would be to excavate to the level of the anomaly to inspect the pile shaft or undertake a performance test on the pile. This may take the form of either dynamic load test or static load test.

97.4.5.2 Features detected using frequency response test methods

The site analyser processes the data from the hammer and velocity transducer and produces a signature response curve showing mobility against frequency. The response curve from the same 'defective' pile is shown in **Figure 97.15**. This also allows a direct comparison of the results when displayed in the time domain and frequency domain.

Interpretation of the response curve would initially be undertaken by measuring the frequency difference between adjacent

peaks. This shows a Δf frequency of approximately 650 Hz. By applying the formula $L = C/2\,\Delta f$, length measurements of approximately 2.7 and 3.1 m can be calculated for the wave propagation speeds (C) of 3500 and 4000 m/s. The phasing of the first harmonic peak is close to Δf frequency (650 Hz) which suggests a reduction in pile impedance. In addition, the pile head dynamic stiffness (E) is calculated to be 2.08 MN/mm and the characteristic mobility (M) calculated to be approximately 300×10^{-9} m/s per N which suggests that the pile has a comparable pile head stiffness to similar pile/soil installations and that pile section, concrete density and wave propagation velocity are within the normal range for the given pile diameter and concrete properties.

Further interpretation of the response curve can be undertaken using numeric simulation techniques. **Figure 97.16** shows a numeric simulation performed on the impulse response curve discussed above: proprietary software is, however, required for this. The simulation includes a reduction in pile section at 2.9 m and shows a close match between the real and simulated response following manual adjustment to both soil and pile variables. The resultant graphics confirm that the inputted localised necking of the pile shaft at approximately 3.0 m is the correct interpretation of the response, as any mismatch of the response curve would require differing pile and soil properties.

Further modelling of the pile section using impedance analysis of the impulse response was first postulated by Paquet (1992). Advances in computer technology have enabled this to become a reality and several equipment manufacturers now include modelling of the pile section in this way. The resulting pile model is termed an impedance-log. The impedance-log technique essentially produces a one-dimensional graphic representing changes in pile impedance.

97.4.5.3 Impedance-log analysis

As noted by Hertlein and Davis (2006) it has always been the ultimate aim of low-strain integrity test specialists to create an image of the as-constructed shape of the pile shaft 'in the ground'. They suggested that the closest to this ideal at that date is the impedance-log analysis method developed by Paquet (1991, 1992). This technique combines the amplified time-domain response from the echo-type test with the characteristic pile shaft impedance measured in the frequency response test. In common with other analytical tests, however, the method is based upon a one-dimensional model, so that an asymmetrical feature such as a partial neck on one side of the pile would not be identified as such. The technique utilises the data from both the time and frequency domains to remove the motion of the pile head caused by the initial hammer blow and the

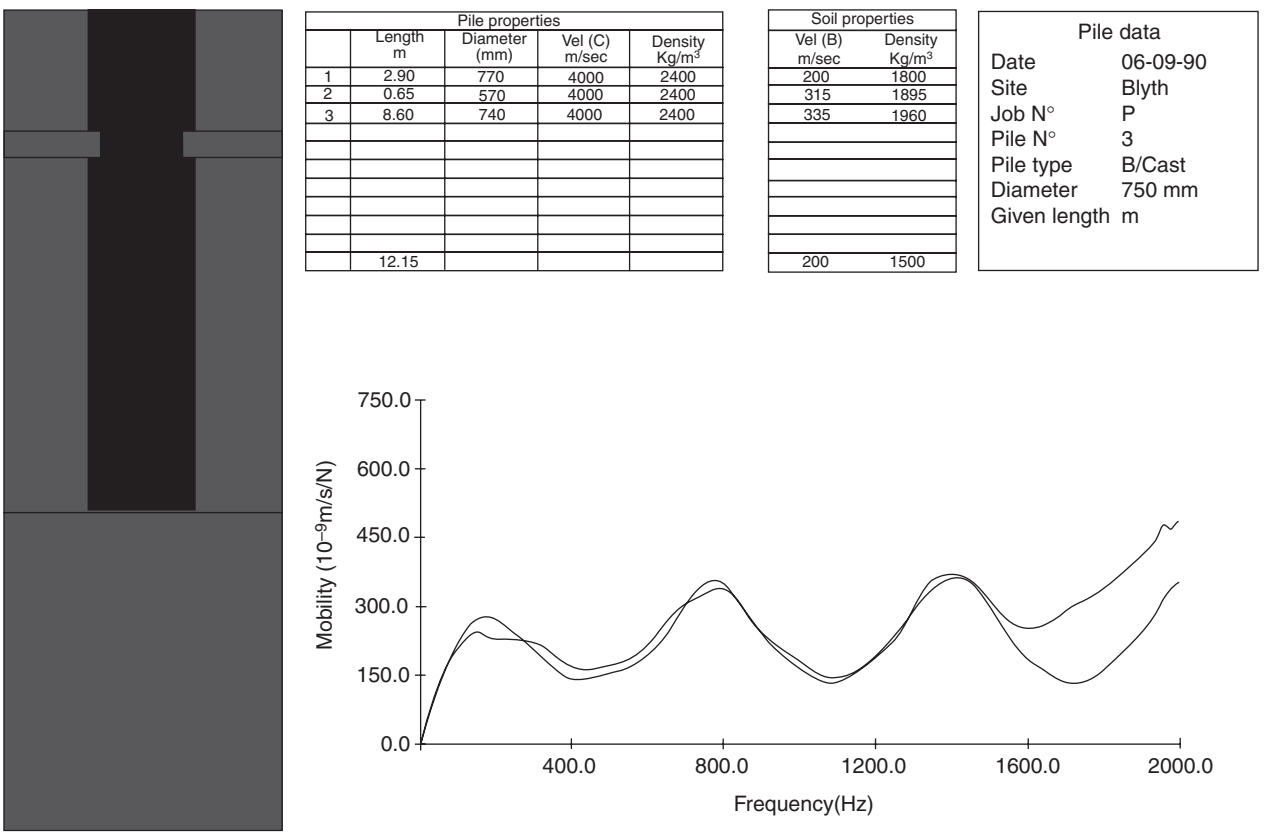

Figure 97.16 Simulation of mobility response and resultant pile section
Courtesy of Testconsult Limited

effect of impedance changes due to the surrounding soil. In principle, this is obtained by calculating a theoretical mobility plot for an infinitely long defect-free pile of the given diameter and predicted ground conditions from the available ground investigation information. In practice this model is typically derived from a simulation analysis on a pile at the site which is considered to be satisfactory. The resulting calculated soil characteristics are then used in the impedance-log model for other piles.

This idealised mobility plot is subtracted from the test response, resulting in a 'reflected' mobility response which contains information about changes in the pile shaft geometry and the surrounding soil. The response in the time domain is then calculated from this plot to produce a 'relative reflectogram', as illustrated in **Figure 97.17(b)**.

Further analysis allows the removal of the soil effects from the model, and the calculation of the impedance down the pile shaft as a function of time, which is equivalent to depth. As described in earlier parts of this chapter, if the density and wave-speed of the pile material are known, or can be reasonably approximated, changes in impedance correspond to changes in the cross-sectional area of the pile, and the resulting impedance-depth relationship can be plotted in terms of impedance versus either the diameter or cross-sectional area of the pile.

A resulting pile impedance-log analysis is shown in **Figure 97.17(c)**. This analysis was undertaken on a pile on a test site at San Jose, California, which was constructed with known defects. It can be appreciated that for such analyses it is most important to have full pile construction details and soil data.

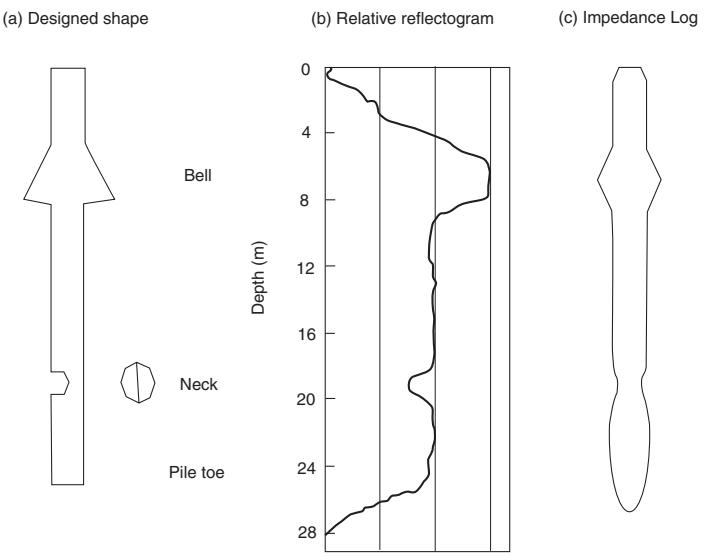

Figure 97.17 The impedance-log and relative reflectogram calculated from the velocity-time reflections for a pile constructed with artificial pile defects
Reproduced from Hertlein and Davis (2006), John Wiley

Further description of the technique is given in Hertlein and Davis (2006).

97.4.6 Analysis, interpretation and reporting of low-strain integrity tests

CIRIA 144 (1997) identified two main fields of use for low-strain integrity testing:

(a) Routine control testing, as part of a pre-planned site quality control regime.

(b) Retrospective investigations, where a problem has become apparent during the works: often while piles are being cut down ready for incorporation into the foundation system. A further use of such testing would be where it was proposed to re-use existing piles following demolition or alterations to an older structure (see Chapman *et al*., 2007 or Butcher *et al*., 2006, for example), or where the testing formed part of a forensic investigation into a possible foundation failure.

In the case of routine control testing, CIRIA 144 (1997) suggests that it should be reasonable to expect that most of the signals from such integrity tests should be understandable to other non-specialist engineers involved with the project. Since the results are of interest, and importance, to a number of contracting parties within the project, CIRIA 144 (1997) suggested that, for a testing programme to be useful, it was also important that the engineering advisers to those parties were able, with proper guidance, to agree to the validity of the basic information.

It is also imperative that such engineers are aware that the results of integrity testing should not serve as the sole basis for the acceptance or rejection of any particular pile. Other information, such as ground conditions, construction records and on-site observations, should also be considered. Crucially, if the interpretation of the test data is perceived by others to be subjective, or even whimsical, then there will be a corresponding decrease of confidence in its use as a quality control tool.

Again, it is important that the non-specialist engineer should be aware that, in practical terms, in some situations the data will allow no clear interpretation.

In an attempt to resolve this problem CIRIA 144 (1997) proposed a signal classification system for both sonic echo and frequency response tests. This was intended to differentiate the simpler signal responses from those that are more complex.

97.4.6.1 Classification of signal responses

CIRIA 144 (1997) classification

To attempt to resolve this problem, CIRIA 144 (1997) suggested a three-fold classification of signal responses:

Type 0 – no distinct return signal received, i.e. no significant impedance change within the pile, for the depth penetrated by the test;

Type 1 – one clear major response, i.e. one significant impedance change within the pile;

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Type 2 – more than one major response, i.e. two or more impedance changes within the pile.

The features of these three categories can be summarised as follows:

Type 0 signal

A Type 0 signal would be one in which the damping effect of the surrounding soil has attenuated any return signals to such an extent that the toe cannot be discerned. Therefore, there is no significant impedance change within the effective penetration depth of the system. The non-specialist engineer would easily appreciate the reason for this, provided that the basic principle of the test was understood.

Figure 97.18 illustrates typical examples of Type 0 signals for time-based and frequency-based systems.

Type 1 signal

A Type 1 signal would contain one clear, major response, indicating that the shaft was responding as a single acoustic unit. This would represent a pile containing a single major impedance change, either from the pile toe or some significant intervening feature. No other significant response would be visible on the recorded trace. Type 1 signal responses should be very similar to the theoretical simple signal expected from the test and be easily recognisable. Hertlein and Davis (2006) also suggested that such a signal response would also be easily simulated by computer modelling.

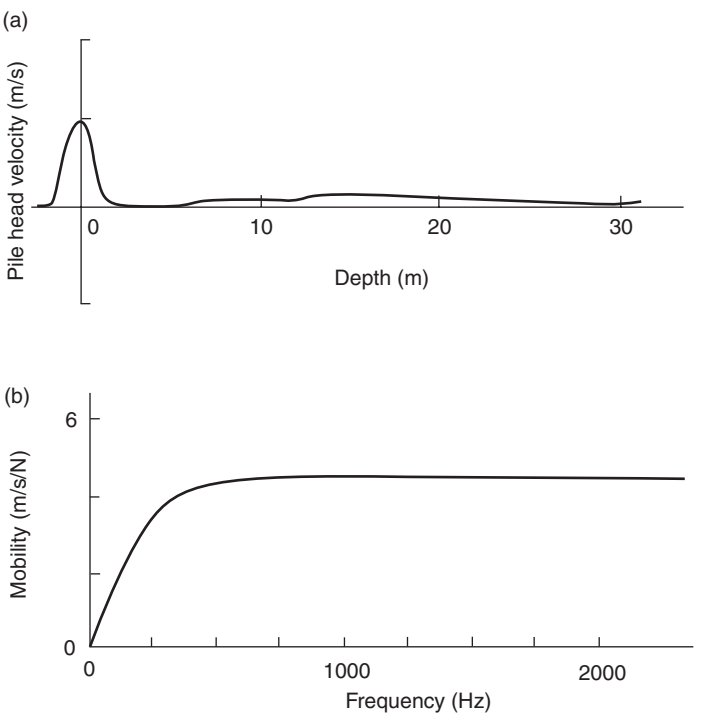

Figure 97.18 Examples of Type 0 signal response: (a) time-based (sonic echo) test; (b) frequency-based (frequency response) test
Reproduced with permission from CIRIA R144 (1997), www.ciria.org

Typical Type 1 signal responses would be like those shown in **Figure 97.19**.

Type 2 signal

A Type 2 signal would be one containing more than one major response, so that the interaction of overlapping responses from different levels within the shaft would make interpretation of the resulting response a complex matter. At one extreme Type 2 signals might display a clear major response from the length of the shaft responding as a major acoustic unit, but with intermediate responses due to local changes in shaft impedance within that acoustic unit, as shown in **Figure 97.20** and in **Figure 97.12**. At the other extreme, Type 2 signals might contain no clear major response to indicate if part of the shaft is responding as a single acoustic unit, as indicated in **Figure 97.21**.

A Type 2 signal would require interpretation by a specialist, because simple models do not easily explain the response. A summary of the CIRIA 144 (1997) classification is provided in **Table 97.2**.

Classification of the signal responses obtained from the piles on an individual site in this way will help to assess how much

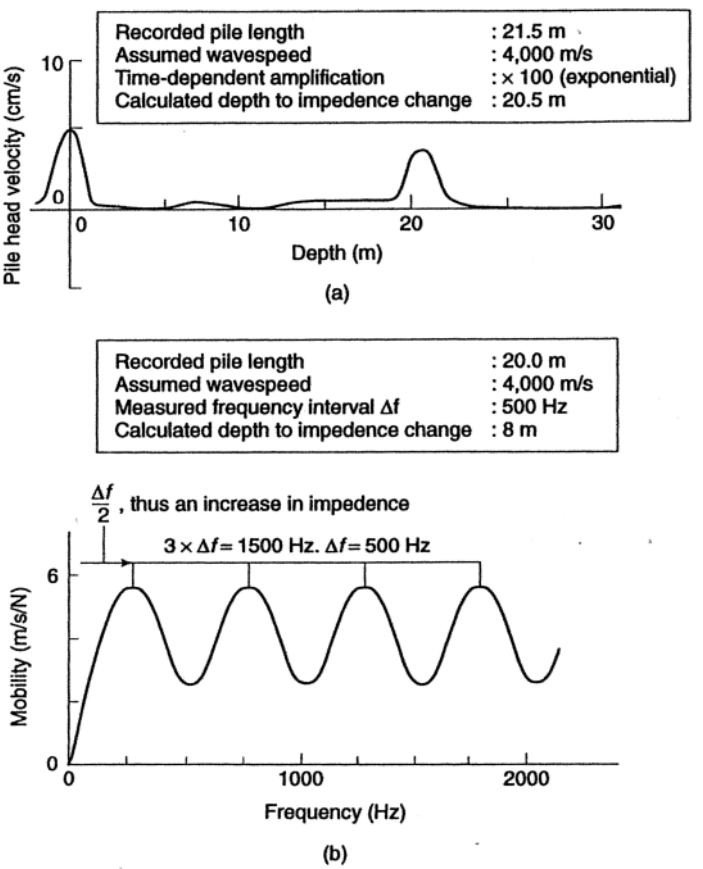

Figure 97.19 Examples of Type 1 signal response: (a) time-based (sonic echo) test; (b) frequency-based (frequency response) test

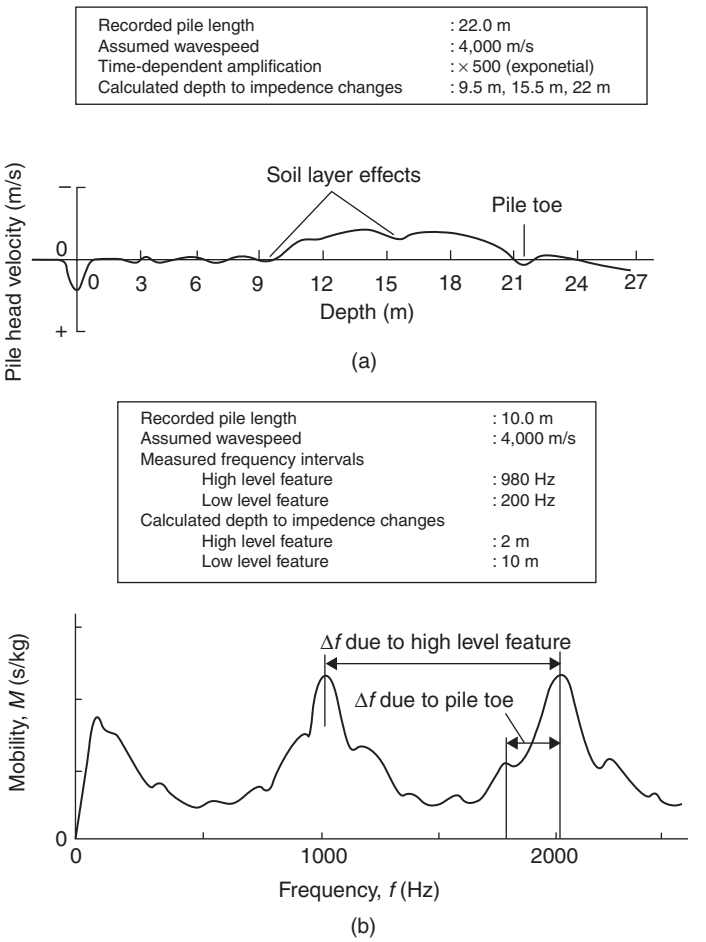

Figure 97.20 Examples of 'clear' Type 2 signal response, clear toe response and additional secondary response: (a) time-based (sonic echo) test; (b) frequency-based (frequency response) test (note: sonic echo test shows inversion of y-axis, so that initial hammer blow response is shown pointing downwards. This is a feature of the particular test system)

Reproduced with permission from CIRIA R144 (1997), www.ciria.org

weight should be given to the test results for the piles on that site. The quality of the test results will depend upon:

- The characteristics of the test system, particularly its dynamic range (the ratio of the specified maximum value and the minimum detectable value of the parameter being measured), its resolution and its signal-to-noise ratio.
- The pile characteristics, especially the length/diameter ratio, the quality of the pile material and the shape of the pile.
- The nature of the surrounding soil: the stiffer the soil, the greater the signal attenuation. In addition, a boundary between soils of different relative stiffness acts as a reflective layer or impedance change within the shaft–soil system.
- The quality and standard of the pile head preparation for the test.

It is important to note that CIRIA 144 highlights that there is a distinction between the analysis of the signal (i.e. what it is

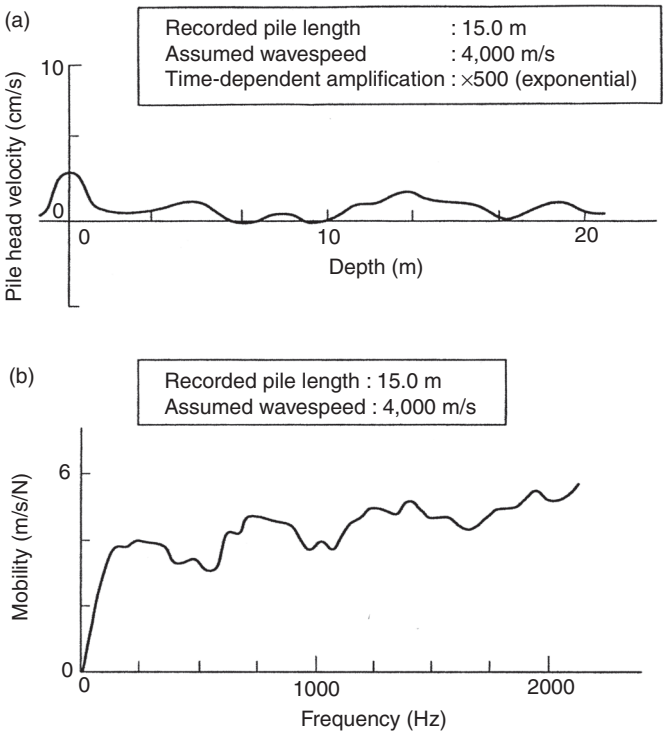

Figure 97.21 Type 2 signal response, no clear response

showing or saying) and its interpretation (i.e. what it means). The CIRIA (1997) classification 0, 1 or 2 is intended as a preliminary *analysis* of the characteristics of the signal: so that the tester can identify to the non-specialist engineer what are the general features of the signal response for each pile. The next step in the process is the tester's *interpretation* of the signal (what it means, and its significance).

An example of this *interpretative* aspect of the analysis process, which has been developed by Testconsult Ltd, in the UK, is outlined below.

97.4.6.2 Testconsult interpretative classification

The interpretative classification system developed by Testconsult seeks to group results from frequency response testing into seven categories as below:

- CAT 1 – Full pile length measured;
- CAT 2 – Damped response;
- CAT 3 – Pile with overbreak;
- CAT 4 – Oversize pile reducing to nominal diameter;
- CAT 5 – Pile with crack in upper shaft;
- CAT 6 – Pile with reduction in properties, i.e. necking;
- CAT 7 – Invalid result due to poor head condition.

It can be seen that a combined CIRIA/Testconsult classification might be, for instance a CIRIA 1 + Cat 1 signal response.

Signal type	Characteristics of signal	Signal responses obtained from		Remarks
		Remote end	Intermediate sources	
0	No impedance change within depth of penetration of signal	Not distinguishable because of soil damping or other effects	Not distinguishable because of soil damping or other effects, or not present	The reason for the response is readily understandable to the non-specialist engineer. Caution required in evaluating depth of penetration of signal
1	One clear impedance change	Clear major signal, indicating the pile system is responding as a single acoustic unit	Absent or very subordinate. Less than 50% of relative magnitude of remote end signal	The response is readily understandable to the non-specialist engineer
2	More than one impedance change	(1) Clearly discernible, reasonably prominent signal	Moderate to strong signals, but not completely obscuring the remote-end response	The response is understandable to a non-specialist engineer only with expert assistance
		(2) Not clearly discernible, because it is similar to or weaker than other parts of signal from intermediate levels	Signals of similar strength to or stronger than remote-end response	The response is not capable of interpretation by a non-specialist engineer

Table 97.2 Summary of CIRIA classification of low-strain integrity test signals

97.4.6.3 Analysis and interpretation

As outlined above, CIRIA 144 (1997) emphasises that there are two stages to the interpretation process. These can be summarised as:

(1) analysis of the acoustical data;

(2) interpretation of the significance of this analysis, taking account of all other relevant information for the pile.

The analysis of the acoustical data includes the identification and depth of impedance changes within the signal response curve, and the evaluation of these to determine whether they are relative increases or decreases in impedance.

The interpretation should take account of the site geology and ground conditions, the pile construction records, and particular features of the piling system (such as the use of permanent casing to the upper section of the pile) or the like.

CIRIA 144 (1997) provides further insight into the way this information should be used by the interpreter to provide a reasoned explanation of the condition of the piles. It emphasises that the purpose of such testing is to help evaluate the pile, not the testing system, so that as much information as possible should be given to the specialist to assist in interpretation.

97.4.7 Testing within the contract

CIRIA 144 provides extensive guidance on the use of control testing within the framework of the contract and the constraints of an active working site. It emphasises that many parties have an interest in the results of such testing but the lines of responsibility and communication are not always clear. This applies especially to low-strain integrity testing, but has application to cross-hole sonic logging also.

Hertlein and Davis (2006) also highlight this problem from US experience, and point out that NDT, when used in quality assurance testing of piles and other foundation systems, can be viewed from two extreme viewpoints. They suggest that NDT is either

- to assist *engineers* to confirm that the design and performance criteria have been met, or
- to check that the *contractor* has supplied the *owner* with the product that the owner has paid for (material quality, minimal geometric requirements, etc.).

From the first point of view, certain deviations from construction specifications can be tolerated and compensated for, provided that there is strong interaction between *engineer*, *contractor* and *tester*. In the second case, no margin for error outside the contract specifications can be allowed, since they are effectively 'set in stone'.

Davis (1998) contends that the NDT methods now available are more suited to the first scenario (performance specification). This is because the variables inherent in drawing conclusions from NDT on piles are numerous, and it is not always possible to clearly define these variables to reach a complete answer to satisfy the materials specification.

In UK practice, there is typically a view that such testing is intended to 'verify' that the construction of the piles is acceptable. However, there is almost always no contractual acceptance criterion against which 'verification' can be judged. Hence acceptability or otherwise of a particular pile or piles becomes a matter of argument or 'discussion'.

UK practice has also tended towards the specifier of the test being the technical representatives of the employer, owner, developer or funder of the project. Unfortunately, in the authors' opinion, the NDT contract is almost always included

within the piling contract. This means that the test contractor must report test results directly to the entity most likely to suffer monetary cost and disruption if adverse results are reported. It is not unusual that the test contractor is specifically instructed not to report to or discuss the test results directly with the employer's technical representative: either by the piling contractor or the general contractor to whom the piling contractor is sub-contracted.

This procurement method has led not only to a 'least cost' rather than a 'best specialist' approach, but also to the production of specialist reports which tend to give as little information and comment as possible about the results obtained.

97.4.8 Guidance on the specification of low-strain integrity testing

In the UK, the Institution of Civil Engineers' (2007) SPERW document provides some useful guidance on the specification for the integrity testing of piles and embedded retaining walls, together with some accompanying guidance notes. Unfortunately, there is some confusion in the document on the identification of the various test methods: partly due to the use of proprietary names rather than the generic terms adopted in CIRIA 144 (1997). In addition, practice, equipment and techniques have advanced further since CIRIA report 144 was first drafted.

Both CIRIA 144 (1997) and Hertlein and Davis (2006) provide guidance on the specification of low-strain testing. Hertlein and Davis in particular provide sample specifications for both low-strain testing and cross-hole sonic logging.

It is not appropriate in this particular chapter to provide a detailed specification, but is probably useful to highlight crucial points to be borne in mind when specifying such tests.

97.4.8.1 Type of test

It can be seen from the earlier discussions that there is a general hierarchy of technical quality as a result of the methodology and techniques employed. In increasing sophistication these can be identified as:

- time-based 'echo' techniques;
- frequency-based techniques;
- frequency-based techniques with simulation modelling, including impedance-log analysis.

In this context it should be appreciated that time-based techniques only examine data in the time domain. Frequency-based techniques can examine the data in both the time and frequency domains and also monitor the input force from the test hammer. Simulation modelling techniques attempt to remove extraneous information from the signal: such as that caused by the influence of the ground within which the pile is embedded, for example.

It is important that the specifier is aware of and appreciates these differences. The more knowledgeable the specifier the better they can target the testing. It is also important to realise that a more sophisticated test, with a correspondingly more complex analysis, should be expected to be more expensive. Hence, the selection of a test organisation on price alone may not be appropriate in many cases.

An important difference between time-based and frequency-based techniques, which may be of major interest to the end user, is that the examination of the data in the frequency domain can assist in examining anomalies close to the pile head. This is because the stress wave imparted by the hammer blow would typically be 1.0–1.5 ms long, which is equivalent to a wavelength of around 2–3 m in a concrete pile. Hence reflections returning from a near-surface anomaly can overlap with part of the downward-travelling wave from the initial hammer blow. The resulting complex signal can be difficult to differentiate and interpret in the time domain. By comparison, in the frequency domain, such a feature would be expected to be visible at a frequency interval of 666–1000 Hz, and might be more readily discernible (see **Figures 97.12** or **97.20(b)**, for example).

As a generality, a defect close to the pile head would often be of greater concern to the design engineer, especially if the bulk of the pile load is carried by shaft friction rather than in end-bearing.

97.4.8.2 Experience of testing specialist

Research testing in the US (e.g. Baker *et al*., 1993; Iskander *et al*., 2001) indicated that integrity testing methods were quite dependent upon the skill and experience of the test operator. Hertlein and Davis (2006) suggest that field testing and preliminary interpretation should be undertaken by an experienced operator with at least one year's experience with the particular method employed. They further suggest that final interpretation and reporting should be performed by, or under the direct supervision of, an engineer or senior technician with at least three years' experience with the specific method being employed.

The testing specialist should be expected to have such experienced and qualified personnel on its staff. It should also be able to provide computer simulations of the anticipated response of the piles at the subject site, given details of pile characteristics (length, diameter, concrete and reinforcement details), cut-off levels and ground conditions from test level.

It should also be able to provide a sample test report, with full explanatory annotation as necessary. The selection of a suitable test specialist is of paramount importance to all parties, and the depth and coverage of a sample test report can be a guide to the test organisation's understanding and ability in this highly specialist field.

97.4.8.3 Pile head preparation

Pile head preparation is most important to the quality of the data acquired for subsequent analysis. It is to be expected that most integrity test houses can provide guidance on pile head

preparation, and for best results this advice should normally be followed.

97.4.8.4 Equipment

Current recommendations suggest that the measuring and data acquisition systems should have certified dynamic ranges of at least 60 dB and flat frequency responses over a minimum bandwidth of 20–2500 Hz, and the analogue to digital resolution should be no less than 16 bits.

All equipment should be provided with calibration certificates traceable to UKAS standards. Impulse hammers, velocity transducers and the data acquisition system should have re-calibration checks at intervals of no more than 12 months.

97.4.8.5 Reporting of test results

A reporting timescale should be specified. This would typically include preliminary 'overview' reporting at the time of test or within 24 hours, with the issue of a formal analysis and evaluation report within three to five working days.

The testing specialist's report should include signal response graphs for each pile, as applicable, and an analysis of the response of each pile.

Analysis and interpretation of the test data for each pile by the testing specialist should include:

(1) whether a clear response has been detected consistent with the level of the pile toe, or any other level within the pile;

(2) whether any secondary responses have been detected;

(3) whether the responses are due to an increase or decrease in pile impedance, and a view of their magnitude and importance;

(4) an interpretation of the cause and significance of these responses or 'features';

(5) recommendations for any further investigation or measures if required.

97.4.8.6 The review of acceptance or rejection criteria for the piles, based upon integrity testing

It is important that the specifying engineer, the main contractor and the piling contractor have in mind how they are going to deal with the results obtained from the testing, and the specification should address this point. It should be appreciated that this is not a minor matter. There is often a major cost implication in terms of delay and disruption to the contract progress, quite apart from the costs of remedial works to the pile(s).

Hertlein and Davis (2006) suggest the following approach:

- If a clear response consistent with the level of the pile toe is detected, with no significant secondary responses from levels above this, then the pile would be deemed acceptable in terms of the integrity testing.
- If no clear response from the pile toe is detected, with no significant secondary intermediate responses above the level of the pile toe, then the supervising engineer of the test house as identified in section 97.4.8.2 above (the experience of the testing specialist), should report what length of the foundation pile may be considered to be proven, based on their interpretation of the test data.
- Reflections interpreted to be from any level above the level of the toe of the pile should be analysed by the testing specialist to determine whether the reflection is from a significant reduction or increase in impedance, since these are consistent, in the main, with a corresponding reduction or increase in the pile cross-section. The probable/possible nature and significance of the reflector should then be assessed, taking into consideration the intent behind the design of the pile. The decision to accept or reject the pile or to require any further investigative works should be made by the engineer responsible to the client for the overall design of the structure.

If the test result is deemed to be inconclusive, the pile head may be trimmed back and the pile re-tested to try and provide more conclusive data. If this is impractical or is not successful, additional testing by other means may be instructed. Such measures would include excavation to expose the area of concern, coring the pile, or undertaking dynamic or static load-testing. Such measures are reviewed in CIRIA 144 (1997).

97.4.8.7 Timing of the testing

CIRIA 144 (1997) discusses the potential clash of interests between the contractor, who might to prefer to test early, and the client, who is really most concerned about the pile immediately before it is incorporated in the works. However, the later the test, the greater is the potential disruption to the overall contract if problems are found. The specifier should address this point, and the specification should be clear on the requirements. As a guide it is not unusual to require that the testing of any pile should be undertaken within 28 days of installation, and that all testing should be complete within 14 days of the installation of the last pile. For cast-in-place piles, it is usual to specify a minimum curing period before testing. This would typically be between three and seven days depending on the characteristics of the concrete mix.

