Four uncommon histologic variants of basal cell carcinoma have been described: an adamantinoid type, a granular type, a clear cell type, and a type with matricial differentiation. *Adamantinoid basal cell carcinoma* shows a great histologic resemblance to dental ameloblastoma or adamantinoma (447). One observes solid masses of basaloid cells with palisading at the periphery. Inside this layer, the cells show elongated nuclei and stellate cytoplasm stretched as thin, connecting bridges across empty spaces, as seen in adamantinoma. In *granular basal cell carcinoma,* some of the tumor cells have the usual appearance of basaloid cells, whereas others show a gradual transition to granular cells. The granular cells show in their cytoplasm numerous eosinophilic granules with a tendency to coalesce (448,449). The eosinophilic lysosome-like granules greatly resemble those seen in granular cell tumor (see Chapter 35). In the *clear cell basal cell carcinoma,* the clear cell pattern may occupy all or part of the tumor islands. The clear cells contain vacuoles of different sizes filled with glycogen (450). The vacuoles often cause peripheral displacement of the nucleus, giving the cells a signet ring appearance (451). In *basal cell carcinoma with matricial differentiation,* islands of shadow cells, as seen in pilomatricoma, are located within a basal cell carcinoma (452).

Although about 75% of basal cell carcinomas are found on staining with dopa to contain melanocytes and melanin is present in about 25% of them (453), large amounts of melanin are encountered only rarely (Fig. 29-91). The melanin is produced by benign melanocytes that colonize the tumor. These tumors are called *pigmented basal cell carcinomas.*

Superficial basal cell carcinoma shows buds and irregular proliferations of tumor tissue attached to the undersurface of the epidermis (Figs. 29-71 and 29-72). The peripheral cell layer of the tumor formations often shows palisading. In most cases, there is little penetration into the dermis. The overlying epidermis usually shows atrophy. Fibroblasts, often in a fairly large number, are arranged around the tumor cell proliferations. In addition, a mild or moderate amount of a nonspecific chronic inflammatory infiltrate is present in the upper dermis.

In *fibroepithelioma,* first described by Pinkus in 1953 (420), long, thin, branching, anastomosing strands of basal cell carcinoma are embedded in a fibrous stroma (Figs. 29-87 and 29-88). Many of the strands show connections with the surface epidermis. Here and there, small groups of dark-staining cells showing a palisade arrangement of the peripheral cell layer may be seen along the epithelial strands, like buds on a branch. Usually, the tumor is quite superficial and is well demarcated at its lower border. Fibroepithelioma combines features of the intracanalicular fibroadenoma of the breast, the reticulated type of seborrheic keratosis, and superficial basal cell carcinoma (420). Fibroepithelioma can change into an invasive and ulcerating basal cell carcinoma (453).

The multiple basal cell carcinomas seen in the *nevoid basal cell carcinoma syndrome* present no features that distinguish them from ordinary basal cell carcinoma, even while they are still in the early nevoid stage and have not yet become invasive and destructive, as they may be later in the neoplastic stage (454). All of the diverse features of basal cell carcinoma, such as solid, adenoid, cystic, keratotic, superficial, and fibrosing formations, can be seen in the lesions of the nevoid basal cell carcinoma syndrome (455). Usually, a histologic distinction between the nevoid basal cell carcinoma syndrome and typical trichoepithelioma is easy because keratotic cysts are more prominent in the latter. However, some lesions of trichoepithelioma show relatively few horn cysts. A histologic distinction in such cases may be impossible (456), and clinical data will be necessary (see Chapter 30).

The palmar and plantar pits are a result of the premature desquamation of most of the horny layer (457). On histologic examination, the epidermal rete ridges beneath the pits are found to be crowded with cells resembling those of basal cell carcinoma. Overlying these rete ridges is a markedly thinned granular layer topped by a very thin layer of loose keratin (406). In some patients, the pits actually show the presence of small basal cell carcinomas at their base (458). In rare instances, one or several clinically visible basal cell carcinomas arise on the palms or soles in patients with palmar and plantar pits (457,459,460).

The jaw cysts represent odontogenic keratocysts. They are lined by a festooned epithelium consisting of two to five layers of squamous cells that form keratin without the presence of a granular cell layer (461). Each jaw cyst may consist of either one large cyst or multiple microcysts (455). Some of the

cutaneous cysts, instead of being epidermal cysts, have the appearance of the jaw cysts and are similar to those cysts seen in steatocystoma multiplex but without showing sebaceous lobules (461).

The basal cell carcinomas in *linear unilateral basal cell nevus* have a variable histologic appearance. The tumor formations may be solid, adenoid, keratotic, or cystic (412,462). In addition, there may be areas resembling trichoepithelioma (411) or eccrine spiradenoma (463). The walls of the comedones show numerous buds of basal cell carcinoma extending into the surrounding dermis (412,414).

The basal cell carcinomas encountered in the *Bazex syndrome* have a variable histologic appearance. Some of them are indistinguishable from trichoepithelioma (416,417). The areas of follicular atrophoderma show a dilated follicular ostium leading into a distorted and underdeveloped pilosebaceous unit (417).

The tumor described in 1926 by Jadassohn and regarded by him as an intraepidermal epithelioma analogous to one previously reported by Borst has been referred to as *Borst-Jadassohn epithelioma.* For a long time this tumor and similar tumors subsequently described were believed to be intraepidermal basal cell carcinomas because the cells composing the intraepidermal islands usually are small and have a deeply basophilic cytoplasm (464). However, on careful examination, it became evident that the cells composing the intraepidermal islands in the presumed intraepidermal basal cell carcinomas possess intercellular bridges and are seborrheic keratoses of the clonal type (77,465). The existence of an intraepidermal basal cell carcinoma is also unlikely because the close relationship that exists between tumor and stroma in basal cell carcinoma excludes the formation of intraepidermal nests, which would lack any contact with the stroma (466).

However, there are several types of tumors, some benign and some malignant, that on occasion show well-defined islands of cells within the epidermis that differ in their appearance from the surrounding epidermal cells (101). This is referred to as the *Jadassohn phenomenon.* Among the tumors that occasionally have an intraepidermal location are the following:

Clonal seborrheic keratosis. Some of these tumors show intraepidermal aggregates of basaloid cells suggestive of a basal cell carcinoma *in situ* (Figs. 29-10 and 29-11) (77), whereas others show intraepidermal islands of an irritated seborrheic keratosis simulating a squamous cell carcinoma *in situ*.

Bowen's disease. Occasionally, one observes clonal aggregates of Bowen's disease within the epidermis (467). At a later stage, there may be dermal invasion (468).

Intraepidermal poroma, also referred to as *hidroacanthoma simplex* (see Chapter 30) (469,470).

Intraepidermal malignant eccrine poroma (471). In cases of intraepidermal metastases of malignant eccrine poroma, the tumor masses extend through the superficial lymphatics from the dermis into the epidermis (see Chapter 31) (472).

The concept of intraepidermal tumors also includes Paget's disease of the breast, extramammary Paget's disease (see Chapter 30), intraepidermal junction nevus (see Chapter 28), and malignant melanoma *in situ* (see Chapter 28) (101).

Some authors still regard the intraepidermal epithelioma of Jadassohn as a distinct entity that may invade the dermis and occasionally cause metastases (473). It has been postulated that this tumor arises from acrosyringium keratinocytes or pluripotential adnexal cells and represents an adnexal carcinoma (473).

The existence of *basal cell carcinomas with features of squamous cell carcinoma* was first postulated in 1922 (474). Two types of basal squamous cell epitheliomas, referred to as *metatypical epitheliomas,* were recognized: a mixed and an intermediary type. The mixed type was described as showing focal keratinization consisting of pearls with a colloidal or parakeratotic center, and the intermediary type as showing two kinds of cells within a network of narrow strands, an outer row of dark-staining basal cells and an inner layer of cells appearing larger, lighter, and better defined than the basal cells and regarded as intermediate in character between basal and squamous cells.

Several authors have accepted the existence of basal squamous cell epitheliomas or metatypical epitheliomas (397, 475–477). They are considered by some to represent a transition from basal cell carcinoma to squamous cell carcinoma. It has been stated that a continuum extends from basal cell carcinoma at one extreme to squamous cell carcinoma at the other (477). The incidence of basal squamous cell carcinomas among basal cell carcinomas has been judged to be 3% (477), 8% (476), and even 12% (475). It has also been stated that basal squamous cell epitheliomas show a greater tendency to metastasize than basal cell carcinomas (397,475,477).

However, the existence of basal squamous cell epitheliomas is questioned by many (431,478–482). It would seem that the entirely different genesis of squamous cell carcinoma—a true anaplastic carcinoma of the epidermis—and basal cell carcinoma—a tumor composed of immature rather than anaplastic cells—makes the occurrence of transitional forms quite unlikely (see Pathogenesis). It can be assumed that the so-called mixed type of basal squamous cell epithelioma represents a keratotic basal cell carcinoma (Fig. 29-90) and that the intermediate type represents a basal cell carcinoma with differentiation into two types of cells (basal cell carcinoma with squamous differentiation). This form of differentiation is often seen deep to an area of ulceration. Other putative examples of basosquamous differentiation are better interpreted as *basal cell carcinoma with follicular differentiation* (Fig. 29-89).

Mixed carcinoma shows a squamous cell carcinoma contiguous to a basal cell carcinoma as a so-called collision tumor. It is likely that, in most instances, the squamous cell carcinoma develops secondary to the basal cell carcinoma. As other chronic ulcerative lesions, such as burns and stasis ulcers, basal cell carcinoma may stimulate the development of a squamous cell carcinoma. Before making a diagnosis of mixed carcinoma, however, one must rule out the possibility of pseudocarcinomatous hyperplasia occurring in a basal cell carcinoma.

Pathogenesis. Krompecher, the original describer of basal cell carcinoma, stated in 1903 that he regarded this tumor as a carcinoma of the basal cells of the epidermis and that those tumors that show a tendency toward gland formation are imitating the potential of the basal cells to form cutaneous glands (483). Krompecher's view is still supported by some (484–486). According to Geschickter and Koehler, only those basal cells with a potential to develop into glandular cells give rise to basal cell carcinoma. They suggested the designation *appendage cell carcinoma* (486a). Mallory held the opinion that basal cell carcinomas are carcinomas of hair matrix cells (486b). In 1947, Foot expressed the view that basal cell carcinomas are carcinomas that have developed from distorted primordia of dermal adnexa rather than from ordinary epidermal basal cells (443). He stated that the tumors imitate the embryonal development of one or all three types of adnexal primordia, that is, hair, sebaceous gland, and sweat gland.

The first author to express doubts that basal cell carcinomas are carcinomas was Adamson; in 1914, he stated that basal cell carcinomas are nevoid tumors originating "from latent embryonic foci aroused from their dormant state at a later period in life" (487). He believed that the latent embryonic foci usually are embryonic pilosebaceous follicles but occasionally are embryonic sweat ducts. Several other authors reached similar conclusions, among them Wallace and Halpert, who stated in 1950 that they regarded basal cell carcinomas as benign tumors arising from cells destined to form hair follicles (488). They proposed the term *trichoma* for them.

In 1948, Lever expressed his belief that basal cell carcinomas are not carcinomas and are not derived from basal cells, but rather are nevoid tumors, or hamartomas, derived from primary epithelial germ cells. In other words, basal cell carcinomas originate from incompletely differentiated, immature cells and not from anaplastic cells (488a). Although g-glutamyl transpeptidase activity is observed in the atypical cells in squamous cell carcinoma, Bowen's disease, and actinic keratoses, no g-glutamyl transpeptidase activity is expressed in the cells of basal cell carcinoma (489). In this view, basal cell carcinoma represents the least differentiated of the appendage tumors.

It was originally assumed, analogous to Adamson's view, that the primary epithelial germ cells giving rise to basal cell carcinoma are in all instances embryonic cells that lay dormant until the onset of neoplasia. Even though this view applies to the linear unilateral basal cell nevus, which is usually present from birth, it is likely that, as suggested by Pinkus, basal cell carcinomas occurring later in life arise not from dormant embryonic primary epithelial germ cells but from pluripotential cells that form continuously during life and, like embryonic primary epithelial germ cells, have the potential of forming hair, sebaceous glands, and apocrine glands (420). The fact that basal cell carcinomas may arise in sun-exposed areas and in areas of radiodermatitis supports this view. Their tendency to local invasion and tissue destruction, their capacity for local persistence and recurrence if not ablated, and their occasional capacity for metastasis support the concept that these lesions are carcinomas, albeit in most instances with little or no capacity for metastasis.

It is now widely accepted that disruption of the Hedgehog-Patched pathway is a key event in development of basal cell cancer. In addition to Patched gene alterations, p53 gene mutations are also frequently present (421–430). Lever's view that basal cell carcinomas are derived from primary epithelial germ cells has been developed in light of the recognition and characterization of epidermal stem cells.

Pilar Differentiation. Differentiation in basal cell carcinoma is predominantly toward pilar keratin. The presence of citrulline in keratinized structures indicates that the origin of the keratin is the hair matrix because epidermal keratin contains no citrulline (480). Studies with monoclonal cytokeratin antibodies support the assumption of pilar differentiation in basal cell carcinoma. Thus, a cytokeratin antibody binding to the follicular epithelium but not to the interfollicular epidermis stains all cells of basal cell carcinoma (490). Furthermore, a monoclonal antibody against basal cell carcinoma keratin stains, in addition to the cells of basal cell carcinoma, all follicular cells below the isthmus portion of normal anagen hair follicles (491). These findings contribute to the general view that basal cell carcinoma should be regarded as a hair follicle tumor rather than an epidermal tumor.

Stromal Factor. The importance of stroma in the development of basal cell carcinomas is borne out by the fact that autotransplants of basal cell carcinomas survive only when they include connective tissue stroma (492). In addition, the rarity of basal cell carcinomas on the palms and soles and the fact that the palmar and plantar pits of the nevoid basal cell carcinoma syndrome very rarely show a full-fledged basal cell carcinoma suggest that the palms and soles do not possess the stromal factor necessary for the formation of basal cell carcinomas (493).

Lack of Autonomy. Basal cell carcinomas, when transplanted to the anterior chamber of the rabbit's eye together with their connective tissue stroma, fail to grow, in contrast to squamous cell carcinoma (494). Furthermore, basal cell carcinomas, in contrast to many human tumors, do not grow when transplanted subcutaneously to athymic nude mice (495). These observations suggest a lack of autonomy of the cells of at least some basal cell carcinomas. Because autonomy of the tumor cell is a prerequisite for the formation of metastases and represents a characteristic feature of malignant tumors (496), the absence of autonomy in basal cell carcinoma is consistent with its inability to metastasize in most instances.

Site of Origin. The usual site of origin of basal cell carcinoma appears to be the surface epidermis. Alternatively, however, the tumor may originate from the outer root sheath of a hair follicle, and in the 2006 World Health Organization classification, basal cell carcinomas were classified with the skin adnexal tumors (1,497,498).

Of particular interest is the manner of growth of *superficial basal cell carcinoma.* Routine sectioning carried out perpendicular to the skin surface shows seemingly independent nests of basal cell carcinoma suggestive at times of the growth of primary epithelial germs in the embryonic skin. Thus it was at one time

widely assumed that the peripheral extension seen in superficial basal cell carcinoma was based on a "multicentric" growth characterized by the formation of new buds of tumor tissue at the periphery. However, on the basis of findings in serial sections and in wax reconstructions of superficial basal cell carcinomas, Madsen favored the theory of a "unicentric" origin (499,500). Madsen was able to show that the tumor strands are continuous but are attached to the undersurface of the epidermis only at intervals, like garlands. Madsen found not only in his wax reconstructions but also in sections cut parallel to the surface of the skin that individual tumor islands are interconnected. Oberste-Lehn (501), using a technique of separating the epidermis from the dermis by maceration, could not find such interconnections, but the possibility could not be excluded, as Madsen pointed out, that the interconnections had ruptured as a result of the maceration. It was subsequently shown, when trypsin was used for the separation of the epidermis from the dermis, that interconnections exist between tumor cell nests in superficial basal cell carcinoma. Similarly, three-dimensional reconstruction by means of serial horizontal microscopic sections and a special computer confirmed a unicentric origin (502).

Electron Microscopy. The predominant cell in undifferentiated basal cell carcinoma is characterized by a large nucleus, poorly developed desmosomes, and rather sparse tonofilaments. Thus the tumor cells differ from normal epidermal basal cells. They resemble the cells of the undifferentiated hair matrix (503) or the immature basal cells of the embryonic epidermis, particularly those of the primary epithelial germ (504,505). In addition to the prevalent large, light cells, a few cells that are smaller, darker, and more irregularly shaped can be found (438,504). The darkness of the latter cells is due to the abundance of ribonucleoprotein particles in their cytoplasm. A well-developed basement membrane separates the tumor from the dermis (503). Processes from the tumor cells do not usually penetrate the basement membrane in basal cell carcinoma, in contrast to squamous cell carcinoma, in which processes extend through a fragmented basement membrane into the stroma (506).

Keratinization is commonly observed by electron microscopy in basal cell carcinoma, especially in the keratotic type. In addition to well-developed desmosomes and many thick bundles of tonofilaments, dense clumps of homogeneous, dyskeratotic material are present in many keratinizing cells. A small number of keratohyaline granules are often seen. They probably represent trichohyaline granules, which occur in the process of keratinization of the inner root sheath and its cuticle (504).

Some basal cell carcinomas show areas of adenoid differentiation in which cells are grouped around glandlike lumina. Such cells may show pronounced infolding of the plasma membrane at their lateral borders as seen normally in eccrine ductal cells (439).

In pigmented basal cell carcinomas, most of the melanin is found within melanocytes of the tumor and in melanophages located in the connective tissue stroma. Although numerous melanosomes are present in the dendrites of the melanocytes, the tumor cells generally do not phagocytize the melanin-containing dendrites, resulting in a blockage of the transfer of melanin from melanocytes to the tumor cells (507,508). This is analogous to the blocked transfer from melanocytes to tumor cells in some pigmented seborrheic keratoses referred to as *melanoacanthoma*. Nevertheless, in occasional instances of pigmented basal cell carcinoma, some transfer of melanosomes to the tumor cells takes place. The tumor cells then contain melanosomes, which are located largely as melanosome complexes within lysosomes (504).

Presence of Amyloid. Cell proliferation in basal cell carcinoma is considerable. The experimentally determined cell-doubling time of 9 days, however, does not conform to the clinical observation that basal cell carcinoma, as a rule, is a very slowly growing tumor (509). This suggests that there must be cell death. In addition to phagocytosis by neighboring tumor cells and macrophages, apoptosis of tumor cells also often takes place, with transformation of the cells into colloid bodies and subsequently into amyloid (439,510). This conversion of epithelial cells into amyloid is analogous to that occurring in lichenoid and macular amyloidosis. Colloid bodies, demonstrable by direct immunofluorescence for immunoglobulin M, have been found in 89% of basal cell carcinomas (439). Amyloid has been observed in the stroma and inside the tumor islands both by histochemistry and by electron microscopy in as many as 65% of basal cell carcinomas (439,511). This amyloid shows positive staining with antikeratin antiserum, indicating that it is derived from tonofilaments (512). The fact that the amyloid is permanganate resistant indicates that it is not secondary amyloid (512). The presence of amyloid may contribute to an apparent lack of sensitivity to radiotherapy (514).

Differential Diagnosis. Differentiation of basal cell carcinoma from squamous cell carcinoma can sometimes be difficult—so difficult that some authors believe that intermediate forms (basal squamous cell epitheliomas) occur. However, as a rule, differentiation is fairly easy. One of the best points of differentiation is that most cells of basal cell carcinoma stain deeply basophilic, whereas most cells of squamous cell carcinoma, at least in low-grade lesions, have an eosinophilic tint due to partial keratinization. The cells in high-grade squamous cell carcinoma may appear basophilic because of the absence of keratinization. However, they differ from basal cell carcinoma by showing much greater atypicality of their nuclei and their mitotic figures. It is important to remember that keratinization is not a prerogative of squamous cell carcinoma; it occurs also in basal cell carcinoma with differentiation toward hair structures (see Keratotic Basal Cell Carcinoma). Keratinization in basal cell carcinomas may be partial and then result in parakeratotic bands and whorls, or it may be complete and result in horn cysts. The keratinization seen in the horn cysts differs from that seen in the horn pearls of squamous cell carcinomas by being abrupt and complete rather than gradual and incomplete. The fairly common presence in basal cell carcinoma of areas of retraction of the tumor cell masses from the surrounding connective tissue also aids in the differentiation of this tumor from squamous cell carcinoma, in which such areas of retraction are rarely found.

The differential diagnosis of basal cell carcinoma from trichoepithelioma is discussed in Chapter 31. Of particular

importance is the differentiation of fibrosing basal cell carcinoma from the relatively recently described desmoplastic trichoepithelioma. Both tumors have in common thin strands of small basaloid cells embedded in a dense, fibrous stroma, but desmoplastic trichoepithelioma also shows a considerable number of horn cysts. Many tumors originally diagnosed as basal cell carcinomas in children and teenagers could be reclassified as desmoplastic trichoepithelioma (515).

In making a biopsy diagnosis it is important to have sections that adequately represent the lesion. It is curious that in punch biopsies the initial sections may not show the tumor. Further sections should always be examined if the clinical diagnosis is one of basal cell carcinoma (517). There is also a limited evidence base to recommend the most effective and economical excision margins. It seems likely that a margin of 3 mm may be adequate in most cases, but in high-risk basal cell carcinoma this may be insufficient (518–521).

EPIDERMAL TUMORS IN IMMUNOSUPPRESSED HOSTS

The widespread use of immunosuppressive therapy as part of organ transplantation and in the treatment of some immunologically mediated diseases has led to a new phenomenon of rapidly developing warts and epidermal tumors (516). There is a spectrum of squamous atypia ranging from typical viral warts through dysplastic or atypical warts to squamous cell carcinomas, which are often very poorly differentiated (Fig. 29-92).

FIGURE 29-92. Squamous cell carcinoma in a renal transplant recipient. The patient has a carcinoma on the chest and multiple keratoses on the back of the hand and arm.

The squamous cell carcinomas have been shown to have similar proliferative potential to similar lesions in hosts with normal immune function (522), although they lack the host immune response that would normally be present (523). They also share the same early expression of keratin 17 seen in a number of epidermal hyperproliferative states (524). Mutations of p53 may play a part in the development of the tumors (525). Rapidly progressing multiple squamous cell carcinomas have also been reported in association with chronic myeloid leukemia (526). Basal cell carcinomas tend to show an infiltrative rather than a nodular growth pattern more frequently in immunosuppressed patients (527). Kaposi's sarcoma can also present as a fulminant process after liver or kidney transplantation (528,529) and may recur with the introduction of cyclosporin A therapy (530). It has also been suggested that HIV-positive hosts have an increased risk of developing malignant melanoma (531).

KERATOACANTHOMA

Two types of keratoacanthoma exist: solitary and multiple.

Solitary Keratoacanthoma

Solitary keratoacanthoma was first described in 1889 by Hutchinson as a "crateriform ulcer of the face," and since 1950 it has been recognized as an entity and differentiated from squamous cell carcinoma, which it often resembles clinically and histologically (532–534). Solitary keratoacanthoma occurs in elderly persons usually as a single lesion; however, occasionally there are several lesions, or new lesions develop. The lesion consists of a firm, dome-shaped nodule 1.0 to 2.5 cm in diameter with a horn-filled crater in its center (Fig. 29-93). The sites of predilection are exposed areas, where about 95% of solitary keratoacanthomas occur, but they may occur on any hairy cutaneous site (535). They have not been reported on the palms, soles, or mucous surfaces, although, in rare instances,

FIGURE 29-93. Keratoacanthoma. The lesion is symmetric, with keratin protruding from its center.

they occur subungually (see text following). Keratoacanthomas located on the vermilion border of the lip probably arise from hair follicles in the adjacent skin (536). Keratoacanthomas usually reach their full size within 6 to 8 weeks and involute spontaneously, generally in less than 6 months. Healing takes place with a slightly depressed scar. In some instances, a keratoacanthoma increases in size for more than 2 months and takes up to 1 year to involute (535).

An increased incidence of keratoacanthoma is observed in immunosuppressed patients (537). In addition, keratoacanthomas commonly occur in the Muir-Torre syndrome of sebaceous neoplasms and keratoacanthomas associated with visceral carcinomas (see Chapter 30). Keratoacanthomas may be the only type of cutaneous tumor present in this syndrome (538,539).

There are three rare clinical variants of solitary keratoacanthoma. In two forms—giant keratoacanthoma and keratoacanthoma centrifugum marginatum—the keratoacanthoma attains a large size. In *giant keratoacanthoma,* the growth rapidly reaches a size of 5 cm or more and may cause destruction of underlying tissues. Nevertheless, spontaneous involution takes place after several months, often accompanied by detachment of a large keratotic plaque. The most common sites are the nose (540,541) and the eyelids (537,542,543). In *keratoacanthoma centrifugum marginatum,* the lesion may reach a size of 20 cm in diameter. There is no tendency toward spontaneous involution; instead, there is peripheral extension with a raised, rolled border and atrophy in the center of the lesion. The most common locations are the dorsa of the hands (544,545) and the legs (546,547). The third rare variant is *subungual keratoacanthoma,* which shows a destructive crateriform lesion with keratotic excrescences under the distal portion of a fingernail. It fails to regress spontaneously, is tender, and by roentgenogram shows damage to the terminal phalanx by pressure erosion (548–550).

Claims have been made that keratoacanthoma can undergo transformation into a squamous cell carcinoma either spontaneously (544,551) or as a result of immunosuppression (537,552). It appears more likely, however, that the squamous cell carcinoma existed from the beginning in such instances (see Differential Diagnosis) (535,553).

Histopathology. The architecture of the lesion in a keratoacanthoma is as important to the diagnosis as the cellular characteristics. Therefore, if the lesion cannot be excised in its entirety, it is advisable that a fusiform specimen be excised for biopsy from the center of the lesion and that this specimen include the edge at least of one side and preferably of both sides of the lesion (554). A shave biopsy is inadvisable because the histologic changes at the base of the lesion are often of great importance in the differentiation from squamous cell carcinoma. Frequently a curettage specimen will be submitted, in which case clear distinction between keratoacanthoma and squamous cell carcinoma may be impossible to achieve with confidence.

In the early proliferative stage, one observes a horn-filled invagination of the epidermis from which strands of epidermis protrude into the dermis. These strands are poorly demarcated from the surrounding stroma in many areas and may contain cells showing nuclear atypia (555), as well as many mitotic figures (556). Even atypical mitoses may be seen occasionally (557). Dyskeratotic cells, that is, cells showing individual cell keratinization, may also be seen in areas that otherwise do not show advanced keratinization. However, even at this early stage, some of the tumor areas show a fairly pronounced degree of keratinization, giving them an eosinophilic, glassy appearance. In the dermis, a rather pronounced inflammatory infiltrate is present (556). Perineural invasion is occasionally seen in the proliferative phase of keratoacanthoma and should not be overinterpreted as conclusive evidence of malignancy (558,559).

A fully developed lesion shows in its center a large, irregularly shaped crater filled with keratin (Fig. 29-94). The epidermis extends like a lip or a buttress over the sides of the crater. At the base of the crater, irregular epidermal proliferations extend both upward into the crater and downward from the base of the crater. These proliferations may still appear somewhat atypical, but less so than in the initial stage; the keratinization is extensive and fairly advanced, with only a thin shell of one or two layers of basophilic, nonkeratinized cells at the periphery of the proliferations, whereas the cells within this shell appear eosinophilic and glassy as a result of keratinization (Fig. 29-95). There are many horn pearls, most of which show complete keratinization in their center. The base of a fully developed keratoacanthoma appears regular and well demarcated

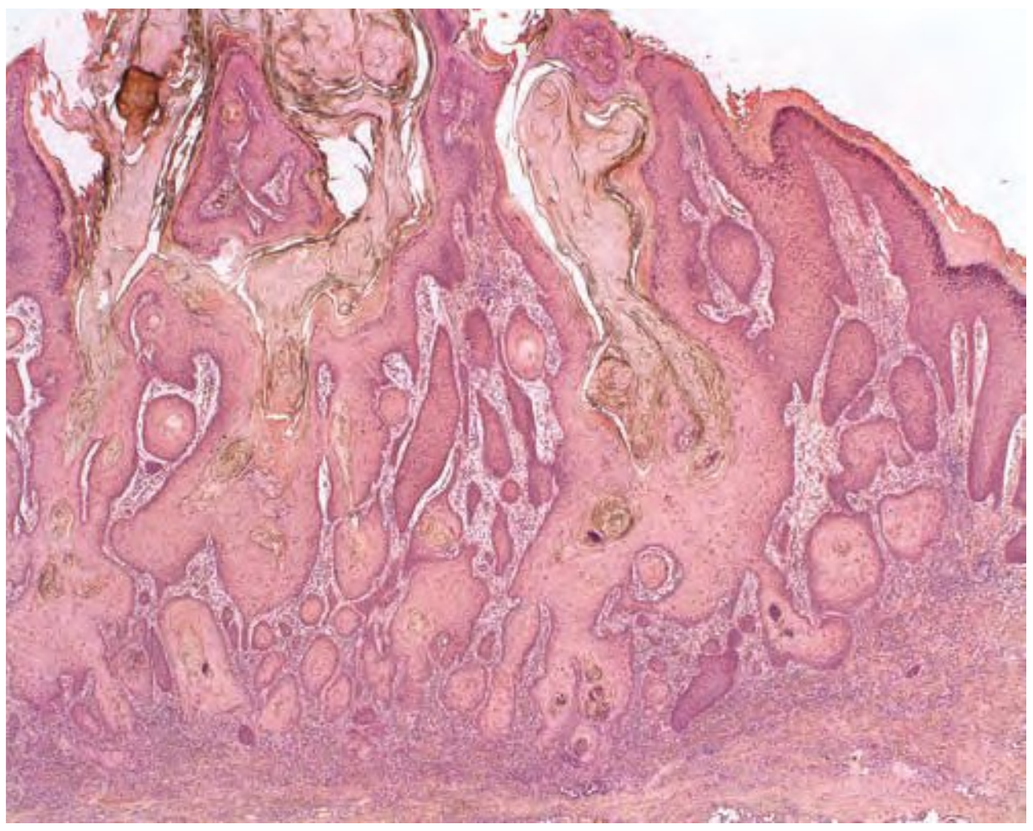

FIGURE 29-94. Keratoacanthoma. Low magnification. There is a central, keratin-filled crater. On the right, the epidermis extends like a buttress over the side of the crater. Irregular epidermal proliferations extend downward from the base of the crater into the dermis. This tumor is quite large and relatively deeply infiltrative, and the term "keratoacanthoma-like squamous cell carcinoma" might reasonably be applied to it.

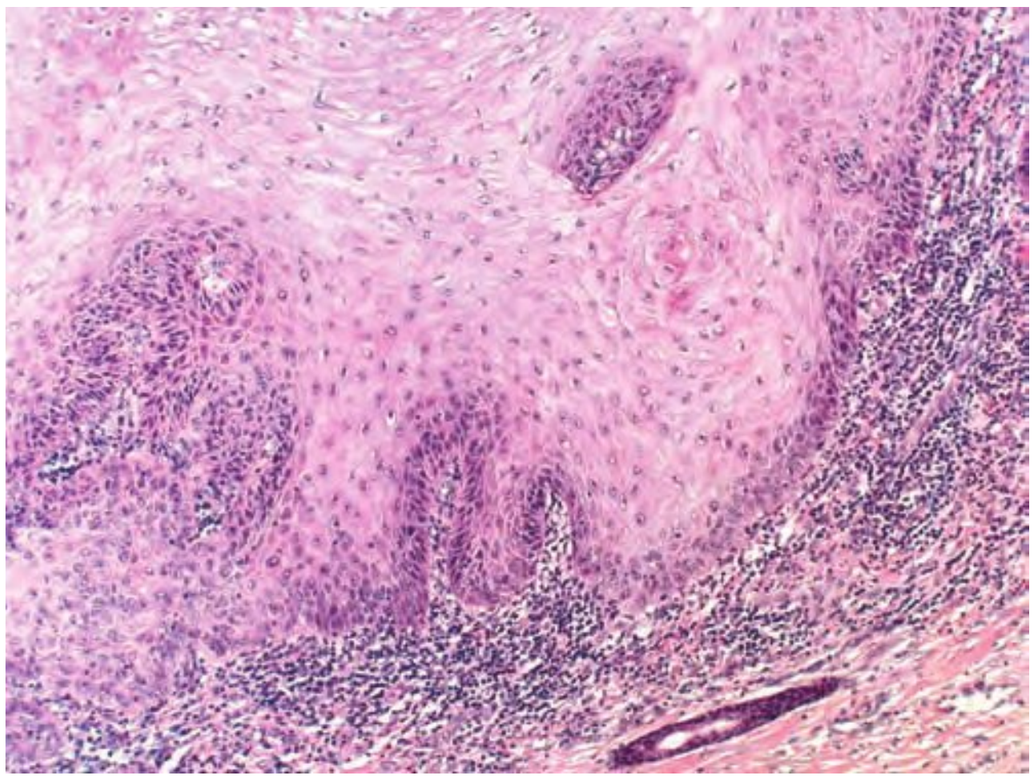

FIGURE 29-95. Keratoacanthoma. Medium magnification. The proliferation at the base to some extent resembles squamous cell carcinoma. However, there is more keratinization than is usual in squamous cell carcinoma, giving the tumor islands a glassy appearance. The lesion lies above the level of the sweat gland coils in the dermis.

and usually does not extend below the level of the sweat glands, in contrast to squamous cell carcinoma, which frequently does. A rather dense inflammatory infiltrate is often present at the base of the lesion (535,560).

In the involuting stage, proliferation has ceased, and most cells at the base of the crater have undergone keratinization. There may be shrunken, eosinophilic cells analogous to colloid or Civatte bodies among the tumor cells located nearest to the stroma as well as in the stroma, suggesting that cell degeneration followed by apoptosis contributes to the involution of the keratoacanthoma (547). Gradually, the crater flattens and finally disappears during healing.

Pathogenesis. It is generally agreed that the lesion starts with hyperplasia of the infundibulum of one or several adjoining hair follicles and with squamous metaplasia of the attached sebaceous glands (561). The application of cutaneous carcinogens to the skin of animals frequently produces, among other tumors, lesions with the histologic appearance of keratoacanthomas, and these tumors also have their origin in the infundibulum of one or several hair follicles (562).

The cause of keratoacanthoma is not known. The theory of a viral genesis has not been confirmed. The electron microscopic findings are largely nonspecific. However, keratoacanthomas, like squamous cell carcinomas and lesions of Bowen's disease, often show the presence of fairly numerous intracytoplasmic desmosomes (563,564).

Differential Diagnosis. Differentiation of typical, mature lesions of keratoacanthoma from squamous cell carcinoma generally is not difficult. In favor of a diagnosis of keratoacanthoma are the architecture of a crater surrounded by buttresses and the high degree of keratinization, which is manifested by the eosinophilic, glassy appearance of many of the cells. Clinical data are also of great value: Rapid development of an exophytic lesion showing a central, horn-filled crater speaks for keratoacanthoma rather than for squamous cell carcinoma.

The greatest difficulties in the differentiation of a keratoacanthoma from a squamous cell carcinoma are encountered in very early lesions because a horn-filled invagination may be seen in squamous cell carcinoma, and cells with an atypical appearance may occur in a keratoacanthoma. Occasionally, an early keratoacanthoma shows a greater degree of nuclear atypia than do some squamous cell carcinomas (565). In addition individual cell keratinization can occur in keratoacanthoma. On rare occasions, even adenoid formations caused by dyskeratosis and acantholysis can occur in keratoacanthoma (566). Thus it was found on reclassification in one study that in only 81% of the cases of keratoacanthoma could a diagnosis of squamous cell carcinoma be fully excluded, and that in only 86% of the cases of squamous cell carcinoma could keratoacanthoma be ruled out with certainty. These findings explain why, on rare occasions, lesions classified as keratoacanthoma cause metastases (553). Great caution is indicated in the diagnosis of giant keratoacanthomas. Several cases diagnosed as such turned out to be squamous cell carcinomas either by metastasizing (567) or by deep invasion into muscle (568).

Because it is widely agreed that squamous cell carcinomas can masquerade as keratoacanthomas clinically and histologically (535,569), it is best to err on the safe side in a case of doubt and to proceed on the assumption that the lesion is a squamous cell carcinoma. Where the tumor is well differentiated and has architectural features of keratoacanthoma, the term "keratoacanthoma-like squamous cell carcinoma" can be used.

Attempts at differentiating between keratoacanthoma and squamous cell carcinoma by histochemical or immunohistochemical methods have shown distinct differences in typical cases but not necessarily in borderline cases.

There are two variants of *multiple keratoacanthoma*: the multiple self-healing epitheliomas of the skin, or Ferguson Smith type, and the eruptive keratoacanthomas, or Grzybowski type. Both variants are rare in comparison with solitary keratoacanthoma.

In *multiple self-healing epitheliomas* of the skin, lesions begin to appear in childhood or adolescence on any part of the skin, including the palms and soles, but especially on the face and the extremities. Subungual lesions have also been described (549). Generally, there are no more than a dozen lesions at any one time (570). The lesions may reach the same size as solitary keratoacanthomas and after a few months heal with a depressed scar (571,572). In some cases, however, the lesions do not heal (534). In some patients, the condition is inherited (573,574).

In *eruptive keratoacanthoma,* lesions do not appear until adult life. Many hundreds of follicular papules are present, measuring from 2 to 3 mm in diameter (575,576). The oral mucosa and larynx may be involved (577,578).

Histopathology. The histologic appearance of the lesions of multiple self-healing epitheliomas of the skin is similar to that of solitary keratoacanthoma (570,572). More frequently than in solitary keratoacanthoma, the cutaneous proliferations in multiple self-healing epitheliomas of the skin are seen to be continuous with the follicular epithelium (579). The cutaneous lesions in eruptive keratoacanthoma show less crater formation than those in solitary keratoacanthoma. The mucosal lesions lack a crater and can easily be misinterpreted as squamous cell carcinoma (578,579).

Pathogenesis. It appears likely that multiple keratoacanthoma basically represents the same condition as solitary keratoacanthoma and that predisposition or genetic factors are responsible for the greater number of lesions (580). In multiple as in solitary keratoacanthoma, lesions arising in hair-bearing parts of the skin have their onset in the upper portion of a hair follicle, whereas the site of origin of lesions arising on the palms, the soles, and the mucous membranes is not apparent (577).

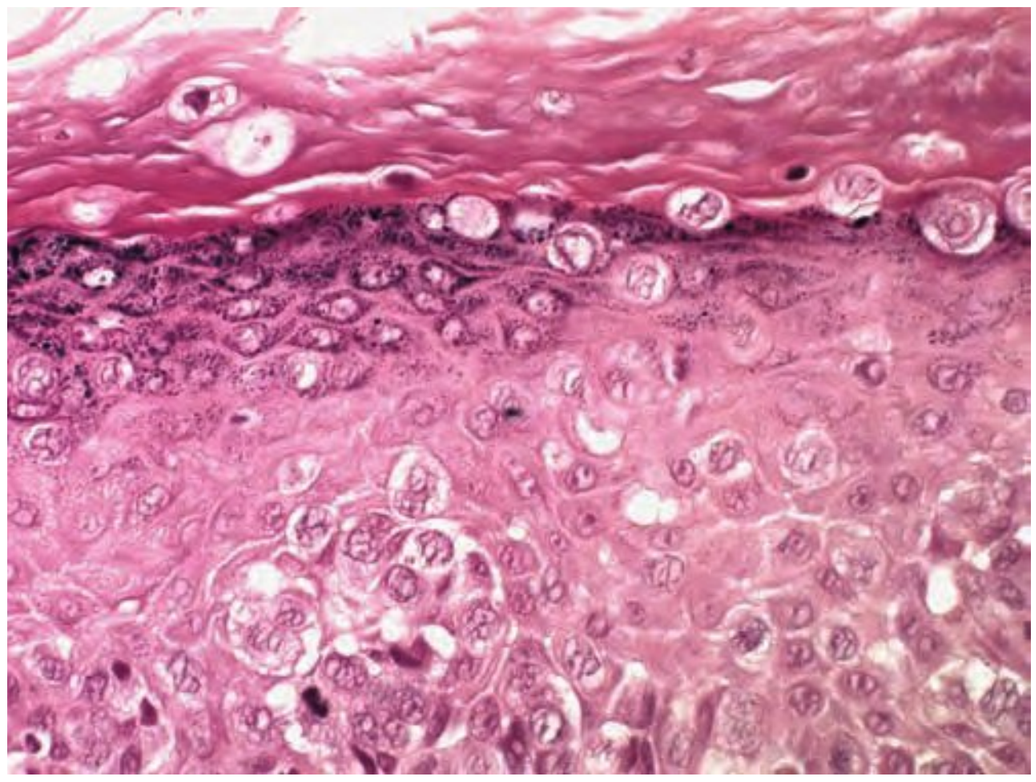

FIGURE 29-96. Paget's disease. High magnification. Large, rounded Paget cells with ample pale-staining cytoplasm, devoid of intercellular bridges, are scattered through the epidermis.

PAGET'S DISEASE

Paget's disease of the breast occurs almost exclusively in women. Only a few instances of its occurrence in the male breast have been described (581). Of interest is its occurrence in the male breast after treatment of a carcinoma of the prostate with estrogen (582). The cutaneous lesion in Paget's disease of the breast begins either on the nipple or the areola of the breast and extends slowly to the surrounding skin. It is always unilateral and consists of a sharply defined, slightly infiltrated area of erythema showing scaling, oozing, and crusting. There may or may not be ulceration or retraction of the nipple.

The cutaneous lesion is nearly always associated with carcinoma of the breast, and in more than half of the patients, a mass can be felt on palpation of the breast. Metastases in the axillary lymph nodes were found by one group of investigators in about 67% of their patients with a palpable mass of the breast and in 33% of those without a palpable mass (583). This contrasts with the experience of others, who encountered no axillary metastases in the absence of a palpable mass of the breast (584).

A clinical picture indistinguishable from that of early Paget's disease of the nipple may be seen in erosive adenomatosis of the nipple, a benign neoplasm of the major nipple ducts (see Chapter 30) (585).

Histopathology. In early lesions of Paget's disease of the breast, the epidermis usually shows only a few scattered Paget cells. They are large, rounded cells that are devoid of intercellular bridges and contain a large nucleus and ample cytoplasm. The cytoplasm of these cells stains much lighter than that of the adjacent squamous cells (Fig. 29-96). As the number of Paget cells increases, they compress the squamous cells to such an extent that the latter may merely form a network, the meshes of which are filled with Paget cells lying singly and in groups. In particular, one often observes flattened basal cells lying between Paget cells and the underlying dermis.

The dermis in Paget's disease shows a moderately severe chronic inflammatory reaction. Although Paget cells do not invade the dermis from the epidermis, they may be seen extending from the epidermis into the epithelium of hair follicles (586).

Histologic examination of the mammary ducts and glands nearly always shows malignant changes in some of them. At first, the carcinoma is confined within the walls of the ducts and glands, but the tumor cells ultimately invade the connective tissue. From then on, lymphatic spread and metastases occur, just as in other types of mammary carcinoma. In mammary Paget's disease, the malignant changes have their onset in the lactiferous ducts and from there extend into the epidermis, but there are rare instances in which the malignant cells are confined to the epidermis of the nipple or involve only the most distal portion of one lactiferous duct (587).

Pathogenesis. As long as *electron microscopic examination* constituted the major factor in analyzing the derivation or the direction of differentiation of the cells in Paget's disease of the nipple, no clear decision could be reached on whether the constituting cells were keratinocytes or glandular cells. The presence of desmosomes between neighboring Paget cells and between Paget cells and keratinocytes seemed to support a derivation from keratinocytes (588). On the other hand, scattered desmosomes are normally found connecting the cells of the lactiferous ducts (589), and wherever cytoplasmic processes of Paget cells lie in contact with the basal lamina, no hemidesmosomes are present, as they would be in the case of keratinocytes. In addition, Paget cells can be found bordering small lumina in areas in which groups of Paget cells lie together (589,590).

Immunohistochemical studies in recent years have proved beyond any doubt the glandular derivation of the Paget cells of both mammary and extramammary Paget's disease. Thus, carcinoembryonic antigen is regularly found in Paget cells. Whereas intervening keratinocytes and melanocytes do not

stain, carcinoembryogenic antigen is present in the cells of normal eccrine and apocrine glands (591). Furthermore, Paget cells express cytokeratins typical of glandular epithelia but do not react with antibodies to epidermal keratin (592). CAM 5.2 is a low–molecular-weight cytokeratin marker that stains Paget's cells in 70% to 90% of cases. The adjacent epidermis, which is rich in high–molecular-weight cytokeratins, does not stain. Cytokeratin 7 is a more sensitive, but not specific, marker for Paget's disease. In addition to staining Paget's cells, it may also stain intraepidermal Merkel cells and Toker cells, and so positive staining needs to be correlated with morphology when interpreting the appearances in a section (616).

Enzyme histochemistry in Paget's disease of the breast has shown the presence of an apocrine enzymatic pattern in the intraepidermal Paget cells consisting of a strong reactivity for acid phosphatase and esterase and only a weakly positive reaction for aminopeptidase and succinic dehydrogenase (593). This finding suggests that the intraepidermal Paget cells in Paget's disease of the breast are derived from mammary gland cells, because the mammary gland represents a modified apocrine gland.

Differential Diagnosis. Paget's disease of the breast must be differentiated from Bowen's disease and the superficial spreading or "pagetoid" type of malignant melanoma *in situ*. Although vacuolated cells may occur in both Paget's disease and Bowen's disease, one observes clear-cut transitions between the vacuolated cells and epidermal cells only in Bowen's disease. Furthermore, one may observe in Bowen's disease, but not in Paget's disease, clumping of nuclei within multinucleated epidermal cells and individual cell keratinization. In addition, the cells in Bowen's disease do not contain carcinoembryonic antigen but react with prekeratin contained in rabbit antihuman prekeratin antiserum (594).

In the superficial spreading or pagetoid type of malignant melanoma *in situ*, as in the epidermis of Paget's disease of the breast, there are large, vacuolated cells scattered through the epidermis. The difficulty in distinguishing between the two types of cells may be increased by the fact that Paget cells occasionally also contain melanin. The most important points to remember in differentiating the two types of cells are as follows: (a) Paget cells are separated in many areas from the dermis by flattened basal cells, whereas melanoma cells border directly on the dermis; (b) Paget cells do not invade the dermis, whereas melanoma cells often do; (c) the tumor cells of malignant melanoma contain abundant cytoplasmic S100 protein, but in tissues from Paget's disease, S100 protein is usually absent in the tumor cells, although it may be seen in myoepithelial cells, Langerhans cells, and Schwann cells of cutaneous nerves (595); and (d) melanoma cells, unlike Paget cells, may be positive for the HMB-45 antigen, Melan-A, and other melanocytic markers.

EXTRAMAMMARY PAGET'S DISEASE

Extramammary Paget's disease most commonly affects the vulva (300), less commonly the male genital area (596) or the perianal area (551), and, in exceptional cases, the axillae, the region of the ceruminal glands (597), or that of Moll's glands (598). In cases with involvement of the axillae, the genital area may also be affected (599). Thus extramammary Paget's disease involves areas in which apocrine glands are normally encountered. Only very few cases of an association between mammary and vulvar Paget's disease have been described (600). In rare instances, extramammary Paget's disease is a secondary event caused by extension of an adenocarcinoma either of the rectum to the perianal region, of the cervix to the vulvar region (601), or of the urinary bladder to the urethra and glans penis (602) or to the groin (603). On the other hand, longstanding genital Paget's disease can extend inward to the cervix and urinary tract (604).

In extramammary Paget's disease, the clinical picture shows a slowly enlarging reddish patch with oozing and crusting. The patch resembles an eczematous lesion but has a sharp, irregular border. In extramammary Paget's disease, in contrast to the mammary type, itching is common.

Histopathology. Extramammary Paget's disease shares with Paget's disease the presence of varying numbers of Paget cells within the epidermis. In some instances, the Paget cells are found to be limited to the epidermis. Frequently, Paget cells can also be identified within the epithelium of some hair follicles or eccrine sweat ducts (605). Such *in situ* malignancy associated with extramammary Paget's disease has the same favorable prognosis as extramammary Paget's disease limited to the epidermis. However, the prognosis is much more serious in cases in which the Paget cells have invaded the dermis from the epidermis (605,606) or from an underlying sweat gland carcinoma (607). In this respect, extramammary Paget's disease differs from mammary Paget's disease, in which invasion of the dermis from the overlying epidermis does not occur (586). Glandular clusters with a central lumen, absent in mammary Paget's disease, may be seen in the lower epidermis in extramammary Paget's disease (605,608).

Immunohistochemical staining typically shows that in primary Paget's disease the Paget cells stain positively for cytokeratin 7, whereas in secondary cases the cells may be cytokeratin 20 positive (616).

In cases of "secondary" extramammary Paget's disease, the process extends either from a mucous-secreting adenocarcinoma of the rectum to the perianal skin (609,610), from a mucous-secreting endocervical carcinoma to the vulva (601), or from a transitional cell carcinoma of the urinary bladder with urethral extension (602,603). The prognosis in secondary extramammary Paget's disease is poor.

The prognosis of "primary" extramammary Paget's disease generally is better than that of mammary Paget's disease. In two large combined series of 123 patients with vulvar Paget's disease, only 26 patients (21%) showed an underlying invasive carcinoma in the dermis at the time of operation (605,606). In the other 79%, the Paget cells were present only within the epidermis and the epithelium of the cutaneous appendages, so that the process was still *in situ*. Thus one author observed only

2 examples of invasive sweat gland carcinoma among more than 100 cases of extramammary Paget's disease (607), and another author reported none among 12 cases (592). However, the rate of local recurrence is high even after seemingly adequate excision. The reasons for this are that (a) the extent of histologically demonstrable disease is often far greater than that of the clinically visible lesion and (b) extramammary Paget's disease, in contrast to mammary Paget's disease, can arise multifocally even in clinically normal-appearing areas of the skin (611).

Pathogenesis. At one time, the view was widely accepted that in primary extramammary Paget's disease the Paget cells in the epidermis are there as a result of an *in situ* upward extension of an *in situ* adenocarcinoma of sweat glands along eccrine or apocrine ducts (608,612). This view is analogous to the generally accepted views that secondary extramammary Paget's disease represents an extension of a rectal, cervical, or urinary bladder adenocarcinoma and that the development of mammary Paget's disease is an extension of an epidermotropic lactiferous duct carcinoma. The fact that an underlying *in situ* adenocarcinoma often could not be demonstrated was explained by the anatomic differences between the breast, which has only 20 large, conspicuous lactiferous ducts, and the genital skin, which has thousands of small apocrine and eccrine glands, making location of the particular small gland involved by carcinoma technically difficult (608). Staining with antikeratin monoclonal antibodies indicated that upward extension of an *in situ* adenocarcinoma derived from malignant secretory cells present within sweat ducts can occur (613).

Even though in some cases extramammary Paget's disease is the result of extension of an underlying apocrine or eccrine sweat gland carcinoma to the overlying epidermis, in most instances it has its origin within the epidermis (606). Careful subserial total sectioning of excised lesions of vulvar Paget's disease showed that the lesions within the epidermis and its appendages have a multifocal origin (611). Another pertinent argument in favor of the independence of the epidermal foci from any appendageal foci is the observation that in cases with extensive epidermal lesions, involvement of eccrine ducts and glands is often sparse and involvement of apocrine ducts and glands almost invariably absent, even though some Paget cells form apocrine glandular structures in the epidermis (605). Even if there is continuity between the epidermal and the ductal foci, there is no certain way of determining whether the extension is in an upward or downward direction. However, the clinching argument in favor of the autonomy of the epidermal foci in primary extramammary Paget's disease is the fact that, in contrast to mammary Paget's disease, dermal invasion generally originates from the epidermis and not ductal or glandular structures (605,606).

In cases in which the extramammary Paget's disease arises within the epidermis and extends from there at a later date into the adnexa and still later from the epidermis into the dermis, the question is, Which cell gives rise to the Paget cell? Two possibilities have been suggested, although proof for either is lacking. The first is that the Paget cell arises within the poral portion of an apocrine duct (614). The second is that, because the disease tends to occur in areas rich in apocrine glands and because there is in some cases unequivocal evidence of apocrine differentiation in the epidermis, intraepidermal Paget cells may be formed by pluripotential germinative cells within the epidermis that go awry trying to form apocrine structures (596,605,605a,605b).

Immunohistochemical studies indicate an apocrine genesis of extramammary Paget's disease. It is true that carcinoembryonic antigen merely indicates that the extramammary Paget cells are glandular rather than epidermal cells and does not decide whether they are apocrine or eccrine (591,592). However, two immunoreactants for apocrine glands—gross cystic disease fluid protein (615) and apocrine epithelial antigen (592)—have been shown to react with the Paget cells of extramammary Paget's disease, providing evidence for an apocrine pattern of differentiation.

The majority of cases of mammary and extramammary Paget's disease are cytokeratin 7 positive. Those few cases that are negative have been reported to be more commonly associated with the presence of an underlying malignancy. In contrast, cytokeratin 20 is found more frequently in cases of extramammary Paget's disease with an underlying malignancy. The pattern of cytokeratin expression can therefore be used to predict the likelihood of the presence or absence of an associated internal malignancy (616).

Differential Diagnosis. Extramammary Paget's disease, like Paget's disease of the breast, must be differentiated from Bowen's disease and especially from superficial spreading or pagetoid malignant melanoma *in situ* (see Paget's Disease, Differential Diagnosis).

ACKNOWLEDGMENTS

I thank Dr. Neil Cox for Figs. 29-1, 29-2, 29-6, 29-10, 29-12, 29-16, 29-36, 29-40, 29-46, 29-49, 29-65, 29-85, 29-92, and 29-93; Dr. James Langtry for Figs. 29-5, 29-19, 29-21, 29-22, 29-26, 29-35, 29-52, 29-70, 29-78, and 29-79; and Dr. Akhtar Husain for Fig. 29-57.

Tumors of the Epidermal Appendages

CLASSIFICATION OF THE APPENDAGEAL TUMORS

Historically, tumors of the epidermal appendages have been classified into four groups, which exhibit histologic features analogous to those of hair follicles, sebaceous glands, apocrine glands, and eccrine glands. In general, this type of diagnostic nosology based on the microscopic attributes of appendageal structures has been practical for the classification of adnexal lesions.

However, in some cases, the diagnosis of adnexal neoplasms presents unique difficulties, in part related to the wide variety of tumors, the substantial frequency of one lesion exhibiting histologic features of two or more adnexal lines, and the complicated nomenclature (1–5). Histogenesis is a concept that implies that the histologic appearance of a tumor is similar to the histology of the organ/structure from which the tumor arose ("cell of origin"). These concepts of appendageal tumorigenesis are being modified by new experimental data describing mechanisms governing the proliferation and differentiation of pluripotent stem cells that may be situated within various niches in the epidermis and associated adnexa.

In general, tumors are not derived directly from mature (differentiated, postmitotic) cells; rather, tumors originate from multipotential stem cells present within the epidermis or its appendageal structures (6). Such cells, when undergoing neoplastic transformation, may aberrantly express one or more lines of appendageal differentiation to varying degrees, given that these cells are not restricted to one line of differentiation. Taken together, these concepts predict that the histologic features of a tumor are related to the activation of molecular pathways responsible for forming the mature adnexal structure. The degree to which the eccrine, apocrine, sebaceous, and follicular differentiation programs are activated and recapitulated gives a tumor its histologic features. These concepts predict that tumors, including adnexal tumors, may imprecisely resemble their mature counterparts and that multiple lines of differentiation may be seen simultaneously in the same tumor (6). Given that tumor cell physiology is somewhat abnormal, it is remarkable that a significant percentage of adnexal neoplasms manifest predominantly one adnexal differentiation program (Table 30-1).

Benign adnexal tumors in which there is an admixture of follicular, eccrine, sebaceous, and/or apocrine differentiation, such as sebaceous units in combination with either eccrine and/or apocrine elements, are occasionally a source of diagnostic confusion. Differentiation is probably influenced not only by genetic potential, but also by field effects such as regional vascularity and molecular microenvironmental attributes of the epidermis, dermis, or subcutis (6). In human skin, keratinocytes with markers of stem cells appear to reside in the "bulge," and cells with the capability of proliferating and differentiating along appendageal lines (progenitor cells) appear to traffic from this site to the basilar epidermis, the sebaceous gland, and the hair follicle (7–9).

In addition to benign tumors, there are carcinomas of the epidermal appendages, which have the potential to metastasize. Three types of glandular carcinoma are recognized: carcinomas of sebaceous glands, eccrine glands, and apocrine glands. Other epithelial carcinomas exhibiting various types of follicular differentiation have been reported, such as pilomatrical carcinoma, malignant proliferating trichilemmal cyst, trichilemmal carcinoma, and trichoblastic carcinoma (Table 30-1).

As noted, the histopathology of a tumor often can be interpreted by comparing it to the histology of skin appendages. For example, clear or pale cell change due to cytoplasmic glycogen may recapitulate the embryonic acrosyringium in a nodular hidradenoma or the glycogenated follicular outer root sheath in a trichilemmoma. Cytoplasmic fat vacuoles that indent the nucleus are typical of sebaceous differentiation, which is seen in sebaceous glands, sebaceous adenomas, and sebaceous carcinomas. Many adnexal tumors contain a distinctive, fibrotic, eosinophilic hyaline stroma that envelops the epithelial elements. This stroma assists in differentiating many basaloid adnexal neoplasms from basal cell carcinoma. Eccrine tumors commonly exhibit a nearly acellular hyalinized eosinophilic stroma with dilated thin-walled vessels (e.g., nodular hidradenoma, eccrine poroma). Tubule formation and focal keratinization occurring in eccrine tumors tend to differentiate them from renal cell or other metastatic clear cell carcinomas. Historically, immunohistochemistry has been of little value in definitively distinguishing among the phenotypic patterns of adnexal neoplasms (10); however, with the identification of specific mutations in genes associated with appendageal neoplasms—for example, CYLD1 in cylindromas (11)—further research on these tumors using current technologies, especially cDNA

TABLE 30-1 Classification of Tumors of Epidermal Appendages

Lesion type	Follicular differentiation	Sebaceous differentiation	Apocrine differentiation	Eccrine differentiation
Hyperplasias, hamartomas	Hair follicle nevus Dilated pore Generalized hair follicle hamartoma Basaloid follicular hamartoma	Nevus sebaceous Sebaceous hyperplasia	Apocrine nevus	Eccrine nevus
Benign neoplasms	Trichofolliculoma Pilar sheath acanthoma Fibrofolliculoma Trichodiscoma Trichoepithelioma Trichoblastoma Trichoadenoma Pilomatricoma Trichilemmoma Tumor of follicular infundibulum Trichilemmal horn Proliferating trichilemmal cyst	Sebaceous adenoma Sebaceoma	Aprocrine hidrocystoma Hidroadenoma papilliferum Syringocystadenoma papilliferum Tubular apocrine adenoma Erosive adenomatosis of the nipple Apocrine cylindroma	Eccrine hidrocystoma Syringoma Eccrine cylindroma Eccrine poroma Eccrine syringofibroadenoma Mucinous syringometaplasia Eccrine spiroadenoma Papillary eccrine adenoma Nodular hidradenoma Chondroid syringoma
Malignant neoplasms	Pilomatrix carcinoma Malignant proliferating trichilemmal tumor Trichilemmal carcinoma Trichoblastic carcinoma	Sebaceous carcinoma	Malignant apocrine cylindroma	Porocarcinoma Malignant eccrine spiroadenoma Malignant nodular hidradenoma Malignant chrondroid syringoma Eccrine adenocarcinoma Microcystic adnexal carcinoma Aggressive digital papillary adenocarcinoma Adenoid cystic carcinoma Mucinous eccrine carcinoma Syringoid eccrine carcinoma Malignant eccrine cylindroma

microarrays, microRNA microarrays, and proteomic studies, may yield additional molecular markers useful for classifying these lesions.

Lesional histology evolves with time and in response to local effects. A trichilemmal cyst, possibly stimulated by inflammatory mediators, may, as it ages, transform into a proliferating trichilemmal cyst and ultimately into the solid pilar tumor of the scalp. It is almost certain that tumor progression, the "process whereby tumors go from bad to worse," also operates in adnexal tumors, as it does in most tumor types. From a clinical point of view, adnexal neoplasms should not always be regarded as precursors of malignancy.

Classification of the Benign Appendageal Tumors

The four groups of benign appendageal tumors with differentiation toward hair, sebaceous glands, apocrine glands, and eccrine glands can be divided, according to a gradient of decreasing differentiation, into three major subgroups: (a) hyperplasias, hamartomas, and cysts; (b) benign tumors; and

(c) malignant tumors (Table 30-1). This classification is similar to the approach of the recent World Health Organization International Histological Classification of Tumours monograph (12).

Of the three subgroups of benign appendageal lesions, the hyperplasias, hamartomas, and cysts are composed of mature or nearly mature structures. The benign neoplasms, in general, show less complete differentiation than the hyperplasias; nonetheless, well-developed, differentiated or partially differentiated structures are present. The malignant neoplasms exhibit a lower degree of differentiation, and these lesions may not form differentiated cells or structures.

Although most of the benign appendage tumors fit well into one of the entities listed in Table 30-1, tumors in an intermediate stage of differentiation are occasionally encountered (13).

Ontogeny of the Benign Appendageal Tumors

Three possibilities exist for the development of benign appendageal tumors: development from primary epithelial germs, from pluripotential stem cells, or from cells of preexisting structures. In 1948, the thesis was advanced that cutaneous tumors differentiating toward hair, sebaceous glands, or apocrine glands developed from primary epithelial germ cells and were primary epithelial germ tumors, and, furthermore, that the hyperplasias, adenomas, and benign epitheliomas arose from primary epithelial germ cells that had attained a certain degree of differentiation before the onset of neoplasia (14).

Given that pluripotent stem cells give rise to cutaneous appendageal structures and that stem cells are continually present in the skin, it is likely that the benign appendageal tumors arise from stem cells that possess the potential of differentiating into tumors with hair, sebaceous gland, or apocrine structures (6). Appendageal tumors associated with genetic syndromes, such as multiple cylindromas, multiple trichoepitheliomas, and the nevoid basal cell carcinoma syndrome, are probably derived from abnormally regulated pluripotent cells that are directed to form abnormal appendageal structures rather than mature appendages. This scenario is likely to be true in sporadic occurrences of these same adnexal tumors. In some instances, pluripotent cells differentiate in more than one direction, as is seen most commonly on the scalp, where a syringocystadenoma may exhibit three different lines of appendageal differentiation.

Terminology

The terms *nevus*, *hamartoma*, and *carcinoma* used in the classification of the benign appendage tumors require definition.

The term *nevus* is used in the literature in two different ways, referring (a) to a tumor composed of nevus cells derived from melanocytes (nevocellular nevus, melanocytic nevus, pigmented nevus) or (b) to a lesion that is usually present at birth and is composed of mature or nearly mature structures, such as nevus sebaceous, eccrine nevus, nevus verrucosus, and nevus flammeus. To avoid confusion, it is advisable to use the term *nevus* with a qualifying adjective and to assume that *nevus* without a qualifying adjective designates a tumor composed of melanocytic nevus cells.

The term *hamartoma* is appropriate for those nevi that have no melanocytic nevus cells and, like congenital hyperplasias, are composed of mature or nearly mature structures. *Hamartoma,* derived from the Greek word *hamartanein* (to fail, to err), was chosen as the designation for "tumor-like malformations showing a faulty mixture of the normal components of the organ in which they occur" (15).

The term *epithelioma* has been used by many authors as a synonym for *carcinoma.* However, because the literal meaning of the word is "tumor of the epithelium," the term may be employed as a designation of benign as well as of malignant tumors of the epithelium, provided that a qualifying adjective is added (16). Because the term has been used for both benign and malignant neoplasms, it seems best to avoid its use except in a clearly defined historical context. The term *carcinoma* is used for malignant epithelial tumors, including those that are characterized by a tendency to inexorable growth with local invasion and tissue destruction as well as those that may in addition have capacity for distant metastasis. As in previous editions, we have selected terms that are widely understood and used, not necessarily those that are above all semantic dissection (17).

TUMORS WITH DIFFERENTIATION TOWARD HAIR FOLLICLE COMPONENTS

Hair Follicle Nevus

This rare, small tumor presents as a small nodule on the face, often at birth. It has also been referred to as congenital vellus hamartoma (18–20). A few reported cases have raised the possibility of a novel neurocutaneous syndrome (21,22).

Histopathology. There are focally increased vellus hair follicles, occasionally accompanied by a few small sebaceous glands (Fig. 30-1) (23).

FIGURE 30-1. Hair follicle nevus. Increased numbers of small hair follicles are present in the dermis.

Differential Diagnosis. The small vellus hair follicles present in the central face resemble the hair follicles in a hair follicle nevus. Other entities to consider in the differential diagnosis include accessory tragus and hair follicle hamartoma (21,24).

Trichofolliculoma

Trichofolliculoma occurs in adults as a solitary lesion, usually on the face but occasionally on the scalp or neck. It consists of a small, skin-colored, dome-shaped nodule. Frequently, there is a central pore. If such a central pore is present, a wool-like tuft of immature, usually white hairs may be seen emerging from it, a highly diagnostic clinical feature (25).

Histopathology. On histologic examination, the dermis contains a cystic cavity lined by squamous epithelium; this cyst contains keratinized material and frequently fragments of hair shafts that are birefringent on polaroscopic examination (Fig. 30-2) (26). In cases with a visible central pore, the cystic space is continuous with the surface epidermis, an indication that the lesion is analogous to an enlarged, distorted hair follicle. In some cases, multiple cystic spaces are present in the dermis. Radiating from the wall of these cysts are many small, yet well-differentiated hair follicles (Fig. 30-3). Well-developed secondary hair follicles often show a hair papilla (Fig. 30-3). Furthermore, these follicles usually have an outer and an inner root sheath, the latter of which may contain eosinophilic trichohyaline granules and, located in the center, a small hair shaft (Fig. 30-3). These fine hairs are visualized best where the secondary hair follicles appear in cross sections. Small groups of sebaceous gland cells may be embedded in the walls of the secondary hair follicles (27). In some of the more rudimentary secondary follicles, one observes a central horn cyst in place of a hair, as seen also in trichoepithelioma (28). The lesional stroma is rich in fibroblastic cells; these cells are oriented in parallel bundles that encapsulate the epithelial proliferations in a manner resembling that of the normal fibrous root sheath (29). Glycogen can be demonstrated in the outer root sheath of the secondary hair follicles, just as it is seen in mature hair follicles (26).

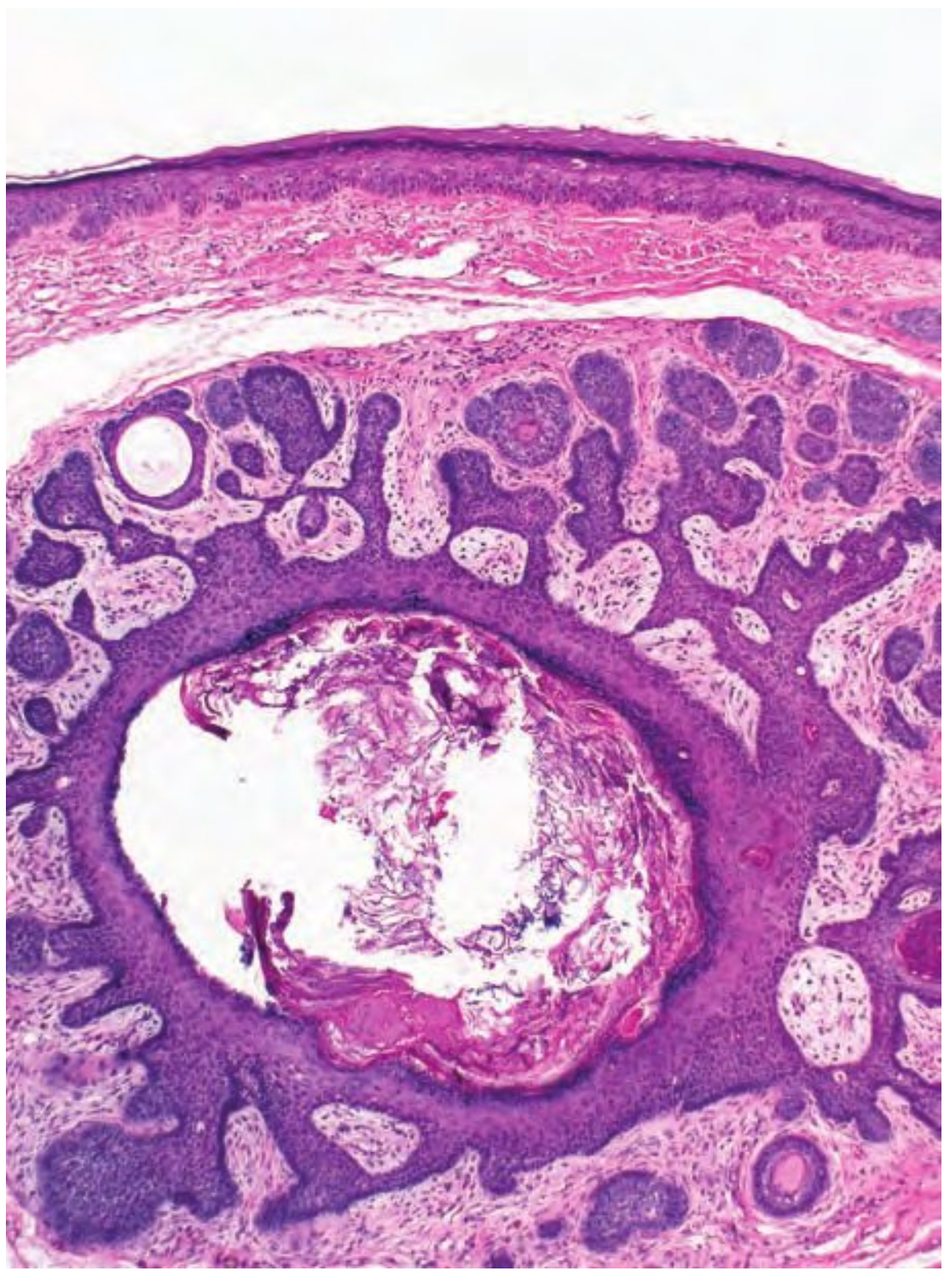

FIGURE 30-2. Trichofolliculoma. In the dermis, there is a keratin-filled cyst lined by squamous epithelium with associated follicular structures.

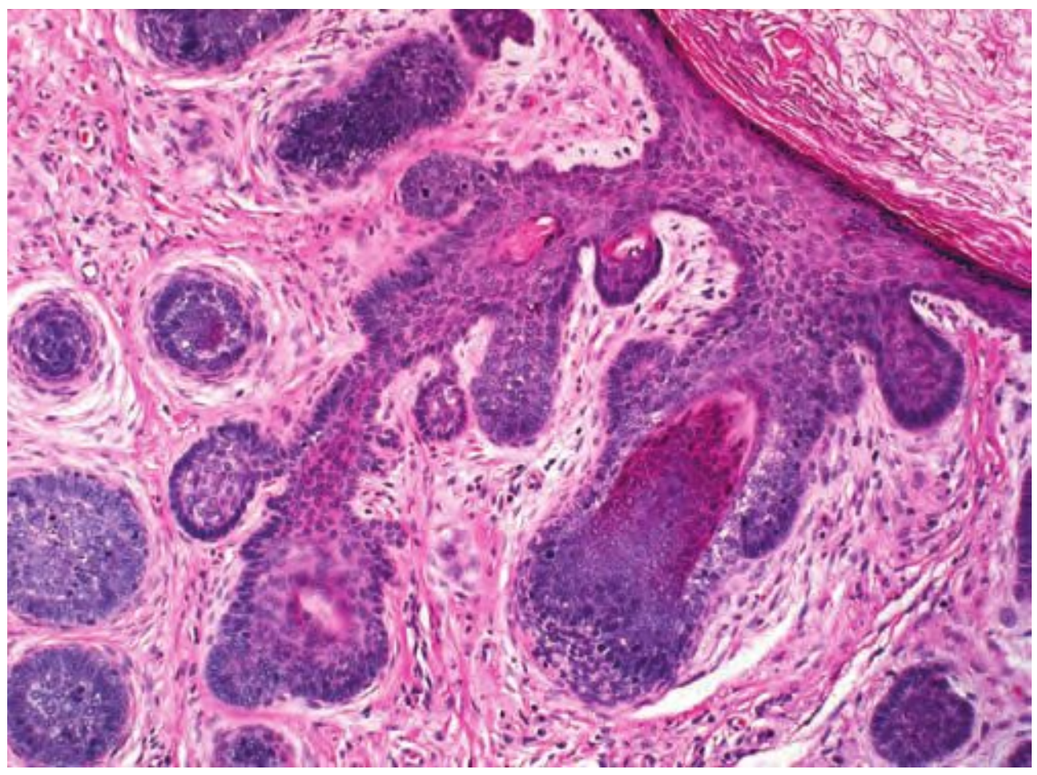

FIGURE 30-3. Trichofolliculoma. Emanating from the cyst wall are numerous small "secondary" hair follicles, some of which show, in addition to a hair and an outer root sheath, an inner root sheath with trichohyaline granules.

In all trichofolliculomas, epithelial strands interconnect the secondary hair follicles. Because these epithelial strands differentiate in the direction of the outer root sheath, the peripheral cell row is palisaded, and because of their glycogen content, the cells within the strands appear large and vacuolated (29).

Additional Studies. Experimental evidence suggests that trichofolliculomas undergo morphologic changes corresponding to the normal hair follicle cycle (30). The folliculosebaceous cystic hamartoma consists of a folliculosebaceous proliferation with a cystlike infundibular dilation and a mesenchymal stroma with variable fibroplasia. Folliculosebaceous cystic hamartoma exhibits many features of a trichofolliculoma, but it typically manifests more prominent sebaceous differentiation and a more prominent surrounding stroma, although some consider it an evolutionary stage of trichofolliculoma (31,32). Transgenic mice that overexpress a stabilized form of the β-catenin protein develop trichofolliculomas (33); therefore, increased signaling through the β-catenin pathway may play a role in the development of trichofolliculomas in humans. Recent work

with transgenic mice expressing increased epidermal expression of the *Noggin* gene, an inhibitor of bone-morphogenetic protein protein signaling, exhibit appendageal tumors resembling trichofolliculomas (34).

Sebaceous Trichofolliculoma

Sebaceous trichofolliculoma, a variant of trichofolliculoma, occurs in anatomic regions rich in sebaceous follicles, such as the nose. This tumor exhibits a centrally depressed, fistula-like opening from which terminal hairs and vellus hairs protrude (35).

Histopathology. There is a rather large, irregularly shaped, centrally located cavity lined by squamous epithelium. Many radially arranged, pilosebaceous follicles connect to the cavity. These follicles contain sebaceous ducts and numerous well-differentiated, large sebaceous lobules, as well as hair follicles containing partially terminal and partially vellus hairs (35).

Differential Diagnosis. Unlike folliculosebaceous cystic hamartoma, which presents as a solitary papule or nodule, sebaceous trichofolliculoma clinically presents with a central porelike opening that exhibits protruding hairs. Histopathologically, folliculosebaceous cystic hamartoma is additionally characterized by stromal mesenchymal prominence, a finding not seen in the previously reported cases of sebaceous trichofolliculoma (36).

Dilated Pore and Pilar Sheath Acanthomas

Dilated pore and pilar sheath acanthomas clinically share with trichofolliculoma and sebaceous trichofolliculoma the presence of a central pore and, histologically, the presence of a large cystic space that is continuous with the surface epidermis, lined by squamous epithelium, and filled with keratinous material.

The dilated pore, described in 1954 by Winer, occurs on the face, usually as a solitary lesion and predominantly in adult males. It has the appearance of a giant comedone and typically does not possess palpable induration (37).

The pilar sheath acanthoma, described in 1978, is usually found on the skin of the upper lip of adults. It is seen elsewhere on the face only rarely. It occurs as a solitary skin-colored nodule with a central porelike opening (38).

Histopathology. The dilated pore differentiates toward the infundibulum both architecturally and cytologically (39). It shows a markedly dilated pilar infundibulum lined by an epidermis that is atrophic near the ostium but hypertrophic deeper in the cystic cavity, where it shows many rete ridges and irregular thin proliferations into the surrounding stroma (Figs. 30-4 and 30-5). The keratin-filled cystic cavity may extend into the subcutaneous fat. In the lower portion, small sebaceous gland lobules and vellus hair follicles may be attached to the lining epithelium (40).

The *pilar sheath acanthoma* differs from the dilated pore by showing a larger, irregularly branching cystic cavity. In place of thin proliferations, as seen in the dilated pore, numerous lobulated masses of cells radiate from the wall of the cystic cavity into the dermis and the subcutaneous tissue (Fig. 30-6) (38). The pilar sheath acanthoma can exhibit some features of the outer root sheath, in that portions of the lesion may show peripheral palisading and contain varying amounts of glycogen (Fig. 30-7) (41). It has been suggested that pilar sheath acanthomas can manifest differentiation of all components of the pilosebaceous unit (39,42).

FIGURE 30-4. Dilated pore of Winer. An irregular cystic cavity containing keratin is present in the dermis.

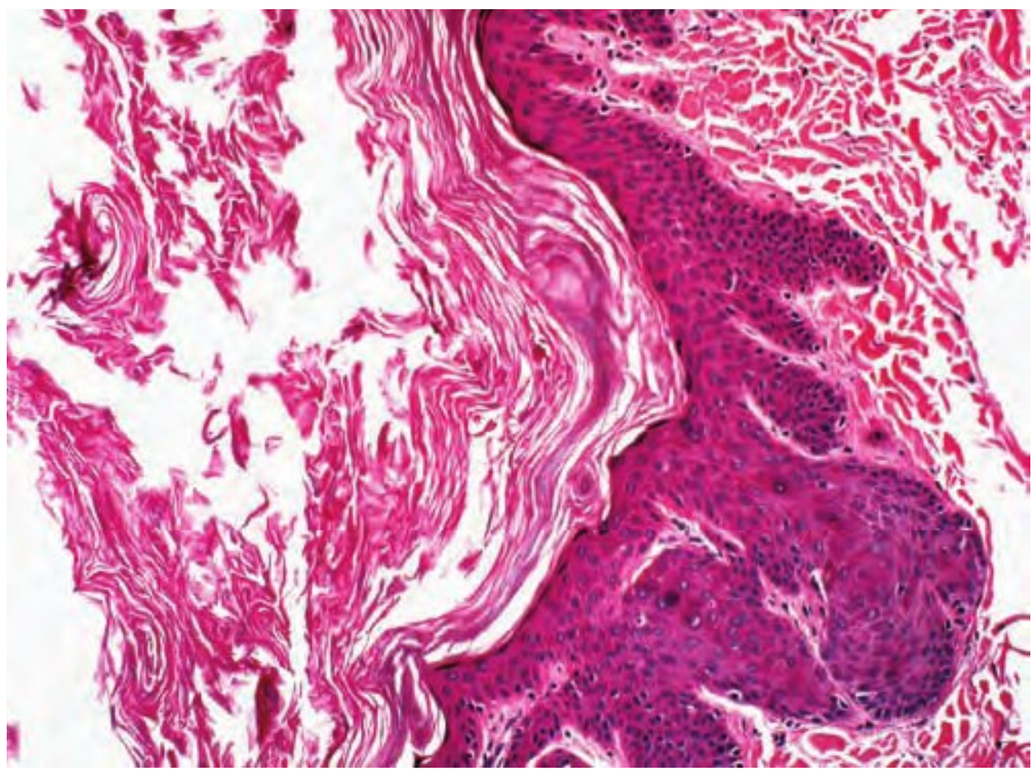

FIGURE 30-5. Dilated pore of Winer. Small projections of epithelial cells extend from the wall of the cyst into the surrounding dermis.

FIGURE 30-6. Pilar sheath acanthoma. Lobulated masses of cells extend from the cystic cavity into the surrounding dermis.

Fibrofolliculoma and Trichodiscoma

Fibrofolliculomas and trichodiscomas consist of 2- to 4-mm, yellow-white, smooth, dome-shaped lesions often on the face. The lesions can be solitary or multiple. Multiple fibrofolliculomas have been described in association with trichodiscomas and acrochordons (43,44). This triad is now referred to as the Birt-Hogg-Dubé syndrome and is inherited in an autosomal dominant fashion (43).

In patients with the Birt-Hogg-Dubé syndrome the lesions are present in considerable number mainly on the face and neck. In such cases, the trichodiscomas are clinically indistinguishable from the fibrofolliculomas (45). In this syndrome, there is an increased risk for the development of renal tumors and colonic polyps (46,47). In a patient reported with a large connective tissue nevus, fibrofolliculomas were present in large numbers within as well as around the connective tissue nevus (45).

Besides occurring in association with multiple fibrofolliculomas, multiple trichodiscomas also occur without them, as small papules either widely disseminated or localized to one area (48,49).

Histopathology. *Fibrofolliculomas* exhibit a central distorted hair follicle that is surrounded by a mantle of basophilic, fibrous stroma (Fig. 30-8). Numerous thin, anastomosing bands of follicular epithelium extend into this stroma (Fig. 30-9) (43,45).

Trichodiscomas are seen in the dermis as an area of fine fibrillary connective tissue containing ectatic blood vessels (Figs. 30-10 and 30-11). Epithelial hyperplasia resembling follicular structures, including those seen in fibrofolliculomas, is often seen. A hair follicle is usually found at the margin of the lesion (43,45). Trichodiscomas have been regarded as hamartomas of the mesodermal component of hair disks (48).

The pedunculated acrochordons seen in association with multiple fibrofolliculomas may contain only dermal connective

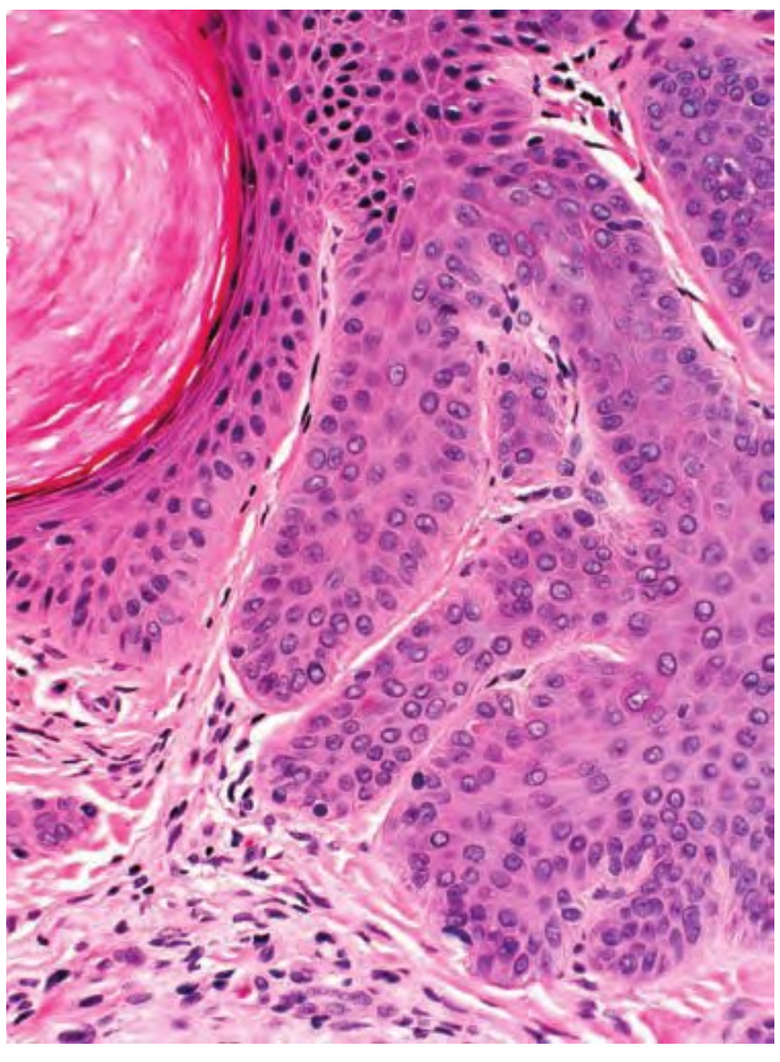

FIGURE 30-7. Pilar sheath acanthoma. The lobulated masses are comprised of bland cells resembling infundibular keratinocytes.

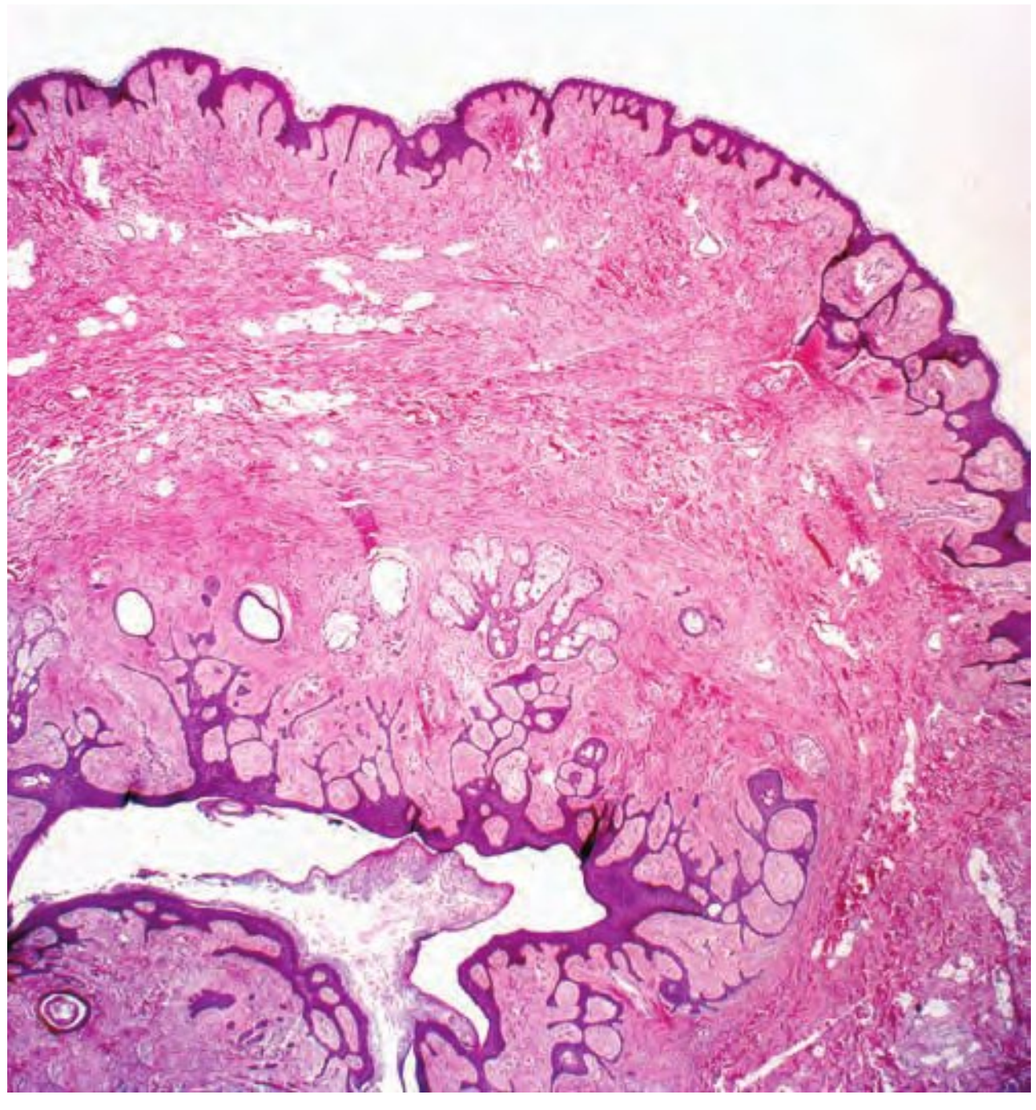

FIGURE 30-8. Fibrofolliculoma. In the dermis, there is a distorted cystic structure associated with epithelial cords and a fibrous stroma.

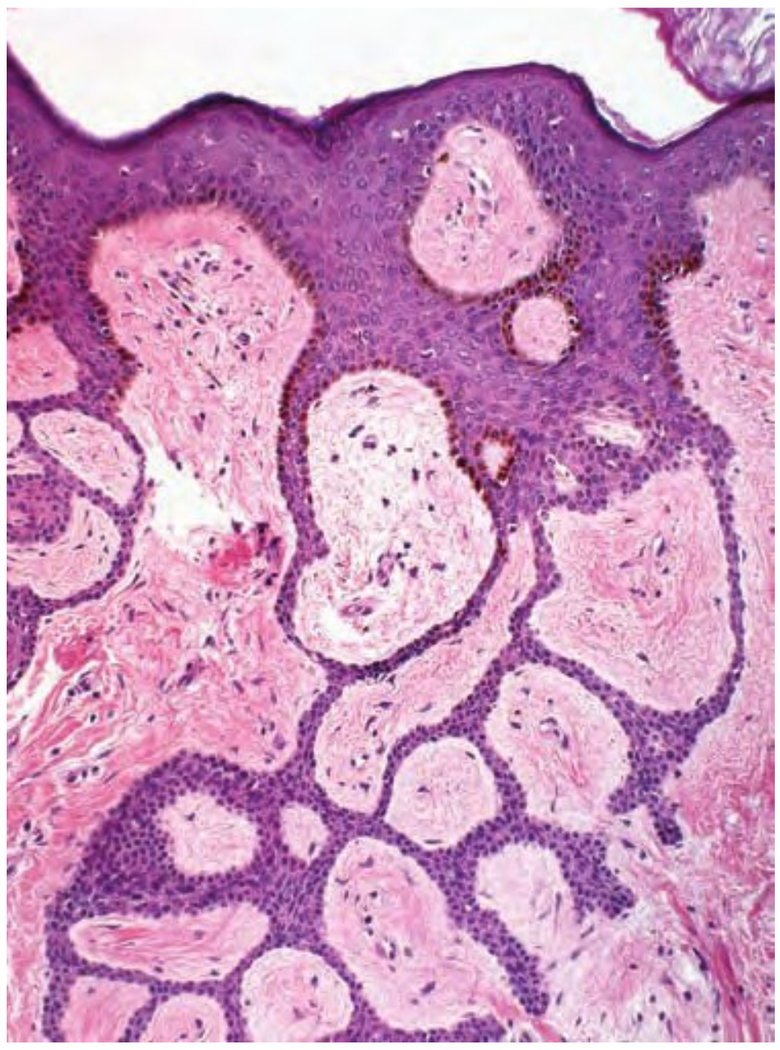

FIGURE 30-9. Fibrofolliculoma. Numerous thin, anastomosing bands of follicular epithelium extend into the bland fibrocellular stroma.

tissue. However, in some instances, they contain thin, anastomosing strands of epithelium; they are regarded as fibrofolliculomas displaying the configuration of an acrochordon (48).

Additional Studies. Birt-Hogg-Dubé syndrome is associated with mutations in the folliculin gene on chromosome 17p; the gene is believed to function as a tumor suppressor, but the function of this molecule is unclear (50). Steffen and Ackerman considered that histopathologically, fibrofolliculoma and trichodiscoma are hamartomas of follicular epithelium, follicular mantles, and perifollicular connective tissue (51). The immunophenotypic characteristics of syndromic-associated and sporadic types are identical and consist of perifollicular

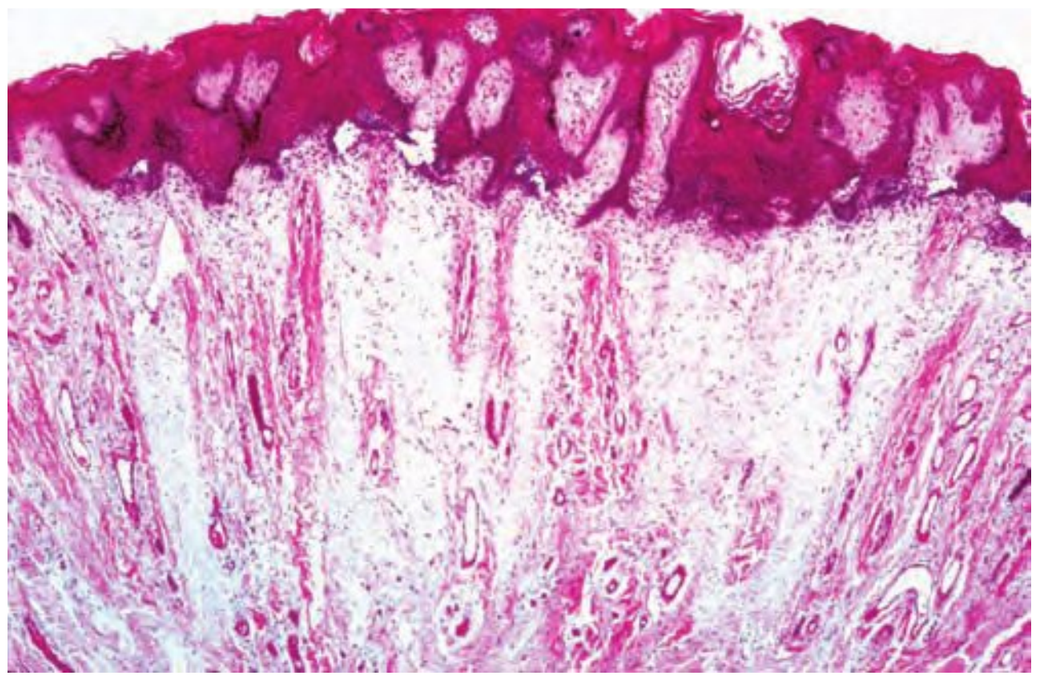

FIGURE 30-10. Trichodiscoma. Present in the dermis are areas of fine, fibrillar connective tissue.

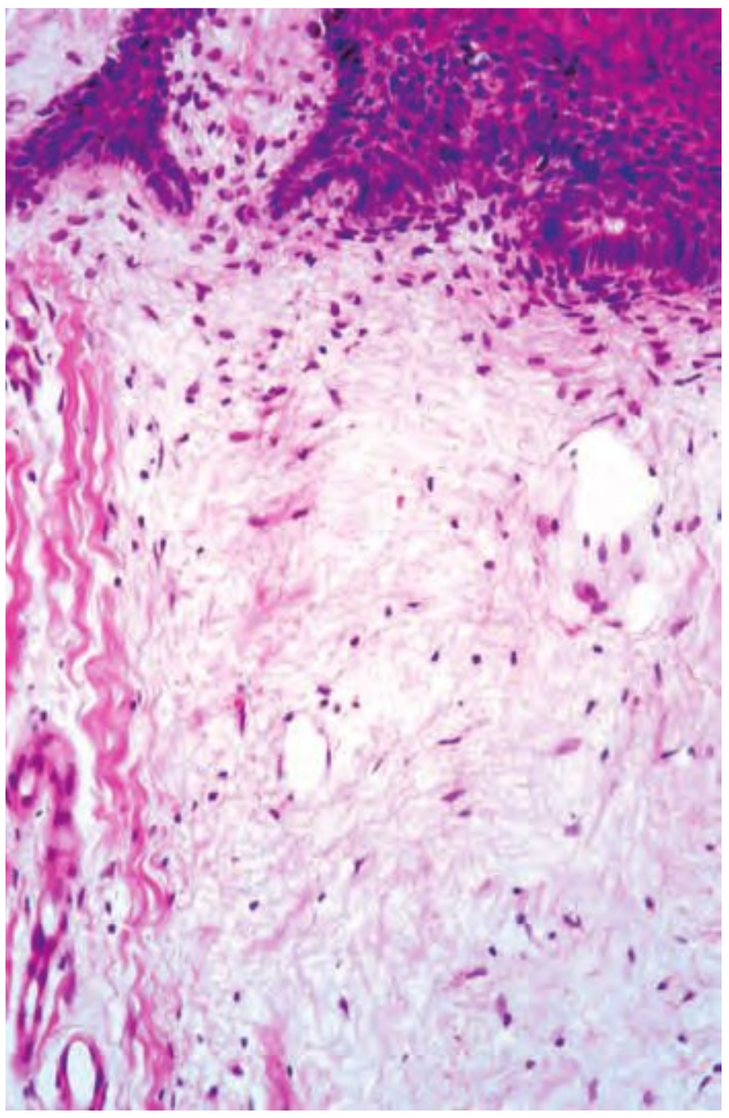

FIGURE 30-11. Trichodiscoma. The altered connective tissue exhibits ectatic vessels, a myxomatous appearance, increased numbers of mature fibrocytic cells, and basaloid follicular epidermal hyperplasia.

spindle cells that are positive for vimentin and CD34 and negative for factor XIII. These findings suggest that these lesions originate from the hair follicle mantle (52).

Trichoepithelioma

Trichoepithelioma occurs either in multiple lesions or as a solitary lesion. The name *trichoepithelioma* is preferable to other designations, such as *epithelioma adenoides cysticum* and *multiple benign cystic epithelioma*, because it is more indicative that the differentiation of this tumor is toward hair structures.

Multiple trichoepitheliomas are transmitted as an autosomal dominant trait (53). In most instances, the first lesions appear in childhood and gradually increase in number (54). Numerous rounded, skin-colored, firm papules and nodules usually between 2 and 8 mm in diameter are seen located mainly in the nasolabial folds, but also the nose, forehead, and upper lip. Occasionally, lesions are seen also on the scalp, neck, and upper trunk. Ulceration of the lesions occurs rarely. Transformation of one or several lesions into basal cell carcinomas is a very rare event. Most of the cases reported as such in the past are now regarded as instances of nevoid basal cell carcinoma syndrome (19,55). Nevertheless, there have been a few cases of basal cell carcinoma arising in the setting of multiple trichoepitheliomas (56–58). The simultaneous presence of trichoepithelioma and cylindroma, the latter of which is also dominantly inherited, has been observed repeatedly (see Cylindroma).

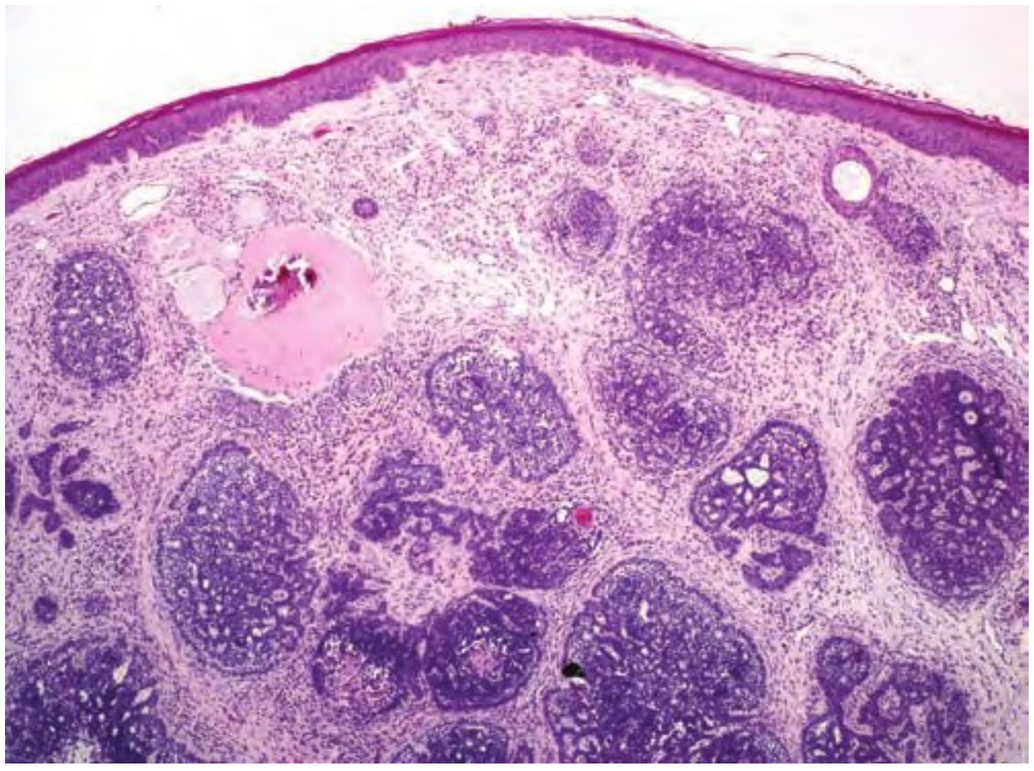

FIGURE 30-12. Trichoepithelioma. A dermal tumor with a prominent stroma, horn cysts of varying sizes, and basaloid epithelial formations.

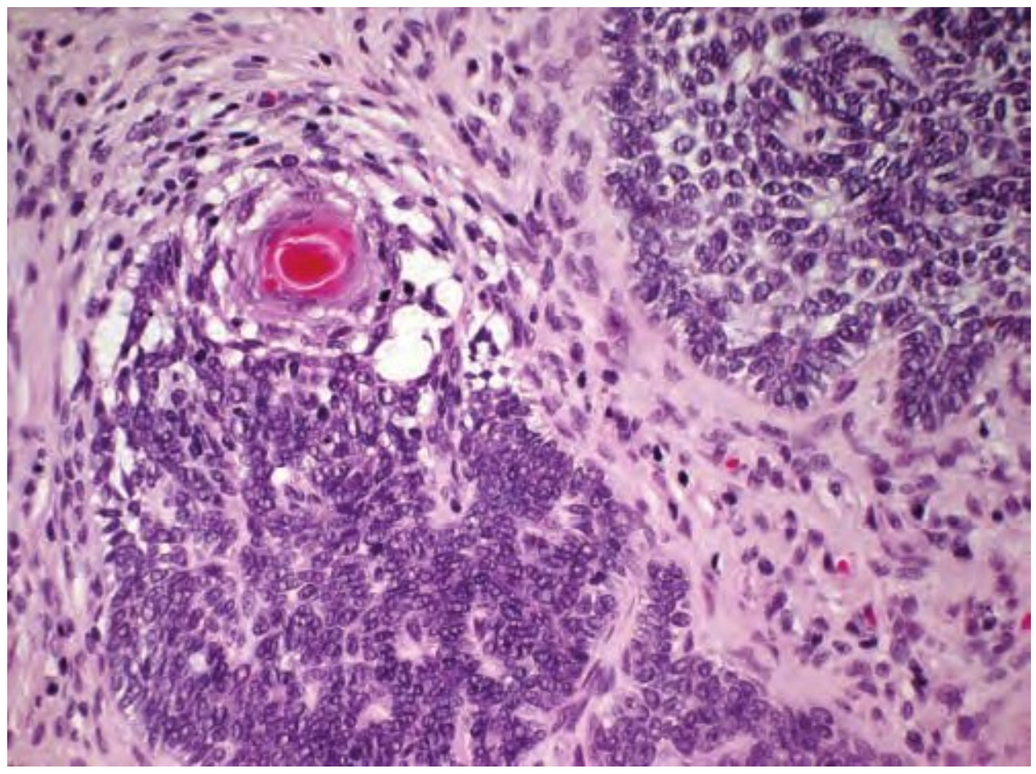

FIGURE 30-13. Trichoepithelioma. Fibroblasts encircle and are tightly associated with the basaloid epithelial islands, lacking the retraction artifact typical of basal cell carcinoma.

Solitary trichoepithelioma occurs more commonly than multiple trichoepitheliomas (54). It is not inherited and consists of a firm, elevated, flesh-colored nodule usually less than 2 cm in diameter. Its onset usually is in childhood or early adult life (59). Most commonly, the lesion is seen on the face, but it may occur elsewhere. The presence within the same tumor of a solitary trichoepithelioma and an apocrine adenoma has been described (60).

Giant solitary trichoepithelioma, measuring several centimeters in diameter, is a distinct variant of trichoepithelioma (61). It arises in later life and occurs most commonly on the thigh and in the perianal region (61,62).

Histopathology. As a rule, multiple trichoepitheliomas are superficial dermal lesions. They appear well circumscribed, small, and symmetric on histologic examination. Horn cysts are the most characteristic histologic feature, although they may be absent in some lesions. They consist of a fully keratinized center surrounded by basophilic cells that have the same appearance as the cells in the basal cell carcinoma, except that they tend to lack high-grade atypia and mitoses, which may be prominent in some but not all carcinomas (Figs. 30-12 and 30-13). The keratinization is abrupt and complete, in the manner of so-called "trichilemmal" keratinization, as opposed to the horn pearls of squamous cell carcinoma. Quite frequently, one observes one or a few layers of cells with eosinophilic cytoplasm and large, oval, pale, vesicular nuclei situated between the basophilic cells and the horn cysts (54).

A second major component of multiple trichoepitheliomas are tumor islands composed of basophilic cells of the same appearance as epidermal or skin appendage basal cells, which usually are arranged in a lacelike or adenoid network but occasionally also as solid aggregates (Fig. 30-13). These tumor islands show peripheral palisading of their cells and are surrounded by a stroma with increased numbers of fibroblasts. The fibroblasts encircle and are tightly associated with the basaloid islands, lacking the retraction artifact typical of basal cell carcinoma (Fig. 30-13). Both the adenoid and the solid aggregates show invaginations, which contain numerous fibroblasts and resemble follicular papillae, also known as papillary mesenchymal bodies (Fig. 30-14) (63).

Additional findings, observed in some but not all trichoepitheliomas, are the presence of a foreign-body giant-cell reaction in the vicinity of ruptured horn cysts, calcium deposits either within the foci of the foreign-body reaction or within intact horn cysts, and amyloid (54,64).

Occasionally, some lesions in patients with multiple trichoepitheliomas show relatively little differentiation toward hair structures. They contain only a few horn cysts, with many areas resembling basal cell carcinoma (54). Such lesions can be difficult to distinguish from those of a keratotic basal cell

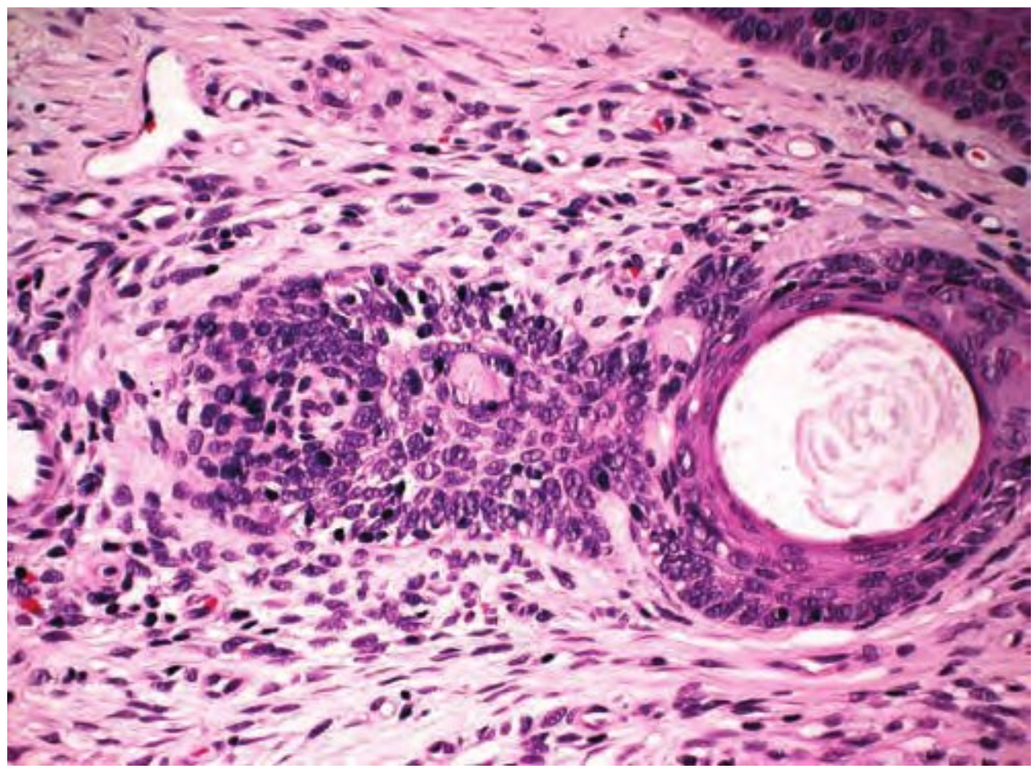

FIGURE 30-14. Trichoepithelioma. Some of the basophilic islands form papillary mesenchymal bodies resembling follicular papillae.

carcinoma, which may also show horn cysts. Thus, on a histologic basis, it may be difficult definitively to distinguish between multiple trichoepitheliomas and basal cell carcinoma (see Differential Diagnosis).

Solitary trichoepithelioma often has a high degree of differentiation toward hair structures. Solitary lesions with relatively little differentiation toward hair structures could be classified as keratotic basal cell carcinoma. If a lesion is to qualify for the diagnosis of solitary trichoepithelioma, it should contain numerous horn cysts and abortive hair papillae and show only few areas with the appearance of basal cell carcinoma (59). Mitotic figures should be rare or absent, and the lesion should not be unduly large, asymmetric, or infiltrative.

Additional Studies. It is assumed that the basophilic cells surrounding horn cysts are similar to hair matrix cells and that the horn cysts represent attempts at hair shaft formation. The eosinophilic cells seen occasionally around horn cysts probably represent cells with initial keratinization and are similar to the nucleated cells seen in normal hair shafts at the keratogenous zone.

Histochemical staining with the Gomori stain for alkaline phosphatase has shown positive staining in many invaginations at the periphery of tumor islands and strands, indicative of a differentiation toward hair papillae (65). An immunohistochemical analysis using a panel of monoclonal antikeratin antibodies suggests that trichoepitheliomas differentiate toward the outer root sheath (66). The expression of cytokeratin 15 in a subset of trichoepitheliomas suggests that these tumors contain cells that are related to hair follicle stem cells in the follicular bulge (67). Electron microscopic study has confirmed that the horn cysts of trichoepithelioma represent immature hair structures, with abrupt development of the horn cells from hair matrix cells (68).

The putative gene for multiple familial trichoepitheliomas has been localized to chromosome 9p21 (69). Several known tumor suppressor genes, including *p15*, *p16*, and *p19*, have been assigned to this region (70). However, loss of heterozygosity on chromosome 9p21 has not been found in sporadic trichoepitheliomas (71). Conversely, in sporadic trichoepitheliomas loss of heterozygosity has been found on chromosome 9q23 (71). In addition, deletions causing overexpression of the human homologue of the *Drosophila* patched gene (*Ptch*) have been found in trichoepitheliomas as in basal cell carcinoma (72). A large body of recent work has demonstrated that mutations in the CYLD2 gene, which appears to function as an ubiquitin-specific protease, are present in some cases of multiple familial trichoepitheliomas (73–79).

The close relationship between trichoepithelioma and basal cell carcinoma has been explained on the basis of the assumption that they have a common genesis from pluripotential cells, which, like primary epithelial germ cells, may develop toward hair structures (14). This hypothesis is supported by the fact that *patched* gene mutations are seen in both tumors (80). Because cells of various degrees of maturity may occur in the same lesion, trichoepithelioma may have areas consistent with the histologic picture of basal cell carcinoma and vice versa.

Differential Diagnosis. The difficulty of differentiating multiple trichoepitheliomas from keratotic basal cell carcinoma on histologic grounds has been pointed out, and the need for clinical data has been stressed. Diagnosis may be assisted, in a given case, by clinical data, such as the number and distribution of the lesions and the presence of hereditary transmission. In addition, certain histologic features, as well as immunohistochemical stains, can assist in differentiating between the two. The presence of well-formed horn cysts, papillary-mesenchymal bodies, and lack of high-grade atypia and mitoses favor the diagnosis of trichoepithelioma (81). Histologic features that favor basal cell carcinoma include the presence of myxoid stroma and stromal retraction or clefting around the basaloid islands (64). Focal positive CD34 staining of the fibroblastic stroma has been shown in trichoepitheliomas, whereas in basal cell carcinoma, this staining pattern was not seen (82). However, in a separate study similar CD34 staining was found in trichoepitheliomas but also in many metatypical basal cell carcinomas (83). Staining of the outermost epithelial layer for bcl-2 has been seen in several trichoepitheliomas. In contrast, basal cell carcinomas frequently stain diffusely (83,84). Immunohistochemistry for CD10 may be helpful in differentiating trichoepitheliomas from basal cell carcinomas. CD10 stains the stromal cells but not the epithelial cells in trichoepitheliomas, whereas in basal cell carcinomas, CD10 is present in the epithelial cells and rarely in the stromal cells (85).

The differentiation of multiple trichoepitheliomas from the nevoid basal cell carcinoma syndrome on histologic grounds can be just as difficult. This, too, often requires clinical information. Although both diseases are dominantly inherited and have multiple lesions, the lesions in multiple trichoepitheliomas present mainly in the nasolabial fold, remain small, and hardly ever ulcerate, whereas the lesions in the nevoid basal cell carcinoma syndrome are haphazardly distributed and, especially in the late, "neoplastic" phase, can grow to considerable size, ulcerate deeply, and show severely destructive growth. In addition, patients with the nevoid basal cell carcinoma syndrome almost invariably show multiple skeletal and central nervous system anomalies and frequently show multiple palmar and plantar pits.

Desmoplastic Trichoepithelioma

Desmoplastic trichoepithelioma, typically a sporadic lesion, was formerly considered a solitary trichoepithelioma (54,59). However, it has sufficient clinical and histologic characteristics to be regarded as a distinct variant of trichoepithelioma. The term *desmoplastic trichoepithelioma* appears preferable to the designation *sclerosing epithelial hamartoma* because it stresses the relationship of the lesion to solitary trichoepithelioma (86,87).

Clinically, the tumor almost always is located on the face, measures from 3 to 8 mm in diameter, and is markedly indurated. In many instances, there is a raised, annular border

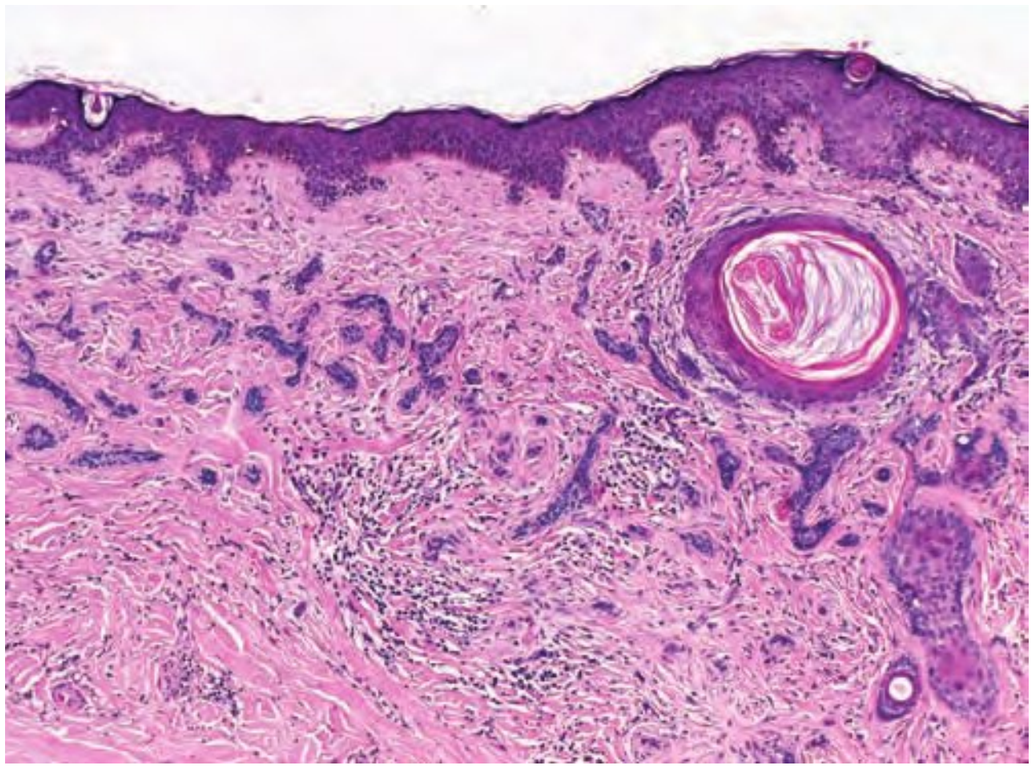

FIGURE 30-15. Desmoplastic trichoepithelioma. Horn cysts and narrow strands of epithelial cells are embedded in a fibrous stroma.

and a depressed nonulcerated center, causing the lesion to resemble granuloma annulare (86). Most commonly, the lesion appears in early adulthood, but it quite frequently appears in the second decade of life (87). It is much more common in females than in males (86). Familial desmoplastic trichoepitheliomas have been reported infrequently (88,89).

