Bulk density is also a useful index and there is generally a good agreement between measured bulk densities and those determined from Equation (35.2), using G_{save} estimated from loss on ignition tests. Hobbs (1986) plotted the bulk density measured on five UK mires and showed that the degree of saturation/gas content was the main influence on bulk density when the water content was in excess of about 600%. About half the samples had bulk densities of less than 1 mg/m^3 when the water content was greater than 500%, indicating that the peat would be buoyant in water. For water contents in excess of about 200%, the volume of gas as a percentage of the total

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

volume is approximately 1-S_r, where S_r is the degree of saturation. The average gas volume indicated by the results of Hobbs (1986) is about 7.5%.

Although not normally considered an index test, the pH can be a useful indicator of the nature of peats and organic soils (Hobbs, 1986). Metabolic activity is influenced by temperature and acidity: the higher the temperature and pH (lower acidity) the faster the decomposition. There is a considerable degree of overlap, but bog peats have a pH in the range 4.5 to 3.3, and transitional peats from 6 to 4. The pH of a fen peat will depend on the water source; however, most tend to have pH greater than 5, with the acid fens being less than 5.

35.3.3 Sampling methods

It can be difficult to obtain 'undisturbed' samples of highly organic soils, particularly fibrous peats. Simple sampling methods which can be used to get continuous or almost continuous disturbed samples, such as gouge augers, can be used to determine a water content/depth profile and thus to identify important stratigraphic variations. Sharp-edged piston samples have been used successfully; however, the samples generally compress and it is important to record the percentage recovered in order to assess the degree of compression due to sampling. Undisturbed samples can be cut from the *in situ* material; however, this becomes impractical with depth. Special samplers, such as Sherbrooke sampler (Terzaghi *et al*., 1996) which essentially allows a block sample to be cut from the base of a borehole using a system of blades, can be used on special projects. Oxidation generally changes the colour of recovered samples when exposed to the atmosphere and biodegradation can occur within the samples. The colour changes are typically limited to the exposed surfaces; however, microbial processes can lead to gas formation which may contribute to excess pore water pressures (Kellner *et al*., 2005). The effect of such microbial process were investigated by Fox *et al*. (1999) by comparing the long-term settlements of an oedometer sample which had been sterilised using radiation to kill bacteria and fungi with untreated samples. This work suggests that biodegradation may be an issue in long-term creep tests, but additional research is required before this can be confirmed.

35.4 Compressibility of peats and organic soils

35.4.1 Introduction

The large compressions that can occur in virgin peats are clearly illustrated in **Figure 35.2**, which presents the vertical strain plotted against the logarithm of the effective stress, as recorded in a number of case histories (Landva and La Rochelle, 1983; additional cases by O'Loughlin, 2007), although some shear deformation and secondary compression is included in some of these data. These results show that a peat stratum can reduce in thickness by more than 50% under a relatively modest increase in effective stress of the order of 50 kPa. Furthermore, secondary compression can be the dominant process, and not 'a rather tiresome appendage' to the consolidation process (hydrodynamic) as is generally assumed (Hobbs, 1986). The large strains will necessarily distort the structure of peats and organic soils

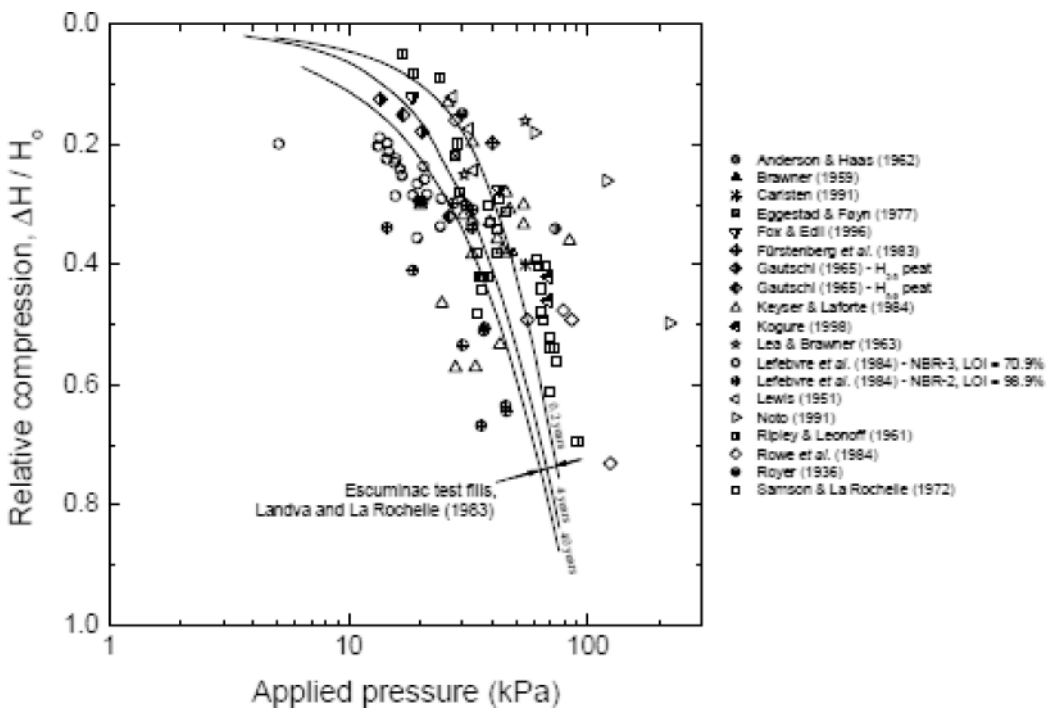

Figure 35.2 Relative compression versus applied pressure (Landva and La Rochelle, 1983, updated by O'Loughlin, 2007)
Reproduced from O'Loughlin (2007)

and hence the permeability and compressibility characteristics change as the soil compresses. Given the genesis of raised bogs with vegetation growth patterns, the properties are not uniform in either the vertical or horizontal direction. There are therefore many complexities in peats compared with mineral soils which must be considered when selecting an appropriate model to estimate settlements.

The terms 'primary' and 'secondary' compression can lead to confusion and to controversy (den Haan, 1996) and many researchers consider that it is better to consider 'primary consolidation' as a hydrodynamic phase in the settlement process that is controlled by the dissipation of excess pore water pressures, and that secondary compression is a continuous process that occurs during both the hydrodynamic phase and continues when the excess pore pressures have essentially dissipated. This introduces some interesting concepts, for example, that secondary compression movements should be estimated from the start of loading rather than from the end of primary consolidation (EOP), as is assumed in the EOP approach, which also affects the interpretation of 'pre-consolidation' or critical pressure.

35.4.2 Magnitude of settlement (constrained deformation)

35.4.2.1 Different philosophies

Secondary compression can be a dominant process in organic soils and there are two fundamentally different schools of thought on the way it should be modelled: one which considers that it begins at the end of primary consolidation (EOP method) and the other which considers that secondary compression occurs both during and after the primary consolidation phase, the primary consolidation being considered as the hydrodynamic phase. The significance of these two approaches for samples of different heights, H_1 and H_2, is illustrated in **Figure 35.3**, where t_p is the time to the completion of primary consolidation. The EOP assumption simplifies the estimation of settlements in that the primary settlements can be estimated in the traditional fashion and the secondary compression included as a separate calculation. The EOP approach would not include the additional settlement that would arise from secondary compression that occurs during the primary phase for a thick layer. The standard 24 hour consolidation test on peats would include some secondary compression, which may reduce the error in practice (Hobbs, 1986).

The EOP approach is frequently used in practice as the calculation models for the continuous approach to date are complex and the additional complexity is generally not justified when other uncertainties are considered, except for very large projects.

35.4.2.2 EOP method

The advantage of the EOP approach is that the primary settlement can be estimated from an e-log σ'_v plot in the normal fashion but necessarily requires some assumption/knowledge of a 'pre-consolidation/yield' pressure (σ'_c). Field and laboratory tests have shown that virgin peats do have an 'apparent' yield point, possibly due to capillary suction forces when in the acrotelm or due to the weight of snow (Hobbs, 1986; Mesri, 2007). This may be estimated from the e-log σ' curve in the normal Casagrande (1936) construction, by using Janbu's method (1963) or from relationships such as that given in Mesri (2007).

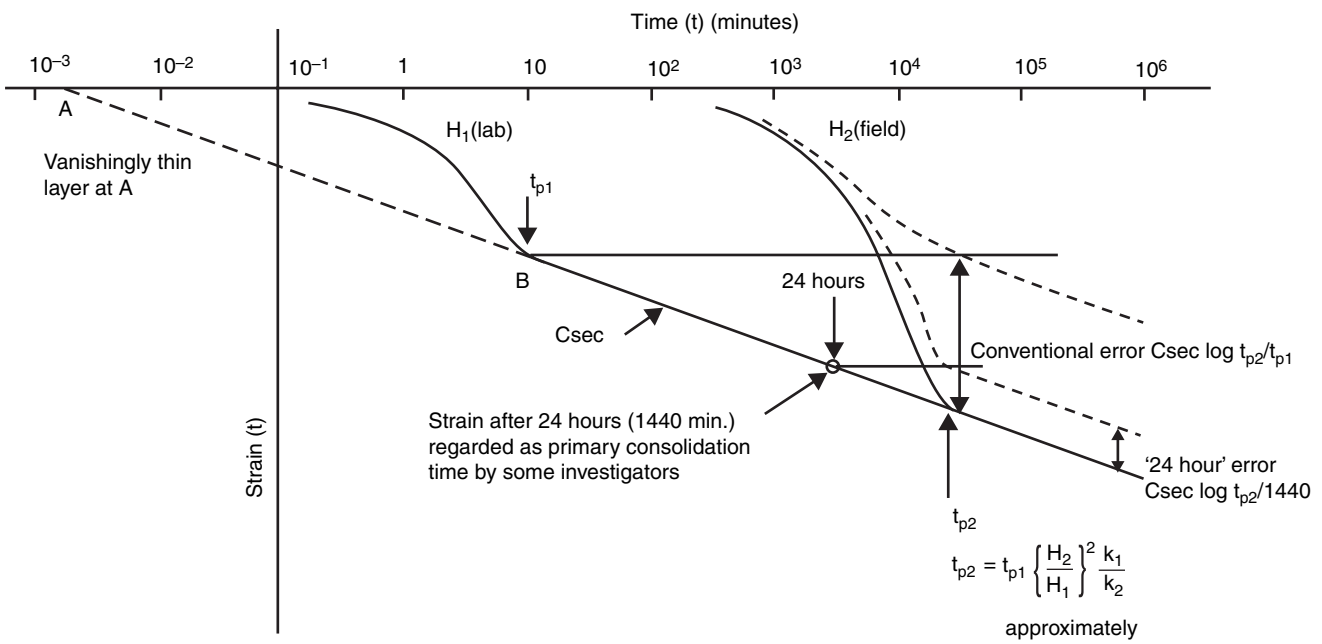

Figure 35.3 Comparison between EOP and continuous assumptions
Reproduced from Hobbs (1986) © The Geological Society

For those soils which have an essentially bi-linear e-log σ' relationship, which is not true for highly organic soils and peats as will be discussed later in this section, the compression and swelling indices, C_c and C_s, can be used to determine the change in void ratio due to a change in effective stress. Hobbs (1986) developed useful relationships for UK peats of $C_c = 0.0065w$ for bog and $C_c = 0.008w$ for fen peat. Mesri *et al*. (1997) suggest that $C_c = 0.01w$. Hobbs (1986) showed that there was a relationship between C_c (from 24 hour incrementally load consolidation tests) and initial void ratio which had a limiting value for peats of $C_c \approx 0.45e_o$.

It is generally more useful to consider the settlements in terms of strain (ε) resulting from an effective stress increase from σ'_{vo} to $\sigma'_{vo} + \Delta\sigma'_{vo}$ which, for increases in vertical effective stress from below to above the pre-consolidation pressure, is:

$$\varepsilon = \frac{\Delta e}{1+e_o} = \frac{C_s}{1+e_o}\mathrm{Log}\left(\frac{\sigma_c'}{\sigma_{vo}'}\right) + \frac{C_c}{1+e_o}\mathrm{Log}\left(\frac{\sigma_{vo}' + \Delta\sigma_v'}{\sigma_c'}\right) \quad (35.3)$$

$$\varepsilon = \frac{\Delta e}{1+e_o} = CR\mathrm{Log}\left(\frac{\sigma_c'}{\sigma_{vo}'}\right) + RR\mathrm{Log}\left(\frac{\sigma_{vo}' + \Delta\sigma_v'}{\sigma_c'}\right) \quad (35.4)$$

where CR and RR are the compression ratio and recompression ratios respectively.

Given that $e_o >> 1$ for peats, this implies that $C_c/(1+e_o) \approx 0.45$ is a limiting value. It also means that for peats, the settlement is virtually independent of the void ratio or water content. The use of the compression and recompression ratios, $CR = C_c/(1+e_o)$ and $RR = C_s/(1+e_o)$ respectively, requires an assumption regarding the initial void ratio and is therefore not a fundamental soil parameter. However, it can be useful in practice to give an indication of the variation in compressibility of normally or lightly consolidated soils. The CR values determined from 24 hour standard incremental consolidation tests are essentially independent of water contents for liquid limits in excess of about 200% (Farrell and O'Donnell, 2007), which supports the contention of limiting values of this parameter (see **Figure 35.4**). As stated previously, these 24 hour results inevitable include some secondary consolidation.

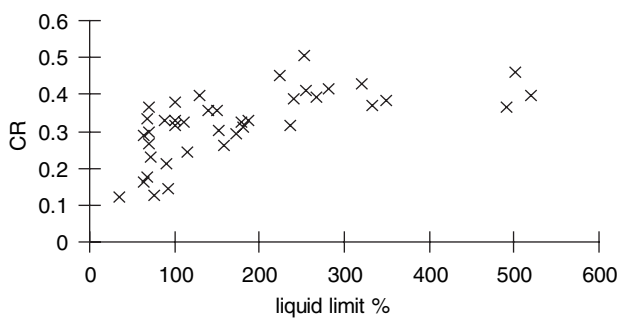

Figure 35.4 Variation of CR with w_L
Reproduced from Farrell *et al*. (2007)

Laboratory tests on highly compressible peat samples have shown that C_c is not constant at large strains (see **Figure 35.5**). This nonlinearity can be considered in the EOP method by using the actual curve e-logσ' (Mesri, 2007) or alternatively the plot can normally be linearised by using natural strain, e^H, in place of linear strain, e^c where $e^H = -\mathrm{Ln}(1-e^c)$. The superscript H refers to natural strains which are attributed to Hencky.

The void ratio and strain due to soil secondary compression under a constant effective stress generally increase linearly with log time; however, there are two parameters used to express this linearity, namely C_{sec}, which is the strain $\{\Delta e/(1+e_o)\}$ per log cycle of time, and C_α, which is Δe per log cycle of time. The strain is normally referenced to the initial height, rather than from the height at the end of primary consolidation. There is some evidence from laboratory tests that these coefficients may increase in time, called tertiary creep (Dhowain and Edil, 1980). The values of C_{sec} or C_α are generally considered to be independent of the applied stress for those stresses above the pre-consolidation/yield stress and for those soils which can be modelled by a constant C_c. There is a stress dependency to C_{sec} or C_α for stresses around the pre-consolidation/yield stress, and for those highly organic soils which cannot be modelled by a constant C_c. Mesri and Godlewiski (1977) consider that similar processes are involved in C_c and C_α, and by defining $C_c = \Delta e/\mathrm{Log}\sigma$ (which can be used above and below the pre-consolidation/yield stress) have shown that the relationship C_α/C_c is relatively constant. Mesri (2007) gives $C_\alpha/Cc = 0.06 \pm 0.01$ for a fibrous peat. Some researchers consider that the laboratory determined values of C_{sec} or C_α tend to underestimate

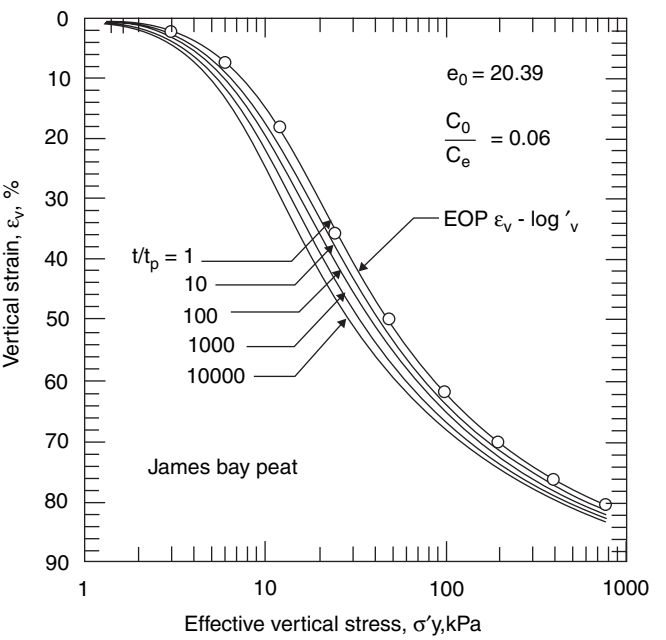

Figure 35.5 Vertical strain versus σ_v'
Reproduced from Mesri (2007), with permission from ASCE

the field creep by a factor of the order of two (Hobbs, 1986), whereas others consider that the values from field observations and laboratory tests are comparable (Mesri, 2007). The change in strain ($\Delta\varepsilon$) at constant σ'_v can be estimated from the relationship $\Delta\varepsilon = C_{sec}\text{Log}\frac{t}{t_P}$, where t is the time from the initial loading and t_p is the time to the end of primary consolidation. Thus the strain at different time increments can be drawn.

35.4.2.3 Continuous secondary compression approach

Several researchers have developed settlement models which consider that secondary consolidation is a continuous process, with that by den Haan (1996), called the abc model, being regarded as particularly appropriate but difficult to apply. The abc model incorporates the continuous creep, as well as other features such as the natural strain (e^H) and varying permeability with void ratio, which will be discussed below. The volume changes in the abc model are expressed in terms of specific volume ($\upsilon = 1 + e$) rather than in terms of void ratio and assume that the creep strain rate is uniquely defined by present stress and strain. The normally consolidated stress–strain relationship is $\text{Ln}v = \text{Ln}v_1 - b\text{Ln}\sigma'$, where v_1 is a reference specific volume at an effective stress of unity. Creep is defined by lines of constant creep rate $\left(\frac{d\varepsilon_c^H}{dt}\right)$ called isotaches, which have a slope b on an $\text{Ln}\upsilon - \text{Ln}\sigma$ plot as shown in **Figure 35.6**. The parameters used in this model are $b = \frac{\delta Lnv}{\delta Ln\sigma'_v}$; $c = \frac{\delta Lnv}{\delta Lnt}$ which are analogous to C_c and C_α respectively; and 'a', which is equivalent to a reload compression index and is defined as $a = \frac{\delta\varepsilon^H}{\delta Ln\sigma_v}$. The model also introduces the parameter called the intrinsic time (τ). Creep at constant effective stress, ε^H, is assumed to be linear when plotted against the logarithm of intrinsic time τ. The use of intrinsic time is necessary because of the complications that arise with a logarithmic scale and may be considered as the time which would be necessary to achieve the present volume if the present stress had been applied immediately to the soil in its freshly sedimented state. The intrinsic time of the base line is given the symbol τ_o. The isotaches are given by:

$$-Ln\frac{v}{v_1} = bLn\sigma'_v + cLn\frac{\tau}{\tau_0} \tag{35.5}$$

The total strain rate $\left(\frac{d\varepsilon^H}{dt}\right)$ is the sum of direct strain rate $\frac{d\varepsilon_d^H}{dt} = a\frac{dLn\sigma_v}{dt}$ and the creep strain rate $\frac{d\varepsilon_c^H}{dt}$ which is related to intrinsic time by $\frac{d\varepsilon_c^H}{dt} = \frac{c}{\tau}$. Thus the total strain rate is:

$$\frac{d\varepsilon^H}{dt} = \frac{d\varepsilon_d^H}{dt} + \frac{d\varepsilon_c^H}{dt} = \frac{a}{\sigma_v}\frac{d\sigma_v}{dt} + \frac{c}{\tau}. \tag{35.6}$$

These relationships define the behaviour of the soil and can be incorporated into a finite difference solution based on continuity of mass to model the hydrodynamic stage of the settlement process (den Haan, 1996). The use of this model is also discussed in O'Loughlin and Lehane (2001). The use of the isotache concept is discussed in detail in Degago *et al.* (2011).

Berry and Poskitt (1972) have used rheological models for peats with some success, but these have not been adopted for general design.

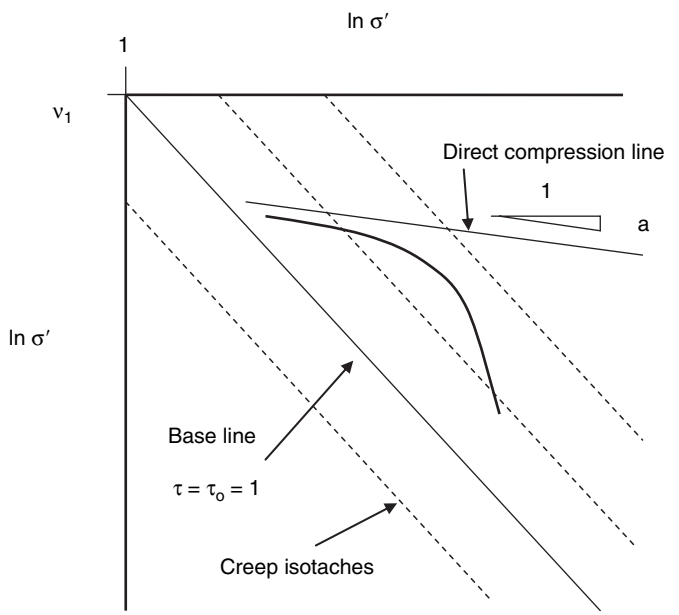

Figure 35.6 Stress vs creep relationship for abc model

35.4.2.4 Numerical modelling

Computer codes are being developed which include many of the features of the settlement soil models discussed above (see section 35.4.2.3) (Blommaart *et al.*, 2000) and these could be of particular benefit in giving confidence in analysing design situations with peat when they have been verified by case studies, such as that by Tan (2008).

35.4.3 Surcharging

Secondary compression settlements, which can give rise to significant serviceability issues for roads and structures founded on peats and organic soils, can be reduced by surcharging, particularly as it can benefit from the high initial permeability of fibrous peats. Care must be taken, however, that the increased load does not give rise to instability. The effectiveness of this method

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

depends on the surcharge ratio $R_s' = \frac{\sigma_{vs}' - \sigma_{vf}'}{\sigma_{vf}'}$ where σ'_{vf} is the post-construction effective vertical stress and σ'_{vs} is the effective vertical stress reached during surcharging (Hanrahan, 1952; Mesri, 2007). The design criterion for a surcharge is usually to build out sufficient settlement during construction that would include both the primary and secondary settlement to be expected over the design life of the structure if a surcharge were not applied. The benefits of a surcharge are illustrated in **Figure 35.7**, where Curve A is the estimated settlement/time using, for example, equation (35.4), with an embankment at the design height with no surcharge, with the total estimated settlement after the design period (t_{design}) to be X, together with an allowance for rebound and swelling. A surcharge is selected to give the settlement X within the construction period as shown in **Figure 35.7**. The soil is allowed to consolidate under a surcharge $\Delta\sigma$; there is a rebound on removal, computed using $C_s \approx 0.1C_c$, long-term rebound (Samson and La Rochelle, 1972), then slight swelling until the creep line for that effective load is reached.

The longer the maximum load is maintained, the greater the delay in recurrence of the secondary compression. In both field and laboratory, the rebound shows a marked increase with surcharge ratios exceeding about three (Hobbs, 1986). The abc model of den Haan (1996) can also be used to estimate the effectiveness of a surcharge.

35.4.4 Rate of settlement

The general experience is that the field permeability of fibrous peat is significantly greater than that recorded in the laboratory consolidation tests (Hobbs, 1986). This is considered to be due to the limited size of the samples tested in the laboratory, to gas, and to the natural heterogeneity of peat to be expected from the plant growth patterns. The relatively high permeability of the acrotelm and the anisotropy of the peat deposits are also considered to contribute to increased field consolidation rates. The reported comparison between the time for primary consolidation of laboratory samples (t_s) and field consolidation times (t_f), and the respective sample height (H_s) and field thickness (H_f) using

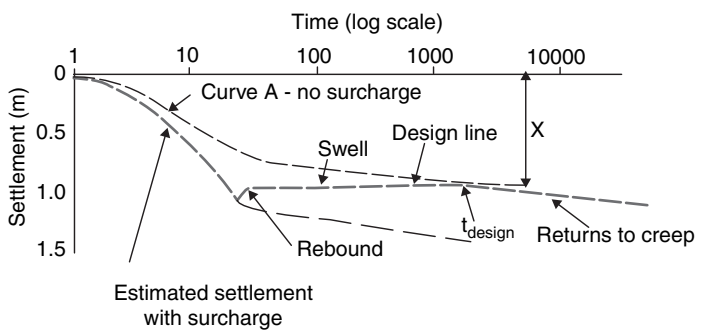

Figure 35.7 Simplified method of assessing effectiveness of surcharging (t_p = time to primary consolidation)

Equation (35.7) give i values from 0 to 2 for peats. Thus i = 0 implies that the time for primary consolidation is independent of the thickness of the peat, whereas if the peat complied with Terzaghi's theory of consolidation, i = 2.

$$\frac{t_f}{t_s} = \left\{\frac{H_f}{H_s}\right\}^i. \qquad (35.7)$$

Hobbs (1986) considers that the time for primary consolidation for peats can only be determined from field trials, which would require the installation of piezometers. Generally researchers have found that the time for primary consolidation in the laboratory, inferred in the normal way using the semi-log plot or Taylor's method, was approximately consistent with the end of the dissipation of excess pore pressures (Lefebvre *et al*., 1984; Mesri, 2007). O'Loughlin (2007), however, found that Taylor's method, and to a lesser extent Casagrande's method, consistently underestimated the time for primary consolidation.

The variation in permeability with effective stress would be expected to vary significantly with the type of peat and organic soil, which depends on the macro- and microstructure of the peat as well as on its degree of decomposition. It is common to express the change in permeability with respect to void ratio as $C_k = \Delta e/\Delta \log k_v$ (where Δe is the change in void ratio and k_v is the permeability in the vertical direction) and Mesri (2007) considers that $C_k = 0.25e_o$ for fibrous peat, where e_o is the *in situ* void ratio. Hanrahan (1954) considered the change in permeability to be linear on a log e–log k plot and derived $k = k_{vo}\left\{\frac{e}{e_o}\right\}^n$, where k_{vo} and e_o are the *in situ* permeability and void ratio respectively. Hobbs (1986) interpreted $k_{vo} = 4 \times 10^{-6}$ m/s, $e_o = 12$, $n = 11.03$ for a fibrous peat, where k_{vo} is the initial coefficient of permeability in the vertical direction. Hogan *et al*. (2006) reported k values of 2×10^{-2} m/s near the surface of a fen peat, which reduced to 10^{-5} to 10^{-6} m/s at 2–3 m depth in virgin peat. Hanrahan (1954) reported a decrease in k_v from an initial value of 4×10^{-6} m/s to 2×10^{-8} m/s under a pressure of 55 kPa for two days which decreased further to 8×10^{-11} m/s after seven months. Generally the horizontal permeability has been found to be significantly greater than the vertical by a factor of between three and ten (Mesri, 2007). The *in situ* horizontal permeability of peat can be estimated in the field by carefully executed variable head permeability tests; however, the reduction in this value with the decrease in void ratio that results from an increase in effective stress would be an important consideration in the interpretation of the test results.

35.5 Shear strength of peats and organic soils

35.5.1 Introduction

Generally the shear strength of peats and organic soils is determined in the traditional manner with s_u for undrained loading

and c′, ϕ' for drained conditions, without special consideration being given to the fibre content, high compressibility or to the relatively high permeability and gas content of some of the fibrous peats. The high compressibility and fibre content do affect the behaviour of fibrous peats in the laboratory and field tests and are poorly considered in current methods used to interpret these tests. In laboratory tests, for example, the high compressibility of peat samples results in necking and dimensional non-uniformities of samples during the consolidation phase of triaxial tests; also the fibre effects mean that drained triaxial tests result in an essentially one-dimensional behaviour, with the result that the soil cannot be taken to 'failure' as defined by Mohr Coulomb criteria. The fibres also affect the interpretation of effective stress parameters in undrained triaxial tests as the low Poisson's ratio of the fibre content of peat means that the pore water pressures rapidly build up to equal the cell pressure, thus making the effective lateral stress equal to zero. Determining the appropriate field strength also has its difficulties as the fibre content affects field vane tests and typically the recorded s_u decreases with an increase in the size of the vane (Landva, 1980).

In practice, the effect of fibres is eliminated in ring shear tests and these give the lower values of ϕ' for conservative estimates. Recently more attention is being given to direct simple shear (DSS) tests, particularly for determining undrained shear strength parameters (Farrell *et al*., 1999; Boylan *et al*., 2008).

35.5.1.1 Effective stress parameters

Peats and organic soils are predominantly frictional materials with values of ϕ' which are very much dependent on the method of test. For example, ϕ_{peak}' values of the order 50–60° have typically been recorded in consolidated undrained triaxial tests on fibrous peats, compared with values of the order of 32–40° for direct shear tests and for ring shear tests on the same material. The accuracy of the interpretation of ϕ' on fibrous peats from undrained triaxial tests is affected by the low lateral effective stresses recorded at failure in these tests, which frequently are essentially zero. Similarly, it is generally not possible to bring a sample of fibrous peat to failure in a drained triaxial test due to the continual compression of the fibres, which can be compared to the compression of a mattress. Direct simple shear tests (DSS) have been used to estimate the effective stress parameters; however, it is necessary to make an assumption regarding the effective horizontal stress at failure. Farrell *et al*. (1999) considered, on the basis of a finite element analysis of the simple shear test, that ϕ' could be estimated from $\phi' = Sin^{-1}\left(\frac{\tau_f}{\sigma'_{vf}}\right)$, where τ_f and σ'_{vf} are the shear stress and vertical effective stress at failure. Tests by Yamaguchi *et al*. (1985a, 1985b) recorded ϕ' of 35° on triaxial compression tests on horizontal samples compared with 51°–55° on vertical samples, with even higher values of 62° being recorded in triaxial

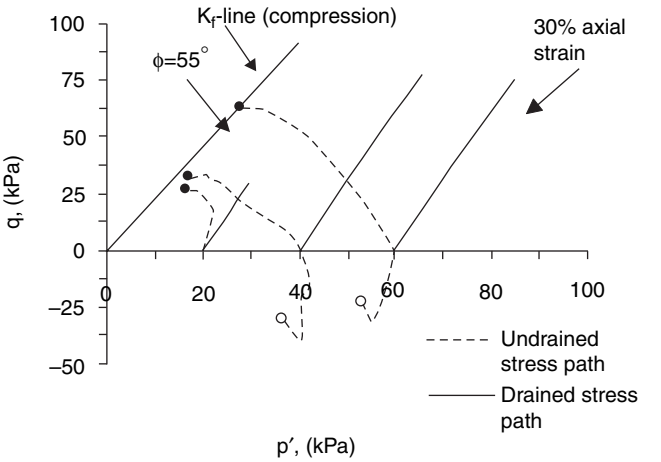

Figure 35.8 Triaxial tests on a fibrous peat
Reproduced from Farrell and Hebib (1998)

extension on vertical samples, which illustrates the inherent anisotropy. It is considered that ring shear tests, and possibly direct shear tests, give the intrinsic ϕ' of the constituents and that the higher values recorded in undrained compression and extension tests on vertical samples include the effects of the fibre structure. The relevance of these higher values must therefore be related to the actual failure mechanism being considered. There is little information on the effect of the possible presence of gas on the effective stress parameters. The results of a series of undrained and drained compression and extension triaxial tests on a fibrous peat reported by Farrell and Hebib (1998) are shown in **Figure 35.8**. Note that the drained tests, which were taken to 30% strain, did not reach the failure line and the ϕ' in compression of 55° was considerably greater than the ϕ' of 39° and 18° measured in the extension tests at initial consolidation pressures of 40 kPa and 60 kPa respectively. The direct shear and ring shear tests on this peat recorded ϕ' of 38°.

The effective stress parameters for organic soils which do not have a fibre structure can be obtained using the normal methods.

The at-rest pressure (K_o), which is normally related to ϕ' by Jaky's equation $K_o = 1 - \sin\phi'$, has generally been measured at between 0.3 and 0.35 on organic soils with water contents in the 330–850% range, which would suggest ϕ' values of the order of 40° to 44° (Mesri, 2007). Edil and Wang (2000), on the basis of laboratory tests, considered that K_o was of the order of 0.49 for amorphous peats and 0.33 for fibrous peats.

35.5.1.2 Undrained shear strength.

The undrained shear strength of organic soils (s_u) can be determined using the traditional methods of consolidated triaxial tests, *in situ* vanes, CPTu, etc. However, the results of these tests are affected by the fibres in the more fibrous peats. Furthermore, the undrained shear strength of some peats is

very low, of the order of 2–4 kPa, which is at the limit of the accuracy of normal testing arrangements. The gas content of peats can also affect their *in situ* behaviour, and this is frequently eliminated in laboratory tests by using a backpressure. This gas content can be lost when sampling the fibrous peat unless special measures are taken, as is evident from the length of samples recovered compared to the length pushed into the ground.

Laboratory tests have shown that peats have a high s_u / σ'_{vc} ratios in compression of about 0.5–0.6, which compares with ratios of about 0.3 for inorganic soils (Mesri, 2007), where σ'_{vc} is the vertical consolidation pressure. Similar high ratios have been recorded in extension. The direct simple shear test is receiving more attention in recent years as the failure mechanism is considered to be relevant to peat slides. Ratios of s_{uDSS} / σ'_{vc} of 0.45 (Porbaha *et al*., 2000), 0.46 (Foott and Ladd, 1981) and 0.5 (Farrell and Hebib, 1998) were recorded on fibrous peats, considerably higher than the ratio of about 0.22 expected for inorganic clays.

The field measurement of the *in situ* undrained shear strength of peats is problematic due to the influence of fibres on the results and also because of the low strengths measured. Boylan *et al*. (2008) show that temperature variations themselves can give rise to significant inaccuracies in CPTu probes, which often result in the interpretation of negative strength values, and advocate the use of full-flow penetrometers such as the T-bar and ball penetrometer for peats (Boylan and Long, 2006). The methods of determining the undrained shear strength of fibrous peats by field tests is an area that requires further research.

In the absence of an alternative field test, the vane is frequently used to determine an s_u of peat despite its significant limitations which have been discussed in Landva (1980). For example, the vane tended to pull the fibres along a surface outside the vane itself, there was compression of the peat in front of the vane and a gap frequently opened at the back of the vane, conditions far removed from a cylindrical shearing surface assumed when interpreting the results. Furthermore, the interpreted s_u values are generally found to decrease with an increase in the size of the vane, as is illustrated on a comparison of s_u values measured in a fibrous blanket bog and shown in **Figure 35.9**. These results are consistent with those reported by Landva (1980) where the s_u interpreted from a 55 mm × 110 mm vane were about twice that of a 75 mm × 150 mm vane and the interpreted undrained strength of this fibrous peat was as low as 2 kPa. Notwithstanding these limitations, the *in situ* vane is frequently used to assess the *in situ* strength of fibrous peats, as well as the increase in strength with consolidation, with the 55 mm diameter vane becoming the preferred size (Noto, 1991) and the test being considered to be an index test only. Mesri (2007) tentatively suggests that s_{uvane} be reduced by 0.5 to get the operational s_u. However, Noto (1991) estimated that the ratio of s_{uvane} / s_{ufield}, with s_{ufield} values being back-calculated from failure experiments on a testing embankment, to vary from 0.38 to 1.24 with an average of 0.74.

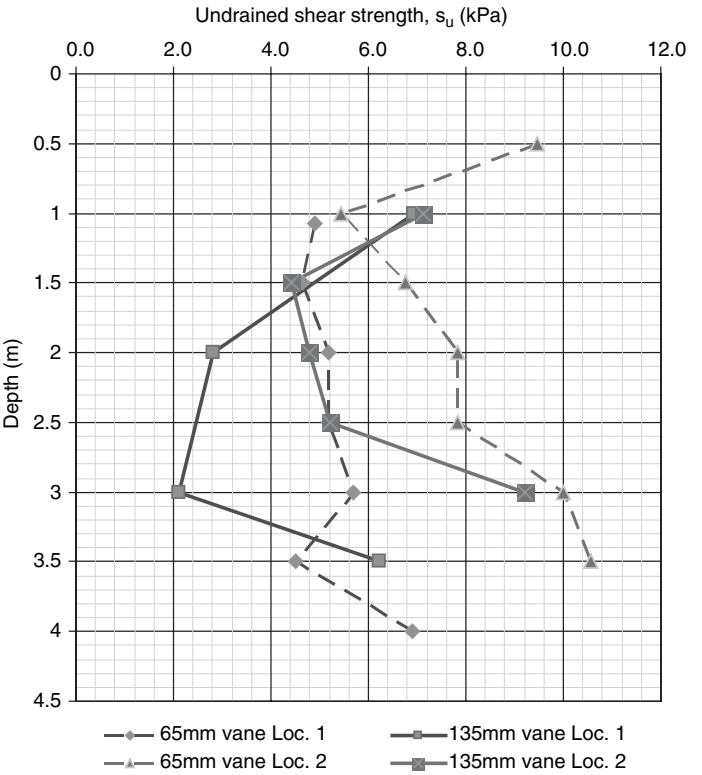

Figure 35.9 Comparison of s_u measured with 65 mm and 135 mm diameter vanes in a fibrous peat

35.6 Critical design issues in peats and organic soils

35.6.1 Roads

Most of the design/construction options for construction on soft inorganic soils can be used for roads on peats and organic soils, but these must be modified to consider the high compressibility/large deformations, the significant secondary compression, the low density of peats, and also the local geology within which the peat was formed. Munro (1991) gives a useful overview of some of the construction methods adopted by road authorities in Northern Europe.

The excavate/replace option is widely used for major roads on relatively thin layers of peats, generally up to about 3–4 m in thickness, as it avoids the uncertainties of long term secondary compression/creep movement which may arise even with surcharging. However, it becomes uneconomical for significant depths of peats due to cost and the environmental considerations of disposal of the excavated material. Additionally, the requirement for the replacement material to extend out from the footprint of the road to avoid surface cracks in the road pavement due to lateral consolidation (see **Figure 35.10**) can also significantly affect costs and land-take requirements. Lateral failure can occur if the granular replacement material is placed against a vertical or near-vertical peat face, due to the low density of the peat compared with a granular material.

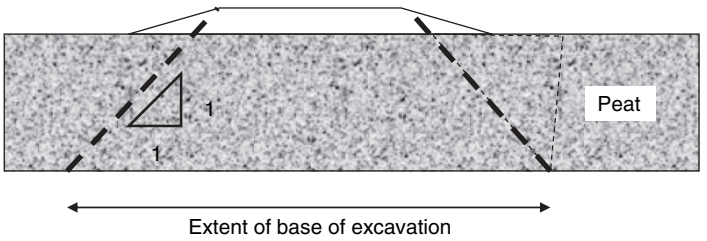

Figure 35.10 Extent of excavate/replace required

The replacement of peat layers may make it difficult to install vertical drains should these be required to speed up consolidation in underlying soft clay layers.

Historically, there is a legacy of old roads that have been constructed directly on top of the peats that currently serve in the minor road networks in the UK and Ireland. These roads, which generally started as gravel roads but were subsequently paved, develop an undulating profile under traffic and require regular maintenance and rehabilitation. The increased deformation under modern traffic also gives rise to transverse cracking, which can be mitigated to some extent by including geosynthetics to reinforce the bituminous layers or sometimes the sub-grade. Raised bogs frequently start their life over very soft lake-clay deposits; consequently the practice of placing additional surface material to periodically regulate the profile has resulted in past failures of the entire road due to shear failure through the soft clays. This problem can be avoided, and the secondary compression settlements reduced, by the use of lightweight fill in road improvement works.

'Floating' roads are a common method of forming access and low-traffic-volume roads on peats. Traditionally these were constructed using tree trunks as a base, but current practice is to use geosynthetics as basal reinforcement to a gravel layer where trees are not available. Such roads, which can carry heavy loads in fibrous peats due to the reinforcing effects of the fibres, are frequently used in forestry and wind farm sites in mountain areas; consequently their effect on the overall stability must be assessed in any design. Scottish Natural Heritage (2010) gives some guidance on the design and construction of floating roads on peat.

Lightweight fill, together with surcharge, is an acceptable construction option on peats and organic soils. Large-scale use of these materials tends to be limited by their costs. Lightweight fill is very efficient when used in combination with surcharge as the effectiveness of surcharge depends on the surcharge ratio, as discussed in section 35.4.3.

Stage construction with surcharging is the most common method for constructing on organic soils, and is sometimes used for peats. The terms 'pre-load' and 'surcharge' are considered to differ in that a pre-load is taken up to the design load whereas a surcharge is taken beyond the design load and, in the case of peats and organic soils, is designed to reduce secondary compression settlements. The principles of the design of surcharges are discussed in section 35.4.3. With reference to **Figure 35.7**, if the expected primary settlements and secondary settlements under a design load are estimated to be X, then the design load and a surcharge are left in place until this amount of settlement has occurred. Secondary compression settlements will occur after that design period, but at a lesser rate than would arise at the end of primary. In some situations, the settlements can exceed the thickness of fill placed, and it is necessary to apply more fill or to use lightweight fill for the initial loadings. The reduction in the effective stress due to submergence of the fill must be considered when estimating the settlements. Where the surcharge is not left in place for a sufficient time, care must be taken to ensure that there are no residual excess pore water pressures within low permeability layers after its removal.

The applicability of vertical drains to speed up the consolidation process depends on the type of peat or organic soil. Their usefulness for low embankments on fibrous peat which have high initial permeability is questionable, particularly as the drains themselves may be affected by the high compressions; however, the permeability decreases significantly at high effective stresses, thus the drains may be required where higher effective stresses are applied. General experience is that sand drains can act to reinforce peat, thus increasing its stability and reducing vibrations under load. Vacuum consolidation has benefits in speeding up consolidation but requires further research for use with the highly organic peats.

Stabilisation of peats and organic soils by mixing in a binder is a common practice in Sweden and Finland and in some other countries but has not been widely used in the UK or Ireland to date. The binder can be mixed in place using an attachment to an excavator as shown in **Figure 35.11** to form a stabilised mass, or alternatively a mixing tool can be used to form stabilised columns as shown in **Figure 35.12**, or a combination of both. Two types of mixing method can be used: the dry method where the binder is injected pneumatically, and the wet process where the binders are mixed in a slurry form before being injected from the mixing tool. The design and construction aspects using these methods are set out in the *EuroSoilStab* (BRE, 2002) and some experiences with Irish raised bogs are given in Hebib and Farrell (2003). The efficiency of this process is very dependent on the mineral content of the peat/organic soil and on the humic acid in the peat, the process being more cost-effective in organic clays than in the high organic peats. Stabilisation of the high organic peats in Ireland has not proven to be cost-effective to date as about 150–200 kg of cement per cubic metre of peat can be required to achieve the required engineering properties (Hebib and Farrell, 2003).

The efficiency of stone columns will depend on the organic content of the soil due to the inevitable lateral consolidation of the columns, and also due to the low strength of the peats. The actual feasibility of constructing *in situ* concrete columns in very soft ground could limit the use of that method.

Piled supported basal reinforced embankments have been constructed on very compressible and very soft peats (Orsmond,

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Reproduced from BRE (2002)

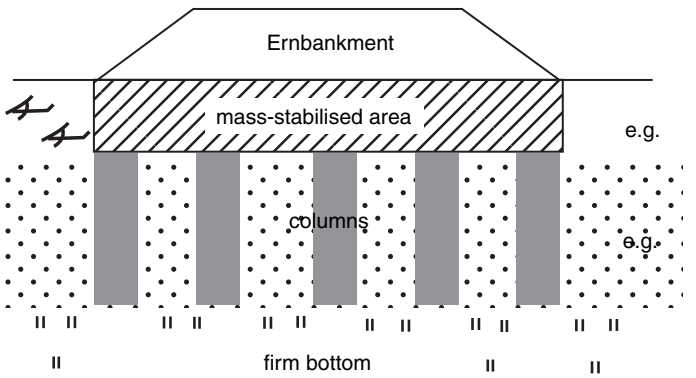

Figure 35.12 Column and mass stabilisation
Reproduced from BRE (2002)

2008). Issues that must be considered include the lateral stability of the entire embankment, the difficulties in maintaining the position of piles, the type of pile and the construction platform required to access the locations. Basally reinforced granular layers have generally provided a suitable platform for light piling rigs, even on very soft peats. Driven piles are commonly used. The feasibility of using cast-in-place or CFA piles will depend on the ability to get access for the rigs and also on the ability of the very soft material to support liquid concrete without radial failure. Although rarely reported in professional journals for legal reasons, failures have occurred in basally reinforced piled embankments due to stockpiling of material adjacent to the structure, giving rise to failure of the piles due to the lateral loadings. This failure mechanism also has implications for the type of structures that can be constructed on land adjacent to such structures.

35.6.2 Structures

The design of structures on peats and organic soil follows the normal procedure for building on soft soils, taking into account the high compressibility of peats. Structures are normally piled, although surcharging (see section 35.6.1 above) has been used in some situations with a rafted structure. It is normally necessary to construct a gravel-on-geogrid working platform to allow access for an appropriate piling rig and this platform will inevitably settle away from any piled structure, leaving a gap in the long term and also giving rise to downdrag forces on the piles. The risk of buckling of piles is assessed in the normal manner.

35.6.3 Slopes

Bog bursts and peat slides are major geohazards, particularly in Scotland and Ireland, and can be caused by environmental or anthropological factors. Major slides have occurred on peat slopes as shallow as 3° and have involved a mass of up to 100 000 tonnes of material covering about 0.5 km in width and over 1.5 km in length. Villages have been destroyed in the past, with one particularly serious incident in Castlegarde, County Limerick, Ireland in 1708 in which 21 people died. Recent research for the development of a landslide database has shown a proliferation of landslides in upland peat areas of Ireland. The Geological Survey of Ireland produced a booklet on landslides (Creighton, 2006), including bogslides, and the Scottish Government has published a document on peat landslide hazard and risk assessment (2006). Given that a peat bog sitting on the side of a hill is made up of over 90% water, it is not surprising that slope stability is a major issue.

Bog failures are generally thin relative to the length of material involved and therefore resemble a planar-type slide as discussed in Chapter 23 *Slope stability*. Typically the upper layers of bogs are fibrous and the reinforcing effects of these fibres prevent a local failure and thus contribute to the formation of a large mass movement with a failure surface at or close to the base of the slide. The determination of the disturbing force ($W\sin\alpha$, where α is the angle of the base to the horizontal) is relatively straightforward; however, the estimation of the resisting force depends on whether the failure is considered in terms of effective or total stress. With reference to section 23.3.2 of Chapter 23 *Slope stability*, and using the terms defined in that chapter, the resistance (R) is:

$$R = (W\cos\alpha - uA)\tan\varphi' + c'A \qquad (35.8)$$

Given the high water tables that normally are present in these bogs, and the fact that the bulk density of peat can be close to or less than that of water, the ($W\cos\alpha - uA$) term can be negligible and the resistance is then $c'A$. Considering the slope in terms of total stress, the disturbing force is the same as for the effective stress analysis, namely $W\sin\alpha$, and the resistance is s_uA; thus the difference in the analyses is whether c' or s_u should be used.

Some blanket bogs are known to have 'pipes' at their base through which water flows during heavy rainfalls (Donnelly, 2008). Water entry to the base of these bogs, with a consequential build-up of water pressures, is also facilitated by tension cracks forming in the peat during periods of dry weather. Given that the bulk density of peat is very close to or even less than that of water, the effective stress can be very small or negligible and the resisting force therefore depends on the apparent cohesion, if this is present. The failure surface of a well-documented peat slide in Pollatomish, County Mayo (Long and Jennings, 2005), which is shown in **Figure 35.13**, was at the interface of the peat and an underlying sand layer following a period of heavy rain, confirming that slide was caused by a loss in effective stress. The presence or otherwise of c' in such an analysis is debatable. The risk of such failures is increased by a prolonged period of dry weather which can dry out the peat, thus reducing the bulk density and which can also give rise to tension cracks which facilitate the access of water. The build-up of water pressures at the base of the peat can also be exacerbated by the presence of an iron pan layer which is sometimes noted at the base of blanket bogs.

When considering the stability of a peat layer of thickness D against planar failure in terms of total stress, with an s_u assigned to the peat, the disturbing force per unit basal area is $\gamma D\sin\alpha$ and the resisting force is a function of s_u, assuming there are no external loads and that the tension capacity of the peat is negligible compared with other forces. The ratio of resisting to disturbing force is then $s_u/\gamma D\sin\alpha$. This ratio therefore decreases with increased thickness, increased slope angle and increased bulk density. Some of the bog failures have occurred on very flat slopes (as low as 3º, but frequently on slopes of about 4–7º). Using this total stress approach, back-analysis of some of the bogslides would indicate s_u values at failure of the order 2 kPa, which is very low and difficult to measure in the field. Farrell (2010) proposed a mechanism to explain how a major bogslide could progress downhill when a local failure is initiated at the higher elevations if the material at the base of the slide is sensitive.

The stability of bogs can be affected by forestry drainage ditches and other anthropogenic factors.

35.6.4 Retaining structures, canals and dams

The special issues arising from the use of peats and organic soil in relation to retaining structures, canals and dams are their low density, high compressibility, high creep rate and generally low strength. Water-retaining structures require particular attention because small changes in the hydrogeology can result in very low effective stresses. Major failures have occurred in the past, for example the Edenderry canal failure of 1989 (Piggott *et al*., 1992), shown in **Figure 35.14**, which resulted in the horizontal movement of a 225 m × 105 m block of peat by a distance of about 60 m.

35.7 Conclusions

Peats and organic soils, which are to be found in many countries and are very extensive in some, present particular challenges to the geotechnical engineer because of their high compressibility, creep, low density and generally very low shear strength. Despite the presence of the cellular structure of organic remains, many of the correlations between the various

Figure 35.13 Peat slide at Pollatomish, 2003

properties and their behavioural patterns are little different from those of a clay, other than their shear strength.

Various processes can be involved in the formation of organic soils and the nature of the process can be important when interpreting the relevant geotechnical parameter and soil stratification appropriate to a particular design/construction situation. Classification systems have been developed to assist in the characterisation of the materials, the von Post (1922) or a variant being the system most generally adopted. The water content is the most important index test as it is a simple parameter to which many engineering properties can be related. However, the organic content, determined by the loss on ignition test, and the pH are also useful, as is the liquid limit which can generally be carried out on peats with a degree of decomposition greater than H_3 on the von Post scale.

The recovery of 'undisturbed' samples of highly organic peats, particularly fibrous peats, is difficult due to the compression of the material during sampling, even with sharp-edged piston samplers. Furthermore, the samples may undergo oxidation when exposed which can lead to decomposition and gas generation, although the effect of this is generally not considered significant except possibly for long-term testing.

The methods of estimating settlements and rates of settlements used for clays are also used for organic soils, although the effect of secondary consolidation/creep on these estimates increases with the organic content. Because of the large settlements involved in the highly organic soils and the natural variability within these deposits, simple behavioural models are usually used which consider secondary consolidation/creep to start at the end of the primary phase. Most sophisticated models which consider that secondary consolidation occurs continuously are difficult to apply but are being incorporated into some software programs. Surcharging of the peat is an effective method of reducing secondary compression/creep.

The undrained shear strength of organic soils and peats is normally determined using *in situ* vanes, cone penetration tests and laboratory triaxial or direct simple shear tests, although the most appropriate test for a particular failure mechanism in fibrous peats requires careful consideration. The very low undrained shear strength of some peats, sometimes of the order of 2 kPa, is below the accuracy of many of the current measurement methods. Similarly, the effective stress parameters determined in triaxial tests can be affected by fibres and by the method of test.

The unique properties of peats and organic soils have to be considered when designing roads and foundations or when assessing the stability of slopes in these soils. Some of the methods that have been adopted in practice have been presented within this chapter.

Mudrock is the general name given to a large variety of fine-grained, clay-rich sedimentary rocks. As these materials occur frequently in the sedimentary rock sequence, they commonly form the natural ground on construction sites and they may also be encountered as Made Ground, fill or construction materials. Depending on compositional and structural factors, they can display a range of engineering behaviours – some of them problematic, including low strength, low durability and susceptibility to volume changes. In addition, it can be difficult to assess their mass properties. This chapter reviews the present state of knowledge concerning the performance of mudrocks in engineering situations. The intention is to provide the reader with a framework for understanding the geotechnical properties of mudrocks, especially with regard to effects induced by construction activities.

36.1 Introduction

The term mudrock is used here to denote a diverse group of fine-grained, clay-rich sedimentary rocks. Since such materials occur widely in the geological sequence, they are very frequently encountered in civil and environmental engineering projects. They are important because they can be the cause of a range of problems both during and after construction. A generally accepted geological definition of mudrocks that is suitable for engineering purposes is proposed by Stow (1981), as follows: mudrocks have a dominant grain-size of <63 μm of more than 50% of the constituents; and more than 50% the mineral constituents are composed of siliciclastic mineral fragments (including clay minerals, quartz and feldspar). Other fine-grained sediments with different compositions are designated accordingly as carbonate mudrocks, silica mudrocks, etc. As explained in section 36.1, there are discrepancies in terminology resulting in disagreement amongst different standards.

Mudrocks typically range from soft soil-like clay deposits to very stiff/hard soils and medium strong rocks. Due to the low strength and high compressibility of the former types, coupled with shrink–swell behaviour and, in the case of harder types, rapid breakdown in response to changes in moisture content and weathering processes, mudrocks present various challenges in civil engineering design and construction work. The controls on the performance of mudrocks and several forms of potentially problematic behaviour in different engineering situations are illustrated in **Figure 36.1**. Such behaviour often arises as a consequence of the combined effects of natural weathering processes and the impact of engineering works, but it is also strongly influenced by composition and structure of the material.

Although **Figure 36.1** is an extensive list of potentially problematic characteristics, mudrocks do have redeeming features. For example, their low permeability makes them ideal for the construction of low-permeability barriers and, as most types also possess high cation exchange capacity, they can remove potentially harmful dissolved species (for example heavy metals from groundwater). Mudrocks are also used as fills and in the construction of earthworks. Because most mudrocks have low strength they are relatively easy to excavate, but nonetheless most types perform satisfactorily as a bearing medium for moderately to highly loaded, low-sensitivity foundations.

Unfortunately, the reasons listed in **Figure 36.1** can hamper attempts to predict problematic forms of behaviour in mudrocks. However, an understanding of the composition and mode of formation of these materials, the selection of suitable methods of investigation and the correct interpretation of test results can all assist with this. Attempts are made to avoid excessive jargon but, where necessary, the reader should refer to the glossary at the head of this chapter for definitions of the relevant terms.

36.1.1 Definition and classification of mudrocks

The purpose of this section is to define the materials being described in this chapter. Besides the different uses of the terminology by geologists and engineers, and by workers from different countries, there is unfortunately a lack of agreement in the literature (including British and Eurocode standards) as to what constitutes mudrock.

Figure 36.2 shows the classification for mudrocks given in the current Eurocode 7 guidance documents. The terms mudstone and shale are shown to consist of a grain size of <63 μm, further defining siltstone as 50% fine-grained particles (2–63 μm) and claystone as 50% very fine-grained particles (<2 μm). As such these definitions are not clear. There are separate schemes described in BS EN ISO 14688–1: 2002 and –2: 2004 (for soils) and BS EN ISO 14689–1:2003 (for rocks), where soils are defined as materials with an undrained shear strength lower than 300 kPa (uniaxial compressive strength of 600kPa), and rocks are materials which are stronger than this. As shown in **Table 36.6**, this corresponds with a material that can be broken by hand pressure. As **Figure 36.2** shows, BS

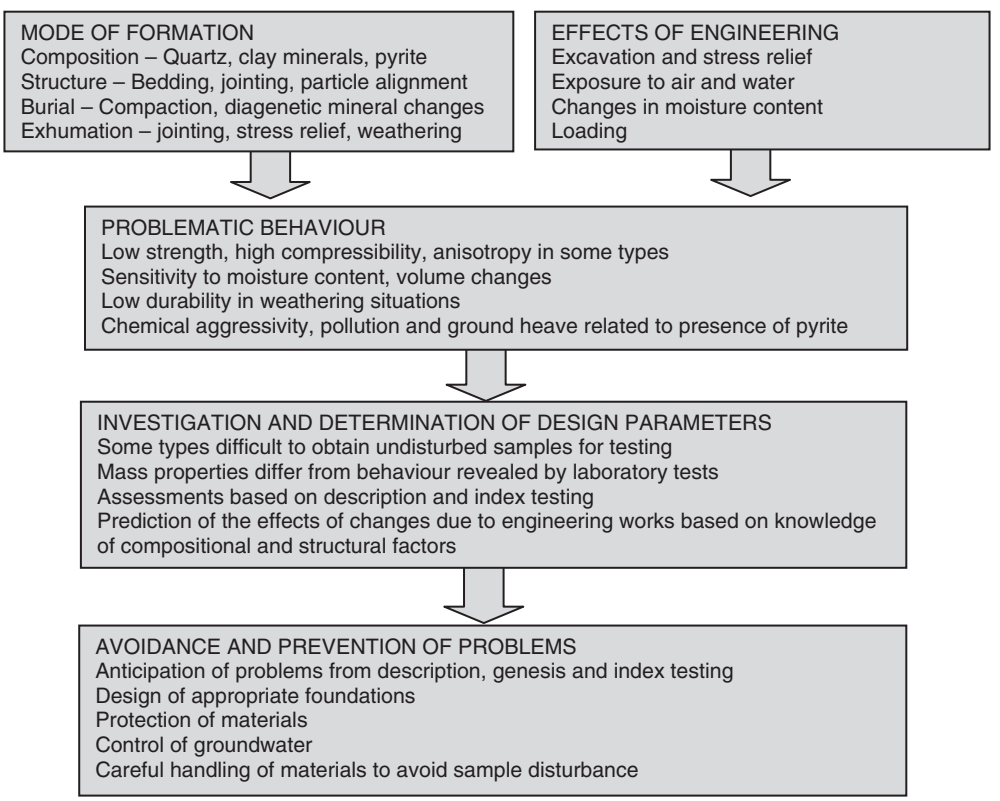
EN ISO 14689–1:2003 defines mudstones as clastic sedimentary rocks composed of grains of quartz, feldspars and clay minerals in which the particles are predominantly smaller than 0.063 mm. The term argillaceous means that they are clay-rich and lutaceous, which is not a commonly used term meaning that they consist of fine-grained material or mud. Unfortunately the distinction between mudstone and siltstone or claystone is not explained, and although it is implied that mudstone comprises both silt- and clay-sized particles, the relative proportions of these is not stated.

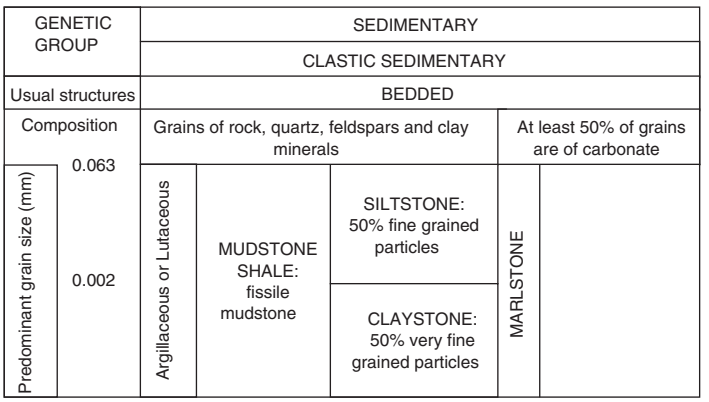
Shale is also referred to in this table, to denote a fissile mudstone, in other words one that will split into thin sheets (see section 36.2.4.1). The term 'fissile mudstone' is preferred over the term shale, except where it is used as part of a formation name, for example Edale Shale. This is because in some mudrocks fissility only becomes manifested as a result of weathering action, so the same material could be called shale or mudstone depending on its weathering grade. In BS EN ISO 14689–1:2003, a division is made between siltstone, in which the particles are mostly between 0.002 and 0.063 mm in size, and claystone, in which most are finer than 0.002 mm. This follows the same approach as in IAEG (1979).

The guidance in BS 5930:1999 + A2:2010 *Code of Practice for Site Investigations* defines mudstone as rocks finer than 0.002 mm, thus using the same definition as for claystone in BS EN ISO 14689–1:2003. With such lack of agreement between standards, it is therefore vital to specify the scheme being used for classification. Further discussion of this issue is presented below and in section 36.1.2, which includes details of Grainger's (1984) classification of mudrocks.

BS EN ISO 14688–2:2004 specification for the classification of soils defines clays as possessing an average grain size of less than 0.002 mm, and advice is offered in section 36.3.2.2 of this chapter concerning the identification and description of such soils using simple physical tests. BS 5930:1999 + A2:2010 also provides guidance on the identification and classification of soils, including fine-grained ones such as clays. It accordingly indicates that the predominant grain size of clays is less than 0.002 mm and suggests that classification should be based on consideration of plasticity rather than grain size alone. In view of the average strength criterion mentioned above, most over-consolidated clays fall within the definition of clay soils.

BS 5930:1999 + A2:2010 and BS EN ISO 14689–1:2003 respectively define calcareous mudstone and marlstone as rock consisting of grains less than 0.063 mm in size with some carbonate. Although both standards indicate that there should be more than 50% carbonate present, it is likely that these rocks will contain less than this. A number of other types of rocks, for example chalk, rocks of chemical origin such as chert, and some rocks of volcanic origin, contain grains of clay size less than 0.002 mm – but as these do not contain clay minerals and detrital quartz grains, they are not regarded as mudrocks.





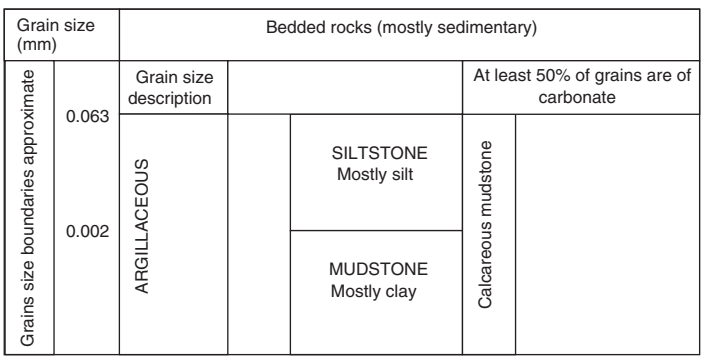


Figure 36.1 Interactions between mode of formation, effect of engineering and engineering problems in mudrocks

(a)

(b)

Figure 36.2 Classification of mudrocks according to (a) BS EN ISO14689:2003 and (b) BS 5930 + A2:2010

Care must be exercised over the use of the term 'clay' which is used in three different ways:

- an average particle size of <2 μm;
- a type of mineral, such as illite, kaolinite, smectite, chlorite;
- a type of soil, including over-consolidated clays, that contains clay minerals and other constituents.

It needs to be understood that whereas clay minerals tend to be very small – they commonly form larger crystals, for example aggregations or flocs may exceed 10–20 μm in size. Although 2 μm is used in European classifications (including British ones) as the upper limit of clay size, some American standards regard 4 or 5 μm as the upper limit. A potential source of confusion arises from the names of some geological formations. For example, although Oxford Clay and similar deposits contain much clay, they also include other lithologies, such as limestone.

As Reeves *et al*. (2006) explain, although particle size is used as the main characteristic to classify mudrocks, it can be difficult accurately to determine the grain size distribution as most of the grains are too small to discern with the naked eye or even with optical microscopy. Furthermore, disaggregation can result in breakage of grains rather than breakage of the bonds holding them together. For instance, Davis (1967) noted that in Mercia Mudstone, clay mineral grains are cemented together in clusters so the measured clay size fraction is less than the actual amount of clay present. Features that can be used to assist with assessment of the grain size and identification are listed in section 36.3.2 of this chapter.

Various authors, including Spears (1980) have suggested that mineralogical data, rather than size, can be used as a guide to the sizes of particles present. However, this approach entails the use of relatively expensive X-ray diffraction or scanning electron microscope (SEM) methods, which therefore hampers its use in everyday investigations.

36.1.2 Compaction and cemented mudrocks

Whether the material behaves in a rock-like or soil-like fashion is highly relevant in many applications. Mead (1936) suggested the use of the terms:

- compaction mudrock – formed just by compaction due to burial;
- cemented mudrock – the grains are attached together by a significant amount of cement.

As further explained in section 36.2.2, in the former, the grains are not bonded together and the materials display soil-like behaviour, whereas intergranular cementation and recrystallisation result in rock-like behaviour in the latter. Mead used the terms compaction and cementation shales, but for the reasons stated above, it is preferable to refer to them as mudrocks. Morgenstern and Eigenbrod (1974), Wood and Deo (1975) and Hopkins and Dean (1984) suggest tests that can be used to distinguish between these types of mudrock.

The scheme shown in **Figure 36.3**, in which mudrocks are classified in terms of grain size, uniaxial compressive strength (σ_c) and second cycle slake durability index (Id_2) (see section 36.3.2.3), was devised by Grainger (1984) to provide a classification that reflects the engineering performance of mudrocks:

Soil (clay)	$\sigma_c < 0.60$ MPa
Non-durable mudrock	$0.60 < \sigma_c < 3.6$ MPa; $Id_2 < 90\%$
Durable mudrock	$3.6 < \sigma_c < 100$ MPa; $Id_2 > 90\%$
Metamudrock*	$\sigma_c > 100$ MPa

*Metamudrock is mudrock affected by low-grade metamorphism.

As mentioned above a uniaxial compressive strength (UCS) of 0.60 MPa is equivalent to an undrained shear strength of 300 kPa, where measurement is made perpendicular to any fissility or cleavage in the rock (see section 36.2.4.1). The quartz content distinguishes between claystone, shale, silty shale, mudstone and siltstone as follows:

Claystone and shale	< 20% quartz
Silty shale and mudstone	20–40% quartz
Siltstone	> 40% quartz

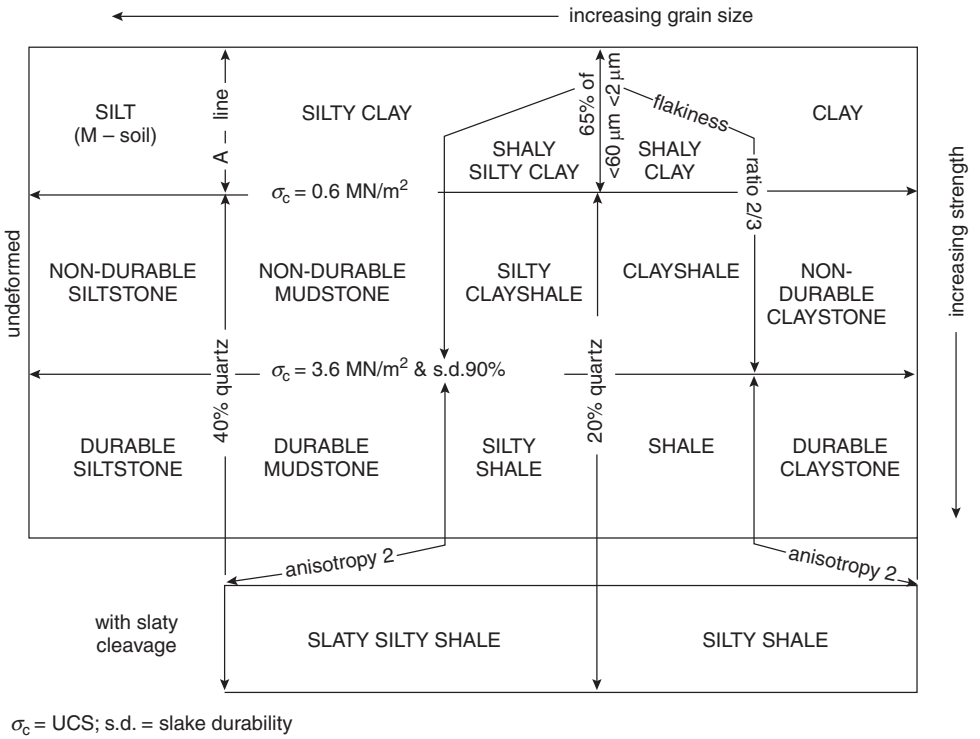

Figure 36.3 Grainger's (1984) classification of mudrocks

where the latter figure conforms with the suggestion made by Spears (1980). Grainger's (1984) classification also separates fissile from non-fissile material, where rocks with a flakiness ratio (i.e. shortest dimension of a fragment divided by the intermediate dimension) greater than 2/3 are regarded as fissile, while those with a ratio less than 1/3 are massive. For durable and slaty mudrocks the anisotropy may be determined using Point Load Test or Cone Indenter Test to determine the compressive strengths parallel and perpendicular to the predominant weakness surfaces (bedding or foliation), with a proposed anisotropy ratio >2 distinguishing fissile mudstones. As noted above, to avoid the possibility of the rock name changing as the rock becomes weathered, it is preferable to avoid the term shale and refer to fissile mudstone or claystone instead. Argillite is an indurated clay-rich rock with a random arrangement of particles, whereas in slate the rock possesses cleavage due to a preferred orientation of grains.

36.1.3 Distribution of mudrocks in the UK

As **Figure 36.4** shows, mudrocks occur widely in the UK. Generally speaking, younger, less indurated varieties underlie large areas of the south and east of England, including the London area. Thus a number of important urban areas and infrastructure routes lie on the outcrop of mudrock formations. Older, more indurated mudrocks occur in the Triassic, Permian and Carboniferous rocks of the Midlands, west and north England, south and north Wales and the central valley area of Scotland. These regions coincide with large urban areas and transport links.

Older terrain, ranging from Precambrian to Devonian in age, outcrops in the western and northern parts of the UK. Whereas most mudrocks in these areas have been metamorphosed into slates and schists, there are isolated outcrops of less indurated rocks. Although less populated, the presence of mudrocks may still affect engineering design and construction in these areas.

36.2 Controls on mudrock behaviour

By definition, mudrocks consist of deposited mineral grains such as quartz and clay minerals, with an average size of less than 0.06 mm. In addition to clay minerals and fine-grained quartz, minor amounts of feldspar, calcite and mica together with organic matter and, as explained below, various diagenetic minerals, may be present. Although the properties of mudrocks are very much affected by the nature and the relative amounts of the mineral constituents, the density and structure are also important.

36.2.1 Constituents of mudrocks

As clay minerals tend to exert a dominant control over the physical properties of mudrocks, knowledge of these minerals assists in understanding mudrock behaviour. Clay minerals have a sheet-like structure typified by mica which, as shown in **Figure 36.5**, is composed of alternating tetrahedral layers of silica (Si_2O_4) and alumina ($Al_2(OH)_6$), accompanied by

intermediate layers of exchangeable cations. Within this basic framework a complex mineralogy exists, based on the number of silica–alumina sheets and their arrangement. Ionic substitution within the basic sheet framework by ions such as Mg^{2+}; Fe^{2+} also influences the properties of the mineral as well as its cation exchange capacity and shrink–swell behaviour.

The formation of clay minerals by the chemical weathering of silicate minerals such as feldspar is illustrated in **Figure 36.6** (see also section 36.2.3). Whether mudrocks originate as *in situ* residual or transported deposits depends mainly on the climatic conditions prevailing in the area. Residual deposits, usually dominated by kaolinite, commonly occur in hot and humid weathering environments (see Lum, 1965). On the other hand, in temperate climates the products of weathering are usually dominated by illite.

The type of rock being weathered also influences the clay mineral assemblage; for instance, kaolinite is derived from granite degradation, whereas illite results from the weathering of pre-existing mudrocks and mica-rich rocks. Smectite forms in volcanic terrains and low silica parent rock. As explained below, some clay minerals referred to as authigenic minerals are precipitated from pore solutions. Chlorite may be present in most mudrocks, particularly those derived from weathering of metamorphic materials such as argillite, phyllite or schist. Several non-clay minerals such as quartz, various carbonates and pyrite, together with organic matter, are commonly present.

Because of the atomic structure of clay minerals, they typically occur as relatively small flat or platy particles where, as illustrated in **Table 36.1**, the average size, specific surface area and activity contrast dramatically with those of equidimensional minerals like quartz and feldspar. The relatively high surface area of swelling clays (such as smectite) is further increased as the interior of the crystal and the exchangeable

ions may be accessed by the pore fluid. Reeves *et al.* (2006) explain that minerals such as illite and smectite and, to a much smaller extent, kaolinite, have a net negative charge on their composite layers due to the substitution of high valency cations by lower valency ones. Such charges are balanced by the interlayer cations and when suspended in water, each clay particle is surrounded by a diffuse double layer of hydrated cations. Due to broken ionic bonds at the edges of clay particles, the edges become negatively or positively charged depending on whether conditions are alkaline or acidic, respectively. The ions adsorbed onto clay particles may be exchanged by other ions in the solution, resulting in changes in the thickness of the double layer and of the mineral, giving rise to cation exchange capacity in clays. The exchange of cations into and out of the double layer occurs in response to imbalances in the concentration of cations in the double layer and the surrounding solution.

The relatively large surface area of clay minerals means that they adsorb large amounts of water onto their surfaces, and the shared water between particles imparts plasticity to clays. The activity, which is a function of plasticity and percentage of particles less than 2 μm, is an indication of the sensitivity of the material to water. A high activity indicates a more plastic behaviour and greater shrink–swell potential in response to changes in moisture content.

The relatively small size of clay particles also means that they are attracted to each other by van der Waals forces, which operate over very short distances, and in addition are subject to electrostatic attraction and repulsion forces which act over longer distances. The strength of the latter forces depends on the ionic strength and composition of the pore water surrounding the particles as well as the distance between them. Thus particles in solution are subject to forces of attraction and repulsion depending on the distance to neighbouring particles and the chemistry of the solution. Generally speaking, in conditions of high ionic strength, in other words saline conditions, the diffuse double layer is suppressed and attraction forces tend to dominate – which causes the particles to form flocculated groups with many face-to-edge contacts. This so-called card-house structure gives rise to a relatively low density, high water content, clay deposit. In low ionic strength conditions, the repulsive forces dominate and the clay particles are deposited in a dispersed state which has lower porosity. High amounts of organic matter also increase the tendency for clay minerals to form dispersed structures.

The non-clay constituents of mudrocks include quartz, feldspar, micas, carbonates, heavy minerals, organic matter, pyrite and iron minerals. Quartz and finely crystalline (cryptocrystalline) forms of silica, such as flint or chert, are usually present as detrital (or deposited) grains. Mudrocks are liable to contain iron oxides and hydroxides as well as the iron sulfide mineral pyrite which, as explained in section 36.2.4.3, is a common and very important, though minor, constituent.

36.2.2 Deposition, burial and diagenesis

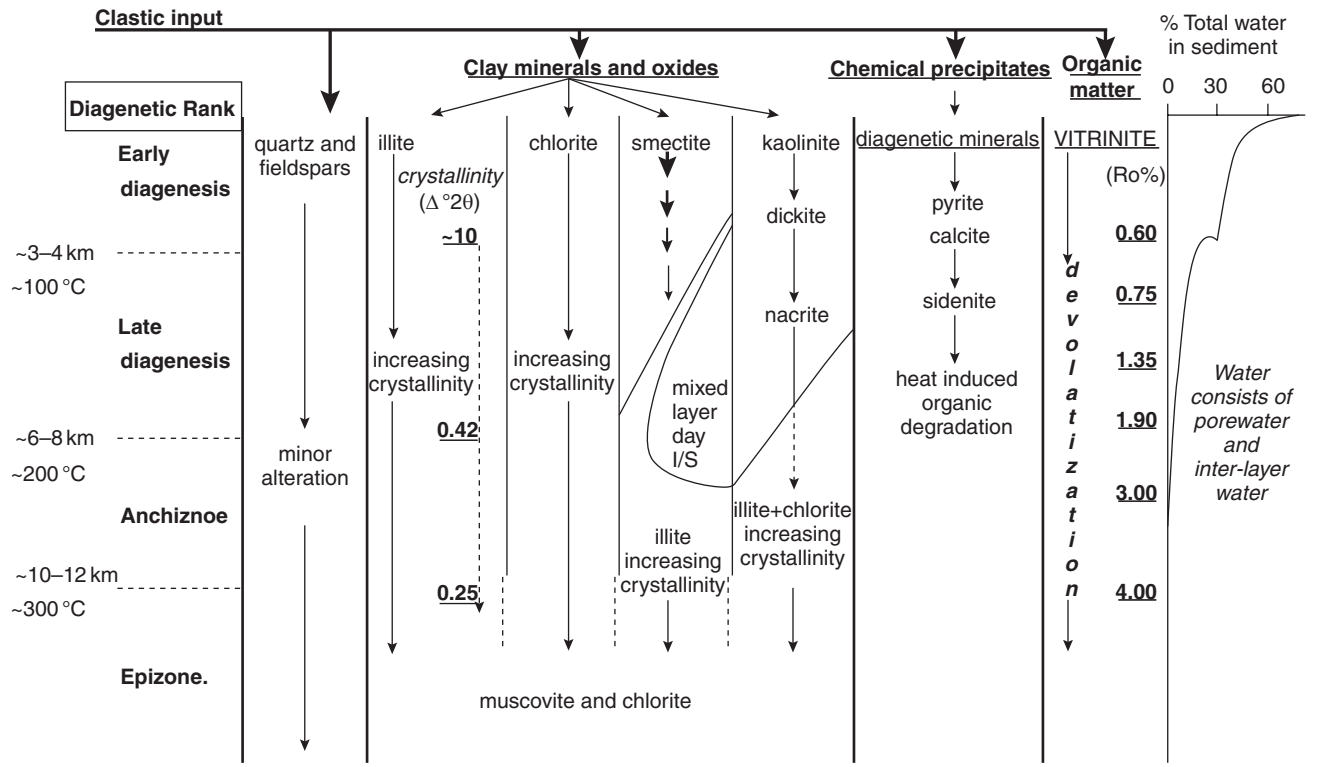
The environment of deposition exerts a strong control – not just over the type of material deposited, but also over the presence and spacing of bedding surfaces and other sedimentary structures. As explained in section 36.2.1, clay particles may be deposited as dispersed individual particles in fairly dense arrangements, with the platy particles aligned approximately horizontally or in flocculated aggregations of clay particles, with an open card-house or honeycomb-type structure in which the particles are in a random arrangement. Such deposits possess relatively high porosity – in the region of 70–90%, and high water content.

Burial of the sediment beneath younger sediments removes access to air and increases both the vertical stress and temperature. An associated reduction in porosity and moisture content is accompanied by the formation of diagenetic minerals, changes to clay minerals and the precipitation of cements, as illustrated in **Figure 36.7**. The exclusion of air can result in sulfate-reducing bacteria releasing oxygen from seawater-derived sulfate (SO_4^-) by reaction with detrital iron in the sediment. The result of this process is the formation of pyrite 'framboids' in the upper levels of the sediment. As **Figure 36.8(a)** indicates, framboids comprise clusters (measuring about 1–10 μm across) of minute pyrite grains. In more oxygenated conditions, nodules or amorphous masses of calcite or iron carbonate (siderite) may be formed (**Figure 36.9**).

Burial of muddy sediment beneath subsequent deposits brings about progressive reductions in porosity and moisture content, as well as changes (diagenesis) to some minerals and production of new authigenic minerals (see **Figures 36.10** and **36.11**). These diagenetic effects increase with burial depth and duration of burial, until depths of 10–12 km are reached, where there is a transition to low-grade metamorphism.

The results of studies into the effects of burial of mud to different depths are summarised in **Figure 36.7** and the related structural changes to mudrocks are illustrated in **Figures 36.11** and **36.12**. Czerewko and Cripps (2006b) explain that in the course of this process, clay minerals are squeezed and re-orientated to fill the voids between the clastic grains. Any surviving clay flocs are destroyed and porosity, water and volatiles are lost. In clay-rich deposits or clay layers in laminated deposits (see **Figure 36.12(c)**), this results in the re-orientation of clay particles towards the horizontal (see **Figure 36.12(b)**), which will tend to render the material anisotropic – so it may be weaker in one direction. The tendency to develop a preferred orientation in deposits comprising clay mixed with silt particles is hindered because the clay particles become packed into the spaces between silt grains (see **Figure 36.12(a)**).

Compaction mudrocks (see section 36.1.2) are liable to contain at least some swelling clay minerals such as smectite and mixed layer illite–smectite. Kaolinite and vermiculite may also be present, and pyrite will typically occur as framboids or very small crystals (see **Figure 36.8(a)**). The compaction experienced by the deposit will have increased its density, with



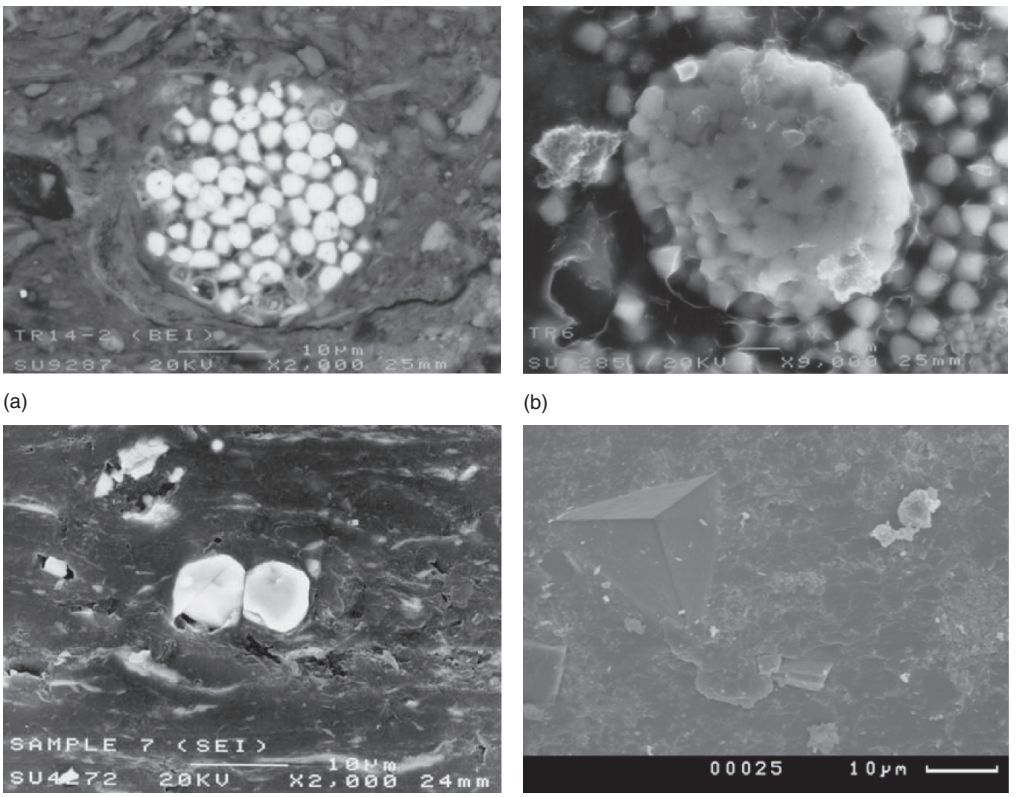


Figure 36.7 Changes in mudrock mineralogy and moisture content associated with burial Mixed layer clay I/S = illite/smectite
Reproduced from Czerewko and Cripps (2006b)

a commensurate reduction in moisture content, but the mineralogical changes will have been relatively minor.

Burial of about 1 km is required to bring about significant changes to clay minerals and pyrite. Besides further reductions in moisture content and increases in density, smectite and smectite–illite mixed layer clays are progressively converted to illite and ultimately, by metamorphic processes, to muscovite or sericite. This process involves the release of ions and water from the interlayer sites of these minerals, which may participate in the precipitation of authigenic clay minerals and cements in the pore space. If the clastic components are sufficient in quantity then, at a certain degree of compaction, a skeletal framework is formed within the deposit (**Figure 36.12(e)**). Where no skeletal clastic framework develops, as in clay-rich muds, then (as illustrated in **Figure 36.12(b)**) a deposit with an approximately horizontal preferred orientation of clay particles is the likely outcome and a fissile mudstone or claystone (see section 36.2.4.1) is produced. Weakly cemented mudrocks may contain some swelling clay minerals with illite of enhanced crystal size, together with a partial skeletal framework. Chlorite may also form during deep diagenesis and vermiculite may be converted during burial diagenesis through mixed layer corrensite to chlorite at depth.

Burial to 2–3 km usually results in a porosity reduction of 3–5% in strongly cemented mudrocks with elimination of most, if not all, of the low-stability clay minerals. A series of discrete bonded crystal domains is produced which, with a continued increase in burial depth and temperature, increase in size. They eventually coalesce to form a continuous framework of cemented grains such that the material progresses to become a cemented mudrock (**Figure 36.12(f)**). Ultimately, at burial depths of approximately 5 km, all the grains may become cemented. Not only is the total pore volume in the deposit decreased, but a reduction in pore throat diameter, which controls the movement of water, also occurs. This (as explained in section 36.3.2.3), together with the removal of swelling clay minerals and increased size of pyrite crystals (see **Figures 36.8(a)–(d)**), considerably enhances the durability of the material. In this process, any microfractures and other structural discontinuities in the material are healed – which augments its resistance to breakdown. As illustrated in **Figure 36.8**, the progressive recrystallisation of pyrite results in the conversion of framboids to fine-grained and larger crystals to the extent that eventually visible cubic crystals are produced.

Ancient residual deposits that have been indurated by compaction and cementation may form mudrock formations similar to those derived from transported clay-rich deposits. However, some residual deposits will appear to display rock-like behaviour due to the effects of high pore suction pressures caused by desiccation. Suction pressures that hold the particles in such

deposits are destroyed by even slight wetting of the material, and with further wetting the material very rapidly reverts to soft clay.

36.2.3 Uplift, unloading and weathering

The changes in void ratio or moisture content, shear strength and effective horizontal stress that accompany burial of muddy sediment followed by reduction of overburden are illustrated by Cripps and Taylor (1981) in **Figure 36.13**. The effects of burial on mineralogy and microstructure are described in section 36.2.2 and are illustrated in **Figures 36.7** and **36.10**. As explained in Chapter 17 *Strength and deformation*, unloading results in the deposit becoming overconsolidated; in other words, it is denser and stiffer than it was for the same value of vertical effective stress during burial. Weathering processes entailing both physical breakdown and chemical alteration result in the fragmentation of the material, together with progressive dissolution of cements and other mineralogical changes. As **Figure 36.13** shows, these processes eventually result in the loss of the effects of diagenetic compaction and cementation, and the material is returned to a condition similar to the state when it was deposited.

One of the physical processes of weathering caused by the removal of overburden entails the vertical expansion of the material and the development of stress relief joints that lie roughly parallel to the ground surface. Due to lateral restraint, the horizontal stress induced by the original overburden pressure is not reduced in a commensurate manner, resulting in high horizontal stress. This is manifested by high K_o values in near-surface overconsolidated clay formations, as shown in **Figure 36.13**, as well as by the formation of systems of inclined fractures. These discontinuities facilitate access for water and gasses that participate in both physical and chemical weathering processes. Weathering processes cause progressive opening of discontinuities as well as the development of new ones. Softening and expansion of the material occurs as a result of the uptake of water and the weakening of bonds. The loss of strength of the material near to the ground surface means that there is a rapid drop in the K_o value at shallow depths.

Whereas in temperate climates physical weathering processes predominate, in tropical zones the bedrock is typically mantled with tens of metres of residual soil formed by chemical alteration of the underlying rock. For example, in Hong Kong the granitic and volcanic areas are mantled by up to 60 m of clay-rich residual soils (see Lum, 1965). The main weathering effects will be concentrated mainly along discontinuities, and a progressive increase in the proportion of weathered products is accompanied by a decrease in the size and number of corestones towards the surface.

Chemical weathering processes are illustrated in **Figure 36.6**; however, as explained in section 36.2.4.3, microbial activities that participate in the weathering of pyrite are also very important. Other biological processes, such as the growth of plant roots, can have both physical and chemical impacts.

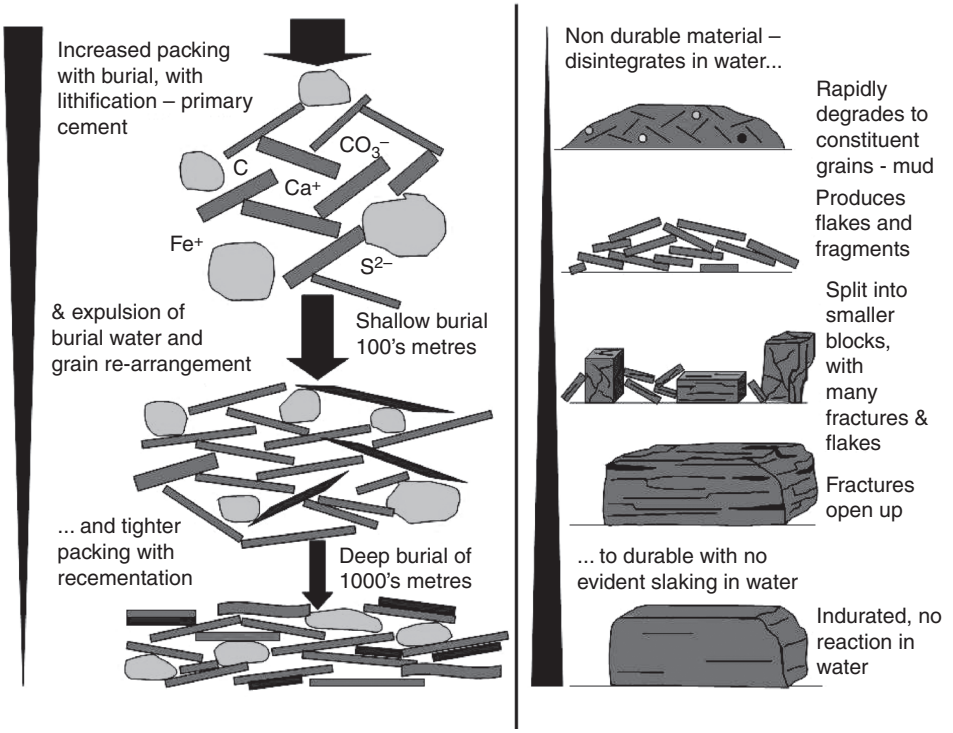

Figure 36.11 Effects of burial on the structure and behaviour of mudrocks

The impact of unloading, and the style and rate of changes to the material in response to weathering action, are strongly influenced by structure and composition, themselves products of the original material and diagenetic changes. Generally speaking, in compaction mudrocks and overconsolidated clays the effects of burial are rapidly lost. However, in cemented mudrocks degradation may occur over a protracted period. The release of stored elastic strain energy leads to the progressive development of fractures with little initial impact on the intact mudrock between the fractures. Subsequently the interparticle bonding and cementation will be weakened and further fractures will form. Ultimately, the effects of burial and diagenetic changes are lost as the material becomes disaggregated and returns to a normally consolidated condition.

The fragmentation process in indurated mudrocks is strongly influenced by their degree of microfracturing (see **Figure 36.14**). In indurated mudrocks, diagenetic cements may provide a rigid framework that encapsulates strained mineral grains and crystals (see **Figure 36.12(e)**). The removal of constraints due to overburden and confinement puts this framework and diagenetic bonding under stress and with weathering-induced removal of the cement and weakening of bonds, the material is apt to slake into sand- or gravel-sized pieces (see **Figure 36.15**). In some rare cases, such as that shown in **Figure 36.16**, rock bursts in with an explosive release of energy.

36.2.4 Genetic features of mudrocks

36.2.4.1 Laminations and fissility

Laminations comprise discrete bedded units less than 20 mm thick and, as **Figure 36.12(c)** illustrates, the units may comprise horizons of differing grain size, or they may be successive units of the same grain size. Mudrocks that possess a laminated structure usually display anisotropy such that they break preferentially along the laminae. The fact that a mudrock can be split into thin laminae defines it as fissile. In some clay-rich mudrocks, fissility is enhanced by a preferred alignment of platy clay particles. As explained in section 36.1.1, fissile mudrocks are sometimes called shales, but because this feature may become apparent only after a degree of weathering action, it is better not to use the term in this way.

36.2.4.2 Nodules and concretions

Nodules or concretions of various shapes, types and sizes are commonly found in mudrocks. They consist of harder, more durable material and are formed by diagenetic processes (see section 36.2.2) in which localised precipitation of minerals has cemented the sediment. Examples are shown in **Figure 36.9**. As explained in section 36.3.1, nodules may sometimes be formed in soil horizons or weathered mudrocks.

36.2.4.3 Pyrite in mudrocks

Pyrite is an iron sulfide mineral which, although constituting only a few percent of the composition of mudrocks and

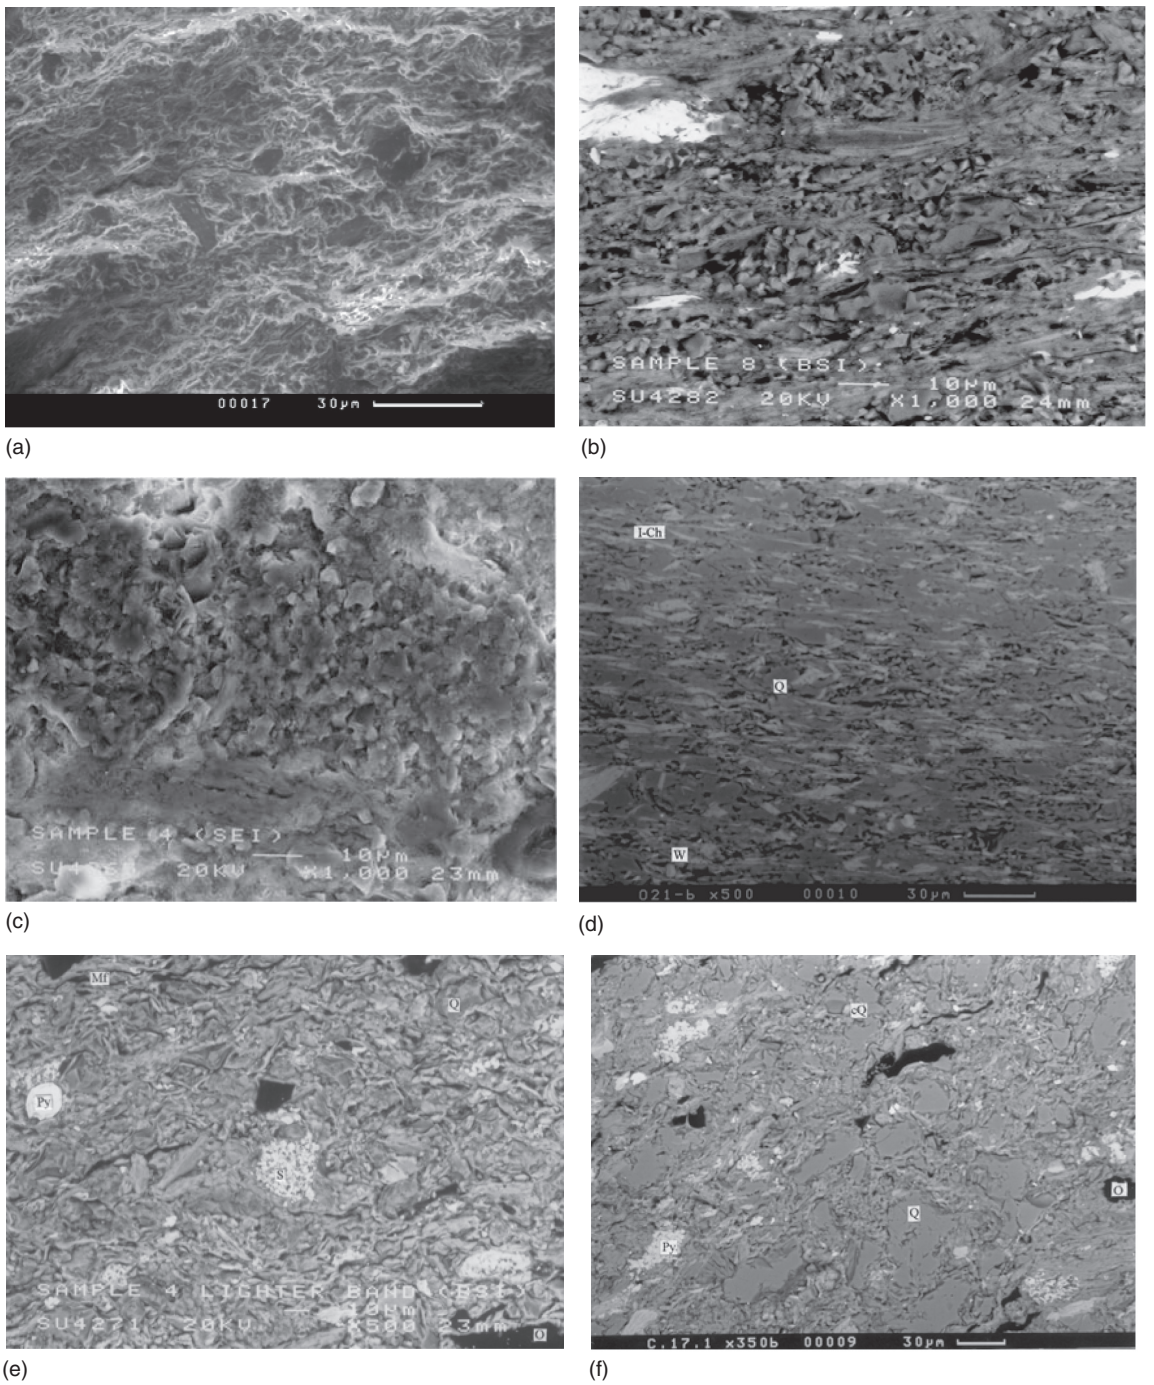

Figure 36.12 Scanning electron microscope (secondary and backscatter) images illustrating the effects of compaction and recrystallisation on the textures of mudrocks. (a) Random orientation of clay particles with wrappingaround silt-size quartz grains in Jurassic Lias Clay. overconsolidated clays, can give rise to several types of problem, as further detailed in sections 36.4.2 and 36.4.6. It is particularly associated with dark coloured organic-rich mudrocks. As Czerewko et al. (2003a) explain, pyrite is not the only potentially troublesome sulfide mineral, but it is the most commonly occurring one. Pyrite commonly occurs as framboids which are spherical clusters typically less than 3 µm across (see **Figure 36.8(a)**). Due to their great collective surface area,

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

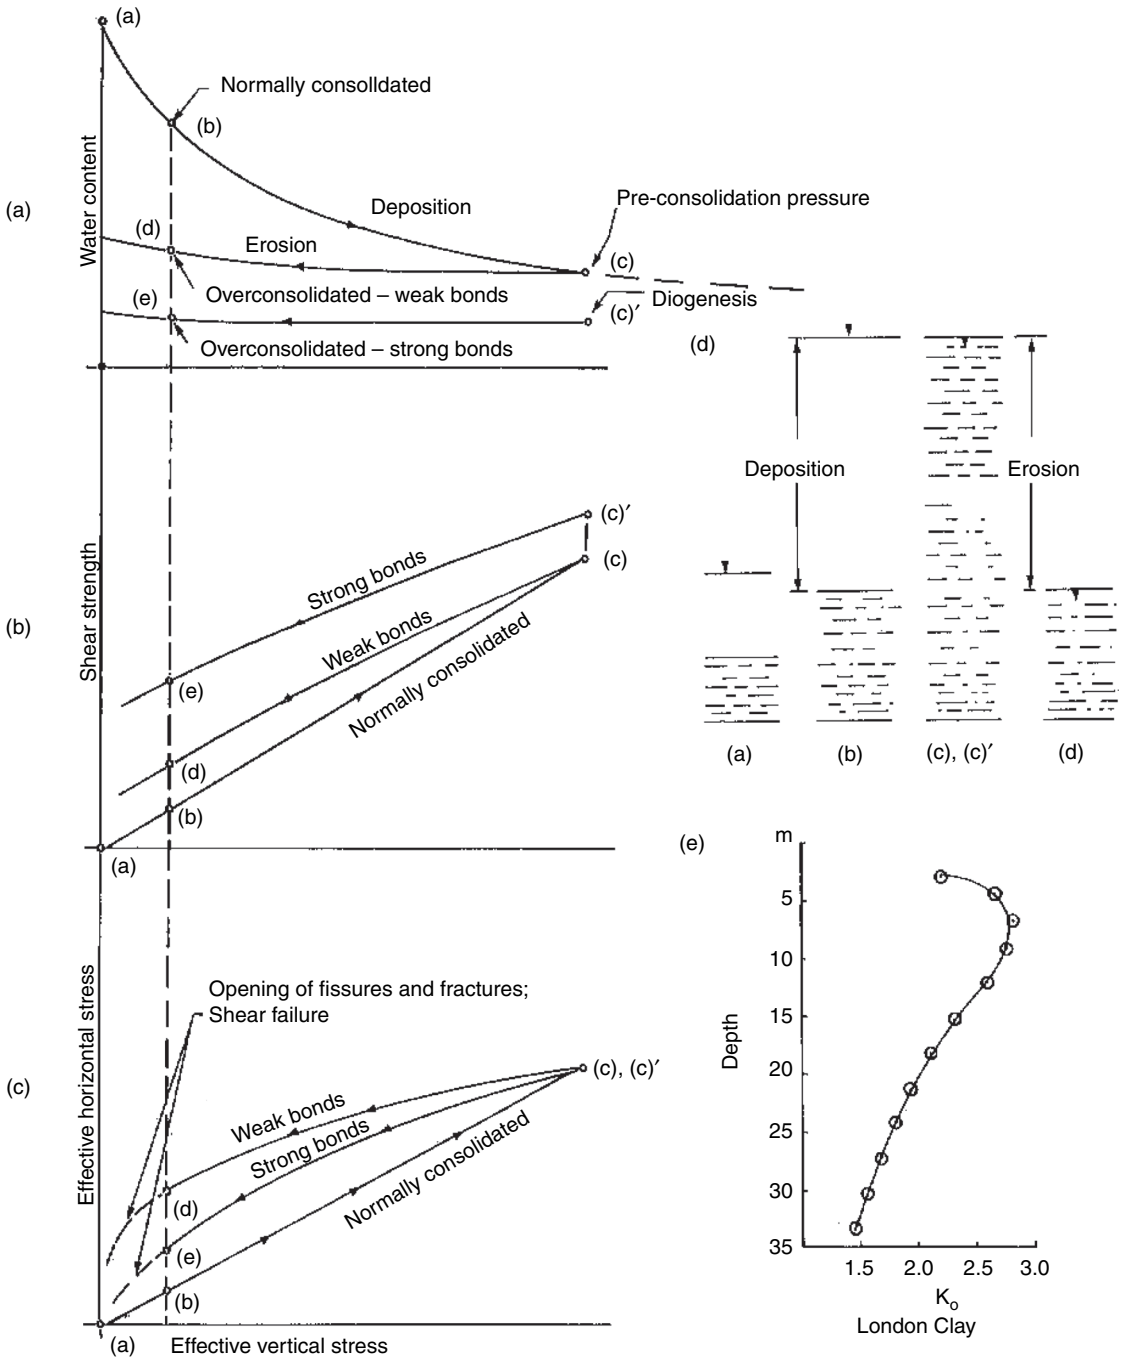

Figure 36.13 Changes in water content, shear strength and horizontal stress due to loading and unloading of sediments
Reproduced from Cripps and Taylor (1981) © The Geological Society of London

pyrite framboids are very reactive in oxygenated and humid weathering environments. **Table 36.2** lists UK sediments that contain pyrite. It is particularly common in marine overconsolidated clays and mudrocks of Jurassic, Cretaceous and Cenozoic ages which occupy about 25% of the land surface of southern and eastern England, and small areas of Wales and Scotland.

Diagenetic processes (referred to in section 36.2.2) progressively convert open textured framboids into octahedral or cubic crystal forms up to several millimetres across. At each stage of the process the pyrite becomes more resistant to oxidation. Exhumation of mudrock formations allows them access to air and water, so the pyrite may become oxidised by the process illustrated in **Box 36.1**.

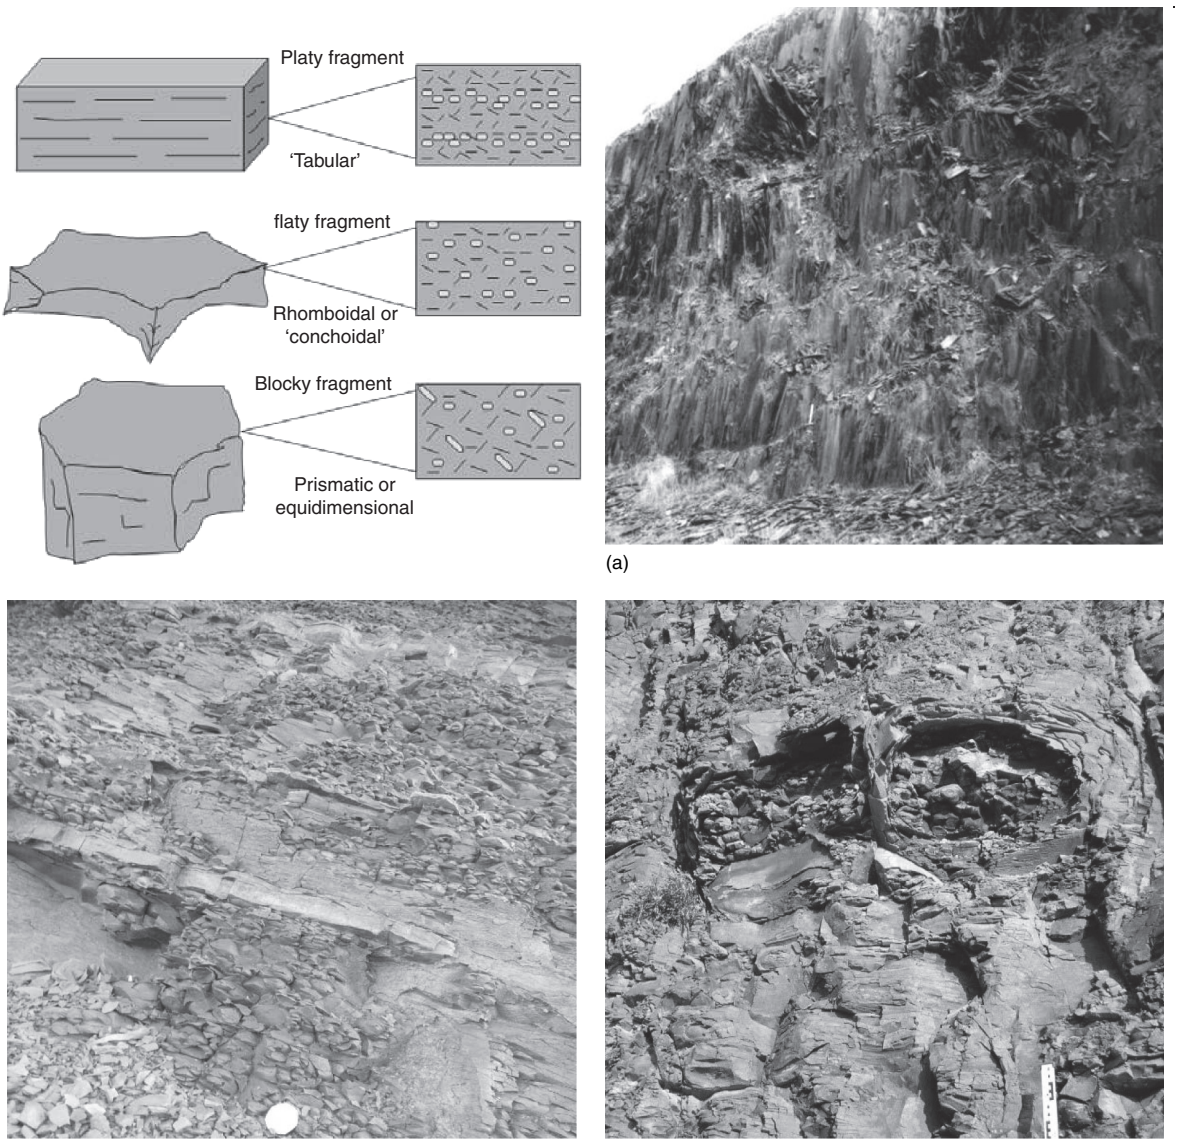

Figure 36.14 Effect of rock microstructure on the morphology of the weathered product. (a) Platy or 'fissile' (Ordovician, West Wales). (b) Flaky (Carboniferous Coal Measures, South Yorkshire); (c) blocky (Carboniferous Coal Measures, South Yorkshire)

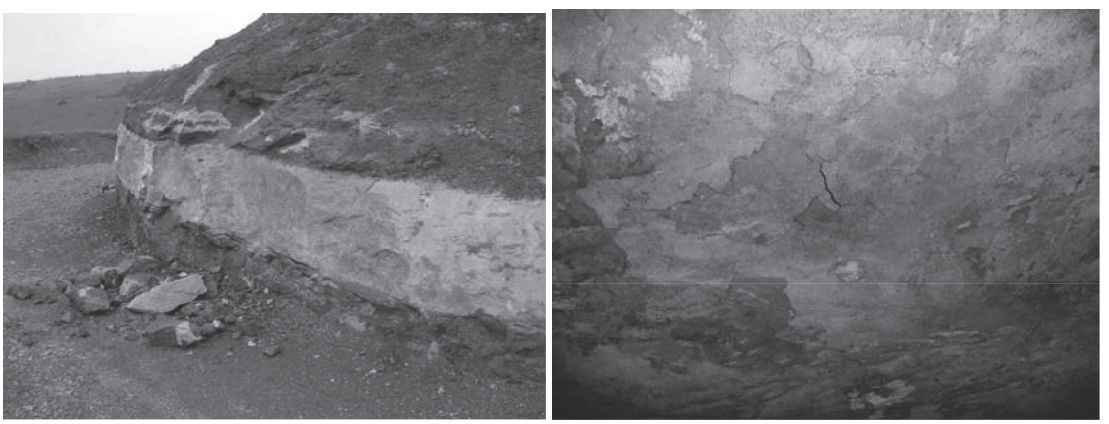
Exposure to oxygen and water facilitates slow chemical oxidation of pyrite according to reaction 1. This reaction is self-limiting at pH < 4. However, ferric iron – which is produced by the activities of sulfate-reducing bacteria – acts as an oxidant to pyrite. The oxidation reaction is exothermic and the conditions become more acidic due to the release of $H^{\cdot}$ ions. As the bacteria are at their most active in warm (~30ºC) acid conditions (pH ~ 3), the reaction proceeds 3 to 100 times faster than for purely chemical oxidation.



If there is insufficient water present for the products of pyrite oxidation to remain in solution, the reaction becomes arrested with the formation of hydrated iron sulfate. In fact the process can have a desiccating effect on clays (see Cripps and Edwards, 1997). Although iron sulfate is stable under acidic conditions, flowing water removes the soluble minerals and sulfuric acid in solution, and produces highly aggressive acid pore waters as are typified by the highly polluting acid mine discharges (AMD) from flooded mines (Banks, 1997) and mine-waste spoil tips.

With abundant water in the system, the acidity is moderated to pH > 4 and iron oxyhydroxide ($Fe(OH)_3$), which is a distinctive highly insoluble orange-brown residue known as ochre, is usually produced. The sulfuric acid generated in the oxidation process is biotoxic and highly corrosive to metals, concrete and rocks. As a strong leachant, its effect is to release potentially harmful elements, including heavy metals, into the environment.

If calcium carbonate is present, it will react with the acid to produce gypsum ($CaSO_4.2H_2O$) or selenite, as **Figure 36.17** shows. Once selenite crystallises it reluctantly redissolves, thus acting as a nucleus for further precipitation of calcium sulfate. The conditions remain acidic (pH < 2.5) if the amount of calcium carbonate is low – so acid attack on illite and albite feldspar produces jarosite ($KFe_3(SO_4)_2(OH)_6$) and alunite ($KAl_3(SO_4)_2(OH)_6$) respectively. On the other hand, a high calcium carbonate content (see **Table 36.2**) renders the environment less hospitable to microbes, so the rate of reaction decreases.

36.3 Engineering properties and performance

36.3.1 Physical properties and characteristics of mudrocks

Mudrocks display a wide range of physical properties and characteristics depending mainly on composition and structure, which depend on the origins and history of the materials (see sections 36.2.2 and 36.2.3). In terms of engineering performance, mudrocks can be divided into three main types, depending upon the extent of intergranular cementation and recrystallisation. Although the burial history rather than age

Table 36.2 Pyrite content range and significant carbonate mineralogy of selected UK mudrock formations
After Czerewko and Cripps et al. (2003a)

exerts a strong control over the state of induration, a general trend of increasing induration and strength with age occurs in UK mudrocks (see Taylor, 1984), as shown below:

Overconsolidated clays	Cenozoic, Cretaceous and most Jurassic clays/ mudstones
Weaker mudrocks	Lias (Lower Jurassic), Mercia Mudstone (Triassic), Permian and some Coal Measures (Carboniferous) mudstones
Stronger mudrocks	Carboniferous mudstones, Devonian and older mudrocks/metamudstones

In some cases, well cemented mudrocks may occur in younger sequences. Conversely, weathering action and/or fracturing can result in weaker materials being present in older formations. **Table 36.3** presents strength and also compressibility and plasticity data typical of UK unweathered mudrocks of different types. The performance of these materials is discussed below. Further data on other formations are given by Reeves *et al*. (2006).

Published values of geotechnical parameters such as those in **Table 36.3** are site-specific and should be used solely for guidance for preliminary designs and to assist with appropriate scoping of investigation and testing programs. This is because the values obtained from geomechanical tests depend on the

sampling, test conditions and other factors. Because weathering has an extremely variable impact on mudrocks, only very general guidance about the likely effects of weathering can be given. The remarks given below are intended only to demonstrate very broad differences in the ways the parameters change for different lithologies.

36.3.1.1 Compaction mudrocks and over-consolidated clays

Only relatively weak interparticle bonds are formed during the burial of compaction mudrocks, so in many engineering situations they have little impact and effective stress has a larger influence on interparticle friction forces. In the UK, as shown in **Figure 36.4**, a number of important overconsolidated clay formations of the Jurassic period and younger occur widely in the east and south of England. The older formations, such as the Lower Jurassic Lias Clay and siltier parts of others, such as Oxford Clay and London Clay, display properties which place them on the boundary between hard soils and weak rocks.

The clay within about 3 m of the ground surface will typically be in partly saturated (partly desiccated) condition and will tend to be stiffer than the material it overlies. Wetting reduces the effective stress and causes rapid softening of the clay, which may then break down into individual grains or partly bonded domains. In compaction mudrocks, the effects of overconsolidation are rapidly destroyed by weathering processes and breakdown is likely within an engineering timescale and, in some cases, a construction timescale. The relative strength of interparticle bonding in mudrocks (which will provide an indicative rate of deterioration) may be assessed from the results of durability tests such as the static jar slake test (Czerewko and Cripps, 2001) or the dynamic slake durability test (Franklin and Chandra, 1972).

Higher values of strength and density with lower moisture content are found for the siltier and more deeply buried clays; in some cases, they are due to the presence of interparticle bonding and some cementation of particular horizons. Higher values of plasticity would indicate the presence of smectite and mixed layer clays. Weathering is typically responsible for reducing the undrained shear strength to about half of the unweathered value, whereas moisture content is increased by up to 50% and liquid limit by about 10% due to weathering processes. In parallel, density is typically decreased by about 5% and compressibility increased by about one order of magnitude.

Some formations contain systems of fissures such that the mass strength will be less than the strength of small laboratory samples. Some display anisotropy due to the presence of laminations and/or the preferred alignment of platy clay minerals. For reasons explained in section 36.2.3, the horizontal *in situ* stress can be three or four times greater than the vertical stress in the upper 10 m or so of the formation. In the UK, weathering effects generally extend to depths of 7–8 m, and in the upper few metres, deformation relieves the horizontal stress. On the other hand, joint and fissure development, which are the result

Box 36.1 Process of the oxidation of pyrite

1. Oxidation of pyrite by molecular oxygen produces ferrous iron in a purely chemical reaction. Under saturated conditions iron remains in solution:

   $2FeS_{2(s)}$ (pyrite) + $2H_2O$ + $7O_2$ $2Fe^{2+}$ (ferrous iron) + $4SO_4^{2-}$ + $4H^+_{(aq)}$.

2. Oxidation of ferrous iron by molecular oxygen to ferric iron which is a strong oxidising agent:

   $4Fe^{2+}$ (ferrous iron) + $4H^+_{(aq)}$ + O_2 $4Fe^{3+}$ (ferric iron) + $2H_2O$.

3. Further oxidation of pyrite by ferric iron which acts as an electron acceptor producing ferrous iron, sulfate anion and protons:

   FeS_2 (pyrite) + $14Fe^{3+}$ (ferric iron) + $8H_2O$ $15Fe^{2+}$ (ferrous iron) + $2SO_4^{2-}$ + $16H^+_{(aq)}$.

4. If calcium carbonate is present the acid will be buffered and gypsum and carbon dioxide will be produced. The reactions require sufficient water for the reaction products to be in solution and gypsum will be precipitated if the water is evaporated or consumed so that the solution becomes saturated in that compound

   $CaCO_3(s)$ + $2H^+_{(aq)}$ + $SO_4^{2-}{}_{(aq)}$ + $H_2O_{(l)}$ $CaSO_4.2H_2O_{(s)}$ + $C0_{2(g)}$.

of overburden reduction, extends to tens of metres below the surface.

The glacial conditions that occurred during the Pleistocene Era had very important consequences on the behaviour of mudrocks throughout the UK. In compaction mudrocks and overconsolidated clays, localised zones of disturbance to near-surface strata were formed and solifluction deposits mantled most escapments and outcrops on sloping ground. The solifluction deposits contain shear surfaces that mobilise shear strength near to the residual value, so they can undergo shearing if subjected to relatively low values of shear stress. Weeks (1969) and Symonds and Booth (1971) describe hillsides that became unstable due to changes in groundwater conditions, loading or the removal of support.

36.3.1.2 Weakly cemented mudrocks

The physical and mineralogical changes that characterise cemented mudrocks also enhance durability by restricting the access of air and water to any remaining reactive clay minerals. However, because distorted mineral particles are restrained by intergranular bonds and cements, the reduction in confining stress and weathering effects results in time-dependent strain energy release. Such materials tend to undergo rapid slaking as the volume changes that accompany alternating changes in moisture content result in the breakage of bonds and interparticle cements.

One of the initial consequences of overburden reduction is the development of systems of sub-horizontal and inclined joints that facilitate air and water penetration into the rock mass.

Together with shrink–swell effects, these result in the development of further joints and microfractures which develop along bedding discontinuities and grain boundaries (see **Figure 36.14**). Generally speaking, these processes result in degradation to sand- to fine gravel-sized mineral grains. Further breakdown of the material to individual mineral grains then usually requires breakage of the interparticle bonds by a combination of fatigue failure – caused by repeated volume changes and dissolution of cements (see **Figure 36.15**).

Weakly cemented mudrocks may well be weak rocks in terms of their undrained shear strength, but they have a tendency to undergo rapid slaking when they are exposed in excavations and slopes, as seen in **Figure 36.14(b)**.

The changes in parameters due to weathering action are greater in cemented mudrocks than in compaction mudrocks, as the former are initially more indurated. However, the product materials are similar, notwithstanding that degradation is more rapid for compaction mudrocks. The moisture content of highly weathered mudstone is typically 30–35%, whereas bulk density will be 1.95–2.05 Mg/m^3, undrained shear strength 70–100 kPa, uniaxial compressive strength 10–500 kPa, and coefficient of volume compressibility 0.1–0.24 m^2/MN. Higher values of moisture content plasticity and compressibility, and lower values of strength and density are liable to be found in less deeply buried, poorly indurated clay-rich deposits, or in more indurated materials containing swelling or mixed layer clays.

Disturbance during the sampling process and sensitivity to changes in stress and moisture conditions render many weakly cemented mudrocks challenging to test and classify, which can lead to the underestimation of the *in situ* behaviour. Soil classification tests, such as particle size analysis and Atterberg limits which require destructuring of material, do not usually provide an accurate indication of its behaviour even on a small scale. For instance, many published values of high activity in Mercia Mudstone are probably the result of the underestimation of the <2 mm fraction rather than an indication that they contain high values of swelling clay minerals.

36.3.1.3 Strongly cemented mudrocks

In strongly cemented mudrocks, a skeletal framework consisting of bonded clay grains and a continuous framework of cemented grains are present with the elimination of any low-strength micro-discontinuities. In addition, stored strain energy due to the presence of distorted mineral grains will have been gradually eradicated by recrystallisation of minerals. Any swelling clay minerals will have been replaced by more stable forms. In practice, like weakly cemented mudrocks, ultimate breakdown to constituent particles is a two-stage process in which the rock mass is initially broken down into sand- or gravel-sized fragments which may then degrade into mineral grains. In strongly cemented mudrocks, the fragments are usually larger and they take longer to break down.

The liquid limit of disaggregated strongly cemented mudrock usually ranges between 35 and 45%, which reflects a predominance of illite in the clay mineral fraction. The extent of degradation due to weathering is greater than for other mudrocks. Typical values of parameters for weathered cemented mudrocks are as follows: moisture content 15–30%, liquid limit 35–45%, bulk density 1.9–2.0 Mg/m^3, undrained shear strength 15–70 kPa.

The impact of weathering on well-bonded mudrocks is particularly apparent in triaxial strength tests on fresh and weathered samples. In the results of tests by Taylor (1988) shown in **Figure 36.18**, a curved Mohr envelope typical of Carboniferous and other fresh cemented mudrocks was obtained. There is apparent cohesion at low values of confining pressure, but at higher confining stress the breakage of grains occurs. The removal of the bonding effects by weathering action results in a linear envelope with a lower friction angle typical of unbonded clays. Shearing results in a further reduction in strength to the residual value as a consequence of the orientation of clay minerals on shear surfaces.

36.3.2 Investigation, description and assessment

In this section, the techniques of investigation are reviewed, particularly with regard to some of the problems that may arise with mudrocks. Features of mudrocks that help with the anticipation and avoidance of adverse forms of behaviour are also discussed.

As explained in section 36.1.1, BS 5930 + A2: 2010 provides guidance on the procedures for carrying out ground investigations for civil engineering works in the UK. It is argued that the money spent on carrying out ground investigations is saved by avoiding additional costs due to changes and delays in the construction programme. Savings in materials and construction costs may be possible because a more refined design can be adopted. Parts of BS 5930:1999 + A2:2010 are superseded by Eurocodes: BS EN ISO 22475–1:2006, BS EN ISO 14689–1:2003 and BS EN ISO 14688–1:2002 and 14688–2:2004.

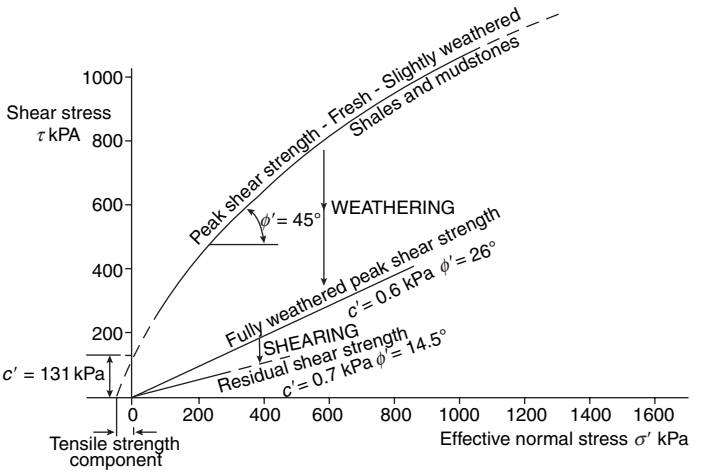

Figure 36.18 Mohr envelopes for bonded and weathered Carboniferous mudrocks

Reproduced from Taylor (1988) © The Geological Society of London

Laboratory classification tests for soils are described in BS 1377:1990. These documents specify minimum standards for commonly occurring engineering situations. So far as mudrocks are concerned, there are a number of deficiencies. Due to uncertainty of meaning, some of the terminology and methods need to be clarified.

The density of the material is an extremely useful parameter for assessing its state of induration and likely performance. As mudrocks have broadly similar compositions it may also be indicative of mineral composition and void volume.

36.3.2.1 Soil and rock

Deciding whether to base designs on soil mechanics or rock mechanics principles is not a straightforward issue for some mudrocks, and assuming a worse case would not normally provide the best engineering solution. Soil mechanics deals with material as assemblages of discrete particles or a continuum (where design is usually based on limit state modelling of a plastic material of low shear strength) and in which changes in moisture content bring about significant changes to plasticity and volume. On the other hand, the rock mechanics approach considers an intact material of a significant rigidity where the mass properties are controlled by the nature and geometry of dislocations present in the rock mass. The engineering assessment of mudrocks and clays needs to consider the most appropriate design approach, given the material and the effects on the material of the imposed stresses and the environmental conditions at different stages of the project.

At a certain stage of induration, the network of cemented grains will resist deformation such that failure of the material requires brittle fracture of the framework. Such behaviour results in fragmentation if the confining stress is low, whereas the same material can deform in a plastic manner in high confining stress conditions. As mentioned in section 36.1.2, this makes the material difficult to classify and, as these changes are progressive, the effects may vary within the formation. Norbury (2010) points out that the boundary between soil and rock is taken as an undrained shear strength of 300 kPa, which is equivalent to a uniaxial compressive strength of 0.6 MPa. He recommends the following field tests to distinguish between soils and rocks. With rocks:

- finger nail does not penetrate the surface;
- fragments behave in a brittle manner in the hands;
- material does not immediately soften or disintegrate on contact with water.

Changes with time must also be considered as some mudrocks degrade rapidly. A small change in weathering grade, which might occur during or after the construction period, has a significant impact on the appropriateness of a construction process or design. It can be very difficult to decide whether it is appropriate to regard the material as an engineering soil or as a rock; sometimes it is necessary to apply both approaches and then optimise the design so that both forms of behaviour are accommodated. Further relevant discussion is presented in the following section.

36.3.2.2 Description

In view of the high possibility of sample disturbance influencing the results of laboratory tests, it is particularly important that descriptions of mudrocks are accurate and clear. Both the material and the structures in the rock or soil mass should be recognised and correctly characterised. In practice, an accurate interpretation of laboratory test results depends on descriptions of the different materials and of their spatial relationships with each other. It is usually possible to obtain good quality undisturbed samples of either strongly cemented mudrocks, which survive the sampling procedures and preparation for testing, or compaction mudrocks, because of their low strength and plasticity.

The aim of description is to record unambiguously essential features of the material so that (a) similar material can be recognised elsewhere, and (b) accurate prediction of the engineering behaviour is possible. Norbury (2010) provides highly useful advice on the description of mudrocks and other geomaterials.

Unfortunately the job of logging cores and exposures is regarded by many as a menial task to be assigned to junior, less experienced staff. This can result in a weak link developing in the transfer of information about the ground conditions to designers and construction engineers. It is also wasteful given the high investment of time, effort and money expended on ground investigations, and the additional costs and delays that inappropriate design can cause. Therefore description of mudrocks should be undertaken in a well-informed and focused manner with thorough attention to detail. Distinguishing between soil and rock is an essential part of description as there are different approaches to describing these materials. However, as discussed in section 36.3.2.1, mudrocks can span the range from rock- to soil-like behaviour and some rock or soil masses contain both materials. It is often necessary to describe the weathered parts of a rock mass using the terminology for soils, whereas some soils contain hard inclusions that need to be described in the manner of rocks. The proportions and relationships between the different materials should also be recorded.

Although it is preferable to use a standard approach to description, according to a specific standard, it is also necessary to ensure that all information that will enable a material to be recognised (and its behaviour to be anticipated) has been recorded. The standard schemes given in BS EN ISO 14688–1:2002, BS EN ISO 14689–1:2004 and BS 5930:1999 +A2:2010 should be regarded as the minimum amount of information. The recording of additional information relating to factors controlling the behaviour of mudrocks facilitates more reliable assessments of their performance in engineering situations. This approach is supported by Franklin and Dusseault (1989); Dick and Shakoor (1992); and Hawkins and Pinches (1992) who emphasise that a thorough geological description

(1) Tests to assess plastic or non-plastic behaviour in terms of dilatancy, plasticity and dry strength are described by BS EN ISO 14688-1:2002.
(2) Strength values for unweathered (fresh) material.

Table 36.4 Identification and classification of mudrocks
Based on data from Potter *et al.* (1980) and Attewell (1997)

is the essential first stage of making an engineering assessment of mudrocks, with further classification based on the results of suitable index testing accompanied by strength and slake durability tests.

Although both BS EN ISO 14689–1:2003 and BS 5930: 1999 + A2:2010 contain deficiencies, they provide good bases for descriptions, and only the aspects requiring additional details are described below. As discussed in section 36.1.1, particular inadequacy of the standards is the choice of rock names; the scheme given in **Table 36.4**, which groups the materials into classes that relate to their engineering performance, is more appropriate.

Using **Table 36.5**, the distinction between soil and rock material is based upon the state of induration determined by the tests described by Norbury (2010) as shown in section 36.3.2.1. Rocks do not readily disaggregate when a dry sample is immersed in water and it is not possible to indent the material with a finger nail. The grain size, in particular in the silt and clay portions, is judged according to the surface texture and appearance of the material. In the case of non-indurated materials the dilatancy, dry strength and plasticity tests (see BS 5930: 1999 + A2:2010 and BS EN ISO 14688–1:2002) should be used. The distinction between indurated mudstone and metamudrock is also based on strength, where the latter is typically medium strong or stronger (UCS > 25 MPa).

According to BS EN ISO 14688–1:2002, BS 5930: 1999 +A2:2010 and BS EN ISO 14689–1:2003, information that needs to be recorded in rock and soil material should include the following aspects, although (as noted above) this should be regarded as the minimum and attention should be given to the details listed in **Table 36.5**:

- strength: very soft to very stiff for soils; extremely weak to extremely strong for rocks (**Table 36.6**);
- structure: lamination and bedding etc.; see **Table 36.7**, and in particular, the footnotes;
- colour: describe in terms of depth, chroma and hue, preferably with reference to a Munsell chart, and record mixing such as mottling or banding;
- fabric: spatial arrangement of solid grains and associated voids, such as graded or granular;
- texture: shape and size of constituent grains, including groundmass, inclusions and clasts, etc.;
- rock or soil name: in capitals such as MUDSTONE or SILTSTONE (see **Table 36.4**);
- other relevant information: includes minor constituents such as fossil debris, calcareous and ferruginous nodules, disseminated or crystalline pyrite, or iron oxide;
- geological formation: where known, such as LOWER LIAS CLAY or LOWER COAL MEASURES.

Attribute	Descriptive Adjectives
Induration	Enables decision on description as soil or rock. If resistant to slaking in water and hard – rock; if susceptible to slaking in water, deformable and 'earthy' consistency – soil. Strength depends on moisture state; dry sediment is stronger than wet, and rock strength varies with moisture content; sampling may impair strength.
Strength	Strength is designated based on the degree of induration. For soil, use field consistency values based on manual assessment, e.g. stiff; when shear strength measurements are made, use strength terms, e.g. high strength. For rock, definition based principally on manual field assessment using geological hammer and knife, may be confirmed with UCS measurement: indurated mudrocks range from extremely weak to medium strong; metamudrocks are stronger depending on weathering.
Structure	Standard terms – see **Table 36.7**. Include description of lithology and textural inter-relationship, as complex features may be present with structured strata such as 'thin beds of cross bedded' mudstone.
Colour	Use Munsell colour chart for consistency. Important for correlation; likely environment of formation and indication of likely behaviour of material, i.e. red colour – likely formation under oxidising continental environment. Most important to mudrocks is relationship between colour on the Fe^{3+}/Fe^{2+} ratio. A decrease in this ratio gives an increase in colour from red → green → grey (more Fe^{2+} indicates the presence of pyrite). Organic carbon controls colour: <0.2–0.3%C = light-grey to olive grey; 0.3–0.5%C = mid-grey; >0.5%C = dark-grey to black.
Accessory minerals	Calcareous (slightly to very) – based on level of effervescence when assessed with HCl). May also be carbonaceous, dolomitic, ferruginous, glauconitic, gypsiferous, pyritic, micaceous, sideritic, phosphatic, etc..
Rock name	See **Table 36.4.**
Additional information	Presence of fossils – record type (generic such as bivalve and retain for identification), abundance, condition, orientation. Inclusions – nodules (with mineral type and details); gravel, sand, silt partings or pockets, etc.
State of weathering	Alteration seen as distinct discolouration, significant strength reduction to discontinuities and presence of lithorelicts (note orientation). Standard Eurocode 7 approach too limited for mudrocks, use specific schemes where available as guides, i.e. Lias and London Clay, Mercia Mudstone.
Fractures	Use EC7 standard terms and procedures. For rock supplement with details such as nature of fragmentation, e.g. conchoidal, hackly, brittle, splintery, slabby, fissile.

Full engineering descriptions of the intrinsic condition and mass properties using descriptive adjectives provided in EC7 (BS EN ISO 14688–1:2002; BS EN ISO 14688–2:2004; BS EN ISO 14689–1:2003, supplemented with additional information to assist assessment.
This list offers limited guidance for key features particular to mudrocks.

Table 36.5 Guide to the description of mudrock features

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

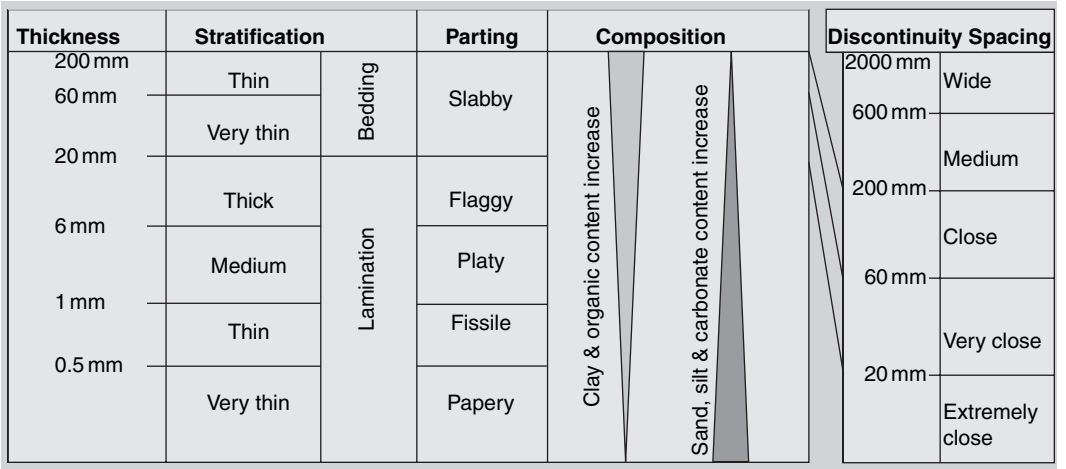
Term	Strength	Description
Strong mudrock	σ_c 50–100 MPa	Can only be scratched by knife or pick end of a geological hammer, and can only be broken with more than one firm hammer blow.
Medium strong mudrock	σ_c 25–50 MPa	Can be deeply scored by a knife or pick end of a geological hammer, and a thin slab can be broken by heavy hand pressure. Specimen is readily fractured with a single firm blow of geological hammer or split with a knife blade. Cannot be peeled with a pocket knife.
Weak mudrock	σ_c 5–25 MPa	Small gravel-sized fragment can be deformed with heavy finger pressure, shallow indentations readily made by firm blow with point of geological hammer. Can be peeled by a pocket knife with difficulty.
Very weak mudrock	σ_c 1–5 MPa	Crumbles under firm blows with point of geological hammer, can be peeled by a pocket knife.
Extremely weak mudrock	σ_c 0.6–1 MPa	Can be indented by thumbnail.
Extremely high strength clay	s_u 300–600	Field description will generally be as a 'very stiff clay'. Crumbles, does not remould, can be indented by thumbnail.
Very high strength clay	s_u 150–300	Determine by testing – field description as 'very stiff clay'.
High strength clay	s_u 75–150	
Medium strength clay	s_u 40–75	Field description will generally be as a 'stiff clay'. Crumbles, breaks, remoulds to lump.
Low strength clay	s_u 20–40	Field description will generally be as a 'firm clay'. Cannot be moulded, rolls to thread.
Very low strength clay	s_u 10–20	Field description will generally be as a 'soft clay'. Moulds by light finger pressure.
Extremely low strength clay	s_u <10	Field description will generally be as a 'very soft clay'. Extrudes between fingers.

σ_c uniaxial compressive strength.
s_u undrained shear strength; $\sigma_c = 2 \times s_u$. Extremely high strength clay soils and extremely weak mudrocks have similar characteristics - choice of term depends on the geological setting and engineering situation.
Field consistency descriptions for clays and strength tests descriptions should be used separately and treated as mutually exclusive.

Table 36.6 Strength criteria for mudrocks

The second part of the description deals with the structure of the rock or soil mass, and includes the following characteristics:

- weathering: description is required of observed material changes including colour changes, differences in strength and fracture state, as well as the presence and character of any weathering products. Where possible, a weathering classification scheme should be used to denote the degree and style of weathering (see **Table 36.8(a) and (b)**);
- discontinuities: information should be recorded about the distribution and features of discontinuities including the type, orientation, spacing, geometrical form, shape, rugosity (surface roughness) and evidence of alteration of rock adjacent to the discontinuities, as well as the nature and thickness of any infill material.



The level of detail it is possible to record depends upon the scale of exposure; for example, it may not be possible to comment on the planarity of joints in borehole cores. **Table 36.5** provides guidance about the terms which should be used in the description of mudrocks. The strength categories in **Table 36.6** are based on measured *in situ* or laboratory shear strength values, whereas the strength assessed using the manual (or hand) tests should use the consistency terms 'very soft' to 'very stiff'. Details of manual tests are given in BS EN ISO 14688–1:2002 and classification based on these tests are presented in BS EN ISO 14688–2:2004. For rock descriptions, guidance is provided in BS EN ISO 14689–1:2003, but as some of these do not give reliable results for mudrocks, the tests detailed in **Table 36.6** are usually more helpful.

Although BS EN ISO 14688–1:2002 and BS EN ISO 14689–1:2003 provide schemes for classifying the spacing of structural features, these lack subdivisions within the thinly and thickly laminated categories that are useful for assessing the potential style and rate of weathering degradation.

The colour of rocks and soils depends on whether the surface is wet or dry. Generally speaking, the material should be described in the condition it was in when it was taken from the ground – but this should be stated. Care must be taken to ensure that the surface of the sample is clean of coating materials which may be different colours from the bulk of the material. Samples should be broken open to facilitate a description of both the interior and exterior. In addition, if there are any changes in the appearance of broken surfaces some hours later, they should be recorded.

Texture of soils and rocks refers to the relationships between the constituent grains, including the variation in size. Mudrocks tend to have a fine granular texture, implying that the main constituents are detrital grains that are cemented together. The particle shapes and crystallinity should be recorded, although this is often impossible even using a hand lens. Details of the composition should also be recorded, for example the presence of organic material (by visual assessment or smell), or carbonate (as indicated by effervescence when hydrochloric acid is applied), using the categories slightly, highly, etc., according to the criteria given in BS EN ISO 14688–1:2002, BS EN ISO 14689–1:2003.

In some cases, it is best to describe the material rather than attempting to determine an accurate geological name. The rock or

Mudrocks that occur without laminations or bedded stratification re described as massive.
Textural features should be used as *descriptive adjectives* when describing mudrocks and not for naming rocks similar to generic schemes used for other rock types, as this may be confusing and ambiguous; for example 'shale' can mean a fissile, or laminated, or massive mudstone or claystone; in preference, use the adjective as a prefix such as fissile claystone, laminated mudstone.
Stratification is a structural feature concerned with the inter-relationship of textural features and lithology caused by differences of grain size, fabric and composition; partings is the tenacity of a mudrock to split along lamination, bedding or mineral orientation, which is greatly enhanced by weathering; whereas discontinuities are mechanical breaks or fractures with low to no tensile strength.

Table 36.7 Description of structural features of mudrocks (stratification, partings and discontinuities)
Data taken from BS EN ISO 14689–1:2003, and Potter *et al.* (1990)

soil type should always be written in capitals, which implies that the rest of the description should be presented in sentence case.

The presence of constituents that are not implied by the rock name should be specified to aid recognition of the material. The description should also include details of observable features not already covered. Examples would include the presence of fossils, nodules, inclusions, etc. Where it is known, the geological formation name should be specified.

The presence of pyrite is a possible adverse feature of mudrocks that should be considered in the description of the materials. Characteristics of mudrocks that make the presence of pyrite more likely are:

- dark coloured (grey or dark grey), organic-rich mudrock or clay;
- finely disseminated gold coloured crystals, greenish grey hue or orange-brown and brown staining;
- sulfurous odour when hit or scratched;
- clear or white-grey crystals on surfaces which can be scratched and broken with a finger nail, or a white surface coating when the material is dried (liable to be gypsum/selenite).

Recording the effects of weathering is a highly important aspect of the description of a rock or soil mass. The appearance of the material should be recorded, particularly any changes in colour, strength or fracture spacing that are a consequence of weathering processes. This is difficult where the material has not been viewed in its fresh state for comparison. If possible, the condition of the rock or soil mass should be classified. Although weathering commences along discontinuities in mudrocks, there also tends to be an impact on the intervening blocks, whereas in stronger rocks there is usually little effect on these – so that core stones are formed. Unfortunately the Eurocode schemes are lacking in this regard and although BS 5930: 1999 + A2:2010 provides a comprehensive scheme, it is suggested that for mudrocks the schemes presented in **Table 36.8** (a) and (b), where (a) provides a scheme for non-indurated mudrocks and clays and (b) provides one for indurated mudrocks and metamudrocks should be used.

The features that need to be recorded in the description of structures should include, where possible, the origin of discontinuities. Where this is not discernable, the term 'fracture' should be used. In some mudrocks, especially weakly cemented types, it can be difficult to distinguish between *in situ* and induced discontinuities, where the latter have been formed during or after removal from the ground. Stress relief, change in moisture content, and physical disturbance may all result in such fracturing. Usually such fractures have a fresher and cleaner appearance than *in situ* ones, but this is not always the case.

Figure 36.14 demonstrates how the characteristics of the weathered material can be used to deduce the internal structure of the material. Platy fragments will be produced in a rock possessing tectonic cleavage or a laminated structure; flaky and blocky fragments are produced by a uniform distribution of the minerals in the rock. The bedding is thicker in the latter case.

36.3.2.3 Durability

Durability is a measure of the rate that a rock will degrade when exposed to weathering action. Compared with most other types of rocks, mudrocks degrade rapidly. Hence significant changes to geotechnical properties occur on timescales of significance to

Classifier	Nature	Typical Characteristic	
Unweathered	Fresh	No visible sign of weathering. Typically grey colour, clean fissured clay or mudrock.	Pyrite
	Faintly Weathered	Trace of brown surface discolouration on discontinuities otherwise intact fissured clay or mudrock	
Partially Weathered	Slightly Weathered	Fissures more closely spaced, slight strength reduction evident as surface softening some bedding disturbance. Discontinuity surfaces with pervasive brown discolouration & slight penetration typically 1-2 mm. Rare selenite crystals on discontinuity surfaces	Increasing Oxidation
	Moderately Weathered	Fissures more closely spaced, slight strength reduction evident as surface softening, some bedding disturbance. Discontinuity surfaces with pervasive brown discolouration & slight penetration typically few mm to cm with centre of fissure bound block still grey Occasional selenite crystals.	Selenite
Distinctly Weathered	Highly Weathered	Fissure spacing much closer with lensoidal fissuring – development of matrix bound regular angular block & platy orientated 'lithorelicts' & matrix as few mm to cm of claysilt on discontinuities, with occasional polished fissures or gleying. Material is generally brown to grey brown with completed discolouration – occasional fissure bound blocks with trace of grey core. Selenite crystals common in matrix & blocks.	Oxidation complete increase in reduction producing gleying
Destructured	Completely Weathered	Greatly weakened material with numerous horizontally aligned ordered lithorelicts in clay-silt matrix. Bedding disturbed. Generally brown & Grey brown may have light grey mottling. Fissure blocks & lithorelicts brown throughout. Selenite crystals common.	
		Greatly weakened material comprising numerous randomly orientated lithorelicts in a clay silt matrix. Lithorelicts are completely discoloured to brown or grey brown and softened. Gypsum crystals common. Bedding heavily disturbed.	
Reworked	Completely reworked or residual soil	Unbound sediment with occasional randomly orientated predominantly sub-angular to sub-rounded lithorelicts and occasional foreign material. No original bedding or structure remaining. Generally mottled brown, orange brown & light grey. Rare selenite crystals may be present but generally absent.	Surface water infiltration - leaching

Table 36.8(a) Weathering classification and description for non-indurated (compaction mudrocks) or overconsolidated clays

engineering designs, whilst for some low-durability mudrocks, changes may occur within the construction period. In the process, a seemingly competent rock material becomes transformed into clay or silty clay, whereas a rock mass may well become degraded into sand and gravel-sized fragments so thus there is a serious loss of strength and increase in compressibility.

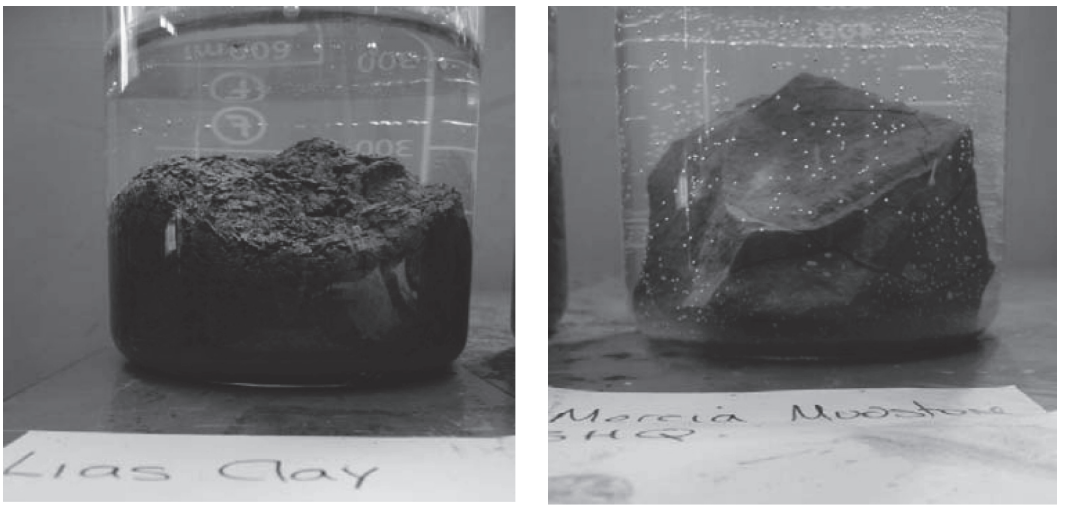
The main process of degradation of mudrocks is slaking, which occurs due to alternating changes in water content. Because volume changes to clay minerals are greater for swelling clay minerals, mudrocks containing smectite or mixed layer smectite–illite are particularly vulnerable to this type of degradation. Pore water suctions, produced as water is drawn out of narrow pores during drying cycles, also cause shrinkage. This effect is greatest in fine-grained rocks, especially where the pore size has been reduced through a certain degree of compaction and cementation. Taylor (1988) attributes the breakdown of mudrocks in colliery spoils to the process of air breakage – resulting from high pore air pressures produced as water enters narrow capillary pores during the saturation of mudrocks. The shrinkage and swelling of the rock, associated with changes in moisture content, stress the intergranular bonds and partly cemented skeletal framework possessed by weakly cemented mudrocks such that breakage predominantly occurs along existing structural weaknesses within the material. This causes the rock mass to break down into sand or gravel-sized pieces, as illustrated in **Figure 36.15**.

Durability tests are designed to provide both qualitative and quantitative assessments of the susceptibility of the rock to degradation processes. Ideally, to provide accurate guidance about the performance of a material, the test used should simulate the dominant degradation processes to which it will be subjected in the engineering environment. Unfortunately, only the slake durability test described by Franklin and Chandra (1972) and ISRM (1979) has been standardised. The test entails subjecting samples to both wetting and drying action and mechanical disturbance. The degree of degradation is assessed by the proportion of particles of less than 2 mm produced by the degradation process expressed as a percentage of the original dry mass of the sample. In the standard test, the number of cycles of drying and slaking (n) equals 2, where $Id_2 > 90\%$ distinguishes non-indurated from indurated mudrocks. However, Taylor (1988) suggested that the third cycle durability value $Id_3 > 60\%$ is a more reliable indication of this boundary; this was later corroborated by Czerewko and Cripps (2001). Two of the drawbacks of this approach

Classifier	Nature	Typical Characteristics
Unweathered	Fresh	No visible signs of weathering or alteration. Primary colours of dark grey, grey, purple, red brown, green grey.
	Faintly weathered	Colour of original material is changed – Discolouration tends to be confined to major discontinuity surfaces – the colour change and extent of discolouration should be described. Generally change to light brown, range brown, light brown and red brown discolouration.
Partially weathered	Slightly weathered	Colour of original material is changes – Discolouration tends to be confined to discontinuity surfaces with pervasive penetrative discolouration. Discolouration should be described and any evidence of material weakening along discontinuity should be described and quantified where possible.
	Moderately weathered	Considerable weakening with alteration & comminuition to matrix of clay and silt penetrating in from discontinuities accompanied by penetrative discolouration. Rock framework intact with <50% of material decomposed. Rick framework generally locked 7 controls strength & stiffness. Matrix affects permeability.
Distinctly weathered	Highly weathered	Generally >50% of rock material decomposed. The rock framework may contribute to strength but weathered decomposed material forming the matrix controls stiffness & permeability – Consider structural design based on Soil Mechanics principles.
Destructured	Completely weathered	Rock material largely decomposed and considerably weakened. The weak 'soil-like' material controls behaviour. Lithorelicts may be present with random orientation. Hard corestones/concretions may be present and affect construction – Consider structural design based on Soil Mechanics principles.
Reworked – Residual soil	Residual/Reworked soil	Unbound soil material comprising of clay and silt with occasional or rare randomly orientated lithorelicts and foreign material. No original bedding, structure or fabric preserved. Properties of soil, moderate compressibility, low permeability, low to moderate soil strength.

Table 36.8(b) Weathering classification and description for cementation or rock-like mudrocks

are that: (a) complete drying of the material in the test does not simulate the more subtle changes in moisture content that occur in weathering environments, and the degradation to particles larger than 2 mm is not directly assessed; (b) there is a lack of sensitivity in compaction mudrocks and some weakly cemented mudrocks, which would make it preferable to carry out static slaking tests. Drawback (a) can be overcome by carrying out plasticity testing on the <2 mm fraction. Difficulty (b) can also be overcome by carrying out plasticity testing on the <2 mm fraction and/or by particle size analyses of the drum-retained fragments. Regrettably these important aspects of durability assessment are frequently omitted.



The static jar slake test procedure was advocated by Lutton (1977) and further developed by Czerewko in 1999, (see Czerewko and Cripps, 2001). Following immersion of an oven-dried sample in water, the degree of fracture development and of slaking are monitored over a 24-hour period. **Figure 36.19** shows the results of jar slake tests on two mudrocks of contrasting durability. Experience with a wide range of UK mudrocks and using strength (UCS), static jar slake (I_j') and dynamic slake durability (Id_3) test procedures, suggests that UCS = 5 MN/m^2, $Id_3 > 60\%$ and $I_j' < 6$ enable bonded and non-bonded mudrocks to be distinguished from each other, as detailed in **Table 36.9**.

The likelihood of rapid degradation of mudrocks and the size of the breakdown products may also be ascertained by observing samples or outcrops that have been subjected to short periods of exposure (see **Figures 36.14** and **36.15**). For example, **Figure 36.20** shows the complete degradation of Lias mudstone over a period of 41 days.

36.3.2.4 Investigation techniques

Sample disturbance is a significant problem with mudrocks, especially weakly cemented ones which can become distorted by the process of taking or extracting samples. They also tend to be vulnerable to volume changes – in response to removal of overburden pressure and changes in moisture content. The use of wire-line coring, triple-tube core barrels or plastic core-lining tubes in double-tube core barrels greatly enhances the recovery and quality of cores. Other methods for obtaining undisturbed samples of mudrocks, which are potentially suitable for strength and compressibility testing, are outlined in **Table 36.10**.

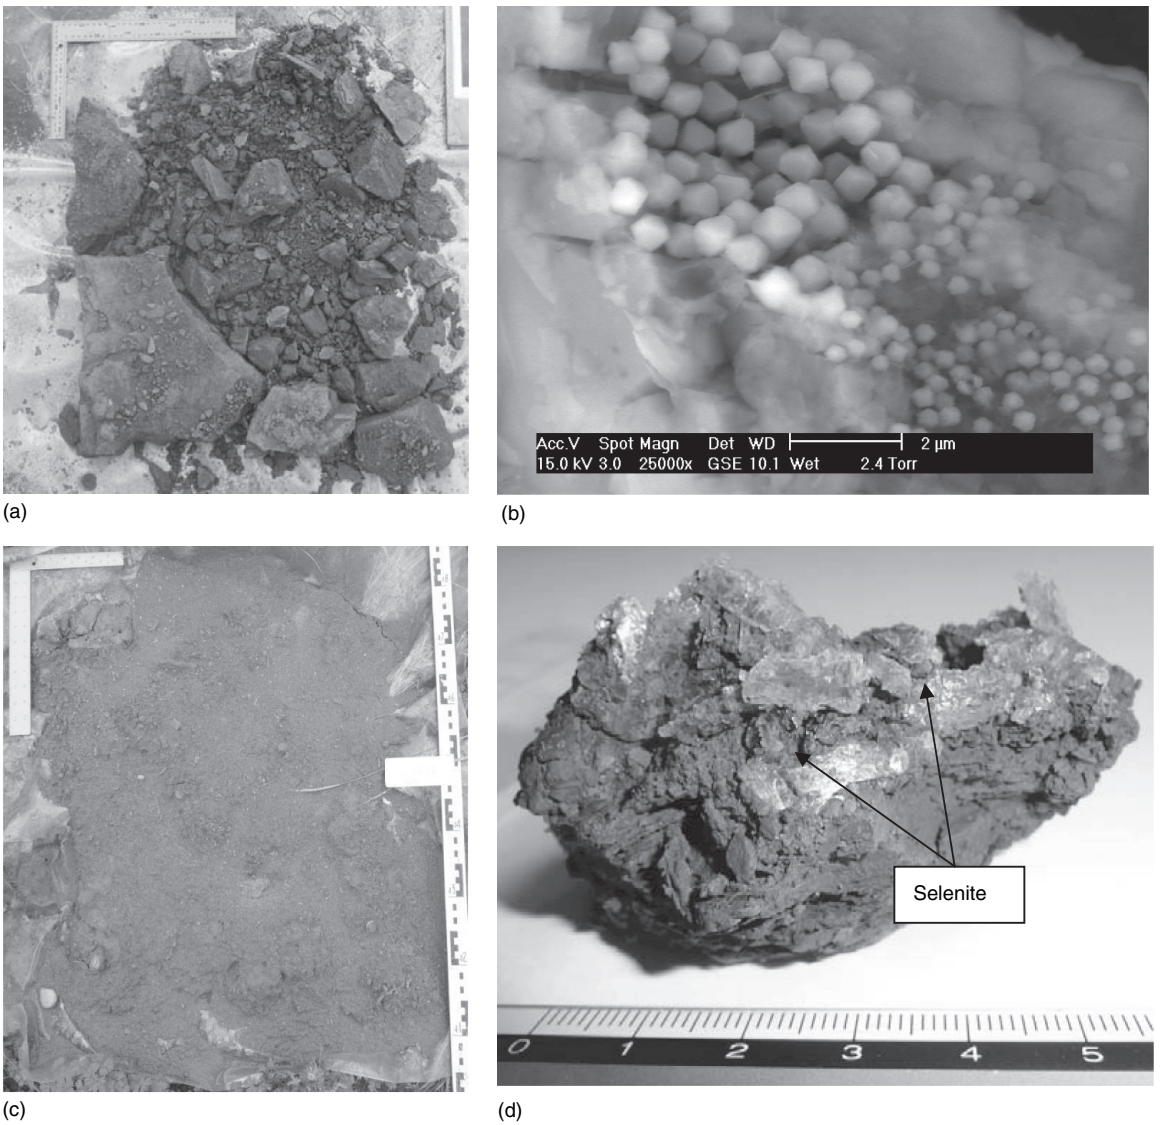
As explained in BS EN ISO 14688–1:2002 and BS EN ISO 22475–1:2006, the undrained shear strength and effective stress shear strength parameters may be determined by triaxial testing, and consolidation and swelling characteristics C_c – compression index; C_s – swelling index; m_V – coefficient of volume compressibility; c_V – coefficient of vertical consolidation can be determined by oedometer testing. The relevant test procedures are given in BS 1377:1990 and are described by Head (1994, 1998). Rock-like materials are classified using geomechanical rock quality classification systems (see Barton *et al.*, 1974; Bieniawski, 1976) which are based on intact uniaxial compressive strength values and mass discontinuity characteristics, usually from detailed descriptions of exposed rock or good quality borehole cores. Additionally, the point load strength (PLS) may be determined on cores or samples from trial pits or exposures. It is likely that point load testing will be the only viable means of strength determination in weakly cemented mudrocks.

(a) (b)

Figure 36.19 Behaviour of non-durable and durable mudrocks to water immersion in jar slake tests. (a) Lias Clay from East Midlands, England: rapid slaking after 3hr immersion to sand-to gravel-sized material. (b) Durable Basal Mercia Mudstone from East Midlands, England showing no slaking after 24h immersion in water.

Slake durability – Id_s (%)	Jar slake – I_j'	Compressive strength – UCS (MPa)	Classification
<60	6–8	<5 (≤ very weak)	Non-durable mudrock
60–80	3–6	5–100 (weak to strong)	Durable mudrock
80–97	1–3		Extremely durable mudrock
>97	1–2	>100 (≥ very strong)	Metamudrock

Table 36.9 Durability classification of mudrocks for engineering purposes



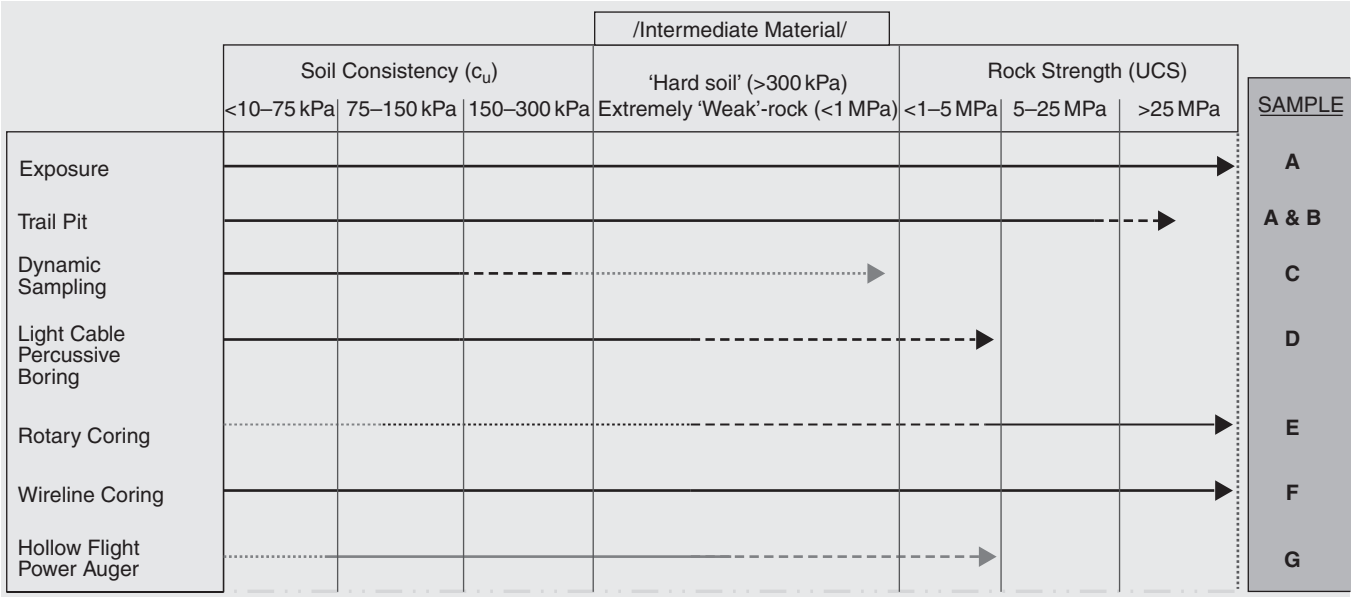
The slake durability test can be used to determine the rate and extent of breakdown included in these rocks. Gamble's (1971) slake durability–plasticity scheme is the most suitable classification for compaction mudrocks; in low durability mudrocks, the slake durability–strength schemes of Grainger (1984) and Taylor (1988) are more suitable; finally, the strength–swell coefficient approach of Olivier (1976) is best for medium strong to strong mudrocks. Triaxial testing of rock to determine shear strength (c' and φ') and elastic deformation (Young's modulus, E; Poisson's ratio, ν) parameters necessitate the preparation of intact samples which will not usually be possible in all but the strongest and most intact mudrocks.

An alternative approach is to estimate strength and deformation parameters from comprehensive descriptions and use of index testing. Various schemes are provided by Hoek and Brown (1997), Hudson and Harrison (2000), Wyllie and Mah (2004). *In situ* pressuremeter tests avoid problems with obtaining samples, but disturbance of borehole walls can still give unrepresentative results. However, examination of excavations and, if possible, boreholes by the use of CCTV, may well be beneficial for obtaining a more realistic assessment of the rock–mass condition.

36.3.2.5 Assessment of pyrite

As explained in section 36.2.4.3, pyrite is a commonly occurring (but minor) constituent of mudrocks that usually has a negative impact in engineering applications. As **Figure 36.8** illustrates, the mineral occurs in a different number of forms, depending upon the state of induration of the rock (see section 36.2.2) and other factors. It can be widely and erratically distributed through the deposit which makes it difficult to detect and to estimate the total pyrite content. Only in the crystalline form is it easy to recognise in hand specimens; furthermore, in this form, it is sufficiently hard to scratch glass and produces a slightly sulfurous odour when struck. Czerewko *et al*. (2003b) explain that other sulfur minerals may also cause problems in engineering situations and they provide guidance concerning the identification and evaluation of the various forms of sulfur.

In compaction mudrocks, pyrite usually occurs in an indiscernible, framboidal or fine-grained dark coloured form (see **Figure 36.8(a)**) which may be a dark greenish grey colour with slightly sparkling appearance and may, when rubbed or hit, produce a slightly sulfurous odour. In this condition, to achieve certain identification requires the use of optical or electron microscopy or X-ray diffraction analysis (see Reeves *et al*., 2006). These methods will facilitate a definite identification but only provide an estimate of the quantity present. The accurate determination of concentration of pyrite in mudrocks requires the use of chemical analysis methods. TRL447 (Reid *et al*., 2005), test 3 is an analysis method specific to sulfide minerals, but usually the amount of pyrite is estimated from the difference between the total sulfur and the amount of acid



(a) (b) (c) (d)

Figure 36.20 Example of the field assessment of material weathering due to pyrite oxidation, allowing consideration for design assumptions and beneficial construction sequencing. (a) Lias Clay material proposed for use as earthwork fill was exposed to atmospheric conditions to observe for signs of deleterious reaction of pyrite. Pyrite: 2% content, with calcite observed as shell debris and nodules. (b) Presence of framboidal pyrite confirmed by SEM analysis. (c) Complete breakdown of sample shown in (a) in a 41day period with oxidation of majority of pyrite and production of ali selenite crystals and significant softening.

soluble sulfur present (TRL447 (Reid *et al*., 2005), tests 1 and 4). If sulfur is present in other substances, for example organic material, or acid insoluble minerals such as barites ($BaSO_4$) are present, this difference method will overestimate the quantity of pyrite present. The carbonate content should also be determined (BS1377:1990) as this provides an indication of the potential for buffering the acid produced by pyrite oxidation (see section 36.2.4.3). In addition, to determine the potential for sulfate attack of concrete and other construction materials, the water-soluble sulfur should be ascertained.

BRE Special Digest 1 (Reid *et al*., 2005) deals with the determination of pyrite with respect to chemical attack of buried concrete and TRL447 (2005) to the performance of fill associated with highway structures. They also make recommendations concerning the taking and storage of samples required for these assessments. Relevant information on the storage of samples is also provided by Hawkins and Pinches (1986) and Czerewko *et al*. (2003c). In particular, precautions are required to ensure that the chemical and mineralogical determinations accurately measure the condition of pyrite in the ground. Contamination of samples with groundwater or drilling water can also cause problems.

Table 36.2 shows UK mudrock formations known to contain pyrite. This list does not include all pyrite-bearing formations and inclusion in the list does not imply the material will always be problematic. In addition, the development of difficulties due to pyrite oxidation depends on diverse environmental factors.

A = *In situ* examination of exposure allows accurate assessment of mass properties and recovery of block samples – limited by age of exposure.
B = Trial pits allow inspection of mass properties and weathering of freshly exposed material; recovery of Class 1 block samples, typically limited to 4–6 m excavation depth; support required for entry.
C = Dynamic samples allow recovery of continuous ground profile; material retained in rigid plastic liner; material damage by percussive driving method; material Class 2–3.
D = Standard UK procedure; percussive recovery of U100 as Class 2–3 sample; weak rock recovered as fragments for confirmation; allows use of hydraulic thin walled push sampler with recovery of Class 1–2 material, limited to approx 100–120 kPa strength material. Gravel inclusions or nodules liable to cause damage to samples and sample tubes.
E = Hard soil and weak rock recovery, improved by use of triple tube retractor barrels (at high cost); use of large diameter (>100 mm) double/triple tube core barrels to aid appropriate recovery of weak material; use of conventional diameter (76–92 mm) core barrels for stronger competent mudrock; choice of tungsten carbide bits for weak material, and diamond impregnated and diamond surface set bits for harder rock; consider cost; sample preservation is paramount.
F = Excellent recovery of all material type as Class 1; may lose borehole progress with bit wipe-out; very expensive and requires heavy equipment.
G = Uncommon in UK due to cost and requirement of heavy equipment; drive samples Class 2–3; unsuitable for continuous sample recovery.

Table 36.10 Outline of sampling options for mudrocks and their limitations

Care must be exercised over application of the guidance, as forms of sulfur other than pyrite may be present in some rocks. Also, as the guidance is intended for the design of commonly occurring applications of concrete and fill materials, the ground aggressivity classification values obtained do not necessarily apply in other situations, for example in open excavations or in fill placed to support floor slabs and shallow foundations.

36.4 Engineering considerations

Problems in engineering are often exacerbated by being unexpected. It is argued here that by taking account of (a) the controls exerted by the composition and structure of mudrocks, and (b) the impact of the environmental changes resulting from the engineering works, unexpected forms of behaviour can be avoided. As explained in sections 36.2.2 and 36.2.3, mineralogy, compaction, cementation and structures are linked and depend on the original sedimentary processes, burial diagenesis and changes due to exhumation and weathering. This section includes descriptions of commonly occurring situations in which problems are liable to arise unless suitable counter measures are taken.

36.4.1 Foundations

Indurated strongly cemented mudrocks in a structurally sound condition present few problems in most engineering situations. Allowable foundation loads are usually derived on an empirical basis such as that described by Lambe and Whitman (1979). It is advisable to construct foundations immediately after excavation to minimise deterioration of the rock mass by exposure to the atmosphere. However, where closely spaced discontinuities or relatively weak rocks are present, the bearing capacity of shallow foundations is liable to be inadequate. It is common practice to use Young's Modulus of elasticity as the deformation modulus, notwithstanding the possibility of unrecoverable stain and a non-linear stress–stain relationship. Anisotropy, displayed by many mudrocks, may cause appreciable differential settlement which would necessitate the use of a strong reinforced concrete raft or provision for articulation in the structure.

In cemented mudrocks, settlements will usually occur immediately loads are imposed during construction, with insignificant post-construction settlement. However, consideration needs to be given to the possibility of weaker, more compressible layers being present within the ground below the structure. The impacts of discontinuities and weaker zones need to be assessed by undertaking loading or pressuremeter tests. If the magnitude and duration of long-term settlements are considered unacceptable, options such as pre-loading or deep foundations may be taken. It is also essential that the weathering grade is correctly assessed and taken into account in designs.

This includes estimation of the extent and effect of weathering, and the proportions of weathered and unweathered materials so that the foundation may be located at an appropriate level.

Where ground conditions are inappropriate for shallow foundations, piled foundations may be used. Bored piling allows more control over the installation process and causes less disturbance to the surrounding ground, although the presence of softened material at the base of the hole may result in low end-bearing resistance. On the other hand, driving piles can result in shattering of the ground and changes in groundwater conditions. This is particularly a problem with cemented mudrocks. A typical design of end-bearing piles would provide for a socket some 3–4 pile diameters deep to be formed in sound rock. Reassurance of sufficient load bearing capacity would be determined by carrying out representative pile load–settlement tests.

Due to the difficulties of taking and testing samples of mudrocks, end-bearing piles and deep foundation are often designed on the basis of the results of dynamic penetration, plate bearing and pressuremeter tests. Although the standard penetration test (SPT) is a useful means of identifying the variability of ground conditions, the parameters are not normally used for design purposes. However, in lower durability mudrocks, *in situ* plate bearing and cone penetrometer tests usually provide reliable data for design. In stronger mudrocks, penetrometer testing may be used to provide the required design parameters.

The end-bearing capacity of piles is usually based on the uniaxial compressive strength and discontinuity spacing, where the former is determined by laboratory index tests.

36.4.2 Ground volume changes

As noted above in section 36.2.4.3, the oxidation of pyrite produces sulfate-rich acidic pore waters. Neutralisation of the acid by reaction with calcite, concrete and clays results in the expansive precipitation of gypsum and other minerals. Precipitation usually occurs some distance away from areas of oxidation, particularly in areas of least stress such as bedding planes, joints or construction interfaces. Nixon (1978) describes structural damage to buildings in northeastern England. A number of cases in eastern Canada are described by Penner *et al*. (1970), and Hawkins and Pinches (1987) give details of a similar problem in Cardiff in South Wales.

Significant problems with the damage to houses in Ireland are apparently due to the expansion of pyrite-bearing fill placed beneath ground supported concrete floor slabs. Theoretical heave pressures are given in **Table 36.11**. Heave may be in excess of 100–150 mm, depending on the loading. Hoover and Lehmann (2009) calculate the potential heave based on the pyrite content of the ground, but the result is dependent on many assumptions.

In compaction mudrocks and overconsolidated clays, pyrite tends to occur as finely disseminated framboids which readily oxidise and produce randomly distributed gypsum crystals, as shown in **Figure 36.17(b)**. On the other hand, in cemented and indurated mudrocks (see **Figure 36.17(c)**), the gypsum will tend to grow as bladed crystals in a stratified manner along discontinuities such as bedding planes and joints, tending to push them apart.

Temperature °C	Concentration of solution c/c_s		
	2	4	10
5	29.2	58.5	97.1
10	29.7	59.7	98.7
20	30.8	61.8	102.2

Table 36.11 Theoretical pressures (MPa) due to the precipitation of gypsum
Data taken from Winkler and Singer (1972)

The crystallisation of selenite gypsum may occur at some distance from the site of oxidation due to solute transportation, resulting in a net translocation of sulfur from the original location. It is very difficult to specify a lower limit for the amount of pyrite acceptable in a fill. Experience in Canada (CTQ-M200, 2001) suggests that problems are unlikely to be encountered if less than 0.5% pyrite is present but that there is a high risk for values above 1%; whether higher amounts cause problems depends on the circumstances. Also, it is uncertain how differences in building construction and climatic conditions between Canada and the UK would influence this value.

Like BRE Special Digest 1 (2005), the maximum values specified by European Standard BS EN ISO13242:2002 + A1:2007 and NSAI document SR21:2004+A1:2007 are related to the chemistry of the ground adjacent to the concrete. In both documents, the total sulfur threshold is 1%, which is equivalent to 1.9% pyrite, but SR21 states that the total sulfur value should be less than 0.1% (0.2% pyrite). BRE Special Digest 1 (2005) recommends less than 0.8% sulfur (1.5% pyrite) for the ground adjacent to high quality concrete. For highway fills, TRL 447 (Reid *et al*., 2005) proposes limits of oxidisable sulfur of less than 0.3% sulfate (0.2% pyrite) and warns against the use of material in which pyrite is in the framboidal form. Hawkins and Pinches (1992) recommend caution as regards ground heave if equivalent pyrite as sulfate is above 0.5% (0.3% pyrite).

Whether a particular pyrite bearing mudrock will cause heave problems depends on many factors, including the nature of the pyrite, the presence of other minerals in the mudrock, the environmental conditions and the design of the structure. For example, in well engineered earthworks the presence of a relatively impermeable capping can limit the extent of pyrite oxidation, so reactions become self-limiting.

Figure 36.17(a) illustrates the breakdown of indurated mudrock (Edale Shale) and in **Figure 36.17(b)** the performance of less indurated Lias Clay is illustrated. Cripps and Edwards (1997) suggest that desiccation due to the removal of water and the action of acid on swelling clays can cause, shrinkage and breakdown of mudrocks.

36.4.3 Degradation of mudrock

The failure in 1984 of the Carsington Dam in Derbyshire, UK, during the latter stages of construction highlighted a number

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

of issues related to the presence of pyrite in the mudrocks used for constructing the embankment. Pyrite oxidation in the mudstone fill may have compromised the effectiveness of the limestone drainage layers contained within it. Pye and Miller (1990) and Anderson and Cripps (1993) suggest that an overly optimistic view had been taken of the shear strength parameters used in the design, especially in view of the rapidity with which the mudstone degraded during construction operations. Further consideration of the engineering problems due to rapid degradation of mudrocks is given in section 36.4.4.

Breakdown processes in mudrocks in colliery spoils were extensively investigated by Taylor (1984), and a summary of this research is given in Taylor (1988). He notes that, depending on the character of the rock (controlled by the presence of structural features), slaking occurs due to wetting and drying under atmospheric conditions, and the volume changes due to swelling clays, if present. Czerewko and Cripps (2001) provide guidance on the assessment of durability and the performance of a number of UK mudrock formations of different ages and states of induration.

Although the use of specific index properties has been found to be useful for predicting the behaviour of the mudrocks in particular situations, applying the classification schemes to other formations or different applications has proved less successful. For example, although Gamble's (1971) scheme – based on second-cycle slake durability and Atterberg limits of the fines – improved on previous classification schemes, it was found to be inappropriate by Olivier (1979) when applied to tunnelling projects in South Africa. Olivier's scheme was based on uniaxial compressive strength and uniaxial free-swell testing. However, Varley (1990) reported that excessive slurrying was not predicted by Olivier's scheme in tunnels in UK Carboniferous Coal Measures mudrock strata. Problems with the operation of tunnelling machines due to the breakdown of Mercia Mudstone in Leicester, UK, were attributed by Atkinson *et al*. (2003) to the presence of swelling clay minerals in the rock.

36.4.4 Excavations and slopes

Most types of mudrocks are relatively easy to excavate using earth excavation machinery. The methods of excavation are usually determined on the basis of the seismic velocity measurements or on an assessment of uniaxial compressive strength and fracture spacing.

The excavation of tunnels, shafts and other underground cavities requires assessment of the slaking properties of the mudrock. This is to allow determination of the stand-up time for the excavations and of the handling and disposal methods for the spoil. Low silt–high clay content compaction mudrocks may be sufficiently strong to remain stable during the excavation process, but may then undergo rapid deterioration before support from the lining is fully operable.

In excavations, mudrocks may undergo lateral displacement as a result of stored strain energy being released. Some low durability cemented or compaction mudrocks, especially those containing swelling clay minerals, undergo significant swelling when the overburden and lateral restraint is reduced, resulting in uplift and lateral displacements. Rigid support systems can become overloaded and on reloading, excessive settlement may occur. This process may be exacerbated by the presence of water and tends to be more rapid in overconsolidated clay deposits than in more durable cemented mudrocks. Heave effects may often be avoided by minimising the time of exposure, for example by immediately covering exposed mudrock with sprayed concrete. Although covering does not prevent uplift due to pyrite oxidation and gypsum precipitation, preventing water entry does reduce clay mineral swelling and slaking.

In sequences of rocks in which mudrocks are inter-bedded with more durable sandstones or limestones, more rapid erosion of the mudrocks may leave overlying more competent beds in an unsupported condition. Although common in surface exposures, this effect may also lead to instability in underground openings. Behaviour of this type may be predicted by examination of the material with associated laboratory testing to assess the relative erosion rates and strengths. The stability is highly dependent on the attitudes of the beds and the rock mass jointing. Solutions to problems of this type include measures such as removal and control bolting of potentially unstable blocks, sprayed concrete or masonry work. The latter methods protect the mudrocks from weathering and erosion as well as regulating run-off and groundwater. Eyre (1973) provides details of these and similar measures required to ensure stability of steep rock faces in sequences of cemented mudstones and limestones in southwest England.

Many slopes in mudrock formations in the south of England are mantled by considerable thicknesses of solifluction deposits that contain shear surfaces which mobilise residual strength. Relatively small increases in loading, the removal of support, or increases in pore water pressures, can lead to instability (see Symonds and Booth, 1971; Weeks, 1969). Some indurated mudrock formations in other parts of the country are also mantled by solifluction or 'head' colluvium deposits, which are liable to become unstable during engineering works.

36.4.5 Highway construction

In highway construction, problems with mudrocks containing pyrite can be reduced by leaving the weathered material in place for as long as possible, or by covering exposed ground with a layer of compacted clay or a geomembrane barrier. An alternative strategy is to expose the mudstone to weathering for a suitable period of time so that pyrite oxidation and the reaction products are generated before construction takes place. The first potential drawback of this procedure is the delay to the construction programme; the second is that the sulfate now present may participate in chemical attack and cause heave due to the dissolution and reprecipitation of sulfate minerals.

Compaction of mudrocks fills is best performed using a sheepsfoot roller, which thoroughly mixes the material and facilitates a more effective reduction of voids, whilst avoiding the

formation of smooth, potentially low-strength surfaces within a layered fill. However, the final proof rolling with a smooth roller will form a smooth, low-permeability surface, which will tend to shed water. Both hot and dry *and* wet weather can cause excessive break up and/or softening of the fill during construction, which may render the material unsuitable for use.

The weight of free-draining uniformly graded granular capping layers placed over freshly exposed pyritic mudrocks in cuttings can act as a surcharge which inhibits expansion. If expansion does occur, such layers can also act as a compressive layer, and thus reduce uplift. Such an interface has the further effect of forming a barrier to the capillary rise of sulfate-rich water that could otherwise cause chemical attack or heave problems. However it is important that a separator layer prevents migration of degraded mudrock into the granular fill.

Improvement in the workability and bearing characteristics of clay soils for road and building construction involves soil stabilisation with one of the following: (a) lime, slaked lime ($Ca(OH)_2$) and cement; (b) granulated ground blast furnace slag (GGBS) and cement; or (c) pulverised fuel ash (PFA) and cement. Such methods are cheaper and more sustainable than the use of rock aggregates Pozzolanic effects produce a cementitious product known as hydraulically bound material (HBM) or cement bound material (CBM). Documented cases in the UK of problems due to expansive sulfate minerals formation include the M40 near Banbury on Lias Clay and the A10 Wadesmill bypass in Hertfordshire (Ground Engineering, December 2004). Snedker and Temporal (1990) explain that in the case of the M40, heave of 150 mm occurred in a 250 mm thick stabilised layer over a few months. It would appear that the treatment of the ground when it is in a dry condition makes heave more likely to occur. Thus timing the treatment and allowing time for reactions to occur, for example over a winter, reduce the risk of problems with expansion. Road and foundation construction may be further proofed against heave problems by the provision of appropriate drainage to maintain the groundwater level and capillary fringe below the stabilised horizon. Well designed flexible drainage is also beneficial in the case of construction of earthworks involving the use of pyritic mudrocks.

Potential problems were detected on recent and ongoing highway earthwork construction projects involving Jurassic Ancholme Clay and Lower Lias Clay (Czerewko *et al.*, 2011) in the east midlands of England. Investigations provided data on the rates of pyrite oxidation and selenite formation in these pyritic, calcite bearing mudrocks. Prior to the use of the mudrock excavated on site for use as fill, it was subjected to a three-week period of exposure oxidation and selenite formation to occur, therefore mitigating post-construction heave.

36.4.6 Aggressive ground conditions

As explained in section 36.2.4.3, the weathering of pyrite gives rise to acidic solutions rich in sulfates that are detrimental to concrete, steel and other materials (see Czerewko and Cripps, 2006a; BRE Special Digest 1, 2005). For many decades it has been standard practice to determine the sulfate content and aggressive nature of soils and fills for the design of cement and concrete in buried structures, thus sulfate attack on buried concrete has been avoided. However, the discovery of serious deterioration of the concrete foundations of 30-year-old bridge structures on the M5 motorway in south-western England revealed serious deficiencies in the assessment methodology used at that time. It is possible that thaumasite sulfate attack on concrete is much more extensive than previously thought, but there has been a lack of reporting of cases of deterioration and, where it has been reported, thaumasite has not been correctly identified.

BRE Special Digest 1 (2005) provides comprehensive guidance on procedures to predict, prevent and mitigate against deterioration of concrete due to the presence of aggressive ground conditions. Various preventative and protective measures are possible including the modified mix designs, the use of bitumen coatings to concrete, and the addition of a capillary break to prevent contact with aggressive solutions.

36.5 Conclusions

As mudrocks occur extensively in the geological sequence and are geographically widely distributed, they are frequently encountered in engineering situations. Certain types are troublesome, in that it is difficult to predict their behaviour during construction and to determine reliable values of geotechnical parameters for design. It has been explained that mudrocks are the product of the burial and subsequent exhumation of muddy sediments which have undergone change due to these processes. The resulting materials are a function mainly of the composition and structure of the original sediment, the depth of burial and local geothermal gradient. It has been suggested that understanding the process of formation of these materials can help with predicting how they will perform in different engineering situations. It is convenient to consider mudrocks under the following headings:

- compaction mudrocks (overconsolidated clays);
- weakly cemented mudrocks;
- strongly cemented mudrocks.

Compaction mudrocks are weak and compressible materials. They will degrade rapidly at the ground surface and in most engineering situations they behave as soils. Most types contain swelling clays and they will therefore undergo volume changes in response to changes in moisture content. They may be anisotropic if clay rich and usually contain pyrite in its more reactive framboidal form.

Weakly cemented mudrocks are stronger and less compressible, ranging across the boundary from strong soils to weak rocks. They are difficult to characterise and in some situations will behave as rocks; in other situations, as soils. Due to stored strain energy, the removal of overburden, and the presence of a partly bonded structure and a skeletal framework, they undergo time-dependent degradation in response to weathering. Cyclical

changes in moisture content are liable to lead to slaking in which the rock degrades into sand- and gravel-sized fragments that are quite durable. Pyrite may be present in its framboidal form.

Strongly cemented mudrocks are stronger and less compressible. They are liable to range downwards into weak rocks, but in most engineering applications they will behave as rocks. Weathering action can result in them consisting of a mixture of weaker and stronger materials. Pyrite is liable to be in a more stable crystalline form although polyframboidal pyrite may be present.

Guidance has been given concerning the investigation, classification and description of mudrocks. The fact that many mudrock formations also contain pyrite gives rise to problems with the generation of chemically aggressive solutions and heave due to the precipitation that the reaction produces. Finally, a number of potential difficulties with engineering works involving mudrocks were presented.

It is recommended this chapter is read in conjunction with

- Chapter 7 *Geotechnical risks and their context for the whole project*
- Chapter 33 *Expansive soils*
- Chapter 40 *The ground as a hazard*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Glossary

The list below contains definitions for terms used in this chapter. Words presented in italics are themselves defined elsewhere in the list. Further definitions are given in *Dictionary of Earth Sciences*, edited by M. Allaby, Oxford University Press, 2008.

Air breakage	Process of *slaking* controlled by air pressures produced by the capillary water in the pore spaces of fine-grained, partly saturated rocks.
Anisotropy	Term describing the physical property which depends on the direction relative to a defined axis, such as *bedding* or *foliation*.
Argillaceous	Sediments or sedimentary rocks that are composed predominantly of *clay* and *silt*-sized material, comprising significant quantities of *clay minerals*.
Argillite	Compact, strong, fine-grained, *clay*-rich sedimentary rock which has been strongly *lithified* by deep burial or *low-grade metamorphism*, but lacking *lamination*, *fissility* or *cleavage* structures.
Authigenic	*Mineral* that has formed *in situ* in deposits during progressive *diagenesis*, resulting from changes in burial and temperature.
Burial diagenesis	*Diagenesis* that occurs due to burial of sediments beneath later sediments.
Cation	An atom (or group of atoms) which is deficient in one or more electrons to produce a net positive charge e.g. Al^{3+}.
Cation exchange capacity	The maximum quantity of *cations* that may be sorbed onto the surfaces of *mineral* particles at a given pH value.
Cement	Mineral material precipitated in the pore space and interparticle chemical bonds that hold grains together.
Cementation	Process by which the grains of geomaterials become attached together by the precipitation of mineral matter between the grains and the formation of interparticle chemical bonds.
Clast	A fragment of rock or *mineral* grain that has been derived by erosional processes from older rock.
Clastic	*Sediment* or *sedimentary* rock that is composed of (broken) fragments of other rocks and minerals derived by *weathering* and *erosional* processes.
Clay grade	An average grain size of less than 0.002 mm. Although clay grade material usually contains significant amounts of *clay* minerals, other material such as quartz, organic matter, sulfides and carbonates may also be present.

Clay mineral	A group of *minerals* of aluminosilicate composition and a phyllosilicate crystal structure similar to that of mica i.e. a sheet layer structure with strong inter- and intrasheet bonding, but weak interlayer bonding. Commonly occurring clay minerals include illite, kaolinite and smectite (montmorillonite).
Claystone	An *argillaceous* sedimentary rock of *clay* size particles (grade) mainly comprising *clay* minerals.
Colliery spoil	Waste rock material produced in the course of coal mining or coal processing. Usually contains a high proportion of mudrocks.
Compaction	In geology, the physical processes that convert loose unconsolidated sediment into a dense coherent rock, but without significant change in mineralogy. In geotechnics, the process of expelling air and moisture from a fill material by application of a dynamic load such as rolling or vibration.
Consolidation	In geotechnics, the reduction in porosity due to the application of a constant *pressure*.
Detrital	Rock or mineral grains derived from pre-existing parent rock by process of *weathering* and/or *erosion*, transported as detritus and deposited as sediments.
Diagenesis	The chemical, physical and biological changes due to burial of sediment, including *consolidation, cementation,* growth of *authigenic minerals* and increases in grain size. Excludes changes due to *weathering* or *metamorphism.*
Diffuse double layer	Part of the ion exchange process common in *clay* minerals caused when clay particles are suspended in water and interlayer *cations* on the surface of the clay particles go into solution, producing a negatively charged *clay* surface surrounded by a diffuse double layer of hydrated cations.
Elastic modulus	Amount of *stress* to produce a unit amount *strain*, where removal of the stress results in recovery to the original dimensions.
Fissility	The ability of a rock to be broken along closely spaced parallel planes, resembling the pages of a book.
Flocc	An aggregation of *clay* particles bound to each other by electrostatic attraction present in a neutral electrolyte fluid.
Flocculation	The process of aggregation of *clay* particles into larger groups, either through chemical or biological means.
Foliation	The planar arrangement of textural features or platy particles in a rock such as schistosity in *metamorphic* rocks.
Framboid	A microscopic spherical aggregate of pyrite grains in a form resembling a raspberry in *argillaceous* deposits
Induration	The natural process of hardening of sediments into rock by pressure, heat or *cementation*.
K_o value	Earth pressure at rest, which is the ratio between horizontal and vertical effective stresses in the ground.
Laminae	Distinct layers of sediment, often with different grain size or colour and typically less than 10 mm (an upper boundary of 20 mm is used in the engineering description of rocks and soils).
Liquid limit	Minimum *moisture content* for wet soil to behave as a liquid under specified conditions.
Low-grade metamorphism	Alteration by the action of heat and/or *pressure* of existing rocks, under conditions in which recrystallisation and new mineral growth in the solid state is just possible.
Lutaceous	A term used to describe a sedimentary rock formed from mud (clay and/or silt-sized particles).
Moisture content	Mass of water contained in a soil expressed as a percentage of the mass of dry solids.
Mudrocks	A rock formed by the *compaction* or *induration* of mud with a modal grain size in the mud grade (<0.063 mm). A generic group name for mudstone, siltstone and claystone, and *over-consolidated* clay.
Mudstone	A fine-grained sedimentary rock that is composed of *silt* and *clay*-sized particles.
Normally consolidated	A condition in which the present *overburden stress* being borne by a deposit is the maximum it has experienced since deposition.
Over-consolidated	A condition in which the *overburden stress* acting on a deposit has been greater in the past than it is at present; thus the deposit has been subject to a cycle or cycles of loading and unloading giving it greater density, *strength*, *durability* and lower compressibility compared to a similar normally *consolidated* deposit.
Periglacial	Climatic conditions experienced in the vicinity of retreating ice sheets or glaciers, entailing freeze–thaw action.
Petrology	The study of rocks through their mineralogy, geochemistry, textures, field relationships and their formation.
Phyllite	An argillaceous rock that has been altered by *low-grade metamorphism*; of coarser grain size and less perfectly cleaved than a slate, but finer grained and better cleaved than a schist.
Phyllosilicates	Sheet or layer silicate minerals composed of tetrahedral and octahedral sheets joined together to form 1:1 or 2:1 layers. In between the layers there may be interlayers of hydrated cations and water, which may compensate excess negative charges arising from the substitution of intra- and intersheet cations by other cations of lower valency.
Plastic limit	Minimum moisture content for soil to behave in a plastic manner – in which it is possible to mould the material by hand pressure and it will retain its shape.
Pressure	Force per unit area.
Schist	A type of 'medium grained' *metamorphic* rock characterised by a distinct crenulated particle alignment (foliation) known as schistosity.
Shale	A *fissile mudrock*. (As fissility is a feature that can develop in mudrocks as a consequence of weathering action, it is preferable to refer to such materials as fissile mudrocks.)
Shear strength	The minimum *shear stress* that causes a specimen to fail under conditions of zero *normal* stress. In a saturated clay, this is half the uniaxial compressive strength.
Siltstone	A fine-grained sedimentary rock consisting of particles of average size between 0.002 and 0.063 mm.
Slaking	A degradation process in geomaterials caused by alternate cycles of wetting and drying.
Solifluction	Process by which layers of soil move downslope due to freeze–thaw action under *periglacial* conditions.
Uniaxial/unconfined compressive strength	Compressive *pressure* to bring about failure of a specimen where loading is applied along only one axis and the specimen is an otherwise unconfined condition.
Weathering	A series of physical, chemical and biological processes by which a material undergoes degradation that brings it into equilibrium with its present environment.

Chapter 37
Sulfate/acid soils

J. Murray Reid TRL, Wokingham, UK

doi: 10.1680/moge.57074.0517

CONTENTS

37.1	Introduction and key background information	517
37.2	Sulfur compounds in soils and rocks	518
37.3	Sampling and testing for sulfur compounds	523
37.4	Specific problems and how to assess them	526
37.5	Conclusions	531
37.6	References	531

Sulfur is widespread in rocks and soils and occurs in two principal forms; in an oxidised state as sulfate, principally gypsum ($Ca.SO_4.2H_2O$); and in a reduced state as sulfide, principally pyrite (FeS_2). Other forms can occur in special circumstances. The oxidation of pyrite and other sulfides can occur as a result of geotechnical activities, when soils and rocks are disturbed and exposed to air and water. This can lead to the generation of high concentrations of sulfate and low pH in percolating rainwater, which can have a number of adverse consequences including attacks on construction materials such as concrete and steel, precipitation of gypsum leading to heave of foundations and floor slabs, and pollution of watercourses with precipitation of hydrous iron oxides (ochre). Pyrite oxidation can also be triggered by mixing susceptible materials with lime or cement; the resulting high pH values lead to formation of expansive sulfates (ettringite and thaumasite) that cause heave of the stabilised soils. Test methods are available but have to be used with care because of the variability of sulfur compounds. Geotechnical engineers have to recognise the types of material and situation that could lead to problems and how these can be avoided or mitigated.

37.1 Introduction and key background information

Chemical reactions within fill materials or between fill materials and structures often come as a surprise to geotechnical engineers in the UK. This may be because many of them have little or no background in geochemistry and assume that chemical reactions only happen in laboratories or under strictly controlled conditions in industrial processes. Soils and rocks are assumed to be inert; once excavated and compacted they will not change their properties, other than physical changes associated with changes in moisture content. Many of the soils and rocks in the UK are chemically inert, but a surprising number will undergo chemical changes when disturbed and most of these changes will have adverse consequences for the civil engineering works in which they occur. Chief among the causes of these problems are sulfur compounds.

Sulfur is the sixteenth most abundant element in the earth's crust, with an average concentration of 260 mg/kg (Krauskopf, 1967), greater than carbon (200 mg/kg), chlorine (130 mg/kg) and zinc (70 mg/kg). It is widespread in rocks and soils and occurs in two principal forms; in an oxidised state as sulfate, principally gypsum ($Ca.SO_4.2H_2O$); and in a reduced state as sulfide, principally pyrite (FeS_2). Other forms can occur in special circumstances, such as gaseous hydrogen sulfide (H_2S) in landfill sites, sewers and areas of active volcanicity. The problems that affect geotechnical engineering works are largely due to sulfate in solution and to changes from one sulfur compound to another. Excavation can allow air and water to reach pyrite and other sulfide minerals, leading to oxidation to sulfates and the generation of acidic conditions. This can result in attacks on concrete, steel and other construction materials, blocking of drains and filters and pollution of watercourses. Treatment of soils with high concentrations of sulfates and sulfides with lime or cement can lead to the formation of complex expansive sulfate minerals that cause heave, with resulting disruption to overlying layers of asphalt or concrete. Heave of soils below floor slabs can also occur in untreated soils due to the inflow of sulfate-rich groundwater, leading to precipitation of gypsum in the fill.

A feature common to many of the problems listed above is that they do not occur immediately but some time – ranging from months to years – after construction. They can, thus, be very expensive to remediate, as the overlying structures may be disrupted to such an extent that they are no longer functional and have to be removed or significantly modified. It is, thus, important for geotechnical engineers to be able to recognise potentially susceptible materials and inappropriate treatments or construction methods and either avoid them or take mitigating measures. It is possible to achieve satisfactory engineering solutions in a number of situations provided the potential problems are foreseen and appropriate measures adopted. Problems mainly occur where they are not foreseen. This chapter will describe the potential situations where problems can arise, how to predict them and, where possible, how to provide engineering solutions.

The examples of problems due to sulfur compounds in soils primarily relate to damage to engineering structures and pollution of the environment. These are serious enough, but sulfur compounds can also lead to death, though thankfully very rarely. Poisoning by hydrogen sulfide can occur in enclosed spaces; this rarely happens other than in contaminated land, sewers or landfill sites, which are not the main focus of this chapter. However, potentially fatal situations can also arise in civil engineering works. **Figure 37.1** shows the memorial to four workmen who were killed due to carbon dioxide (CO_2) poisoning in a manhole during the construction of Carsington

Figure 37.1 Memorial to workmen killed by CO_2 poisoning, Carsington Dam, Derbyshire

Dam, Derbyshire, in 1982. The dam was being constructed of local highly weathered mudstone fill, with drainage blankets of limestone to help dissipate the pore pressure during construction. The fill was acidic with high levels of sulfate; this attacked the limestone, precipitating gypsum in the drainage blankets and generating carbon dioxide, which travelled down the drainage system to the manhole where the workmen entered. The behaviour of sulfur compounds is, thus, more than just an academic or engineering issue; it can be a matter of life and death, and something that geotechnical engineers need to be aware of.

37.2 Sulfur compounds in soils and rocks

37.2.1 Sulfur minerals

One of the confusing things about sulfur is that it can occur in a variety of forms and can change from one to another under certain conditions. The most common sulfur minerals are listed in **Table 37.1**. The principal form of sulfur in natural soils and rocks is in the reduced form, as sulfide. Pyrite (FeS_2) is the most common sulfide mineral and is a common minor constituent of many igneous, metamorphic and sedimentary rocks and the soils derived from them. Many mineral ores are sulfides, including galena (PbS) and sphalerite (ZnS). Sulfide minerals generally have very low solubility and are not in themselves a hazard to construction materials. However, weathering of sulfides under oxidising conditions gives rise to sulfates (SO_4^{2-}), which are soluble and can attack construction materials. Under natural conditions, weathering of sulfides normally leads to production of gypsum ($CaSO_4.2H_2O$), which has limited solubility under neutral pH conditions. This is the normal form of sulfate in near surface soils.

Sulfates also occur naturally in evaporate sequences as gypsum, anhydrite ($CaSO_4$), barytes ($BaSO_4$), epsomite ($MgSO_4.7H_2O$) and other salts. Barytes is extremely insoluble, but anhydrite, epsomite and other salts are highly soluble; as a result, in the UK they have generally been leached out of the near surface zone where most civil engineering works are carried out, and are only likely to be encountered in shafts and tunnels at depth. They can cause serious problems to civil engineering works in these situations, due to corrosion (they are often associated with chlorides and other salts) and swelling when exposed to water. These situations will not be considered further in this chapter.

Mineral	Formula	Description
Anhydrite	$CaSO_4$	Found in evaporite strata at depth; white crystals, highly soluble
Barytes	$BaSO_4$	Common minor constituent in wide range of rocks; white crystals, dense, very insoluble
Celestine	$SrSO_4$	Rare mineral, occasionally found in evaporite deposits
Epsomite	$MgSO_4.7H_2O$	Common in evaporite sequences; highly soluble, only found at depth
Gypsum	$CaSO_4.2H_2O$	Widespread occurrence in soils and rocks; white crystals and powder; slightly soluble at neutral pH, soluble in acid
Jarosite	$KFe_3(OH)_6(SO_4)_2$	Weathering product of pyrite often found in mudrocks, usually as a yellow-green powder
Marcasite	FeS_2	Found as nodules in chalk and limestone; different crystal structure to pyrite
Mirabilite (Glauber's salt)	$NaSO_4.10H_2O$	Found in evaporite strata at depth; highly soluble
Pyrite	FeS_2	The most common form of sulfur in soils and rocks, ranges from large yellow cubes to fine-grained crystals invisible to the naked eye; insoluble but oxidisable
Pyrrhotite	FeS	Occasionally found in soils and rocks; different crystal structure to pyrite
Organic sulfur		Common in peat and organic soils

Table 37.1 Sulfur minerals found in UK soils and rocks

Pyrite is immediately recognisable when present in large crystals as 'fool's gold'. It is bright brassy yellow, heavy (specific gravity 4.9), often occurring as cubes and octahedra. However, it can also be present in very fine-grained forms that are invisible to the naked eye; these forms are much more damaging because the crystals will react much more rapidly when exposed to air and water than the large visible crystals. Gypsum can occur in a wide variety of forms, from large clear crystals in undisturbed strata to fine white powdery crystals growing on exposed surfaces of reactive clays or mudstones. **Figure 37.2** shows white crystals of gypsum left behind when a pool of rainwater evaporated in a cutting in the Ancholme

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Clay, a Jurassic mudstone rich in sulfides and sulfates. Such fine white powders often form on the surface of fill materials that have a high sulfate or sulfide content, and are a sure sign of trouble. They are often accompanied by orange brown deposits of hydrous iron oxides (ochre), which are another product of pyrite oxidation (Equation (37.1)). These deposits can block drains and blanket the beds of watercourses, leading to the death of all aquatic life. It is important for geotechnical engineers to be able to recognise telltale signs such as precipitates of gypsum and ochre on fill surfaces, in seepages or pools at the toe of an embankment; they are better indicators of trouble than any number of chemical test results.

37.2.2 Weathering of pyrite

37.2.2.1 Weathering reactions: what happens?

The main weathering reaction under natural conditions is the oxidation of pyrite and other sulfide species to sulfates. This occurs slowly under normal conditions of soil formation. The top 2–3 m of natural strata in the UK often contain very low concentrations of sulfates and sulfides, as they have been leached out by rainfall. At the base of this zone there may be accumulations of sulfates, which may cause a hazard for foundations. At greater depths, sulfide is the dominant form except in evaporite sequences. This transition from sulfate to sulfide corresponds to the depth of surface weathering, often with black or dark grey colours at depth and yellow, brown or mottled colours in the weathered zone. Profiles like this are particularly common in overconsolidated clays and mudstones, which are widespread in the UK (see Chapter 36 *Mudrocks, clays and pyrite*).

Accelerated weathering can occur as a result of civil engineering works, particularly when materials are excavated and placed as fill with percolating rainwater and air; free-draining embankment fill is one of the most oxidising environments in nature. In these situations acidic conditions can develop, leading to greatly increased solubility of sulfate and metals and potential attack on construction materials. Oxidation of sulfides can also be greatly accelerated by microbiological activity. Initially, the iron is oxidised to the ferrous state (Fe^{2+}) and remains in solution. When the percolating water leaves the embankment and is exposed to the atmosphere, however, the iron is oxidised to the ferric state (Fe^{3+}) and precipitates as hydrous iron hydroxide, usually as an amorphous orange sludge. The main chemical reactions in the oxidation of pyrite are summarised below. While the details of the reactions can be complex and dependent on the specific situation, the overall result is the conversion of pyrite to iron hydroxides (ochre) with the production of sulphuric acid and generation of pH values as low as 2 or 3.

$$4FeS_2 + 15O_2 + 14H_2O \rightarrow 4Fe(OH)_3 + 8H_2SO_4. \quad (37.1)$$

If carbonate minerals such as calcite are present, the acid will react with them to produce gypsum and carbon dioxide.

$$CaCO_3 + H_2SO_4 + H_2O \rightarrow CaSO_4.2H_2O + CO_2. \quad (37.2)$$

The precipitation of gypsum involves a large increase in volume and can lead to heave of the strata involved; Bell (1983) quotes an eightfold increase in volume, exerting pressures of up to about 0.5 MPa. This is a major cause of problems with sulfur compounds. If carbonate minerals are not present, the acid may attack clay minerals producing minerals such as jarosite (**Table 37.1**). The drainage water from areas of pyrite oxidation can be highly acidic, with pH values in the range 2 to 4, and very high concentrations of dissolved sulfate and metals such as iron, manganese and aluminium. When these waters encounter the atmosphere, the iron is rapidly oxidised and precipitates as ochre, causing pollution of watercourses and blockage of drains (**Figure 37.3**).

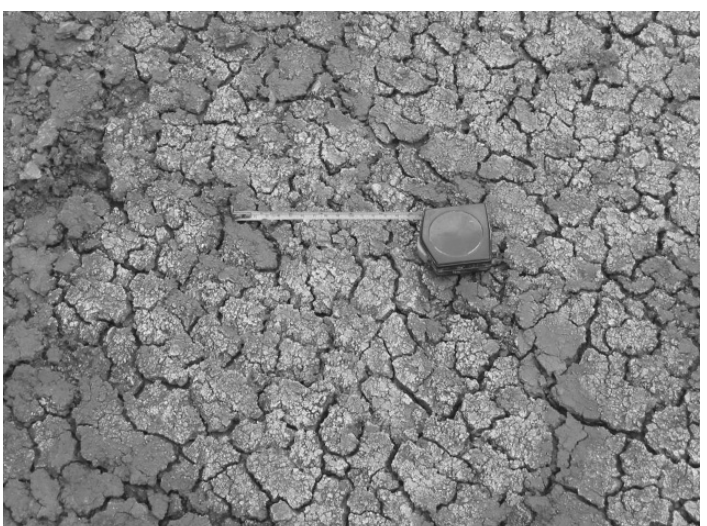

Figure 37.2 Precipitate of gypsum on surface of Ancholme Clay

Figure 37.3 Drainage outflow from mudstone embankment dam showing precipitation of ochre

37.2.2.2 Rate of reactions: how quickly will it happen?

A key factor in whether pyrite or other sulfides will cause problems in civil engineering works is the rate at which it will be oxidised to sulfates in any given situation. This depends on a number of variables:

- mineral grain size;
- form of mineral present;
- access to air and water;
- microbiological activity;
- total amount of sulfide present.

Mineral grain size

One of the most important influences on the rate of reaction of any mineral is the grain size. Reactivity is related to the specific surface area of individual particles, which is related to the inverse square of the grain size (surface area of a sphere $A = 4\pi r^2$). Large crystals visible to the naked eye will, thus, be much slower to react than very fine-grained crystals at a scale of a few microns. This leads to the paradox that pyrite is generally dangerous only if you cannot see it; it might be dubbed 'the invisible menace'. In any garden centre, ornamental lumps of granite and slate with abundant visible pyrite can be purchased for use in rockeries, with no fear that the pyrite will undergo any reactions (**Figure 37.4**). However, microscopic clusters of pyrite crystals known as 'framboids' are particularly reactive. These can be identified by electron microscopy (**Figure 37.5**), but this is not a tool available for routine investigation and assessment.

Figure 37.4 Coarse-grained granite with visible pyrite

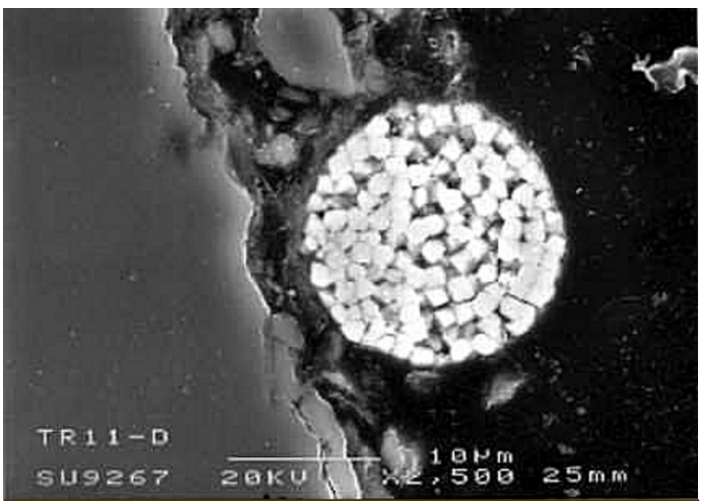

Figure 37.5 Framboidal pyrite from alluvial sand

Form of mineral

The reactivity of sulfides is also linked to the form or degree of crystallinity of the minerals. In general, the older the mineral, the more likely it is to have been recrystallised at higher temperatures and pressures, and the slower it is likely to be to react under atmospheric or in-ground conditions at the present day. This may explain why sulfides in granites and slates tend to be less reactive than those in mudstones and overconsolidated clays. The particularly high reactivity of framboids may be because in some cases they have formed very recently in alluvial strata such as sands and silts. However, where strata have been subject to weathering before being disturbed for civil engineering works, they are likely to be more reactive than fresh strata, regardless of their age. Thus, even older rocks that have been highly weathered may be susceptible to oxidation when exposed in engineering works. This aspect is harder to quantify than grain size, but it is important to bear in mind when assessing how likely a particular material will be to undergo sulfide oxidation reactions.

Particular problems may arise if certain iron sulfide minerals are present; these are found principally in recent alluvial or estuarine sediments, where they form in reducing conditions owing to the decay of organic matter. They generally only occur in very specific situations, in particular in backfill to sheet piles in marine works just below mean water level (Tiller, 1997). These compounds are particularly corrosive and cause major problems for steel sheet piles, but they do not occur in the majority of soils and rocks.

Access to air and water

Both air and water, in sufficient quantities, are required for sulfide oxidation (Equation (37.1)). However, unless the products of reaction are removed and a fresh supply of air and water provided, equilibrium will soon be reached and no further reaction will occur. If the strata are below the water table, very little reaction will occur because the supply of air is limited, although there may be an abundant flow of water. Above the water table a steady percolation of water and air

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

through the strata is required to drive the reactions, removing the products through drainage and causing problems elsewhere. Embankments present a suitable environment for ongoing oxidation reactions. At Roadford Dam, Devon, the weak mudstone fill was found to contain pyrite during the site investigation phase, and measures were put in place to monitor the extent of this during construction and operation (Davies and Reid, 1997). Observations over a period of 20 years show that pyrite oxidation reactions are continuing to occur at much the same rate as during construction, despite the fill being covered by an asphaltic upstream membrane, an asphalt road on the crest, and topsoil and vegetation on the downstream shoulder (Hopkins *et al*., 2010). The rate at which reaction products are leached is controlled primarily by rainfall and the reservoir level. Similarly, use of colliery spoil to top up canal embankments subject to mining subsidence can lead to poor quality of seepage water due to oxidation of pyrite in the spoil (Perry *et al*., 2003).

Microbiological activity

The oxidation of pyrite occurs in a number of stages, which are discussed by numerous authors including Reid *et al*. (2005) and Chapter 36 *Mudrocks, clays and pyrite*. Many of these stages are catalysed by bacteria, which enable the reactions to proceed more rapidly than might be expected from considerations of chemical equilibrium alone. Different bacteria can feed off the oxidation and reduction of sulfur and iron, obtaining energy and nutrients from the reactions. They can exist and even thrive in the most extreme environments, including the very acidic conditions generated by oxidation of sulfides. So if a reaction is likely to occur, it should be assumed that microbiological activity will assist the process.

Total amount of sulfide present

It might be expected that the total quantity of sulfide would be the main factor in determining the extent of the reaction. In fact, as illustrated by the factors in the preceding sections, it is relatively unimportant; grain size, form of mineral and exposure to air and water are more important in determining the extent of reaction. Thus, some materials can have quite high contents of sulfides in the form of large crystals and cause no problems for engineering works, whereas other materials with small quantities of highly active sulfides can cause very significant problems. Sulfide concentrations have to be almost at the limit of detection before it can be certain that they will not cause problems. This causes difficulties for geotechnical engineers, as simple reference to sets of limiting values may give a conservative view of the likelihood of sulfide oxidation and its potential consequences. Moreover, while the total sulfur content of soils and rocks can be determined relatively reliably and cheaply, determination of the total sulfide content is more difficult. Even if this can be determined, an assessment then has to be made as to whether the sulfide is likely to oxidise and, if so, at what rate and what effect this will have on the works or the environment.

This is illustrated in **Table 37.2**, which summarises the rate of reaction from four sites in the UK that have experienced problems due to sulfur compounds. There is no relation between the sulfur content and the rate of reaction or the extent of the damage. The most severe damage occurred in the material with the lowest sulfur content, the alluvial sand and gravel, though this was also the application most sensitive to sulfate and acid attack. For the two embankment dams, the higher rate of reaction at Roadford is due to the greater permeability of the fill material compared to Carsington, which allowed greater percolation of air and water and more rapid reaction despite a significantly lower total sulfur content. The effects of the reactions were more severe at Carsington, however. Where large volumes of fill are concerned, even a small proportion of active material can have significant effects. For the case study of the M5 bridges (Thaumasite Expert Group, 1999), the quantities are much smaller but the extent of reaction appears to have been much greater due to the specific circumstances, which encouraged the thaumasite form of sulfate attack: disturbance

Construction type	Material	Total sulfur (% S)	Rate of oxidation	Effects of reaction
Roadford Dam	Carboniferous mudstone	0.6	0.15% over 1 year	No effects on fill detected; drainage outflow still requires treatment after 20 years because of high metal and suspended sediment content
Carsington Dam	Carboniferous mudstone	3.2	0.005% over 4 years	Attack on concrete and drainage blankets in original dam. Measures taken to mitigate damage in reconstructed dam. Drainage outflow requires treatment
A564 Hatton – Hilton – Foston	Alluvial sand and gravel	0.3	90% over 4 years	Rapid severe corrosion of galvanised corrugated steel buried culverts, which had to be replaced; fill removed and replaced with inert material
Backfill to bridge foundations on M5, Gloucestershire	Lias Clay	1.6	15% to 50% over 25 years	Attack on concrete to a depth of up to 40 mm (thaumasite form of sulfate attack)

Table 37.2 Rate of pyrite oxidation from UK sites
Data taken from Reid *et al*. (2005)

of the fill allowed oxidation of pyrite to start; cool, damp conditions; mobile groundwater; and the presence of carbonate aggregate in the concrete. Only by taking all the circumstances of each case into account and being aware of the likely geochemical behaviour of the materials can predictions be made of the likely results. Having done this, however, it may be possible to avoid or mitigate them.

37.2.3 Occurrence of sulfur compounds

Sulfides, particularly pyrite, are common as minor constituents in igneous, metamorphic and sedimentary rocks and in the sediments and soils derived from them. Lists of geological formations in the UK known to contain pyrite in sufficient quantities to cause problems are given in BRE Special Digest 1 (Building Research Establishment, 2005) and HA Advice Note 74 (Highways Agency *et al*., 2007). Some of the materials that are particularly likely to cause problems are discussed below; however, it is important that every situation is evaluated on its merits and not by reference to lists of 'usual suspects'.

37.2.3.1 Mudstones and clays

Mudstones and overconsolidated clays are particularly likely to contain significant concentrations of pyrite in fresh strata and a mixture of pyrite and gypsum in weathered strata. The top 1 to 2 m of natural ground may be low in both sulfates and sulfides as a result of leaching by rainfall, but for several metres below this the concentrations of sulfate and sulfide can be highly variable horizontally and vertically. Potential problems due to sulfates and sulfides should always be considered when engineering works in these strata are proposed. Among the key strata in this group are:

- mudstones of Carboniferous and more recent age;
- Mercia Mudstone (Keuper marl – sulfates only, not sulfides);
- Lower Lias Clay;
- Kimmeridge Clay (the Ancholme Clay in **Figure 37.2** is a lateral equivalent of the Kimmeridge Clay);
- Oxford Clay;
- Weald Clay;
- Gault Clay;
- London Clay;
- glacial till or other drift deposits derived from any of the above.

These strata are also likely to pose other problems for engineering works, including seasonal shrink-swell behaviour, low long-term shear strength in slopes and excavations and the presence of organic matter. These aspects are discussed by Cripps and Czerewko in Chapter 36 *Mudrocks, clays and pyrite*.

37.2.3.2 Alluvial strata

Active sulfates and sulfides are not restricted to fine-grained soils and rocks; a number of cases have been reported of problems due to sulfur compounds in alluvial sands and gravels. In these cases the sulfide is often in framboidal form and, hence, highly active (**Figure 37.5**). The framboidal pyrite is probably secondary in nature, derived from primary pyrite in the heavy mineral assemblage of the sediments. As these strata often have little or no carbonate content, highly acidic conditions can develop if they are excavated and used as fill, even if the sulfide and sulfate content is quite low. An example of this is given by Reid *et al*. (2005), where alluvial sands and gravels were used as backfill to galvanised corrugated steel buried culverts; this led to rapid corrosion of the steel and the culverts had to be replaced before the road was opened to traffic. Similar examples of problems in granular soils are reported by Sandover and Norbury (1993).

Organic soils, including peat, can also contain a significant sulfur content. These soils are also often acidic, owing to humic acid from decaying organic matter, but this will not produce pH values below about 3.5, whereas sulfuric acid can lower them to as low as 2 (Building Research Establishment, 2005).

37.2.3.3 Colliery spoil and related materials

Colliery spoil consists of strata excavated in the course of mining for coal. It includes strata immediately above and below the coal seams, fragments of the coal seams and strata from the driving of roadways and shafts to access the seams. For a large colliery working a number of seams it can, thus, be highly variable in composition. The dominant material tends to be mudstone and this can often contain significant amounts of sulfides, particularly in marine mudstones, which often form the roof of coal seams. The spoil will also contain significant amounts of coal, which also tends to have a high sulfide content. Modern collieries extract coal from considerable depths, so the spoil may contain high concentrations of chloride from the seawater in which the mudstones were laid down. The carbonate content can be highly variable, with significant concentrations of calcite in some marine mudstones. The mudstones and sandstones immediately below the coal seams generally have a low calcite content. Fresh colliery spoil generally has a pH in the range 7.5 to 8.5, but on exposure to the atmosphere, oxidation of the sulfides can occur and the pH can drop to values as low as 2 or 3.

The potentially corrosive properties of colliery spoil have long been recognised (West and O'Reilly, 1986) and it is not permitted as backfill to concrete and structural metallic elements by the UK Specification for Highway Works (Highways Agency *et al*., 2009a).

Colliery spoil that has been placed loosely in tips has often suffered ignition, resulting in combustion of the coal particles and changes to the chemical and physical properties of the material. Most noticeable is a change in colour from dark grey to red, accompanied by an increase in the particle strength, so that well-burnt colliery spoil is a more versatile and useful fill material than unburnt material, and is permitted in a wider range of applications by the Specification for Highway Works

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(Highways Agency *et al.*, 2009a). Most sulfide is oxidised to sulfate during the combustion process. Spent oil shale is similar in many ways to burnt colliery spoil; it is the residue from the extraction of oil from oil shale of Carboniferous age in the Lothian area of central Scotland. The shales were heated in retorts to drive off the oil, leaving a red material with variable quantities of sulfate but generally low sulfide content. Both burnt colliery spoil and spent oil shale are known colloquially as 'blaes' in Scotland.

37.3 Sampling and testing for sulfur compounds

In order to assess their potential impact on civil engineering works, it is necessary to quantify the amount of different sulfur compounds present in a material. This first requires the taking of representative samples and their storage in a way that preserves the compounds in the form that they were in when the sample was taken.

37.3.1 Sampling and storage

Generally it will be necessary to sample both the soil strata and groundwater for sulfur compounds during the site investigation. Samples of groundwater are particularly valuable, as this is the medium in which sulfur compounds can cause most damage to materials or the environment. It is important that water samples for chemical testing, whether obtained from boreholes, trial pits, seepages or watercourses, are taken in accordance with best practice guidelines and preserved so that the chemical composition does not change before analysis in the laboratory. It is also useful to determine basic parameters of the sample at the time of sampling, in particular temperature, pH value, conductivity and redox potential/dissolved O_2. These will aid interpretation of the results later and give a good general indication of the chemistry of the water and whether it is likely to be of concern.

Soil samples for chemical testing should also be taken and stored in accordance with best practice. This is particularly important given the propensity of sulfur compounds to change from one form to another when removed from the ground. Trials by Reid *et al.* (2005) found that significant changes can occur if samples are stored inappropriately. They recommended that samples be placed in airtight containers, stored at 0–4ºC and analysed as soon as possible. These protocols should be observed for samples taken during site investigations and also for samples taken during construction works as a check on the composition of materials being used in the works; samples left lying around a site laboratory or a storage container in plastic bags at ambient temperatures for months before analysis are unlikely to accurately represent conditions in the ground.

Ground investigation and testing in the UK is now covered by BS EN 1997–2:2007 and the corresponding National Annex, NA to BS EN 1997–2:2009. These documents state that chemical testing of soils should continue to be carried out in accordance with BS 1377–3 with the exception of pH value determination (acidity and alkalinity), where Annex N.5 of BS EN 1997–2 may be used. Further information on how to use the various tests in BS 1377–3 is given in NA3.15 of the National Annex.

37.3.2 Water-soluble sulfate (WS)

The most common, and useful, test is the sulfate content of water samples or the water-soluble sulfate content of soil or rock samples. This is the form of sulfate that attacks construction materials and instigates other chemical reactions in fill materials and waters; it, thus, represents the immediate danger posed by the material or water. For soil or rock samples, the sulfate is brought into solution with a 2:1 extraction in distilled water for 24 hours, after which the solution is filtered and the sulfate concentration determined. Traditionally, the sulfate content has been determined gravimetrically by adding barium chloride in acid solution to precipitate barium sulfate. This is still the reference method in the British Standard test methods for soils (BS1377–3) and aggregates (BS EN 1744–1). However, most commercial laboratories prefer to use rapid automated methods such as inductively coupled plasma – optical emission spectroscopy (ICP-OES) to determine the amount of sulfate directly in solution, and this method is described in TRL447 Test 1 (Reid *et al.*, 2005). For water samples, the amount of sulfate can be determined directly from the sample, though filtering may be necessary if it contains suspended solids.

The results should be expressed as mg/l SO_4, as this is the form used by most guidance documents when setting limiting values for specific applications and is the form recommended by TRL447. However, various formats are used by different standards. BS 1377–3 recommends reporting the water-soluble sulfate as g/l SO_3 or as % SO_3 (soil samples only). The BS EN 1744–1 test results are also reported as % SO_3. Sulfate occurs as SO_4, so this is the most useful way to express the results; SO_3 concentrations can be converted to SO_4 by multiplying by 1.2, and % SO_3 can be converted to g/l SO_3 by multiplying by 5 because the extraction ratio is fixed at 2:1. For all tests involving sulfur compounds, it is important to be clear about which units are being used when results and test methods are quoted.

When determining the water-soluble sulfate content of a soil or rock sample, it is useful to measure the pH value of the 2:1 water extract at the same time; this is recommended in TRL447 Test 1. The pH value of a soil may be determined in accordance with BS1377–3, but there is no test method for the pH value of aggregates, so it is important to measure it during the water-soluble sulfate test. The pH value may be determined in accordance with Annex N.5 of BS EN 1977–3, but this merely states that the electrochemical method (i.e. BS 1377–3 method) is the preferred method.

The water-soluble sulfate content is assigned the symbol WS in guidance documents such as TRL447 and BRE Special Digest 1. The water-soluble sulfate test will extract readily

soluble sulfates such as epsomite and mirabilite. Gypsum is sparingly soluble in water at neutral pH, so if this is the only salt present WS will not exceed about 1500 mg/l SO_4. If the pH is acidic, however, much higher values of WS can be obtained even if gypsum is the only sulfate present. Determination of the pH value, thus, helps to interpret the WS value and assess the threat posed by the material or water.

37.3.3 Acid-soluble sulfate (AS)

While the WS test determines the soluble sulfate content of a soil or rock in contact with distilled water, the total sulfate content may be significantly higher than this if the sulfate is in the form of sparingly soluble minerals such as gypsum. However, if the material was in contact with acidic water, the soluble sulfate content could rise considerably and this could pose a hazard to civil engineering works and the environment. It is, therefore, useful to determine the acid-soluble sulfate content. Test methods for this are given in TRL447 (Test 2), BS1377–3 and BS EN 1744–1. The tests involve grinding a sample to pass through a 2 mm sieve and extracting it with an excess of 10% hydrochloric acid to dissolve all the sulfate present. The sulfate content is determined from the extract gravimetrically by precipitation of barium sulfate (BS 1377–3 and BS EN 1744–1) or instrumentally by ICP-OES or similar methods (TRL447). The BS 1377–3 and BS EN 1744–1 test results are reported as % SO_3. The TRL447 Test 2 results are reported as % SO_4. The SO_3 values can be converted to SO_4 by multiplying by 1.2. Sulfate occurs as SO_4, so this is the preferred term for test results. As with the WS test, when instructing tests and assessing the results it is important to be clear what test methods are to be used and how the results are to be reported.

The acid-soluble sulfate content is assigned the symbol AS in guidance documents such as TRL447 and BRE Special Digest 1. It is used directly as a limiting value for some applications for fill materials, but can also be used in combination with the total sulfur content to provide an indirect estimate of the sulfide content. The AS content will include all potentially reactive sulfate minerals, but unreactive sulfates such as barytes are not mobilised by the extraction.

37.3.4 Total sulfur (TS)

The total sulfur content of a soil or rock will include the sulfur present as sulfate, sulfide and other forms of sulfur. These other forms include organic sulfur, which can be present in mudstones, overconsolidated clays and alluvial strata and sulfur present as inert minerals such as barytes, which occur as minor constituents in many limestones, sandstones and other rocks. Other forms of inert sulfur compounds are found in recycled concrete aggregate; many of the additives added to concrete mixtures contain organic sulfur compounds, and gypsum is often added to cement at up to 3% by weight to retard setting.

Two methods for determining total sulfur are given in TRL447 (Test 4 Procedures A and B); procedure A involves microwave digestion to bring the sample into solution followed by determination of the sulfur content by ICP-OES; procedure B involves direct determination of the total sulfur content by rapid high-temperature combustion (HTC) analysis. The results are reported as % S. In practice, the HTC method is more widely used as it is much quicker and cheaper. A chemical method for finding the total sulfur content is given in BS EN 1744–1; in this method, sulfides are converted to sulfates by treatment with hydrochloric acid and hydrogen peroxide, which is a powerful oxidising agent, and the sulphate content is determined gravimetrically as before. The results are given as % S.

The total sulfur content is assigned the symbol TS in guidance documents such as TRL447 and BRE Special Digest 1. It is rarely used directly as a limiting value, but is used to calculate two parameters that are used as limiting values:

- The total potential sulfate content (TPS) is the total amount of sulfate that could be generated if all the sulfur compounds in the sample were converted to sulfate. It, thus, gives a worst-case figure for the sulfate threat from a particular material. It is calculated as:
  - TPS (% SO_4) = 3 × TS (% S).
- The oxidisable sulfides content (OS) is the sulfate that could be produced if all the sulfur present as sulfides in the sample is oxidised to sulfates. It is, thus, lower than the TPS and is usually calculated indirectly from TS and AS as:
  - OS (% SO_4) = [3 × TS (% S)] – AS (% SO_4).

These three tests – WS, AS and TS – are the main ones that are routinely performed on soils and rocks. They have the advantage of being relatively rapid and cheap, thus allowing a large number of samples to be tested without incurring excessive cost or delay. This is important as sulfur compounds can be highly variable in soils and rocks, so it is necessary to carry out a number of tests to establish the range of concentrations that is present. Both TRL447 and BRE Special Digest 1 recommend that at least five samples should be tested for any material proposed for use as backfill to structures, with the mean of the highest two values used for comparison with limiting values.

37.3.5 Total reduced sulfur and monosulfides

The content of reduced sulfur compounds can be estimated from the difference between TS and AS (see section 37.3.4); however this figure will also include other inert forms of sulfur such as organic sulfur or barytes, and will, hence, be an overestimate of the sulfide content. It will also be of limited accuracy, particularly at low values, as there will be error margins associated with the measurement of both TS and AS. A direct test for the reduced sulfur content would improve the accuracy of the estimates. A number of methods were investigated by Reid *et al.* (2005), and chemical methods were developed for the total reduced sulfur content (TRS) (TRL447 Test 3) and the monosulfide content (MS) (TRL447 Test 5). However, these are specialist chemical tests that should only be carried out by skilled personnel; unlike the tests for WS, AS and TS they

are not automated and are liable to be expensive. They may be useful in specific situations to identify the nature of sulfur compounds present in a material in more detail. The results are reported as % S. A similar test to the TRS test is given in BS EN 1744–1 for acid-soluble sulfides.