97.5 Cross-hole sonic logging

97.5.1 Introduction

The method is a development of the ultrasonic pulse velocity (UPV) test method commonly used to determine ultrasonic transit time in concrete. The UPV test method is described in detail in BS EN12504-4:2004.

Vertical ducts are cast into the pile over its full length. Two probes, one a transmitter and one a receiver, are lowered to the bottom of adjacent ducts. An ultrasonic pulse from the transmitter is detected by the receiver and the signal is captured by the data acquisition system, as illustrated in **Figure 97.22**.

A continuous series of such measurements is taken as the probes are simultaneously raised up the ducts, so that a

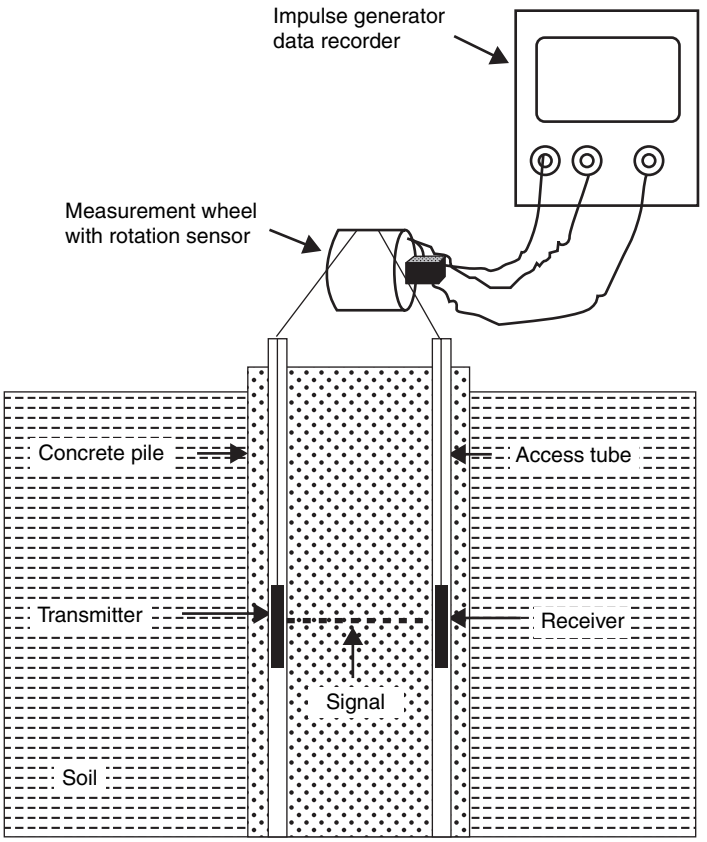

Figure 97.22 Schematic of cross-hole sonic logging system
Reproduced from Hertlein and Davis (2006), John Wiley

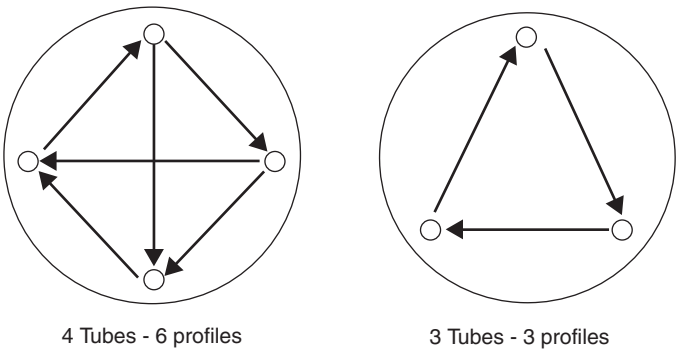

Figure 97.23 Plan view of cross-hole sonic logging access tube configuration

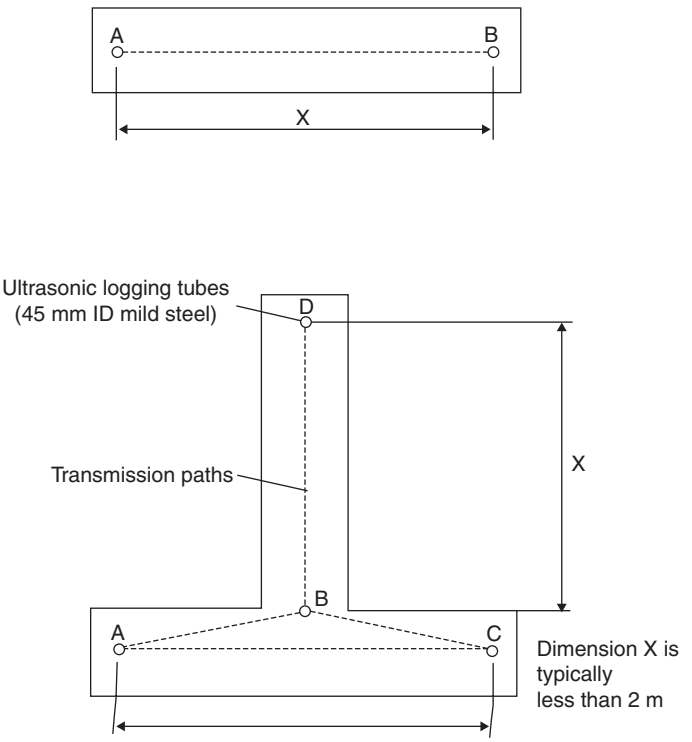

Figure 97.24 Plan view of sonic logging ducts within diaphragm wall panels
Reproduced from Stain and Johns (1987), Deep Foundations Institute

continuous profile of the transit time and characteristics of the wave-train generated by each pulse is built up at successive levels in the pile.

97.5.2 Description of the technique

Cross-hole sonic logging is usually used on piles with a diameter of 600 mm or greater. Steel or, less usually, plastic access tubes are cast into the pile during the construction phase. However, plastic tubes can often suffer from debonding from the concrete, rendering the test ineffective. Hence steel tubes are preferred in most cases. They are typically attached to the inside of the reinforcing cage over the full length of the pile and extend above ground level by approximately 500 mm. A minimum of three tubes are used, usually increasing to a minimum of four for pile diameters of 750 mm or more. The tubes are usually equispaced around the circumference of the reinforcing cage to provide a minimum of three longitudinal 'profiles' of the concrete between the tubes for a three-tube configuration, and up to six for a four-tube configuration as illustrated in **Figure 97.23**. The steel tubes are generally approximately 40 mm in internal diameter to facilitate the passage of transmitter and receiver transducers.

Prior to the test, the tubes are filled with clean water to act as a coupling medium for the transducers.

The technique is also suitable for use in diaphragm wall panels or barettes. A typical layout of ducts within diaphragm wall panels is illustrated in **Figure 97.24**.

The transit time (t) of the wave-train from each pulse is a function of the distance between the tubes (L) and the propagation velocity (c) of the concrete between the piles. In turn, the propagation velocity of the pulse is a function of the modulus, E, density, ρ, and Poisson's ratio, ν, of the pile concrete. Hence

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

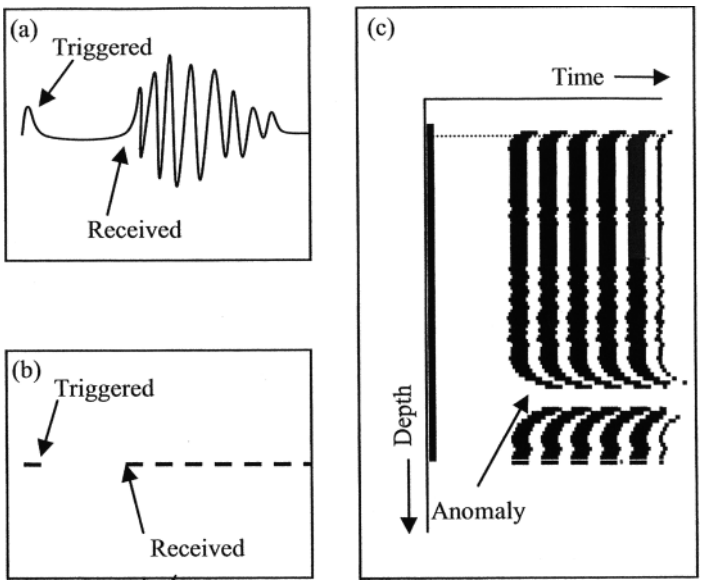

Figure 97.25 Compilation of a cross-hole sonic logging plot: (a) Original single pulse; (b) Pulse data modulated to form a single positive/negative dashed line; (c) Modulated pulses stacked to form the complete 'waterfall' plot

Reproduced from Hertlein and Davis (2006), John Wiley

anomalies within the pile, such as voids, soil inclusions or low-modulus concrete, would be expected to give an increase in the transit time: provided that the access tubes remain at a constant relative position apart (i.e. L remains constant). In addition, if the anomaly was caused by voided or poorly compacted material, for instance, this might also lead to an attenuation of the signal.

The two probes (transmitter and receiver) are slowly raised up the tubes, and a reading is taken every 20 mm. Each received ultrasonic pulse is collected and the wave-train would have the form illustrated in **Figure 97.25(a)**.

With the system developed by CEBTP, each received ultrasonic pulse is processed by the data acquisition system so that each 'positive' peak of the wave-train is printed as a black line with a width matching that of the original peak; conversely each 'negative' trough is printed as a gap. Hence a dashed line is created as illustrated in **Figure 97.25(b)**, which contains all of the timing and much of the amplitude information of the original record. Each consecutive pulse is printed contiguously to form a vertical profile of the data for that particular pair of tubes, as illustrated in **Figure 97.25(c)**. This profile is often known as a 'waterfall plot' or a 'sonic profile'. In this way any changes in transit time can readily be distinguished from the mean value and identified for further investigation.

Other cross-hole sonic logging systems measure the arrival time of the first peak in the ultrasonic pulse wave-train, known as the first arrival time, or FAT, together with the overall amplitude of the early part of the pulse, as illustrated in **Figure 97.26**.

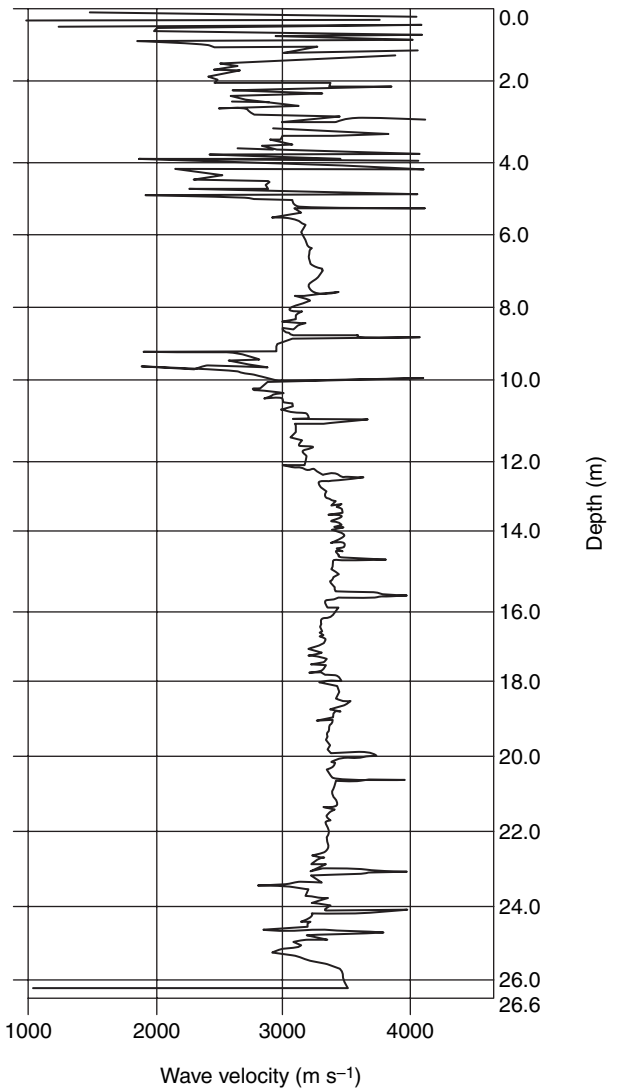

Figure 97.26 Typical FAT (first arrival time) cross-hole sonic logging plot

Reproduced from Hertlein and Davis (2006), John Wiley

Hertlein and Davis (2006) suggest that a drawback of this method is that the system has to detect the first arrival peak in a digitised wave-train, and has to be able to differentiate between background noise and the arriving signal. Thus a threshold level has to be set that eliminates the background noise, as illustrated in **Figure 97.27**. Unfortunately the signal pulse is a relatively small 'noise', and construction sites tend to be noisy. Hence if the first or second peak in the arriving wave-train falls below the threshold level, the computer will identify the 'first arrival' as the first peak that exceeds the specified threshold, be it the second, third or even later arrival.

97.5.3 The detection of defects

As noted in CIRIA 144 (1997), the test identifies the shortest acoustic path between the transmitter and receiver.

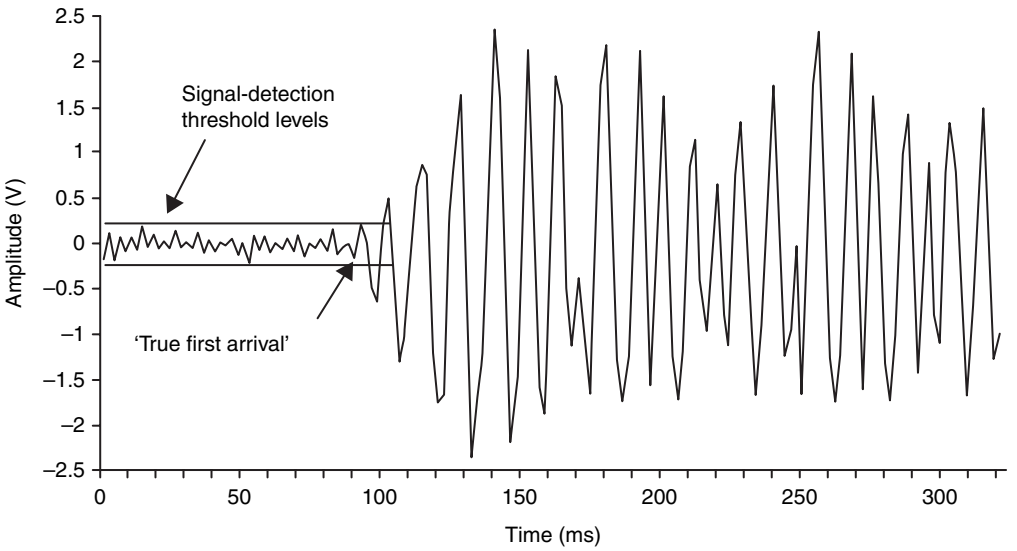

Figure 97.27 Typical cross-hole sonic logging pulse, with illustration of signal threshold levels and 'first arrival time'
Reproduced from Hertlein and Davis (2006), John Wiley

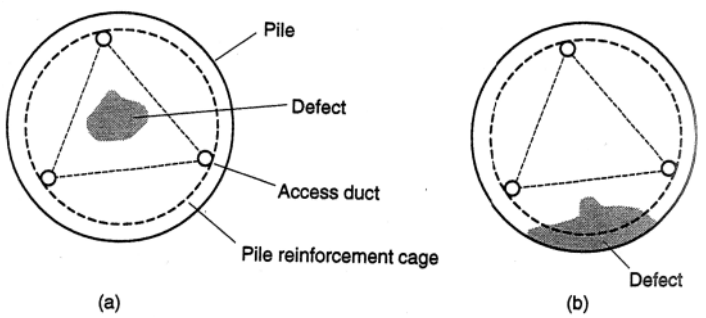

Figure 97.28 Cross-hole sonic logging. Examples of possible defects off the shortest direct path between probes: (a) defect in centre; (b) defect on perimeter
Reproduced with permission from CIRIA R144 (1997), www.ciria.org

With a three-tube system, for example, it is possible that a feature at the centre of the pile would not be detected, as illustrated in **Figure 97.28(a)**. Similarly, since the access ducts are usually attached to the pile reinforcement, a defect such as loss of concrete cover would not typically be detectable as in **Figure 97.28(b)**.

97.5.4 Features detected using the cross-hole sonic logging method

A typical test result from a defective diaphragm wall section is given in **Figure 97.29**.

Interpretation of the results is generally straightforward when signal loss increases dramatically but the threshold for what is considered to be anomalous concrete is less clear. In practice an increase in transit time of less than 10% is not considered to be significant unless all profiles are affected. If this is the case then further investigation may be required which could include coring the pile, reference to the pile construction records, test cube analysis and further clarification of axial loading and bending moments on the pile.

The association between ultrasonic propagation velocity and concrete strength has been advocated in several technical papers and an argument does exist to suggest that this may be applied to data collected from CSL data. Tube spacing is, however, an additional variable which needs to be taken into consideration. For further reading on the correlation between concrete strength and ultrasonic pulse velocity, refer to Turgut (2004).

Signal damping is often a feature of the CSL results and this may be due to debonding of the access tubes or a thin layer of contaminated concrete surrounding one or more of the tubes. Signal damping with no associated increase in transit time is not considered to be significant.

Three-dimensional computer tomography has been introduced by several equipment manufacturers since 2000. As noted by Fleming *et al*. (2009), this can model the extent and form of a defect or anomaly within the pile in 3D form by utilising and combining, for example, the six 2D profiles obtained from a four-tube layout. The vertical position of such anomalies, together with the significance of relative increases in transit time between adjacent pairs of tubes is colour-weighted to produce a 3D colour-coded graphical representation of the pile and help visualise the potential anomalies.

The nature of these anomalies and their structural significance is, however, still subject to the analysis and interpretation of the test specialist. An example of computer tomography is presented in **Figure 97.30**.

97.5.5 The specification of CSL

Similar consideration to those highlighted in section 97.4.8 for low-strain integrity testing would also apply to the specification of CSL testing. Again, the ICE's (2007) SPERW document, and both Turner (1997) and Hertlein and Davis (2006) provide guidance on this issue. The latter document also references the French AFNOR and US ASTM D6760 standards.

In a similar manner to that proposed for low-strain testing, Hertlein and Davis (2006) suggest that the person responsible

for analysis and reporting on the CSL test data should be able to demonstrate a minimum of, say, five years' experience in CSL testing, with at least three CSL projects in each of those years. Similarly they recommend that field personnel responsible for performing or supervising the performance of the CSL test shall be able to demonstrate at least two years' experience with CSL testing, with a minimum of three projects in each of those years

Hertlein and Davis also recommend that the text of the CSL report should include a description of any anomalous zones identified by the test data and a discussion of the apparent difference in pulse velocity. Account should be taken of the sources of possible variation. One particular point that is highlighted is that when assessing the likely significance of an anomaly, any available information concerning test strengths or other actual measurements of concrete properties should be included in the report. These authors highlight that it is not unusual for actual concrete strength to significantly exceed the design strength, in which case the concrete in an anomaly that shows a 15–20% reduction in pulse velocity may still meet or exceed project specifications.

With regard to the review and acceptance/rejection of the piles, a time period (typically three working days) should be specified for the engineer to evaluate the CSL report and determine whether or not the tested piles are acceptable. If the pile is not acceptable, the engineer should decide what additional testing, investigation or analysis is necessary in order to properly characterise the anomaly and determine whether or not the pile needs any repair or remediation. In such an eventuality the repair technique to provide satisfactory remediation must be proposed and agreed between the parties.

97.6 Parallel seismic testing

The parallel seismic test was developed to address the problem of assessing pile integrity once the pile under investigation had been incorporated into the foundation system. This might be as a result of proposed re-use of the foundation or to augment quality control on a construction project after the option for more normal testing has passed.

The test involves installing an access tube adjacent to the pile to a depth exceeding the expected depth of the pile toe level. The tube can either be plastic or steel and, if it is not in intimate contact with the soil, it must be grouted in place to form a good acoustic coupling with the surrounding soils. Prior to the test, the tube is filled with water: again to ensure an acoustic coupling. The arrangements for the test are illustrated in **Figure 97.31.**

The principle of the test is to measure the time taken for a stress wave to travel from the structure to a receiver probe as it is lowered down the access tube. This is achieved by striking the structure adjacent to the pile with a small hand-held hammer and recording the transit time of the resultant stress wave. The test is repeated by lowering the probe incrementally (usually in steps of 500 mm) and recording the transit time for the impact-induced stress wave. A graph of probe depth versus

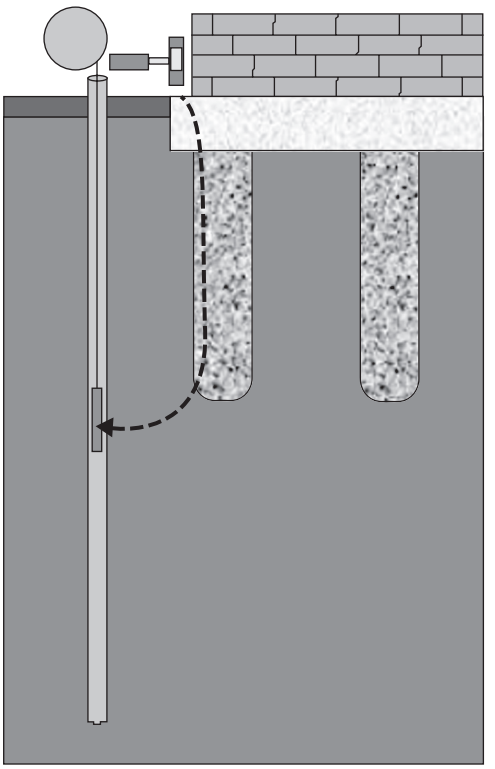

Figure 97.31 Arrangements for parallel seismic test
Courtesy of Testconsult Limited

first arrival time is built up from the data series as shown in **Figure 97.32**.

The test utilises the fact that the propagation velocity of the stress wave through soil is considerably lower than through concrete or steel. As the probe passes the toe of the pile, or a defect such as a discontinuity in the pile shaft, the path length of the stress wave will be increasingly through the soil, and the transit time will correspondingly increase at a greater rate, as indicated in **Figure 97.32**. A change in gradient of the first arrival time at the probe depth should therefore indicate the base of the pile (or, alternatively, of course, it could be indicative of a discontinuity in the pile shaft).

97.6.1 Limitations

A limitation of the test is that a borehole must be drilled alongside the pile to provide a duct for the receiver. This needs to be sensibly parallel to the pile (usually vertical) and typically within one metre of the pile under test. The method is ineffective in dry or loose granular material or unconsolidated fill.

The impact point on the structure for the test hammer must have a good mechanical coupling to the top of the foundation and be as close as possible to the axis of the pile.

97.7 High-strain integrity testing

High strain dynamic load testing is described in Chapter 98 *Pile capacity testing* of this manual. Incidental to predictions of the

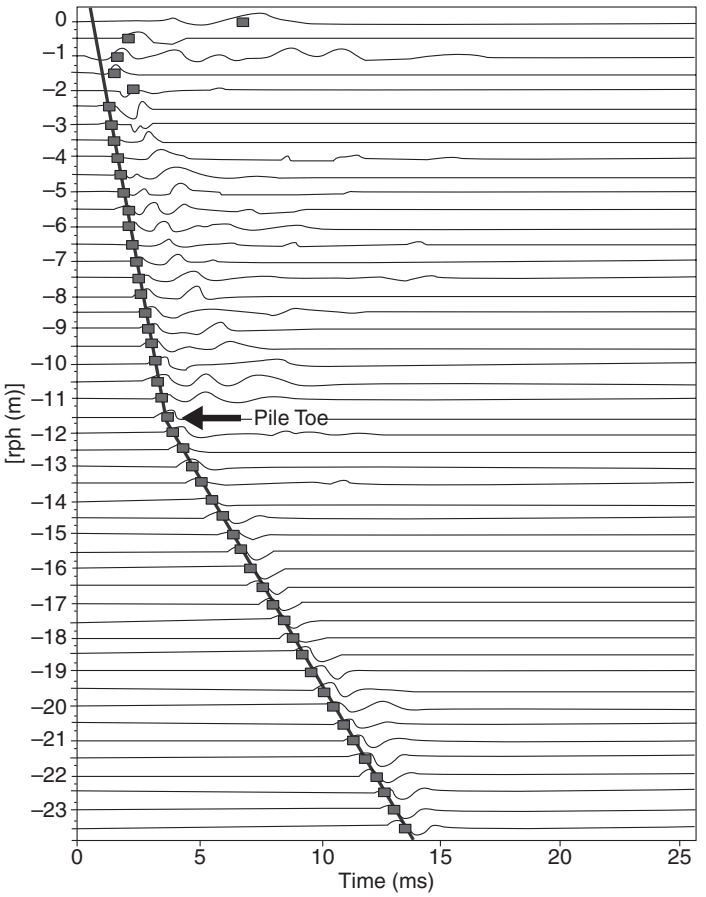

Figure 97.32 Typical parallel seismic test result
Courtesy of Testconsult Limited

load-carrying capacity of the pile is the possibility of detecting significant flaws in the pile which may be as a result of overdriving, or construction defects in the case of a cast *in situ* pile.

The dynamic load test (DLT) involves instrumenting the pile head with strain gauges and accelerometers to measure both upward and downward forces in the pile shaft. The raw data from the instrumentation take the form of total force (F) from the strain gauges (F = strain × cross-sectional area × Young's modulus) and force measured by the processed accelerometer data (F = pile impedance, Z, times pile head velocity, V). If these two sets of data are plotted on the same graph, as illustrated in **Figure 97.33**, any divergence between the two data series will be as a result of changes in pile support from the surrounding ground or the impedance of the pile. In the example shown in **Figure 97.33** the divergence is shown as an increase in force derived from strain measurements (F_t) and a decrease in force based upon velocity measurements (Z.v). This has been generated as a result of shaft skin friction.

If the pile shaft has been damaged due to overdriving or constructed with a shaft defect then this will present itself as

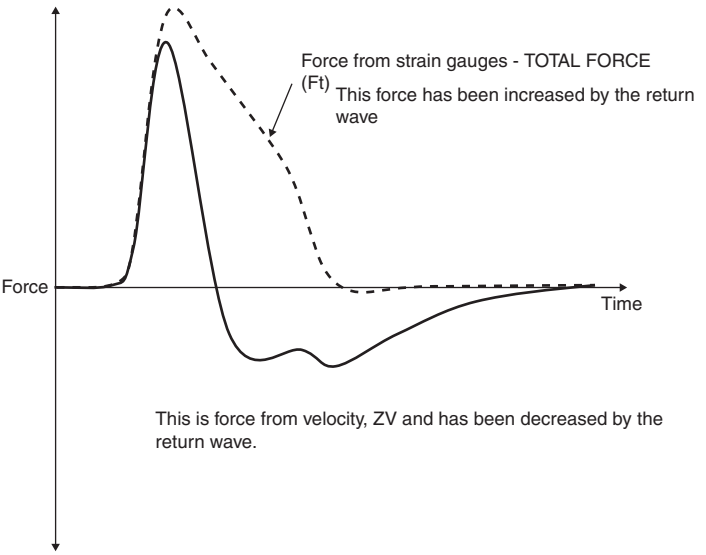

Figure 97.33 Force diagram from dynamic load test

a decrease in the F_t force and a corresponding increase in Z.v force at the point on the timescale representing the depth to the anomaly.

97.7.1 Features detected using high-strain dynamic load testing

The detection of pile defects using the high-strain DLT should be considered a by-product of the load test and should not be relied upon as the principal method for confirming pile integrity. The reason for this is that the duration of the hammer impact overlaps any return signal from defects close to the pile head, effectively masking them. In addition, if a defect is limited to a partial reduction in section as may be the case with a bored cast *in situ* pile, the stress wave will pass the anomaly and continue towards the pile toe. The partial returning signal under these circumstances may be mistakenly identified as a change in soil characteristics at the indicated depth.

This method is, however, useful in identifying damage to pre-cast driven piles which may be due to overdriving. A crack or fracture along the shaft and in particular close to the pile toe will exhibit a recognisable change in both total force and Z.v data. CIRIA 144 (1997) provides further information on interpretation and limitations of this method.

97.8 The reliability of pile integrity testing

97.8.1 Introduction

The reliability and even 'trustworthiness' of integrity testing as a quality control (QC) or quality assurance (QA) tool is a question that constantly arises within any discussion or dispute on the results being found on a particular site. Such a question is linked not only to the ability or reliability of the test method to detect an anomaly or defect within the pile or group of piles, but also to the issue of whether, as discussed in section 97.3.2,

such an 'anomaly' represents a 'defect', and whether such a defect could be

- minor, and not significant to the performance of the pile (a 'flaw' as described by Amir, 2001; see section 97.3.2 above), or
- major, and potentially detrimental to the pile (a true 'defect' according to Amir, 2001).

In the latter case, such a defect could lead to the rejection of a particular pile, or its acceptance at a reduced load or after some agreed secondary repair or investigations.

The following section reviews the implications of the 'reliability' of an integrity test method, and how this is linked to the question of how large a percentage of the total pile population should be tested to provide an acceptable level of assurance of the adequacy of the piled foundations. It also discusses the corresponding implications of providing for a degree of redundancy within the foundation design.

The planning and implementation of a test programme should also to take into account how many unacceptable defects might, on average, and on past experience, be anticipated within the pile population installed at a particular site, and this is also reviewed in this section.

97.8.2 Considerations on the reliability of the test

As highlighted by Cameron and Chapman (2004) the methods of integrity testing are not infallible. An erroneous classification of the quality or characteristics of a pile by an inaccurate integrity test, or an inaccurate interpretation of the test result, can lead to a defective pile not being detected (a false-negative result) and consequently incorporated into the foundation system. Alternatively, it could lead to a sound pile being wrongly condemned (a false-positive result) and subjected to unnecessary inspection or remediation work, or even rejection and replacement.

Hertlein and Davis (2006) identify the following 'links' in the chain of reliability for low-strain integrity testing methods:

(1) adequacy of pile head preparation for the pile head sensor, including trimming the pile to its test level;

(2) correct and recent calibration of load cells and sensors;

(3) suitable data acquisition, signal filtering and processing systems;

(4) trained and experienced site operatives;

(5) the degree of signal damping of the signal response: high length/diameter (l/d) ratios, stiff confining soils, and bulges in the upper portion of the shaft all cause high signal damping;

(6) the presence or absence of multiple anomalies down the pile length (where an anomaly can be a bulge, a neck, cracking, honeycombing or soil/laitance inclusions);

(7) the experience of the testing engineer in test data interpretation (the 'personal' component).

They suggest that these factors can be combined into a 'lumped' reliability model.

It can be appreciated that the breakdown of a single component in this model can throw the reliability of the system into question. Problems with links (1) to (4) can be improved by the test organisation and the site management. Problems associated with links (5) to (7) can minimised by improvements in both the testing hardware and software. Of particular note is the use of equipment capable of improved data analysis, using methods such as the impedance-log analysis described above.

Hertlein and Davis suggest that the present state-of-the-art test methods are very reliable if:

(1) l/d ratios are less than 30:1 in relatively soft soils;

(2) when significant defects are limited to the upper two thirds of the pile length.

Conversely, reliability decreases rapidly with:

(1) high l/d ratios in 'stiff' soils; and

(2) when defects are in the bottom third of the shaft; or

(3) there are multiple defects.

Further insight into these features has been given in the preceding text or can be seen in Hertlein and Davis (2006).

For cross-hole sonic logging the 'chain of reliability' can be identified as:

(1) the quality of the bond between the access tubes and the surrounding concrete;

(2) trained and experienced site operatives;

(3) distance between access tubes;

(4) number of tubes per unit area of shaft cross-section;

(5) distance of perimeter access tubes from the perimeter of the pile;

(6) experience of the testing engineer in the interpretation of test data (personal factor).

Item (2) was considered less important by Hertlein and Davies, but, as noted in CIRIA 144 (1997), cross-hole testing is also reliant upon the field expertise of the site operative: particularly if there is a need to examine an anomaly in greater detail.

97.8.3 The frequency of occurrence of potential flaws or defects within piles.

Cameron and Chapman (2004) reviewed the frequency of defective bored piles identified by low-strain integrity testing, as published in the technical literature. This review noted that within six published papers a range of 1.5–10% of such tests identified piles as being defective, or perhaps more strictly, potentially defective. One of these references, Fleming *et al.* (2009), which covered UK practice, reviewed the results of

time-based 'sonic echo'-type pile integrity testing undertaken in 1981 and 1982. The data suggested that defects were identified in between 1.5% and 1.9% of piles tested (on total numbers of piles tested of between 5000 and 4550 piles per year). Of these, the percentage due to pile construction defects was recorded at 0.4–0.6%. The balance, amounting to 60–80% of the defects detected by the test, was due to damage after the construction of the pile.

A further reference was Ellway (1987), who reported on the results of frequency-based integrity testing in the UK on some 4400 small diameter bored piles in 1985. He suggested that just over 4% of the piles showed signs of 'potentially significant structural faults'. Some one third of these were attributed to post-construction damage from mechanical plant or pile trimming techniques. A further third were due to weak or contaminated concrete within the upper 2 metres of the pile. The remaining third (1.4% of the piles) suggested evidence of soil contamination or loss of section below 2 m.

These two sets of data are now over 25 years old, and it appears to be the general view of the industry that the quality of pile construction has improved greatly since that time: particularly in the case of continuous flight auger (CFA) piles. The improvement in construction quality in the latter technique is largely driven by the now widespread use of instrumentation to monitor and record the pile construction process. The development of these systems also enabled users to better understand and gave a greater insight into the pile construction process.

Taking these factors into account, the available data probably suggest that perhaps 0.5–1.0% of bored cast-in-place piles might be expected to display imperfections within their acoustical response which *might* have some structural significance to the load-carrying capacity or durability of the pile. Although this is a relatively low frequency, the implication is still that, on a site containing a large number of piles, it is to be expected that some piles will be identified as requiring further engineering investigation and evaluation.