Histopathology. The three characteristic histologic features are narrow strands of tumor cells, horn cysts, and a desmoplastic stroma (Figs. 30-15 and 30-16) (86). The tumor strands usually are from one to three cells thick and are composed of small basaloid cells with prominent oval nuclei and scant cytoplasm. Usually there are numerous horn cysts, which in some cases are large (90). Considerable amounts of densely collagenous and hypocellular stroma are present. Large aggregates of tumor cells are not seen. Foreign-body granulomas at the site of ruptured horn cysts and areas of calcification within some of the horn cysts are seen in many tumors.

Differential Diagnosis. The resemblance to microcystic adnexal (eccrine) carcinoma and syringoma may be considerable, especially if a superficial specimen is taken for biopsy. Like desmoplastic trichoepithelioma, microcystic adnexal carcinoma has horn cysts, strands of basaloid cells, and a dense desmoplastic stroma. It differs, however, by showing ductal structures, a deeply infiltrating growth, and often perineural invasion (91). The diagnosis of microcystic adnexal carcinoma should be considered in any tumor resembling a trichoepithelioma or a syringoma in which the lesional cells extend to the base of the specimen. Syringomas, which usually are periorbital, rarely have horn cysts, foreign-body granulomas, or calcification (86).

Desmoplastic trichoepithelioma may also resemble morphea-like (fibrosing) basal cell carcinoma. However, in morphea-like basal cell carcinoma, horn cysts are absent. Of value in ruling out basal cell carcinoma, especially the morphea-like form, are the absence of mitoses, individual cell necrosis, and mucinous stroma and the lack of foci of separation artifact of lesional epithelium and stroma (86). The immunostains for CD34 and bcl-2, discussed previously, also may assist in discriminating between the two lesions (83,84,92). In addition, matrix metalloproteinase stromelysin-3 (ST-3) expression has been demonstrated in morphea-like basal carcinomas but not desmoplastic trichoepitheliomas (93). The presence of Merkel cells has been shown in desmoplastic trichoepitheliomas and not morphea-like basal cell carcinomas (94).

Occasional lesions of solitary or desmoplastic trichoepithelioma cannot reliably be distinguished from keratotic or morphea-like basal cell carcinomas, respectively. A descriptive report and a recommendation for complete excision are appropriate in such cases.

Trichoblastoma

Trichoblastomas are benign skin lesions that recapitulate in some form the developing hair follicle. They differ from trichoepitheliomas in size, location, and lack of keratinizing cysts (95). Trichoblastomas are usually about 1.0 cm in size and most commonly occur on the scalp (Fig. 30-17) (96). Multiple lesions have been described (97). As mentioned, these lesions are benign, and aggressive forms may represent a type of basal cell carcinoma (98,99).

Histopathology. Trichoblastomas consist of a proliferation of follicular germ cells manifested by a combination of various proportions of mesenchymal and epithelial cells. A spectrum of lesions is seen, depending on the proportions of mesenchymal and epithelial components. At one end of the spectrum is the predominantly mesenchymal variant, termed the trichogenic fibroma, and at the other end is the classic trichoblastoma composed predominantly of basaloid epithelial islands (96). The classic large lesion is comprised of islands of basaloid cells occupying the dermis with occasional extension into the subcutaneous fat (Fig. 30-18). These basaloid islands demon-

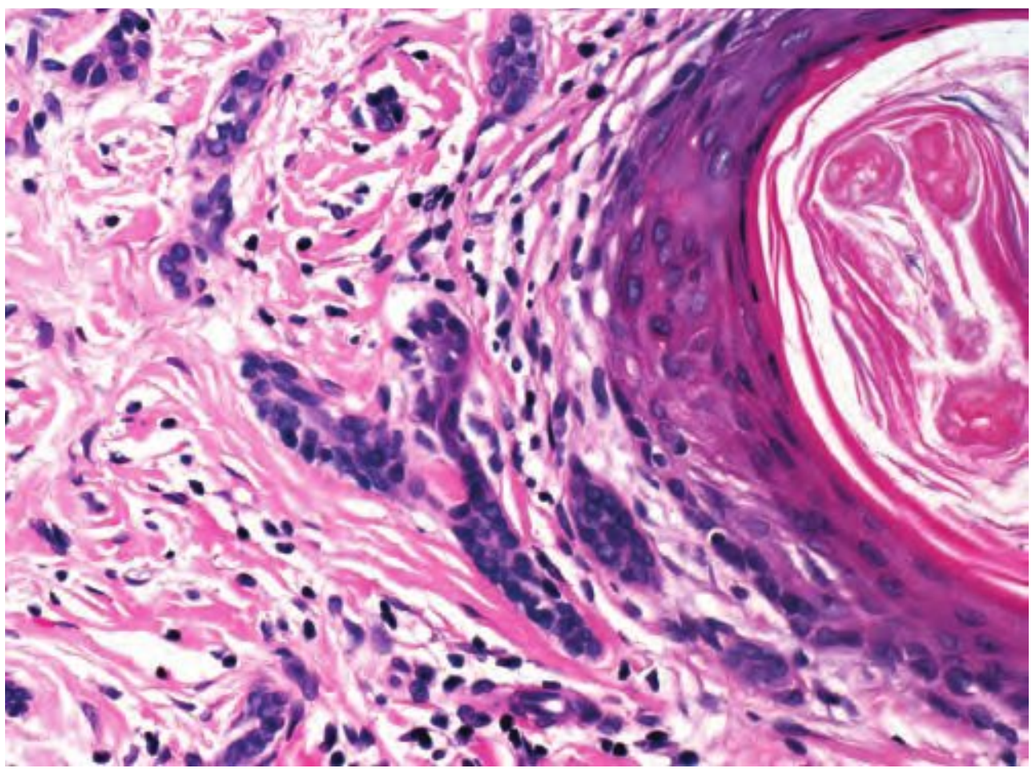

FIGURE 30-16. Desmoplastic trichoepithelioma. The strands of tumor cells are comprised of small basaloid cells and are usually one to three cells thick.

FIGURE 30-17. Trichoblastoma. A circumscribed, pigmented nodule is noted on the scalp.

strate peripheral palisading and a fibrocellular stroma similar to that surrounding follicles; mitotic activity can be seen (Fig. 30-19). There is no overlying epidermal connection. The trichogenic fibroma variant displays small basaloid epithelial islands, exhibiting follicular differentiation, dispersed in a fibrotic stroma (Figs. 30-20 and 30-21). Less common variants have been described, including giant, clear cell, pigmented, rippled-pattern trichoblastomas, and cutaneous lymphadenoma (100–104).

FIGURE 30-18. Trichoblastoma. Large islands of basaloid tumor cells are present in the dermis exhibiting peripheral palisading associated with a fibrous stroma.

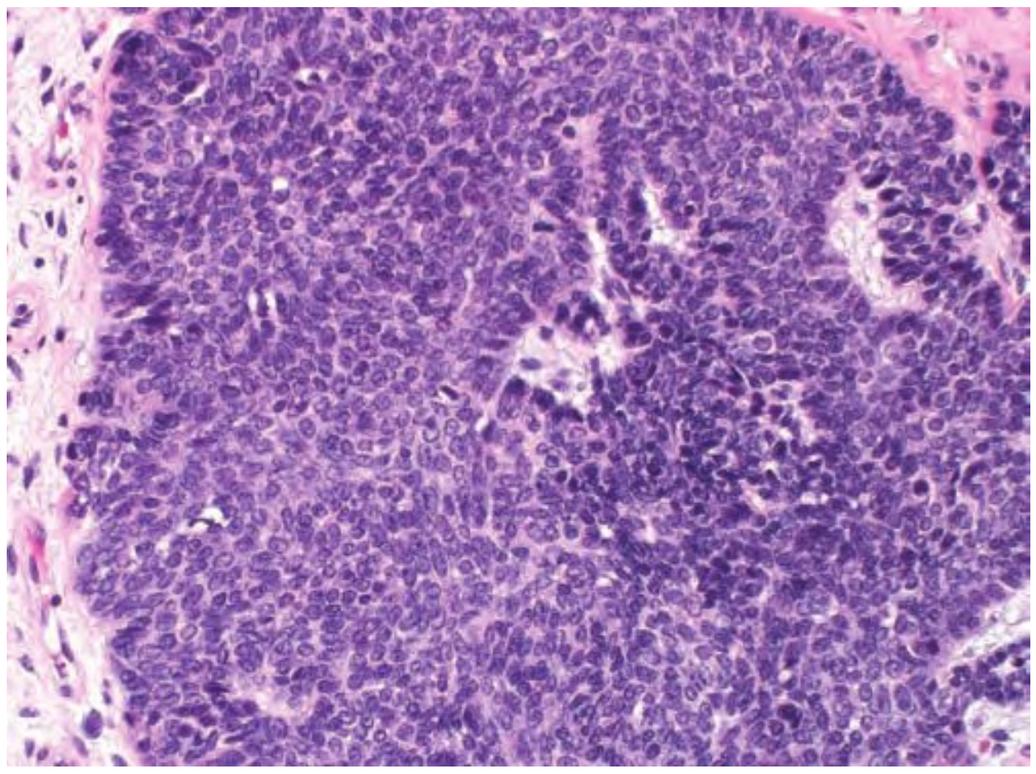

FIGURE 30-19. Trichoblastoma. Higher power showing epithelial structures reminiscent of follicular germs and occasional mitotic activity.

Similar lesions that are infiltrative, exhibit cytologic atypia, and mitotic activity may be termed *trichoblastic carcinoma*, but these lesions may overlap with basal cell carcinoma (Figs. 30-22 and 30-23). Such problematic lesions may be signed out descriptively as *malignant adnexal neoplasm* with a description of the apparent differentiation. Criteria that may have value in distinguishing trichoblastomas and trichilemmomas from basal cell carcinomas include the following: the presence in the former of symmetry, circumscription with smooth margins and "shelling out" of the normal tissue, and follicular and "racemiform" patterns of lesional cells, the lack of a clefting

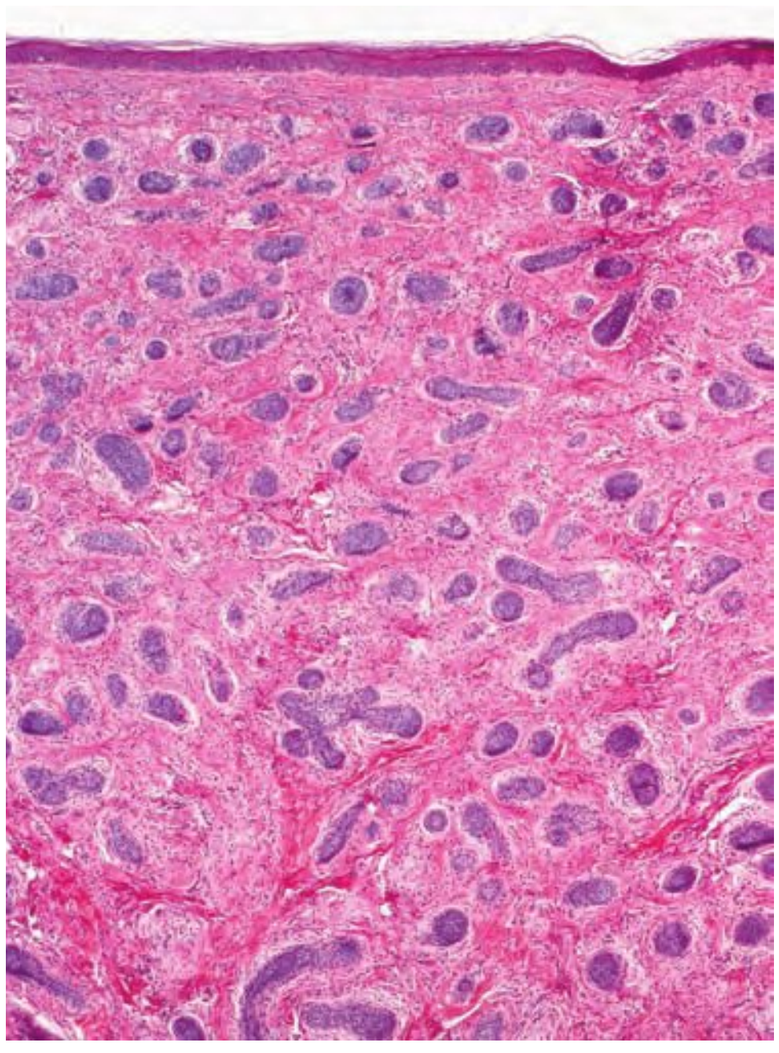

FIGURE 30-20. Trichogenic fibroma. The lesion manifests small basaloid islands in a prominent fibrotic stroma.

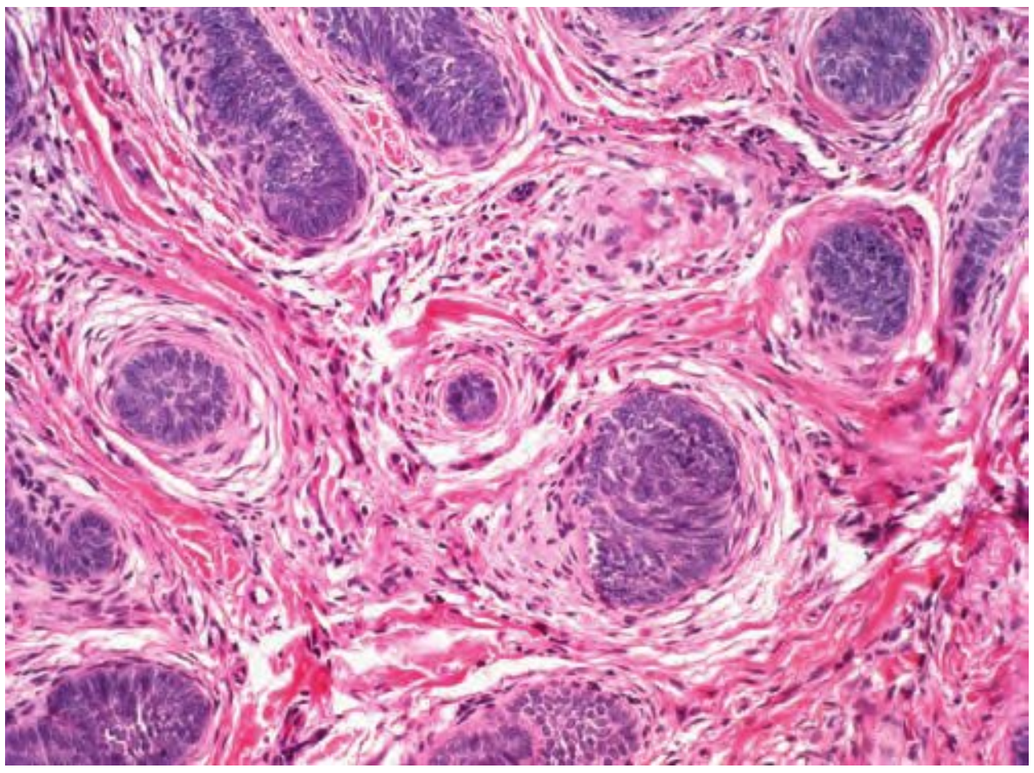

FIGURE 30-21. Trichogenic fibroma. The epithelial-stromal structures mimic those of hair follicles.

artifact between stroma and epithelium that is characteristic of basal cell carcinoma, the lack of stromal edema and lymphocytes, the formation of a delicate stroma reminiscent of that formed around immature hair follicles, and the lack of ulceration (105).

Trichoadenoma

A rare, solitary tumor first described in 1958, trichoadenoma usually occurs on the face or buttocks as a solitary nodular lesion and varies from 3 to 15 mm in diameter (106,107). It may arise anytime during adult life. It may clinically mimic basal cell carcinoma.

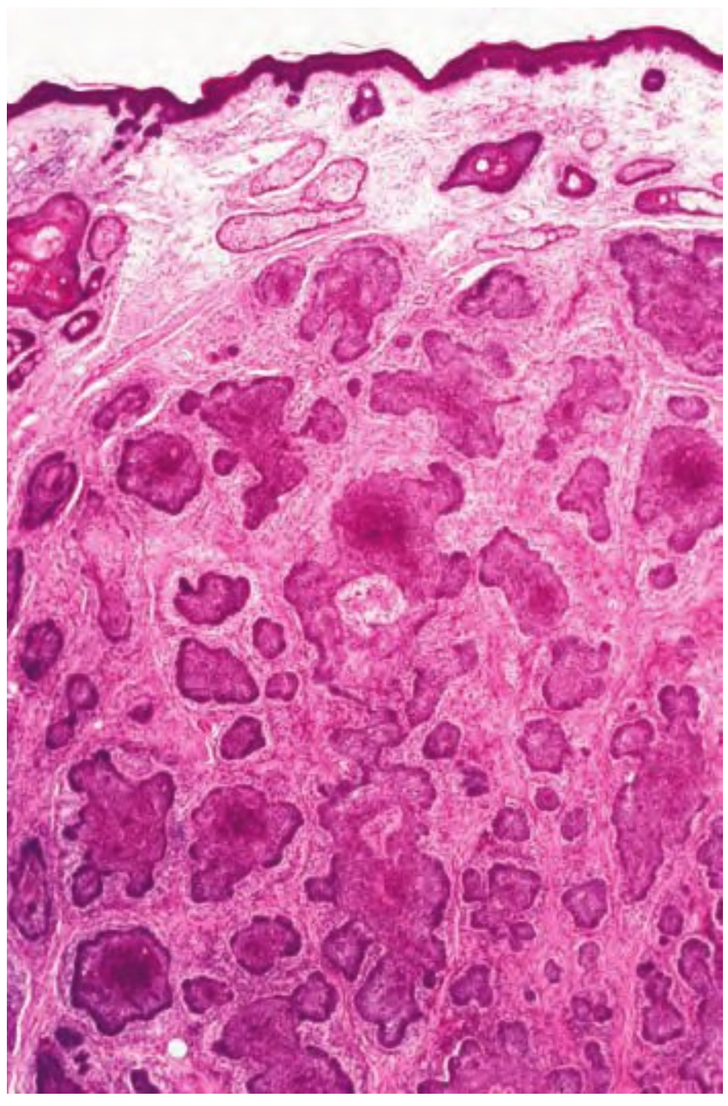

FIGURE 30-22. Trichoblastic carcinoma. A large dermal tumor comprised of irregular epithelial islands.

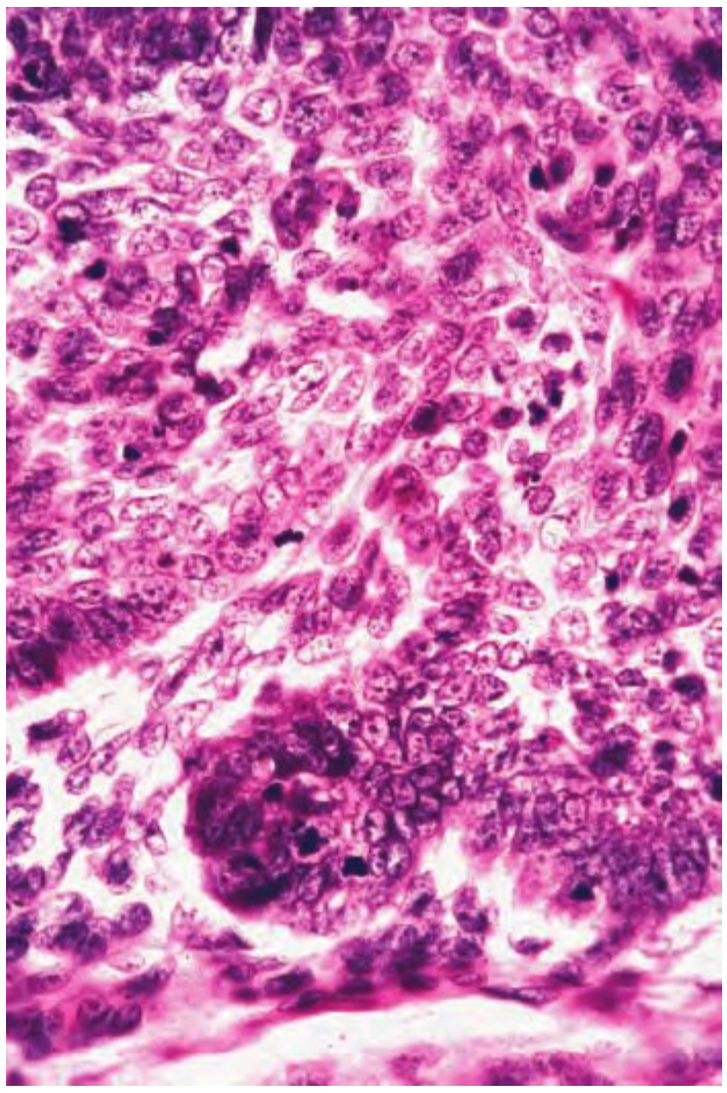

FIGURE 30-23. Trichoblastic carcinoma. Higher power demonstrates cytologic atypia, numerous mitoses, and a fibrocellular stroma.

Histopathology. Numerous horn cysts are present throughout the dermis (Fig. 30-24). They are surrounded by eosinophilic cells, which greatly resemble the eosinophilic cells that are often seen in trichoepithelioma located between the basophilic cells and the central horn cysts (Fig. 30-25). In some instances, a single layer of flattened granular cells is interpolated between the horn cysts and the surrounding eosinophilic cells (107–109). Some islands consist only of eosinophilic epithelial

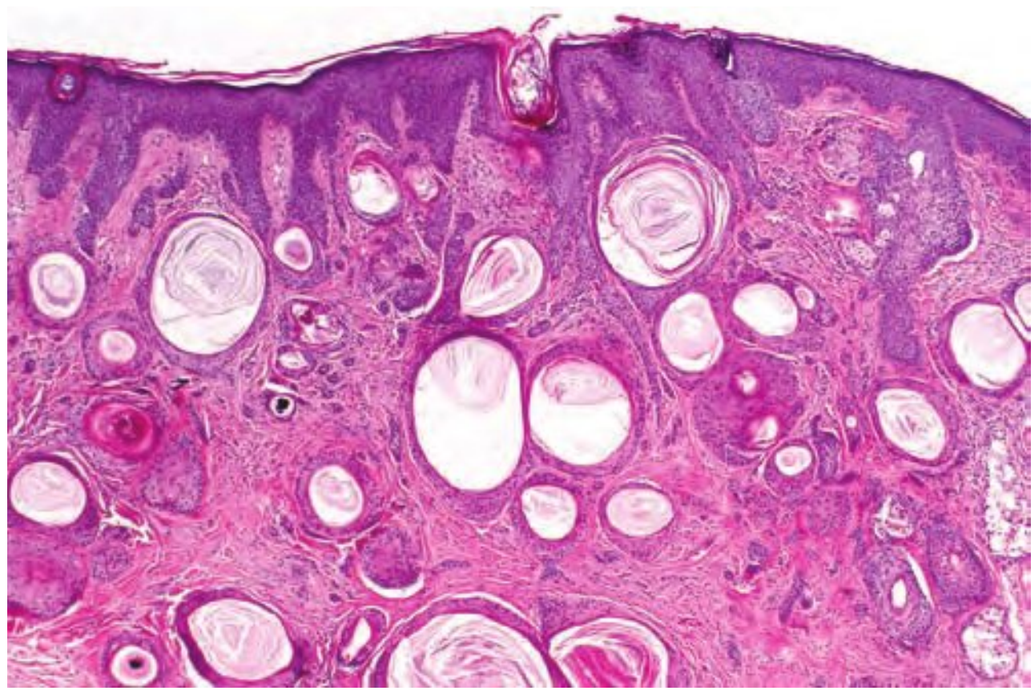

FIGURE 30-24. Trichoadenoma. Numerous horn cysts are present in the dermis.

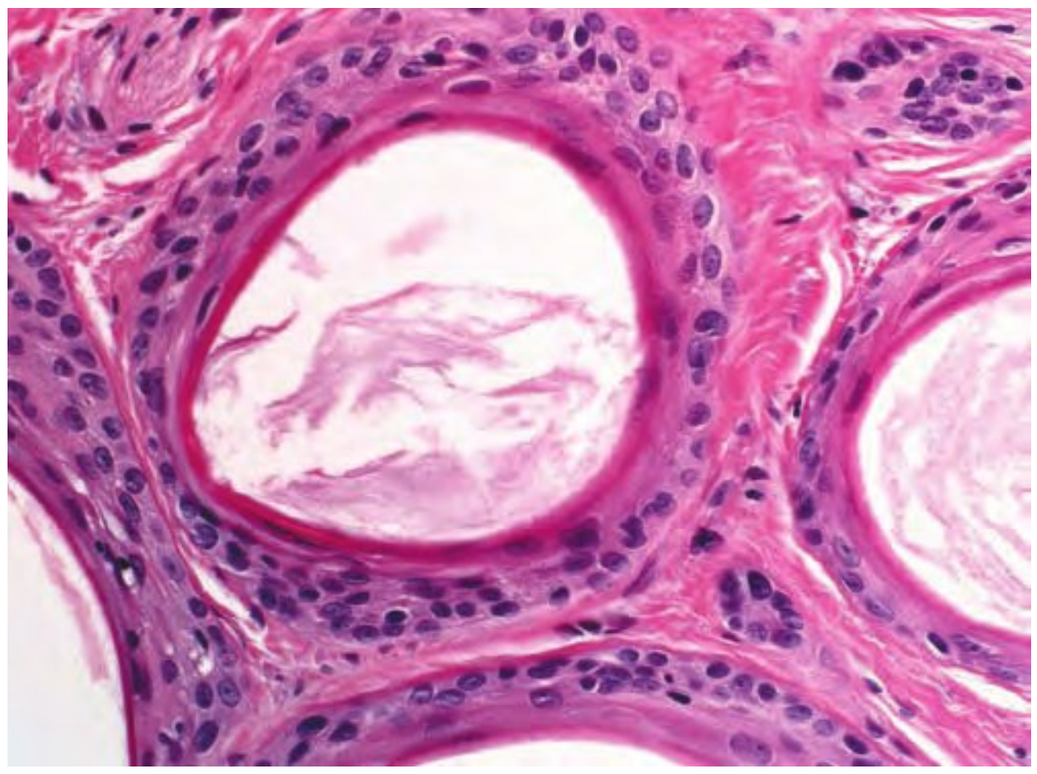

FIGURE 30-25. Trichoadenoma. The horn cysts are lined by eosinophilic cells and contain keratin.

cells without central keratinization. Sparse intercellular bridges have been observed between the eosinophilic cells. Foci of foreign-body granuloma are present at the sites of ruptured horn cysts (106). A variant has been described, termed verrucous trichoadenoma, which clinically resembles a seborrheic keratosis (110).

Additional Studies. In terms of morphologic differentiation, the trichoadenoma is situated between a trichofolliculoma and a trichoepithelioma (111). The general architecture of trichoadenoma greatly resembles that of trichoepithelioma and thus suggests the development of immature hair structures. However, because the cyst wall consists of epidermoid cells and the keratinization may take place with formation of keratohyaline, it has been suggested that the tumor differentiates largely toward the infundibular portion of the pilosebaceous unit (107). In fact, the keratin expression pattern of trichoadenomas resembles that seen in follicular infundibula and the follicular bulge (112).

Generalized Hair Follicle Hamartoma and Basaloid Follicular Hamartoma

Only a few cases have been described of generalized hair follicle hamartoma, a distinctive condition characterized by progressive alopecia starting in adulthood, diffuse papules and plaques of the face, and an association with myasthenia gravis (113–116).

Basaloid follicular hamartoma was originally described as a localized patch of alopecia on the scalp (117). Solitary and multiple familial lesions have since been described (118,119). A few rare syndromes have been described that among their many manifestations have lesions reminiscent of basaloid follicular hamartomas (113,120). An autosomally dominant inherited form with multiple basaloid follicular hamartomas has been described and named *dominantly inherited generalized basaloid follicular hamartoma syndrome*. Generalized lesions have been described without other associated abnormalities (121). These syndromes all may represent contiguous gene syndromes or different allelic forms of the same gene mutation (122,123).

Histopathology. In both hamartomas, the hair loss is the result of damage inflicted on each hair follicle by gradually growing "hair follicle hamartomas."

In the generalized hair follicle hamartoma, areas of alopecia without papules or plaques reveal more or less advanced replacement of the hair follicles by a lacelike network of basaloid cells with follicular differentiation resembling trichoepithelioma (113,115). The papules and plaques of the face show a complete lack of hair structures and extensive proliferations of basaloid cells embedded in a cellular stroma with formation of horn cysts in some areas. The histologic appearance is indistinguishable from that of trichoepithelioma (114).

The basaloid follicular hamartoma reveals strands and cords of small, basaloid cells emanating from the infundibular portion of the hair follicle (Figs. 30-26 and 30-27) (123,124). The tumor stroma is mildly fibrocellular. There is no significant cleft-ing between tumor and stroma, and mitotic activity is rare (Fig. 30-27). These lesions may have a similar appearance to infundubulocystic basal cell carcinoma, but usually they can be distinguished on clinical and histologic grounds (123,125,126).

Differential Diagnosis. Linear unilateral basal cell nevus shows similar basaloid proliferations, some of which may resemble trichoepithelioma and basal cell carcinoma, but the clinical picture is different because the lesion is congenital and unilateral (127).

Additional Studies. Transgenic mice with increased epidermal expression of *smoothened* demonstrate activation of the Sonic Hedgehog signaling pathway and exhibit lesions similar to basaloid follicular hamartomas (128).

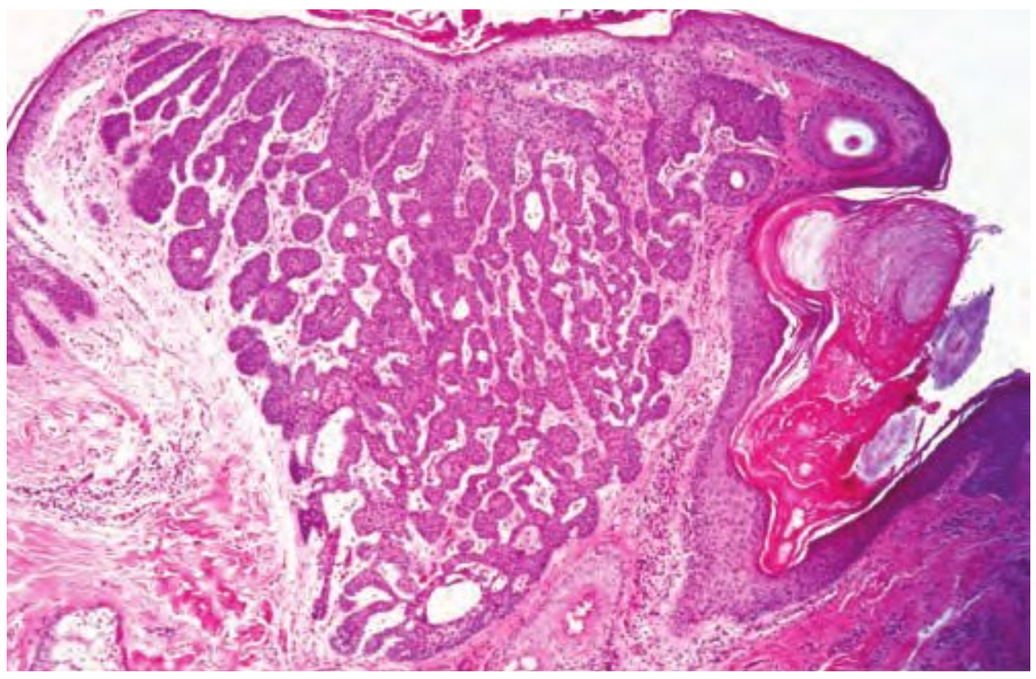

FIGURE 30-26. Basaloid follicular hamartoma. Present is a small, well-circumscribed lesion comprised of strands of epithelial cells with scattered cystic structures.

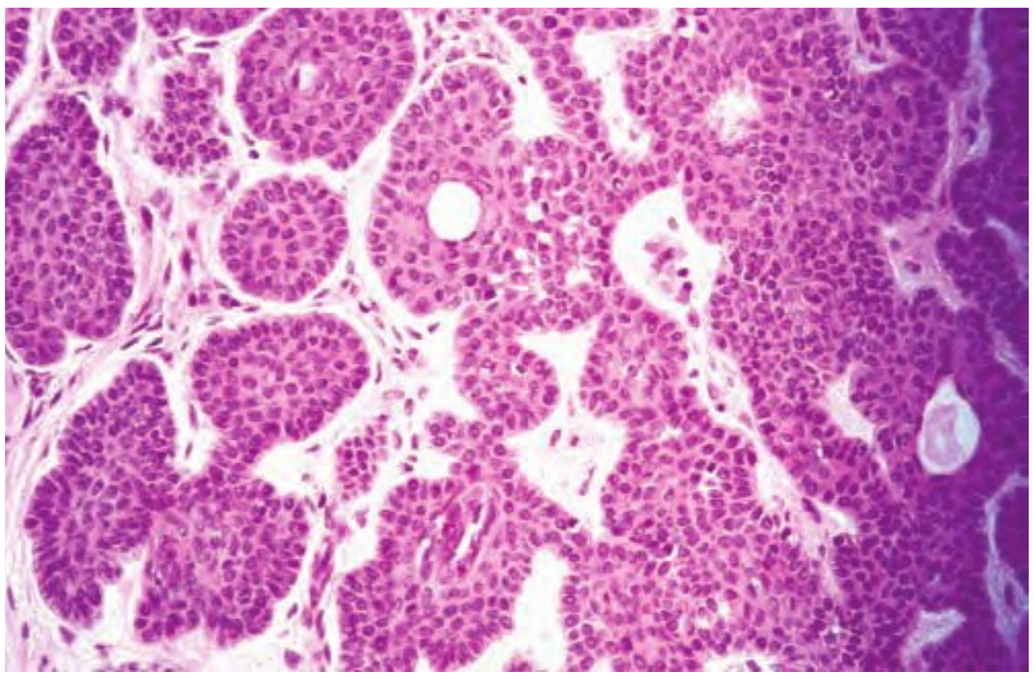

FIGURE 30-27. Basaloid follicular hamartoma. The lesion exhibits small basaloid cells lacking necrosis or mitotic activity. A mildly fibrocellular stroma is seen.

Pilomatricoma

Pilomatricoma (pilomatrixoma), or calcifying epithelioma of Malherbe, is a tumor with differentiation toward hair cells, particularly hair cortex cells. Pilomatricoma occurs usually as a solitary lesion. The face and the upper extremities are the most common sites. Generally, the tumor varies in diameter from 0.5 to 3.0 cm, but it may be as large as 5 cm. The tumors may arise in persons of any age, but about 40% of them arise in children younger than 10 years of age, and about 60% in persons in the first two decades of life (129).

It frequently presents as a firm, deep-seated nodule that is covered by normal skin. Occasionally, however, the tumor is more superficially located, causing a blue-red discoloration of the overlying skin, and, rarely, it protrudes as a sharply demarcated, dark-red nodule. Rapid enlargement of a pilomatricoma may occur as the result of formation of a hematoma (130). Perforation may take place with extrusion of parts of the contents (131). Although, as a rule, pilomatricoma is not hereditary, there are a few instances of familial occurrence, and in some of these cases the tumor is associated with myotonic dystrophy (132,133). Pilomatricoma-type changes can be seen in the epidermal cysts of Gardner's syndrome (134). Unusual clinical variants include large, extruding, or perforating examples, multiple eruptive cases, familial cases, and malignant examples termed *pilomatrix carcinoma* (see text following) (135–139).

Histopathology. The tumor is sharply demarcated and often surrounded by a connective tissue capsule (Fig. 30-28). It is usually located in the lower dermis and extends into the subcutaneous fat. Embedded in a rather cellular stroma are irregularly shaped islands of epithelial cells. As a rule, two types of cells, *basophilic cells* and *shadow cells*, compose the islands (Fig. 30-29) (140). In some tumors, however, basophilic cells are absent. The basophilic cells possess round or elongated, deeply basophilic nuclei and scanty cytoplasm, so that the nuclei lie close together (Fig. 30-29). The cellular borders of the basophilic cells often are indistinct, so that it appears as if

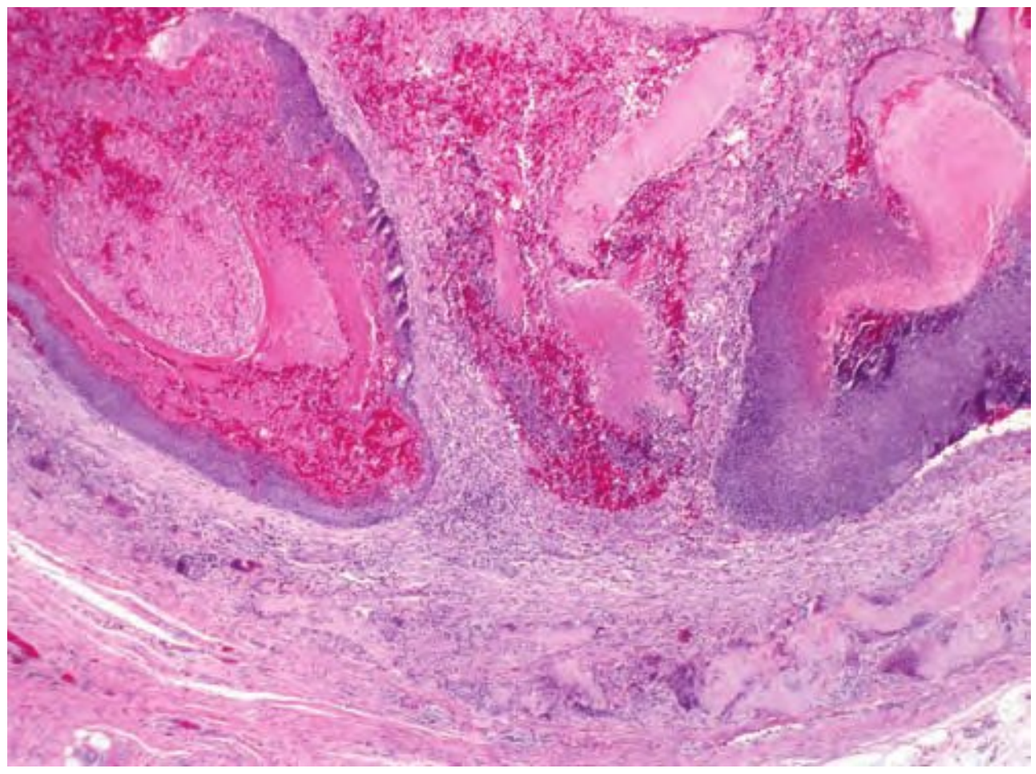

FIGURE 30-28. Pilomatricoma. The tumor is often well circumscribed and composed of epithelial islands embedded in a cellular stroma. Two types of cells comprise the islands: basophilic cells and shadow cells. The basophilic cells resemble hair matrix cells. The shadow cells show a central unstained shadow at the site of the lost nucleus. In the center of the field, one can see transformation of the basophilic cells into shadow cells.

the nuclei were embedded in a contiguous mass. The basophilic cells are arranged either on one side or along the periphery of the tumor islands. In some areas, the transition of basophilic cells into shadow cells is abrupt, whereas in others the transition is gradual. In areas of gradual transition there are cells showing a gradual loss of nuclei and ultimately appearing as faintly eosinophilic, keratinized shadow cells. The shadow cells have a distinct border and possess a central unstained area as a shadow of the lost nucleus. In tumors of recent origin, numerous areas of basophilic cells usually are present. As the lesion ages, the number of basophilic cells decreases because of

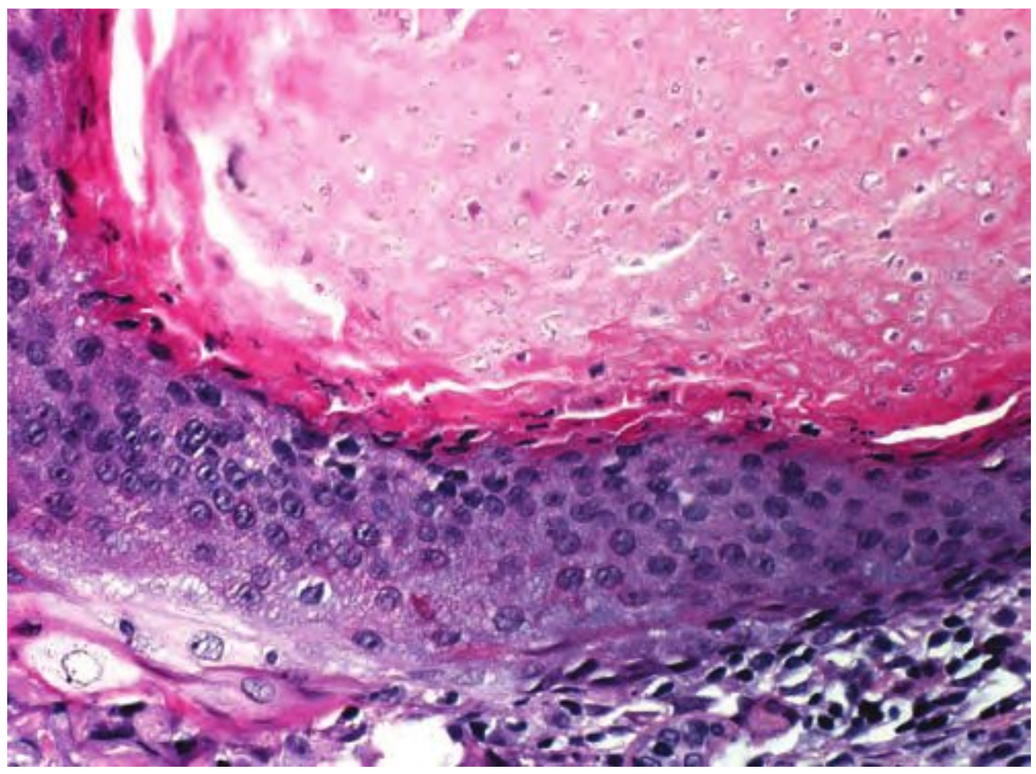

FIGURE 30-29. Pilomatricoma. The transformation of basaloid cells into shadow cells is associated with loss of nuclei.

development into shadow cells, and in tumors of long standing few or no basophilic cells remain.

In many tumors, small, round, eosinophilic centers of keratinization are seen within areas of basophilic cells or within aggregates of shadow cells. The keratinization within these centers is abrupt and complete (141). In some tumors, melanin is present, as can be expected in tumors with differentiation toward hair bulbs. It is found most commonly in shadow cells or within melanophages of the stroma. A variant of pilomatricoma with numerous dendritic melanocytes located in the islands of basophilic cells has been described and termed melanocytic matricoma (142–144).

With the von Kossa stain, calcium deposits are found in approximately 75% of the tumors (145). Usually, the calcium is already apparent as deeply basophilic deposits in sections stained with hematoxylin-eosin. Most of the tumors containing calcium are composed largely of shadow cells. The calcium is seen either as fine basophilic granules within the cytoplasm of the shadow cells or as large sheets of amorphous, basophilic material replacing the shadow cells. Occasionally, foci of calcification are seen in the stroma of the tumors. Areas of ossification are seen in 15% to 20% of the cases (146). Ossification takes place in the stroma next to areas of shadow cells, probably through metaplasia of fibroblasts into osteoblasts. Bone morphogenic protein-2 has been shown in the cytoplasm of shadow cells but not in basophilic cells, indicating a possible role in bone formation (147). Calcium-rich shadow cells may act as inducing factors (148). The stroma of pilomatricomas often shows a considerable foreign-body reaction containing many giant cells adjacent to the shadow cells (Fig. 30-30).

Additional Studies. Pilomatricoma was originally described in 1880 as calcified epithelioma of sebaceous glands; however, it was recognized in 1942 that the cells of the tumor differentiate in the direction of hair cortex cells, a finding that was subsequently confirmed by electron microscopic studies (149,150). On this basis, the designation *pilomatricoma* was suggested (146).

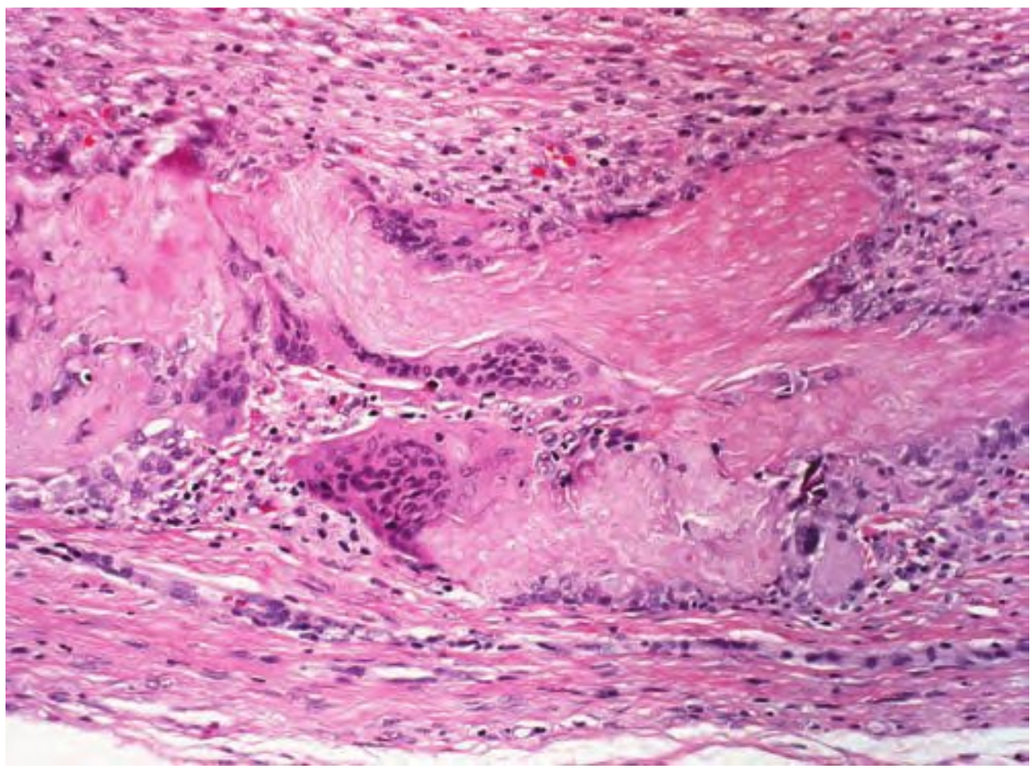

FIGURE 30-30. Pilomatricoma. The stroma often contains numerous multinucleated giant cells reacting to tumoral keratin.

Histochemical studies have revealed in most tumor cells a strongly positive reaction with the periodic acid-Schiff stain for sulfhydryl or disulfide groups. This reaction is indicative of keratinization (145,146,151). As further evidence of keratinization, the shadow cells show strong birefringence in polarized light (152). A very similar birefringence is seen in the keratogenous zone of hair (146).

Electron microscopic examination has revealed a few desmosomes and a moderate number of tonofilaments in the areas of basophilic cells (153). In cells that are in transition to shadow cells, numerous tonofilaments are seen aggregated into thick keratin fibrils. They form keratin without the appearance of keratohyaline granules. A striking resemblance exists between cells that are in transition to shadow cells and cells in the keratogenous zone of normal hair because both types of cells show thick keratin fibrils concentrically arranged around a faintly visible nucleus. Fully developed shadow cells show numerous fused, electron-dense keratin fibrils surrounding the empty nuclear area (151,153,154).

Several studies using immunohistochemistry and *in situ* hybridization with various cytokeratins and hair-specific keratins further support the notion that pilomatrixomas differentiate toward cortical cells of the normal hair shaft during their maturation process (155–157).

Mutations in the gene for β-catenin (*CTNNB1*) have been described in pilomatricomas (158,159). The resulting mutation stabilizes the β-catenin protein, which translocates into the nucleus, where it activates gene transcription through members of the Lef/Tcf family (160).

Differential Diagnosis. The wall of trichilemmal cysts also contains basophilic cells, which as they keratinize gradually lose their nuclei and often undergo calcification. The peripheral layer of basophilic cells in trichilemmal cysts, however, shows a palisading pattern, whereas the basophilic cells of pilomatricoma do not. Furthermore, shadow cells characterized by a central unstained area at the site of the disintegrated nucleus are seen only in pilomatricomas and, exceptionally, in basal cell carcinomas with foci of matrical differentiation (161).

Pilomatrix Carcinoma

Pilomatrix carcinoma is the rare malignant counterpart of pilomatricoma. The lesions have a male predominance and occur in older patients. Some pilomatricomas show apparent transformation into carcinomas (162,163). Other cases are malignant from the onset (164,165). Pilomatrix carcinomas are not necessarily larger than benign pilomatricomas. Pulmonary and bone metastases may occur (137,166,167). The lesions have a tendency to recur if not widely excised (136).

Histopathology. Pilomatrix carcinomas are asymmetric, cellular, infiltrative neoplasms (Fig. 30-31). Many areas, especially at the periphery of the tumor, show proliferations of large, anaplastic, hyperchromatic basophilic cells with numerous mitoses (Fig. 30-32); however, this can be seen in pilomatricomas on occasion (163). Toward the center of the tumor, there

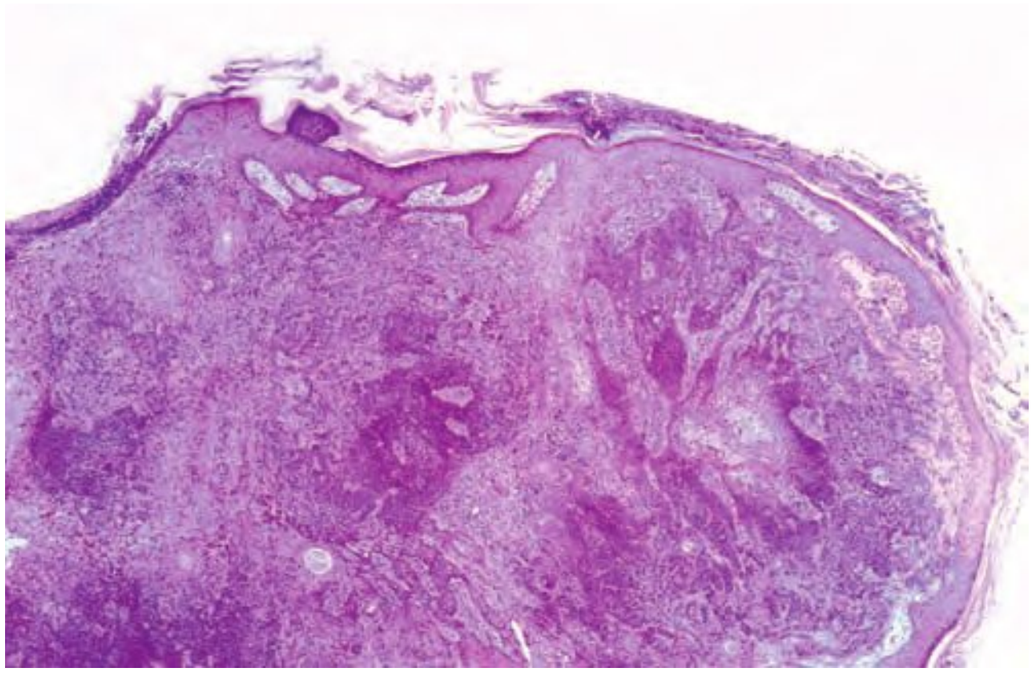

FIGURE 30-31. Pilomatrix carcinoma. There is a cellular, asymmetric, ulcerated tumor that infiltrates the dermis.

may be transformation of basophilic cells into eosinophilic shadow cells of the type seen in benign pilomatricomas, or there may be large cystic centers containing necrotic debris (165,168). Features that are helpful in making the diagnosis include asymmetry and poor circumscription, presence of several markedly sized and variably shaped basaloid aggregations of tumor cells, continuity of basaloid cells with the epidermis, extensive areas of necrosis en masse, infiltrative growth pattern, and presence of ulceration (169).

Additional Studies. Pilomatrix carcinoma has been found to express keratins 5, 14, and 17, whereas pilomatricomas typically lack these keratins (170).

Proliferating Trichilemmal Cyst

The proliferating trichilemmal cyst, also referred to as proliferating trichilemmal tumor, is typically a single lesion; rarely, there are multiple lesions (171,172). Another common designation used for this lesion is proliferating pilar tumor. About 90% of the cases occur on the scalp, with the residual 10% occurring mainly on the back. More than 80% of the patients are women, most of them elderly (173).

Starting as a subcutaneous nodule suggestive of a wen, the tumor may grow into a large, elevated, lobulated mass that may undergo ulceration and thus greatly resembles a squamous cell carcinoma (173). The tumor may occur in association with one or even several trichilemmal cysts of the scalp (174,175). There is evidence that a proliferating trichilemmal cyst may develop from an ordinary trichilemmal cyst (173,176). However, the tumor may also give rise to one or several trichilemmal cysts, which ultimately may separate from it (172). In several instances, rapid enlargement of nodular scalp lesions indicated malignant transformation (177). In such cases, metastases may arise.

Histopathology. The proliferating trichilemmal cyst, or proliferating trichilemmal tumor, usually is well demarcated from the surrounding tissue (178). It is composed of multiple, variably sized lobules of squamous epithelium, and the epithelial lining is typically thicker than that seen in pilar cysts (Fig. 30-33). Some of the lobules are surrounded by a vitreous layer and show palisading of their peripheral cell layer (172). Characteristically, the epithelium in the center of the lobules abruptly changes into eosinophilic amorphous keratin (Fig. 30-34). This amorphous keratin is of the same type as that seen in the cavity of ordinary trichilemmal cysts (179). In addition to showing trichilemmal keratinization, some proliferating trichilemmal cysts exhibit changes resembling the keratinization of the follicular infundibulum. These changes consist of epidermoid keratinization resulting in horn pearls, some of which resemble "squamous eddies" (173).

The tumor cells in many areas show some degree of nuclear atypia, as well as individual cell keratinization, which at first glance suggests a squamous cell carcinoma (Fig. 30-34) (174,180). The tumor differs from a squamous cell carcinoma by a rather sharp demarcation from the surrounding stroma, as

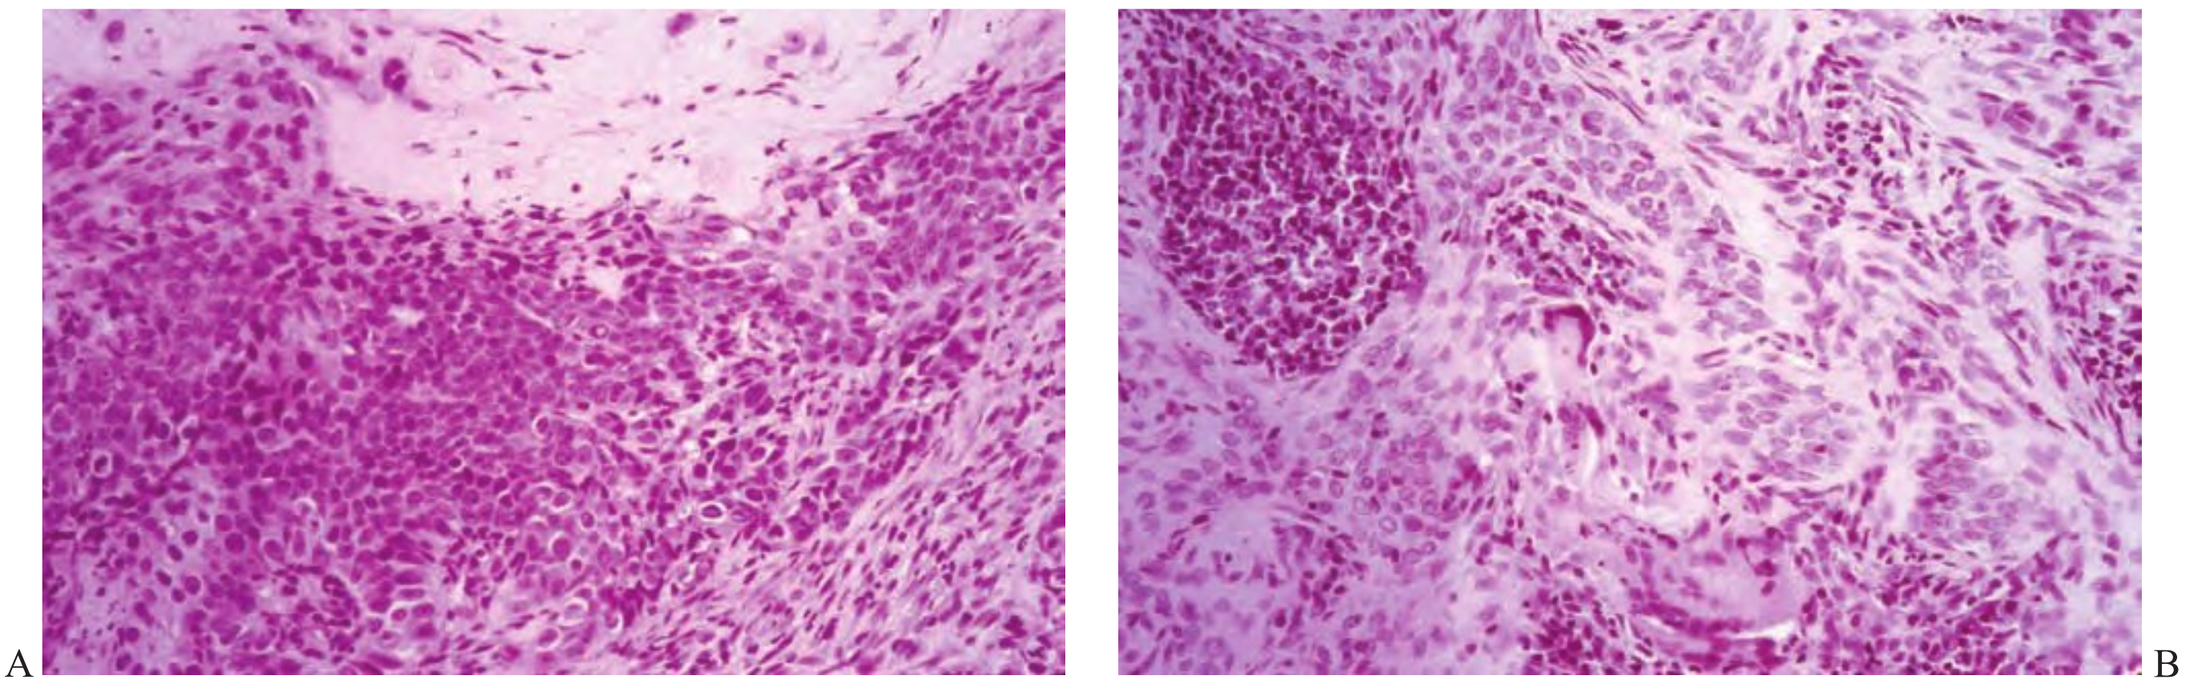

FIGURE 30-32. (A-B) Pilomatrix carcinoma. Hyperchromatic, anaplastic cells exhibit mitotic activity and transition into shadow cells.

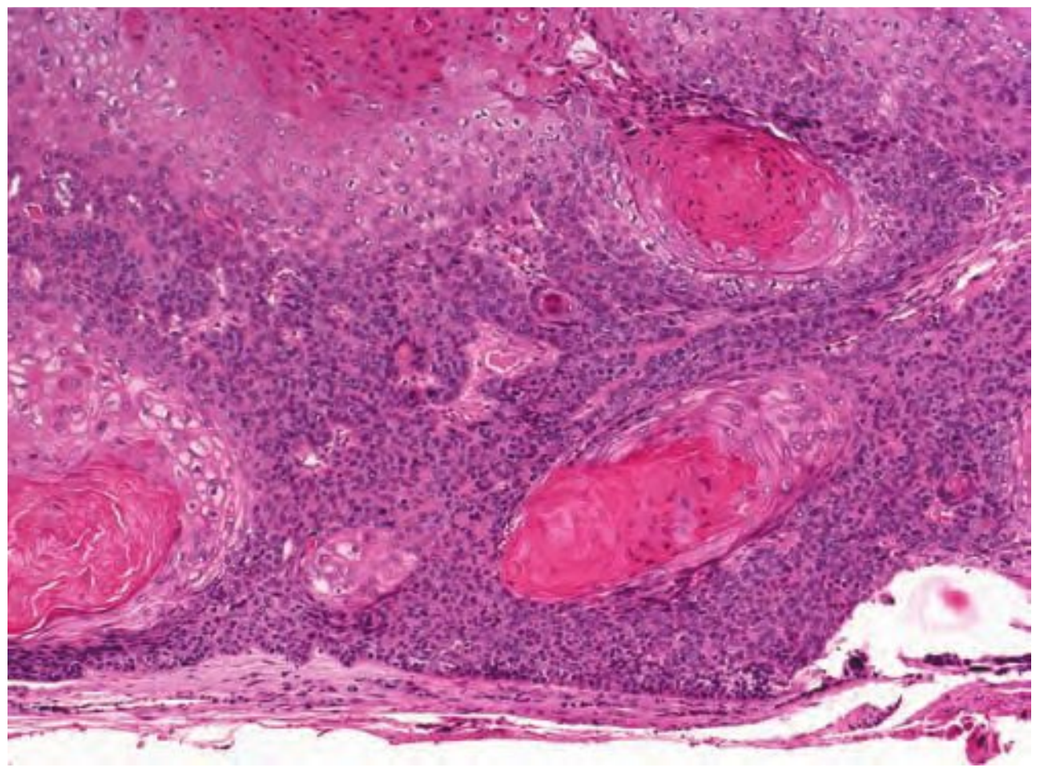

FIGURE 30-33. Proliferating trichilemmal cyst. The tumor is composed of irregularly shaped lobules of squamous epithelium undergoing an abrupt change into amorphous keratin. Central portions of the lobules demonstrate amorphous keratin.

well as an abrupt mode of keratinization (178). Foci of calcification, although generally small, are often present in the areas of amorphous keratin (175,178). Some tumors show vacuolization or clear cell formation of some of the tumor cells as a result of glycogen storage (174,179).

Differential Diagnosis. In addition to its well-circumscribed nature, the presence of numerous sharply demarcated areas of amorphous eosinophilic keratin in the center of the tumor

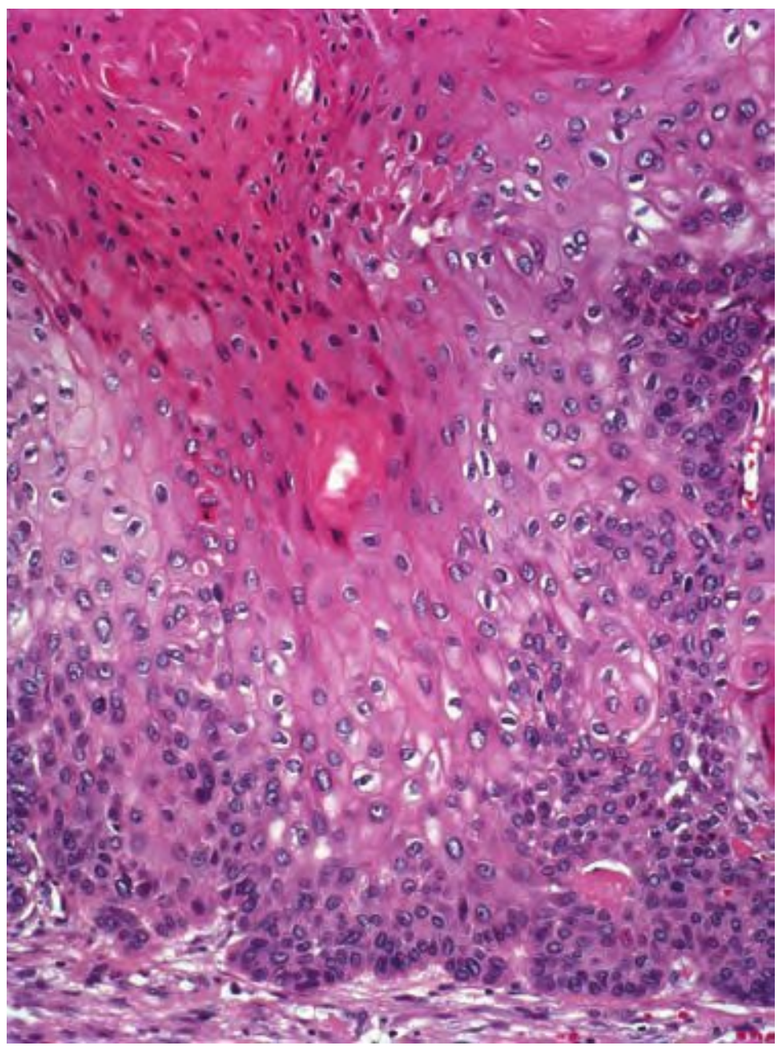

FIGURE 30-34. Proliferating trichilemmal cyst. Large, pale keratinocytes undergo abrupt keratinization without keratohyaline granules.

strands and lobules and the absence of extensive areas of severe atypia and of invasion of the surrounding tissue usually permit differentiation from squamous cell carcinoma.

Additional Studies. Keratinization in proliferating trichilemmal cysts is of the same type as in ordinary trichilemmal cysts. The "trichilemmal" keratinization in both is analogous to that of the outer root sheath as seen normally at the follicular isthmus above the zone of sloughing of the inner root sheath and in the sac surrounding the lower end of the telogen hair (174,181). Analogous to the outer root sheath, proliferating trichilemmal cysts show (a) an abrupt change of squamous epithelium into amorphous keratin, (b) vacuolated cells containing glycogen, like the cells of the outer root sheath, and (c) a prominent glassy layer of collagen surrounding some tumor formations (179). Focal calcification within the amorphous keratin is a feature that proliferating trichilemmal cysts and ordinary trichilemmal cysts have in common.

Malignant Proliferating Trichilemmal Tumor

In rare instances, malignant transformation of proliferating trichilemmal cysts takes place, indicated by rapid enlargement of the nodule (177). There have been several reported instances of metastases, most of them regional (174,182,183). In one instance, however, the metastases were generalized and fatal (184). Penetration of the tumor into cerebral sinuses has occurred, causing death (185).

Histopathology. Malignant proliferating trichilemmal tumors show extensive areas of severe atypia and invasion of the surrounding tissue (177). Even though areas of trichilemmal keratinization are still evident, tissue invasion and the presence of nuclear atypia and giant nuclei indicate malignancy (184).

Additional Studies. Unlike proliferating trichilemmal cyst, there is loss of CD34 expression (186). DNA aneuploidy and a higher proliferation index have also been observed (186). There appears to be a spectrum of cases ranging from a proliferative trichilemmal cyst to a frankly malignant proliferating trichilemmal tumor (187). In addition, similar to squamous cell carcinomas, loss of heterozygosity at chromosome 17p and increased p53 immunoreactivity have been observed in proliferating trichilemmal cysts (188,189). It has been proposed by some researchers that proliferating trichilemmal cysts may be low-grade carcinomas (190,191). Regardless, both lesions should be treated with wide local excision and adequate follow-up (187).

Trichilemmoma

Trichilemmoma is a fairly common solitary tumor. In addition, multiple facial trichilemmomas are specifically associated with Cowden's disease.

Solitary Trichilemmoma

Solitary trichilemmoma, first recognized as an entity in 1962, generally is a small tumor, 3 to 8 mm in diameter, occurring

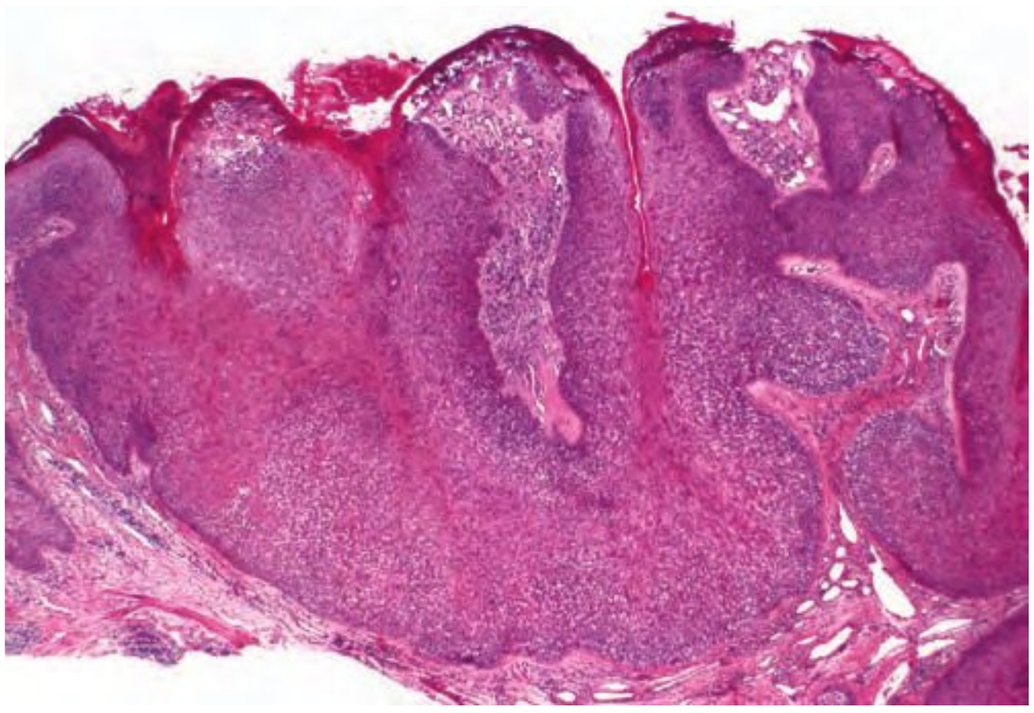

FIGURE 30-35. Trichilemmoma. The tumor shows verrucous hyperplasia with lobular formations extending into the superficial dermis. As a result of their differentiation toward outer root sheath cells, many cells appear clear.

usually on the face (192,193). Occasionally, it measures several centimeters in diameter (194). It has no characteristic clinical appearance. In some instances, it is found at the base of a cutaneous horn (195).

Histopathology. One or several lobules are seen descending from the surface epidermis into the dermis. In some instances, the lobules are oriented about a central hair-containing follicle (192). A variable number of tumor cells have the appearance of clear cells because of their content of glycogen (Figs. 30-35 and 30-36). The periphery of the tumor lobules usually shows palisading of columnar cells and a distinct, often thickened basement membrane zone resembling the vitreous layer surrounding the lower portion of normal hair follicles (Fig. 30-36) (193). Paradoxically, trichilemmomas do not show the trichilemmal type of keratinization seen in trichilemmal cysts and proliferating trichilemmal cysts. Instead, at the surface, trichilemmomas display epidermoid keratinization, which is frequently pronounced, often associated with verrucous hyperplasia, and may even lead to the formation of an overlying cutaneous horn (196).

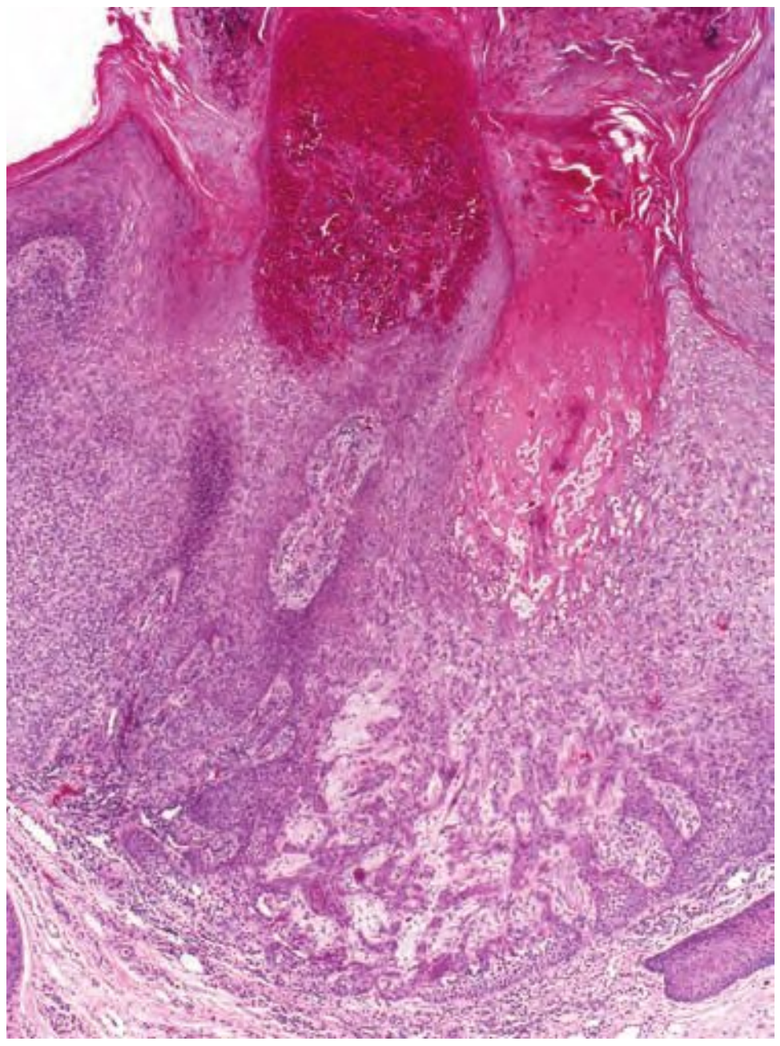

FIGURE 30-37. Desmoplastic trichilemmoma. The lesion exhibits features of a trichilemmoma with focal infiltrative growth in the dermis.

In *desmoplastic trichilemmoma* there are irregular extensions of cells of the outer root sheath type that project into sclerotic collagen bundles and mimic invasive carcinoma (Figs. 30-37 and 30-38) (197). Superficially, the lesion shows changes of a trichilemmoma, a finding that aids in the distinction from an invasive carcinoma. In addition, unlike basal cell carcinomas, desmoplastic trichilemmomas stain with CD34 (198).

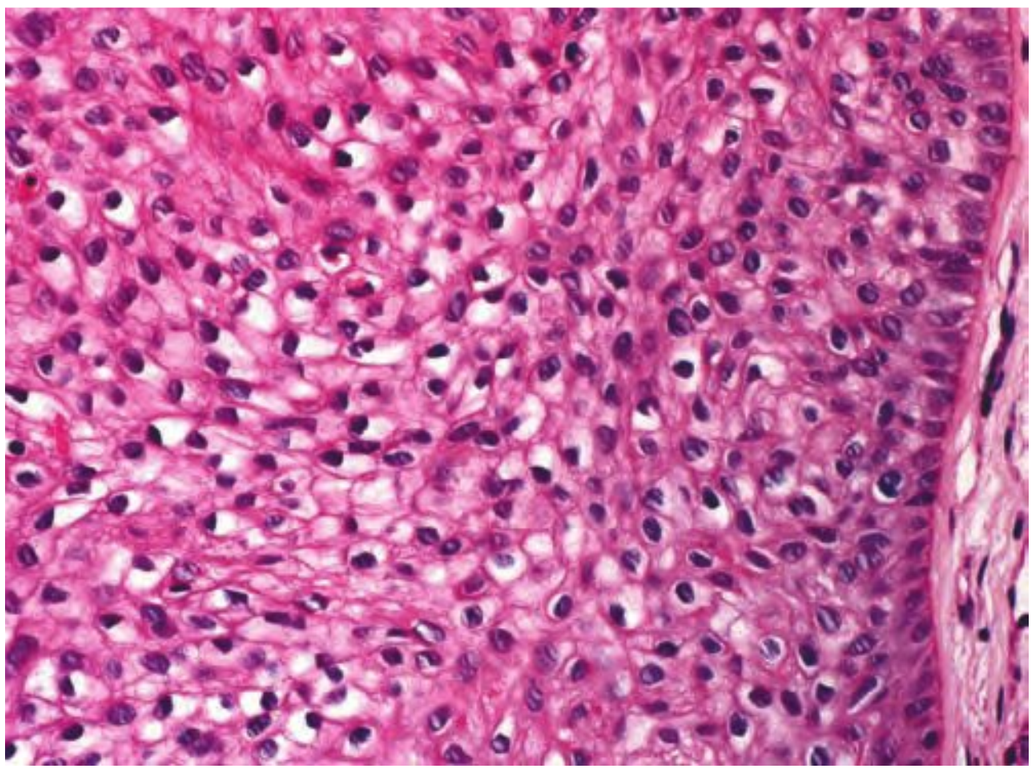

FIGURE 30-36. Trichilemmoma. Many cells demonstrate clear cytoplasm. The peripheral epithelial cells demonstrate palisading.

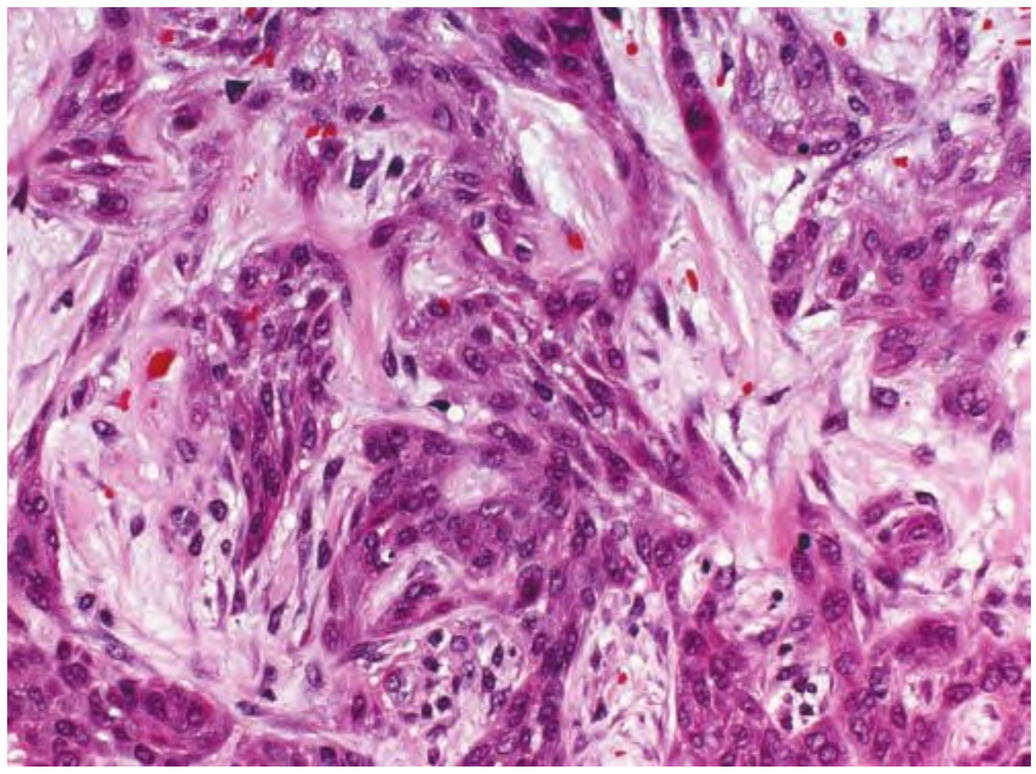

FIGURE 30-38. Desmoplastic trichilemmoma. Cords of bland epithelial cells infiltrate the dermis mimicking invasive carcinoma.

Differential Diagnosis. In instances with relatively few clear cells and marked hypergranulosis and hyperkeratosis, differentiation from a verruca vulgaris may be difficult. A PAS stain for the demonstration of glycogen may aid in differentiating these two lesions. However, old verrucae, which often lack viral cytopathic changes, may acquire cytoplasmic glycogen and mimic many features of trichilemmoma. Trichilemmomas differ from ordinary verrucae by their lobulated rather than papillary (verrucous) configuration, their localization about follicular infundibula, the presence of basaloid palisading at the periphery of tumor lobules, and the presence of a thickened, hyalinized basement membrane that can be highlighted by a PAS stain. Molecular studies have not supported the notion that all trichilemmomas result from human papillomavirus infection (199).

Multiple Trichilemmomas in Cowden's Disease

Cowden's disease, or multiple hamartoma syndrome, is an autosomal dominant genodermatosis with distinctive mucocutaneous and systemic findings (200). The syndrome is characterized by multiple hamartomas in several organ systems including the skin, breast, thyroid, gastrointestinal tract, endometrium, and brain. The mucocutaneous lesions are a near-constant manifestation and include trichilemmomas, oral papillomatoses, and acral and palmoplantar keratoses. The most frequent systemic findings include fibrocystic breast disease, breast fibroadenomas, thyroid adenomas, goiter, and intestinal polyposis (201). Individuals are at highest risk for the development of breast cancer, but other visceral malignancies, including thyroid and endometrial carcinomas, may occur (202,203). An association with Lhermitte-Duclos disease (dysplastic cerebellar gangliocytoma) and Bannayan-Riley-Ruvalcaba syndrome (macrocephaly, lipomatosis, hemangiomatosis, and speckled penis) has been noted, suggesting that they are all overlapping syndromes characterized by germline *PTEN* mutations (204–207).

Multiple trichilemmomas are found in all patients with Cowden's disease (202). They are limited to the face, where they are found mainly about the mouth, nose, and ears. They consist of flesh-colored, pink or brown papules that may resemble verrucae vulgares (208). Multiple trichilemmomas precede the development of breast cancer and thus can identify women with a high risk of developing this cancer (202). Thus, recognition of Cowden's disease is important because of the high incidence of breast cancer in women with this disease. In addition, there may be closely set oral papules, giving the lips, gingiva, and tongue a characteristic "cobblestone" appearance, as well as multiple small acral keratoses. Small hyperkeratotic papillomas are commonly found on the distal portions of the extremities (209).

The gene for Cowden's disease was localized to chromosome 10q22-23 and subsequently identified as *PTEN* (phosphatase and tensin homologue deleted on chromosome 10) (210,211). *PTEN* encodes a dual-specificity phosphatase and is the major 3-phosphatase in the phosphoinositol-3-kinase pathway, which inactivates signals from (PI-3K)/AKT kinases, an antiapoptotic pathway; therefore, loss of *PTEN* function results in increased antiapoptotic signaling in the PI-3K/AKT pathway (212). Mutational analysis has revealed germline mutations in the gene in multiple members of afflicted families (213,214).

Histopathology. Multiple biopsy specimens may be needed to find the diagnostic histologic picture of trichilemmoma in the facial lesions. Thus, in one series, only 29 of 53 facial lesions showed findings diagnostic of trichilemmoma (196).

The oral lesions may show a fibromatous nodule composed of relatively acellular fibers patterned in whorls (sclerotic fibroma) or fibrovascular tissue with acanthosis (196,209,215). The extrafacial cutaneous lesions may resemble verruca vulgaris or acrokeratosis verruciformis (see Chapters 6 and 25). Only few specimens show mild follicular hyperplasia as seen in trichilemmoma (209).

Differential Diagnosis. See Differential Diagnosis under Solitary Trichilemmoma.

Tumor of the Follicular Infundibulum

The tumor of the follicular infundibulum was first described in 1961 (216). It usually occurs as a solitary, flat, keratotic papule on the face (216). Clinically, it may resemble a basal cell carcinoma. Rarely, multiple papules are present (217). In addition, lesions may occur in Cowden's disease and nevus sebaceous (218).

Histopathology. There is a platelike growth of epithelial cells in the upper dermis extending parallel to the epidermis and showing multiple connections with the lower margin of the epidermis (Fig. 30-39). The peripheral cell layer of the tumor plate shows palisading, and the centrally located cells show a pale-staining cytoplasm as a result of their glycogen content; small cysts

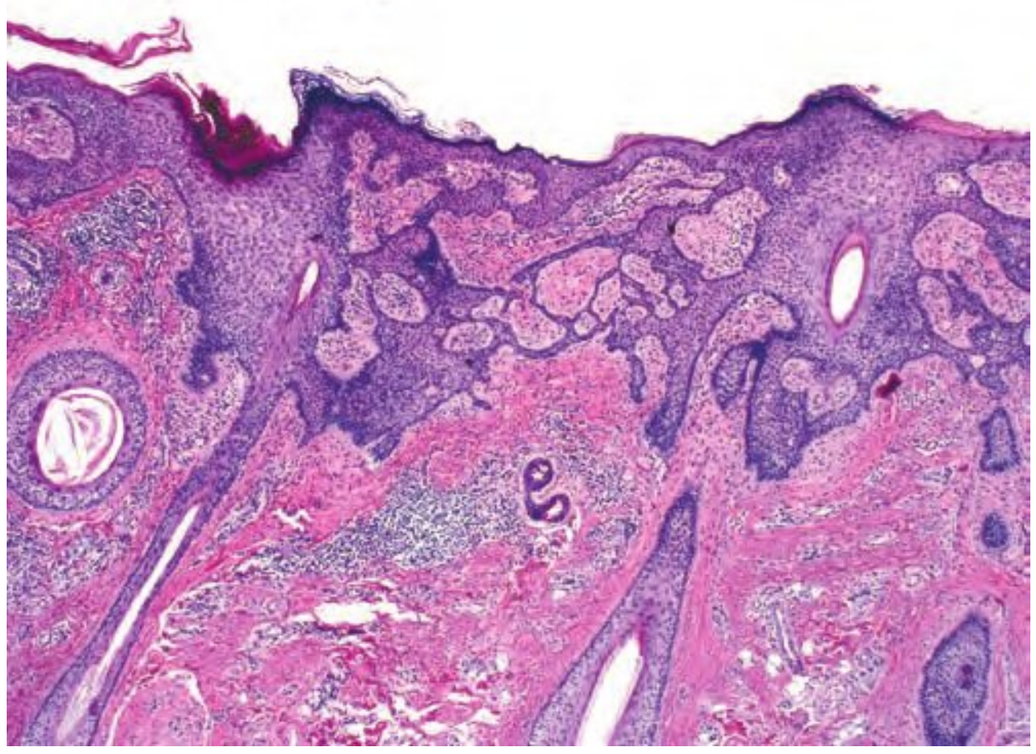

FIGURE 30-39. Tumor of the follicular infundibulum. A platelike growth of anastomosing epithelial cords extends parallel to the epidermis in the upper dermis and shows multiple connections with the epidermis.

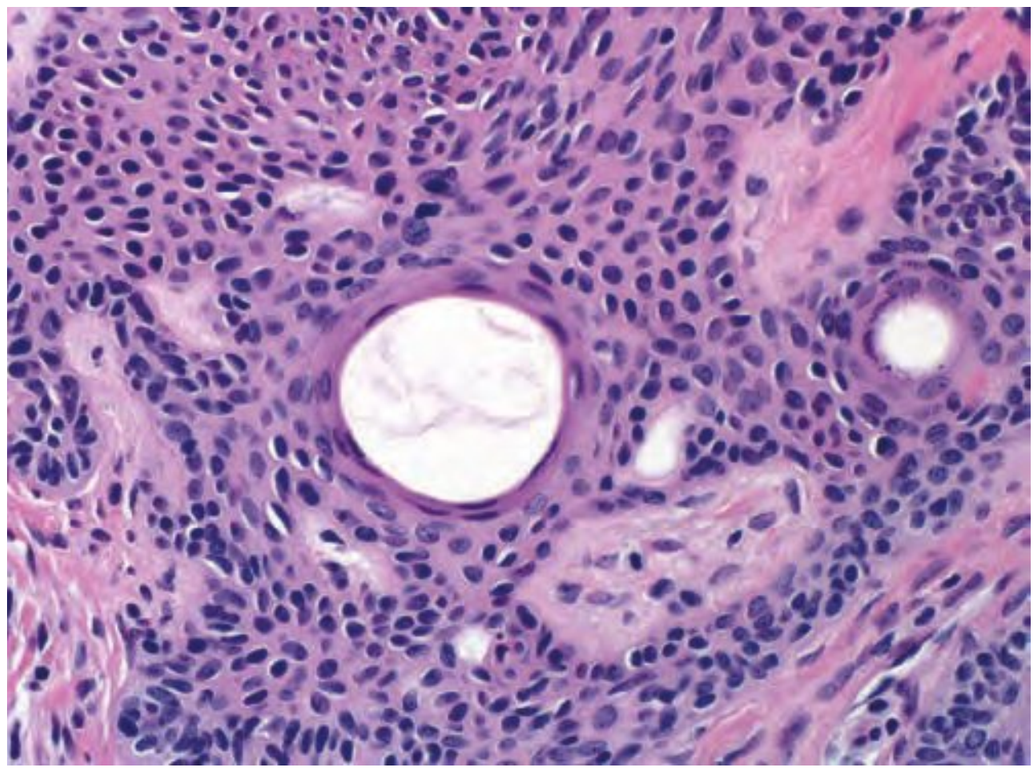

FIGURE 30-40. Tumor of the follicular infundibulum. Lesional cells demonstrate focal cytoplasmic clearing and horn cyst formation.

resembling the follicular infundibulum are seen often (Fig. 30-40). Small hair follicles enter the tumor plate from below and lose their identity and then are no longer recognizable (216). Along the lower margin of the plate, there may be invaginations that resemble hair papillae (217). Focal sebaceous differentiation and ductal proliferation have been seen (219,220).

Differential Diagnosis. The platelike growth with multiple connections to the epidermis resembles superficial basal cell carcinoma, which may also show peripheral palisading. However, the cells of the tumor of the follicular infundibulum possess a greater amount of cytoplasm, in which, furthermore, PAS-positive material is present (221). Atypia, necrosis, and mitotic activity are generally lacking. Other entities to consider are trichilemmoma, inverted follicular keratosis, and a seborrheic keratosis (172). The key histologic finding in tumor of the follicular infundibulum, as mentioned previously, is the presence of a platelike growth of epithelium with multiple connections to the epidermis.

Trichilemmal Horn; Trichilemmomal Horn

Trichilemmal and trichilemmomal horns clinically have the appearance of a cutaneous horn, as seen in several other conditions (see Chapter 29). Both are solitary. The more common trichilemmal horn may be seen in many different areas; the trichilemmomal horn occurs on the face or scalp (195,222).

Histopathology. In a *trichilemmal horn,* trichilemmal keratinization occurs. At the base of the lesion there is a prominent basement membrane zone, with palisading of the basal cell layer and a tendency of the viable epithelial cells to become large and pale staining. As trichilemmal cells, they keratinize without a granular layer (222,223). Some nuclear atypia analogous to a carcinoma *in situ* has been observed (224). A seborrheic keratosis or verruca vulgaris with exuberant trichilemmal keratinization may mimic a trichilemmal horn (225). Immunohistochemical staining with CD34 has been shown, confirming an outer root sheath origin (226).

In a *trichilemmomal horn,* a trichilemmoma is seen at the base of the lesion. At the surface, the trichilemmoma shows a cutaneous horn displaying epidermoid keratinization that is frequently pronounced, with a thick granular layer and massive hyperkeratosis (Fig. 30-37, top) (195).

Trichilemmal Carcinoma

Trichilemmal carcinoma occurs largely on the face or ears as a slow-growing epidermal papule, indurated plaque, or nodule that may ulcerate (227–231). Unlike trichilemmomas, trichilemmal carcinoma is an unusual finding in Cowden's disease (232). Recurrence and metastases are uncommon, and conservative surgical excision with clear margins is curative (227,229,233).

Histopathology. This tumor is histologically invasive and consists of cytologically atypical clear cells resembling those of the outer root sheath (19). The lesional cells have abundant glycogenated clear cytoplasm. The lesional cells form solid, lobular, or trabecular growth patterns with foci of pilar-type keratinization and with peripheral palisading of cells with subnuclear vacuolization. Cytologic atypia is prominent, and there may be pagetoid spread of lesional cells into the epidermis, mimicking melanoma. The cells have hyperchromatic, pleomorphic, very large nuclei (233). The cytoplasm contains glycogen, and this is PAS positive and diastase sensitive (231). Areas of trichilemmal keratinization are frequently present (234).

Differential Diagnosis. A trichilemmal carcinoma may resemble a trichilemmoma by showing a lobular architecture or may resemble a "tumor of the follicular infundibulum" by replacing the surface epidermis (231,233). Differentiation from other carcinomas with clear cell features such as squamous cell carcinoma, basal cell carcinoma, and sebaceous carcinoma may be difficult. Typical features of these carcinomas are usually seen adjacent to the clear cell component.

Additional Studies. The pathogenesis of trichilemmal carcinomas is unclear. The distribution of lesions suggests that sunlight may play a role. A few cases have been reported in association with a burn scar, irradiation, and xeroderma pigmentosa (230,235,236). Loss of *p53* has been shown in a trichilemmal carcinoma arising from a proliferating trichilemmal cyst (237).

TUMORS WITH SEBACEUS DIFFERENTIATION

Nevus Sebaceus

Nevus sebaceus of Jadassohn is nearly always located on the scalp or the face as a single lesion and is present often at birth. In childhood, this lesion consists of a circumscribed, slightly raised, hairless plaque that is often linear in configuration, but it may be round or irregularly shaped. In puberty, the lesion becomes verrucous and nodular (238).

Less commonly, nevus sebaceus consists of multiple extensive lesions found on the face, neck, or trunk. Usually, at least some of the lesions have a linear configuration (239). In addition, some patients with extensive nevus sebaceus show

evidence of a "neurocutaneous syndrome," epilepsy and mental retardation, neurologic defects, or skeletal deformities (240–243). In some patients, the linear nevus is a combination of a linear nevus sebaceus and a linear epidermal nevus (241,242). Thus, the "neurocutaneous syndrome" that is associated with nevus sebaceus overlaps with the abnormalities associated with the epidermal nevus syndrome, in which skeletal deformities and central nervous system abnormalities may also occur (see Chapter 6) (244). The involvement of the central nervous system that may be seen in extensive cases of both linear nevus sebaceus and linear epidermal nevus closely resembles that of tuberous sclerosis by computed tomography and x-ray studies (see Chapter 32) (245).

Histopathology. The sebaceous glands in nevus sebaceus follow the pattern of normal sebaceous glands during infancy, childhood, and adolescence. In the first few months of life, they are well developed (246). During childhood the sebaceous glands in nevus sebaceus are underdeveloped and, therefore, greatly reduced in size and number. Thus, the diagnosis of nevus sebaceus may be missed. However, the presence of incompletely differentiated hair structures is typical of nevus sebaceus. There often are cords of undifferentiated cells resembling the embryonic stage of hair follicles (238). Some hair structures consist of dilated, keratin-filled infundibula showing multiple buds of undifferentiated cells (Fig. 30-41).

At puberty, the lesion assumes its diagnostic histologic appearance. Large numbers of mature or nearly mature sebaceous glands and overlying papillomatous hyperplasia of the epidermis are seen. The hair structures remain small, except for occasional dilated infundibula. Ectopic apocrine glands develop in about two thirds of the patients at puberty and sometimes at a younger age (Fig. 30-41) (238,247). There are often buds of undifferentiated cells that resemble foci of basal cell carcinoma and represent malformed hair germs (Fig. 30-42) (247). The apocrine glands are located deep in the dermis beneath the masses of sebaceous gland lobules.

Quite commonly, in addition to the infantile and adolescent phases, there is a third stage in adulthood when various types of appendageal tumors develop secondarily within lesions of nevus sebaceus. Syringocystadenoma papilliferum has been found in 8% to 19% of the lesions of nevus sebaceus (Fig. 30-43) (238). In two large case series, the most commonly associated appendageal tumors were trichoblastoma and syringocystadenoma papilliferum (248,249). Less commonly found appendage tumors include nodular hidradenoma, syringoma, sebaceous epithelioma, chondroid syringoma, trichilemmoma, trichoade-

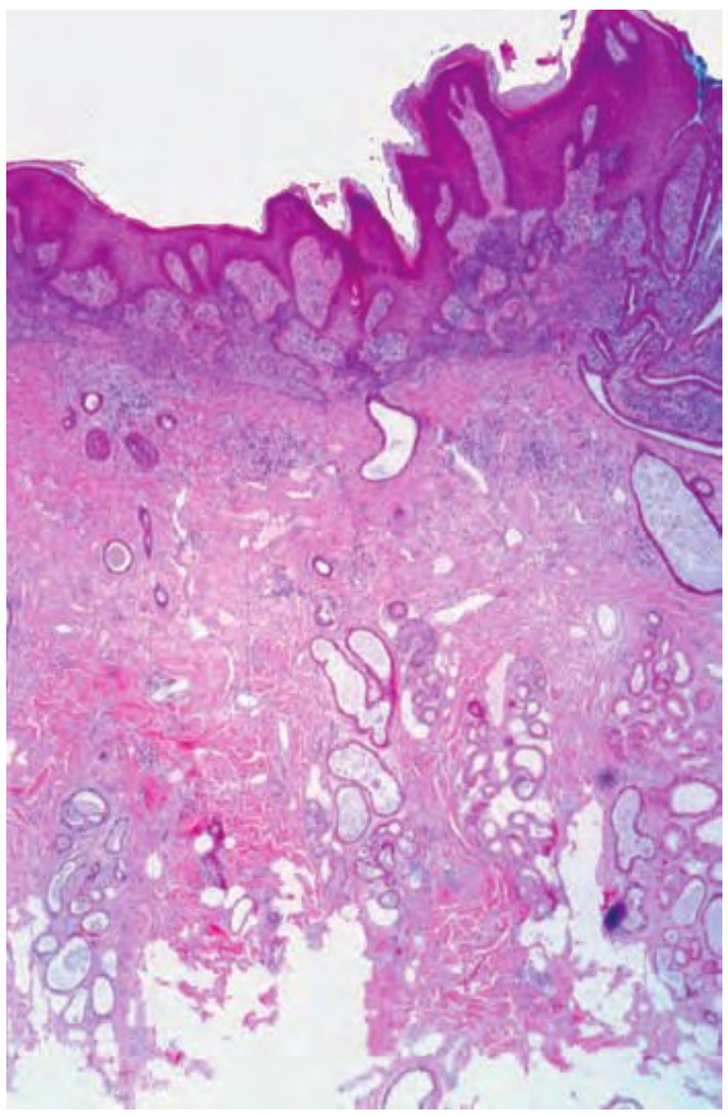

FIGURE 30-41. Nevus sebaceus. There is epidermal hyperplasia and papillomatosis. Superficially, a basaloid epithelial neoplasm is seen, and dilated apocrine glands are present in the dermis. This scalp lesion lacks anagen follicles.

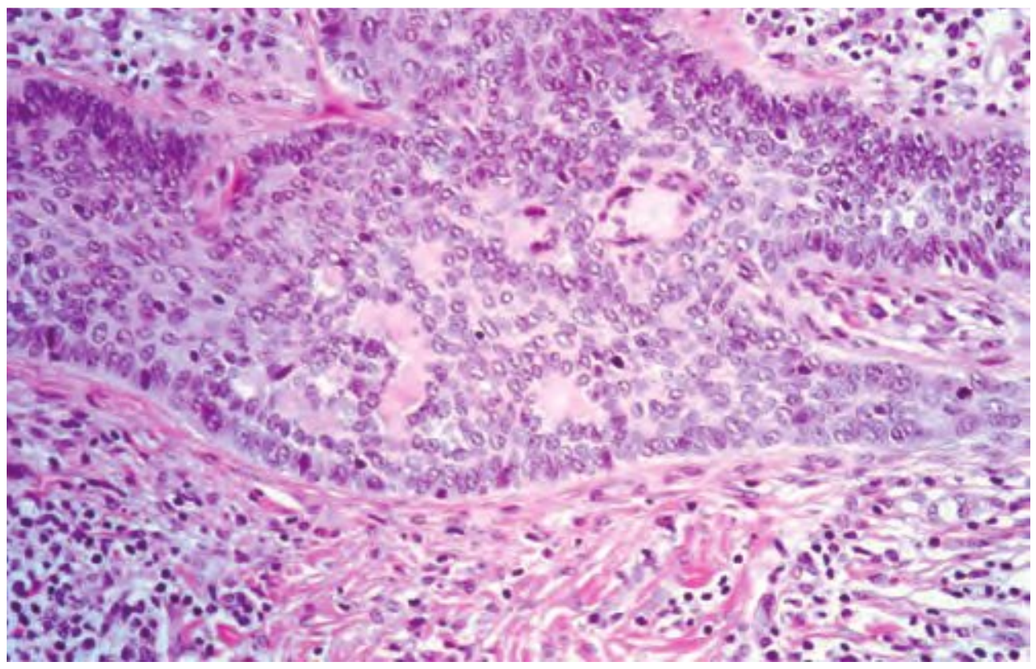

FIGURE 30-42. Nevus sebaceus. The basaloid epithelial proliferations often resemble basal cell carcinoma. However, the proliferations exhibit features of appendageal neoplasms as evidenced by the hyaline material within the lesion.

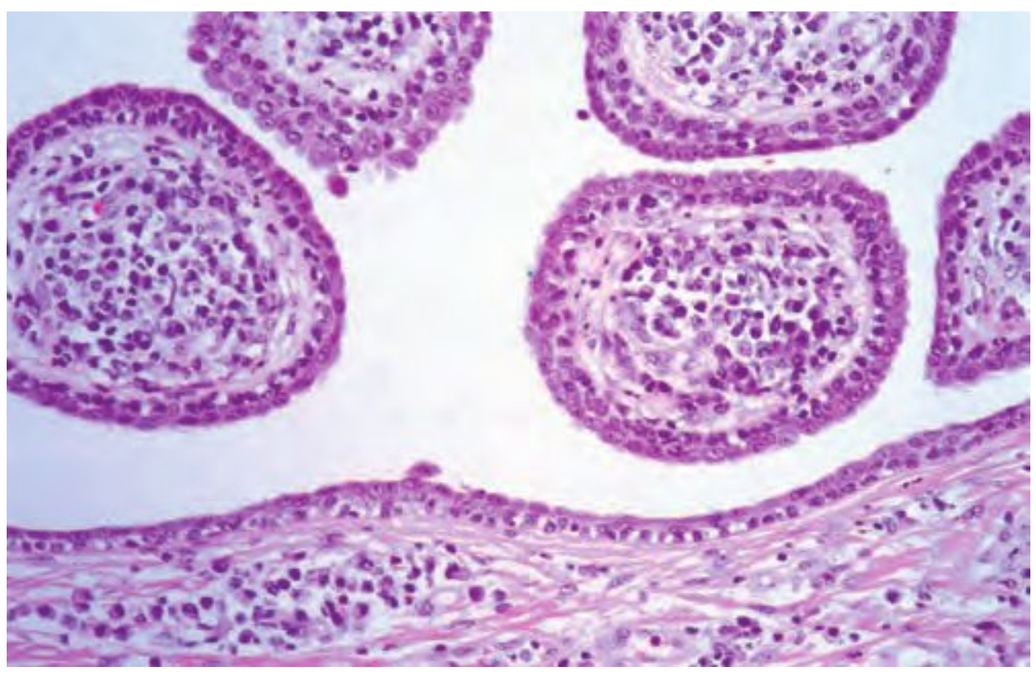

FIGURE 30-43. Nevus sebaceous. A syringocystadenoma papilliferum was also present in this lesion.

noma, sebaceous carcinoma, and proliferating trichilemmal cyst (238,250–252).

Basaloid epithelial proliferations resembling basal cell carcinoma are clinically evident in 5% to 7% of the cases of nevus sebaceus (247,253). In many instances, however, basal cell carcinomas are found that are small, clinically not apparent, and show no aggressive growth pattern (247). It is not always possible to differentiate histologically between a basal cell carcinoma and the "basaloid proliferations" that arise in as many as half of all cases of nevus sebaceus (253). As original evidence that the basal cell carcinoma–like proliferations in many instances are not true basal cell carcinomas, some proliferations contain Sudan-positive granules as an indication of sebaceous differentiation or glycogen as an indication of pilar differentiation (254). Other proliferations show follicular differentiation with formation of hair papillae and hair bulbs (255). Furthermore, in critical reviews, several groups proposed that most reported basal cell carcinomas arising in nevus sebaceus are actually trichoblastomas (248,249,256).

In only rare instances does a squamous cell carcinoma develop within a nevus sebaceus. This may be associated either with regional lymph node metastasis or with generalized metastases (257). Apocrine carcinomas and, in one instance, a malignant eccrine poroma have developed in nevi sebacei, and these lesions, too, may lead to regional or even generalized metastases (257,258).

Additional Studies. The frequent association of nevus sebaceus with other appendageal tumors and with apocrine glands suggests that nevus sebaceus is derived from the primary epithelial germ (247). Moreover, as has been reported in basal cell carcinomas, loss of heterozygosity of the human homologue of the *Drosophila* patched gene (*Ptch*) has been demonstrated in nevus sebaceus (259–261). This could partly explain the association of basal cell carcinomas and other basaloid appendageal tumors with nevus sebaceous. However, a separate study of 11 lesions of nevus sebaceus found no demonstrable loss of heterozygosity (262). The reason for the discrepancy is uncertain; however, differences such as sampling during microdissection of other cell populations may account for discrepancy (262).

Sebaceous Hyperplasia

The lesions of sebaceous hyperplasia nearly always occur on the face, chiefly on the forehead and cheeks, in elderly persons. It has also been reported in the vulva, penis, and aerola (263–266). Rarely, sebaceous hyperplasia occurs in early adult life (267). Apparent familial forms have also been reported (90,268). It clinically presents as one or, more commonly, several elevated, small, soft, yellow, slightly umbilicated papules. The usual size is 2 to 3 mm in diameter.

Histopathology. Most lesions consist of a single, enlarged sebaceous gland composed of numerous lobules grouped around a centrally located, wide sebaceous duct (Fig. 30-44). Its opening to the surface corresponds to the central umbilication of the lesion. Serial sections show that all sebaceous lobules grouped around the central duct are connected with that duct. Large lesions may consist of several enlarged sebaceous glands and contain several ducts, with sebaceous lobules grouped around each of them. Although some sebaceous gland lobules appear fully mature, others show more than one peripheral row of undifferentiated, germinative cells in which there are few or no lipid droplets (269).

FIGURE 30-44. Sebaceous hyperplasia. The lesion consists of an enlarged sebaceous gland lying in close proximity to the epidermis.

Additional Studies. Labeling with tritiated thymidine has shown that the migration of sebocytes from the basal cell area to the center of the sebaceous lobules and into the sebaceous duct is distinctly slower in cases of sebaceous hyperplasia than in normal sebaceous glands (269). Microsatellite instability has been detected in very few cases of sebaceous hyperplasia as compared to other sebaceous neoplasms (270,271) (see Muir-Torre syndrome). Immunohistochemical staining for androgen receptors has been shown to be fairly specific for sebaceous lesions as compared to basal cell carcinomas, squamous cell carcinomas, and clear cell acanthomas (272).

Differential Diagnosis. In rhinophyma, which also shows large sebaceous glands and ducts, there is no grapelike grouping of the sebaceous lobules around the ducts, and the lesion is not sharply demarcated. In nevus sebaceus, ductal structures are less apparent than in sebaceous hyperplasia, and apocrine glands are often found beneath the sebaceous glands.

Fordyce's Spots and Montgomery's Tubercles

In Fordyce's spots, groups of minute, yellow, globoid lesions are observed on the vermilion border of the lips or on the oral mucosa. The incidence of the disorder increases with age, so that 70% to 80% of elderly persons show such lesions, which represents ectopic sebaceous glands (273). Montgomery's tubercles are ectopic mature sebaceous glands located on the areola of the breast (274).

Histopathology. Each lesion consists of a group of small but mature sebaceous lobules situated around a small sebaceous

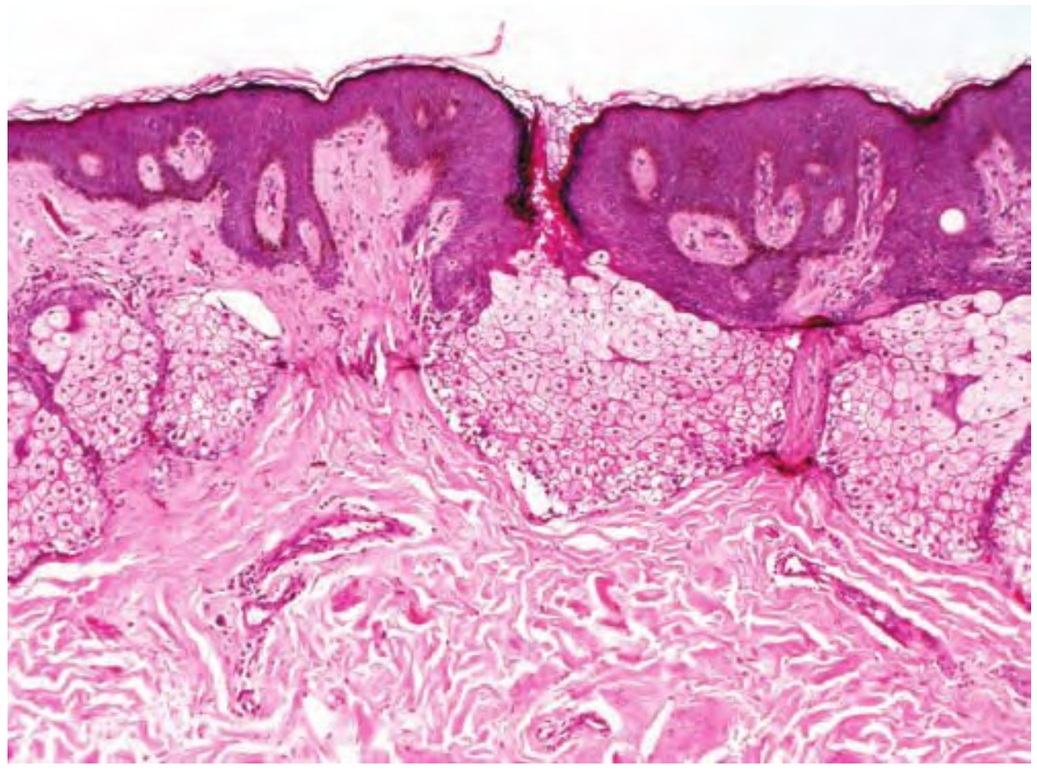

FIGURE 30-45. Montgomery's tubercle. A mature sebaceous lobule in continuity with the epidermis is seen.

duct leading to the surface epithelium (Fig. 30-45) (273,275). Because of the small size of the sebaceous duct, serial sections may be required to demonstrate the duct.

Sebaceous Adenoma

Sebaceous adenoma presents as a yellow, circumscribed nodule located on either the face or scalp. Prior to 1968, sebaceous adenoma was regarded as a rare solitary tumor, and there were few publications about it (276–278). Since then, however, both solitary and multiple lesions have been well documented in patients with Muir-Torre syndrome (see text following).

Histopathology. On histologic examination, sebaceous adenoma is sharply demarcated from the surrounding tissue. It is composed of incompletely differentiated sebaceous lobules that are irregular in size and shape (Fig. 30-46). Two types of cells are present in the lobules. The cells of the first type are identical to the cells present at the periphery of normal sebaceous glands and represent undifferentiated basaloid cells (Fig. 30-47). The cells of the second type are mature sebaceous cells (Fig. 30-47). In addition, there often are some cells in a transitional stage between these two types (279). Distribution of the basaloid and sebaceous cells within the lobules varies. Some lobules contain mainly sebaceous cells and thereby resemble mature sebaceous lobules. Frequently, the proportion of mature sebaceous cells exceeds that of the surrounding basaloid cells (Fig. 30-47). However, at most the two types of cells occur in approximately equal proportions. Fat stains, on properly preserved specimens, reveal the presence of lipid material in the sebaceous and transitional cells. Some large lobules contain cystic spaces in their center formed by the disintegration of mature sebaceous cells. In addition, there may be foci of squamous epithelium with keratinization. These foci probably represent areas with differentiation toward cells of the infundibulum. Cystic sebaceous adenomas seem to occur exclusively in patients with Muir-Torre syndrome (280).

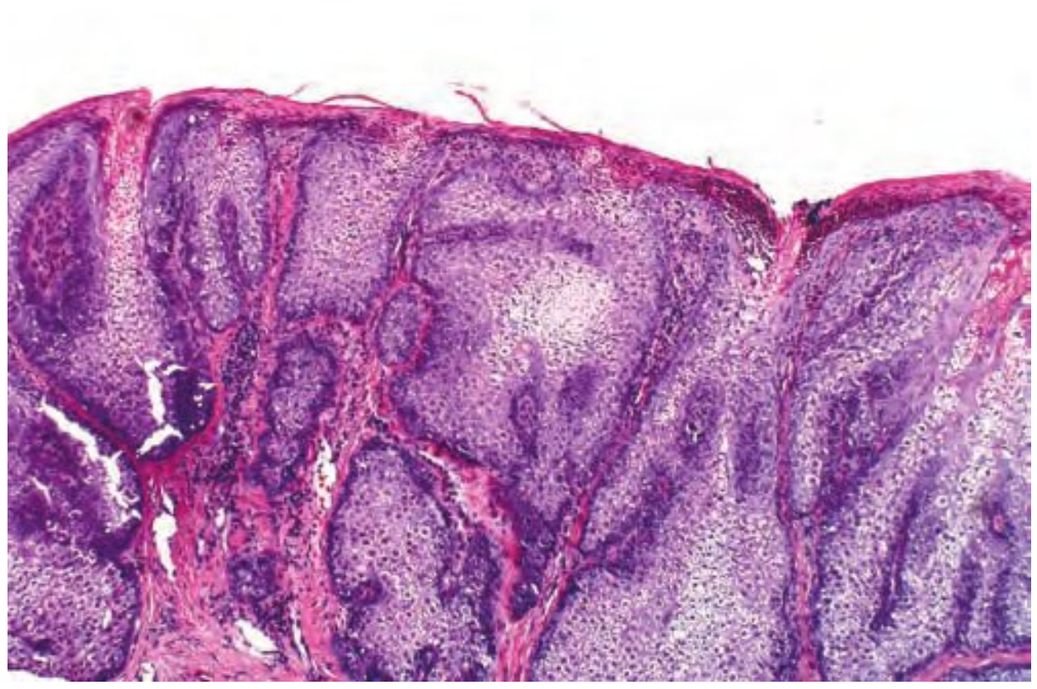

FIGURE 30-46. Sebaceous adenoma. The tumor is composed of enlarged sebaceous lobules of varying size and shape.

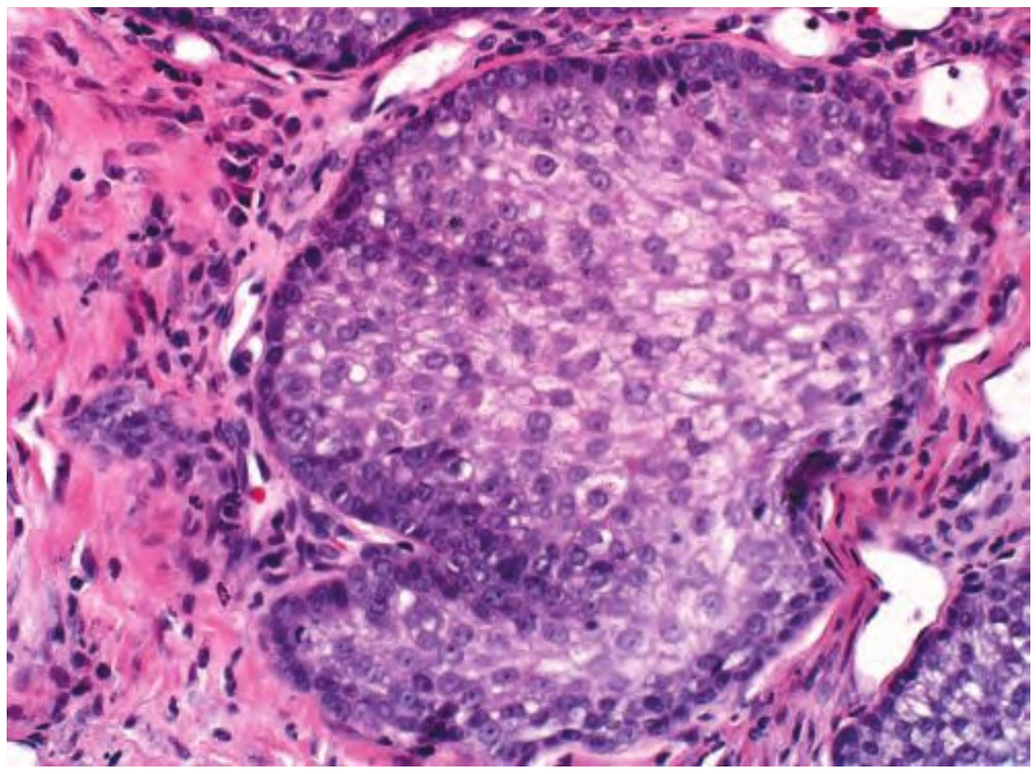

FIGURE 30-47. Sebaceous adenoma. In the lobules, two types of mature cells can be recognized: basaloid and sebaceous cells. However, sebaceous cells predominate. Cytologic atypia is not seen.

Differential Diagnosis. In terms of differentiation, sebaceous adenoma stands between sebaceous hyperplasia, in which sebaceous lobules appear fully or nearly fully matured, and sebaceous epithelioma or sebaceoma (see text following), in which the tumor is composed predominantly of irregularly shaped cell masses and the percentage of tumor cells with sebaceous differentiation is less than 50%. Sebaceous adenoma and sebaceous epithelioma lack nuclear atypia and invasive, asymmetric growth patterns, which are hallmarks of sebaceous carcinoma. Considerable mitotic activity in the basaloid regions, however, may be present in either lesion.