Oxidisable sulfides (OS) can be determined directly from TRS as:

$$\text{OS } (\%\ SO_4) = 3 \times \text{TRS } (\%\ S).$$

37.3.6 Other tests

Techniques such as X-ray diffraction (XRD) can be used to test for the presence of pyrite, gypsum and other minerals on a qualitative basis in soils and rocks. This technique also gives information about other minerals in the material, such as carbonates and clay minerals. X-ray fluoresence (XRF) analysis of soils or rocks can give the overall chemical composition, including an estimate of the total sulfur content, but is less accurate than direct chemical determination. Scanning electron microscopy (SEM) can be used to investigate the crystal form and grain size of fine-grained sulfur compounds, as in **Figure 37.5**. This can be very helpful in understanding how reactive the compounds may be in a particular situation; however, the technique is expensive and not suitable for routine testing purposes.

37.3.7 Reactive sulfides

The oxidation of sulfides to sulfates in fill materials can be a major source of problems in civil engineering works; however, the extent to which this will occur in any given situation is hard to estimate. Results from four sites are given in **Table 37.2** and show a very wide range of oxidation rates. Where large volumes of fill are involved, however, even a small amount of sulfide oxidation can have serious consequences, particularly where critical structural elements such as metallic reinforcement or anchors are concerned. Limiting values for sulfides are usually based on the OS value, on the assumption that all the sulfides in the material will oxidise to sulfate. This will be a conservative assumption in most cases (**Table 37.2**), particularly where pyrite is present in a coarse-grained crystalline form where it will be very slow to react. The difficulties of measuring the sulfide content accurately have already been referred to in sections 37.3.4 and 37.3.5, adding to the difficulties in setting realistic limiting values for this parameter. It would be useful to have a test method for reactive sulfides as well as the OS test, in a similar way to the WS and AS tests for sulfates.

To address this issue, Reid and Avery (2009) investigated an accelerated weathering test. This involved grinding samples to pass through a 2 mm sieve and putting them in a climate chamber at 40ºC and 95% humidity for 28 days. Measurements of the pH value and conductivity, using the BS 1377–3 method, were taken at 0, 7, 14, 21, 28 and 35 days. The aim was to provide an atmosphere conducive to oxidation of any sulfides that were present; oxidation of sulfides would result in a rise in conductivity and a drop in the pH value if the amount of acid produced exceeded the buffering capacity of the material. For limestone, other calcareous materials and recycled aggregates with a high proportion of concrete, the buffering capacity would probably be greater than the amount of acid produced, so little or no drop in pH value would be expected; however, oxidation of sulfides would be revealed by a rise in the conductivity over the period of the test.

Trials were carried out with five commercially available aggregates, including two granites, a limestone, a recycled aggregate produced from highway arisings (concrete and asphalt) and a recycled aggregate produced from demolition and excavation material (brick, concrete and soil). A shale with visible pyrite and an acidic colliery spoil were also included in the trial. The results for pH and conductivity are shown in **Figures 37.6(a)** and **(b)**. The pH and conductivity of the aggregate samples did not change during the trial, but the pH of the shale dropped from 7.5 to 5.7 and the conductivity rose from 380 to 2555 µS/cm. This suggested that oxidation of the pyrite

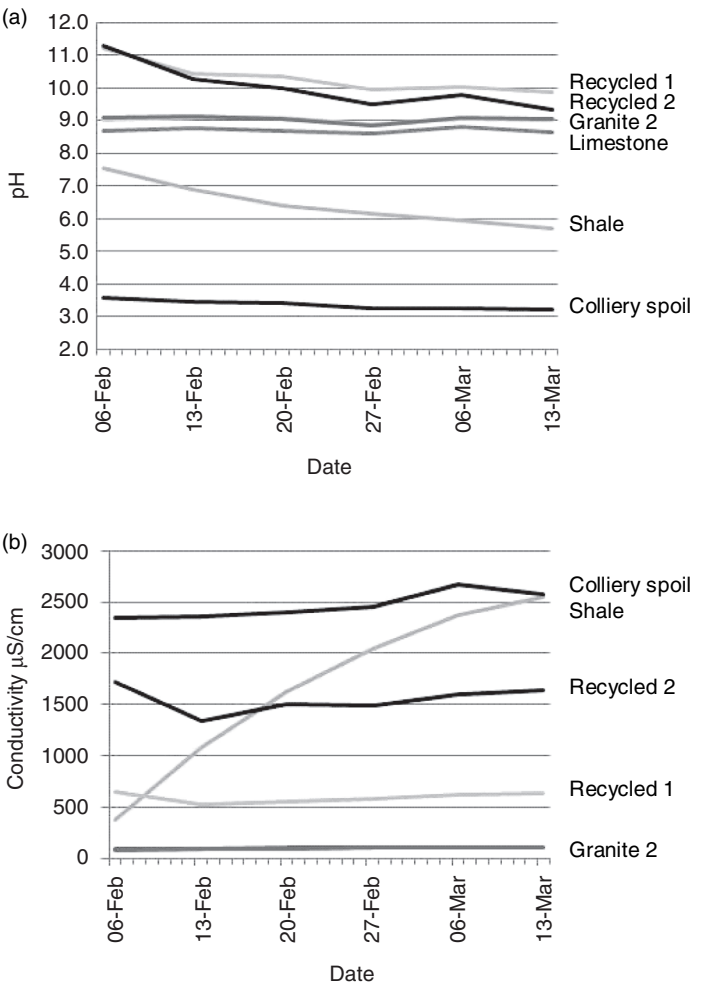

Figure 37.6 Change in pH value and conductivity during accelerated weathering test

Reproduced by permission of Mineral Industry Research Organisation (MIRO) from Reid and Avery (2009)

in the shale occurred during the test and correlated well with the behaviour of the material in the field; it is an overburden material from a quarry and is known to give acidic drainage after it has been exposed to the weather for some time (Reid and Avery, 2009).

The trial suggested that the accelerated weathering test may be a way to distinguish materials with reactive sulfides from those where the sulfides are not reactive. Further work is required to see if the method can be developed into a routine test method. It has the advantage of simplicity but requires a period of 28 days to carry out. It may, therefore, be appropriate as a characterisation test for aggregates or borrow pit materials, which would enable their suitability for various applications to be assessed in conjunction with the WS, AS and TS tests discussed above.

37.3.8 Test methods used for limiting values

Over the years, limiting values for different sulfur compounds have been set for different applications. The specific limiting values will be discussed where appropriate in section 37.4. The following are the main parameters for which limiting values are given in various specifications at the present:

- WS and pH value of groundwater;
- WS and pH value of soils and rocks;
- OS (usually derived from TS and AS) of soils and rocks;
- TPS (derived from TS) of soils and rocks;
- AS of soils and rocks.

In specific situations further information may be required, for instance:

- Magnesium content of groundwater or soil: water extract for concrete in brownfield locations (BRE, 2005).
- Chloride ion content, organic content, resistivity, redox potential and microbial activity index for backfill to anchored earth and reinforced soil structures (Highways Agency *et al*., 2009a).

It is important to remember that sulfur compounds are only one aspect of the chemistry of a material or water, and that it may be necessary to undertake a wider analysis to establish if there are likely to be any problems and to design mitigating measures.

It is important that sufficient samples are tested to obtain a clear picture of the concentration and distribution of sulfur compounds in the ground to enable selection of appropriate characteristic values for comparison with published limiting values for various applications [see Section 37.3.4, TRL447 (Reid *et al*., 2005) and BRE Special Digest 1 (Building Research Establishment, 2005)]. However, the limiting values for OS are known to be conservative (see section 37.3.7), so provision was made in TRL447 (Reid *et al*., 2005) for materials that exceed the limiting values for OS and TPS to be used if it can be established to the satisfaction of the client that:

- the material has been used in the past for the proposed application without leading to problems with sulfur compounds; and
- the reason why the material will not cause a problem is known, based on an understanding of its chemistry and mineralogy.

These provisions are included in the Notes for Guidance for the Specification for Highway Works, NG600 Series (Highways Agency *et al*., 2009b). The accelerated weathering test may provide a more quantitative method for assessing the risk from reactive sulfides in the future.

37.4 Specific problems and how to assess them

37.4.1 Attack on concrete

It has been known for over 70 years that sulfates and acids in the ground can attack concrete, resulting in cracking, expansion and softening of the concrete in the worst cases. Guidance on how to assess the risk and design concrete to withstand attack has been issued by the Building Research Establishment in a series of digests and guidance notes dating back to 1939. The most recent version is BRE Special Digest 1, published in 2005. This sets out detailed guidance for all parties involved in the design and construction of concrete structures, including the geotechnical specialist, who is responsible for carrying out the site investigation and making an assessment of the design sulfate class (DS class) and the aggressive chemical environment for concrete class (ACEC class) for the structure and passing this information to the designer of the building or structure.

To make an assessment of the DS class and the ACEC class, the geotechnical specialist has to carry out a desk study and site walkover to identify the type of site – e.g. whether it is a brownfield site or not – and assess whether the ground conditions are likely to be aggressive to concrete. Particular care is needed if the ground is liable to contain pyrite, as this increases the risk of attack on concrete. The groundwater conditions have to be assessed and classified as static, mobile or flowing, and concentrations of aggressive chemicals in soil and groundwater determined. A series of flowcharts and tables are then used to assign the DS class and ACEC class, from which the designer can produce a mix design and additional protective measures that will ensure the concrete can resist the anticipated chemical conditions. Flowcharts are given for three different types of site:

- locations on natural ground sites except where soils may contain pyrite;
- locations where disturbance of pyrite-bearing natural ground could result in additional sulfate; and
- locations on brownfield sites except where soils may contain pyrite.

Five DS and ACEC classes are defined, ranging from low concentrations of sulfates and sulfides and neutral pH values for DS-1 and AC-1 to very high values of sulfates and sulfides and highly acidic pH values for DS-5 and AC-5. The ACEC Classes are labelled AC-1 rather than ACEC-1. The system does not exclude any materials, but provides the designer with measures

to design concrete to withstand whatever the anticipated ground conditions will be. There are various subdivisions of the AC classes depending on factors such as whether the groundwater is static or mobile. The higher the AC class, the more expensive the concrete will be, so it is important to strike a balance between prudence and overdesign. It is, thus, important to carry out an adequate number of tests to be able to establish the DS class of the site with a degree of certainty; if only a few WS results are available, the highest measured sulfate concentration should be taken as the characteristic value. If five to nine WS results are available, the mean of the highest two sulfate test results should be taken as the characteristic value.

The limiting values for the DS and AC classes are for design purposes rather than pass/fail criteria. However, limiting values for backfill to concrete, cement-bound materials, other cementitious materials or stabilised capping forming part of the permanent works are given in the UK Specification for Highway Works (Highways Agency *et al.*, 2009a), Clause 601.14. These limiting values are based using the top of the DS-2 class from Special Digest 1 and roughly correspond to the solubility of gypsum at neutral pH values. The limiting values are, as at November 2009:

- WS content not exceeding 1500 mg/l SO_4 (TRL447 Test 1);
- OS content not exceeding 0.5% SO_4 (TRL447 Tests 2 & 4); and
- pH value not less than 7.2.

These limiting values are designed to ensure that materials placed directly against the concrete will not cause sulfate or acid attacks; this is subtly different to the BRE Special Digest 1 approach, which is based on the existing ground conditions. Backfill to structures can either be generated from arisings on site or imported to site if suitable material is not available on site. Hence, it is necessary to set pass/fail limits for this particular application.

While Special Digest 1 relates to concrete in the ground, structural concrete may often be exposed to fill materials above ground or subject to percolation of water through overlying embankment fill that then comes into contact with the foundation concrete, particularly for bridges. When assessing the DS and AC classes, the composition of any fill material that impacts on the concrete should be considered. An embankment is potentially a highly oxidising environment, so if materials containing active sulfates and sulfides are placed in an embankment, the implications for concrete structures on the site need to be assessed. The limiting values for backfill in the Specification for Highway Works normally only apply to material up to a distance of 500 mm from the structure, so it is possible for fill behind this clean structural backfill layer to generate acidic, sulphate-rich drainage that could attack the foundation concrete.

Problems could arise with bulk fill materials such as colliery spoil that are known to frequently contain high concentrations of sulfates and sulfides (section 37.2.3.3). This was the case in two highway improvement schemes in Yorkshire and Humberside; both required the import of large volumes of bulk fill for embankments, and colliery spoil was the most readily available material. Chemical testing showed that the colliery spoil had high concentrations of sulfates and sulfides; while it was suitable for use as bulk fill, it would not have been suitable in locations where it could shed drainage onto structural concrete. The problem was solved by increasing the area of clean structural backfill – a local limestone – so that it formed a wedge rising over the colliery spoil in a series of benches away from the structure. In this way the colliery spoil was always below the structural backfill and, hence, could not drain into it. This enabled large volumes of colliery spoil to be used as bulk fill, preserving primary aggregates for higher value uses such as structural backfill.

37.4.2 Attack on structural metallic elements

Metallic elements forming part of the permanent works are particularly susceptible to corrosion from sulfates, sulfides and acids; hence, it is very important to ensure that they are not exposed to drainage from fill materials that contain such compounds. Applications where structural metallic elements are used in civil engineering include reinforcing elements in anchored earth and reinforced soil, and corrugated steel buried culverts. The commonest metals used are galvanised steel and stainless steel. There are limitations on the materials allowed as fill to these structures – argillaceous rock is specifically excluded, for example – and on their chemical properties. Key references are Table B.1 of BS EN 14475: 2006, Execution of special geotechnical works – Reinforced fill, and Tables 6/1 and 6/3 of the UK Specification for Highway Works (Highways Agency *et al.*, 2009a). Guidance is also given in the UK Design Manual for Roads and Bridges in BD12/01 Design of Corrugated Steel Buried Structures with Spans Greater than 0.9 Metres and up to 8 Metres (Highways Agency *et al.*, 2001) and BD70/03 Strengthened/reinforced soil and other fills for retaining walls and bridge abutments (Use of BS 8006: 1995) (Highways Agency *et al.*, 2003). The recently published revision of BS 8006 (British Standards Institution, 2010) refers to Table B.1 of BS EN 14475 for electrochemical properties of fills used with metallic reinforcement.

It has been known for many years that some materials, such as colliery spoil and argillaceous rocks in general, are liable to cause corrosion of structural metallic elements (West and O'Reilly, 1986; Winter *et al.*, 2002), and these materials are not permitted as backfill to reinforced soil, anchored earth or corrugated steel buried structures in the Specification for Highway Works (Highways Agency *et al.*, 2009a). However, there have been problems with other materials such as alluvial sands and gravels (Reid *et al.*, 2005); acid generated by pyrite oxidation caused corrosion of a number of corrugated steel buried culverts in a highway scheme in England (**Figure 37.7**). The culverts and the backfill material had to be replaced before the road could be opened, causing considerable delay and expense.

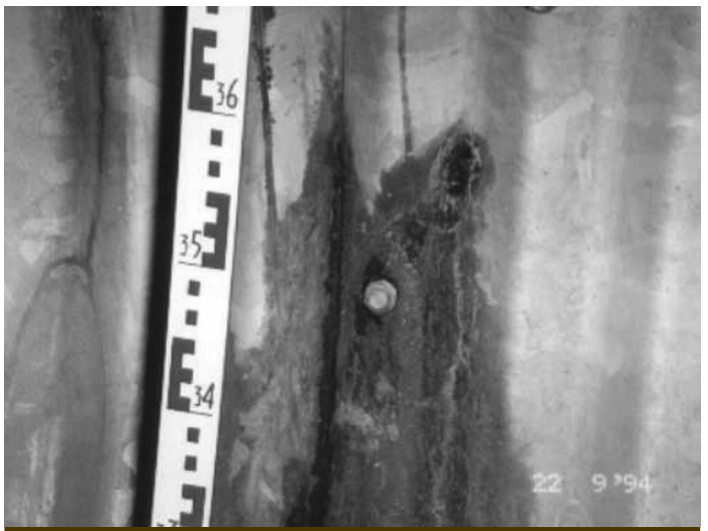

Figure 37.7 Corrosion of corrugated steel buried culvert due to pyrite in alluvial sand and gravel used as backfill

		Within 500 mm of structural metallic elements (Clause 601.15, UK Specification for Highway Works)	
Parameter	**Units**	**Galvanised steel**	**Stainless steel**

OS	% SO_4	0.06	0.12
Min pH	Units	6	5
Max pH	Units	9	10

Table 37.3 Limiting values for backfill to structural metallic elements

The limiting values for backfill vary slightly between galvanised and stainless steel, and are shown in **Table 37.3**.

Limiting values are also given for chloride content, organic content, resistivity, redox potential and microbial activity index. These values do not apply to backfill to ancillary metallic structures such as manholes and drain covers. Where the metallic elements are encased in concrete, the limiting values for backfill to concrete should be used (see section 37.4.1). The limiting values are very tight because of the sensitivity of the applications, and should only be applied to backfill to structural metallic elements, not to more general applications such as unbound subbase, capping or general fill.

A number of natural and recycled aggregates have been found to have OS values in excess of those in **Table 37.3**, although they have been used successfully for backfill to structural metallic elements in the past. The investigation carried out by Reid and Avery (2009) using an accelerated weathering test showed that five commercially available aggregates did not appear to contain reactive sulfides (see section 37.3.7), although measurement of the OS values showed that three of the five exceeded the limiting values in **Table 37.3**. The accelerated weathering test, thus, suggests that these materials would be suitable as backfill to structural metallic elements. Problems are unlikely to arise with aggregates from sources with a long history of production, as they are likely to have been thoroughly tested and any problems would have been identified. Problems are more likely where new sources are being developed and with borrow pit materials, which may be more variable and less well investigated. The problems with the alluvial sand and gravel discussed by Reid *et al*. (2005) were in this category; in this case a borrow material obtained on site was used rather than an aggregate supplied from an external quarry.

37.4.3 Attack on sheet pile walls

Steel sheet piles are widely used in civil engineering and are susceptible to corrosion from acid, sulfates and sulfides. In oxidising situations, e.g. above the water table in granular soils, corrosion will result from the mobilisation of sulfates and acidity in accordance with the reactions set out in section 37.2.2. However, in situations where oxygen is scarce or absent, a different set of reactions may occur; sulfates may be reduced to sulfides, leading in some cases to generation of highly corrosive monosulfides of iron or gaseous hydrogen sulfide. These reactions can occur in organic silty sediments in estuarine areas, which are often locations where extensive sheet piling is employed in harbour works. The high salinity associated with such environments, plus the diurnal change of water level due to tides, leads to conditions particularly suited to the formation of these reactive monosulfides. Tiller (1997) describes the mechanisms of corrosion specific to these environments together with various methods for combating them.

37.4.4 Degradation of bulk fill materials; geotechnical and environmental aspects

The consequences of pyrite oxidation in bulk fill materials in terms of potential attacks on concrete and structural metallic elements have already been described in sections 37.4.1 and 37.4.2. However, these reactions can also have significant effects on the fill material itself, both in terms of the long-term geotechnical properties and the leaching of polluted drainage waters into nearby watercourses.

The materials most susceptible to degradation of their geotechnical properties are weak rocks such as mudstones and shales, and materials such as colliery spoil, which contain large quantities of these primary components. These materials are widely used as bulk fill for highway and other embankments and for embankment dams; the latter, in particular, can require several million tonnes of fill and can reach heights of up to 40 m. They are also expected to have a service life of 200 years or more, so any potential long-term deterioration in their geotechnical properties is important, as this could lead to a decrease in the factor of safety and loss of serviceability. Embankment dams are generally constructed using the materials available within the footprint of the proposed reservoir, as

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

it is seldom practicable or economic in the UK to import large volumes of fill material. It is, therefore, particularly important to understand any potential degradation of the fill materials and design the embankment to cope with it.

These issues were investigated thoroughly for two major embankment dams in the UK during the 1980s and 1990s. The dams were Carsington in Derbyshire and Roadford in Devon; both were constructed using locally available weathered mudstones of Carboniferous age, which contained significant quantities of sulfide and sulfate minerals. Among the potential issues identified were:

- loss of shear strength of the fill materials due to leaching by sulfuric acid;
- chemical attack on drainage materials by sulfuric acid;
- clogging of drains by precipitation of gypsum or ochre;
- increased compressibility of the fill due to leaching with sulfuric acid;
- attacks on concrete and metal; and
- pollution of downstream watercourses by acidic drainage waters with high concentrations of metals and sulfates.

The results of the investigations and the records of measures taken during construction are described by Chalmers *et al.* (1993) for Carsington and Wilson and Evans (1990) and Davies and Reid (1997) for Roadford. It was concluded that chemical weathering was unlikely to lead to a significant loss of strength or performance of the fill, but an allowance was made for a drop of 1.5° in the peak drained friction angle (ø′) in the long term. Potential attacks on concrete and steel were avoided by taking appropriate protective measures in view of the likely sulfate and pH conditions. The biggest concerns were potential chemical attacks on drains and the treatment of drainage waters to protect high-quality watercourses downstream of the embankments.

The original Carsington Dam failed in 1984 when construction was nearly complete (Skempton and Vaughan, 1993); the embankment had included drainage blankets of limestone in the weak mudstone fill, and these had suffered chemical attack, leading to precipitation of gypsum in the drainage blankets (**Figure 37.8**) and the generation of carbon dioxide (see section 37.1). In the reconstruction of the embankment, drainage layers were not used and the basal drain and chimney drain were specified to be of inert quartz gravel to avoid any chemical reactions (Chalmers *et al.*, 1993). The basal drain was designed to be below the water table at all times, to avoid any oxidation of the iron-rich drainage water; consequently, when the drainage water emerged from the drainage outfall, the iron in solution oxidised and precipitated as ochre, an orange deposit of hydrous iron oxides (**Figure 37.3**). The drainage water was treated with sodium hydroxide to raise the pH and precipitate the iron and other metal oxides before being released into the downstream watercourse.

Figure 37.8 Limestone drainage blanket in acidic mudstone fill, Carsington Dam, showing precipitation of gypsum in the drain

At Roadford Dam, it was discovered at a late stage that the material proposed for the basal drain was calcareous and could potentially be attacked by acid draining from the embankment fill of weathered pyritic mudstone (Davies and Reid, 1997). As it was not practical to arrange for an inert fill material given the remote location of the site, investigations were carried out to assess the potential effect on the drainage blanket (Davies and Reid, 1997). It was found that the loss of permeability due to precipitation of gypsum would be minor due to the design of the drain, which again was permanently below the water table with a continuous flow of water through it. The drainage water was monitored during construction and found to have neutral pH and a high sulfate content, whereas drainage from the embankment fill had markedly acidic pH and even higher sulfate content. Chemical reactions between the drainage from the embankment fill and the drainage blanket were clearly occurring, but the drain has continued to function successfully for over 20 years since construction (Hopkins *et al.*, 2010).

The drainage water also had a high content of iron, manganese and suspended solids, and it has to be treated prior to release to the River Wolf downstream. The chemistry of the drainage water has been monitored for over 20 years and shows an annual cycle, with a peak in sulfate concentrations in the winter months when drainage from the embankment is greatest (**Figure 37.9**). The pH value shows the opposite trend, being lower in winter and higher in summer, but has remained above 7.0 except for a short period during the exceptionally wet winter of 2000/01 (**Figure 37.9**). The calcium concentration remains almost constant, indicating that the drainage water is saturated with calcium carbonate due to dissolution of calcite in the drainage blanket.

For both Carsington and Roadford Dams, a lot of useful information on the chemical reactions that could occur was obtained from observations of trial embankments constructed during the ground investigations. These were primarily designed to give

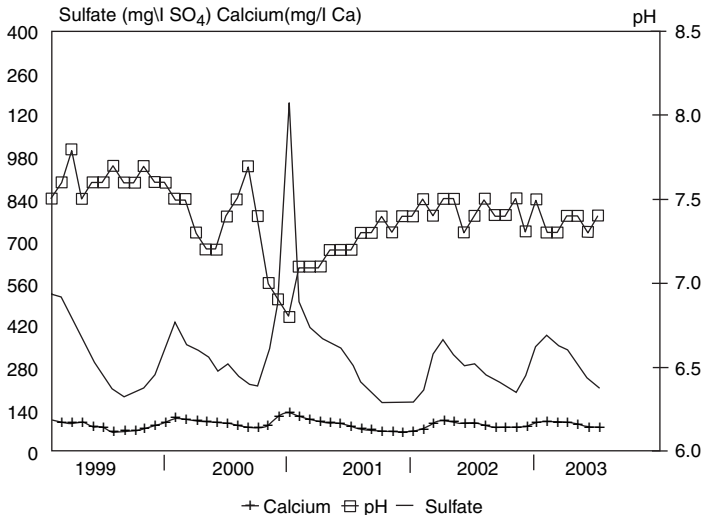

Figure 37.9 Concentrations of sulfate, calcium and pH value in drainage water from Roadford Dam
Reproduced by permission of South West Water from Hopkins *et al.* (2010)

information about the compaction behaviour of the various fill materials but also yielded much information about the nature and scale of the chemical reactions. Observations of precipitates of ochre and gypsum in drainage pools at the toes of the embankments and precipitates of white powdery gypsum on the surface of the embankments a few weeks after construction were a very visible indication of the chemical reactions that occurred when the materials were excavated and exposed to air and water. Chemical analyses of the drainage waters gave an indication of the scale of the problem and enabled design decisions to be made to deal with it. Much of this might have been missed had it not been for the sharp eyes and enquiring minds of the inspectors and engineers supervising these trial embankments. It is important for engineering geologists and geotechnical engineers to be able to recognise the signs of chemical reactions and understand their significance. Trial embankments are a particularly useful way of assessing the potential chemical reactivity of proposed fill materials, and provision should always be made for recording observations of any changes in the materials and chemical analysis of drainage waters.

Where it is not possible to construct trial embankments, engineers should try to examine embankments of similar materials and obtain information about their performance, including any issues with poor quality of drainage waters. Predictions can then be made for the performance of the proposed embankment material. The accelerated weathering test described in section 37.3.7 may also help to assess the likely scale of reactions in the full embankment.

A material that is particularly susceptible to chemical reactions is colliery spoil. In the aftermath of the Aberfan tragedy, a lot of research was carried out to assess the geotechnical properties of colliery spoil, including the effects of chemical weathering on shear strength; the results are summarised by Taylor (1984). The worst-case long-term residual shear strength was estimated to be an apparent effective cohesion (c') of zero (kN/m^2) and internal friction angle (ϕ') of 22°. The specific effect of acid leaching due to sulfide oxidation on the shear strength of mudstone was investigated by Anderson and Cripps (1993). Colliery spoil can be used successfully for bulk fill in embankments, as illustrated by the two examples of highway schemes in section 37.4.1, provided that its properties are known and the works are designed to ensure that they do not cause geotechnical or environmental problems.

37.4.5 Heave of stabilised soils

The treatment of soils such as sands, silts and clays with binders such as lime, pulverised fuel ash, slag or cement is often carried out to improve the geotechnical properties of the materials. This may simply involve drying out wet soils to make them suitable for use as bulk fill materials, but may also include creating stronger layers *in situ* for use as capping or as an unbound subbase in place of imported granular materials. This topic is covered in more detail in the Design Manual for Roads and Bridges HA74/07, Treatment of fill and capping materials using either lime or cement or both (Highways Agency *et al.*, 2007). Reactions between the binders and the soil result in the formation of cementitious compounds in a strongly alkaline environment at pH values in excess of 12. These extreme conditions can result in various chemical reactions with adverse consequences for the treated materials.

At these high pH values, sulfates in the soil react with the cementitious compounds to form a highly expansive calcium sulfo-aluminate hydrate called ettringite ($3CaO.Al_2O_3.3CaSO_4.31H_2O$) and gypsum; these minerals also cause expansive attacks on concrete (section 37.4.1). This is compounded because the high pH conditions accelerate the oxidation of pyrite, thus, generating even more sulfate to react with the stabilised soil. The reactions often do not occur immediately, but several months later, possibly due to seasonal changes in the moisture content supplying the water required for the formation of the expansive minerals. By this time, the treated layer has been overlain by pavement layers, foundations or floor slabs, and heave of the stabilised layers causes disruption to the pavement or building. This is then very expensive to remediate, as the overlying structure has to be broken out to replace the expansive material below. An example of the reactions that can occur and the remedial works that were required for a major highway scheme in the UK are given by Snedker and Temporal (1990).

Guidance on how to assess materials for potential swelling is given in HA 74/07 (Highways Agency *et al.*, 2007) for bulk fill and capping applications. Rather than setting specific limiting values, engineers are required to go through a process of trial mixtures, which are then allowed to soak for 28 days and the swell measured; if the swell exceeds acceptable limits, the material should not be used. Materials that are particularly susceptible to these reactions include overconsolidated clays,

drift deposits derived from them, and colliery spoil (see section 37.2.3). Where soil is to be stabilised *in situ* to form a hydraulically bound subbase layer, a limit of 0.25% as the SO_4 content for the total potential sulfate (TPS) is set in the Specification for Highway Works (Highways Agency *et al*., 2009a, Clause 840.3). Soil with a TPS equal to or greater than 0.25% can only be treated where this has been agreed with the overseeing organisation.

Unlike use as bulk fill (section 37.4.4), where the potential issues can be worked through in many cases, there are few options available for stabilisation if the material to be treated contains significant quantities of sulfates or sulfides. There is some evidence that the use of granulated ground blast-furnace slag leads to less swelling compared to cement or lime (Higgins *et al*., 2002). However, great care should be taken when assessing the potential for stabilisation of clay soils to ensure that they will not be susceptible to swelling.

37.4.6 Heave of floor slabs

Heave of floor slabs can also occur due to precipitation of gypsum in the underlying fill material under certain conditions. This can occur where the underlying material contains high sulfate levels and there is a high water table. As the interior of the building is heated, groundwater is drawn into the fill material below the floor slab by capillary action. The water evaporates, leading to crystallisation of gypsum in the void spaces in the fill material. This generates very high swelling pressures, which cause heave and disruption of the floor slab.

This type of problem is particularly common where buildings are founded on shales, mudstones or overconsolidated clays that contain significant concentrations of sulfides and sulfates. The disturbance due to construction works allows air to oxidise some of the sulfides, which are then transported by capillary action to the fill immediately below the floor slab, where they precipitate as gypsum. Examples from the UK have been reported by Hawkins and Pinches (1987) and Wilson (1987). The problem has been recognised for a long time and guidance was given by Nixon (1978), suggesting a limit of 1% FeS_2 in fill material below floor slabs.

While the majority of incidents have been due to construction directly on sulfate- and sulfide-rich strata with a high water table, similar problems can also occur if fill materials for use below floor slabs contain significant sulfates, sulfides or other expansive minerals. Guidance issued by the BRE (1983) specifies that all materials for use below floor slabs must be non-expansive.

37.5 Conclusions

The chapter has indicated how sulfur compounds can be a hazard in geotechnical engineering works, potentially leading to corrosion of concrete and steel, clogging of drains, loss of shear strength, heave of pavements and floor slabs and pollution of watercourses. These hazards can be avoided if they are recognised at an early stage and appropriate measures taken, either to adopt mitigating measures or to avoid use of unsuitable materials. Guidance is available to deal with most of the situations discussed; the main concern is for engineers to be aware of the potential dangers and to ensure that they are assessed properly during the ground investigation and design stages of the project. This does not just involve carrying out laboratory tests and comparing the results against various sets of limiting values, but understanding the materials and how they will behave when used in the proposed engineering works. In other words, exactly the same approach as in all geotechnical engineering design and construction work.

Chapter 38
Soluble ground

Tony Waltham Engineering geologist, Nottingham, UK

Limestones, gypsum, salt and varieties of these are the rock materials soluble in natural water, which can, therefore, be eroded to create ground cavities, which in turn can be the cause of ground failure and surface subsidence. These are features of karst terrains. The dominant karst geohazard is the development of new sinkholes within soil profiles overlying cavernous rock, where the rock remains stable but the soil is washed downwards into the open fissures. Most of these are induced by engineering activity, therefore they are preventable. Engineering problems are also caused by highly irregular rockhead profiles, and by cavities that may underlie foundations. Assessment of karst ground is very difficult, but the broad characteristics of karst are now well known and should be appreciated in practice. Less well known is the karst hazard in sabkhas, with increasing instances of ground failure encountered, but poorly documented, in the construction boom in the Middle East.

38.1 Introduction

Naturally occurring soluble ground materials are limestones (including dolomite and chalk), gypsum (and also anhydrite) and salt (halite), in order of decreasing abundance and increasing solubility. Exposure of all of these to rainwater, stream water and groundwater commonly leads to the development of subsurface cavities, with all the attendant consequences of collapse and ground subsidence. Long-term underground erosion creates cave networks, which can take all of the surface drainage. The essentially streamless landscapes, with their distinctive suites of landforms, are known as karst. Any karst terrain, on any of these rocks, presents some degree of geohazard, which may include slow ground subsidence, catastrophic collapses and destructive sinkhole development.

38.2 Soluble ground and karst

Soluble rocks present a variety of geohazards where they lie within a few tens of metres of the ground surface (and sometimes also at greater depths). Direct dissolution of the rock is only rapid enough to undermine a built structure within its lifetime in the case of salt, and to a lesser extent gypsum; in both cases any significant loss of ground would take place only where it is exposed to a significant flow of aggressive water. Limestone dissolution is so slow that it would take thousands of years to impact on a structure founded upon it. The hazards for limestone, and gypsum, are created by open fissures and cavities that are dissolved out of the bedrock over geological time scales. Soil-filled fissures within a buried rockhead commonly form very difficult ground for founding structures, but collapses of rock over open caves are rare. The major hazard is presented by bedrock voids, which are capable of swallowing large volumes of unconsolidated soil cover possibly within 12 hours or days; the consequence is the formation of the most common type of sinkhole.

38.2.1 Sinkholes

Sinkholes are closed depressions, 1–100 m in diameter and depth, that are the diagnostic landforms of karst terrains (Waltham *et al.*, 2005); they are correctly known as dolines by geologists, but the sinkhole term dominates in the American and the engineering literature. The term implies that the ground has sunk; water does normally sink into them too, but few have visible streams sinking into them. It is important to recognise the contrasting types of sinkhole (see **Figure 38.1**). Small numbers of collapse sinkholes, formed where the rock collapses into a cave below, are found in most karst terrains, but the chances of a new failure are so low at any site that they present a negligible risk to engineering. Nearly all large collapse sinkholes have expanded in sequences of failure events, further minimising the risk of massively destructive ground collapse.

The main karst geohazard is the formation of subsidence sinkholes in the soil cover over a fissured and cavernous limestone (**Figure 38.2**). Not only are these the most abundant, but new subsidence sinkholes can form by rapid movement of the soil cover and, therefore, have the greatest impact on engineered structures. The suffosion and dropout types differ due to the properties of their soil cover and, therefore, in their mode of failure – either the slow ravelling in a sandy soil or an arch failure into an undermined void in a more fine-grained soil. A soil-filled buried sinkhole constitutes an extreme form of rockhead relief, perhaps described as a soft spot, and sometimes developing a shallow compaction sinkhole in the surface above. Sinkholes may also develop purely by rock dissolution, but these are long-term erosional features comparable to valleys in non-karst

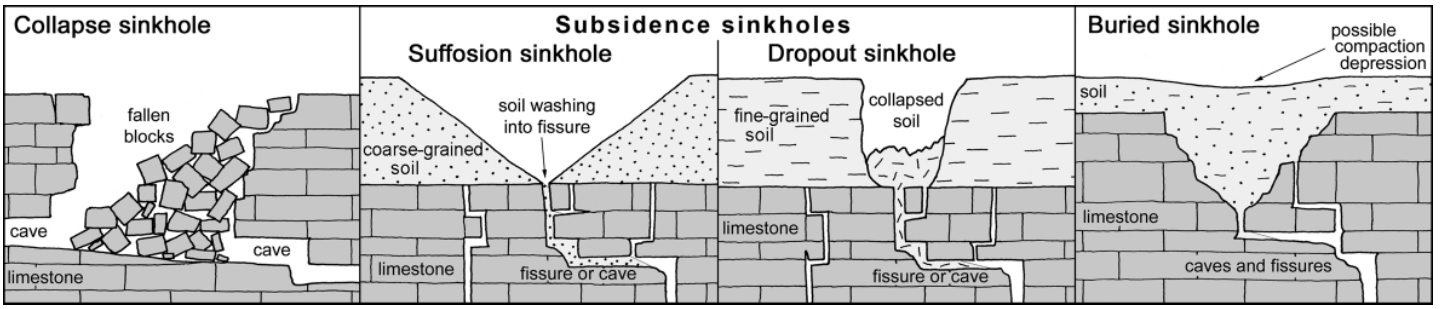

Figure 38.1 The main types of sinkhole developed in or above soluble rocks in karst terrains
Modified from Waltham and Fookes (2003)

Figure 38.2 A recently developed subsidence sinkhole in clay-rich alluvial soils in Turkey; this formed by a rapid collapse in the style of a dropout, but its slopes are already degrading to a wider profile; the bedrock is gypsum, which is visible at the outcrop in the background

terrains, and have little engineering significance except that the ground beneath is more likely to be more cavernous than adjacent ground. A shallow bowl, rather like a compaction sinkhole, can also be formed by localised rockhead dissolution, especially of salt. The engineering significance of both subsidence sinkholes and rock collapse are described in sections 38.3 and 38.4 below.

38.2.2 Distribution

Soluble rocks are widely distributed in all sedimentary sequences. Britain offers an assemblage of ground conditions that reasonably represents the proportions of the land area with soluble ground geohazards that can be found across the world (**Figure 38.3**). Limestones and varieties of carbonate rocks are the most widespread, with outcrops in almost every country in the world, but these do present considerable variation in the scale of their karst geohazards. It is notable in the British example that only some of the limestones are old, strong and cavernous, and, thereby, have widespread karst geohazards, while the weaker limestones rarely provide major difficulties for construction. Also, chalk is a special case, where rock strength and weathering are generally more significant than karstic conditions (Lord *et al.*, 2002). Worldwide, limestone karst causes the most extensive engineering difficulties in huge swathes of southern China, in large parts of the eastern USA and in the Dinaric karst that extends across the nations of the former Yugoslavia.

Gypsum is far less widespread than limestone. The small outcrops in the Midlands and northern England mean that Britain is perhaps under-represented when comparisons are made worldwide; the American mid-West and the Ukraine are the two large regions most impacted by their gypsum karst. Salt is of even more restricted extent, both in Britain and worldwide; its geohazards are well known in the developed lands of Britain and America, but it is the Middle East of south-western Asia that has the greatest areas directly underlain by salt.

38.3 Influences on the geohazard of limestone karst

Dissolution causes the most conspicuous karst features in pure, strong limestones (unconfined compressive strength, UCS > 70 MPa) where extensive fractures can be enlarged to create fissures and caves between blocks of intact strong rock. Weaker and softer limestones, such as England's Cotswold oolites, are more porous, so have more diffuse groundwater flows through micro-fissures; chalk also has diffuse flows, but much of its groundwater is transmitted through open fissures, and caves can occur (Lord *et al.*, 2002). On a broad scale, the age of the limestone is irrelevant; Carboniferous limestones in England, Jurassic limestones in France and Tertiary limestones in South East Asia have identical engineering properties. Dolomites and dolomitic limestones are rather less prone to dissolution, so generally have a reduced scale of karst features. Larger cavities develop where streams of aggressive water enter the limestone from adjacent impermeable rock outcrops, so there is a tendency for increased karst development adjacent to geological boundaries. Beyond that, rock structure and lithology influence cavity development, which is mainly at large fractures and chemically favourable inception horizons, and the guiding features can be recognised in most mapped cavities. But the distribution, pattern and positions of caves cannot be predicted within the hugely variable structure of natural ground conditions.

The scale of karst development may vary considerably, as recognised by a broad classification of karst ground conditions (see **Figure 38.4**). Any description and assessment of karst for engineering purposes should not only define the limestone

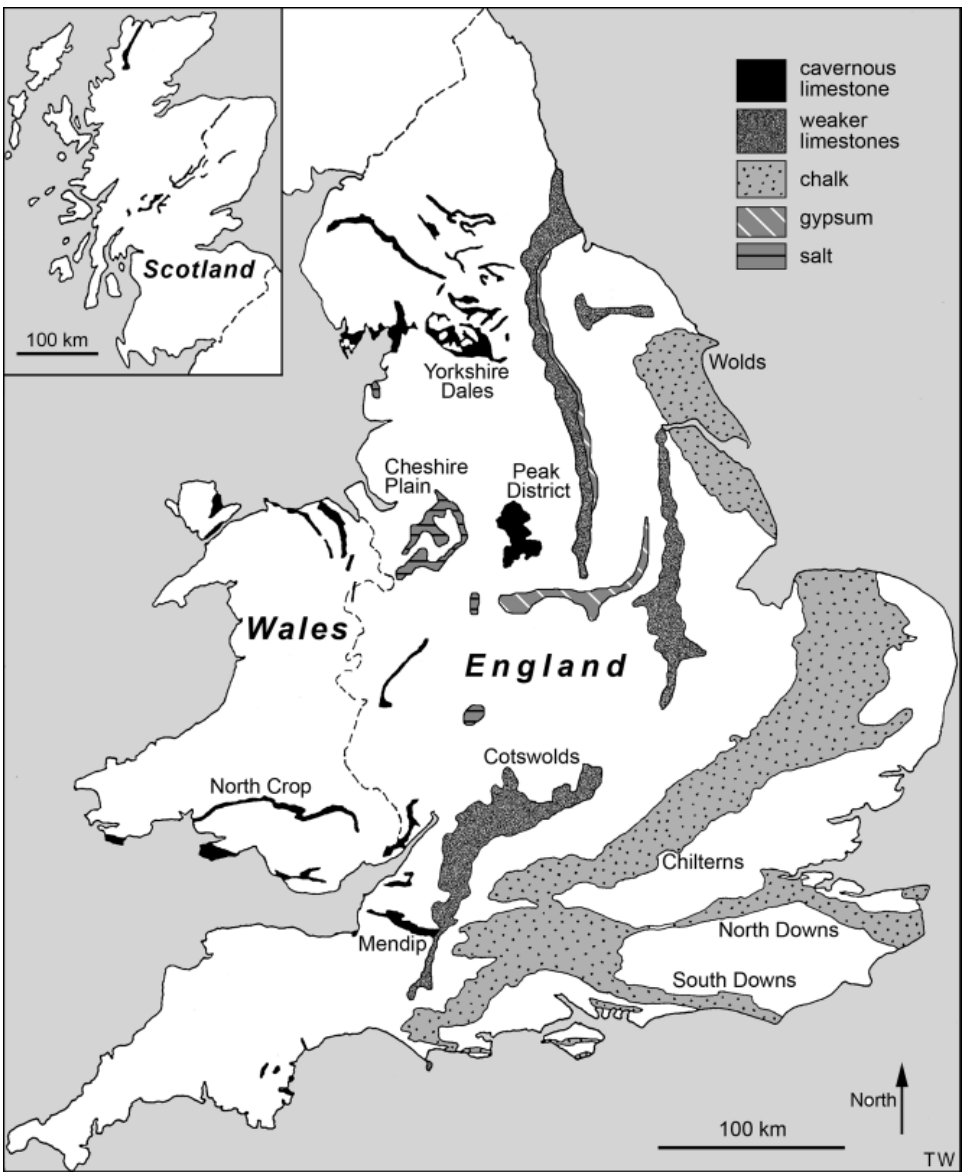

Figure 38.3 The distribution of soluble ground in Britain; all these areas are prone to karst geohazards, but recognisable karst landscapes are only widely developed on the cavernous limestones and on some of the chalk outcrops

lithology and the karst class, but should also determine or estimate approximate values for the three key parameters: typical cave size, frequency of new sinkholes and rockhead relief (Waltham and Fookes, 2003). Limestone dissolution in water is dependent on carbon dioxide to create soluble bicarbonate ions, and most dissolved carbon dioxide is derived from biogenic sources within soil profiles. Consequently, the scale of karst features, and, therefore, the karst class, is closely related to plant cover and, therefore, to the climate, and also to past climates. Karst in the colder climates of high latitudes and altitudes, such as in Britain and Canada, typically shows restricted development, to classes kII or kIII, with cave passages, rockhead fissures and rare new sinkholes all typically measuring less than 10 m. This contrasts with the humid tropics, such as in South East Asia or the Caribbean, where very well-developed karst terrains of classes kIV and kV have giant caves, pinnacled rockheads and numerous sinkholes, all with dimensions that approach or exceed 100 m. Limestones in hot and dry environments, such as in Australia and the Middle East, have modern karst development restricted by low rainfall, but commonly have isolated large caves and other karst landforms relict from wetter climates during the Pleistocene.

Though the natural environments dictate the overall scale of karst development, it is important to recognise that individual events of ground subsidence or collapse are commonly generated by man's activities that bring a sudden change to equilibrium situations. Engineering works that either remove or introduce water, or add an imposed load, all happen at far greater rates

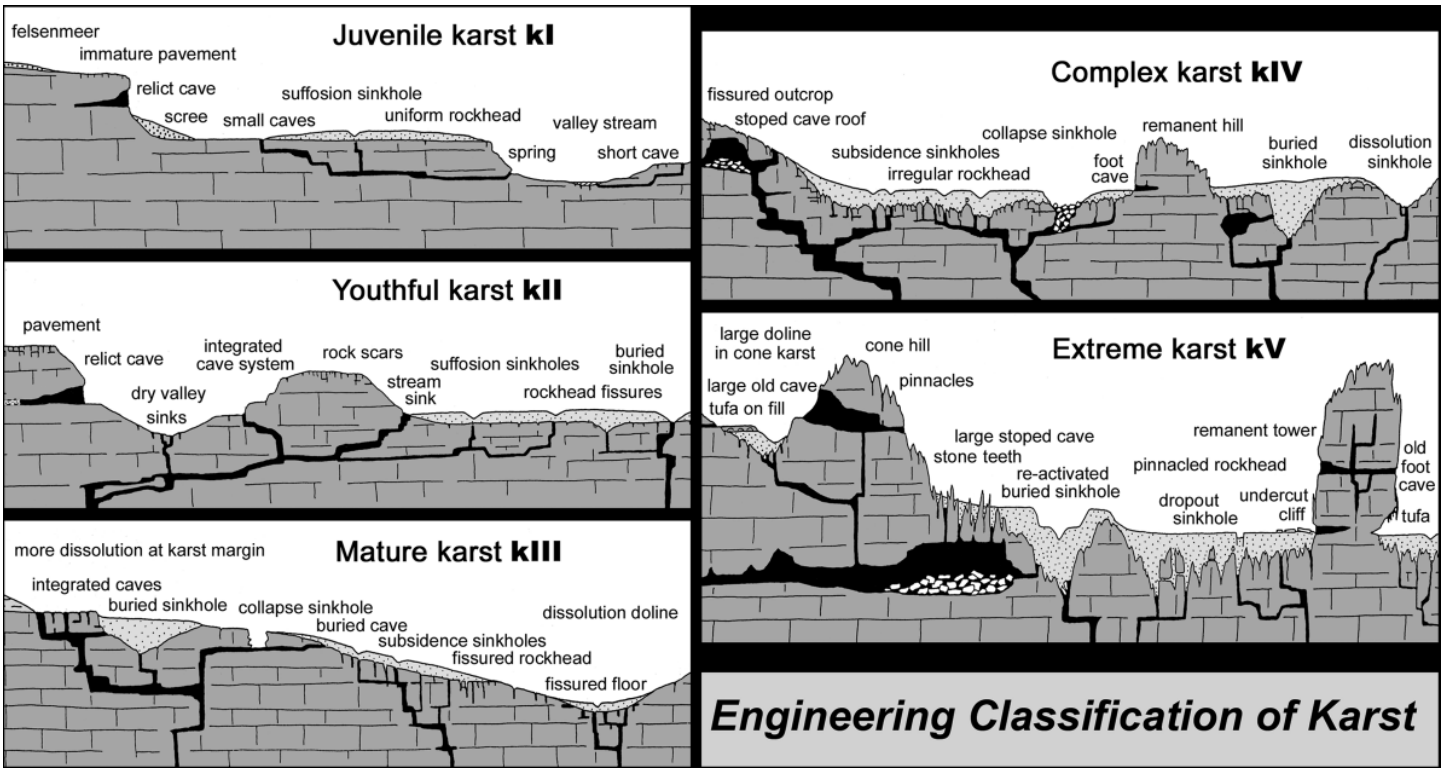

Figure 38.4 The five classes of karst that broadly demonstrate the variety and scale of landforms and ground conditions relevant to engineering
Modified from Waltham and Fookes (2003)

than normal geological evolution. In a natural and undisturbed karst, ground movements and collapses do occur, but typically as isolated events separated by hundreds or thousands of years. But any such event may be triggered prematurely by inappropriate engineering activity. A karst geohazard may be regarded as an event waiting to happen, unless appropriate precautions are exercised to avoid undue disturbance of the existing environment; these include thorough control of the drainage to avoid accelerated soil loss (see section 38.4.1), and the avoidance of excessive loads imposed on unstable rock (see section 38.5.1).

38.4 Engineering works on soil-covered limestones

The major geohazard of karst is the development of new subsidence sinkholes within the soil cover over fissured bedrock, because the process can develop very rapidly, well within structure lifetimes and even within construction periods (**Figure 38.5**), and without any imposed loading. Any unconsolidated soil lying over karst bedrock is prone to loss by downward migration, known as suffosion or ravelling, into the bedrock voids. Clean sand flows with ease and can, therefore, cause a slow lowering of the surface until the stable profile of a suffosion sinkhole is reached, with a throat at a bedrock opening (**Figure 38.1**). A soil with almost any clay content loses ground first from immediately above the rockhead, and it has the capability of developing a large soil void beneath an unstable soil arch. There is, therefore, no surface indication of the impending failure, until the thinned soil arch fails, instantly producing a dropout sinkhole (**Figure 38.1**). In reality, most soils have some degree of apparent cohesion, created in part by the negative pore water pressures, so they can develop soil voids and produce surface failures that vary between instantaneous and progressive; the profiles of most dropout sinkholes degrade into those of suffosion sinkholes either within a few days of the wall slumping or over longer periods. A thick soil mantle tends to reduce infiltration, such that the number of new sinkholes is greatly reduced in soils much more than about 10 m thick, but this is not an absolute limit, and ground failures have been recorded where the cavernous rock lies more than 100 m below the surface level.

38.4.1 Drainage and induced sinkholes

The suffosional removal of soil takes place almost entirely as downwashing by percolating water. It is, therefore, crudely predictable that many new sinkholes will develop during or soon after major rainstorms. However, the locations of new sinkholes are not predictable, as they will be located above open fissures that are unseen in the soil-mantled rockhead until the sinkhole develops (**Figure 38.6**). It is, however, significant that subsidence sinkholes are most likely to develop where and when there is a change to an existing equilibrium in rainfall infiltration and groundwater flow. Such a change

Figure 38.5 Collapse of a road on a bridge approach undermined by a new subsidence sinkhole in alluvial soils in Pennsylvania; this was one of many ground failures that developed within the zone of the decline of the water table around a deep quarry that was kept dry by continuous pumping

Figure 38.6 Numerous small subsidence sinkholes in a thin soil of glacial till over limestone in the Yorkshire Dales; there is no pattern to the sinkholes, as each has developed over an open fissure in the buried limestone, comparable to the exposed fissures in the bare patches of the limestone pavement

may be increased input at any point, either by concentrated run-off from a built structure, by inappropriate use of a soakaway or infiltration pond, or from a fractured pipeline. Equally, the change may be the increased drawdown of surface water due to a water table that has declined within an aquifer that is over-pumped. More than 90% of new sinkhole appearances are related to the disturbance of the drainage equilibrium by civil engineering activities (Newton, 1987; Waltham *et al.*, 2005).

Because most new sinkholes and karstic ground failures are induced by man's activities, the key feature to good engineering practice is to minimise or eliminate the hazard by control of the drainage. This includes the total collection of run-off from all built structures and areas of sealed ground, the proper disposal of that run-off directly into the bedrock or away from the site, the sound maintenance of all pipelines and stream channels, and the avoidance of increased infiltration when ground is exposed or replaced with granular fill during construction works. Failure or inadequate actions for any of these will almost inevitably lead to soil loss and sinkhole development, which will require far more costly remediation at some future date. Where sinkholes are induced by a decline of the water table, there may be no simple remedy that can be applied within the confines of a site or construction project. If that decline is due to groundwater pumping for municipal or private supply, to dewater ground to keep a quarry or mine dry, or temporary dewatering for a construction project, the costs of subsidence damage may simply have to be factored into that operation's budget, unless the economics determine a replacement water supply, a quarry closure or an alternative method of constructing deep foundations.

The placing of structural foundations within the soil profile over karst limestone is inevitable in the case of most roads, and also for many small, built structures over thick soil profiles. They can be perfectly appropriate where the proper drainage measures ensure that the ground is not unduly disturbed. Each project should be treated individually; foundations should be provided appropriate to that particular site (Sowers, 1996; Waltham *et al.*, 2005). A host of alternatives may involve engineered soils, geogrids, rafts and mattresses, partial excavations, replacement soils, load transfer to bedrock pinnacles, and reinforced foundations; all of these measures should be designed to minimise soil ravelling and to bridge any small voids that may develop subsequently (useful examples are provided by Vandevelde and Schmitt, 1988; Lei and Liang, 2005).

Grouting can be appropriate, but the sealing of all fissures within a karst limestone is likely to prove very expensive because huge quantities of fluid grout can be lost into large but unseen open voids. Compaction grouting, within the soil just above the rockhead, can effectively prevent the downward loss of soil, which is densified in the same process, and this commonly yields better results (Henry, 1987; Stapleton *et al.*, 1995).

Where an existing structure exhibits settlement damage following a history of stability, the key to remediation is to determine and rectify the feature that caused the new movement. In many cases this will be a drain or pipeline failure, and repairs may be all that is required to recover the integrity of the structure. Pressure grouting within the soil may be appropriate if action is not been taken before settlement damage becomes too severe. New open sinkholes commonly require repair, and this should entail backfilling with selected sizes of materials so that the sinkhole is choked to prevent further soil loss but it may be required to still drain surface water safely into bedrock fissures (Waltham *et al.*, 2005).

38.5 Engineering works on limestone bedrock

Foundations carried through to the bedrock eliminate the major dangers of soil movement and sinkhole development within the overburden, but karst ground buried beneath soil cover is

very variable and not easily assessed. It offers two major difficulties: an uneven, fissured or pinnacled rockhead, and the threat of open caves lying just beneath any footings.

Dissolution down limestone joints, which may occur before soil cover is emplaced but also matures beneath the soil cover, creates open or soil-filled fissures within the buried karstic surface that is the rockhead. These fissures may be widely spaced, irregular or closely spaced, leaving blocks or pinnacles of bedrock between them; a pinnacled rockhead has a forest of narrow rock pinnacles between networks of wide fissures (**Figure 38.7**). Individual blocks or pinnacles may be loose, due to dissolutional undermining along sub-horizontal fractures or beddings, and are only held in place by the surrounding soil; completely loose blocks within the soil are known as floaters. The depths of fissures, and the heights of pinnacles, are commonly some metres in any karst, and may be many tens of metres in tropical karsts of classes kIV and kV. It is, therefore, not abnormal to find depths to the rockhead varying by tens of metres at adjacent investigation boreholes or structural piles that are only a few metres apart. On a larger scale, rockhead profiles may include buried sinkholes where bedrock depressions up to 100 m or more across are completely filled with breakdown, sediment and soil. These may cause small surface settlements in the form of compaction sinkholes over the soft soil fills, and may have floors of highly fissured bedrock that offer no easily definable sound footing for deep foundations.

Figure 38.7 Pinnacled rockhead in mature limestone karst (of class kIV), exposed on a construction site in southern China; some pinnacles have already been broken down (with sledge hammers) to create a solid and almost level footing for a new hotel; the grey top of the pinnacle on the right originally projected above the soil level, as do some undisturbed pinnacles in the background

Most deeply fissured and cavernous karst limestones are strong materials, so structural loads may be carried safely on pinnacles that have been proven to be of adequate width and are not disconnected from the underlying bedrock. In such cases reinforced foundations can bear on the pinnacles and span the intervening soil-filled fissures and buried sinkholes. Driven piles with any significant end-bearing on rockheads of strong limestone (UCS > 70 MPa) present their own difficulties (see **Figure 38.8**); it can be very difficult to gain a safe seating on steeply sloping bedrock surfaces, so it is normally necessary to drill sockets into the rock, and this can also be difficult through a steeply inclined interface. In chalk terrains, the ground profile generally lacks any sharp contrast between soft soil and

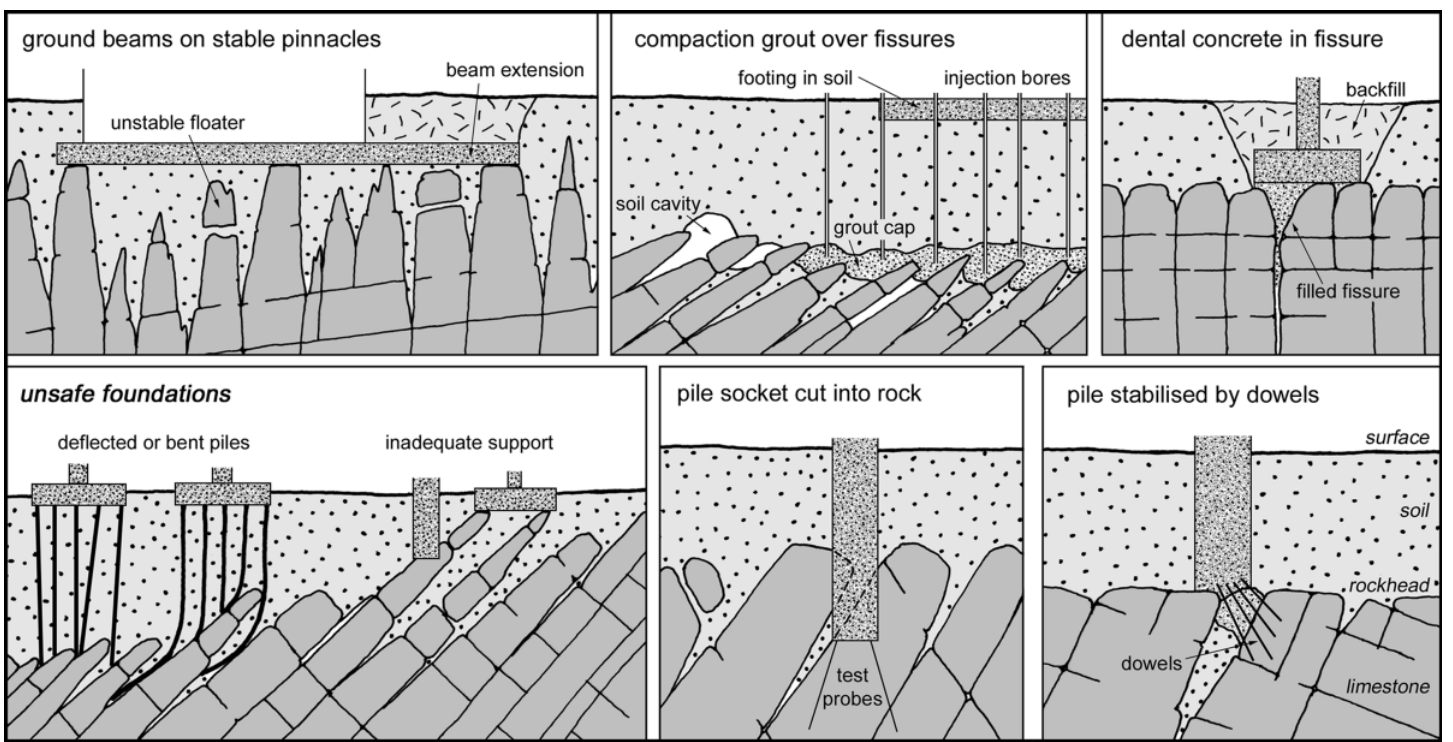

Figure 38.8 Various examples of good and bad foundations on soil-covered limestone karst (Waltham *et al.*, 2005), with due credit to the ideas and experience of the late George Sowers

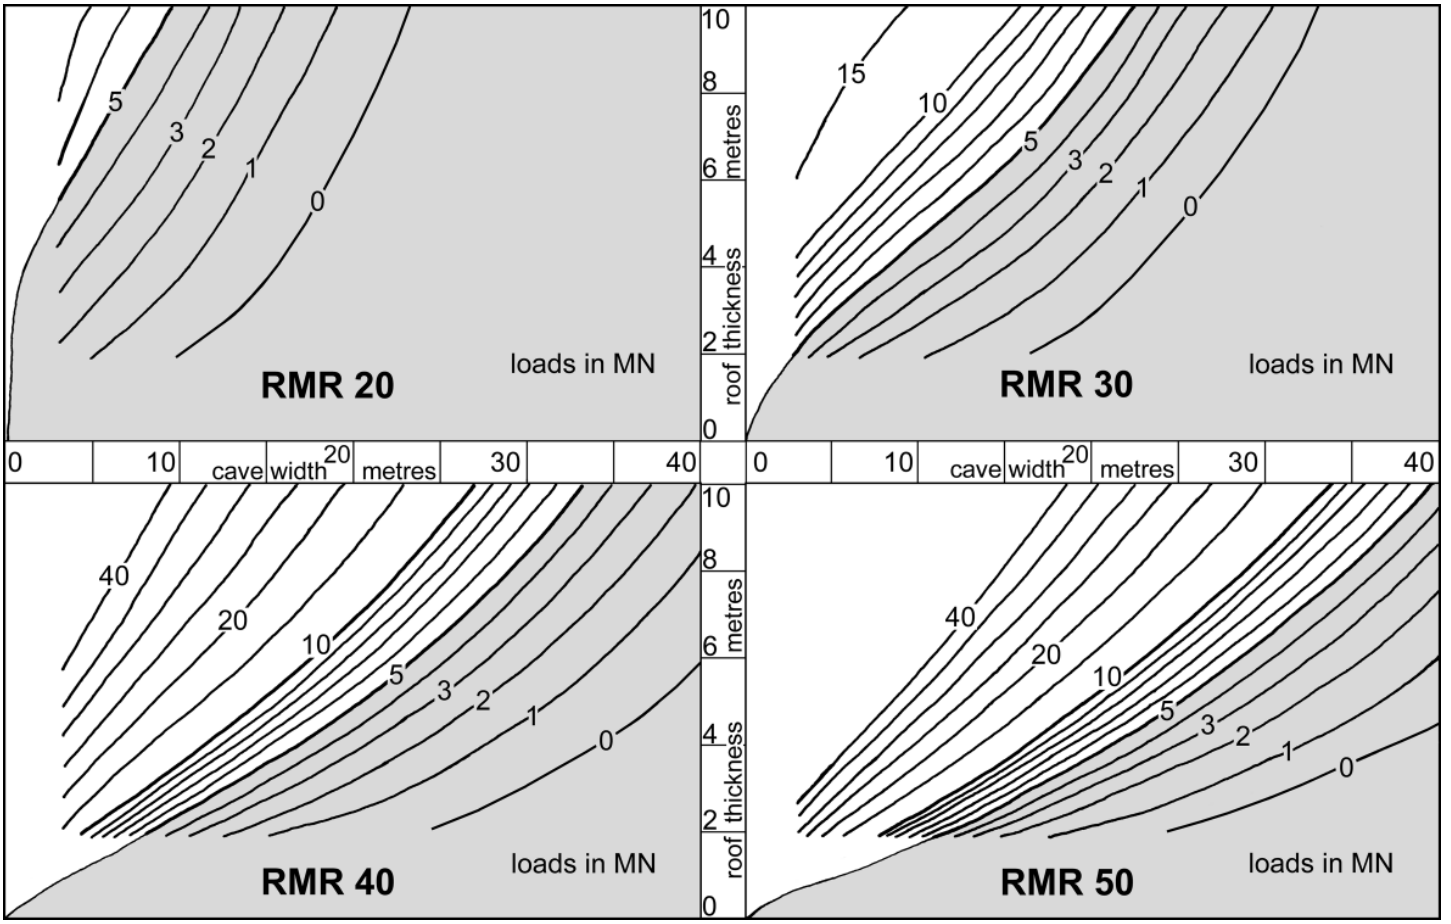

Figure 38.9 Nomograms that relate failure loads to cave width and roof thickness in ground of various rock mass ratings; the pink or grey shaded areas represent situations that should be regarded as unsafe for footings with imposed loads of 1 MN that lie directly over the caves
Modified from Waltham and Lu (2007)

strong rock, and a zone of weathered chalk further softens the rockhead, so foundations are simply taken to whatever depth is required to find adequate bearing capacity. Pinnacle loading on chalk is inappropriate, and details of the rockhead profile are less significant, except that buried sinkholes and filled solution pipes within chalk are frequently the sites of surface subsidence whenever soil movement is re-activated due to modified drainage or leaking pipelines (Edmonds, 2008).

38.5.1 The hazard of unseen caves

Where structural loads are carried down into bedrock limestone, the remaining concern is the presence of an unseen cave directly beneath. In nearly all karst terrains, there is only an extremely small statistical chance of a building being threatened by a cave that is directly beneath, that is large enough and that lies beneath a critically thin rock cover. Many structures have been inadvertently placed over large caves in tropical terrains, but collapse has not been instigated by the imposed loads, which are commonly very modest compared to the self-loads of the rock. The main geohazard from open caves in karst is to end-bearing piles with high point loads, and particularly to any heavily loaded bored piles or caissons. Guidelines exist for the thickness of roof required in limestones of various qualities in order to safely span caves of various sizes when loads are applied to them (Waltham and Lu, 2007); a cave generally has to be significantly wider than its cover thickness to create a threat (**Figure 38.9**). This means that, except in tropical karsts where large caves are typical, only a few metres of sound rock cover are generally required to provide integrity and render any deeper cave irrelevant to structural loading. Cases of rock failure in karst, as opposed to soil failure over karst, are extremely rare, and have only occurred where ground investigations have been grossly inadequate (Waltham, 2008).

Dam foundation and reservoir impoundment attract a whole series of problems when carried out on, or partially on, karstic limestone. Most limestones are strong enough to bear the loads imposed, but the problems of leakage can be massive and very complex, and are beyond the scope of this account. Both foundation problems and hydrological situations are comprehensively reviewed by Milanovic (2004), based on extensive

experience in the Dinaric karst. The Kalecik Dam in Turkey provides an accessible case history of karst leakage and its remediation (Turkmen, 2003).

38.6 Ground investigation and assessment of karst

Because karst is so extremely variable, each ground investigation is almost unique and has to be assessed in the light of local conditions and the available data. An overview of the local karst is essential for broadly evaluating the key parameters of sinkhole frequency, cave size and rockhead relief that may be anticipated; interpretation of these factors usually benefits from wider experience in karst terrains. Beyond that, the design of suitable structures and foundations can only be based on a sensible assessment of the immediate ground conditions in light of the recognised hazards and perceived risks. Numerical modelling of karst ground is likely to be unrealistic, because too many features and factors will always remain unseen or unknown. The morphological complexity of karst fissures and cavities means that any ground assessment based on borehole logs will inevitably be oversimplified; this applies to both unseen caves and rockhead profiles (**Figure 38.10**). Following even the most extensive borehole investigation, unforeseen cavities will almost certainly be revealed by any extensive ground excavation in karst; these will best be remediated on the spot by filling, sealing or spanning by means that can only be assessed after they are revealed. There is no simple answer to how many boreholes should be drilled to assess a karst terrain; the number required is as many as it takes to give the engineer confidence that the likely ground conditions are known or understood to a level that is adequate and appropriate for the risks involved in his particular project. Too few boreholes can create an unacceptable risk, while an excess of boreholes can be a frustrating necessity (Waltham *et al.*, 1986). Extra care may be needed where water flush can induce suffosional soil loss over limestone, or can cause rapid dissolution of gypsum and salt; drill rigs have been known to fall into self-induced sinkholes.

Though boreholes and probes do provide valuable insights into ground conditions, almost every investigative drilling into karst will intersect some extent of open voids or soil fills, most of which will have little or no influence on the overlying ground integrity. The length of a void, or the soil fill, down a single borehole is rarely critical; if it is down a narrow fissure, it is almost irrelevant. The critical factor is the void width in relation to the rock cover, and this can only be assessed from a number of closely spaced probes, or perhaps from a down-hole camera. The depths to which investigation boreholes should be taken into bedrock is indicated by the safe cover thickness that is required (**Table 38.1**). It is normally necessary to prove every pile site or loaded rockhead pinnacle with one or more probes, treating each one as an individual ground investigation.

The overall extent of bedrock voids encountered by boreholes may be used to indicate the scale of potential soil loss by suffosion from a soil cover, though such losses should be regarded as possible in almost any karst. The dominant factor in soil loss and sinkhole development is always the drainage, and this must be properly controlled on all construction

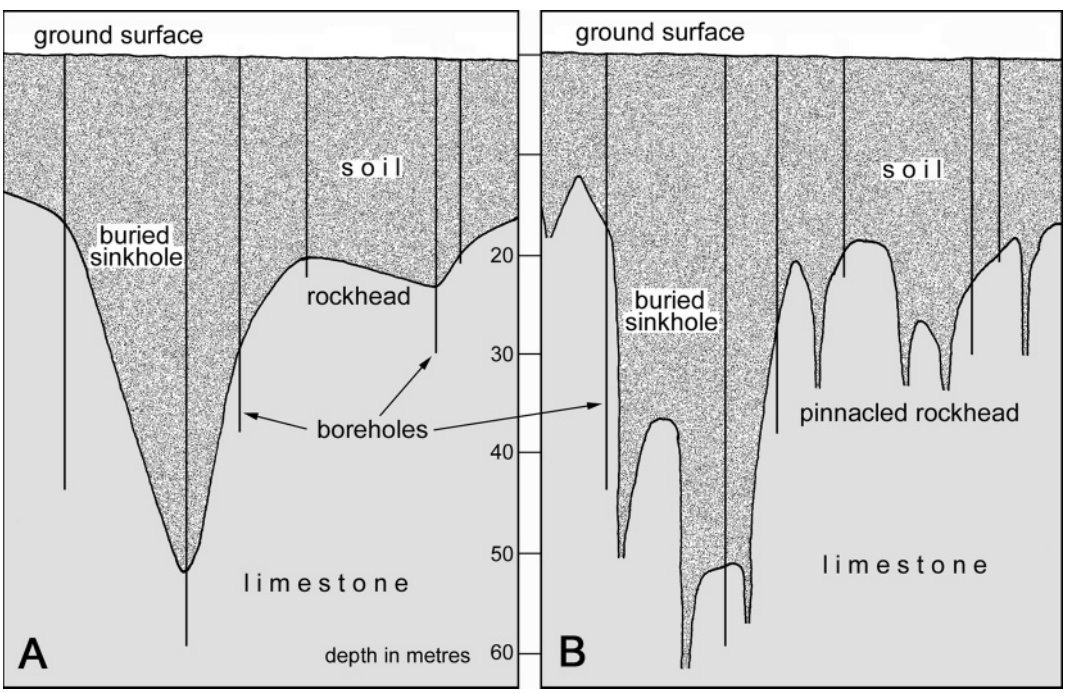

Figure 38.10 Two interpretations of the rockhead profile investigated beneath the site of a new tower block in Kuala Lumpur, Malaysia; (a) is the basic interpretation from the borehole data; (b) is a more likely interpretation based on an understanding of the pinnacled rockheads that are well known in the area

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Rock	Imposed load (kPa)	Karst class	Cave width, likely maximum (m)	Safe roof thickness (m)
Strong karstic limestone	2000	kI – kIII	5	3
		kIV	5–10	5
		kV	> 10	7
Weak limestone and chalk	750		5	5
Gypsum	500		5	5

Table 38.1 Safe roof thicknesses for various cave situations, and, therefore, a guideline to the depths to be proven by probing prior to construction
Data taken from Waltham *et al.* (2005)

projects; the borehole data may only offer a broad indication of how much infiltration of rainfall directly into soil areas may be tolerated close to or within a developed site.

A construction project over a large area of karst ground may reap benefits from appropriate geophysical surveys that can focus attention on the areas of most fissured or cavernous ground. The various methods all require expert interpretation, and even then can only identify ground anomalies that must be validated individually by boreholes or excavation; the proving may be more difficult where the anomalies are offset from the causative features. Only microgravity surveys directly indicate ground voids as missing mass, but these may fail to distinguish between networks of narrow fissures and more hazardous large voids. Seismic or electrical tomography in 2D or 3D can provide more useful data where boreholes are available (Waltham *et al.*, 2005).

Karst ground conditions are probably the most variable that a civil engineer may encounter, and may, therefore, be the most difficult where responses to their extreme and unpredictable variability have to be within a reasonable budget. Major errors, unwarranted expenses and possible catastrophes occur where the rather special nature of karst ground conditions are not recognised at an early stage within a project. Those with no experience or understanding of karst can make the most elementary of errors. All too often, karst is only considered on a site after the first new sinkhole has appeared amid the construction works. Yet if karst is recognised early, if it is given due consideration, and if all site drainage is properly controlled, its geohazard may be marginalised to a point where risks are reduced to acceptable levels. Because most karst ground failures are induced by engineering activities, the geohazard should be largely eliminated by good practice.

38.7 Geohazards on gypsum terrains

Gypsum karsts are very similar to those on limestone, except that there are no climatic constraints on the extent and distribution of gypsum dissolution; they also lack the extreme landforms of vertical cliffs and tall towers, because the rock is mechanically weaker. The most widespread geohazard on gypsum is the development of new sinkholes within the soil cover, and in this respect the conditions, the processes, the extents and their assessment are very comparable to those in a limestone karst (Johnson and Neal, 2003).

Gypsum differs from limestone in that it is much more rapidly dissolved in natural water, so that rock removal by dissolution can become a factor within the lifetime of an engineered structure (though dissolutional loss is still hugely slower than soil movement with reference to the hazard of new sinkholes). As in the case of limestone, proper drainage control is the key to surface stability in gypsum karst. However, the simple disposal of large flows of water into clean bedrock fissures may not be appropriate in gypsum, where a raised level of dissolution activity may rapidly create new cavities and modify the existing drainage with negative side effects. Similarly, remedial sealing or blocking of any open voids or known sinkholes within gypsum may only deflect future processes, problems and subsidence to adjacent ground. The rapidity of gypsum dissolution makes it especially susceptible to environmental change due to engineering works, and this is a widespread hazard in the sabkha terrains of the Middle East (see section 38.8). Reservoirs impounded over gypsum have a significant failure rate because leakage is generated not only by the washing of sediment fills out of the bedrock fissures, as in any karst, but is then exacerbated due to dissolutional erosion by the large induced flows. Abstraction for water supply can also cause accelerated dissolution, and ground subsidence, by drawing in flows of unsaturated water, though on a much smaller scale than in salt terrains.

Caves and open bedrock voids are generally not as large in gypsum as they are in limestone, because gypsum is a weaker material within which caves collapse at an earlier stage. On the other hand, the weakness of bedded gypsum and its changes to and from anhydrite allow more rapid upward cavity migration by progressive roof failure (**Figure 38.11**), so small rock collapse features are more common. Collapse sinkholes more than 100 m across, known in some gypsum karsts, have developed by multiple failures that have extended the collapsed ground laterally, and not in single large collapse events. Ground failures can also be induced by engineering loads imposed on the gypsum bedrock. Buried cavities are generally small but they require a proportionately thicker cover to ensure the integrity of overlying structures, for even the most modest loadings, which is appropriate for a rock weaker than most limestones; this determines the depth of probes required to prove stable ground in gypsum karst (**Table 38.1**).

38.8 Geohazards in salt terrains

Salt (also known as rock salt or halite) is an evaporite material widespread in sedimentary sequences that have accumulated in arid environments. Because it is so rapidly soluble in rainwater, its occurrence and geohazard are restricted to three

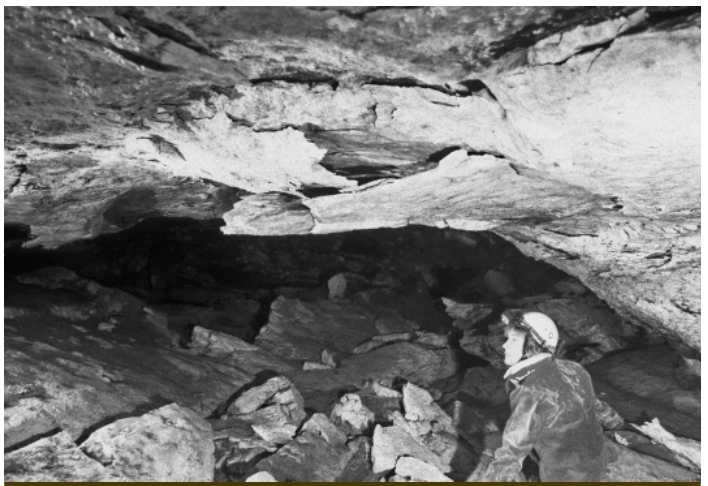

Figure 38.11 Cavity migration by progressive roof failure over a cave passage in massive gypsum at Pinega, Russia; flakes that are peeling away from the roof deform and sag before they break off

Figure 38.12 Collapsing ground on a salt dome in southern Iran; the person is standing at the edge of an active sinkhole in about 4 m of residual soil that is being undermined by rapid dissolution of the heavily eroded and cavernous salt beneath

environments: modern desert salars, salt domes in semi-arid terrains and buried rock sequences elsewhere.

Salars, salt pans, playas and continental sabkhas are areas of newly deposited evaporite salt, commonly with other minerals in thicker sequences. Groundwater is normally saturated, thereby restricting dissolution. Karstic cavities some metres across, which lie at shallow depths and may be revealed by smaller collapse openings at the surface, are generally restricted to marginal areas where the salt has been reached by aggressive surface run-off or groundwater input from adjacent hills. As active salt areas are largely prone to seasonal inundation, construction on them is very limited, but roads and driving routes that cross them can be threatened by the concealed cavities close to their margins.

Salt diapirs, or salt domes, rise from stratiform salt at depths of some kilometres. The salt is generally lost to rainfall at an outcrop, so that only caps of less soluble gypsum, anhydrite and clay survive at an outcrop. Actively rising salt diapirs form significant salt mountains, with or without salt glaciers flowing from them, but there are few beyond the many in the semi-arid Zagros Mountains of southern Iran (Talbot and Aftabi, 2004). These constitute mobile and cavernous terrains that are unsuitable for any development (Bosak *et al.*, 1999). Their thick mantles of residual soil are pitted by closely packed subsidence sinkholes that are actively collapsing and ravelling into dissolution cavities within the underlying salt (**Figure 38.12**). Cave chambers are up to 15 m across, with block failure and roof migration continuing at rates that are orders of magnitude faster than in limestone caves, so that bedrock collapses impact the ground surface as frequent events. Only when a diapir's rise virtually ceases, does surface lowering dominate, and then the residual mantle can become thick enough to prevent most rainfall reaching the salt, and its surface, therefore, will approach stability. By that stage, the salt sub-crop lies beneath a lowland terrain with chaotic sinkhole topography, but it is stable enough to be crossed by highways with minimal subsidence problems.

38.8.1 Subsidence over buried salt

Within environments of significant rainfall, salt does not appear at outcrops, but only survives beneath a cap of residual soil. In England's Cheshire Plain, a glacial drift 10–50 m thick overlies dissolution breccia that is around 50 m thick and consists of collapsed blocks of the mudstone that was originally interbedded with salt (Waltham, 1989). Underneath, the thick salt beds remain *in situ*, creating wide sub-crops due to their low angles of dip. Ground stability is ensured where any voids within the salt are filled with saturated brine, but subsidence takes place over any sites where the input of freshwater allows renewed dissolution of the salt. This is most extensive along linear subsidences (typically 1–10 m deep, 100–400 m wide and 1–5 km long) that develop over 'brine streams' of concentrated groundwater flow through the permeable dissolution breccia at the rockhead.

Subsidence is hugely accelerated when brine is pumped from these zones on an industrial scale, thereby drawing fresh water into the breccia. Even more destructive ground collapses and large sinkholes develop where brine is pumped from old flooded mine workings, so that support pillars are dissolved by the input of replacement water. These styles of brine-pumping have now been stopped in Cheshire, so the catastrophic collapses and rapid movements in the linear subsidences have virtually ceased, but comparable practices continue to cause surface damage in other parts of the world. Beds of salt with no outcrops can also create major surface subsidences where water and brine are able to flow through them. Some events are due to poorly managed brining operations, but the USA has many cases of large collapse sinkholes that developed after nearby wells, drilled for fresh water or petroleum through salt beds, were left uncased or poorly cased, thereby allowing brine outflow into aquifers that previously had no connection (Johnson and Neal, 2003).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Flows from brine springs, in Cheshire and elsewhere, indicate that dissolution of buried salt can continue in an undisturbed natural environment. The result is ground subsidence, albeit on a modest scale, that can only be described as natural and uncontrollable. An appropriate engineering response may be the construction of houses on rafts, which prevent structural damage and are prone only to tilting; these may then be jacked back to horizontal, in the manner that was common on a large scale in past times of active brining in Cheshire, though current movements are generally too small to warrant such an operation. Natural subsidence, generally on a small scale but locally with sinkhole development, is widespread over salt beds in the USA (Johnson, 2005), and can extend to the rare formation of large collapse sinkholes as at the McCauley Sinks in remote country in Arizona (Neal and Johnson, 2003).

38.9 Karst geohazards on sabkha

Geohazards within the sabkha environment of arid coastal plains have grown in importance with the huge increase of construction activity on the lands fringing the Arabian Gulf. Coastal sabkhas are supratidal flats up to about 10 km wide, formed of evaporites and carbonates typically with a thin cover of aeolian sand (Warren, 2006). Continental sabkhas in inland basins are dominated by halite, with the attendant hazards due to dissolution (see section 38.8). Coastal sabkha lithologies are normally only a few metres thick, but can accumulate to significant thicknesses along the margins of subsiding basins; when subsequently uplifted, the carbonate and sulphate materials are subject to erosion and the consequent development of the more conventional karst geohazards.

The special concern for sabkha relates to the modern sediments that immediately underlie the coastal plains. These include relict and buried sabkha horizons within sequences dominated by aeolian sands that extend some kilometres inland from the active sabkhas. Sediments include carbonate sands, algal mats and dolomitised facies, or are dominated by clastic quartz with variable amounts of carbonate. Typically these are poorly consolidated to depths of 5–10 m; sandy materials have weak cements of anhydrite, gypsum and calcite, which are prone to loss by dissolution when the groundwater regime is changed. Denser, more competent and more lithified sediments persist at greater depths, where any halite in the coastal sabkhas may have been lost by dissolution during diagenesis.

The primary source of a sabkha's karst geohazard is due to gypsum that occurs at shallow depths within the poorly lithified sequence. This is deposited both within the capillary zone and beneath the shallow water table. Beds of almost pure gypsum are generally no more than a metre thick; they contain nodules of anhydrite and have an open texture with small cavities (vugs) and high primary permeability. Halite is locally present, but is not in massive beds; carbonates are present, but only in some of the sand grains. Groundwater in a sabkha is dominated by brines leaking upward from buried aquifers, and these are normally saturated with respect to gypsum. Consequently, evaporation causes interstitial precipitation of gypsum, which converts easily to anhydrite with the characteristic chicken-wire texture, producing ground with locally reduced bearing capacity.

38.9.1 Sinkholes on sabkha

Natural ground subsidence on sabkha appears to be rare, as there are few known or documented examples, and natural ground cavities are almost unknown. This is because dissolution is almost impossible in the undisturbed environment of solute precipitation from saturated waters, and the minimal rainfall is too low to disturb this equilibrium. Karstic ground subsidence, including sinkhole development, is, however, widespread throughout the Gulf coastal regions, where there have been reports of multiple sinkholes developing on construction sites. Most new sinkholes are no more than 5 m across and 2 m deep, appearing in ground at the perimeter of a construction works but rarely impacting the built structures, so they have been rapidly filled and forgotten. Some much larger sinkholes have also occurred.

All recorded new sinkholes on sabkha appear to have developed as a consequence of engineering activities that include leaking pipelines, uncontrolled drainage disposal, site dewatering and drilling with water flush that is not sulphate saturated. Many of these appear to have developed from dissolutional cavities in the underlying, gypsum-rich, Neogene sequences and not in the thin sabkha cover itself. It remains uncertain as to how much cavitation is due to dissolution of sabkha gypsum horizons at multiple levels within the Quaternary sequences. But it does appear that all have been the consequences of rapid dissolution in gypsum horizons, mostly within a few metres of the surface, when stable groundwater was replaced by the input of unsaturated water subsequent on engineering works. Suffosion of the unconsolidated cover sands then produced the sinkholes (**Figure 38.13**).

38.9.2 Sabkha karst in the Gulf region

A second subsidence mechanism occurs where the new input of unsaturated water dissolves the sulphate or halite cement of the sabkha sands, allowing localised compaction and displacement of the loose material. Of the many undocumented 'collapse settlements' in Saudi Arabia, one event at a large, steel-framed desalination plant near Jubail involved a number of column bases, founded on pads 1 m below the surface level, each sinking by about 50 mm (Sabtan, 2005); this was the result of leakage from old, corroded and fractured pipelines, which had been observed for some time before the implications were appreciated. The structure was remediated with mini-piles, 15 m long, driven into stable ground. The collapse potential is high in some of these sabkha silts, but they do not show instantaneous compaction in the style of hydrocollapse, because time is required for the dissolution of the natural cement, so conventional oedometer testing interrupted by inundation is not indicative.

As the dissolution of sabkha soils and their subjacent gypsum sequences is largely or entirely at shallow depths,

Figure 38.13 A small new sinkhole, already partly backfilled, which developed within a construction site on the coastal sabkha of the Arabian Gulf, after engineering works appeared to have induced dissolution of the gypsum that lies within either the bedrock sequence or the Quaternary cover
Photo courtesy of Laurance Donnelly, Halcrow

geohazards may be avoided by the use of deep pile foundations. This is normal practice for large built structures in the Gulf region, which have, therefore, not been affected by the sinkholes that their construction has undoubtedly triggered in adjacent ground. But the sinkhole hazard persists for roads and infrastructure that lack deep foundations, and where there is any failure to control all water movement. While it appears that direct rainfall can infiltrate the ground without disturbing the chemical equilibrium, any points of localised run-off from large built structures and areas of hard standing may displace saturated groundwater and permit new dissolutional activity after rare rainfall events. Soakaways and infiltration basins, which may be appropriate on some types of permeable ground, cannot be used for rainwater disposal on sabkha and the associated coastal plains. Where cavities are detected or become apparent, remedial action may include induced compaction, sinkhole sealing and spread footings.

It may be significant that sinkholes have developed, and ground cavities have then been revealed, on sites where prior investigation drilling had found no voids or karstic features. Small ground cavities, followed by larger surface sinkholes, may have developed only after disturbance and hydrological change were induced by the construction activity. Such a timescale is likely where halite is present, and it is possible in sulphate lithologies, though it is impossible in carbonate rocks. It is also possible that borehole disturbance exacerbated the geohazard, either with chemically aggressive water flush or by linking aquifers and changing the groundwater flow within the sabkha horizons. Sealing an area of ground with grout may merely deflect dissolutional activity into adjacent ground with soluble materials, unless the causative input of water is at the same time controlled and disposed of properly. Remediation of subsided ground by grout injection may also run certain risks when water-based grouts are used in such rapidly soluble ground.

Karst processes in sabkha soils are still not completely understood, and are subordinate to flooding, settlement and sulphate attack in terms of the geohazard. But it does appear possible that all sinkhole events on sabkha and its underlying gypsum are induced by engineering activity, so the established karst mantra of 'control the drainage' is even more critical than usual.

38.10 Acknowledgements

The author is grateful to Laurance Donnelly (Halcrow Group) and Andrew Farrant (British Geological Survey) for helpful discussions over the little-known sabkha environment.

Chapter 39

Introduction to Section 4

Anthony Bracegirdle Geotechnical Consulting Group, London, UK

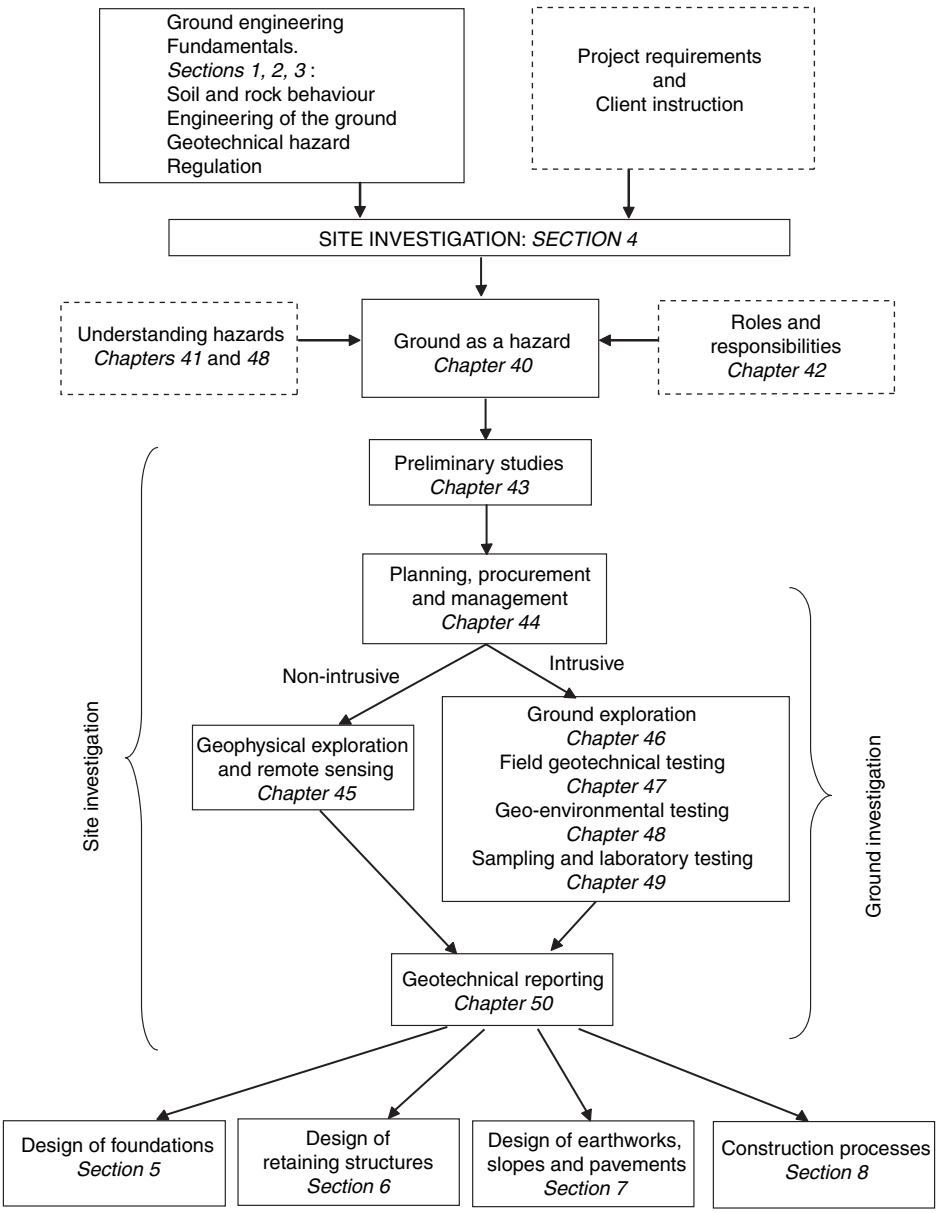

Figure 39.1 The structure of Section 4 and its relationship to other Sections

Site investigation provides a bridge to link the requirements of a specific project with its successful design and execution. Knowledge of the fundamental principles of material behaviour, ground hazards and construction risk are necessary at the outset, and these are discussed in the preceding sections.

In preparing this section, the authors have focussed on providing general guidance on principles, without overly delving into detail. For example, general classifications systems for soils and rock are provided in standard texts such as BS EN ISO 14688 (British Standards Institution, 2002, 2004) and 14689 (British Standards Institution, 2003) and reference to other detailed texts may be required for material-specific classification systems. The emphasis here is on the importance of thought and knowledge to site investigation practice and the section begins with an appeal for its application.

An understanding of land processes, topography, geology and the influence of human activity on the environment are essential. As discussed in Chapters 40 *The ground as a hazard*, 41 *Man-made hazards and obstructions* and 48 *Geo-environmental testing*, practitioners should have a rudimentary knowledge of potential ground hazards, including natural hazards, man-made hazards and contamination. The legal framework and the roles and responsibilities of all parties should be clearly defined and understood and this subject is outlined in Chapter 42 *Roles and responsibilities*.

As shown in **Figure 39.1**, the term 'site investigation' describes a process that encompasses a desk study and geotechnical reporting. The term 'ground investigation' refers to the physical activity of carrying out intrusive or non-intrusive investigations: laboratory and field testing are a part of this process. Desk studies are described in Chapter 43 *Preliminary studies* and planning and procurement in Chapter 44 *Planning, procurement and management*.

Chapters 45 *Geophysical exploration and remote sensing and geophysical exploration* to 49 *Sampling and laboratory testing* deal with the mechanics of ground investigation: geophysics, intrusive exploration, geotechnical and environmental field testing, sampling and laboratory testing. The product of the site investigation process is, of course, the geotechnical report, which, as discussed in Chapter 50 *Geotechnical reporting*, must be clear and unambiguous. The report should be as easily understood and as informative years after writing as it should be immediately after writing. To this end, it is important that any standards or classification systems used are clearly defined; not only should there be a description of what was done, there should also be an explanation of what could not be achieved and why, together with highlighted areas of uncertainty or potential error.

All too often, it is the failure of this important process that has led to compromised safety and economic loss. It hoped that the discussion within this section will be of interest to readers and help practitioners cross the bridge between aspiration and the successful execution of projects.

Chapter 40

The ground as a hazard

An appeal for an intelligent view of the ground

Jackie A. Skipper Geotechnical Consulting Group, London, UK

How humans interact with hazardous ground conditions governs the resultant ground risk. Potentially hazardous ground conditions frequently attract engineering development because of important aesthetic or economic considerations. Many are successfully undertaken, but success requires sufficient investment, sound ground knowledge and an appropriate design. Yet in many projects, the ground is the least well-understood material, and this can lead to expensive problems being discovered during the construction phase.

This chapter encourages the reader to become actively knowledgeable about the ground of their project by first discussing the main types of geological hazard which may be encountered on a UK engineering site or project. Secondly, sources of ground information (many of which are now freely available online) are discussed, along with a system by which these can be interrogated to increase knowledge of ground conditions and design an effective site investigation. Finally, the use and communication of an intelligent understanding of these conditions has been shown to be extremely important in the success of engineering projects, ensuring that the engineer avoids becoming a victim of potentially hazardous ground.

40.1 Introduction

Humans often see the ground as hazardous. However, the Earth is simply influenced by gravity, water, heat or lack of it, plants and animals, and the sun. Humans often make the ground hazardous (or rather, it is how we behave that increases risk) by where we have chosen to live and work. For example, crumbly cliffs may be hazardous, but they do not represent a risk until humans decide they like the view from the steep crumbly cliffs overlooking the sea, and make their home there. The success of humans as a species has propelled us to develop, live and work in areas which were previously uninhabited (e.g. steep mountains, bogs), often for good economic or social reasons. We have remarkably short memories of risks related to hazardous ground events and we frequently emotionally weight an advantage (e.g. a lovely view) over a disadvantage (unstable ground). Fortunately, because of modern advances in civil engineering, there are few environments that we cannot engineer if enough money, a good understanding of the ground and a suitable design are invoked. Ultimately, ground hazards only become risks if they are unforeseen and unmitigated (for detail on ground profiles see Chapter 13 *The ground profile and its genesis*). This introduction is therefore an encouragement to understand the ground better before attempting to engineer it.

Geotechnical engineering is one of the most challenging of engineering specialities because the ground is far more diverse and variable than any man-made material. Considering how important the ground is in the success of most construction projects (amazingly, it frequently keeps buildings upright, sometimes for many hundreds of years), it is one of the poorest understood of the materials we utilise on a regular basis. On the majority of projects, for example, we have a far better sampling and testing regime and an infinitely better understanding of the behaviour of concrete and grout mixes on site than we have of the ground – our ultimate material. The exception is, of course, when a contractor wants to make a claim for unexpected ground conditions.

On some projects it is clear that people end up as victims of the ground rather than understanding and mastering it. 'Understanding the ground' is, however, not the same thing as doing a 'preliminary investigation' (see Chapter 43 *Preliminary studies*) and a 'design investigation' (see Chapter 44 *Planning, procurement and management*). Understanding is the process by which ground information is made into a ground model, augmented if necessary, communicated to all the relevant parties in the project, and if possible, added to throughout the project.

Why bother understanding the ground better? Why not, as an engineer once asked, just drill a couple of boreholes, test what comes up and base your design on that? My response was to use an analogy: if the ground is represented by a wedding cake at the bottom of a black plastic bag, and the borehole is your hand reaching into the black plastic bag, completely blind, to grab a piece, you may end up basing your design on a rosebud. Boreholes represent a miniscule fraction of the ground and, moreover, the ground frequently does not consist of straight lines between two boreholes. Hence the ground in between the boreholes will not necessarily be the same as that recovered in the boreholes.

Many companies try to save money by having a 'cheap' site investigation, and this is a process in which data may be lost. As Chapman amply discusses in Chapter 7 *Geotechnical risks and their context for the whole project*, saving money with a 'cheap' site investigation is practically the worst investment

in the construction industry over the long term – hence the inverted commas. However, despite improvements in standards of site investigation over the past few years (see Chapters 42 *Roles and responsibilities* to 48 *Geo-environmental testing*), there will always be economic downturns. 'Cheap' site investigations will always be sought and may not be avoidable, but can miss important changes in the ground. This is not only because fewer boreholes, maybe of a cheaper type, will give you less data, but because low-paid staff are frequently poorly trained in what they are logging – taking samples for testing, and the testing itself. Even with a full EC7-approved site investigation it is possible for important information about the ground to slip through the cracks between the specification and the interpretative report. So it is important to make the most of every piece of available information.

In geotechnical engineering we can compensate for less adequate site investigations by adopting a conservative design – by taking no risks, or alternatively by taking the basic minimal information available and taking the risk that the ground will be fine. However, those extremes have been shown repeatedly (Chapman and Marcetteau, 2004) not to be the smartest and most cost-effective solutions. Understanding the ground to the best of our ability, and designing with the ground in mind, makes the best economic sense (see also Chapter 2 *Foundations and other geotechnical elements in context – their role*).

40.2 Ground hazards in the UK

Most of the common types of hazardous ground in the UK are dealt with in this volume and the relevant sections are linked. These ground hazards can generally be grouped into three categories: geological hazards, geomorphological and topographical hazards, and anthropomorphic hazards, and are discussed below.

40.2.1 Geological hazards

This category includes the results of events that occur naturally on Earth which we consider unreasonable. Examples include dramatic geohazards such as volcanic activity – resulting in debris or mudflows, and earthquakes – resulting in the possibliliy of tsunamis. In the UK we are generally considered low risk for these hazards since we are a long way from tectonically active centres. However, we do have occasional earthquakes in certain areas and have (in the past) had tsunamis due to earthquakes or underwater landslide failures. Seismic hazards do therefore need to be considered for long-life projects, sensitive projects (such as large tunnels, nuclear power stations) and coastal projects. Volcanoes are even less common in the UK – the last ones to erupt on the UK mainland were probably about 55–60 million years ago. However, bear in mind that *many* of our soils and rocks contain layers of volcanic ash laid down or reworked within them, and these ash deposits frequently contain swelling clays which may precipitate or exacerbate landslips, slow down tunnelling operations, and impede soil handling and re-use (see section 40.2.2). If in doubt, the clay minerals need to be analysed.

The British Geological Survey (BGS) has very useful information, historical data and risk maps for these tectonism geohazards on their website.

The second part of this category includes ground types which are harder, weaker, softer, looser, have more and bigger holes or caves in them, are more variable, less stable, more aggressive, or contain water or gas at higher pressures than would be desirable. These types of ground are discussed in great detail in Section 3: Problematic soils and their issues, while folded or faulted rocks are dealt with in Chapter 18 *Rock behaviour*.

In an ideal engineering world, all geological deposits would be laterally extensive, of uniform and predictable thickness, and homogeneous in nature. Unfortunately the ground is usually variable. While it is possible to be exceptionally lucky and encounter tens of meters of thickness of well-behaved, unweathered, unfaulted, horizontally-bedded strata across an entire project site, it is actually not the norm. The reason for this is the variability of processes which contribute to the deposition of soils and rocks, and which alter them afterwards (see Chapter 13 *The ground profile and its genesis* for more detail). Generally the most uniform, homogenous and laterally extensive rocks are marine sediments, which can be deposited as essentially the same type of soil or rock over hundreds of thousands of kilometers; but do not be lulled into a false sense of security. Even amazingly thick, fully marine deposits sediments like Chalk, Carboniferous Limestone and London Clay vary vertically in strength, texture and permeability due to changes in water depth while they were being deposited. The nearer to the shore we get with environments of deposition, the more variable the sediments get (think Carboniferous Coal Measures, which were deposited in swamp to delta environments, or the Mercia Mudstone Group, which varied from desert to floodplain in origin). In addition, with worldwide fluctuations in sea level and the extremes of climate variation over geological time, we can end up with a stack of potentially very variable sediments indeed. Once we superimpose on this the deposition or intrusion of igneous rocks, or start to look at the processes of folding, faulting and metamorphosis, this variability increases further. However, it is important to remember that variability is still only a potential risk if it is not anticipated.

40.2.2 Geomorphological and topographical hazards

This category includes all the hazards which are primarily concerned with how gravity and erosion affect the ground, and how water interacts with the ground near or above its surface. Landslips and landslides, mudslides, coastal erosion and flood risk all come into this category. Tectonism (the action of the Earth's tectonic plates moving in relation to each other, resulting in, amongst other things, mountain-building events) has a lot to answer for. Topographically higher ground is (in geological terms) just waiting for gravity to act on it, to be weathered and fall down, to be talus until it falls further and gets washed into a river, and eventually it breaks down into sand and gets deposited in the sea as sediment. It is important to recognise once more that humans love to build in high places, near

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the sea and everywhere in between – but that hilly areas can fall down, and that coastal and low-lying areas often flood.

40.2.3 Anthropomorphic hazards

In the last few thousand years, humans have had an enormous impact on the surface and sub-surface of the Earth. In the last 200 years we have changed the planet more than in all the previous several thousand years put together. Our skills as humans have, in this short time, enabled us to use fossil fuels to drive transport and industry (often leaving large holes in the ground where they were abstracted from) and our skills in civil engineering have enabled us to master many formerly forbidding environments and locations.

An awareness of how an area has changed over time may reveal a wide range of human activities, many of which will have implications for particular projects. For example, in the area of east London where I used to live there was, in chronological order: a Bronze Age trackway development (archaeology), a coal gas production plant (probable contamination), Joseph Bazalgette's Northern Sewage Outfall (Victorian tunnels and obstructions), and past and present industry associated with the London Docks (archaeology, pollution *and* obstructions). Superimposed on these layers and issues were the abundance of munitions dropped in the area during the Second World War 1939–1945 (possible unexploded ordnance), the relatively new Dockland Light Railway and its tunnels, and normal everyday services. There are many companies who will, for a reasonable fee, help steer a way through this potential multiplicity of man-made hazards, provide site-specific environmental risk information and historical mapping for a given site area.

40.3 Predicting what the ground may have in store

Using personal computers, we are fortunate to be able to access more information about the ground of a potential site faster than ever before. Programs such as Google Earth can give us aerial imagery which previously required long waits or searches, and possibly special viewing equipment. Not only can we look up our site in seconds, but in one click we can discover what volcanoes or earthquakes have occurred nearby (try ticking Gallery in the Layers folder and then go to Old Hawkinge in Kent if you want to find an earthquake in the UK), the approximate elevation, and distances between interesting points. Using Street View within Google we can get a close-up of topography and buildings in the area. Using the Historical Imagery facility (in the View dropdown menu) we can even see if the area has changed over the previous few years – useful for landslip or redevelopment projects.

Armed with Google Earth and a geological map of your site area, it is possible to assemble a great deal of quality information to assist your understanding of the ground in your project area within an hour or so, using the topography–water–anything odd (TWA) system:

Topography Running the cursor over the aerial view of the site and the surrounding area will give you an idea of variations in topography. The next question to ask is – does the topography make sense and, if not, why is it like this? If you look at the geological map, is there an obvious reason?

Water Where is the water in this area? Is it in rivers, streams, lakes, marshes, an estuary, the sea? Does it make sense where the water is, or is there poor drainage due to impermeable strata? Is the site in an obvious flood risk area (i.e. at or near sea level, or at the same level as the local rivers run)? Is there no water at all in this area? Why? Where could it have gone?

Anything odd? Is there anything that does not seem quite right, or any colours or shapes on the ground that do not make immediate sense in terms of natural or human activity? Are there any areas where buildings 'should be' but are not? Road names can be useful indicators of geological or former engineering hazards. Are there road or lane names near your site which include such words as: Watermeadow, Flood, Spring, Cave, Swallow or Swallowhole (possible flood or solution hazards), Brick, Kiln, Mine or Quarry (former mining or quarrying), Undercliff, Zigzag, Slip (possible ground instability problems)? Cave or Dene can also indicate natural or man-made cavities. In Google Earth, Street View can be another useful source of information, picking up uneven ground surfaces, major cracks in walls, and repeatedly re-made roads.

If, for any reason, you cannot use Google Earth, there are an increasing number of other remote viewers which are free to use such as Yell.com and Bing Maps, both of which allow 3D inspection of built sites in UK cities.

40.4 Geological maps

Geological maps can, to the average engineer, be slightly confusing. They use bizarre colours and odd symbols. However they do contain vast amounts of useful information if you have a little patience. If you want help, ask a geologist or put 'how to read geological maps' into a search engine. A note of caution: engineers often consider geological maps to be 'gospel'. They are not – they are produced by clever geologists who do a lot of field work, incorporate as many good quality boreholes as possible, and then extrapolate their findings. Without X-ray vision, their geological maps, while a very good best guess of what the ground consists of, can occasionally be wrong. Another important point to mention here is that just because a geological formation is called Kimmeridge Clay, or Lias Clay, or Gault Clay, etc., it does not mean that the formation is only clay. Likewise, formation names with 'sand' at the end (e.g. Lower Greensand, Arden Sandstone) rarely consist entirely of sand. Soils and rocks of any age or name usually contain naturally occurring harder layers, or weaker layers, or indeed sandier layers – be prepared and read the geological map carefully. Again, the BGS has very useful tools on their website such as the lexicon of named rock units (also useful for looking up soils – 'rock' means rock *or* soil in this instance). The BGS

onshore borehole historic database is now largely free, too, and in combination with the lexicon will probably tell you far more than you ever thought you needed to know about the strata in the area of your project, and this information will act as the basis for a refined ground model based on a well-designed site investigation.

40.5 Conclusions

Having a better understanding of the ground is a huge leap forward and will help enormously in planning and designing for a project, but what appears to make the greatest difference is communicating this understanding to others (Skipper, 2008). I first experienced this principle in 2003 when working on the Dublin Port Tunnel, where I found that communication of the ground model to *all* levels of staff (from site investigation staff to designers and foremen to site workers) made a huge difference to their collaboration, communication and feedback. This improved level of understanding allowed the use of the observational method in what was complex and challenging geology in a very sensitive location (Long *et al*., 2003). Since then I have been involved in the use of this principle in a wide range of projects from the small to the very large. I have seen it result in a wide range of improvements, from better specified site investigations to improved ground descriptions and interpretations, in turn leading to optimised design and better risk management. So to conclude, an intelligent understanding of the ground makes the best technical and economic sense, and communicating this understanding with, and to, others, maximises this value to engineering projects.

41.7	Services	564
41.8	References	564

Man-made hazards in the ground take many forms. The principal forms discussed here are voids, contamination, unexploded weapons, obstructions and buried services. Many different geological materials have been mined in the UK over thousands of years. These include materials used for fuel (coal and oil shale), a wide variety of metal ores, non-metals and stone itself. Voids left by mining activity occur in a wide range of geological settings and both the mining methods and the nature of the voids themselves also are similarly varied. References are made to methods of void detection and treatment. Man-made contamination in the ground is common in previously developed sites, especially those with an industrial history. A legacy of war is the risk of encountering unexploded munitions in the ground. Processes for minimising the risks associated with contamination and unexploded weapons are discussed in this chapter. Man-made obstructions in the form of buried structures or parts of structures are commonly encountered in ground investigations and ground works. These can be particularly hazardous if they contain voids. Underground services are an almost ever-present hazard for ground investigations. Risk minimisation techniques are also discussed for these classes of hazard.

41.1 Introduction

This chapter briefly describes man-made hazards and obstructions that might delay or compromise the implementation of ground investigations. These man-made hazards and obstructions may well also affect subsequent design or construction, creating obstructions to penetration of foundations, hard areas or variability. This is discussed in only a limited way here.

In the context of ground investigations a hazard is taken here to be something man-made within the ground that has the capacity to cause harm in an occupational health and safety sense. Above-ground operational health and safety hazards are not discussed.

An obstruction is taken here to be something man-made within the ground that has the capacity to delay or prevent progress of a ground investigation. Some examples of pre-ground-investigation bureaucratic processes that can cause delay if not addressed are also given.

The possible occurrence of both the physical and bureaucratic issues raised here should be addressed in the desk study, and the scope and form of any subsequent ground investigation should be adjusted accordingly. See Chapter 43 *Preliminary studies* for more detail on the scope and content of desk studies.

41.2 Mining

Great Britain has a long and rich history of mineral extraction using mining techniques, dating back to Roman and even Neolithic times. Man's desire to obtain minerals of special value and use has driven the development of mining activity through time. As a result significant areas of land contain mined ground and a legacy of ground instability.

Historical mine workings present a significant subsidence hazard to existing and new-build construction as well as a risk of personal injury or death. From a health and safety perspective it is therefore necessary to identify where the mine workings are, the nature and extent of the void space and the degree of risk posed to the surface.

For coal mining areas the investigation and treatment of workings and mine entries needs to be notified and agreed in advance with the Coal Authority. Outside of coalfields it is usual to agree such matters with the local council, who may wish to involve the Mineral Valuer and the Health & Safety Executive. Awareness of the legal framework, such as the Mines and Quarries Act 1954, is important as well.

41.2.1 Mineral types

From a historical mining perspective it is convenient to think of mineral types in terms of coal and related minerals (e.g. fireclay and gannister, also iron ore and oil shale) extracted within the many coalfield areas of Great Britain (see **Figure 41.1**) and those minerals that were mined outside of coalfield areas.

Minerals that were extracted in non-coalfield areas include metal ores (e.g. iron, lead, zinc, copper, silver, gold, tin); non-metals (e.g. fluorspar, calcite, barytes); evaporites (e.g. gypsum and salt); and stone (e.g. slate, sandstone, limestone, chalk). For reference, the recorded spatial distribution of non-coal mining is also shown in **Figure 41.1**.

Currently mining is restricted to coal, salt, potash, gypsum and others (silica sand, limestone, barytes, fluorspar, slate and haematite). Further details can be obtained from publications such as the *United Kingdom Minerals Yearbook* (Bide *et al.*, 2008).

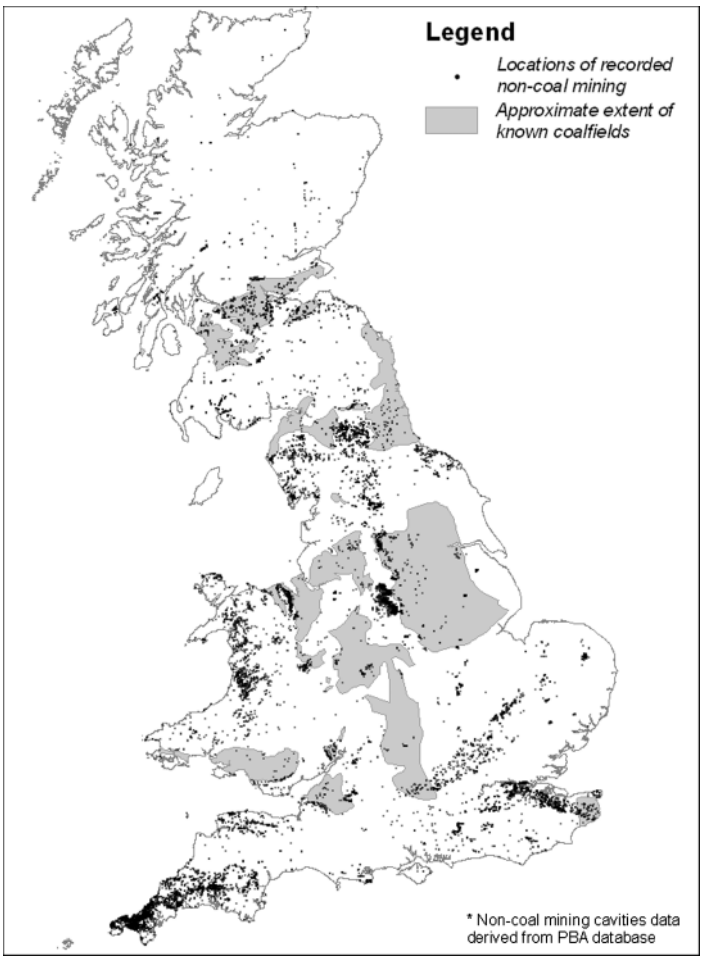

Figure 41.1 Spatial overview of mining in Great Britain

41.2.2 Methods of mining

Methods of mining have changed with time and technology, but also reflect differing geological settings.

A mineral at outcrop would be extracted by quarrying. However, as the overburden rock/soil thickness that needs to be removed from above the mineral layer increases, extraction by adits driven through the quarry face becomes more efficient for continuing the extraction underground without the need to remove the overburden (see **Figure 41.2**). For minerals that occur at shallow level in layers that do not dip steeply the next simplest style of mining is the 'bellpit'. A narrow, unsupported shaft was dug down to the mineral layer and the extraction continued outwards from the shaft base radially to form a 'bell shape' (see **Figure 41.2**). Other regional variants were also developed, for example in the chalk of southern and eastern England, such as deneholes, chalkwells and chalkangles (Edmonds *et al*., 1990).

Later, more advanced forms of mining referred to as 'pillar-and-stall workings' were developed. The workings, accessed via shafts and adits, comprised a series of tunnels (stalls) excavated outwards from the entry point, linked by cross-tunnels to create a grid of intervening pillars to support the mine roof (see **Figure 41.2**). For coal extraction the pattern of tunnels and pillars that were created, and the names referring to them, varied regionally (Littlejohn, 1979).

For many minerals (e.g. limestone, chalk and gypsum) this form of mining continued as the preferred method of working. However, for coal, the mining style was further developed into the 'longwall' method. This technique involved coal being completely extracted along a 'longwall' face, progressing forwards below large areas. Access to the working face and removal of the mined coal was achieved via connecting, perpendicular roadways. Propping was used to support the working face. In the areas between the roadways the roof was allowed to progressively fail and subside as the working face moved forward. The original mines were hand-dug, but in time the process became mechanised (see Healy and Head, 1984).

Other methods of mining were developed to suit the particular characteristics and geological setting of the mineral. Where a mineral exists in the form of an irregular ore body or steeply dipping vein it is common to follow the depositional pattern extending through the host rock. In limestones the ore or vein may be accessed via naturally occurring karstic cavities. Larger ore bodies or veins can be mined upwards (stoping). These forms of past mining are typical in areas like the Pennines, North and South Wales, Peak District, Lake District, Mendip Hills and Cornwall.

The soluble nature of salt has been used to extract it by brine pumping (solution mining), particularly in parts of Cheshire (Bell, 1975), Lancashire, Somerset, Staffordshire and Worcestershire.

41.2.3 Mining history and information sources

Many of the mining techniques described above date from the Middle Ages and earlier; however, mining activities notably intensified from the late 1600s, through the 1700s and 1800s, continuing into the 1900s as well. It is evident that mining activities may have started and ceased in an area before publication of the first-edition Ordnance Survey (OS) maps (typically dating from the 1870s/1880s). Consequently, reliance on the use of historical OS maps alone should be treated with caution when researching the history of a site in a mining area.

Information on coal and non-coal mining is available from a wide variety of sources, often not mainstream or easily accessible. Specialist knowledge may be required to fully interpret and understand the data. However, since the early 1990s a number of national and regional studies have been published (e.g. Arup Geotechnics, 1990), making information more accessible. The recorded mining data have been captured digitally and made available by the British Geological Survey and Peter Brett Associates LLP. For coalfield areas a large digital mining archive is held by the Coal Authority. Other smaller collections of data are held by various councils, and caving and mining-history organisations. Obtaining relevant mining information from these sources is essential for a desk study to check for the potential for current and past mining activities.

41.2.4 Ground instability hazard

Collapses over abandoned mines pose a ground instability hazard. Common subsidence triggers include leaking water-carrying services and soakaways, changes in water table level, heavy rainfall, disturbance by excavation and surface loading.

The most common form of instability relates to the collapse of old shaft entries, often left poorly sealed and backfilled. Large ground movements can result if a shaft has deteriorated, and failing ground can move both vertically down and laterally into open, connected void space at depth (see **Figure 41.3**). Subsidence may also occur over shallow workings and adit entrances, but again depends on the failure mechanism and the extent of remnant interconnected mine void space at depth.

Large-scale mining of a succession of coal seams can produce widespread subsidence troughs, problematic for properties and infrastructure at the surface (see Healy and Head, 1984). Other forms of longer-term ground movement over coal mining areas can be associated with fault lines and major discontinuities where stress relief may be concentrated (e.g. Donnelly *et al*., 2008).

A range of ground instability problems caused by abandoned mines associated with a variety of other mineral types is presented in the Technical Review Case Study Reports prepared by Arup Geotechnics (1990) as part of a national review study.

Discussion of how local authorities and developers should take account of ground instability relating to mining, in the context of planning and development, is set out in PPG 14: Development on Unstable Land (Department of the Environment, 1990), Annex 1 (Department of the Environment, 1996) and Annex 2 (Department of the Environment, Transport and the Regions, 2000).

41.2.5 Investigating mine workings

A wide variety of direct and indirect investigation techniques exist for detecting mine workings. For investigations of coal mine workings advance permission must be obtained from the Coal Authority.

Indirect techniques include the use of aerial photography and satellite imagery to look for shafts, adits or associated surface excavations, spoil heaps and infrastructure. The viewing of historical images as well as utilising different parts of the electromagnetic spectrum can be useful. There are many texts describing the types of analogue/digital data available together with methods of image manipulation and interpretation (e.g. Lillesand *et al*., 2008).

Other forms of indirect techniques comprise geophysical surveying. In a mining context the techniques need to be sensitive to the detection of open voids, partially to fully collapsed voids, water-filled voids, broken or collapsing rock/soil sequences, Made Ground backfills, brick or metal shaft linings, etc. Depth to the mine void and the surface environmental setting of the survey both play a part in the final choice of survey – if a survey is even feasible. There are many texts describing the theory and practice of geophysical surveying (e.g. Reynolds, 1997).

Again, there is a range of direct investigation techniques that can be used to detect mine workings. Considerations for the choice of method depend on a number of factors, such as, geology, depth of mineral, style of mining, whether intact or collapsed, access, and health and safety risks. The potential for hazardous gas or polluted water escapes also needs to be evaluated. In the case of soluble strata or collapse situations the choice of drilling flush is important. Inaccessible open voids may be viewed directly using down-hole closed circuit television (CCTV) cameras, which allow the style of mining and condition of the workings to be evaluated. In circumstances where there is a need to measure the size and orientation of open workings, down-hole laser survey techniques can prove useful (see **Figure 41.4**). Where access is possible and safe, direct visual inspection can then be undertaken (see **Figure 41.5**). The various investigation techniques are described in detail elsewhere in this manual.

41.2.6 Mine working investigation case history

In order to illustrate how a combination of indirect and direct investigation techniques can be used effectively to detect historical mine workings, the following account briefly describes the investigation approach at Field Road, Coley, Reading (SU710728 area).

A major ground subsidence occurred on 4 January 2000, causing the collapse and loss of the fronts of two houses, their gardens, the pavement and adjacent road. The collapse measured about 9 m across and was several metres deep (see **Figure 41.6**).

After initial infilling of the collapse a surrounding ring of close-centred dynamic probes was undertaken to establish the likely cause of the collapse. The results revealed a series of open voids that were interpreted to be old chalk mine workings, having a mine roof level at about 7.5 m to 11 m below ground level (bgl) and a mine floor level at about 13 m to 14 m bgl. A typical probing profile is shown in **Figure 41.7**. The ring of probes was extended outwards in a grid pattern that revealed yet more mine workings forming an irregular pillar-and-stall style of working. A smaller number of light cable percussion boreholes were positioned strategically to provide sampled geological profiles to confirm the interpretations being made for the probing profiles. A good geological correlation was achieved (see **Figure 41.7**).

To check how far the mine workings might extend, a microgravity geophysical survey was conducted initially as a trial along the road, south of the collapse. The trial was successful in detecting the pattern of mine workings as a series of Bouguer anomalies, and so the survey was extended further along the road in a southerly direction and outwards into the adjacent garden areas. The survey interpretation was then checked by carrying out additional dynamic probes. **Figure 41.8** shows an example of the microgravity survey results compared with the actual mapped mine workings detected by dynamic probing. The geophysical survey results demonstrated that the microgravity technique provides a good indication of where mine workings are to be found, so useful in a reconnaissance sense, though locating the exact mine tunnel positions was less precise.

When faced with the task of mapping out the pattern and extent of larger-scale pillar-and-stall mine workings there is a tendency to use a grid pattern of exploratory holes. If the mine workings are in an advanced state of collapse, or have collapsed, then this approach may be unavoidable. However, where there are sections of open, intact mine workings it is possible to reduce the number of exploratory holes being bored.

Figure 41.6 A major ground subsidence, 4 January 2000
Courtesy of Peter Brett Associates LLP

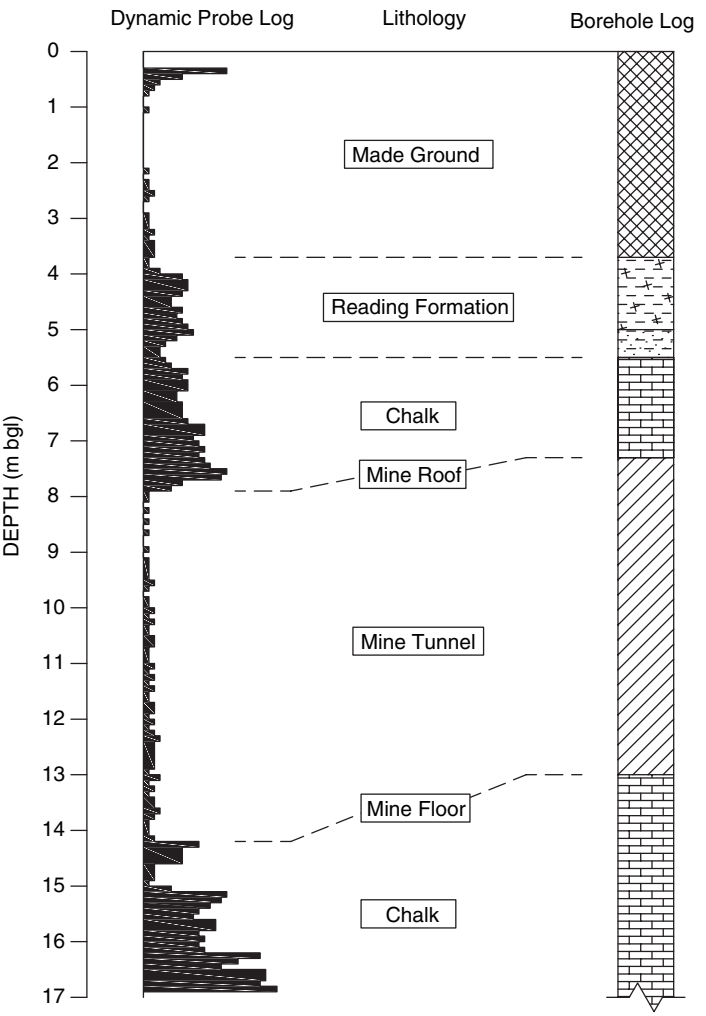

Figure 41.7 A typical probing profile

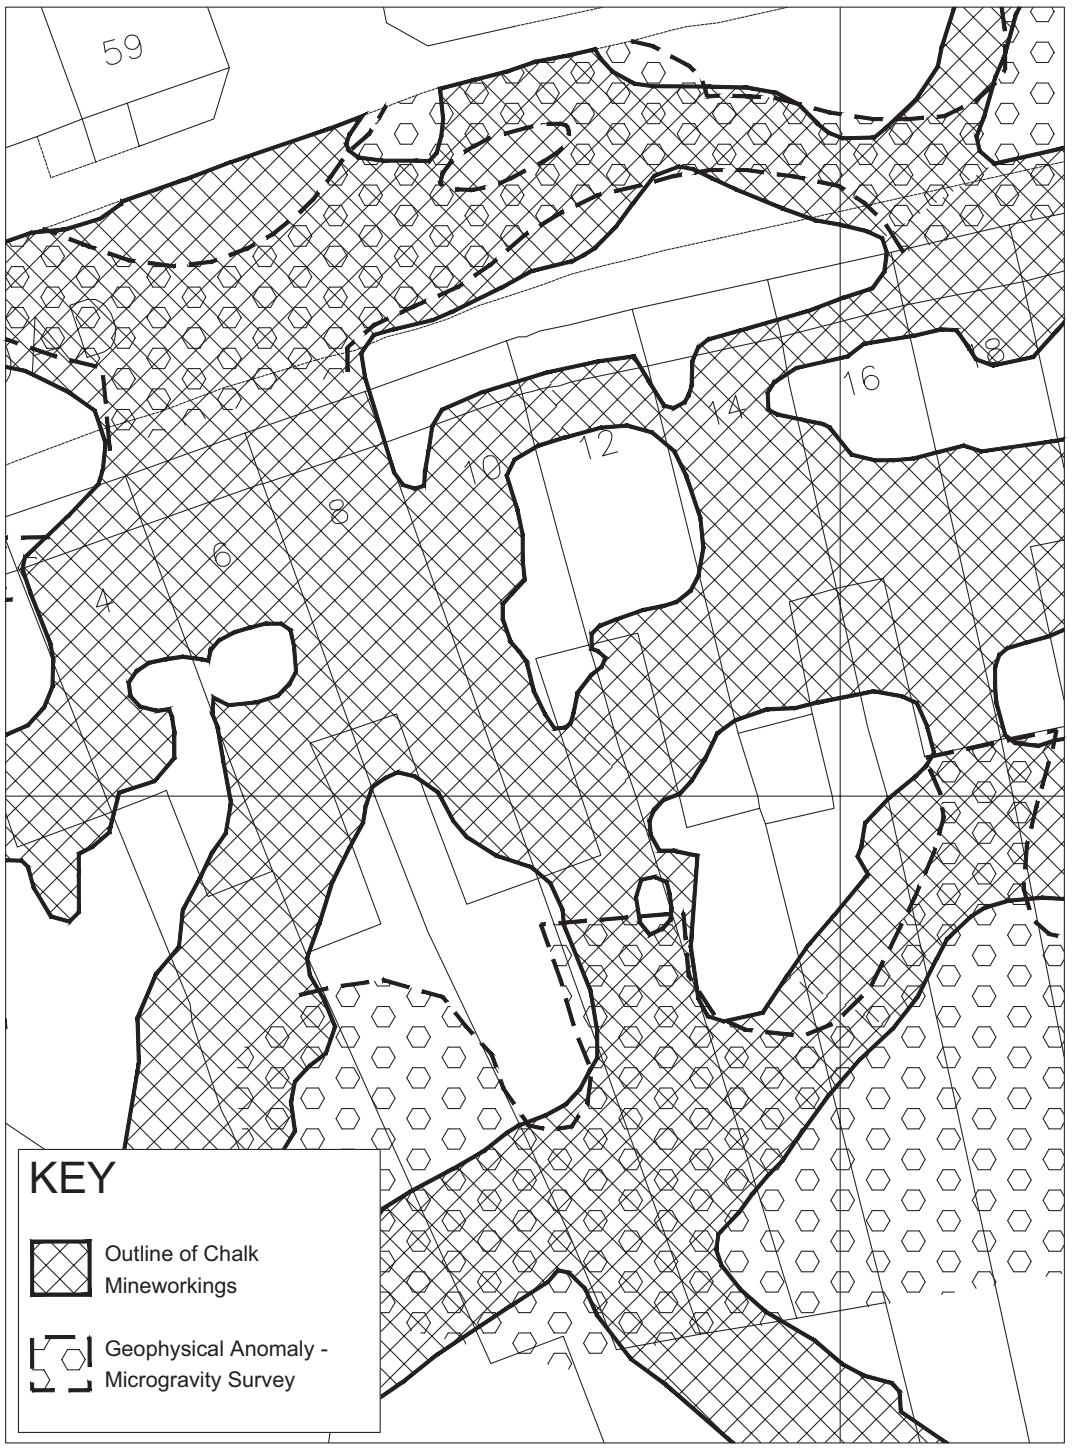

Figure 41.8 An example of the microgravity survey results compared with the actual mapped mine workings detected by dynamic probing

At Field Road, for example, if a probe encountered a void, the access to the void was enlarged using a window sampler borehole and plastic casing inserted into the hole to the roof level of the void. A small diameter borehole CCTV camera was then introduced via the casing, and a visual survey of the mine void was undertaken (see **Figure 41.9**). The direction of the mine tunnel was inferred from the survey, and the next probes were positioned accordingly, some 5–10 m away to intersect the tunnel further along, and the survey process was repeated again. This offered a cost-effective way of mapping the mine tunnels present, greatly reducing the numbers of probes required compared with adopting a conventional grid-pattern approach.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 41.9 Visual survey of a mine void using a small diameter borehole CCTV camera

Where dynamic probes cannot penetrate to sufficient depth to map mine workings, or angled holes beneath a building are required, rotary drilled boreholes can be used instead (see **Figure 41.10**).

Figure 41.10 An example of the use of rotary drilled boreholes
Courtesy of Peter Brett Associates LLP

41.2.7 Treatment of mine workings

Depending upon the nature and extent of the mine workings defined by the ground investigation, there are a variety of remedial mine treatment options. It is often the case that historical mine workings will comprise a mix of open voids, collapsed ground and further disturbed/broken ground over and around the mine workings.

Sometimes access to the mine workings may be possible from ground level, providing a means to infill and stabilise the workings using grouting techniques, e.g. progressive infilling behind shuttering (see **Figure 41.11**).

Often, though, it is unsafe to enter the mine workings, in which case the infilling works have to be undertaken from the surface, involving grout injection via boreholes. Open voids can be stabilised using bulk infilling methods (e.g. pumped as grout or another filler such as sand or pulverised fuel ash (PFA) washed in using water). Broken rock sequences overlying collapsed workings can be strengthened using pressure grouting techniques (high slump grouts) to seek out and infill dispersed voids or within unconsolidated sequences using compaction grouting techniques (low slump grout) to compact the loose material.

Where shaft entries have collapsed they may be infilled with a granular material, which is then solidified with a cementitious grout as necessary to counter settlement and loss at the base with time. The shaft top is then capped with a reinforced slab, whose depth below surface and size depends upon the nature of the near-surface ground conditions, shaft diameter and construction (see Healy and Head, 1984).

Figure 41.11 Infill and stabilisation of mine workings using grouting techniques
Courtesy of Peter Brett Associates LLP

Often raft foundations are utilised in areas of past mining to protect the structure from subsidence damage. However, if there is still a risk of voids rising to the surface, consideration needs to be given to the design span and cantilever of the raft versus the likely size of crown hole. In situations where the near-surface ground conditions are of poor quality but the risk of subsidence is deemed to be low, then piled foundations can be considered.

For shallow workings it might be feasible to pile down through the mine floor level, end-bearing into the stable ground below. Such piles need to be sleeved through the ground above the mine floor level to resist negative skin friction as the ground settles/collapses and to free-stand through voids if necessary.

In mined areas consideration also needs to be given to protecting services and infrastructure against subsidence damage. Some additional protection can be given by placing high-tensile-strength geogrid within the road pavement construction and below service runs.

The various ground treatment techniques and foundation types are described in detail elsewhere in this manual.

41.3 Contamination

Contamination of the ground by pollutants can be both a hazard and an obstruction. The nature of any possible contamination should be addressed in the desk study and this should be carried through to construction design and management (CDM) risk assessments for site activities by the investigation designer, regardless of the status of the investigation in CDM terms. The ICE Ground Investigation Specification (Site Investigation Steering Group, 1993) has a simple but somewhat dated site health and safety classification scheme for contaminants. This is useful in a contractual sense and should be completed, but it does not replace the need for a comprehensive designer's risk assessment. See Chapter 48 *Geo-environmental testing* for further discussion of the philosophy, sampling and testing of potentially contaminated ground.

If it is not addressed directly, contamination can also be a significant bureaucratic hazard in the UK. Where ground investigations are for projects involved in the Local Authority Planning process then third parties (the Local Authority and the Environment Agency (EA), or SEPA in Scotland) have a significant interest in the content of ground investigations and can control their content by the use of Planning Conditions. See Planning Policy Statement 23 Annex 2, which is available online (see section 41.11).

Failure to consider the needs of the Local Authority or the EA/SEPA or consult with them when designing a ground investigation could result in further investigation being required by planning condition. This is a significant matter. Such conditions would typically require an additional investigation to be completed and assessed before development could be commenced. The text of typical conditions is given in appendix 2B of Planning Policy Statement 23 Annex 2. An example is given below; it is clear that failure to discharge this condition could lead to a great deal of delay. This type of condition would apply to any type of site, even those where the apparent risk of 'contamination' appears to be very low. What the Local Authority seeks is a demonstration that the risk of contamination is negligible, or measures to deal with any confirmed source–pathway–target linkages.

> 'The development hereby permitted shall not begin until a scheme to deal with contamination of land and/or groundwater has been submitted and approved by the LPA and until the measures approved in that scheme have been fully implemented. The scheme shall include all of the following measures unless the LPA dispenses with any such requirement specifically and in writing:
>
> 1. A desk-top study carried out by a competent person to identify and evaluate all potential sources and impacts of land and/or groundwater contamination relevant to the site. The requirements of the LPA shall be fully established before the desktop study is commenced and it shall conform to any such requirements. Two full copies of the desk-top study and a non-technical summary shall be submitted to the LPA without delay upon completion.
>
> 2. A site investigation shall be carried out by a competent person to fully and effectively characterise the nature and extent of any land and/or groundwater contamination and its implications. The site investigation shall not be commenced until:
>
> (i) a desk-top study has been completed satisfying the requirements of paragraph (1) above;
>
> (ii) The requirements of the LPA for site investigations have been fully established; and
>
> (iii) The extent and methodology have been agreed in writing with the LPA. Two full copies of a report on the completed site investigation shall be submitted to the LPA without delay on completion.
>
> 3. A written method statement for the remediation of land and/or groundwater contamination affecting the site shall be agreed in writing with the LPA prior to commencement and all requirements shall be implemented and completed to the satisfaction of the LPA by a competent person. No deviation shall be made from this scheme without the express written agreement of the LPA. Two full copies of a full completion report confirming the objectives, methods, results and conclusions of all remediation works shall be submitted to the LPA.'
>
> Appendix 2B, Planning Policy Statement 23 Annex 2

Ground investigations have the ability to promote the transport of contaminants. Great care needs to be given to the design of ground investigations where mobile contaminants exist adjacent to aquifers or surface waters. Prosecution can be the result of a careless approach. See Chapter 48 *Geo-environmental testing* for more detail.

41.4 Archaeology

The possibility of archaeological remains being present on a site should be addressed in the desk study, preferably by approaching the Local Authority Planning Department in the UK. Where archaeological remains are likely to be found the Local Authority is likely to seek to influence the content and form of the ground investigation. This may have a significant impact on the duration, content and conduct of the investigation, and early consultation is strongly recommended. Specific archaeological investigations may be required, either as part of the ground investigation or as a separate exercise. See Chapter 43 *Preliminary studies* for more detail on desk studies and archaeology.

The archaeological content of combined archaeological and geotechnical investigations could range from a watching

brief for trial pits and boreholes, where an archaeologist examines the near-surface deposits as the geotechnical investigation passes through them, to specific boreholes and trial pits. Where archaeology-specific boreholes are required they usually involve continuous sampling of near-surface deposits. The destructive examination of these continuous samples, often off-site, usually precludes the use of these parts of the borehole for any geotechnical use. The Institution of Civil Engineers produces a useful standard specification and contract terms and conditions for archaeological investigations.

Finding archaeological remains, especially human bones or burial grounds, can cause significant delay to a ground investigation. Where bones are found that are suspected to be human the police should be called immediately. In these cases the police are likely to initially consider the site to be a crime scene. This will cause delay; however, the consequences of not contacting the police could be significantly more onerous. Testing for specific bacteria and viruses may be required, depending on the context of the find.

Archaeology can present significant restrictions to design and construction works. In a number of instances the archaeology must be left in place, and either bridged over or minimally disturbed by piling. See the English Heritage (2007) guidance note on piling and archaeology. Construction may be subject to delays in a similar fashion to the site investigation.

41.5 Ordnance and unexploded ordnance (UXO)

There are obvious hazards and potential delays associated with inadvertently finding buried explosives in a ground investigation. Guidance on assessing such risks and on mitigation techniques is given in CIRIA Report C681 (Stone *et al*., 2009). Higher risk areas are typically those in urban and industrial areas of major cities that, because of their historic situation, are such that the entry points of unexploded bombs might have gone unnoticed. Examples would be inter-tidal areas or areas of already demolished or damaged buildings. Desk-study information that can be used to assess UXO risks includes:

- historical maps (comparison of pre- and post-war maps);
- wartime bomb damage maps;
- wartime records of 'abandoned' unexploded bombs.

Detailed guidance is given in CIRIA Report C681 (Stone *et al*., 2009).

Unexploded bombs can move significant distances laterally below ground at the time of impact. Unexploded bombs can also move significant distances after impact where they have fallen into large tidal rivers. There are even known instances of unexploded bombs being unknowingly picked up, placed in fill, and then dug up again several years later.

Backfilled explosion craters also raise the possibility of otherwise unexpected ground conditions and the selection of inappropriate ground investigation techniques. These issues should be considered at the desk-study stage. Where backfilled craters are expected, low-cost simple techniques that can be used at relatively close centres can be used to identify variations in backfill thickness. These would include trial pits in general and window sampling for pits filled with the local natural soil if that is generally suitable for this technique. Buried craters in urban areas are more likely to be backfilled with coarse demolition rubble. Craters in more rural settings, such as airfields, are more likely to be backfilled with the soil displaced by the impact and explosion. Geophysical techniques may also be of use in this scenario. The choice of technique will depend on the nature of the backfill compared to the natural soil.

Where there is considered to be a higher than usual risk of encountering UXO in a borehole, the usual mitigation choices are to move the borehole, to abandon the borehole, or to employ surface or more usually down-hole magnetometer techniques to assess the presence of a bomb before the borehole reaches it. This activity requires the use of stainless steel casing and, as such, must be pre-planned.

As the site investigation is the first intrusion on to a site, the requirements of the investigation are often more onerous than during later construction. However, probing or further magnetometer surveys may be required during piling, and strict procedures followed when employing bulk excavation.

41.6 Buried obstructions and structures

Made Ground can contain man-made obstructions in the form of cobbles and boulders of natural and man-made materials, either placed as fill or as a result of *in situ* demolition. Typically, any large clasts like these are going to be stronger materials (rock, concrete, brick, steel and timber). These are likely to cause some degree of difficulty for any drilling or probing technique and possibly for trial pitting using smaller machines. The use of larger machines may be constrained on-site by space constraints and off-site by difficulties in accessing the site with low loaders. The desk study can indicate to a modest degree the likelihood of encountering these types of obstructions.

There are many different types of buried structure that a ground investigation might experience as an obstruction. Examples include foundations, old floors, basements, tunnels, culverts, machine chambers and membranes. These structures can be solid or can contain space filled with other solid material, liquids or gases, possibly under pressure. Consideration of these matters is a basic part of a desk study, and identification of significant obstructions would normally be a defined aim of ground investigations. In addition to probing or other intrusive methods of locating these, various geophysical techniques can be used (see Chapter 45 *Geophysical exploration and remote sensing*).

When considering this issue during a desk study it is useful to classify buried structures in one of two ways, those in use and those that are disused. Buried structures that are in use typically have owners who are keen to protect them. Their advice should be sought. This advice may significantly constrain the form and content of the investigation, for example restrictions

on drilling close to tunnels. Examples of such structures would be major sewers, major pipelines, communications ducts or tunnels, railway and road tunnels, buried storage tanks, culverts and penstocks.

Disused and 'ownerless' underground structures are rare and are necessarily harder to indentify. The types of structure that might be encountered are all those listed above plus air-raid shelters and other historical military and civil defence infrastructure.

Since many people are very interested in these types of underground spaces the internet is a useful source of data. In the UK, Subterranea Britannica can be a good source of information and further links, particularly for disused military and civil defence infrastructure (see section 41.11).

The desk study and walkover (Chapter 43 *Preliminary studies*) present the best opportunity to identify disused buried structures before ground investigation commences. This issue should be actively considered in each and every desk study. The ground investigation has the potential to significantly damage a buried structure and in so doing create hazards by instigating collapse or by releasing liquids or gases. The desk study should address the likelihood of encountering buried structures and identify strategies for dealing with that occurrence. Buried structures can also be affected by ground investigations even though the ground investigations do not directly encounter the structure. Examples of this possibility would include excavations leading to settlement damage, excavations damaging tree roots, and pumping of groundwater leading to settlement of nearby structures.

Where ground investigations have finding buried structures as a specific aim then the choice of technique will depend on safety considerations. Questions about whether the structure can afford to be damaged, and consideration of the consequences of any damage, need to be addressed before a technique can be selected. Machine-dug trial pitting is often used for shallow robust structures. Shallow structures which cannot be damaged will often be investigated using hand-dug pits with suitable support. If the structures contain voids, non-intrusive geophysical techniques such as ground probing radar may be useful (see Chapter 45 *Geophysical exploration and remote sensing*).

41.7 Services

Buried services constitute one of the greatest health and safety hazards in ground investigation. If encountered and damaged they can also be the source of significant delay and expense and can instigate pollution of the ground. All ground investigations, especially those on brownfield and urban sites, should incorporate some or all of:

- risk assessment;
- searches with utility providers;
- surveys to locate and trace services;
- hand-dug starter pits.

Contractual responsibilities for these activities should be clear, and sufficient time and money should be allowed for their completion. See Chapters 42 *Roles and responsibilities* and 44 *Planning, procurement and management* for more information on roles and responsibilities.

Since searches with utility providers can take several weeks to complete, this activity should be started as early as possible in the desk-study process. Clients and designers have responsibilities in this area, particularly under CDM regulations (see Chapter 42 *Roles and responsibilities* for more detail). Consideration should be given to carrying out pre-investigation service traces. The cost of this can be mitigated if this work is combined with topographic surveys in cases where the project requires such surveys anyway. Ideally such surveys will involve lifting manhole covers and inducing signals along services that can be reliably traced at the surface. This information can then be rechecked on-site at the time of the ground investigation using portable 'Cat Scanning' equipment. This equipment, however, is not effective with all services and great care should be used when relying on its use in the absence of other information or surveys.

Disused and derelict sites may contain both live and dead services. Dead or disused services can still be hazardous and should be treated with the same caution as live services. Disused gas pipes can still contain explosive gas, fuel pipes can contain fuel, and so on. Older high voltage (HV) cables often contain asbestos paper wraps and can contain toxic oil-filled jackets. It is often useful to consider the former and current uses of a site. Was HV required and where? How were structures heated? Was fuel (gas/oil) distributed around the site and how?

It is recommended this chapter is read in conjunction with

- Chapter 7 *Geotechnical risks and their context for the whole project*
- Chapter 8 *Health and safety in geotechnical engineering*
- Chapter 48 *Geo-environmental testing*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles.* A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation.*

Chapter 42
Roles and responsibilities

Jim Cook Buro Happold Ltd, London, UK

doi: 10.1680/moge.57074.0567

This chapter provides guidance on the roles and responsibilities of the participants involved in site investigations. The guidance is based upon key documents, which have been published by various organisations involved in this industry. These documents are referenced and it is recommended that they be read.

The chapter focuses on the non-technical issues regarding site investigation work. Comments are given on the Institution of Engineers Site Investigation Steering Group guides and on the obligations under the Construction (Design and Management) Regulations 2007, Corporate Manslaughter and Health and Safety.

The section on conditions of engagement provides commentary on tendering requirements and submissions, including comments on the current status of conditions of contract.

The timing of when ground investigations ought to be carried out is discussed and comparisons are made between the design stages recommended by the Association for Consultancy and Engineering and the Royal Institute of British Architects.

Commercial issues relating to consultants and ground investigations are discussed with comments on the traditional methods of procurement, the one-stop shop approach and the situation when the consultant carries out the ground investigation.

Underground services are also mentioned and the chapter concludes with guidance on commercial issues that need to be considered, such as insurance.

42.1 Introduction to site investigation guides

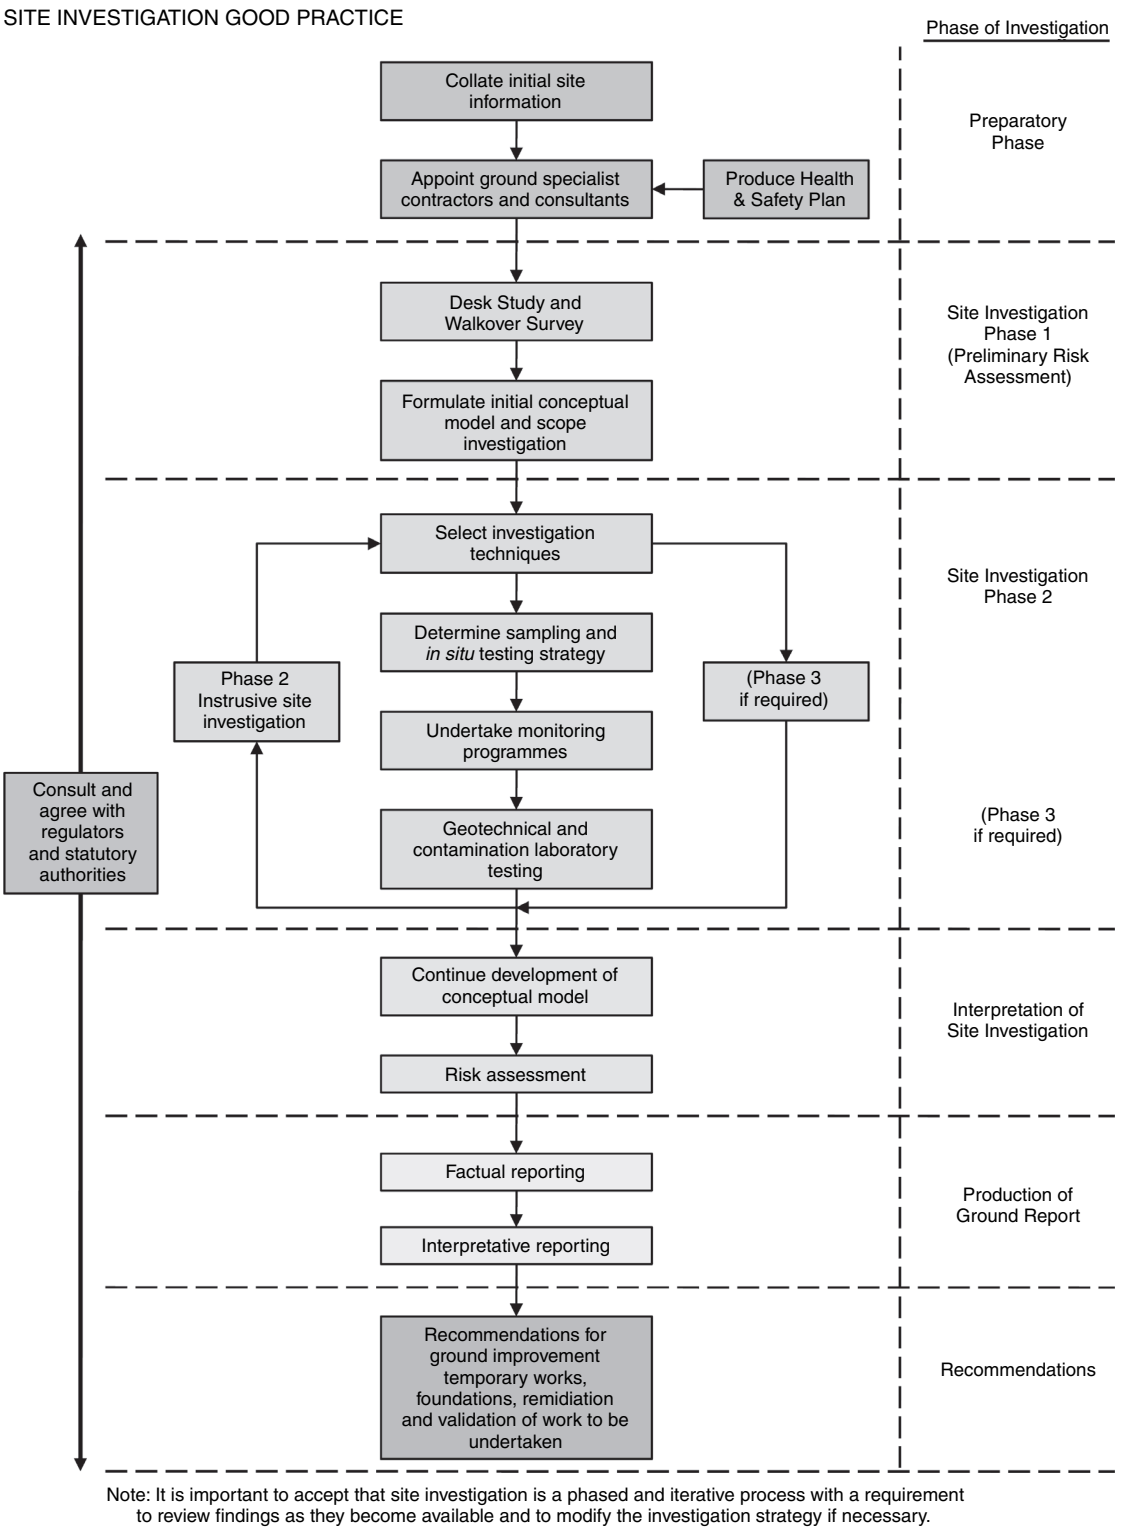
It is important to understand the elements of work that make up a site investigation and which people are going to do what and their individual responsibilities. It is usual that the work elements of a site investigation are undertaken by separate organisations. There are usually two entities: a consultant and a specialist contractor, both of whom work on behalf of the client (the employer).

The client, aside from their normal obligations, is usually responsible for obtaining all the appropriate planning and building regulation approvals and possession of the site prior to the commencement of any site inspection or intrusive investigation work.

It is incumbent upon the organisation (usually the consultant) that is producing the site investigation tender documentation to provide all available information including client-supplied information or advise where it can be obtained or viewed.

The objective and scope of a site investigation should reflect the requirements of the intended structure or building. It is important that the briefing section of the tender document provides all relevant information and any particular requirements or potential hazards in undertaking an intrusive investigation, e.g. boreholes or trial pits constructed close to or near to existing structures that may be above or below ground.

The method to be adopted for carrying out a site investigation should be appropriate to the ground conditions at the site and the ground-engineering testing and sampling requirements. These methods are usually specified by the consultant, who would approve the specialist contractor's method statement.



Cottington and Akenhead (1984) provide useful guidance on the contractual responsibilities of the parties involved in carrying out a site investigation.

Figure 42.1 shows the sequence of activities for a site investigation. Notice that it is an iterative process.

First, a desk study is produced, which is usually undertaken by a consultant. This is followed by fieldwork, which is usually called the ground investigation, and this is then followed by laboratory testing and factual reporting. The ground investigation can be intrusive or non-intrusive (or a combination of both) and it may be carried out in several phases. This element of the investigation is usually undertaken by a specialist contractor. The factual report provided by the specialist contractor is generally reviewed by the consultant and the interpretative report and recommendations are produced by the consultant.

There are variations on the above, generally dependent upon the size of the project, the client's requirements and so on.

A basic responsibility for the consultant, who has been appointed to arrange and procure the investigation on behalf of the client, is to ensure the work is undertaken in accordance with the appropriate specification, standards and conditions of engagement. All work should be carried out in accordance with what is known as 'best practice'. The Institution of Civil Engineers (ICE) has produced a specification and conditions of contract document and the Association of Geotechnical and Geoenvironmental Specialists (AGS) provides very good guides on these matters (details are given in Further reading). Details on codes and standards and their relevance can be found in Chapter 10 *Codes and standards and their relevance*.

Note: It is important to accept that site investigation is a phased and iterative process with a requirement to review findings as they become available and to modify the investigation strategy if necessary.

Figure 42.1 Site investigation activities
Reproduced from AGS (2006)

ICE has produced a series of documents, the *Site Investigation in Construction Series* (ICE, 1993), under the guidance of the ICE Site Investigation Steering Group (SISG), a body which includes various learned societies and trade associations. These documents were supported and endorsed by many major organisations such as the Association of Consultancy and Engineering (ACE), the British Geotechnical Association (BGA), the Institution of Civil Engineers (ICE), the Department for Transport (DfT), the Department of the Environment, Transport and the Regions (DETR), the Construction Industry Research and Information Association (CIRIA), then National House Building Council (NHBC), to name but a few. The above documents quickly became accepted as the industry norm but since their publication the methods and techniques of undertaking a ground investigation have changed and geo-environmental aspects have come more to the fore in view of the increase in brownfield development. As a result, the series is currently being revised by the steering group to take these changes into account and will be published by ICE Publishing in 2011/12. It is expected that the revised *Site Investigation in Construction Series* will quickly become key industry guides.

42.2 CDM regulations (2007), corporate manslaughter and health and safety

Site investigation is an investigation into the ground conditions at a particular site, which could be a greenfield site, where no development has previously been carried out, or, more likely in the United Kingdom, a brownfield site, where the land is to be redeveloped. Any work carried out on site, be it a simple walkover survey as part of a desk study or a full intrusive investigation, involves varying degrees of risk (see Chapter 43 *Preliminary studies*).

The Construction (Design and Management) (CDM) Regulations 2007 apply to all construction projects which include a site investigation. Section 2.1 of the regulations details their application and gives the responsibilities required, and these are discussed below.

42.2.1 Application of the CDM Regulations (2007)

The application and obligations of the client regarding ground investigations are fully described in AGS's *Client's Guide to Construction (Design and Management) Regulations (CDM) 2007 for Ground Investigations* (AGS, 2008). This guide was published subsequent to the CDM regulations that came into force on 6 April 2007. The following section is mainly based upon the AGS guide, which should be read, with supporting comments from the author.

It is important to note that under the CDM regulations, the client has the ultimate responsibility even if the investigation is procured or planned by a third party. In the case of a ground investigation any intrusive fieldwork, such as boreholes or trial pits, is considered as construction work.

The CDM regulations are applicable to all ground investigations that involve any form of intrusive work in the ground. A key issue concerning CDM regulations is whether a ground investigation is notifiable to the Health and Safety Executive (HSE). A ground investigation is notifiable if the construction period is likely to comprise 500 person-days or more, or the construction work is likely to last 30 project working days or more. The client is required to appoint a competent CDM coordinator and principal contractor for a notifiable ground investigation project. If the ground investigation is included within an existing or intended project, it will be notifiable as part of that particular project.

For a ground investigation where no specific development is planned and the work is wholly non-intrusive then the CDM Regulations 2007 probably do not apply. However, if site visits or walkover surveys are to be undertaken, due consideration must be given to health and safety issues for personnel undertaking this type of work, i.e. site visit risk assessments and method statements will be required anyway.

For site investigations that are to be carried out in potentially high-risk environments, e.g. over water, on or adjacent to railways and highways or underground, specialist training is likely to be required within a more rigorous health and safety regime.

42.2.1.1 Client's obligations

It should be noted that the client's responsibilities under the latest CDM regulations have increased compared to the previous regulations of 1994. A key issue is statutory obligations, any breach of which is a criminal offence. The client cannot abdicate their responsibilities but can delegate particular tasks to others, including third parties. For notifiable projects the CDM coordinator is obliged to advise and aid the client to comply with their duties.

The client's key responsibility is to establish the health and safety regime. This is achieved by undertaking the following for all projects:

- engage suitability qualified designers and contractors, who have been fully assessed for competency;
- ensure all relevant parties (including designers and contractors) receive appropriate pre-construction information as soon as it becomes available;
- ensure that all parties (including the client) have sufficient resources at all stages of the project;
- ensure the project timeline is appropriate for each stage of the project.

If a project is deemed to be notifiable, additional duties are required:

- Appoint a suitably qualified CDM coordinator and principal contractor. This should be carried out either at or (ideally) before the design stage.
- Ensure the CDM coordinator is given all relevant project information as soon as it is available.
- Ensure a health and safety plan for the site work is in place. This should be produced in liaison with the CDM coordinator and client. Site work should not commence until this is in place.

- Ensure adequate staff facilities are in place on site before work commences.
- Ensure the CDM coordinator has produced a health and safety file. This should be passed to the client at the end of the project, and will require updating if modifications to the structures are carried out.

When a client fails to appoint a CDM coordinator or principal contractor, the duties of these parties default back to the client. The designer also has an obligation to make the client aware of their duties with regard to the CDM regulations. The designer also has obligations under the CDM regulations for any design decisions undertaken by the client.

42.2.1.2 Advice to clients

Where intrusive work is undertaken as part of a ground investigation, the CDM regulations apply even if the project is not notifiable. Clients should carry out the following:

- Provide pre-construction information to designers, contractors or others to allow them to plan and manage their work effectively and comply with Regulation 10 (which deals with the client's duty in relation to information) as follows:
  - a description of the project including the programme, key dates and arrangements for managing health and safety;
  - information available from the existing health and safety file (if there is one);
  - details on existing statutory services (and private services if available);
  - details of existing structures (including drawings, specifications, etc.) if available;
  - details of any environmental restrictions and any existing on-site risks;
  - details of activities on or adjacent to the site that might impact on the ground investigation.
- Confirm whether or not a project is notifiable to the HSE.
- Ensure competent designers and contractors are always appointed. This also applies to CDM coordinators and principal contractors where appropriate.
- Ensure reasonable management arrangements are in place throughout the project to ensure construction work can be carried out, so far as reasonably practicable, safely and without risk to health.
- Ensure suitable welfare facilities are to be provided from the start and throughout the construction phase by the contractor or principal contractor, as appropriate.
- On notifiable projects appoint, in writing, a CDM coordinator and principal contractor.
- Ensure construction work does not start until a suitable construction plan has been prepared and welfare arrangements are in place.
- Ensure the health and safety file is retained and updated if the structures described in it are modified.

42.3 Corporate manslaughter

Corporate manslaughter is now on the United Kingdom statute books through The Corporate Manslaughter and Corporate Homicide Act 2007. This is a landmark in law and came into force on 6 April 2008. Under this act, companies can be found guilty of corporate manslaughter (or corporate homicide in Scotland, as there is no such thing as 'manslaughter' under Scottish law) as a result of serious management failures resulting in a death or deaths as a direct result of a gross breach of their duty of care. The act clarifies the criminal liabilities of companies including large organisations where serious failures in the management of health and safety result in a fatality.

An organisation is guilty of corporate manslaughter if the way in which its activities are managed or organised causes a death and amounts to a gross breach of a relevant duty of care to the deceased. Companies and organisations should keep their health and safety management systems under review, in particular, the way in which their activities are managed and organised by senior management.

Sadly the first conviction under this act occurred in February 2011, when a geotechnical company was deemed to be responsible for the death of a young geologist who was killed whilst working inside an unsupported excavation. Concerning this very important piece of legislation, the reader should refer to *A Guide to the Corporate Manslaughter and Corporate Homicide Act 2007* published by the Ministry of Justice (2007) and the Health and Safety Executive and Crown Prosecution Service websites given in the references.

42.4 Health and safety

The revised ICE *Site Investigation in Construction Series* (ICE, 1993) provides guidance on health and safety issues, some of which is based upon the British Drilling Association (BDA) document *Guidance for Safe Intrusive Activities on Contaminated or Potentially Contaminated Land* (BDA, 2008), which was published in 2008. The BDA document provides health and safety information and recommendations on best practice for ground investigations.

This document describes the rationale and the need for new guidance for ground investigations, mainly due to an increase in statutory and regulatory legislation, changes to working practices and an increase in brownfield site development.

This guide is comprehensive: it has 17 chapters ranging from appropriate legislation, including four acts and 11 regulations, followed by chapters on competence, training and qualifications, managing health and safety, risk assessment and so forth.

Further information regarding health and safety can be found in Chapter 8 *Health and safety in geotechnical engineering* of this manual.

42.5 Conditions of engagement

A ground-investigation specialist can be engaged using bespoke terms, which are drawn up specifically for a particular

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

project, or using the terms and conditions of contract produced by public bodies such as the Highways Agency.

ICE has produced two sets of *ICE Conditions of Contract for Ground Investigation*, the first set was published in 1983 and the latest set (the second edition) was published in November 2003 together with a set of guidance notes (ICE & CECA, 2003).

ICE, ACE and the Civil Engineering Contractors Association (CECA) are sponsoring bodies of the Conditions of Contract Standing Joint Committee (CCSJC). Representatives of members of CCSJC and members of the BGA and AGS all provided input and guidance into the second edition.

The second edition has been specifically written to focus on the contractual requirements of ground investigation and in particular on fieldwork, including laboratory testing and factual reporting. The second edition is not considered to be appropriate for producing interpretative reports and, therefore, a different form of agreement should be used for this type of work. A form of ACE agreement could be used for interpretative reports.

It is recommended that where possible the second edition is used for ground-investigation contracts.

The ICE conditions of contract can be used for all types and sizes of ground investigation. Normally for building projects, the engineer, who would be acting on behalf of a client, would have an 'in-house' specialist ground-engineering team. This team would review the client's requirements with the structural engineer and architect and then design an appropriate site investigation including the ground investigation.

Ground investigation includes fieldwork, laboratory testing and factual reporting. Management, site supervision, technical reviewing and all engineering reporting would be carried out by the engineer's ground-engineering team.

This specialist team would produce a ground-investigation tender document, which would comprise a specification, bill of quantities and a commercial package based upon the *ICE Conditions of Contract for Ground Investigation Revision 2*. It is good practice to include supporting appendices, which may include assessments of potentially hazardous sites, a CDM hazard questionnaire and any pertinent client-provided information on site constraints, e.g. buried services.

The commercial package would include all aspects deemed necessary on behalf of the client including: cost, programme, insurance, damages, liabilities, payment terms and retention as appropriate. The tender document, including the conditions of contract, should be agreed with the client prior to being issued.

The tender would then be sent out to an agreed number of client-approved ground-investigation specialist contractors. As part of the tender return submission, and in addition to completion of the commercial package, the specialist contractor should also submit appropriate documentation concerning how the work is going to be undertaken, e.g. method statements. Most codes recommend a phased approach; the RIBA stages (see section 42.6) are a useful guide to the requirements of each stage.

The above process is also a suitable basis for civil engineering-type projects as well as building-type projects.

In situations where the main engineering assignment for the client is carried out by the lead engineer under the ACE Conditions of Contract, there are two elements of site investigation work deemed to be included within the overall fee package. These are a desk study and the production of a ground-investigation specification. Any other requirements of the site investigation, such as site supervision, fieldwork, laboratory testing and interpretative reporting, are items of additional work, which need to be priced and included in the ACE agreement. Geotechnical design, including foundation specification, is deemed to be included within the overall agreed fee.

For smaller ground-investigation projects, it is not uncommon for a simple exchange of letters, between either an architect or a structural engineer acting on behalf of the client and a specialist site investigation contractor, to form the basis of the contract.

In this situation it is important that the specialist site investigation contractor has the appropriate level of resource, competence and experience to undertake all the work required, including a desk study, designing a specification, fieldwork, laboratory testing and producing an interpretative ground-engineering report.

It should be noted that support for the ICE Conditions of Contract has been withdrawn by ICE and support for these conditions is expected to be taken over by ACE and CECA. It is also likely that the New Engineering Contract (NEC3) conditions of engagement (Institution of Civil Engineers, 2005) will be developed to include ground-investigation work. The ground-engineering industry together with NEC will need to decide if one of the main options in the NEC3 conditions of contract is adopted or alternatively whether *Engineering and Construction NEC3 Short Contract* (ECSC; ICE, 2005) can be used and tailored to suit this specialist type of work.

42.6 When should a ground investigation be carried out?

The intrusive part of a site investigation can be carried out during a single site visit or over several phases of fieldwork. It is usual that at least a desk study is undertaken for a project that is going to be submitted for planning approval, as required by ODPM PPS 23 (ODPM, 2004). This is called a phase 1 site investigation.

Subject to project requirements, an initial ground investigation is undertaken focusing on geo-environmental concerns for brownfield sites.

The phase 1 site investigation work could also include geotechnical as well as geo-environmental aspects and, thus, it is generally more prudent and economic to have a combined phase 1 site investigation focusing on both aspects.

AGS are currently proposing to the building regulators that a combined ground investigation should be mandatory during planning approval.

Ground investigations should be carried out on a phased basis and need to take into account the design process. There

are several design phases in building design and these generally comprise:

1. feasibility and concept design;
2. scheme design;
3. design development;
4. final (detailed) design;
5. production information and tender;
6. construction to practical completion;
7. after practical completion.

RIBA phasing has design stages A, B, C, D to L while ACE has design stages C1, C2, C3, C4 to C8. These are given in the following references: RIBA Outline Plan of Work 2007 Amended 2008 and ACE Agreement B (1) 2002 (revised 2004) Civil/Structural Engineering Non Lead Consultant.

The above ACE 2004 document was revised in 2009 and renamed ACE Schedule of Services Part G (a) Civil and Structural Engineering Single Consultant or Non Lead Consultant for Use with ACE Agreement 1 – Design 2009. These revised work phases are given in the fourth column in **Figure 42.2**. In current practice the earlier 2004 version is still in extensive use in the industry. The different stages and services are compared in **Figure 42.2**. The ground-engineering input required in the RIBA stages is shown in **Figure 42.3**.

From **Figure 42.3** it can be seen that the site investigation spans the early stages of design for RIBA (stages A to C). A phase 1 ground investigation would typically be undertaken during stages A or B during the site appraisal and the phase 2 detailed ground investigation would be completed ideally before stage D commences.

Phase	RIBA Stage	ACE B1 2002 rev 2004	ACE Part G(a) 2009
Feasibility	A (Appraisal)	C1	G2.1
	B (Strategic Briefing)	C2	G2.2
Pre-Construction	C (Outline Proposals)	C3	G2.3
	D (Detailed Proposals)	C4	G2.4

42.7 Consultants and ground investigations

42.7.1 Background

It is becoming more commonplace that consulting engineers are asked to provide a 'one-stop shop' and to incorporate the provision of ground investigation and laboratory services within the scope of their design contract with the client or the client's agent.

Consequently in this instance the consultant is required to employ a ground-investigation contractor directly or to perform the ground investigation using his own staff with his own or hired equipment. The consultant, therefore, becomes the employer of the specialist ground-investigation contractor and is acting in the role of a contractor (rather than just a consultant) to his client or his agent. For some consultants acting as a contractor is an entirely new situation.

AGS has produced a document, *Consultants Undertaking Ground Investigation Contracting*, within the *AGS Toolkit* suite of guides (AGS, Toolkit), concerning this change of role. The following comments are not an exhaustive description of how to deal with all the issues associated with the changes that consulting engineers must now adopt; instead they are intended to raise awareness of some of the issues that will be faced by consulting engineers so that further guidance, as appropriate, can be obtained.

One of the key issues here is that the consultant bears the financial risk of the cost of the specialist ground-investigation contractor. The guide identifies the need for the development of an appropriate standard contract form for use between the consultant and his client in this scenario.

Traditionally for site investigation work, consultants have acted as the engineer as defined in the ICE Conditions (ICE & CECA, 2003) and other similar contract forms such as ACE (2004). Under this arrangement the consultant has no direct contractual arrangement with the ground-investigation contractor.

In circumstances where the consultant procures the ground-investigation services on behalf of the ultimate client under the contractual scope of supply, there will be obligations to the ground-investigation and laboratory contractor that will need to be properly dealt with in the contract with the client. The

consultant will need to be remunerated for the additional effort and business risks.

Generally the most successful ground investigations have been performed within a contractual relationship that readily allows flexibility in work scope due to variations in anticipated ground conditions.

There has also been a tendency for clients or their agents to request 'lump sum' ground investigations (which include laboratory testing). It is likely that a lump sum form of contract that constrains the ground-investigation work scope, with resulting inflexibility, potentially places the party holding the risk of the lump sum in a conflict between commercial and professional obligations.

The AGS guide (AGS, 2008) provides a background to the way ground investigations have traditionally been procured and comments on the one-stop shop and lump sum approaches.

There are different types of contract that can be used for ground-investigation work and the most popular in recent times has been the *ICE Conditions of Contract for Ground Investigation Version* (ICE & CECA, 2003). These conditions are generally well known to consultants and ground-investigation contractors and have been used for many ground-investigation projects. They may be suitably modified for the one-stop shop role. Other forms of contract such as ICE Minor Works (Institution of Civil Engineers, Association of Consulting Engineers, Civil Engineering Contractors Association, 2001) and NEC can be used.

See also Chapter 44 *Planning, procurement and management*.

42.7.2 Traditional approach

The traditional procurement route of engagement is where the client engages a consultant engineer who undertakes the procurement of a ground-investigation contractor on behalf of the client to undertake a ground investigation. This process is fully described in the AGS guide (AGS, 2008).

There are advantages and disadvantages of this method of appointment, which are well explained in the guide. The risks to the client (e.g. an increase in overall contract costs) and the responsibilities of the client (e.g. prompt payment) are all listed.

The duties of the engineer (e.g. certification of invoicing) and the responsibilities of the contractor (e.g. carrying out the work to the agreed programme) are also given in detail.

The commercial arrangements for the client in this approach mean that there has to be a separate contract for the consultant to deal with the requirements of the ground investigation and there has to be another contract for the ground-investigation contractor.

This two-contract approach may seem cumbersome and this has probably resulted in the adoption of the single appointment, the one-stop shop.

In this arrangement, the agreement between the client and the consultant can be an ACE or ICE-type consultancy agreement, and that between the client and the ground-investigation contractor can be the *ICE Conditions of Contract for Ground Investigation* (ICE & CECA, 2003).

42.7.3 One-stop shop approach

The one-stop shop approach is a non-traditional arrangement that allows the client to have a single agreement with the consultant to deal with the requirements of the ground investigation and the ground-investigation contractor.

This arrangement transfers a certain degree of the client's commercial risk to the consultant, who would usually lead the arrangement. These issues include risks such as responsibility for payment of the ground-investigation contractor, whose input into the project is usually substantially more than the fees attributable to the consultant's input. The risk of default by the client and funding claims for extra work can be substantial.

The additional responsibilities that the consultant takes on need careful consideration and may be considered as being unfair. There are also possible concerns from the ground-investigation contractor's point of view.

The key issues for both consultants and ground-investigation contractors in undertaking one-stop shop investigations are discussed in the AGS guide (AGS, 2008).

42.7.4 When the consultant undertakes the ground investigation

Consultants have successfully carried out ground investigations for several years without the benefit of a form of contract that has been specifically developed for the combined role. There are risks associated with this form of arrangement, which are the same as those which a ground-investigation contractor may have faced outside those of the normal consulting agreements.

These risks are listed in the AGS guide (AGS, 2008) and include damage to underground services, health and safety issues (see sections 42.2 and 42.4) and loss of samples, to name but a few.

Additional areas of concern for the consultant are given in the guide and key concerns are the provision of necessary and suitable insurance, as standard insurance arrangements may not be adequate. The consultant would be well advised to ensure project cover is in place (typically through a project contractor's all-risks policy).

Regarding the ground investigation, the guide gives three options as to how this may be undertaken, that is, through subcontracting, work packaging and project managing, but all three are led by the consultant.

There are various forms of contract for undertaking this type of assignment but they may require some modification. The use of the ICE form of agreement may be considered but it should be borne in mind that the *ICE Conditions of Contract for Ground Investigation* (ICE & CECA, 2003) were specifically produced for the ground-engineering contractor to carry out the fieldwork, laboratory testing and factual reporting.

42.7.5 Particular issues when the consultant employs a ground-investigation contractor under the ICE contract

There are several fundamental points to be noted when the ICE conditions of contract (ICE & CECA, 2003) are used in the situation where the consultant employs a ground-investigation contractor. The consultant becomes the employer and also the engineer at the same time. This can cause major concerns, in particular the express contractual provision for the engineer to act impartially and regarding the resolution of disputes. These two matters require modification to clauses 2(7) and 66 of the ICE conditions.

There are at least 10 key responsibilities listed in the AGS guide (AGS, 2008) that affect the consultant who is acting as an employer; these include payment, liabilities for unforeseen ground conditions, wayleaves and permission, etc.

The guide gives comments and certain courses of action for the consultant, which may be adopted in setting up the contract, which are likely to minimise the consultant's level of risk. The guide also provides advice and 'health warnings' for the consultant if they propose to use the *ICE Conditions of Contract for Ground Investigation Version* (ICE & CECA, 2003).

42.7.6 Other insurance

In addition to the contractor's all-risks insurance mentioned above, there are three important types of insurance that should be considered by both consultants and ground-investigation contractors: professional indemnity (PI) insurance, public liability (PL) insurance and employer's liability insurance.

PI insurance is usually carried by consultants or ground-investigation contractors to cover liabilities arising from their interpretation, engineering, design and recommendations for a project. For geo-environmental aspects the level of cover offered by insurance companies can be much lower than those offered for geotechnical aspects due to the perceived higher risk of dealing with contaminated ground.

PL insurance is usually taken out by companies to cover the potential affects to third parties caused in carrying out their business activities. This includes bodily harm or death to members of the public or damage to property.

Regarding PI and PL insurance, organisations should consider all potential risks in order to decide upon the level of insurance needed and the amount of insurance cover deemed appropriate. It is important to note that the level of insurance cover offered in a contract does not necessarily limit the degree of exposure (total liability) to the sum insured unless specifically agreed.

The Employer's Liability (Compulsory Insurance) Act 1969 sets out a minimum level of employer's liability insurance cover, which is currently at £5 000 000. This insurance cover is needed as the employer is responsible for the welfare of employees when they are at work, either in the office or on site.

Further information should be obtained from the various insurance companies and brokers, who offer advice and guidance. The Insurance Institute of London provide publications on the above and other types of insurance.

42.8 Underground services and utilities

The likelihood of there being underground services and utilities is extremely high for sites in developed areas and less so for more greenfield sites. It is also worth mentioning that there are above-ground services and utilities that should be considered and these are not dealt with here. In undertaking any form of intrusive ground investigation, albeit trial pits or boreholes, there is a risk of encountering services and utilities.

In general, the client's engineer provides the location plans, showing the existing services and utilities for the project, to the ground-investigation contractor. These may be provided to the engineer by the service or utility-owner company. The ground-investigation contractor would then arrange for a non-intrusive survey (cable and pipe locating) to be carried out to confirm the location on the ground and subsequently excavate a test pit to confirm the existence of the services and utilities for each borehole or trial pit.

The question of responsibility is one which needs to be carefully considered. The recently published Health and Safety Executive document *Avoiding Danger from Underground Services* (Health and Safety Executive, 2000) provides guidance and also outlines dangers and risk reduction methods.

This publication focuses specifically on health and safety but also points out that by considering this there will be a reduced risk of damage to services and property. This guide is targeted at all parties that could be involved including owners, clients, designers, planning supervisors, contractors, operators and employees of the aforementioned.

The dangers of damaging underground services and safe systems of work are mentioned together with a flow diagram. There are sections on training and supervision, planning, design and also where CDM applies includes duties and responsibilities. This document is comprehensive and also provides appendices on legislation and suggested advice for site personnel.

42.9 Contamination

The degree of contamination of a site is normally determined during the first phase of a geo-environmental site investigation, the phase 1 site investigation. This study would usually be carried out early in the project in order to meet the requirements of obtaining outline planning approval, as given in PPS 23 (ODPM, 2004).

Following the phase 1 investigation, if deemed necessary because of the identification of potential contaminants, a more detailed geo-environmental investigation will be required possibly together with a geotechnical site investigation. From the results of the desk studies, site work and laboratory chemical tests, a geo-environmental risk assessment will be made of the site and remediation options recommended if necessary.

In the event that elevated levels of previously unidentified contaminants are discovered on site during construction, the responsibility for dealing with these will be subject to the contractual arrangements between the contractor, consultant and client. The general principle is the 'polluter pays'; however, this is subject to commercial arrangements between the

original owners and the purchaser, and the nature of any land-use changes for the new development.

AGS collaborated with the Environmental Industries Commission (EIC) and ACE to produce a paper *The Terms upon which Contaminated Land Consultants are Employed* (AGS, EIC & ACE, 2007). This document is available from the AGS website. This guide was developed to support the commercial arrangements for studying contaminated land and more specifically to highlight the common contractual issues that should be considered by consultants. It provides guidance on key contractual issues such as the limitation of liability, collateral warranties, strict obligations and fitness for purpose, insurance clauses, indemnities, incorporation of standard forms, assignment and duration of risk.

42.10 Footnote

This chapter is generally based upon literature published by AGS and others, which has been referenced and acknowledged. These documents are generally readily available for download on the organisations' websites. At the time of writing, some of the documents and guidance notes referenced are subject to continual update and change. There have been recent changes in legislation and there are likely to be more in the future.

The recent introduction of the Eurocode 7 parts 1 and 2 for the ground-engineering industry is slowly working its way through the design and implementation processes, which will provide issues of concern as the well-known British Standards are withdrawn.

42.11 Disclaimer

Although every reasonable effort has been made to check the information and validity of the guidance provided in this chapter and the AGS documents referred to, neither the author, any individuals, members of Buro Happold, members of the Working Group, nor the AGS provide any warranty or guarantee as to the accuracy of the contents and do not accept any liability or responsibility whatsoever for any inaccuracy, misstatement or misrepresentation contained herein or for any loss, damage, expense, cost, claim or the like arising directly or indirectly from any reliance upon it, howsoever arising.

Chapter 43
Preliminary studies

Vicki Hope Arup Geotechnics, London, UK

Preliminary geotechnical studies are a key element in managing ground risk in construction. They take the form of a desk study in which relevant available documentary information about the ground at a site is identified, obtained and reviewed. A walkover site survey adds significant value. The preliminary study should be completed before scoping and specifying a ground investigation (GI), to help focus the GI and to maximise its value and relevance.

43.1 Scope of this guidance

No guidance manual could supply the diversity of knowledge, skills and experience necessary to generate comprehensive preliminary geotechnical studies appropriate for every possible project, at every possible site. This section of the Manual, therefore, sets out to: (i) outline the types and sources of information that should typically be reviewed when writing a preliminary geotechnical study; and (ii) encourage the writers of preliminary studies to regard their reports as the all-important first step in the process of managing ground-related risks in a construction project. Focus is given to preliminary studies for sites in the UK, but much of the guidance is applicable to sites overseas.

43.2 Why do a preliminary geotechnical study?

Preliminary studies, often called desk studies, are an efficient and cost-effective way of gathering and scrutinising available information at the earliest stages of a project with the aim of understanding the ground and ground-related hazards at a site. Within the construction industry, project delays and cost overruns can frequently be linked to encountering 'unforeseen ground conditions' when construction starts on site (Chapter 7 *Geotechnical risks and their context for the whole project*). A well-planned, well-executed preliminary study can assist greatly in reducing – although it can never wholly eliminate – the likelihood of meeting unexpected problems in the ground during construction.

Undertaking a preliminary study is a requirement of all relevant codes in the UK:

- British Standard BS 5930: Clauses 6.1.1 and 6.2 (BSI, 1999);
- Eurocode 7 BS EN 1997–1: Clauses 3.1 and 3.2.2 (BSI, 2004);
- National House Building Council Standards Chapter 4.1 (NHBC, 2011).

The preliminary study should be viewed as the essential first link in the geotechnical project risk management chain (see **Figure 43.1**). The chain progresses through each stage of the geotechnical engineering of a construction project (Chapter 42 *Roles and responsibilities*). In essence:

- The preliminary study identifies likely ground-related hazards.
- The ground investigation explores the hazards and their associated risk (see Box 43.1).
- The geotechnical design reassesses the ground risks and mitigates the associated hazards to appropriate levels.
- Any remaining (known) ground-related hazards that are not mitigated at the design stage can, in liaison with the project management team, be communicated to the construction team via specifications and other contract documents, to help ensure that these issues do not come as a surprise on site during construction.

Box 43.1 Hazards and risks are not the same

A **hazard** is a source of potential harm. The **risk** associated with a hazard is the likelihood of that harm occurring, factored by its impact if it were to occur. For example, flooding is a hazard. The risk would depend on how prone an area is to flooding, and the degree of damage and loss that would be caused by a flood event.

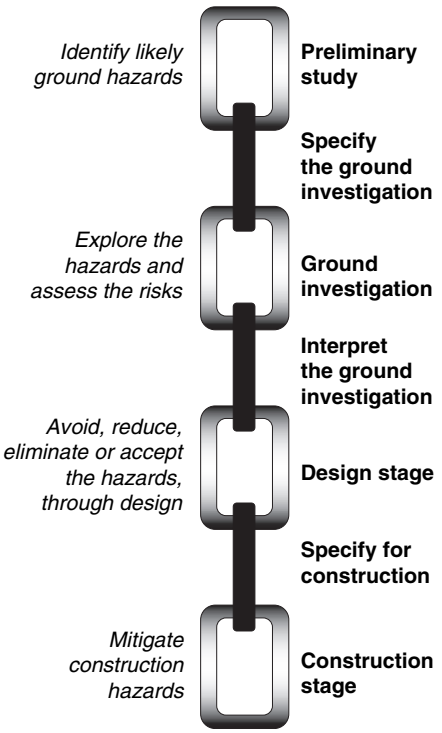

Figure 43.1 The geotechnical risk management chain

43.3 What goes into a preliminary geotechnical study?

The factual core of a preliminary geotechnical study typically encompasses:

- *site details*, including its location, address, grid reference, boundaries, topography, present use, proposed use, access routes, land ownership, neighbouring land usage, etc.;
- *site history*, including an interpretative review of historical maps, ideally extending back to rural fields; aerial photographs and satellite imagery; prior site usage; archaeological potential; listed buildings and scheduled monuments; water courses; tunnels; mine workings (Chapter 41 *Man-made hazards and obstructions*); possible unstable ground (as defined in PPG14, 1990); underground infrastructure; flood records; buried obstructions; old foundations; underground services and utilities; possible sources of contamination from current or previous site activities, and initial assessment of these; historical changes in topography; presence of trees, etc.;
- *site walkover*, including observations of the site and its vicinity;
- *site geology*, including an interpretative review of all available geological maps and memoirs, including old map series; well records and borehole logs; data from previous ground investigations at the site or in its vicinity; an assessment of the likely site stratigraphy; groundwater regime and hydrogeology; seismicity, if relevant, etc.;

plus a variety of project-specific and site-specific variations on these core themes.

Guidance on the archaeological assessment of sites is published in the *Standard and Guidance for Archaeological Desk-Based Assessment* by the Institute for Archaeologists (2008), and this is not repeated here. In relation to site contamination, a preliminary study is termed a Phase 1 study, and a ground investigation is a Phase 2 study. These must follow prescribed legislative requirements. Guidance on the requirements for Phase 1 studies is presented in British Standard BS10175 *Investigation of Potentially Contaminated Sites* (BSI, 2011); Environment Agency CLR11 *Model Procedures for the Management of Contaminated Land* (Environment Agency, 2004); and in the *Institution of Civil Engineers' Design & Practice Guide Contaminated Land, Investigation, Assessment and Remediation* (Strange and Langdon, 2007). Chapter 48 *Geo-environmental testing* addresses Phase 2 studies.

The preliminary geotechnical study report should also cover the following interpretative elements, each of which demands some knowledge of the proposed development, as well as knowledge of the site itself:

- *Recommendations for the ground investigation:* outlining the scale and scope of the proposed ground investigation, and highlighting any special site-specific or project-specific aspects identified in the desk study that should be addressed in the ground investigation.
- *Details of ground-related site constraints:* cataloguing the identified site-specific factors that may affect ground investigation works, foundation options and foundation construction.
- *List of ground-related hazards:* describing and prioritising the identified ground hazards (see Box 43.2 for some examples), and outlining how these could be investigated further and how they could be mitigated. Ground hazards can usefully be treated in three categories: topographic, geological, and man-made. The format of the listing should give priority and emphasis to the site-specific and project-specific geohazards that are particular to the site: these should not be lost or overwhelmed by a long list of generic issues that could apply at any site.

The inclusion of a list of ground-related hazards in a preliminary geotechnical study benefits both the client and the project team because it:

- helps convert the preliminary study findings into risk management information that is of direct use from the earliest stages of a project, by identifying ground-related factors that may affect costs and the programme;
- translates the preliminary study findings into a practical format that is readily understood by non-geotechnical colleagues and clients;
- acknowledges the importance of risk-based methods in contemporary project planning, and integrates the preliminary geotechnical study within that process from the outset of the project;
- brings considerable value to a project, yet makes use of material that the geotechnical team has already gathered and should already have thought about.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Box 43.2 A partial list of hazards: some ideas to consider…

Topography
slope stability issues
site access
possible GI drill rig locations
potential for flooding

Groundwater
need to dewater? effects?
rising groundwater
tidal variations
potential for aquifer contamination
discharge of pumped groundwater

Voids/soft spots
mining
karsts
backfilled quarries
backfilled basements
old wells

Trees
present on site? – walkover
recently removed? – archive photos
clay soils: shrink/swell potential
species, height and maturity
removal *versus* retention

Buried features
operational and disused tunnels
services and utilities
foundations, basements, tanks
UXO (unexploded ordnance)

Heritage issues
listed buildings
archaeological planning constraints
need for a watching brief during GI
impact on programme of finds
Scheduled Ancient Monuments

Neighbours
proximity to existing structures
sensitivity of existing structures
ground movements at excavations
noise and vibration
need for party wall agreement?

43.4 Who should write a preliminary geotechnical study?

Preliminary geotechnical studies should be written by suitably experienced geotechnical engineers or engineering geologists. One can speculate that if an engineer and a geologist were set to work in isolation of each other on desk studies about the same site, they would probably generate very differently focussed reports. In practice, for all sites, a combination of both technical perspectives is invaluable: each specialist can gain a deeper insight of a site by liaising and collaborating with the other. The balance in the input needed from each specialist will depend largely on the site's location and geology: a pipeline in a remote mountainous region would typically benefit most from an engineering geologist, whereas a building in a city on an alluvial plain would probably benefit most from a geotechnical engineer.

Appropriate knowledge and experience are essential in order to understand fully the significance of the information gathered. The responsibility for a preliminary study, therefore, should not be assigned to the most junior member of the team, although, if properly supervised by an experienced senior colleague, preliminary studies are valuable training grounds for junior engineers and engineering geologists.

Beyond knowledge and experience, useful characteristics for writers of preliminary studies include a high level of observant curiosity, a persistent and creative attitude to seeking data, and a methodical and thorough approach to reviewing data. These attributes are needed because a preliminary study often must draw together disparate – and sometimes incomplete – data to form as complete and insightful a picture as possible of the ground at the site of interest. That cannot be achieved in a routine or formulaic way: it requires inquisitiveness underpinned by a systematic approach to obtaining and assembling relevant information.

43.5 Who should read a preliminary study report?

The report should be circulated to the client and the design team, including the architectural team. If a preliminary study has been undertaken thoroughly and effectively, the resulting report should:

- be essential reading for whoever is tasked with scoping and specifying the ground investigation;
- probably contain some items of useful information that were not previously known to the rest of the design team, and which may well influence their thinking;
- summarise the currently available ground information in one convenient volume, including ground-related hazards;
- engage and interest the client, especially about the history of their property.

The contents, or a summary of the contents, of a preliminary geotechnical study should usually be made available to the construction team (the contractor), alongside the ground investigation factual reports. Any concerns about releasing an interpretative study to a third party can be dealt with via a suitably phrased third-party caveat in the text of the report. In terms of controlling ground risk in a project, it is beneficial that the construction team are as fully informed as possible about a site's history and the anticipated ground conditions at the site. They can then assess the likelihood and potential impact of these factors on their site works.

43.6 How to get started: sources of information in the UK

In the UK, the following are useful starting points for gathering data from which to develop a preliminary geotechnical study.

This list is not exhaustive, and new sources of information – especially online sources – become available each year.

- Geological maps and cross-sections published by the British Geological Survey (BGS, www.bgs.ac.uk) at 1:10 000 and 1:50 000 metric scale. Both drift and solid maps should be reviewed, along with the relevant geological memoir. Older maps can also be highly informative, despite changes in the names of geological formations. Additional information can be gained from mineral extraction maps.
- The GeoRecords service at the National Geoscience Data Centre (www.bgs.ac.uk) can be used to obtain old well records and borehole logs, from the archive held at the BGS. The archive can be searched via an online map.
- Ordnance Survey (OS) maps (www.ordnancesurvey.co.uk), dating from the mid-nineteenth century to the present, can assist greatly in tracking historical changes at a site. Small-scale OS maps (1:1250 and 1:2500 at metric scale) show local detail, including street names (see Box 43.3) and the outlines of individual buildings. OS maps include topographic data, expressed as spot heights and contours, relative to sea level (see Box 43.4).

Box 43.3 Place names

Place names can provide valuable information and insight into the history of a site, its topography and even its hydrogeology. An unusual place name should always trigger an enquiry into the origin of the name, and an assessment of its implications for the proposed works at the site. For example, a street called 'Flask Walk' in Hampstead is close to Well Lane and Well Walk: all three derived their names from the iron-rich mineral waters that were sourced and bottled there from the seventeenth century onwards. Many older place names, especially Anglo-Saxon names, provide information about the natural landscape. Some examples of the many Celtic, Saxon and Viking root words used within place names in the UK include:

- allt: the side of a hill;
- beck, bourne, burn: a stream;
- glan: the bank of a river;
- gill: a valley;
- hamps: a stream that is dry in summer;
- ings: a meadow or marsh;
- keld, kelda: a spring;
- mere: a pool or lake;
- moss: a marsh, bog or swamp;
- pant: a hollow;
- slack: a stream within a valley.

Box 43.4 Liverpool and Newlyn

When using early Ordnance Survey maps or old well logs dating from before the 1920s, be aware that the UK height datum system changed during the 1920s. From 1844, the height elevation datum was at Victoria Dock in Liverpool. After 1921, the UK national height datum system was based on tidal measurements at Newlyn in Cornwall. The difference in heights between the Liverpool and Newlyn systems is not large, but it is just enough to cause confusion unless it is taken into account. The height conversion factor between the two systems differs by differing amounts across the country. The Ordnance Survey has an online conversion calculator at www.ordnancesurvey.co.uk.

- Historical maps were produced by a variety of map-makers. Some maps were semi-pictorial views, but others were more rigorously cartographic, notably those of Roque, Cary, Horwood and Stanford. Copies of old maps are available from online suppliers, and some have been published as books.
- From the late 1830s, church tithe maps showed land parcel boundaries and building outlines, but the maps were of variable quality. Most local history centres hold the tithe maps for their area.
- Maps made for fire-insurance purposes by Charles E. Goad Ltd from the mid-1880s to 1970 show the commercial districts of many UK towns and cities. At a scale of 1:480, they show a building-by-building mapping, with details such as industrial use, construction materials, number of storeys and basements. The Map Library at the British Library (www.bl.uk) has an extensive collection of UK Goad fire maps. Scanned Goad maps are also available commercially from online map suppliers.
- The Coal Authority Mining Reports Office (www.coal.gov.uk) can be used to obtain details of documented mining operations, and mining and brine-extraction ground stability reports (see Chapter 41 *Man-made hazards and obstructions*). Its website includes a gazetteer indicating the areas of Great Britain where mining-related ground stability is likely to be an issue.
- Topographic data can be obtained from several sources, including the OS Land-Form Profile Service (www.ordnancesurvey.co.uk), which covers the UK. The data are presented as x,y,z values (derived from photogrammetry) with an accuracy of approximately ±1 m in plan and ±1.8 m vertically.
- Documentary searches of underground services and utilities plans can be commissioned from commercial search firms (see Box 43.5). As well as shallow utility services, the search should include transportation and utility tunnels.

Box 43.5 Utility searches by commercial agencies

In the UK, several commercial organisations offer 'one-stop shops' for obtaining, collating and reporting documentary searches of utility plans of statutory service undertakers (gas, water, electricity, telecoms, etc.). A request for a documentary utility search should state clearly the footprint and the depth of the proposed development. The searches can take several weeks to complete, as they rely on receiving responses from third parties. Be aware that the documentary search results will show only the approximate location of the buried utilities – not exact positions – and they will not show buried utilities within a private property boundary or within buildings.

- The possible presence of disused historic tunnels should not be overlooked (for example the Post Office railway in London or Williamson's tunnels in Liverpool). Identifying such infrastructure often relies upon local knowledge, or access to it.
- Public libraries usually hold a collection of local history books, including out-of-print publications that may not be readily available elsewhere.
- Certain below-ground infrastructure such as emergency bunkers and strategic telecoms tunnels are, by their nature, not widely advertised. Some disused facilities have been reported by enthusiastic amateurs (such as at Subterranea Britannica www.subbrit.org.uk). For operational facilities, enquiries should be made to the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

relevant bodies to ascertain where any 'hidden' infrastructure is in relation to the proposed development.

- The archives at the Institution of Civil Engineers (www.ice.org.uk) are a useful resource for obtaining information and records of historic engineering structures (Chrimes, 2006).
- Details of grade-listed buildings and Scheduled Ancient Monuments in England are available from English Heritage (www.english-heritage.org.uk) and its searchable online archive of images of grade-listed structures (www.imagesofengland.org.uk).
- Historic aerial photography of England from the 1940s onwards, including wartime images showing bomb damage, can be obtained from the National Monuments Record Centre (English Heritage). The NMR archive in Swindon can be visited in person. Alternatively, a 'priority search cover' can be ordered, which lists the date, location, scale, stereo-pairing and verticality of the aerial images. Detailed interpretation of aerial photographs is a specialist skill, as is the photogrammetric analysis of stereo-pairs of images to quantify dimensions and levels from aerial imagery.
- Comparable services in Wales and Scotland are provided by, respectively, the Royal Commission on the Ancient and Historical Monuments of Wales (www.rcahmw.gov.uk) and the Royal Commission on the Ancient and Historical Monuments of Scotland (www.rcahms.gov.uk).
- Information about wartime bomb damage and unexploded ordnance (UXO) can be obtained from several sources. For London, hand-coloured OS maps were used to record the degree of bomb damage; these are available in book format. The Department of Communities and Local Government (www.communities.gov.uk) maintains a list of known, abandoned UXO. Information about known UXO at a site can be obtained from the department, by emailing details of the site location (address, grid reference, map). The likelihood of UXO being present at a site is partly, but only partly, a function of the density of bombing that occurred in that district. A readily accessible summary of bombing densities across the UK is available at www.zetica.com.

43.7 Using the internet

The internet is a powerful – but not an all-powerful – tool. Internet searches can offer a quick and low-cost way to find information about a site. Maps, satellite imagery (for example at www.google.co.uk), reports, journal papers and images can often be found online and downloaded almost immediately. At its best, the internet can provide, or lead to, useful information that would otherwise be difficult, time-consuming and costly to obtain. At its worst, however, the internet provides low-grade, unverified and sometimes erroneous information.

When using the internet as part of a preliminary study, be conscious that:

- Data available on the internet are often incomplete, undated and unreferenced – and, hence, potentially unreliable. Online data should be checked independently where possible. Be aware that some websites simply recycle material from other online sites, although the material may have been in error in the original source.
- The successful exploitation of internet search engines relies on selecting appropriate and well-chosen keywords, and then refining and re-focussing the search as it progresses.
- Material pre-dating the internet may not be readily revealed by an internet search. Traditional desk study research methods – and some legwork – may still be needed. For example, local history centres and archives nowadays often list their catalogues online, but a visit in person to the collection may be necessary in order to see the material. Be aware that an online search will only reveal documents that have been catalogued using the same keywords used in a search. Discussion with a knowledgeable curator may uncover other relevant material, which may not have been revealed by a simple keyword search.

43.8 The site walkover survey

If permitted and if possible, a site walkover survey should be undertaken. Ideally, the walkover should be done about two-thirds of the way through the period assigned for the preliminary study, by which time enough background documentary information will have been gathered to inform what is seen on site, and sufficient time will still be available to follow up any unexpected observations and to integrate the walkover results into the overall site interpretation.

The planning of a site walkover visit should include due consideration of safety, and an appropriate risk and mitigation assessment should be carried out beforehand. Potential hazards are site dependent, and may range from aggressive livestock in rural areas to unfriendly locals in urban areas. In most cases, at least two people should undertake a walkover visit together, to avoid the hazards of lone working.

What to look for during a walkover survey will depend on the context: walkover surveys at a hill farm and at a city street would be substantially different. An experienced practitioner will have a mental checklist of basic items to look for (such as utility service covers; repairs in roads and pavements; drains and ditches; marshy ground; uneven ground; cracks in structures; geomorphology; rock outcrops; slopes and slope instability; evidence of cut and fill; species of trees; types of buildings; presence of basements; possible sources of contaminants; access for ground investigation drill rigs; likely locations for boreholes; overhead constraints) plus a long list of project-specific and site-specific items.

On site, all relevant features should be noted and photographed. Photocopies of site maps or satellite images can be annotated with observations and comments. For large or rural sites, a hand-held GPS to record coordinates of features can be helpful. Photography is an essential tool. Plenty of photographs should be taken: not all need be used in the report, but a photograph can often help answer an unforeseen query when reviewing data back at the office. The preliminary study report should include a photographic key plan showing the location and direction of each photograph reproduced in the report.

The walkover survey should not be limited to the site itself, but should also look beyond the site boundaries. If access onto neighbouring land is not possible, then a visual assessment can usually be made across the boundary line.

It can be useful to talk to local people, as they usually know their area and its history. However, it is important to

verify anecdotal recollections independently, and to indicate clearly any anecdotal information that is included in the report. When undertaking a walkover survey, especially when talking to locals, a degree of circumspection may be appropriate. Before undertaking a walkover visit, one should check how much of the proposed project is public knowledge, and whether the project is considered sensitive either locally or commercially, particularly if planning consent has not yet been granted.

43.9 Writing the report

When writing a preliminary report, much inspiration can be gained by looking at good examples of previous reports for other sites, but these should never be relied upon wholly. Each site is unique. Factors that may not have been relevant at another site, and which were, therefore, disregarded in its report, may be critical at the site of interest.

As with all technical report writing, the preliminary study report should be written clearly and carefully. Useful guidance on writing geotechnical reports is presented in three guides produced by the Association of Geotechnical & Geoenvironmental Specialists (AGS) and available at www.ags.org.uk:

- *Guide to Good Practice in Writing Ground Reports*;
- *Management of Risk Associated with the Preparation of Ground Reports*;
- *Guidelines for the Preparation of the Ground Report*.

The AGS guides emphasise the importance of taking care when writing a technical report because, for example, a negligent and damaging error could potentially lead to claims against the organisation that issued the report.

The structure of the report will be partly dictated by the material that has been reviewed. The list of items in 'What goes into a preliminary study?' (section 43.3) can be used as a basis for the overall report structure, and as headings for sections and sub-sections.

As in any professional technical report, it is important to distinguish between factual and interpretative elements. The report should include a clear statement of what sources of information have been reviewed in preparing the report. Equally, if any key items have *not* been reviewed (perhaps a document that is known to exist but has not been received in time, or has been withheld by a third party), this should be stated in the report, as it affects the scope and completeness of the report.

The source of all material used in the report should be clearly stated, even if the material is not copyrighted (see Box 43.6). The aim should be to provide readers with enough information to enable them to find the same material again. As a minimum, this should include the source and date of the material. By doing this, a signal is sent to the reader about the provenance and, hence, the likely reliability of the information upon which the preliminary study has been based.

Box 43.6 Copyright

Care is needed when using material, especially images, taken from copyrighted sources. Preliminary studies are produced for clients, and are, thus, commercial reports. Under UK copyright law, the consent of the copyright owner should be sought if an extract of their work, or an adaptation of their work, is to be included within a commercial report. Also, the owner of the copyrighted material should be clearly stated in the report. For fuller details of copyright issues and UK copyright law, check the UK Intellectual Property Office's website (www.ipo.gov.uk).

If reproducing Ordnance Survey (OS) maps, these should be clearly labelled as being Crown copyright material. The OS operates a licensing system for businesses wanting to reproduce OS maps in professional reports. A copy of the OS's *Paper Map Copying Licence* can be downloaded from the OS website www.ordnancesurvey.co.uk.

43.10 Summary

The preliminary geotechnical report is the essential first link in the chain of geotechnical project risk management (see **Figure 43.1**). Site information, ground models, geohazards, uncertainties and ground-related risks identified in the preliminary study will form the basis for the next stages of the project, and may potentially influence the direction of the project and the engineering solutions adopted.

A well-planned, well-executed preliminary study that is followed through with a suitable ground investigation can help significantly in reducing the likelihood of unexpectedly encountering problematic ground conditions during construction, although it cannot reduce that likelihood to zero.

44.2	Planning the ground investigation	585
44.3	Procuring the site investigation	593
44.4	Managing the site investigation	598
44.5	References	600

Coherent planning is required for every ground investigation in order to ensure that it is carried out simply and cost-effectively and produces all the requisite information. Poorly planned ground investigations cause significant problems in terms of damage to neighbourly relations and damage to buried utilities, the latter exposing the site operators to severe safety risks. A well-planned two-phase campaign can offer advantages for longer and more complex investigations, as information discovered in the first phase can be further investigated in the second. A clear form of contract and specifications reduces the risk of disputes. Regular review of the information recovered is the ultimate success of a grand investigation campaign.
A well-planned campaign is essential to anticipate future likely changes in the scheme. It saves construction cost and programme by revealing important site features at an early stage which can then be planned for.

44.1 Overview

The success of a ground investigation depends on the extent of prior planning, the clarity of the procurement processes used and the care with which it is managed. These factors become even more important for larger ground investigations. The trend towards frameworks and large infrastructure projects means that some ground investigations are now becoming very large indeed.

A ground investigation can be considered to have failed if:

- The process does not gather all the data intended, or if a party subsequently realises that more or other data should have been gathered at the same time, or if the ground investigation reveals aspects of the site which should have been considered before. Note that ground investigations can never discover everything about a site, and the possibility of surprises should never be discounted. The discovery of legitimately new information in the investigation should be regarded as a success rather than a failure.
- The process results in a significant misunderstanding or dispute involving the client, the contractor, a landowner, an authority or some other body. These aspects should have been considered beforehand and the contract documents should have set out clear rules to avoid such an occurrence.

The standard guidance documents for ground investigation are those of the *Site Investigation in Construction* series, produced by the Site Investigation Steering Group, introduced in Chapter 42: *Roles and responsibilities.*

44.1.1 Key messages in this chapter

- Ground investigation is done most efficiently if properly planned in advance.
- Planning a ground investigation is firmly based on logic, but balancing the many conflicting constraints and priorities sometimes makes it akin to an art-form. The planner must not lose sight of the main objective, which is to gather sufficient data for the design of the planned development and minimise ground risk. The various constraints imposed on the ground investigation must not compromise the final information to any unacceptable level.
- Safety is a key objective. There may in some circumstances be some conflict between the safety of the site investigation operatives and the need to gather information to minimise the risk to the workforce on the main development. In those circumstances, careful consideration will be needed. Any residual risk in the site investigation must be fully communicated to all those going on site and every effort must be made to mitigate the remaining risks to tolerable levels.
- Ground investigations often take longer than many people would wish. Completion of the site works is not the end of the story. Sufficient time should be allowed in the overall project programme for timely completion of the ground investigation before the information is needed for design.
- Choosing the right people to undertake the various geotechnical activities – design and investigatory – depends on the relative strengths of the various project participants. But it is important to facilitate as far as possible a coherent geotechnical design process – disjointed steps in that process are a major source of project risk.
- As for any construction activity, a clear specification and contract with equitable terms should reduce the risk of disputes.
- Locating unforeseen conditions in a ground investigation should be seen as a success and not a failure, even if the ground investigation is pushed over budget.

44.2 Planning the ground investigation

44.2.1 Developing a coherent campaign

44.2.1.1 Meeting the needs of clients, designers and contractors

Planning for a ground investigation can only take place after an understanding has been gained of the likely geology

(see Chapter 40 *The ground as a hazard*) and the desk study has identified the key uncertainties and hazards on the site (see Chapter 43 *Preliminary studies*). Rudolf Glossop said in his 1968 Rankine lecture: 'If you do not know what you should be looking for in a site investigation, you are not likely to find much of value' (Glossop, 1968).

Planning of a ground investigation should target the particular development scheme proposed and it is important that all aspects of the scheme and its implications are known, for instance:

- a six-storey building over a two-level basement; perimeter retaining wall needed on north side; foundations may be piled to 30 m depth, large surface car park to west.

Thus if a tall tower is added or if the building location changes, further supplementary ground investigation will be needed. The effects of the location of buried utilities, highways works and the necessary traffic management on the investigation also need to be considered early, as these issues often require lengthy negotiation and agreement (see Chapters 41 *Man-made hazards and obstructions* and 42 *Roles and responsibilities*). Leaving these aspects until too late, for instance delegating them to the contractor, who cannot start the negotiations until appointed, can lead to delay and extra costs.

The development of a coherent campaign of ground investigation requires considerable planning, particularly where third-party property owners believe they will be affected by the site works. Site occupants and immediate neighbours will be directly affected. Generally the ground investigation is the first physical sign of the new development that they experience, and so any opposition or concern to the development may be focused on the ground investigation fieldwork campaign. Thus special care at this stage is needed, as a carelessly executed ground investigation that causes much inconvenience can sour neighbourly relations for some time and complicate the main construction process,

Often, ground investigations are carried out while existing buildings on the site remain fully occupied and operational. This is because the site is only usually vacated in preparation for demolition; few clients will commit to demolishing while they can continue to receive rent and will delay evicting occupants until they have let the contract to build the new structure or building. The demolition cannot be let until the structural design has been completed, which relies on the completed ground investigation. The ground investigation therefore usually has to fit around occupants and operational business. This can be a significant cause of conflict unless the planning of the site investigation ensures that occupants are not unduly disturbed, operation of the facilities is not unduly impaired and safety of the normal site occupants is not compromised. These aspects are discussed in more detail in section 44.2.3.

Often formal permissions or licences may be needed in order to undertake the investigation, especially when access is required across neighbouring land, or where parts of the investigation have to be undertaken off the site, for instance on the public highway. The programme for the investigation needs to allow time to make all agreements, obtain all necessary licences and follow any restrictions legitimately placed on the operations by relevant parties.

Ground investigations next to live railways tend to be the most tightly regulated, because of the severe consequences if a rig overturns or a slope is destabilised next to the operational railway. The person planning the investigation needs to be aware of all specific rail-related regulations and procedures that may affect the work, including training of site workers and appointment of railway look-outs. Ground investigations next to water should receive similar attention in planning.

The Party Wall Act etc. 1996 often governs the interface with neighbours when any form of construction work is being undertaken. A very thorough explanatory leaflet is available from the Department for Communities and Local Government, published in March 2002.

Section 6 of this Act applies where a landowner wants to excavate, or excavate and construct foundations for a new building or structure, within:

- 3 m of a neighbouring owner's building or structure, where that work will go deeper than the neighbour's foundations; or
- 6 m of a neighbouring owner's building or structure, where that work will cut a line drawn downwards at 45° from the bottom of the neighbour's foundations (see **Figure 44.1**).

The limit for excavations is sometimes taken to mean excavations for ground investigations, although it is not thought that that was the intention of the Act. Unfortunately, excavations for ground investigation are not explicitly excluded under the Act, so the Act can sometimes be deemed to apply even to small boreholes or limited trial pits. Where the Party Wall Act may apply, it is therefore prudent to obtain the requisite permissions, especially if neighbourly relations are not good.

44.2.2 Considering all aspects of the site and all users for the data

Ideally the ground investigation is planned to address several needs at the same time, for instance:

- Carrying out geotechnical design of foundations and sub-structures for the new development, including all significant ancillary works such as retaining walls and car parks.
- Producing information for the design of temporary construction works, such as excavation slope stability or dewatering during construction, as otherwise tendering contractors will have no other source for the data and will make conservative assumptions that will push up the construction price.
- Gaining knowledge of current foundations for existing buildings in order that any necessary structural changes can be designed to allow the new development to proceed.
- Understanding the state of contamination of ground or groundwater or establishing levels of deleterious or harmful substances in the ground.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

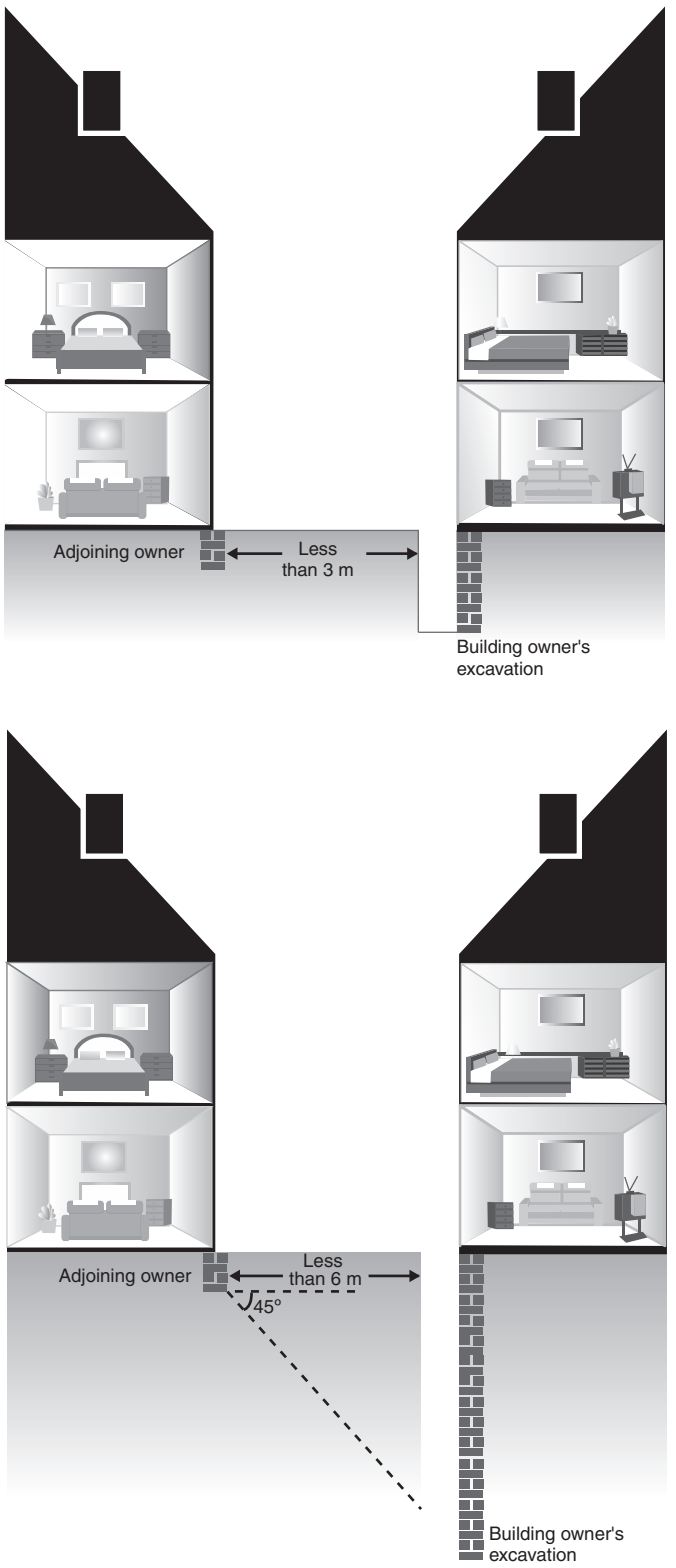

Figure 44.1 Application of Party Wall Act
Reproduced from DCLG (2004) © Crown Copyright

- Determining underground water flows under or around the site.
- Collecting data on existing buried services, sometimes just to ensure that they are avoided by the ground investigation but often to ensure their locations are known for main construction so that they can be avoided, diverted or protected.
- Examining the ground for any evidence of surviving archaeology and coordinating the campaign with any necessary archaeological excavations.

In such cases the site operations need to be organised and phased so that all relevant consultants have the opportunity to input. Their input is needed in planning to integrate all requirements, and during the site works to satisfy them that their specifications are being followed and the right information is being obtained in a holistic way, efficiently and minimising effects on people affected by the work. Sometimes these operations are carried out in a disjointed way with little coordination – such an approach usually leads to fewer data being obtained at greater cost and increased disruption. Sometimes aspects are neglected, such as those for temporary works – these omissions can prove exceptionally costly, either due to lack of appropriate information for tendering contractors or failure to identify key features until they are discovered during construction.

On complex sites where many of these requirements are not straightforward, one person should be responsible for ensuring that the campaign is executed coherently. That person may be an engineer's representative for the employer or a well-briefed agent for the contractor, depending on which approach is most appropriate.

A two-phase ground investigation campaign is recognised as being a valuable way to investigate the ground, particularly on sites with greater ground uncertainty, because it allows the second phase to build on the results of the first one, to refine what is found and to respond to new information. Generally the first phase would be a sparse but deep investigation, to detect the major geological formations and identify those that need greatest focus in the second phase. The second phase can then refine the results of the first phase, filling in details and providing appropriate design parameters for each major stratum. This approach is most valuable when there is significant uncertainty about the geology beneath the site, which can at least be partially clarified in the first phase. On major infrastructure projects, there may be several phases of investigation. Eurocode 7, Part 2 (BS EN1997-2:2007) (BSI, 2007) also supports a two-phase approach for larger and more complex investigations.

Major constraints to the execution of the ground investigation should be determined, e.g. existing tunnels beneath the site which need to be avoided, so that an optimal campaign can be planned.

Sometimes, the site constraints prevent a coherent campaign being planned to properly investigate the hazards. In that case, two options are possible:

- Defer the troublesome activities until a later time when they become possible, for instance by waiting for a window between the site being vacated and the start of demolition. This means that

important information will not be gathered until relatively late in the design process. This may not matter much provided the first phase of investigation gathers enough information for design, but perhaps omits information relevant to construction planning; however, it is not appropriate to delay the collection of information that may lead to a misunderstanding of the ground conditions in design.

- Accept the increased risks and make the development less dependent on them, e.g. adopt a more conservative design basis which can accommodate greater uncertainty. This may have a higher direct cost, but may be expedient in terms of a quicker programme and hence be more economical in terms of overall costs to the client.

An example of the first approach would be on a site where the variation in level of a particular stratum interface is in doubt. The first phase would confirm the general level and the design parameters. Proving the level of an interface sufficiently for construction, e.g. choice of temporary casing length for piling, need only be done immediately prior to letting the construction contract ,so that accurate prices can be obtained from the tendering contractors.

On some sites, and particularly those smaller sites where environmental concerns are greater, sometimes an initial geotechnical investigation is merged into a combined 'Phase 1' geotechnical and geo-environmental investigation as explained in Chapter 42 *Roles and responsibilities*. Such investigations sometimes fail to collect important geotechnical information such as adequate depth of investigation, proper soil descriptions, water level measurements and strength determinations. Failing to collect these data at an opportune time is a missed opportunity that increases project risk – every effort should be made to ensure that a Phase 1 environmental investigation also provides meaningful geotechnical information.

Providing easy access to all the data produced can be a challenge, particularly for large ground investigations. Hence consideration of how the data will be managed is important. For larger investigations, incorporation of the results into a GIS system can pay dividends in the subsequent design phases.

44.2.3 Timing, programme and space: balancing the constraints of site and project

Knowledge is more useful the earlier it can be obtained. However, a ground investigation usually has to be delayed until:

- The scheme it is to address has crystallised into what is likely to be built, at least in broad terms – doing it too early may mean a supplementary ground investigation is required later.
- The client is sufficiently committed to the scheme to invest significant resources in it – although ground investigations are a very small proportion of the total project cost, they are often the first construction-related activity on site and so represent the client's first large payment to a contractor. Hence this hurdle is sometimes a useful barometer for a client's commitment to a project.
- The start of ground investigations does not alarm current site occupants or neighbours, who in some circumstances may be opposed to the development objectives and plans.

A way to reduce these effects and to allow earlier collection of ground investigation data is to use a two-phase approach to the ground investigation as introduced in section 44.2.2:

- First phase to check key hazards, confirm any variation in the stratigraphy across the site and obtain outline design parameters.
- Second phase to provide more complete coverage and to confirm the applicability of design parameters.

The two-phase approach is especially valuable for sites where the ground conditions are not well known at the outset, as it permits some understanding to be gained by the ground investigation designer between collection of the data used to formulate the basic ground model, and filling in the detailed information needed for each layer.

An early ground investigation will normally take place while the site is still occupied, so sensitivity is needed to avoid causing excessive disruption to occupants, users and neighbours. The main forms of disruption are:

- Occupation of space – in addition to the space needed at each exploration point, the ground investigation contractor will need space for stores, spare drilling equipment (for instance, extra lengths of casing), waste skips, offices and parking.
- Restriction of access or impairment of site operations – some of the exploration positions may impede main access routes for vehicles and pedestrians or block loading bays.
- Noise and vibration – the exploration is often the first major construction activity for the new development, and so noise and vibration could be a cause of concern to neighbours and residents. On very restricted sites, boreholes or trial pits will inevitably encounter buried reinforced concrete or masonry, which will have to be broken out by pneumatic tools – limiting their use to particular times can do much to improve neighbourly relations but will increase ground investigation cost and programme. BS 5228: Part 2 (*Code of Practice for Noise and Vibration Control on Construction and Open Sites – Vibration*) (BSI, 2009) and CIRIA TN142, *Ground-Borne Vibrations arising from Piling* (Head and Jardine, 1992), although primarily intended for piling operations, provide useful guidance on controlling noise and vibration control and appropriate limits for ground investigation sites.
- Disruption to services - potentially, the investigation can lead to buried services being damaged or cut, which will affect the site occupants and may cause financial losses due to business interruption. Ideally, services these will have been identified and deactivated when planned works are in close proximity to them.
- Impairment of safety by extra vehicular movements or lack of care.
- Level of reinstatement – whether tarmac is fully reinstated; whether standpipes are made flush with the ground or raised etc. These aspects are best agreed in advance so that the contractor's cost can allow for the level that will be required, and to prevent higher costs being sought at a late stage.

A ground investigation can be modified to use less space, but cost and programme will consequently have to increase, and the technical output may be compromised. Examples include:

- A normal cable percussion ('shell and auger') boring rig needs a working area of at least 7 m × 3 m and direct vehicular access.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

A man-handleable portable rig can be used in confined areas, but is restricted in borehole diameter, depth and numbers of 'strings' of casing that can be inserted.

- Machine-dug trial pits may need a space of 3 m square; hand-dug trial pits can be done in a smaller area, but need to be shored and are significantly slower with increased concerns for safety. They may still need to break through buried reinforced concrete, so may not be quieter, and if slower may prolong the agony of neighbours.

A typical programme for the procurement and execution of a ground investigation is given in **Figure 44.2**. The programme is often significantly longer than clients expect, so it is worthwhile explaining the rationale for each of the programme elements in order that an instruction to proceed is given appropriately early and results can be available when needed.

44.2.4 Parameters and information needed

44.2.4.1 Information and requirements of different projects

The parameters collected in a ground investigation depend on the nature of the site and what one plans to build on it. A particularly hazardous site or a complex development will obviously need a more elaborate analysis to address the key risks in the most economical way. The more detailed the analysis, the more parameters usually need to be determined for the results of the analysis to be meaningful. There needs to be a degree of iteration around the *scheme–analysis–parameters–investigation* loop to ensure that the ground investigation is carefully targeted. A geotechnical adviser with experience across all these disciplines is most suitable to plan the ground investigation, draw together the disparate strands and not produce an overall investigation that responds disproportionately to the most vocal demands.

The need for ground investigation depends on what is intended to be built – and in turn, in extreme circumstances, what can be built depends on the results of the ground investigation. Thus the ground investigation needs to correctly anticipate the likely form of foundations. This cycle is illustrated graphically in **Figure 44.3**.

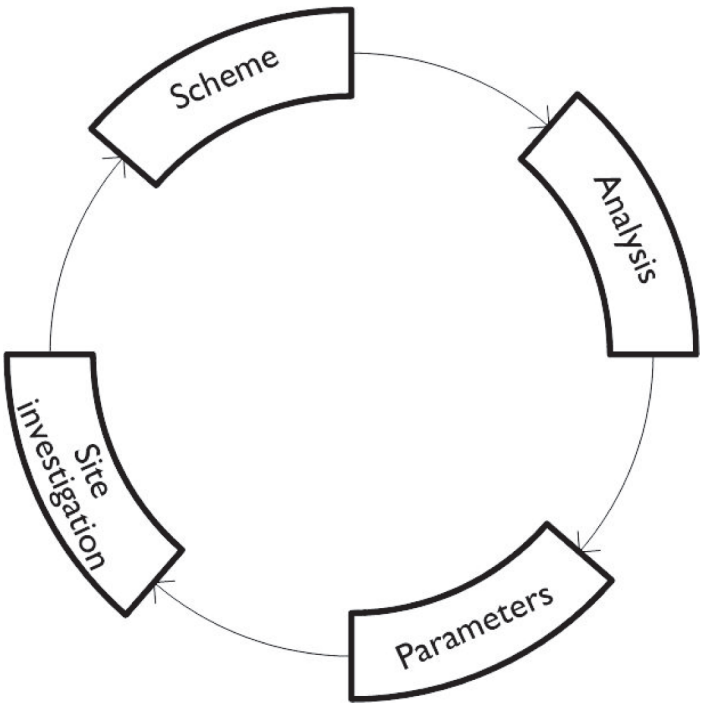

Figure 44.3 Loop connecting scheme with geotechnical analysis, soil parameters and site investigation

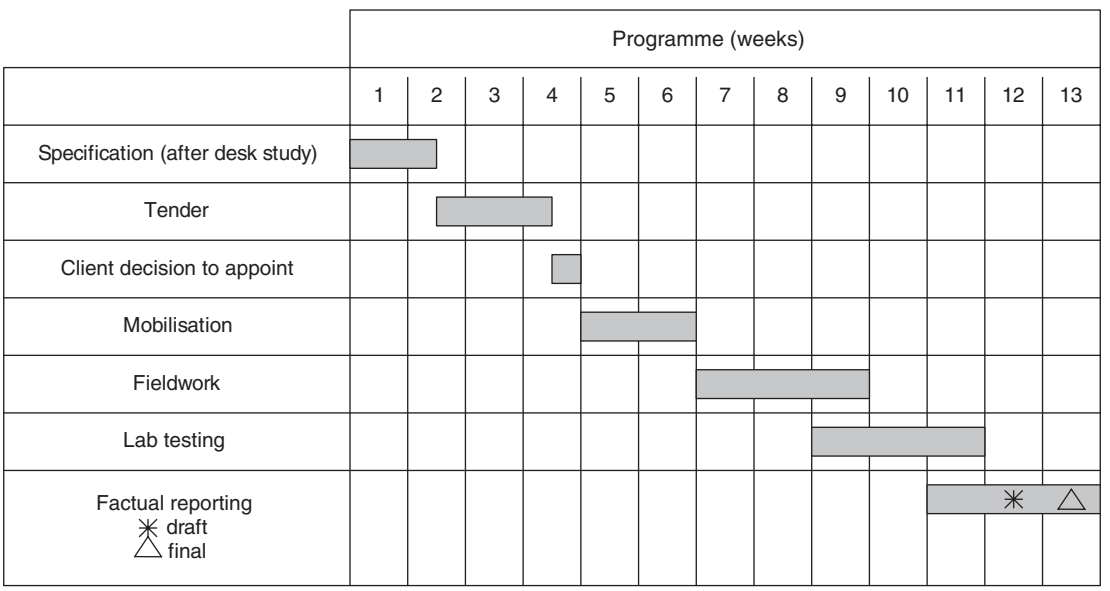

Figure 44.2 Typical overall ground investigation programme

As a minimum, the ground investigation should determine the following features:

- stratigraphy and its variation across the site;
- groundwater regime on and around the site; pressure variation with depth and time; directions of flow across the site;
- characteristics of principal strata in terms of their likely behaviour;
- strength, stiffness, *in situ* stresses and permeability for key strata.

A further aspect needing investigation is the near-surface ground. This is to detect:

- obstructions and buried services – see Chapter 41 *Man-made hazards and obstructions*;
- extent and levels of neighbouring foundations;
- weaker ground that could present a hazard for piling platforms (see Building Research Establishment, 2004) or other relevant temporary needs;
- tree roots in plastic clays, which could lead to desiccation shrinkage and movement of shallow foundations.

The ground investigation should appreciate the possibility of real geological variability and not just expect to validate the planner's preconceptions. The sorts of variability are explained in more detail in Chapter 40 *The ground as a hazard*, but could include, for instance, the presence of a significant sand channel in an estuarine deposit such as the Lambeth Group, or heavily reworked sand or clay such as the very deep post-glacial scour features that occur in London Clay sporadically but often associated with the confluence of old rivers.

It is important at the outset that the designer of the ground investigation is clear about the information that will be needed in the later analyses. It is seldom possible to repeat elements of the ground investigation without considerable disruption, expense and embarrassment.

The parameters that need to be gathered depend on the analyses required to complete the design. They must address all the key design issues in order to allow the most economical methods of construction and least project risk, as shown in **Table 44.1**.

44.2.5 Examples of scope issues

The following points need to be considered in determining the scope of a ground investigation:

- If piles are expected, boreholes will generally need to go deeper.
- If foundations on clay are next to trees, the extent of clay desiccation will need to be assessed.
- If the main construction works are likely to need extensive dewatering, the permeability for each of the strata will need to be estimated.

Clearly, on any site, the ground investigation for a low-rise housing development will be very different from that for a tall office block over a deep basement. Therefore ground investigation reports will always be scheme-specific rather than site-specific. While an old geotechnical report should provide very useful information about a site, its scheme-specific recommendations should be used with caution for subsequent and adjacent developments.

A ground investigation scope is always a balance between more comprehensive coverage and a limited budget. On any project, funds will be tight, particularly for up-front activities. On the other hand, it is not cost-effective to have to repeat site operations because parts of the ground investigation were omitted. It is therefore important that the geotechnical consultant should consult widely with the other team members, prior to completing the scope to:

- Include all requirements, not just those of the structural engineers needing foundations, as explained at the start of this chapter. Others may include the site-wide infrastructure engineer planning roads and car parks, the public health engineer who might be considering SUDS (sustainable urban drainage system), the services engineer who may wish for trial pits to explore existing service routes, and the architect who might be concerned about zones of ground with greater archaeological potential.
- Consider the effects of the whole development on the ground. Thus the car parking requirements may lead to a need for tiered retaining walls; the most cost-effective way to build a basement may be in open cut for which an increased knowledge is needed of the site's hydrogeology and strata permeabilities.