97.8.4 How many piles to test?

When electing to use low-strain integrity testing on a particular site it is necessary to also consider what should be the minimum number of tests to be undertaken on the piles. A difficulty is that defects or problems with piles are not always randomly distributed, but might be associated with more difficult ground conditions in a part of the site, or the poor workmanship of a particular rig operative, or some other factor.

CIRIA 144 (1997) suggested that it was the considered view of most practitioners that a statistical approach was often difficult to apply in practice. Hence the decision on whether to test or not on a particular site had to take account of all the circumstances at the site, such as the availability of other construction records or data, the consistency or variability of the ground conditions across the site, and the type of pile and piling systems. As a general recommendation, CIRIA 144 (1997) suggests that, in situations where low-strain integrity testing is considered to be worth doing, all the piles on the site or in a particular area of concern should be tested. However, if the picture emerging from the test results was sufficiently consistent, the designer might consider reducing the number of tests. At the same time, if no meaningful information was being obtained from the tests, the designer might choose to dispense with the testing. This advice was intended to highlight that the designer and the project team should be able to make informed decisions on the applicability and/or usefulness of the testing on a particular site, and to modify the test programme if this was considered appropriate.

Williams and Stain (1987) outlined a testing strategy or 'decision tree', as illustrated in **Figure 97.34**, that also served to give pragmatic guidance on 'when', and 'how many', to test. This suggested, as a guide, that a minimum of around 30 tests would give a useful guide to the condition of the piles on a site.

Cameron and Chapman (2004) have given further consideration to the statistical approaches that may be adopted in selecting the number of piles that should be tested to achieve pre-determined acceptable confidence limits. Such methods require an estimate of whether a percentage of defective piles can be tolerated within the foundation (in the case of a piled raft foundation, for example). Importantly, these authors also included within their review a consideration of the reliability of the testing system.

Clearly, the options available when planning an integrity testing programme are to examine all of the piles or none of them, or a selected sample. Cameron and Chapman (2004) give particular attention to the last option, where conventional sampling theory can allow conclusions to be drawn about the pile population on a particular site, based upon testing a sample of the piles. These authors also highlight the effects of planning the foundation design based upon a degree of redundancy within the overall foundation design. They compare the relative advantages and disadvantages of using either single piles or multiple piles in groups to support individual loads. In the former case, the occurrence of defects is clearly more critical to the structural performance of the foundation (**Figure 97.35**). A similar consideration would apply to piles constructed on strip or grid formations, as illustrated in **Figure 97.36**. Thus, if the interconnecting ground beams are capable of spanning to transfer the reduction in capacity within a structure due to a potentially faulty or unacceptable pile onto the adjacent piles, then such a robust foundation solution may justify a reduced integrity testing regime. At the least it can allow a reasoned view to be taken of the effect of such a predicted shortfall of capacity.

Cameron and Chapman (2004) also point out that such a comparative exercise can often highlight the perceived relative costs and savings of using single piles to support individual high column loads, compared with a notionally more expensive solution using multiple piles, providing a relatively high degree of redundancy. In the former case, the consequential programme

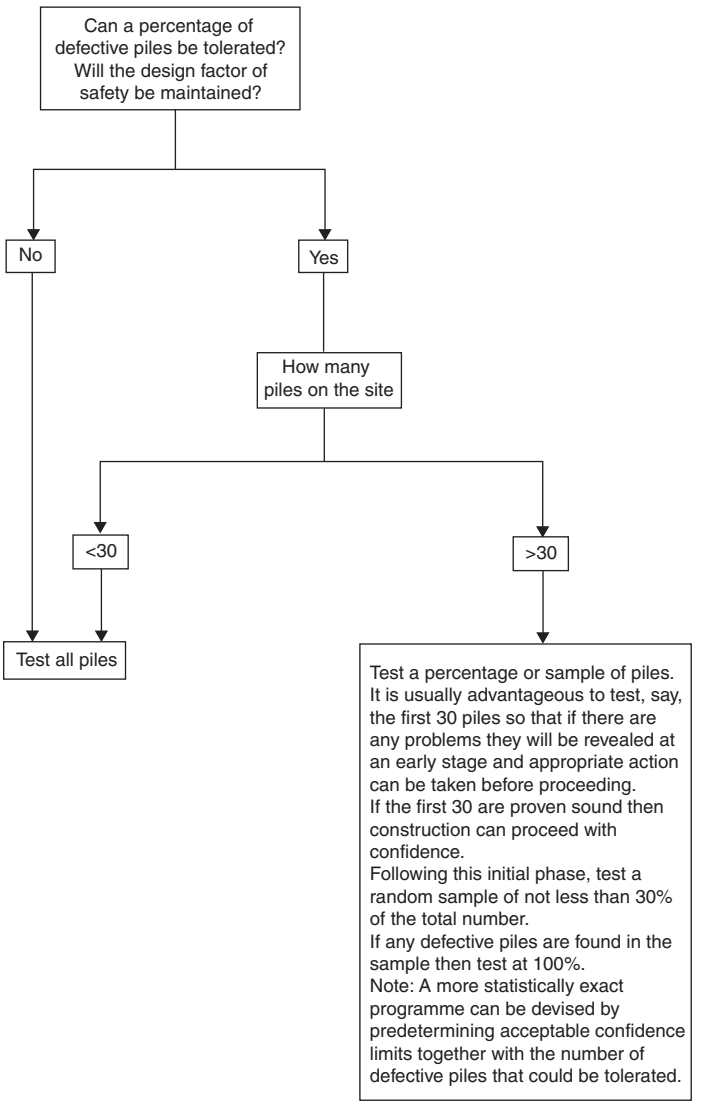

Figure 97.34 Evaluation of numbers of piles to test on a site
Reproduced from Williams and Stain (1987), Engineering Technics Press

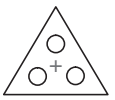
risks of the failure or rejection of such a pile, including delays from re-testing or repairing such a pile, have to be considered. It is often not appreciated how, on a major, fast-track project, the overall costs of the piled foundations are often small compared with overall project and programme costs.

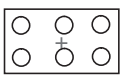
As noted earlier, however, if the reliability of the integrity testing system is also factored into the picture, then, even with 100% testing, it is not possible to be 100% certain that all the piles are defect-free.

Cameron and Chapman highlight a statistical approach developed by Preiss and Shapiro (1979) which gave quantitative guidance on the level of testing necessary to achieve a required degree of 'assurance' in the foundations. **Figure 97.37** shows the relationship between sample size, the percentage of defective piles which are acceptable within the pile population on that particular site and the statistical implications of the number of defective piles detected in the test sample.

As an example, consider that the foundation designer requires a confidence level of at least 90% that there will be less than a certain number of 'defective' piles among both the tested and non-tested piles in the population. Consider that 10% of the piles might be allowed to be defective. In such a case, from **Figure 97.37**:

- If 20% of the piles are tested and no defective piles are detected, then the 90% confidence limit is satisfied.
- If, however, one defective pile is identified, then 31% of the piles must be tested, with no further 'defectives'.
- If two defective piles are detected, the sample must be increased to over 40% of the piles, with no further 'defectives'.
- If five defective piles were detected the sample size would again need to increase: to around 70% of the piles.





The exercise would clearly continue until either the number of tested piles, the sample size, and the number of defective piles identified within the sample size complied with the required degree of confidence, or all the piles had been tested.

However, Cameron and Chapman also highlight a further complication in the Preiss and Shapiro analysis: it is based upon the test being 100% accurate. If the reliability of the test is less than 100%, then this, of course, affects the confidence level of an accurate prediction. If a system was only 80% reliable, then even testing all the piles would not give an overall confidence level in the test results of higher than 80%.

The practical outcome from a less reliable test is that a greater number of false-positive, false-negative or 'inconclusive' results are likely to be obtained, which might have to be followed up by some other examination or review – such as coring the pile, or excavating alongside it to determine its true condition.

As an example, **Figure 97.38** illustrates the increase in confidence gained for every additional 10% of piles which are integrity tested within a pile population, using a test system which has an 80% 'reliability'. In this case the results are shown for a foundation system that can tolerate between 0% and 4% of defective piles. **Figure 97.38** illustrates that, where the foundation system can tolerate up to 4% of defective piles, the greatest benefit comes from the initial tests on the pile population. However, where the foundation system cannot tolerate any defective piles, then the full benefit only comes when testing the last 20% or so of the piles. Hence, the greater the reliance on each individual pile within the pile population, the more important it is to check the integrity of every single pile.

It should be borne in mind that, although statistically in most practical cases the most important piles are the first 20–40% of those tested, these do not necessarily equate to the first piles installed on the project. The sample must be representative of the whole population, and not skewed in some way: by different ground conditions, different piling operatives or equipment, or other considerations. This has particular relevance where there

	Non-redundant	Working load is equal to failure load Extremely unsafe with potentially very large settlements	Total loss of pile capacity Ultimate failure
	Non-redundant	Deficient pile on the verge of failure Very unsafe	Failure is likely
	Non-redundant	Just sufficient capacity to avoid failure by much tilting	Failure still likely as centre of support offset from centre of load
	Logically non-redundant	Support reduced to two piles providing full and two piles providing half support. Likely to be extra settlement and reduced factor safety	Support reduced to just two piles Factor of safety equals 1.0, therefore stability is marginal
	Clearly redundant	Minimal effect	Support reduced to potentially three or four piles, depending on location of deficient pile. Lowered factor of safety but performance may be adequate
	Clearly redundant	Minimal effect	Minimal effect

Legend: ○ Pile ▭ Pilecap + Position of column load

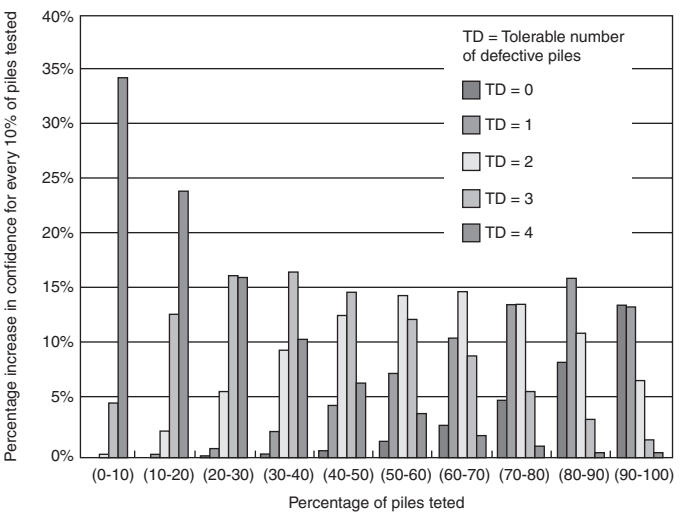

Figure 97.38 Additional increase in confidence by testing each additional 10% of the pile population, using a test system with an 80% reliability
Reproduced from Cameron and Chapman (2004)

is particular pressure in terms of cost and programme to omit some piles from testing.

Cameron and Chapman point out that in some cases the added value of testing the last piles (**Figure 97.38**) could be judged to not be worth the time and consequential cost. **Figure 97.38** also demonstrates that such an omission may be possible only if the tolerable proportion of defective piles is high. Hence there would be programme advantages in selecting a more redundant foundation system.

97.9 Selection of a suitable test method

Table 97.3 summarises the features of the four integrity test techniques outlined in this chapter.

For each technique the table outlines the property measured by the test, details of any pre-planning requirements, and the type of pile suited to the test.

In addition, the table gives a guide to the approximate relative cost of the particular test, its availability and its relative frequency of use. Any other relevant points are noted in a c omments section.

Test method	Low-strain integrity tests	Cross-hole sonic logging	Parallel seismic tests	High-strain integrity tests
Property measured	Characteristics of the behaviour of acoustic shock waves or stress waves travelling through the pile	Transmission time of an ultrasonic wave through the pile material	Transmission time of acoustic shock waves or stress waves through the pile and intervening soil to a detector	Characteristics of the behaviour of stress waves travelling through the pile from a heavy impact
Pre-planning required?	None	Access ducts have to be cast into preselected piles	Sinking of measurement bore alongside pile	Not strictly necessary, but access for heavy plant may have to be provided
When can test be carried out?	After concrete has achieved design strength (usually 5–7 days min.)	After concrete has achieved design strength (usually 5–7 days min.)	After construction	After concrete has achieved design strength and typically 7 days min. after construction
Type of pile suited to test method	All types	Large diameter cast-in-place typically (usually 600 mm diameter or larger)	Any pile	All types
Approximate relative cost	Low	Low to medium	Medium to very high	Medium to high
Relative frequency of use:				
Control testing	5	4–5	Not applicable	1–2
Retrospective investigation	3–5	Not applicable	0–1	1–2
Availability	Readily available from specialist testing houses	Available from specialist testing houses	From specialist testing houses	Readily available from piling contractor and specialist test house
Test affected by pile length?	Yes, signals increasingly attenuated with depth	No	Yes	No, not within normal pile depth
Comments	Very common technique. Pile response is investigated in terms of time and/or frequency	Mainly used for large diameter cast-in-place piles, piers and barettes. Especially large single piles supporting high column loads. Not usually suitable for retrospective investigation because of necessity to install access ducts	Used for retrospective investigation only	Not commonly used in routine testing. Typically may be used to investigate a post-installation problem, such as pile damage

Key to symbols:
Relative frequency of use: Scale 0 to 5: 0: very rare. 1: rare 2: occasional 3: sometimes 4: common 5: very common
Approximate relative cost: Scale Low–Very high: Low <10% of pile cost. Medium: 10–50% of pile cost. High: 50–100%. Very high: >100% of pile cost
Note: relative cost excludes mobilisation costs.

Chapter 98

Pile capacity testing

Michael Brown University of Dundee, UK

As there is still uncertainty in accurately predicting the performance of piled foundations based upon design calculations there remains a need to test piles. Several methods of pile testing are available some of which have been in common usage for many years, while others are relatively recent developments. Static pile testing is a well understood and simple test technique that has been in use for many years. This approach has the benefit of directly producing test results but is hindered by the increasing size of associated testing infrastructure as pile capacity increases. A recent variation of classic top-down static testing is bi-directional testing which relies on the incorporation of a specialised loading jack or jacks in the pile shaft at some depth below ground surface. This technique has the ability to apply test loads that greatly exceed those possible in other pile test types. Alternative pile testing techniques come in the form of rapid and dynamic load tests that have the benefit of quick testing and reduced testing infrastructure but require more complicated analysis and interpretation techniques due to the rapid/dynamic nature of the tests.

98.1 An introduction to pile testing

Although pile design has advanced in recent decades, the determination of axial pile capacity is still dependent on the use of empirical correlations. As a result, it is only possible to estimate capacity to ±30% in many soil types (Randolph, 2003). Owing to the uncertainty associated with predicting load-settlement behaviour using existing design methods, it is common practice to carry out pile load tests for verification.

The information obtained from pile load testing may be used in a number of ways (Poulos, 2000) including:

- construction and quality verification;
- verification of design information;
- to allow for a more refined or confident design with potential cost savings for subsequent piling works.

As pile testing may prove expensive (especially on small contracts), the need for pile testing may be considered in terms of risk reduction. On larger sites, where significant numbers of piles are being installed, pile testing may be considered from a perspective of potential cost saving. Through testing, improved design parameters may be determined resulting in optimisation of the piles through a reduction in length, for example. The pile testing strategy recommended by the *ICE Specification for Piles and Embedded Retaining Walls* (2007) (often referred to as SPERW) is shown in **Table 98.1**.

Eurocode 7 allows pile design based upon a pile load test(s) and states that pile tests should be undertaken in the high- to medium-risk situations highlighted in **Table 98.1**. Eurocode 7 also allows the characteristic resistance of axially loaded piles to be derived directly from pile load tests with the level of correlation increasing with increasing number of piles tests (from one to five). For five pile tests or more direct correlation is allowed with the measured test results which in turn are reduced by a partial factor to obtain the design resistance (see British Standards Institution, 2004, EC7, for further detail). This prescriptive approach to factoring may be considered an improvement over the *ad hoc* manner in which pile load tests have previously been used to influence safety factors. Further information, with respect to pile testing as part of the Eurocode framework, is available in BS EN1536, *Special Geotechnical Works: Bored Piles* and in the future through EN/ISO 22477-1, *Geotechnical Investigation and Testing: Testing of Geotechnical Structures – Part 1: Pile Load Test by Static Axially Loaded Compression* (currently in draft form). Piles may be tested at different stages throughout a project depending on how the outcome of the test will be used. For instance, preliminary or trial piles are tested prior to the main works or pre-contract and are designed to validate design and achievable performance along with checking construction techniques in certain ground types. It is important that preliminary piles are tested sufficiently in advance of the main works such that findings from the tests can be incorporated in working pile designs. Piles tested that will form part of the final structure are referred to as working piles.

As well as the stage of the project at which piles should be tested, it is also important to consider the time after installation at which piles should be tested. For instance, driven or displacement piles installed in clay cause significant disturbance of the ground. This results in changes to the local effective stress regime which with time equalise depending on the soil's permeability and the size of the pile. For instance, SPERW (2007) suggests a minimum of four days between installation and testing of any pile type, although it does go on to say that a 12 hour delay between installation and testing is adequate for driven piles installed in coarse-grained soils. In contrast, Fleming *et al*. (2009) suggest 1 to 3 weeks between installation and testing depending on soil type and experience.

Pile load testing methods include static tests, dynamic tests and kinematic or rapid load tests. There are also alternative static load test methods such as bi-directional testing in the form of the Osterberg Cell (O-Cell). Generally, static pile testing methods are expensive and time consuming (Fleming *et al*., 2009) becoming more so with increased load requirements, but have the advantage of simple analysis and interpretation. Conversely, dynamic and rapid load testing methods are quick to carry out and become cheaper than static tests with increased load requirements but require more specialised equipment and analysis. Comparisons of some of the typical pile test characterisitics are shown in **Table 98.2**. Note that this table is based upon current typical approaches to testing and does not dictate use of the techniques; for instance, dynamic tests may be undertaken on cast *in situ* piles but this may not be a frequent occurrence.

98.2 Static pile testing

98.2.1 What is static pile testing and what types of test are there?

The most common method of pile load testing, static testing, may take one of two forms. These are the maintained load test (MLT) and the constant rate of penetration test (CRP). The names of the two tests are derived from their methodology. Since the invention of tests such as the O-Cell method, these types of testing are often referred

Characteristics of the piling works	Risk level	Pile testing strategy
Complex or unknown ground conditions	High	Both preliminary and working pile tests essential
No previous pile test data		1 preliminary pile test per 250 piles
New piling technique or very limited relevant experience		1 working pile test per 100 piles
Consistent ground conditions	Medium	Pile tests essential
No previous pile test data		Either preliminary and/or working pile tests can be used
Limited experience of piling in similar ground		1 preliminary pile test per 500 piles
		1 working pile test per 100 piles
Previous pile test data available	Low	Pile tests not essential
Extensive experience of piling in similar ground		If using pile tests either preliminary and/or working pile tests can be used
		1 preliminary pile test per 500 piles
		1 working pile test per 100 piles

Table 98.1 Typical pile testing strategy based upon risk levels
Reproduced from Institution of Civil Engineers (2007) (SPERW, 2007)

	Type of pile test		
Characteristic	**Static[1]**	**Rapid**	**Dynamic**
Load duration	1–24 hours	100 milliseconds	7 milliseconds
Tests per day	1	2–6	8
Reaction mass required (as a percentage of pile capacity)	120%	5–10%	1.5–2%
Time needed for results	Directly	10 minutes	4 hours
Pile types tested			
precast	yes	yes	yes
cast *in situ*	yes	yes	yes
tubular steel	yes	yes	yes
Perceived reliability	high	experience too limited to assess	intermediate
Cost[2] (Pounds per kN of pile capacity)	0.42–0.75	0.45	0.05–0.1
Cost per pile	850–1500	400	50–200

(1) Static definition here does not include O-Cell (top-down).
(2) Based upon testing at 1000–2000 kN capacity piles on the same site, note dynamic test costs assume a pile driving rig is present on site. Costs given in GB pounds.

Table 98.2 Comparison of typical features of pile testing techniques

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

to as top-down as the loading is applied at the head of the pile.

98.2.2 Maintained load compression test (ML or MLT)

This type of test is often referred to using the acronyms ML or MLT. ML testing works by applying and maintaining increments of load to the head of the pile for a minimum specified time (**Table 98.3**) and until a specified rate of settlement criterion is satisfied (**Table 98.4**), at which point the load is either increased or reduced (Tomlinson and Woodward, 2008). The minimum time for holding of an increment typically varies from 30 minutes to 6 hours, with unloading increments typically held for 10 minutes. An example of the pile response seen during an ML test is shown in **Figure 98.1**.

Generally, this test method is not used to prove the pile ultimate load capacity or generate 'plunge' as it is difficult to maintain constant load at high settlement rates. Additionally, it is typical to increase the pile load in 25% increments (**Table 98.3**) of the working design verification load (DVL, see definition in **Table 98.3** and specification section later), which may mean the application of many hundreds of kN's between load increments. It is then possible for the actual ultimate load to be missed resulting in an underestimation of ultimate capacity as the pile plunges at a higher load increment. To avoid the underestimation, the load increment may be reduced to 10% DVL throughout the test or when load stability issues occur as is recommended for testing of preliminary piles (SPERW, 2007).

98.2.3 Constant rate of penetration testing (CRP)

The CRP test varies from the ML test in that a varying load is applied to the pile to maintain a constant rate of penetration. The rate of penetration is typically chosen to reflect the main soil type that the pile installation encounters (**Table 98.5**). Due to these penetration rates, tests are completed relatively quickly. For instance, a 600 mm diameter pile installed in clay pile can be taken to a penetration equal to 15% of the pile diameter (90 mm) in 2.5 hours. It can be seen in **Table 98.5** that the rates used for CRP in US practice may be 50% slower or faster than those specified for UK use. It should also be noted when comparing tests or correlations from the US that there is also a different ML test referred to as the quick load test method (QLT) where load increments are only held for 2.5 minutes (ASTM D1143–81:1994).

The CRP test is not considered appropriate for most testing situations and is typically reserved for research purposes. Although testing is faster, it may require greater capacity from

Load*	Minimum time of holding load for a single-cycle pile test	Minimum time of holding for a multi-cyclic pile test
25% DVL	30 minutes	30 minutes
50% DVL	30 minutes	30 minutes
75% DVL	30 minutes	30 minutes
100% DVL	6 hours	6 hours
75% DVL	n/a	10 minutes
50% DVL	n/a	10 minutes
25% DVL	n/a	10 minutes
0% DVL	n/a	1 hour
100% DVL	n/a	1 hour
100% DVL + 25% SWL	1 hour	1 hour
100% DVL + 50% SWL	6 hours	6 hours
100% DVL + 25% SWL	10 minutes	10 minutes
100% DVL	10 minutes	10 minutes
75% DVL	10 minutes	10 minutes
50% DVL	10 minutes	10 minutes
25% DVL	10 minutes	10 minutes
0% DVL	1 hour	1 hour

*SWL denotes Specified Working Load; DVL denotes Design Verification Load

Table 98.3 Minimum loading times for a maintained load compression proof test
Reproduced from Institution of Civil Engineers (2007) (SPERW, 2007)

Pile head displacement range	rate of settlement criteria
< 10 mm	≤0.1 mm/hour
between 10 and 24 mm	≤1% × pile head displacement/hour
> 24 mm	≤0.24 mm/hour

Table 98.4 Rate of settlement to be used along with minimum hold times
Data taken from Institution of Civil Engineers (2007) (SPERW, 2007)

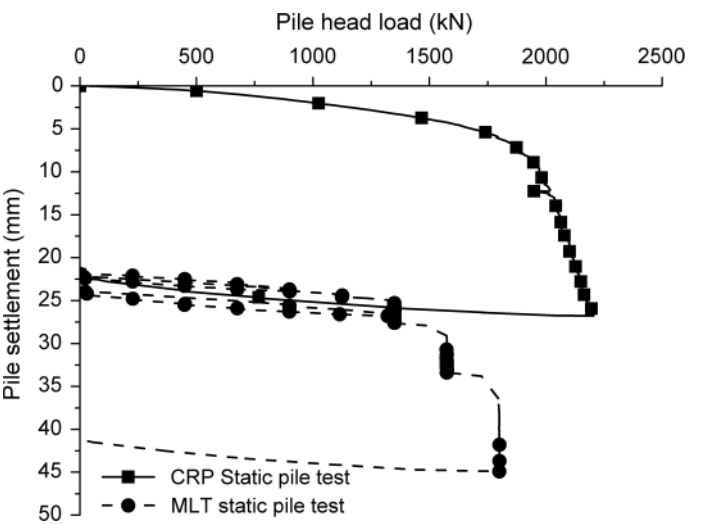

Figure 98.1 Example of CRP and MLT static load tests on a 12 m long, 600 mm diameter cast *in situ* bored pile in glacial till (see Brown *et al.*, 2006 for more information on the pile installation and testing)
Data taken from Brown *et al.* (2006)

the loading and reaction systems to produce plunge. There are also reservations about the relatively high penetration rates and short test duration (rate effects) especially where piles are installed in clay. It has been shown that as the penetration rates in CRP increase so does the ultimate pile capacity and stiffness (**Figure 98.1**). In terms of representing meaningful structural loading rates, it may be argued that the loading rate should be selected based upon the permeability of the soil specific to the pile installation and effective drainage path length. It should also reflect whether the desired behaviour to be proven is drained or undrained.

98.2.4 How it works and the various test set-ups

Static pile testing systems typically require a structure to react against to allow the application of load to the pile. A typical reaction or anchor pile type arrangement for pile testing is shown in **Figure 98.2**. Alternatively, the reaction to the hydraulic jack can be provided by placing kentledge (reaction mass) above the jacking arrangement (**Figure 98.3**). If the pile is a preliminary pile, i.e. one that is required to validate construction performance prior to construction of the working piles, then either arrangement of pile test would be suitable. Where load tests are required on piles that will form part of the final structure (working piles) then the test arrangement using kentledge would appear more appropriate. Unfortunately, if several working pile tests were needed, multiple individual test

	Rate of penetration mm/s (mm/min)			
Major soil type	SPERW 2007	BS8004	ASTM D1143–81	EN1536–2000
Fine-grained soils (e.g. clay)	0.01 (0.6)	0.0125 (0.75)	0.0042–0.021 (0.25–1.25)	0.01667 (1)
Coarse-grained soils (e.g. sand or gravel)	0.02 (1.2)	0.025 (1.5)	0.0125–0.042 (0.75–2.5)	0.01667 (1)

Table 98.5 Examples of different pile penetration rates specified for CRP testing
Note BS8004 has now been superseded

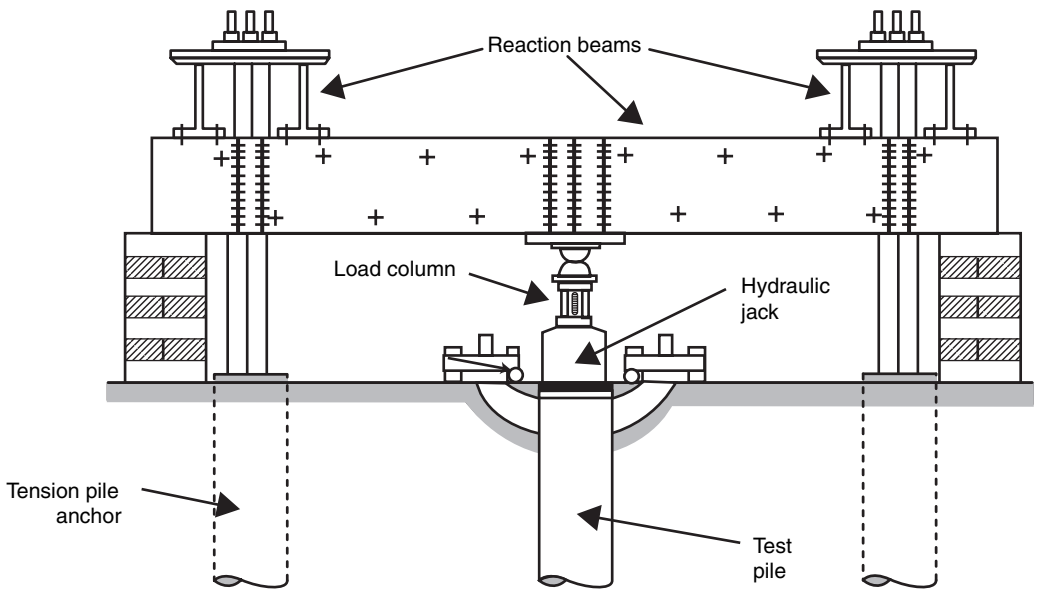

Figure 98.2 Top-down static pile testing arrangement utilising a tension pile reaction system
Modified with permission from CIRIA PG7 Weltman (1980), www.ciria.org

arrangements would be required to avoid time delays. Greater detail regarding pile testing procedure and equipment arrangements is given by Weltman (1980).

Application of the load to the test pile is usually undertaken using a large hydraulic jack with manual or automated control of hydraulic oil flow to allow either a maintained load to be applied or varying load for constant penetration rates (**Figure 98.4**). Historically load has been measured with a manually read calibrated load column placed between the jack and the reaction system (**Figure 98.4**). It is now more likely that an automated strain gauge-based load cell will be used which produces readings that can automatically be logged by a laptop PC. Similarly the piles' deflection has been measured using manually read dial gauges (mounted on a reference beam placed three diameters or 2 m from the test pile) whereas these have been replaced by displacement transducers that can be logged by a laptop (Fleming *et al*., 2009). Measurement by displacement transducers or dial gauges should also be verified by optical levelling to an accuracy of 0.2 mm. Developments in monitoring equipment along with reliable and cost-effective servo hydraulic control systems (which allow true stress and displacement controlled tests to be undertaken) have led to the development of fully automated test rigs that can be operated remotely (England, 2002). Automating such a system means that staff spend less time on an individual site and less time travelling between sites.

Another advantage of automation is that site operatives do not have to spend long periods close to highly stressed structures which in extreme cases have failed causing injury. There is also less need for shift working which may result in operatives working on deserted sites during the hours of darkness.

98.2.5 Static tension tests

Tension or uplift testing of piles utilises similar equipment and testing procedures to compression testing (**Figure 98.5**) although two jacks may be used to avoid inducing bending stresses in the pile. Connections to cast *in situ* piles are similar to those employed in tensile reaction piles whereas preformed steel piles may require additional welded brackets (Tomlinson and Woodward, 2008; Fleming *et al*., 2009). It is normal to test more than one pile that may be subject to tension and at least 2% of piles where a large number are subject to tension.

98.2.6 Static lateral load testing

As well as tensile load, piles are often subject to combined lateral, vertical and moment loading which in certain circumstances, such as foundations for offshore structures, may be cyclic in nature. It is not easy to achieve such complicated load paths in full-scale pile tests but both monotonic and cyclic lateral tests may be specified. Typically an adjacent pile(s) is used as reaction with a jack placed in between the reaction pile(s) and the test pile (**Figure 98.6**). Where cyclic loading is required automated jacks and monitoring systems are recommended. Similar load/deflection measuring techniques may be used as per axial pile load tests but it is also advisable to

Figure 98.4 Pile head loading arrangement showing loading jack placed on the pile with calibrated load column above with spacers to the reaction frame. Note the dial gauges for settlement measurement in contact with the head of the pile

measure relative movement of the test pile to the reaction piles and pile head rotations. In addition, valuable information for test analysis can be obtained by instrumenting the pile (Reese and van Impe, 2011) to allow determination of moments with depth. When selecting the number of lateral piles to be tested, close attention should be given to the variability of the ground over the top few metres of the test pile as this zone has significant effect on the lateral pile behaviour.

98.2.7 Advantages and disadvantages of static testing

The advantages of static testing lie in the simplicity of the test and it having been a long accepted technique. Generally, interpretation is simple and results can be produced quickly without the need for specialist interpretation or in some cases with only limited knowledge of the ground conditions.

Static tests are relatively slow. For instance, a typical ML test generally takes a minimum of 19 hours but may take much longer depending on the particular test specification. This also neglects the time required for setting up the test equipment. This has programme issues and implications regarding site safety with the need in some cases for 24-hour working.

The main disadvantages of static testing stem from the need to have enough reaction at ground level to apply loading. This results in infrastructure-intensive reaction frames connected to tension piles or kentledge (**Figures 98.2** and **98.3**). Such systems are time consuming to construct, expensive and may have significant space requirements both in terms of footprint and materials handling. The need for such large reaction (120% of anticipated ultimate capacity, **Table 98.2**) also means that the reaction system is highly stressed during testing, resulting in potential safety concerns.

One of the possible drawbacks of the anchor pile or kentledge-based reaction systems is that they interfere with the behaviour of the pile under test. Poulos (2000) suggests that the use of kentledge may cause an increase in test pile capacity and stiffness. Predictions in sand suggest that pile capacity and stiffness might be increased by 10–20% due to the presence of kentledge (Poulos and Davis, 1980). With this in mind, SPERW suggests that there should be a minimum separation of 1.3 m between the kentledge supporting arrangement and the test pile, BS EN1536 suggests a minimum of three times the test pile diameter. For a reaction pile arrangement where the reaction piles are shorter than the test pile, there should be a minimum separation of 2–3 m (depending on guidance consulted) or three times the test pile diameter. If the reaction piles are longer than (or inclined) the test pile the spacing should be increased to five times the diameter of the largest pile (test or reaction) unless the base capacity of the test pile is 20% less than that of the reaction piles. In the case of tension tests, any ground beams or adjacent compression piles used to support the reaction system should be at least three times the test pile diameter away from the test pile.