Sebaceoma (Sebaceous Epithelioma)

Clinically, sebaceoma, or sebaceous epithelioma, varies from a circumscribed nodule to that of an ill-defined plaque. Some of

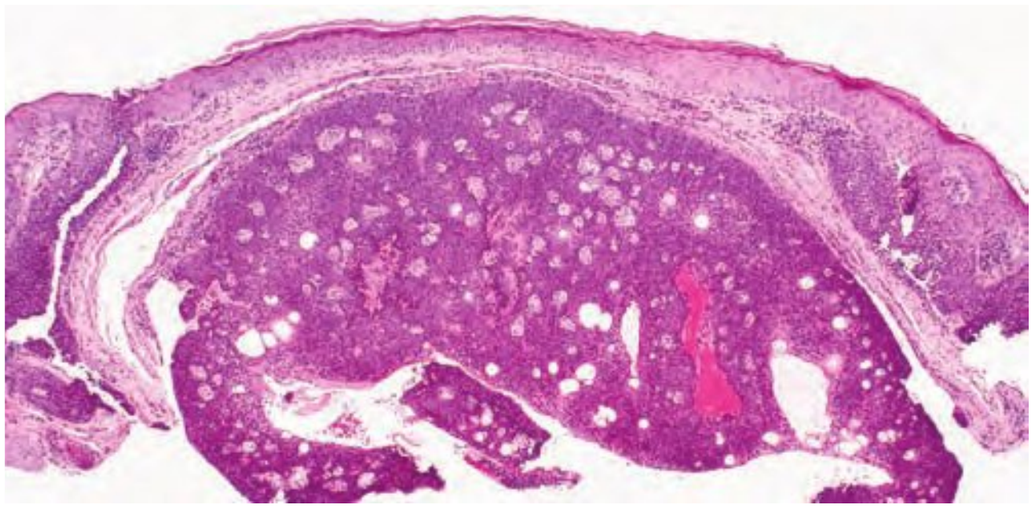

FIGURE 30-48. Sebaceoma. The tumor is a well-circumscribed nodule and comprised of basaloid epithelial cells. Scattered areas of clearer (sebaceous) cells are seen.

the lesions are yellow (281). Most lesions are located on the face or scalp. In addition to occurring as a primary lesion, a sebaceus epithelioma occasionally arises within a nevus sebaceus (238,247). Sebaceous epitheliomas may also be found among the multiple sebaceous neoplasms that occur in association with multiple visceral carcinomas and are referred to as Muir-Torre syndrome (see text following).

Histopathology. The histologic spectrum extends from that seen in sebaceous adenoma to lesions that may be difficult to distinguish from sebaceous carcinoma. Generally, a sebaceoma shows either a well-circumscribed nodule or irregularly shaped cell masses in which more than half of the cells are undifferentiated basaloid cells but in which there are significant aggregates of mature sebaceous cells and of transitional cells (Figs. 30-48 and 30-49) (282). Disintegration of sebaceous cells is seen in some areas (281). Lesions verging on a sebaceous carcinoma show some degree of irregularity in the arrangement of the cell masses, and, although the majority of cells are basaloid cells, many cells show differentiation toward sebaceous cells

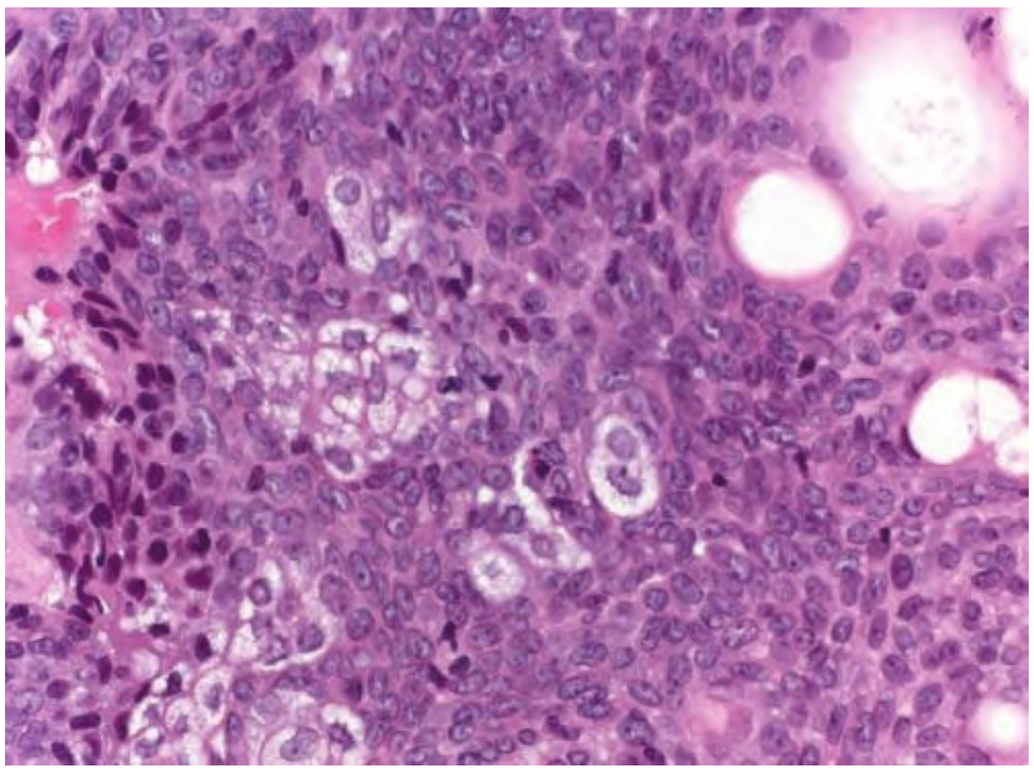

FIGURE 30-49. Sebaceoma. The majority of the lesion is composed of undifferentiated basaloid cells with islands of sebaceous cells and occasional sebaceous ducts.

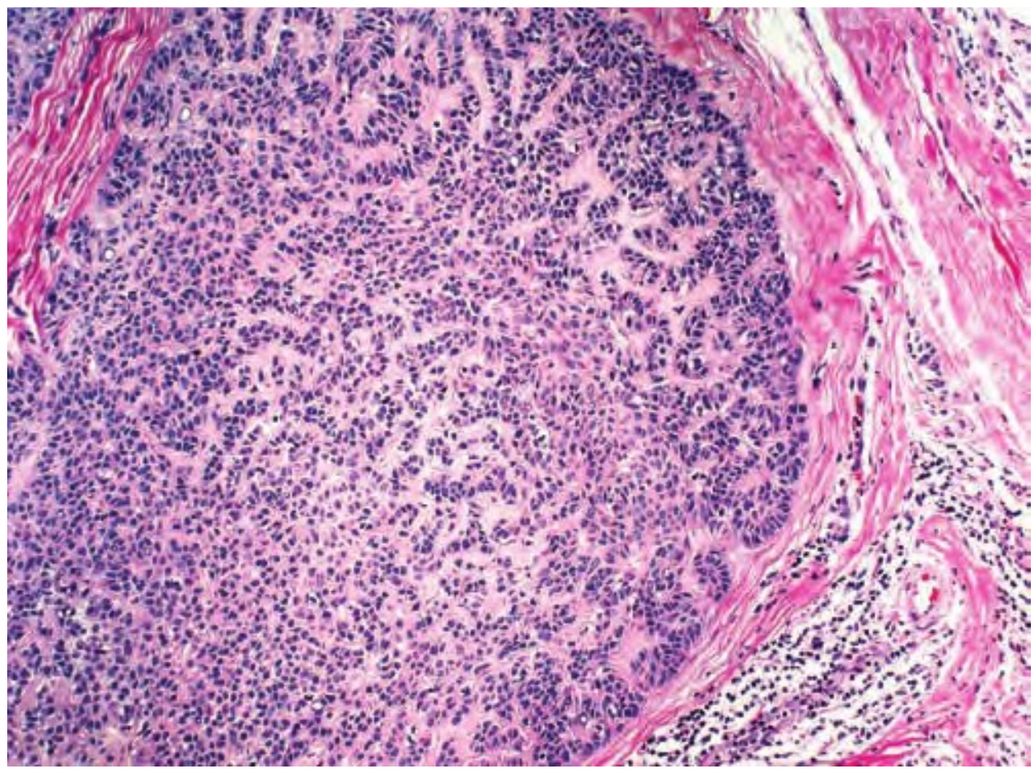

FIGURE 30-50. Rippled-pattern sebaceoma. Parallel arrangements of cells and nuclei are seen at low power.

(283). A verruca/seborrheic keratosis type of sebaceoma has been described, in which the upper part of the lesion mimics a verruca or seborrheic keratosis (284).

Differential Diagnosis. Criteria that may be of assistance in differentiating sebaceous adenoma from sebaceoma include the often greater size and depth of the latter and the lack of structures resembling normal sebaceous lobules. Nuclear atypia is "rare," and mitoses may be numerous in sebaceomas, in contrast to adenomas, in which they are few or absent (285).

Rippled-Pattern Sebaceoma. This variant of sebaceoma exhibits a unique arrangement of small, monomorphous, cigar-shaped basaloid cells in linear rows parallel to one another, resembling Verocay bodies; this arrangement of cells produces the rippled pattern (Fig. 30-50). Scattered sebaceous cells and ducts are also typically seen (Fig. 30-51) (286–289).

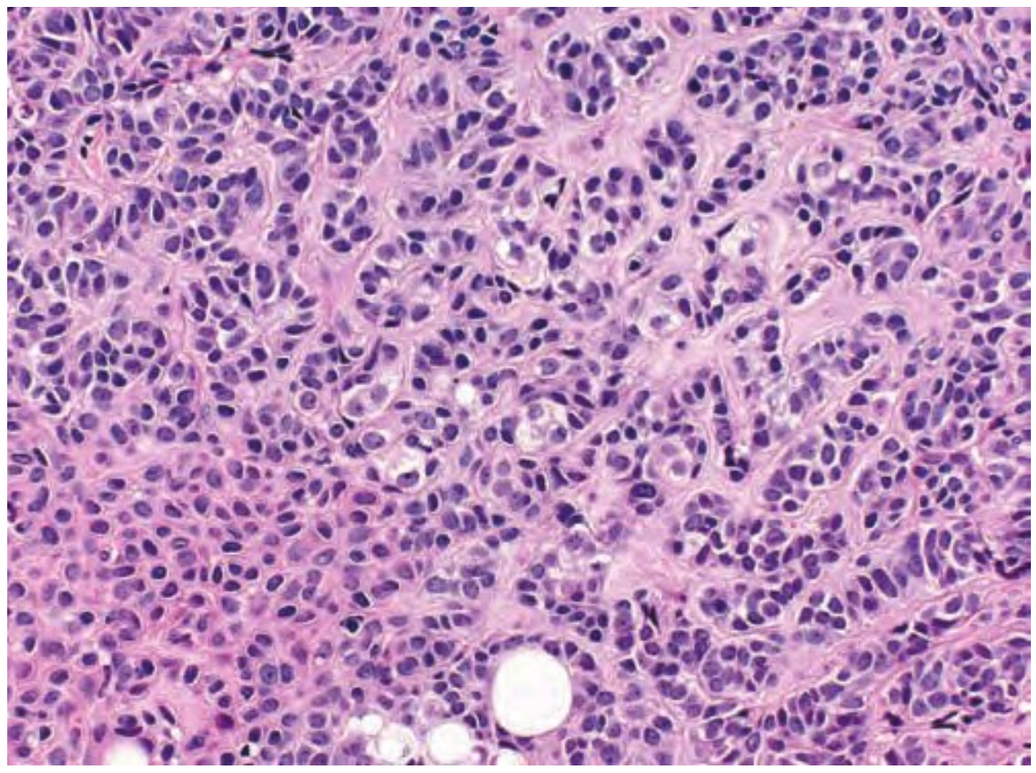

FIGURE 30-51. Rippled-pattern sebaceoma. The lesion is composed of undifferentiated basaloid cells with occasional sebaceous cells and sebaceous ducts.

Muir-Torre Syndrome

The Muir-Torre syndrome is defined by the combined occurrence of at least one sebaceous skin tumor and one internal malignancy in the same patient. Since 1967, when the first publication by Muir appeared concerning the coexistence of frequently multiple sebaceous tumors and usually multiple visceral carcinomas, scores of cases have been reported (290,291). Keratoacanthomas also have occurred in these patients, in some cases without sebaceous lesions, in association with visceral malignancies (292,293). The cutaneous lesions can often precede the first manifestation of internal malignancy (294).

Among the internal malignancies, colon carcinoma is the most common malignancy, although a wide tumor spectrum exists, including carcinomas of the genitourinary tract (including bladder, renal, pelvis, ovary, and uterus), breast, head and neck, small intestinal, and lymphoma (291,294). Adenomatous colonic polyps are also common. Many of the malignant tumors are of relatively low malignancy, with only a slight tendency to metastasize (295).

Cutaneous lesions vary from just 1 to more than 100 lesions (296). Although the lesion in many instances is recognizable as a sebaceous tumor by its color or as a keratoacanthoma by its crater, histologic examination may be required to establish a diagnosis.

Histopathology. Sebaceous adenomas are the most distinctive cutaneous markers of the Muir-Torre syndrome. They may be solid, cystic, or keratoacanthoma like (279). Cystic sebaceous adenomas seem to occur exclusively in patients with Muir-Torre syndrome (280,297). Although ordinary keratoacanthomas occur in the Muir-Torre syndrome, often they have an accompanying sebaceous proliferation (298). In addition to sebaceous adenomas, sebaceomas, and basal cell carcinomas with sebaceous differentiation, there are tumors with unusual appearance, so that a hard-to-classify sebaceous proliferation should be considered as a possible manifestation of the Muir-Torre syndrome (298). In addition, sebaceous carcinomas occur, but no metastases have been reported (296,299).

Genetics. A genetic predisposition was described in some cases of the Muir-Torre syndrome, and the Muir-Torre syndrome has been found in association with the "cancer family syndrome," now known as hereditary nonpolyposis colorectal carcinoma (291,300). Muir-Torre syndrome shares several clinical and pathologic characteristics with hereditary nonpolyposis colorectal carcinoma syndrome (300). Microsatellite instability was demonstrated in a subset of patients with Muir-Torre syndrome (301). Subsequently, germline mutations in the DNA mismatch repair genes *hMLH1* and *hMSH2* were found (302–304). The presence of microsatellite instability in sebaceous neoplasms and even benign skin lesions is helpful in the detection of an underlying inherited DNA mismatch repair defect (270,305). Moreover, immunohistochemical staining for MSH2 or MLH1 protein expression in Muir-Torre syndrome–associated skin tumors can also be used as a diagnostic screening tool to identify patients with germline mutations (306,307).

Sebaceous Carcinoma

Sebaceous carcinomas have been traditionally classified into ocular and extraocular types. The ocular type most frequently occurs on the eyelids, typically originating from the meibomian glands and less commonly from the glands of Zeis. Extraocular sebaceous carcinoma has been reported most commonly on the head and neck, but also on the vulva, penis, and rarely other locations (308–310). On the eyelids, sebaceous carcinoma may be easily mistaken for chronic blepharoconjunctivitis or a chalazion (311). On extraocular sites, sebaceous carcinoma usually manifests as a nodule that may or may not be ulcerated (283,312).

Sebaceous carcinomas of the eyelids quite frequently cause regional metastases. In addition, there may be orbital invasion, and in 22% of the cases reported in one study, death resulted from visceral metastases (313). Extraocular sebaceous carcinomas also may cause regional metastases (314–316). However, death resulting from visceral metastasis in extraocular sebaceous carcinomas originally was believed to be uncommon (312,317). It has been suggested that extraocular sebaceous carcinoma can widely metastasize and cause death just as frequently as ocular types (318). The sebaceous carcinomas that may be found among the multiple sebaceous neoplasms occurring in association with multiple visceral carcinomas in the Muir-Torre syndrome do not metastasize, although the visceral malignant tumors may (319). In some instances, a sebaceous carcinoma represents the only cutaneous manifestation of the syndrome (320).

Histopathology. The irregular lobular formations show great variations in the size of the lobules (Fig. 30-51). Although many cells are undifferentiated, distinct sebaceous cells showing a foamy cytoplasm are present in the center of most lobules (Figs. 30-52 and 30-53) (312). Many undifferentiated cells and sebaceous cells appear atypical, showing considerable nuclear and nucleolar pleomorphism (Fig. 30-53) (316). In addition,

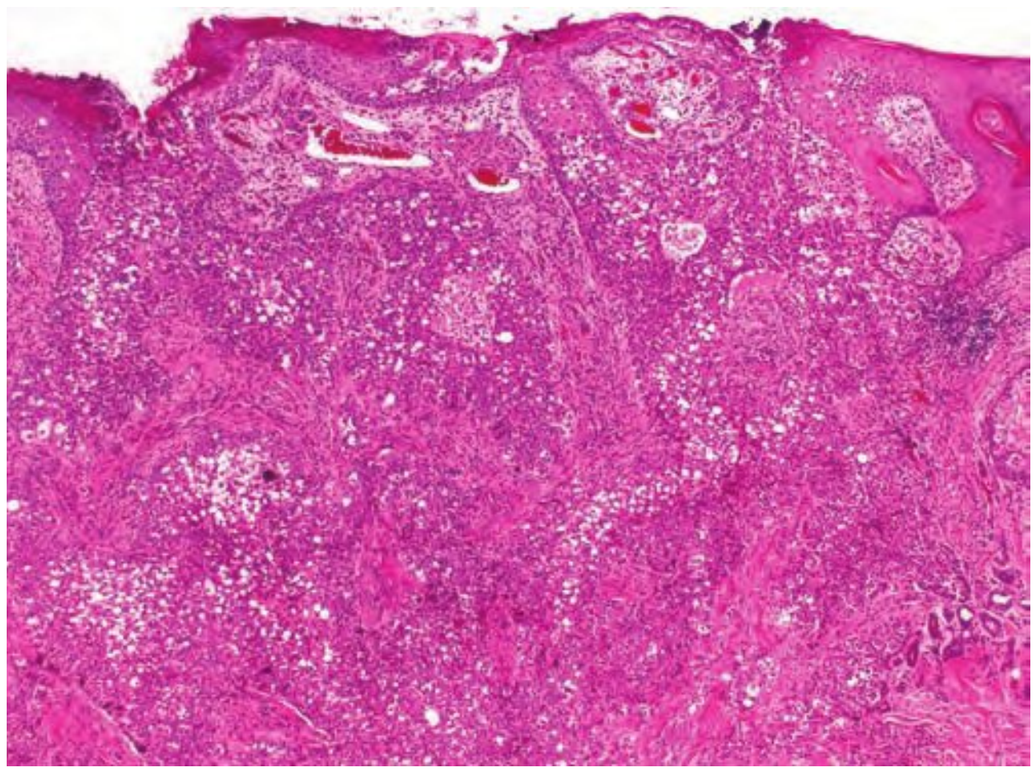

FIGURE 30-52. Sebaceous carcinoma. Irregular epithelial lobules are associated with epidermal ulceration and an infiltrative growth pattern in the dermis.

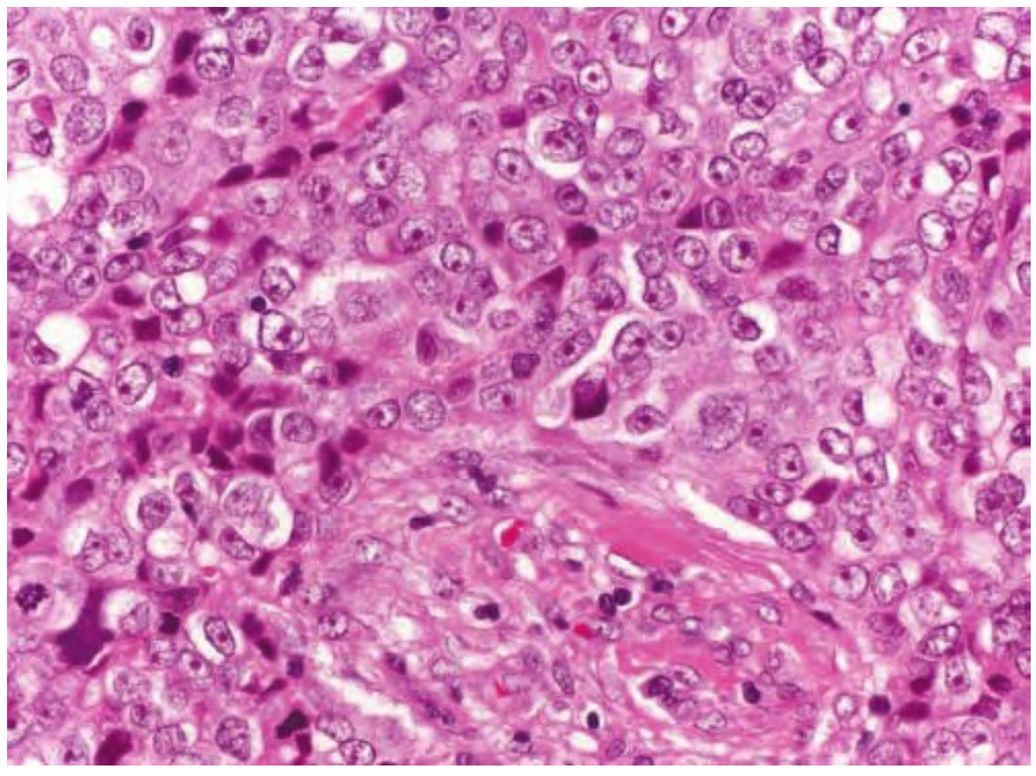

FIGURE 30-53. Sebaceous carcinoma. Lesional cells demonstrate marked cytologic atypia, mitotic activity, and focal sebaceous differentiation.

many of the undifferentiated cells have an eosinophilic cytoplasm, and when fat stains are used on frozen sections, the cells are found to contain fine lipid globules (311). Some of the large lobules show areas composed of atypical keratinizing cells, as seen in squamous cell carcinoma (283).

Sebaceous carcinomas of the eyelids in nearly half of the cases examined showed a pagetoid spread of malignant cells in the conjunctival epithelium or the epidermis of the skin of the lid or both (313). These changes are seen very rarely in extraocular sebaceous carcinoma (317). The pagetoid cells contain no mucopolysaccharides but stain positively for fat with oil red O (313). Recognition of the pagetoid growth pattern in biopsy material can be essential to recognition of the existence of an underlying sebaceous carcinoma (321).

Additional Studies. Certain strains of human papillomavirus have been implicated in the pathogenesis of sebaceous carcinoma (322). Mutations in the *p53* gene have been seen in invasive but not *in situ* sebaceous carcinoma, and immunohistochemical staining for proliferating cell nuclear antigen and p53 seem to have some prognostic value (323,324).

Differential Diagnosis. The tumor cells in sebaceous carcinoma are often large and squamoid in appearance or show basaloid differentiation with only inconspicuous lipidization. In the latter case, the tumor must be distinguished from basal cell carcinomas with sebaceous differentiation, and in the former case the differential diagnosis includes squamous cell carcinomas with hydropic changes (325,326). Other malignant neoplasms with clear cells must also be considered, including metastatic lesions (318).

Sebaceous carcinomas do not show the typical changes seen in basal cell carcinomas. Instead, the undifferentiated cells of sebaceous carcinoma show a more eosinophilic cytoplasm, greater cytologic atypia, and greater invasiveness (327). Clear-cell squamous cell carcinoma usually shows evidence of keratinization in the form of dyskeratotic cells and squamous parakeratotic whorls. Using an immunohistochemical battery, including epithelial membrane antigen (EMA), anti–BCA-255 (BRST-1), and CAM 5.2, can be helpful in distinguishing sebaceous carcinoma from basal cell carcinoma and squamous cell carcinoma (328).

The malignant neoplasms with clear cells do not show sebaceous differentiation. The cytoplasmic clearing is due to glycogen accumulation, which causes the nuclei to be positioned eccentrically. In contrast, neoplastic cells with sebaceous differentiation show scalloped, centrally situated nuclei and microvacuolated cytoplasm secondary to lipid deposits. When sebaceous carcinoma is suspected or found at frozen section, additional sections should be saved for fat stains. Sebaceous ductal differentiation consists of ductal structures lined by an eosinophilic corrugated cuticle similar to that of the normal sebaceous duct. Finally, metastases to the skin from malignant neoplasms composed of clear cells, namely renal, breast, bladder, and prostatic carcinoma or melanoma, also may mimic sebaceous carcinoma. Histochemical and immunohistochemical methods can help in narrowing the differential diagnosis appropriately (328).

As in other malignant adnexal neoplasms, zones of necrosis, marked nuclear atypia, and abnormal mitotic figures are common in sebaceous carcinoma (Fig. 30-53). Pagetoid proliferation of tumor cells in the epidermis or conjunctiva may extend widely and confers a poorer prognosis. Other adverse prognostic attributes include multicentric involvement, poor differentiation (i.e., sparse lipid), necrosis, paucity of reactive lymphocytes, extensive local invasion, and vascular or bony invasion (324). Metastases first involve regional lymph nodes of the periauricular, submaxillary, and cervical chains. Visceral spread may occur and lead to death. Additional criteria that may be of assistance in differentiating sebaceous carcinoma and sebaceoma are that carcinomas are larger, asymmetric, infiltrative, and poorly circumscribed, whereas sebaceomas may extend into the subcutis but are circumscribed and symmetric. Carcinomas may ulcerate the epidermis, and there may be extensive necrosis ("necrosis en masse"). The ratio of differentiated (vacuolated) to undifferentiated (nonvacuolated) sebocytes varies but tends to be higher in sebaceomas. Nuclear atypia is often striking, and mitotic figures are numerous and sometimes atypical in carcinomas. Sebaceomas, in contrast, lack striking nuclear atypia but may have few or many mitoses (285).

TUMORS WITH APOCRINE DIFFERENTIATION

Apocrine Nevus

Large numbers of mature apocrine glands are frequently present in lesions of nevus sebaceus and syringocystadenoma papilliferum. However, the pure apocrine nevus is a rare tumor. Apocrine nevi have presented as papules, facial nodules, and, most frequently, soft tissue masses of the axillae (329–333).

Histopathology. These lesions comprise increased numbers of apocrine glands, usually situated in the reticular dermis with occasional extension into subcutaneous tissue (329–337).

Immunohistochemistry. Studies demonstrate positive staining for carcinoembryonic antigen, gross cystic disease fluid protein, epithelial membrane antigen, and low–molecular-weight keratins (331,337,338). Lesions are typically negative for S100 and high–molecular-weight keratins.

Apocrine Hidrocystoma

Apocrine hidrocystoma occurs usually as a solitary, translucent cystic nodule (330–341). The term "apocrine cytsadenoma" has also been used to describe these lesions (339). Lesional diameter usually ranges from 1 to 15 mm; however, "giant" lesions, measuring 20 mm, have been described (342). Frequently, the lesions have a blue hue and can resemble a blue nevus (Fig. 30-54). The usual location of apocrine hidrocystoma is on the face, but it is occasionally seen on the ears, scalp, chest, shoulders, or vulva (341,343–348). Multiple apocrine hidrocystomas are rarely encountered (349,350). Lesions described as occurring on the penis have been reclassified as median raphe cysts (see Chapter 29) (351).

The blue color in some of the cysts is not fully explained. According to most authors, it is a Tyndall effect caused by the scattering of light in a colloidal system and the resultant reflection of blue light (343,349).

Histopathology. The dermis contains one or several large cystic spaces into which papillary projections often extend (Fig. 30-55). The inner surface of the cyst and the papillary projections are lined by a row of columnar secretory cells of variable height showing "decapitation" secretion indicative of apocrine secretion (Fig. 30-56). Peripheral to the layer of secretory cells are elongated myoepithelial cells, their long axes running parallel to the cyst wall (343). In some cases, one finds superficially located lumina lined by a double layer of ductal epithelium in addition to the cysts lined by secretory cells (339).

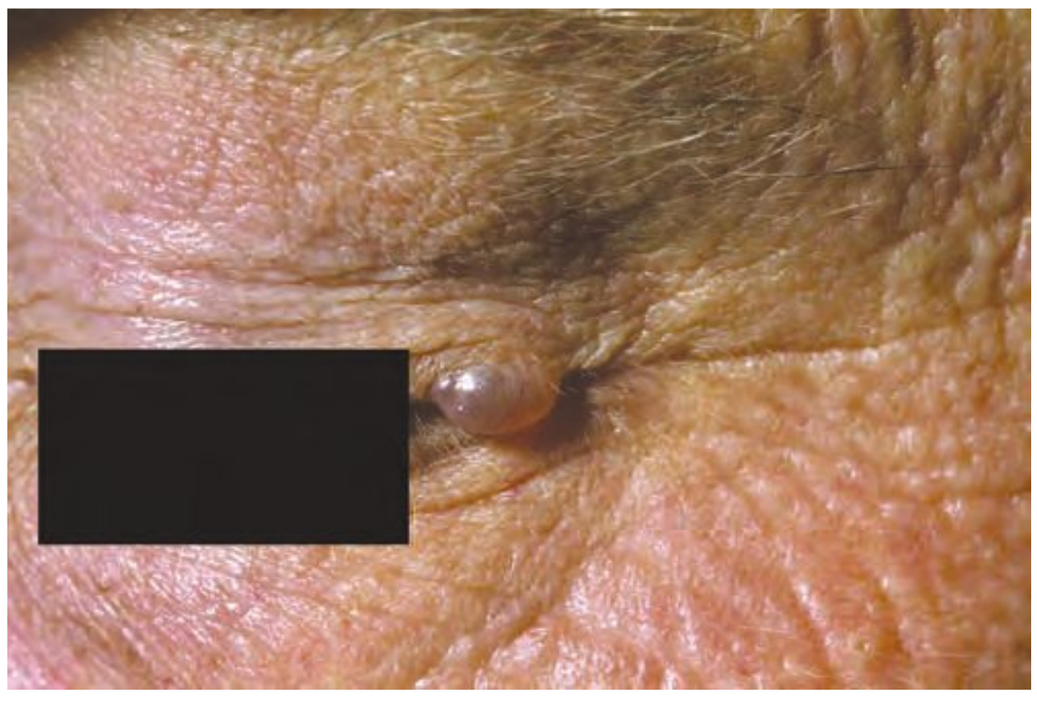

FIGURE 30-54. Apocrine hidrocystoma. A translucent cystic lesion with a bluish hue is noted.

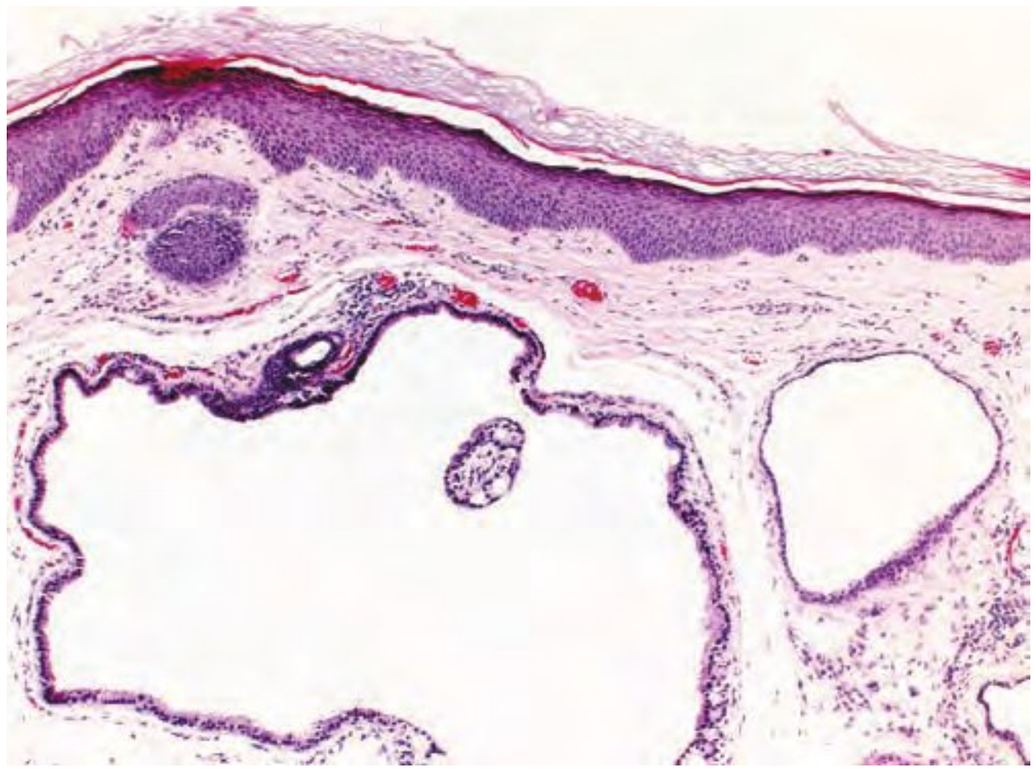

FIGURE 30-55. Apocrine hidrocystoma. The dermis contains a multiloculated cystic lesion lined by epithelial cells with occasional papillary projections.

Additional Studies. The apocrine nature of the secretion of the luminal cells has been demonstrated by the presence of numerous large PAS-positive, diastase-resistant granules in the secretory cells and by electron microscopy. Electron microscopic examination shows abundant secretory granules of moderate density and uniform internal structure in the secretory cells of apocrine hidrocystoma, particularly in their luminal portion, and evidence of apocrine secretion (352–354).

The apocrine hidrocystoma can be regarded as a cystic adenoma rather than as a retention cyst because the secretory cells do not appear flattened, as they would be in a retention cyst, and because papillary projections can extend into the lumen of the cystic spaces (339).

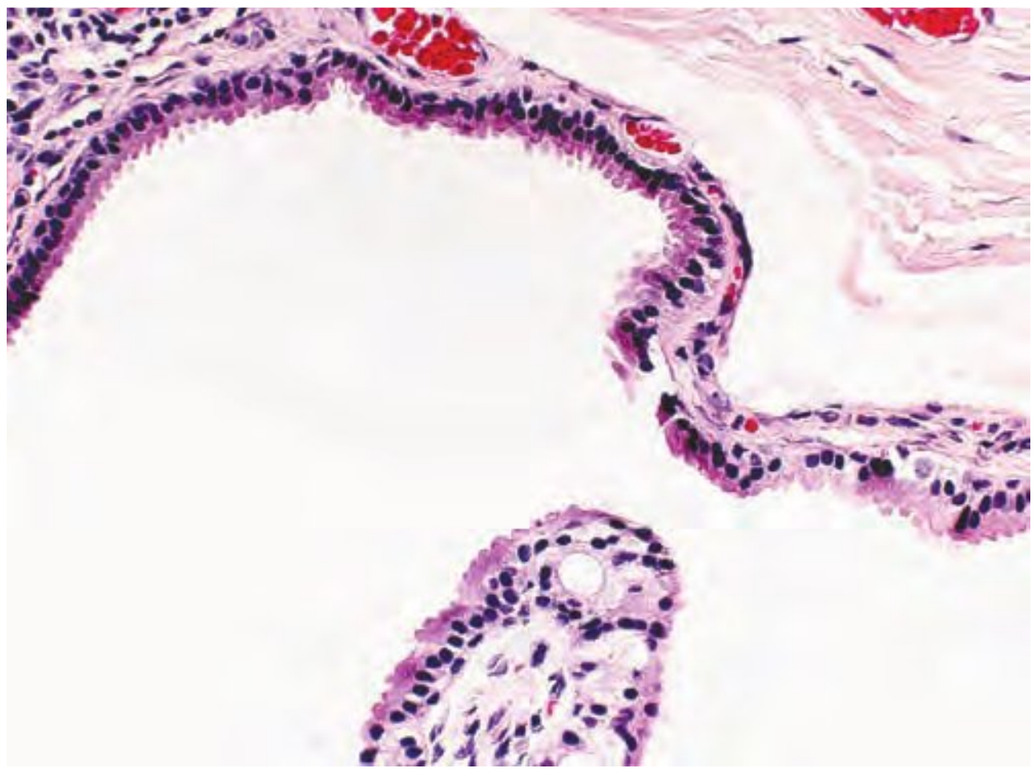

FIGURE 30-56. Apocrine hidrocystoma (cystadenoma). The cyst is lined by a single row of columnar cells showing decapitation secretion. Peripheral to the row of secretory cells are elongated myoepithelial cells.

Differential Diagnosis. Eccrine hidrocystomas, which are lined by ductal cells, differ from apocrine hidrocystomas by the absence of decapitation secretion, of PAS-positive granules, and of myoepithelial cells. However, those portions of an apocrine hidrocystoma in which the cystic spaces are lined by ductal epithelium have the same appearance as the cystic spaces in eccrine hidrocystomas, except that the latter usually are unilocular and apocrine hidrocystomas are often multilocular. Median raphe cysts of the penis, which have been mistakenly reported as apocrine hidrocystomas, show a pseudostratified columnar cyst wall without evidence of decapitation secretion and without a row of myoepithelial cells (351).

Hidradenoma Papilliferum

Hidradenoma papilliferum usually occurs in women, usually on the labia majora or in the perineal or perianal region (355–358). In males, it has been reported as a perineal lesion or ectopically as an arm lesion (359,360). Occurrences on the upper eyelid and in the external ear canal have been reported (361,362). The tumor is covered by normal skin and measures only a few millimeters in diameter. Malignant changes have been reported in hidradenoma papilliferum, as aggressive adenosquamous or squamous cell carcinomas (363,364).

Histopathology. The tumor represents an adenoma with apocrine differentiation (365). It is located in the dermis, is well circumscribed, is surrounded by a fibrous capsule, and shows no connection with the overlying epidermis (Fig. 30-57). Some tumors have a peripheral epithelial wall showing areas of keratinization (197). Within the tumor, one observes tubular and cystic structures (Fig. 30-58). Papillary folds project into the cystic spaces. The lumina are lined occasionally with only a single row of columnar cells, which show an oval, pale-staining nucleus located near the base, a faintly eosinophilic cytoplasm, and active decapitation secretion as seen in the secretory cells of apocrine glands (Fig. 30-58) (365). Usually, the lumina are surrounded by a double layer of cells consisting of an inner layer of secretory cells and an outer layer of small cuboidal cells with deeply basophilic nuclei that are myoepithelial cells (Fig. 30-58) (366).

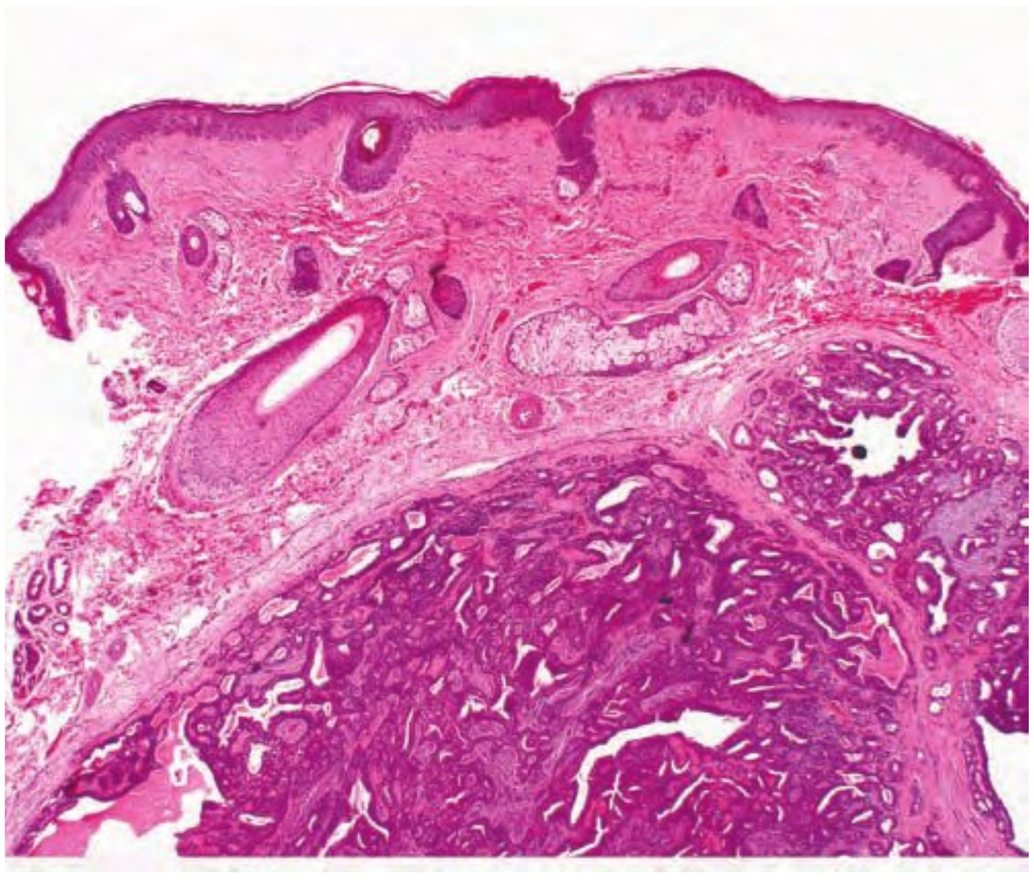

FIGURE 30-57. Hidradenoma papilliferum. The tumor consists of a well-circumscribed dermal nodule with scattered cystic and branching spaces.

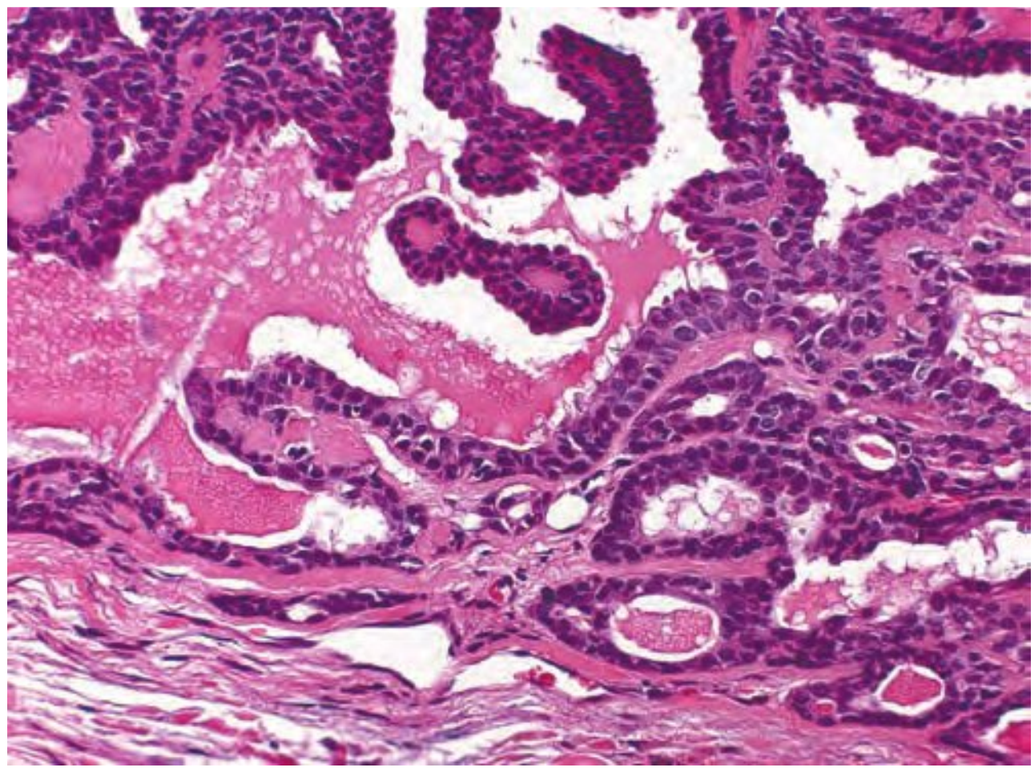

FIGURE 30-58. Hidradenoma papilliferum. Numerous papillary projections are seen within the lesion. The papillary folds are lined by one layer of high cylindric cells, which show evidence of active "decapitation" secretion like that seen in apocrine glands. A basal layer of small cuboidal cells is also present.

Additional Studies. The apocrine nature of the secretion in hidradenoma papilliferum has been established by histochemical, enzyme histochemical, and electron microscopic examinations.

Histochemically, the luminal cells contain many large, PAS-positive, diastase-resistant granules as seen in the secretory cells of apocrine glands. In addition, the luminal cells are positive for nonspecific esterase and acid phosphatase, the so-called apocrine enzymes, and negative for phosphorylase, a typical eccrine enzyme. Furthermore, the outer row of cells stains positive for alkaline phosphatase, as myoepithelial cells normally do (365).

Electron microscopic examination demonstrates two features of the luminal cells that are regarded as characteristic for apocrine secretory cells. First, numerous membrane-limited, secretory granules that are of varying size and density and that contain lipid droplets are present in the apical portion of these cells. Second, as evidence of decapitation secretion, portions of apical cytoplasm containing large secretory granules are released into the lumen (366). The peripheral layer of cells contains numerous myofilaments.

Syringocystadenoma Papilliferum

Syringocystadenoma papilliferum occurs most commonly on the scalp or the face; however, in about one fourth of the cases,

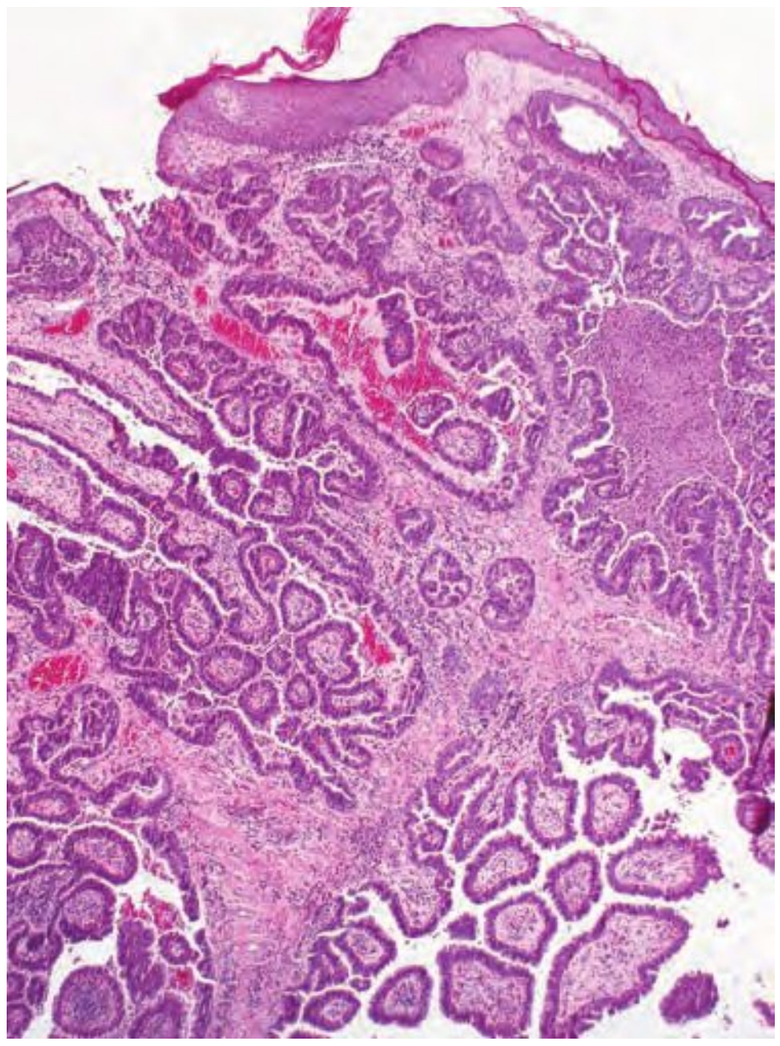

FIGURE 30-59. Syringocystadenoma papilliferum. The lesion exhibits a cystic invagination extending into the dermis, with numerous papillary projections.

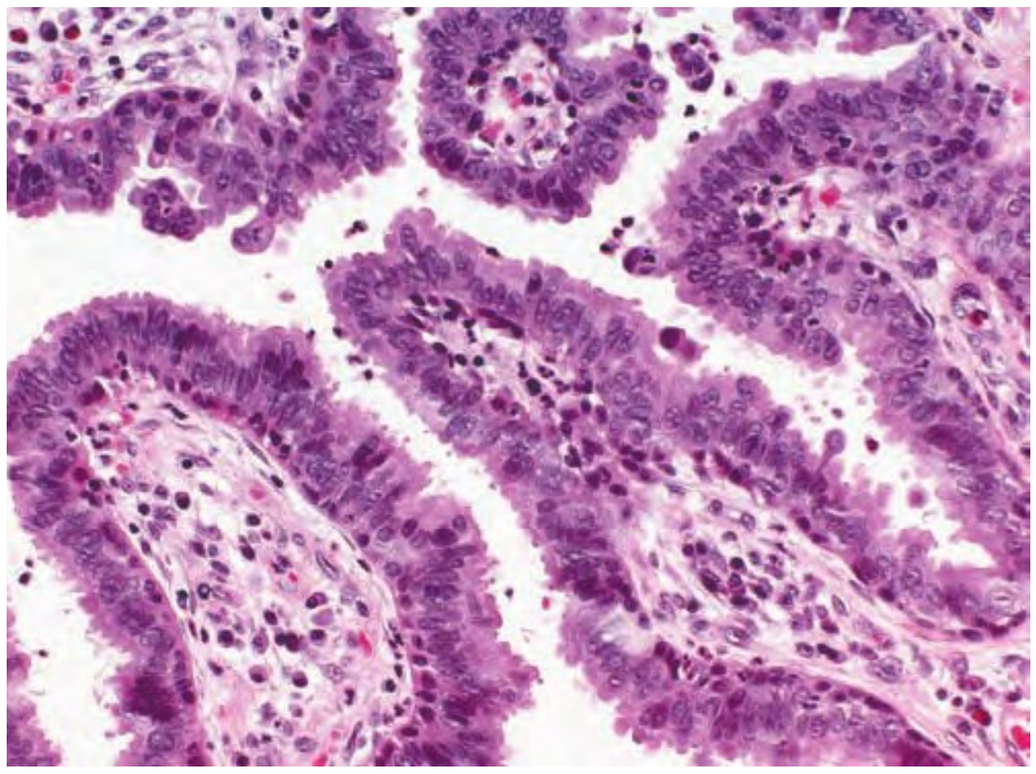

FIGURE 30-60. Syringocystadenoma papilliferum. The papillary projections are lined by two rows of cells. The luminal row of cells consists of columnar cells with evidence of active "decapitation" secretion. The outer row of cells consists of small cuboidal cells. Plasma cells are usually seen in the papillary core.

it is seen elsewhere (367–370). It is usually first noted at birth or in early childhood and presents as a papule or several papules in a linear arrangement or as a plaque. The lesion increases in size at puberty, becoming papillomatous and often crusted (371). On the scalp, syringocystadenoma papilliferum frequently arises around puberty within a nevus sebaceus that has been present since birth.

Histopathology. The epidermis shows varying degrees of papillomatosis. One or several cystic invaginations extend downward from the epidermis (Fig. 30-59). The upper portion of the invaginations and, in some instances, large segments of the cystic invaginations are lined by squamous, keratinizing cells similar to those of the surface epidermis (372). In the lower portion of the cystic invaginations, numerous papillary projections extend into the lumina of the invaginations. The papillary projections and the lower portion of the invaginations are lined by glandular epithelium often consisting of two rows of cells (Fig. 30-60). The luminal row of cells consists of high columnar cells with oval nuclei and faintly eosinophilic cytoplasm. Occasionally, some of these cells show active decapitation secretion, and cellular debris is found in the lumina (14,373). The outer row of cells consists of small cuboidal cells with round nuclei and scanty cytoplasm. In some areas, the cells of the luminal layer are arranged in multiple layers and form a lacelike pattern resulting in multiple small, tubular lumina (368).

Beneath the cystic invaginations, deep in the dermis, one can find in many cases groups of tubular glands with large lumina. The cells lining the large lumina often show evidence of active decapitation secretion, indicating that they are apocrine glands (Fig. 30-60) (14,371). Connections of the apocrine glands deep in the dermis with the cystic invaginations in the upper dermis can be traced when step sections are carried out (14).

A highly diagnostic feature is the almost invariable presence of a fairly dense cellular infiltrate composed nearly entirely of plasma cells in the stroma of this tumor, especially in the papillary projections (Fig. 30-60). These are predominantly of the immunoglobulin G (IgG) and IgA classes (374,375).

Frequently, there are malformed sebaceous glands and hair structures in the lesions of syringocystadenoma papilliferum (371). In about one third of the cases, syringocystadenoma papilliferum is associated with a nevus sebaceus. In about 10% of the cases, a basaloid epithelial proliferation resembling basal cell carcinoma develops, but this is noted only in lesions that also exhibit a nevus sebaceous (368). A few instances of transition of a syringocystadenoma papilliferum into an adenocarcinoma with regional lymph node metastases have been reported (376).

Additional Studies. Syringocystadenoma papilliferum can exhibit both apocrine and of eccrine differentiation. For example, positive immunoreactivity for gross cystic disease fluid proteins 15 and 24 and zinc α-2 glycoprotein demonstrates evidence of apocrine differentiation (338,377). On the other hand, immunohistochemical analysis of cytokeratins in syringocystadenoma papilliferum demonstrates similarities to eccrine poromas and the ductal component of eccrine glands (378). In addition, light and electron microscopic features of some lesions show evidence of eccrine differentiation (13). It is probable that syringocystadenoma papilliferum arises from undifferentiated cells with the potential to exhibit both apocrine

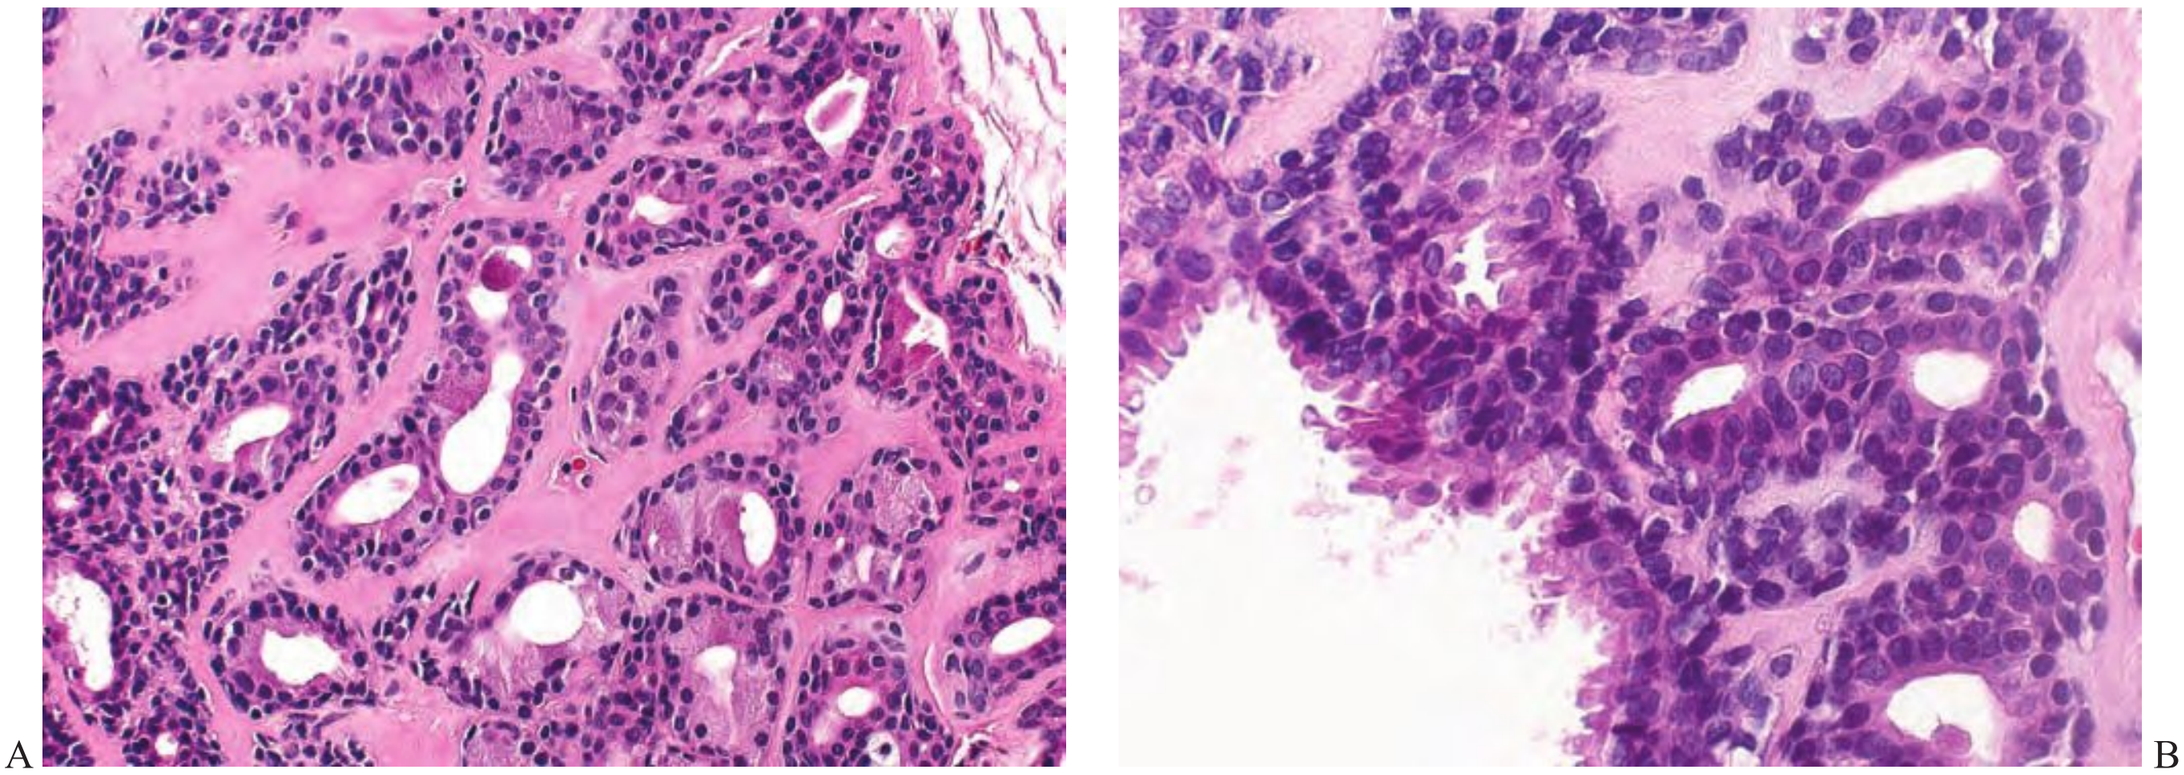

FIGURE 30-61. Tubular apocrine adenoma. A: There are numerous irregularly shaped tubular structures in the dermis. B: The tubules are usually lined by two layers of epithelial cells—an indicator of benignancy. The peripheral layer consists of cuboidal or flattened cells, and the luminal layer is composed of columnar cells. Some of the tubules have a dilated lumen with papillary projections. Eosinophilic debris can be seen in the tubular lumens.

and eccrine modes of epithelial secretion. Of interest, the view expressed by Pinkus probably is correct: Most lesions of syringocystadenoma papilliferum exhibit apocrine differentiation; however, some demonstrate eccrine features (371). Studies have demonstrated loss of heterozygosity for Patched and p16, a negative regulator of the cell cycle, in syringocystadenoma papilliferum, suggesting that these molecules may play a role in the pathogenesis of these lesions (379).

Tubular Apocrine Adenoma

First described in 1972 (380), additional cases of tubular apocrine adenoma have been reported (381–385). The tumor typically presents as a well-defined nodule that is located on the scalp. Most tumors are less than 2 cm in diameter, although one reported lesion located on the scalp measured 7 by 4 cm (380).

Histopathology. This tumor manifests numerous irregularly shaped tubular structures that are usually lined by two layers of epithelial cells (Fig. 30-61). The peripheral layer consists of cuboidal or flattened cells, and the luminal layer is composed of columnar cells (380). Some of the tubules have a dilated lumen with papillary projections extending into it (Fig. 30-61). Decapitation secretion of the luminal cells is seen in many areas. In addition, cellular fragments and eosinophilic granular debris are seen in some lumina. In some cases, tubular apocrine adenomas can arise in association with syringocystadenoma papilliferum (SCAP), and often the SCAP is situated in the superficial portion of the "combined" lesion (382,384,386).

Additional Studies. Electron microscopy has revealed secretory granules and evidence of apocrine-type decapitation secretion in the luminal cells (380,383). In contrast to hidradenoma papilliferum, the peripheral cell layer contains no myofilaments. Enzyme histochemistry is also consistent with apocrine differentiation (380).

Differential Diagnosis. In tubular apocrine adenomas with marked papillary proliferations, there may be some nuclear pleomorphism, which suggests sweat gland carcinoma or a metastatic adenocarcinoma. However, the presence of a peripheral layer of cuboidal or flattened cells is a feature favoring benignity (381).

Tubular apocrine adenomas resemble papillary eccrine adenoma, and these two tumors were once regarded as identical (384). Because of their differences in decapitation secretion, in enzyme histochemistry, and in electron microscopy, the suggestion was made that they be referred to as *tubulopapillary hidradenoma*, with apocrine or eccrine differentiation, as the case may be (387). For a description of papillary eccrine adenomas, see page 890. The term *tubulopapillary hidradenoma* may be considered to conceptualize a spectrum of lesions that includes tubular apocrine adenoma and papillary eccrine adenoma, and these are also closely related to syringocystadenoma papilliferum (388,389).

Apocrine Adenoma; Apocrine Fibroadenoma

Rare variants of apocrine adenomas can occur in apocrine areas, such as in the axilla (390) and in the perianal region (391,392).

Histopathology. Apocrine lumina are readily recognized by the presence of decapitation secretion. In addition, there may be cystically dilated spaces (390,391). A stromal component resembling that in fibroadenomas of the breast has been described (392).

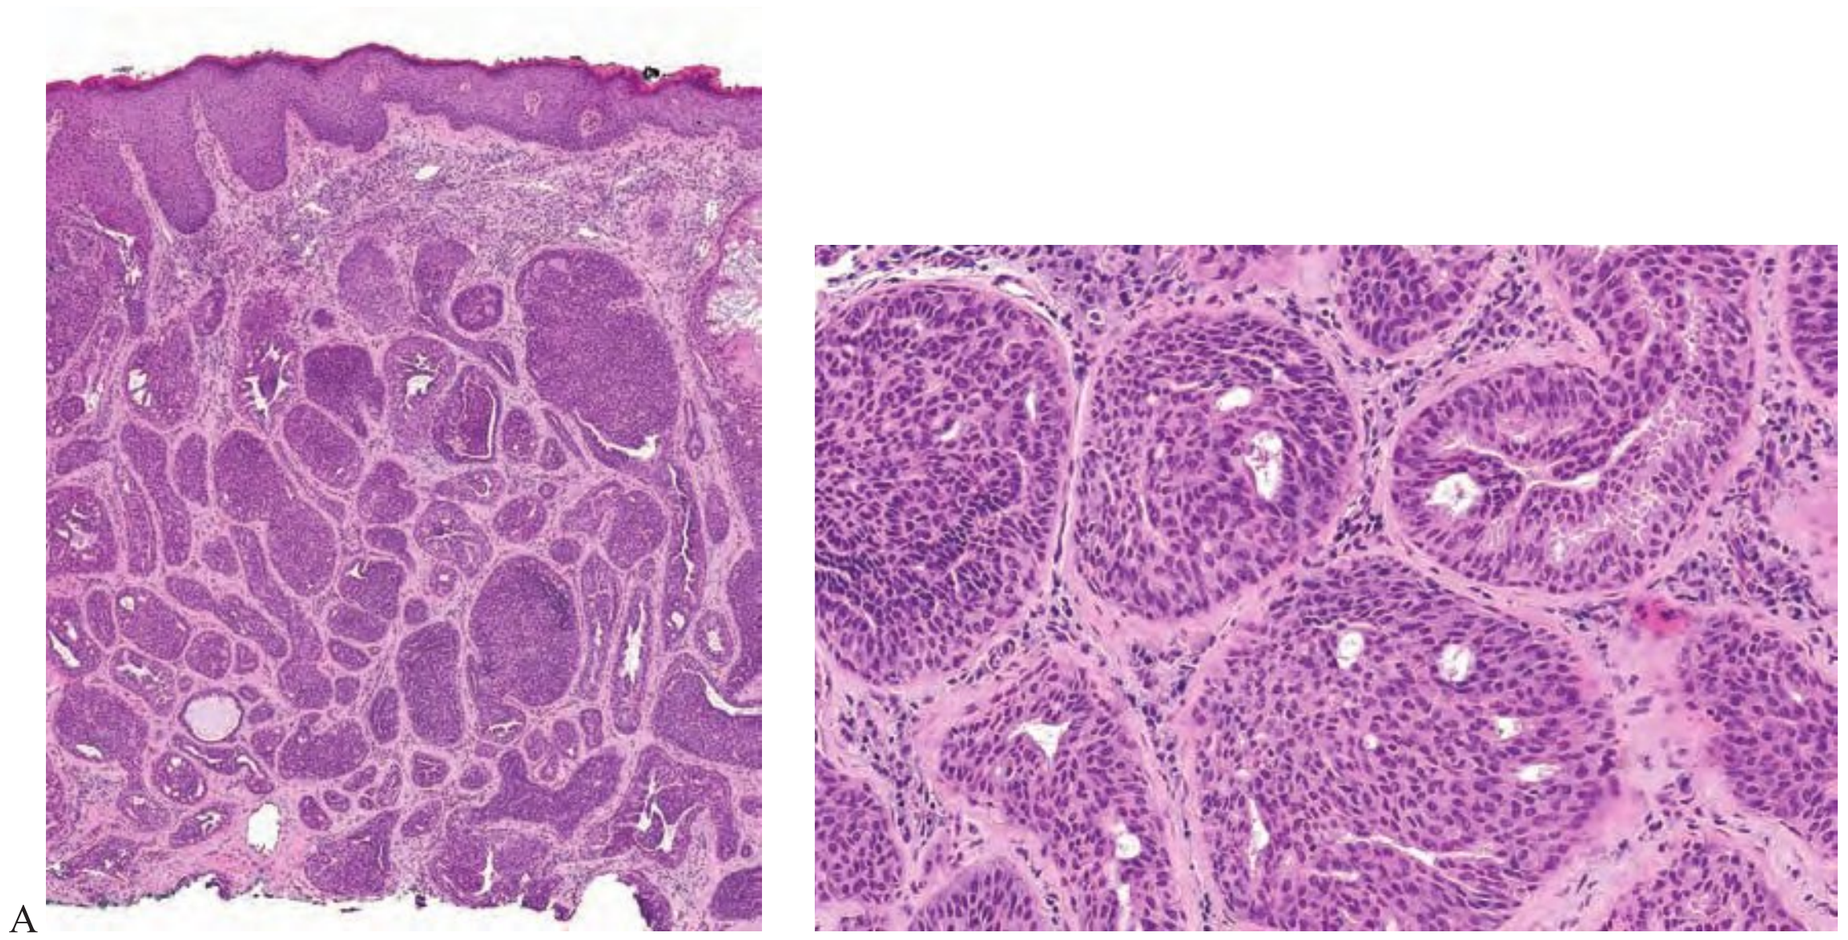

FIGURE 30-62. Erosive adenomatosis of the nipple. A: Dilated tubular structures are present at the dermal–epidermal junction and throughout the dermis. B: The dilated tubules are lined by a peripheral layer of cuboidal cells and a luminal layer of columnar cells that occasionally exhibit decapitation secretion. Other tubules exhibit a more solid proliferation resembling "papillomatosis" of mammary duct epithelium.

Erosive Adenomatosis of the Nipple

Erosive adenomatosis (papillary adenoma, florid papillomatosis) of the nipple represents an adenoma of the major nipple ducts (393–396). In the early lesions, the nipple appears eroded and inflamed, often with a serous discharge. During this early erosive phase, clinical differentiation from Paget's disease of the breast may be impossible. Later, the nipple shows nodular thickening; differentiation from Paget's disease is then easier. Peak incidence for erosive adenomatosis is in the fifth decade of life; cases in girls as young as 8 years of age have been reported (397).

Histopathology. Extending downward from the epidermis are irregular, dilated tubular structures resembling those seen in tubular apocrine adenoma (Fig. 30-62) (393). These tubules are lined by a peripheral layer of cuboidal cells and a luminal layer of columnar cells that occasionally demonstrate secretory projections at their luminal border (393). Some of the tubules demonstrate papillary proliferations of columnar cells that extend into the lumen; these proliferations may be so pronounced as to nearly fill the entire lumen. In other areas, detached, partially necrotic cells may be seen in the tubular lumina. In some lesions, considerable acanthosis of the epidermis is seen, with extension of squamous epithelium into some of the superficial ductal structures.

Differential Diagnosis. Erosive adenomatosis of the nipple must be differentiated from intraductal carcinoma, which shows larger cuboidal cells and uniform atypicality of the nuclei, frequently with necrosis. Immunohistochemical studies have demonstrated myoepithelial cells within lesions of erosive adenomatosis, which would help to differentiate these lesions from intraductal carcinoma (398). Hidradenoma papilliferum, in contrast to erosive adenomatosis of the nipple, shows no connections of the tubular structures with the surface epidermis (399).

Cylindroma

Cylindroma occurs more often as a solitary lesion than as multiple lesions (400). Cases with multiple lesions are dominantly inherited and show numerous dome-shaped, smooth nodules of various sizes on the scalp. Occasionally, scattered nodules are also present on the face and, in rare instances, on the trunk and the extremities (401). The lesions begin to appear in early adulthood and increase in number and size throughout life. The tumors present as scalp nodules ranging in size from a few millimeters to several centimeters (Fig. 30-63). Nodules on the scalp may be present in such large numbers as to cover the entire scalp like a turban. For this reason, they are referred to occasionally as *turban tumors*.

The association of multiple lesions of cylindroma with multiple lesions of trichoepithelioma is quite common (400,402–405). In these cases, the lesions of the scalp are cylindromas, and those elsewhere are partially cylindromas and partially trichoepitheliomas. Brooke-Spiegler syndrome refers to a dominantly inherited disorder in which patients demonstrate multiple cylindromas, spiradenomas, and trichoepitheliomas (403,405–408). In several instances, multiple cylindromas have been found in association with eccrine spiradenoma (400,409,410).

FIGURE 30-63. Cylindroma. The lesions typically present as scalp nodules.

Sporadic, solitary cylindromas are not inherited; they appear in adulthood and occur either on the scalp or the face. Their histologic appearance is the same as that of multiple cylindromas (400).

Histopathology. Cylindromas represent a tumor that may manifest both apocrine and eccrine differentiation; however, features of apocrine differentiation usually predominate (400). The tumors of cylindroma are composed of numerous islands of epithelial cells. Varying considerably in size and shape and lying close together, separated often only by their hyaline sheath and a narrow band of collagen, the islands of epithelial cells seem to fit together like pieces of a jigsaw puzzle (Figs. 30-64 and 30-65). The hyaline sheath surrounding the tumor islands like a cylinder is quite variable in thickness. In addition, droplets of hyalin are present in many islands, and some islands consist largely of hyalin and contain only a few cells. The hyalin is PAS positive and diastase resistant (373).

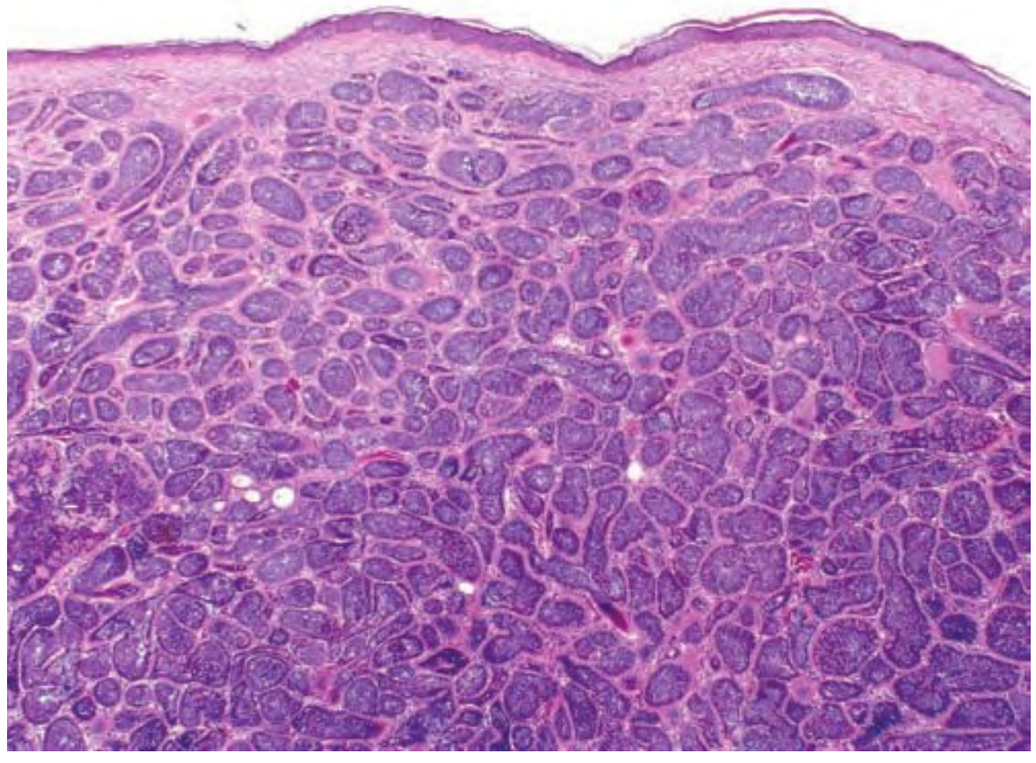

FIGURE 30-64. Cylindroma. The tumor is composed of irregularly shaped islands that fit together like pieces of a jigsaw puzzle. The islands are surrounded by a hyaline sheath.

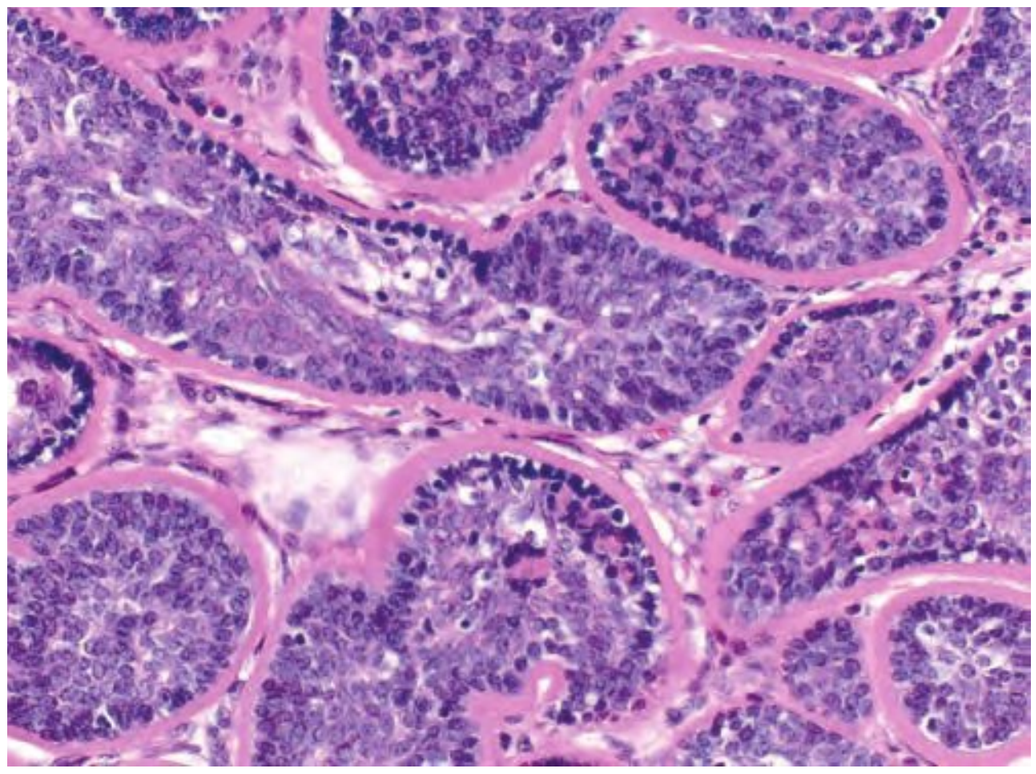

FIGURE 30-65. Cylindroma. Two types of epithelial cells comprise the islands: cells with small dark nuclei representing undifferentiated cells, and cells with large pale nuclei representing cells with a certain degree of differentiation toward ductal or secretory cells. Droplets of hyaline material are seen in the islands.

Two types of cells constitute the islands: Cells with small, dark-staining nuclei are present predominantly at the periphery of the islands, often in a palisade arrangement, and cells with large, light-staining nuclei lie in the center of the islands (Fig. 30-65). In addition, tubular lumina are often present. In some cases, they are quite numerous, whereas in others only a few are found after a thorough search. The lumina are lined by cells that usually have the appearance of ductal cells (411). Occasionally, however, the luminal cells show active secretion, like the secretory cells of apocrine glands (14). Often, amorphous material is found within the lumina; it contains both neutral and acid mucopolysaccharides, as demonstrated by positive staining with the PAS reaction and Alcian blue (373).

Additional Studies. The ultrastructural and immunohistochemical features best fit differentiation toward the intradermal coiled duct region of eccrine sweat glands (412–414), with myoepithelial cell participation (415).

Electron microscopic examination, similar to examination by light microscopy, has revealed two major types of cells: undifferentiated basal cells with small, dark nuclei, and differentiating cells with large, pale nuclei. Most of the differentiating cells still appear immature as "indeterminate cells," but some show a certain degree of differentiation toward secretory or ductal cells and are in part arranged around lumina (411,416,417).

Of interest, an early study of two large pedigrees led to the conclusion that cylindromas and trichoepitheliomas are different manifestations of the same disorder and not merely examples of genetic linkage (405). Genetic studies have identified a single gene, *CYLD1*, on 16q12-q13 as being altered in familial cylindromatosis syndrome (Brooke-Spiegler) (11). Loss of heterozygosity at the 16q12-q13 locus has been demonstrated in

familial cylindromatosis and sporadic cylindromas (11). The CYLD1 gene has been cloned; the molecule contains cytoskeletal binding domains and domains similar to ubiquitin hydrolases (418). Frameshift mutations in the CYLD1 gene have also been associated with familial cylindromatosis (419). The various tumors associated with familial cylindromatosis may arise from different types of mutations in the CYLD1 gene; however, this has not been definitively demonstrated (419).

The thick hyaline band surrounding the tumor islands of cylindroma is composed mainly of an amorphous substance identical to the subepidermal lamina densa. It is connected with the tumor cells by half-desmosomes. Enmeshed in it are aggregated anchoring fibrils and thin collagen fibrils (13). This thick hyaline membrane and also the particles of hyaline present between the cells of the tumor islands react positively to staining with antibodies against type IV collagen and laminin, analogous to the subepidermal lamina densa. This hyaline is synthesized by the tumor cells and is similar to the deposits of basement membrane protein demonstrated in hyalinosis cutis et mucosae (420).

Malignant Cylindroma

Cylindromas rarely undergo malignant degeneration; however, a number of cases have been reported (421–427). In most of these patients, there were multiple cylindromas of the scalp, but in several cases a single tumor was present (421–429). Usually only one tumor was malignant, but in some cases malignant progression had occurred in several tumors (430,431).

Death usually ensued through visceral metastases, but in a few patients it occurred as the result of invasion of the skull with ensuing hemorrhage or meningitis. Local excision of the tumors of the scalp may result in a cure.

Histopathology. Areas of malignant degeneration are characterized by islands of cells showing marked nuclear anaplasia and pleomorphism, many atypical mitotic figures, loss of the hyaline sheath, loss of palisading at the periphery, and invasion into the surrounding tissue.

TUMORS WITH ECCRINE DIFFERENTIATION

Eccrine Nevus

Eccrine nevi are very rare. They may show a circumscribed area of hyperhidrosis (432,433), a solitary sweat-discharging pore (434), or papular lesions in a linear arrangement (435).

In the so-called eccrine angiomatous hamartoma, there may be one or several nodules (436) or a solitary large plaque (437). The lesions are generally present on an extremity at birth. Hyperhidrosis and/or pain may be apparent (438).

Histopathology. Eccrine nevi show an increase in the size of the eccrine coil or in both the size and the number of coils. In other cases there is ductal hyperplasia consisting of thickening of the walls and dilation of the lumina.

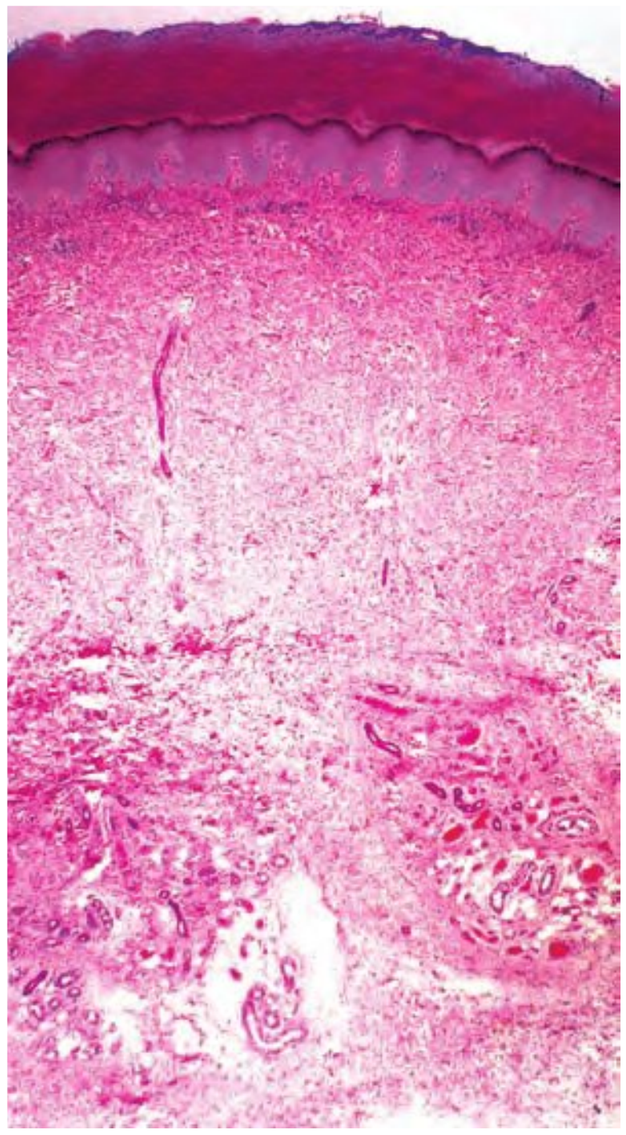

FIGURE 30-66. Eccrine angiomatous hamartoma. There is an increased number of eccrine structures and capillary channels in the deep dermis.

Eccrine angiomatous hamartomas usually lie in the deep dermis and contain increased numbers of eccrine structures and numerous capillary channels surrounding or intermingled with the eccrine structures (Figs. 30-66 and 30-67) (439). These hamartomas may also contain fatty tissue and pilar structures (440,441).

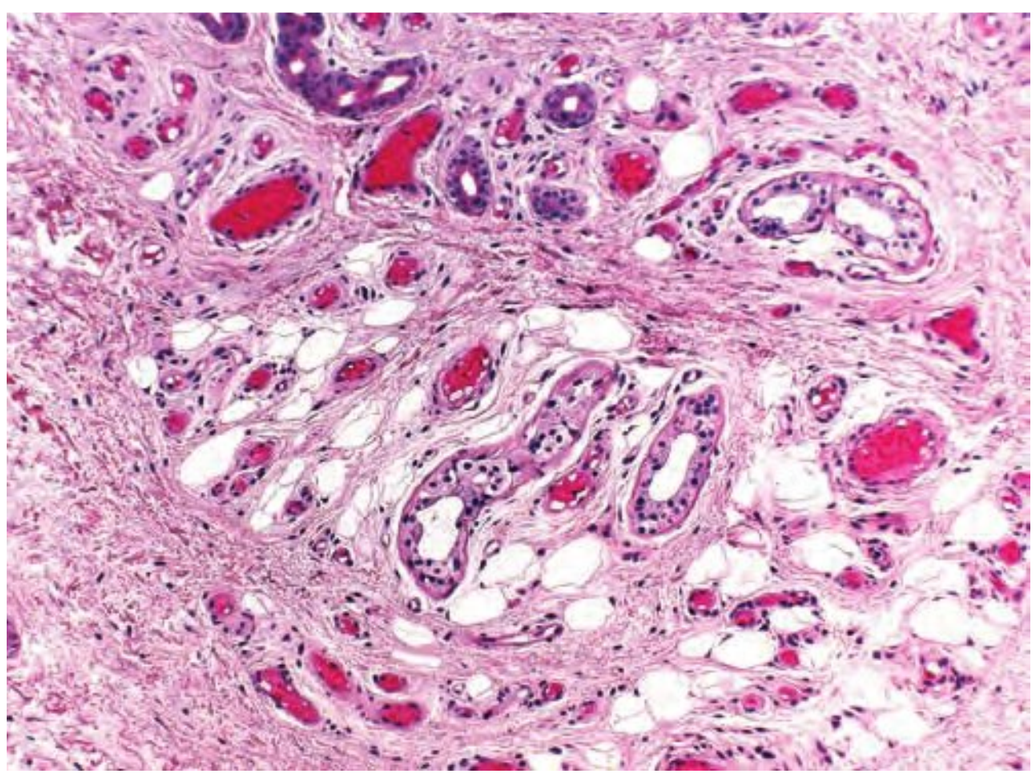

FIGURE 30-67. Eccrine angiomatous hamartoma. The eccrine coils and capillaries are associated with fatty tissue.

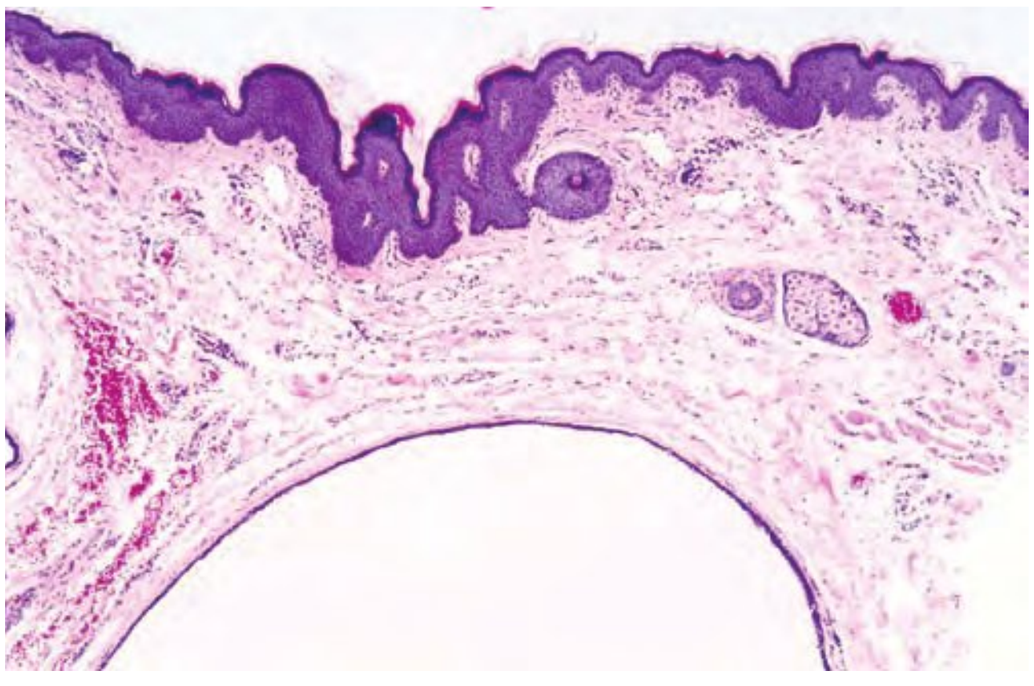

FIGURE 30-68. Eccrine hidrocystoma. A solitary cystic lesion is seen in the dermis.

Eccrine Hidrocystoma

In this condition, usually one lesion, but occasionally several, and rarely numerous lesions are present on the face (442). As in apocrine hidrocystoma, the lesion consists of a small, translucent, cystic nodule 1 to 3 mm in diameter that often has a bluish hue. In some patients with numerous lesions, the number of cysts increases in warm weather and decreases during winter (443).

Histopathology. Eccrine hidrocystoma shows a single cystic cavity located in the dermis (Fig. 30-68). The cyst wall usually shows two layers of small, cuboidal epithelial cells (Fig. 30-69) (442). In some areas, only a single layer of flattened epithelial cells can be seen, their flattened nuclei extending parallel to the cyst wall. Small papillary projections extending into the cavity of the cyst are observed only rarely (444). Eccrine secretory tubules and ducts are often located below the cyst and in close approximation to it, and, on serial sections, one may find an eccrine duct leading into the cyst from below (416). However, typically no connection is found between the cyst and the epidermis.

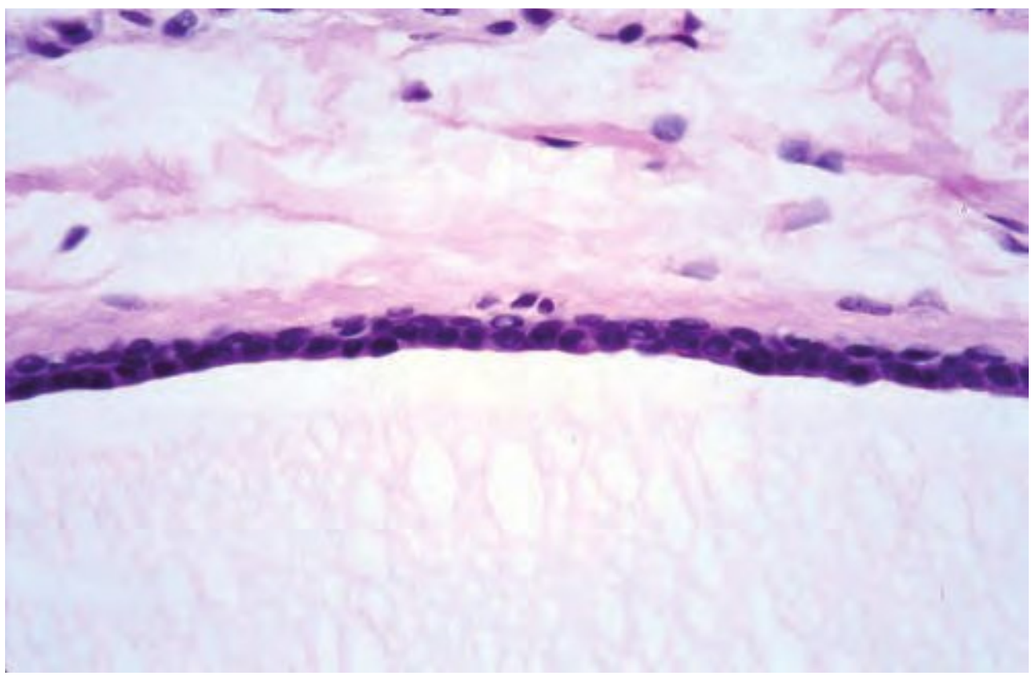

FIGURE 30-69. Eccrine hidrocystoma. The cyst is lined by a single layer of cuboidal epithelium.

Additional Studies. Electron microscopy of eccrine hidrocystoma has established that the cyst wall is composed of ductal cells, because the luminal cell membrane shows numerous microvilli and no secretory granules (445). Tonofilaments are seen in the luminal portion of the cells, and desmosomes connect the cells (446). Enzyme histochemistry in cases with numerous cysts has revealed phosphorylase and succinic dehydrogenase, which are eccrine enzymes, in the cyst walls (445,446).

It is likely that obstruction of eccrine ducts leads to either temporary or permanent retention of sweat (446).

Differential Diagnosis. For a discussion of differentiation of eccrine from apocrine hidrocystoma, see page 877.

Syringoma

Based on histochemical and electron microscopic findings, syringoma represents an adenoma of intraepidermal eccrine ducts. It occurs predominantly in women at puberty or later in life. Although occasionally solitary, the lesions usually are multiple and may be present in great numbers. They are small, skin-colored or slightly yellow, soft papules usually only 1 to 2 mm in diameter. In many patients, the lesions are limited to the lower eyelids. Other sites of predilection are the cheeks, thighs, axillae, abdomen, and vulva (285,447–450). In so-called eruptive hidradenoma or syringoma, the lesions arise in large numbers in successive crops on the anterior trunk of young persons (451). Rarely, the lesions of syringoma show a unilateral, linear arrangement (452). In rare instances, occult syringomas of the scalp are associated with diffuse thinning of the hair (453) or with cicatricial alopecia. Inapparent syringoma has been found incidentally in close approximation to basal cell carcinoma (454).

Histopathology. Embedded in a fibrous stroma are numerous small ducts (Fig. 30-70), the walls of which are lined usually by two rows of epithelial cells (Fig. 30-71). In most instances, these cells are flat. Occasionally, the cells of the inner row appear vacuolated. The lumina of the ducts contain amorphous debris (Fig. 30-71). Some of the ducts possess small,

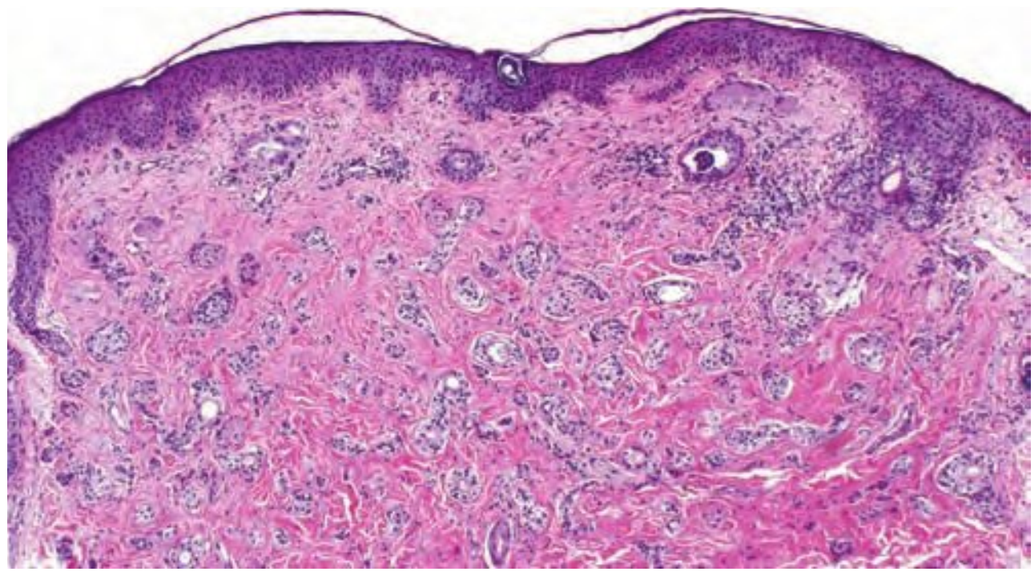

FIGURE 30-70. Syringoma. In the dermis, numerous tubular structures are embedded in a dense, collagenous stroma.

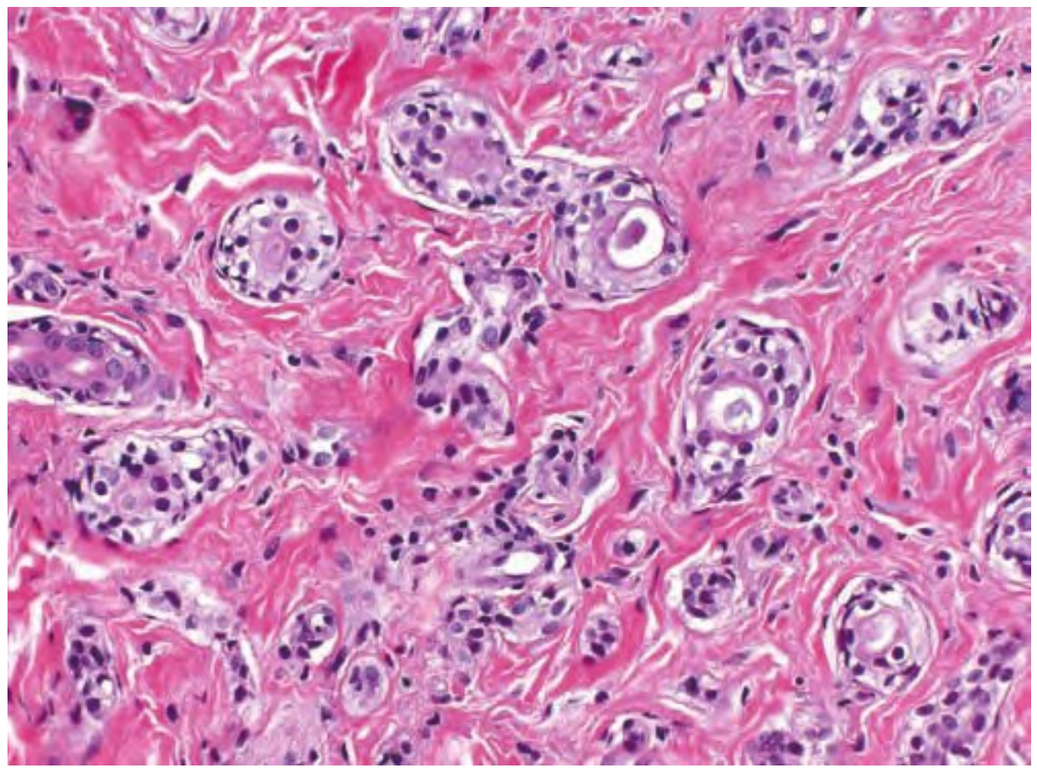

FIGURE 30-71. Syringoma. The walls of the ducts are predominantly lined by two rows of epithelial cells. Some ducts are lined by an eosinophilic cuticle, whereas others have comma-like tails. Granular eosinophilic material is seen in some ducts.

comma-like tails of epithelial cells, giving them the appearance of tadpoles. In addition, there are solid strands of basophilic epithelial cells independent of the ducts.

Near the epidermis, there may be cystic ductal lumina filled with keratin and lined by cells containing keratohyaline granules (451). These keratin cysts resemble milia. Sometimes they rupture, producing a foreign-body reaction.

In rare instances, many of the tumor cells appear as clear cells secondary to glycogen accumulation (455). Typically, one observes only a few ductal structures and epithelial cords but predominantly cell islands that are irregular in shape and size. With the occasional exception of the peripheral cell layer, these islands are usually composed entirely of clear cells and have more cell layers than are generally seen in ordinary syringomas (Fig. 30-72) (456).

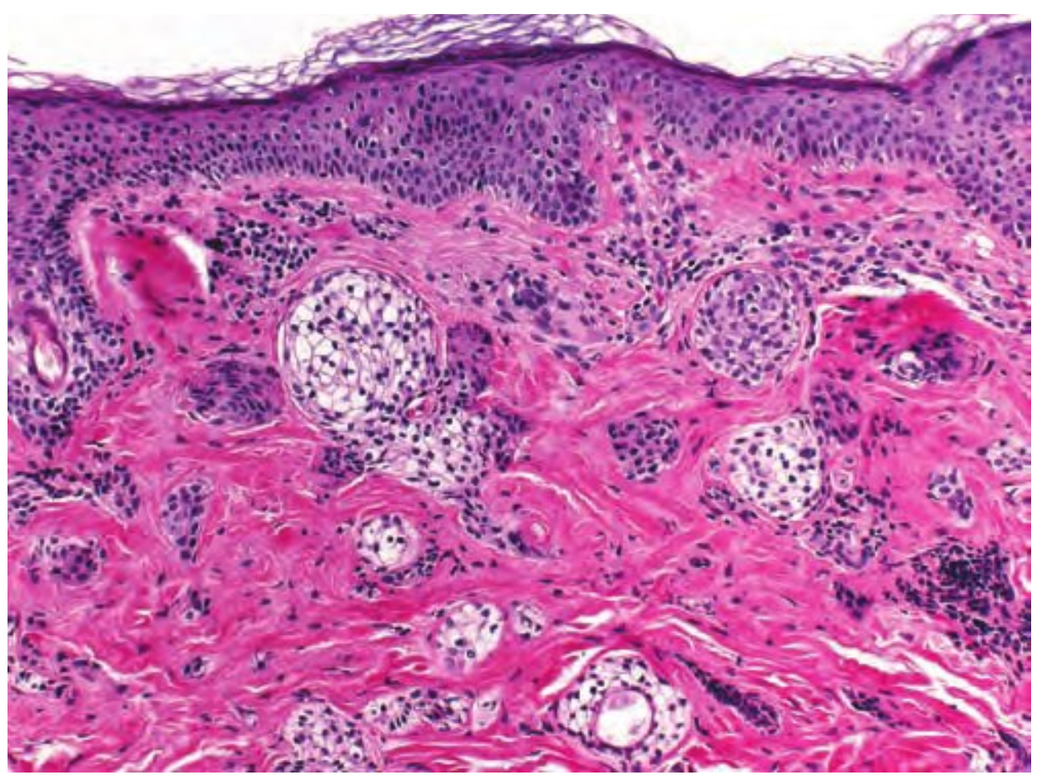

FIGURE 30-72. Clear cell syringoma. In this rare variant, the tumor islands consist largely of clear cells as a result of glycogen accumulation.

Additional Studies. Enzyme histochemical and electron microscopic studies have established syringoma as a tumor with differentiation toward intraepidermal eccrine sweat ducts (416,457). The enzyme pattern in the cells of syringoma shows a prevalence of eccrine enzymes such as succinic dehydrogenase, phosphorylase, and leucine aminopeptidase (458,459). In contrast to apocrine structures, syringomas react only weakly to lysosomal apocrine enzymes such as acid phosphatase and β-glucuronidase, except in a narrow, lysosome-rich periluminal zone (451).

Electron microscopic examination reveals that the lumina of the ducts are lined not by secretory but by ductal cells showing numerous short microvilli, interconnecting desmosomes, a periluminal band of tonofilaments, and many lysosomes. In some tumor cells, intracytoplasmic cavities are formed by lysosomal action. Coalescence of several such intracytoplasmic cavities to form an intercellular lumen is the mode by which the ductal lumina are formed in syringoma; this is identical with the mode of formation of the embryonic and the regenerating intraepidermal eccrine ducts (416,451).

The finding of cystic ductal lumina filled with keratin near the epidermis is compatible with the natural keratinizing propensity of the luminal cells of the intraepidermal eccrine sweat duct toward the upper strata of the epidermis (451).

Differential Diagnosis. The solid strands of basophilic epithelial cells embedded in a fibrous stroma seen in some cases of syringoma have an appearance similar to that of the strands seen in fibrosing basal cell carcinoma. However, fibrosing basal cell carcinoma lacks ductal structures containing amorphous material. The horn cysts near the epidermis in syringoma resemble those occurring in trichoepithelioma, and their presence in syringoma was formerly misinterpreted as the occurrence of both types of tumors within the same lesion (14). Although trichoepithelioma (including desmoplastic trichoepithelioma) shows solid strands of basophilic epithelial cells and horn cysts, it lacks ductal structures. Syringoma can be distinguished from microcystic adnexal carcinoma by its smaller size, greater symmetry, superficial dermal location, lack of prominent horn cyst formation, and infrequent single-file strand formation. In addition, microcystic adnexal carcinoma, a much larger tumor than syringoma, extends into the subcutaneous tissue (91). The diagnosis of microcystic adnexal carcinoma should always be considered in any apparently syringomatous or trichoepitheliomatous neoplasm that extends to the base of a superficial biopsy.

Eccrine Poroma

Initially described in 1956, eccrine poroma is a fairly common solitary tumor (460). In about two thirds of the cases, it is found on the sole or the sides of the foot, occurring next in frequency on the hands and fingers (461). Eccrine poroma has also been observed in many other areas of the skin, such as the neck, chest, nose, and eyelid (462–465). Eccrine poroma generally arises in middle-aged persons. The tumor has a rather firm

consistency, is raised, is asymptomatic, is often slightly pedunculated, and usually measures less than 2 cm in diameter.

An unusual clinical variant is *eccrine poromatosis*, in which more than 100 papules are observed on the palms and soles (466). In one reported case, the papular poromas, in addition to involving the palms and soles, showed a widespread, diffuse distribution (467).

Histopathology. In its typical form, eccrine poroma arises within the lower portion of the epidermis and it extends downward into the dermis as tumor masses that often consist of broad, anastomosing bands of epithelial cells (Fig. 30-73). The border between epidermis and tumor is readily apparent because of the distinctive appearance of the tumor cells: They are smaller than epidermal keratinocytes, have a uniform cuboidal appearance and a round, deeply basophilic nucleus, and are connected by intercellular bridges (Fig. 30-74). The lesional cells tend not to keratinize within the tumor, but they are able to keratinize on the surface of the tumor in instances in which the tumor has replaced the overlying epidermis. Although the border between tumor formations and the stroma is sharp, tumor cells located at the periphery show no palisading.

Characteristically, the tumor cells contain significant amounts of glycogen, which is associated with cytoplasmic clearing, usually in an uneven distribution (468). Melanocytes and melanin often are absent, although they may be present in tumors of individuals from various racial backgrounds (469–471).

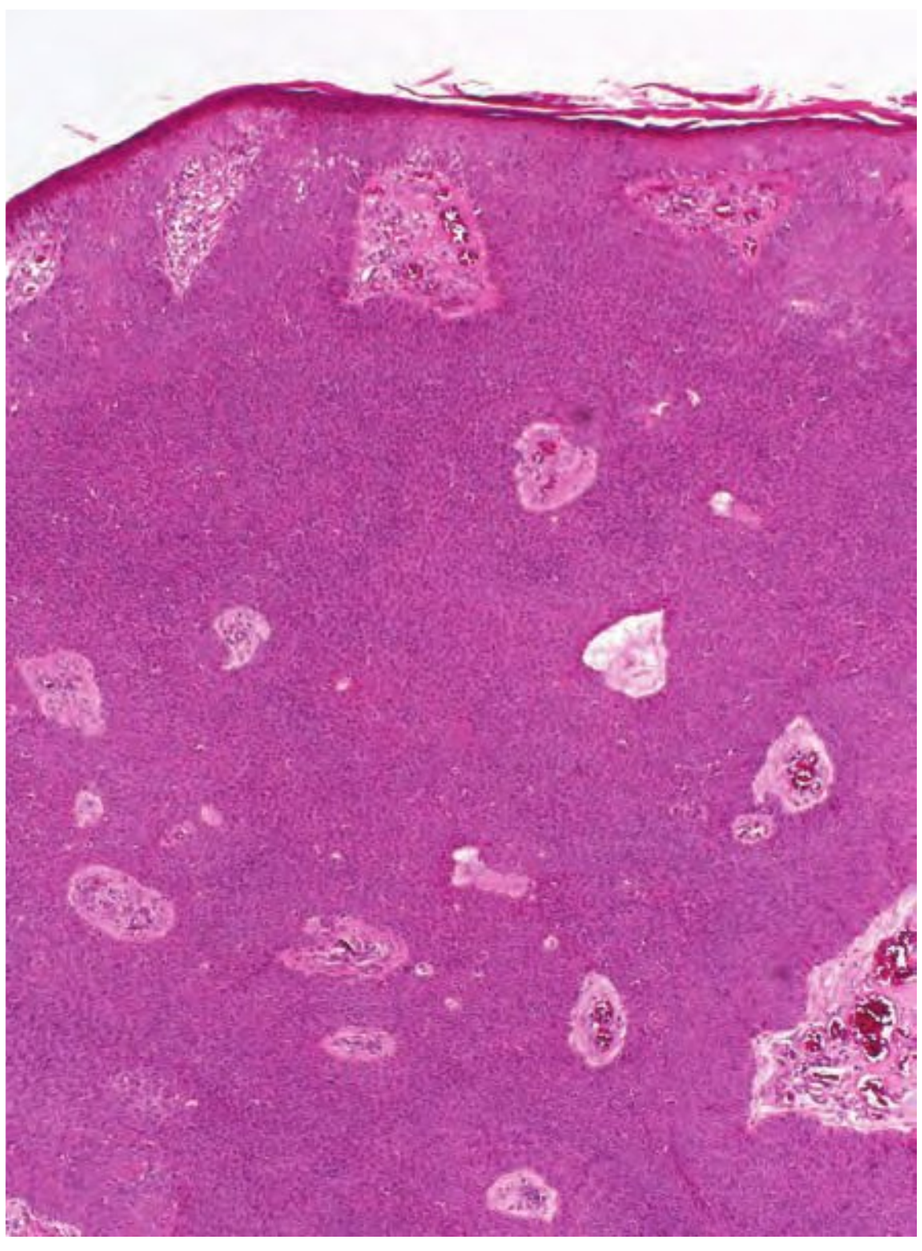

FIGURE 30-73. Eccrine poroma. The tumor consists of broad, anastomosing bands emanating from the epidermis.

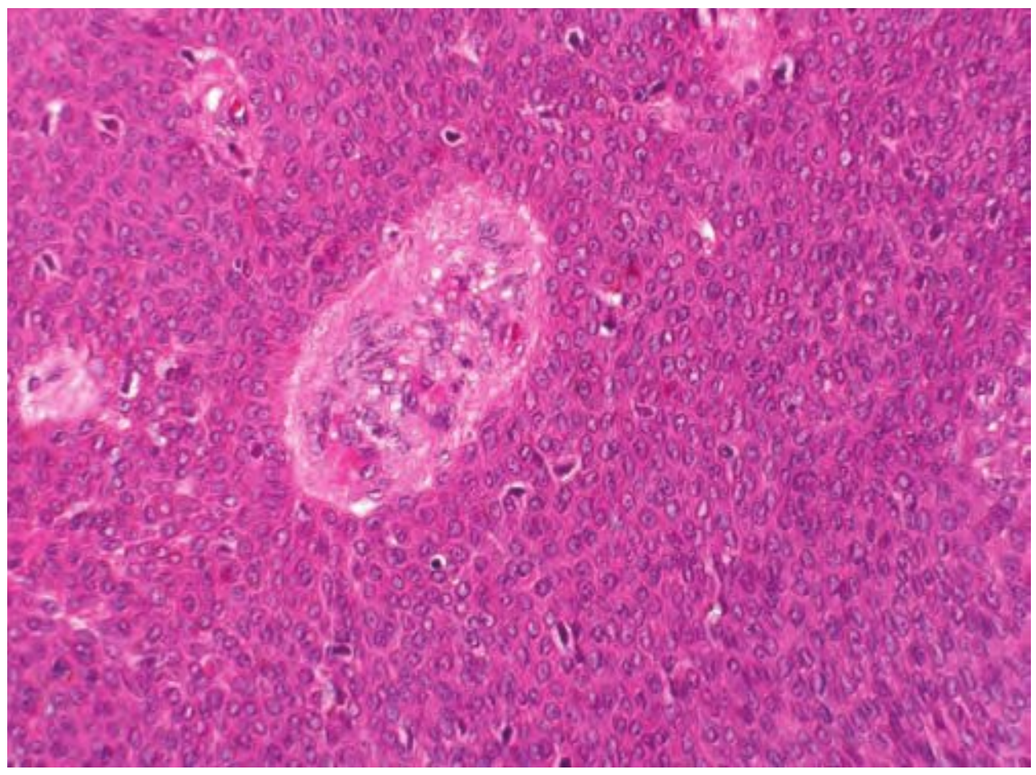

FIGURE 30-74. Eccrine poroma. The cells comprising the tumor have a uniformly small cuboidal appearance and are connected by intercellular bridges. The tumor vessels demonstrate a hyalinized stroma.

In a majority of eccrine poromas, narrow ductal lumina and occasionally cystic spaces are found within the tumor bands (468). They are lined by an eosinophilic, PAS-positive, diastase-resistant cuticle similar to that lining eccrine sweat ducts.

Poromas can be situated entirely within the epidermis, where the lesion appears as a number of distinct cellular aggregates. Such intraepidermal poromas were first described under the designation *hidroacanthoma simplex*, about the same time at which poroma was first described (Fig. 30-75) (472,473). These lesions represent one example of the so-called Borst-Jadassohn phenomenon of intraepithelial epitheliomas. A few ductal lumina lined by an eosinophilic cuticle can often be seen within the intraepidermal islands (474). Eccrine poromas may

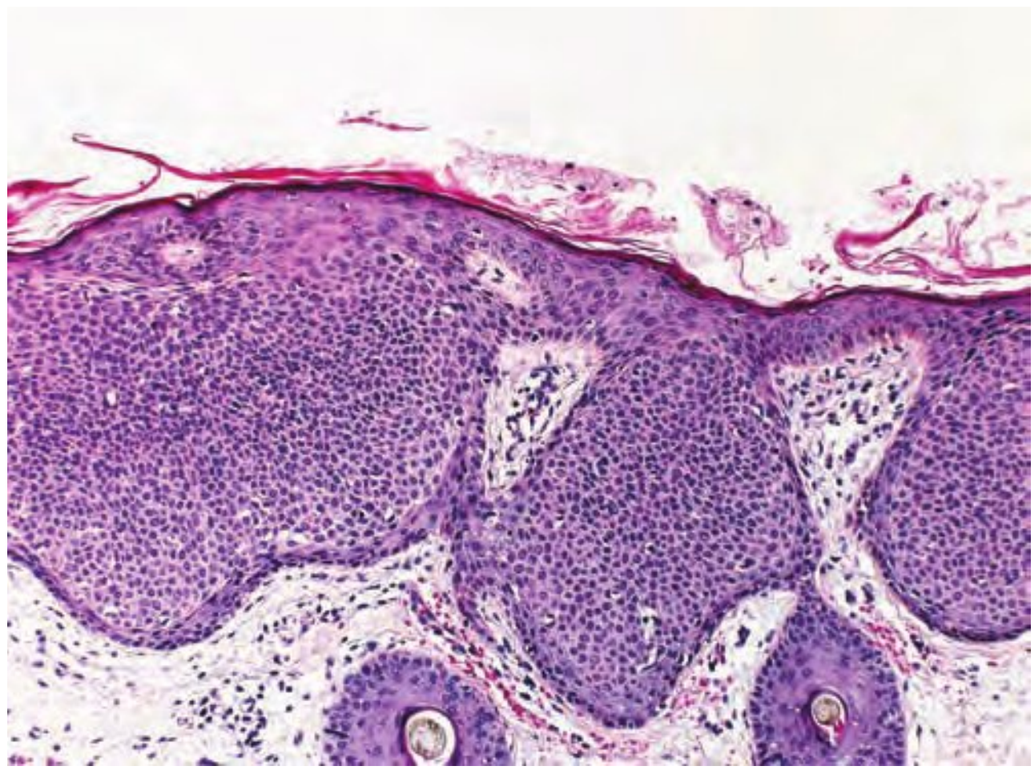

FIGURE 30-75. Hidroacanthoma simplex. There are discrete aggregates of poral cells in the epidermis, constituting one example of the so-called Borst-Jadassohn phenomenon of intraepithelial epitheliomas.

also be located largely or entirely within the dermis, where they consist of variously shaped tumor islands containing ductal lumina; these lesions are referred to as *dermal duct tumors* (475).

Syringoacanthoma of Rahbari represents a clonal variant of eccrine poroma in which variously sized nests of small, deeply basophilic, ovoid or cuboidal sweat duct–like cells are embedded within an acanthotic epidermis (476).

Additional Studies. Enzyme histochemical staining has shown the prevalence of eccrine enzymes in eccrine poromas, particularly phosphorylase and succine dehydrogenase (475,477,478).

Electron microscopic examination reveals that the tumor cells, except for the luminal cells, contain a moderate number of tonofilaments, are connected with each other by desmosomes, and appear identical to the cells that compose the outer layer of the intraepidermal eccrine duct (poral epithelial cells) (477). The luminal cells show a periluminal filamentous zone and, extending into the lumen, numerous tortuous microvilli coated with amorphous material that forms the eosinophilic cuticle seen by light microscopy. Some of the tumor cells may also exhibit features considered indicative of dermal duct differentiation (416,479).

Differential Diagnosis. Eccrine poroma must be differentiated from basal cell carcinoma and seborrheic keratosis. In basal cell carcinoma, the cells have no visible intercellular bridges, are more variable in size, often show peripheral palisading, and contain little or no glycogen. The cells of eccrine poroma greatly resemble the small basaloid cells of seborrheic keratosis, especially because they possess clearly visible intercellular bridges. However, seborrheic keratoses have an even demarcation at their lower border; moreover, their cells have the potential to keratinize, and when they keratinize, they form pseudo–horn cysts. In addition, both basal cell carcinoma and seborrheic keratosis lack ductal lumina lined with an eosinophilic cuticle. Furthermore, these two types of tumors very rarely occur on the sole of the foot.

Malignant Eccrine Poroma (Porocarcinoma)

Malignant eccrine poroma, or porocarcinoma, may arise *de novo* (480,481); however, it usually develops in a longstanding eccrine poroma (471,482–484). The tumor favors extremities, particularly legs and feet, usually in adults of either sex. In some instances, the malignant eccrine poroma is localized, manifesting itself as a nodule, plaque, or ulcerated tumor (481,482,484,485); in other cases, there are multiple cutaneous metastases, which are usually associated with visceral metastases, resulting in death (471,483–485). The propensity to form multiple cutaneous metastases is an unusual feature of malignant eccrine poroma.