So when planning the ground investigation, a number of choices have to be considered such as the likelihood of:

- shallow or deep foundations;
- retaining walls or open cut;
- alternative access road routes;
- finding contamination or archaeology.

Element being designed	Analysis method	Parameters that need to be measured	Method of measurement
Pile design	Hand calculations	Stratigraphy, water pressures, ground strength	SPT/CPT tests in boreholes; lab tests on samples recovered from boreholes
Pile constructability		Borehole seepages, borehole collapses during boring	Index tests on borehole samples to identify changes in material
Concrete durability	BRE SD1	Sulfate content	Lab tests on borehole samples

Table 44.1 Relationship between pile design and need for information from the ground investigation

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

44.2.6 Appropriate testing

44.2.6.1 Matching the testing schedule to the information requirements

The AGS's excellent *Guide to the Selection of Geotechnical Soil Laboratory Testing* (Association of Geotechnical and Geoenvironmental Specialists, 1998) addresses this subject.

Soil testing fulfils two essential aims:

- It confirms quantitatively the variation in nature of each stratum, spatially and with depth – this allows particular strata to be more simply considered together for engineering design, or indicates where a more complex sequence of strata needs to be considered (geologists tend towards more, detail whereas civil engineers tend towards simplification in terms of considering the engineering properties of different geological strata).
- It provides data for design – engineering design of foundations and sub-structures requires a quantitative basis in terms of strength and stiffness for the subsequent analyses.

When planning tests, it is often worthwhile considering these two aspects separately. A simple investigation, such as following the NHBC rules for house foundation design, will be principally concerned with the general characterisation of the soils beneath the site. A major building with deep basement will need to more accurately quantify strength and stiffness for each layer, and may also need other parameters such as permeability. Before planning the test strategy, it is useful to have clarity on the division into likely key strata.

The relative reliance on field and laboratory tests varies between different countries according to local practice. A balance has to be struck between:

- Making measurements crudely on the actual ground at the correct density and *in situ* stresses and in relatively undisturbed state.
- Taking discrete samples back to a laboratory where tests can be made under more controlled conditions, albeit on samples that have been disturbed during fieldwork and subsequent transportation and examination.

Attempts have been made to improve the level of technology applied in field tests – e.g. pressuremeters – and to make laboratory tests more representative – e.g. stress path triaxial tests. In fact, for most typical design cases, the usefulness of all tests depends on their ability to simply apply previously observed behaviour of real foundations in the field to the new situation.

A simple classification of all common test types used on soils in the UK is given in **Table 44.2**.

The range of possible contamination tests is very wide and is addressed in Chapter 48 *Geo-environmental testing*.

For larger structures where more complex analyses are planned, the data gathered in the ground investigation need to be geared towards those analyses – inputting less accurate data into complex analyses can result in meaningless output. Therefore some redundancy is needed to allow a more refined choice of parameters, so sometimes parameters should be deduced from several test types, both field and laboratory.

An advantage of field tests over laboratory tests is that their results are available relatively quickly. A drawback of advanced laboratory tests – particularly tests on clay either in the triaxial cell or shear box at a drained rate of shearing – is that the results can take a considerable length of time to become available. The results may arrive after important design decisions for the whole project have already been taken. The geotechnical designer should not wait for these parameters as the basis for conservative analyses in order to retain the confidence of the rest of the design team and to be able to influence the design correctly.

Laboratory and field techniques for investigating the ground are described in more detail in Chapters 47 *Field geotechnical testing* to 49 *Sampling and laboratory testing*.

44.2.7 Frequency and depths of fieldwork

44.2.7.1 Choosing the right techniques and equipment

The amount of investigation that is appropriate depends on the consequences of missing possible variations. Basing a design on just one exploration point suggests confidence that all stratum boundaries are reliably flat over the whole site and soil properties do not vary. In previously unexplored conditions, three boreholes are needed to define the angle of dip of key stratum boundary planes, assuming no folding or faults in the planes.

The key aim of any investigation is to sensibly investigate the strata and interface levels that are important for design. Thus a presumption towards a building founded on piles might indicate a much more complex investigation than one where

	Field tests	Laboratory tests
Characterisation	SPT cone	Grading (sieve and pipette)
		Atterberg limits mineralogy
Strength	Hand vane pocket penetrometer cone	Triaxial shear box
	Pressuremeter indirectly from SPT	
Stiffness	SPT pressuremeter	Triaxial with local strain measurement
Permeability	Pumping test with pumping well and observation wells (standpipes)	Oedometer test
	Rising/falling head tests	Permeameter

Table 44.2 Range of common soil tests

only shallow foundations need be considered. The implications of these ground investigation planning decisions should be explained to the rest of the design team, so that factors which might invalidate them can be explored.

If parameter uncertainty is the only variable, a poor quality or less extensive investigation can be compensated for by a more conservative design, albeit at a likely higher overall direct cost to the project. For instance, a conservative assessment of skin friction in pile design can obviate the need for more boreholes and more testing. However, reducing the extent of the site investigation may cause one to miss a significant change in ground conditions that would invalidate the choice of pile type. The project will then suffer serious cost and programme penalties while the team designs a more appropriate pile type and the contractor waits with expensive equipment standing idle.

BS 5930:1999 (BSI, 1999), Clause 12.6, recommends the spacing between exploration points:

- a relatively close spacing between points of exploration, e.g. 10–30 m, is often appropriate for structures;
- for structures small in plan area, exploration should be made at a minimum of three points, unless other reliable information is available in the immediate vicinity;
- where a structure consists of a number of adjacent units, one exploration point per unit may suffice;
- certain engineering works, such as dams, tunnels and major excavations, are particularly sensitive to geological conditions, and the spacing and location of exploration points should be related more closely to the detailed geology of the area than is usual for other works.

Eurocode 7, Part 2 (BS EN1997-2:2007; BSI, 2007), Clause 2.4.1.3, advises:

> The locations of investigation points and the depths of the investigations shall be selected on the basis of the preliminary investigations as a function of the geological conditions, the dimensions of the structure and the engineering problems involved.

It goes on to require:

> The depth of investigations shall be extended to all strata that will affect the project or are affected by the construction. For dams, weirs and excavations below groundwater level, and where dewatering work is involved, the depth of investigation shall also be selected as a function of the hydrogeological conditions. Slopes and steps in the terrain shall be explored to depths below any potential slip surface.

Appendix B3 to BS EN1997-2 (Eurocode 7, Part 2) provides useful guidance on investigation point spacings for a range of situations, including a spacing of 15–40 m for 'high-rise and industrial structures', less than 60 m for 'large area structures' and 20–200 m for long linear structures such as roads, railways, retaining walls, pipelines or tunnels. It should be noted that these spacings do not necessarily indicate frequent deep and expensive boreholes – just enough exploration points to detect the more critical changes in ground conditions. For pile design in London Clay, the critical variable with the likely widest variation is the surface level of the London Clay: it can sometimes vary by several metres due to the routes of old rivers, or even by several tens of metres due to scour hollows. This means that more boreholes need to reach and prove the surface of the London Clay than boreholes that go right through the whole stratum and prove its base. Similarly, Made Ground is much more variable and may change over very short distances. Its surface thus needs to be proven more frequently, and its inherent variability needs to be recognised and allowed for in design. Adopting this philosophy should result in the most cost-effective extent of fieldwork-economical but still effective in reducing the key risks.

Where the extent of the development is uncertain, a balance has to be struck between the right level of fieldwork for the most extensive development and the savings that can be made by planning for a more modest development, with the possibility of a return visit later. The choice may need to be discussed with the client to agree what is most appropriate – the client may be prepared to live with the risk that more work will be required later to realise a potential saving. Particularly where the difference in cost is relatively small and the project programme is tight, the client may not be able to live with the risk of missing critical information. Sometimes a compromise is possible where sufficient data are gathered to enable scheme design for all options, but there are only enough data for complete design of the less extensive option. It also depends on the procurement route chosen for the main contract and the mechanism for transferring risk.

As stated earlier, the ground investigation should provide the data for the likely temporary works (so far as they can be predicted at the time). There is unlikely to be time later in the temporary works design for fresh information to be obtained, so the project's overall risks (and probably costs) will be higher if this is not done at an early stage.

44.2.8 Clear campaign aims

Once a campaign of ground investigation has been planned, it is important there is a clear strategy for its execution. For larger and more complex investigations, it is good practice to set out the strategy on a site plan and on an idealised geological section. As each hole is completed, its contribution to the overall campaign can be tracked. This is especially important when there are a number of aspects of the investigation which need to be resolved spatially and with depth. The strategy, if properly executed, should ensure that sufficient results are obtained without breaching the budget. Features that often need a formal strategy at the start of the campaign include:

- stratigraphy – proving the surface of each important layer to get a good spread spatially;
- water pressures – variation with depth, spatially and in each stratum;

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- geotechnical test results – variation in each stratum with depth; detecting spatial variations;
- contamination test results – variation of different chemical determinands in each area of suspected contamination.

An example is shown in **Figure 44.4**.

Without clearly defined aims at the outset, a ground investigation can quickly collapse into chaos, as a huge flow of unrelated data can overwhelm the recipients.

44.3 Procuring the site investigation

44.3.1 Typical costs

The site investigation operations of desk study and ground investigation are some of the best-value operations possible in terms of reducing risks on construction projects. The old adage says, 'you pay for a ground investigation whether you have one or not'. A poorly conceived or planned ground investigation often costs more in the end than a good one, because the cost of project change typically increases as the programme progresses.

Typical costs for ground investigations are shown in **Table 44.3**. Although these data are old, the values for buildings correspond to current experience.

Current costs of ground investigation for buildings are typically in the range 0.1–0.2% of the building cost. For small domestic works, investigation costs can often be higher – perhaps 0.5–1.0% of the works cost.

Thus, for a £30 million structure, the cost of the ground investigation would be typically £30 000 to £60 000. Higher rates apply either where the ground hazards are greater or where the proposed foundation methods may make higher demands on the ground than normal. The lower proportion normally applies when the site investigation is being carried out for a 'park' of several adjacent buildings, and efficiencies are possible, or where the structural form chosen is particularly expensive, but the foundations use simpler techniques.

For major infrastructure projects, current costs of the ground investigation phase prior to construction are in the range 0.1–0.15% of the project value. This does not include the cost of any initial phases of investigation carried out at preliminary design phases.

The ground investigation must target the specific site hazards, so arbitrary limits on its cost based on a fixed sum or typical proportions are likely to lead to a greater exposure to risk for the project. As explained in Chapters 7 *Geotechnical risks and their context for the whole project* and 40 *The ground as a hazard*, ground risks are some of the most extreme faced by most projects and economising at the expense of investigating hazards tends to result in increased costs later, so a very false economy.

A ground investigation is essentially an exploratory process, so its out-turn costs may vary enormously depending on what is found. It must be recognised by all parties at the outset that a ground investigation rig being delayed by obstructions is much cheaper and less programme-disruptive than, for example, the piling rig being delayed by the same obstructions.

Laboratory testing is a significant element of the ground investigation budget, so the extent of testing should not be underestimated when compiling the budget.

A rough rule of thumb is to allow £100–200 per linear metre of borehole drilled, including most types of field and laboratory testing. Thus, an investigation for a £300 million highways project involving 120 boreholes with an average depth of 20 m would be expected to cost approximately £360 000.

A ground investigation cost-overrun as a result of unexpected ground conditions being encountered may be regarded

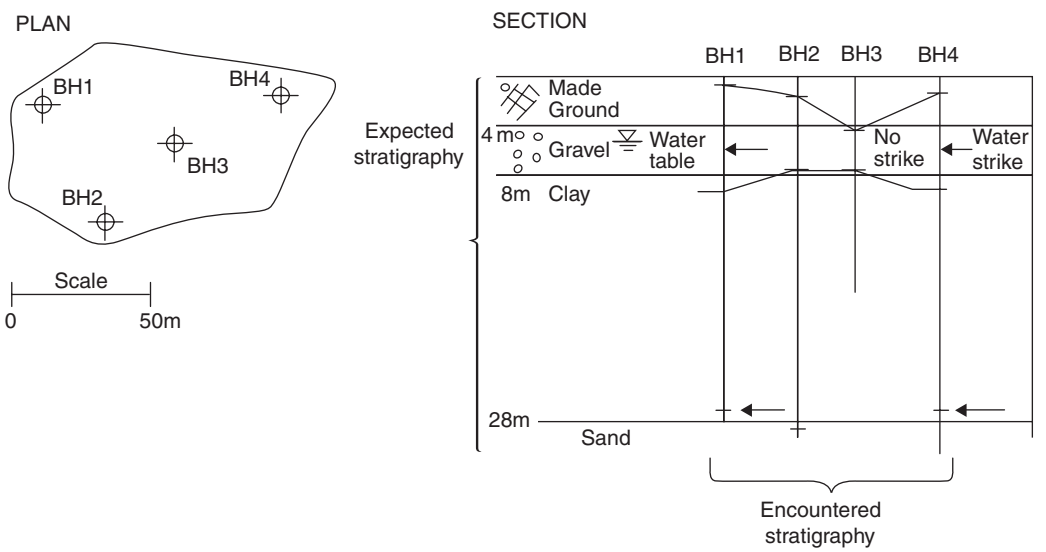

Figure 44.4 Example showing comparison of expected and encountered stratigraphy to assist with managing a ground investigation

as a success, because potential problems have been discovered early and measures can be taken to guard against them during the main construction works. Close, proactive control of the investigation by the geotechnical engineer and a responsive approach from the ground investigation contractor should allow the correct parameters to be determined within the overall investigation budget.

It is prudent to allow a sensible contingency which can be expended during the ground investigation in response to the evolving understanding of the ground. Normally, the contingency is derived partially from a generous estimate for rates which are more likely to be exceeded, plus an extra 10% to allow for unexpected conditions. A full schedule of rates covering all foreseeable tests should be obtained with the ground investigation tender.

If very unusual conditions are revealed, there may be a need for the project team to re-evaluate and agree a new ground investigation budget. The contractual form should allow for the investigation to be varied according to the findings.

44.3.2 Selecting consultants and contractors

Buying a ground investigation is like any other purchase – the buyer wants to make sure they get what and when they want and expects that there will be no nasty surprises on price or programme. The analogy of buying any commodity can be helpful: the buyer wants to be protected against things they do not expect. The more careful buyer will read all the small print and might negotiate to get what they want. But once the contract is signed, they are committed to their particular purchase.

A first step is to make sure that a proper brief is prepared. As few clients are expert in buying ground investigations, professional assistance is needed. The success of the purchase will depend on the clarity of thought that has gone into defining what will be required, and the clarity of specification in explaining that to the supplier. The next two sections explain how to choose the necessary professional assistance. The following sections explain how to describe the work needed in a contractual framework that provides protection to the client.

Type of work	% of capital cost of works	% of earthworks and foundation cost
Earth dams	0.89–3.30	1.14–5.20
Embankments	0.12–0.19	0.16–0.20
Docks	0.23–0.50	0.42–1.67
Bridges	0.12–0.50	0.26–1.30
Buildings	0.05–0.22	0.50–2.00
Roads	0.20–1.55	(1.60)?–5.67
Railways	0.60–2.00	3.5
Overall mean	0.7	1.5

Table 44.3 Typical site investigation costs
Data taken from Rowe (1972)

For a large building project, the **architect** may take on the role of *principal technical adviser* recommended in Part 2 of the *Site Investigation in Construction* series (Site Investigation Steering Group, 1993): *Planning, Procurement and Quality Management* (see Chapter 42 *Roles and responsibilities*). Normally, though, for a building project, it is usually the **structural engineer** who recognises the need for geotechnical support and who advises when it should be commissioned. Most development teams rely on their structural engineer to recommend the approach for geotechnical investigation and design. Their advice is likely to rely on the following factors:

- Geotechnical abilities of the structural engineering firm – especially whether it employs sufficiently skilled geotechnical professionals with experience in assessing ground variability and hazards.
- Attitude to geotechnical risk of the structural engineer – some tend to delegate as much responsibility as possible to other organisations in the belief that their own exposure to the geotechnical risk will correspondingly reduce. This is obviously not true if the choice leads to a greater overall risk to the project from disjointed design. If overall project risk increases, then all will be affected by the consequences.
- Special skills demanded by the particular development, for example whether special investigation techniques or advanced geotechnical analysis will be required.

A structural consultant who also operates as a ground investigation contractor may offer a complete ‘one-stop shop’ service, providing integrated structural and geotechnical design and geotechnical investigation capabilities.

To some extent, it is up to the project promoter to decide whether or not to seek the advice of the structural engineer also for geotechnical matters. This will depend on the confidence he or she has developed in the structural engineer to control what are potentially the highest project risks. A key factor for assessing the competence of the structural engineer for allocating ground risk is to understand the geotechnical ability of the company. If they directly employ or have ready access to experienced geotechnical advice, then they are more likely to engage in the reduction of ground risks.

The project roles outlined at the start of this chapter offer a useful means for assessing the geotechnical competence of the organisations proposed. The *geotechnical adviser* has a key role; previous successful experience and track record on similar projects are good indicators of the suitability of the individual. Before appointing a geotechnical adviser, it is worth challenging their:

- experience with projects of similar structural complexity and demands on the ground;
- familiarity with the expected ground conditions and special hazards faced;
- understanding of the full investigation, design and construction process – beware people who offer a scope of investigation

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

without understanding the likely extent of basement and types of foundations;

- views of previous clients for previous projects: Did they perform their duties well? Were they proactive in spotting problems and reducing risks?
- ability to add value to the project and call on extra resources if needed.

An enthusiastic geotechnical adviser should offer a strategy for completing all the geotechnical work for the project, with project-specific ideas on how to reduce risks and improve buildability at each stage. The new UK Register of Ground Engineering Professionals (RoGEP) provides an appropriate qualification route.

The *Site Investigation in Construction* series documents (Site Investigation Steering Group, 1993) make sound recommendations for the employment of a geotechnical adviser to oversee a coherent geotechnical design process. They suggest that the need for this geotechnical adviser should be suggested to the client by the principal technical adviser, who for many projects will be the architect.

Figure 44.5 shows the typical decision-making process for ground investigations proposed by the Site Investigation Steering Group (SISG).

Some geotechnical advisers work for companies that are pure consultancies – that is, they need ground investigation contractors to be separately employed-while some work for companies that also operate equipment and laboratories. There are pros and cons to both alternatives, but generally the combined approach offers advantages for smaller and simpler commissions and ground investigations, while the separated approach is better for larger and more complex investigations, particularly where the client is suspicious of an integrated contractor proposing extra ground investigation purely to increase its own revenue and profit.

44.3.3 Defining the scope of work

The scope of work can be defined either by the consulting engineers providing geotechnical services for the project or by the ground investigation contractor. The former route permits a competitive tender for the work to be carried out fairly – it is unfair (and bad practice) to invite tendering contractors to compete on the extent of work, as that rewards those who are prepared to suggest the least work. This apparent saving will mean that hazards are investigated less thoroughly; contractors tendering for the main construction work will face greater uncertainty and risk, for which they will price, or which will not become clear until unexpected conditions develop during construction.

The scope of ground investigation depends on the scope of the planned construction.

When planning the scope of work needed in a ground investigation, beware of artificial restrictions on its extent – normally imposed by an overly cost-conscious client who does not understand the increased risks the restrictions might lead to. If limitations are placed on the scope, those limitations should be spelled out in the report: either budgetary or on extent caused by lack of access. This allows:

- others to understand risks identified but not followed up, so that the design can address that additional uncertainty;
- responsibility for lack of coverage to be properly apportioned.

44.3.4 Ground investigation contract documents

A clear set of contract documents is needed for any ground investigation to describe the task and to regulate how it is carried out, and these are introduced in Chapter 42 *Roles and responsibilities*. In broad terms, it is helpful to separate these concepts into *specification* and *contract*. The specification should provide the technical requirements and scope, while the contract documents should regulate how the work is carried out in order to avoid disputes. The two parts are distinct and input should clearly be for one purpose or the other, and not mixed. The bill of quantities will reflect both.

44.3.4.1 Specification

The purpose of a technical specification is to clearly define the work that is to be carried out, in terms of both extent and quality. A clear specification offers the following advantages:

- prior to tender it allows the design team to discuss and reach agreement on what work needs to be done;
- during tender, it unambiguously informs each tendering contractor what should be allowed for in the price;
- during the works, it provides a basis for discussion between the client team and contractor should any disagreement occur;
- after the works are complete, it allows fair payment to be made.

Phrases like ‘to the satisfaction of the engineer’ are unhelpful in specifications, because the contractor can never know how easy the engineer will be to satisfy. It rewards more lax contractors who might assume a lower standard over more responsible or experienced contractors, who might make a more realistic or generous allowance. It is seldom necessary to use such phrases, as the engineer can normally replace it with the criteria that he or she would wish to invoke.

A clear technical specification describes:

- the background to the work – its purpose, i.e. what will be built; the expected ground conditions; the current usage of the site, etc., including access and necessary constraints;
- the work that is needed;
- the standards to which the work should be carried out, referring as much as possible to national standards.

Part 3 of the *Site Investigation in Construction* series (Site Investigation Steering Group, 1993): *Specification for Ground Investigation* (the ‘yellow book’), provides a very well-formatted

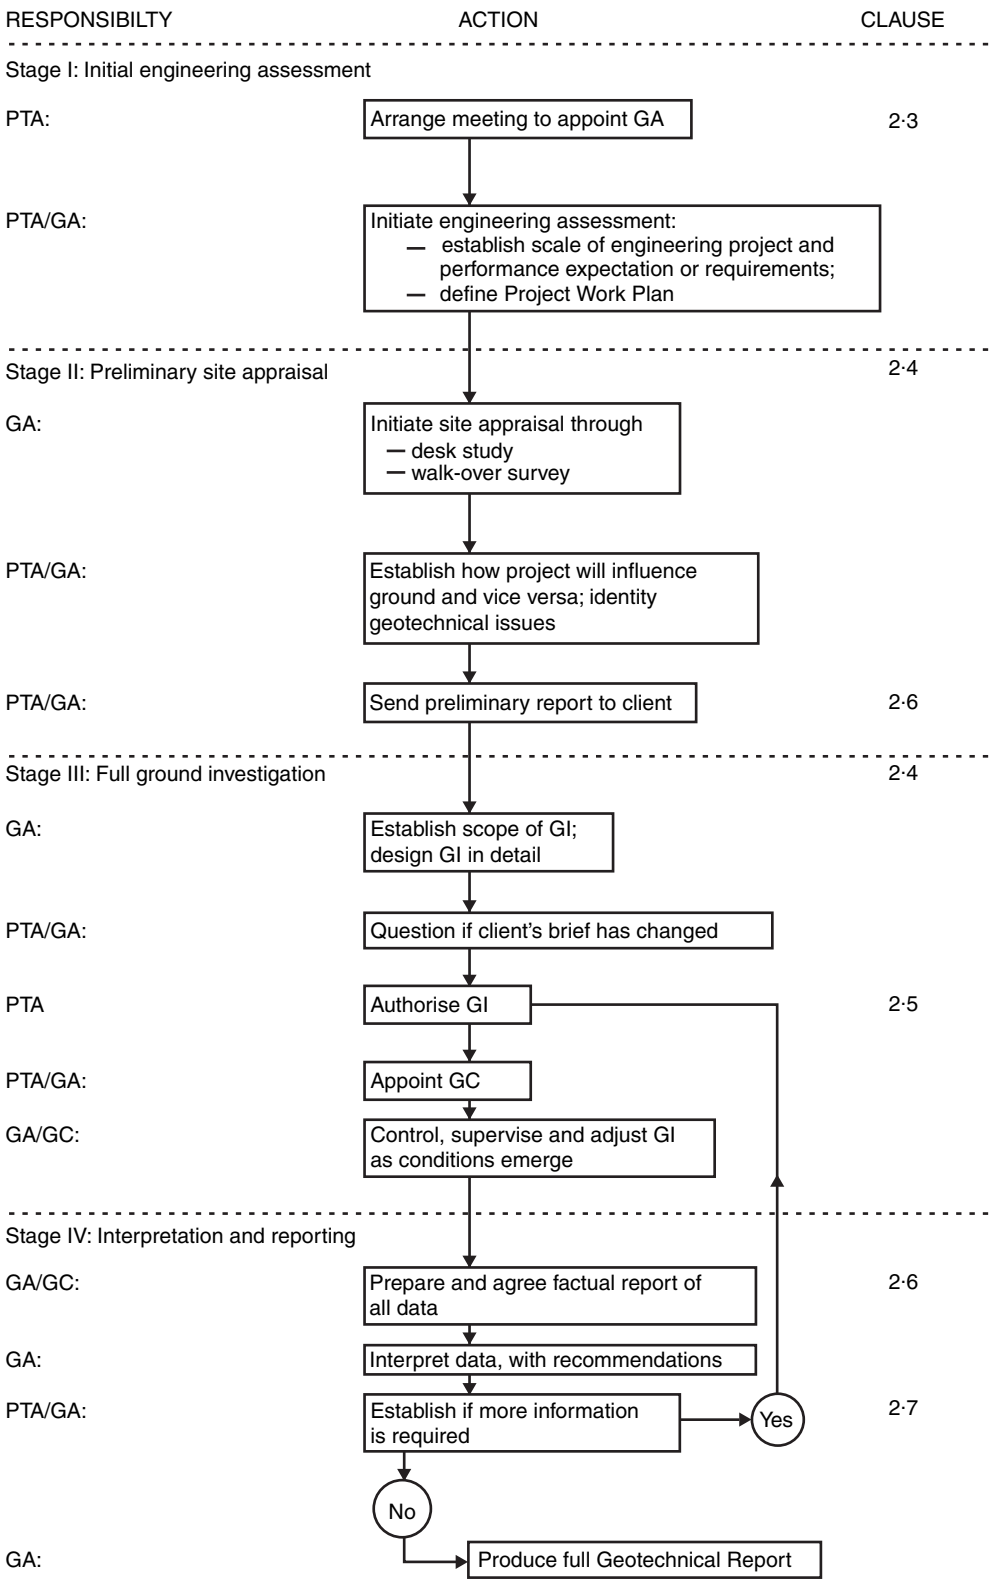

Figure 44.5 Decision-making process of site investigation
Reproduced from Site Investigation Steering Group (1993) Part 2: *Planning, Procurement and Quality Management*

national specification for the UK. National specifications are better than client or engineer specifications because:

- contractors should automatically carry out work to the required standard;
- contractors should be aware of the normal requirements, which facilitates easy tendering with less risk of omissions;
- all work in the UK should comply with the minimum standards, so when a completed ground investigation report is given to a new consultant, the consultant should find it easier to accept its findings.

The yellow book includes a general specification which addresses most of the issues needed for most ground investigations. It also includes draft bills of quantities. It allows the specifier freedom to fully describe the scheme-specific details in a series of schedules:

- Schedule 1 gives the background to the project and describes in words what is needed, together with key constraints, such as access.
- Schedule 2 is a table that lists for each exploration hole what is needed. It can give options – such as borehole depth, which can either be given in absolute terms, or can require the ground investigation contractor to continue to a certain penetration into a stratum.
- Schedule 3 is a list of facilities needed by the site supervisor – normally the engineer's representative under ICE forms of contract.
- Schedule 4 is a list of any amendments that the specifier might wish to make to the standard specification.
- Schedule 5 is a list of additions to the specification, either where extra requirements are being imposed, or where new areas of work are required which are not covered by the standard specification.

44.3.4.2 Forms of contract

For all forms of construction, a pre-agreed contract is necessary for the share of risk between client and contractor to be clear. This is also true for ground investigation contracts to govern what happens if things go wrong. Some common disputes in ground investigations are payment (like all contracts!) and who is responsible if buried services are damaged during the fieldwork.

The conditions of contract must address:

- what the contractor is required to do;
- delegated decision-making powers;
- commencement, programme and completion date;
- alterations and change process;
- delay procedures;
- measurement protocols;
- certification requirements;
- insurances, ownership of the works and safety;
- method of payment (lump sum or re-measurement to bills of quantities), including retentions (for instance to protect the client, who derives little benefit from the fieldwork until the contractor's factual report is delivered; or in case of inadequate reinstatement) and bonds;
- repair of defective work;
- termination clause;
- resolution of disputes.

Many different forms of contract are available. What the investigation will find is uncertain at the outset, so the contract should allow the supervisor to change the order and scope of the works, without too cumbersome a control and approval process.

ICE forms of contract have fallen out of favour recently, because many clients do not like the amount of control delegated to the engineer to make changes without client agreement. However, this feature makes it a very suitable contract for a site investigation, which must be varied if it is to respond nimbly to unexpected conditions. Normally, the amounts being spent are relatively small in the context of the overall project, so the degree of control is less of an issue. The 7th edition of the ICE *Standard Conditions of Contract* Institution of Civil Engineers, 2003b; (current at the time of writing) need modifying to make them useful for use in site investigations. Fortunately, ICE has reissued the second edition of its *Conditions of Contract for Ground Investigations* (CCGI; Institution of Civil Engineers, 2003a), and this is recommended for use where possible. If other forms of contract are used, it is important that they are made so as to allow a swift reaction to unexpected findings. Other forms of contract, such as JCT forms, tend not to work well as they are intended to limit flexibility on site, which can be counterproductive. The New Engineering Contract (NEC) has not so far penetrated the ground investigation market to any great extent. Ground investigation contractors may add a risk allowance to cover unfamiliar contract conditions.

Ideally, for a ground investigation, a resident engineer from the designer will be on site to witness key elements of work and to understand what has been uncovered. If only part-time coverage is provided, the contractor must have clear instructions of how to proceed if unexpected conditions evolve, and a fair way of paying the contractor so that the individual takes the initiative to get the best results for the whole project. The key is to involve the designer, geotechnical adviser and ground investigation contractor in a collaborative approach to solving problems and obtaining the appropriate parameters for the project.

The complete contract documents should encompass:

- conditions of contract, including the form of agreement;
- technical specification;
- priced bills of quantities;
- accompanying drawings, possibly including site location plan, borehole location plans, service routes and historical or geological figures from the desk study.

44.3.4.3 Bill of quantities

The bill of quantities (or sometimes schedule of rates with provisional quantities, to emphasise the potential for variation) allows a tender price to be agreed. The method of measurement

should also be defined, as otherwise differences in measurement understanding may lead to disputes. Beware using provisional sums or 'rate only' items, as in the former case no cost is agreed, and in the latter case, the contractor's tender total is not penalised by the use of high rates.

44.3.5 Risk sharing

In most contractual relationships, the client tries to pass risk to the contractor. In ground investigations, because of the fundamental uncertainty about what might be found, there is greater risk sharing and the client must accept the possibility that more work may be required. A ground investigation that identifies serious features meriting greater attention, resulting in cost and programme overruns, should be seen as a great success and not a failure. The consequences of those features remaining undiscovered until construction would be far worse than identifying them at an early stage.

Where a main contractor is on site and suitable plant is available, the main contractor may be in a better position to negotiate access for the ground investigation with landowners and provide temporary access tracks for investigation plant. Responsibility for, and thus risk on, access could then be removed from the ground investigation contractor's contract, leading to a more competitive price.

44.3.6 Tender evaluation and award

It is important that all tenders are fairly evaluated, on the same basis. Therefore careful consideration is needed to ensure that each restriction or exclusion is evaluated. While the tenders should be evaluated for the understanding demonstrated of the site and tasks, it is too late to regret seeking tenders from a less competent contractor who happens to submit the lowest price. If there were doubts about the contractor's competence, they should not have been invited to submit a tender.

44.4 Managing the site investigation

44.4.1 Safety management

All construction sites are potentially dangerous places. This section highlights some essential features of safety on ground investigations, but should not be taken as a definitive guide. Statutory guidance changes with time, and users must ensure that they comply with the latest regulations – in particular the Construction (Design and Maintenance) Regulations (2007), also known as the 'CDM Regs' – see Chapter 42 *Roles and responsibilities*.

Typical hazards in site investigations include:

- Trial pit collapses, often due to inadequate shoring. This topic is addressed by the leaflet *Safety in Excavations* (Health and Safety Executive, 1997). Regulation 12 of the Construction (Health, Safety and Welfare) Regulations 1996 (SI 1592) requires that 'All practicable steps shall be taken, where necessary to prevent danger to any person, to ensure that any new or existing excavation or any part of such excavation which may be in a temporary state of weakness or instability due to the carrying out of construction work (including other excavation work) does not collapse accidentally.' This used to be set at a 1.2 m safe depth before shoring was required, but the current regulations are more general.
- Injuries in cable percussion boring caused by use of heavy weights – particularly to fingers.
- Hitting buried services – this is a potential cause for major injury to site workers, dispute and disruption to neighbours and businesses. The hazard is so great that time should always be made to obtain plans from all owners of buried services and carry out site scanning before work starts.
- Investigation of potentially contaminated sites.

The location of buried services is critical prior to digging holes on a site. The various steps that should be taken are:

- Contact all the likely owners of buried services to receive contemporary plans – these are often inaccurate and seldom show domestic connections. Sometimes unusual services can be found, like strategic oil pipelines. Ask around. Contact Groundwise.com for the normal range of buried utilities or Linesearch.org for pipelines, in the UK. For sites where the owner has a maintenance department, talk to the people who have worked on the site for a long time.
- Lift manhole and drain covers on the site to locate likely service routes. Lines of replaced concrete or tarmac are often associated with service laying.
- Use a scanner to try to detect pipes and cables – note they seldom find plastic pipes. This can be done in conjunction with representatives from the companies owning the services on site for best results.
- Depending on the likelihood of buried services remaining undiscovered, hand-dig 'starter pits' at each location to reduce the chances of damage being caused. Vacuum excavation techniques are also available to ensure the safety of site workers.

Sometimes major services are a significant constraint on ground investigation operations – both buried utilities and overhead cables. See Chapter 41 *Man-made hazards and obstructions*.

The Control of Substances Hazardous to Health Regulations 2002 (COSHH) require employers to control exposure to hazardous substances which could put people's health at risk.

In buildings dating even to the mid 1980s, the presence of asbestos in lagging to pipes, walls and ceilings should always be suspected. If the presence of asbestos is suspected, no intrusive work should be carried out until its absence has been verified by sight of the building's asbestos register.

The person planning the ground investigation must not locate boreholes and trial pits in locations which could be more hazardous if other safer locations are feasible. For example:

- boreholes under overhead power lines pose a significant hazard for those erecting and using the boring rig;
- trial pits next to a cliff pose a significant threat to the operator of the excavator;

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- machine-excavated trial pits over live buried services pose a threat to all in the vicinity.

However, it may be that after consideration of the aims of the ground investigation, no other locations offer such benefits, in which case the designer must try to mitigate the risks as far as possible, for instance by following the guidance for digging near services, and by only using air blowing or vacuum excavation or hand-digging techniques until all the services have been found.

Particular care is needed when planning investigations inside buildings. Where it is necessary to bore from ground level through a basement, a number of checks are needed:

- make sure that no cables, pipes or ducts will be damaged at any level by the breaking out or boring works;
- make sure that the suspended slab is capable of supporting the weight of the boring rig, especially when a hole has been broken in the floor.

44.4.2 Supervision

A strong case can be made for the ground investigation contractor to provide full-time technical supervision on site. This person will be involved in maintaining technical quality, ordering the works, reacting to anomalies, logging pits, borehole samples and drill runs, and selecting suitable samples for later laboratory testing. Doing these activities rapidly is often essential for samples for subsequent chemical analysis. However, it must be noted that there is a cost associated with provision of such a person, and standard fieldwork rates are seldom adequate to enable the ground investigation contractor to provide that person without some payment. Hence it is helpful if the specification and bill of quantities define the expected basis.

Additional audits should be carried out, normally by the designer or geotechnical adviser, to ensure that supervision is being carried out properly and that the specification is being reliably followed. Such visits should apply both to siteworks and to the testing in laboratories. Often laboratory checks are neglected as it is difficult to arrange the timing so that the particular samples from the site can be witnessed.

It is also of great value if the geotechnical designer can see the actual ground conditions on site, and so additional visits for this purpose should be made. Visits coinciding with the opening of trial pits prove most valuable as the stability of excavations and the inflow of water can be assessed.

44.4.3 Quality management and quality control

Quality management should be undertaken by a registered quality system to ISO 9001 by both consultants and ground investigation contractors. Quality control is vital to ensure that the tasks are carried out diligently and to a reliable set of procedures. Such quality procedures are very important for the simple repetitive testing carried out in soil testing laboratories where small changes in operator procedure can have a profound effect on the results.

44.4.4 Data management

A ground investigation produces considerable quantities of data, and these are usually best managed in electronic form. The ground investigation contract should specify that all data are to be produced in Association of Geotechnical and Geoenvironmental Specialists (AGS) format. This simple, standardised format allows the data to be imported into all spreadsheet packages and specialist borehole management software. From here, the data can be imported into geographical information systems (GIS) and 3D virtual construction models to aid integration with the design model.

Current products under development include robust site datalogger tablets. These will enable the ground investigation operatives to input data direct from the borehole or trial pit and transmit them in real time to the geotechnical adviser. Other useful innovations include GPS tagging of site photographs and barcoding of samples.

44.4.5 Fulfilling vital campaign aims

The ground investigation should have had clear aims at the outset. Those are sometimes changed as the work takes place, but they should remain visible and coherent. Hence, at key stages, it is worth reviewing whether those aims have been met, before it becomes too late. Such reviews can be tricky as at such key stages there are usually many more data and clarity can be difficult. It is worth formally reviewing the aims a week before the ground investigation contractor leaves site, after which time any further fieldwork will become extremely expensive and disruptive, and at the time of scheduling the last tranche of laboratory tests, after which time there is a severe risk of delaying the main deliverable from the ground investigation, the contractor's factual report.

44.4.6 Effects on site occupants and neighbours

The works for the ground investigation are usually the first manifestation of the new project on site. For the reasons outlined in section 44.2.3, occupants and neighbours may not welcome the start of the ground investigation. Therefore, it needs to be started sensitively, and with good supervision to intervene between anxious residents and the site operatives. It is often a good idea to agree a simple communications plan to handle queries, complaints and correspondence in a consistent and professional way.

Every reasonable effort should be made to reduce the level of disruption. If not, the local authority environmental health officer (EHO) in UK locations may become involved and impose severe restrictions on working hours. Where periods of noisy work are inevitable, it is best to inform stakeholders – including the EHO – beforehand, and then keep any promises made.

The level of reinstatement needs to be carefully considered. On the one hand, it can be seen as wasted expenditure, as the main development will obliterate it. On the other hand, a degraded site environment will make it less attractive to users,

may render parts of the site unusable and could make it unsafe. Issues to consider include:

- reinstatement of slabs, hard standings, roadways and grassed areas;
- future protection of standpipe and piezometer stopcock covers.

44.4.7 Reinstatement

It is important that the site after completion of the fieldwork is left in a condition acceptable to the site occupiers/owners. This means that:

- Paved areas should be reinstated as needed.
- Grassed areas should be rehabilitated; this includes wheel marks for access.
- Structures should be repaired, and at least made safe. It is not unusual in investigations in buildings for boring to be made from ground floor level through a basement: in such cases the holes should be securely fixed and may need to be made weatherproof to prevent water leaking into the basement, creating a further safety hazard.
- All the old spoil should be cleared away; some contractors have even been known to abandon equipment at the site.

In addition, the investigation should not leave the subsoil in a condition that could cause problems in the future:

- Boreholes should be grouted up on completion. Ungrouted boreholes can leave a connection between different aquifers, which can spread pollution and can also be a source of hazard for piling and tunnelling work.
- Trial pits should be well compacted. Loosely compacted trial pits later become zones of unexpectedly weak ground. This can be a hazard for shallow foundations and for temporary piling platforms. For this reason, for housing developments it is preferable to position pits away from the footprint of the houses where known.

44.4.8 Contract administration and completion

As in all contracts, standard resident engineer (RE) records should be kept so that payment items can be fairly evaluated. The RE may be required to resolve misunderstandings with neighbours, particularly when the contractor has no professional staff on site. Payments need to be processed according to the contract, with certificates provided as necessary.

The RE records should be kept, as they may be instructive in understanding any anomalies detected on the site subsequently – for instance a length of rotary cored drill-hole over which no core was recovered may have been thought to have been lost because of poor drilling but it may later transpire to be due to cavities in the ground.

This chapter provides a brief overview of the range of geophysical methods (surface and down-hole) and remote sensing available for use in engineering investigations. The techniques described are well proven, and when used in a properly designed site investigation can add significantly to the robustness and cost effectiveness of such a survey, especially when used in combination with intrusive methods.

The chapter explains the role of geophysics and describes how best to procure geophysical surveys. Current best practice is to engage the services of an independent engineering geophysical adviser to design the works, supervise the fieldwork and undertake the detailed analysis, modelling and integrated interpretative reporting. Guidance is provided as to which geophysical techniques are best suited to which applications.

The most commonly used geophysical techniques are described with examples of outputs available. These include micro-gravity and magnetometry; electrical methods (resistivity tomography, induced polarisation, self polarisation); electro magnetic methods (including ground penetrating radar); seismic methods (refraction, reflection, surface waves and ground stiffness); over-water surveys (hydrographic and sub-bottom profiling); and borehole logging techniques.

A brief overview of remote sensing image analysis is also provided for optical (e.g. Landsat, SPOT, ASTER), synthetic aperture radar (SAR), LIDAR and thermal infra-red (TIR) techniques.

45.1 Introduction

Investigating the ground remotely can be achieved with a range of techniques, from satellites orbiting the Earth using optical imaging, through to radio waves being generated from a hand-held sensor on a concrete slab inside a building to locate steel reinforcement bars. Sensors can be deployed from different platforms to produce information for regional investigations over thousands of square kilometres to ultra-high-resolution testing on a decimetre scale.

With advances in technology over the last few years there is also a blurring of the boundaries between the modes of deployment of techniques. For example, LIDAR (LIght Detection And Ranging) using laser measurements was originally made from fixed-wing aircraft to produce high-resolution digital elevation models of the ground surface. Now the same technique is also available from ground stations looking laterally at rock cliffs to monitor slope stability and from boats to image marine infrastructure, for example. Individual geophysical sensors have become smaller and more sensitive, and capture data faster with modern electronic and computer technology. Multiple sensors can be mounted on a wide range of platforms (hand-held, towed devices, booms and stingers on aircraft, 'birds' suspended from helicopters; single sensors, horizontal and vertical gradiometers, and multi-channel systems with many sensors mounted in a range of configurations).

Many geophysical techniques have been transformed over the last few years by faster and more efficient data acquisition, so that much more information can be captured in much less time, making it possible to increase the spatial resolution by at least an order of magnitude. Sensors have become more sensitive, so permitting the detection of ever smaller targets. There has also been massive improvement in geophysical data processing capability, and in the availability of increasingly sophisticated software. Recently, it has become possible and practical to combine both geophysical and borehole data analytically into 3D ground models.

This chapter provides a very brief overview of the range of geophysical and remote sensing methods that are available. Every modern engineer should be aware of these techniques, which have all become well established and are thoroughly proven. The chapter is sub-divided into an overview of geophysical methods (including over-land and water, airborne and down boreholes) and a brief description of key remote sensing techniques.

45.2 The role of geophysics

The primary role of geophysics is to reduce risk. By undertaking a professionally designed and executed survey it should be possible to:

- *reduce* health and safety risks – avoiding buried utilities, locating voids, etc.;
- *reduce* professional indemnity risks – not missing key features on a site;

- *reduce* over-engineering of structures to cover uncertainty in ground investigations;
- *reduce* project delays and associated costs through 'unforeseen ground conditions'.

And it should be possible to:

- *increase* the technical reliability of site investigation information;
- *increase* the cost-effectiveness of the site investigation through targeting intrusive tests on anomalous areas;
- *increase* the technical robustness of ground models through integrating multiple data sets and types.

The primary benefits of geophysical surveying (Reynolds, 1996) include:

- rapid areal coverage (hectares per day);
- fine spatial resolution (to $\ll 1$ m);
- volumetric sampling rather than spot measurements;
- non-invasive and environmentally benign nature;
- time-lapse measurements;
- quantitative rather than qualitative data.

One of the primary benefits of geophysical investigations is that they are environmentally benign by being largely non-intrusive. Most methods involve a technician moving a sensor either across the ground or just above its surface, or placing metal electrodes or spiked geophones into only the top few centimetres of the ground surface. The measurements are made without disturbing the subsurface, which makes some methods ideal for time-lapse surveys, where profiles are re-surveyed after a period of time to determine any changes in the subsurface environment. In contrast, a borehole, for example, might provide a pathway for fluid flow, thereby affecting the local hydrology; removal of the borehole casing does not restore the situation to a pre-borehole status.

Geophysical methods are able to sample at a fine spatial interval, often of the order of every 10 cm, or in the case of ground penetrating radar, at less than every centimetre. By covering whole swathes of a site these techniques provide almost complete coverage of the available ground. At the most basic level, such surveying provides 2D reconnaissance by which anomalous areas can be identified. This on its own is only of qualitative use. It might indicate relative anomalies that might show high and low values of apparent conductivity, but not what might be causing such values to occur. This is where the intrusive testing is so valuable. As will be demonstrated later, intrusive investigations, where deep enough and appropriately detailed, can complement geophysical techniques and permit the translation of variations in a geophysical parameter to specific ground conditions (Reynolds, 2004). By correlating the material types with the apparent conductivity anomalies, the spatial extent of these materials might be indicated.

Where geophysical techniques are used to provide information about both horizontal and vertical variability along a profile, and where the analysis provides the means of determining depths to subsurface targets, detailed borehole logs can be invaluable in providing ground truth data. Borehole logs can define layer thicknesses and material types that can be used to constrain geophysical modelling, so reducing a degree of freedom in the interpretation process. It is important to emphasise that geophysical methods do not necessarily reduce the number of intrusive tests required but permit the positioning of such tests in places where they are needed. This makes the combination of methods far more effective than intrusive testing alone and can reduce overall costs significantly.

It is crucial, however, that geophysical surveys are designed to meet a particular technical objective, such as to map the boundary of a former closed landfill. This dictates the spatial sampling required, the likely techniques to be used, what kind of analysis is needed to yield the necessary information, and how the survey should be undertaken. A common mistake in procuring geophysical investigations is to choose a method based on its familiarity to the specifier or on the general availability of equipment, rather than selecting the most appropriate method(s) to meet the survey objectives. Data acquisition is a means to an end, not an end in itself. Many unsuccessful geophysical surveys undertaken have been a waste of money because they have been incorrectly specified, poorly designed or undertaken with inadequate field practices (sometimes using inappropriate techniques), with inadequate position fixing and/or even misusing the equipment. Furthermore, there are many examples of cases where perfectly adequate field data have been wrongly interpreted, as little thought has been given at the design and specification stage to the analytical methods required once the data had been collected. It is fundamental to the integrity of each geophysical survey that thought is given first to the design and execution of the analysis, data processing and interpretation of the geophysical results and only secondly to the specification of the data acquisition. For many modern-day surveys, a specialist independent engineering geophysical adviser (EGA) should be appointed to the project team along with a geotechnical adviser, as recommended by the guidelines on engineering geophysics (McDowell *et al*., 2002). Best practice is for the EGA to design the overall geophysical investigation (from data acquisition through to integration of results and interpretation) and also to supervise the site works and undertake the detailed interpretation of the final results. Data acquisition can be undertaken by suitably experienced geophysical contractors. Further advice on the use of geophysics in engineering has been provided by Schoer (1999), Darracott and McCann (1986), Anon. (1988), Reynolds (1996), McCann *et al.* (1997) and, for archaeological investigations, David *et al*. (2008).

Given the range of geophysical methods generally available, it is possible to categorise the applications to which they are most suited or not appropriate at all. An extremely general

guide to the possible usefulness of the various methods is given in **Table 45.1**. However, in many cases it is advisable to use more than one method in order to reduce possible ambiguity in the interpretation and to respond to different physico-chemical characteristics within the same environment. For example, in the investigation of a former landfill, electrical resistivity tomography is an ideal method to sense the conductive waste and possible leachate plumes migrating away through the base and/or sides. The resistivity results would respond predominantly to the electrical properties of the fluids present rather than to the lithological boundaries, for which the seismic refraction method might be better suited. Consequently, these two techniques are both applicable and are complementary. Similarly, in environmental investigations over brownfield sites, a common pairing of techniques is electro magnetic mapping with magnetometry. Furthermore, coincidence of anomalies can help to increase confidence in the interpretation. The information given in **Table 45.1** should not be used prescriptively for survey design or specification purposes. To increase the benefit of any geophysical survey, the design and specification should be prepared by an experienced and suitably qualified EGA. A guide to the physical properties of materials and the corresponding geophysical techniques sensitive to those properties is given in **Table 45.2**.

45.3 Surface geophysics

There are four groups of geophysical techniques in common usage and each of these is described briefly in turn. While the emphasis is on the use of these methods over the ground (or water) surface, some techniques can also be readily deployed in airborne and/or down-hole modes. Most commonly, 1D soundings and 2D profiles are acquired. Data from closely

Key: 0 = Not considered applicable or untried; 1 = limited use; 2 = used, or could be used, but not best approach, or has limitations; 3 = excellent potential but not fully developed; 4 = generally considered as excellent approach, techniques well developed.
Note: Applicability of techniques is dependent upon a range of parameters including physical/chemical contrast with host material, target dimensions, scale of survey and intended depth penetration, site suitability, site dimensions and access, surface topography and material type, local noise, etc. It is always best to select the method(s) on a site-specific basis and with respect to the nature of the targets being sought. It is emphasised that this table is a very general guide only and actual suitability of a technique to a site may vary from the values indicated above. Always seek advice from a professional geophysicist.

Key: P = Primary method; s = secondary method; m = may be used but not necessarily the best approach or has not been developed for this application; (!) = unsuitable.

Table 45.2 Common geophysical methods, their dependent physical properties and their generalised main applications
Data taken from Reynolds (2011)

spaced 2D profiles can be incorporated into a 3D volume. For specialist applications it is possible to acquire true 3D data sets by deploying a grid of detectors all of which sense signals from a common source (e.g. 3D resistivity and seismic reflection surveys). Re-surveying profiles/grids after a significant period of time permits the acquisition of time-lapse surveys, by which it is possible to determine changes as a function of time. It is beyond the scope of this chapter to explain the principles of operation in any detail; readers are directed to more comprehensive sources of information (e.g. Milsom, 2003; Reynolds, 2011).

45.4 Potential field methods

45.4.1 Gravity

The gravity method is sensitive to variations in the density of the ground, and gravimeters are designed to detect changes in the Earth's gravity field. This is measured by determining the changes in length of a spring resulting from the force exerted on a mass suspended on the spring. Modern micro-gravity meters are capable of making measurements to an accuracy of better than 5 μGal with a daily productivity rate of between 50 and 80 stations per day, with typical anomaly amplitudes of several tens of μGal in engineering investigations (such as in void detection) (1 μGal = 1 cm/s²). It is essential to be able to survey in each measurement point to an accuracy of better than ±0.1 m horizontally, and ±0.02 m vertically to achieve the best results. Given their heightened sensitivity, modern gravimeters pick up noise and vibrations, including distant earthquakes, which can degrade the data quality and slow the survey rate. The instrument provides values of gravity measured over discrete time periods, typically 60 s at each measurement 'station'. The values are averaged either to give a mean figure over that time period or until a designated standard deviation has been achieved. It is essential also to establish a base station at which values of gravity are measured at intervals typically no greater than every 2 hrs, depending upon the type and characteristics of the instrument being used. These base station values are used to derive the diurnal drift of the instrument, which has to be compensated during the data correction process.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Gravity values (g_{obs}) are influenced by earth tides, the position on the Earth's surface with respect to its shape (oblate spheroid) and surface elevation, terrain, isostacy (in the case of larger scale surveys), physical movement if the gravity meter is being used from a moving platform (ship or aircraft), and the physical presence of the ground itself. These corrections are required to reduce the values of g_{obs} to what is known as the Bouguer anomaly (Δg_B). This may need to have the regional gravity gradient removed and also the values corrected for the presence of buildings and walls, so that the data to be interpreted are corrected for all above-ground influences. The resultant anomaly is known as the residual Bouguer anomaly, which should indicate only the variations in the density of the materials beneath the gravimeter at a given station.

The residual Bouguer anomaly data can be plotted as 2D contour maps showing the variation in values across a site. Low values represent areas of density deficiency that might be attributable to the presence of voids or poorly consolidated backfill; high values may represent dense infill or higher-density bedrock. Commonly, data along extracted profiles can be modelled to produce 2D sections indicating the dimensions of a target, its depth of burial, and its density contrast with the surrounding material (indicating for instance if a void is air-filled, partially filled with loose material, etc.) (**Figure 45.1**).

45.4.2 Magnetometry

Modern caesium vapour magnetometers measure the total intensity of the Earth's magnetic field, which varies from around 30 000 nT (nanotesla) at the equator to 60 000 nT at the poles (Finlay *et al.*, 2010). If magnetisable objects are present, they distort the Earth's field in characteristic ways. Magnetometers are capable of measuring to 0.01 nT sensitivity with a sampling rate of up to 10 measurements per second, with common anomaly amplitudes ranging from a few tens of nT to many hundreds of nT. The ground coverage achievable is dependent upon the speed at which the instrument is transported along a profile (transect). At walking speed this equates to about one measurement every 10–20 cm. Position fixing with a differential global positioning system (dGPS) can be achieved and recorded simultaneously with the magnetic field intensity values. It is possible to use magnetometers either singly or with multiple sensors to measure horizontal and/or vertical magnetic gradients.

Recorded data can be displayed as 2D colour contoured maps of the magnetic field intensity and horizontal or vertical magnetic gradient (nT/m), and as discrete profiles. Interpretation is significantly more complicated than for micro-gravity, as magnetic measurements are a function of both the induced magnetisation of the target given a magnetic susceptibility, and any inherent remanent (permanent) magnetisation. Where induced magnetisation is the predominant cause, the anomaly shape and size are also dependent upon the orientation of the target, its dimensions, and its depth of burial. Magnetic profiles can be modelled and field values compared with synthetic values derived for a user-selected model, which is changed until the difference between the observed and synthetic data

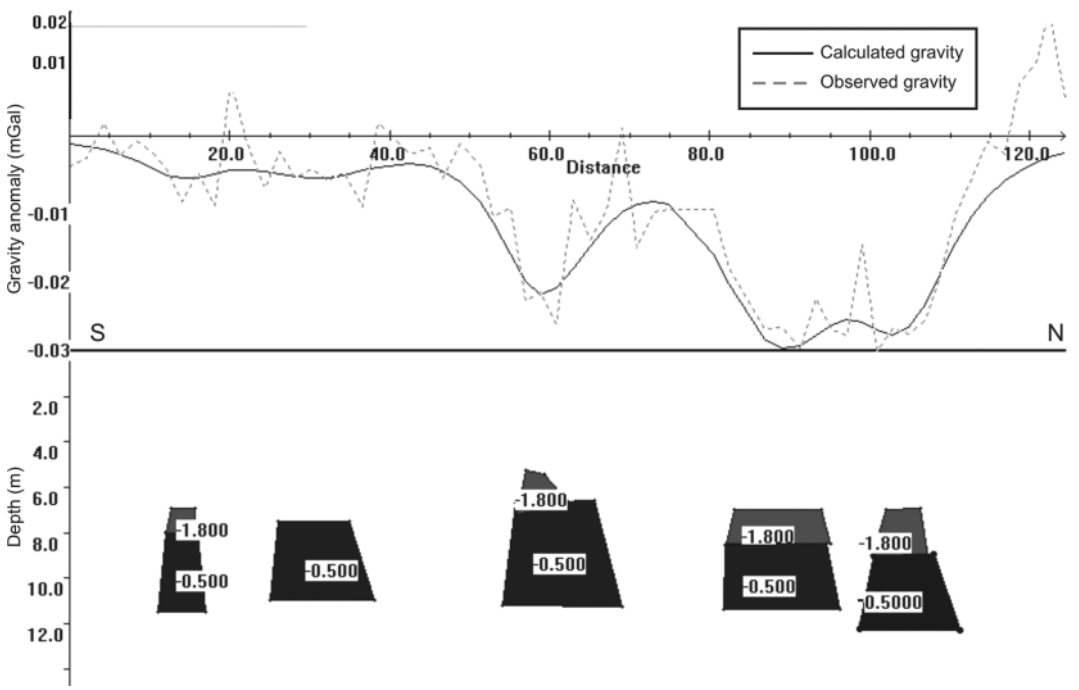

Figure 45.1 Bouguer anomaly micro-gravity profile showing observed and modelled values over mine galleries in chalk. The negative values refer to the density contrast with the host rock, with −1.8 Mg/m³ indicating an air-filled void and −0.5 Mg/m³ a partially back-filled void. These results were confirmed by subsequent probe drilling.

falls within a predetermined standard deviation or RMS error (**Figure 45.2**).

Common applications of magnetometry in engineering investigations are to locate ferrous metal objects (underground storage tanks (USTs), iron pipes, steel drums), but it can also be used to map magnetically susceptible material such as ash, clinker and bricks, and to delineate zones with different materials within landfills. A growing use of magnetic methods is in the detection of unexploded ordnance (UXO), such as ferrous metal bomb casings, mortar shells, etc. However, the technique will not find UXO devices specifically designed to avoid detection, such as modern land-mines.

45.5 Electrical methods

45.5.1 Electrical resistivity

Electrical resistivity techniques detect changes in the electrical potential between a pair of electrodes generated by a separate pair of electrodes through which a low-frequency alternating current is injected. By increasing the separation between electrodes, greater depth penetration can be achieved. The technique effectively measures the resistance for a given electrode geometry to produce an *apparent* resistivity (ρ_a). This value in itself is a form of volumetric average and has no direct physical significance. There are two principal modes of use: (a) vertical electrical sounding (VES), and (b) electrical resistivity tomography (ERT).

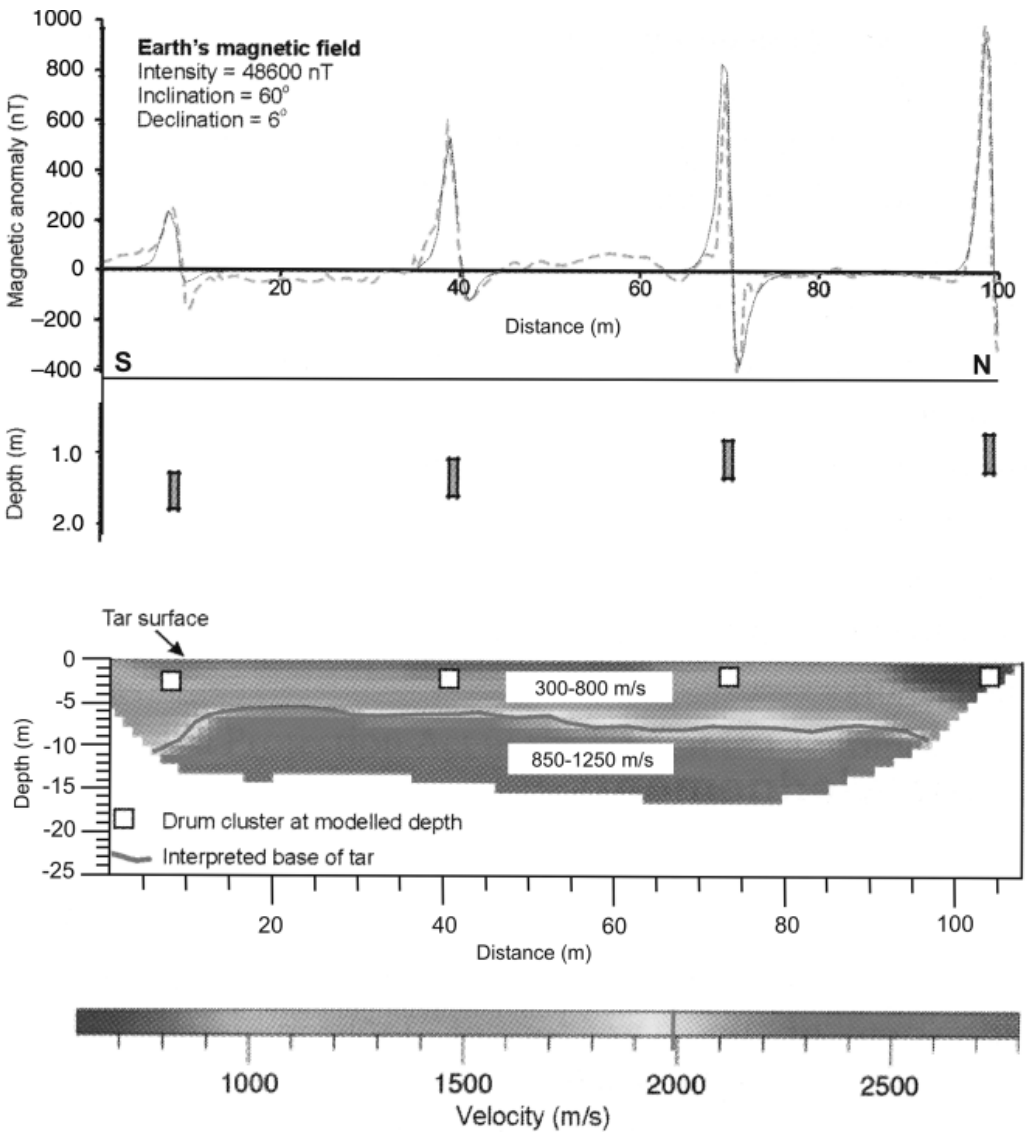

Figure 45.2 (Top) Profile of magnetic field intensity showing observed results (solid line) and those generated by modelling (dashed line) the depth of burial of steel drum targets in an acid tar lagoon. (Bottom) Small squares indicate the position of the steel drums as derived from the magnetic modelling, superimposed on the results of seismic refraction velocity modelling, indicating their positions within viscous tar above a solid base

VES is achieved by measuring ρ_a using an expanding array of electrodes to produce a one-dimensional vertical profile (sounding) of ρ_a as a function of electrode separation. VES curves can be analysed (using a process called 'inversion') with commercially available software (e.g. IX1D, Interpex Ltd.) to produce an interpretation comprising a series of horizontal layers whose thickness and *true* resistivity are derived by the inversion process. The *true* resistivity is characteristic of the type of material present.

The ERT method uses a series of electrodes, commonly 72 or more, connected by a multi-core cable to a resistivity meter by which a 2D panel of apparent resistivity values is constructed. The resistivity data can be inverted using specialist software (e.g. RES2DINV, Geotomo Software) to produce 2D sections showing modelled values of true resistivity along the profile as a function of depth (**Figure 45.3**). The software also permits topographic corrections to be applied.

ERT is used more frequently than VES nowadays, although the latter is extremely useful in providing better vertical resolution of a layered structure; soundings are, however, sensitive to 3D structures, making the 1D inversions unreliable under these circumstances. Software is available to produce 2D and 3D models of resistivity so as to be able to test the detectability of particular structures and targets.

Resistivity techniques are used particularly where fluids in the pore spaces within materials have contrasting resistivity values, such as in mapping leachate plumes and imaging landfills. They are also useful for investigating natural and man-made voids and mine workings, for hydrogeological investigations, for imaging through landslides and in geohazard studies.

Two other electrical techniques are also used in geoengineering and environmental applications, namely *induced polarisation* (IP) and *self (spontaneous) polarisation* (SP).

45.5.2 Induced polarisation (IP)

Induced polarisation profiles are acquired in a similar manner to ERT sections but in addition to measuring the apparent resistivity, values of chargeability, which are a measure of the amount of polarisation observed, are also acquired. IP is used in base metal, geothermal and groundwater exploration, but also increasingly in environmental investigations.

45.5.3 Self polarisation (SP)

The SP method uses two non-polarisable electrodes to measure the electrical potential between them generated by the flow of ion-rich water. The method is used in landfill studies and especially to detect leaks through embankments and natural dams, and also in hydrogeological investigations.

45.6 Electro magnetic (EM) methods

45.6.1 EM methods – non-GPR

There are a wide range of electro magnetic (EM) techniques available, of which the commonest and most widely used (and abused) is ground penetrating radar (GPR). In this section, non-GPR techniques are described. There are two main types of EM equipment: (a) frequency-domain EM (FEM) and (b) time-domain EM (TEM). FEM uses a pair of coils at a fixed separation (the dipole length); one coil is used to generate an EM field that propagates into the ground. A subsurface conductor responds to the primary EM field by setting up eddy currents within itself that in turn generate a secondary field that travels back to the surface and is measured by the secondary receiver coil. The ratio of the primary and secondary fields is a measure of the *apparent* conductivity of the volume of material being sampled. Conductivity is the inverse of resistivity; apparent conductivity is a function of the conductance of the ground and the geometry of the dipole arrangement and in

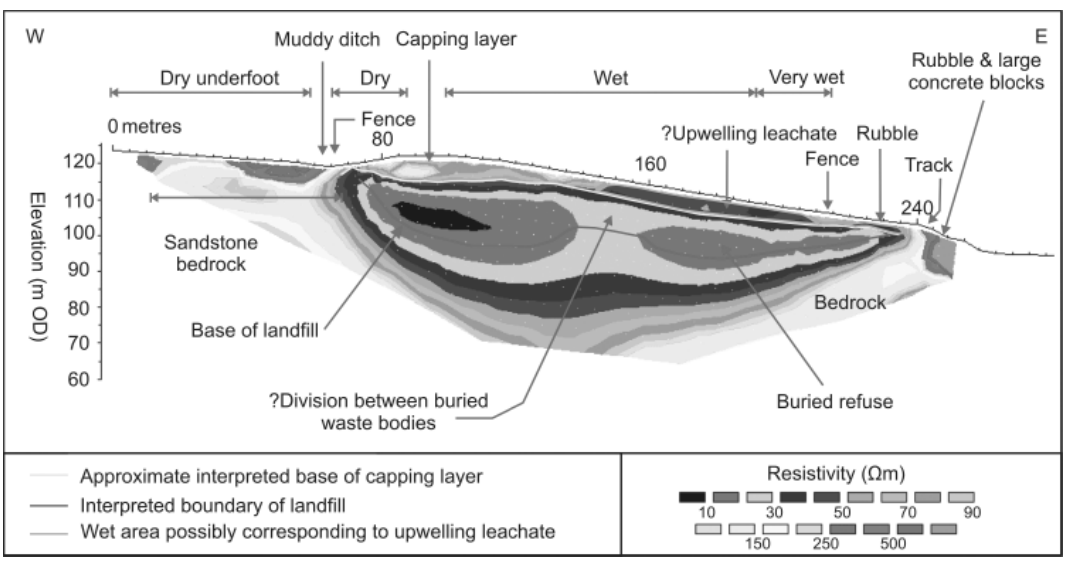

Figure 45.3 Electrical resistivity tomography section across a closed landfill

Figure 45.4 Geonics electro magnetic ground conductivity meters: (a) an EM31 with GPS antenna, and (b) an EM34 (white coils)

itself is not physically diagnostic of material properties. The most popular EM equipment is made by Geonics Ltd. They produce a family of EM ground conductivity meters, ranging from the smallest, the EM38 (nominal depth of penetration to 1.5 m) that is used predominantly for archaeological and agricultural surveys, through the EM31 (nominal depth of penetration to 6 m) with two coils in a rigid boom (**Figure 45.4(a)**) to the EM34, that has three sets of dipole separations (10 m, 20 m and 40 m) with separate coils (**Figure 45.4(b)**), giving nominal depths of penetration to 15 m, 30 m and 60 m respectively. Other manufacturers have developed instruments (e.g. GEM2) that comprise a fixed dipole separation with two coils in a rigid boom but achieve a graduated depth of penetration by using different frequencies, with the highest frequencies being used for the shallowest investigations and increasing depth of penetration with lower frequencies. Typically, these instruments have five to eight different frequencies available. All of these instruments measure two components of the EM field, the in-phase and quadrature components. The latter, which is 90° out of phase, is a measure of the apparent conductivity, while the in-phase component gives an indication as to the presence of metalliferous material (ferrous and non-ferrous). Data can be recorded simultaneously with position-fixing data from connected dGPS systems, permitting very rapid ground coverage and display of apparent conductivity and in-phase component at each measurement point. All of these systems are capable of recording up to 10 values a second. These displays show the relative variation in apparent conductivity across a site and are very useful at a reconnaissance stage of an investigation.

FEM surveys are extremely effective where the targets are conductive, such as in landfill investigations, leachate plumes, brownfield investigations, searches for metal culverts, detection of live electric cables, etc.

TEM systems work on a different principle from FEM systems. A coil of wire is energised by passing a current through it. This generates an EM field that propagates into the ground. The current is then switched off and a receiver coil is used to measure the residual response of the decaying secondary field. The rate of decay is affected by the conductivity of materials present. Measurements of the secondary field are made as a function of time following shutting off the current. Coil sizes are very large where great depth of penetration is required (many hundreds of metres). Special shallow-sensing devices known as very early time-domain EM (VETEM) instruments are used where higher resolution is required in the near surface, typically the top few tens of metres. TEM systems are used to produce a 1D vertical sounding at each location. Profiles are produced by undertaking a series of soundings along a transect and then gridding the results to form a 2D section. TEM soundings can be inverted like 1D VES profiles to produce an interpretation with layer thicknesses and *true* conductivities that are physically diagnostic of the material present. The results from adjacent 1D soundings can be correlated and gridded to form a 2D true conductivity-depth model.

Geonics Ltd. also make geophysical metal detectors based on the TEM principle (EM61-MK2 and EM63). Two small flat-lying coils are mounted vertically above each other and the time decay measured. These instruments have a shallow depth of penetration (< 5.5 m) and high lateral resolution, and are used effectively and extensively for the detection of UXOs and USTs.

45.6.2 EM methods – ground penetrating radar (GPR)

GPR works on the basis of transmitting radio waves with a known centre frequency from an antenna and measuring the time it takes for signals to be reflected back to a receiving antenna. By measuring the two-way travel time (TWTT) and by knowing (or assuming) the speed at which the radio waves travel through the material present, it is possible to measure the depth to a target. In many respects the technique is conceptually similar to the seismic method where sound waves are used.

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

GPR systems have been developed for specific uses. Broadly, these fall into very low frequency systems (frequencies < 10 MHz) for deep investigations (≫ 100 m), particularly of polar ice sheets and glaciers; those for geological applications (25–500 MHz); those for engineering investigations (500 MHz–1.5 GHz); and those for non-destructive testing (NDT) investigations, (frequencies above 900 MHz to 2.5 GHz) , where the required depth of penetration is of the order of decimetres but the resolution needed is down to around 1 cm or less. Special GPR systems have been developed for utility mapping and to be used by non-specialist technicians. GPR antennae can be deployed by dragging an antenna system across the ground, towing it behind a vehicle or mounting it on a boat or aircraft. As a general rule: high frequency, fine vertical resolution; low frequency, coarse vertical resolution. GPR techniques are not effective in highly conductive environments due to the high attenuation of the radar signal, i.e. they should not be used in saline or conductive clay-rich environments.

GPR surveying works on the principle that reflections will occur where there is a contrast across an interface between the relative dielectric permittivities of the materials present. Consequently, the reflection characteristics can be as important in interpretation as the TWTT values. The biggest uncertainty in interpreting GPR data is the variability in radio-wave velocities when translating time-domain radargrams (the raw data images) to depth images. GPR will not achieve any significant depth of penetration in areas with high conductivity, such as in saline environments or over seawater. It is, however, capable of imaging through fresh water. In the UK, typical depths of penetration are of the order of a few metres; in resistive environments, imaging can be achieved to more than 10 m using a low-frequency system.

The GPR method is used in a myriad of applications such as: geological mapping; environmental, engineering and archaeological investigations; surveys of highways and airfields; bridge decks; ballast surveys for railways; and in mapping animal burrows. It can be used to measure the water table and its characteristics, and groundwater and contaminant movement (DNAPLs and LNAPLs, dense and light non-aqueous phase liquids, respectively). Hydrocarbons floating on the water table can be imaged in the right conditions.

Raw radar data can be processed much in the same way as seismic data, with a wide range of processing techniques available to filter, amplify, enhance and migrate the data to aid interpretation (**Figure 45.5**). As with seismic data processing it is full of potential pitfalls and opportunities to make mistakes for the unwary, and GPR data processing and interpretation should be undertaken only by skilled and experienced radar processors and interpreters.

45.7 Seismic methods

Seismic methods use the generation and propagation of elastic body waves through the ground and the measurement of their respective travel times. A wide variety of sources exist by which the signals are generated, such as a sledge-hammer strike onto a base plate, blank shotgun shells fired vertically into the ground (e.g. 'Buffalo' gun), accelerated weight drops, and explosives, to name but four. The signals are detected by geophones (on land) or hydrophones (in water). The type of source is chosen based on anticipated ground conditions and target depths. As with the GPR technique, there is a trade-off between vertical resolution and depth of exploration.

There are three broad styles of seismic surveys, ranging from seismic refraction and reflection through to the use of surface (Rayleigh) waves. Each of these will be described briefly in turn.

45.7 1 Seismic refraction

A seismic refraction survey comprises an array of geophones and an energy source, such as a hammer strike onto a ground plate ('shot'). Each shot generates seismic waves that travel to a boundary across which it is assumed that the seismic velocity increases; the energy is refracted along the interface and re-radiated back towards the surface at the critical angle (i_c) of refraction, where $\sin i_c = V_1/V_2$ where V_1 and V_2 are the seismic velocities above and within the refractor, respectively, and $V_1 < V_2$. By measuring the time taken from the shot to when

the signals arrive at each of the geophones, a time–distance graph can be constructed, from which it is possible to compute the seismic velocities of the surface, and deeper, layers causing the refraction. After careful processing, seismic velocity images can be produced showing 2D sections along a profile that indicate the lateral and vertical variations in sound-wave velocity (**Figure 45.6**). Depths to refractor interfaces can also be derived.

Refraction surveys are used to determine the depth to bedrock, to locate disturbed zones indicating faulting, to measure the depth of landfills and backfilled quarries, for foundation surveys for large dam construction, to locate major solution features, and for ground investigations for other major engineering structures (tunnels, roads, embankments, etc.). For shallow engineering investigations, depths of investigation are typically less than 20 m.

45.7.2 Reflection seismology

Seismic reflection measures the two-way travel time taken for a seismic wave to travel from a source vertically down into the ground and back to the surface. It provides information about the geometry of subsurface structures, and on the physical properties of the materials present. These techniques are highly developed in the hydrocarbon industry and there is an increasing transfer of such technology to the high-resolution shallow engineering and environmental sector.

The reflection method uses the same types of sources as refraction surveys, and depths of investigation range from at least 20 m (at the shallowest) down to several hundred metres. There are many ways to process the recorded data, using a wide range of commercially available software. Typically, the raw data are edited, filtered, amplified, processed to remove the effects of the geophone array geometry and subjected to the analysis of seismic velocities, to produce a 2D section, which is typically what is then interpreted. Further data processing is possible to enhance the data to aid further interpretation and to translate time sections to depth sections. Details of the type of data processing available have been described extensively by Yilmaz (2001). Seismic reflection surveying is commonly used in engineering studies for deep bridge foundations, and road and tunnel route surveys to map geological structures.

45.7.3 Surface waves

There are a number of different techniques that use surface shear waves or Rayleigh waves to determine physical properties of subsurface materials. For the purposes of this chapter, two common methods are discussed, namely, (a) ground stiffness sounding, and (b) multi-channel analysis of surface waves (MASW).

45.7.3.1 Ground stiffness sounding

The majority of strain levels within the ground at working loads are typically less than 0.1%. It is therefore important that stiffness values to be used in geotechnical calculations should also be measured at these small strain levels. One way to measure the very small strain stiffness, G_{max}, is to use ground stiffness 'sounding' or continuous surface wave seismics (CSW), which is a non-invasive analogue of the cone penetration test (CPT) or standard penetration test (SPT) (Butcher and Powell, 1996). A vertical 1D sounding comprises the determination of the variation of G_{max} as a function of depth to provide the required information on the geomechanical properties of the subsurface layers (i.e. hard and brittle, soft and plastic, etc.). The technique works on the basis of using a multi-frequency vibrating source, typically weighing 70 kg (**Figure 45.7(a)**), which can be tuned to a given frequency (f) in the range from 1 Hz to several hundred Hz. At the chosen frequency, the seismic vibrator generates Rayleigh waves through the surface of the ground that are detected by a short array of between two and six geophones. Nominal depths of penetration are equivalent to one third of the wavelength, which is controlled by the frequency of the source wave. By measuring the phase difference and wavelength across the geophone array for a given frequency it is possible to derive the ground stiffness at a range of depths. A 1D ground stiffness sounding is achieved by taking measurements at discrete frequencies from high to low frequencies, giving the mechanical strength of the materials in terms of the resistance to shearing forces. Rayleigh wave velocity (V_r) is typically 5% lower than that of shear waves (V_s) so the derived velocities are adjusted accordingly (Butcher and Powell, 1996), as G_{max} is proportional to V_s^2. Ground stiffness soundings can reach to depths of 20 m or more (**Figure 45.7(b)**), depending upon the materials present, and can reveal detailed variations in value up to several hundred MPa.

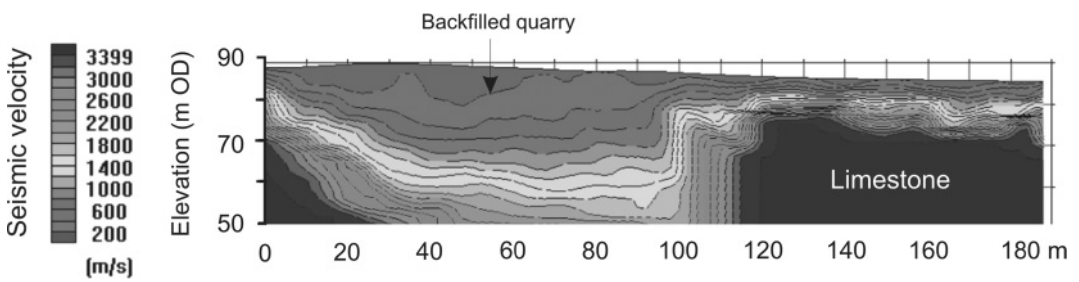

Figure 45.6 Seismic refraction velocity section across a closed landfill in a former quarry in limestone

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

The MASW method uses the same layout as for seismic refraction. A shot record is produced and processed, and the shear wave velocity is determined as a function of depth below the given geophone array. The results of each sounding are juxtaposed to form a 2D section displaying the variation in shear wave velocity as a function of depth and position along the array (**Figure 45.8**). The method is used to map zones of weak ground, fractured rock and voiding.

45.7.3.2 Over-water hydrographic and seismic surveys

For engineering investigations over water, such as for bridge foundations, mapping palaeochannels, offshore wind farms, etc., hydrographic and seismic surveys are commonly used. The principle of these surveys is similar to those used for hydrocarbon exploration, but they are suitably scaled down for the intended applications. Over-water hydrographic and seismic surveys can be undertaken in lakes and artificial lagoons, rivers, estuaries, docks and canals, in water depths as shallow as 0.5 m.

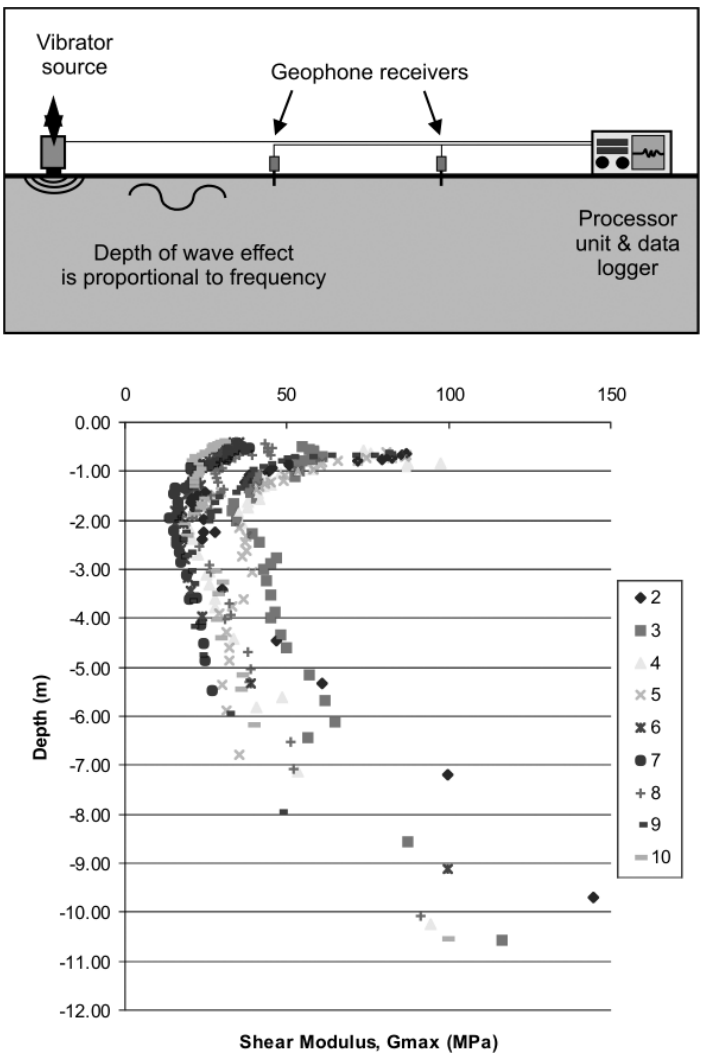

Figure 45.7 (a) Schematic showing the general layout of equipment to derive a ground stiffness vertical profile using a Rayleigh wave generator. (b) Example 1D ground stiffness profiles through landfill material

Side-scan sonar – This is a water-borne technique where high-frequency (100–600 kHz) pulses of sound are beamed from a towed transducer through the water column vertically below the survey vessel and to either side as the vessel progresses. Reflections are produced from objects within the water column below the sensor and from the seabed surface, and their locations and acoustic characteristics are recorded and displayed on a sonograph, which is effectively an image of insonified features. Side-scan sonar images are processed to form scaled mosaic pictures of the seafloor (analogous to aerial photographs of the ground surface), from which seabed features (e.g. sand waves and ripples, gravel and clay patches, iceberg and trawl scours, boulders, wrecks, anchor chains, etc.) can be identified. Individual features, such as a boulder as small as 0.3 m high, can be imaged.

Swathe bathymetry – Traditional echo sounding provides an estimate of water depth vertically below the acoustic transducer. Bathymetric maps are produced by contouring echo sounding values across an area. However, far greater spatial accuracy is achieved by using multi-beam echo sounding (MBES; swath bathymetry), which uses an oblique-facing transducer to isonify a swathe of ground at right angles to the direction in which the transducer is being moved. This permits the determination of values of water depth for pixels of 0.5 m size, with vertical resolution of 0.1 m across a swathe width typically four times the water depth. Systems can also produce a back scatter image analogous to **side-scan sonar** that produces an acoustic image of the seafloor or lake bed. By geo-referencing each pixel, 2D side-scan sonar images can be draped over the swathe bathymetry results to produce 3D acoustic images of the seafloor or lake bed.

To investigate below the seafloor or lake bed, it is necessary to deploy a high resolution **sub-bottom profiling** system. Seismic sources typically consist of a single transducer system with very high resolution (Pinger), or a Boomer plate source, which is used with a string of hydrophones in a single oil-filled buoyant flexible tube (streamer). Vertical discrimination is of the order of 30 cm. Where greater depth penetration is required (at the expense of vertical resolution) higher energy sources such as a Sparker (which generates a sound pulse by an electrical discharge in salt water), air gun or water gun can be used. The acoustic source generates sound waves that travel in all directions. The waves that penetrate into the subsurface are reflected back to a string of hydrophones towed close to the seismic source to produce a seismic image. At a basic level of interpretation, such as for dredge studies, several reflections are picked to produce simple line interpretations showing the elevations of selected interfaces along each survey profile. However, if the data are converted to an internationally recognised data format standard called SEG-Y it is possible to undertake much more sophisticated data processing

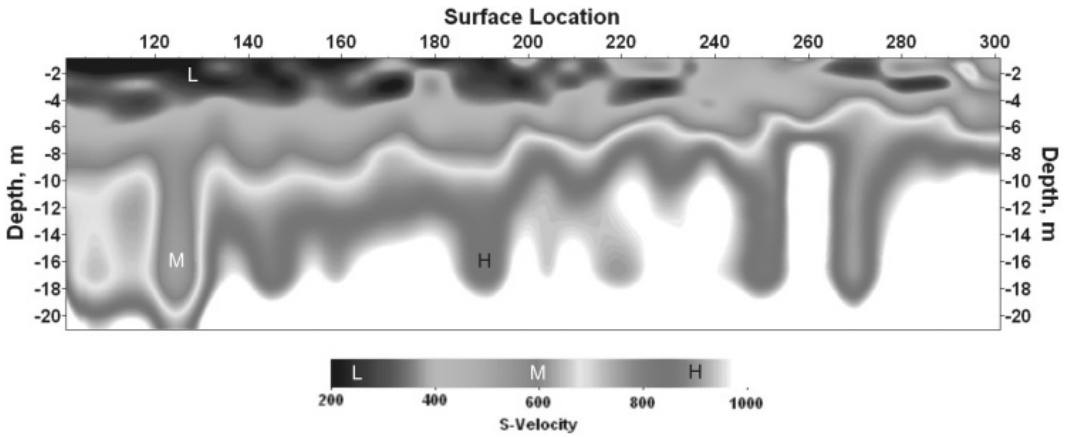

Figure 45.8 An MASW shear-wave velocity section across an area with areas of weak ground

and analysis, such as minimising the effects of multiple reflections, and filtering to enhance the primary reflections. It is also possible to analyse the data in oil-industry-standard 2D and 3D interpretation software, in which it is also possible to display borehole data. Lithological boundaries can be identified and projected onto the seismic data to facilitate the selection of the corresponding reflection events, which can be gridded to produce 3D seismic surfaces. While the levels of post-processing and analysis are much higher than for the most basic single-channel interpretation, the resulting interpretations have a greater level of confidence and technical robustness. Such high levels of analysis are justified for major engineering investigations such as for large-bore tunnels (e.g. Crossrail and Thames Tideway projects) in London and for offshore wind farm investigations prior to finite-element engineering design for pile foundations.

45.7.3.3 Integration with other data sets

Geophysical data are commonly interpreted without reference to other information, i.e. an unconstrained interpretation (satisfies statistical error limits, appears physically plausible and is internally consistent). Many geophysical models can have an almost infinite number of equally valid solutions. Where complementary geophysical techniques have been used over the same ground, separate interpretations can be produced for each method and compared with each other to achieve consistency. For example, it might be possible to use seismic refraction results to yield estimates of depth to bedrock. A corresponding resistivity section might then show that, for example, conductive leachate is migrating into and through this otherwise resistive bedrock, as the resistivity sections would respond to the pore fluid component rather than the solid matrix on which the seismic method depends. Although it is possible to jointly process complementary geophysical data sets to yield a single interpretation, this is non-standard currently.

A more comprehensive approach would be to integrate other forms of information, such as historical data from a desk study, aerial photographs, remote sensing images, airborne or downhole geophysical results, etc., so that a more holistic interpretation can be produced. This can be achieved where each data set is geo-referenced to a common coordinate system; where appropriate the information can be managed through geographical information system (GIS) software. Some dedicated geophysical software also permits this approach, such as Oasis Montaj (Geosoft) and Surfer (Golden Software). It is possible to integrate geophysical software with GIS, which also permits the incorporation of borehole data in digital (AGS) format (**Figure 45.9**).

45.7.3.4 3D visualisation

If 2D geophysical data can be incorporated into a 3D interpretation package, it is possible to produce 3D interpolations and surfaces that can then be viewed from a 3D perspective. Surfaces can be shaded and illuminated from different directions to aid the visualisation of the 3D model. Fly-throughs of the model can also be generated.

45.7.3.5 UXO investigations

A sad legacy of war and other forms of military conflict is the presence of unexploded ordnance, much of which in the UK, for instance, was delivered through aerial bombardment during World War Two. However, UXOs are also found on military bombing and firing ranges. Consequently, there is an ongoing requirement to develop techniques that will successfully and unambiguously detect remnant ordnance so that it can be rendered harmless and cleared. In 2008 CIRIA published the first comprehensive guidance for the construction industry on unexploded ordnance (Stone *et al.*, 2009). Despite the fact that geophysical techniques form one of the most significant methods of remote detection of UXOs, this publication barely mentions the techniques, or more worryingly, the limitations of such methods.

Primarily, magnetic, electro magnetic (FEM and TEM) and GPR techniques are used for UXO detection. Commonly,

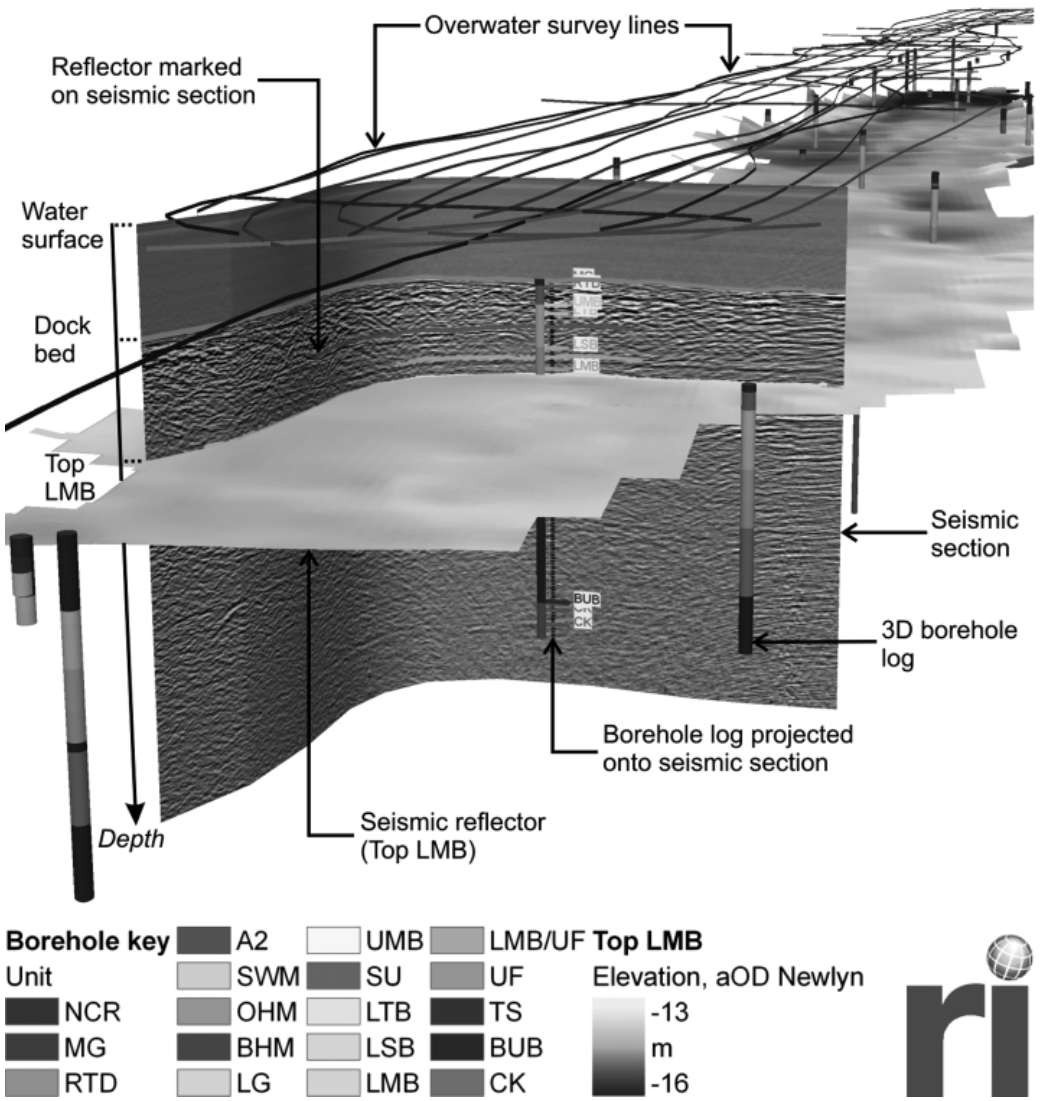

Figure 45.9 Boomer seismic reflection data, Boomer survey track plots and borehole data integrated within a 3D interpretation package

instruments are deployed using a single operator, who may carry a number of magnetic sensors, for example walking across a site; or instruments can be deployed as multiple sensor arrays from a variety of platforms to investigate a swathe of ground in a single pass. For coverage of large areas, such as bombing ranges, helicopter-mounted multiple sensor arrays of magnetometers or TEM coils can be used, where the helicopter flies with a ground clearance as low as 1 m (**Figure 45.10**). Where the presence of UXOs is suspected in sediments beneath water, suitable submersible sensors can be deployed, such as marine magnetometers or gradiometers, or TEM systems (such as the Geonics EM61-SS).

Magnetometers can also be used with a cone penetrometer test rig, where the sensor is pushed into the ground or inserted into a pre-drilled borehole (with non-magnetic casing), the hole being constructed in 1–1.5 m stages and the sensor lowered into each hole extension incrementally. Both the borehole and CPT approach require the sensor to be able to detect the presence of ferrous UXO within 1–1.5 m ahead of the hole.

Some software packages are available that provide specific tools to help pick potential UXO targets. However, such programs do not guarantee that all possible UXOs will be identified, and a manual interpretation by a geophysicist experienced in UXO detection should also be undertaken to help reduce uncertainties in the interpretation. Neither is there an increased guarantee of higher quality of work if a military search team is involved. In all cases where UXO risk is to be assessed, clients must spend time determining the qualifications and experience of the teams to be contracted to investigate a site. The 2008 CIRIA guidance is useful in providing information on how to do this.

45.8 Borehole geophysics

An important adjunct to surface ground investigations is the deployment of geophysical sensors down boreholes. These can be as single sensors, or down-hole tools in which a number of different sensors are installed. There are two main forms of deployment: (a) single *down-hole techniques* (borehole logging), where the output is a vertical log of a measured parameter as a function of depth down the hole, or (b) *cross-hole tomography*, where a pair of normally vertical boreholes is used with some form of geophysical source being placed at various depths in one hole and the series of detectors being located in the other hole. Signals are transmitted between the holes to produce a 2D panel of data between the boreholes. Borehole tomography is commonly undertaken using seismic, electrical or radar methods. The separation between boreholes should not normally be more than 10 times the minimum dimension of the target being sought, i.e. boreholes should be no more than 10 m apart to image a target with a 1 m diameter. Cross-hole tomography uses techniques that are analogous to their surface equivalents and will not be discussed further here.

There is a wide range of borehole logging tools available (**Table 45.3**) for a large number of different applications. As with surface geophysical techniques, tools should be selected depending upon the most diagnostic physical properties of the targets being sought. Borehole logging can have a very high vertical resolution but may have a very limited penetration beyond the wall of the borehole. However, inter-borehole correlation can also be used to define geological structure (**Figure 45.11**). Geophysical CPT sensors (soil moisture probe, seismic cone) and traditional down-hole tools should also be considered in survey design.

Specialist borehole logging contractors are available through whom advice can be sought about the most appropriate logging tools to be used for a given purpose. Before constructing access boreholes, the size of the down-hole tools, and whether they can work in cased or uncased boreholes or in air- or fluid-filled boreholes, should be determined.

45.9 Remote sensing

Remote sensing represents a wide spectrum of techniques relating to optical, infra-red and radar imaging, predominantly from orbiting satellites. However, there is an increasing range of additional platforms from which observations can be made, such as aircraft (fixed-wing and helicopters for aerial photography, LIDAR, thermal infra-red (TIR), hyperspectral imaging), blimps (unpowered, unmanned inflatable platforms), drones and related autonomous unmanned vehicles (AUVs – airborne and submersible), and elevated aerial platforms and masts from surface vehicles, such as for near-surface TIR imaging. Hyperspectral imaging uses between 100 and 200 spectral bands of relatively narrow bandwidths (5–10 nm), in contrast to multi-spectral data sets, which usually comprise about 5 to 10 bands of relatively large bandwidths (70–400 nm). For the purposes of this chapter, discussions are restricted to satellite imaging, LIDAR and TIR methods.

45.9.1 Optical remote sensing

Optical remote sensing has revolutionised the geosciences in being able to image large areas of the Earth's surface with increasing levels of accuracy and ground resolution. Not only are 'pictures' produced but also multi-spectral data sets that can be analysed in ever more sophisticated ways to determine a number of properties of the Earth's surface. The choice of image type is a function of the ground area to be covered, the required ground resolution, and the purpose of obtaining the imagery (with the largest image sizes having the coarsest ground resolution). For example, different applications might require panchromatic (black and white only), four-colour (red, green, blue and near infra-red (NIR)) or more spectral bands. The level of processing of the image data is also dictated by the application, i.e. whether to use the image for illustrative purposes (lowest level of processing) through to full ortho-rectification, which is the technique by which distortions are corrected in image geometry resulting from the combined effect of variations in terrain elevation and non-vertical angles from

Table 45.3 Suitability of borehole geophysical methods for a range of shallow engineering applications

the satellite to each point in the image at the moment of acquisition. Ortho-rectification allows the image to be incorporated into a geographic information system to maintain full spatial referencing in a designated coordinate system.

Widespread coverage of the Earth's surface was originally provided by Landsat satellites, the first of which was launched on 23 July 1972. Subsequent missions have provided improved sensor capabilities, with Landsat 5 being launched on 1 March 1984 with both multi-spectral (resolution 57 m by 79 m) and thematic mapper (resolution 30 m) sensors on board; the thermal image scene has a resolution of 120 m. Landsat 7, launched on 15 April 1999, has eight spectral bands (three visible, two NIR, one TIR and one panchromatic) all with 30 m ground resolution, plus a thermal band with 120 m ground resolution. Landsat 5 and 7 both provide scenes with an area of 170 km by 185 km. Since October 2009, all Landsat imagery has been freely available. The Landsat Data Continuity Mission is due to be launched in 2012 to provide imagery through to 2020.

The ASTER system comprises three separate sensors – visible and near-infra-red (VNIR; 15 m ground resolution), short-wave infra-red (SWIR; 30 m), and TIR (90 m), with a scene size of 60 km by 60 km. The system images to latitudes

of ±83° of the equator. In 2009, an ASTER Global Digital Elevation Model was made available at 30 m resolution. Geo-rectified images can be draped over this DEM to provide 3D perspectives (**Figure 45.12**).

Higher-resolution multi-spectral and panchromatic images are available from a number of satellite platforms, such as, for example, SPOT, IKONOS, FORMOSAT-2, KOMPSAT-2 and Quickbird, with increasing levels of ground resolution. The latest SPOT imagery (SPOT5) is available in scenes 60 km by 60 km with ground resolutions of 2.5 m, 5 m, 10 m and 20 m in panchromatic and colour, with an additional option of colour at 20 m ground resolution. Stereo imaging is also possible; from

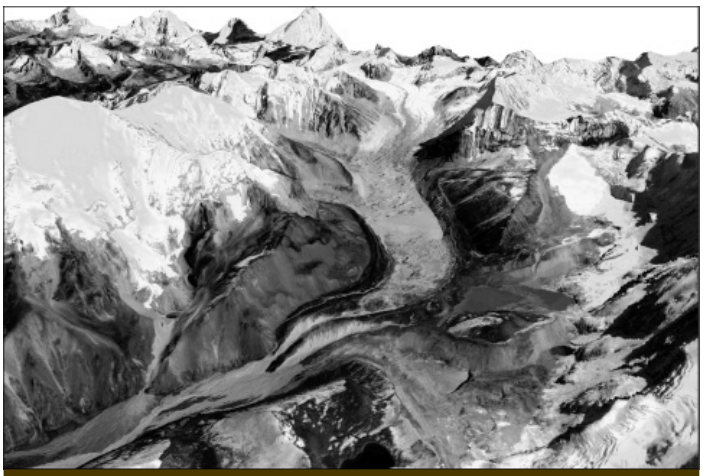

Figure 45.12 A colour ASTER image pan-sharpened and draped over a digital terrain model for a scene in Tibet (shown as grey scale)

this, digital elevation models (DEM) can be derived, although for best results, users should provide accurate ground control points within the area of coverage of the scenes to calibrate the DEM. IKONOS has been available since September 1999 with panchromatic and four-colour images at 1 m and 4 m ground resolution, respectively, and a revisit period of three days. FORMOSAT-2 has 2 m and 8 m ground resolution in panchromatic and four-colour mode, respectively, with a daily revisit capability, making it ideally suited for rapid imaging after natural disasters. KOMPSAT-2 has 1 m and 4 m ground resolution in panchromatic and colour modes with a 28-day revisit period and scene size of 15 km by 15 km. The satellite with the finest ground resolution is Quickbird, which was launched in October 2001. It achieves resolutions of 0.61 m and 2.44 m in panchromatic and four-colour modes, respectively, over a scene size of 16.5 km by 16.5 km. The EROS satellite produces panchromatic-only images over 13.5 km by 13.5 km with a 1.8 m resolution, although hyper-sampling can refine this to 1 m over an area of 9.5 km by 9.5 km.

Interpretation of images can range from photo-interpretation techniques through to software-controlled terrain analysis. Time-separated images can be used to measure rates of change by tracking the lateral movement of surface objects or through comparison of changes in surface emissivity.

45.9.2 Synthetic aperture radar (SAR)

While optical satellite imagery can be restricted by daylight and visibility limited by cloud cover, radar imaging can be used at any time and through cloud cover. A number of radar satellite imaging systems are available, such as INSAR and TerraSAR-X. The latter, for example, provides three ranges of ground resolution: *Spotlight*, ≤ 1 m over an image 10 km wide and 5 km long; *Stripmap*, ≤ 3 m, 30 km wide by 50 km long; and, *Scansar*, ≤ 18 m resolution, 100 km long by 150 km wide.

Radar sensing can be used not only to provide images of the ground covered by extensive cloud cover, but also can be used to derive changes in surface elevation arising from earthquakes or hydrocarbon exploitation, for instance, using interferometric methods. Rates of lateral movement of the ground surface can be measured through rapid repeat imagery, where flow rates as small as 2 cm per day can be resolved over Himalayan debris-covered glaciers.

45.9.3 LIDAR

Light detection and ranging (LIDAR) has now become an established, very high-resolution remote mapping tool that is predominantly deployed from aircraft but is increasingly becoming available for ground-based lateral scanning of near-vertical faces. As the survey aircraft flies over a designated survey area, a wide-aperture laser beam scans across the line of flight measuring the transit time from up to four returns from the reflective surfaces beneath, each return generating a data point within a point cloud. The transit time is converted to distance from the sensor, and, knowing the exact height and aspect of aircraft, the elevation and position of the reflective surface can be determined; thus a digital surface model (DSM) can be created. The first return may be associated with the tree canopy and vegetation, while the last return is normally associated with the ground; from this, a digital terrain model (DTM) can be derived. Intermediate returns may provide information from within the tree canopy (giving information about the species of trees, for example). Using specialist software it is possible to remove the effects of trees and buildings from a DSM to generate the DTM. This can provide detailed topographic information otherwise obscured by vegetation. LIDAR has been used highly effectively to map landslides and archaeological remains concealed beneath dense tree canopies. Ground resolution is of the order of 0.25 m and vertical topography determined to within 0.1 m, subject to survey control.

Similar technology is now available for terrestrial lateral LIDAR scanning by which detailed point clouds can be obtained within a range of ~1.2 km of steep surfaces, such as rock cliffs or man-made superstructures. Point clouds can be used to generate 3D images and also to map changes in surface elevations over time, such as for pseudo-real-time monitoring of slope stability. It is now also possible to deploy LIDAR scanners from boats; images can be combined seamlessly to produce a continuous image from the seafloor and the submerged part of marine infrastructure using high-resolution multi-beam swathe bathymetry to the exposed superstructure using boat-based LIDAR.

LIDAR images can be used to generate topographic maps, DTMs and a wide range of topographic products, as well as providing the base onto which aerial photographic or satellite images can be draped to produced 3D isometric images and animated ‘fly-throughs’. As the data produced are geo-rectified, they can be integrated into GIS databases and merged with other spatially rectified data sets in common coordinate sets. For example, LIDAR data can be integrated with airborne geophysical data sets, and airborne geomagnetic data can be

presented in colour contoured format overlain on panchromatic satellite imagery draped over a LIDAR-derived DTM.

45.9.4 Thermal infra-red (TIR)

TIR imaging can be achieved using sensors deployed on satellites and airborne or surface-mounted platforms, such as telescoping masts. The principle is based on being able to convert radiated or reflected heat into real-time pictures or images and depends on there being a detectable surface thermal contrast present, such as from a hot lava flow, exothermic methanogenesis within a landfill, an underground fire within a tyre dump, or man-made infrastructure (pipes, buildings, electric cables, etc.). For engineering applications, ground-based or aerial surveys are undertaken. Subsurface heat sources may be indicated at the ground surface through thermal conduction. Timing of surveys should be planned to enhance the thermal contrasts, such as just after dawn. While thermal imaging can be undertaken at night, it is more often undertaken in daylight in conjunction with optical imaging (photography/video) to aid interpretation.

Chapter 46
Ground exploration

John Davis Geotechnical Consulting Group, London, UK

This chapter describes the main intrusive techniques available for ground exploration. These techniques are some of the tools by which the ground profile and soil behaviour elements of the geotechnical triangle are established.

46.1 Introduction

Ground exploration is defined as the collection of data from intrusive ground investigation techniques. Non-intrusive techniques such as geophysics or surface loading are not discussed here.

Ground exploration includes techniques to expose the ground or collect samples for visual inspection or testing, intrusive testing of the ground without collection of samples, and any subsequent installation of monitoring instrumentation in the ground. Describing and testing of recovered samples and any interpretation of recovered *in situ* or monitoring data is covered in other chapters (Chapters 49 *Sampling and laboratory testing* and 50 *Geotechnical reporting*).

The major ground exploration activities are divided into two types: those that involve intrusive means to characterise and/or sample the ground, and those involving subsequent monitoring of the ground.

When planning a ground investigation it is important to choose a suite of ground exploration techniques that are appropriate to the likely ground conditions and that also provide the data the project requires. Guidance on this is given in Chapters 43 *Preliminary studies*, 47 *Field geotechnical testing*, 48 *Geo-environmental testing*, and 49 *Sampling and laboratory testing*.

It is important to understand that each technique provides both opportunities and constraints for data collection. Data requirements range from soil or rock description, through quantifying parameters (via lab and *in situ* testing), to provision of monitoring opportunities. Other chapters provide further guidance on these issues. An alternative source of detailed advice on the applicability of the various ground investigation techniques is a specialist ground investigation contractor.

46.2 Techniques

This chapter describes the nature of the main techniques and outlines the pros and cons for:

- different types of soils and rocks;
- sampling, *in situ* testing;
- monitoring.

Techniques are divided into three classes: excavation techniques, probing techniques and drilling techniques. The list of techniques discussed is not exhaustive.

46.3 Excavation techniques

46.3.1 Trial pits

Trial pits can be hand-dug or machine-dug. Hand-dug trial pits are typically used as starter pits to identify and avoid services or to uncover details of existing shallow foundations. They are normally limited to relatively easy-to-excavate soils and to very shallow depths. The need to provide shoring and the inevitable slow rate of progress mean deeper hand-dug pits are not often specified.

Suitable ground conditions and depths for machine-dug trial pits are determined by the capacity of the machine. All natural soils are suitable, as are some weaker weathered and fractured rocks. Care must be taken in very soft soils and sands and gravels below the water table, as excavations of these materials are particularly liable to collapse. In these cases it is not usually possible to recover the required information from below the water table.

Trial pits are excellent for displaying the fabric of the ground and for obtaining large disturbed samples such as those required for some compaction tests. Generally trial pits are only used to obtain disturbed samples. Shallow (<1 m) trial pits are also often used to carry out plate bearing tests or *in situ* California bearing ratio (CBR) tests. Care should be taken to site trial pits in areas where the backfilled pit will not cause problems for any subsequent construction. It is possible to install standpipes for monitoring gas and groundwater in trial pits as they are backfilled.

46.3.2 Trial trenches

These are similar to trial pits but are long compared to their width, and useful for finding features at shallow depths that might have a limited extent in plan, such as old foundations, or systematic changes in rockhead level, such as the edges of buried cliffs.

46.3.3 Trial excavations

Trial excavations are used to investigate the feasibility of much larger excavations. A trial excavation is defined here as an excavation which contains the excavation plant.

46.4 Probing techniques

Probing techniques are those that recover information about the ground but do not recover a sample. The principal types are:

- dynamic probing;
- static cone penetration testing.

In dynamic probing, a series of rods with a standard cone-shaped shoe are driven rapidly into the ground by repeated blows of a standard-weight hammer falling through a repeated fixed distance. A penetration resistance in the form of blow count per unit length is recorded and logged, typically blows per 100 mm. Different standards exist for hammer weight and hammer drop length. More information on the various types can be found in British Standards or Eurocodes. The technique is broadly analogous to continuous standard penetration testing (SPT) (see below). However, it is important to realise the results cannot normally be used to safely generate equivalent SPT 'N' values. The technique is useful for rapid and inexpensive determination of variations in penetration resistance, such as where soft spots are thought to exist and their extent needs to be determined. The equipment used is typically light and portable and can be used in spaces with restricted access such as basements. The technique is unlikely to achieve significant penetration in stiff clays or dense granular deposits.

In static cone penetration testing, a series of rods are driven hydraulically and continuously into the ground, typically from a purpose-built heavy vehicle which provides a reaction to the hydraulic thrust. The lowest rod (the 'cone') can contain various sensors used to measure properties of the ground it passes through. The most commonly used sensors measure the resistance the ground provides to the end of the cone as it is pushed into the ground, and the frictional resistance the ground provides to the sides of the cone. A continuous and instantaneous read-out of these values is provided. These parameters can be interpreted to give an indication of the soil type and to provide various strength and stiffness parameters. These values of cone resistance and cone friction can also be used directly in some design calculations. One of the great advantages of cone penetration testing is its ability to identify very thin clay or granular layers in other strata. These can have significant impacts on geotechnical processes and are easily missed by many other ground exploration techniques.

Other types of cone can be used to give measurements of pore pressure and seismic velocity. Other varieties of cone also exist. This is discussed in greater detail in section 46.5.3.3. Cone penetration trucks can also be used to recover very small diameter continuous disturbed samples, though not at the same time as or exactly in the same location as any other cone penetration testing as described above.

The technique is applicable to most soils; achievable penetration depths depend on the strength of the soil and the reaction provided by the equipment the cone is mounted on. Typically, significant penetration is limited to clays that have a consistency less than stiff, and to granular soils whose relatively density is less than medium dense. Penetration will be greater in finer soils compared to coarse soils. Penetration in very coarse soils (gravels and coarser) will be limited regardless of relative density. Penetration is not limited by the presence of groundwater. In soft or loose soils great depths (around 40 m) can be achieved very rapidly and in these conditions a single truck-mounted cone can achieve several hundred metres of testing in a day. A typical cone 'truck' is a highway-legal road vehicle weighing approximately 18 tonnes. Lighter vehicles with large low-pressure tyres are available for very soft sites. Cone penetration equipment can also easily be mounted on pontoons or jack-up rigs for offshore work and can be skid mounted for work in restricted access sites, though in this case consideration needs to be given to provision of a reaction by the use of props, anchors or kentledge.

Neither dynamic probing nor static cone penetration testing provides for the installation of instrumentation or post-fieldwork monitoring.

46.5 Drilling techniques

46.5.1 Window sampling

A window sampler is a tube with an open slot or window down one side which is driven rapidly into the ground using high-speed percussion. Window samplers are typically 1–3 m long and less than 100 mm in diameter and may or may not contain a rigid plastic liner. The logging of the soil can be done through the window. 'Windowless' samplers are also available. In suitable self-supporting ground, they can achieve depths of 7 m or more by repeated extraction and reinsertion of progressively smaller sampler tubes using rods to extend the depth. They are generally only suitable for obtaining disturbed samples. It is sometimes possible to install standpipes for monitoring gas and groundwater using window sampling equipment. The principal advantages of window-sampling are speed and cost-effectiveness. The equipment is small and portable and can easily be used in areas with restricted access. It is often used alongside other techniques as an inexpensive way of providing a widespread and large number of sampling points for contaminated-land testing.

Window sampling of groundwater is difficult. Recovery in soils where the largest clasts, such as gravel, are similar to or larger than the internal diameter of the tube is not easy. Recovery of samples in granular soils below the water table is very difficult. High soil strengths and relative densities also restrict the depths achievable with this technique. Another drawback is that the equipment is noisy for its size.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

46.5.2 Auger drilling

In geotechnical investigation (as opposed to mineral prospecting) auger drilling normally uses hollow stem continuous flight augers. The hollow stem typically has a removable plug at the lower end and the auger is 'corkscrewed' into the ground. The material retained on the auger flights on extraction gives an approximate profile of the strata encountered, and the hollow stem and the plug can be removed from the surface to allow the use of driven samplers in the hollow stem. The technique is fast and can cope with most soil types, though sands and coarser soils generally inhibit the use of the hollow stem. Anything other than relatively shallow depths requires a powerful rig. The technique is not commonly used in geotechnical investigations and tends to be restricted to sampling for contamination testing.

46.5.3 Cable percussion boring and rotary drilling

46.5.3.1 Casing

Casing is used in both cable percussion and rotary boreholes to support the borehole walls and to seal off inflows of groundwater. It is typically formed of lengths of robust steel tubing with threaded ends allowing simple connection. A cutting shoe or bit is always present at the bottom of the lowest section of casing. Casing is not always required. Typically the base of the casing during drilling is always slightly higher than the base of the borehole. Casing is typically installed using the principal method of the rig involved – percussion for cable percussion rigs and rotary drilling techniques on rotary rigs.

46.5.3.2 Cable percussion boring

Cable percussion boring is also commonly known as shell and auger boring and is the mainstay of the UK geotechnical investigation industry. It is used routinely in most materials from soft organic soils up to very weak rocks. The term 'shell and auger' is misleading as augers are almost never used in this context in the UK.

A cable percussion rig consists of a winch with a friction clutch or brake that winds a wire rope to and fro over a pulley at the apex of two connected A-frames. The winch is used to repeatedly lift and drop a variety of steel boring tools into the ground to create the borehole and to remove the displaced soils.

A 'claycutter' is, unsurprisingly, used to advance the borehole in clay soils. It has a similar form to a window sampler in that it is a steel cylinder, open at the bottom end where it is fitted with a cutting shoe and with two open slots in the side. When this relatively heavy tool is dropped on to the base of the borehole, clay is forced up inside it. The cutter is then raised to the surface and the clay is knocked out through the shoe by inserting a metal bar through the open slots.

A shell is used to recover sands and gravels. This is a steel cylinder, open at the bottom end, where it is fitted internally with a hinged circular plate which forms a non-return valve or 'clack'. The sands and gravels are often recovered by surging the shell up and down just above the base of the hole. This draws water into the hole and loosens the soils allowing them to pass above the clack and be retained by it. Water is often added to the borehole to facilitate this process. One of the disadvantages of this technique is that the samples it produces tend to under-represent the finer-grained fractions of the sands and silt that may actually be present in the ground.

A variety of chisels are also available for breaking through hard layers.

The recovered materials are removed frequently (typically at least every 0.5 m) by dropping or knocking them from the shell or claycutter onto a board adjacent to the top of the hole. Some or all of this material is collected as both small ('jar') and bulk ('bag') samples for logging by the engineer or geologist either at the rig site or later elsewhere. These samples can also be used for laboratory index testing.

Two other important tools are routinely used: the SPT hammer, in many materials, and the U100 sampler, in clay soils.

46.5.3.3 The standard penetration test

The standard penetration test (SPT) is a commonly used *in situ* index test. It can be carried out successfully in almost all soils and in some weak rocks. The SPT equipment consists of a trip hammer which drops a standard-sized weight (65.5 kg) through a standard distance (760 mm). The hammer drives either:

- a solid rod of a standard length (610 mm) and diameter (2 ft or 50.8 mm) with a standard-shaped cone on the lower end;
- an open-ended split sample tube of a standard length and diameter with a standard-shaped cutting shoe or 'spoon' on the lower end.

The solid rod is used in rocks and soils with significant gravel or larger content, and the split spoon sampler in finer grained soils. The samples obtained in this way are taken as small disturbed samples.

The test is carried out by repeatedly dropping the hammer and recording the penetration for each of six successive penetrations of 75 mm. The lowest four sets of 150 mm blow counts are totalled to give the SPT 'N' value. Various corrections can be made to this N value to account for the effects of variations in grain size, overburden pressure and hammer calibration. N values have been correlated with many soil and rock parameters. For further information on this see section 46.6 below. Where resistance to penetration is very high, equivalent N values are often extrapolated from tests with less than the normally required penetration.

The test is not always very successful in very weak soils, where the tool can sink under its own weight or penetrate several hundred millimetres with a single blow. The test is also unreliable in soils with many larger clasts (gravel and larger), where the strength of individual clasts dominates the results. The test is very useful in some very weak rocks (such as high porosity sandstones), where it is sometimes the only source of quantitative information. The test is now considered to be an

unreliable indicator of geotechnical properties in chalk. The test can also be carried out in rotary bored holes.

46.5.3.4 The U100 sampler

The U100 sample is a low-quality undisturbed sample that is obtained by driving an open metal cylindrical tube into the soil. The tube is 450 mm long and has an internal diameter of 100 mm. The lower edge of the U100 sample tube sits within a steel cutting shoe containing a sprung core catcher, and its upper edge is connected to a driving head and rod. A sliding hammer connected to the rig winch moves over this rod and is repeatedly lifted and dropped, driving the sample tube into the ground. The material retained in the cutting shoe is usually sampled separately as a small disturbed sample. The open ends of the U100 tube are normally sealed with wax and covered with plastic end caps. The samples obtained in the U100 sample tube are commonly referred to as 'undisturbed'. This is not strictly true and if high quality samples are required for advanced triaxial testing then thin-walled push samples or samples taken from a rotary core should be used. U100 sampling is used in all types of clay soils. It is often not very successful in very soft or strong clay soils or clay soils with a high stone content. The number of blows used to fill the sample tube cannot be used in any way to correlate with SPT N values.

Eurocode 7 classifies a U100 sampler as a thick-walled sampler (see British Standard Institution, 2006, Table 3). This effectively disallows its use as a means of obtaining samples for quantitative design (a requirement for most EC7-compliant design). Modified thinner-walled U100 sampling tubes are beginning to become available and the use of these partially overcomes this problem. These sampling tubes are inevitably less robust than their thicker-walled predecessors and this can cause problems in some soils traditionally sampled with U100s such as tills and weaker clay-based rocks. In most cases EC7 compliant sampling in these soils can be achieved by using rotary coring methods.

46.5.3.5 Thin-walled and piston samplers

This type of sampler is typically used to obtain high-quality undisturbed samples in soft clays where other forms of sampling would be likely to cause excessive sample disturbance. They vary in diameter but are typically 100 mm or larger. Lengths also vary. Thin-walled samplers feature a non-return valve at the top of the sampler to allow escape of water or air during sampling. Thin-walled samplers are typically pushed continuously from the surface using a hydraulic jack or using the rig winch in conjunction with pulleys. Piston samplers are a type of thin-walled sampler. The sample tube is pushed by the drill rods into the soil over a close-fitting piston head which can be held in a fixed position by surface-operated clamps. Both types can be used with rotary rigs and cable percussion rigs. Piston samplers for use in stiff clay soils have also been developed

46.5.3.6 Rotary drilling

There are many different types of rotary drilling technique used in ground exploration. One of the main distinctions is between cored and non-cored techniques. Within the cored category there are further distinctions between conventional, wireline and sonic coring. Choice of a flushing medium is also an important consideration. The sections below give an outline of these techniques. This, however, is a complex subject and it is recommended that these choices be discussed with a prospective ground investigation contractor at an early stage of the investigation procurement process.

46.5.3.7 Flush

Most rotary drilling systems involve the use of some sort of flush (air or liquids; the liquids include muds, foams and mists). The flush is circulated by pumps down through the drill bit and back up to the surface through the annulus between the boundary of the hole and the drill 'string' (the sequence of bit core barrel and drill rod or cable in the borehole). One of the main purposes of the flush is to remove cuttings away from the bit and transport them up the hole to the surface. Another significant benefit of flush is in resisting any sub-artesian groundwater pressures encountered during drilling.

46.5.3.8 'Open hole' rotary drilling

Rotary drilling that does not involve the collection of core is often called 'open hole' drilling. In open hole drilling the bit occupies the full cross-sectional area of the borehole as it is advanced, and all the material below the bit is fragmented and passed up the borehole as cuttings by the flush. This is a very rapid drilling technique. Typical applications are those that require high metreages to be drilled but do not require the recovery of core. Examples are searching for voids, such as those found in abandoned mines, and the rapid creation of boreholes for the installation of instrumentation where the ground conditions are well known or established. Open hole techniques are also used within short lengths of borehole to pass through strata where coring techniques might struggle to progress.

The only way to log rotary open hole boreholes is by examination of 'cuttings' in the flush returns. In soils, these are likely to be minimal. In rocks, examination of the small rock chips returned in the flush gives a broad view of the nature of the strata being drilled. This examination must be done *at the rig at the time of drilling*. Voids such as coal mine workings are often identified by a loss of flush. Unworked coal seams are usually identified by the distinctive arrival of black coal chips in the cuttings.

Where boreholes are being entirely drilled using open hole techniques a system commonly known as ODEX is used. ODEX is a trade name that has come to be associated with equipment that allows the borehole casing to be advanced at the same time as the bit. Such systems often utilise 'down the hole hammers' (DTH) to increase the rate of penetration.

46.5.3.9 Rotary coring

There are three main types of rotary cored drilling: conventional, wireline and sonic. Conventional and wireline coring share many characteristics and will be discussed first. Coring of soils and rocks involves the recovery of a cylindrical 'stick' of the ground using a rotating 'core bit' and 'core barrel'. These combine to create a cylindrical tube with a cutting surface around the lower edge. Typically in geotechnical investigations most barrels are 'double' tubed. In these systems the inner barrel is decoupled from the outer rotating barrel that carries the cutting edge to minimise disturbance to the core. This system usually also incorporates a rigid 'core liner' within the inner barrel. This liner is a plastic tube in which the core is collected and retained as it is placed in the core box at the end of the core run.

Each run has its own fresh length of liner. Spring systems are used to retain the core within the barrel as it is returned to the surface at the end of the core run. Core barrels come in a variety of lengths and diameters. Typical geotechnical investigation core diameters are between 70 mm and 100 mm. The wider diameters tend to maximise the likelihood of good core recovery. Core barrels are typically less than 3 m long. Core 'run' lengths (the length of borehole drilled in a single attempt) are typically restricted to less than the barrel length.

The difference between conventional and wireline systems is speed of operation in deeper (say greater than 30 m) boreholes. In conventional rotary coring the barrel is delivered to the bottom of the hole using coupled rods; these provide a rigid means of delivering the rotary motion and the flush to the bit. If the ground conditions require the hole to be cased then a typical sequence of operations would be:

- Attach the barrel to the rotary head on the rig and lower it into the existing hole until the head is just above ground level.
- Clamp the top of the barrel, remove the head and pick up a rod, attach the rod to the top of the core barrel, unclamp it and lower the rod and barrel until the head is just above ground level.
- Repeat until the bit is at the base of the hole.
- Turn on the flush pumps, core a length of the ground (the 'run'), then repeat the sequence in reverse to remove and empty the barrel.
- Add a length of casing to the top of the casing string and drill this down to just above the base of the new hole created by the barrel.
- Repeat to the specified base of the hole.

In a wireline system a length of casing is added at the top of the borehole and the barrel is lowered into the casing using a cable. At the base of the hole the barrel locks into the lowest section of casing and the casing is used to delivering the rotary motion and the flush to the bit. When the run is complete the barrel is unlocked from the casing and withdrawn using the cable; this is much faster than the constant connection and disconnection of rods in the conventional method.

Sampling of rock core for testing is straightforward for most competent rocks: the samples can be taken directly from the core liner or core box. Samples of rocks that are likely to dry out prior to strength testing (most rocks) should be protected from moisture content change by immediately wiping away excess drilling fluids, wrapping in clingfilm, and waxing. It is even more important that similar treatment be given to any core samples of overconsolidated clays required for anything other than simple index testing as soon as possible after the core is removed from the barrel.

SPT testing is possible in rotary cored or open holes, though the process can be time-consuming compared to normal rates of drilling. Incorporation of SPT testing can be one of the few reliable sources of information in some weak rocks, particularly weak porous sandstones, which tend to be destroyed by the coring process and are often recovered as sand. Thin-walled push samplers, used for obtaining high-quality samples of clays, can also be used in suitable soils by most rotary rigs.

46.5.3.10 Sonic coring

Sonic coring is an entirely different arrangement. It is a rapid coring technique capable of achieving great depths and continuous complete recovery through almost any material. The technique utilises a high frequency vibration either with or without rotation to advance what is typically a long single-tube core barrel (rigid liners can be used in some circumstances). No flush is used. As with the techniques discussed above, the drilling technique can be adopted to provide opportunities for conventional coring, SPT testing and piston or U100 sampling. The technique is not often used in geotechnical investigations but is increasingly used for installation of geotechnical instrumentation during construction. A number of constraints limit the use of the technique in geotechnical investigations:

- The high-frequency vibrations produce high sample temperatures and densify some soils; this means that any solid core samples recovered by this technique in soils or weak rocks should be considered disturbed from a laboratory testing point of view. The vibrations and temperatures can make even simple laboratory index test results unreliable in many soils.
- The vibrations can produce rock cores with a low solid core content compared to conventional rotary coring in the same materials.
- The use of single barrels and the lack of flush (to balance groundwater pressures) mean that significant quantities of information can be lost when coring strata that contain groundwater under artesian and sub-artesian pressures.
- The cores are typically removed from the barrel by the use of vibration, increasing the potential for disturbance.

46.6 *In situ* testing in boreholes

This topic is discussed in detail elsewhere. The notes below relate only to some of the practical issues involved in utilising these techniques.

Dynamic probing, static cone penetration testing and standard penetration tests are all forms of *in situ* testing and are all discussed above.

46.6.1 Permeability testing

Open boreholes, partially and fully cased boreholes, standpipes and standpipe piezometers are all potentially suitable for carrying out variable head permeability tests. Inflow tests using single or double packers (lengths of hollow rod surrounded by a rubber membrane that can be inflated to seal off a section of open borehole) can be carried out in stable open rotary cored boreholes.

46.6.2 Vane testing

The borehole vane test is directly analogous to the laboratory shear vane test. A large cruciform vane is lowered into the ground below the base of the borehole (typically into soft clays) and rotated, with the torque required to rotate the vane being recorded; the data can be converted into a value of undrained shear strength. The procedure is typically carried out using a cable percussion rig.

46.6.3 Plate bearing tests

It is possible to carry out plate bearing tests in boreholes. There are, however, many practical difficulties involved with obtaining a clean borehole base and continuous contact between the base of the hole and the inserted plate. Such tests are rarely carried out.

46.6.4 Pressuremeters and dilatometers

Pressuremeters and dilatometers are devices which use expanding membranes to measure strength stiffness and *in situ* stresses in the ground. Most of these instruments are utilised by lowering them into a test section of borehole that has been rotary cored and that is of a diameter only slightly larger than the instrument. Tight tolerances between the instrument and hole are needed to minimise the amount of expansion the instrument undergoes before contacting the borehole wall. As a result materials that are prone to collapse or swell if the borehole is left unsupported can be difficult to test in this way. These problems can be overcome by the use of a 'self-boring' pressuremeter. Strata that tend to produce rough irregular borehole walls can puncture the instrument's membranes. The pressure capacity of the instrument needs to be broadly matched to the strengths and stiffnesses that are to be measured.

46.7 Monitoring installations

46.7.1 Groundwater

Measurement of groundwater levels and pressures is a key objective of almost all geotechnical investigations. Successful design of groundwater instrumentation requires some knowledge of basic hydrogeology, in particular the distinctions between unconfined and confined aquifers and the difference between groundwater 'levels' and groundwater pressures (see Chapters 15 *Groundwater profiles and effective stresses*, 16 *Groundwater flow*, and 80 *Groundwater control*).

There are two main types of instrumentation for measuring groundwater: standpipes and piezometers. There are also several different types of piezometer, which are described below. A common feature of all types is an area within the instrument which allows groundwater to enter the instrument or which responds to groundwater pressure: this area is placed in the borehole where groundwater information is required (the response zone).

All piezometers are installed in boreholes in a similar way. The borehole is backfilled, usually with bentonite cement grout, to the base of the response zone. A permeable material, the nature of which varies with the type of instrument, is then backfilled around the instrument throughout the length of the response zone. Another bentonite cement grout seal is added above the response zone. The location of this upper seal in relation to the groundwater level varies according to the type of instrument.

46.7.1.1 Standpipes

Standpipes measure groundwater levels in unconfined aquifers (i.e. in relatively permeable strata). They typically consist of a tube with a diameter between 19 and 50 mm with a slotted section that is placed within the response zone. In a standpipe the response zone and the slotted section extend above the unconfined groundwater level. The groundwater level measured in the tubing directly replicates the groundwater level in the ground. Groundwater level is measured using a dipmeter. This is a tape measure containing wires connected to a battery and a buzzer at the surface. At the other end of the tape is a sensor. When the sensor breaks the surface of the water in the tube an electrical circuit is made and the buzzer sounds. The depth to groundwater can be read off the tape.

Measurements of ground gas composition are also a routine part of ground investigations. Standpipes of 50 mm diameter are typically used for this purpose. They are installed with continuous slotted sections above the water table and an upper bentonite seal close to the ground surface. The top of the tube is fitted with a bung containing a gas tap to which a gas analyser and flow meter can be attached

46.7.1.2 Piezometers

Piezometers measure groundwater levels or pore pressures in specific zones within the borehole. Zones are targeted for measurement on the basis of the aims of the investigation and the observations made during drilling. There are several types of piezometer.

46.7.1.3 Standpipe piezometers

Standpipe piezometers are the commonest and simplest form of piezometer. They typically consist of 19 or 24 mm tubing that is fitted with a porous 'element' of known permeability

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(typically 10^{-4} m/s) at its base; this element varies in length but is typically < 300 mm long in UK ground investigation practice. The porous element is installed in a response zone filled with sand. This sand filter is isolated in the borehole by bentonite seals above and below. The porous element allows water in the ground to enter the piezometer tubing. The height that the water reaches in the tubing reflects the pore pressure present in the response zone. If correctly located the bentonite seals either side of the response zone isolate the pore pressure in the response zone from any other different pressures that may be present in the ground.

Practical considerations involved in achieving seals above and below response zones mean that it is unusual to install more than two standpipe piezometers in a borehole.

Standpipe piezometers can be used in all types of ground. However, in low permeability materials the height of water in the tubing can take a very long period of time to come to equilibrium with the pore pressures in the ground. Standpipe piezometers can be used to carry out variable head permeability tests. Water level in the tubing is measured using a dipmeter as described above.

46.7.1.4 Other types of piezometers

In a pneumatic piezometer twin pneumatic tubes run from the piezometer tip to the surface. The top of the piezometer contains a diaphragm which separates water pressure in the ground and gas pressure fed down one of the tubes from the surface. Gas pressure is provided by bottled nitrogen. Water pressure readings are obtained by adjusting the surface gas pressure with the water pressure. When they are equalised, gas is forced into the second tube and this is detected at the surface and the pressure recorded. These systems typically form part of long-term datalogged monitoring systems where a single datalogger and gas control system can be set up to log several boreholes. A pneumatic piezometer can be used to measure short-term negative pore pressures.

In a vibrating wire piezometer a tensioned wire in the piezometer tip is made to vibrate using an electromagnetic field. The tension in the wire varies according to external water pressure on a diaphragm in the tip. This varies the frequency at which the wire vibrates. The variation in this frequency can be measured and calibrated in units of water pressure. This system is suitable for use with automatic dataloggers or with hand-held readout units. The prinicipal advantage of vibrating wire piezometers is that they come to equilibrium very rapidly in low permeability soils. This allows them to be installed directly in cement bentonite grouts rather than in conventional sand filters. Vibrating wire piezometers cannot reliably measure negative pore pressures and can become unreliable for measuring positive pressure if they are exposed to negative pressures. Great care is needed in their installation.

Pumping wells in ground investigations are installed with an associated array of monitoring piezometers when there is a need to carry out a pumping test. This test provides information on permeability, transmissivity and storage within an aquifer and is required when a project involves dewatering. The key differences between a pumping well and a piezometer are usually greater diameter (to permit submersible pump access) and the presence of a well screen. A well screen is normally used to line the borehole in the region where the water is to be pumped from, while the rest of the hole is normally lined with impervious casing. The screen's purpose is to permit passage of water from the ground to the hole whilst at the same time supporting the sides of the hole and controlling the quantity of material drawn into the hole by the flowing water. Successful screen design can be complex and consideration should be given to seeking expert advice before carrying out installation and testing.

46.7.2 Movement and load monitoring

46.7.2.1 Monitoring horizontal movement

Inclinometers are used to measure and monitor horizontal movement within the ground. This need typically arises where there are slope instability concerns or where excavations and retaining structures are being monitored. An inclinometer installation in a borehole takes the form of a circular tube installed to the full depth of the borehole, where the bottom of the borehole is well below the expected zones of movement. The annulus between the borehole and tubing is filled with grout and the lower end of the tubing is closed so the inside of the tubing remains full of water and/or air. The inside of the tubing contains four grooves or 'keyways' at 90° intervals. The lengths of tubing are connected using external sleeves in such a way as to ensure that the four keyways are continuous throughout the borehole and that each keyway is in the same orientation.

As the ground moves, the inclinometer tubing bends with it. The degree and location of the distortion of the tube is measured using an inclinometer. This is a metal 'torpedo' containing two pairs of wheels on sprung arms at either end of the torpedo. Both pairs of wheels are in the same plane. The wheels sit in a pair of the keyways in the tubing and the sprung arms hold the torpedo centrally in the tube. The torpedo contains a series of accelerometers oriented in the plane of the wheels and also at 90° to this. These accelerometers measure information on the inclination of the torpedo and these inclinations can be used to calculate horizontal displacement of the inclinometer tubing. In use the torpedo is lowered to the base of the tubing using its data cable. It is then pulled up 0.5 m at a time with a reading taken every 0.5 m and this information is usually recorded on a datalogger. The whole exercise is repeated with the torpedo turned through 90° and inserted in the remaining pair of keyways. The resulting data are processed using specialised software to give a profile of horizontal movement against depth. As this is repeated through a programme of regular monitoring a picture of displacement versus depth versus time is built

up. Inclinometers that are used horizontally are also available. These are occasionally used to check settlement profiles in earthworks embankments.

46.7.2.2 Monitoring vertical movement

Extensometers are used to measure vertical movement within the ground. The vertical movement can be heave or settlement. Typically a borehole installation involves the placing of a central access tube similar to inclinometer tubing to below the zone of likely movement. A series of magnetic 'spiders' are slid over this tubing at intervals during the grouting of the borehole /tubing annulus and grouted into place. As the ground moves up or down the 'spider' legs are held by the grout and ground and move up or down relative to the tube. The location of the spiders relative to the tubing is measured using a probe lowered down the central access tube.

Deep datum installations are also used to monitor the movement of the ground surface relative to a fixed point in the ground below any zones of movement. This is typically required where settlement or heave might be generated over a wide area and a reliable survey datum might otherwise have to be far from the site. These installations involve anchoring the base of a stainless steel or fibreglass bar into the ground at depth and isolating the remainder of the bar from the ground and borehole grout by some means, typically using an inner casing or sleeve. The top of the bar at ground level is then used as a datum for conventional topographic surveying techniques.

Monitoring of loads caused by soil or rock fill is often a part of earthworks operations rather than ground investigations. Plate-like pressure cells, typically vibrating wire pressure cells, are installed at the points of interest and wired to remote dataloggers for long-term monitoring. Such cells can be installed vertically behind retaining structures to verify active and passive pressure design assumptions.

46.8 Other considerations

Many of the issues identified in the desk study and walkover survey can have a considerable impact on the conduct of a ground investigation. Some of these are listed below:

- access for rigs;
- working space for rigs;
- location of underground services;
- water and power supplies;
- underground and overhead obstructions;
- soft ground in relation to stability of investigation plant;
- many drilling rigs find operating on sloping ground difficult;
- railway work has many unique bureaucratic requirements and access issues;
- overwater and inter-tidal work often requires special plant to enable access.

46.9 Standards

The UK standard that applies to execution of ground investigations is Eurocode 7, Part 2 (British Standards Institution, 2007). The previous standard, BS 5930:1999 (British Standards Institution, 2010), has undergone amendment and will later undergo revision. It is being retained as a normative reference.

There are a large number of 'attachments' to Eurocode 7, Part 2. These are listed below. At the time of writing many of these had not been published and some parts of older British standards still applied. This situation is complex and regular checks should be made with the British Standards Institution as to the current status of these documents.

46.9.1 Ground investigation and testing: sampling methods and groundwater measurement

BS EN ISO 22475-1	Part 1: Technical Principles for Execution
BS EN ISO 22475-2	Part 2: Qualification Criteria for Enterprises and Personnel
BS EN ISO 22475-3	Part 3: Conformity Assessments of Enterprises and Personnel by Third Parties

46.9.2 Ground investigation and testing: field testing

BS EN ISO 22476-1	Part 1: Electrical Cone and Piezocone Penetration Tests
BS EN ISO 22476-2	Part 2: Dynamic Probing
BS EN ISO 22476-3	Part 3: Standard Penetration Test
BS EN ISO 22476-4	Part 4: Menard Pressuremeter Test
BS EN ISO 22476-5	Part 5: Flexible Dilatometer Test
BS EN ISO 22476-6	Part 6: Self Boring Pressuremeter Test
BS EN ISO 22476-7	Part 7: Borehole Jacking Test
BS EN ISO 22476-8	Part 8: Full Displacement Pressuremeter Test
BS EN ISO 22476-9	Part 9: Field Vane Test
BS EN ISO 22476-10	Part 10: Weight Sounding Test
BS EN ISO 22476-11	Part 11: Flat Dilatometer Test
BS EN ISO 22476-12	Part 12: Mechanical Cone Penetration Test
BS EN ISO 22476-13	Part 13: Plate Loading Test

46.9.3 Ground investigation and testing: geohydraulic tests

BS EN ISO 22282-1	Part 1: General Rules
BS EN ISO 22282-2	Part 2: Water Permeability Test in Borehole without Packer
BS EN ISO 22282-3	Part 3: Water Pressure Test in Rock
BS EN ISO 22282-4	Part 4: Pumping Tests
BS EN ISO 22282-5	Part 5: Infiltrometer Tests
BS EN ISO 22282-6	Part 6: Closed Packer Systems

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

46.9.4 Ground investigation and testing: laboratory testing

BS 1377:1990 Parts 1–8 remain in force until further notice (this situation should be checked with the BSI).

46.9.5 Ground investigation and testing: identification and classification of soil

BS EN ISO 14688-1:2002 Part 1: Identification and Description

BS EN ISO 14688-2:2004 Part 2: Principles for a Classification

46.9.6 Ground investigation and testing: identification and classification of rock

BS EN ISO 14689-1:2003 Part 1: Identification and Description of Rock

46.9.7 Other standards

The British Drilling Association (BDA) runs accreditation schemes for drillers in the UK. The use of accredited drillers has been a common contractual requirement in UK ground investigation practice for a number of years. The BDA also publishes a number of best practice guides related to the execution of ground investigations. Details of these documents can be found on their website.

The Institution of Civil Engineers (ICE) publishes a widely used standard specification (Site Investigation Steering Group, 1993) and standard form of contract for ground investigations (ICE & CECA, 2003).

The Association of Geotechnical Specialists (AGS) has produced a standard format for production of digital geotechnical investigation data (so-called 'AGS data'). This has been widely adopted in the UK, and a number of commercial software packages exist for the manipulation of this data format. Use of such a package can greatly speed the interpretation of geotechnical investigation results. Further details can be found on the AGS website.

Information relating to ground conditions can be obtained in a number of ways, for example through remote sensing, boring and drilling, and sampling and laboratory testing. This chapter deals with common methods of testing *in situ* using penetration testing, vane testing, plate load testing, pressuremeters and *in situ* permeability tests. Equipment and test methods are briefly described, and potential difficulties and corrections noted. References to further information, sources of interpretation methods and to standards are given.

47.1 Introduction

Before geotechnical design can start, the engineer needs to collect and generate a wide range of information on site ground conditions. This is typically done through a walkover survey and desk study, by making boreholes, taking samples and testing them in the laboratory, and through field testing. BS EN 1977-2 (British Standards Institution, 2007b) and BS 5930 (British Standards Institution, 2010) clearly outline the best practice in planning this process. This chapter deals with some of the field geotechnical testing options available to those planning investigations. This is an area in which a number of standards and specifications are anticipated to be published in the next few years; engineers need to check the current status of the standards or specifications that they are using.

Field geotechnical testing makes a number of vital contributions to the site characterisation and ground modelling process, through:

- index and classification information;
- profiling;
- parameter determination.

Whilst data for this can be obtained from laboratory tests or from field geotechnical tests, the use of both types of test is generally advisable.

The engineer should carefully consider what tests to use and when. **Table 47.1** (Lunne *et al.*, 1997; their Table 1.1) and Table 2.1 in BS EN 1997-2 (British Standards Institution, 2007b) give useful general guidance to the parameters that might be obtained from various field tests and also the ground conditions they might be used for. Field geotechnical testing can have the following advantages:

- It can be used when sampling is impossible (e.g. in granular soils), or where sampling disturbance will significantly affect laboratory test results.
- It can test larger volumes of the ground than is possible in a laboratory test.
- The ground is tested as it exists in the field, i.e. at the *in situ* effective stress level, and with a representative particle size and fracture distribution.
- A near continuous record can be obtained with depth from some tests, allowing classification, and the development of a very good soil profile.
- *In situ* tests are often faster than sampling and laboratory testing, and may therefore be cheaper.

On the other hand, field geotechnical testing can have some significant disadvantages:

- In many tests, the soil type being tested is not seen, and cannot be described.
- Results may be affected by test rates that are often high, compared with laboratory loading rates, and especially when compared with construction rates of loading.
- Boundary conditions with respect to stress, strain and drainage are often poorly controlled, limiting the applicability of such tests (for example, to the determination of undrained strength or stiffness parameters).
- Deformation of the soil around an *in situ* test may be dissimilar to that around the proposed construction (e.g. horizontal, rather than vertical, under a foundation), and coupled with non-uniform imposed stress and strain fields, and lack of drainage control, this may make interpretation uncertain.
- Some disturbance may occur during boring, where this is necessary, or during insertion of any apparatus.

In general, it is sensible to determine key parameters using a combination of laboratory and field geotechnical testing and this approach is consistent with that in BS EN 1997-2 (British Standards Institution, 2007b).

The adoption of the geotechnical Eurocodes and associated standards should lead to greater harmonisation of testing and ground investigation (GI) practices in the future (see Chapter 10 *Codes and standards and their relevance*). In the sections below reference will be made to both current and forthcoming EN (European) standards; in the latter case many of the documents

Applicability: A = high; B = moderate; C = low; – = none
1. φ' depends on the soil type.
2. Only when a pore pressure sensor is fitted.
3. Only when a displacement sensor is fitted.
Soil parameter definitions: u is the *in situ* static pore pressure; φ' is the effective internal friction angle; s_u is the undrained shear strength; m_v is the constrained modulus; c_v is the coefficient of consolidation; k is the coefficient of permeability; G_o is the shear modulus at small strain; σ_h is the horizontal stress; OCR is the overconsolidation ratio; σ-ε is the stress–strain relationship and I_D is the density index.

Table 47.1 The applicability and usefulness of *in situ* tests
Reproduced from Lunne *et al.* (1997); Taylor & Francis Group

are finalised but publication has yet to happen. Once they are published then they will replace any existing British Standards.

47.2 Penetration testing

Penetration testing is widely used in geotechnical practice, and can provide valuable data in almost all ground conditions. Penetration testing can be classified in a number of ways, e.g.

- dynamic (impact driving) vs quasi-static (pushing);
- requiring a borehole, or not;
- 'continuous' or intermittent.

47.2.1 The Standard Penetration Test

The Standard Penetration Test (generally known as the 'SPT') is probably the most widely used geotechnical test in the world. At the time of writing it is standardised in the UK in BS EN 1997-2:2007 (British Standards Institution, 2007b) and BS EN ISO 22476-3 (British Standards Institution, 2005b) – note that there are amendments available to both these documents. In the USA it is standardised in ASTM D1586 (ASTM, 2008a).

The test is dynamic, and intermittent, being carried out in a borehole, typically at 1.5 m intervals of depth. When the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

required test depth has been reached, a standard 50 mm outside diameter 'split-spoon' penetrometer (see **Figure 47.1**) is lowered to the bottom of the borehole on rods, and is driven into the soil using repeated blows of a 63.5 kg weight falling through 760 mm (note that this test is used worldwide, and that the exact dimensions may differ slightly in individual country specifications, the adoption of the EN ISO standard should bring practices into closer alignment). The SPT *N* value is the number of blows required to achieve a penetration of 300 mm, after an initial seating drive of 150 mm; corrections can then be applied to obtain a 'corrected' *N* value for a standard hammer energy and (in coarse-grained soil) overburden pressure (see below).

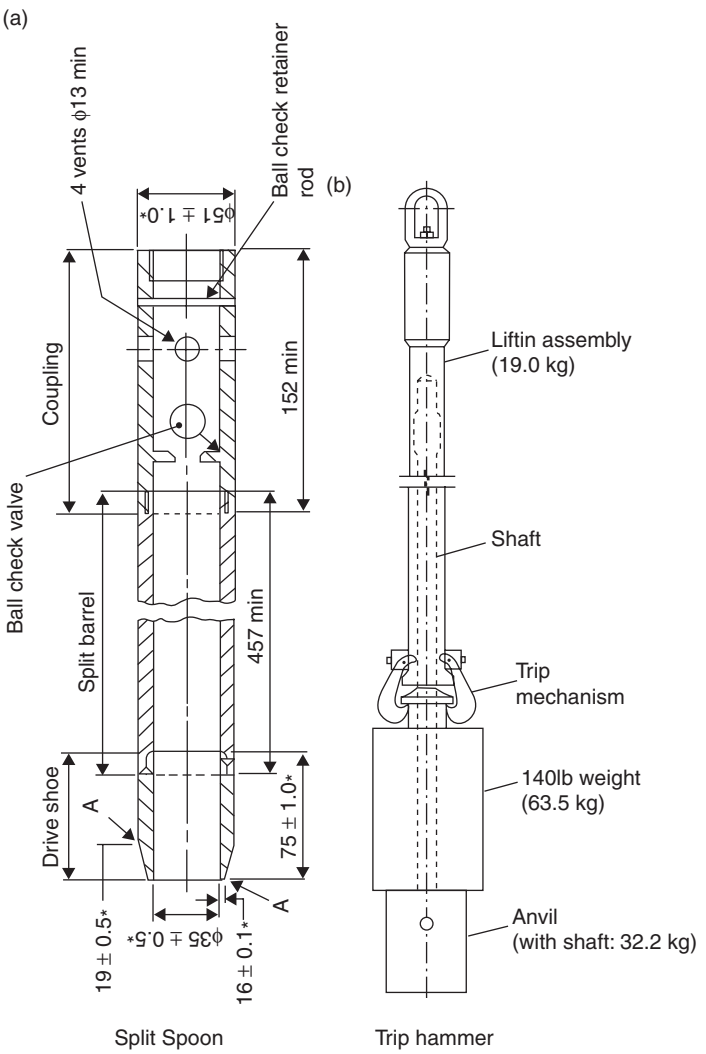

Figure 47.1 Standard Penetration Test (SPT): split-spoon sampler (left) and automatic trip hammer (right). Corners marked 'A' may be 'slightly' rounded

(Left) Reproduced with permission from BS 1377-1 © British Standards Institution 1990; (Right) Reproduced with permission from CIRIA R143 (Clayton, 1995)

Despite widespread criticism the SPT continues to be popular worldwide because:

1. It uses simple equipment.
2. It can be used in almost any ground conditions (including clays, sands, coarse granular soil and fractured weak rock).
3. It provides a sample, allowing basic visual identification of the ground in which it is conducted.

It can be used, through empirical correlations, to estimate many of the strength and stiffness parameters needed for design.

Apart from the ground conditions in which the test is made, the result of the Standard Penetration Test is influenced by three main groups of factors:

- The drilling or boring technique used to reach the test depth;
- The SPT equipment used for the test;
- The test procedure.

The most significant of these factors are described below (the wider adoption of the EN ISO standard, if adhered to, should improve the situation; however, these factors need to be considered when using historical information). For a more complete review see Clayton (1995) or Clayton *et al*. (1995).

In coarse-grained soil, *borehole disturbance* can be very large. Experience has shown that UK practice, using a 'shell' and light percussion boring can reduce the SPT *N* value by a factor of up to 5. Hollow-stem auger drilling, when used badly, is thought to be capable of loosening the soil so that *N* is reduced by a factor of about 3. The SPT *N* value can also be increased through the compaction of granular soil ahead of the drilling tools. Control of soil loosening can be achieved by:

1. Ensuring that the borehole is full of water at all times, so that piping does not occur as a result of the upward inflow of groundwater;
2. Using a small diameter borehole, so that the depth of borehole disturbance (typically about 1.5 to 3 times the borehole diameter) is restricted, and preferably less than the 150 mm seating drive (BS ISO EN 22746-3 requires that the borehole diameter is always reported).
3. Avoiding the use of a casing (for example, by using drilling mud to support the bottom of the borehole), thus reducing the concentration of groundwater inflow.
4. Reducing the vigour with which the driller advances the borehole, for example, by restricting the rate at which the hollow-stem auger plug is pulled from the centre of the auger, immediately prior to the SPT.

In most clays where SPT is appropriate, it is considered that the borehole disturbance will not be as severe as in silts and sands. The effects may be large when testing in soft and

sensitive soil, but the SPT should be considered inappropriate in such materials due to the potential for disturbance and also as it will yield too low an *N* value to be of great use in design.

SPT *equipment* is known to have a number of important effects, the two most significant of which are due to:

- the hammer design and use;
- the split-spoon design.

A wide variety of hammer designs are used across the world and most can be used in a variety of ways. They will deliver different amounts of energy per blow, and can be more or less consistent, blow-by-blow, depending upon the design. Since the SPT *N* value is inversely proportional to the energy delivered per blow, this means that it will vary according to hammer type and use. Therefore, the energy imparted by the SPT hammer must be measured and reported. BS EN ISO 22476-3 (British Standards Institution, 2005b) requires that all SPT hammers are calibrated regularly. The International Reference Test Procedure (IRTP) (ISSMGE, 1999) suggests that SPT *N* values should be corrected to 60% of the free-fall energy, N_{60}, and this is now considered in British practice through BS EN ISO 22476-3 (British Standards Institution, 2005b). It has been estimated (Clayton, 1995) that hammer energy variations around the world can lead to variations in the *N* value of -25% to +35%.

In the UK it is routine practice to use an automatic trip hammer with a relatively large anvil. Measurements suggest that this will typically deliver about 70% of the free-fall energy, producing an *N* value of the order of 15% lower than that of the 60% standard energy. Reading *et al.* (2010) show quite clearly the wide variations in energy imparted by 'standard' hammers in the UK, in some cases simply due to lack of maintenance but also related to equipment type.

When very short rod lengths are used between the hammer and the split spoon there will be some reduction in energy transfer. BS EN ISO 22476-3 (British Standards Institution, 2005b) suggests that in sands a correction to the *N* value should be considered.

The design of the split spoon can also have an effect on penetration resistance, if varied from standard. The user should be wary of two particular variations. In a few countries (including the UK) the practice has been to substitute a 60° solid cone for the split-spoon cutting shoe, when testing in gravel. Evidence from the UK suggests that in sands this can approximately double the measured penetration resistance. The use of a solid cone should be avoided if possible, and if used should be clearly reported as an SPT(C) test in accordance with BS EN ISO 22476-3 (British Standards Institution, 2005b).

Another potential problem occurs where, as in some countries, the split spoon is fitted with a liner, to allow easy sample collection. The omission of a liner from a spoon designed to take one has been found to cause a decrease in the *N* value of about 10–30%.

The *test procedure* is fairly uniform in the UK, where blow counts are typically recorded by the rig foreman for six 75 mm sections of drive (the first two for the seating and the remaining four are the test drive) – an amendment to BS EN ISO 22476-3 (British Standards Institution, 2005b) originally stipulated 150 mm drive lengths but now allows for 75 mm drives, as per UK practice. However, procedures can vary when testing either in loose or weak soil or in dense soil and weak rock. In the former case, penetration under the self-weight of the rods and hammer historically may or may not have been recorded but now, under BS EN ISO 22476-3, it has to be reported. In the latter case, the full 450 mm of penetration may not be achieved, and in this case it is now stated in BS EN ISO 22476-3 (British Standards Institution, 2005b) that it is acceptable to report the number of blows and the penetration achieved; a clear note identifying this variation is required in the report.

As with other *in situ* penetration tests, the SPT is useful for profiling, for classification and for parameter determination. When used for profiling, ideally more tests should be carried out than is common in UK practice, say at 1 m centres. As with the dynamic penetration test (described below), the SPT split spoon could be driven continuously, but this is not normal, as friction and adhesion on the drive rods tend to increase penetration resistance at depth. Classification is possible through the use of a sample (albeit of very low quality in clays, and unable to provide representative gradings in coarse granular soils) combined with the measured penetration resistance. This is based upon the relative density in granular soils, the consistency in fine-grained soils and the strength in weak rocks (see Clayton, 1995, for example).

The SPT is a small-diameter dynamic, rapid test to failure. The principal *soil properties affecting the SPT N* value are therefore:

- effective angle of friction (granular soils);
- relative density (granular soils);
- effective stress level (granular soils);
- grain size (coarse granular soils and silty granular soils);
- undrained shear strength (cohesive soils);
- cementing (weak rocks, granular soils);
- jointing (weak rocks).

Because interpretation depends upon the soil type, this must be known. Fortunately, as noted above, in most ground conditions a small sample will be retrieved from the split spoon.

The effective stress level needs to be taken into account when interpreting tests carried out in granular soil. For example, an SPT carried out from the original ground level would be expected to be higher (and sometimes very considerably higher) than one carried out in a general excavation (below

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

the original ground level) during construction, as a result of the reduction in the vertical effective stress that has occurred. Modern practice is to correct N as measured in granular soils to its equivalent value under a vertical effective stress of 100 kPa (1 ton/ft^2), which is termed 'N_1'. N corrected for both hammer energy and for effective overburden pressure is termed '$(N_1)_{60}$'.

Soil grain size is an important consideration when interpreting SPT data. The standard correlations and interpretations used in granular soil are for sands. Evidence suggests (Tokimatsu, 1988) that once the mean particle size (D_{50}) exceeds about 0.5 mm, penetration resistance climbs rapidly, approximately doubling at D_{50} = 10 mm. Correlations obtained for sands cannot be assumed to hold true for gravels, and larger diameter penetrometers have therefore been used in investigations of, for example, the liquefaction potential of gravels. Coarse-grained materials are not the only issue – the fines content is thought to contribute to lower penetration resistance (due to the development of pore pressures during driving) in silty sands.

In clays, the penetration resistance seems to be primarily controlled by the undrained shear strength. Unless there is a very significant drilling disturbance (which may well be a factor in soft and sensitive soils), this will not change significantly during drilling. Therefore the SPT N value is not corrected for overburden pressure in clays. N_{60} is used in design. Care must always be taken when looking at correlations or design procedures as to what form of N value (corrected or not, and, if corrected, specifically what corrections were used; different forms of correction can be found in the literature for the same thing, see BS EN 1997-2). Guidance on interpretation both for geotechnical parameters (see **Table 47.1**) and direct design methods can be found very widely in the literature (e.g. Clayton, 1995; see also conferences listed in 47.6 Further reading)) and in Annex F of BS EN 1997-2 (British Standards Institution, 2007b) with the associated caveats in the UK National Annex (British Standards Institution, 2009a), but care must always be taken as to their applicability for the ground under investigation.

47.2.2 Dynamic probing

Because it does not require a borehole, dynamic probing provides a simple, rapid and relatively inexpensive way of profiling a site. It is a dynamic, intermittent test. It is suitable for small depths of exploratory work and to fill in or extrapolate data from more expensive and sophisticated tests, using site-specific correlations. The equipment is generally light and compact and is ideal for work on sites with restricted access.

A dynamic probing test (DPT) consists of driving a solid steel cone vertically into the ground, via an anvil and extension rods, with successive blows of a free-fall hammer. Lightweight hammers may be raised by hand, but in most cases a motorised device, incorporating an automatic latch and release mechanism, is used. **Figure 47.2** shows a motorised dynamic probing rig.

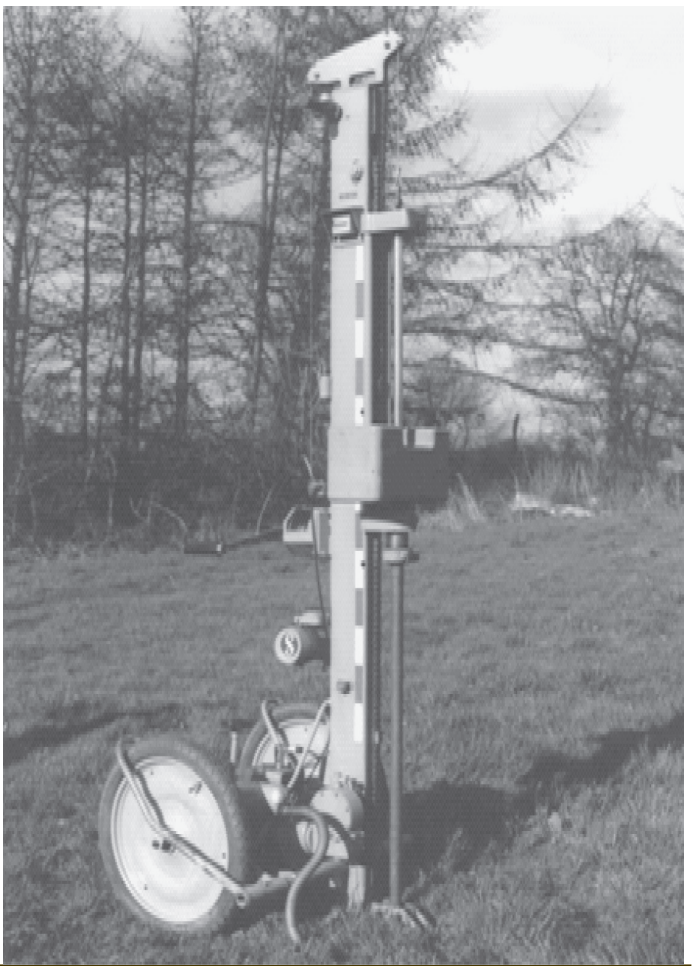

Figure 47.2 Motorised dynamic probing rig

The number of blows required to drive the cone a fixed distance (10 or 20 cm depending on the test specification) is recorded. The cone may be fixed to the extension rods, or loose-fitting, in which case it will be lost when the rods are withdrawn at the end of the test (sacrificial cone). Driving is halted every metre to add a further extension rod; at this point the torque required to rotate the rods in the ground is measured to assess the ground friction acting on them, which also has the effect of relieving friction for subsequent tests. The torque value can be used to correct the blow count to compensate for friction.

A variety of equipment has been developed and standardised over the years, with varying sizes of cones and hammer weights. Dynamic probing is now standardised in the UK through BS EN ISO 22476-2 (British Standards Institution, 2005a), which lists five configurations of equipment with varying cone size and drop weight (DPSH-A is not used in the UK). These configurations are generally the same as those that have been common in the UK and other countries (based on ISSMFE, 1989) for many years, except DPM, which has now changed to using a larger cone [The

configuration for DPM is now that of DPM15, given in earlier versions of BS5930 (British Standards Institution, 1999). The range gives increasing specific work per blow from CPL through to DPSH.

The different equipment configurations detailed in BS EN ISO 22476-2 (British Standards Institution, 2005a) are reproduced in **Table 47.2**. Standard ranges of blows are given as 3–50 for DPL, DPM and DPH and 5–100 for DPSH; it is recommended that if the minimum is not reached then the results cannot be used for quantitative purposes.

Figure 47.3 shows the acceptable shapes of the fixed and sacrificial cones. In the UK many companies use sacrificial cones of the same shape as the fixed cone. In general DPL, DPM and DPH have the same hammer drop height but different hammer weights and DPH and DPM use the same extension rod mass. The DPSH-B test is designed to closely resemble the Standard Penetration Test (SPT), as can be seen in **Table 47.2**, but differs from the other tests because it counts the number of blows per 20 cm penetration, rather than 10 cm. BS EN ISO 22476-2 (British Standards Institution, 2005a) recommends that the imparted energy should be measured for each new device, in a similar way to the SPT. In addition it recommends the actual energy E_{meas} transmitted to the drive rods is found from calibration when the test results are to be used for quantitative evaluation purposes, i.e. parameter determination.

47.2.2.1 Results and analysis of data

The probing results are recorded as blows for 10 cm (N_{10}) or 20 cm (N_{20}) penetration and should fall within the standard range of values stated in BS EN ISO 22476-2 (British Standards Institution, 2005a). Note that the values will be specific to the configuration used and the annexes of the standard suggest that the use of an extra subscript, N_{10L} or N_{10M} for example, would avoid any confusion when presenting results. With BS EN ISO 22476-2 (British Standards Institution, 2005a), it is now a requirement to measure the torque on the rods at least every metre and this has to be recorded and reported. The effect of rod friction on the $N_{10/20}$ values can be significant and now it is a requirement in the standard that this shall be considered, but there is no mention of how this should be done. Examples of the effects are given in the annexes to the standard.

The N_{10} values can be converted into unit cone resistance (r_d) or dynamic cone resistance (q_d), and this can allow different configurations of equipment to be brought to a common basis; both parameters can be derived from pile-driving formulae; see BS EN 22476–2 Annex E, thus:

$$q_d = \frac{M}{M + M'} r_d \tag{47.1}$$

$$r_d = \frac{Mgh}{Ae} \tag{47.2}$$

		Test specification

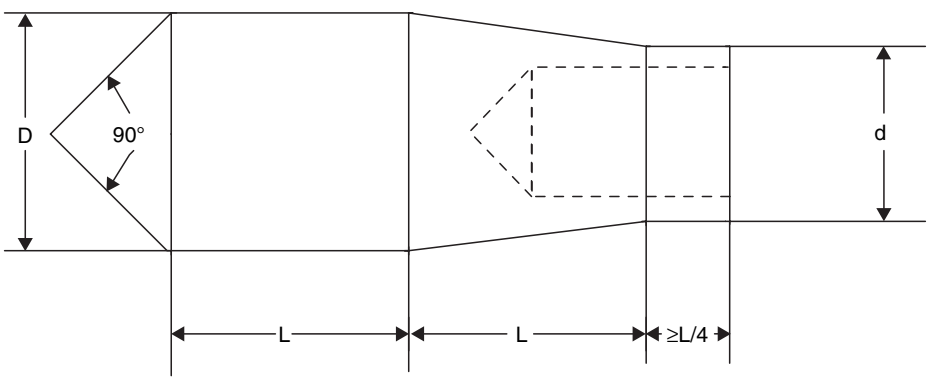
Data taken from BS EN ISO 22476-2:2005 (British Standards Institution, 2005a)

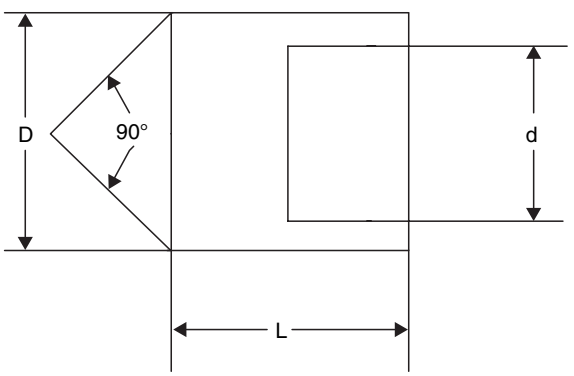
ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

where r_d and q_d are resistance values in Pa, M is the mass of the hammer in kilograms, g is the acceleration due to gravity in m/s^2, h is the height of fall of the hammer in metres, A is the projected area of the cone in m^2, e is the average penetration in metres per blow ($0.1/N_{10}$ from DPL, DPM15, DPM and DPH, and $0.2/N_{20}$ from DPSH), and M' is the total mass of the extension rods, the anvil and the guiding rods in kilograms.



The value of r_d represents the work done in penetrating the ground and q_d modifies the r_d value to take account of the inertia of the driving rods, anvil and hammer during impact. The inclusion of the hammer weight, height of fall and cone size permits a comparison of the different configurations by way of r_d, but the inclusion of the size and mass of the extension rods in the calculations of q_d better normalises the results from the different equipment configurations. **Figure 47.4** shows typical data for a stiff clay site when three equipment configurations (DPL, DPM15 and DPH) were used. The results show how the different profiles for N_{10} are largely the same when plotted as r_d and q_d.

47.2.2.2 Rod friction



Friction on the rods will affect the recorded values of N_{10} or N_{20}. Experience has shown that torque readings in excess of 200 Nm generally mean that the driving rods have been forced off line and that further driving would permanently bend them, probably resulting in the driving rods no longer complying with BS EN ISO 22476-2 (British Standards Institution, 2005a). To avoid this, tests should be terminated when a torque reading reaches 120 Nm.

BS EN ISO 22476-2 (British Standards Institution, 2005a) provides for the introduction of drilling mud (bentonite slurry) to reduce rod friction. A specially perforated rod carries the cone and the drilling mud is introduced down the hollow rods and out through the perforations. For stiff clay sites, the mud can be poured into the rods to be sucked out or forced out by gravity into the annulus behind the probe cone. The level of bentonite should be topped up after the addition of each extension rod. For soft clay, a pressure just above the mean *in situ* stress needs to be applied to force the mud into the space behind the probe cone.

In its most common use, dynamic probing is used to look at variations within a profile and to map their extent laterally; however, in many countries considerable experience has been built up to convert the results into other parameters (see **Table 47.1**) particularly in coarse-grained deposits. For example,

Fixed cone

Sacrificial cone

D = cone diameter
d = extension rod diameter
L = cone body length

Figure 47.3 Acceptable shapes for fixed and sacrificial DPT cones

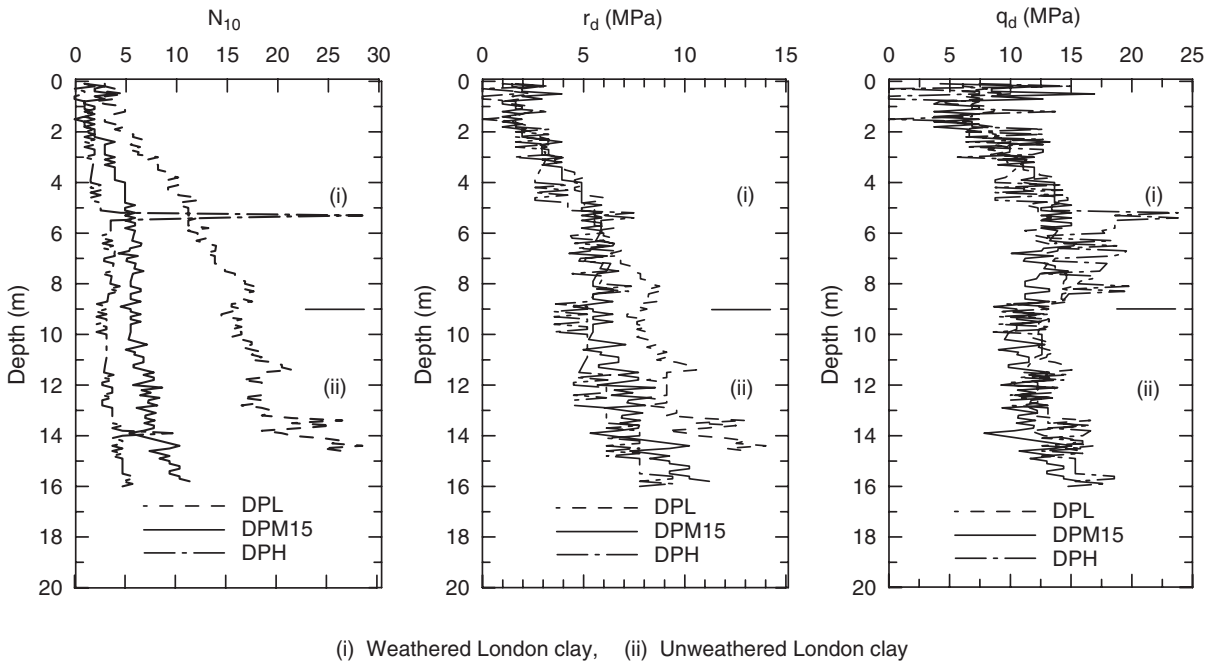


Figure 47.4 Results (N_{10}, r_d and q_d values) for three configurations of dynamic probing (DPT) for a stiff clay site

in the Annexes to BS EN ISO 22476-2 (British Standards Institution, 2005a) there are examples of the various factors that can affect DPT results and in BS EN 1997-2 Annex G (British Standards Institution, 2009a) some examples are given of interpretation of DPT results in coarse-grained materials. Other examples can be found in the literature (see Further reading). It is vital to ensure that any correlations used have been validated for the local soil types and DPT configuration; in the future with better calibration and energy measurements it may be possible to transfer correlations between configurations. Little has been published on their interpretation in clays but Butcher *et al.* (1995) give examples of the potential for interpretation in clays to determine geotechnical parameters. BS EN ISO 22476-2 (British Standards Institution, 2005a) does point out that because of hammer fall energy losses, it is recommended to know by calibration the actual energy E_{meas} transmitted to the drive rods when this test is used for quantitative evaluation purposes.

47.2.3 The cone penetration test (CPT)

Among the many *in situ* test devices available, the electric static cone penetrometer (CPT) and the piezocone (CPTU) are among the best. CPT is a quasi-static test that is near continuous; it is generally undertaken without a borehole but can be used with boreholes to advance past obstructions or to increase the depths achieved. Tests are rapid, can generate detailed ground profiles, can classify the ground, and the results can be used to calculate a wide range of geotechnical parameters that accurately reflect ground properties. The test is covered by an International Reference Test Procedure (IRTP) (ISSMGE, 1999) BS 1377 Part 9 (British Standards Institution, 2007a), BS EN ISO 22476-1 (British Standards Institution, in preparation, f; when published, this will replace the IRTP and BS 1377 Part 9) and BS EN 1997-2 (British Standards Institution, 2007b). In some countries older-style cones may be encountered that use remote mechanical systems for force measurement (CPTM) – these are covered by BS EN ISO 22476-12 (British Standards Institution, 2009b).

47.2.3.1 Test equipment

The diameter of the standard 60° cone is 35.7 mm (giving a cross-sectional area of 10 cm^2) and the area of the friction sleeve is 150 cm^2. The cone resistance and sleeve friction are normally measured via strain-gauged load cells. **Figure 47.5** illustrates the main components and terminology of cone penetrometers. The CPT and CPTU systems generally include an inclinometer, to warn if the cone is going off vertical, which can easily happen if hard obstructions are encountered.

Although a cone penetrometer with a 10 cm^2 base area cone and an apex angle of 60° is specified in the International Reference Test Procedure (ISSMGE, 1999) and BS EN 22476-1 (British Standards Institution, in preparation, f) as the reference test (being the same size as the original mechanical cone), other sizes of cone exist. Apart from the 10 cm^2 device, the 15 cm^2 cone is the only one routinely found in land-based practice but the use of 2 and 5 cm^2 devices can be found in the offshore environment (along with the larger sizes).

The standards detail all necessary requirements with regard to shape, dimension and area, and their tolerances, as well as operational procedures. Provided the equipment dimensions

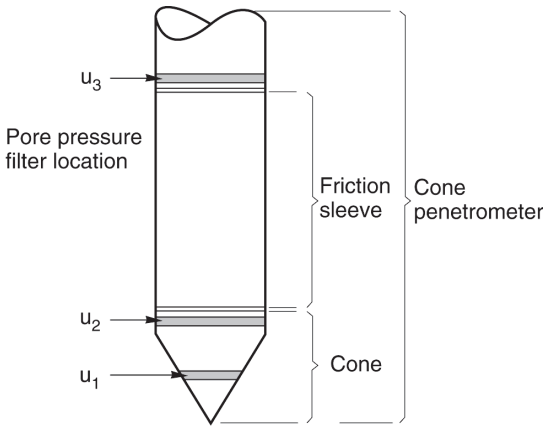

Figure 47.5 Main components of the CPT cone, also showing the positions for pore pressure measurement

are kept within these tolerances, the likely errors in measured parameters, simply from wear, will be kept to less than a few per cent.

The addition of a pore water pressure measuring system within the CPT (CPTU) has greatly enhanced its capability for both profiling and parameter determination. **Figure 47.5** shows that the pore pressure may be measured at several locations: 'u_1' (on the cone), 'u_2' (behind the cone) and 'u_3' (above the friction sleeve). Generally, it is recommended that the pore pressure is measured just behind the cone shoulder (at the 'u_2' position) for the following reasons:

1. good protection from damage, relative to 'u_1';
2. relatively easy saturation;
3. gives good profiling detail;
4. generally good dissipation data;
5. correct location to determine q_t (see corrections below).

However, the other locations may be useful in certain conditions (see Lunne *et al.*, 1997).

The pore pressure measurement system should be designed in such a way that it is easy to saturate and to keep saturated. This is because successful CPTU profiling depends very much on good saturation of the pore pressure measurement system, particularly in clays.

In order to attain satisfactory accuracy it is essential that the instrument is calibrated regularly and over load ranges appropriate for the ground being tested. On every project, and at regular intervals on a large project, the engineer should check that the calibration information being used is current and appropriate. It is also important to take, report and review sensor base readings before and after each full penetration – this is a requirement in the IRTP and BS EN ISO 22476-1 standard (British Standards Institution, in preparation, f). Calibration enables the assessment of the stability of the sensors and any change due to damage, especially of the load cells. In both cases significant changes in the base readings for the load cells can be converted into measured load and then into an assessment of the potential inaccuracy in the results. The IRTP and BS EN ISO 22476-1 (British Standards Institution, in preparation, f) introduce the idea of accuracy classes (in the former) and application classes (in the latter) and these set requirements for the accuracy of the equipment as a function of soil type and likely end use of the results, e.g. profiling or property determination. They require that the CPTU is used when geotechnical parameters are to be determined from the results. These classes are a critical item in the specification of appropriate tests, and in their interpretation. **Table 47.3** shows how the classes relate to the requirements for equipment and usage.

47.2.3.2 Test method

The cone, on the end of a string of rods, is pushed into the ground at a constant rate and near-continuous or intermittent measurements are made of the resistance to penetration of the conical tip. Measurements are also made of the resistance to penetration of the friction sleeve, above the cone. When using a piezocone, pore pressure measurements are also made.

The cone is normally pushed into the ground at a rate of 20±5 mm/s. A wide range of systems have been developed over the years to carry out the pushing operation, both on land and at sea. On land, pushing usually consists of hydraulic jacking against reaction systems specially built for the purpose; but sometimes the pushdown of an anchored drill rig is used. Hydraulic jack stroke lengths of 1–1.2 m are typically used, but shorter lengths may be adopted when working in limited headroom. Offshore systems exist that can either operate continuously down a drill string or by pushing from a jacking unit on the seabed.

During penetration, measurements are taken from all sensors at a fixed frequency so as to give discrete readings for forces, pore pressures and inclination, as appropriate (i.e. for the accuracy or application classes). Typically the minimum frequency is once every second or 2 cm of penetration; faster rates can be used to increase the detail of the ground profile (see Lunne *et al.*, 1997). In this way near-continuous profiles of the measured parameters are generated. A typical mixed profile is shown in **Figure 47.6**.

At any point during a test, penetration can be stopped and the CPTU left stationary, with measurements of pore pressure taken as a function of time (many standards also require cone resistance and sleeve friction to be recorded); this is referred to as a pore pressure 'dissipation test'. These tests can be used to determine the coefficient of consolidation. When penetration pore pressures are left to dissipate it is possible to estimate the *in situ* static pore pressure–depth relationship.

47.2.3.3 Cone parameters

The measured total force, Q_C, acting on the cone end, divided by the projected area of the cone, A_C, gives the measured cone resistance, q_c. The total measured force acting on the friction sleeve, F_S, divided by its surface area, A_S, gives the measured

Application class	Test type	Measured parameter	Allowable minimum accuracy[1]	Maximum length between measurements	Use	
					Soil[2]	Interpretation and evaluation[3]
1	TE2	Cone resistance	35 kPa or 5%	20 mm	A	G, H
		Sleeve friction	5 kPa or 10%			
		Pore pressure	10 kPa or 2%			
		Inclination	2°			
		Penetration length	0.1 m or 1%			
2	TE1 TE2	Cone resistance	100 kPa or 5%	20 mm	A	G, H*
		Sleeve friction	15 kPa or 15%		B	G, H
		Pore pressure[4]	25 kPa or 3%		C	G, H
		Inclination	2°		D	G, H
		Penetration length	0.1 m or 1%			
3	TE1 TE2	Cone resistance	200 kPa or 5%	50 mm	A	G
		Sleeve friction	25 kPa or 15%		B	G, H*
		Pore pressure[4]	50 kPa or 5%		C	G, H
		Inclination	5°		D	G, H
		Penetration length	0.2 m or 2%			
4	TE1	Cone resistance	500 kPa or 5%	50 mm	A	G*
		Sleeve friction	50 kPa or 20%		B	G*
		Penetration length	0.2 m or 2%		C	G*
					D	G*

NOTE For extremely soft soils even higher requirements for accuracy may be needed.

1. The allowable minimum accuracy of the measured parameter is the larger value of the two quoted. The relative accuracy applies to the measured value and not the measuring range.
2. According to EN ISO 14688–2:
   - A Homogeneously bedded soils with very soft to stiff clays and silts (typically $q_c < 3$ MPa);
   - B Mixed bedded soils with soft to stiff clays (typically $q_c \leq 3$ MPa) and medium dense sands (typically 5 MPa $\leq q_c < 10$ MPa);
   - C Mixed bedded soils with stiff clays (typically 1.5 MPa $\leq q_c < 3$ MPa) and very dense sands (typically $q_c > 20$ MPa);
   - D Very stiff to hard clays (typically $q_c \geq 3$ MPa) and very dense coarse soils ($q_c \geq 20$ MPa).
3. G profiling and material identification with low associated uncertainty level;
   - G* indicative profiling and material identification with high associated uncertainty level;
   - H interpretation in terms of design with low associated uncertainty level;
   - H* indicative interpretation in terms of design with high associated uncertainty level.
4. Pore pressure can only be measured if TE2 is used.

Table 47.3 Application classes from EN ISO 22476-1
Data taken from BS EN ISO 22476-1 (British Standards Institution, in preparation, f)

sleeve friction, f_s. In CPTU, the pore pressure is measured as discussed above. The friction ratio, R_f, is obtained by dividing the sleeve friction by the cone resistance and is expressed as a percentage.

Pore pressure measurements can be used to correct measured results for geometrical effects (see below). However, a pore pressure measurement may not always be achievable, for example in unsaturated soils and above the groundwater table.

47.2.3.4 Effects of penetration rate, pore pressure and verticality

The results of a test are to some extent dependent on how fast the penetrometer is inserted into the ground. The speed of penetration should be 20 ± 5 mm/s according to the International Reference Test Procedure (ISSMGE, 1999) and BS EN ISO 22476-2 (British Standards Institution, 2005a). The rate of penetration, especially when using the piezocone in fine-grained soil, affects pore pressure generation and there may in addition be viscosity effects on q_c and f_s. The penetration rate may also influence creep and particle crushing. Typically a tenfold increase in the rate causes a 10–20% increase in the measured cone resistance in stiff clays and 5–10% in soft clays (e.g. Powell and Quarterman, 1988). If the standard is followed, the rate should not be a problem in clays and sands; however, in intermediate soils the effect of rate changes may be more significant for the measured parameters. The rate may change most noticeably when the pushing equipment is reaching capacity and may slow down.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

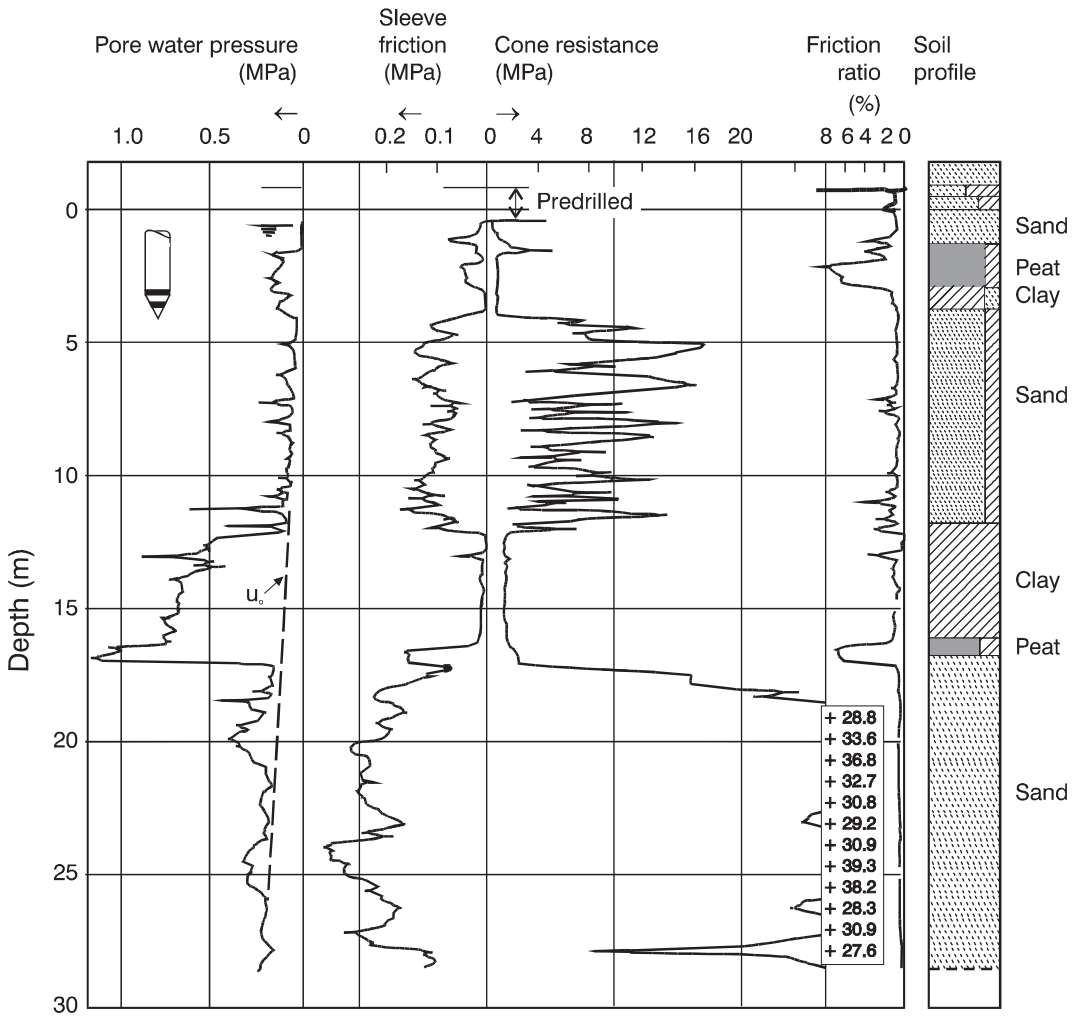

Figure 47.6 Example profile of measured and derived parameters from a CPTU profile

As has been noted, the most common onshore insertion method is to push the cone penetrometer into the soil using a rig with hydraulic jacks, with a stroke length of about 1 m. At the end of each stroke, the pushing stops and the jacks return to their start position. This is referred to as 'intermittent testing'. In some soils this causes 'unrepresentative readings' every time the test is stopped and a new rod added. These effects can be even more pronounced after pauses for dissipation tests when, because of the drop in pore water pressure and resultant consolidation, local increases in both q_c and f_s can be observed; there may also be a delay in the pick-up of the pore pressure response. This behaviour could be misinterpreted as a local ground feature if not anticipated.

The measured cone resistance is affected by pore water pressures acting downwards, on the top of the cone (**Figure 47.7**). The magnitude of the effect will vary from cone to cone depending on the geometry and will result in significantly different (40%) measurements of q_c in the same soft fine-grained soil. This variability of results may be avoided by using the CPTU since the pore water pressure effects may be corrected for by using:

$$q_t = q_c + u_2 (1 - a) \tag{47.3}$$

where q_t is the corrected cone resistance, q_c is the measured cone resistance, u_2 is the pore water pressure measured just behind the cone and a is the area ratio (that area affected by the pore water pressure ranges from 0.35 to 0.95, typically 0.7-0.85, see Lunne *et al.*, 1997).

This correction is a requirement in the IRTP and BS EN ISO 224476-1 (British Standards Institution, in preparation, f) for some 'accuracy' or 'application' classes and when the results are to be used to interpret geotechnical parameters. Friction sleeves are also affected by pore water pressure effects but correction is more difficult because it requires measurement of both u_2 and u_3, as shown in **Figure 47.7**. The effects can be reduced significantly if the end areas A_{st} and A_{sb} are equal.

Another correction that should be considered is for errors in depth measurement due to deviation of the cone from the

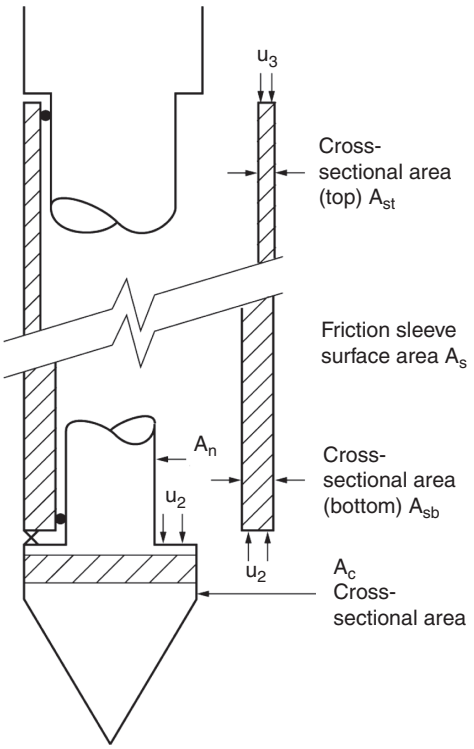

Figure 47.7 Effect of pore pressure on cone resistance

vertical. Most electric cone penetrometers contain simple slope sensors to measure the non-verticality of penetration. This is useful in avoiding damage to equipment due to sudden deflection. Where penetrations are deep, inclinations in excess of 45° are not uncommon, especially in stratified soil, and can result in wrongly identifying the depth of changes of the strata. This correction is a requirement in both the IRTP and BS EN ISO 22476-1 (British Standards Institution, in preparation, f) for some 'accuracy' or 'application' classes.

The CPT and /CPTU test probably has the widest range of ground parameters that can be derived from its results, mostly by correlation (see **Table 47.1**). The applicability of any correlation used must be ensured if confidence in the resulting parameters is to be achieved. Deriving 'site-specific' correlations is often useful. Results from CPT and CPTU tests can also be used directly in design, e.g. pile capacity, settlement predictions, for assessment of liquefaction potential or the effect of ground improvement. A number of sources can be used – see Lunne *et al*. (1997), BS EN 1997-2 Annex D (British Standards Institution, 2007b), as well as various technical conferences involving CPTs, some of which are listed in section 47.6 Further reading.

47.3 Loading and shear tests

Loading and shear tests are of most benefit when representative samples cannot be taken, for example in made ground, very soft and sensitive clays, granular or stony soils, or fractured rocks. Some (e.g. the vane test) are relatively easy and low cost. Others (e.g. large-diameter plate tests and the more sophisticated pressuremeter tests) are expensive, can be time consuming, and are not used during routine investigations.

47.3.1 The vane test

The vane shear test is used to determine the undrained shear strength of soft soils (although it is used in stiffer materials in some countries). It is standardised in BS 1377 part 9 (British Standards Institution, 2007a), BS EN 1997-2 (British Standards Institution, 2007b) and the anticipated BS EN ISO 22476-9 (British Standards Institution, in preparation, d) – when published, this standard will replace BS 1377 Part 9. The test most commonly used consists of pushing a cruciform vane mounted on a solid rod into the soil and rotating it from the ground surface whilst measuring rotation and torque. In different countries, vane tests may be carried out either by pushing the device from ground level, or from the base of a borehole, or both. The use of a borehole, brings with it the risk of strength reduction as a result of borehole drilling disturbance, and this must be recognised and dealt with. As a result of developments in the offshore industry, where measurement at the surface would be unrealistic, equipment is now available for both land and offshore work where the torque and rotation are measured electronically (down-hole) close to the vane head.

In its conventional form (**Figure 47.8**), the field vane has four rectangular blades and with a height-to-diameter ratio (H/D) of two. In the UK the dimensions of field vanes are controlled by BS 1377 (British Standards Institution, 2007a) and BS EN ISO 22476-9 (British Standards Institution, in preparation, d). BS 1377 gives suitable overall dimensions based on experience and these are shown in **Table 47.4**.

By implication, BS 1377 considers that the field vane will not be suitable for testing soils with undrained strengths greater than about 75 kPa. However, in some countries the vane test is used in stiffer soils and BS EN ISO 22476-9 (British Standards Institution, in preparation, d) recognises this; see **Table 47.5**.

The test is generally not suitable for fibrous peats, sands or gravels, or in clays containing laminations of silt or sand, or stones.

Four types of vane are in use around the world. In the first, the vane is pushed unprotected from the bottom of a borehole or from the ground surface. In the second, a vane housing is used to protect the vane during penetration, and the vane is then pushed ahead of the bottom of the vane housing before the test is started. In the third, the vane rods are sleeved to minimise friction between the ground and the rods during the test. Finally, some vanes incorporate a swivel just above the blades, which allows about 90º of rod rotation before the vane is engaged. This simple device allows the measurement of rod friction (which can be significant when the vane is pushed from ground level) as an integral part of the test.

In all tests it is important that the vane is pushed ahead of any disturbance caused either by the vane housing or any boring

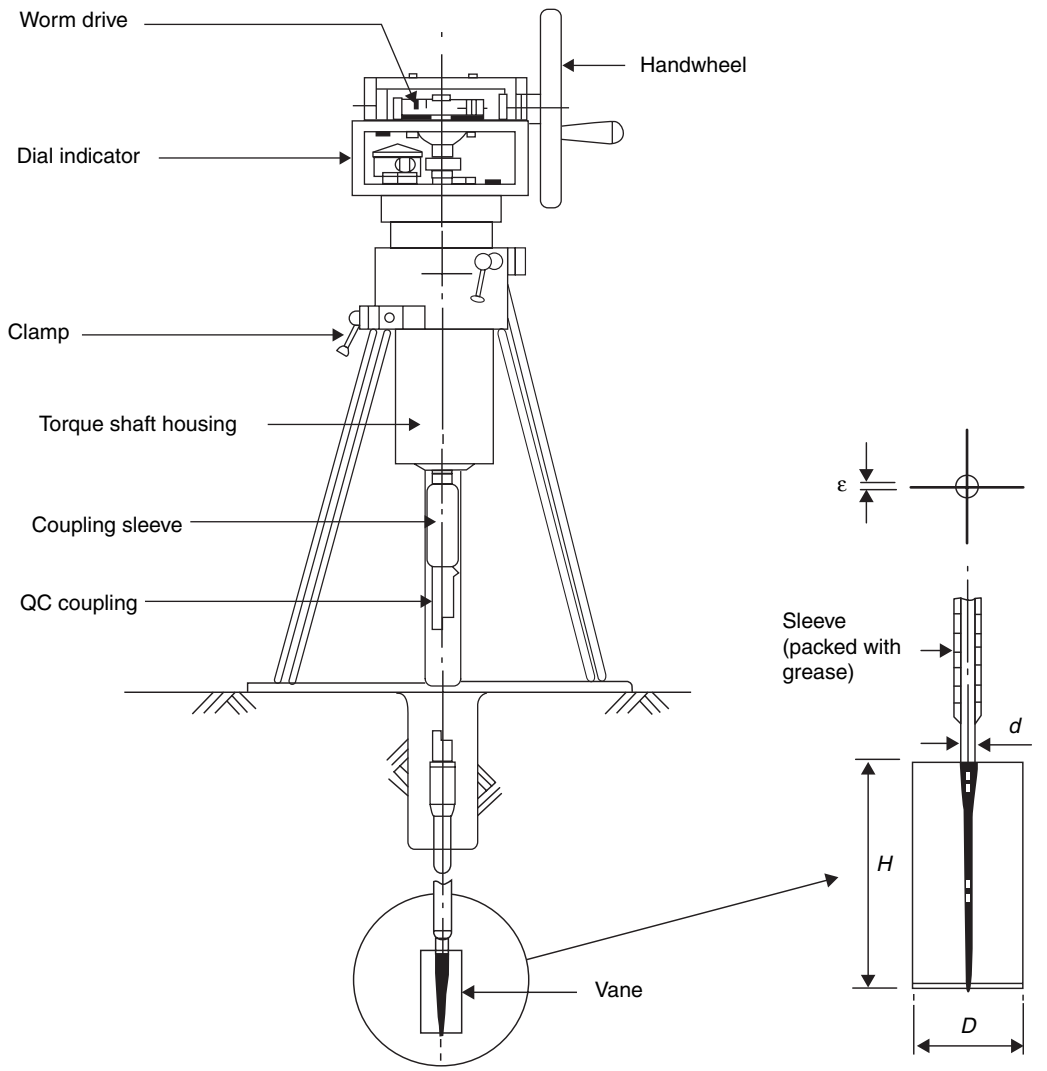

Figure 47.8 Field vane testing equipment
Reproduced from Clayton *et al.* (1995); Wiley-Blackwell

Undrained shear strength (kPa)	Vane diameter (mm)	Vane height (mm)	Rod diameter (mm)
<50	75	150	<13
50–75	50	100	<13

Table 47.4 UK specifications for vane blades (British Standards Institution, 2007a)

Soil type	Undrained shear strength (kPa)	Vane diameter suggestion[1] (mm)
Very stiff to stiff clays and silts	50–300	30–50
Medium stiff clays and silts	20–50	50–75
Soft clays and silts	10–20	75–100
Very soft clays	< 10	≥ 100

1. Still using H/D of 2.

Data taken from BS EN ISO 22476-9 (British Standards Institution, in preparation, d)

operations. ASTM D2573 (ASTM, 2008b) specifies that the vane should be pushed five vane-housing diameters ahead of the vane housing before testing, and that when a borehole is used to get down to the test depth the vane should be advanced at least five borehole diameters ahead of the bottom of the borehole. BS EN ISO 22476-9 will have similar requirements (British Standards Institution, in preparation, d). During this process it is important that vane rotation follows the relevant standard.

Once the vane has been pushed to the required test depth, the test procedure is as follows:

1. Attach a torque wrench, or preferably a purpose-built geared drive unit, to the top of the vane rods, and turn the

rods at a steady but continuous rate. This should be fast enough to ensure the test is undrained but slow enough to ensure readings can be taken and potential rate effects are not significant. A rate of rotation of between 6 and 12° min is typically used. During this phase record the relationship between rod rotation and measured torque by taking readings of both at intervals of 15–30 s.

2. Once maximum torque is clearly achieved, or in the case of BS EN ISO 22476-9 a rotation of 180° is reached, the vane is then rotated rapidly through a minimum of 10 revolutions.
3. The shearing is then restarted at the previous slow rate, to determine the remoulded strength of the soil.

A torque–rotation curve is obtained from the measurements made during the test stages, but the reliability of this will depend on the accuracy of the rotation measurements (or assumed rotation); BS EN ISO 22476-9 (British Standards Institution, in preparation) gives the requirements for the accuracy of these measurements.

The vane test is routinely used only to obtain the 'undisturbed' peak undrained shear strength (based on the maximum or peak torque), and the remoulded undrained shear strength (using the torque in the retest) of soft soils, and thereby to give an assessment of a soil's sensitivity. BS EN ISO 22476-9 (British Standards Institution, in preparation) also defines a 'residual' undrained shear strength derived from the torque at 180° rotation in the initial phase). The test results should be reported as 'vane' shear strengths. BS EN 1997-2 (British Standards Institution, 2007b) and BS EN ISO 22476-9 (British Standards Institution, in preparation) use c_{fv} for the 'undisturbed' shear strength, c_{Rv} for the residual value and c_{rv} for the remoulded value. In BS EN ISO 22476-9 (British Standards Institutionin preparation), the sensitivity is c_{fv}/c_{rv}. In interpretation it is assumed, amongst other things, that the penetration of the vane causes negligible disturbance, that no drainage occurs during shear, and that the soil fails on a cylindrical shear surface, whose diameter is equal to the width of the vane blades.

The results of a vane shear test may be influenced by many factors, namely:

1. type of soil, especially when a permeable fabric exists or stones are present;
2. strength anisotropy;
3. disturbance due to insertion of the vane;
4. rate of rotation (strain rate);
5. time lapse between insertion of the vane and the beginning of the test;
6. progressive failure of the soil around the vane.

It is necessary to carry out the vane test rapidly, in an attempt to ensure that the shear surface remains reasonably undrained. The presence of sand or silt lenses or laminations within the test section will certainly make this assumption invalid, but (again in common with many *in situ* tests) it is not normally possible to know what type of material is about to be tested. Free-draining materials should not be tested. In higher plasticity clays, the shear strength is likely to be increased by viscous effects, and there is evidence (Parry and McLeod, 1967) that unreasonably high values can be obtained.

The presence of stones or fibrous peat will mean that the assumption of a cylindrical shear surface with a diameter equal to the vane blade width is invalid. Again, the shear strength will tend to be overestimated.

Perhaps the most serious problem can result from the disturbance induced in the ground by the insertion of the vane blades. La Rochelle *et al*. (1973) reported that thicker vane blades result in lower undrained shear strength values because of greater soil disturbance and also because of the induced increase in pore water pressure in the soil surrounding the vane. In a typical test, a torque is applied shortly after insertion, and this pressure does not have time to dissipate. Hence, the time interval between the moment of vane intrusion and the time of failure is also of importance in influencing measured strength. BS 1377 part 9 (British Standards Institution, 2007a) specifies that the area ratio (the volume of soil displaced, divided by the volume of soil within the assumed cylindrical shear surface), which is given by:

$$A_r = \frac{\left[8t(D-d)+\pi d^2\right]}{\pi d^2} \tag{47.4}$$

where t is the vane blade thickness, D is the vane diameter and d is the diameter of the vane rod, below any sleeve and including any enlargements due to welded joints,

shall not exceed 12%. The disturbance caused by vane insertion is a matter for concern, and engineers should ensure that the dimensions of the vanes that they use are recorded.

A torque–rotation curve is generally obtained from the measurements of rotation and torque, but the reliability of this will depend on the accuracy of the rotation measurements (or assumed rotation); BS EN ISO 22476-9 (British Standards Institution, in preparation, d) gives the requirements for the accuracy of these measurements.

It is usual to correct 'vane' undrained shear strengths before using them in design and several examples are given as guidance in BS EN 1997-2 Annex I (British Standards Institution, 2007b). The applicability of these corrections must always be checked for the ground conditions under investigation.

47.3.2 Plate testing

Techniques for carrying out the plate loading test have been described by ASTM D1194-72 (ASTM,), in BS EN ISO 22476-13 (British Standards Institution, in preparation, e), and in BS 5930 (British Standards Institution, 2010) and BS 1377 part 9 (British Standards Institution, 2007a). When published, BS EN ISO 22476-9 (British Standards Institution, in

preparation, d) will replace BS 1377 part 9. In the most common form of the test a relatively rigid metal plate (minimum diameter 300 mm) is bedded onto the soil to be tested, either using sand/cement mortar or plaster of Paris. A load is applied to the plate in successive increments of about one-fifth of the design loading, and held until the rate of settlement reduces to an acceptable level (**Figure 47.9**).

BS 1377 part 9 (British Standards Institution, 2007a) suggests that 'the load should preferably be maintained at each increment until the penetration of the plate has ceased. Tests on cohesive (fine-grained) soils should be continued at least until all the primary consolidation is complete, judged according to the settlement versus log time plot'. Clayton *et al*. (1995) suggest that each load be held until the rate of settlement is less than 0.004 mm/mm, measured for a period of at least 60 minutes, and that load increments are applied either until:

1. shear failure of the soil occurs; or more commonly
2. the plate pressure reaches two or three times the design bearing pressure proposed for the full-scale foundation.

The load is usually applied to the plate via a calibrated hydraulic load cell and a hydraulic jack. The hydraulic jack may either bear against beams supporting concrete blocks, or (preferably) a reaction may be provided by tension piles or ground anchors installed on each side of the load position. For lighter loads, a reaction against a suitable piece of plant is also possible.

At each load increment, a note is made of the load on the plate and dial gauge readings are made on a 'square of the integer' basis (i.e. 1, 4, 9, 16, 25 mm, etc.) after load application. This will ensure sufficient readings in the early stages of each load application when movement occurs most rapidly.

The results of these measurements are normally plotted in two forms: a time–settlement curve for each applied load, and a load–settlement curve for the entire test.

The number of tests required depends on both the soil variability and the consequences of poor data for geotechnical design. Tests should not normally be carried out in groups of less than three, and in order to allow assessments of variability any plate testing should be carried out at the

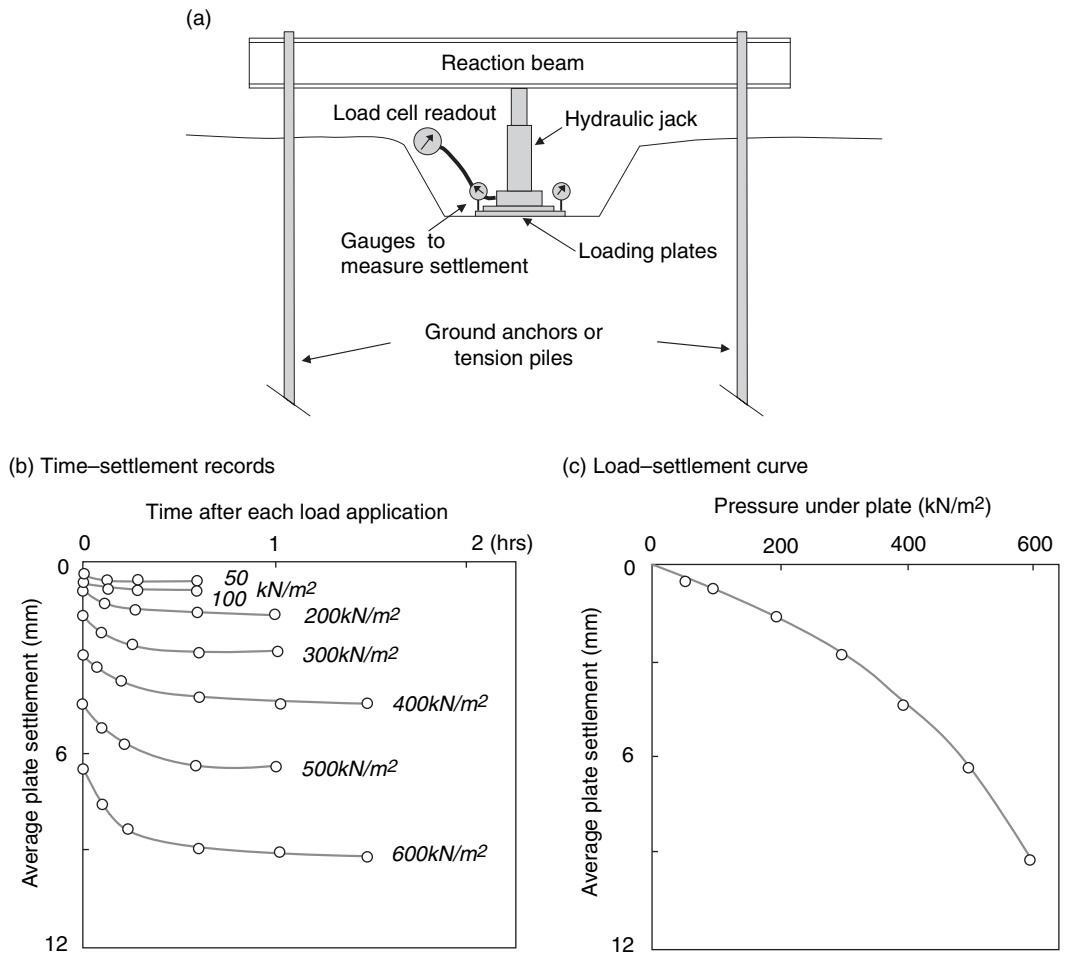

Figure 47.9 Plate load test equipment and results
(b,c) Reproduced from Clayton *et al*. (1995); Wiley-Blackwell

end of a site investigation, or as part of a supplementary investigation.

The size and location of plate tests should be assessed on the basis of *in situ* testing and visual examination of the soil or rock to be investigated. As a general rule of thumb, the plate diameter should never be less than either six times the maximum soil particle size or six times the maximum intact rock block size. The use of this rule of thumb ensures that enough discontinuities or inter-particle contacts exist in the stressed zone to give representative results, but it does not aid in extrapolating results when tests are carried out only at the proposed foundation level.

It is quite clear from the literature that the extrapolation of settlement from small plates to large loaded areas on granular soils is rather unreliable, and therefore the plate loading test on granular material should be regarded as giving a modulus of compressibility value for the soil immediately beneath the test location. Elastic stress distributions indicate that the soil will only be significantly stressed to a depth below the plate of about 1.0–1.5 times the width of a square or circular loaded area.

Plate tests on rocks appear to present a rather more attractive proposition, partly because reliable methods of predicting the settlement on rocks are almost non-existent, and also because the sorts of structure for which good estimates of the settlement on rock are required will normally justify the high expenditure necessary. Most civil engineering structures will be founded in the upper, more weathered rock zones. Ward *et al*. (1968) and Hobbs (1975) have shown that in these zones it is the compressibility of the discontinuities, and not the intact rock, which controls the compressibility of the rock in the mass. The compressibility of joints and bedding planes can be assessed visually, based on experience, but actual values under working loads can only be obtained satisfactorily from a (sufficiently large) *in situ* loading test.

A logical approach to the problem is to use a plate of sufficient size to determine a modulus value, and either to carry out tests at different levels, or to correlate tests on different materials with their weathering grades. However, the cost of large borehole plate tests is normally prohibitive. For plate tests intended to give elastic moduli values for soils or rocks BS EN 1997-2 Annex K.2 (British Standards Institution, 2007b) uses the equation for a uniformly loaded rigid plate on a semi-infinite elastic isotropic solid,

$$E = \frac{\pi q B}{4} \frac{(1-\nu^2)}{\rho} \tag{47.5}$$

where E is the elastic modulus, q is the applied pressure between the plate and the soil, B is the plate width, ρ is the settlement under the applied pressure q and ν is Poisson's ratio.

For granular soils and soft rocks Poisson's ratio will normally be between 0.1 and 0.3, and so the term $(1 - \nu^2)$ has a relatively small effect. Where plate tests are carried out in the stressed zone of a proposed foundation the value of q can be taken as the vertical foundation stress to be applied at the level of the plate test, or alternatively, a safety margin can be incorporated by taking q to be 50% (for example) higher than the estimated applied stress.

Where plate tests are intended to give values for the shear strength or bearing capacity in fine-grained soils, the load is not applied in stages. The plate is pushed downwards to give a constant rate of penetration, and the undrained shear strength is deduced from the ultimate bearing capacity; see BS EN 1997-2 Annex F (British Standards Institution, 2007b).

Two enhancements have sometimes been used in conjunction with larger, more expensive, plate tests, such as are used for major investigations (reactor foundations or underground caverns) in weak rocks:

- Multi-point borehole extensometers may be placed under the plate, in order to allow the determination of strain levels at various distances away from the loading (for example, see Marsland and Eason, 1973 and Barla *et al*., 1993). Stress changes at the measuring points must be determined from elastic theory, even though this may be rather unreliable.
- An oil-filled pad (similar to a flat jack) may be placed between the plate and the rock in an attempt to remove the concentration of stresses at the plate edge due to its rigidity. When this is done, the estimates of stress change are improved, but an interpretation of surface movements should be made on the basis of the settlement of a fully flexible loaded area on an elastic half space.

Smaller plate loading tests are routinely carried out down-hole in some countries during investigations that rely upon correlation with a visual description. This combination has proved particularly valuable above the water table in hard, gravelly or unsaturated and saprolitic soils, all of which can be very difficult to sample and test. The plate test is carried out in a large-diameter hole, which is formed using an auger-piling rig. Another adaptation of the plate test is the 'skip test'. Here a heavy-duty waste-disposal skip is used to simulate the relatively low levels of loading produced, for example, by low-rise housing. This type of test is now the subject of a standard: BS 1377 part 9 (British Standards Institution, 2007a). Settlements are measured using levelling.

47.3.3 Marchetti dilatometer test (DMT)

The Marchetti dilatometer test (DMT) [DD CEN ISO/TS part 11 (British Standards Institution, 2006), BS EN 1997-2 (British Standards Institution, 2007b), ASTM D6635 (2007) (ASTM, 2007)] is a versatile tool for *in situ* ground testing. It is relatively quick and robust, can generate profiles of information and the results can be interpreted for a wide range of geotechnical parameters or used directly for design. Despite this, it is relatively rarely used in the UK, and for that reason will only be discussed briefly.

The blade (**Figure 47.10**) is pushed vertically into the ground, using rods. It is 250 mm long, 94 mm wide and 14 mm thick, with a tip angle of 16º. It has a flat, circular steel membrane mounted flush on one side. The blade is normally jacked into the ground using available field equipment such as the rigs normally used

Figure 47.10 Marchetti dilatometer blade

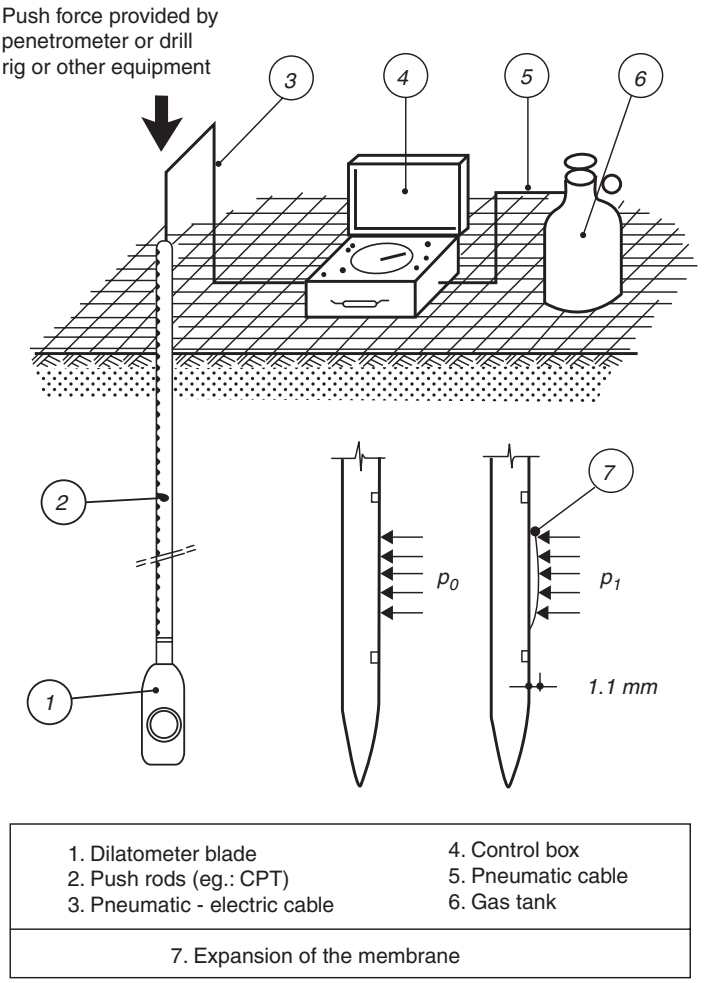

Figure 47.11 Layout of test equipment for DMT testing

for the cone penetration test (CPT), or drill rigs. The general layout of the dilatometer test is shown in **Figure 47.11**. At regular intervals (typically every 0.2 m) penetration is halted, and a test is performed by inflating the membrane by gas pressure.

The blade is connected to a control unit at the ground surface by a tube that transmits both the gas pressure and an electrical signal, running through the push rods. After penetrating to a test depth, the operator inflates the membrane using the control unit, and takes, in about one minute, two (or three) readings:

- the pressure required to just move the membrane against the soil; this 'lift-off' pressure, denoted the A pressure, is identified by the cessation of an audible signal;
- the pressure required to move the centre of the membrane 1.1 mm into the soil; this B pressure is identified by the audible signal re-starting;
- optionally, a third 'closing pressure', denoted the C pressure, can be taken by slowly deflating the membrane soon after B is reached until the membrane returns to the 'lift-off' position; this pressure is identified by the audible signal starting again after deflation.

The pressure readings A, B and C are corrected by calibration to take into account the membrane stiffness. They are then converted into pressures termed p_0, p_1 and p_2. Using p_0, p_1 and p_2, the *in situ* pore pressure and the vertical stress, three 'intermediate dilatometer parameters' are derived, namely:

- the material index, $I_{D;}$
- the horizontal stress index, K_D;
- the dilatometer modulus, E_D.

These 'dilatometer' parameters form the basis of an interpretation via a wide range of correlations to geotechnical properties such as soil type, shear strength, overconsolidation ratio, stiffness, density, etc. **Figure 47.12** shows a typical profile of results in a layered sand and clay deposit. The DMT is suitable for use in sands, silts and clays, where the grains are small compared to the membrane diameter (60 mm), with a very wide range of strengths, from extremely soft clay to a hard soil or soft rock. It is not suitable for gravels, although the blade is robust enough to pass through gravel layers of no more than about 0.5 m thickness. The DMT has also been quoted as being used for a variety of direct applications such as the settlement

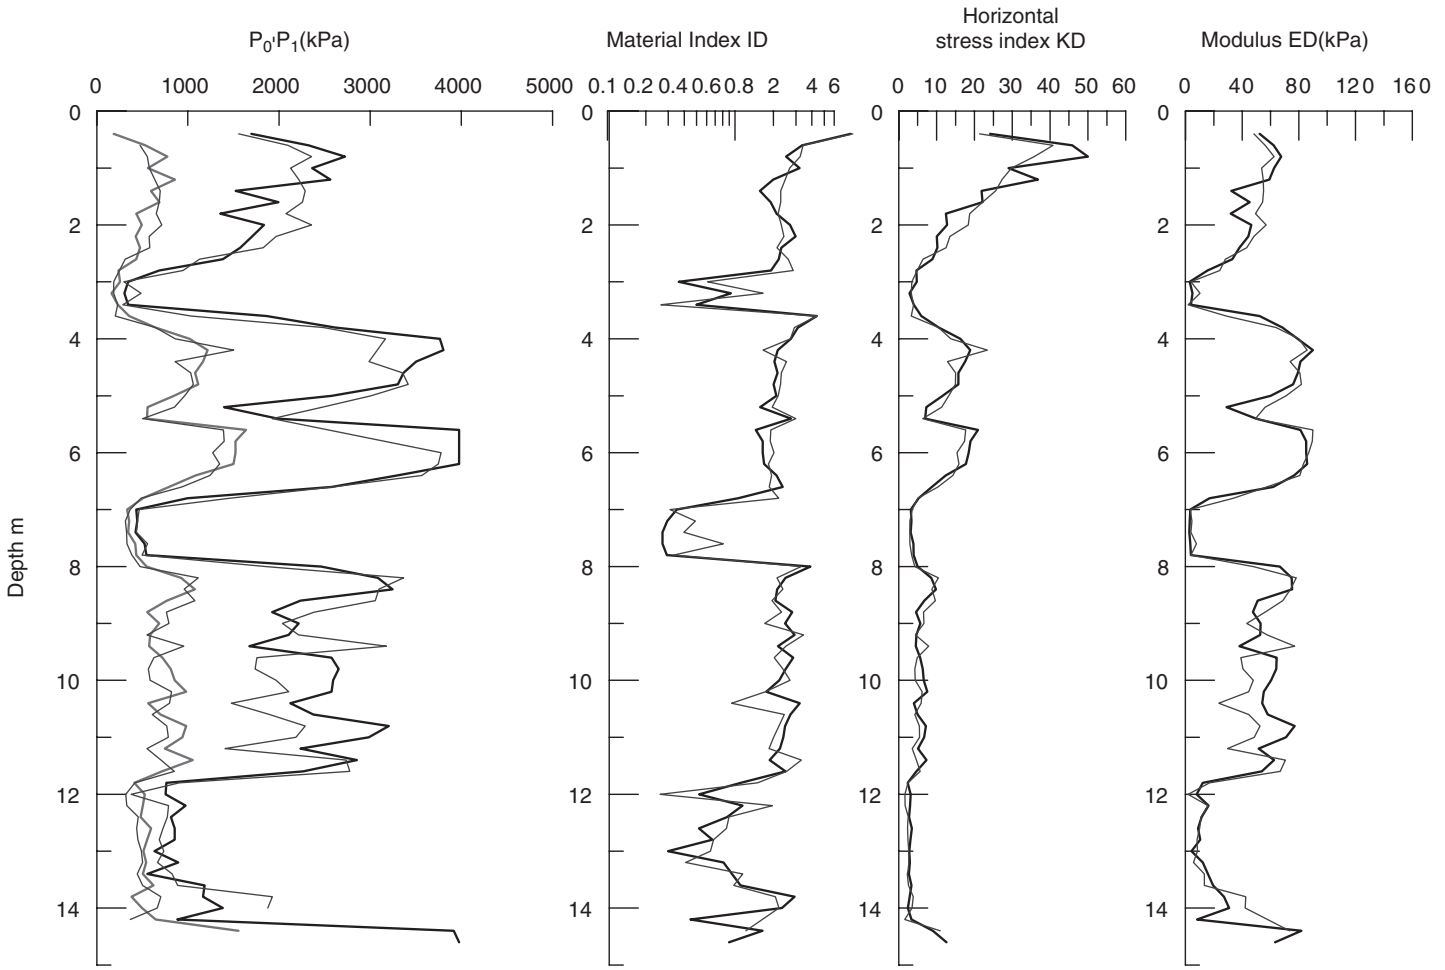

Figure 47.12 Typical profile of DMT results in layered sand and clay

of shallow foundations in clays and sands, the axial capacity of piles, the lateral behaviour of piles, compaction control, the liquefaction of sands and the detection of slip surfaces.

Further information can be found in Marchetti *et al.* (2001) and experience in UK soils is described in Powell and Uglow (1988b). More information is available in the *in situ* test conferences listed in section 47.6 Further reading. As with the interpretation for any *in situ* test, it is important to ensure that the source of the correlations used is fully appreciated and applicable to the ground conditions under investigation.

47.3.4 Pressuremeters and dilatometers

Although a number of different designs and test methods exist, all pressuremeters consist of a cylindrical cell, which is installed vertically and applies uniform radial pressure to the ground via a flexible membrane, connected by cabling and tubing to a control and measurement system at the ground surface. Higher pressure devices of this type, designed for use in hard soils or rocks, are sometimes referred to as 'dilatometers'. The aim of a pressuremeter test is to obtain the stiffness, and in weaker materials the strength, of the ground, by measuring the relationship between the applied radial pressure and the resulting deformation. BS 5930 (British Standards Institution, 2010) and BS EN 1997-2 (British Standards Institution, 2007b) give some guidance.

Three principal types of pressuremeter are in use:

- *Borehole pressuremeter* A borehole is formed using any conventional type of drilling rig capable of producing a smooth-sided test cavity. The pressuremeter has a slightly smaller outer diameter than the diameter of the hole, and can therefore be lowered to the test position before being inflated. Borehole pressuremeters have been widely used around the world, but they are not in common use in the UK. A typical test arrangement for a borehole pressuremeter test is shown in **Figure 47.13** and will be covered by BS EN ISO 22476-5 (in preparation, g). The most commonly used version of this type worldwide is the Ménard pressuremeter (MPM), and will be covered by BS EN ISO 22476-4 (British Standards Institution, in preparation, a).
- *Self-boring pressuremeter (SBP)* Borehole disturbance can have a very great effect on the soil properties determined from *in situ*

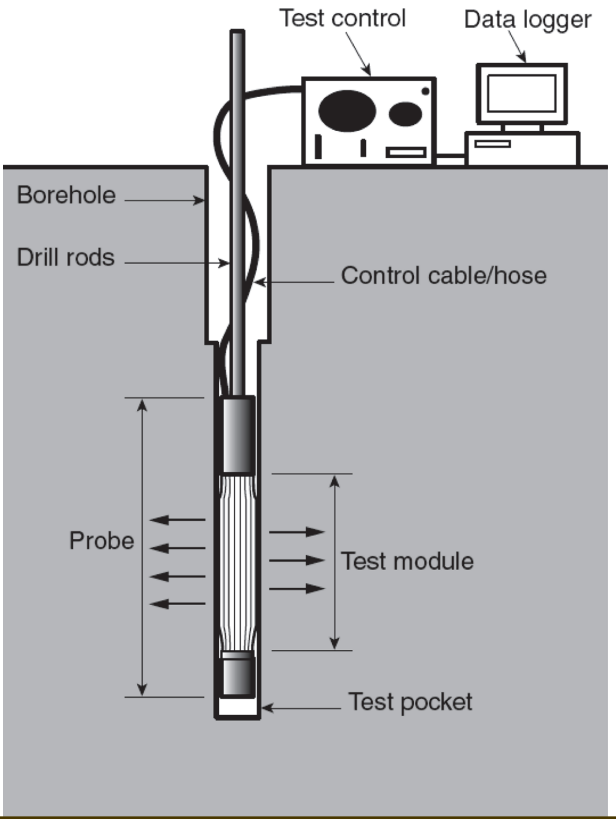

Figure 47.13 Borehole pressuremeter equipment

testing, as already noted in the case of SPT. A self-boring pressuremeter incorporates an internal cutting mechanism at its base; the probe is pushed hydraulically from the surface, whilst the cutter is rotated and supplied with flush fluid. The soil cuttings are flushed to the ground surface via the hollow centre of the probe, as the pressuremeter advances. Self-boring pressuremeters have been widely used in the UK for high-value investigations in stiff clays. They will be covered by BS EN ISO 22476-6 (British Standards Institution, in preparation, b).

- *Full-displacement pressuremeter* (FDP) Displacement pressuremeters are pushed into place and have, to date, been used only rarely in conventional, onshore, site investigations but are seeing increased interest. The push-in pressuremeter (PIP) was primarily intended for offshore investigations, where it was used with wire-line drilling equipment. The cone-pressuremeter (CPM) is a full displacement device mounted above a CPT and is seeing increased interest. Full-displacement pressuremeters will be covered by BS EN ISO 22476-8 (British Standards Institution, in preparation, c).

Because of the wide variety of this type of device, and their sophistication, a detailed description of pressuremeters is beyond the scope of this chapter (see Clarke, 1995 for more details).

A pressuremeter is inserted to a predetermined depth and then expanded. Expansion is either pressure-controlled (most common) or strain/expansion controlled. Pressure-controlled tests expand the membrane using increments of pressure each of which is held for a short period whilst the expansion is recorded. Pressure increments continue until either the maximum system pressure or the maximum expansion of the membrane has been reached. In expansion-controlled tests the rate of radial expansion is controlled and these tests therefore generally require more sophisticated systems (SBPs are generally of this type as are many of the full-displacement systems). At the completion of a test, a plot of applied pressure against radial expansion can be generated, examples of which are shown in **Figure 47.14**. The three types of device generate very different relationships between the pressure and radial strain, although these are essentially different parts of the same pressure–expansion curve.

The principal differences between the three classes of pressuremeter described above lie in the stresses applied to the probe at the start of the test. Borehole pressuremeters start from a horizontal total stress level close to or equal to zero. Self-boring pressuremeters should start the test at approximately the horizontal total stress level in the ground before insertion. Displacement pressuremeters (because they push soil aside during installation) start with a horizontal total stress, which is usually much greater than originally existed in the ground. The increase in horizontal total stress applied during a test is intended to take the soil to failure, although in rock this may not be achievable because of limited system pressure. Unload/reload iterations can be performed during any of the tests.

The interpretation of pressuremeter test data may be semi-empirical (typically the case for borehole pressuremeters and Ménard tests) or based on first principles (because the boundary conditions are well defined, a more rigorous theoretical analysis than other *in situ* tests can be performed, based on the expansion of a cylindrical cavity. There are many methods for interpreting these tests and they can even derive full stress–strain curves of the material from the test results). But essentially, all types of pressuremeter give data that is normally used to calculate, or estimate:

- the *in situ* horizontal total stress;
- the stiffness, normally the horizontal Young's modulus, or shear modulus;
- the strength (where maximum system pressure and volumetric strain permit);
- the drained parameters in sands (although more difficult than testing in clays).

All three types of device are useful and should be considered with regards to cost, reliability and consistency of the data generated.

SBP tests require significant experience if they are to be used successfully. Potentially they can give the best results but are expensive. MPM and pre-bored tests are simpler but require 'consistent' drilling and installation. Softening can occur around the borehole walls. FDP tests can generally be installed with 'repeatable' disturbance but they need further development for some areas of interpretation.

In principle, self-boring pressuremeters should provide the best estimate of the *in situ* horizontal stress and shear modulus,

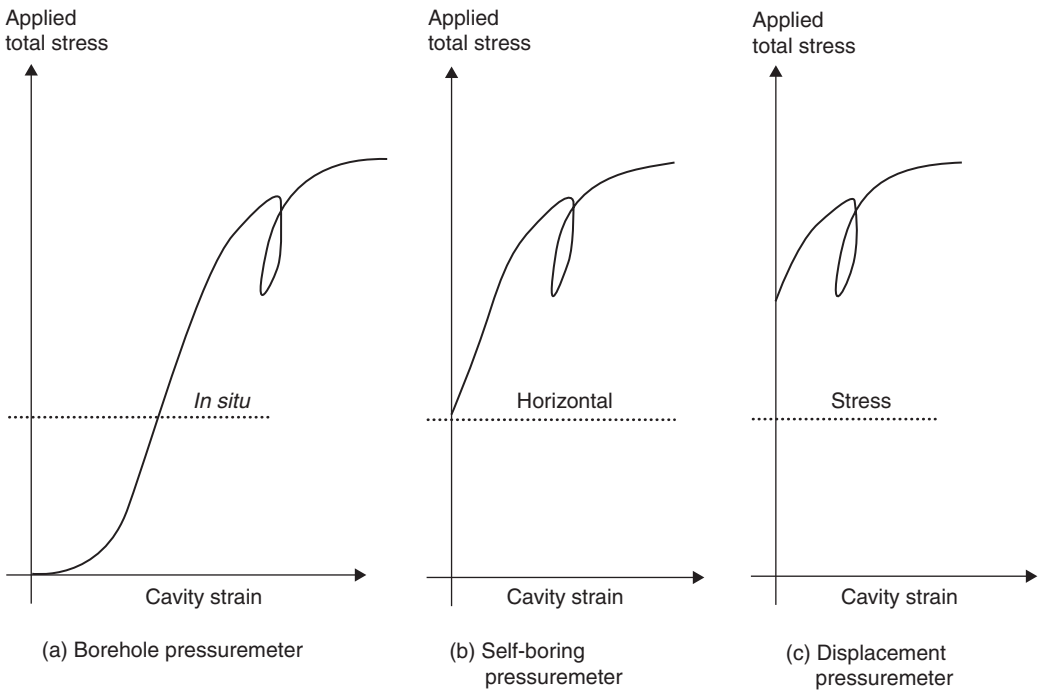

Figure 47.14 Applied pressure/radial expansion curves for three types of pressuremeter
Reproduced from Clayton *et al.* (1995); Wiley-Blackwell

provided (as should be the case) that installation disturbance is controlled. Borehole pressuremeters and dilatometers are the most rugged of the devices, but drilling disturbance and bedding between the cell and the borehole wall make the interpretation of *in situ* stress rather more uncertain, and this can lead to significant underestimates of stiffness. A displacement pressuremeter imposes very significant strains on the soil, and may de-structure it; however, the disturbance is generally 'repeatable'. Experience has shown that, when installed well, in clays the strength derived from all three types is similar and, provided the soil is not cemented, very similar results can be obtained for the stiffness from unload/reload iterations. The pre-bored devices cannot measure as small a strain level as the other devices. When interpretation methods exist, pre-bored and displacement pressuremeters can give reliable indications of the *in situ* horizontal stress (see **Table 47.1**).