98.2.8 Interpretation of static tests

Inspection of the load-settlement curves determined from pile testing can be used in several ways. Firstly, by inspection the shapes of the curves may hint at the adequacy or integrity of the installation and highlight problems occurring during pile formation. Additionally, the result may be used to check performance criteria.

98.2.8.1 Settlement criteria

Pile design is typically based upon determining both ultimate and serviceability limit cases. When assessing performance from pile tests, it seems that settlement criteria at working loads is given more attention (in an onshore setting) than ultimate pile capacity. This is probably a result of ultimate capacity being associated with settlements that would cause serviceability damage to structures.

For working load tests, SPERW (2007) suggests that settlement criteria should be in the range of 5–10 mm at the design verification load (DVL) and 15–25 mm DVL + 0.5 SWL, although this should be assessed based on the specific building type.

98.2.8.2 Determination of ultimate capacity and test termination

Another potential barrier to using ultimate pile capacity to define performance seems to lie in the various definitions of what constitutes the ultimate pile load or capacity. For example, Tomlinsons and Woodward (2008) list seven different recognised techniques. These may be based upon the load at a certain settlement defined by the pile diameter (for instance, 10–15% of the test pile diameter) or a feature related to the shape of the

load-settlement curve such as the load at which settlement continues to increase without further increase in load. Definitions such as the latter may be problematic; for instance, in granular soils it is common to see gradual increases in capacity with increasing settlement, i.e. the criterion is never met.

EC7 seems relatively vague on this point but does state that where there is difficulty in determining the ultimate capacity a value equal to 10% of the diameter should be assumed. SPERW (2007) avoids the use of a specific settlement criterion and defines the ultimate capacity in MLT as the maximum load that can be applied whilst achieving the specific settlement rate criteria (**Table 98.4**). Conversely, though, CRP tests in SPERW (2007) are terminated on the basis where loads are reducing for at least 10 mm or a settlement equal to 15% of diameter is achieved.

If a preliminary pile does not reach ultimate capacity then results may need to be extrapolated to give an indication of the expected capacity. Methods proposed by Chin (1972) and Fleming (1992) referred to as hyperbolic methods are often used for this with varying degrees of performance for particular pile and soil types. The Chin method is based on the assumption that measured pile load-settlement behaviour can be represented by a hyperbolic function such that the ultimate capacity (U) of a rigid pile can be represented by

$$U = \frac{\Delta}{\left(\Delta/P\right) - K} \tag{98.1}$$

where Δ represents the pile head settlement at any pile head load (P), and K is the intercept on the horizontal axis (Fleming, 1992). Chin observed that if Δ/P was plotted against settlement (Δ) a straight line was obtained (**Figure 98.7**). The gradient of the straight line is the ultimate capacity of the pile (Equation 98.1). **Figure 98.7** also shows the CRP test previously presented in **Figure 98.1** with the ultimate pile capacity predicted from the Chin analysis shown as an asymptote at 2323 kN.

The form of the hyperbolic function was then improved upon by Fleming (1992) through incorporating parameters from back analysis of a large pile testing database and the effects of pile shortening. Fleming (1992) also separates consideration of pile shaft (denoted subscript s) and base (denoted subscript b) components such that:

$$\Delta_s = \frac{M_s D_s P_s}{U_s - P_s} \tag{98.2}$$

where the pile diameter (D_s) has been incorporated to recognise its influence on load settlement behaviour and M_s is a dimensionless flexibility factor with low variance with typical values between 0.001 and 0.0015 (Azizi, 2000). Pile base settlement is based upon the assumptions made for linear-elastic settlement of a footing and assessment of soil secant modulus (E_b) from a real load/settlement relationship under a footing at one quarter of the ultimate stress (U_b/4).

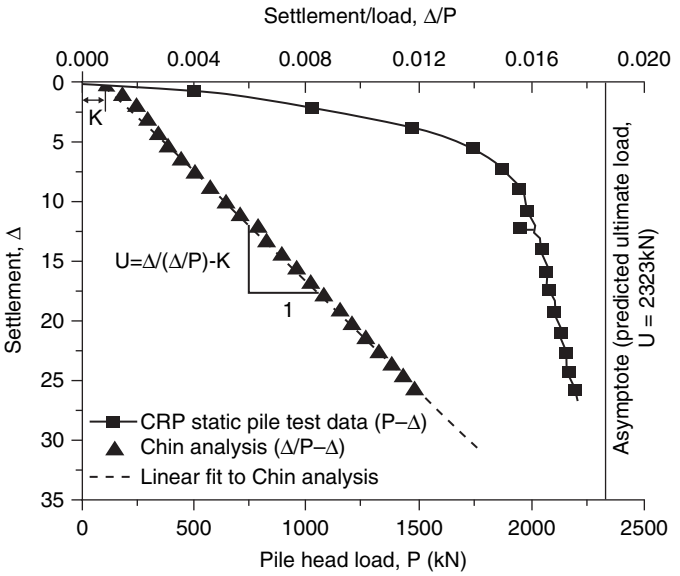

Figure 98.7 Chin analysis of a CRP static load tests on a 12 m long, 600 mm diameter cast *in situ* bored pile in glacial till

$$\Delta_b = \frac{0.6 U_b P_b}{D_b E_b \left(U_b - P_b\right)} \,. \tag{98.3}$$

Note that equations 98.2 and 98.3 above are for consideration of a rigid pile only. See Fleming (1992) for modifications that allow shortening to be incorporated. A useful summary of typical soil secant modulus values (E_b) can be found in Azizi (2000).

More detail of these techniques and interpretation of the results of static testing can be found in Fleming *et al*. (2009) and Tomlinson and Woodward (2008).

One of the aims of pile testing may be to verify or update design parameters and techniques. Where this requires specific knowledge of separate shaft and tip resistance and settlement it is recommended that the test pile is appropriately instrumented rather than attempting to derive such information based upon pile head measurements alone.

98.2.9 Specifying a static pile test

The magnitudes of the applied load increments for an ML test (**Table 98.3**) are chosen to verify the ability of the pile to carry the design loads associated with the structure and the resulting settlement. Typically, up to 10 mm of settlement is considered acceptable at the design verification load for insensitive buildings. The design verification load (DVL) referred to in SPERW is typically 40–50% of the anticipated or previously measured ultimate bearing capacity. The load a pile will actually carry in service is referred to as the specified working load (SWL). The DVL should account for the SWL and any specific differences that may occur between the pile load test and the pile in service, for example pile downdrag or variations in final levels

of the site. Working piles are typically loaded to the DVL plus 50% of their SWL (proof load test). Preliminary piles may be further subject to increments of 25% of their SWL. When calculating the anticipated static capacity it should be remembered that the calculated capacity should be as realistic as possible and avoid the adoption of unnecessarily conservative soil parameters.

98.3 Bi-directional pile testing

98.3.1 What is bi-directional load testing?

The bi-directional static load test is an alternative to the top-down static load tests described above (England, 2008). The method varies from the top-down load tests in that the major component of the system is a sacrificial, purpose-built high capacity jack (or jacks) cast in the pile length. The most common form of this type of system is referred to as the O-Cell, which is receiving increased use and acceptance.

The bi-directional O-Cell method of testing was originally developed by Professor Jorj Osterberg to load the pile from the pile base rather than from the head and more specifically for the evaluation of skin friction and end-bearing in rock sockets. On pressurising the jack(s), reaction is provided by the pile end-bearing capacity to mobilise the pile's skin resistance and *vice versa* until the capacity of either the jack or the upper or lower components of resistance are exceeded. More recently, individual jacks or multiple jacks have been installed at various levels within cast *in situ* piles and diaphragm walls (barrettes) to allow testing of different sections of the foundation length (Randolph, 2003; England, 2008; England and Cheeseman, 2010).

98.3.2 How does bi-directional testing work?

The system typically works by incorporating a purpose-built, low friction jacking device within a cast *in situ* pile (**Figure 98.8**). The loading arrangement is attached to the reinforcing steel or other support structure to ensure precise location and depth (**Figure 98.9**). When pile construction is complete and the concrete has attained sufficient strength, the jack is then pressurised using a hydraulic pump with the water pressure monitored by a pressure transducer attached to the hydraulic return line. The foundation is then effectively separated into two elements which are subjected to simultaneous loading.

During testing, the separation of the jack is monitored by displacement transducers (LVDTs or LVWDTs) mounted between the two faces of the jack. Telltales are also attached to the top of the jack that extend up to the head of the pile, which allow the compression of the pile shaft to be monitored and the location of the top and bottom of the jack(s) to be determined. The movement of the pile head is also monitored along with compression of the pile. On completion of testing, the jack(s) and the annulus around the jack(s) can be grouted up through the hydraulic circuit to allow the pile to be integrated into the structure as a working pile. The Osterberg Cells come in various diameters from 230 mm to 870 mm, with capacities from

2 MN to 27 MN. Test loads as high as 320 MN have been applied using several O-Cells installed at the same level (www.loadtest.com).

98.3.3 The advantages and disadvantages of bi-directional testing

The bi-directional type of load test has several obvious advantages over static top-down methods. The systems require no large surface reaction such as kentledge or anchored steel reaction frames thus reducing space requirements, set-up time and transportation costs. The system is also safer with the loads being applied at depth. There are also reported cost savings with bi-directional load testing being comparable in cost with top-down static load tests at 5–10 MN (SPERW, 2007) but then becoming much more cost effective at higher loads. There is also the potential with the O-Cell to apply loads that cannot be achieved by top-down reaction or kentledge systems. Although the design of the O-Cell lends itself to use in auger bored cast *in situ* piles it has also been successfully been deployed in continuous flight auger piles (CFA), Fundex piles and both steel and concrete driven piles.

Another advantage is to use an O-Cell bi-directional test as a substitute for tension tests at high loads and push the pile up instead of attempting to pull the pile upwards from ground level.

One specific disadvantage associated with the bi-directional approach is that the jacking system needs to be pre-installed. This means it is not possible to select a random working pile for testing. The other disadvantage of the system is that the components installed within the pile are not recoverable after testing. This means the O-Cell and some of the instrumentation is sacrificial which has a cost implication.

98.3.4 Interpreting the data from bi-directional testing

Typical results from a single O-Cell installation similar to that shown in **Figure 98.8** are shown in **Figures 98.10** and **98.11**. To estimate the load-displacement behaviour at the head of the pile several techniques can be used. The two most direct methods are to sum the measured responses and include the additional elastic shortening or alternatively model the response of each of the pile elements using Cemsolve (Fleming, 1992) and then add together the geotechnical behaviour and corresponding total anticipated elastic shortening.

The total load-displacement responses can be obtained by adding together the loads measured above and below the O-Cell (at the same level of displacement). Where one section has mobilised less displacement than the other, for instance in the case of the movement of the upper section (**Figure 98.10**), it may be necessary to extrapolate the obtained results using methods such as the Chin approach (Chin, 1972) for a single hyperbolic function or the Cemsolve approach (Fleming, 1992) to obtain the sum of the measured response as shown in **Figure 98.11**.

During the bi-directional loading some elastic compression is contained within the results. During top-down static loading

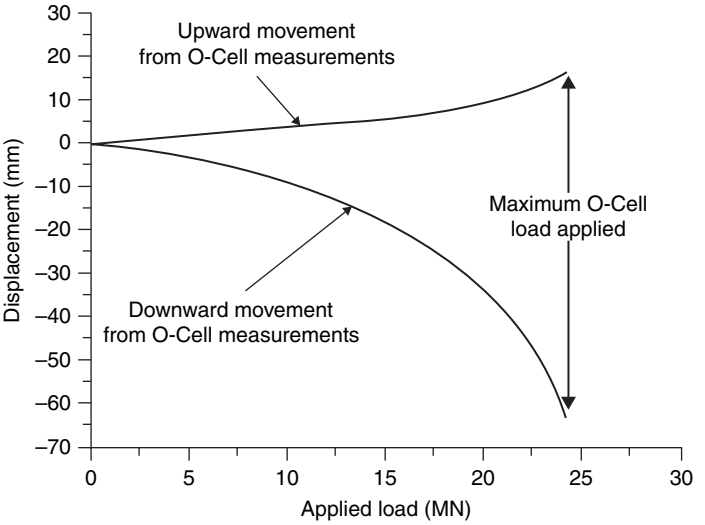

Figure 98.10 Example of results from a typical bi-directional load test
Data supplied courtesy of Fugro Loadtest

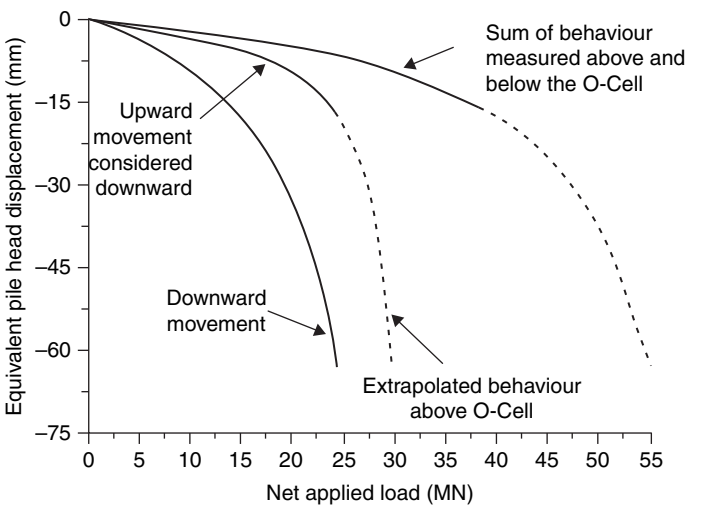

Figure 98.11 Sum of the measured responses from a bi-directional load test
Data supplied courtesy of Fugro Loadtest

where the full load is applied to the pile head additional elastic shortening would occur. This feature can be modelled and added to the results of bi-directional loading. Alternative approaches to analysis are discussed by England (2008).

98.3.5 Standardisation and guidance for bi-directional testing

As a relatively new method of pile testing bi-directional testing has historically suffered from a lack of guidance to aid specification; for instance, it is not specifically mentioned in Eurocode 7. This has been addressed recently in the UK by the second edition of the specification for piling and embedded

retaining walls (ICE, 2007). The Federation of Piling Specialists (FPS, www.fps.org.uk/) has also published guidance on use of the technique as part of a general pile testing guide. A more critical appraisal of the technique with case study comparisons can be found in a review of innovative pile testing techniques by Paikowsky (2004). For Eurocode 7 purposes (and other codes and specifications where bi-directional testing is not specifically mentioned), it may be adequate to class the O-Cell test as a full-scale static load test.

98.3.6 Specifying a bi-directional test

Care needs to be taken when specifying systems where the jack is to be installed in a preliminary test as the optimum level will be where the frictional capacity upwards (above the cell) matches the available reaction below the cell. In an ideal test, the skin friction below the cell (downwards) is fully mobilised with sufficient of the end-bearing mobilised to allow characterisation before the ultimate skin friction above the cell (upwards) is mobilised. Where elements of the pile are not fully mobilised, back analysis to reveal ultimate capacity may be used (as discussed above) where sufficient movement has occurred.

If the required test loads cannot be accommodated at a single level due to limitations on pile diameter it may be appropriate to consider multiple installation levels so that the entire foundation element may be mobilised in turn during phased testing. A specific advantage of using multiple level jack installations is that it allows individual pile sections to be mobilised separately. Cells placed close to the pile tip should also give due regard to the quality of the base and concrete at this level with cells typically placed one to two diameters above the base.

As the O-Cell applies load via jacking systems it is possible to specify load increments, hold periods and loading rates as per static tests.

98.4 High strain dynamic pile testing

98.4.1 What is high strain dynamic testing?

The previously discussed load application techniques used to measure pile capacity typically have load application durations in terms of hours. Dynamic pile testing differs in that loading the pile occurs by a drop weight applying a very short duration impact (≈5 ms) load at the head of the pile. The impact of the weight produces a stress wave that travels down the pile. Where the movement of the pile is resisted or there is a change in impedance such as at the pile tip, a wave will be reflected back up the pile. Based upon comparing the waves travelling up and down the pile it is possible to assess the dynamic pile reaction. Through further analysis it is possible to derive the equivalent static pile load-displacement behaviour.

98.4.2 Methods available for dynamic testing

Dynamic testing has the advantage that the main equipment required for monitoring the test is relatively compact and where the piles are being driven on site the normal pile-driving hammer can be used to produce the required stress wave. Piles are typically tested some time after installation which is referred to as re-strike. This involves the piling rig returning briefly to the test pile to deliver a series of hammer blows (typically five, depending on the approach taken). If the tests are being carried out on a cast *in situ* pile or are re-strike tests of driven piles where pile driving for installation is complete then it may be necessary to mobilise a separate drop weight system (**Figure 98.12**).

98.4.3 How does dynamic testing work?

Measurements are taken during the hammer impact from a pair of accelerometers and strain gauges that are attached above ground level to the pile head either during or after driving (**Figure 98.13**). The response of this instrumentation is logged during and after the weight impact on a specifically designed logging and analysis device, for example the Pile Driving Analyser (PDA) produced by Pile Dynamics Inc. Data from the instrumentation are used to derive the force (F) applied to

Figure 98.12 SIMBAT mini dynamic drop weight system (1000 kg hammer). Note pile head instrumentation installed on exposed concrete after local removal of temporary casing
Photograph courtesy of Testconsult Ltd; all rights reserved

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the pile by multiplying the measured strain by the cross-sectional rigidity of the pile and the velocity (v) from integration of the accelerometer readings.

The force measured by the strain gauges at the pile head due to the hammer impact is compared with the equivalent force derived from measurements made by the accelerometers (**Figure 98.14**). The data shown are for a re-strike test on a 250 mm square pre-cast concrete pile where the pile tip was 23.2 m below the strain gauges.

It is assumed, in stress wave theory, that both force and velocity are proportional as the wave travels through a material. Where:

$$v = \frac{F}{Z} \tag{98.4}$$

$$\text{or } F = v \times Z \tag{98.5}$$

Figure 98.13 Installation of instrumentation (strain gauge and accelerometer) on a pre-cast concrete driven pile (pile hammer visible at top of image)

$$\text{the pile impedance } Z = \frac{E_p A_p}{c} \tag{98.6}$$

where E_p is the Young's modulus of the pile, A_p is the piles' cross-sectional area and c is the wave velocity in the pile which can be found based upon the stiffness and density of the pile (ρ_p):

$$c = \sqrt{\frac{E_p}{\rho_p}}. \tag{98.7}$$

Where the movement of the pile is resisted, or there is a change in impedance such as at the pile tip, a wave will be reflected back up the pile (**Figure 98.15**). The total dynamic resistance of the pile (R) to the stress wave passing up and down the pile has been shown to equal the sum of the downward travelling force ($F_{(t_0)}$), force measured at maximum pile head velocity, ($v_{(t_0)}$) plus the upward travelling force that arrives back at the pile head ($F_{(t_0+2L/c)}$) at approximately $2L/c$ (where L is the pile length, **Figure 98.15**) after the initial peak load (Rausche *et al.*, 1985; Randolph, 2003).

$$R = \frac{F_{(t_0)} + F_{(t_0+2L/c)}}{2} + Z\left(v_{(t_0)} + v_{(t_0+2L/c)}\right). \tag{98.8}$$

98.4.4 Advantages and disadvantages of dynamic testing

The advantages of dynamic testing come from the simplicity of the equipment and the speed of testing. If driven piles are being tested it is typical to test at re-strike at some time after driving. The on-pile strain gauge and accelerometer are quickly bolted to the test pile (**Figure 98.13**) with logging undertaken on a small hand-held logging and analysis system (**Figure 98.16**). This means the system can be operated by a single operator with quick instrument installation causing little disruption to construction. As the piles can be tested during installation

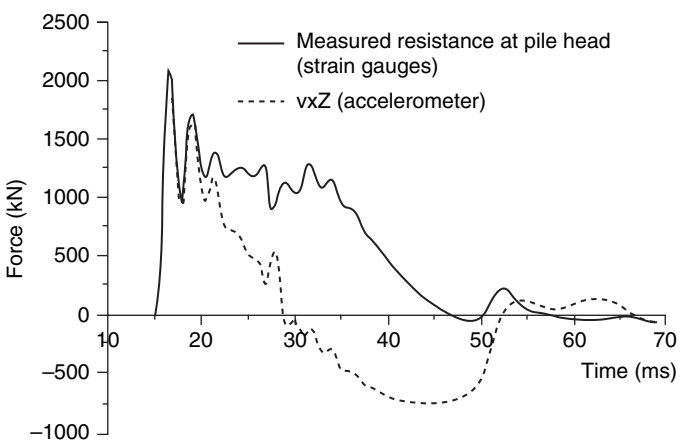

Figure 98.14 An example of measured pile stress wave data
Data provided by Technical Services Ltd

many working piles can also be tested without concerns over testing altering working performance. This data collection process has been improved recently with the development of wireless instrumentation and the option of replacing strain gauge load determination with direct pile head load cell readings.

If the piles are cast *in situ* piles or are driven piles tested after the original pile driving rig has been demobilised then it is possible to mobilise a drop weight system. Tests up to 36 MN have been undertaken by dropping 36 tonne masses. Typical loads achieved are 1 MN for 1000–1500 kg drop weight systems (typically 1.5–2% of the applied load is required) and 3 MN for 4000 kg drop weight systems. The ability to produce large loads with limited drop mass significantly reduces cost (**Figure 98.12**).

Other benefits associated with the nature of the test mean that it may be possible to verify the integrity of the pile during normal testing. Through analysis it is also possible to investigate the distribution of resistance down the pile and the split of base to shaft resistance without the need for additional instrumentation as is required in techniques where only pile head measurements are made.

Due to the nature of using the test during pile driving the test only gives an indication of the pile resistance during the installation process. Depending on the soil type the capacity of the pile may change significantly after driving due to, for instance, the dissipation of pore pressures which may lead to increases in capacity with time, which is often referred to as set-up. This may lead to the need for re-strike testing at various times after driving to verify pile capacity. This is not a problem specific to dynamic testing but may need to be considered for any pile testing method where displacement piles are being tested.

98.4.5 Interpretation of dynamic testing

It has previously been briefly explained how the dynamic pile resistance can be derived from pile head measurements during dynamic testing. It is then necessary to determine the ultimate static pile resistance from these measurements. Several methods are available to do this with the most common approaches based upon signal processing and numerical models (Holeyman, 1992).

98.4.5.1 CASE method

One of the earlier methods developed for signal processing is referred to as the CASE method (Rausche *et al.*, 1985). This simple technique may be used to quickly assess capacity in the field based upon an individual blow. It requires the determination of a damping force (R_d) which is assumed to be proportional to the pile tip velocity (v_{tip}) that can be removed from the total dynamic resistance to give the equivalent static resistance.

$$R_d = JZv_{tip} = J\left(F_{(t_0)} + Zv_{(t_0)} - R\right) \quad . \tag{98.9}$$

The performance of this technique is dependent on the soil-dependent CASE damping factor (J). Suggested values for the damping factor are shown in **Table 98.6**.

98.4.5.2 Signal matching

The most common methods of analysing dynamic load tests presently used are based upon lumped parameter finite

Soil type	Damping factor, J (s/m)
Sand	0.05–0.20
Silty sand/sandy silt	0.15–0.30
Silt	0.20–0.45
Silty clay/clayey silt	0.40–0.70
Clay	0.60–1.10

Table 98.6 Values for CASE damping coefficient
Data taken from Rausche *et al.* (1985)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

difference or finite element techniques where the pile is modelled as an assembly of interconnected masses with varying properties. These properties, predominantly soil parameters, are varied until computer-simulated pile head forces and velocities match those measured. Several computer packages have been developed that utilise this 'signal matching' method such as CAPWAP (Case pile wave analysis program), TNOWAVE and SIMBAT (Stain, 1992).

Common issues that may affect analysis are:

- insufficient pile settlement mobilised during testing to allow determination of ultimate pile capacity;
- variation in material properties or cross-section down the pile length;
- stresses locked in the pile as a result of pile driving.

It should be noted that these issues are not specific to dynamic testing and may cause problems to both static and rapid pile testing, especially where pile instrumentation is being used to supplement testing.

To allow the ultimate behaviour of a pile to be assessed from dynamic analysis it is necessary to mobilise adequate settlement in the pile and allow appropriate strain levels in the surrounding soil. Dynamic analysis based upon low settlement levels is likely to lead to a conservative assessment of pile performance, i.e. an underestimation of pile capacity. Where insufficient settlement is mobilised analysis is not compromised but reflects the mobilised soil resistance rather than ultimate pile capacity. Unfortunately, in the case of rapid load testing insufficient settlement may render analysis difficult. The situation of low mobilisation may come about due to ignorance of the importance of mobilising adequate settlement but more commonly it is a result of specifying rigs that are unable to apply the required load levels. Another reason for low mobilisation may be a limit on load/stress levels due to concerns over pile damage.

As dynamic test analysis is dependent on knowledge of the pile cross-sectional stiffness it is necessary to accurately know the cross-sectional profile of the pile and the stiffness of the pile material. These properties may be easy to determine for a steel or pre-cast concrete pile that is constructed to tight size tolerances and is cured in a factory environment. Where cast *in situ* piles are formed the profile of the pile may be less certain or complex, for instance in the case of a screw pile or under-reamed pile. There are also material issues, i.e. how does the inclusion of reinforcement affect the pile stiffness and does site-cured concrete have the same properties as laboratory-cured samples? Where piles have complex known geometry this can easily be incorporated in dynamic analysis if as mentioned the geometry is known. Where less information is available for the test, for instance in the case of pile re-use assessment where there is little information about the length, cross-section and quality of historic piles (Butcher *et al*., 2006), dynamic testing may not be appropriate.

98.4.6 Standardisation of dynamic testing

The dynamic pile testing method has been in common use for many years. In the UK, it is well documented in SPERW (2007) and the FPS general pile testing guide (FPS, 2007). In the US, there is an ASTM standard test method for high-strain dynamic testing of piles (ASTM D4945-08). One common thread throughout the guidance documents is the need for experience of the dynamic load testing in similar soils and on similar pile types (EC7). Where such experience does not exist or certain ground conditions prevail such as fine-grained and laminated soils it is recommended that the tests are calibrated against a site-specific static test (SPERW, 2007).

98.4.7 Specifying a dynamic test

It is important that the installation equipment being used for dynamic pile testing is first capable of driving the piles to the required depth or capacity and that it can mobilise the pile adequately during testing. Where time allows, details of the piles being driven and the driving equipment should be analysed prior to installation by the dynamic pile testing specialist. This wave equation analysis can be used to assess the ability of the proposed driving system to install the pile to the required capacity and desired penetration without exceeding allowable driving stresses in the pile material.

The other important decision to be made during dynamic testing is when to test, due to set-up and change of capacity with time. As mentioned, testing can be undertaken at the end of initial pile installation and through re-strike at any time after installation.

The piles to be tested dynamically should be designed to resist the driving stresses. They should also be designed to have at least 300 mm sticking up above ground at the end of pile testing to avoid sensor damage. To allow sensor installation it is important that there is adequate working room near the pile heads for sensor mounts to be installed prior to lifting piles. For cast *in situ* piles it may be necessary to include an extension to the top of the pile to approximately three pile diameters above ground level. This may be achieved by incorporating a section of casing above the pile head and filling with concrete while pouring the main pile concrete. Once the concrete has set windows may be cut in the casing to allow instruments to be attached to the concrete (**Figure 98.12**). Instrumentation is typically installed at a minimum of two pile diameters below the pile head.

98.5 Rapid load testing

98.5.1 What is rapid load testing?

The main difference between rapid load pile testing and static and dynamic testing is the duration of application of load. A rapid load test usually has a load duration of 90–250 ms which is approximately 30 to 40 times that of a dynamic pile load test (ASTM D7383-08; Holscher and van Tol, 2009). The duration of the loading has been designed such that piles less than 40 m in length remain in compression throughout the loading event

resulting in negligible stress wave effects and simpler analysis (**Figure 98.17**).

98.5.2 Methods available for rapid load testing

Several different techniques are available to produce rapid loading events. Statnamic testing works by rapid burning of a solid fuel that produces gas in a pressure chamber (**Figure 98.18**). The venting of this gas is used to accelerate a mass upward that in turn imparts a load on to the foundation pile below the Statnamic device. The load is applied and removed smoothly through the controlled venting of the gas. Alternatives to this approach typically take the form of a drop mass system where the load duration is increased through various cushioning techniques, for instance a spring or springs in the pseudo static pile load tester (Schellingerhout and Revoort, 1996) and spring hammer systems (Matsuzawa *et al*., 2008) and specialised cushioning in the hybrid dynamic test (Miyasaka *et al*., 2008).

98.5.3 What are the advantages and disadvantages of rapid load testing?

The main advantage of rapid load testing devices comes about as a result of the method of load application. For example, in the rapid load testing method known as Statnamic a reaction mass is accelerated upwards resulting in a load application of 3.5 MN from 18 tonne. Typically, for Statnamic testing the reaction mass is only 5% of the equivalent static load reaction mass required to produce the same load. This results in rapid load testing devices being significantly smaller and lighter than static equivalent set-ups. This means that they can be used on sites with space restrictions, are easier to mobilise and quicker to set up and test. For example, a 3 MN Statnamic rig (**Figure 98.19**) can be mobilised with one articulated truck and a 70 tonne crane. If the rig incorporates a hydraulic catch mechanism (catches the reaction mass) it can test up to 10 individual piles a day or allow multiple load cycles to be carried out on an individual pile with minutes between cycles.

Typically disadvantages of rapid load testing methods stem from the rapid nature of the load application which may result in piles displacing at rates measured in metres per second resulting in very high strain rates in the soil (**Figure 98.17**). In fine-grained soils, such as clay, such high strain rates have been shown to significantly increase the strength of the clay. This may result in pile ultimate capacity up to three times the measured or predicted static pile capacity (Holeyman, 1992). This effect appears to become more pronounced as the plasticity of the clay increases. It is important to be aware of this effect to

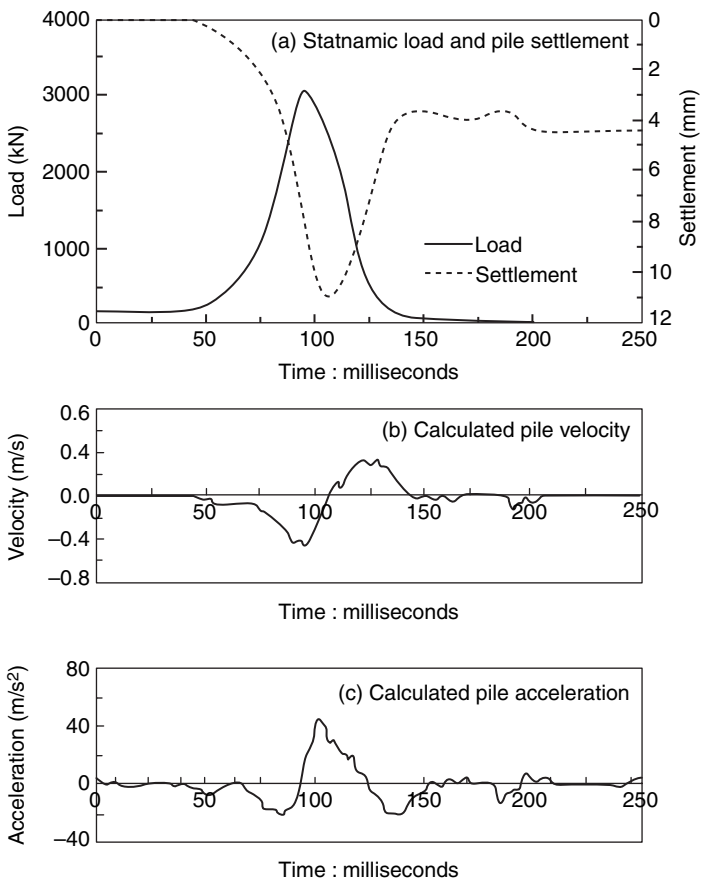

Figure 98.17 Measured and calculated results from a 3000 kN Statnamic load cycle
Reproduced from Brown and Hyde (2006)

Figure 98.18 Statnamic pressure chamber with load cell at its base shown mounted on a test pile

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

avoid specifying rapid load testing devices that are incapable of adequately mobilising a pile. For instance, the maximum capacity of rigs currently available in the UK is 3 MN with larger rigs available from mainland Europe.

Another major drawback is that certain techniques such as Statnamic may operate over a very discrete loading range; for instance, a 3 MN Statnamic rig may apply loads as high as 3.5 MN but would not be able to apply loads below 700 kN.

98.5.4 How does Statnamic work?

As Statnamic is the most widely deployed method of rapid load testing it is described in more detail. As mentioned previously, load is applied vertically down a pile by burning a rapid-burning fuel which produces significant volumes of gas within a piston which accelerates reaction mass upwards. The duration and shape of the load pulse (**Figure 98.17**) are controlled by venting of the gas. The reaction mass is forced upwards and is caught by either gravel in the case of large load tests 20–60 MN or by hydraulic catch mechanisms for smaller rigs (3–20 MN, **Figure 98.19**). As Statnamic load application is independent of gravity the device can easily be used to test raked piles and has been deployed horizontally to test piles laterally and simulate impacts on structures.