Histopathology. Malignant eccrine poroma may be seen associated with an eccrine poroma or hidroacanthoma simplex (482,484). In such cases, one observes areas composed of eccrine poroma cells with a benign appearance adjacent to areas of anaplastic cells. The malignant cells have large, hyperchromatic, irregularly shaped nuclei and may be multinucleated (Figs. 30-76 and 30-77) (484). Lesional cells are rich in glycogen (480).

FIGURE 30-76. Porocarcinoma. Large islands of tumor cells are seen, many with central necrosis.

In the primary tumor, the malignant cells may be limited to the epidermis or may extend into the dermis (Fig. 30-76). Some islands of tumor cells may lie free in the dermis. The epidermis often shows considerable acanthosis as a result of the proliferation of numerous well-defined tumor cell nests within it. Cystic lumina may be seen within the epidermal and dermal tumor nests. The tumors are asymmetric, with cords and lobules of polygonal tumor cells, typically with a cribriform pattern. Nuclear atypia is evident, with frequent mitoses and necrosis

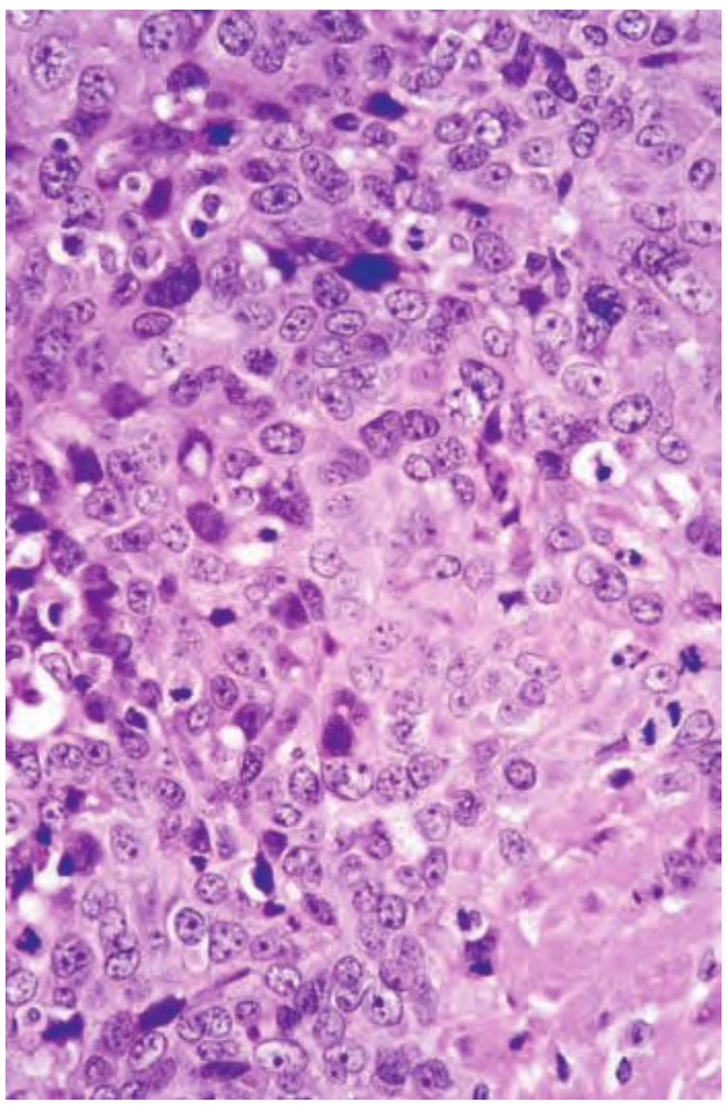

FIGURE 30-77. Porocarcinoma. Lesional cells demonstrate marked atypia, mitotic activity, and necrosis.

(Fig. 30-77). Useful clues to eccrine differentiation include spiraling ductular structures, ducts lined by cuticular material, zones of cytoplasmic glycogenation, and also intraepidermal cells in discrete aggregates, often centered on acrosyringeal pores. Foci of squamous differentiation may resemble well-differentiated squamous cell carcinoma (486). The stroma may be fibrotic, hyalinized, highly myxoid, or frankly mucinous. The distinction from metastatic adenocarcinoma, especially of breast and lung origin, can be difficult, especially for less differentiated tumors. Ductular differentiation with formation of a PAS-positive cuticle is strong evidence against a metastasis. An extracutaneous primary adenocarcinoma should be clinically ruled out.

The term *ductal eccrine carcinoma* has been used to refer to tumors that may appear in the dermis as an infiltrative poroma (porocarcinoma) or as a moderately differentiated adenocarcinoma (487). About one third of ductal eccrine carcinomas are fatal, usually because of distant metastasis (488).

Malignant eccrine poroma, analogous to its benign variant, can show a clonal ("intraepithelial epithelioma") pattern of its anaplastic acrosyringeal cells. The intraepidermal clones of such *malignant syringoacanthomas* may remain *in situ* or become invasive (476).

In cutaneous metastases, numerous nests of tumor cells may be present in both the epidermis and the dermis. In the epidermis, sharply defined small and large nests of tumor cells are seen surrounded by the squamous cells of the hyperplastic epidermis, resulting in a "pagetoid" pattern (471,480). Some of the tumor nests in the dermis are located within dilated lymphatic vessels, suggesting spread of the tumor in the lymphatics of the skin (480). From the lymphatics, the tumor cells invade the overlying epidermis because of the "epidermotropic" nature of the tumor cells.

Eccrine Syringofibroadenoma

First described in 1963, this usually is a solitary, hyperkeratotic, nodular plaque, several centimeters in diameter, on one extremity (489–491). Eccrine syringofibroadenoma and acrosyringeal nevi have many similarities, and some researchers, but not all, consider them to be equivalent lesions (489–493). In one instance, a linear lesion has been reported to extend along a lower extremity (494). Eccrine syringofibroadenomatosis has been associated with inherited palmar-plantar keratodermas, including hidrotic ectodermal dysplasia and Schopf's syndrome (495–497). Carcinomatous transformation of these lesions is rare but has been reported (498,499).

Histopathology. Slender, anastomosing epithelial cords of acrosyringeal cells, with or without formation of lumina, are embedded in a fibrovascular stroma (Figs. 30-78 and 30-79) (490). The netlike pattern of epithelial cells resembles that seen in fibroepithelioma (494). Lesions demonstrating prominent clear cell change have been described (500,501).

Additional Studies. Immunohistochemical studies and electron microscopy studies provide evidence for acrosyringeal differentiation in eccrine syringofibroadenomas (502–506).

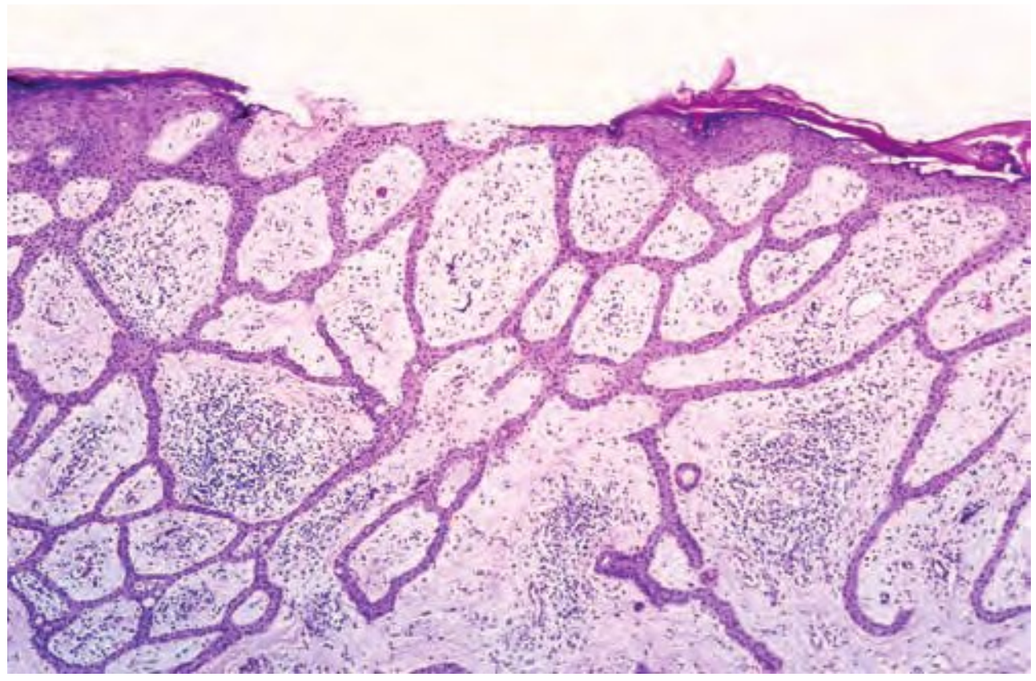

FIGURE 30-78. Eccrine syringofibroadenoma. The tumor is composed of thin, anastomosing epithelial cords associated with a fibrous stroma.

Mucinous Syringometaplasia

A rare condition first described in 1974, mucinous syringometaplasia occurs as a solitary lesion in two different forms: as a verrucous lesion in an acral location on the sole of a foot or a finger and as a plaque resembling a basal cell carcinoma in a more central location (312,507,508). With pressure, serous fluid can often be expressed (312).

Histopathology. An invagination lined by squamous epithelium extends into the dermis. One or several eccrine ducts lead into the invagination. They are lined in part by mucin-laden goblet cells (312). In addition, there may be mucinous metaplasia in the underlying eccrine coils (508,509). The epithelial mucin is PAS positive and Alcian blue reactive, suggesting that it is sialomucin.

Eccrine Spiradenoma

Eccrine spiradenoma usually occurs as a solitary intradermal nodule measuring 1 to 2 cm in diameter. Occasionally, there

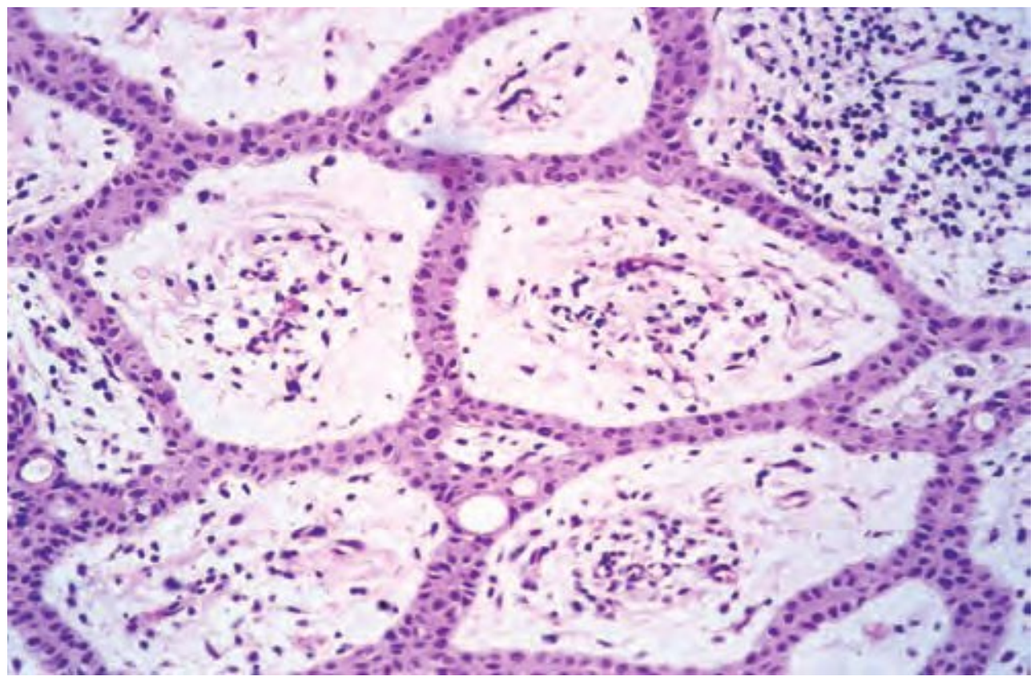

FIGURE 30-79. Eccrine syringofibroadenoma. The epithelial strands are comprised of mature acrosyringeal cells, which may form lumina and are embedded in a fibrovascular stroma.

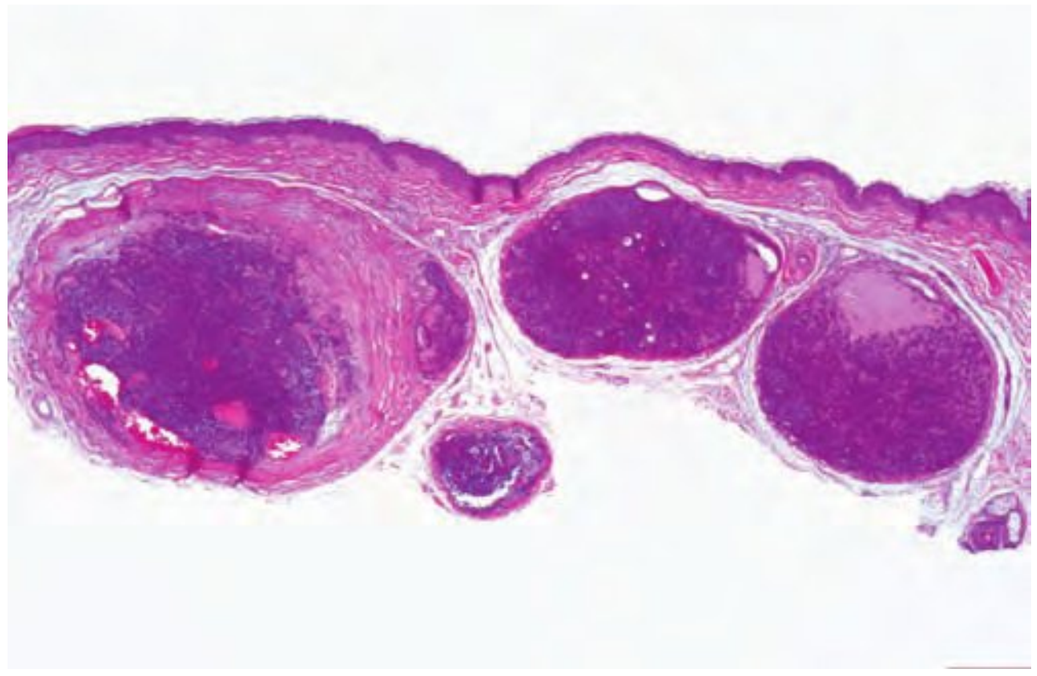

FIGURE 30-80. Eccrine spiradenoma. Well-circumscribed aggregates of blue tumor cells are seen in the dermis.

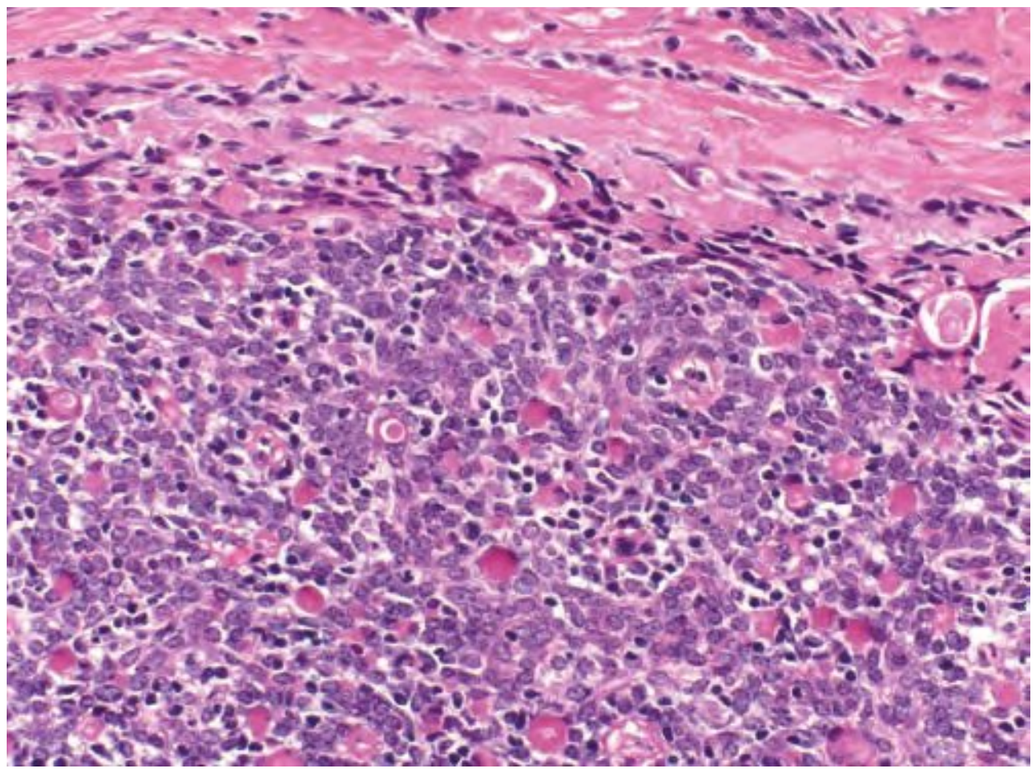

FIGURE 30-81. Eccrine spiradenoma. The epithelial cells are arranged in intertwining bands. Two types of cells can be seen. Cells with small, dark nuclei lie at the periphery of the bands; they represent undifferentiated cells. Cells with large, pale nuclei lie in the center of the bands and around small lumina. Collections of hyalinized material are seen.

are several lesions, and, rarely, there are numerous small nodules in a zosteriform pattern or large nodules, up to 5 cm, in a linear arrangement (510–513). In most instances, eccrine spiradenoma arises in early adulthood. Lesions can arise in a variety of locations, and the nodules are often tender and occasionally painful.

Histopathology. The tumor may consist of one large, sharply demarcated lobule, but more commonly there are several lobules located in the dermis without connections to the epidermis (Fig. 30-80). The lobules are evenly and sharply demarcated and may display a fibrous capsule (514). On low magnification, the tumor lobules often appear deeply basophilic because of the dense packing of nuclei.

On higher magnification, the epithelial cells within the tumor lobules are found to be arranged in intertwining cords (515,516). These cords may enclose small, irregularly shaped islands of edematous connective tissue (517). Two types of epithelial cells are present in the cords, both of which possess only scant amounts of cytoplasm (Fig. 30-81). The cells of the first type possess small, dark nuclei; they are generally located at the periphery of the cellular aggregates. The cells of the second type have large, pale nuclei; they are located in the center of the aggregates and may be arranged partially around small lumina observed in about half of the tumors (514). The lumina frequently contain small amounts of a granular, eosinophilic material that is PAS positive and diastase resistant (515). In the absence of lumina, the cells with pale nuclei may show a rosette arrangement. Glycogen is absent in the tumor cells or is present in insignificant amounts.

In some cases of eccrine spiradenoma, hyaline material is focally present in the stroma that surrounds the cords of tumor cells (Fig. 30-81). In addition, hyalin may be seen within some of the cords among the tumor cells as hyaline droplets (515). The stroma surrounding the tumor lobules occasionally shows lymphedema with dilated blood vessels or lymphatics (515). A heavy diffuse lymphocytic infiltrate, mainly of T cells, may be present (518). Malignant progression can occur but is rare.

Additional Studies. Enzyme histochemical staining has revealed a prevalence of eccrine enzymes in eccrine spiradenoma, but the reactions are not as strong as in syringoma or eccrine poroma (512,517,519).

Electron microscopic examination, similar to light microscopic examination, has shown two types of cells: undifferentiated basal cells with small, dark nuclei, and differentiating cells with large, pale nuclei. Most of the differentiating cells are immature ("indeterminate cells") and, in some tumors, may show no further differentiation (517). In most instances, however, there is some degree of differentiation toward intradermal eccrine ductal cells or toward eccrine secretory cells. Around the same lumen, some cells may show numerous microvilli and a well-developed periluminal zone of tonofilaments and thus resemble ductal cells, whereas other cells have only a few thin microvilli and thus resemble secretory cells (416,512). All secretory cells demonstrate features of serous cells (clear cells) (520). A few myoepithelial cells with typical myofilaments are present occasionally at the periphery of tubular structures (512).

Eccrine spiradenoma exhibits features of both the dermal duct and the secretory segment of the eccrine sweat gland. However, the weakness and inconsistency of the enzyme histochemical reactions, the presence largely of undifferentiated and indeterminate cells, and the absence of dark mucus cells indicate a rather mild degree of differentiation. Immunohistochemical studies for cytokeratins demonstrate that the large, pale epithelial cells expressed keratins similar to those of luminal cells in the transitional portions between the secretory portions and the coiled ducts (521). The small, dark cells expressed cytokeratins similar to the basal cells in the transitional portions of the eccrine gland.

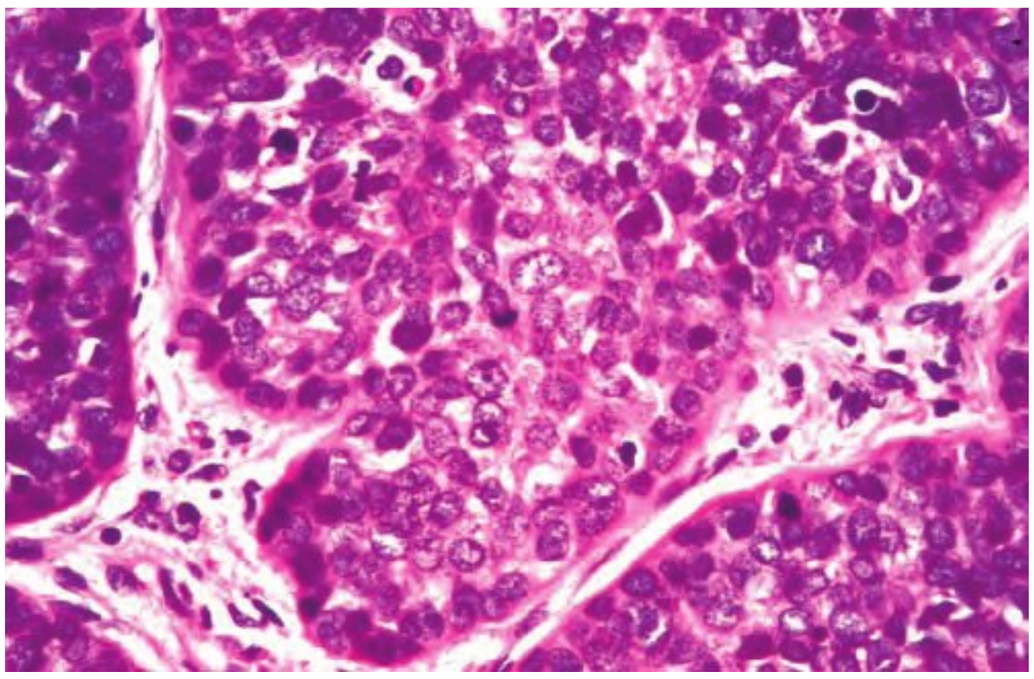

FIGURE 30-82. Malignant eccrine spiradenoma. Lesional cells demonstrate marked atypia with a predominance of larger atypical cells. Cellular necrosis and mitotic activity are seen.

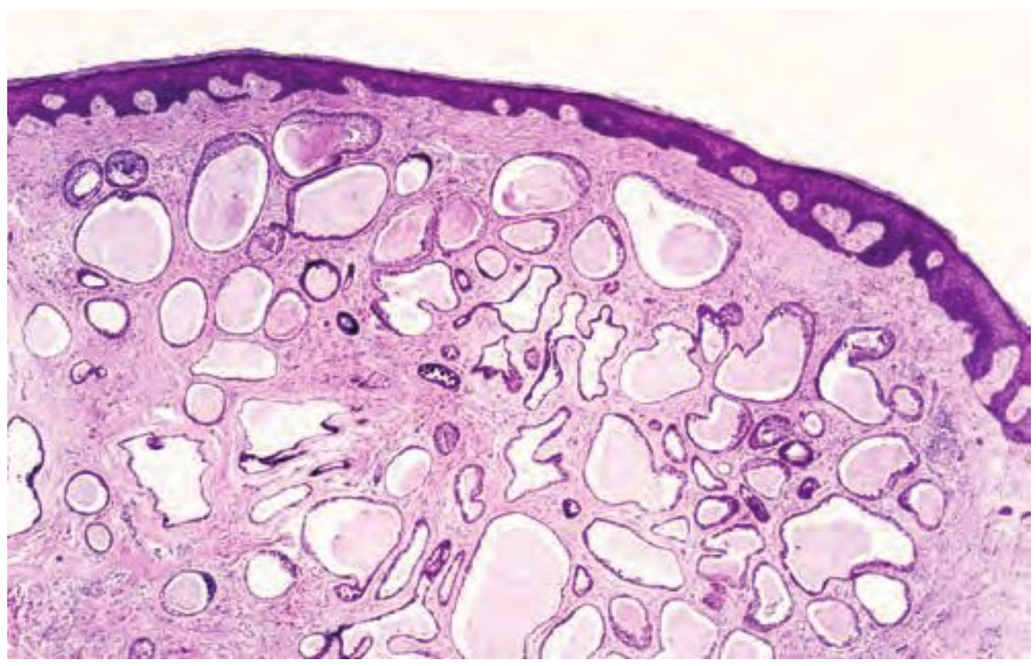

FIGURE 30-83. Papillary eccrine adenoma. The tumor is well circumscribed and symmetric and consists of dilated, occasionally branching tubular structures.

Malignant Eccrine Spiradenoma

Occasionally, malignant degeneration occurs in eccrine spiradenomas; usually such lesions have been present for years (429,522,523). However, malignant transformation of spiradenomas has been reported in lesions with a clinical history as short as 7 months (524). Metastases can occur; fortunately, few patients die of generalized metastases (523–525). Regional lymph node metastasis has been reported (524,526). Notable clinical features may include a history of enlargement in a previously stable lesion.

Histopathology: In malignant lesions, two distinct components typically are seen: benign eccrine spiradenoma and carcinomatous regions associated with areas of transitions (524,526). However, lesions consisting of well-demarcated zones of spiradenoma and spiradenocarcinoma have also been described (524). The carcinomatous lesion may display glandular formation, squamous differentiation, sarcomatous change, or no evidence of differentiation (524,526–530). Although mitoses may be seen in benign eccrine spiradenomas, malignant spiradenomas usually show a high mitotic rate (Fig. 30-82) (524,526). Other histologic features indicative of malignancy include the loss of two cell populations, increased nuclear-to-cytoplasmic ratio, and hyperchromasia (Fig. 30-82) (524). Because the malignant changes may be focal in a benign spiradenoma, the malignancy may be missed if the specimen is inadequately sampled (531).

Papillary Eccrine Adenoma

Papillary eccrine adenoma is a benign tumor that exhibits prominent eccrine differentiation and architectural features similar to tubular apocrine adenoma. First described in 1977, it occurs most commonly on the distal portions of the extremities as a small, solitary nodule (532).

Histopathology: As in tubular apocrine adenoma, the tumor comprises a well-circumscribed, symmetric collection of dilated, occasionally branching tubular structures lined by two layers of epithelial cells (Figs. 30-83 and 30-84). Papillary projections extend into the lumina (532). The ducts may contain amorphous eosinophilic material (Fig. 30-83) (533). However, evidence of decapitation secretion is lacking (387). Small microcysts representing dilated ducts may be present (387,534–537). The low-power impression may suggest a benign breast lesion, such as intraductal hyperplasia, especially when, as is characteristic, the tumor is located within the superficial and deep dermis and is not continuous with the overlying epidermis. Amorphous and granular eosinophilic secretions are present in many of the duct lumens, and occasionally there are small, keratin-filled cysts. Adenomatous regions present variably spaced ducts and glands lined by one to several layers of cuboidal epithelium. The presence of a dense fibrovascular stromal tissue distinguishes this lesion from dermal endometriosis, which has a more cellular stroma. The tumor may recur locally but does not metastasize systemically.

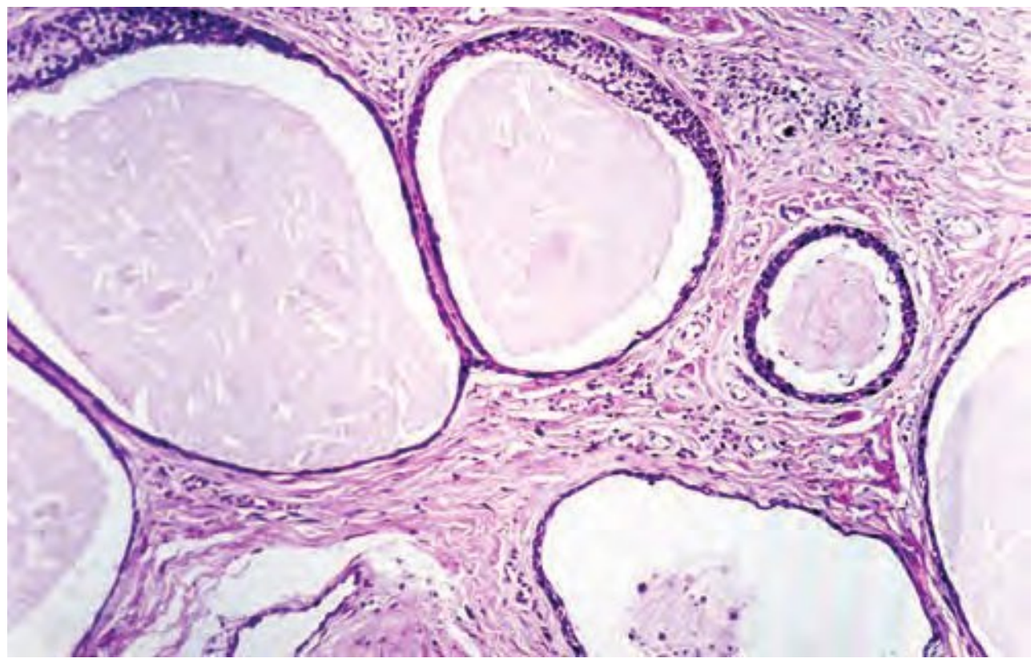

FIGURE 30-84. Papillary eccrine adenoma. The dilated tubular structures are lined by two layers of cells and contain amorphous eosinophilic material.

Additional Studies. The amylophosphorylase reaction indicates eccrine differentiation is prominent, but the reaction with acid phosphatase, an apocrine enzyme, shows practically no staining in the tumor (387). Immunoreactivity for S100 protein, CEA, and EMA is typically present, consistent with differentiation toward the secretory epithelium of sweat glands (533,536,537).

Nodular Hidradenoma

Nodular hidradenoma is a fairly common cutaneous neoplasm that has been referred to as *clear cell myoepithelioma*, *clear cell hidradenoma*, *eccrine sweat gland adenoma of the clear cell type*, *solid cystic hidradenoma*, and *eccrine acrospiroma* (519,538–543). Nodular hidradenoma can arise in a variety of anatomic sites.

Nodular hidradenoma exhibits eccrine differentiation based on its enzyme histochemical and electron microscopic features (544). The tumor is usually solitary; however, on rare occasions, multiple lesions have been reported (544). The tumors present as intradermal nodules and in most instances measure between 0.5 and 2.0 cm in diameter, although they may be larger. They are usually covered by intact skin, but some tumors show superficial ulceration and discharge serous material (542). Although clinically the tumor only rarely gives the impression of being cystic, gross examination of the specimen often reveals the presence of cysts (540,543).

Histopathology. The tumor is well circumscribed and may appear encapsulated. It is composed of epithelial lobules located in the dermis, which may extend into the subcutaneous fat. Within the lobulated masses, tubular lumina of various sizes are often present (Figs. 30-85 and 30-86). However, such lumina may be absent or few in number, so that step sectioning is needed to find them. The tubular lumina in some instances are branched. There are often cystic spaces, which may be of considerable size and contain a faintly eosinophilic, homogeneous material (Fig. 30-85) (542). The tubular lumina are lined by cuboidal ductal cells or by columnar secretory cells. Occasionally, the secretory cells show active secretion suggestive of decapitation secretion (540,544). The wide cystic spaces are only rarely lined by a single row of luminal cells; more frequently, they are bordered by tumor cells that show no particular orientation and occasionally show degenerative changes (540). This suggests that the cystic spaces may result from tumor cell degeneration.

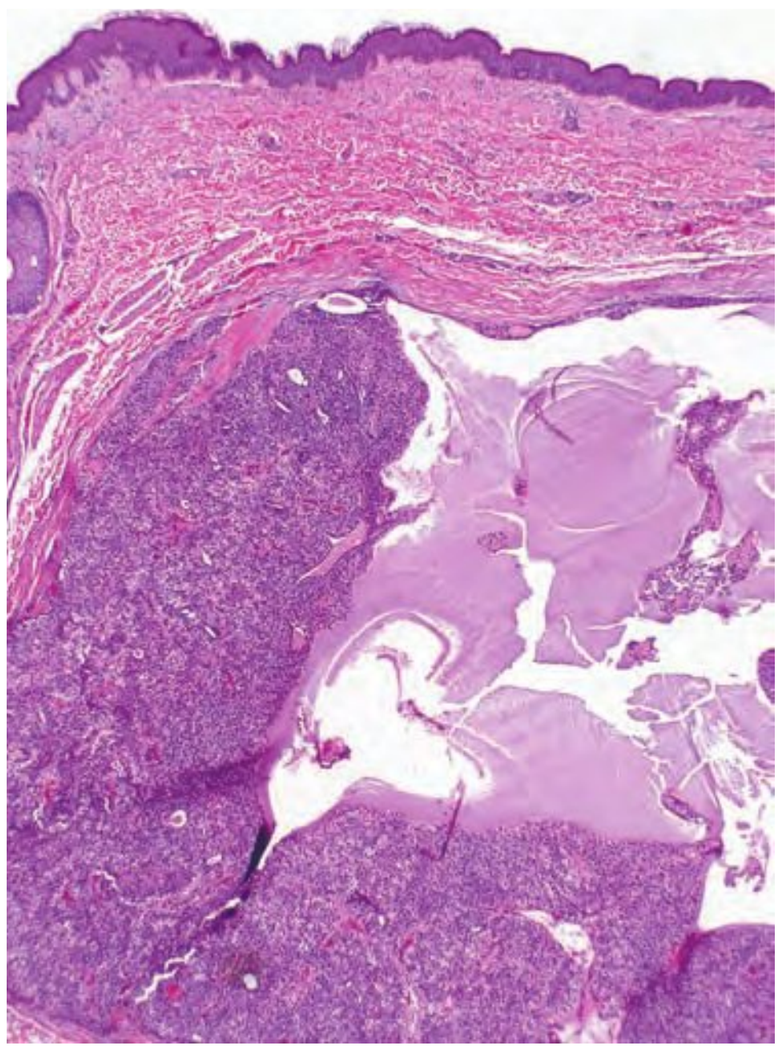

FIGURE 30-85. Nodular hidradenoma. Multiple lobules of lesional cells are present in the dermis. Focal cystic change is seen.

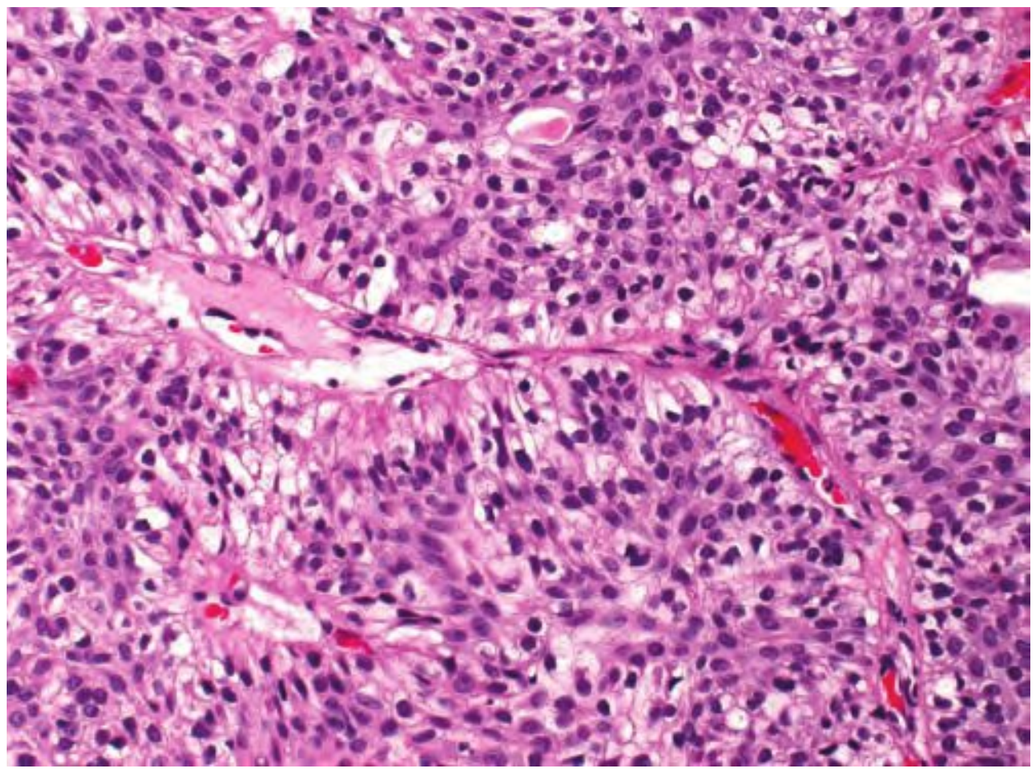

FIGURE 30-86. Nodular hidradenoma. The tumor comprises clear and polygonal cells, some of which appear fusiform. Foci of eosinophilic material and small ductal lumina are seen.

In solid portions of the tumor, two types of cells can be recognized (540,542,545,546). The proportion of these two types of cells varies considerably from tumor to tumor. One cell type is polyhedral with a rounded nucleus and slightly basophilic cytoplasm. These cells may appear fusiform and show an elongated nucleus (Fig. 30-85). Another cell type is usually round and contains very clear cytoplasm, so that the cell membrane is distinctly visible; the cell nucleus appears small and dark (Fig. 30-85). There also are cells with features of both varieties; these cells usually show a rather light, eosinophilic cytoplasm. The clear cells contain considerable amounts of glycogen, but they may show, in addition, significant amounts of PAS-positive, diastase-resistant material along their periphery (545). In some tumors, squamoid differentiation is seen, with the cells appearing large and polyhedral and showing eosinophilic cytoplasm (Fig. 30-86) (547). There even may be keratinizing cells with formation of horn pearls (Fig. 30-86) (540,541). In other tumors, groups of squamous cells are arranged around small lumina that are lined with a well-defined eosinophilic cuticle and thus resemble the intraepidermal portion of the eccrine duct (543,545).

In most cases, no connections of the tumor lobules with the surface epidermis are noted; however, in some instances, the

tumor replaces the epidermis centrally and merges with the acanthotic epidermis at the periphery of the tumor (540,541,543). The tumor nodules are frequently associated with foci of a characteristic eosinophilic hyalinized stroma (Fig. 30-86).

Additional Studies. The polyhedral and fusiform cells, because of their location peripheral to the luminal cells and because of their shape, were originally regarded as cells exhibiting myoepithelial differentiation (540,544). However, the absence of alkaline phosphatase and, ultrastructurally, of myofilaments has disproved their relationship to myoepithelial cells.

Enzyme histochemical staining has established the presence in nodular hidradenoma of high concentrations of eccrine enzymes, particularly phosphorylase and respiratory enzymes, including succinic dehydrogenase and diphosphopyridine nucleotide diaphorase (519,546). Immunohistochemical reactivity for keratin, EMA, CEA, S100 protein, and vimentin is characteristic (548).

Electron microscopy has demonstrated tonofilaments in the polyhedral and fusiform cells and an abundance of glycogen in the clear cells. These tumor cell types resemble those of eccrine poroma and those that compose the outer layers of the intraepidermal eccrine duct (546). In addition, four types of luminal cells can be recognized: a secretory type, dermal-ductal and epidermal-ductal types, and an immature type (546). It can be concluded that nodular hidradenoma shows differentiation toward intraepidermal and intradermal eccrine structures ranging from the poral epithelium to the secretory segment (538,546). Thus, ultrastructurally, nodular hidradenoma seems to be intermediate between eccrine poroma, with its largely intraepidermal ductal differentiation, and eccrine spiradenoma, with its dermal-ductal and secretory differentiation. From this point of view, the clear cells represent immature poral epithelial cells, and the horn-pearl formation can be regarded as the keratinization of poral epithelial cells.

Differential Diagnosis. Nodular hidradenoma shares with trichilemmoma the presence of clear cells rich in glycogen. Foci of keratinization may also be found in both. However, only nodular hidradenoma usually shows the presence of large cystic spaces and of tubular lumina, and only trichilemmoma shows peripheral palisading of its tumor cells.

Although tumor nuclei may be hyperchromatic and there may be coarsely clumped chromatin, marked pleomorphism and frequent or atypical mitoses are not observed. If such changes are present, the tumor should be considered to have a potential for aggressive behavior. Zonal or diffuse patterns of necrosis also suggest malignancy, but the most important indicator of malignancy is an infiltrative, poorly circumscribed, and asymmetric perimeter.

Nodular hidradenomas may occasionally reform after local excision. Associated distortion and fibrosis may impede the diagnostic interpretation when the histology of the primary lesion is unknown or unavailable. Lesions that have frequent mitoses or nuclear atypia but lack clear evidence of asymmetric invasive growth may be termed atypical, and a reexcision to ensure their complete removal may be contemplated.

Malignant Nodular Hidradenoma

Malignant nodular hidradenomas, also known as hidradenocarcinomas, are rare and usually malignant from their inception; however, malignant lesions may arise from benign nodular hidradenomas (549,550). Malignant nodular hidradenomas usually present as a solitary nodule on the head, trunk, or distal extremity. Most reported cases are in patients older than 50 years of age, though they may occur at any age. These lesions tend to metastasize, and they may cause death. Although there is insufficient evidence in the literature, the recurrence rate may be estimated at about 50%, and the metastasis rate is about 60%, including metastases to regional nodes, bone, viscera, and skin (550–554).

Histopathology. Whereas nodular hidradenomas are typically well demarcated, malignant nodular hidradenomas are usually larger, asymmetric, and show invasion into the surrounding tissue (Fig. 30-87). In addition, there may be angiolymphatic invasion (555). Mitoses are usually easily detected, and some may be atypical. Tumor necrosis, areas of high cellularity, and focal or diffuse areas of marked cytologic atypia in which differentiated elements are unrecognizable are present in some examples (Fig. 30-88). In these, the diagnosis of malignancy may be evident, but the recognition of adnexal origin and the precise subclassification may be problematic. In some cases of malignant nodular hidradenomas, nuclear anaplasia may be only slight to moderate or even absent in both the primary tumor and the metastases (556). Nuclear anaplasia, if present, may be limited to the clear cells or found in both the polyhedral and the clear cells.

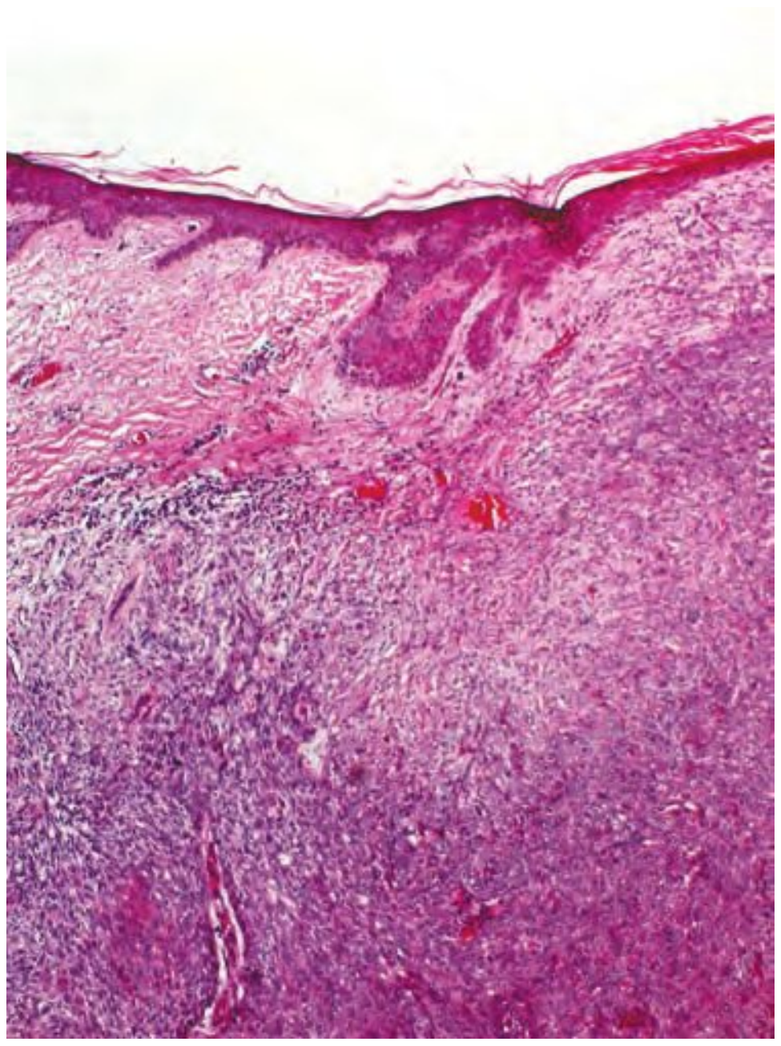

FIGURE 30-87. Malignant nodular hidradenoma. A large, cellular tumor with infiltrative borders is seen.

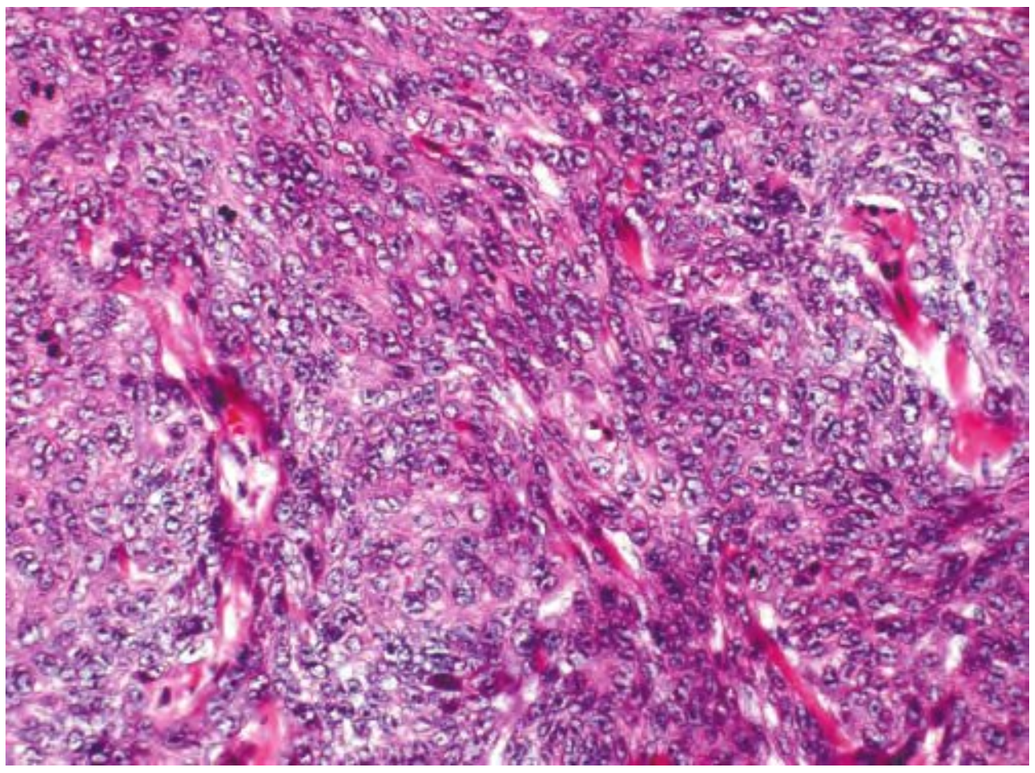

FIGURE 30-88. Malignant nodular hidradenoma. Sheets of atypical epithelial cells exhibit mitotic activity.

Chondroid Syringoma (Mixed Tumor of the Skin)

The condition known by the term *chondroid syringoma*, introduced in 1961, is also known as *mixed tumor of the skin* because the tumor is epithelial, with associated mesenchymal changes (557,558). Chondroid syringomas are firm intradermal or subcutaneous nodules. Although the overlying skin may be attached to the tumor, it otherwise appears normal. Mixed tumors occur most commonly on the head and neck (557,558). Their usual size is between 0.5 and 3.0 cm.

Histopathology. Histologically, two types of chondroid syringomas can be recognized: one with tubular, cystic, partially branching lumina, and the other with small, tubular lumina (558). The former type is much more common than the latter.

Chondroid syringoma with tubular, branching lumina shows marked variation in the size and shape of the tubular lumina; it also shows cystic dilation and branching (Figs. 30-89 and 30-90). Embedded in an abundant stroma, the tubular lumina are lined by two layers of epithelial cells: a luminal layer of cuboidal cells, and a peripheral layer of flattened cells (Fig. 30-90). Furthermore, there are large and small aggregates of epithelial cells without lumina, as well as single epithelial cells widely scattered through the stroma. It appears that cells from the peripheral cell layer of the tubular structures and from the solid aggregates proliferate into the stroma (557). In most instances, the tubular lumina contain small amounts of amorphous, eosinophilic material that is PAS positive and resistant to digestion with diastase. In general, the tubular structures are suggestive of eccrine differentiation (557). Occasionally, the luminal cells show an apocrine type of decapitation secretion, at least in some areas (558–562).

The abundant stroma in many areas has a mucoid, faintly basophilic appearance. As a result of shrinkage of the mucoid substance, the fibroblasts and epithelial cells that are scattered through it are surrounded by a halo, so that they resemble the cells of cartilage (Fig. 30-90). The mucoid stroma stains with Alcian blue, mucicarmine, and aldehyde-fuchsin. The Alcian blue material is not appreciably decreased by predigestion with hyaluronidase (557). Furthermore, on staining with toluidine blue or the Giemsa stain, there is distinct metachromasia (559). Therefore, it can be concluded that the mucin consists largely of sulfated acid mucopolysaccharides or chondroitin sulfate. The stroma is histochemically similar to normal cartilage (557). In a few areas, the

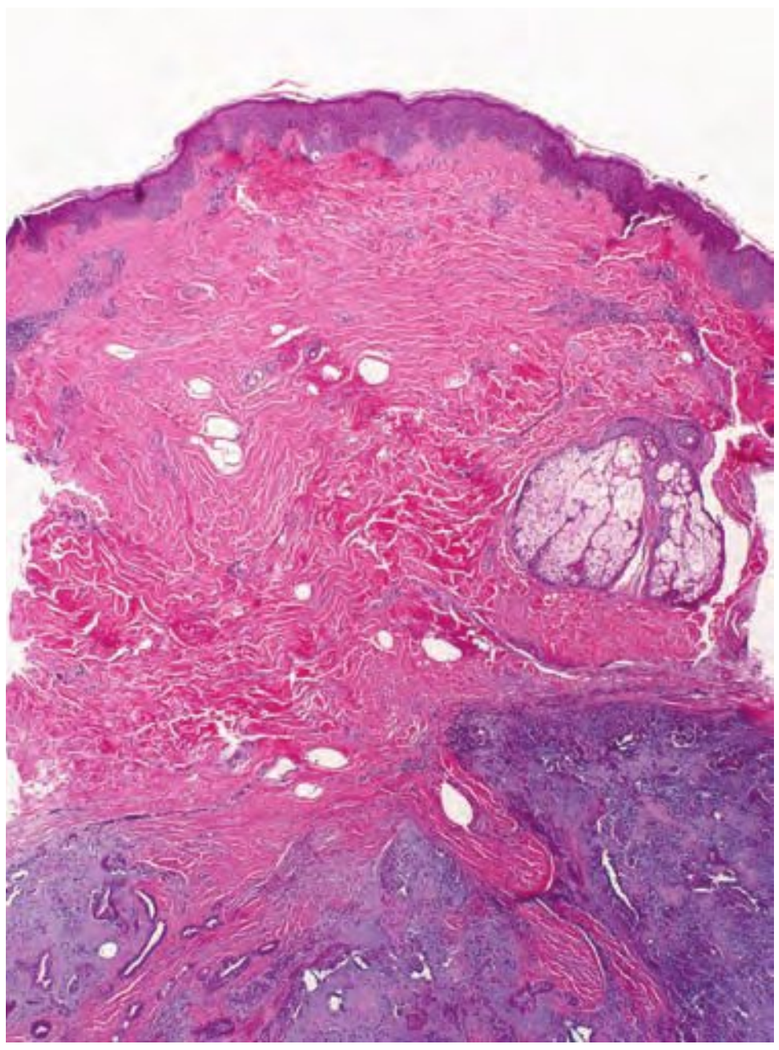

FIGURE 30-89. Chondroid syringoma. In the dermis, there is a nodular tumor comprised of branching tubular epithelial elements embedded in a basophilic stroma.

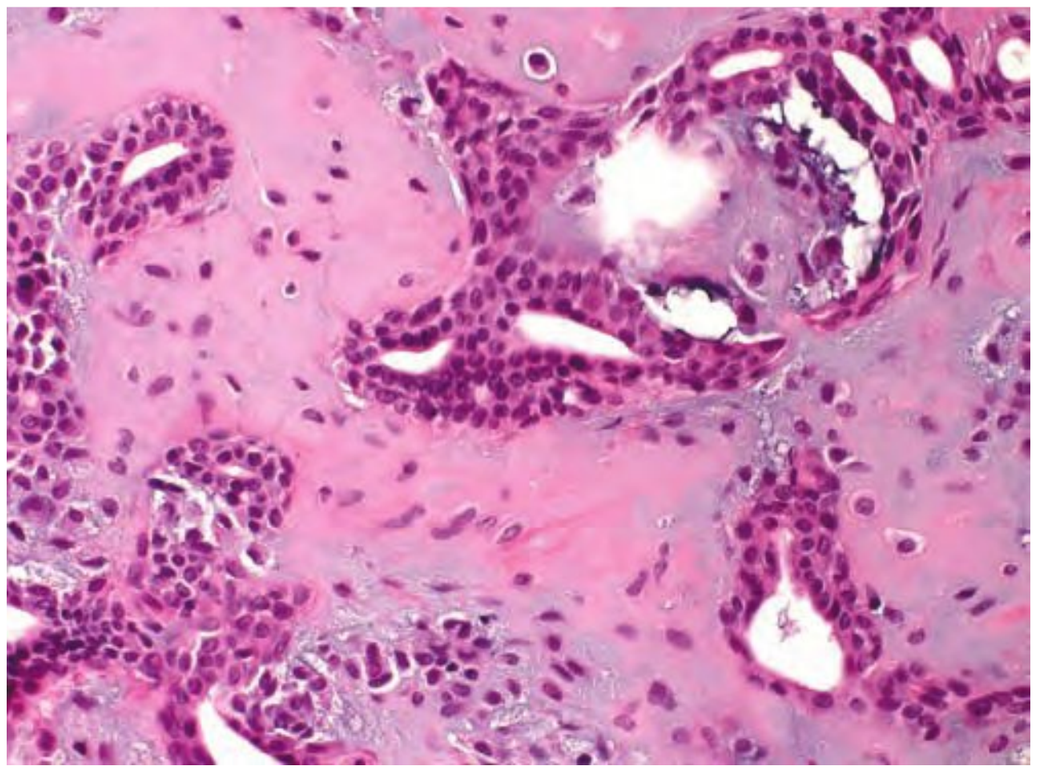

FIGURE 30-90. Chondroid syringoma. The tubular lumina are lined by two layers of cells: a luminal layer of cuboidal cells and a peripheral layer of flattened cells. Cells in the mucoid stroma have the appearance of chondrocytes.

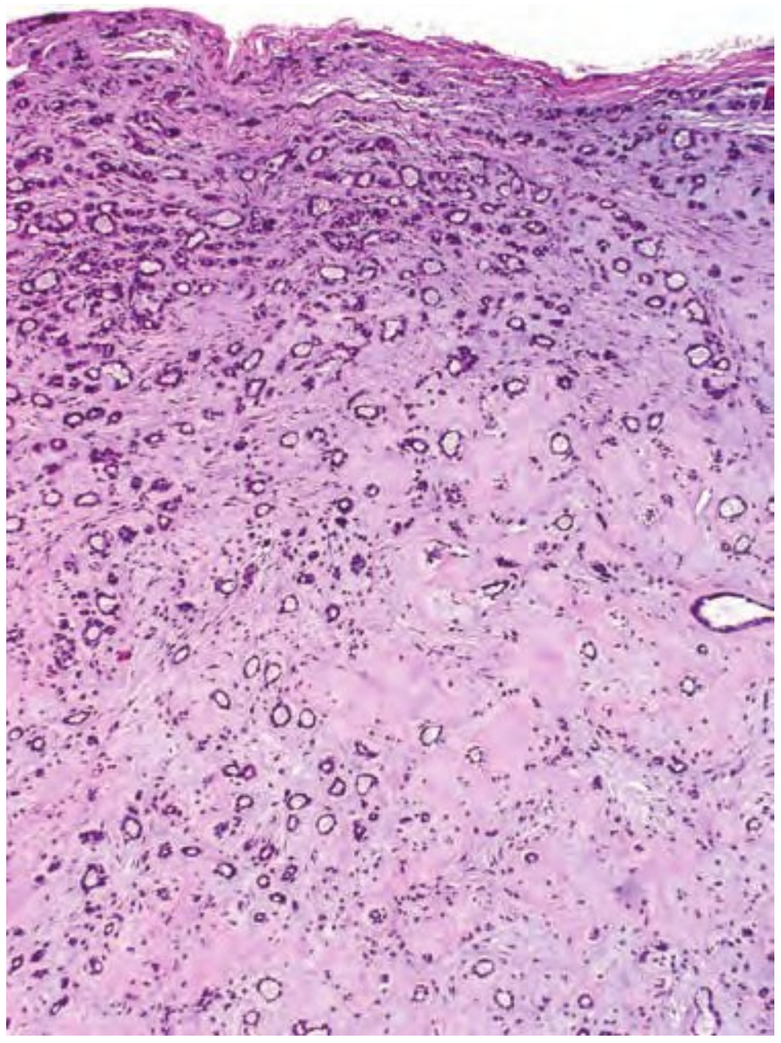

FIGURE 30-91. Chondroid syringoma, small tubular variant. In the dermis, there is a tumor comprised of nonbranching tubular epithelial elements embedded in an abundant stroma.

stroma may appear homogeneous and eosinophilic, like hyalin, and is then PAS positive and diastase resistant (557,561).

Chondroid syringoma with small, tubular lumina shows numerous small ducts, as well as small groups of epithelial cells and solitary epithelial cells scattered through a mucoid stroma (Fig. 30-91). The tubular lumina usually are lined by a single layer of flat epithelial cells, from which small, comma-like proliferations often extend into the stroma, resembling a syringoma (Fig. 30-92) (558). The mucoid stroma contains

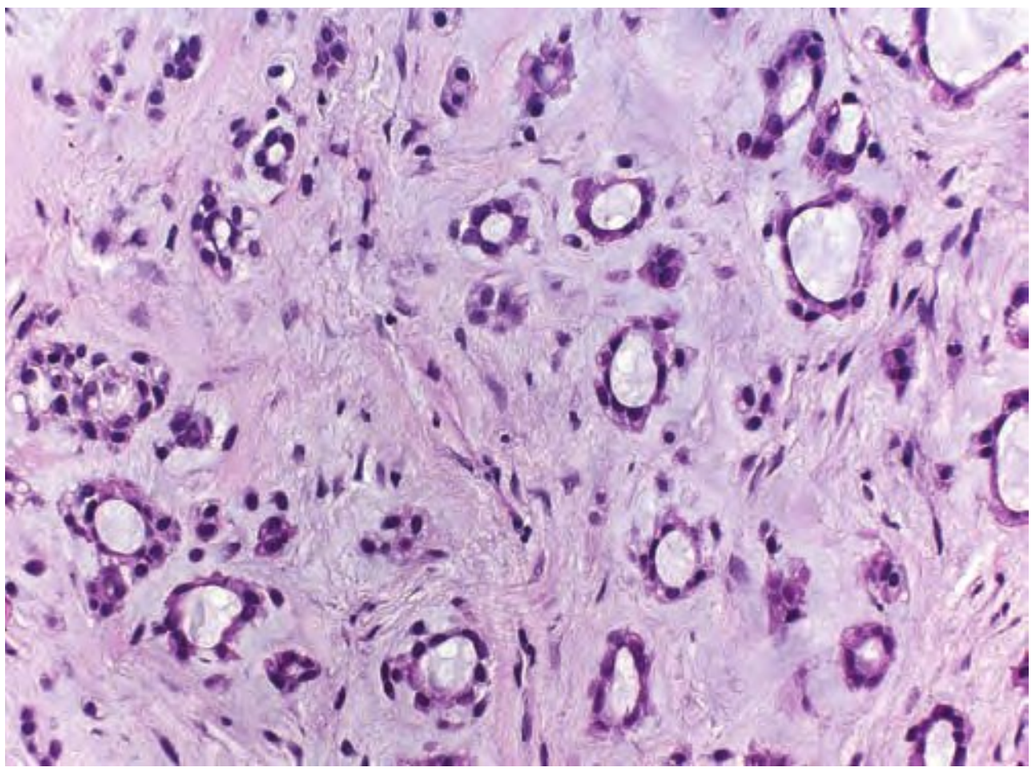

FIGURE 30-92. Chondroid syringoma, small tubular variant. The tubular lumina are lined by one or two layers of cells and are dispersed in the basophilic stroma.

acid mucopolysaccharides that stain metachromatically with toluidine blue.

Additional Studies. By immunohistochemistry, the inner-layer cells express cytokeratin, CEA, and EMA. The outer cell layer, when discernible, is positive for vimentin, S100 protein, neuron-specific enolase, and, occasionally, glial fibrillary acidic protein (563–566). The tumor can show either eccrine or apocrine differentiation. In three cases examined by electron microscopy, eccrine differentiation was noted (561,567). On the other hand, immunohistochemical examination with gross cystic disease fluid protein indicated apocrine differentiation in both cases tested (377). The stroma appears to evolve. Initially, delicate stellate, fibroblast-like cells possibly related to ductal myoepithelial cells are suspended in the Alcian blue–positive, hyaluronidase-resistant myxoid stroma. Stromal cells may acquire cytoplasmic lipid, resulting in a scattering of mature signet ring fat cells within the myxoid background. In some lesions, there is complete synthesis and secretion of solid hyaline cartilage populated by cells in lacunae showing ultrastructural features of true chondrocytes and S100 positivity.

Electron microscopy demonstrates that both ductal and secretory lumina are present, with the secretory lumina lined by clear and dark cells as in eccrine secretory lumina (567). The cells of the outer layer of the tubuloalveolar and ductal structures, like myoepithelial cells, contain numerous filaments and extend into the chondroid matrix, which they apparently produce (561). No chondrocytes were seen in the chondroid matrix in one study (561). In another study, the stroma showed epithelial cells and fibroblasts embedded in a fibrocollagenous matrix and islands of cartilaginous tissue containing chondrocytes with ultrastructural features similar to those of mature cartilage (567). In this case, foci of ossification were also observed, indicating that metaplasia into cartilage and bone had taken place.

Differential Diagnosis. Although most mixed tumors do not recur after surgical excision, seeding and regrowth of stromal and epithelial elements may occur, especially after an incomplete curettage. Lack of symmetry and an infiltrative pattern of growth are important features in distinguishing between benign mixed tumors and the rarely encountered malignant variant (see text following) (568).

Malignant Chondroid Syringoma

In most cases of malignant chondroid syringoma, anaplastic changes are present from the beginning (569). Rarely, a chondroid syringoma of many years' duration suddenly undergoes malignant changes with widespread metastases (570,571). The degree of aggressive behavior varies with malignant chondroid syringomas. For example, there may be only a local recurrence, but some cases have shown regional lymph node metastases or an osseous metastasis (569,572,573). In several cases, fatal visceral metastases have occurred (570,574–576). When this tumor metastasizes, it generally does so as an adenocarcinoma, often losing the tendency to form chondroid stroma.

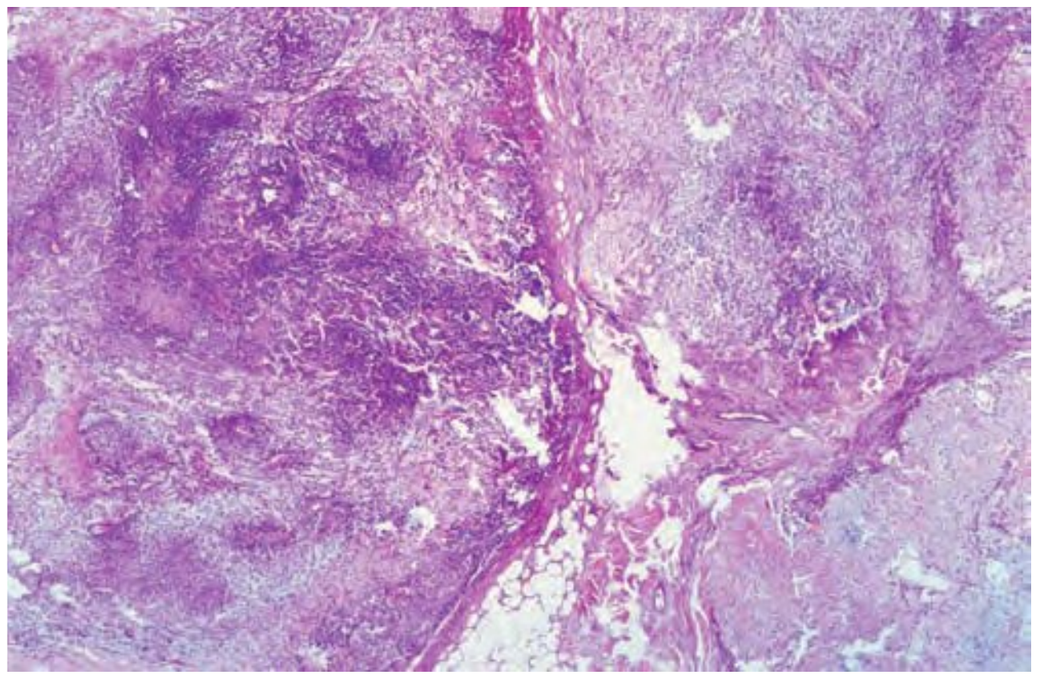

FIGURE 30-93. Malignant chondroid syringoma. An asymmetric cellular tumor is seen in the dermis.

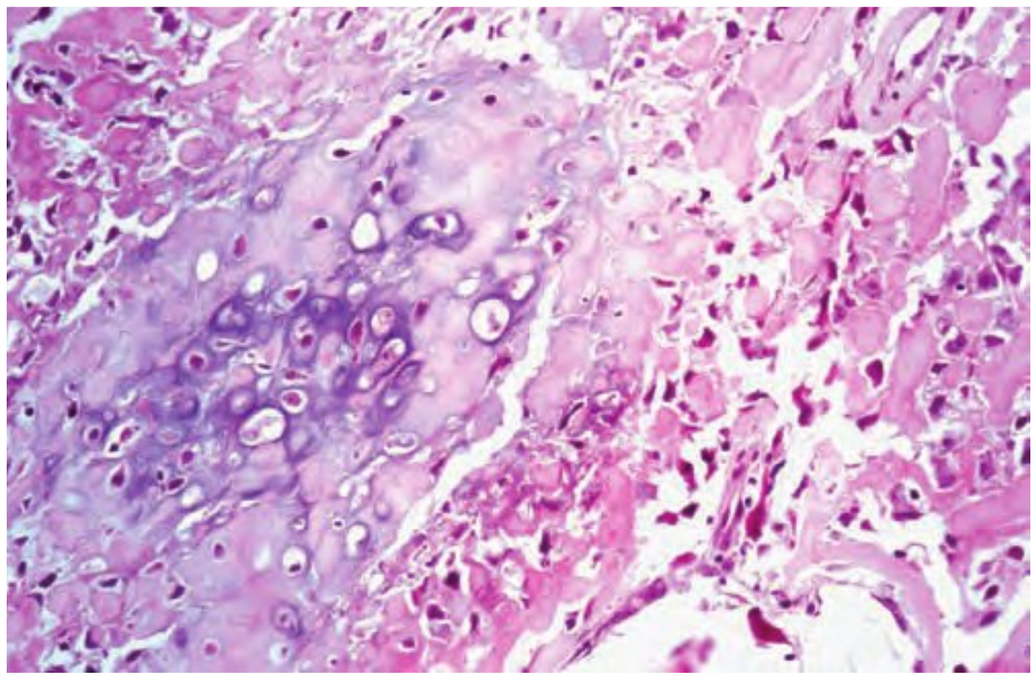

FIGURE 30-95. Malignant chondroid syringoma. Focally, cells embedded in a mucoid stroma reminiscent of chondroid syringoma are seen.

Histopathology. Histologically, malignant chondroid syringoma is composed of epithelial structures with glandular differentiation and carcinomatous features embedded in a mucinous stroma with spindle mesenchymal cells and areas of chondroid differentiation (Figs. 30.93 to 30-95). Sheets of atypical cells with increased mitotic activity can also be seen (Fig. 30-94). Unlike biphasic synovial sarcoma, in which both components express cytokeratins, only the epithelial structures of malignant chondroid syringoma are cytokeratin positive. The malignant tumor and its metastases are recognizable as chondroid syringoma through their chondroid stroma and tubular structures (Fig. 30-95). However, tubular differentiation is much less evident than in benign lesions (574). Most of the epithelial cells in the malignant tumor are arranged in irregular cords or sheets (Fig. 30-94) (572). The tumor cells appear atypical and hyperchromatic (573). In addition, an increased mitotic rate, vascular invasion, infiltration into the surrounding tissue, and necrosis have been noted (569).

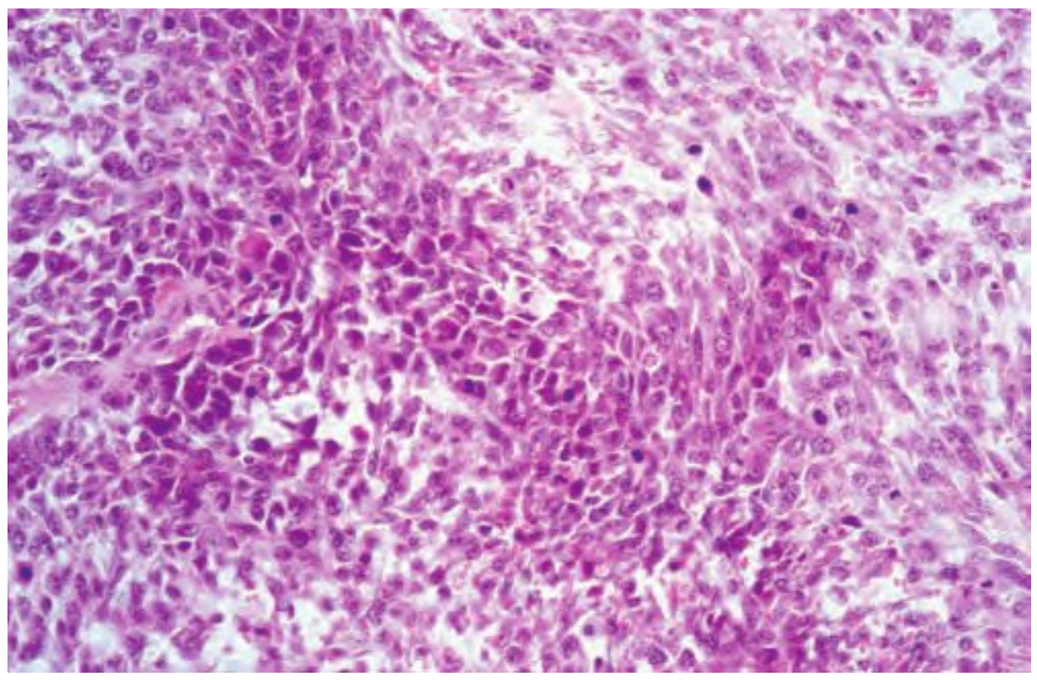

FIGURE 30-94. Malignant chondroid syringoma. Sheets of anaplastic cells are present.

CARCINOMAS OF APOCRINE AND ECCRINE GLANDS

Carcinomas exhibiting apocrine and eccrine differentiation can be classified in several different ways. One logical classification scheme distinguishes lesions based on whether the carcinoma may frequently evolve from a benign lesion. In reality, this group of tumors may derive either from a benign precursor through tumor progression or *de novo* as a malignant lesion. In this group are malignant cylindroma, malignant eccrine poroma, malignant eccrine spiradenoma, malignant nodular hidradenoma, and malignant chondroid syringoma, lesions that have already been discussed. The second group comprises apocrine and eccrine carcinomas that appear to have no benign precursor. In this group are carcinoma of apocrine glands, eccrine adenocarcinoma, syringoid eccrine carcinoma, microcystic adnexal carcinoma, mucinous (adenocystic) carcinoma, adenoid cystic carcinoma, and aggressive digital papillary adenocarcinoma.

CARCINOMAS OF APOCRINE GLANDS

Carcinomas of apocrine glands are rare tumors (390,577–581). These lesions occur primarily in the axillae and in other anatomic regions endowed with apocrine glands, including the anogenital region (390,578). Lesions can occur elsewhere on the skin (577,579). Apocrine carcinomas can also occur in the external auditory meatus, where ceruminous glands, which represent modified apocrine glands, are located (582,583). These tumors may involve the ear and preauricular skin (584).

Some cases of carcinoma of apocrine glands exhibit only local invasiveness, but other lesions metastasize to regional lymph nodes (390,578,579). In fact, some patients have died from widespread metastases (577,579).

Histopathology. The histologic picture is that of an adenocarcinoma that may be well, moderately, or poorly differentiated (590).

In well-differentiated apocrine gland carcinomas, nuclear atypicality and invasiveness are limited. Well-developed

glandular lumina are present; these lumina may be cystic and show branching (390). The cytoplasm of the tumor cells is strongly eosinophilic. Evidence of decapitation secretion, typical of apocrine glands, is present, at least in some areas. In addition, the cytoplasm of the tumor cells contains PAS-positive, diastase-resistant granules and often contains iron-positive granules (390). Myoepithelial cells are seen rarely (579).

In moderately or poorly differentiated apocrine gland carcinomas, recognition of apocrine histopathologic features may be difficult to assess, although even poorly differentiated tumors often demonstrate regions with prominent apocrine differentiation (390).

Additional Studies. Enzyme histochemical determinations are of value in establishing an apocrine genesis. Apocrine gland carcinomas show strong activity for apocrine enzymes, such as acid phosphatase, β-glucuronidase, and indoxyl acetate esterase, and low activity or absence of eccrine enzymes, such as phosphorylase and succinic dehydrogenase (577,579).

Differential Diagnosis. Apocrine gland carcinoma of the axilla must be differentiated from a carcinoma arising in ectopic breast tissue. Features that favor the diagnosis of a carcinoma of apocrine glands are the presence of neoplastic glands high in the dermis, apocrine glands near the tumor, and intracytoplasmic granules of iron (390).

Classic Type of Eccrine Adenocarcinoma

Only few lesions of primary eccrine carcinoma possess a clinical appearance suggesting an eccrine malignancy. Although they may arise on the palms or on the soles, they more commonly arise elsewhere, particularly in the head and neck region (13,585–587).

The classic type of eccrine gland adenocarcinoma has a high incidence of metastases. Of 68 patients followed for 5 years or more, 29 had regional lymph node metastases, and visceral metastases were present in 26 (588).

Histopathology. The histologic configuration in the classic type of eccrine gland adenocarcinoma varies from areas of fairly well differentiated tubular structures to anaplastic cells in other areas, not recognizable by themselves as eccrine sweat gland structures (586). The tubular structures usually show only small lumina that are lined by either a single layer or a double layer of cells (586). In some areas, the lumina are lined by secretory cells, which appear large and vacuolated because of the presence of glycogen and which also often contain PAS-positive, diastase-resistant granules (15,589).

Additional Studies. Immunohistochemical techniques have been of little help in characterizing these lesions (585). So-called eccrine enzymes, such as amylophosphorylase and succinic dehydrogenase, may be present in moderate amounts, but their role in identifying the tumors as eccrine rather than as metastatic has not been well defined (13,590).

Differential Diagnosis. It is often difficult to differentiate the classic type of eccrine sweat gland carcinoma from a metastatic adenocarcinoma. Therefore, the diagnosis of metastatic adenocarcinoma should always be given serious consideration before a diagnosis of eccrine sweat gland carcinoma is decided on.

Syringoid Eccrine Carcinoma

This tumor was originally referred to in 1969 as *basal cell tumor with eccrine differentiation* (591) and subsequently as *eccrine epithelioma* (592); the term *syringoid eccrine carcinoma* is preferable because the tumor differs from basal cell carcinoma in its cytologic and enzymatic patterns. It represents a relatively well differentiated form of eccrine carcinoma (593). Although first reported as a deeply invasive and destructive tumor of the scalp (591), it also occurs in other locations, and metastases rarely occur (593).

Histopathology. Syringoid eccrine carcinoma resembles syringoma by showing ductal, cystic, and comma-like epithelial components and by containing eccrine enzymes such as phosphorylase and succinic dehydrogenase (Figs. 30-96 and 30-97) (591). It differs from syringoma by its cellularity, anaplasia, and deep infiltrative growth (Fig. 30-96). This uncommonly diagnosed tumor is probably related to the microcystic adnexal carcinoma. A clear cell variant of syringoid eccrine carcinoma has been described (594,595).

Additional Studies. Immunohistochemical analysis revealed that most tumor cells expressed simple epithelial cytokeratins (cytokeratins 7, 8, 18, 19), consistent with sweat gland secretory differentiation (596).

Microcystic Adnexal Carcinoma

Microcystic adnexal carcinoma, or sclerosing sweat duct carcinoma, may best be considered as a sclerosing variant of ductal eccrine carcinoma (597,598). This tumor is most commonly seen on the skin of the upper lip, but occasionally also on the chin, nasolabial fold, or cheek (598,599). Rare cases of multiple primary microcystic adnexal carcinomas have been reported (600). Microcystic adnexal carcinoma is an aggressive neoplasm that invades deeply. Local recurrence is common; however, metastases have not been reported.

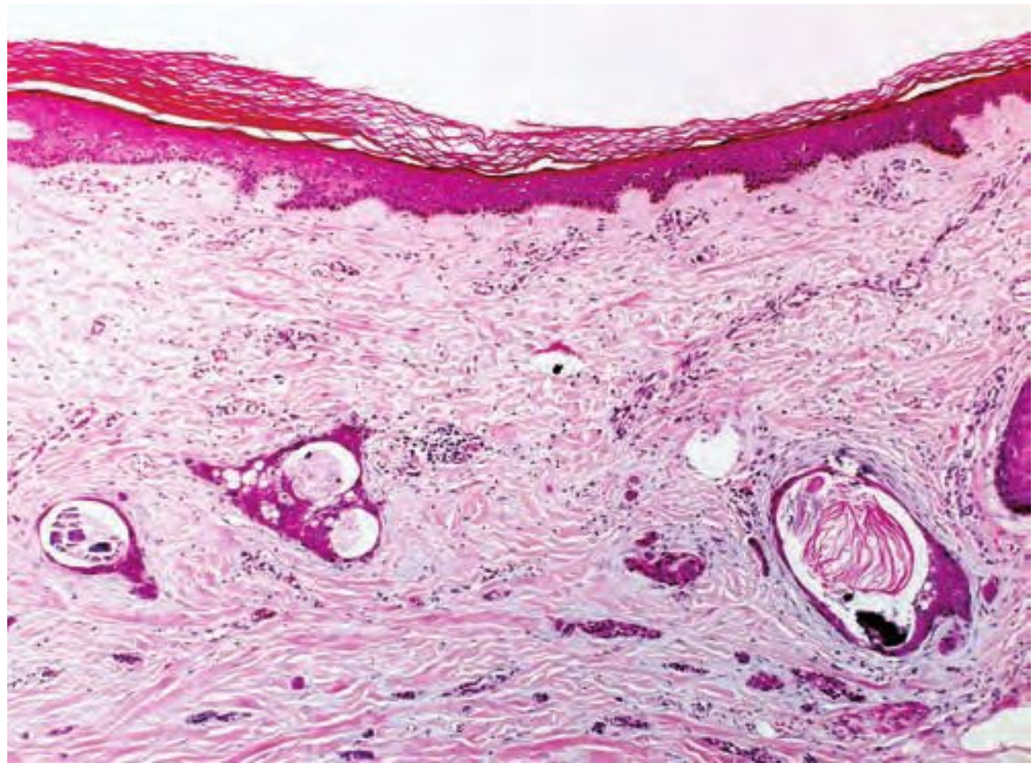

FIGURE 30-96. Syringoid eccrine carcinoma. An infiltrative tumor exhibiting ductal differentiation is identified.

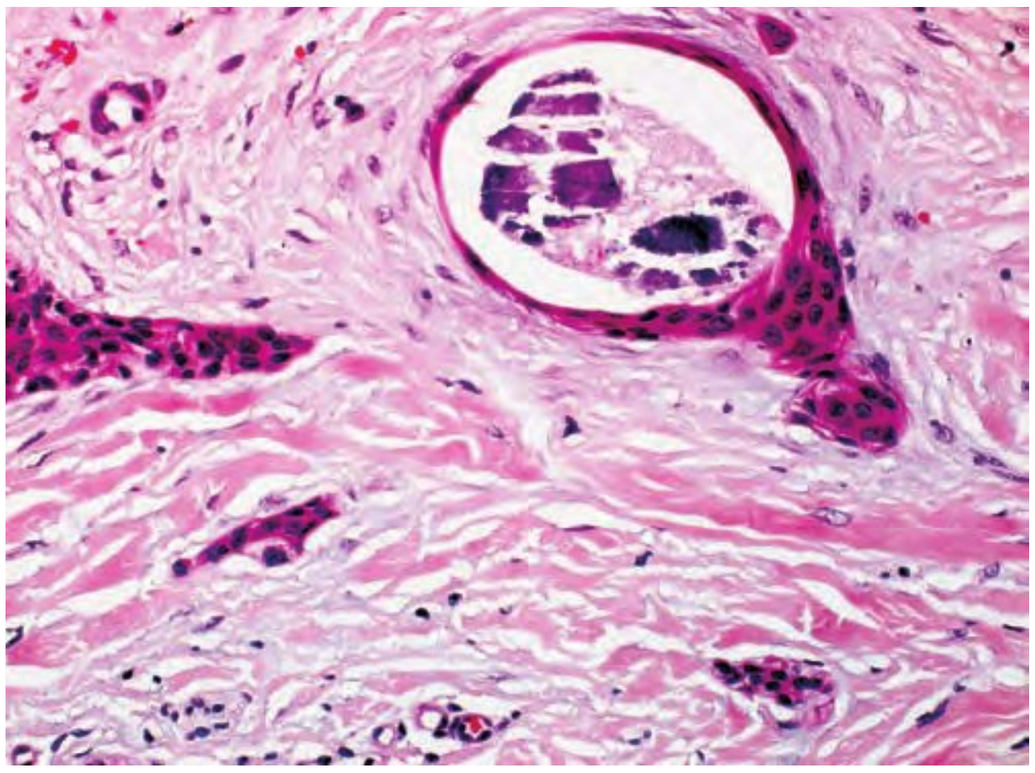

FIGURE 30-97. Syringoid eccrine carcinoma. Infiltrative epithelial elements resembling a syringoma are seen.

Histopathology. Microcystic adnexal carcinoma is a poorly circumscribed dermal tumor that may extend into the subcutis and skeletal muscle (Fig. 30-98). Continuity with the epidermis or follicular epithelium may be seen. Two components within a desmoplastic stroma may be evident. In some areas, basaloid keratinocytes are seen, some of which contain horn cysts and abortive hair follicles; in other areas, ducts and glandlike structures lined by a two-cell layer predominate (Figs. 30-99 and 30-100) (599). The tumor islands typically reduce in size as the tumor extends deeper into the dermis. Cells with clear cytoplasm may be present, and sebaceous differentiation has been reported (601). Cytologically, the cells are bland without significant atypia; mitoses are rare or absent. Perineural invasion may be seen, a feature that may account for the high recurrence rate.

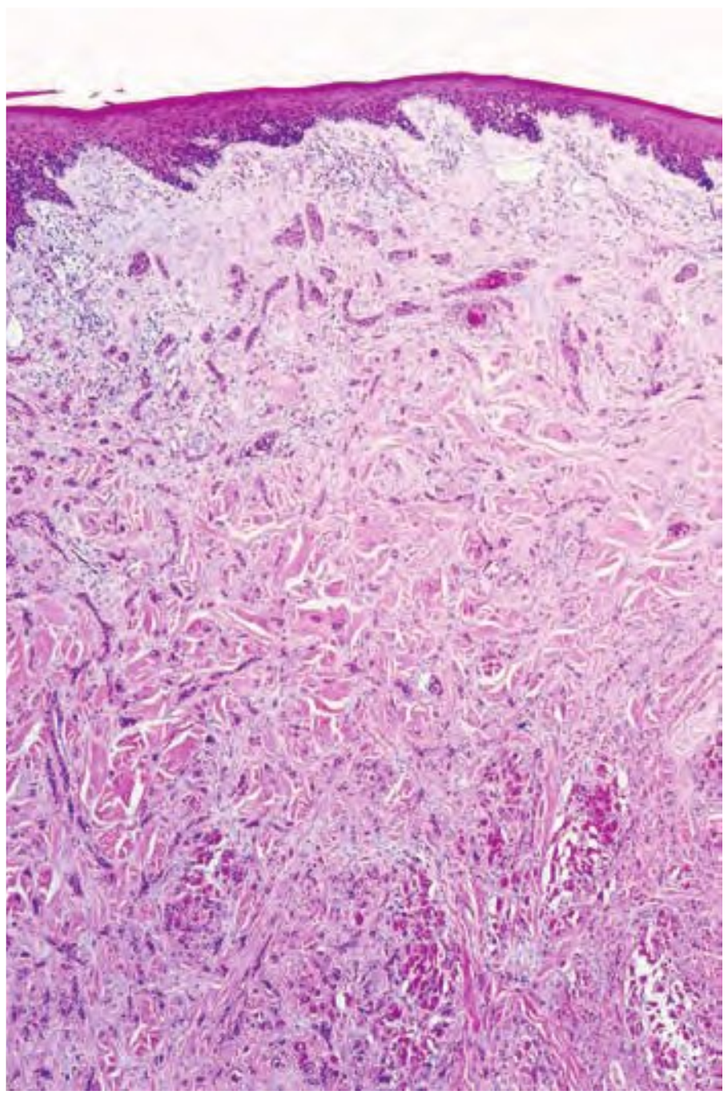

FIGURE 30-98. Microcystic adnexal carcinoma. There is a large, poorly circumscribed tumor comprised of epithelial cords that invades deeply into the dermis.

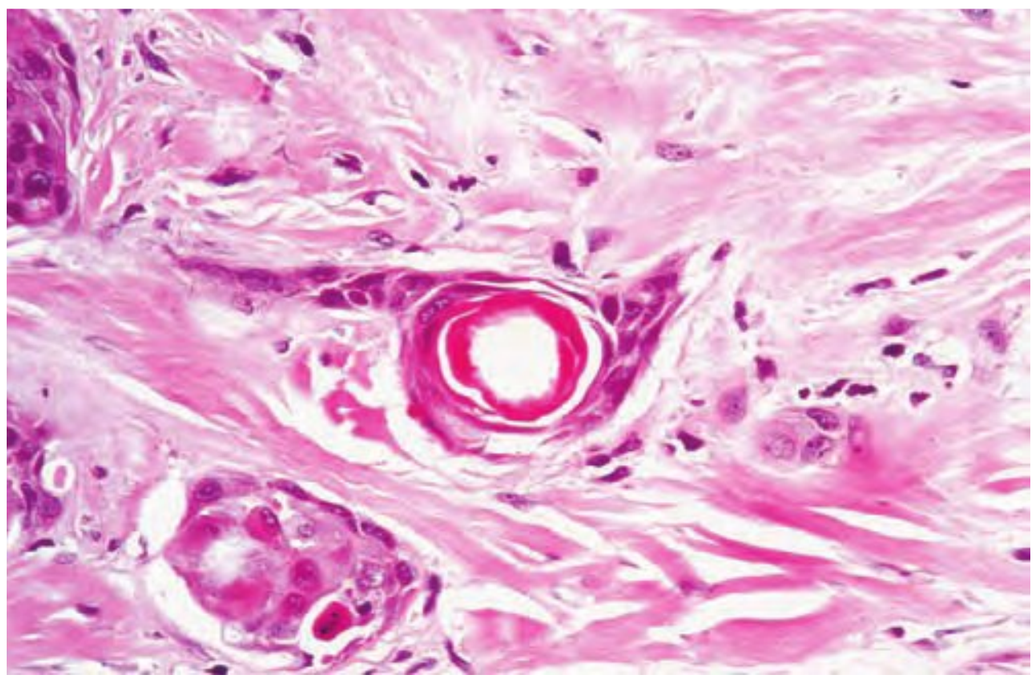

FIGURE 30-99. Microcystic adnexal carcinoma. Superficially, keratin-filled cystic glands are present and may be mistaken for the cysts of a trichoepithelioma, but the lesion invades deeply into the dermis.

Additional Studies. Immunoperoxidase staining for carcinoembryonic antigen stains the glandular structures but not the pilar structures (598). The presence of both pilar and eccrine structures allows differentiation from desmoplastic trichoepithelioma and syringoma. Lack of circumscription, deep dermal involvement, and perineural involvement all aid in diagnosis because the cytology mimics benign adnexal neoplasms. This diagnosis should always be considered and complete excision contemplated when a syringomatous or trichoepithelioma-like proliferation extends to the base of a biopsy, especially in an elderly patient. Immunohistochemical studies have shown that CD23 can help to distinguish microcystic adnexal carcinoma from desmoplastic trichoepithelioma (602).

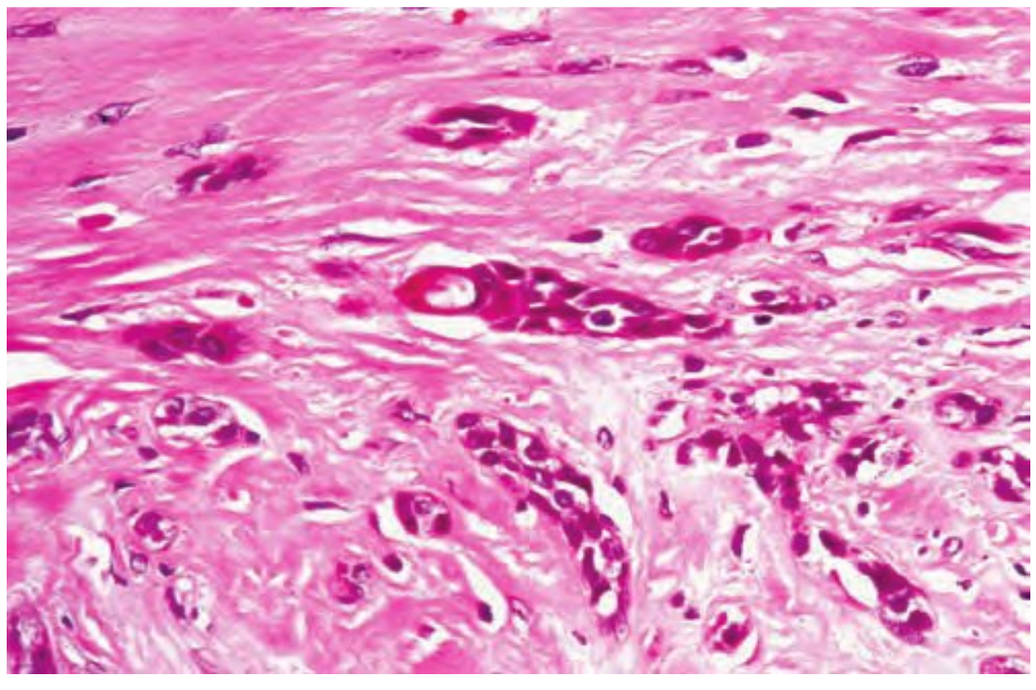

FIGURE 30-100. Microcystic adnexal carcinoma. In the deep dermis, cords of bland epithelial cells demonstrate focal ductal differentiation. A marked desmoplastic response is noted.

Mucinous Eccrine Carcinoma

First described in 1971, mucinous eccrine carcinoma is a rather uncommon tumor that metastasizes to regional lymph nodes occasionally (603,604). Widespread metastases have been described only very rarely (605).

Histopathology. The histologic appearance of mucinous eccrine carcinoma is highly characteristic (606). The tumor is divided into numerous compartments by strands of fibrous tissue. In each compartment, abundant amounts of pale-staining mucin surround nests or cords of moderately anaplastic epithelial cells, some of which show a tubular lumen (Figs. 30-101 and 30-102) (603,607). The mucin shows strongly positive reactions with both PAS and colloidal iron. The mucinous material is resistant to diastase and hyaluronidase but is sensitive to digestion with sialidase. The reaction with Alcian blue is positive at pH 2.5 but negative at pH 1.0 and pH 0.4, which indicates that the mucin is nonsulfated (608). It can be concluded that the mucin represents sialomucin, an epithelial mucin (603,607).

Additional Studies. Enzyme histochemical studies have revealed a prevalence of eccrine enzymes in these tumors (607). Electron microscopy has revealed two types of secretory cells in the tumor—dark and light—analogous to the two types normally encountered in eccrine coils. The sialomucin is secreted by the dark cells (609). Immunohistochemical results also suggest differentiation toward eccrine secretory coil (610).

It is important to differentiate this tumor from a metastatic mucinous adenocarcinoma, in which the primary lesion most commonly is located in the large intestines (603). In both primary and metastatic mucinous adenocarcinoma, islands of tumor cells appear to be floating in lakes of mucin, but the tumor cells are more atypical in the metastatic type, and the atypical cells invade between collagen bundles at the margin of the nodule (611). Exclusion of primary visceral carcinomas is often impossible by histology alone.

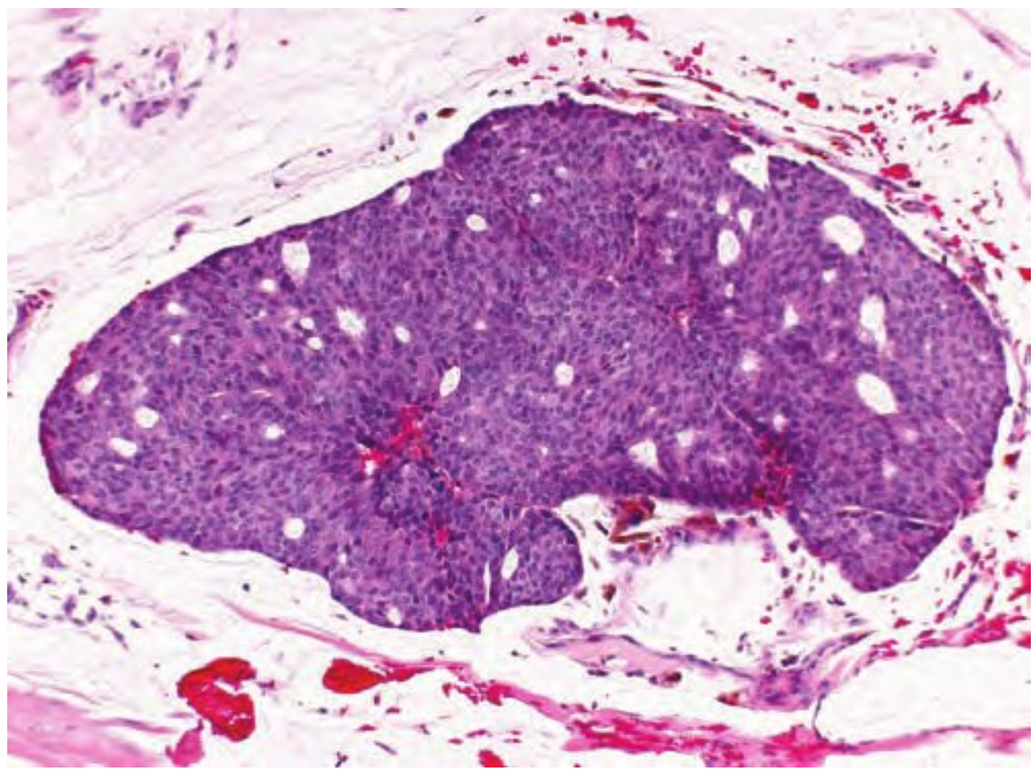

FIGURE 30-102. Mucinous eccrine adenocarcinoma. The islands of tumor cells show mild cytologic atypia and focal duct formation.

Mucoepidermoid (Low-Grade Adenosquamous) Carcinoma

This tumor, which combines well-differentiated squamous and glandular epithelium, is histologically identical to that of sali-

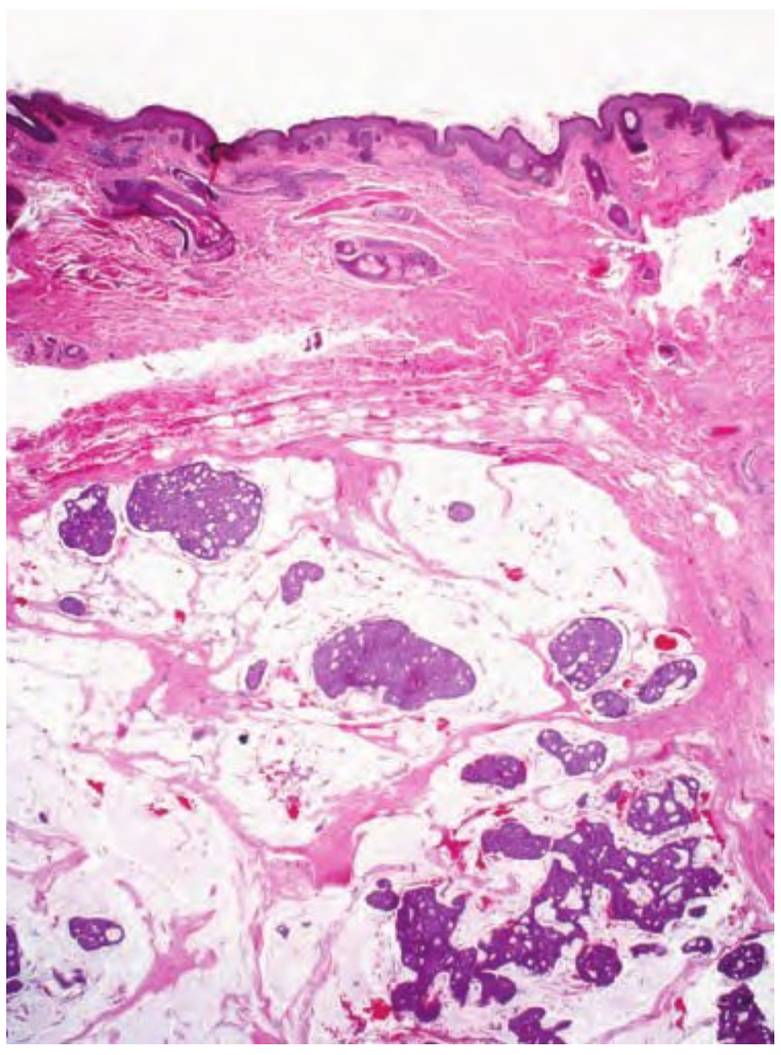

FIGURE 30-101. Mucinous eccrine adenocarcinoma. The tumor is divided into numerous compartments. In each compartment, abundant amounts of mucin surround small islets of tumor cells.

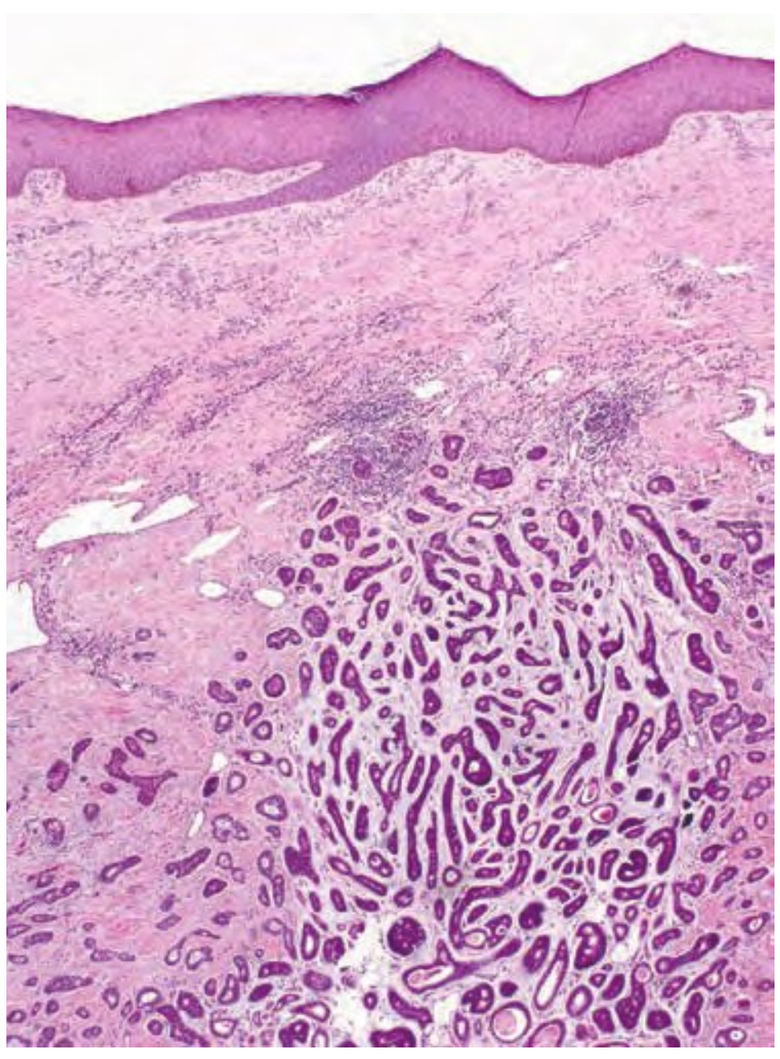

FIGURE 30-103. Adenoid cystic carcinoma of eccrine glands. A large cell mass shows an adenoid or cribriform pattern. In addition, many small, solid epithelial islands are present.

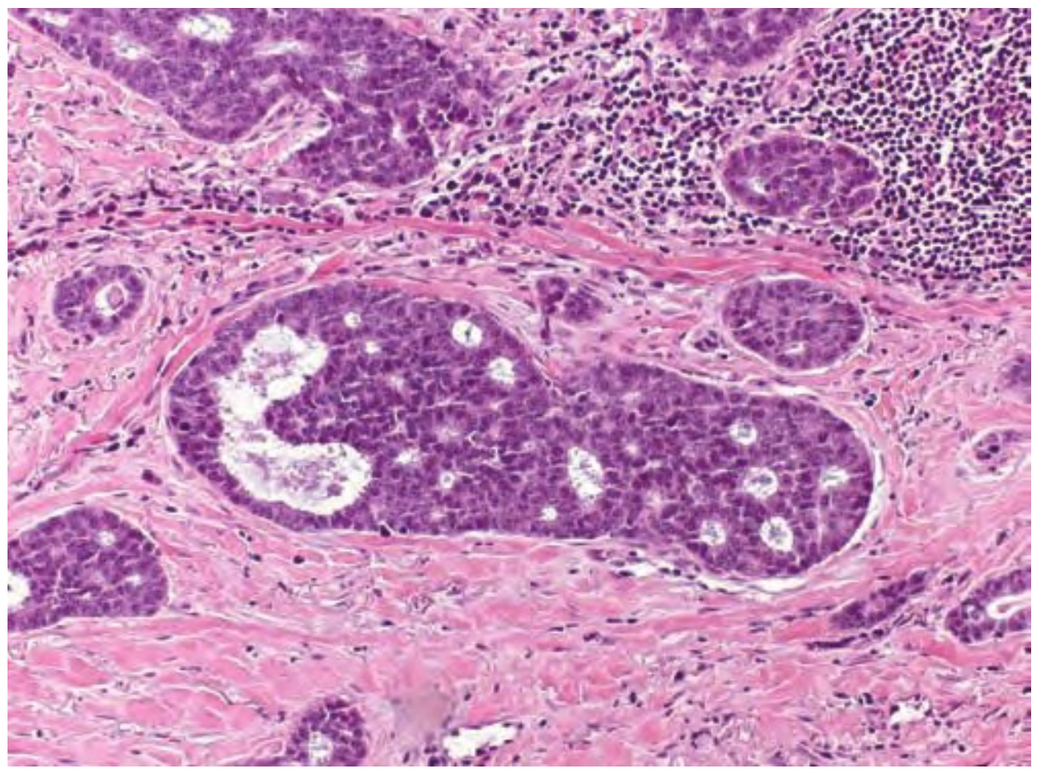

FIGURE 30-104. Adenoid cystic carcinoma of eccrine glands. Some epithelial islands demonstrate a cribriform pattern.

vary glands and may occur as a primary cutaneous malignancy (612–614).

Adenoid Cystic Carcinoma

One of the rarest types of eccrine carcinomas is the adenoid cystic carcinoma, first described in 1975 (615). Metastases have been reported but are uncommon (616). This indolent tumor, like its more aggressive counterpart in salivary glands, spreads in perineural spaces and, therefore, recurs in 20% of cases (616,617).

Histopathology. Microscopic examination reveals lesions exhibiting an adenoid or cribriform pattern comprised of many small, epithelial islands (Fig. 30-103). Round spaces formed by malignant epithelial cells and containing amphophilic basement membrane–like material occur in the cribriform type and tubular variants (Fig. 30-104) (618). Through the accumulation of mucin, the adenoid spaces may be transformed into multiple cystic spaces lined by a flattened cuboidal epithelium. The adenoid and cystic spaces contain pale-staining mucin that in some cases is hyaluronidase sensitive but in others was resistant to hyaluronidase digestion and reacted with the Alcian blue stain at pH 2.5 and pH 0.5 (619,620). In several instances, there has been extension along perineural spaces.

Additional Studies. Adenoid cystic carcinoma is immunoreactive for carcinoembryonic antigen, amylase, and S100 protein (620).

Adenoid cystic carcinoma of eccrine glands must be distinguished from the adenoid type of basal cell carcinoma, from which it differs by lack of continuity with the epidermis or hair sheath and by the absence of peripheral palisading (619). In addition, the adenoid type of basal cell carcinoma shows negative reactions to carcinoembryonic antigen, amylase, and S100 protein (620). Cutaneous extension from a parotid tumor or scar recurrence should be ruled out in adjacent body sites.

Aggressive Digital Papillary Adenocarcinoma

These tumors, originally described in 1987, occur on the fingers, toes, and adjacent skin of the palms and soles, especially in adult males, as a single, often cystic mass that rarely ulcerates but often invades soft tissue (621).

Histopathology. Aggressive digital papillary adenocarcinoma shares some histologic features with papillary eccrine adenoma. These tumors are usually cellular, dermal nodules with cystic cavities (Fig. 30-105). Characteristic histologic findings of this lesion include tubuloalveolar and ductal structures associated with papillary projections protruding into cystically dilated lumina (Figs. 30-106 and 30-107) (621). Macropapillae lined by atypical epithelial cells project into microcysts. These areas may merge with more cellular regions of moderately differentiated adenocarcinoma. Mitotic activity and cytologic atypia are

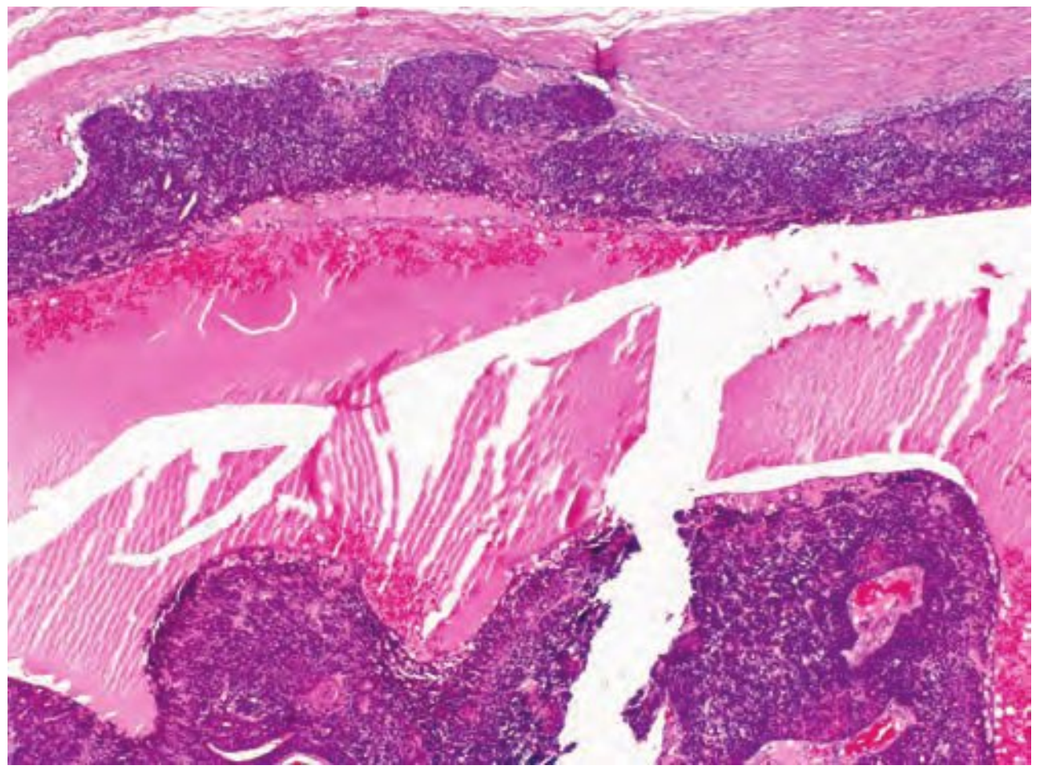

FIGURE 30-105. Aggressive digital papillary adenocarcinoma. A large, lobulated dermal tumor with focal cystic change is seen in the dermis of acral skin.

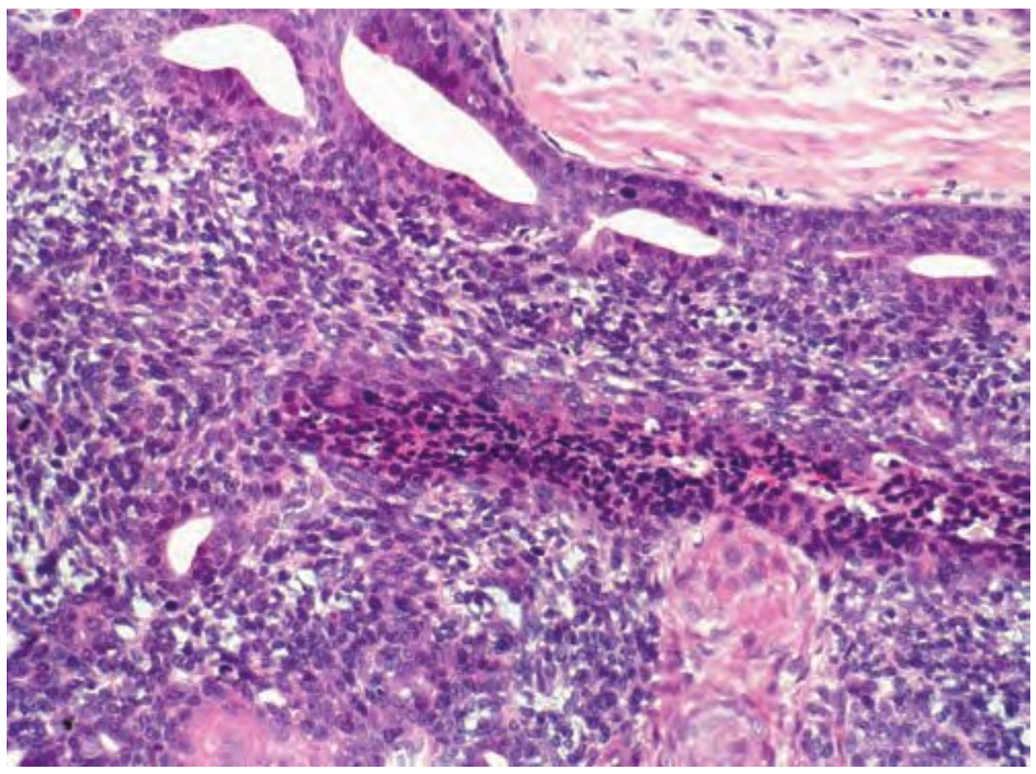

FIGURE 30-106. Aggressive digital papillary adenocarcinoma. Gland formation and focal squamoid differentiation are seen.

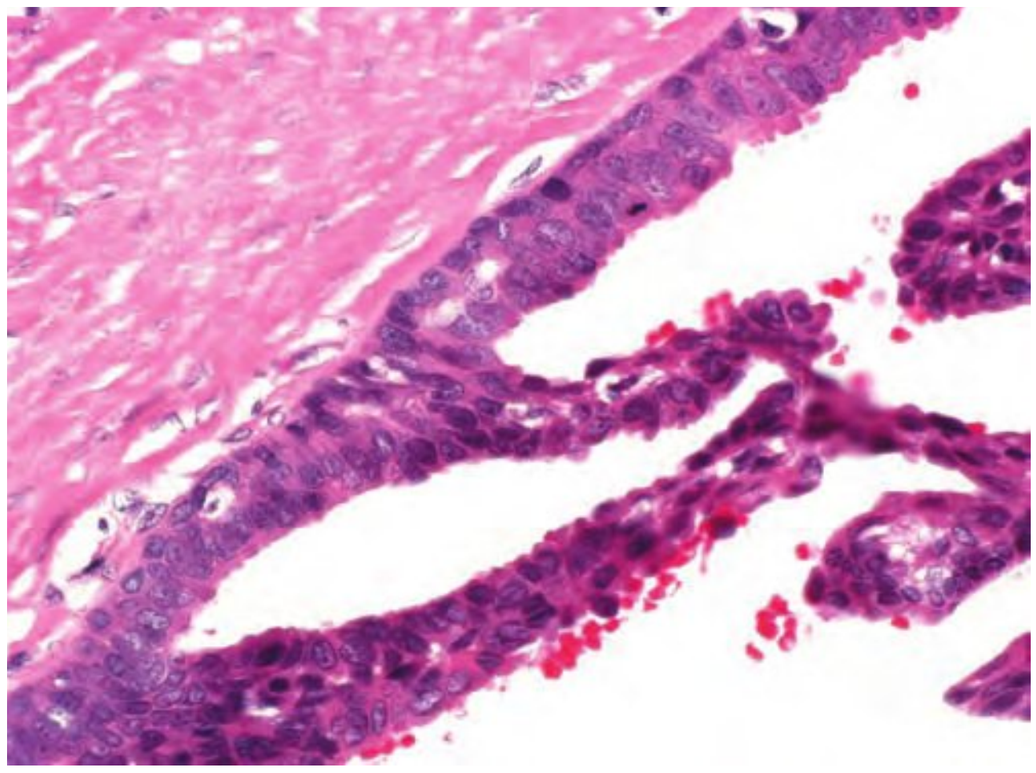

FIGURE 30-107. Aggressive digital papillary adenocarcinoma. Micropapillary structures are seen and mitotic activity is present.

often present (Fig. 30-107). Metastatic papillary carcinoma from breast, lung, thyroid, and ovary are in the histologic differential. Initially, a low-grade variant—"aggressive digital papillary adenoma"—was described that differed from adenocarcinoma based on degree of pleomorphism, mitotic rate, and necrosis (621). However, recent studies suggest that histologic features alone cannot reliably predict clinical behavior, and, therefore, all lesions should be considered aggressive digital papillary adenocarcinomas (622,623). When metastases develop, they often involve the lung.

CHAPTER 31

Mei-Yu Hsu
George F. Murphy

Cutaneous Lymphomas and Leukemias

The subject of cutaneous lymphoma and leukemia has long been one of conceptual confusion and diagnostic challenge. Aside from the inherent difficulties in differentiating hyperplastic from neoplastic hematopoietic cells in skin, the recent evolution in classification schemas for lymphoma and leukemia have contributed significantly to this dilemma. Moreover, some traditional didactic treatments of this issue too often provide information so abundant as to confound the overview necessary for a practical, confident, and accurate diagnostic approach to potential lymphoproliferative disorders of skin.

The classification system adapted to skin and used in this chapter is that of the 2005 World Health Organization (WHO)/European Organization for Research and Treatment of Cancer (EORTC) Consensus Classification of cutaneous lymphomas (1). This recent and seminal contribution reflects the understanding that primary cutaneous lymphomas have a distinctive clinical behavior and prognosis from histologically similar nodal diseases and require different management and treatment regimens. The new classification pays special attention to recognizing only those diseases that represent distinct clinicopathologic entities and offers pathologists, dermatologists, oncologists, and geneticists a universal system for lymphoma/leukemia classification. In this regard, a synthesis of clinical, histopathologic, immunohistochemical, molecular, and cytogenetic features are often required to define individual disease entities.