The Ménard pressuremeter test generally relies on determining parameters specific to the test method, see BS EN ISO 22476-4 (British Standards Institution, in preparation, a), and these are then used in 'rules' during design, etc., see BS EN 1997-2 Annex E (British Standards Institution, 2007b). As with all these tests the 'rules' should be validated for the soil types under investigation.

More information on the interpretation of pressuremeter tests both for geotechnical parameters as well as their use in direct design can be found in the Further reading section at the end of this chapter.

47.3.5 Field geophysics

Field measurement of the seismic shear wave velocity can be an effective way to determine the shear modulus of made ground, natural ground and fractured rocks, since the relationship between the shear wave velocity and the very small strain shear modulus is a simple one:

$$G_0 = \rho V_s^2 \tag{47.6}$$

where G_0 is the shear modulus at very small strain levels, V_s is the measured shear wave velocity and ρ is the bulk density of the ground.

Suitable methods for determining the required values include:

- continuous surface wave testing;
- down-hole testing (which could be, in suitable ground, a version of CPT or DMT);
- cross-hole testing.

Surface wave testing is discussed briefly in Chapter 45 *Geophysical exploration and remote sensing* of this manual. A brief introduction to these techniques, together with examples of their use and interpretation, can be found in Clayton *et al.* (1995), McDowell *et al.* (2002) and Clayton (2011).

47.4 Groundwater testing

A good knowledge of the groundwater regime and permeability of the ground is essential for any realistic geotechnical

engineering design. The pore pressure regime on a site can be determined using other forms of *in situ* testing (see the section above on cone penetration testing, for example). However, on most sites it will be necessary to install piezometers to measure groundwater levels in the soil. On rocky sites, packer tests can be used to determine the permeability and its spatial variability.

The permeability of a granular, layered, anisotropic or fissured soil is unlikely to be obtained with sufficient accuracy from laboratory tests on specimens from normal diameter boreholes, and therefore *in situ* permeability tests are in widespread use. They can be carried out in soils or rocks, in open boreholes, using piezometers, or in sections of drillhole sealed by inflatable packers. Two common types of test are:

1. rising and falling head tests;
2. packer or Lugeon tests.

47.4.1 Rising and falling head permeability tests

The rising or falling head test is generally used in relatively permeable soils, such as sands and gravels – see BS 5930 (British Standards Institution, 2010) and BS EN ISO 22282-2 (British Standards Institution, in preparation, h). It is usually carried out in a cased borehole or a simple piezometer set in a sealed borehole section, such as a Casagrande piezometer. Where the groundwater level is below the bottom of the borehole or piezometer, the test is started by adding water from a bowser. Where the groundwater level is above the base of the borehole, it is preferable to start the test by bailing water out, since this will reduce the effect of any smear caused by boring. Water-level measurements are then taken at suitable time intervals until the water level returns to equilibrium (see **Figure 47.15**).

The data are interpreted using Hvorslev's basic time lag method (**Figure 47.15(c)**). This requires that the equilibrium water level is known, so that H_0, the driving head at the start of the test, can be calculated. If the equilibrium value is unknown it can be found by trial and error, since for the correct value a plot of $\log_e (H/H_0)$ against (linear) time will yield a straight line. When the time equals the basic lag, then:

$$T = \frac{A}{Fk} \text{ so that } k = \frac{A}{FT} \tag{47.7}$$

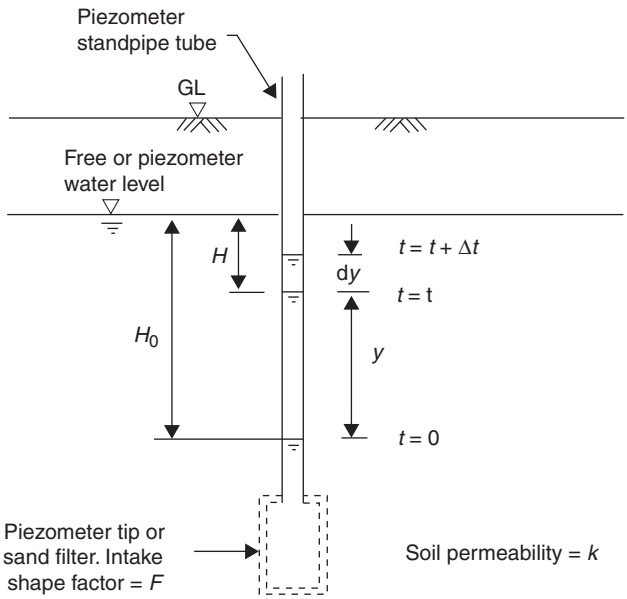
where k is the permeability of the soil, T is the basic time lag and F is the shape factor of the test section (normally a pocket of sand).

For a cylindrical piezometer or standpipe sand pocket, or a cased borehole, of length L and diameter D

$$F = \frac{2\pi L}{\log_e \left[\frac{L}{D} + \sqrt{\left(1 + \left(\frac{L}{D} \right)^2 \right)} \right]}. \tag{47.8}$$

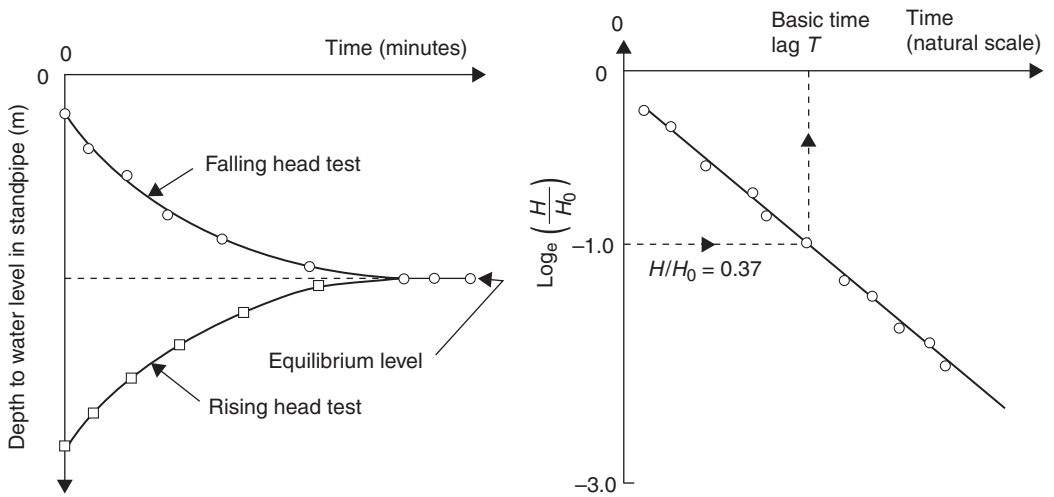
If $\log_e (H/H_0)$ is plotted as a function of time, the value of the basic time lag can be found from the straight line at $\log_e (H/H_0) = -1.0$.

The test interpretation assumes that the soil will not swell or consolidate, that the geometry of the test pocket is known, that it contains material that is very much more permeable than the *in situ* soil under test, that there is no smear on the soil wall, and that other test errors, such as those due to air in the soil or pipes, do not occur.



The time necessary to conduct a rising or falling head test increases dramatically as soil permeability reduces. Test times are prohibitively long in clayey silts and silty clays. At the same time, the assumption that there is no contribution from swelling or consolidation to the measured rate of flow becomes unreasonable. Laboratory testing can be used, providing that undisturbed samples can be taken, and these are large enough to contain representative fabric (e.g. laminations, varves and fissures).

47.4.2 Packer tests



Packer tests, also sometimes known as Lugeon tests, are used to determine the permeability of fractured rock masses – see BS 5930 (British Standards Institution, 2010) and BS EN ISO 22282-6 (British Standards Institution, in preparation, i, j). A test may be carried out in the base of a drillhole using a single inflatable packer to seal off the test section, or after the hole is complete, testing may be carried out at a variety of depths using a double packer to seal the top and bottom of the test section.

The construction of a packer is critical if leakage is to be avoided, and the greater the length of a packer, the more effective the test. A test is carried out by lowering the packer or packers to the required depth and inflating them using gas pressure supplied from a nitrogen bottle. When expanded, the length of each packer should be at least five times the borehole diameter. The test section is often about 3 m long. Packers are supported on drill rods, which are also used to supply water under pressure to the test section. At the top of the borehole the rods are connected via a water swivel to a system for measuring pressure and volume take, and a water pump.

Testing is carried out in constant pressure stages, which cycle up to a maximum pressure and then down again. A maximum pressure should be specified to ensure that hydraulic fracture is avoided. A test is normally carried out using stages such as 1/3, 2/3, 1, 2/3 and 1/3 of the maximum allowable gauge pressure. At each stage, the pressure is held constant and the volume measured over two or more periods of 5 min. Permeability is calculated from the length and diameter of the test section, the measured volume of flow and the net dynamic head applied to the test section. Alternatively, for deeper test sections, the results can be quoted in terms of 'lugeons', where one lugeon is the water take measured in litres per metre of test section per minute at a pressure of 10 kg/cm^2 (= 1 000 kN/m^2).

Under current UK legislation and planning regulations, the assessment of a site has to address potential contamination and associated environmental risks and waste management issues. Typically this will involve a qualitative and/or quantitative risk assessment which requires collection and interpretation of appropriate geo-environmental data and relevant environmental surveys. Data are required relating to contamination sources, including the chemical composition of soils, groundwater and soil gas, in addition to potential receptors which may be impacted. The quality of this data depends on the use of good practice in the selection, collection, handling, storage and analysis of samples. The value of the risk assessment further depends on the processing and interpretation of the data. In the context of a ground investigation, there are significant benefits in combining the collection of geo-environmental data alongside geotechnical requirements, provided it is done in an appropriate and targeted manner.

48.1 Introduction

Geo-environmental testing commonly forms part of ground investigations tasked with providing information to support both geotechnical design and contamination issues such as risk assessment and remediation design. Current guidance for undertaking investigation of potentially contaminated sites is provided in BS 10175:2011. The understanding of the ground conditions is paramount to the success of an investigation, and geo-environmental testing forms a major part in obtaining data to develop that understanding. The need for geo-environmental testing can be driven by various factors and the scope is usually determined from the initial desk study supplemented by site observation. The desk study should identify where samples are required for testing because of potential chemical hazards in the ground. Obtaining, transporting, handling, preparing and testing of samples must be addressed when planning and undertaking an investigation.

Typically geo-environmental testing may be undertaken to enable qualitative and quantitative risk assessment of pollutant linkages based on current UK guidance and assessment criteria such as SGVs and GACs, derived using the CLEA model which undertakes contaminant exposure modelling using HCV. Testing may also be required to undertake modelling to derive remediation targets and classification of material for waste disposal. The suite of analysis applied to samples should be bespoke to the site conditions and the purpose of the testing, albeit likely to be based around a generic suite(s) to assist the laboratory and minimise costs. However the validity and value of geo-environmental testing will be questionable if it is not done with full understanding of the reasons behind it, the objectives in undertaking such testing and the factors that influence the quality of data and its assessment.

48.2 Philosophy

The philosophy behind geo-environmental testing is distinctly different from that found in conventional geotechnical testing. Firstly, testing is done with a view to some comparison with criteria set out by national regulators and not for the purposes of pure investigation of a particular quality, such as shear strength or particle size. Secondly, the accuracy to which these determinations are made depends on equipment, sample preparation and the laboratory in a way that even the most leading edge geotechnical testing is not. The testing of blank samples and the routine re-evaluation of results from commercial analytical laboratories is not a process normally seen in geotechnical testing. Thirdly, some criteria set by the regulators, particularly with regard to water standards, cannot be achieved routinely by commercial laboratories. Finally, the testing is regularly specified to prove the absence of a particular contaminant. This is akin to undertaking a plastic limit test on a sand to prove it is a non-plastic material.

Added to this subtle difference in philosophy are the myriad changes in guidance from regulators and the steady improvement in the ability to measure very small concentrations of any particular contaminant. When this is set against a material being tested, usually Made Ground or a dynamically changing fluid source, which are thoroughly non-homogeneous and potentially unrepeatable, the treating of test results in isolation as ‘absolute’ is nonsensical.

Once results are obtained they are routinely processed statistically in a manner that is only now in 2011 being introduced into geotechnical testing in the UK by Eurocode 7.

The objective is to quantify the risk to human health, the risk to buildings and construction materials, the risk to controlled waters, and waste classification. Once these are established and a remediation methodology adopted, there is a requirement for

verification testing against criteria set out in a RIP. The nearest analogy is earthworks control testing, but with tens of separate variables – rather more than are usually tracked in an earthworks contract.

The consequence is that sampling and testing protocols and the impact of variations need to be clearly understood.

48.3 Sampling

Given the variability within soils sampled for geo-environmental purposes, sampling is not an exact science. However, the aim of sampling is to obtain *appropriate* samples for testing: 'targeted' to assess what is likely to be the worst contamination, or 'representative' for waste classification or verification.

Targeted sampling will be based on background information from the desk study (see Chapter 43 *Preliminary studies*) plus observations of the specific ground conditions including visual and olfactory evidence. Representative sampling may be undertaken at regular intervals within an exploratory hole or soil mass (**Figure 48.1**).

Composite samples are rarely used for geo-environmental purposes, unless to test bulk, basically homogeneous, materials. The inherent human factor involved in sampling decisions cannot be eliminated, but good sampling practice can minimise the scope for errors.

48.3.1 Protocols

48.3.1.1 Soils

There are many and varied ways of getting soil samples from the ground. Generally, methods are typically variations on those techniques used to obtain the samples used for geotechnical purposes, as discussed in Chapter 46 *Ground exploration*. However, these variations may be critical to the validity of the samples for the required testing or to the protection of the environment. Some typical examples of good practice are identified below.

- Drilling of boreholes in certain geological conditions may result in the transfer of contaminants to deeper levels by introducing a pollutant migration pathway. In this case, clean drilling techniques may be required in contaminated soils using dual string casing with appropriate seals.
- It is often necessary to add water to cable percussion boreholes to aid drilling. The quantities of water should be kept to a minimum and only clean water used.
- Lubrication of the drilling tools should be kept to a minimum during drilling and only vegetable oils should be used, if absolutely necessary, and their use recorded.
- In the case of rotary boreholes, drilling fluids need careful consideration and recording.
- During window sampling, plastic core liners can also be used to limit the potential for cross-contamination (**Figure 48.2**).
- All samples must be taken using clean equipment, including trowels, spades, gloves and, where necessary, power washers and detergents (e.g. Decon 90) should be used. Equipment cleaning must be done between holes and samples, if necessary, to minimise cross-contamination.

Figure 48.1 Sampling from trial pit

Typically geo-environmental samples are small disturbed samples, but collection into a plastic bag is not appropriate. Samples should be compacted into a container to minimise headspace and sufficient sample volume taken to enable the required testing. Typically a 1 kg plastic tub and a 250 ml glass jar are ample, but larger samples may be needed for some testing suites. Certain organics tests require glass containers and VOCs may require a McCartney vial.

Once a material has been identified for sampling, a full description is required, ideally to BS 5930:1999 and full records kept of the process. Photographs can also be useful. In addition, records are needed of anything that may require the laboratory to take precautions, such as broken glass, possible asbestos or potential biological contamination (details may be found on the Health Protection Agency website). Such samples should be double-bagged, sealed and clearly labelled with reference to the potential hazard.

48.3.1.2 Water

Groundwater (and gas, see section 48.3.1.4) monitoring installations may be installed in boreholes or window sample holes, and not within trial pits. Correct borehole installation is critical for monitoring purposes and construction details will be determined by site conditions. Relevant issues are listed below.

- The well size must be appropriate for the required sampling method.
- The response zone should be placed such that it monitors groundwater in the correct position in the aquifer. This will take account of the potential for free product, i.e. hydrocarbon in liquid or non-aqueous phase, and/or tidal/seasonal fluctuations. In the case of free product, the well screen should extend above the water table such that free product may be captured.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- Where more than one aquifer is present (e.g. perched waterbody and a deeper aquifer) the response zone must not cross both water bodies. Additionally, a seal (typically bentonite or similar) must be placed between the two water bodies to limit the potential for cross-contamination.
- Well construction materials should not interfere with the prevailing groundwater. PVC casing must be threaded and no glue or other adhesive used to seal the joints, and the filter material should comprise washed chemically inert granular material.

On completion of the installation, a full written log of the well design should be maintained and the well developed to settle the gravel pack, bail out any non-representative water and to cleanse the strata around the borehole. This involves bailing or pumping the well until the recovered water is free from suspended solids. This may require removal of 10 or more borehole volumes. The well should ideally be left for one week prior to purging and sampling.

If required, gas monitoring should be completed prior to water sampling. A record of site conditions should be made, and the well purged to ensure representative water conditions are sampled. Typically at least three times the well volume should be purged prior to sampling. Alternatively, measurements of geochemical parameters such as conductivity, pH, temperature, dissolved oxygen and redox can be continuously monitored during purging until these parameters stabilise. It is good practice to record these parameters during purging and sampling.

Groundwater samples can be taken using a bailer (stainless steel or Teflon) or by using pumping techniques, depending on conditions. Samples should be taken with minimal disturbance and aeration of the sample to avoid chemical changes in the water. All equipment should be cleaned thoroughly between sampling points and dedicated bailers (and string) or tubing should be used for each well.

Sample containers appropriate for the type of testing, as provided by a laboratory, and of sufficient volume, should be used. Containers for VOC analysis should be filled first and all containers should be filled until a positive meniscus forms on the top of the container to avoid air/headspace in the sample.

48.3.1.3 Surface water

When taking surface water samples the following points should be considered:

(i) samples of the water surface should be avoided unless sampling for floating free product;

(ii) sample containers must be submerged below the surface and solid material such as plant debris should be removed;

(iii) avoid taking samples from the bank of the river or stream;

(iv) samples should be taken downstream of the sampling point in the direction of the flow of water;

Figure 48.2 Sampling from open window sampler

(v) sample the flowing parts of the watercourse where possible, avoiding areas of stagnant or standing water.

48.3.1.4 Gas

Gas wells should be installed in accordance with CIRIA 665 and BS 8485:2007 and the final design should be based on the ground conditions encountered. Note that:

(i) it is vital that an adequate bentonite seal is placed around the top of the borehole and should be a minimum depth of 0.5 m;

(ii) pipework comprising threaded joints should be used. Glue or adhesive should not be used to seal pipework.

Typically, bulk gas is measured *in situ* (see section 48.4.2.3), but for laboratory analysis, especially if trace gases are of interest, a sample may be required. There are numerous sampling options; commonly used containers are Gresham tubes (sealed steel containers into which a pressurised bulk gas sample can be collected) or a Tedlar bag (typically 1 litre sample for trace gases) filled via the pump on monitoring equipment (**Figure 48.3**).

There are a number of occurrences in gas monitoring wells which must be borne in mind during sampling as they can impact the results obtained. Firstly, gas can layer in wells, as methane is lighter than air and carbon dioxide is heavier than air. In addition, during construction the soil gases within the well reflect that of atmospheric air. Over time, carbon dioxide and methane, etc., will diffuse into the well. In high permeability soils, equilibrium can be reached fairly quickly. Wells in low permeability soils may take longer to equilibrate. This should be taken into account when planning the monitoring programme.

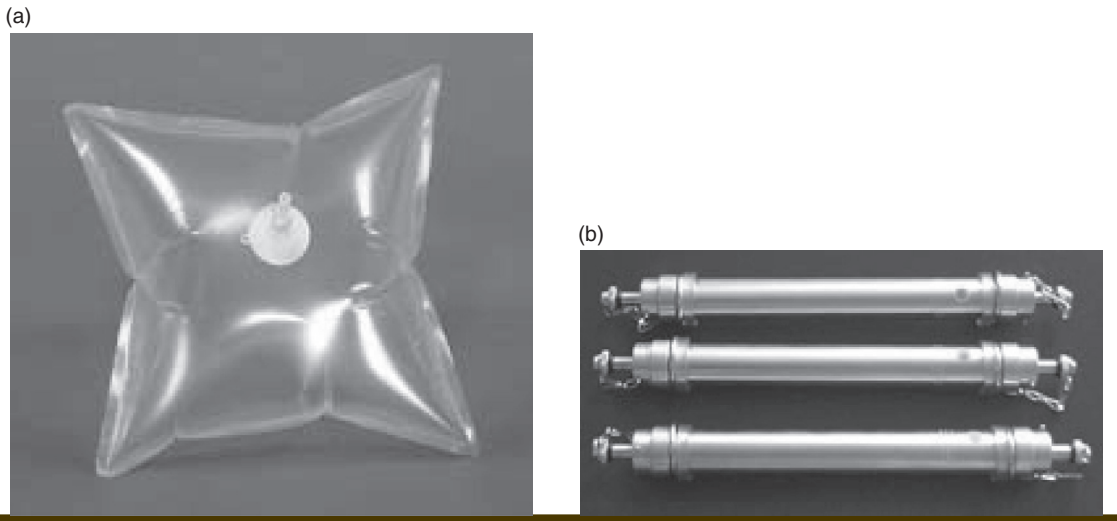

Figure 48.3 (a) Tedlar bag and (b) Gresham tubes

48.3.2 Handling and transport

All sample containers should be labelled accordingly with indelible marker – but not only on the lid. Sample containers should be placed immediately in a cool box containing frozen ice packs (and preferably maintained below 4°C) and dispatched to the laboratory. All samples should be carefully packed to prevent damage during transportation.

Each sample will be recorded on 'chain of custody' documentation, which is required to accompany the samples when transported. The chain of custody form is one of the most important documents in verifying quality assurance during environmental sampling and is often the key weakness in legal cases. This documents the transport and arrival dates of samples at the laboratory and the condition in which they were received. Each laboratory has a standard version.

All details requested on the form should be filled in and a copy retained for the project file for tracking purposes. Once samples have been received at the laboratory, a receipt should be issued, along with confirmation of the testing schedule, as appropriate.

48.3.3 Storage

Sample holding times can significantly affect the quality of results obtained. This is particularly important for certain tests which have limited holding times such as the testing of BOD or volatile organics. Analyses performed outside of the recommended holding time will usually be considered invalid or not representative. Laboratories will advise on holding times for specific analyses. If appropriate, sample containers with preservatives may be used.

48.4 Testing methods

48.4.1 Purpose

Geo-environmental testing not only allows quantification of pollutants in various media, but it also enables an understanding of the geochemical environment in the soil and groundwater to predict the fate and transport of pollutants. It is important that the scope for geo-environmental testing is considered in relation to the findings of the desk study and with due regard for future requirements or more detailed assessments.

It is absolutely critical that the testing method produces results which are relevant for the assessment required, and that limits of detection are below the appropriate assessment criteria. Inappropriate testing is a waste of time and money and can lead to, at best, an over conservative assessment and, at worse, wrong interpretation.

48.4.2 *In situ* testing

In situ testing is primarily used as a support tool in geo-environmental assessments to complement laboratory testing. The benefit of *in situ* testing is that it can provide a large volume of data in a cost effective manner. Real time results also enable 'on the spot' decisions to be made. However, *in situ* testing is not a replacement for laboratory testing, due to issues associated with accuracy, detection limits and reliability.

48.4.2.1 Soils

In situ testing of soils is typically used to fill data gaps in conventional laboratory testing and is also a useful method to delineate areas of contamination for remediation or verification purposes.

There are various *in situ* testing methods currently available, but generally they fall into three main categories, as discussed below.

Hand-held field testing kits

Portable hand-held field testing kits are available for a wide range of contaminants such as hydrocarbons and heavy metals (**Figure 48.4**). All have limitations which need consideration before use. Since many hand-held testing kits are sensitive to

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Figure 48.4 *In situ* testing

various parameters, have a range of limitations and involve the use of dangerous or controlled substances (e.g. solvents, X-ray technology), they must only be operated by appropriately trained individuals.

Mobile laboratory units

Mobile laboratories are a useful resource, particularly on large scale projects, where accurate real time data are needed. Mobile laboratories analyse samples in a similar way to that undertaken in the laboratory and are manned by a suitably qualified laboratory chemist. A broad range of contaminants can be measured depending on the specification of the mobile laboratory. Chemical test results from mobile laboratory units can be UKAS accredited. However, mobile laboratories are generally only economic on larger projects or projects with strict program constraints (**Figure 48.5**). Detailed pre-use discussions with the regulatory bodies are advisable to ensure that the testing methods have been agreed up-front and that any concerns are addressed.

Modified probes

In situ probes can provide real time data in a fast, efficient and economical way to characterise large areas of contamination in soils and groundwater. They also enable decisions to be made

Figure 48.5 Mobile laboratory

regarding targeting of site investigation or remediation and can provide data to give a rapid estimate of the volume of contamination within the sub-surface.

Cone penetration testing, typically used for geotechnical applications, has been modified to detect an array of contaminants in the ground. Techniques have been developed which use fluorescence to identify petroleum hydrocarbons via a modified cone driven using standard CPT equipment in both soils and groundwater. Free phase hydrocarbon product can be detected as well as residual concentrations in soil and it can also provide an indication of the type of petroleum hydrocarbon present (e.g. diesel, petrol, oil). Volatile organic contaminants such as chlorinated hydrocarbons and BTEX compounds can also be detected using MIPs.

48.4.2.2 Waters

In situ testing of waters is also routinely undertaken for various physicochemical parameters to provide information on the geochemical conditions in the waterbody. These parameters are used to determine if conditions are suitable to promote the natural degradation of the contaminants and thereby support the remediation decision-making process. The *in situ* geochemical parameters that are usually measured in groundwaters and surface waters are summarised in **Table 48.1**.

These parameters can be measured at the laboratory. However, *in situ* testing of these parameters is preferred since some parameters, such as dissolved oxygen and pH, are very sensitive to exposure to atmospheric air and changes in pressure – which can result from bringing water samples from depth to ground surface. For these reasons, taking a representative reading from groundwater at depth overcomes various challenges.

Hand-held meters come equipped with probes on long cables that can be lowered into a groundwater monitoring well. These meters can provide an accurate *in situ* reading, though are generally expensive.

Hand-held probes require a water sample to be brought to the surface and decanted into a vessel from which the measurement

Parameter	Description	Reason for measurement
pH	Measure of acidity or basicity of the waterbody	Can affect microbial activity, solubility of contaminants, speciation of metals and can interfere with reduction/oxidation processes
Redox potential	Describes the oxidation state of the waterbody	To determine if conditions in the waterbody are likely to be oxidising or reducing, either of which can impact upon the degradation of contaminants. For example, the natural degradation of some chlorinated hydrocarbons can be enhanced by reducing conditions. For other contaminants (such as benzene), reducing conditions would inhibit natural degradation
Temperature	Temperature of the waterbody	Can affect microbial activity and solubility of contaminants
Electrical conductivity	This measures the ability of the water to conduct an electric current	This can indicate if the water is freshwater, brackish or saline
Total dissolved solids	This is a measure of the concentration of dissolved ions in the water	This is essentially measured by converting measurements for electrical conductivity using a conversion factor. This helps to determine if the water is freshwater, brackish or saline
Dissolved oxygen	This a measure of the amount of oxygen dissolved in the waterbody	Provides an indication of whether conditions in the waterbody are aerobic or anaerobic

Table 48.1 Summary of typical geochemical parameters measured in water bodies

is taken. These are relatively inexpensive and provide indicative information on aquifer conditions, but the disturbance caused during sampling reduces confidence in the results obtained, which should not be relied upon for decision making.

Current best practice combines the use of low flow sampling techniques with the use of a flow-through cell. The low flow sampling results in minimal disturbance and aeration of the aquifer during sampling, and the flow-through cell minimises contact with atmospheric air as readings are taken.

48.4.2.3 Gas

Typically bulk gas measurements are taken using *in situ* measurement techniques in boreholes with specialist equipment capable of measuring gas concentrations and flow. In terms of assessing gas risks for construction purposes, monitoring for concentrations alone is worthless – without the corresponding flow reading.

Prior to monitoring, clean atmospheric air should be run through the instrument. Flow measurements should be taken first, then measurement of gas components at regular intervals until steady state conditions are reached. Records should be kept of atmospheric pressure and air temperature. On completion, the groundwater level should be recorded.

Certain conditions can affect the validity of monitoring results. Wind blowing across the vent outlet of the flow meter can seriously affect the recorded flows, and layering of gas within the borehole should be allowed for, with sufficient time spent to observe changes in gas proportions as gas is extracted from the full depth of the well.

Gas measurements are not limited to boreholes and where an understanding of direct surface emissions is necessary, flux box testing may be of use. This places a sealed container on the ground and emitted gases are trapped within the container for subsequent measurement. A FID is recommended for measuring trace surface gases.

In landfill applications, where information on changes in concentrations within the gas may be critical (e.g. for flaring or utilisation), *in situ* monitoring may be valuable. In-line measurement and datalogger equipment, such as a GasClam, can be used as an alternative to a hand-held monitor for taking regular measurements.

48.4.3 Laboratory testing

Laboratory testing gives an accurate measurement of concentrations of specific chemicals or substances in a sample such as soil, water, leachate or gas. Typically only a small percentage of the sampled material is tested and the portion used for each test is randomly selected. Therefore the validity of the testing is dependent on good sampling practice, combined with the selection of suitable methods. It should also be noted that most samples for chemical testing require sub-division and preparation in the laboratory, either by crushing, drying, solvent extraction or leaching. Therefore all laboratory testing involves a delay between samples arriving and the testing procedure commencing. Typically, in the UK, most testing can be completed within five to eight days. A more rapid turnaround, where possible, incurs additional costs.

48.4.3.1 Methodologies

The choice of method is important. It can affect the result and what it means. Some screening tests are quick, inexpensive and provide the required data, and may be more appropriate than a slower, expensive and more complex, accurate test. The method selected should reflect the future purpose of the data and be able to achieve a LOD below the relevant assessment criteria. If the LOD is too high, all samples may have to be assumed to exceed permitted concentrations, leading to false negatives and overconservative risk assessments. Conversely, too stringent LODs can result in unnecessary expense. It is outside the scope of this manual to discuss all the various

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

methods available. All laboratories can provide a list of the sample methodologies they offer, the quality accreditations associated with each method and the limits of detection. These should be checked for any new laboratory used. It should be noted that the LOD is also a function of the quality procedures and statistical manipulation of the data to comply with quality accreditations. The LOD does not necessarily reflect the resolution of the testing machine, although it can mean that the laboratory cannot test to a sufficient resolution, especially where scientific advances refine the assessment criteria and the laboratories have to adapt testing methods as a result. The reason for LODs in excess of assessment criteria should be checked with the laboratory before test scheduling, if they are critical to the assessment.

It is recommended for consistency that the same laboratory is used for the whole of a project, but should this not be possible, the testing methods should be kept consistent between laboratories, so that data are comparable.

48.4.3.2 Suites

For practical purposes, geo-environmental testing is usually broken down into standard suites, such that similar substances are tested together (e.g. metals, PCBs, hydrocarbons, pesticides). Standard suites can also be added together to produce generic suites, as may be offered by a laboratory, or bespoke suites for particular customers or projects. Agreeing a suite of tests is generally much more cost-effective than specifying individual tests on each sample.

However, the appropriateness of suites needs to be checked for each project and, where necessary, parameters added or subtracted from generic suites, based on the contaminants of concern identified from the conceptual site model. Typically, a site without any known contaminative history would be tested for a basic generic suite including metals (e.g. As, Cd, Cr, Cu, Ni, Zn, Pb, Hg, Se, V), basic inorganics (e.g. pH and sulphate), and basic organics (e.g. PAH and phenols). Cyanides, TPH, solvents, pesticides, herbicides, PCBs, asbestos, or any other relevant potential contaminants would be added, depending on site-specific or surrounding conditions. For construction projects where material is to be disposed of off-site, a generic plus targeted suite of testing will be necessary for all Made Ground and waste acceptability criteria testing may also be required.

In the case of unusual substances, the specialist analytical chemists employed by the laboratories can often provide advice on the type and suitability of tests available.

For some testing the methodology must comply with specifications set out in guidance documents and regulations. For example, waste acceptability testing requires testing to a specific method involving several stages of sample preparation.

48.4.3.3 Accreditation

A UKAS accredited laboratory should be used for all geo-environmental testing requirements. Additionally, MCERTS accredited testing procedures should be used, where available, for all testing which will be used for legal or regulatory purposes. However, it is noted that only soils are covered by MCERTS at present and certain tests or determinands may not yet be accredited. This will vary between laboratories.

48.4.4 Complementary testing

In addition to chemical testing, geo-environmental assessment and detailed groundwater quantitative risk assessment in particular require some basic geotechnical information. Typically such information relates to porosity, permeability and moisture content.

48.5 Data processing

48.5.1 Assessment criteria

48.5.1.1 Human health

Current best practice for the assessment of geo-environmental data for human health risk is laid out in the model procedures within CLR 11, and within those procedures, the processing of soil data requires the Chartered Institute of Environmental Health (CIEH) statistical approach. It is necessary to understand the basis and limitations of how such statistical tests are applied so that the scope of geo-environmental testing is suitable to complete such assessments. The current approach uses the calculated mean at the 95% confidence value for comparison against SGVs. These calculated values are derived from the CLEA model which uses a toxicological approach to calculate acceptable soil concentrations for various land uses and assumes a soil organic content of 6%, which is representative of typical topsoil. At the time of writing, only a relatively small number of SGVs have been published for three specific land uses. The SGVs are also generic and conservative values being based on UK defaults for standard receptors and exposure pathways. For anyone wishing to carry out assessments for different parameters or different soil organic matter (SOM), CIEH in conjunction with LQM has published a set of GACs for 40 determinands derived using the CLEA model for SOM at 1%, 2.5% and 6%. However, these too are generic and, if values are needed which are specific to a particular site, GACs have to be derived from first principles using the CLEA model.

48.5.1.2 Waste classification

The scope and, in some cases, the methods of environmental testing required for waste classification are similar, but different to that required for environmental risk assessment. The drivers for testing are the Hazardous Waste Directive (HWD) and the Landfill Directive, which are translated into law in England and Wales via the Hazardous Waste (England and Wales) Regulations (2005) and the Landfill (England and Wales) Regulations (2002), respectively. (Note that Scotland has separate waste management regulations.)

The HWD defines hazardous wastes as those possessing one or more of 14 identified hazardous properties. All wastes are listed in the European Waste Catalogue (EWC) (2002) which includes a list of those automatically deemed to be hazardous,

known as 'absolute entries'. Some wastes may be either hazardous or non-hazardous and are known as 'mirror entries' in the EWC. All other wastes are classified as non-hazardous waste, but this category includes a further sub-division of inert waste.

These classifications correlate with the three categories of landfill, i.e. landfills licensed to accept hazardous, non-hazardous or inert waste. Within the hazardous waste category, some wastes are also unacceptable for disposal to landfill if they exceed certain limits. In addition, under the Landfill Regulations, certain wastes are automatically prohibited from disposal to landfill, e.g. liquid, tyre, clinical, flammable, explosive, corrosive, oxidising and chemical waste.

The process of waste classification is summarised in **Figure 48.6**.

Once a waste has been identified and confirmed as acceptable for disposal, the process continues with assessing if it is hazardous. Once waste has been assessed as either hazardous or non-hazardous, it may require testing for acceptability for landfill. 'Absolute entry' substances only need testing for acceptability to landfill. Material that is non-hazardous and not inert does not need acceptability testing. However, in most geo-environmental/geotechnical contexts, the waste will be a natural soil or Made Ground which is a mirror entry, EWC code 17 05 03* or 17 05 04 – soils and stones. The asterisk (*) denotes the hazardous waste containing dangerous substances. The waste will require testing to determine its component substances and to demonstrate whether it is hazardous or not. This process is based on assessing the waste materials against limit values for various chemicals, determined using the hazard codes and risk phrases allotted to various substances in the waste – as indicated in the current classification, labelling and packaging (CLP) regulations of chemicals.

The acceptability testing is commonly referred to as WAC. This is a suite of soil and leachate tests, the latter being carried out on leachates prepared in a specified two stage process (EN 12457–1 to 3).

It is crucial that testing of the soil for total contaminant concentrations is carried out before or alongside WAC testing. WAC testing alone is generally meaningless as the test is mostly a leachability test and assessment limits relate specifically to inert or hazardous waste categories. The waste category cannot be determined without data on total soil concentrations, see **Figure 48.6**.

WAC testing can be carried out as a full suite, where the waste type is unknown and data are needed for expediency, or limited to a reduced suite specific to inert or hazardous wastes, if known. WAC testing is not needed for non-hazardous waste.

48.5.1.3 Waters

Water test results are generally assessed against a number of criteria depending on the aquatic sensitivity of the site. For a site which sits within a groundwater protection zone or which otherwise provides a potable water supply, standards relevant to drinking water apply. Typically, these are EU or WHO standards. For groundwater or surface water which does not impact on a potable supply, environmental quality standards are more appropriate, but not necessarily less stringent.

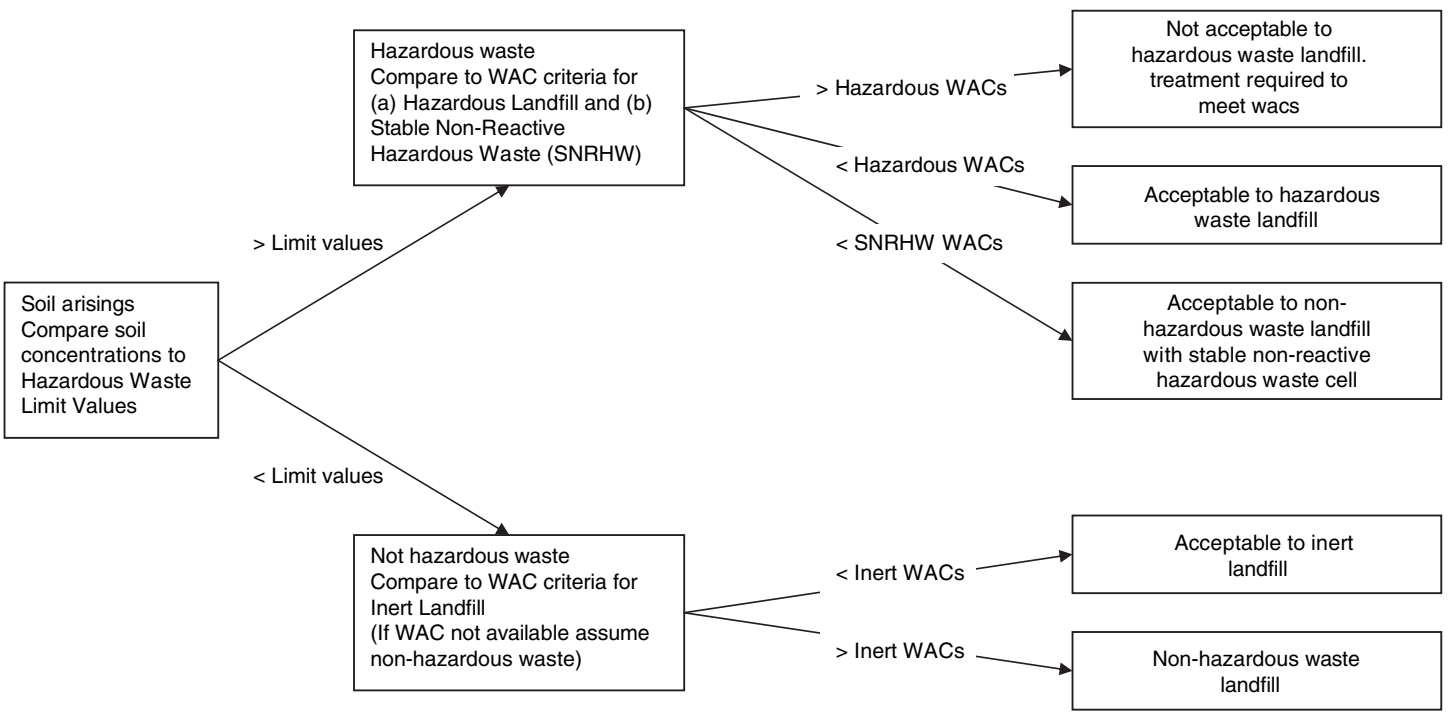

Figure 48.6 Flow chart for waste classification

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Unlike with soil assessment, there is no compulsory statistical analysis required. Where there is soil contamination which may pose a risk to groundwater, it can be assessed initially by comparing leachate test results against the relevant water quality standards. For more detailed quantitative assessment, there are two UK models in common use and advocated by the Environment Agency. The remedial targets methodology is a deterministic groundwater contaminant fate and transport model which estimates the maximum allowable soil and/or groundwater concentration to limit contamination of controlled waters to a stated maximum. ConSim is a probabilistic contaminant fate and transport model which calculates the probability of exceeding a groundwater concentration from a known source.

48.5.1.4 Building materials

Some chemical testing is carried out to assess the suitability of soils for underground construction, such as pipes, concrete, membranes.

For protecting concrete in the ground, specific testing for pH and sulphates is required, with assessment in accordance with the identified groundwater and soil conditions and associated flow charts and tables published in BRE Special Digest 1 (2005). The results of testing for pH, sulphate and occasionally magnesium in soil and groundwater are used to determine the design sulphate class and the aggressive chemical environment for concrete (ACEC) site classification.

If there are high phenols in the soil or groundwater in contact with structural concrete, specialist advice on the design of concrete to resist such conditions should also be sought.

Water supply pipes are particularly sensitive to contamination in the ground. As a rule, plastic pipes will not be permitted within contaminated soil due to the potential for damage to the pipes and/or possible tainting of the water supply. UK Water Industry Research Ltd (UKWIR) has published specific guidance on investigation and analysis to support selection of pipe materials. In addition, each water company may have specific requirements for testing and assessment of soils into which water supply pipes are to be laid. These can be quite onerous, and the water company should be contacted if plastic pipes are proposed to ensure that conditions are acceptable.

In situations where a barrier membrane may be installed on the ground, or be in contact with ground-borne liquids or gases, the durability and resistance of such membranes must be checked against the chemicals present in the ground. This information may be available on datasheets or from the manufacturer. For unusual chemicals, or low specification membranes, this information may not be available.

48.5.1.5 Verification

Verification testing is carried out to confirm whether remediation works have achieved the target concentrations. These are generally a set of values agreed with the regulator, i.e. the local authority or the Environment Agency. Soil concentrations at or below those values are acceptable and concentrations above are unacceptable. Typically these values are based on the result of quantitative risk modelling. The use of SGVs and water quality standards may not be appropriate criteria for remediation and may be overly stringent. Verification data for soil is relatively limited in availability and is compared directly to the target concentrations. Statistical analysis of such data are rare, but is occasionally used if a limited number of tests out of a large batch marginally exceed limits or if such analysis is appropriate given site conditions and usage. However the use of such an approach has to be agreed in advance with the regulator.

Groundwater validation data are generally collected over a period of time, typically ranging from three months to five years, to assess trends as well as direct comparison of concentrations against targets.

48.5.2 Rogue data

All analytical results should be reviewed by a suitably qualified person to check for potential errors or unusual results; this would include:

- looking for transcription errors or missing data;
- considering if the data are within the expected or valid ranges for that contaminant or the site (based on previous monitoring rounds);
- understanding the site conditions (e.g. potential for contamination, soil type). Do the results match the observed contamination such as free product?
- looking at potential conflict between results (e.g. low PAH concentrations but high aromatic TPH concentrations, or the presence of ammonia and high dissolved oxygen);
- assessing other field measurements which may explain spurious results (e.g. high suspended solid content).

Identified rogue data should be checked with the laboratory and, if necessary, samples re-tested, or re-sampling undertaken to confirm the results. The majority of anomalies will be readily explained by re-testing or by the application of common sense; others will actually appear correct, only because of the absence of an explanation to the contrary. Contamination concentrations can, however, radically vary across a relatively small area, such as found in a 'hot spot'. In some circumstances, such as with volatile material, concentrations will also vary significantly with time and exposure.

48.6 Quality assurance

48.6.1 Site model

It is a requirement for a CSM to be developed for an individual site as part of a planning condition in the UK. The source, pathway and target for identified groups of contaminants have to be set out and one of the most simple processes for any QA checking is to compare the CSM with the type and amount of testing done in any investigation. The identifying of the potential for a contaminant plume of a specific hydrocarbon (which is not complemented by testing of the water for a specific range

of hydrocarbons across a site in a number of places) instantly places the quality of the investigation into doubt.

48.6.2 Sampling strategy

The distribution patterns of sampling positions are much loved by statisticians and academics alike. Unfortunately they assume a homogenous media in which the contaminant lies – and a client with a very large testing budget. Both are rare. The locating of previous contaminating processes from historical maps and plans becomes crucial and the numbers of tests becomes a matter of judgement, not statistical random sampling. That said, it is easier to identify the wrong strategy rather than specify a generic and therefore inadequate ideal. The following should act as a guide:

- Do not take samples only from shallow depth when fluid contaminants such as diesel might have spread downwards into natural horizons. Many environmental investigations sample only the top 500 mm of a site.
- Do not just test the man-made soils, but test the underlying natural soils to establish if contamination has migrated and impacted other soils.
- Do not just focus testing only on potential 'hotspots' such as around buried tanks or process building, but look to establish the potential for 'background' or 'unaffected' levels.
- Do not ignore the groundwater; remediation of this can be many times more expensive than dealing with soils.
- Do not ignore soil gas as a remediation issue in itself and an indicator of other contamination.
- Samples can be too few in number, particularly on small sites and can overwhelm the interpretation on larger sites without a clear assessment of the causes of distribution.

48.6.3 Laboratory

Laboratories are commercial organisations and it should be expected that despite accreditation and various levels of quality assurance procedure their performance and reliability will vary significantly. It is important to consider that procedures are insufficient and that human and mechanical errors will occur at times in the best of laboratories.

As a principle, a single laboratory should handle the testing from one site from investigation to remediation. Indeed a known and planned throughput can see economies in scale.

On large projects it is recommended that the laboratory is visited and inspected and testing requirements, timescales and alternative options of analysis discussed. In certain circumstances, it might also prove necessary for a backup laboratory to be identified and compatibility of analytical techniques and sample preparation thoroughly checked.

Laboratories should be able to provide appropriate accreditation across the widest range of testing suites.

A principal safeguard is the 'believability' check by an experienced geo-environmental engineer who should be able

QC sample location	Duplicate QC sample	Blank QC samples	Standard/spiked QC samples	Errors or variability detected
Waterbody	Sampling duplicate (i.e. repeat entire sampling procedure)	Not possible	Not possible	Total of: purging/short term natural variability plus errors below
Sampling equipment	Equipment duplicate (i.e. repeat use of sampling equipment)	Equipment field blank1	Equipment field standard/spike1	Total of: sampling equipment/some short term natural variability (in the case of duplicate), plus errors below
Prior to treatment (e.g. filtering/preservation)	Pre-treatment duplicate (split sample prior to treatment, then treat both samples identically)	Pre-treatment field blank	Pre-treatment field standard/spike	Total of: field treatment (filtering/preservatives), plus errors below
Prior to bottling	Post-treatment duplicate	Post-treatment field blank	Post treatment field standard/spike	Total of: ambient conditions plus errors below
Prior to transport	Not possible	Trip blank	Trip standard/spike	Total of: handling and transport plus errors below
Sample bottles	Not possible	Bottle bank (i.e. place deionised water in bottle and submit for analysis)	Bottle standard/spike (i.e. place standard or spiked sample in bottle and submit for analysis)	Total of: bottle material and preparation plus errors below
Delivery to laboratory	Laboratory duplicate	Laboratory blank	Laboratory standard/spike	Total laboratory errors(1)
Type of errors detected	Random only	Random and systematic gains only	Random and systematic gains and losses	

(1) Only possible if equipment is removable. For dedicated sampling equipment, this QC sample becomes less important. N.B.: this table only relates to the sampling process. Further QC samples should be prepared in the laboratory in order to detect errors during the laboratory handling and analytical process.

Table 48.2 Summary of QC sample types

Data taken from Environment Agency (2000) © Crown Copyright

QC sample type	Advantages	Disadvantages
Duplicate	• Sampling process itself can be duplicated (sampling duplicate), providing information on errors in the entire sampling/analysis process. • Relatively easily performed. • Can be applied for all determinands.	• Only detects random errors; systematic errors are not detected.
Blank	• Easily performed. • Can be applied to all determinands. • Detects some random and systematic errors.	• Cannot be applied to initial sampling. • Only detects gains in determinands; losses are not detected.
Standard/spike	• Detects all random and systematic errors from point of QC sampling.	• Requires laboratory prepared standard solution. Can be more difficult to perform. • Each sample usually applies to only one determinand.

Table 48.3 Comparison of QC sample types

to critically appraise the results received and identify rogue data.

However, on certain projects it may be necessary to undertake quality control sampling to provide a measurement of data errors and variability in sampling. There are a number of ways of taking quality control samples including duplicate samples, blank samples and standard/spiked samples. The types of quality control samples and the types of errors they detect are summarised in **Table 48.2**.

A summary of the advantages and disadvantages of the three quality control sample types are presented in **Table 48.3**.

48.6.4 Checking and review

The number of data points and the statistical manipulation of them can obscure the random error from the checking and review process and it is important that there is a specific independent data verification check done before conclusions are drawn from the processed raw data. Ideally this is done as part of the initial calculation process by staff of similar experience. More senior staff tasked with the review of the processed data can only realistically select random samples and follow these through set processes. As with all checking operations, the process is as valuable as the experience of the individual carrying out the check.

It should be expected that the final review should be signed off by an appropriately professionally qualified individual holding chartered status as an environmentalist or similar relevant profession.

- Chapter 8 *Health and safety in geotechnical engineering*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Glossary

BOD	Biological oxygen demand
BTEX	Chemical compounds benzene, toluene, ethylbenzene and xylene. BTEX are constituents of petrol
CLEA	Contaminated land exposure assessment
CLR	Contaminated land report
CPT	Cone penetration test
CSM	Conceptual site model
FID	Flame ionisation detector
Free Product	Hydrocarbons in a liquid phase i.e. 'free' or non aqueous
GAC	Generic assessment criteria – an assessment value derived by non-government agency using a contaminant fate and transport model – usually CLEA in the UK
Hazardous waste	Waste which, because of its quantity, concentration or characteristics, may be hazardous to human health or the environment when improperly treated, stored, transported or disposed of
HCV	Health criteria value – typically in the form of an index dose (ID) or tolerable daily intake (TDI), this is the estimate of the daily intake of a contaminant that can be experienced over a lifetime without appreciable health risk (or cancer risk in the case of an ID)
Inert waste	Waste which is neither chemically nor biologically reactive and will not decompose
LOD	Limit of detection – lowest value to which a test result is reported
MCERTS	Monitoring certification scheme introduced by the Environment Agency
MIP	Membrane interface probe
Non-hazardous waste	Waste which is neither hazardous nor inert

PAH	Polyaromatic hydrocarbon
Pollutant linkage	Interaction between a contaminant source, transfer pathway, and vulnerable receptor. The linkage only exists if all three are in place
Purging	Process of removing stale water from a borehole to ensure representative sampling
QC	Quality control
Redox	Reduction oxidation potential of water – measure of how likely chemical reactions are to occur
RIP	Remediation implementation plan
SGV	Soil guideline value, an assessment value derived by the Environment Agency using a CLEA model
TPH	Total petroleum hydrocarbons
UKAS	United Kingdom Accreditation Scheme
VOC	Volatile organic compound a human health assessment value
WAC	Waste acceptability criteria
XRF	X-ray fluorescence

Chapter 49

Sampling and laboratory testing

Chris S. Russell Russell Geotechnical Innovations Limited, Chobham, UK

The development of a good ground model relies upon a successful ground investigation with appropriate sampling techniques and laboratory testing. The involvement of all stakeholders in the process, open communication and supervision are essential for high quality parameter determination for the foundation or temporary works design. Various sampling techniques and their validity for parameter determination are discussed in a process-based fashion along with an insight into the various laboratory tests available. The list of laboratory tests is not exhaustive but lists many of the common test types (and some specialist considerations) associated with modern design requirements from low-rise buildings to advanced construction. The reader is given the main principles of sampling and sample disturbance with reference to the effects on laboratory testing and parameter determination which may be used as a basis for investigations worldwide.

49.1 Introduction

From previous chapters and sections the engineer will have created and planned the site investigation and have a list of requirements needed to satisfy the construction program from the initial desk study phase through to the finished construction (see Chapter 4 *The geotechnical triangle*). These plans will have been laid out in a 'best practice' manner but should allow for some deviation especially when dealing with the 'unknowns of nature' in what lies beneath the surface. Plans that are too rigid may lead to problems later when dealing with the running of the project and certainly may cause problems in the ground investigation phase. The budget for ground investigations are always only a few percent of the overall project cost but it is here that major savings can be made in the overall design phase if thought and care is taken.

The design of the ground investigation will lead on from the desk study which will have identified the expected stratum and ground conditions. The ground investigation will verify these conditions and identify any deviations which may require further attention or categorisation leading to a ground model suitable for the engineering or design purposes intended. Laboratory tests are routinely used to calibrate ground models, however, *in situ* conditions (sometimes dominated by discontinuities or complex horizons) may require more expensive and time-consuming field tests for full categorisation (see Chapter 47 *Field geotechnical testing*). This sounds simple on paper but is in fact crucial for the design and construction stage. Failings here could have disasterous consequences. If in doubt seek advice. It should be noted that this chapter pays attention to the physical properties of the ground and so does not address testing for chemical properties or ground contamination (refer to Chapter 48 *Geo-environmental testing*). For further information with regard to the task/project in hand, you may wish (amongst others) to refer Chapter 13 *The ground profile and its genesis*; Section 3 *Problematic soils and their issues*; Chapters 43 *Preliminary studies* to 46 *Ground exploration*.

49.2 Construction design requirements for sampling and testing

The categorisation of the site should be comprehensive and provide the best possible parameters for the foundation design whether it be for simple load-bearing calculations for a strip footing through to finite element analysis which are often required for more complex or fragile construction. The required parameters drive the testing schedules for laboratory testing in order to gain accurate knowledge of the physical (and chemical – refer to Chapter 48 *Geo-environmental testing*) properties of the site (the ground model) to indicate uniformity/non-uniformity of the ground (both laterally and with depth). It is this coverage which is required for any form of foundation design or physical modelling. Soil tests should be identified to provide the parameters required for design.

Basic categorisation can be carried out on site through trial pitting, but drilling and sampling will be required for depth profiles to be identified. Each site or contract should be treated as unique and specifications must be reviewed for each contract in light of this. The complexity of the construction and the nature of the ground play a most important role in the parameters required. Interestingly the process of desk study followed by ground investigation and subsequent laboratory testing has required much thought for the layout and sequence of this chapter. It is the output in parameters required for the design that will dictate the sample types which need to be taken during the initial ground investigation phase, or a two-phase ground investigation may be required if the construction is complex or fragile. In this respect the order of description in this chapter has had to be reversed as the parameters for design will dictate the test types and therefore the sample quality which will finally control the sampling methods and preparation of the samples for the tests. In other words, think about what you need before you try and achieve it. The cost savings are in the planning of this and it can be expensive (apart from commercially embarrassing) to get this wrong. The parameters (and some associated tests) you may require can be summarised as follows.

49.3 The parameters and associated test types

In their simplest form, the results of laboratory testing may be used to categorise our area of interest and identify uniformity or non-uniformity of ground characteristics both laterally and vertically whilst more advanced parameters are based around the stability or reaction of the soil with regard to the loading (or unloading) of the construction, both in the short and long term. These values are related to soil strength and stiffness (possibly anisotropy), compressibility and permeability. For the short-term requirements and very low permeability materials we may be more interested in undrained scenarios whilst for the long term or high permeability materials we would be more interested in the fully drained conditions. These properties all vary with different stress states and again the ground investigation should be targeted to gain knowledge of these so that laboratory testing can be representative of the *in situ* conditions and be used with confidence in the foundation design stage. Test standards are listed in the appendix to this chapter for most common laboratory tests and some history/background of these tests and their basic methodology can be found in the *Manual of Soil Laboratory Testing* (Head, 1986).

49.4 Index tests

These are the most common and routine of all site characterisation techniques and are used as a profiling tool both vertically and laterally to build the ground model suitable for the project in hand. They may be carried out using both disturbed and undisturbed material and are relatively cheap and quick to perform. Index tests may be used to support 'expected' basic ground behaviour and identify where more expensive tests (or increased parameter interest) may be required for design. Such routine tests generally comprise moisture content determinations, particle-size distribution and Atterberg limits. When combined these provide very useful profiling tools which can also be used to calibrate ground models and verify the results of any further laboratory tests to be carried out. They provide information which can be combined with drilling logs to identify and corroborate with the height of the water table, variation of soil type and the expected soil behaviour, so giving clarity to the ground model.

49.4.1 Moisture content

This is the simplest and cheapest of the soil tests to be carried out in laboratories and can be carried out on both undisturbed and disturbed samples. The test consists of a small sample of soil being weighed before and after drying to determine the ratio of solid particles to water. Interestingly though, it is the moisture content of soils or weak rocks which often dictates or certainly can dominate their engineering behaviour. The 'engineering' of moisture content only improves the workability or placement of some materials (say for compaction in a landfill liner or dam core) but can cause catastrophic failure through loss of shear strength/cohesion if calculated or carried out incorrectly. Moisture content profiles of depth and lateral distance can be used to indicate zones of differing soil properties. Clays with 'high' moisture contents are often soft (or softened) compared to their drier counterparts (with identical mineral composition). They are also more likely to compress and collapse. The effect of desiccation and the possibility of ground heave can be identified through moisture content profiling to nearby vegetation or drawdown situations. Higher localised moisture contents can even be used to identify the location of broken drains and water pipes which may be the cause of undermined foundations (amongst other engineering problems).

'Natural' moisture content determinations require the material to be tested to be sealed in its natural state. This may appear obvious, but many people get it wrong. The sample should be taken from the ground at whatever depth without the influence of outside water/drill fluid/evaporation and should be immediately sealed in a fully airtight fashion. If the bag is not sealed immediately it will change its moisture content and be unrepresentative (if it is raining, water may enter the sample, and if it is warm and sunny then water may evaporate from the sample). Cohesive materials recovered from rotary cores or where drill flushes have been in contact with the material should be sub-sampled away from the periphery of the material (in contact with the drill flush). The natural moisture content in these material types will be preserved in the centre of the core for a while due to their low permeabilities. Conversely it is almost impossible to gain a natural moisture content of many non-cohesive materials (especially gravels) as the high permeability of such materials prevents retention of the water during sample extraction from the ground. Thought should

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

also be given to the materials scheduled for these tests, especially if they are likely to contain hydrated minerals such as gypsum. In such instances the oven drying temperature used in the laboratory determination should be below the level at which such minerals 'dehydrate' or release water from their crystal matrix (if present). If the oven temperature is above 110°C (hence 105–110°C for standard BS 1377 determinations) other volatile fluids will be evaporated other than water leading to erroneous test values. For materials containing (or suspected to contain) gypsum the oven temperature should not be more than 80°C. The drying stage is complete when successive weighings are within 0.1% at four-hour intervals (BS 1377:Part 2:1990). Saline pore waters can also lead to incorrect determinations and in such instances other tests may be more appropriate.

49.4.2 Atterberg limits

These are used to classify fine-grained soils and commonly identify two of the original seven limits defined by Albert Atterberg. The limits are based upon the moisture content of the soil and can be carried out on both undisturbed and disturbed samples. The plastic limit is the moisture content at which the soil changes from a semi-solid to a plastic state whilst the liquid limit is the moisture content at which the soil changes from a plastic to a viscous state.

Liquid limit determinations are carried out either by measuring the penetration of a calibrated cone into a known volume of fully mixed material at four increasing moisture contents (four-point cone method) or by 'bumping' material in a calibrated Casagrande system using a grooving tool again at four different moisture contents. There are alternatives to the four-point systems described here, but they are not ideal. The plastic limit (PL) is determined by the point at which soil can be 'rolled' in a calibrated way to form a thread 3 mm in diameter which has shears both transversely and longitudinally. This part of the test (PL) may yield variable results due to differing operators and levels of experience. This is a basic test but not a simple one to carry out!

The difference between the plastic (PL) and liquid limit (LL) is known as the plasticity index (PI). The relationship allows approximate determinations of compressibility, permeability and strength and is therefore very useful for soil classification. The derived plasticity index (PI) can also be used to determine the amount of clay present. High PI values indicate significant clay contents whilst low PI values indicate the dominance of silt particles. A PI of zero indicates the absence of both clay and silt and is termed 'non-plastic'. Generally the higher the PI value the greater the soil's potential to change volume. High PI values would signify a large volume change when wetted and large shrinkage when dried, etc. This general rule, however, does not take into account the presence of particles larger than 425 μm (removed by sieving before the test commences) and so the modified plasticity index (I_p') is often more appropriate, but only for overconsolidated clays. The calculation for the modified plasticity index was founded by the Building Research Establishment (BRE) and is:

Modified Plasticity Index (I_p') = PI × (% <425 μm/100%).

The National House Building Council (NHBC) has used this same calculation but has modified the percentages which identify high, medium and low volume change/shrinkage potentials. Values should be recorded as percentages as the general terminology of high, medium and low I_p' values are slightly different between the BRE and HSBC references. It can be seen very quickly that such tests can yield very good information and confidence in the material properties of fine-grained materials, especially when profiled.

49.4.3 Particle size distribution (PSD) analysis

This test can be carried out on both undisturbed and disturbed samples. A PSD determination is the mass of particles within designated size ranges expressed as a percentage of the complete sample mass. The range of sample sizes split the soil into its component groups ranging from clay to silt, followed by sand and gravel upwards in size (through to cobbles and boulders). For a complete analysis two distinct test types are performed. For particles larger than 63 μm (for British Standard Tests, 75 μm for ASTM standards) the material is graded by passing through sieves of decreasing sizes. The definitive method for these 'coarse' grains is by wet sieving whilst a quantative test may be carried out by dry sieving (for soils containing insignificant quantities of silt and clay). For wet sieving the particles less than the smallest sieve size are washed from the material and retained for the second part of the test. Particles less than the smallest test sieve are then graded by settling from suspension (with time) in either the hydrometer test or by pipette methods.

From the visual description of soils we make estimations of the percentages of the various sediment sizes which make up our sample. The PSD determination scientifically derives the exact percentages of each soil size fraction within the sample. It is therefore possible that a visual description may be slightly different to that recorded from a PSD analysis, but they can be used to calibrate each other and expose inaccuracies in logging and drilling records. The particle size distribution of a soil will also indicate the permeability and, possibly, compressibility characteristics to be expected from other tests which may allow test specifications to be designed for the material types in question.

Beware: it is not unknown for the sampling of some materials to be carried out badly, especially when retrieving granular material from depth. It is very easy to wash out the fines in the drill fluid or allow the sample tube to drain out water (carrying away fines in suspension) which will lead to an inaccurate PSD analysis. The author has even seen junior lab technicians pour the coarse material from the sample container/bag to be tested and leave the fine sediment in the bottom to be discarded. Both these instances would lead to a very inaccurate PSD analysis and an erroneous judgement of material properties.

Many other index tests exist and may be used in combination or with the main three tests listed above in order to complement soil characterisation. It is most important to remember that any test result is only as good as the representative sample taken and delivered to the laboratory and should be representative of the stratum from which it was taken. Coarse material should be taken in large quantities in order to be representative (see BS 1377:Part 2:1990 for required sample sizes for PSD and other analyses).

49.4.4 Compaction-related tests

These are a series of tests which identify the relationship of density (often with changing moisture content), with a known compactive force. These tests are mainly carried out on disturbed material or material to be classified for engineered fill (which by their nature are 'disturbed'). Compaction itself is a process where the density of the soil is increased by packing the soil particles closer together and so reducing the volume of air (without significantly changing the moisture content). The addition or reduction of moisture content for each test stage simply alters the strength characteristics of the soil and its 'compactibility'. These tests are common for field design of engineered fills as they will provide optimum moisture contents for the fill material with regard to compactive effort available (see Chapter 75 *Earthworks material specification, compaction and control*). Common forms of these tests for varying engineering uses and soil types are as follows:

- determination of dry density/moisture content relationship (2.5 kg rammer);
- determination of dry density/moisture content relationship (4.5 kg rammer);
- determination of dry density/moisture content relationship (vibrating hammer);
- determination of maximum and minimum dry density;
- determination of moisture condition value (MCV);
- determination of California bearing ratio (CBR);
- determination of chalk crushing value (CCV).

Please refer to the relevant current standards for full descriptions of the above methods with regard to the soil types to be tested. Of the tests listed above it is only the CBR which provides an empirical strength criterion (CBR value), and is often associated with pavement construction (see Chapter 76 *Issues for pavement design*).

49.5 Strength

This is defined as the limiting shear stress that a material can sustain as it suffers large shear strains (Atkinson, 2007). The response of the soil in both strength and stiffness are related to the 'state' of the soil. This state is related to the density of the material and stress level which is linked to pore pressure, and therefore, 'effective stress'. It is interesting that so many parameters and stress states are closely linked but all ultimately controlled by the principles of effective stress. 'All measureable effects of a change in stress, such as compression, distortion, and change of shearing resistance, are due exclusively to changes of effective stress' (Atkinson, 2007). The following is a list of laboratory tests including triaxial and direct shear types (amongst others). Triaxial tests are a family of tests whose subtleties are controlled by varying boundary, drainage and loading conditions, but 'appear' to use similar equipment.

49.5.1 Triaxial test types

For basic boundary, drainage and loading conditions see **Figure 49.1**.

- *Unconfined compressive strength* (UCS). This is a total stress test (no pore pressure measurement) and is carried out without radial confinement. It may also be termed 'unconfirmed' compressive strength, and unfortunately has the same acronym associated with the uniaxial compressive strength (UCS test) carried out on rocks. Although the applied stresses are all the same in these tests the standards, methods and test equipment used for soils and their rock equivalents are distinctly different.
- *Unconsolidated undrained triaxial test* (UU). Again this is a total stress test as pore water pressure is not measured. For this test a radial (confining) pressure (σ_3) is applied to the sample and is of a magnitude which relates to the depth of sample origin. Shearing rates are standardised for these tests and reference should be made to the relevant regional standards for further information. This test should not be confused with a UUP test (see below) which often goes under the same name.
- *Unconsolidated undrained triaxial test with pore pressure measurement* (UUP). An effective stress test which gives the undrained shear strength for the material. Be aware that the effective stress measured for such tests may not be representative of the mean effective stress of the material *in situ* due to the effects of sample disturbance. For more advanced testing the pore pressure may be measured both at the base and mid-height of the sample.
- *Isotropically consolidated undrained triaxial test* (CIU). As above but the sample is isotropically consolidated to a mean effective stress relevant to the *in situ* depth of the sample or a particular stress/depth condition which is to be modelled.
- *Isotropically consolidated drained triaxial test* (CID). This is for the 'drained' or long-term condition of the above test. For clay materials this may be a test of very long duration due to the very low permeability associated with such particle sizes and mineralogies, but for sands and free-draining materials it is usual to carry out drained triaxial tests rather than undrained shearing because the short- and long-term conditions should approximate (due to the high permeabilities). Undrained conditions are unusual for sands (unless in a fully confined state) within the ground unless one is trying to model a very specific ground or construction condition. Undrained shear tests in non-cohesive materials cause immediate dilation of the material which is often unrepresentative of field conditions.
- *Anisotropically consolidated triaxial tests* (CAUC, CAUE, CADC, CADE –see section 49.6).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

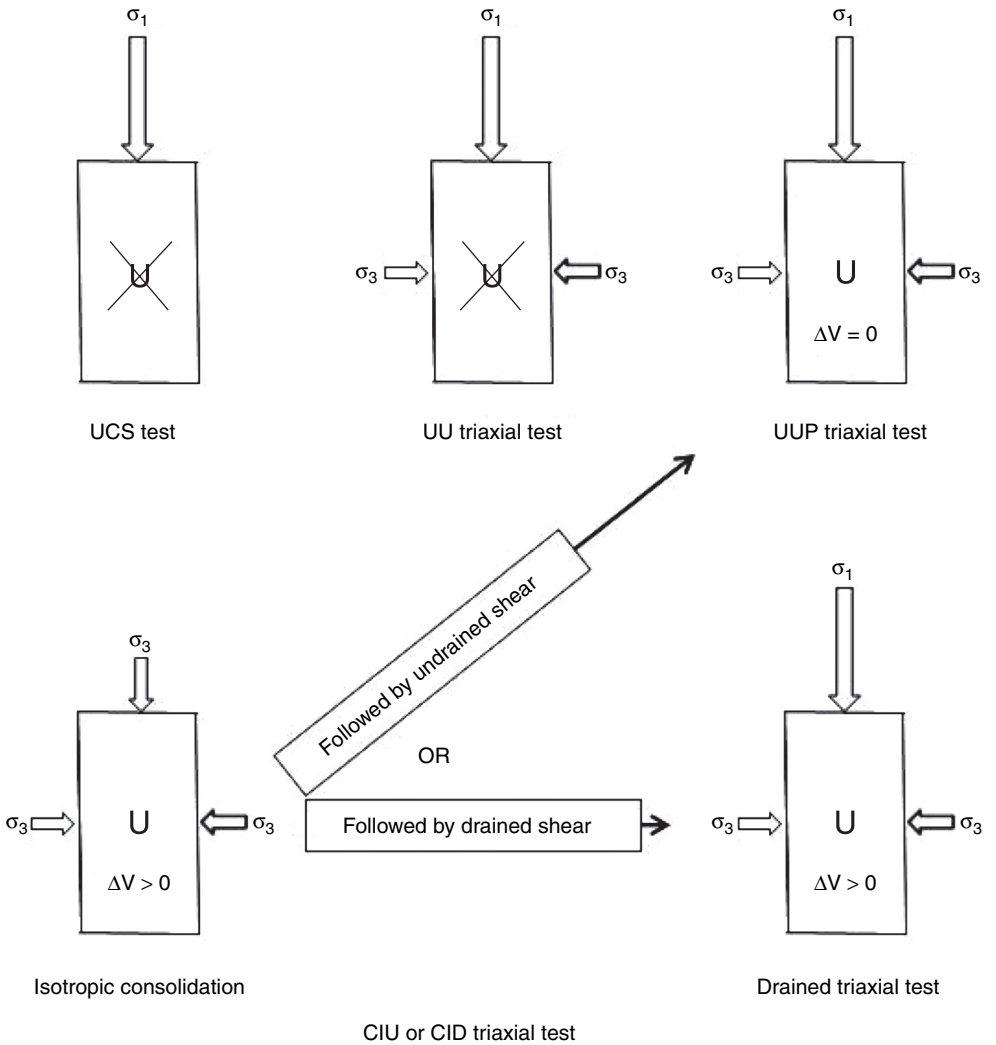

Figure 49.1 Triaxial test: boundary and loading conditions

Reference should be made to Chapter 17 *Strength and deformation behaviour of soils* for the interpretation of different strength parameters and 'ideal' triaxial tests. All of the triaxial tests listed above require undisturbed samples to be taken. Information and guidance is given later in this chapter as to the sampling types and methodologies which should be planned from the outset of the ground investigation. It can also be seen from the list of tests above that rates of testing are mentioned. For effective stress tests pore water equalisation is required in order to measure strength and stiffness correctly (see section 49.6).

Figure 49.2 shows a typical triaxial loading frame with a modern cell pressure and backpressure control system on the left and the transducer logging system on the right. Historically, pressures were applied manually and the measuring instruments were read manually by either reading dial gauges or writing down the specific outputs from digital readout units. Modern technology has advanced triaxial testing so that stress control and instantaneous measurements of transducers are becoming increasingly the norm. Load measurement can also be carried out in several different ways in laboratories and **Figure 49.3** shows the types of load measurement commonly available.

The original external load measuring devices commonly used were in the form of a load ring whose calibrated deflection could be read manually by an operator. These were superseded by load rings with integral digital readouts which can be manually read or their output logged by computers and read remotely. Electronic load measurement devices have become common now, but as with all previous versions the drawback of all of these is that they are generally not waterproof and therefore need to be mounted externally to the cell. This leads to the load transducer measuring the friction of the ram as it passes into the cell leading to errors in load measurement. Calibrations of ram friction can be made to minimise this error; however, slight non-concentric loading can lead to the

ram 'sticking' and giving 'false' load readings. It is possible to utilise rotating bushes where the ram passes into the cell but these are not without problems themselves. The ultimate load measuring device is the submersible load cell which is mounted on the end of the ram and remains in direct contact with the sample within the cell whilst any loading occurs. In essence any load which is applied to the sample will also be seen by the submersible load cell without any external effects and so is the ultimate load measuring instrument. The cost of such devices is often prohibitive in many institutions and so external load measurement is most likely to be the norm.

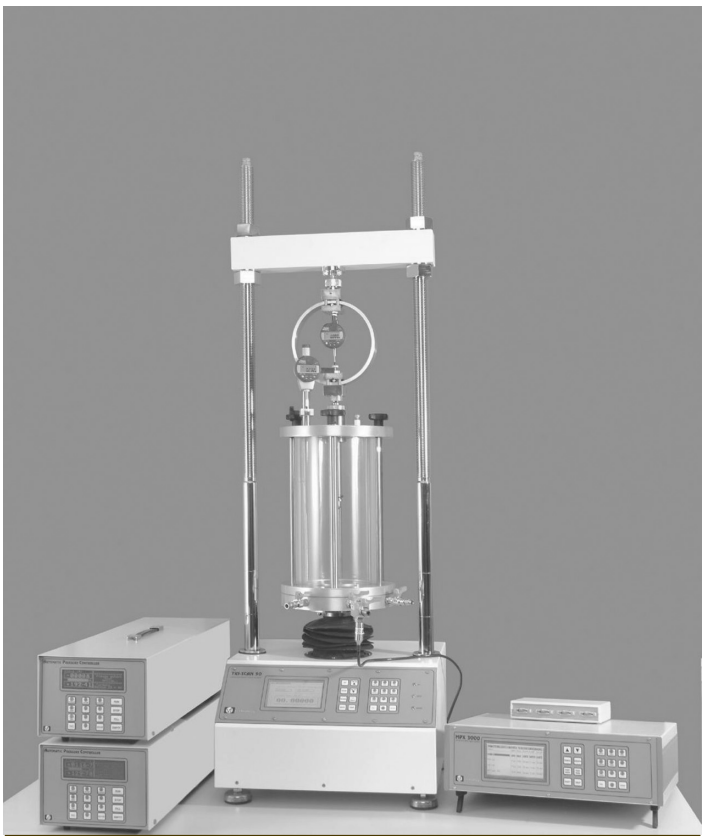

Figure 49.2 Triaxial test equipment
Courtesy of VJ Tech Ltd

It should be noted that testing of organic soils, especially peat, can produce rather 'unexpected' test results compared to those associated with sands and clays. This is due to the type, fabric, percentage and orientation of organic material which may be present in such samples. Undrained tests do not take into account the high compressibility of such materials and would yield low shear strengths whilst drained shearing stages will display very high strains and again possibly unrealistic shear strengths due to the complex nature of the material and the boundary conditions which exist in triaxial samples. These tests are certainly possible but care should be taken in the design and expectations of shear strength tests on such materials. More will be said about such materials as we move on.

Rock strength is dominated by its mineralogy and cementation along with the presence and orientation of discontinuities. Reference should be made to Chapter 18 *Rock behaviour* for further understanding and categorisation of the material. Commonly strength tests are carried out as uniaxial compressive strength tests (unconfined), but may also be carried out as confined or even effective stress tests using specialist high pressure/stress equipment. Reference is made to the main standards for such common test types in the appendix to this chapter. It should be noted that rock tests require very different equipment for preparation and testing than soil tests; however, there is a grey area where we might classify a soil as a weak rock and vice versa. In this instance, experience will prevail over which tests and equipment to adopt. As with all testing, these will require specialised personnel with significant skill

Figure 49.3 Triaxial load measuring equipment (Left: Load ring with manual dial gauge. Middle: Load ring with digital dial gauge. Right: Submersible electronic load cell)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

and experience. The 'art' of these tests is in the sample preparation and the specific equipment used (along with sample orientation with regard to discontinuities and preferred fabric). Check with your nominated testing laboratory that they have the correct equipment and expertise to carry out such tests.

The cutting and facing of the sample if carried out incorrectly can reduce the strength of the test specimen by up to two thirds by the introduction of point loads and non-parallel faces. Cutting equipment should have very thin diamond blades and work by the rock core being moved (whilst rigidly supported) across the cutting blade, not vice versa as in concrete cutting equipment. All cutting marks must then be removed by facing. This involves the polishing of the sample surface until both ends are completely flat and parallel (tolerances can be found within the standards listed in the appendices at the end of this chapter). The samples must then be mounted on specially hardened platens (which are calibrated for flatness) which have a diameter either the same or no greater than 2 mm larger than the specimen diameter, one of which will have a spherical seat and be placed on the top of the specimen. The loading surfaces of the compression machine itself will be rigid, parallel and unable to rotate. One can appreciate that rock testing is a highly specialist form of material testing and there are few laboratories which can carry out this form of testing correctly.

49.5.2 Direct shear tests

Alternative strength tests such as the shearbox test are also common where phi angles and cohesion intercepts are required for design purposes. Such tests can be carried out on both undisturbed and disturbed samples (depending upon the desired engineering use for the material). The historical test is the shearbox which can yield values for phi and cohesion (see **Figure 49.4** for test mechanism).

Originally designed for testing sand, the equipment is now used commonly on non-cohesive and cohesive materials alike. The equipment comes in a range of sizes which provide testing for a range of particles from fine through to coarse. The shearbox consists of a 'hollow box' which is split horizontally and into which a sample is placed. The sample is consolidated to a desired normal stress and then sheared horizontally. The bottom half of the box is displaced whilst the top half of the box reacts against a load measuring device measuring the resistance to shear. These tests are usually carried out as a set of three tests where the first test is consolidated at half the calculated effective stress for the material, the second is at the calculated effective stress and the third is at double the calculated effective stress. The values from these tests should be used in total stress calculations only (although there is some argument). The only point at which we know the effective stress of the material (during the test) is at the end of the consolidation stage. As pore pressures are not measured throughout the following shear stage we are unable to verify the true effective stress of the material at failure and certainly along the plane of shear.

Consolidated peak strengths are obtainable from this equipment along with residual strengths.

Residual strengths in clays in particular are often in error from this equipment as it is not possible to form a perfectly flat shear plane. Residual values are reached only at very high strains compared to peak characteristics and the shearbox has limited travel. Some attempts to overcome this are in the test standards by reversing the direction of shearing until a consistent 'apparent' residual state is measured. For non-cohesive materials and silts this method may work, but due to the 'platey' nature of the clay particles, the perfect (flat and polished) shear plane can only develop by continued shearing in a singular direction (no reversals as per the standard shear box). This problem was overcome with the invention of the Ringshear apparatus (E. Bromhead). The normal loading and relative displacements induced during the test can be seen in **Figure 49.5** whilst a commercially produced ringshear apparatus is shown in **Figure 49.6**.

49.5.3 Ringshear test

Rather than linear movement of a block of soil, the ringshear rotates constantly and so the linear displacement (in a single direction) is limitless (or at least until all the soil has been 'squeezed' from the test annulus). Note that two opposing load measuring devices are used on this equipment. This is most necessary as the cell rotates and it is actually torsion which is measured. The use of two load measurements (being of matched stiffness) balance the top cap under rotation and are designed to prevent friction being measured from the central locating pin for the top cap.

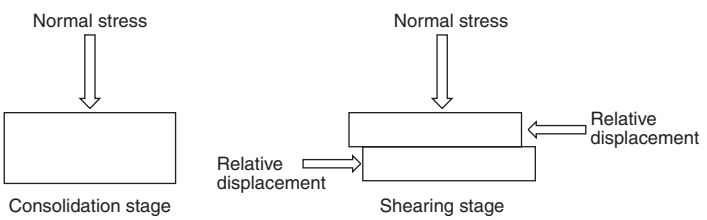

Figure 49.4 Loading and shear displacement in shearbox test

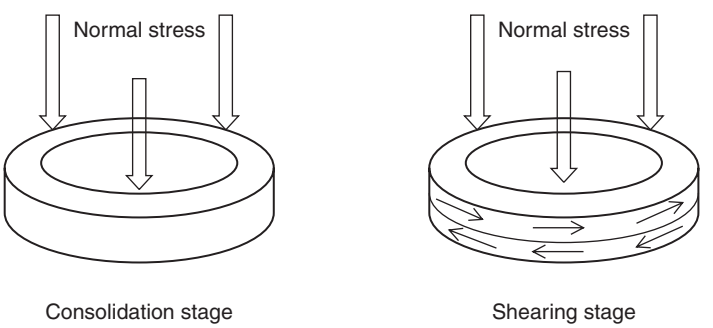

Figure 49.5 Loading and shear displacement in ringshear test

If we are interested in residual values (say for slope stability calculations) in clays, this is the test to perform. Peak strengths are not available from the 'Bromhead' or 'small' ringshear due to the fact that the sample must be remoulded as part of the test preparation. The material needs to be pressed into a tight annulus and benefits from having any structure or bonding destroyed. This allows for accelerated reorientation of the clay particles (shortening test times) and more repeatable test results through the homogeneity of the sample. This equipment is suitable for pure clays only. The presence of coarse particles may roll along the shear surface during the test and will destroy it by reorientating the clay particles. This will lead to higher (non-repeatable) residual values being obtained which may be disastrous where the true residual angle is actually lower still. For clays containing coarser material and non-cohesive samples the engineer should revert to the standard shearbox test (along with its known and well-documented limitations).

49.6 Stiffness

There are many technical definitions of stiffness, but they all relate to the gradient of the line of stress plotted against strain and it is most important to consider that soils display a nonlinear stress–strain response (outside the highest levels of research). It should be remembered that the strength of the soil dictates its ultimate load-bearing capacity with large strains whilst stiffness identifies the compressibility (or strains) in the material at working loads (see **Figure 49.7**).

In general these parameters are not derived from the routine tests listed previously and require the highest quality undisturbed samples, specialist capabilities, instrumentation (**Figure 49.7**) and high levels of knowledge and experience. For stiffness of rock material reference should be made to Chapter 18 *Rock behaviour* for additional information. It is possible to fully instrument the following triaxial tests for the determinations of Young's modulus: UUP, CIU and CID. Shearing of samples may take place in either compression or

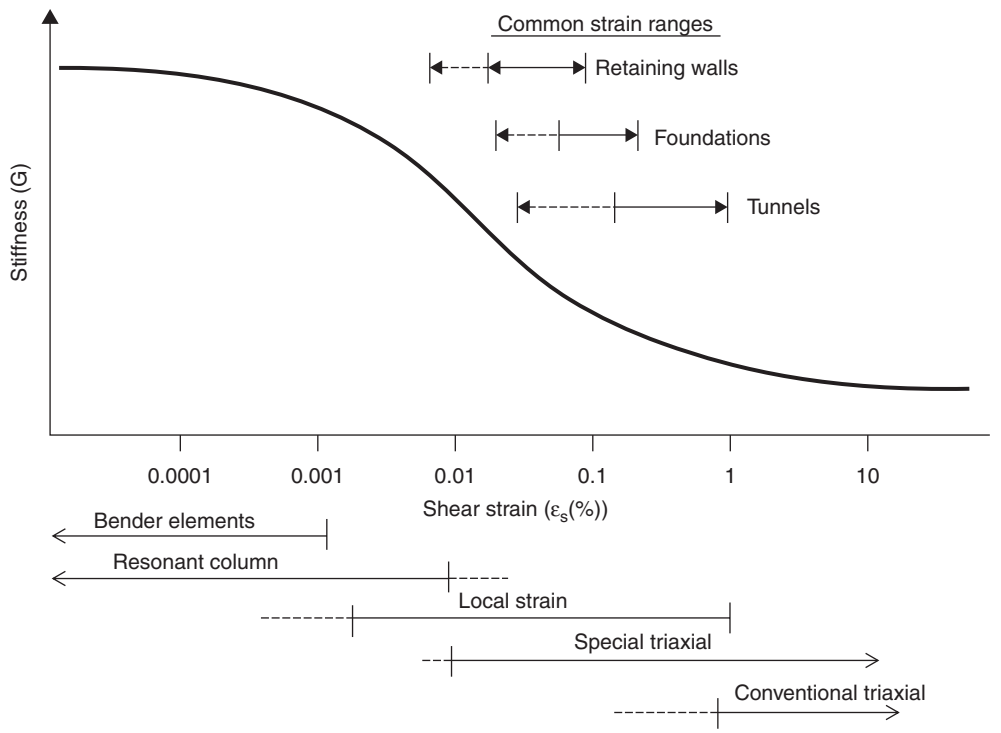

Figure 49.7 Idealised variation of stiffness with strain

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

extension and so a suffix may be added to the above abbreviations in the form of a C (compression) or E (extension).

The highest level of triaxial effective stress test is known as a stress path test or anisotropically consolidated undrained (or drained) triaxial test (CAU or CAD) and again may have the C or E suffix depending upon the final shearing direction. High-resolution transducers are attached directly to the sample to measure axial strains for the determination of Young's modulus and when combined with a radial strain transducer can be used to determine Poisson's ratio, Shear modulus (G) for undrained shearing and Bulk modulus (K) for drained shearing. In addition it is possible to measure Gmax using bender elements which measure sample stiffness beyond the resolution of local small strain instrumentation (see **Figure 49.8** for typical advanced instrumentation).

These tests are designed to take the specimen through its recent stress history in order to minimise any effects of sample disturbance and return the specimen to its true *in situ* mean effective stresses or to a particular stress level required for modelling.

Figure 49.9 shows an advanced triaxial test with local axial and radial strain instrumentation, base/mid-plane pore water pressure measurement along with measurement of Gmax using bender elements in all three possible directions. This specialist

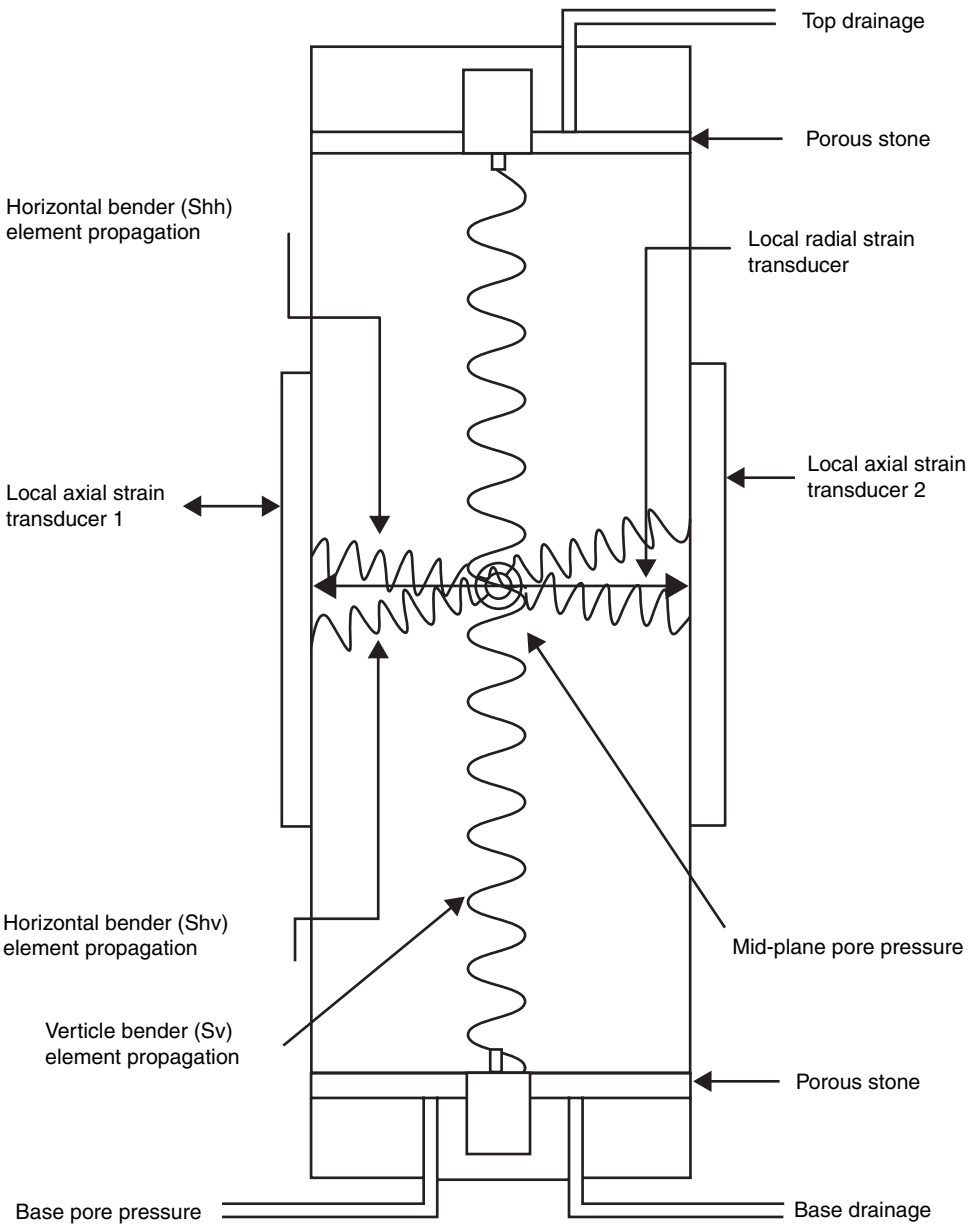

Figure 49.8 Typical advanced triaxial instrumentation for CAUC, CAUE, CADC and CADE test types

Figure 49.9 Triaxial stress (CAUC) tests with advanced instrumentation
Courtesy of Russell Geotechnical Innovations

instrumentation is used not only for the measurement of very small strain stiffness, but the utilisation of both base and mid-plane pore water pressure measurement allows verification of effective stress measurement.

The use of local axial and radial strain transducers allows the measurement of small strains directly on the sample and minimises the boundary effects (bedding and localised stress distributions) caused by the soil being in contact with the (much stiffer) end platens. Bender elements measure stiffness at even lower strains than local strain instrumentation and provide a completely non-destructive measurement of stiffness. They can be mounted in three orientations on a triaxial specimen and provide a very good indication of general sample condition and/or possible anisotropy.

During normal triaxial testing the pore water pressure is traditionally measured only at the base of the sample throughout the test. As the sample is in contact with far more rigid (usually metal) base pedestal and top cap, the areas at the specimen ends suffer boundary effects caused by the contact with the far stiffer material. For the calculation of shearing rates (time to failure) as per BS 1377:1990 we calculate that pore pressure dissipation is 95% only at the time of failure of the sample. The use of mid-plane pore pressure allows a second reference for pore pressure measurement and not only is unaffected by the metal pedestal (as it is in the central region of the sample), but can be used to display full pore water pressure equalisation throughout the sample (and not just at one end). This is ideal for drained shearing stages where the base and mid-plane pressures should remain the same if we are shearing at the correct rate. If the mid-plane pressure begins to deviate (increase) from the base measurement then excess pore pressures are being generated due to the sample being sheared too fast. For undrained shearing the pore pressures should react in unison and in the same direction (whether in compression or extension) again providing evidence that the correct shearing rates have been used. Interestingly, deviation between the base and mid-plane

may occur later during sample rupture as pore pressures may be generated/dissipated in different ways depending upon the inclination and orientation of any shear planes which may form in the specimen (and continued shear along rupture surfaces).

For rocks we can measure stiffness by carrying out a more advanced version of the uniaxial compressive strength test which also has additional high-resolution instrumentation which measures axial and radial strains. Because rock specimens fail at strains (usually an order of magnitude) lower than those of soils, specialist strain transducers (unsuitable for soil testing due to their very small range) are bonded axially and radially to the central third of the rock specimen. These are logged throughout the loading test and used to measure Young's modulus and Poisson's ratio.

Again, high technical competence is required for these tests. An ideal example is that the bonding agent used to bond the strain transducers to the sample must be able to not only prevent the gauges from creeping on the sample by bonding the gauge fully and remaining so throughout the test, but be of a lower stiffness than the sample itself so that they measure the natural strains evolving in the sample under load rather than the artificial strains caused by a stiffer bonding agent which may have locally filled the voids within the sample (causing a localised 'stiffer' response).

49.7 Compressibility

This is a term often used in soil mechanics and largely describes the relationship between stress and strain. It is the stiffness of the ground which determines the strains and displacements with changing stress and so by combining the stress level and stiffness of the material its compressibility can be determined. Laboratory tests associated with these parameters are:

- *Oedometer consolidation test*. Useful for Cv and Mv. The coefficient of consolidation (Cv) has the units M^2/year which is the 'scaled up' time (for consolidation) from the laboratory test to the full-scale field material being modelled. The coefficient of volume compressibility (Mv) has the units M^2/kN and is the slope of the porosity against the applied effective stress curve resulting from the test. Since porosity and void ratio are related quantities it also follows that Mv can be calculated from the void ratio against effective stress curve. It should always be remembered though that the value of Mv is dependent on the stress level applied.
- *Hydraulic cell consolidation test*. This is the full effective stress version of the above and is able to impose various loading conditions and drainage paths on the specimen. In addition the hydraulic cell can be used to measure the permeability of the sample at each consolidation stress along the drainage path used for the test.

Typical test equipment for these two types of test can be seen in **Figure 49.10** and a simplified line drawing of the loading and boundary conditions is given in **Figure 49.11**.

Reference should be made to **Figure 49.12** for an idealised consolidation curve. The first stage (primary consolidation) is the result of reorientation and re-packing of the soil particles with the expulsion of water from the voids. Secondary consolidation is the actual compression of the soil particles themselves with a further expulsion of water (mainly from the particles as they themselves compress). It is most important to identify the presence of organic materials, especially peats, and understand their compressibility characteristics as settlements may be orders of magnitude higher than those associated with non-organic soils. Both the oedometer and hydraulic cell can also be used for secondary consolidation or 'creep' monitoring. Secondary consolidation is the continued compression of a soil after primary compression is complete and is caused by viscous behaviour of the soil grain–water system or the physical compression of organic matter. For quartz sands we expect

Figure 49.10 Oedometer (left) and hydraulic cell (right)
Courtesy of VJ Tech Ltd

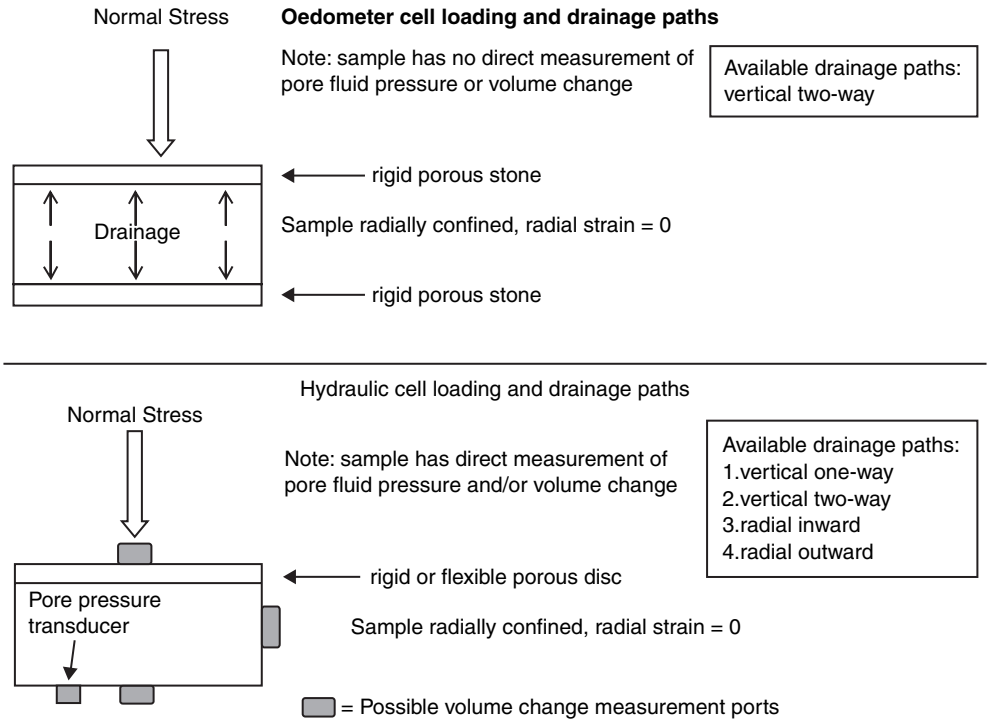

Figure 49.11 Oedometer (top) and hydraulic cell (bottom) loading and drainage paths

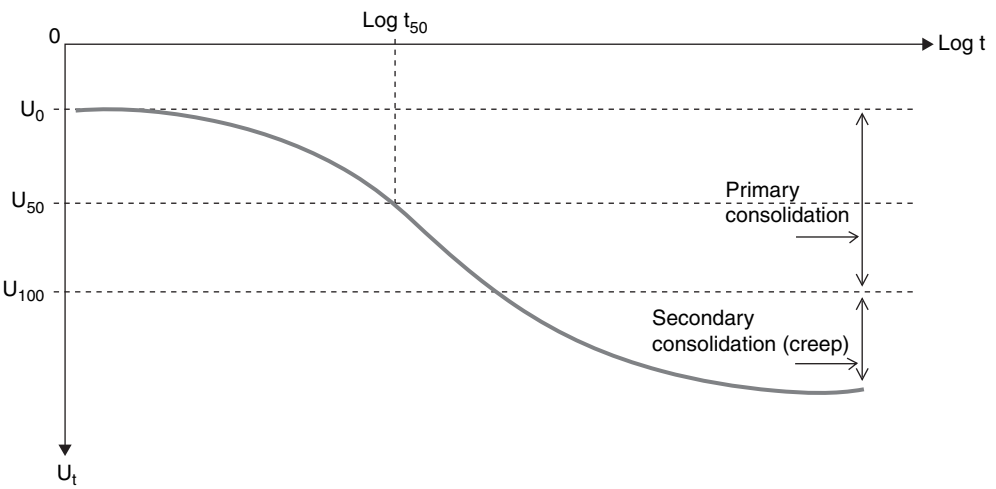

Figure 49.12 Log time consolidation curve

that creep (secondary compression) would be negligible as the sand grains are generally non-compressible. Other sand types (such as calcareous or carbonate sands) may show different behaviour or 'sudden collapse' if the normal stress exceeds the ultimate strength of the grains (and their asparites), leading to failure of the grains themselves. For peats and organic soils the soil 'solids' are themselves highly compressible and so a two-phase consolidation process is often seen with organic materials. Secondary consolidation also occurs in clays and can play important roles especially when dealing with very soft clays. When scheduling tests with the requirement for secondary consolidation parameters always bear in mind that these tests may take days, sometimes weeks per loading stage and have not only time but cost implications to match over the 'standard' tests where the interest is in primary consolidation only. It should also be noted that due to the fabric/structure of peaty materials they may show highly anisotropic behaviour especially with regard to drainage directions due to the orientation of the long axis of the vegetative material causing preferred drainage paths. In instances where these preferred paths have been identified it may well be preferable to schedule the use of the hydraulic cell and schedule a suitable drainage path/direction.

For rock materials we often assess compressibility from the intact strength of the rock material along with its discontinuity spacing and aperture (rock quality designation – RQD). It is possible to test rock samples for compressibility in high stress equipment; however, remember that you are only testing the intact material. *In situ* the bulk strength and compressibility of rock materials are usually dominated by their discontinuity spacing/orientation, aperture spacing/orientation and aperture contact areas. Other means (preferably field-based) should be used to assess these engineering characteristics.

It can be seen from the parameters gained from such tests that the soil structure and fabric (which controls drainage paths) are the controlling factors (material properties) that are being measured. Undisturbed samples of known orientation are the basic prerequisite for such tests. Re-moulded samples may be used if the construction requires design parameters to be used for such 'engineered' materials. Attention to sample quality and test preparation is paramount, especially as such small samples are tested and then the results scaled-up to the field model. Small errors magnify!

49.8 Permeability

For design purposes or interest in seepage problems we need to think about drained and undrained conditions or short- and long-term behaviour of the ground. This is dominated by the particle size, orientation and packing of the soil grains and whether they are cemented (in the case of hard pans or calcareous zones), cohesive or non-cohesive. Careful thought should be given to the sampling of such materials as the size, orientation and packing of the particles can lead to strong anisotropy *in situ* leading to high variations in permeability with flow direction. Sampling and the correct orientation of samples selected for laboratory testing is of paramount importance if true ground conditions are to be modelled representatively. Laboratory tests associated with the determination of permeability are:

- *Constant head permeameter*. For non-cohesive materials. Sample is radially confined, therefore lateral strain is zero.
- *Constant head permeability determination in a triaxial cell*. Normally for cohesive materials and where desired mean effective stresses are required. The sample is isotropically consolidated and a pressure differential applied (driving head) to the separate top and base drainage lines causing flow to occur.
- *Permeability determination in a hydraulic cell*. This equipment, mentioned previously, can be used to measure permeability along different vertical or horizontal drainage paths and can be carried out as part of a test which also gives consolidation parameters. For the possible flow directions available see **Figure 49.10**.

For rock samples, intact specimens can be tested (usually constant head), but it should be remembered that the permeability of the *in situ* material may be dominated by the presence of discontinuities and their aperture/orientation, infill, spacing and persistence.

49.9 Non-standard and dynamic tests

By mentioning the broad range of basic (and some more advanced) parameters which can be gained from the test types outlined previously, it would also be prudent to write a little about the more 'advanced' types of test which are also available in a few specialist laboratories. These tests are certainly not routine and require the use of highly specialist equipment and highly experienced staff.

Due to modern construction requirements and the need for design with dynamic loadings (such as wind turbine monopiles, etc.), geotechnical engineers are increasingly asked for the dynamic parameters more associated with those for foundation design in earthquake regions. Other tests are not necessarily 'dynamic' but are equally more towards the research end of testing. As with the anisotropic triaxial tests and their advanced instrumentation, these test types are often more appropriate to advanced numerical analysis designs and studies. They are certainly not routine and often come with a price tag to match; however, you do get what you pay for (as long as open and clear communication prevails throughout).

The following list is not exhaustive but is intended to highlight some of the more common research-level tests available and the apparatus associated with them.

49.9.1 Cyclic triaxial test

As it is named, this is a 'hybrid' triaxial testing frame which is built to 'cycle' the soil/weak rock sample by either stress or strain control around a mean level at rates commonly around 0.3 Hz with data capture of the transducers at many times a second. Cyclic strength depends upon many factors, including density, confining pressure, applied cyclic shear stress, stress history, grain structure, age of soil deposit, specimen preparation procedure, and the frequency, uniformity and shape of the cyclic wave-form (ASTM D5311). In addition it should be noted that non-uniform stress conditions are imposed by the specimen end platens which may cause a redistribution of void ratio within the specimen during the test. These tests are often carried out on non-cohesive soils and, since such materials are unable to withstand tension, the maximum cyclic shear stress that can be applied to the specimen is equal to one half of the initial total axial pressure (ASTM D5311). Care should obviously be taken in the design of such tests, and thought given to the fact that uneven pore pressure distributions throughout the sample may result depending upon the permeability of the soil and the rate at which it is cycled. Young's modulus and soil damping properties can also be evaluated for specialist design using this test type (ASTM D3999).

49.9.2 Simple shear

This can be carried out either as a monotonic test or as a dynamic cyclic test. The shear strength is measured under constant volume conditions that are equivalent to undrained conditions for a saturated specimen; hence, the test is applicable to field conditions where soils have fully consolidated under

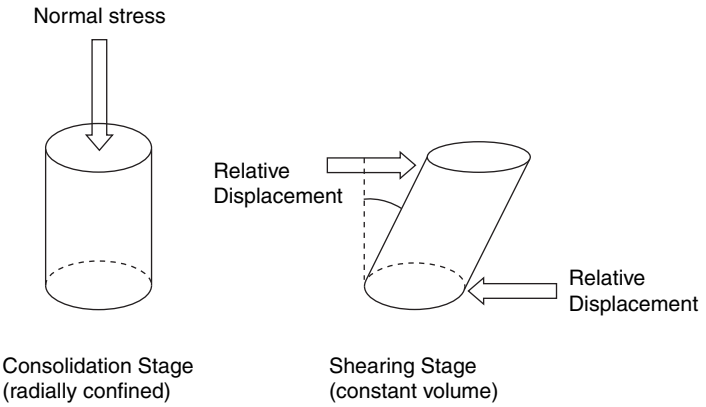

Figure 49.13 Simple shear mechanism

one set of stresses, and are then subjected to changes in stress without time for further drainage to occur (see **Figure 49.13**). The constant volume (undrained strength) is a function of stress conditions (plane strain) and the principal stresses continuously rotate due to the application of shear stress. This simple shear stress condition occurs in many field situations including zones below a long embankment and around axially loaded piles (ASTM D6528).

49.9.3 Resonant column

Figure 49.14 shows a resonant column with the cell top removed. The top part of the equipment is used to induce torsional movement to the top of the sample by an electromagnetic drive system which can run at a range of frequencies to determine the resonant frequency of a sample.

Such tests and test equipment are used to evaluate the shear moduli and damping characteristics of soil at very small strain amplitudes. Although there are two distinctly different equipment types for these tests, both apply torsion/rotation to the top of the sample in order to find the resonant frequency of the material at a controlled stress. These test methods are non-destructive if the strain amplitudes are less than 10^{-4} radians and many measurements may be made on the same sample and with various states of ambient stress (ASTM D4015).

49.9.4 Hollow cylinder test

Certainly the rarest of commercial tests, this equipment allows a rotational displacement to be imposed on a 'hollow' cylindrical specimen where independent control can be maintained for all three principal stresses (unlike triaxial tests which can only independently control two of the three principle stresses (where $\sigma_2 = \sigma_3$)). For this reason studies can be made of the intermediate principal stress (σ_2), sample anisotropy and the effects of principal stress rotation. These are 'research level' tests and the parameters derived are usually only used for the most advanced numerical analysis. Tests are available for both soil and rock and the hollow cylinder is most useful in the definition and determination of anisotropic material properties.

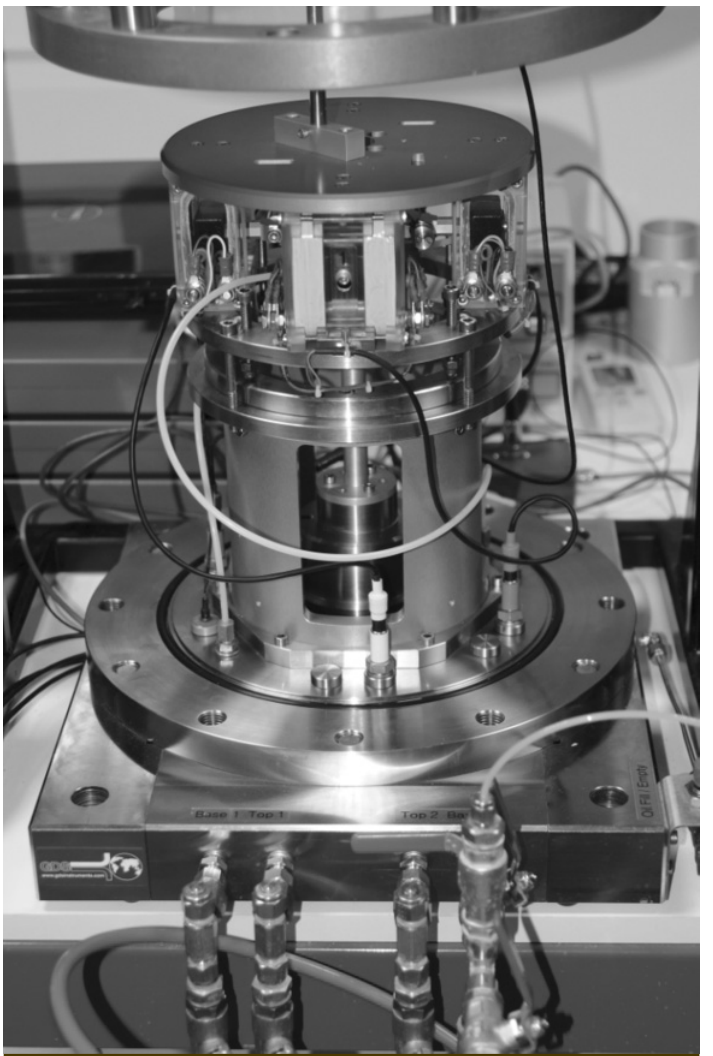

Figure 49.14 Resonant column apparatus
Courtesy of Russell Geotechnical Innovations

Simpler but equally non-routine tests can be used to model specific behaviour of soils and materials. The shearbox can be used to model the frictional behaviour which occurs at the interface between soil and a geotextile/steel/concrete surface. A ringshear can be used to model the soil behaviour at an interface between soil and a steel pile (Jardine *et al.*, 2005). In addition tests can be carried out to determine the dispersion or erodibility of soils and rocks when abraded or exposed to persistent high moisture contents or flowing water. The tests listed in this section are certainly non-exhaustive and complete volumes could be written about laboratory testing and parameter determination. A good general series of volumes to read are those by Head (1986), *Manual of Soil Laboratory Testing*.

49.10 Test certificates and results

Test results are issued as certificates which identify the parameter requirements, data and graphs in accordance with the test methods and standards used. There should be no problem

requesting further detail from the laboratories involved, to understand or verify any particular test conditions or methods used. It is here that open communication is important, and always remember that you are the paying customer. This line of communication should also allow the laboratory to freely communicate any observations or potential sample problems which may lead to unexpected results. It is this knowledge sharing that will improve the resultant parameter and overall design quality.

In order to supplement our ground model and design requirements we can see that careful planning at all stages of the ground investigation process is required and hence, why the natural process order of this chapter has been reversed somewhat. This process of investigation from sampling techniques through to sample storage, transport and laboratory testing requires careful planning and supervision. Any loss in integrity of the sample material properties at any stage in this sequence could have catastrophic effects on the parameters supplied from the testing house. These parameters are largely interlinked, especially moisture content and the sample physical integrity which dominate the effective stress characteristics. Geotechnical engineering is one of the only sciences which starts with a natural material being removed from a stable environment (the ground) and taken through a series of potentially damaging processes, through water addition/loss, exposure to atmosphere, physical handling (including jarring and vibration), temperature cycles and, finally, to a 'stable' environment where the material is tested for specific parameters which are to be representative of the ground from whence it came. How do we do it? This is the difference between a good site investigation (and all of the processes involved therein) and a not so good site investigation.

Fundamental in this way of thinking is the preservation of the sample moisture content. The determination of moisture content in the laboratory is only accurate if the sample retains the same moisture content that it had at that time in the ground. The determination of bulk density, strength, effective stress and stiffness, to name but a few, are all controlled by moisture content. If this is allowed to change between sampling (or altered by the sampling method) and the final test then the design will be based on erroneous values.

To realise this from the planning stage will help to identify possible problems and build them into the specification, and drive the ground investigation in the correct way from the start. If all stakeholders are involved in the initial stages and the project expectations and responsibilities are clear then the majority of these 'integrity loss' components can be minimised. The sample tested in the laboratory is only as good as the sample received there and this also assumes that the correct test was scheduled and that the laboratory was proficient in that particular method.

49.11 Sampling methods

This part of the project will have been conceived at an early stage as the ground investigation contractor will need the relevant equipment and correct experience for the project awarded. They will need to extract the samples from the ground and to deliver them to the laboratory for testing in the best possible condition. Here a chain of custody is formed and the 'smooth' operation of this will depend upon the sharing of information and open communication which will allow some flexibility to be built in for 'on-the-job' improvement. In an ideal world the laboratory will test a soil or rock which is in the same condition (and is therefore entirely representative) of the material *in situ*. This chain begins with the excavation of a trial pit or the drilling of a hole. A sample is then taken in various ways (to be explained later in more detail) and sealed in order to maintain its integrity. This sample is then either stored or immediately transported to a laboratory for testing, where again it may be stored (in a queue) whilst awaiting testing. Sampling for chemical and contamination testing is dealt with in Chapter 48 *Geo-environmental testing* of this volume and should be referenced as necessary. Here we are dealing specifically with sampling of the ground for the physical testing required for design parameters. There are many sampling methods available globally, but may be categorised simply as bulk samples, block samples, tube samples and rotary-cored samples. Each category has associated levels of disturbance and some indication of these is given along with the basic requirements for sample preservation. The following list is certainly not exhaustive but should indicate the main principles for 'good practice'. The reader must also adhere to the provisions of Eurocode 7 or other prevalent standards depending upon the geographical location of the investigation or agreed project requirements. Eurocode 7 is very prescriptive in terms of the sample types which may be used for various types of test as are many of the other standards generally used worldwide.

49.12 Bulk samples

This constitutes probably the simplest but the most disturbed sample type. Samples are often hand- or machine-excavated from a trial pit or spoil heap and placed in bags for logging purposes or index tests only. These samples should be of sufficient size to be representative of the horizon of interest, uncontaminated by material from other horizons, and of sufficient quantity for the testing required.

For bulk samples the material should be sealed in a bag with as much air evacuated as possible in order to prevent the sample from 'sweating' or the production of mould during storage. No samples, even if fully sealed, should be left in sunshine as this will not only cause the sample to 'sweat', but will also cause non-uniform heating leading to expansion/contraction of any fissures or textural fabric or aid the growth of mould, fungus or microbial organisms which again may alter the material properties. Any sample should be kept at a constant temperature and away from any localised heat sources. In the UK such temperatures should be no more than 20°C and no less than 5°C (under which the sample may begin to freeze). This is a range of temperature in which the sample may be kept, but it should not be cycled more than 3°C over a mean temperature if at all possible.

49.13 Block samples

Block samples are undisturbed hand-dug blocks which are usually some 0.5 metres square or diameter and at least 0.3 metres in depth. They are then sealed with an impermeable barrier followed by a rigid supporting container constructed around them. This is followed by careful paring from the substrata and removal for total sealing and support for storage and transport. Bearing in mind the preservation of the sample which is required, site- and environment-specific methods would be required for taking block samples and preserving the *in situ* characteristics of the medium sampled. Such samples are limited by access and depth of interest as space is required for personnel to cut the block safely and extract it from the horizon of study.

49.14 Tube samples

Tube samples are taken in a variety of ways depending upon equipment available and access.

The most common tube sampler used in the UK is the U100 and is often used in conjunction with light percussion drilling techniques (tripod-type rigs) where the tubes are driven into the ground. You will easily visualise the disturbance which the material may undergo by having a tube 'hammered' into it. This is part of the reason why U100 tube samples are not suitable for undisturbed testing parameters (but fine for index tests only and logging purposes). Tubes may also be 'pushed' into the substrate using piston-type (fixed piston) equipment which 'jacks' the tube into the bottom of the borehole. This method is superior and when used in conjunction with thin-wall sample tubes provides acceptable quality undisturbed samples. For thin-wall push samples, make sure that the end of the tube has been sharpened, has no burrs and that it is straight and true (at least before it is used). After sampling, also check that the tube has remained straight and true. If the tube has buckled or deformed during the sampling process then the soil within will have deformed (strained) as well, rendering it unsuitable for high quality parameter determination. For tube sampling the basic stages are outlined in **Figure 49.15** (Hight, 2000). From this we can determine the stresses to which the sample is exposed. Disturbance may be caused at any stage in the process but probably the most destructive is when the sample tube actually penetrates the bottom of the borehole (Hight, 2000).

For sampling to take place, the tube (and cutting shoe for U100s) is required to be pushed into the ground. Due to this additional material (sampler) being introduced into the natural soil the bulk density of the material into which they are inserted changes whilst the sampler is intruded into the bottom of the borehole. With this in mind we should in theory use a sampler which has as thin a wall and as sharp a cutting tip as possible in order to prevent local ground densification and undue strains or fabric disturbance. The sampler should be pushed in smoothly and without side movement or jarring (not percussive techniques). From this it can be understood that the area ratio (%) of a sampler plays an immense role in the disturbance of the sample taken. The area ratio is calculated as the volume of soil displaced by the sampler as a proportion of the sample volume (calculated by measuring the internal and external diameter of the cutting shoe or edge). In theory, the lower the value, the less disturbed the material within. Clayton and Siddique (1999) examined the different effects of tube geometries and used examples from the four main sample tube geometries used in the UK at that time plus a fifth experimental design. The geometries of these tubes are shown in **Figure 49.16**.

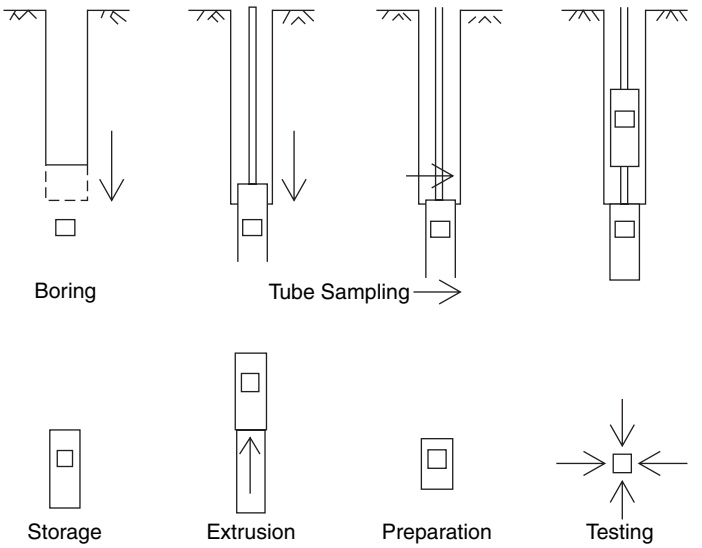

Figure 49.15 U100 Sampling stages
Reproduced from Hight (2000)

Sampler 1 is the geometry of the cutting shoe used on standard 'metal' U100 sample tubes and has an area ratio of 27%. Inside clearance is obtained by a step out from the cutting shoe where it screws onto the sample tube above it.

Sampler 2 is an upgraded version of sampler 1. It has a very similar area ratio, but with an inner step which is replaced with a slight taper and the cutting edge tapers that have been reduced (sharper).

Sampler 3 is the version of the UK cutting tube used for U100 samplers with plastic liners. The area ratio is considerable at 48% and again a small step inside produces the inside clearance between the shoe and the liner.

Sampler 4 is the 'thin-wall' push sampler which has been widely used in many circumstances to produce quite high quality samples. The original tube was described by Harrison (1991) and consists of a tube (normally stainless steel) with a 15° taper on the cutting edge. This tube is 'pushed' into the bottom of the borehole rather than 'hammered' like the previous samplers.

Sampler 5 is an experimental sampler (Hight, 2000) which is similar to sampler 4 but is sharper (5° taper) and has a 0.1 mm flat at the cutting tip.

This is not intended to be an academic publication but it is more than prudent to give some background to the sampler types with regard to sampling and disturbance and link them to the parameters required from the samples. From research

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

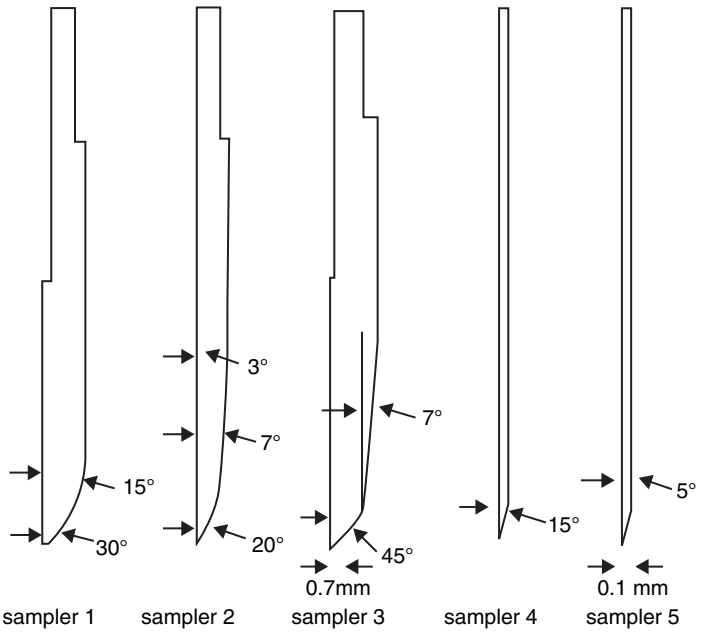

Figure 49.16 Tube sampler geometries
Reproduced from Clayton and Siddique (1999)

testing and some very high grade commercial tests it is known that on natural stiff clays such as London Clay failure occurs at axial strains in the region of 0.75–2.0%. Clayton and Siddique (1999) studied the sampler geometries and made strain predictions along the centre line of the sample as it would be taken using the different geometries (**Figure 49.17**).

From this we can see that samplers 1 and 3 are likely to fail the natural stiff clays during sampling due to the strains imposed on the specimen with sampler 3 being by far the worst offender. The thin-wall push samplers outperform all geometries modelled and sampler 4 should be used as a minimum if stiffness parameters are required. For normally consolidated and lightly overconsolidated clays Hight (2000) notes that the strains at the periphery of the sample, during sampling, causes a zone of re-moulded soil which combines with shear-induced pore water pressures which increase across the sample and are at their highest at the periphery. This leads to an overall reduction in mean effective stress caused by an increased water content in the centre of the sample as the sample re-equilibrates (due to the highly disturbed periphery). The same outcomes are true for overconsolidated clays along with damaged material structure and fabric.

Due to the high permeability of sands, tube sampling will be 'drained' and both volumetric and shear strains will occur (Hight, 2000). Levels of sample disturbance will vary with the *in situ* density of the material and destructuring/density changes will result due to the yield strain at the particle contacts being very low.

For all tube sampling methods it is imperative that the base of the borehole is cleared of debris before the sample is

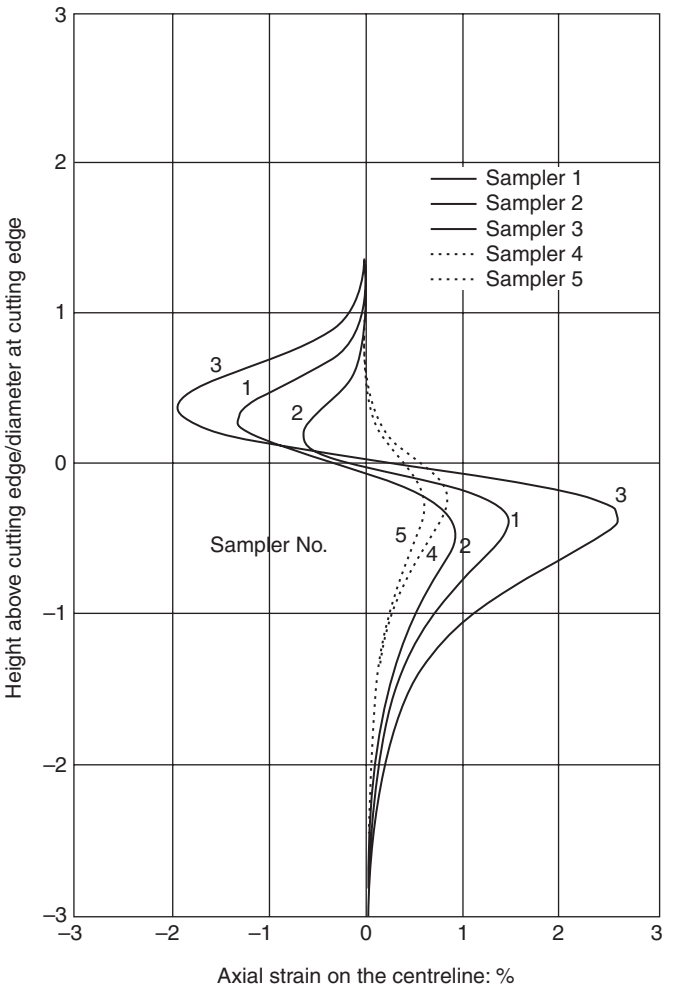

Figure 49.17 Sampler predicted axial strains
Reproduced from Clayton and Siddique (1999)

taken. If this does not occur, the tube will be filled with varying amounts of highly disturbed material which may have very high moisture contents leading to incorrect borehole logs and unrepresentative soil parameters.

On extraction from the borehole the sample tubes should be cleaned and any excess water immediately removed. The intact samples recovered should have their ends painted with low melting point wax and an identification label (indelible ink) placed in the top of the tube and marked as the 'top'. In cases where full recovery has not occurred, an inert non-compressible material should be used to fill the void left in the tube before the sealing caps are put in place. This is carried out to prevent the intact sample sliding around in the tube. The tubes should be stored and transported upright with the top of the sample uppermost. This is most important where soft samples have been taken which may try and 'flow' down the tube if knocked or vibrated during handling or transportation. Even the more competent samples may suffer from fissures opening up if stored on their side when moved

or transported. The end sealing caps should be clearly marked with all the samples' details and way up, again with indelible ink. The tubes should be preferably marked both ends just in case the identification from one end is unreadable or removed (markings on the side of the tube are often rubbed off during handling and transport). A waterproof identification label should also be placed within the top of each tube as a failsafe.

49.15 Rotary core samples

This sampling method is probably the most common high quality method used extensively in the UK and in many circumstances is superior to thin-wall push samples. The advantage here is that the material is removed from the cutting face of the drill bit and so the sampler does not densify the soil as it is inserted but simply 'reams' a stick of intact material from the ground. The drawback is that some lubrication in the form of drill flush is required which means the possible addition of moisture to the sample; however, with sufficient expertise and thought this can largely be overcome.

Rotary drill rigs come in various sizes depending upon access and depth of hole required. A lorry-mounted rotary rig can be seen in **Figure 49.18** whilst a smaller tracked rotary rig (**Figure 49.19**) can be used for slopes or where there is limited access.

These rigs can use a variety of drill bits and drill flush agents depending upon the types of material encountered. They are far too numerous to list here, but if in doubt, drilling trials can be written into the ground investigation plan in order to verify sample quality and recovery before the main exploration phase begins. Typically triple barrel core tubes are used in which the innermost barrel is a semi-rigid plastic liner which enables the sample to be removed without undue stress. Using such equipment correctly and safely requires specialist contractors with knowledge and experience and care should be taken when choosing such contractors. With this method it is possible to sample not only rock, but firm through stiff to hard clays and compact sands. With the correct drill equipment, cutting heads and flush recovery should be very good.

Following is an overview of the field sampling procedure in order to identify the main processes. Variations are allowable depending upon particular requirements and conditions but these must be agreed by or scheduled by the client.

1. Gain a suitable sample from the ground.
2. Clean the sample in such a way that will preserve its strength and fabric retaining the properties of the same material *in situ*.
3. Sub-sample and/or trim the specimen to a size (normally H:D = 3:1) that is suitable for a laboratory test (triaxial or other).
4. Preserve the specimen so that it may be stored until testing is required.
5. Protect the sample from the effects of time and any changes to environmental conditions which may alter the properties or integrity of the sample such as storage temperatures, cycling ambient temperatures, transport shocks and vibrations, ultraviolet light.

The full specification for the preparation and storage of samples from drilling a rotary core ready to be tested in the laboratory may take the form of (but not be limited to the following):

- Remove the core from its liner immediately on extraction from the ground in order to remove drill fluids used and protect the natural moisture content and physical integrity of the core. The core liner should be split diametrically in two halves by using some form of counter-rotating opposing blades set so that they cut the plastic tube (liner) without cutting into or marking the sample within. The use of sharp knives for this operation should not only be prohibited for health and safety reasons but also due to the force required to penetrate and then pull along the tube. This may not only damage the sample within but there is a high risk of operator/spectator injury when slips occur.
- Clean off by wiping with an absorbent cloth any drill fluid or flush/water from the outside of the core.

Figure 49.18 Lorry-mounted rotary drill rig

- Log the core and sub-sample by carefully cutting for laboratory testing. Samples intended for triaxial testing should have an approximate length to diameter ratio of 3:1 (which will allow for later trimming in the laboratory).
- The sub-samples should then have their extremities prepared for sealing. Rotary-cored samples with very high permeabilities – compact sands for example should have any drill flush removed from their extremity and immediately be sealed. Clays should have the outer 5 mm of the sub-sample carefully trimmed off in a soil lathe in order to expose 'fresh' material which has not been contaminated with drill fluids. This process should be carried out very quickly for both material types but for slightly different reasons. For sandy materials it is important to prevent moisture loss (due to the relatively high void ratio and permeability) and for clay-type samples to prevent moisture ingress softening the sample and reducing its effective stress. Care should be taken that this process is carried out swiftly and in an environment suitable to reduce evaporation and localised heating of the sample.
- The sub-sample should then be sealed in such a way to trap minimal air, not only to maintain its natural moisture content but also its physical integrity for storage and transport. Often samples are wrapped in a layer of aluminium foil for the first layer, which is fine for most sample types as it can be lightly moulded in order to expel air and maintain contact with the sample surface as an impermeable barrier. Some thought should be taken though as salt water and some alkali pore water along with alkali minerals (gypsum) can react with the aluminium causing loss of sealing and reaction with the sample itself. In these instances non-permeable plastic film should be used as the first layer. Traditionally (and because it is commonly available from the local shop) many core sealing operations are carried out using plastic food wrap. The only problem with this is that this stretchy plastic 'food wrap' is by its nature osmotic or semi-permeable, and therefore not ideal. It has been found that the plastic film used to wrap pallets is not only stretchy, strong and seals against itself but is non-osmotic and impermeable. The sample should then have a layer of such material wrapped round two to three times to completely encase it. A label should be enclosed providing the sample identity and orientation. The complete sample should then be coated with low melting-point wax (which is usually a mixture of 50% petrolatum and 50% paraffin wax) which is quite soft and 'sticky'. *Not pure candle wax* (as its melting point is too high). This wax should be heated only to the temperature required for melting and not to the point of boiling. This is not only a health and safety issue but the idea is that as soon as the wax contacts the cooler specimen it will set whilst transferring minimal heat to the sample. The sample should not be dipped in the hot wax pot but should be painted with a brush dipped in the warm wax. These alternating coatings/layers can be repeated in order to protect the sample further, but the sample identity should always be clearly visible. Strong tape such as carpet tape should then be wrapped around the ends of the sample to protect the wax and layered coatings from damage. Finally the sample may be placed in split core liner which is then taped in order to give support to the sample. This core liner (or suitably rigid material) should be cut to the length of the sample so that the sample is retained rigidly and is unable to move about within its support. Caps should be placed over the ends in order to complete the encapsulation. The sample should be relabelled in an indelible fashion with full identification and orientation (top/bottom).
- In essence the sample is to be preserved as near as possible to the condition as it was *in situ*, but isotropically de-stressed. This preservation must be able to withstand handling transportation and storage which in some instances may be for some appreciable time.

49.16 Transport

This is a simple process, but very often overlooked. The samples should be transported in such a way that they are not shocked, dropped or vibrated. If sample integrity is an issue then the samples should be protected accordingly. Personal delivery and transport within the chain is often the only way to maintain high integrity. External transport contractors often do not appreciate the care required when handling a piece of 'soil' and so this should be avoided. Many couriers see such parcels as just 'heavy' rather than highly fragile scientific material. The samples should be transported 'upright' and in a way that they are supported laterally (padded boxes) to prevent toppling, rattling and vibration. Even when transported personally, the samples should not be placed in footwells where they are near heating/cooling vents which may locally heat/cool the samples. This completes the chain of custody to the testing laboratory who will then test the samples for the parameters required.

49.17 The testing laboratory

There are many testing houses available throughout the world, and offer testing to many levels and standards. Care should be taken in choosing the testing laboratory as it is relatively simple for them to buy the equipment to carry out tests but this does not mean that they are proficient in that particular test. Make sure that you are clear about the parameters you require from your tests and the identity of the samples to be tested. Bear in mind that you will need sufficient soil sample of the correct quality in order for the tests to be representative. It is often a good idea to visit prospective laboratories, if possible, and again this promotes the sharing of information and keeping up-to-date with the latest testing and contractual developments. You will also be able to assess the level of expertise, the equipment and processes involved with your proposed testing. Some tests may be beyond the scope of external accreditation bodies (and the accreditors!) and in this instance the reputation and experience of the staff carrying out the tests will prevail.

Over the years the writer has seen some 'very interesting' practices carried out in a range of laboratories; some with high levels of external accreditation. These accreditations are not a guarantee of high quality but proof of a level of proficiency and management system on the day of the audit. Procedures, systems and tests are audited (often by external auditors) so that a certificate can be issued providing evidence of compliance and repeatability. However, this does not necessarily mean that the result issued will be correct. It is very possible to follow an incorrect method repeatedly and gain the incorrect results repeatedly and still be accredited for this! There are many good laboratories out there. Find them and use them.

The new Eurocodes are addressing the standardisation of modern drilling and sampling practices and their relative merits with regard to sample quality for laboratory testing. Hopefully

the demise of the U100 plastic liner sampling system has arrived as samples from such tubes are 'highly disturbed' and are therefore of little value for laboratory testing apart from index properties. Strength, compressibility and permeability determinations will be in varying degrees of error to the material *in situ*. Where the intention is to study the variation of these parameters with depth, U100 tube samples are not good and often contribute to the 'scatter' we see in plots with depth. This, along with other 'mishaps' and lapses in attention or detail in the chain from sampling to testing, all adds to the error band or 'scatter'. Much of this can be avoided very simply through care and attention to detail. Unfortunately this is sometimes lost in the pressure of 'getting the job done'. The parameters we require from these samples for our design should be representative of the material *in situ* and not to the environments which the material has been exposed to on its journey from the ground to the laboratory (and subsequent test methods).

This completes the physical sampling/testing loop of ground investigation. You should have spare material if possible for alternative or repeat tests should you find the need for additional testing. It is very expensive to re-drill or have further boreholes sampled at a later date. All data from testing should be available if required for further analysis even down to the weights for moisture contents or the cone values and moisture contents for Atterberg determinations.

It is understood that in some instances and in some areas around the world some deviations from these guidelines will be required; however, the same principles and ideals should be followed. Notes should be kept as to the methods used and the environment in which the samples were taken and sealed including dates, times and personnel involved. Everything that we do as professionals should be able to withstand scrutiny but also provide sufficient data to repeat or improve our activities in the interests of a forward-looking science. The attention to detail in the complete chain of custody will pay dividends in the quality of the subsequent tests and parameters derived.

ASTM International (formally known as the American Society for Testing and Materials), contains many internationally recognised references for soil and rock testing; www.astm.org

Home of the British Geotechnical Association, contains information for updates of many relevant technical Standards and links to many other sites of interest; http://bga.city.ac.uk

British Standards Institution, references for UK and European Standards including training and accreditation; www.bsigroup.com

Engineering Group of the Geological Society (EGGS), many useful references for rock behaviour and categorisation; www.geolsoc.org.uk

International Society for Rock Mechanics, contains the European suggested methods for various rock tests (the 'Blue Book'); www.isrm.net

It is recommended this chapter is read in conjunction with

- Chapter 17 *Strength and deformation behaviour of soils*
- Chapter 18 *Rock behaviour*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Appendix A
Standard soil and rock tests

The standards named here are generally applicable to the UK and should be used in association with the present guidelines required to apply to *Eurocode 7: Geotechnical Design – Part 2: Ground Investigation and Testing* (BS EN1997-2: 2007). Eurocode 7 is applicable to European construction and may be accepted in other parts of the world. It should be noted that different standards may apply depending upon the various locations around the world where the construction is to occur. The other major standards applied worldwide are the ASTM standards and these should be applied or used where applicable.

The list here is not exhaustive and is only an indication of some of the more common soil and rock tests available. It should also be noted here that the European standards for the identification and classification of soils and rocks (BS EN ISO 154688-1 (2002), BS EN ISO 154688-2 (2004) and BS EN ISO 14689-1 (2003) implemented into UK practice in 2007 have all been incorporated into BS 5930:1999 Amendment 1 which incorporates a revised section 6 (published in 2007). Earlier versions of BS 5930:1990 do not meet the requirements of the new Eurocodes and would not comply with the recent code changes.

50.6	References	697

Geotechnical reports exist in a number of different forms, each with its own distinct purpose. However, all geotechnical reports should be written with an understanding of the project that they have been prepared for and the use to which the report will be put. Geotechnical reports of all forms must be clear and concise, such that the information contained within them is accessible and unambiguous. If the project programme is such that some information to be contained within the report is required urgently, it may be appropriate to produce multiple reports, or addenda to a main report, rather than delay issuing the time-critical information. Since a report can provide useful information long after it was first commissioned it is important to ensure that all reporting is properly archived, and thought is given to how the information contained within the report will remain accessible.

50.1 Factual reporting

50.1.1 Introduction

The primary purpose of a geotechnical factual report is to accurately and precisely describe the ground 'as found': as it occurs *in situ*. While this description should be made with the knowledge that the end-user of the report is likely to make use of the report to design and construct some form of construction, a factual report is not interpretative: the report should be factually accurate and as complete as possible, and not written on the assumption that construction will be of a certain form or use certain techniques. Factual reports are mostly typically the method of reporting site or ground investigations. Such investigation works are often undertaken at an early stage in a project, and the information from the site and ground investigations may result in changes to the layout, nature or methodology of construction of the proposed works. Hence a factual report should always be a complete record of all factual information available, and no attempt should be made to interpret data, or assign design parameters or make design recommendations. If interpretation and recommended parameters are required, this requires completion of an interpretative report (see below).

Thus a factual report should be a clear, concise, complete and accurate description of the ground 'as found'. The nature of this description is dependent on the methods and techniques which have been used to obtain the information which is being reported.

It is important to realise that the true behaviour of the ground *in situ*, and its response to any construction work that may be undertaken which affects it, can rarely if ever be precisely determined through investigation techniques. All methods of inspection, sampling and testing of the soil that are available by their nature are limited to testing a limited volume of soil: this may amount to many tens of cubic metres of soil for *in situ* testing, or as little as a few grams of soil in a laboratory test. However, no test truly determines the response of the entire *in situ* soil mass for the full range of conditions. The difference in volume of soil testing can result in apparently factual data that are inconsistent: for example, it is well known that the factual result of laboratory permeability testing gives a different indication for a soil's permeability than a variable head test undertaken in a borehole. This is a reflection of the scale effects that apply: the structure of a small intact laboratory sample is much less likely to contain large fissures than the volume of soil affected by an *in situ* variable head test, and as a result often gives permeability results two orders of magnitude lower than the field test. Both tests are 'correct' and give factual information; neither necessarily gives an entirely true and accurate value for the soil permeability. Clearly, any report giving the measured permeability of the soil would need to give complete information on the nature of the test used to determine permeability, so that the end-user would have some indication of whether the test was obtained from a small sample or larger soil mass.

Factual reporting also needs to provide complete information about the nature of the techniques used to recover and test samples, since it is necessary to allow for how such techniques may have affected the information obtained. For example, soil and rock core recovered from rotary-drilled boreholes may have drilling-induced fractures which are not indicative of the state of the material *in situ*; methods of sampling can induce stresses and/or deformations in a sample, affect moisture contents and soil suctions, etc. Thus reporting a laboratory test without reporting the method by which the soil sample was obtained may render the entire test worthless, if the result may have been significantly affected by sampling disturbance.

In undertaking factual reporting, there is already much guidance. The majority of ground investigation techniques used on site, and laboratory test methods applied to determine soil parameters, are defined through British standards. These have relatively recently been supplemented or superseded by European standards, which while not identical in their

requirements, are equivalent in defining methods of undertaking and reporting work. Beyond this, there are national accreditation schemes, applicable to laboratory testing in particular (both geotechnical and environmental), which provide further guidance on the format and content of test reports. Other publications, for example the Specification for Ground Investigation (Site Investigation Steering Group, 1993), also include guidance as to what data should be reported as part of a factual report. However, there are still many techniques or tests where the available guidance is incomplete or absent, and particular project/client requirements or new research leading to changes in the understanding of how a test or technique works may result in the requirement to report factual information in a non-standard manner.

50.1.2 Methods of obtaining details

The information provided in a factual report obviously depends on the nature of the works being reported.

50.1.2.1 Non-intrusive

There are a variety of non-intrusive works that may be undertaken for engineering or geotechnical purposes that require reporting. Most typical would be a simple site walkover. This may be of a relatively small site, but could equally extend to very large worksites, particularly for larger infrastructure projects, where the site may be very linear in nature. Where sites are extensive in nature, the simple walkover may be supported or even replaced by aerial photographic survey. There is also the potential for geophysical surveys to be undertaken, which may be by surface (using hand-held or vehicle-mounted equipment) or airborne. Geophysical surveying may also be undertaken in a marine/overwater environment from boats.

Both the site walkover and the aerial photographic survey are fundamentally visual surveys, aiming to identify and report the same types of features. The intention is to identify and report those features of the ground that constitute potential hazards to the proposed project. Most commonly, this is areas of unstable land: active or relic landslips. Reporting such surveys therefore requires that all indications of current or previous ground movement be identified: distorted fences, tilted walls or trees and slip-scars are all obvious features. Aspects of site drainage are also important to identify, and this can be done through reporting of obvious drains, streams or larger watercourses, including those dry at the time of the survey. However, general geomorphology and land use (particularly the nature of the vegetation growing in a location) may also provide useful indication of the presence or absence of groundwater.

A specific form of visual survey is geological mapping. In many cases, the nature of the underlying geology can be adequately determined by a desk study, but there may be instances where accurate identification of a geological boundary is required.

Thus it can be seen that there is no convenient checklist in completing and reporting a visual site inspection: on one site, the nature of the vegetation may be irrelevant, on another it may give critical guidance to the presence of groundwater. A visual site inspection report needs to be as complete and accurate as possible, and to be undertaken with knowledge and understanding of the proposed project; each site inspection report must by its nature be as individual as the site to which it applies.

Where geophysics methods have been undertaken on a site, the information to be reported clearly depends on the particular method or methods employed. However, geophysical investigations are frequently undertaken and reported by specialist sub-contractors, and the reports normally include some degree of data processing or interpretation. This is acceptable within a factual report; however, the geophysical report should contain all relevant details of calibration applicable to the test, and the full test data from the tests should be included within the report (possibly as an appendix; due to the volume of data, an electronic format will likely be most suitable), such that further analysis/re-analysis of the test data can be undertaken.

50.1.2.2 Intrusive, large-face excavations

'Large-face excavations' refers to any situation where it is possible to view a section through the ground. Most commonly in ground investigations, this is obtained through the excavation of trial pits and trial trenches, for which there are codes and standards defining what should be reported. However, good information on the soil stratigraphy can also be obtained from natural exposures (for example sea-cliffs), and from large-scale man-made excavations. Such excavations may be connected to construction, possibly even the project for which data are being reported, and take the form of large box excavations or vertical shafts, giving a section through the ground from surface. There may also be more linear features at ground surface (cuttings, canals) or at depth (tunnels). Quarries and sand pits (whether operational or closed) also frequently provide potential for inspection of sections through the ground.

Whatever form the excavation takes, certain basic information should always be reported. The codes for reporting of trial pits should always be reviewed for any such excavation, since regardless of how the excavation was formed, it is, in effect, a trial pit. Precise location (in plan and elevation) must be given, along with details of date and weather. The excavation faces should be sketched (with scale/dimensions shown), and it is good practice to include photographs as well. Where samples are taken, it is important to accurately locate where these were taken, showing face of excavation, depth and orientation: again, photography can be useful here, with 'before' and 'after' images of where the sample was taken. Similarly, any *in situ* testing needs to be accurately located. Reporting of large-face excavations should also include details of how the face was created, when and by whom (as applicable). The absence of something within a large-face excavation can often be as important as its presence: for example, any trial pit or trench should generally indicate where groundwater was encountered, and if not encountered then this should be

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

expressly stated. In other situations, it may be significant to report the absence of fissuring or a particular stratum, or of evidence of contamination.

50.1.2.3 Intrusive, small-sample size investigations

Intrusive small-sample size investigation invariably means boreholes of some form. There are a variety of techniques for forming boreholes, but any borehole formed for construction purposes should be undertaken broadly in accordance with the British/European standard, and will therefore be reported accordingly. If reporting is to deviate from the appropriate standard, it needs to be specifically instructed. It is important therefore to know what standard the work is being undertaken to and to be familiar with the reporting requirements of that standard, before the work commences on site, so that if variation from the standard is required, it can be instructed in good time.

50.1.2.4 Intrusive, non-sampling: *in situ* testing

In addition to boreholes, which are an intrusive technique that provides for recovery of soil samples, there are numerous methods of undertaking field testing of the soil. These vary greatly in the scale of the sample they test: pocket penetrometers and hand vane tests test a small volume of soil at shallow depth (typically within the wall of a trial pit); cone penetration testing tests a relatively small area of soil, but can test a continuous column of soil tens of metres deep; a plate loading test may be carried out at ground surface or in a shallow excavation, but affects a volume of soil to some depth below the level of the test plate. Hence, the reporting of such testing is specific to the method being applied. Most such field testing is fully defined by British/European standards, which accordingly define the reporting requirements.

While in some cases, the data from this type of test are relatively straightforward to report (for example, a pocket penetrometer), in other cases, considerable volumes of data may be created by the test – for example, pressuremeter tests. These tests require consideration of how all the data can be reported, and often require some degree of electronic/digital reporting as well as any printed report (see section 50.2).

Calibration records, where applicable, should always be included in any field test report. Where the report output is generated by processing of field readings, the actual instrument data should always also be made available as part of the factual reporting, to allow for re-analysis of the data if some discrepancy is detected at a later date. Additionally, any problems encountered during the testing or unexpected results from the tests should be highlighted when reporting *in situ* testing.

It is common for the more complex *in situ* tests (e.g. pressuremeter testing) to be reported in a sub-report appended to the main factual report. The specialist test report is often a combined factual and interpretative report even when submitted as part of the factual report, since the direct output of the tests is rarely in a format that is directly useful to an engineer: the tests may give pressures within the instrument or displacements of parts of the instrument, which are interpreted through appropriate calibration factors to give soil material properties.

50.1.2.5 Specialist down-hole tests

In addition to the range of standard tests that may be carried out during drilling, there are numerous tests that are undertaken after completion of a borehole; typically, these involve some form of groundwater monitoring, including pump tests, variable head permeability tests and packer tests. All these type of tests are well covered by appropriate standards and codes of practice, which include reporting requirements.

Another form of testing that may be done during boring but is often undertaken in completed boreholes is geophysics. These tests generate a variety of data, and therefore the reporting requirement is specific to each test. Typically, however, down-hole geophysics gives data that vary with depth. The data reported should always include sufficient information on the equipment used and details of installation so that the test could be repeated from the reported information. As with *in situ* tests and non-intrusive geophysics, the specialist nature of intrusive geophysical investigations means it is common for the report of the fieldwork to combine the factual information with an interpretation of this information, but for this combined factual/interpretative geophysics report to be included as a discrete sub-section within a factual report. Again, calibration information and raw data from the tests should be included within the report.

50.1.3 Reporting of field techniques

As detailed above, practically all field investigation techniques that may be used and which will hence need reporting are covered by a British and/or European standard, and thus the reporting requirements are fully defined. However, while such standards provide guidance to best practice, variation from them is possible. Regardless of whether a standard is being strictly followed or not, certain data must always be reported.

Any factual report of a field investigation technique needs to clearly state what method was used to obtain the data. Moreover, the actual type of equipment used should also be reported. Different sizes or makes of plant may perform differently, providing different results: for example, it has long been recognised that the type of SPT rod used during a test can affect the result. However, accurate recording of the type of plant and where appropriate the individual rig provides useful quality control on the works, and can be vital in interpreting the data recovered. As a further example, a particular rotary drilling rig repeatedly failed to recover soil core from a particular stratum, while other rigs had no problem. Knowing that it was the same rig that failed to obtain core recovery meant that the areas of 'no-recovery' shown on the log could be attributed to a problem with the drilling method, and were not indicative of a true soil condition.

Similarly, the actual operatives of any plant should be recorded: in the above case, different drillers operated the rig,

so it was known that the problem was not operator-dependent. However, it is possible to see apparent operator-dependent results in some cases: for example, using the same type of plant across the same site, a case has been observed by the authors where SPT results from one driller were consistently and significantly higher than those obtained by a second driller, despite boring in the same ground conditions. The project concerned was undertaken before the routine measurement of SPT hammer energy ratio, and had this form of calibration been available at the time of the works, this may have explained the variation in the recorded data. However, by knowing which driller worked on which borehole, it was possible to account for the apparently inconsistent test data from across the site.

All investigation locations need to be accurately located and orientated (if applicable). Someone picking up the report of the work at any point in the future, be it a year's time or a hundred years' time, should be able to work out exactly where the work was undertaken. For this reason, simple sketches of the worksite on their own are not adequate: the road layouts, buildings, trees, etc. shown on such sketches may completely change if the site is redeveloped, making locating the works impossible; cut or fill operations can change ground elevations by many metres, making it impossible to determine the level of the works.

It is therefore good practice to ensure that all works are surveyed to a recognised datum. Within the UK, the best and most obvious choice is the Ordnance Survey National Grid, since this is well established, widely accessible and unlikely to become redundant within the foreseeable future. Specific project grid/data may be used, but care should be exercised in selecting this option, since details of the project grid may become unavailable in the future (through disposal or other loss of records), leading to the reported information becoming unusable. Where project-specific grids/data are used, it should be clearly stated that the information on location and elevation is to a project grid, and the report should include details of the project grid.

For larger-scale projects, or those extending beyond the boundaries of the O/S (or other) national grid, altitude and longitude information may be provided, along with height above mean sea level, typically determined through use of a global positioning system (GPS). However, even here, there are different systems of mapping and determination of coordinates, so the equipment and methodology used in determining the site position should be explicitly stated.

While sketch plans alone are not adequate, such a sketch, or even better a scalable drawing or site plan, should be included in any report. Such drawings can be particularly valuable where works have some degree of orientation: trial trenches or inclined boreholes, for example, will have a definite orientation, while geological mapping of strata is likely to require reporting of stratigraphic dip direction.

The date of all works should always be given, with the text of any factual report stating the date of the full work period, and individual field test or borehole logs showing the date for that particular operation. Where applicable, times should also be given: an example of where this would be appropriate is where groundwater levels are to be monitored close to a tidal waterway and so may be showing tidal variation.

Weather conditions are also an external factor that should be reported: results of field testing or monitoring may be influenced by temperature, moisture or atmospheric pressure.

Any test or method of investigation reported should always include full records of any appropriate calibration factor that has been applied to the test, and also full records of cleaning, maintenance or calibration of any instrumentation used, if applicable: some instrumentation is capable of showing significant drift from true results if not regularly and correctly maintained, so without the calibration records, the data from such instrumentation cannot be treated as being reliable.

Zero readings and the absence of some material or behaviour should be reported where appropriate. By way of example, any intrusive investigation into the ground capable of identifying groundwater should always state where it occurred, or that it was not encountered. If gas monitoring is undertaken, readings indicating zero concentrations of particular gases should be explicitly reported. Knowing that there is the absence of something may be more valuable than knowing its concentration where it is present.

Individual features of the report by nature must always be tailored to the information being reported. While data such as borehole logs are typically reported to standard scales (often either 5 m a page or 10 m a page), the important thing is that the information is reported clearly and unambiguously. If, for example, the concentration of data obtained from a borehole to be reported makes a 4 m per page scale most suitable, this is the best scale to use, and the scale used should then be clearly stated.

50.1.4 Reporting of laboratory tests

Since the vast majority of laboratory tests are undertaken in accordance with an established code or standard, the reporting requirements are generally also prescribed. However, variations from the standard reporting format may be undertaken where specific project requirements demand it. In such cases, care needs to be taken to ensure that such non-standard reporting is undertaken consistently throughout. It should also be noted that any variation from the established codes/standards reporting requirements will prevent the test being reported as to the standard, even though the actual testing phase was entirely in accordance with the standard. If data are being reported to be supplied to a third party, there may be a requirement from that party that all tests are to a particular standard, so non-standard reporting may render the entire test unacceptable.

Non-standard reporting may be required because of a perceived weakness in the standard for reporting, perhaps because the precision of the standard reporting fails to provide sufficient discretion for the project underway. Alternatively, it may

represent improvements in the theoretical understanding of a particular test or soil behaviour in general, which has yet to be incorporated into the standards.

As with field monitoring techniques, laboratory tests may have applicable calibration factors that apply to the output data, calibration requirements for the equipment, or method detection limits indicating the smallest quantity that can be detected. Such information should be reported. Where a quantity is less than the detection limit, this should be explicitly reported: it is not correct to report zero concentration, where the test being used is incapable of discriminating between zero concentrations and very low non-zero concentrations.

50.1.5 Reporting of down-hole tests

In addition to the various field techniques and laboratory tests that require reporting, there are a variety of tests which may be undertaken in the field after the main period of fieldwork has been completed. These most typically relate to groundwater, involving tests to determine permeability, and as such the implementation and reporting of these tests is covered by published codes and standards, in the same way as intrusive field investigations and laboratory tests are.

However, such testing may also include geophysical investigations, or geo-environmental sampling and field testing of groundwater or ground-gas. The reporting of such tests may not be covered by established guidance, but may be treated as if it were a field test undertaken during on-site works, with the same requirements to report equipment used, calibration factors, location and orientation, date and weather, etc.

Reporting of field tests undertaken after the main fieldwork period does lead to potential issues over timing of reporting, as discussed in sections 50.4 and 50.5.

50.2 Electronic data

The traditional method of delivering a report, whether factual or interpretative, has been in the form of a bound hard copy. Smaller reports may constitute only a few pages, and be issued as 'letter reports'; large investigations may require reports consisting of many volumes. However, hard copy reports of this form alone are not necessarily the most convenient form for a factual report, since it is not easy to extract and manipulate data. Additionally, producing several copies of multi-volume reports typically requires a significant quantity of paper to be used, which may be at odds with modern standards of good environmental practice. For these reasons, there is an increasing acceptance of the need for electronic data transfer and reporting using electronic media.

The most common form of electronic data transfer in the UK is AGS: that is, data transfer according to the Association of Geotechnical and Geoenvironmental Specialists' Electronic Transfer of Geotechnical and Geoenvironmental Data format (AGS, 1999). This provides a common framework for transfer of geotechnical and geo-environmental data, enabling the data to be readily transferred and manipulated, or input into a database. While in theory, the use of this format means that data can be transferred seamlessly, the reality is that considerable work may still be required in manipulating data before they can be used.

While there is an increasing tendency for laboratories and ground investigation contractors to utilise systems that automatically generate AGS data during the reporting process, this is not universal. Some organisations generate AGS by manually inputting data. As a result, there is the potential for data to be mis-entered, leading to factual inaccuracies and inconsistencies to develop within the data file. There is software available that can check for the latter, but it is very difficult to confirm that factual inaccuracies are not present in the data. Knowledge of how the data are generated is therefore vital, as is information regarding the standard of the quality management system employed by the company or individual generating the data. It is good practice to spot-check any electronic data received against the printed master copy, but if there is any doubt as to the quality control of the data generating process, extensive checking is vital. Such checking is laborious and time-consuming, and unfortunately often not carried out to a sufficient standard. However, no electronic data should be used if there is any doubt as to their accuracy.

While the AGS format is very comprehensive, there are still tests or aspects of tests that cannot be adequately described using it. Geophysics results in particular are not readily reported through AGS. In such situations, it is normally appropriate to use a spreadsheet format for the data. The need to thoroughly check all such data remains.

While electronic data formats allow for rapid and easy data transfer, the real value is in the ability to create databases of project information that can be easily interrogated to enable specific data to be accessed in their entirety and with minimal delay. However, the ease with which data can be extracted means that where a database exists, it may be relied upon to such an extent that it becomes the sole source of data, and the data may not be referenced against the printed master copy. It thus is imperative that where a database exists, it is strictly controlled. While the ability to extract data needs to be limited only to the normal operational procedures of the company involved, subject to any appropriate commercial confidentiality, the ability to input or change data within a database needs to be controlled, and any data to be entered into the database need to have been checked fully beforehand.

The above points refer primarily to use of electronic data transfer/storage of traditional geotechnical factual data. The development of digital technology enables a range of new information to be obtained. For example, it is now possible to obtain digital data from monitoring instruments on rotary borehole rigs, which show factors such as drilling advance rates, rotational speeds and various pressures. Such information appears so far to be principally of value to the drilling contractor while doing the work on site, but may prove to have value in interpreting the ground conditions. Since the use of

this form of instrumented plant has not yet become widespread, such data are not, at the time of writing, routinely available. However, it illustrates how the range of data that may be available for reporting is not a constant, but will change as technology and methods of working change.

A form of digital reporting that is now routinely encountered is that of the Adobe Acrobat format (PDF files); it is now increasingly common practice for the master hard copy report to be provided in this format also, often directly from the original word-processing software used to create the report. Such electronic reports are very valuable, since they can generally be transferred easily, by CD, datastick or email, and they enable multiple copies of a report to be created and issued without the expense or environmental impact of multiple printed copies. However, a good quality electronic copy of a report requires some degree of processing: this file format allows pages to be bookmarked, such that for example, the first page of each chapter can be found through selecting the appropriate on-screen button. Large reports where this has not been done are considerably less useful than where the report is fully and sensibly bookmarked, since much of the time-saving that can be gained from using an electronic report is lost. While a PDF file provides a convenient form for storage and transfer of a report, the information cannot generally be readily extracted and manipulated, so the provision of a PDF format report can supplement, but does not replace, AGS format data transfer.

Another form of digital data that represents a new form for data to be presented is that of digital photography and digital imaging. Provision of core photographs has long been a standard requirement of any ground investigation involving rotary drilling for core; the widespread introduction of good quality digital cameras has resulted in the majority of such core photographs being provided not just as printed copies, but also as digital image files, which, as with electronic format reports, offers considerable advantages in copying or transferring the images. Care needs to be taken in the use of digital photography that any printed image is a true likeness of the actual soil, since the print is often made using a standard office printer, where the quality of colour reproduction may fluctuate. However, the same issue can occur in developing and printing of conventional film, so is not an issue that prohibits use of digital imaging. Digital photographs also offer the opportunity to manipulate colour or contrast of the image, which can be of great assistance in examining and identifying details of soil structure. Similarly, sample photography is now most likely undertaken with digital cameras, offering the same advantages and limitations as for core photography.

Where digital images are provided, the image file should be named in a sensible and consistent manner, such that it is obvious from the file name what the image shows.

A relatively new variant of core photography is the use of high-resolution core scanning. This generates a high quality image of the entire core, which with the appropriate software can be readily manipulated. The quality and resolution of the image is such that small details of the soil structure can be identified, and the images are far superior to traditional core photography. However, the availability of the scanners is currently limited, the scanning process is more involved than photographs, and requires more resources on site, and the digital size of the images is very large, leading to some problems storing or transferring the images (images cannot be emailed routinely due to their size).

In any form of electronic or digital data storage or transfer, there are a number of issues that must be addressed. AGS is a standard format across the industry, and the widespread use of Microsoft Office software makes it likely that any spreadsheet-based data will also be readily accessible. However, other electronic data formats may require specialist software to enable the data to be viewed/extracted. If the software is hard and/or expensive to acquire, or difficult to use, or consumes a lot of digital storage space on the computer, it may not be possible for all would-be users of the data to run the software. Even where the software is common, care must be taken to allow for different versions of the software. While newer versions of software are commonly written to be compatible with earlier versions, if the data are produced using the latest version of a piece of common software, a user operating an older version may be unable to fully access the data.

This leads to two related issues that need to be considered when considering electronic reporting. If a project is expected to be running over a prolonged period, it is possible that commercially available software used to report data at the start of the project will be upgraded during the course of the works. A decision will then need to be taken as to whether to upgrade the software, and accept that there will be some degree of inconsistency in the project data set, or continue to operate using the older software, which may lead to problems if companies generating the data have updated their systems, or if the software version ceases to be supported by the manufacturer.

Thought must also be given to the long-term availability of any software. Factual reporting from ground investigations is typically used relatively soon after it is generated, but often continues to be of use for many years after. If software is not common, then the problems of having the appropriate software available to access the data are likely to become more pronounced with time. It is possible that if the software operation requires a licence to function and the supplying company has ceased trading, the software will be completely unusable, and hence the digital data will be lost. Even if this does not occur, if data are supplied in an obscure format, it is important to record (non-digitally) what the format and appropriate software to access the data is, such that at any future time, it is possible to identify this and access the data.

Having focused on the potential difficulties of long-term data access due to software, it is appropriate to mention long-term data storage as a further issue affecting reporting. The lifespan of the printed page is well proven: the lifespan of a CD-ROM, or datastick, or magnetic storage tape, is less well demonstrated. If

digital data are to be archived, thought needs to be given to the environmental conditions in which it will be stored, such that the lifespan of the storage medium is maximised. Consideration also needs to be given to security and back-up copies. Archived data need to be accessible only to those who have authorisation to access the data, but depending on the value of the data concerned, thought should be given to having back-up copies stored separately from the main archive.

One issue applicable, but not unique, to electronic reporting is the need for personnel using software to be adequately trained. Knowing how a piece of software functions makes it less likely that errors will be made in generating/inputting data, and gives the operator a better idea of where problems are most likely to occur. It is important therefore that personnel involved in reporting are familiar with any software being used.

If the software is being used for any sort of analytical or interpretative function, then there is also a requirement to ensure that its operation is adequately validated. Commercial software does not always provide sufficient details or validation of its operation that its use would meet a reasonable quality system without further proof of its reliability.

50.3 Interpretative reporting

Interpretative reporting follows on from the factual report, and provides the manner in which the strictly factual data can be related to the specific project for which they have been obtained. Thus while it can useful to know what the proposed development of a site is to be when preparing a factual report, it is vital for an interpretative report.

The exact content of an interpretative report is, however, still open to some variation: the report may be being produced for a fully scoped and planned proposed development, or the proposals may still be quite vague. In the first instance, the proposals may already have determined that the foundations are to be piled, and the interpretative report is thus required to give guidance on the details of the piles likely to be required; in the latter case, part of the function of the interpretative report may be to provide recommendations as to the basic nature of the foundations (raft, piles, etc.). It is thus important that the requirements of the client in respect of the content and use of the interpretative report are well established and understood.

Interpretative reports are commonly also used to give guidance on design parameters for the soil. Again, where this is to be done, the client's requirements need to be fully understood. Design parameters can be presented as recommended values, design lines (possibly showing variation of a parameter with depth), upper bound and lower bound lines for maximum/minimum credible values, upper bound and lower bound lines for maximum/minimum possible values, etc. The nature of the proposed development and the expected method of design will affect which of these formats for reporting data is required. It is also possible that specific design parameters are not required, only combined plots showing the actual field and laboratory test data, enabling a design consultant to review the data and select their own design values. Alternatively, particular design codes, standards or methodologies may specify how geotechnical design parameters should be selected. The data available may also affect the method of selecting design parameters: many field tests tend to give results exhibiting significant scatter in value, where boundary lines may be more appropriate than a single design line. Conversely, if the available data are very limited in quantity, a conservatively selected single value may be more appropriate.

Interpretative reports also enable details of the factual report to be reviewed and possibly explained. A factual report may contain borehole logs, and such logs may be present on a cross-section, but it is incorrect to interpret the geology between boreholes in a factual report. In an interpretative report, interpreting the geological stratigraphy between boreholes is generally a fundamental part of producing the report, since it provides the understanding of the form and nature of the soil mass. Through such a process, various geohazards may be identified, for example faults identified from vertically displaced stratigraphic boundaries, or buried river channels with possible high volume groundwater flow from unexpected soil types encountered in a borehole. Thus while it is relatively simple to complete a factual report, since it merely requires complete and accurate reporting of all information, the interpretative report is more difficult to complete to a useful standard. It is not an exercise in repeating information from the factual report, but requires an intelligent and informed assessment of that factual information relative to the proposed development for which the information has been gathered. Moreover, the briefing to produce the report may require that it allows for a variety of design methods, construction techniques, building layouts, etc., since all aspects of site investigation and reporting tend to occur early in a project's life when quite fundamental changes to the project may still occur.

Interpretative reports often include recommendations for further investigations, where the assessment of the available factual information reveals deficiencies in the quality or quantity of the available data.

It should be noted that an interpretative report may be combined with a factual report, where the requirement of the report is both to provide full and complete factual information and to include an assessment of the data meeting the standards of an interpretative report.

50.4 Other geotechnical reports

The most common form of geotechnical reports are the factual and interpretative reports that result from some form of site or ground investigation. However, there are a number of other geotechnical reports which may be encountered.

Generally, the discussion of reporting given here is focused on geotechnical reporting only, with some consideration of geo-environmental issues. However, geotechnical issues are not the only concern at many sites, and it is often most efficient to combine all investigation and reporting of a site into one work package. Thus both factual and interpretative reporting may be required to consider factors such as geology and geohazards,

environmental contaminants (in soil, water and air), broader environmental issues (e.g. flood risk, naturally occurring radon gas) and heritage and archaeological issues (including possible issues of unexploded ordnance). Such issues should typically have been identified in the desk study, and may have been adequately addressed at that stage, but there is the potential for specific site works related to these aspects which will then need to be reported and the implications of what was found will need to be discussed.

The introduction of Eurocode 7 has led to the production of ground investigation reports (GIR) and geotechnical design reports (GDR). The GIR broadly combines the factual report with interpretation to generate design parameters which are then fed into the GDR; the GIR in fact forms part of the GDR. Eurocode 7 defines the format for presenting information, and requires known limitations of test results to be stated, so that users of the data have an indication of their reliability. The GDR provides the foundation design and recommendations that may formerly have been encountered in an interpretative report. It must include the assumptions and data that feed into the design, the methods used in the design, and verification of safety and serviceability. It also requires that supervision, monitoring and maintenance requirements of the completed structure be reported and provided to the owner/client. The specific requirements of the GIR and GDR are stated more fully in EC7.

Geotechnical baseline reports (GBR) are a specialist form of geotechnical report which are produced for commercial rather than technical purposes. They may also be known as ground reference conditions. They draw on and interpret the available data to define baseline conditions relevant to the proposed construction. These baseline conditions are applicable to a specific contract and establish what conditions a contractor should expect to encounter in the ground when undertaking works under that contract. If conditions are worse than these, and the contractor can demonstrate a resulting loss or delay, then a compensation event may be triggered. A GBR must contain statements that are concise, measurable and clearly defined, with no ambiguity or uncertainty, and which are based on a reasonable and realistic assessment of what will be encountered. They define what ground conditions are foreseeable, and hence what ground conditions are unforeseeable, relative to the works to which the report relates. A GBR is not an interpretative report, nor is it a basis for design; it is a means by which the allocation of ground risk is assigned between contractor and client; the ground conditions should normally be stated as accurately as possible: if the conditions are stated to be better than they actually are, the client will be liable to increased claims for compensation; if a worst-case attitude is taken and the ground conditions are described as worse than they actually are, the contractor will assume that there is an increased risk, and will price for the works accordingly, again leading to financial loss to the client. However, in practice, the commercial nature of a GBR does sometimes result in an unrealistic assessment of the ground conditions, reflecting the client's attitude to financial risk.

Another specialist form of geotechnical report is a risk register. In reality, a risk register is not specifically a geotechnical report, since it should apply to all aspects of a project, and list all risks to the project. The risk register is, as its name indicates, a means of identifying and tracking all risks to the project. Typically, the register would detail the nature of the risk, the likelihood of it being encountered and its potential impact on the project, to give an overall risk status, using standard risk assessment procedures. Recommendations as to how to mitigate the risk may then be given, with the party responsible for undertaking the mitigation identified, and the residual risk after mitigation being stated, along with where that residual risk lies. While a risk register is not specifically a geotechnical report, geotechnically related risks are often some of the more significant to a project, due to uncertainty about the ground; hence risk registers routinely require a geotechnical input.

Where field monitoring or instrumentation is installed, there will generally be a requirement for ongoing monitoring. Such monitoring will require to be reported. The frequency and manner in which these reports are issued will depend on the frequency of the monitoring, and the requirement of the project. Typically, following ground investigation works, groundwater monitoring instruments are placed in the ground. Monitoring of these tends to be daily while site works are ongoing, but then becomes less frequent post-site work. Monitoring at monthly or three-monthly periods is not untypical, and while the results of each site visit should generally be provided to the engineer within a day or two of the visit, the contractor would normally only be expected to produce a factual report on the monitoring at the end of the monitoring period. However, monitoring of instrumentation can continue into the construction and post-construction period, in which circumstances, reporting may need to be more formal and frequent. This may require, for example, formal issue of daily groundwater data, or real-time remote monitoring of displacements of a retaining wall. In such cases, reporting is most likely to be electronic, perhaps with a summary printed report periodically. Where this type of data is being generated and issued, it is important to ensure that the critical data are prominent, and that the ability to generate and issue huge quantities of data is not allowed to swamp the recipient of the report, potentially resulting in significant information not being identified and acted upon. The requirements for frequency and format of monitoring reporting will generally be identified in the specification for the broader works.

50.5 Reporting production and timescale

Having considered the nature of what may be reported in a geotechnical report, and how that information may be reported, consideration needs to be given to the practicalities of the report.

A geotechnical report from a ground investigation is often required early in a project's life, and may be a requirement before the proposed design can be progressed. Therefore, the timing of the report is of importance. Where ground investigation works

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

are very large, the time required to complete and issue a report may be considerable, as potentially will be the time needed to fully check and correct the report. Allowance needs to be made in any project programme for this time period. In some circumstances, it may be appropriate to issue reports in stages: long-term monitoring by definition is completed many months after the fieldwork stage of a ground investigation is completed, so it would be inappropriate to delay issuing the factual report from the fieldwork until the monitoring is complete. Similarly but less obviously, some laboratory testing (particularly drained tests on clay soil specimens) can take prolonged periods to complete. Where the available laboratory resource to complete these tests is limited and multiple tests are required, it may take several months before this part of the laboratory test programme is completed. In such cases, the demand for basic stratigraphic information may require that these laboratory tests are reported as a later addendum to the factual report.

The programming of production and issue of the interpretative report can also be a significant factor. It is not uncommon for the interpretative report to draw on data from more than one report: there may be a desk study, several phases of ground investigations for the project concerned, and a variety of historical data. As previously noted, the interpretative report is in some ways harder to produce than the factual report, since it is not a simple statement of fact, and therefore may take considerably longer to complete than the factual reports upon which it is based.

When generating a report, it is necessary to consider how many copies of the report are required. It will rarely be sufficient to generate just a single copy for the client: additional copies may be needed by one or more design engineers, and other interested parties (architects, insurers, etc.). However, efforts should be made to ensure only the number of reports actually required are produced, both for commercial and environmental reasons. Production of electronic copies of the report are valuable in this respect, since they allow the report to be readily issued as required, in whole or in part.

In some circumstances, the issue of payment for the report also needs to be carefully considered. The typical factual report from a small ground investigation will be relatively straightforward, and a simple lump sum for its production may be appropriate. However, if the works are larger in scope or undertaken under a term contract and may vary considerably in nature and extent, such a mechanism may be inequable. Allowance for reporting costs to be based on the value of the fieldwork undertaken is in some circumstances appropriate.

Section 5: Design of foundations

Section editor: **Anthony S. O'Brien**

doi: 10.1680/moge.57098.0731

Chapter 51

Introduction to Section 5

Anthony S. O'Brien Mott MacDonald, Croydon, UK

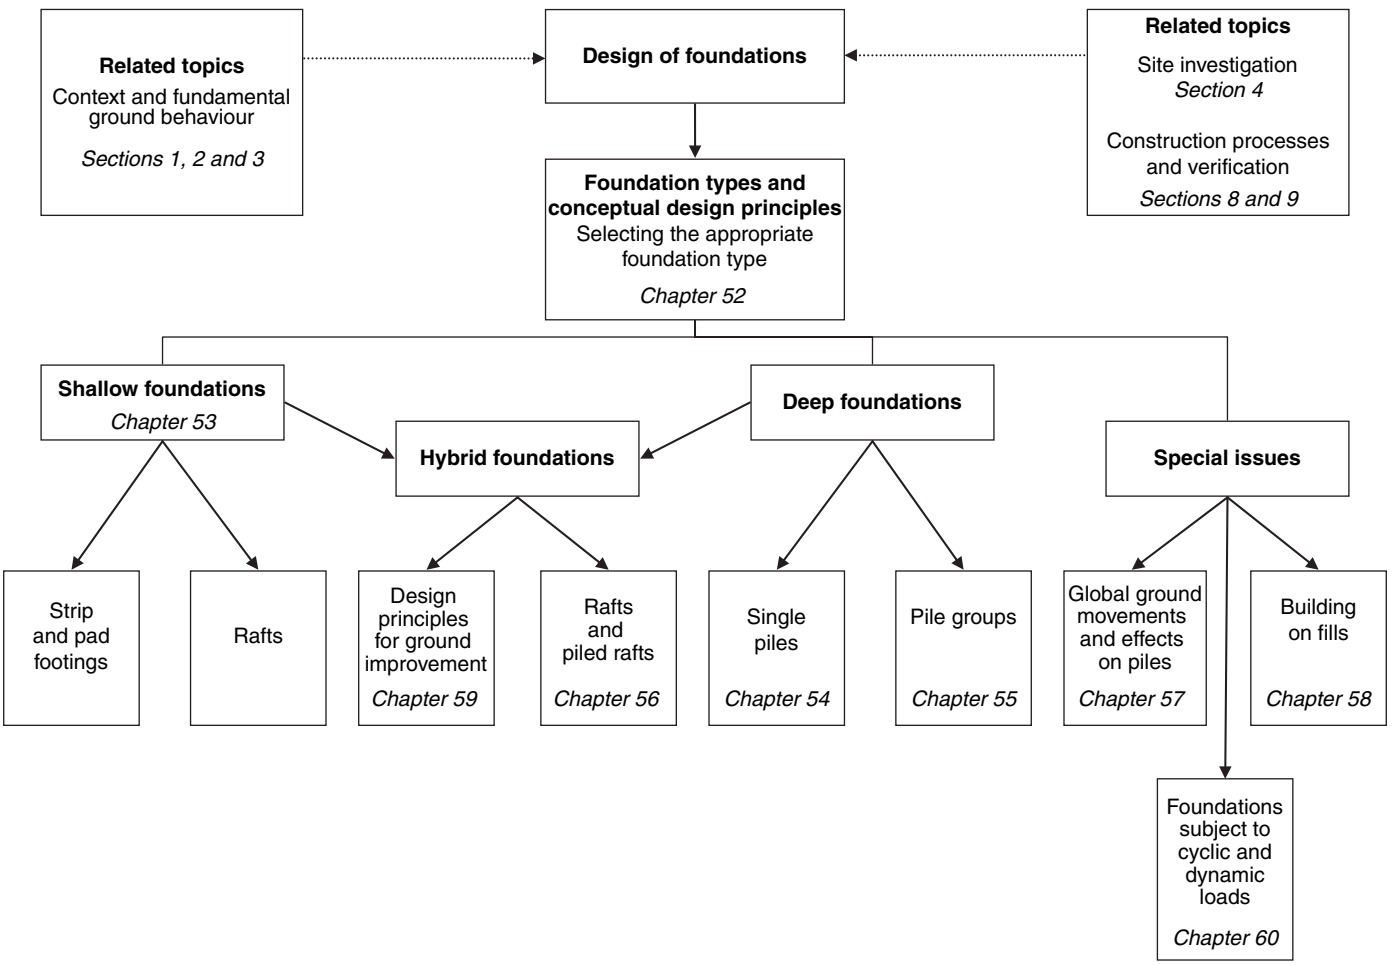

Figure 51.1 Layout of chapters in Section 5

Figure 51.1 outlines the layout and contents of Section 5 *Design of foundations*.

Foundation design is usually divided into two broad categories: shallow and deep, and these categories are also used here. In modern foundation engineering it is helpful to consider a third category: hybrid. Hybrid foundations have their own unique features, although their design usually requires an assessment of both shallow and deep foundation behaviour. Examples of hybrid foundations include deep ground improvement and piled rafts.

The final set of topics, special issues, include building on fills, the influence of global ground movements on deep foundations, and foundations subject to cyclic and dynamic loading, including earthquakes.

In common with other sections of this manual, this section is intended to provide guidance to practising engineers. Given the enormous breadth of the subject and the vast range of ground conditions and structures which a foundation designer may encounter, this section cannot, within the available space, be completely comprehensive. The intent is to outline:

- the fundamental principles of good design practice;
- the key mechanisms of ground and ground–structure interaction behaviour which need to be considered;

- commonly used design methods;
- the need to integrate a range of specialist disciplines at different stages of the design process;

and to provide:

- references for detailed study;
- some brief case histories which highlight key issues.

A quote from Terzaghi (1936) is particularly pertinent:

> Whoever expects from soil mechanics a set of simple, hard and fast rules for settlement computations will be deeply disappointed…The nature of the problem strictly precludes such rules.

Hence, it is essential for the foundation designer to think carefully about the likely deformation and failure mechanisms which may occur both during and after construction; then compile a checklist of questions which need to be considered and answered.

There have been enormous developments in foundation engineering during the last few decades. Despite these developments, failures still regularly occur and there are also numerous examples of grossly overconservative design and poor construction practice. There are several commercial and technical factors that can cause these problems. Technically, it is important to:

(i) Recognise that foundation engineering is a 'process', and that success depends on a series of interlinked activities during *both* design and construction.

(ii) Have a coherent approach to ground risk management; the 'geotechnical triangle' is a valuable framework in this context. An understanding of the site's history and its groundwater regime are critically important.

(iii) Have good communication across different design/construction teams.

(iv) Develop a good understanding of ground–structure interaction. It is vitally important for geotechnical and structural engineers to have early two-way discussions, so that the overall behaviour of the proposed works are understood. In particular, the best opportunity for economic foundation design is to set realistic (rather than arbitrary and usually overconservative) limits on foundation movement.

(v) Have a good awareness of relevant case histories of past foundation performance, and to carefully assess the relevant parameters for assessing stability – and in particular, foundation deformation. Sophisticated analysis is not a substitute for a proper selection of design parameters, based on well designed and supervised ground investigations.

Chapter 9 *Foundation design decisions* provides an introduction to these themes, and these are developed in more detail throughout Section 5.

Although it is a simplification, it is fair to state that routine ground investigation and analysis methods can lead to:

(i) overconservative design of foundations in heavily overconsolidated soils, such as stiff clays;

(ii) unsafe foundation design in normally and lightly overconsolidated soils, such as soft clays.

Modern developments in ground investigation and geotechnical analysis can avoid these problems, although these modern techniques are still under-used across the civil engineering industry. The chapters in Section 5 highlight some of the developments which are mature enough to be used more routinely. It is hoped that Section 5 will stimulate an improvement in foundation design practice.

The main types of foundation include: shallow foundations (pad, strip, raft); deep foundations (piles, caissons, barettes) and hybrid foundations (deep ground improvement, piled rafts). Foundation engineering requires a broad range of skills, from an appreciation of geology and hydrogeology to structural engineering. The performance of foundations is dependent not only on how they are designed, but also on how they are constructed. The overall design process needs to be well managed, to ensure that there are good communications between different design teams and between design and construction. To provide a framework for selecting the most appropriate type of foundation, a useful mnemonic is 'the 5 S's':

S – Soil; S – Structure; S – Site; S – Safety; S – Sustainability

The magnitude of allowable foundation movement is a key factor in determining the type, size and cost of foundations, and this chapter provides guidance on routine limits. Parameter selection is a common pitfall, and the critical information requirements are described.

52.1 Introduction

This chapter outlines the types of foundation that are commonly used, together with the key factors which need to be considered before selecting a particular foundation type.

Foundation engineering requires a working knowledge of:

- geotechnical engineering;
- construction methods;
- ground-structure interaction.

Professor Peck (1962) outlined the three areas of knowledge that are needed in geotechnical engineering:

(i) a knowledge of precedents, i.e. a knowledge of case histories;
(ii) a working knowledge of geology;
(iii) familiarity with soil mechanics.

In the vast majority of cases, a foundation design is developed on the basis of an appreciation of the site geology, the nature of the proposed structure and any particular site constraints. The role of analysis is then to check that a proposed foundation design will be acceptable. Although analysis is important it is just one part of the overall design process.

Many young civil engineers will have some knowledge of (iii), but it is important that they endeavour to develop their knowledge of (i) and (ii) above. A knowledge of geology (and hydrogeology) is critically important, since it enables many of the risks associated with foundation engineering at a particular site to be assessed. Simplifying assumptions have to be made before any analysis can be carried out (this includes sophisticated computer modelling). The site geology and hydrogeology have to be considered and understood, as early as possible in the project. Discussions should be held with an experienced geologist. Relevant technical literature and, particularly, local case histories should be reviewed. Once this has been done then the appropriateness, or not, of certain assumptions inherent in a particular method of calculation can be judged, and the likely errors associated with the predictions from calculations can be assessed. A knowledge of case histories is probably the most important of the three attributes, since this enables the engineer to have an understanding of:

(i) what has worked, or not, in the past;
(ii) the consequences of particular construction activities on subsequent performance;
(iii) past performance, against which the reliability of different methods of analysis can be compared;
(iv) when a proposed activity is going beyond what has been attempted before – this will then require a special effort and expert advice in order to safely develop the design.

A foundation is a structural member and supports a superstructure. So an awareness of the sources and nature of structural loads, the structure's tolerance of foundation movements, and an understanding of ground–structure interaction is also needed. Finally, the foundations must be built economically and safely. Hence, a designer needs to have an appreciation of construction methods and equipment, in order to develop a design that is practical to build.

This list of attributes, which a foundation designer needs to possess, is rather intimidating. The author has not yet come across the god-like creature who possesses a perfect knowledge of all these topics. Therefore, first and foremost, the foundation designer must be prepared to ask questions and discuss these with other design and construction specialists (e.g. geologists, structural and material engineers, specialist sub-contractors, etc.). Good foundation design is usually the result of a multidisciplinary team effort, where two-way communications across the team occur regularly and frequently.

52.2 Foundation types

There are two generic types of foundation: shallow and deep. Foundations developed on improved ground can be considered to be a hybrid of both shallow and deep foundations, although ground improvement design requires additional considerations. The advantages and disadvantages of different foundation types are outlined in **Table 52.1**.

(1) *Shallow foundations*: these typically comprise pad, strip or raft foundations; refer to **Figure 52.1**. Pad foundations, **Figure 52.1(a)**, may be square, circular or rectangular. A pad foundation usually only supports one or two columns. Strip foundations (**Figure 52.1(b)**) are commonly used to provide support to a load-bearing wall or for several closely spaced columns. The length of a strip foundation is much greater than its width. A raft foundation (**Figure 52.1(c)**) could support the entire structure or a substantial part of it. A 'compensated' raft (also known as a 'buoyant' raft) is a special type of raft. It includes a void, thereby reducing the 'net' increase in bearing pressure (section 52.5) on the ground below the foundation. This will increase the factor of safety against bearing capacity failure and reduce foundation settlement, compared with a conventional raft. The structural form of shallow foundations can vary, but pad and strip foundations could comprise either mass concrete or reinforced concrete, whereas raft foundations usually comprise reinforced concrete. The soil resistance to the loads applied by the structure are predominantly developed by the near-surface soil below the base of the foundation. Shallow foundations are usually constructed using simple excavation plant and general labour. Tomlinson *et al*. (1987) gives useful advice on routine foundation design for low-rise buildings.

(2) *Deep foundations*: for the majority of routine structures, deep foundations comprise piles; refer to **Figure 52.2**. There are numerous different types of pile, discussed in Chapter 54 *Single piles* although piles are usually classified as either driven or bored. Pile construction is a specialist activity and should only be carried out by contractors who have the appropriate equipment and experience.

The layout of pile foundations can vary substantially from a single pile below a load-bearing column, to a large number of piles in a group supporting the entire structure, via a pile cap (which transfers load from the structure directly into the piles). For a conventionally designed pile group, it is assumed that the piles carry the entire load.

Deep foundations also include barettes, shafts or caissons, which tend to be bespoke foundations for special circumstances. Caissons, barettes and shafts typically have a large diameter or cross-sectional area relative to their depth in comparison with conventional piles. Barettes are rectangular in plan, and are installed using diaphragm-wall construction techniques. Both shafts and caissons are circular in plan; however, they are usually constructed by different methods. Shafts could be hand-dug or excavated using back-actors, with excavation support installed top-down, using pre-cast concrete rings or cast-*in situ* concrete lining. Caissons are usually jacked or sunk into place using combinations of kentledge, excavation and perimeter lubrication (using bentonite). For both piled foundations and deep shafts the load transfer to the ground is via shear along the vertical sides of the shaft or pile and by end-bearing resistance.

Piled rafts are a hybrid type of foundation with the structural load being transferred to the soil via the raft (as for a shallow foundation) and the piles (as for a deep foundation). The principal difference between a piled raft and a conventional pile group is that the piles are designed to mobilise most of their ultimate load-bearing resistance and act as settlement-reducing elements whilst the raft provides the appropriate overall factor of safety against bearing capacity failure. Compared with a conventional pile group, a piled raft has a relatively small number of widely spaced piles (**Figure 52.3**). Piled-raft design requires specialist input.

(3) *Foundations on improved ground*: in general, the purpose of ground improvement is to increase the strength and stiffness of the ground below a proposed structure, and then shallow structural foundations are constructed on the surface of the improved ground (**Figure 52.4**). Below the structural foundations, a granular layer (sometimes reinforced with geogrids) is often used to transfer loads into the reinforcing elements (**Figure 52.4**). The mechanism of ground improvement is usually either:

- **(i)** Mass reinforcement – usually for clays, silts or made ground. A large number of stiff elements are introduced into the compressible layer.
- **(ii)** Densification – usually for sands or gravels. A compaction process forces a rearrangement of the soil particles into a denser state.

Reinforcement: techniques such as vibro stone columns or deep soil mixing facilitate the replacement of soft compressible materials by stronger materials introduced into the ground via specialist equipment. These stronger elements carry most of the foundation load. However, the remaining soft compressible materials will also carry some of the foundation loads, hence the term 'reinforcement'. It is important to note that the reinforcing elements usually have negligible tensile and bending resistance. Sometimes reinforcing elements such as stone columns are called 'stone piles'; however, this is quite incorrect and misleading. Foundations built upon improved ground will behave in a quite different manner to piled foundations (**Figure 52.5**).

Densification: soils such as loose sand with a low silt or clay content can be compacted into a denser state. Once densified the sand will be a more competent stratum and be able to carry the foundation loads directly. Hence, conventional shallow foundations can be placed on the densified layer.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Densification may be carried out via a wide range of specialist equipment. The key issue for densification projects is usually the relative density that can be achieved compared with the value which is needed to ensure that foundation settlement is acceptable.

The success of ground improvement (both by reinforcement or densification) is sensitive to the nature of the soil profile and the soil macrofabric. For example, densification by vibrocompaction may be straightforward if the sand is homogeneous and has a low silt or clay content. Compaction will be much more difficult and often less effective if there are numerous bands of silt or clay in the sand. These soil features can be easily missed by conventional boreholes and sampling at discrete depth intervals. Continuous sampling or profiling techniques (such as static cone penetration testing, CPTs) are usually very beneficial when designing ground improvement. Similar considerations can apply to reinforcement techniques. Quality control and field testing in order to verify the effectiveness of ground improvement are a significant component of any ground-improvement project.

52.3 Foundation selection – conceptual design principles

52.3.1 Information requirements and the foundation design process

Figure 52.6 outlines the typical information requirements, the design deliverables (reports, etc.) and the project phases that are followed to design and construct a foundation. During the early stages the key questions are:

(1) *Site geology, hydrogeology and history*: what are the geological age and the depositional environment of the main deposits under the site? What subsequent changes may have occurred (e.g. landslides, man's influence)?
(2) *What will be built?*: form of structure, likely construction methods, main site constraints, applied loads, principal constraints (e.g. allowable structural movements)?
(3) *Engineering knowledge*: what existing knowledge do we have? For example, relevant technical literature, good case histories, local customs and experience or expertise.

This collation of available data into a desk study report is an important and cost-effective means of managing ground risks on a project. Sole reliance on boreholes in the absence of a proper desk study is potentially very dangerous. The main ground hazards can be identified from the desk study and the key features of ground behaviour can be assessed. This will inform the design of intrusive ground investigation (refer to Chapters 40 *The ground as a hazard*, 41 *Man-made hazards and obstructions*, 43 *Preliminary studies* and 44 *Planning, procurement and management*). It is often the case that designers 'inherit' ground investigation reports from previous or adjacent projects and studies. It is very important that the scope, adequacy and reliability of this information are assessed in the context of the current project requirements. If the structure has been relocated, or more onerous loading or allowable movement criteria are required, then an additional ground investigation may be needed (perhaps using more sophisticated investigation techniques).

Foundation design is an iterative process. Once relevant information has been obtained for the site, the key data should

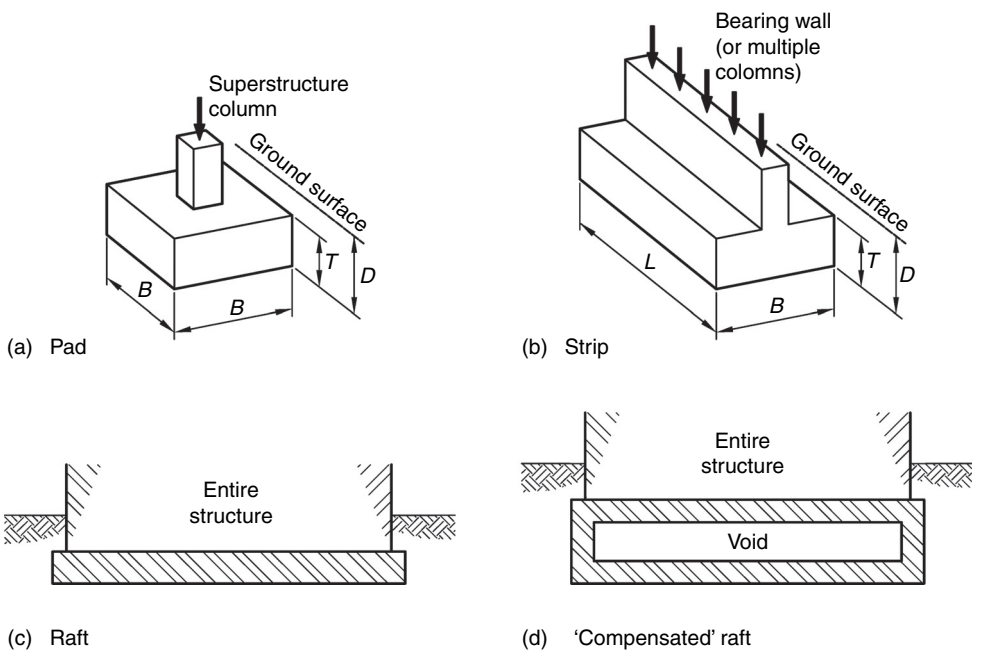

Figure 52.1 Types of shallow foundations

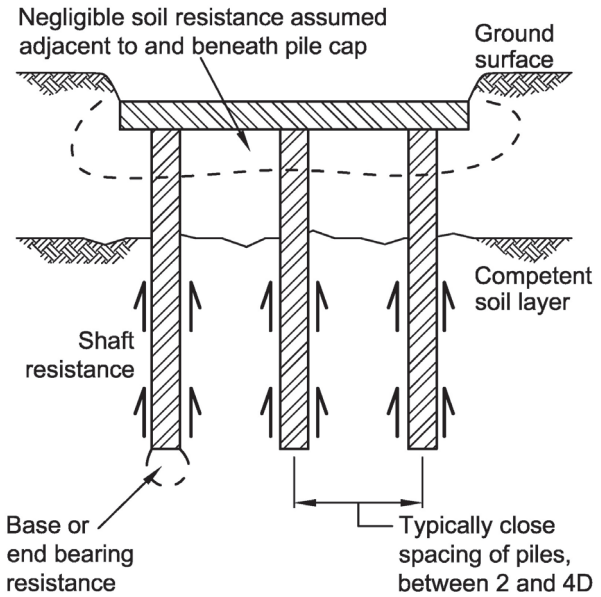

Figure 52.2 Deep foundation, conventional pile group

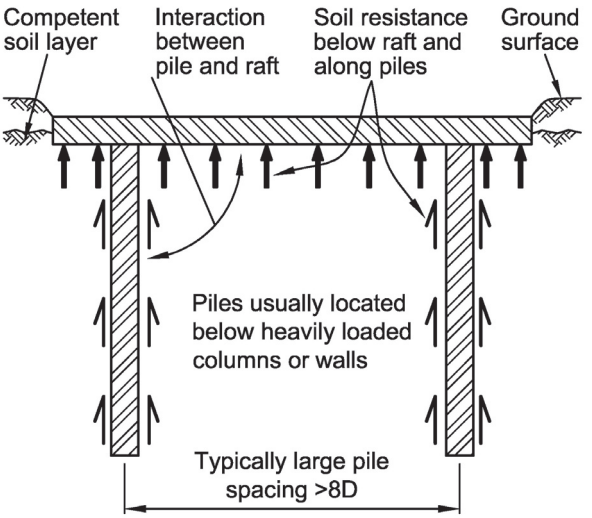

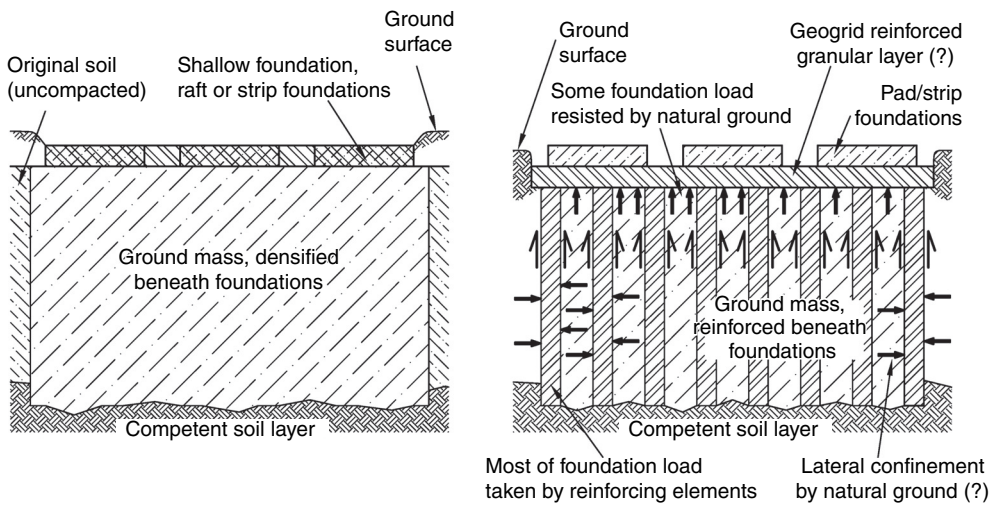

Figure 52.3 Hybrid foundation, piled raft

(a) Ground improvement by densification

(b) Ground improvement by reinforcement

Figure 52.4 Hybrid foundation – deep ground improvement

be summarised on a plan and vertical cross-sections through *and* beyond the site boundaries. Drawn to scale, with levels referenced to an appropriate survey datum, as a minimum, the following features should be drawn:

- **(i)** the previous and proposed ground surfaces;
- **(ii)** any previous and neighbouring structures and underground services;
- **(iii)** ground profile, strata boundaries (including selected ground properties from testing);
- **(iv)** groundwater levels;
- **(v)** outline of the proposed structure and proposed locations for foundations;
- **(vi)** list as bullet points, the key site constraints and hazards.

Based on a knowledge of the ground profile, the type of structure and key site constraints, an experienced engineer should be able to identify appropriate conceptual designs for the foundations. Analyses would then be carried out to check that this concept had an acceptable level of stability and that foundation movements were acceptable. If these are not acceptable, then the concept would be modified (say, pile foundations would

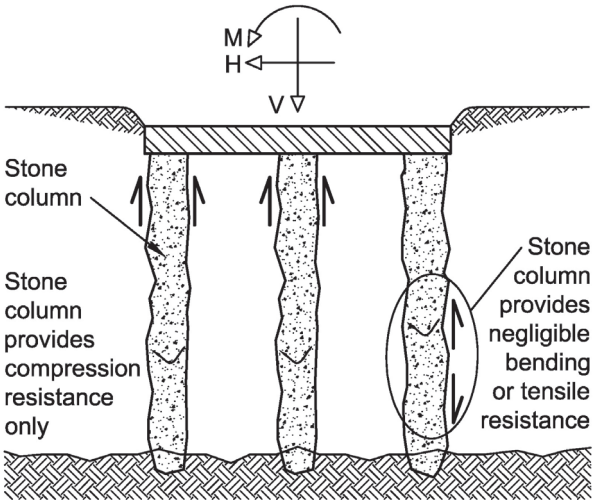

Figure 52.5 Ground improvement as a reinforcement method has limited bending and tensile resistance

be deepened, or shallow foundations would be widened) and rechecked. It is common to consider a few different options. Once technically acceptable foundations are identified, then the costs are assessed. Throughout this conceptual design process, the way in which uncertainties can be best managed in order to minimise risks needs to be considered, together with the buildability of the concept (in essence, 'buildability' is a consideration of how simple, quick and safe the proposed design will be to construct). Once an acceptable foundation design has been identified, more detailed analysis is carried out to finalise the design and prepare drawings and specifications for construction. The nature of the ground risks will usually inform the development of site-specific specification requirements, which may involve observations by experienced engineers or geologists at critical construction stages or specific field tests.

The foundation design process does not end when design drawings are issued. Given the intrinsic uncertainties associated with variations in ground conditions, and the way in which different construction processes may affect subsequent ground behaviour, it is always important that the designer has the opportunity to verify critical design assumptions. However, with some forms of modern contracts and procurement practices (e.g. Design and Build), it can be challenging for a designer to get adequate site supervision opportunities. Nevertheless, it is important that this happens.

52.3.2 General considerations

Any foundation design has to include a consideration of the following:

(i) acceptable stability and deformation;
(ii) risk management;
(iii) costs and programme for construction.

Foundation type	Advantages	Disadvantages
Pad/strip footing	(1) Simple to construct (2) Cheap and quick	(1) Competent soils (note 1), need to be reasonably close to ground surface (typically less than 3 m or 4 m) (2) If the groundwater table is above the base of the footing and there are permeable soils then barriers or dewatering are needed during construction (3) Limited application if applied loads include large horizontal forces or overturning moments (4) Vulnerable to large differential settlements if applied loads vary significantly across structure or if ground conditions are heterogeneous (5) Interaction between adjacent footings, if closely spaced?
Raft foundations	(1) Simple to construct (2) Specialist equipment and sub-contractors not required (3) If sufficient rigidity, then potential for differential settlement is significantly reduced (4) Can 'bridge' across local soft pockets of soil	(1) As noted above (2) As noted above (3) Large area of excavation required, hence, large amounts of spoil generated (particular problem if excavated soils are contaminated) (4) Depth of influence of significant increases in stress will be considerable, will it affect underground infrastructure? Are weak layers present at depth? (5) Raft deformation needs to be carefully checked, is movement acceptably small?
Shallow foundations generally	(1) Simplicity (2) Cheap if appropriate conditions	(1) Inappropriate if site affected by 'global' ground movements (note 2) (2) Excessive depth may be needed to locate foundation below seasonal changes in moisture content or frost penetration (note 3), or, if close to rivers, potential scour depth (3) Inappropriate if desired footing depth would lead to undermining of existing foundations, utilities, roads, canals, railways, etc.

(Continued)

Foundation type	Advantages	Disadvantages
Piled foundations	(1) Large variety of pile types, diameters, depths are possible, so very large applied loads can be resisted (2) If near-surface soils are weak or of variable thickness then pile lengths can be readily modified to suit (3) If near-surface soils are contaminated then exposure can be minimised by appropriate choice of pile type (4) If site boundaries limit width of shallow foundations then piled foundations may be more appropriate (5) Horizontal and moment loads can be resisted (although a pile group may be more appropriate, rather than a single pile)	(1) Can be relatively expensive (2) Construction will require specialist contractor input, hence, construction sequence may become complex (3) Piling construction can be adversely affected by local variations in ground and groundwater conditions; technical and commercial implications? (4) Pile capacity can be significantly affected by construction method and equipment and timing of key activities (5) Costs and time to carry out pile testing (6) Pile construction may adversely impact adjacent structures, utilities, etc.
Caissons/shafts/ barrettes	(1) Can provide extremely high capacity foundations for 'special' structures (2) Can provide relatively high stiffness/capacity to resist large horizontal loads or overturning moments (3) Shafts, in appropriate circumstances, can provide high capacity foundations in sites with limited plan area or headroom	(1) May be complex or expensive to construct (2) Design and construction requires expert input, these skills are usually in short supply (3) Verification of design assumptions may be challenging (4) Deformation behaviour requires careful assessment, may not be amenable to routine analysis methods
Deep ground improvement	(1) Can create cost-effective foundations in poor ground conditions (2) Wide variety of techniques are available, which can allow a broad range of ground conditions to be improved (3) Techniques can optimise the behaviour of the *in situ* ground, hence is a 'sustainable' solution, with a relatively low carbon footprint	(1) The wide range of techniques can be difficult for non-specialists to understand, hence, selection of appropriate method can be challenging (2) Effectiveness of ground improvement can be very sensitive to local changes in ground conditions and to changes in 'workmanship', installation method and equipment (3) A significant effort is needed to verify the effectiveness of ground improvement, this can often be underestimated (in terms of cost/time and complexity of interpretation)
Piled rafts	(1) More economic than conventionally designed pile groups (2) Since fewer piles to install, quicker to construct (3) Appropriately located piles, below large column loads, can significantly reduce structural forces in raft, hence, raft can be thinner, with less steel reinforcement	(1) Complex ground-structure interaction analysis is required, expert input will be required (2) Due to (1) above, more sophisticated ground investigation and interpretation of ground conditions may be required (3) Raft behaviour is important. Hence, as for conventional rafts, competent soils needed at reasonable depth below ground surface (4) Due to (3) above, may not be appropriate if adjacent construction activities lead to 'undermining' of raft

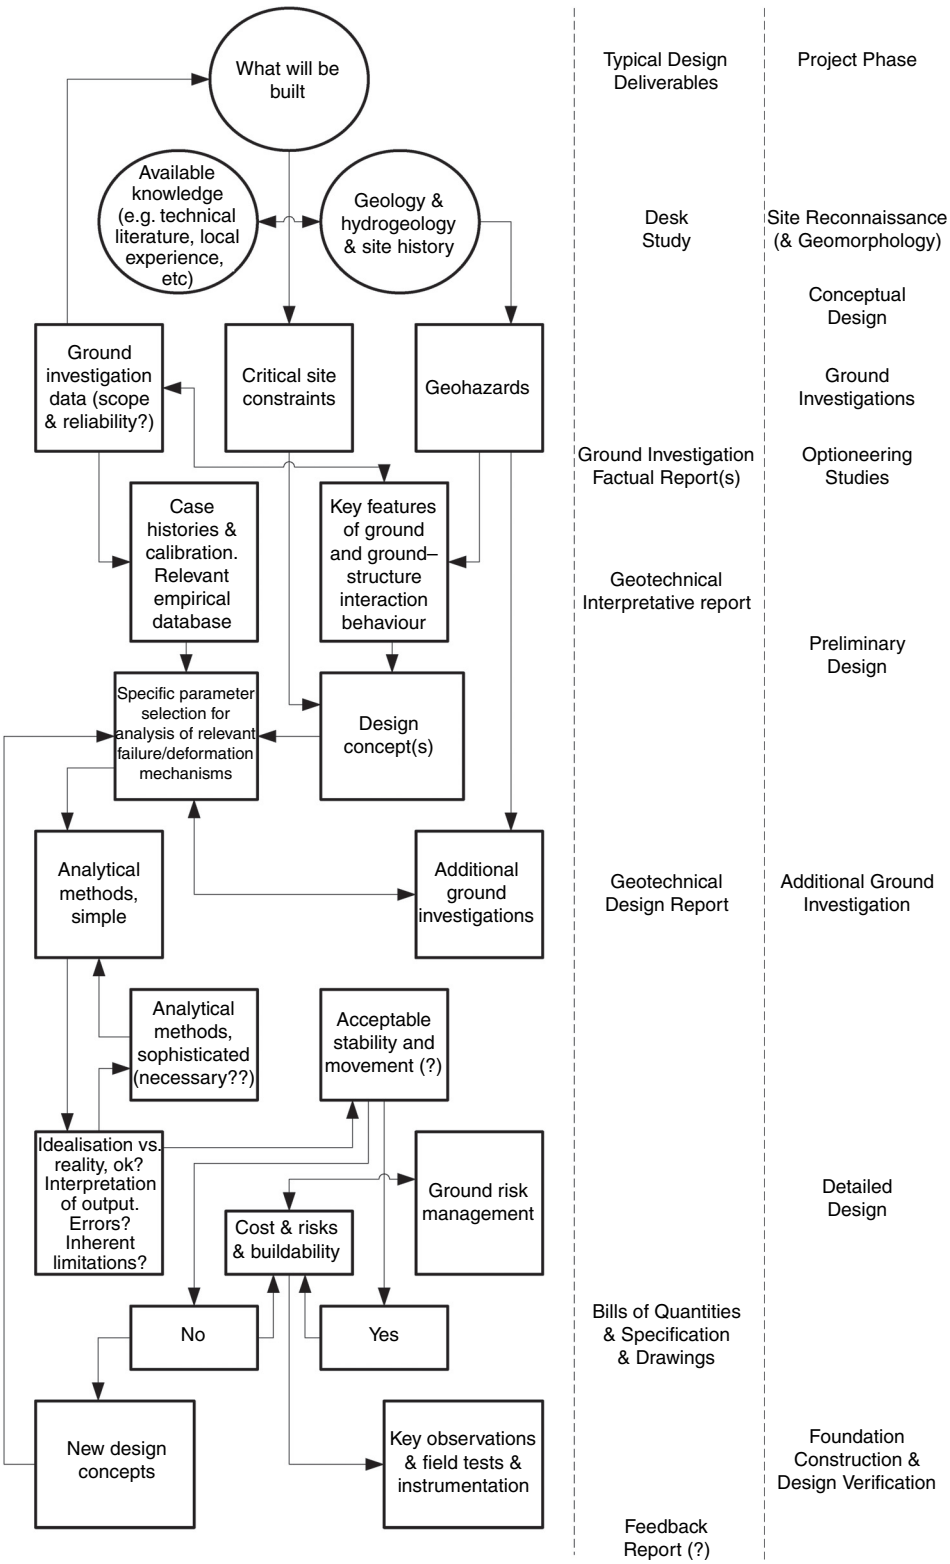
Notes

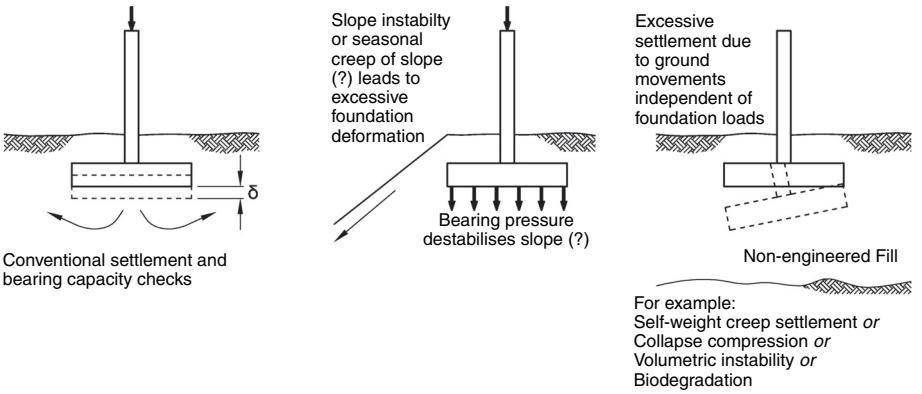
1. The definition of 'competent' soils will depend upon the foundation loads and allowable movements. Typically, competent soils include firm to stiff clays, becoming very stiff at depth, or medium dense to very dense sands.
2. Global ground movements may develop due to a wide range of causes which are independent of the proposed foundation loads, refer to Chapter 53 *Shallow foundations*. For example, the presence of old mine workings, solution features, adjacent slope movements, etc. may lend to 'global' ground movements.
3. Minimum depths for frost protection and seasonal moisture content (pore water pressure) change are given in local building regulations and codes, also refer to Chapter 53 *Shallow foundations*. Seasonal moisture content changes are mainly affected by the type of vegetation present on site; if there are high water demand trees on high plasticity clays then the effects can be significant and extensive (refer to NHBC Standards, 2003 and Chapter 53).

Table 52.1 Advantages and disadvantages of different foundation types

52.3.2.1 Acceptable stability and deformation

The foundations need to carry the foundation loads safely; hence, adequate factors of safety against collapse are required and excessive foundation movement must be prevented. There can be a wide range of different collapse or deformation mechanisms that may need to be considered (**Figure 52.7**). One pitfall can be to focus only on considering collapse or deformation mechanisms for the foundation operating in isolation, solely due to the structural loads imposed by the superstructure. Additional collapse and deformation modes may exist due to the nature of the soil and groundwater regime; the site's location (e.g. if the site is adjacent to an unstable slope); the site's history (e.g. if it has been affected by mining or quarrying); or due to the nature of the regional hazards (e.g. earthquakes, flooding, etc.). In many cases detailed analysis is inappropriate, and eliminating the hazard (e.g. relocating foundations, stabilising the ground mass, preventing erosion, etc.) is the best approach. 'Global' ground movements across a site need to be considered. **Figure 52.7(g)** illustrates a common situation where a sloping site requires cut and fill earthworks to create a level platform in order to build the





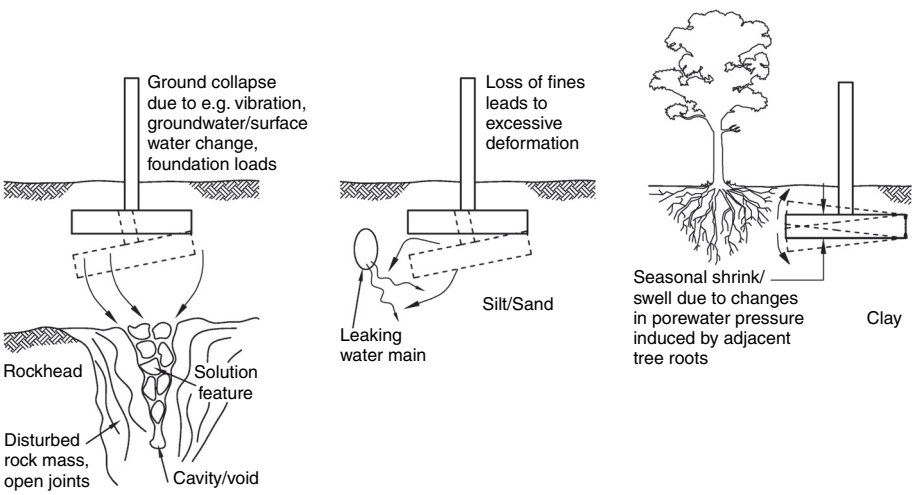


Figure 52.6 Information requirements and the foundation design process

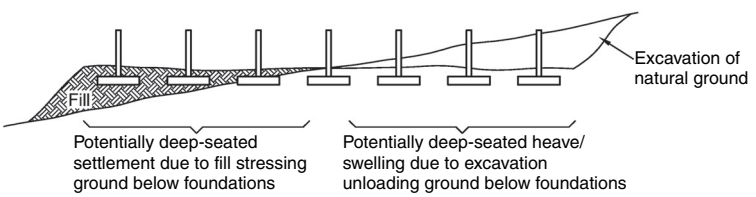
(a) Acceptable stability and deformation under applied superstructure loads

(b) Potential interactions with adjacent slopes (or adjacent retaining walls, foundations, etc.)



(c) Non-engineered Fill Excessive Deformation independent of foundation loads

(d) Excessive deformation due to void/cavity collapse in solution feature (or mineworkings)

(e) Seepage erosion and loss of fines, causing excessive deformation

(f) Seasonal shrink/swell due to trees

(g) 'Global' ground movements due to cut/fill to form level site

Note:
This is not intended to be a comprehensive summary of all potential deformation and collapse modes. Important to recognise that excessive deformation/collapse may occur due to a variety of causes, some of which are independent of applied foundation loading.

Figure 52.7 Examples of various deformation and collapse modes

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

new structure. Strip foundations form the foundations for the new structure. In this situation, even if the earthworks are well engineered and properly constructed, significant global ground movements may develop since:

(i) Beneath the zone of fill there will be deep-seated increases in the vertical stress, due to the weight of the fill, in the underlying natural ground; this will cause settlement (in addition to any settlement due to the bearing pressure on the strip foundation).

(ii) Similar to (i), beneath the zone of excavation there will be deep-seated decreases in the vertical stress in the underlying natural ground, this will cause heave and swelling. This may be larger than any settlement induced by the foundation bearing pressure below the strip foundations, and may lead to a *net upward* movement of the foundations.

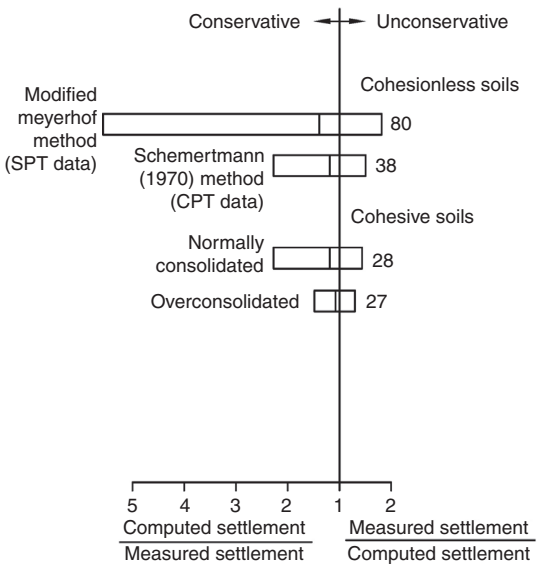


Figure 52.8 Reliability of deformation calculations. The figure gives a comparison between computed and measured settlements of spread footings. Each bar represents the 90% confidence interval (i.e. 90% of the settlement predictions will be within this range). The line in the middle of each bar represents the average prediction and the number to the right indicates the number of data points used to evaluate each method

Based on data from Burland and Burbridge (1984), Schmertmann (1970), Wahls (1985), Butler (1975)

Failure mode	Foundation type	Historic practice: typical overall factor of safety	Limit state codes, e.g. EC7: partial factor on soil strength		
Base sliding	Shallow	1.5 to 2.0	tan φ	c′	S_u
Bearing capacity	Shallow	2.5 to 3.5	1.25	1.25	1.4
			1.25	1.25	1.4
Overall stability	Shallow	1.3 to 1.5	1.25	1.25	1.4
Shaft resistance	Deep	1.5 to 2.5	Pile resistance		
			Shaft		Base
			Varies depending on pile type and test regime		
Base resistance	Deep	2.0 to 3.5			

Table 52.2 Typical factors of safety for foundation design

Site-specific factors	Typical issues
Intrinsic complexity of geology and hydrogeology	Soil profile homogeneous? Artesian or sub-artesian groundwater pressures? Challenging soil behaviour (e.g. sensitive 'quick' clays)
Onerous design criteria	Allowable settlement very low? Is horizontal displacement or rotation critical?
Consequences of failure	Potential loss of life? Major economic loss?
Nature of applied loads	Large and frequent cyclic loads? Occasional wind load? Or accidental impact load?
Availability of local experience and case history data	What has been published? What is known by local engineers from past experience?
Scope and reliability of ground investigation	Appropriate tests and locations investigated? Well supervised? Factual data checked?
Level of geotechnical risk	Ductile or brittle failure mechanism? Complexity of soil–structure interaction?
Construction uncertainties	Can design assumptions be verified? Level and quality of site supervision?
	Foundation behaviour intrinsically sensitive to workmanship?

Table 52.3 Some considerations for selecting a factor of safety

Any calculations of foundation movement would need to consider the stress changes induced by the cut and fill activities, as well as those induced immediately below the strip footings. Potentially the foundations underlain by the area of fill could suffer substantial settlement, and the foundations in the area of excavation could suffer substantial upward movement. Consequently significant differential movement could develop across the interface between the cut-and-fill areas. The magnitude of the movements depends upon: the compressibility and stiffness of the natural ground; the magnitude and areal extent of the cut and fill required; the plan dimensions of the shallow foundations and the magnitude of the foundation bearing pressure. If differential movements were excessive then consideration could be given to: movement joints in the structure; relocation of the structure so it was either solely in an area of fill or solely in a cut area; use of a raft instead of isolated pad or strip footings; or piling. If piles are chosen the pile design needs to consider the negative skin friction below the fill area and the heave-induced tension below the excavation areas. Potential

causes of movement, independent of foundation loads, associated with a range of different soils, rocks and fills are also discussed in Section 3 *Problematic soils and their issues* and Chapters 40 *The ground as a hazard* and 41 *Man-made hazards and obstructions* of the Manual.

Throughout the design life of the structure, foundation deformations need to be acceptably small and allowable deformation will usually be the governing design criterion. Historically, there has been little confidence in the reliability of deformation calculations. **Figure 52.8** provides a comparison between computed and measured settlements for several different foundations in a range of ground conditions. As shown, the actual settlement can be quite different to the predicted value. Hence, codes of practice used to recommend large factors of safety in order to limit foundation deformation. More recently, limit state codes of practice have been published (e.g. Eurocode, EC7) and typically their partial factors of safety against various collapse modes (e.g. ultimate limit state) are lower than those previously recommended, for example, see **Table 52.2**. **Table 52.3** summarises the site-specific issues that should be considered before selecting a factor of safety. Factors of safety given in codes are minimum values, and there may be a need for higher factors of safety if there are significant uncertainties. In favourable circumstances, the new limit state codes can facilitate more economic designs. However, when using limit state codes there is more onus on a designer to exercise judgement, particularly concerning the reliability of deformation calculations (serviceability limit state). For example, since the 1980s there has been a considerable improvement in understanding the stiffness characteristics of overconsolidated clays subject to monotonic increases in stress. In contrast, there remains significant uncertainty about the deformation behaviour of soils subject to cyclically varying loads.

The overriding requirement for assessing deformation behaviour is an understanding of past observations of foundation performance. To be of practical benefit, this experience needs to be based on a careful analysis of foundation performance of similar foundation types under comparable loading, within similar geology and hydrogeology. Case history data can then be used to calibrate the proposed calculation model, and for practical applications the model needs to be as simple as possible whilst still capturing the key features of the soil–foundation interaction. Great care is required if extrapolation is necessary beyond the existing database of knowledge (for example, due to the magnitude of the loading, scale or complexity of the foundations, etc.). In these circumstances, expert advice, special investigations, field trials, etc., are likely to be required. When utilising a database of past performance and an associated calculation model, it is vitally important to verify that the geology is relevant to the site under consideration. For example, Burland and Burbidge (1984) developed an empirical method for calculating the settlement of silica sands. It would be quite dangerous to use this method to calculate the settlement of sands with a different mineralogy, e.g. calcareous or micaceous sands.

52.3.2.2 Risk management

Risks, during and after foundation construction, need to be assessed and managed. There can be a wide range of different types of risk:

- health and safety;
- technical issues, e.g. ground, groundwater and foundation behaviour;
- performance of foundation constructor;
- environmental;
- commercial (costs and programme);
- design interfaces (communication).

Because of the broad range of issues that may need to be assessed, it can be beneficial for the project risks to be assessed formally via a risk workshop, attended by key members of the project team including the geotechnical and structural engineers. In addition, at an early stage of the project, it is helpful to carry out 'Peer Assist' (Powderham, 2010; SCOSS, 2009). Peer Assist involves one or two senior engineers carrying out a proactive independent review of the available project data (including desk-study and ground-investigation data), the project brief and constraints, and assessing the foundation engineering options identified by the project designers. A review of the risk register and challenging the assumptions and design methods used by the designers are important aspects of Peer Assist. Peer Assists are best carried out in a workshop environment with the project design team. The duration of Peer Assist can vary from half an hour for simple projects to several days for complex projects.

The geotechnical triangle is a valuable framework for ground risk management. The geotechnical triangle is introduced in Chapter 4 *The geotechnical triangle* and practical applications are discussed in Chapter 9 *Foundation design decisions*. All aspects of the triangle must be considered. If one or more elements of the triangle are forgotten or poorly implemented then foundation failures are much more likely. The identification of ground risks requires a deep understanding of ground behaviour (in the context of the site's history, geology and hydrogeology) and of the envisaged construction process.

Uncertainty is an intrinsic part of foundation engineering. Hence, there is a need to be aware of what could potentially go wrong and assessing the consequences. The most critical aspect of risk management is to identify risk mitigation measures that are practical to implement and verify on site. For the design to be robust the foundation's behaviour should be relatively insensitive to small changes in ground or groundwater conditions. Construction, particularly below ground, is seldom perfect. Therefore the design should be simple to build and allow for normal construction tolerances and workmanship. The foundation designer will usually need to make several assumptions, and during foundation construction the designer will need to ensure that these key assumptions can be readily verified. This verification process may involve tests, monitoring and observations.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

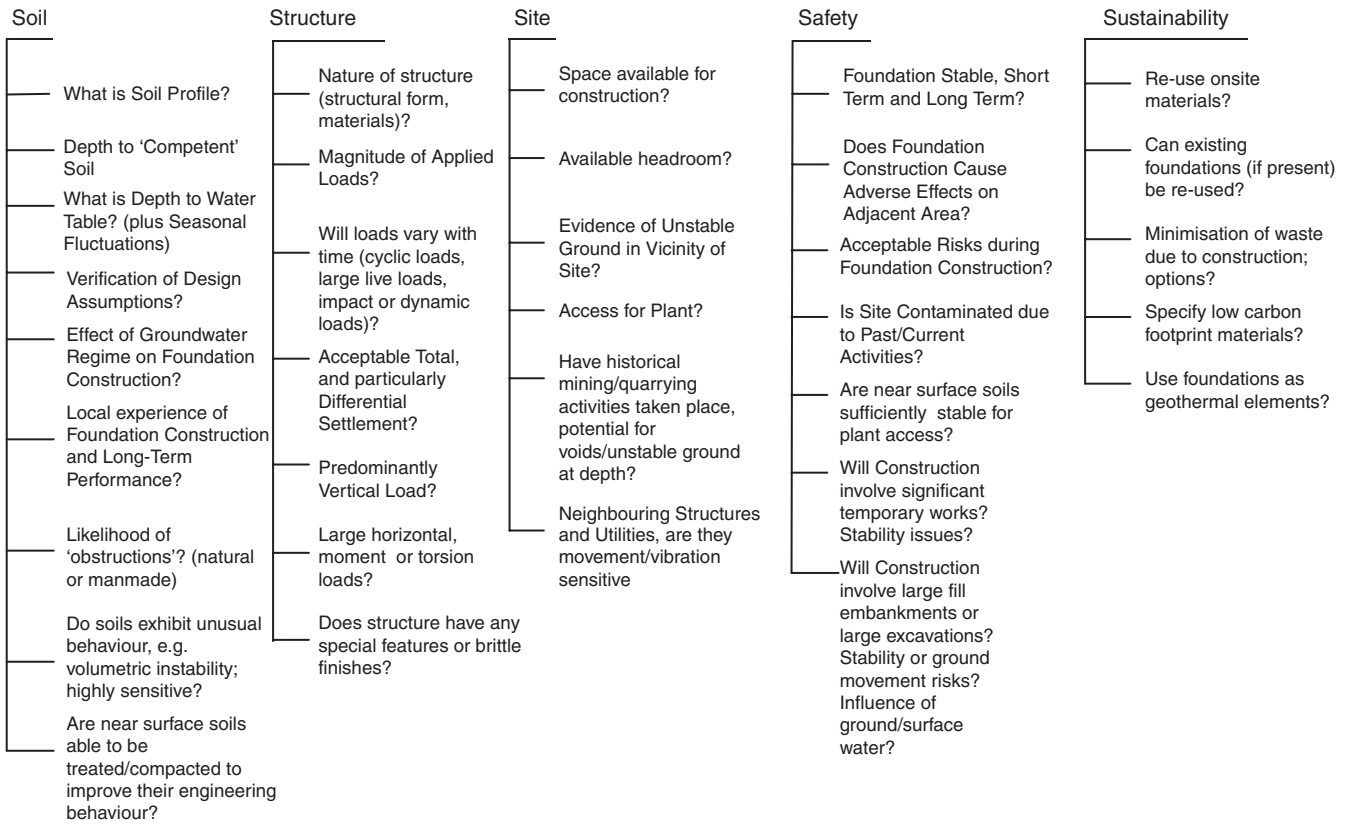

Table 52.4 Foundation selection, 'the five S's'

The verification process could vary from a simple inspection and observation of the exposed ground at foundation level, and verifying that the foundation will be placed on ground that is as strong and stiff as that assumed during design, through to complex instrumented load tests. These observations and tests are an important part of the foundation design process. If a design assumption cannot be readily verified and there are serious consequences if the assumption is not valid, then consideration should be given to changing the design to one which can be more easily verified. Foundation construction below the water table or in a maritime environment can be particularly challenging in this respect. For example, if soft soils are supposed to be dredged below water prior to foundation construction, how can the designer check that all the soft soils have been removed? If soft soils are left behind, instability may result.

52.3.2.3 Costs and programme

The preferred foundation solution will usually be the most economical to build, provided that the long-term performance and associated risks are deemed to be acceptable. Calculating the foundation costs may be based on assessing the quantities (e.g. volume of concrete for strip footing, or number, depth, etc. of piles) for the permanent works, and using unit rates for each of the main foundation elements (e.g. cost per m^3 for forming strip footing). A major problem with this approach is that it may not allow for:

(a) cost of temporary works, e.g. lowering the groundwater if excavations are required below the water table;
(b) cost of supporting excavations if movement sensitive structures or utilities are nearby;
(c) cost of removing obstructions if present, e.g. large boulders in glacial till or old foundations from previous buildings on the site;
(d) costs of treating or removing contaminated soils, if present;
(e) cost of verification tests (e.g. for ground improvement or piling this can be significant).