Figure 98.19 3.5 MN Statnamic rig with hydraulic catch mechanism ready for testing

During the test, load is measured directly by a calibrated load cell incorporated in the base of the combustion piston which sits on the pile head (**Figure 98.18**). Displacement is also measured directly using a non-contact system either by a photovoltaic sensor mounted in the piston which is excited by a remote laser beam or the movement of targets mounted on the pile are recorded by means of a remote optical displacement tracking system. As the Statnamic event may induce stress waves in the ground it is important that the remote component of the measuring device is located far enough away from the pile to avoid disturbance during the duration of the loading event (Brown and Hyde, 2006). The recording of displacement–time history can then be differentiated once or twice to determine pile velocity and acceleration, both of which are required for test analysis.

It is also commonplace for the system to incorporate an accelerometer which can be used for direct recording of acceleration. The acceleration–time history can also be integrated to determine velocity which may be less 'noisy' than that found by differentiation and for a second time to verify optical or laser-based displacement measurements.

98.5.5 How to interpret the data

Rapid load tests must be analysed to remove both the effects of inertia associated with the pile/soil and strain rate-dependent response of the ground. The most common approach for this is referred to as the unloading point method (UPM).

Based on inspection of load-displacement curves from Statnamic tests Middendorp (2000) observed that during the unloading, the pile velocity reached zero which in coarse-grained soils corresponded approximately to the ultimate static resistance of the pile. This point (the unloading point) was then used to determine a constant damping coefficient to correct the measured Statnamic data for the velocity-dependent resistance of the soil. Unfortunately, when this technique is applied to piles installed in fine-grained soils there is a tendency for the ultimate pile capacity to be significantly overpredicted. In order to correct for this effect, a series of soil-dependent average correction factors were developed (**Table 98.7**) which the derived

Soil type	Rate effect factor (μ)	FOS without μ	FOS with μ
Rock	0.96	2.0	2.0
Sand	0.91	2.1	2.0
Silt	0.69	2.8	2.0
Clay	0.65	3.0	2.0

Note: FOS = Factor of safety

Table 98.7 Correction factors for UPM analysis
Information taken from Paikowsky (2004)

static load was then multiplied by to obtain a corrected UPM analysis (**Figure 98.20**). More recently, it has been proposed that much greater average correction factors in clay are required resulting in a μ value of 0.47 (Weaver and Rollins, 2010).

In response to the known shortcomings of the UPM technique, a series of alternative methods have been developed which have their basis in the velocity or strain rate-dependent behaviour of soils. One nonlinear velocity-dependent method of analysis was developed by Brown (2004). The main conceptual difference from UPM is that the method is reliant on the user input of soil-specific rate parameters:

$$F_u = \frac{F_{STN} - Ma}{1 + \left(\frac{F_{STN}}{F_{STNpeak}}\right)\alpha\left(\frac{\Delta v}{v_0}\right)^{\beta} - \left(\frac{F_{STN}}{F_{STNpeak}}\right)\alpha\left(\frac{v_{\min}}{v_0}\right)^{\beta}} \qquad (98.10)$$

where F_u is the derived static pile resistance, F_{STN} is the measured Statnamic load, Ma is the pile inertia, Δv is the pile's velocity relative to the soil and v_{min} is the velocity of the static CRP pile test used to define the soil-specific rate parameters α and β (β is normally set to 0.2 in clay). Both Δv and v_{min} are normalised by v_0 which is assumed to be 1 m/s. This form of analysis has evolved from the analysis of dynamic tests where the majority of the pile capacity is developed through skin friction (Randolph, 2003). The value of α may be selected based on the tentative relationship with plasticity index (PI) as proposed by Powell and Brown (2006):

$$\alpha = 0.03PI(\%) + 0.5\,. \qquad (98.11)$$

98.5.6 Guidance and standardisation of rapid load testing

Like bi-directional testing, rapid load pile testing has historically suffered from a lack of guidance to aid specification. This has again been addressed recently in the UK by SPERW (2007) and the FPS pile testing guide (FPS, 2007). In the US, there is an ASTM standard for rapid load testing of deep foundations (ASTM D7383-08) along with guidance produced for the federal and state highways agencies (McVay *et al*., 2003; Paikowsky, 2004). The Japanese Geotechnical Society has also produced a testing specification, an English language draft of which was published in 2000. A European standard within the Eurocode framework is currently under development and will be published along with guidance on test interpretation (BS EN/ISO 22477-4; Hoelscher *et al*., 2010). Rapid load testing is also mentioned briefly in EN1536-2000 with regard to the testing of bored piles and the need to provide evidence of correlation with static maintained load tests in similar ground.

98.5.7 Specifying a rapid load test

Prior to specifying a rapid load test it is necessary to have access to the results of geotechnical investigation and laboratory testing to allow selection of adequate testing equipment and loading levels. The encountered ground will also influence the analysis approach adopted. For analysis of tests in fine-grained soils, regular determination of the plastic and liquid limits should be undertaken down to at least the depth of the toe of the pile.

In granular soils and pile installed in rock, the applied loads will be similar to the anticipated ultimate pile capacity with additional loading capacity required for the inertial forces generated by the pile and soil. In addition to the inertial resistance, load testing devices used in fine-grained soils such as clays will need to be capable of applying additional loads due to strain rate effects. For example, in a low to medium plasticity clay the ultimate capacity measured during rapid loading may be 1.8 times greater than the anticipated static capacity (**Figure 98.21**).

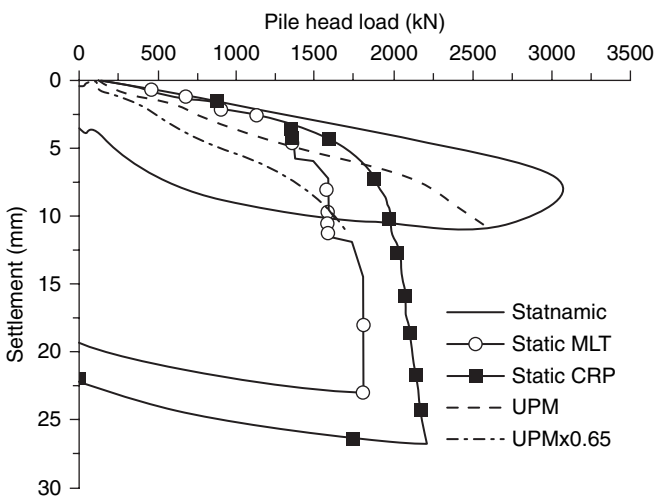

Figure 98.20 Performance of UPM correction of Statnamic data. The pile tests have been reset to zero settlement to allow comparison

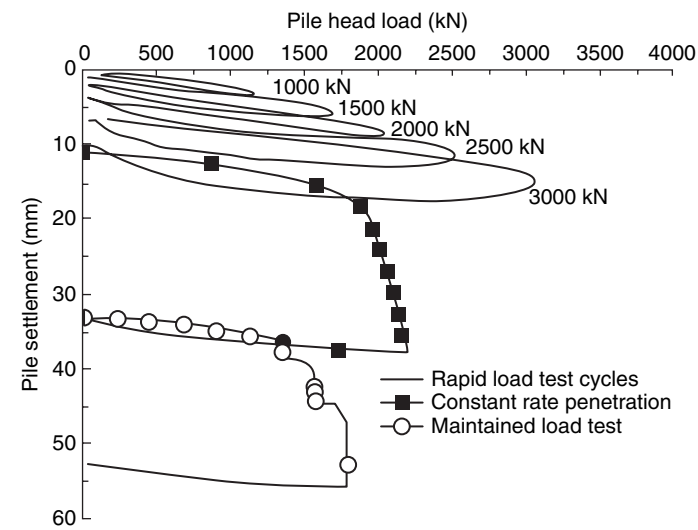

Figure 98.21 Cycles of Statnamic loading compared with CRP and MLT static tests (see Figure 98.1)
Reproduced from Brown *et al*. (2006)

In high plasticity clays the test may need to apply loads of 3.5 times the static capacity or higher. The need to apply such high loads should be considered when designing and specifying test piles.

98.6 Pile testing safety

98.6.1 Why do we need to be careful?

The testing of piles poses a safety hazard for several reasons. The most obvious of these are the high tensile and compressive loads generated in both the pile and reaction system during testing. Failure in any part of the system may lead to rapid release of energy and collapse of the testing arrangement. Other issues may arise due to the specific reaction system: for instance, kentledge relies on placing weights above a supporting frame, this frame needs to be stable throughout erection and testing thus requires appropriate structural design and checks on bearing capacity.

98.6.2 Good practice

As relatively high loads are applied over the relatively small area of the pile head it is important that all attempts are made to reduce eccentricity of loading on the pile and in other areas of the reaction system such as connections to anchor piles. Excessive eccentricity can lead to large moments that the load or reaction system has not been designed for. Eccentricity can be minimised by accurate setting out of reaction piles relative to the test pile, correct alignment of the load column and proper mating of contact surfaces and levelling of reaction beams.

An obvious means of reducing risk to site and testing operatives is to restrict access to the load testing set-up and reduce the need to be close to the heavily loaded elements or reduce the need to work under kentledge. This can be achieved by restricting access only to relevant personnel. The need for direct access to the load column can also be reduced or removed through the use of computer-controlled loading jacks and displacement transducers. Fully automated testing systems have been developed which can be controlled remotely (England, 2002) although it is generally advised that tests should not be left unattended whilst loading.

Good practice can also be incorporated in design of the loading system. For instance, where the testing system uses reaction piles this should ideally incorporate a minimum of three anchor piles as systems based upon two reaction piles are significantly less stable. The use of a two-pile reaction system should be reserved for relatively low loading levels with high tolerance pile and reaction system positioning.

98.6.3 Loading and inspection

It is important that the maximum test load to be applied to the pile is agreed in advance of the test so that the test pile/pile cap and all associated elements of the load testing equipment can be designed and specified to apply the maximum test load safely. This information must be communicated to the relevant operatives and where possible relevant limiting capacities should be marked on individual elements of the testing equipment (see **Figures 98.4**, **98.5**, **98.6**).

It may be the intention during testing to take the pile to its ultimate capacity and cause significant permanent settlement. In some cases a pile's capacity during testing may exceed that anticipated prior to testing and require additional loads to prove ultimate behaviour. Although the goal may be to prove ultimate behaviour, this should never be used to justify exceeding the maximum test load the testing system has been designed for.

During the course of the load test the whole system should be monitored for eccentricities and excessive deflections with appropriate action taken if this occurs. Typical signs of distress may include:

- excessive deflection of the reaction beams;
- upward movement of tensile bars cast into reaction piles;
- horizontal deflection of the reaction system;
- movement of kentledge;
- difficulty in maintaining test loads.

Further key safety issue guidance is given in FPS (2006).

98.7 Simple overview of pile testing methods

Selection of the most appropriate pile testing technique will vary from one situation to the next. Criticism is often levelled at the different techniques for their shortcomings whereas any form of pile test (if correctly undertaken and analysed) should be viewed as a tool to give confidence in the design assumptions made, improve efficiency in construction and verify as-built performance. For instance, where a static load test identifies problems with trial pile performance during working pile construction, rapid or dynamic testing techniques can be rapidly deployed to assess the effect on the constructed working piles. This may then allow modifications to pile design and construction that can be used to mitigate problems during construction without significant effect on the construction programme. **Table 98.8** summarises some of the pros and cons of the methods described in this chapter and offers suggestions for potential deployment considerations. This table only serves as a quick summary and should not be used for definitive selection of a test. Decisions on the most appropriate testing method are influenced by many factors: for example, if there is a pile driving rig on site it will likely be more cost effective to undertake dynamic testing than to mobilise another technique. Definitive guidance should be sought from the specific providers of such techniques who can offer cost-effective and bespoke solutions both for deployment and subsequent analysis and interpretation.

Test Type	Advantages	Limitations	Potential deployment
Static	• Simple test • Simple & quick interpretation • Well understood & accepted	• Slow tests • Significant infrastructure (especially as loads increase) • High space requirements • Safety concerns with increasing loads	• Lower loading (<20 MN) • Low pile numbers • Trial piles/limited number of working piles
Bi-directional	• Capable of very high test loads (higher than other techniques) • Low infrastructure • Low space requirement • Cost effective as load magnitude increases	• Pile for testing needs to be preselected • Less experience • Analysis needs to take account of different surface boundary conditions • Specialised analysis and interpretation	• Medium to very high loading (2–320 MN) • Low pile numbers • Trial piles/limited working piles
Dynamic	• Low infrastructure • Low space requirement • Fast tests • Quick repeat testing • Mature technique	• Pile damage may be a concern • Perceived reliability: Intermediate • Tests may be influenced by pile material and geometry • Specialised analysis and interpretation	• Medium to high loading (1–35 MN) • Low to high pile numbers • Trial and working piles • Where pile driving equipment already on site
Rapid	• Low infrastructure • Low space requirement • Rapid testing • Quick repeat testing	• Limited experience • Analysis techniques under development • Limited case study experience • Availability of high capacity equipment	• Medium to high loading (0.6–40 MN) • Medium to high pile numbers • Trial and working piles • Quality control of working piles • Problems with working pile performance

Table 98.8 Summary of pile test characteristics and potential deployment criteria

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 99

Materials and material testing for foundations

Stuart Pennington Ove Arup & Partners, London, UK

An introduction to construction materials and their verification for the geotechnical engineer is presented. Verification is discussed in terms of its forms, levels of complexity, documentation and appropriate tests, with an emphasis on UK practice. A selection of materials are introduced and discussed in terms of verification, and an introduction to the verification of existing foundations for re-use is presented.

99.1 Introduction

The geotechnical engineer is faced with a variety of construction materials as most geotechnical structures involve more than just soil and rock. There is often an overlap with other disciplines, such as structural engineering or materials technology. Verification of these materials during construction requires an understanding of the designer's intent, the characteristics of the material being verified and practical experience of the verification process.

This chapter introduces verification and presents a selection of common materials encountered in the construction of geotechnical structures, with an emphasis on UK practice and standards to illustrate the verification process. Verification by testing is addressed in terms of the general requirements for each material rather than the requirements for a material in a specific structure (e.g. grout rather than grout for anchors). The chapter concludes with an introduction to foundation re-use. Discussion of pavements and contamination is not included in this chapter.

At the end of this chapter, a selected list of documents and websites provide more specific information on the topics addressed throughout the chapter.

As there are numerous overlaps for the issues discussed in this chapter with other parts of this manual, the reader should peruse the contents list to identify potential sources for more detail. This is particularly relevant to topics such as earthworks, integrity testing, ground investigation, ground improvement, site supervision, fill, pavements and reinforced soil.

99.2 Eurocodes

The introduction of European Standards has made construction verification a requirement for designs under their jurisdiction. Documents relevant to material verification include:

- EN eurocodes, e.g. BS EN 1997:1–2004 (BSI, 2004);
- national annexes, e.g. NA to BS EN 1997:1–2004 (BSI, 2007);
- investigation and testing standards, e.g. BS EN 12620–2:2002 (BSI, 2002);
- execution standards, e.g. BS EN 12715:2000 (BSI, 2000);
- non-contradictory complementary information, e.g. BS 8004:1986 (BSI, 1986).

This array of documents shows that there are many scattered references to construction verification of materials that an engineer is required to consider.

99.3 Materials

Geotechnical structures often involve a variety of construction materials in addition to soil and rock such as polymers, timber, steel, concrete and grout. The processes of production, transport, placement and use will influence the method of verification. For example, materials can be:

- relatively unprocessed single materials (e.g. timber);
- processed composite materials (e.g. concrete);
- imported to a particular site (e.g. fresh concrete);
- transported within a particular site (e.g. excavated soil);
- used as is (e.g. *in situ* soil);
- used with other materials (e.g. geosynthetics);
- in a ready-to-use format (e.g. reinforcement cages);
- placed underwater (e.g. fresh concrete);
- used underwater (e.g. piles);
- in need of specific on-site management (e.g. fresh concrete);
- re-used (e.g. old piles).

While specialist understanding of a material is necessary to determine appropriate methods of verification, the practical application of verification of a material can be undertaken once a more general understanding of its composition, potential problems and suitable methods of testing is gained.

99.4 Verification

Verification of materials during construction is the process of checking (by an appropriate or specified method) that the materials brought to site and used in a structure are what the designer intended. While the designer's intent and requirements should be clear in the construction specifications and drawings, a face-to-face meeting with the designer will be invaluable. It should be recognised that verification other than that specified by the designer may be necessary or prudent.

When one thinks of verification of materials, testing in a laboratory may spring to mind. However, this is only one part of the process and should be complemented by other verification procedures such as:

- visual inspection;
- collection and review of records and certificates (e.g. concrete lorry tickets);
- review of quality control procedures at the point of manufacture (e.g. geosynthetics);
- engineering judgement;
- appropriate sampling;
- field testing (e.g. flow table for concrete);
- comparable experience;
- source quality control and certification (e.g. Conformité Européenne (CE) marking);
- understanding the material being verified;
- knowing when to request additional testing;
- being prepared to say that a material is not satisfactory.

The level, quantity and complexity of verification, and responsibility for verification, will depend upon factors such as:

- the category of the structure in which it is used;
- the level of quality control provided at source;
- the type of material;
- the parameters used in design and the extent to which the designer is relying on the testing of materials during construction;
- the importance or size of the structure;
- material origin;
- the construction contract.

Guidance is included in standards such as BS EN 206 (BSI, 2000a) and BS EN 1990 (BSI, 2002).

In considering what verification is required, the following questions should provide the engineer with a starting point for further thought:

- What are the verification requirements in the designer's specification?
- What are the referenced standards in the specification and in the construction contract?
- Who is responsible for the various aspects of verification?
- Is the material covered by a manufacturing standard (e.g. CE marking)?
- What can go wrong with the material once it arrives on site?
- What level of responsibility do you have as a geotechnical engineer on site?
- Is on-site testing required to progress or verify the design?
- Does the specification adequately address verification requirements?
- What level of verification control is required?
- Are the records that are being provided adequate?
- Are there materials that are not covered by standards?
- What has happened to the material since it arrived on site?
- Is the material being stored and handled correctly?
- What are the limitations of any controlling standards?
- What is the process for rejecting a material?
- What are the requirements for personnel or companies undertaking material testing?
- Has a plan for verification been created?
- Is quality control at the material source satisfactory?
- How are the results of verification to be communicated to the designer?

99.5 Concrete

99.5.1 General

The use of concrete in geotechnical applications is extensive; for example, piles, shallow foundations, retaining walls, facing units, tunnel linings and masonry blocks.

In simple form, concrete is comprised of cement, fine and coarse aggregate and water. Typically by volume, cement is 6–16%, fine aggregate is 20–30%, coarse aggregate is 40–55% and water is 12–20%. The water–cement ratio can range from 0.3 to 1.0 (Illston and Domone, 2001). A more complex mix can include admixtures and cement replacement materials which enhance its performance. Admixtures can include plasticisers, superplasticisers, accelerators, retarders, air-entraining agents and foaming agents. Cement replacement materials can include pulverised fuel ash/fly ash, ground granulated blast furnace slag, silica fume, metakaolin and natural pozzolans.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Concrete is batched using hopper dispensers and mixing drums which combine the constituents (**Figure 99.1** shows an example of a batching plant). Concrete is either poured or pumped into the ground (e.g. pile) or formwork (e.g. retaining wall or pre-cast unit). The use of a tremie may be required, particularly if concreting is undertaken below water, to prevent segregation (see **Figure 99.2** for an example of tremie use on a bored pile). Concrete placed in formwork is typically vibrated when fresh to expel air and compact it. Concrete hydrates and typically achieves an initial set after two to four hours, a final set after many hours, and then hardens over weeks to months.

Concrete is typically delivered to site as ready-mix or as pre-cast units, although on-site batching may be undertaken in special circumstances.

Figure 99.1 Concrete batching plant
Courtesy of Texnokat

Figure 99.2 Tremie being used to pour concrete into a bored pile

99.5.2 Potential problems

Problems with concrete can occur when it is fresh, during setting, or when it has hardened, as a result of the mix proportions, the mix constituents, the environment in which it is used or how it is handled during placement.

While concrete is fresh it can suffer with respect to its consistency, compactability and cohesiveness. For example, if workability is reduced it may be difficult to plunge a reinforcement cage for a continuous flight auger (CFA) pile (**Figure 99.3** shows an example of a CFA reinforcement cage becoming stuck and bent during plunging). Alternatively, if concrete is dropped through water that has collected at the base of a pile, it may segregate.

When concrete is setting it can suffer from bleed, plastic settlement and plastic shrinkage. Once concrete has hardened it can suffer from durability issues caused by internal or external attack, and by physical or chemical attack (e.g. sulfate, sea water, acid, alkali–aggregate reactions, abrasion and freeze/thaw).

During the time that concrete is fresh or setting, the problems it may encounter are mainly associated with mix design

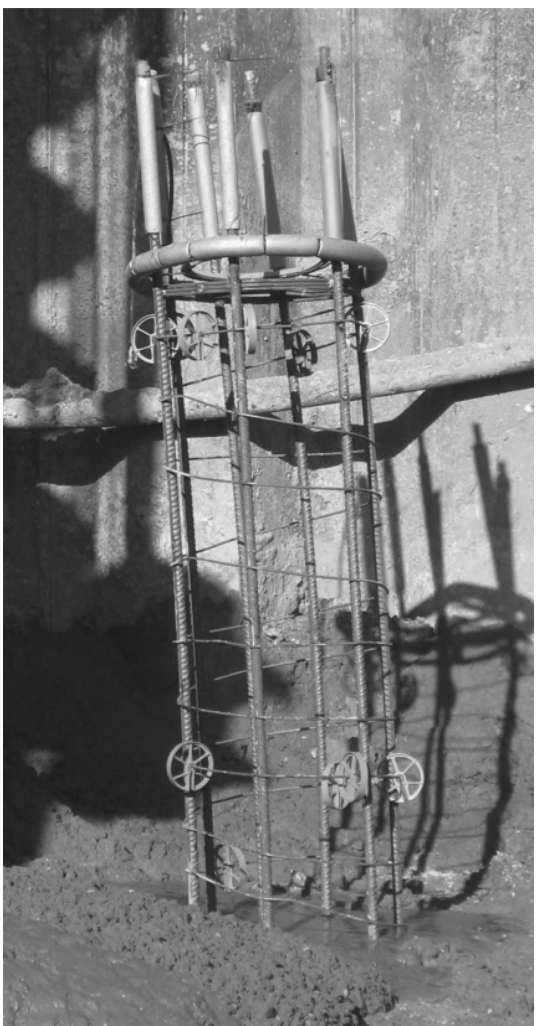

Figure 99.3 Partially plunged and bent CFA cage

and handling, whereas problems during its design life are more typically associated with mix constituents and quality of construction.

99.5.3 Verification

Verification of concrete starts with the mix design which can be specified in various ways. For example, a designed mix is chosen by the concrete supplier; a prescribed mix is chosen by the designer. Mix constituents and proportions are covered by standards and are typically controlled by requirements for workability (short-term performance), durability (long-term performance) and strength. If the mix design is not typical then trial mixes in a laboratory and subsequently in the field may be required.

For concrete batching plants supplying ready-mix concrete or factories manufacturing pre-cast concrete, there should be quality controls in place that monitor performance as detailed in the relevant standards. Ready-mix suppliers may subscribe to QSRMC (UK quality scheme for ready-mixed concrete) and pre-cast concrete may be CE marked.

The first check for fresh concrete should be a review of the delivery ticket; the contents of which are specified by standard. The ticket includes information such as the time of batching, volume, strength class, mix description and consistency. No materials (including water) should be added to ready-mix concrete unless required by the producer and this should be recorded on the delivery ticket. On-site verification tests prior to use (which are covered by standards) address issues of consistency, compactability and cohesiveness. Consistency can be assessed by the slump test, vebe test or flow table test; compactability can be assessed by the compacting factor test; and cohesiveness can be assessed visually. Further verification typically involves the preparation of cube or cylinder samples which are then tested for strength (typically after 7, 28 and 56 days of curing). When referring to concrete strength grade under Eurocode terminology, for example C32/40, note that the '32' refers to the cylinder strength and the '40' to the cube strength.

Box 99.1 Case study – flow table test

The flow table test is similar to the slump test in that it measures the consistence of fresh concrete. The flow table test is suited to high consistency mixes, such as those used in CFA piles, which would be difficult to measure using the slump test. The test procedure is detailed in Part 5 of BS EN 12350–5:2000 (BSI, 2000), however, in simple terms it involves:

- compaction of concrete into a cone (see **Figure 99.4(a)**);
- removal of the cone to release the concrete (see **Figure 99.4(b)**);
- jolting of the concrete on a flow table;
- measurement of the spread of the concrete (see **Figure 99.4(c)**).

Subsequent to the checks, testing and sampling undertaken at delivery time, the quality control of ready-mix concrete, until it has hardened, relates primarily to execution rather

(a)

(b)

(c)

Figure 99.4 Flow table test (a) compaction of concrete into cone; (b) removal of cone; (c) measurement of flow width

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

than material verification and generally involves inspection of placement techniques, compaction and curing.

Verification of hardened concrete can be undertaken indirectly, destructively or non-destructively. Indirect verification may involve inspection of surface quality or dimensional tolerance in the case of concrete cast using formwork. Destructive verification may involve full scale load testing of a specially prepared member or small-scale testing of a core sample (see **Figure 99.5** for an example of concrete core from a pile with defects). Non-destructive verification can include rebound hammer testing, resonant frequency testing and ultrasonic pulse testing (Illston and Domone, 2001); however, these tests need to be correlated with core sample testing. Non-destructive verification for piles is generally termed 'integrity testing'.

99.6 Steel and cast iron

99.6.1 General

The use of steel and cast iron in geotechnical applications is extensive. For example, structural sections can be used as piles (e.g. H-piles or sheet piles) or as temporary props. **Figure 99.6** illustrates the use of sheet piles to form a cofferdam. Reinforcing bars (generally 8 to 40 mm in diameter) are used in reinforced concrete, soil nailing and anchors. Steel tendons are also used in anchors. Cast iron is used in tunnels in the form of spheroidal graphite iron lining segments. Stainless steel can be used in the same manner as non-stainless steel, where additional protection against corrosion is required. Steel fibres are used in segmental concrete tunnel linings and shotcrete.

Steel and cast iron primarily consist of iron alloyed with carbon and to a lesser extent with other elements such as silicon (for cast iron), chromium and manganese. Steel is typically formed by hot rolling or cold working and then bent/welded to form more complex sections (reinforcement cages, girders, hollow tubes, etc.); the length of any section generally being limited to the length of a delivery truck (12 m). Cast iron, such as that used in tunnel lining segments, is moulded and then bolted together.

In the UK, structural steel is typically grade S275 or S355 (where 'S' denotes structural steel and the number represents the yield strength in MPa). Reinforcing bars are typically grade B500A, B500B or B500C (where the initial 'B' denotes reinforcing steel, the number represents the yield strength in MPa, and the final letter represents the ductility rating; A being the lowest).

99.6.2 Potential problems

The primary issue with steel and cast iron is their durability, as their strength and stiffness properties are closely controlled by factory production. They can be degraded by dry oxidation, but more so by wet corrosion which may be chemically or biologically based. However, it should also be noted that steel can be damaged mechanically once delivered to site if it is subjected to excessive bending.

The extent to which steel in reinforced concrete corrodes is very much dependent upon the density, quality and thickness of concrete cover (generally 75 mm or more for concrete cast against the ground), and if there any chemicals in the concrete that may attack the steel. In applications where steel or cast iron is exposed to the environment (e.g. sheet piles), alternative measures such as good design/detailing, coatings, cathodic protection or sacrificial thickness are necessary. **Figure 99.7** illustrates how corrosion can vary over relatively short distances. In this case, the steel in the splash zone (central part of photograph) has corroded significantly more than that above and below.

Figure 99.5 Concrete core showing defects

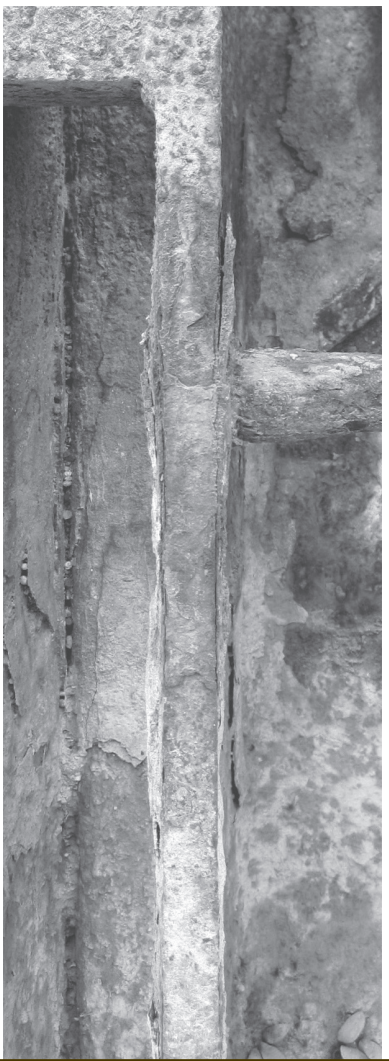

Figure 99.7 Variability in steel corrosion near the waterline

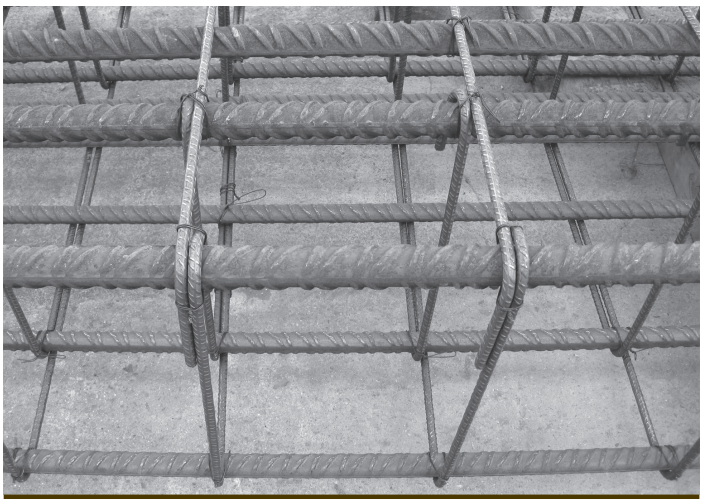

Figure 99.8 Reinforcement cage for barrette

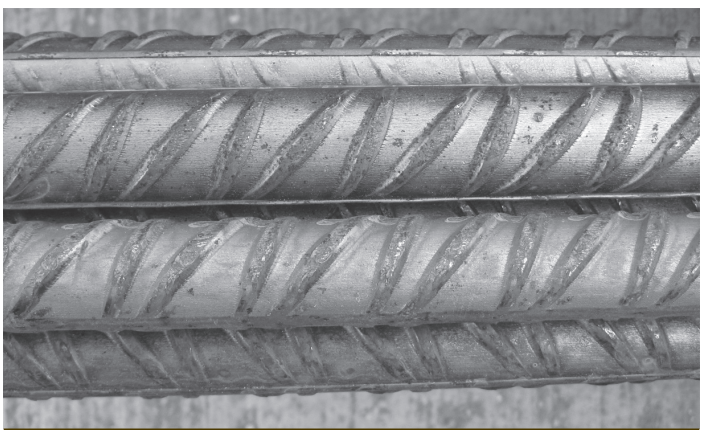

Figure 99.9 Reinforcing bars showing a rib pattern

99.6.3 Verification

For mills supplying steel and cast iron, there should be quality controls in place that monitor performance, as detailed in the standards. CE marking can be used to guarantee certain characteristics and producers often subscribe to CARES (Certification Authority for Reinforcing Steels).

Verification of steel and cast iron typically starts with their delivery to site where inspection of delivery records and the material should take place. Pertinent material characteristics should be checked on identification labels. Reinforcing bars produced by a CARES-certified body may have identifying rib patterns. The material should be free of scale rust, although a dusting of iron oxide is acceptable. Dimensions should be as specified, subject to allowable tolerances.

Samples can be taken for laboratory testing as there is not usually scope for on-site testing to verify material properties such as strength or composition. However, an example of where steel can be verified on site (albeit indirectly) is in the case of anchors – where steel tendons are tested non-destructively during the performance of load tests.

Where a protective coating is specified, for example on sheet piles, this should ideally be applied under factory conditions, and once delivered to site should be inspected for composition, integrity, quality and thickness.

Box 99.2 Case study – reinforcement cage check

Steel reinforcement used in piles or barrettes typically arrives on site as a cage (see **Figure 99.8** for an example of a barrette cage). Verification against construction drawings should comprise the checking of:

- overall dimensions (width, length, breadth, diameter);
- number of bars, bar spacing, bar diameter;
- integrity testing installations (e.g. sonic logging ducts);
- cleanliness (absence of rust and soil);
- steel grade via identification tags and rib patterns (see **Figure 99.9**);
- robustness for lifting purposes;
- interface/couplers for multiple cages.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Verification of welding is not addressed here. However, it is worth noting that high yield strength bars should not be heated (e.g. by welding) as this can lead to them becoming brittle.

99.7 Timber

99.7.1 General

Timber can be used for driven piles, retaining walls, shoring/falsework and formwork. It can be described as a low-density, cellular, polymeric composite (Illston and Domone, 2001). At the microscopic level, timber is classed as:

- softwood (cells are primarily vertical, density generally lower, e.g. pine); or
- hardwood (cells are more anisotropic, e.g. oak).