The treatment of lymphoproliferative disorders detailed in this chapter is in no small part indebted to the outstanding foundations that have been developed in previous editions of this text. In particular, the classification, images, and related commentary provided by LeBoit and McCalmont (2) as well as Murphy and Schwarting (3) were integral to the development of the present material and represent a major advance in the textural treatment of this difficult and rapidly evolving topic.

Lymphoproliferative disorders of the skin fall into two major categories: primary cutaneous neoplasms (those where lymphoma presents in the skin without extracutaneous involvement at the time of diagnosis) and extracutaneous neoplasms that may secondarily involve the skin. Furthermore, most cutaneous lymphomas have putative histogenetic origin from the distinct cell types of the immune system (4). The specific diseases that follow will thus be grouped according to the following schema in order to include the vast majority of conditions recognized by the current WHO/EORTC classification that have specific relevance to the skin (Table 31-1).

CUTANEOUS HEMATOPOIETIC INFILTRATES: OVERVIEW AND GENERAL CONCEPTS

Hematopoietic Cell Lineage: Relevance to Cutaneous Immune Surveillance and Lineage Differentiation

One of the major functions of skin is protection against environmental hazards, including infectious organisms. Evolution has allowed the development of a highly effective two-tiered defense mechanism composed of a rapid "innate" and a sustained "adaptive" response. The innate immunity is mediated by macrophages, leukocytes, natural killer (NK) cells, γ/δ T cells, and dendritic cells, which detect nonspecific epitopes commonly shared by different pathogens (such as glycolipids, lipoproteins, peptidoglycans, and double-stranded RNA) and mount immediate responses. In contrast, the adaptive arm of the cutaneous immune system targets specific protein antigens in a major histocompatibility–restricted manner through effectors like α/β T and B cells. Most cutaneous lymphomas have putative lineage derivation from and perhaps biologic behavior attributed to the distinct cell populations of the immune system and their evolutionary stages of maturation (4). Malignant T cells and myeloid cells tend to recapitulate morphologic and antigenic features of cells undergoing intrathymic/postthymic and intraosseous maturation, respectively. Malignant B cells also have definite developmental relationships to normal B-cell ontogeny within bone marrow and lymphoid organs. Because B-cell malignancies compose a clinically and morphologically diverse group of diseases, it is helpful conceptually to relate specific disorders to developmental stages of normal B-cell maturation. Figure 31-1 is an adaptation of the current classification schema that attempt to achieve this end.

T- and B-cell Infiltration Patterns

While numerous exceptions exist, there are fundamental and often reproducible trends in the patterns produced when lymphocytes infiltrate the skin (5). This is based in part on differences in adhesive ligands between B and T cells, resulting in

TABLE 31-1 Classification of Cutaneous Lymphoproliferative Disorders

Primary Cutaneous Lymphoproliferative Disorders
Mature B-cell lineage
- B-cell lymphomatoid hyperplasia
- Cutaneous follicle center lymphoma
- Cutaneous marginal zone B-cell lymphoma (MALT type)
- Cutaneous diffuse large B-cell lymphoma, leg type
- Cutaneous diffuse large B-cell lymphoma, other
  - Extraosseous plasmacytoma

Mature T-/NK-cell lineage
- T-cell lymphomatoid hyperplasia
- Mycosis fungoides
- Variants of mycosis fungoides
  - Localized pagetoid reticulosis
    - Follicular, syringotropic, granulomatous variants
  - Subtype of mycosis fungoides
    - Granulomatous slack skin
  - Sézary syndrome
- Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders
  - Lymphomatoid papulosis
  - Primary cutaneous large T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Primary extranodal NK-/T-cell lymphoma, nasal type
- Primary cutaneous peripheral T-cell lymphoma, unspecified
- Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma (provisional)
- Cutaneous γ/δ T-cell lymphoma (provisional)
- Primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma (provisional)

Myeloid lineage
- Extramedullary hematopoiesis
- Myeloid sarcoma (aleukemic leukemia)

Precursor plasmacytoid dendritic cell lineage
- $CD4^+/CD56^+$ hematodermic neoplasm (blastic NK-cell lymphoma)

Secondary Lymphoproliferative Disorders Affecting Skin
B-cell lineage
- Precursor B-lymphoblastic leukemia/lymphoma
- Chronic lymphocytic leukemia/small lymphocytic lymphoma
- Follicular lymphoma, nodal type
- Mantle cell lymphoma
- Diffuse large B-cell lymphoma, nodal type
- Intravascular large B-cell lymphoma
- Lymphomatoid granulomatosis
- Hodgkin's lymphoma

T-/NK-cell lineage
- Secondary extranodal NK-/T-cell lymphoma, nasal type
- Adult T-cell leukemia/lymphoma
- Peripheral T-cell lymphoma/angioimmunoblastic T-cell lymphoma
- Anaplastic large cell lymphoma
- Precursor T-lymphoblastic leukemia/lymphoblastic lymphoma
- T-cell prolymphocytic leukemia

Myeloid lineage
- Acute myeloid leukemia
- Chronic myeloid leukemia

Precursor plasmacytoid dendritic cell lineage
- Plasmacytoid dendritic cell leukemia/lymphoma

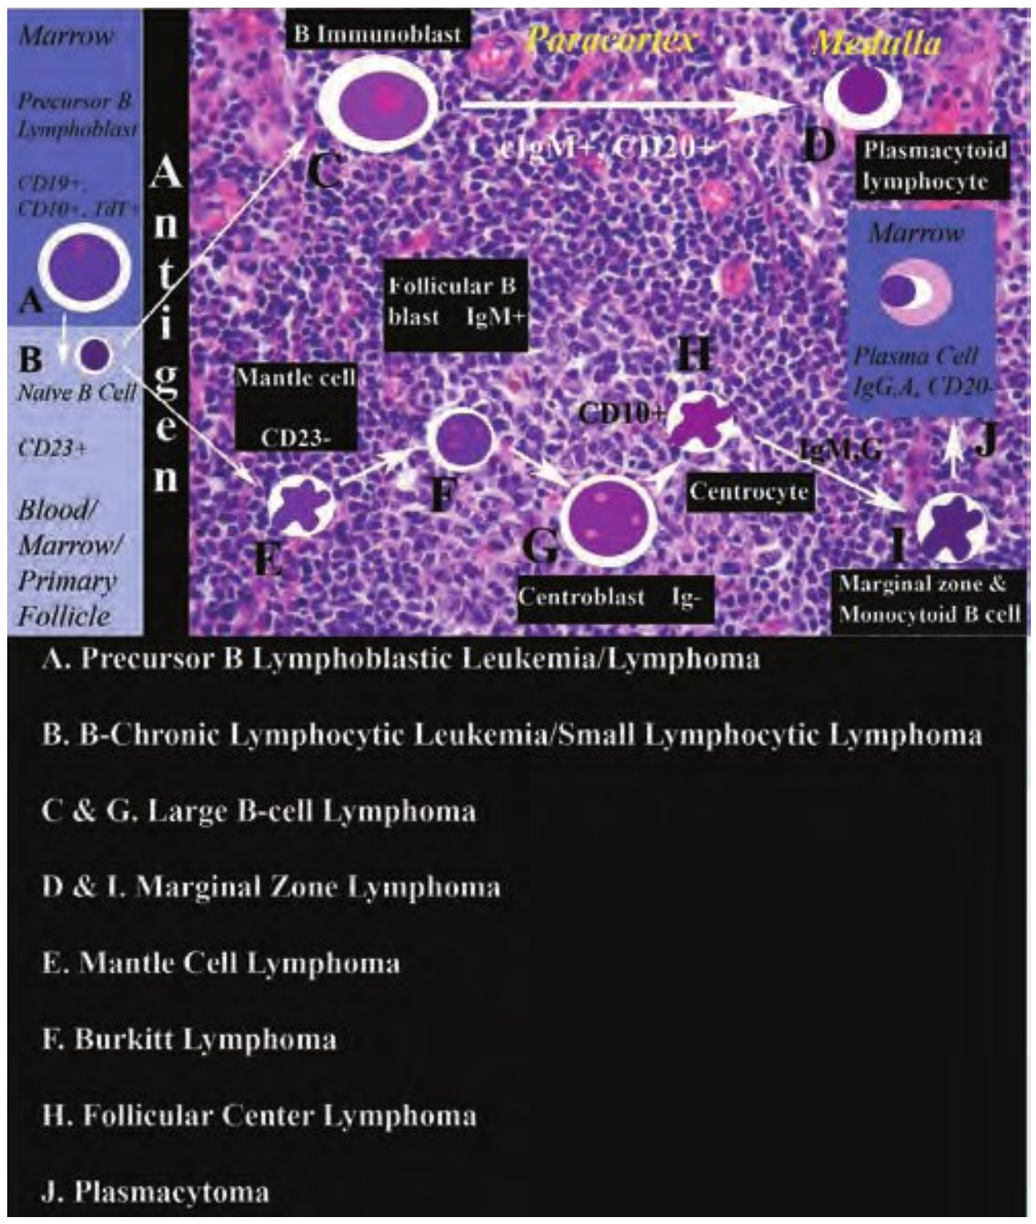

FIGURE 31-1. Schematic diagram of B-cell differentiation in relationship to sites of nodal maturation, relevant markers, and corresponding lymphomas that may develop.

differential affinity for various compartments within the skin. Moreover, chemokinetic and chemotactic signals may influence the migration of various classes of lymphoid cells in different ways. The best example of this is the tendency for both benign and malignant T cells, but not B cells, to migrate into epithelial structures, including the epidermis and its adnexae. This results in the phenomena of "epidermotropism" and "folliculotropism," accounting for the tendency to identify T cells within the epidermal layer and often as a band of cells within the underlying papillary dermis (Fig. 31-2A). Occasionally, as is the case in epidermotropic phases of mycosis fungoides (MF), T cells may align along the basement membrane zone of the dermal–epidermal junction, a finding that may have a basis in expression by these cells of integrin receptors for the specific membrane components (6). This "T-cell pattern" of infiltration is not invariable among T-cell malignancies, however, and epidermotropism may be blunted as tumors evolve and progress to more aggressive and poorly differentiated states. B cells, on the other hand, do not demonstrate the same affinity for the epidermis and adnexae, and seldom are these cells detected in significant numbers within the epidermis or papillary dermis. The sparing of the latter produces the characteristic "grenz zone" seen in B-cell pattern infiltrates of the skin. Moreover, perhaps because of the innate proclivity of B cells to aggregate into follicular structures, B-cell infiltrates in the skin often (but not invariably) show a nodular architecture (Fig. 31-2B).

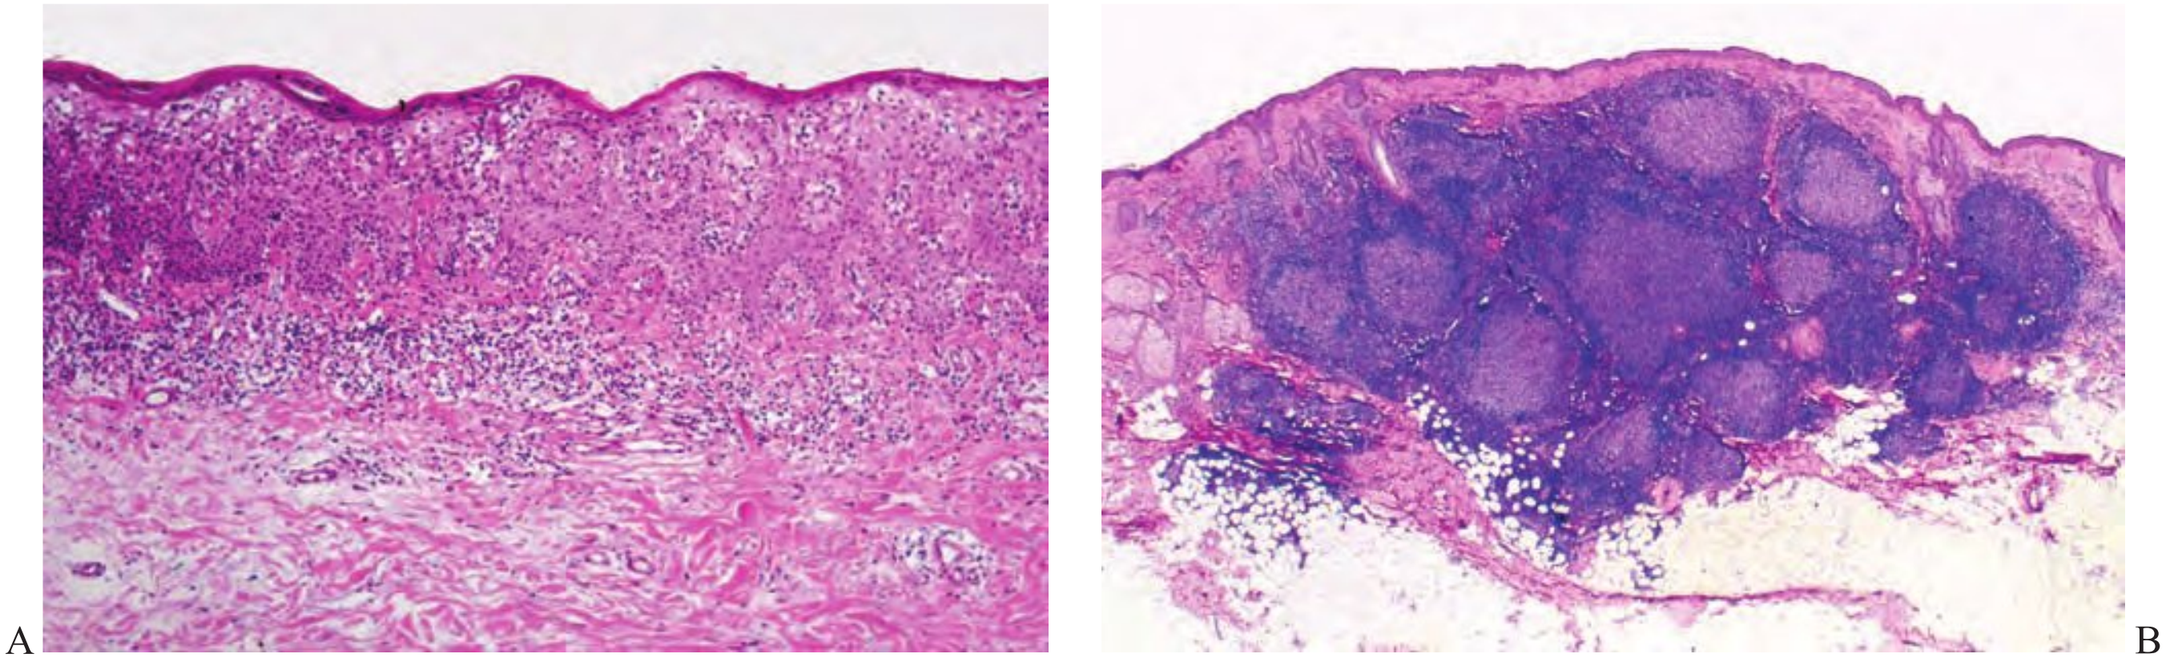

FIGURE 31-2. Patterns of T- and B-cell infiltration. A: T-cell pattern. B: B-cell pattern with grenz zone and germinal center formation.

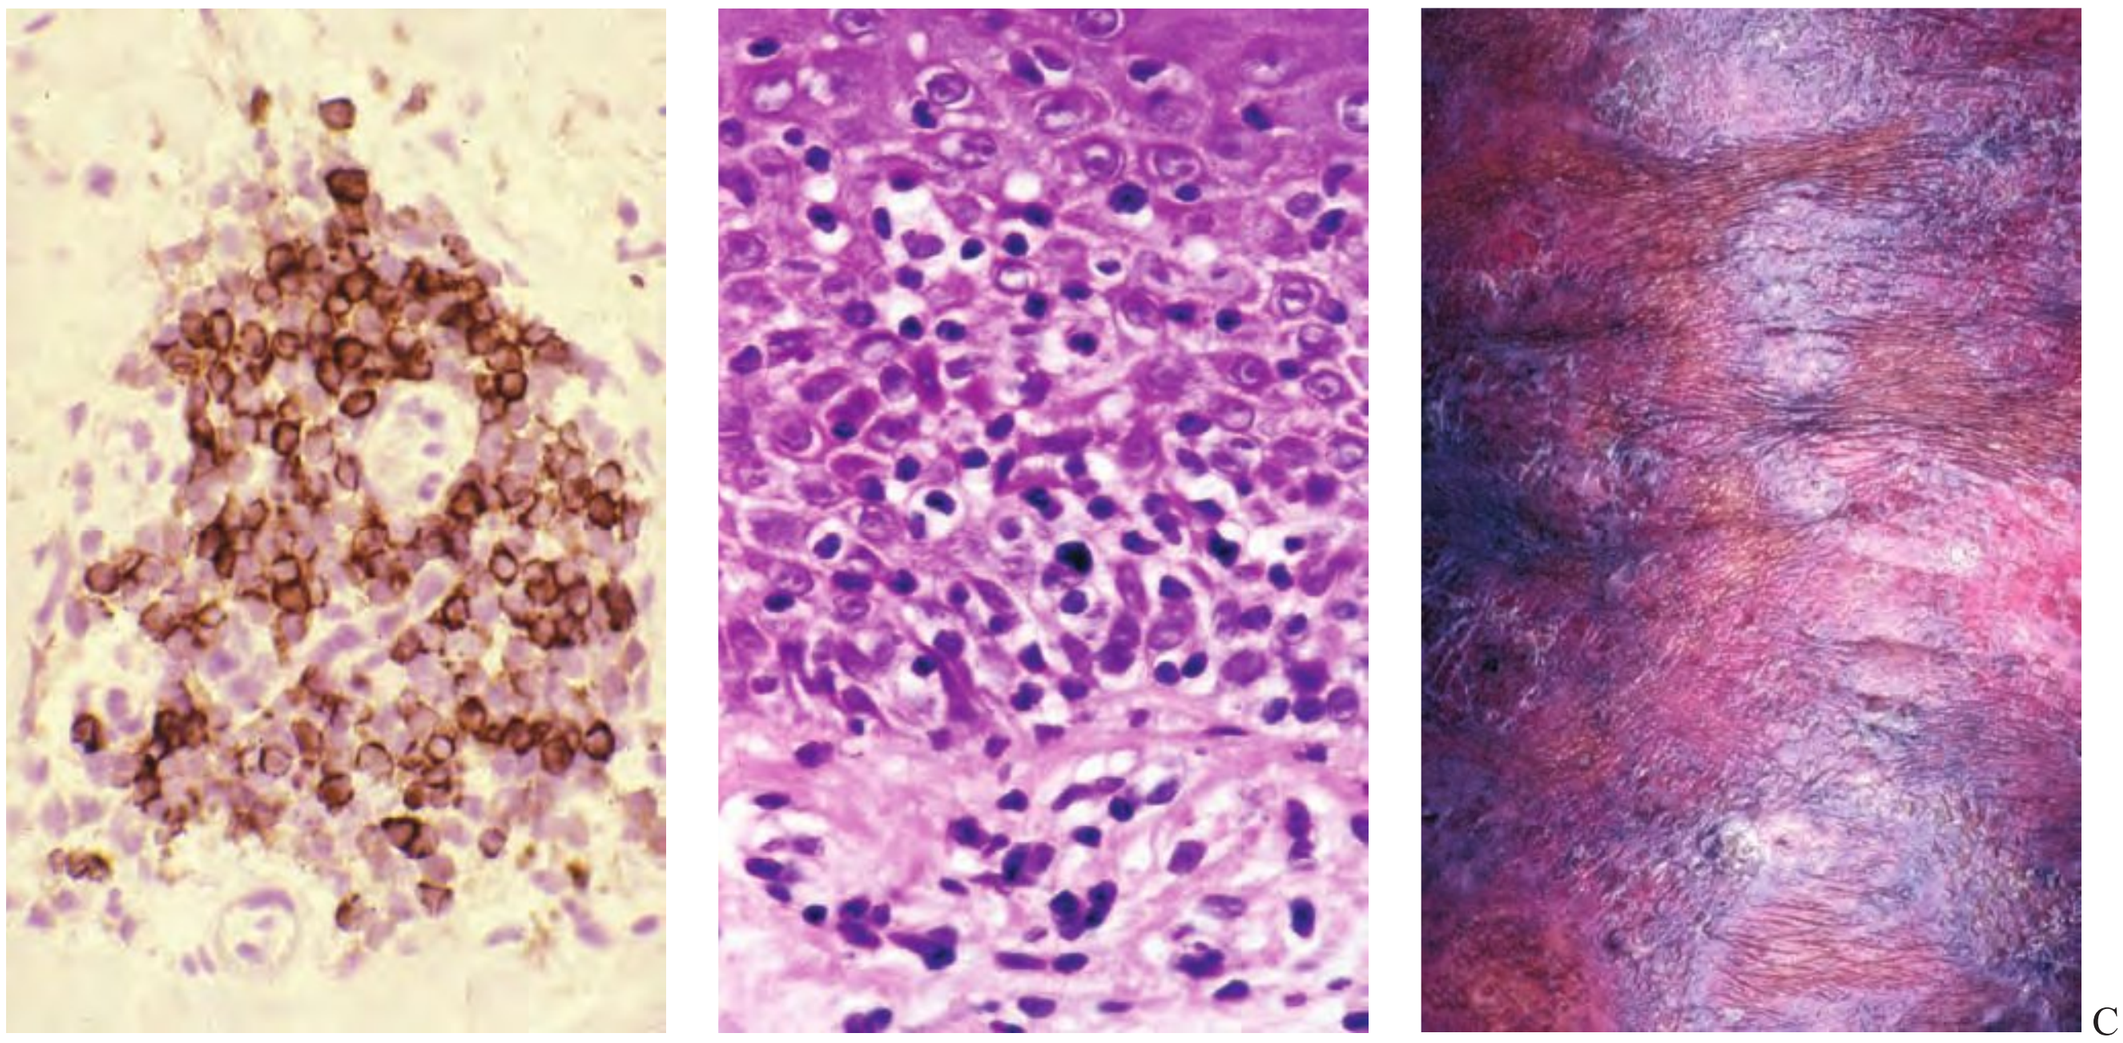
T- and B-cell patterns are potentially helpful in presumptive assignment of cell lineage, but they are not invariable, cannot be used as a reliable surrogate for immunohistochemical detection of lineage-related antigens, and do not permit separation of reactive from dysplastic and malignant (Table 31-2). Although this latter distinction frequently depends on cytology, immunophenotype, and genotype, the architecture or "trafficking patterns" of hematopoietic cells in the skin may also provide insight into the biologic potential for aggressive behavior.



Abnormal Trafficking: Distinction from Inflammation

Skin is a lymphoid organ, and both the epidermal and dermal layers represent interactive immune systems that contribute to and partially regulate inflammatory cell trafficking (7,8). In both T- and B-cell responses in skin, circulating lymphocytes initially adhere to activated endothelium lining dermal postcapillary venules. Migration across the vessel wall results in perivascular or angiocentric dermatitis (Fig. 31-3A). If further migration is stunted, this exclusive angiocentric localization may produce a pattern that may lead to a specified number of differential diagnostic considerations based on correlation with clinical parameters (e.g., as in erythema chronicum migrans). Migration away from the vessel wall is presumably swift enough that in the case of T cells, papillary dermal accumulation and epidermotropism, in addition to a persistent angiocentric pattern, may result. However, activated T cells on an immunologic mission, as in the case of contact hypersensitivity, psoriasis, or cytotoxic dermatitis, generally alter the epidermis as they enter it by way of the cytokines and growth factors that they produce. Thus, reactive T-cell exocytosis is often accompanied by epithelial spongiosis, acanthosis, or apoptosis. In the case of malignant epidermotropic T-cell infiltration, in contrast, the epidermis tends to be "passive," with T-cell infiltration resulting in permissive aggregation of variably atypical lymphocytes within the epidermis (Fig. 31-3B) and sometimes also or exclusively in adnexal epithelium. This infiltration is not generally associated with reactive epithelial alteration in the form of spongiosis or apoptosis but rather may be associated with epithelial injury in the form of localized mucinous degeneration, a potential contributing factor to the development of Pautrier microabscesses and follicular mucinosis that may accompany MF (9). Moreover, as the epidermis becomes more extensively infiltrated, impaired maturation often manifests as clinical abnormalities in scale production. Hence, many T-cell lymphoproliferative disorders will show surface hyperkeratosis that in early stages may mimic dermatitis clinically (Fig. 31-3C).

Infiltration of the skin by reactive B cells often results in a perivascular accumulation of cells usually without significant epidermotropism or papillary dermal/interstitial involvement (i.e., producing a grenz zone of papillary dermal sparing). With persistence of antigenic stimulus, as may occur in the setting of some insect bite reactions, nodular aggregates of B cells may form in order to variably recapitulate the formation of germinal centers within the dermis (Fig. 31-4A). These patterns of infiltration contrast sharply with those of malignant B cells. Although malignant B cells may also form nodules vaguely reminiscent of germinal centers, or even induce the formation of associated reactive B-cell infiltrates, the former tends to show a destructive relationship to preexisting structures (Fig. 31-4B). Accordingly, malignant B cells will frequently infiltrate in an interstitial pattern (versus perivascular), resulting in splaying apart of collagen bundles and mesenchymal cells (e.g., smooth muscle cells forming arrector pili muscles) within the reticular dermis. Moreover, nodular

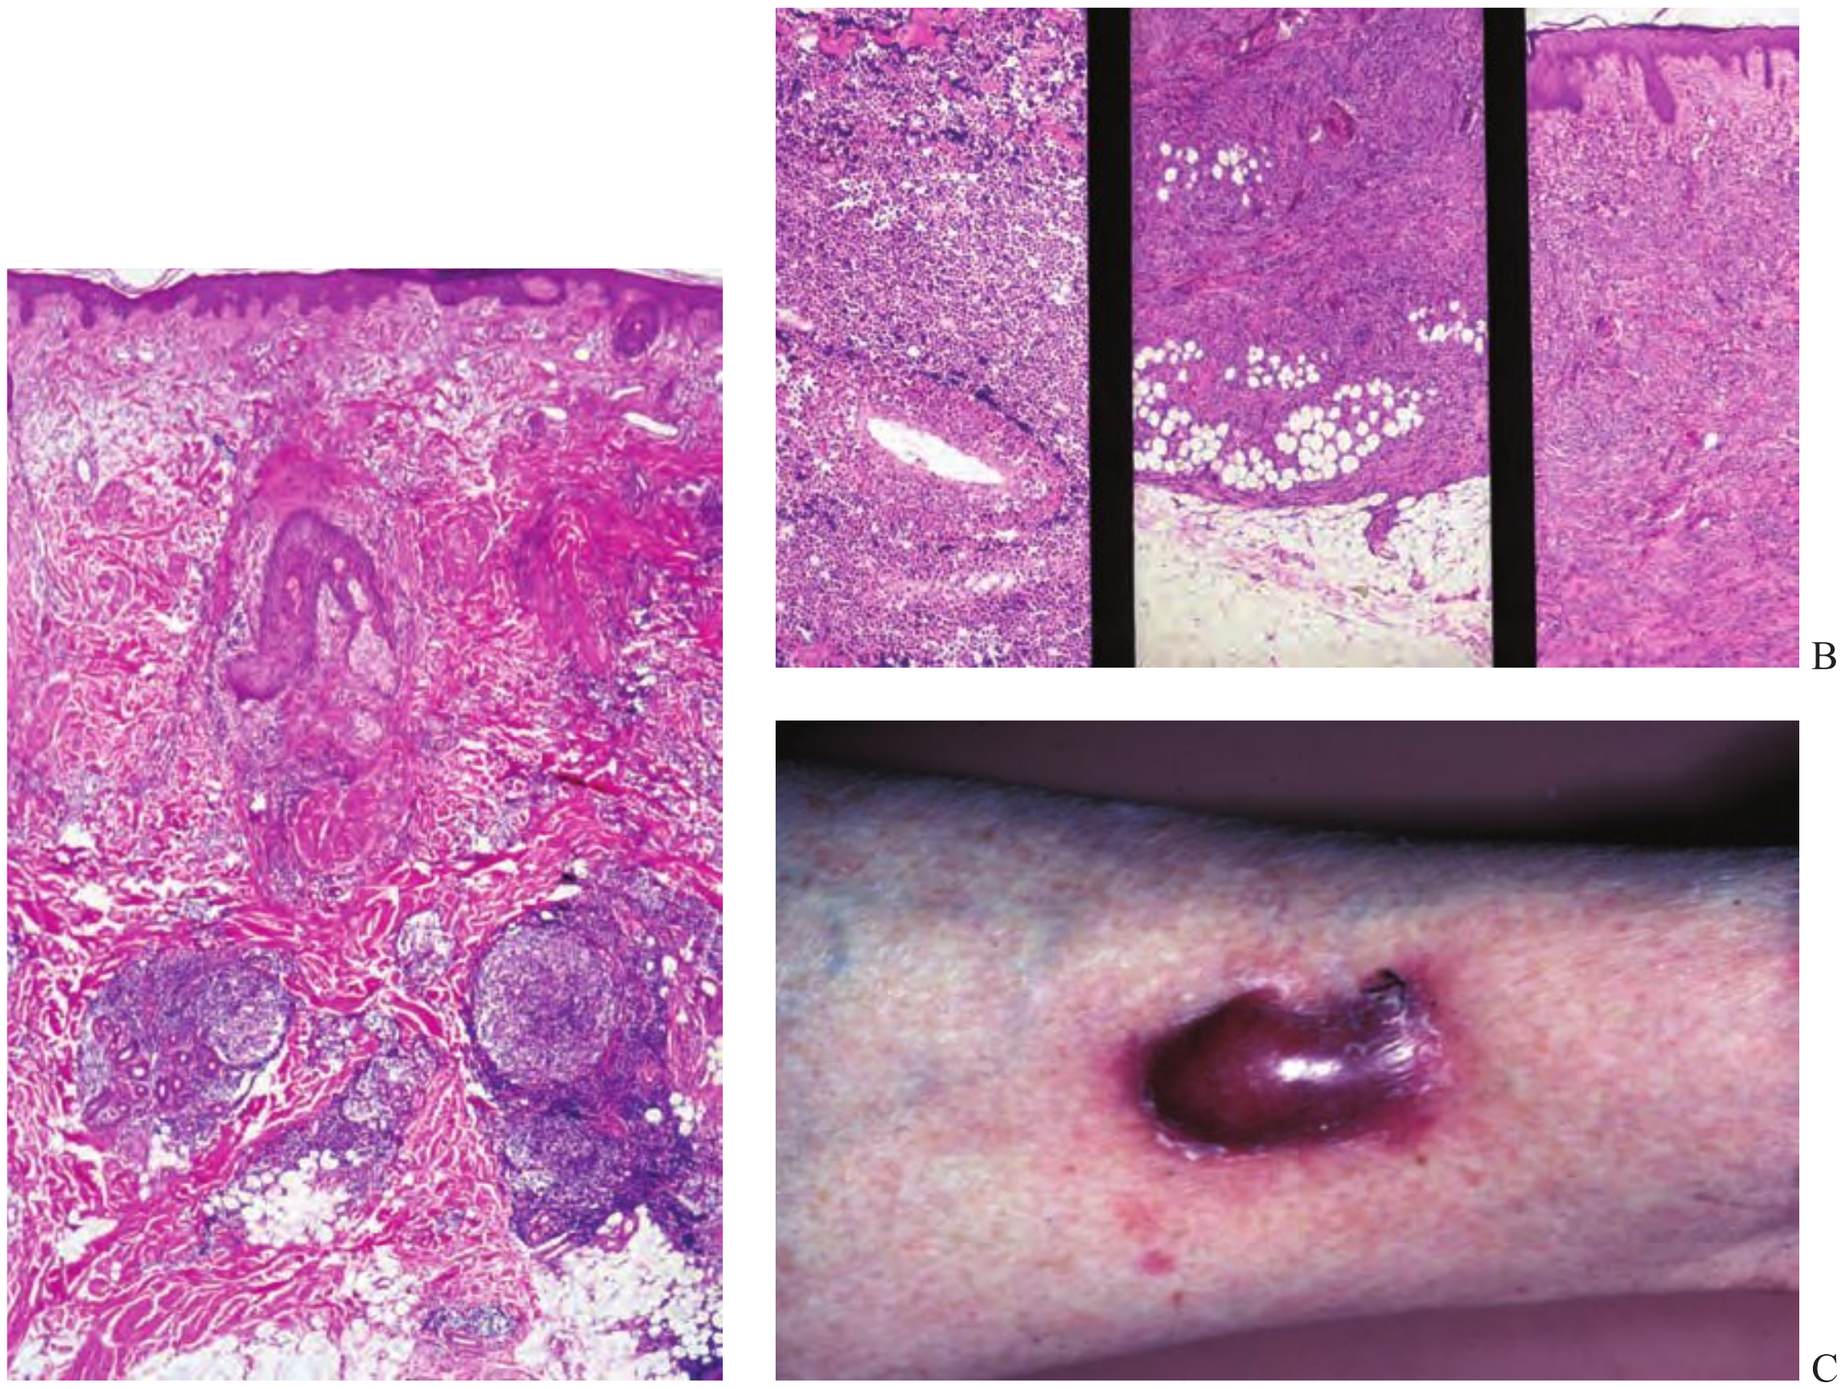


TABLE 31-2 T-Versus B-cell "Trafficking" Pattern

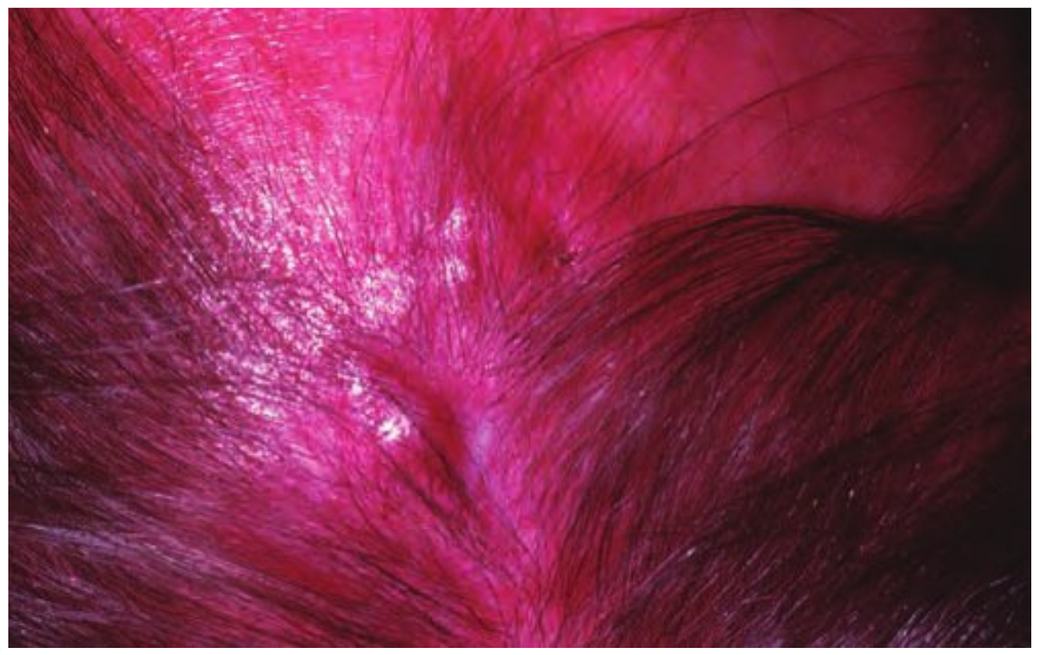
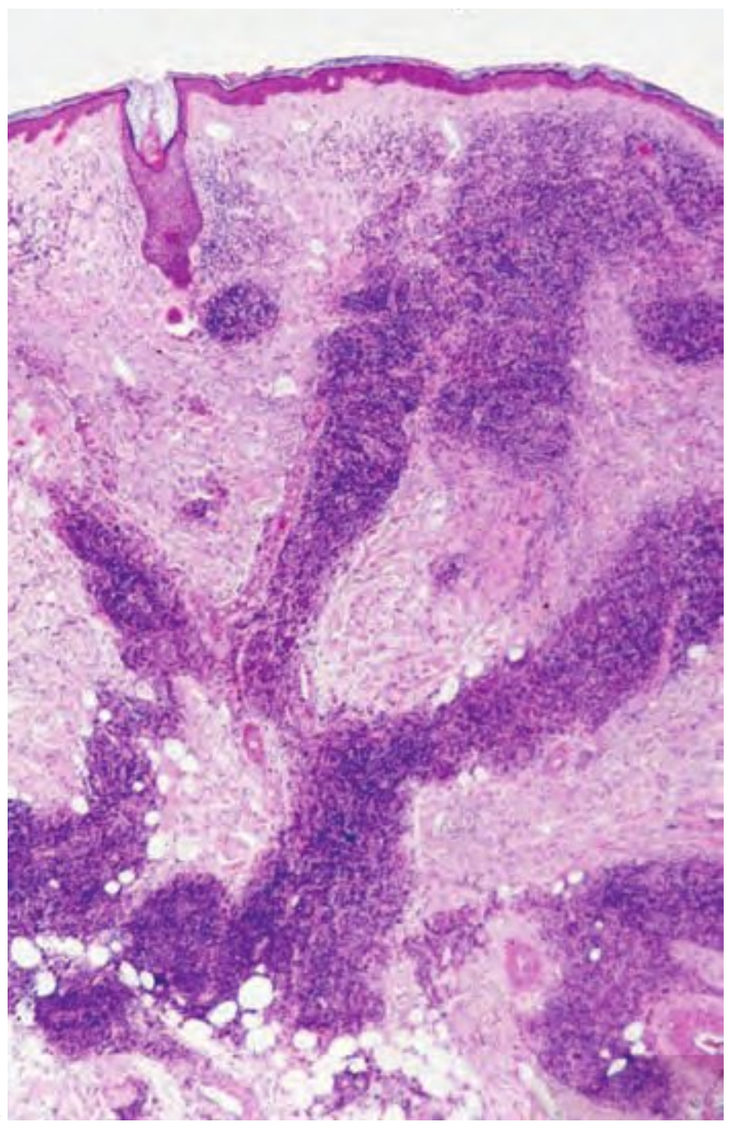
aggregation of malignant B cells tends to displace adnexal epithelium, resulting in their distortion and occasionally in their ischemic destruction in the process.

Circulating leukemic cells, like inflammatory cells, may show a perivascular pattern of infiltration on initial infiltration of skin. However, unlike reactive and malignant T cells, they will avoid epithelial infiltration, and like other malignant cells, they will soon infiltrate in an interstitial pattern within the dermis. This interstitial architecture, albeit suggestive of abnormal trafficking inherent to malignancy, does not invariably correlate with a malignant phenotype. In this regard, it should be recalled that histiocytes in the setting of certain evolutionary stages of palisaded granulomatous dermatitis, lymphocytes in early inflammatory lesions of morphea, and immature myeloid cells in the setting of extramedullary hematopoiesis may also show similar interstitial patterns.

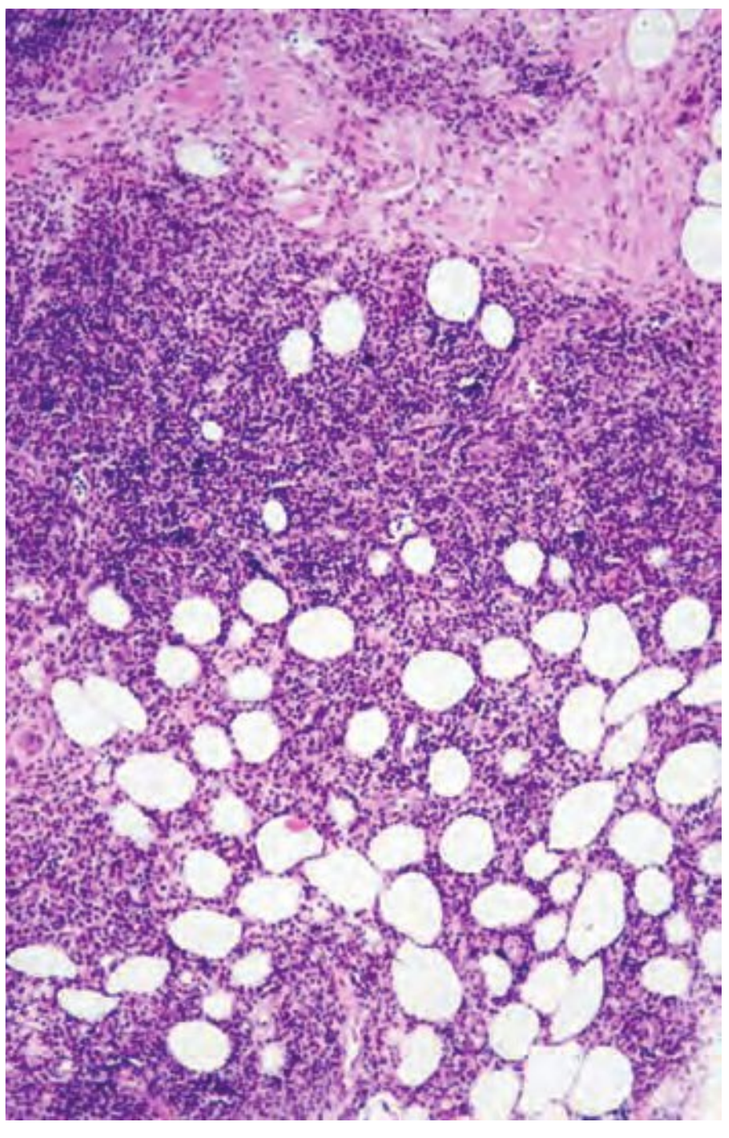


The tendency for progressive dermal infiltration with relative sparing of the epidermal layer in both B-cell and many leukemic malignancies results in clinical lesions that are red to plum colored and covered by thin, shiny (nonkeratotic) epidermal surfaces (Fig. 31-4C).

PRIMARY CUTANEOUS B-CELL LYMPHOPROLIFERATIVE DISORDERS



B-cell Lymphomatoid Hyperplasia



Critical to consideration of B-cell malignancies of the skin is understanding of the patterns and compositions inherent to forms of cutaneous lymphoid hyperplasia where B-cells predominate. Because such lesions have been confused with true lymphomatous infiltrates, the unfortunate term *pseudolymphoma* has been coined, and its use is discouraged for obvious semantic reasons.

Clinical Features. Typically, B-cell lymphomatoid hyperplasia (B-CLH) develops as one or several clustered nodular lesions without evidence of epidermal involvement (e.g., scaling). The head, neck, and trunk are most frequently involved, although any site is potentially vulnerable. The color is often red to

A

B, C

FIGURE 31-5. Clinical and histologic features of B-cell lymphomatoid hyperplasia. A: Clinical lesions. B: Scanning magnification of dermal infiltrate. C: Involvement of deep dermis and subcutis.

purple, and thus the clinical appearance may overlap with that of true B-cell lymphoma (Fig. 31-5A). Lesions may persist for many months before resolution occurs, and on occasion, evolution to lymphoma has been documented.

Histopathology. Infiltrates may show a nodular or diffuse architecture, and although many lesions will be most concentrated in the more superficial dermal layers, equal or preferential involvement of the deeper dermis and subcutis may be seen (Fig. 31-5B, C). This "bottom heavy" pattern of infiltration that by convention has been associated with B-cell malignancies does not reliably permit exclusion of B-CLH. Unlike true B-cell lymphoma, however, hyperplastic B-cell infiltrates generally do not exhibit a pattern of infiltration that destroys preexisting structures (e.g., vessels, adnexae). While hair follicles may be distorted and hyperplastic in certain cases where primary follicular pathology presumably incites the B-cell proliferative response (so-called pseudolymphomatous folliculitis), this is distinct from secondary follicular injury that may be seen in the setting of true lymphoma.

The hallmark of B-CLH is the formation of true lymphoid follicles (Fig. 31-6A). These follicles contain a cytologic continuum of B-cell maturation, and this exhibits lymphocytes with small and large, cleaved and uncleaved nuclear contours (Fig. 31-6B, C), immunoblasts, and tingible-body macrophages (macrophages containing particulate basophilic debris within their cytoplasm), the so-called starry-sky pattern. Mitotic figures and apoptotic cells may be numerous in follicles showing florid evidence of immune activation (Fig. 31-6D). Reactive follicles may show expanded mantle zones, whereas follicle-like structures formed in certain B-cell lymphomas tend to show thinned or absent mantle zones. Because reactive follicles are generally polyclonal, both kappa and lambda light chains are expressed by immunohistochemistry. Moreover, immunoglobulin gene rearrangements are usually not present, although clonal proliferation within B-CLH has been described (10), and this feature alone should not be used to separate reactive from malignant infiltrates of B cells.

Histogenesis. The cause is often unknown, although persistent localized immune responses to injected or extruded antigens, as may occur with arthropod bite assaults or even in the context of follicular cyst rupture, have been implicated. Certain drugs may also result in B-cell as well as T-cell pattern cutaneous infiltrates that may mimic lymphoma both clinically and histologically (11,12).

Differential Diagnosis. B-CLH must be differentiated from follicle center lymphoma, which is a lesion that generally shows a follicular pattern of dermal infiltration. Immunohistochemical and molecular analyses generally permit differential in difficult cases where cytologic features that separate reactive from neoplastic lymphoid follicles are not present (see below). It is noteworthy that establishing the presence of reactive germinal centers in a skin infiltrate does not definitively exclude lymphoma, because some forms of B-cell lymphoma are typically associated with admixed reactive follicles (e.g., extranodal marginal cell lymphoma). Moreover, as has been mentioned, patients with established B-CLH must be monitored over time in recognition of the fact that on occasion, this presentation will be a harbinger of eventual development of a clonal B-cell malignancy. Numerous eosinophils may be observed in association with some forms of B-cell cutaneous lymphoid hyperplasia, including lesions of angiolymphoid hyperplasia with eosinophilia and its localized variants.

Table 31-3 summarizes distinguishing characteristics that may be useful in differential diagnosis of benign vs. malignant B-cell lymphoproliferative disorders in the skin.

TABLE 31-3 Salient Differential Features of Reactive and Neoplastic Cutaneous B-cell Proliferations

	B-cell lymphomatoid hyperplasia	B-cell lymphomas
Distribution of infiltrate	Often top heavy	Often bottom heavy
Pattern of infiltrate	Nodular/Diffuse	Nodular/Diffuse/Interstitial
Destructive growth	Absent (adenexae spared)	Present (destructive growth affecting adnexae)
Composition of infiltrate	Mixed	Monomorphous with atypia
	Polyclonal	Clonal
	Light chain unrestricted	Light chain restricted
Follicle formation	Benign polarized follicles with expanded mantle zone	Loss of follicular polarization with thinned/absent mantle zone
Mitotic activity	Only in germinal centers	Both within and outside germinal centers
Prominent vasculature	Present	Absent

C: One-micron, toluidine blue– stained section of germinal center composed of admixture of lymphocytes in various stages of maturation. D: Reactive germinal center characterized by mitotically active follicular center lymphocytes.

Primary Cutaneous Follicle Center Lymphoma

Primary cutaneous follicle center lymphoma (PCFCL), one of the most common types of primary B-cell lymphoma of the skin (comprising approximately 11% of cutaneous lymphoma [1,13]), is a neoplasm derived from follicular center B cells (centrocytes/cleaved follicular center cells [FCCs]) and centroblasts/noncleaved FCCs.

Clinical Features. PCFCL occurs primarily as one to several red- to plum-colored nodules (Fig. 31-7A) often on the head and trunk of the elderly without sex predilection and, unlike overt nodal follicular lymphoma, tends to remain localized in the skin where local therapy may be effective (14). Lesions with exclusive skin involvement tend to show a more favorable prognosis (5-year survival >95%) than is the case when skin is

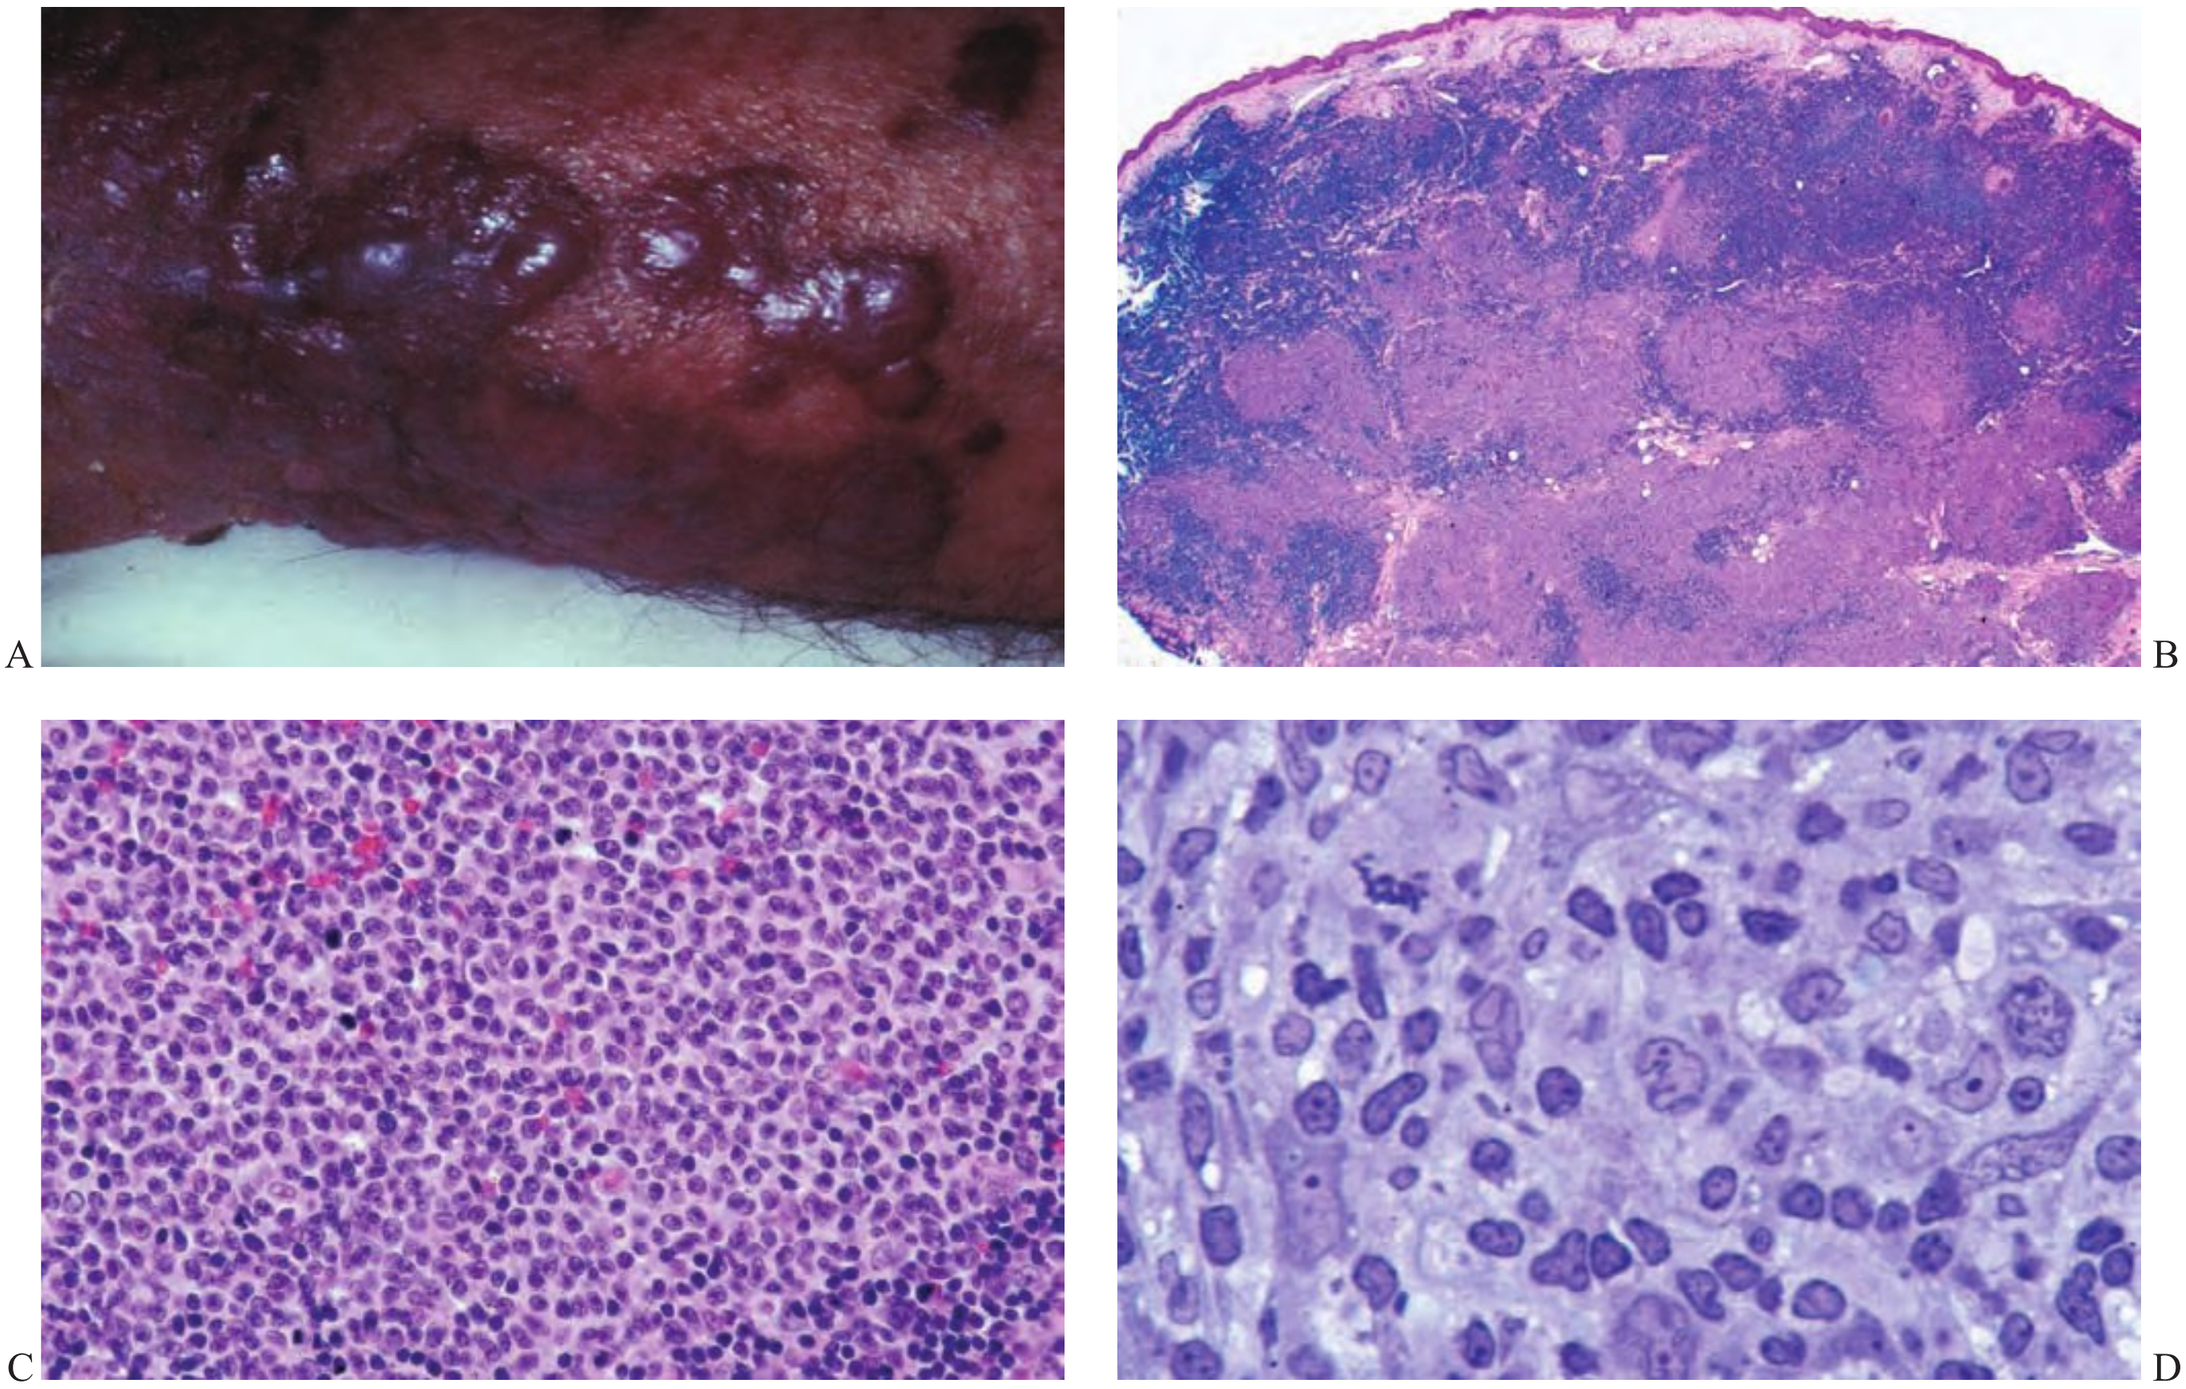


FIGURE 31-7. Primary cutaneous follicle center cell lymphoma. A: Clustered plum-colored nodules covered by thinned, glistening epidermal layer. B: Scanning magnification showing coalescent nodules forming follicle-like architecture. C: Higher magnification of malignant centrocytes and centroblasts. D: One-micron, toluidine blue–stained section showing cytologic features of centrocytes and centroblasts.

infiltrated secondary to nodal disease (15,16). Although recurrences are often observed, the overall prognosis is good (5-year survival of 95%), with spread beyond the skin being exceedingly rare.

Histopathology. Primary skin involvement (17,18) presents as nodular dermal infiltrates that may often extend to the subcutis (19). The dermal nodules initially may resemble germinal centers (17) but are composed of monomorphic neoplastic cells devoid of mantle zones (17). The neoplastic follicles are depolarized and do not show a prominent starry-sky pattern, and other regions may be characterized by a more diffuse pattern with associated sclerosis. Based on these architectural features (Fig. 31-7B), lesions may be classified as follicular (>75% follicular architecture), follicular and diffuse (25% to 75% follicular architecture), and minimally follicular (<25% follicular). Rarely, exclusively diffuse growth pattern may also be seen, where the diagnosis must be based on cellular composition. Cytologically, two types of neoplastic lymphocytes are observed in follicular lymphoma (Fig. 31-7C, D). The predominant cell is the centrocyte, or cleaved FCC, a small- to medium-sized lymphocyte with scant cytoplasm and with angulated, infolded, or twisted nuclear contours and inconspicuous nucleoli. Similar but often smaller centrocytes may also be present in the interfollicular regions. Centroblasts, or noncleaved FCCs, are larger transformed lymphocytes with round to oval nuclei with vesicular chromatin and several visible nucleoli. On occasion, an even admixture of centrocytes and centroblasts, or even a predominance of centroblasts, may be encountered. Unlike nodal follicular lymphoma, histologic grading of PCFCL is not advised by the WHO/EORTC, as the growth pattern and number of blast cells do not appear to have prognostic relevance (20–22).

Histogenesis. Germinal center B cells are believed to represent the cell of origin of follicle center lymphoma. Tumor cells tend to express surface immunoglobulins on frozen sections (immunoglobulin IgM, IgD, IgG, and rarely IgA); BCL6; CD10; and the B-cell associated markers CD20, CD19, CD22, and CD79a. Most cases are negative for CD5 (in

contrast to chronic lymphocytic leukemia [CLL]/small lymphocytic lymphoma [SLL]). Although BCL2 expression is useful in differentiating neoplastic follicles in extracutaneous sites from normally negative hyperplastic germinal centers, it should be noted that in PCFCL, BCL2 is frequently negative. The finding of BCL2 positivity in a follicular lymphoma at a cutaneous site should raise the strong suspicion of secondary cutaneous involvement of nodal follicular lymphoma. The t(14;18)(q32,q21) rearrangement of the BCL2 gene typical of nodal follicular lymphomas is not frequently detected in PCFCL, suggesting that these two entities may be separate diseases (23,24). Rearrangement of immunoglobulin heavy and light chain genes is the rule (Fig. 31-8), and cytogenetic abnormalities affecting the immunoglobulin heavy chain locus are identified (25).

Differential Diagnosis. PCFCL must be differentiated from nodal follicular lymphoma with secondary cutaneous involvement, cutaneous lymphoid hyperplasia of the B-cell type (B-CLH) (26,27), and other conditions associated with the formation of reactive follicles (e.g., primary cutaneous marginal zone lymphoma [PCMZL] and mantle cell lymphoma [MCL]) (Table 31-4). As mentioned previously, in contrast to nodal follicular lymphoma, PCFCL frequently lacks BCL2 immunoreactivity and t(14;18)(q32;q21). B-CLH often is clinically manifested by one or more erythematous to plum-colored plaques and nodules. Any site may be affected, but there is a predilection for skin of the face and scalp. The underlying cause is often unknown, although speculated etiologies include reactions to topical agents or to injected antigens, as may occur in insect bites, or localized infection

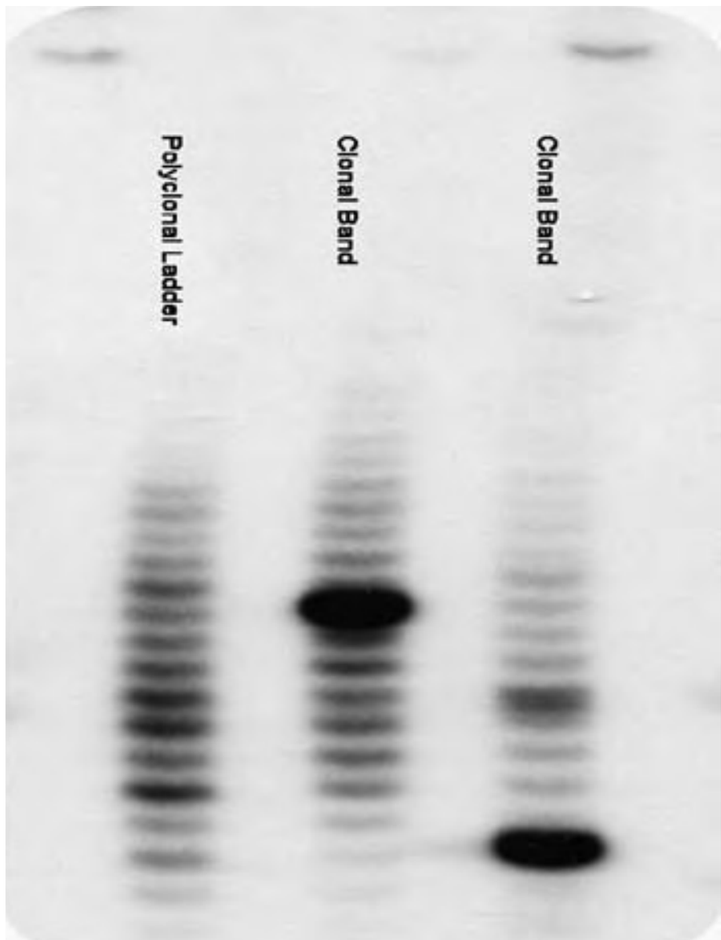

FIGURE 31-8. PCR analysis for clonal IgH gene rearrangements. The left lane shows a polyclonal ladder with no evidence of gene rearrangement, whereas the middle and right lanes show dominant bands in a background polyclonal ladder, indicating clonal IgH gene rearrangement in two cases of B-cell lymphoma.

with the spirochete *Borrelia burgdorferi* (28–30). Histologically, there may be a nodular to diffuse interstitial infiltrate that often involves the deep dermis and occasionally the subcutis. Germinal center formation may be variably pronounced, but occasionally these structures are indistinguishable from those

TABLE 31-4 Morphologic and Immunohistochemical Differential Diagnosis of Cutaneous B-cell Lymphoproliferative Disorders With a Follicular Growth Pattern

	Follicular growth pattern		Immunohistochemical markers

encountered in reactive lymph nodes. Specifically, in addition to smaller lymphocytes with cleaved nuclei (centrocytes) and larger lymphocytes with noncleaved nuclei (centroblasts), they will contain an admixture of immunoblasts, antigen-presenting follicular dendritic cells, and macrophages containing phagocytized cellular debris (tingible body macrophages). Moreover, there tends to be aggregation of centroblasts and tingible body macrophages at one pole of the hyperplastic follicle and of centrocytes at the opposite pole, producing darker and lighter-staining regions, respectively. Immunohistochemistry will reveal both kappa and lambda immunoglobulin light chain expression in B-CLH, as opposed to monotypic expression in follicular lymphoma. Genotypic analysis may also be of assistance in establishing a diagnosis of B-CLH when it fails to reveal clonal immunoglobulin gene rearrangements. However, it must be noted that on occasion, cases of B-CLH appear to evolve over time into more aggressive clonal processes or may harbor a malignant clone in the midst of otherwise reactive histologic and immunophenotypic changes (31). While PCFCL displays a BCL2^{-}/CD5^{-}/CD10^{+}/BCL6^{+} phenotype, PCMZL cells are BCL2^{+}/CD5^{-}/CD10^{-}/BCL6^{-}. MCL expresses CD5 and cyclin D1. Morphologic distinction between PCFCL with a purely diffuse pattern from diffuse large B-cell lymphoma, leg type (PCDLBCL, leg type) is difficult, especially in cases where centroblasts predominate in the infiltrate. Immunohistochemical profiling is most useful in this scenario. Although both entities express BCL6, CD10 is often negative in the latter. In addition, PCFCL lacks BCL2 and multiple myeloma-1/interferon regulatory factor-4 (MUM-1/IRF-4) expression, both of which are strongly positive in PCDLBCL, leg type (32) (Table 31-5).

Primary Cutaneous Marginal Zone B-cell Lymphoma

PCMZL belongs to a group of extranodal marginal zone B-cell lymphomas, referred to as *mucosa-associated lymphoid tissue* (MALT) lymphoma, in which these neoplasms were first recognized (33) and includes cases with high numbers of plasmacytoid cells previously designated as primary cutaneous immunocytoma. PCMZL comprises approximately 7% of all cutaneous lymphoma cases (1).

Clinical Features. MALT lymphoma is responsible for <10% of all B-cell lymphomas, and the gastrointestinal tract is the primary site of involvement in 50% of cases (33). Other sites may be affected, with skin infiltration noted in 11% of cases (32). The male-to-female ratio is 1.0:1.2, and the median age of occurrence is 61 (34). Chronic lymphoid hyperplasia caused by antigenic stimulation may be a predisposing feature, with *Helicobacter pylori*–associated

chronic gastritis (35,36), Hashimoto thyroiditis (37–39), and autoimmune sialadenitis (40,41) representing important examples. Other examples of MALT lymphoma being associated with an infectious agent are orbital lymphoma (*Chlamydia psittaci*) and cutaneous MALT lymphoma (*B. burgdorferi*) (42–45). Patients with hepatitis C have a higher incidence of splenic marginal zone lymphoma (46). Conceptually, MALT lymphomas are divided into a "native" type that arises in extranodal anatomic compartments where lymphoid tissue is normally present and an "acquired" type that emanates from tissue that normally lacks lymphoid tissue. In general, MALT lymphoma is an indolent form of lymphoma (with a 5-year survival close to 100%) that responds well to a variety of therapeutic modalities, including eradication of chronic antigenic stimulus in cases where infectious agents are implicated.

Histopathology. A characteristic feature of PCMZL is the tendency of the neoplastic cells to infiltrate around reactive B-cell follicles. This infiltration is in a marginal zone distribution (external to the mantle zone), and expansion of these areas may result in confluent zones that displace and separate the reactive follicles (47,48). Marginal zone B cells have small- to medium-sized nuclei with slightly irregular contours and inconspicuous nuclei and thus resemble centrocytes (Fig. 31-9). The cytoplasm is variably visible and pale, with cells showing less cytoplasm resembling small lymphocytes and those with more ample cytoplasm acquiring a monocytoid appearance. Variable plasmacytic differentiation may also be present. A minority population of centroblasts and immunoblasts may also be observed. Colonization of the reactive germinal centers by neoplastic cells may occasionally produce a picture that initially resembles follicular lymphoma.Transformation to diffuse large B-cell lymphoma (DLBCL) (see below), although rare, has been described.

Histogenesis. The cell of origin is speculated to be a post-germinal center marginal zone B cell. Tumor cells express immunoglobulins (most often IgM) and show light chain restriction. The typical immunophenotype is $CD20^+$, $CD79^+$, $CD21^+$, $BCL2^+$, $BCL6^-$, $CD5^-$, $CD10^-$, and $CD23^-$, although a marker entirely specific for MALT lymphoma does not presently exist. It is worth noticing that abnormal BCL10 expression common to MALT lymphomas is absent in PCMZL (49). Immunoglobulin genes are rearranged. More recently, understanding of the underlying genetic abnormalities in MALT lymphoma has increased (43,45,50,51). In contrast to gastric MALT lymphomas, t(11;18)(q21;q21), in which the apoptosis inhibitor gene API2 on chromosome 11 partners with the MALT1 gene on chromosome 18, has not been observed in PCMZL (25,52,53). Instead, a novel t(14;18)(q32;q21) recurrent translocation involving IgH and MALT1 was documented in about one third of cases of PCMZL (25).

Differential Diagnosis. The differential diagnosis includes other small B-cell lymphomas as well as B-CLH. Absence of CD5 and cyclin D1 are useful in separating PCMZL from MCL, absence of CD5 alone in excluding B-CLL/SLL, and absence of CD10 and BCL6 in ruling out follicular lymphoma. Presence of expanded interfollicular zones by B cells with cytologic and immunophenotypic features of PCMZL should distinguish this entity from most cases of B-CLH where interfollicular regions, if expanded, should contain a predominant population of T cells (Table 31-4).

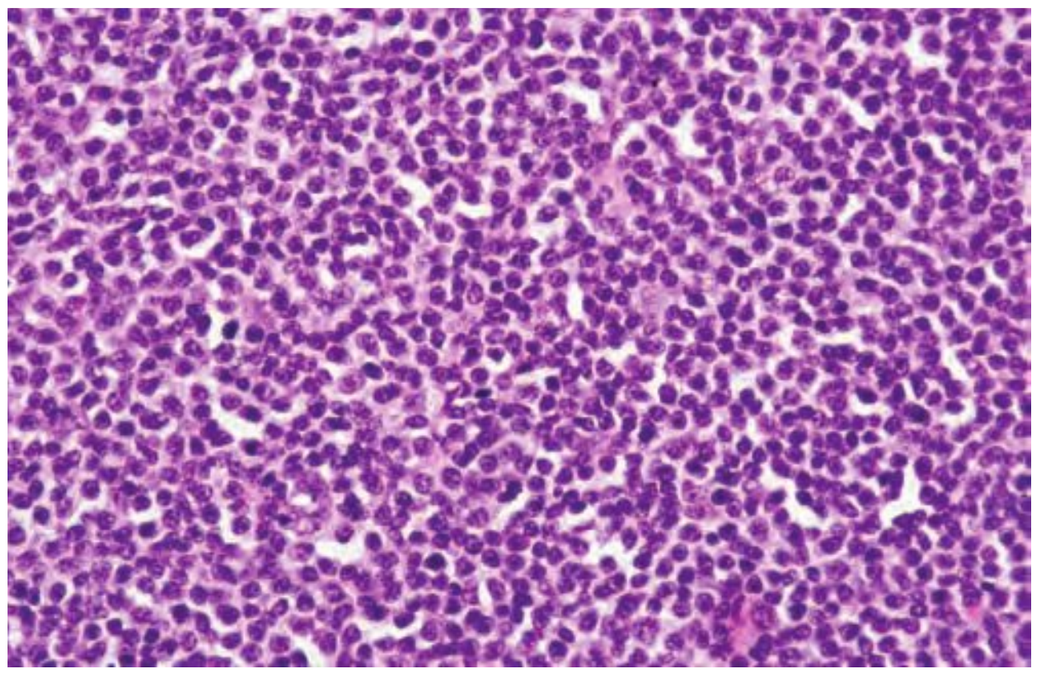

FIGURE 31-9. Extranodal marginal B-cell lymphoma (MALT lymphoma). The interfollicular confluent infiltrate is composed of B cells that resemble centrocytes.

Primary Cutaneous Diffuse Large B-cell Lymphoma, Leg Type

Previously, PCLBCL, leg type was not recognized by the WHO classification as an entity, and cases were incorporated into the general group of DLBCL. The WHO/EORTC consensus classification now defines PCLBCL, leg type as a primary cutaneous large B-cell lymphoma with a predominance of centroblasts and immunoblasts.

Clinical Features. Although the disease typically presents on the leg of elderly women, lesions with a similar morphology and phenotype can arise at any cutaneous site. The overall prognosis is poor, with a 5-year survival of 55% and a tendency to disseminate to extracutaneous sites. Ulceration, primary manifestation on the leg, or multiple lesions at presentation are associated with adverse prognosis (54,55).

Histopathology. Histopathologically, PCLBCL, leg type exhibits a dense monotonous dermal infiltrate of predominantly medium-sized to large cells with round (noncleaved) nuclei, prominent nucleoli, and frequent mitoses resembling centroblasts and/or immunoblasts obliterating the adnexae. Focal epidermotropism with Pautrier-like microabscesses may be seen (56) and should be distinguished from cutaneous T-cell lymphoma (CTCL). Extension into the subcutis may be observed.

Histogenesis. PCLBCL, leg type has a B-cell differentiation profile of post-germinal center (activated) B cells (57).

Consistent with this, the neoplastic cells strongly express MUM-1/IRF-4 and BCL2 but not CD10. Most cases also express BCL6, a marker for B-cell germinal center differentiation. Cytogenetic studies have demonstrated frequent translocations, similar to those in systemic DLBCL, involving IgH, myc, and bcl-6 loci (58).

Differential Diagnosis. Differential diagnosis includes PCFCL, diffuse type and PCLBCL, other (Table 31-5). Cytomorphology may provide clues to differential diagnosis (cleaved small- to medium-sized centrocytes with inconspicuous nucleoli in PCFCL vs. large, round centroblasts with prominent nucleoli in PCLBCL). Occasionally, cases of PCFCL may exhibit an admixture of centrocytes and centroblasts or even predominance of centroblasts. In the latter scenarios, immunohistochemical profiling is paramount for diagnosis. In contrast to PCDLBCL, leg type, which strongly expresses BCL2 and MUM-1/IRF-4, PCFCL, diffuse type is negative for both markers. Cases with a prominent centroblast component but lacking BCL2 expression are currently classified as DLBCL, other under the new WHO/EORTC consensus classification (24).

Primary Cutaneous Diffuse Large B-cell Lymphoma, Other

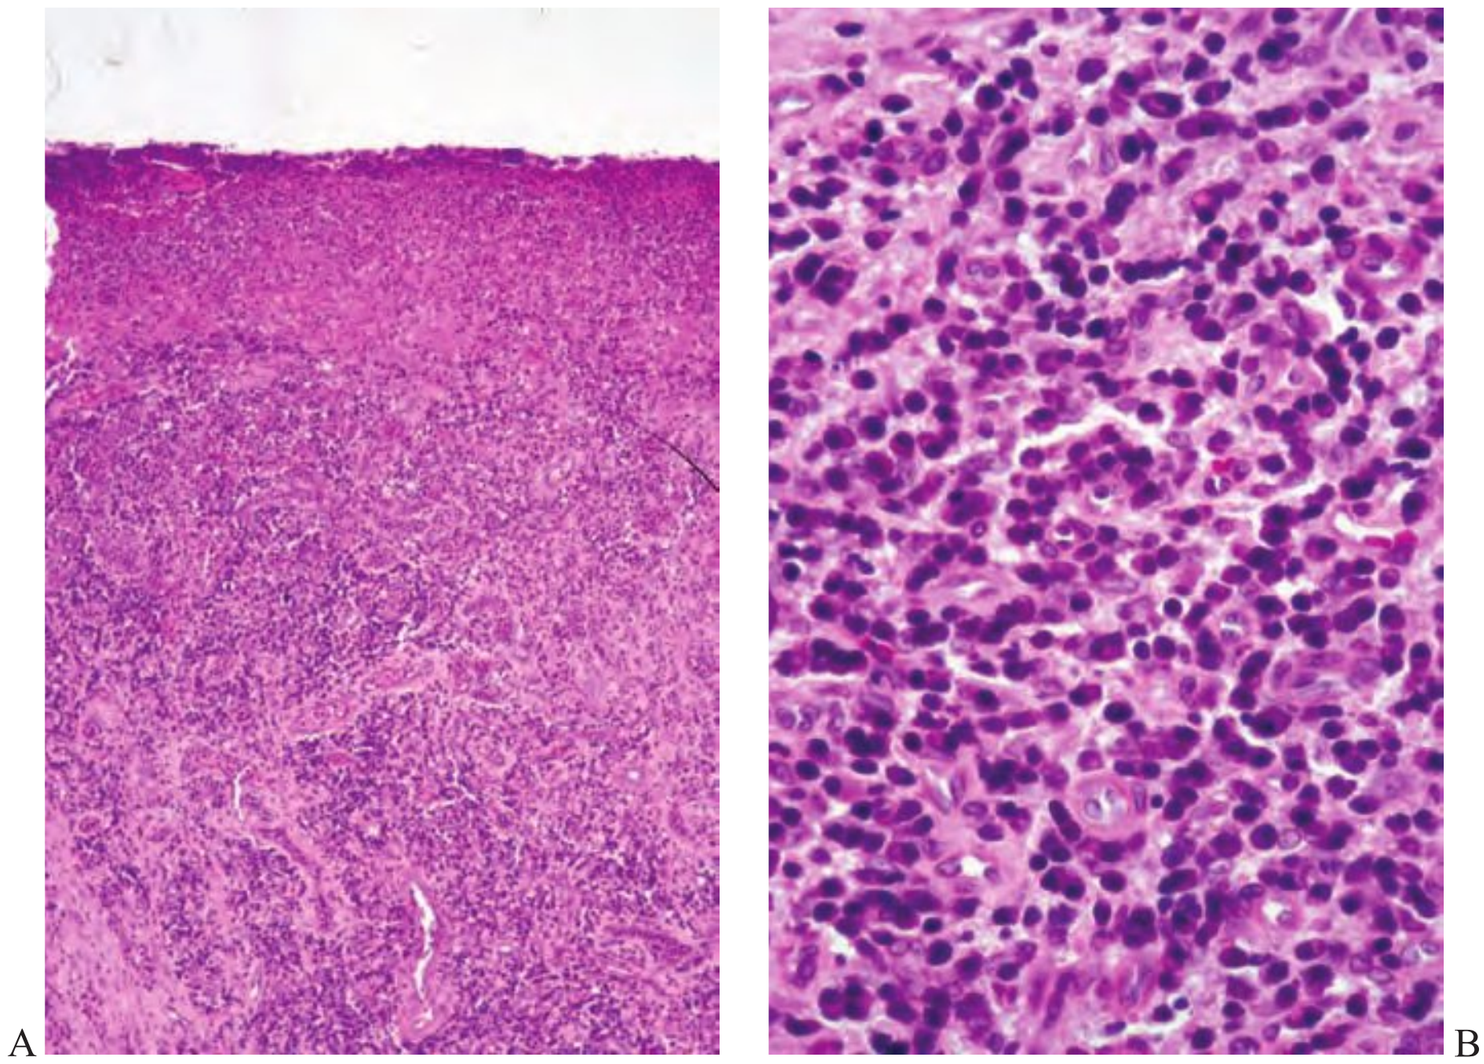
Primary cutaneous diffuse large B-cell lymphoma, other refers to rare cases of PCLBCL that do not fit the diagnostic criteria for PCFCL and PCLBCL, leg type (i.e., BCL2-negative PCDLBCL with centroblastic round-cell morphology). These include rare cases of T-cell/histiocyte-rich DLBCL, where Reed-Sternberg–like large B cells with clear cytoplasm and multilobular nuclei scatter within a background of small reactive T cells and epithelioid histiocytes (59,60). The large neoplastic cells express B-cell markers CD19, CD22, and CD79a, and display light chain restriction. In contrast to Hodgkin's lymphoma (HL), the Reed-Sternberg–like cells are negative for CD15 and CD30 (61). The IgH gene rearrangement may be difficult to demonstrate due to the small number of neoplastic cells as well as admixed reactive B cells. Despite that the WHO/EORTC classification defines PCLBCL, other as a separate entity, it is unclear whether these represent a BCL2-negative variant of PCDLBCL, leg type or a large cell variant of PCFCL, diffuse type (62). Further follow-up studies are required to clarify whether these cases indeed show distinct clinicopathologic features that warrant distinction as a disease entity (62).

Extraosseous Plasmacytoma

Extraosseous plasmacytoma is a neoplasm of plasma cells that occurs at primary sites other than bone marrow and as such represents only a small percentage of all plasma cell neoplasms (63).

Clinical Features. The majority of affected individuals are middle-aged adult males (male-to-female ratio is 2:1). Although lesions may present in skin, most such tumors occur in tissues of the oropharynx, nasopharynx, and nasal sinuses as well as the larynx (64). Approximately 15% to 20% of patients will have a monoclonal gammopathy, but neoplastic cells, by definition, spare the bone marrow and peripheral blood. Prognosis seems to be related primarily to the presence of solitary versus multiple lesions, with the former responding well to either surgical excision or radiotherapy and the latter associated with a significant rate of mortality.

Histopathology. There is diffuse to nodular dermal infiltration by mature and occasionally less differentiated (plasmablastic) plasma cells (Fig. 31-10A). Occasional cells may have polylobated nuclear contours, nucleoli, and/or binucleation (Fig. 31-10B). It is of note that nuclear immaturity and pleomorphism tend not to occur in the setting of reactive plasma cell infiltrates. The cytoplasm of the neoplastic plasma cells may contain a variety of inclusions usually related to abnormal accumulation of immunoglobulin, including round eosinophilic (Russell) bodies. However, such cytoplasmic changes are not specific for neoplastic plasma cells. In cases where systemic dissemination occurs or when primary myeloma involves skin secondarily, abnormal plasma cells may be detected in bone marrow aspirates (Fig. 31-10C).



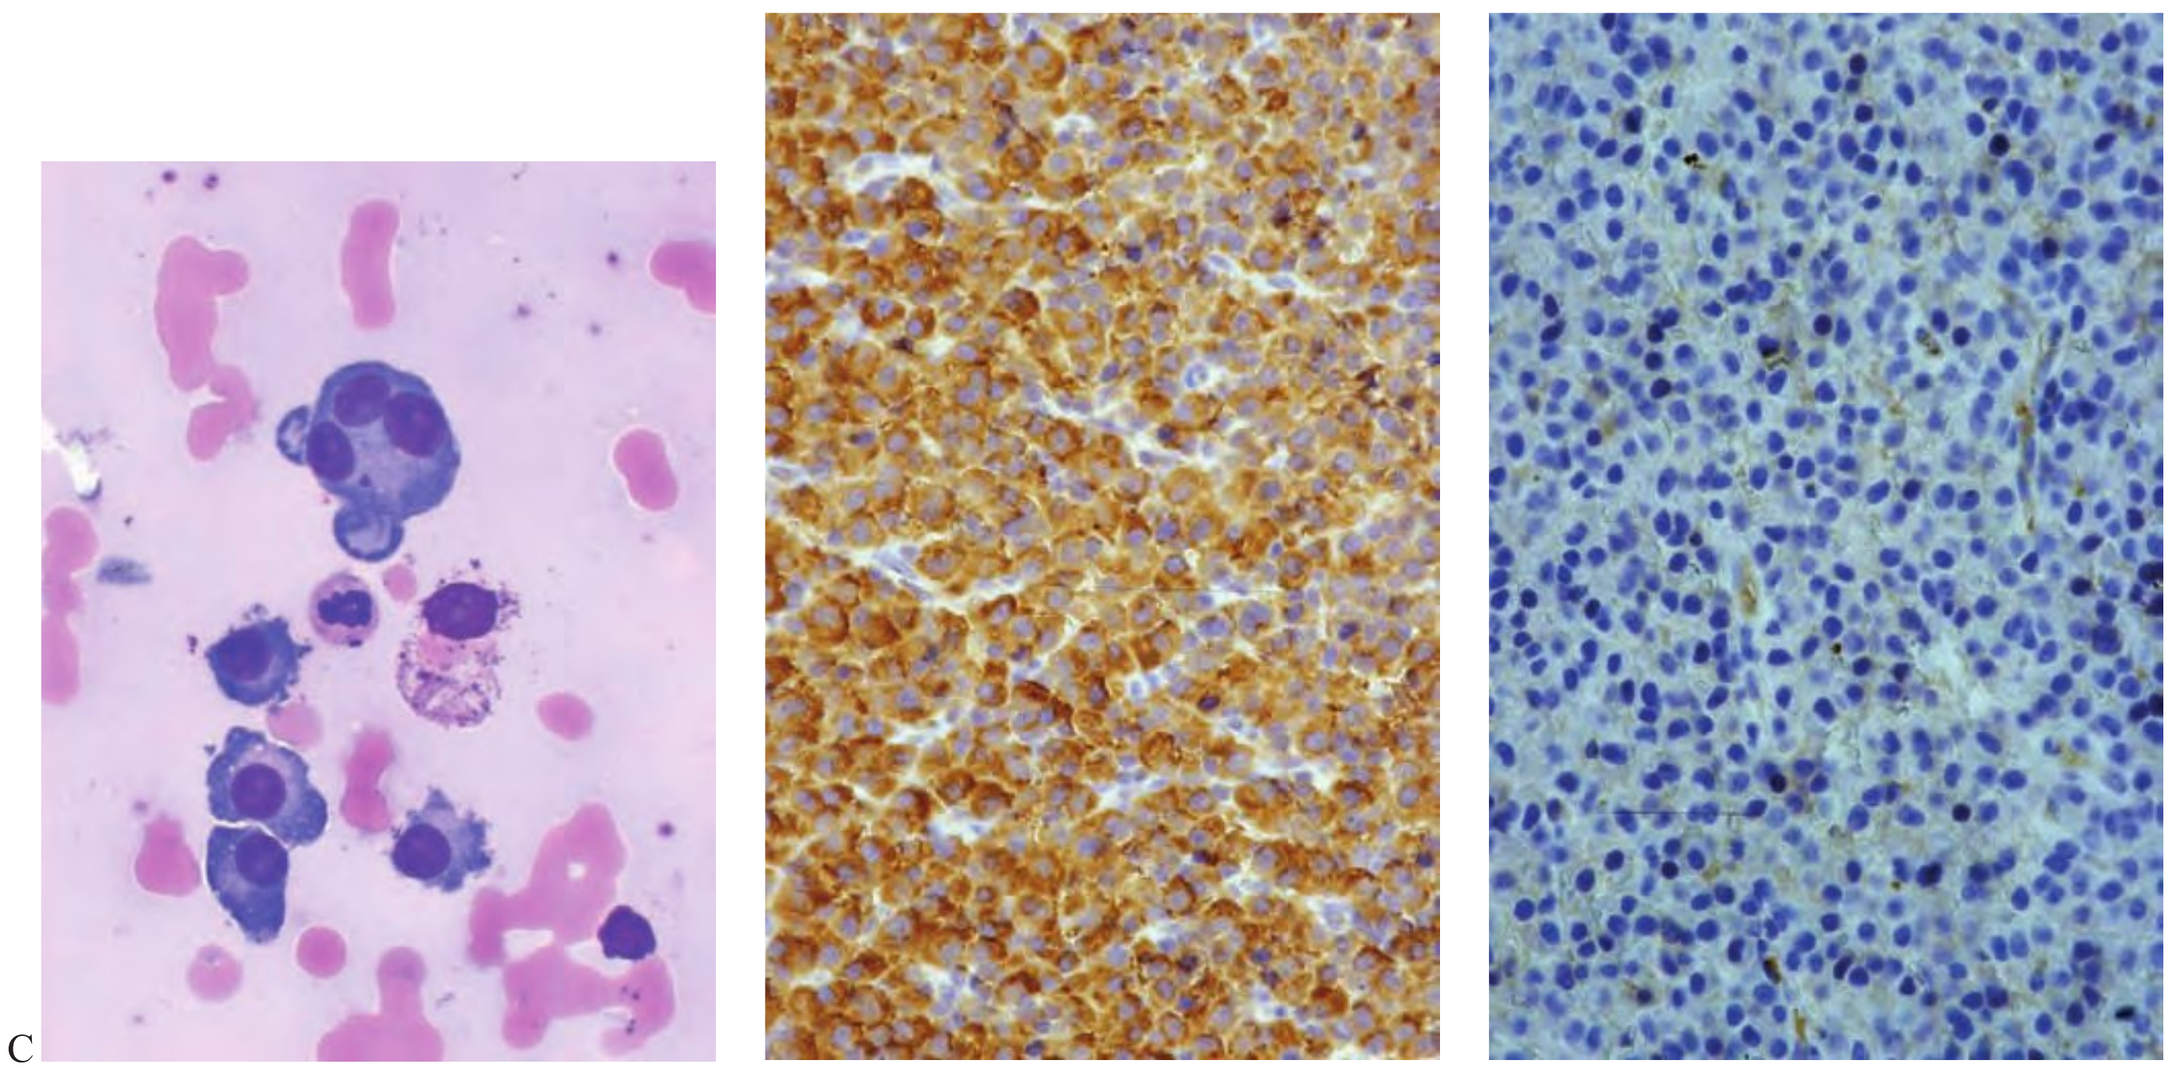
Histogenesis. Clonal transformation of a peripheral plasma cell is the most likely cell of origin. A key feature, therefore, is the expression of monotypic cytoplasmic immunoglobulin and light chain restriction that, unlike cell surface-associated monotypic immunoglobulin in B-cell lymphomas, is generally demonstrable in formalin-fixed, paraffin-embedded material (Fig. 10D, E), CD38 and CD79a are usually expressed, although most but not all plasma cells lack pan-B-cell antigens, CD19 and CD20. Molecular studies generally reveal rearrangement of immunoglobulin genes.

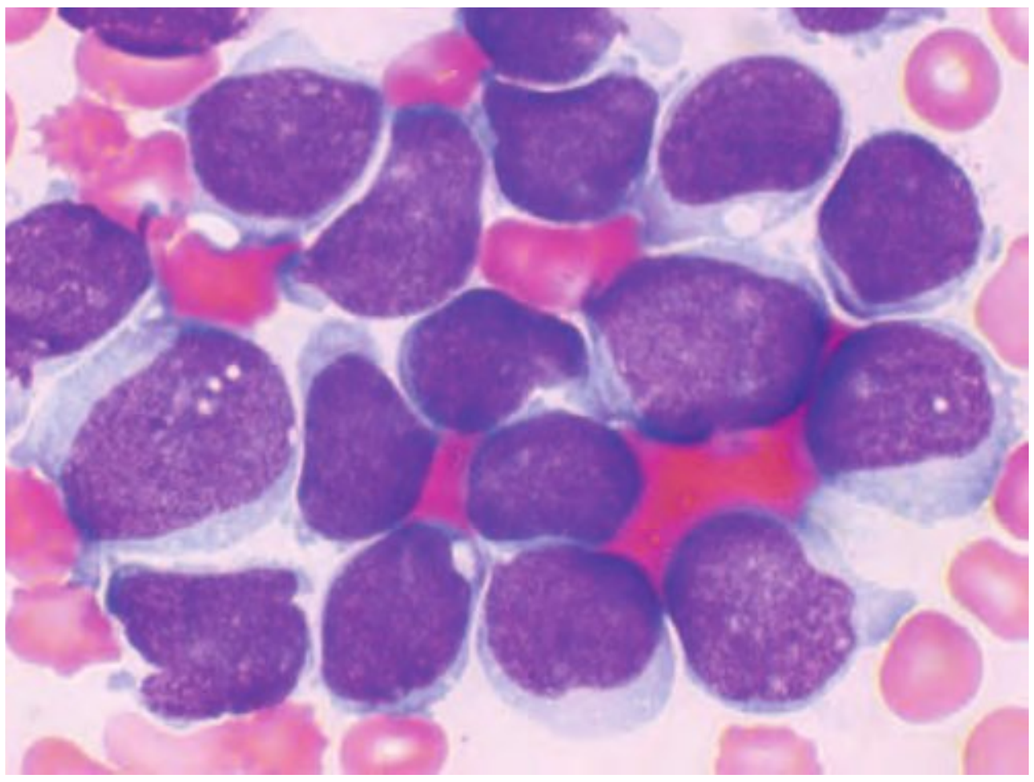
Differential Diagnosis. The differential diagnosis includes extranodal, marginal zone B-cell lymphoma (MALT type, see above) with marked plasmacytic differentiation and reactive, plasma cell-rich, immune responses.

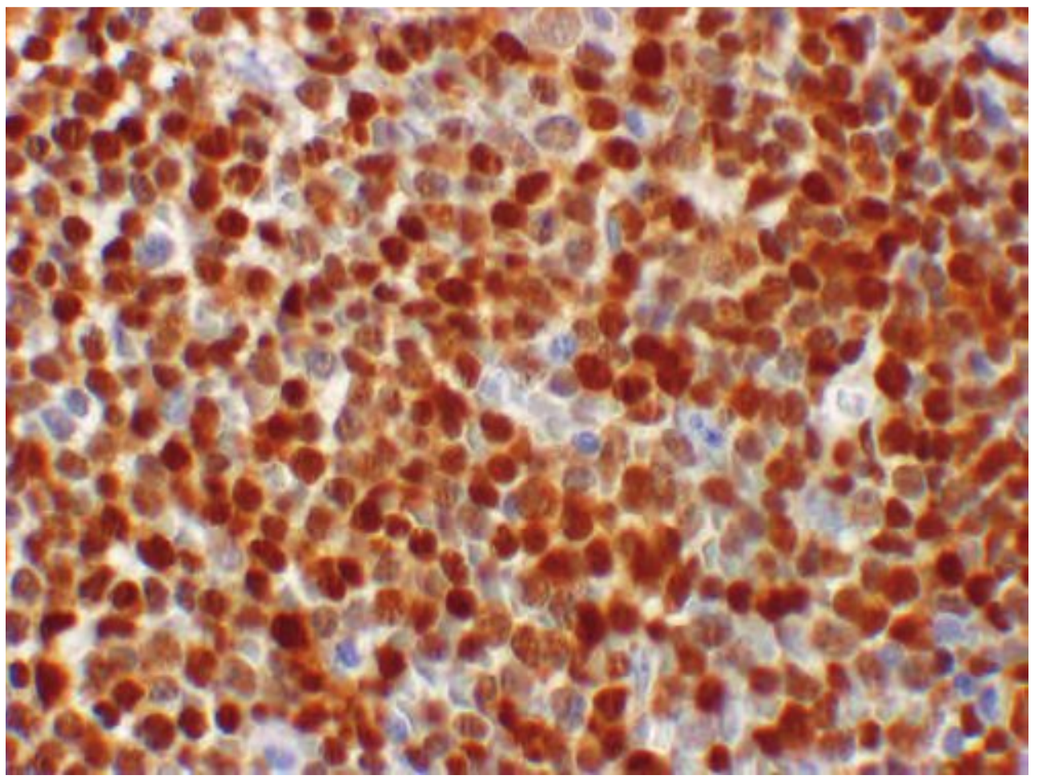
SECONDARY B-CELL LYMPHOPROLIFERATIVE DISORDERS AFFECTING SKIN

Precursor B-cell Lymphoblastic Lymphoma

Precursor B-cell lymphoblastic lymphoma (B-LBL) is a relatively rare neoplasm of B lymphoblasts (accounting for only 5% of all non-HL) with a tendency for skin, lymph node, and bone marrow involvement. It may also present primarily in a leukemic







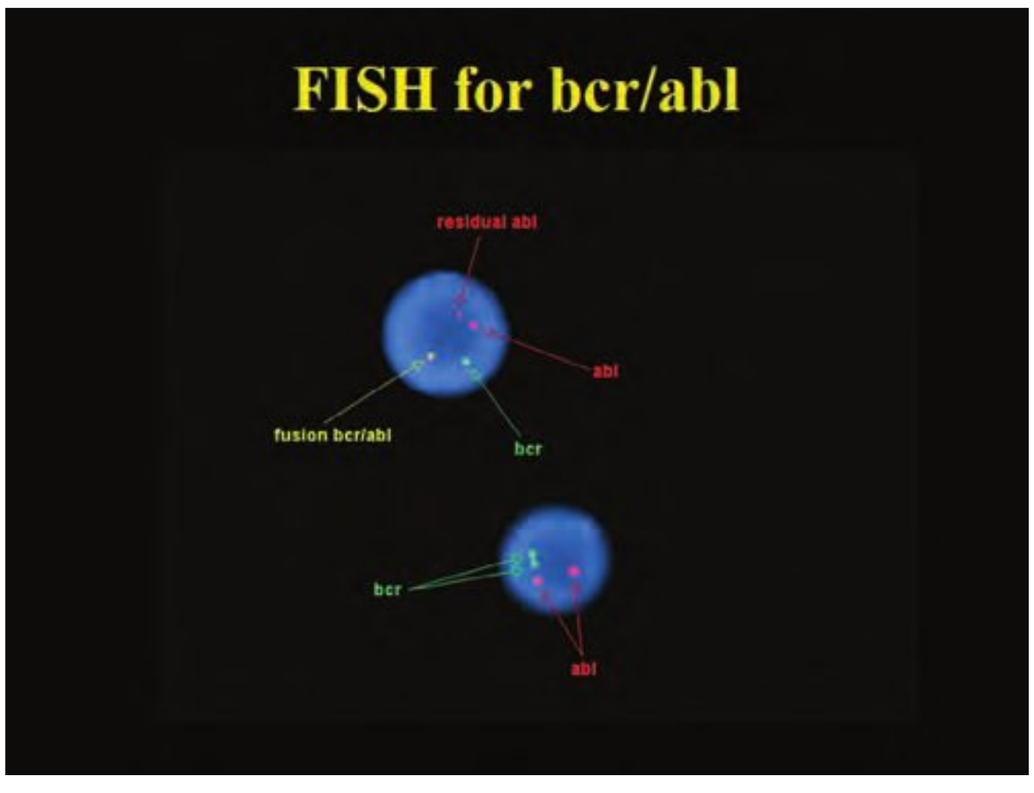


FIGURE 31-10. Cutaneous plasmacytoma. A: There is diffuse interstitial infiltration of the dermis associated with surface erosion. phase, where it is known as precursor B-cell acute lymphoblastic leukemia (B-ALL). Lymphoblastic lymphomas may be of either T- or B-cell lineage (see separate discussion of precursor T-cell lymphoblastic leukemia/lymphoma under secondary T-/NK-cell lymphoproliferative disorders, page 951). Although the majority of systemic lymphoblastic lymphomas are of T-cell lineage, those with a tendency for cutaneous involvement have shown a curious tendency toward B-cell lineage (65).

Clinical Features. B-LBL usually affects children and young adults who are younger than 35 years of age. Bone marrow involvement is generally extensive at time of presentation, with

associated anemia and thrombocytopenia and symptoms related to bone or joint pain. Patients may show lymphadenopathy as well as hepatic and splenic enlargement on physical examination. Skin lesions, which may occasionally occur without blood or marrow involvement (66,67), may take the form of multiple papules and nodules often involving the head and neck. The outlook is favorable if skin is exclusively involved at the time of diagnosis, as compared to an unfavorable prognosis if disease is disseminated (68). There tends to be a high rate of remission, with median survival of approximately 5 years (66).

Histopathology. Skin involvement may be nodular or diffuse within the dermis, consisting of dense, homogeneous infiltration by mitotically active lymphoblasts with variably convoluted nuclei containing finely stippled chromatin and inconspicuous nucleoli (Fig. 31-11A). Cytoplasm is sparse and may be difficult to detect in routinely prepared tissue. The epidermis is spared, often separated from the region of dermal involvement by a thin subepidermal mantle of unaffected dermis (grenz zone). Further classification, including distinction between T- and B-cell lymphoblastic differentiation, requires immunohistochemical analysis.

Histogenesis. The neoplastic cells of B-LBL lack surface immunoglobulin expression and may harbor cytoplasmic μ chain (pre–B-cell leukemia) or no immunoglobulin at all (progenitor B-cell leukemia); thus, they are generally considered to be precursor B cells. The characteristic cytochemical/immunohistochemical profile consists of positive terminal deoxynucleotidyl transferase (TdT) (Fig. 31-11B), CD179a/b (69), CD19, cytoplasmic CD79a,

CD10 (also known as *common acute lymphocytic leukemia antigen* [CALLA]), and CD24 positivity and variable expression of CD22 and CD20. Stains for surface immunoglobulin and myeloperoxidase are characteristically negative. Cytogenetic abnormalities are numerous and frequently correlate with prognosis and treatment protocols, particularly in pediatric patients (70–72). The arsenal of tests assessing molecular abnormalities includes conventional cytogenetics, polymerase chain reaction (PCR), and fluorescence *in situ* hybridization (FISH). Hyperdiploid karyotypes with >50 chromosomes ordinarily convey favorable prognosis, while hypodiploidy predicts unfavorable outcome. Examples of lymphoblastic lymphoma with adverse outcomes include t(9;22) (Philadelphia chromosome), t(4;11) involving the mixed lineage leukemia (MLL) gene locus, and t(1;19). Along with chronic myelogenous leukemia, some lymphoblastic leukemias/ lymphomas express the chimeric bcr-abl gene that encodes for a tyrosine kinase that is constitutively activated, thus playing a key role in leukemogenesis (Fig. 31-11C).

Differential Diagnosis. Lesions may be differentiated from morphologically similar infiltrates of malignant T-cell lymphoblasts (refer to detail on page 935 under primary T-cell lymphoproliferative disorders) and myeloblasts by cytochemistry/ immunohistochemistry. Occasionally, mitotically active lesions in children may resemble the starry-sky pattern of Burkitt lymphoma (Fig. 31-11D), and lesions in adults may mimic MCL (Tables 31-4 and 31-5); TdT determination is of value in establishing a diagnosis of B-LBL in such cases (73,74) (Table 31-5).

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

CLL/SLL is an indolent disseminated or solid neoplastic proliferation of a monotonous population of small lymphocytes of B-cell lineage.

Clinical Features. CLL/SLL is relatively common, generally affects older adults, and shows a male-to-female ratio of 2:1. Patients diagnosed with CLL have bone marrow and peripheral blood involvement, and the lymph nodes, liver, and spleen are also typically infiltrated. Other sites of occasional infiltration by leukemic cells are the skin, breast, and ocular adnexae. When tissue infiltration occurs without evidence of bone marrow involvement, a diagnosis of SLL can be made histologically. Although not usually curable, the disease tends to run an indolent course, unless transformation to a high-grade large B-cell lymphoma supervenes. This phenomenon, known as *Richter syndrome*, occurs in approximately 3.5% of cases. When cases with plasmacytoid differentiation (previously termed *immunocytoma* or *plasmacytoid lymphoma*) affect skin primarily, there is often a single nodule on the trunk or extremity and less frequently on the head and neck. Lesions tend to be multiple with secondary cutaneous involvement and may be associated with immunoglobulin production, resulting in autoimmune sequelae, or in the case of secretion of IgM, a Waldenstrom macroglobulinemia picture.

Cutaneous involvement may produce papules and nodules or occasionally more diffuse skin infiltration that results in irregular thickening and furrowing (75). Sometimes, leukemic cells may infiltrate sites of preexisting dermatitis where adhesive interactions with inflamed vessels are presumably augmented.

Histopathology. Involved tissues are infiltrated by uniform populations of small lymphocytes containing rounded hyperchromatic nuclei and a variably inconspicuous nucleolus (76,77) (Fig. 31-12). In lymph nodes and occasionally in other sites, pseudofollicles (alternatively termed *proliferation* or *growth centers*) that contain a continuum of small to large lymphocytes, including prolymphocytes and paraimmunoblasts, will produce a nodular pattern of regularly distributed pale-staining areas at scanning magnification. Cases with plasmacytoid differentiation may preferentially affect the superficial dermis or show a vertically oriented perifollicular distribution and be composed of heterogeneous populations of cells, including, in addition to plasmacytoid lymphocytes, immunoblasts, plasma cells, histiocytes, eosinophils, and reactive lymphoid follicles (17,78).

Skin involvement may take the form of an angiocentric pattern within the superficial and deep dermis and subcutis (Fig. 31-12A), an interstitial pattern where small lymphocytes are present among collagen bundles and adipocytes (Fig. 31-12B) as well as around vessels, and a mixed diffuse/nodular pattern (79). In the latter, proliferation centers similar to those typical of nodal involvement may occasionally be encountered. As with B-cell pattern infiltrates, the epidermis and follicular epithelium is spared, and the papillary dermis is usually uninvolved, producing a typical grenz zone. Cytologically, the infiltrating cells are identical to those that involve lymph nodes and other extranodal sites (Fig. 31-12C).

Histogenesis. The typical immunophenotype of the tumor cells consists of positivity for CD5, CD19, CD79a, CD23, and CD43. They generally only weakly express surface IgM or IgM and IgD, CD20, CD22, CD11c and are negative for CD10 and cyclin D1. It should be recalled that light chain restriction is confined to surface immunoglobulin in CLL/SLL; thus, unlike plasma cells that contain cytoplasmic immunoglobulin, immunoglobulin restriction can only be demonstrated in fresh, frozen (unfixed) sections. Heavy and light chain immunoglobulin genes are rearranged, and this can be demonstrated by molecular analysis using PCR. At the molecular level, two groups of CLL can be distinguished, one without somatic mutations in the immunoglobulin VH regions being the equivalent of recirculating $CD5^+$, $CD23^+$, IgM^+, IgD^+ naive B cells that are normally detected in blood and in primary follicles and mantle zones (80,81), and one with somatic mutations in the variable genes corresponding to post-germinal center

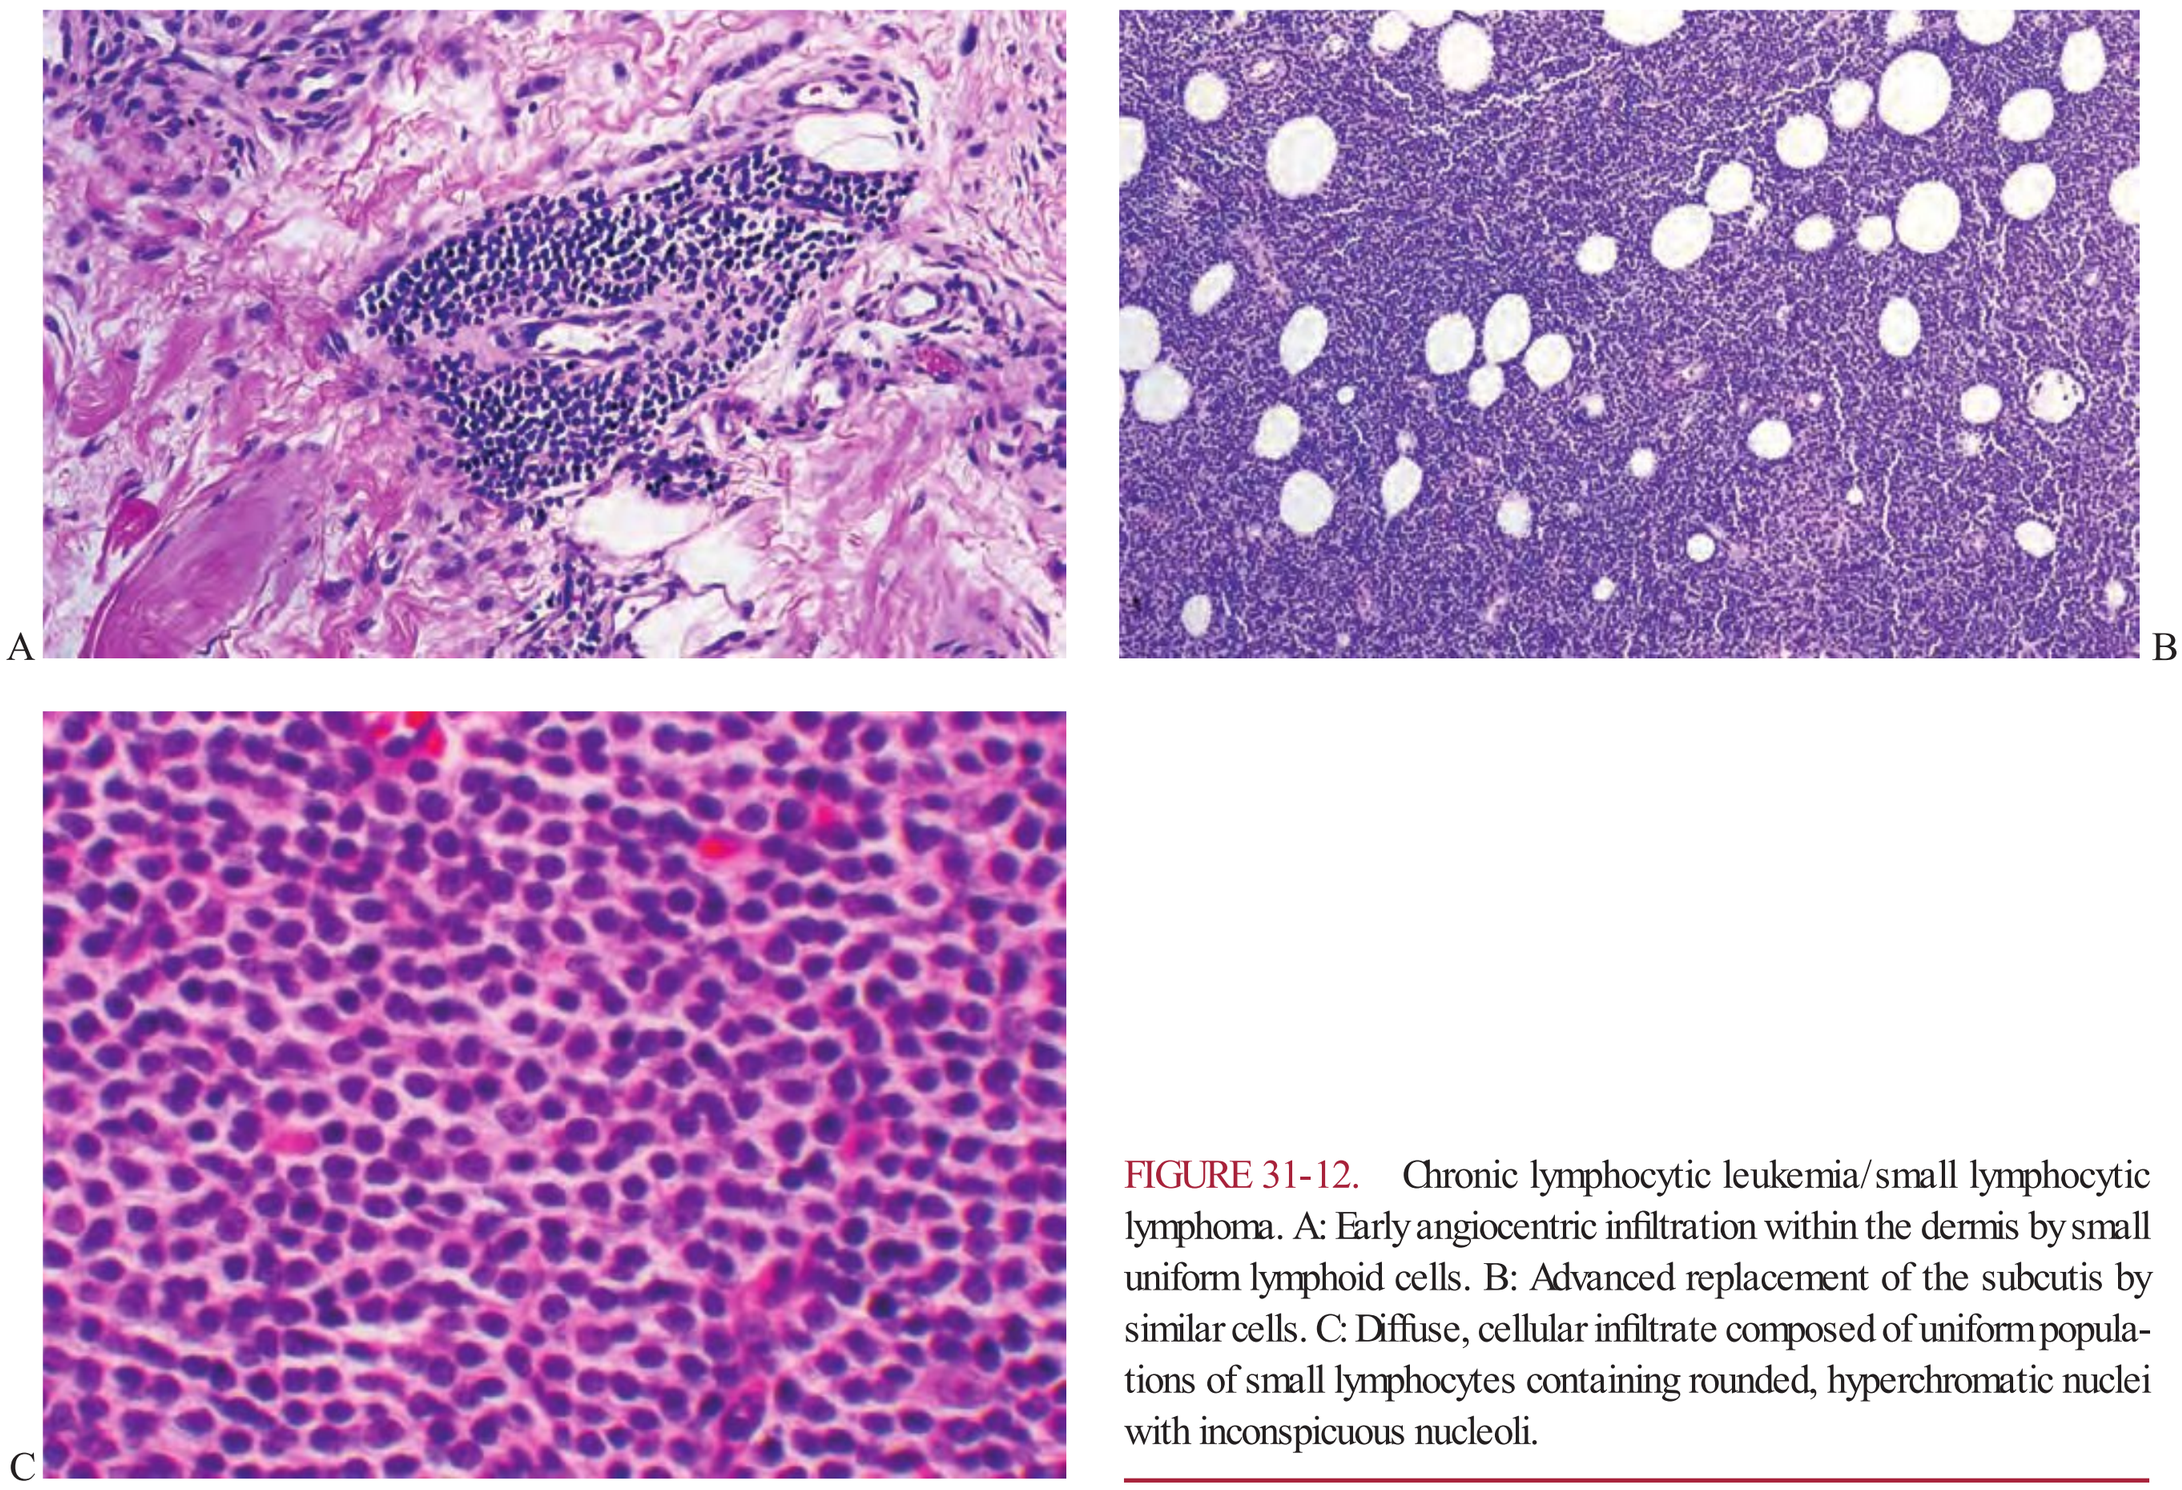

FIGURE 31-12. Chronic lymphocytic leukemia/small lymphocytic lymphoma. A: Early angiocentric infiltration within the dermis by small uniform lymphoid cells. B: Advanced replacement of the subcutis by similar cells. C: Diffuse, cellular infiltrate composed of uniform populations of small lymphocytes containing rounded, hyperchromatic nuclei with inconspicuous nucleoli.

B cells. The majority of CLL exhibit chromosomal abnormalities. Unmutated types of CLL are more commonly associated with trisomy 12, while the mutated forms may present with deletions at 13q14. Previous cases with reported clonal bcl-1 gene rearrangement may have been misdiagnosed cases of MCL. Distinguishing between the two ontogenetic types of CLL carries prognostic significance: the prospect of CLL with germ line VH genes is significantly less favorable than those with hypermutated VH genes. Flow cytometric detection of CD38 (82,83) and, more recently, of zeta-associated protein 70 (ZAP-70) (84–89), that appears to enhance signal transduction, have been utilized as surrogate markers to detect germ line VH gene types of CLL with predictable poor outcome.