Hence, the normal methods used for assessing the costs of civil engineering construction may be quite unreliable when used for underground construction. To estimate foundation costs reliably it is important to take account of any necessary temporary works and to understand how the site's history and geology may impact upon foundation construction costs. Foundation construction is often on the critical path for a project. Hence, the preferred foundation solution will often be the one which is quickest to construct and has the least effect on other site activities, since overall project costs are often dominated by the overall duration for construction. 'Unforeseen' ground conditions are the most

common cause of project delays and cost increases (TRL, 1994). In particular, problems caused by groundwater are often the root cause of geotechnical problems on site. Therefore, reliable cost and programme estimates for foundation construction will be heavily dependent on carrying out good project risk management and upon the advice of the geotechnical engineer.

52.3.3 Foundation selection – the five S's

Table 52.4 provides a series of questions that a foundation engineer should ask him (or her) self, before developing a conceptual design. They can be remembered as the five S's: Soil, Structure, Site, Safety and Sustainability. Each will be briefly discussed in turn.

52.3.3.1 Soil (and groundwater)

Once the soil profile and groundwater regime are known, and the local geology and hydrogeology are understood, then the decision between shallow or deep foundations or ground improvement will usually be straightforward. Construction planning will also be heavily dependent on an understanding of the soil profile and groundwater regime. On the basis of geological age, it is often helpful to consider the following four soil types:

(a) *Geologically old, pre-glacial deposits* – These are usually heavily overconsolidated 'competent' foundation materials. When they are encountered close to the ground surface (say within 3 to 4 m) then shallow foundations can often be utilised.

(b) *Glacial deposits* – These soils are often extremely heterogeneous. Some glacial deposits, such as lodgement tills, can be stiff or very stiff clays or dense or very dense sands and be of very low compressibility. As for (a) above, if they are close to the ground surface then simple shallow foundations will often be appropriate. However, some glacial deposits (such as outwash or melt-out deposits) can be very soft and compressible. Changes can occur rapidly from one soil type to another (within lateral distances of 10 or 20 m or less). The interpretation of ground investigation data can be challenging, and input from experienced geologists will be important. Large strong boulders can often be present, which can make piling problematic.

(c) *Post-glacial deposits* – This class of material is seldom suitable as a founding material. These are recent (less than 10 000 years old) deposits and often comprise soft compressible clays or peats or very loose sands or silts. Geologically they are usually classified as normally consolidated. However, many of these deposits can be lightly overconsolidated in a soil mechanics sense (i.e. the pseudo pre-consolidation pressure or yield stress is higher than the current vertical effective stress, but foundation bearing pressures may exceed the pre-consolidation pressure). This may mean that shallow foundations could be feasible for lightly loaded buildings, especially if 'compensated' foundations are used (**Figure 52.1**). However, expert advice and special ground investigations (to verify the magnitude of the pre-consolidation pressure profile) are required. More commonly, for lightly loaded structures, ground improvement is utilised. For heavily loaded structures, piles are used to take the foundation loads to more competent strata at a depth below the post-glacial deposits.

(d) *Made ground and non-engineered fills* – Foundation construction is often carried out in areas that have been affected by previous human activities. These may have involved excavating the shallow natural soils and rocks and backfilling with any readily available materials, including domestic refuse and industrial waste materials. Unless the fill was properly engineered, using acceptable inert materials and well compacted, then it is unlikely to be a suitable founding stratum. Sometimes, lightly loaded foundations can be built on non-engineered fills, although special measures may be needed; foundation engineering in fills is discussed in more detail in Chapter 58 *Building on fills*.

For any of the above scenarios, and particularly for (a) and (b) above when shallow foundations may be used, it will be important to check if subsequent events (either due to man's activities or geological processes) have significantly affected the site, such as mining, quarrying or landslips.

Groundwater regime: it is always important to consider the groundwater regime. Its importance cannot be overstated, and is best summed up by the memorable statement from Terzaghi (1939):

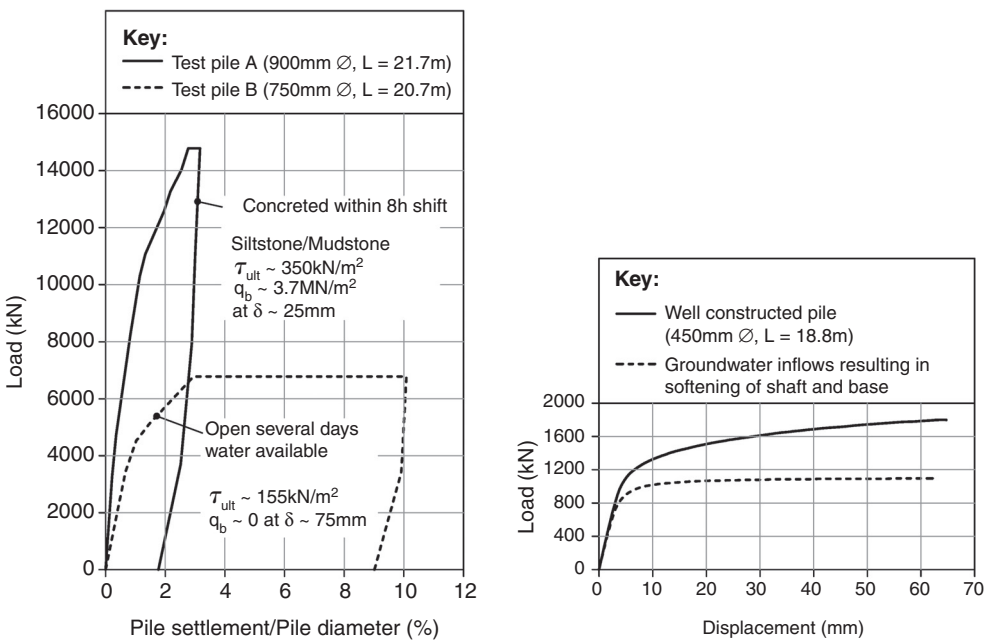
> …in engineering practice difficulties with soils are almost exclusively due, not to the soils themselves, but to the water contained in their voids. On a planet without any water there would be no need for soil mechanics.

Despite its importance many ground investigations do not provide reliable data about a site's groundwater regime. No reliance should normally be placed on groundwater strike information during borehole drilling to assess if a particular soil layer is 'dry' or not. Reliable groundwater information requires careful installation of piezometers, and then monitoring the piezometers over a prolonged time period, preferably covering a period over the winter and spring, when groundwater pressures may be at a maximum. In geotechnical practice, the time period for piezometer monitoring is often inadequate. There is a high risk to any foundation engineering activity, if there is an inadequate understanding of a site's groundwater regime. In addition to piezometric data, local experience of groundwater problems should be considered and discussions held with an experienced hydrogeologist.

As noted by Day (2000): *'probably more failures in geotechnical and foundation engineering are either directly or indirectly related to groundwater and moisture migration than any other factor*.' Some simple examples in foundation engineering are given below:

(i) *Shallow foundations*: forming a shallow excavation above the water table will be relatively quick and cheap, using

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers



conventional plant and general site labour. However, in permeable soils, if the water table is above the base of the foundation level then the works will be more complex, expensive and time consuming. The groundwater will usually need to be excluded, by, for example, forming an impermeable cut-off wall, or by lowering the groundwater table by pumping from wells. Both these activities will often require specialist sub-contractors. Groundwater lowering may lead to ground settlement concerns or concerns with disposal of the pumped water (especially if it is contaminated). Installation of a cut-off wall by driven sheet piling may lead to concerns about noise and vibration. If the groundwater is not properly controlled, then the sides or base of the excavation may become unstable. The bearing capacity and long-term settlement performance would then be adversely affected.

(ii) *Deep foundations*: bored piles are commonly used in the UK. However, groundwater inflows and unbalanced groundwater pressures can seriously reduce the shaft friction and base resistance of a bored pile. If bored piles are to be drilled through cohesionless soils, weak fractured rocks, low plasticity silts or clays below the water table, then some combination of temporary casing, water balance or support fluid (such as polymer or bentonite) will usually be required. Pile test data are shown in **Figure 52.9**, which illustrates the dramatic reduction in pile capacity due to unbalanced groundwater pressures in weak rock and in an interbedded sequence of overconsolidated clays and sands. A common alternative to conventional bored piles are continuous flight auger (CFA) piles. The decision to use either conventional bored or CFA piles is usually dependent on the risks associated with groundwater.

52.3.3.2 Structure

The size and height of the structure, its structural form and the layout of structural supports (spacing of columns) and the type, magnitude and direction of the applied loads will have a major impact on the choice of foundations. For example, the modern trend for multi-storey building design is to create large internal spaces, which leads to relatively large column loads, and the consequential requirement for piled foundations. In addition to the magnitude and distribution of loads, the way in which the load varies over time is also important. The bulk of foundation design experience has been gained with structures that have live loads of less than 15% to 30% of the dead load and change infrequently. Foundation problems are often associated with tanks, silos and industrial units where the ratio of live to dead load is high and the live loads change frequently. The reliability of deformation predictions when cyclic loading is significant remains poor. These potential risks are exacerbated if large cyclic horizontal or moment loads are also applied.

One of the most important, but frequently overlooked, decisions is agreeing a sensible allowable settlement limit for the structure (with the structural engineer), based on a realistic appraisal of its purpose and vulnerability to damage. All too often over conservative and arbitrary limits are placed on total settlement, which then leads to unnecessary increases in foundation costs. The important topic of allowable foundation

(a) Weak rock

(b) Interbedded stiff clays and dense sands

Figure 52.9 Influence of groundwater on pile capacity for weak rock, stiff clay and dense sand

deformation is discussed in more detail in section 52.4. The main opportunity for a geotechnical engineer to design economic foundations, is to agree realistic limits for foundation deformation.

52.3.3.3 Site

In most industrialised countries, such as the UK, foundation construction (for either buildings or rail and road links) often takes place adjacent to existing structures. Old foundations may lie buried across the site. In addition, structures may be located on the site and have to be demolished, prior to the commencement of new foundation construction. Therefore, space for the construction of new foundations is often severely limited. This may mean that either there is inadequate space to create a large pad or strip footing, or there is limited headroom, which means certain piling or ground improvement equipment cannot be used.

A consequence of development in an urban environment is that there are often neighbouring structures or utilities, which may be sensitive to movement or vibration. If this is a concern it would preclude certain foundation types and methods of construction.

The site's history may mean that it is underlain by unstable ground due to past mining or quarrying activity; a thorough desk study (refer to Chapter 43 *Preliminary studies*) is essential. Because of the above considerations, it is usually important to visit the site and to understand the constraints that may affect foundation selection. When visiting the site it is also important to scrutinise neighbouring areas, since this may provide evidence of past problems due to unstable ground or long-term movements. Following completion of a desk study, the main environmental constraints (such as ecologically sensitive areas or areas with special environmental classifications) should be known. How these may affect foundation construction should also be considered.

52.3.3.4 Safety

Under CDM regulations (refer to HSE, 2007) a designer has a duty to formally assess the risks that may arise during construction. Given the uncertainties and the site-specific nature of ground hazards, the foundation designer needs to carefully review all the available information from:

- desk studies;
- ground investigations;
- site visits;
- local experience.

And consider this in the context of:

- planned construction activities at the site;
- condition of neighbouring land and structures, etc.

A particular concern when developing many sites across the UK (and other industrialised countries) is that past industrial activity has left a legacy of chemical or biological contamination. This contamination may have impacted the soil, groundwater and ground gas. In this case, foundation engineering will need to be coordinated and integrated into the strategy for minimising risks due to contaminated land. Often this will affect the choice of foundation type, depending on whether there will be large-scale removal and treatment of contaminated near-surface soils or if the site is to be capped off and the contaminated soils left *in situ*. For example, the use of a displacement piling system may be preferred to bored piles, so contaminated soils are not brought to the surface. Similarly, if ground improvement was being considered then a dry bottom-feed vibro system may be preferred to alternative wet vibro systems, which require subsequent treatment of the wet contaminated slurry.

52.3.3.5 Sustainability

Sustainability comprises three main elements:

- environment;
- social;
- economic.

Environmental impacts can be wide ranging varying from: the challenges and constraints associated with working adjacent to an environmentally sensitive area; the potential impact of contaminated land or groundwater; through to minimising the use of materials with a high embodied energy or carbon footprint.

Social impacts may include, for example, the effects of noise and vibration induced by pile driving in an urban area, or lorry movements associated with removing excavation arisings or spoil from bored piling, or spoil from a large excavation for a raft.

In highly sensitive locations, environmental and social issues may dictate the chosen foundation solution. In general, the objective is to minimise the environmental and social impacts of a project, whilst implementing it at a reasonable cost. Current themes in foundation engineering are:

(a) foundation re-use;
(b) the use of foundations as geothermal elements (refer to Adam and Markiewicz, 2009).

Foundation re-use: it may be possible to re-use existing foundations of, say, an old bridge or building, for the new superstructure. For many practical applications the old foundations are either supplemented by additional new foundations or are strengthened. Foundation re-use can apply to both shallow and deep foundations. Foundation re-use is reasonably common for transportation projects, such as railway bridge refurbishment, and is increasingly being considered for many building projects. CIRIA report C653 (2007) provides an introduction to the topic, and Butcher *et al.* (2006) provides more detailed background information. The current technical literature mainly focuses on the issues associated with re-using piles. Similar issues also apply to re-using shallow foundations, although physical investigations and inspections of shallow footings

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

are often easier than for piled foundations. The key technical issues concerning foundation re-use are:

(i) Old foundations in the correct location? What is the plan location of old foundations relative to the new superstructure loads, e.g. a new building column grid may be offset from the old piles? Can new sub-structures, e.g. new beams or rafts, be built economically to transfer loads from the superstructure into the old foundations?

(ii) Load-carrying capacity and settlement characteristics: the ultimate geotechnical and structural capacity of the old foundations, and their likely movement under the new superstructure loads, needs to be assessed. Since the ground has consolidated (and strengthened) under the old foundation loads and will be subject to an unload-reload cycle (due to demolition of the old superstructure, and then reloading by the new superstructure), the settlement of old foundations would usually be relatively small until the old foundation load is exceeded. Once this load is exceeded much larger movements could develop. If, as is often the case, there is a mix of old and new foundations for the new superstructure then the different settlement characteristics of the different foundation types need to be carefully considered. Normally, the aim is to keep the net bearing pressures under the new superstructure to a smaller value than those under the old structure. Hence, an assessment of the loads that were applied by the old structure is fundamentally important.

(iii) Durability: over time the old foundations may have degraded, e.g. steel may have corroded or concrete may have been subject to sulphate attack. Assessing the residual design life of the old foundations can be the most complex part of foundation re-use assessment. Geotechnical engineers will usually need to get additional advice from materials specialists.

52.4 Allowable foundation movement

The magnitude of the allowable settlement is critical in determining the type and size of foundations that will be required, and, therefore, the foundation cost (see Chapter 19 *Settlement and stress distributions* for an introduction to methods of settlement prediction). It is important that the foundation engineer is involved in discussions with the structural engineer before the allowable settlement is decided, and challenges values that are unreasonably small. Reference to Chapter 5 *Structural and geotechnical modelling*, will be helpful in understanding the differences in approaches between structural and geotechnical engineers. As noted by Burland *et al.* (1977):

> Compared with the literature on the prediction of foundation movements, the influence of such movements on the function and serviceability of structures and buildings has received little attention. Yet major and costly decisions are frequently taken on the design of foundations purely on the basis of rather arbitrary limits on total and differential settlements.

Ideally, the foundation engineer would be able to predict the amount of differential settlement a structure can tolerate, and then predict the differential settlement that will actually occur due to the imposed structural loads and the response of the ground below the foundations. For most practical situations, it is impossible to make this prediction. As noted by Fang (2002):

> It is an extremely complex indeterminate analytical problem.

And he warns that:

> If an attempt is made to model analytically the structure and calculate the effect of differential settlements, one obtains ridiculously low allowable differential settlements because of the unrealistically large bending moments that will be calculated.

The factors that will affect real soil–foundation–superstructure interaction behaviour (Boone, 1996) include:

- variations in soil properties;
- variations in the construction sequence of the foundations and superstructure;
- uncertainties regarding the rigidity of connections across the foundation and within the superstructure;
- flexural and shear stiffness of the superstructure;
- changes in stiffness of the superstructure during construction and how load redistribution to the foundations will be affected;
- degree of movement (or 'slip') between the foundation and the ground;
- overall shape of the ground-movement profile and the location of the structure within it;
- building shape (both in plan and height);
- uncertainties in the way that the loads will redistribute in the long term as the structure settles differentially;
- variable influence of time, both in the rate of settlement of the ground, and how creep and yield within the structure will develop.

Because of the above complexities there is a need for simple guidelines based on previous experience. The assessment of allowable settlements and the development of criteria for routine limits on allowable settlements have been established empirically on the basis of observations of settlement and damage in actual structures. The paragraphs below summarise these observations and provide simple guidelines. It should be emphasised that these are 'routine limits' for conventional structures and are *not* intended to be rigid rules. They will not apply to all structures; Burland *et al.* (1977) and Powderham *et al.* (2004) describe case histories where the simple guidelines were *not* appropriate. This is an area of engineering where both geotechnical and structural engineers must work closely together.

Firstly it is important to distinguish between the following:

(1) Total Settlement – this may cause damage to services connecting into a structure, but will not lead to damage to the structure itself.

(2) Differential Settlement – due to rigid body rotation or tilt, which may be noticeable in high buildings and affect lifts or escalators, etc.

(3) Differential Settlement – due to relative displacements within the structure. It is this movement which can lead to structural damage. For example, there may be differential settlement between adjacent building columns or bridge piers.

In the literature there is a wide range of terminology, the most commonly used terms are described in Chapter 26 *Building response to ground movements*.

There can be confusion about the criteria that need to be satisfied when assessing appropriate settlement or movement limits (see Chapter 26 *Building response to ground movements* for a full discussion of building responses to ground movements). In general, three basic criteria need to be considered:

(1) Visual appearance – this includes deviation of walls, columns or floors from the vertical or horizontal, respectively, and cracking of walls or cladding. These matters are highly subjective and vary between different people and across different regions of the world. Burland *et al.* (1977) have given a five-point classification system for visible damage, which is widely used. It should be noted that the system is not intended to be a direct measure of the degree of damage and relates specifically to the ease of repair of the brickwork, masonry and plaster. The two lowest categories of degree of damage are very slight (crack widths less than 1 mm) and slight (crack widths less than 5 mm). At these damage categories the building would be remote from structural instability. However, crack widths of 3 to 5 mm would be unsightly. Walls, columns and floors which deviate from the vertical or horizontal by more than 1 in 250 would usually be noticeable, and judged to be unacceptable. Whether these movements affect the functionality or serviceability of the structure depends on the nature and configuration of the structure.

(2) Serviceability limit state (SLS) – a loss of serviceability typically means that there is:

- loss of weather tightness;
- loss of fire resistance;
- loss of thermal or sound resistance;
- connections to external pipework (water, gas, etc.) are damaged;
- lifts, cranes or internal machinery cannot operate properly;
- doors or windows sticking.

(3) Ultimate limit state (ULS) – this means that individual structural members may fail, or in an extreme case the whole structure may collapse. Structural distress is usually associated with excessive bending or shear stress in superstructure members. These limiting stresses are defined in the relevant structural design codes.

For the majority of buildings, the allowable settlement will be governed by (1) or (2) above, i.e. visual appearance or serviceability limits rather than by structural damage. For residential buildings (1) is likely to be most important, whereas for industrial buildings criteria (2) will be more relevant. For bridges, serviceability limit states for foundations are usually governed by avoiding SLS or ULS limits in the bridge deck and movement joints at piers and abutments.

52.4.1 Routine guides on limiting settlement

Published guidance on routine limits for allowable settlement consider sands separately to clay. The reason for this is that structures are more likely to suffer damage if the settlement occurs rapidly than if it develops slowly over many years. Hence, the settlement limits for sands are lower than for clays. **Figure 52.10(a)** plots maximum differential settlements against maximum settlement for buildings on raft foundations and **Figure 52.10(b)** provides a similar plot for frame buildings on isolated foundations (e.g. pads, strip, footings, etc.).

Most of the data has been taken from studies by Skempton and MacDonald (1956) and Grant *et al.* (1972). The data for buildings founded directly on clayey soils is shown separately to those founded on a stiff layer (such as dense sand or gravel) overlying the clay. In a few extreme cases, differential settlements (for both rafts and pads or strips) are nearly as large as the maximum settlements, and lie above the Bjerrum (1963) guidelines for the relationship between differential and maximum settlements. However, for the vast majority of situations the Bjerrum guidelines seem to be conservative. For rafts founded on overconsolidated London and Lambeth group clays, Morton and Au (1974) report differential settlements equal to about 25% of the maximum settlement. Isolated foundations, such as pad or strip footings, would normally be considered to be 'flexible' when considering the overall interaction of the foundation and superstructure. Although, as individual elements they may be assumed to be rigid when calculating settlement by routine methods (refer to Chapter 53 *Shallow foundations*).

The routine limits for the maximum total settlement for buildings are summarised in **Table 52.5.**

Foundations on sands seldom exhibit large settlements due to monotonic increases in stress; typically settlements will be less than 75 mm (Bjerrum, 1963; Terzaghi, 1956). Most problems with foundations on sand are due to vibration or other forms of cyclic loading, or due to groundwater seepage and erosion. In areas of the world that are prone to seismic activity, earthquake shaking can cause large-scale instability and highly damaging movements of foundations on sands (refer to Chapter 60 *Foundations subject to cyclic and dynamic loads*).

According to the data shown for frame buildings on isolated foundations, in **Figure 52.10(b)**, damage usually occurs when

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

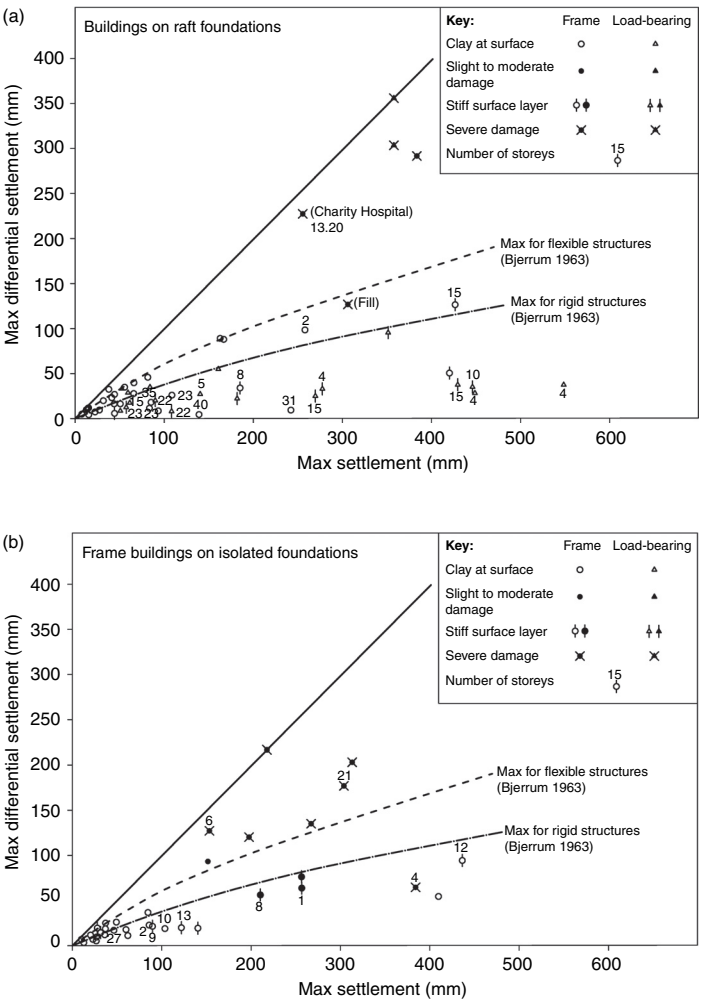


Figure 52.10 Observations of damage. Settlement and differential settlement. (a) Raft foundations; (b) isolated foundations, pad and strip footings
Data taken from Burland *et al*. (1977)

Foundation type	Soil type	Routine limits: maximum total settlement (mm) (Smax), note 6	Typical differential settlement
'Isolated', Pad, strip (note 1)	Clay	65	< 0.66 Smax, if Smax ≤50 mm < 0.5 Smax, if Smax >200 mm (note 2), (note 3)
Raft	Clay	100	< 0.33 Smax (note 4)
'Isolated', Pad, strip (note 1)	Sand	40	< 0.75 Smax (note 5)
Raft	Sand	65	

Notes:

1. Pad and strip footings are normally considered to be 'flexible' when assessing the overall interaction of the foundations and superstructure. As individual elements they may be rigid, depending on their thicknesses compared with their lengths or widths (ref Chapter 53).
2. These limits apply when the clay is immediately below the foundation. When a stiff layer is between the foundation and the clay, then the differential settlements can be substantially reduced and typically the differential settlement < 0.5 Smax. This stiff layer could be natural (say, due to a dense sand or gravel stratum) or be constructed as part of the foundation design.
3. Assume linear interpolation to assess differential settlement, when maximum settlements are between 50 mm and 200 mm.
4. This is usually conservative, as the relative raft bending stiffness increases (refer to Chapter 53 *Shallow foundations*), the differential settlements can be substantially reduced, to values of less than 0.15 Smax.
5. Differential settlements on sands can exceed 0.75 Smax (Bjerrum, 1963).
6. These routine limits are only intended for low-risk situations and simple structures, also refer to **Table 52.7**.

Table 52.5 Routine limits for the maximum total settlement of buildings

differential settlements exceed about 50 mm, or maximum settlements exceed about 150 mm. Based on an analysis of 69 case studies, Ricceri and Soranzo (1985) suggested a settlement limit of 80 mm to avoid structural damage. For buildings on rafts (**Figure 52.10(a)**) significantly larger settlements seem to be tolerable, with damage only being recorded for maximum settlements in excess of 250 mm. It is notable that some buildings founded on relatively rigid rafts have tolerated maximum settlements in excess of 400 mm, without suffering significant damage. For these structures, the raft rigidity has limited the differential settlement to about 10% of the maximum settlement. More recently Zhang and Ng (2005) have collated a large database of building damage. This database comprises about 300 buildings, of which about 100 buildings were in Hong Kong, and includes a variety of different building types (office blocks, warehouses, factories, hotels, hospitals, etc.), mainly on isolated foundations. Structural types include steel and reinforced-concrete frame and load-bearing wall structures. Underlying ground conditions include sand, clay and alluvium. **Figure 52.11(a)** shows histograms of the settlement for 95 buildings, for both shallow and deep foundations. They classified damage as either intolerable (where repair work is needed to the structure) or tolerable, and these categories are, therefore, different to the damage categories shown in **Figure 52.10**. Most buildings with settlements of less than 100 mm are undamaged and there were no reports of damage when the settlement is less than 50 mm. However, when the settlements exceed 200 mm intolerable damage becomes common; see **Figure 52.11(a)**. For angular distortion, Zhang and Ng report that values which are more severe than 1 in 400 are usually intolerable. Therefore, based on the case history data shown in **Figures 52.10** and **52.11(a)**, the routine limits for the maximum settlement given in **Table 52.5** will usually be conservative. This is particularly the case when raft foundations are used.

Moulton (1985) carried out a comprehensive study of tolerable movements of highway bridges in the United States of

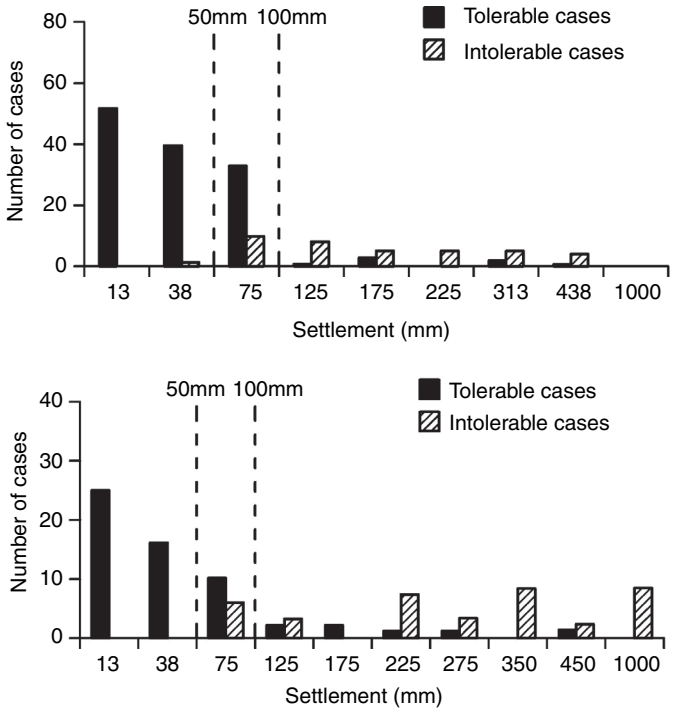

Figure 52.11 Observation of (a) building damage and settlement; (b) bridge damage and settlement
Reproduced from Zhang and Ng (2005)

America and Canada. The bridge types included steel, concrete and composite, and were continuous spans or simply supported. They were small to medium span (less than 50 m span) bridges and of simple structural form (e.g. cable stay and suspension bridges were not considered). The bridges were built on a range of soils (clays, sands) and rocks. Of the 580 bridges which were studied, 439 experienced some form of significant movement. The primary causes were excessive movements of approach embankments, inadequate lateral resistance and large foundation displacements. **Figure 52.11(b)** provides a histogram of settlement for 171 bridges. From this data it can be seen that intolerable damage is usually observed if settlements exceed about 75 mm to 100 mm. Zhang and Ng also report that if angular distortion exceeds 1 in 250 then intolerable damage is usually caused. Movements are usually tolerable if settlements are less than 50 mm or if angular distortions are less severe than 1 in 500. Barker *et al.* (1991) note that settlements are more damaging when accompanied by horizontal movements (and if the structure has inadequate horizontal strength).

Table 52.6 summarises routine limits for allowable movements for a range of structures and associated infrastructure such as drains, lifts, etc.

52.4.2 Site-specific assessments

It should be emphasised that the routine limits given in **Table 52.5** should only be used for low-risk site conditions and for simple structures. For more complex situations (some examples

Factor	Comments
Heterogenous ground conditions	Significant variations in soil type, layer thickness or competence of the soil layers below different parts of the foundation
Variations in loading	Different loads applied across foundation
Variations in construction duration	May induce increases in differential settlement, if the degree of consolidation of clay layers varies significantly
Variations in site history	Part of the site has been pre-loaded by old foundations, or part of the site has been excavated and the underlying clay has swelled and softened
Variations in site topography	If foundation is on side long ground, then different amounts of excavation may lead to substantial changes in net foundation bearing pressure
Changes in superstructure stiffness across the foundation	Changes in configuration of the structure, connection joint stiffnesses or cladding details, e.g. height, thickness or spacing of columns, walls, etc., could lead to local stress concentrations and increased sensitivity to differential ground movements.
Form of structure, potential for 'brittle' behaviour	Certain forms of structure, for example, short or thick columns and flexible floor slabs, are vulnerable to relatively small differential ground settlement, see, e.g. Burland *et al.* (1977)

Table 52.7 Factors that could increase the risk of damage due to differential ground movements

are outlined in **Table 52.7**) a more detailed consideration of differential ground movements and allowable limits for foundation design may be necessary. As noted earlier, realistic analysis of stresses within the structure due to differential ground movements are seldom practical or necessary. If a more detailed assessment is necessary, then consideration should be given, firstly to:

(i) Identify the component(s) of the structure that will be most sensitive to foundation movement, and when they will be built (or a likely construction sequence), and the relative weights of the main components of the structure.
(ii) The sequence of construction and likely immediate settlements or differential settlements that may arise due to the weight of each of the principal components of the structure, assuming the structure is flexible.
(iii) Each component of the structure will only be vulnerable to differential settlement and any resulting damage, which occurs *after* the component is built into the rest of the structure.
(iv) Following (ii) and (iii), assess the relative rigidity of the foundation or sub-structure and apply corrections in order to derive the appropriate differential settlements (refer to Chapter 53 *Shallow foundations*).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Type of structure	Type of damage	Criterion	Routine limits	Comments
Framed buildings and reinforced load-bearing walls	ULS structural damage	Angular distortion	1 in 150 to 1 in 250	ULS concerns at these limits
Framed buildings and reinforced load-bearing walls	SLS cracking of walls, cladding, partitions	Angular distortion	1 in 300 to 1 in 500	Typically SLS concerns at these limits
Unreinforced masonry walls	Visual onset of cracking	Deflection ratio	Sagging 1 in 2500 (L/H = 1) 1 in 1250 (L/H = 5) Hogging 1 in 5000 (L/H = 1) 1 in 2500 (L/H = 5)	At these limits, there is only the onset of cracking; the damage is very slight. Tolerable movements are several times larger L= length of structure, H = height of structure
Steel, fluid storage tanks	SLS leakage	Angular distortion	1 in 300 to 1 in 500	
Utility connections	SLS	Maximum settlement	150 mm	Less for sensitive utilities, such as gas mains
Crane rails	SLS crane operation	Angular distortion	1 in 300	Depends on specific crane configuration
Floors, slabs	SLS drainage	Angular distortion	1 in 50 to 1 in 100	Depends on specific falls, alignment
Stacking of goods	ULS, collapse	Tilt	1 in 100	
Machinery	SLS, efficient operation	Angular distortion	1 in 300 to 1 in 5000	Depends on machine type and sensitivity. Bjerrum (1963) suggests 1 in 750 as 'typical'
Towers, tall buildings	Visual	Tilt	1 in 250	Tilts in excess of this will be noticeable and concerning, though possibly remote from collapse, depending on structure configuration. For the Leaning Tower of Pisa the tilt is 1 in 10
Towers, tall buildings	Lift and escalator operation	Tilt, after installation	1 in 1200 to 1 in 2000	Sequence of construction and timing of lift and escalator installation is important
Bridge	SLS	Angular distortion	1 in 250 to 1 in 500	Depends upon bridge deck characteristics and articulation arrangements
Bridge	SLS	Maximum settlement	60 mm	Typical values
Bridge	SLS, bearing	Horizontal displacement	40 mm	Typical values

Note:
Above limits based on: Burland and Wroth (1974); Day (2000); Barker *et al.* (1991); Boone (1996)

Table 52.6 Routine limits for allowable movements

(v) Compare the resulting differential settlements and angular distortion against the routine limits (given above) for the appropriate component of the structure.

Simple examples are given below for a frame building on a raft and a single-span bridge. The relevant settlements that need to be considered for a particular stage are those that are time dependent due to previous construction stages, together with those that are short term plus time dependent due to later construction stages. **Figure 52.12** shows a plot of settlement against time for different parts of a frame building. During excavation some heave occurs. The raft is constructed first and it is affected by subsequent differential settlements. As additional elements of the structure are built, short-term settlement occurs due to the incremental increases in weight of the structure. The parts of the structure that are built and tied together will experience differential settlement (and potentially be vulnerable to damage) due only to the settlements that occur after the element under consideration has been built. During construction the cladding will be added and internal components such as lifts and escalators will be built and connections to external utilities will be made. Finally the live load will be applied. Hence, the maximum settlements and differential settlements experienced by different parts of the building may be very different. The differential settlement of the raft will be larger than internal structural members, and much larger than for elements such as the cladding or lifts, which are usually the most sensitive to differential settlement. The risk of structural damage reduces as the ratio of live load to dead reduces, and the risk of visual or serviceability damage reduces if the construction of cladding and other sensitive components are delayed as much as possible.

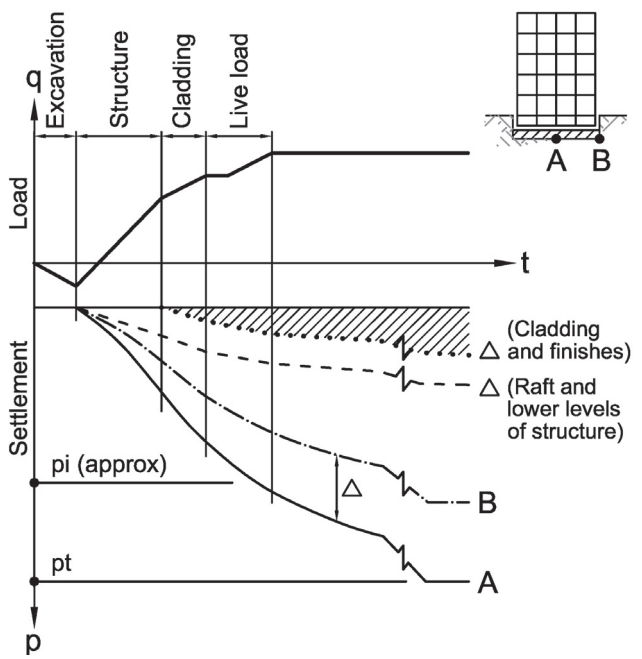

Figure 52.12 Frame building settlement vs. time

Figure 52.13 shows a plot of settlement and horizontal displacement against time for a single-span bridge. Most of the weight of the bridge and resulting settlement will be due to the abutments and their backfill. The settlement, and particularly the differential settlement experienced by the bridge deck, will usually be the main concern, and the residual differential settlement experienced by the bridge deck may be a small fraction of the maximum settlement of the bridge abutments. It is also apparent that the bridge-deck settlement and, the horizontal displacement of the bridge-deck bearings will be affected by the timing of backfilling to the abutments, relative to the bridge-deck construction. If the abutments are backfilled first, then the subsequent movements, which may affect the deck and bridge bearings, will be much smaller than if the deck is constructed before the abutment backfill.

52.5 Design bearing pressures

The superstructure loads calculated by a structural engineer will enable the *gross* foundation bearing pressures to be determined (see Chapter 21 *Bearing capacity theory* for an introduction to bearing capacity theory). However, it is the *net* foundation bearing pressure which should be used for both bearing capacity and settlement calculations (**Figure 52.14**), *not* the gross bearing pressure. The *net* pressure is that part of the gross applied pressure that requires the shear strength of the ground to support it. Hence, a factor of safety should always be considered in the context of *net* pressures only. There can be confusion about the terminology that is used for foundation bearing pressures, therefore, the following definitions are important:

q, *gross foundation pressure* – total applied load at founding level (includes the weights of the superstructure, sub-structure and foundation) divided by plan area of foundations

q_n, *net foundation pressure* – gross pressure minus the overburden pressure at founding level

q', *effective foundation pressure* – gross pressure minus the groundwater pressure

q_f *or* q_u, *ultimate bearing pressure* – value of bearing pressure at which the ground fails in shear

q_s, *maximum safe bearing pressure* – value of bearing pressure at which the risk of shear failure is acceptably low

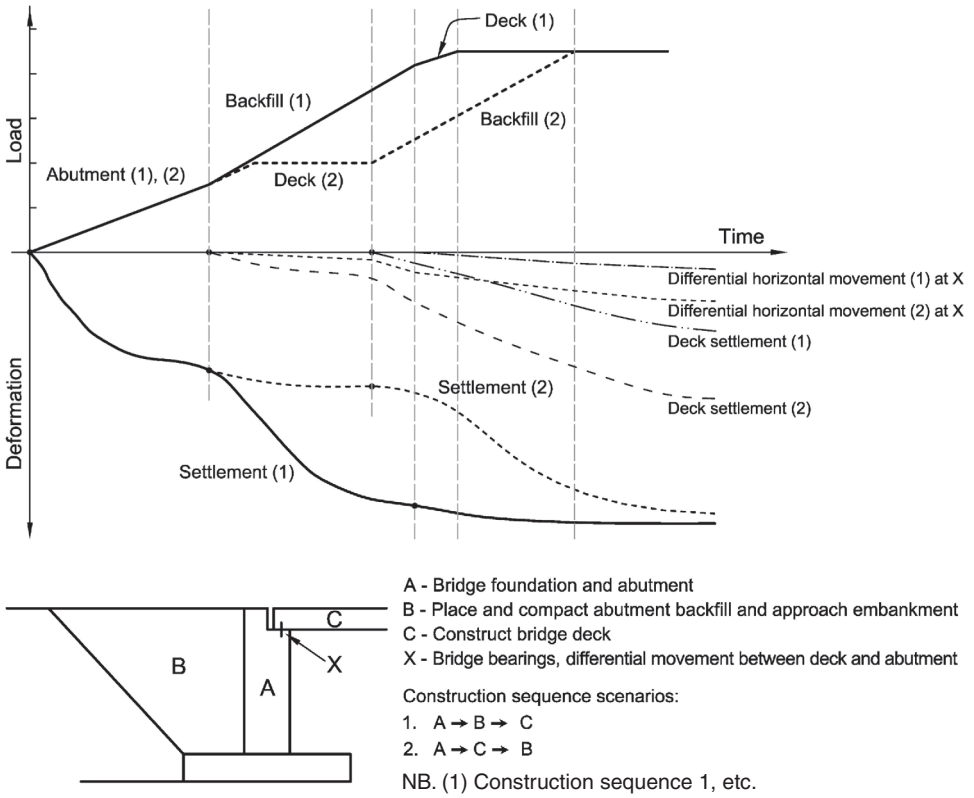
q_a, *allowable bearing pressure* – value of bearing pressure at which the risk of excessive deformation and shear failure is acceptably low

q_w, *working pressure* – value of bearing pressure applied to foundations.

For limit state code calculations, q_s refers to the ultimate limit state and q_a to the serviceability limit state.

The application of transient loads should consider both the type of ground at founding level and whether ultimate or serviceability limit states are being considered. The total settlement of clays would usually consider the dead load plus a fraction of the live load (typically about 25%), since clay

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers



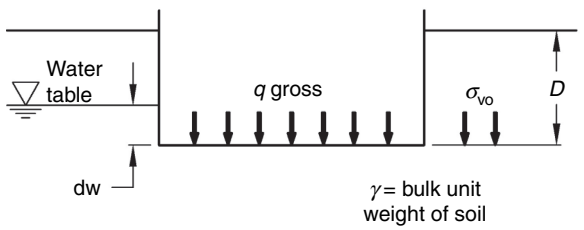


Figure 52.13 Bridge abutment movement vs. time

$q_{net} = q - \sigma_{vo}$, net total pressure
$q'_{net} = q' - \sigma'_{vo}$, net effective pressure
$\sigma_{vo} = \gamma D$, $\sigma'_{vo} = \gamma D - \gamma_w d_w$ (γw = bulk unit weight of water)
$q' = q' - \gamma_w d_w$ and
$q_{net} = q'_{net}$

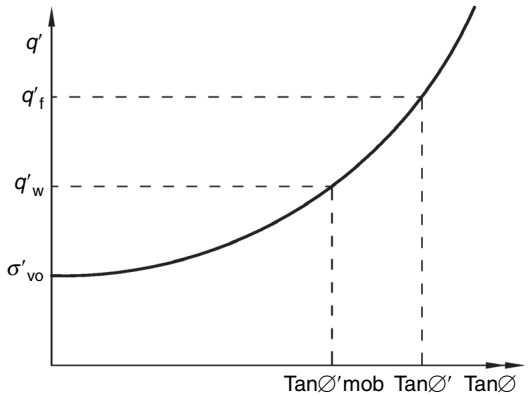
Figure 52.14 Definitions of net and gross bearing pressure

consolidation will not be significantly affected by short-term transient loads (such as wind loads). In contrast, the stability of foundations on clays should consider both the dead and the full-live loads, and since the maximum bearing pressure will usually include short-term transient loads, the strength of clay should be based on undrained rather than drained (effective stress) parameters. For clays and other cohesive soils, undrained bearing capacity is usually more critical than drained. Although, if in doubt (especially for inclined loading conditions) both undrained and drained conditions should be checked. For cohesionless soils, it is the drained bearing capacity which is relevant.

It is important to clearly define the factor of safety that is being used. Different codes use different definitions and they are not necessarily equivalent. For example, for cohesionless soils (sands, gravels, etc.) two common definitions are:

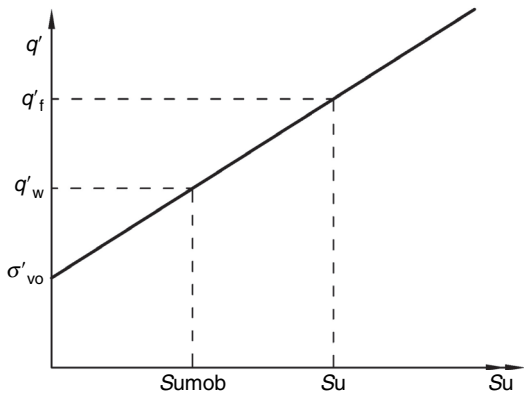
(i) Factor of safety for strength (angle of friction, φ'),

$$F_{sd} = \frac{\tan \varphi'}{\tan \varphi'_{mob}} \tag{52.1}$$



(ii) Factor of safety for drained bearing capacity, $F_{bd} = \dfrac{q'_f(net)}{q'_w(net)}$. (52.2)

From **Figure 52.15(a)** it is clear that F_{bd} does *not* equal F_{sd}, and that F_{bd} is much greater than F_{sd}.



In contrast, for the undrained bearing capacity, $F_{bu} = F_{su}$ (refer to **Figure 52.15(b)**), where

$$F_{bu} = \frac{q_f(net)}{q_w(net)} \text{ and } F_{su} = \frac{S_u}{S_{umob}}$$

and S_{umob} is the mobilised undrained shear strength under q_w (net).

(a) Drained bearing capacity and mobilised friction angle

(b) Undrained bearing capacity and mobilised undrained strength

Figure 52.15 Bearing capacity and mobilised strength

52.6 Parameter selection – introductory comments

Poor parameter selection is a common pitfall in foundation engineering. Parameter selection can appear to be a black art, both for young geotechnical engineers and to general civil and structural engineers. Parameters such as soil strength and compressibility are significantly affected by a wide range of factors, including the testing methods, rate and direction of loading, the volume of ground tested, etc. Sampling disturbance affects the reliability of many laboratory tests and *in situ* tests can be difficult to interpret. Hence, parameters cannot be easily and accurately measured or used indiscriminately in a wide range of different calculations.

The ground investigation needs to, as a minimum, identify the following:

(i) Key soil characteristics, including: strength, compressibility, the presence of water-bearing layers (sand or silt), and the presence of weak layers.
(ii) Likely variability of properties: variation in soil strata thicknesses, relative density, strength, etc.

For routine ground investigations, soil strength can usually be more reliably established than soil compressibility or stiffness. Routine sampling often induces significant disturbance and, hence, variability in laboratory measurements of strength and stiffness. Therefore, variability in properties is usually best assessed via *in situ* test methods such as: static cone (CPT) profiling or via continuous sampling and split/describe/photograph and high-frequency classification tests (e.g. moisture contents, Atterberg limits, particle grading, etc.). Understanding the nature of the soil fabric is important in terms of assessing overall behaviour, e.g. in terms of rates of drainage or softening (Rowe, 1972).

In addition to ground investigation methods, the following factors will also need to be considered when selecting design parameters:

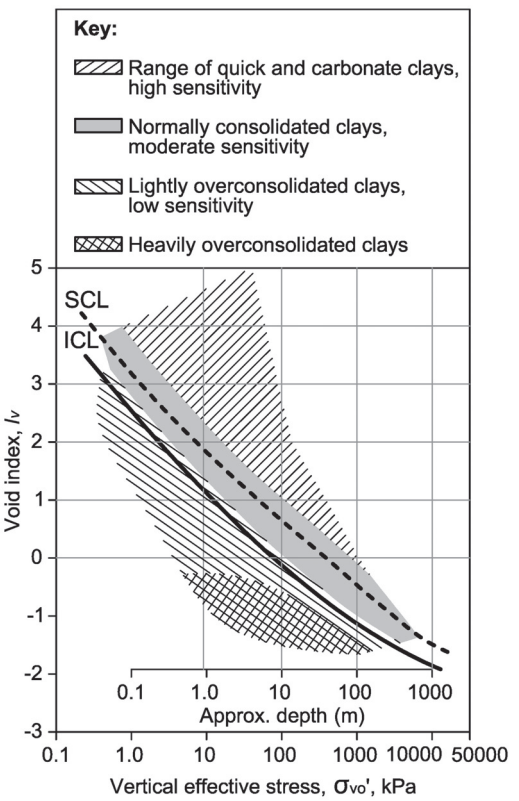
(i) the soil type, and its geological origins and subsequent history;
(ii) the nature of the chosen method of analysis;
(iii) the magnitude, direction and type of loading;
(iv) the scale and type of failure mechanism, and construction influences;
(v) the overall philosophy, for factor of safety selection.

Once all the factual data from a ground investigation has been assembled, data interpretation follows four main steps:

(i) Derive strength and compressibility from the factual information, usually directly from laboratory data, or indirectly via *in situ* tests (from theoretical analyses or empirical correlations).
(ii) Identify representative values for each stratum, which usually involves deleting excessively high or low values (due to sampling or testing errors or local 'hard' layers).
(iii) Cross-correlate different types of data to check that consistent and logical changes in strength and compressibility have been derived.
(iv) Once robust reliable data sets have been collated, design profiles can be determined; this may involve some statistical analysis (especially of index tests or penetration tests), but is largely dependent on experienced judgement.

Table 52.8 gives comments on some of the most common issues that affect soil strength and compressibility parameter selection. These basic parameters always need to be assessed. A clay's strength and compressibility characteristics are fundamentally linked to its:

- plasticity index;
- overall macrofabric (presence of silt, sand layers; presence, spacing and orientation of fissures);
- stress history, in particular its overconsolidation ratio.



The liquidity index can be approximately correlated with a clay's overconsolidation ratio, e.g. near-surface clays (within

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Soil type, geological origins and subsequent history	Soil strength and stiffness are usually anisotropic due to bedding and stress history. If the yield stress is within the foundation bearing pressure then substantial changes in compressibility will occur following yield (**Figure 52.18(b)**). The ground shear (or Young's) modulus can degrade by an order of magnitude with strain amplitude (**Figure 52.18(c)**). Thin low strength layers may substantially affect the safe bearing pressure or overall stability.
Method of analysis	Ground investigation data typically provides simplified parameters: laboratory data are affected to some extent by disturbance and *in situ* tests are difficult to correlate to fundamental behaviour. It is essential to check the relevance and reliability of the analytical method for the soil type considered and the design situation. Parameter selection for all methods (even Cat 3 methods) depends to an extent on careful calibration of selected output against good case history data.
Magnitude, direction and type of loading	Deformation estimates are critically dependent on selection of stiffness and compressibility parameters (e.g. Young's modulus). If these are linear elastic, then the modulus must be appropriate to the stress–strain range and loading direction. The mobilised strength and deformation modulus under different loading regimes, say sustained cyclic loads, impact loads or long-term monotonic 'static' loads, is quite different.
Scale and type of failure mechanism, and construction influences	A cautious approach is needed if failure could occur within a small zone of the soil, e.g. beneath a narrow pad, strip or small diameter end bearing pile. A less conservative approach is appropriate if failure will inevitably involve shearing across a large mass of ground, e.g. where there is large raft or shaft resistance along a friction pile. Softening, loosening and remoulding of soil may occur during construction, especially if exposed to surface or ground water.
Magnitude of factor of safety and definition	Many codes used to adopt large factors of safety (2.5 to 3.5 for bearing capacity) in order to limit deformation and to allow for crude ground investigation methods. Some modern codes adopt lower factors of safety (1.25 to 1.4); these require more careful interpretation of strength and the designer may need to allow for factors, such as strain rate, anisotropy, etc.

Table 52.8 Factors which may influence the selection of soil strength and compressibility parameters for subsequent analysis

say 10 to 15 m depth) that have a liquidity index close to zero, or negative values, are likely to be heavily overconsolidated, whereas clays that have large positive values (say in excess of +0.3) are likely to be lightly overconsolidated or normally consolidated. Burland (1990) introduced a similar (but more robust) parameter, termed the void index. A plot of the void index versus the vertical effective stress (which can be readily derived from basic index tests), can provide a good indication of the clay's compressibility behaviour (**Figure 52.16**). Clays that plot well below the intrinsic compression line (ICL) are likely to be heavily overconsolidated and form competent founding strata. Clays that plot close to the ICL are likely to be lightly overconsolidated or normally consolidated and of moderate to low sensitivity (sensitivity is the ratio of peak to remoulded undrained shear strength). Clays which plot close to or above the sedimentation compression line (SCL) are also likely to be lightly overconsolidated or normally consolidated but will be of high sensitivity.

NB.
1. Void index, $I_v \sim 2I_L - 1.0$, I_L = liquidity index.
2. For clays plotting to right of ICL, yield stress (or p'c) approximately equal to $3S_u$, S_u is peak undrained strength in triaxial compression (high quality samples).
3. ICL = intrinsic compression line, SCL = sedimentation compression line

Figure 52.16 *In situ* stress states in terms of void index for different clay types
Data taken from Chandler *et al.* (2004)

Any sites underlain by clays that plot above the SCL are likely to be extremely challenging; and these clays have been associated with significant geotechnical problems. Conventional empirical methods are likely to be unreliable in these soils, and specialist advice and more sophisticated investigations and analyses are likely to be necessary. The selection of other parameters, such as permeability, coefficient of consolidation, coefficient of earth pressure, etc., tends to be more demanding. If required, then usually more sophisticated ground investigation methods and specialist engineering expertise are needed to select the appropriate values. Some common foundation design scenarios that lead to different strength or stiffness parameters being assumed for design are illustrated in **Figure 52.17**.

The different categories of analysis are outlined in **Table 52.9**, and it is worth remembering that even the more theoretically sound analytical methods (categories 2B or 3B) will depend on some empiricism (e.g. back analysis and calibration against case histories). Methods of analysis (and their associated input parameters) will commonly only be appropriate for a limited set of design situations and it is vital that the geologist or engineer understands when a particular analysis method (and associated parameters) is relevant to the problem under consideration.

Most foundation analyses involve Category 1 or 2A procedures. For simple deformation analyses, which usually assume linear elastic soil behaviour, the assessment of an elastic modulus, such as Young's modulus, is often required. Refer to Chapter 17 *Strength and deformation behaviour of soils* for a discussion of the properties of linear elastic porous materials. Research during the last 25 years has clarified many of the factors that affect the mobilised stiffness and compressibility of soils. The competent heavily overconsolidated soils, which are usually utilised as founding strata, can, for practical purposes, be characterised as nonlinear elastic. It is important to differentiate between different elastic moduli (shear, Young's, bulk) and whether secant or tangent moduli are being considered; see **Figure 52.18(a)**. Key features of nonlinear elastic behaviour are:

- **(i)** The stiffness at very small strains, less than 0.001% strain (characterised by small strain shear modulus, G_o) is practically the same for static and dynamic loading.
- **(ii)** G_o applies for both drained and undrained conditions.
- **(iii)** For overconsolidated soils G_o will be higher for horizontal loading than vertical loading.

G_o provides a useful reference value (or 'anchor point') for assessing the stiffness of overconsolidated soils. Appropriate test methods are described in Chapter 47 *Field geotechnical testing*.

Prior to the 1980s, there was considerable confusion concerning the mobilised stiffness of soils. It was only after the

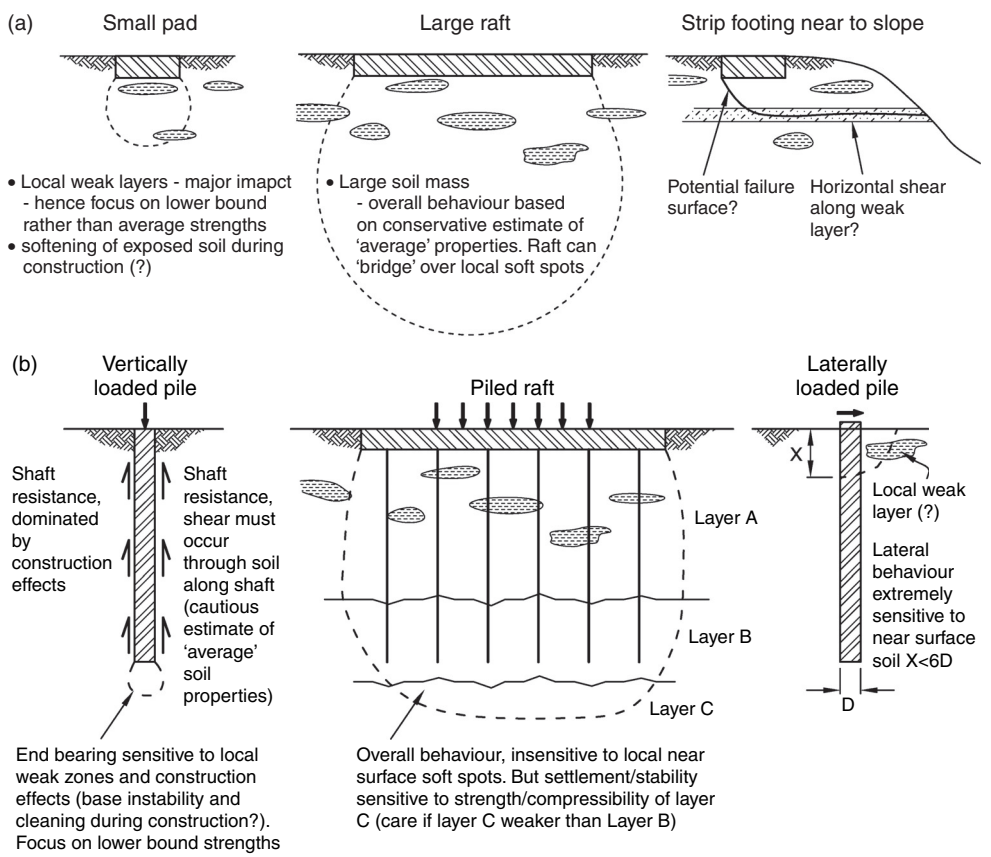


Figure 52.17 Parameter selection, general issues. (a) Shallow foundations, (b) deep foundations

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Category	Sub-division	Characteristics	Typical method of parameter selection	Level of complexity/ empiricism
1	A	Empirical (direct)	Simple *in situ*, e.g. penetration tests (SPT 'N' or CPT 'q_c'). Direct application of *in situ* test data	
	B	Empirical (indirect), plus some basic theory	*In situ* (as 1A) plus correlation to soil parameters (such as Young's modulus)	
2	A	Simplified theory, uses soil mechanics principles, e.g. bearing capacity (plasticity) or settlement (elasticity)	Routine *in situ* and laboratory tests, together with empirical correlations	
	B	As 2A, but theory allows for nonlinearity in a simplified manner	May use correlations with routine testing, more sophisticated testing or published data and back analysis	
3	A	'Basic' numerical modelling. Theory is isotropic, linear elastic or perfectly plastic. Allow for some interactions or topography variations	Rely on empirical correlations for soil stiffness and compressibility. Back analysis of case histories. Reliability of foundation movement predictions mainly dependent on selection of 'elastic' (?) moduli. Ground movements remote from foundation likely to be unreliable, potential for differential movements to be underpredicted	
	B	Nonlinearity or anisotropy allowed for in a simplified manner. More realistic assessment of interactions possible. Monotonic loading usually	Usually needs sophisticated test data (both *in situ* and laboratory), together with back analysis of case histories	
	C	Nonlinearity or anisotropy allowed for via proper constitutive models. Rarely used in current practice	Needs specialist tests (via research labs?) and advice for selecting input. The interpretation of the output is likely to be difficult	

Note.
Advanced methods of ground investigation and analysis tend to be more appropriate if there is local experience or the case history data is poor; there is a high level of geotechnical risk; the design objectives are complex; or there is a high potential for cost savings.

Table 52.9 Categories of analysis

importance of the strain amplitude on the mobilised elastic moduli was appreciated (Jardine *et al.*, 1984) that a rational basis for selecting elastic moduli could be developed. The assumption that the soil behaves as a nonlinear elastic material is reasonable provided that, following application of the foundation bearing pressure, the effective stresses in the ground are remote from the soil's pre-consolidation pressure (or yield stress) (refer to **Figure 52.18(b)**). The soil's 'elastic' modulus can degrade by more than an order of magnitude from G_o (or equivalent E_o values) with increasing strain amplitude (**Figure 52.18(c)**). Hence, the judgement required in selecting an appropriate modulus for linear elastic analyses is largely associated with understanding the likely strain amplitude induced by the foundation loads.

For sands many of the correlations between elastic moduli and penetration resistance are of extremely doubtful reliability. Some recent correlations between penetration resistance and G_o are more useful, see **Figure 52.19** and Box 52.1, although care is still required. Penetration resistance and the shear (or Young's) modulus are both affected by a wide range of factors, but the influence of these factors on the penetration resistance and the shear modulus differs to a great extent. Hence, the penetration resistance can only be a crude indicator of soil stiffness. Cross-checks between

Box 52.1. Empirical correlations for G_o in sands and clays

Note: It is recommended that G_o is assessed by more than one method; also refer to **Figures 52.19** and **52.20**. When appropriate G_o should also be measured by *in situ* and by laboratory tests.

Sands and silts

(a) SPT 'N' $G_o = a\ ('N')^b$

based on Clayton, 1995. For alluvial and glacial silts and sands:

a varies between 12 and 17, and

b varies between about 0.6 and 0.7.

Correlations in gravels are much less reliable.

Note: 'N' is the SPT blow count and the units for G_o are MN/m^2.

(b) *Mean effective stress:* $G_o = 220\ k\ (p'_o)^{0.5}$

based on Seed and Idriss (1970), where k is a function of the sand's relative density.

Relative density	*k*
Medium density	35 to 55
Dense	55 to 65
Very dense	65 to 75

Note: G_o, p'_o are in kN/m$_2$, p'_o is the *mean* effective stress.

Box 52.1. (Continued)

(c) *CPT* Average $G_o = q_c$ [1634 / (q_c / (σ'_{vo})$^{0.75}$], for uncemented quartz sands, after Rix and Stokoe, 1992.

Potential range of G_o = Average ± 0.5 (Average). Relatively high values for geologically old, dense sands and relatively low values for geologically young, loose sands.

Note: G_o, q_c and σ'_{vo} are in kN/m^2.

Clays

Based on Larsson and Muladic (1991). For medium to high plasticity clays:

G_o = 20,000/PI + 250

where PI is the plasticity index (%), having values between 25% and 50%.

Note: G_o is in MN/m^2.

different methods for assessing G_o for sands are strongly recommended. For clays, correlations between undrained shear strength and G_o have been developed and between G_o and the plasticity index, mean effective stress and overconsolidation ratio, see Box 52.1 and **Figure 52.20**, respectively. The latter relationship is applicable to a wider range of clays.

Poulos *et al.* (2001) provide some approximate relationships between modulus degradation and the factor of safety; these are shown in **Figures 52.20** and **52.21**. Based on these figures, the following can be concluded:

(1) The secant shear modulus decreases with a decreasing factor of safety.

(2) For a given factor of safety, the secant shear modulus for the shallow footing is lower than for a laterally loaded pile, which is lower than for a vertically loaded pile. This difference reflects differences in the induced strains around a particular type of foundation.

The relationships shown in **Figure 52.21** are intended mainly for preliminary assessment purposes and it should be emphasised that many simplifying approximations have been made to develop the plotted curves. However, these relationships emphasise the point that different elastic moduli should be anticipated for different foundation applications and the mobilised secant modulus will drop rapidly as the factor of safety reduces.

One of the practical implications of nonlinear elastic behaviour is that for most foundation engineering applications the mobilised 'elastic' modulus will exhibit an increase with depth, even when the soil strength is judged to be reasonably constant (Jardine *et al.*, 1986). For many practical applications, the soil strength will also increase with depth. Hence, if using linear elastic analyses, then the appropriate profile of the elastic modulus would usually increase rapidly with depth, as in **Figure 52.22**. For example, at the QE2 conference centre in London (Burland and Kalra, 1986), the selected profile for the elastic moduli for the London clay (based on a back analysis of several case histories across central London), for a raft of approximate plan dimensions 65 m by 75 m, exhibited a variation in the drained Young's modulus, for

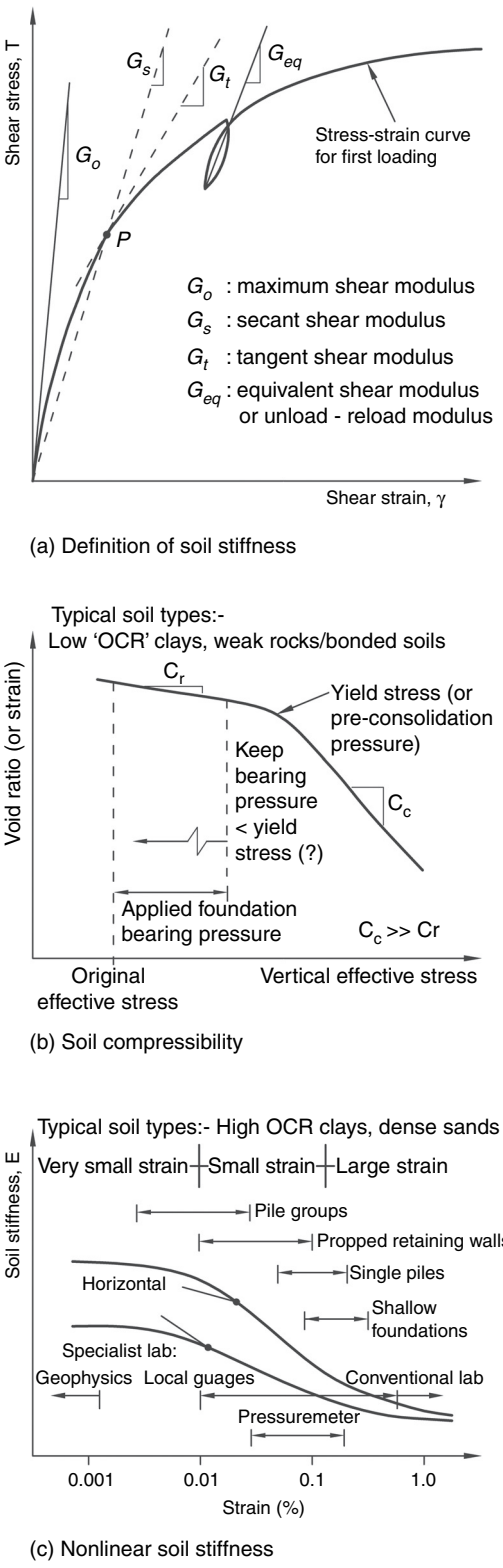

Figure 52.18 Ground stiffness and compressibility – fundamental considerations

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

vertical loading, varying with depth from a value of about 100 times the clay's undrained shear strength, S_u, at the clay surface, to about 450 S_u at a depth of 20 m below the clay surface. These drained stiffnesses were, on average, several times higher than those derived from routine oedometer tests.

The assumption of linear elastic behaviour is usually acceptable when the behaviour of a foundation can be considered in 'isolation', for example, when calculating the bending moments in a raft or the overall settlement of a strip footing on stiff clay. Linear elasticity is usually inappropriate if assessments have to be made of interactions between, say, a new foundation and adjacent infrastructure, or when ground movements outside and beneath a loaded area become important, or when the foundation behaviour is intrinsically sensitive to nonlinearity, e.g. interactions between piles within a pile group or the interaction between foundations and adjacent retaining walls or earthworks (say new embankments or cuttings). For these situations nonlinear elasticity (or more complex stress–strain models) may need to be used, and it will also be important to have early expert advice and guidance.

52.7 Foundation selection – a brief case history

A single-span bridge was required to carry heavy rail freight traffic across an existing road. The new bridge was to be built adjacent to an old rail bridge, which was in a poor condition. The original foundation design envisaged a conventional pile group (**Figure 52.23**), comprising 24 × 600 mm diameter bored piles (in a 6 × 4 group) about 6 m deep, socketed about 1 m deep into weak coal measures rocks. Because of the existing approach embankment, a temporary excavation was required to construct the pile cap. The excavation was to be supported by a sheet piled retaining wall. When work commenced on site, it was discovered that this solution could not be built due to a 132 kV electricity cable passing beneath the proposed pile cap. Numerous other services were also identified, and the owners of these services refused to allow sheet piles to be driven. The original foundation design had to be abandoned. A new foundation designer was appointed to develop a revised foundation solution. The revised foundation design was carried out under a sub-consultancy agreement to the original designers, who specified the foundation loads and allowable movements. A review by the new designers indicated that the available geotechnical data was inadequate: a report indicated that coal mining was 'suspected' in the area; however, a comprehensive desk study had not been carried out; four boreholes had

NB.
$\frac{G_o}{p'} = A(\frac{p'_o}{p'_r})^n(OCR)^m$; where Go is shear modulus at very small strain (parameters A, n and m are material parameters dependent on plasticity index; P'_o is the *in situ* mean effective stress = $(\sigma_v' + 2\sigma_h')/3$, σ_v' is vertical and σ_h' is horizontal effective stress; OCR is overconsolidation ratio. Go is most sensitive to variations in A and least sensitive to variations in OCR; P′r is a reference stress (equal to 1.0 kN/m^2)

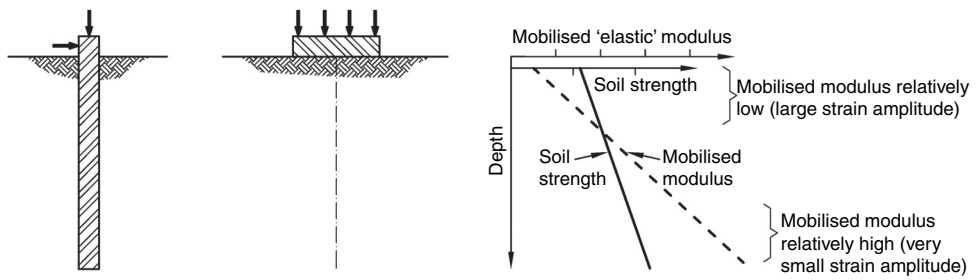

Figure 52.22 Mobilised 'elastic' modulus vs. depth, typical scenarios

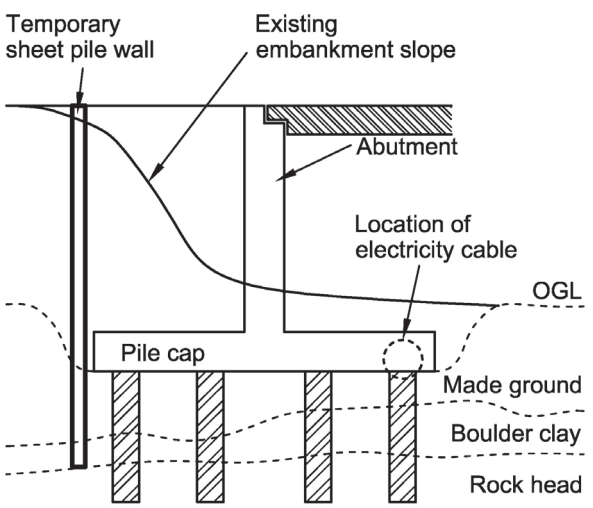

Figure 52.23 Foundation selection, case history. Original (unbuildable) foundation design

been drilled, but these were too shallow and only penetrated a couple of metres into the rockhead; data on rock strength, groundwater and ground contamination were lacking and the condition of the coal seams were unknown.

52.7.1 Ground conditions and site history

A desk study was carried out, which indicated that coal mining had been carried out at several levels below the site and that a chemical manufacturing works had been active adjacent to the site in the late 19th and early 20th centuries. Within the upper 35 m, three coal seams were identified and it was expected that some or all had been extensively worked, and that two shafts were identified adjacent to the site boundary. The subsequent investigation comprised four deep 100-mm-dia triple-tube rotary-cored boreholes (two 25 m deep, two 40 m deep) and down-hole geophysical logging was used to supplement physical logging of the condition of the rock mass by a highly experienced geologist. The subsequent ground investigations confirmed the presence of two worked coal seams in the upper

20 m (numerous voids and soft mining backfill materials were recorded), and unstable abandoned shafts. The third coal seam, at 35 m depth, appeared to have been unworked. The coal measures rocks were predominantly mudstone, with variable and relatively low strengths (fluctuating between a very stiff clay and a very weak rock) and were heavily fractured (with low Rock Quality Derignation, RQD, values) in the upper zones overlying the upper two coal seams. In one area there was evidence that the coal workings had collapsed causing significant disruption to the overlying rock mass. At greater depths, below the second coal seam, the mudstone strength increased markedly, becoming moderately weak to moderately strong, together with higher RQD values. A variable thickness of loose made ground (up to 3.5 m thick) and a discontinuous layer of firm to stiff glacial till up to 4 m thick were identified above the rockhead level. The made ground comprised industrial wastes and end-tipped clays and sands (probably from the old shaft excavations) and was chemically contaminated.

52.7.2 Site preparation

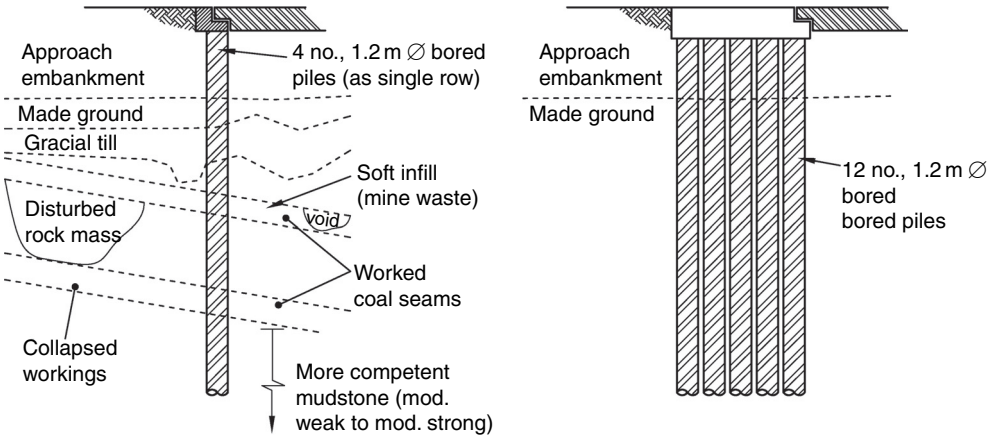
The site was in an unsafe and unstable condition. Therefore, before foundation construction could begin, it was essential to carry out preliminary works to infill and stabilise the old mine workings and remove heavily contaminated materials, which could harm the environment. Because of the scale of the works that were necessary (and the uncertain time period required to complete these works), this was let as a separate construction contract prior to the main foundation contract. The stabilisation works comprised mainly:

(i) infilling the worked seams and overlying disturbed rock mass with grout of varying viscosity;
(ii) probing and uncovering the shafts, infilling with mass concrete and constructing new reinforced concrete caps.

The deep grouting involved both vertical and inclined rotary open-hole drilling (inclined holes were needed, due to limited access, in order to stabilise the area below the foundation and approach embankment). Low-pressure grouting was then carried out. Grout take volumes varied from about 0.2 tonne per hole to a maximum of 29 tonne per hole (introduced during three separate grout phases). These variable grout takes reflected the disturbance of the rock mass arising from local collapses of the worked coal seams.

Quality control of the grouting, including permeability testing of the grouted areas and high-quality rotary coring to check the post-grouted condition of the coal seams, was essential to verify the effectiveness of the ground stabilisation.

52.7.3 Selected foundation type, design verification and construction control



The foundation type was largely dictated by:

- the limited available space along the site boundary (and existing utilities, which could not be diverted);
- an expectation that large obstructions were likely to be encountered in the made ground (demolition rubble, old concrete foundations, etc.), and the need to drill through the moderately strong mudstone at depth;
- the need to minimise temporary works, in particular the avoidance of sheet piles.

The initial foundation solution was to construct at each abutment four 1200-mm-diameter bored piles 26 m deep (with the pile toe below the second worked seam, but well above the third unworked coal seam), immediately below the plan location of the new bridge deck bearings. These piles were formed as a load-bearing contiguous bored-pile retaining wall (**Figure 52.24(a)**). Unfortunately, the original designer insisted that changes to the bridge bearings would not be allowed and that these could not tolerate more than 6 mm of horizontal displacement. Despite several discussions and alternative bridge bearings (that were more tolerant of foundation movement) being proposed, this constraint was not removed. This allowable movement constraint had a significant impact on foundation costs, with the final design solution comprising twelve 1200-mm-diameter piles. The horizontal stiffness of the foundation was maximised by forming piled wing walls, U-shaped in plan, together with a 1.5-m-deep pile cap, to ensure pile head fixity (**Figures 52.24(b)**, **52.25**). The piling rig had to be sufficiently powerful to penetrate through obstructions. The contiguous bored-pile wall also acted as a retaining wall for the approach embankments.

The analyses used for design checks were relatively simple:

(i) Vertical capacity: the shaft capacity, in the disturbed ground above the first coal seam, was ignored. Below the first seam, the shaft capacity was limited to avoid overstressing the deeper worked coal seam, see (v) below. A maximum ultimate shaft resistance of 240 kN/m^2 was assumed in the competent mudstone below the second coal seam, and an ultimate shaft resistance of 70 kN/m^2 was assumed in the weathered mudstones and disturbed ground between the first and second coal seams. The allowable end bearing pressure was limited to 2000 kN/m^2 in order to minimise pile settlement. The overall factor of safety was 3.0 for the shaft and the base resistance (to allow for the complex geology, site history and residual uncertainties). The group capacity, based on the plan area of the 'U-shaped' block, was more critical than the sum of the individual pile capacities.
(ii) Vertical deformation: since limited end bearing pressures were assumed, and a high factor of safety was being used, the total settlement was expected to be less than 10 mm overall (allowing for group effects) and less than 5 mm after deck construction.
(iii) Horizontal capacity: this was based on the method of Broms, e.g. refer to Fleming *et al.* (1992).
(iv) Horizontal deformation: this was based on linear elastic pile group analyses, refer to Fleming *et al.* (1992).

(a) Revised Design (initial option)

(b) Revised Design (to achieve allowable horizontal movement of 6 mm)

Note. This would have achieved all design requirements, except alternative bearings needed to tolerate larger horizontal movements

Figure 52.24 Foundation selection, case history. Revised foundation design options

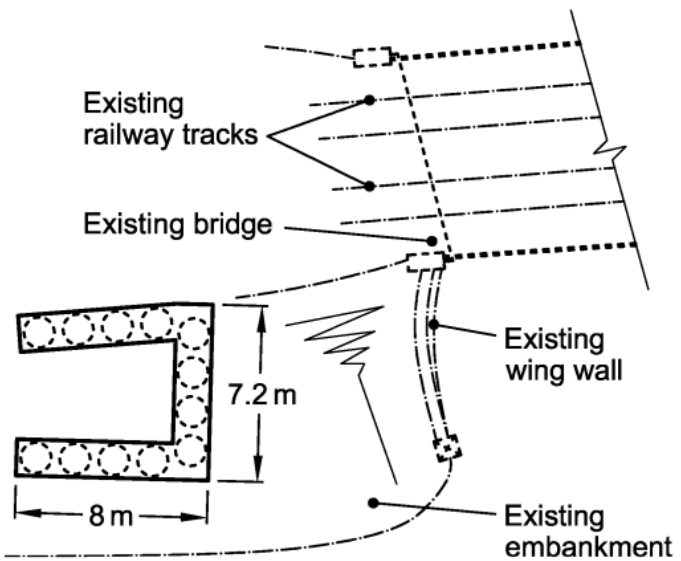


Figure 52.25 Foundation selection, case history. Revised foundation design, plan

(v) A maximum allowable bearing stress on the coal seams of less than 150 kN/m^2 was assumed. This was assessed by assuming an equivalent raft at two-thirds of the working shaft depth (below the first seam) and a 1 in 4 (horizontal to vertical) load spread above the 'raft' and 1 in 2 (horizontal to vertical) below.

A relatively small number of piles formed the bridge abutments; hence, it was not cost effective to carry out preliminary or working pile tests. It was more economical to use a large factor of safety rather than carry out relatively expensive load tests on large piles (if the piling contract comprised a much larger number of piles, then the cost–benefit balance would move towards carrying out preliminary tests and reducing the factor of safety).

The main construction controls were therefore:

(1) to log the pile bore arisings and verify that the depth was sufficient so as to be below the deepest worked coal seam, and that the piles were founded in competent mudstone at the specified depth;

(2) to carry out cross-hole sonic logging to check the pile concrete integrity was adequate.

52.7.4 Concluding remarks

This case history highlights the importance of:

(1) Careful collation of all relevant information for a site into a desk study report, including geology, historical activities (coal mining in this case) and existing site constraints (such as existing services). The original foundation design was unbuildable due to the presence of a 132 kV electricity cable. The presence of unstable mine workings beneath the proposed pile group had not been identified by the original designers.

(2) High-quality ground investigation data. The initial investigation had been poorly designed and supervised, the boreholes were too short, and important tests to identify the mechanical and chemical characteristics of the soils and rocks had not been scheduled. During the second ground investigation, high-quality logging of the rock mass

characteristics by an experienced geologist was profoundly important in deciding upon the appropriate toe level for the piles.

(3) Risk management. The site was in an unsafe condition and the mine workings had to be stabilised, by grouting, prior to bringing large (100 tonne) piling rigs onto the site. There were several intrinsic uncertainties associated with the grouting works (timescale, grout volumes, etc.), hence, from a commercial perspective, it was best to implement these works as a preliminary contract, prior to the main bridge-construction contract.

(4) Allowable movement criterion. The onerous limit on the allowable horizontal movement meant that the final design had three times the number of piles than an alternative option (which would have been technically viable if the movement limit had been 15 mm rather than 6 mm).

52.8 Overall conclusions

- Foundation engineering requires a broad range of knowledge and skills in construction methods; ground–structure interaction; geology; soil and rock mechanics; and understanding relevant case histories. The foundation designer must be prepared to ask questions and discuss these with other specialists. Good foundation design is usually the result of a multi-disciplinary team effort.
- The main types of foundations are: shallow (pad, strip, raft) and deep foundations (piles, barettes, caissons). Hybrid foundations include aspects of both shallow and deep foundation designs, examples include deep ground improvement and piled rafts.
- Design requires a consideration of: foundation stability and deformation; risk management; costs and programme for construction. The 'geotechnical triangle' is a valuable framework for ground risk management; all aspects of the triangle must be considered. Peer Assist carried out at an early stage can provide significant benefits.
- Foundation selection requires a consideration of the Five S's: **S**oil or rock types (and groundwater); **S**tructure type, including loads, allowable movements; **S**ite, including available space, headroom, neighbouring structures and sensitive environmental areas; **S**afety, in particular the site history may have left the site in an unstable or chemically contaminated state; **S**ustainability, there are often major opportunities when designing foundations, including the re-use of excavated materials, foundation re-use and the use of the ground as an energy source.
- Major and costly decisions are often taken on foundation design, on the basis of arbitrary and overconservative limits on total and differential settlements. Routine limits for total settlement vary between 40 mm and 100 mm depending upon the soil and foundation type. The actual risk of damage is dependent on differential movements and the construction sequence. The timing of the installation of sensitive components, such as architectural cladding, internal machinery such as lifts and escalators, etc., is particularly important.
- Selection of parameters, such as strength and deformation modulus, is challenging, because of the wide range of factors that may influence the value which is mobilised in a particular design, and the inherent limitations of analytical methods to model the complexity of real-ground behaviour. Routine investigation methods induce significant disturbance to the ground, which exacerbates the difficulties associated with interpretation of factual data. Ground investigations should include both *in situ* and laboratory testing. Continuous profiling of soil properties, either by methods such as CPTs or continuous sampling and detailed logging, is vitally important to understand the soil fabric.
- In the last 25 years or so, there have been major improvements in understanding the deformation characteristics of soils. Stress–strain behaviour is highly nonlinear, and the stiffness at very small strain (often known as G_o or G_{max}) is a useful reference or 'anchor' point. Stiffness degrades rapidly with increasing strain amplitude, so that at large strains it is often more than an order of magnitude smaller. Conventional tests, such as oedometer tests, measure stiffness (or compressibility) at large strains. Different foundation types (or different applied loads) induce different strain amplitudes in the ground, hence the *mobilised* deformation modulus can vary significantly (even for the same soil type). Commonly the *mobilised* deformation modulus will increase rapidly with depth below the ground surface.

The design of shallow foundations is exceptionally wide ranging, and can vary from simple strip footings for a lightly loaded domestic property to the design of a large raft for a nuclear power station. The likelihood of geohazards affecting a site must always be assessed, irrespective of the scale of the project. This is best assessed by a comprehensive desk study and a site walkover by an appropriately experienced specialist. The prime requirement for successful design and construction is an understanding of the site history and the ground and groundwater conditions across the site. Sophisticated analysis will not compensate for a lack of knowledge of these issues. Prior to detailed analysis it is worthwhile considering the likely behaviour of the whole structure (which may comprise multiple closely spaced strip or pad footings) in the context of the overall geology, adjacent structures and the site topography. The potential risk of adverse interactions within, beneath and around the proposed structure should be considered. Foundation settlement will often be a more critical consideration than bearing capacity. Simple methods of analysis are usually adequate; the biggest challenge is to make reliable estimates of the compressibility of the ground. The bearing capacity and settlement of rocks will be sensitive to the orientation, spacing and characteristics of discontinuities in the rock mass, the degree of weathering and voids (either natural or man-made).

53.1 Introduction

The geotechnical design of shallow foundations can vary from very simple footings for small lightly loaded domestic buildings to the complex requirements of a raft for a nuclear power station. **Table 53.1** poses some questions that should help the foundation designer identify the most appropriate level of sophistication for the ground investigation(s), analyses and subsequent supervision and monitoring. The table is based upon the geotechnical categories proposed in Eurocode 7. For Category 1 structures, site-specific calculations are often unnecessary, and the design can be based on 'presumed bearing pressure values' in local codes or past experience. If calculations are deemed necessary, then only the most basic methods would be required. The geotechnical category should be assessed at the start of the project, and may be revised as more information becomes available. The intent of the process is to indicate the level of effort required during design and construction, together with the level of expertise of the geotechnical engineers required for the project. It is particularly important to note that the geotechnical category is not solely related to the size and complexity of the superstructure. For example, a simple structure may be Category 3, if the site geology is particularly complex. For shallow-foundation design, many textbooks focus on the analysis of bearing capacity and settlement; however, prior to these design checks the overall site geology, site history and associated hazards must be carefully considered. As discussed in Chapter 52 *Foundation types and conceptual design principles*, the five S's should be assessed for the site before deciding that shallow foundations are the most appropriate foundation type.

In order to facilitate these decisions a comprehensive desk study should be produced for the site under consideration. This will then provide a coherent framework for planning ground investigations, and in some cases (if the geology is well known) allow a preliminary design to be carried out.

This chapter firstly considers the causes of foundation movement (which can be independent of applied loads from the superstructure), provides an introduction to some of the construction processes that the designer would need to consider, and then gives an overview of foundation layout issues and potential interaction effects. A summary of bearing-capacity and settlement analysis methods is given in sections 53.5 and 53.6 of this chapter for foundations in clay, sand and rock. Finally the key topic of parameter selection is discussed in section 53.7.

Because of space constraints, the behaviour of soft clays (and associated analytical methods and parameters) is not discussed in detail. Normally, they would not be considered to be appropriate founding strata. However, if soft clays are present within the zone of influence of the foundations then great care will be required (refer to Chapters 17 *Strength and deformation* and 19 *Settlement and stress distributions*), and expert advice should be sought.

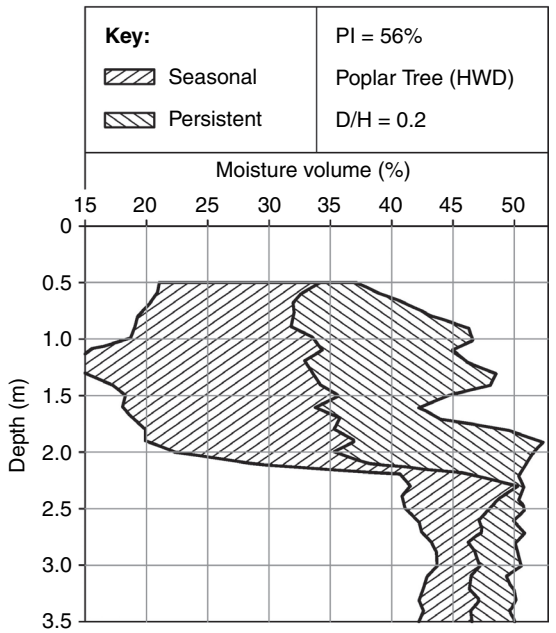
53.2 Causes of foundation movements

It is important to recognise that foundations may settle excessively due to a variety of causes that are independent of the applied bearing pressures from the superstructure. **Table 53.2** summarises these geohazards in the context of shallow foundations. Reference should also be made to Chapter 52 *Foundation types and conceptual design principles* (section

Questions	Category 1, Simple	Category 2, Intermediate	Category 3, Complex
1	Is structure small and simple?	If NO to all Category 1 and 3 questions.	Is structure very large or unusual?
2	Site geology well known and understood?		Is site geology complex or poorly understood?
3	Are ground conditions known from comparable experience to be sufficiently straightforward that routine methods may be used for investigations, design and construction?		Does it involve unusual or exceptionally difficult ground?
4	If excavation below water table is required, does comparable experience indicate that it will be straightforward?		Does it involve abnormal risks?
5	Is site free from abnormal risks, such as onerous differential settlement criteria, unusual or significant cyclic loading, or 'global' hazards such as earthquakes?		Can significant economies or reductions in construction programme be achieved by utilising Category 3 methods?
6	If yes to all above then, Category 1		Can improvements in safety or sustainability be achieved by utilising Category 3 methods?
7			Are the differential settlement criteria onerous (refer to Chapter 52 *Foundation types and conceptual design principles*)?
8			Are the loading conditions unusual or exceptional (e.g. high ratio of live to dead load, frequent large cyclic loads, large lateral loads)?
9			Is site subject to significant global hazards, such as earthquakes?
Likely investigation requirements	Desk study, plus a few trial pits, penetration tests and index tests to confirm site geology and ground conditions at founding levels	Desk study plus full range of conventional investigation methods. Sufficient testing to characterise ground properties below foundations (particular attention to zone within two-thirds of foundation width), and assess construction methods, and project risks	Desk study, plus comprehensive suite of ground investigations, including: highest quality sampling techniques; advanced ***in situ*** and laboratory testing; may be a need for large-scale instrumented load tests
Likely analysis methods	If deemed necessary: Clays – simple bearing-capacity checks plus high FoS (3.0) to ensure low settlement (refer to section 53.5) Sands + Rocks – simple empirical checks to verify low settlement (for sands, refer to section 53.6)	Analytical methods, outlined in sections 53.5 and 53.6	Nonlinear numerical modelling or more advanced analytical methods for bearing-capacity and settlement assessment
Likely construction supervision requirements	Visual inspection of ground at foundation level	Specialist supervision during key phases, local probing and testing may be needed to verify design assumptions; monitoring of, say, groundwater may be needed to control key project risks	Full-time specialist supervision plus subsurface instrumentation to monitor ground response

Table 53.1 Shallow foundations: likely design issues and requirements related to geotechnical categories

52.2, **Figure 52.8**) and Chapter 9 *Foundation design decisions* (**Table 9.1**). The global movements caused by these geohazards can be extremely large (some can be in excess of a metre, and are often in excess of 100 mm) and can lead to ultimate or serviceability limit state failures. Identification of these hazards is critically important and is usually best achieved by a combination of a desk study (to understand the site's geology and history) and a site walkover by suitably experienced specialists. If the hazard is present it is usually best to eliminate the hazard directly, or to relocate the foundations if feasible.



ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Cause of movement	Comments	Typical mitigation measures
Non-engineered fills	Large movements may occur due to physical, chemical or biological degradation mechanisms. Refer to Chapters 29 and 58. Examples include collapse settlement on wetting; expansion of iron and steel slag; decomposition of organic material and gas or leachate generation	Ground improvement can be effective in loose fills, e.g. methods such as dynamic or vibrocompaction, preload/surcharge, provided organic materials are largely absent. If deformation mechanisms are due to chemical or biological factors conventional compaction methods may be ineffective
Interaction effects	The construction of new structures, services, earthworks, etc., may induce global ground movements, which can cause additional foundation movements	Design and construction of any new infrastructure needs to assess likely interaction effects, and mitigate if damaging movements are anticipated. Appropriate phasing of construction sequences may reduce adverse effects
Vibration	Loose or very loose coarse-grained soils (silts, sands and gravels) are vulnerable to large differential settlement when subjected to vibration from an external source, e.g. road traffic, machinery, etc.	Ground improvement to densify the coarse-grained soils into a dense or very dense state, e.g. dynamic or vibrocompaction, refer to Chapter 59 *Design principles for ground improvement*
Erosion	Uniform fine sand or silt is particularly vulnerable to erosion from surface or groundwater flows	Variety of erosion-protection measures, from natural, well-graded, granular filter layers, through to propriety geotextile products
Vegetation and shrink–swell	Magnitude of movement will increase as plasticity index of clay increases, and 'water demand' of trees increases. Not relevant for non-plastic soils; refer to NHBC, 2003	For ground affected, or likely to be affected, by trees, then special foundation design measures will be required, refer to NHBC, 2003. This may include piled foundations (able to resist heave and swelling pressures) and suspended floors on void formers to avoid swelling forces and upward movement
Adjacent slopes	Sloping ground near foundations can increase the risk of bearing-capacity failure. The slope may (without foundation loading) be close to failure, and near-surface soils on the slope may be vulnerable to seasonal movement and creep	Detailed inspection and assessment of slopes. Take into consideration for bearing-capacity checks, and assess 'global' stability. If factors of safety are inadequate, then slope stabilisation will be necessary
Bulk earthworks, cut and fill	Large-scale filling or excavation will change the stresses in the underlying natural ground; hence, settlement or swelling (respectively) will result. The fill itself may also settle or swell if it is fine grained	If possible, allow sufficient time for settlement or swelling to occur, prior to building new foundations. If not feasible, then foundation deformation calculations will need to allow for additional ground movements due to cut and fill
Metastable or voided ground	Ground previously mined is likely to be unstable. Natural deposits, such as limestone and chalk can contain voids and caves	Investigations need to be carefully designed and targeted. If voids suspected, then large-scale grouting is normally required, refer to Chapter 59
Frost	Silts, chalk and fine sands can be vulnerable to frost heave	Locate foundations below depth affected by frost. In the UK this is typically about half a metre

Note: Groundwater changes are also a common cause of global ground movements; refer to Table 9.1, Chapter 9 *Foundation design decisions*

Table 53.2 Potential causes of foundation movement independent of applied bearing pressures

The most common cause of excessive foundation movement for shallow foundations in the UK is probably seasonal shrink–swell movement induced by trees. These movements can affect foundations on clay soils, and are particularly significant in high-plasticity clay where trees are growing, or where previous tree growth has desiccated the clay. For example, if trees are removed prior to foundation construction then the clay soils will swell as the soil moisture content increases back to its equilibrium value. This can result in significant foundation movement and structural damage. If a tree is allowed to grow adjacent to a foundation in clay soil, then the tree can induce significant seasonal shrink–swell movement in the foundation leading to structural damage. For foundations on clay in open ground (remote from any significant vegetation such as a hedge, trees, etc.) a foundation depth of 0.9 m is usually adequate, in order to minimise the risk of excessive shrink–swell movement. For foundations on clays that could be affected by vegetation, NHBC (2003) has provided simple and comprehensive guidance. **Figure 53.1** gives an example of seasonal moisture-content change for a high-plasticity clay affected by high-water demand trees. **Figure 53.2** shows a comparison between moisture content and soil suction measured at a high-plasticity clay site, for a location remote from trees, and in an area affected by trees. The stress change induced by the trees (equivalent to the difference between the 'remote' and 'close to trees' suction measurements) is a maximum of about 500 kN/m^2 at a depth of 3 m, which is a far larger change in stress than would be applied by most conventional structures. Hence, the associated ground movements can be large, and can be of the order of 100 mm to 150 mm. NHBC provides simple rules for appropriate foundation depths, which will reduce the risk of structural damage. They define 'shrinkable' soils as soils

NB.
D = distance from tree
H = height of tree
PI = plasticity index of clay
HWD = high water demand
'Persistent' = reduction in moisture content due to tree, will only increase back to natural once tree dies or is cut down
'Seasonal' = change in moisture content between summer and winter

Figure 53.1 Example of changes in moisture content due to trees, Gault Clay

Modified plasticity index	Volume-change potential
≥ 40%	High
20% to 40%	Medium
< 20%	Low

Notes:
1. MPI, Modified plasticity index = [(Plasticity index) (particles < 425 μm, %)] / 100; i.e. if MPI = 30% and only 50% of particles pass through a 425 μm sieve then MPI = 15%.
2. Shrinkable soils are vulnerable to volume change as their moisture content changes.

Table 53.3 Volume-change potential
Data taken from NHBC (2003)

that contain more than 35% fines (particle size <60 μm) and with a *modified* plasticity index (MPI) of more than 10%. The volume-change potential is based on MPI; see **Table 53.3**. The risk of excessive foundation movement will also depend on the type of trees growing close to the foundations. Different tree types have been classified according to their 'water demand', and NHBC provides water demand categories and mature tree heights for common species. For example, oak, poplar and willow are classified as 'high water demand'. The appropriate foundation depth is dependent on the MPI of the soil, the water demand and the mature tree height of existing trees or new trees that may be planted; **Figure 53.3** provides an example of one of the NHBC charts.

53.3 Construction processes and design considerations

53.3.1 Foundation excavations

Foundation excavations will usually be on the critical path for a project's construction programme, since many activities will not be able to start until they are completed. Hence, although apparently simple, some thought is needed. **Figure 53.4** provides a flowchart, which outlines the main decisions that need to be made. Although much of the detail of the temporary works will be the responsibility of the contractor, the foundation designer needs to consider these matters, at least conceptually, to check that the proposed works are buildable, safe and do not endanger adjacent infrastructure, buildings, etc. Sometimes, it is quicker and cheaper to excavate an area in one large operation than in several small independent excavations. In many soils and rocks, excavation faces can stand at steep angles (in excess of 45°) for a short period following excavation. With increasing time (which may vary from minutes to months) the steep temporary slopes will fail and move towards slope angles similar to those of 'permanent' slopes (refer to Chapter 72 *Slope stabilisation methods* and Chandler, 1984). The period of time before a temporary slope fails is not predictable solely by theoretical calculations. The use of local experience in selecting appropriate temporary slope angles is extremely important. **Figure 53.5** highlights some typical issues. Health and safety regulations require that all excavations deeper than 1.2 m should be designed by a competent person. Excavations also need to be inspected regularly by a competent person. Contingency measures should be planned. These should be implemented, if adverse slope movements are detected.

53.3.2 Groundwater control

Groundwater control is an important consideration for any site that has a water table above the foundation excavation level. In most parts of the UK, the groundwater table will be within a few metres of the ground surface. Poor groundwater control is probably the most common cause of ground-related problems during construction. The consequences of poor groundwater control can vary from project delays to catastrophic collapse of excavations. The adverse effects can be classified as:

(i) *Seepage effects* – If seepage is concentrated across a relatively small area, then steep hydraulic gradients may arise. Steep hydraulic gradients can lead to: excavation slope instability, since the pore water pressures will reduce the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

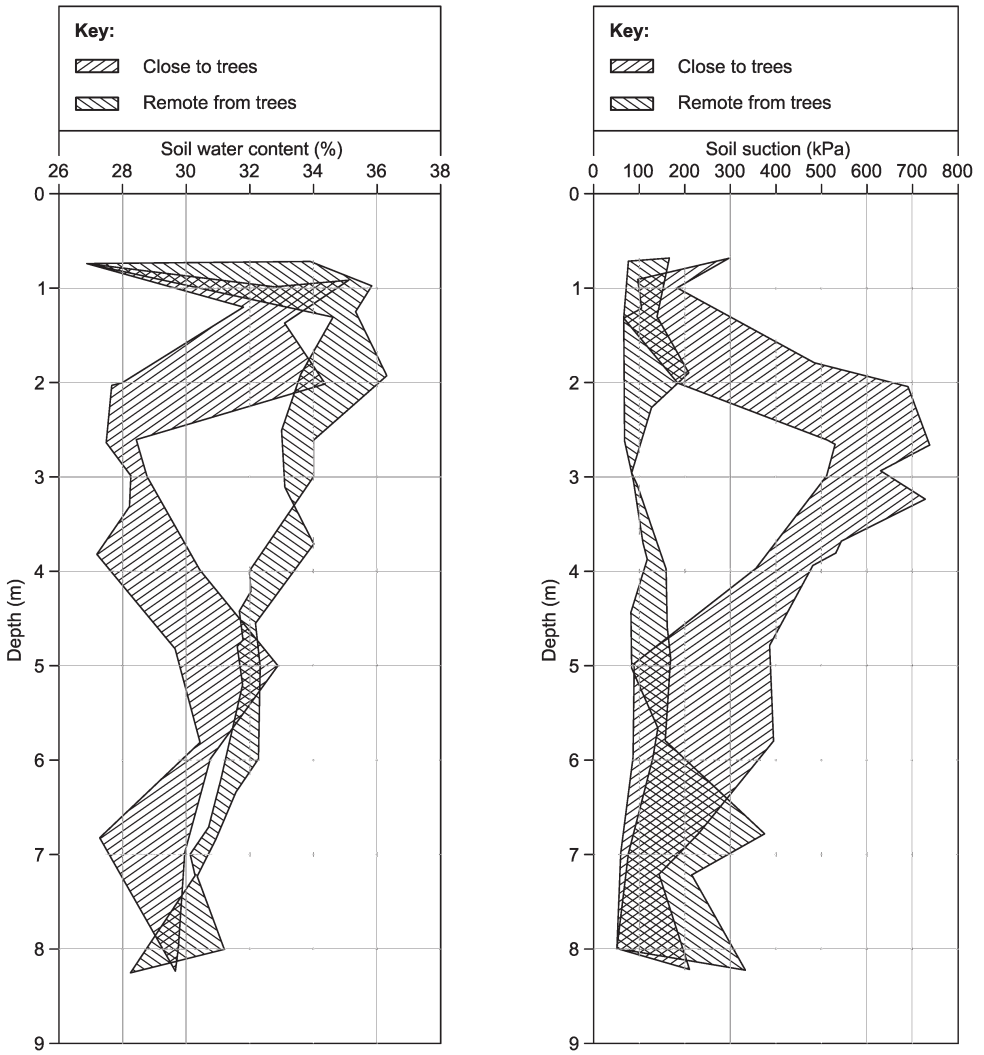


Figure 53.2 Water content and soil suction profiles remote and close to trees
Modified from Crilly and Driscoll (2000)

resistance to rotational or sliding failure; erosion of silts and sands, leading to piping, which can cause excavation basal instability or loss of lateral support to retaining walls; rapid weakening of otherwise strong competent soils (such as stiff clays, weak rocks) – layered 'laminated' soils with alternating low- and high-permeability layers (such as stiff clay with thin silt or sand layers) are particularly vulnerable.

(ii) *Hydraulic uplift* – In alternating layers of clays and sands instability will arise if the groundwater pressure in a sand layer (below the excavation base) exceeds the overburden stress due to the overlying clay layers, between the excavation level and the sand layer.

(iii) *Excessive foundation settlement* – Instability may not develop. However, if competent foundation soils, such as dense sands, stiff clays or weak rocks are affected by groundwater seepage, then this can cause reductions in the relative density of the sands or gravels; softening of stiff clays or joint opening in fractured rocks. Hence, excessive settlement may then occur once the foundation loads are applied. The original ground stiffness parameters of the soils or rocks in their undisturbed state will no longer be relevant. An example of the foundation problems caused by groundwater is given in Chapter 9 *Foundation design decisions.*

Figure 53.6 provides a sketch of the range of problems and some possible solutions to strong groundwater seepage and hydraulic uplift. The two main methods of avoiding serious groundwater problems are:

(a) lowering the groundwater pressure, by installing pumped wells or well points around the perimeter of the excavation;

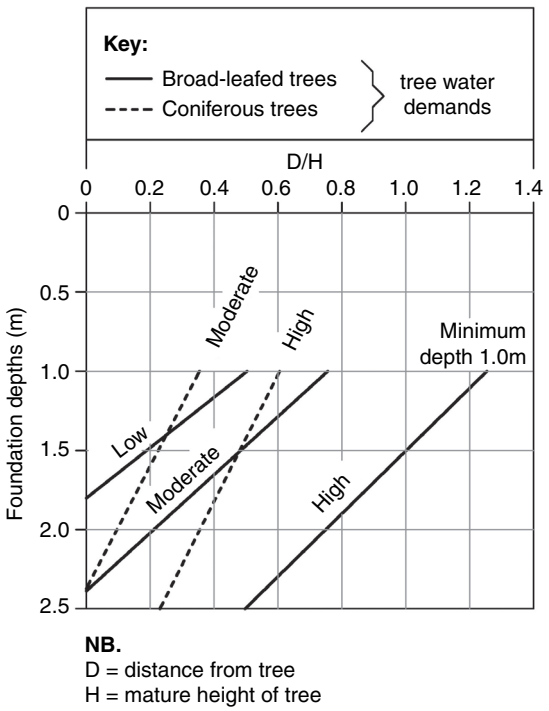

Figure 53.3 Example of NHBC foundation depth charts (soil with high volume-change potential, MPI≥40%). Shrinkable soils are defined as soils with more than 35% fines (finer than 60 μm) and have an MPI of 10% or greater
Reproduced from NHBC (2003)

(b) increasing the length of the groundwater flow path, either by installing deeper cut-off walls, providing more extensive grouted zones, or loading the excavation base with appropriately graded filter material.

Passive relief, or bleed, wells (drilled holes, backfilled with permeable filter material) can reduce the risk of hydraulic uplift, since the groundwater pressure gradient will be reduced from sub-artesian to hydrostatic. In highly permeable soils, passive relief wells may be 'swamped' and become ineffective.

For dewatering and depressurisation schemes, three main factors need to be considered:

(1) How much groundwater is present and how quickly it will be replenished, i.e. what groundwater flow rates need to be managed. In turn, this depends on ground permeability, continuity of permeable layers, presence of free water sources (rivers and lakes) and their connectivity to permeable layers.

(2) How the properties of the soils within and around the boundaries of the excavation will be affected. For example, the risk of loss of fines or risk of settlement once pore water pressures are reduced.

(3) How much water will need to be disposed of and the ease of disposal. Groundwater disposal requires approval of the regulator. The state of the groundwater, particularly the degree to which it may be contaminated will often be a critical consideration.

If the above factors are favourable, then dewatering can be relatively cheap, when pre-planned, compared with using cut-off walls or grouting. For complex situations a combination of cut-off walls, grouting and depressurisation may be necessary. Chapter 80 *Groundwater control* provides more detailed guidance on groundwater control. A wide range of different dewatering systems are available from discrete pumped wells to well points, the pros and cons are discussed in Chapter 80 *Groundwater control*. As a general rule, it is always preferable to locate the groundwater control systems, so that groundwater is extracted *outside* the footprint of the excavation, since this positively reduces hydraulic gradients below the base of an excavation. Sump pumping from shallow holes at the base of an excavation is often used, since it is relatively cheap and simple. However, it is not recommended, except for low-risk situations, e.g. occasional removal of small volumes of seepage water from perched water contained in limited zones of sand or gravel. Continuous pumping from sumps located inside the excavation is high risk, since hydraulic gradients are not reduced, and there is a high probability of loss of fines and piping instability.

53.3.3 Buoyancy and flotation

For sites with a high groundwater table or those sites that are vulnerable to flooding, it is important to check that the structure has an acceptable factor of safety against buoyancy failure, both during construction and in its permanent condition. Basement-type structures and cellular rafts (compensated foundations) are particularly vulnerable. Groundwater exerts uplift pressure on any overlying non-vertical surface; see **Figure 53.7**. The four main methods of reducing the risk of buoyancy failure are:

(i) Ensure that the sub-structure, once sealed against water inflow, always exerts a larger downward force than the uplift force from the water. The sub-structure must be structurally strong enough to withstand the water pressure acting on all external faces.

(ii) Allow the sub-structure to flood once the water level goes beyond the critical level for buoyancy. This can be acceptable during construction, but it is not appropriate for permanent structures! A simple means of achieving this is to install 'bleed' or pressure relief wells through the base of the sub-structure (**Figure 53.7**) or install holes through the sides of the sub-structure. The 'spill-over' level for the relief wells would be set at the level which maintains the target factor of safety against buoyancy.

(iii) Have dewatering or depressurisation systems available to keep the water level below the critical level. However, the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

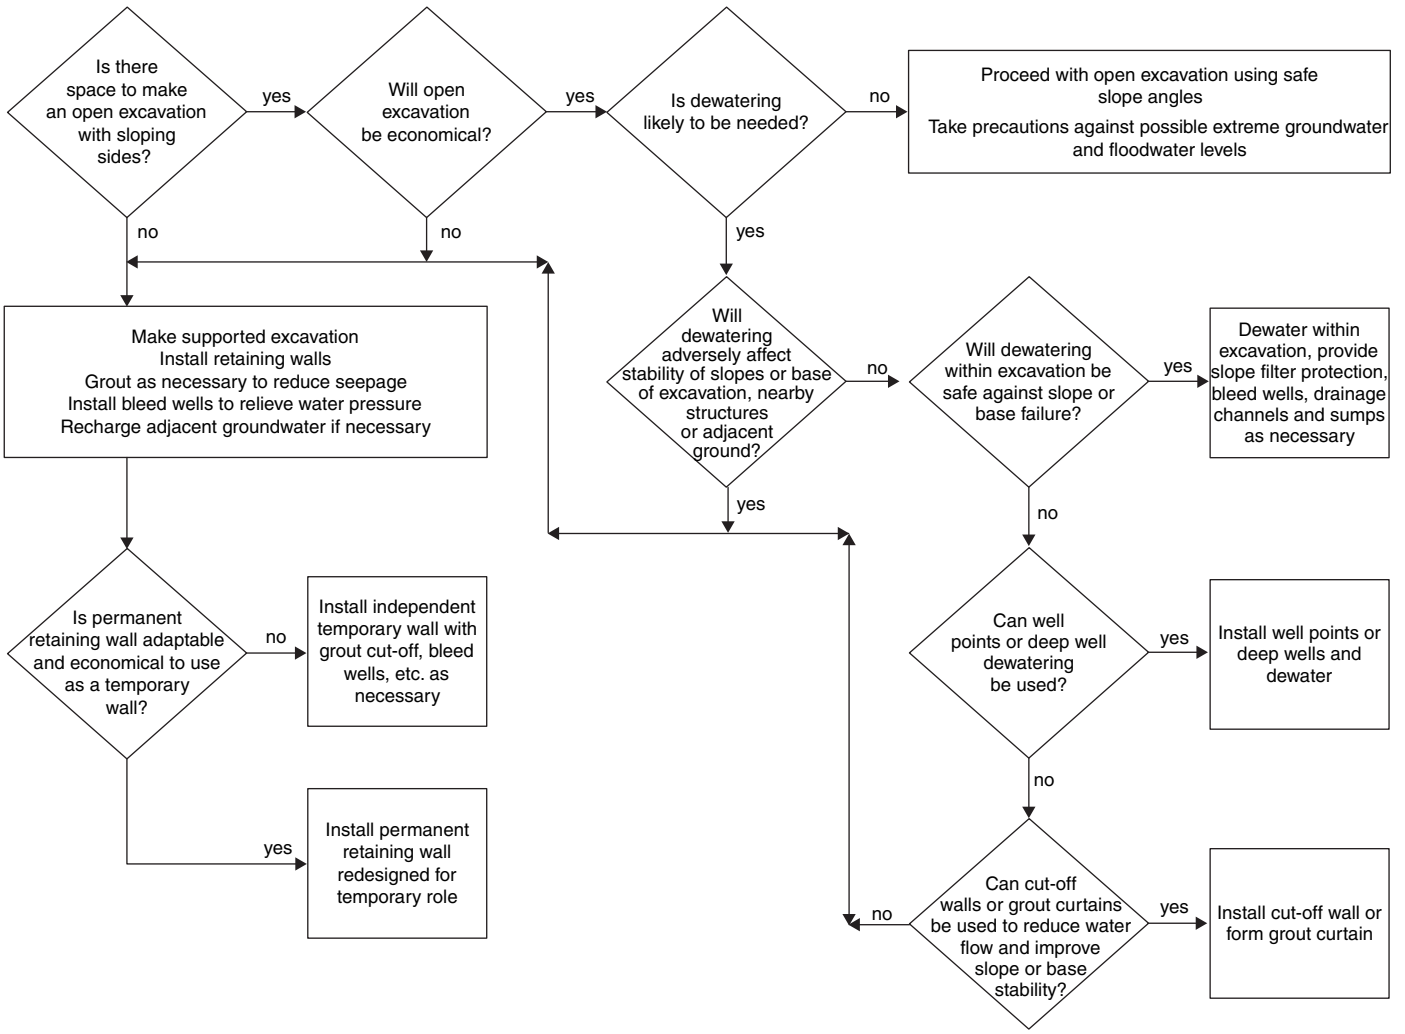

Figure 53.4 Excavation method, decision diagram
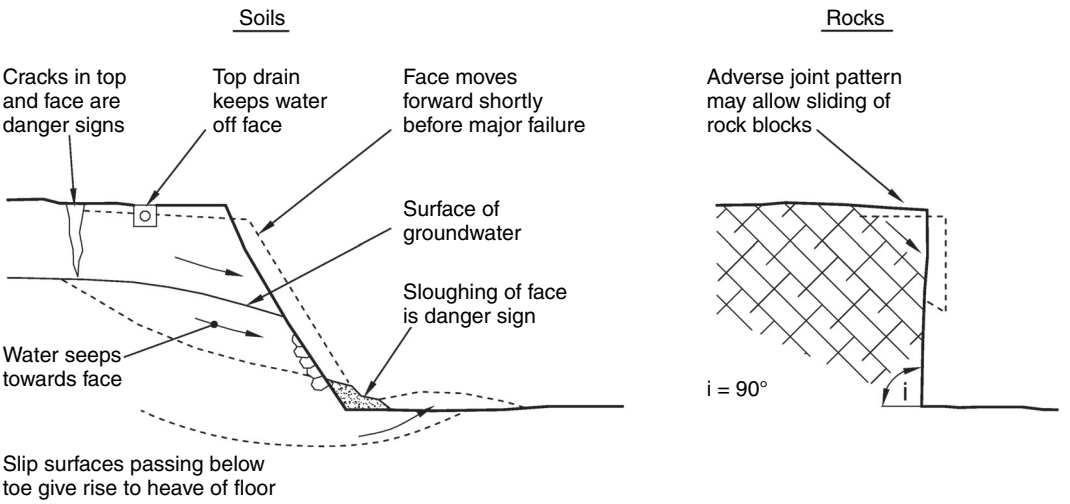
Reproduced from Cole (1988)

reliability and maintainability of these systems needs to be carefully considered. Dewatering can be appropriate to deal with groundwater, but will not be effective against surface-water flooding.



(iv) Ground anchors can be installed to anchor the structure to competent ground (**Figure 53.7**).

During construction, when the structure is incomplete, an additional stabilising load (say granular fill, concrete blocks, etc.) can be used. The kentledge can be removed, once the permanent structure has sufficient weight. To prevent overturning, the centre of the uplift force should be close to the centre of gravity of the structure.

53.3.4 Preparation of foundation formation

The settlement of shallow foundations can be sensitive to how carefully the excavated surface is prepared, prior to pouring foundation concrete. In wet climates, such as the UK, in addition to properly dealing with groundwater, care is required when excavating in inclement weather to minimise softening of exposed soils to rainfall. A practical means of minimising softening is to carry out bulk excavation to within say one metre to half a metre of the foundation level. The final excavation stage is subsequently carried out as a final task, in short bay widths, and the exposed soil or rock is immediately (or within the same work shift) protected by structural quality blinding concrete. When dewatering is carried out, the groundwater surface level should be kept a minimum of half a metre, and preferably more than one metre below the foundation level.

Foundation works for many sites may require the removal of old foundations, large boulders and ‘soft spots’. This may result in an irregular profile, partly below the foundation level. A final trim should be made to remove disturbed material. Then voids below foundation level will need to be infilled with good quality coarse-grained fill or mass concrete. Coarse-grained fill is only

Typical short-term slope angles: stiff clays 35 to 60°; sandy clays 35 to 50°; these angles assume dry conditions. These slopes will degrade and become unstable over time, which may vary from minutes to months depending on mass permeability of ground. Laminated/varved clays are particularly vulnerable to rapid degradation. Good drainage, groundwater control and protection of slope from weather are critically important.

Beware adverse joint pattern, may allow sliding of blocks. Some rocks, notably mudstones/shales deteriorate rapidly once exposed to air/water (wetting/drying).

acceptable *if* it can be properly compacted. The possible presence of soft spots can be assessed by probing (Chapter 47 *Field geotechnical testing*) or by observing if ruts develop when large plant traverse across the formation. At this stage if it is apparent that the ground conditions are different to those assumed by the designer, then it is vital that the designer is informed and has the opportunity to modify the foundation design.

53.4 Applied bearing pressures, foundation layout and interaction effects

53.4.1 Applied bearing pressures

Gross and net bearing pressures are defined in Chapter 52 *Foundation types and conceptual design principles* (section 52.5). The net bearing pressure is used to check the factor of safety against bearing-capacity failure and assess the total settlement of foundations. This is the principle that is used to design 'floating' or 'compensated' foundations (Chapter 52 *Foundation types and conceptual design principles*, Figure 52.1), where the weight of the structure is close to the weight of soil removed at the base of the foundations, so that the net bearing pressure on the soil is close to zero. D'Appolonia and Lambe (1971) summarise observed movements of compensated foundations on very soft clays, all of which exhibited very small settlements, which terminated shortly after construction.

The applied loads on a foundation will usually comprise a variety of different types of loads, including dead loads (weight of sub-structure, superstructure) and transient (or live) loads including wind, impact (or accidental) loads, etc. It is important to consider the different types of loading in the context of the ground behaviour adjacent to the foundation. For example, it would be inappropriate to carry out a drained bearing-capacity analysis for clays for a load combination that included an impact load which lasts a fraction of a second. In contrast, foundations on sands can be vulnerable to significant incremental increases in settlement if subjected to regular transient loads, due to a ratcheting-type deformation mechanism (e.g. tall towers or chimneys subjected to high wind loads). When calculating the long-term settlement of clays, occasional transient loads can be ignored, and usually only a fraction of the live load would be considered (say 25% to 30%).

53.4.2 Foundation layout and interaction effects

When carrying out bearing-capacity and settlement checks it is important to consider the behaviour of the whole structure, in addition to the individual foundation elements, within the context of the site and adjacent structures and topographical features. **Figure 53.8(a)** and **(b)** highlights an example of shallow foundations for a building where the strip footings are located

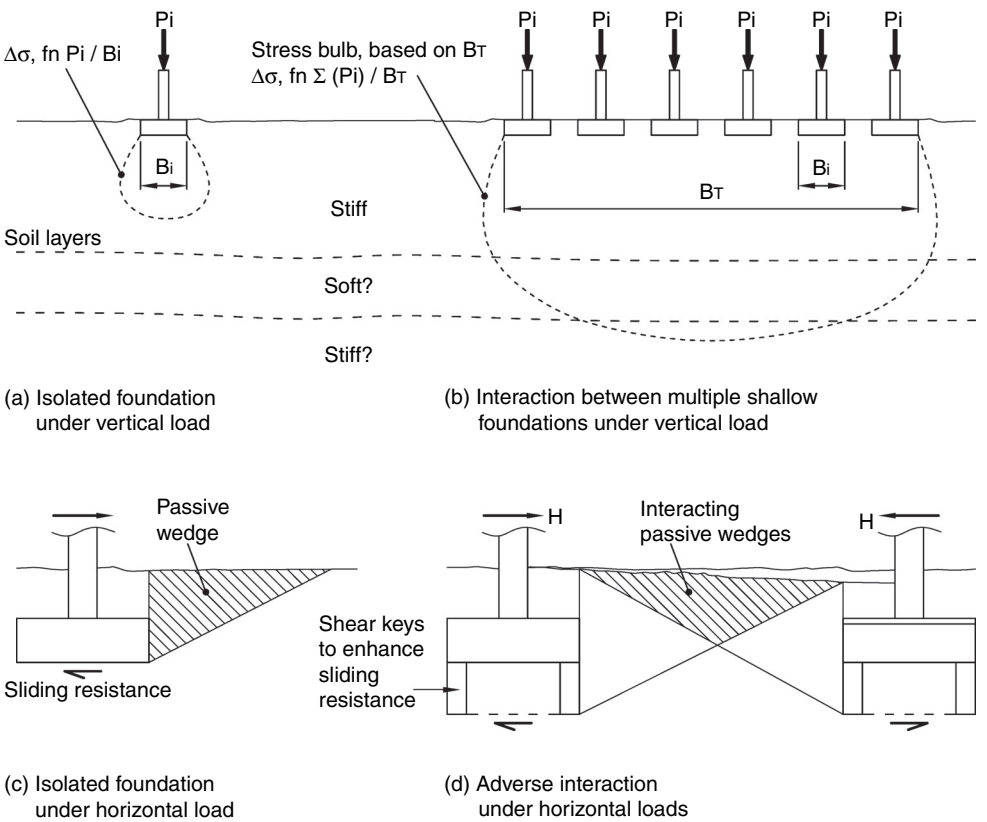

Figure 53.8 Multiple shallow foundations, examples of interactions under vertical and horizontal loads

relatively close to one another. For this situation it would be wise to carry out two separate checks:

(i) Check the bearing capacity and settlement of an isolated footing.

(ii) Check the bearing capacity and settlement of a hypothetical raft beneath the entire building, subjected to an equivalent net bearing pressure (based on the overall building weight and the width and length of the structure).

Particular care is required if a foundation is subjected to a lateral load, since this increases the risk of adverse interaction effects; see **Figure 53.8(c)** and **(d)**. **Figure 53.8(d)** illustrates a small single-span bridge founded on shallow pad footings. Shear keys can be designed to resist the applied horizontal loads. However, if the 'passive wedges' in front of the shear keys for each bridge abutment interact, then the available passive resistance will be much less than that for a single isolated foundation. Care is also required if forming shallow foundations that are adjacent to existing shallow foundations, adjacent to slopes or if drain and service trenches will be constructed close to shallow foundations. For these situations the bearing-capacity and settlement checks must take account of the potentially adverse interaction effects.

53.5 Bearing capacity

53.5.1 General comments

The bearing capacity can be defined as the maximum load per unit area that can be imposed on a soil at a given depth before failure occurs. It is a function of many parameters, including physical properties of the soil, foundation geometry, foundation depth, soil failure mode and load inclination or eccentricity. The key parameters are illustrated in **Figure 53.9**.

53.5.2 Basic formulae for strip footings close to ground surface

Chapter 21 *Bearing capacity theory* should be studied for an introduction to the topic.

In the effective stress bearing-capacity equation, the appropriate value for N_γ can be controversial and a bewildering array of different formulae have been published. It should be noted that the formulae by Terzaghi and Vesic are now considered to be grossly unconservative (Poulos *et al.*, 2001). The more conservative equations by Brinch and Hansen (1970) or Davis and Booker (1971) are recommended. The Brinch-Hansen equation is given in Chapter 21 *Bearing capacity theory*.

It should be noted that as the angle of friction increases beyond 30°, the bearing-capacity factors increase rapidly, and even small increases in the angle of friction lead to dramatic increases in the bearing capacity.

53.5.3 General bearing-capacity formulae

For many practical situations the simple bearing-capacity formulae given in Chapter 21 *Bearing capacity theory* have to be modified to take into account the effects of:

(i) Soil compressibility: Important for relatively loose sands and sands with non-silica mineralogy, or intermittent organic and clay layers or pockets. This correction will lead to a reduction in bearing capacity.

(ii) Stress level: As mean effective stress at failure increases, the ability of sands to dilate is reduced. Hence, as foundation depth or foundation width increases, the mobilised angle of friction will tend to reduce.

(iii) Groundwater table and groundwater pressures: Important for sands, could lead to a significant reduction in bearing capacity, especially if sub-artesian or artesian groundwater conditions are present.

(iv) Shape and depth corrections: Appropriate for all soils, depending upon shape and depth of foundations.

(v) Increasing strength with depth, soil layering and anisotropy of strength: For clays the simple formulae assume the clay's strength is constant with depth and is isotropic. This is sometimes inappropriate and the simple formulae can then be unsafe.

(vi) Combined vertical, moment, horizontal loads: For sands and clays the empirical correction factors that have been developed and published in codes and textbooks can be appropriate for use if the resultant load inclination is relatively modest (within the middle third of the footing width, or a load inclination of less than about 18°). For more severe resultant load inclinations, these empirical corrections become less reliable. A radically different approach to dealing with complex load combinations has been developed over the last twenty years or so (mainly stimulated by offshore engineering). These methods are

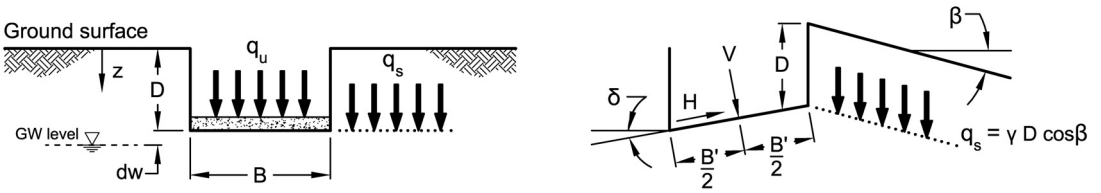

Figure 53.9 Geometry and parameters for ultimate bearing capacity

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

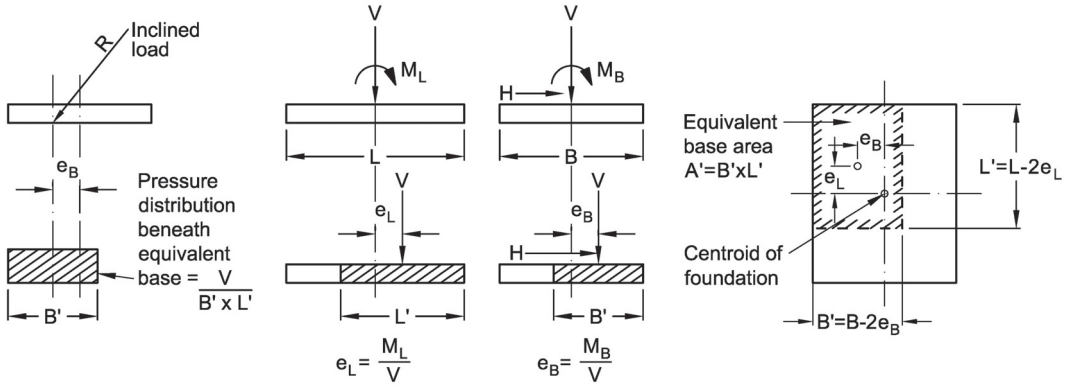

Figure 53.10 A shallow foundation subject to eccentric load and the equivalent area carrying a uniform vertical pressure

briefly outlined in Chapter 21 *Bearing capacity theory*. Load inclination, especially for sands, can lead to a dramatic reduction in bearing capacity.

A useful overview of recent developments in bearing capacity theory is given by Poulos *et al*. (2001), and Randolph *et al*. (2004).

The general bearing-capacity formula for undrained saturated clays and drained soils is outlined in Chapter 21 *Bearing capacity theory*. Shape and depth factors are given, and methods to deal with inclined and offset loads are also outlined. **Figure 53.10** outlines Meyerhof's simple method for eccentric, or offset, vertical loads. For eccentrically loaded foundations, the plan dimensions of the foundations should be reduced to:

$$B' = B - 2e \tag{53.1}$$

and the equivalent gross bearing pressure will be

$$q_e = w / (B' \times L) \tag{53.2}$$

where B' is the corrected width, e is the eccentricity of the load, w is the foundation load, B is the actual width and L is the length.

Based on q_e, the net bearing pressure over the effective base area for the eccentrically loaded foundation should be calculated, q_{ne}; q_{ne} should then be used for both bearing-capacity and settlement checks. The above approach of deriving an 'effective foundation area' is recommended when the eccentricity falls within the 'middle-third' of the foundation width (i.e. $e < B / 6$). The alternative approach of assuming a linear variation of bearing pressure (of trapezoidal or triangular shape) below the base is not recommended. If the eccentricity falls outside the middle third, then it is generally wiser to ensure more uniform loading by reconfiguring the foundation geometry rather than attempting more sophisticated analysis. For sustained eccentric loads, the foundation can be designed more efficiently by placing the superstructure column off-centre, so that the resultant of the axial and lateral loads passes through the centroid of the foundation footing.

53.5.4 Allowing for soil compressibility and stress level

It is often assumed that bearing capacity is dependent purely on the ground strength; in practice it is also a function of its compressibility (**Figure 53.11**). The compressibility of sand is a function of its relative density, its mineralogy and, if present, local lenses of clays. A dense silica sand or stiff clay may develop a well-defined ultimate resistance, which is associated with 'general shear failure'. In contrast, the failure of more

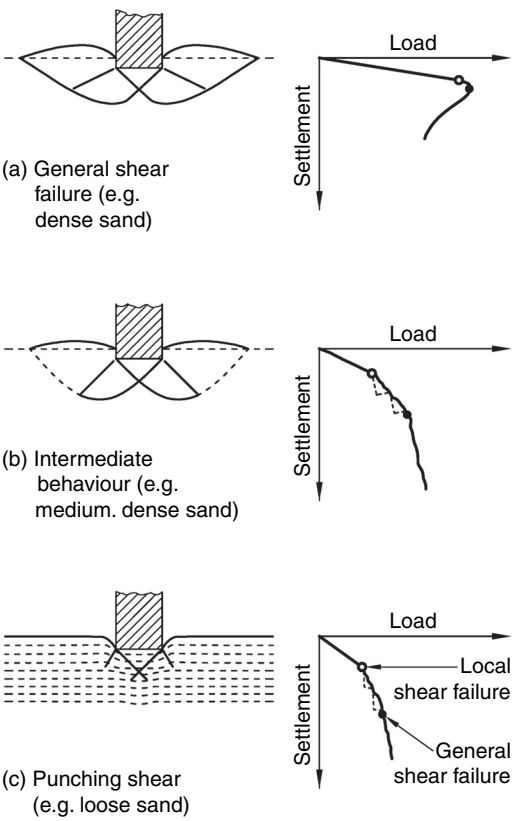

Figure 53.11 Influence of soil compressibility on the bearing-capacity failure mechanism

compressible soils is characterised by progressive downward movement, often referred to as 'punching' or 'local' shear failure. The basis of conventional bearing-capacity theory is 'general shear failure', which is only appropriate for the drained failure of dense or very dense silica sands and the undrained failure of clays. 'Punching' shear is likely to occur in very loose to medium dense silica sand, any sand which is intrinsically compressible (such as calcareous or micaceous sands), or during the drained failure of clays, and requires the bearing-capacity factors for general shear failure to be corrected. A simple means for allowing for soil compressibility is to reduce the soil's angle of friction in the formula for drained bearing capacity. For loose and very loose sands, the mobilised angle of friction is assumed to be two-thirds of the characteristic or moderately conservative value (interpreted from ground investigation data); for dense and very dense sands the mobilised angle of friction is assumed to be equal to the characteristic value; for medium dense sands an assumed mobilised angle of friction of about 80% of the characteristic value is usually appropriate.

53.5.5 Influence of groundwater table level and groundwater pressure

The general bearing-capacity equation is based on the assumption that the water table is located well below the foundation ($dw \geq B$). However, if, as is often the case, the water table is close to the foundation, then some modifications to the unit weight and surcharge terms (γ and q, respectively) are necessary depending on the location of the water table (**Figure 53.9**):

Case 1: If the water table is located above the bottom of the footing, then the effective surcharge is $q = q'$ (the vertical effective stress at the foundation level is γD-u, where u is the groundwater pressure at the foundation level). The unit weight of the soil needs to be adjusted as follows:

$$\gamma' = \gamma_{sat} - \gamma_w \tag{53.3}$$

where γ_{sat} is the saturated unit weight, γ_w is the unit weight of water and γ' is the buoyant unit weight.

Case 2: If the water table is located at the foundation level, i.e. $dw = 0$, then q is the total vertical stress at the foundation level (since the groundwater pressure is zero).

$$\gamma' = \text{buoyant unit weight (as Case 1).} \tag{53.4}$$

Case 3: If the depth to the water table $dw \geq B$, then q is the total vertical stress at the foundation level and

$$\gamma' = \text{saturated unit weight.} \tag{53.5}$$

Case 4: If, assuming no seepage forces, the water table is located at a depth $dw < B$ (i.e. the depth to water is within a depth less than the footing width) then interpolate between Cases 2 and 3 above:

$$q = \gamma D \text{ (as Case 3).} \tag{53.6}$$

The unit weight in the first term of the bearing-capacity equation must be replaced by the factor

$$\gamma_{mod} = \gamma' + d/B\ (\gamma - \gamma'). \tag{53.7}$$

Case 5: If the water table is at the foundation level, $dw = 0$, and there is uniform upward seepage (of gradient $du / dz > \gamma w$), then

$$\gamma' = \gamma - \frac{du}{dw}$$

and

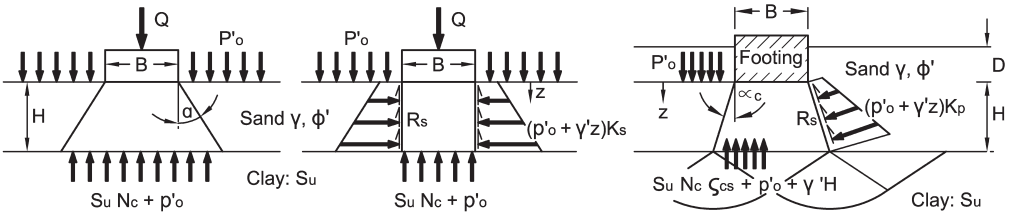
$$\gamma' = \gamma - \gamma w\ (1+i) \tag{53.8}$$

where i is the hydraulic gradient (hence, a positive gradient can substantially reduce the bearing capacity).

53.5.6 Sand overlying clay

Various theoretical and experimental studies have been conducted into the ultimate bearing capacity of a footing on a layer of sand overlying clay, e.g. Hanna and Meyerhof (1980) and Okamura *et al.* (1998). This is a common scenario in foundation engineering and punch-through failure may be a genuine concern, particularly for relatively thin sand layers overlying clays.

Conventional analyses of the bearing capacity of sand over clay use limit equilibrium techniques and generally look at two proposed failure mechanisms, as shown in **Figure 53.12**. In each case the strength of the sand is analysed in terms of effective stress, using the effective unit weight (γ) and the friction angle (ϕ), while the analysis of the clay is in terms of total stress, characterised by its undrained shear strength (S_u). In the case of the 'projected area' method an additional assumption about the angle α (**Figure 53.12(a)**) is required, although a value of 30° is often assumed.



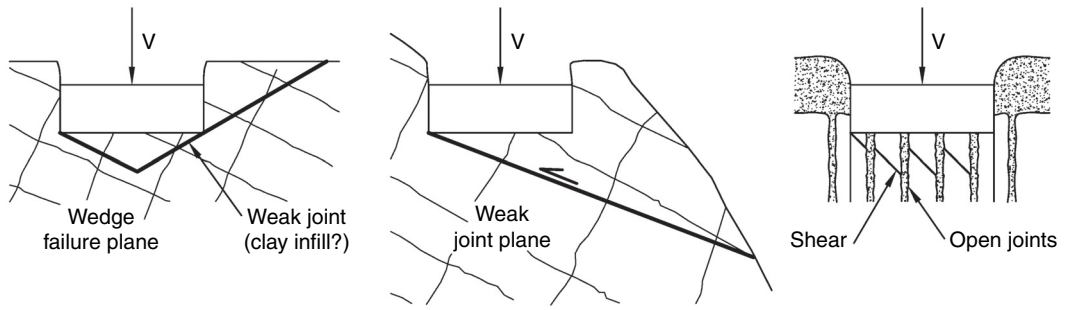
Okamura *et al*. (1998) assessed the validity of these two approaches and proposed an alternative failure mechanism; see **Figure 53.12(c)**.

53.5.7 Foundations on rock

When foundations are founded on intact rock then the bearing capacity is a function of the unconfined compressive strength of the rock and in most cases is more than sufficient to provide the required bearing capacity. However, the vast majority of rocks are not intact and have discontinuities, which, depending on their orientation and spacing, and the properties of the discontinuity infill material (if present), will have a significant impact on the bearing capacity of the rock. Franklin and Dusseault (1989) describe several different failure mechanisms:

(1) General bearing-capacity failures, similar to those which occur in soil are uncommon in rock. These failures may occur beneath heavily loaded foundations on weathered, weak, highly fractured mudstone.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers



(a) Projected area method

(b) Hanna and Meyerhof method

(c) Okamura *et al.* (1998) method

Figure 53.12 Alternative failure mechanisms, sand over clay

(a) Wedge failure

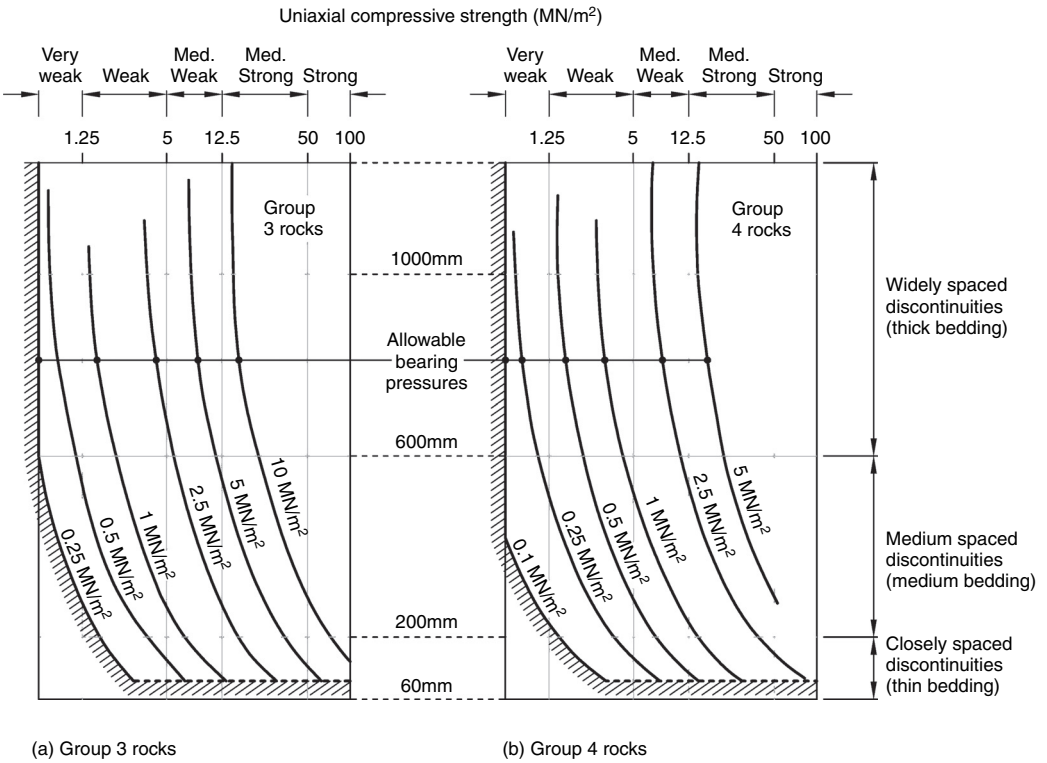
(b) Sliding failure (adverse joint orientation)

(c) 'Unconfined' failure (open vertical joints)

Figure 53.13 Typical failure mechanisms for jointed rock masses

(2) 'Consolidation' failures in weathered, fractured rocks, where unweathered rock corestones fail due to a combination of low shear strength along clay-coated vertical joints and voids or compressible fillings along horizontal joints.

(3) 'Punching' failure in porous rocks, such as volcanic tuffs, limestone and chalk, due to local crushing of the rock adjacent to voids where the rock is heavily stressed.



(4) Wedge or sliding failure along unfavourably inclined joints (**Figure 53.13**). For this situation, the overall equilibrium of the foundation due to potential sliding along the discontinuity is checked by resolution of forces, and consideration of the specific shear strength characteristics of the critical discontinuities. If these are infilled with clay, fault gouge or are slicksided, the shear resistance may be very low.

(5) Subsidence due to collapse of strata, undercut by subsurface voids, where the voids are natural or mining induced. Natural voids can be formed by solution weathering of soluble rocks, such as gypsum, rock salt, chalk and limestone. These can form deep pipe or cave-like features covered by metastable arches of soil. These may subsequently collapse, due to changes in the stress or groundwater regime.

The bearing capacity of a jointed rock mass was discussed by Wylie (1991), who also discusses the stability assessment of foundations on rock slopes and on steeply bedded formations. If the rock mass contains numerous open joints, then the ultimate bearing capacity will be equivalent to the unconfined compressive strength of the rock (**Figure 53.13(c)**).

For relatively weak and fractured rocks BS8004 provides a simple set of charts for preliminary assessment of allowable bearing pressures; see **Figure 53.14**. The curves shown are for 'Group 3' and 'Group 4' rocks. The allowable bearing pressures for more competent 'Group 1' and 'Group 2' rocks are higher (BS8004). These curves are only intended to be used for the design of simple, small structures. The charts assume joints are closed, and if open joints are suspected, then the allowable bearing pressures will need to be reduced, perhaps halved. For other structures more detailed analysis is required (e.g. refer to Wyllie, 1991).

When the rock material is very weak, has very closely spaced discontinuities, or is very heavily weathered or fragmented, the rock can be treated as a soil mass and designed on the basis of the conventional bearing-capacity equations. For situations where there is a mix of strong and weak materials with complex discontinuity patterns then the Hoek–Brown strength criterion (Hoek and Brown, 1997) should be used to evaluate the bearing capacity of the rock mass (Hoek, 1999; Hoek *et al.*,

(a) Group 3 rocks

(b) Group 4 rocks

NB.
Allowable bearing pressures in hatched areas to be assessed after inspection and/or making tests on rock.
Group 3: Very marly limestones, poorly cemented sandstones; cemented mudstones/shales; slates and schists.
Group 4: Uncemented mudstones and shales.
More competent rocks in Groups 1 & 2 (e.g. limestones, igneous rocks) have higher allowable bearing pressures, refer to BS8004.

Figure 53.14 Allowable bearing pressures for square pad foundations bearing on rock (for settlement not exceeding 0.5% of foundation width)
Reproduced with permission from BS8004 © British Standards Institute 1986

2002). Specialist advice should be sought where inclined or eccentric loads are applied to footings on rock, and when voids are suspected in the rock (rocks such as limestones, chalk and carbonate-based rocks are susceptible to voiding or karstification). Argillaceous rocks (mudstone, shale and siltstones) are apt to swell once unloaded during foundation excavation, and exposure to water or cycles of wetting and drying will lead to softening and degradation.

53.6 Settlement

53.6.1 Introduction

The settlement of a foundation must be within tolerable or acceptable limits, as discussed in Chapter 52 *Foundation types and conceptual design principles*. For most shallow foundations the estimated settlement will be a more critical design consideration than bearing capacity. There are a wide range of methods available to estimate settlement and some of the commonly used methods will be discussed in this section. However, for all methods the most challenging aspect is establishing the soil or rock properties and the associated deformation parameters. The use of more sophisticated analytical methods will not compensate for poor ground investigation data or an inappropriate interpretation of ground properties. If ground movements do not occur due to external sources (refer to section 53.2), then the main components of settlement due to foundation loading are summarised in **Table 53.4**. The basic methods involved in calculating the settlement in sands and clays are described in Chapter 19 *Settlement and stress distributions*.

Clays and silts experience both undrained shear and primary consolidation settlement. Creep settlement is usually assumed to be negligible for heavily overconsolidated clays and silts (which would usually be the founding materials), but can be significant for normally or lightly overconsolidated clays and silts (especially for highly organic materials, such as peat).

Settlement component	Relevant ground conditions	Comments
1. Undrained shear distortion (no change in volume/void ratio)(1)	Clays, clayey silts, very weak and weak argillaceous rocks	Becomes more significant as the factor of safety reduces. Typically, EOC settlement is 10% to 20% of total settlement for soft clays and about 50% to 75% of total settlement for stiff clays(2)
2. Primary consolidation settlement due to a reduction in volume/void ratio, due to an increase in effective stress	All soils and rocks	Main component of settlement for most conditions. Case histories show significant primary consolidation settlement occurs during construction, for overconsolidated clays, sands and rocks
3. Creep, or secondary consolidation, settlement, due to a reduction in volume/void ratio, at constant effective stress	Soft lightly overconsolidated and normally consolidated clays and peats	Becomes significant once pre-consolidation pressure exceeded. Creep increases as organic content increases, and as clay sensitivity increases
4. Deformation along or across joints, fissures or discontinuities	Rocks	At high stresses, creep can be significant, refer to text. Chalk can be vulnerable to creep once yield stress exceeded. Manifested as a time-dependent 'creep' settlement. Swelling during excavation, or poorly controlled groundwater conditions, can exacerbate 'creep' during subsequent loading
5. Change in volume/void ratio due to cyclic loading or vibration	Sands, gravels and sandy silts	Observations (e.g. Burland and Burbidge, 1984) indicate that conventional foundations exhibit time-dependent settlement, even under 'static' load (implying 'creep' deformation, see point 3 above). But significant increases in time-dependent settlement occur if 'fluctuating' loads are applied

Notes:
1. For saturated soils.
2. End of construction settlement (EOC) includes both undrained and a proportion of the primary consolidation settlement.

Table 53.4 Components of foundation settlement, due to applied bearing pressure

The commonly used methods of settlement analysis implicitly assume linear elastic ground behaviour, or simple nonlinear behaviour in the form of either a nonlinear elastic response or by distinguishing between the changes in compressibility, which occur between overconsolidated and normally consolidated states (or pre-yield and post-yield states for bonded soils and some weak rocks). As outlined by Burland *et al*. (1977), for the case of foundations that are loaded vertically, with a factor of safety in excess of three, the major principal stress increments remain practically vertical beneath most of the loaded area and the axes of stress and strain increments are mainly coincident. Hence, for this situation the behaviour of elastic, plastic and viscous materials is practically the same and relatively simple stress–strain relationships are adequate. If the foundation is subject to large inclined loads (due to significant moment and horizontal load combinations), then the situation is potentially far more complex, since significant principal stress rotations occur, and principal strain increments will not necessarily be coincident with principal stress increments. It should always be remembered that the main body of experience in shallow foundation behaviour is related to foundations subjected to vertical loads (some nominal horizontal or moment loads may be present, due to say wind loads, but these are relatively minor and transient). For other situations a more cautious approach is necessary.

If a foundation is subjected to an offset or eccentric vertical load, the Meyerhof method described in section 53.5 (refer to **Figure 53.10**) can be used to calculate the equivalent uniform bearing pressure. Conventional methods can then be used to assess the overall foundation settlement.

53.6.2 Stress changes due to applied bearing pressures

Theoretical considerations are discussed in Chapter 19 *Settlement and stress distributions*. For practical applications, the changes in stress with depth are mainly based upon homogeneous, isotropic, linear elastic theory, e.g. Boussinesq, or similar. Burland *et al*. (1977) have discussed in detail the influence of a wide range of factors on the accuracy of predicted stress changes with depth. For many ground conditions the equations based upon linear elastic theory give a reasonably accurate estimate of *vertical* stress changes with depth.

A useful design chart for estimating vertical stress changes with depth has been produced by Janbu, Bjerrum and Kjaernsli (1956) and is shown in **Figure 53.15**. This chart gives the increase in vertical stress beneath the centre of a uniformly loaded flexible area of strip, rectangular or circular shape.

53.6.3 Elastic methods

Elastic methods should not be used when the final stress state in a layer exceeds the pre-consolidation or yield stress of the ground (i.e. $\sigma'_{voi} + \Delta\sigma_{vi}' > p'_{ci}$), where σ'_{voi} is the initial vertical effective stress and $\Delta\sigma_{vi}'$ is the vertical effective stress increment for the layer under consideration. p'_{ci} is the pre-consolidation pressure or yield stress.

The undrained settlement of clays is often *mislabelled* as 'elastic settlement', because elastic theory has been used for calculation purposes; this erroneous terminology should not be used. It is now widely accepted that a wide range of overconsolidated soils and rocks can be treated as 'elastic' for predicting the *total* settlement (where total settlement is undrained

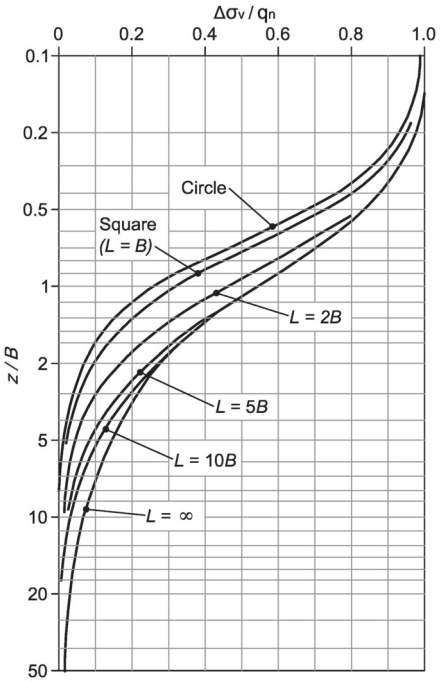


Figure 53.15 Vertical stress increase beneath centre of flexible footings of varying geometry.
Reproduced from Janbu *et al.* (1956)

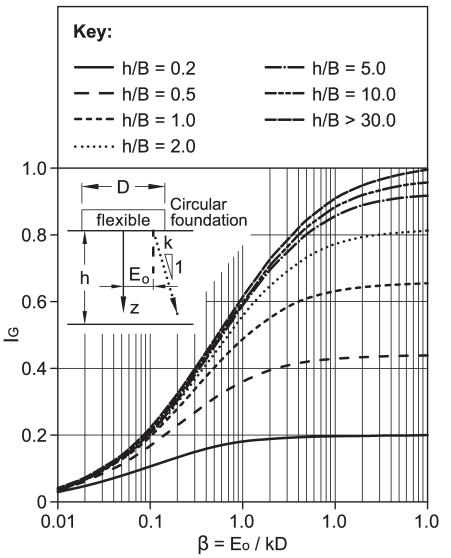

Figure 53.16 Displacement influence factors for the settlement of a flexible circular foundation

plus time-dependent settlement), e.g. see Burland *et al.* (1977), and Mayne and Poulos (1999).

Shallow foundation settlement can be assessed very quickly by using displacement influence factors derived from elastic theory. Unfortunately, many published solutions assume the elastic material has a constant value of Young's modulus with depth and the elastic material is of infinite thickness. These types of elastic solutions are *not* recommended. Mayne and Poulos (1999) provided solutions for the settlement of a shallow foundation resting on an isotropic elastic material of finite thickness, whose Young's modulus increases linearly with depth (i.e. $E = E_0 + kZ$, where E_0 is Young's modulus directly beneath the foundation base at $Z = 0$ and kZ is the rate of increase of the modulus with depth); as noted in Chapter 52 *Foundation types and conceptual design principles*, this type of stiffness variation is relevant for many design situations:

$$S = q\, D\, I_G\, (1 - \nu^2)\, f_R f_d / E_0 \qquad (53.9)$$

where S is the foundation settlement, q is the net bearing pressure, D is the diameter of the circular foundation, I_G is the influence factor for non-uniform ground stiffness, given in **Figure 53.16**, ν is Poisson's ratio, E_0 is Young's modulus directly beneath the foundation, f_R is the correction factor for the foundation stiffness, refer to section 53.6.7 and f_d is the correction factor for the foundation depth, refer to Mayne and Poulos (1999).

The influence factor for non-uniform ground stiffness is plotted against the dimensionless term, $\beta = E_0 / kD$, where k is the increase in Young's modulus with depth. Although developed for circular foundations, this method can be used for square and rectangular foundations (for $L \leq 3B$, where L is the foundation length and B is the breadth) and has been shown to compare well against more rigorous solutions. For rectangular foundations where $L > 3B$, Meigh (1976) has produced appropriate elastic solutions.

53.6.4 Settlement of clay

This section considers heavily overconsolidated clays only. The commonly used methods for estimating the settlement of clays are summarised in **Table 53.5**. The use of elastic methods has been outlined above. For the classical one-dimensional method the foundation settlement is calculated from:

$$S_{oed} = \sum_{i=0}^{i=n} (m_{vi}\, \Delta\sigma'_{vi}\, H_i) \qquad (53.10)$$

where m_{vi} is the coefficient of volume compressibility derived from oedometer testing. The one-dimensional method has been criticised as being too crude, and a variety of other methods, which offer a more sophisticated approach, have often been preferred. Burland *et al.* (1977) carried out an objective analysis of the accuracy of the various methods, which is discussed in detail in Chapter 19 *Settlement and stress distributions*. The main conclusion is that the one-dimensional method, for soils that are approximately elastic in their response to monotonically increasing stresses, provides results that are at least as accurate, and often more accurate, than results from apparently more sophisticated methods. Hence, for overconsolidated

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Method	Compressibility parameters	Advantages/disadvantages	Comments
(1) One-dimensional method, general comment	See below	Simple. Soil layering readily taken into account. Vertical stress changes reliable for many practical situations	Burland *et al.* (1977) showed that the one-dimensional method is more reliable than more complex methods, ***if*** soil compressibility is appropriate for stress change and strain amplitude
(a) Oedometer	Coefficient of volume compressibility, m_v	Principal problem is reliance on m_v from oedometer tests, which are usually unreliable due to sample disturbance	For overconsolidated clays, settlement is grossly overpredicted due to deficiencies in conventional oedometer test data
(b) Modified	Constrained modulus, D′	Constrained modulus can be related to moduli obtained from wide variety of tests, such as oedometer, triaxial and bender element (see 53.6.4)	Most appropriate method for stiff overconsolidated clays; modulus for each layer specific to stress level and strain amplitude, see sections 53.7 and 53.8
(c) Compression Indices	Compression indices, pre and post pre-consolidation pressure (C_r and C_c)	Compression indices can be correlated to carefully conducted oedometer tests, or, more commonly, empirical correlations	Most appropriate method for soft clays; pre-consolidation pressure is the critical parameter
(d) Skempton and Bjerrum	m_v and 'correction factor' U_g	Historically justified to 'correct' the settlement derived from routine oedometer tests. Calculates 'consolidation' settlement only; extra calculation needed for undrained settlement	As noted by Burland *et al.* (1977), this method is obsolete and does not improve reliability of predictions
(2) Linear elasticity (a) Classical equation	Young's modulus and Poisson's ratio	Principal flaw is reliance on horizontal stress change, which for many practical situations (involving anisotropy, increasing stiffness with depth and nonlinearity) is unreliable. Experience indicates mobilised Young's moduli will increase rapidly with increasing depth below foundation	Inappropriate for soft clays. Commonly used method and utilised in commercially available software and simple models in finite element codes. Can be acceptable, when reliable moduli are available from relevant case history data (similar foundation size and stress changes)
(b) Displacement influence factors	Young's modulus and Poisson's ratio	Very simple and rapid method. Published charts often assume uniform modulus and infinite depth; these are unreliable for most practical situations	Methods that allow for increasing stiffness with depth are useful for preliminary design checks. Inappropriate if significant layering below foundation
(c) Stress path method	Young's modulus, Poisson's ratio and correction factors	Theoretically attractive, but overly complex. Complexity not justified by improved reliability	As noted by Burland *et al.* (1977), reliability of method likely to be poor when anisotropy or nonlinearity are significant

Table 53.5 Common methods for calculating the settlement of clays

clays (which are typically anisotropic with higher horizontal than vertical stiffness, and whose stiffness typically increases with depth and which exhibit nonlinear elastic stress–strain behaviour) the one-dimensional method is sufficient for most practical purposes. The principal problem is that the traditional one-dimensional method for overconsolidated clays has relied upon oedometer test data, which often gives excessively high m_v values (and, hence, gross overestimates of the total settlement), due to errors introduced during sampling and testing, and inherent shortcomings in the test method. These problems can be overcome by using a modified one-dimensional method:

$$S_{od} = \left[\sum_{i=0}^{i=n} \left(\Delta\sigma'_{vi} H_i / D'_i\right)\right] f_R f_d \qquad (53.11)$$

where D'_i is the constrained modulus for layer i, $\Delta\sigma'_{vi}$ is the change in the vertical effective stress for layer i and H_i is the thickness of layer i. f_R and f_d are correction factors for the foundation depth and rigidity (section 53.6.7), respectively, and S_{od} is the foundation settlement.

The constrained modulus, D′, can be related to other isotropic elastic parameters as follows:

$$D' = 3K' (1 - \nu') / (1 + \nu') \qquad (53.12)$$

$$D' = E' (1 - \nu') / (1 + \nu') (1 - 2\nu') \qquad (53.13)$$

where K' is the bulk modulus, E' is the drained Young's modulus and ν' is the drained Poisson's ratio. For overconsolidated clays, ν' is close to 0.1 and, therefore, D' is approximately equal to $2.5K'$ or about equal to E'. For the recompression portion of the vertical strain vs log σ'_v oedometer curve (i.e. where the clay is overconsolidated), it can be shown that:

$$D' = \frac{1}{m_v} = \left(1 + e_o\right)\sigma'_{vo} \ln(10) / C_r \qquad (53.14)$$

where e_0 is the initial void ratio, σ_{v0}' is the initial vertical effective stress and C_r is the recompression index.

For anisotropic soils:

$$D' = E'v / [\,1 - 2\,\nu'_{VH}{}^2 (n' / 1 - \nu'_{HH})] \qquad (53.15)$$

where $E'v$ is Young's modulus in the vertical direction, ν'_{VH} is Poisson's ratio for the effect of vertical strain on the horizontal strain, ν'_{HH} is Poisson's ratio for the effect of horizontal strain on the complementary horizontal strain and $n' = E'_H / E'_V$, where E'_H is Young's modulus in the horizontal direction.

The above relationships allow the one-dimensional approach to utilise data from a wide range of different test types in order to assess the ground's compressibility characteristics across a wide range of changes in stress and strain amplitude. For overconsolidated clays:

$$S_{od} = S_T \tag{53.16}$$

where S_T is the total settlement, and:

$$S_{PC} = S_T - S_U \tag{53.17}$$

where S_{PC} is the primary consolidation settlement and S_U is the undrained settlement.

The ratio of the undrained to the total settlement has been studied for a variety of situations (e.g. Burland and Wroth, 1974). As the rate of increase of stiffness with depth increases, the ratio of the undrained to the total settlement decreases. At a typical stiffness increase for London Clay, the ratio of the undrained to the total settlement is about a third. Observations of settlement for numerous structures on overconsolidated clays (London Clay, Lambeth Group and Gault Clay) indicate a typical ratio for the end of construction to the total settlement of about 0.6. Hence, a proportion of the primary consolidation settlement is likely to have taken place rapidly, and undoubtedly the end of construction settlement includes some consolidation settlement, as well as the undrained settlement. Independent analysis (described by Atkinson, 2000) also suggests the end of construction settlement includes some consolidation settlement. Hence, the long-term settlement, which occurs after construction is completed, will often be much lower than indicated by theoretical calculations that assume the clay is undrained during construction. **Table 53.6** summarises several case histories of shallow foundation settlement and this data is plotted on **Figure 53.17**, for both high- and low-plasticity overconsolidated clays. The influence of the plasticity index is clear, with high-plasticity clays exhibiting larger settlements than the low-plasticity Lodgement Tills. The influence of overconsolidation ratio is also significant. The New York Varved Clays are low-plasticity clays and silts, which are only moderately overconsolidated, with overconsolidation ratio (OCR) between 3 and 6, and they exhibit similar settlement to the more heavily overconsolidated clays (typical OCR > 10), which have a high-plasticity index (such as London, Frankfurt and Gault Clays). **Table 53.7** provides a summary of typical index properties for the clays included in **Table 53.6** and **Figure 53.17**.

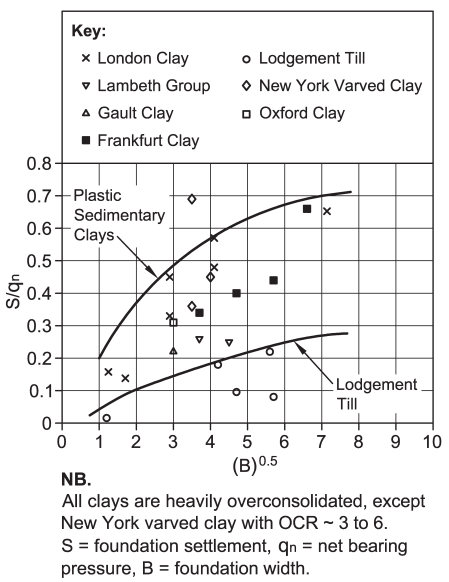

Figure 53.17 Stiff clays, observed settlement ratios versus the square root of foundation width

53.6.5 Settlement of sand

Excessive settlement of sand is seldom a practical problem; most observations of foundation settlement on sands indicate that settlement is less than 40 mm. Large settlements are usually only associated with loose or very loose sands, or sands containing a high organic content or clay layers. In addition the bulk of the settlement takes place during construction, so the post-construction settlement, which may lead to structural damage, is relatively small. Cases of structural damage for foundations on sand are extremely rare. Therefore, the first step for the practising engineer is to qualitatively check if there is likely to be any real settlement problem. **Table 53.8**, based on a study by Clayton (1988), summarises those situations that may lead to significant settlement. For more common situations a simple approach to estimating settlement is often sufficient. **Figure 53.18** is based upon a compilation of field measurements of foundation settlement on silica sand, and three broad categories are given based on a visual description or the average of the standard penetration test (SPT) 'N' values: 'loose' (SPT 'N'<10); 'medium dense' (SPT 'N'=10 to 30); and 'dense' (SPT 'N' > 30). Fairly well-defined upper limits are given for medium-dense and dense silica sand. There is much greater scatter for loose sands, and these soils would usually be considered as unsuitable as founding materials (without prior ground improvement to densify or stiffen the sand). Hence, for many routine structures it is sufficient to use **Table 53.8** in conjunction with **Figure 53.18**, firstly to assess if any problems are likely, and if not use **Figure 53.18** to assess the settlement of medium-dense and dense silica sands. The 'probable' settlement is likely to be about half the upper-limit settlement. Based upon a review of settlement observations, Burland *et al.* (1977) stated that small plate tests (less than 1 m wide) are unlikely to be a reliable basis for assessing the settlement of much wider foundations. This should be borne

Note:
1. SG is sand/gravel; LC is London Clay; LG is Lambeth Group; GC is Gault Clay; Till is Lodgement Till; FC is Frankfurt Clay; MS is medium sand; VSC is New York Varved silt/clay (Glacial Lake Deposits).
2. End of construction (EOC) settlement as a percentage of total settlement varies between about 50% and 75%; typically it is about 60%. For EOC settlement, construction periods typically last 6 months to two years.
3. Construction problems caused an increase in settlement at some piers.
4. Multiple pad footings at close spacing.
5. References: COSOS (1974), Clark (1997), De Jong and Harris (1971) and Parsons (1976).

Table 53.6 Stiff overconsolidated clays, observed shallow foundation settlement for various sites

Soil type	Moisture content (%)	Plasticity index (%)	Liquidity index	Undrained strength (kN/m²)	Description
Weathered London Clay	30 to 35	50	0 to +0.1	40 to 70	Firm to stiff
Unweathered London Clay	25 to 30	40 to 50	0 to -0.1	70 to 250	Stiff to very stiff
Gault Clay	20 to 30	50	0 to -0.2	100 to 300	Stiff to very stiff becoming hard
Lambeth Group	20 to 30	20 to 50	0 to -0.1	150 to 400	Very stiff to hard
Frankfurt Clay	30 to 35	35 to 55	+0.1 to -0.1	80to 200	Stiff to very stiff
Lodgement Tills	10 to 15	10 to 20	0 to -0.5	150 to 500	Very stiff to hard
New York Varved Clays	30 to 45	5 to 40	+0.1 to +0.3	95 to 140	Firm to stiff varved clay

Notes: For New York Varved Clays, the overconsolidation ratio (OCR) is between 3 and 6; for other clays the typical OCR > 10 at shallow depth.

Table 53.7 Stiff clay case histories – typical index properties

NB.

q_g = gross foundation pressure, S = settlement, N is average SPT 'N' over depth = 1.5B below foundation. Probable settlement is about one half of upper limit. Settlement is 'short-term' settlement, refer to for Burland *et al.* (1984) for assessment of 'creep'.

Figure 53.18 Sands, upper-limit settlement ratios
Reproduced from Burland *et al.* (1977)

Factor	Comment
1. Narrow (<1.5 m), heavily stressed foundations	Carefully check bearing capacity. High risk of failure or low factor of safety, especially if disturbance occurs to sands (reduction in density). Good construction control needed
2. Very wide (>10 m) foundations	Careful assessment of variation of compressibility with depth (e.g. weak layers?)
3. Metastable ('collapsing' sands), e.g. dune sands and lightly cemented sands (e.g. sabkha)	Site geology needs to be well understood. If lightly cemented sands, penetration tests will be misleading. Large plate tests may be needed to assess 'yield' stress of bonded or cemented sand
4. Sands containing layers of organic or clayey material	Static cone penetration tests could identify layers. Sampling and laboratory testing of discrete layers required. SPT's and spaced sampling may miss critical layers
5. Non-silica sands (mineralogy)	Empirical penetration test-based settlement methods are only based on performance of silica sands. Micaceous or calcareous sands, for example, may exhibit far larger settlement. If in doubt, the sand mineralogy should be checked. Specialist technical literature and testing and analytical methods will need to be considered

Table 53.8 High-risk situations for excessive settlement of sands
Reproduced from Clayton (1988)

in mind when assessing the type of testing needed to check the effectiveness of ground improvement methods. Small plate tests are still commonly used as field tests and, although useful as a quality control test, they will not be sufficient to assess full-scale foundation settlement.

When more detailed quantitative methods are needed to calculate the settlement of sands, then the following two methods are recommended:

(i) Burland and Burbidge (1984);

(ii) Schmertmann *et al.* (1978).

Burland and Burbidge (1984) is mainly based on empirical correlations with SPT 'N' values (although a simple correlation is provided between SPT 'N' and CPT q_c values). In contrast Schmertmann makes direct use of CPT q_c data. Both of these methods are well described in several references

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(e.g. Clayton, 1999 and Lunne *et al*., 1997) and will not be repeated in detail here.

Comparative studies indicate that both methods have a similar level of reliability and accuracy. Many other methods of predicting sand settlement have been published. Tan and Duncan (1991) carried out an assessment of the reliability of 12 different methods and showed that some methods can exhibit a systematic bias in settlement predictions. More sophisticated analytical methods (including finite element analyses) do not necessarily improve the reliability of predictions. A prediction symposium (Briaud and Gibbons, 1994) involved making Class A predictions of a footing (3 × 3 m) loaded to 4000 kN (factor of safety of 2.5) for a sand layer with an average SPT 'N' value of 20. A settlement of 14 mm was measured, whereas a sophisticated finite element analysis gave a value of 75 mm.

53.6.6 Settlement of rock

Assessments of foundation settlement on rock routinely utilise linear elastic methods (refer to section 53.6.3); however, the processes and concepts used to assess the deformation characteristics of the rock mass are fundamentally different to those used for soil. A soil mass is usually assumed to be a continuum, whereas for a rock mass the assessment of the nature, orientation and frequency of joints and other discontinuities is absolutely critical, in order to assess the rock mass deformation properties. The orientation of the dominant discontinuity sets in relation to the loading direction can have a significant influence on the deformation behaviour of the rock mass. Based on *in situ* load tests, Barton (1986) defined three characteristic modes of deformation behaviour. Joint surfaces are usually irregular; hence, forces across joints will be transmitted by reduced contact areas. As foundation bearing pressures increase, the contact stresses across the joints may become extremely high, which may lead to local yield and time-dependent creep.

Engineers often erroneously assume that 'rock' will provide a very strong competent foundation; however, this is not always the case. When considering a rock, engineers often visualise strong igneous rocks, such as massive unweathered granite (with widely spaced joints). However, many rocks, especially of sedimentary origin, can be heterogeneous and of very poor quality. Weak rocks may need to be investigated and assessed far more carefully than soil deposits, before an appropriate foundation design can be prepared. A commonly used index to assess rock mass quality is the RQD value and Hobbs (1974) used a 'mass factor' j to relate the modulus for a rock mass, Em, to the intact properties of the rock (refer to section 53.7.4), via RQD values. The modulus for a rock mass is then used in either the classic linear elastic (refer to section 53.6.3) or the modified one-dimensional method (refer to section 53.6.4) to assess settlement. For the vast majority of weak rocks, Young's modulus for a rock mass will increase rapidly with depth, especially beneath weathered material. Meigh (1976) used a linear elastic approach to back analyse the observed settlement of foundations in weak rock.

Three weak rock types commonly encountered across the UK are:

(i) Triassic Series (Mercia Mudstone and Sherwood Sandstone), which outcrops across much of the Midlands, north-west England and parts of south-west England and southern Wales;

(ii) Chalk, which outcrops across much of southern and eastern England and parts of the Yorkshire and Lincolnshire Wolds;

(iii) Carboniferous Coal Measures rocks, which are encountered across many parts of northern England.

For foundation design in these rock types, one of the main challenges is their variability in strength and compressibility, which can change from heavily weathered 'soil' to relatively strong unweathered 'rock'.

A summary of observed settlements for shallow foundations on a number of UK rocks is given in **Table 53.9**. **Figure 53.19** gives a plot of observed settlement ratio against foundation width for structures founded on Mercia Mudstone. For Mercia Mudstone when bearing pressures and foundation widths are modest (pressures less than about 300 kN/m^2, widths less than about 10 m) the observed settlement of an isolated foundation is usually less than about 25 mm, provided weathering grade IV mudstone is largely absent. Settlement occurs mainly during construction, so differential settlement can be largely built out.

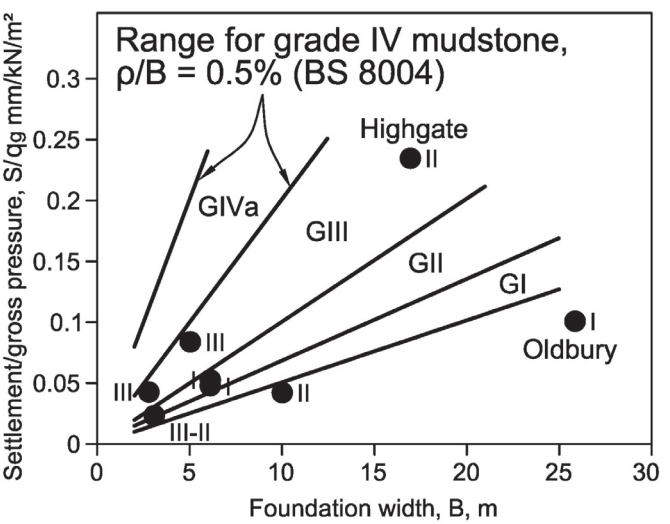

Figure 53.19 Mercia Mudstone, observed settlement ratios versus foundation width
Modified from CIRIA C570, Chandler and Forster, (2002), www.ciria.org

Site	Foundations B (m)	L (m)	Type	Ground profile	Foundation pressure (kN/m2)	Observed settlement (mm)

Second Severn Crossing Bridge	6	27	Caissons	Grade 2, locally 4, Mercia Mudstone	600 (gross)	<25
Oldbury Nuclear Power Station	26 dia		Circular raft	Grade 1, Mercia Mudstone	1100 (net)	105 to 125[1]
4 silos, Bury St. Edmonds	22.9 dia		4 Circular rafts	Low-density chalk	350	45 to 75
South Abutment Thames Barrier	14.7	31.5	Pad	High-density chalk	480	20
4 storey building, Basingstoke	3.3	3.3	Pad	Low-density chalk	365	7
Bridge, Luton	8.5	20	Pad	Low-density chalk	300	9
Hinckley Point 'B' Nuclear Power Station	19 dia		Circular raft	Interbedded mudstone and limestone, Lower Lias	1200 (net)	Reactor 3,14 to 16[2] Reactor 4, 30 to 35[2]

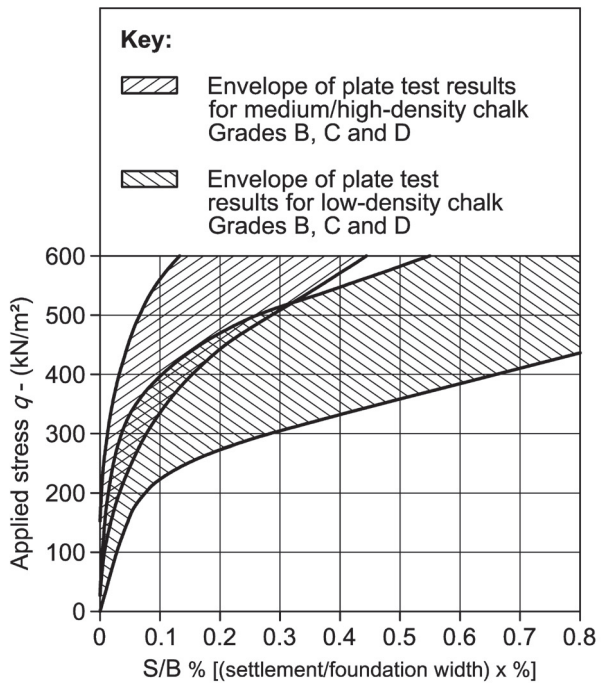
Notes:
1. End of construction settlement, approximately 80 to 95 mm, subsequent time-dependent settlement (9 year period) described as creep.
2. End of construction settlement, approximately 7 to 8 mm (Reactor 3) and approximately 16 to 18 mm (Reactor 4). Time-dependent settlement took about 10 years to complete.
3. The 13.7 m-deep basement excavation caused 55 to 60 mm heave and swelling of mudstone. End of construction settlement about 35 mm.

Table 53.9 Weak rocks, observed shallow foundation settlement for various sites

Figure 53.20 provides a plot of applied stress versus settlement ratio (settlement divided by foundation width) for structures on chalk. For chalk, foundation settlement increases rapidly once bearing stresses exceed the yield stress, q_y; refer to section 53.7.4. Hence, it is prudent in order to limit settlement to keep the foundation bearing pressure below q_y. At stresses below q_y, an isolated 5 m wide foundation would be expected to settle less than 10 mm (CIRIA C574, Lord *et al.*, 2002), provided weathering grade Dm chalk is absent. For larger foundations or higher foundation bearing pressure, CIRIA C574 provides more detailed guidance on appropriate methods of settlement assessment.

An interesting feature of the case history data is that significant time-dependent settlement can develop once foundation bearing pressures become relatively high. At Oldbury, on unweathered Keuper Sandstone and Siltstone, under a net bearing pressure of 1100 kN/m^2 (compared with UCS values mainly in excess of 10 MN/m^2), post-construction settlement, after a period of about 10 years, had increased by about 50% to 60% compared with the settlement that occurred during construction. The time-dependent settlement was ascribed to creep in a 13 m-thick 'leached' zone (where gypsum nodules had gone into solution, and left a porous sandstone with numerous small cavities) (Meigh, 1976). At Hinkley Point, two large foundations were built on interbedded unweathered mudstone and limestone of the Lower Lias of Jurassic age. The net bearing pressure was about 2000 kN/m^2 for both foundations (less than 10% of the UCS for the moderately strong rock). For Reactor 4, there was negligible post-construction settlement, whereas for Reactor 3 settlement increased by about 50% over a 12 year period and the final settlement was about double that of Reactor 4, which was in similar rock. The much greater settlement of Reactor 3 was ascribed to ineffective dewatering of the high groundwater pressures, which caused joint opening in the fractured limestone and softening of the unloaded mudstones (Haydon and Hobbs, 1974). The settlement of Reactor 3 was about three times larger than that originally predicted.

53.6.7 Corrections for foundation rigidity and foundation depth



The classic one-dimensional and elasticity equations are based on a flexible foundation resting on the surface of a compressible medium. Hence, corrections are necessary for:

(i) the actual rigidity of the foundation;

(ii) the actual depth of the foundation below the surface of competent ground.

The settlement of a rigid footing is usually assumed to be 0.8 times that of a flexible footing. Horikoshi and Randolph (1997) provide a rigidity correction factor that can be applied to the full range of foundation rigidities (between perfectly rigid and flexible) and geometries (from circles, squares to strips).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

NB.
Observed settlements of foundations on chalk fall within above envelope, if appropriate shape correction factors applied, refer to CIRIA C574.

Figure 53.20 Chalk applied stress – settlement ratios
Reproduced from CIRIA C574, Lord *et al.* (2002), www.ciria.org

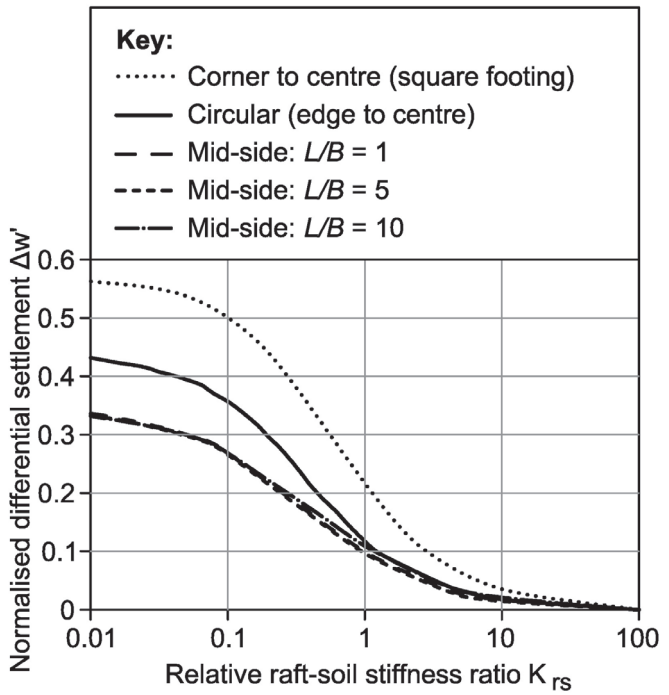


Figure 53.21 Normalised differential settlement as a function of raft stiffness ratio

Figure 53.21 gives a plot of the normalised differential settlement versus the relative raft–soil stiffness ratio K_{rs}:

$$K_{rs} = 5.57\,(E_f / E_{Sav})\,[(1 - \nu_s^2)/(1 - \nu_f^2)]\,(B/L)^{0.5}\,(t_f/L)^3 \quad (53.18)$$

$$\Delta S^* = (S_A - S_B) / S_{av} \quad (53.19)$$

where S_A is the settlement at the centre, S_B is the settlement at the middle of the short side of a footing or the settlement of a corner (**Figure 53.21**), S_{av} is the average settlement of a footing, E_f is Young's modulus for the footings or raft material (e.g. reinforced concrete), E_{Sav} is the representative Young's modulus for the ground beneath the foundation (i.e. the value of E_s at a depth equal to the radius of a circular footing or half the foundation width), t_f is the footing thickness, B is the footing width, L is the footing length, ν_s is Poisson's ratio for the soil and ν_f is Poisson's ratio for the footing material.

To use equations (53.18) and (53.19), it is most convenient to assume that the foundation is initially rigid (i.e. apply a correction factor of 0.8) and then modify the results in accordance with **Figure 53.21** and equations (53.18) and (53.19). It is apparent from the figure that foundation rigidity changes rapidly with changes in the ratio t_f/L. Hence, many foundations will either be practically flexible (K_{rs} <0.1) or practically rigid (K_{rs} >5).

The effect of foundation embedment on reducing settlement is often overestimated, in particular Fox's depth correction factor (given in many textbooks) significantly overpredicts the influence of embedment depth for shallow foundations. The correction factor given by Mayne and Poulos (1999) is more realistic.

53.6.8 Heave and swelling

When the ground is unloaded beneath an excavation, undrained heave will develop and additional upward movement can also develop due to time-dependent swelling. For sands and gravels, heave and swelling are assumed to be negligible; however, for clays and argillaceous rocks (particularly mudstone, shale, etc.) heave and swelling can be significant. Most of the published data are for undrained heave of medium- to high-plasticity overconsolidated clays. Vertical deformations due to heave and swelling of the order of 60 mm and 100 mm have been measured beneath 14 m and 20 m deep excavations, respectively, in bentonitic shale (e.g. Chan and Morgenstern, 1987 and De Jong and Morgenstern, 1973). Interbedded layers of water-bearing limestone facilitate rapid swelling of Frankfurt Clay and movements of up to 140 mm have been reported for 25-m-deep excavations (Breth and Amann, 1974).

The mechanisms associated with heave and swelling of overconsolidated fissured clays and mudstone or shales are more complex than those associated with settlement. Some shales and mudstones that contain active clay minerals (e.g. montmorillonite) can swell considerably following stress release due to water absorption by the clay minerals, together with exposure to air. Weathering of iron sulphide minerals (e.g. pyrite) accelerated by oxidising bacteria can also occur (often associated with lowering of the water table), leading to additional volumetric expansion. Terzaghi *et al*. (1996) provide a more detailed discussion of the above mechanisms, which can lead to a progressive weakening of the soil or rock mass. This can mean that if the ground mass at the base of an excavation is exposed for prolonged periods of time, then it is likely to deteriorate. The subsequent settlement of shallow foundations will then be much larger than would be expected, based on the 'undisturbed' ground properties. Hence, it is extremely important that the ground surface at foundation level is protected as much as practical, refer to section 53.3.4.

53.6.9 Simplified nonlinear methods and numerical modelling

Since the mid-1980s, there have been numerous research studies and published papers on the nonlinear stiffness characteristics of soils and weak rocks. Nevertheless, routine analytical methods and commonly used stress–strain models within commercially available finite element and finite difference software usually assume linear elastic, or linear elastic-perfectly plastic behaviour. Some sophisticated nonlinear models are used in industry, but these are very complex and difficult to use correctly. Highly trained specialists are needed to run the software and a high level of expertise is needed to define the model inputs and review the output, in order to obtain reliable predictions. For foundation design, sophisticated modelling is rarely required; however, there are situations when engineers may need to consider the influence of nonlinear ground behaviour in more detail, as discussed below. Some simplified nonlinear methods have been outlined in the literature, and these are summarised in **Table 53.10**. Each method has its own intrinsic advantages and disadvantages, although in general there is still very limited experience in their use across the industry. Hence, if these techniques are used, they need to be used with some caution and under the guidance of a suitably experienced specialist. One of the main benefits of these methods is that the variation in settlement with changes in net bearing pressure can be assessed. Nonlinear methods may be useful when the following are being assessed:

(i) the interaction between adjacent structures;

(ii) differential settlement adjacent to, or beneath, a shallow foundation;

Method	Type of analysis	Nonlinear parameters	Foundation geometry	Soil layering	Comments
Stroud (1990)	Elasticity, plus bearing capacity	Normalised Young's modulus versus degree of loading	Isolated strip, circular pad or footing	No. A single 'representative' Young's Modulus is used	Bearing-capacity theory used to assess 'degree of loading' (inverse of factor of safety), then empirically derived correlation with normalised Young's modulus (E'/N or E'/S_u). Conventional elastic equations used to assess foundation settlement. Drained (total) settlement of clays or sands can be calculated
Osman and Bolton (2005)	Plasticity theory	Mobilised undrained strength versus shear strain (linked to applied load and foundation settlement via scaling factor)	Isolated circular footing on clay	No. A single 'representative' stress–strain curve is used	Footing load-settlement behaviour is linked to triaxial stress–strain curve, via bearing-capacity theory and scaling factors to link triaxial shear strain to footing settlement. Can also be used to assess horizontal and rotational deformation of foundation under horizontal and moment loads. Undrained deformation of clays only
Atkinson (2000)	Elasticity theory	Normalised Young's modulus (E_s/E_0) versus axial strain (linked to applied load and foundation settlement via scaling factor)	Isolated circular, strip or pad footings	No. A single 'representative' stress–strain curve is used	Footing load-settlement behaviour is linked to triaxial stress–strain curve, via elasticity theory and scaling factors to link triaxial strain to footing settlement. Can also be used to assess horizontal and rotational deformation of foundation under horizontal and moment loads. Undrained and total settlement of clays; total settlement of sands
O'Brien and Sharp (2001)	Modified one-dimensional method	Constrained modulus versus axial (vertical) strain	Any geometry, both isolated and multiple closely spaced footings	Yes. Multiple layering and variations of stiffness with depth	Elastic theory used to calculate vertical stress changes. Constrained moduli at various stress and strain amplitudes can be assessed from oedometer, triaxial and geophysics data, or empirically. Input data also needed for in situ mean effective stress and variation of stiffness parameters with depth. Total settlement of clays only

Table 53.10 Simplified nonlinear methods for foundation settlement

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Issues	Comments
1. What is the key objective of numerical modelling, e.g. vertical or horizontal movements, structural forces or stresses?	A numerical model can produce a plethora of different outputs. Intrinsic limitations of most constitutive models mean that different outputs from a particular analysis will be of variable reliability.
2. What relevant case histories are available for the calibration of the model?	The use of uncalibrated models is poor practice and can provide highly misleading results.
3. Is the ground investigation adequate enough to supply appropriate parameters?	There is no value in carrying out sophisticated modelling in the absence of a good quality ground investigation. Specific testing may be needed to provide appropriate input parameters.
4. How will key input parameters be checked, e.g. strength and compressibility (which is more important as the stress–strain model becomes more complex)?	It is important to run computer simulations of 'element' behaviour under relevant drainage conditions and stress paths, e.g. undrained or drained strength in triaxial compression or extension, compression and swelling of oedometer; and to compare against laboratory data. Influence of sampling disturbance? Differences between field and lab data?
5. Will groundwater flow or seepage influence behaviour ('undrained' analyses may be unrealistic)?	Below the water table, in permeable horizons, local drainage and consolidation may have a marked effect on behaviour, necessitating coupled analyses.
6. What is the construction sequence, are there other miscellaneous effects?	The construction sequence can significantly influence many ground–structure interaction problems; hence realistic sequences need to be developed. Construction effects, such as vibration, may be important in sandy soils.

Table 53.11 Numerical modelling: some questions to consider

(iii) the potential for a more economic foundation design is being considered, e.g. factors of safety against bearing-capacity failure of less than three;

(iv) settlement and differential settlement of sensitive structures (say, a limiting settlement of less than 25 mm);

(v) negative skin friction and displacement of 'floating' piles in stiff clays (refer to Chapter 57 *Global ground movements and effects on piles*);

(vi) heave-induced tension, and displacement, of piles beneath excavations in stiff clay (refer to Chapter 57 *Global ground movements and effects on piles*).

One of the important practical consequences of soil nonlinearity is that subsurface settlements and settlements adjacent to a foundation become concentrated much closer to the foundation than indicated by linear elastic predictions (Jardine *et al.*, 1986). A practical application of the modified one-dimensional method is outlined in a short case history in section 53.8 below, which facilitated foundation re-use for a new settlement-sensitive structure. When numerical modelling is used, the questions in **Table 53.11** need to be considered very carefully.

53.6.10 Unsaturated soils and non-engineered fills

Deep deposits of unsaturated natural soils are commonly encountered across many parts of the world (such as Central Asia, South Africa, the Americas, etc.), although, in the context of foundation design, they are rarely a serious concern in temperate climate zones such as the UK. For shallow foundations, the principal concern is the metastable volume-change potential of unsaturated soils; see **Figure 53.22**. Below the threshold stress, if moisture content (or pore water pressure) increases then heave can develop, whereas above the threshold stress, large collapse-type settlement will occur if moisture content (or pore water pressure) increases. These movements can develop quite rapidly, as the moisture content increases, and have caused substantial structural damage. The assessment of unsaturated soil behaviour is a specialist task. Fredlund and Rahardjo (1993) provide detailed guidance on the theoretical and practical issues.

In the UK, the practical foundation problems associated with unsaturated ground are usually associated with non-engineered fills (discussed in detail in Chapters 34 *Non-engineered fills* and 58 *Building on fills*) or with clays that have been desiccated by vegetation (discussed in section 53.2 above).

53.7 Information requirements and parameter selection

53.7.1 Ground profile and site history

Many of the serious problems that occur with shallow foundations are due to a misinterpretation of the site's history or geology, which means that soft compressible soils are found at foundation level rather than competent low-compressibility soils. Two simple examples are given below:

(i) A low-rise building was to be founded on shallow strip footings. The local geology was Bagshot Beds (interbedded stiff clay and dense sands) over stiff London Clay. Boreholes had been sunk in the vicinity of the building. During initial excavations for the strip footings very soft to soft black sandy clay was encountered, rather than the stiff clays and dense sands originally anticipated.

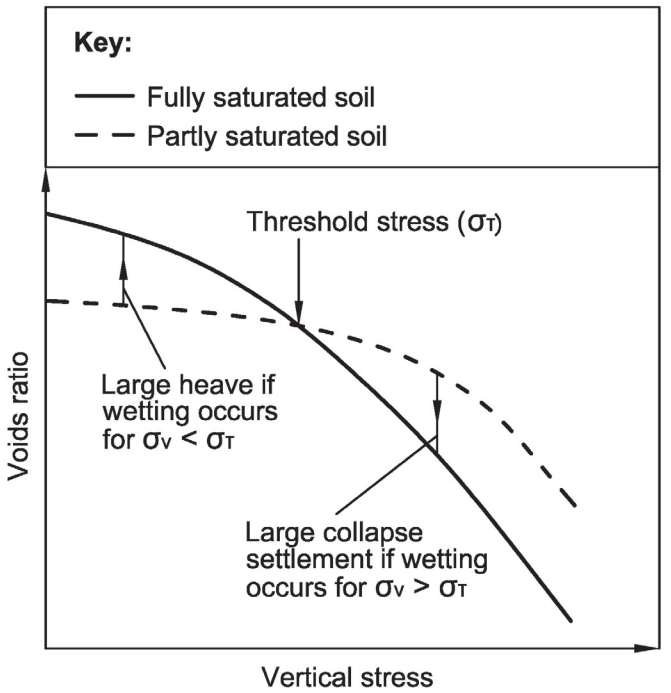

Figure 53.22 Metastable settlement and heave behaviour for partly saturated soils

Excavations down to 5 m depth did not find any improvement in strength. The original shallow foundation design had to be abandoned and replaced by piled foundations, with substantial cost increases and a large delay to overall completion of the project. Subsequent investigations revealed that the area had been used as a brick pit; the natural competent soils had been excavated and stockpiled. Once brick-making had finished the natural soils were end-tipped loosely into the pit. The borehole logs had proven to be completely unreliable.

(ii) Several low-rise buildings were successfully designed and constructed, with shallow strip footings, and an additional building was then commissioned close to the site perimeter. The location for the proposed building was being used for agricultural purposes, and intrusive ground investigations could not be carried out due to access and land ownership problems. No problems were anticipated due to the positive experience from the previous works. Once access into the area was achieved, construction commenced straight away. Unfortunately excavations for the strip footings only found very soft clays. Piled foundations were eventually used, instead of the original strip footings. Aerial photographs of the area indicated the existence of an old pond, which had subsequently been infilled.

With the benefit of hindsight it may seem surprising that these problems occurred, especially since experienced designers had been involved in both the sites. Desk studies and ground investigations must be implemented with great care and thoroughly checked. Even if old investigation data are available for a site, it is prudent to carry out some additional investigations to check the reliability of the old data. It is important that investigations are fully supervised by experienced staff.

The scope and scale of ground investigations will vary depending upon the size and complexity of the proposed structures, local experience and the nature of the geomorphology, geology and hydrogeology in the vicinity of the site. A comprehensive desk study is always required. The objectives of the subsequent investigations will include:

- confirmation of the conceptual ground and groundwater models derived from the desk study;
- assessment of the local variability of the ground properties;
- derivation of simple strength and compressibility parameters (often from empirical correlations with penetration tests or basic laboratory testing);
- assessment of likely construction problems (especially when groundwater related).

For simple (Category 1) projects (with shallow pad or strip footings) in an area with well-known geology, it may be sufficient to carry out trial pits, dynamic probing or static cone penetration tests. For Category 2 and 3 projects a broader range of more sophisticated *in situ* and laboratory tests will be necessary. In general, for sites underlain by clays, the emphasis for carrying out laboratory testing of strength and compressibility should be a small number of tests on high-quality samples (push-in thin wall tubes, triple-tube rotary coring with foam flush for stiff clays or push-in piston tubes for soft clays), rather than carrying out a mass of routine triaxial and oedometer tests on relatively poor-quality driven thick-walled U100 tubes. The case history in section 53.8 highlights the advantages of this approach.

For sands, if the foundation requirements are particularly onerous, the sands have unusual mineralogy (micaceous or calcareous) or contain significant clay or organic content then laboratory testing of reconstituted samples for strength and compressibility should be considered. As noted below (section 53.7.3) empirical correlations between penetration resistance and sand compressibility are of limited reliability. More sophisticated testing, including plate tests or pressure-meter tests, may need to be considered for complex situations.

The assessment of groundwater conditions will usually require piezometers to be installed in boreholes. The groundwater levels should be monitored over several months (preferably including a winter and spring period). *In situ* permeability tests should also be carried out in more permeable layers that may be the source of groundwater problems during construction.

For all projects, irrespective of their scale and complexity, the ground investigation should include both *in situ* testing, sampling and laboratory testing. They are complementary

techniques, with their own particular advantages. *In situ* testing is intrinsically better suited to assessing ground variability, whereas laboratory testing is better suited to assessing fundamental strength and compressibility characteristics provided the sample quality is sufficiently high. It is always important to sample and inspect the soil visually and describe it in a comprehensive and consistent manner using engineering descriptions consistent with appropriate codes (Rowe, 1972).

A major deficiency with conventional practice is that sampling is usually carried out at discrete depth intervals that are too large, typically 1.5 m depth intervals. Most foundation settlement will be due to settlement occurring within a depth of about two-thirds of the foundation width. Hence, *continuous* sampling of boreholes is recommended, down to a depth of about 1.0*B*, where *B* is the proposed foundation width. Laboratory testing and penetration tests should be particularly intensive within a depth of about two-thirds of the proposed foundation width.

Much of the UK is underlain by glacial soils; these soils are often competent and suitable for shallow foundations, indeed piling can often be far more problematic; refer to CIRIA C504 (Trenter, 1999); however, investigations can be challenging due to the potential presence of:

- significant spatial variability in soil type (exhibited by large changes in strength, overconsolidation ratio, compressibility and consolidation properties);
- large variations in depth to rockhead and associated variations in the thickness of overlying compressible soils;
- water-bearing layers of silt, sand, gravel of variable thickness and continuity;
- artesian groundwater pressures;
- cobbles and large boulders.

Figure 53.23 shows a profile through glacial deposits in northeast England, where a weaker, lightly overconsolidated, glaciolacustrine layer underlies a very stiff heavily overconsolidated lodgement till. In these ground conditions the full range of ground investigation methods may be necessary in order to adequately characterise the ground conditions.

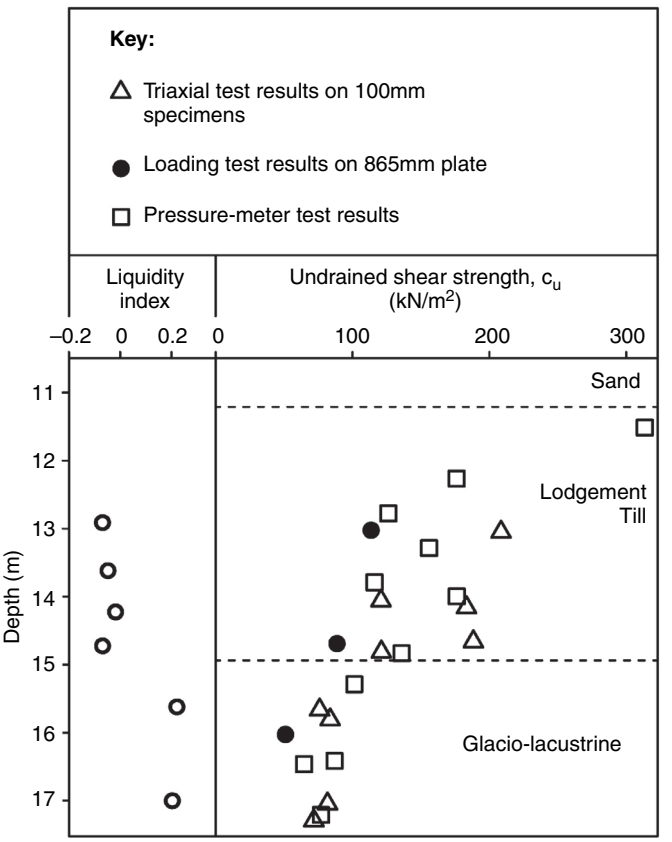

Figure 53.23 Glacial deposits, weaker layer beneath stiff clay
Reproduced from CIRIA C504, Trenter (1999), www.ciria.org

53.7.2 Strength and compressibility of clays

Classification: As noted in section 53.6.4 (**Tables 53.6** and **53.7** and **Figure 53.17**) the observed settlement of shallow foundations is closely linked to the plasticity index (PI) and degree of overconsolidation (OCR) of the underlying clays. The shear strength of clays are similarly dependent on PI and OCR, and are also significantly affected by their macrofabric and structure (i.e. the presence of silt and sand lenses, fissures and bonding). Classification test data can be used to derive void indices (Burland, 1990) and compare these against intrinsic and sedimentation compression lines (ICL and SCL, respectively); refer to Chapter 52 *Foundation types and conceptual design principles* and **Figure 52.21**. Void index plots can provide a robust framework for assessing settlement behaviour, especially for soft clays.

Reference should be made to Chapter 17 *Strength and deformation behaviour of soils* for an introduction to the strength and deformation behaviour of clays.

Heavily overconsolidated clays – undrained strength (Su): The common method in the UK for measuring strength is to sample with driven thick-walled tubes (U100) and carry out quick undrained triaxial (QUT) tests (time to failure of about 2–5 min). This is a very crude method and data usually exhibit significant scatter. **Figure 53.24** gives examples of the differences between different test data. For Lodgement Till, the plate tests indicate an increase of strength with depth, whereas the U100 QUT data indicate a reduction of strength with depth. The misidentification of soft layers can be a common problem, especially in clays with silt or sand lenses. This is due to the clay softening after sampling as water migrates from the silt and sand to the adjacent clay. *In situ* tests (such as CPT or SPT) can be a valuable means of identifying more realistic strength profiles. SPT is a simple and robust means of assessing undrained strength for a wide range of stiff clays. Stroud (1990) provides further guidance; with Su ~ *fi* (N), where N is the SPT blow count and *fi* is a correlation factor, which varies

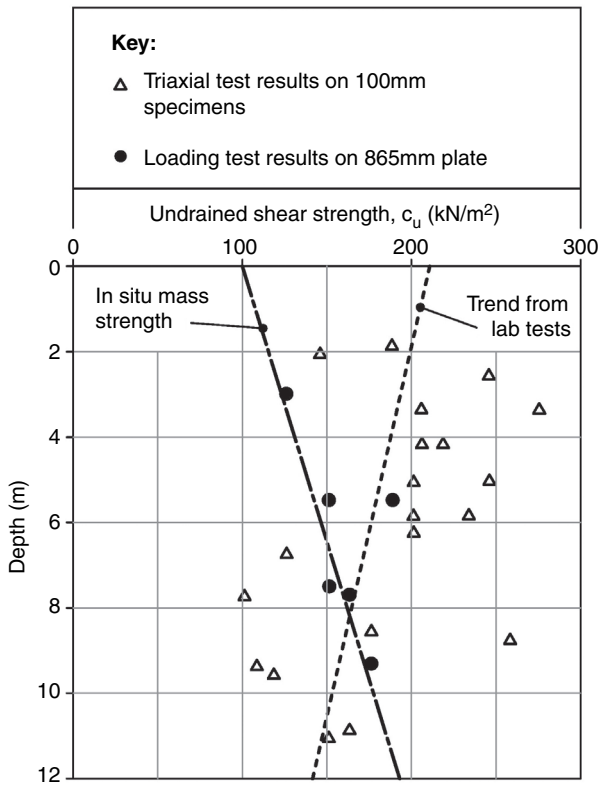

Figure 53.24 Undrained shear strength data for a stiff clay

from about 4 to 4.5 for high-plasticity overconsolidated clays to about 5.5 to 6 in low-plasticity overconsolidated clays. Lunne *et al*. (1997) give guidance on deriving the undrained strength from CPT's in stiff clays, where the correlation is dependent mainly on fissure spacing.

If the project is relatively simple and a high factor of safety (say, 3.0 or more) against bearing-capacity failure is used, then the potential errors introduced by routine sampling and testing will usually be of little practical consequence. However, if a more economical design is being developed with a lower factor of safety (e.g. Eurocode 7 allows a factor of safety on undrained strength of 1.4 to be used), then the potential errors can become critical and high-quality sampling together with more sophisticated testing is strongly recommended.

Heavily overconsolidated clays – compressibility: When carrying out preliminary estimates of total settlement and using linear elastic analytical methods, then (based on Stroud, 1990):

$$E'_v = 200S_{um} \text{ for high-plasticity clays} \quad (53.20)$$

$$E'_v = 250S_{um} \text{ for low-plasticity clays} \quad (53.21)$$

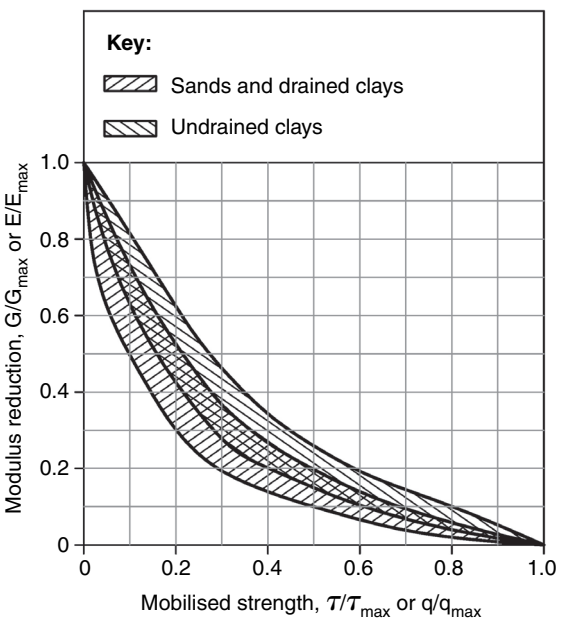
where $E'v$ is the drained Young's modulus for vertical loading and S_{um} is a cautious estimate of the mean undrained strength profile.

It is now well known that the deformation modulus (or compressibility) of soils is highly nonlinear, and may change by more than an order of magnitude between very small strain and large strain amplitudes. Hence, the confusing range of soil stiffness correlations quoted in various technical publications. Research has shown that the degradation of deformation modulus, with increases in strain amplitude or shear stress, forms a consistent pattern; **Figure 53.25** plots data for a wide range of soil types under undrained and drained loading. Atkinson (2000) and Clayton and Heymann (2001) give additional information on this topic. **Figure 53.26** plots drained Young's moduli from oedometer and geophysical tests (i.e. at large and very small strain, respectively) for a site in central London (QE2 Conference Centre, Burland and Kalra, 1986). Also shown are mobilised Young's moduli back analysed from observations of foundation settlement. It can be seen that at shallow depths the mobilised stiffness tends towards large strain values (from oedometer tests), but rapidly increases with depth towards very small strain values (from geophysical tests). Also shown is the Young's modulus profile based on equation (53.20) above, which underestimates the rate of increase of mobilised stiffness with depth.

53.7.3 Strength and compressibility of sand

Classification: To assess the strength and compressibility of sands the following basic information will be required:

- geological age (e.g. post-glacial, glacial or pre-glacial) and likely OCR (overconsolidated or normally consolidated);
- particle grading and particle angularity;



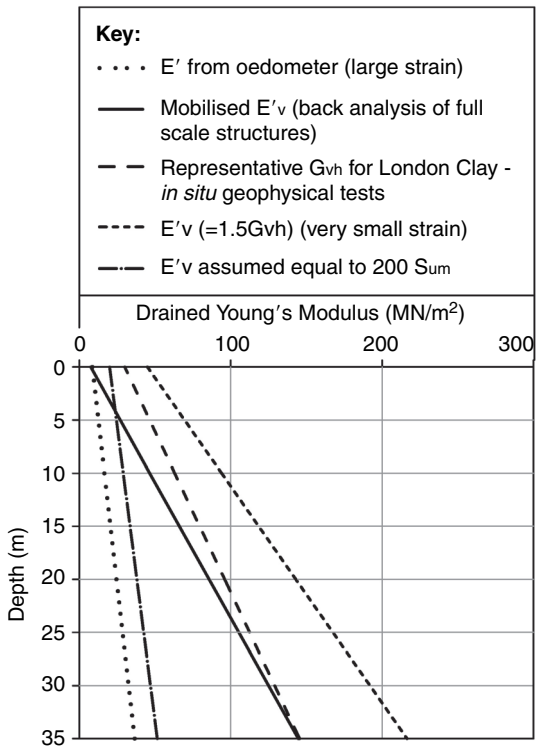


Figure 53.25 Modulus reduction versus mobilised strength for clays and sands
Modified from Mayne (2007)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

NB.
Mobilised E′v and oedometer E′v (after Burland and Karla, 1986).
Representative Gvh for London Clay (derived from Hight *et al.* 2003).
Gvh = vertical shear modulus;
Sum = mean undrained strength.

Figure 53.26 Drained Young's moduli versus depth for a stiff plastic clay

- mineralogy (silica or non-silica);
- relative density.

Clayton (1995) and Lunne *et al.* (1997) provide guidance on the derivation of relative density from SPT 'N' and CPT q_c values, respectively.

Chapter 17 *Strength and deformation behaviour of soils* gives an introduction to the strength and deformation behaviour of sands.

Strength: A simple and coherent approach to assessing the strength of sands has been described by Bolton (1986):

$$\text{Peak angle of friction, } \Phi'_p = \Phi'_{cv} + \psi_d \quad (53.22)$$

$$\text{For triaxial conditions, } \psi_d = \Phi'_p - \Phi'_{cv} = 3I_R \quad (53.23)$$

$$\text{and } I_R = I_D\,(Q - \ln p') - 1 \quad (53.24)$$

where Φ'_{cv} is the critical state angle of friction, which is mainly dependent on particle shape, grading and mineralogy (refer to **Table 53.12**) and ψ is the dilatancy of the sand, which is mainly dependent on the relative density and the stress level at failure. I_R is a relative density index, with values between zero and 4. I_D is the relative density, p' is the mean effective stress at failure (for $p' \geq 150$ kN/m^2) and Q depends on the strength or 'crushability' of the grains (refer to **Table 53.13**).

Dilatancy as a function of relative density and mean effective stress is given in **Figure 53.27**, for quartz and feldspar sand. For micaceous and calcareous sands, dilatancy will be much reduced, especially at high stress, since Q is lower (i.e. the particles are more easily crushed).

In general, making direct estimates of peak angles of friction from penetration tests is NOT recommended. An assessment of the critical state angle of friction should be made based on: the sand mineralogy (e.g. from geological memoirs), visual description of particle angularity and particle grading and by reference to **Table 53.12**. The dilatancy component of the strength can be assessed from equations (53.23) and (53.24) above (or **Figure 53.27**). An appropriate use of penetration test data is to assess the dilatancy component of the strength, from an assessment of relative density (i.e. I_D in equation (53.24) and **Figure 53.27**). If necessary, appropriate laboratory tests can be carried out (Bolton, 1986). A cautious estimate of dilatancy is required. However, for dense sands it would be overconservative to ignore dilatancy completely.

Compressibility: It is recommended that the original paper by Burland and Burbidge is reviewed together with the subsequent published discussion (Proceedings of ICE, December, 1986), which provide insights into the various issues that can affect the settlement of sand. It is important for the engineer to appreciate the limitations of any method of settlement prediction that is based on the results of penetration tests. In particular it should be noted that the sand's stress history has a significant influence on its compressibility, but has a negligible influence on penetration resistance. In addition to any intrinsic problems with penetration tests the natural variability of sands tends to be high. **Figure 53.28** gives the results of a statistical study by Burland and Burbidge (1984) for 13 sites. This shows that the ratio of the maximum to the minimum settlement of practically identical footings (subject to the same loads) is large, and a ratio of maximum to average settlement of 1.6 is a reasonable bound to the data spread.

If it is necessary to derive Young's moduli from SPT 'N' values, then **Table 53.14** provides some guidance, and Lunne *et al.* (1997) also provide guidance for interpretation of CPT data (for E' mobilised at strain amplitudes of about 0.1%, and the variation of Young's moduli with degree of loading, for various CPT q_c values). Many of the old published correlations for relating penetration test values to Young's moduli are unreliable.

53.7.4 Strength and compressibility of rocks

Classification: Assessing the strength and compressibility of rocks is predominantly concerned with determining the discontinuity characteristics and degree of weathering of the rock. If the rockhead is close to the ground surface, then trial pits or trial trenches will be valuable for assessing the rock mass characteristics; for deeper deposits, large diameter (P

2. *Q* can be assumed equal to the natural logarithm of the particle crushing strength in kN/m^2.

Table 53.13 Crushability Q for some sands

or S size core, i.e. 90 to 100 mm diameter) triple-tube coring is recommended, together with logging by an experienced geologist. A common error is to carry out rotary coring with too small a diameter, which can be highly misleading. The initial steps in assessing the rock mass properties typically comprise:

(i) Classify the rock mass with respect to its geological origin (i.e. igneous, metamorphic or sedimentary).

(ii) Assess the rock mass quality by assessing the nature, orientation and spacing of all discontinuities and joints, including if the joints are open or closed, the strength and compressibility of discontinuities and any infill (which may include soft clay) in the joints. Practical applications normally utilise a rock mass classification system (such as the Geological Strength Index, GSI, Hoek *et al.*, 1995).

(iii) Assess the weathering grade of the rock; a number of weathering schemes have been developed following Chandler (1969), although no weathering scheme can be universally applied. In complex interlayered sequences (say of interbedded mudstone and sandstone) more weathered material may underlie less weathered material.

A general problem with very weak and weak rocks is that poorer zones of rock are often not sampled. Hence, reliance on laboratory tests can lead to an unsafe bias in the data on strength and compressibility. Hence, *in situ* tests, such as weak rock self-boring pressure-meter and geophysics, can be valuable.

Strength: The discontinuity characteristics, orientation and spacing need to be understood. Investigation techniques are discussed by Wylie (1991).

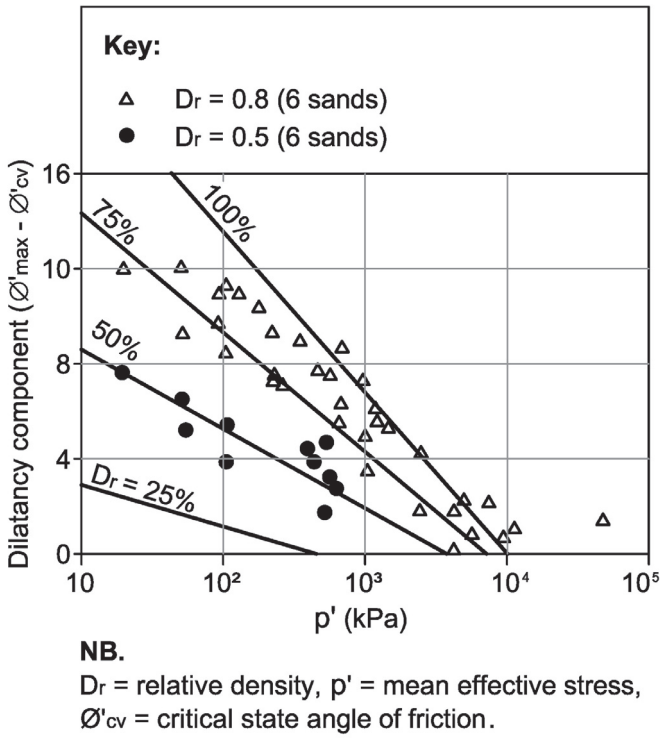

Figure 53.27 Variation of dilation (Φ′max – Φ′cv) versus relative density and mean effective stress
Data taken from Bolton (1986)

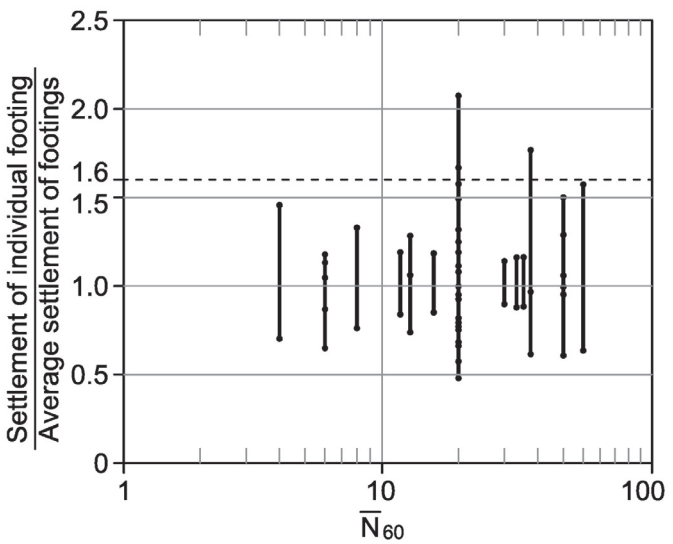

Figure 53.28 Variability of sand. Observed variations of footing settlement at a site
Reproduced from Burland and Burbidge (1984)

Standard penetration value (blows/300 mm), N	E′/N (MN/m²) at Lower limit (large strain)	Mean (small strain)	Upper limit (2) (very small strain)
< 4	0.4 to 0.6	1.6 to 2.4	3.5 to 5.3
10	0.7 to 1.1	2.2 to 3.4	4.6 to 7.0
30	1.5 to 2.2	3.7 to 5.6	6.6 to 10.0
> 60	2.3 to 3.5	4.6 to 7.0	8.9 to 13.5

Note:
1. Based on back analysis of Burland and Burbidge (1984) database and for initial guidance only
2. The upper-limit values should not be used in routine practice, site-specific verification required via geophysical or other independent tests or correlations
3. *E′* = 'N' and *E′* = 2'N' are often used in UK practice for normally and overconsolidated sands respectively.
4. For important projects, site-specific testing may be required.

Table 53.14 Correlation between SPT 'N' and Young's modulus
Data taken from Clayton (1995)

For a wide range of rocks the Hoek–Brown failure criterion (Hoek and Brown, 1997) provides a coherent and practical approach to assessing appropriate strength parameters. CIRIA reports C574 (Lord *et al.*, 2002) and C570 (Chandler and Forster, 2001) provide specific guidance on Chalk and Mercia Mudstone respectively.

Compressibility: As indicated by **Figure 53.29** the compressibility of a rock mass (due to the influence of discontinuities) can be far higher than the compressibility of the intact material. This figure compares the intact stiffness of chalk in the laboratory with the mass stiffness derived from surface-wave geophysics and large (1.8 m- diameter) plate tests. At comparable strain amplitudes, the intact lab stiffness is several times higher than the mass stiffness. Hobbs (1974) has related the rock mass quality via RQD, to a rock mass factor, j, which reduces the intact Young's modulus (typically measured in the laboratory) to a 'mass' modulus, from:

$$E_m = j\,(E_i) \tag{53.25}$$

where E_m is the mass modulus, j is the mass factor and E_i is the intact modulus. The relationship between rock quality and j is given in **Table 53.15**. Some care is needed when using RQD since it takes no account of joint opening or infill materials (which are assessed in more comprehensive rock mass classification systems such as the GSI or RMR systems). An open joint infilled with clay would lead to a much lower mass modulus than one with closed joints. Hoek and Diederichs (2006) outline a more sophisticated empirical approach based on GSI.

For preliminary settlement assessments and routine design of simple structures, it can be assumed that $E_i = Mq_{uc}$, where M is the ratio between the intact modulus E_i and the unconfined compressive strength q_{uc}. Values of M for different rock types

are given in **Table 53.15**. For some very weak rocks, such as Mercia Mudstone, it may not be practical to obtain samples of sufficient quality for reliable laboratory measurements of stiffness and compressibility, and then more reliance will need to be placed on *in situ* loading tests such as the pressure-meter. Some care is required, since a horizontal undrained modulus will be measured and a vertical drained stiffness will need to be derived for settlement estimates. Mass compressibility parameters for the design of shallow foundations in chalk are given in **Table 53.16**.

For Mercia Mudstone, profiles of rock mass Young's modulus versus depth, based on the back analysis of foundation settlement in unweathered mudstone, siltstone (typically Grades I and II) and sandstone, are given in **Figure 53.30**. Meigh (1976) suggested that for weathered mudstone/siltstone, typically mobilised drained Young's modulus, is about 4 MN/m^2 at the surface and increases at about 4 MN/m^2 per metre depth (i.e. similar to firm-stiff clays); hence weathering could change mobilised Young's modulus by more than an order of magnitude in weak rocks.

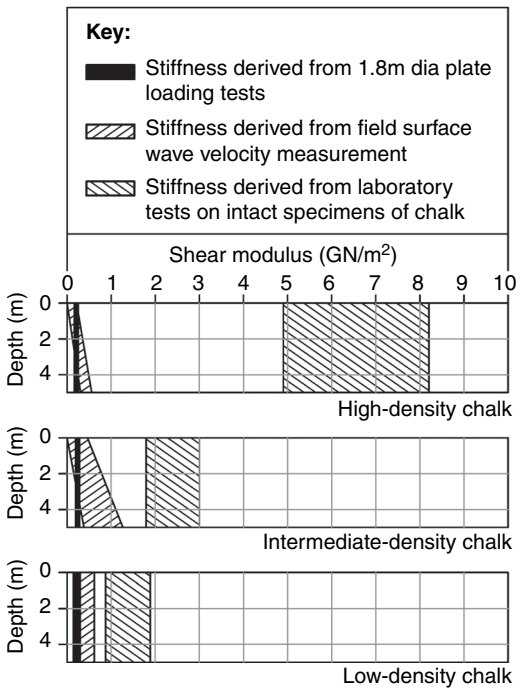

Figure 53.29 Comparison of initial modulus from 1.8-m-diameter plate tests with stiffness measured on intact chalk, and derived from surface-wave geophysics

53.8 Case history for a prestigious building on glacial tills

53.8.1 Introduction

A large public building was to be constructed in an urban area. An important architectural feature was a special glass frontage across one corner of the building. This meant that an onerous differential settlement criterion was imposed. The maximum net foundation bearing pressure was 250 kN/m^2.

A desk study and preliminary ground investigations indicated a surface layer of loose and variable made ground, about 2 to 3 m thick. Beneath this was a stiff to very stiff layer of glacial till. An existing old building covering the proposed site constrained use of the site, both for carrying out ground investigations and for construction of the new building (since demolition was on the overall project critical path).

The building was to be constructed under a 'design and build' contract, and there were very severe penalties under the contract if the building was completed late. The consultant responsible for the building design (including the foundations) was commissioned by the building contractor.

Quality classification[1]	RQD (%)	Fracture frequency per metre	Velocity index[2] (Vf/Vl)^2	Mass factor [j]
Very poor	0–25	15	0–0.2	0.2
Poor	25–50	15–8	0.2–0.4	0.2
Fair	50–75	8–5	0.4–0.6	0.2–0.5
Good	75–90	5–1	0.6–0.8	0.5–0.8
Excellent	90–100	1	0.8–1.0	0.8–1.0

	Rock type	Modulus ratio, Mr[3]
Group 3	Very marly limestones, poorly cemented sandstones, cemented mudstones and shales, slates and schists (steep cleavage and foliation)	150
Group 4	Uncemented mudstones and shales	75

Notes:
1. As BS 5930.
2. *Vf* is the wave velocity in the field and *Vl* is the wave velocity in the laboratory.
3. M_r is the modulus ratio, where $E_m = j\, M_r q_{uc}$; E_m is the modulus for a rock mass, j is the mass factor and q_{uc} is the unconfined compressive strength.
These approximate correlations are for preliminary settlement estimates only. Site-specific tests may be necessary depending on project requirements.

Table 53.15 Approximate correlations for rock mass stiffness

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Density	Grade	Es [1] (MPa)	q_y (kPa)	Ey[2] (MPa)	q_u[3] (MPa)
Medium/high	A	1500–3000	>1600–2400	?[4]	>16
Medium/high	B	1500–2000	300–500	35–80	4.0–7.7
Medium/high	C	300–1500	300–500	35–80	4.0–7.7
Low	B and C	200–700	250–500	15–35	1.5–2.0
	Dc	200[5]	225–500	20–30	-
	Dm	6	?	-	-

Notes:
1. E_s is the initial modulus, but standardised at a net applied stress of 200 kPa; q_y is the yield stress.
2. E_y is the post-yield modulus, assumed to be fully developed once ρ/D exceeds about 0.4%.
3. q_u is the ultimate stress, measured at ρ/D = 10–15% of the plate diameter.
4. Yield has not been observed for this grade of chalk.
5. Values given in this table are short term, based upon plate loading tests. In the long term, this figure reduces to 75 MPa.
The above values are for initial guidance only, site-specific tests may be necessary.

Data taken from CIRIA C574, Lord *et al.* (2002), www.ciria.org

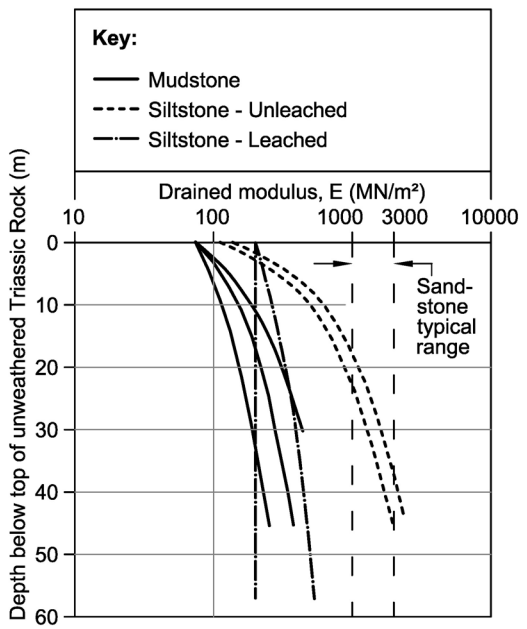

Figure 53.30 Measured secant drained Young's moduli in unweathered Triassic rocks
Data taken from Meigh (1976)

53.8.2 Ground conditions and site history

Desk studies had shown that neither mining nor quarrying had affected the site. A key observation from the ground investigation was the presence of numerous boulders within the glacial till. The description of the glacial till indicated it was consistently stiff or very stiff and its liquidity index was about –0.2 (±0.1) in the uppermost 5 m of the till. These were indicators of the heavily overconsolidated nature of the till and together with the plasticity index, which was typically about 15%, indicated that compressibility of the till would be very low. The above observations were consistent with the relevant technical literature and local experience, which was collated during the desk study.

53.8.3 Foundation options and risks

The initial design criterion was for foundation settlement to be less than 5 mm. As a consequence, bored piles were initially selected for the new building foundations. There were serious risks with this foundation type, because the numerous boulders would form significant obstructions to pile boring. Hence, there was a major risk of large delays to the overall construction programme. Past experience had shown that shallow foundations on stiff glacial tills usually exhibit small settlement under the envisaged foundation bearing pressures. The old building foundations were pad foundations and the decision was taken to supplement the existing shallow foundations, so mass concrete was used to broaden and lengthen the existing pads, which were then overlain by reinforced concrete pads. In addition, negotiations with the architectural finishes supplier enabled a less onerous differential settlement criterion to be agreed of 10 mm.

53.8.4 Additional ground investigations and geotechnical analysis

An additional ground investigation was carried out. This comprised three 4 m-deep trial pits to expose the glacial till and enable high-quality block samples to be taken. Advanced laboratory tests were then carried out to obtain realistic drained stiffness parameters for the till. Glacial till is often heterogeneous and, because of access constraints (due to the existing building), there were several areas across the site where there was no geotechnical data. To mitigate this risk, static cone tests (CPT's) were carried out as soon as the existing building was demolished and before foundation construction for the new building began. The CPT's could be carried out and interpreted

quickly. Cone penetration was limited, typically to about 7 or 8 m depth, due to boulders, but this was adequate given the limited depth of influence of the narrow, circa 2 m wide, pad footings. These tests confirmed the till strength was adequate across the whole site for the proposed design.

The undrained strength and compressibility data are plotted in **Figures 53.31** and **53.32**. The routine triaxial data (on U100 samples) obtained from the first investigation indicated relatively low undrained strengths, compared with the block samples taken from the trial pits. The subsequent CPT profiles indicated that the till was reasonably uniform and that strength increased with depth. The design profiles were based on the block samples and the CPT's.

To assess the till's compressibility across a wide range of strain amplitudes several different test techniques were specified: geophysical (bender element) tests for compressibility at very small strain; oedometer tests for large strain compressibility and triaxial tests with local instrumentation to measure compressibility at intermediate strain amplitudes. The data derived from some of these tests are shown in **Figure 53.32**. It is worth noting that the oedometer tests (using relatively large load increments/decrements of 100 kN/m^2 plus) on U100 samples (taken during the first ground investigation) gave an average coefficient of volume compressibility m_v of 0.1 m^2 MN, whereas oedometer tests on the block samples (with load-unload-reload loops and small load increments on reloading, typically 20 to 30 kN/m^2) gave m_v values that were between two and four times smaller.

Bearing-capacity checks showed that the factor of safety was greater than three. In view of the onerous different settlement criterion, a careful analysis of the foundation settlement was required. The main method of settlement analysis was a modified one-dimensional method, which allowed for the variation of deformation modulus with both strain amplitude and mean effective stress due to foundation loading (O'Brien and Sharp, 2001). The configuration of the pad and strip footings beneath the building footprint was quite complex; however, this was easily taken into account by allowing for superposition of vertical stress increments (calculated from Boussinesq theory).

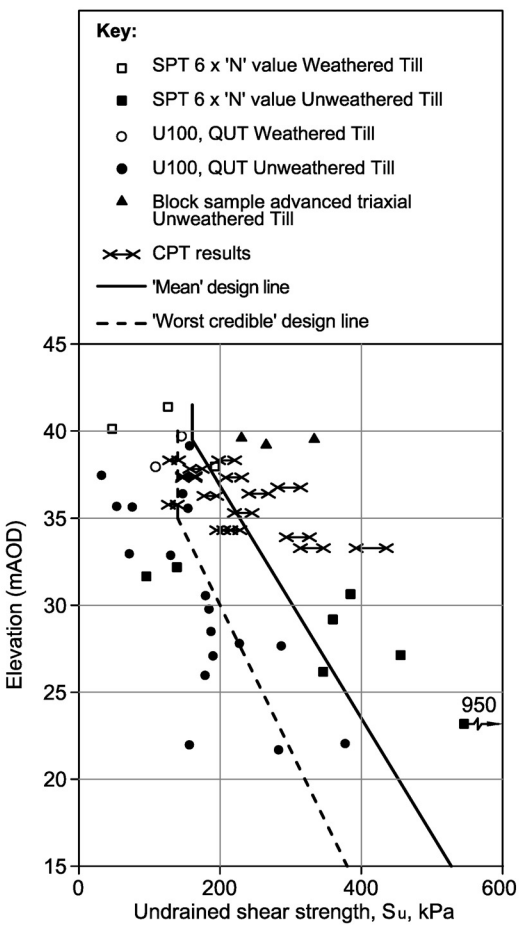

Figure 53.31 Case history, glacial till undrained shear strength data

53.8.5 Design verification and construction control

A critical risk was the potential for the till to soften rapidly if it was exposed to water (either groundwater or rainfall). During trial pitting, no problems were encountered with water seepage. Nevertheless, the construction specification required the till at foundation level to be carefully protected. In particular, a protective layer of till 0.6 m thick was to be left above the foundation level, and once final excavation was carried out the till was be covered with a structural-quality layer of blinding concrete 100 mm thick within the same shift.