At a smaller scale, timber can be subdivided into:

- sapwood (outer growing later);
- heartwood (dead centre section);
- latewood (formed late in growing season); and
- earlywood (formed early in growing season).

Timber should be obtained from sustainable sources and is typically dried before use. Natural timber is available as whole logs or as a sawn product. Timber can also be processed to produce products such as plywood for formwork applications, although these applications are not discussed here.

99.7.2 Potential problems

Natural timber cannot be controlled in the same way that, for example, steel production is. Its properties vary according to, for example, density, grain structure, temperature, knots, ring width, cell structure, moisture content, time and splits. There is a need to consider the small-scale structure as well as gross features. **Figure 99.10** illustrates the effect of a knot on timber structure.

Timber needs to be seasoned before use, otherwise it can be attacked by fungi and its strength and stiffness will be lower. Timber (particularly heartwood) has a natural resistance to deterioration provided its moisture content is kept low; ideally below 20% (Illston and Domone, 2001). However, it should be remembered that timber is hygroscopic (it attracts moisture from the atmosphere).

Timber is mainly susceptible to attack by biological organisms and fire. Other forms of attack, such as chemical and mechanical, are of lesser concern. When timber is placed below groundwater level it is essentially immune from deterioration as there is very little air. However, where water can be oxygenated and in marine environments where borers (animals that eat wood) are present, decay can occur.

While timber has a natural resistance to deterioration due to natural chemicals within it, these chemicals vary between species and depend on the part of the tree used. Chemical processing typically provides more resistance. However, its success depends on the part of the tree (e.g. sapwood or heartwood), the tree species, and the moisture content of the timber. Preservatives can be tar oil based, water based or solvent based. Tar oil and water based products are typically used for in-ground applications. It is noted that EU regulations restrict/forbid the use of many traditional preservatives such as copper–chromium–arsenic (CCA) and creosote (Illston and Domone, 2001).

Figure 99.10 Timber is not a uniform material

99.7.3 Verification

Timber for structural use should be graded into strength classes according to its anticipated performance. Grading is either by visual or machine inspection, and a strength class is assigned to each piece of timber on this basis. In terms of durability, timber is classified according to its life when in contact with the ground. CE marking can be used to guarantee certain characteristics.

Verification of timber on site should start with an inspection of the delivery records and the grade stamps/marks. Samples can be taken for testing to verify various material properties. However, it should be remembered that the size of the sample will affect the measured properties due to the presence of gross features, and that the testing of timber samples usually only informs the values presented in standards.

Grade stamps/marks (an example of which is shown in **Figure 99.11**) should record information such as:

- strength class (C14 to C50 for softwood and D30 to D70 for hardwood – the higher the number the higher the strength);
- species;
- condition (e.g. dry);
- origin (e.g. forest stewardship council (FSC) or programme for the endorsement of forest certification (PEFC) scheme for sustainable sources);
- supplier name;

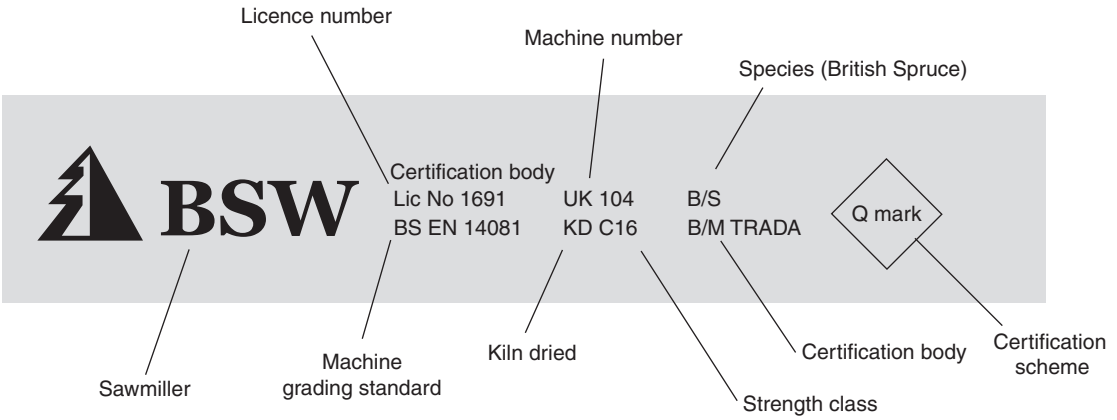

Figure 99.11 Example of a grading stamp
Courtesy of BSW Timber Ltd

- certifying body;
- standard use;
- grading method (i.e. visual or machine).

Dimensions should be verified against construction drawings subject to allowable tolerances, and checks should be made for straightness and imperfections. Timber should be stored in a sheltered location off the ground so as to avoid changes in moisture content, and handled appropriately to avoid damage (see **Figure 99.12**).

Where preservatives are specified, these should be applied under factory conditions and once delivered to site, the integrity and quality of the preservative application should be inspected. If timber is subsequently cut, drilled or poorly handled on site, the integrity of the preservative should be reassessed.

Box 99.3 Case study – timber decay at wharf

The importance of verification with respect to characteristics such as species, heartwood versus sapwood, type and application of preservative is illustrated in **Figure 99.13**. The timber in **Figure 99.13(a)** has not been immersed in water and, apart from some surface discolouration, is essentially fresh. However, just below in the splash zone (**Figure 99.13(b)**) the timber has decayed and crumbles in the hand.

99.8 Geosynthetics

99.8.1 General

Geosynthetics in geotechnical applications can be used to separate materials, reinforce soil (see Chapter 73 *Design of soil reinforced slopes and structures* for further information), permit drainage, provide filtration or act as an impermeable barrier. Geosynthetics can be subdivided into various forms such as geotextiles, geogrids, geomembranes, geocomposites and geonets. **Figure 99.14** illustrates a geogrid and a geocomposite.

Geosynthetics are typically composed of polymers such as polyester, polyethylene, polypropylene and polyamide, and can be formed by processes such as extrusion, spinning, stretching, weaving and bonding. Geosynthetics may be reinforced with fibres or they can be combined with other materials such as bentonite.

Figure 99.12 Storage of timber

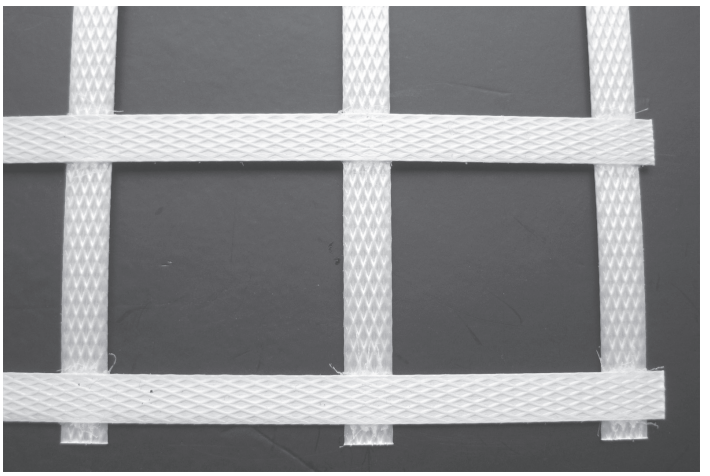
99.8.2 Potential problems

During construction, issues for geosynthetics include durability and interface friction. The durability of geosynthetics can be affected on site by acids, alkalis, heat, abrasion, fungus, oxidising agents, UV light and construction plant. While a designer should take account of interface friction and stress–strain behaviour, poor construction practice can adversely affect assumptions made during design.

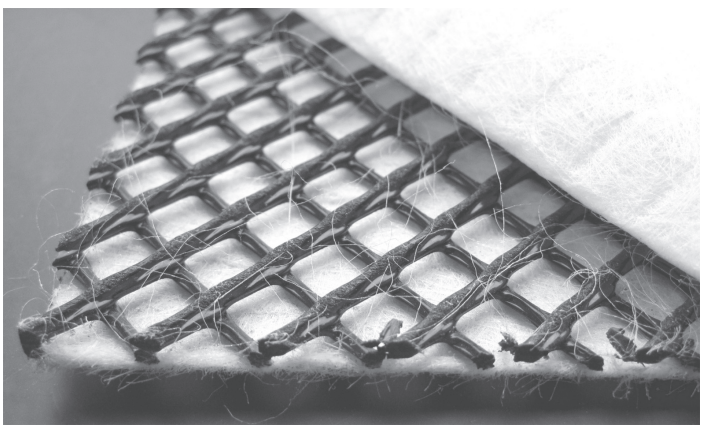
99.8.3 Verification

For factories supplying geosynthetics, there should be quality controls in place that monitor performance, as detailed in the relevant standards. CE marking can be used to guarantee certain characteristics.

On-site verification of geosynthetics should start with inspection of delivery records. They should be clearly labelled,



(a)



(b)

Figure 99.13 Variability in timber decay (a) above waterline; (b) below waterline

(a)

(b)

Figure 99.14 Example of (a) a geogrid; (b) a geocomposite

stored in the shade and handled with care. Geosynthetic products should be inspected for quality, consistency and integrity. Samples can be taken for off-site testing to verify various material properties, such as tensile strength. However, if tests are undertaken they should be consistent with service conditions.

The surface onto which geosynthetics are to be placed should be appropriately prepared (e.g. level, free of protruding objects) and then inspected to verify that the potential for damage to the geosynthetic to be laid is minimised. While most testing is laboratory based, it may be specified that on-site testing be undertaken to assess the impact of damage from construction plant on a particular geosynthetic being used.

Once a geosynthetic is laid, inspection of lapping or welded joints and flatness (i.e. lack of ripples) should be undertaken, and fill promptly placed to protect it. **Figure 99.15** illustrates the verification of welded joints by pressure testing.

99.9 The ground

99.9.1 General

The ground (soil/rock) is primarily used to support structures in its natural state. However, when excavated, processed, transported or emplaced (i.e. fill/made-ground) it can be used, for example, to raise surface levels, form part of concrete, act as a drainage filter or provide protection against erosion. Its characteristics generally vary according to its origin and composition.

Figure 99.15 Pressure testing of welded joints
Courtesy of Escambia

Figure 99.16 Soil/rock exposure in an excavation

99.9.2 Potential problems

Natural ground can hide many potentially problematic issues and, whilst undisturbed, these issues are generally not of concern. However, once people interact with the ground, these issues often become problems. Soft soils can settle, erosion features may collapse, excess water pressures can cause collapse, aggressive chemicals may attack concrete, sensitive soils are susceptible to landslide, hard rock can cause excavation problems and clay can expand. Man-made ground can hide additional issues such as poor compaction and contaminants.

99.9.3 Verification

The ground can be divided into four groups for the purposes of verification:

- *in situ* ground (existing natural or man-made);
- engineered ground (engineered fill);
- treated ground (improved existing ground);
- excavated material.

Verification of *in situ* ground during construction should be an extension to earlier desk study work and intrusive ground investigation (see Section 4 of this manual for further information on site investigation). It should be used to validate design assumptions, but may be used to fill gaps in knowledge or investigate features previously inaccessible. The simplest form of verification could involve recording strata and groundwater in cuttings, excavations or pile bores (see **Figure 99.16**). Simple portable assessment tools may be used (e.g. a handheld shear vane – see **Figure 99.17**). Existing groundwater installations may be used to monitor water levels. More complex verification could involve intrusive sampling and testing through boreholes, or field experiments such as load testing, pumping trials or plate load tests.

Verification of engineered ground that is emplaced during construction requires additional verification measures – such as density testing, and classification of materials with respect to their ultimate use and compaction characteristics.

Verification of ground that is treated during construction (to improve its geotechnical properties) requires additional verification specific to the properties being improved. The Mackintosh probe (see **Figure 99.18**) is a simple hand tool that can be used relatively quickly to assess improvement in strength over the top few metres of ground.

Verification of excavated material relates to ground that is going to be moved from its source location for use elsewhere. Verification of this type of ground will be specific to its end use and generally involves laboratory testing and visual inspection, for example, maximum dry density testing for clay fill or

Figure 99.17 Shear vane test

Figure 99.18 Mackintosh probe test

durability testing of rock for armourstone would take place in the laboratory; a visual assessment of excavated ground could show it was free of contaminants such as wood or plastic.

99.10 Aggregates

99.10.1 General

Aggregates have a number of geotechnical uses. For example, they can be used in concrete, as drainage filters, as protection against scour, as fill for embankments, in road pavements or in ground improvement (e.g. stone columns) (see Section 7 of this manual for further information on earthworks and pavements). Aggregates range from sand to boulder in size, they can be angular to smooth in shape, and their strength and durability will vary according to their origin. They can be heavyweight such as those sourced from igneous rocks or lightweight such as pumice. Natural aggregates can be collected from locations such as buried channels, riverbeds, river terraces and glacial outwash. However, they are also often produced by excavation and crushing of rock (**Figure 99.19** illustrates the use of a rock crusher). Aggregates can also be man-made, in that they are created by recycling materials such as concrete, asphalt, blast furnace slag or plastic.

Figure 99.19 Crushing plant (Komatsu BR380 JG-1)
All rights reserved

99.10.2 Potential problems

Aggregate problems typically relate to their formation process and constituents. Strength is usually only important in high strength concrete. Of more importance are durability, participation in chemical reactions and physical characteristics.

When some rocks are excavated, exposed to air, mixed with other materials or loaded, they may react to produce undesirable side effects. Potential issues to be addressed by selection and testing include fines content, shell content, resistance to fragmentation, resistance to polishing, resistance to wear, freeze/thaw, drying shrinkage, chloride content, alkali-silica reactivity, carbonate content, shape, size, density, porosity and impurities.

99.10.3 Verification

The production or collection of natural aggregates should be controlled at source. While verification typically starts when aggregates are delivered to site, visits to the proposed source quarry will be beneficial, particularly if suitability has not been addressed during ground investigations.

Once on site, delivery records should be inspected and features such as origin, mass distribution, shape and integrity verified as satisfactory. Samples can be taken for testing to verify material properties such as particle size grading, abrasion value (resistance to wear), magnesium sulphate soundness (resistance to weathering) and 10% fines value (resistance to crushing). An example of aggregate testing is illustrated in **Figure 99.20** which shows the test apparatus used to undertake the Los Angeles abrasion test (steel balls and aggregate are placed in the central drum which is then rotated).

Man-made materials such as recycled concrete may be produced on site. Depending upon their intended use, they should be subjected to similar suites of tests as undertaken for natural aggregates. Recycled material may be required to undergo contaminant testing.

Figure 99.20 Los Angeles abrasion test apparatus

99.11 Grout

99.11.1 General

Grout can be used in geotechnical applications to reduce permeability (e.g. rock grouting), stiffen soils (e.g. compaction grouting), stabilise ground (e.g. permeation grouting), provide support (e.g. jet grouting), compensate for ground movement (e.g. compensation grouting) and fill cavities.

Grouts are commonly cement based, silicate based or resin based and are classified in terms of their particle size as mortars, pastes, suspensions, colloids or solutions (Rawlings *et al.*, 2000). Depending upon the application, they can contain other materials such as cement replacements, clay, sand, fillers, chemicals, admixtures and water. They can be thick and viscous, thin and fluid, weak or very strong.

99.11.2 Potential problems

Problems occur with grouting for a variety of reasons: when the ground being treated is not fully understood; when the grout or grouting technique being used is not appropriate to the situation at hand; when the mix is poorly designed; when control over the procedure is inadequate; or when the grout behaviour is not understood by those using it.

99.11.3 Verification

As grout is often mixed on site, verification of the ingredients and the mixed product is necessary. As there are many possible ingredients, only the mixed product is considered here.

During construction, testing should be undertaken at regular intervals. Of the tests available, typical on-site tests for fresh grout include rheology (viscosity, gel strength, penetrability, thixotropy, workability, bleed) and setting time. For grouts where strength is important, grout cubes made from fresh grout should be prepared. **Figure 99.21** shows a group of freshly prepared grout cubes and a cylinder of grout being used to measure bleed.

Field trials (appropriate to the scale of the project) should be undertaken to demonstrate that the grout is achieving the aims of the designer, especially where there is no prior experience. This may involve intrusive testing or exhumation for verification.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 99.21 Fresh grout cubes and cylinder bleed test

Box 99.4 Case study – cone test

The cone test is used to provide a viscosity measurement for grout. A common cone used for this test is the marsh cone; however, there are others such as the one presented in BS EN 445:2007. It is important to understand which cone is being specified as different cones may have different volumes and discharge orifice sizes. However, the principles of the test are generally the same and comprise:

- filling the cone with a set volume of grout whilst blocking the discharge orifice (see **Figure 99.22(a)**);
- timing how long it takes a set volume (typically less than was input) of grout to drain from the cone (see **Figure 99.22(b)**);
- using the same procedure, calibrating the cone with water instead of grout.

Post-grouting verification can include laboratory testing of hardened grout samples or field techniques, similar to those used during trials.

99.12 Drilling muds

99.12.1 General

Bentonite and polymer drilling muds are used in the construction of bored piles and diaphragm walls to provide stability to the excavation and assist in the removal of cuttings. Bentonite typically comprises natural or activated sodium bentonite (a type of clay) while polymer comprises long chain molecules.

(a)

(b)

Figure 99.22 Cone test (a) filling of the cone; (b) timing of the discharge duration

99.12.2 Potential problems

Without adequate site control by a specialist contractor, these muds can easily affect the performance of piles or walls in an adverse manner. Problems can include reduced concrete/soil interface friction, reduced reinforcement bond and excavation collapse.

99.12.3 Verification

As drilling muds are often mixed on site, verification of the ingredients and the mixed product is necessary; however, only the mixed product is considered here.

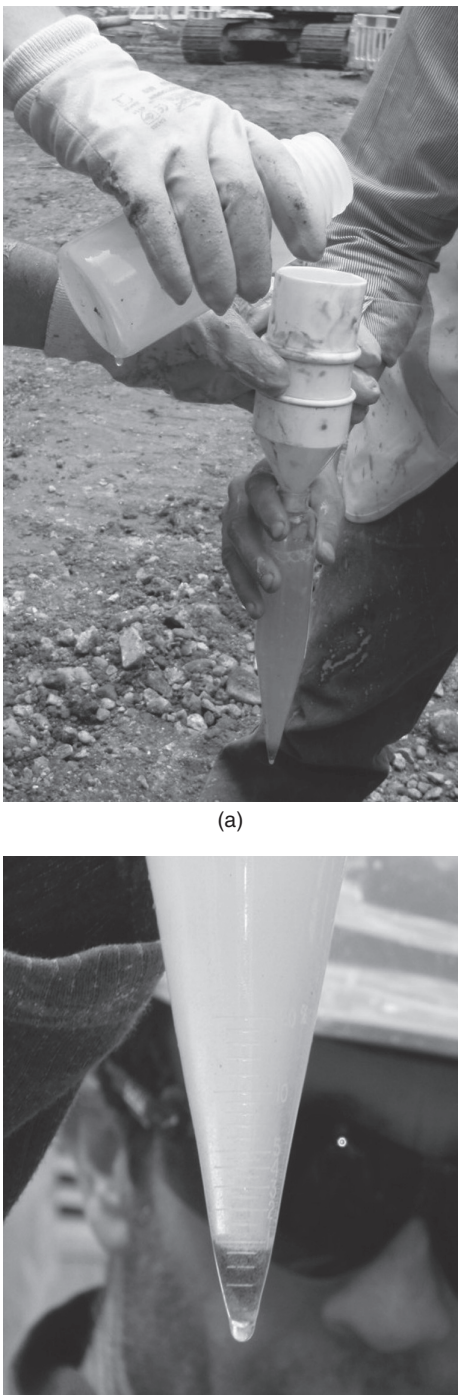
Verification should start with checking that mixing of the constituents with water is thorough and in the correct proportions. The chemical composition of the drilling mud should be noted.

Once in use, testing should take place at various stages throughout excavation and until concrete is placed. Testing should be undertaken on fresh mud and mud that has been cleaned. It should comprise the measurement of density, viscosity, pH and sand content. For bentonite, additional tests for setting time, gel strength and fluid loss/filter cake thickness are necessary. Samples of the drilling mud should be taken from an appropriate point so as to obtain a representative sample – for example, from near the base of a pile bore for sand content prior to concreting. **Figure 99.23** illustrates parts of the sand content test – final washing of the sieve and measuring the sand content. **Figure 99.24** illustrates the apparatus used to determine drilling mud density.

99.13 Miscellaneous materials

99.13.1 Vegetation

Vegetation is often used as a cover for slopes or retaining walls but is often unsuccessful due to lack of control. Use on soil/rock slopes can help to reduce erosion and provide an increased level of stability. However, on steep slopes vegetation is likely to require temporary support until it is established, and in some cases it may need permanent support (see **Figure 99.25**).



If seeds are being used they should be sampled for testing. If germinated seeds or matured plants are being used, test beds can be set up on site to provide a control. If plants are delivered to site they should be covered while in transport and acclimatised on site. Roots should not be exposed for longer than necessary.

99.13.2 Water

Water is used in many applications on site. Generally, potable water is fine to use without further testing whereas sewage water is not. Non-potable water should be subjected to a preliminary inspection for visual signs of contamination and simple hand-held testing such as pH. Subsequent testing may involve laboratory testing for chemicals. However, the extent of testing should be appropriate to the end use of the water.

99.13.3 Polystyrene blocks

In a similar manner to lightweight aggregates, polystyrene blocks can be used to reduce the impact of embankments on soft soils or earth pressures on retaining walls. Problems that may be encountered during construction include hydrocarbon (e.g. petroleum) attack, heat and UV light damage, although these issues are generally easy to manage with appropriate on-site storage/protection. **Figure 99.26** illustrates the use of polystyrene blocks behind a retaining wall.

(a)

(b)

Figure 99.23 Sand content test (a) washing sand from the sieve into a vial; (b) measurement of the sand content

Testing is generally undertaken prior to delivery to site; however, samples may be collected to determine properties such as density, and compressive and shear strengths. Delivery records should be reviewed, dimensions checked (subject to allowable tolerances) and checks made for imperfections.

99.14 Re-use of foundations

The re-use of foundations has drawn much attention in recent years due to concerns over future use of sites and conservation of resources.

Assessment of existing foundations for re-use essentially involves three investigation steps:

- desk study (records of construction);
- physical (i.e. material testing); and
- performance (i.e. load testing and historical behaviour).

However, it is important that in this process there is continual appraisal of viability between the design and the assessment components (Butcher *et al*., 2006).

In terms of verification of materials, the physical investigation is most relevant to this chapter. Its aims are to determine the geometry, integrity, strength and durability of the ground and foundation elements.

Investigation of the elements can be intrusive or non-intrusive. Intrusive testing comprises coring to obtaining samples for laboratory testing. Non-intrusive testing comprises external field testing. It is important to understand the limitations of the various non-intrusive tests and their needs in terms of calibration and correlation. Non-intrusive tests include ultrasonic echo testing (to derive the thickness and location of objects – see **Figure 99.27**), radar testing (to locate reinforcement), low strain testing (to derive pile length and integrity), parallel seismic testing (to derive pile length), mise à la masse (to locate reinforcement and the length of steel piles), rebound hammer (to derive concrete strength – see **Figure 99.28**) and cover meters (to derive the thickness of concrete cover).

This chapter describes the use of the observational method (OM) on engineering projects. Traditional ground engineering projects are usually based on a single, fully developed, robust design. This can lead to conservative but costly designs. The objective of OM is to achieve greater overall economy by having less conservative designs without compromising safety. Successful implementation of OM relies on a structured approach to both design and construction, an assessment of the most realistic design parameters, comparing these with the cautious design parameters used in traditional designs, having a rigorous monitoring and observation strategy, having a design/construction which in the light of the monitoring data can be modified in a timely way, and having a strong management and reporting structure with well predefined contingency plans in case problems occur. These key ingredients to the successful implementation of OM are described with the help of some case examples. OM can also be used when a project, designed by traditional methods, is in difficulty and the 'best way out' approach is required; this is also discussed. Finally, Eurocode 7 (EN1997-1:2004) (EC7) allows the use of OM in design, but has shortcomings which are also highlighted.

100.1 Introduction

This chapter aims to provide guidance to engineers on the use of the observational method (OM) on engineering projects. It describes the important differences between carrying out designs based on the traditional approach, using 'characteristic values' of parameters (defined in *Eurocode 7: Geotechnical Design, Part 1*: EN1997-1:2004 (EC7)) and those developed using realistic parameters ('most probable') when using OM. It also explains that traditional designs are by their very nature conservative and not flexible to change, but that OM allows the project team to produce an integrated approach to both the design and construction, which can yield significant cost and programme savings. It also fosters good working relationships between all the team members and can be very satisfying, but only if it is implemented properly.

The use of OM is permitted in EC7 but engineers should be aware that there are some shortcomings, which need to be understood before applying EC7. The use of OM reduces the safety margins on design compared with traditional designs, but this can be managed within a rigorous monitoring and observation strategy, implemented within a coordinated team, to still give safe designs. Before applying OM, the management of ground risks and pre-agreed contingency plans (should things not go according to plan) need to be carefully evaluated and explained to the client/stakeholders. Approval for implementation of OM should be agreed with the client in the knowledge that it provides benefits and that there may be some drawbacks (e.g. implementing pre-agreed contingency plans), even if the risks are low. Approval from other third-party checking engineers may also be required before implementing OM.

Whilst the OM approach is intended to provide overall economy, obviously there are higher associated costs for increased instrumentation and monitoring, for implementing a stronger management team to implement the OM, for increased design services and reviewing of the monitoring data. However, on complex projects much of this cost may already be accounted for as instruments and monitoring are required for other reasons, and usually there is already a strong contractor's management team established on site.

The OM approach is not intended to be used where there is a risk-averse client, where there is likely to be a lack of total commitment from any member of the project team, where there is no thorough investigation of the ground and water conditions, and where there is a likelihood of a rapid or brittle mode of failure of the ground (including temporary structural elements).

This chapter guides the engineer through the principles of the use of OM on projects from inception (referred to as the 'ab initio' approach) and also, on projects under construction which for unexpected reasons are running into difficulty (referred to as 'best way out' approach). It relies heavily on the work of some key authors, named below, amongst others:

- *The Observational Method in Ground Engineering*, CIRIA C185 (Nicholson *et al*., 1999);
- Peck (1969);
- Powderman and Nicholson (1996).

These authors provide plenty of examples on the structured implementation of OM on engineering projects. Additional examples from Europe are also given in a recent study carried out by a working party on the use of OM in Europe (GeoTechNet, 2005); this includes seven case examples of the 'structured' use of OM on both building and civil engineering projects and also highlights the overall cost and programme savings made, which the reader might find useful.

100.1.1 Differences between Peck's and CIRIA's approach to OM

The observational method has developed over the last 60 years and was initially applied on a 'trial and error' basis to improve designs. It was not until Peck's Rankine lecture (1969) that an integrated process for predicting, monitoring, reviewing and modifying designs was advocated operating within a framework of OM, and without compromising the safety of the structure.

To successfully implement OM, Peck (1969) identified that it was necessary to have two designs compared with the traditional single design approach in geotechnics. A range of foreseeable conditions needed to be considered, which Peck associated with the most likely condition to happen in practice ('most probable') and the least likely condition to happen ('most unfavourable') (refer to section 100.3.2 for definitions, also illustrated in **Figures 100.4** and **100.5**). He suggested a design starting with the most probable (best estimate) condition and varying the design and/or construction to the planned most unfavourable condition, should observed behaviour be worse than that predicted based on best estimate parameters. Peck's (1969) eight key ingredients for successful use of OM are given in **Table 100.1**.

This approach is fundamentally different to the recent work on OM, published by the Construction Industry Research and Information Association (Nicholson *et al*., 1999). The approach advocated in Nicholson *et al*. (1999) starts with initial moderately conservative parameters (the same as 'characteristic' parameters in EC7), to be relaxed to a likely real situation (i.e. most probable condition) during construction, should the observed behaviour warrant it. This approach is also known as *progressive modification* to the design and was first suggested by Powderham (1994). The setting up of a rigorous traffic-light trigger system (red, amber and green) to deal with uncertainties in the ground during construction was also established after Peck's work. Both these modifications result in improvement to the use of OM on projects, leading to safer designs.

100.1.2 Definition of OM

The best definition of the OM approach is described in CIRIA 185 (Nicholson *et al*., 1999) (see **Box 100.1**). Often engineers mistake monitoring instruments on a project as following an OM approach, and **Box 100.1** shows that there is a proper operational framework for carrying out OM and monitoring is just part of this process.

1	There must be sufficient site investigation
2	Design is developed on most probable (best estimates) to predict behaviour
3	Develop monitoring strategy on calculated values for best case
4	Perform calculations on most unfavourable conditions
5	Identify contingency plans for most unfavourable
6	Monitor and evaluate actual conditions
7	Modify design to suit actual conditions if triggers are exceeded
8	OM can only be done if there is adequate time to make decisions and implement

Table 100.1 Peck's (1969) eight key ingredients for OM

Box 100.1 Definition of OM (CIRIA 185 (1999))

'The Observational Method in ground engineering is a continuous, managed, integrated, process of design, construction control, monitoring and review that enables previously defined modifications to be incorporated during or after construction as appropriate. All these aspects have to be demonstrably robust. The objective is to achieve greater overall economy without compromising safety.'

100.1.3 Comparison between traditional designs and OM design

Traditional ground engineering projects are usually based on a single, fully developed, robust design and there is no intention to vary the design during construction. Instrumentation and monitoring may also be carried out but it plays a very *passive* role, to check original predictions are still valid and provide confidence to third-party checkers, e.g. designers for adjacent building owners affected by a development. In CIRIA (1999) this traditional design is termed 'predefined design'. In comparison, in OM the monitoring plays a very *active* role in both the design and construction, allowing planned modifications to be carried out within an agreed contractual framework that involves all the main parties (client, designer and contractor). The differences in the two design approaches are illustrated in **Table 100.2**.

Peck (1969) defined two OM approaches:

- the 'ab initio' approach, adopted from inception of the project;
- the 'best way out' approach, adopted after the project has commenced and some unexpected event has occurred that is different to the predefined design or failure occurs, and where OM is required to establish a way of getting out of a difficulty.

Predefined design process (traditional design)	The OM process
■ Permanent works	■ Temporary works
■ One set of parameters	■ Two sets of parameters
■ One design/predictions	■ Two designs and predictions
■ Outline of construction method	■ Integrated design and construction methods
■ Contractor's temporary works design/method statement	■ Methods relate to triggers
■ Monitoring checks predictions not exceeded	■ Comprehensive and robust monitoring system
■ If checks are exceeded, consider: (a) best way out approach to design; or (b) redefine the predefined design approach reassessing the geotechnical uncertainties in the ground (see **Table 100.5**)	■ Review and modify process – Contingency plan – Improvement plan
■ Emergency plan	■ Emergency plan

Table 100.2 Comparison of the predefined design process and the observational method

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Case examples presented on the GeoTechNet site give examples of both the 'ab initio' and 'best way out' OM approaches. A paper by Nicholson *et al*. (2006) suggests a structural framework for operating the 'best way out' approach for recovery of deep, multi-stage excavation projects when problems occur during construction, like that which occurred at Nicoll Highway, Singapore (COI, 2005). This operational framework for carrying out the 'best way out' is also described in section 100.5 of this chapter.

100.2 Fundamentals of OM implementation and pros and cons of its use

100.2.1 General

Eurocode 7 does not clearly define the framework to be followed when adopting OM and there are other drawbacks which can be strengthened if use of CIRIA (1999) is also made on OM projects, as described below.

100.2.2 OM drawbacks in Eurocode 7 (2004)

The OM method described in Clause 2.7 of EC7 has been reproduced in **Box 100.2** below to illustrate the main drawbacks, which are as follows:

- It is primarily aimed at the ab initio approach to OM, although it does not exclude the 'best way out' application of OM.
- Whilst it refers to 'acceptable limits of behaviour' it does not define how these may be derived, since EC7's premise for design is based on use of 'characteristic values' which present a lower cautious limit in design, but not the upper limit to represent the most likely behaviour (most probable case), needed to implement the OM approach.
- No trigger limits are defined to establish planned contingency actions to check behaviour.
- There is no operational framework described for management of the OM within a contract, either within national policy or in a project organisation.

Box 100.2 Eurocode 7, clause 2.7 (2004)

Observational method

(1) When prediction of geotechnical behaviour is difficult, it can be appropriate to apply the approach known as 'the observational method', in which the design is reviewed during construction.

(2) The following requirements shall be met before construction is started:

- acceptable limits of behaviour shall be established;
- the range of possible behaviour shall be assessed and it shall be shown that there is an acceptable probability that the actual behaviour will be within the acceptable limits;
- a plan of monitoring shall be devised, which will reveal whether the actual behaviour lies within the acceptable limits (the monitoring shall make this clear at a sufficiently early stage, and with sufficiently short intervals to allow contingency actions to be undertaken successfully);
- the response time of the instruments and the procedures for analysing the results shall be sufficiently rapid in relation to the possible evolution of the system;
- a plan of contingency actions shall be devised, which may be adopted if the monitoring reveals behaviour outside acceptable limits.

(3) During construction, the monitoring shall be carried out as planned.

(4) The results of the monitoring shall be assessed at appropriate stages and the planned contingency actions shall be put into operation if the limits of behaviour are exceeded.

(5) Monitoring equipment shall either be replaced or extended if it fails to supply reliable data of appropriate type or in sufficient quantity.