Differential Diagnosis. In certain cases, the small lymphocytes of CLL/SLL may show moderate irregularity of nuclear contour, raising suspicion for MCL (Table 31-4). The presence of pseudofollicles or prolymphocytes and paraimmunoblasts, along with positive CD23 and negative cyclin D1 immunoreactivity, will permit a diagnosis of CLL/SLL in such instances (90,91). It should also be noted that in occasional cases, there may be plasmacytoid differentiation by the neoplastic lymphocytes, corresponding to so-called plasmacytoid immunocytoma of previous classification systems (92) and resulting in potential diagnostic confusion with MZL (15) (Table 31-4).

The perivascular pattern in CLL/SLL may result in confusion with forms of dermatitis characterized by a predominant or exclusive angiocentric architecture of inflammatory cell infiltration. This differential would therefore include polymorphous light eruption (see Chapter 12), dermal forms of lupus erythematosus (see Chapter 10), certain dermal delayed hypersensitivity responses to drug or injected antigen (see Chapter 11), and the family of gyrate erythemas (e.g., erythema annulare centrifigum and erythema chronicum migrans) (see Chapter 7). Although all of these conditions contain small lymphocytes, the cells of CLL/SLL tend to be more homogeneous at high magnification. Moreover, most forms of dermatitis are predominated by T cells, not B cells, and the B cells of CLL/SLL will also characteristically aberrantly express CD5.

Nodal Follicular Lymphoma

Nodal follicular lymphoma is a relatively common, often low-grade neoplasm of B lymphocytes differentiating toward follicle center cells (e.g., centrocytes [cleaved FCCs] and centroblasts [noncleaved FCCs]). These tumors at least focally show a nodular/follicular architecture on tissue infiltration.

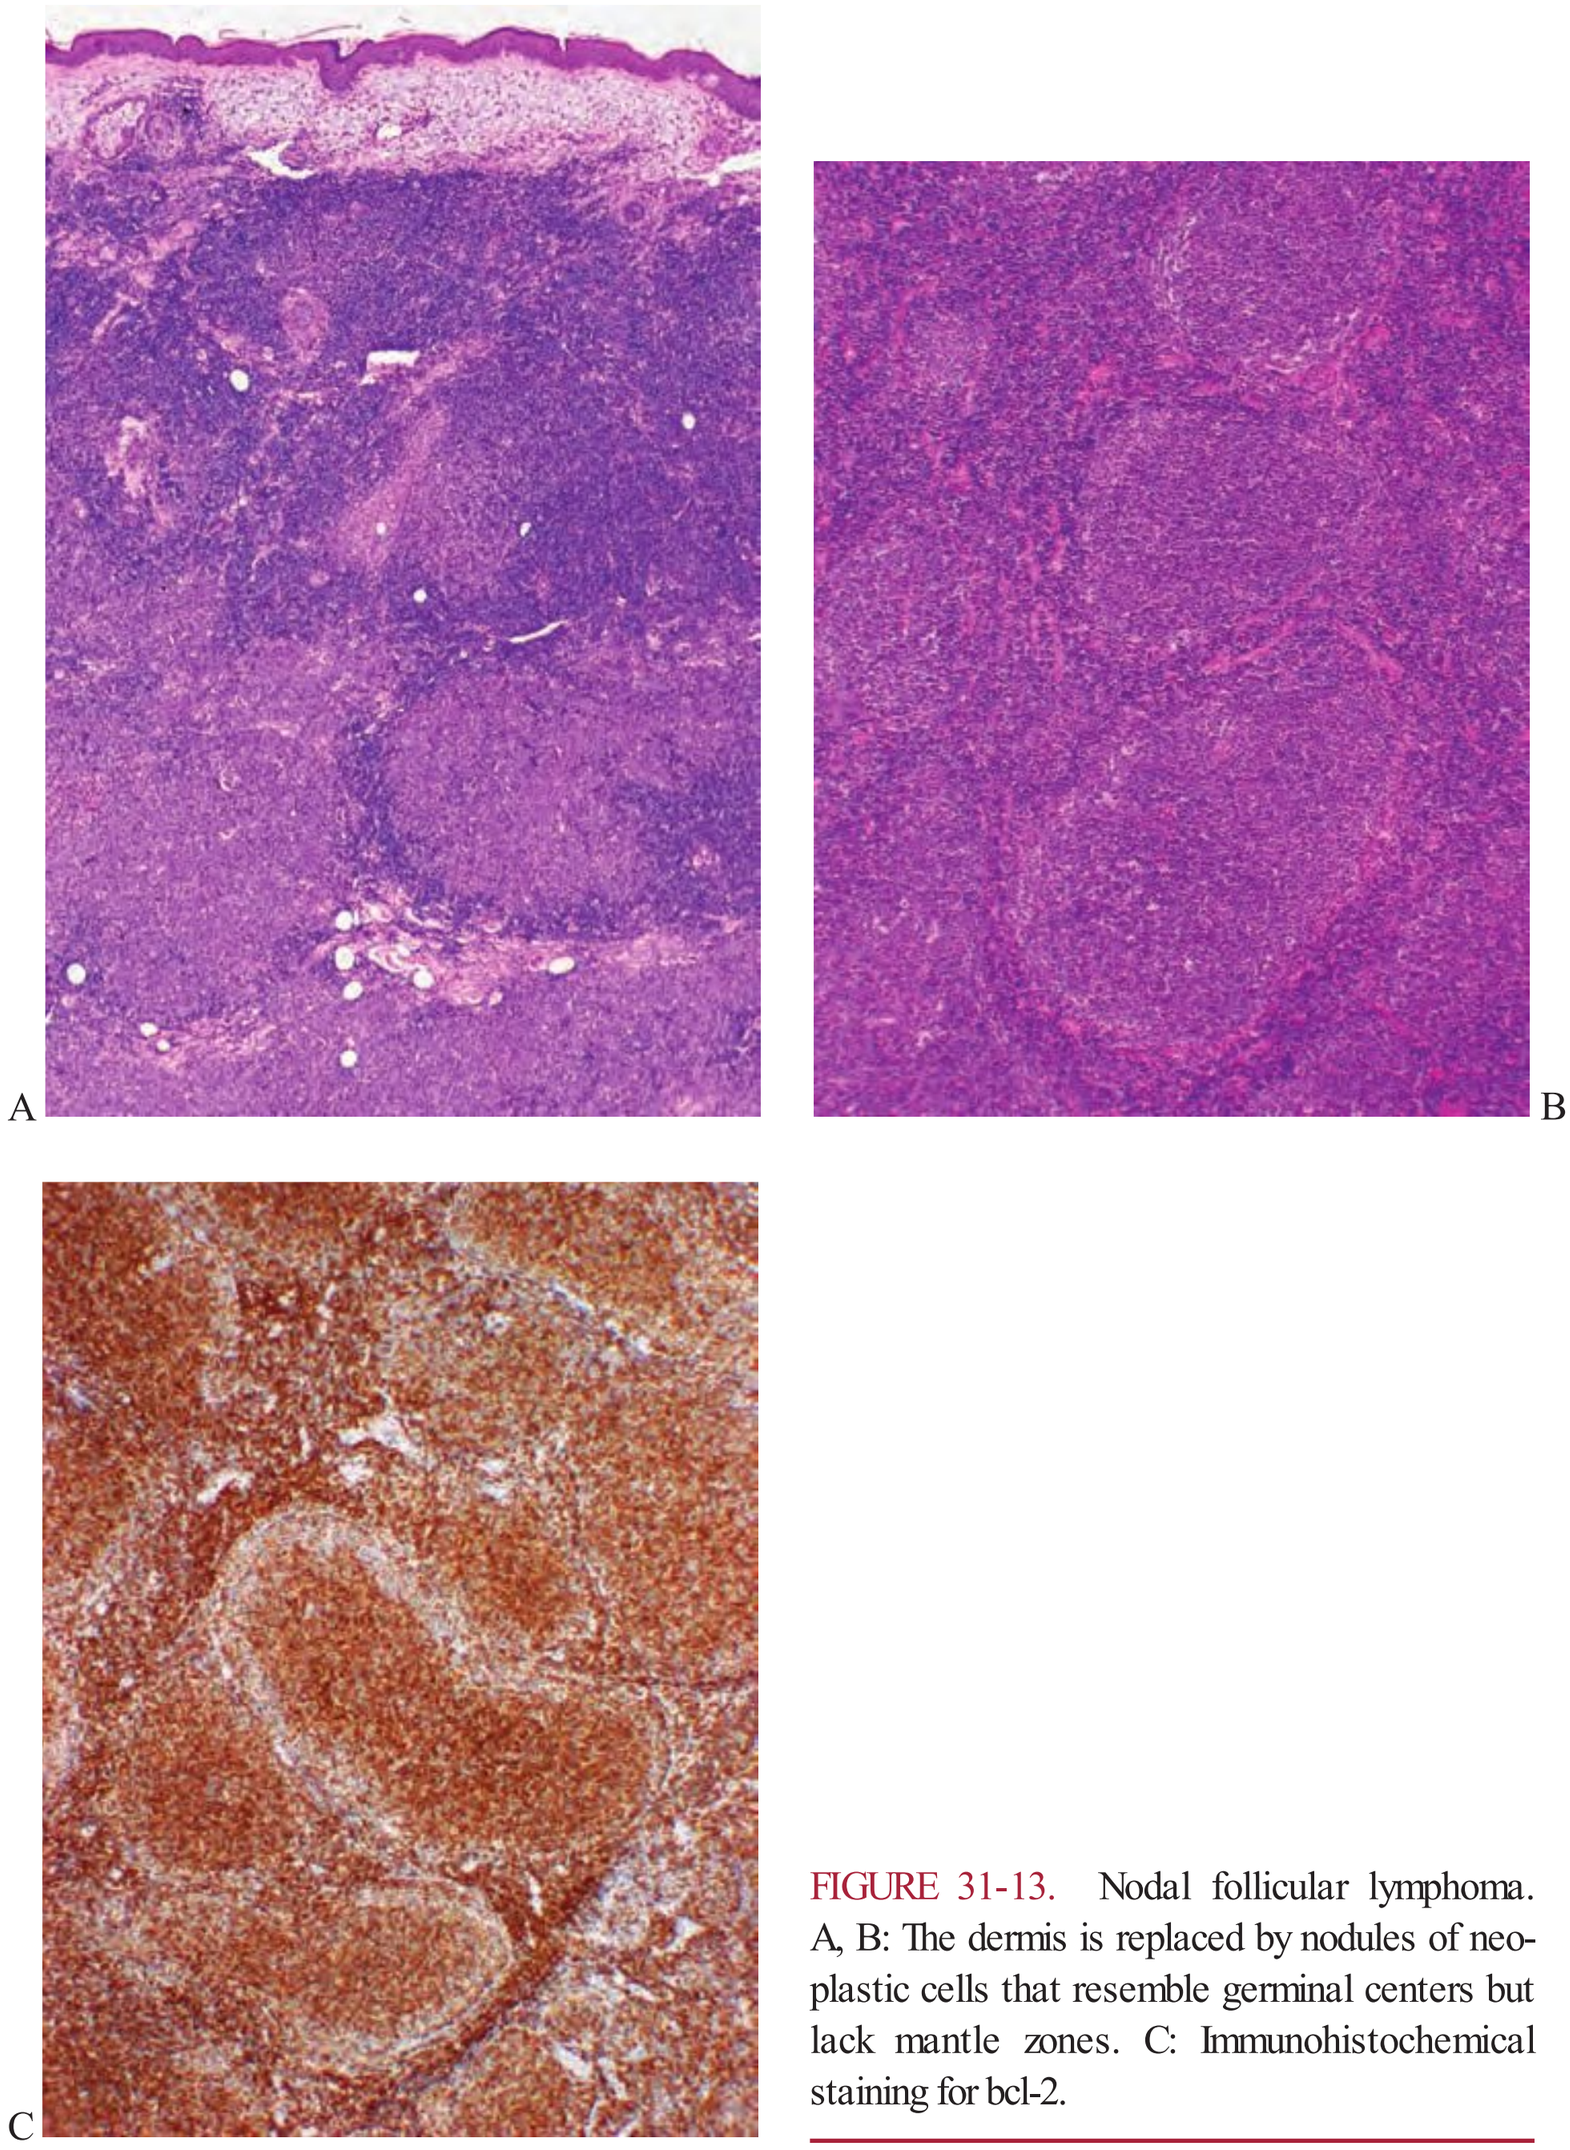

FIGURE 31-13. Nodal follicular lymphoma. A, B: The dermis is replaced by nodules of neoplastic cells that resemble germinal centers but lack mantle zones. C: Immunohistochemical staining for bcl-2.

Clinical Features. This type of lymphoma affects primarily older adults, with a median age of 59 and a male-to-female ratio of 1:1 (93). When children are affected, lesions tend to be localized to the head and neck, and approximately half of tumors are of the large cell type (see below). In addition to lymph node involvement, the bone marrow, spleen, blood, Waldeyer ring, gastrointestinal tract, skin, and soft tissues may be affected. Follicular lymphoma is generally incurable, showing an indolent waxing and waning course. The overall median survival is 7 to 9 years regardless of whether therapy is aggressive or symptomatic. Of all cases of nodal follicular lymphoma, approximately 4% will show evidence of secondary skin involvement, which must be differentiated from PCFCL because the latter tends to respond to local therapy and shows a more favorable prognosis.

Histopathology. The characteristic architecture consists of multiple closely packed nodules that initially may resemble germinal centers but that are composed of neoplastic cells devoid of mantle zones (17) (Fig. 31-13A, B). These follicular regions are devoid of polarization and do not show a prominent starry-sky pattern, and other regions may be characterized by a more diffuse pattern with associated sclerosis. Based on these architectural features, lesions may be classified as follicular (>75% follicular architecture), follicular

and diffuse (25% to 75% follicular architecture), and minimally follicular (<25% follicular). Rarely, exclusively diffuse follicle center cell lymphomas may also be seen, where the diagnosis must be based on cellular composition. Cytologically, two types of neoplastic lymphocytes are observed in follicular lymphoma. The predominant cell is the centrocyte, or cleaved FCC, a small- to medium-sized lymphocyte with scant cytoplasm as well as angulated, infolded, or twisted nuclear contours and inconspicuous nucleoli (Figure 31-7C). Similar but often smaller centrocytes may also be present in the interfollicular regions. Centroblasts, or noncleaved FCCs, are larger transformed lymphocytes with round to oval nuclei with vesicular chromatin and several visible nucleoli (Fig. 31-7C). On occasion, an even admixture of centrocytes and centroblasts or even a predominance of centroblasts may be encountered. These ratios provide the basis for a grading system based on proportional numbers of centroblasts in 10 neoplastic follicles, with grade 1 equal to the average count of 0 to 5/high power field (hpf), grade 2 equal to 6 to 15/hpf, and grade 3 equal to >15/hpf (94–96).

Secondary skin involvement, like PCFCL, presents as nodular dermal infiltrates that may initially resemble germinal centers (19). While secondary cutaneous involvement tends to have significant morphologic overlap with features seen in lymph nodes, nodal FCL may also show overlap to mucosal lymphoma (MALToma) and marginal zone lymphoma of the spleen.

Histogenesis. Germinal center B cells are believed to represent the cell of origin of follicular lymphoma. Tumor cells tend to express surface immunoglobulins (IgM, IgD, IgG, and rarely IgA), BCL2, and CD10 and the B-cell associated markers CD20, CD19, CD22, and CD79a. Most cases are negative for CD5 (in contrast to CLL/SLL) and CD43. Although BCL2 expression is useful in differentiating neoplastic follicles (Fig. 31-13C) from normally negative hyperplastic germinal centers, it should be noted that in contrast to nodal follicular lymphoma, PCFCL is frequently negative for BCL2. Rearrangement of immunoglobulin heavy and light chain genes is the rule, and cytogenetic abnormalities are almost always present (97), with the t(14;18)(q32;q21) rearrangement of the bcl-2 gene the most common. The BCL2 protein is situated on mitochondrial membranes and serves as an inhibitor of programmed cell death. Consequently, BCL2 expression in nodal follicular lymphoma appears to lend the tumor cells a distinct survival advantage when compared with their benign germinal center counterparts that undergo apoptosis.

Differential Diagnosis. Cutaneous involvement by nodal follicular lymphoma must be differentiated from B-CLH (26,27) and other conditions associated with the formation of reactive follicles (e.g., MCL and MZL) (Table 31-4). B-CLH often is clinically manifested by one or more erythematous to plum-colored plaques and nodules. Any site may be affected, but there is a predilection for skin of the face and scalp. The underlying cause is often unknown, although may involve a reaction to injected antigens, as may occur in insect bites or localized infection with the spirochete *B. burgdorferi* (28–30). Histologically, there may be a nodular to diffuse interstitial infiltrate that often involves the deep dermis and occasionally the subcutis. Germinal center formation may be variably pronounced; however, occasionally, these structures are indistinguishable from those encountered in reactive lymph nodes. Specifically, in addition to smaller lymphocytes with cleaved nuclei (centrocytes) and larger lymphocytes with noncleaved nuclei (centroblasts), they will contain an admixture of immunoblasts, antigen-presenting follicular dendritic cells, and macrophages containing phagocytized cellular debris (tingible body macrophages). Moreover, there tends to be aggregation of centroblasts and tingible body macrophages at one pole of the hyperplastic follicle and of centrocytes at the opposite pole, producing darker- and lighter-staining regions, respectively. Immunohistochemistry will reveal both kappa and lambda immunoglobulin light chain expression in B-CLH as opposed to monotypic expression in follicular lymphoma. Genotypic analysis may also be of assistance when establishing a diagnosis of B-CLH when it fails to reveal clonal immunoglobulin gene rearrangements. However, it must be noted that on occasion, cases of B-CLH appear to evolve over time into more aggressive clonal processes or may harbor a malignant clone in the midst of otherwise reactive histologic and immunophenotypic changes (31). Some of these differences are summarized in Table 31-4.

Mantle Cell Lymphoma

MCL is a B-cell neoplasm that is composed of uniform populations of small- to medium-sized lymphocytes that resemble FCCs, or centrocytes, but that tend to have somewhat less irregular nuclear contours (90–103). The normal cellular counterpart thus resides in the mantles that surround secondary lymphoid follicles in lymph nodes. Unlike follicular lymphoma, which accounts for approximately one third of all non-HLs in the United States, MCL is considerably less common, accounting for only 3% to 10%. Unlike B-CLL/SLL, proliferation centers are absent. Because it rarely involves skin, it is discussed here briefly.

Clinical Features. This disease affects middle-aged and older individuals with a male-to-female ratio of 2:1 (31,100, 101,104–106). Disease is usually advanced at time of detection (stage III or IV) and generally affects lymph nodes, spleen, bone marrow with or without peripheral blood involvement, and gastrointestinal tract (100,106–108). When multiple sites of polypoid gastrointestinal involvement by lymphoma are encountered, the diagnosis is generally MCL (109–111). Occurrence in the skin is rare but potentially underreported. Presentation in the skin is generally followed by development of overt extracutaneous involvement, consistent with the notion that cutaneous MCL is a more aggressive process than PCFCL or plasmacytoid B-CLL/SLL variants (19,112). Median survival is 3 to 5 years, and cure is unusual (105–108,113,114).

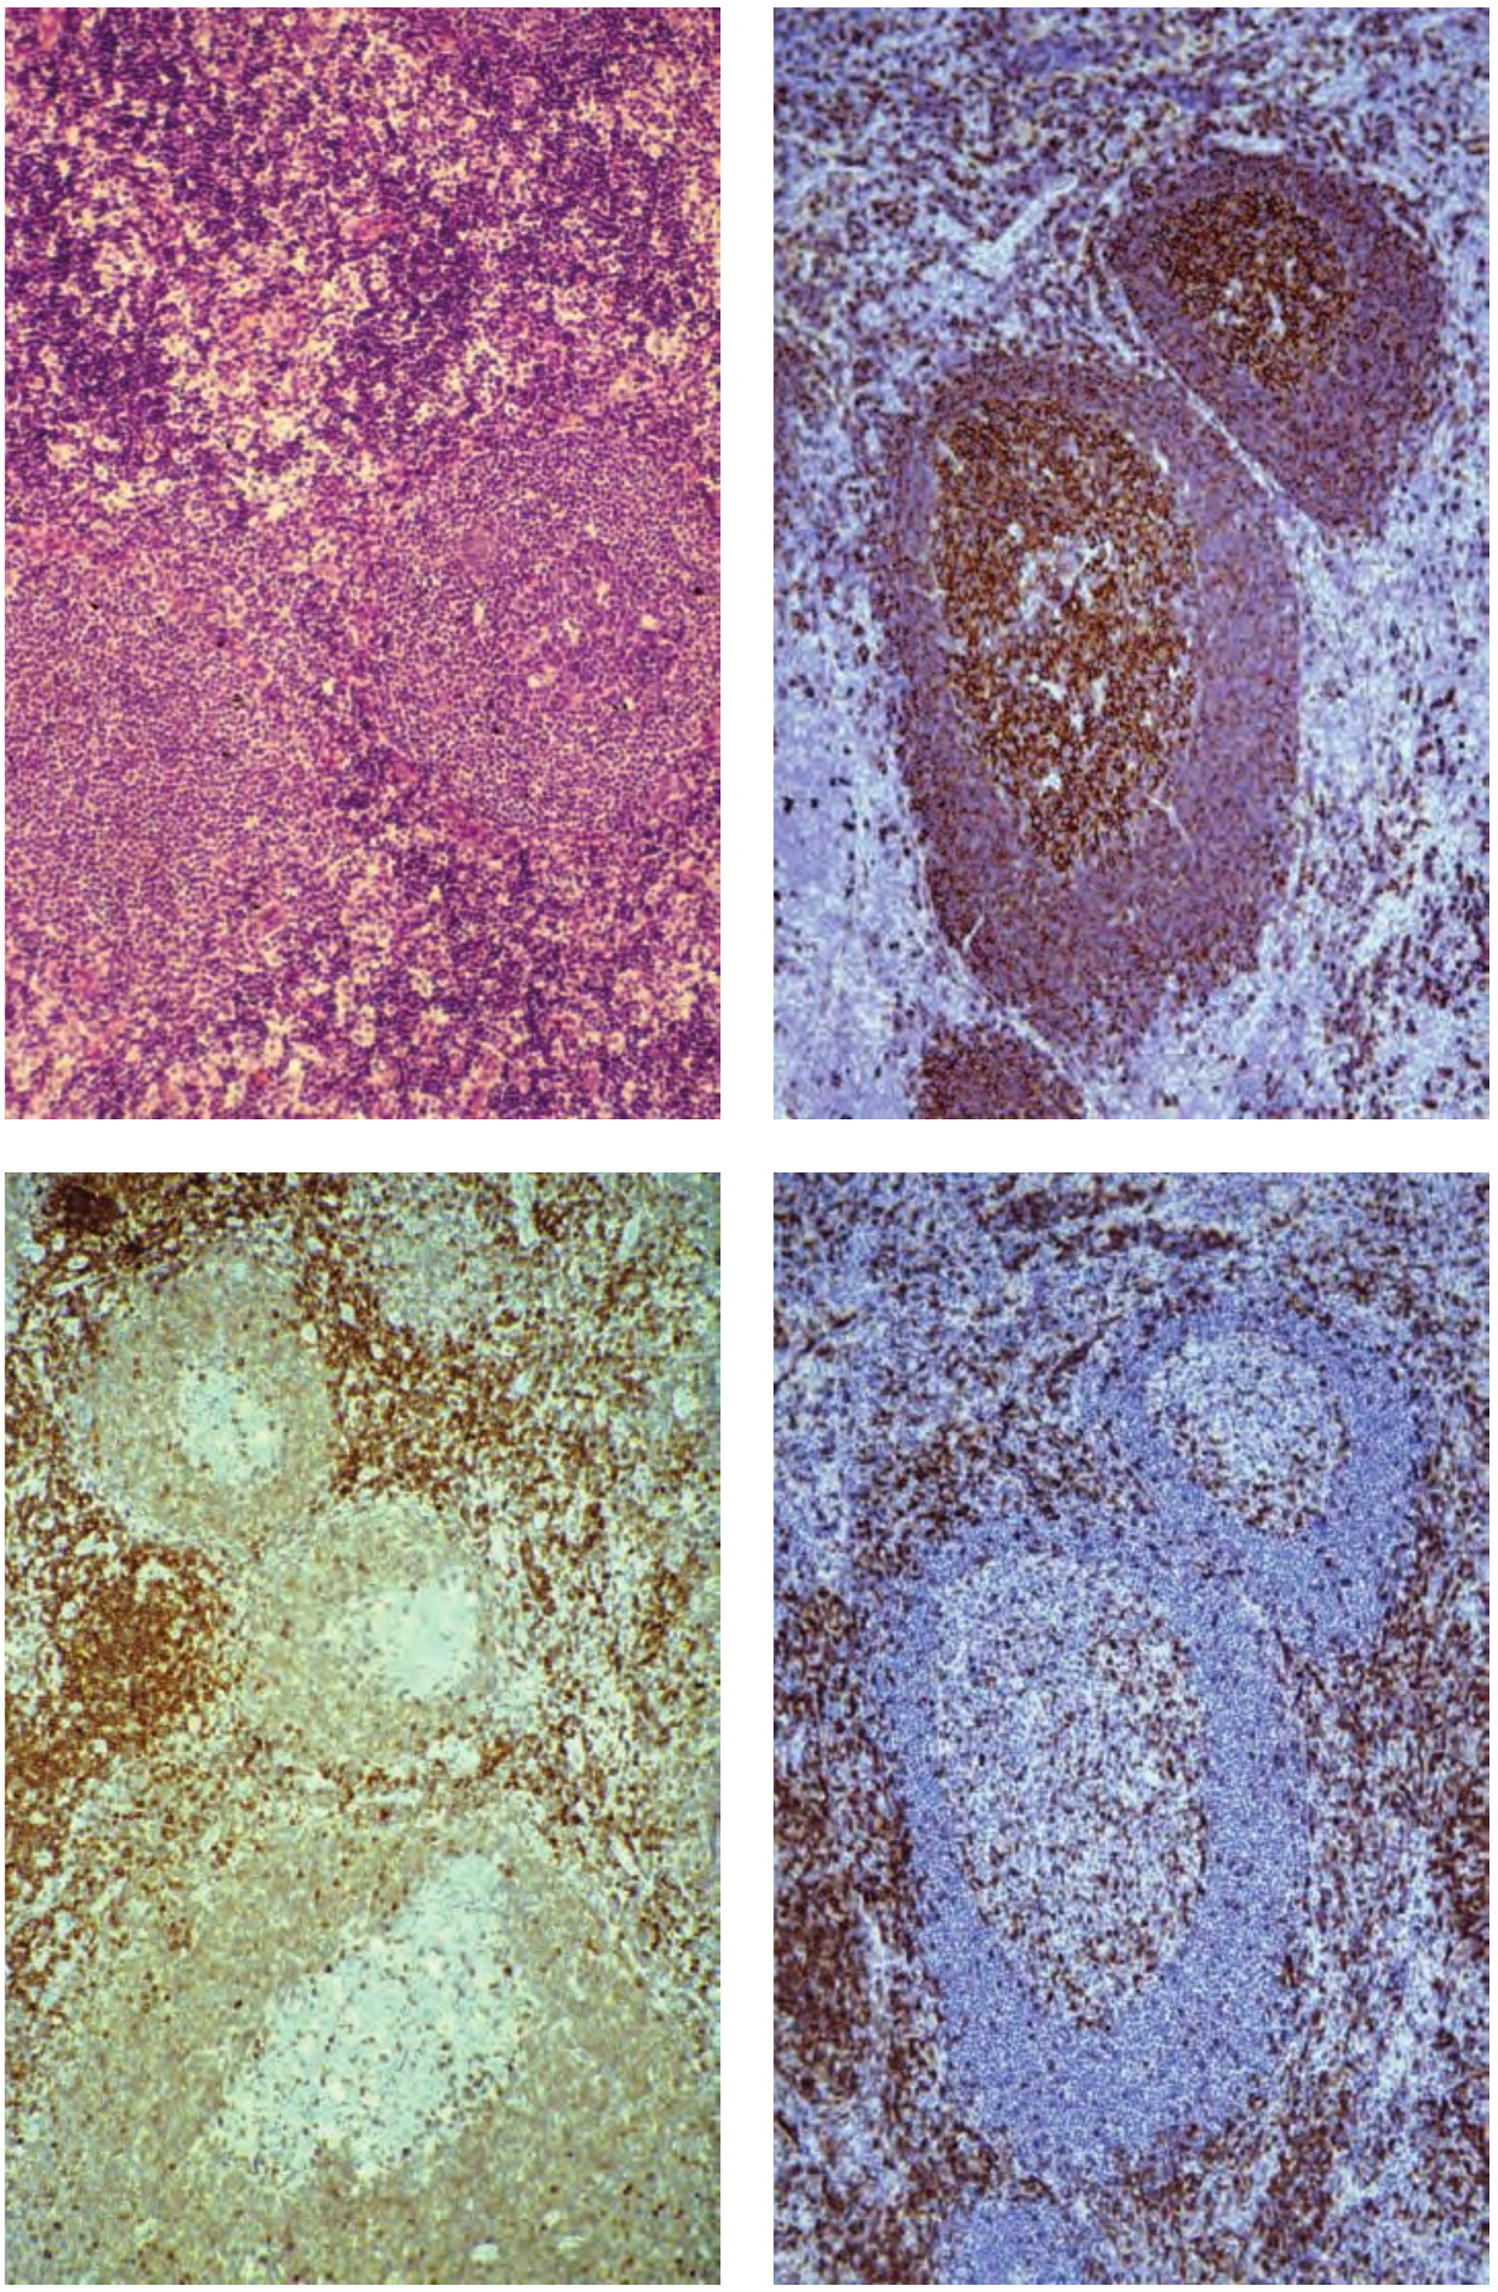

FIGURE 31-14. Mantle cell lymphoma. A: There is a vaguely nodular to diffuse infiltrate composed of small- to medium-sized lymphocytes. B: Immunophenotypically, the cells are characterized by strong reactivity for the B-cell marker CD20. C, D: Reactivity for CD5 that here compared with T cells (upper left) forms a mantle zone pattern about compressed lymphoid follicles (C) and negativity for T-cell marker CD3 (D).

Histopathology. The majority of cases show a vaguely nodular to diffuse pattern of growth composed of small- to medium-sized lymphocytes with variably irregular nuclear contours (Fig. 31-14A). The chromatin pattern is dispersed and nucleoli are inconspicuous. These cells most closely resemble centrocytes. Smaller cells resembling those of B-CLL/SLL may also be present. Transformed tumor cells (e.g., those resembling centroblasts, immunoblasts, or paraimmunoblasts) and pseudofollicles are not seen. Other cells that are sometimes admixed include occasional plasma cells, histiocytes dispersed in a pattern that may resemble the starry-sky of Burkitt lymphoma, and endothelial cells forming hyalinized vascular profiles. A characteristic feature of some lesions of MCL is the tendency of neoplastic lymphocytes to surround and compress nonneoplastic lymphoid follicles (so-called mantle zone pattern). Skin infiltration may be nodular to diffuse, and occasional lesions will show preferential infiltration of the more superficial dermal layers. Rarely, recurrent lesions will show more nuclear atypia and numerous mitoses, qualifying for the designation of "blastoid MCL."

Histogenesis. The tumor is believed to arise from a peripheral B cell of the inner mantle zone of the lymphoid follicle. Accordingly, the tumor is characterized by a clonal proliferation of $CD20^+$ B cells (Fig. 31-14B) that express surface IgM with or without associated IgD (99,100,103,113). They also tend to express CD5 (Fig. 31-14C), CD43, and BCL2 protein and are negative for CD10 and CD23 (100,113,115–120) (Fig. 31-14D). CD5 negativity does occasionally occur and may be associated with more indolent biologic behavior (121). Interestingly, gastrointestinal lesions are associated with expression of the gut homing receptor, alpha4 beta7 (122). The clonal nature of the process may be demonstrated via rearrangements of immunoglobulin heavy and light chain genes, and virtually all cases have cytogenetic abnormalities using FISH (123,124). Most cases of MCL have undergone clonal heavy and light chain gene rearrangement with germ line configuration in the VH gene region that is consistent with pregerminal center origin. The cytogenetic hallmark of MCL is t(11;14)(q13;q32) with participation of the cyclin D1 gene and the immunoglobulin heavy chain locus (113,125–129). Cyclin D1 (Prad-1, bcl-1) is an important cell cycle regulatory protein involved in restriction point control between the G1 and S phase. The genetic abnormality is detectable by conventional cytogenetics, FISH analysis, or PCR; overexpression of the gene product can be readily assessed by immunohistochemical stains with antibodies directed against the nuclear cyclin D1 protein. More recently, pathogenesis of MCL has been linked to alterations of the ataxia-telangiectasia mutated (ATM) gene that encodes a protein critically involved in the cellular response to DNA damage (130–132). It has been known for a long time that patients with hereditary ataxia telangiectasia are predisposed to develop malignant lymphomas. Of all malignant lymphomas, MCL is most commonly associated with mutations of the ATM gene, most of which are nonsense mutations resulting in truncated proteins followed by missense mutations. The underlying molecular mechanism leading to ATM mutations in MCL is unknown.

Differential Diagnosis. The most common differential diagnostic problem is differentiation of MCL from other processes where lymphoid follicles or their mimics are present. Table 31-4 summarizes the salient differential features for MCL compared with other cutaneous B-cell lymphoproliferative disorders.

Diffuse Large B-cell Lymphoma, Nodal Type

DLBCL is a relatively common type of non-HL that primarily affects adults and frequently presents with involvement of extranodal sites, including the skin. It is an aggressive lymphoma characterized by diffuse tissue infiltration by monotonous populations of large, "histiocytoid" malignant lymphocytes.

Clinical Features. Although elderly individuals are most often affected, with the median age in the seventh decade of life, the disease may affect a wide age range, and children are occasionally affected (104). Patients often present with signs or symptoms of a rapidly enlarging tumor at either a nodal or extranodal site, the latter of which commonly involves skin, soft tissue, and numerous viscera (2). On more thorough staging, disease is often found to be advanced and thus disseminated (30,85), although this aggressive lymphoma is potentially curable with aggressive chemotherapy. Lesions generally arise *de novo*, although some lesions represent transformation within preexisting more indolent lymphomas (e.g., CLL/SLL, follicular lymphoma, lymphomatoid granulomatosis [LYG], or marginal zone lymphoma). One important predisposing factor is immunodeficiency, particularly in the presence of seropositivity for Epstein-Barr virus (EBV).

In the skin, DLBCL forms red to purpuric papules, nodules, and infiltrated plaques. Occasionally, only the skin is found to be involved after careful staging work-up, and such cases may be considered to be primary in the skin (PCDLBCL), including skin of the back (114). Such lesions confined exclusively to the skin have proven to be more amenable to treatment (e.g., localized irradiation), although those involving the lower extremities have been noted to be more aggressive (21).

Histopathology. Tissue infiltration in DLBCL generally results in local destruction and effacement of preexisting structures (Fig. 31-15A), occasionally associated with zones of fibrosis. The dermal infiltrates may be diffuse or nodular. Frequently, deep dermis is preferentially affected, producing a so-called "bottom-heavy" pattern. Cytologically, there is a uniform, monomorphous population of large transformed lymphoid cells resembling centroblasts (Fig. 31-15B). These cells have scant cytoplasm, large nuclei with vesicular nuclear chromatin patterns, and often prominent nucleoli. Immunoblastic, T-cell/histiocyte-rich, and anaplastic variants have been described, but significant problems exist in terms of interobserver variability in subclassifying lesions according to variant forms (133).

Histogenesis. The presumed cell of origin is a peripheral germinal center or post-germinal center B cell. Accordingly, one or more pan-B-cell markers (e.g., CD19, CD20, CD22, CD79a) are expressed (Fig. 31-15C). Surface or cytoplasmic immunoglobulin is demonstrable in the majority of cases, the latter tending to correlate with plasmacytoid features of the large malignant B cells (134,135), and immunoglobulin gene rearrangements are regularly encountered. Anaplastic variants tend to express CD30 more consistently than their nonanaplastic counterparts (136). CD5 and BCL2 expression are also variably encountered in DLBCL (137). Twenty-five percent of DLBCLs demonstrate alterations of the BCL6 (LAZ-3) gene at 3q27, which encodes a zinc finger protein with homology to several Drosophila transcription factors (138–145). BCL6 protein is readily recognizable by immunohistochemistry and is expressed in normal germinal center lymphocytes. It should be emphasized that DLBCL represents a heterogeneous group of malignancies reflected in

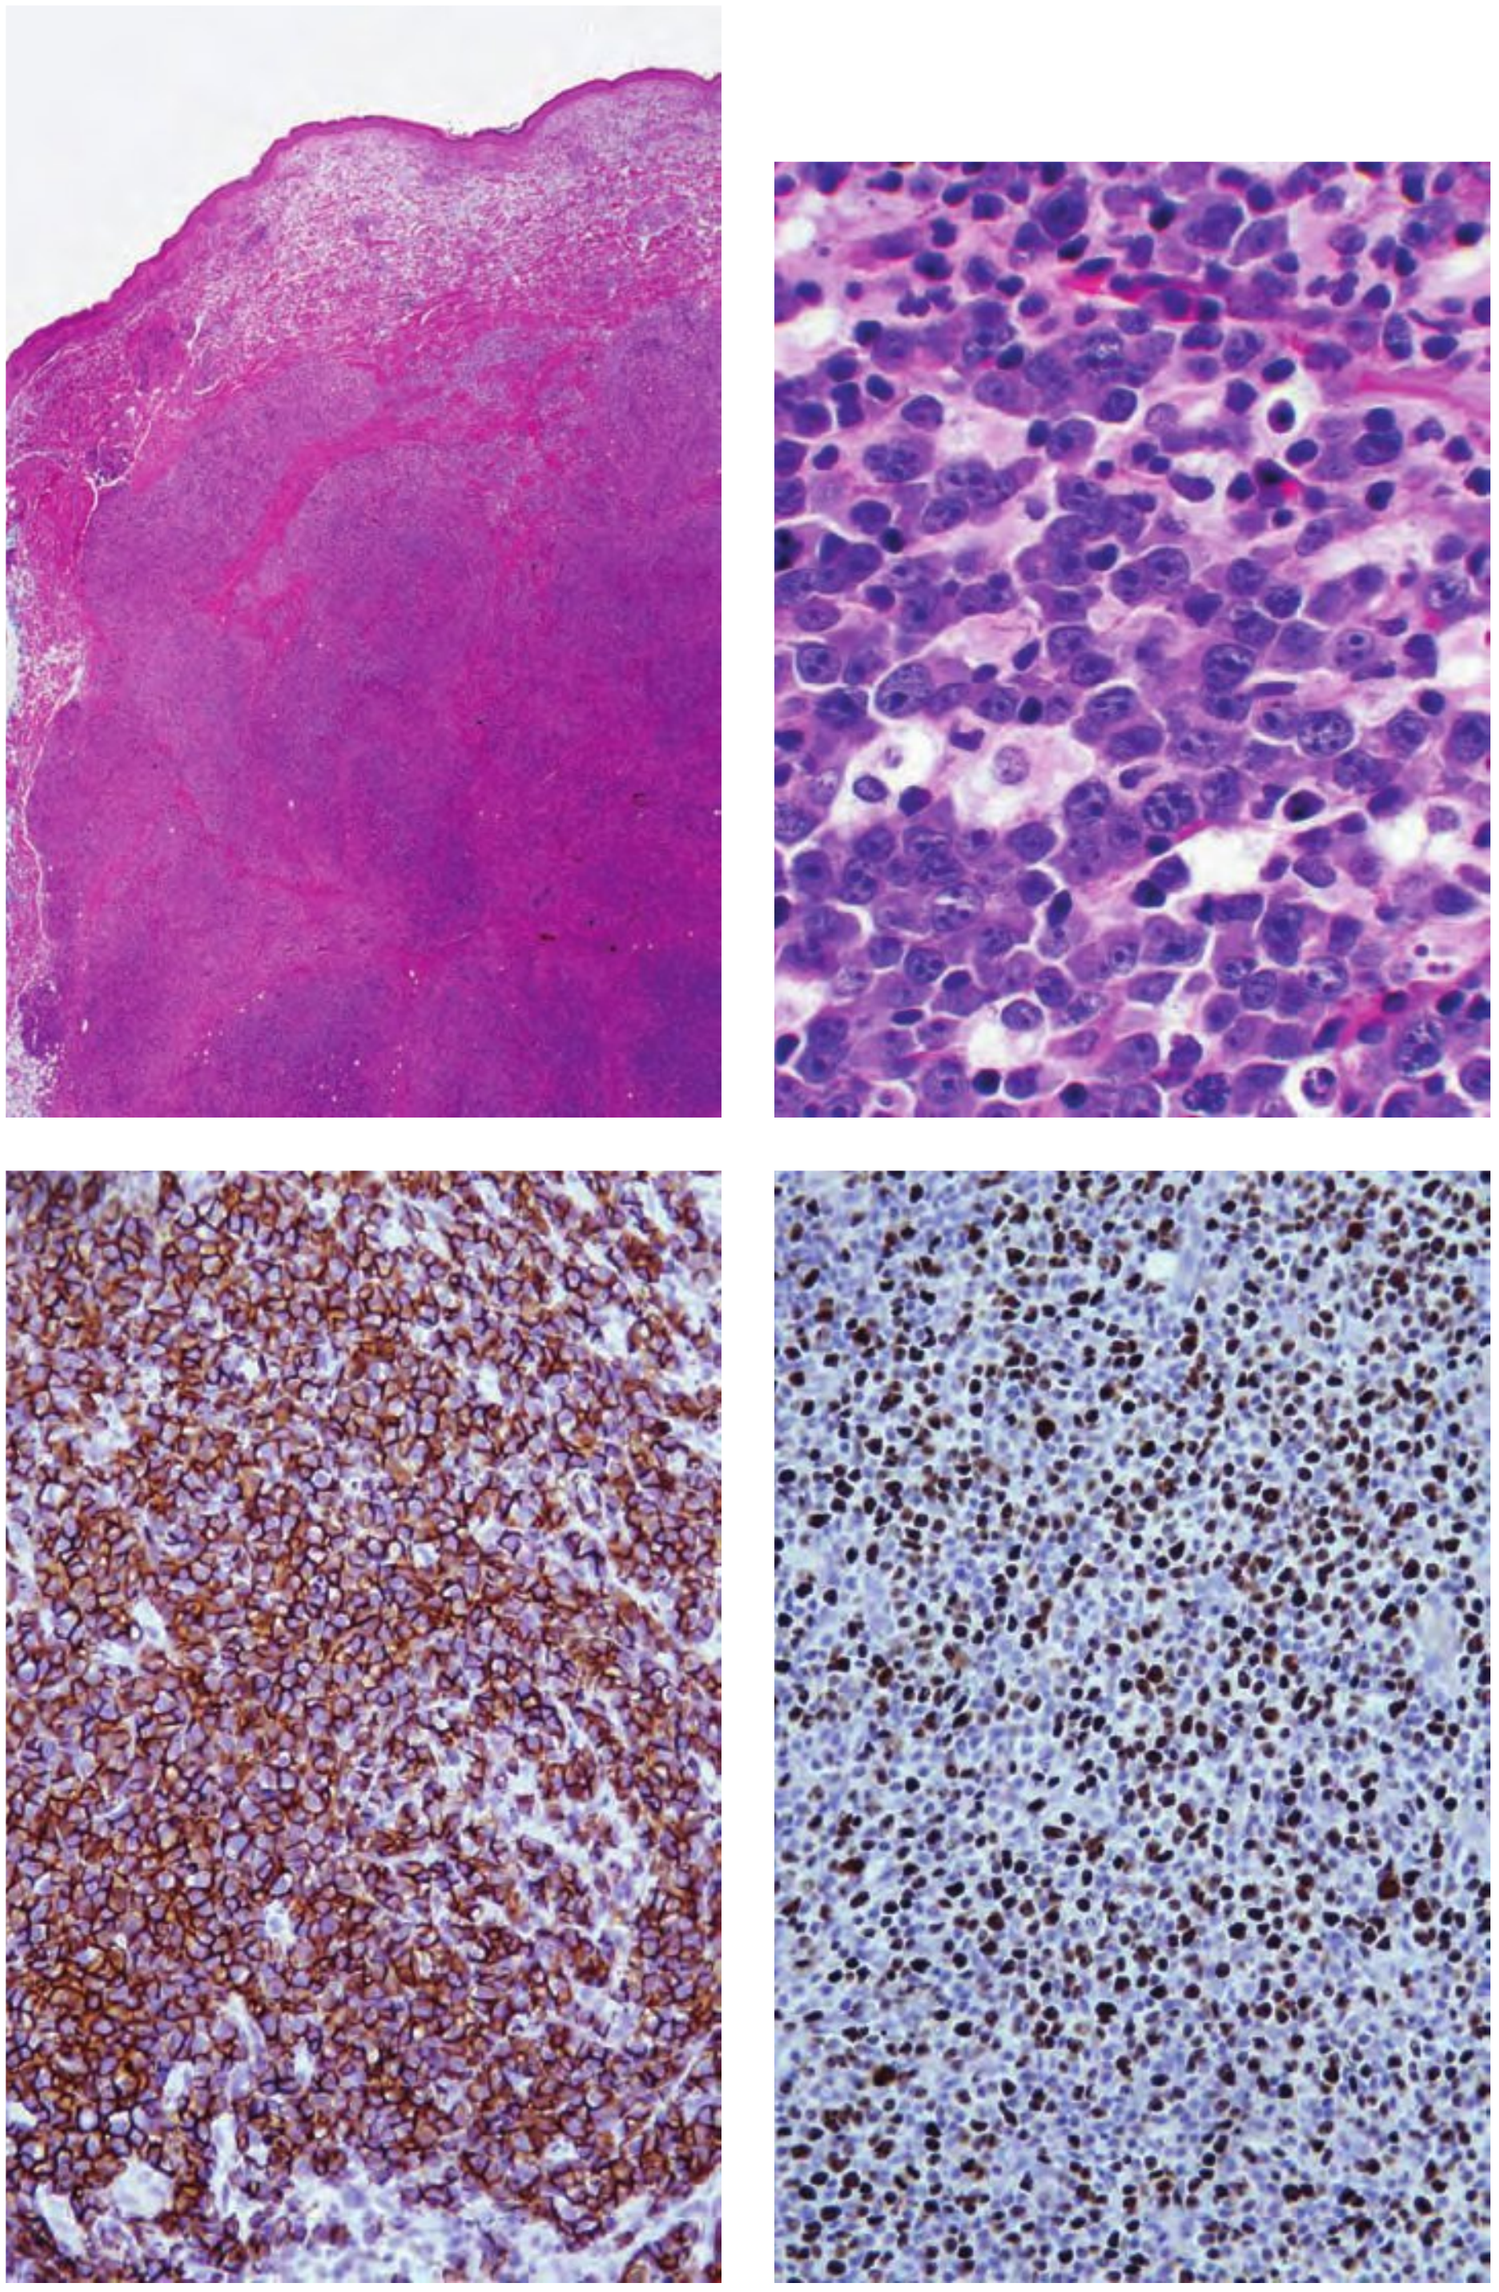

FIGURE 31-15. Diffuse B-cell lymphoma, nodal type. A: The dermis is diffusely effaced by a destructive infiltrate. B: High magnification showing infiltrate composed of large neoplastic lymphocytes. C, D: Immunohistochemistry shows the malignant cells to express CD20 (C) and evidence of a high proliferative rate based on Ki-67 reactivity (D).

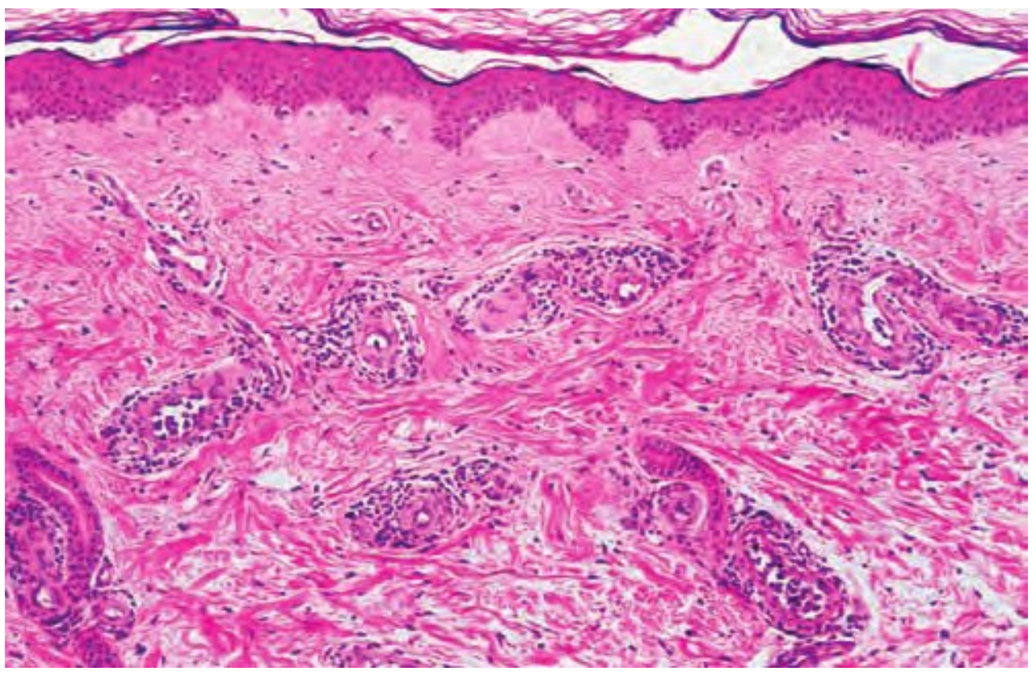
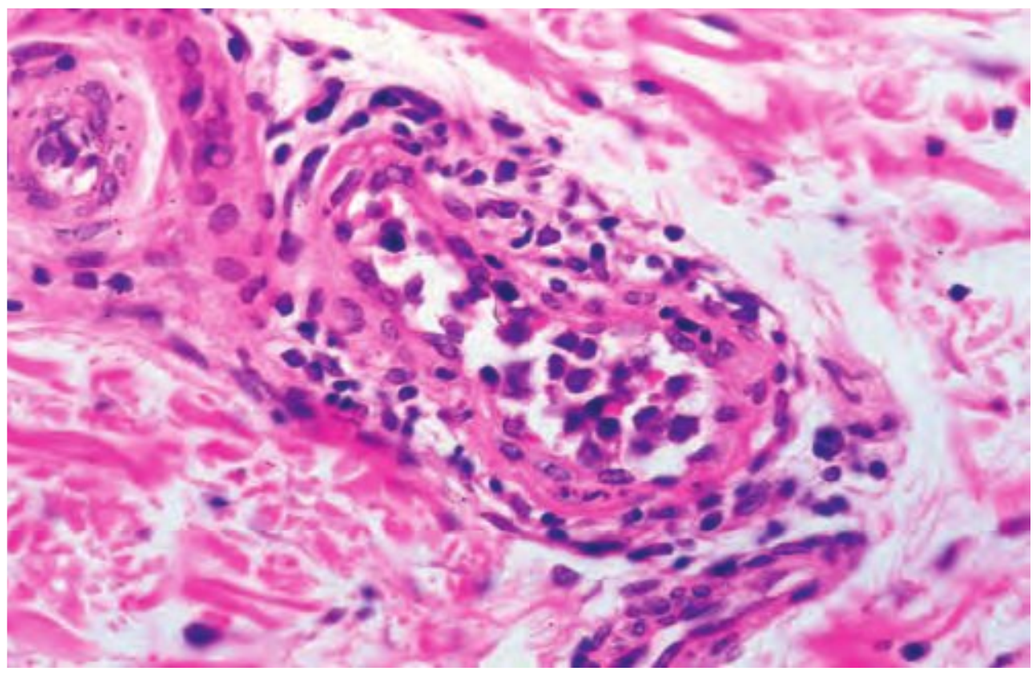
variable immunophenotypical and genetic expression. Gene expression data obtained from microarrays suggest two distinct groups of DLBCL, one of which resembles the genetic makeup of germinal center cells (GCC), while the other one corresponds to the genetic makeup of nongerminal center B cells. DLBCL derived from GCC consistently express BCL6 and have a significantly better prognosis than DLBCL derived from non-GCC (146,147). High proliferative rates may be attested to on Ki-67 staining (Fig. 31-15D).

Differential Diagnosis. Occasional lesions may be dominated by medium-sized lymphoid cells, resulting in confusion with leukemia cutis or Burkitt lymphoma, and immunohistochemistry is required for definitive classification. Unlike blastoid variants of MCL, cells of DLBCL are negative for

cyclin D1 expression. Anaplastic lesions may raise the differential diagnosis of dermal involvement by anaplastic carcinoma and amelanotic melanoma, and in such cases, immunohistochemical screening for lineage-related markers (e.g., CD45, cytokeratins, Melan A) is a useful initial point of departure for diagnostic evaluation.



Intravascular Large B-cell Lymphoma



Considered a rare subtype of DLBCL, intravascular (angiotropic) B-cell lymphoma (formerly and mistakenly termed *malignant angioendotheliomatosis*) is an aggressive process that prototypically demonstrates intralumenal aggregation of large malignant B cells within vessels of involved tissues (148–153). The estimated 5-year survival is approximately 50% (13). It has long been postulated that the intravascular trapping of the neoplastic cells is associated with defects in homing receptors on the lymphoid cells and/or adhesion molecules on the endothelial cells. However, the precise mechanisms are still not fully elucidated.

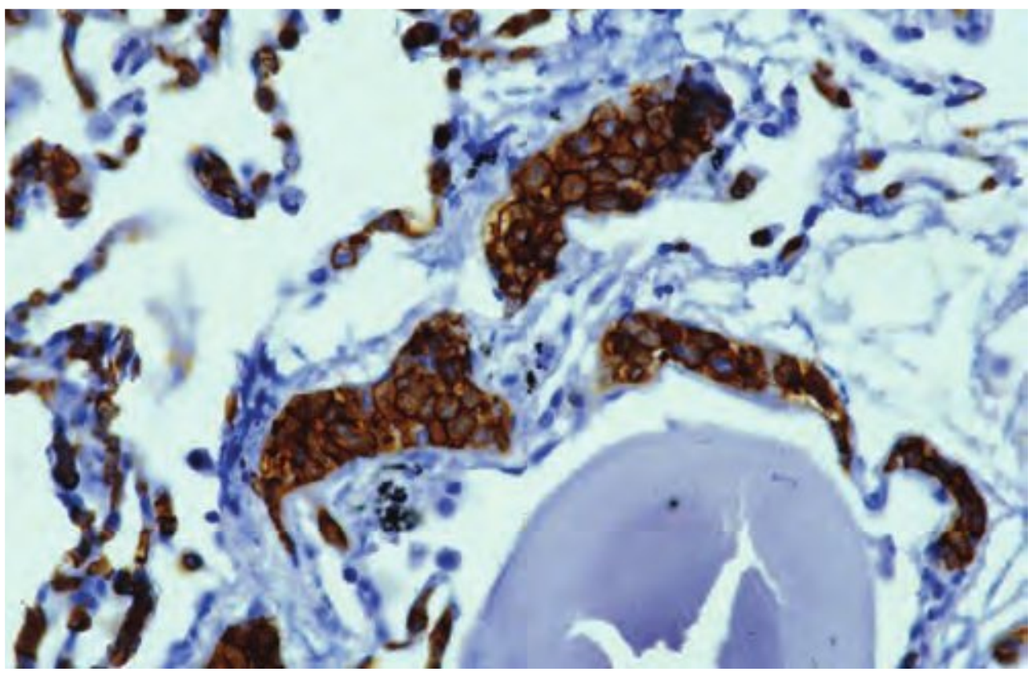
Clinical Features. Intravascular large B-cell lymphoma is a disease of adults. It presents as widely disseminated involvement of extranodal tissues, including the skin, lung, central nervous system, kidney, and adrenal glands. Because signs and symptoms relate primarily to vascular occlusion, clinical presentation often is highly variable. Skin lesions tend to be red plaques and nodules. Telangiectasia and epidermal changes due to ischemia, including scaling and ulceration, also may be observed.

Histopathology. Involved vessels are either entirely or partially occluded by populations of large, malignant-appearing lymphoid cells enmeshed in fibrin (Fig. 31-16A). In the case of the latter, these cells may adhere to inconspicuous and attenuated underlying endothelium, producing the false impression of endothelial atypia or malignancy (Fig. 31-16B). Cytologically, tumor cells contain large nuclei with vesicular chromatin patterns and prominent nucleoli.

Histogenesis. The malignant B cells of peripheral germinal center or post-germinal center origin are believed to express defective homing receptors (e.g., CD11a/CD18), resulting in their tendency for intravascular accumulation due to impaired ability for diapedesis (154,155). Confirmation of B-cell origin may be accomplished by immunohistochemistry for CD20 (Fig. 31-16C). There is variable expression of CD5 and CD10 (150,156–164). Diffuse large B-cell lymphoma with hemophagocytic syndrome (BCL-HS) has been reported mainly in Asia and is regarded as a distinct variant of intravascular lymphoma. Rare cases of intravascular lymphoma with a T-cell phenotype have been documented (164,165).

A

B



C

FIGURE 31-16. Intravascular large B-cell lymphoma. A: Superficial dermal vessels are partially occluded by hyperchromatic malignant cells. B: Higher magnification discloses malignant-appearing lymphocytes partially adherent to the endothelial surface of involved vessels. C: CD20 reactivity for malignant B cells within pulmonary vessels from a patient with diffuse extracutaneous involvement.

Differential Diagnosis. Because lesions typically show malignant cells to be exclusively confined to vascular lumens, the primary differential diagnosis involves differentiation of these cells from malignant and reactive endothelium (e.g., angiosarcoma and diffuse dermal angiomatosis/reactive angioendotheliomatosis [166,167]). In this regard, it should be remembered that both endothelial cells and many cells of hematopoietic origin express the CD34 marker. Differentiation from other intravascular malignant deposits (e.g., inflammatory carcinoma of the breast) may be confirmed by using lineage-related immunohistochemical markers.

Lymphomatoid Granulomatosis

LYG is a rare and variably aggressive lymphoproliferative disorder characterized by angiocentric and angiodestructive infiltration of extranodal tissues, including the skin, by EBV-transformed B cells and reactive T cells (168–170).

Clinical Features. Adult males are generally affected by LYG (male-to-female ratio of 2:1), although immunosuppressed children may also present with this disease. Although multiple organs may be involved, the lung is the most common and if not infiltrated at time of presentation tends to be affected at some point during the natural evolution of the disease. Skin involvement is quite common, being demonstrable in 25% to 50% of all cases. Nodal tissue and spleen are rarely affected (171–174).

Histopathology. Unlike most non-HLs, LYG shows an angiocentric and angiodestructive architecture and a polymorphous cytology (171,173) (Fig. 31-17). The infiltrating mononuclear cells show permeation and focal destruction and fibrinoid necrosis of vessel walls (175), and adjacent zones of ischemic necrosis may result. The cellular composition includes variably atypical lymphocytes with cleaved and elongated nuclear contours, immunoblasts, plasma cells, and histiocytes (176,177). Although MF may rarely produce angiodestructive lesions (178), the lymphoid cells in LYG tend not to have true cerebriform contours. Scattered immunoblasts and histiocytoid cells with some morphologic overlap with Reed-Sternberg variants may express B-cell markers as well as EBV protein. Occasional foci of epidermotropism may be observed in some lesions. Grading of lesions (I–III) based on proportion of EBV-positive cells, extent of atypia, and necrosis may correlate with biologic behavior for some lesions (179).

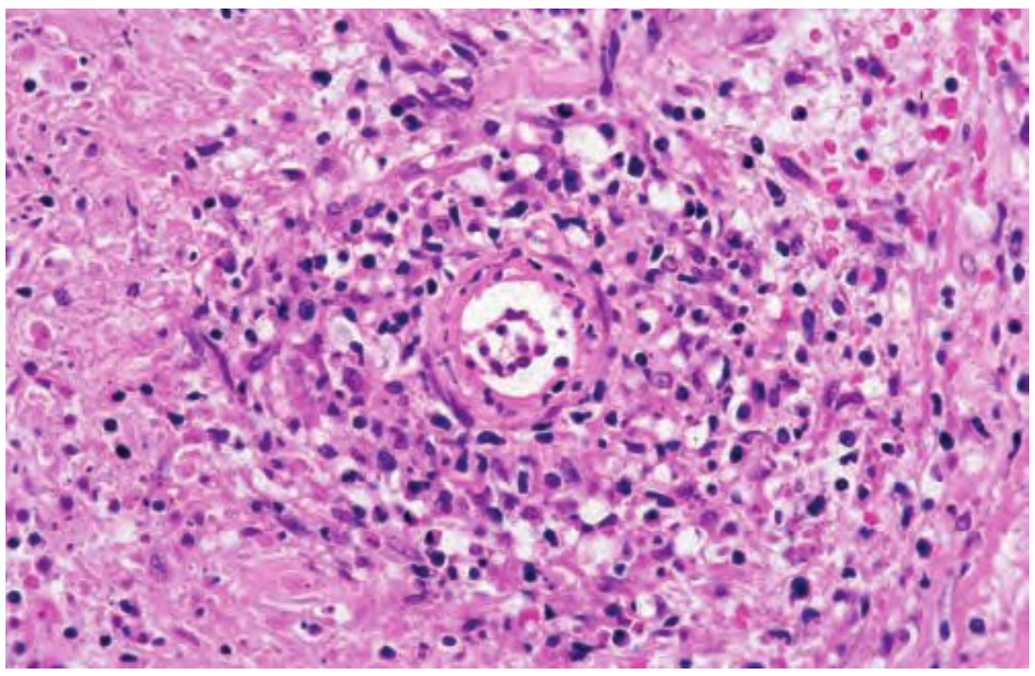


FIGURE 31-17. Lymphomatoid granulomatosis. Atypical lymphocytes have infiltrated and partially destroyed the involved vessel walls.

Histogenesis. The underlying cause of LYG appears to be related to EBV-driven abnormal B-cell proliferation in the setting of immunodeficiency (180,181). Large EBV-positive cells are also reactive for CD20, variably positive for CD30, and negative for CD15. The background lymphocytes are $CD3^+$, with CD4 >CD8. Higher-grade lesions tend to show clonality of immunoglobulin genes (174,182).

Differential Diagnosis. LYG must be differentiated from hematopoietic malignancies that also may show an angiodestructive growth pattern, such as extranodal NK-/T-cell lymphoma of the nasal type (182), and rare instances of MF with a vasculitic component (178). Identification of EBV-positive cells that express CD20 is helpful in separating LYG from these entities. There should not be diagnostic confusion with intravascular large B-cell lymphoma, which fails to show true primary vascular destruction.

Hodgkin's Lymphoma

HL constitutes a group of a relatively common type of lymphoproliferative conditions that share the common features of frequent origin in cervical lymph nodes, tendency toward occurrence in young adults, presence of Reed-Sternberg cells and their variants, and instances of rosette-like rimming of these cells by T lymphocytes. Although the skin is rarely involved, HL is discussed here briefly because it may be considered in the differential diagnosis of other cutaneous lymphoproliferative disorders (183–188).

Clinical Features. There are two major variants of HL: the common classical Hodgkin's lymphoma (CHL) and the far less frequently encountered nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL). The former consists of four histologic subtypes (see below). CHL tends to affect adolescents and young adults and typically presents as peripheral lymphadenopathy localized to one or several node groups. NLPHL affects young to middle-aged patients with a male predominance. Slightly less than half of these patients will also have systemic signs of disease (fever, sweats, and weight loss).

Histopathology. All forms of HL result in a polymorphous hematopoietic infiltrate that may efface nodal architecture and preexisting tissue structure. The histologic variant forms of

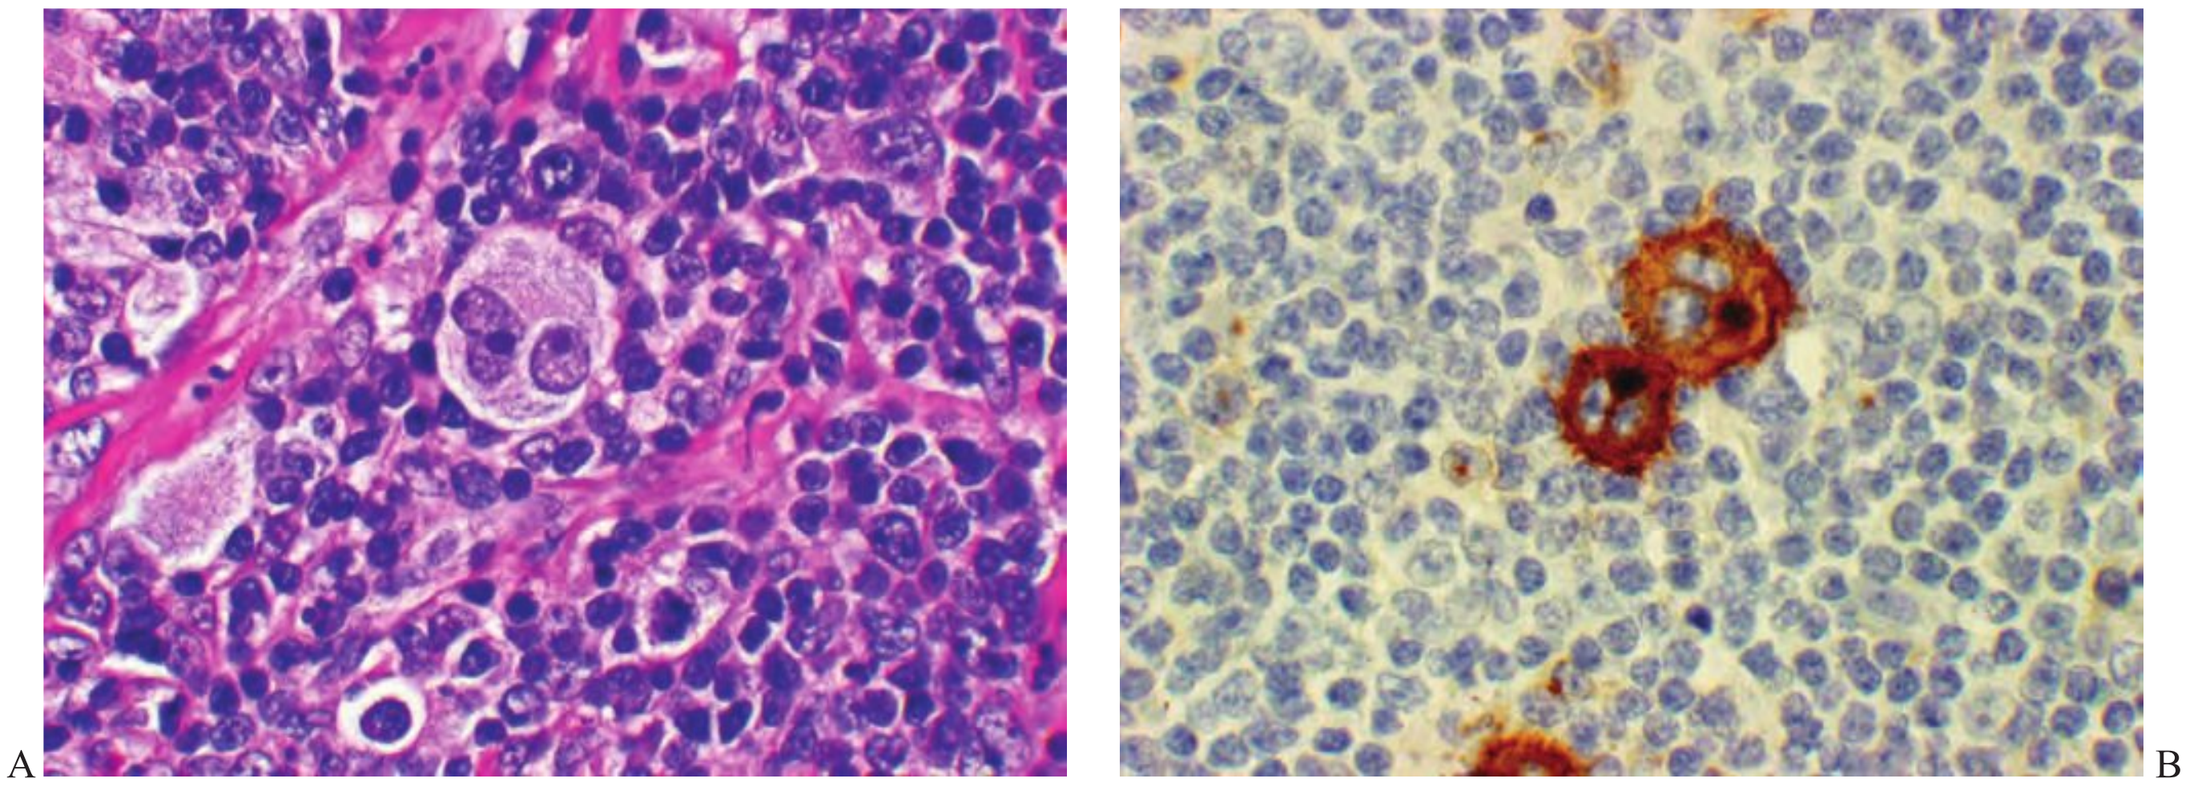

FIGURE 31-18. Hodgkin's lymphoma. A, B: CHL showing pleomorphic infiltrate and a characteristic Reed-Sternberg cell (A) that is reactive for the CD30 antigen (B).

CHL are lymphocyte rich (LRCHL), nodular sclerosis (NSHL), mixed cellularity (MCHL), and lymphocyte depleted (LDHL). CHL contains variable numbers of neoplastic Hodgkin's Reed-Sternberg (HRS) cells with abundant cytoplasm and at least two nuclear lobes, each containing prominent eosinophilic nucleoli and expressing CD30 by immunohistochemistry (Fig. 31-18A, B). By contrast, NLPHL is characterized by a cytologically and immunophenotypically distinct neoplastic cells known as the *L&H cells* (lymphocytic and/or histiocytic Reed-Sternberg cell variants). These cells have infolded and multilobed nuclei that may resemble popcorn, containing often multiple, small, basophilic nucleoli. The key features of each type of HL are summarized in Table 31-6. Skin involvement by HL generally resembles nodal disease. Architecturally, dermal infiltration is nodular or diffuse with absence of epidermotropism.

Histogenesis. The majority of cases of CHL are believed to be derived from mature germinal center B cells (189,190) that are rich in somatic mutations in the VH immunoglobulin genes. NLPHL is uniformly positive for B-cell markers (CD19, CD20, CD22, etc.), while classic types of HD express CD30 (191) in most instances. It appears that HL, despite morphologic similarities, represents a spectrum of disease entities rather than a single malady. NLPHL shows invariable expression of nuclear transcription factor Oct-2 that regulates the immunoglobulin promoter gene together with its cofactor BOB-1 (192–195). Classical types of HD tend to be positive

TABLE 31-6 Key Features of Each Type of Hodgkin's Lymphoma

	NLPHL	LRCHL	NSHL	MCHL	LDHL
Architecture	Nodular or nodular and diffuse	Usually nodular, rarely diffuse	Nodular, with collagen bands	Diffuse, no collagen bands	Highly variable
Cytology	Polymorphous, with L&H cells	Small lymphocytes, admixed with HRS cells	Polymorphous, HRS cells often in lacunar spaces	Polymorphous, HRS cells, granulomas	Variable, high ratio of HRS to lymphocytes
Immunophenotype	L&H cells $CD20^+$, $CD30^-$, $CD15^-$, $EMA^{+/-}$	HRS cells variably $CD20^+$, $CD30^+$, $CD15^+$, EMA^-	HRS cells variably $CD20^+$, $CD30^+$, $CD15^+$, EMA^-	HRS cells variably $CD20^+$, $CD30^+$, $CD15^+$, EMA^-	HRS cells variably $CD20^+$, $CD30^+$, $CD15^+$, EMA^-
EBV status	−	Many +	Many +	Many +	Many +

NLPHL, nodular lymphocyte-predominant Hodgkin's lymphoma; LRCHL, lymphocyte-rich classical Hodgkin's lymphoma; NSHL, nodular sclerosis Hodgkin's lymphoma; MCHL, mixed cellularity Hodgkin's lymphoma: LDHL, lymphocyte-depleted Hodgkin's lymphoma; L&H, lymphocytic and histiocytic; HRS, Hodgkin's Reed-Sternberg; EMA, epithelial membrane antigen; EBV, Epstein-Barr virus.

for PAX-5 encoded B-cell specific activator protein (BSAP) (194,196–199) and show variable expression for EBV in the tumor cells (200–203), either decorated by antibodies against latent membrane protein (LMP-1) and EBNA-1 or visualized by *in situ* hybridization to the RNA of EBV (EBER-1). A plethora of cytokines (interleukins, colony-stimulating factors, transforming growth factor-β, etc.) contribute to the variegated histologic appearance of HD (204–207).

Differential Diagnosis. HL only rarely involves the skin, and such events are almost always secondary to nodal disease. HL involving the skin may be confused, however, with T-cell–rich large B-cell lymphoma, DLBCL, anaplastic T-cell lymphoma, and reactive lymphoid hyperplasia. Careful correlation of clinical, histologic, and immunophenotypic features will generally assist in definitively excluding HL from these differential diagnostic considerations.

$CD30^+$ cells may occur in a variety of settings in addition to HL, including anaplastic T-cell lymphoma, MF, and lymphomatoid papulosis (LYP), and these conditions occasionally may develop in the same patient, resulting in speculation that they may be biologically interrelated (208). Careful evaluation and correlation of coexisting clinical parameters, immunohistochemical, and molecular studies may be necessary for accurate classification of atypical cutaneous infiltrates containing more than occasional $CD30^+$ large lymphoid cells. Fortunately, skin involvement by HL in the absence of overt nodal disease is so rare as to make its inclusion in this differential an academic one.

PRIMARY CUTANEOUS T-CELL LYMPHOPROLIFERATIVE DISORDERS

T-cell Lymphomatoid Hyperplasias

T-cell lymphomatoid hyperplasia refers to the occurrence of epidermotropic cutaneous immune responses composed of activated/proliferative T cells that produce a pattern that may mimic MF and its variants. It is arbitrarily divided into several clinicopathologic variants in order to better illustrate the patterns most likely to result in potential diagnostic confusion with T-cell malignancy.

Clinical Features. Because these conditions all share the feature of epitheliotropism, they—like various forms of MF—may be associated with the formation of scaling erythematous and variably indurated patches and plaques and occasionally with foci of alopecia. On occasion, subacute to chronic spongiotic or lichenoid dermatitis may be associated with lymphoid epidermotropism in the relative absence of intercellular edema or apoptosis, thus bringing to mind consideration of possible T-cell dyscrasia. Certain immune responses may also show a T-cell pattern in the setting of drug-induced immune dysregulation and therefore mimic T-cell dyscrasia or lymphoma.

Histopathology. Dermatitis with epidermotropism in the relative absence of associated spongiosis or evidence of cytotoxic injury will generally show more typical findings on evaluation of deeper sections. Multiple biopsies may occasionally be required to better assess the sequential evolution of lesions and to identify stages where more characteristic inflammatory changes predominate. The finding of Langerhans cell microgranulomas (209) favors a reactive process, although care must be taken not to confuse these structures with true Pautrier microabscesses (see page 937) (Fig. 31-19A). Importantly, many examples of T-cell pattern lymphomatoid dermatitis will lack the uniform cytologic atypia within the epidermotropic component more characteristically seen in MF. An exception to this, however, are T-cell pattern reactive infiltrates occurring in patients with altered immune function, as may be seen in certain lymphomatoid drug eruptions (Fig. 31-19B), as described by Brady and associates (210). In these settings, cytologically atypical epidermotropic infiltrates may closely mimic MF and even may show immunophenotypic (e.g., diminished CD7

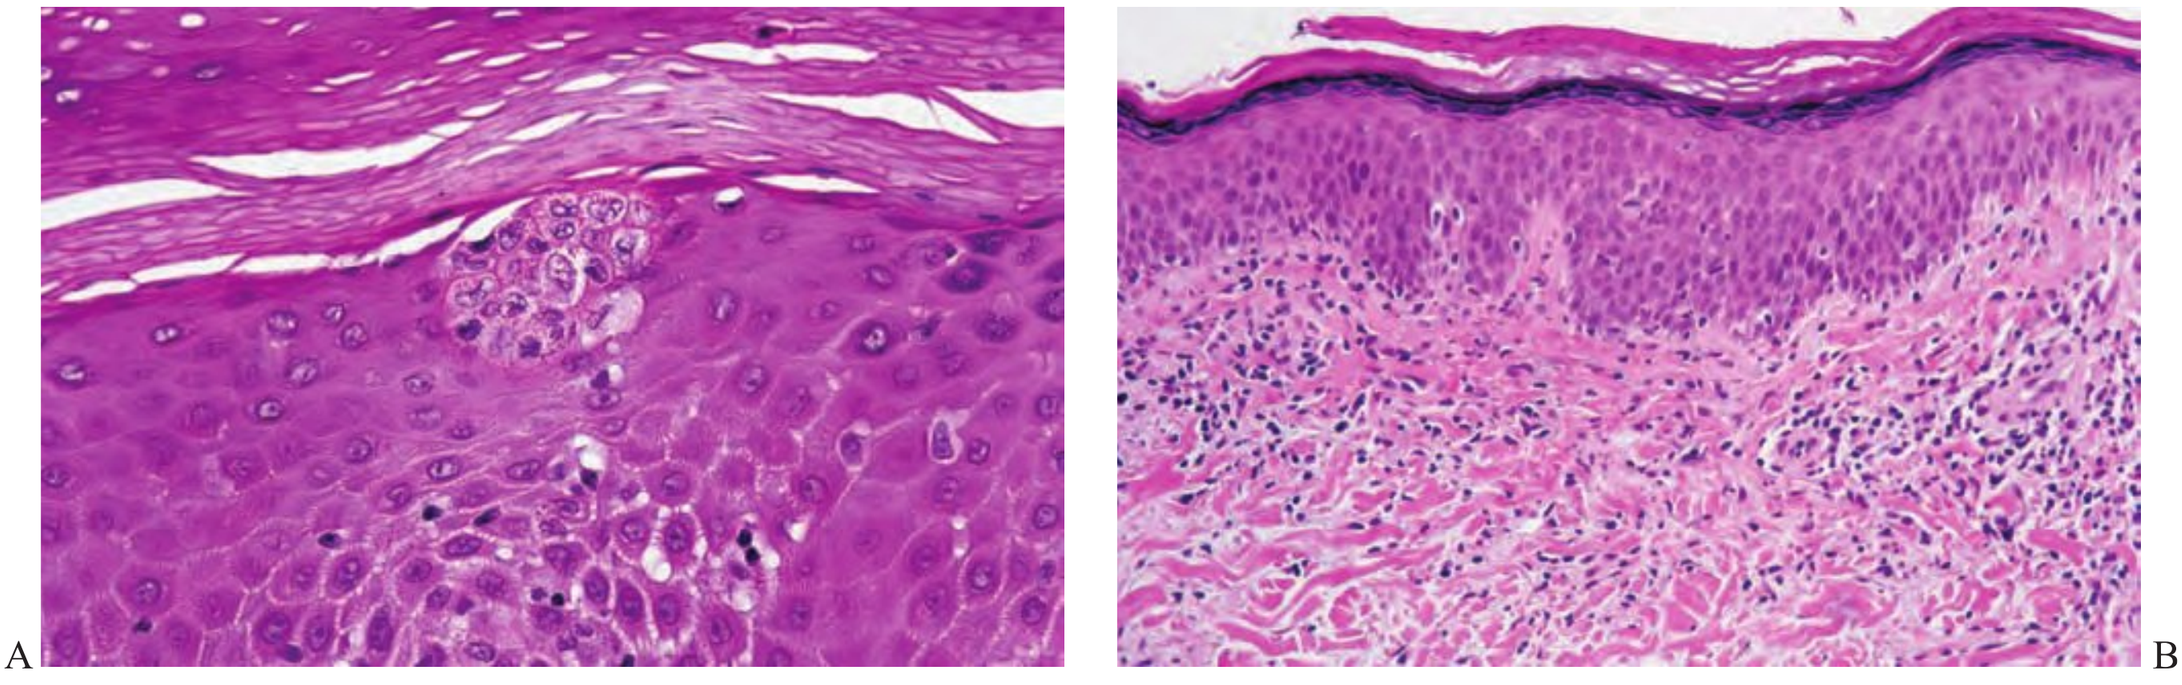

FIGURE 31-19. T-cell lymphomatoid hyperplasia. A: Langerhans cell microgranuloma associated with T-cell immune response may mimic Pautrier microabscess. B: Lymphomatoid drug eruption, with papillary dermal interstitial and focally epidermotropic infiltrate of variably activated lymphocytes in a characteristic T-cell pattern.

expression) or genotypic (e.g., T-cell receptor [TCR] gene rearrangements) abnormalities that are reversible on drug cessation (211).

Histogenesis. The histogenesis of T-cell pattern drug-induced lymphoid dyscrasia seems to relate to the concurrence of cutaneous hypersensitivity reactions caused by drugs that themselves are capable of inciting some level of immune dysregulation. These drugs include anticonvulsants, antidepressants, phenothiazines, calcium channel blockers, and angiotensin-converting enzyme inhibitors.

Differential Diagnosis. The primary differential diagnosis is the T-cell pattern immune response in the setting of immune dysregulation. Careful consideration of clinical factors, including duration of lesions, response to previous therapy, and potential relationship to drugs that influence lymphocyte function should be undertaken before definitively excluding a lymphomatoid drug eruption in the differential diagnosis of epidermotropic T-cell malignancies.

T-/NATURAL KILLER–CELL NEOPLASMS

Mycosis Fungoides

MF is the prototype of CTCL that typically begins as slowly progressive dermatitis-like patches and plaques, and if untreated evolves to nodules and eventual systemic dissemination. The patch/plaque stage of the disease is the result of intraepidermal and superficial dermal infiltration by small- to medium-sized malignant T cells with characteristically cerebriform nuclear contours, while the more advanced stages develop as a consequence of exclusively dermal involvement by nonepidermotropic, often cytologically more atypical malignant T cells.

Clinical Features. MF is relatively rare, accounting for $<1\%$ of non-HLs. However, of lymphomas that arise primarily in skin, it is the most common (13), comprising approximately 44% of cutaneous lymphomas. It is a disease predominantly of adult males (male-to-female ratio of 2:1), although children are occasionally affected. MF has a plethora of clinicopathologic manifestations. Typical lesions initially present as large erythematous scaling patches and plaques (many centimeters in diameter and may show arcuate or polycyclic configurations) that generally are resistant to antiinflammatory therapy (Fig. 31-20A). Zones of alopecia may occur due to infiltration and mucinous degeneration of hair follicles (alopecia mucinosa). Occasional lesions may show epidermal atrophy, prominently dilated superficial dermal blood vessels, and patchy hyper- and hypopigmentation (poikiloderma vasculare atrophicans variant), while others may show excessive epidermal thickening and scaling (psoriasiform variant). In one rare form of the disease, lesions are generally solitary, involve acral skin, and clinically resemble squamous neoplasia as a result of epidermal thickening and scale formation (pagetoid reticulosis variant). The dermal component is occasionally associated with granulomatous inflammation that compromises the integrity of elastic fibers (granulomatous slack skin [GSS] variant).

The natural history of MF is one of slow progression, with the patches and plaques giving rise over time to nodules that may eventually ulcerate (Fig. 31-20B). Rarely, nodules are documented from the outset (d'emblee variant), although this rare presentation is not well characterized, and some of these patients may have other forms of T-cell malignancy (e.g., adult T-cell leukemia/lymphoma [ATLL]; primary cutaneous peripheral T-cell lymphoma; unspecified, primary cutaneous $CD4^+$ medium-sized pleomorphic T-cell lymphoma; and $CD30^+$ large T-cell lymphoma) (212). Diffuse erythroderma may be associated with systemic dissemination and may represent either a manifestation of late evolution of localized disease (213) or blood involvement from the outset (Sézary syndrome). When extracutaneous spread eventuates, the lymph nodes, spleen, liver, and lungs are often involved, in addition to the peripheral blood. Lymph node enlargement at such advanced stages must

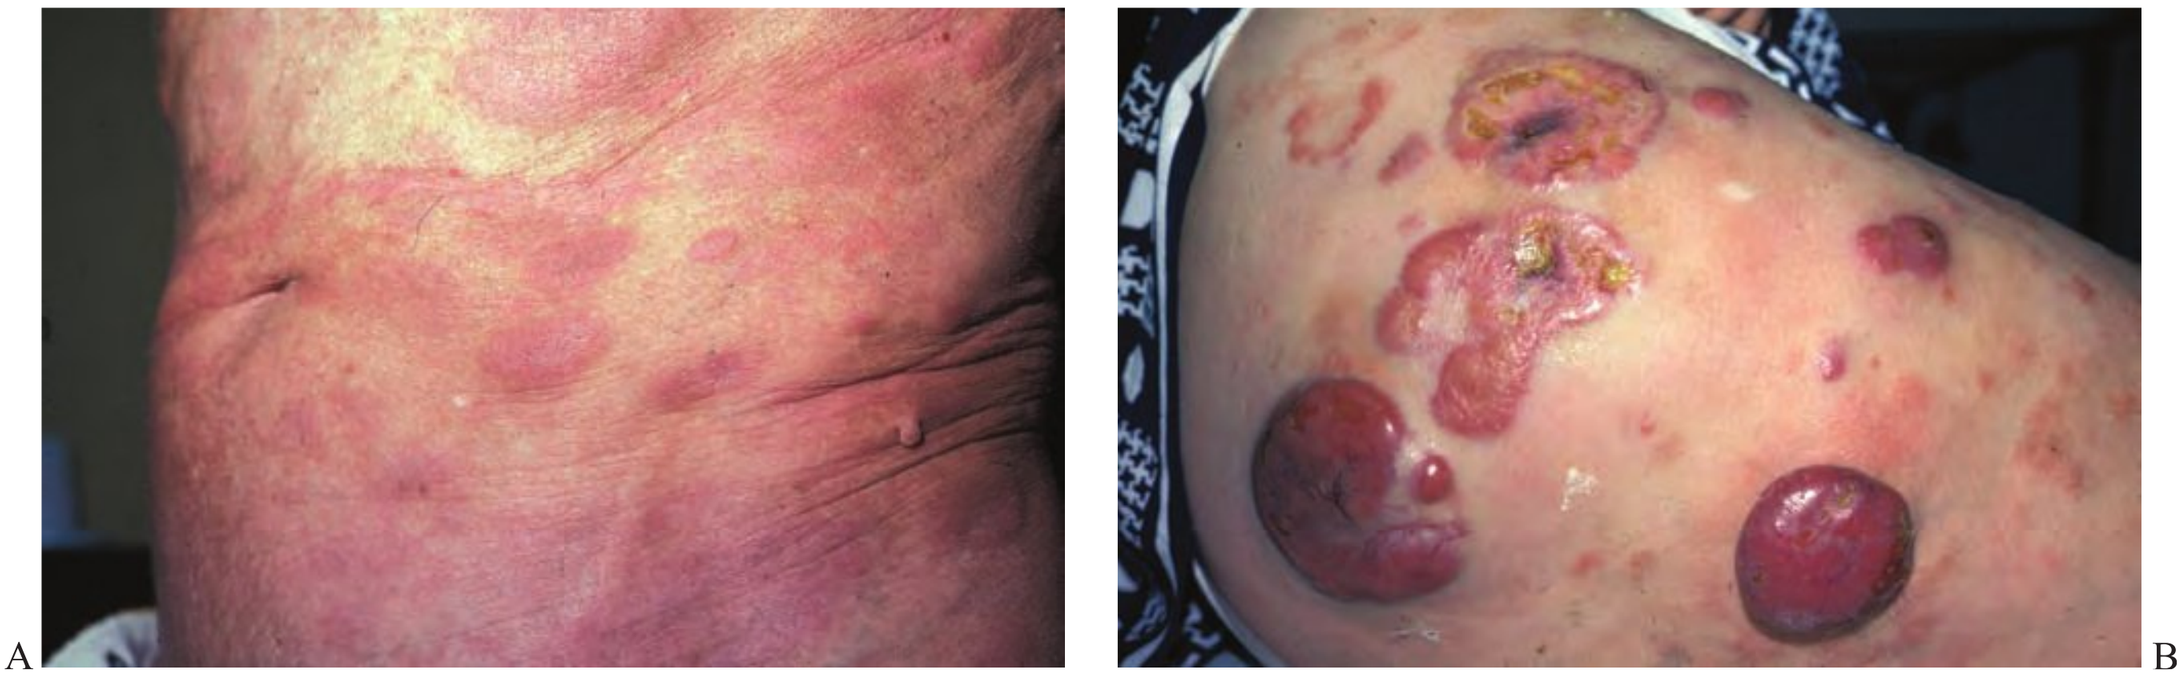

FIGURE 31-20. Mycosis fungoides: clinical features. A: Erythematous scaling patches and plaques of early disease. B: Plaques and nodules of advanced disease.

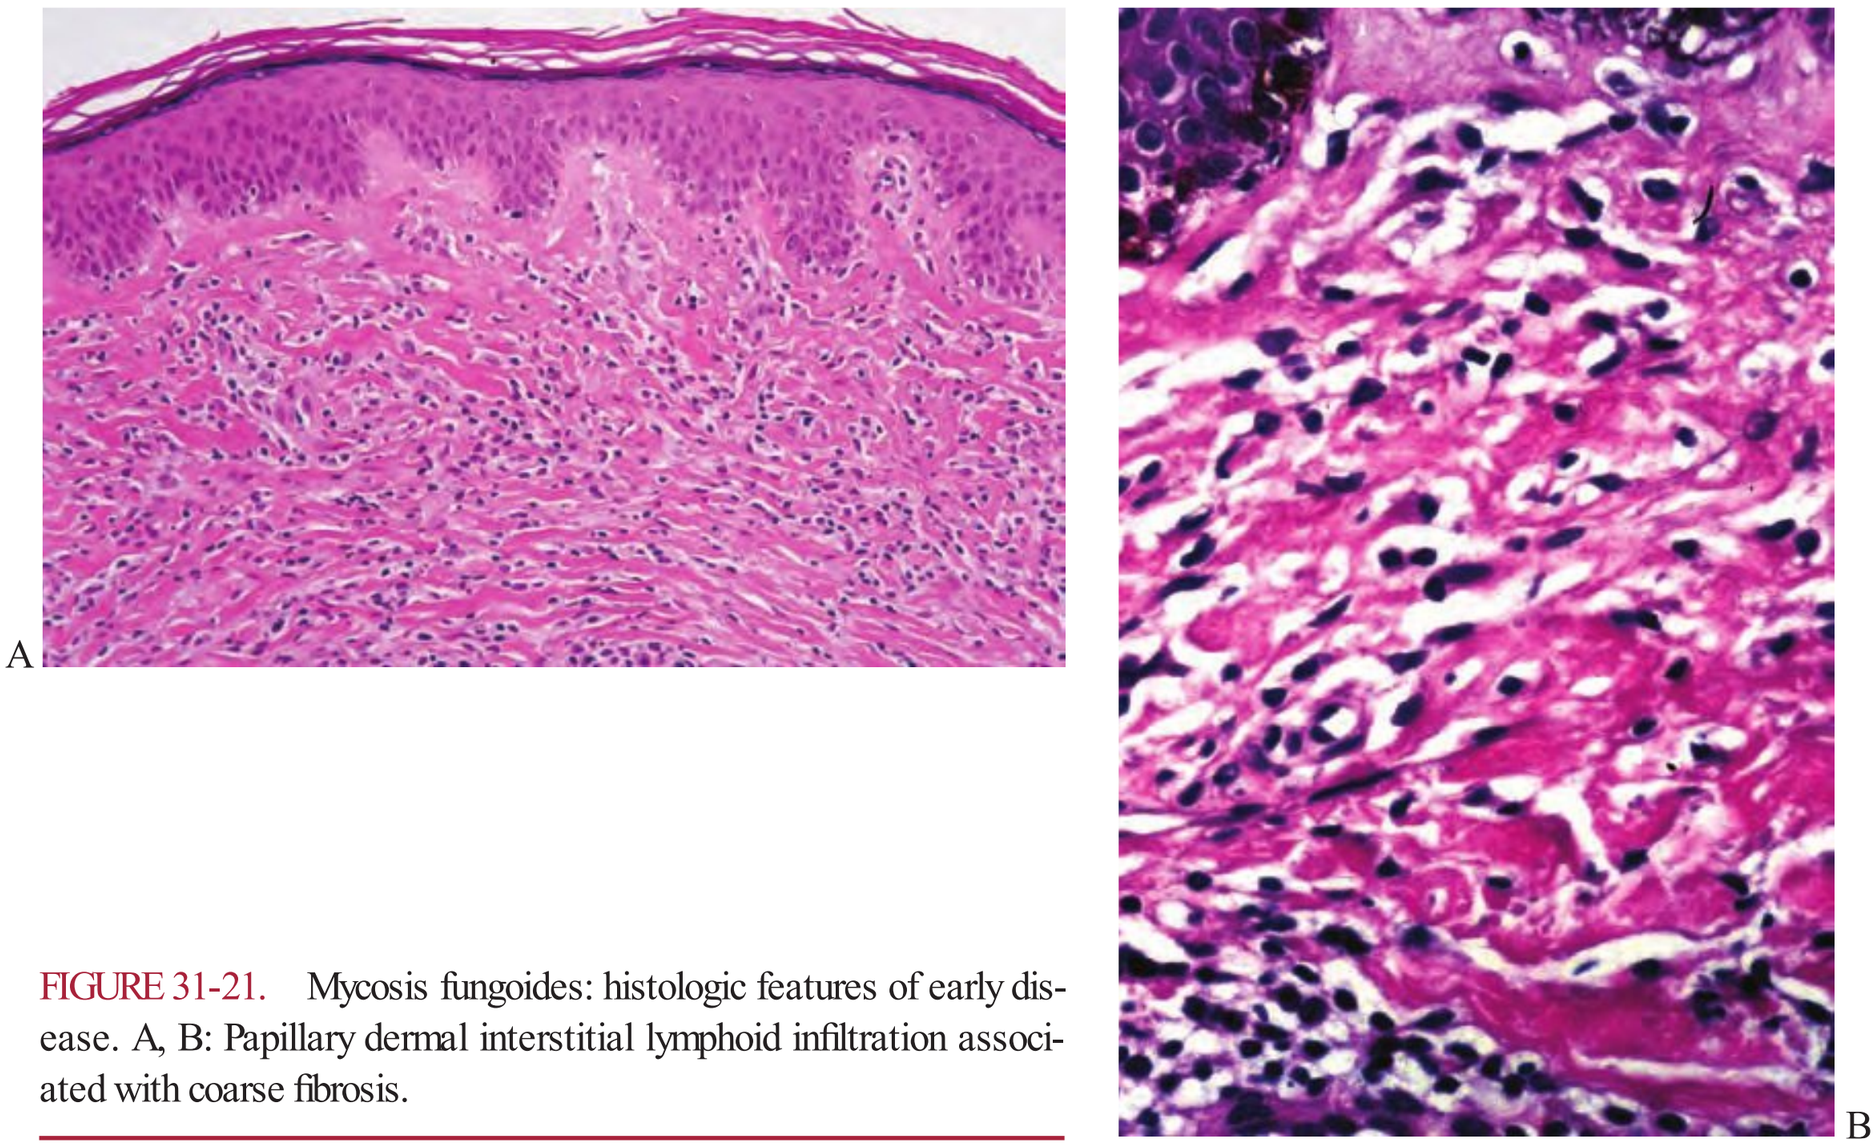

FIGURE 31-21. Mycosis fungoides: histologic features of early disease. A, B: Papillary dermal interstitial lymphoid infiltration associated with coarse fibrosis.

be differentiated from nodal hyperplasia resulting from chronic drainage of involved sites (dermatopathic lymphadenopathy).

Clinical staging of MF involves four categories: stage I indicates disease confined to skin as localized (<10% body surface, stage IA) or disseminated (≥10% body surface involvement, stage IB) patches/plaques; stage II signifies nodal enlargement without histologic evidence of nodal lymphoma (generally dermatopathic changes only, IIA) or cutaneous tumors (IIB); stage III implies generalized erythroderma; and stage IV connotes nodal or visceral dissemination (214). Prognosis is directly related to extent of disease progression, with stage I and II lesions having an excellent outcome and more advanced presentations (nodules and extracutaneous dissemination) showing aggressive courses (13,213,215–218).

Histopathology. Early lesions of MF show a patchy bandlike lymphocytic infiltrate within the papillary dermis, often associated with coarse fibrosis (Fig. 31-21A, B). The lymphocytic component may in part be reactive, with an admixture of eosinophils, plasma cells, and monocytes, and in this mixture of cells, the characteristic cytology of MF cells may be difficult to document. Care must be taken to identify foci of epidermotropism or folliculotropism that generally involve the malignant T-cell clone. These foci may consist of a lentiginous pattern (linear accumulation associated with the basement membrane zone, frequently described as *tagging*) (Fig. 31-22A, B) or a pagetoid pattern with either single-cell infiltration (Fig. 31-22C) or clustered epidermotropic atypical lymphocytes, also known as *Pautrier microabscesses*, into a "passive" epidermal layer (Fig. 31-22D). Lymphoid epidermotropism in MF, unlike lymphoid exocytosis in dermatitis, is generally unassociated with significant epidermal or follicular spongiosis or evidence of cytotoxicity (basal cell layer vacuolization or apoptosis). Rather, the epithelium may appear passive, resulting in seemingly permissive accumulation of atypical lymphocytes within lacunar spaces that separate seemingly indifferent keratinocytes. These spaces appear by sequential analyses to result from minute regions of epithelial mucinosis. When hair follicles are infiltrated by malignant T cells, accumulation of mucin may produce widened intercellular spaces between epithelial cells and ultimately result in inability of follicles to support existing or recycle new hair shafts (follicular mucinosis).

Cytologically, the malignant T cells in MF are small- to medium-sized lymphocytes that characteristically contain nuclei with dense heterochromatin and elaborately indented (cerebriform) nuclear contours (Fig. 31-23A, B). Occasionally, these cells may be difficult to differentiate from cytokine-activated T cells, although one helpful feature is the tendency for epidermotropic malignant T cells to predominantly or exclusively show cerebriform nuclear features and clear perinuclear halos. However, intraepithelial aggregates of malignant T cells in MF must be differentiated from similar aggregates of larger mononuclear cells also with irregular, frequently indented, nuclear profiles (so-called Langerhans cell microgranulomas [8], commonly associated with dermatitis; also see differential diagnosis and Table 31-7). Malignant T cells with cerebriform nuclei, although present predominantly in the epidermis, also may be detected within the dermal component of lesions. However, their frequent admixture with reactive lymphocytes and mononuclear cells may make their reliable identification more difficult, especially in early lesions. With advanced disease, when lesions become nodular and there is often loss of

TABLE 31-7 Differential Diagnosis of Mycosis Fungoides and Dermatitic Mimicks

	Mycosis fungoides	Reactive dermatitis
Architecture of infiltrate	• Early/Patch stage: patchy bandlike • Plaque stage: lichenoid • Tumor stage: nodular/diffuse	• Superficial perivascular • Superficial and deep perivascular
Pattern of infiltrate	Epidermotropism with Pautrier microabscesses	Exocytosis with Langerhans cell microgranulomas
Composition of infiltrate	Predominance of atypical lymphocytes	Admixed lymphocytes, macrophages, eosinophils, mast cells, and plasma cells
Epidermal changes	Psoriasiform hyperplasia without associated spongiosis or apoptotic keratinocytes	• Associated spongiosis and apoptotic keratinocytes • Psoriasiform hyperplasia may be seen in chronic disease
Papillary dermal changes	Coarse fibrosis	May be fibrotic if long standing or previously traumatized
Cytology of lymphoid cells	• Small to medium • Cerebriform hyperchromatic nuclei • Perinuclear halos	• Small, round, and regular
Immunophenotyping	$CD2^+$, $CD3^+$, $CD4^+$, $CD5^+$, and $CD8^-$ with loss of CD7 (rare $CD8^+$ variant reported)	Mixed $CD4^+$ and $CD8^+$
TCR gene rearrangement	Clonal	Polyclonal (rarely clonal)

TCR, T-cell receptor.

epidermotropism, the dermal infiltrate is composed of nodular to diffuse interstitial populations of more uniformly atypical T cells (Fig. 31-24A, B). Transformation to large, highly atypical CD 30^+ lymphocytes in the dermal component is associated with development of an aggressive biologic course (219,220).

Apart from the classic MF described previously, there are a number of clinicopathologic variants and subtypes of MF, some of which are recognized by the WHO/EORTC consensus classification. These include the following:

Adnexotropic mycosis fungoides (221). This form of the disease may occur anywhere, although the skin of the face and the scalp as well as sun-exposed extremities are often involved. Epidermotropism may be minimal to absent, and diagnosis may be overlooked when biopsies are too superficial. Infiltration of hair follicles by characteristically atypical T cells (222) (folliculotropic MF) may result in Pautrier microabscesses and be associated with follicular mucinosis where keratinocytes forming affected follicles produce intracellular mucin and eventually degenerate, culminating in alopecia (Fig. 31-25A–C). There are no reliable clinical, histopathologic, or molecular criteria that allow a distinction to be made between "benign" alopecia mucinosa and MF-associated follicular mucinosis (folliculotropic MF [223]). Eccrine involvement (syringotropic MF) may also be observed, with or without follicular lesions. Infiltration of the eccrine coil

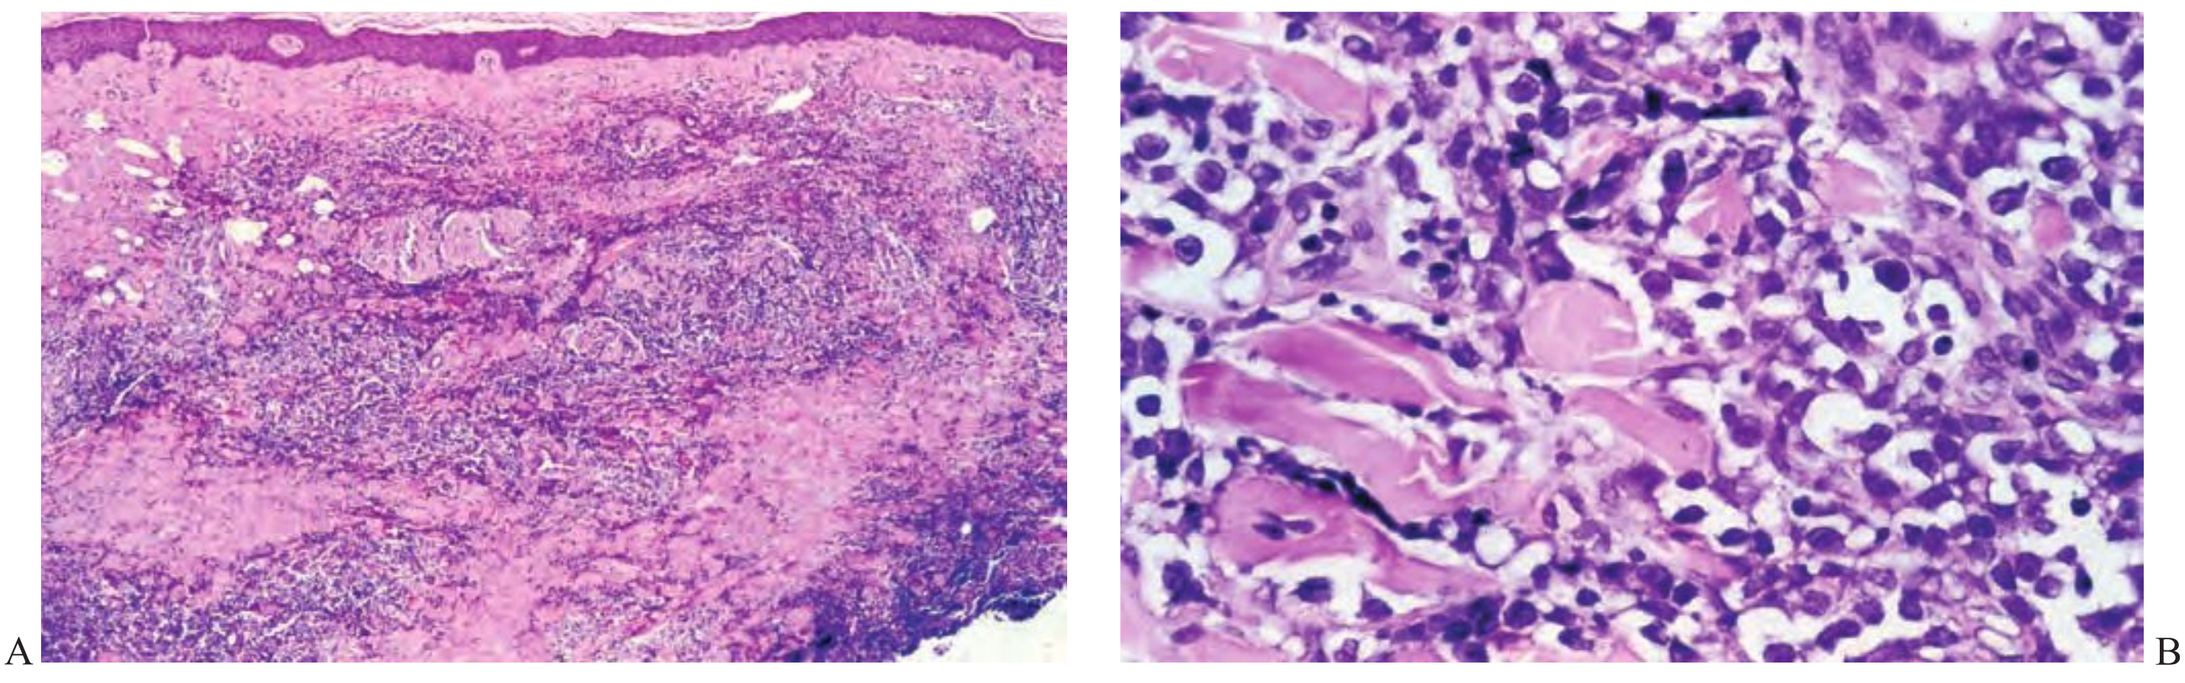

FIGURE 31-24. Mycosis fungoides: nonepidermotropic. A: There is a nodular to diffuse dermal infiltrate with relative sparing of the superficial dermis and epidermis. B: Cytologically, atypical lymphocytes produce an interstitial pattern of dermal infiltration.

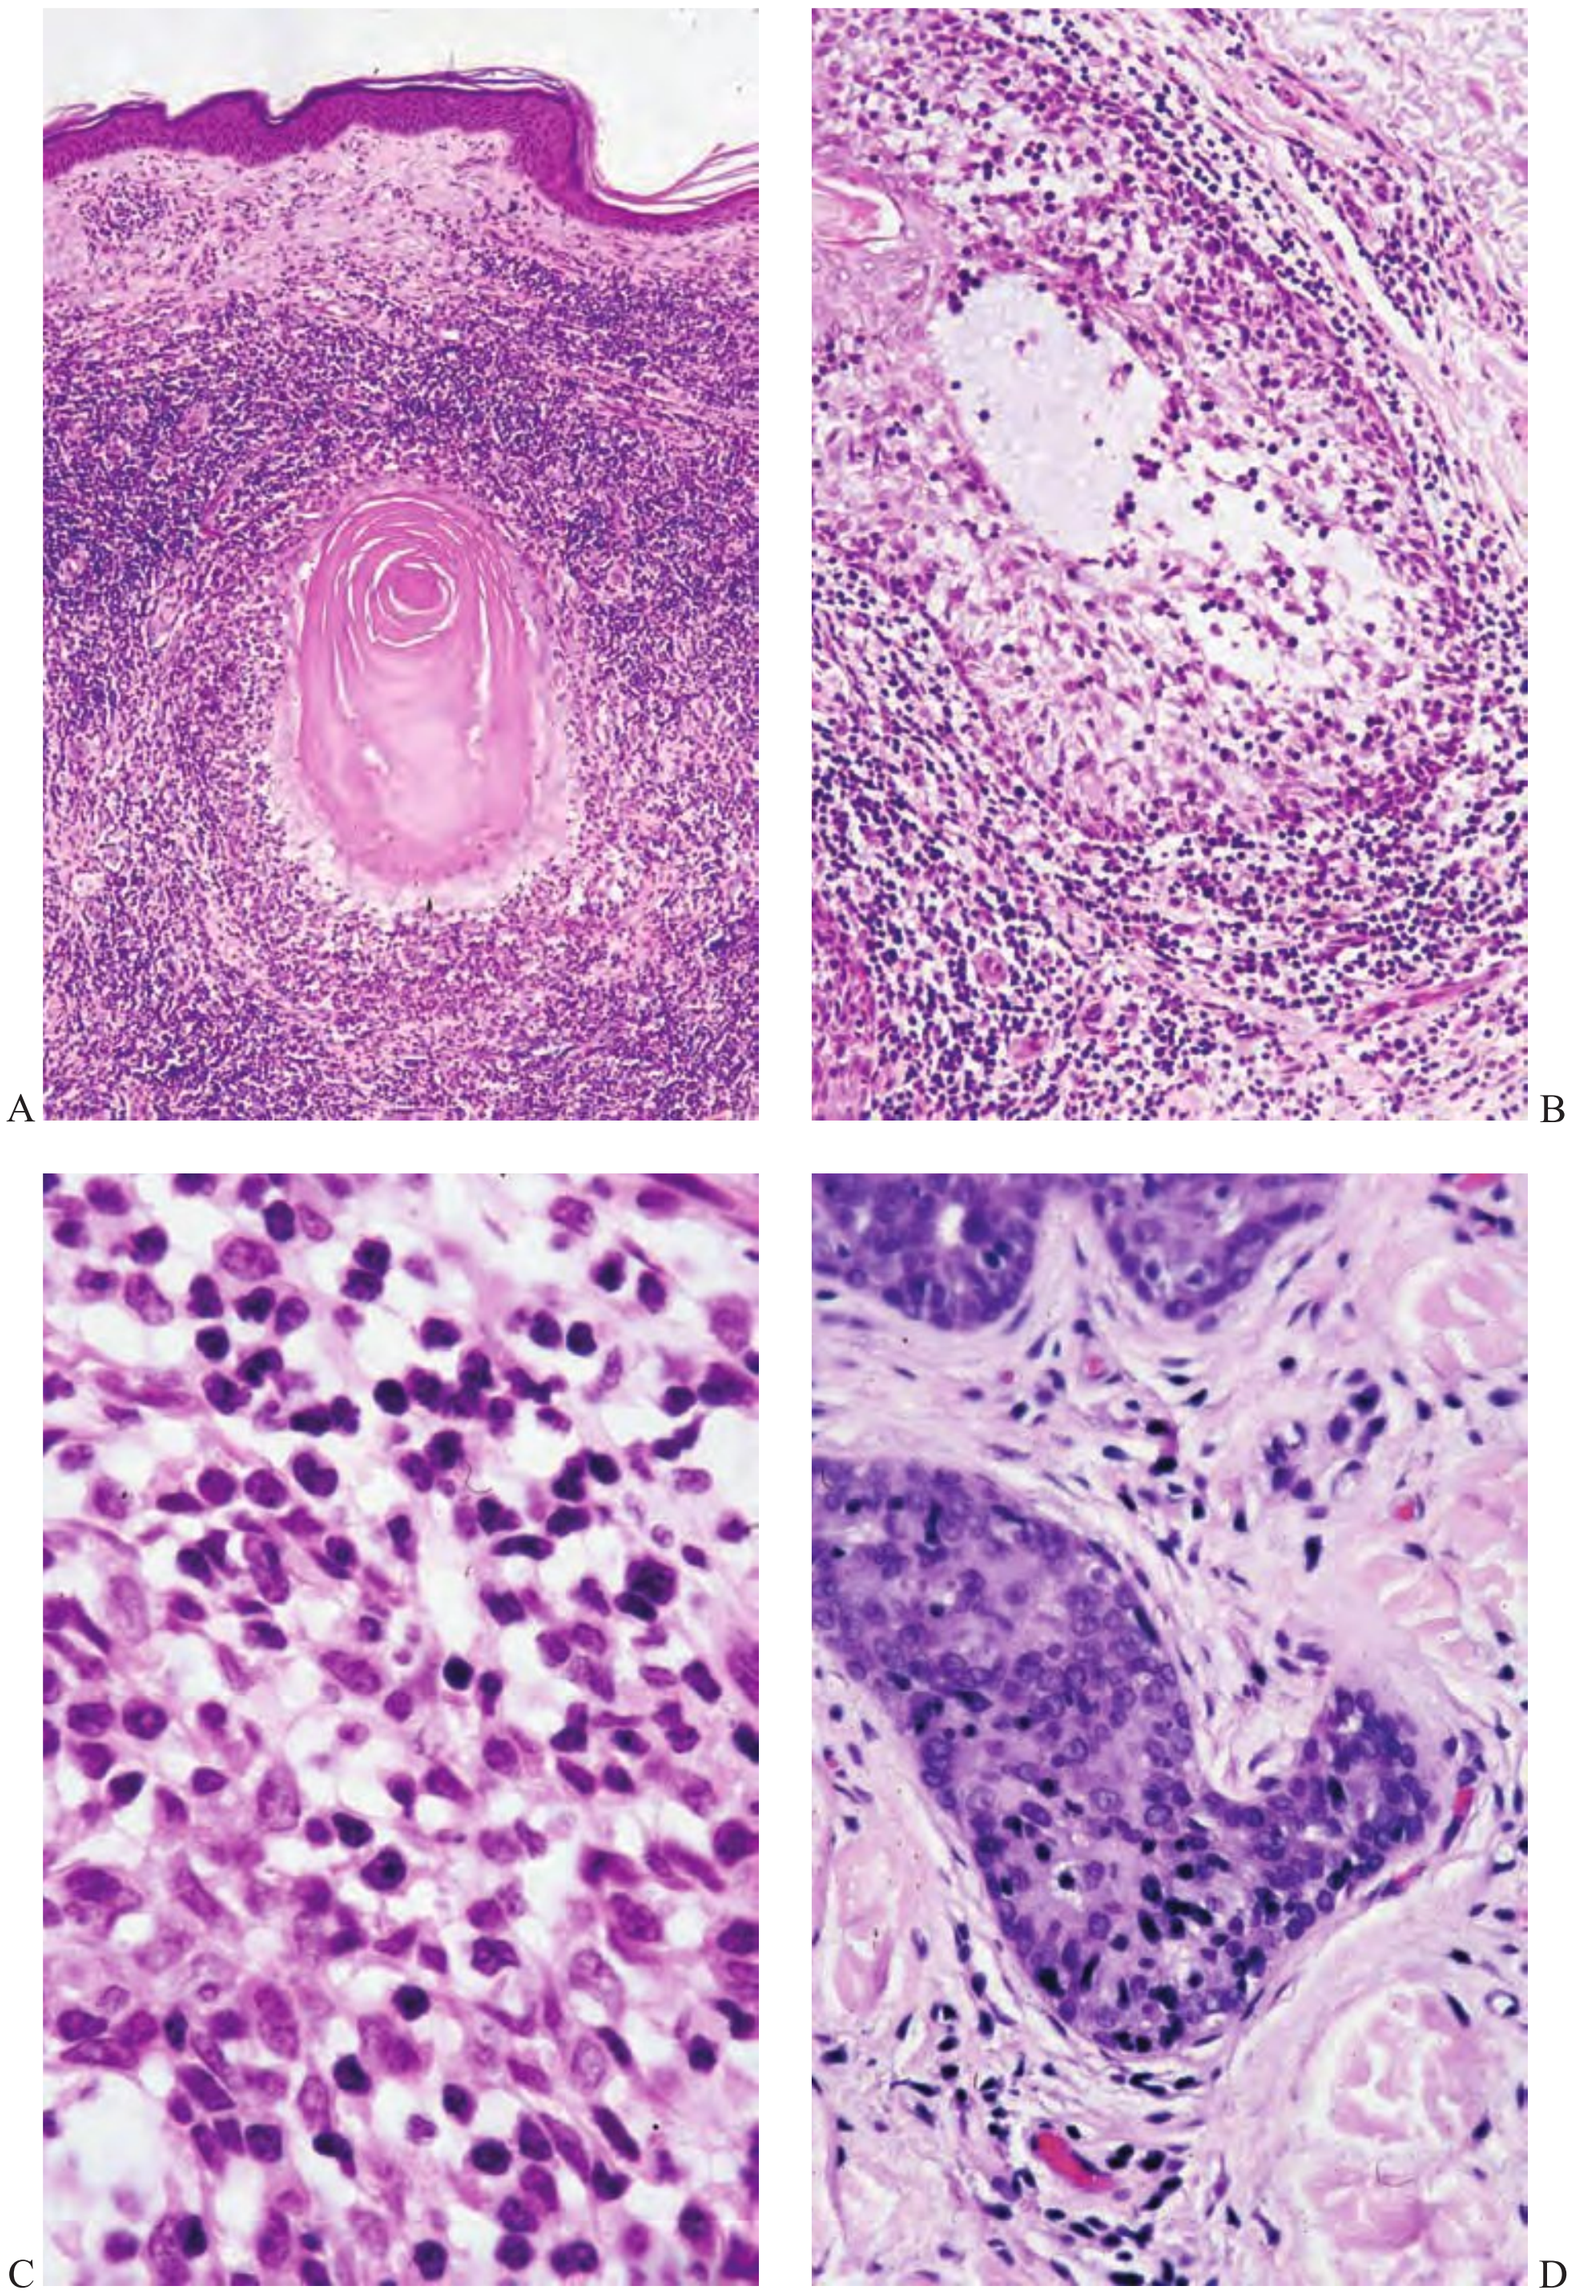

FIGURE 31-25. Adnexotropic mycosis fungoides. A: Infiltration is associated with architectural distortion and destruction of follicular structures. B: Follicular mucinosis characterized by pools of pale blue–staining mucin. C: Atypical T cells in a mucinous background. D: Eccrine involvement by atypical lymphocytes, associated with syringosquamous metaplasia.

may be associated with syringometaplasia but not mucinosis (Fig. 31-25D). Prognosis is generally favorable, although potentially less so than in early evolutionary stages of classic epidermotropic patch/plaque-stage disease (13). From the clinical point of view, an additional relevant feature of adnexotropic MF includes the deeper localization of neoplastic infiltrate, which may render reduced response to skin-targeted therapies.