The shallow foundations were constructed rapidly and without difficulties, and the project was completed ahead of schedule. Subsequent monitoring indicated foundation settlement of less than 10 mm, which was consistent with the predictions derived from the additional ground investigation data.

53.8.6 Conclusions

The building featured a special glass frontage with an onerous settlement criterion. It was built under a fast-track design and build form of contract. If piling had been attempted it is likely that severe delays would have adversely affected the project, due to large boulders within the glacial till. Local experience generally indicated that shallow foundations exhibited only small settlement when founded on the very stiff heavily overconsolidated till. The first ground investigation, using routine sampling and testing methods, indicated that shallow foundation settlement would be excessive. Hence, additional investigations were carried out using modern testing methods. This high-quality data was used together with a modified one-dimensional settlement analysis (section 53.6.4), which took account of nonlinear elastic behaviour, to demonstrate that shallow foundations would perform satisfactorily. The old building foundations were re-used and supplemented by new shallow foundations, and the new building was successfully completed.

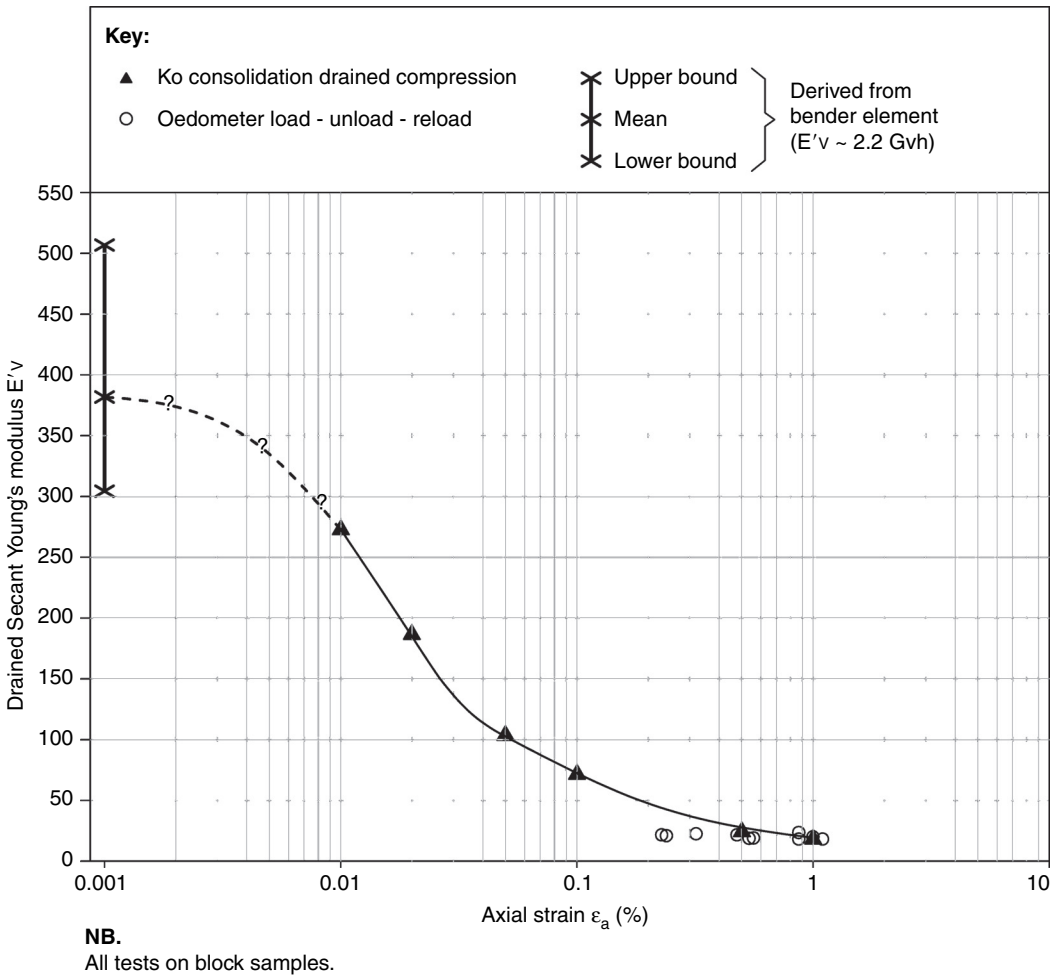

Figure 53.32 Case history, glacial till drained secant Young's modulus variation with strain amplitude

53.9 Overall conclusions

- There can be several causes of shallow foundation movements, which are independent of the applied bearing pressures imposed by a superstructure (**Table 53.2**). The global ground movements caused by these geohazards can lead to serviceability or ultimate limit state failure of structures. The seasonal shrink–swell movement of clay soils, induced by trees, is a common cause of excessive shallow foundation movement.
- The temporary stability of excavations and the potential for groundwater inflow require careful consideration, because of the safety and cost implications.
- The applied loads on a foundation usually comprise a variety of different types of load, including dead loads and transient loads (including wind, impact and accidental loads). It is important to understand the nature of the applied loads before carrying out bearing-capacity and settlement calculations. For example, when calculating the long-term settlement of clays, occasional transient loads would usually be ignored.
- When carrying out bearing-capacity and settlement checks, it is important to consider the behaviour of the whole structure, in addition to the individual foundation elements, within the context of the site, adjacent structures and topographical features. The risk of adverse interaction between adjacent structures tends to increase if foundations are subject to lateral loads.
- There have been significant developments in bearing-capacity theory beyond the original equations proposed by Terzaghi and Skempton. A wide range of situations, including increasing strength with depth, anisotropy, soil layering and allowances for soil compressibility and stress level can be analysed. Foundations subjected to combined vertical, horizontal and moment loads have conventionally been assessed by applying inclination factors to the bearing-capacity factors for vertical loading. However, the reliability of these correction factors reduces as the load inclination (*H*/*V* ratio) increases, and for angles beyond 18° to the vertical these correction factors are not recommended. More recent bearing-capacity theories based on a *V*/*H*/*M* failure surface (Chapter 21 *Bearing capacity theory*) are more appropriate.
- The bearing capacity and settlement of rock will be sensitive to the orientation, spacing and characteristics of discontinuities within the rock mass (**Figure 53.13**), the degree of weathering and the presence of voids.

- Vertical stress changes beneath a foundation predicted by homogeneous, isotropic, linear elastic theory are reasonably accurate for many practical situations, which may involve anisotropy, nonlinearity and increasing stiffness with depth. In contrast, horizontal stress changes predicted by elastic theory are often inaccurate for these situations.
- Foundation settlement can be assessed quickly by using displacement influence factors derived from elastic theory. Published solutions that assume the elastic material has constant Young's modulus with depth or is of infinite thickness are not recommended. Solutions that allow for finite thickness and with Young's modulus increasing with depth will generally provide more realistic predictions.
- For heavily overconsolidated clays the simple one-dimensional method can be used to calculate the *total* settlement, and this method is as accurate as (and often more accurate than) many more sophisticated methods. The major difficulty is reliable measurements of compressibility, which are appropriate for the relevant stress changes and strain amplitudes. The modified one-dimensional method, which uses the constrained modulus D, is helpful in this respect since D can be related to a variety of measureable parameters that are relevant for a wide range of strain amplitudes.
- The settlement of medium dense and dense silica sands is usually small (some exceptions are summarised in **Table 53.8**) and for simple structures the use of the empirical correlations in **Figure 53.18** will often be sufficient to estimate the likely bounds of settlement. A variety of more complex methods are available; however, these usually depend on relating penetration resistance (from SPT's or CPT's) to sand compressibility and will, therefore, be of limited reliability.
- Many of the serious problems that occur with shallow foundations are due to a lack of understanding of the site's history, geology or hydrogeology. Hence, comprehensive desk studies are always important and ground investigations must be implemented with great care and thoroughly checked.
- For shallow foundations on heavily overconsolidated clays, settlement is concentrated immediately beneath the foundation and more than half of the settlement will generally occur over a depth of about half the foundation width. Hence, much more emphasis needs to be placed on measuring soil properties in this area. The *mobilised* soil stiffness generally increases rapidly with depth (typically from 'large strain' values immediately beneath the foundations to 'very small strain' values remote from the foundations).
- For soft clays and bonded materials (such as chalk) perhaps the most critical parameter for foundation design is the assessment of the yield stress (commonly known as the pre-consolidation pressure for soft clays). The yield stress for chalk is reasonably well established (**Table 53.16**) and at net bearing pressures below the yield stress, settlement will be small. The compressibility of a rock mass will generally be far higher than the intact material because of the influence of discontinuities.

It is recommended this chapter is read in conjunction with

- Chapter 19 *Settlement and stress distributions*;
- Chapter 21 *Bearing capacity theory*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 54
Single piles

Andrew Bell Cementation Skanska Ltd, Doncaster, UK
Christopher Robinson Cementation Skanska Ltd, Doncaster, UK

This chapter considers the design of single piles, from selection of appropriate pile type(s) through to pile load testing strategies. Methods which are commonly used for estimating axial pile capacities in three principal ground types, as well as layered soils, are discussed, covering both empirical and theoretical methods. Other aspects of single pile design covered by this chapter relate to factors of safety, pile settlements and pile response to lateral loading.

54.1 Introduction

Piles are generally required to transfer load from a superstructure through weak or compressible strata, or through water, on to stiffer and less compressible soils and rock. Piles are also required to reduce both overall and differential settlements of the supported structure and may be required to enable construction processes such as top-down construction. They may also be required to resist uplift loads as well as compressive loads when used, for example, to support tall structures which are subject to overturning forces caused by wind. Where basements are to be constructed piles may also be subject to heave-induced tension. A more recent additional use of piles is within ground source heating and cooling systems as part of a development's renewable energy strategy.

Piles used for marine structures are often subject to lateral loads from ship impact and wave forces. Many land-based piles are also subject to lateral forces; for example, in bridge works there are earth pressure forces, expansion and contraction forces and braking and traction forces. Combinations of vertical and horizontal forces and bending moments are common and pile sections have then to be designed according to the relevant structural codes in addition to geotechnical considerations. Foundations beneath machinery may also be subject to cyclic and vibration forces.

Before embarking on the design of a piled foundation, it is essential to have a thorough understanding of all the relevant factors that might affect the performance of the pile being considered.

The design of piled foundations has traditionally been based on a combination of simple empirical methods and local experience, but over the past few decades there has been a gradual change towards more soundly based theoretical methods. Poulos (1989) provided a summary of the range of analysis and design methods available for piled foundations, ranging from simple empirical methods to the most sophisticated non-linear numerical analysis methods. When selecting the appropriate design approach, the following factors should be considered:

- the quality of the site investigation and scope of geotechnical data available;
- the design stage, e.g. conceptual design or detailed design;
- the budget and timescale for foundation design;
- the scale and sensitivity of the proposed structure, especially allowable total and differential settlements;
- the complexity of the ground conditions and loading regime.

54.2 Selection of pile type

Foundation selection is discussed in Chapters 9 *Foundation design decisions* and 52 *Foundation types and conceptual design principles*.

The key factors that usually affect the choice of pile type and ultimately the design of the pile itself are as follows:

1. *Ground conditions*
   - Strength or weakness of the overlying and founding strata
   - Ground variability
   - Potential for downdrag or heave loading, or lateral loading
   - Presence of obstructions
   - Aggressive ground conditions
2. *Construction constraints*
   - Location
   - Access
   - Working area
   - Sensitivity of adjacent assets
   - Underground utilities and structures
3. *Safety and environmental constraints*
   - Risk to operatives and the public

Risks to adjacent structures and underground utilities assets

Risk of contamination to surrounding environment

Effects of noise

Effects of vibration

4. *Nature and magnitude of loads*

   Direction of foundation loading (e.g. lateral, tensile, compression)

   Source and characteristics of loadings (e.g. heave, downdrag, cyclic, static)

5. *Economic considerations*

   What it will cost and whether there is a more economic solution

Prior to embarking on the design of a pile, it is essential that the designer first assesses the type of piles and construction methods that are most appropriate for the particular site under consideration. There is clearly no sense in designing a driven pile in an area where noise and vibration will be an issue. Conversely, designing a continuous flight auger pile 35 m deep when available plant will only reach 30 m is equally futile. Under current health and safety regulations (Health and Safety Executive, 2007), it is also essential for the designer to take into account the risks associated with the installation of the proposed pile solution during the design and specification process; to complete this satisfactorily the designer will need at least a general understanding of the various pile types available and the advantages, disadvantages and key safety considerations of each.

Before any design work is carried out it is essential that an assessment of pile buildability is carried out. Reference should be made to Chapters 52 *Foundation types and conceptual design principles*, 79 *Sequencing of geotechnical works* and 81 *Piling problems* in this respect.

It is important to recognise that each pile type and installation method disturbs the ground in different ways, and as such the design method and considerations may vary between the different systems. This disturbance can improve or reduce both skin friction and end-bearing, and as such will affect the bearing capacity of the complete pile.

Piles of varying type and length may be used on a site provided a suitable assessment of likely differential settlement is carried out. This should include:

- pile size (diameter and length), i.e. geotechnical axial load capacity in compression and tension of a single pile;
- displacement at working load of a single pile;
- differential settlement between adjacent foundations;
- influence of lateral loading, assessment of geotechnical and structural capacity, and lateral displacement;
- assessment of pile group behaviour under vertical and lateral loading (see Chapter 55 *Pile-group design*);
- objective of piles – if it is to reduce settlement/bending moments in a raft then consider piled raft (see Chapter 56 *Rafts and piled rafts*);
- influence of any 'global' ground movements both during construction and long term (see Chapter 57 *Global ground movements and their effects on piles*);
- testing strategy for checking integrity of pile;
- testing strategy for checking vertical and/or lateral load behaviour;
- potential for foundation reuse.

54.3 Axial load capacity (ultimate limit state)

The approach described in this chapter to assess the resistance of piles to compressive loads is the static 'soil mechanics' method for piles loaded axially. Dynamic methods of design and analysis are available but have not been included in this section and attention will be limited to problems involving static or quasi-static axial loading of single piles only.

The general simplified formula for the design of bearing piles typically takes the form of

$$Q_{ult} = Q_b + Q_s - W_p, \tag{54.1}$$

where Q_{ult} is ultimate pile capacity, Q_b is base capacity, Q_s is shaft capacity and W_p is pile self weight.

Furthermore, $Q_b = q_b A_b$ and $Q_s = q_s A_s$, where q_s is unit shaft resistance, q_b is unit base resistance, A_b is area of pile base and A_s is area of pile shaft.

The diagram in **Figure 54.1** shows this relationship, for circular piles.

The above approach, separating the evaluation of shaft and base capacity, forms the basis of all static pile capacity calculations. These components can be broken down further to resistance per unit shaft or base area, and the relative magnitude is dependent on the combination of pile geometry, pile installation method and ground conditions.

Typically, the shaft capacity of a pile is mobilised at much smaller displacements than the base capacity. Shaft capacity can be fully mobilised at movements of only 0.5% to 2% of pile diameter, whereas displacements of around 10% to 20% of pile diameter may be required to mobilise the base resistance, even more if the soil at the base of the pile is disturbed as part of the installation process. It is essential that these differences between the load deformation characteristics of the pile shaft and base are considered early during the pile design process; **Figure 54.2** shows this as an idealised load displacement response curve. Generally, long slender piles are more efficient than short fat piles with regard to settlement control but limitations on the installation technique may often dictate the pile geometry.

There can be concerns about the axial pile capacity under tension loads. De Nicola and Randolph (1993) showed that shaft capacity under tension load is between about 70% and

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

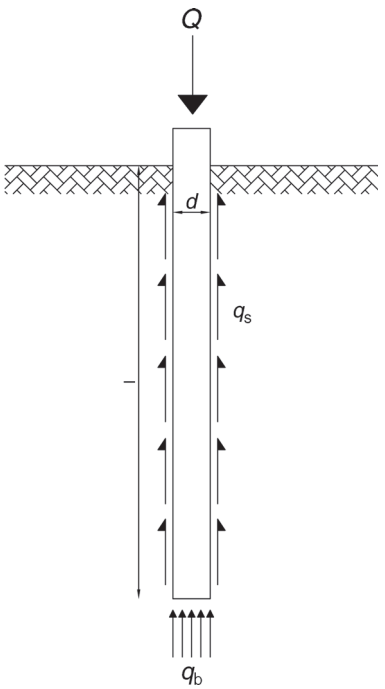

Figure 54.1 Pile under vertical load
Courtesy of Cementation Skanska

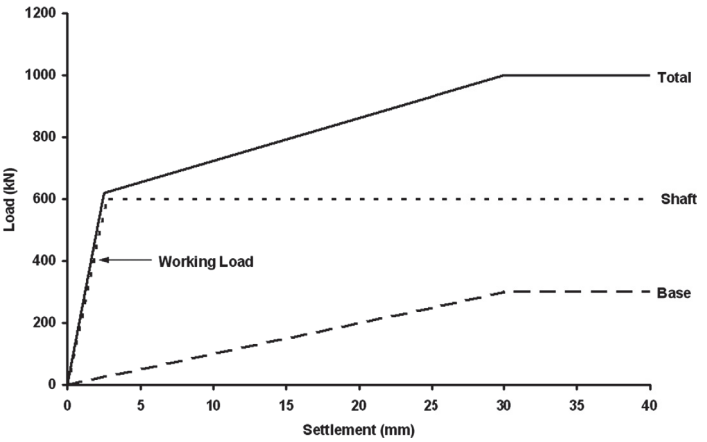

Figure 54.2 Idealised load displacement response
Courtesy of Cementation Skanska

90% of the shaft capacity under compression loads (depending on the relative soil/pile compressibility). However, most codes require higher factors of safety for piles subject to tension loads than those for piles subject to compression. If these higher factors of safety are used, then there is no need to reduce the shaft capacity calculated by routine methods, since the potential adverse effects are taken into account by the use of a larger factor of safety. For piles subject to tension, the base resistance is ignored.

54.3.1 Fine-grained soils

54.3.1.1 Total stress

End-bearing

Whilst the long-term 'effective stress' drained end-bearing capacity of a pile in clay will be significantly larger than the undrained capacity, unfortunately the movements required to mobilise such capacity would be unacceptable for most structures. Furthermore, the pile will require sufficient capacity in the short term to provide the initial load-carrying capability required, and the rate of build-up of load over time will depend on the speed of construction, something which continues to increase as construction technology advances. For these reasons, the end-bearing of piles in fine-grained soils is generally considered using total stress methods, in terms of the undrained shear strength of the clay, S_u, and a bearing capacity factor, N_c, where

$$q_b = N_c S_u. \tag{54.2}$$

The bearing capacity factor relevant for the depth of most piles is usually taken as 9 after Skempton (1951). Allowance should be made for the potential of a softened or disturbed base in some circumstances, particularly when considering underreamed piles, with enlarged bases. In such cases a reduction in S_u should be applied. A reduced value of N_c should also be considered when the pile tip only just penetrates the founding fine-grained strata. A value of $N_c = 6$ is recommended for founding in the top of such founding strata, increasing linearly to 9 after 3 pile diameters' penetration into the stratum.

Shaft friction

Piles in fine-grained soils generally derive most of their capacity in shaft friction, with the base resistance often not mobilised under working loads, particularly in the short term.

Shaft friction, in terms of total stress, is generally calculated using an empirical factor α, where

$$q_s = \alpha S_u. \tag{54.3}$$

The value of α adopted for bored piles typically ranges from 0.3 to 0.6 for straight-shafted piles; higher values have been proven for ribbed or irregular pile shafts. Values of 0.45 to 0.6 are generally adopted for bored piles in stiff overconsolidated clays but can be as high as 0.7 for driven displacement piles. The value of α depends on a combination of the pile type and installation method and the nature of the fine-grained soil. In the UK, the LDSA London District Surveyors Association's *Guidance Note 1* (2009) gives clear recommendations on appropriate values for α for bored and CFA piles founding in London Clay. It is also important for more complex and variable fine-grained soils, such as glacial till, that reference is made to specific guidance such as Weltman and Healy (1978) and Trenter (1999). **Figure 54.3** details the variation of α with

undrained shear strength in glacial till, after Weltman and Healy (1978).

Poulos (1989) summarised some of the most commonly used methods in calculating α for driven piles, an extract of which is included in **Table 54.1**.

It is generally considered good practice to limit the average skin friction in fine-grained soils to 100 kN/m^2 unless proven higher by pile load testing or by suitable experience of pile performance in similar ground condition.

The S_u value in equation (54.3) is really an empirical index value, closely linked to historical sampling/lab test methods together with back analysis of pile test data, rather than a 'fundamental' soil parameter. In the UK, the method is mainly based on experience in London Clay, with the results of Quick Undrained Triaxial (QUT) tests on U100 samples being compared with the results of maintained load tests (refer to Patel, 1992 for further background). Shaft failure requires shearing to take place through a large volume of ground; hence, the S_u value selected for design is a 'mean' value (where the mean is based on representative data, excluding spurious high or low values).

54.3.1.2 Effective stress (fine-grained soils)

Historically, the use of effective stress calculations for the design of piles in fine-grained soils has been limited, but recent research has provided more accurate methods of using this approach. The Imperial College design methods (Jardine *et al.*, 2005) provide recommendations on appropriate methods of calculation for both end-bearing and shaft resistance for driven steel piles in terms of effective stress. Chapter 22 *Behaviour of single piles under vertical loads* provides guidance on effective stress design to assess the capacity of single piles subjected to vertical loading. It is important with such methods to limit the calculated values of end-bearing and shaft friction to those achievable in the field for the pile type and pile construction methods being employed.

An important application of effective stress methods is for piles below or adjacent to deep excavations (say in excess of 4 m deep), when total stress methods may be unsafe.

End-bearing

The use of effective stress methods to calculate the end-bearing of piles in clay soils is, in general, not recommended. It would only be appropriate to adopt such an approach based on the results of suitable pile load testing or appropriate experience in similar ground conditions.

Shaft friction

Reproduced from Burland *et al.* (1979)

destroys all cohesion so that $c' = 0$, then the unit shaft friction can be calculated using

$$q_s = \sigma'_h \tan \delta, \tag{54.4}$$

where σ'_h is horizontal effective stress following pile installation and δ is effective interface friction angle.

For bored piles δ would usually be assumed to equal the critical state angle of friction, φ'_{cv}, whereas for driven piles it would be assumed to equal the residual angle of friction, φ'_{res}.

A simplification can be made if σ'_h is assumed equal to $\sigma'_v K$, in which case $q_s = \sigma'_v K \tan \delta$, further simplified, where $K \tan \delta = \beta$, to $q_s = \beta \sigma'_v$.v Values of β can vary significantly depending on consolidation history (i.e. normally consolidated or overconsolidated) and method of pile installation (driven or bored). Examples of typical values of β and K are given in **Tables 54.2** and **54.3**.

The main challenge in applying equation (54.4) above is to assess the appropriate values of σ'_h or K. As shown in **Figure 54.4** the value of K is very sensitive to the site's stress history and also depends on stress changes during pile installation. Further discussion can be found in Bown and O'Brien (2008).

The β approach is particularly useful for normally consolidated or lightly overconsolidated soils where K_0 can be assumed to be close to $1 - \sin \varphi'$. Then, for example, in the case of a driven pile, if the angle of effective friction is taken as, say, 21°, the ultimate friction becomes $0.25\sigma'_v$. For a very wide range of normally consolidated soils, the value of β is likely to be between 0.2 and 0.3. This value is often used as the basis for calculation of downdrag or 'negative friction'.

54.3.2 Coarse-grained soils

Approximate design methods for piles in coarse-grained soils are well documented and reference should be made to Fleming *et al.* (2008) and Tomlinson (2004) for a wider understanding of the range of design methods available. Recent research has focused on steel-driven piles, aimed predominantly at the offshore, industry, and reference should be made to the work by Randolph and White (2008) and Jardine *et al.* (2005).

54.3.2.1 End-bearing

The end-bearing capacity of piles in coarse-grained soils can be calculated by the formula

$$q_b = \sigma'_{vB} N_q, \tag{54.5}$$

where σ'_{vB} is effective vertical stress at the pile toe and N_q is bearing capacity factor.

N_q is often derived based on a correlation with φ. A commonly used method is that by Berezantzev *et al.* (1961) (**Figure 54.5**). The main problem with this approach is that it is unduly sensitive to small changes in φ', and does not allow for the reduction in mobilised φ' as effective stress levels increase. It also implies that end-bearing pressure will continue to increase proportionally with depth. An alternative approach is that given in Fleming *et al.* (2008), which relates N_q to relative density, effective stress and the critical state angle of friction φ'_{cv}, shown graphically in **Figure 54.6** for $\varphi'_{cv} = 30°$. φ'_{cv} values for a range of sands are summarised by Stroud (1989) and Bolton (1986). Relative density can be assessed from standard penetration test (SPT) 'N' or cone penetration test (CPT) 'q_c' values (section 54.3.4).

Routinely used methods that can be used to calculate end-bearing are summarised in **Table 54.4**.

With any design approach, it is very important to limit the calculated end-bearing to achievable values to ensure serviceability limits are achieved; this is discussed further in section 54.3.5 below. It is possible with theoretical bearing capacity based methods to significantly overestimate the end-bearing resistance, particularly for piling methods that may disturb the soil at the pile toe or for short piles that are highly dependent on end-bearing.

The end-bearing capacity of a pile in a uniform layer of coarse-grained soils will not continue to increase proportionately with depth. Research has shown that the end-bearing pressure soon reaches a limiting value (Vesic, 1977), typically for pile lengths in excess of about $20D$ (where D is the pile diameter). For this reason end-bearing is often limited

conservatively to between 10 and 15 MN/m^2 for dense sands or gravels, depending on the pile installation method, and to about half these values for medium-dense sands or gravels. Higher values can be adopted based on the results of suitable pile load testing or appropriate experience in similar ground conditions. For loose coarse-grained soils very little end-bearing resistance may be mobilised at displacements which are small enough for normal foundation requirements.

54.3.2.2 Shaft friction

The ultimate shaft friction of piles founding in sands or gravels is generally calculated using

$$q_s = K_s \sigma'_v \tan \delta, \tag{54.6}$$

where K_s is earth pressure coefficient after pile installation, σ'_v is effective vertical overburden pressure and δ is angle of skin friction of the pile.

δ is generally derived from φ'_{cv}, with the correlation dependent on the roughness of the pile–soil interface, resulting from the combination of pile installation method and soil characteristics, generally ranging from 0.75 to 1.0. For most bored piles the angle of skin friction may be taken as approximately equal to the critical state angle of friction of the soil. φ'_{cv} values are typically between 30° and 33° for uniformly graded sands; 34° and 37° for well-graded sands and gravels; lower values are relevant for coarse-grained soils with rounded particles, and higher values if particles are angular; the above assume clay contents are low, say less than 5–10%. Reference should be made to Fleming *et al.* (2008) for further details. For full displacement driven piles, assuming δ equals $0.75^{-1}\,\varphi'_{cv}$ would usually be appropriate.

For most bored piles, $K_s = 0.7$ is appropriate, but for CFA piles the value of K_s is more sensitive to the soil characteristics and appears to be dependent on technique. The following values are recommended for the design of CFA piles:

Clean medium/coarse sand	$K_s = 0.9$
Fine sand	$K_s = 0.7$–0.8
Silty sand	$K_s = 0.6$–0.7
Interlayered silt and sand	$K_s = 0.5$–0.6

For full displacement driven piles K_s can be estimated as $N_q/50$; this relationship gives a typical value of $K_s = 1.2$ for such piles, and limiting values between 0.7 and 2.0 are suggested. For partial displacement piles K_s values will be lower than for full displacement, and the K_s value is usually reduced by 20%. For driven cast *in situ* piles some reduction in horizontal stress will occur when the casing is extracted, and normally a K_s value of 1.0 is assumed (if wet concrete is placed).

For auger or rotary displacement piles, there are examples of K_s values derived from pile load testing well in excess of 1.2 (Bell, 2010). Such installation methods can produce significant improvements in shaft friction over conventional bored or driven piles but the use of such high values must be used with caution and in conjunction with suitable pile load testing. The shaft friction of such piles is also highly dependent on the shape of the drilling tool, of which there are numerous variants in the marketplace.

The basic formula for calculating q_s can be further simplified to $q_s = \beta\sigma'_v$ and a range of typical β values are included in **Tables 54.5** and **54.6**.

It is important, particularly with long piles in coarse-grained soils, to limit the calculated skin friction to achievable values: a sensible limit to average shaft friction of 110 kN/m^2 should be applied. Values well in excess of this can be achieved for various installation techniques, but should ideally be proven by suitable pile load testing or relevant experience in similar ground conditions.

The ultimate shaft friction of driven piles in coarse-grained soils will approach a limiting value for pile lengths in excess of 20 pile diameters, a similar phenomenon to that for end-bearing. The limiting value is dependent on several factors (including installation methods, due to friction fatigue effects). White and Lehane (2004) provides a useful reference for this in addition to the work carried out by Jardine *et al.* (2005).

It is also important, particularly for bored and CFA piles in sands, especially silty sands, not to place too much reliance on the base capacity of the pile at working loads. It is common practice to design such piles with a factor of safety greater than 1.0 on the shaft capacity alone to limit settlements at working

Material	β value	Reference

loads to acceptable levels as determined through specified serviceability limits. If base resistance needs to be mobilised at working loads (even for driven piles), then a separate serviceability check must be carried out to assess if the working load can be mobilised at tolerable settlements.

54.3.3 Layered soils

From sections 54.3.1 and 54.3.2 above it should be clear that piles in coarse-grained soils may mobilise relatively high end-bearing capacity compared with fine-grained soils. Hence, when designing piles in interbedded sand and clays the location of the pile toe is of fundamental importance. A common practical situation when designing driven piles would be to attempt to take advantage of the potentially high end-bearing resistance of coarse-grained layers. However, if the pile toe is close to the interface with adjacent fine-grained layers then the pile will *not* develop its full end-bearing capacity (i.e. the end-bearing resistance which would be calculated by the methods outlined in 54.3.2 above).

Meyerhof (1976) first considered this important issue, and suggested that end-bearing capacity would be reduced if the pile toe was within 10B (where B is pile diameter) of the adjacent weaker layer (**Figure 54.7**). Subsequent work by Meyerhof and Sastry (1978) and Matsui (1993) indicates that Meyerhof's original guidance is, in general, overconservative; nevertheless it remains a useful guide for preliminary design.

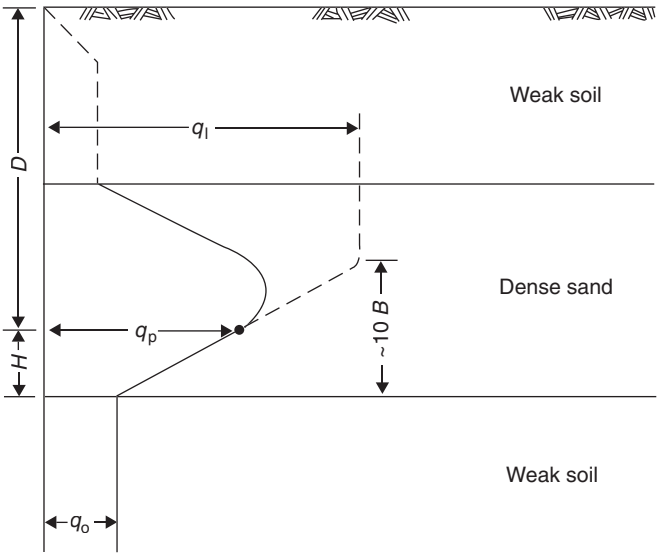

Figure 54.7 Relation between ultimate point resistance of pile and depth in thin sand overlying weak soil
Reproduced from Meyerhof (1976), with kind permission of ASCE

When the pile toe is within the zone of influence of the adjacent weaker layer, the end-bearing capacity can be assessed from **Figure 54.7** by interpolating between the capacity for the coarse-grained founding layer and the adjacent weaker layer.

A key practical issue for pile design in layered deposits is the reliable identification of the level, thickness and continuity of the proposed coarse-grained founding layer. Hence, a large number of boreholes/CPTs may be required to verify that the founding layer does not thin out, and is not in the form of isolated lenses.

If there is significant uncertainty, which can be a particular issue in glacial deposits, then it may be appropriate to base pile design on the worst credible stratification unless proven otherwise by full-scale testing. A common approach is to seek a factor of safety on shaft capacity alone in excess of 1.0, based upon the worst-case stratigraphy in terms of shaft capacity, and to place a limit on end-bearing, e.g. assuming a clay soil is present at the pile toe.

54.3.4 Correlations with SPT/CPT

In general, it is possible to use either 'indirect' or 'direct' correlations. In the 'indirect' approach the SPT or CPT is used to correlate the measured *in situ* test value with laboratory test parameters or other indices of soil behaviour (such as relative density for sands/gravels). The methods outlined in section 54.3.1 or 54.3.2 are then used. In the 'direct' approach, the measured *in situ* test value is directly correlated with shaft friction or end-bearing capacity. Both approaches can be of value, especially when there is a high level of uncertainty associated with predicting the ultimate pile capacity, e.g. driven piles in coarse-grained soils.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Many of the most recently developed driven pile design methods directly use CPT data to derive the pile capacity, and the available evidence indicates that these methods are more reliable than the older empirical methods. When driven piles are proposed it is strongly recommended that CPTs are used to the maximum practical extent.

54.3.5 SPT

54.3.5.1 Fine-grained soils

A number of correlations between SPT results ('N' value) and *in situ* undrained strength, S_u, of silts and clays have been proposed. The most commonly adopted correlation within the UK for heavily overconsolidated clays is that proposed by Stroud and Butler (1975): $S_u = 4$ to $6 \times$ 'N' kN/m².

Other published correlations are available, but these can be unreliable. Some of the differences in correlations may result from variations in the methodology adopted in the field whilst undertaking SPTs, or the types of, or interpretive methods used for, pile tests rather than any significant differences in the soils being tested. It is to be noted that any correlations should be compared to all other available data, e.g. results from triaxial tests, field shear vane test results, etc.

There are direct methods of calculating single pile capacities from the results of SPTs undertaken in fine-grained soils, although there is limited experience with their use for UK conditions, and they should therefore be used cautiously.

Poulos (1989) has proposed the relationship

$$q_s = \alpha + \beta N, \tag{54.7}$$

where q_s is the unit ultimate shaft friction, N is the SPT penetration resistance, and α and β are constants depending upon soil and pile type.

The relationship between SPT N value and unit ultimate end bearing proposed by Poulos is

$$q_b = KN, \tag{54.8}$$

where K is a constant depending upon soil and pile type and N is the SPT penetration resistance.

The values of α, β, and K are highly dependent on the type of pile and method of pile construction. CIRIA Report 143 and Poulos (1989) give suggested values of α, β and K.

54.3.5.2 Coarse-grained soils

Correlations between SPT 'N' and peak friction angle are available, and the correlation by Peck *et al.* (1967) is often used and is usually conservative. This correlation is given in **Table 54.7**, and although fairly crude (it ignores many fundamental factors which govern mobilised friction in coarse-grained soils), it is useful for the preliminary assessment of the end-bearing resistance of small diameter (say less than 0.5 m) driven piles of moderate length (say 10–15 m long). The SPT 'N' values are uncorrected.

It is usually appropriate to also use SPT 'N' values to assess relative density, with:

- overburden correction, $N_1 = C_N N$;
- overburden correction factor, $C_N = 2/[1 + (\sigma'_v/100)]$;
- relative density, $D_r = [(N_1)_{60}/60]^{0.5}$.

Here, N is measured SPT 'N', σ'_v is vertical effective stress, and $(N_1)_{60}$ is the SPT blow count normalised to a vertical effective stress of 100 kN/m² and corrected to 60% of free-fall energy. The above relationships are for uncemented, normally consolidated sands (with a median particle size of less than 0.5 mm). For soils of large particle size (i.e. gravels/cobbles) the above correlations are unconservative. CIRIA report 143 provides further guidance.

Meyerhof (1976) proposed a set of direct correlations between SPT 'N' values and end-bearing resistance/shaft friction as follows:

$$q_b = 0.4\ \text{'N'}\ (\text{MN/m}^2) \text{ for sands, when } P > 6D, \tag{54.9}$$

$$q_b = 0.3\ \text{'N'}\ (\text{MN/m}^2) \text{ for silts, when } P > 6D. \tag{54.10}$$

Note: P is penetration of pile toe beneath surface of coarse grained soil. The 'N' value is averaged over about 3 pile diameters above/below the pile toe. For shaft friction, Meyerhof recommends the following:

$$q_s = 2\ \text{'N'}\ (\text{MN/m}^2) \text{ for driven piles,} \tag{54.11}$$

$$q_s = 1\ \text{'N'}\ (\text{MN/m}^2) \text{ for bored piles.}$$

54.3.6 CPT

54.3.6.1 Indirect methods – fine-grained soils

As with the SPT a number of correlations between *in situ* undrained shear strength, c_u and CPT cone resistance, q_c, have been proposed.

SPT 'N'	φ' (degrees)
< 5	28
5	29
10	30
15	31.5
20	33
25	34.5
30	36
35	37
40	38
> 40	38

N.B. use $\varphi' > 38°$ with caution

Table 54.7 SPT 'N' correlation to φ'

The general relationship is given by

$$c_u = q_c/N_k + p_0, \quad (54.12)$$

where Nk is a cone factor, q_c is the unit cone end resistance (kN/m²) and p_0 is the total overburden pressure (kN/m²).

It is important to note that some correlations include the effect of overburden pressure, p_0, within the cone factor, N_k. Some correlations are specifically for use with the piezone.

The cone factor, N_k, is a variable which is affected by many factors, including the rate of penetration, strength anisotropy, soil fabric (e.g. fissuring, laminations), the degree of overconsolidation of the clay deposit and the reference tests which the CPT is compared against. Overconsolidated clays generally tend to exhibit significantly higher values of N_k (especially if fissured) than normally consolidated clays.

Comprehensive guidance for the selection of appropriate values of N_k can be found in Lunne *et al*. (1997).

54.3.6.2 Direct methods – fine-grained soils

Fully mobilised unit end-bearing, q_{bu}, of a pile can be directly correlated to the unit cone end resistance, q_c, determined by CPT testing. Effects of scale and rate of testing mean that the ratio q_{bu}/q_c is usually less than one (Poulos *et al*., 2000).

The Imperial College Pile (ICP) design method (Jardine *et al*., 2005) provides methods for calculating base capacity for both closed and open-ended driven piles directly from CPT tests. The ICP design method does not, however, provide a direct correlation to pile shaft friction.

Estimates of pile shaft friction for driven piles can be made from CPT sleeve friction, e.g. $q_s = f_c$, but a high degree of caution is required, since there may be large differences in the degree of consolidation of the soil around the pile when compared to the CPT test. Results of pile tests have indicated that long-term shaft friction values can be as much as 500% greater than those measured during driven pile installation (Fleming *et al*., 2008).

Correlations between unit cone end resistance, q_c, and unit shaft friction, q_s, generally yield more reliable results than those derived from CPT sleeve friction. These correlations themselves have a reasonably wide degree of variation, e.g. $q_s = q_c/10$ (Fleming and Thorburn, 1983) and $q_s = q_c/40$ (Thorburn and McVicar, 1971).

A more reliable method for assessing pile shaft friction is usually attained from the methods outlined in section 54.3.1.

54.3.6.3 Coarse-grained soils

As noted in Chapter 22 *Behaviour of single piles under vertical loads*, where a pile toe is located within a granular stratum, the CPT cone tip can be regarded as a model of the pile toe, and so the base capacity, q_b, will correlate with the cone resistance, q_c. Care needs to be taken to suitably derive an appropriate value of q_c given the typical variability of the magnitude of q_c. White and Bolton (2005) have carried out a careful comparison of ultimate base capacities measured in pile tests against measured values of CPT q_c. They found that

$$q_{bu} = 0.9\, q_{cm}, \quad (54.13)$$

where q_{bu} is ultimate, or 'plunging failure', capacity (refer to section 54.8 below) and q_{cm} is the weighted average of q_c values within the zone of influence of the pile toe (up to 8D above and 4D below the toe, where D is pile diameter), based upon the 'Dutch' method.

Lehane *et al.* (2005) carried out further analysis on a relatively large pile test database and found that

$$q_{b0.1} = 0.6\, q_{cm}, \quad (54.14)$$

where $q_{b0.1}$ is bearing capacity mobilised at a pile settlement equal to 10% of the pile diameter and q_{cm} is as given above in equation (54.13).

In both the above studies, the important influence of adjacent weaker layers was emphasised, and this is readily taken into account by the selection of q_{cm} based upon the Dutch method.

Shaft resistance is correlated to q_c in both the ICP design and UWA design methods (Lehane *et al*., 2005).

54.3.7 Rock

The consideration of pile design in weak rocks differs widely for replacement piles (bored and CFA) and displacement piles (driven or bored). This is predominantly because it is possible to install significant rock sockets with replacement techniques, particularly when using modern high-torque piling rigs, whereas displacement systems typically meet refusal at the top of the weak rock strata or at a very short penetration into the rock. Generally strong rocks underlying a development site would not require bearing piles to penetrate them by any significant distance. There are of course occasional exceptions to this general rule, for example where adjacent railway running tunnels are required to be isolated from bearing pile loads with slip liners.

54.3.7.1 Shaft capacity, i.e. rock sockets (generally applicable to replacement piles only)

Transfer of pile loads by shear transfer along the pile-shaft-to-rock interface is relatively complex and depends on a number of factors including:

- rock strength;
- rock socket roughness;
- rock–concrete bond;
- degree of 'contamination' of the rock socket with overlying superficial deposits;
- potential degradation (smearing/polishing) of rock socket through the boring/drilling process.

Comprehensive details of load transfer mechanisms can be found in CIRIA report R181 (Gannon *et al*., 1999).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Driven piles will generally not penetrate significant distances into rock of moderate strength. For driven piles in weak to moderately strong rock, skin friction can be calculated from the equation

$$q_s = 0.5\, K_s\, \sigma'_{vo} \tan \delta, \qquad (54.15)$$

where K_s is an earth pressure coefficient, σ'_{vo} is the effective overburden pressure and δ is the angle of friction between the rock and pile shaft.

In general, pile driving into mudstone will create a 'skin' of remoulded material around the shaft, and mobilised shaft friction will only be a small fraction of that mobilised around bored (replacement) piles.

Skin friction in weathered argillaceous rocks, particularly weathered mudstones/siltstones, can be calculated using methods described in section 54.3.1 – pile capacity in fine-grained deposits – although care is needed to suitably account for remoulding of material at the pile–ground interface.

For bored cast-in-place piles (replacement piles) a number of correlations between the unconfined compressive strength of the rock and rock socket skin friction have been proposed. The most common correlations are those proposed by Horvath (1978), Rosenberg and Journeaux (1976), Williams and Pells (1981) and Rowe and Armitage (1987).

Whitworth and Turner (1989) summarised the various proposed formulae for calculating ultimate unit shaft friction (see **Table 54.8**):

Pile design method	Ultimate unit shaft friction, q_s (kN/m²)
Horvath (1978)	$0.33(q_{uc})^{0.5}$
Horvath and Kenney (1979)	$0.20–0.25(q_{uc})^{0.5}$
Meigh and Wolski (1979)	$0.22(q_{uc})^{0.6}$
Rowe and Armitage (1987)	$0.45(q_{uc})^{0.5}$
Rosenberg and Journeaux (1976)	$0.375(q_{uc})^{0.515}$
Williams and Pells (1981)	$\alpha\beta(q_{uc})$

Table 54.8 Typical correlations between q_{wc} and ultimate shaft friction

here, q_{uc} is unconfined compression strength, α is a reduction (adhesion) factor relating to unconfined compression strength and β is a correction (rock socket side friction) factor related to discontinuity spacing within the rock mass.

Clearly, the above correlations can yield a wide range of values for ultimate shaft friction. Some of these differences may be due to the construction methods adopted for test piles, different back analysis methods to derive the correlations, or difference of the rock materials and/or rock masses in which back analysed test piles were constructed. A common approach is to take an average value from each of the correlations to gain a starting position in terms of design values and use additional information from historical pile testing in a given geographical area or rock formation for similarly constructed piles to those under consideration.

It must be noted that particular care needs to be taken when calculating design values for rock socket friction for mudstones. Experience has shown that the calculated values for unit shaft friction based on mudstone rock strengths are rarely achieved in practice, largely due to softening/polishing effects during rock socket construction.

The most recent published guidance for pile shaft friction in chalk is based on an effective stress approach. Reference should be made to CIRIA report PR86 (Lord *et al.*, 2003) for specific guidance.

54.3.7.2 Base capacity (applicable to both displacement and replacement piling techniques)

Where piles are driven to practical refusal on strong rock the limiting factor on pile capacity is usually the maximum allowable direct stress on the pile cross-section. In the UK this is typically taken as $0.25 \times f_{cu}$. Care should be taken when driving pre-cast concrete piles to ensure that the piles are not overdriven, as this could result in damage to the pile section. When driving steel piles, care should be taken not to overdrive the pile, as this could cause shattering of the bearing stratum, resulting in a reduced pile capacity. Care should also be taken to ensure that the design assumptions relating to rock material (e.g. strength) are compatible with the rock mass (e.g. joint infilling, joint orientation, joint aperture, solution features, weaker underlying strata).

Bored piles can also be constructed to practical refusal on strong rock. The definition of practical refusal should be agreed in advance with the engineer where it is anticipated this will occur. In certain circumstances the definition of practical refusal may be qualified subject to undertaking satisfactory maintained load tests.

For both driven and bored piles constructed within rock, the ultimate unit end-bearing capacity is often taken as the design UCS value for the rock stratum, i.e. allowable unit end-bearing $q_{b\,all}$ = UCS/FoS. The factor of safety is usually a reasonably high value, typically 2.0–2.5, which will ensure that the rock present at the toe of the pile will not become overstressed, even for predominantly end-bearing piles, again subject to maintaining compatibility between rock material and rock mass.

Where piles derive a significant proportion of their capacity from shaft friction, there may be less concern over consideration of the end-bearing component of capacity in terms of the pile load–settlement behaviour, particularly if the pile has a factor of safety on shaft capacity alone of 1.5 or greater.

Where a significant proportion of the pile capacity is being derived from the end-bearing component, care must be taken to ensure that the pile toe remains in intimate contact with the rock. Factors such as soil heave (from overburden removal or driving further displacement piles) and disturbance due to breaking down the piles can lead to lifting of the pile toe,

which will result in greater settlements upon loading than would otherwise have been experienced. For driven piles it is often considered to be good practice to re-drive piles (subject to programme and access constraints) to ensure the toe of the pile is in good contact with the bearing stratum.

Sloping bedrock can pose particular risks to pile construction. Driven and bored piles may be deflected by steeply bedded rock surfaces. Driven piles may be installed to a refusal criterion yet upon loading cause instability of the inclined rock mass due to downward sliding of blocks of rock. Infilled quarries can pose a particular risk to piling: the position of the highwall is critical in assessing the required pile lengths and suitability of particular construction techniques. It may not be possible or practicable to construct piles in the zone where highwalls are located.

When constructing bored piles within rock, care should be taken to ensure that the base of the pile bore is thoroughly cleaned, so that the design end-bearing capacity can be achieved without adversely affecting the piles' load–settlement behaviour. This can only be realistically achieved when large diameter bored piling techniques are adopted, facilitating the use of cleaning buckets. Typically, large diameter bored piling ranges from 600 mm to 3 m diameter.

Reference should be made to CIRIA report PR86 (Lord *et al.*, 2003) for specific guidance on constructing piles within chalk.

54.4 Factors of safety

54.4.1 Global safety factors

Historically, the design of piles in the UK has adopted global factors of safety where the safe working load, SWL, is given as

$$\mathrm{SWL} = Q_b/F_b + Q_s/F_s. \tag{54.16}$$

Although overall factors of safety are not necessarily the best way to govern pile performance, the numbers traditionally adopted are:

- 2.0 overall minimum – usually with load test verification on expendable piles;
- 2.5 overall or 1.5 (on shaft) with 3.0 (on base) – usually with working pile load tests;
- 3.0 overall – may not require any load testing.

According to BS8004, for spread foundations a factor of safety of 3 is usually adopted, and for piles a value of between 2 and 3 is normally used, the lower value representing conditions where there is reliable information on the ground and pile behaviour. The above factors of safety should only be used as a guide and different values and combinations can be used in conjunction with suitable experience.

There are a number of ground conditions where different factors are used, placing more reliance on either end-bearing or shaft friction. Examples include piles in chalk, where large factors on end-bearing are adopted, as high as 10, to allow for the potential for soft spots and dissolution features beyond the pile toe. Similarly the design of bored or CFA piles in weak rocks may often be dictated by ensuring a factor of safety as high as 1.5 on the shaft capacity alone to allow for the potential for machining/polishing or softening/remoulding of the pile shaft, or disturbance of the pile base, and to limit settlements at working load.

If a pile relies predominantly on end-bearing, then great care will be required both for design and construction, and more specialist techniques and expertise will normally be required. Site-specific preliminary pile tests may be needed unless there is significant previous experience in similar ground conditions and using similar piling techniques.

54.4.2 Partial safety factors

Partial factors are commonly used in structural design and these are applied to the particular parameters and loading conditions to reflect more accurately where the uncertainties lie. Most modern design codes, in particular the Eurocodes such as EC7 (BS EN1997 Part 7), recommend pile design based on the use of partial safety factors. This code does allow reduced factors of safety where there are several pile tests on a site. Such an approach encourages the use of preliminary pile testing.

The factor of safety, whether partial or a lump factor, is a factor on strength. However, as reported by Atkinson (2000), the key parameter that governs pile behaviour is stiffness of both the ground and the pile. The factor of safety is only of relevance in determining the likelihood of satisfactory performance beyond working load. For example, an end-bearing pile can fail to meet the required performance at working load because of low stiffness and still have the prescribed factor of safety. Conversely it can perform at working load and still not meet the required factor of safety. In either case it is necessary to determine whether the behaviour is of sufficient concern to be detrimental to the structure.

The main difficulty is in selecting criteria for settlement and factors of safety that are compatible and allow for the likely variability of the ground. This can only be done by making a prediction of pile behaviour based on the best estimate of the soil parameters and allowing a reasonable margin in the permitted test criteria to allow for natural variability in the ground.

54.5 Pile settlement

Structures do not generally suffer due to total settlement *per se*. It is differential settlement of, and the vulnerability of services connected to, structures that give rise to most concern. Refer to Chapter 52 *Foundation types and conceptual design principles*.

One of the reasons for introducing a lumped factor of safety when considering allowable pile capacity (such lumped safety factors applied to calculated ultimate pile capacities are most often in the range 2.0–3.0) is to ensure that settlement of single piles under working load (i.e. at serviceability limit state) is within tolerable limits for most structures.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

A specified factor of safety does not guarantee a specific settlement and it is important to review the risk of excessive settlement as part of the pile design process. For most piling techniques in a range of ground conditions, except those that rely predominantly on end-bearing, it is good practice to ensure a suitable factor on the shaft capacity alone to limit settlements under working loads, i.e. to ensure suitable serviceability performance. It is recommended that the settlement of end-bearing piles is always assessed. Group settlements will need to be subject to separate consideration to ensure that pile group settlement is tolerable for the structure (refer to Chapter 55 *Pile-group design*).

It is widely acknowledged that more settlement is required to mobilise end-bearing than shaft friction. It is also generally to be expected that piles which rely significantly on end-bearing (carrying a low proportion of the total applied load in shaft friction), will settle more under load than piles which are predominantly frictional piles (i.e. piles which carry the majority of applied load by shaft friction). Patel (1992) has summarised pile test data for friction piles in London Clay (**Figure 54.8**), which indicates that at typical working loads (factor of safety of 2 or more) the single pile settlement would be expected to be less than about 1.0% of the pile diameter. Similar behaviour would be expected for comparable stiff overconsolidated fissured clays (Gault Clay, Weald Clay, etc.).

An additional factor which must be considered in any assessment of pile settlement is the magnitude of pile head displacement caused by elastic shortening of the pile under load. This can be a significant proportion of the total pile head settlement under load, but becomes increasingly significant when considering long slender piles constructed through deep weak deposits (i.e. transmitting a significant proportion of applied load to competent strata).

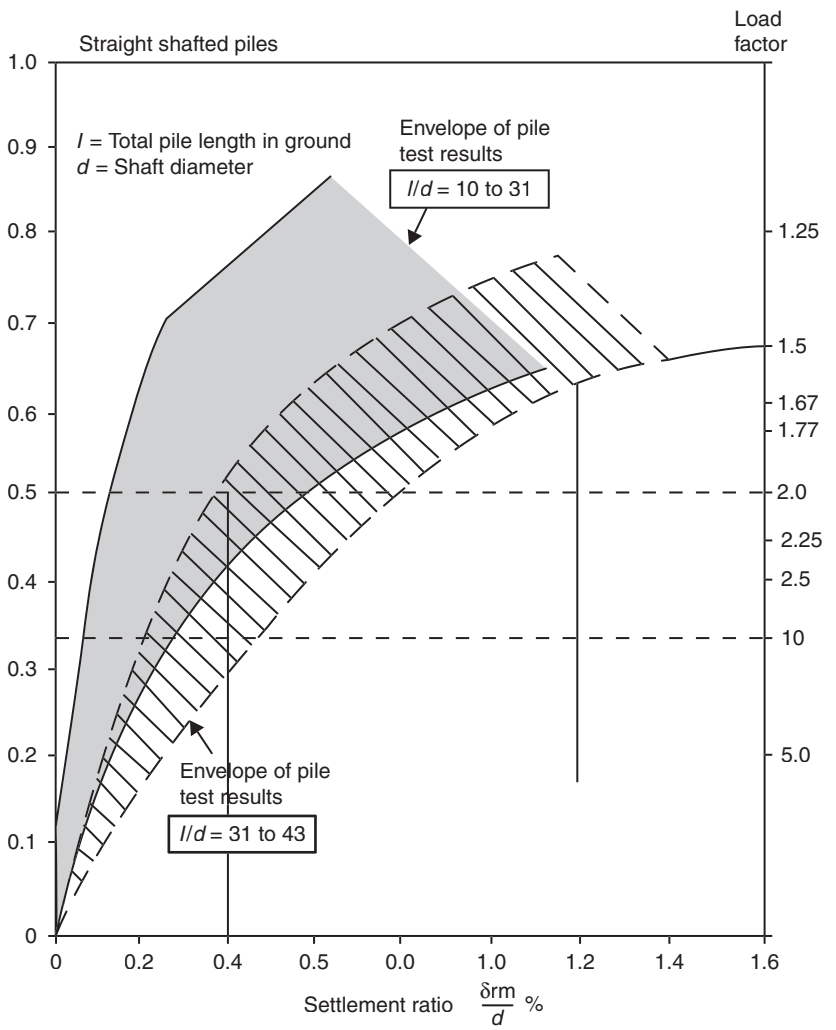

Figure 54.8 Results of loading tests on straight shafted bored piles in London Clay – normalised load settlement chart
Reproduced from Patel (1992)

A number of different methods have been proposed over recent years: elastic approaches (e.g. Poulos and Davis, 1968; Tomlinson, 2004), simplified empirical methods (e.g. Burland *et al*., 1966), finite element/boundary element analyses, and hyperbolic analytic methods (e.g. Fleming, 1992).

Burland's proposed simplified empirical approach is specifically for the assessment of settlement of end-bearing under-reamed piles in London Clay (Burland *et al*., 1966). Burland showed that where plate load tests are taken to failure, the normalised load settlement curve can be plotted, and provided the base factor of safety exceeds 3, the settlement of the pile base can be obtained for any diameter of pile base. Full details of this empirical method are provided in Burland *et al*.'s paper. Alternatively reference may be made to Tomlinson (2004).

In his paper, Fleming (1992) noted that sophisticated analytical techniques require sophisticated input data (e.g. certain geotechnical parameters) which are not usually available from routine site investigations. The method described by Fleming combines hyperbolic functions describing both the shaft and base components of pile capacity, together with the component of pile settlement derived from elastic shortening of the pile. The method takes advantage of the fact that the hyperbolic function adopted requires definition only of its origin and either its initial slope or a single point. The shaft flexibility parameter, M_s, does not vary significantly, with M_s values typically between 0.0010 and 0.0025 for many pile types and ground conditions. However, as expected the base stiffness parameter, E_b, varies across a wide range for different pile and soil/rock types, and is particularly sensitive to pile construction methods and workmanship. E_b, should not be confused with other 'elastic' soil parameters which are quoted in the literature: it is essentially an empirical parameter derived from back analysis of pile tests and is as sensitive to pile construction method as to the fundamental soil properties. Guidance on appropriate parameters is given in Fleming (1992). The definition of axial capacity adopted within Fleming's method is the plunging-failure (or asymptotic) definition, i.e. that load at which the soil resistance is fully mobilised and where settlement continues indefinitely for the load magnitude reached. Corke *et al*. (2001) provide interesting practical examples of Fleming's method, in the context of developing pile testing performance criteria.

Fleming's method is a powerful and simple method for single pile settlement analysis; it is especially useful for large diameter piles (say in excess of 1.0 m diameter) and for end-bearing piles.

Fleming's method has a significant additional benefit, in that it can be used in reverse to back analyse the results of maintained load tests to determine shaft friction, end-bearing and elastic shortening of the pile, subject to the pile test having moved the pile sufficiently to mobilise end-bearing sufficiently, typically more than about 5% of the pile diameter.

54.6 Pile behaviour under lateral load

54.6.1 Introduction

Piles can be subjected to lateral loads arising from different sources. These sources typically fall into two main categories: *active* loading (where external forces are applied to the pile) and *passive* loading (where movement of the soil immediately adjacent to the pile imposes bending stresses on to the pile). A more refined classification of the sources of lateral load may involve the following (after Elson, 1984):

- Static: e.g. structural reactions, lateral earth pressure.
- Dynamic – cyclic: e.g. from operating reciprocating equipment, earthquake, cyclic wind loading (wind turbines), wave action.
- Dynamic – transient: e.g. general wind loading, berthing, vehicular braking (impact) loads.
- Other: e.g. undrained soil movements, soil consolidation adjacent to piles, thermal movements, soil creep, soil shrinkage/expansion (soil moisture changes).

Geotechnical capacity is rarely an issue even in weak/soft soils. The issues are usually either ones of serviceability (i.e. pile deflection/deformation) or structural capacity of the pile. Passive loading is a particularly high risk in soft soils, where large global ground movements may readily develop (refer to Chapter 57 *Global ground movements and effects on piles*).

Piles subjected to cyclic loading require particularly close attention since cyclic loading will tend to modify soil behaviour and can lead to progressive failure. Consideration of dynamic cyclic and dynamic transient loads falls outside the scope of this chapter of the manual (refer to Chapter 60 *Foundations subject to cyclic and dynamic loads*).

54.6.2 Deformation/failure modes due to 'active' loading

Piles subjected to lateral loads will experience an increase in normal stress in front of the pile (in the direction of the lateral load), and a decrease behind the pile. Pile deformation is usually limited to approximately 10 pile diameters below ground level; the concept of a critical pile length (which is dependent upon the ratio of soil/pile stiffness) is particularly useful in this context (reference should be made to Fleming *et al*., 2008).

There are two principal failure modes for unrestrained (or free headed) single piles subjected to 'active' lateral loading (**Figure 54.9**). Unrestrained short rigid piles will fail by rotation when the passive resistance of the soil (in front of the pile above the point of rotation, and behind the pile below the point of rotation) are exceeded. Long piles will tend to fracture at some depth down the pile shaft. For the purposes of analysis a plastic hinge is assumed to develop which is capable of transmitting shear. The upper portion of the pile shaft above the plastic hinge will deform whilst the lower pile shaft, below the hinge, will not move significantly.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

For restrained (or fixed headed) piles (**Figure 54.10**) there are three possible failure modes:

(a) translation;

(b) 1-hinge failure (at underside of pile cap/restraint);

(c) 2-hinge failure (at underside of pile cap/restraint and at some depth).

54.6.3 Fixed and free headed piles

Fixed headed piles are restrained at head level, typically by a pile cap (pile groups of three or more) or ground beams (pairs of piles or single piles) or potentially by a structural slab (if so designed). Piles need to be restrained in two orthogonal directions to be considered truly fixed headed.

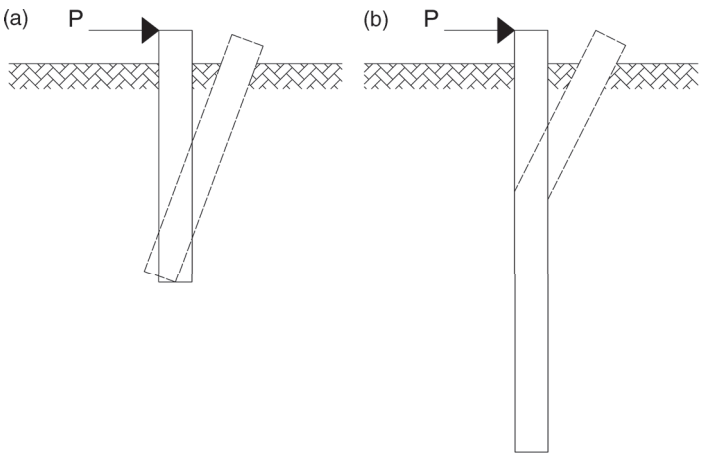

Figure 54.9 Possible failure modes for free headed piles: (a) rotation; (b) hinge failure (Broms, 1964a,b)
Courtesy of Cementation Skanska

Free headed piles are free to rotate and are not subject to orthogonal restraint.

In free headed piles the bending moment in the pile at ground level is positive and acts in the same direction as the applied lateral load.

In fixed headed piles the bending moment in the pile at ground surface is negative and acts in the opposite direction to the applied lateral load.

54.6.4 Lateral resistance of single piles

The ultimate lateral resistance of single piles can readily be estimated from the solution proposed by Broms (1964a, 1964b). Whilst Broms's solution may be considered to be on the conservative side, it is often recommended for routine design given the relative simplicity of the solution and the fact that the governing criterion is rarely the ultimate lateral soil resistance.

Other authors have provided more detailed/refined solutions. Full details of these solutions can be found in CIRIA Report 103 (Elson, 1984), Appendix A.

Once the bending moment and shear force envelopes have been derived adopting appropriate analysis methods, the pile can be designed in accordance with relevant structural design codes of practice (e.g. BS EN1997 Part 2).

54.6.5 Lateral deformation

When considering the lateral deflection of laterally loaded piles, the near-surface soil parameters merit particular attention. This can often cause some problems since the very near surface deposits (generally the upper 2–3 m) are often those about which very limited information is obtained during the ground investigation.

Lateral pile loading tests are occasionally specified to be undertaken on piles. It is the authors' experience that these are often specified without full cognizance being taken of the head

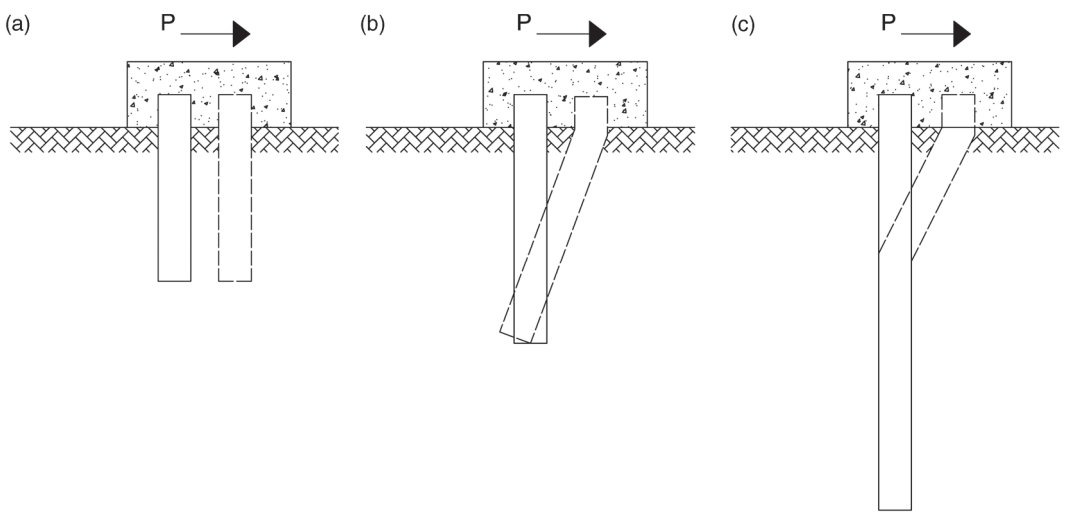

Figure 54.10 Possible failure modes for fixed headed piles: (a) translation; (b) 1-hinge failure; (c) 2-hinge failure (Broms, 1964a,b)
Courtesy of Cementation Skanska

fixity of the piles in the final construction. The lateral load–deformation behaviour of a fixed head pile is very different from that of a free headed pile, and this must be taken into account when considering how the results of a lateral pile test (usually free headed) will be analysed and used for the design of permanent piles (usually fixed headed). The analysis method used for lateral pile test interpretation and permanent works design must be sophisticated enough to allow for:

(i) potential changes in pile head fixity;

(ii) potential differences in load eccentricity between pile test and permanent works;

(iii) potential changes in near-surface ground conditions between pile test and permanent works.

If there is a coherent testing and analysis strategy then lateral load testing of piles, particularly those whose load deflection behaviour is deemed to be of significant importance, or where particularly high lateral loads will be applied to the pile (relative to the ground conditions and the pile geometry), can provide a very useful check on performance of piles and the analysis techniques adopted for pile design.

The two analysis approaches commonly adopted for calculating the lateral displacement of single piles subjected to lateral loads are the sub-grade reaction approach and the elastic continuum approach. Lateral load–deformation behaviour is strongly nonlinear even under moderate lateral loads, and linear elastic methods are usually inappropriate for piles subject to significant lateral loads. Ignoring nonlinear behaviour can lead to grossly inaccurate and unconservative predictions of lateral deformation.

The sub-grade reaction approach models the ground as a series of discrete springs along the length of the pile shaft, i.e. as a Winkler idealisation of the soil mass. A refinement of the early models allows the spring stiffness to vary along the length of the pile (Reese and Matlock, 1956) and a further refinement is the p–y form of the Winkler soil model (Matlock, 1970; Reese *et al*., 1974, 1975). The disadvantage of the p–y form of the model is that selection of reliable p–y curves requires careful judgement, although typical forms of the curves have been presented by Reese *et al*. (1974) in sand and by Matlock (1970) in clays, and are summarised in the API code (American Petroleum Institute, 2000).

Both Poulos (1971) and Randolph (1981) have published solutions relating to the behaviour of piles under lateral loads based on elastic continuum models. One principal advantage of the elastic continuum models over sub-grade reaction models is that the method can be extended to pile groups, since interaction between adjacent piles can be modelled. Where large lateral loads are required to be resisted by piled foundations, for example marine/offshore structures or complex/unusual superstructures, it will be more appropriate to assess lateral displacements by adopting nonlinear elastic plastic methods. A useful practical procedure for estimating lateral load–deformation behaviour, proposed by Brettmann and Duncan (1996), is the 'characteristic load' method. Parameters are provided for sands and clays, and for free and fixed headed piles.

54.7 Pile load testing strategy

Strategies for pile load testing often lack clear objectives. The requirements for testing are frequently driven by a desire to comply with regulations and to follow common practice. Testing is rarely seen as a part of a value engineering process, and therefore opportunities to optimise the foundation solution are often missed.

It is important that load testing of piles is considered as early as possible and included in the initial cost plan and programme stage. The programme must allow sufficient time for suitable tests to be carried out and for an objective appraisal of the test results and subsequent design revisions or value engineering to be carried out.

Without such an early review to set clear load testing objectives, combined with poorly specified requirements, avoidable problems will arise. Common problems include:

- inappropriate test method specified and lack of flexibility in the testing regime;
- final working conditions not modelled by the load tests;
- piles not tested to failure or sufficient load to allow suitable evaluation;
- insufficient time to carry out tests and to evaluate the results;
- unrealistic/unachievable performance criteria specified;
- no provision for value engineering;
- unrealistic expectations of the possible benefits of load testing.

54.7.1 Objectives

The strategy for pile testing needs to be established at the time the piles are designed. For most projects the main purpose of pile testing is to validate the design before construction and to check compliance with the specification during construction. However, in many cases there are considerable benefits in using testing for design development in order to identify the optimum solution. Testing strategies can therefore be divided into four main categories:

- design development;
- design validation;
- quality control;
- research.

The scope of testing will depend on the complexity of the foundation solution, the nature of the site and the risk of piles not meeting the specified requirements. The designer therefore needs to assess the risks and develop the testing regime accordingly. So what are the main considerations when assessing the risks?

- Site investigation data – are they sufficient?

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

- Previous knowledge – are there similar piles that have been tested on adjacent sites?
- Time – is there enough time to verify the design? If not, a conservative approach is needed.
- Cost – can the testing provide cost savings? What are the cost and/or construction programme implications of tests failing?

For simple structures on a site where the ground conditions are well understood and there are test data from adjacent sites which have used similar piling solutions then the risks are low and the testing can usually be restricted to routine checks for compliance with the specification. For situations where the ground conditions or structural requirements are complex and there is little experience of similar piling work, then careful evaluation of the piling proposals is essential prior to embarking on the main piling works. The testing regime therefore needs to be considered in two phases, comprising preliminary pile testing before the main piling works, and testing of working piles.

54.7.2 Preliminary pile tests

Preliminary testing is carried out in advance of the main piling works to verify that the design assumptions and construction method will achieve the required performance. The testing strategy for preliminary pile testing should address a specific set of stated objectives, which should include the following:

- minimise risk – uncertainties about ground conditions, contractor's experience, novel techniques;
- optimise the design – pile diameters, lengths and factors of safety;
- confirm pile installation criteria – founding strata identification, pile set, refusal criteria;
- assess buildability – site variability, pile integrity, pile uplift and displacement, soil remoulding;
- check the pile performance meets the structural requirements – load/settlement behaviour, compression, tension and lateral loading;
- confirm safety procedures – piling platform, working method, inspection, testing methods;
- assess environmental impact – noise, vibration, pollution.

Where piles are required to carry very heavy loads, it may be impractical to carry out full-scale load tests. In such circumstances, consideration should be given to carrying out tests on smaller diameter piles using the same method of construction, provided the results of the tests can be extrapolated with some degree of confidence to predict the load settlement characteristics of the larger piles. The test piles should be founded at the same level and in the same soil as the works piles.

For preliminary pile tests it is essential to have a borehole and/or CPT close to the test pile so that the test results can be reliably evaluated.

54.7.3 Working pile tests

Working pile tests are carried out during the main piling works to verify that the workmanship and materials meet the specified requirements. Testing on the working piles comprises a range of quality control checks. These checks will normally include load tests, integrity tests and materials testing.

The strategy for testing working piles should address the following issues:

- load/settlement behaviour – if settlement criteria are specified then load tests should be carried out;
- risk of integrity problems – the number of tests should reflect that certain ground conditions and pile systems may have increased risk;
- installation criteria – use pile records, sets and dynamic testing where appropriate to confirm the installation criteria are being met.

The testing strategy for working piles should relate to the level of risk and the characteristics of the piling project. Test results and pile records should be continually reviewed during the works to reassess the risk level.

54.7.4 Number of tests

The need for preliminary testing in advance of the working piles, or in advance of new areas of piling on large projects, should be weighed against their cost and the time taken for installation, testing and analysis of results. It may be more economical and more logical to adopt a more conservative approach to design, for example by using larger or longer piles or reduced pile loads. Also, it may be more beneficial to undertake further site investigation to obtain information which is key to the success of the installation and hence achieve the necessary confidence in the piling. The value of preliminary testing undertaken to prove the design approach or pile performance is wasted unless the ground conditions are sufficiently well defined to allow the design to be applied to piles elsewhere on site.

The level of testing of working piles should consider the variability of the ground conditions from the point of view of the demands these place on the control of pile construction, area by area. Ensuring experienced supervision and monitoring, plus good pile records, can be preferable to increasing the level of control testing above the typical 1% of all piles installed.

54.7.5 Methods of load tests

The various available methods of testing piles are best characterised by the duration that the force is applied to the pile and the strain induced in the pile. Tests involving large forces applied for several minutes or hours, such as static load tests (also known as maintained load tests), are used to assess pile load capacity, and small-energy low-strain tests are used to assess pile integrity. In dynamic and kinetic tests, although the force is comparable in magnitude to a static test, it is applied over a much shorter period than in a static load test. Careful consideration is therefore needed in the interpretation of the dynamic

effects in order to derive static load capacities. The various test methods and their applications are detailed in Chapter 98 *Pile capacity testing* of this manual. There are a number of published documents dedicated solely to the subject of pile testing, such as Weltman (1980) and Handley *et al.* (2006), and these should be referred to for more detailed information on the subject of pile load testing. Chapter 98 *Pile capacity testing* of this manual focuses specifically on pile load testing.

54.8 Definition of pile failure

The definition of axial load capacity (or pile 'failure') needs to be clearly understood, since this can be the cause of confusion. Unambiguous definition becomes very important for piles which rely mainly on end-bearing resistance. Two definitions are commonly used:

(i) Ultimate capacity, 'plunging failure' – failure is defined as the load at which settlement continues indefinitely, shown as P_u in **Figure 54.11**. This is often a theoretical concept rather than a practical reality as most pile tests are not taken to sufficient load to reach this value. Calculation methods based on bearing capacity theory will usually derive a 'plunging failure' load.

(ii) Deformation controlled capacity, '10% failure load' – because the 'plunging failure' load cannot often be practically reached and measured during a pile test. Most codes/standards define failure as the load which is measured at a settlement equal to 10% of the pile base diameter, shown as $P_{F0.1}$ in **Figure 54.11**.

For friction piles, there may be little practical difference between the above definitions. However, for end-bearing piles there can be a considerable difference between the capacities derived by (i) and (ii) above. Referring to **Figure 54.11** Pile A and B both have the same 'ultimate' capacity, but in terms of a deformation controlled capacity (consistent with most code definitions of failure) Pile A has a higher capacity than Pile B. For end-bearing piles, the deformation controlled capacity will be a function of the mobilised deformation modulus of the ground immediately beneath the pile toe.

- Chapter 82 *Piling problems*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 55
Pile-group design

Anthony S. O'Brien Mott MacDonald, Croydon, UK

doi: 10.1680/moge.57098.0823

Pile design often focuses on ultimate geotechnical capacity. When piles are located within a pile group a wide range of additional factors need to be considered, including the deformation of the pile group and the structural forces induced in the piles and pile cap. Interaction between adjacent piles depends on several factors, including the direction of applied loads. When large horizontal loads are applied, a complex range of interaction effects may need to be considered. Computer-based analytical methods are commonly used; nevertheless, it is important to use simplified methods of analysis both for preliminary design and to judge the reliability of output from computer-based methods. Pile-group deformation is usually more critical than group capacity, and, hence, the selection of appropriate deformation moduli is particularly important. Case history data and predictions from nonlinear modelling are compared with linear elastic methods. The delegation of design responsibility for pile-group design requires careful judgement and is also discussed.

55.1 Introduction

The design of single piles is discussed in Chapter 54 *Single piles*, where the main focus is the assessment and verification of the ultimate geotechnical capacity of the pile. For pile groups a wider range of factors will need to be considered. The design must consider the overall performance of the whole foundation system (**Figure 55.1**). It is often the case, especially for larger pile groups, that pile-group deformation and the structural forces (bending moments and shear forces) induced in the piles are the main design issues, rather than ultimate geotechnical capacity. A pile group will stress a much larger zone of soil than a single pile (**Figure 55.2**) and this will be extremely important when considering how to develop an appropriate analytical model and input parameters, and assessing potential failure and deformation mechanisms. For example, if there is a soft compressible layer at depth below the pile toe, it may have little effect on single-pile behaviour, but could cause excessive pile-group deformation or even collapse. The overall behaviour of pile groups is affected by their geometry. An important parameter is the pile-group aspect ratio R (Randolph and Clancy, 1993) defined as $R = (ns/L)^{0.5}$, were n is the number of piles in the group and s and L are the pile spacing and length, respectively (both in metres). When the pile-group aspect ratio is large (**Figure 55.3(a)**), then most of the applied load is likely to be shed into the ground via compression of the deposits below the pile-toe level. In contrast, if R is small, **Figure 55.3(b)**, then most of the applied load is likely to be shed into the ground via shear around the pile-group perimeter.

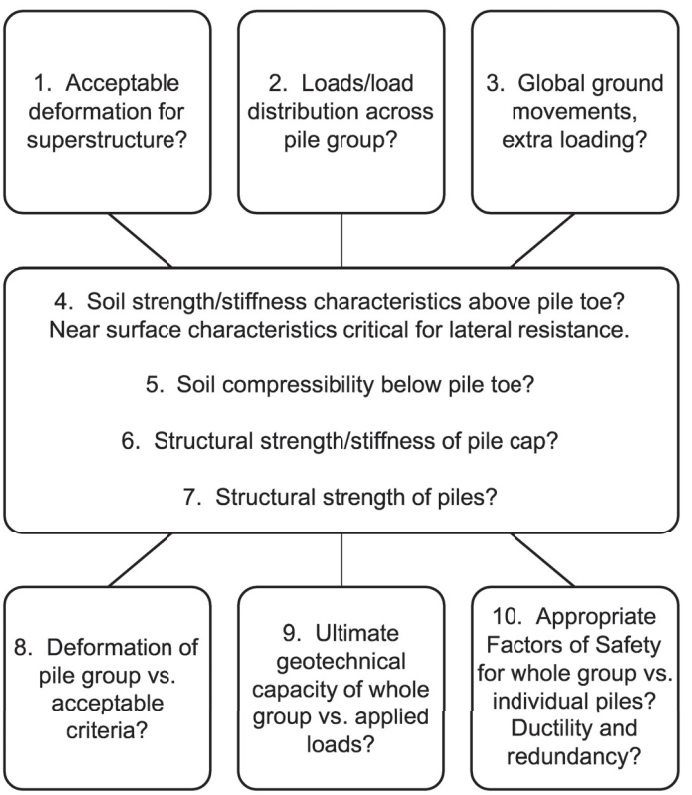

Figure 55.1 Design considerations for pile groups
Modified from O'Brien and Bown (2010)

In modern engineering practice, the analysis of pile-group behaviour is usually based on commercially available computer software. However, most software has a number of limitations, namely:

(i) soil behaviour is assumed to be linear elastic;

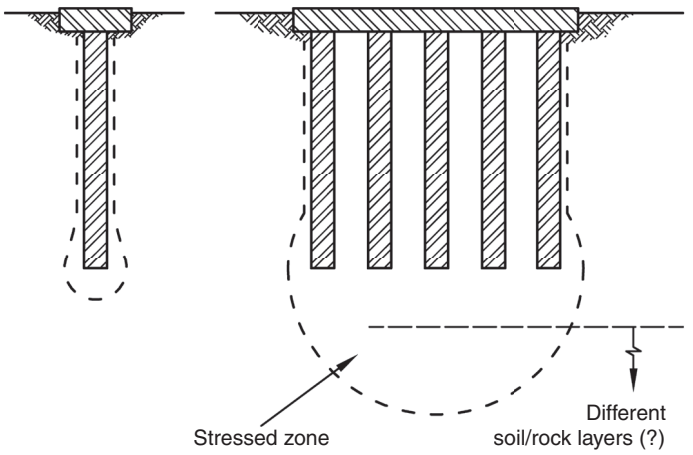

Figure 55.2 Comparison of influence zones beneath single piles and pile group

(ii) the influence of soil layering below the pile-toe level may be poorly simulated.

Analytical methods for pile-group analysis are often complex, therefore, the main intent of this chapter is to highlight:

(i) the key factors that will affect pile-group behaviour;

(ii) several simplified analytical methods, which can be useful either for preliminary design or to check computer output;

(iii) when linear elastic methods can give output that is appropriate for practical design, and when more complex methods are necessary;

(iv) how selected output, in particular axial load distributions, can be interpreted to facilitate more economic design.

55.2 Pile-group capacity

Independent calculations should be made of ultimate capacity based upon:

(i) the sum of the individual pile capacities (based on capacity of isolated piles, see Chapter 54 *Single piles*), **Figure 55.4(a)**;

(ii) failure of the 'block' that encloses the perimeter of the pile group, **Figure 55.4(b)**;

(iii) failure of rows of piles, **Figure 55.4(c)**.

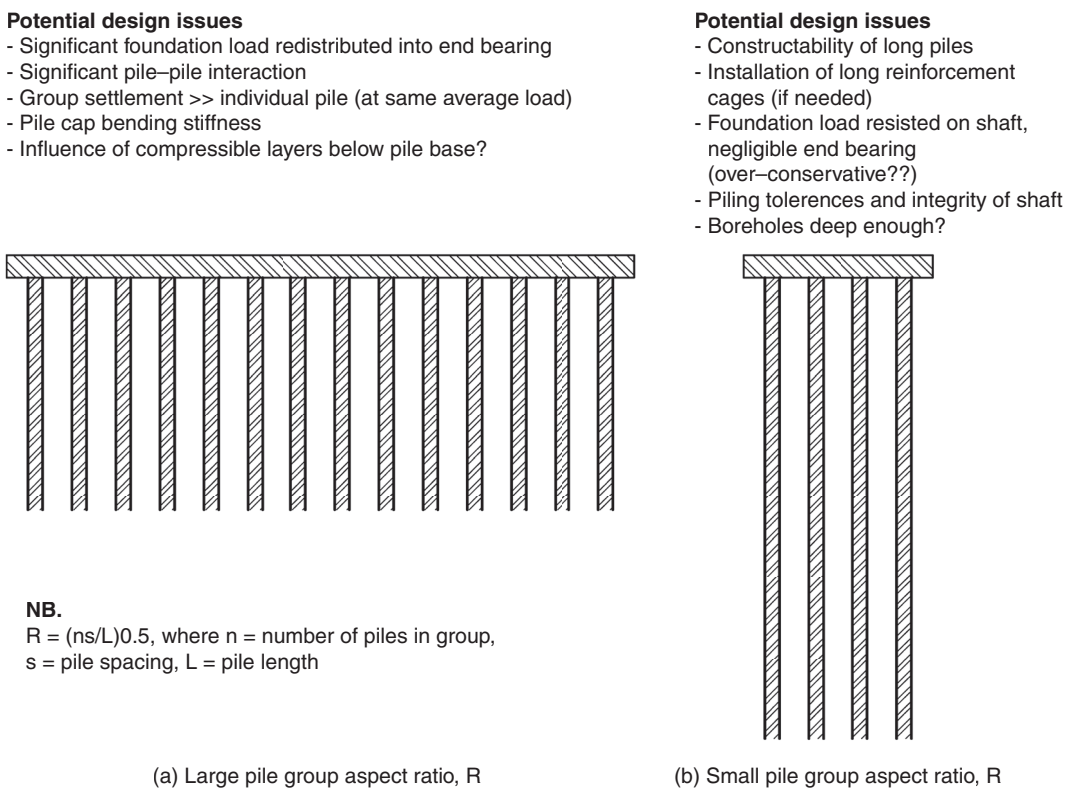

Figure 55.3 Pile-group aspect ratio, *R*, and potential design issues

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

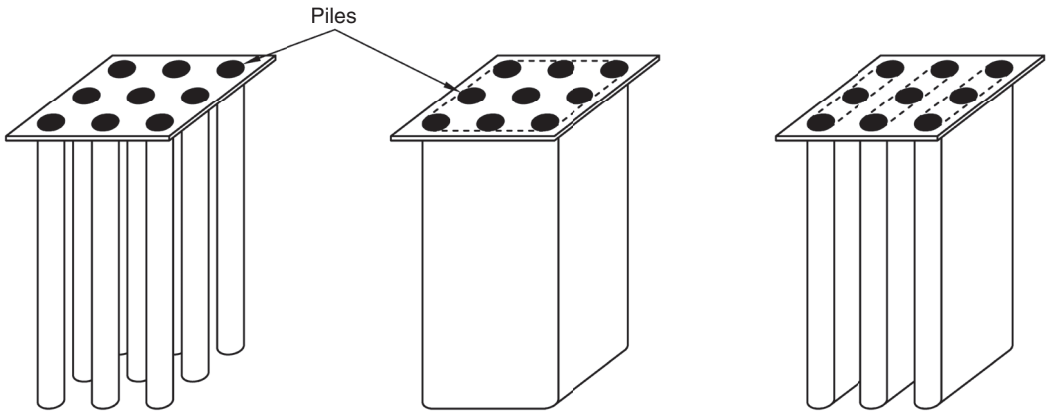

Figure 55.4 Failure modes for pile groups
Reproduced from Fleming *et al.* (2009)

For vertically loaded pile groups, usually only (i) and (ii) will need to be checked; failure mode (iii) becomes more important if the spacing between pile rows is variable or if the horizontal or moment loading is relatively large.

The failure of pile groups is rare; however, the following situations require particular care:

(i) When large global horizontal ground deformations develop around the pile group, usually due to out-of-balance loading on a soft clay or peat layer (**Figure 55.5(a)**), either due to placing fill or excavating adjacent to the pile group.

(ii) When a layer of soft clay underlies a thin competent layer, and end-bearing piles are toed into the competent layer (**Figure 55.5(b)**).

(iii) When end-bearing piles are toed in rock, which contains either dipping clay-filled discontinuities or voids (**Figure 55.5(c)**). Voids may arise in a rock mass either due to natural solution features, or due to historic mining activity.

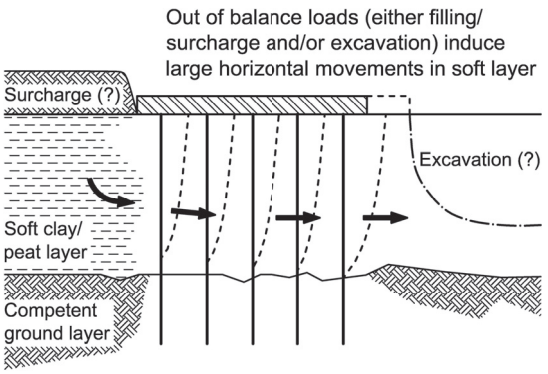
In the author's experience, (i) above is the most common cause of pile-group failure (usually due to inadequate structural pile strength). This has occurred when the pile designers or constructors did not appreciate the potential impact of global ground movements and this failure mode was completely overlooked. Chapter 57 *Global ground movements and their effects on piles*, discusses the influence of global ground movements (both vertical and horizontal) on pile-group behaviour. This failure mode can often be avoided either by appropriate ground improvement (Chapter 59 *Design principles for ground improvement*) or by appropriate construction planning and sequencing. For example, installing the piles *after* the fill or excavation, adjacent to the pile group, has been completed.

The analytical methods used to assess ultimate pile-group capacity are based on conventional bearing-capacity theory (refer to Chapter 21 *Bearing capacity theory* and Chapter 53 *Shallow foundations*). Hence, for *vertical loading of a pile group in clay* the ultimate capacity of the block of soil encompassed by the group is:

$$Q = 2D\,(B + L)\,S_{\text{uave}} + S_{\text{ub}} f_s\, N_c\, BL \qquad (55.1)$$

where D is the pile length or embedded depth, B is the pile-group width, L is the pile-group length (i.e. the plan dimension), S_{uave} is the average undrained shear strength around the group perimeter, S_{ub} is the undrained shear strength beneath the group (the average between the pile-toe level and 0.5 B below the toe level for homogeneous conditions), f_s is the shape factor for the pile-group plan dimensions, B and L (**Figure 55.6(b)**), and N_c is the bearing-capacity factor allowing for appropriate depth and width (**Figure 55.6(a)**). **Figure 55.6** summarises the appropriate bearing-capacity and shape factors. Total stress methods are commonly used for clays. However, effective stress methods can be utilised (refer to Chapter 54 *Single piles*) and are recommended if deep excavations (say in excess of 4 m) are constructed above or adjacent to the pile group (since the excavation would lead to a reduction in the clay's mobilised strength in the long term).

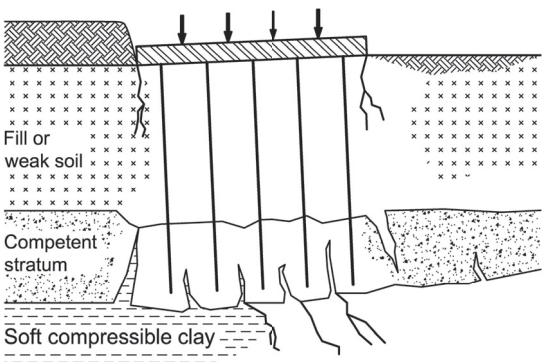
The influence of an underlying compressible layer on the ultimate capacity of the group (acting as a block or equivalent pier, refer to section 55.5.4) can be assessed (based on studies by Matsui, 1993) as follows:



$$Q_b = Q_{u2} \qquad \text{for } Z_c/d_b \le 0.5 \qquad (55.2)$$

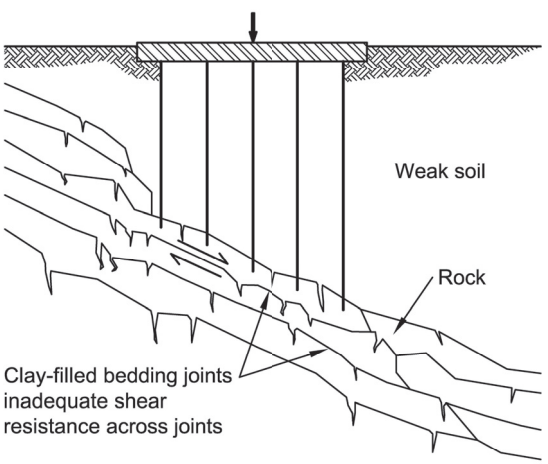
$$Q_b = Q_{u1} \qquad \text{for } Z_c/d_b \ge 3 \qquad (55.3)$$

and for Z_c/d_b between 0.5 and 3



$$Q_b = Q_{u2} + (0.4\,Z_c/d_b - 0.2)\,(Q_{u1} - Q_{u2}) \qquad (55.4)$$

where Q_b is the ultimate bearing capacity of the base, Q_{u1} is the ultimate bearing capacity of the upper layer, Q_{u2} is the ultimate bearing capacity of the underlying weak compressible layer,



Ground deformation induces large bending moments/shear forces in piles

(a) Global ground movements induce extra loading and pile group deformation

(b) Load applied to group of piles causes shear failure of soft clay

(c) Pile group bearing on sloping rock surface, shear failure due to clay infill in rock joints

Figure 55.5 Pile-group failure, some high risk situations

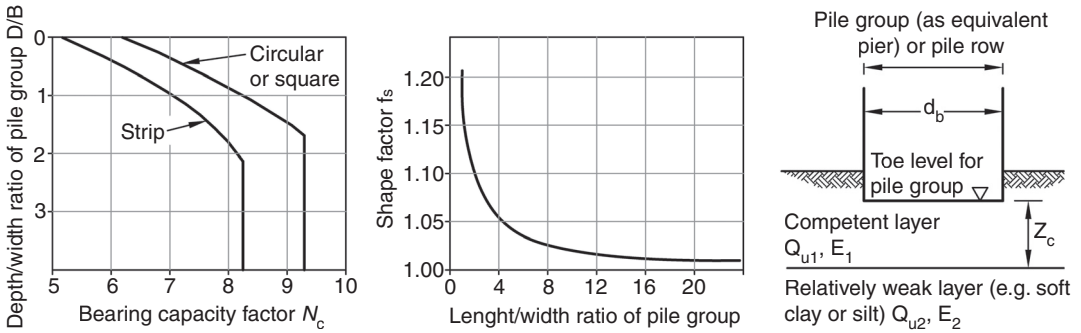
Z_c is the depth of the underlying layer below the pile-group toe level and d_b is the equivalent pier diameter (**Figure 55.6(c)**).

If the upper layer is sand or gravel then Q_{u1} can be assessed by using conventional bearing-capacity theory based on effective stress parameters (refer to Chapter 21 *Bearing capacity theory* and Chapter 53 *Shallow foundations*) together with appropriate shape and depth correction factors. For weak rocks, the nature and spacing of discontinuities in the rock mass need to be considered, as outlined in Chapter 53 *Shallow foundations*. For clays, conventional bearing-capacity theory can be used, together with appropriate shape and depth correction factors, see (55.5) below.

$$\text{Ultimate bearing pressure, } q_b = f_s N_c S_{ub} \qquad (55.5)$$

where f_s, N_c and S_{ub} are defined above, for (55.1).

For pile groups subject to horizontal or moment loading and underlain by relatively weak layers, the potential for edge failure should be checked by assessing the bearing resistance beneath the outer (more heavily loaded) pile row. It is usually sufficient to calculate an average bearing pressure at the toe level beneath the row (based on the mobilised end bearing pressure). The factor of safety against local failure can then be checked against equations (55.2) to (55.5) above.



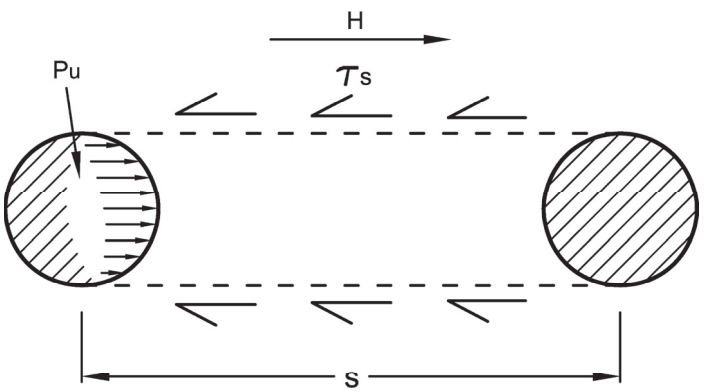
Historically, there was some concern about the capacity of a group of piles relative to the sum of individual pile capacities, and the term group 'efficiency' has been discussed in some textbooks. This concept has led to confusion. It should be noted that the efficiency factors quoted are based on a limited set of small-scale model tests, and general experience (together with full-scale tests, e.g. O'Neil *et al*., 1982) indicates that there is little merit in using efficiency factors. For piles driven into sand, the group capacity is likely to be much higher than the sum of individual capacities. However, settlement considerations will usually be critical and the actual ultimate capacity will not govern the design. For bored piles (in sands or clays), it could be argued (with some justification) that there would be an overall relaxation of horizontal ground stress around the pile group (thus reducing the pile-group capacity). However, this will be counterbalanced by the fact that shear failure would occur mainly through an undisturbed soil mass (rather than through the highly disturbed or remoulded ground adjacent to an individual pile shaft). In summary, therefore, the use of group efficiency factors is *not* recommended for calculations of ultimate capacity.

For pile groups subject to horizontal loading, the most likely geotechnical failure mode is shown in **Figure 55.4(c)**; commonly this will be more critical than the sum of individual pile capacities due to the 'shadowing' effect of adjacent piles in a row (**Figure 55.7**). The failure of pile rows under horizontal loading is discussed by Fleming *et al*. (2009).

For practical purposes the ultimate lateral capacity of a pile group can be estimated as the lesser of:

(i) the sum of the ultimate capacities of individual piles in the group (Chapter 54 *Single piles*);

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers



(a) Bearing capacity factor N_c (after Meyerhof)

(b) Shape factor for rectangular pile groups (Meyerhof-Skempton)

(c) Pile group (or row) founded on a competent layer over a weak layer (after Matsui, 1993)

Figure 55.6 Bearing-capacity and shape factors for pile groups
Modified after Tomlinson (1987)

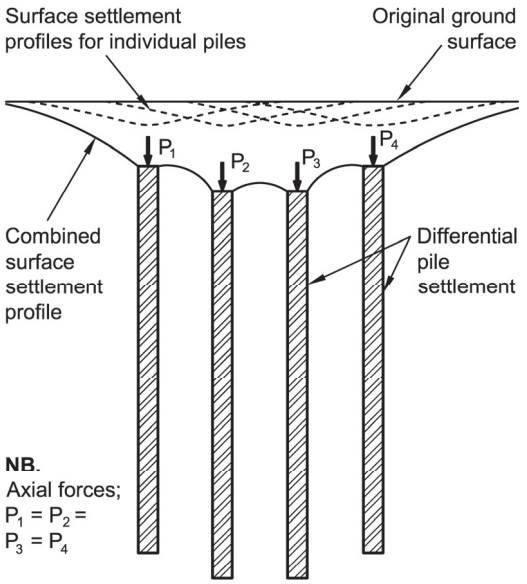
NB.
Pu = ultimate lateral force, per unit length,
S = pile spacing, τs = ultimate shear stress,
H = horizontal force

Figure 55.7 Failure and deformation mechanism ('shadowing') for a pile row under a horizontal load

(ii) the ultimate capacity of an equivalent block containing the piles and soil;

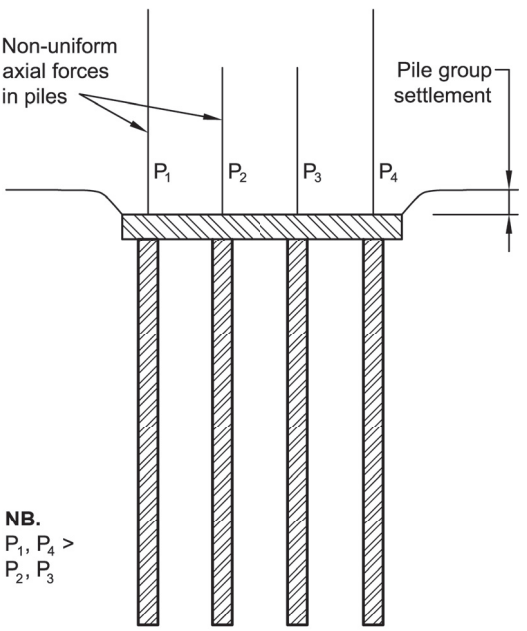
(iii) the sum of the ultimate capacities of the pile rows.

For (ii) above, only the 'short-pile' case is relevant (Fleming *et al*. 2009), and failure mode (ii) is only likely to be critical when there is a large number of closely spaced and relatively short piles. For this scenario, the soil shear strength would only be ignored across a depth equal to 1.5 times the pile diameter.



Pile-group failure under a lateral load will usually involve rotation as well as horizontal translation of the group. The ultimate geotechnical capacity will then be a function of both the axial and lateral capacities, with piles behind the axis of rotation failing in tension and piles in front of the axis of rotation failing in compression. In situations involving large horizontal or moment loading, the induced structural forces (bending moment, shear force, axial forces, tension or compression) and horizontal or rotational movements will usually be more critical than the ultimate geotechnical capacity. Pile-group deformation and induced structural forces will be discussed later in this chapter.

55.3 Pile-to-pile interaction: vertical loading



When piles are constructed close to one another, their subsequent load-deformation behaviour is affected by the presence of the neighbouring piles. **Figure 55.8(a)** provides a simple example of these 'pile-to-pile' interaction effects; it shows four piles under equal vertical loading (via a flexible pile cap). Each pile settles under the load and a zone of soil settlement develops around each pile. These soil settlement zones overlap and interact; hence, the middle piles settle more than the outer piles (and all the 'group' piles settle more than an individual isolated pile). If the pile group has a rigid pile cap, **Figure 55.8(b)**, each pile has to settle by an equal amount (because the pile cap is rigid) but the axial loads in the piles will now vary across the group with the outer piles developing higher axial loads than the middle piles (because the outer piles are stiffer than the inner piles and, hence, attract more load). Hence, the pile-to-pile interaction and how it affects both pile-group deformation and the redistribution of forces across piles (and into the pile cap) within a group is of fundamental importance. In practice, the pile-to-pile interaction depends on a large number of factors (**Table 55.1**).

In the context of assessing pile-group settlement, two parameters are useful:

$$\text{Settlement ratio, } R_s = \frac{\text{Average group settlement}}{\text{Settlement of single pile at same average load as a pile in the group}} \quad (55.6)$$

(a) Flexible pile cap, non-uniform pile settlement

(b) Rigid pile cap, non-uniform axial forces

Figure 55.8 Effects of pile-to-pile interaction, vertical loading

$$\text{Group reduction factor, } R_g = \frac{\text{Average group settlement}}{\text{Settlement of single pile at same total load as the group}} \quad (55.7)$$

R_g is conceptually difficult since it is physically meaningful only for an elastic soil when failure cannot occur. R_g is, however, useful when comparing the performance of different pile groups (of different geometries or pile numbers). R_g is simply related to R_s by $R_s = n\,R_g$, where n is the number of piles in the group. The value of R_g varies between $1/n$ and 1.0.

An important practical conclusion from various studies (e.g. Butterfield and Douglas, 1981) is that the precise layout of the piles has a negligible influence on the group settlement ratio R_S; for example a square pile group has the same value of R_s as a rectangular or circular group, at the same average pile spacing.

R_s is a convenient way of assessing the effects of interaction on pile-group behaviour. Two of the most important factors which influence R_s are:

(i) the variation of the ground stiffness with depth (which may be expressed in terms of the shear modulus G or Young's modulus E);

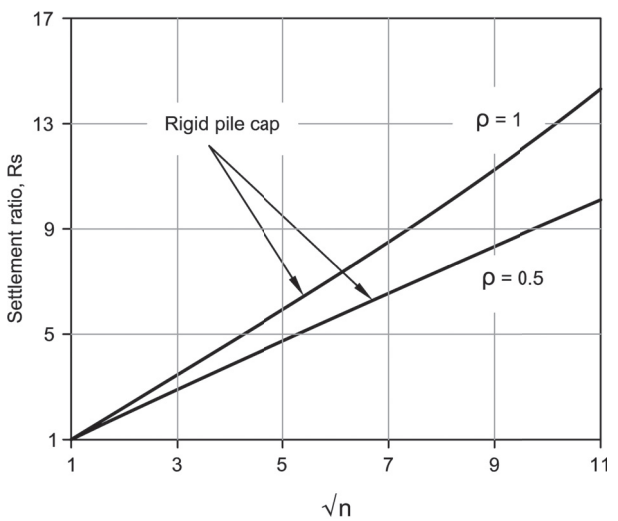
(ii) the influence of a rigid (or a relatively much stiffer or stronger) layer at some depth below the toe of the pile group.

The influence of these factors is illustrated in **Figures 55.9** and **55.10**. **Figure 55.9** compares the values of R_s for a pile group in a soil layer that has constant stiffness with depth ($\rho = 1$) against a group in a soil layer that has stiffness increasing linearly with depth ($\rho = 0.5$). In both cases the soil layer is infinitely deep. It can be seen that the degree of interaction (and the value of R_s) is much less when the stiffness increases linearly with depth (which occurs commonly in practice, in many geologies, due to the combined effects of increasing effective stress and reductions in weathering with depth). **Figure 55.10**(a) plots a correction factor, F_h, against the ratio of compressible layer thickness, h, to the pile length, L. F_h is defined by

$$F_h = \frac{R_s \text{ for finite layer of depth } h}{R_s \text{ for infinitely deep layer}} \quad (55.8)$$

This effect becomes more significant for larger pile groups, with F_h values of between 0.6 and 0.8 for a wide range of scenarios. The correction factor will increase as pile spacing increases (Poulos and Davies, 1980).

Figure 55.10(b) shows the potential difference in R_S value (indicated by the correction factor, F_b) for friction piles 'floating' in an infinitely deep homogeneous layer compared with end-bearing piles toed into a layer of varying stiffness, relative to the overlying strata (E_b/E_S). From **Figure 55.10(b)** it can be seen that R_s decreases (i.e. the pile-to-pile interaction decreases, and, similarly, the axial load distributions will become more uniform) as the relative stiffness of the bearing layer increases. The effect is most significant for short stiff piles. However, for slender piles (e.g. $L/d = 100$) the bearing layer has little effect, since little load is likely to reach the pile toe under normal working load conditions.



In practice, piles are often installed in geological sequences that exhibit marked variations in stiffness with depth, or 'layering'. The layers beneath the pile are either stiffer or softer than

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Factor	Vertical loading		Horizontal loading	
	Group settlement ratio	Non-uniformity of axial loads	Group deformation	Stresses in piles
Increase of ground stiffness with depth	–	–	– (if < L_c)	– (if < L_c)
Ground layering, relatively stiff layer at depth below pile toe	– –	– –	NE	NE
End- bearing pile (compared with friction pile)	–	–	NE	NE
Ground layering, relatively compressible layer at depth below pile toe	+++	+++	+	+
Ground, nonlinear stress–strain behaviour	–(1)	–(1)	++	++
Pile installation	– –	– –	+	+
Pile-group layout	NE	NE	+	+
Pile spacing (s > 3d)	–	–	–	–
(s < 3d)	+	+	+	+
Increasing displacement	–	–	++	++
Near-surface soils (<6d) (relatively weak layer)	NE	NE	+++	+++
Pile-cap stiffness reduces	NE	– –	NA	NA
Pile head fixity, fixed to free head condition	NA	NA	+++	Depends on pile location in group

Key
– Leads to a reduction in interaction effects, e.g. smaller group settlement, more uniform axial loads.
+ Leads to an increase in interaction effects, e.g. larger group deformation, more non-uniform axial loads and stresses in piles.
– – or ++ Indicates major effects, etc.
NE = negligible effect
NA = not applicable
L_c is the critical pile length for horizontal loading.
(1) Particularly important for large pile groups.

the layer at the pile-toe level. Although this is a common situation, computer software is often not able to accurately model the influence of these layers on pile-group behaviour. **Figure 55.11** illustrates two different situations. Firstly, **Figure 55.11(a)** shows the increase or decrease in pile-group settlement (for pile groups increasing in size up to 121 piles, pile spacing of 3D, and pile length of 25 m) due to underlying layers of lower or greater stiffness respectively. **Figure 55.11(b)** shows the increase in settlement due to an underlying layer of lower stiffness (for piles groups with up to 64 piles, pile spacing of 4D and pile length of 15 m). The following can be observed from **Figure 55.11**:

(i) the effect of the underlying layer is more significant for larger pile groups;

(ii) for large pile groups, settlement may be increased by a factor of three or more, when underlain by a more compressible layer;

(iii) if underlain by a relatively stiff layer, pile-group settlement may be more than halved.

Therefore, the potential exists either to seriously overestimate or underestimate pile-group settlement, if the presence of underlying layers are either ignored or not detected. Axial

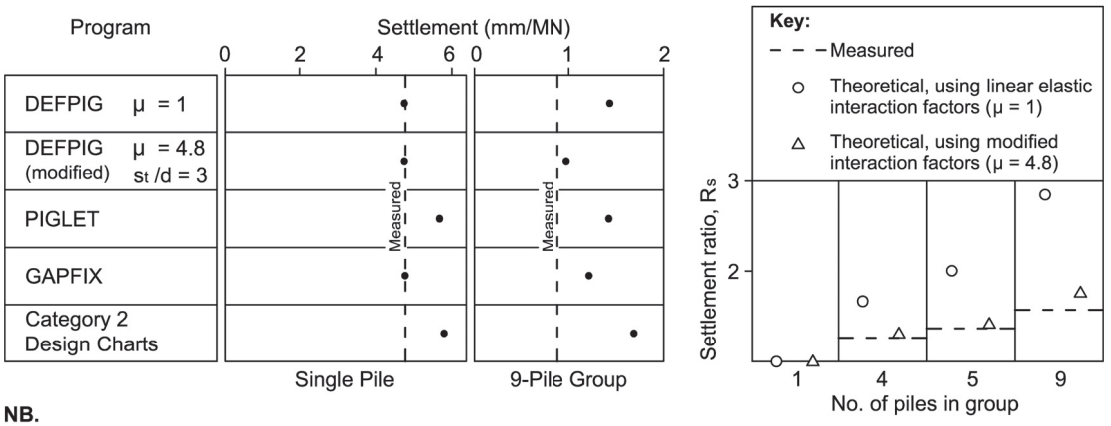
load distributions across a pile group will be similarly affected: more compressible underlying layers will lead to more non-uniform axial loads across the group (higher axial loads in piles around the pile-group perimeter and lower loads in central piles) whereas stiffer underlying layers will lead to more uniform axial loads across the group.

Pile-group analyses often assume that the soil behaviour is linear elastic and that pile installation has no effect on soil properties. Both these assumptions lead to an overestimation of pile-to-pile interaction effects. **Figure 55.12** illustrates the influence of nonlinear elastic versus linear elastic assumptions for soil behaviour; **Figure 55.12(a)** indicates that modelling the soil behaviour as linear elastic will tend to overpredict the soil settlement adjacent to a pile. **Figure 55.12(b)** plots contours of soil strain around a pile (derived from a sophisticated nonlinear soil model), which indicates that most of the soil adjacent to the pile experiences strains of less than 0.01%, whereas close to the top of this relatively compressible pile there is a zone of soil that has become plastic. Hence, the mobilised soil stiffness close to the pile will usually be lower than that mobilised further away from the pile, at any given depth below the ground surface. This effect will be exacerbated by the influence of pile installation. For either bored piles or driven piles, there will be a zone of soil immediately adjacent to the pile that will be intensely disturbed and remoulded. **Figure 55.13** compares predictions from a range of different software with measured pile-group settlements (Poulos, 1989). **Figure 55.13(a)** indicates that although some software could accurately predict single-pile settlement, the group settlement was overpredicted, i.e. the interaction effects, or equivalent R_s value, were overpredicted. **Figure 55.13(b)** plots R_s versus the number of piles in the group. This indicates that the conventional linear elastic analysis overpredicts R_s and this overprediction becomes worse as the pile-group size increases. Relatively good predictions are made for a modified analysis in which the soil between the piles was assumed to be stiffer than that immediately adjacent to the piles. For the site in Texas, USA, used for **Figure 55.13(b)** (O'Neil *et al*., 1982), which was underlain by stiff overconsolidated low- to medium-plasticity clays, the modified analysis assumed a Young's modulus of $750S_U$ for the remoulded soil adjacent to the driven steel tubular piles, and a Young's modulus of about $2500S_U$ for the soil beyond the remoulded zone (this was equivalent to the modulus at very small strain derived from cross-hole geophysics data).



As noted above, pile-to-pile interaction leads to a redistribution of axial loads across a pile group. It is affected by the same factors as those which affect group settlement, with greater interaction causing higher axial loads in piles around the group perimeter and lower axial loads for central piles. End-bearing piles toed into a relatively stiff layer will have a more uniform distribution of axial loads than friction piles 'floating' in a deep layer with constant stiffness (**Figure 55.14**). Measurements of axial loads in pile groups are rare; however, Mandolini *et al*. (2005) have collated available data

and this is plotted in **Figure 55.15**. The figure indicates that typically the ratio of corner to centre pile axial loads is between about 2.0 and 2.5 (and the full range is between about 1.5 and 3) for common pile spacings of about 2.5 to 4 times the pile diameter. It is apparent that pile axial loads become more uniform with increasing pile spacing, and that interaction effects appear to be negligible for pile spacings of more than 8 times the pile diameter. **Table 55.2** gives measured axial load ratios (V_{max}/V_{min}) for a few specific case histories. At Stonebridge Park, given the large pile-group aspect ratio, a much larger

Pile group	Ground profile	Pile type	Pile length (m)	Pile diameter (m)	Number of piles	Spacing (m)	Pile-group aspect ratio	Axial load ratios		Pile-cap stiffness
								C/I	E/I	
Stonebridge Park (Cooke *et al.*, 1981)	Deep layer of overconsolidated clay (London Clay)	Bored (friction)	13	0.45	351	1.61	6.6	2.2	1.7	Flexible

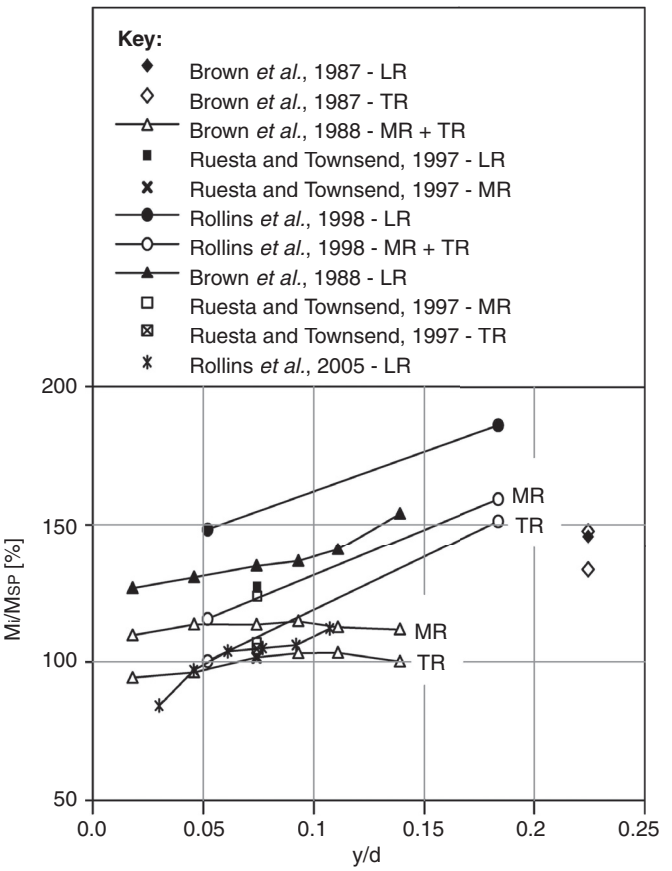
Reproduced from O'Brien and Brown (2010)

value of V_{max}/V_{min} would have been expected. In this case, the pile cap was relatively flexible, which led to more uniform pile axial loads. For the Cargliano Bridge, the end-bearing piles led to a relatively low value of V_{max}/V_{min}. The pile-group test reported by Koizumi and Ito, with friction piles in a deep compressible layer and a rigid pile cap, led to relatively high values of V_{max}/V_{min}.

Figure 55.16(a) summarises the results of a study by O'Brien and Bown (2010), which plots the ratio of corner to centre pile axial loads plotted against pile-group size. V_{max} is the maximum predicted axial load, which for square pile groups occurs



in the corner piles. V_{min} is the minimum predicted axial load, which occurs in the piles close to the centre of the pile group. This shows that linear elastic analyses overestimate the load redistribution across the group when compared with nonlinear analyses and case history data, and that this discrepancy increases with increasing pile-group size.

For large groups, if pile axial loads are predicted by linear elastic methods then it is inevitable that corner piles will have an apparently low geotechnical 'factor of safety' even when the overall group factor of safety is two or more (**Figure 55.16(b)**). This can be a problematic issue when considering how to apply code requirements. This is discussed in section 55.10.

55.4 Pile-to-pile interaction: horizontal loading

For piles subject to a horizontal load the main design issue is usually the stresses that develop in the piles relative to their structural strength.

Mandolini *et al*. (2005) summarise several studies on pile-group behaviour when horizontal loads are applied. Pile-to-pile interaction under a vertical load is fully developed at relatively small displacements, and nonlinearity at larger displacements is focussed in the thin layer of soil around the pile–soil interface (and does not amplify group interaction effects at larger displacements). In contrast, under horizontal loading, interaction between piles grows as the pile-group displacement increases. **Figure 55.17** provides some measured data from instrumented pile groups and centrifuge tests (Mandolini and Viggiani, 2005) for free head conditions. The ratio between the maximum bending moment in different piles in a group and in a single isolated pile is plotted against the pile-group displacement (the ratio is derived for the same average horizontal load per pile). The moments in the group piles are generally larger than the single pile, and the ratio increases with increasing displacement. Larger bending moments develop in the leading row (LR) piles compared to either the middle (MR) or trailing row (TR) piles (**Figure 55.17**); this phenomenon has been attributed to 'shielding' or 'shadowing' effects between adjacent piles in the same row (refer to **Figure 55.7**). This means that for horizontal loading, different group configurations, e.g. square vs rectangular vs circular, etc., will exhibit different group interaction effects even if the number of piles and average spacing is the same (this contrasts with group interaction effects under a vertical load, which are practically unaffected by the group configuration for a given number of piles and similar average spacing). Hence, for piles under horizontal loading it is potentially unsafe to assess the bending moments in piles within a group from an assessment of single-pile behaviour under horizontal loading; in addition the assumption of linear elastic behaviour can also be unsafe. The use of *p–y* curves is well established for predicting the behaviour of single piles under horizontal loads. However, the use of *p–y* multipliers to account for group interaction effects is of more doubtful validity because of the large number of complicating factors that can affect real pile-group behaviour under horizontal loading.

NB.
Mi = maximum bending moment in pile in a group; Msp = maximum bending moment in a single isolated pile; LR = piles in a leading row MR = piles in middle of a row; TR = trailing piles

55.5 Simplified methods of analysis

55.5.1 General comments

There are four simplified methods that may be used to assess pile-group settlement:

(i) pile-group settlement ratio;

(ii) elastic interaction factors;

(iii) equivalent pier;

(iv) equivalent raft.

Each method has distinctive advantages and disadvantages (which are summarised in **Table 55.3**). When applied appropriately, the methods are helpful supplementary tools to

Simplified method	Advantages	Disadvantages
Empirical settlement ratio	Very quick and simple. Best suited for friction piles, in deposits with increasing strength and stiffness with depth	The influence of specific geological features, pile or ground properties cannot be assessed
	Useful as a 'sense' check of more complex methods	Potentially unsafe if weak or compressible strata underlies the bearing stratum. Potentially overconservative, if a relatively stiff layer underlies the bearing stratum
Elastic interaction factors	Influence of varying pile length, diameter and spacing can be quickly checked	Cannot directly check influence of underlying strong or weak layers (refer to **Figures 55.10** and **55.11**)
	Best suited for friction piles in deposits with increasing strength and stiffness with depth	Care needed in amplifying single-pile settlement for large groups, use initial tangent pile stiffness, rather than secant; otherwise can be overconservative
Equivalent pier	Well suited for pile groups with relatively small aspect ratio, $R < 3.0$	Not appropriate for large pile-group aspect ratios, $R > 3.0$
	If using elastic solutions for single pile, then is quick to use	Inappropriate if pile lengths in group vary significantly
	Flexible, method can also be used within sophisticated numerical models, in axisymmetric mode	
Equivalent raft	Most appropriate simplified method for checking influence of strong or weak layers at depth	Overconservative for pile groups with a small aspect ratio, $R < 3.0$
		Significant judgement needed to assess appropriate raft level and dimensions

Table 55.3 Pile-group settlement: Advantages and disadvantages of simplified methods

computer-based methods (which may also have serious limitations in certain situations) and can facilitate a quick check of more sophisticated methods (which can be more prone to error). It is probably fair to say that methods (i) to (iii) above are under-used, whereas method (iv) is over-used.

There are no simplified methods for checking axial load distributions across a group, but **Figures 55.15** and **55.16** indicate ranges of V_{max}/V_{min} that could be reasonably anticipated, and **Figure 55.14** and **Tables 55.1** and **55.2** indicate the factors that may influence axial load distribution.

It should be noted that the use of structural analysis software (which typically simulate pile behaviour as independent elastic springs) is not recommended, since pile-to-pile interaction is not modelled. Poulos and Davis (1980) give examples of some of the errors that can be produced.

55.5.2 Pile-group settlement ratio, R_{Se} (empirical correlations)

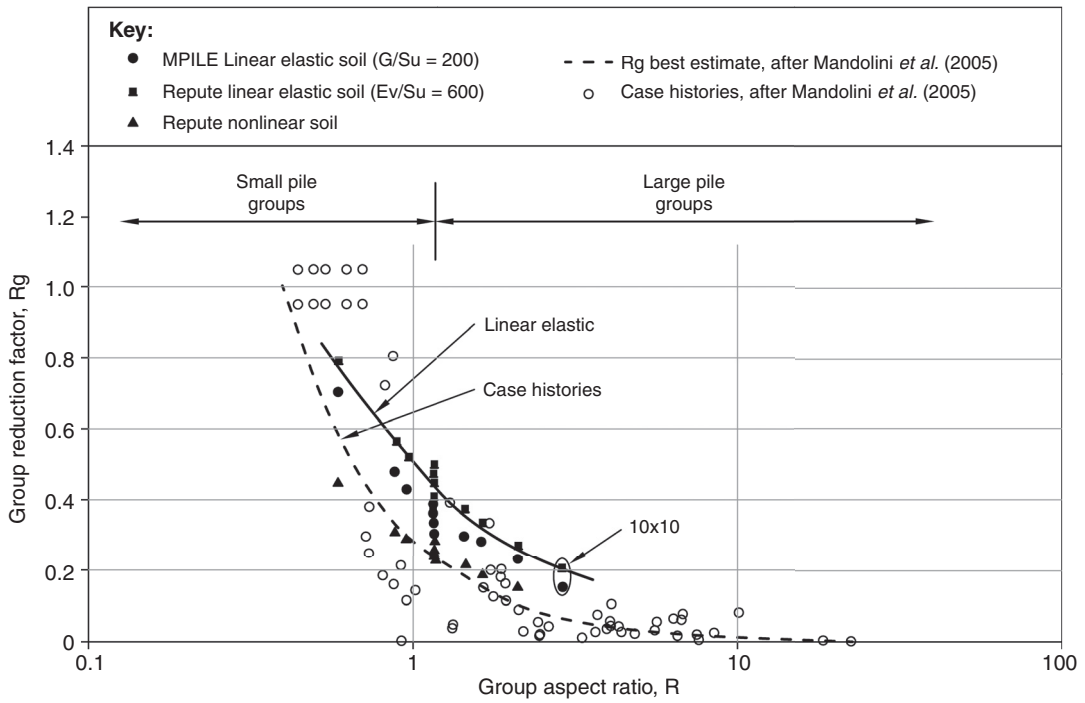
Mandolini *et al.* (2005) proposed an empirical correlation between the pile-group settlement ratio R_{Se} and the pile-group aspect ratio, based on an analysis of 63 case histories (for pile groups in varying geologies, and with varying pile length, type, diameter, etc.), which is shown in **Figure 55.18**. Equations have been developed for the upper-bound, best-estimate and lower-bound settlements:

$$\text{Best estimate, } R_{Se} = \frac{a}{(R)^b} = \frac{0.29}{(R)^{1.35}}(n) \qquad (55.9)$$

where n is the number of piles in the group, the pile-group aspect ratio $R = (ns/L)^{0.5}$ and R_{Se} is the empirical pile-group settlement ratio.

$$\text{Pile-group settlement, } W = R_{Se} W_S \qquad (55.10)$$

where W_s is the single-pile settlement under the average working load of piles within the group (Q/n) and Q is the total vertical load applied to the pile group.



The single-pile settlement W can be calculated by using either relevant pile test data or Fleming's method for single-pile settlement (Fleming, 1992). The latter has been found to be reliable for a wide range of pile types and ground conditions (refer to Chapter 54 *Single piles*). The upper- and lower-bound values of R_{Se} are:

$$\text{Upper bound } R_{Se} = \frac{0.5}{R}\left[1 + \frac{1}{3R}\right]n \qquad (55.11)$$

$$\text{Lower bound } R_{Se} = \frac{0.17}{(R)^{1.35}}(n) \qquad (55.12)$$

Hence, application of the above equations enables a rapid estimate to be made of the likely range of the pile-group settlement.

Experience indicates that (55.9) is generally appropriate for friction piles with soils with strength and stiffness increasing gradually with depth; (55.11) applies if relatively deep and uniform soils underlie the pile group and (55.12) applies if

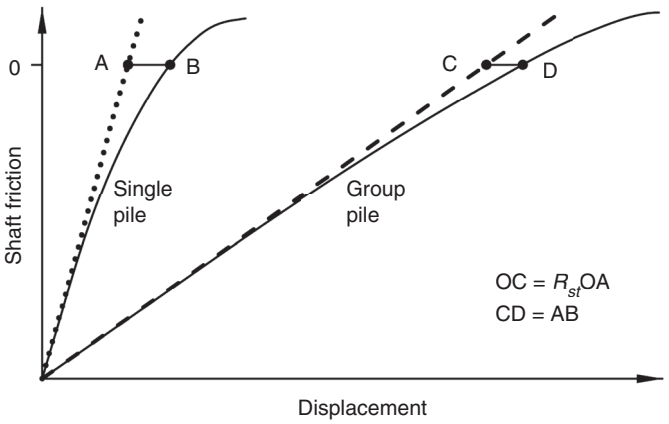
NB.
Settlement ratio, Rs = nRg, n = number of piles in group, Rg = group reduction factor. Group aspect ratio, R = (ns/L)0.5, s = pile spacing, L = pile length. G = soil shear modulus, Ev = soil Young's Modulus, Su = undrained shear strength

Figure 55.18 Group reduction factor *Rg* versus Group aspect ratio *R*. Field measurements and parametric study
Data taken from Mandolini *et al*. (2005); O'Brien and Bown (2010)

the soil or rock beneath the group exhibits a rapid increase in strength and stiffness.

55.5.3 Elastic interaction factors (design charts)

Elastic interaction factors have been widely published (for example Poulos and Davies, 1980). However, many of the early solutions relied on unrealistic assumptions (e.g. an infinite elastic medium with constant Young's modulus, rigid pile, etc.) and overestimated the interaction between the piles and, therefore, the pile-group settlements (and the non-uniformity of axial loads) were overpredicted. Pile installation effects and soil nonlinearity lead to reduced interaction between piles. Randolph (1994) has outlined a simple and practical approach to improve the reliability of elastic interaction factors, which is shown in **Figure 55.19**. The initial stiffness derived from the single-pile load-settlement response is given by the tangent line OA (and will be a function of the small strain stiffness of the soil). Plastic strain, which will develop at higher load levels, leads to the offset AB. This plastic strain will develop locally adjacent to the pile shaft. Group interaction effects under vertical load are predominantly due to elastic, rather than plastic, strains. Therefore, the pile-group settlement ratio (derived from linear elastic theory) R_{St} is only applied to the elastic component of the single-pile settlement. Hence, the elastic pile-group settlement is shown as OC in **Figure 55.19** where OC = R_{St} OA and the total pile-group settlement OD = OC + CD (with CD = AB). For most conventionally designed pile groups, which will have overall factors of safety well in excess of 2.0, the plastic component of settlement will be relatively minor. Back analysis of a wide range of case histories by Mandolini and Viggiani (1997) confirms that Randolph's approach is usually more appropriate than applying the group settlement ratio R_{St} to the single-pile secant stiffness at the average working load of the piles within the group.



To a reasonable approximation, the group settlement ratio is (Fleming *et al*., 2009)

$$R_{St} = n^{e} \tag{55.13}$$

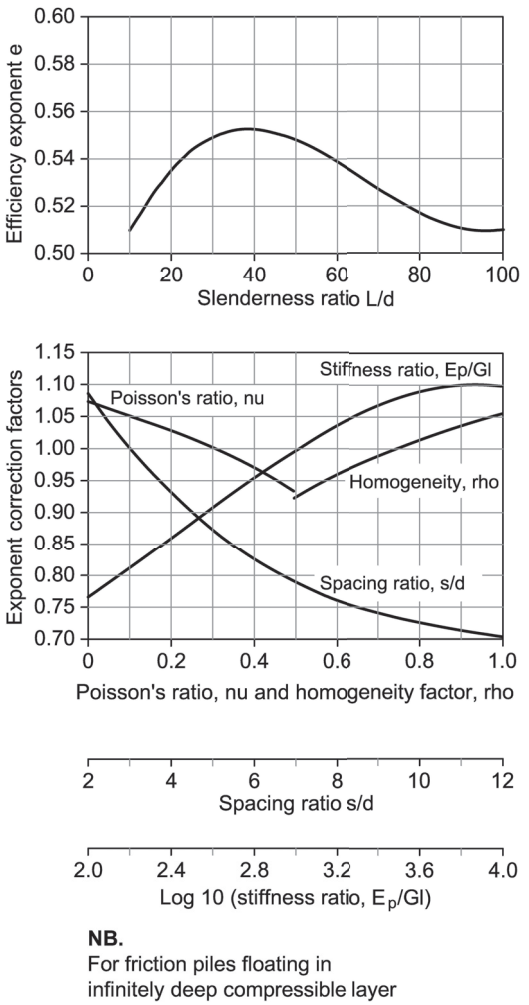
and

$$W = R_{St}\, W_{Se} + W_{Sp} \tag{55.14}$$

where W is the pile-group settlement, R_{st} is the group settlement ratio derived from linear elastic theory, W_{Se} is the elastic settlement under the average working load of piles within the group (Q/n), n is the number of piles in the group, Q is the total vertical load applied to the group and W_{Sp} is the plastic settlement of a pile at Q/n.

NB.
R_{st}, group settlement ratio (from elastic theory) = We/Wse. We = elastic pile group settlement, Wse = single pile elastic settlement (under same average load)

Figure 55.19 Applying elastic theory to pile interaction and nonlinear load-settlement behaviour for vertical loading
Reproduced from Randolph (1994)



For piles working mainly in shaft friction, e is typically between 0.3 and 0.5. Based on Randolph (1994), **Figure 55.20** gives a set of design charts; the exponent e is given by a base value (depending on the pile slenderness ratio L/d) e_1 and four correction factors, c_1, to c_4:

$$e = e_1\, c_1\, c_2\, c_3\, c_4 \tag{55.15}$$

where c_1 is a function of the pile stiffness to the ground stiffness, $E_p\,/G_L$ and E_p is Young's modulus for the pile. G_L is the ground shear modulus at the pile-toe level, c_2 is a function of the pile spacing s to the pile diameter d, c_3 is a function of the rate of increase of the ground shear modulus with depth, rho = G_{av} / G_L, G_{av} is the ground shear modulus halfway down the pile and c_4 is a function of Poisson's ratio, ν'. The value of e_1 is based on $E_p\,/G_L = 1000$, $s\,/\,d = 3$, $\rho = 0.75$ and $\nu' = 0.3$. These charts assume an infinitely deep elastic layer. Reference to **Figures 55.10** and **55.11**, allows judgements to be made about the influence of a finite layer thickness and stiffer or weaker layers below the pile toe. Poulos (1989) indicates that for friction piles at typical working loads (factor of safety in excess of 2.0), plastic deformation would be expected to only increase single-pile settlement by between 10% and 25% compared with the elastic response derived from the initial pile stiffness.

55.5.4 Equivalent pier and equivalent raft

Equivalent pier: the equivalent pier approach replaces the pile group by a buried 'cylinder' of appropriate dimensions and stiffness (**Figure 55.21**). Solutions for calculating the single-pile settlement can then be used to calculate the settlement of the equivalent pier (provided due account is taken of the compressibility of the cylinder, the stiffness of the soils below the base and the shear stiffness of the interface around the sides of

NB.
For friction piles floating in infinitely deep compressible layer

Figure 55.20 Design charts (linear elastic soil) for pile-group settlement ratio, R_{st}
Reproduced from Fleming *et al.* (2009)

the cylinder). Alternatively the settlement of the equivalent pier can be simulated within an axisymmetric numerical model.

For a pile-group of area A_g the diameter of the equivalent pier d_{eq} is

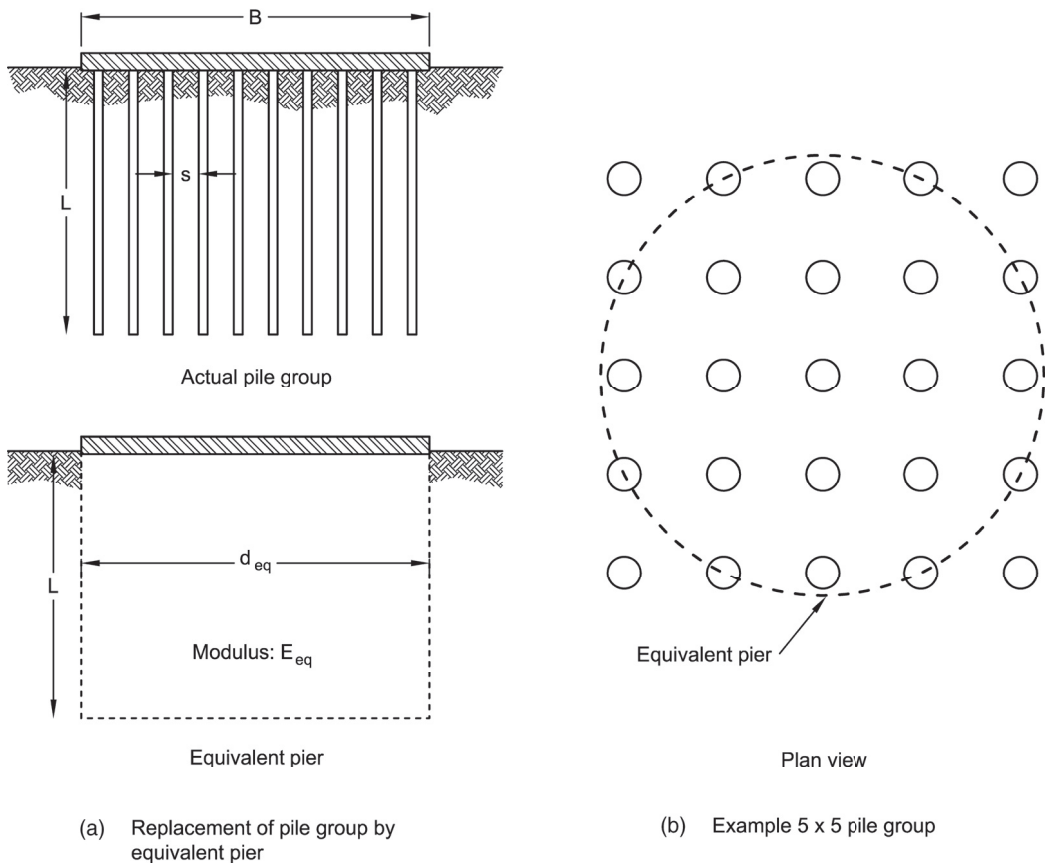
$$d_{eq} = \left(\frac{4}{\pi} A_g\right)^{0.5} = 1.13\,(A_g)^{0.5}. \tag{55.16}$$

The equivalent Young's modulus E_{eq} of the pier is

$$E_{eq} = E_S + (E_p - E_S)\,(A_p\,/A_g) \tag{55.17}$$

where E_P is Young's modulus of the pile, E_S is the average Young's modulus of the soil penetrated by the piles, A_P is the total cross-section area of the piles in the group and A_g is the total plan area encompassed by the pile group.

The elastic solutions for settlement of a single pile presented by Randolph (1994), which allow for the relatively low aspect ratio of equivalent piers (for typical pile-group geometries) can



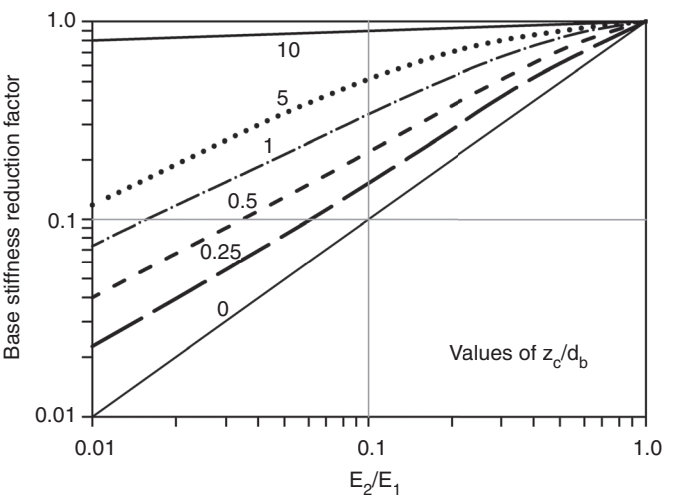


Figure 55.21 Replacement of pile group by an equivalent pier

be conveniently programmed in modern spreadsheets to facilitate rapid analyses of pile-group settlement. Alternatively, the nonlinear approach proposed by Fleming (1992) can be used (refer to Chapter 54 *Single piles*), although it should be noted that the strength and stiffness properties for the base and shaft resistance around the equivalent pier should mainly be representative of the undisturbed soil mass, rather than the disturbed remoulded soil immediately adjacent to an individual pile.

The influence of an underlying compressible layer on the load-settlement behaviour of the equivalent pier can be assessed (based on studies by Poulos, 2005) from **Figure 55.22**. **Figure 55.22** provides a plot of the base stiffness reduction factor as a function of Z_c/d_b and E_2 and E_1 (where E_2 and E_1 are the Young's moduli of the upper and lower layers, respectively), refer to **Figure 55.6(c)**. The base stiffness reduction factor is defined as the ratio of the base stiffness with the underlying layer E_2 to the base stiffness of E_1 only (i.e. with no underlying layer present).

Equivalent raft: the equivalent raft method has been used extensively for estimating pile-group settlement and is described in many textbooks. The pile group is replaced by a raft foundation acting at a representative depth below the surface with some equivalent dimensions. Many variants are available; however, the approach by Tomlinson (1987) is relatively simple and widely used. It is shown in **Figure 55.23**. As

NB.
For definition of z_c, d_b, refer to **Figure 55.6(c)**

Figure 55.22 Base stiffness reduction factor for pile group (equivalent pier) underlain by compressible layers
Reproduced from Poulos (2005) with permission of ASCE

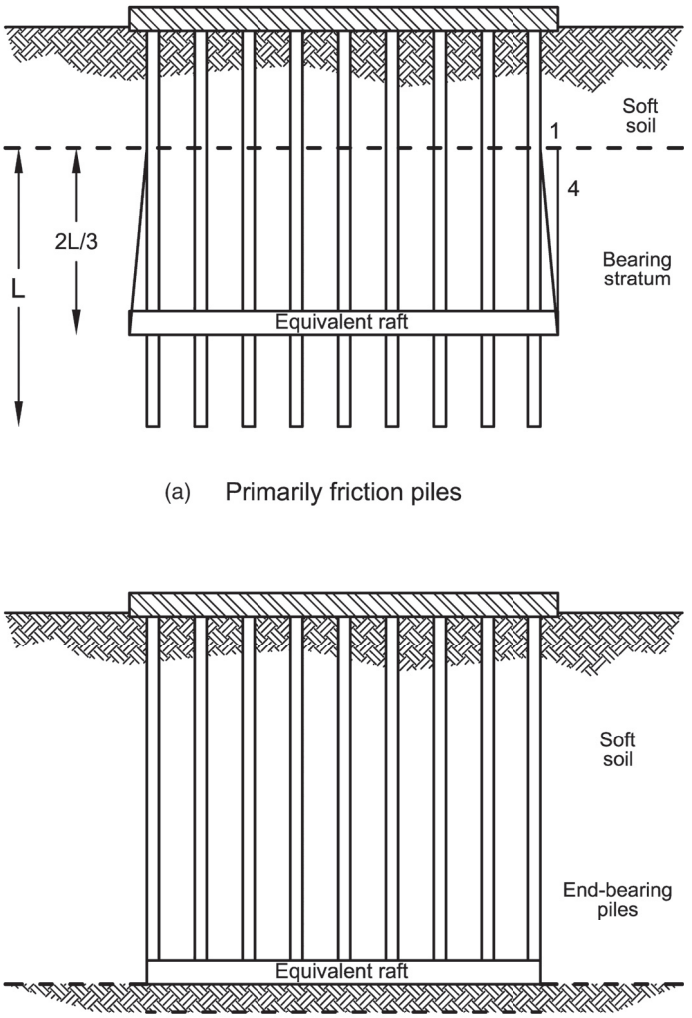

Figure 55.23 Replacement of pile group by an equivalent raft

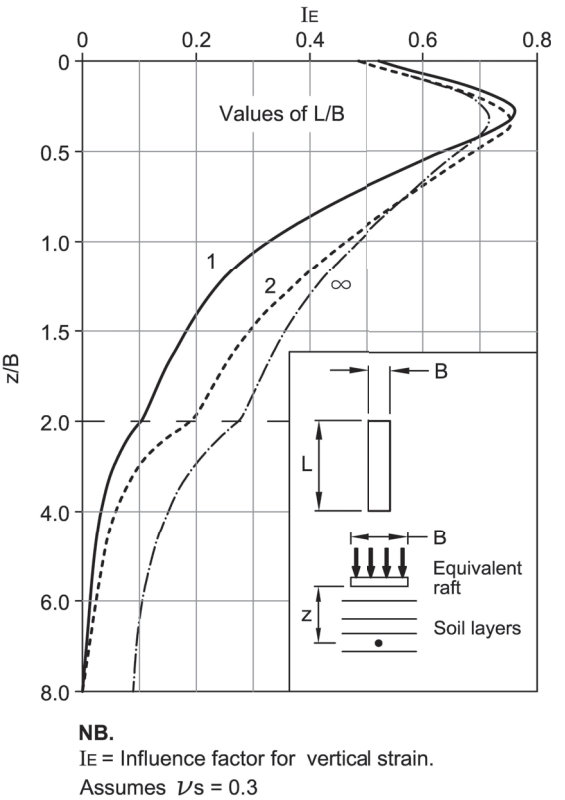
noted by Poulos *et al*. (2001), this method relies on considerable engineering judgement to assess the representative depth and appropriate raft dimensions, which depend on an understanding of the relevant load transfer mechanism for the pile group under consideration. Once the equivalent raft is established then the settlement can be computed using the analysis methods used for shallow foundations.

The average pile-group settlement W_{av} is then

$$W_{av} = W_{\text{raft}} + \Delta W \tag{55.18}$$

where ΔW is the elastic compression of the piles above the equivalent raft level (acting as free standing columns). Assuming elastic soil behaviour:

$$W_{\text{raft}} = F_{av}\ F_D\ q \sum_{i=1}^{n} \left(\frac{I_E}{E_S} \right) h_i \tag{55.19}$$



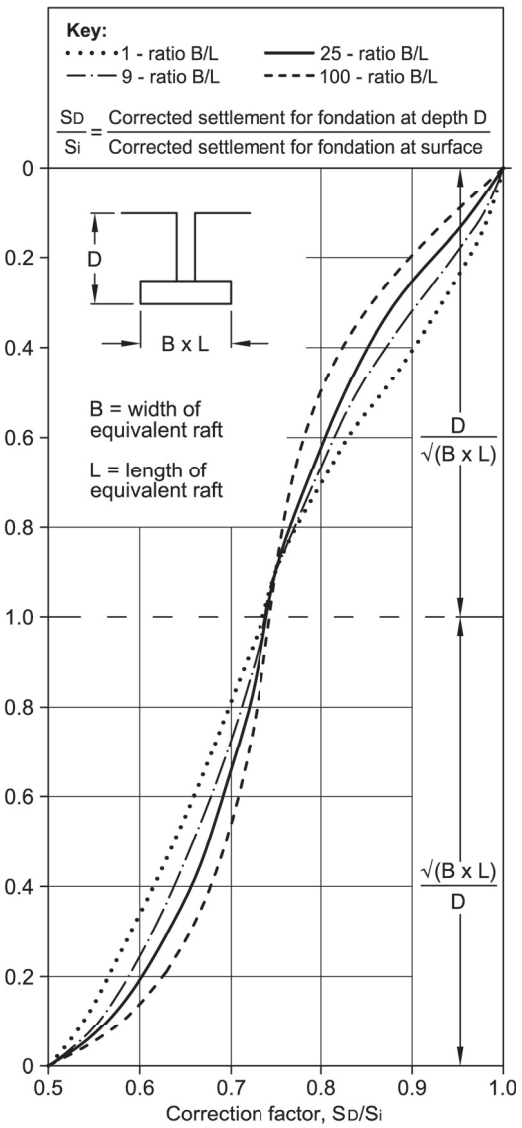


Figure 55.24 Equivalent raft settlement using elastic theory. Strain influence factor versus depth
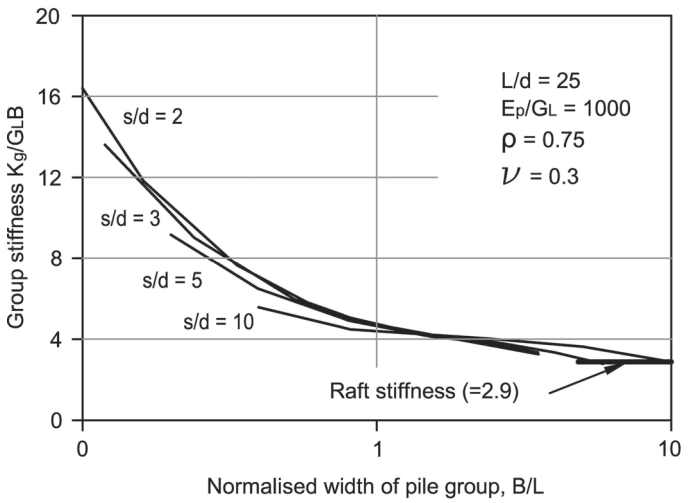
Data taken from Randolph (1994)

where Wraft is the equivalent raft settlement, q is the average pressure applied to the raft, I_E is an influence factor (refer to **Figure 55.24**) for the ith layer, h_i and E_S are the layer thickness and secant Young's modulus, respectively, for the ith layer, F_D is a depth correction factor (as derived by Fox, refer to **Figure 55.25**) and F_{av} is equal to 0.8 (to correct from centreline settlement to average raft settlement). The embedment depth of the raft should be assumed to be the depth below the competent bearing stratum, rather than the ground surface (**Figure 55.23**).



It should be noted that care is required both in method and input parameter selection; for example analytical methods and parameters that are purely empirically derived from observations of shallow foundation settlement are unlikely to be appropriate. In general, the use of elastic methods, such as (55.19) (e.g. Poulos, 1993), are likely to be suitable for most situations. For overconsolidated clays, if a drained Young's modulus is used, then total settlement (i.e. undrained plus consolidation settlement) will be calculated. Elastic analyses will *not* be appropriate if a layer of normally or lightly overconsolidated clay is present at depth below the pile-toe level, *and* the pile-group bearing pressures below the base cause the preconsolidation pressure (or yield stress) to be exceeded.

The main advantage of the equivalent raft method is that it enables the influence of softer or stiffer soil layers below the

NB.

NB.
G_L = shear modulus of soil at pile toe, B = width of pile group, K_g = pile group stiffness = (total load/average settlement), ρ = increase of shear modulus with depth (= G_{AV}/G_L), G_{AV} = shear modulus of soil halfway down pile

Figure 55.26 Normalised stiffness of pile groups and equivalent raft versus normalised width
Reproduced from Randolph (2003)

toe level of a pile group to be assessed in a simple and transparent way. This is particularly important in situations where softer soil layers may exist at some level below the pile group; as noted above, some commercially available software cannot analyse the situation reliably and a separate check is essential.

55.5.5 Which is appropriate, equivalent raft or equivalent pier?

When deciding between an equivalent pier or raft it is important to carefully consider the load transfer mechanism. If the piles are mainly dependent on shaft friction and the pile group is relatively deep and narrow, the resistance mobilised around the perimeter of the equivalent pier is likely to substantially exceed the applied working load. Hence, the load reaching the base of the pile group is likely to be negligible and the working load will be dissipated in shear around the pile-group perimeter. For this situation, an equivalent pier will be appropriate. In contrast, if the piles are mainly end-bearing or the pile group is relatively wide, then a substantial proportion of the applied working load will need to be resisted at the base of the pile group. In this case the equivalent raft will be an appropriate analogue for analysis purposes.

The choice between using either an equivalent raft or equivalent pier is mainly dependent on the overall pile-group aspect ratio or normalised width: **Figure 55.26** illustrates this quite clearly. When the normalised pile-group width (B/L; B is the group width and L is the pile length) is less than 1.0, the normalised pile-group stiffness is much higher than for the equivalent raft. Hence, the equivalent raft approach would tend to be overconservative and the equivalent pier should be used. Once the normalised width exceeds 1.0, then the pile-group stiffness tends towards that of an equivalent raft. Randolph (1994) has suggested that, for friction piles, if the pile-group aspect ratio exceeds about 3 or 4, then an equivalent raft is appropriate, whereas for lower values of R an equivalent pier is more appropriate. Typically, the accuracy of the equivalent pier is likely to be within 20% of more rigorous solutions, Randolph (2003), which is perfectly satisfactory for practical design purposes.

55.6 Differential settlement

Pile-group analysis commonly assumes that the pile cap is perfectly rigid or, occasionally, that the pile cap is perfectly flexible. Most pile-group analysis software cannot carry out analyses with a pile cap of intermediate stiffness. When pile caps are of small plan area, then assuming they are rigid is usually reasonable for practical purposes. However, as the pile-group size increases, it will be important to check the stiffness of the pile cap. This will be important for two reasons:

(i) as the pile-cap stiffness reduces the differential settlement across the pile group will increase;

(ii) as the pile-cap stiffness reduces the axial load distribution will become more uniform.

The decision to use pile groups is often driven by the wish to reduce settlement, in particular to reduce differential settlement, in order to reduce the risk of superstructure damage (refer to Chapter 52 *Foundation types and conceptual design principles*). Hence, a check on likely differential settlement will be important, especially for large pile groups or sensitive structures.

Pile-group differential settlement depends on the pile-group aspect ratio and on the pile-cap stiffness. Randolph and Clancy (1993) have shown that the normalised differential settlement of pile groups, with a fully flexible pile cap, is mainly a function of the pile-group aspect ratio R. Normalised differential settlement is reasonably independent of the precise number of piles, spacing, etc. Hence, for a flexible pile cap:

$$\Delta W_{\text{flex}} = f\,(R/4)\,W_{av} \qquad (\text{for } R \le 4) \qquad (55.20)$$

$$\Delta W_{\text{flex}} = f\,W_{av} \qquad (\text{for } R > 4) \qquad (55.21)$$

with $f = 0.3$ for differential settlement between the centre and mid-side, $f = 0.5$ for centre to corner; ΔW_{flex} is the differential settlement across a flexible pile cap, R is the pile-group aspect ratio and W_{av} is the average pile-group settlement.

The pile-group differential settlement ΔW is:

$$\Delta W = F_R\,\Delta W_{\text{flex}} \qquad (55.22)$$

where ΔW_{flex} is derived from equations (55.20) or (55.21) and F_R is the pile-cap rigidity, which can be assessed from solutions given in Chapter 53 *Shallow foundations* (for varying raft flexural stiffnesses).

55.7 Time-dependent settlement

Time-dependent settlement of pile groups under foundation loading can occur due to:

(i) primary consolidation, due to dissipation of excess pore pressure, in clays and silts (Hooper, 1979, Katzenbach *et al*., 2000);

(ii) settlement due to creep, in sands, gravels and weak rock (Mandolini and Viggiani, 1997).

The pile-group aspect ratio and load transfer mechanism are important factors in controlling the amount of time-dependent settlement. For small aspect ratios when load transfer is primarily due to shear, the time-dependent settlement at normal working load would be expected to be small. Studies by Poulos (1993) indicate that consolidation settlement would be less than about 15% of total settlement. In contrast, compression of the ground below the pile-group base will become increasingly important when the aspect ratio increases to large values (say, in excess of 3 or the B/L values are greater than 1.0), and then time-dependent behaviour will approach that for shallow raft foundations. Mandolini *et al*. (2005) compared observations of 'end of construction' settlement with observations of time-dependent movements for rafts and piled rafts in Frankfurt and London Clay (both stiff overconsolidated plastic clays). End of construction settlement (which probably includes some primary consolidation settlement) varied between 50% and 75% of the total, with the ratio increasing as B/L reduced (from 2.5 to 1.0). Poulos and Small (2001) suggest that creep settlement may become important at low factors of safety, i.e. less than about 1.4, but that creep is unlikely to be significant at normal working loads.

A separate issue that can cause relatively large time-dependent settlement is when large groups of full displacement (closed-end) piles are driven at close spacings into soft clays, silts or peats. Significant heave and lateral displacement can occur during pile driving. The shearing and remoulding of soft soils can generate substantial excess pore pressures, which will lead to large settlement of the heaved clay as the pore pressures dissipate. If the pile group is end-bearing then negative skin friction forces will result and if it is acting in friction then large pile-group settlements will develop (Bjerrum, 1967; Adams and Hanna, 1970; and Brzezinski *et al*., 1973). This will be independent of, and additional to, any settlement due to foundation or structure loading.

55.8 Optimising pile-group configurations

Once the decision has been made to use pile groups, some thought will be needed on how to optimise the layout of the pile group in terms of the length, diameter and spacing of the piles. This will be dependent on a number of factors:

(i) *A shallow foundation would have adequate bearing capacity, but is it likely to suffer excessive settlement?* If a shallow foundation such as a raft has adequate bearing capacity and the requirement is to control settlement, differential settlement or raft bending moment, then a piled raft may be the appropriate solution; this is discussed in more detail in Chapter 56 *Rafts and piled rafts*. A piled raft would usually comprise a small number of widely spaced piles, normally located beneath the superstructure columns.

(ii) *Does a shallow foundation have adequate bearing capacity?* If not a conventional pile design approach would be

utilised. A single pile may be adequate (Chapter 54 *Single piles*), although for heavily loaded foundations a deep large-diameter pile may be needed. An alternative may be to form a small pile group by installing several smaller piles and a pile cap. This may be advantageous since the mobilisation costs for a smaller piling rig would be lower: the overall cost-benefit of different piling options will be dependent on several site-specific issues (refer to Chapter 52 *Foundation types and conceptual design principles*), in particular, site access and headroom. A holistic approach to site development is needed in terms of the requirements for all foundations across the site and matters such as overall construction sequence and programme, and the available space for foundation construction plant and for building pile caps.

(iii) *Site geology*: if there is a distinctive competent bearing stratum at depth and the piles act predominantly as end-bearing piles, then the appropriate pile length will be obvious, and the main design variables will be diameter and spacing. Alternatively, if the bearing stratum exhibits a gradual increase of strength or stiffness then the benefit of increasing the pile length, versus the number or diameter of piles, may not be immediately obvious; this is discussed in more detail below.

(iv) *Applied loads*: if high horizontal loads will be applied, then increasing the pile diameter will generally be more effective than increasing the pile length. A critical pile length L_C can be defined (Fleming *et al*., 2009) for lateral loading. L_C/d depends on the relative soil to pile stiffness, but is typically between $6d$ and $10d$ (where d is the pile diameter). Piles longer than L_C will not reduce lateral pile deflection. Structural strength will often be the critical issue for laterally loaded pile groups, and structural strength rapidly increases with increasing pile diameter. For friction piles, if vertical loading and associated pile-group settlement is the key consideration, then increasing the pile length will usually be more cost-effective than increasing the pile diameter. For friction piles there is a critical pile length L_t beyond which further increases in length will not reduce settlement (Fleming *et al*., 2009). L_t is approximately 1.5 $(E_p/G_L)^{0.5}$ d, where E_p is Young's modulus for the pile concrete, G_L is the shear modulus at the pile toe and d is the pile diameter. For friction piles an equally important consideration is the pile spacing. Provided ultimate group capacity is adequate, a relatively small number of widely spaced piles can provide similar pile-group stiffness as a larger number of more closely spaced piles. The design charts, shown in **Figure 55.20**, can facilitate a rapid comparison between the effectiveness of varying any of pile-group length, diameter and spacing on pile-group settlement performance. Pile spacing is often chosen to be $3d$ for conventionally designed pile groups; increasing the pile spacing to $4d$ or $5d$ may be worthy of consideration since pile interaction effects will be substantially reduced. Pile spacings below $3d$ are usually inappropriate since pile interaction effects become more significant and the potential benefits (in terms of bearing capacity and settlement) may be negligible relative to the increased costs.

In general, on the basis of observed performance (e.g. Mandolini *et al*., 2005) it is reasonable to assume that pile-to-pile interaction is negligible for practical purposes at pile spacings of $8d$ or more for both vertical and horizontal loading. At these spacings, the pile design can be based on single-pile behaviour; refer to Chapter 54 *Single piles*.

Raking piles: raking piles are sometimes used to support foundations subject to horizontal loads and they can provide a very stiff support system. Although horizontal deformation will be relatively small compared with vertical piles (under an equivalent horizontal load), the use of vertical piles is usually favoured for several practical and technical reasons:

(i) Construction tolerances tend to be far poorer for raking piles than for vertical piles. The relevant tolerances are the position and alignment tolerances, that is, comparing the intended toe position with its actual position.

(ii) Construction problems: e.g. installation damage for driven piles or potential integrity problems for bored cast *in situ* piles. Any potential problems associated with pile installation, such as groundwater inflows, pile bore instability, penetration into or through hard strata or obstructions, etc. will all be far more challenging for raking than vertical piles. Because of this, raking piles will often be more expensive and slower to install than vertical piles.

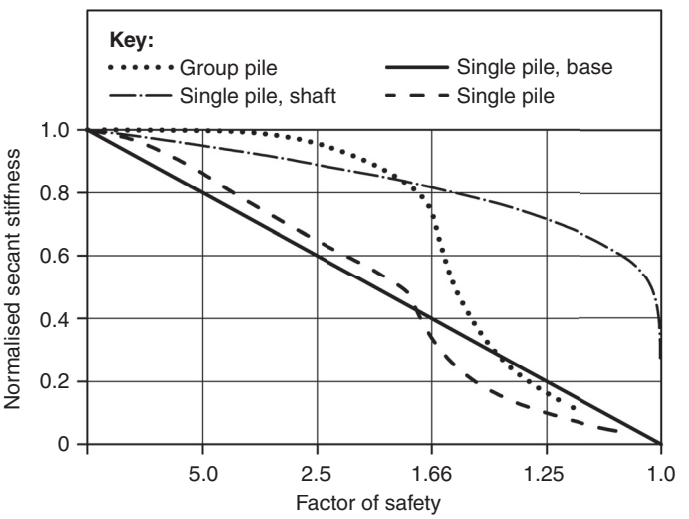
(iii) Raking piles should *not* be used in situations where there are likely to be large global ground movements, such as for bridge foundations on soft soils when adjacent approach embankments are likely to induce large vertical and horizontal ground movements (or, for similar reasons, adjacent to deep excavations); nor for heavily loaded foundations that are likely to undergo large settlement. In both situations the relative soil–pile movements are likely to induce bending stresses in the raking piles. In these circumstances, raking piles are vulnerable to being overstressed.

Raking piles were often used historically because of the lack of adequate analytical tools to assess the lateral load-deformation behaviour of vertical piles. Nowadays, there is a wide range of elastic (and nonlinear) continuum pile-group analysis software available to practitioners, which allows lateral load behaviour to be readily analysed. Therefore, for most circumstances, groups of vertical piles should be adequate. Nevertheless, there are some situations when raking piles can be cost-effective, examples include maritime applications when vertical loads may be negligible but there are substantial horizontal loads, such as for ship berthing facilities. Marine applications also

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

tend to favour the use of driven piles, which are generally better suited to being installed at a rake than bored piles.

55.9 Information requirements for design and parameter selection



Golder and Osler (1968) described the performance of five pile groups (each with 32 piles, 20 m long), which were constructed to support an industrial facility. The piles were founded at a high level in a layer of dense sand. A pile test indicated a settlement of about 1 mm at the working load and pile-group settlement was expected to be less than 10 mm. Fifteen years after construction, the observed settlements were more than 70 mm and continuing to increase. The settlement of the pile groups at each end of the row of five groups showed significant tilt, due to interaction with the adjacent pile groups. Subsequent analysis indicated that layers of compressible clay (about 3 m below the pile-toe level) were mainly responsible for the excessive pile-group settlements, which were predicted to reach 90 mm. About 80 mm, out of the total of 90 mm, was due to settlement of the underlying clay layers. This (and other) experience indicates that supporting a structure on a large pile group does not necessarily eradicate all risk of excessive foundation movement. It also highlights the importance of a proper understanding of the overall ground conditions and ground–structure interaction. Clearly, if considered in isolation, the results of a pile load test can be misleading.

The requirements for a proper desk study and comprehensive ground investigations are just as important for piled foundations as they are for other aspects of geotechnical engineering. For pile groups, an appreciation of the relative strength and compressibility of strata below the pile group is particularly important. A minimum of the pile-group width and, depending on the overall geology, up to two to three times the width should be investigated below the pile-toe level. Hence, deep boreholes may be necessary, together with careful logging and index testing at close centres, to check for weak layers within and below the anticipated bearing stratum. If lateral loading is significant, then the strength and compressibility of near-surface soils (typically the uppermost 6*d*, where *d* is the pile diameter) will be particularly important. This is challenging since near-surface soils can be very variable. Cost-effective investigations of near-surface soils will probably include some form of penetration or probing tests (refer to Chapter 47 *Field geotechnical testing*) to obtain rapid and cheap coverage across the site, together with several trial pits to facilitate interpretation.

The critical load case for pile-group design (especially for bridges and maritime structures) will often include a significant transient live load (due to, for example, vehicle impact or wind loading). For this type of short-term loading then undrained strength and stiffness parameters should be used for pile groups founded in clays.

Randolph (1994) discusses the implications of nonlinear soil behaviour on both single-pile and pile-group settlement. **Figure 55.27** summarises the output from these analyses, plotted as normalised secant stiffness versus factor of safety for a large pile group. The pile-group settlement remains relatively linear until the overall factor of safety reduces below about 1.6. At a factor of safety of 2.0, the secant stiffness for the soil within the pile group is more than 80% of the initial tangent stiffness. The relationship between choice of elastic modulus and pile-group size is shown schematically in **Figure 55.28**. **Table 55.4** provides guidance on the selection of the appropriate linear elastic moduli for single piles and pile groups of varying size at different factors of safety.

For lateral loading, the pile-group behaviour can be more strongly influenced by soil stiffness degradation. For linear

NB.
Normalised secant stiffness = 1.0, when G_{mob} (E_{mob}) = G_0 (E_0); G_{mob} = mobilised shear modulus, G_0 = shear modulus at very small strain.
E = Young's Modulus. For large pile group (>25 piles)

Figure 55.27 Normalised secant stiffness versus factor of safety. Nonlinear settlement for a single pile and a pile group
Modified from Randolph (1994)

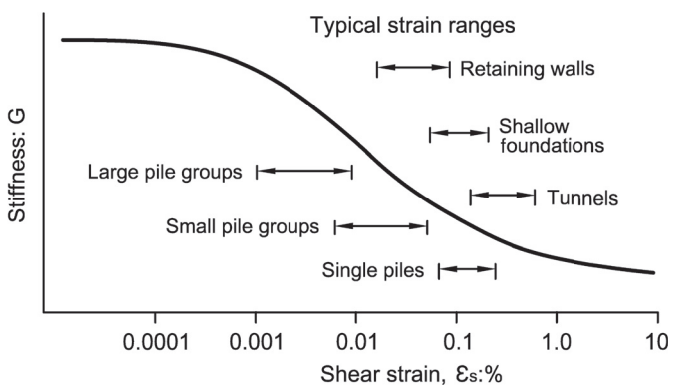


Figure 55.28 Influence of pile-group size on the selection of the appropriate 'elastic' modulus

Factor of safety	G/Gmax		
	Single pile	Small- to medium-sized pile group	Large pile group
> 5.0	> 0.6	0.7 to 0.8	> 0.9
3.0	0.4 to 0.5	0.6 to 0.8	0.8 to 0.9
2.0	0.3 to 0.45	0.5 to 0.7	0.7 to 0.8

Notes:
The above values are for vertical loading and are intended as preliminary guidance only. A small- to medium-sized pile group has 5 to 25 piles. A large pile group has more than 25 piles. G_{max} is the shear modulus at very small strain for vertical shear. The values are relevant for linear elastic analysis and they assume the pile spacing is 3d. As the spacing increases, the guide values will be increasingly conservative.

Table 55.4 Tentative values of shear modulus ratio (G/Gmax)

elastic analyses, this can be crudely replicated by selecting a large strain (say a strain amplitude of 1% or above) stiffness for the soil adjacent to the top of the pile, and an intermediate strain (say a strain amplitude of 0.1%) stiffness for the soil at a depth equal to the critical pile length L_c with a linear variation between these levels. For laterally loaded pile groups, the sensitivity of pile bending moments and group deformation to variations in shallow soil stiffness (within the upper 6d to 10d, where d is the pile diameter), perhaps by doubling and halving soil stiffness compared with a best estimate, should be checked. For critical situations, specialist advice should be sought and more sophisticated nonlinear analyses may be required. Fleming *et al*. (2009) suggest assuming shear moduli for lateral loading that are a factor of two lower than those used for axial loading, in recognition of the high strain levels, which will develop locally adjacent to the top of a laterally loaded pile. An alternative recommendation by Fleming *et al*. (2009) is to assume zero shear modulus at the ground surface, increasing to the full value for axial loading at a depth equal to L_c (the critical pile length for lateral loading). Hardy and O'Brien (2006) discussed the influence of soil nonlinearity on the predictions of bending moment in pile groups subjected to horizontal loads. **Figure 55.29** shows that the pile bending moments are sensitive to the soil constitutive model (hyperbolic or linear elastic) and, for the linear elastic model, the magnitude of the selected moduli. If the design is substantially influenced by lateral load effects then nonlinear analyses offer the possibility of more economic design and more realistic predictions of pile-group deformation (O'Brien, 2007). However, these analyses are more challenging and will require specialist input and guidance. The above observations are consistent with those reported elsewhere (e.g. Mandolini *et al*., 2005). Clearly, for lateral loading when using linear elastic analyses a cautious approach is needed and some checks on the sensitivity of pile-group deformation and pile stresses to variations in shear modulus are essential.

When considering the selection of input parameters for pile-group analysis, and, in particular, comparing single pile with

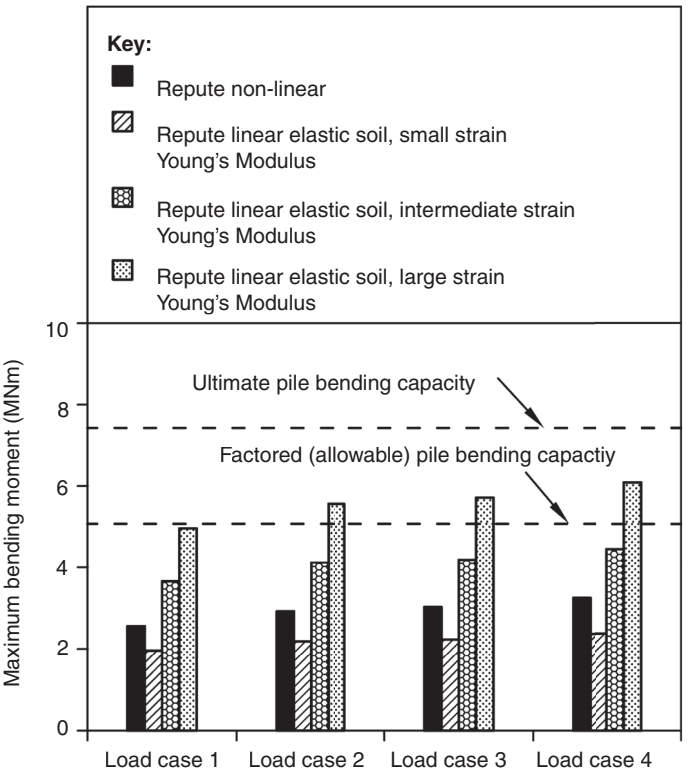

Figure 55.29 Influence of soil model and selected Young's modulus on the peak bending moment under horizontal loading
Reproduced from Hardy and O'Brien (2006)

group performance, it is helpful to consider the different regimes that will influence behaviour, **Figure 55.30**, and the relevant information, which will be needed for making decisions. Five separate zones, and associated moduli, can affect behaviour:

(i) The secant stiffness of the soil or rock close to the pile shaft. The stiffness of this zone will strongly influence the settlement of a single pile at typical working loads. This zone will be affected by the construction process (remoulding and horizontal stress changes), either due to pile boring or pile driving.

(ii) The stiffness of the soil or rock close to the pile base. The stiffness of this zone is dominated by the construction process and is more sensitive to the construction process than shaft stiffness. The base stiffness will be important for end-bearing piles; however, for many piles (which often gain significant shaft resistance) the base stiffness only becomes influential at low factors of safety. For driven piles the base stiffness will be relatively high, compared with the original soil stiffness. For bored piles, the ground stiffness will tend to be lower, sometimes much lower, than the original soil or rock stiffness, and will be dependent on factors such as the effectiveness of base cleaning activities (Fleming, 1992).

(iii) The stiffness of the ground close to the ground surface, will strongly affect pile behaviour under horizontal

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

loading. Ground investigations frequently overlook the characterisation of this zone and it can be heterogeneous. It should also be emphasised that site redevelopment (excavation and filling) will often change the nature of this zone. Pile concrete stiffness under lateral loads will tend to be lower (due to yield, creep and cracking) than that for compression.

(iv) Soil stiffness between the piles. The stiffness of this zone is important for pile-group settlement. This zone will not be significantly affected by construction activities. As noted earlier, the relevant modulus, for linear elastic analysis, will be close to the very small strain stiffness of the soil or rock and will also depend on the pile-group size.

(v) Soil stiffness well below the pile-toe level. As for (iv) this zone will not be affected by construction activities. It will not affect the behaviour of single piles, but will influence pile-group behaviour. The settlement of pile groups with a large pile-group aspect ratio will be strongly influenced by these deeper layers.

Hence, the information required will involve a consideration of:

(i) Construction effects and the back analysis of single-pile behaviour (for example, Fleming, 1992; England, 1999). For laterally loaded piles, tests on single piles will usually be free headed whereas piles in a group will generally be fixed headed. This different head fixity must be allowed for when comparing isolated piles and pile-group behaviour.

(ii) Data from relevant case histories (for example, Mandolini *et al.*, 2005). Case histories are particularly useful for calibration of software. Software calibration is particularly important for large pile groups or more sophisticated non-linear analytical methods.

(iii) Site-specific ground investigation data. Useful additional data (although seldom provided by routine investigations) would be measurements of G_0 or G_{max}. Modern empirical correlations (for example Atkinson, 2000) are helpful for the selection of the appropriate moduli.

Pile capacity is mainly dependent on local conditions at the pile–soil interface, which are strongly affected by construction methods and exhibit significant variability (NCHRP Report 507, 2004). In contrast, pile-group stiffness is determined primarily by far-field conditions, and is relatively unaffected by construction processes (**Figure 55.31**). Hence, pile-group deformation can be more reliably predicted than the ultimate capacity of a single pile (Randolph, 2003). This is in stark contrast to many other aspects of geotechnical engineering (such as predicting movements around retaining walls or shallow foundation movements), where predicting movement is perceived as more difficult than predicting ultimate capacity.

Piles around the perimeter of a pile group tend to carry higher loads than those in the centre. Hence, it would usually

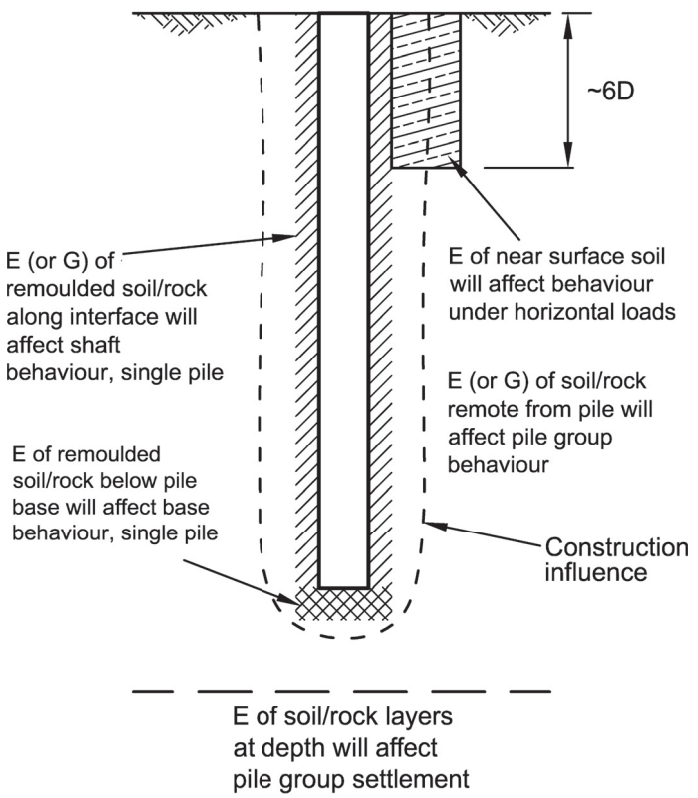

Figure 55.30 Different ground moduli that may influence single-pile and pile-group behaviour

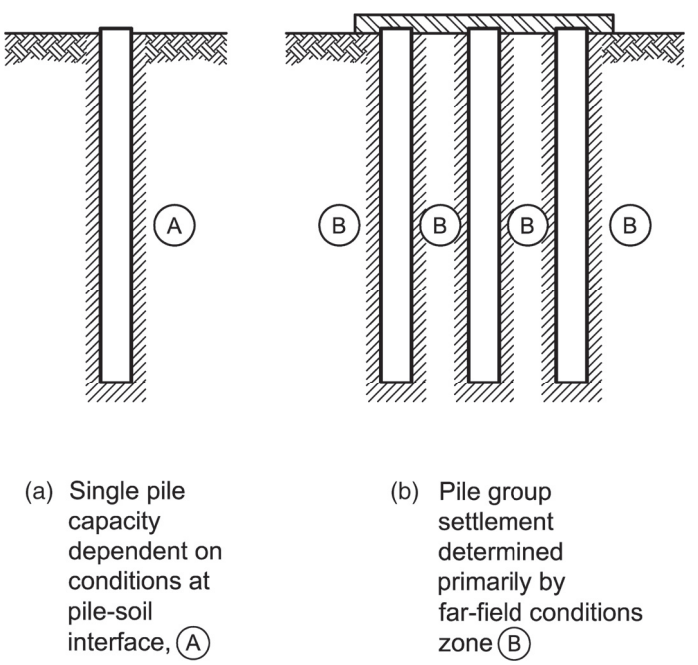

Figure 55.31 Influence of (a) the pile–soil interface on single-pile capacity and (b) far-field conditions on pile-group settlement
Reproduced from Randolph (2003)

be appropriate to focus most of the pile testing effort (both integrity and load tests) on the perimeter piles.

55.10 Ductility, redundancy and factors of safety

Burland (2006) highlighted the profound importance of understanding the mode of foundation failure mechanisms. Routine geotechnical and structural engineering practice is based on the assumption of ductile behaviour. The load-settlement behaviour of pile foundations is usually ductile. However, this is not always the case; for example, experience indicates that some rock socket piles can exhibit brittle behaviour, examples include: piles socketed into some rocks, such as limestone and sandstone; or end-bearing piles toed into thin competent strata and underlain by soft clays. If brittle behaviour is anticipated then a cautious approach is essential. Rather than summing shaft friction and end-bearing capacity, it would be more appropriate to consider a deformation-based capacity (i.e. discounting some fraction of either shaft or end-bearing resistance). Preliminary pile tests to failure would clearly be helpful. Pile-group design would need to limit pile-group deformation to ensure brittle failure was not induced.

For more normal situations, when pile load-settlement behaviour is ductile, the following issues will influence the selected factors of safety:

(i) pile-cap and sub-structure stiffness;

(ii) number of piles in the group (i.e. level of redundancy);

(iii) code requirements;

(iv) nature and direction of applied loading, e.g. cyclic or monotonic loads, vertical or horizontal loads;

(v) analysis methods;

(vi) reliability and scope of ground investigations.

Table 55.5 gives a commentary on the above issues.

Many codes and standards do not make specific statements about factors of safety for pile-group design. However, Eurocode 7 provides the following (Clause 7.6.2.1):

- The stiffness and strength of the structure connecting the piles in the group shall be considered when deriving the design resistance of the foundation.
- If the piles support a stiff structure, advantage may be taken of the ability of the structure to redistribute load between the piles. A limit state will occur only if a significant number of piles fail together; therefore a failure mode involving only one pile need not be considered.
- If the piles support a flexible structure (or flexible pile cap), it should be assumed that the compressive resistance of the weakest pile governs the occurrence of a limit state.
- Special attention should be given to possible failure of edge piles caused by inclined or eccentric loads from the supported structure.

In general, the axial loads calculated by linear elastic analyses should *not* be compared with the geotechnical capacity of individual piles. As noted by Burland (2006), when attempts are made to satisfy conventional factors of safety for each and every pile in a pile group (compared with axial loads from linear elastic analyses), then the result is a grossly conservative pile-group design with significant (and unnecessary) cost increases. A pragmatic solution for small vertically loaded pile groups is to design the piles and pile cap to have sufficient structural strength (compared with predicted forces from elastic analysis), and then check that the overall geotechnical capacity for the group (the sum of individual piles or block enclosing the group perimeter, whichever is less) satisfies the code factor of safety against geotechnical failure. For large pile groups (in excess of 25 piles) with rigid pile caps, nonlinear analyses can provide more realistic axial load distributions. For large pile groups, the flexibility

Factor	Comment
Pile-cap and sub-structure stiffness	A stiff pile cap or sub-structure can redistribute axial loads; hence, the individual pile factor of safety is not significant. If the pile cap is flexible then individual pile factors of safety need to be considered.
Number of piles in the group	If more than 5 piles, then there is redundancy and 'failure' of a pile within group does not imply failure of the group. For large pile groups there is considerable redundancy.
Code requirements	Many codes do not discuss pile groups in detail and mainly focus on single piles. EC7 provides some guidance, see text. AASHTO (and NCHRP Report 507, 2004) gives guidance on reduced risk of failure associated with varying levels of redundancy.
Direction of loading	For horizontal and moment loading, carefully check structural strength of piles, pile-cap and pile-to-pile cap connections. A factor of safety in excess of 1.3 to 1.4 along the perimeter pile row should be met if large long-term moment loading, to avoid excessive group rotation in the long term (creep).
Analysis method	For nonlinear methods reliable calibration of model is important. Use simple methods to check factor of safety against failure. Computer-based methods more appropriate for assessing deformation and stresses induced in piles.
Reliability and scope of ground investigations	Most important factor to consider. Especially important to verify the strength and stiffness of layers below the pile group. Near-surface materials important for laterally loaded pile groups. The greatest uncertainty lies with establishing the geological model, the idealisation of the ground profile for analysis and the selection of appropriate geotechnical parameters.
Nature of loading	Guidance in this chapter is solely for pile groups with predominantly static, monotonic loading. Under prolonged cyclic loading, significant degradation of shaft resistance can occur, with associated substantial increases in deformation and reductions in ultimate capacity (Jardine, 1991).

Table 55.5 Factors that may influence the factor of safety for a pile-group

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

of the pile cap can substantially influence the axial load distribution and should be checked. Hence, for vertically loaded pile groups, a key issue is to check that the pile cap has adequate structural strength and stiffness to be able to safely redistribute the axial load across the group, and then the geotechnical factor of safety need only be applied to the overall group resistance, *not* to individual piles. For pile groups subject to moment or horizontal loads, the geotechnical resistance of the outer rows of piles should be checked (again the geotechnical capacity of individual piles does not need to be considered).

In the context of assessing an appropriate geotechnical factor of safety for axial resistance, the redundancy of a foundation system is also an important consideration. Design guidance in the USA (NCHRP Report 507, 2004) suggests that a fully redundant pile group (of more than five piles) requires a factor of safety of about 70% of that for a single pile, based on achieving the same overall reliability (i.e. the statistical probability of failure is the same). This is a logical consequence of the inherent variability of the geotechnical capacity of individual piles, given the significant influence of construction methods on ultimate resistance. If the consequence of pile failure is severe, say a single pile supports a bridge pier (where there may be limited opportunity for load redistribution), then the appropriate factor of safety may need to be larger than the code requirement. It follows that for a large pile group (say 25 or more piles) with a stiff pile cap, then the appropriate geotechnical factor of safety for axial resistance could be lower than normally required. However, for large pile groups the geotechnical factor of safety is unlikely to be critical; pile-group deformation and structural forces induced in the piles and pile cap are likely to be more critical.

The structural strength of piles, pile cap and pile-to-pile cap connections should always be checked and be sufficient to resist the induced axial forces, bending moments and shear forces. For pile groups subject to large moment or horizontal forces this is particularly important, since inadequate structural strength in any part of the overall foundation system could lead to a brittle and progressive collapse of the structure.

55.11 Pile-group design responsibility

Two options are normally considered: contractor's design or engineer's design.

(a) *Contractor's design* – This is commonly used, especially for small building projects. The engineer employed by the client as the overall project designer will provide the piling tenderers with relevant information, including: site history, ground conditions, applied structural loads, acceptance criteria for pile loading tests, etc. Then the contractor is responsible for detailing the appropriate pile length, diameter and reinforcement to resist the specified loads. The pile-cap is usually designed by the overall project designer.

(b) *Engineer's design* – Under this arrangement, design responsibility lies with the overall project designer, who would design and detail the pile lengths, reinforcement, etc. This arrangement is often followed for major civil engineering projects, such as bridges or large building projects. The contractor is responsible for workmanship and method of construction.

There are advantages and disadvantages with both options. The specialist piling contractor will have a lot of expertise on how to best utilise his materials, plant and labour. He may also have local experience on the likely pile capacities that can be achieved in particular geological sequences. Therefore option (a) will favour those situations where the geotechnical pile capacity is the dominant consideration, where buildability is very challenging (due to poor access, etc.) or if particular proprietary piling systems are well suited to local conditions. Option (a) is less appropriate if pile-group deformation is critical or if there are broader ground–structure interaction problems (due to complex loading or if global ground movements are a concern). A particular problem with option (a) for pile-group design is the appropriate specification of pile loads and pile test acceptance criteria. For example, axial loads will not be uniform across the group, and the stresses induced in the piles and pile cap will be a function of the pile length, diameter, etc., and the pile-cap bending stiffness. The deformation of the pile group is dependent on several factors and not just the settlement characteristics of an isolated pile. Hence, the overall designer needs to have a good understanding of these soil–structure interaction issues before realistic and sensible specification requirements for pile capacity and settlement (for an isolated pile) can be developed. In many cases, if design responsibility is to be split then it is more appropriate to split responsibility at the top of the pile-cap level rather than at the top of the pile level. The overall designer then only needs to specify the appropriate loads at the pile-cap level, and the acceptable limits for overall pile-group deformation and differential settlement across the pile cap. Option (b) will also be more appropriate for large pile groups or for pile groups underlain by compressible layers (where single-pile performance cannot be easily correlated with pile-group performance).

55.12 Case history

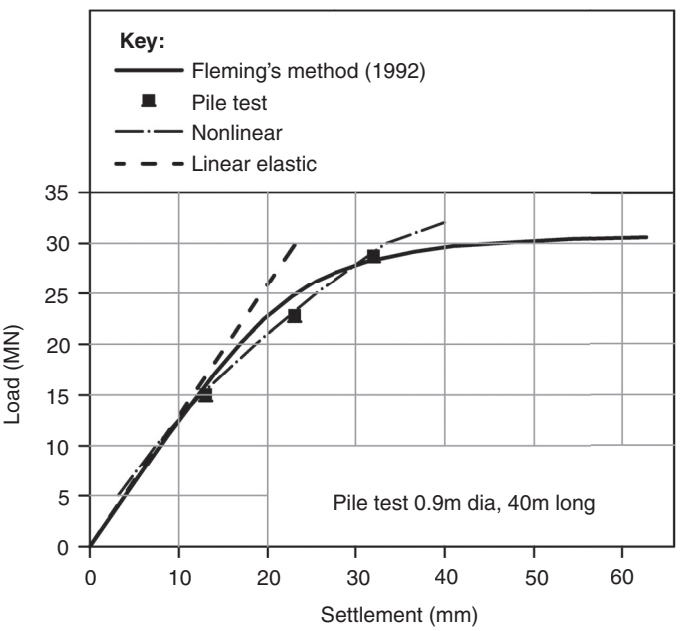
Pile-group analyses are briefly described for the Emirates Twin Towers in Dubai and they are compared with observed performance. The foundation design is described in detail by Poulos and Davids (2005).

The ground conditions mainly comprise interbedded calcareous sandstone and siltstone. The measured unconfined compressive strength is variable and typically between about 0.5 MN/m^2 and 1.5 MN/m^2. The stiffness at very small strain was measured by cross-hole geophysical tests and shear moduli varied between 2 and 3.5 GN/m^2. A summary of the ground profile is given in **Table 55.6**. The twin towers were founded on two triangular-shaped pile groups comprising 92 and 102 1.2-m-diameter piles, 40 m long. The estimated ultimate geotechnical capacity of a single pile was about 42 MN.

Strata number	Strata designation	Typical depth of strata base (m bgl)	Description
1	Silty sand	5	Uncemented calcareous silty sand, loose to moderately dense
2	Sand	10	Variably and weakly cemented calcareous silty sand
3	Calcareous sandstone	29	Calcareous sandstone, slightly to highly weathered, well cemented
4	Cemented sand (?)	35	Calcareous silty sand, variably cemented, with localised well cemented bands
5	Calcareous siltstone and conglomerate	56	Variably weathered, very weakly to moderately well cemented
6	As Unit 5	70	As Unit 5

Table 55.6 Case history: ground profile

Strata	Linear elastic[1]	Nonlinear[2]	
	Secant Young's modulus (MN/m²)	Tangent Young's modulus (small strain) (MN/m²)	Interface Strength τ(kN/m²)
Silty sand	15	20 + 8Z	20 + 5.5Z
Sand	50		
Calcareous sandstone	250	1500 + 40Z	150 + 12Z
Cemented sand (?)	50		
Calcareous siltstone and conglomerate	200	3000 + 50Z	500



Notes:
1. Linear elastic model, pile base stiffness, E′ = 40 MN/m².
2. Non-linear model, hyperbolic constants, *R* shaft = 0.65, Rbase = 0.99, maximum shaft friction = 500 kN/m², maximum base pressure = 2700 kN/m² and pile base modulus E'_0 = 750 MN/m² (E'_0 = small strain tangent stiffness).

Z is the depth below the ground surface.

Table 55.7 Linear elastic and nonlinear input parameters used in the REPUTE analyses of the case history

Based on data published by Poulos and Davids (2005) two different analyses have been carried out, the first using a computer-based method and the other using a simple empirical method. The computer-based analysis, using the software REPUTE, was used with two different models to simulate the stress–strain behaviour of the ground. The models were a linear elastic model and a nonlinear hyperbolic model. The input parameters are summarised in **Table 55.7**. The load-settlement behaviour of a single pile was modelled initially and calibrated against preliminary pile test data for a 0.9 m-diameter, 40-m-long pile, **Figure 55.32**, prior to modelling the entire pile group. For the single-pile calibration, Fleming's method (Fleming, 1992) was helpful in deriving reasonable nonlinear parameters for use in the hyperbolic model.

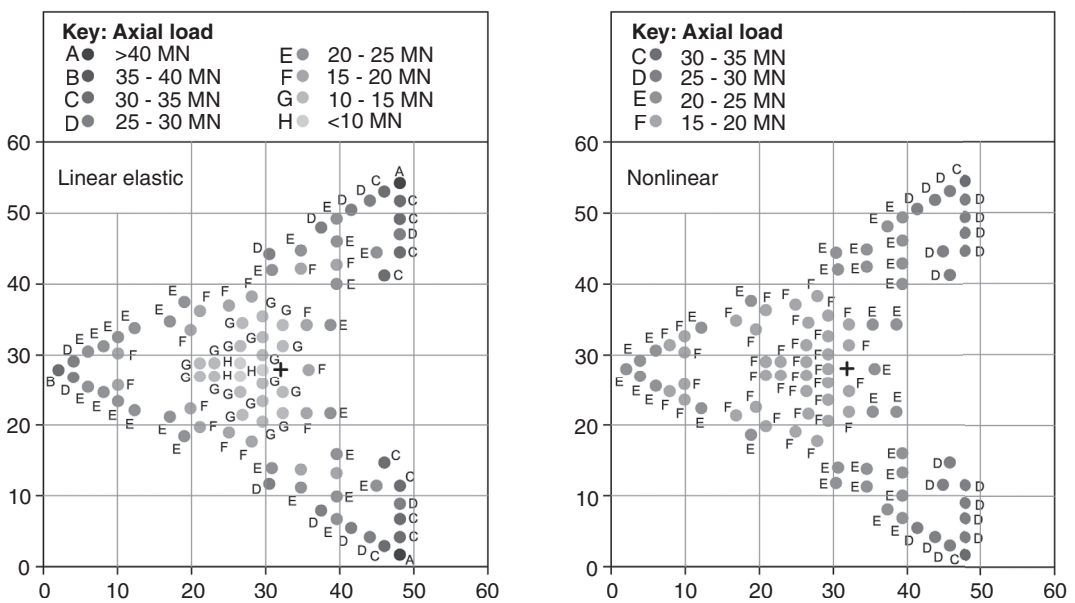
The analysis predictions of the axial load distribution across the pile group and the pile-group settlement are summarised in **Figure 55.33**. The linear elastic analysis predicts a highly non-uniform distribution of the axial load; in particular, axial loads in the corners are especially large. The linear elastic analysis predicts maximum axial loads of 43 MN compared with a maximum of 31 MN from the nonlinear analysis. The ratio of corner to central pile axial load from the linear elastic analysis is about 5, and for the nonlinear analysis, it is about 2. Hence, the local factor of safety for a pile in the group (based on linear elastic analysis) is less than 1.0, although the overall factor of safety for the pile group is about 2.0. This is similar to the results from boundary element analysis reported by Poulos and Davids (2005), where they state that 'a number of the piles reached their full geotechnical design resistance (i.e. the factor of safety for some piles was about 1.0), but the foundation

At a load of 15MN, Geo Factor of safety ~ 2.0	
Analysis/Data	Settlement (mm)
Linear elastic	11.6
Nonlinear	12.3
Pile test	12.9

Figure 55.32 Case history: pile test in weak rock

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

as a whole could still support the ultimate design loads'. The pile-group settlement was observed to be about 8 to 10 mm after 70% of the load had been applied, and the estimated final settlement is between 20 and 40 mm. The nonlinear analysis indicates a settlement of 25 mm, compared with 55 mm from the linear elastic analysis (**Figure 55.33**).



The pile-group aspect ratio is about 2.9 and Mandolini's empirical correlations for pile-group settlement (refer to section 55.5.2) gives settlement ratios R_{se} between 4 and 7. Based on the site geology (weak rock with stiffness increasing with depth) the best-estimate and lower-bound pile-group settlement ratios are relevant (equations (55.9) and (55.12)). The single-pile settlement at the average working load of 21 MN is about 10 to 11 mm. Hence, based on Mandolini's empirical method, the pile-group settlement would be expected to be between about 40 and 75 mm. Although conservative relative to observations and the estimated final value, it is more accurate than the designer's original estimate of about 90 to 140 mm (based on a linear elastic boundary element analysis). Poulos and Davids describe the two main reasons for the initial overprediction using boundary element analysis:

(i) overestimation of pile-to-pile interaction;

(ii) underestimation of the ground stiffness for Unit 5 (**Table 55.6**).

Poulos and Davids produced revised analyses where the stiffness varied radially from each pile, so that the ground stiffness between the piles was five times stiffer than that adjacent to the piles (to values of about 2 to 2.5 GN/m^2, i.e. close to the geophysics, G_0, values), and the ground stiffness for Unit 5 was increased from 80 to 600 MN/m^2. This revised analysis indicated a settlement of between 23 and 40 mm, (allowing for differential settlement across the pile cap). With the benefit of hindsight, it seems likely that the laboratory-measured stiffness for Unit 5 was too low because of sample disturbance.

This case history re-emphasises the challenges in deriving realistic ground stiffness values, especially in weak rocks, and the potential errors even when sophisticated analyses are utilised. It also highlights the value of simple empirical methods to check computer output. It is likely that the axial loads around the perimeter of the pile group were high and the factor of safety against geotechnical failure for the perimeter piles was much lower than code values (nonlinear analyses predict 'local' factors of safety of about 1.3 to 1.4 for the perimeter piles). Nevertheless, the overall group factor of safety is code compliant (equal to about 2.0), the piles and pile cap have adequate strength and stiffness to redistribute forces across the group and therefore the overall pile-group performance has been satisfactory.

1.2m dia piles, ultimate capacity ~42MN, Geo Facor of Safety for group ~2.0		
	Peak Axial Load	Group Settlement (mm)
Linear elastic	43MN	55mm
Nonlinear elastic	31MN	25mm
Estimated settlement (*in situ* measurements) ~20 to 40mm

55.13 Overall conclusions

- The overall behaviour of pile groups is affected by their geometry. An important parameter is the pile-group aspect ratio (**Figure 55.3**). Where R is large, the group settlement will be many times larger than the settlement of an isolated pile (at the same average load). For pile groups with a large aspect ratio, $R > 3$, then an 'equivalent raft' analogy is appropriate for simplified analyses; where R is < 3 then an 'equivalent pier' analogy will be more appropriate.
- The failure of pile groups is rare; the risk of failure increases when: global movements develop around the group (typically for out-of-balance loads on soft clays and peats); end-bearing piles toed into a thin competent layer are underlain by soft clay; or piles are toed into steeply dipping fractured rock or rock containing voids.
- Pile-to-pile interaction, under vertical or horizontal loads, depends on many factors (**Table 55.1**), including pile spacing and the variation of ground stiffness with depth, especially 'hard' or 'soft' layers beneath the pile toe (for vertical loads) or adjacent to the pile head (horizontal loads). For horizontal loads, the pile head fixity is important, whereas for large pile groups under vertical loads the pile-cap stiffness is important.
- For small- to medium-sized vertically loaded pile groups (say, less than 16 to 25 piles), linear elastic analysis will usually be adequate for a practical design. However, for larger groups or pile groups subject to large horizontal loads, linear elastic analyses are likely to be inappropriate. For small- to medium-sized pile groups simplified methods of analysis (based on empirical settlement ratios, elastic interaction factors or an equivalent pier) will often be sufficient to calculate the group settlement.
- When considering the selection of input parameters for pile-group analysis, it is helpful to consider the five separate zones (and associated deformation moduli) that can affect behaviour (**Figure 55.30**): (i) the stiffness of the ground adjacent to the pile shaft, (ii) the zone immediately below the pile toe, (iii) the stiffness of the ground close to the pile head, (iv) the ground stiffness between the piles and (v) the ground stiffness at depth below the pile-toe level.
- The appropriate values for factors of safety selected for pile-group design depend on several factors, refer to **Table 55.5**. These include pile-cap and sub-structure stiffness, the number of piles in a group (redundancy), code requirements, the nature and direction of loading, analysis methods and the reliability and scope of ground investigations. In addition, the ductility or brittleness of pile load-settlement behaviour is an important consideration.
- If design responsibility is split for pile-group design then careful thought is required regarding the most appropriate point to divide responsibility (pile-head or pile-cap level). When pile-group deformation is critical, or if global ground movements or complex loads are applied, then pile and pile-cap design should be considered together, so that the soil–structure interaction is properly assessed.

Rafts can provide a very cost-effective foundation solution. Their design requires a careful assessment of the soil–structure interaction. Many factors, including soil and raft stiffness, superstructure and sub-structure stiffness, local yield and soil nonlinearity and time-dependent effects, can influence differential settlement and structural forces in the raft. Errors associated with assuming that a raft sits on a bed of uniform soil 'springs' are discussed, and a practical alternative is outlined.

Piled rafts, which are a hybrid foundation comprising a raft and piles, can offer many benefits. Currently there is little guidance in the codes and there is confusion about appropriate design methods. Piled-raft behaviour is potentially very complex. Significant simplifications are possible, which facilitate practical design and greater confidence in analysis output. A key aspect is a clear definition of two different types of piled raft: the raft-enhanced pile group and the pile-enhanced raft (previously known as a raft with settlement-reducing piles). The design concepts for each type of piled raft are very different. The intermediate zone between these two types should be avoided.

56.1 Introduction

This chapter provides guidance on the design of rafts and piled rafts.

Chapter 52 *Foundation types and conceptual design principles* describes the main foundation types, which include shallow foundations such as pads or strip footings and deep foundations such as piles. If individual pad or strip footings are relatively large or closely spaced it may be more practical and cost effective to create a single reinforced-concrete raft beneath the structure. The rule of thumb that is commonly used is that if the pad or strip footings occupy more than about half of the superstructure footprint, then it is usually more appropriate to use a raft. However, site-specific issues may change this simple criterion. The four main reasons for using raft foundations are:

(i) The individual excavations for numerous pad or strip footings are relatively close to one another, and for construction purposes it is easier to create a single large excavation.

(ii) The differential settlement between individual footings is excessive, and the use of a relatively rigid raft is needed to minimise differential settlement to a tolerable value. As noted in Chapter 53 *Shallow foundations* (Figure 53.8) it is necessary to check the influences of the interaction between pads and strips when assessing the overall settlement and differential settlement of a structure. Figure E1.10 indicates that buildings on raft foundations have withstood large total settlements (in excess of 100 mm) with negligible damage, because the bending stiffness of the raft has been sufficient to reduce differential settlement to tolerable levels.

(iii) There is a reduced risk of damaging differential settlements in heterogeneous ground conditions: in some situations it may be difficult to confidently assess the likely total and differential settlement, and past experience has shown that rafts can provide effective and economic foundations that mitigate this risk. An example is the use of rafts for house foundations on deep layers of non-engineered fill (refer to Chapter 58 *Building on fills*), sometimes with the building weight balanced by partial excavation to reduce the net imposed load. There may be other situations where it is deemed appropriate to use rafts in order to minimise the risk of damage due to site-specific geohazards, refer to Chapter 52 *Foundation types and conceptual design principles.*

(iv) There is a reduced risk of bearing-capacity failure and excessive settlement or differential settlement through using cellular rafts in soft clays: the raft is placed at the base of an excavation and the building weight is compensated for by the weight of soil that is excavated.

Piled foundations are often used because there is a concern about excessive settlement of shallow foundations, even though a raft would have an acceptable factor of safety (FoS) against bearing-capacity failure. Conventional design of the pile group would then ignore the resistance provided by the pile cap or raft, and solely consider the resistance provided by the piles (refer to Chapters 54 *Single piles* and 55 *Pile-group design*); i.e. all the design load is transferred through the piles. In the past two decades there has been increasing recognition that this conventional assumption is overly conservative when shallow foundations can be founded on competent soils (such as stiff clays). It is now known that a hybrid foundation can be designed, which makes use of both a raft and piles, and allows for load sharing between the raft and piles. This foundation

type is usually known as a piled raft. Unfortunately, current codes and standards do not provide specific guidance on piled-raft design, and there are still some misunderstandings about the design of piled rafts. The main intent of this chapter is to provide clear and coherent guidance on the key concepts that should be used for piled-raft design.

There are several reasons why a piled raft may be used:

(i) to minimise total settlement, and, in particular, differential settlement;

(ii) to reduce bending moments and shear forces in the raft (especially effective where there are a small number of heavily loaded columns);

(iii) a further practical advantage from (ii) above is that the raft thickness can be minimised, overcongested reinforcement can be reduced, and, perhaps, excavation below the water table avoided.

This chapter builds upon many of the design issues described in Chapters 53 *Shallow foundations*, 54 *Single piles* and 55 *Pile-group design* and it is assumed that these will be referred to by the reader. This chapter is split into the following sections:

56.2 – *Analysis of raft behaviour*: describes the main soil–structure interaction issues that affect raft design and particularly the pitfalls associated with a 'raft on springs' design approach.
56.3 – *Structural design of rafts*: introduces the key practical design and detailing issues for raft design.
56.4 – *Design of a real raft:* reviews the main steps in the design process and buildability considerations, and includes a mini case-history example.
56.5 – *Piled rafts, conceptual design principles*: this outlines fundamental differences in behaviour between different types of piled raft, provides a new terminology for piled rafts, and gives guidance on appropriate ground conditions.
56.6 – *Raft-enhanced pile groups:* summarises the main design issues and outlines appropriate design approaches, including those for compensated raft-enhanced pile groups.
56.7 – *Pile-enhanced rafts:* introduces a simple design approach.
56.8 – *Case history*: of a pile-enhanced raft.
56.9 – *Key points:* provides a summary of the main design issues.

56.2 Analysis of raft behaviour

56.2.1 Design requirements

Raft design requires an assessment of:

(i) total settlement, and, particularly, differential settlement;

(ii) bending moment and shear forces across the raft, either due to uniformly distributed loads or concentrated loads from superstructure columns;

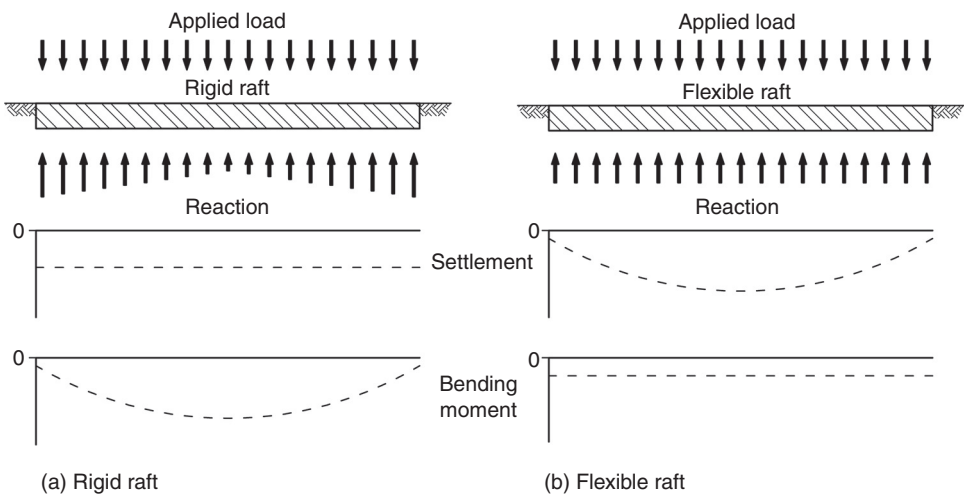
(iii) practical issues related to the thickness of the raft, the density of reinforcement, location of the groundwater table, size of excavation, etc.

Total settlement can be assessed by the methods of analysis outlined in Chapter 53 *Shallow foundations*; (iii) above will be discussed in more detail in section 56.4 below. The next section focuses on the assessment of differential settlement, bending moment and shear force. Initially some of the key soil–structure interaction issues will be discussed together with the pitfalls associated with commonly used 'raft on spring' methods. Finally, a practical approach to raft–soil interaction analysis will be described.

56.2.2 Raft–soil interaction

Several different factors can influence raft differential settlement, bending moments and shear forces, and these include:

(a) the relative soil–raft stiffness, **Figure 56.1** and **56.2**;



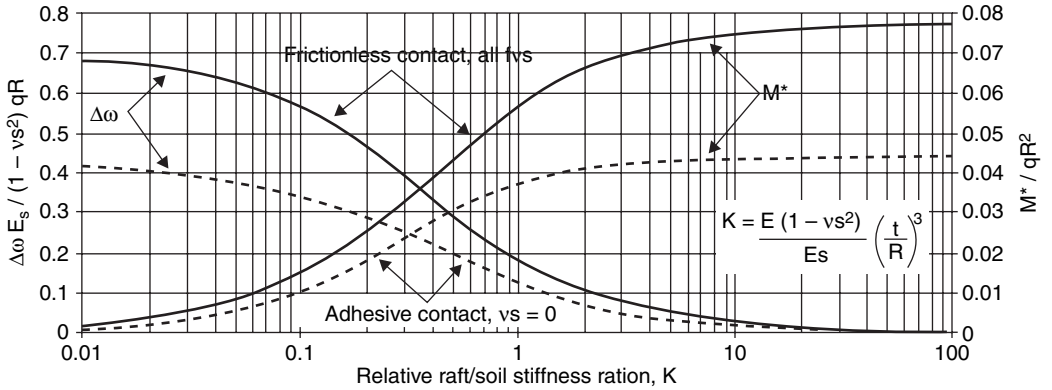


Figure 56.1 Influence of raft stiffness on behaviour

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

NB.
"Adhesive" contact means full soil strength mobilised at raft-soil interface, this is not an appropriate assumption for design purposes.
M* = maximum raft bending moment, Δω = diffenrential settlement
E, ν = Young's modulus and Poisson ratio respectiverly, for raft
Es, νs = Young's modulus and Poisson ratio respectively, for soil
t = raft thickness, R = raft radius

Figure 56.2 Maximum differential settlement ($\Delta\omega$) and bending moment (M^*) for a uniformly loaded circular raft on a deep elastic layer
Data taken from Brown (1969) and Hooper (1974)

(b) the influence of the superstructure or sub-structure stiffness on the 'effective' raft stiffness, **Figure 56.3**;

(c) the influence of variations in the soil stiffness and the thickness of the compressible layer;

(d) the influence of soil nonlinearity and local yield, **Figure 56.4**.

Figure 56.1 illustrates the fundamental influence of the raft stiffness on differential settlement and bending moment. For a raft that is practically rigid, **Figure 56.1(a)**, the differential settlement is negligible, but the maximum bending moment is very high. In contrast, for a raft that is practically flexible, **Figure 56.1(b)**, the differential settlement is large, and the bending moment is zero. The stiffness of many real rafts will be between these two extremes, and then the relative soil–raft stiffness and soil–structure interaction needs to be considered.

Figure 56.2 shows the variation of differential settlement and maximum raft bending moment for a uniformly loaded circular raft on a deep elastic soil layer, based on studies by Brown (1969) and Hooper (1974). This indicates that for the relative soil–raft stiffness $K < 0.1$ the raft is effectively 'flexible' (and therefore ineffective in reducing differential settlement) and for $K > 5$ the raft is practically rigid (and therefore differential settlement is negligible). For the zone $0.1 < K < 5$ the relationship between the raft bending moment and differential settlement changes rapidly. The practical value of these sorts of charts is that:

- A simple calculation of K can indicate if the raft is sufficiently stiff to limit differential settlement to acceptable values.
- For rafts at either extreme, very simple models can be used to assess both structural forces and foundation settlement, since the soil–structure interaction has a limited effect.
- For rafts of intermediate stiffness ($0.1 < K < 5$) a more sophisticated method of analysis will be necessary, since the soil–structure interaction will have a dominant effect on raft behaviour.

A general approach to calculating K for rectangular rafts of varying aspect ratios is given in Chapter 53 *Shallow foundations*.

Figure 56.3 illustrates the importance of properly assessing how the sub-structure or superstructure may contribute to the 'effective' stiffness of the raft. The raft is only 0.76 m thick, and would be expected to be flexible given its small t/B ratio (t is raft thickness and B is its width or length). However, agreement between measured and computed differential settlement was only obtained by allowing for the high bending stiffness of the lowermost two storeys of the structure, which comprised stiff continuous shear walls. The actual differential settlement was negligible, but only at the expense of relatively high bending moments, which would be underpredicted if the sub-structure stiffness had been ignored. The influence of the superstructure or sub-structure on raft behaviour will depend on their relative stiffnesses, as discussed by Brown and Yu (1986), Lee and Brown (1972), Fraser and Wardle (1975), amongst others. Hence, as for the case above, the stiffening effect of rigid reinforced-concrete shear walls on the raft is significant; whereas for a flexible light steel-framed structure the effect on raft behaviour will be small. This example illustrates the advantages that shear walls can have in reducing differential settlements of a raft.

In general as the soil stiffness increases, the raft settlement and differential settlement will tend to reduce, and, as a consequence, the raft bending moments will also reduce. Hence, the compressibility of the soil, especially close to the raft base (typically within half the raft width) must be carefully assessed. For wide rafts, the influence of relatively stiff soils (say dense

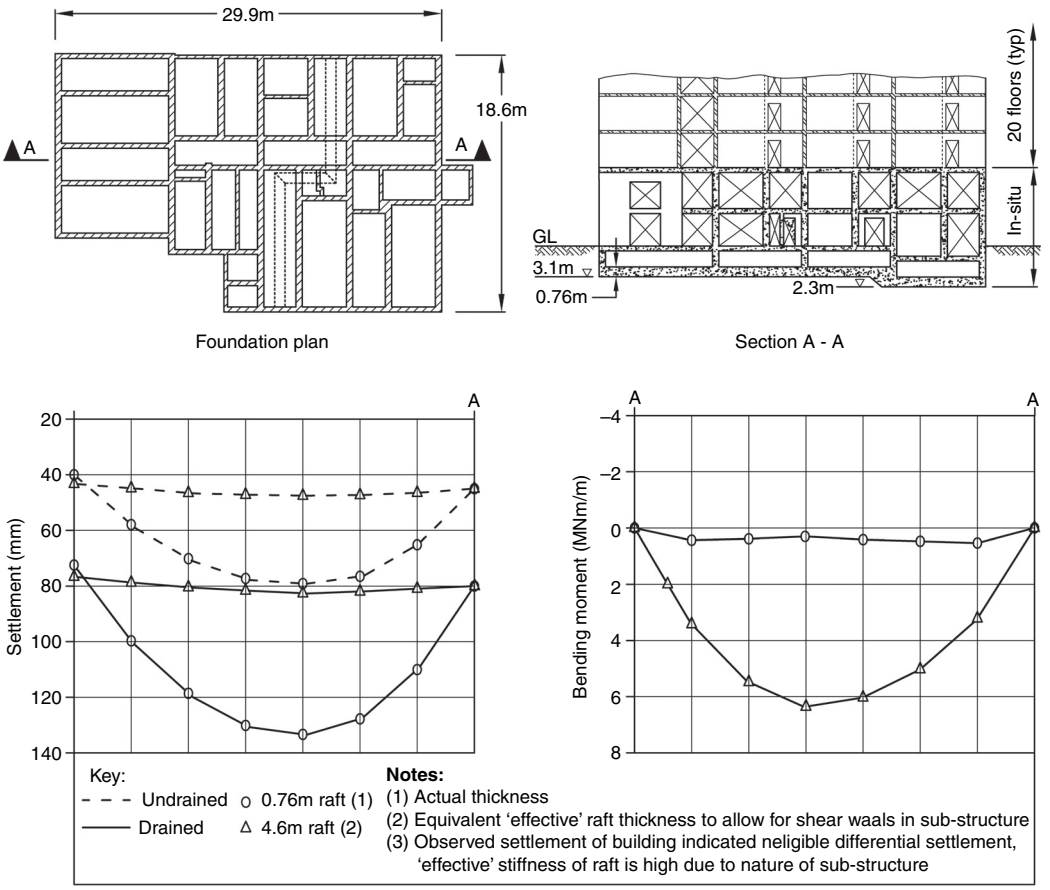

Figure 56.3 Influence of sub-structure stiffness on 'effective' raft stiffness
Modified from Hooper and Wood (1977), all rights reserved

sands or weak rock) at depth can be important (especially if within a depth of one times the raft width). These stiff layers will reduce raft settlement, differential settlement and bending moment. **Figure 56.4** illustrates the important influence of local yield on the distribution of contact stress along the underside of a raft. For an idealised linear elastic soil, the contact stresses are relatively low across the centre of the raft, and then increase towards the edge of the raft to extremely high values of p/q (where p is the local contact stress and q is the vertical pressure applied to the raft). For a real soil (which will fail *locally* once the contact stress fully mobilises the soil strength) the distribution of contact stress differs from the idealised elastic profile. As the applied vertical pressure increases (varying from a pressure equivalent to an undrained factor of safety against bearing-capacity failure of about 10 to a value of 1.1) the contact stress becomes more uniform, particularly for drained conditions. The rule of thumb commonly used by designers of limiting the contact stress to between 50% and 100% above the average applied pressure from the structure appears reasonable.

Referring back to **Figure 56.2**, it can be seen that if it is assumed that the full soil shear strength can be mobilised at the soil–raft interface, then the predicted maximum bending moment is substantially reduced. However, as noted by Hooper (1983) it is usually very unwise to rely on significant raft–soil interface strength for the purposes of structural design. Usually, a frictionless or very low interface strength should be assumed to avoid unsafe provision of raft reinforcement. This should be remembered if numerical models (finite elements, etc.) are used for raft design, and it will be essential to include special interface elements along the underside of the raft model, with appropriately low values of strength specified.

56.2.3 Soil models for analysis: springs vs continuum

Structural engineers usually wish to model the soil as a series of springs, since this allows conventional structural analysis software to be used. Traditionally the soil springs have a uniform stiffness equivalent to the soil's modulus of sub-grade reaction. There are problems with this approach, which are well known in the geotechnical engineering community; for example, the spring stiffness cannot be directly related to measurable soil parameters, since parameters such as the sub-grade reaction moduli are also affected by the foundation width. Also the spring stiffness cannot directly allow for the effects of soil layering. However, the more fundamental problems with 'spring-type'

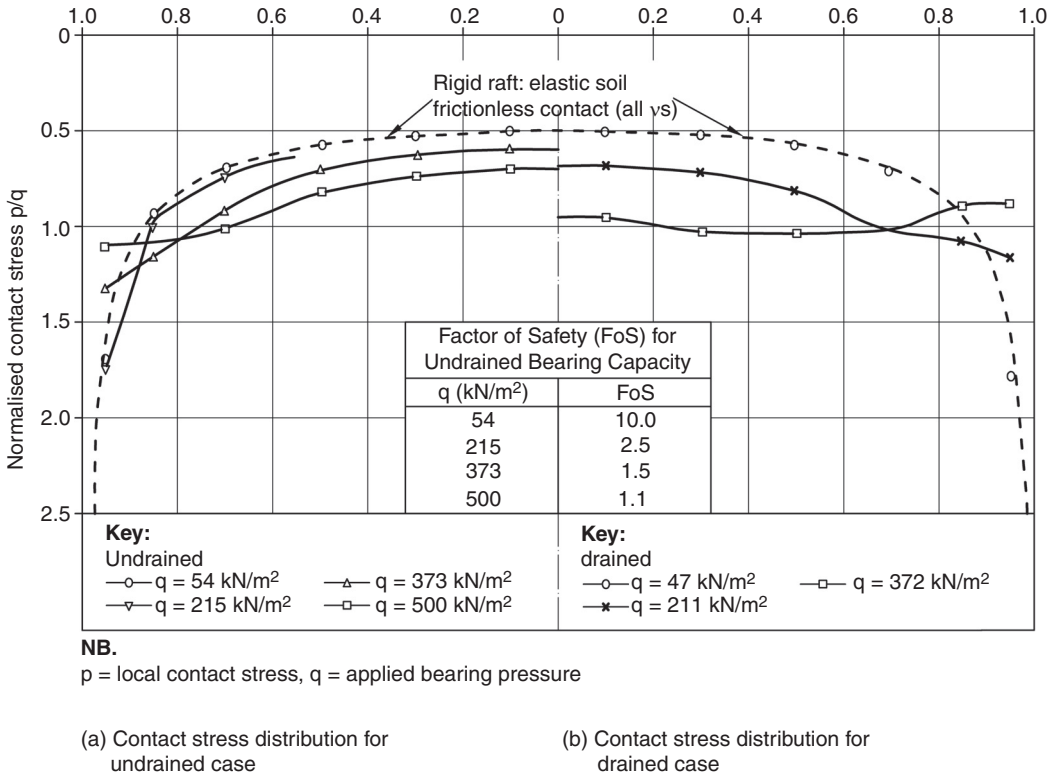

Figure 56.4 Influence of local yield on raft contact stress distribution
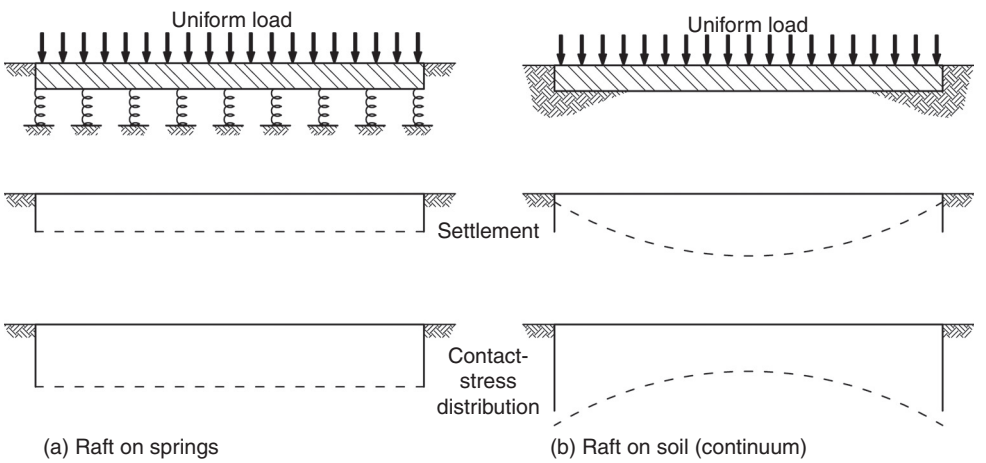
Modified from Hooper (1983)



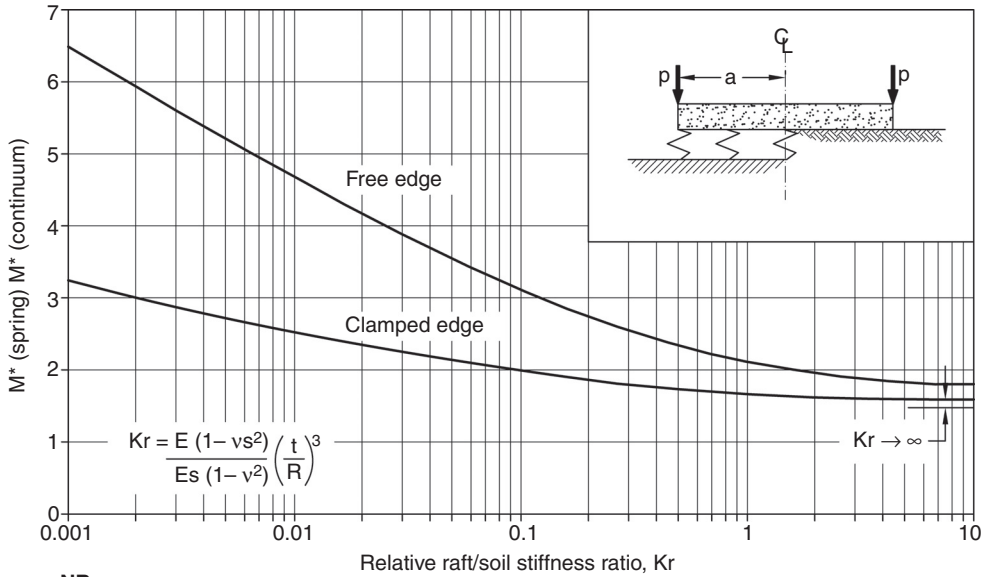


Figure 56.5 Raft on springs compared with raft on soil

models are often less understood. **Figure 56.5** illustrates a fundamental flaw in spring-type models: if a raft of uniform stiffness is subject to uniform loading and is analysed using soil 'springs', then it will settle a uniform amount, **Figure 56.5(a)**. This is inconsistent with real raft behaviour: a raft of finite stiffness will settle more in the centre than at the edges, **Figure 56.5(b)**. For a spring model to generate this curvature, the soil springs at the centre must be less stiff than those at the edges. Hence, appropriate soil spring stiffnesses cannot be uniform and are dependent on a range of factors, which will be dependent on: the raft and the structure, the soil and the distribution of applied loads. The serious errors that can result from a non-interactive approach are illustrated in **Figures 56.6** and **56.7**. For a raft subject to edge loads, **Figure 56.6**, the error

NB.
M* = maximum raft bending moment
E, ν = Young's modulus and Poisson ratio respectively, for raft
Es, νs = young's modulus and Poisson ratio respetively, for soil
t = raft thickness, R = raft radius

Figure 56.6 Ratio of maximum bending moments for an edge-loaded circular raft of varying stiffness (*Kr*), spring vs continuum model
Modified from Hemsley (1987)

associated with a spring model is dependent on the relative soil–raft stiffness and on the rotational stiffness of the edge of the raft (e.g. it may be 'clamped' by a stiff perimeter wall). In this case the spring model is conservative. However, it is not possible to provide any generalised set of 'correction' factors, since spring models can lead to significant overestimates or underestimates of bending moment depending on the magnitude and distribution of the applied load (Hemsley, 1987). This is illustrated in **Figure 56.7**, where the raft differential settlement and bending moments predicted by the spring model are wildly different (and of opposite sign) to the more realistic continuum model.

The key practical conclusion is that the traditional approach of providing sub-grade reaction moduli for 'uniform' soil springs and then running an independent structural analysis can lead to serious errors and should *not* be used for raft design.

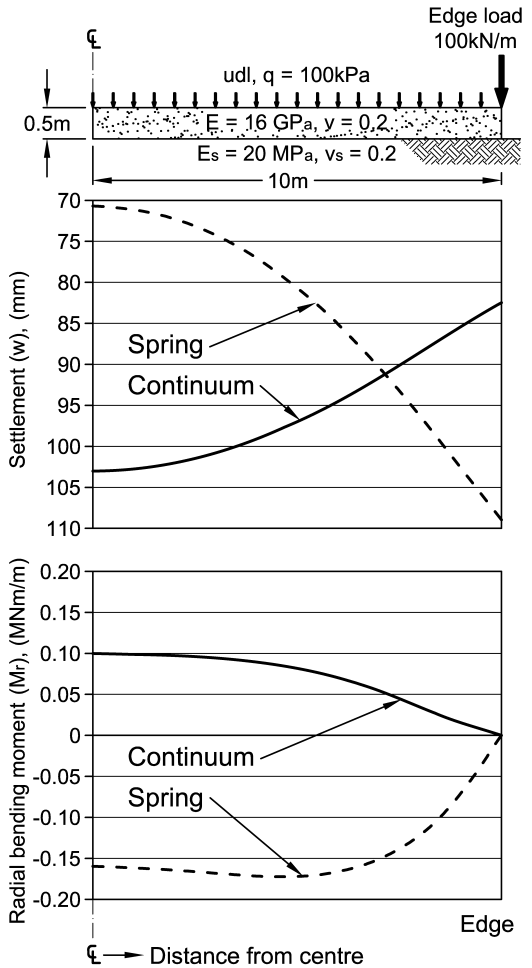
56.2.4 Simplified methods for raft–soil interaction analysis

For the simple situation of a rectangular raft that is uniformly loaded, the maximum bending moment and differential settlement can be assessed from charts developed by Horikoshi and Randolph (1997). The estimation of differential settlement is discussed in Chapter 53 *Shallow foundations* (Figure 53.21 and associated text, 53.6.7). Hemsley (1998) also provides charts that are useful for preliminary assessment purposes. Unfortunately, the various published charts are usually too idealised to be sufficient for detailed structural design. Usually the structure-specific loading distribution, spatial arrangement of walls, columns, etc. differs substantially from those assumed in published solutions. Nowadays, it is possible to carry out 3D numerical modelling of soil–raft systems; although it is usually inappropriate (due to complexity, cost, time and lack of necessary specialist input) to implement a highly complex analysis for the majority of structures. A practical approach, which avoids the pitfalls associated with a non-interactive spring-type model (discussed above), is summarised in the flowchart in **Figure 56.8**. This relies upon a structural spring model and a soil continuum model being run in tandem, and both are iterated several times until there is sufficient convergence between the spring stiffness values (say 95% convergence). Depending upon the design phase (preliminary or detailed design), the geotechnical category for the site, the structure, etc., the structural and soil models can be of varying levels of sophistication. The 'interactive spring stiffness', S_i, is defined as:

$$S_i = \frac{\text{Structural spring reaction force}}{\text{local soil continuum displacement at spring location}} \quad (5.1)$$

The soil continuum model assumes the raft is flexible.

The iterative analysis is usually started by estimating the spring stiffness from the overall raft settlement (calculated by conventional soil mechanics methods, Chapter 53 *Shallow*



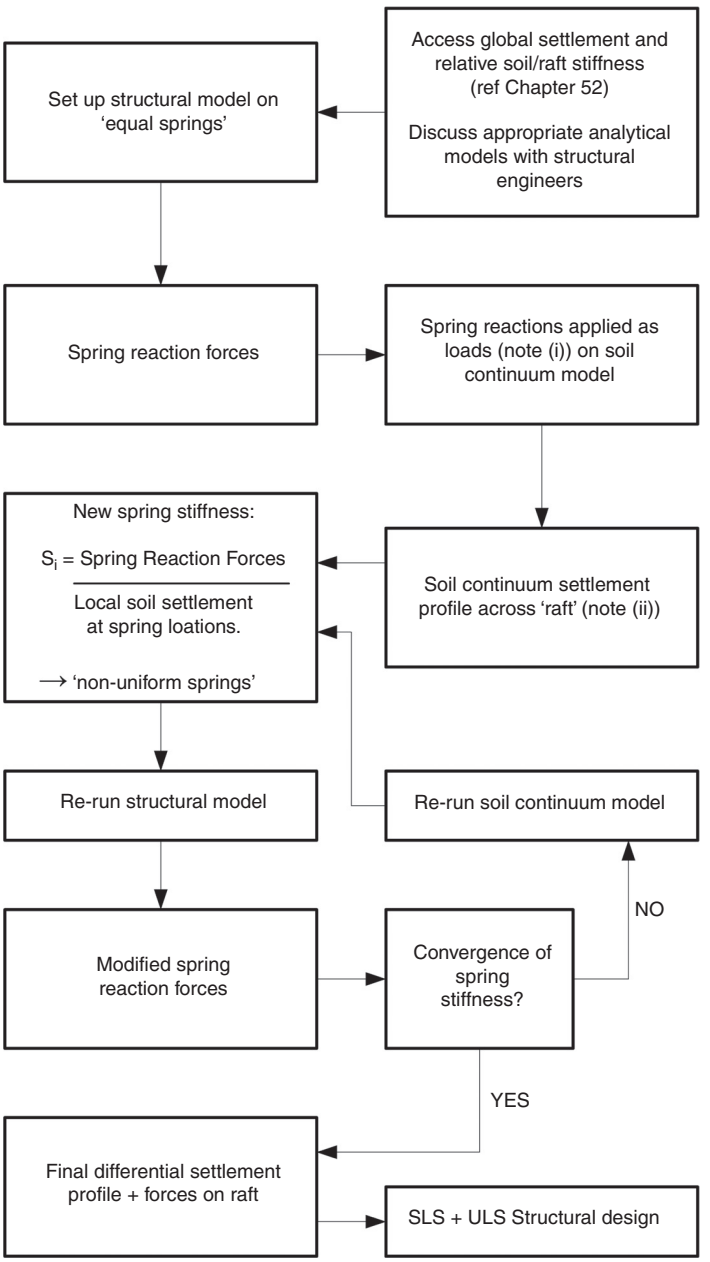


Figure 56.7 Settlement and bending moment for circular raft subject to uniform pressure and edge load, continuum model versus spring model
Data taken from Hemsley (1987)

Notes
(i) Raft assumed "flexible" in soil continuum.
(ii) Consider gross and "net" forces for short-term and long-term settlement respectively, refer to text.

Figure 56.8 Flowchart for raft–soil–structure interaction analyses

foundations). These spring stiffnesses are then used in a structural model (with appropriate raft and sub-structure stiffnesses, applied loading for columns, walls, etc.). The spring reaction forces are then applied as loads in the soil continuum model, with appropriate characterisation of the soil behaviour (stiffness, layering, etc.). This will provide a non-uniform settlement profile along the 'raft' base, which is then used to recalculate the new spring stiffnesses of Equation 5.1. These values are re-input into the structural model and re-run. This process is repeated until the deflections from the soil continuum and structural models are similar at all spring locations. The stiffness of the soil springs will usually vary significantly beneath the raft, typically with softer springs in the centre and stiffer springs around the edge of the raft.