100.2.3 Operational framework for following OM

The operational framework for implementing OM is illustrated in **Figure 100.1**. The OM has to be carried out within the framework of any national and corporate policies governing design codes, specifications, quality management systems and health and safety regulations (e.g. in the UK this is Health and Safety (HSE) Regulations, and Construction Design and Management (CDM) Regulations, 1994). This

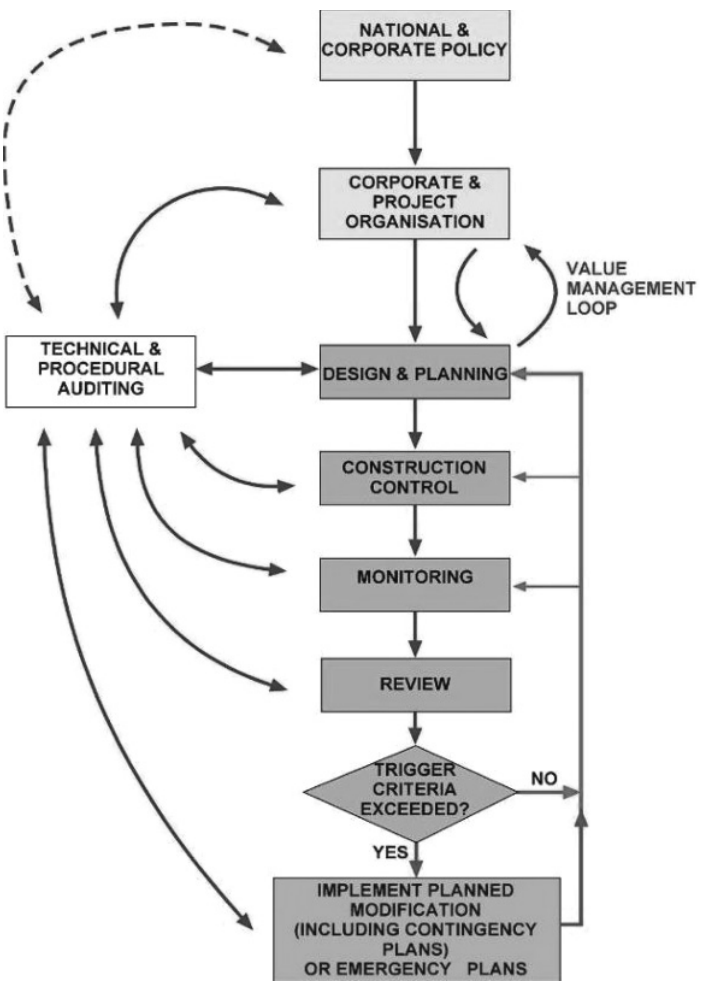

Figure 100.1 The observational method
Modified with permission from CIRIA R185 (Nicholson, Tse and Penny, 1999). www.ciria.org

is represented by the upper box in **Figure 100.1** (see also section 100.3.5 for details).

The second box defines the structure of the key players in the stakeholder's organisation (i.e. the client, designer, contractors, third-party checkers and other inspectors), their roles and responsibilities, and the relationship between organisations and the individuals. This needs to address the culture of each organisation, the level of staff training, experience, openness to communication and management commitment to implementing the OM approach. The stakeholders also need to 'buy into' the technical and commercial risks should any planned contingency or emergency measures need to be implemented, even if this risk is considered low.

Once the OM is agreed at 'project organisation' level, the remaining boxes describe the robust management structure required to implement OM at both design and construction stage and to control the monitoring and reviewing aspects of the observational method when the works are on site. The works have to progress to an agreed plan, with risks being recognised at each construction phase. Daily construction progress has to be under the control of a management structure that ensures any deviation from the method is fully thought through by all members of the project team and covered by an amendment to the plan. A monitoring regime has to be set in place, with competent staff made available to check, review and respond to all monitoring results within a given timescale from when they become available. There then needs to be clear instructions to all involved for all foreseeable situations. Finally, contingency plans need to be in place that can be rapidly implemented should preset 'trigger' limits be breached or any other unforeseen situation develops.

'Auditing', preferably by an independent geotechnical firm, is essential as it checks that the OM designer and project team are following established procedures and reaching the correct technical interpretations. Ideally this should be carried out by a designer who is unconnected with the OM process.

100.2.4 OM management process on site

At site level, there are usually many layers of contracting organisations involved in a project and all the main players need to (a) buy into the OM process and (b) have clearly defined responsibility levels. An example of the interaction between these organisations and the *managed* reporting of the construction and monitoring process is given in a paper by Chapman and Green (2004) for a deep basement project in central London; this structure chart is illustrated in **Figure 100.2**. On this project successful implementation of the OM relied on a clear understanding of the process, roles and responsibilities between the main contractor (HBG), the groundworks contractor (McGee), the concreting contractor (Byrne Bros), the instrumentation contractor (Soil Instruments) and the designer/reviewer (Arup). The management and reporting structure was defined under a 'traffic-light' system of green, amber and red trigger levels, so that all parties were clear of their responsibilities, should pre-agreed contingency or emergency plans need to be implemented (see also section 100.4 of this chapter for details). These plans consisted of increased monitoring, stopping work and implementing additional propping or berms and/or reverting to the predefined design. In the event, the measured movements of the walls during construction were within acceptable limits, thus allowing considerable savings to be made as the alternative design allowed the excavation of double height basements to be sequenced for faster top-down construction.

100.2.5 Pros and cons of OM

OM offers potential savings of time and money and the monitoring provides the needed assurance concerning safety. Some potential benefits of OM are illustrated in **Figure 100.3** and seven detailed case examples of the benefits provided to clients are described in GeoTechNet (2005) (see also CIRIA 185).

However, whilst there are significant advantages associated with the OM application, there are extra costs associated with prescribing a higher level of management and control on site, more instrumentation, preparing for contingency plans and readiness to use back-up plans, e.g. extra propping, and reporting compared with a conventional design situation.

100.3 OM concepts and design

100.3.1 Uncertainty and serviceability

OM is most effective where there is a wide range of uncertainty. **Table 100.3** summarises the types of uncertainty that are often encountered in geotechnical projects.

The OM approach is not suitable where there is a possibility of 'brittle' behaviour in the structure or rapid deterioration in the materials which does not allow sufficient warning to implement any planned modifications (e.g. 'discovery–recovery' contingency plans to be used). Examples of such are rapid deterioration of soils caused by groundwater or non-ductile failures of structural members (struts/walling connections) in multi-propped basements.

100.3.2 Selection of design soil parameters

Where there is a wide range of uncertainty in the soil parameters the OM process in CIRIA 185 uses the terms 'most probable' and 'most unfavourable' to describe the range of soil conditions as illustrated in **Figure 100.4**.

The 'most probable' is a set of parameters that represent the probabilistic mean of all the data, although a degree of engineering judgement must be used in assessing this to take account of the quality of the data. The 'most unfavourable' parameter represents the 0.1% fractile of the data as shown in **Figure 100.4**, and this represents the worst value that the designer believes might occur in practice. The moderately conservative parameter (CIRIA 185) or 'characteristic value' of geotechnical parameters (defined in EC7, clause 2.4.5.2) represents a 'cautious estimate of the value affecting the occurrence of the limit state', and should ideally result in prediction of the upper 5%

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

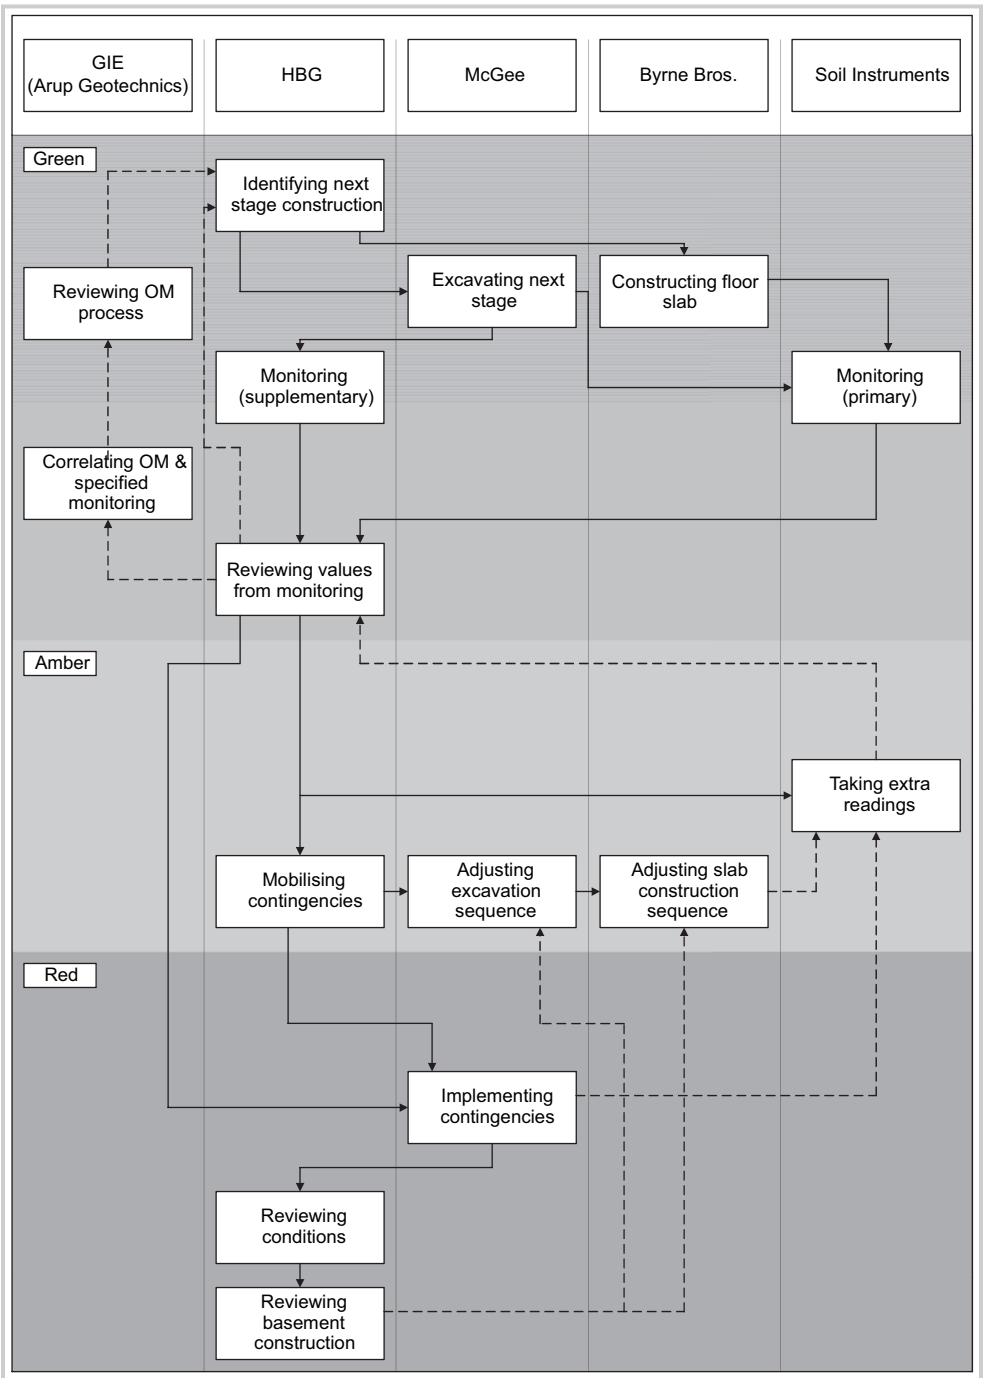

Figure 100.2 OM management and reporting structure on site
Data taken from Chapman and Green (2004)

fractile of the *measured deflections* as shown in **Figure 100.5**. The moderately conservative parameter is therefore not a precisely defined value. It is a *cautious estimate* of a parameter, worse than the probabilistic mean but not as severe as the most unfavourable as shown in **Figure 100.4**. In assessing these parameters the designer should carefully consider the quality of the site investigation data and assess their appropriateness for use in the OM approach. Often the original data may be appropriate for a more robust 'predefined design' approach but may not be of a higher quality for purposes of implementing OM. In this case it may be necessary to carry out further investigations, for instance if there is a lack of groundwater table information.

A typical example of the two sets of OM parameters (most probable and moderately conservative) which were used for a

20-m-deep basement wall design into London Clay is illustrated in **Table 100.4** (Chapman and Green, 2004). When selecting the most probable parameter for use in OM it is important that the designer can justify the choice; for instance this may be proven experience from other projects or back analysis of case studies.

100.3.3 Serviceability and ultimate limit state prediction

When designing to EC7, checks are required to ensure that the following ultimate limit states (ULS) are not exceeded:

- loss of equilibrium of the structure or the ground;
- internal failure or excessive deformations of the structure or structural elements;
- failure or excessive deformations of the ground due to loss of strength;
- loss of equilibrium of the structure or ground from uplift water pressures;
- hydraulic heave, internal erosion and piping of ground caused by hydraulic gradients.

EC7 also require checks on 'serviceability' limit states (SLS); states which are less serious than ULS but which are nevertheless undesirable and would need intervention or repair. In (traditional) predefined designs, calculations are used to check these states use 'characteristic values'.

In OM, the acceptable limit of behaviour is a 'serviceability' calculation, made using both the 'most probable' and 'characteristic' parameters and conditions. These provide the predictions against which the field performance can be monitored and reviewed. Trigger values can be established and contingency plans introduced as illustrated in **Figure 100.5** and **Table 100.5**.

The OM approach illustrated in **Figure 100.5** is for a cantilever wall design but the principle applies to other examples. The green, amber and red zones represent the trigger limits or traffic-light control system used in OM. The precise deflections set for the trigger values will depend on the 'discovery–recovery' contingency plans being used and not simply on the calculated values of predictions made. For instance, if the contingency plans involve a berm in front of the cantilever wall or introduction of a raking prop, then the time taken to implement these measures will influence the setting of these trigger limits. The triggers may then be based on two criteria: the first being wall deflection and the second based on the rate of wall movement to ensure that sufficient time remains to implement the contingency measure. The SLS wall deflection limit is sometimes used as an easily measured proxy for a range of undesirable outcomes, including bending moment failure and buckling of props. It should be noted that OM should not result in excessive movements and that, if limits were breached, the risk of a collapse would still be remote.

In respect to ULS predictions, EC7 identifies three sets of partial factors to apply when assessing the ultimate limit case. These partial factors are applied to 'characteristic values' of the ground but in essence the ULS design values are then similar to the most unfavourable conditions (see **Figure 100.5**). Although, for example in retaining walls, the ULS predictions are used for assessing structural forces, moments and shear,

Parameter	Moderately conservative Conventional design	Most probable (OM)	Reference

Most probable	50% likelihood of movement predictions being exceeded
Characteristic values (EC7) or moderately conservative (CIRIA185)	5% likelihood of movement predictions being exceeded
Most unfavourable (CIRIA 185)	0.1% likelihood of movement predictions being exceeded

Table 100.5 Definitions of most probable, characteristic values and most unfavourable
Data taken from CIRIA R185 (Nicholson, Tse and Penny, 1999)

the ULS deformations of the wall can also be a useful guide to determining the maximum predicted movements in the red zone (**Figure 100.5**). This 'upper limit' of wall deformation (or curvature) can provide a useful input when developing emergency plans of unexpected behaviour in OM and also with the 'best way out' approach in OM, provided the problem has been identified in time to implement a disaster and recovery plan before a ULS condition occurs, and with due regard to safety.

100.3.4 Factors of safety

The design values for ULS (stability) calculations are chosen so that the probability of failure will be acceptably small. It should

be noted that the intent of OM is to take out uncertainties in the ground (see **Box 100.2**), *not reduce factors of safety*, when assessing the ultimate limit state condition in design.

UK standards and those of some other European countries have traditionally applied 'factors of safety' on the design soil parameter, which can vary depending on the type of foundation and type of redistribution of load in the ground (e.g. piled rafts operate differently from single piles per column). EC7, on the other hand, applies partial factors on the characteristic value of the ground parameters. **Figure 100.6** illustrates how the two approaches can produce different factors of safety and how they can vary for different assumed design soil parameters.

100.3.5 Setting OM within the context of a contractual model and safe design

In the UK, there are essentially two forms of main design contracts:

- The client appoints a consulting practice to carry out the permanent design ('engineer design') and the contractor is responsible for carrying out the specified works. In this form of contract the contractor is only responsible for any temporary works design required to complete the permanent works.
- The client appoints a 'design and build' contractor to complete the design based generally on an outline or scheme design performed by a consulting engineering firm.

Other variations to this also occur when a construction manager or project manager is appointed by a client to manage the overall contract. It should be noted that in some European countries the contractual model is very different, responsibilities between parties are less clear, the legal obligations on parties may be severe, and so the application of OM also needs to consider these factors.

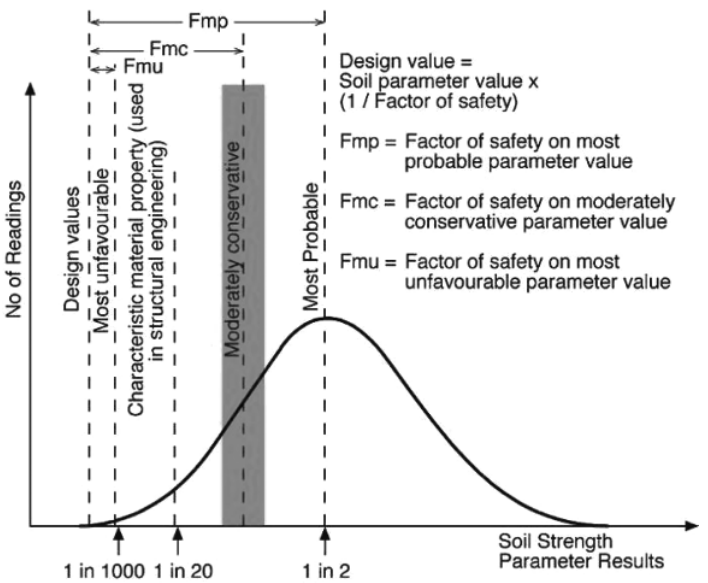

Figure 100.6 Application of factors of safety to different types of design soil parameters
Modified with permission from CIRIA R185 (Nicholson, Tse and Penny, 1999). www.ciria.org

The OM process can be applied to both forms of contract in the UK model described above. In both cases the design product comprises:

- drawings;
- work specifications and bills of quantities;
- calculations.

In addition to this, the UK Construction (Design and Management) (CDM) Regulations 2007 place new duties on the client, designers and contractors to take health and safety into account in both the design and construction of a project. For the designer this means that the design is no longer a set of calculations but must also:

- address buildability issues;
- identify hazards and risks in respect to safety;
- eliminate hazards through good design or, where it is not possible, to reduce the risk to a low level;
- show how this process has evolved in the design by producing a 'risk register';
- address impact on adjacent structures (above or below ground).

These regulations are intended to produce stronger links between the designer and the contractor and minimise risk of failures, via:

- production of 'heath and safety plans' by both the engineer and contractor;
- appointment of a planning supervisor by the client, who vets these plans before and during construction;
- seeking approval from third-party checkers.

Therefore, the CDM Regulations are in line with the OM objective of integrating the design and construction process to produce safe designs and construction practices. From work carried under Work Package 3 of GeoTechNet funded by the European Commission the UK contractual model with appropriate CDM Regulations and risk assessments do not appear to exist in all countries in Europe. Again, when carrying out OM in these countries, the national polices and regulations need to be fully understood and incorporated within the OM process.

On NATM tunnelling projects, HSC (1996) also describes the process of managing risk through the use of a 'discovery–recovery' model before an unacceptable failure scenario is reached, and this approach is entirely aligned with the OM approach.

100.3.6 Rapid deterioration

In certain engineering situations, rapid deterioration can be controlled by modifying the construction sequence as follows:

(1) **Using the multi-stage construction process** – for instance, an example may be an embankment construction over soft

clays. In this situation a rapid deterioration in the factor of safety can be controlled by 'staged' filling, between rest periods, using monitoring to control when the next lift is done (an example of this is given in **Figure 100.7**).

(2) **Using the incremental construction process** – for instance, an example may be in NATM tunnelling work, where the rate of advancing the tunnel face and controlling face loss is a critical component in determining how the ground movements are controlled in the discovery–recovery programme (see **Figure 100.8**) using the traffic-light system described above. This figure shows that the later the problem is discovered, the higher the risk and the longer the structure remains in a state of reduced stability (red zone). Late instigation of decision-making and recovery would also have the same effect. In such instances, trigger limits can be set as both absolute values and/or rate of movements.

The importance of early decision-making to instigate actions for recovery is an important feature of the UK Health and Safety Executive (HSC, 1996) discovery–recovery model, and is a legal requirement for use on all UK construction sites. The use of trigger values described below, an essential feature of OM, can also be used in the 'predefined designs' (see section 100.1.3) to allow sufficient time for implementation of emergency measures when monitoring is being used.

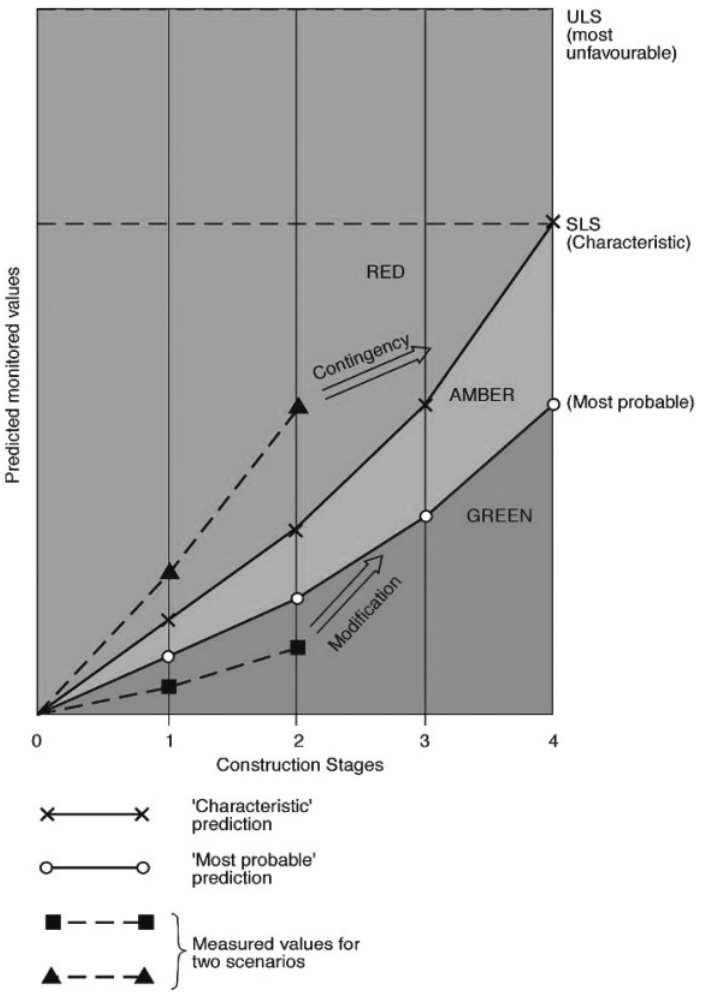

Figure 100.7 Multi-stage construction trigger values
Modified with permission from CIRIA R185 (Nicholson, Tse and Penny, 1999). www.ciria.org

100.4 Implementation of planned modifications during construction

100.4.1 Trigger values

As previously mentioned OM uses a 'traffic-light' system with green, amber and red response zones which allow construction to be controlled, should there be a risk of exceeding the safe green limit, as follows:

- green – continue construction;
- amber – continue with caution and prepare to implement contingency measures, increase rate of monitoring;
- red – stop progress, do everything possible to slow movements, implement contingency measures.

In setting the trigger values the following should be noted:

- The values set may be absolute values or rates of movements or both.
- The trigger limits set should also consider the accuracy of the instrument and whether it is practically measurable.
- The choice of instruments to measure movements should therefore be appropriate for the project and not based simply on lowest cost.

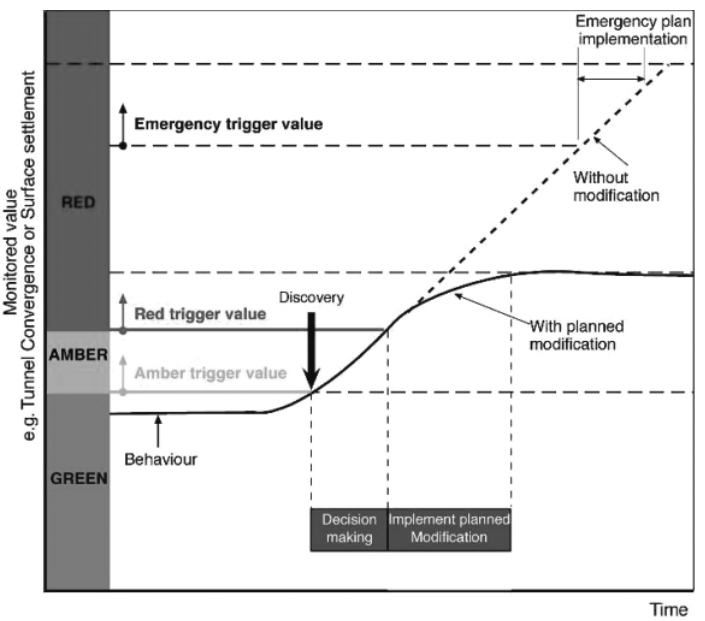

Figure 100.8 Traffic-light system for an incremental excavation (tunnels) process
Modified with permission from CIRIA R185 (Nicholson, Tse and Penny, 1999). www.ciria.org

- The amber/green limits should be sensibly set based on the design so that the likelihood of breaching this limit is small (e.g. values may occasionally stray outside the green zone) but also treated seriously if it is breached.
- The contingency/implementation plans should be taken seriously if the trigger limits are being breached.
- The choice of the instrumentation should be treated seriously and the monitoring contractor should be experienced in this type of work.

The trigger limits should be linked to the 'most probable' (green/amber limit) and the 'characteristic values' (amber/red limit) for implementation of the planned modifications in OM, as illustrated in **Figures 100.5**, **100.7** and **100.8**. A further example, for use with cantilever retaining wall movements is illustrated in **Figure 100.9**. It can be seen that in this example the measured movements were also well below the most probable conditions.

100.4.2 Monitoring systems

Monitoring systems will vary depending on the type of construction project in which OM is implemented. It is also very important to define both 'primary' and 'secondary' monitoring systems in OM. For example in multi-prop deep basements, the primary system (e.g. inclinometers and wall-mounted settlement gauges on neighbouring party wall structures) may be the main instruments relied upon to allow implementation of any contingency measures in OM, whilst the secondary system (e.g. 3D targets at top of walls or levelling surrounding ground) might be a more frequent and fast monitoring system to quickly assess the progress of the excavation works and aid a broader understanding of the pattern of ground movements on a site. When considering the amount of instrumentation for use on a project, considerations should be made in respect to whether to monitor using remote methods (can be expensive) or by manual methods (labour-intensive) and if the latter, how long it will take to carry out a round of monitoring in a single day. This will then allow assessments of the most important instruments to be monitored to be made as part of the overall OM strategy.

An essential part of OM is that the primary system needs to be immediately repaired if damaged on site, to ensure that OM can be continued. Chapman and Green (2004) explain the use of primary and secondary instrumentation for a deep basement in London, in the context of the trigger limits and the process owner (see **Figure 100.2**).

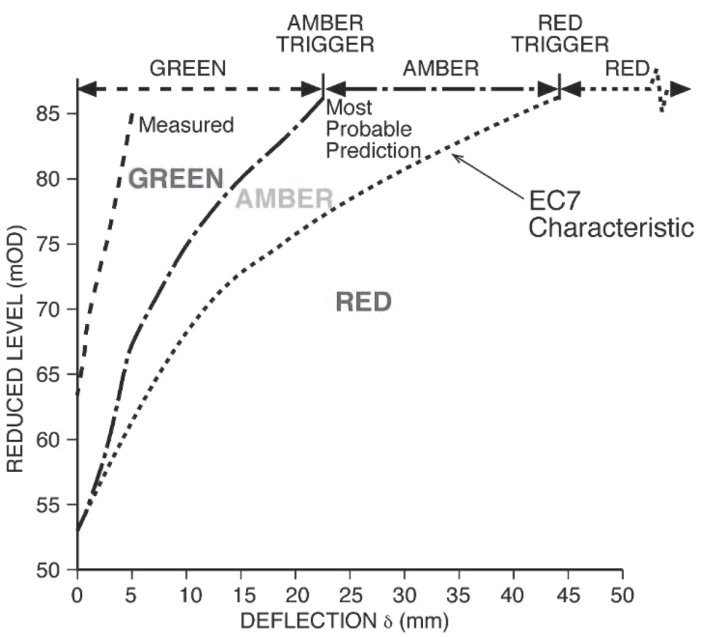

Figure 100.9 Example of trigger limits in retaining walls
Modified with permission from CIRIA R185 (Nicholson, Tse and Penny, 1999). www.ciria.org

100.4.3 OM quality plans

It is essential to have a quality plan before implementing OM on a site. This plan would present the designer's movement predictions based on the defined construction sequence. Each stage of construction sequence should also show the acceptable limits of predicted behaviour using the traffic-light system described above.

Simple graphical outputs that the whole project team can understand are essential and an example of this is illustrated in **Figure 100.10** for a 20-m-deep basement, excavated in a top-down manner, in London. This quality plan shows the predicted green and red limits for wall deflection at each dig stage, for a planned double height excavation technique, to allow floors to be built quickly. The actual movements recorded from inclinometers can then be plotted for comparison with predicted behaviour. These graphs allow the OM reviewer to make informed judgements and the whole project team are brought into the decision-making process: whether to continue to the next dig level, or to implement contingency measures before continuing. For the example illustrated, contingency measures involved additional propping, use of natural berms in front of the wall before proceeding to the next level, and changing the construction sequence to the original 'predefined design' which involved progressing excavation/floors one after another.

100.4.4 Construction control

Successful construction control is a vital part of OM; the main process is as follows.

- A construction control proforma is used to record all details of construction operations, strengths of materials exposed during staged excavations, the fabric and structure of exposed materials and the deterioration of surfaces exposed to water (see example of cutting **Figure 100.11**).
- This control has to be fully integrated within the project team, simple to use and the data easy to read; graphical outputs are essential for informed decisions to be made (see **Figure 100.10**).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

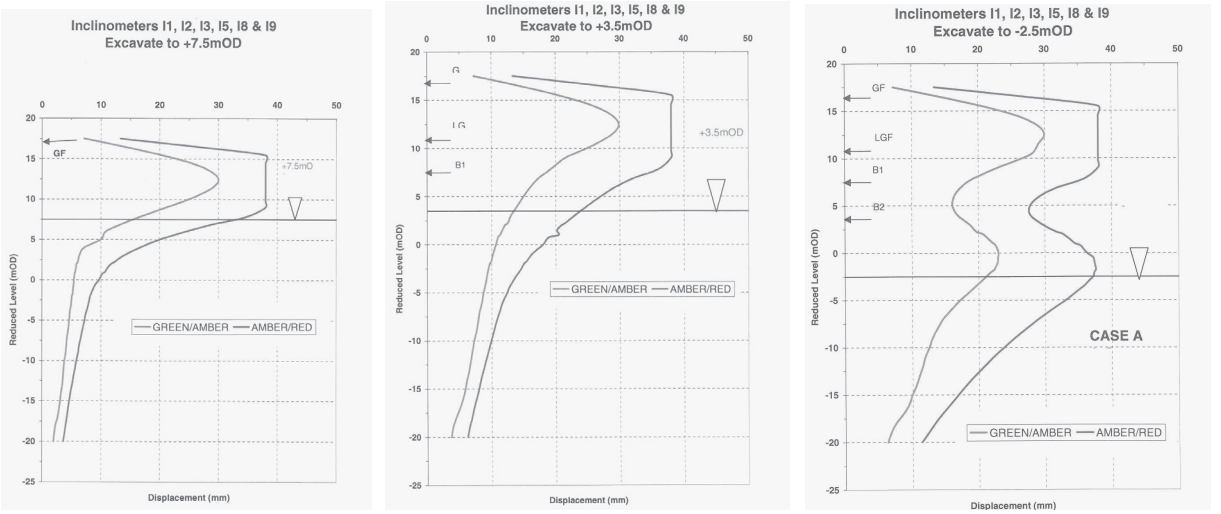

Figure 100.10 Typical quality plan developed for a phased top-down basement excavation
Reproduced from Nicholson, Dew and Grose (2006)

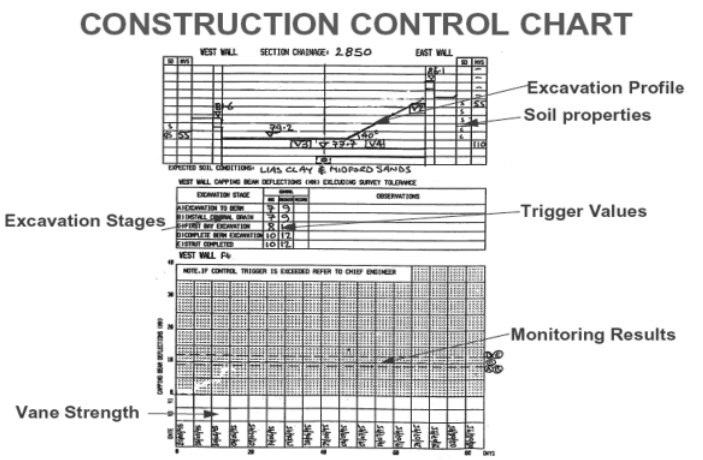

Figure 100.11 Example of construction control proforma sheets on site prepared by a contractor
Reproduced from Nicholson, Dew and Grose (2006)

- Each process has to have a process owner, with certain levels of responsibilities and implementing of actions, as illustrated in **Figure 100.2** and described in Chapman and Green (2004). Where there are many trade sub-contractors involved in a project, the key organisation for making the decision for reviewing the values from the site monitoring and implementing planned contingencies is often the main contractor, who has greater control and powers to immediately stop works on site.