Solitary pagetoid reticulosis (Woringer-Kolopp disease). In the past, cases of pagetoid reticulosis were considered to be a distinct entity. Only recently, phenotypic criteria have allowed them to be reclassified. Solitary pagetoid reticulosis (Woringer-Kolopp disease) is now regarded as a rare variant of MF, whereas cases of generalized pagetoid reticulosis (Ketron-Goodman disease) represent, for the most part, examples of aggressive $CD8^+$ T-cell lymphoma (56). Solitary pagetoid reticulosis (Woringer-Kolopp disease) is a rare low-grade and peculiar form of MF associated with exclusively epidermal infiltration by medium- to large-sized malignant T cells with abundant pale cytoplasm, often in the form of a solitary acral

lesion where associated epidermal acanthosis and hyperkeratosis results in the clinical impression of a squamous neoplasm. The pagetoid growth pattern of the neoplastic T cells may be attributed to their strong expression of adhesion molecules, cutaneous lymphocyte-associated antigen (CLA) and αEβ7, in particular, which facilitate interactions with endothelial cells and keratinocytes, respectively (224). Immunophenotypic studies have also disclosed the malignant T cells to be either $CD4^+$, $CD8^+$, or double negative for both epitopes, and TCR gene rearrangements may be demonstrated (225). Histopathologically, because of the pronounced epidermotropism, pagetoid reticulosis may mimic superficial spreading melanoma, pagetoid squamous carcinoma *in situ*, Paget's as well as extramammary Paget's disease. However, differential diagnosis can be readily achieved based on cytomorphologic and immunophenotypic features (CD45, S100, pan-cytokeratin, epithelial membrane antigen [EMA], and carcinoembryonic antigen [24,226,227]).

Granulomatous mycosis fungoides. This unusual variant accounts for up to 4% of MF. Clinically, the lesions present as papules, plaques, and tumors that are not distinctive from classical cases (228). Histopathologically, granulomatous MF is characterized by the presence of variable granulomatous inflammation, which may take the forms of interstitial, tuberculoid/sarcoidal, or palisading granulomata reminiscent of granuloma annulare and/or necrobiosis lipoidica (229–231). Multinucleated giant cells, usually of the foreign body type (although Langerhans and Touton giant cells have been described as well) with or without focal elastophagocytosis, may be seen (228,232,233). Recent studies suggest that granulomatous MF may have an aggressive course, with nearly 40% of patients dying from the disease and 50% within 5 years of the onset of cutaneous lesions (234,235). Special stains for microorganisms are useful in excluding concurrent infection in a patient with classical MF. Despite rare cases showing overlapping features, granulomatous MF can be differentiated from GSS clinically by the absence of bulky skin lesions and histologically by the lack of extensive elastolysis/elastophagocytosis and dense infiltrate with deep subcutaneous involvement (236).

Granulomatous slack skin (GSS). This subtype indicates the presence of elastolytic granulomas that develop in association with the dermal lymphomatous component, which is typically dense and extends deep into the subcutis. Histologically, atypical T-cell infiltrates, often associated with epidermotropism or folliculotropism, are intimately associated with noncaseating dermal granulomas formed by histiocytes and multinucleated giant cells that may contain ingested elastic fibers (237) or engulfed lymphocytes (emperipolesis). In established lesions, there is marked reduction of elastic fibers. Clinically, zones of skin with increased folding and decreased elasticity gradually develop, with preferential involvement of intertriginous sites, as a result of loss of elastic fibers. Despite therapy, lesions generally progress slowly over time.

In addition to the variants and subtypes listed by the WHO/EORTC consensus classification, other variants of MF have been described. Despite characteristic features that allow for their distinction, these variants share a similar clinical course and prognosis with classical MF and may represent a clinicohistopathologic spectrum of the disease. Nonetheless, because of their clinical and histopathologic similarity to reactive dermatoses, recognition of these variants will facilitate differential diagnosis (212).

Poikiloderma vasculare atrophicans. This is a reaction pattern that may occur in lesions of MF, although it is not synonymous with T-cell lymphoma and may be seen in other settings. Early lesions may involve either large plaques or small papules arranged in a netlike configuration. Lesions show erythema, mild scaling, epidermal thinning, mottled hypo- and hyperpigmentation, and telangiectasia, and the clinical picture may resemble changes of radiodermatitis. Histopathology discloses epidermal atrophy; epidermal infiltration by atypical lymphocytes; a variable band of lymphocytes, histiocytes, and melanophages in the papillary dermis; and ectasia of superficial dermal vessels. The finding of atypical lymphocytes, potentially supported by a characteristic immunophenotypic and molecular profile for MF, should assist in separating this rare variant from other causes of acquired poikiloderma, including dermatomyositis and lupus erythematosus.

Psoriasiform mycosis fungoides. In the authors' experience, this variant is rare and may in some instances be the consequence of superimposed lichen simplex chronicus. Epidermotropism is present, consisting of accumulation of single and clustered atypical small- to intermediate-sized lymphocytes within the epidermal layer (Fig. 31-26). However, there is marked acanthosis frequently in association with coarse papillary dermal

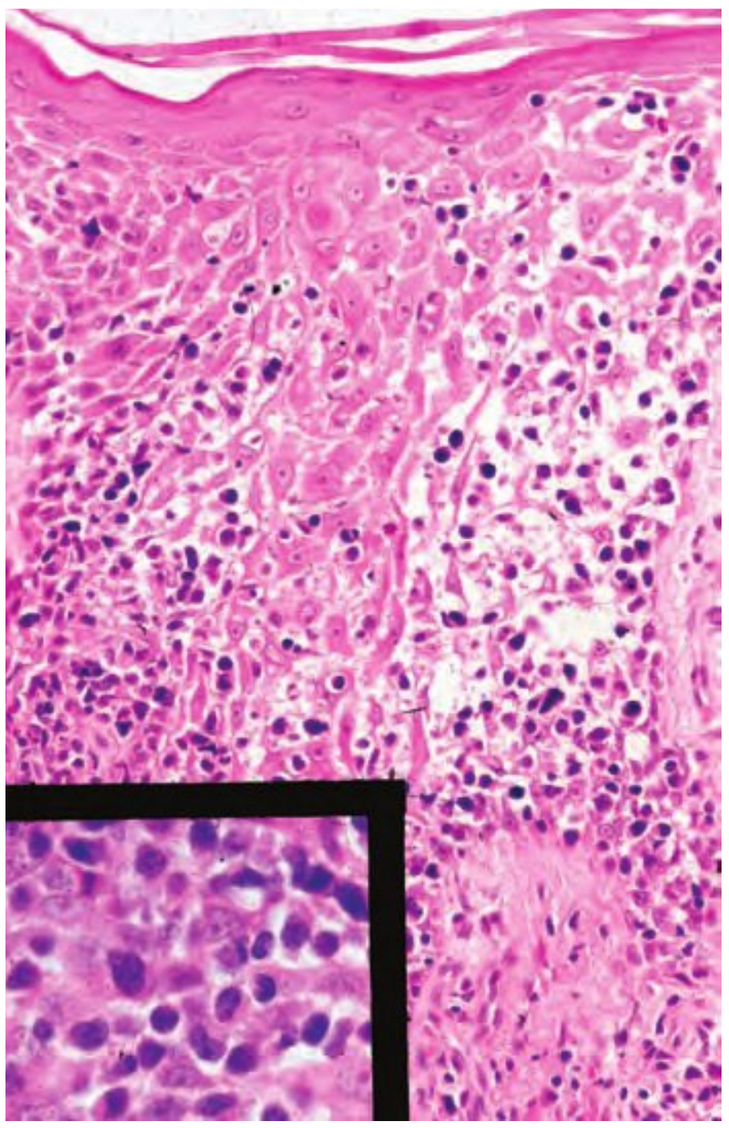

FIGURE 31-26. Psoriasiform mycosis fungoides. There is epidermal hyperplasia associated with pronounced epidermotropism by atypical lymphocytes (inset).

fibrosis. In one study of 222 biopsies where MF produced patterns that mimicked various forms of dermatitis, including psoriasiform dermatitis, diagnostic clues included epitheliotropism in the relative absence of spongiosis, alignment of atypical lymphocytes in association with the basal cell layer (so-called "tagging"), lymphoid atypia, and broad areas of compact hyperkeratosis with subtly interspersed parakeratosis (238).

Bullous/Vesicular mycosis fungoides. Bullous MF manifests clinically as blisters that may develop on normal skin or within typical plaques and tumors of MF (239–242). This variant may be of significant clinical relevance in terms of prognosis, as in one study, almost 50% of patients died within a year following the onset of blisters (240). In addition to common histologic features of classical MF, there is associated clefting, which may occur at different planes—subcorneal, intraepidermal, and subepidermal. Although the precise mechanism of the blister formation is not clear, it has been proposed that the subcorneal and intraepidermal separation may result from confluence of Pautrier microabscesses, and the subepidermal blister may be secondary to reduced keratinocyte adherence to the basement membrane in response to cytokines produced by the lymphoma cells (243). Unlike immunobullous disorders, immunofluorescence studies are consistently negative in bullous MF.

Hypopigmented mycosis fungoides. This variant is predominantly seen in young patients with dark skin (244,245). The lesions appear as asymptomatic or slightly pruritic, hypopigmented patches that may or may not be accompanied by typical patches and plaques of classical MF. The underlying mechanisms leading to hypopigmentation have been a subject of controversy. Some studies have found degenerative changes in melanocytes secondary to nonspecific cellular injuries (228,229), while others demonstrated impaired melanosome transfer to keratinocytes (246). Apart from prominent pigment incontinence, hypopigmented MF is indistinguishable from classical MF histopathologically. Although a recent report described a frequent $CD8^+$ phenotype in the former, the two variants share similar clinical course and prognosis (247).

Hyperpigmented mycosis fungoides. This is a rare variant characterized by diffuse macular hyperpigmentation (248,249). Histopathologically, there is often marked elongation of the rete ridges with basal hyperpigmentation and dermal melanophages superimposed on features of classical MF (248). Ultrastructural studies have revealed giant melanin granules in the tumor cells, keratinocytes, Langerhans cells, and macrophages (248).

Mycosis fungoides palmaris et plantaris. This variant defines cases where the MF lesions are limited to, predominantly affecting, or initially presenting on the palms and/or soles (250). The lesions may present as annular hyperpigmented patches and plaques (250,251), vesicles (239), pustules (252–254), hyperkeratotic/verrucous plaques (255–257), psoriasiform plaques (258), ulceration (259), and nail dystrophy (257). Regardless of the associated variable secondary epidermal changes that may complicate the clinical differential and microscopic interpretation, the presence of histopathologic findings of classical MF and clonal rearrangement of the TCR genes will help in reaching the correct diagnosis.

Verrucous/Hyperkeratotic mycosis fungoides. Typical lesions are hyperkeratotic/verrucous and occur on lower extremities, face, and trunk (260). There may or may not be associated classical patches and plaques of MF. Histologically, lesions are characterized by classic features of MF in a background of epidermal hyperplasia with hyperkeratotic scale (260–262).

Acanthosis nigricans–like (vegetating/papillomatous) mycosis fungoides. As the name implies, the lesions often resemble acanthosis nigricans or seborrheic keratosis clinically and have the predilection for the flexural sites (axillae and groin), neck, nipple, and areolae (263–265). Microscopically, the lesions have combined features of seborrheic keratosis and typical MF (e.g., a bandlike atypical lymphoid infiltrate with epidermotropism, elongated interconnected rete ridges, and pseudohorn cysts) (263–265).

Pustular mycosis fungoides. Pustular MF presents as pustular eruptions that may be limited to the palmoplantar areas (MF palmaris et plantaris) or generalized (252–254,266). Intraepidermal collections of atypical lymphocytes with neutrophils and eosinophils constitute the characteristic histopathologic findings (253,267). Production of high levels of interleukin-8 by the lymphoma cells has been implicated in the formation of pustular lesions (268).

Ichthyosiform mycosis fungoides. This is another rare variant of MF, which accounts for 1.8% of cases (269). The lesions are pruritic and ichthyosiform, often with excoriations. There may be accompanying comedo-like areas and/or follicular keratotic papules. Microscopically, the ichthyosiform areas show typical features of MF with compact orthohyperkeratosis and hypergranulosis, whereas the follicular papules exhibit cystic dilatation of hair follicles with keratotic plugs and folliculotropic atypical lymphocytes (212,269).

Histogenesis. The cell of origin in MF is believed to be a peripheral epidermotropic T cell. The immunophenotype is $CD2^+$, $CD3^+$, $CD4^+$, $CD5^+$, and $CD8^-$ (Fig. 31-27A–E), although rare cases have been described that are $CD8^+$ (270,271). Lesions often show absence of CD7, particularly in the atypical epidermotropic T cells (the admixed nonneoplastic lymphoid infiltrate in the dermis may preserve CD7 reactivity), even at early evolutionary stages of the disease, although this finding in itself does not reliably permit differentiation of MF cells from reactive T cells (270). The skin-homing antigen, CLA (recognized by HECA-452 antibody), is expressed in most cases, consistent with association of the malignant clone with a peripheral epidermotropic T cell. Although occasional $CD30^+$ cells may be identified in the dermal infiltrates, this epitope is not expressed by most cells comprising the malignant clone. However, in advanced tumor-stage disease, especially with

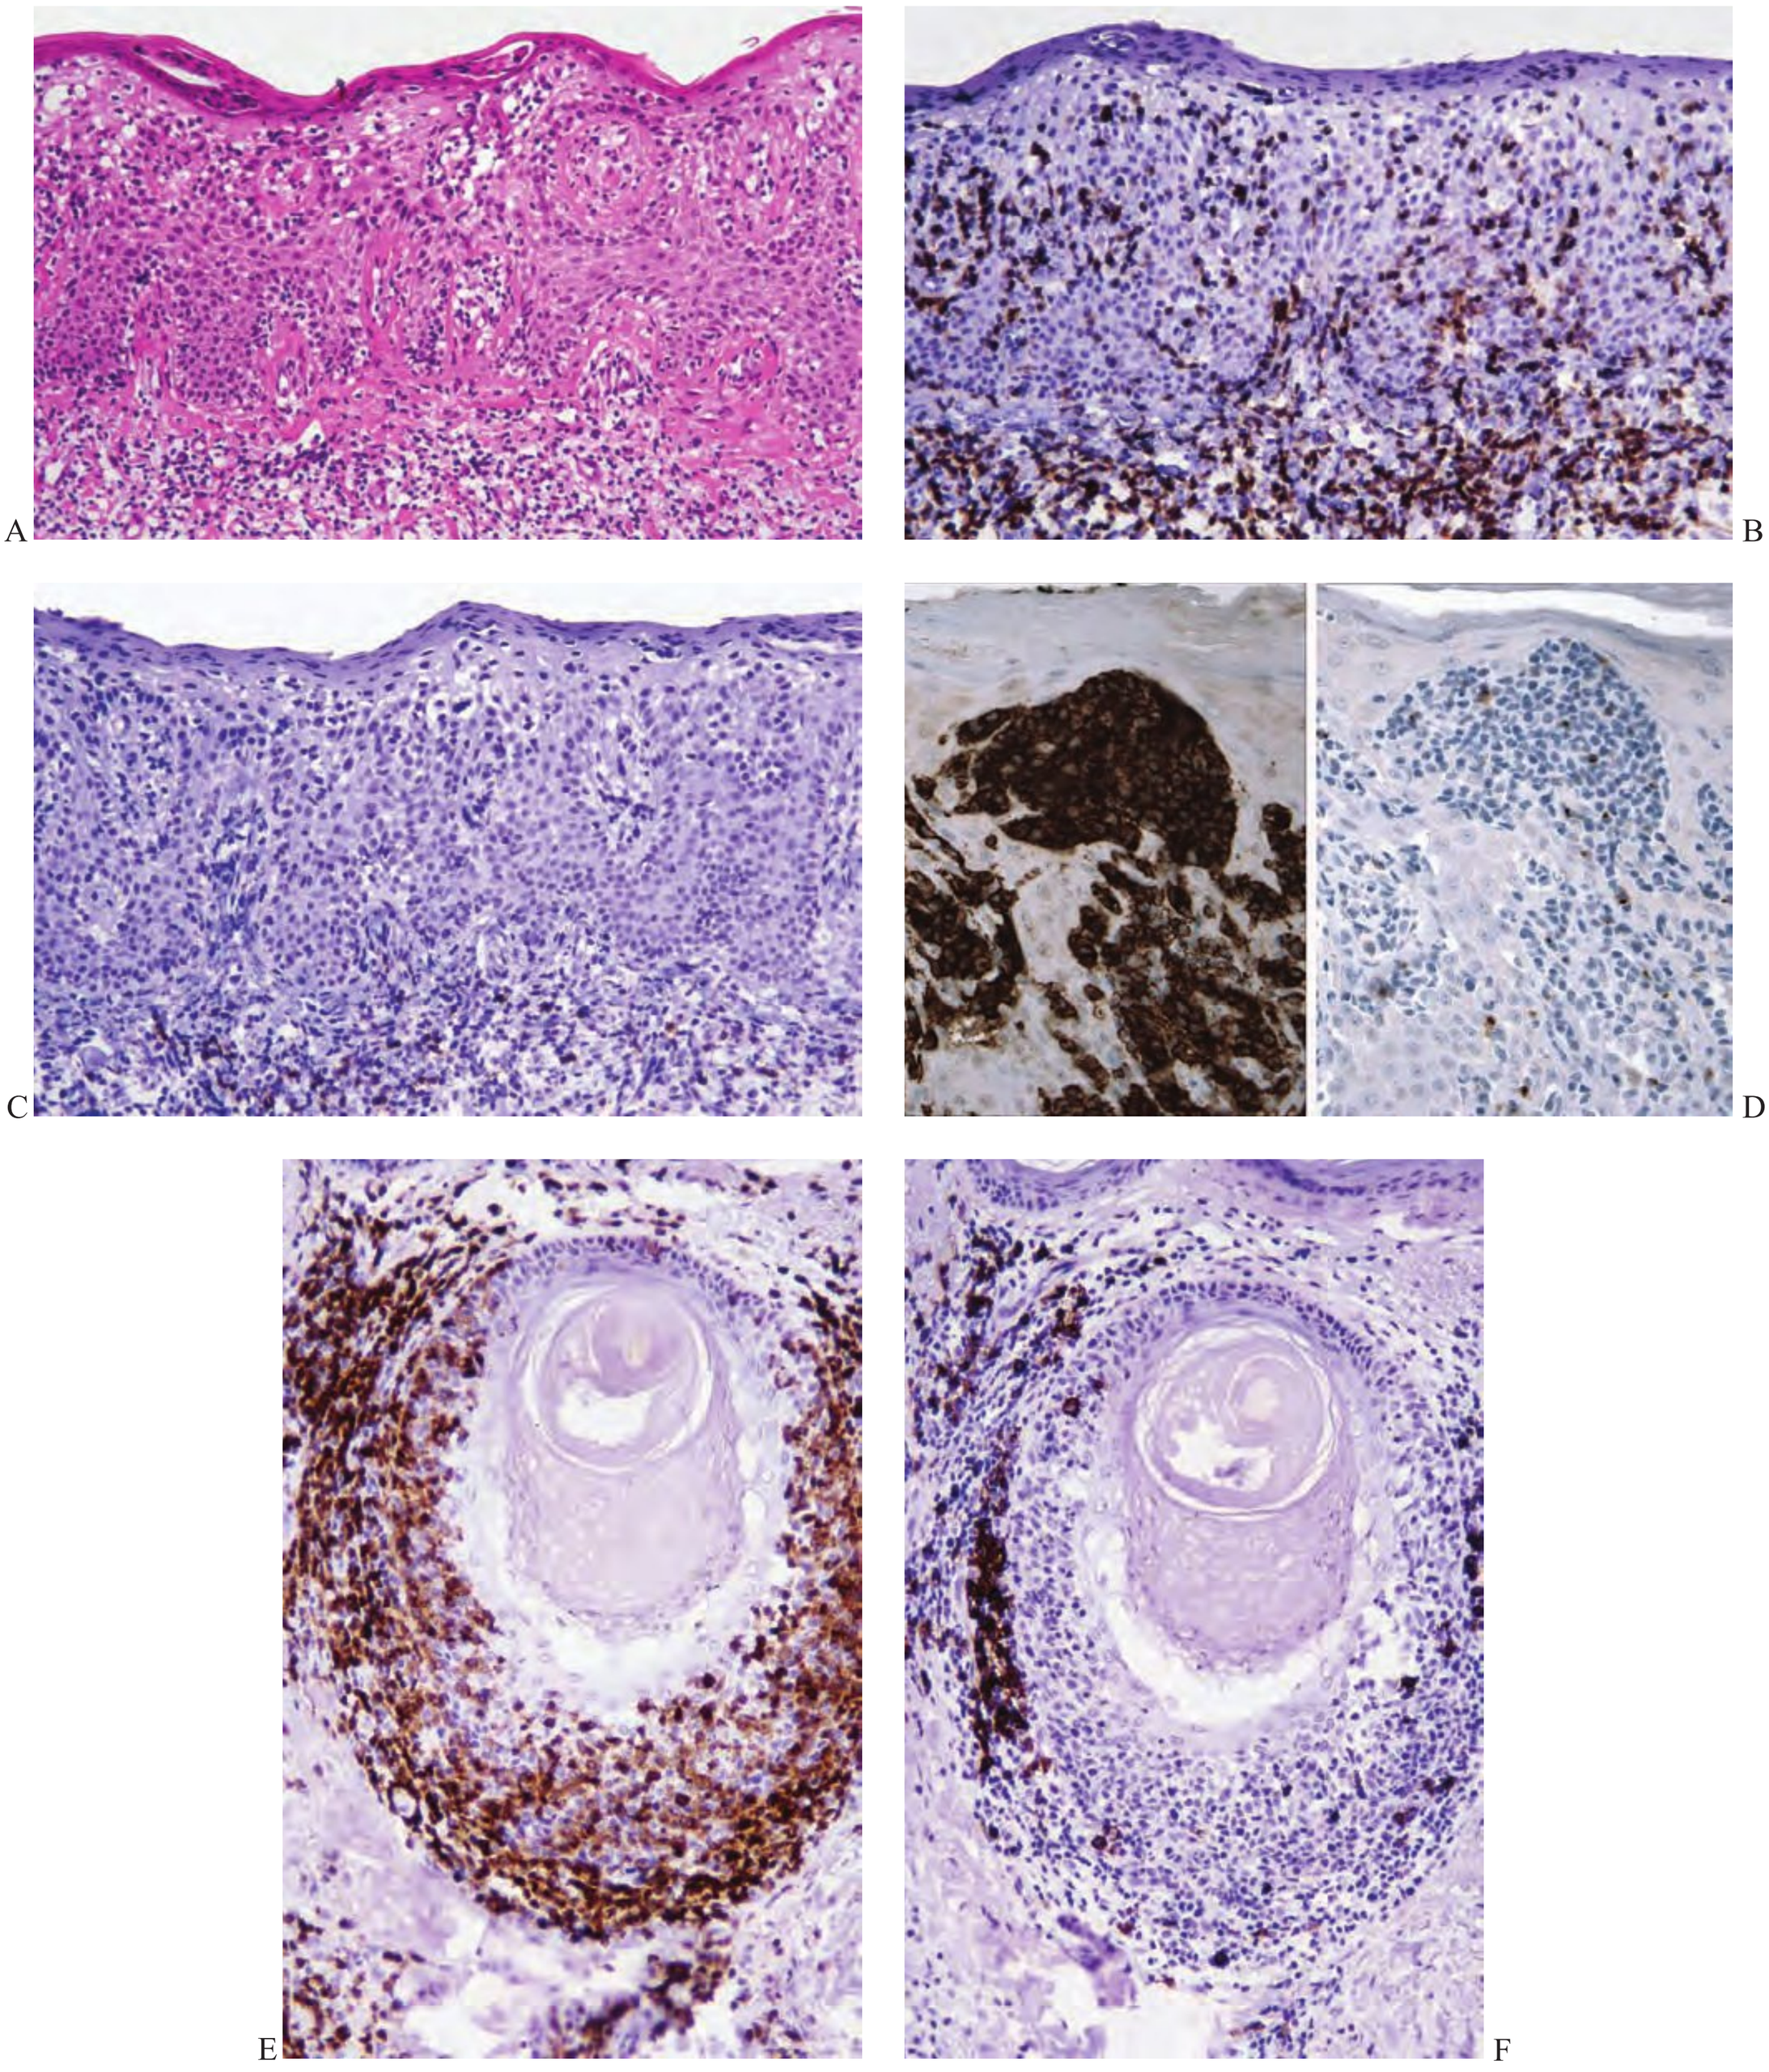

FIGURE 31-27. Immunophenotypic features of mycosis fungoides. Serial sections through a plaque-stage lesion with marked epidermotropism (A) reveal that most of the epidermotropic cells (in particular, those displaying nuclear atypia) express CD4 (B) but not CD8 (C). In addition, the epidermotropic CD4^{+} malignant T cells (left panel, D) may exhibit aberrant loss of other T-cell markers, such as CD7 (right panel, D). Similar findings are observed for folliculotropic T cells (E, CD4, F, CD8).

large cell transformation, the cells may acquire CD30 expression as well as a cytotoxic phenotype and thus cytotoxic granule-associated proteins, such as TIA-1, granzyme B, and perforin, also may be demonstrated (272). TCR genes are clonally rearranged, and this may be a helpful, albeit not entirely specific, diagnostic adjunct in early disease.

Differential Diagnosis. The practical differential diagnosis of classical epidermotropic MF involves primarily reactive T-cell infiltrates with exocytosis or an abnormal papillary dermal homing pattern (Table 31-7). True dermatitis may show lymphoid exocytosis and development of Langerhans cell microgranulomas that superficially may resemble Pautrier microabscesses. However, the former is generally associated with spongiosis or evidence of cytotoxic epidermal injury, and CD1a positivity by immunohistochemistry (209) and the latter with large cells containing ample cytoplasm, pale-staining infolded nuclei. Adnexotropic lesions must be separated from forms of dermatitis primarily centered about hair follicles and sweat glands. Again, the finding of uniformly atypical epitheliotropic lymphocytes and their tendency to be predominantly $CD4^+$ by immunohistochemistry should assist in this differential. While occasional cases of dermatitis show TCR gene rearrangements, most do not. Accordingly, PCR analysis is also an important adjunct in differentiating MF from its inflammatory imitators. As discussed previously, careful clinical history is required to access the relationship of onset of atypical T-cell pattern epidermotropic infiltrates to drugs that may produce immune dysregulation and eruptions that are morphologically, immunophenotypically, and even genotypically difficult to differentiate from MF. Clearing of the skin lesions following discontinuation of the offending drugs or lack of correlation of TCR gene rearrangement among lesions is also helpful in establishing the diagnosis. Other common histologic mimickers of MF include persistent arthropod bite reaction, secondary syphilis, nodular scabies, actinic reticuloid, fungal infection, lichen sclerosus in the early inflammatory stage, lichen striatus, lichenoid keratosis, pigmented purpuric dermatitis, connective tissue disorders, inflamed vitiligo, and regressed melanoma (273).

It is possible that very early evolutionary stages of MF involve a dysplastic phase in tumor progression. Such lesions may fulfill some but not all of the features required for a diagnosis of patch-stage disease. The authors generally refer to such lesions as being compatible with possible evolving T-cell dyscrasia, close follow-up and interval biopsy sampling to assess disease evolution are recommended. Some such lesions may be referred to by a variety of potentially confusing clinical descriptors, including *large plaque parapsoriasis*. The notion that small plaque parapsoriasis is an indolent form of MF is questionable in view of the accepted requirement for most malignant cells to exhibit features of tumor progression over time.

Late-stage disease, where epithelial involvement is minimal to absent and cytologic features may be higher grade, must be distinguished from B-cell lymphomas involving the skin. Distinction between aggressive $CD30^+$ transformed tumor stage MF (MF with large cell transformation) and primary cutaneous anaplastic large cell lymphoma (PC-ALCL) relies mainly on clinical history of presence or absence of typical patches and plaques of classical MF.

Sézary Syndrome

Sézary syndrome refers to a potentially aggressive leukemic form of CTCL characterized by generalized redness and scaling of the skin (erythroderma), lymphadenopathy, and presence of malignant T cells in the skin and peripheral blood (274). Because these malignant T cells have phenotypic and antigenic overlap with those of MF, Sézary syndrome is sometimes regarded as a MF variant. However, important clinical and histopathologic differences exist between classical MF and Sézary syndrome, and in the new WHO-EORTC classification, the term *Sézary syndrome* is restricted to cases that do not have a history of MF.

Clinical Features. Patients generally present with diffuse skin erythema and lymphadenopathy. There may also be itching, hair loss, nail dystrophy, and hyperkeratosis affecting the skin of the palms and soles (12). In addition to lymph node, skin and blood involvement, malignant T cells may also infiltrate viscera in late stages, although bone marrow is often spared (12,193). The prognosis is poor, with a median survival between 2 to 4 years (275).

Histopathology. Affected skin may show changes similar to those of patch/plaque-stage MF, although the infiltrate is often sparse and multiple sections may be required in some cases to identify convincing epidermotropism by atypical lymphocytes (Fig. 31-28A). Involved lymph nodes are characterized by effacement of their architecture by infiltrates of atypical cells. The peripheral blood contains atypical lymphocytes with cerebriform nuclear contours, with smaller versions referred to as *Lutzner cells* and larger ones as *classical Sézary cells* (Fig. 31-28B). Diagnosis of Sézary syndrome requires at least 1,000 such cells per mm^2 in most series (13,213). Flow cytometry will generally indicate elevation in a CD4: CD8 ratio of 10 or higher and increased numbers of cells with a $CD4^+/CD7^-$ phenotype (276). Molecular analysis will show clonal rearrangement of the TCR gene in most cases (13,277).

Histogenesis The neoplastic peripheral epidermotropic T cells generally are $CD2^+$, $CD3^+$, $CD4^+$, $CD5^+$, and $CD7^{+/-}$. Aberrant T-cell phenotypes are common, often with loss of T cell markers such as CD2, CD3, CD4, CD5, and CD7; rare $CD8^+$ variants have been described (13).

Differential Diagnosis. Sézary syndrome must be differentiated from other dermatitic causes of erythroderma (e.g., atopic dermatitis, seborrheic dermatitis, pityriasis rubra pilaris, and psoriasis). Because the histopathology of skin involvement in Sézary syndrome may be subtle, it is often critical also to

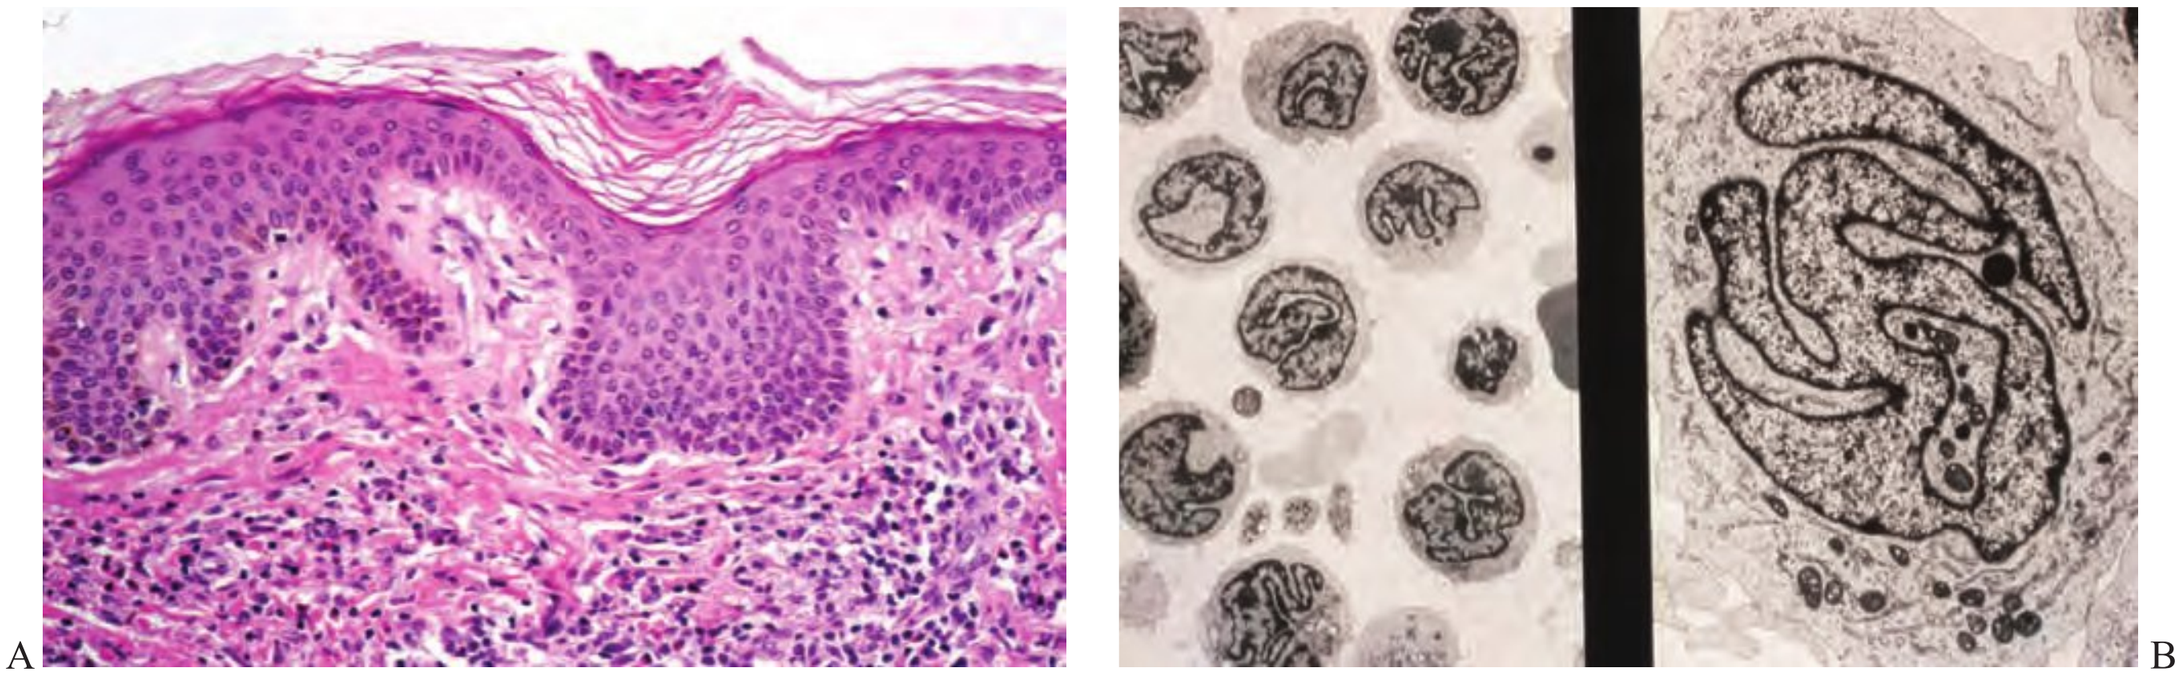

FIGURE 31-28. Sézary syndrome. A: There is a bandlike papillary dermal lymphoid infiltrate with minimal epidermotropism. B: Ultrastructural examination of peripheral blood buffy coat revealing numerous Sézary cells.

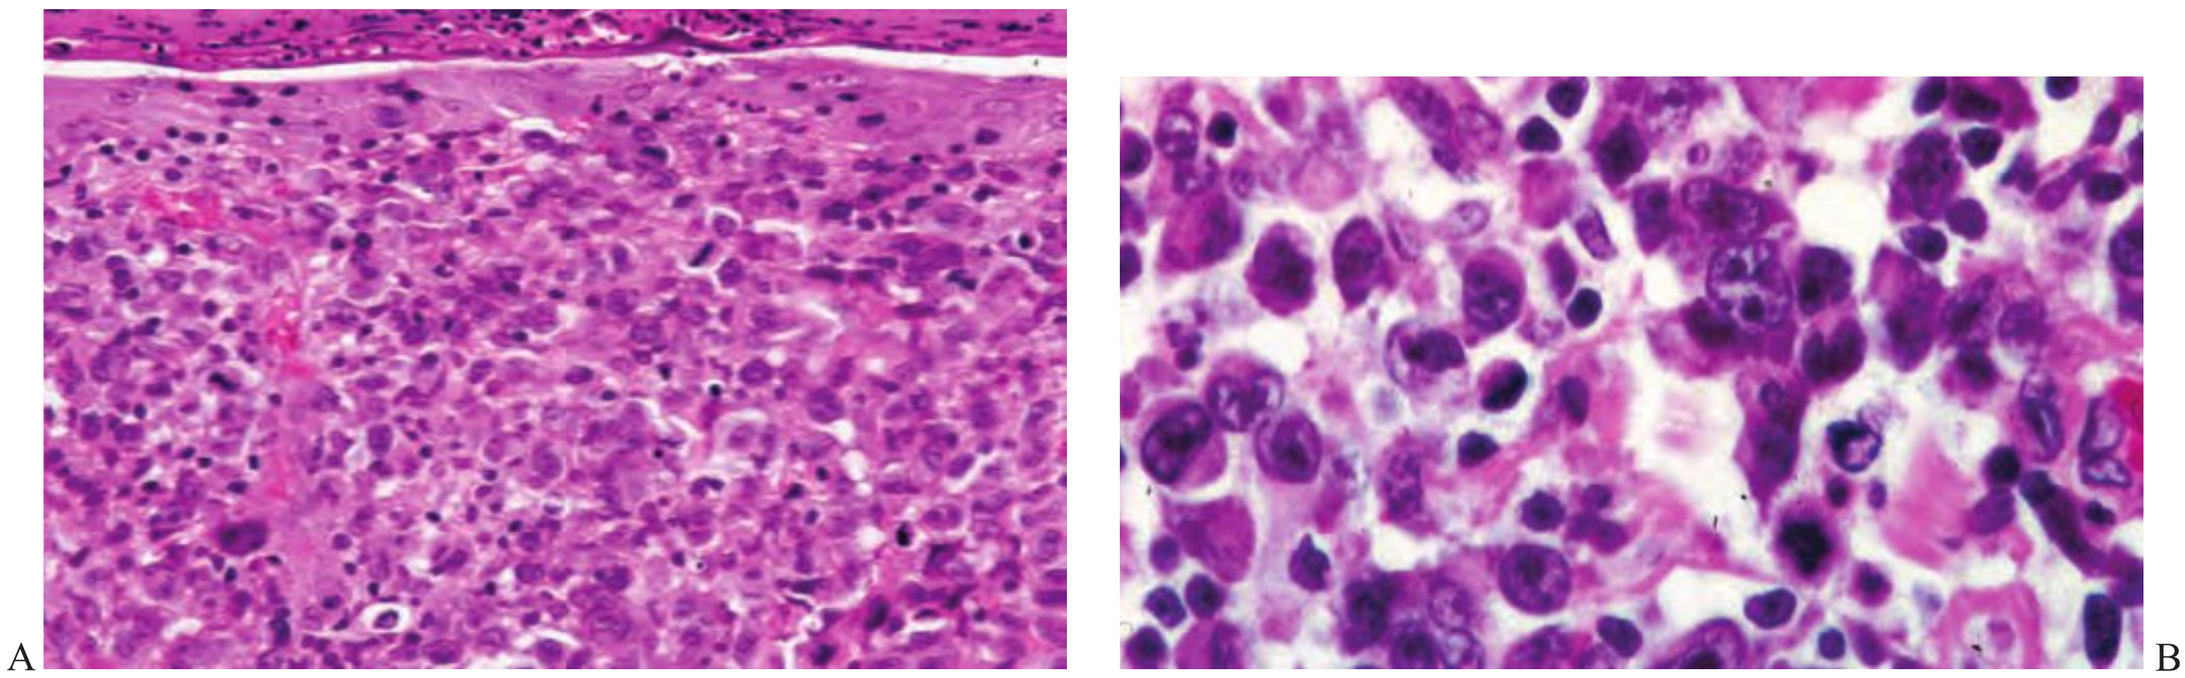
examine routine buffy coat preparations as well as flow cytometry of peripheral blood in establishing a diagnosis of Sézary syndrome. Immunohistochemistry to identify epidermotropism by predominantly to exclusively $CD4^+$ T cells, loss of CD7, and molecular analysis for TCR gene rearrangements are also important adjuncts to correct diagnosis. Although patients with advanced MF also may develop leukemic dissemination by malignant cerebriform T cells, the clinical course and presence of advanced plaques and nodules should separate these individuals from patients with true Sézary syndrome. Patients with ATLL have circulating atypical T cells. However, these tend to be polylobated rather than cerebriform, and cutaneous lesions are generally multiple nodules rather than diffuse erythroderma. Finally, detection of human T-cell lymphoma/leukemia virus-1 (HTLV-1) confirms the diagnosis.

Primary Cutaneous CD30-positive T-cell Lymphoproliferative Disorders

Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders is a category that refers to a spectrum of related, relatively low-grade disorders that primarily affect the skin and develop from an activated or transformed large T cell that expresses the CD30 antigen (142,278). Although these conditions may occur together in a given patient and show clinical, histologic, and antigenic overlap, the clinicopathologic features are sufficiently distinctive for considering them in the context of the following categories: (a) PC-ALCL, (b) LYP, and (c) borderline lesions.

Clinical Features. Skin lesions of PC-ALCL consist of one or more localized nodules or occasionally papules (13,278). Lesions must be differentiated by careful staging from systemic anaplastic large cell lymphoma (ALCL) with secondary skin involvement and from high-grade large cell lymphomas that may also express CD30, since these latter conditions have a considerably worse prognosis. Partial or complete regression of individual lesions may occur, although relapse is common (279). Eventual extracutaneous dissemination to lymph nodes occurs in about 10% of patients with primary skin involvement, particularly in individuals who have multiple primary lesions (276,278). Primary cutaneous anaplastic large cell lymphoma (PC-ALCL) is associated with a favorable prognosis with a 10-year survival >90% (278). LYP typically develops as multiple diffusely distributed "juicy" red papules and nodules that usually regress within one to several months (217,279) (Fig. 31-29). Lesions are generally <2.5 cm in diameter, and extracutaneous dissemination only occurs in a minority of cases (4%) that progress to overt lymphoma, such as MF, PC-ALCL, or HL (217). Although clinically typical cases of LYP can be easily distinguished from classical cases of PC-ALCL, a huge area of overlap exits, and these two entities are better understood as a continuum.

FIGURE 31-29. Primary $CD30^+$ lymphoproliferative disorders: lymphomatoid papulosis. Lesions clinically present as multiple "juicy" red papules and nodules.



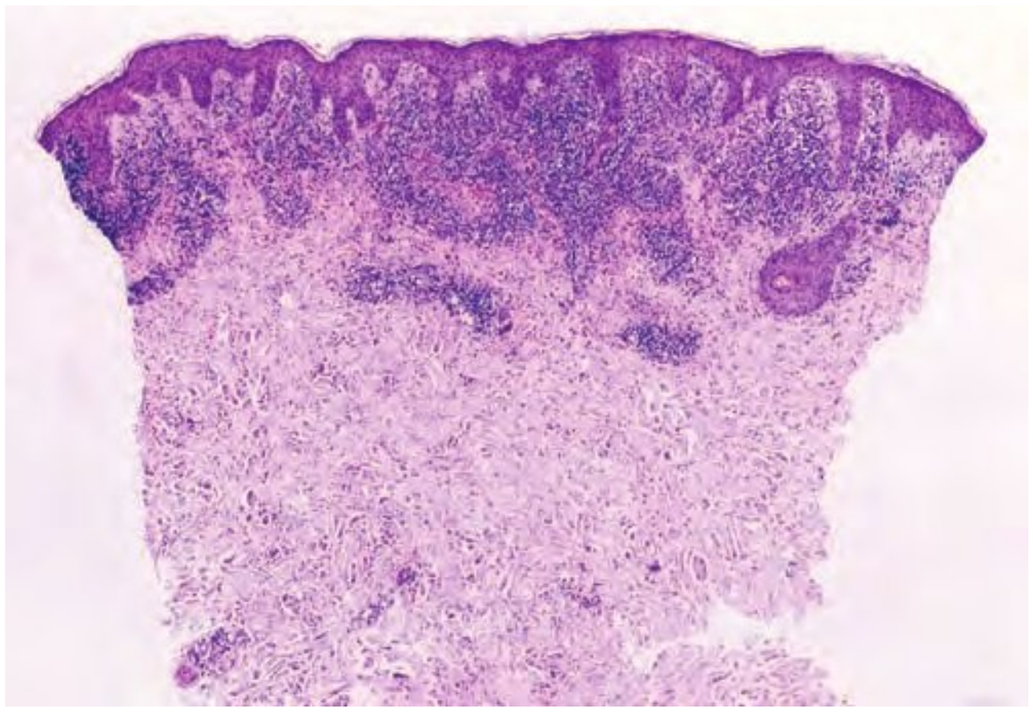


FIGURE 31-30. Histology of primary cutaneous anaplastic large cell lymphoma. A: Skin infiltrate composed of tumoral infiltrate of large atypical lymphocytes with associated incipient epidermal erosion. B: High magnification of the large anaplastic lymphocytes forming an infiltrate in PC-ALCL

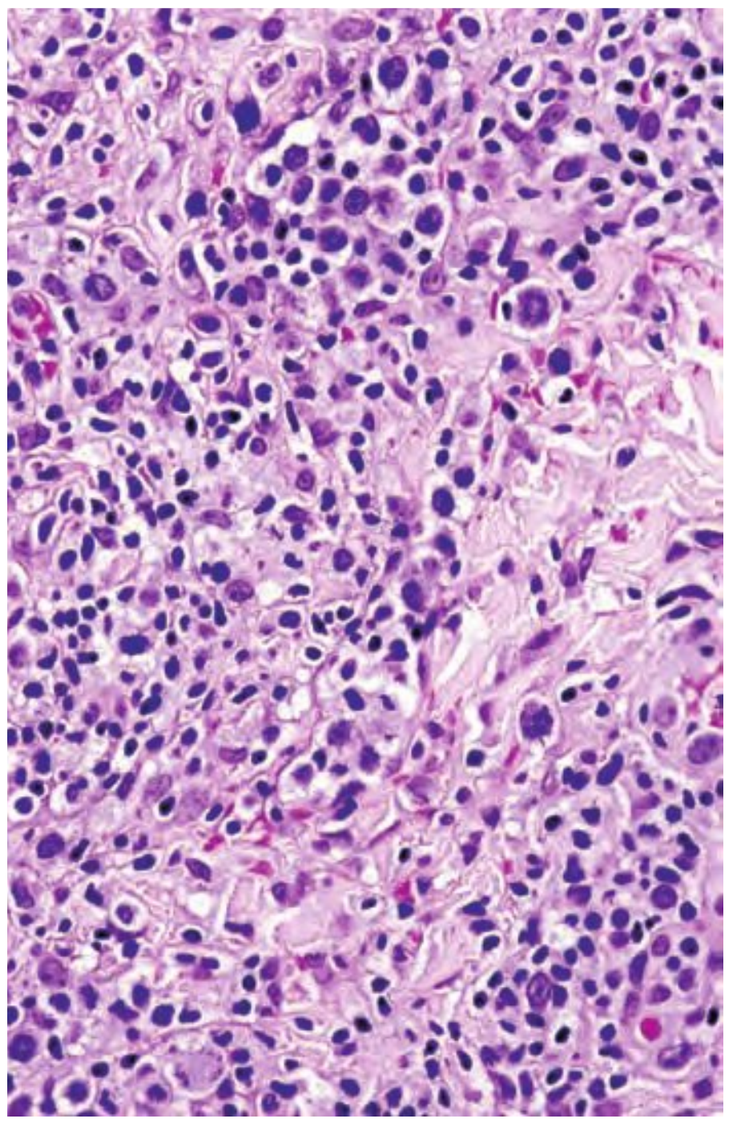
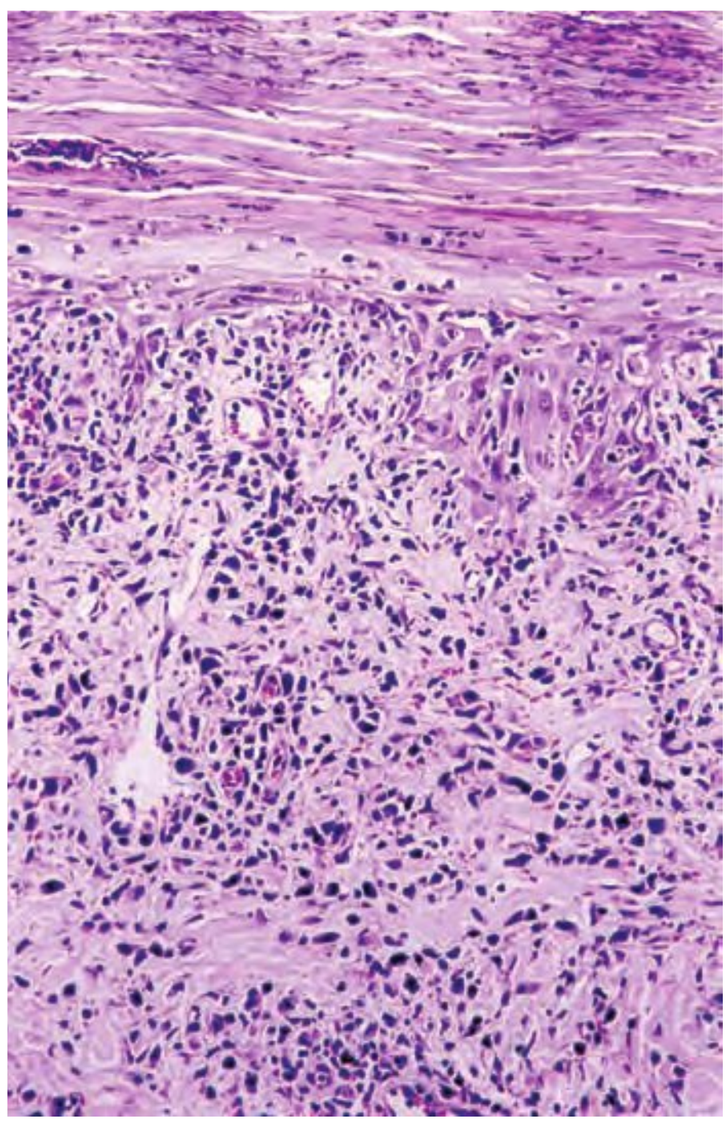


Histopathology. Nodules are formed by infiltrates that typically involve the superficial and deep dermis and occasionally the subcutis, in a diffuse, interstitial pattern (13) (Fig. 31-30A). Cytologically, biopsies of PC-ALCL may closely resemble those of systemic ALCL with secondary skin involvement (Fig. 31-30B), although Reed-Sternberg–like cells and highly pleomorphic, multinucleated giant cells may be more numerous in the former. The large atypical cells should account for the majority of cells composing the infiltrate, although a background of secondary inflammatory elements may be observed. Marked epidermal hyperplasia, sometimes with keratoacanthoma-like features; invasion by atypical cells; and ulceration are often present.



By contrast, the architecture of LYP tends to be more restricted, forming a wedge-shaped infiltrate extending from the superficial into the mid and deep dermis (Fig. 31-31A). This is composed of an admixture of various cell types, including variably activated lymphocytes, histiocytes, neutrophils, and eosinophils. However, an admixed minority population composed of atypical large lymphocytes is required for the diagnosis, and these may either resemble Reed-Sternberg–like cells (type-A LYP) or the cerebriform cells of MF (type-B LYP). In the latter, epidermotropism similar to that seen in patch/plaque-stage MF may be present. Occasional biopsies will show hybrid features between these two types of LYP. There is an angiocentric deposition of infiltrating atypical cells (Fig. 31-31B), often accompanied by vascular injury. Epidermal changes include hyperkeratosis, parakeratosis, and occasional foci of neutrophil infiltration and central erosion/shallow ulceration (Fig. 31-31C). In rare instances, clinical features of LYP may be present in the setting of histologic characteristics of PC-ALCL (predominance of large atypical cells), and these lesions are referred to as *borderline* or *type-C LYP*. Rarely, a solitary tumor more in keeping with PC-ALCL will show histopathology more like LYP (atypical cells in the minority), and such lesions have been termed *anaplastic lymphoma, LYP-like* (278).

Histogenesis. All forms of primary cutaneous $CD30^+$ T-cell lymphoproliferative disease are believed to be derived from an activated skin-homing T cell. In PC-ALCL, in addition to CD30 positivity by >75% of the cells forming the infiltrate (13,279), there is CD4 expression as well as frequent expression of cytotoxic granule proteins (granzyme B, perforin, TIA-1) (279,280). Aberrant T-cell phenotypes with loss of CD2, CD3, and/or CD5 may be observed. Importantly, unlike many cases of systemic $CD30^+$ lymphomas, most primary cutaneous lesions are negative for EMA (13) and rarely carry the t(2;5) translocation, hence negative for ALK-1. However, a positive ALK-1 does not necessarily imply a secondary cutaneous manifestation of extracutaneous ALCL (281). A similar immunophenotype is expressed by the minority population of large atypical cells in type-A LYP (Fig. 31-31D), although CD30 expression may not be detected in type B lesions, in which Reed-Sternberg–like cells are infrequent to absent. Most cases of PC-ALCL and about half of cases of LYP (predominantly the type A variant) show clonal rearrangements of the TCR.

Differential Diagnosis. The single most important consideration in the diagnosis of primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders is their differentiation from primary systemic lymphomas that may express CD30 and show a considerably worse prognosis. This may generally be accomplished by careful assessment of correlative clinical and histologic and immunohistochemical parameters (see above) as well as by meticulous clinical staging. Distinction of PC-ALCL from LYP is similarly possible by evaluation of clinical parameters and assessment of lesion architecture and

D: CD30+ cells are numerous within the superficial dermal component of the infiltrate.

relative percentages of large atypical $CD30^+$ cells within the cutaneous infiltrates (>75%). In addition, CD30 positivity may be observed in tumor-stage MF, particularly in cases with large cell transformation (typically with a history of conventional patches and plaques of MF), and other reactive conditions, including arthropod bites, drug erruptions, and viral infection (e.g., herpes simplex virus 1 and 2) (282). Unlike HL, the Reed-Sternberg–like cells in PC-ALCL generally do not express CD15 (283).

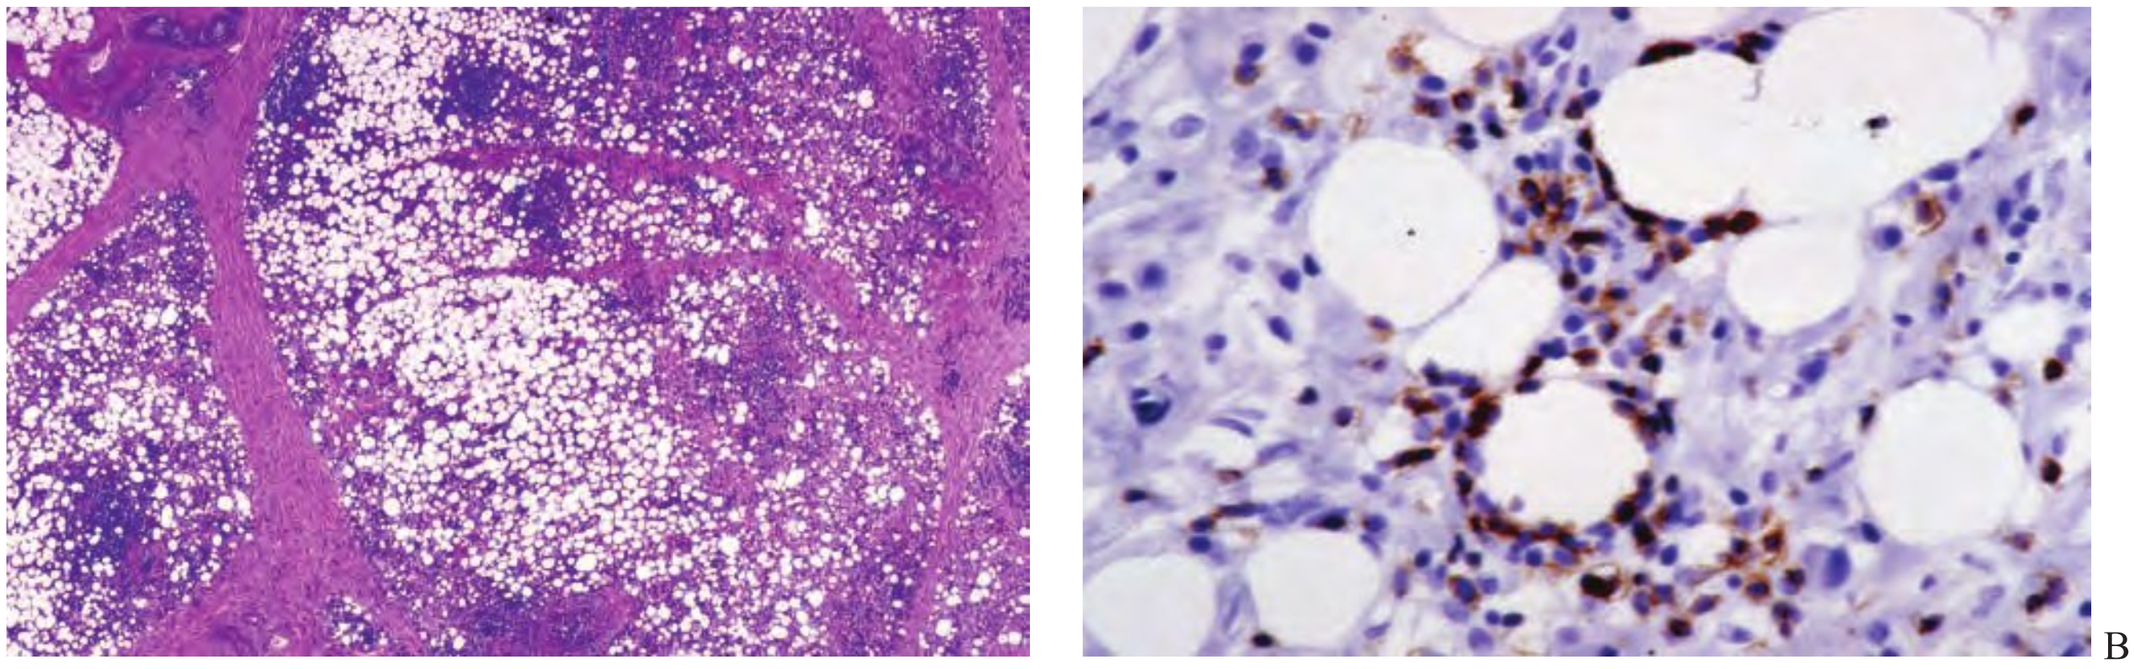

FIGURE 31-32. Subcutaneous panniculitis-like T-cell lymphoma. A: Lobular and septal pattern of subcutaneous infiltration. B: TIA-1 immunohistochemistry showing characteristic rimming about individual adipocytes.

Subcutaneous Panniculitis-like T-cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) is defined as a rare lymphoma that (a) primarily infiltrates subcutaneous tissue, (b) shows high-grade cytologic features, and (c) is composed of $CD8^+$, α/β^+ T cells with a cytotoxic phenotype.

Clinical Features. While the majority of cases occur in young adults, a broad age range has been reported, and the disease tends to show an equal gender distribution (284). Affected individuals generally present with symptoms related to formation of deeply seated and variably sized cutaneous nodules often involving the extremities and/or trunk. The disease has a protracted but indolent course with a 5-year survival of 82% (285). Rare systemic symptoms and signs of fever, fatigue, and weight loss, when present, may relate to hemophagocytic syndrome and a more rapidly progressive course (286).

Histopathology. There is a diffuse, variably cellular infiltrate involving both septae and lobules within the subcutis (Fig. 31-32A), with relative sparing of the overlying dermis. The infiltrate is composed of smaller lymphocytes with visible cytoplasm admixed with larger transformed cells with hyperchromatic nuclei. Initial biopsy in which the more atypical elements are not well represented may appear deceptively banal. Cells characteristically show peripheral alignment (rimming) about individual adipocytes (Fig. 31-32B). Fat necrosis, karyorrhexis, and associated infiltration of reactive histiocytes may also be noted. Necrosis, nuclear fragmentation, and vascular injury may all be observed. A hemophagocytic syndrome, which is associated with a rapidly progressing course, may occur but is much less common than in γ/δ^+ T-cell lymphoma with panniculitis-like lesions (286) (see page 950).

Histogenesis. The malignant cells express a mature $CD2^+$, $CD3^+$, $CD4^-$, $CD5^+$, $CD8^+$ T-cell phenotype. In keeping with their presumed derivation from a cytotoxic T cell, they also are reactive for the following proteins: granzyme, perforin, and T-cell intracellular antigen (TIA-1). TCR genes are rearranged, and EBV sequences cannot be demonstrated. In the WHO/EORTC classification, SPTCL is restricted for cases derived from α/β T cells, whereas those with a γ/δ T-cell phenotype are included in the category of cutaneous γ/δ T-cell lymphoma. The latter often exhibit both CD4 and CD8 negativity but reactivity for CD56 (287) and have a poor prognosis.

Differential Diagnosis. SPTCL should be differentiated from benign panniculitis, such as lupus erythematosus panniculitis. The presence of plasma cells and lymphoid follicles with germinal centers and the lack of clonality in TCR gene rearrangement studies favor the latter. *In situ* hybridization for EBV should be performed to rule out NK-/T-cell lymphoma, nasal type, which frequently exhibits subcutaneous involvement and is positive for EBV.

Extranodal Natural Killer–/T-cell Lymphoma, Nasal Type

Extranodal NK-/T-cell lymphoma, nasal type is characterized by angiocentric and angiodestructive infiltrates of malignant cells with NK- or cytotoxic T-cell phenotype that often but not invariably involve tissues of the nasal cavity (288–291). It has been known by numerous appellations, including pleomorphic reticulosis and lethal midline granuloma. Besides the nasal cavity, skin is the second most commonly affected site, and cutaneous involvement may be the primary manifestation of the disease. Regardless of whether the cutaneous involvement is primary or secondary, the disease runs an aggressive course and requires the same treatment (291–295).

Clinical Features. Extranodal NK-/T-cell lymphoma tends to more often affect adult males, with a geographical distribution showing concentration in Asia, Mexico, Central

America, and South America. Sites most often affected include the nasal cavity and nasopharynx, skin and soft tissues, gastrointestinal tract, and testis and has secondary lymph node involvement (296–304). Nasopharyngeal involvement is often associated with extensive destruction of soft tissue and bone, and rapid and widespread dissemination may occur. Skin may be either a site of secondary spread or a primary manifestation of the disease. Cutaneous nodules, often with ulceration, are most often encountered. Advanced disease is the rule at the time of presentation, and an associated hemophagocytic syndrome may also be noted (300,305), with fever, cachexia, and other systemic symptoms (291,298,299,306). In those advanced cases where marrow and peripheral blood involvement are encountered, there is overlap with aggressive NK-cell leukemia. As mentioned previously, although patients presenting with only skin lesions have a better prognosis than those with both cutaneous and extracutaneous disease (median survival of 27 months vs. 5 months), both groups exhibit a highly aggressive clinical behavior and require the same treatment (291–293, 307).

Histopathology. The characteristic histopathology involves a diffuse, focally angiocentric and angiodestructive dermal/subcutaneous infiltrate of variably sized, mitotically active lymphoid cells with moderate quantities of pale cytoplasm and nuclei with irregular and occasionally elongated profiles. Chromatin tends to be coarsely granular, and nucleoli are inconspicuous. Some cases will show an admixture of reactive inflammatory cells, including activated lymphocytes, plasma cells, and eosinophils. Infiltration and fibrinoid necrosis of affected vessel walls and zones of necrosis and apoptosis are characteristic findings (175). The epidermis or squamous epithelial mucosa may be ulcerated or in some instances may show florid pseudoepitheliomatous hyperplasia.

Histogenesis. In most instances, the cell of origin is believed to be an NK cell or a cytotoxic T cell. The typical immunophenotype is $CD2^+$, $CD56^+$, and surface $CD3^-$ (182,297, 308–310). Cytotoxic granule–associated proteins (TIA-1, granzyme B, perforin) are usually detected, and CD4, CD5, and CD8 are generally negative. Interestingly, TCR and immunoglobulin genes are in the germ line configuration in most cases of extranodal NK-/T-cell lymphoma, although a variety of cytogenetic abnormalities have been recorded. There is a strong association with EBV, suggesting a possible causal role for this agent (311–316). In rare $CD56^-$ cases, detection of EBV by *in situ* hybridization and expression of cytotoxic proteins are required for diagnosis (317).

Differential Diagnosis. The differential diagnosis includes other neoplastic lymphocytic infiltrates that are angiocentric and angiodestructive. LYG has historically been considered in the context of extranodal NK-/T-cell lymphoma, although the former is now recognized to represent a form of EBV-positive B-cell lymphoproliferative disorder that may contain numerous reactive T cells (310). Vasculitic variants of MF have been described, although these can be distinguished by the absence of cytotoxic markers that characterize most cases of extranodal NK-/T-cell lymphoma. One caveat is that tumor stage MF may acquire a cytotoxic phenotype. In such patients, clinical history of previous conventional MF lesions allows differentiation from extranodal NK-/T-cell lymphomas.

Primary Cutaneous Peripheral T-cell Lymphoma, Unspecified

Primary cutaneous peripheral T-cell lymphoma, unspecified (PC-PTCL-u) accounts for approximately 10% of all CTCL and is designated for all CTCLs that do not fit into any of the better defined subtypes of CTCL, including the three provisional entities described below (24). The majority of cases in this category were classified as primary cutaneous $CD30^-$ large T-cell lymphoma in the EORTC classification.

Clinical Features. Patients are middle-aged to elderly individuals (median age 68 years) with a male-to-female ratio of 2.5:1.0 (318). Lesions may present as solitary or localized but more frequently generalized nodules or tumors (318–320). The prognosis is generally poor, with a 5-year survival $<$20% (318–321).

Histopathology. Diffuse or nodular infiltrates with variable numbers of medium-sized to large pleomorphic or immunoblast-like T cells are typical. For the designation of PC-PTCL-u, the large cell component should constitute at least 30% of the neoplastic infiltrate (refer to differential diagnosis with the provisional entity, primary cutaneous $CD4^+$ small- to medium-sized pleomorphic T-cell lymphoma, next page, in which $<$30% admixed large cells can be seen). Epidermotropism is generally mild or absent.

Histogenesis. Most cases show an aberrant $CD4^+$ T-cell phenotype with variable loss of pan-T-cell markers, such as CD5 and CD7. CD30 staining is negative or restricted to few scattered tumor cells. Rare CD56 expression or cytotoxic proteins (granzyme B, TIA-1) may also be observed (318). TCR genes are rearranged, but cytogenetic alterations are largely uncharacterized.

Differential Diagnosis. Distinction from MF with large cell transformation relies on the lack of clinical history of MF.

Primary Cutaneous Aggressive CD8-positive T-cell Lymphoma (Provisional Entity)

This provisional entity primary cutaneous aggressive $CD8^+$ T-cell lymphoma is characterized by a proliferation of epidermotropic $CD8^+$ cytotoxic T cells and an aggressive clinical course (322,323), which includes cases of generalized pagetoid reticulosis (Ketron-Goodman disease). Cases of this provisional entity were grouped together with the PTCL-u category in the old WHO classification (317).

Clinical Features. Primary cutaneous aggressive $CD8^+$ T-cell lymphoma affects middle-aged to elderly patients with a median age of 53 years and a male-to-female ratio of 1.4:1.0 (322). Clinically, patients present with localized or disseminated eruptive papules, nodules, or tumors with central ulceration and necrosis or hyperkeratotic patches and plaques on the face or upper arms (291,322). Spreading to other visceral sites, such as the lung, testis, central nervous system, and oral mucosa, has been documented, but lymph nodes are often spared (322). The clinical course is aggressive, with rapid progression and a median survival <32 months (4).

Histopathology. Early lesions are characterized by epidermotropic atypical pleomorphic T lymphocytes ranging from small to medium size that are scattered throughout the epidermis in a pagetoid pattern. In fully developed lesions, the atypical lymphocytes may form bandlike or diffuse infiltrates with angiocentricity/angioinvasion as well. The epidermis may be acanthotic or atrophic with variable numbers of apoptotic keratinocytes and spongiosis. Occasionally, associated ulceration or blister formation may be observed. Adnexal and subcutaneous involvement is frequently present. The atypical lymphoid infiltrate may be accompanied by a variable number of reactive histiocytes and dendritic cells as well as rare eosinophils and plasma cells (322,324).

Histogenesis. The neoplastic cells display a $CD3^+$, $CD4^-$, $CD8^+$, $CD7^{-/+}$, $CD45RA^+$, granzyme B^+, perforin$^+$, TIA-1^+ phenotype, characteristic of cytotoxic T cells. With disease progression, the malignant clone may acquire CD7 or lose CD2 expression. A recent study showed association of the $CD2^-$, $CD7^+$ phenotype with a more aggressive course (323). TCR gene rearrangement studies are typically positive, and the lesion is absent for EBV (322).

Differential Diagnosis. Differentiation from other types of CTCLs expressing a $CD8^+$ cytotoxic T-cell phenotype, such as rare cases of MF, LYP, and PC-ALCL, is largely based on clinical presentation and disease course (322).

Primary Cutaneous CD4-positive Small-/Medium-sized Pleomorphic T-cell Lymphoma (Provisional Entity)

Primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma is an entity that is defined as small- to medium-sized, $CD4^+$, pleomorphic CTCL without a history of classic patches and plaques of MF and a favorable clinical course (320). In the past, the majority of cases were diagnosed as idiopathic T-cell lymphomatoid hyperplasia.

Clinical Features. The median patient age is 69 years with a male-to-female ratio of 0.5:1.0 (318). The clinical lesions range from multiple reddish papules to solitary plaque/nodules, generally involving the upper half of the body without a history of patches or plaques to suggest MF (325–327). Despite that the entity is not very well characterized, patients seem to have a very good prognosis, with a disease-specific 5-year survival rate of up to 75% and an overall 5-year survival rate of 60% to 80% (328).

Histopathology. Typically, there is a dense diffuse or nodular infiltrate of predominantly small- to medium-sized pleomorphic T-cells with a tendency to involve the subcutis. Epidermotropism may be seen focally (4). The infiltrate may contain a small percentage (<30% by definition) of large pleomorphic cells (320) and admixed small reactive B cells or histiocytes, eosinophils, and plasma cells (328,329).

Histogenesis. The neoplastic cells are of helper T-cell phenotype and express CD3 and CD4 but not CD8, TIA-1, granzyme B, and CD30. Pan-T-cell markers are lost in some cases (325,330). TCR genes are rearranged, but no consistent cytogenetic abnormalities have been observed (24).

Differential Diagnosis. Differential diagnosis includes T-cell lymphoid hyperplasia, PC-PTCL-u, and MF. Demonstration of an aberrant T-cell phenotype and clonality are useful criteria to differentiate these from reactive T-cell lymphoid hyperplasia (331). PC-PTCL-u has a large cell morphology (with large cells representing at least 30% of total tumor cell population) (321,322) rather than the predominance of small- to medium-sized T-cells in primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma, which may harbor a small percentage of admixed large cell component. Because morphologic and immunophenotypic distinction between primary cutaneous $CD4^+$ small-medium-sized pleomorphic T-cell lymphoma and MF can be difficult, by definition, the diagnosis of primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma should only be entertained after exclusion of MF by clinical history.

Cutaneous γ/δ T-cell Lymphoma (Provisional Entity)

Cutaneous γ/δ T-cell lymphoma (CGD-TCL) was previously characterized as subcutaneous panniculitis-like T-cell lymphoma (SPTCL) with a γ/δ phenotype (13,317). The new WHO/EORTC classification defined this provisional entity as a cutaneous lymphoma originated from a clonal proliferation of mature, activated γ/δ T cells with a cytotoxic phenotype and with an aggressive clinical behavior.

Clinical Features. Young to middle-aged adults (median age of 49 years) are affected with a male-to-female ratio of 1.5:1.0. Typical lesions include disseminated scaly plaques and ulcerated nodules/tumors often on the extremities (291,332–334). Systemic involvement of mucosal and other extranodal sites is common, but the lymph nodes, spleen, or bone marrow are generally spared (292,335,336). A hemophagocytic syndrome with associated constitutional symptoms, such as fever, malaise, fatigue, chills, and weight loss, has been described in patients

with panniculitis-like lesions (286,337). The prognosis is disappointing even with systemic chemotherapy, with a median survival of 15 months (334,336). Patients with subcutaneous disease have a worse prognosis compared with those with epidermal or dermal infiltrates only (334).

Histopathology. The infiltrate may be epidermotropic, diffusely dermal, panniculitic, or combinations of the above patterns either in one biopsy or in different specimens (334,338). The cytomorphology is monomorphous, medium to large in size, with irregular nuclei, prominent nucleoli, and coarsely clumped chromatin. Angiocentricity and angiodestruction are common (339). Subcutaneous involvement may show rimming of adipocytes, similar to SPTCL. In cases associated with hemophagocytic syndrome, phagocytosis of blood cells by histiocytes are observed (336).

Histogenesis. The neoplastic cells display a $CD3^+$, $CD2^+$, $CD4^-$, $CD5^-$, $CD7^{+/-}$, $CD8^-$, and $CD56^+$ phenotype with strong expression of cytotoxic proteins such as TIA-1, granzyme B, and perforin (336,340,341). Consistent with the γ/δ T-cell lineage, the neoplastic cells are strongly positive for TCR γ/δ in frozen sections, and the TCR γ/δ genes are rearranged. Isochromosome 7q is the most common cytogenetic abnormality (336). EBV sequences cannot be demonstrated.

Differential Diagnosis. Differential diagnosis includes SPTCL and extranodal NK-/T-cell lymphoma. In the new WHO/EORTC classification, SPTCL is designated to tumors with an α/β phenotype, while CGD-TCL characterizes those with a γ/δ phenotype. In contrast to CGD-TCL, extranodal NK-/T-cell lymphoma is positive for EBV.

SECONDARY T-/NATURAL KILLER–CELL LYMPHOPROLIFERATIVE DISORDERS AFFECTING SKIN

Peripheral T-cell Lymphoma, Unspecified

PTCL-u corresponds to a relatively large group of predominantly nodal T-cell lymphomas that occur in Western countries and that frequently also show involvement of the bone marrow, liver, spleen, peripheral blood, and skin (13,342–344). The modifier "unspecified" emphasizes that most cases are clinicopathologically heterogeneous and thus do not fit well into better defined entities of T-cell neoplasia. In the skin, these lesions are separate from MF and Sézary syndrome, possessing distinctive histologic, antigenic, and genotypic attributes.

Clinical Features. The majority of cases involve adults without gender predilection, although reports exist of children being affected. Clinical presentation generally involves constitutional symptoms and lymphadenopathy. The lymphoepithelioid cell variant (see below) is a low-grade variant of peripheral T-cell lymphoma where systemic signs may include enlargement of cervical lymph nodes, hepatosplenomegaly, fever, and skin involvement in <10% of cases (345). Skin lesions may take the form of eczematous plaques or erythematous tumors; pruritis, peripheral eosinophilia, and hemophagocytic syndromes have also been described (217). The 5-year survival rate ranges from 30% to 35%, even with standard chemotherapy (346).

Histopathology. There are two variant forms of this entity: the *lymphoepithelioid cell variant* (previously referred to as *Lennert's lymphoma*) and the *T-zone variant*. The lymphoepithelioid variant is characterized by small lymphocytes with variable, often minimal, irregularities in nuclear contour, admixed with clusters of epithelioid histiocytes, eosinophils, plasma cells, and occasional Reed-Sternberg–like cells (347). These cells may infiltrate the dermis in a nodular or diffuse pattern, and the papillary dermis and epidermis may also be involved (348). The T-zone variant derives its name from its pattern of nodal involvement that primarily involves the interfollicular zones, with preservation of lymphoid follicles. Tumor cells are small to intermediate in size and often lack significant pleomorphism (Fig. 31-33). As with the lymphoepithelioid variant, reactive cells, including plasma cells, epithelioid histiocyte, eosinophils, and Reed-Sternberg–like cells, may also be noted. It is likely that definitive separation of these two variants will require evaluation of lymph node rather than skin involvement.

Histogenesis. The tumor is a malignancy of T cells, and the most common nodal immunophenotype is $CD4^+$, $CD30^{+/-}$, and $CD8^-$, with frequently aberrant T-cell antigenic profiles (e.g., loss of pan-T-cell differentiation markers) (349,350). Moreover, there tend to be clonal rearrangements of TCR genes (351), as documented by PCR analysis. While there is no consistent trend in karyotypic abnormalities, an association between trisomy 3 and the lymphoepithelioid variant (Lennert's lymphoma) has been reported (352).

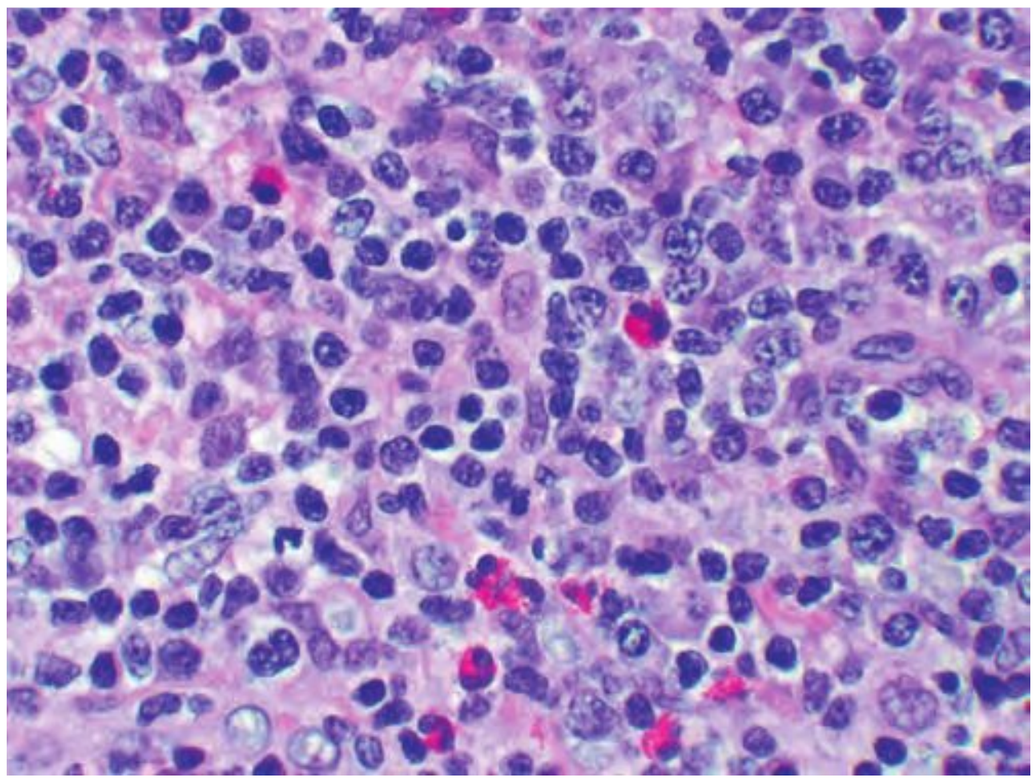

FIGURE 31-33. Peripheral T-cell lymphoma. Note relatively monomorphic lymphoid cells of intermediate size.

Differential Diagnosis. The lymphoepithelioid variant may occasionally mimic the granulomatous variant of MF, although the latter is characterized by clinical lesional evolution that involves initial formation of inconspicuous patches. Because lesions may be $CD30^+$, they should not be confused with ALCLs that differ cytologically. Whereas nodal cases also differ in that ALCLs often express cytotoxic granule associated proteins (287,353–357), it must be noted that extranodal involvement by peripheral T-cell lymphoma may also have a cytotoxic T-cell phenotype, including CD56 expression (296). EBV is generally absent on tumor cells but may be noted in the reactive components of lesions, in particular the Reed-Sternberg–like cells (358). Because these cells may be noted, along with a polymorphous reactive component, care must be taken not to mistake lesions as the rare event of cutaneous involvement by HL.

Angioimmunoblastic T-cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) accounts for approximately 15% to 20% of peripheral T-cell lymphomas.

Clinical Features. The disease typically affects middle-aged to elderly patients and presents with generalized lymphadenopathy and hepatosplenomegaly as well as constitutional symptoms such as high fever, night sweats, and weight loss (318,359–361). Laboratory findings typically show hemolytic anemia, leukocytosis, and polyclonal hypergammaglobulinemia. About 50% of patients develop cutaneous eruptions, most commonly macules and papules over the trunk and extremities. In rare cases, purpura, infiltrated or urticarial plaques, papulovesicular lesions, nodules, and erythroderma have been reported (362). AITL has an aggressive clinical course, with a median survival $<$3 years (317).

Histopathology. The involved lymph nodes show partial or complete architectural effacement with an interfollicular mixed polymorphous infiltrate of small- to medium-sized lymphocytes, plasma cells, eosinophils, epithelioid histiocytes, and immunoblasts as well as prominent arborizing high-endothelial venules (317,360, 361). The cutaneous lesions are generally subtle and vary considerably histologically. The most common features comprise a superficial perivascular infiltrate with or without atypical lymphocytes. Additional patterns documented include a dense superficial and deep perivascular atypical lymphoid infiltrate, leukocytoclastic vasculitis (362), and necrotizing granulomas (359).

Histogenesis. Immunohistochemical studies demonstrate a $CD3^+$ T-cell infiltrate with a predominance of $CD4^+$ over $CD8^+$ phenotype. TCR gene rearrangement of cutaneous lesions may display an identical clonal population to that detected in lymph nodes (361–363). EBV is positive in the majority of lymph nodes but rarely is detected in cutaneous lesions (362).

Differential Diagnosis. Because of the subtle and wide spectrum of histopathologic manifestations, the histologic differential diagnosis is broad and includes inflammatory dermatoses with superficial or superficial and deep perivascular patterns, leukocytoclastic vasculitis, infection, sarcoidosis, and other primary granulomatous conditions.

Anaplastic Large Cell Lymphoma

ALCL is a nodal T-cell malignancy that is characterized by homogeneous proliferation of large atypical lymphocytes that express the CD30 (Ki-1) antigen. It must be differentiated from PC-ALCL, which is a lesion with a considerably better prognosis.

Clinical Features. Of non-HLs, approximately 3% of adult lymphomas and 10% to 30% of lymphomas in children are accounted for by ALCL (364). Lesions may be further divided according to expression of ALCL kinase (ALK), with most positive cases affecting males in the second to third decades of life and most negative cases occurring in older individuals with relatively equal distribution according to gender. Of extranodal sites, the skin is involved in more than 20% of cases, followed by the bone, soft tissue, lung, and liver (364,365). Fever and adenopathy are common, with presentation in advanced stages of disease the rule.

Histopathology. Although a wide morphologic spectrum has been described (133,366–371), most cases share the presence of large anaplastic mononuclear cells containing abundant cytoplasm and an eccentric, reniform nucleus (370) (Fig. 31-34A, B). Occasional intranuclear cytoplasmic inclusions ("doughnut" cells) and multinucleated forms may be observed (372). The chromatin pattern is generally finely aggregated, and nucleoli are variably prominent and usually multiple. In addition to lesions where these cells predominate (the common variant), others may show these cells to be admixed with large numbers of histiocytes (lymphohistiocytic variant) or with cytologically similar, albeit smaller atypical lymphocytes (small cell variant). In general, however, the hallmark large anaplastic lymphocytes are recognizable cytologically and as a result of their tendency to aggregate about blood vessels. The dermal infiltrates tend to have a nodular architecture. The presence of epidermal hyperplasia tends to correlate with primary cutaneous ALCL rather than systemic ALCL.

Histogenesis. The presumed cell of origin for ALCL is a mature cytotoxic T cell. The majority of cases express T-cell antigens, and even those without T-cell antigen expression ("null cell" phenotype) have evidence of T-cell lineage at a genomic level (356). Pan-T-cell maturation markers (e.g., CD3, CD5, and CD7) are frequently negative, which is consistent with an aberrant T-cell phenotype. The majority of cases show strong CD30 reactivity on the cell membrane and in association with the Golgi zone (Fig. 31-34C). This reactivity is especially prominent on the hallmark large anaplastic cells and less pronounced on the smaller variant forms (241). ALK expression (see below) is present in 60% to

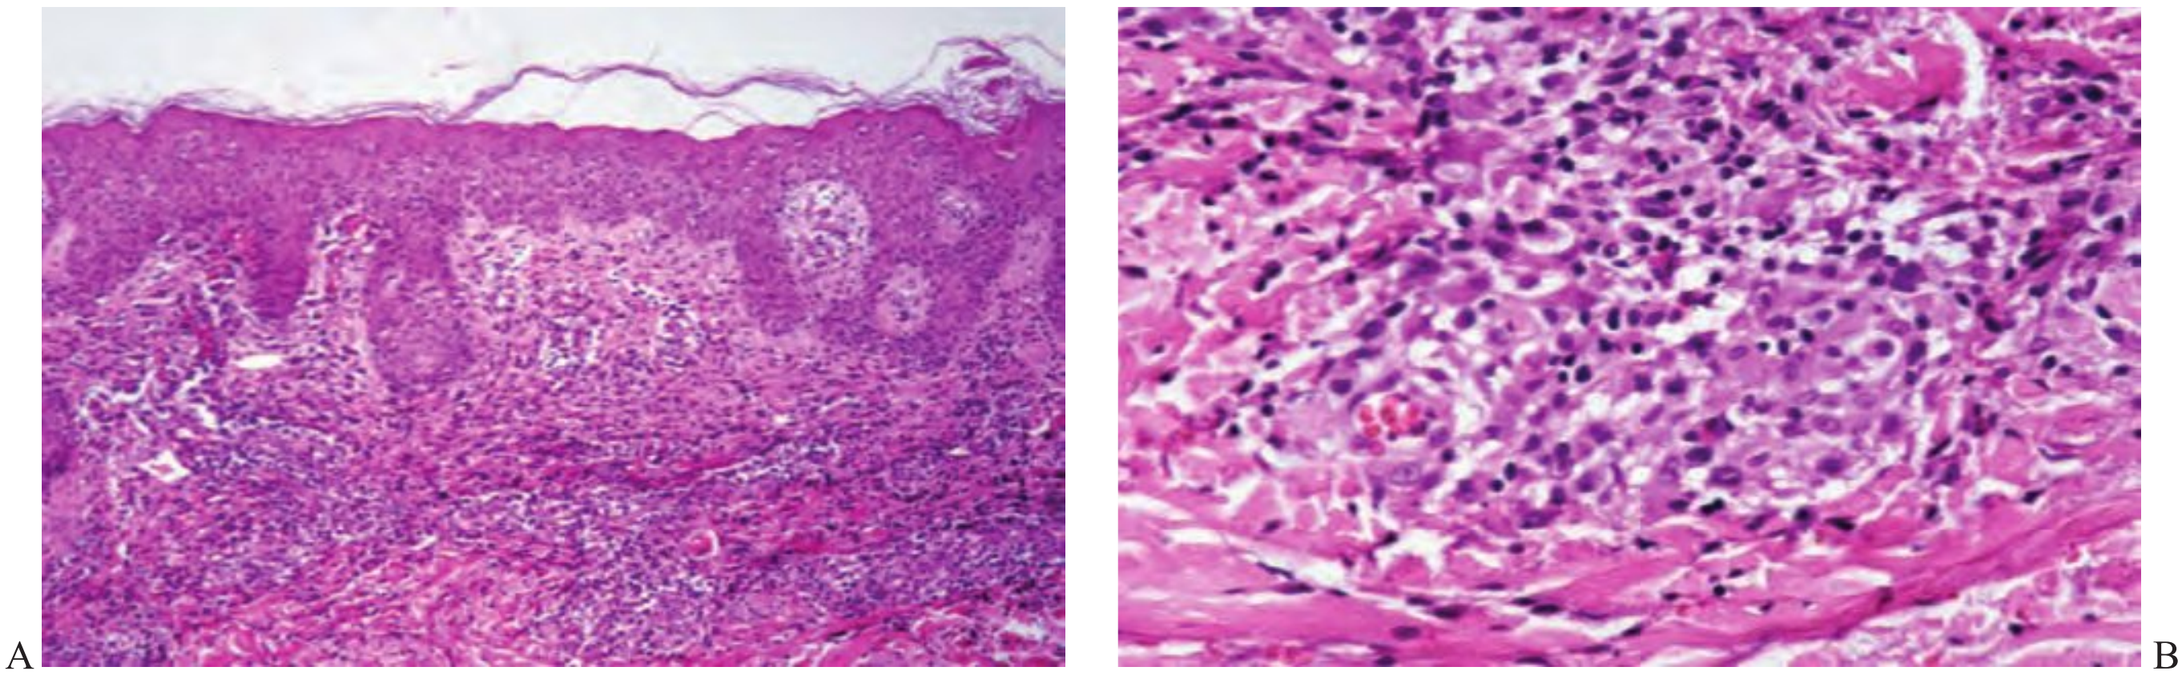

FIGURE 31-34. Anaplastic large cell lymphoma. Low (A) and higher (B) magnification showing dermal infiltrate by large anaplastic lymphoid cells. C: Immunohistochemistry for CD30.

80% of cases, and the majority of these are also positive for EMA (366,370). In addition, most cases show positivity for cytotoxic-associated markers, including TIA-1, granzyme B, and/or perforin (355,356). Tumor cells are consistently negative for EBV, although they may show perinuclear staining for lysosomal enzymes as well as reactivity with some probes that identify CD68, and accordingly, caution must be exercised in not assuming histiocytic lineage in such instances (372). The majority of cases demonstrate clonal rearrangements in the TCR irrespective of expression of T-cell markers.

Overexpression of the ALK protein is caused by alterations of the ALK gene at chromosome 2. Most commonly, t(2;5)(p23;35) is seen with the participation of the ALK gene on chromosome 2 and nucleophosmin (NPM) gene on chromosome 5. However, breakpoints on chromosomes other than 5 can partner with the ALK gene. Classic t(2;5) leads to ALK protein overexpression resulting in both cytoplasmic and nuclear stain with antibodies directed against this molecule. The ALK protein functions as a tyrosine kinase receptor, and its gene belongs to the insulin receptor superfamily. ALCL are invariably negative for EBV genomes, separating them from EBV+ classic types of HL.

Differential Diagnosis. The primary differential diagnostic considerations include HL, particularly when Reed-Sternberg–like cells are present. However, the immunophenotypic profile of ALCL is sufficiently distinctive to permit distinction of ALCL from the rare occurrence of HL with skin involvement. Systemic ALCL (discussed here) presents in the skin in advanced stages and therefore may be further differentiated from PC-ALCL and its regressing variants (e.g., LYP) based on clinical parameters and immunoreactivity to ALK-1 (discussed in greater detail previously under PC-ALCL).

Adult T-cell Leukemia/Lymphoma

ATLL is a peripheral high-grade lymphoid neoplasm caused by the human retrovirus HTLV-1.

Clinical Features. ATLL occurs most often as an endemic disorder, primarily in Japan, the Caribbean basin, and Central Africa, with the disease distribution mirrored by the prevalence of HTLV-1 infection (373). The disease is also detected in populations in certain parts of the southeastern United States where HTLV-1 seropositivity is high. The virus may be transmitted by blood and body fluids, including breast milk, and the disease is believed to have a long latency period before becoming overt. The median age is 55 years, with males slightly more affected than females (374). Widespread lymphadenopathy and peripheral blood involvement are present from the outset. The skin is the most common extralymphatic site of involvement, with lesions documented in more than half of the cases. *H*ypercalcemia, *o*steolytic bone

lesions, *T*-cell leukemia, and *s*kin lesions (HOTS) represents a clinical syndrome that along with lymphadenopathy represents a prototypical presentation for ATLL. Skin lesions generally take the form of multiple papules, plaques, and nodules that may be explosive in onset (Fig. 31-35A). Clinical course is variable, and acute (leukemia, rash, hypercalcemia), lymphomatous (lymphadenopathy without leukemia or hypercalcemia), and chronic/smoldering (skin lesions without leukemia or hypercalcemia) variants have been described. Cutaneous lesions may be seen in all variants. In general, individuals afflicted with the acute and lymphomatous types have a significantly worse prognosis (375). The 4-year survival rates are 5.0% for the acute type, 5.0% to 7.0% for the lymphomatous type, 26.9% for the chronic type, and 62.8% for the smoldering type (376).

Histopathology. Skin lesions may show nodular to diffuse infiltrates of atypical lymphocytes, with or without papillary dermal involvement or epidermotropism. Lesions thus are generally indistinguishable from MF in plaque to nodular stages of evolution (Fig. 31-35B). Cytologically, the neoplastic lymphocytes contain enlarged hyperchromatic nuclei with irregular, often convoluted nuclear profiles (Fig. 31-35C). Anaplastic cells with clumped nuclear chromatin and prominent nucleoli may also be observed (374,377). The peripheral blood contains atypical cells with characteristically hyperlobated nuclear profiles ("flower cells"), a feature that may serve to distinguish ATLL cells from those of Sézary syndrome and systemically disseminated forms of MF (Fig. 31-35D).

Histogenesis. Tumor cells are $CD4^+$ T cells that also express T-cell–associated antigens CD2, CD3, CD5, and CD25, but generally lack CD7 and CD8. As in all cases of T-cell lymphoma, rare cases that express CD8 but not CD4 or double-negative ($CD4^-/CD8^-$) cases may occur. Tumor cells may also express CD30 but unlike ALCL lack ALK, TIA-1, and granzyme B (378,379). TCR gene rearrangements are present (380). Interestingly, the $CD3^+/CD4^+$ neoplastic cells of ATLL may demonstrate suppressor, rather than helper/inducer, function *in vitro*. Clonally integrated HTLV-1 is present. The HTLV-1 transactivator, Tax, has been implicated as the viral oncoprotein (381).

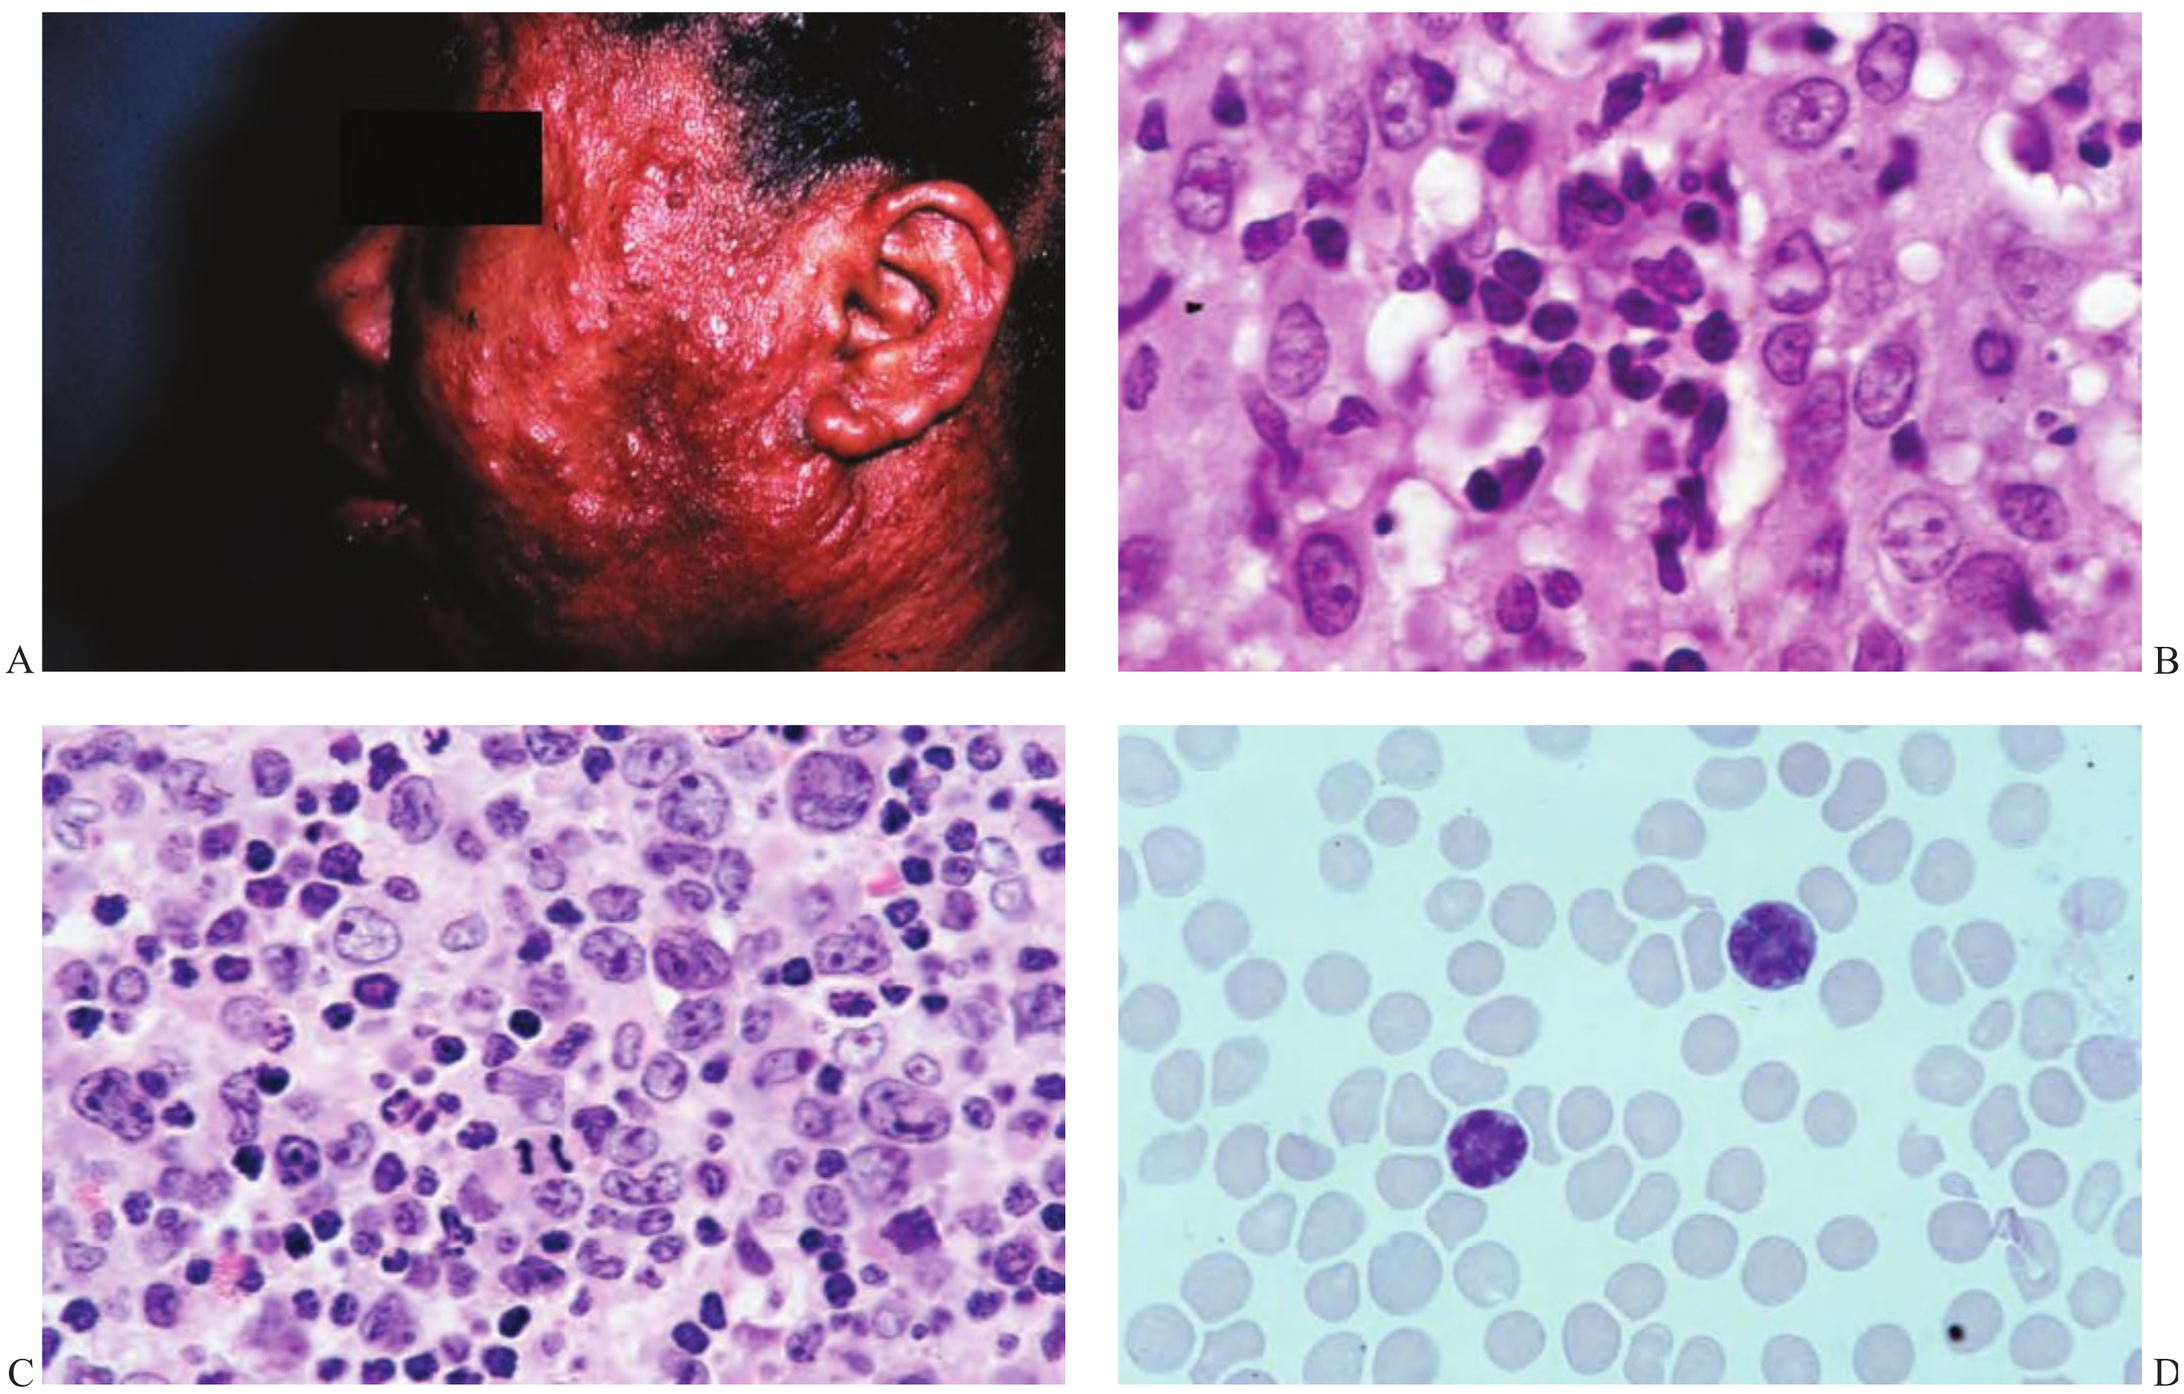

FIGURE 31-35. Adult T-cell leukemia/lymphoma. A: Clinical appearance, where multiple nodules explosively developed within several weeks in this patient with hypercalcemia. B: Epidermotropic atypical lymphocytes are indistinguishable by conventional paraffin histology from MF. C: Tissue infiltration by tumor cells with variably hyperchromatic and convoluted nuclear contours. D: Peripheral blood showing enlarged lymphoid cells with characteristically hyperlobated nuclear contours.

Differential Diagnosis. The differential diagnosis includes primarily MF and Sézary syndrome. The presence of patch-stage disease, both clinically and/or histologically, is of assistance in differentiating MF from ATLL. However, in more advanced lesions, distinction by histology alone may be impossible. Because most ATLL patients are not erythrodermic, this clinical feature may assist in differentiating this condition from Sézary syndrome. It should also be noted that the cytology of peripheral blood involvement in ATLL is distinctive, showing cells with hyperlobated, "flower-like" nuclear contours rather than the cerebriform nuclei of Sézary cells. In suspected cases of ATLL, HTLV-1 serology should be performed (382), although definitive diagnosis ultimately will depend on demonstration of HTLV-1 gene integration within the malignant cells in skin or blood by Southern blot analysis (383).

Precursor T-lymphoblastic Leukemia/Lymphoblastic Lymphoma

Precursor T-lymphoblastic leukemia (T-ALL)/lymphoblastic lymphoma (T-LBL) is a high-risk neoplasm that is derived from pre- and intrathymic T lymphocytes. The distinction between the designation of leukemia and lymphoma is somewhat arbitrary, with the former preferred when there is extensive marrow and blood involvement and the latter when there is a mass lesion at presentation and $<$25% lymphoblasts in the marrow and minimal peripheral blood involvement (384).

Clinical Features. The most typical presentation is that of a mediastinal mass in children and young adults. Involvement of bone marrow and peripheral blood is frequent. The lymph nodes, liver, spleen, Waldeyer ring, central nervous system, gonads, and skin may all be involved. Infiltration of the skin results in erythematous to hemorrhagic papules and nodules, with skin of the head and neck region preferentially involved (68). Whereas the leukemic counterpart tends to affect children, the lymphomatous phase is more often encountered in men (38).

Histopathology. As with other poorly differentiated T-cell infiltrates of skin, the dermis is preferentially involved by a diffuse interstitial infiltrate, with little or no epidermotropism. Cytologically, the tumor cells are uniformly atypical, with scant cytoplasm and nuclei characterized by slightly irregular, sometimes grooved contours and moderately condensed to evenly dispersed chromatin patterns with inconspicuous nucleoli (68,385) (Fig. 31-36A). Occasionally, eosinophils will be present within the dermal infiltrate.

Histogenesis. The cell of origin is believed to be a precursor T-lymphoblast. The tumor cells are TdT^+ and may express CD1a, CD2, CD3, CD4, CD5, CD7, and/or CD8 to variable degrees. Of these, reactivity for CD3 and CD7 are the most common (Fig. 31-36B, C). Lineage ambiguity of these primitive cells may occur, however, as evidenced by occasional expression of the B-cell marker CD79a or myeloid markers CD13 and/or CD33. Clonal rearrangements of the TCR are also commonly observed.

Differential Diagnosis. Skin involvement by T-ALL/T-LBL must be differentiated from B-cell lymphoblastic leukemia/lymphoma and acute myeloid leukemia, and this requires immunohistochemistry and/or histochemistry for lineage-associated antigens and enzymes. In children, extranodal involvement by Birkitt lymphoma, and in adults, by the blastoid variant of MCL, may enter into the differential diagnostic algorithm. Because lymphoblastic lymphoma is the only lymphoma that shows nuclear TdT positivity, these possibilities may be readily eliminated. Primary neuroendocrine carcinoma of the skin may occasionally be confused with T-ALL/T-LBL, especially when the former shows a diffuse interstitial pattern of dermal involvement. Again, immunohistochemistry will establish the hematopoietic and lineage characteristics of T-ALL/T-LBL in this setting.

T-cell Prolymphocytic Leukemia

T-cell prolymphocytic leukemia (T-PLL) is a relatively rare, aggressive form of T-cell leukemia composed of cells of mature, postthymic phenotype, that tend to involve the lymph nodes, liver, spleen, and skin (20% of cases) in addition to the blood and bone marrow (386).

Clinical Features. The vast majority of afflicted individuals are adults who present with generalized lymphadenopathy and enlargement of the spleen and liver. Anemia, thrombocytopenia, and atypical lymphocytosis are present; HTVL-1 serology is negative. Unlike Sézary syndrome, skin lesions are not erythrodermic but rather infiltrative. The leukemic infiltrates tend to form plaques and nodules that are variably erythematous to hemorrhagic in appearance.

Histopathology. Skin involvement takes the form of dense dermal infiltrates with a focal tendency for periadnexal localization. However, epidermotropism is not present (387,388). Peripheral blood in most cases contains numerous (often $>100 \times 10^3$/L) small- to intermediate-sized lymphoid cells characterized by basophilic cytoplasm and nuclei with irregular contours and detectable nucleoli. Occasional cases will show such prominent irregularities in nuclear contour that the cells may resemble Sézary cells (389), while others will show a predominance of small lymphocytes with inconspicuous nucleoli (small cell variant). Important common features, however, are the presence of cytoplasmic blebs from the plasma membranes and Golgi region staining for alpha-naphthyl acetate esterase (281). Bone marrow will contain these cells as well, although the characteristic diagnostic features may be more difficult to establish in this tissue.

Histogenesis. Cases show various combinations of CD4 and CD8 reactivity, with most expressing CD4 and showing clonal rearrangements of TCR gamma and beta chains. Strong CD7 staining and coexpression of CD4 and CD8 in 25% of patients along with weak reactivity for CD3 suggest that T-PLL may be differentiating toward a stage intermediate between a cortical thymocyte and a mature peripheral blood

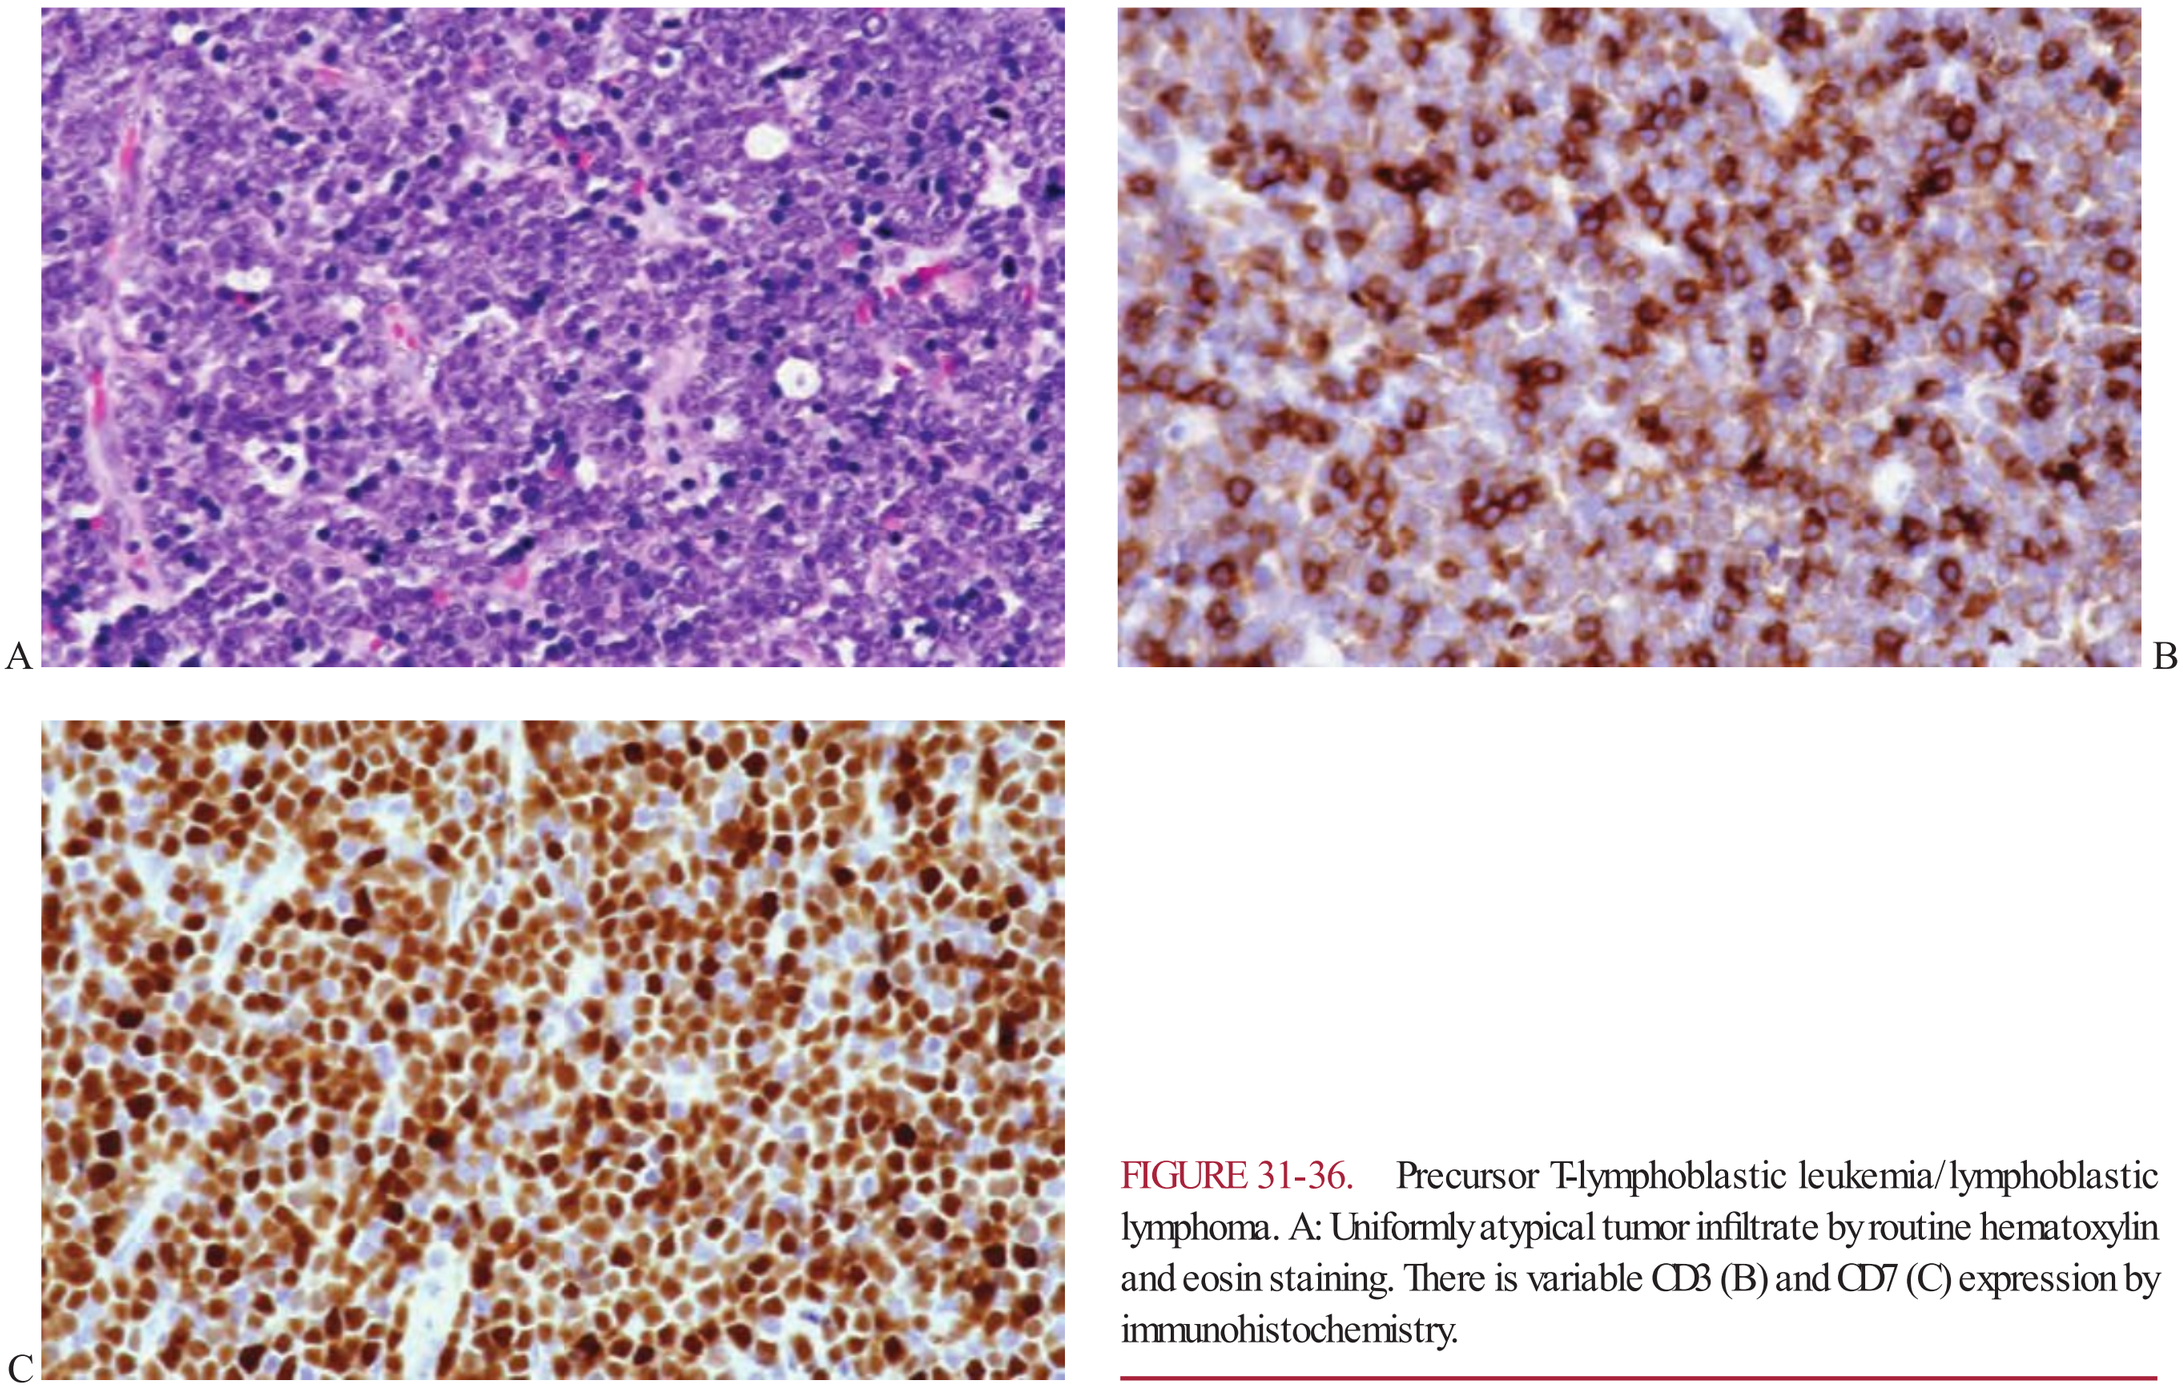

FIGURE 31-36. Precursor T-lymphoblastic leukemia/lymphoblastic lymphoma. A: Uniformly atypical tumor infiltrate by routine hematoxylin and eosin staining. There is variable CD3 (B) and CD7 (C) expression by immunohistochemistry.