Some care is required when the raft is located at the base of an excavation, and there is a significant difference between the gross and net bearing pressures (refer to Chapter 52 *Foundation types and conceptual design principles* for definitions). The structural analysis will require gross pressures; however, the long-term soil settlement will be dependent on net bearing pressures (based on the changes in effective stress). For rafts on clay, gross bearing pressures would be used for undrained settlement and net bearing pressures for drained (total) settlement (or swelling, if the net effective bearing pressure is

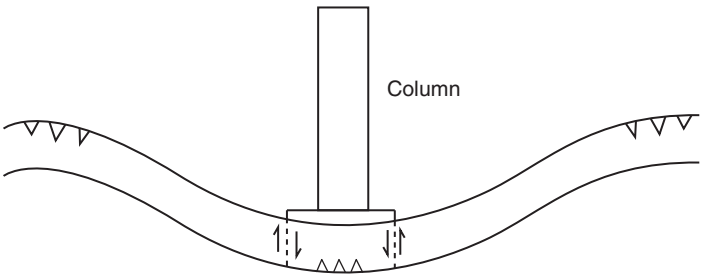

Figure 56.9 Modes of failure of rafts

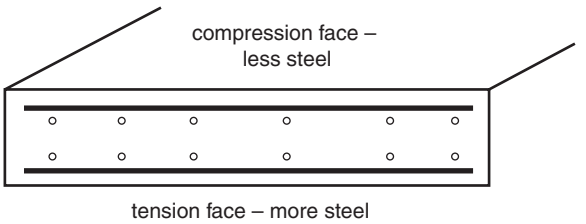

Figure 56.10 Typical bending of steel in a raft designed for sagging

negative, allowing for overburden removal and any changes in the water table level).

56.3 Structural design of rafts

As for all foundations, rafts must remain structurally integral and not deflect excessively and cause unacceptable angular distortions in the structure above. There are two main modes of potential structural failure:

(i) bending;

(ii) shear.

These are illustrated in **Figure 56.9**.

While unreinforced concrete has some capacity to resist both these sets of forces, generally steel reinforcement is used to augment capacity and provide adequate resistance. In both cases, structural codes (such as BS8110 or Eurocode 2) provide detailed guidance on how to design reinforced concrete. The purpose of this part of the chapter is to outline basic principles.

Simple beam theory states:

$$\frac{f}{y} = \frac{E}{R} = \frac{M}{I} \tag{5.2}$$

where f is the peak stress in the extreme fibre of the section at distance y from the neutral axis; E is Young's modulus for the concrete and R is the induced radius of curvature (note that for small curvatures, the radius of curvature is high); M is the corresponding applied moment in the concrete section and I is the moment of inertia for the section, which is (1/12) bd^3 for a rectangular section, where d is the depth and b is the breadth, equal to 1 m per metre run.

The equation is often simplified to

$$M = EI / R \tag{5.3}$$

so that the product of the moment and the radius of the induced curvature is equal to the section's flexural rigidity EI, and from this it can be deduced for any section that the bending moment and radius of curvature are inversely related. Hence adding more steel, so that the section can resist greater moments, will reduce the radius of curvature, i.e. it will increase the actual curvature and hence differential settlements. However, a stiff section may attract load, so the benefit of continually adding more steel may reduce.

Excessive bending in a structural element also causes cracks in the extreme tension fibres of the concrete, which can reduce durability. The significance of cracks in structural elements that are exposed to saturated soil with no free oxygen is a topic of debate, but structural codes provide firm guidance.

Bending resistance is provided by steel on the tension face, and sometimes also by steel on the compression face too. Thus a raft often includes two distinct layers of steel, in two perpendicular directions. This is shown in **Figure 56.10**. For lightly reinforced rafts, mesh reinforcement is sometimes used.

A critical consequence of bending is the induced curvatures, which lead to differential settlements between different parts of the raft. A key issue in raft design is to control these differential settlements so that the supported structure above remains fully functional, i.e. angular distortions in the structure are acceptable, finishes are undamaged and the building function isn't impaired by excessive tilt.

Shear reinforcement in a concrete raft is needed when either a column or a pile may 'punch' through the element, as shown in **Figure 56.11(a)**. If a base plate is added beneath the column, the plane of potential rupture is forced further out and a greater perimeter of concrete is mobilised to resist rupture, see **Figure 56.11(b)**. **Figure 56.12** shows a simplified shear stress example. The shear force down is 5000 kN - 200 kN/m^2 × 1 m^2 = 4800 kN and the area of concrete resistance is 1.2 × 1 × 4 = 4.8 m^2. Therefore, the shear stress is 4800 kN / 4.8 m^2 = 1000 kN/m^2 = 1 N/mm^2. Since unreinforced concrete can resist a shear stress of up to 1 N/mm², normally no special shear reinforcement is needed. For higher induced shear stresses, extra reinforcement may be needed to resist these shear stresses.

In the case shown in **Figure 56.12**, the induced shear stress in the concrete v_c is 1 N/mm², which is at the limit where shear reinforcement might usually be needed. As shear reinforcement is difficult to fabricate, other options to avoid or limit its use might include:

- widening the column base to extend the shear perimeter;
- thickening the raft, although the extra excavation and concrete will be expensive, and in a basement may necessitate also a deeper retaining wall;

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

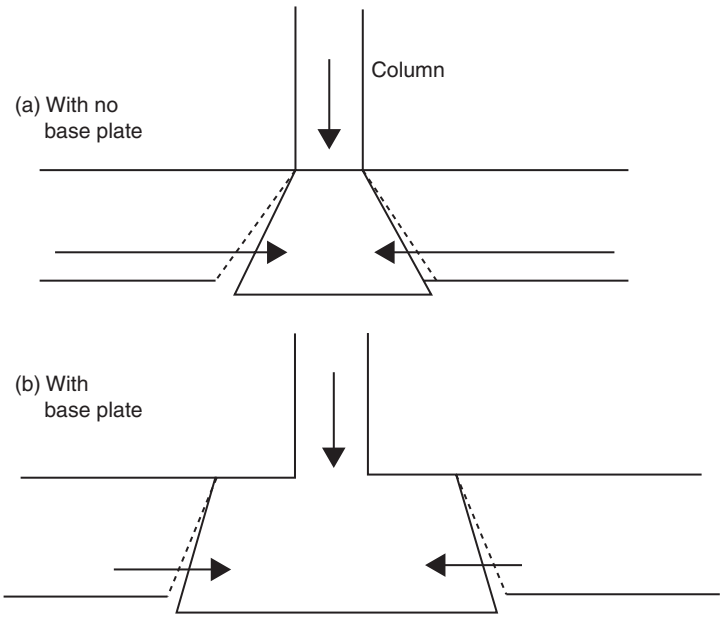

Figure 56.11 Punching of a column through a raft slab

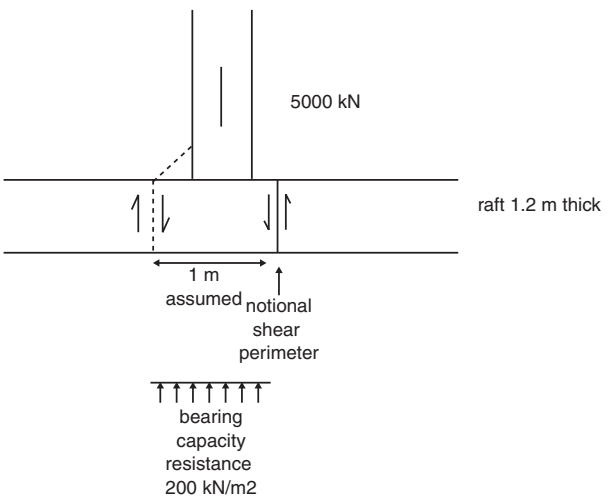

Figure 56.12 Simplified shear stress example

- adding a 'shear-reducing' pile beneath the column location to increase the soil resistance locally and hence reduce the net load that needs to be shed out into the rest of the raft.

56.4 Design of a real raft

56.4.1 Bracketing by load cases

Raft design needs to accommodate a wide range of design cases and the induced forces and deflections are very sensitive to those load cases. The design cases include loads from the structure and loads and reactions from the ground. Loads from the structure range from a minimum of the dead load only to a maximum of the full dead and live loads. The ground loads include water pressures and heave pressures (which can be maxima or minima) from under a basement and a range of ground reactions based on upper and lower bound ground stiffnesses. These various combinations give a wide range of curvatures, often with sagging or hogging at the same location for different cases, and hence the steel needed in upper and lower reinforcement layers can originate from apparently odd load combinations. An example of a set of load combinations for a raft design is given in **Table 56.1**.

56.4.2 Design steps

Raft design, almost more than the design of any other geotechnical element, depends on mutual comprehension between geotechnical and structural engineers. As the raft design process is more complex, often piles are chosen ahead of rafts, even though the raft design may be more efficient in terms of cost, ease of construction, programme, risk reduction and even carbon saved.

The design complexity depends on:

- the magnitude of loads, connected to the building height and column grid layout;
- whether there is a basement, and if there will be water or heave pressures;
- the number of load cases that should be considered;
- the magnitude of variation in loads, particularly between adjacent columns;
- whether the ground is relatively soft;
- the drive for extreme economy in the raft.

The complexity of analysis needed crudely depends on the compatibility between the structural and the geotechnical analyses. A typical process is shown in **Figure 56.13**. Where the two sets of analyses yield relatively close agreement at first iteration, then a less rigorous design process can be followed.

As stated earlier, the structural analyses usually assume the ground reaction can be modelled by simple springs while the geotechnical analyses model the ground response following Boussinesq or similar principles that more accurately model settlement interactions between adjacent loaded areas, such as the OASYS PDISP analysis program. The errors associated with spring models are described in section 56.2.3 above. Geotechnical analyses are usually seriously limited in their ability to model structural behaviour.

Sometimes a sufficiently accurate simplification can be achieved by performing a second structural iteration, refining the springs to better approximate the likely soil displacements. Otherwise a longer series of iterations between structural and geotechnical analyses will yield a better approximation, as discussed in 56.2.4 and shown in **Figure 56.8**. The structural analysis is initially run to give a load disposition over a number of loaded areas, those loads are then fed into a geotechnical

Basic load cases (1)	Additional load cases (4)

Table 56.1 Example of a set of load cases for a raft design

analysis, which gives a new disposition of settlements taking into account adjacent effects; those settlements are used to refine the springs assumed in the structural analysis and it is again re-run. The process is continued until a reasonable state of convergence is achieved between the structural and geotechnical analyses.

Finite element (FE) techniques can be used to give even more precise results. An FE approach combines the structural and geotechnical modelling into a single analysis. But even 2D FE modelling can require too much simplification as both building layouts and settlements are very 3D by their nature, so often a 3D analysis is required. And once 3D analyses are applied to a wide range of load combinations, the whole design process can become very time consuming and expensive.

In addition to these interactions, crude checks are needed at an early stage for global and local bearing-capacity failure. It is rare to find a raft that could exhibit a kinematically valid bearing-capacity failure mode, as the more likely modes are excessive displacement or a structural failure, but this relatively rapid check remains important as an indicator of potential design problems.

Whenever there are significant water loads, a check for net buoyancy should also be made for the critical load stages, which could include a future partial demolition of the building above.

56.4.3 Factor of safety considerations

Usually a factor of safety calculation is less critical in raft design than in other types of geotechnical design, as usually movements (serviceability) are more critical than ultimate failure considerations. As for other aspects of design, it is easy to muddle geotechnical and structural safety factors and design codes. Both British Standards and Eurocodes offer little guidance. Hence, careful thought is needed to identify and resolve these potential inconsistencies. Generally as the magnitude of the resisting forces is very large, a lumped factor of safety of 2 is assumed to be sufficient margin against bearing-capacity failure.

Simplistically for a pure raft, the structural analysis considers the deflected shape and external forces acting on the element while the geotechnical analysis considers movement and the global bearing-capacity failure of the whole raft foundation. Local bearing-capacity calculations can sometimes be relevant, but are usually obviated as the structural check against failure prevents a local failure of a discrete part of the raft from being kinematically admissible.

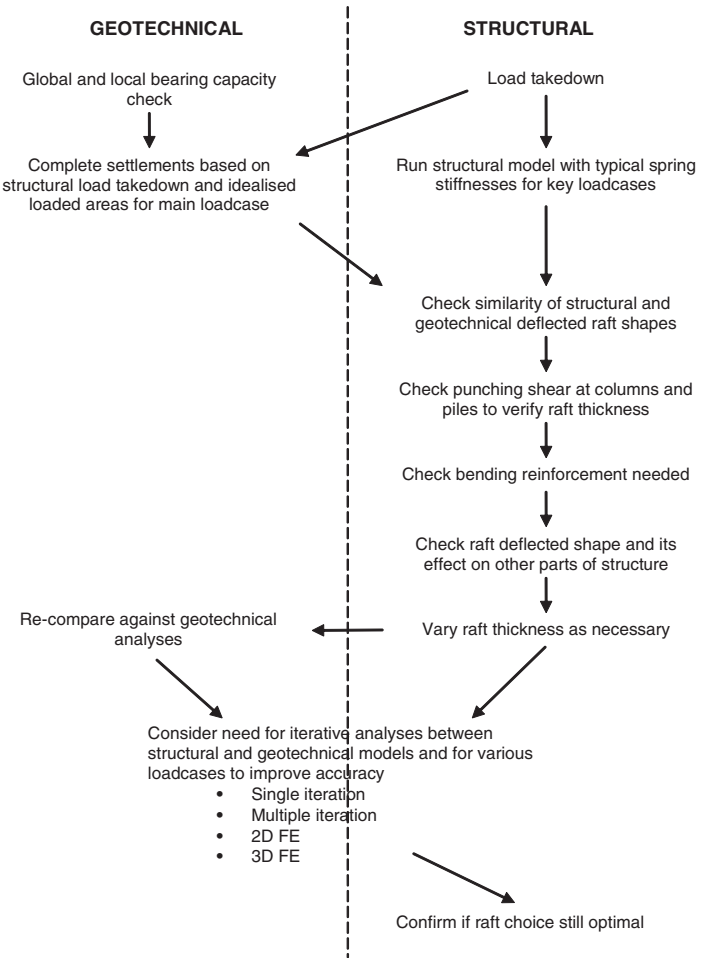

Figure 56.13 Simplified raft design process

56.4.4 Buildability considerations for raft construction

The first set of buildability choices relate to the raft's formation level, which corresponds to the chosen raft thickness. The formation layer should ideally be dry, well drained and above the water table. Often it will be necessary to thin a raft to bring its formation level above a likely water table level. From a structural perspective, it is expedient to thicken a raft beneath columns to resist the increased shear forces, but such stepped formations are difficult and potentially less safe to build.

Steel is relatively expensive and slow to place in cages, especially significant quantities of shear steel. There is always a trade-off between a thicker raft with less steel and a thinner raft with more steel. If a raft has too much steel it can be difficult to compact the concrete and so the raft may be more prone to defects, long-term durability and water-penetration issues.

If the ground contains some contamination or there is a risk that it may, a thinner raft needing less excavation may be advantageous. Ground gas penetration can be an issue, especially at joints, for instance with a retaining wall or at any penetrations through the raft.

If the design calls for an under-slab drainage layer to reduce the design water pressures, the layer needs to be considered carefully. Consideration of price alone suggests gravel-filled grip drains, while broader buildability and construction-safety considerations will probably result in a no-fines concrete drainage layer that can also act as a blinding layer. Care must be taken to ensure that the no-fines concrete has high permeability, rather than just porosity, and will not be prone to clogging. Often a roddable pipe network is included as a precaution, connected to manhole covers that can lift if water pressures exceed the design levels.

56.5 Piled rafts, conceptual design principles

56.5.1 Different types of piled raft and key definitions

Piled rafts have significant benefits when used in suitable ground conditions:

(i) costs can be significantly reduced (the number of piles, the raft thickness and reinforcement quantities can all be reduced);

(ii) construction can be simplified and the time for foundation construction can be reduced.

Associated with (i) and (ii) there may also be safety and sustainability benefits. A number of different terms have been used to describe piled rafts and the associated design philosophies. For the purpose of this chapter, the following terms will be used:

(a) *Raft-enhanced pile group*: both the piles and raft will work within a pseudo-elastic range of behaviour. The pile-group capacity will *not* be fully mobilised at the anticipated working load (based on the expected raft or pile load share). The key parameter that governs behaviour is the relative stiffness of the pile group to the raft. It will be important to assess the upper and lower bound stiffnesses for the raft and pile group. Although the piles will usually be stiffer than the raft and attract most of the design load, the raft can be designed to resist a substantial proportion of the design load. The pile and raft stiffness will be a function of the stiffness of the ground, and the variation of ground stiffness with depth.

(b) *Pile-enhanced raft:* the piles will be designed to mobilise all their ultimate capacity. The raft will usually carry the bulk of the design load. The piles will usually be located beneath heavily loaded superstructure columns. For this type of design it will be important to assess both the lower and upper bound pile capacity with a high level of confidence, and the pile load-settlement behaviour *must* be *ductile*, i.e. the pile resistance must be maintained at relatively large settlements (*circa* 50 to 100 mm).

These different modes of behaviour are illustrated in **Figure 56.14**, which shows a load-settlement curve for a raft

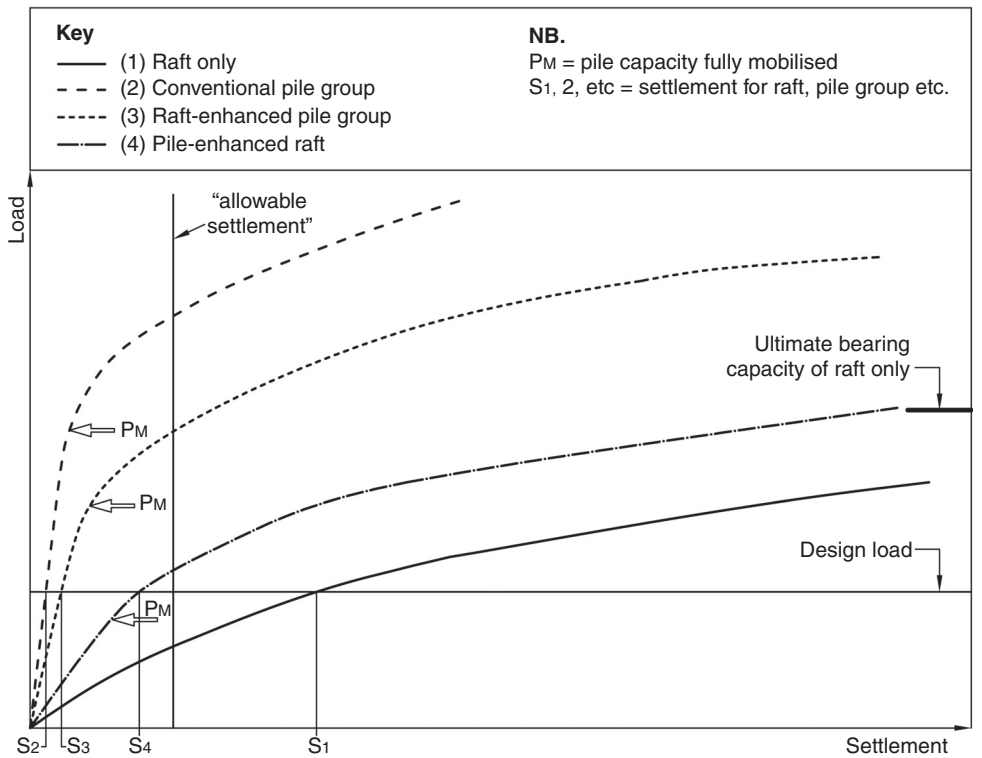

Figure 56.14 Load-settlement behaviour of rafts, conventional pile groups and different types of piled raft

(curve 1), a conventionally designed pile group (curve 2), a raft-enhanced pile group (curve 3) and a pile-enhanced raft (curve 4). The raft has a substantial ultimate bearing capacity, but the settlement at working load is deemed to be excessive (as noted in Chapter 52 *Foundation types and conceptual design principles*, the magnitude of 'allowable' settlement needs to be carefully scrutinised). The conventionally designed pile group is very stiff and its settlement at the working load is far smaller than the 'allowable' settlement (as noted in Chapter 55 *Pile-group design*, conventional analysis of pile groups often significantly overpredicts pile-group settlement). The raft-enhanced pile group (curve 3) is also relatively stiff and this is achieved with a smaller number of piles than the conventionally designed pile group, because the piles are operating more efficiently. The pile-enhanced raft (curve 4) exhibits more settlement than the conventional pile group and raft-enhanced pile group, but is stiffer than the raft and can achieve the allowable settlement for this structure. The load-settlement curve for the pile-enhanced raft is within the nonlinear range. It is apparent that if the allowable settlement is set at too low a value, then the opportunity to use piled rafts, especially 'pile-enhanced rafts', will usually be lost. Hence, defining a realistic value of allowable settlement is important; Chapter 52 *Foundation types and conceptual design principles* (section 3) discusses this topic in more detail. The term 'settlement-reducing piles' was used by Burland *et al*. (1977) to describe the concept of a pile-enhanced raft, and they stated that:

> *Traditionally engineers engaged in pile group design have asked themselves 'How many piles are required to carry the weight of the building?' When settlement is the conditioning factor in the choice of piles designers should perhaps be asking the question: 'How many piles are required to reduce the settlements to an acceptable amount?' The number of piles in answer to the second question is invariably significantly less than in answer to the first question, provided it is accepted that the load-carrying capacity of each pile will probably be fully mobilised.*

A clear distinction must be drawn between raft-enhanced pile groups and pile-enhanced rafts. The design concepts and methods are very different. As shown in **Figure 56.15***, there is an intermediate zone between a raft-enhanced pile group and a pile-enhanced raft, which should be avoided*. If it isn't avoided, with the wide range of load cases, it is entirely possible that one column will feel a soft response while a neighbouring column may experience a stiff response, setting up large differential displacements in the building.

In a raft-enhanced pile group or pile-enhanced raft, the two sets of elements need to be considered together, with the sum of both components of capacity being useful in resisting the imposed loading. However, the detail of the consideration is

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

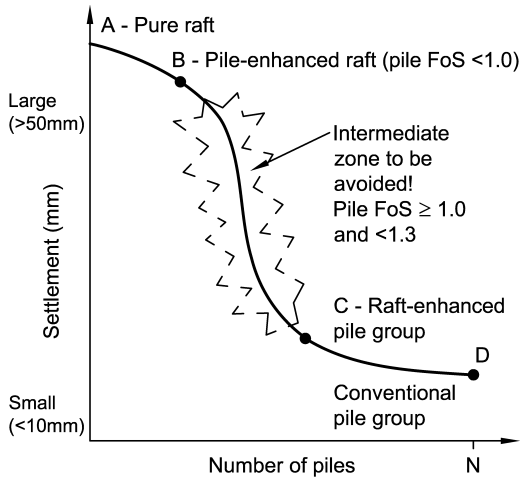

Figure 56.15 Pile-enhanced rafts versus raft-enhanced pile groups (avoid intermediate zone)

different in philosophy, and clarity is needed about what each component is meant to contribute. These issues are discussed in sections 56.6 and 56.7 below.

For a pile-enhanced raft, consideration of the ultimate global geotechnical capacity isn't usually an issue, and the piles are provided to reduce peaks of either raft displacement or shear stress in the raft. For these cases it is not usually relevant to separately add the piles' capacity component into the overall geotechnical bearing-capacity calculation.

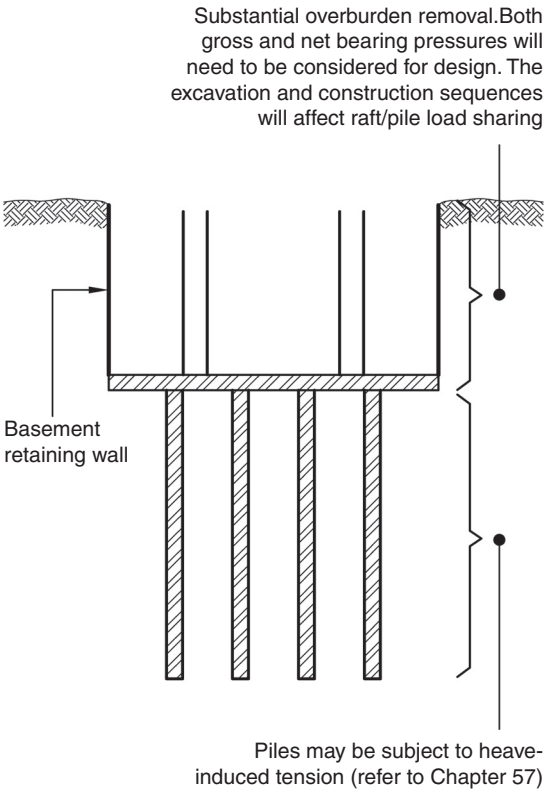
For raft-enhanced pile groups, however, the main advantage of considering both is that the extra raft component of capacity allows fewer piles to provide the same overall margin against failure. Clearly the ultimate bearing stress used for the raft's component must be compatible with the pile's performance, and so may need to be reduced according to compatibility of the deformation between the two; see Equation 5.4 below.

Some additional terms are used in the context of raft and piled-raft design, and these include:

(i) *Compensated raft*: refer to Figure E1.1(d), a raft designed as a 'deep box', with the void within the raft reducing the net increase in bearing pressure.

(ii) *Compensated piled raft*: refer to **Figure 56.16**, this type of foundation is situated within a deep excavation, and because of the large reduction in overburden stress, this type of piled raft has additional design considerations (discussed in section 56.6 below) beyond those of a piled raft close to the ground surface. Heave-induced tension is likely to be an issue for pile design and raft/pile load sharing, and Chapter 57 *Global ground movements and their effects on piles* should be referred to.

(iii) *Creep-piling*: the term 'creep piles' has been used to describe the behaviour of pile-enhanced rafts, founded on soft lightly overconsolidated clays, where sufficient



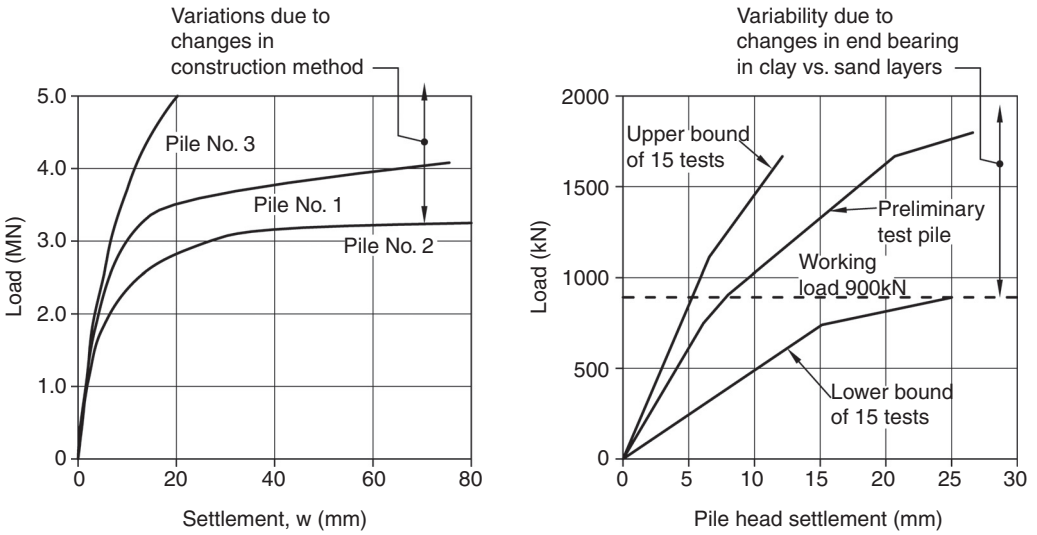


Figure 56.16 Compensated piled raft

piles are included to reduce the net bearing pressure on the raft to a value which is less than the soft clay's pre-consolidation pressure or yield stress (refer to Chapter 52 *Foundation types and conceptual design principles*, and Figure E1.24(b)). This is a highly specialist application of piled-raft design. It requires a high level of expertise to safely implement and will not be discussed in detail in this chapter. Although this is a special application of pile-enhanced rafts, it is not new and Zeevaert (1957) described the use of a compensated raft with friction piles in the compressible soft volcanic clays of Mexico City.

56.5.2 Appropriate pile types and ground conditions for piled rafts

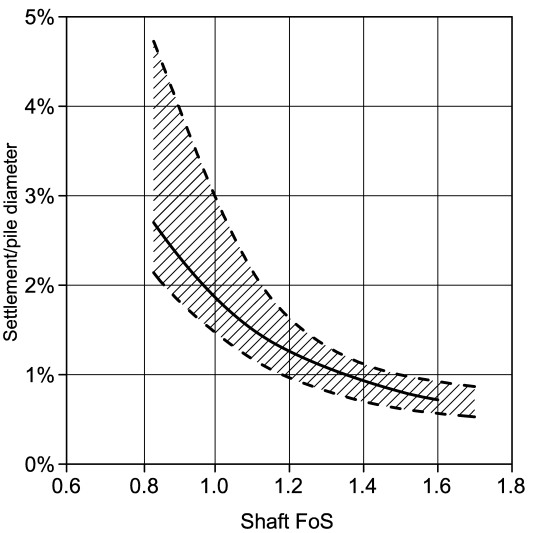
The potential variations in pile load-settlement (stiffness) behaviour are important for raft-enhanced pile groups, whereas the variability in pile ultimate capacity is a key consideration for pile-enhanced rafts. Chapter 54 *Single piles* discusses the fundamental differences between friction piles (shaft capacity >> end bearing) and end-bearing piles. Variations in ultimate pile capacity and pile stiffness are sometimes observed at an individual site; these are usually due to variations in pile construction methods (or workmanship problems) or to variations in soil properties across the site. Some examples are shown in **Figure 56.17**. **Figure 56.17(a)** illustrates the behaviour of CFA piles in alluvial soils, and it can be seen that the stiffness

(a) CFA piles in alluvial soils (after Mandolin *et al.*, 2005)

(b) Driven piles in glacial till (after Corke *et al.*, 2001)

Figure 56.17 Examples of load-settlement curves for CFA and driven piles

is reasonably similar despite wide variations in ultimate capacity (due to changes in construction method). However, **Figure 56.17(b)** illustrates the wide variation in pile stiffness and capacity of driven piles in a soil, which varies between sandy clay and clayey sand. The variation is mainly due to the large changes in end-bearing resistance when the piles are toed into 'sand' rather than 'clay'. If piles are operating at shaft factors of safety of between 1.0 and 1.3 then pile resistance, at a particular raft deformation, may be extremely variable, which could lead to excessive raft differential settlement. Many rafts are designed for a wide range of load cases and so there is a high risk of excessive differential settlement between adjacent columns. **Figure 56.18** indicates that where the *shaft* factor of safety is more than about 1.2 to 1.3, the pile settlement becomes much smaller and more consistent. Hence, it is not the overall factor of safety (i.e. shaft plus base), but the *shaft* factor of safety which mainly controls its stiffness. For end-bearing piles, both their stiffness and ultimate capacity tends to be more variable than for friction piles, because end-bearing behaviour is more sensitive to local variations in ground conditions and construction method than shaft behaviour. Therefore, before deciding upon the use of a raft-enhanced pile group or a pile-enhanced raft it is important to consider the type of piles that can be used, the nature of the ground conditions beneath the site and the potential variations in pile capacity (especially for pile-enhanced rafts) and stiffness together with the methods that can be used to minimise these variations. A raft-enhanced pile group will typically be more tolerant of variations in ground conditions and pile behaviour; however, a pile-enhanced raft may often be more economical than a raft-enhanced pile group.



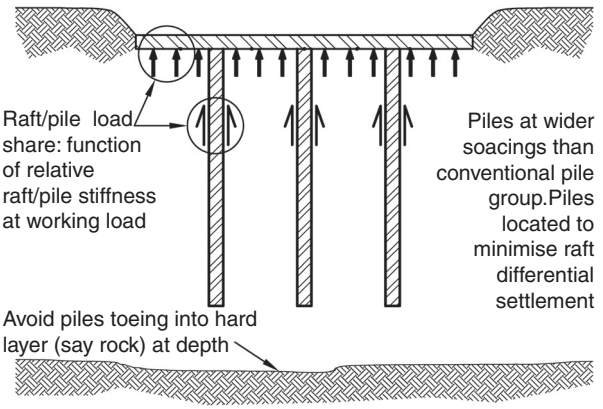


Figure 56.18 Pile settlement versus factor of safety on shaft capacity
Modified from Corke *et al.* (2000), all rights reserved

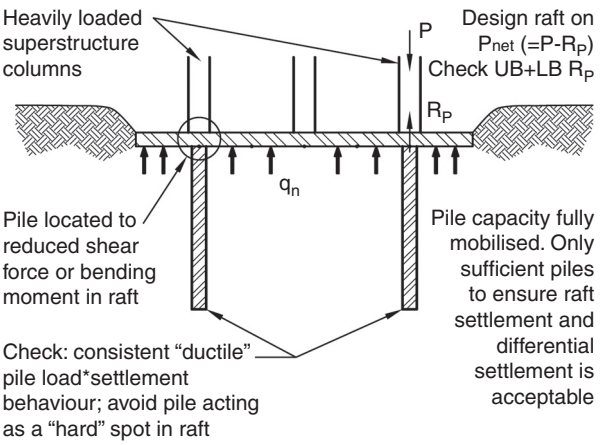

Figure 56.19 illustrates a raft-enhanced pile group and a pile-enhanced raft, together with guidance on the soil profiles that would be most appropriate for their application. A raft-enhanced pile group can be used in a broad range of ground conditions, provided the soils beneath the raft are competent enough (i.e. stiff clays or dense sands) to ensure that the raft can carry a reliable proportion of the design load throughout the structure's design life. Both friction piles and end-bearing piles can be used. For a pile-enhanced raft relatively uniform ground conditions are desirable, and typically would comprise

Favourable ground conditions
Comptenet soils at raft level (stiff clays, dense sands) and depth. Interbedded sands/clays OK.

Typical design scenario
A value-engineered pile group, often the raft was provided as a pile cap, but is then used to provide significant capacity.

(a) Raft-enhanced pile group

NB.
qn = net contact stress on underside of raft
P = column laod, Rp + pile capacity
UB = upperbound, LB = lower bound

Favourable ground conditions
Deep deposits of homogeneous clays. Typically stiff clays at raft level.

Typical design scenario
A raft which doesn't quite work, a small number of piles are added to resolve local non-compliances (eg. differential settlemeny, shear or bending moment)

(b) Pile-enhanced raft

Figure 56.19 Raft-enhanced pile group versus pile-enhanced raft

relatively deep deposits of stiff homogeneous clays. In these ground conditions, the ultimate capacity of friction piles (and the lower to upper bound range) should be fairly consistent across a site (provided a good standard of workmanship during pile construction is maintained) and their load-settlement behaviour should be ductile. As noted on **Figure 56.19**, the starting point for raft-enhanced pile groups and pile-enhanced rafts will often be very different. The former is usually a large pile group, which is value-engineered to make use of the pile cap for resisting the applied loads. In contrast, the latter is a raft that doesn't meet all the design criteria, so a few piles are used to resolve the non-compliance. **Table 56.2** provides a summary of some piled rafts that have been reported in the technical literature. It is worth noting the wide range of piled-raft geometries, ground conditions and observed settlements. The long-term performance of piled rafts has been satisfactory, and their use has resulted in significant economies compared with conventional foundation design.

There are some ground conditions that are unfavourable for the use of piled rafts and these include:

(i) Soil profiles containing heterogeneous non-engineered fill, soft clays or loose sands close to the underside of the raft, which are underlain by more competent soils at depth in which the piles will be located. In this case, the raft will not provide significant stiffness or bearing capacity compared with the piles. The piles should then be designed conventionally.

Reference / structure	Ground conditions	Pile spacing (s/*d*)	Pile length (m)	Raft width (m)	Pile-group area raft area	Settlement (mm)	Raft load (%)
Urawa Building (Yamashita *et al.*, 1994)	Interbedded sands and clays	8	15.8	23	0.9	15	51
Stonebridge Park Building (Cooke *et al.*, 1981)	London Clay	3.6	13	21	0.95	12	23
Carigliano Bridge (Russo and Viggiani, 1995)	Interbedded clays or sands and gravels	3.0	50	10.6	0.88	52	20
MesseTurm (Sommer *et al.*, 1991)	Frankfurt Clay	3.5 to 6.0	27 to 35	59	0.85	140	45
Japan Centre (Katzenbach *et al.*, 2000)	Frankfurt Clay	5.5	22	43	0.45	60	60
DG Bank (Katzenbach *et al.*, 2000)	Frankfurt Clay	4 to 6	30	54	0.52	110	50
Hyde Park Barracks (Hooper, 1979)	London Clay	4.3	25		0.72	20 to 25	40
QE2 Conference Centre [1] (Burland and Kalra, 1986)	London Clay	N/A	16	33.5	N/A	16 to 20	>90
Napoli Tanks (Mandolini *et al.*, 2005)	Medium dense sand	5 and 5.8	13.7 and 9.7	12.5 and 10.5	0.82	10 to 15 and 20 to 25	46 and 50
Canary Wharf South (Nicholson *et al.*, 2002)	Stiff clay (raft level), very dense sand (pile toe level)	4	25.5	25	0.9	45	16

Note
1 The sole purpose of the piles was to reduce the shear stresses and bending moments in the raft, beneath a few heavily loaded columns.

Table 56.2 A selection of piled-raft case histories

(ii) Site locations and soil profiles that may be vulnerable to significant settlement due to external causes. Chapters 9 *Foundation design decisions*, 52 *Foundation types and conceptual design principles* and 53 *Shallow foundations* describe a number of situations where significant ground movements may develop independently of structural loads. These must be carefully assessed before piled rafts are used.

There is a particular risk with (i) and (ii) above that the ground support provided to the raft will be lost or seriously reduced over time. The key issues and questions that need to be considered by designers are summarised in **Table 56.3**.

56.6 Raft-enhanced pile groups

56.6.1 Design process

Poulos (2001) outlined the main steps in piled-raft design:

(i) 'Conceptual' design: assess the feasibility of using a piled raft and the required number of piles to broadly satisfy the design requirements (settlement and bearing capacity).

(ii) 'Preliminary' design: assess where the piles are required, the pile characteristics (length, diameter, etc.) and the differential settlement of the raft.

(iii) 'Detailed' design: finalise the optimum number, location and configuration of the piles, and calculate the detailed distribution of settlement, the bending moment, the shear force in the raft, pile loads, moments, etc.

Stages (i) and (ii) should be based on an appraisal of the ground conditions, the type of pile which will be suitable and on relatively simple calculations (outlined below). The detailed design stage will require appropriate analytical software, which can account for the interactions between piles, raft, soil and superstructure. This can vary from a modified version of the iterative and interactive spring approach outlined above for assessing raft behaviour through to 3D nonlinear numerical modelling. Although, even when sophisticated analytical methods are used, there would normally be two separate models: one focusing mainly on structural behaviour and the other focusing mainly on soil behaviour.

In the conceptual design stage it is essential to consider first:

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Ground conditions	Are the overall geology and hydrogeology well known and understood? Is there competent ground (stiff clay or medium dense or dense sand) at raft level?
Global ground movement	Are significant ground movements likely to develop adjacent to the raft in the future? Could these lead to a loss of support to the raft?
Raft bearing capacity and settlement	Would the raft have an adequate bearing capacity (say factor of safety in excess of 2) under anticipated loads? What is the likely upper and lower bound settlement?
Allowable settlement and differential settlement	Is the raft settlement acceptable? Can the allowable settlement be increased?
Pile type	Given the nature of site, what types of piles are appropriate: friction or end-bearing? Is there potential variability in pile stiffness and capacity? Is the behaviour ductile?
Piled raft	If the ground is competent at raft level, could a piled raft be used if the raft settlement is excessive, or if the bending moment or shear force in the raft is excessive? What type of piled raft is appropriate: a raft-enhanced pile group or a pile-enhanced raft?
Analysis requirements and design competency	Are appropriate analytical tools available? Are specialist staff available to deliver design?
Additional field tests	Are additional ground investigations required (e.g. to verify ground conditions at the raft or ground stiffness characteristics)? What additional pile tests are required?

Table 56.3 Piled rafts – key questions to consider

(a) raft behaviour without the piles (bearing capacity, settlement and differential settlement);

(b) pile-group behaviour without the raft (ultimate capacity, settlement and differential settlement).

For (a) and (b) relatively simple methods (described in Chapters 53 *Shallow foundations* and 55 *Pile-group design*) are appropriate. If the ultimate capacity of the raft on its own is a small fraction of the required ultimate capacity, or would be adversely affected by global ground movements that are independent of the applied structural loads, then a conventional pile-group design would usually be appropriate. However, if the raft can be founded on reasonably competent ground, which can provide reliable long-term resistance, then the raft can be used to significantly reduce the piling requirements that are required to achieve the design criteria (ultimate capacity, settlement, etc.).

The next steps are to assess the ultimate capacity and settlement of the combined piled-raft system. A critical part of this process is to assess load sharing between the raft and piles across a range of different loads.

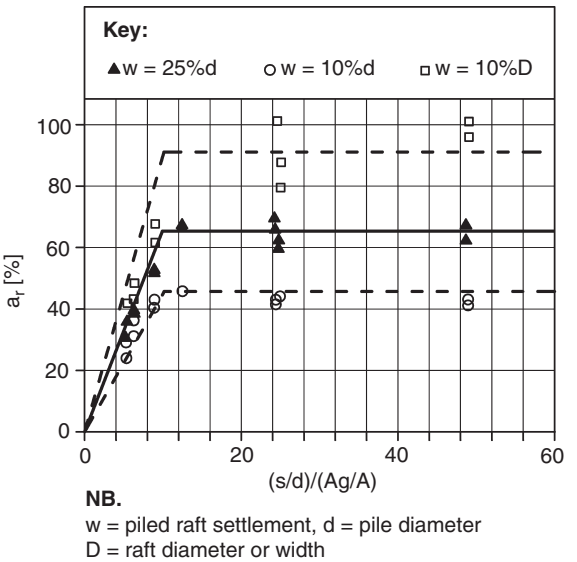

Figure 56.20 Pile raft ultimate capacity factor, α_r, versus pile spacing and area
Modified from Mandolini *et al.* (2005), all rights reserved

56.6.2 Simple models for load sharing and piled-raft behaviour

Ultimate capacity: the vertical bearing capacity can be taken as the lesser of:

(i) the capacity of the block containing the piles and raft, plus a portion of the raft beyond the pile-group perimeter;

(ii) the factored ultimate capacity of the raft plus the piles, as indicated in Equation 5.4 below.

Mandolini *et al.* (2005) indicate that pile-group block failure is likely at small values of pile spacing, below S_{crit}, with S_{crit}/d varying between 2.5 (for 3x3 pile groups) and 3.5 (for 9x9 pile groups), where d is the pile diameter. For pile spacings larger than S_{crit} then the piled-raft ultimate geotechnical capacity, Q_{PR}, can be taken as the lesser of

$$Q_{PR} = \alpha_R Q_R + \alpha_P Q_P \qquad (5.4)(a)$$

where α_R varies as shown in **Figure 56.20** and $\alpha_P = 1.0$. It is clear from **Figure 56.20** that the value of α_R is dependent on the definition of failure (i.e. the magnitude of the piled-raft settlement at 'failure'). A limiting value for α_R of 0.65 for a piled-raft settlement equal to 25% of d is generally appropriate for this bearing-capacity check, although at typical pile spacings and group geometries α_R is between 0.3 and 0.5; or

$$Q_{PR} = f_{PR}(Q_R + Q_P) \qquad (5.4)(b)$$

where $f_{PR} = 0.8$ (based on Mandolini *et al.*, 2005).

The lesser of Equations 5.4(a) or 5.4(b) should be taken as the ultimate geotechnical capacity of the foundation and used for ULS checks. The ultimate geotechnical capacity of individual components of the foundation (i.e. raft, pile group or individual piles) does not need to be code compliant.

Note that Q_R is the ultimate capacity of the raft alone and Q_P is the ultimate capacity of the pile group.

Load sharing at working loads: based on observations of load sharing for 22 piled rafts (mainly for piled rafts in London Clay and Frankfurt Clay), Mandolini *et al*. (2005) provide a useful plot of raft load (%) vs the dimensionless parameter $(s/d)/(A_g/A)$, with s and d the pile spacing and diameter respectively, A_g is the area of the pile group (plan area of pile-group 'block', i.e. not the sum of individual pile cross-sections) and A is the area of the raft; this empirical relationship is shown in **Figure 56.21**. Typically, the raft takes between 20% and 50% of the overall load for raft-enhanced pile groups; some caution is required if the raft load share is estimated to be more than 50%.

Based on elastic theory, Randolph (1994) has shown that the proportion of the load carried by a raft is

$$\frac{P_r}{P_t} = \frac{P_r}{P_r + P_p} = \frac{\left(1-\alpha_{rp}\right)K_r}{K_p + \left(1-2\alpha_{rp}\right)K_r} \qquad (5.5)$$

where P_r is the load carried by the raft, P_p is the load carried by the piles, P_t is the total load, K_r is the stiffness of the raft, K_p is the stiffness of the pile group, K is the stiffness (load divided by settlement) and α_{rp} is the interaction factor between the raft and piles.

The stiffness of the raft and the pile group can be assessed by the methods described in Chapters 53 *Shallow foundations* and 55 *Pile-group design*, respectively. If the pile spacing is greater than 8d then the pile to pile interaction will be negligible and the pile-group stiffness will be the sum of the individual pile stiffnesses, as assessed by the methods described in Chapter 54 *Single piles*.

It should be noted that the load share between raft and piles will change over time, due to the influence of:

(i) Changes in ground stiffness due to the transition from undrained to drained conditions for clay soils and the influence of creep in sandy soils. Typically, this will lead to the load carried by the raft reducing with time.

(ii) Changes in the groundwater pressure over time. This is particularly important for compensated piled rafts where the buoyancy force is typically a significant proportion of the total load so that the raft carries a greater proportion of the total load (e.g. Sales *et al.,* 2010).

Hence, analyses of pile and raft load sharing will need to take account of the changes in ground stiffness between short- and long-term conditions and, particularly for compensated piled rafts, changes in applied loads and the buoyancy force with time. For example, at Stonebridge Park the raft initially carried 40% of the total load during construction and this reduced to less than 25% in the long term as the London Clay consolidated. For situations where the proportions of the load carried by raft and pile components varies over time, each must be designed for their greater percentage of load, and care must be taken that the combined solution doesn't end up more expensive than a pure piled solution or a pure raft.

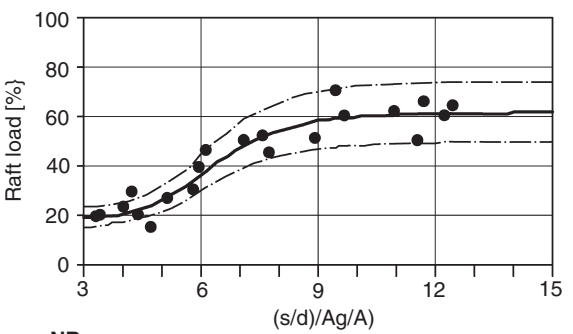

Figure 56.21 Observed load sharing between raft and piles, 22 case histories

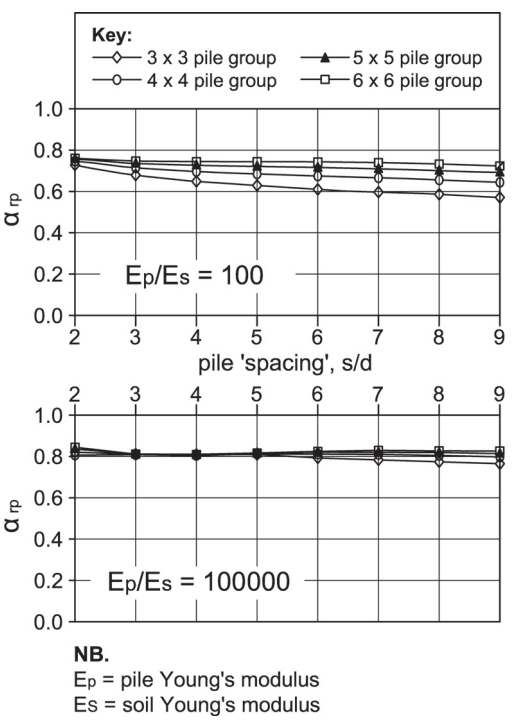

Figure 56.22 Pile–raft interaction factor, (α_{rp}), versus pile spacing and pile-group size
Data taken from Clancy and Randolph (1993)

Figure 56.22 summarises the variations of α_{rp} for varying pile spacing, pile-group size and soil–pile stiffnesses. It can be seen that α_{rp} only varies across a small range of values, between 0.65 to 0.8 (Randolph, 1994).

Poulos (2001) suggested a simplified tri-linear load-settlement curve for preliminary analysis, shown in **Figure 56.23**. For simple preliminary calculations it could be assumed that the raft and pile-group behaviour is linear–elastic, in which case the stiffness of the piled raft, K_{pr}, is

$$K_{pr} = [K_p + (1–2\alpha_{rp})K_r] / [1 – (\alpha_{rp})^2 (K_r/K_p)] \qquad (5.6)$$

The pile-group capacity is fully mobilised at a total applied load of P_1 (**Figure 56.23**), given by

$$P_1 = (Q_P) / (1\text{-}P_r/P_t) \qquad (5.7)$$

where P_r/P_t is calculated using Equation 5.5 and Q_P is the ultimate capacity of the pile group.

For loads beyond P_1 the stiffness of the piled raft is simply equal to the raft alone (K_r), until the ultimate capacity of the piled raft (from Equation 5.4) is reached. The relative stiffness between the raft and pile group controls the load sharing, the overall stiffness of the raft-enhanced pile group and the magnitude of P_1, as shown on **Figure 56.23**. The plausible upper and lower bound stiffnesses of the raft, K_r, and the pile group, K_p, need to be carefully assessed for application in Equations 5.5 and 5.6 (see **Figure 56.24**).

It is strongly recommended that this simplified overall load-settlement response is calculated for any piled raft. At later design stages the component behaviour of the raft and piles can be computed by assuming nonlinear elastic behaviour. A raft-enhanced pile group should be operating within the initial, relatively stiff, part of the tri-linear load-settlement curve (Figure 56.23) with the design load ≤ P_2, whereas a pile-enhanced raft will be operating in the 'softer' second part of the load-settlement curve with the design load > P_3. For the plausible range of applied loads, it is important that the raft-enhanced pile group does not traverse across P_1 on **Figure 56.23**. To reduce the risk of traversing across P_1, a mobilisation factor should be applied to the ultimate pile-group capacity, Q_P. For friction piles a factor of about 0.75, and for end-bearing piles a factor of about 0.6, would be appropriate. The mobilisation factor should not be confused with a factor of safety: it is simply a pragmatic means of ensuring that the raft or pile load sharing (and associated structural forces) is constrained within reasonably predictable bounds. Large conventionally designed pile groups typically have overall factors of safety of well in excess of 2.5 to 3.0. Assuming a raft carried about 30% of the overall load (a fairly typical value) then the above mobilisation factors would typically allow the number of piles to be reduced to about a half to two-thirds of a conventionally designed pile group.

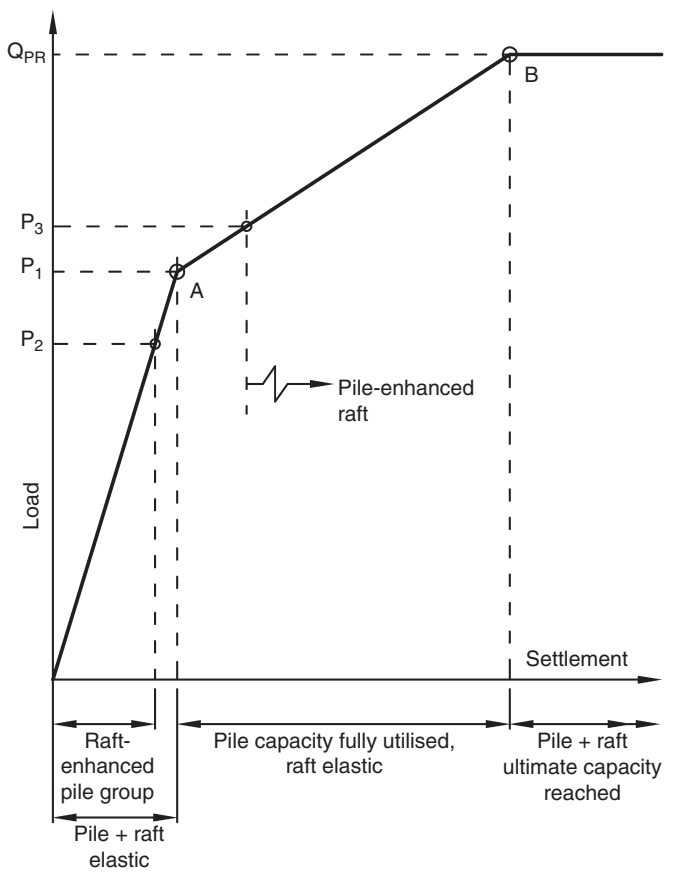

Figure 56.23 Simplified load-settlement curve for a piled raft

56.6.3 Pile–raft interaction

Parametric studies by Randolph (1994), Poulos (2001) and Katzenbach *et al.* (1998) have provided useful insights into piled-raft behaviour, and some key aspects of behaviour are summarised in **Table 56.4**. In the general case of a piled raft, very complex interactions take place between the various elements. These are summarised in **Figure 56.25**, which shows a piled raft with non-uniform applied loading and the raft in

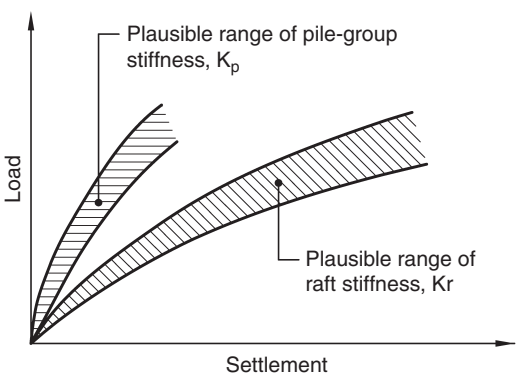

Figure 56.24 Raft-enhanced pile groups. Key design check against relative raft and pile stiffnesses

Design issues	Comment
Number of piles	Increasing the number of piles will be of limited benefit, once a threshold number is exceeded
Pile location	Typically, for optimum effectiveness focus on the area beneath the most heavily loaded columns and across the central half of the raft
Pile length and spacing	A smaller number of longer piles will be more effective than a large number of short piles. Keep the pile spacing as wide as possible, typically in excess of 4*d*
Raft thickness	A thicker raft will reduce differential settlement, at the expense of higher bending moments. Raft thickness has a negligible effect on load sharing or maximum settlement
Distribution of applied loads	Important for assessment of differential settlement and raft bending moment, negligible effect on maximum settlement or raft/pile load sharing
Soil–structure interaction analysis	Most methods tend to overpredict the proportion of load carried by the piles, and therefore underpredict the load carried by the raft. Hence, care is needed in the structural design of a raft. Sophisticated 2D analyses are likely to be less accurate than approximate methods that allow for the 3D nature of problem

Table 56.4 Piled rafts – some factors influencing behaviour

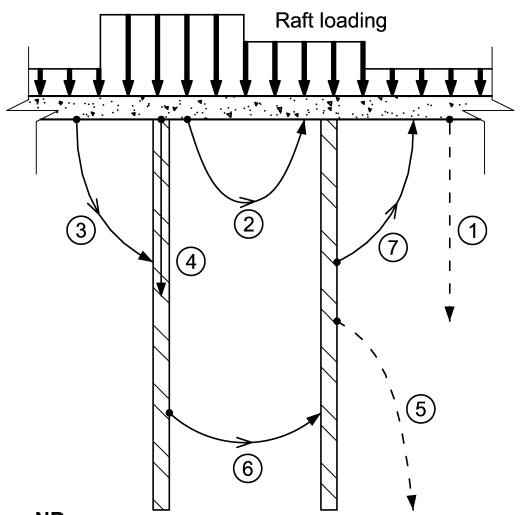

Figure 56.25 Interactions between different components of a piled raft

contact with the underlying soil. The figure shows the following interactions:

1. *Raft–soil interaction:* The contact stresses between the raft and the soil are transmitted into the soil and settlement of the raft takes place.
2. *Raft–soil–raft interaction:* Interaction takes place through the soil with other parts of the raft.
3. *Raft–soil–pile interaction:* The raft contact stresses are also transmitted through the soil and interact with the piles.
4. *Raft–pile interaction*: Loads are transmitted into the piles directly by the raft.
5. *Pile–soil interaction*: The pile loads disperse into the ground surrounding the piles.
6. *Pile–soil–pile interaction*: Interaction takes place between each pile through the soil to other piles.
7. *Pile–soil–raft interaction*: Interaction also takes place between each pile through the soil to the underside of the raft.

A comprehensive analysis of the behaviour of a raft-enhanced pile group would require sophisticated 3D numerical modelling, which would need to include:

- A nonlinear stress–strain model for the soil: as noted in Chapter 55 *Pile-group design* the modelling of small-strain nonlinearity can lead to a more economic pile-group design, because interaction effects between piles are more realistically simulated (and will be lower than predicted by a linear elastic-plastic soil model). Similarly, interaction effects between piles and raft will also be more realistically predicted.
- Appropriate modelling of the sub-structure stiffness: as discussed in section 56.2 above, the 'effective' stiffness of a raft is often relatively high, due to the influence of the superstructure.
- Interface elements between soil–raft and soil–pile elements: appropriate strength and stiffness characteristics need to be selected otherwise erroneous and potentially unsafe predictions of structural forces can be predicted (for example, refer to **Figure 56.2**).

The above requirements are challenging and require a significant input by appropriately qualified specialists. Careful calibration of these complex models is extremely important and should include:

(i) checking that the load-settlement characteristics of the raft only and a single pile are realistically simulated;

(ii) checking that the load-settlement characteristics of the pile group only (without a contribution from the raft) is realistic;

(iii) back analysis of a relevant case history for a similar raft-enhanced pile group.

An important observation from the studies reported by Poulos (2001) is that most soil–structure interaction analyses (which usually assume linear elastic or linear elastic-perfectly plastic soil behaviour beneath the raft) tend to underestimate the load carried by the raft at working loads. This is probably due to the influence of a nonlinear small-strain stiffness, which will modify the soil–structure interaction behaviour at working

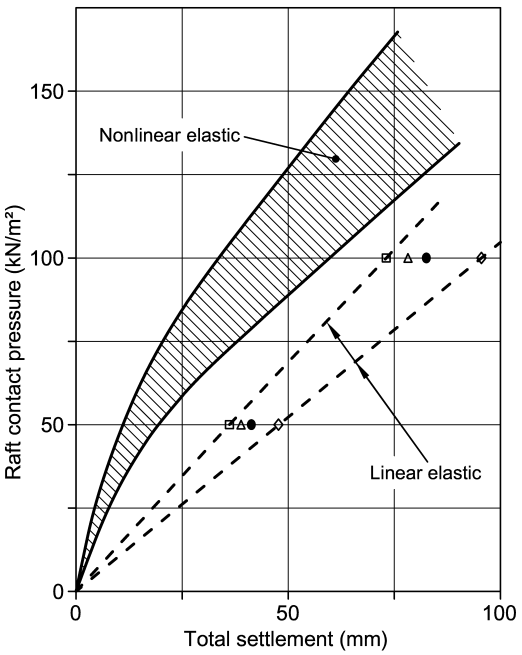

Figure 56.26 Influence of small-strain nonlinearity on raft settlement
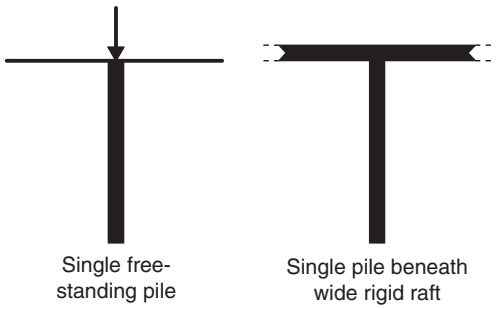
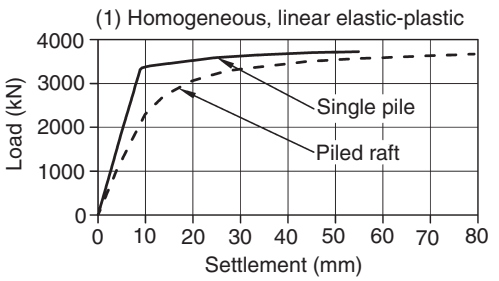
Modified from O'Brien and Sharp (2001), Emap

loads and lead to a stiffer initial load-settlement response for the raft (Jardine *et al.,* 1986). Hence, the raft stiffness, K_r in Equation 5.5, will often be higher than estimated from conventional linear-elastic methods and soil-stiffness correlations. As discussed by O'Brien and Sharp (2001) a modified 1D method (refer to Chapter 53 *Shallow foundations*) provides a simple and practical approach to assessing the influence of nonlinearity, **Figure 56.26**. This shows that at moderate settlement, typical of raft-enhanced pile groups (25 mm to 50 mm), the raft stiffness indicated by the nonlinear method is nearly double that of linear elastic methods, whereas similar stiffnesses are indicated at large settlements (because the empirically derived stiffnesses usually used in linear elastic methods are derived from rafts that exhibited relatively large settlements and the derived moduli are consistent with 'large strain' soil stiffnesses).



Pile–soil–pile interaction will occur when the piles are spaced at less than about 6*d* to 8*d* (*d* is the pile diameter), which will usually be the case for raft-enhanced pile groups. Hence, the piles below the raft will effectively act as a group. Pile–soil–pile interaction effects are discussed in Chapter 55 *Pile-group design*. The piles around the perimeter of the pile group will be stiffer, and attract more load, than the piles in the centre of the group. Therefore, for an efficiently designed pile group, especially within a raft-enhanced pile group, it is inevitable that some piles around the perimeter will mobilised close to their ultimate capacity. In turn, this means that nonlinear methods will need to be used for detailed design (nonlinear effects are discussed in Chapter 55 *Pile-group design*). Nevertheless, as noted above, the ultimate capacity of the pile group should not be fully mobilised within a raft-enhanced pile group. As noted below, this will simplify analysis and design.

Studies by Burland (1995) and Katzenbach *et al*. (2000) indicate how the raft–pile interaction modifies the behaviour of piles below a raft, compared with 'conventional' piles (i.e. without a raft in contact with competent soil) and how the contact stress beneath a raft is modified by the piles.



Burland (1995) describes a preliminary numerical study (later extended) of the behaviour of a single free-standing pile, 1 m in diameter and 20 m long, loaded to full mobilisation of the shaft compared with the behaviour of an identical pile beneath a very wide rigid raft foundation, which is loaded such that the shaft resistance of the pile is fully mobilised, **Figure 56.27(a)**. Three types of soil were studied (1) homogeneous, linear elastic-perfectly plastic, (2) increasing stiffness with depth, linear elastic-perfectly plastic and (3) nonlinear elastic-perfectly plastic. Cases (2) and (3) are representative of most realistic situations. Fully drained conditions were assumed and the maximum shaft friction was specified as 50 kPa, the equivalent of half the undrained strength ($\alpha = 0.5$). **Figure 56.27(b)** shows the load/settlement behaviour of the free-standing single pile compared with that of the pile beneath the raft for each of the above cases. It can be seen that for cases (2) and (3) the load carried by the pile mobilises a little less rapidly than for the equivalent free-standing pile. **Figure 56.27(c)** shows a graph of the normalised settlement against depth beneath the raft and the relative displacement (between pile and soil) of a rigid pile beneath the raft. Full mobilisation of shaft friction requires a finite relative displacement between the soil and pile (typically between about 5 mm and 10 mm). For a pile beneath a raft, the relative displacement varies from zero at the top of the pile to a maximum at the pile toe. As raft settlement increases, shaft friction is mobilised at the pile toe and progressively moves upwards with increasing raft settlement. The rate at which shaft friction is mobilised will depend significantly on the variation of soil stiffness with depth. When soil stiffness increases rapidly with depth (a common occurrence in practice) the shaft friction will then be mobilised more rapidly than for the case when stiffness is constant with depth. However, there will always be a small region close to the pile head where the shaft friction is not fully mobilised.

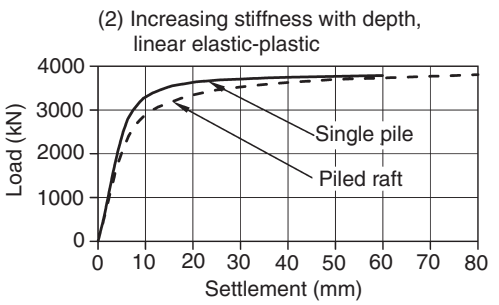


Figure 56.28 is for the case (2) soil conditions and shows the distribution of the vertical shear stress around a single free-standing pile and the corresponding pile beneath a raft at a settlement of 50 mm. It is evident that the differences between the two piles are small but the stresses are slightly more concentrated around the pile beneath the raft. At a radius of about 6 times the diameter of the pile the vertical shear stresses have reduced to less than about 5% of the shaft friction. It is worth noting that near the top of the pile beneath the raft, the shaft resistance is not fully mobilised due to the raft–soil–pile interaction.

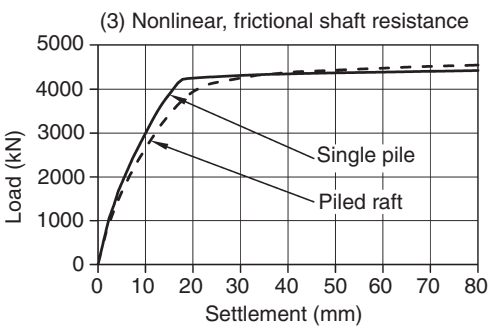
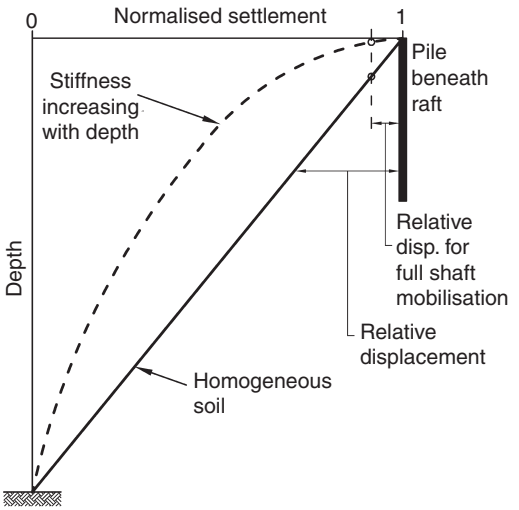
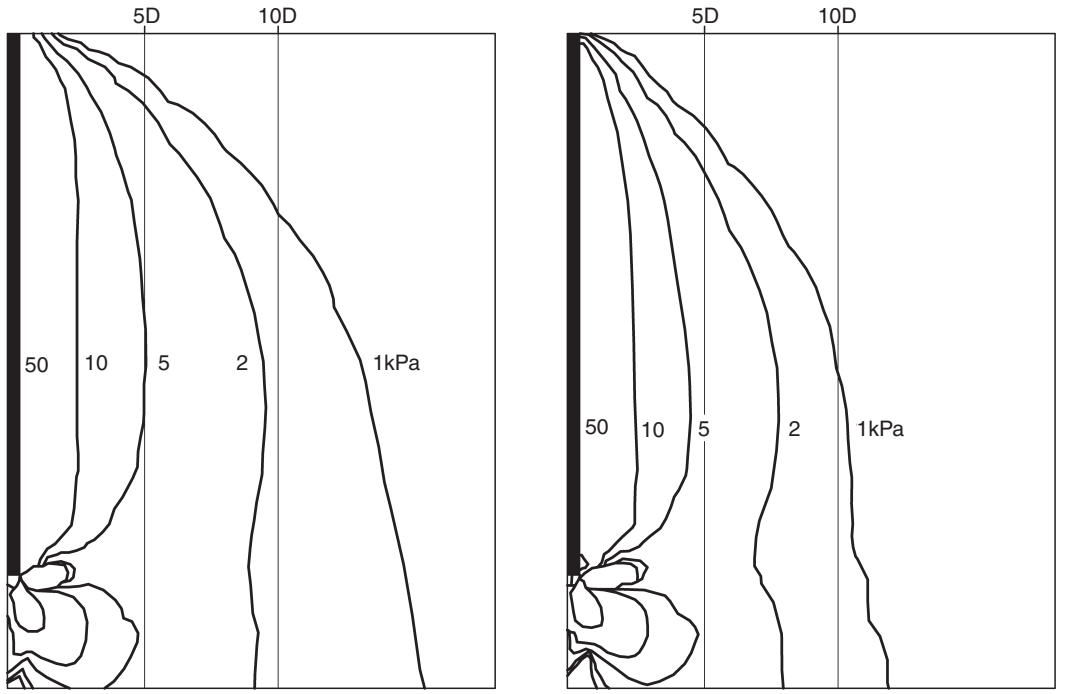


The pile beneath a raft also influences the raft behaviour. Figure 56.29, from Katzenbach *et al*. (2000), shows that the



(a) Scenarios considered



(b) Mobilisation of load with settlement - compariosn between a free standing pile and a single pile beneath a wide raft for three ground conditions. (Note that the settlement of the raft = total displacement of th raft minus the displacement at the depth of the pile base in the far field).

(c) Relative displacement between soil and pile beneath a wide raft

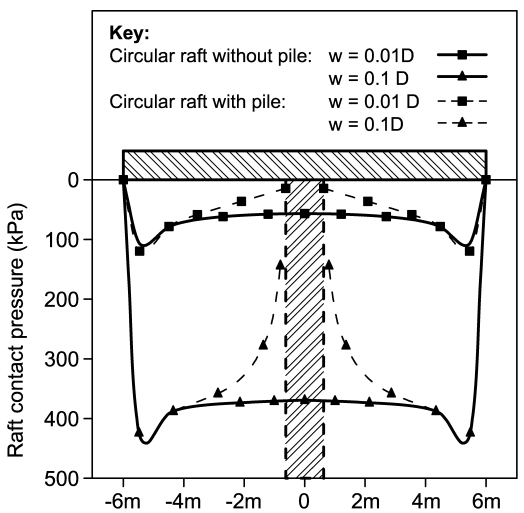

Figure 56.29 Influence of pile–soil–raft interaction on contact stress distribution beneath a piled raft

Modified from Katzenbach *et al.* (2000), all rights reserved

contact stress on the underside of a raft is locally reduced around the pile shaft (within about 2*D* to 2.5*D* of the pile centreline where *D* is the pile diameter).

The influence of nonlinear stress–strain behaviour on the pile–raft interaction has been assessed by Katzenbach *et al.* (2000). Figure 56.30 summarises the load-settlement characteristics of two piled rafts. Both rafts are 45 m wide and founded on a deep layer of stiff clay. Model M1 has 64 piles and M2 has 16 piles. The nonlinear load-settlement behaviour of the raft and pile group was included within the modelling. The load sharing between the piles and raft is summarised on **Figure 56.30(c)** for M1 and M2. It can be seen that the load share for M1 is practically constant across a wide range of applied loads. **Figure 56.30 (a)** indicates that the ultimate pile-group capacity for M1 is larger than the applied load. For model M2, the load share is also reasonably constant, until the ultimate capacity of the pile group is fully mobilised (for loads in excess of *A* as shown on **Figures 56.30(b)** and **56.30(c)**). At larger applied loads, the load share between the raft and piles becomes strongly nonlinear. Therefore, provided the pile-group capacity is *not* fully mobilised, then the analysis of raft-enhanced pile groups can be simplified, since the influence of nonlinearity on pile/raft load sharing can be assumed to be negligible. Hence, the elastic interaction factors shown on **Figure 56.22** can be assumed to be sufficiently accurate for practical design purposes.

56.6.4 Optimum location and number of piles in a piled raft

Studies by Randolph (1994) and Katzenbach *et al.* (1998) provided some useful insights into the optimum location and number of piles in raft-enhanced pile groups. **Figure 56.31**

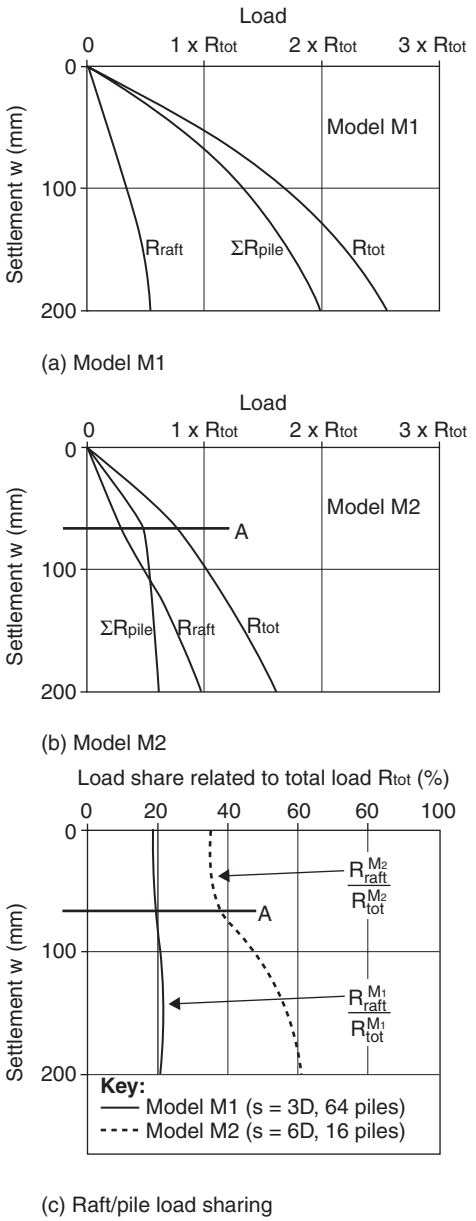

Figure 56.30 Influence of pile-group capacity on load sharing between the raft and pile group

Modified from Katzenbach *et al.* (2000), all rights reserved

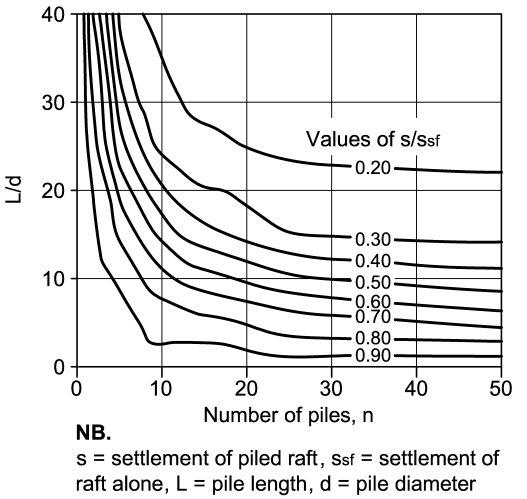

Figure 56.31 Piled-raft interaction diagram showing settlement reduction versus pile length and number of piles

plots the relative settlement (the ratio of piled-raft to unpiled raft settlement) against the number of piles and their length to diameter ratio, L/*d*. In this example, 50 piles are required for a conventional pile-group design. Considerable reductions in settlement are achieved with the installation of 10 piles, especially if those piles are relatively long (*L*/*d* >20); however, only minor additional reductions in settlement are achieved by using more than 20 piles. Similar observations have been made for very large pile groups. Viggiani (1998) back analysed the pile group for the Stonebridge Park Building in London (comprising 350 450-mm-diameter, 13-m-long piles), and found that a reduction in the number of piles to a third of the original value (i.e. 117) would have only caused a small increase in settlement (of about 5 mm to 10 mm). The raft would have then carried about 20% to 25% of the building load.

Conventional approaches for pile-group design tend to adopt a uniform distribution of piles beneath the raft. Total settlement will be reduced by the piles and differential settlement will be reduced as a consequence of the lower total settlement. A more direct and efficient approach is to locate piles in such a way as to minimise the differential settlement directly. The optimum location of piles in a piled raft will depend primarily on whether the applied structural loads can be characterised as either uniformly distributed (say through a stiff sub-structure) or are concentrated beneath a small number of heavily loaded columns. For a uniformly distributed load the principles for differential settlement control are shown on **Figure 56.32**: if a small number of piles are located beneath the central area of the raft then the differential settlement can be minimised. For a uniformly distributed load on a relatively flexible raft there will be a tendency for the raft to 'sag'. By locating the piles near to the middle, the sagging will be reduced. Similarly for a rigid raft there will be a concentration of contact stress near the edges. Again, by locating the piles near the centre of the raft a more uniform contact-stress distribution will be achieved, reducing raft bending moments and shear stresses. **Figure 56.33**, from Randolph (1994), shows an example of the effectiveness of this approach. A conventional pile group (81 0.8-m-diameter 20-m-long piles at 5*d* spacing) reduces the differential settlement by a small amount, compared with the unpiled raft. In contrast, the installation of just 9 1.5-m-diameter, 30-m-long piles, situated within the central third of the raft reduces the differential settlement far more effectively, across a wide range of loads. For concentrated superstructure loads, Poulos (2001) provides a set of linear elastic solutions, which may be useful

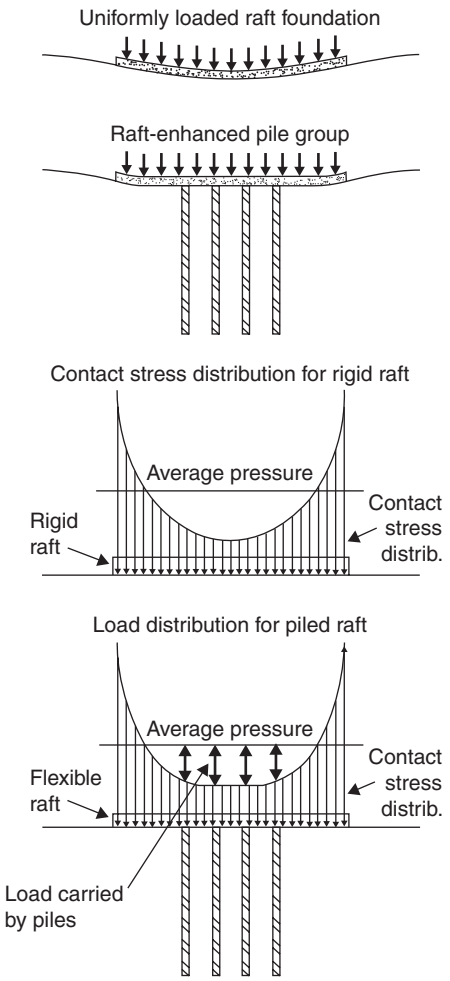

Figure 56.32 Optimising the pile locations for a uniformly loaded piled raft

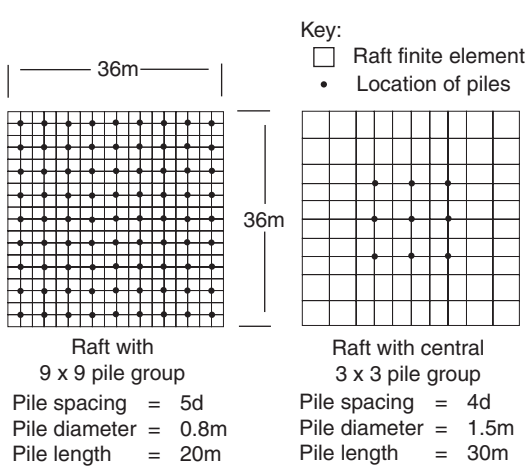
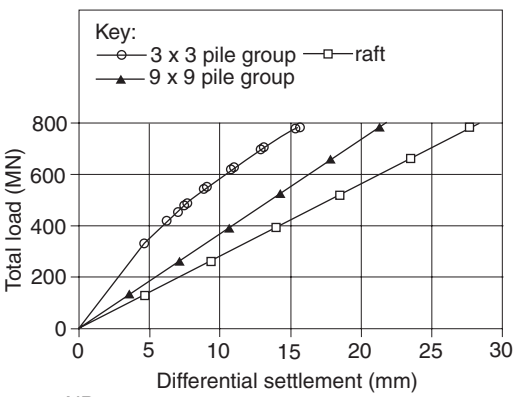
Modified from Randolph (1994), all rights reserved



for preliminary analysis. The main effect of concentrated column loads is to generate relatively large raft bending moments compared with uniform loading, whereas raft/pile load sharing and total settlement are practically unaffected. The detailing of the raft steel needs to be carefully considered. The connections between raft bars and those sticking up from piles below is often an issue. If the raft steel is especially heavy, exceptionally careful orientation of the pile steel is required to ensure it fits the same orthogonal pattern, for instance, by use of a rectangular cage over the upper section of the pile.

In the context of practical design, the examples given in **Figures 56.31**, **56.32** and **56.33** are rather idealised; nevertheless the important practical conclusion is that in order to minimise the total and differential settlement the use of a smaller number of longer piles located across the central area of a raft will often be far more effective than a large number of short piles uniformly distributed across the whole raft.



56.6.5 Compensated piled rafts

When piled rafts are located at the base of a deep excavation (known as 'compensated piled rafts') their behaviour is different to piled rafts located close to the ground surface (as discussed by Sales *et al.,* 2010) in the following respects:

- a compensated piled raft experiences less settlement;
- the piles take a smaller proportion of the load and the raft a larger proportion;
- the pile behaviour and the distribution of load between the raft and piles will be modified by the excavation and pile installation sequence;
- the presence and magnitude of a buoyant force (due to the raft being below the water table) will significantly affect the overall behaviour, and the raft load will be particularly sensitive to the magnitude of the buoyant force.

Table 56.5 Compensated piled raft – example for Hyde Park Barracks
Data taken from Sales *et al.* 20103

Table 56.5 shows an example of the building loads compared with the weight of excavated soil and the buoyant force from groundwater pressure, for the Hyde Park Barracks in London. This case history was described by Hooper (1973) and back analysed by Sales *et al*. (2010). The basement is nearly 9 m deep and the groundwater table is about 4 m below ground level. For this project, the weight of excavated soil is about 32% of the total load from the structure, and the weight of excavated soil plus the buoyancy force is about 44% of the total load from the structure. Clearly, for a compensated piled raft, any analysis ignoring the influence of the weight of excavated soil and the buoyancy force will give erroneous predictions of the piled-raft behaviour. The modelling of the construction process should be split into several key stages, for example:

Stage 0: Excavate to raft formation level.

Stage 1A: Raft concreting: the wet concrete will apply a load onto the base of the excavation. At this stage the raft is flexible and the 'piled raft' is ineffective. The settlement of sandy soils may be largely completed before the concrete has hardened, whereas for clayey soils some undrained settlement will occur and time-dependent consolidation settlement will occur after raft hardening (and hence lead to some raft–pile load sharing).

Stage 1B: Subsequent construction of the structure will take place with an effective piled raft after the raft has hardened, and there will be load sharing between the raft and piles. At this stage the weight of the structure is less than the weight of the excavated soil and the buoyancy force; only towards the end of 1B will the net effective weight be positive.

Stage 2: Throughout this stage, the structural weight exceeds the weight of excavated soil plus buoyancy force. The increment of soil settlement that occurs should be based on the net loads, i.e. the weight of structure minus (the weight of the excavated soil plus buoyancy force). In contrast, the loads that are transferred through the raft and piles should be based on the weight of the structure only.

Stage 3: This is the long-term condition, after consolidation of the soil.

The axial loads in the piles will be directly affected by the construction sequence. If the piles are installed before the bulk excavations for the basement, then heave-induced tensile forces will be induced in the piles, due to short-term heave of the piles (this is discussed in Chapter 57 *Global ground movements and their effect on piles*). If the piles are constructed after basement excavation, then short-term heave-induced tensile forces will not be generated in the piles. During Stage 1, when the structure weight is less than the weight of the excavated soils and the buoyancy force, there will be two components of vertical soil deformation: undrained settlement due to increments of load from the construction of the structure, and time-dependent swelling (i.e. upward movement) due to the net reductions in vertical effective stress at the base of the excavation. The overall 'net' effect (i.e. the overall downward or upward movement) will be dependent on the soil permeability compared with the speed of construction. If the soil is relatively permeable there will be a net upward movement, whereas for relatively low-permeability soils there will be a net downward movement. For the back analysis of Hyde Park Barracks, Sales *et al*. (2010) used a continuum model (finite element for the raft and boundary element for soil and piles). The soil below the raft is assumed to behave as a linear elastic-perfectly plastic material. In order to match the observed behaviour, the following were important:

(i) An increase in the 'elastic' modulus for the soil immediately below the raft (from a value of about 57 MN/m^2 to 284 MN/m^2, i.e. five times higher and close to the very small strain modulus, E_o or E_{max}, refer to Chapter 52 *Foundation types and conceptual design principles*).

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(ii) An increase in the flexural stiffness of the raft to replicate the stiffening effect of the sub-structure shear walls; the actual raft thickness was 1.5 m, but locally in the model this was increased to 10 m, to simulate the much higher effective flexural stiffness of the basement structure.

The change in groundwater pressure over time was replicated by assuming a linear increase in the buoyancy force with time from month 4 (after excavation) to the full buoyancy force after month 16. This is a simplified way of allowing for the dissipation of excess pore water pressures in the stiff clay with time. For other (more permeable) soils this could occur more rapidly.

56.6.6 Lateral loads on raft-enhanced pile groups

The potential for friction to be mobilised on the underside of a raft, means that lateral loads can be shared between the raft and piles in a similar manner to vertical loads. However, a cautious approach is necessary to ensure that the piles are structurally strong enough to resist their share of the applied horizontal load. If not, they could fail in a brittle and progressive manner. The critical scenario for lateral loading is a careful assessment of the lower-bound contact stress on the raft. This is likely to occur for the lower-bound soil stiffness close to the underside of the raft (hence a relatively 'soft' raft stiffness), and an upper-bound soil stiffness at depth (and hence a relatively stiff pile-group stiffness). The behaviour of pile groups under a horizontal load is introduced in Chapter 55 *Pile-group design*.

56.7 Pile-enhanced rafts

56.7.1 Introduction

Sections 56.2 and 56.3 describe approaches for the analysis of settlement and the structural performance of raft foundations, respectively. Usually, for a raft foundation the bearing capacity is not a limiting factor. When analysis indicates that the settlement (total or differential) is excessive or the structural resistance of the raft is exceeded locally, consideration has to be given on how to improve the design. The structural performance of a raft can be modified by increasing its thickness. However, this can prove costly. Moreover local thickening is often undesirable as changes in the excavation level are best avoided and the associated reinforcement details can be difficult and expensive to implement.

Reducing settlement will usually require piles. The conventional methods of pile design are essentially based on providing an adequate factor of safety against bearing-capacity failure. As pointed out in section 56.1 this leads to the question 'How many piles are required to carry the weight of the building?' Thus, what is essentially a limiting settlement problem is converted into a bearing-capacity problem, which can result in a very expensive solution. When settlement is the controlling factor, it is more appropriate to pose the question 'How many piles are required to reduce the settlement to an acceptable amount?' The approach of providing a sufficient number of piles to limit settlement can also be used to control differential settlement, bending moments and shear stresses in the raft. Rafts that are designed with these objectives are called *pile-enhanced rafts*. Note that this term is more appropriate than *settlement-reducing piles*, which was originally proposed by Burland *et al.* (1977) and Burland (1995).

56.7.2 Ductile load-settlement behaviour of piles

Straight-shafted piles are used for pile-enhanced rafts and an essential requirement is that their load-settlement behaviour should be ductile. This is usually the case for straight-shafted piles in clayey soils. As pointed out in Chapter 22 *Behaviour of single piles under vertical loads*, shaft resistance is essentially a frictional phenomenon and once it is fully mobilised it usually does not change significantly with further displacement. Some examples of pile tests on a wide variety of clay soils are given in the following.

Reese and O'Neill (1988) present numerous load-settlement results for straight-shafted bored piles in clay soils. These show that the carrying capacity is fully mobilised at settlements of about 10 mm and thereafter remains approximately constant for large settlements. The results of the classic research by Whitaker and Cooke (1966) on bored piles in London Clay are of particular relevance for pile-enhanced rafts. **Figure 56.34** shows the

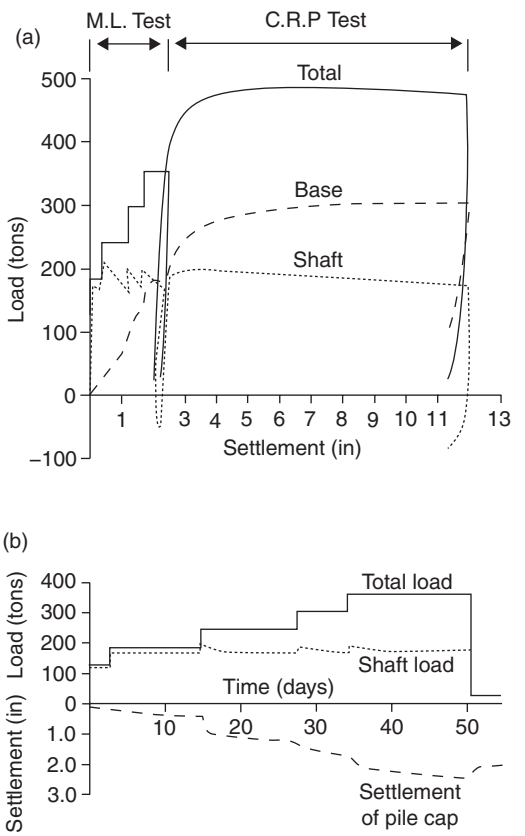

Figure 56.34 Load test on instrumented under-reamed bored pile in London Clay. Length is 12.2 m, shaft diameter is 0.79 m and base diameter is 1.68 m (Whitaker and Cooke, 1966)

results of a test on an under-reamed bored pile in London Clay in which a load cell was used to separate the base resistance from the shaft resistance. For the first part of the test the loads on the pile were applied in increments with the load at each stage being maintained constant until settlement had practically ceased. In some cases the load was held constant for 15 or more days. The second part of the test consisted of carrying out a constant rate of penetration test on the pile so as to determine its ultimate carrying capacity. The full line in **Figure 56.34(a)** shows the load-settlement behaviour of the pile as a whole.

The broken line labelled 'shaft' in **Figures 56.34(a)** and (b) shows the measured load-settlement behaviour of the shaft. It is clear that the carrying capacity of the shaft is fully mobilised at very small settlements – less than 10 mm. The jagged 'saw tooth' shape of the load settlement curve is of interest. When an additional increment of load is applied to the pile, the load carried by the shaft initially increases and then reduces as settlement takes place, as can be seen from **Figure 56.34(b)**. The temporary increase of load carried by the shaft is a 'rate effect' due to the initial high rate of settlement with time (Burland and Twine, 1988). As the rate of settlement steadily reduces so the load carried by the shaft reduces back to its previous value with the reduction in shaft load being shed to the base. It can be seen that the equilibrium fully mobilised carrying capacity of the shaft remains remarkably constant with increasing settlement, confirming the ductile nature of the shaft behaviour. All of the pile test results reported by Whitaker and Cooke show similar behaviour. As pointed out in Chapter 22 *Behaviour of single piles under vertical loads*, it is important to note in **Figure 56.34(a)** that, for working loads in excess of about 170 tons, the pile is operating with full mobilisation of the shaft carrying capacity. There must be tens of thousands of large-diameter bored piles operating satisfactorily in this way worldwide.

Figure 56.35(a) shows the load-settlement behaviour of a 762-mm-diameter 55-m-long open-ended tubular pile driven into a soft low-plasticity clay at Pentre, England (Cox *et al.,* 1992). The dotted line shows the measured elastic shortening of the pile. It can be seen that the peak resistance develops at a relative settlement of about 10 mm (total settlement minus elastic shortening). Thereafter there is a small reduction in capacity for an additional settlement of about 60 mm. The reduction in capacity is less than 10%.

Figure 56.35(b) shows the load-settlement behaviour of a 762-mm-diameter 33.5-m-long open-ended tubular pile driven into hard till overlying Oxford Clay at Tilbrook Grange, England (Cox *et al.,* 1992). The behaviour is remarkably similar to the pile in the soft Pentre clay. Peak resistance develops at a relative settlement of about 10 mm and thereafter there is a small reduction of carrying capacity with increasing settlement up to more than 70 mm.

In conclusion, shaft resistance is essentially a frictional phenomenon and as such it is permanent and reliable provided the effective stresses acting normal to the pile shaft do not change significantly. Numerous test results on straight-shafted driven and bored piles in clayey soils show that full mobilisation takes place at settlements of between about 5 mm and 10 mm and

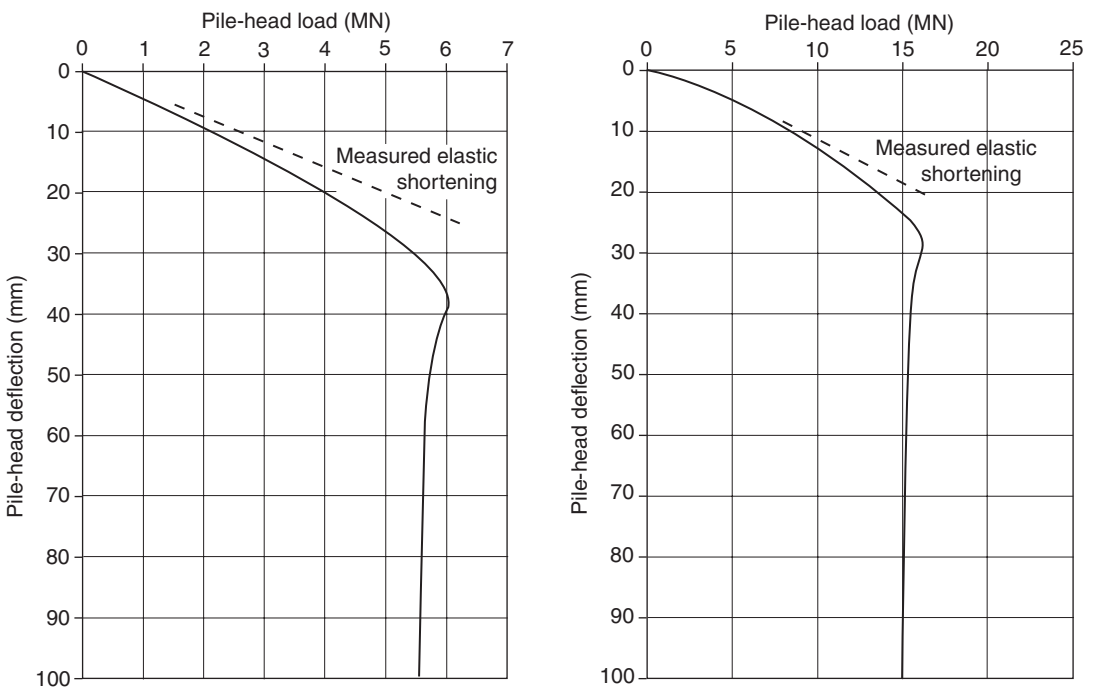

Figure 56.35 (a) Load test on 762-mm-diameter, 55-m-long open-ended pipe pile driven into normally consolidated low PI clay at Pentre; (b) load test on 762-mm-diameter, 33.5-m-long open-ended pipe pile driven into hard overconsolidated Oxford Clay at Tilbrook Grange

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

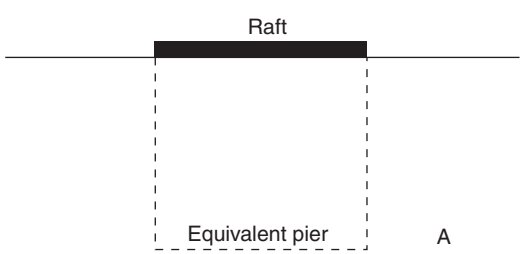
that at larger settlements little or no reduction or increase in shaft resistance takes place. If a pile-enhanced raft is proposed it is prudent to carry out loading tests to large settlements on the proposed type of pile to confirm that the load-settlement behaviour is sufficiently ductile.

56.7.3 Basic mechanisms of behaviour of pile-enhanced raft foundations

We return to the question posed previously but expand it a little:

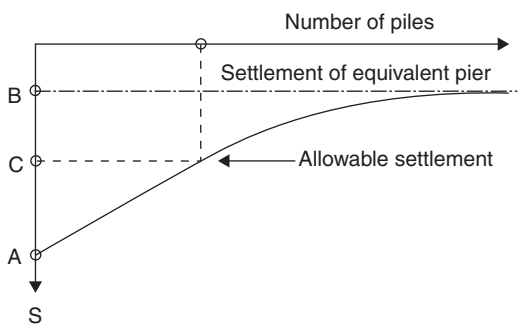
> *How many piles are required, together with their arrangement, to reduce the settlement (both total and differential) or the stresses in the raft to an acceptable level*?

This question lies at the heart of designing a pile-enhanced raft.



We deal first with the question of the number of piles required to limit the settlement to an acceptable amount. **Figures 56.36(a)** and (b) show, respectively, a raft foundation on a deep layer of clay and a graph of settlement vs the number of piles. With no piles the calculated maximum final long-term settlement is given by point *A* in **Figure 56.36(b)**. After a consideration of the structural and architectural requirements of the building to be supported by the raft, it is concluded that the settlement (or, usually, the differential settlement) is unacceptably large so that piles are required to reduce the settlement. In this situation a full pile group designed by conventional methods can be represented by an equivalent pier as shown in **Figure 56.36(a)** – see Chapter 55 *Pile-group design* (section 4.5.5). A settlement calculation of the equivalent pier will give a much reduced settlement represented by point *B* in **Figure 56.36(b)** but at considerable cost.

If, instead of the conventional approach, the decision is taken to adopt a pile-enhanced raft solution, it will first be necessary to decide on an acceptable maximum settlement – see Chapter 52 *Foundation types and conceptual design principles* (section 1.3). Point *C* in **Figure 56.36(b)** represents the chosen maximum allowable settlement for this case. Straight-shafted (ductile) piles are used and the load required to fully mobilise the shaft resistance of each is calculated. If a small number of piles are used, the settlement of the raft will be sufficient to fully mobilise their shaft resistances. The upward resistance of each pile acting on the raft foundation will reduce the load transmitted to the ground through the raft by the mobilised shaft resistance. If we proceed to add one pile at a time it will be found that the settlement of the raft will initially reduce in inverse proportion to the number of piles as shown in **Figure 56.36(b)**. This is because the spacing between the piles is large and there is little or no interaction between them. As the number of piles is increased the spacing between them reduces until there comes a point where the interaction between the piles and the raft foundation begins to become significant. The relationship between the settlement and the number of piles then becomes nonlinear and approaches the settlement of the equivalent pier foundation asymptotically. Provided the chosen allowable total settlement is large enough to be consistent with the guidance summarised in Chapter 52 *Foundation types and conceptual design principles* then the number of piles is likely to be small enough (and the spacing between them large enough) for there to be negligible interaction between them.



Burland (1995) drew the following conclusions from a study of pile–raft interaction (described in 56.6.3 above):

1. The raft–soil–pile interaction results in the pile beneath the raft mobilising its shaft resistance less rapidly with settlement than a free-standing pile. However, for raft settlements greater than 20 mm, more than 90% of the total shaft resistance of the equivalent free-standing pile is mobilised.
2. Computed contours of vertical shear stress around the pile beneath the raft show that the pile–soil–pile interaction can be ignored for spacing factors greater than about 6, where the soil stiffness increases rapidly with depth.
3. The pile–soil–raft interaction and the raft–soil–pile interaction can be simply accounted for in design by reducing the fully mobilised capacity of the piles by about 10%.

Observations of the pile–soil–pile interaction, by Mandolini *et al*. (2005) for a broad range of soil types, indicates that

(a) Raft, piled raft and conventional pile group geometry

(b) Raft, piled raft and conventional group settlement

Figure 56.36 Relationship between number of piles and settlement of a piled raft

interaction is negligible beyond about 8*d*. The critical spacing factor for the pile–soil–pile interaction to be negligible, depends on the variation of ground stiffness with depth. If the soil stiffness is relatively uniform a spacing factor of 8 will be an appropriate assumption, whereas if the soil stiffness increases rapidly with depth, then a spacing factor of 6 will be appropriate.

56.7.4 A simple design approach

The practical importance of these conclusions is that the analysis of a pile-enhanced raft can be carried out by a standard raft computer program (see section 56.2) in which the raft is modelled as plate elements and the deflections of the ground are derived from elastic half-space theory or the 1D method (see Chapter 53 *Shallow foundations*). The actions of the fully mobilised piles are simply modelled as appropriate upward forces applied at the chosen pile locations. For a given raft geometry and loading distribution, the locations of the piles can be successively adjusted to minimise the differential settlements, bending moments and shear stresses in the raft.

The above approach is illustrated in **Figure 56.37(a)**, which shows a raft foundation on a relatively uniform deep layer of clay and subjected to local high column loads. As shown in **Figure 56.37(b)** the raft foundation will undergo significant settlement in a sagging mode and there will be high local bending moments beneath the columns as shown in **Figure 56.37(c)**. By placing a suitably designed ductile pile under each column it is possible not only to reduce the bending moments in the raft as shown in **Figure 56.37(c)** but also the total and, in particular, the differential settlement as shown in **Figure 56.37(b)**.

Figures 56.32 and **56.33** illustrate how pile locations can be optimised to minimise differential settlements for raft-enhanced pile groups. Exactly similar approaches can be adopted for pile-enhanced rafts but the analysis will be much simpler, since pile–raft and pile–pile interactions can be ignored. If the pile spacing ratios turn out to be less than about 6 to 8 (depending on the variation of soil stiffness with depth) then a pile-enhanced raft will not be appropriate. However, it is worth revisiting the reasons for the choice of the maximum allowable settlement. Increasing the allowable total settlement will reduce the number of piles but this does not necessarily lead to increases in differential settlement or raft stresses provided the piles are located appropriately.

Love (2003) describes a case history of the design of a pile-enhanced raft foundation on London clay for which there was a considerable saving both in the number of piles and in the raft thickness when compared with a conventional design of a fully piled rigid raft. The building is a reinforced-concrete framed structure, seven storeys high, with a basement. Love stresses the following design requirements:

1. The load-displacement behaviour after full mobilisation should be as near as possible constant.
2. In practice the actual load deflection relationship will not be perfectly constant, see for example **Figure 56.35**. Unlike conventional pile designs, overcapacity can be as much as a problem as undercapacity; see **Figure 56.38**.
3. Raft settlement should always be greater than the amount required to mobilise full shaft friction.
4. Reasonable upper and lower bounds should be set for the fully mobilised pile loads, **Figure 56.38**, and the raft design checked for both extremes. **Figure 56.39** is taken from Love's paper and illustrates the designed upper and lower bound settlement profiles across the raft at various sections. It should be noted that a pile was not needed beneath every column.
5. In order to reduce the potential variation between the lower and upper bound pile capacities, the end-bearing resistance was eliminated. A variety of different methods can be used to eliminate, or reduce, end bearing if thought necessary.
6. Three pile tests were carried out and the tests were required to pass the design upper and lower bound load-settlement

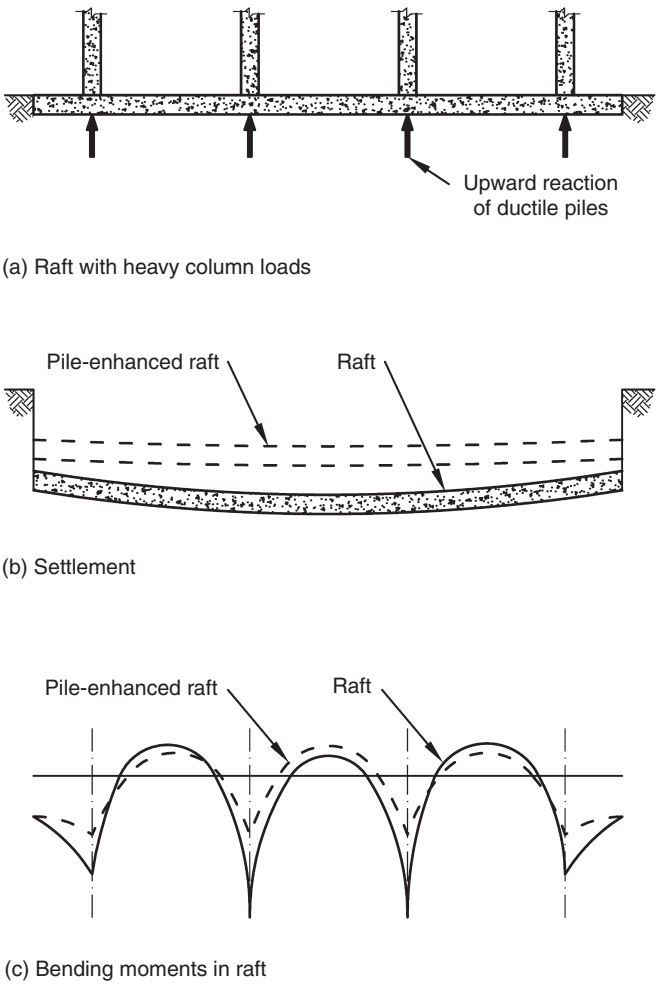


Figure 56.37 Illustrative example of a pile-enhanced raft foundation showing how the use of ductile piles beneath heavily loaded columns can reduce the total and differential settlement and the bending moments

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

criteria set for the design, points 1 and 2 in **Figure 56.38**. In order to capture the full load-settlement behaviour of the pile, the load tests were run as load controlled up to yield and as displacement controlled thereafter. As mentioned in section 56.6.2, it should be noted that the shaft resistance is rate dependent and a constant rate of displacement of 2 mm/min is likely to give shaft resistances about 15% higher than the static resistance (Burland and Twine, 1988).

56.7.5 Lateral loads on pile-enhanced rafts

The use of pile enhancement for rafts and footings carrying lateral loads has the potential for achieving very significant economies. In the traditional approach to pile-group design most of the vertical load is assumed to be carried by the piles. This leads to difficulties in carrying lateral loads since no reliance can be placed on frictional resistance between the base of the raft and the underlying ground, as would be the case for an unpiled foundation. Therefore, either the pile group has to be designed to carry the horizontal loads or raking piles must be introduced. Both these solutions are expensive and unsatisfactory for a variety of reasons. It is evident that a 'vicious circle' has developed in which an excessive number of vertical piles inhibits the ability of the foundation to transfer horizontal loads into the underlying ground.

However, if a pile-enhanced raft design is adopted, the number of piles can be substantially reduced and a significant contact stress between the raft and the ground is retained. Hence the frictional resistance between the underside of the foundation and the ground can be utilised to transmit the horizontal shear stresses into the ground and the need for additional piles, either vertical or raking, is eliminated. This approach requires a careful assessment of the likely horizontal displacements of the raft together with the associated induced bending moments at the top of the piles. It is important to note that the relative stiffness of the piles and raft under lateral loads needs to be considered (and *not* just their ultimate capacity), in order to assess the load share between the raft and piles. The reader is referred to Chapter 54 *Single piles* for an introduction to the design of single piles subject to lateral loads.

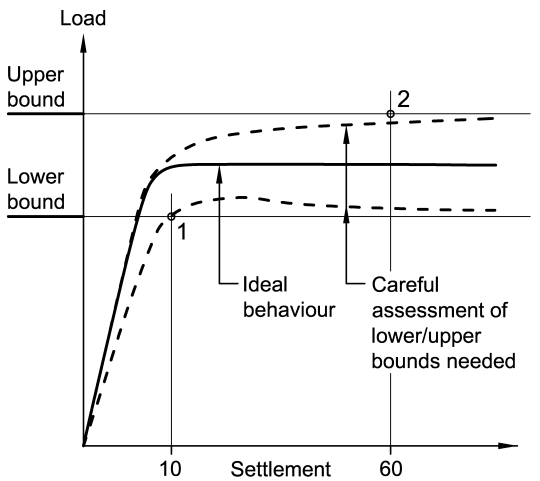

Figure 56.38 Pile-enhanced rafts – pile load-settlement response

56.8 A case history of a pile-enhanced raft – the Queen Elizabeth II Conference Centre

An early application of pile-enhanced rafts was the design of the foundations of the Queen Elizabeth II Conference Centre in Westminster, London (Burland and Kalra, 1986) – see **Figure 56.40**. The conference centre is founded on a 2-m-thick raft in a relatively shallow excavation. The calculated maximum total settlement was in excess of about 20 mm. Over half of the total weight of the superstructure is transmitted to the raft by means of a few columns, which are located at the edges of the raft and carry loads of up to 26 MN. The preliminary analysis of the raft identified local areas of high bending moments and shear forces and concern was expressed that the bearing pressures under some of these columns might induce local yielding and excessive settlement in the underlying London Clay.

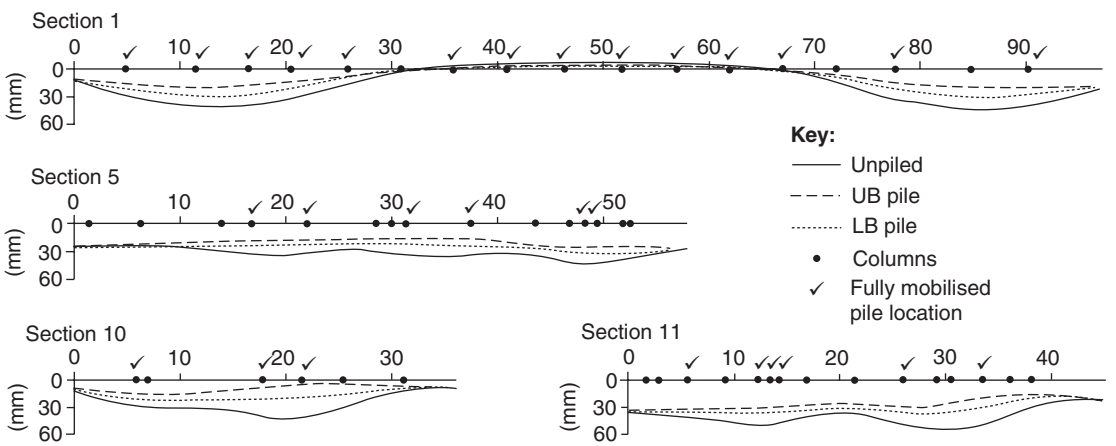

Figure 56.39 Upper and lower bound settlement profiles for a pile-enhanced raft compared to an unpiled raft (Love, 2003)

One method of dealing with the problem would have been to thicken the raft locally. This would have been a costly and time-consuming approach with the potential for causing delays and difficulties in the construction of the major raft foundation. The local thickenings would have been at the edges of the raft and there were significant 'knock-on' costs in the design of the retaining walls.

A pile-enhanced raft appeared to be a suitable solution. Single straight-shafted piles were placed directly beneath the most heavily loaded columns in the knowledge that the settlement of the raft would be sufficient to fully mobilise the shaft resistance of the piles. The effect was to apply a constant upward force beneath each column. By this means the resultant loads transferred from the columns into the raft were significantly reduced. The piles are each 16 m long and 1.8 m in diameter. The calculated ultimate shaft resistance was 6.4 MN giving effective reductions in the resultant column loads of between 25% and 46%.

Figure 56.40 Queen Elizabeth II Conference Centre

Figure 56.41 shows the calculated bending moments along a 3-m-wide edge strip with the locations of the columns indicated by arrows. The bending moment labelled 1 relates to the undrained case without piles. The crosses refer to the worst values for some other cases considered, including the fully drained long-term case and partially drained cases involving some heave. The bending moment labelled 2 is the undrained case with stress-reducing ductile piles in place beneath the columns. This proved to be the worst case considered using such piles. It can be seen that the presence of the ductile stress-reducing piles beneath each column results in a considerable reduction in the bending moments, particularly beneath the columns.

In view of the novelty of this approach the Building Research Establishment was invited to instrument one of the piles to measure the magnitude of the load transferred to it through the raft foundation. A full description of the investigation is given by Price and Wardle (1986).

Figure 56.42 shows the results of the measurement. The full line and the broken line represent the measured pile-head loads and the calculated column loads, respectively, noting that they are plotted to different scales. Early on in construction the pile-head loads showed some fluctuations due to intermittent load applications with a tendency for the underlying clay to swell during intervening periods. The main construction began in the middle of 1982 as can be seen by the rapid increase in the column loads. The measured pile-head loads reflect the loads on the columns. Construction was completed during 1984. It can be seen that by 1986 the measured pile-head load was in good agreement with the calculated value of 6.4 MN for the fully mobilised shaft resistance. Measurements continued through to 1996 and it is clear that no significant change in the load carried by the pile has taken place over a period of about ten years.

56.9 Key points

(1) Rafts – the differential settlement and bending moment induced in a raft is fundamentally affected by its stiffness. Raft stiffness is a function of soil and concrete stiffness, and, particularly, the ratio of raft thickness to raft width (or diameter).

(2) Raft on springs vs soil continuum – a structural design often assumes the soil beneath a raft acts as a bed of

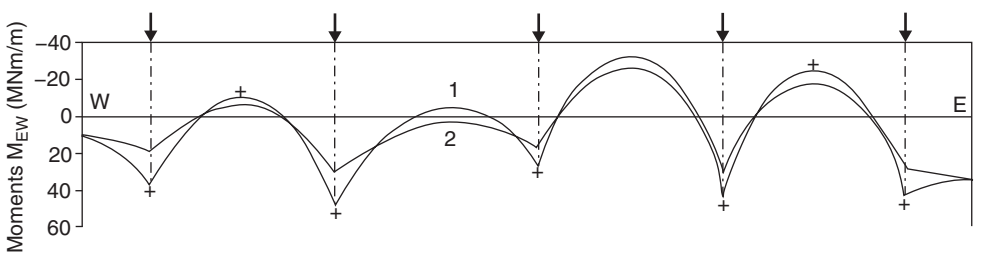

Figure 56.41 Queen Elizabeth II Conference Centre: calculated bending moments on a 3-m-wide strip at the edge of the raft: (1) is for the raft alone and (2) shows the effects of the ductile piles
Modified from Burland and Kalra (1986)

Data taken from Burland and Kalra (1986)

uniform springs. There are many pitfalls and associated errors with this approach and it is *not* recommended. A practical and more realistic approach is to have 'interactive' spring stiffnesses, with a structural spring model run in tandem with a soil continuum model. This will result in non-uniform springs, typically stiffer towards the raft edge and softer at the centre.

(3) Piled rafts – compared with conventionally designed rafts and pile groups, a piled raft can provide many benefits when used in suitable ground conditions, e.g. reduced costs and easier and safer construction. There are two main types of piled raft: the raft-enhanced pile group and the pile-enhanced raft. The design concepts are very different and must *not* be mixed.

(4) Raft-enhanced pile group – both the raft and pile group behave in a pseudo-elastic manner. A key issue is to assess the load sharing between the pile group and raft, which is dependent on the relative stiffness of the pile group and raft. The upper and lower bound stiffnesses of pile group and raft need to be assessed. This type of piled raft can be thought of as a 'value-engineered pile group', with piles omitted to the extent that raft resistance can be relied upon.

(5) Pile-enhanced raft – the piles will have fully mobilised their capacity. It is essential that the pile load-settlement behaviour is ductile. A key issue is to assess the upper and lower bound pile capacities. This type of piled raft acts predominantly as a raft, with additional local support by piles, beneath heavily loaded columns. The term 'pile-enhanced raft' is considered more appropriate than the term 'settlement-reducing piles', because the main benefits may be broader than settlement reduction alone. A pile-enhanced raft is generally chosen when a raft by itself just fails to work.

Chapter 57

Global ground movements and their effects on piles

Edward Ellis University of Plymouth, UK
Anthony S. O'Brien Mott MacDonald, Croydon, UK

CONTENTS

57.1	Introduction	887
57.2	Negative skin friction	888
57.3	Heave-induced tension	891
57.4	Piles subject to lateral ground movements	893
57.5	Conclusions	897
57.6	References	897

Global ground movements may occur for a variety of reasons, but are most commonly associated with cut-and-fill operations, particularly in clay soils. The impact on structural elements such as piles depends strongly on construction sequence, and normally the presence of soft clay or peat is most problematic, since large movements may occur over several months or years. The chapter considers negative skin friction, heave-induced tension and lateral interaction. Lateral ground movements are of particular concern since they have led to the structural failure of piles and pile groups on many occasions.

57.1 Introduction

Global ground movements may occur for a variety of reasons, but are most commonly associated with cut-and-fill operations, particularly in clay soils. The impact on structural elements such as piles depends strongly on construction sequence, and normally the presence of soft clay or peat is most problematic, since large movements may occur over several months or years. The chapter considers the following aspects:

1. Negative skin friction (in soil which is settling, e.g. beneath an embankment). This increases the axial load on piles, and will tend to increase pile settlement significantly.
2. Heave-induced tension (in soil which is heaving upwards, e.g. beneath an excavation). This may cause tensile failure of the piles.
3. Lateral interaction (in soil which is moving horizontally, e.g. adjacent to an embankment or excavation, or in an unstable slope). This can be particularly damaging since the piles may fail in bending or shear. This is a common cause of pile or pile group failure if this mode of ground movement is overlooked.

In each section the response of a single (individual) pile is initially considered, before proceeding to additional considerations for the group response. Generally speaking piles at the centre of a group tend to be 'sheltered' from interaction effects and therefore the assessment of a single pile response tends to be conservative for pile groups. When lateral interaction develops, progressive structural failure may be an issue (because the structural failure mode is often brittle, rather than ductile) and then a cautious approach is necessary.

Owing to the importance of construction sequence, close communication and coordination is likely to be required between the contractor or project manager and the designer. Close control of activities on site, particularly where sub-contractors may not be aware of or prefer to ignore the implications of their actions, is also important.

Owing to the complexity of many of the problems and their relation to subtle aspects of soil behaviour, input from a geotechnical specialist will be essential. The text below highlights the main points and indicates key references for more detailed information. However, most of the references are published in specialist geotechnical journals, which will assume prior knowledge of geotechnics.

Often the most pragmatic approach may be a practical 'engineering solution', which substantially 'removes' the problem. For instance:

1. inherently reduce soil movement, e.g. by carrying out ground improvement;
2. wait for significant soil movement to be substantially complete before constructing the piles;
3. isolate the piles from the soil movement.

Point 1 above normally requires that the cause of movement is largely removed, for instance by constructing an embankment from lightweight fill or by carrying out ground improvement.

Point 2 highlights the difficulty of low-permeability clay soils, which are likely to require months or years to fully consolidate. It may be undesirable to wait this long. Time-dependent ground movements tend to be predominantly vertical, whereas significant lateral ground movements mainly occur during construction (unless there is ongoing instability). Hence, when lateral ground movements are the main concern point 2 can be effective.

An example of point 3 is the use of double casings for bored cast *in situ* piles. The annulus between the two casings can isolate the pile from the outer casing, which moves with the soil.

Figure 57.1 shows an example of the extreme consequences of global ground movements on foundations. In this situation it appears that lateral interaction (due to excavation on one

side and stockpiling on the other) was a significant contributory factor, which led to a catastrophic collapse (China Daily, 2009). This failure illustrates a few key principles:

(i) it is vital to have an awareness of all the construction processes and their relationships with site topography, existing structures and infrastructures, both across a site and beyond the site boundaries;

(ii) the sequence and timing of activities can be important;

(iii) piles which are designed solely for vertical loads (common for buildings) can be extremely vulnerable to lateral ground movements.

The above means that temporary works can have a significant impact on the permanent works. Temporary and permanent works are often designed by separate organisations and the commercial and procurement environment will also be a factor, as well as technical issues. The avoidance of these major hazards, although often obvious with the benefit of hindsight, can require a major coordination effort both during design and construction.

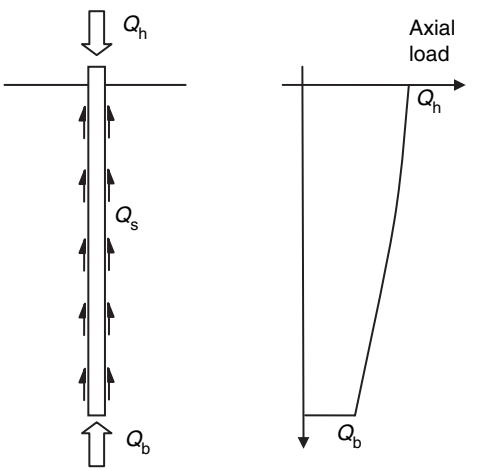
57.2 Negative skin friction

57.2.1 Introduction

As shown in **Figure 57.2(a)**, ordinarily for piles the vertical load applied at the head (Q_h) is resisted by a combination of the resistance on the shaft (Q_s) and the base (Q_b); see Chapter 10 *Codes and standards and their relevance* and Chapter 54 *Single piles* for further details. Hence:

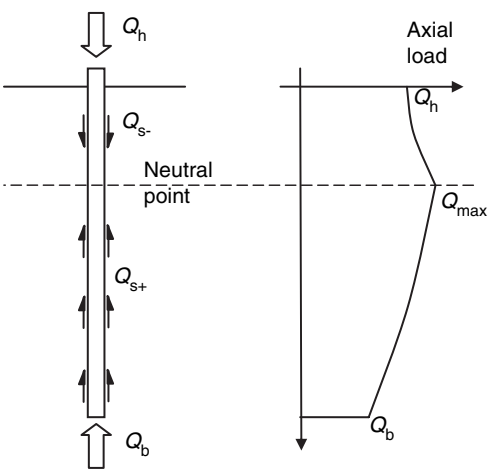
$$Q_h = Q_s + Q_b. \tag{57.1}$$

The maximum axial load in the pile is Q_h.



It is assumed that the pile displaces downwards, whilst the surrounding soil is static except near the pile, where it will tend to move with it. However, as shown in **Figure 57.2(b)**, if the soil inherently tends to settle more than the pile over at least part of the length, then there will be both 'positive' and 'negative' skin friction (Q_{s+} and Q_{s-} respectively). The transition from positive to negative skin friction is the point where settlement of the pile and soil are equal, and will be referred to as the neutral point. When there is negative skin friction (NSF) the maximum axial load in the pile (Q_{max}) occurs at the neutral point and exceeds Q_h:

$$Q_{max} = Q_h + Q_{s-} = Q_{s+} + Q_b. \tag{57.2}$$



Thus, any NSF on the pile increases the maximum axial load, which may have implications for the structural design of the pile. However, settlement of the pile will also be increased, and this is likely to be the most significant practical issue that will govern design (Poulos, 2008).

(b) Negative skin friction

Figure 57.2 Effect of negative skin friction compared to normal pile action

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Settlement of the soil layer is likely to be due to imposition of a surcharge (e.g. fill material) at the surface, although lowering of the water table may also cause significant settlement without any change in load at the surface (especially for soft clays or peat). Furthermore, vegetation-induced changes in effective stress may cause both settlement and heave; refer to Chapter 53 *Shallow foundations*. The settling material may actually be fill material, which has been recently placed and is settling with the underlying material that it has loaded, as well as potentially settling within its own thickness. Where the soil is clay it will take significant time for the settlement to occur. If the thickness of compressible soil is variable, say soft clay on a steeply dipping rockhead, then lateral movement may also develop in addition to settlement. This would then require a consideration of lateral interaction effects; refer to section 57.4 below.

57.2.2 Single piles: end-bearing and 'floating'

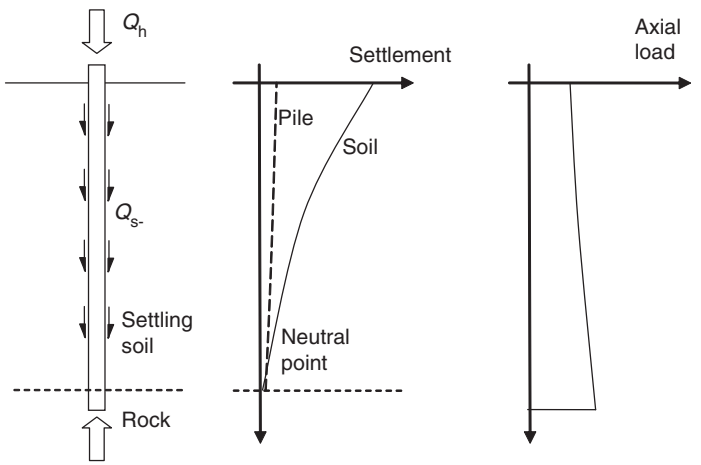
57.2.2.1 End-bearing piles

As shown in **Figure 57.3(a)**, the simplest form of NSF loading is for a pile that derives nearly all of its capacity from end-bearing in an underlying stratum, which is significantly stiffer or stronger than the overlying soil (e.g. rock). The neutral point can then be assumed to be close to the bottom of the settling soil layer, and it will be slightly conservative to assume that negative skin friction exists over the entire length of the shaft ($Q_{s-} = Q_s$, $Q_{s+} = 0$). Equation (57.2) then becomes:

$$Q_{max} = Q_h + Q_{s-} = Q_b. \tag{57.3}$$

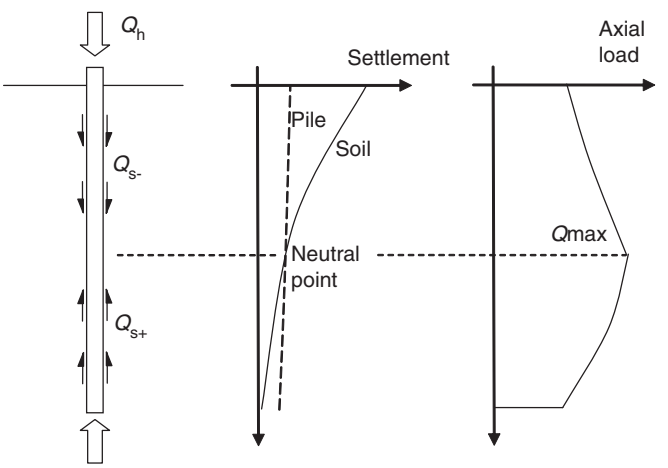
If the pile also derives a significant shaft capacity in the underlying stratum (i.e. $Q_{s+} > 0$), then the original version of equation (57.2) may be appropriate. However, the neutral point is still assumed to occur at the boundary between the two strata and, hence, determination of Q_{s-} and Q_{s+} is relatively straightforward.

When NSF is induced by soft clays or peats it is common to assess this by using total-stress methods. However, there are a number of problems: firstly the empirical alpha values quoted in the literature are not directly relevant for NSF (since they have only been derived from conventional load tests to measure positive shaft friction); secondly, there is usually a wide spread of alpha and c_u values, so selection of appropriate design values is problematic; and finally, depending upon the magnitude of the surcharge, the total-stress method may be either unsafe or overconservative.



For soft clays or peats, it is recommended that NSF is calculated by using an effective-stress (β) approach (refer to Chapter 22 *Behaviour of single piles under vertical loads* and Chapter 54 *Single piles*).

57.2.2.2 'Floating' piles



As shown in **Figure 57.3(b)**, where there is a more gradual increase of soil strength or stiffness with depth, the situation becomes more complicated, since the depth of the neutral point will not be immediately apparent. Rather, it depends upon a comparison of estimates of soil and pile settlement with depth.

57.2.2.3 End-bearing piles and brittle response

The design of end-bearing piles is generally more straightforward, since the location of the neutral point can be readily assumed. However, despite the complication of establishing the depth of the neutral point for floating piles, the response will be relatively ductile (or 'self-correcting'), since if Q_{s-} is larger than anticipated, the pile settlement will be increased, but this will in turn move the neutral point upward, tending to reduce Q_{s-}. For end-bearing piles this will not be the case, and the base resistance must have sufficient reserve capacity to cope with uncertainties in the assessment of negative skin friction. For piles which are socketed into rock, particular care may be required if they are subjected to negative skin friction. The shaft friction that develops in some rocks (sandstones,

(a) End-bearing pile – substantially stiffer/stronger substratum

(b) Floating pile – gradual increase in soil strength/stiffness with depth

Figure 57.3 End-bearing and floating piles

limestones) can exhibit brittle behaviour (i.e. the shaft friction reduces after a limiting displacement has developed). Hence, the value of any 'factor of safety' (FoS), which is applied, would need to vary depending upon which of the above three scenarios was relevant (i.e. from relatively low values for floating piles, intermediate for end-bearing piles and relatively high for piles with 'brittle' resistance characteristics).

57.2.3 Design considerations for single piles

Even for a large pile group, a consideration of the behaviour of a single pile is likely to be a logical starting point for design.

57.2.3.1 Determination of skin friction load

Determination of Q_{s+} and Q_{s-} (and Q_b) is likely to be based on routine methods as outlined in Chapter 54 *Single piles*. The shaft capacity will normally be assessed using effective-stress methods in free-draining soils or a total-stress approach in clay. However, an effective-stress approach may be used in clay, potentially leading to a reduced estimate of Q_{s-} (Cheong, 2007). Where an effective-stress approach is used in an overconsolidated clay, determination of the earth pressure coefficient near the soil surface, and the influence of pile construction-related effects will require careful consideration (Bown and O'Brien, 2008).

Since skin friction is mobilised at relatively small pile–soil displacement it may normally, and conservatively, be assumed that the 'switch' from Q_{s+} to Q_{s-} at the neutral point occurs instantaneously. The estimation of base capacity as settlement of the pile increases is likely to be more important, as discussed below.

57.2.3.2 Determination of the soil settlement profile with depth

The profile of soil settlement is an important element of any NSF design. It will require knowledge of the increment in vertical effective stress and the one-dimensional stiffness with depth (see Chapter 19 *Settlement and stress distributions* and Chapter 53 *Shallow foundations*). The distribution of strain and, hence, settlement with depth can then be derived. The resulting profile is likely to have a curvature as shown in **Figure 57.3(b)**, representing reducing strain with depth. The increment of vertical stress will reduce with depth to some extent, particularly as the depth becomes large compared to the extent of the load. Furthermore, the stiffness of the soil is likely to inherently increase with depth. This effect is compounded since soil stiffness also reduces significantly as strain increases (see Chapter 53 *Shallow foundations*), so that the relevant 'operational' stiffness may increase very significantly as strains reduce with depth. Ignoring the curvature of the settlement profile (**Figure 57.3(b)**) can lead to significant overestimation of the thickness and, hence, magnitude of NSF loading (Cheong, 2007).

The interdependence of strain and stiffness can be accounted for in a finite element analysis with a suitably sophisticated soil constitutive model, but care will also be required that the non-linearity of the response is correctly modelled by conducting the analysis in sufficiently small increments (Potts, 2003). An iterative analytical method, which can be undertaken using a spreadsheet, is described by O'Brien and Sharp (2001a and 2001b).

Once the 'free-field' soil settlement profile (i.e. not specifically accounting for the pile) has been determined, it is likely to form an input to the subsequent analysis, and can be assumed to remain constant. This will be conservative, particularly for large pile groups (see below), since the presence of the piles will tend to locally reduce settlement of the soil. A finite element analysis including the piles can potentially be used to overcome this assumption, inherently incorporating the soil–pile interaction. However, implementation of the analysis will require an experienced user, and a software package suitable for geotechnical applications. Furthermore, an appropriate soil constitutive model will be required, and modelling of the pile–soil interface properties will require careful consideration.

57.2.3.3 Determination of the pile settlement profile with depth

Generally speaking, the vertical strain of concrete in the pile will be one or two orders of magnitude lower than the strain in the surrounding soil if the soil is settling significantly. Hence, an assumption that the pile is rigid will often be appropriate, leading to a profile of settlement with depth, which is a vertical line on a plot such as **Figure 57.3**.

Settlement at the toe of the pile is likely to be significant except where there is a very stiff bearing layer. Fleming (1992) presents a relatively simple method based on hyperbolic functions, which can be used for estimation of the base response. Alternatively a suitable factor on the ultimate bearing capacity can be used to limit settlement at the toe of the pile (see Chapter 54 *Single piles*).

57.2.3.4 Determination of pile length

Routine design of a pile (**Figure 57.2(a)**) is likely to require some iteration in the sense that even for a given pile diameter the required pile length will initially be unknown, and will be dictated either by the FoS against ULS failure, or the allowable settlement at the head. Normally the pile will be 'made longer' until these criteria are achieved.

As described above, for an end-bearing pile (**Figure 57.2(a)**) the design is likely to follow this approach. The total load (Q_h + Q_{s-}) must be resisted in the stronger substratum. Note that the pile will need to extend a few diameters (approximately three to six) into the stronger substratum to develop the full bearing capacity of this layer in any case (see Chapter 54 *Single piles* and Chapter 55 *Pile-group design*). Any weathering of this material near the top of the layer will also be an issue. It may be decided to extend the pile a significant distance into the stronger layer so that a significant Q_{s+} can also be exploited. However, the ability of piling plant to extend (drive or bore) the pile into this layer may be a constraint, particularly as diameter increases.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

For a floating pile the design will be governed by serviceability. A practical starting point for design is to assume that the pile is rigid and settles uniformly by an amount corresponding to the maximum allowable settlement at the pile head. Using the soil settlement profile this then allows determination of Q_{s-}, and hence ($Q_{s+} + Q_b$) required for equilibrium. Since the calculation is a serviceability calculation a relatively small factor can be applied to Q_{s+}; however, as mentioned above Q_b will require more careful consideration or a larger factor to account for potentially significant settlement at the toe. For piles in stiff clay, Q_b is typically quite small compared with Q_{s+}; hence, it could be conservatively ignored for a simple assessment. The importance of an accurate estimation of the distribution of settlement with depth is stressed, since this can have a significant impact on Q_{s-} for a given settlement.

Poulos (2008) gives guidance on the factor of safety required in the 'stable' (non-settling zone), which should limit settlements to acceptable values. In the discussion of that paper Bourne-Webb (2009) highlights the potential importance of settlement at the toe, arguing that this approach should not rely heavily on Q_b unless this can be justified. The value of Q_b will be very important if the pile is toed into cohesionless soil or rock (when Q_b will be relatively large compared with Q_{s+}).

57.2.4 Pile groups

Lee *et al*. (2002) report finite element modelling of pile group effects on NSF loading. As might be expected, they found that piles near the centre of a large group are 'sheltered' from the effect of NSF. Thus, the estimation of the effect on a single pile as above is conservative.

Lee *et al*. (2006) furthermore consider the effect of a pile cap on group behaviour. Again, piles at the edge of the group are most prone to NSF, and tend to cause settlement of the group, which is resisted by piles in the centre. In the absence of a significant external vertical load on the pile group this can lead to tension at the head of the outer piles as they pull the cap down. This would need to be carefully considered in the structural design of the connection of the pile head to the pile cap.

Global ground movements will affect the distribution of axial forces in a pile group. For example, observations of axial forces in a piled bridge abutment at Newhaven (Reddaway and Elson, 1982) indicated a relatively uniform load distribution across the group; whereas a conventional linear elastic analysis (which ignored the influence of adjacent embankment settlement) gave axial forces in the front row of piles that were nearly three times larger than the rear row.

57.2.5 Methods to reduce NSF

For pre-cast driven piles the pile may be coated with a low-friction material (e.g. bitumen) over the depth where NSF is anticipated, thus reducing Q_{s-}. However, there is a risk that the coating will be removed as the pile is driven. Even if the coating is undamaged, the NSF over this length will not be zero.

For bored piles a double casing can be used over the upper portion of the pile. The outer casing is directly in contact with the settling soil, but not the inner casing or pile. The inner casing allows the pile to be cast *in situ* through the full depth. However, the piles are then laterally unsupported over this length, which may have implications for buckling under an axial load or there may be a significant loss of capacity to carry a lateral load.

57.3 Heave-induced tension

57.3.1 Single piles

Heave-induced tension (HIT) occurs when piles are constructed in clay soil beneath a deep excavation, where upward movement is ongoing, or in an expansive swelling soil (e.g. due to changes in the water table or saturation) – see section 57.3.3 below.

Here, the main issue is that if there is insufficient load at the head of the pile tension will occur, with consequent cracking of the concrete if there is insufficient tensile reinforcement. **Figure 57.4(a)** shows the situation with no load at the pile head. The top portion of the pile is 'pulled 'upwards by what would conventionally be 'positive' skin friction, and vertical equilibrium is preserved by an equal amount of 'negative' skin friction anchoring the pile into the soil at greater depth, which is heaving less. There is no load at the base of the pile which is being 'lifted'. Since soil strength tends to increase with depth the neutral point is likely to be approximately at a depth of between half and two-thirds of the pile length. For the situation shown in **Figure 57.4(a)**:

$$Q_{s+} = Q_{s-} = \frac{Q_s}{2}. \tag{57.4}$$

Therefore a pragmatic safeguard against tensile failure of piles due to HIT is to provide sufficient tensile reinforcement to carry a load equal to half the shaft capacity through the full length.

As shown in **Figure 57.4(b)**, if there is some compressive load Q_h at the head of the pile, tension will still occur near the bottom of the pile unless $Q_h > Q_s$. However, the position of the neutral point is lower and the heave of the pile is reduced.

For clay soils beneath an excavation, the strength and effective stresses will reduce as swelling occurs. Hence, if the pile is installed before excavation then there should be a check on the heave-induced tension for both short- and long-term conditions to ensure the critical condition is identified. Typically, short-term conditions will be critical for structural design, and either short- or long-term conditions may be critical for serviceability (i.e. upward movement) of the pile, depending upon the magnitude of the compressive load at the pile head. If the pile is installed after excavation, the structural design checks would be similar to those above; however, upward movement would solely be due to time-dependent movement (the total minus undrained movement).

A free-field profile of soil heave versus depth can be calculated, as in section 57.2, based on a reduction in the effective

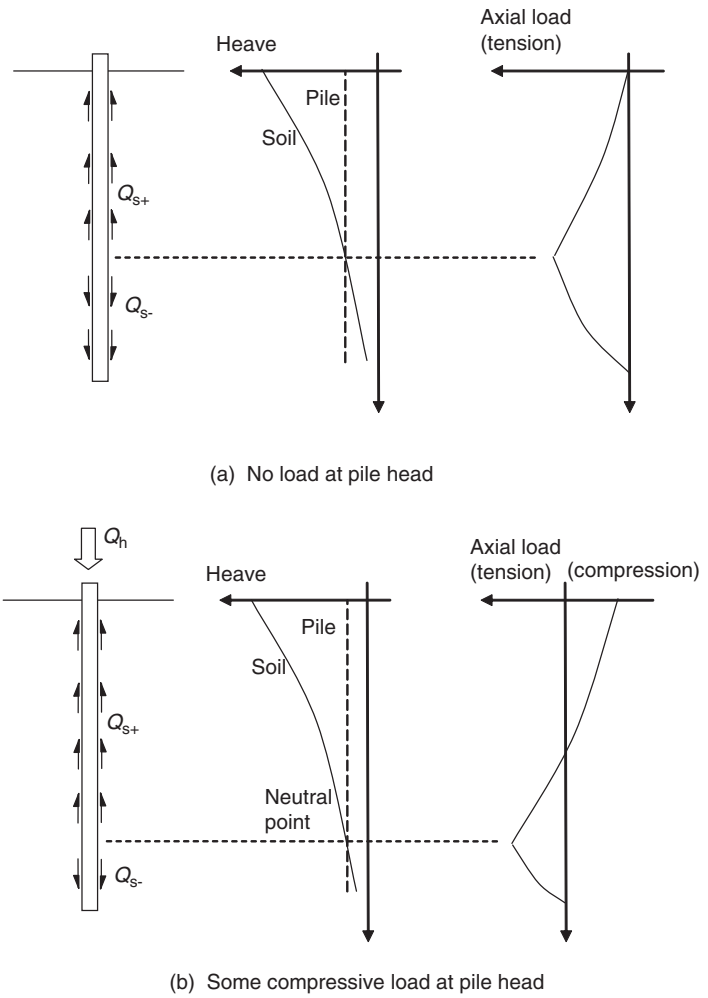


Figure 57.4 Heave-induced tension

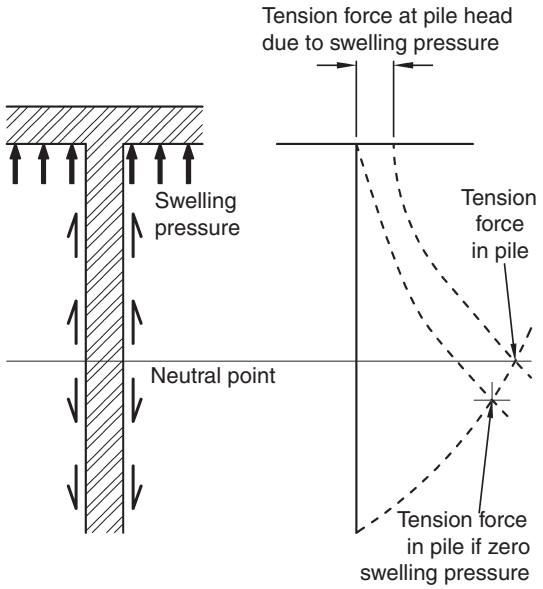
stress. The soil swelling curve will tend to be strongly nonlinear, and this is an important consideration for making reasonable estimates of the soil–structure interaction.

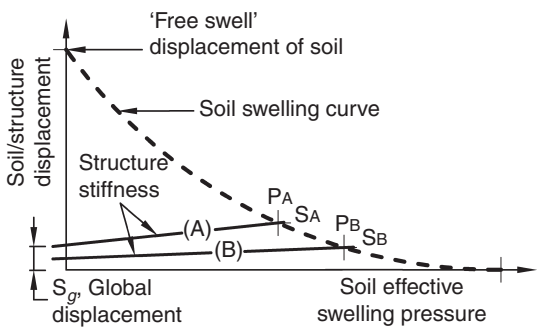
57.3.2 Pile groups and floor slabs

Where a floor slab will be cast near ground level, it is most likely that it will be designed to be suspended from the pile caps, and cast onto a void former, which collapses at a small load on the underside of the floor slab as the soil heaves beneath. Where the slab is not isolated from movement and uplift pressure of the soil beneath, the connection to the piles would be required to carry tension, and the slab would need to be designed for large hogging bending moments induced by the soil uplift pressure.



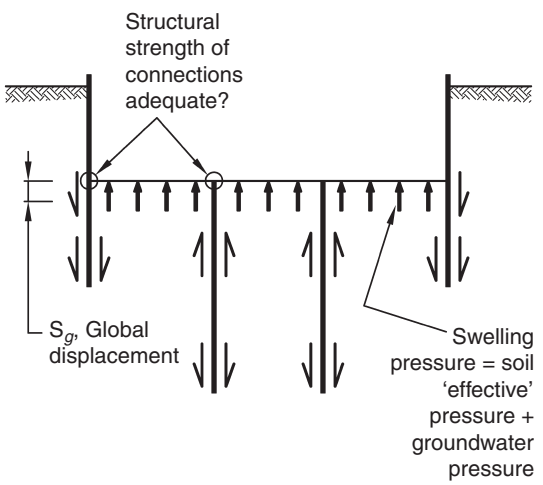
Where a pile cap is used for a pile group, the underside of the pile cap will also be subject to uplift pressures unless it is isolated from the underlying soil using a void former. Piles near the centre of the group will probably be 'sheltered' from the effect of soil heave to some extent, whereas HIT on the outer piles will tend to cause uplift of the pile cap. If there is an insufficient external load on the pile cap (including its weight), there may be significant tension acting at the heads of the central piles as the cap is lifted by HIT on the outer piles. This is essentially a reversal of the situation described above for pile groups subject to NSF, where the outer piles are potentially subject to tension. An important difference between piles subject to unrestrained swelling (i.e. a suspended base slab) and restrained swelling (a base slab or pile cap in contact with the ground) is the development of shaft friction with depth. For unrestrained swelling, the relative pile–soil displacement (and shaft resistance) can develop near the pile head and move progressively downwards. In contrast, for restrained swelling, shaft resistance will develop at depth and move upwards, since the base slab or pile cap will inhibit the relative soil–pile displacement near the pile head.

Soil–structure interaction will develop between the slab, piles and swelling soil in contact with the floor or base slab. The swelling pressure will have two components: the soil 'effective' pressure plus the groundwater pressure. The magnitude of the soil 'effective' swelling pressure, and the tensile forces and displacement of the piles will depend on the stiffness of the structure, the pile length and the swelling characteristics of the soil. **Figure 57.5** illustrates the inter-relationship between some of these factors. The swelling pressure will lead to an increase in the tensile force in the pile, **Figure 57.5(a)**, the neutral point will move upwards and the upward displacement of the pile will increase. As the upward displacement of the structure increases, the swelling pressure on the slab will reduce, **Figure 57.5(b)**. Therefore, a relatively stiff structure (B) will move less, S_B, but larger swelling pressures P_B, will be 'locked in', compared with a more flexible structure (A), **Figure 57.5(b)**. Hence, an interactive analysis is needed to assess the equilibrium values of the swelling pressure, the ground and structure displacements and the forces induced in the piles and structure. Irrespective of the 'internal' structural stiffness of the structure, some global upward displacement, *Sg*, will develop as friction develops on the basement walls and piles. Typically this situation will occur for deep basement structures and the 'global' stiffness and displacement of the whole structure needs to be considered, as well as the local interactions between the pile, slab and soil, **Figure 57.5(c)**. It is particularly important to check that the structural strength of connections between the pile, slab and basement walls is adequate. The groundwater pressure is unaffected by the soil–structure interaction, and needs to be added to the effective swelling pressure from the soil. The incorporation of drainage beneath the slab can eliminate the groundwater pressure acting directly on the underside of the slab and reduce the soil swelling displacement, swelling pressures and forces induced in the structure. However, the drainage must be easy to maintain, in order to remain effective throughout the structure's design life.



57.3.3 Expansive and collapsible soils

Collapsible and expansive soils are considered in Chapter 32 *Collapsible soils* and Chapter 33 *Expansive soils*, respectively.



ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

(a) Swelling pressure and tensile force in pile

(b) Interaction between structure stiffness, soil swelling and swelling pressure

(c) Deep basement, global interaction – swelling pressure/head induced tension

Figure 57.5 Heave-induced tension, floor slab in contact with swelling soil

The behaviour of such soils is very complex, and in certain scenarios it may not be clear which situation will arise (i.e. negative skin friction or heave-induced tension) – see Chapter 53 *Shallow foundations*. It may then be necessary to adopt a robust structural design for the piles, which will cope with both eventualities (NSF and HIT, respectively). Furthermore, the piles will be required to penetrate to sufficient depth where the soil is known to be unaffected by tendencies for expansion or collapse.

57.4 Piles subject to lateral ground movements

57.4.1 Single piles

This form of interaction is most often considered using a horizontal plane normal to the axis of the pile (which is normally vertical), as shown in **Figure 57.6(a)**. The simplest situation is for an 'isolated' single pile where the boundaries are at a large distance compared with the diameter of the pile. The relative pile–soil displacement in the horizontal plane will be referred to as δ. Relative movement most commonly occurs when the pile carries a horizontal load applied at the head and it moves relative to the stationary soil, which resists this movement – see Chapter 54 *Single piles*. However, this chapter considers the reverse situation – where the soil moves and loads the pile. Examples of this type of interaction are considered in section 57.4.2 below.

In the most fundamental consideration of this interaction, it is immaterial how Δ originates, and a horizontal load acting on the pile (often expressed as an equivalent pressure), p, will result as shown in **Figure 57.6(b)**. As is often the case the interaction may initially be idealised as elastic, ultimately reaching a value of plastic yield. However, the actual response shows a more gradual transition between these extremes of behaviour.

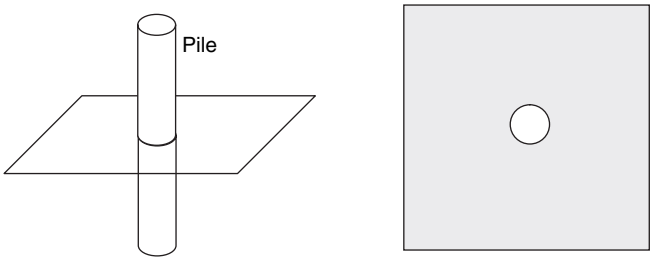
Such loading can be particularly damaging, since it generates bending moments and shear forces in the pile, which will therefore require adequate bending capacity. Historically semi-empirical methods have been used to allow estimation of the soil loading or maximum moment directly. However, such methods tend to rely on a very general consideration of behaviour and are inherently limited in their ability to accurately represent specific circumstances. Finite element analysis is now likely to be considered appropriate where a complex and potentially damaging soil–structure interaction problem is identified. However, the complexities of such an approach should not be underestimated (see section 57.4.3 below). A preliminary set of analyses using one, or preferably two, of the available simplified methods should always be carried out first before undertaking complex finite element analyses.

The text below will first consider situations where this type of interaction may occur. As described in section 57.1 the construction sequence, etc. may have a significant impact and 'engineering solutions' may exist to avoid significant lateral interaction effects. This is generally the best course of action, rather than attempting complex analysis. Key references are listed, which may be of use in making simplified preliminary calculations. The incorporation of this type of interaction in a finite element analysis is then briefly considered.

The piles will often be in rows or groups. Some of the references below specifically consider group interaction effects. Progressive structural failure may be an issue for multiple pile rows exposed to an interaction; if the structural failure mechanism (which often involves combined bending and shear) is brittle, then this must be carefully considered and avoided.

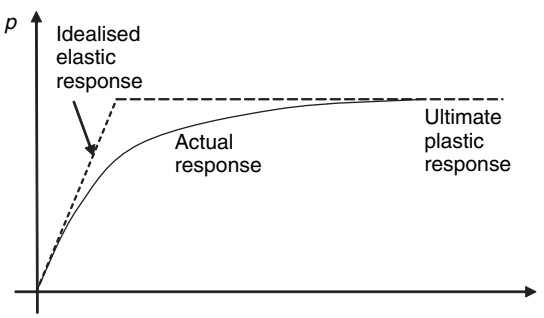
57.4.2 Examples of piles subjected to lateral ground movements

57.4.2.1 Piles adjacent to embankments on soft clay



When an embankment is constructed on soft clay or peat the soil beneath tends to move horizontally outwards, rather like toothpaste being squeezed from a tube. As shown in **Figure 57.7**, where piles are situated at the edge of an embankment they will be horizontally loaded by the soft clay, in addition to any structural loading at their head. The effect of a pile-head restraint should be considered – where the pile head is restrained against rotation this reduces the displacement of the pile but, hence, increases the interaction loading from the soft clay. Where an abutment structure is supported by the piles, there may be additional interaction issues associated with the embankment fill 'arching' onto the abutment due to loss of support from the soft clay (Ellis and Springman, 2001).

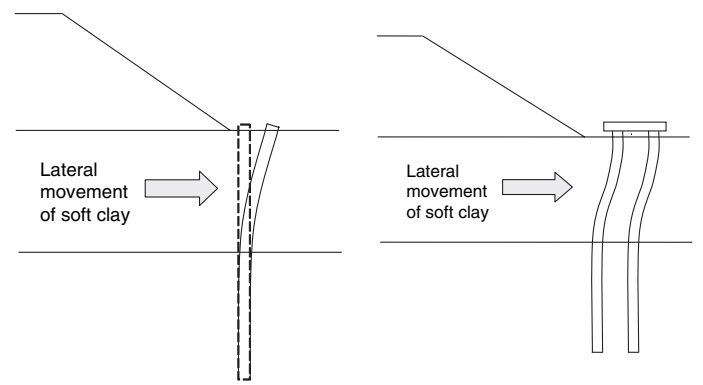
In this situation there will be an immediate undrained movement, which is specifically associated with construction of the embankment and, thus, the construction sequence is of significant impact. Using a lightweight fill (e.g. expanded polystyrene blocks), or supporting the embankment itself on piles or improved ground (refer to Chapter 59 *Design principles for ground improvement*) may be considered to reduce soil movement. It may be possible to isolate the piles from the moving soil, e.g. using an annulus of soft bentonite clay, or inside an oversized liner. However, the structural design of the pile must then consider the pile to be laterally unsupported by the soil over this height. In general it is preferable to reduce the problem at source, i.e. construct the piles after the embankment has been constructed and allowed to settle, or use lightweight fill or ground improvement of the underlying soil.



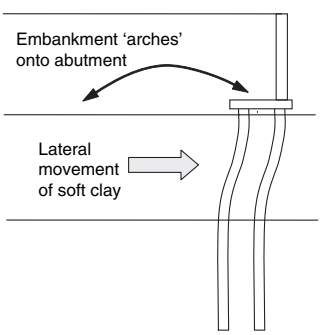
Key references

DeBeer and Wallays (1972) (also summarised in Fleming *et al.*, 2008) give an example of a 'pressure-based method' for the direct estimation of the lateral pressure on piles near an embankment as a fraction of the nominal increase in vertical stress from embankment loading (q). The ratio of q to the undrained shear strength of the soft soil (c_u) is also considered, and many other later methods, see below, also use this ratio. Ultimate bearing failure occurs at a value of (q/c_u) = 5, but the risk of damage to the piles is generally considered to become significant when a value of about 3 is reached.

Springman and Bolton (1990) proposed a method for the simple calculation of soil deformation and, hence, pressure



(a) Soil–structure interaction in horizontal plane normal to vertical pile axis



(b) Increase in pile load (p) with pile–soil relative displacement (δ)

Figure 57.6 Fundamental concepts of lateral pile–soil interaction

loading due to adjacent loading on a soft clay layer. The method also considers the resulting bending moment distribution in the piles.

Stewart *et al*. (1994) give a useful summary of existing analytical methods at that date. A method for direct but approximate estimation of the maximum pile moment loading is proposed, and the method proposed by Springman and Bolton (1990) is reviewed and modifications are proposed.

Goh *et al*. (1997) give a numerical procedure for the determination of pile pressure and moment loading resulting from known 'free-field' soil movement (which would occur in the absence of the piles). They compare the results with some case studies, and propose an equation for the simple direct estimation of the maximum moment in the piles.

Chen and Poulos (1997) give a boundary element procedure for consideration of pile loading again from known 'free-field' soil movement. They use this approach to produce design charts, which potentially can be used for the 'preliminary design' of piles near embankments or piles used to stabilise slopes (see below). Leroueil *et al*. (1985) present case study information regarding the lateral displacement associated with the construction of an embankment on soft clay.

Ellis and Springman (2001) describe physical model testing and plane strain finite element analyses of full-height piled bridge abutments on soft clay. A mechanism of arching onto the pile cap (**Figure 57.7(c)**) was highlighted for this type of structure. The authors conclude that empirical methods which do not account for specific boundary conditions of the piles are likely to be inadequate for a direct estimate of the pile moment loading in complex situations. However, a simple structural analysis of the pile under the actual boundary conditions and pile pressure load obtained via one of the methods above may be adequate for preliminary design. For more detailed design a finite element approach should be used, and the paper demonstrates that a plane strain analysis can be used provided there is some facility for incorporating lateral interaction between the soil and pile row (see section 57.4.3).

57.4.2.2 Piles near excavations

Where an excavation (e.g. an open excavation or a cantilevered retaining wall) is constructed near a pile, the ground will tend to move towards the excavation, causing interaction loads on the pile and a corresponding deformation (**Figure 57.8**). Again the deformation and load in the pile will be affected if the pile is restrained against rotation or movement at the head.

For a simple cantilevered wall the zone of deformation may be assumed to be an 'active wedge' (**Figure 57.8**). The amount of movement will be reduced (perhaps considerably) if the excavation is braced, and the zone of influence will also be affected.

A plane strain finite element analysis of the wall and pile row can be undertaken (see section 57.4.3). Alternatively, if 'free-field' soil deformations have been estimated, the load on a pile can be established and the bending moment in the pile can be estimated. Long (2001) and Clough and O'Rourke (1990) have published comprehensive summaries of ground movements around deep excavations in a variety of soil types. For excavations in soft clays, the magnitude of the ground movement is very sensitive to the factor of safety against basal instability. Movement of the pile tends to reduce the relative pile–soil displacement and hence the interaction pressure, thus, it is conservative if it is assumed that the pile does not move.

It may be possible to isolate the piles from the moving soil, e.g. inside an oversized liner. However, the structural design of the pile must then consider it to be laterally unsupported by the soil over this height.

Key references

Poulos and Chen (1997) present a method for analysing the response of piles to a nearby excavation, focusing on braced excavations in clay. Design charts for maximum bending moment and deflection of the piles are presented.

57.4.2.3 Piles in unstable slopes

Piles are often deliberately constructed in unstable slopes in an effort to 'dowel' the potential slip (**Figure 57.9(a)**). For reasons of economy and to minimise the use of resources 'discrete' piles are spaced at a distance s along the row, typically 2 to 5 times the pile diameter (d). However, it is critical that the unstable soil loading the piles 'arches' across the gap between adjacent piles and does not 'flow' through it (**Figure 57.9(b)**). Piles constructed in an unstable slope for any other reason will attract similar loading.

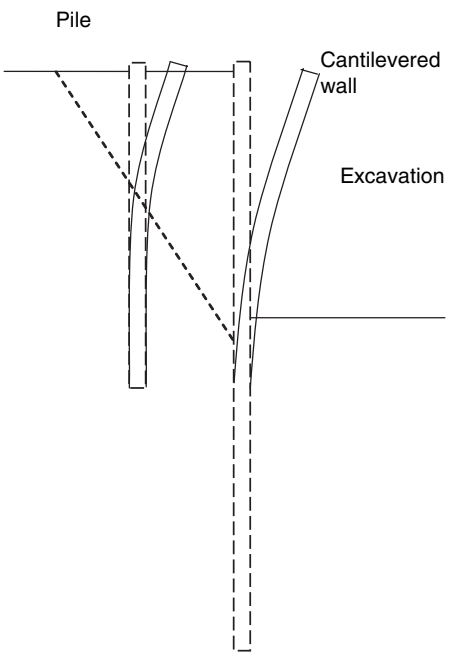

Figure 57.8 Piles near an excavation

There are a number of aspects of any design:

- Establishing the critical slip (where there is not a well-defined existing slip), and required stabilising force to give the desired factor of safety for the slope.
- The location of the piles in the slope, which is likely to be affected by the practicality of construction and the desire to protect infrastructure either at the crest or toe of the slope.
- Choice of spacing ratio (s/d).
- Provision of adequate moment capacity in the piles (noting that the load per pile increases in proportion with s).
- Sufficient embedment of the piles in the underlying stable material to give the required resistance, and so that a deep failure cannot pass beneath the piles.
- Horizontal restraint may be provided at the pile head using a capping beam, which is itself restrained by ground anchors or raking piles. This reduces displacement of the pile head and the maximum moment in the pile.

Note that the use of a 'free-field' soil displacement to determine the loading on the piles (e.g. Chen and Poulos, 1997) is not that common in design. Instead the required stabilising force is normally used to determine the pressure on the piles above the slip.

Key references

Viggiani (1981) gives a simple method for the derivation of the moment in piles by assuming that the loading from unstable and underlying stable material is uniform with depth.

Chen and Poulos (1997) give a boundary element procedure for consideration of pile loading from known 'free-field' soil movement. They use this approach to produce design charts, which potentially can be used for the 'preliminary design' of piles in unstable slopes.

Hayward *et al*. (2000) examine the effect of pile spacing for the stabilisation of a clay cutting using the results of geotechnical centrifuge tests.

Carder and Temporal (2000) give a good overview of the topic and associated references at the time of publication.

Smethurst and Powrie (2007) give a recent case study with monitoring data.

Ellis *et al*. (2010) refer to many recent numerical studies, and give guidance on various generic aspects of design including critical pile spacing.

57.4.2.4 Piles near tunnels

Tunnelling can have a significant effect on the surrounding ground, depending on the tunnelling method and increasing with volume loss. Where existing piled foundations are in the vicinity of a tunnel that is to be constructed there should be an assessment of the effect on the pile (**Figure 57.10**).

Generally speaking construction of a tunnel will cause movement of soil towards the tunnel with consequent relaxation of both vertical and horizontal stresses in the soil (**Figure 57.10**). This will have a negative impact on the pile capacity,

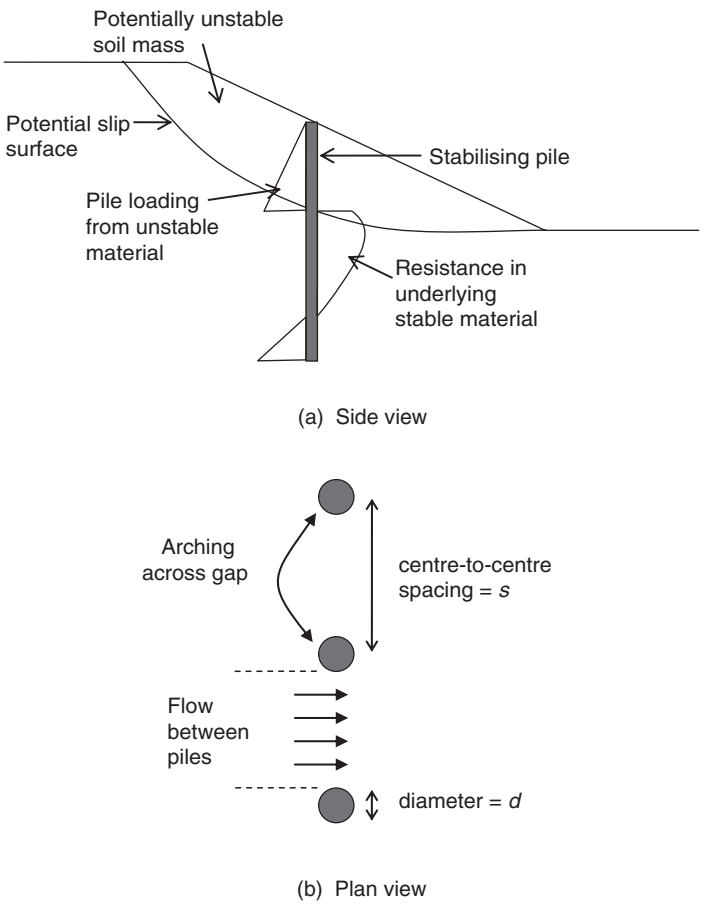

Figure 57.9 Discrete pile row stabilising slope

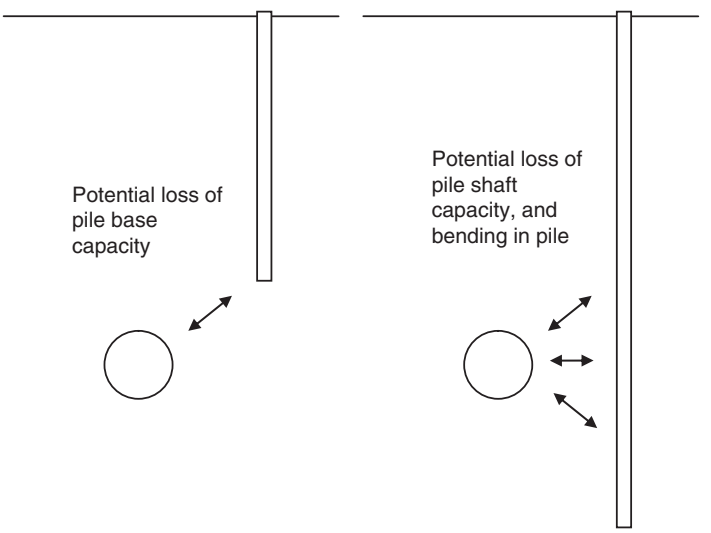

Figure 57.10 Tunnelling near piles

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

particularly if the pile relies significantly on the end-bearing capacity and the tunnel is near the toe of the pile. Assuming that the pile is subject to a constant vertical load at the head the reduction in capacity will cause increased settlement. In the extreme this may cause failure of the pile.

Furthermore, lateral movement of the soil towards the pile may cause bending and shear forces in the pile.

Key references

Chen *et al*. (1999) consider the effect of tunnelling-related movement on piles. The effect on the lateral and axial pile response is then used to produce simple design charts (e.g. for settlement at the pile head).

Jacobsz *et al*. (2003) consider the effect of tunnelling on driven piles. Selemetas *et al*. (2005) give a study of the response of full-scale piles to tunnelling, whilst Chung *et al*. (2006) present physical modelling of the pile–tunnel interaction.

57.4.3 Numerical analysis

Early computational methods used bespoke software based on specific analytical approaches. Such methods often rely upon an estimate of the 'free-field' ground movement (in the absence of piles) to derive the interaction pressure on the pile, or estimate this directly. Once this has been done it is still necessary to combine this loading with other conditions of restraint on the pile (both structural and from soil that is not moving) to derive a bending moment distribution. Consequent deformation of the pile tends to reduce the interaction, and thus iteration may be required, or it is conservative to assume that the pile does not move.

More recently finite element analysis is likely to be considered appropriate, and can inherently consider the simultaneous compatibility of pile–soil relative displacement and restraint and the structural loading of the pile. Plane strain modelling will require the use of 'link' elements to model the interaction, and there are other considerations for 'scaling' the three-dimensional pile row to the plane strain equivalent (e.g. Ellis and Springman, 2001). Three-dimensional analysis offers the benefit of removing these complications. However, other significant complications are introduced beyond the increased computation effort required to run the analysis (e.g. Ellis *et al.*, 2010).

It should be emphasised that this type of soil–structure interaction analysis requires extremely complex numerical modelling, and it should not be attempted in normal geotechnical practice.

57.5 Conclusions

Pile-supported structures are often considered to be 'safe', and therefore may not receive the attention they deserve. When piles fail, it is often because they were loaded in unexpected ways. The impact of global ground movements can be severe and numerous failures have occurred, including the recent catastrophic collapse of a building in Shanghai, **Figure 57.1**. Usually these failures are due to a lack of awareness, on the part of designers and constructors, that global ground movements could occur. Fragmentation across different design and construction teams can exacerbate the technical challenges, and therefore the procurement process, managed by client organisations, needs to facilitate proper coordination across any design or construction interfaces. Therefore, the following are particularly important:

(i) Awareness of the situations when significant global ground movements may develop, either during construction or in the long term. This will usually require input by a senior geotechnical engineering specialist at an early stage of the project.

(ii) An appreciation of the interaction that may develop between temporary and permanent works; this may need the temporary works to be carefully controlled or the permanent works design to be modified. Hence, the loading scenarios for design or specifications may need to be tailored to suit specific circumstances.

(iii) An appreciation of the interactions that may develop between existing and new structures or which may develop due to intrinsic site hazards (e.g. non-engineered fills, Chapter 58 *Building on fills,* or due to the site's history or geology).

(iv) As stated earlier, it is usually wise to avoid adverse interactions developing due to global ground movements, e.g. by selecting an appropriate construction sequence (which would then need specifying on drawings, CDM registers, etc.) rather than attempting a complex analysis.

CONTENTS

58.1	Introduction	899
58.2	Engineering characteristics of fill deposits	899
58.3	Investigation of fills	900
58.4	Fill properties	902
58.5	Volume changes in fills	904
58.6	Design issues	907
58.7	Construction on engineered fills	909
58.8	Summary	910
58.9	References	910

This chapter will outline the main issues to consider when building on filled ground, and the references includes further reading relevant to each topic. Successful construction depends not only on the load-carrying characteristics of the fill, but also on the sensitivity of the structure to ground movement. Due to the variability inherent in filled ground, the application of the geotechnical triangle (Chapter 4 *The geotechnical triangle*) is particularly important.

58.1 Introduction

It is often necessary to construct buildings on areas covered by fill, for which the engineering properties are almost always poorer than the parent material. Whilst this chapter will consider the issues related to construction on fills, other issues considered in the design such as sloping ground, should not be neglected (see Chapter 9 *Foundation design decisions*).

Generally, little or no control was exercised over the disposal of non-engineered fills and so they may be highly variable in composition, placement and geometry. All of these provide potential risks to development. This means that the engineering behaviour of non-engineered fills is difficult to predict and that they are likely to afford very variable support to any building or structure constructed upon them.

When construction is carried out on an engineered fill placed for a different development, the investigation must identify whether the fill properties and engineering behaviour are suitable for the development being undertaken. If an engineered fill is to be placed for the development, the choice of materials and placement methodology should take into consideration the requirements of the structure to be supported. The behaviour of the materials below the fill should also be considered.

Because the settlement distribution over the loaded area of a fill, even under uniform loading conditions, may be very irregular, it is often necessary to design so that the total, as well as the differential, movements are restricted or can be withstood without damage. Hence, the structure should either be sufficiently rigid to redistribute the loads and thereby reduce relative settlement, or should be relatively flexible to accommodate them without cracks appearing in the structure. Foundation design, therefore, has to consider the predicted fill–structure interaction. Long continuous structures should be avoided by dividing them into sections with flexible joints passing completely through the structure and foundation. Ordinary pad and strip footings are rarely adequate. Wide reinforced strip footings may be adequate otherwise a reinforced raft is necessary. If a fill is relatively thin and it can be penetrated and overlies a suitable stratum, then a beam and pier or beam and pile foundation may prove an alternative.

This chapter will outline the main issues to consider when building on filled ground, from investigation, characterisation of fill properties, causes of volume change and foundation design.

All construction requires appropriate investigation allied to careful design. In the subsequent sections, only those issues which are different, or require a different approach or interpretation from the 'normal' design process are highlighted.

Section 3 *Problematic soils and their issues* discusses the behaviour and characterisation of fills in depth. A summary is given here.

58.2 Engineering characteristics of fill deposits

Some of the characteristics of a fill relevant to the design of foundations are related to the nature and extent of the deposit, and not just to the material of which it is composed. These should be identified as far as possible by desk studies and confirmed by investigation (See Section 4 *Site investigation* for more on this).

58.2.1 Surface extent and depth

The boundaries of the filled area need to be established reliably. With well-defined infilled excavations, such as old docks, this may be simple, but with other infilled excavations it may be more difficult. The depth of the fill is important in assessing its behaviour, and in evaluating the applicability of various ground treatment techniques and foundation designs.

Abrupt changes in depth may lead to differential settlement. Some old excavations such as docks have vertical sides, and it may be necessary to excavate the sides to a flatter slope to reduce subsequent differential settlement.

58.2.2 Age

The age of a fill deposit can have several different effects on its engineering behaviour:

- *Environment*. An old fill may have already been subjected to many changes in moisture content, water level and loading conditions, which may make it less vulnerable to large movements under future changes.
- *Fill material*. The length of time that has elapsed since fill placement is of major importance for fills containing a significant proportion of biodegradable materials where settlement is largely related to decomposition.
- *Deposition*. The rate of long-term settlement under self-weight is related to the time that has elapsed since fill placement. Other time-related phenomena affecting a fill deposit include desiccation and weathering leading to the formation of a surface crust.

58.2.3 Method of placement

The mode of formation will have a major influence on subsequent behaviour. Fills may have been placed in thin layers and heavily compacted or they may have been end-tipped in high lifts in dry conditions or into standing water. The method of placement affects the density of the fill and the homogeneity of the deposit. Many of the problems with non-engineered fills are related to their heterogeneity. Depending on the method of placement and the degree of control exercised during placement, there may be variability in materials, density and age. Much of the usefulness of ground treatment (see Chapter 59 *Design principles for ground improvement*) techniques is related to reducing this variability. **Figure 58.1** shows an example of some control exercised in fill placement.

Hydraulic placement of materials generally produces fills with a high moisture content in a relatively loose or soft condition. Segregation of different particle sizes is likely.

58.2.4 Groundwater level

The groundwater level within a fill is controlled by a variety of factors such as the surrounding hydrogeology, whether there is an impermeable crust on the surface of the fill, the permeability of the fill or whether there is fill drainage.

The current level of the water table, the amount by which it has fluctuated in the past and the possibility of future fluctuations may have important consequences. A rise in the water level that inundates a fill for the first time may cause collapse compression in the fill. Lowering the water table can cause settlement due to the increase in effective stress within the fill.

Figure 58.1 Placement of fill in deep lifts

58.3 Investigation of fills

Non-engineered fills are difficult to investigate – their variability is a key characteristic that can be difficult to quantify. Engineered fills should have lesser variability, but this should be confirmed by records and intrusive investigation. In addition, even when fills can be penetrated, fill properties are often altered dramatically by the investigation process and standard correlations based on natural soils are rarely appropriate. Given the challenges in identification and characterisation, it is vital that a good desk study identifies what might be present and that the engineer sees the resulting material, as descriptions may not convey the characteristic of the material. As investigation necessarily only tests properties in the short term, it does not give a great deal of indication of how properties or settlements may change over time (see also Section 4 *Site investigation*).

58.3.1 Desk studies and walkovers

A key component in the investigation of fills is the desk study. Possible areas of filled ground can be identified by previous site or local land use and from British Geological Survey (BGS) mapping (see Chapter 32 *Collapsible soils*). As it is unlikely that fill has been transported a significant distance, local arisings can be identified. Types of fill generated by different processes are discussed in Chapter 34 *Non-engineered fills*. Possible contamination arising from processes should also be identified; a good source is the Department of the Environment (DoE) industry profiles available online at the Environment Agency website. The depth of infilled ground may be discerned from the evolution of the site, and also from knowledge of the processes that may result in a large depth of non-engineered ground (or from deep holes!), i.e. opencast mining, deep mining, quarrying or landfilling. Processes such as landscaping usually result in shallower depths of fill.

A walkover may identify regular patterns of hummocks or hills indicating a man-made origin, variations in vegetation or significant areas of ‘empty space’ near built-up areas. A combination of desk study and walkover may also help identify areas of infilled basements.

The investigation of the site and local area is a key component in identifying the likely presence, type and history of the fill as well as other site issues requiring investigation and design. This allows key risks to the development to be identified early and the scope of intrusive investigation defined.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

58.3.2 Non-intrusive investigation

Some geophysical techniques may aid the identification of the depth of fill where significant differences in stiffness, density or water content of the filled and natural ground exist (see Chapter 45 *Geophysical exploration and remote sensing*). Before specifying the technique, it is worth noting the change in properties that is detectable by each – a change in stiffness for example and finding out whether there may be a sufficient change in the property to enable the technique to locate the features required. In each case some form of intrusive confirmation is recommended.

58.3.3 Intrusive investigation

The techniques available to the engineer are likely to be:

58.3.3.1 Trial pits

For shallow fills a key element is simply digging trial pits. This will enable a good visual description (the number of trial pits required depends on how variable the fill may be and the type of construction required). Bulk disturbed samples will enable basic characterisation of the components by description, particle size, moisture content and Atterberg limits as appropriate. The visual characteristics of deposition may also be visible, such as layered or very variable. Some chemical testing may be required.

Depending on construction requirements, shallow *in situ* tests such as plate or skip tests may be a useful way of characterising the bearing capacity and immediate settlement. Care must be exercised that a sufficient volume of fill will be tested, and a number of tests may be necessary to assess variability. *In situ* CBR tests must be analysed with particular care, as the size of test is small. If the fill is amenable to treatment, further testing on samples is helpful; if mixing is a possible treatment then consider compaction testing and chemical testing.

58.3.3.2 Window samples (WS) and dynamic probing (DP)

Dynamically driven window samplers may penetrate fills to a few metres, although they will refuse on large or flat hard obstructions. The samples obtained will be small; hence, they may not be representative of larger particles, and will be disturbed by the driving process. It is likely that a higher density will be retrieved and some particle breakdown will be caused.

Information from such samples, whether descriptive or a classification, should be interpreted with care.

Dynamic probing may be one of the only tests available. A dynamically driven cone is used to penetrate the fill and the number of blows per 100 mm step is recorded. Some indication of density, with a similar caveat on obstructions, can be obtained. A number of test profiles can give an idea of the variability and help refine additional test locations.

58.3.3.3 Deep *in situ* tests

Deep *in situ* tests can be divided into those involving pushing (CPT, CPTU), drilling (self-boring pressure meter) or carried out from a borehole (DMT, PMT, SPT). For more information see Chapter 48 *Geo-environmental testing*.

Few CPT, correlations are relevant for fills and so this form of profiling and testing should be used with care. CPTs are also liable to refuse on or be damaged by obstructions and so are rarely used. Where the fill is similar to a natural soil (particularly some granular fills) it is, however, a useful tool and can readily identify both variability and improvement due to treatments such as dynamic compaction.

Pressure meter and dilatometer testing is also rarely carried out, primarily because the sample size tested is not representative of a highly variable deposit. The cost of a large number of tests required allied to the potential for remoulding caused by the drilling process means they are often inappropriate.

SPT tests are often carried out where boreholes can be drilled, and give some indication of the strength of the fill as altered by the drilling and testing process. Due to the small sample size and lack of appropriate correlations these tests should be analysed with care. However, SPT testing may be the only data that can be readily obtained.

58.3.3.4 Drilling and sampling

Cable percussion (CP) drilling is likely to break down and densify fills, where water is added during the drilling process this will often aid this breakdown. Samples retrieved from CP boreholes should be analysed and described with care and are likely to be disturbed.

Rotary drilling may retrieve little material; where it does these will have been altered by the drilling and the drilling fluid.

Samples are very unlikely to be suitable for testing for strength or stiffness.

58.3.3.5 Monitoring

Monitoring of water levels, gas and also long-term settlement are important tools for understanding the current state and future behaviour of a fill; refer to section 58.6.4 of this chapter.

58.3.3.6 Trials

Where treatment is to be carried out that addresses deep-fill behaviour an initial trial area in which a greater density of monitoring is carried out is worthwhile. This may well lead to optimisation in the treatment method or increased confidence in its efficacy.

In summary, when investigating a fill, routine methods for drilling and testing are often not useful in determining the behaviour or design parameters. A trial pit to determine the nature of the material (and care is needed to ensure that the material sampled and viewed is representative), backed up by a good desk study and monitoring information is often the most useful source of information. Some information on boundaries can usually be supplemented by direct investigation. The properties that can be identified by intrusive investigation are listed in **Table 58.1**.

Information from case histories on similar fills or large-scale tests may be very useful. Again, care should be taken that the test is representative of the scale and type of behaviour anticipated. A small short-term load test on a fill where self-weight settlement or creep is still occurring is not likely to reveal the

	Disturbed Samples				*In situ* testing		Shallow load testing
Property	**Trial pits**	**WS**	**CP**	**Rotary**	**DP**	**SPT**	**Plate**
Density	x	x	x	x		Some indication	Inferred
Compactive state	Visual indication	x	x	x	x	x	Inferred
Water content	y	y	May be altered by drilling		x	x	x
Particle size	y	y			x	x	x
Plasticity	y	y – fines content may be altered by drilling			x	x	x
Strength	x	x	x	x		Some indication	y depending on load
Stiffness	x	x	x	x	x	x	y
Over-consolidation	x	x	x	x	x	x	x
Variability	Depends on number of locations tested						

y – technique likely to give some indication of the property
x – property unlikely to be determined by the technique

performance that a large structure built on the fill may experience over a number of years!

58.4 Fill properties

As fills may be difficult to investigate, information from tests on similar materials is vital for the designer.

58.4.1 Index and classification properties

Simple index and classification of properties enable fills to be classified in ways that are relevant to their engineering characteristics. BS 1377-2:1990 (British Standards Institution, 1990) describes classification tests for soils.

58.4.1.1 Particle-size distribution

Particle size has a strong effect on soil behaviour and provides a useful method of classification. Sieving and sedimentation can be used to determine the distribution by particle size. There are basic differences in behaviour between coarse 'granular' soils and fine 'cohesive' soils. Coarse soils tend to have high shear strength and permeability whereas fine soils generally have lower strength and permeability. The percentage of silt- and clay-sized particles (i.e. finer than 0.06 mm) is important; when this percentage is high (usually taken as $Fc > 35\%$), the soil will cease to behave as a coarse soil. In reality, the distinction between 'granular' and 'cohesive' behaviour is a function of other properties in addition to particle size. With a well-graded soil, it may not be immediately obvious whether the behaviour will be that of a coarse or a fine soil. The *BSI Code of Practice* (British Standards Institution, 1999) for site investigations gives helpful advice on this transition.

An uncompacted clay fill composed of lumps of stiff clay may behave more like a granular fill than a cohesive fill when loaded in the absence of water, but if inundated it may undergo collapse compression and subsequently behave like soft, saturated clay fill.

58.4.1.2 Moisture content and degree of saturation

Water is invariably present in fill materials. The moisture content for saturated fills is typically from 20% to 80%. The placement moisture content affects the properties of fills, and the behaviour of clayey fills is very moisture dependent. Moisture content changes can cause volume changes in fills.

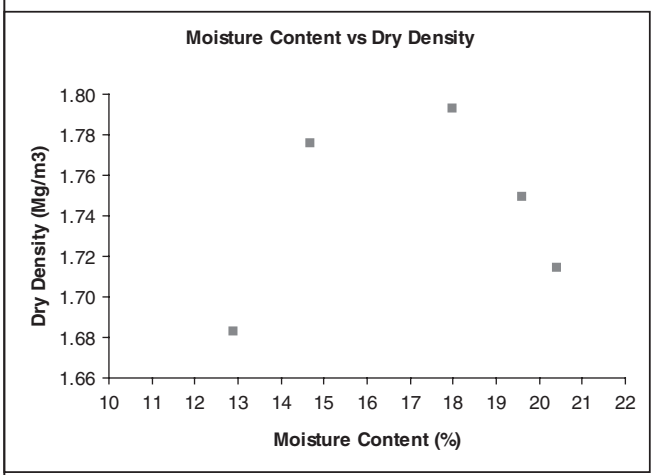
58.4.1.3 Density

The density or 'compactness' of a fill has a major influence on its behaviour. This is a function of the method of placement of the fill and its subsequent stress history. The term 'compaction' is used to describe processes in which equipment is used to compress the fill into a smaller volume, increasing its density. Usually, engineering properties are improved with increased density. As solid soil particles and water are virtually incompressible, compaction reduces the percentage of air voids.

58.4.1.4 Coarse fills

For a fairly clean coarse hydraulic fill, the dry density is typically 1.6 Mg/m^3. A well-compacted rockfill might be used in an embankment dam and its porosity will typically be in the range 20% to 25%. In contrast, an uncompacted opencast backfill of similar material has a much higher porosity of about 40%.

58.4.1.5 Fine fills



The amount of densification that can be achieved for a given compactive effort on a clayey soil is a function of moisture content. Laboratory compaction test results are usually plotted as the variation of dry density with moisture content. Such plots are a useful way of representing the condition of a partially saturated fill. The density that can be achieved by a particular compactive effort on a clay fill depends on the moisture content of the fill. For a given compactive effort there is a maximum dry density, which is achieved at the optimum

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Moisture Content and Dry Density Relationship Test

In accordance with BS 1377-4:1990

Hole No/Sample Ref:	R2	Test Procedure:	2.5 kg hand hammer
Depth (m):	1.00	Mould Type:	1 litre
Soil Visual Description:	Firm to stiff (medium to high strength) orange patched grey slightly sandy CLAY with frequent flint gravel (8.3% retained on 20mm sieve)		

Natural Moisture Content (%)	18.50

Moisture Content (%)	Dry Density (Mg/m^3)
12.90	1.683
14.70	1.776
18.00	1.793
19.60	1.749
20.40	1.714

Optimum Moisture Content (%)	Maximum Dry Density (Mg/m^3)
16.41	1.794

Note:

Figure 58.2 Proctor test results for a fine-grained fill

moisture content. The expressions 'maximum dry density' and 'optimum moisture content' refer to a specified compaction procedure and can be misleading if taken out of the context of that procedure. With a moisture content that is less dry than the optimum, the specified compaction procedure will result in a fill with larger air voids. For a moisture content that is significantly wetter than the optimum, the specified compaction procedure will produce a fill with a minimum of air voids, typically between 2% and 4% (see **Figure 58.2**).

The fundamental factors listed above demonstrate that the moisture content during placement is key to the density and, hence, engineering performance to be expected.

58.4.1.6 Liquidity and plasticity indices

In this context, the term plasticity describes the response of fine fills (or the finer fractions) to changes in moisture content and is the same property as for natural soils.

Care should be taken when assessing index tests related to the matrix, as the impact of this will be differerent for fills compared with natural materials.

58.4.1.7 Compressibility and stiffness

A wide range of compressibility is possible. Different relationships can be used below and above the optimum moisture content, and the relationships will also depend on the nature of the fill material and whether the grading envelope means that the voids are 'filled' or 'unfilled'. When fills are not close to failure, it is often convenient to describe their behaviour using elastic parameters even though fills generally exhibit nonlinear non-recoverable stress-dependent behaviour (see Charles and Skinner, 2001b).

Conventionally Young's modulus, E, and Poisson's ratio, ν, are used to describe linear elastic behaviour. However, these parameters have little direct relevance to the stress conditions that generally pertain to fills. In practice, the settlement for many fills is closely related to one-dimensional compression, and the constrained modulus, D, is of more direct application.

Typically for non-engineered fills it may be assumed that $D = 1.3E$ to $1.8E$.

When a uniform load is applied over a wide area of the surface of a fill, the resulting compression is largely one dimensional. An application of load will produce an immediate compression in a partially saturated fill. Effective stress is not a simple concept for partially saturated soil and, for most practical purposes, compressibility can best be described by a constrained modulus expressed in terms of total stress. The constrained modulus is the ratio of the increment of applied total vertical stress, $\Delta\sigma_v$, to the increment of vertical strain, $\Delta\varepsilon_v$, which it produces under drained conditions:

$$D = \Delta\sigma_v/\Delta\varepsilon_v. \tag{58.1}$$

It should be noted that $D = 1/m_v$.

The constrained modulus can be measured in oedometer tests, but is usually not representative of *in situ* behaviour because of the small test size (**Table 58.2**).

Fill	D_{sec} (MPa)	ε_v (%)
Sandstone rockfill (I_D = 0.8)	12	0.83
Sandstone rockfill (I_D = 0.5)	6	1.67
Colliery spoil (compacted)	6	1.67
Colliery spoil (uncompacted)	3	3.3
Clay fill (I_p = 15%, I_L = 0.1)	5	20

Table 58.2 Typical values of the constrained modulus (D_{sec}) and strain for vertical stress increments of 100 kPa (from 30 kPa)

58.4.2 Time dependency for fine fills

A fundamental difference between the deformation behaviour of fine fills, such as a clay fill, and coarse fills, such as a sand fill or a rockfill, is due to permeability.

Time-dependent movement depends on the nature and thickness of the fill, the method of placing and the nature of the underlying ground, especially the groundwater conditions. The best materials in this respect are obviously well-graded, hard and granular. Fills containing a large proportion of fine material, by contrast, may take a long time to settle. Similarly, old fills and those placed over low-lying areas of compressible or weak strata should be considered unsuitable unless tests demonstrate otherwise or the structure can be designed for low bearing capacity and irregular settlement. Frequently, poorly compacted old fills continue to settle for years due to secondary consolidation. Mixed fills that contain materials liable to decay, which may leave voids or involve a risk of spontaneous combustion, afford very variable support and such sites should generally be avoided. Some materials such as ashes and industrial wastes may contain sulfate and other products that are potentially aggressive to concrete.

Generally, for uncompacted materials, rockfills will settle about 2.5% of their thickness, sandy fills about 5% and cohesive materials around 10%. The rate of settlement decreases with time, but in some cases it may take 10 to 20 years before movements are reduced within tolerable limits for building foundations. In coarse-grained fills most of the movement generally occurs in the early years after the completion of filling and, often, after five years, settlements are small.

58.4.3 Strength

58.4.3.1 Undrained shear strength

The undrained behaviour is of practical importance for saturated clay fills when applied loads change faster than the induced pore pressure can dissipate. The undrained shear strength (c_u) is a function of moisture content, fabric and effective stresses. Plastic silt and clay hydraulic fills are cohesive and can be characterised by a profile of undrained shear strength versus depth. With a high water table, effective stresses in a hydraulic fill will be low. Some desiccation is likely to occur at the surface of the fill, forming a stiff crust.

58.4.3.2 Drained shear strength

Non-engineered fills are likely to be in a loose condition. Consequently, their strength may be close to the constant volume angle of shearing resistance, $\varphi'cv$. For a granular fill this angle of shearing resistance is usually similar to the angle of repose. If instability should occur, loose fill materials may be vulnerable to liquefaction and flow slides.

Box 58.1 Example: Colliery spoil

The shear strength parameters of a coarse discard do not exhibit any systematic variation with depth in a spoil heap, and so are not related to age. This suggests that a coarse discard is not seriously affected by weathering. As far as the effective shear strength of a coarse discard is concerned, the angle of shearing resistance usually varies from 25° to 45°. The angle of shearing resistance and, therefore, the strength, increases in spoil that has been burnt. With an increasing content of fine coal, the angle of shearing resistance is reduced. Also, as the clay mineral content in the spoil increases, so its shear strength decreases.

The shear strength of a discard within a spoil heap and, therefore, its stability, is dependent upon the pore water pressure developed within it. Pore water pressures in spoil heaps may develop as a result of the increasing weight of material added during construction or by seepage through the heap by natural drainage. A high pore water pressure is usually associated with fine-grained materials that have a low permeability and high moisture content. Thus, the relationship between permeability and the build-up of pore water pressure is crucial. In fact, in soils with a coefficient of permeability of less than 5×10^{-9} m s^{-1} there is little significant dissipation of the pore water pressure, whilst above 5×10^{-7} m s^{-1} the pore water pressure is generally completely dissipated. The permeability of a colliery discard depends primarily upon its grading and its degree of compaction. It tends to vary between 1×10^{-4} and 5×10^{-8} m s^{-1}, depending upon the amount of degradation in size that has occurred.

58.4.4 Permeability

A number of important effects and processes are influenced by water movement and permeability, including the following:

- the rate of dissipation of excess pore pressure and the associated primary consolidation of saturated clay fills;
- the influence of undrained or drained behaviour;
- collapse compression of loose unsaturated fills;
- the liquefaction of saturated fills;
- the loss of ground due to erosion of fills.

Uncontrolled seepage can cause the migration of fine particles out of the fill or into the pores of a coarser soil. Where water flows out of a fill, local instability may occur at the exit point. If water is flowing through a fill, which is susceptible to erosion, then erosion can be prevented or controlled by protection of the fill with adequate filters, which will halt the loss of material.

58.5 Volume changes in fills

One of the most important assessments of the suitability of any fill for building purposes is of the likely volume changes within the fill, which could be observed as settlement, heave or lateral movements. Changes can occur as a result of the

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

passage of time or in response to changes in stress or environmental conditions.

58.5.1 Self-weight

Stress changes caused by placement of fill over a wide area differ from the stress changes due to building foundations, which usually apply loads to relatively small areas. The wide extent of fill placement has the following consequences:

- loading and compression behaviour of the fill is largely one-dimensional;
- the full depth of the existing fill may be affected by the loading caused by the extra fill;
- underlying natural strata may be significantly loaded by the fill.

Similar conclusions hold for removal of layers of fill, although the stiffness properties may be very different on unloading, and stiffness is often significantly greater.

Movement caused by settlement or heave of the fill occurs in two stages:

- 'immediate' movement as the applied stress increases or decreases;
- time-dependent movement after the change in applied stress.

58.5.1.1 Movement during and shortly after fill placement

Any immediate compression occurring during an earthmoving operation before construction on the fill has no practical effect on the structures.

As extra fill is placed, most of the resulting compression of a coarse fill occurs immediately. The one-dimensional compression behaviour of coarse granular fills can be described in terms of the constrained modulus, D, which depends on the fill type, placement conditions including initial density and moisture content, the stress level and stress history. In contrast, the behaviour of a saturated or almost saturated clay fill, when extra fill is placed, differs considerably. The load will initially induce an excess pore pressure in the clay fill, and there is little immediate settlement. There may be some immediate settlement resulting from compression of any remaining air voids. This is followed by primary consolidation as the pore pressure dissipates. Any investigation should identify whether primary consolidation is still occurring. Often this is identified by changes in pore pressure.

58.5.1.2 Long-term movement

When movements due to the self-weight of the fill occur subsequent to building on the fill, damage to structures may result. The magnitude and rate of movement subsequent to fill placement are therefore of major interest.

For most fills, there is an approximately linear relationship between creep compression and the logarithm of time. This is often expressed as

$$\alpha = \Delta s/[H \log (t_2/t_1)] \qquad (58.2)$$

Fill type	Compaction	α (%)[1]	Case history[2]
Sandy gravel fill	Heavy vibrating roller	$0.04\sigma'_v$	Megget
Mudstone fill	Heavy vibrating roller	$0.12\sigma'_v$	Brianne
Sandstone or mudstone rockfill	Heavy vibrating roller	$0.13\sigma'_v$	Scammonden
Sandstone or mudstone rockfill	No systematic compaction	0.9–1.5	8
Stiff clay fill	Heavy systematic compaction	0.5	2

[1] σ'_v in MPa
[2] The first three examples refer to case histories of embankment dam construction: Megget (Penman and Charles, 1985a), Brianne (Penman and Charles, 1973) and Scammonden (Penman *et al.*, 1971).

Table 58.3 Creep compression rate parameter α for engineered and non-engineered fills
Data reproduced from Charles and Watts (2001)

where compression $\Delta s/H$ of a fill of height H occurs between times t_2 and t_1.

Some of the results reported in Charles and Watts (2001) are given in **Table 58.3**.

58.5.2 Change in applied stress due to weight of buildings

Whereas fill placement is usually over a wide area, the weight of buildings will generally be concentrated onto relatively small foundation areas. Where the foundation size is small, stresses will be significantly increased over only a relatively shallow depth immediately beneath the footing. In any evaluation of ground deformations caused by the weight of a building, it is important to have some knowledge of the stress distribution below the foundation, because in predicting settlement it is necessary to know to what depth the foundation will effectively stress the fill. The stress distribution below foundations is discussed in Chapter 53 *Shallow foundations*. Furthermore, for a foundation load of 50 kN/m, the ground is significantly stressed only to a depth of 2 m to 3 m.

Apart from the immediate settlement of clay fills under undrained conditions, most movement due to the weight of structures is attributable to a volume reduction resulting from an increase in effective stress. Movement occurs both during and after construction. If movements are very large, structural damage can result from movements during construction; however, these can often be built out and may cause little damage. However, significant settlement occurring after construction can seriously damage a structure.

In addition, some time-dependent strains will occur under a constant applied foundation load:

- For coarse fills, settlement will be caused by creep movements occurring at constant effective stress.
- For fine fills, settlement will be caused by primary consolidation as the pore pressure induced by construction loading slowly dissipates, followed by secondary compression at constant effective stress.

Long-term settlement due to constant imposed foundation loads often shows a linear relationship with the logarithm of time since construction, analogous to creep settlement arising from self-weight of the fill.

58.5.3 Change in water content

58.5.3.1 Change in groundwater level

The effective stress within a fill deposit depends strongly on the groundwater level. A rise in the groundwater level reduces effective stress, and a fall in the groundwater level increases effective stress. The smaller the particle density of the fill, the greater the percentage change in effective stress will be caused by a given change in the groundwater level. The magnitude of the movements caused by these changes in effective stress will depend on the stiffness of the fill. The changes will occur over large areas and so deformations will be largely one-dimensional. The movements can be described by a constrained modulus appropriate to the particular stress change. As the change in water level will usually result in unloading or reloading of the fill, the stiffness may be much larger than that operative during the first loading of the fill. The rate at which the groundwater level within a fill adjusts to any changes in external constraints is a function of the fill permeability. When an unsaturated clay fill is subjected to a rise in groundwater, the change may be rapid at first. Following softening of the clay lumps, often accompanied by large settlement, further changes are slowed by the significantly lowered permeability.

58.5.3.2 Swelling and shrinkage

The volume change of saturated clay fill, particularly high-plasticity clay, is moisture-content dependent. Drying may cause considerable shrinkage. As the fill dries and shrinks, the soil moisture exerts more suction. If water comes into contact with the fill, it is absorbed and the clay swells. These types of movement have caused damage to houses with shallow foundations on natural clay soils, and clay fills are vulnerable to the same processes. Shrinkage can occur through:

- movement of moisture near the ground surface, due to evaporation and recharge;
- the action of the roots of vegetation: the demand for moisture in dry weather increases with the amount of vegetation;
- heating of the ground.

58.5.3.3 Collapse compression

Partially saturated fills may undergo a reduction in volume, known as collapse compression, when inundated. Inundation may occur owing to a rise in groundwater level or by downward migration of water. Most types of partially saturated fill are susceptible to collapse compression under a wide range of applied stress when inundated or wetted for the first time, if they have been placed in a sufficiently loose or dry condition. This phenomenon can occur without any change in applied total stress. When construction is about to take place on such a fill, susceptibility to collapse compression may be the most significant hazard because, where collapse compression occurs after construction has taken place, buildings may be seriously damaged (**Figure 58.3**). This most important facet of fill behaviour is examined in some detail in Charles and Watts (2001).

Figure 58.3 Damage to a building caused by collapse compression

58.5.4 Biodegradation

The age of refuse landfill is important in evaluating the potential for further settlement. Not only has older refuse landfill had more time for organic matter to decompose, it is often an inherently better material with a much higher ash content than more recent refuse. Settlement behaviour is also affected by a number of other factors:

- composition of the waste;
- initial bulk density;
- initial moisture content;
- level of leachate within the fill;
- the time over which the fill was placed.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Long-term movement can occur as biodegradation causes a reduction in volume, which may be in addition to movement caused by physical creep compression (both can be described by logarithmic compression rate parameters, see Watts and Charles, 1999).

58.5.5 Chemical action

Volume changes, usually expansion, may occur due to chemical reactions within the fill. Loss of material due to dissolution of carbonates could occur in some fills. In addition to a volume change of the waste fill, there may be an interaction between the construction materials and chemically aggressive ground.

Chemical reactions may have been occurring slowly since the waste fill was deposited. However, building development on the site could lead to an acceleration of these reactions as a result of effects connected with construction, such as the following:

- earthmoving may lead to mixing of wastes, which brings different substances into contact and may introduce oxygen into the waste fill;
- leaking drains may cause water to infiltrate the waste fill.

Fills that are particularly vulnerable include:

- sulfate-bearing waste material;
- iron and steel slag;
- pyritic shale;
- alkali waste.

For these materials, expert advice will be required.

58.6 Design issues

In foundation design, it is important to distinguish between the settlement attributable to the weight of the building and settlement attributable to other causes such as self-weight of the fill or collapse compression. The concept of bearing capacity is based on the premise that the settlement resulting from the weight of the building is the critical factor. With small structures on deep fills, almost invariably settlement attributable to causes such as self-weight of the fill or collapse compression will dominate and, consequently, the bearing capacity can be a misleading concept. Foundation design should be based on an assessment of the magnitude of differential movements of the fill subsequent to construction. It is necessary to identify first the cause of settlement. The small scale of many developments makes it difficult to ensure that there is an adequate investigation of the fill.

58.6.1 Bearing capacity

Whilst the performance of building foundations on fills is rarely determined by bearing capacity, it is a design issue. For less settlement-sensitive structures (embankments or gravity retaining walls for example) the bearing capacity is of key importance. The maximum stresses that can be applied to and by fills is also of relevance when considering the pressures on walls (compaction pressure, heave), and also in slope stability calculations.

Standard bearing capacity calculations can be used, but care should be taken with the fill properties used and a range of probable values must be considered (refer to Chapter 53 *Shallow foundations*).

58.6.2 Settlement

Settlement under applied loads, or due to fill settlement caused by other factors, is covered earlier in this chapter. The design must assess which type of settlement effects will apply in the situation under consideration. Following this, the anticipated amount and likely variability of settlement and its distribution (or heave) must be calculated.

Calculation approaches are often driven by the quantity and quality of data on fill properties on the site, and often may take the form of simple estimates. These may be based on elastic analogies (Boussinesq-type stress distributions), on semi-empirical approaches (such as Charles, 1996) or be fully empirical (Burland and Burbidge, 1985).

58.6.3 Geometry

Distortion and damage of buildings are related to the magnitude of the differential settlement across the building rather than the total settlement. Variation in the depth of fill under a building can be a cause of differential settlement and may also result in damaging horizontal movements. There are particularly acute problems associated with differential settlement at the edges of a filled area.

In a backfilled excavation, the severity of the differential settlement will depend on the steepness of the face of the excavation, and many different situations are commonly encountered:

- an old dock with vertical sides;
- a quarry in hard rock with a near vertical face;
- gravel and clay pits with slopes that are not so steep;
- buried changes of the gradient of a slope;
- the sloping base of an excavation.

There is a need to define the areas from which buildings should be excluded because the rate of change in fill thickness gives the potential for unacceptable long-term differential settlement. If unsafe decisions are made and exclusion zones are too small, there may be damage to the building and consequently legal action. On the other hand, an overconservative approach will needlessly sterilise large areas of land and could make many sites uneconomic to develop. In determining the area of land where ground surface movements may be unacceptably large owing to variations in the depth of the fill, consideration needs to be given to both the properties of the fill and the geometry of the fill. Further consideration and prediction of the settlement pattern due to changes in fill depth can be found in Charles and Watts (2001) and Charles and Skinner (2001a).

58.6.4 Monitoring

In assessing the condition of a fill, the performance of a treatment or the condition of a structure it is often helpful to carry out monitoring, which may include:

- surface levelling stations to measure the settlement of the fill surface;
- extensometers (magnet or rod) to measure the settlement of incremental depths of fill;
- standpipe piezometers to measure groundwater levels within the fill (local weather observations are also useful);
- load tests for direct estimation of the settlement produced by a load (**Figure 58.4**).

Such measurements can form one of the most important parts of an investigation of a filled site.

Surface settlement can be monitored by precise optical levelling. The settlement of the levelling stations is due to the vertical compression of the fill, in which the station is installed, together with any movement of the underlying natural ground. Surface levelling stations may be very simple, and are easy to install. The levelling stations should be sufficiently robust to resist damage due to construction traffic and where the stations protrude above the ground surface, it is usually necessary to provide protection such as concrete manhole rings.

(a)

(b)

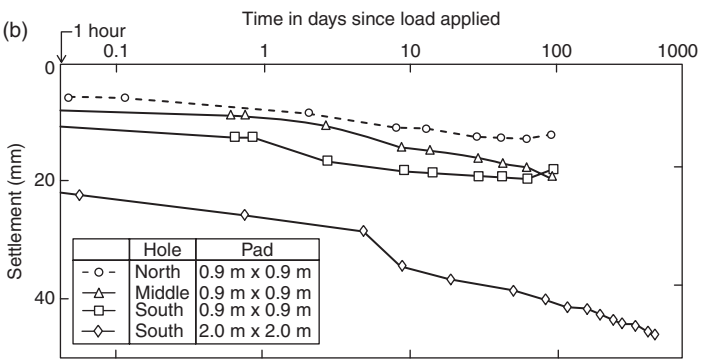


Figure 58.4 (a) Load testing using a skip; (b) load settlement results
Reproduced from Charles and Watts (2001)

Although filled sites can be subject to large settlements, monitoring often takes place over a short period or may be intermittent. Accurate measurements are required to establish the rate of settlement reliably over a relatively short period. Measurements should be made to an accuracy of at least 1 mm. It can be helpful to locate levelling stations in a number of traverses with the stations at quite close intervals. In this way an indication of the likely differential settlement over the area of a building can be obtained.

Settlement at different depths within a deep fill can be measured by installing a magnet extensometer, whereas rod extensometers may be appropriate for shallow fills.

It is also important to measure water levels within a fill. Simple standpipe piezometers can be sealed into boreholes. In low-permeability fills the response time of a standpipe piezometer to a change in piezometric pressure may be too long. Pneumatic or vibrating wire piezometers can be installed in boreholes and will give a much more rapid response.

The period for monitoring depends on the situation. For example, to establish trends in settlement and groundwater levels reliably on a site a minimum period of at least a year will be required, and several years would be preferable. Where a site is being investigated for building development it will rarely be possible to monitor over such long periods. However, even where the period is quite short, it may be very advantageous to perform some monitoring. Monitoring may be used to identify when treatment, or the rate of settlement, has reached some design level. In each case the interval, period and type of monitoring should be linked to the parameter being measured. Further guidance on monitoring is given in Chapters 94 *Principles of geotechnical monitoring* and 95 *Types of geotechnical instrumentation and their usage*.

Post-construction settlement of buildings on fill should be monitored where possible and BRE Digests 343 and 344 (BRE, 1989, BRE and Longworth 1989b) provide guidance on measuring the movements of low-rise buildings.

58.6.5 Shallow foundations

Shallow foundations (see Chapter 53 *Shallow foundations*) are generally less than 3 m deep, so in a shallow fill (<3 m deep) a shallow foundation is all that is required to found the structure on the underlying natural stratum. With medium-depth (3 m to 10 m) and deep (>10 m) fills, either deep foundations into the underlying natural stratum, or a shallow foundation is adopted and the structure is founded on the fill. Where small structures are to be built on medium-depth or deep fills, the only economic solution may involve founding the structure on the fill. It should be ensured that:

- the bearing capacity of the fill is adequate;
- settlement under the working load will not damage the structure;
- settlement due to causes other than building loads will not damage the structure.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Where fill is vulnerable to significant movement, ground improvement prior to construction on the fill should be considered. Ground treatment methods, when appropriately used should limit and control settlement; they will not normally eliminate settlement (refer to Chapter 59 *Design principles for ground improvement*). Many types of ground treatment will not improve the full depth of a deep (>10 m) fill, but they may stiffen the upper part of the fill sufficiently to prevent excessive differential settlement.

The following basic approaches to shallow foundation design may be adopted:

- Construct shallow foundations on fill that has been sufficiently improved by ground treatment so that deformations are acceptably small.
- Design shallow foundations that are sufficiently stiff to withstand the anticipated deformations in the fill; this may not be difficult with small buildings, but tilt may still be a problem.
- Design shallow foundations and structures that are sufficiently flexible to tolerate the anticipated deformations in the fill.

In practice, solutions may comprise both ground treatment and special foundation design.

Fill that is susceptible to collapse compression on wetting is of particular concern. Several ways of dealing with the problem are listed below and a combination of these approaches may often be the most suitable:

- eliminate susceptibility to collapse by pre-inundation (not generally feasible);
- eliminate or greatly reduce susceptibility to collapse by some other form of ground treatment (depth of effectiveness may be limited);
- prevent inundation of the fill during the life of structure (this often cannot be guaranteed);
- design the foundations and structure to survive collapse movements (difficult if potential movements are large).

Reinforced concrete rafts with edge beams, sometimes termed semi-rafts or stiffened edge rafts, have commonly been used for housing on non-engineered fills. They have usually been designed so that some of the length will act as a cantilever over a potential void. However, where large differential movement may occur, very substantial foundations may be required and tilt may still be unacceptably large. Atkinson (1993) has described typical designs.

The problems associated with shallow foundations for low-rise buildings on filled ground can be minimised by:

- avoiding building across the edges of filled areas where the structure would be partly founded on fill and partly on undisturbed natural ground;
- restricting construction to small units and not building long terraces of houses.

Relative movement between the building and any services entering it, and between various sections of these services, merits careful consideration. If the movements are not likely to be large, the use of short lengths of pipes with flexible connections may be sufficient. In more severe cases it may be necessary to use flexible pipes, or to carry services on piles bearing on a firm stratum beneath the fill. Falls given to drains should be adequate to reduce the risk that settlement will cause backfalls.

58.6.6 Deep foundations

Where a large structure is to be built on shallow or medium-depth fill, the poor load-carrying characteristics of the fill can be circumvented by using piled foundations and a suspended floor. The piles will be designed to transmit the loads applied by the weight of the building down through the fill to a competent stratum underlying the fill (refer to Chapters 54 *Single piles* and 55 *Pile-group design*).

There may be problems where piles hit obstructions. If the depth of fill is not accurately known at a pile location, it may be incorrectly assumed that the pile has reached natural ground.

The piles should be designed for downdrag (negative skin friction) caused by settlement of the fill. The downdrag can be calculated in terms of the effective stress (Burland, 1973) (see Chapter 55 *Pile-group design*). In some situations it may be considered that the downdrag will cause too large a settlement of the pile. The use of a slip coating or a permanent sleeve can reduce its effect, but careful detailing (to ensure effectiveness) is required and complicates pile construction. Often it will be more cost effective to increase the pile length.

Special attention is needed in the design of services that span from the filled ground into buildings founded on piles.

In a fill in which methane gas or other dangerous gases are generated by the decay and decomposition of organic matter, piles could form paths for the escape of the gas.

58.7 Construction on engineered fills

In some cases a fill is placed to support a building or other structure. The characteristics of the site should be considered with regard to the impact of the fill and other applied loads. Ideally the fill should be placed such that simple foundations can be utilised. Sometimes this is not the case, and in these circumstances the nature of the fill should be designed so it has the required properties, e.g. it can be penetrated by piles but will support the ground slab, or can be compacted by vibro after placement.

Where suitable fill material is placed to an appropriate specification under controlled conditions, most of the problems associated with construction on fills should be greatly reduced if not eliminated. The two major considerations are, firstly, the preparation of an appropriate specification, and, secondly, the provision of adequate site supervision to ensure compliance with it.

The required behaviour of the fill should be well defined and it should be possible to make reliable estimates of settlement under working loads including long-term settlement and bearing capacity. However, sometimes problems have been experienced because inappropriate specification or inadequate

control of the placement of engineered fills has led to excessive settlement or heave in service.

While the specified fill may be adequate to support the building, other causes of settlement or ground failure must be considered:

- the stability of the natural ground;
- settlement of the underlying natural ground due to the weight of a fill;
- settlement of an engineered fill due to self-weight;
- movement in an engineered fill due to changes in groundwater level, pore pressure or seasonal changes in moisture content.

The specification of the engineered fill should define acceptable materials for the fill and the method of placement and compaction. Specifications for highway construction have often been used for the specification of fills to support buildings or other structures, but may not be adequate. Trenter and Charles (1998) have produced a model specification for fills for building purposes.

58.8 Summary

Construction on fills is often more challenging than for similar structures on natural soils. However, additional risks can be minimised provided that:

- there is an understanding of the problems associated with the various type of fill and fill deposits;
- the construction is appropriate;
- thorough investigations are carried out;
- the design recognises that movement may not just be related to construction;
- adequate specifications for construction and monitoring are produced;
- construction is carried out to the specifications, with appropriate quality control and feedback.

Chapter 59

Design principles for ground improvement

Robert Essler RD Geotech, Skipton, UK

The use of ground improvement on projects has increased worldwide as its design and application becomes more common. Many major projects now routinely adopt ground improvement and this experience is then disseminated through technical publications, which in turn increases knowledge. Hence, there is a better understanding of how and when such techniques can be incorporated into projects and what associated risks may be attached. In the UK there still remains a perception by some that ground-improvement techniques are difficult to design securely, that the design knowledge is restricted to a small number of engineers or that the techniques are only to be used when there is an unexpected problem on site. It is, therefore, important that young practising engineers have a basic grounding in the design of ground-improvement techniques so that they can recognise at an early stage when such processes could be used to advantage on their projects and have the confidence to propose such schemes. It is equally important that when such a situation arises that the engineer is able to progress the design knowledgably whether by discussion with contracting specialists or by referral to experienced engineers within their organisations or other companies.

59.1 Introduction

It is a difficult task to summarise the design principles of so many varied processes with different methodologies and applications. It is, therefore, hoped that the techniques set out below and described in outline will allow the engineer to at least understand which processes might be suitable and where to look for further insights to better inform the decision-making process. **Table 59.1** gives some insight into the selection of a ground-improvement process in terms of applicability, performance and risks.

59.1.1 Background

The improvement of ground by injection of grout dates back to at least 1802 (Littlejohn, 2003). This would suggest then that in the 21st century it should be a well-practised, well-understood technique. It is, therefore, surprising that ground improvement, particularly by grouting, is still perceived as a process that is not very well understood and can be difficult to incorporate within a project to provide definable performance. There is no doubt that until the seventies or eighties there was very little technical knowledge in the public domain, but from this time onwards the technical literature has increased substantially. In the USA, the first specialist grouting conference was in 1982 (New Orleans, 1982) and attracted a total of 64 papers. By the third conference (New Orleans, 2003), this number had risen to 127 from 21 countries. Because the UK construction market is significantly smaller than that in Europe or the US, the development of these more experience-driven techniques is not as advanced and limited to specialists who, generally, belong to larger groups working worldwide. In 2008 the probable size of the European ground treatment (grouting) market was in excess of £500 million annually. This should be compared to the UK where the market is probably on average £10–£20 million annually and is distorted when large projects stretch the available resources. Therefore, it is critical to the development of these techniques that they become more understood and, thus, more available as tools for the engineer to employ in design.

59.1.2 Definition of ground improvement

Ground improvement can be defined as the introduction of materials or energy to soils to affect a change in performance of the ground such that it performs more reliably and can be incorporated within the design process.

59.1.3. Types of ground improvement

The major forms of ground improvement discussed within this chapter are as follows:

a. void filling;

b. grouting (permeation, compaction and jet grouting);

c. improvement by densification or replacement (vibrocompaction, dynamic compaction and stone columns);

d. soil mixing.

There are other forms of ground improvement but the processes set out above can be regarded as the major techniques

Technique	Depth capability					Suitable ground					Cement-based grouts			Chemical grouts	
	0–2	2–5	5–10	10–20	20+	Clay	Silt	Sand	Gravel	Rock	Cement PFA	Cement bentonite	Other cement grouts	Silicate	Resin others

Table 59.1 Selection of ground-improvement techniques

used for a very high proportion of the ground improvement carried out. Of all these techniques, jet grouting, soil mixing, vibrocompaction and vibroreplacement probably represent most of the ground improvement carried out and should be considered carefully.

59.2 General design principles for ground improvement

The following general principles apply to ground improvement and need to be followed to ensure that the design is appropriate and the application successful.

59.2.1 Ground conditions

Because most ground-improvement techniques require some interaction with the ground, the correct identification of the soils present is of vital importance. It is, therefore, important that adequate site investigation is carried out prior to any ground improvement to ensure that the correct decisions are taken as to which technique is most suitable.

Problem soils to consider carefully would be very soft organic clays, peats and single-sized sands and silts.

As well as carrying out normal laboratory testing, chemical testing is also important as some chemicals can affect the strength development of some binders.

Table 59.2 sets out some soils that need careful investigation to ensure that appropriate ground improvement can be designed. It should be stressed that adequate and thorough ground investigation is always a prerequisite for successful ground improvement.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Soil type	Issues	Investigation techniques	Ground-improvement techniques
Sands and gravels	Fines content and collapse potential	Obtain representative samples for laboratory testing	All forms of ground improvement
Soft clays	Long-term settlement	Obtain undisturbed samples, carry out CPT testing	Compaction grouting, vibrocompaction and dynamic compaction. Soil mixing and vibroreplacement (insensitive clays, Cu > 15 kPa)
Peat and organic clays	Acidic ground, secondary compression	Chemical testing and if possible large diameter undisturbed sampling	Jet grouting and soil mixing
Karstic rock	Presence of solution features	Geophysics and intrusive surveys	Compaction grouting
Fills	Presence of organic materials, obstructions and chemicals	Chemical testing, geophysics and intrusive surveys	Vibrocompaction or dynamic compaction, compaction grouting

Table 59.2 Ground-related issues for ground improvement

59.2.2 Site trials

It is inevitable that for some applications there will be some doubt as to what degree of improvement might be obtained. Site trials are invaluable for informing the design on a project-specific basis and it is always recommended that some form of trial, whether an initial period of more intensive monitoring, validation at the start of the works or a completely separate advance trial, is carried out. The exact form of a trial will depend on both familiarity with the process within the soils under consideration and equally the criticality of the degree of improvement to the design. The works programme should be developed assuming some period of initial trialling so that due allowance can be made for any resultant changes. Where the ground-improvement performance is critical then advance trials are preferred with sufficient programme time not only for the actual site works but also for the on-site and off-site testing and evaluation.

A good example of this was the jet grouting carried at the Kingston Bridge, Glasgow (Coutts *et al.*, 1992) where the proposed jet grouting was critical to the stabilisation of a major bridge and merited a separate advance trial to confirm the performance. A recent example was the construction of a sandwich wall in Amsterdam where jet grouting was critical to the support of a historic building and a series of trials were carried out well in advance of the actual works (De Wit *et al.*, 2007).

59.2.3 Performance

It is always important when designing ground-improvement works that the performance required is documented to such a degree that it can be validated on site. It is imperative that whatever design parameters are required from the ground-improvement scheme are correctly translated into field performance that can be validated so that the design can be assured. For example, a designer must decide whether the design parameters need to be the average of field results, the minimum, the maximum or even to have some other relationship.

59.2.4 Environmental issues

Environmental issues resulting from ground improvement can either be due to polluting the ground with the cements or chemicals used or equally as a result of changes to the local groundwater hydrogeology. When considering ground-improvement design it is, thus, important to review these potential effects.

59.3 Design principles for void filling

59.3.1 Methods and key issues

Void filling is most commonly employed to deal with abandoned mines or redundant underground structures and involves the drilling of holes on a regular grid and the injection of either a fluid grout or paste.

Generally the design is to firstly create a perimeter barrier around the area to be treated to economise the operation. This is most often formed by drilling larger diameter holes (100–250 mm in diameter) and introducing gravel-sized material washed in with a grout to bind the gravel together.

Figure 59.1 shows how perimeter holes are executed using a mix of gravel and grout, which will not travel and, thus, when set forms a barrier to the more fluid infill grout. Typical perimeter holes would be installed on a 2–3 m grid.

The design of the main works is then executed by drilling holes (50–75 mm in diameter) on a regular grid, typically ranging from 3 m to 6 m, and injecting a cement-based grout or paste. The design of the grid to adopt is based on how open the void is and, thus, how easy it will be for the grout to travel. Usually the works are carried out following the recommendations of CIRIA Special Publication 32 *Construction over Abandoned Mineworkings* (Healy and Head, 1984), which sets out the extent of treatment beyond the structures of interest.

Key design issues relate to the control of any groundwater trapped within the voids, which may need to be pumped out as the void is filled, and ensuring that access shafts are located and treated as these can be a source of future settlement.

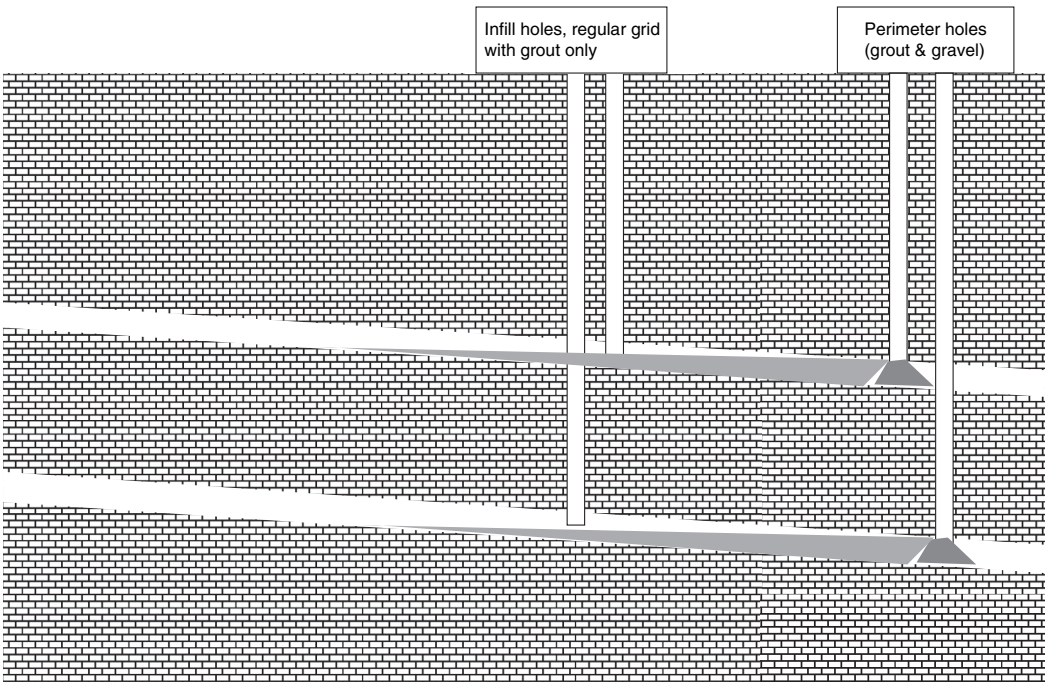

Figure 59.1 Schematic of perimeter and infill grouting for void filling

Groundwater pumped from these voids could be contaminated and should be disposed of appropriately.

Quite often there are underground records of the mines and these can be used to design the works and assess the amount of infilling required and expected drilling depths. Historically a cement and pulverised fuel ash (PFA) mix was used in the proportion of 1 part cement to 10–20 parts PFA. The Environment Agency is now reluctant to sanction the use of PFA as it contains heavy metals and, thus, can itself introduce contaminants into the ground. Replacement grouts can be foam concrete or simple cement and sand mixes.

59.3.2 Design principles

Designing for void filling is essentially observational with probe holes being drilled on a regular grid to locate any voids and subsequently grouting them. The design process should ensure that the depth of drilling is sufficient to investigate all known voids and the plan area treated should include the potential collapse zone of voids at the boundary of the site. Adequate site investigation is, thus, very important. As the resultant void is infilled, the grout is contained and a low strength of less than 5 MPa is usually sufficient.

It is essential good practice when developing a new site to check available coal mining records. These are available from the Mining Records Office in Mansfield.

59.3.3 Execution controls

Execution is controlled by documenting all holes drilled and using this information to develop the underground void profile. The grout or paste injected is controlled by testing its properties against a testing and inspection plan, which sets out limits on properties such as density, viscosity and bleed.

59.3.4 Validation

Validation is usually by the use of the ongoing probe holes within secondary or tertiary grid positions and proof grouted. Where complete filling is important then validation by secondary grouting can be carried out using a more fluid grout and higher pressures.

59.3.5 Typical performance obtained

Generally about 95% of the void can be expected to be filled as some *in situ* bleed can take place. Filler strengths have a wide range depending on individual project design. Historically, void filling of mine workings is regarded as a low-tech solution and there are very few instances of problems arising from this type of work. Care should be taken, however, when the void being infilled is of a different type such as an abandoned tunnel within an urban environment as performance here can be more critical and post pressure grouting may be required. Where the infilled void is likely to be loaded by subsequent construction, the grout properties need to be considered in more detail as higher strengths may be required.

59.4 Design principles for compaction grouting

59.4.1 Methods and key issues

Compaction grouting, probably originating in the United States, is most commonly employed to increase the relative

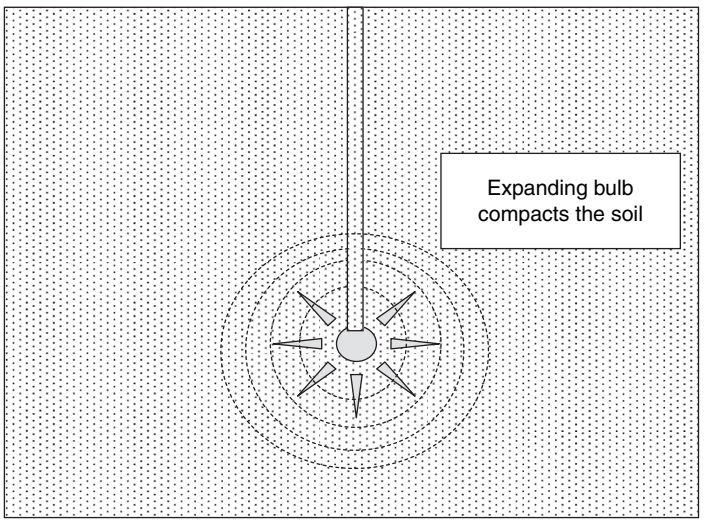

Figure 59.2 Compaction grouting

density of granular materials to improve stiffness or reduce future settlement liability. Compaction grouting is essentially the injection of a low-slump (typically 25–100 mm) grout such that an expanding frictional bulb forms. **Figure 59.2** shows the schematic effect of the technique. This expansion causes deformation and densification around it and ultimately improves the ground. This expansion will continue until the ground has densified sufficiently to resist the expanding pressure. This is observed during the process of grouting through the increasing injection pressure and also by ground heave. If the slump is relatively high then a hybrid form of grouting is used where both expansion and hydro-fracture occur.

The design is, thus, based on expanding cavities within the ground until a maximum relative density is achieved. The design process generally considers the improvement midway between injection points as this will be the least improved. In the UK compaction grouting is mainly restricted to ground improvement where neither waterproofing or underpinning is required. It is sometimes used for settlement control but as control is more difficult than the use of fracture grouting, it is not favoured. Compaction grouting, on the other hand, is commonly used in the United States for settlement correction, ground improvement and seismic risk mitigation, where it has a long history of success. Typical uses in the UK are restricted to grouting to improve made ground or solution features formed within limestone or chalk. Compaction grouting has the advantage that the compactive effort coupled with the associated high pressures mean that a wider hole spacing can be used than for permeation grouting and, thus, it can be more economical in improving granular soils.

A secondary benefit when using compaction grouting to stabilise solution features is that the improvement can be achieved without the introduction of significant volumes of fluid grout or water, which could further destabilise the feature. For historic or domestic properties, there is also an advantage that the original foundation support can be left in place without significant rebuilding as the soil itself is improved and no new load carrying capacity is required.

The technique is most appropriate for granular soils where the compactive effort is greatest. In silts the technique appears to work well and assists in forcing water from the silt and increasing strength. In clays the process is likely to cause significant pore water pressure response, which although causing improvement to the clay in the long term can result in settlement. It is, thus, unusual to apply compaction grouting in clays unless they exist as thin layers or bands within the main body of improvement.

Historically, compaction grout is a mix of cement, bentonite and sand with an approximate water solids ratio of 0.1 to 0.2 by weight, designed to be pumpable but having a low slump. Where available PFA can be added to increase pumpability but environmental issues may preclude its use in the future. There are now proprietary mixes available in Europe, such as Blitzdammer manufactured by Heidleberg Cement, which are supplied ready mixed in dry form and which allows a much smaller site set-up.

59.4.2 Design principles

Generally compaction grouting is designed on the basis of an expanding bulb compacting the ground around it. The degree of improvement depends on the soil type and existing overburden, as compactive effort is lost when the ground starts to heave. When designing compaction grouting, the hole spacing, which usually ranges from 1.5 m to 3.5 m, is related to the depth of the compaction grouting and the zone of improvement required. A closer spacing is used where confinement is least and also where the treatment is at shallow depths. Treatment up to ground level is not possible as the compactive effort is minimal and in this case the shallow zone can be excavated and replaced in layers while applying compactive effort or treatment by another form of ground improvement.

Table 59.3 gives an approximate indication of hole spacing and the likely degree of improvement. Care needs to be taken when dealing with fills as the variable composition can lead to unpredictable results.

Generally the density of the ground can be improved such that standard penetration test (SPT) N values are increased by a factor of up to three depending on the fines content. The closer the spacing, the higher the degree of improvement but overburden plays an important part in providing the necessary confinement for the expanding bulb.

Design grouting pressures range from 40 bar at depths greater than 15 m to no more than 10 bar at depths less than 5 m. Holes are drilled to depth and the casing withdrawn in 0.5 m to 1 m stages while injecting grout. Typically stage volumes are controlled by pressure or resultant movement: the grout is injected until either the target pressure is reached or movement is triggered.

Soil type	Depth of treatment (m)	Hole spacing (m)	Improvement range (%)
Loose sands and sandy gravels	<3	1	150–200
	5–10	1–2	150–300
	>10	2–3	<300
Medium dense sands	<3	1	125–150
	5–10	1–2	150–175
	>10	2–3	<200
Silts	<3	1	<150
	5–10	1–2	<200
	>10	2–3	<200

Table 59.3 Hole spacing for compaction grouting

Grout strength is not usually an issue as the cement in the mix is sufficient to produce cube strengths in excess of 10 MPa. Low-strength compaction grout can be produced by substitution of the cement with non-cementitious material.