100.5 'Best way out' approach in OM

The 'best way out' approach is used when monitoring checks in a predefined design (**Table 100.1**) exceeds, for unexpected reasons, predicted values but before an emergency condition is reached. Peck (1969) gives some good examples of the 'best way out' approach in which OM is adopted in response to some unexpected events or failure to establish a way out of a difficulty. Nicholson *et al*. (2006) present a more structured approach for recovery of deep, multi-stage excavation projects when problems occur during excavation. These authors studied the post-inquiry reports following the collapse of Nicoll Highway (COI, 2005), and to avoid such failures occurring again suggested a 'best way out' solution which is described below.

In the event of a 'discovery', the 'best way out' approach would trigger an '*initial recovery decision-making*' stage as shown in **Figure 100.12**.

In all cases this will result in stopping work and/or implementing emergency planned measures to secure the safety of site staff and the general public while the unexpected event is fully investigated. This assessment will inevitably be somewhat qualitative rather than quantitative as decisions need to be made rapidly at this initial stage.

Once the safety of the site has been secured, the project team can then turn their attention to recovery of the project back to a fully stable condition which means first carrying out a 'design review process' of the unexpected event, by back analysis of the actual conditions and comparison with the original design. This process can be broken down into four processes (termed 'RADO') as shown in **Figure 100.12**. These processes are briefly described in section 100.5.1 below.

Following this design review, the project team can then consider the following two stages:

- whether to initiate OM 'best way out', in which case this approach would follow the OM framework illustrated in **Figure 100.1** and described in this chapter; or
- whether to make a complete re-design based on a traditional, but revised, predefined design.

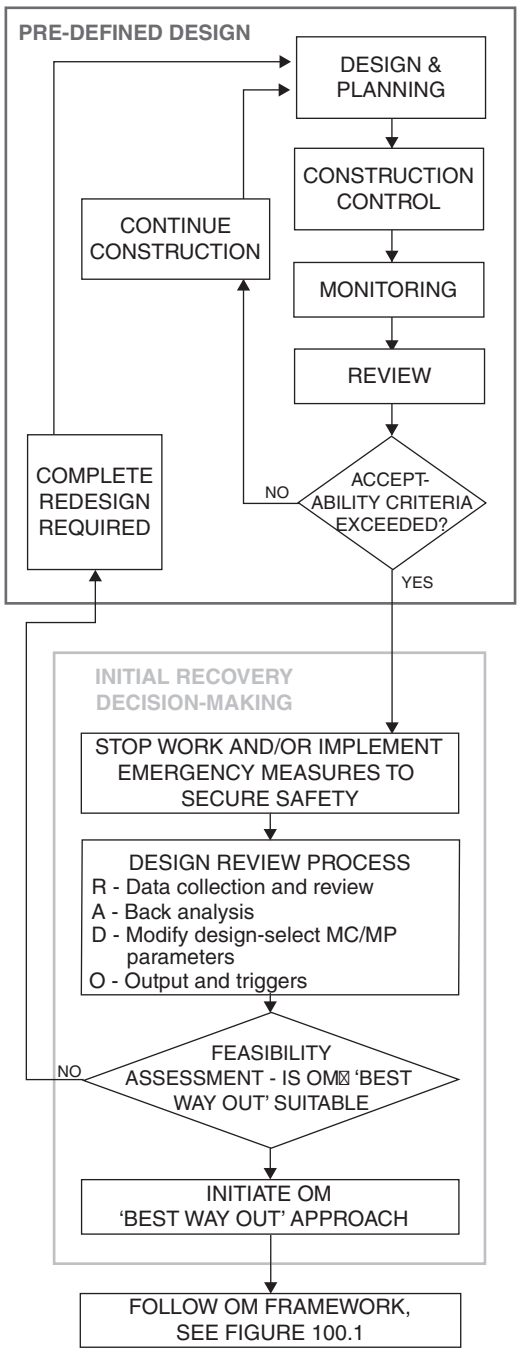

Figure 100.12 'Best way out' operational framework
Reproduced from Nicholson, Dew and Grose (2006)

100.5.1 Four processes of design review (RADO)

100.5.1.1 Process R: data collection and review

This process involves collecting all available data to define the behaviour of the structure for use in the back analysis. Particular emphasis should be placed on understanding the actual conditions and behaviour operating in the field, rather than justifying the original design assumptions. Sources of data should include: soil data and stratigraphy; construction records; actual sequence of events to inform back analysis process; and observations and physical measurements leading up to the unexpected event.

100.5.1.2 Process A: back analysis

The purpose of this process is to refine the designer's understanding of the actual behaviour of the structure and reduce uncertainty in the design. The process involves: establishing most probable parameters; developing a satisfactory model using most probable parameters; comparing results with monitoring data and field observations; reviewing/revising parameters if good agreement is not achieved; and once a reliable model has been produced, proceeding to design.

100.5.1.3 Process D: verify modified design

This process involves predicting the future behaviour using the realistic model and set of parameters developed from back analysis, for the remaining construction stages, but adopting a level of conservatism into the model. The structure behaviour should adopt moderately conservative (characteristic) parameters for the serviceability design and 'worst credible' or factored parameters for stability checks (see sections 100.3.3 and 100.3.4)

100.5.1.4 Process O: Output plans and triggers

If the OM 'best way out' is to be used then the process of OM as described in this chapter has to be agreed with all stakeholders in the project, with appropriate contingency and monitoring plans and setting up of trigger values and management teams.

100.6 Concluding remarks

This chapter provides an overview of the use of OM in engineering projects. It provides a structural framework for carrying out OM for both the 'ab initio' (projects from initial conception) and 'best way out' approaches (traditionally designed projects running into difficulty). An extensive guide to OM is the UK CIRIA 185 (1999), and this was consulted widely in preparing this chapter. The reader is also asked to consult this document should OM be considered, as it sets out a proper framework for operating the observational method and is more rigorous than currently described in Eurocode 7. Other case examples quoted in this chapter also provide an excellent history of the use of OM on more recent projects since CIRIA 185.

The geotechnical close-out report is intended to describe, collate and summarise the geotechnical works that occurred during the construction phase of the works together with any post-construction monitoring. The report forms an essential part of the construction verification process and it provides information relevant for maintenance, demolition or re-use purposes by future owners of the asset. The close-out report should represent the final step in the geotechnical reporting cycle.

101.1 Introduction

This chapter describes the relevance and importance of producing a close-out report. Although it is often a contractual requirement of major civil infrastructure projects the close-out report rarely attracts the right level of attention to do it justice. Typically this report is produced in a rush, after the event, without the continuity of staff and during a period when the emphasis is on staff leaving site and demobilisation of the design team.

The importance of the close-out report during its production is not always immediately apparent to the author, as it is not until some future event (usually involving others) that the recorded information and specific details are required. In recognition of this, the report should be prepared on the basis that it forms an essential and valuable part of the design and construction process rather than a contractual compliance.

The geotechnical close-out report is the culmination of the geotechnical reporting cycle which includes preliminary studies and geotechnical reporting of the factual, interpretative and design data (see Chapter 50 *Geotechnical reporting* and Eurocode 7). The report may also be known as a feedback, completion, verification or validation report.

101.2 Reasons for writing close-out reports

It is good practice to record and document the geotechnical elements of the construction phase of a project as part of the construction verification in a close-out report. In some instances, as described below, it is a requirement to produce one. The report is an essential component of assessing re-use of the geotechnical elements in future projects (see BRE EP73, BRE EP75 and CIRIA C653). For example, faced with 100 30-year-old piles, there can be much greater confidence if there is a final as-built plan and knowledge that only piles numbered 23 and 76 had non-conformance reports (NCR) and that they were satisfactorily resolved, together with full details of installation and testing.

The close-out report provides a means of demonstrating the verification and implementation of the geotechnical design (from the geotechnical reporting phase) and records any changes to the design during the construction phase. As-built works frequently differ from those shown on the 'design' or 'for construction' drawings. **Figure 101.1** shows a chalk slope cut to the 'for construction' requirement, while **Figure 101.2** shows the additional remedial works added during site works to maintain stability of the infill deposits prior to topsoiling the slope.

A key element of the report is feedback on constructability issues which can then lead to more cost-effective buildable designs. This is an important feature for infrastructure owners, such as the UK Highways Agency, where feedback can be incorporated into future improvements to their standard specifications. An example would be reporting on how earthworks material behaved when placed and compacted which was just outside the specified grading envelope and whether the standard compaction criterion had to be altered to achieve a compliant compaction.

Figure 101.1 Cut slope in chalk formed to the 'for construction' slope angle

Figure 101.2 Cut slope to be recorded on the 'as built' drawing after remedial works

Figure 101.3 Historical foundations and well encountered during site clearance

The close-out report also provides information on the geotechnical works for ongoing maintenance, demolition, re-use and on rare occasions for forensic investigations when problems had occurred, such as excessive foundation settlement to the works.

Projects designed under the Eurocodes require the production of a Geotechnical Design Report (see Chapter 50 *Geotechnical reporting*). This design report, which is detailed in Eurocode 7 (EN1997-1:2004) as a Principle, has a requirement to provide a 'plan of supervision and monitoring' for the works. This plan identifies items to be appropriately checked and monitored both during and after construction of the works. When the checks and monitoring are completed Eurocode 7 requires the checks and monitoring results to be recorded as an 'addendum to the [Geotechnical Design] Report'. The close-out report can be used as a means of recording and providing the 'addendum' to the design report.

Box 101.1 Illustration of the benefit of a close-out report

The designed foundation solution for a 10-storey development in central London was for pile groups supporting the column loadings. During construction the following were noted by the supervision team: (a) some of the installed continuous flight auger (cfa) pile depths were shortened due to the reassessment of pile capacities using the results from site pile tests; (b) the installed pile reinforcement was of varying depth (10 m design length, 8 to 10 m installed lengths) due to difficulties in pushing the cage into the fresh concrete; and (c) the presence of historical mass concrete footings and a well (see **Figure 101.3**), which meant that a number of pile cap arrangements were re-designed to avoid the footing. Recording all these variations in the design in a close-out report means that in the future these piles could be assessed for re-use in a future redevelopment. Additionally, the report can provide information on the piles as an obstruction to tunnelling projects, or the foundation information can be used to assess the effects that ground movement from a tunnelling project would have on the piles.

An important justification for producing a close-out report is in satisfying the requirements of the UK CDM 2007 regulations. When these regulations apply to a project, there is a requirement for a 'Health and Safety File' (see Chapter 42 *Roles and responsibilities*) to be produced on completion of the project. This file is intended to provide information to future users, designers and contractors. A close-out report can be used as the mechanism for recording the relevant information for inclusion into the file. It should be noted that other parties to the construction works also input to the 'Health and Safety File' and that agreement should be reached between these parties as to the scope of their individual input. This agreement reduces the potential of either overlap and conflicting information or gaps in the information supplied.

The Highways Agency, one of the main UK infrastructure owners, has recognised the importance of recording the construction activities on its projects and as part of its design standards has a requirement for a feedback report which is described in HD 22/08 *Managing Geotechnical Risk* (2008). The piling industry has also understood the need for recording its on-site construction activities and has included the requirement for a 'Completion Report' in the widely used industry standard piling specification 'ICE specification for piling and embedded retaining walls' (2007).

The 'Reuse of Foundations for Urban Sites' (RuFUS) international conference held at the Building Research Establishment in 2006, highlighted the problem of verification of existing foundations from available information for re-use in new works. The proceedings (BRE EP73) and its associated best practice handbook (BRE EP75) provide useful background information of what information is required for assessing the re-use of foundations. This was further augmented in 2007 by CIRIA C653 *Reuse of Foundations* (Chapman *et al*., 2007) which provided greater detail of the information required for assessing the re-use of piled foundations, but the principles described could be applied to other foundation solutions. Important issues relating to insurance and liability of foundation re-use

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

are described in the paper by Chapman *et al*. (2001) and in CIRIA C653.

The AGS (2005) report *AGS Guidelines for the Preparation of the Ground Report* includes reasons for producing a close-out report of which the main points have been summarised in this chapter.

101.2.1 Key learning points

- A close-out report can demonstrate the verification and implementation of the geotechnical design in accordance with the design specification.
- The report brings together and records design changes and how they were implemented during the construction phase.
- The report provides useful information for the future re-use of the works.

101.3 Contents of close-out reports

The close-out report should be a stand-alone report that may cross-reference the design reports or the design specifications (including drawings). It does not completely replace them but should add to the geotechnical knowledge bank of the works. Therefore, the report should describe the site, the geotechnical works, verification and monitoring data in succinct text and be supported by material such as drawings, figures and photographs (see **Figure 101.4**). The source material should accompany the report, either as appendices to the report or as stand-alone reports, to which cross-reference is made. 'As-built' drawings are also an essential component of a close-out report detailing the actual constructed works. Photographs, properly referenced (e.g. with date, orientation, subject) also provide a good record of the works on site. A key element of the report is the inclusion of the site documentation, construction and supervision records (see Chapter 96 *Technical supervision of site works*).

The close-out report is not intended to be verification/validation of any geoenvironmental works carried out as part of the construction works. Geoenvironmental works include works such as testing of samples for contamination and remediation of contaminated ground. However, salient factors from the geoenvironmental works, such as contamination barriers, should be included in the close-out report. A separate report dealing with the verification/validation of any geoenvironmental works is generally required for issuing to the relevant authorities.

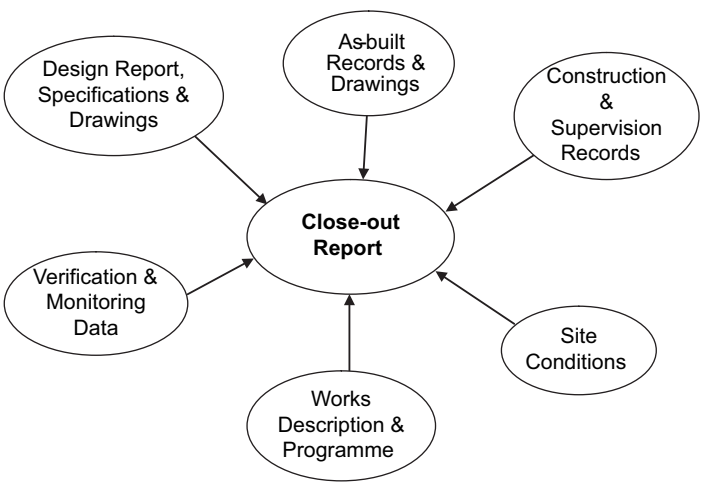

Figure 101.4 Major inputs to close-out reports

The majority of projects will generate large quantities of data that can be difficult to present or understand in the context of the overall project. The close-out report should present this information clearly within a logical framework. Summary data can often be presented more effectively in graphical format such as time series graphs or as spatial plots (**Figure 101.5**). In common with all reporting the presentation and clarity is important. Guidance on good practice in writing ground reports is given by the AGS (2007) *Guide to Good Practice in Writing Ground Reports*.

As a minimum the contents of a close-out report should be tailored to the size and complexity of the works and for the geotechnical works include details of the following:

- project organisational structure involved (e.g. client, consultant, main works contractor, groundworks contractor);
- description of the works (main and geotechnical) and other relevant works (e.g. geo-environmental remediation);
- works programme;
- works location related to a nationally recognised survey grid;
- description of the site background and original site conditions;
- summary of the relevant site investigation reports (including design reports);
- detail of additional site investigation works;
- site documentation, construction and supervision records;
- description of the ground and groundwater conditions encountered;
- geotechnical and compliance testing (including calibration certificates);
- monitoring of the works and its effects on adjacent buildings, structures and utilities;
- temporary works (including as-built details if significant);
- as-built records including drawings, schedules and registers (e.g. piles, soil nails, etc.);
- non-conformance reports or similar together with remedial actions;
- site and progress photographs;
- environmental monitoring (e.g. vibration from piling or plant movements);
- details of communications with regulators (e.g. the UK Environment Agency);
- post-works monitoring arrangements and maintenance requirements;
- critical requirements for decommissioning of the works.

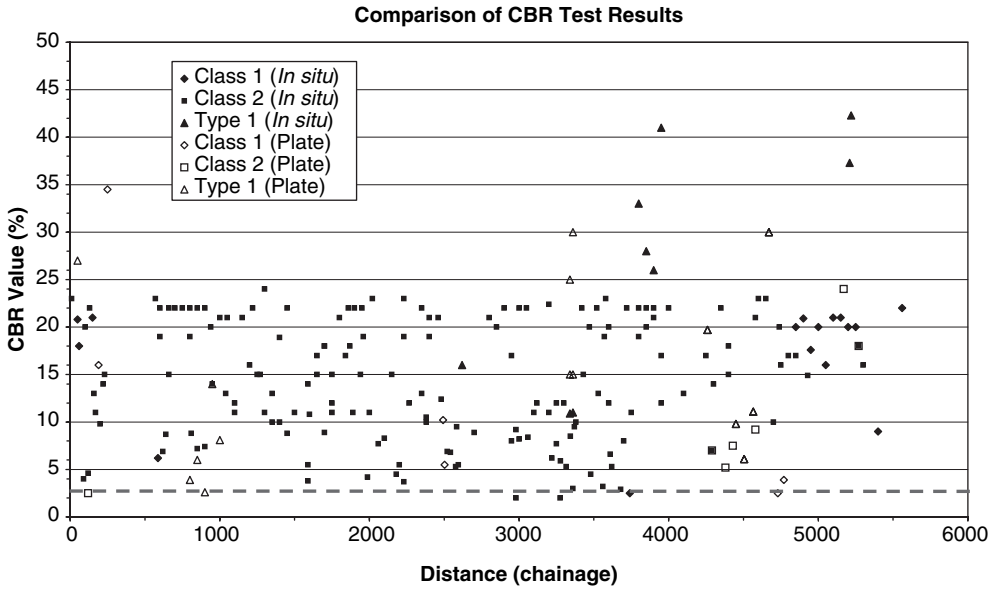

Figure 101.5 Example of graphical presentation of data

The UK Highways Agency, in their design standard HD 22/08, provides a detailed format for their feedback report. This format and content listing could form the starting point for close-out reports for other infrastructure-based projects. Further advice on the preparation and content of a close-out report has been published by the AGS (2005).

101.3.1 Key learning points

- Close-out report is to succinctly describe the site, the geotechnical works, verification and monitoring data and be supported by drawings, figures and photographs.
- The report should clearly record any changes made on site from that detailed in the geotechnical design report, specifications and construction drawings.

101.4 Reporting on quality issues

The quality system in place for the construction of the main works and geotechnical works should be described in the close-out report. The quality assurance strategy for the supervision of the works should also be described in the report. Relevant records relating to quality issues for the geotechnical works should be included in the close-out report together with a summary of the key quality issues and their resolution.

NCRs or similar are to be expected on geotechnical works due mainly to the variability of the ground (conditions and response) and the limitation on the extent that the ground can be assessed by the ground investigations (see Chapter 44 *Planning, procurement and management*). The resolution of NCRs should be described in the close-out report together with the remedial action taken and its effects on the design, construction and use of the geotechnical works. The fact that an NCR has been raised often means that there has been a variation in the construction of the geotechnical works and this would require additional design considerations. Therefore, the close-out report needs to show that the NCR has been rationally considered and the appropriate action taken to close out the NCR.

101.4.1 Key learning points

- Inclusion of quality-related records aids the verification process of the works.
- Reporting on the resolution of construction-related non-conformances is a key part in proving the quality of the works.

101.5 Reporting on health and safety issues

The designers of the geotechnical works will have identified the key health and safety issues and risks relating to their design. The preferable method of communicating these issues and risk is for them to be shown on the 'for construction' drawings typically as notes. These issues/risks should relate to the designer's significant assumptions on construction, maintenance and decommissioning. On completion of the construction activities the designer's significant assumptions on maintenance and decommissioning should be included on the 'as-built' drawings and summarised in the close-out report.

At the construction stage where a significant issue has been detailed by the designer, such as a suggested construction sequence, the contractor may adopt this sequence or develop their own alternative approach. This may significantly alter the original designer's assumptions relating to the maintenance and decommissioning of the works. Therefore these issues or risks would need reassessment by the contractor and/or designer before being included on the 'as-built' drawings.

The majority of geotechnical works once constructed are buried and not readily accessible for inspection/survey and

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

therefore accurate and detailed recording of exposed features and their treatment during the construction works are necessary. The following are examples of features that could have health and safety issues relating to maintenance, decommissioning or re-use for inclusion in the close-out report:

- observations on founding stratum, e.g. replacement areas of poor founding material;
- groundwater in excavations, e.g. amount, quality and from which stratum;
- areas where contaminated ground was encountered;
- historic man-made obstructions, e.g. foundations, archaeological remains, wells;
- newly created man-made obstructions, e.g. test piles, sheet piles left in place;
- utility services, especially on private land;
- temporary works, e.g. sheet piles, soil nails, extent of excavations/slopes, dewatering;
- areas of slope/excavation failures;
- details of adjacent structure foundations;
- areas of in-ground testing, e.g. piles, ground treatment, soil nails;
- locations of basements and voids.

Further information is described in the CIRIA SP136 *Site Guide to Foundation Construction* (1996), which contains useful information relating to observations to make during the construction works.

101.5.1 Key learning points

- Significant health and safety issues where appropriate should be included on the as-built drawings.
- Observations made during construction works are important and need to be recorded even if they do not impact on the current design.

101.6 Documentation systems and preserving data

Consideration needs to be given to the maintenance and accessibility of close-out reports. To facilitate the handling and storage of reports it is increasingly common for such reports and supporting data to be stored in electronic form. Various international standards are available that relate to the indexing, handling and transferring of electronic information. Electronic storage is subject to fast-moving technological changes in storage media type, availability of software (e.g. backward compatibility) to read the electronic version of the report and hardware able to support this software. It is recommended that hard copies are maintained as a safeguard, for example against software compatibility issues or corruption of electronic data.

Where a paper print-out of an electronic file (typically a spreadsheet) is provided then the format of the print-out should visibly include all the computational steps that were undertaken within the spreadsheet to produce the end result. For example, the steps in conversion of a frequency reading from a vibrating wire piezometer into a groundwater level should be shown together with cross-reference to the appropriate calibration data sheets.

In addition to providing the close-out report to their client, the consultant or contractor should hold such reports, information and data for the period required by their contract (typically six or 12 years). Note Eurocode 7 recommends 10 years with the more important documents stored for the lifetime of the relevant works. There should be mechanisms in place to have the ability to read the electronic data even if this means opening and re-saving the data using current software/hardware to safeguard against software/hardware becoming obsolete. However, the drawback is that data might be lost or damaged during this process and holding a hardcopy would allow the electronic copy to be verified against the hard-copy version. Finally, consideration should also be given to the safeguarding of the documentation storage site with off-site back-up of electronic data being a benefit against total loss of the main storage site. With the rising cost of storage there will be continuing pressure on destruction of the original design information. Consequently, the close-out report will become an invaluable reference for future works, be they ongoing maintenance, demolition or re-use.

101.6.1 Key learning points

- Maintain a hardcopy of the close-out report.
- Review software/hardware backward compatibility at regular intervals.

101.7 Summary

The close-out report, the final part of the geotechnical cycle, is intended to describe, collate and summarise all relevant geotechnical works that occur during the construction phase of the works together with any post-construction monitoring. It forms an essential part of the construction verification process. The report also provides valuable information on the geotechnical works allowing the future re-use of these works and hence increasing the sustainability profile of the initial works.

It is recommended this chapter is read in conjunction with

- Chapter 78 *Procurement and specification*
- Chapter 93 *Quality assurance*
- Chapter 96 *Technical supervision of site works*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

dynamic compaction, 276
micro-piles or root piles, 277
stone columns, 276–277
vibrocompaction, 276
in situ testing of, 657–658
landslides in, instruments for monitoring, 1398
liquefaction of, 266–267, **267**, 940–942
factors influencing, 941
safety factors against, 941–942
slope failure caused by, 945–946
made ground and non-engineered fills, 744
microstructure of, 158
mineral dimension, *156*
mixing, 1003
nails, 277
as natural material, 108, *109*
non-homogeneous and variable nature of, 109–110, *109*
nonlinear with complex stress–strain behaviour of, 111, *109*
particle shape, 157
particle size, 156–157
as particulate materials, 153–161, **153**
permeability, 1186
phase relationships of, 153
post-glacial deposits, 744
property determination techniques, 262
field measurement techniques, 261–262
laboratory measurements techniques, 261–262
red tropical, 342, *353*
reinforcement, 277, 1094–1095, 1095–1096
residual, 341, *350*
sampling, 655, **655**
settlement profile with depth, determination of, 890
skeleton, 153
small strain shear modulus, **265**, 263–264
stabilised soils, heave of, 530–531
stiffness profile on pile-group settlement, influence of, 827
strain-dependent behaviour of, 259–260, **260**
strain-dependent shear modulus, 264–265, **265**
strength, factors affecting, 754
strength model, 247–248
sulfate and acid, 517–531
theoretical behaviour of, 262–263
two- or three-phase nature of, 108–109, *109*
types of, 149, *156*
wave propagation in, 260–261
wave velocity in, 260–261
wind-blown, 393–394
soil–structure interaction, 5, 992–993
soil suction test, 1241
soil water characteristic curve (SWCC), 354
soil water retention curve (SWRC), 354
soldier pile walls, *see* king post walls
solidification, *see* stabilisation
soliflucted chalk, shallow foundation on, 101
soluble ground, 533–544
and karst geohazards, 533–534
distribution of, 534, **535**
geohazards
on gypsum terrains, 541, **542**
on sabkha environment, 543–544
on salt terrains, 541–543, **542**
investigations for karst geohazards, 540–541, *541*
investigations for karst hazards, **540**
limestone bedrock, engineering works on, 537–540, **538**
unseen caves, hazard of, 539–540
limestone kurst geohazard, impact of, 534–536, **536**
sinkholes, 533–534, **534**
soil-covered limestones, engineering works on, 536–537, **537**
solute suction, 353
sonic coring, 623
South Dahshur Pyramid, failure of, 11
spaced bored piles, 1076, *see also* pile(s/ing)
specialist down-hole tests, 691
specification for piling and embedded retaining walls (SPERW), 1191, 1197
specifications, 1163–1164
codes of practice, 1163–1164
design responsibility, 1164
Execution Codes, 1163

spectral analysis of surface waves (SASW), 261
spoil heaps, 451–452, 454, 456
SPOT, 616–617
sprayed concrete, in soil nail construction, 1309, **1309**
springs vs continuum, 856–858
square pad foundations bearing on rock, allowable pressures for, 777
squeezing rocks, 204, *see also* rocks
stabilisation, 277–279
  cement, 278–279
  lime, 277–278, **278**
stabilised soils, heave of, 530–531
stabilising fluids, 1197, **1198**
stability charts, 1044
standard penetration test (SPT), 218, 261, 267, 348, 349, 383, 620, 621–622, 632–633, 901, 942, 915, 916, 932, 1241, 1260, 1407
standpipe piezometers, 624–625, *see also* piezometers
standpipes, 624
state developers, 59, *see also* developers
static pile capacity testing, 1452–1458, *see also* pile capacity testing
  advantages and disadvantages of, 1456
  application of, 1455
  characteristics and potential deployment criteria, *1468*
  constant rate of penetration testing, 1453–1454
  lateral load tests, 1455–1456
  maintained load compression test, 1453
  settlement criteria, 1456
  specifying, 1457–1458
  tension tests, 1455
  top-down, **1454**
  types of, 1452–1453
  ultimate capacity determination and test termination, 1456–1457
  working principle of, 1454–1455
steel, 1475–1477
  box piles, 1211
  corrosion near the waterline, variability in, 1475
  -intensive basements, 1280
  problems associated with, 1475
  reinforcement cage check, 1476
  sheet pile cofferdam, 1475
  tube piles, 1214, 1215
  verification of, 1476–1477
steep-sided chalk cutting, failure of, 1297
steep slopes, 1289
  fill materials, placement of, **1292**
  monitoring and supervision of, 1293
  reinforcement, placement of, 1292, **1292**
stiffened rafts, 429–431, **430**, **431**
stiffness, 674–677
  of fills, 903, *904*
  of rocks, 198–200
  with strain, idealised variation of, **674**
stone columns, 276–277
stone piles, 734
stool leg, brittle and ductile behaviour of, 29
straight-shafted anchors, 1021, *see also* ground anchors
strain compatibility, 1095
strain-dependent behaviour, of soils, 259–260, **260**
strain-dependent shear modulus, 264–265, **265**
strains in simple rectangular beams, 284
  limiting values of Δ/L and limiting tensile strain, 285–286
  limiting values of Δ/L for very slight damage, 286
  relationship between Δ/L and levels of damage, 286–287
stratified rocks, 204, *see also* rocks
stratigraphy, 66
strength, 670–673

vibroreplacement, 276, 929–932
design principles for, 930–932
methods and key issues of, 930
vibro stone columns (VSCs), 1059, 1250–1252
aggregate requirements, 1252–1254
case histories, 1258–1259
cautions, 1257
design of, 1252
dry bottom-feed technique, 1250–1251
dry top-feed technique, 1250
practical issues, 1256–1257
dealing with obstructions, 1256
gas venting, 1256
installation tolerances, 1257

lateral forces, 1256
pre-boring, 1256
slopes and interceptor drains, 1256
stabilised platforms, 1256
working platforms, 1256
specifications for, 1252
wet top-feed technique, 1251–1252
virgin compression line, 184
visco-plastic method, 45–46
application of, 45–46
limitations of, 46
viscosity of rocks, 198, **207**
void filling, 913–914
design principles for, 914
execution controls, 914
methods and key issues of, 913–914
performance of, 914
perimeter and infill grouting for, 913
validation of, 914
volatile organic compound (VOC), 653, 655, 656
volume change, in fills, 904–907
applied stress due to building weight, 905–906
biodegradation, 906–907
chemical action, 907
self weight, 905
water content, 906
volume change potential (VCP), 421
classification of, *426*
shrink–swell potential based on, **427**
volumetric strain, 188–189
von Post system, *465*

wadis, 322
wall friction (adhesion), 1034–1035
around excavations, 1035–1036
effects on earth pressure, 224–225, *225*
walls
anchored bored-pile, 1080
and beam, connection between, **53**
buttress, 11
contiguous pile walls, 1280
bored, 963–964
crib, 960
crosswalls, 1003
diaphragm, *see* diaphragm walls
embedded, *see* embedded walls
fill materials, placement of, 1291
flood defence, 1280–1281
gabion, 960–961
masonry, 959
dry-stack, 960
modular, 959
monitoring and supervision of, 1293
multi-propped, 995
non-modular, 959
in plane strain analysis, modelling of, 50–51
porcupine, **960**
pre-cast reinforced-concrete stem, *966*
and prop
full connection between, **54**
pin-jointed connection between, **54**
quay, 1280–1281
reinforced, *see* reinforced soil walls
reinforcement, placement of, 1292
retaining, *see* retaining walls
sheet pile, *see* sheet pile walls
soft, with pre-cast walls or steel sheet insertions, 1287
and soil stiffness, 995
unreinforced mix-in-place, 1287
vertical and near-vertical, 1289
wall–soil friction, 993–994
Waltham Abbey, Essex, 1348, **1348**
warning signs, 1359
warning systems, 1296
Waste (England and Wales) Regulations (2005), 660
waste
acceptability criteria (WAC), 653, 661
classification, 660–661, **661**
hierarchy inverted triangle, 126, **126**
inert, 653, 660
reduction, 126, 130
Waste and Resources Action Programme (WRAP), 130, 1139
water, 1484
acceptability criteria, 661
in situ testing of, 658, *659*
ingress, 1359
removal of, 272–275
electro-osmosis, 275
pre-loading, 274
vertical drains, 274–275
water resource management, 126, 130–131, *see also* groundwater
aquifer recharge and recovery, 130–131
aquifer storage and recovery, 130–131
in geotechnical construction, 131
geotechnical project, impact of, 130, **131**
reduced operational energy, design for, 131
sustainable drainage systems, 130
water-soluble sulfate, 523–524, *see also* sulfate
water table
conditions above, 165
perched, 165
watertightness, grades of, 1031–1032
water treatment works, differential swelling, 92–93, **93**
wave propagation, in soils, 260–261
wave velocity, in soils, 260–261
weakly cemented mudrocks, 498–499
wellpoints, 1179, **1179–1181**, 1243–1244
horizontal, **1181**
installation, horizontal, **1181**
multi-stage, **1180**
for trench work, **1180**
wells
collector, 1183–1185, **1184**
combi steel, *see* combi steel walls
deep wells with submergible pumps, 1181–1182, **1181**, **1182**
ejector, 1182, **1183**
observation, 1380
pumping, 275
relief, 1183, **1184**
well-windowed experience, 17, 19, 30, 91
West Tower of Ely Cathedral, **33**
wet soil mixing, 1336–1337, *see also* soil mixing
wetting of unsaturated dry soils, 160–161
whole-life asset management, of earthworks, 1068
whole-life management, 127, 133, **133**
wind-blown soils, 393–394, *see also* soils
window sampling, 620, 901