A good example of the use of compaction grouting was the Castle Mall shopping centre at Norwich. The site was underlain by chalk at shallow depth containing numerous solution features of variable size and depth. The infill material to these features was also variable but generally very weak. The development consisted of an 18-m-deep excavation within a perimeter of piled retaining walls and the presence of solution features within the site complicated the foundation design. Because the site investigation had located some features (8 out of 68 boreholes) but other features were likely to be present, the foundation design had to take account of the random location and nature of the features. The foundation design considered three solutions:

1. piled foundations, permanently cased through the features;
2. raft, spanning over any feature;
3. pad foundations combined with compaction grouting to improve the infill material.

The chosen foundation solution was pad foundations with ground improvement, as this allowed the chalk bedrock to be utilised for the majority of the foundations and compaction grouting would then allow the remaining foundations to be safely supported.

The engineer developed a strategy for dealing with the presence of features according to location and size, which is shown in **Figure 59.3**. This strategy was followed for the site works and was either a simple probe and bulk fill with low-pressure grouting or high-pressure compaction grouting.

The performance of the compaction grouting was based on post-testing using the SPT. This was set at an average of 15 and a minimum of 10. About 7% of the site area was discovered to contain features; there were 60 in number with a maximum size of 12 m in diameter. The largest feature had a plan area of 200 m^2. Grout volumes per metre of hole ranged from 0.26 m^3 to 1.0 m^3.

59.4.3 Execution controls

As with most ground improvement, execution controls are twofold: quality control of the materials employed and the resultant effect on the ground. Compaction grouting is controlled by ensuring a consistent low slump for the grout whilst monitoring for excessive line pressure or resultant movement.

59.4.4 Validation

The most common validation for compaction grouting is to compare *in situ* testing before and after treatment, usually using a cone penetration test (CPT) or SPT. The designer normally sets a post-treatment minimum value to be obtained based on the required degree of improvement. On some projects where justified, zone testing can be carried out, although the additional information gained may not justify the significant cost of the testing. **Figures 59.4** and **59.5** show typical results for SPT and CPT testing before and after treatment.

59.5 Design principles for permeation grouting

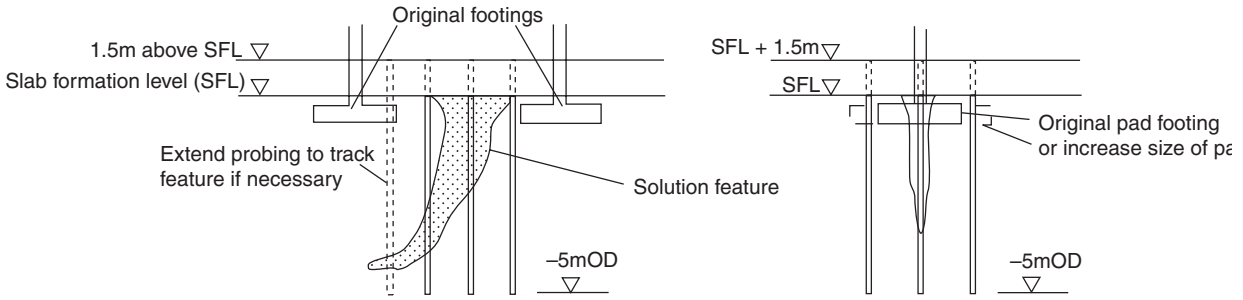
59.5.1 Methods and key issues

Permeation grouting by definition requires that grout is injected into the interstitial pores of the ground to replace air or water and, hence, bind the individual particles together.

A number of techniques are available, which are described below in Section 59.5.2.

59.5.1.1 Grout selection

With permeation grouting the design of the grout is important, as it must penetrate the interstitial pores with minimum disturbance. If the grout viscosity is too high or the particulate size is too large then complete uniform permeation will not be possible and this will cause problems with both treatment quality and also resultant movement.



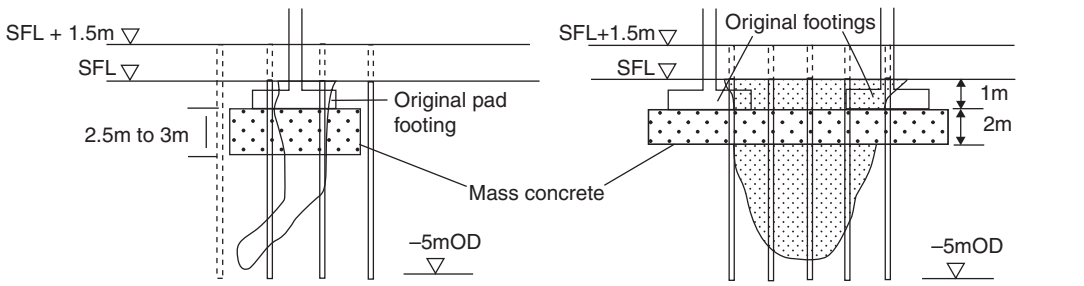
The design of the grout to be used depends both on the ground conditions and the technique being used. Ultimately, when using permeation grouting only limited types of grout can be used for lancing and end-of-casing grouting due to the relatively poor nature of the delivery system. This is discussed below for the above mentioned systems. Only Tube A manchette grouting can use a variety of grouts and the selection of grout for this system can greatly influence the quality of the end product.

Figure 59.6 shows the range of penetrability for the various grouts; most usually either cement bentonite or silicate-based grouts are used. As an example Thames gravels are commonly treated with either cement bentonite or silicate grouts or a combination of the two.

59.5.1.2 Cement bentonite

When used as an installation and injection grout, a typical mix would have a water/cement ratio of 2 with 10% bentonite to

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

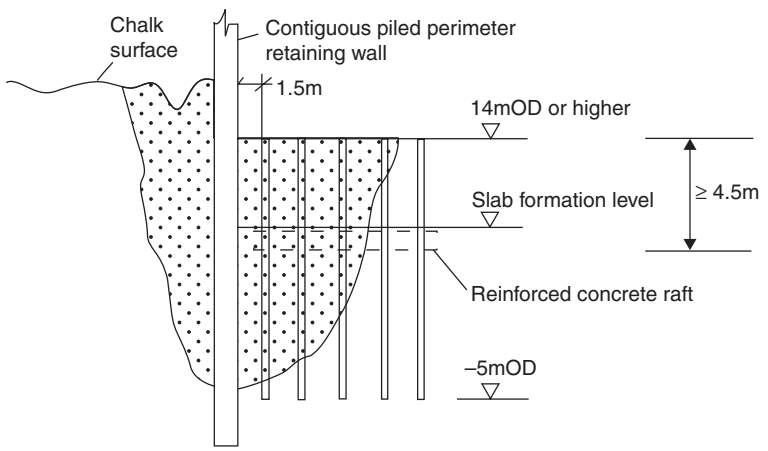


CASE 1 ▪ Features up to 4m across clear of foundations or up to 3m across at contiguous piled wall

Treatment ▪ Probe and bulkfill grout from 1.5m above slab formation level

CASE 2 ▪ Features up to 2m across beneath foundations

Treatment ▪ Probe and bulkfill grout from 1.5m above slab formation level



CASE 3 ▪ Features between 2m and 4m across beneath foundations

Treatment ▪ Probe and bulkfill grout from 1.5m above slab formation level
▪ Found original footings on mass concrete

CASE 4 ▪ Features larger than 4m across beneath foundations

Treatment ▪ Probe and compaction grout from 1.5m above slab formation level
▪ Found original footings on mass concrete

CASE 5 ▪ Features greater than 3m diameter at contigruous piled wall

Treatment ▪ Probe and compaction grout from high level
▪ Combine footings into a raft bearing on treated material

Reproduced from Wilder, Smith and Gómez (2005)

cement. The unconfined compressive strength is in the range 2–4 N/mm^2 and the bleed <5%.

Sometimes the cement is replaced by a cement/PFA pre-blend where lower strength is required. An example might be where piling occurs after the grouting and there are concerns about penetrating grouted ground.

59.5.1.3 Silicate

In the UK, for grouting, the silicate is usually a proprietary brand, and the brands have different specific gravities. The silicate solution is mixed with a hardener based on organic esters, which react and cause the mix to gel. The gelling time depends on the type (specific gravity) of the silicate being used and the percentage of hardener added. The setting time is around 20–45 minutes and depends, broadly, on the hardener percentage, but is also temperature sensitive.

It is important to know the specific gravity when detailing the mix as differing dilutions will require differing amounts of hardener. A typical mix will contain 35–45% of silicate solution, 5–7% hardener and 50–60% water.

59.5.1.4 Microfine cement

Microfine cement is available in the UK in a number of grades.

The fineness of cement is given by the Blaine value, which is the surface area of particles per unit weight usually expressed as m^2/kg. The larger the value the finer the particles.

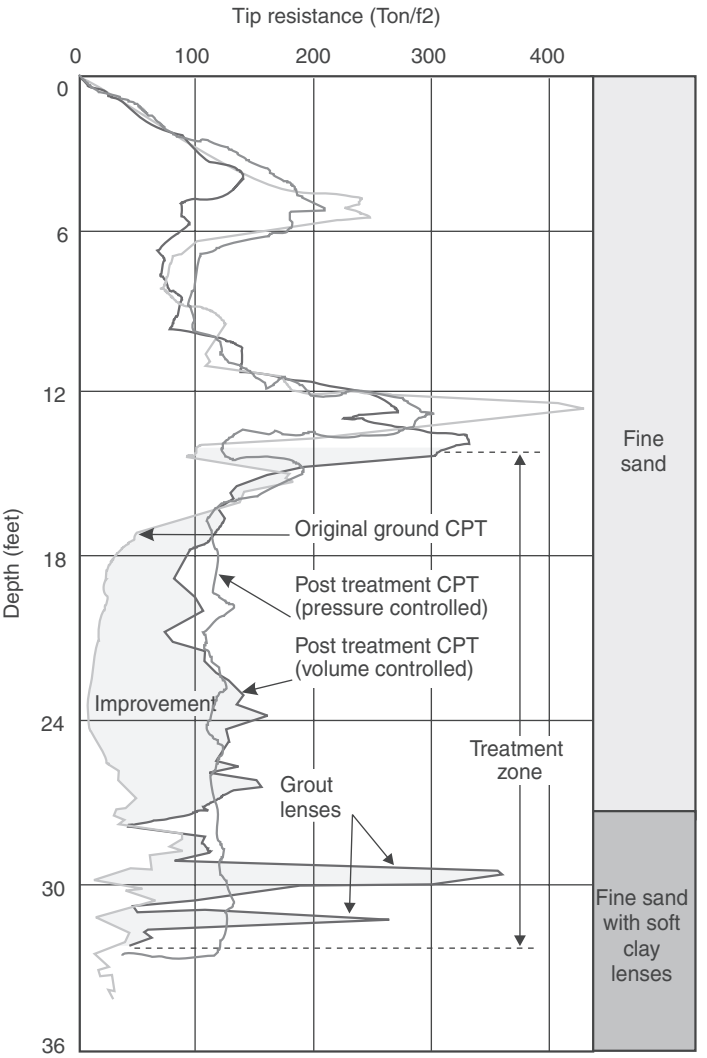

Figure 59.5 Example of pre- and post-testing for compaction grouting using CPT
Reproduced courtesy of Hayward Baker Inc © 2004

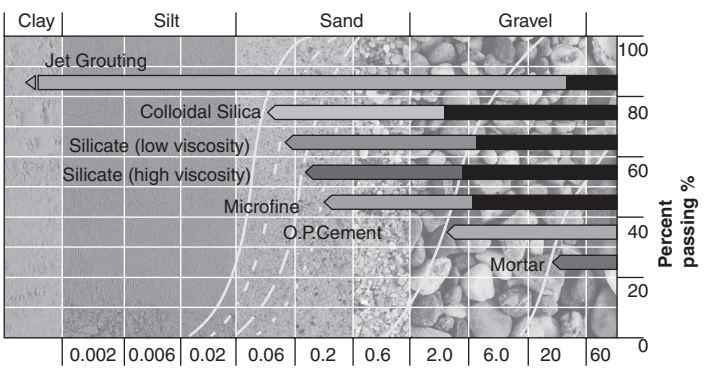

Figure 59.6 Range of penetrability for various grouts
Based on a figure from Keller brochure 67-03 E: Soilcrete® (jet-grouting process); Keller Group plc

As a rough guide the Blaine values for some cement-based materials are set out below

Material	Blaine value (m^2/kg)
O.P. cement	290–390
Rheocem 650	625
Rheocem 900	900

Microfine cement is normally utilised at relatively high water/cement ratios (1–3) and must be used with a plasticiser and bleed inhibitor to reduce the risk of blockage and to reduce the bleed. The finer the material the faster the setting time and with Rheocem 900, for example, penetration will be impaired after one hour from mixing.

Microfine cements are somewhat peculiar in that cubes taken for strength testing will bleed severely and may not set properly, but if mixed with sand will set quickly and produce a high strength. This can sometimes lead to problems on site if the engineer is not familiar with this behaviour.

59.5.1.5 Colloidal silica

This is a relatively recent grout and is a 'two-component' injection system, based on a nanometric colloidal silica suspension. The working time can be adjusted with an accelerator. The product may be used between +5°C and +40°C and contains neither solvents nor toxic components.

The grout will penetrate quite fine materials such as the Thanet, Harwich or Upnor Formation and has been used for the Channel Tunnel Rail Link for this purpose.

59.5.2 Design principles

59.5.2.1 Lancing

Lancing is one of the simplest of techniques but can be effective if carried out in the right circumstances. It is commonly used for temporary groundwater control for excavations below the water table but with very little head. **Figure 59.7** shows how an angled hole can be used to insert grout beneath a footing and improve bearing capacity. Lanced underpins are possible but risky as quality can be variable and, hence, can lead to settlement or even collapse. The most common use is to proof grout beneath slabs when settlement has taken place, loadings are increased or voids are present under slabs. Lancing is the process of driving a hollow tube or lance, at close spacings (usually less than 1 m), and injecting grout through the end as the lance is withdrawn. The lances are typically 25–38 mm in diameter. The tubes have a rivet blocking the drive end. A lance is driven in using a hand-held pneumatic drill and on reaching the desired depth it is withdrawn slightly so that the rivet can be knocked out by inserting a strand into the lance. Normally the depth is limited to 1–2 m but on occasions this has been increased to 3 or even 4 m in the right ground conditions. The grout injected is either a cement bentonite or silicate grout.

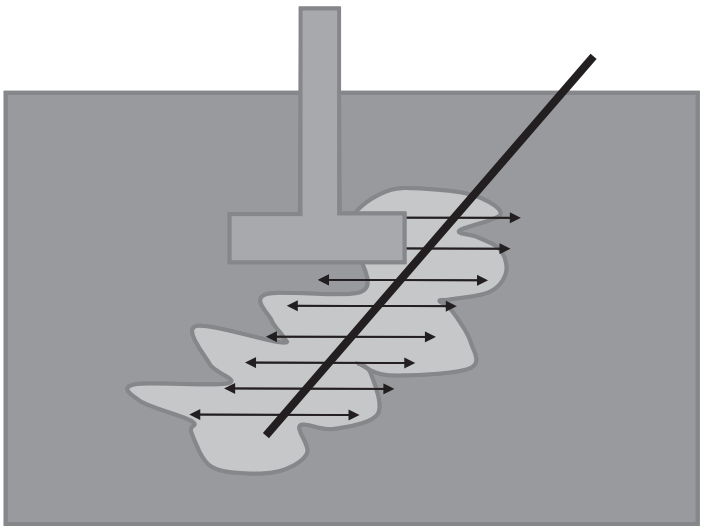

Figure 59.7 Example of hand lancing to improve the bearing capacity of a soil

Lancing is, therefore, restricted to the most open types of ground such as clean gravels and some forms of made ground. It can also be used to prove ground for voids where it is very cost effective.

Currently hand lancing is not favoured and should not be considered at the design stage, as prolonged use of the pneumatic tool leads to a condition called 'white finger' where feeling is lost in the fingers, which then leads to compensation claims. Health and safety issues mean that this work is very limited and the wearing of anti-vibration gloves is recommended. This makes the work more costly and its limited penetrability means that it is used less and less.

Because of the limited penetration, the hole spacing should be designed accordingly. Typically, the hole centres are 0.5 m to 0.75 m apart, except when carrying out under-slab proof grouting when the spacing can be increased to 1 m or 1.2 m. As a guide expect to inject only 10–15% of the ground by volume unless the ground is very open or voided when injected volumes could rise to 25%.

59.5.2.2 End-of-casing grouting

Typically, end-of-casing (EOC) grouting is used as a first-stage grouting in open or voided ground in advance of a second-stage tube A manchette (TAM) or compaction grouting scheme where use of the TAM or compaction grouting to fill voids and open ground would be slower and more costly. This type of grouting is used for probing and filling voids or open ground at depth. For example, it can be used for grouting around sheet piles when they have been jetted in and there is concern about toe restraint, canal lock and gate structures that are subjected to voided ground and as a precursor to more sophisticated grouting techniques.

End-of-casing grouting is a technique quite commonly used in open ground. As the name implies, the system comprises the

drilling in or driving of a 75–114 mm casing to depth, the withdrawal of the drill rods or removal of the drive point and the injection of grout. It can be used to quite considerable depth but is usually limited to 10 m. It is limited by breakout of grout around the casing. It is now commonly used at shallow depths due to the health and safety issues of hand lancing as described above.

It is limited to relatively open ground as the injection pressures are relatively low. Cement bentonite or silicate-based grouts are commonly used. It has the advantage over hand lancing in that the casing can be advanced through most ground conditions. All rig sizes can be used as the casing can be handled by the smallest of rigs. Generally EOC grouting can be used at wider spacings than hand lancing as the confining pressure is somewhat increased and some sealing of the casing can take place. Typical spacings would be 1.0 m to 1.5 m depending on soil type. Grout types are either cement-based (common) or silicate (rare). The grout mix can vary from cement/bentonite in open ground to cement/PFA in voided ground. The selection of mix is determined from the size of void and, therefore, the ease of injection.

59.5.2.3 Tube A manchette grouting

Tube A Manchette (TAM) grouting or sleeve port pipe grouting as it is known in the United States is one of the more sophisticated of permeation grouting techniques. It is probably the most commonly used technique, with jet grouting, for most ground treatment applications. In its conventional form it is used for permeation grouting but can also be used for compensation grouting where it is used effectively as a displacement grouting technique. Because the pipes are sealed into the ground the problems associated with EOC grouting are overcome and both the quality and range of application are increased. It can be used for groundwater control, underpinning, excavation retention, slope stability and bearing capacity enhancement.

It is widely used throughout the world and is a technique common to most countries and, hence, can be expected to be available from local specialists, although the technique is variable so control is important.

Figure 59.8 shows the principle of operation of a tube A manchette. The system comprises a 50–60 mm diameter steel or plastic pipe with openings at predetermined spacings, usually either 2 or 3 per metre length through which grout can be injected. The openings are covered with flexible sleeves, which open when pressurised by the grout and seal again when the pressure is removed. The injection or TAM pipe is installed in 90–150 mm diameter boreholes and sealed in with a cement/bentonite grout with typical Unconfined Compressive Strength (UCS) in the range 3–5 N/mm^2.

Each injection position can be isolated from the rest of the sleeves in a pipe by the use of a double packer. These are devices that are lowered to straddle the position of the sleeve and two flexible sleeves are inflated to isolate the injection. Grout is introduced down the centre of the packer and out through the sleeve. Sometimes, for small diameters, mechanical packers with leather washers can be used. In this way the injection

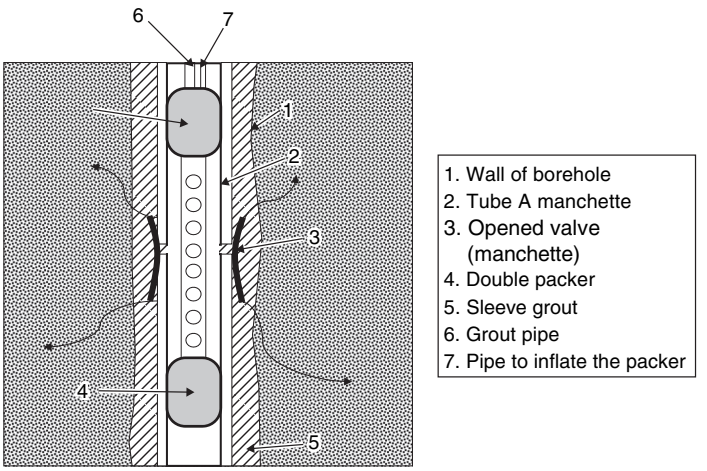

Figure 59.8 Operation of tube A manchette

volume, pressure and location of injection can be controlled to a high degree. For larger projects some of the major specialists use computer-controlled injection modules where a high degree of control and verification can be obtained. At the end of the day, the experience of the site supervisor and engineer will have a large influence on the quality of work carried out and the reliance on such modules should be limited to an ability to translate the designer's scheme into practice.

TAM grouting has been used for a number of years and **Figure 59.9** shows the layout from a project in the 1960s. **Figures 59.10** and **59.11** show typical layouts for tunnelling and dam construction.

With the sealing in of the injection pipes there is effectively no path for the grout except into the ground. In certain cases this will inevitably lead to either injection of grout into ground that it cannot permeate or reinjection into ground where there is no available pore space. Either of these situations will eventually lead to ground or structural heave and this should be taken into account in both design and specification. An assessment of services or structures at risk should be carried out and an appropriate monitoring regime implemented. Heave of 10–20 mm can occur when injecting silicate grouts into gravels without careful control and can be higher with cement-based grouts. It is possible to eliminate most heave by careful sequencing and volume control. This heave can be of use in compensation grouting, which is discussed below.

During design, careful attention should be paid to the location of any service or underground structure, as the grout can end up in services, especially old sewers where the lining is not competent. It is essential to identify such services prior to grouting and consider the effects of the grouting on the service. In particular for sensitive services (i.e. gas or chemical pipelines) additional monitoring and control will be required. For grouting adjacent to tunnels, due consideration to the effects of the injection pressure need to be considered especially for segmental construction.

The sequence of injection needs to be carefully designed to avoid the risk of trapped groundwater. If the sequence is

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

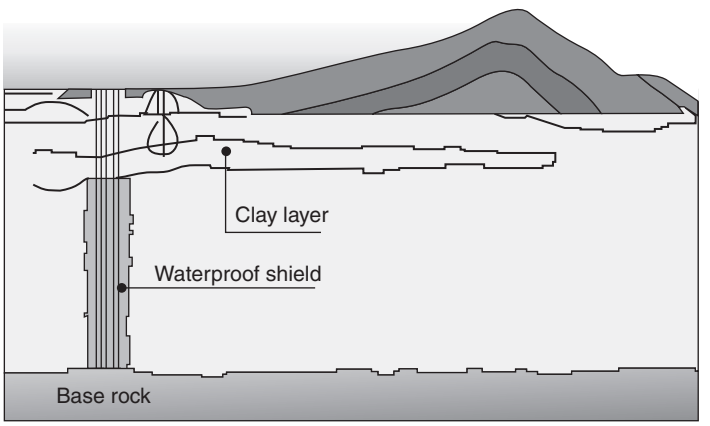

Figure 59.11 Example of use of permeation grouting to provide cut-off for a dam

such that as the grouting programme proceeds there is no flow path for the displaced groundwater, then it can emerge into structures or above ground or if unable to be displaced it can prevent ground treatment taking place as the grout cannot penetrate the ground. An escape path needs to be allowed when considering the injection sequence and the scheme monitored for excess water pressure.

The hole spacing is generally in the range 1.2 to 1.7 m, usually with a triangular grid. Wider spacing is rarely used as the ability to permeate such distances becomes more problematic. The effect of hole deviation is discussed below for jet grouting where it is considered in detail but is also applicable to permeation grouting.

The design must consider hole spacings, grout type and target grout injection volumes.

For most applications the holes are installed on a triangular grid and the target injection is derived from the following equation

$$Q = \frac{D^2 \sin 60° n}{N} 1000 \qquad (59.1)$$

where Q is the target injection volume per sleeve (litres), D is the hole grid spacing (m), n is the ground porosity and N is the number of sleeves per metre.

Typically for a 1.5 m grid in ground similar to Thames Gravel, the target injection volume will be about 150 litres.

Figure 59.12 shows the required injection volumes per metre for varying ground porosity and hole spacing.

The rate of injection is also important and injection rates of 8–12 litres per minute are typically used, leading to injection times of 10 to 20 minutes for each sleeve. Silicate grout should be injected at the lower end of these rates as penetration can be more difficult in finer ground.

Injection pressures are usually based on pressures measured at the top of the holes or at the injection module. Typical injection pressures are 0.25 bar to 0.5 bar per metre of overburden. Some of the more sophisticated modules can carry out line calibrations to determine the pressure loss through the system to the packer and correct for this on the pressure recording system. This is useful as most historical work was based on manual injection through a distributor arrangement (banjo) at or close to the borehole mouth. Hence, the line loss between the pump and borehole was effectively eliminated and the 0.25–0.5 bar injection pressures work on this basis. Overcorrecting could lead to excessive pressures in the ground, which could encourage hydro-fracture rather than permeation.

The use of silicate grouts will lead to lower ground strengths and lower deformation moduli than when cement-based grouts are utilised. Typically, the strength of treated ground will have a UCS of around 1–3 MPa.

An example of the use of permeation grouting was on the Channel Tunnel Rail Link (CTRL) where the new railway lines passed under the existing London–Southend railway lines. **Figure 59.13** shows the section at the crossing. The resulting cofferdam was predicted to cause too much movement to the adjacent viaduct and it was decided to install a grouted plug to reduce movements. Because of the presence of the alluvium, the plug did not have to provide waterproofing and, hence, it was decided that permeation grouting would be acceptable.

Figure 59.14 shows the TAM layout and also the distribution of grout injected. Both silicate- and cement-based grout were utilised and **Figure 59.15** shows the improvement in SPT test results following grouting. The cofferdam was excavated with movements of less than 10 mm.

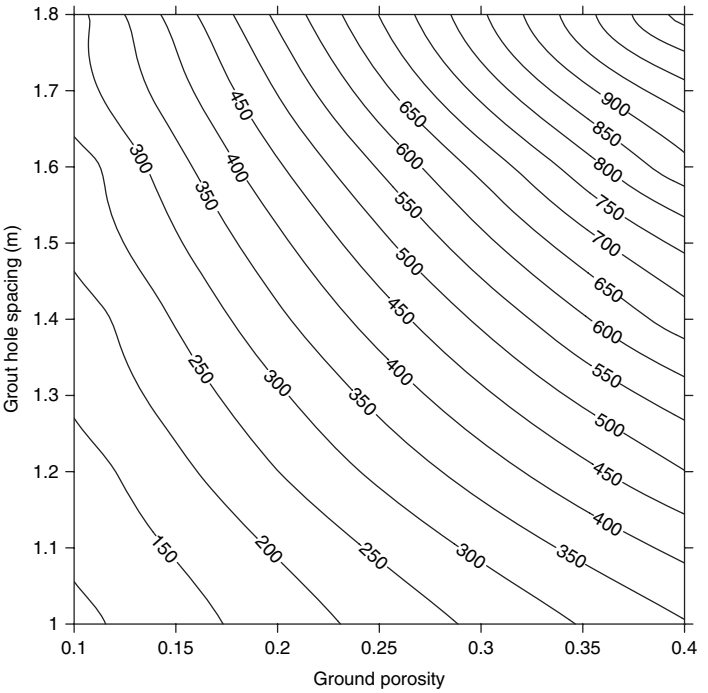

Figure 59.12 Required grout volumes per metre for differing ground porosities and hole spacing

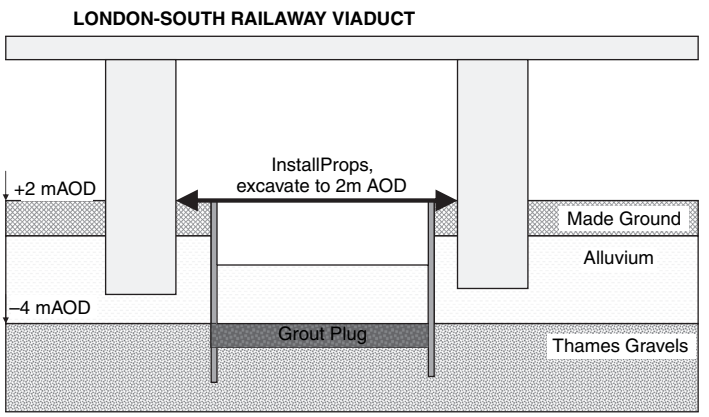

Figure 59.13 Section at CTRL railway crossing

59.5.3 Execution controls

Most execution control relates to initially ensuring that the injection holes are installed in the right locations and then monitoring the injection of grout. Secondary controls can be evaluating movements caused by the grouting.

For the simpler systems such as lancing or end of casing, execution control is limited and generally will be paper-based simple records of hole numbers and volumes of grout injected. Additional refinements can be to record volumes injected for each stage of injection.

TAM grouting tends to push the limits of capability of ground treatment and, hence, needs careful control to avoid mistakes on site. In particular, the large number of injections requires a high degree of site control to ensure each sleeve is injected into the correct hole. With the advent of site computers this is now more easily and efficiently accomplished and their use should now be regarded as a specified requirement for most projects.

59.5.4 Validation

Validation for hand lancing is not generally carried out except by the drilling and grouting of holes at intermediate positions. Where lancing is used for proof grouting under a slab or void filling, then additional intermediate holes are useful to assess the degree of coverage.

Validation for EOC grouting is generally restricted to either falling or rising head tests within the casing installed for testing

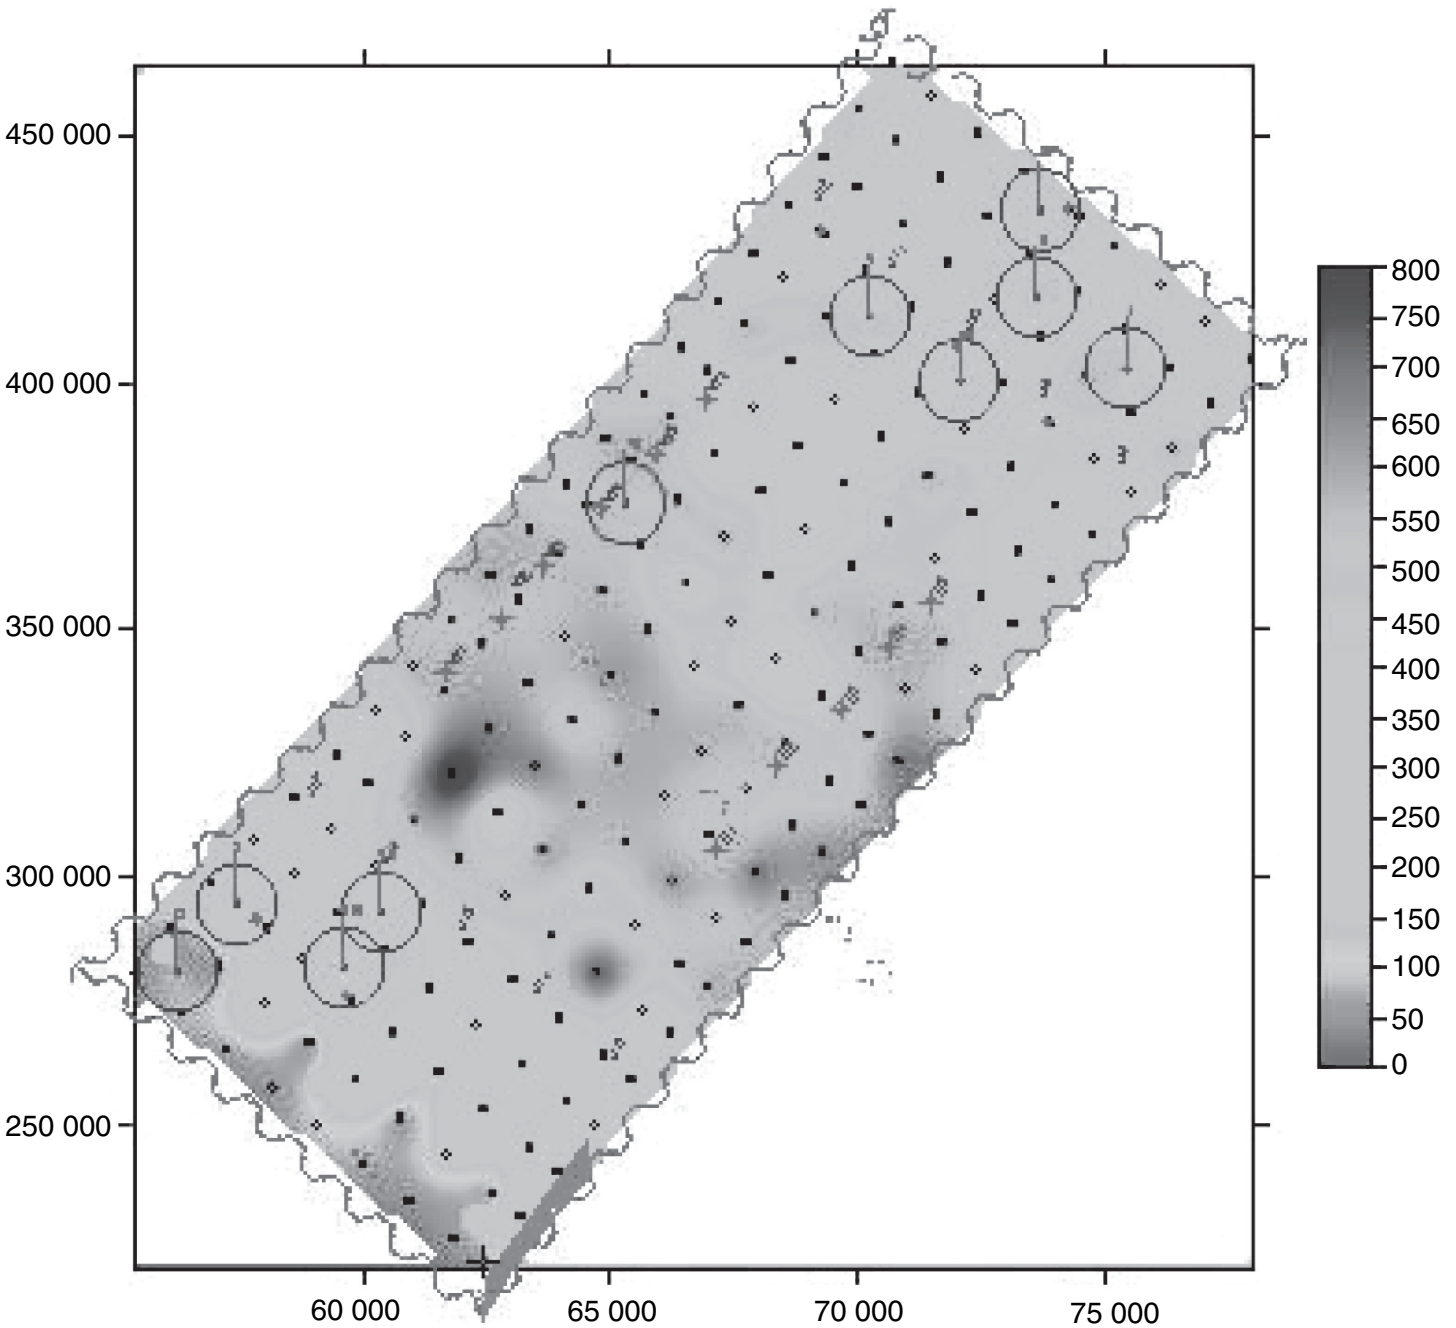

Figure 59.14 Example of validation of permeation grouting by reviewing injection data

purposes, or through piezometers installed following ground treatment. A further test could be the drilling and grouting of intermediate holes, the results being judged on the grout take. If strength or deformation is an issue then either coring or pressure meter testing could be carried out but test cell formation can be a problem and core recovery poor due to the fact that the material consists of relatively strong aggregate grouted with a relatively low-strength grout.

Validation for TAM grouting is essentially as described for EOC grouting above. Additionally it is possible to re-inject through sleeves to assess grout take and refusal pressure. When assessing the success of a TAM grouting project it is common practice to review the primary and secondary grout injection volumes. Normally one would expect to see a reduction in grout take from primary to secondary grouting coupled with some increase in refusal pressures. **Figure 59.14** shows

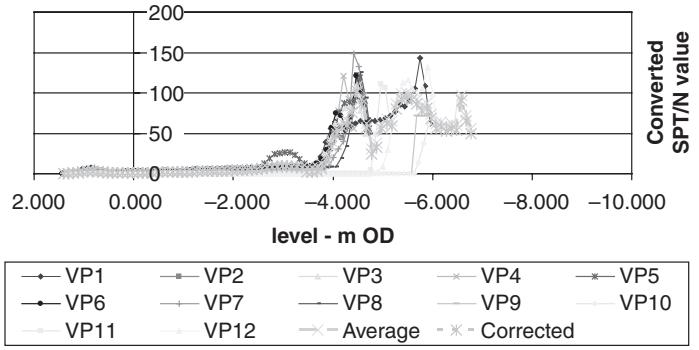

Figure 59.15 Comparison of pre- and post-testing

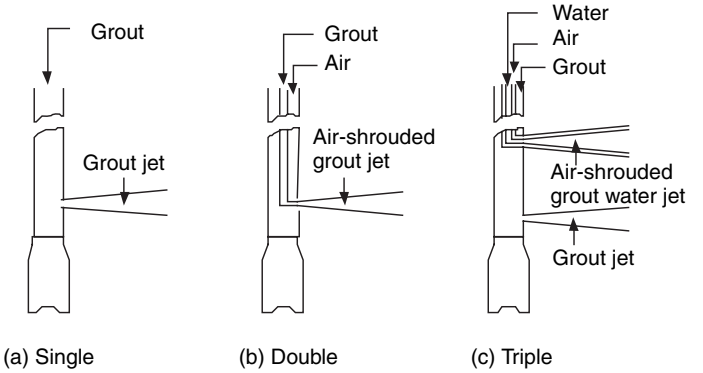

Figure 59.16 Jet-grouting systems
Reproduced from Essler and Yoshida (2005); Taylor & Francis Group

such a validation following completion of grouting in terms of grout volumes and **Figure 59.15** shows a validation in terms of *in situ* testing.

59.6 Design principles for jet grouting

59.6.1 Methods and key issues

Jet grouting differs from permeation grouting in that the intent with the latter is not to disturb the fabric of the ground whereas with the former this has to be the case for successful application. Because the product of jet grouting tends to be more structural in nature, it has a great range of application. When installed beneath buildings it can extend foundations through poor ground or support them while excavations, often unsupported, are carried out next to them. It can provide support underground where openings are necessary such as for tunnel boring machine (TBM) break-out or break-in, cross passages or equally to support tunnel faces. Because it does not rely on passage through the ground its product is usually more predictable and significantly less dependent on ground strength or composition. It can provide groundwater control at the base of excavations and can prop retaining walls at the same time. It is a multi-application tool for support and groundwater control, and simultaneously increases the efficiency of site usage.

There are three basic systems available:

(1) single system;

(2) double system;

(3) triple system.

The three systems are illustrated in **Figure 59.16**.

The single system is the injection of only grout at high pressure. This was the first system to be used. The column diameter is limited and the borehole has a tendency to become blocked, often resulting in ground heave. The design column diameters are small, usually up to 1.2 m in diameter. Some designers take the view that the single system provides the highest-strength columns and that air bubbles trapped in the columns from the other systems reduce strength.

The double system is effectively the single system with the addition of an air shroud to the nozzle. The addition of the air shroud increases jetting efficiency dramatically, typically giving a 30% increase in design diameter for the same jetting energy. These are very versatile and powerful systems with a design column diameter up to 4–5 m in most soils although such large diameters are only practical on large projects with no site constraints. Typical column diameters in normal use would range from 1 m to 3 m.

The triple system differs from the single and double systems in that erosion of the ground is carried out by a high-pressure water jet shrouded with air with an additional low-pressure grout line. The design column diameters achieved with this system are greater than those of the single system but as the energy is relatively low compared to the double systems, columns are usually only up to 1.7 m to 2 m (in exceptional ground) in diameter. In the US an advanced super triple system can deliver much higher energies and as a result design diameters of 3–4 m are possible.

The range of design applications for the systems are similar and selection is a site-specific requirement. The single system is most commonly used for horizontal applications, where air may cause problems. For most other applications the choice normally rests between the use of the double or triple system.

Generally the triple system will produce more spoil but is usually less viscous and, hence, offers less risk for blockage and probable structural or ground movement.

Jet grouting, historically, has been considered a risky ground treatment process due to the high pressures involved and the spoil generation. With good experience, site operatives, site control and design, jet grouting is not riskier than other processes.

The main risks associated with the process are the use of high pressures and the potential generation of movement. When jet grouting beneath buildings, care must be taken to ensure that heave of the walls or floors is maintained within agreed limits. It is absolutely critical that the construction details of the floors and walls are understood so that the effect of jet grouting can be considered. Where floor construction is poor and unsealed then it is advisable to maintain visual inspection and continual monitoring during jet grouting. Wall movement during jet

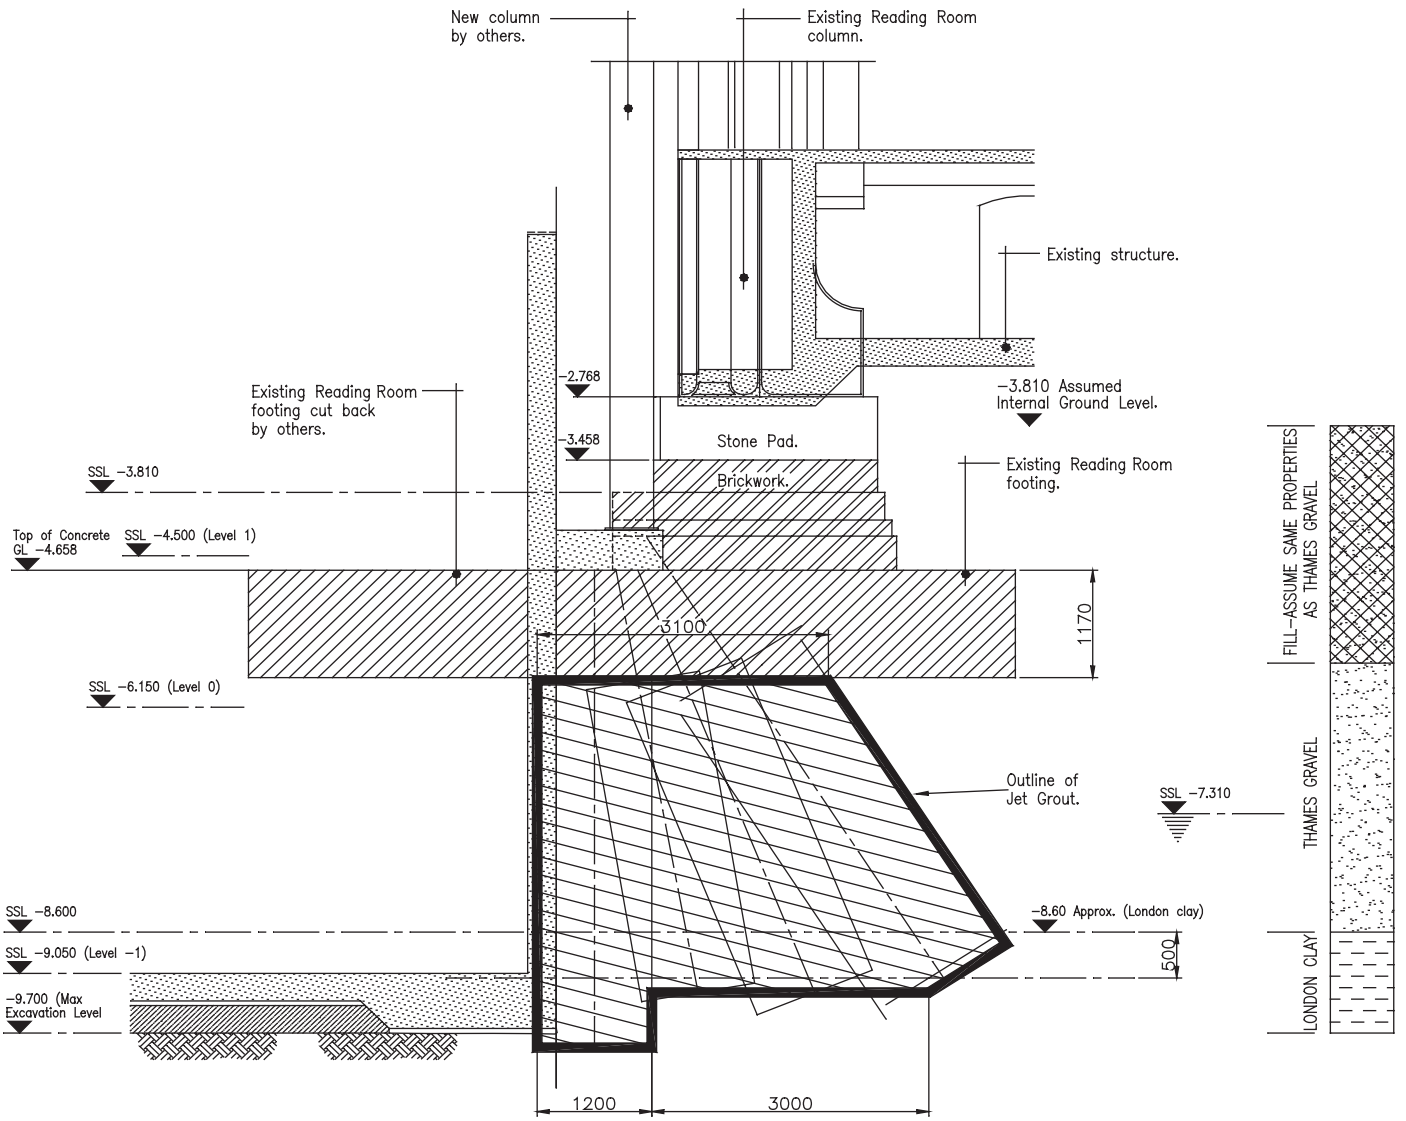

Figure 59.17 Cross-section of British Museum jet-grouted underpin
Reproduced with permission from CIRIA SP199, Scott and Essler (2003), www.ciria.org

grouting can be controlled in the long term by precise levelling and in the short term by the use of rotating laser targets fixed to the wall.

Design of the grouting sequence is extremely important for underpinning operations as there is the possibility of loss of support if too large an area is jetted. Where the structural foundation condition is poor, i.e. with poorly cemented masonry or brick, then a pre-grouting exercise using lancing or end of casing can be considered with the intent to reinforce the available bonding and reduce the risk of partial wall collapse into a freshly completed column. For underpinning work it is usual to restrict the jetting of adjacent columns to intervals of at least 24 or 48 hours. For isolated foundations, the jetting sequence must be designed to prevent loss of support and in extreme cases, temporary load transfer should be provided during the jet grouting operation. There is usually excellent bonding between the foundation and the jet-grout columns as subsequent adjacent columns always treat this zone and ensure perfect contact.

Grouting close to an underground structure needs careful consideration and any grouting carried out within 3–5 m of any underground structure will require a specific risk assessment. Wherever possible, consultation with the original designer is advisable to agree the specifics of the ground treatment.

The most common application for jet grouting is either underpinning or to restrict movement within excavations. **Figure 59.17** shows the use of jet grouting to underpin the Reading Room of the British Museum (Scott and Essler, 2001, 2002). This is a Grade 1 listed building and the jet grouting provides permanent support. **Figure 59.18** shows the effect of

the installation of a deep jet-grout strut within an excavation in significantly reducing movements (Driesse *et al*., 2006). Such jet-grouted struts are widely employed worldwide but have had little use to date in the UK.

59.6.2 Design principles

Because of the ability of jet grouting to bond ground and create relatively strong bodies (UCS range 2–10 MPa), the design process is similar to the design of brick or masonry.

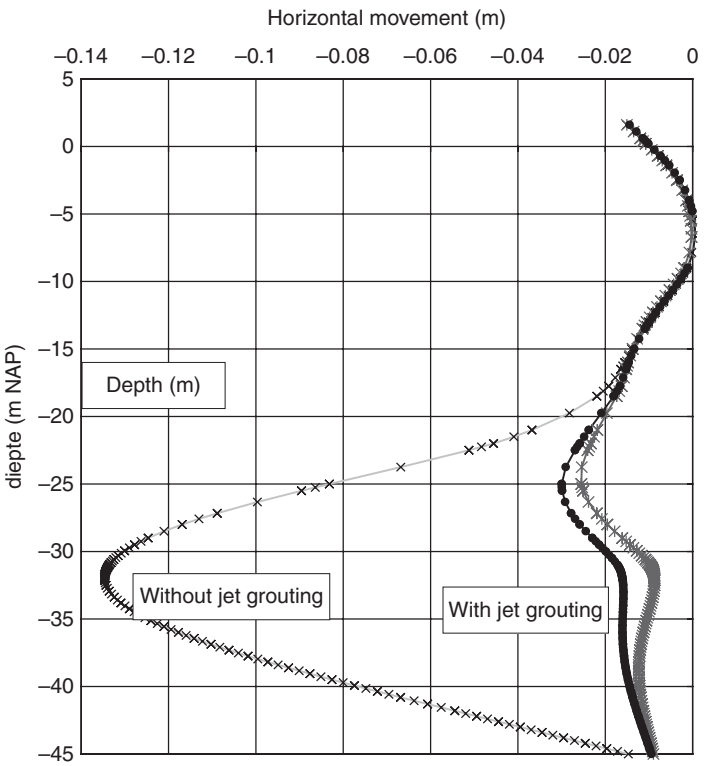

Figure 59.18 Effect of installation of jet-grouted strut at 33 m

The strength of treated ground is usually assessed on the basis of unconfined compressive strength tests on samples obtained by coring. The histograms shown in **Figure 59.19** demonstrate experimental unconfined compressive strengths in sandy and cohesive soils. The Japan Jet Grouting Association has adopted these distribution charts, defining that the unconfined compressive strength used in design as a minimum safe value should be adopted as within the 1% to 3% range of these charts.

This definition gives the standard unconfined compressive strengths set out in **Table 59.4** (where the water/cement ratio of the grout is typically 1).

It has to be stated that the adoption of these design values in certain conditions could lead to conservative designs in granular soils. Typical values of UCS adopted for design in the UK would be in the range 5–10 MN/m^2 for granular materials. Strength is usually only an issue for (deep excavations or tunnelling projects) base slabs and shaft break-out or break-in. In these cases, strength can influence the design as the jet grouting is required to span across openings and, hence, has to be designed with a minimum structural integrity.

Jet-grout column layout is designed based upon the hole deviation (i.e. the vertical tolerance) and the column diameter.

For most operations, when drilling holes, the hole tolerance is unlikely to be better than 1 in 100 and is typically specified at 1 in 75. For shallow holes this does not create an issue but as depth increases then it becomes a more important influence on the design of the jet-grout layout.

When creating a jet-grout base slab, the design is normally based on a triangular grid.

Figure 59.20 shows the effect when a single column deviates from the design position. The solution is to decrease the column spacing. This can have a significant influence on cost as the column diameter and spacing effect the number of columns.

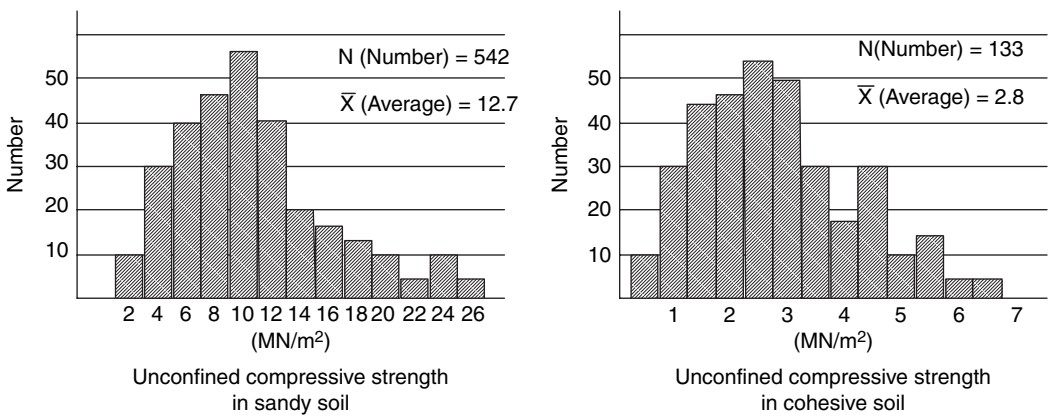

Figure 59.19 Typical strength distribution for jet-grouted soils for sandy and cohesive soils
Reproduced from Shibazaki (2003)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

Consider the design for a base slab 20 m by 20 m, at a depth of 10 m below ground level (Case A) and 20 m below ground level (Case B).

59.6.2.1 Case A

If we assume that the current jet-grout system will produce column diameters of 1.5 m and that the expected hole tolerance is 1 in 75 then:

Jet-grout design spacing assuming no deviation	1.2 m	
Expected hole deviation	0.133 m	
Hole spacing to take account of deviation	1.0667	
Column spacing in ***x*** direction	1.0667 m	
Row spacing in ***y*** direction (60° grid)	1.0667 sin 60°	= 0.924 m
No. of columns in row	20/1.0667	= 19
No. of rows	20/0.924	= 22
No. of columns for 10-m-deep base slab	22 × 19	= 418

Soil type	Q_u: Unconfined compressive strength (MN/m²)	*C*: Cohesive strength (MN/m²)	*f*: Bond strength (MN/m²)	σ_t: Bending tensile strength (MN/m²)
Cohesive	1	0.3	0.1	0.2
Granular	3	0.5	0.17	0.33

Table 59.4 Typical design values for jet-grouted materials

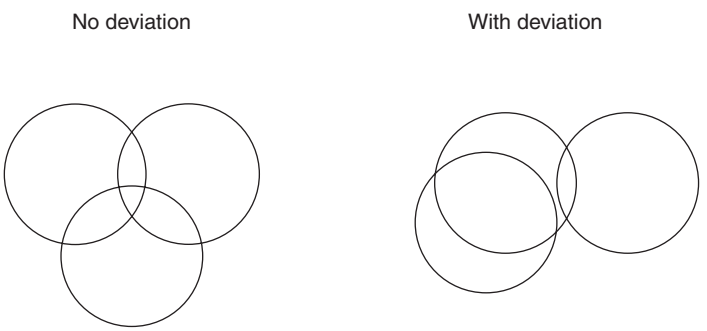

Figure 59.20 Effect of drill-hole deviation on column overlap

59.6.2.2 Case B

By the same calculation but with a depth of 20 m and, thus, allowing for more deviation, the number of columns increases to 550, an increase in the number of columns of 32%.

Therefore, it is important to understand that depth plays a significant role in determining cost and potentially the jet-grout system. It is good practice to measure the hole deviation when depth becomes an issue (usually at depths greater than 15 m) and some specialists can offer hole deviation measurement using the jet-grouting equipment, thus, reducing delays to a minimum

If on the other hand we consider the same scenario except this time we use a more powerful system capable of 3-m-diameter columns, the number of columns changes as shown in **Table 59.5**.

Clearly we see a difference in that with 1.5-m-diameter columns, the number of columns increases by 132 from case A to B, but for 3-m-diameter columns this increase is only 18 columns.

The above highlights the current drive to increase column diameter as this not only reduces cost but provides more security at depth as the column interlock is not as critical.

The other factor that influences cost and, hence, design is the actual column volume cut versus the volume required.

If we consider the above cases, the volume of column cut per metre is respectively 1.767 m³ and 7.069 m³ for 1.5 m and 3-m-diameter columns. **Table 59.6** illustrates the comparison.

The volume jetted will affect both cost and spoil production as they vary linearly in proportion to the meterage jetted.

Good examples of the correct design of jet grouting are the base struts incorporated into the design of the station boxes (Driesse *et al*., 2008 a,b) and the sandwich wall at central station (De Wit *et al*., 2006, 2007) on the North–South project in Amsterdam (Driesse *et al*., 2008a, b). **Figure 59.18** shows that

Case	Depth (m)	Column diameter (m)	Nominal design spacing (m)	Number of columns	Percentage increase with depth
A	10	1.5	1.2	418	
B	20	1.5	1.2	550	32
A	10	3.0	2.7	72

Table 59.6 Effect of column diameter and depth on column volume required

without these struts, the wall deflection would have been excessive with resultant damage to the adjacent historical buildings. The initial design of the jet grouting is shown in **Figure 59.21** and essentially mimicked conventional strutting; however, as the strut was some 33 m below ground level, it ignored the difficulties of achieving positional accuracy without which the strut would not transmit the required loads. The resultant redesign assumed a uniform distribution of the columns within the station box with a nominal overlap. Extensive finite element analysis of over 1000 layouts of columns randomly positioned based on assumed diameter and positional accuracy demonstrated that the strut would behave as designed. **Figure 59.22** shows the revised layout. Designing jet grouting based on a statistical investigation of the column diameter and position is important and is recommended for any design where the depth and soil conditions could have significant effects. It is especially relevant for designs where the jet grouting is required for waterproofing, as column variations and, hence, gaps between columns actually control the water flow.

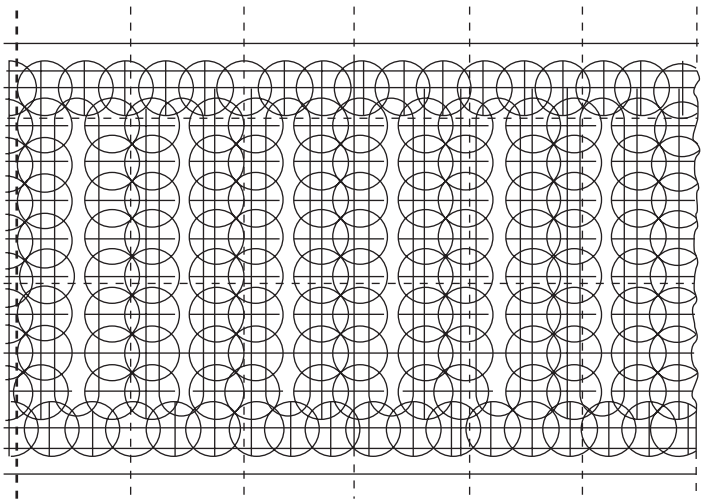

Figure 59.21 Initial column design layout for the North–South Line, Amsterdam

59.6.3 Execution controls

Execution controls comprise the quality assurance of the grout materials and the grouting process. Generally, most jet-grouting rigs are fitted with sophisticated instrumentation that records all the required process parameters. This gives the designer confidence that the columns have been constructed reliably. There are some systems that include a built-in borehole deviation system that can be used to actually monitor the as-built locations of individual columns. As the rigs are instrumented, the drilling energy can be easily plotted against depth and this can give the designer valuable insights into ground variability and it can drive process adjustment.

59.6.4 Validation

Validation is generally as for TAM grouting. The validation process consists of quality control of the grout materials and the column jetting parameters followed by post jet-grouting testing. Because jet grouting generally is structurally sounder, coring can be more successful if care is taken. In addition the process lends itself to trial exposure whereby a number of initial columns are jetted on site and then exposed after 24–48 hours to determine size and uniformity. With jet grouting, the column diameter tends to be the most important parameter for validation as this is fundamental to the construction of gravity or underpinning blocks. In granular ground, strength is not usually an issue.

Laboratory testing of cores can be carried out and the designer needs to be careful in relating potentially solid core results to the mass properties. **Figure 59.23** illustrates results of destructive

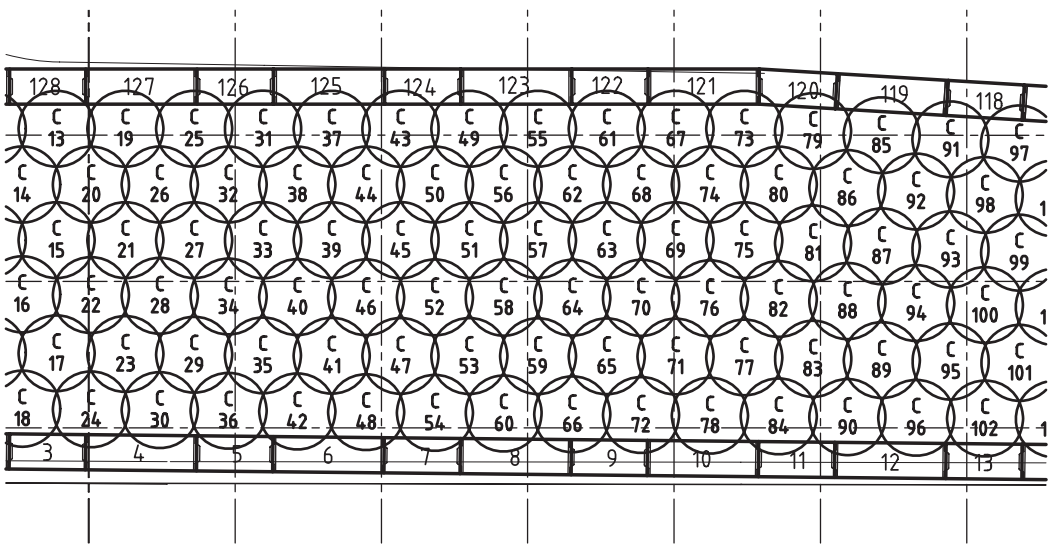

Figure 59.22 Revised column layout for the North–South Line, Amsterdam

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

drilling, which is relatively quick and economical. It is a powerful validation tool during design and it can be calibrated against coring and subsequent laboratory testing. Destructive drilling must be instrumented and the drilling energy then plotted against depth. There is a correlation with the core strength, which can be used to identify zones of low strength. This methodology should be considered on all major projects where repetitive testing of large numbers of columns is required.

59.7 Design principles for vibrocompaction and vibroreplacement

59.7.1 Methods and key issues

Kirsch (1993) describes the techniques in detail but typically vibrocompaction is carried out by inserting a vibrating closed-end steel tube of diameter 300 mm to 500 mm, commonly known as a poker, into the ground, thus, causing the surrounding ground to be densified by the ground vibrations. The design of individual pokers is commercially sensitive but in principle they operate by hydraulically rotating an eccentric weight horizontally within the poker. In this way the vibrations have a significant horizontal amplitude and cause ground densification.

The vibrations cause the soil grains to be rearranged into a more dense packing and, thus, improve the soil density. Water jetting can be used in association with the poker to assist penetration of the poker and flush out soft finer material. It also has the effect of locally reducing the effective stresses and aiding ground restructuring.

Generally the poker is lowered to depth and then raised in stages as the ground is compacted. The applied energy can be monitored during compaction as higher energy is needed when the surrounding ground becomes densified. The poker can be systematically raised and lowered in stages with the lowering phase used to judge the compaction of the underlying ground.

Care needs to be taken with this process to ensure that the ground can be densified solely by compaction. Problems occur if the content of silt and clay is too high. If bands or layers of silt or clay are present these are unlikely to be improved leading to unexpected settlement. The layout of penetration points is usually triangular with the spacing generally following from the soil type and available poker power. Generally, the more powerful the poker, the wider the spacing. Very powerful pokers have been developed over the years to deal with large areas

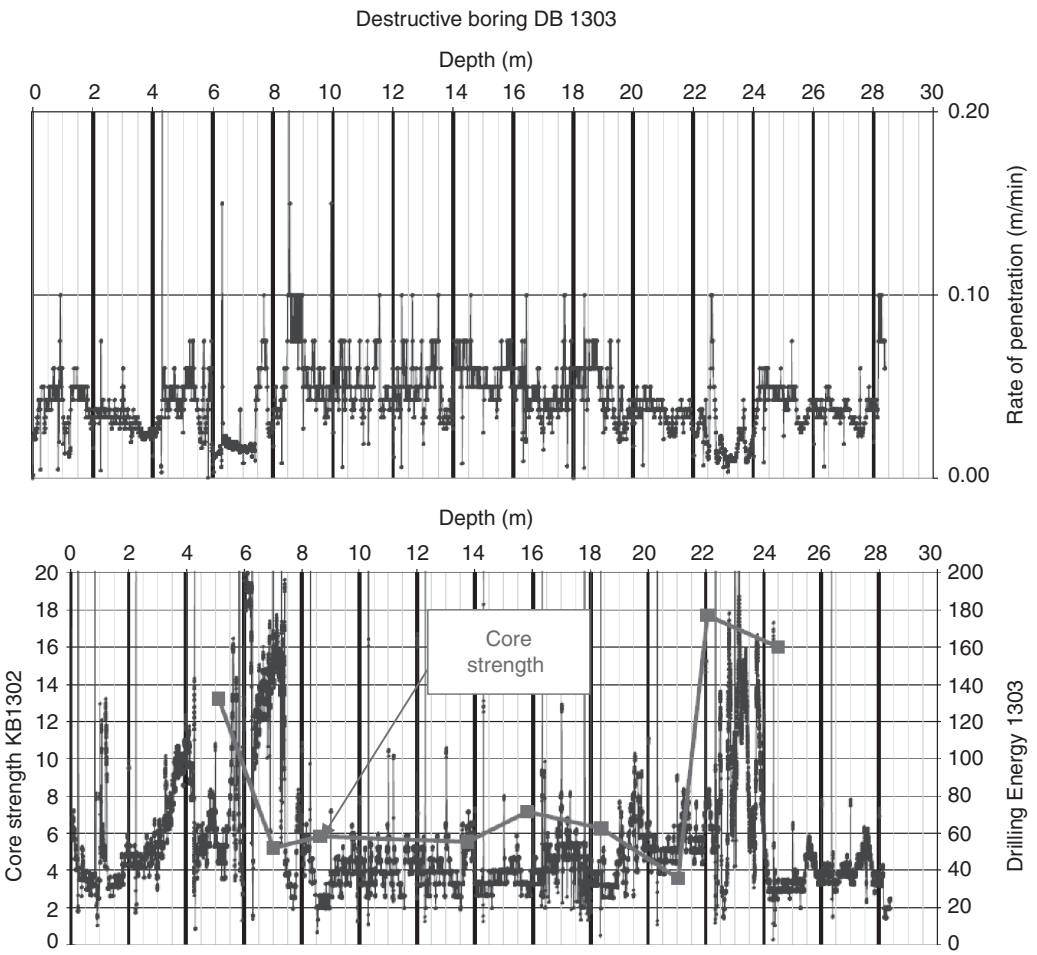

Figure 59.23 Use of destructive drilling to check jet-grout columns

of marine sands and reclaimed materials where wide spacings can be economically employed.

Vibroreplacement or stone columns is a similar process to vibrocompaction but it relies on creating columns of compacted stone, which will transmit load or resist shear. On reaching depth, stone is introduced either at the top of the hole or at the bottom via a special tube built into the poker. These methods are known as top feed and bottom feed, respectively. The stone is compacted as the poker is withdrawn and thereby improves the ground. Bottom feed is used where there are weak soils with a high water table and, thus, the column may be unstable.

59.7.2 Vibrocompaction and vibroreplacement design principles

Vibrocompaction is commonly utilised to provide reduced total or differential foundation settlements or to provide seismic improvement to weak soils. **Figure 59.24** indicates the range of soils suitable for treatment.

Design methods are generally based on the principle of overall ground density improvement (vibrocompaction) or an overall improvement based on the percentage area of improved ground.

Typical expected settlements are as set out in **Table 59.7**.

Priebe in 1995 produced an excellent paper on vibroreplacement and **Figure 59.25** gives an indication of the improvements possible.

The area ratio is defined as the area of a column (A_c) as a percentage of the area supported by the column (A). The improvement factor is effectively the increase in stiffness or shear capacity over the original soil. Thus, if around 20% of the area were replaced with stone columns, this would provide around 200% to 250% improvement in settlement reduction.

The use of area ratio gives a guide to the column spacing, assuming that column diameters range from 0.5 m to 0.75 m.

An initial simple design concept is to consider vibro-stone columns as relatively strong springs (although of lesser rigidity than piles) surrounded by the weaker springs of the soils requiring treatment. The applied load is then shared between a composite structure of stone column and soil on an areal basis. This can be expressed as:

$$Aq = Q_c + (A - A_c)\sigma_s \tag{59.2}$$

where A is the area supported per stone column, q is the applied pressure, Q_c is the safe capacity of the stone column, A_c is the cross-sectional area of the stone column and σ_s is the safe capacity of the surrounding soil.

In this formula the safe capacity of the soil is sometimes taken as zero for better post-treatment settlement performance.

Soil type	Bearing pressure (kPa)	Settlement (mm)
Made ground: mixed cohesive and granular	100–165	5–25
Made ground: granular fill, ash, brick rubble, etc.	100–215	5–20
Natural sands or sands and gravels	165–500	5–25
Soft alluvial clays	50–100	15–75

Table 59.7 Bearing pressures and settlements for vibro-improved ground

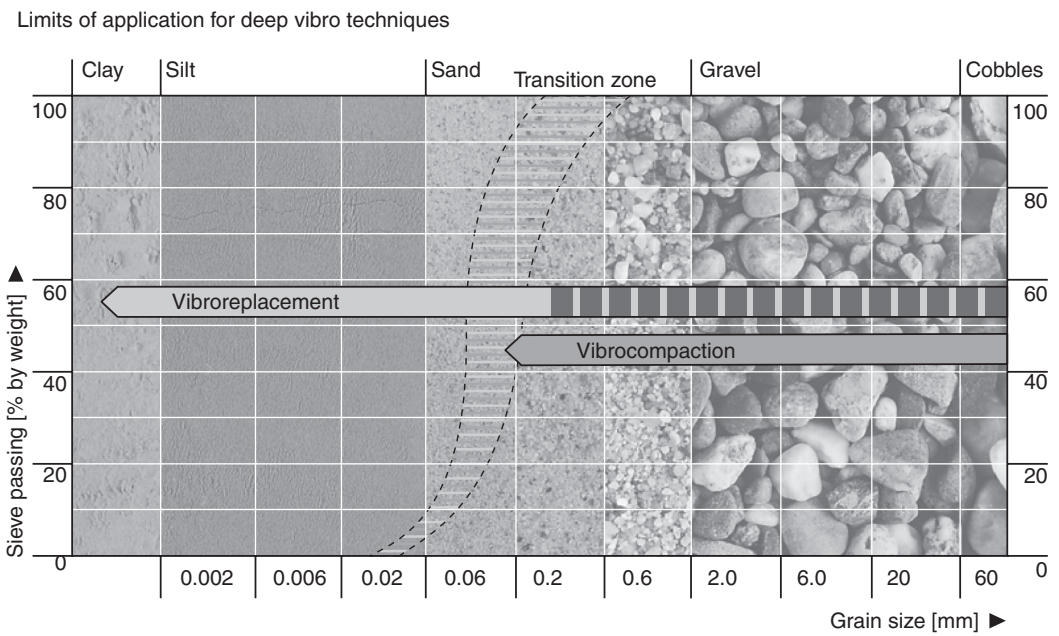

Figure 59.24 Range of application of vibroreplacement and vibrocompaction
Reproduced from Keller brochure 10-02 E: Deep Vibro Techniques; Keller Group plc

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

There are three main design procedures used in the UK:

(1) Hughes and Withers (1974);

(2) Baumann and Bauer (1974);

(3) Priebe (1995).

The most commonly used method for an initial calculation of the safe capacity of a stone column is that of Hughes and Withers:

$$\sigma_v' = (1+\sin\varphi_c)(\gamma_b h_c + 4c_u + P)(1-\sin\varphi_c) \qquad (59.3)$$

where σ_v' is the ultimate vertical effective stress in the soil (kN/m^2), ϕ_c is the friction angle for the stone column material (typically 45°), γ_b is the bulk density of the soil (kN/m^3), h_c is the critical depth (m), c_u is the undrained shear strength of the soil (kN/m^2) and P is the surcharge (kN/m^2).

The critical depth h_c is often taken as the depth from ground level to the base of the foundation plus one stone column diameter.

The safe capacity of the stone column is then given by:

$$Q_c = \sigma_v' A_c F \qquad (59.4)$$

where Q_c is the safe capacity of the stone column (kN), A_c is the area of the stone column (m^2) and F is the factor of safety.

Figure 59.26 shows how the capacity of a stone columns varies with depth and soil type.

When loads are applied rapidly, e.g. when building road embankments on soft ground, silos, coal stockpiles, etc., an allowance should be made for the development of excess pore water pressures in the soils surrounding the stone columns. This is often taken as $-u$ within the bracket of the first formula or as an ru percentage. Thus in the first equation, ρ is replaced by $\rho - u$ or $\gamma_b h_c$ replaced by $ru\gamma_b h_c$.

The majority of stone-column bearing capacity and reduced settlement designs now use the Priebe (1995) method where the area ratio of **Figure 59.25** can be used to assess the initial settlement reduction factor that is applied to the untreated settlement within the treatment depth. There will then be further potential settlements due to the imposed loads beneath the treatment depths, as well as ongoing self-weight settlements within fills and made ground, secondary consolidation, etc.

However, the Priebe method then considers the beneficial effects of column rigidity, depth of overburden and group effects to further refine the post-treatment settlement predictions. As a result many geotechnical consultants and specialists provide computer-generated calculations using this method.

Clearly, the treatment depth is a fundamental factor in the design, which will also dictate the vibro-equipment that is to be used to construct the stone columns (see Chapter 74 *Design of soil nails*).

One of the largest vibroreplacement contracts was carried out in Barrow-in-Furness in 1991 for a proposed on shore gas terminal (Raison, 1999). Before development, the majority of

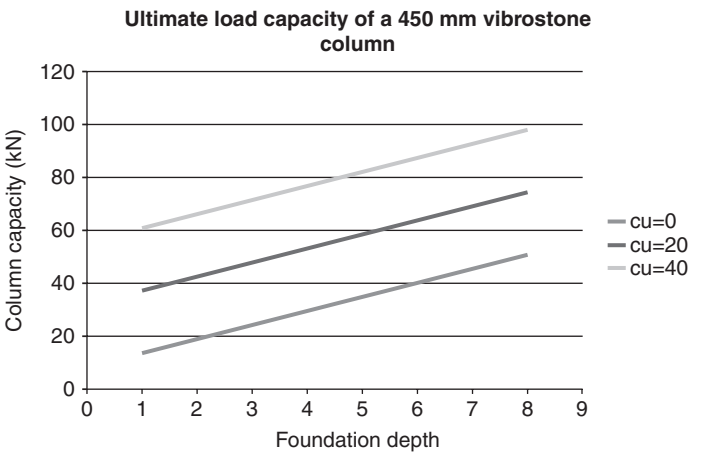

Figure 59.26 Stone column capacity for various depths and soil types

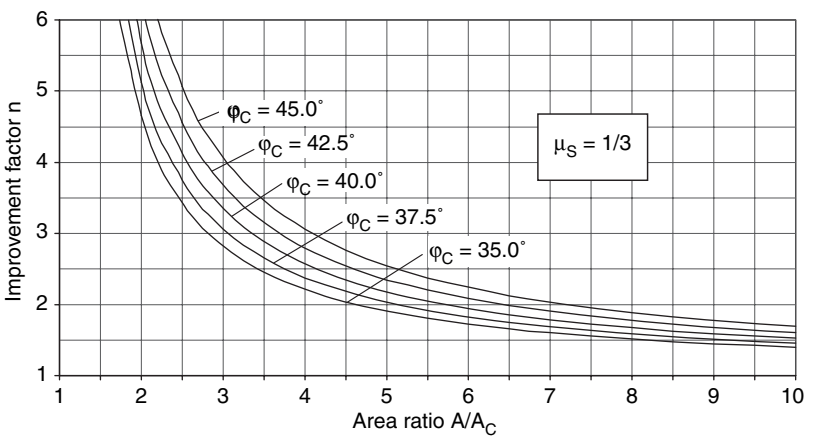

Figure 59.25 Design of stone columns
Reproduced from Priebe (1995)

the site comprised three former settlement lagoons containing saturated pulverised fuel ash (PFA), a waste product from the adjacent coal-fired Roosecote power station. Site investigations revealed ground conditions beneath the PFA as comprising very loose silty gravelly alluvial sand over more dense glacial sands, with glacial till and sandstone at depth. Ground conditions were locally variable and simplifications were necessary for design purposes. A typical geological section and variation of SPT with depth is shown in **Figure 59.27**. Particle size grading of the PFA indicated a sandy silt, which was often clayey. It was concluded during the project design stage that protection from seismic episodes, although small in the UK, was required and a combination of driven piles and vibroreplacement was selected by the contractor, Keller. While the vibroreplacement was not deemed suitable for improvement of the very soft clayey PFA, which was deemed too fine being a sandy silt, it could improve the underlying soils and, thus, provide an acceptable foundation for the driven piles, which would be considerably shorter as a result. **Figure 59.28** shows the selected combination of driven piles and vibroreplacement columns. Driven piles were generally installed at 2 m centres and the vibro stone columns were installed at centres ranging from 2.75 m to 3 m.

59.7.3 Execution controls

Execution control is limited to setting out and depth, measurement of stone consumption or the compaction energy (usually measured as hydraulic or electric power consumed). The above parameters can usually be measured by the rig instrumentation and provides an execution record for each column.

59.7.4 Validation

Validation is typically in the form of SPT or CPT testing prior to and post-testing in association with plate load tests of individual columns or zone testing on a group of columns (Greenwood, 1991). **Figure 59.29** shows the validation for the Barrow project in terms of CPT testing.

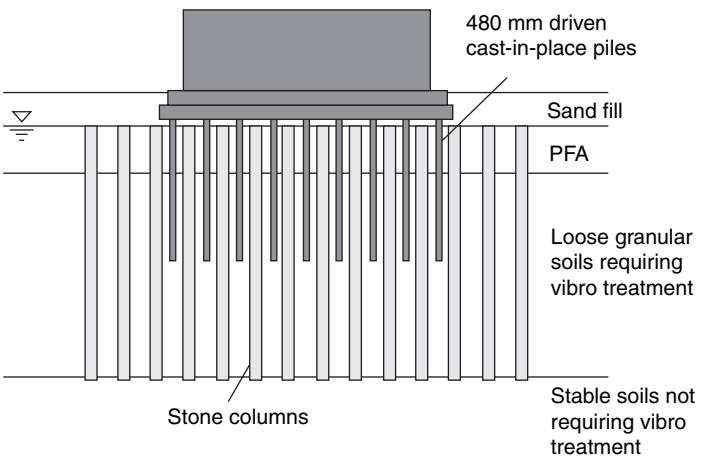

Figure 59.28 Proposed foundation improvement for Barrow
Reproduced from Raison *et al.* (1995)

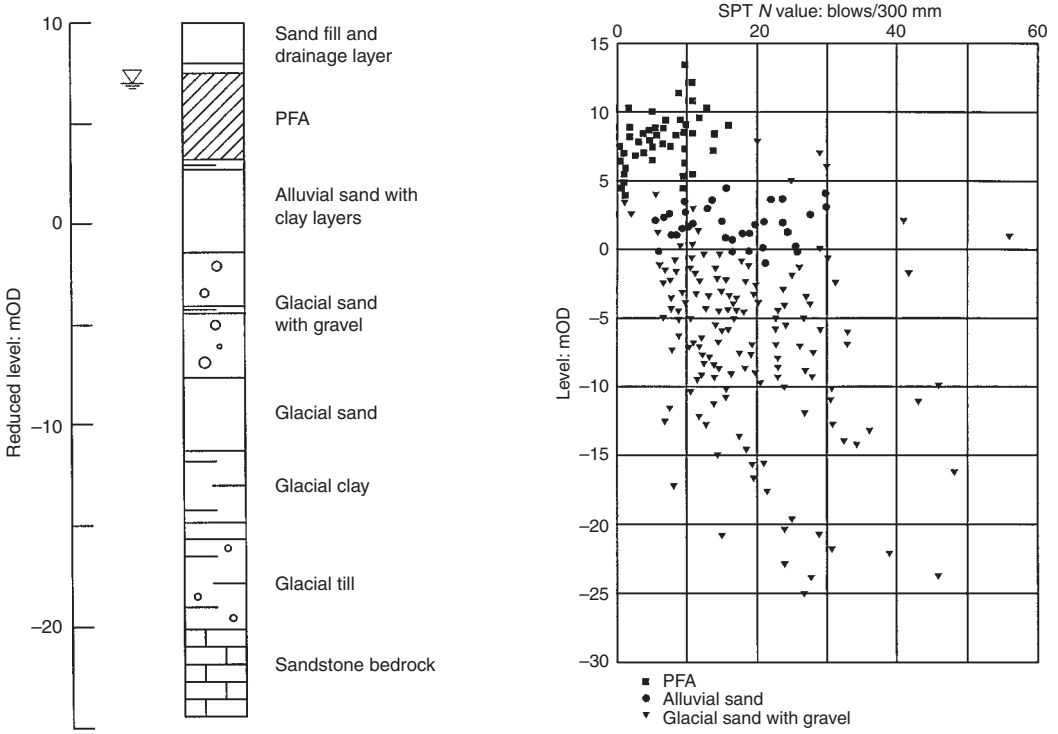

Figure 59.27 Ground conditions at Barrow
Reproduced from Raison (1999)

59.8 Design principles for dynamic compaction

Dynamic compaction is similar to vibrocompaction in that the intent is to compact the ground and, thus, increase stiffness. It is more effective in granular materials although it has been historically successful in finer materials.

Dynamic compaction involves the repetitive dropping of heavy weights at fixed grid points to compress the ground. Historically, Menard owned a patent for this work and carried out pioneering works in Europe and the Far East. The weight of their dynamic tampers were as heavy as 40 tonnes and supported on very high specially constructed tripods.

The design of dynamic compaction is based on the input of a minimum dynamic energy per volume of ground and is carried out in a series of phases or passes.

The maximum depth of treatment depends both on the weight of tamper and height of drop and is typically given by the following relationship

$$\text{Depth of treatment} = 0.5 \times (\text{height of drop} \times \text{weight})^{0.5}.$$

Thus, considering the use of a 20-tonne weight dropping 20 m, the depth of treatment would be limited to around 10 m. Fines content has a significant effect on compactive effort and care also needs to be taken if there are bands or layers of clay or silt, which will not be improved.

Typically, depending on the depth of treatment the compaction is carried out in three phases to ensure that the full depth of the soil is treated:

Pass 1

This will be based on widely spaced points and is designed to compact the deepest soils first. Spacing might be 7–10 m for a 10–12 m depth of treatment.

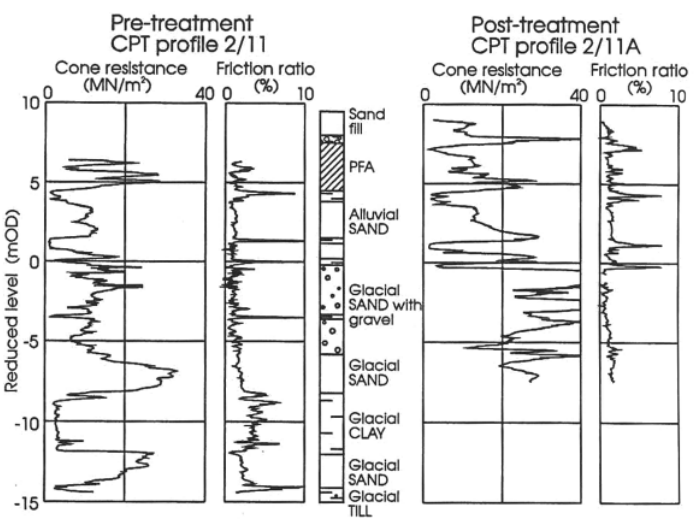

Figure 59.29 Results of pre- and post-CPT testing at Barrow
Reproduced from Raison *et al.* (1995)

Pass 2

This might be carried out on a 4–5 m spacing and is designed to compact the intermediate depths of ground below around 2 m.

Pass 3

This is a final pass on a close grid, which is almost the plan area of the tamper, and is designed to compact from 1 m to 3 m depth. Sometimes the tamper configuration will be changed to provide a larger area.

Often a final surface compaction is necessary to complete the densification.

As an approximate guide the application of around 25–30 tonne·m energy per cubic metre would provide a significant compaction of up to 60–70% relative density for 'clean' cohesionless soils (say less than 15% clay or silt content). **Table 59.8** is a guideline for the energies that might be required.

59.8.1 Methods and key issues

Key issues associated with dynamic compaction are the high vibration levels associated with the process, which can be detrimental to nearby structures. This means that dynamic compaction must occur at least 20–30 m from buildings (or perhaps 50 m from relatively sensitive buildings), although this would need to be established on a project-specific basis. Results of ground-borne vibrations are shown in **Figure 59.30**.

59.8.2 Execution control

Execution control is limited to ensuring that the correct energy is applied. This requires control of the height and the number of drops for each grid point. The craters formed by the process are usually dozed level and a further guide to the improvement made can be seen by surveying the reduction in ground level.

59.8.3 Validation

Validation is similar to vibrocompaction and replacement and typically consists of cone penetration or other *in situ* testing. Zone testing can also be carried out, although the limited depth of influence of the zone tests needs to be recognised compared with the proposed foundations.

Type of deposit	D_{50} (mm)	PI	Permeability range (m/s)	Total energy (tonne·m/m³)
Pervious coarse-grained, e.g. sand	> 0.1	0	$> 1 \times 10^{-4}$	< 20
Semi-pervious, e.g. silt	0.01 to 0.1	< 8	1×10^{-4} to 10^{-8}	< 30
Impervious above the water table, e.g. silt or clay	< 0.01	> 8	$< 1 \times 10^{-8}$	< 30
Landfill				< 50

Ciria Report C573 – A Guide to Ground Treatment

59.9 Design principle for deep soil mixing

Deep soil mixing (DSM) was first established by Intrusion-Prepakt in the mid-1950s and then further developed in Japan in the 1960s. The level of research and development activity in Japan in relation to DSM remains the highest in the world and annual DSM construction in Japan alone exceeds 1 million cubic metres of ground treated, with an accumulated total in excess of 25 million cubic metres.

The two generic forms of deep soil mixing are dry-soil mixing and wet-soil mixing. Dry-soil mixing consists of injecting a powder binder while mechanically disaggregating the soils. Wet-soil mixing consists of injecting a fluid binder while mechanically disaggregating the soils.

Dry-soil mixing is principally used in very soft to soft clays, silts and peats because the equipment was historically used for these soils, whereas wet-soil mixing can be used in more granular and stiffer soils.

Dry-soil mixing tends to remould the material while injecting the binder, while wet-soil mixing is designed more to try and mix in the binder to create a homogeneous material.

59.9.1 Design methods and key issues

The design of soil mixing is based on the required composite shear strength of the improved soils to achieve an appropriate factor of safety using limit equilibrium analysis.

For vertical support, columns can be utilised in interlocking patterns or as isolated columns. Where applied to resist shear, isolated columns are not recommended as their bending resistance is low and, thus, are typically utilised as panels of soil-mixed columns (typically 600 mm diameter at 500 mm centres perpendicular to the shear direction). Some configurations are shown in **Figure 59.31**.

The composite shear strength is based on the following equation:

$$C_{u\ (\text{composite})} = a\ .\ C_{u\ (\text{column})} + (1–a)\ C_{u\ (\text{soil})} \qquad (59.5)$$

where a is the area replacement ratio of the treated ground. Hence, if the strength of the soil-mixed columns $C_{u\ (\text{column})} = 150$ kPa, the strength of the untreated material $C_{u\ (\text{soil})} = 20$ kPa and a composite shear strength of around 50–60 kPa was needed then an area replacement ratio of about 25–30% would be required. This would correspond to panels with 600mm-diameter columns (at 500 mm centres) spaced about 1.6 m to 2 m apart.

The detailed design should establish the area replacement ratio and soil-mixed column strengths required.

For drained, analysis typical parameters are:

$$c'_{(\text{column})} = bC_{u(\text{column})} \text{ and } \phi'_{(\text{column})} = 30°\ . \qquad (59.6)$$

Typically b is around 0.3; this value can be used for the initial design but should be established for individual site conditions.

As with all ground-improvement techniques, both laboratory and field trials are extremely important to confirm the design requirements.

Peats and organic clays are especially difficult to improve due to the high sulphate and acidic water content, which can depress cement hydration and lower the strengths of the mixed materials.

Most soil mixing is designed on the basis of consideration of the final *in situ* water/cement ratio as this ultimately affects the strength development as defined classically by Abrams in the 1920s.

Figure 59.32 shows data obtained by Swedish researchers for various soils and water/cement ratios.

To estimate the required binder content, the initial moisture content of the soil is required together with any water added

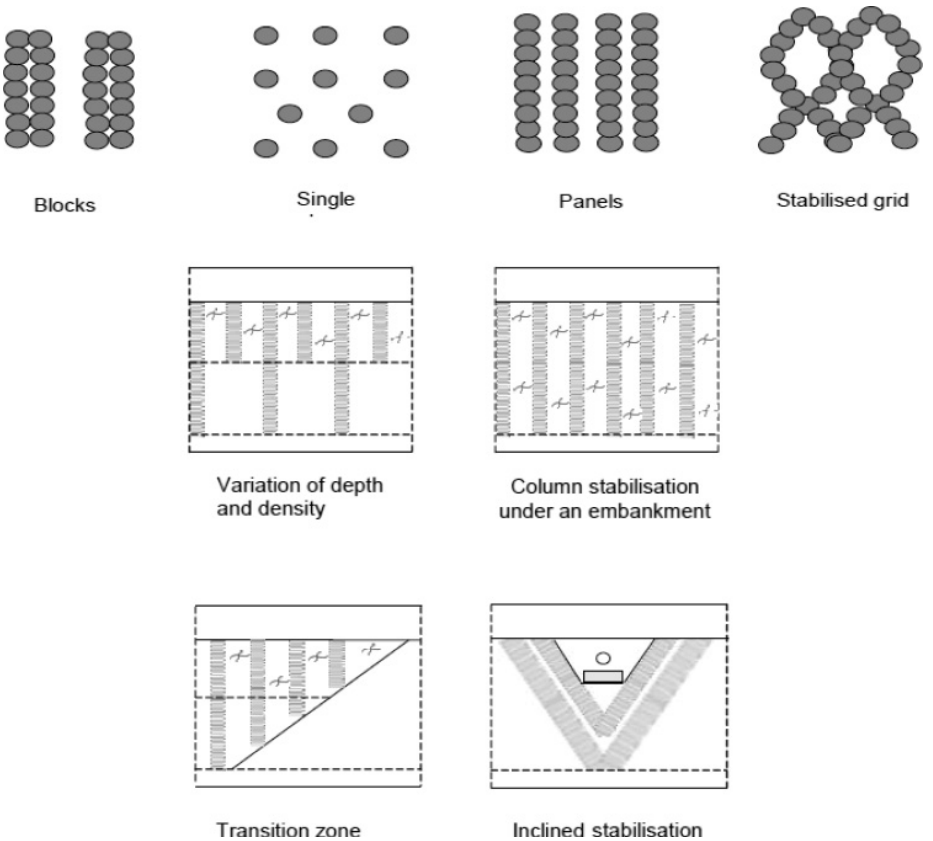

Figure 59.31 Examples of soil-mix column layout
Reproduced from EuroSoil Stab (2002); IHSBRE Press

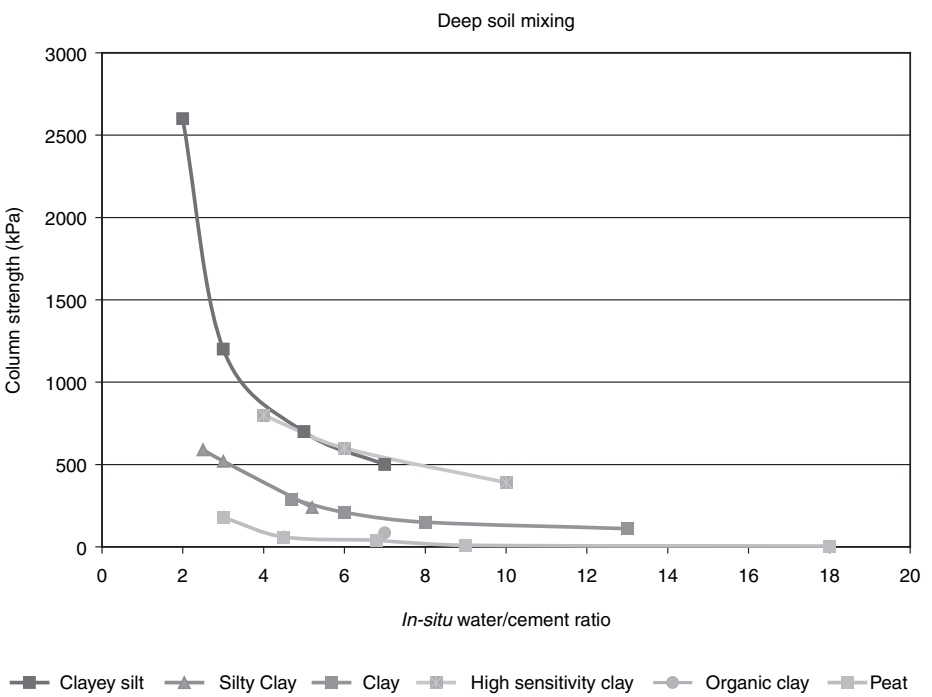

Figure 59.32 Expected soil-mix column strengths based on *in situ* water/cement ratio
Data taken from Åhnberg *et al.* (1995)

from the binder (if fluid) and the overall water/binder ratio is calculated based on a design addition of binder.

For peats and organic clays, a binder containing ground granulated blast furnace slag (GGBFS) is preferred as this binder tolerates sulphates and acid, and it provides a higher strength.

One of the first successful large-scale uses of dry-soil mixing in the UK was carried out within the Port of Tilbury. Overloading of an aggregate stockpile caused a failure within the underlying soft clays and resultant failure of the quay wall. **Figure 59.33** shows the cross-section of the mode of failure. A number of solutions were considered based on piling, vibroreplacement and soil mixing and it was decided that dry-soil mixing offered the most cost-effective and technically acceptable solution. Dry-soil mixing in panels was carried out to improve the soft clays and provide support to the aggregate stockpile. To create panels, 800-mm-diameter columns were installed to the top of the underlying gravels with columns spaced at 700 mm. Individual panels were spaced at 2.3 m to 2.8 m centres. The replacement volume for the soil-mixed columns varied from 25% to 33% assuming a column shear strength of 150 kN/m^2. Over 3000 columns were installed and the design was verified using an initial trial where columns were tested *in situ* and also exhumed. Extensive production testing was carried out using both CPT and pull-out testing and this is described by Lawson *et al.* (2005). **Figure 59.34** shows a comparison between CPT, pull-out testing (PORT) and laboratory testing. In general, the field tests gave similar results whereas the laboratory testing gave much lower results, which was attributed to sample disturbance.

59.9.2 Execution controls

Execution controls consist of controlling the binder content during mixing and most specialists provide instrumentation on the rigs that record all important parameters.

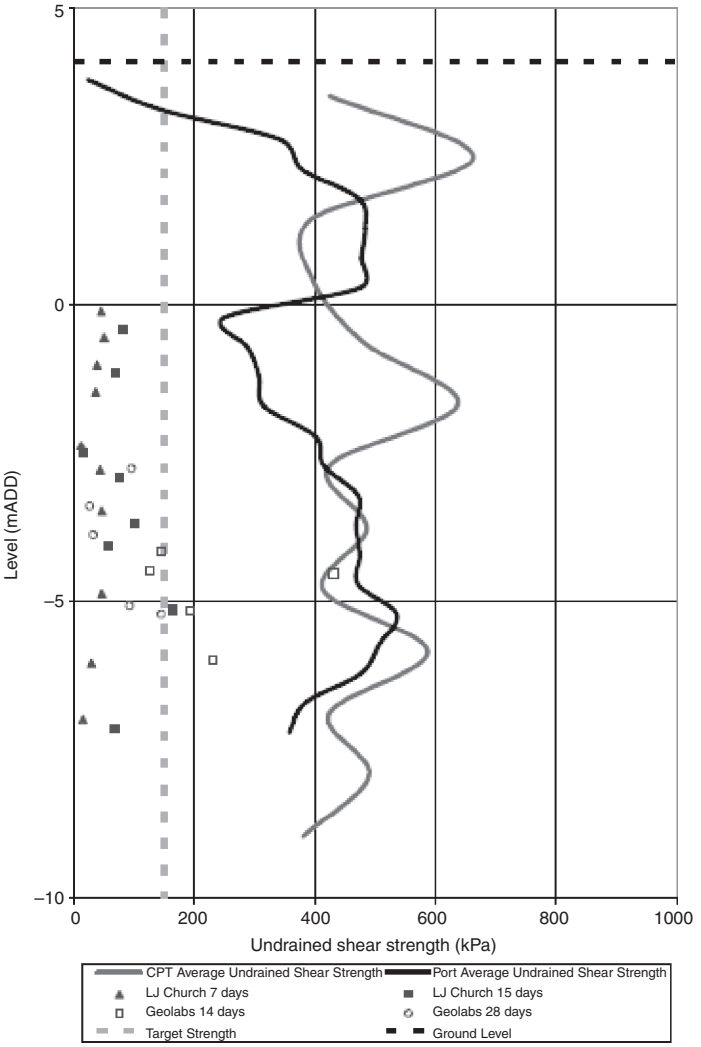

Figure 59.34 Results of testing for dry-soil mixing, Tilbury
Reproduced from Lawson *et al.* (2005)

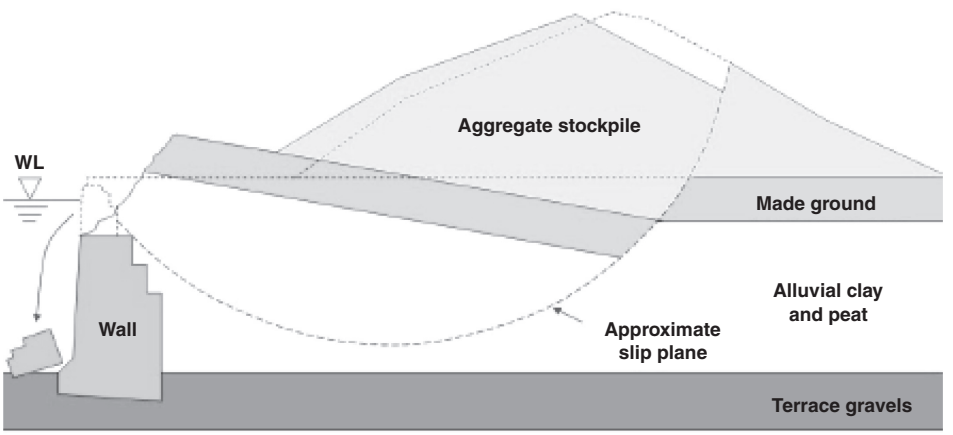

Figure 59.33 Failure of quay wall at Tilbury
Reproduced from Lawson *et al.* (2005)

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

For wet-soil mixing additional controls are required for grout batching as for other forms of grout mixing.

59.9.3 Validation

Validation is generally by *in situ* testing. This can be cone penetration testing, plate testing or zone testing. Additionally for dry-soil mixing a special vane penetration and pull-out test has been developed. The vane, which is around 0.45 m wide, is inserted below the mixing head with a cable running up the Kelly bar. The mixing head is inserted as usual and the column is mixed, leaving the vane in place centrally and immediately below the column. After a set period of time, normally between three and seven days, the vane is withdrawn at a fixed rate of 2 cm/s and the extraction load monitored. This can then be related to the *in situ* strength using empirical relationships. Care needs to be taken to ensure that cable friction is taken into account and it is common for the vane to be withdrawn around 0.5 m within 24 hours of column construction to break or reduce this friction.

It is recommended this chapter is read in conjunction with

- Chapter 25 *The role of ground improvement*
- Chapter 84 *Ground improvement*
- Chapter 100 *Observational method*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Chapter 60

Foundations subjected to cyclic and dynamic loads

Milutin Srbulov Mott MacDonald, Croydon, UK
Anthony S. O'Brien Mott MacDonald, Croydon, UK

CONTENTS

60.1	Introduction	939
60.2	Cyclic loading	939
60.3	Earthquake effects	940
60.4	Offshore foundation design	948
60.5	Machine foundations	950
60.6	References	951

The basic concepts and references concerning shallow and deep foundation response to earthquake, wave and machinery effects are introduced. The information provided in this chapter will be useful to many readers because available recommendations in the codes and standards concerning the response of foundations subjected to cyclic and dynamic loads is limited with regard to the requirements encountered in practice. Soils tend to respond nonlinearly even at rather small strain. Nonlinear dynamic analysis and testing can produce chaotic results and the best approach to a problem solution is to understand the fundamental issues associated with the problem, have an idea about the possible range of results and know the limitations of analysis methods used for its solution.

60.1 Introduction

Foundations can be subjected to large cyclic and/or dynamic loads in the following situations:

(i) seismic loads triggered by earthquakes;

(ii) wave forces imposed on offshore (marine) structures;

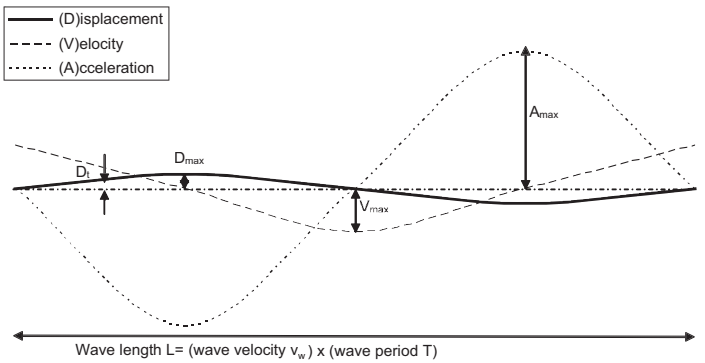
(iii) foundations which support vibrating machines.

Cyclic load effects may also need to be considered for tall slender structures subject to wind loading, although the cyclic loads will tend to be relatively minor compared with the situations for (i) to (iii) above. The design of foundations which are subjected to cyclic/dynamic loads is a complex matter and should only be carried out by appropriately qualified specialists. Hence, the intent of this chapter is to give a brief introduction to the topic and provide a list of technical references which give more detailed guidance. The adverse effects of cyclic/dynamic loading include:

(i) degradation of ground strength, which can lead to failure at foundation loads below those expected based on 'static' strength;

(ii) degradation of ground stiffness and/or 'ratcheting' type effects, leading to an accumulation of permanent foundation displacements;

(iii) dynamic loading can induce site/structure-specific amplification of loads/movements due to resonance type phenomenon;



(iv) earthquake loads can induce large-scale ground instability which will impose large additional forces on foundations or cause catastrophic collapse.

It is noted in Chapters 52 *Foundation types and conceptual design principles* to 55 *Pile-group design*, inclusive, that the main body of experience is for foundations which are loaded vertically. A feature of cyclic/dynamic loading is that it commonly involves large horizontal loads, and therefore it is far more difficult to predict foundation behaviour. Hence, a more cautious approach to foundation design is required.

60.2 Cyclic loading

Vibration of foundations occurs when loads on them (from machinery) or their base displacements (from earthquakes) vary in time or a structure is forced out of its equilibrium position (by blast) and left to oscillate freely. In the case of dynamic loads, the inertial forces are significant in comparison with the acting static loads. More details about dynamic and seismic loading of soil are given in Chapter 24 *Dynamic and seismic loading of soils*. The main parameters of cyclic behaviour are:

- **Amplitude of vibration** indicates how much a cyclic state differs from the steady state condition of a body (**Figure 60.1**). Acceleration amplitude is directly proportional to the inertia force acting on a body. Square of velocity amplitude is directly proportional to the kinetic energy of a vibrating body. Displacement amplitude of a vibration is proportional to the amount of deformation (strain) in cyclic condition (strain is the ratio between induced displacement and length over which such displacement has been achieved). The ratio between particle and wave propagation velocity equals the strain induced by unidirectional vibration within a body. Product of unit density, particle velocity and wave propagation velocity equals the stress acting within a body during its unidirectional vibration, e.g. Kramer (1996), Timoshenko and Goodier (1970) (stress is the ratio between applied force and the area over which it has been applied).
- **Vibration period** is the time difference between two equal states of body vibrations. Product of vibration period and wave propagation velocity equals to wave length. Vibration period, i.e. its reciprocal value called vibration frequency, is important. If the vibration period of free oscillation of a body corresponds to the vibration period of vibration excitation then resonance could occur, which

Shear strain γ_t at time t = (displacement D_t at time t)/(v_w x t) = (particle velocity v_{pt} at time t)/ (wave velocity v_w)
Shear force T_t at time t = (mass m) x (acceleration A_t at time t)
Shear stress τ_t at time t = T_t /(cross sectional area)= (unit density ρ) x v_{pt} x v_w
Kinetic energy E_t at time t = (mass m) x (particle velocity V_{pt}^2 at time t)/2

Figure 60.1 A sketch of sinusoidal transversal wave with amplitude related values

can lead to the increase of the amplitudes of the source of vibration and damage or destruction of the oscillating body. In the case of harmonic (sinusoidal) vibration caused by machinery, the maximum amplitudes of displacement D, velocity V and acceleration A are related to each other as $V = \omega D$, $A = \omega V = \omega^2 D$, where ω is so-called circular frequency $= 2\pi f$, f is vibration frequency. Earthquakes are chaotic and the predominant periods (frequencies) of acceleration, velocity and displacement are different.

- **Number of cycles** (i.e. duration of vibration) is important because longer vibration duration can cause greater damage to materials (due to so-called fatigue effect) than a few vibration cycles if the amplitudes are the same. Prolonged vibration causes (micro) cracks even in metals and in soil it can cause a number of problems such as state of liquefaction, flow type failure of slopes, loss of bearing capacity as well as excessive settlements and horizontal displacements of foundations. Seed *et al*. (1975) developed the concept of an equivalent number of significant stress cycles (caused by the horizontal ground acceleration) to represent an irregular time history of shear stresses by a uniform series of harmonic (sinusoidal) stress cycles. The equivalent number of uniform stress cycles N_{eqv} was selected to cause pore pressure build-up equivalent to that of an actual shear stress history at harmonic stress amplitude of 65% of the maximum actual shear stress (caused by the peak horizontal ground acceleration). Seed *et al*. (1975) data can be approximated by a simple formula $N_{eqv} = 0.0008\, M_L^{4.88}$, where M_L is local (Richter) earthquake magnitude. Other researchers related N_{eqv} to different magnitude types (e.g. Hancock and Bommer, 2004) and showed that N_{eqv} depends also on the site-to-source distance and depth below ground level (e.g. Green and Terri, 2005), i.e. soil type. Sarma and Srbulov (1998) used a large number of actual acceleration time histories caused by earthquakes to show that 95% of energy contained within a strong motion recorded corresponds to the level of acceleration equal to about 0.65 of the peak acceleration.

An example of the effect of soil liquefaction on loss of bearing capacity of shallow foundations and tilting of the whole buildings is shown in **Figure 24.12** of Chapter 24 *Dynamic and seismic loading of soils*. In other cases, buildings sunk vertically or pipes and shafts floated due to soil liquefaction. Piles can be damaged or destroyed in liquefied soil when a significant lateral movement of ground occurs due to flow type failures. A devastating effect on the piled foundation caused not by soil liquefaction but by 'double resonance' condition (amplification of bedrock motion by the soil deposit and amplification of the soil motion by the structure) is shown in **Figure 60.2**. The peak horizontal bedrock acceleration was only 0.03 g to 0.04 g but has been amplified several times (e.g. Kramer, 1996).

60.3 Earthquake effects

60.3.1 Overall design considerations

The design process would normally involve the following main steps:

(i) Assess the earthquake magnitude and source location. Often several 'design' earthquakes will be considered, varying from a relatively small event (for this the foundation would be expected to remain serviceable with minimal repair requirements) to a large event (for which there would be a 'no collapse' requirement). The earthquake properties will be defined for bedrock level.

(ii) Assess the overall topography in the vicinity of the proposed structure, in particular location of slopes/embankments and cuttings/ditches/river banks, etc.

(iii) Assess local amplification/attenuation of bedrock earthquake motion through overlying soil deposits.

(iv) Assess whether soil liquefaction may occur.

(v) Assess consequences of soil liquefaction, which may vary from local settlement to global failure.

(vi) Assess dynamic soil–structure interaction effects.

(vii) Depending upon (v) or (vi), assess the type and extent of deep ground improvement to mitigate the potential adverse effects.

60.3.2 Soil behaviour

A detailed description of soil behaviour in cyclic condition is given in Chapter 24 *Dynamic and seismic loading of soils*. In summary, both loose to medium dense sand and silt and soft to firm clay can exhibit a decrease of shear strength and stiffness with increase in the number of cycles and cyclic amplitudes. The loss of shear strength of sands during earthquakes is known as liquefaction. Liquefaction has been the cause of catastrophic and extensive structural damage and loss of life. Liquefaction is induced by the generation of significant excess pore pressures during an earthquake, which results in a loss of shear strength and stiffness. Following earthquake shaking, the excess pore water pressures will dissipate as seepage takes place between zones of high excess pore water pressure to zones of low excess pore water pressure. The resulting upward groundwater flow

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

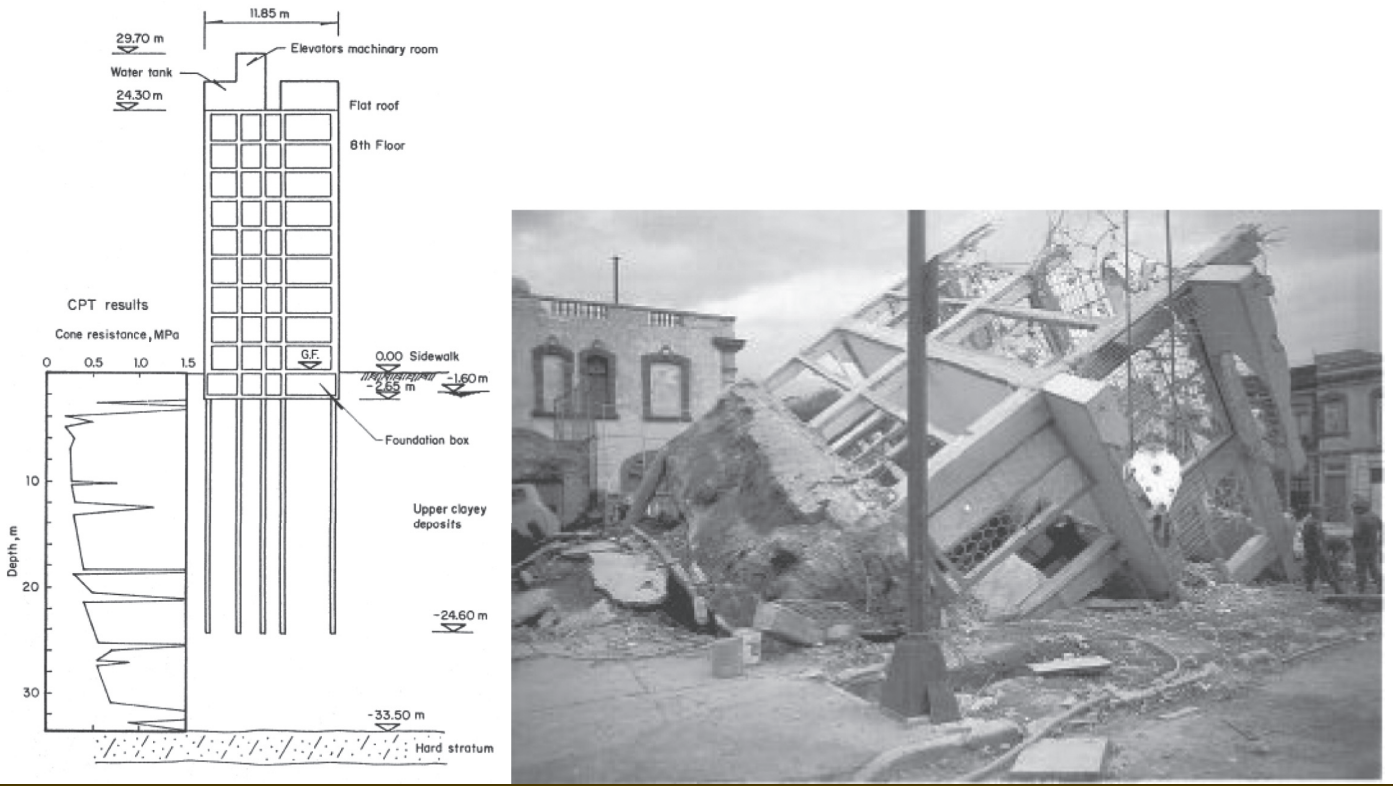


Figure 60.2 Elevation of the ten-storey building in Mexico City and after toppling
Reproduced from Meymand (1998)

greatly complicates the assessment of the effects of an earthquake, and cannot be reliably quantified by laboratory testing or computer-based analyses. Considerable engineering judgement is required. An important factor is the 'layering' of the soil deposits. The presence of a clay layer in loose sand could cause global instability, as upward seeping water becomes trapped beneath the clay seam leading to reduced soil shear resistance. The factors which influence the risk of liquefaction are reasonably well understood and include:

(1) **Soil type and ground water table level**: saturated coarse-grained soils (particularly fine/medium sands and coarse silts) in areas with a high water table level are at most risk. In general, the younger and looser the deposit the more vulnerable it will be to liquefaction. In general, deposits which are of Pleistocene age or older are usually considered to be at low risk. Dense coarse-grained soils, with a relative density greater than 80% are not likely to liquefy.

(2) **Depth**: with increasing depth, the confining pressure increases and liquefaction resistance increases. Commonly observed liquefaction depths are less than about 15 m. There are no recognised 'maximum' depths for liquefaction, although in general the risk of liquefaction below 20 m or 25 m depth is believed to be low.

(3) **Drainage conditions and soil fabric**: poor drainage allows pore pressure build-up and increases the risk of liquefaction; and as noted above, if loose sands are sandwiched between clay layers the loss of strength may be more serious due to seepage effects.

(4) **Earthquake-induced shear stress**: as the intensity of ground shaking increases the shear stress increases and liquefaction is more likely.

(5) **Earthquake duration**: as duration increases (generally a function of earthquake magnitude) the number of loading cycles increases, leading to an increase in excess pore water pressure.

Simplified empirical analysis procedures have been developed, and the factor of safety against liquefaction = CRR / CSR (e.g. refer to Youd *et al.*, 2001; BS EN1998-5:2004); CRR = cyclic resistance ratio of the soil at a particular depth and CSR is the cyclic shear stress ratio imposed by the earthquake at a particular depth. The CSR is usually calculated by using Seed and Idriss' simplified equation. For more challenging situations ground response analyses (GRAs) can be carried out, but GRAs should only be carried out by seismic experts. Seed and Idriss' simplified equation is:

$$\mathrm{CSR} = 0.65 \frac{a_{\max}}{g} \frac{\sigma_v}{\sigma'_v} \mathrm{r_d} \qquad (60.1)$$

In the above equation, $a_{\max}$ is the peak ground surface acceleration for the design earthquake, σ_v and σ'_v are total and effective

vertical stress respectively, r_d is a stress reduction factor which is depth-dependent. For simple projects, the value of a_{max} at ground surface can be estimated from the local seismic codes (http://www.iaee.or.jp/), which provide the peak horizontal accelerations at bedrock but also amplification factors for different soil types. The liquefaction resistance can be estimated empirically from *in situ* tests (commonly standard penetration tests (SPT) and cone penetration tests (CPT)), e.g. Figure B.1 of BS EN1998-5:2004, or from laboratory tests. The use of laboratory tests to assess CRR is challenging and requires very high quality samples and specialist laboratory testing (e.g. cyclic simple shear tests). It can be useful for sandy soils with high fines content (e.g. sandy silts or very silty sands), or sands/silts which are suspected to be overconsolidated, and where empirical SPT/CPT based methods may be overly conservative. Comprehensive guidance on assessing liquefaction risks is given in Youd *et al*. (2001) and Kramer (1996).

Clays and cohesive silts can suffer a loss of strength/stiffness during earthquake shaking, usually termed 'cyclic mobility'. Fundamentally the overconsolidation ratio and strength sensitivity (ratio of peak to remoulded strength) are important factors. Bray *et al*. (2004) have suggested the following classification based on moisture content (w), liquid limit (w_L) and plasticity index (I_p):

(a) $w/w_L \geq 0.85$ and $I_P \leq 12$: susceptible to liquefaction or cyclic mobility*;

(b) $w/w_L \geq 0.8$ and $12 < I_P < 20$: moderately susceptible to liquefaction or cyclic mobility*;

(c) $w/w_L < 0.8$ and $I_P \geq 20$: no liquefaction or cyclic mobility, but may undergo significant deformation if cyclic shear stress > Static undrained shear strength (S_u).

* This classification may be revised on a site-specific basis using data from laboratory cyclic shear testing of good quality field samples (e.g. samples obtained using thin-walled tube samples with sharpened (i.e. >5°) cutting edge and no inside clearance).

Bray *et al*. (2004) suggest that the residual strength (S_r) for silt and clay zones be determined as per guidelines given below:

(a) $w/w_L \geq 0.85$ and $I_P \leq 12$:S_r = remoulded shear strength ($S_{remoulded}$), unless appropriate testing of undisturbed samples can show greater strength;

(b) $w/w_L \geq 0.8$ and $12 < I_P < 20$: $S_r = 0.85s_u$ where s_u = static undrained shear strength;

(c) $w/w_L < 0.8$ and $I_P \geq 20$: $S_r = s_u$.

Coarse-grained soils like gravel can also liquefy in certain circumstances based on case studies (e.g. Kokusho *et al*., 1995). Dense to very dense coarse granular soil and overconsolidated fine-grained soil tend to dilate initially during shearing (i.e. after initial cycles) and exhibit greater shear resistance and stiffness than normally consolidated soil.

Dynamic soil–structure interaction effects are dependent on the variation of soil shear modulus with depth and with strain amplitude. Empirical correlations are available for G_{max} (or G_o) (refer to Chapter 52 *Foundation types and conceptual design principles*); however, whenever feasible site-specific *in situ* measurements of G_{max} should be carried out (using, for example, seismic-cone or down-hole geophysics tests). The variation of shear modulus with strain amplitude is usually based on cyclic triaxial tests (ASTM D3999-91) or resonant column tests (ASTM D4015-92). When the results of tests of soil stiffness are not available, BS EN1998-5:2004 provides a table of average soil damping ratios and average reduction factors (± one standard deviation) for shear wave velocity v_s and shear modulus G (for upper 20 m depth range) as a function of peak horizontal ground acceleration, which are plotted in **Figure 60.3**.

When the results of tests of shear strength of sandy soil in cyclic condition are not available, the frictional angles of sandy soil φ can be inferred from the critical cyclic stress ratios τ/σ' (= tanφ) that were proposed initially by Seed and Idriss (1971) as the boundaries between liquefied and non-liquefied

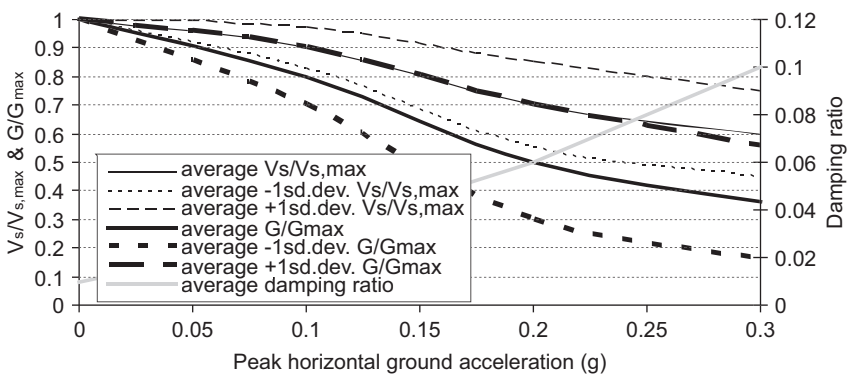

Figure 60.3 Average soil damping ratios and average reduction factors (± one standard deviation) for shear wave velocity v_s and shear modulus G within 20 m depth

Reproduced with permission from BS EN 1998-5 © British Standards Institution (2004)

sandy soil and later included in BS EN1998-5:2004 (**Figure 60.4**). For dense sand, the friction angle in cyclic condition is assumed to be equal to the angle in static condition, which can be inferred from e.g. Peck *et al*. (1974).

60.3.3 Earthquake loading

In most cases, earthquakes are caused by sudden slip of a tectonic fault or tectonic plate in the subduction zone. Earthquake magnitude represents a measure of the energy released at the source unlike earthquake intensity, which is a measure of earthquake effects at a site. Besides active tectonic faults, earthquakes can be caused by large landslides, cave collapse, volcanoes and explosions. There are different types of earthquake magnitudes.

- Richter local magnitude M_L (Richter, 1935) is the logarithm of the maximum trace amplitude (in micrometers) recorded on a Wood-Anderson seismometer located 100 km from the epicentre of an earthquake.
- Surface wave magnitude M_s (Gutenberg and Richter, 1936) is a world-wide magnitude scale based on the amplitude of Rayleigh waves with a period of about 20 s.
- Body wave magnitude m_b (Gutenberg, 1945) is a world-wide magnitude scale based on the amplitude of the first few cycles of longitudinal waves (usually with the period of about 1 s).
- Moment magnitude M_w (Kanamori, 1977; Hanks and Kanamori, 1979) is proportional to the logarithm of seismic moment M_o, which is a product of a tectonic fault rupture area, the average amount of fault slip and the rock stiffness.
- Other types of magnitudes exist but are less frequently used. Correlations between various common magnitude scales were plotted by Idriss (1985).

Ambraseys (1990) derived the following relationships between various common earthquake magnitude scales:

$$\begin{aligned} 0.77 \cdot m_b - 0.64 \cdot M_L &= 0.73 \\ 0.86 \cdot m_b - 0.49 \cdot M_S &= 1.94 \\ 0.80 \cdot M_L - 0.60 \cdot M_S &= 1.04 \end{aligned} \qquad (60.2)$$

Maximum amplitudes of ground motion caused by earthquake at a site can be estimated from various attenuation relationships (e.g. Douglas, 2011) or from national seismic codes (www.iaee.or.jp/). The published attenuation relationships do not consider one or more of the following important factors affecting earthquakes:

- tectonic fault type (normal, strike-slip, reverse, oblique);
- seismic wave path (site-to-source distance, rupture directivity and fling step in the near field);
- sediment basin depth and near edge effect;
- local soil layer thickness and stiffness;
- topography (slopes, ridges, canyons);
- wave bounce from Moho surface (i.e. the Earth's crust and mantle boundary).

When the above factors have not been considered in the attenuation relationships, their effects are accounted for by adding one standard deviation to the average value of ground motion amplitude, which is predicted by the attenuation relationship. More information on the effects of these factors is provided by Stewart *et al.* (2001).

Seismic wave amplitudes and wave periods (lengths) affect both foundations and structures above them. Foundations tend to average ground wave amplitudes along foundation lengths (Yamahara, 1970; Newmark *et al*., 1977) because of different stiffness of foundations and underlying soil and in this process undergo additional stressing. Averaged amplitude values are smaller than the peak values but wave amplitude averaging causes also additional rotation (Newmark, 1969). Seismic body waves are considered to propagate nearly vertically under ground surface because of a number of their refractions at the layer boundaries along their path from the source to the surface. Vertically propagating body waves exhibit phase shift when soil layers through which they propagate have different thicknesses so the waves arrive at the surface with different amplitudes spatially at time instants. Piles cause averaging of amplitudes of seismic body and near-surface propagating waves. Shallow foundations cause averaging of amplitudes of near-surface propagating waves such as Reyleigh and Lowe waves as well as of the amplitudes of body waves when their amplitudes at the surface vary spatially at time instants. For very long structures,

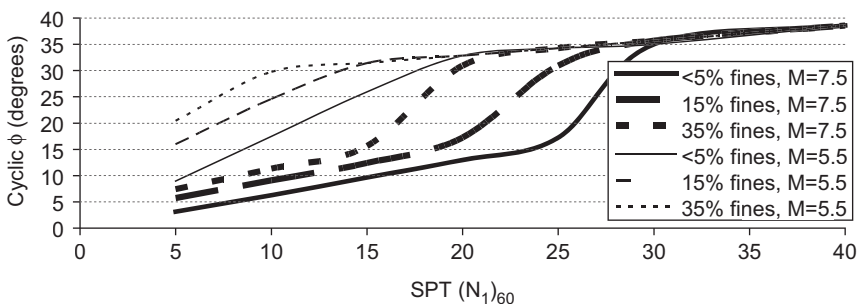

Figure 60.4 Dependence of friction angle π in cyclic condition on normalised SPT blow count $(N1)_{60}$ and earthquake magnitude M
Data taken from BS EN 1998-5:2004 and Peck, Hanson and Thornburn (1974)

phase shift in the vibrations of the foundations at the ends is considered. Foundations are also affected by inertia forces caused by ground acceleration and foundation mass but such forces may be relatively small in comparison with structural inertial forces if the structural mass and acceleration are significantly greater than foundation mass and acceleration.

Structural vibration can be amplified or attenuated with respect to the foundation vibration depending on the fundamental vibration period (frequency) of a structure. A damped single degree of freedom oscillator (assumed to be 'elastic') on a rigid base is used to define the so-called response spectra, which describe the maximum response of the oscillator to a particular input ground motion as a function of the fundamental frequency (period) and damping ratio of the oscillator. The smoothed envelope of many response spectra are given in seismic design codes for the design of structures. The effect of local soil layers on design spectral values is usually considered by application of multiplying coefficients to bedrock spectral values for different soil classes. BS EN1998-5:2004 (BSI, 2004) specifies in which cases site-specific dynamic soil–structure interaction analyses must be considered and what factors such analyses need to involve but not how the analyses are to be performed. Soil–structure interaction generally increases the period of vibration and damping ratio of structures (e.g. ATC, 1978; BSSC, 1995). The increase in the structural period may appear to be beneficial according to smoothed design spectra, whose amplitude decreases with the period increase after a threshold period usually in the range of 0.5 s to 1.0 s. However, site-specific acceleration spectra like the ones in Mexico City (e.g. Kramer, 1996) and in Kobe (e.g. Gazetas and Mylonakis, 1998) indicate that an increase in structural vibration period can be responsible for structural damage due to resonance effects between the vibration of a structure and soil layers, when the period of vibration of the soil deposit is relatively large (e.g. 2 s in Mexico City and 1 s or more in Kobe). Stewart *et al*. (1999) evaluated soil–structure interaction effects for 77 strong motion data sets at 57 building sites and found a pronounced influence of structure-to-soil stiffness ratio on inertial interaction, as well as secondary influences from structure aspect ratio and foundation embedment, shape and flexibility. They found that kinematic interaction effects on the 'input' motion at the bases of structures are found to be relatively modest in many cases, whereas inertial interaction effects on the structural response to these motions can be significant. Wolf (1994) provides simplified expressions for the calculation of an equivalent period T_e of soil–foundation–structure systems. Some codes also provide simplified expressions. These can be useful in order to assess resonance type effects.

Seismic codes specify only amplification of bedrock acceleration by overlying soil layers. Srbulov (2003) plotted the ratios between the horizontal peak accelerations at the surface and at depth (equivalent to 'bedrock') shown in **Figure 60.5** from 66 recorded case histories. This shows that peak ground surface acceleration is attenuated for peak horizontal accelerations at depth (i.e. bedrock) greater than 0.3 g to 0.4 g. Attenuation of large bedrock accelerations is most likely because of soil yield at greater accelerations. Idriss (1990) also indicated attenuation of bedrock acceleration on soil sites when the acceleration on rock sites exceeded about 0.3 g to 0.4 g (but Idriss' relationship is based on calculations rather than recorded data).

60.3.4 Global failure/deformation mechanisms

During earthquakes, the propagation of seismic waves causes cracking and elevation differences even on level ground. However, the greatest ground deformations are caused by slope failures, rupture of ground surface by tectonic faults and soil liquefaction followed by flow type failures.

Keefer (1984) studied the effects of 40 historical earthquakes on slope failures. The types of failures, their relative

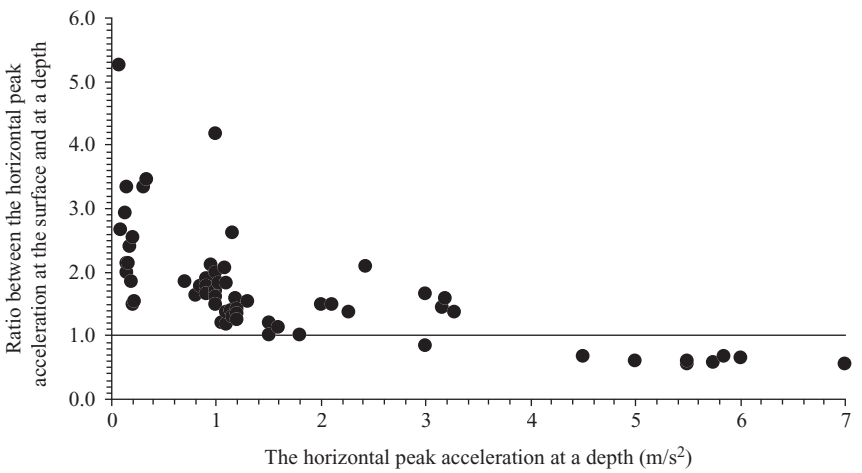

Figure 60.5 Ratios between the recorded horizontal peak accelerations at the surface and at depths (soil or rock) versus the horizontal peak accelerations at depths

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

frequency and minimum triggering earthquake magnitudes are given in **Table 60.1**.

Keefer (1984) and Rodriguez *et al*. (1999) plotted the graphs of the maximum recorded distances of occurrence of landslides depending on their type and earthquake magnitudes. Their graphs indicate that no slope failures are expected beyond 120 km epicentral distance even from earthquakes with the magnitudes up to 8 and that disrupted landslides are more prone to earthquake triggering than coherent landslides, spreads and flows. More information on slope stability issues is provided in Chapter 23 *Slope stability* and on slope stabilisation methods in Chapter 72 *Slope stabilisation methods*.

If a tectonic fault causes a rupture of ground surface, it results in destruction of structures crossing the fault and therefore placement of structures over active faults must be avoided wherever such faults exist.

If liquefaction occurs then the consequences can vary enormously from modest ground settlement to catastrophic large-scale ground instability. A range of factors will influence the nature of any consequences including: the earthquake characteristics; site stratigraphy and topography; nature of structures (and their foundations) and earthworks on the site. Three important consequences are:

(i) reduction of soil shear strength, leading to global instability of the ground (e.g. embankment collapse leading to failure of adjacent pile foundations) and increase in lateral pressure on retaining structures;

(ii) settlement caused by reconsolidation of liquefied soil;

(iii) lateral deformation of gently sloping ground.

Figure 60.6 indicates how site-specific features and the spatial distribution of liquefied zones can affect the consequences of liquefaction.

Type of slope failure	Frequency of occurrence during earthquakes	Minimum triggering earthquake magnitude M_L
Rock falls, disrupted soil slides, rock slides	Very frequent	4.0
		4.0
Soil slumps, soil block slides	Frequent	4.5
Soil lateral spreads		5.0
Soil avalanches		6.5
Soil falls	Moderately frequent	4.0
Rapid soil flows, rock slumps		5.0
Sub-aqueous landslides	Uncommon	5.0
Slow earth flows, rock block slides		5.0
Rock avalanches		6.0

Table 60.1 Types of slope failures, relative frequency and minimum triggering earthquake magnitudes

(a) **Figure 60.6(a)** shows a continuous layer of liquefied soil which daylights in a river bank, leading to post-earthquake instability and collapse of the building.

(b) **Figure 60.6(b)** a liquefied layer at depth, with no potential for lateral instability, leads to post-earthquake settlement, which does not cause serious damage to the building, but may cause damage to connections into the building (e.g. gas mains, water pipes) if they have insufficient flexibility. Ishihara and Yosmine (1992) and Cetin *et al*. (2004) provide guidance on methods to assess reconsolidation settlement.

(c) **Figure 60.6(c)** shallow pockets of sand cause differential settlement and associated damage to the building (but not collapse).

(d) **Figure 60.6(d)** a zone of liquefied soils leads to post-earthquake instability of the embankment (termed 'flow' failure) (because the overall soil shear resistance is less than the 'static' shear stress imposed by the embankment, as conventionally assessed by slope stability analyses. The key difference is that the 'residual' shear strength of the liquefied layer needs to be assessed.) The lateral deformation of the ground will lead to additional forces on the piles, which could lead to structural failure of the piles if they are inadequately designed.

During earthquake shaking, ground deformations can be assessed from Newmark's (1965) sliding block method. This method is useful for obtaining approximate estimates of deformation, especially for embankments/slopes comprising non-liquefiable soils. Lateral spreading deformations of mildly sloping ground can be assessed by several methods, including the empirical approach of Youd *et al*. (2002). It is commonly assumed that liquefied soil has zero shear strength. However, in most circumstances the liquefied soil will maintain 'residual' shear strength because of fast dissipation of excess pore water pressure. Olson and Stark (2002) have provided relationships for the residual shear strength of liquefied soil based on SPT and CPT results. Recently, Srbulov (2011) back analysed 14 case histories of flow type slope failures in liquefied soil. In layered deposits, not all soil layers liquefy. Often the uppermost soil layer (or 'crust') will not liquefy when the water table level is at depth and the soil is not fully saturated. Excess pore water pressure causes ejection of sand and water at the ground surface in forms of sand volcanoes (**Figure 60.7**).

When the top non-liquefied soil layer is thick enough to prevent formation of sand volcanoes then sills (intrusions) are formed within non-liquefied layers. It also means that such layers are subjected to uplift pressure, which decreases their bearing capacity.

Soil liquefaction can cause not only flow type failure of slopes but also loss of bearing capacity of foundations and their excessive settlement and horizontal movement. Shallow foundation can tilt or sink (e.g. Liu and Dobry, 1997). Piled

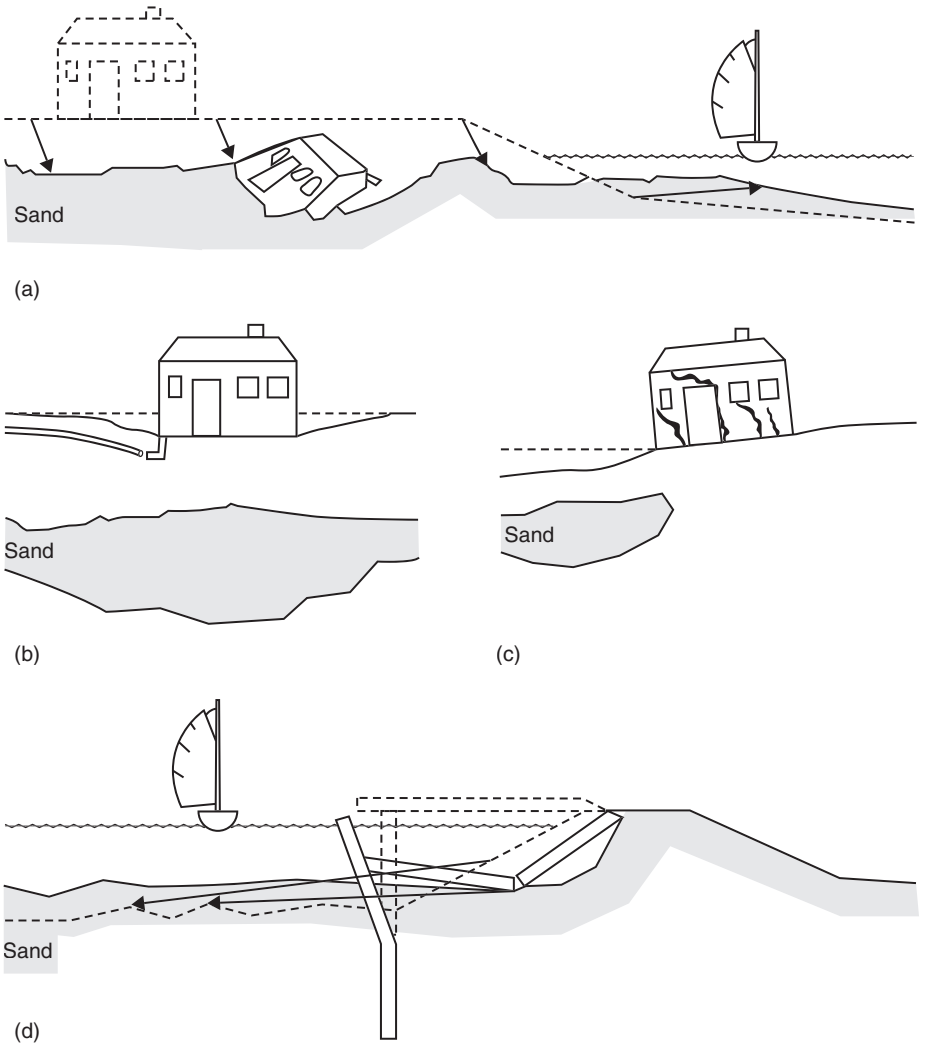

Figure 60.6 Effects of soil liquefaction: (a) flow type slope failure leading to a building collapse, (b) deep soil layer and building excessive settlement with break of a pipe, (c) differential settlement and severe damage of a building, (d) flow type slope failure of an embankment and damage to the deck and supporting piles

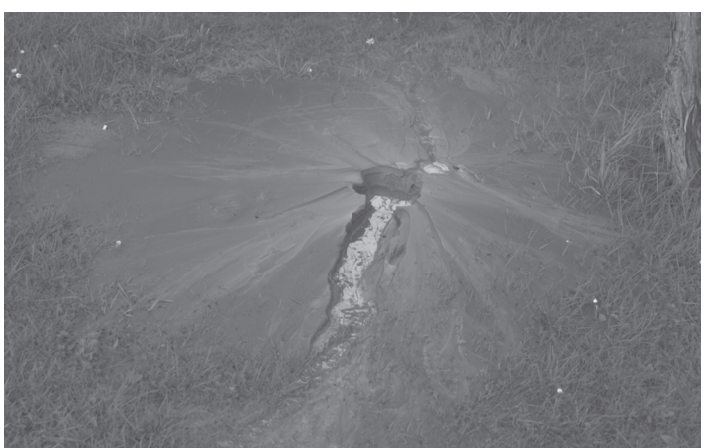

Figure 60.7 An aerial view of sand volcano caused by sand ejection at the surface due to its liquefaction
© Jon Sullivan

foundation can be sheared in case of flow type slope failure (e.g. Hamada, 1992) because the top non-liquefied crust exerts significant lateral force, which equals the passive lateral resistance of the layer.

60.3.5 Shallow foundations

The failure mechanisms for shallow foundation in cyclic conditions are the same as those for static conditions, which are considered in Chapter 53 *Shallow foundations*. Soil bearing capacity, foundation sliding and overturning resistances are usually checked by using static methods with addition of an inertia force from the foundation and structural acceleration. Soil properties in cyclic conditions need to be used with the static methods. Also, the effect of inertial force on soil under the foundation needs to be considered, for example using an equivalent inclined foundation or inclined ground surface. The angle of inclination may correspond to the angle necessary to

rotate the resultant of gravity and inertia forces acting on the soil under the foundation into the vertical. BS EN1998-5:2004 (BSI, 2004) provides an informative formula for assessment of seismic bearing capacity of shallow foundations. The formulae for static bearing capacity that use the coefficient $N\gamma = 2(N_q + 1)\tan\phi$ are not considered safe to use.

Settlement of shallow foundation during earthquakes is caused by soil densification, i.e. decrease in soil porosity due to ground shaking (soil porosity is the ratio between the volume of voids and the total volume of soil). Recently, Srbulov (2011) calculated earthquake-induced settlement of a shallow foundation. Sliding of shallow foundations can be estimated using Newmark's (1965) sliding block method and charts derived from this method for level ground (e.g. Ambraseys and Srbulov, 1995). Permanent rotation of foundation can be assessed using a rotating block method (e.g. Srbulov, 2011).

Seismic codes contain limited recommendations for analyses of shallow foundation vibration. For simplified soil–structure interaction analyses, shallow foundations are represented by equivalent vertical, horizontal and rotational springs K and dampers C as sketched in **Figure 60.8**. Ground motion can be applied at the ends of the springs and dampers or on a structure. Vertical springs and dampers are needed even if only the horizontal ground motion component is considered because of coupled horizontal and rocking mode of vibration, with the vertical component at the edge of the foundations.

The formulae for calculation of values of the dynamic stiffness and damping coefficients are tabulated in relevant textbooks (e.g. Gazetas, 1991; Wolf, 1994). If foundation vibration is considered excessive for the intended use of the structure then foundation vibration isolation can be used. Recently, Srbulov (2010) performed simplified numerical analysis of the response of a rubber bearing isolated building in Japan during a strong earthquake.

60.3.6 Deep foundations

For deep foundation types, piles are most frequently used although vertical shafts and caissons are used occasionally. Deep foundations are subjected to kinematic and inertial interactions.

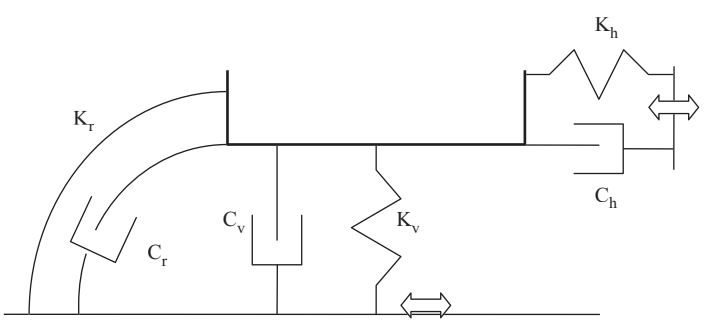

Figure 60.8 Soil and foundation stiffness and damping represented by equivalent springs and dampers

Kinematic interaction is caused by different stiffness of foundation and surrounding soil. A stiffer foundation tends to average ground movement and in this process becomes stressed. The largest effects occur at the interfaces between layers with different stiffness including liquefied layers. Large differential horizontal displacements of different layers may cause significant bending moments in deep foundations and require the use of continuous reinforcement along the whole foundation length. In simplified analyses, the effects of kinematic interactions are determined using horizontal equivalent soil P–y springs (e.g. API RP 2A-WSD, 2007), which ends are subjected to the horizontal displacements that are calculated considering one-dimensional wave propagation in the vertical direction in the free field (**Figure 60.9**). As y values represent differential horizontal displacement between a pile and adjacent soil and not absolute horizontal soil displacement, several iterations are necessary to calculate the values of y from applied previous P forces on a pile based on previous estimates of y values. Kinematic pile interaction has positive effect on decreasing the peak horizontal acceleration that is transferred to the superstructure above the piles and increasing the vibration period of structural vibration, which in turn results in decreased input acceleration, in general.

Inertial interaction occurs because of structural mass, which together with structural stiffness causes a different vibration frequency (period) for a structure with respect to the adjacent ground. Different structural periods cause different periods of pile vibration, which tend to oscillate asynchronously with the ground. A superposition of incoming ground waves to a pile and outgoing ground waves from a pile vibration can cause superposition of wave amplitudes and new wave pattern as sketched in **Figure 60.10**.

Seismic codes contain limited recommendations for deep foundations during earthquakes. For simplified soil–structure interaction analyses, the formulae for calculation of values of the dynamic stiffness and damping coefficients of individual

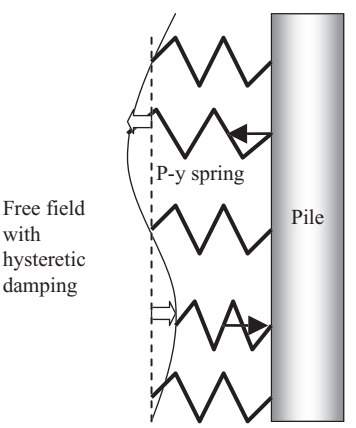

Figure 60.9 Sketch of the horizontal P-y springs and their connections with the free field boundary and a pile

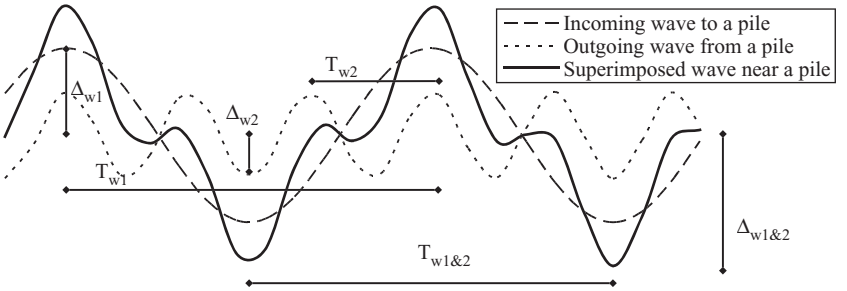

Figure 60.10 Sketch of superposition of wave amplitudes near a pile due to different vibration properties of the adjacent ground and piles

piles are tabulated in relevant textbooks (e.g. Gazetas, 1991) for different variations of soil stiffness modulus with depth.

Recently, Srbulov (2011) used simple engineering beam theory for analyses of inertial and kinematic interaction for 11 case histories of piled foundations subjected to earthquakes.

If large lateral ground displacement occurs in the post-seismic stage then the effect of lateral forces imposed on piles can be analysed using the methods described in Chapter 57 *Global ground movements and effects on piles*.

60.3.7 Risk reduction measures

Risk reduction measures are dependent on the cause of risk. When foundation response is a source of hazard, in competent ground but during strong earthquakes, then the increase in number, depth or diameter of piles can be helpful. The use of raking piles to support horizontal load is still debatable because some inclined piles behaved very well and the others failed during earthquakes. If brittle failure of concrete piles represents risk then the use of reinforcement along full pile length and addition of a steel sleeve provides the desirable ductility of the foundation. On the other hand, concrete infill prevents buckling of steel pipe piles during strong ground motion. When behaviour of weak ground is a source of hazard then the following measures can be considered:

- Slope stabilisation methods are described in Chapter 72 *Slope stabilisation methods.*
- When the amount of fines does not exceed about 20%, stone columns are efficiently used for increase of ground density, permeability and shear strength, which all decrease the potential of soil liquefaction.
- Ground drains and trenches can be used for speeding up the dissipation of excess pore water pressure. Ground drains may become clogged in time by siltation, when groundwater level varies, and by bacteria and algae growth.
- Soil mixing with binders can be used for the increase in stiffness of soil and decrease of amplitudes of its vibration when vibration and lateral deformations caused by stone column installation are not acceptable and when the spacing is limited, such as among existing piles and anchors (e.g. Kramer, 1996; Port and Harbour Research Institute, 1997). More details on ground improvement are provided in Chapters 59 *Design principles for ground improvement* and 84 *Ground improvement*.

60.4 Offshore foundation design

60.4.1 Typical condition and wave loading

Wave heights are determined from meteorological observations at sites of interest. The periods of sea waves range from about 2 to 27 s (e.g. Poulos, 1988b) and therefore the inertia forces arising from wave load are not significant but the effects of cyclic loads are significant and the equivalent static analyses, which are usually performed, need to consider soil properties in cyclic condition. An exception is pile driving, which can induce peak pile accelerations greater than 10 g although during a period of a millisecond. Detailed description of pile drivability analyses is provided by Dean (2009). The number of hammer blow counts from drivability analyses is used to calculate fatigue damage to pile steel and remaining useful lives in years based on so-called S-N curves (e.g. Offshore Technology Report, 2001; API RP 2A-WSD, 2007). The effect of cyclic wave loading on fatigue damage to pile steel is also considered using S–N curves. Other dynamic loads offshore involve debris flow, fast spreads, underwater avalanches and seaquakes which can be analysed using the methods applied to onshore events (e.g. Srbulov, 2008).

For most offshore foundations, the allowable deformations are relatively large, and usually the critical design criterion is an acceptable factor of safety against collapse under a severe storm event.

60.4.2 Soil behaviour

Soil behaviour in cyclic condition is described in Chapter 24 *Dynamic and seismic loading of soils*. Offshore marine clays can have very soft consistency or be underconsolidated and prone to cyclic degradation. Specific ground types encountered offshore are calcareous sand and corals. Calcareous sand has fragile grains that are crushed under impact load (e.g. Kolk, 2000) and can exhibit very small shear resistance, like very soft clay. Coral structure may be collapsible because of the presence of cemented skeletons and numerous voids between the parts of skeletons (e.g. Touma and Sadiq, 1999). Global and local scour could reach significant depths offshore in loose top sand. Local scour causes gapping, which can significantly decrease the lateral pile resistance and affect vibration period

 ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

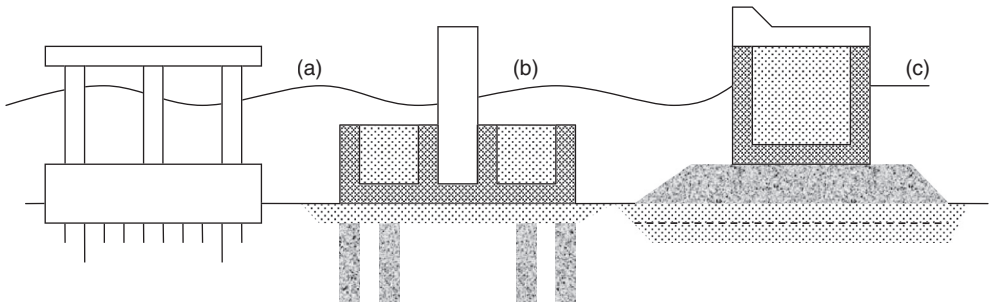

Figure 60.11 Sketches of (a) foundation with skirts and dowels under a gravity platform, (b) foundation of a pylon of a wind turbine with stone columns for ground improvement, (c) caisson breakwater on rubble mound over reinforced sand layer

(frequency). For this reason scour protection is often used. Global scour decreases vertical effective stress around piles. Even submerged, soil offshore may be partially saturated due to presence of natural gas.

60.4.3 Shallow foundations

Typical foundation types are shown schematically in **Figure 60.11**.

A number of recommendations exist for design of offshore shallow foundations such as: API RP 2A-WSD (2007), DNV-OS-J101 (2007), DNV classification notes 30.4 (1992), De Groot *et al*. (1996), BS 6349-7:2010 and others. The issues concerning shallow foundations onshore, which are described in Chapter 53 *Shallow foundations*, are also relevant for offshore foundations.

As noted earlier, the soil shear strength and stiffness used for design must allow for degradation due to cyclic loading (**Figure 60.12**). Another common feature of offshore design are the high horizontal loads, which need to be resisted (due to large waves during storm events). Hence, the correction for inclined loads and load eccentricity become significant (refer to Chapters 21 *Bearing capacity theory* and 53 *Shallow foundations*). Modern developments in bearing capacity theory, using V-H-M failure envelopes have been stimulated by the inadequacies of conventional theory (with its plethora of correction factors) for offshore design requirements. Offshore foundations are often very large and issues such as soil layering, stress level (for coarse-grained soil) and strength variations with depth (for fine-grained soil) can be important.

Besides ground-bearing capacity at the ultimate limit state, foundation settlement in the serviceability limit state needs to be considered. A large number of cycles generated during storms induce excess pore water pressures in the ground under shallow foundation. Dissipation of such pressure causes additional settlement in loose to medium dense sandy soils and soft clay/silts. The additional settlement may affect connecting tubes between an offshore structure and fluid exporting pipelines if such settlement has not been considered in design. The design considerations frequently lead to recommendations for ground improvement, which are sketched in **Figure 60.11(b)** and **(c)**.

60.4.4 Deep foundations

Typical deep foundations offshore are shown in **Figure 60.13**.

Offshore foundations typically need to resist larger loads (especially horizontal), and relatively large cyclic loads, than onshore foundations and the methods of construction (e.g. installation of caisson using suction) will usually be quite different. However, in other respects the general design principles for offshore foundations are similar to deep foundations onshore. Modern mono-piles that are used for offshore wind farms are several metres in diameter and have mass of several hundred tons. As mentioned before for the shallow foundations offshore, it is important to consider the effect of cyclic loads on soil properties but not inertia forces for the periods of vibrations of a few seconds. Dean (2009) describes in detail the foundations, methods for their design and installation, applicable codes and available literature. A number of recommendations exist for design of offshore deep foundations such as: API RP 2A-WSD (2007), DNV-OS-J101 (2007), SNAME TR-5A (2002) and others.

Cyclic wave loading during storms causes degradation of ground shear strength and stiffness, which in turn cause decrease of pile shaft friction and increase of lateral deformation of piles. The degradation of shaft resistance under axial loading is a function of the cyclic displacement and the number of load cycles. A cyclic stability diagram is an important concept (Poulos, 1988a), and three main regions need to be identified: a cyclically stable region; a cyclically metastable region (in which cyclic axial loading causes a reduction of shaft capacity, but the pile does not fail within the specified number of cycles); and a cyclically unstable region, in which cyclic loading leads to failure within the specified number of axial load cycles. Randolph (1983) has provided guidance on the boundary between stable and metastable regions. Reduced soil shear strength and the use of P–y curves in cyclic conditions are often used in order to account for lateral load effect, although several important phenomena are still the subject of ongoing research.

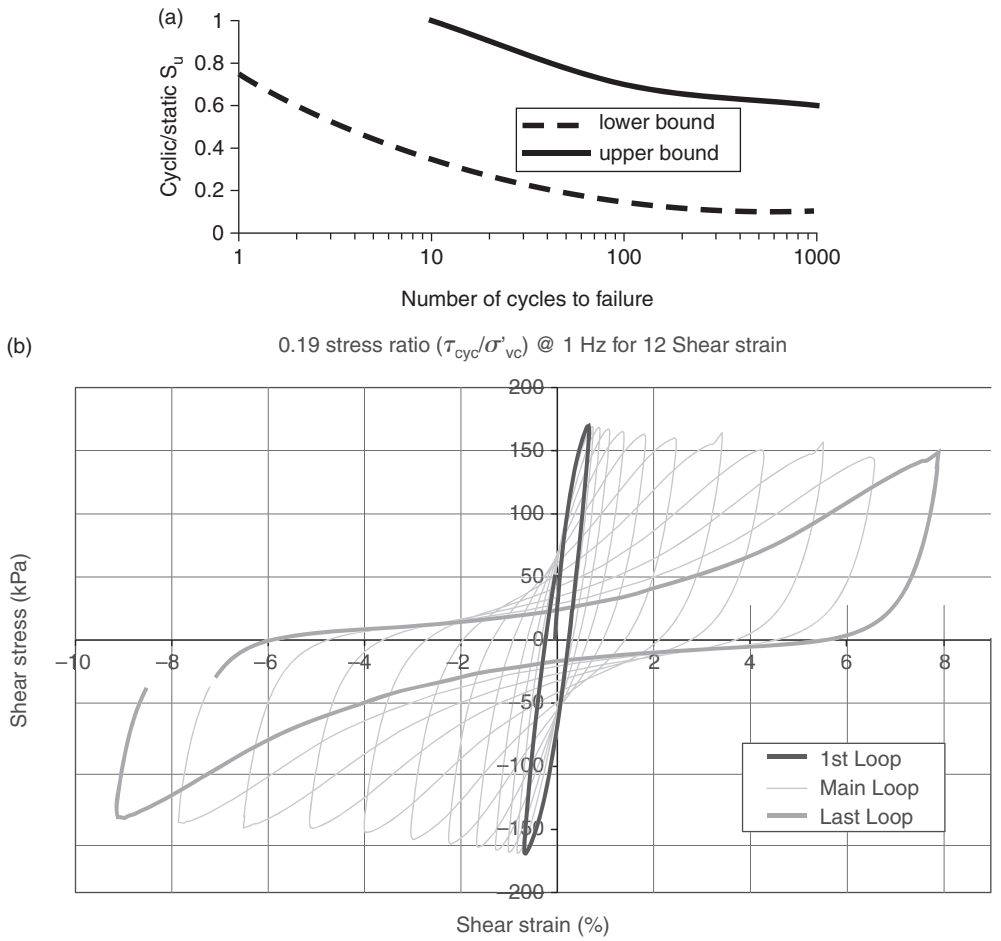

Figure 60.12 Effects of number of cycles on (a) ratio of cyclic to static undrained shear strength Su of clays (from data by Lee and Focht, 1976), (b) degradation of stiffness (ratio between shear stress and strain) of a non-plastic silt specimen in a cyclic simple shear test

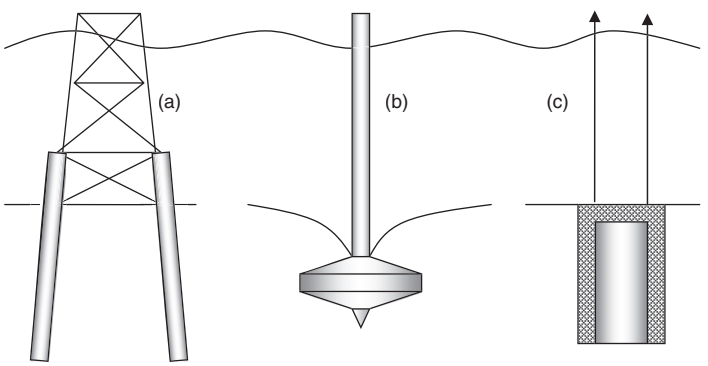

Figure 60.13 Sketches of (a) piled foundation of a jacket,(b) spud-can foundation of a jack-up (mobile platform), (c) caisson foundation of a tension leg or a deep water anchor

60.5 Machine foundations

Machine foundations are typically subjected to a large number of loading cycles with relatively small amplitudes. The operational conditions given below are an example of the requirements specified by the manufacturer of a particular machine:

- large compressor (MAN) foundation velocity < 2.8 mm/s in operational condition and < 6 mm/s in accidental case between frequencies from 25 to 190Hz;
- gas turbine (EGT) foundation velocity < 2 mm/s and where a peak to peak amplitude of any part of the foundation is less than 50 μm at the operating frequency of 250 Hz.

The specified frequency (i.e. its range) must be avoided in order to avoid resonance effects between the machinery and its foundation, which will damage the machine unless it has been switched off. The vibration resonance is indicated as the increase in vibration amplitude ratio at resonant frequency in **Figure 60.14** for harmonic vibration (e.g. Clough and Penzien, 1993), where $\beta_t = f_d/f_o$ is the tuning ratio, f_d is the frequency of machine vibration, f_o is the frequency of foundation free vibration, ξ is the damping ratio, a_o is the acceleration amplitude of foundation, and a_i is the acceleration amplitude of machine vibration.

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

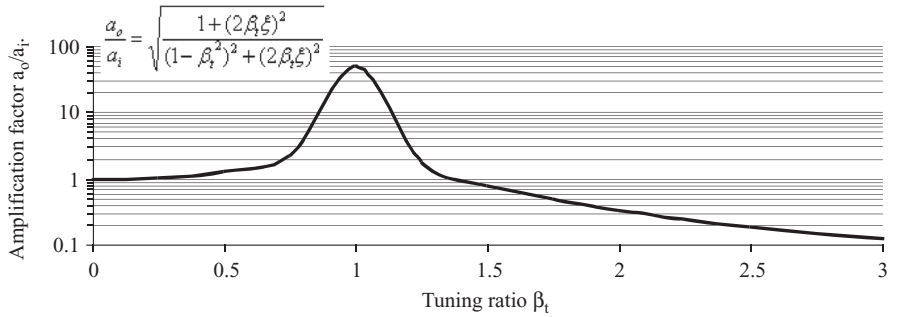

Figure 60.14 Amplification factor for a harmonic vibration with 1% damping ratio

Vibration type	Slender and potentially sensitive masonry walls	Propped or tied walls or mass gravity walls
Intermittent vibration	10@the toe 40@the crest	50% to 100% greater than for slender and potentially sensitive masonry walls
Continuous vibration	1.5 to 2.5 times smaller than the intermittent vibration limits	

Table 60.2 Threshold peak particle velocities in mm/s for minor or cosmetic damage according to BS 5228-2:2009

Foundations can be subjected to vibration with the origin located at a distance. For example, BS 5228-2:2009 (BSI, 2009) specifies the limits of peak particle velocities to which retaining walls are allowed to be subjected for minor or cosmetic damage (**Table 60.2**). The same limits are applicable to foundations.

Machine-induced vibrations usually only cause very small strains in the ground and therefore elastic soil properties are used for dynamic analyses. Also, soil damping ratio is small, in the order of 1%. The energy dissipation is mainly achieved by radiation damping.

Vertical vibration of machine foundations is usually considered separately from the horizontal and rocking vibrations, which are coupled. The basic equation of foundation motion arises from Newton's second law.

$$m \cdot a + c \cdot v + k \cdot d = F \cdot \sin(2 \cdot \pi \cdot f \cdot t). \quad (60.3)$$

In the above equation, m is foundation and machine mass, a is acceleration of foundation, c is damping coefficient (which is frequency dependent value), $c = \xi k/(\pi f)$, ξ is damping ratio (about 0.01), f is vibration frequency, v is velocity of foundation, k is stiffness coefficient, d is displacement of foundation, F is maximum amplitude of dynamic unbalanced force, and t is time. The formulae for calculation of values of the dynamic stiffness k and damping coefficients c are tabulated in relevant textbooks (e.g. Gazetas, 1991; Wolf, 1994). The formulae are provided for homogeneous soil and a soil layer over bedrock and should not be used for layered soil. If foundation vibration is considered excessive according to the requirements set by the manufacturer then foundation vibration isolation can be used. Recently, Srbulov (2010) performed simplified numerical analysis of the response of a rubber bearings isolated foundation block under a compressor in Holland.

The horizontal motion is coupled with the rotational motion, which equation is:

$$I_a \cdot \theta_a + c_\theta \cdot \theta_v + k_\theta \cdot \theta - e \cdot (c \cdot v + k \cdot d) = M \cdot \sin(2 \cdot \pi \cdot f \cdot t). \quad (60.4)$$

In the above equation, I is foundation and machine mass moment of inertia with respect to the centre of the masses, θ_a is rotational acceleration, c_θ is rotation damping coefficient, θ_v is rotational velocity, k_θ is rotational stiffness coefficient, θ is rotation of foundation, e is the eccentricity of the base of foundation with respect to the centre of mass of foundation and machine, and M is the maximum amplitude of rotational moment from unbalanced force with respect to the centre of mass of foundation and machine. The formulae for calculation of values of the rotational stiffness k_θ and damping coefficients c_θ are tabulated in relevant textbooks (e.g. Gazetas, 1991; Wolf, 1994).

Simple guidance exists for determination of minimum foundation mass for vibration control (e.g. Anyaegbunam, 2011). Older publications contain examples of foundation vibration analyses by hand calculations (e.g. Irish and Walker, 1969), which may be used for rough check of results of modern numerical analyses by computers. CP 2012-1 (1974) exists for foundations for reciprocating machinery, which generates biharmonic loads (e.g. steam engines, internal combustion engines, piston-type compressors and pumps), with normal rotational frequency range from 5 to 25 Hz and is relevant for machines placed on a rigid block. DIN 4024-1 (1988) & 2 (1991) contain useful recommendations. A frequently cited book is Richart *et al*. (1970). Not only theoretical but also experimental methods have been used for analyses of foundation vibration.

It is recommended this chapter is read in conjunction with

- Chapter 24 *Dynamic and seismic loading of soils*
- Chapter 45 *Geophysical exploration and remote sensing*

All chapters in this book rely on the guidance in Sections 1 *Context* and 2 *Fundamental principles*. A sound knowledge of ground investigation is required for all geotechnical works, as set out in Section 4 *Site investigation*.

Section 6: Design of retaining structures

Section editor: **Asim Gaba**

doi: 10.1680/moge.57098.0957

Chapter 61

Introduction to Section 6

Asim Gaba Arup Geotechnics, London, UK

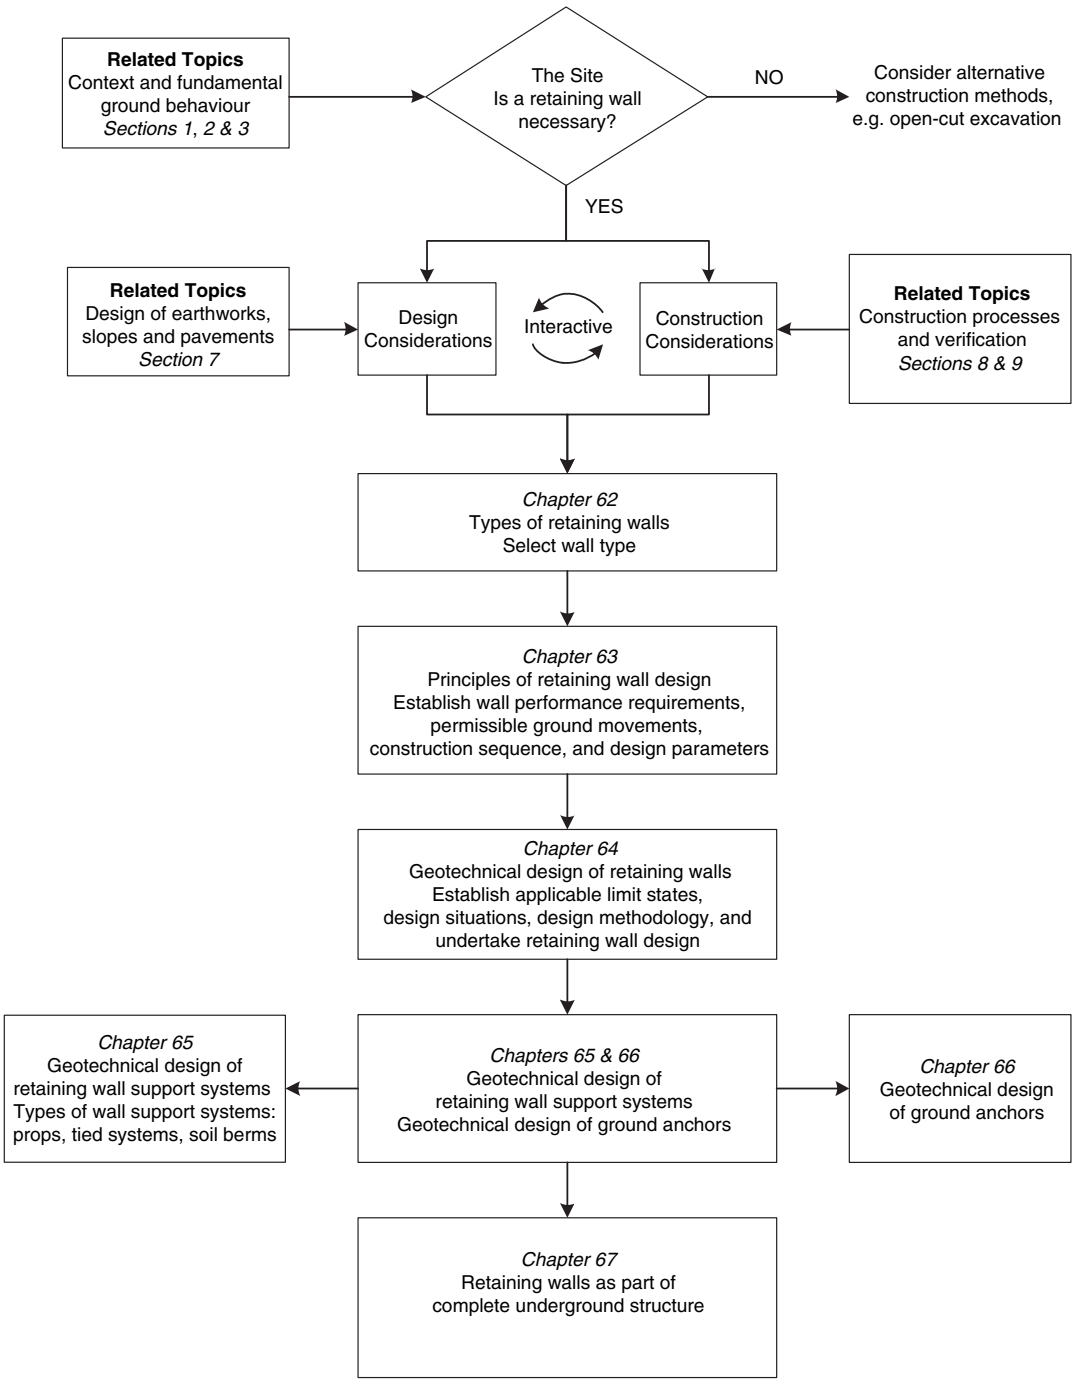

Figure 61.1 Relationships between the chapters in Section 6

Retaining walls are typically used to retain the ground at a steeper angle than that which can be sustained by the ground acting unsupported on its own. Common applications vary from modest terracing of sloping ground to perimeter walls for multi-storey basements and underground structures.

Retaining walls are usually divided into two broad categories: 'gravity' retaining walls and 'embedded' retaining walls and this distinction is also made in this Section. However, there is a third category – 'hybrid' walls – these have their own particular characteristics and their design may demand an approach that requires consideration and assessment of both gravity and embedded wall behaviour. An example of a hybrid wall would be a gravity wall supported partially by piles embedded into the ground beneath the gravity structure.

In common with other sections of this manual, this section is intended to provide guidance to practising engineers on the design of retaining walls. Given the considerable breadth of the subject and the vast range of ground conditions which a retaining wall designer may encounter, this section cannot, within the available space, be completely comprehensive. The intent is therefore to provide outline guidance to designers on:

- considerations of wall performance criteria, wall selection, construction methods and associated ground movements;
- fundamental principles of good design practice in relation to the selection, design and construction of retaining walls and their support systems;
- key mechanisms of ground and ground–structure interaction behaviour, which need to be considered;
- commonly used design methods for gravity and embedded retaining walls and their support systems;
- additional references for detailed study.

Figure 61.1 shows the relationships between the chapters in Section 6.

The chapters are arranged in a sequence to guide the reader in following a systematic approach in considering and dealing with the key issues that relate to the design of retaining walls, recognising that retaining walls may form part of an overall structure. It is important not to lose sight of the fact that the client's priority is the entire structure and not just the retaining walls.

Chapter 62 *Types of retaining walls* identifies different types of retaining wall along with the particular characteristics of each. The advantages and limitations of each wall type are compared and guidance is provided on the selection of the most appropriate wall type to satisfy the particular site and project requirements.

Chapter 63 *Principles of retaining wall design* provides guidance on the determination of key wall performance and design criteria, setting permissible limits for the associated ground movements and identifying the appropriate construction sequence for particular applications. The chapter also provides guidance on the assessment of drained and undrained ground behaviour and the selection of parameters appropriate for temporary and permanent works design.

Chapter 64 *Geotechnical design of retaining walls* offers good practice guidance on the geotechnical design of retaining walls. Using the approach outlined in this chapter, the reader will be able to size retaining walls to ensure adequate stability and calculate load effects to be used in the structural design of walls.

Chapters 65 *Geotechnical design of retaining wall support systems* and 66 *Geotechnical design of ground anchors* give the reader an overview of a wide range of different methods of providing lateral support to both gravity and embedded retaining walls for temporary and permanent situations. Chapter 65 provides guidance on the appropriate selection and design of propping systems and berms for the lateral support of a wall. Chapter 66 is a complementary and comprehensive chapter that deals with the design of ground anchors for the support of retaining walls and should be read in conjunction with Chapters 74 *Design of soil nails*, 88 *Soil nailing construction* and 89 *Ground anchors construction* of this manual.

Chapter 67 *Retaining walls as part of complete underground structure* deals with the situation where the retaining walls are part of an overall structure. It provides holistic considerations of the ground–structure interaction, retaining wall water tightness requirements and the importance of communications between the retaining wall designer and other design and construction professionals.

Following this theme, it is important to recognise that a retaining wall designer cannot function in isolation of others. To overcome the potential fragmentation of design and construction that can accompany the process of retaining wall design, it is important that the designer considers all parts of the construction sequence and, in doing so, communicates effectively with other complementary design and construction professionals. The client, designer and constructor and, where appropriate, the architect and the quantity surveyor, should be involved as early as possible to:

- optimise the temporary and permanent use of a retaining structure (such as adopting one wall instead of two to serve both the temporary and permanent requirements), which is also compatible with long-term maintenance requirements;
- establish appropriate design and performance criteria for the retaining structure, such as acceptable limits for wall deflection and associated ground movement;
- consider an appropriate wall type;
- consider an appropriate method and sequence of construction to ensure buildability.

Initial ideas should be reviewed and alternatives explored before agreeing the preferred solution. It is important to involve individuals with appropriate expertise and experience at all stages of the project to maintain adequate continuity and communication between the personnel involved in data collection, design and construction.

The term retaining wall applies to structures that retain the ground at a steeper angle than the ground can sustain acting on its own. Common applications vary in scope from modest terracing of sloping landscaping to perimeter walls for multi-storey basements and underground spaces. Several different forms of retaining wall exist with different performance characteristics in terms of water retention, strength and stiffness, as well as constructability characteristics such as land-take and requirements for specialist plant and equipment. The different characteristics of retaining walls must be fully appreciated as part of the process of selecting a wall for a particular application.

This introductory chapter to Section 6 identifies the different forms of retaining wall along with their particular characteristics.

62.1 Introduction

Retaining walls exist in many shapes and forms but can be considered in terms of three different groups:

- gravity walls;
- embedded walls;
- hybrid walls.

These are discussed in detail below.

62.2 Gravity walls

A gravity wall gains resistance to sliding and overturning through the weight of the wall and friction on its underside. Gravity walls are generally constructed on a flat surface prior to backfilling behind the wall to create the height difference that the wall retains. As such they are commonly used where the ground profile is being raised locally, e.g. to retain a highway or railway embankment.

Gravity walls can also be used to support excavations below ground level. For these scenarios the excavation is typically an open-cut and backfill is provided behind the wall. This requires additional excavation and backfilling as well as temporary land-take during construction.

Drainage provision in the form of interceptor drains behind the wall is a common feature of gravity walls in order to reduce the water-pressure load acting on the wall.

Key references for gravity retaining walls include:

- CIRIA C516 (Chapman *et al.*, 2000) – Section 2 and Section 4 mostly;
- BS8002 (BSI, 1994) – Section 4;
- Eurocode EC7 (BSI, 2004).

62.2.1 Modular and non-modular walls

Modular walls may be constructed using a wide variety of techniques and materials. They share the common feature that their construction involves the erection of a number of mainly similar modular elements.

Examples of modular walls include:

- pre-cast reinforced-concrete stem walls;
- masonry walls;
- dry stack masonry walls (e.g. porcupine walls);
- crib walls;
- gabion walls.

For modular walls, the modules are constructed off-site and can be assembled on site with a minimum of specialist site operations. In contrast, non-modular walls are predominantly constructed on site, e.g. *in situ* reinforced-concrete walls. As such they require a greater level of site activity and more significant specialist activities such as shuttering, steel fixing and *in situ* concreting.

62.2.2 Reinforced-concrete stem walls

Reinforced-concrete stem walls are constructed from *in situ* or pre-cast reinforced concrete. The walls are L-shaped or inverted T-shaped walls where the concrete stem cantilevers from the wall base to support the retained material behind the wall. A shear key may be used to increase the shear resistance; see **Figure 62.1**. The walls are not reliable as water-retaining structures and, therefore, are usually designed and constructed with suitable drainage behind the wall to limit the build-up of water at the back of the wall.

Pre-cast walls are typically from 1 m to 3 m in height.

62.2.3 Masonry walls

Masonry walls are made with brick, block, natural or manufactured stone, conventionally bedded with mortar and founded on mass or reinforced-concrete foundations; see **Figure 62.2**.

The walls should be provided with a coping layer to avoid water saturation and possible frost damage. Details for the use of copings, drainage, damp-proof courses and waterproofing to prevent saturation of the wall and improve durability are given in BS 5628 Part 3 (BSI, 2001). The walls should be constructed

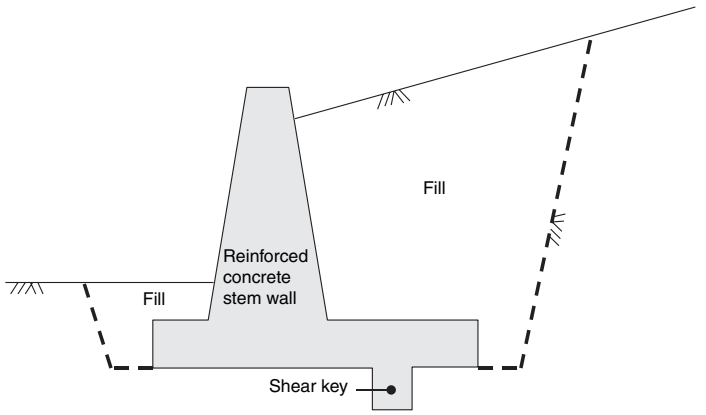

Figure 62.1 T-shaped reinforced-concrete stem wall with shear key

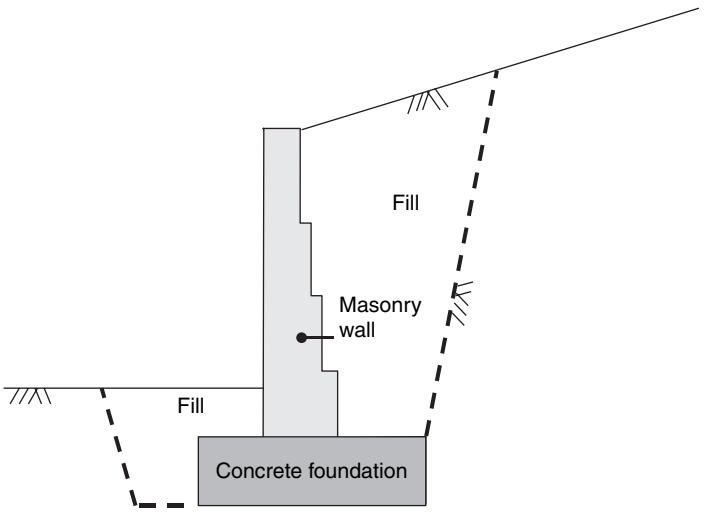

Figure 62.2 Typical masonry wall

in panels, up to 10 to 15 m in length, with movement joints at the ends.

62.2.4 Dry-stack masonry walls

Dry-stack masonry walls consist mainly of pre-cast concrete special blocks and occasionally bricks that are designed to interlock with each other and produce a solid wall face; see **Figure 62.3**. A dry-stack wall relies upon gravity to support the retained material and will have an interlock shear resistance between each layer of blocks. The presence of the interlock assists with the accurate placing of successive layers of blocks.

The wall foundations may be mass, reinforced or possibly pre-cast concrete with interlocks compatible with the wall units.

Most of the walls are relatively free draining, but some may require granular backfill material and a drain to avoid the build-up of water behind the wall.

The walls can be constructed vertically but are typically inclined or battered to provide better stability for greater

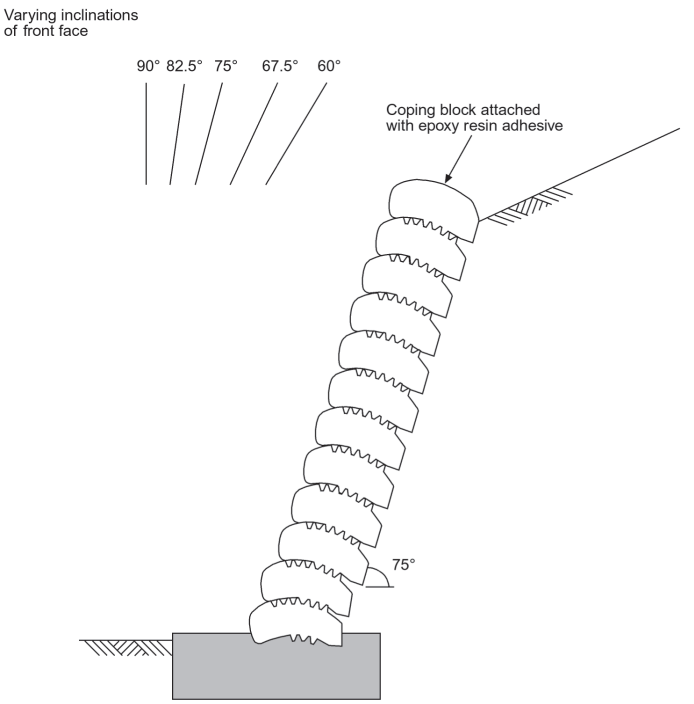

Figure 62.3 Porcupine wall: typical single-width dry-stack masonry wall

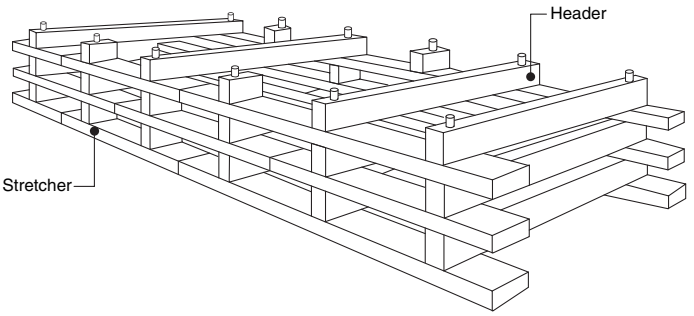
heights. The coping blocks at the top of the wall, often attached to the rest of the wall with adhesive, are to prevent damage to the wall through vandalism.

62.2.5 Crib walls

Crib walls comprise a grillage of header and stretcher units placed on firm foundations, usually of mass or reinforced concrete. The header and stretcher elements may be made of reinforced concrete or timber and are designed to be interlocking, to give the wall continuity. Walls can be made with single or multiple rows of cribs at the base with single rows used for low walls and multiple rows for higher walls. See **Figure 62.4**.



The spaces between the crib grillages are filled with a free-draining, non-aggressive coarse granular material. The spaces can also be filled with lean-mix concrete making it more akin to a masonry wall.

Even without interceptor drains, the open structure of the granular fill can allow water to flow through the wall. Interceptor drains behind the wall will be required with a lean-mix concrete fill to prevent the build-up of water behind the wall.

Crib walls are often laid to a batter, an angle corresponding to 1 horizontal to 12 vertical is typical; however, for shorter walls, generally less than 2 m, the walls are sometimes built with a vertical face provided their width exceeds their height.

62.2.6 Gabion walls

Gabion walls are free-draining walls constructed by filling rectangular mesh cages with broken stone. The cages are made

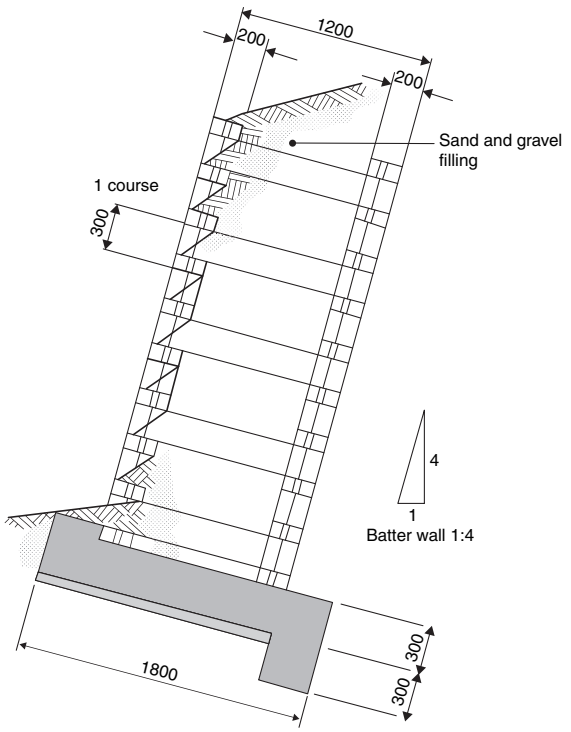


Figure 62.4 Crib wall
Reproduced with permission from CIRIA C516, Chapman *et al.* (2000), www.ciria.org

from sheet mesh strips or woven wires. Differing degrees of corrosion resistance of the steel mesh can be provided by galvanising (zinc or zinc–aluminium coating) or coating with a bonded plastic, thermoplastic or epoxy resin polymer coating. They are placed side by side and laced together in a stepped course to form a gravity structure; see **Figure 62.5**. The walls are typically constructed with either a front stepped face or a back stepped face to incline the wall by at least 6°–8° from the vertical toward the retained material.

The walls are typically constructed in 0.5 m to 1.0 m heights, corresponding to the standard size of gabion-basket units. Two forms of cage are common, basket and mattress. Mattress cages tend to be long in relation to the height and are often used as a lower level to a gabion wall.

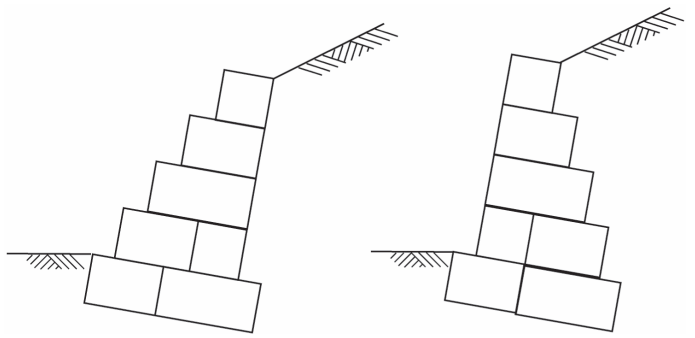

Figure 62.5 Gabion wall
Reproduced with permission from CIRIA C516, Chapman *et al.* (2000), www.ciria.org

The flexibility of gabion walls makes them more suitable where the sub-grade soil is poor, as the walls can accommodate larger total and differential settlements than other wall types.

The permeability of the walls also makes them well suited to saturated conditions such as near to rivers. In such conditions, the grading of the fill behind the wall and in the wall needs to be carefully chosen so that the fines in the fill are not washed out by flowing water.

A variation of the gabion wall is a bastion. Bastion walls are collapsible wire or geotextile mesh multicellular structure systems, which are designed for rapid erection from a flat-pack delivery. When assembled, the bastion forms a series of individual cells, which are lined with a non-woven geotextile. The cells are filled with granular material, e.g. sand, ballast, earth, stone or concrete. They are most often used for emergency works such as flood protection.

To be used for permanent works, measures need to be incorporated to prevent the loss of fill material through the mesh and the use of a facing to protect any geotextile mesh against ultraviolet degradation.

62.2.7 Reinforced soil

Reinforced soil can be considered as a gravity wall. In contrast to the gravity walls described above, the gravity structure is provided by reinforcing the ground itself rather than providing a separate structure; see **Figure 62.6**.

Reinforced soil walls are described in Chapters 63 *Principles of retaining wall design* and 73 *Design of soil reinforced slopes and structures.*

62.3 Embedded walls

An embedded retaining wall penetrates into the ground at its base to gain lateral support from the passive resistance of the ground in front of the lower part of the wall. This resistance may be used as a sole resistance to provide stability for the wall or may act in conjunction with anchorages, props or other sources of lateral support for stability; see **Figure 62.7**.

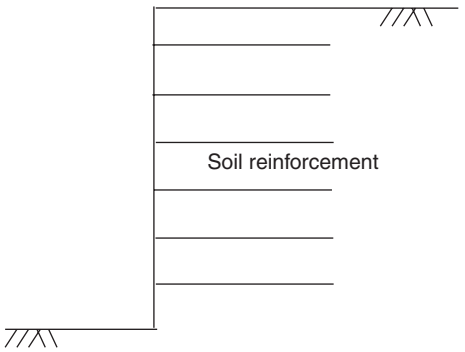

Figure 62.6 Reinforced soil wall

Embedded retaining walls are often used in conjunction with lateral support. Methods of lateral support are described in Chapter 65 *Geotechnical design of retaining wall support systems*.

In contrast to gravity walls, embedded walls require specialist plant and operations on site. Embedded walls are often adopted in preference to gravity walls when:

- deep excavations are required;
- temporary land-take is not available for a temporary open-cut excavation;
- buildings or other structures are in close proximity to the excavation and need to be supported or protected;
- high groundwater conditions require excessive dewatering for a temporary open-cut excavation.

Key references for embedded retaining walls include:

- CIRIA C580 (Gaba *et al*., 2003) – Section 3.2 and Appendix D mostly;
- BS8002 (BSI, 1994) – Section 4;
- *Piling Handbook*, 8th edition (ArcelorMittal, 2008);
- *Steel Intensive Basements*, SCI Publication P275 (Yandzio and Biddle, 2001).

62.3.1 Sheet pile walls

The key references for sheet pile walls are the *Piling Handbook* (ArcelorMittal, 2008) and *Steel Intensive Basements* (Yandzio and Biddle, 2001).

Steel sheet pile walls are constructed by driving, vibrating or pressing steel sheets into the ground without any material being removed. They are traditionally installed by means of driving methods using heavy hammers, which can result in significant noise and vibration that are often unacceptable in urban locations.

Sheet pile walls can be installed in the majority of soils. However, they can be unsuited to ground conditions with hard inclusions such as boulders or man-made obstructions, as these can lead to refusal of the pile driving or pushing. Pre-boring for the sheet piles or jetting along the toe of the sheet pile during installation may improve the penetration of sheet piles; however, these methods are often associated with additional settlement.

There are a number of standard shape profiles for sheet piles as shown in **Figure 62.8**. These can be combined together or with circular or beam steel sections to create a number of sheet pile combinations with improved strength and stiffness performance. A selection of these combinations is shown in **Figure 62.9**.

If seepage through the sheet pile interlock is controlled, a sheet pile wall can be used for water-retaining applications. Sealing systems include non-swelling sealants, hydrophilic (water-swelling) sealants, combination systems and welding of the interlocks. Details of typical construction processes are provided in Section 8.

Advantages of sheet pile walls include:

- provides an economic wall with a predictable surface finish;
- no arisings;
- suitable as water-retaining walls;
- can be used as both a temporary and permanent wall.

Reproduced with permission from ArcelorMittal (2008); all rights reserved

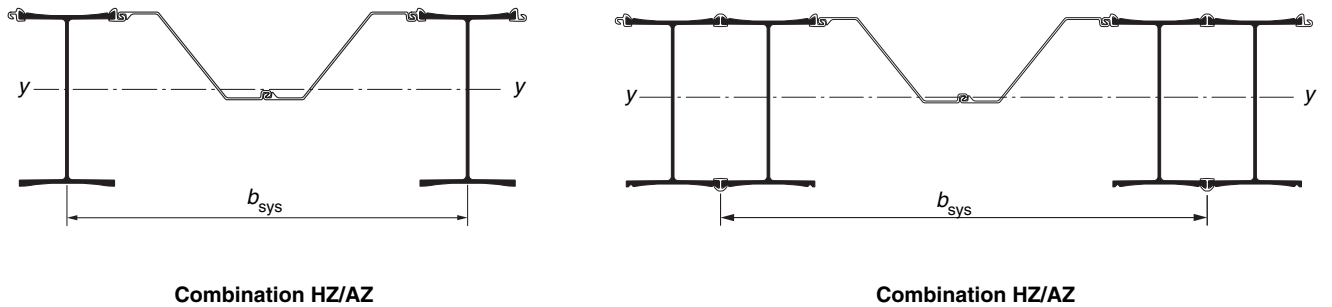

Figure 62.9 Sheet pile combinations
Reproduced with permission from ArcelorMittal (2008); all rights reserved

Disadvantages of sheet pile walls include:

- maximum pile length approximately 30 m;
- corrosion can lead to a reduced section size;
- potential declutching in coarse-grained soils or in hard driving conditions.

62.3.2 King post walls

King post walls are also known as soldier piles with lagging or Berlin walls.

Isolated steel beams or posts are installed along the line of the wall either driven into position or placed in bored cast-in-place piles. As the excavation proceeds the space between the posts is filled using either timber railway sleepers, pre-cast concrete elements, *in situ* or spray concrete. As such, the wall is not suitable for excavation below the water table in coarse-grained soils without significant dewatering outside of the excavation. The posts are typically spaced 1 to 3 m apart and can be varied, making it easier to layout the wall to avoid localised obstructions. See **Figure 62.10**.

Propped excavations up to 20 m can be achieved; however, shallower depths of excavation are common due to the requirements for groundwater control.

62.3.3 Contiguous bored pile walls

A contiguous pile wall consists of bored cast-in-place piles installed along the line of the wall. The piles are installed with a

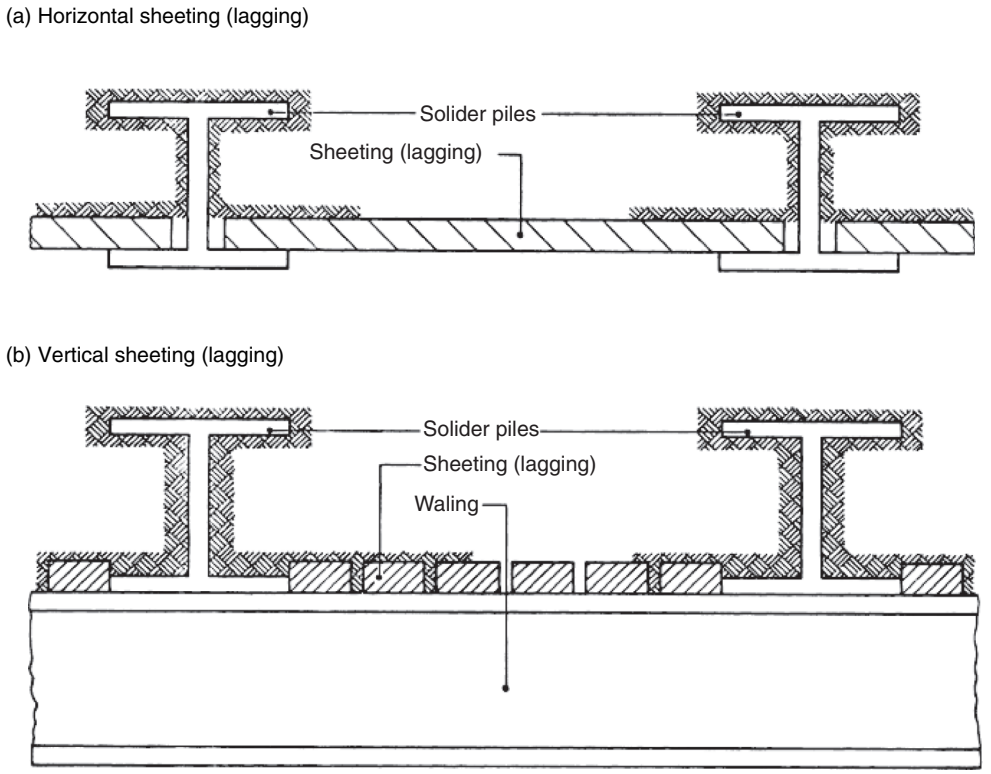

Figure 62.10 Soldier pile wall
Reproduced with permission from BS8002 © British Standards Institute (BSI, 1994)

gap between individual piles. The size of the gap is chosen on the basis of the site dimensions and also the particular ground conditions but is typically 50 mm to 150 mm; see **Figure 62.11.**

The piles can be installed as either continuous flight augur (CFA) or traditional bored piles using casings where required. The choice of pile type will depend on the ground conditions and depth of the wall. Details of the design and construction of piles are provided in Sections 5 and 8.

Due to the gap between individual piles, the wall is not water retaining and is, therefore, not suited to construction below the water table in coarse-grained ground conditions. Traditional bored piles with thick-walled casings may be required to overcome harder strata and obstructions.

Contiguous piled walls cannot be used as a permanent wall due to the gaps between individual piles; however, they can be made into a permanent solution through the use of a structural facing wall.

For CFA piles, the depth of retaining wall will be limited by the maximum depth of the CFA piles (refer to Section 8). Propped excavations up to 20 m can be achieved using contiguous pile walls.

62.3.4 Secant bored pile walls

A secant pile wall consists of intersecting bored cast-in-place piles installed along the line of the wall; see **Figure 62.12**. The pile construction may either use traditional piling rigs or CFA rigs. Refer to Chapters 79 *Sequencing of geotechnical works*, 81 *Types of bearing piles* and 82 *Piling problems* for more details on piling methods.

The female piles are installed first followed by the male piles, which cut through the female piles during installation. This overlap or secanting of individual piles provides a barrier to groundwater flow across the wall. The male piles are constructed with full strength reinforcement and provide the structural strength of the wall.

Three varieties of secant pile wall can be considered and are defined by the strength of the female piles as follows:

- hard/soft – a soft pile mix, typically cement and bentonite or bentonite and sand with a characteristic compressive strength of 1–3 N/mm^2;
- hard/firm – a 'firm' mix, with a characteristic compressive strength of 10–20 N/mm^2, and a retardant to reduce the strength of the piles during the drilling of the male piles;
- hard/hard – a full strength concrete, which can also be reinforced; see **Figure 62.13**.

The size of the piles is based on standard pile diameters.

The size of the overlap and pile spacing is chosen on the basis of the site dimensions and consideration of the installation tolerance of the piles and the depth of overlap or secanting required.

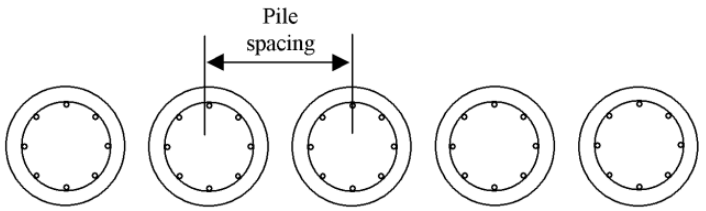

Figure 62.11 Contiguous pile wall
Reproduced with permission from CIRIA C508, Gaba *et al.* (2003), www.ciria.org

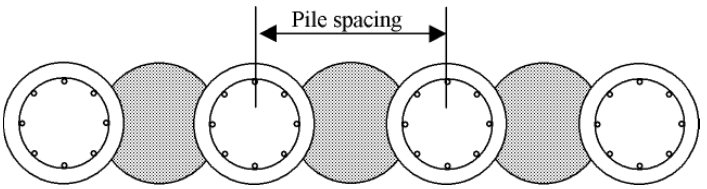

Figure 62.12 Hard/soft or firm secant pile wall
Reproduced with permission from CIRIA C508, Gaba *et al.* (2003), www.ciria.org

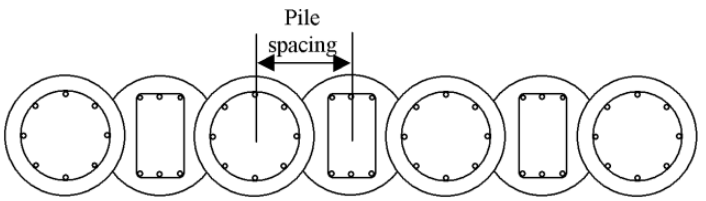

Figure 62.13 Hard/hard secant pile wall
Reproduced with permission from CIRIA C508, Gaba *et al.* (2003), www.ciria.org

The hard/soft wall is not a preferred solution for permanent water-retaining walls due to shrinkage and cracking of the soft pile mix. To create permanent water retention a structural internal lining wall can be cast against the face of the wall.

For hard/firm and hard/hard basement walls, the need for an additional facing wall, e.g. a drained cavity and blockwork wall, will depend on the basement grade that is specified (refer to BS8102 (BSI, 2009)).

As a water-retaining wall, secant pile walls are suitable for permeable ground conditions where excavation is to extend below the water table. They are also suited to coarse-grained materials above the water table where the gaps in a contiguous piled wall could result in a loss of fines from the material retained behind the wall. Where permeable ground conditions are present above low permeability strata, e.g. gravels above clay, the female piles may be terminated with only limited penetration into the clays with the male piles extending lower to form a contiguous wall within the clays.

Secant pile walls are suitable for most ground conditions.

For CFA piles, the depth of the retaining wall will be limited by the maximum depth of the CFA piles (refer to Section 8). The maximum depth of a secant wall may be dominated by the installation tolerance of the wall and, therefore, the depth at which effective overlap of the piles can be achieved to provide a barrier to groundwater flow. Propped excavations up to 20 m can be achieved or up to 25 m for cased hard/hard solutions.

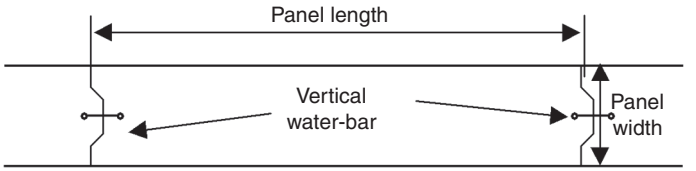

Figure 62.14 Diaphragm wall panel and joint
Reproduced with permission from CIRIA C508, Gaba *et al.* (2003), www.ciria.org

62.3.5 Diaphragm walls

Diaphragm walls are interlocking reinforced-concrete panels; see **Figure 62.14**.

The panels are formed by excavation under fluid to support the surrounding ground and lowering a prefabricated reinforcement cage into the trench excavation. Concreting is undertaken from the base of the pile using a tremie tube to displace the support fluid. Due to the requirements for a support fluid and the large volume of individual panels, diaphragm wall construction requires a larger laydown construction space than other forms of wall construction.

Panel widths and lengths are a function of the construction equipment available. Typical widths are 600, 800, 1000, 1200 or 1500 mm, which corresponds to the width of the grab or cutter used to form the hole. The typical grab length is 2.8 m but may be reduced to 2.2 m. The lengths are a function of the number of bites used to form the panel; see **Table 62.1**. For larger panel lengths, the ability of the support fluid to act in conjunction with the ground to arch around the large excavation to maintain a stable excavation should be considered.

Diaphragm walls are suitable for most ground conditions.

The depth of the wall is limited by the reach of the excavation machinery. Walls have been constructed to depths of up to 120 m; however, at this depth stringent installation tolerances are needed to provide an effective overlap of the panel width to the full depth of the walls. For such deep panels, detailed planning is required in relation to the practical difficulties of splicing cage sections together; the crane capacity to lift the cage; and the overall construction duration for the panels.

Due to the size of the individual panels, diaphragm walls are less flexible in dealing with any changes in the alignment of the wall and are, therefore, more suited to long straight walls as opposed to more complicated or changing geometries.

Water-bars constructed across the joints between individual panels make a diaphragm wall into a water-retaining wall.

Diaphragm walls are also known as slurry walls; however, care should be taken with this terminology as in the UK a slurry wall is an unreinforced wall used as a cut-off or containment wall rather than an embedded retaining wall.

Number of bites	Panel length, m Minimum	Maximum	Excavation sequence
1	W	W	1
2	W + T	2 x W – T	1 2
3	2 x W + T	3 x W – 2 x T	1 3 2

Notes:
1. W is the grab length available (typically 2.8 m).
2. T is the grab width: 600, 800, 1000, 1200 or 1500 mm.

Table 62.1 Diaphragm wall: typical panel widths
Data taken from CIRIA C580, Gaba *et al.* (2003), www.ciria.org

Variations can include:

- T-shaped panels for increased strength and stiffness;
- post-tensioned panels;
- pre-cast panels, with or without pre-tensioning.

Pre-cast panels are constructed by lowering the panel into the support fluid filled trench and sealed into the ground with *in situ* concrete or grout placed by means of a tremie pipe. The size of the panels for pre-cast walls is limited practically by the ability to lift the panels and place them into the trench.

62.4 Hybrid walls

Hybrid walls combine aspects of gravity and embedded elements to retain the ground. An example of a hybrid gravity wall is a concrete stem wall, L-shaped or T-shaped, founded on individual piles; see **Figure 62.15**. Such a hybrid solution is suited to circumstances where there is insufficient sliding or bearing capacity for a gravity wall but sufficient capacity can be achieved using piled foundations for the wall.

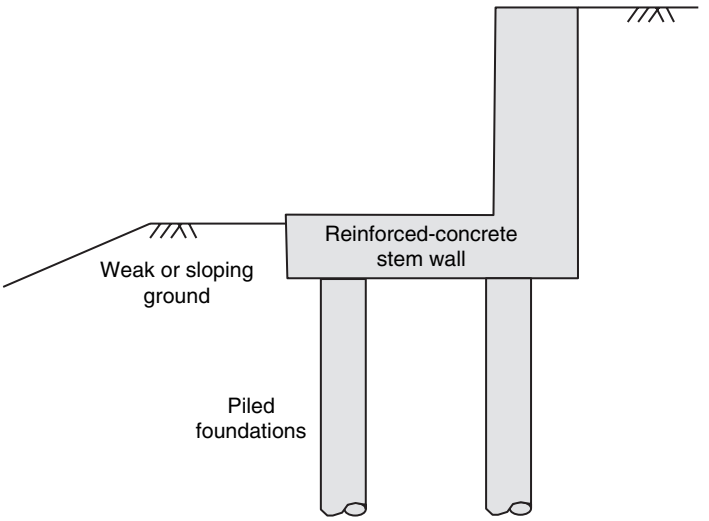

Figure 62.15 Example of a hybrid retaining wall

62.5 Comparison of walls

A comparison of the advantages and disadvantages of the different retaining wall types is given in **Table 62.2**. Chapter 63 *Principles of retaining wall design* gives further information on factors affecting the choice of retaining wall types.

Wall type	Advantages	Disadvantages
Gravity walls – general	■ Minimises construction activities on site by using pre-cast or modular systems ■ Cost-effective retaining wall solution for supporting raised ground levels	■ Requires site dewatering for construction below the water table ■ Requires temporary open-cut excavation for retaining wall construction below existing ground level
Pre-cast reinforced-concrete stem walls	■ Provides a wall with a predictable surface finish	■ Height of wall may be limited practically by transporting and lifting requirements. 1 to 3 m typical retained height ■ Changes in retained height or plan alignment need to be planned in detail for prefabrication of units ■ Non-draining, appropriate drainage required
Masonry walls	■ Can provide a wall with a predictable surface finish ■ Can be installed around obstructions at isolated points ■ Can be built to a batter	■ Construction requires bricklaying skills ■ Foundation slab required ■ Non draining, appropriate drainage required
Dry-stack masonry walls	■ Simple manual construction ■ Distinctive course effect ■ May be used with planting ■ Can produce curves in plan	■ Foundation slab required ■ Non draining, appropriate drainage required
Crib walls	■ Simple manual construction ■ Distinctive 'honeycomb' appearance ■ May be used with planting ■ Can produce curves in plan	■ Foundation slab required ■ Free draining although back drain may also be required ■ Backfill in compacted layers

Table 62.2 Comparison of retaining walls
Reproduced with permission from Gaba *et al.* (2003) and Chapman *et al.* (2000)

Wall type	Advantages	Disadvantages
Gabion walls	■ Simple construction ■ Foundation slab may not be required ■ Fully draining, no back drain required unless they are filled with non-draining materials ■ Can be used with planting ■ Can produce curves in plan	■ A flexible system which can result in an undulating wall profile
Embedded retaining walls – general	■ Minimise volume of excavation ■ Enable deep excavation adjacent to existing structures and utilities ■ Enable deep excavation below the water table (water-retaining embedded walls only)	■ Specialised construction plant and operation on site ■ Costly in comparison with open-cut construction methods
Sheet pile walls	■ Provides an economic embedded wall with a predictable surface finish ■ No arisings to be removed ■ Suitable as a water-retaining wall ■ Can be used as both a temporary and a permanent wall	■ Maximum pile length approximately 30 m ■ Potential declutching in coarse-grained soils
King post walls	■ Can be installed around obstructions at isolated points	■ Not suitable for retaining water in the long term ■ Cannot be used for excavation below the groundwater table in coarse-grained soils
Contiguous bored pile walls	■ The cheapest form of concrete piled wall	■ Not a water-retaining solution ■ Not a permanent solution in any soil due to the gaps between piles, unless a structural facing is applied
Hard/soft secant bored pile walls	■ Acts as a water-retaining temporary wall ■ The use of soft piles enables hard piles to be formed using lower-torque rigs than for hard/hard secant piles	■ Not usually a permanent solution for retaining water ■ The soft pile mix is not significantly cheaper than concrete. Local concrete plant is often unable to batch the soft material, so site batching is required ■ Depth is limited by the verticality tolerance, which may determine the depth of secanting
Hard/firm secant bored pile walls	■ A permanent water-retaining wall ■ The firm material for the primary (female) piles is either a standard concrete mix, retarded to reduce its strength when the secondary (male) piles are constructed or a reduced strength concrete mix	■ Depth is limited by the verticality tolerance, which may determine the depth of secanting
Hard/hard secant bored pile walls	■ A permanent water-retaining wall ■ Installed using standard piling plant with high-torque rigs	■ The cutting of the hard primary (female) piles requires high-torque rigs or oscillators ■ Depth is limited by the verticality tolerance, which may determine the depth of secanting
Diaphragm walls	■ A permanent water-retaining wall ■ Can be installed to great depths provided the verticality tolerances can be accepted ■ In some circumstances the face of the diaphragm wall can form the final finish subject to some surface cleaning and removal of protuberances ■ Fewer joints compared with piled walls	■ Horizontal continuity is difficult to achieve between panels ■ Cannot follow intricate plan outlines ■ The installation equipment is extensive, requiring a large site area for accommodation of the support fluid plant, reinforcement cages and the excavation plant ■ Disposal of the support fluid is costly
Hybrid walls	■ Provide a practical retaining wall solution where the site conditions will not allow a gravity wall but do not require an embedded retaining wall	■ Combination of different wall and foundation elements results in site- and solution-specific wall type

Chapter 63
Principles of retaining wall design

Michael Devriendt Arup, London, UK

CONTENTS

63.1	Introduction	969
63.2	Design concepts	969
63.3	Selection of design parameters	973
63.4	Ground movements and their prediction	977
63.5	Principles of building damage assessment	979
63.6	References	980

Prior to carrying out the design of a retaining wall, basic concepts relating to the principles of design should be understood by the designer. Considerations such as the characterisation of the wall, the construction sequence to form the retaining wall, performance criteria and the selection of an appropriate wall type should be understood. Following this appreciation of basic concepts, it is common for a designer to select design parameters for analysis in accordance with appropriate standards. The designer should also understand serviceability issues relating to the magnitude of ground movements and the potential for damage to nearby structures.

This chapter provides the reader with a basic understanding of the above conceptual issues relating to the design of retaining walls and provides references to other material where more detailed descriptions may be found.

63.1 Introduction

This chapter provides a description of the basic concepts that govern retaining wall design. The concepts described should be appreciated by designers before carrying out the design of a wall as outlined in Chapters 64 *Geotechnical design of retaining walls* to 67 *Retaining walls as part of complete underground structure*. This chapter, therefore, serves as a basis for describing many of the conceptual issues that need to be addressed when planning the design of a retaining wall.

63.2 Design concepts

63.2.1 Geotechnical characterisation of retaining walls

When designing a retaining structure, it is important to understand how the retaining wall can be characterised. As described in Chapter 62 *Types of retaining walls*, retaining structures can broadly be considered to be characterised as gravity or embedded walls or a combination of both. Methods of analysis of the wall types are given in Chapters 64 *Geotechnical design of retaining walls* to 67 *Retaining walls as part of complete underground structure*.

For analysis or back analysis of a retaining structure it is fundamental to obtain an understanding of ground and groundwater conditions. The use of soil parameters and adopting different groundwater conditions in design is discussed in greater detail later in this chapter and in Chapters 64 *Geotechnical design of retaining walls* to 67 *Retaining walls as part of complete underground structure*.

63.2.2 Construction sequence

63.2.2.1 General

The construction sequence that is followed to construct a retaining wall can have a significant effect on the design, cost and time spent constructing the wall. This section discusses the conceptual decisions that influence the selection of an appropriate construction sequence.

63.2.2.2 Design

Displacement of the retaining wall influences the *in situ* stress state in the ground around the retaining wall. Earth pressure theory was introduced in Chapter 20 *Earth pressure theory*. During installation of the wall and as displacement of the wall occurs, earth pressures will change from an *in situ* Ko condition to active and passive states depending on whether relaxation or compression of the soil occurs behind or in front of the wall respectively. Further information relating to earth pressure theory may be found in Chapter 20 *Earth pressure theory*.

Figure 63.1 illustrates this concept of the amount of displacement (or strain) governing the stress state on the active

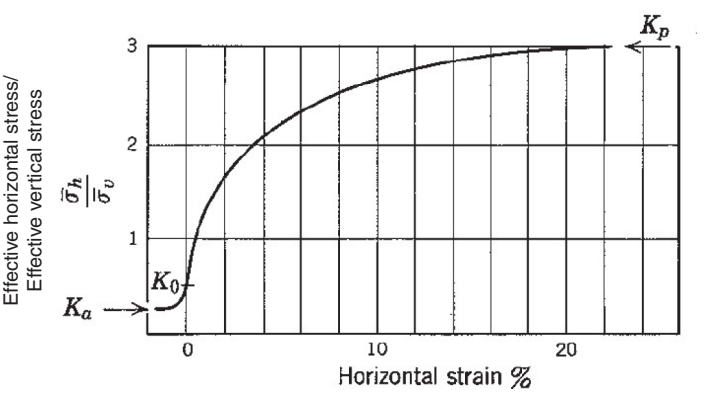

Figure 63.1 Relationship between earth pressure and horizontal strain by Terzhagi (1954) for normally consolidated sand (different scales for active and passive)

Reproduced from Simpson (1992), all rights reserved

and passive sides of the wall. An active state (K_a) is reached at relatively small strain, while larger strains are required to reach a passive state (K_p). The earth pressures in front or behind a retaining structure will influence the bending moment, shear forces and any prop forces supporting the wall. The construction sequence that is followed can also influence the displacement of a retaining structure and, therefore, affect the design of the retaining structure.

To appreciate the differences caused by construction sequence, an analysis that considers staged construction is necessary (i.e. the limit equilibrium method of analysis described in Chapter 64 *Geotechnical design of retaining walls* is not suitable). The use of more complex analysis methods such as pseudo and full finite element or finite difference programs are required to accommodate the effects of construction sequence. The use of such programs is discussed in Chapter 6 *Computer analysis principles in geotechnical engineering* and their use for retaining wall design in particular is also covered in Chapters 64 *Geotechnical design of retaining walls* to 67 *Retaining walls as part of complete underground structure*.

Displacements of the wall and those caused from construction of the wall itself will influence ground movements around the retaining wall. This is discussed in further detail in section 63.3.

63.2.2.3 Basement construction

The excavation of basements, particularly in confined urban sites, is a situation where the construction sequence has a significant impact on the successful outcome of the project. In particular, careful consideration of the construction sequence is required where there is an existing basement that occupies the site and the retention of existing basement retaining walls is necessary.

63.2.2.4 Top-down and bottom-up

Where retaining walls are used for excavation of basements and confined spaces such as station box structures, two generic forms of construction sequence are commonly used to form the basement space: 'top-down' and 'bottom-up'. Variants of these generic sequences are also commonly adopted to suit particular site constraints.

Top-down sequences involve constructing sequential permanent basement slabs to support the retaining walls as the excavation progresses. Bottom-up sequences use temporary propping to support the basement space during the excavation, then construct the permanent basement slabs after the excavation is complete.

The two generic sequences are compared in **Table 63.1** through reference to some common considerations. Photographs of construction carried out in top-down and bottom-up sequences are shown in **Figures 63.2** and **63.3**.

The construction sequence followed can have a significant effect on the programme and the cost of the proposed development. In particular, the programme for development in urban sites can have an effect on the overall successful completion of a project. The effect of delay on costs is discussed in greater detail in Chapter 7 *Geotechnical risks and their context for the whole project*.

63.2.3 Design requirements and performance criteria

63.2.3.1 General

Prior to the design of a retaining structure, the designer must first gather the generic performance criteria for the structure. The performance criteria may vary depending on the requirements of the structure during its design life (for instance, taking into account that vertical loading will be applied to the retaining structure at some time in the future).

63.2.3.2 Design life

The design life of a structure may influence several issues relating to the design of a retaining wall.

The forces exerted on a retaining wall may also be influenced by variable loads such as wave or seismic loading. The magnitude of these forces is commonly related to a return period and probabilistic approach of exceedance for a given structural design life; refer to Eurocode 8 Parts 1 (BSI, 2004b) and 5 (BSI, 2004c) and BS6349 Parts 1 (BSI, 2000) and 2 (1988) (BSI,

Property	Top-down	Bottom-up
Construction of superstructure	Allows concurrent construction of basement and superstructure	Generally basement must be constructed prior to construction of superstructure
Bearing piles used to support superstructure within plan area of basement space	Piles installed with low cut off and columns plunged into piles	Piles can be installed before or after basement excavation. If before excavation, the use of plunged tubes for reception of columns may be necessary
Spoil removal	Spoil needs to be removed from moling hole in slab	Allows 'clear space' excavation of spoil generally allowing quicker excavation of spoil provided lorry movements at surface aren't restricted
Ground movements	Generally a greater stiffness basement space is created, therefore, minimising ground movements	Temporary propping tends to be less stiff than permanent propping resulting in greater movements; however, this can be mitigated by using additional temporary propping

Table 63.1 Top-down and bottom-up considerations

2000) on how to select return periods. The proposed design life of a structure can influence the return period that is considered in the design and, therefore, the magnitude of loads. In particular, for the design of retaining walls in seismic regions the size of the active and passive zones may be affected by the effect of seismic loading. Consequently the positions of any tie backs should be reviewed with respect to the seismic design.

The integrity of the overall structural form of the retaining wall and structural support also needs to be considered. Where a structure is exposed to adverse conditions (for instance sheet piles exposed to corrosion in a saline environment) the reduction in thickness of section needs to be accounted for in the design – see the *Piling Handbook* (ArcelorMittal, 2008).

63.2.3.3 Temporary and permanent works

The responsibility for design of the permanent and temporary works is often split between companies or groups of designers. As identified in section 63.2.2, the construction sequence that is followed can have a significant effect on the design of the retaining wall. It is, therefore, important that the temporary and permanent works designers share design input information and the construction sequence that each respective designer anticipates is clear. In particular consideration to respective prop and retaining wall properties and wall stiffness parameters should be considered. An analysis should be carried out to check the entire sequence (both temporary and permanent works).

63.2.3.4 Drained or undrained

When determining whether drained or undrained soil conditions apply, account should be taken of the rapidity with which drained conditions are achieved. For fully saturated soil, undrained conditions are characterised by there being no changes in volume, although a change in shape can occur. It is possible for such conditions to prevail in the short term in low-permeability soils such as high-plasticity sedimentary clays where excess water pressure dissipates slowly and suction is generated, by loading and unloading, respectively. The detailed fabric of the soil dominates the magnitude of the water pressure at equilibrium. The importance of obtaining an accurate record and gaining a good understanding of the soil fabric cannot be over-emphasised (refer to Chapters 13 *The ground profile and its genesis* to 15 *Groundwater profiles and effective stresses* and 46 *Ground exploration*).

Stiff overconsolidated clays are generally jointed, fissured and layered as a result of their depositional history. Although the permeability of the clay between the joints and discontinuities may be low, the presence of small sandy or silty partings can have a disproportionate effect on the magnitude of the coefficient of permeability of the soil. This influences the rate at which water may flow from one part of the soil mass to another and the rate at which water may be drawn into the soil. To assess whether undrained conditions are likely to prevail for a significant time the following factors should be considered:

- Soil stratigraphy and fabric. There is usually no dilation of pre-sheared surfaces, which means that shearing can occur at constant volume under drained residual conditions. This should not be confused with undrained behaviour.
- The mass *in situ* permeability of the soil (in the vertical and horizontal directions).
- The proximity and likelihood of available water.
- The soil stiffness, which affects the value of the coefficient of consolidation, c_v. This might be particularly high following a change in the direction of the stress path.
- Previous experience of construction in similar ground conditions.

The designer should evaluate drainage paths and assess the duration over which drained conditions may be restored.

As a general guide, undrained conditions may be assumed in the short term where the mass *in situ* permeability of the ground is low (i.e. a coefficient of permeability of the order of 10^{-8} m/s or less; see BS 8002 (BSI, 1994)). Where the mass permeability is not low and in coarse-grained soils, drained conditions should be assumed in design.

63.2.3.5 Cycling of loads on integral bridges

For the design of bridges, it is common to have an earth-retaining structure forming part of the bridge abutment supporting either side of the bridge deck; see **Figure 63.4**. To avoid the use of bearings to support the deck structure, which can reduce long-term maintenance costs, it is common to make the abutment integral with the deck (an integral bridge).

For integral bridges, temperature variations will induce cyclic movement of the abutments and the soil retained behind them. The effect of these cyclic movements on the earth pressure influences the design of the retaining wall. In addition, in granular soils, the cyclic behaviour may result in settlement occurring behind the retaining wall. This may have an effect on the design of the road or railway approach structure to the bridge.

Various design approaches have been proposed to account for the increased earth pressures due to cyclic loading; see, for instance, the UK's Highways Agency document, BA42/96 (1996). An appraisal of design approaches is given by Lehane (2006) through reference to centrifuge laboratory model testing.

63.2.3.6 Performance criteria for horizontal and vertical support

Although the primary function of a retaining wall is, in many instances, to provide lateral support and retention of the ground and groundwater, some retaining walls, particularly those used for basement construction, may also be required to provide vertical support. For these scenarios both the allowable vertical

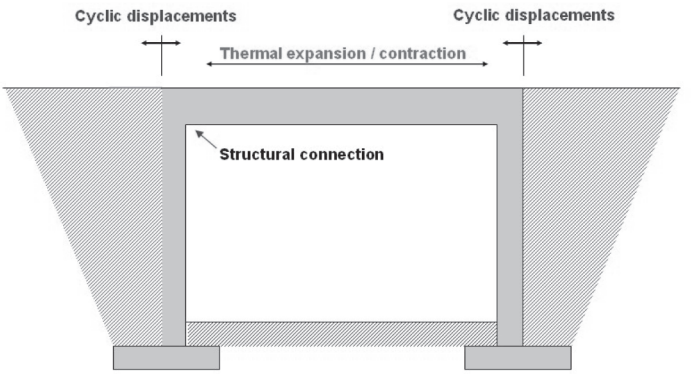

Figure 63.4 Schematic of integral bridge

Factor	Description or comment
Availability of space around perimeter of site for retaining wall construction	Where there is a space constraint and the client wants to build up to the property boundary an embedded retaining wall is generally favourable over a gravity wall. The thickness of an embedded retaining wall section is also a consideration. Greater thickness walls generally increase stiffness and reduce movement; however, they will take up more space.
Unsupported height of retaining wall	Where large unsupported heights of a retaining wall are desirable, generally a thicker retaining wall section will be required to have sufficient moment capacity and limit displacements of the wall to acceptable magnitudes.
Water retention	The permeability of the ground and requirements for the basement space influence the selection of wall. Generally, the fewer the connections in the wall, the lower the leakage rate and the greater the water retention. Improved long-term basement space may be obtained by using drained cavities or inner lining walls. Guidance on how to achieve watertightness requirements for bored piles, diaphragm walls and sheet pile walls is provided in CIRIA Report 139 (Johnson, 1995) and BS 8102 (BSI, 1990).
Stiffness	Higher system stiffness (i.e. the wall and its support system) leads to reduced wall and ground movement. This is achieved by increasing the thickness of the wall or increasing the number of props or ties supporting the wall.
Cost	Cost savings may be obtained where continuous support is not required for the purpose of water retention (for instance, selection of a contiguous bored pile wall rather than a secant wall). The relative costs of materials (for instance steel for sheet piles) will also fluctuate with time.
Programme	Similar to the cost section above, savings in the programme can be made if contiguous bored pile walls are feasible rather than a secant wall. Savings can also be made by reducing the overlap for secant walls or increasing the diameter of the piles (therefore, reducing the number of piles to install).
Design life	The design life of a retaining wall is a primary consideration where the imposed forces on a retaining wall are governed by design life (for instance seismic or wave loading) or where the wall degrades or corrodes with time (for instance sheet piling in a maritime environment).
Embodied energy	The total energy used in forming the retaining wall. Further details of these considerations are given in Chapter 11.

Table 63.2 Factors influencing the selection of retaining walls

ICE Manual of Geotechnical Engineering © 2012 Institution of Civil Engineers

and horizontal displacement should be considered. Further discussion regarding the design for horizontal loading is given in Chapter 64 *Geotechnical design of retaining walls* and for designing for vertical loading in Chapter 67 *Retaining walls as part of complete underground structure*.

63.2.3.7 Design of retaining structures in a marine environment

Further consideration, when designing structures in a marine environment, are the effects of tide levels, swell, storm surge, wave impact loads and sea level rise over the design life of the retaining structure. By considering these effects, overtopping of the retaining wall can be minimised. Allowance should also be made for the water level difference between the active and passive sides of the retaining wall. BS6349 Parts 1 (2000) and 2 (1988) (BSI, 2000) should be referred to for further guidance on appropriate considerations for design in a marine environment.

63.2.4 Consideration for wall selection

Chapter 62 *Types of retaining walls* describes the main types of retaining wall that are commonly constructed to retain soil and groundwater.

Table 63.2 provides a summary of the factors that influence the selection of retaining walls.

63.3 Selection of design parameters

63.3.1 Design philosophy and approach (limit states, moderately conservative, most probable)

63.3.1.1 Limit states

For the design of retaining walls, appropriate soil and groundwater parameters need to be selected for the calculations. The objective of design calculations is to demonstrate that a limit state will not be exceeded. Various limit states are generally considered. Current guidance (BS EN 1997–1:2004: Eurocode 7, BSI, 2004a) identifies that a designer must check that ultimate, serviceability or accidental limit states are not exceeded.

A serviceability limit state (SLS) defines the limit of satisfactory functioning of the structure or structural members under normal use, the comfort of those affected by the design and the appearance of the construction works. Exceedance of a serviceability limit state will typically result in inconvenience, disappointment and less manageable costs.

An ultimate limit state (ULS) is breached where one or more of the following occurs:

- loss of equilibrium of the structure or any part of it considered as a rigid body;
- failure by excessive deformation or transformation;
- deformation resulting in a mechanism or rupture;
- loss of stability of the structure or any part of it, including supports and foundations;
- failure caused by fatigue or other time-dependent effects.

Exceedance of an ultimate limit state will result in serious failure involving risk of injury or major cost. An appropriate design must render this very unlikely or make this an 'unrealistic' possibility.

63.3.1.2 Selection of characteristic soil parameters

The zone of ground governing the behaviour of a geotechnical structure at a limit state is much larger than a test sample or the zone of ground affected in an *in situ* test. Consequently the value of the governing parameter often requires careful consideration of a range of values covering a large surface or volume of the ground.

The characteristic value should be a cautious estimate. Therefore, the selection of the characteristic value should be more conservative than selecting a most probable value.

If statistical methods are employed in the selection of characteristic values for ground properties, the methods used should differentiate between local and regional sampling and should also consider any experience in using comparable ground properties. If statistical methods are used, for the limit state the characteristic value is calculated so that the probability of a worse value is not greater than 5%.Under certain circumstances the use of statistical methods may not be appropriate: an example is given in Case Study 1.

All the geotechnical expertise of the designer is incorporated in the assessment of the characteristic values of ground properties.

Reference should be made to Chapters 17 *Strength and deformation behaviour of soils* and 27 *Geotechnical parameters and safety factors* for further discussion on the selection of design parameters.

Examples of the selection of characteristic soil parameters are given in Simpson and Driscoll (1998) *Eurocode 7 – A Commentary*. An extract from this document including an example is provided in Case Study 1.

63.3.2 Case Study 1

Figure 63.5(a) shows the results of a series of undrained shear strength measurements in London Clay. The measurements were made using unconsolidated undrained triaxial tests. A statistical mean line has been drawn through the data and it is clear that undrained strength increases with depth. A characteristic line is required and this should depend on how the characteristic values will be used – what is the limit mode being considered? For example, if the undrained strength is needed for the calculation of ground movements around a retaining wall, a value such as the 'cautious (average)' value on the figure could be used. However, for a problem in which failure might take place in a small zone of soil, such as an isolated foundation placed at deep level, a more cautious value – the 'cautious (local)' value – should be adopted. From these boreholes, results from standard penetration tests were also available, as shown in **Figure 63.5(b)**. In London Clay, there is usually a constant factor between standard penetration and undrained shear strength results; the factor is about 4.5 to 5. However,