T cell. Eighty percent of patients show inversion of chromosome 14 with breakpoints involving the long arm at q11 and q32 (390,391). Additional cytogenetic alterations, such as trisomy 8 and cMyc amplification have also been documented (388).

Differential Diagnosis. T-PLL must be differentiated from other forms of T-cell lymphoma showing skin involvement and a leukemic phase, such as Sézary syndrome, ATLL, T-CLL, and T-ALL. The clinical features at presentation, absence of epidermotropism, absence of HTLV-1 positivity, characteristic cytoplasmic blebbing in peripheral blood smears, and coexpression of CD4 and CD8 (a feature virtually unique to T-PLL) should all assist in differential diagnostic exclusion of this rare yet aggressive condition.

PRIMARY CUTANEOUS MYELOID HYPERPLASIA/NEOPLASIA

Extramedullary Hematopoiesis

Extramedullary hematopoiesis refers to abnormal trilineage maturation of hematopoietic elements in tissues other than the bone marrow. In the skin, the process has been referred to as *dermal hematopoiesis*. Occasionally, extramedullary hematopoiesis is restricted to cells of erythroid lineage, a phenomenon termed *dermal erythropoiesis*, which may occur in neonates in association with the stress of various viral infections or in adults with myelofibrosis.

Clinical Features. Lesions typically present as macules, papules, and occasionally nodules that have a dull blue-red hue. Dermal hematopoiesis in neonates tends to affect the head and neck (so-called "blueberry muffin baby"). In adults, cutaneous extramedullary hematopoiesis frequently involves the trunk and occasionally in surgical scars after splenectomy, a procedure that in itself appears to augment the phenomenon.

Histopathology. Poorly formed micronodules of pleomorphic cells are present in the dermis, and the pattern may initially mimic leukemia cutis or an unusual dermal inflammatory reaction. Maturing erythrocytes can be identified as clustered "colonies" of cells containing round basophilic nuclei rimmed by eosinophilic cytoplasm. Admixed myeloblasts, metamyelocytes, and characteristically large megakaryocytes containing prominently multilobated nuclei are often also present. These latter cells are reactive for CD61, a helpful marker in further confirming their lineage identity.

Histogenesis. Although normal hematopoiesis occurs in the bone marrow, the occurrence of extramedullary hematopoiesis in the skin and other tissues underscores the fact that under certain conditions, extramedullary tissues contain the appropriate precursor cells and growth factors to serve as surrogates for the marrow microenvironment.

Differential Diagnosis. Extramedullary hematopoiesis in the skin must be distinguished from reactive and dysplastic

polymorphous infiltrates that may contain large atypical cells (e.g., LYP containing large Reed-Sternberg–like cells) and from forms of leukemia cutis that harbor cells with primitive myeloid features. Clinical information may be helpful in determining whether patients have predisposing factors for this phenomenon. The morphologic identification of erythropoiesis and the presence of megakaryocytes, and further confirmation of the latter via immunohistochemistry for CD61, should assist in those rare circumstances when true extramedullary hematopoiesis is detected in the skin.

Myeloid Sarcoma

Myeloid sarcoma refers to a tumor formed by myeloblasts or immature myeloid cells that affects an extramedullary site, such as the skin. The mass, also referred to as a *extramedullary myeloid tumor, granulocytic sarcoma,* or *chloroma,* may precede (aleukemic leukemia) or present simultaneously with a systemic myeloproliferative disorder, including acute and chronic myeloid leukemias (see below) and myelodysplastic syndromes, or represent a relapse of disease previously in remission. Acute monoblastic leukemia giving rise to extramedullary myeloid tumor is referred to as *monoblastic sarcoma.*

Clinical Features. Lesions may be solitary or multiple and may show clinical features indistinguishable from secondary cutaneous involvement by acute and chronic myeloid leukemia (see below).

Histopathology. Most commonly, myeloid sarcoma is composed of an admixture of myeloblasts, neutrophil precursors, and mature neutrophils (granulocytic sarcoma). Less differentiated (blastic) variants are formed primarily by myeloblasts, whereas the immature and differentiated variants are composed primarily of myeloblasts and promyelocytes, or of promyelocytes and more mature forms, respectively. Rarely, myeloid sarcomas may be composed principally of monoblasts. In situations involving transformation of chronic myeloproliferative disease, trilineage hematopoiesis may also be observed.

Histogenesis. The postulated cell of origin is a myeloid hematopoietic cell. Tumor cells stain positively for myeloperoxidase, lysozyme, and chloroacetate esterase. The myeloblastic components may express CD13, CD33, and CD117, as also would be anticipated in acute myelogenous leukemia. Tumors with monoblastic differentiation may express CD14, CD116, and CD11c as well as lysozyme and CD68. CD43 also is expressed by the majority of myeloid sarcomas.

Differential Diagnosis. Tumors containing primarily blastic and immature elements must be differentiated from various non-HLs, poorly differentiated carcinoma, melanoma, and Langerhans cell histiocytosis. In general, in any poorly differentiated malignant skin infiltrate of confirmed hematopoietic lineage, myeloid differentiation should be considered and excluded by appropriate immunohistochemical panels. Distinction from extramedullary hematopoiesis can be achieved by the identification of megakaryocytes and normoblasts.

SECONDARY MYELOID NEOPLASMS AFFECTING SKIN

Acute and Chronic Myeloid Leukemia

Leukemia cutis is an important differential consideration in the assessment of atypical hematopoietic/lymphoproliferative infiltrates of the skin. Some lymphomas may occur along a continuum with leukemic phases, and thus certain forms of leukemia have already been discussed under T- and B-cell lymphoid neoplasms. Because circulating leukemic cells may always potentially deposit in the skin, there is a wide range of disorders that come into consideration in this section. The WHO classification, for example, considers acute myeloid leukemias according to categories that relate to the presence of recurrent genetic abnormalities, association with multilineage dysplasia, and those that are of ambiguous lineage or not otherwise categorized. Chronic myeloproliferative conditions are also classed into multiple groups, as is exemplified by chronic myelogenous, neutrophilic, and eosinophilic leukemias and polycythemia vera, to name a few. Because the nuances of these classification schemes rely heavily on morphologic, immunophenotypic, and genotypic findings in the bone marrow, a detailed discussion is beyond the scope of this section, which will focus on common features of neoplastic myeloid infiltrates of skin and how to recognize them.

Clinical Features. Clinical symptoms and signs are often related to marrow replacement by malignant cells and thus tend to relate to anemia, thrombocytopenia, and alteration in normal leukocyte function (infection). Peripheral blood generally shows leukocytosis as a result of involvement by malignant cells, although occasionally, these may not be detectable despite massive marrow involvement. In such situations, involvement of solid tissues, such as skin, may be the initial presenting feature of leukemia in evolution. Chronic leukemias are more indolent neoplasms that are composed of more mature myeloid cells that slowly replace the marrow compartment and seed the blood. Acute leukemias are more aggressive neoplasms that are composed of less mature myeloid cells and that more rapidly and completely replace normal hematopoietic marrow and seed the blood. Cutaneous infiltrates may present as red to purpuric patches, plaques, papules, or nodules, with or without ulceration (392) (Fig. 31-37). Mucosae may also be affected. There exist, in addition, numerous paraneoplastic findings that may be associated with leukemia, including gingival hyperplasia, vasculitis, Sweet's and pyoderma neutrophilic dermatitis, urticaria, erythema multiforme, and erythema nodosum, to name a few.

FIGURE 31-37. Acute myeloid leukemia. Multiple erythematous to hemorrhagic plaques and nodules are observed.

Histopathology. Myeloid leukemias may recapitulate various forms of myeloid lineage, and accordingly, these neoplasms may be described as showing myeloid, myelomonocytic, monocytic, and megakaryocytic differentiation. Acute myeloid leukemia may be divided into M0 to M7 subtypes according to differentiation patterns described in Table 31-8.

Architecturally, early acute myelogenous leukemia cutis may produce an angiocentric infiltrate, although interstitial permeation among collagen bundles within the reticular dermis soon supervenes (Fig. 31-38A). Vague nodules may form as the dermis becomes progressively expanded by malignant cells, which express myeloperoxidase (Fig. 31-38B). Malignant myeloid cells forming the dominant cell type of acute myeloid leukemia cutis tend to appear monotonous and homogeneous cytologically (Fig. 31-38C). Nuclei are round to oval, chromatin may be evenly dispersed, and nucleoli are multiple but potentially inconspicuous. On rare occasion, immature eosinophils containing typical cytoplasmic granules in the absence of bilobed nuclear contours may be helpful in assigning a presumptive diagnosis (Fig. 31-38D). However, histochemistry and immunohistochemistry are generally required for confirmation as well as examination of the peripheral blood and bone marrow (Fig. 31-38E).

It is noteworthy that myeloid leukemia cutis may mimic an angiocentric inflammatory infiltrate architecturally, and cytologically immature myeloid cells, although homogeneous, may not appear overtly anaplastic. Accordingly, it is appropriate to consider the differential possibility of acute myeloid leukemia cutis in the initial histologic evaluation of any atypical or malignant nonepidermotropic lymphoid infiltrate of presumed lymphoid origin (Fig. 31-38E). In cutaneous infiltrates with similar architectural features but containing mature myeloid elements, in addition to myeloblasts, the less common possibility of chronic myeloid leukemia cutis should be considered.

Histogenesis. Both acute and chronic forms of myeloid leukemia are derived from myeloid progenitors in the bone marrow. As such, cells are histochemically positive for myeloperoxidase (Fig. 31-38B), Sudan black B, chloroacetate esterase, and Leder stains. Myeloid cells do not express B-lineage (CD19, CD20, CD22, CD19a) or T-lineage (CD2, CD3, CD5, CD7) markers but may show immunohistochemical staining for the myeloid markers CD13, CD33, CD15, CD117 or megakaryoblastic antigens C41 and CD61.

Differential Diagnosis. In addition to possible confusion with T- and B-cell leukemia/lymphoma cutis, acute myeloid leukemia cutis must be differentiated from other interstitial dermal infiltrates dominated by monotonous populations of mononuclear cells. Mastocytosis may produce an interstitial pattern, and mast cells may react positively with the Leder stain but not with more specific markers for myeloid differentiation (e.g., myeloperoxidase). Myeloblasts, along with more mature myeloid elements, may occur in skin involved by chronic myelogenous leukemia as well as by extramedullary hematopoiesis. However, in the latter, maturing cells of erythrocyte and megakaryocytic differentiation are generally detectable.

TABLE 31-8 World Health Organization Classification of Acute Myeloid Leukemias

Acute myeloid leukemia with recurrent genetic abnormalities
- Acute myeloid leukemia with t(8;21)(q22;q22);(AML1/ETO)
- Acute myeloid leukemia with abnormal bone marrow eosinophils inv(16)(P13q22) or t(16;16)(p13;q22);(CBFβ/MYH11)
- Acute promyelocytic leukemia (AML with t(15;17)(q22;q12)(PML/RARα) and variants) (M3)
- Acute myeloid leukemia with 11q23 (MLL) abnormalities

Acute myeloid leukemia with multilineage dysplasia
- Following a myelodysplastic syndrome or myelodysplastic syndrome/myeloproliferative disorder
- Without antecedent myelodysplastic syndrome

Acute myeloid leukemia and myelodysplastic syndromes, therapy related
- Alkylating agent related
- Topoisomerase type II inhibitor related (some may be lymphoid)
- Other types

Acute myeloid leukemia not otherwise categorized
- Acute myeloid leukemia minimally differentiated (M0)
- Acute myeloid leukemia without maturation (M1)
- Acute myeloid leukemia with maturation (M2)
- Acute myelomonocytic leukemia (M4)
- Acute monoblastic and monocytic leukemia (M5)
- Acute erythroid leukemia (M6)
- Acute megakaryoblastic leukemia (M7)
- Acute basophilic leukemia
- Acute panmyelosis with myelofibrosis

Myeloid sarcoma

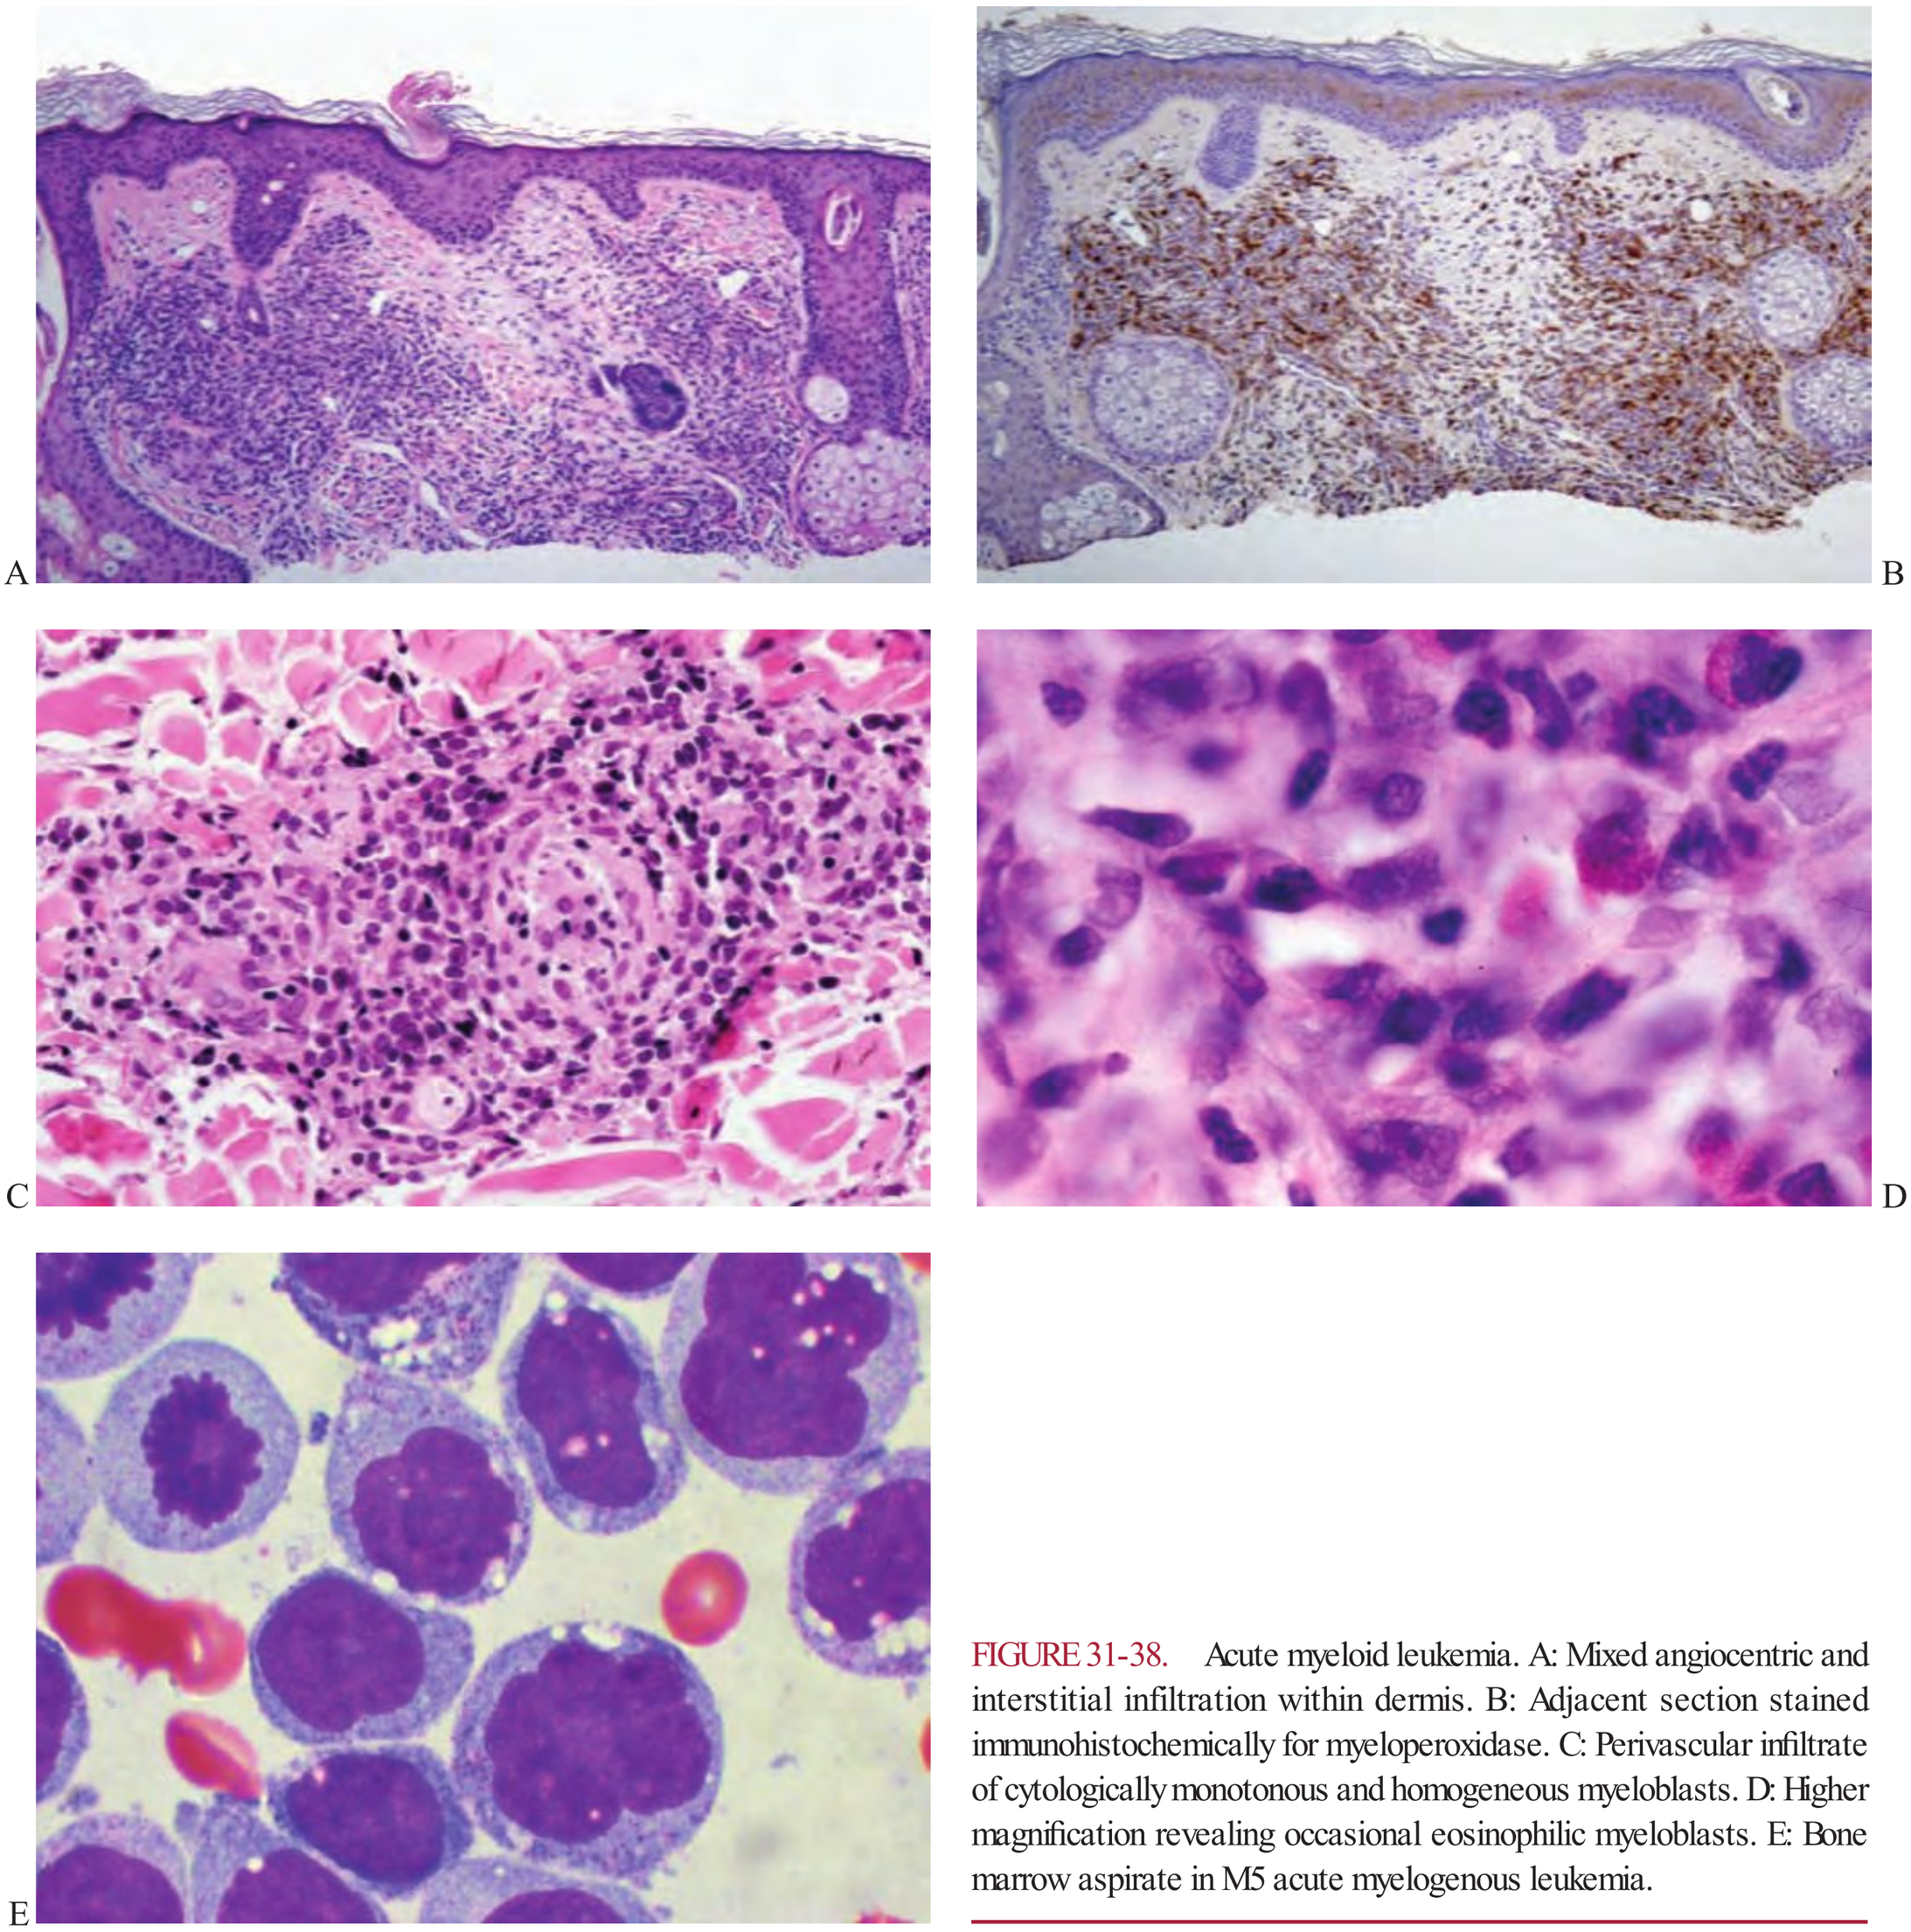

FIGURE 31-38. Acute myeloid leukemia. A: Mixed angiocentric and interstitial infiltration within dermis. B: Adjacent section stained immunohistochemically for myeloperoxidase. C: Perivascular infiltrate of cytologically monotonous and homogeneous myeloblasts. D: Higher magnification revealing occasional eosinophilic myeloblasts. E: Bone marrow aspirate in M5 acute myelogenous leukemia.

Precursor Plasmacytoid Dendritic Cell Lineage

CD4 and CD56-positive Hematodermic Neoplasm (Blastic Natural Killer–cell Lymphoma)/Plasmacytoid Dentritic Cell Leukemia/Lymphoma

$CD4^+/CD56^+$ hematodermic neoplasm/plasmacytoid dentritic cell leukemia/lymphoma is a controversial entity that was previously termed *blastic NK-cell lymphoma*, since the oncogenic origin was thought to be NK-cell precursors. More recent studies, however, have suggested a lineage derivation from a plasmacytoid (type 2) dendritic cell precursor (393). The neoplastic cells characteristically coexpress CD4 and CD56 without B-, T-, and NK-cell or myeloid lineage-specific markers. The new WHO/EORTC consensus classifies this entity as $CD4^+/CD56^+$ hematodermic neoplasm or "early" plasmacytoid dendritic cell leukemia/lymphoma (pDCL) if systemic disease is present at presentation. The condition is rare, representing $<$1.0% of acute leukemia (393) and 0.7% of cutaneous lymphomas (394).

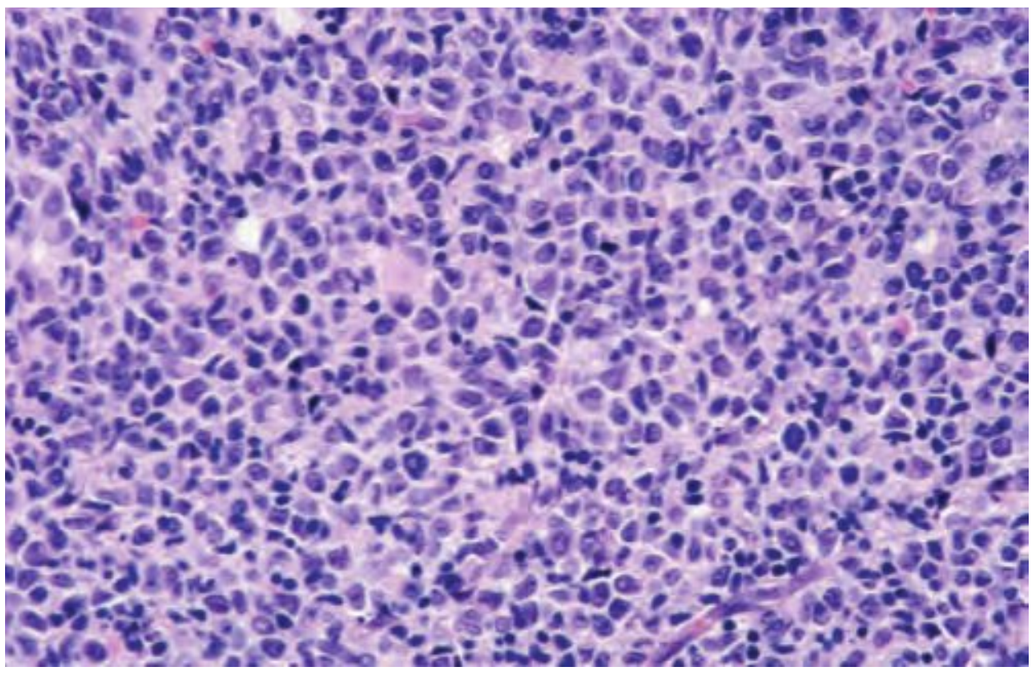

FIGURE 31-39. CD4/CD56 hematodermic neoplasm (blastic NK-cell lymphoma). The dermis is replaced by a monotonous infiltrate of intermediate-sized mononuclear cells with some morphologic overlap with myeloblasts.

Clinical Features. This lymphoma tends to affect middle-aged and elderly individuals, who at time of presentation demonstrate an isolated skin lesion that rapidly evolves to multiple sites and often with soft tissue, lymph node, bone marrow, and/or peripheral blood involvement (395). Skin involvement occurs in 87% of cases and may take the form of localized plum-colored, contusiform plaques or tumors covered by a glistening, attenuated epidermal layer. Oral mucosal lesions are common. The clinical course is aggressive, with a median survival of approximately 14 months.

Histopathology. The dermis is diffusely infiltrated by a monotonous population of intermediate-sized lymphoid cells with round or pleomorphic nuclei and a clumpy chromatin pattern that may suggest lymphoblastic or myeloblastic leukemia (Fig. 31-39; also see below). There is sparing of the epidermis and an absence of zonal necrosis or angiocentric infiltration, as may occur with extranodal NK-/T-cell lymphoma of the nasal type. On rare occasion, tumor cells may aggregate to form rosette-like structures resembling Homer-Wright rosettes (396). Azurophilic cytoplasmic granules are variably detected by Giemsa staining (397). Extravasation of erythrocytes is common, corresponding to the plum-colored bruise-like lesions clinically.

Histogenesis. Although a precursor NK-cell origin has been postulated previously, evidence now suggests that the malignant clone arises from plasmacytoid dendritic cells (pDC). The neoplastic cells tend to be $CD3^-$, $CD4^+$, $CD56^+$, TdT^+ (focal), $CD123^+$, and $TCL1^+$ (398). This disease entity is immunophenotypically somewhat ill defined, and the diagnosis should be made only in the absence of myeloid (such as myeloperoxidase, lysozyme, CD13, and CD15) and T-lineage markers other than CD4 (including TIA-1), particularly in light of the fact that both AML and T-ALL can express CD56. Distinct from NK-cell malignancies, EBV is invariably absent (1). Because of the dendritic cell lineage of the neoplastic cells, there is no clonal rearrangement of TCR genes.

Differential Diagnosis. Because of potential confusion with myeloblastic and precursor T-lymphoblastic lymphoma/leukemia, the diagnosis of $CD4^+/CD56^+$ hematodermic neoplasm is best made when neoplastic cells are negative for CD3, myeloperoxidase, and CD33 and preferably also when they fail to demonstrate TCR gene rearrangements.

Tumors of Fibrous Tissue Involving the Skin

CLASSIFICATION OF FIBROUS TISSUE AND RELATED TUMORS BY CLINICAL BEHAVIOR

The main importance of correctly identifying and classifying fibrohistiocytic and soft tissue tumors lies in being able to predict their biological potential and hence appropriate treatment. Changes in our understanding of these entities have given rise to a system of classification based on expected clinical behavior (1,2). The principles of this system are used in this chapter and summarized in Table 32-1, although some lesions do not fall neatly into these recognized categories.

Although many of the tumors described in this chapter can be diagnosed on the basis of histologic features on hematoxylin-eosin–stained sections, immunohistochemistry is essential at times (Table 32-2). This should be used as an adjunct to standard histologic methods and clinical data. Additional techniques such as cytogenetics and electron microscopy can also be of value in categorizing some tumors. The possibility that a malignant lesion represents a metastasis must always be considered.

SO-CALLED FIBROHISTIOCYTIC TUMORS

Benign

Dermatofibroma (Fibrous Histiocytoma/Sclerosing Hemangioma)

Dermatofibromas (fibrous histiocytomas) are common skin tumors predominantly occurring on the extremities or trunk of young adults. They present as small, firm, solitary nodules that are red to brown in color, often due to increased intraepidermal melanin or tumoral hemosiderin. This may suggest a melanocytic lesion clinically. Dermatofibromas are seen only rarely on the palms and soles (3) and are relatively uncommon on the face, where they are more likely to recur (4). Multiple tumors have been reported associated with immunosuppressive therapy (5), pregnancy (6), HIV infection (7), and after antiretroviral therapy (8). Although most lesions are usually only a few millimeters in diameter, they occasionally measure 2 to 3 cm. The cut surface is white to yellow or brown, depending on the proportions of fibrous tissue, lipid, and hemosiderin present (Fig. 32-1A). Dermatofibromas usually persist, although spontaneous involution has been observed (9).

Histopathology. The epidermis is usually hyperplastic, with hyperpigmentation of the basal layer and elongation of the rete ridges, separated by a clear (Grenz) zone from the tumor in the dermis (Fig. 32-1B). This is composed of fibroblast-like spindle cells, histiocytes, and blood vessels in varying proportions (Fig. 32-1C–E). Foamy histiocytes and multinucleate giant cells containing lipid or hemosiderin are frequently present, sometimes in large numbers, forming xanthomatous aggregates. Prominent lipid accumulation is seen in the lipidized ("ankle type") dermatofibroma. Capillaries may be plentiful in the stroma, giving the lesion an angiomatous component. When there is also associated sclerosis, such lesions have been referred to as "sclerosing hemangioma." Some dermatofibromas may be poorly cellular and subtle, with spindle cells extending between collagen bundles associated with apparent "rounding up" of collagen fibers. More cellular forms often exhibit a storiform pattern of interwoven, fascicled spindle cells. Tumors are typically poorly demarcated.

Significant hyperplasia of the overlying epidermis occurs in more than 80% of dermatofibromas (10) and assists in making the diagnosis and distinguishing the atypical variant from atypical fibroxanthoma (11). Hyperplasia usually consists of regular rete ridge elongation, often with hyperpigmentation of the basal epidermis. In some cases the changes resemble a seborrheic keratosis, and, occasionally, downgrowths show hair matrical differentiation (12). In up to 5% of dermatofibromas the downgrowths show areas that closely resemble superficial basal cell carcinoma (13). In rare instances, genuine invasive basal cell carcinoma development has been documented (14,15).

Dermatofibroma Variants

Cellular Fibrous Histiocytoma

This is a rare, densely cellular variant with a fascicular to storiform growth pattern and frequent extension into subcutis (Fig. 32-2A, B). The tumors occur on the head and neck or trunk and may mimic dermatofibrosarcoma protuberans (DFSP) histologically. Identification of areas of more typical dermatofibroma assists in making this differentiation (16,17). Paradoxically, cellular atypia is often more pronounced in these tumors than in DFSP, and factor XIIIa staining is often negative (16). Areas of CD34 positivity may be present, but only focally at the edge of the tumor. There is an increased risk of recurrence, with rare metastases to regional nodes and the lung reported (16–19).

TABLE 32-1 Classification of Soft Tissue Tumors by Clinical Behavior

Benign

Benign behavior is the rule, but in exceptional circumstances tumors in this category may metastasize (e.g., fibrous histiocytoma, diffuse giant cell tumor of tendon sheath)

Intermediate biological potential

1. Locally aggressive

Recurrence may occur with tissue infiltration and destruction, but metastases are not expected (e.g., abdominal desmoid tumor)

2. Rarely metastasizing

A small proportion (<2%) of cases may metastasize, and these cannot be reliably predicted from histologic examination (e.g., plexiform fibrohistiocytic tumor, angiomatoid fibrous histiocytoma)

Malignant

Malignant behavior is to be anticipated

Adapted from Fletcher CDM. The evolving classification of soft tissue tumours: an update based on the new WHO classification. Histopathology 2006;48:3–12; and Fletcher CDM, Rydholm A, Singer S, et al. Soft tissue tumours: epidemiology, clinical features, histopathological typing and grading. In: Fletcher CDM, Unnik K, Mertens F, eds. World Health Organisation classification of tumours. Pathology and genetics of tumours of soft tissue and bone. Lyons: IARC Press, 2002:9–18.

Aneurysmal Fibrous Histiocytoma

In these tumors, collections of capillaries, foci of hemorrhage, siderophages, and foamy macrophages surround cleft-like and cavernous blood-filled spaces in the center of the tumor. The changes may simulate a vascular neoplasm, but other areas show more typical features of dermatofibroma (20,21) (Fig. 32-3). To avoid confusion with angiomatoid fibrous histiocytoma (a tumor of intermediate malignancy; see later discussion), it has been suggested that these tumors should be referred to as "dermatofibroma with aneurysmal change" (22).

Atypical Fibrous Histiocytoma

Atypical cells are occasionally present in dermatofibroma, which may lead to misdiagnosis as atypical fibroxanthoma (11,23), and there is some overlap with cellular fibrous histiocytoma histologically. These tumors are usually small but occasionally reach 2.5 cm or greater in diameter (24). The atypical cells show enlarged, pleomorphic nuclei, sometimes referred to as *monster cells* (24,25). Mitoses of normal morphology may be evident. Multinucleated giant cells with bizarre, large, hyperchromatic nuclei with little cytoplasm or irregular, vesicular nuclei with abundant foamy cytoplasm may also occur (Fig. 32-4A, B)(11). Extension into superficial subcutis and focal necrosis may be seen. The presence of more typical appearing dermatofibroma in the background is very helpful to enable the correct diagnosis in these lesions (26). Variable staining for smooth muscle actin and CD34 are reported, with no staining for factor XIIIa. Atypical fibrous histiocytomas may recur with very occasional metastases (26).

Epithelioid Fibrous Histiocytoma

This distinctive variant, originally described as epithelioid cell histiocytoma (27), is composed of cells showing abundant eosinophilic cytoplasm, with occasional multinucleated forms. Areas of spindle cell forms may also be present with a complement of foamy macrophages. Tumors form an exophytic nodule with an epidermal collarette resembling pyogenic granuloma or

TABLE 32-2 Selected Immunohistochemical Stains as an Aid to the Diagnosis of Spindle Cell Tumors of the Skin

	Atypical Fibroxanthoma	Dermatofibrosarcoma protuberans	Cellular Fibrous Histiocytoma (Dermatofibroma)	Spindle Cell Squamous Cell Carcinoma	Desmoplastic Melanoma	Leiomyosarcoma

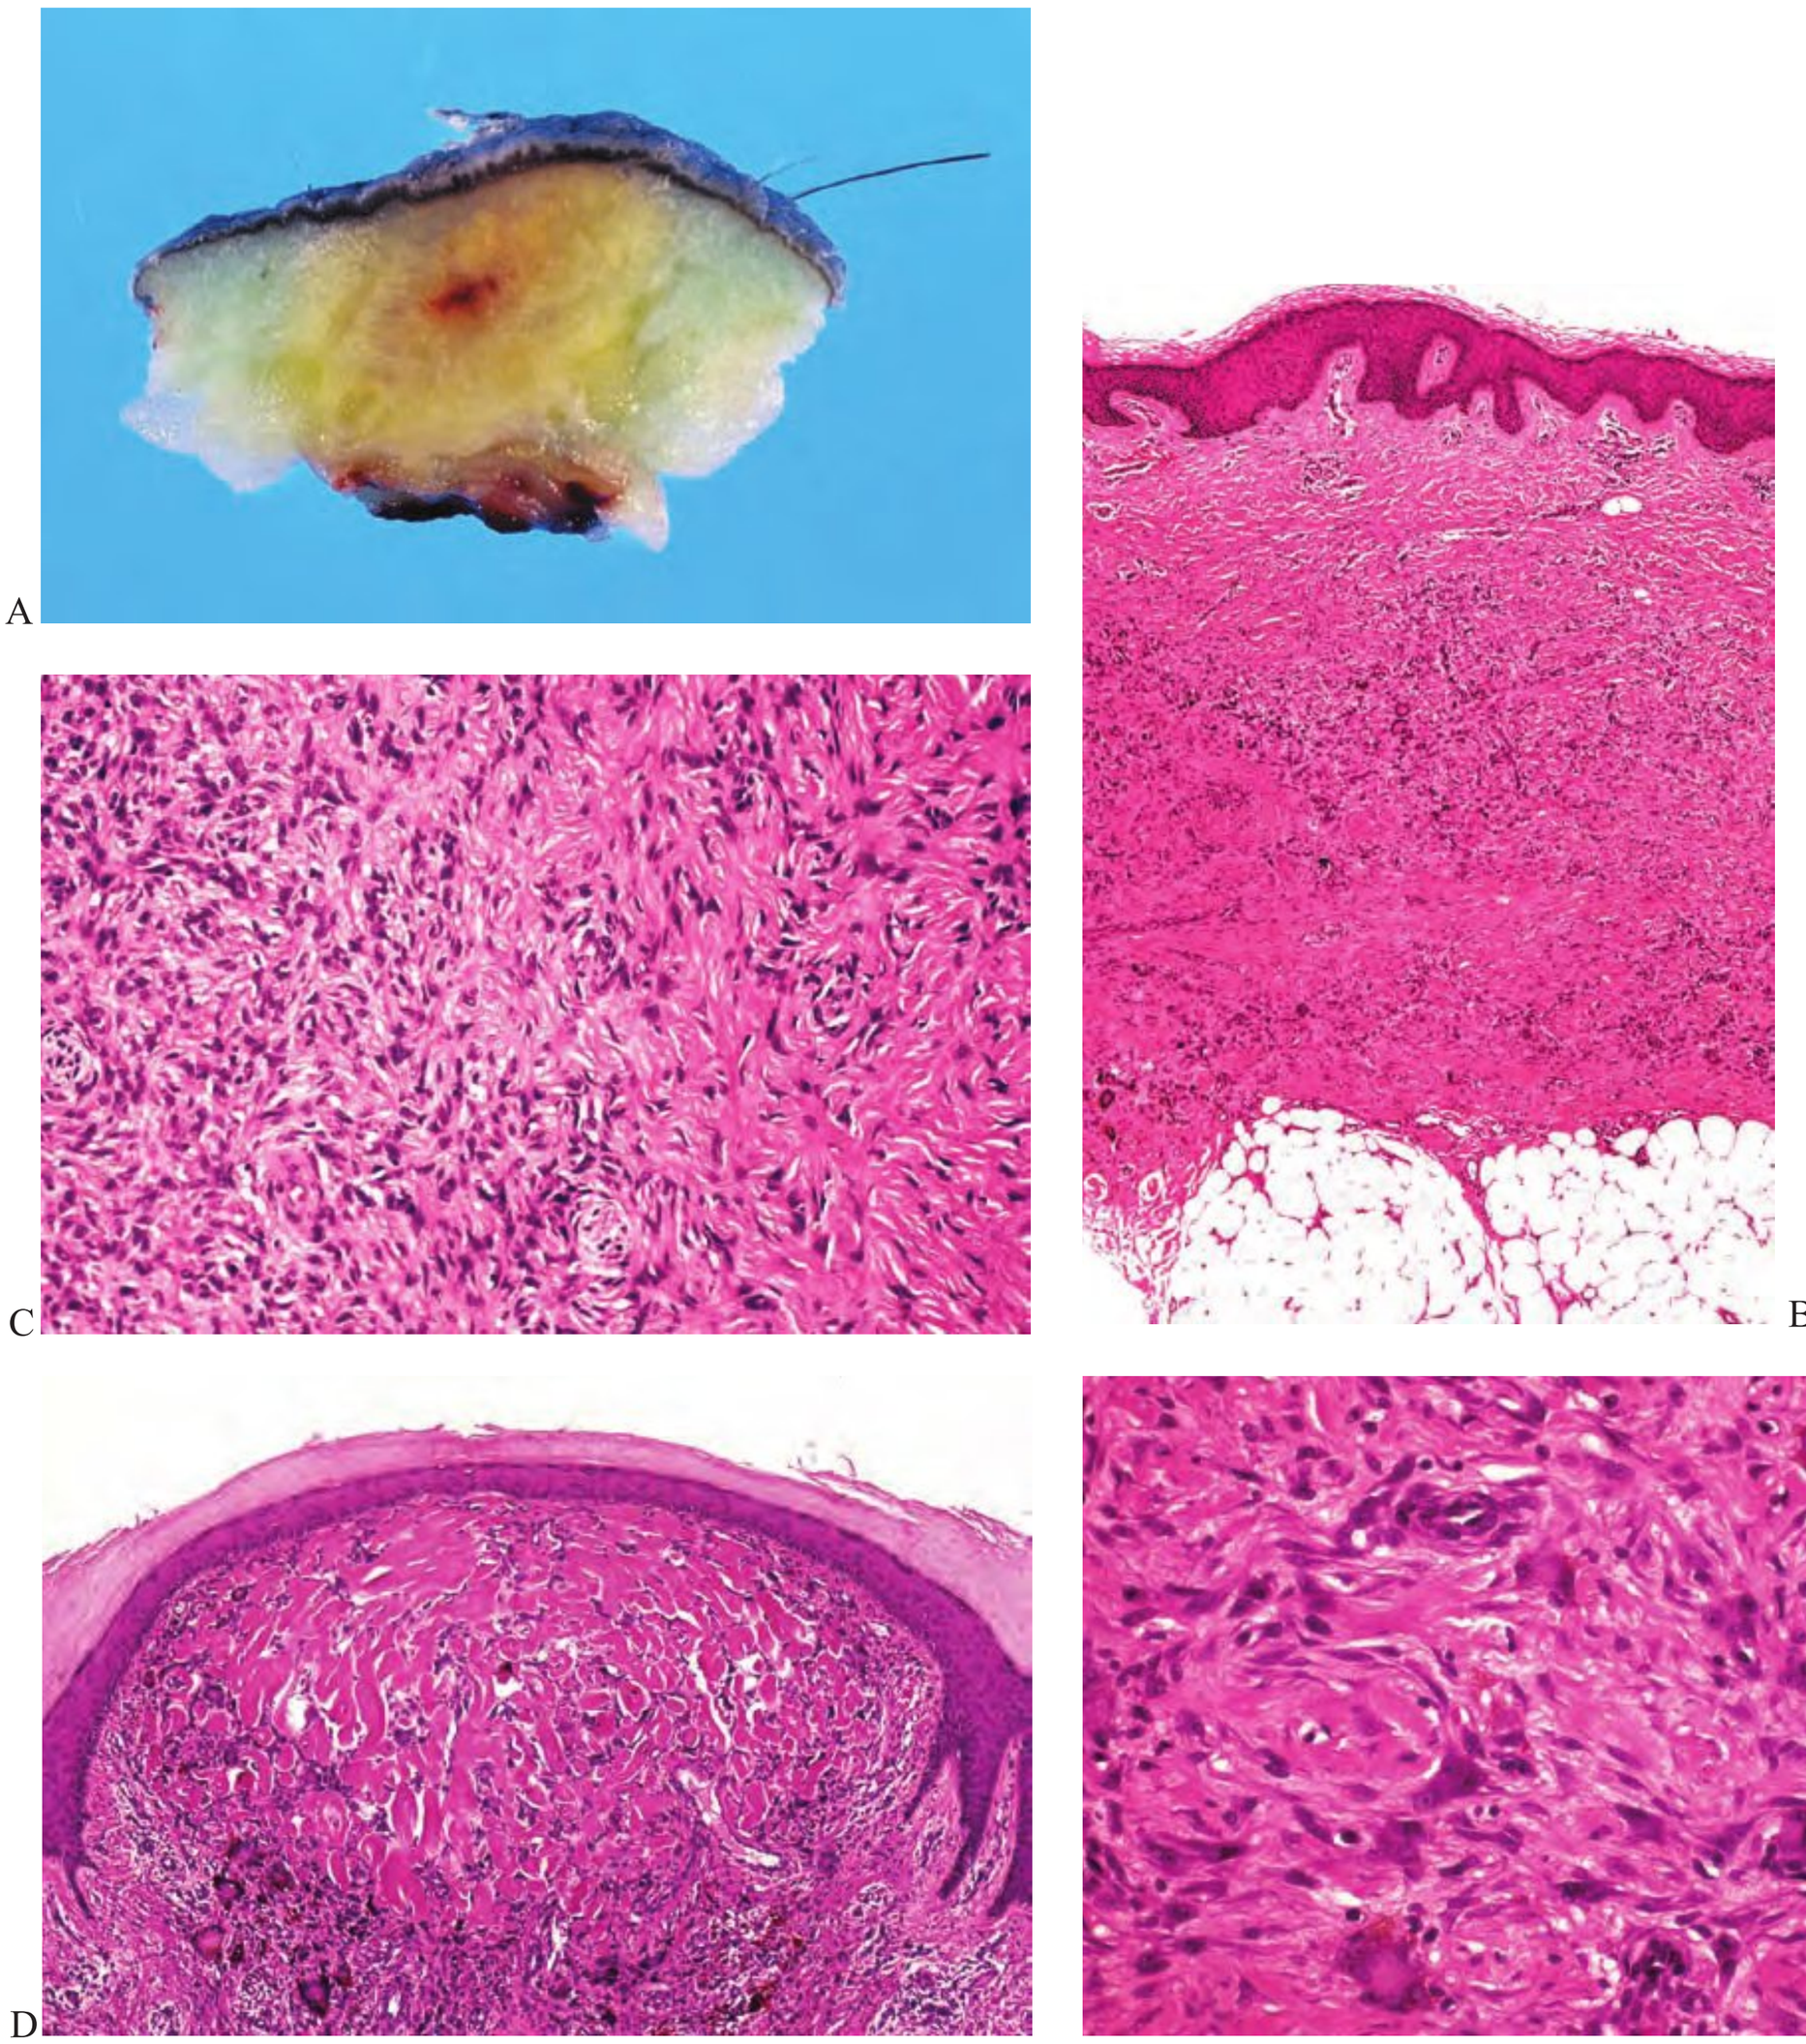
Note: Immunohistochemistry should be used as an adjunct to routine histologic methods and clinical data.
R, rarely positive; V, variable; −, negative; +, positive.



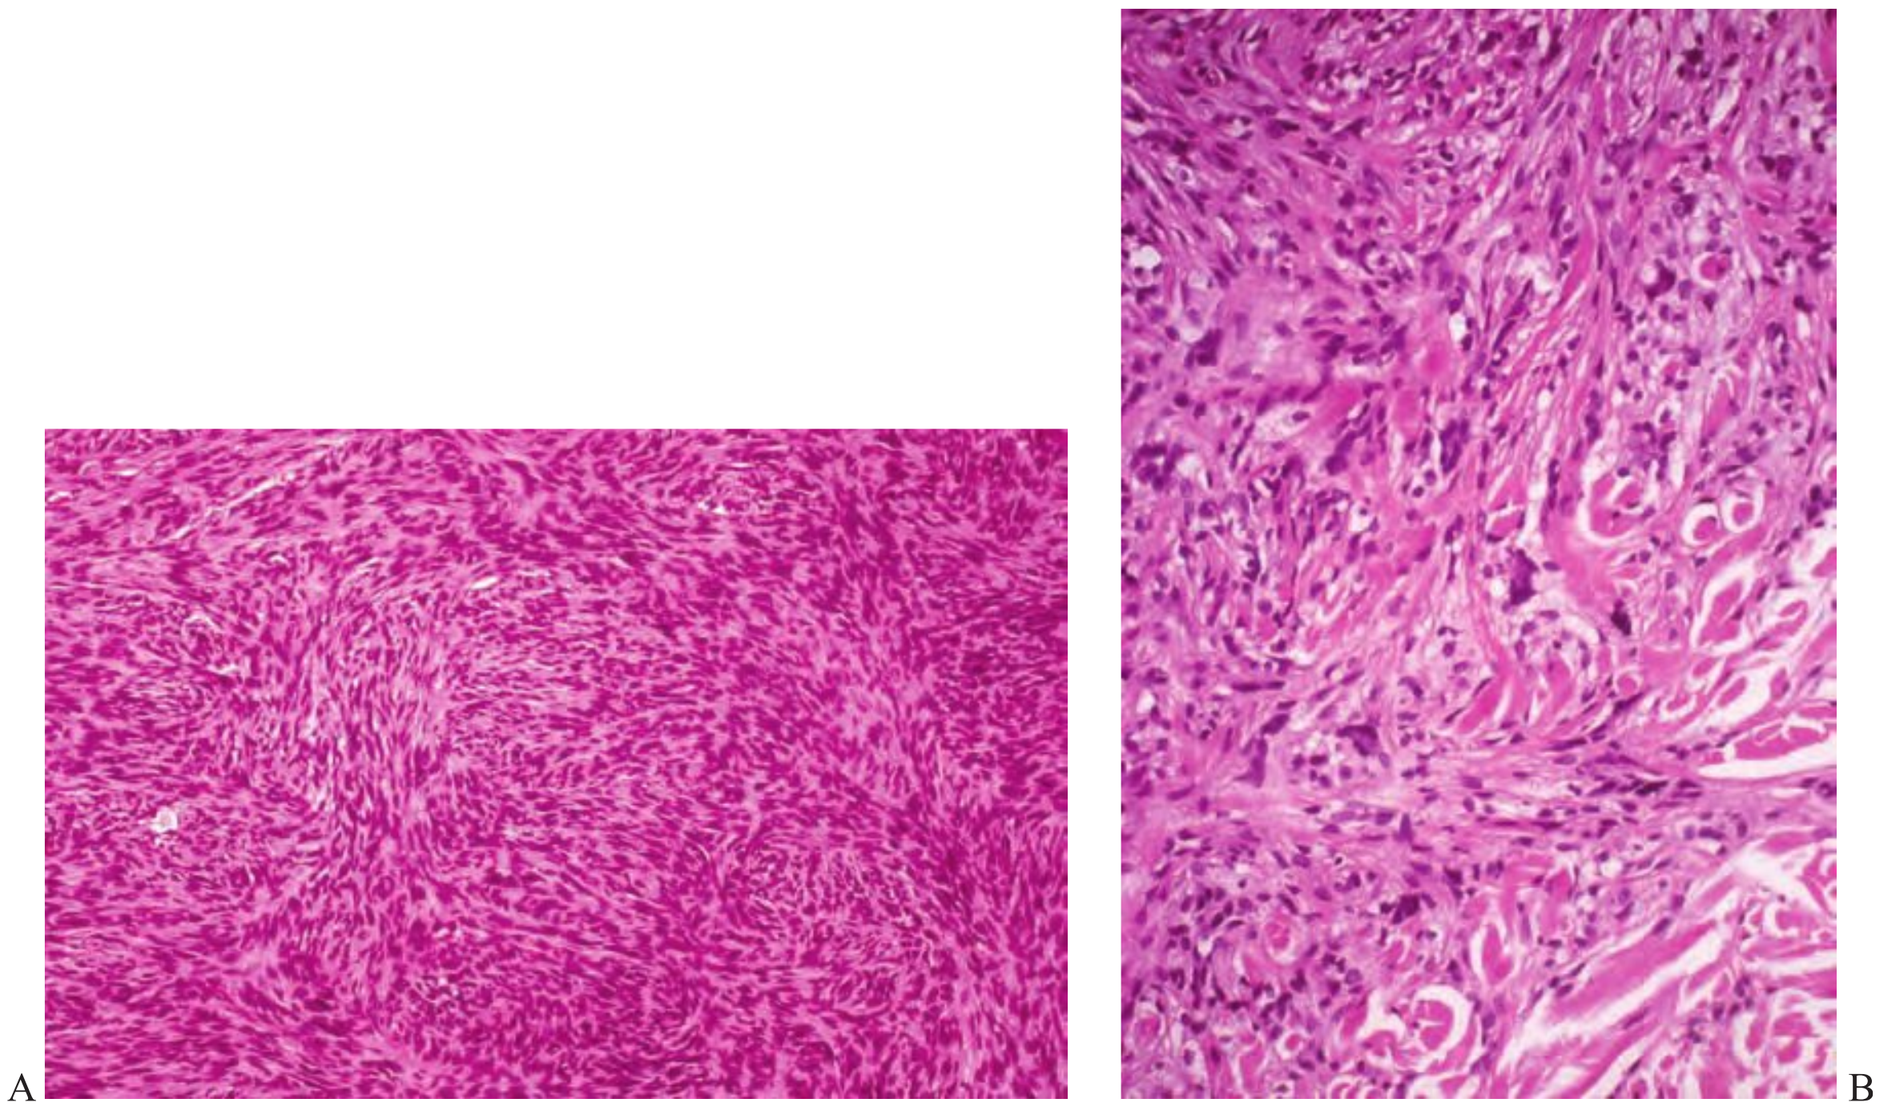


FIGURE 32-1. Dermatofibroma (fibrous histiocytoma). A: Gross specimen. A poorly circumscribed dermal lesion is present with overlying increased epidermal pigmentation and acanthosis. The tumor has a yellow cut surface with focal hemorrhage present centrally. B: The epidermis is hyperplastic and separated by a narrow clear zone from a moderately cellular spindle cell tumor extending into the deep dermis. C: The tumor is composed of variably sized spindle cells with pale eosinophilic cytoplasm in a collagenous stroma. D: This dermatofibroma shows prominent hyalinization and pigmentation. E: Hemosiderin and multinucleated giant cells dominate in this zone of another dermatofibroma.

intradermal Spitz nevus (Fig. 32-5) (28,29). The lesions are often well circumscribed. Immunohistochemistry may be required to differentiate the lesion from a melanocytic proliferation, for example. The tumor shows the expected staining pattern of a dermatofibroma.

Deep Fibrous Histiocytoma

This is a rare form that develops entirely within subcutaneous tissue, deep soft tissue, or parenchymal organs (30). Unlike typical dermatofibroma, deep fibrous histiocytoma tends to be well circumscribed, with a pseudocapsule and foci of hemorrhage

A B

FIGURE 32-2. Cellular dermatofibroma (fibrous histiocytoma). A: The tumor consists of spindle cells arranged in densely cellular fascicles with storiform areas. B: At the border of the lesion the spindle cells surround individual collagen bundles.

consisting of monomorphic spindle cells resembling the cellular variant (31).

Other less common variants include clear cell (32), granular cell (33), lipidized (34), myxoid (35), myofibroblastic (36), osteoclastic (37), keloidal (38), atrophic (39), and palisading forms (40).

Neoplasm Versus Reactive Process

It is unclear whether dermatofibromas are true neoplasms or reactive processes following minor trauma, such as an insect bite. This has given rise to the term "nodular subepidermal fibrosis" (41), with some authorities regarding the lesions as fibrosing inflammatory processes, even in the presence of "monster cells" (24,42). The demonstration of clonality in some cases of dermatofibroma (43,44) and reports of metastasizing dermatofibroma (16–19), however, suggest a neoplastic nature. Analysis of X chromosome inactivation in 31 dermatofibromas showed a variable pattern, suggesting that the lesions are heterogeneous, with some being reactive, others possibly neoplastic in nature (45–48).

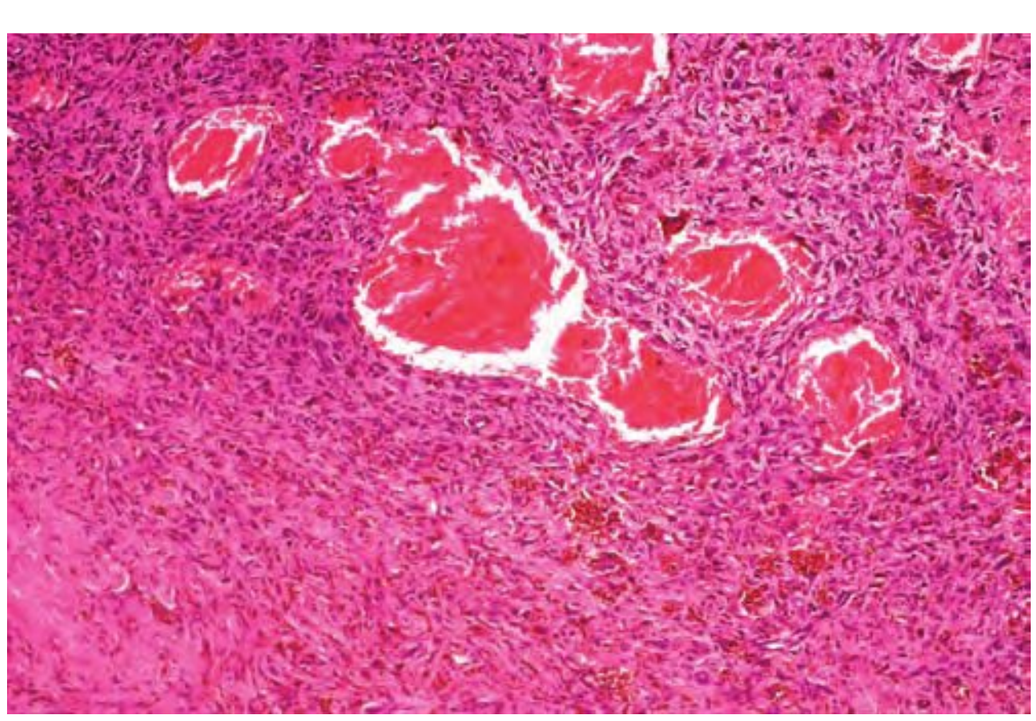

FIGURE 32-3. Aneurysmal fibrous histiocytoma (dermatofibroma). Dilated blood-filled spaces are prominent in this variant, with associated hemorrhage. Bland spindle cells and siderophages are seen in the surrounding tissue.

Histogenesis. Enzyme histochemical, electron microscopic, and immunohistochemical studies have suggested histiocytic, myofibroblastic, and fibroblastic differentiation, possibly indicating a cell of primitive mesenchymal origin (49). The term *dermal dendrocytoma* has been suggested on the basis of immunohistochemical studies using antibodies to factor XIIIa (a marker of normal dermal dendrocytes) and the histiocytic marker MAC 387 (50,51). Most cells in these tumors were found to react with factor XIIIa, whereas only a few were MAC 387 positive. Other investigators, however, believe that the factor XIIIa–positive cells seen in fibrous histiocytomas represent included reactive stromal cells rather than the true tumor cells (49,52), which often express vimentin and smooth muscle actin (52). Electron microscopic studies have variously described the cells of fibrous histiocytomas as fibroblasts, histiocytes, and myofibroblasts (53–55).

Enzyme Histochemistry. The results of enzyme studies on dermatofibromas have shown variable reactions. Positive staining

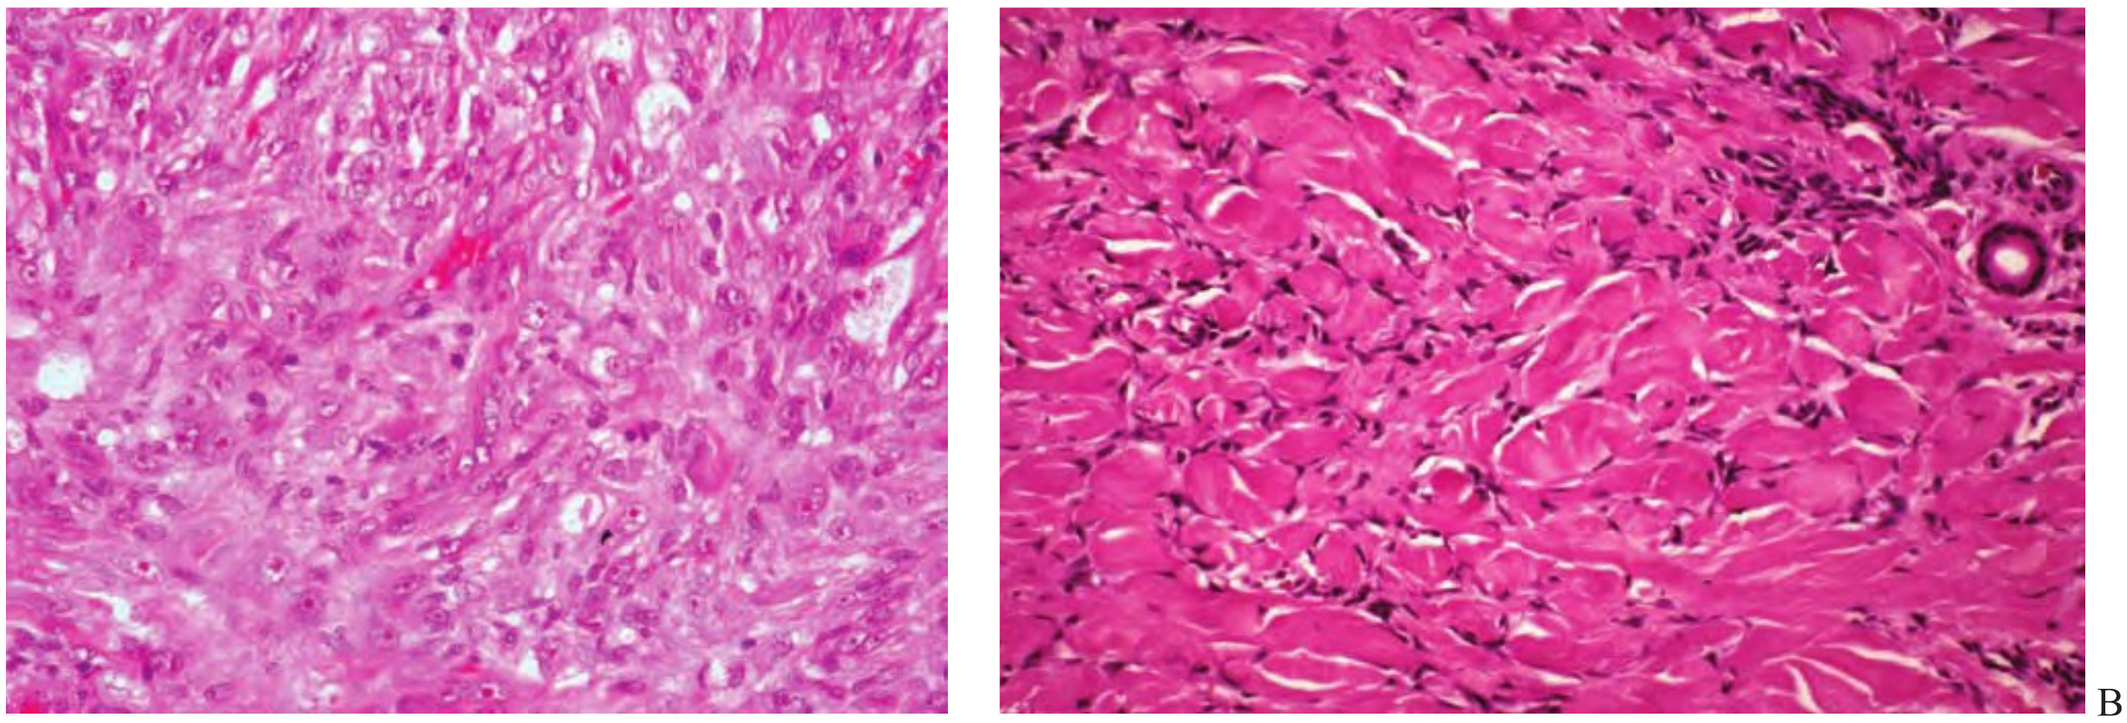

FIGURE 32-4. Atypical fibrous histiocytoma (dermatofibroma). A: This tumor shows histiocyte-like cells with enlarged and pleomorphic nuclei with prominent nucleoli. B: At the border of this tumor the cells are arranged around individual collagen bundles in the pattern typical of the more usual form of dermatofibroma.

for lysozyme and α_1-antitrypsin have been interpreted as indicating histiocytic differentiation (56,57), whereas negative results for these enzymes have led to speculation that the fibroblastic and histiocyte-like cells in these tumors arise from primitive mesenchymal cells (58). The presence of HLA-DR antigens in the majority of cells in dermatofibromas has also been regarded as evidence in favor of a histiocytic origin (59).

Differential Diagnosis. The cellular variant of dermatofibroma must be distinguished from DFSP. Points of distinction are that dermatofibromas show overlying epidermal hyperplasia, a heterogeneous population of tumor cells, often with more pleomorphism, and extension of tumor cells at the edge of the lesion around individual hyalinized collagen bundles (60). Cellular fibrous histiocytoma also extends into subcutis along the interlobular septae or in a bulging, expansile pattern rather than in the characteristic infiltrating honeycomb-like pattern of DFSP (17). DFSP is usually a larger lesion at the time of diagnosis, often consisting of multiple nodules. Cellular fibrous histiocytoma may also be confused with leiomyosarcoma, but this has plumper spindle cells, with eosinophilic cytoplasm and nuclei with rounded ends, and shows positive staining for desmin and α-smooth muscle actin (49). It should be noted that some dermatofibromas may express CD34, and some DFSP may express factor XIIIa (61). This has lead to the suggestion of a biological spectrum between fibrous histiocytoma and DFSP, with coexistence of two different cell populations in indeterminate lesions (62). Tenascin (an extracellular matrix glycoprotein) expression has been demonstrated immunohistochemically at the dermoepidermal junction overlying fibrous histiocytomas but not DFSP (63,64).

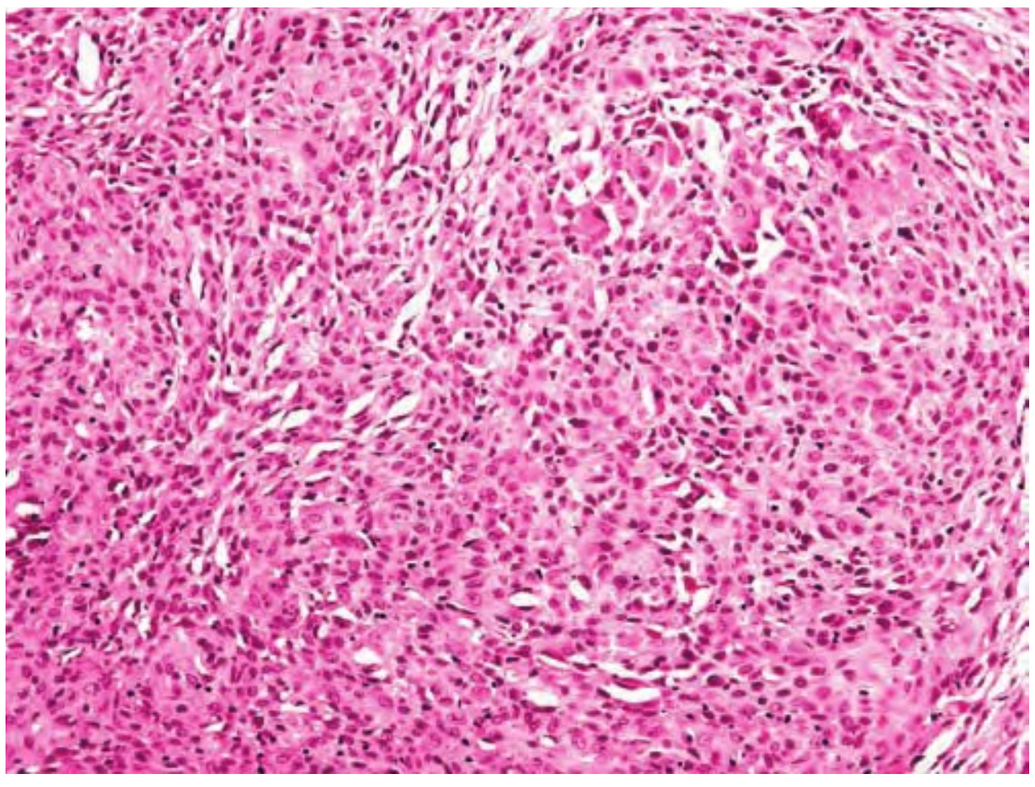

FIGURE 32-5. Epithelioid fibrous histiocytoma (dermatofibroma). The lesion shows sheets of epithelioid cells with eosinophilic cytoplasm. Differentiation from a melanocytic lesion such as a Spitz nevus may require immunohistochemistry in some cases.

Fibrous histiocytoma with aneurysmal change (aneurysmal fibrous histiocytoma) may be confused with neoplasms of vascular origin. Distinction can be made by demonstrating that factor VIII, CD31, and CD34 do not outline the apparent vascular spaces in fibrous histiocytoma, in contrast to true vascular lesions. Kaposi's sarcoma shows slit-like spaces containing erythrocytes and a monomorphic $CD34^+$ spindle cell population (49). Angiomatoid fibrous histiocytoma is distinguished by its presentation in a younger age group (sometimes with systemic symptoms), subcutaneous location and the presence of eosinophilic histiocytoid cells, a prominent lymphocytic infiltrate, and a thick pseudocapsule (65,66).

Epithelioid dermatofibroma (epithelioid cell histiocytoma) can resemble Spitz nevus and pyogenic granuloma clinically and histologically (29). The lesion differs from pyogenic granuloma by the presence of epithelioid cells between blood vessels, which are not arranged in lobules, with a less prominent inflammatory component and lack of protuberant endothelial cells. Intradermal Spitz nevus has a nested pattern superficially, spindle as well as epithelioid cells, intranuclear

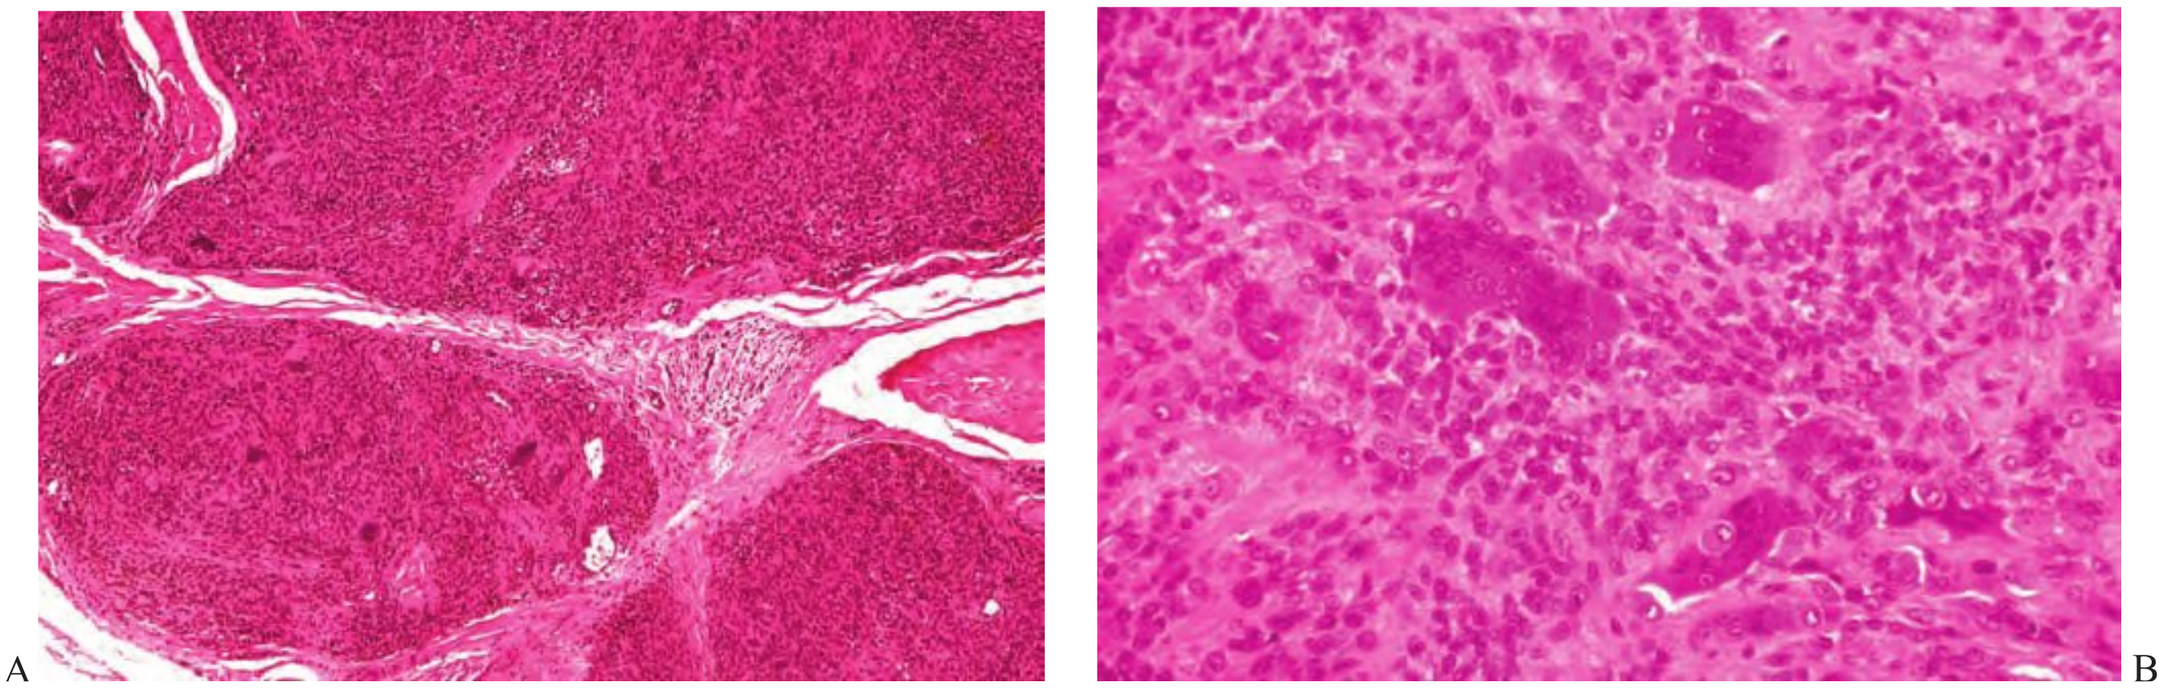

FIGURE 32-6. Giant cell tumor of tendon sheath. A: The tumor is composed of sharply circumscribed, densely cellular lobules surrounded by fibrous tissue. B: Giant cells with multiple nuclei, resembling osteoclasts, are scattered among plump epithelioid and spindle cells.

cytoplasmic inclusions, maturation with depth, and, frequently, Kamino bodies in the epidermis. Immunostaining of Spitz nevi reveals positivity for S100 and other melanocyte markers and negative staining for factor XIIIa.

Atypical fibroxanthoma differs from atypical dermatofibroma by its frequent location on sun-exposed skin of the head and neck of elderly patients, frequent ulceration, severe cellular pleomorphism, numerous mitoses, including atypical forms, and the lack of a background of more typical dermatofibroma.

Giant Cell Tumor of Tendon Sheath

Giant cell tumor of tendon sheath occurs most commonly on the tendon sheath of young and middle-aged adults on the dorsum of the fingers, hands, and wrists. They can also be found on the feet and around the ankle and knee joints. Tumors are firm in consistency, with a yellowish to tan cut surface, and are from 1 to 3 cm in diameter. There is no tendency toward spontaneous involution. The tumor may erode the adjacent bone and, on rare occasions, may even extend into the overlying skin (67,68). The lesions are benign, although they may recur. Recurrences are cured by local reexcision (69). Although it has been suggested that this tumor is an inflammatory proliferation (70), other reports indicate that the lesion is neoplastic (71).

Histopathology. The tumor consists of lobules of varied cellularity surrounded by a fibrous pseudocapsule (Fig. 32-6A). In cellular areas, most cells are macrophage-like mononuclear cells with folded, kidney-shaped or grooved, oval nuclei and abundant eosinophilic cytoplasm. There is a variable number of foamy macrophages, which may be associated with cholesterol clefts and siderophages. Less cellular areas consist of spindle cells within a fibrous or hyalinized stroma (67,72). The characteristic osteoclast-like giant cells (73) are scattered through both the cellular and fibrous areas. Their cytoplasm is deeply eosinophilic and contains a variable number of haphazardly distributed nuclei (Fig. 32-6B). Although mitotic figures are seen in a large proportion of cases and may be frequent (74), they are not atypical. There is no evidence that mitotic activity is related to metastasis, which is an extremely rare event, but it may be associated with an increased risk of recurrence (75).

Histogenesis. Ultrastructural (73,76), enzyme (72), and immunohistochemical studies (72,77–79) have indicated variously that the cells may be related to synovial cells, monocytes, and osteoclasts.

Intermediate Biological Potential (Locally Aggressive)

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans is a slowly growing dermal spindle cell neoplasm of intermediate malignancy. It typically forms an indurated plaque on which multiple congested, firm nodules subsequently arise, sometimes with ulceration (Fig. 32-7A). The trunk and proximal limbs of young adults are most commonly affected, with occasional involvement of the head and neck or other sites (80,81). Some cases have been reported in childhood and, rarely, as congenital lesions (82–84). Local recurrence is common, and transformation to fibrosarcoma can occur, but metastasis is rare (85,86).

Histopathology. DFSP is composed of fascicles of densely packed, monomorphous spindle cells arranged in a storiform (mat-like) pattern. Lesions are poorly circumscribed, with diffuse infiltration of dermis and subcutis yielding a honeycomb pattern (Fig. 32-7B–D) (17). Infiltration into the underlying fascia and muscle occurs as a late event (86). Cytologically, the cells have a deceptively bland appearance, which can result in difficulty in defining the margin of the lesion. Mitotic activity is generally limited, typically less than 5 mitoses per 10 high-power fields. Myxoid areas may occur, especially in recurrent

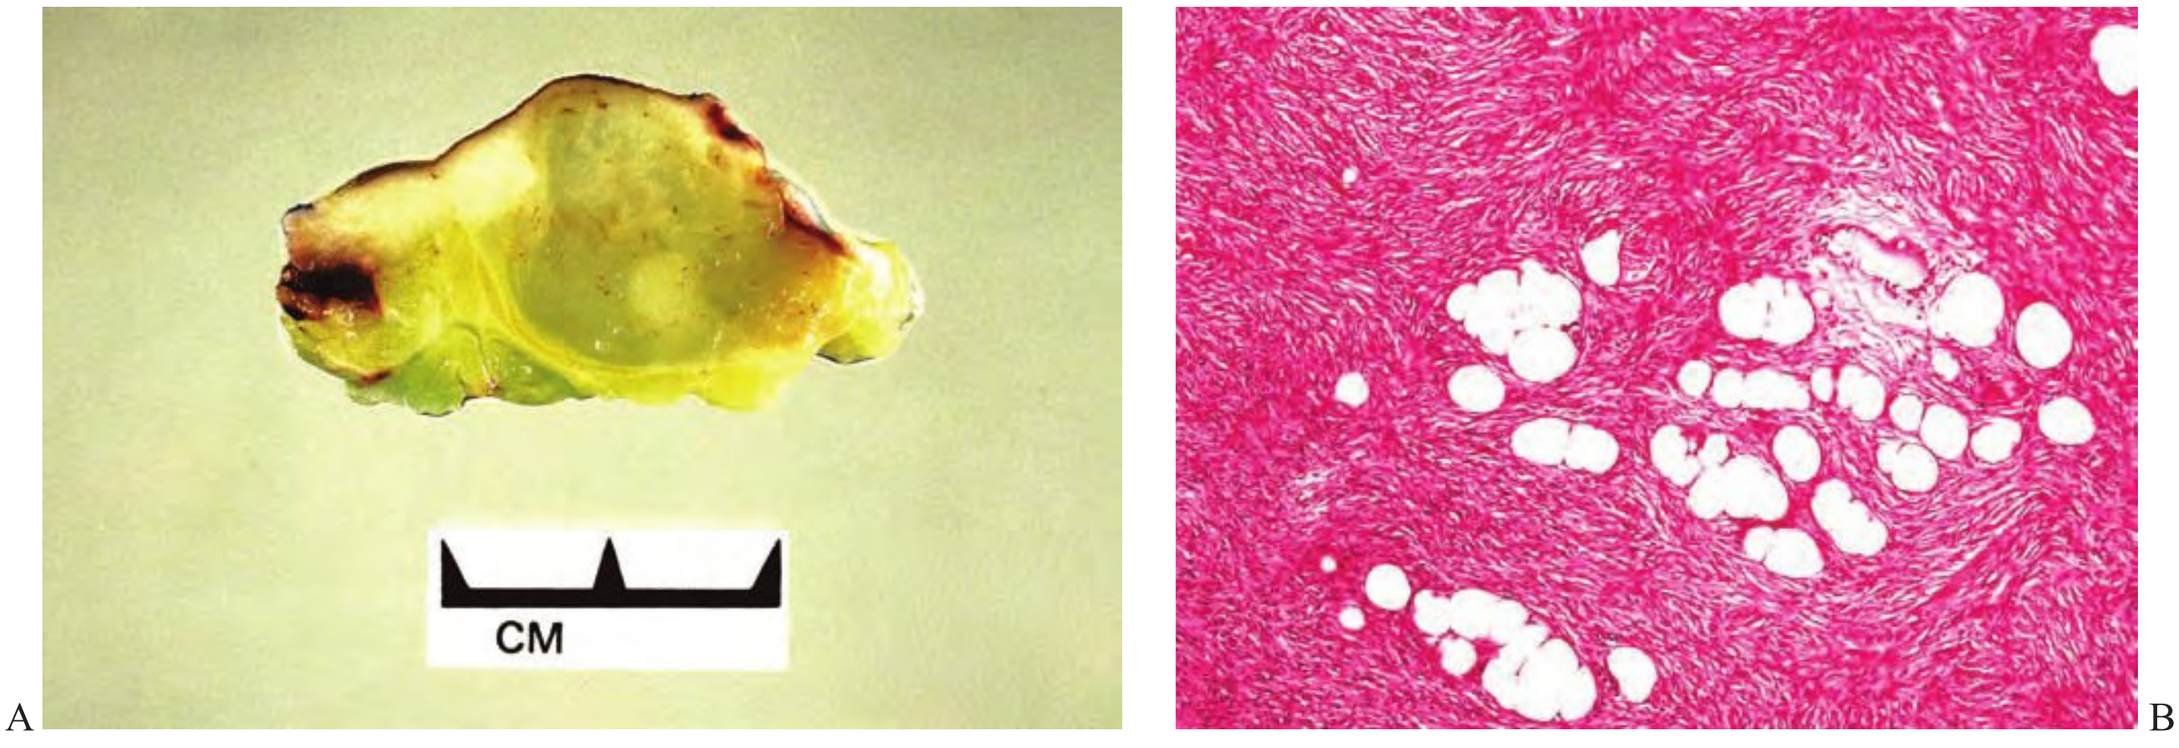

FIGURE 32-7. Dermatofibrosarcoma protuberans (DFSP). A: Gross specimen of a myxoid variant of DFSP. The lesion is better circumscribed than the more typical form of DFSP and forms a central nodule extending into subcutis, with lateral extension in the dermis showing a component of firmer white tissue. B: Densely packed spindle cells are present, arranged in a storiform pattern extending around fat cells. C: Strands of bland spindle cells infiltrate subcutis, producing a honeycomb-like pattern. D: This DFSP exhibits an area with a prominent fibrosarcoma-like pattern. This feature is not said to be of prognostic significance (see text).

tumors. Sometimes there is a vascular component of fine anastomosing blood vessels with a "chicken-wire" appearance resembling myxoid liposarcoma (Fig. 32-8) (87).

Pigmented melanosome-containing cells can be identified in the tumors on rare occasions—the *Bednar tumor* (pigmented DFSP, storiform neurofibroma) (88–90). A number of congenital presentations of this tumor have been recorded (91).

Fibrosarcomatous areas are seen in a small proportion of DFSP, characterized by a fascicular or herringbone growth pattern (92–94). This variant does not appear to have any greater propensity for local recurrence, provided that the lesion is adequately excised (94). Giant cells are rarely seen in otherwise typical DFSP but are characteristically prominent in the juvenile variant of DFSP, giant cell fibroblastoma (see next section) (95–100).

Histogenesis. Electron microscopic studies suggest that the tumor cells are fibroblasts because they show active synthesis of

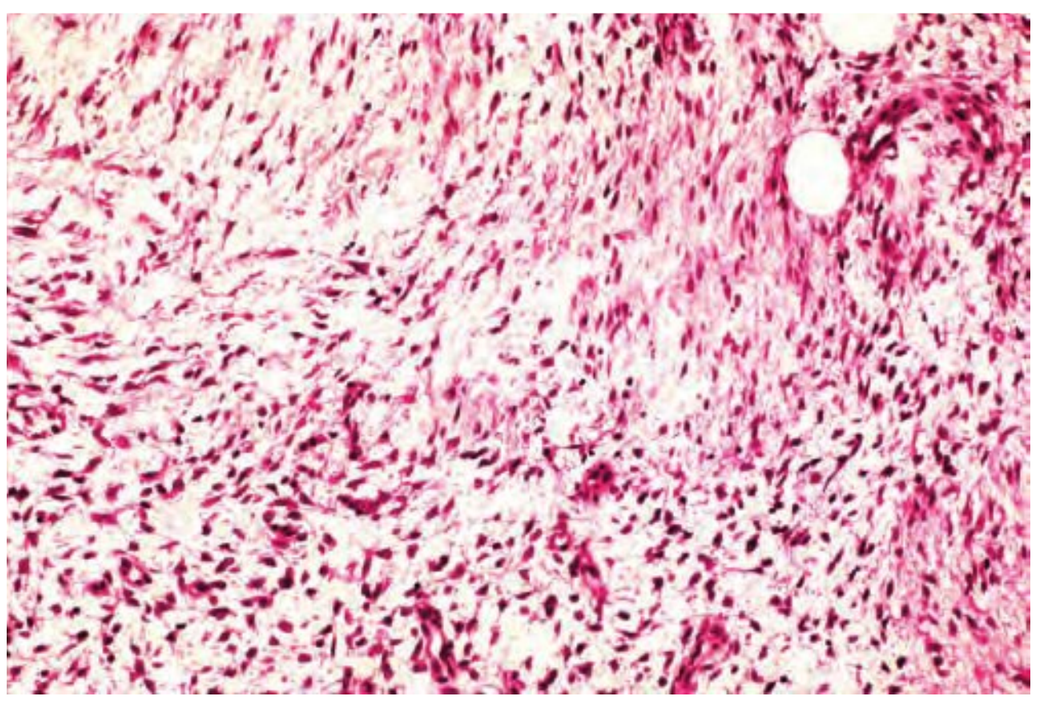

FIGURE 32-8. Myxoid dermatofibrosarcoma protuberans (DFSP). This DFSP shows a myxoid appearance as it extends into subcutis. Myxoid change is more common in recurrent tumors.

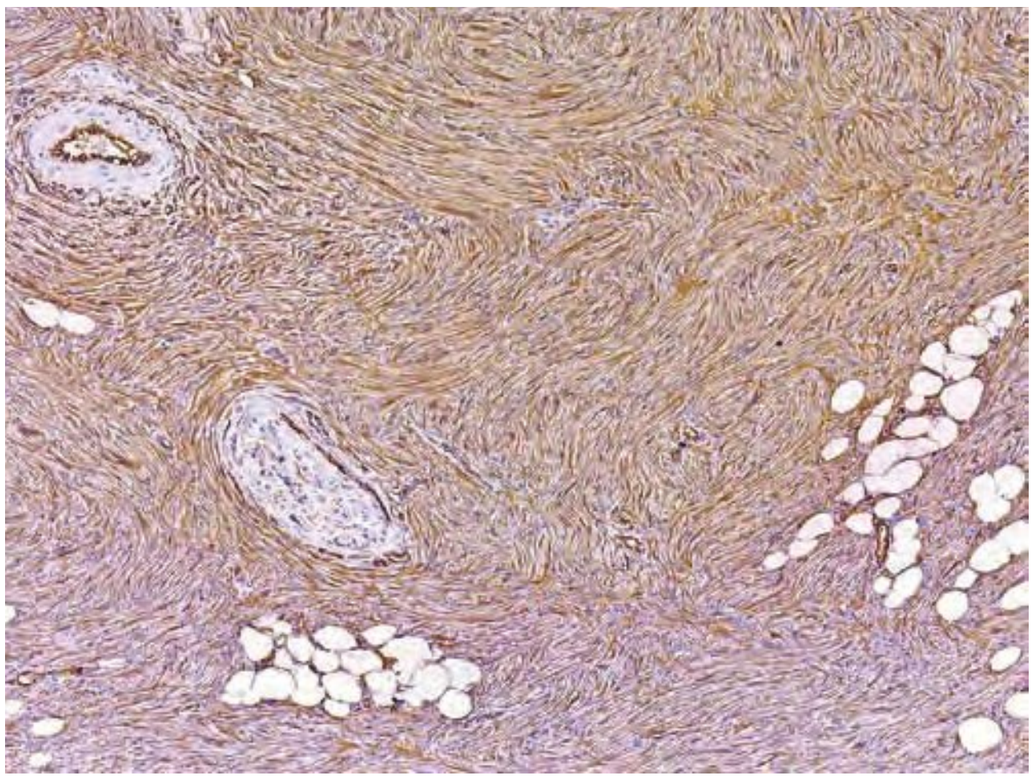

FIGURE 32-9. Dermatofibrosarcoma protuberans. Immunohistochemistry shows strong, uniform positivity for CD34 in the lesion. (Courtesy of Dr. E-C. Jung, University of California, San Francisco, California.)

collagen in a well-developed endoplasmic reticulum (101,102). In some tumors the presence of interrupted basement membrane–like material along the cell membrane suggested that the cells are modified fibroblasts with features of perineural and endoneural cells (103). Epithelial membrane antigen expression in a few cases and consistent CD34 positivity raised the possibility of a perineural origin (104). Although DFSP is commonly regarded as a fibrohistiocytic tumor, immunohistochemical and ultrastructural evidence indicates that a fibroblastic origin is most likely (87,105–107).

Cytogenetic studies have revealed a t(17;22) translocation in more than 90% of cases of DFSP, leading to formation of a ring chromosome in some tumors (108). The translocation involves the COL1A1 gene on chromosome 17 and the platelet-derived growth factor B gene on chromosome 22. Although management of this disease continues to be primarily surgical, high rates of clinical response have been achieved through the use of imatinib to inhibit platelet-derived growth factor receptors in patients with unresectable or metastatic DFSP (109).

Differential Diagnosis. DFSP is generally characterized by more uniform spindle cells and a more prominent storiform pattern than that seen in dermatofibroma. Small biopsies may make assessment of architecture impossible, so caution is required in these cases. In contrast to cellular dermatofibroma, the epidermis overlying DFSP is usually attenuated or ulcerated rather than hyperplastic, and a clear (Grenz) zone between the epidermis and tumor may be absent. DFSP has a more infiltrative pattern of growth, in contrast to the well-demarcated bulging deep margin of cellular dermatofibroma, although this tumor may also extend into subcutis, predominantly along septae (17,60). CD34 staining is usually diffusely positive in DFSP and negative in most forms of dermatofibroma (110–112) (Fig. 32-9), but there is some overlap in the expression of CD34 in these conditions (62). Demonstration of tenascin at the dermoepidermal junction overlying dermatofibroma but not DFSP may help in the differential diagnosis (63,64). It has also been shown that dermatofibromas strongly express CD44 with only faint stromal hyaluronate, whereas DFSP shows reduced or absent CD44 and strong stromal hyaluronate deposition (113). Apolipoprotein D has recently been identified immunohistochemically in the majority of cases of DFSP but not in dermatofibromas (114). Neurofibroma expresses S100 protein, which is absent in DFSP, and shows other features of neural differentiation, without the dense, uniform cellularity of DFSP.

Giant Cell Fibroblastoma

Giant cell fibroblastoma represents a juvenile variant of DFSP and was first formally reported in 1989 (95). It is a rare tumor

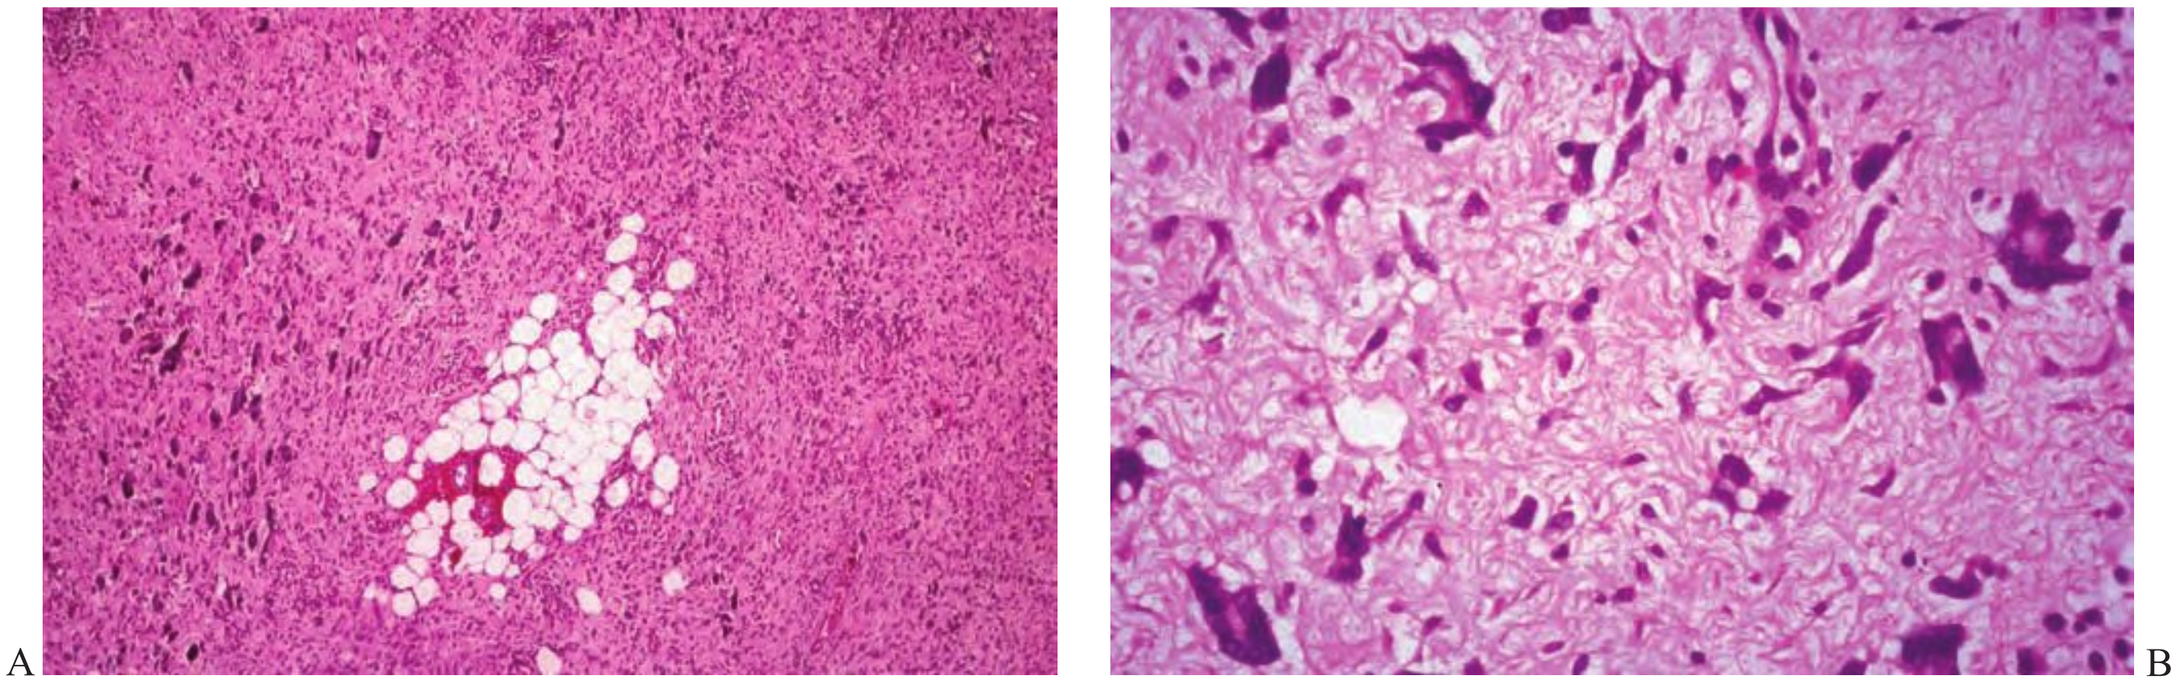

FIGURE 32-10. Giant cell fibroblastoma. A: The growth pattern resembles that of dermatofibrosarcoma protuberans with infiltration of subcutaneous fat by uniform spindle cells, with the additional feature of numerous giant cells. (Courtesy of Dr. I. Strungs, Adelaide Children's Hospital, Adelaide, Australia, and Dr. P. W. Allen, Flinders Medical Centre, Bedford Park, SA 5042, Australia.) B: Numerous multinucleated giant cells are present on high power, some with pleomorphic, multilobated nuclei.

occurring almost exclusively in children, with more than 75% of patients younger than 20 years old (115). Lesions are solitary and most often sited on the trunk or thigh. Local recurrence after incomplete excision is common (116), but no metastases have been reported (117). Fibrosarcomatous change is very rare (115).

Histopathology. The proliferation is sited in the dermis and subcutis, usually with areas showing the honeycomb pattern typical of DFSP (Fig. 32-10A). In contrast, multinucleated giant cells line small clefts in the tissue (Fig. 32-10B), and foci of hemorrhage and perivascular lymphocytes may be seen (115). Zones of myxoid to hyalinized stroma are also present and often prominent. Electron microscopy suggests that the giant cells are not in fact multinucleated, but that the appearance represents multiple lobations of a single nucleus (95).

Histogenesis. Ultrastructurally, the cells resemble fibroblasts. Immunohistochemistry shows CD34 positivity (including in the giant cells) with no staining for S100, smooth muscle actin, or desmin (115,118).

The concept that giant cell fibroblastoma is a variant of DFSP is supported by the coexistence of areas of both tumors in a single lesion in some instances, the same immunogenetic and cytogenetic profile, and the recurrence of DFSP as giant cell fibroblastoma and vice versa (95–100). As in DFSP, the translocation t(17;22), sometimes forming an extra ring chromosome, has been repeatedly identified (108,119), and responsiveness to imatinib in inoperable cases might therefore be anticipated (109).

Differential diagnosis includes fibrous hamartoma of infancy (page 986). Points of distinction are the patient's age, the presence of three "zones" in fibrous hamartoma, and its lack of multinucleated cells.

Intermediate Biological Potential (Rarely Metastasizing)

Plexiform Fibrohistiocytic Tumor

Plexiform fibrohistiocytic tumor is a rare multinodular neoplasm of the dermis and subcutis composed of histiocyte-like cells, fibroblasts, and multinucleate giant cells in a plexiform pattern (120). This distinctive lesion occurs as a slowly growing mass, usually involving the arm of the young, especially females. Infants are occasionally affected (121). The lesion is considered to be of intermediate biological potential, with local recurrence common but with only rare metastases to lymph nodes or viscera (122). No features predictive of recurrence or metastasis have been delineated.

Histopathology. A biphasic pattern is seen, with nodules of histiocytes surrounded by fascicles of spindle cells intersecting the stroma in a plexiform pattern. Osteoclast-like giant cells are seen in the majority of cases, but not all (Fig. 32-11A) (123–125). The proportion of different cellular elements varies from case to case. Mitotic activity with mild nuclear atypia and pleomorphism may be present.

Histogenesis. Ultrastructural and immunocytochemical studies have indicated histiocytic and myofibroblastic differentiation (122,126) in the different cellular components (Fig. 32-11B). No consistent genetic changes have been identified.

Differential Diagnosis. Cellular fibrous histiocytoma and dermatomyofibroma do not have the distinctive nodules of histiocytic-like cells of plexiform fibrohistiocytic tumor, whereas fibromatosis and nodular fasciitis are usually more deeply situated and lack the characteristic plexiform growth pattern. Fibrous hamartoma of infancy has no histiocytic nodules or giant cells (116).

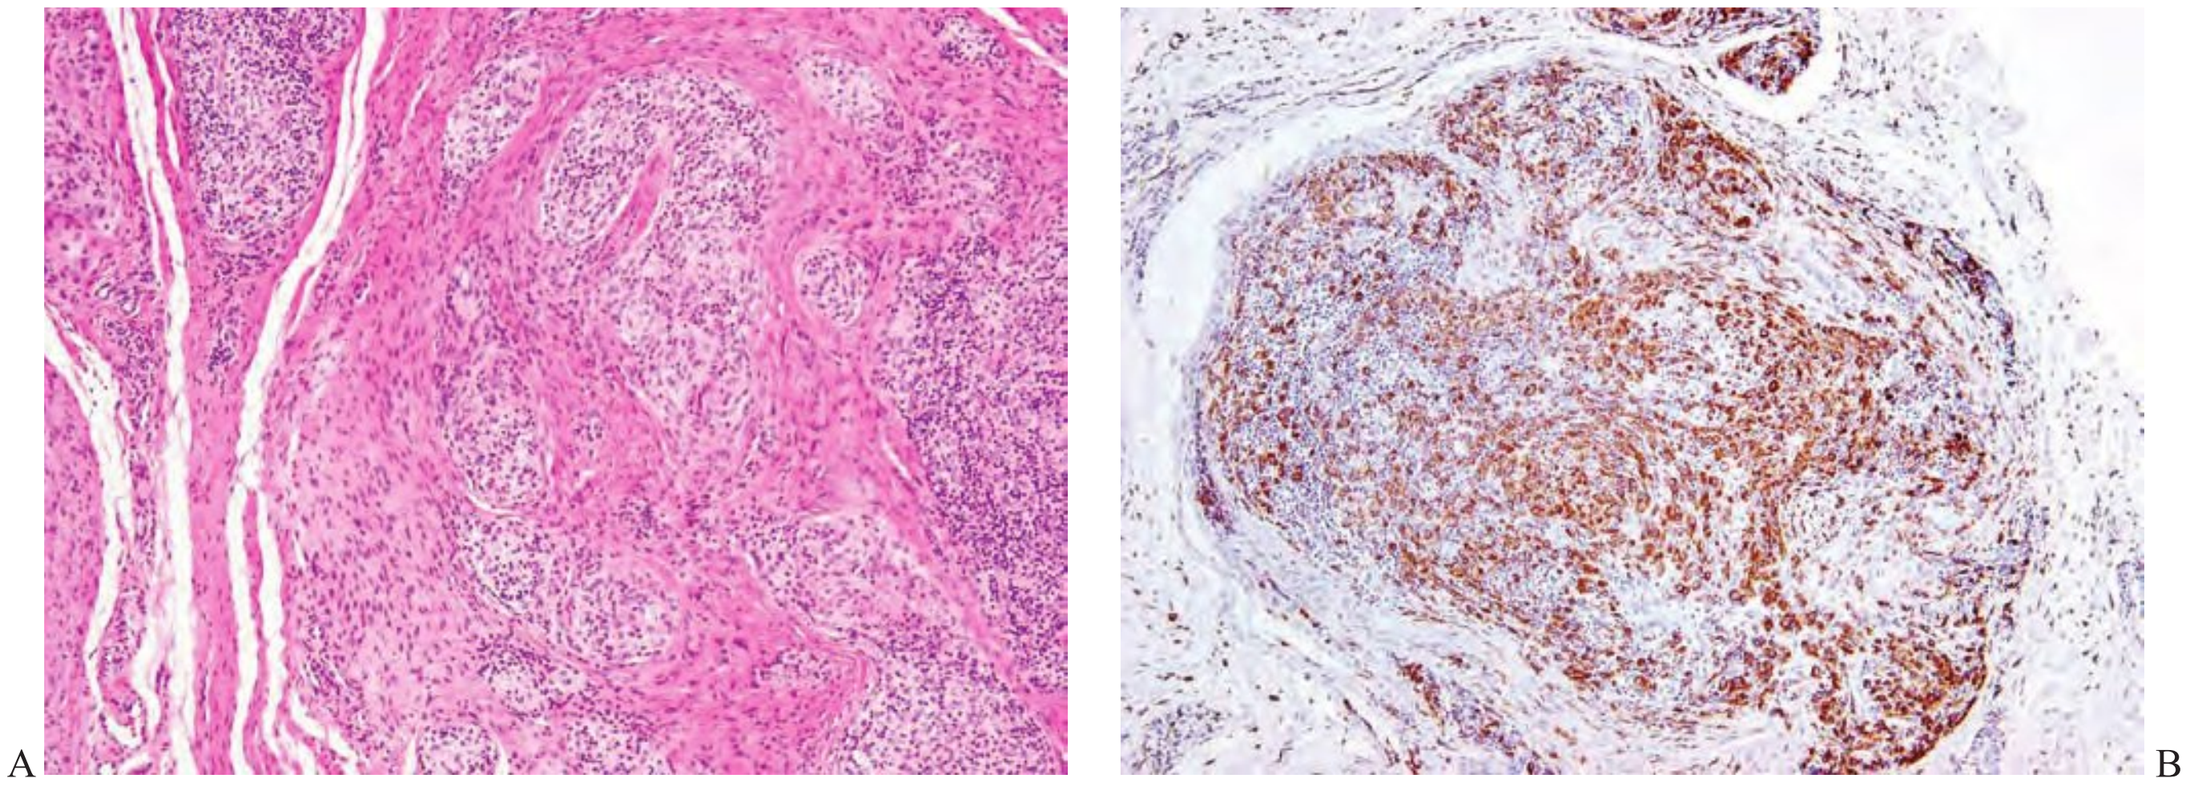

FIGURE 32-11. Plexiform fibrohistiocytic tumor. A: Pale, nodular groups of histiocyte-like cells are present between collagenous bands in the dermis and subcutis. B: Immunohistochemistry demonstrates that many of the pale cells are CD68 positive.

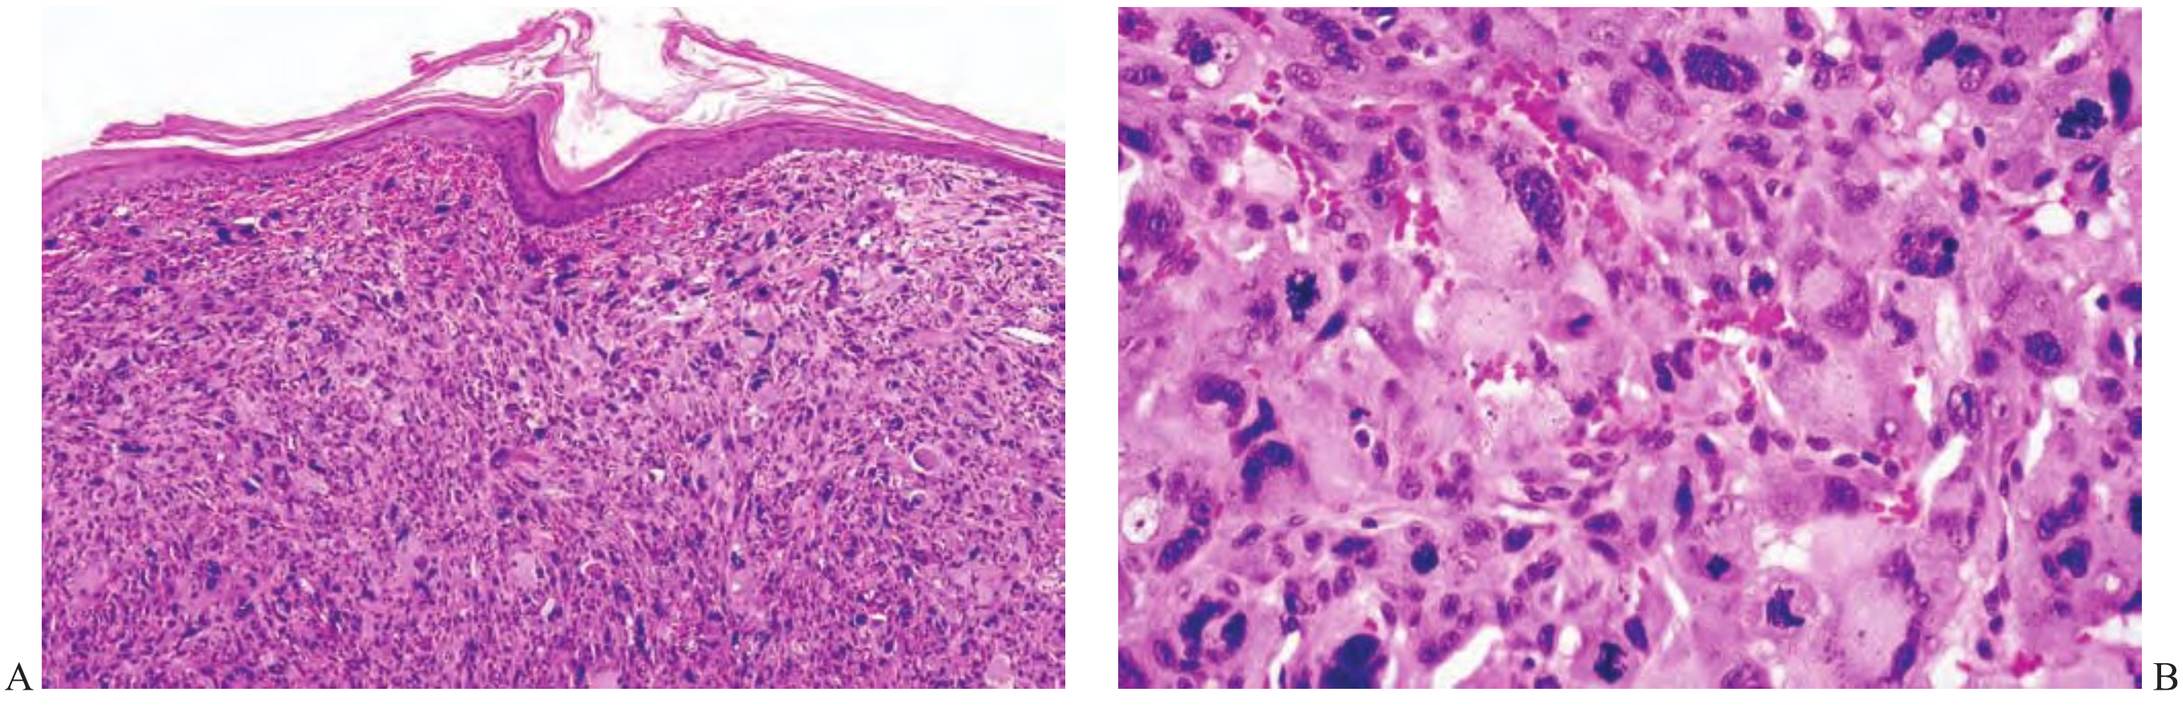

FIGURE 32-12. Atypical fibroxanthoma. A: The tumor is composed of a cellular mass of malignant cells that are unconnected to the epidermis. A lack of keratinization and pigmentation are clues to the diagnosis in these pleomorphic tumors, but immunohistochemistry is recommended in all cases for definitive diagnosis. B: Highly pleomorphic spindle cells are present with some multinucleated giant cells and scattered mitoses, including atypical forms.

Atypical Fibroxanthoma

Atypical fibroxanthoma (AFX) is characterized by a malignant histologic appearance but a generally benign course with only occasional recurrences and exceptionally rare metastases (127–136). Lesions are typically associated with actinic damage and so tend to present on the head, neck, or dorsum of the hand of elderly patients. AFX usually forms a solitary nodule up to 2 cm in diameter, often with a short history of rapid growth.

Histopathology. AFX is a dermal tumor with no or only limited involvement of the subcutis. Lesions are cellular, with marked and often striking pleomorphism and atypia of the constituent cells. Mitoses are readily identified with some atypical forms (Fig. 32-12A, B) (130,133,137). Most tumors are predominately composed of spindle cells, with areas of more epithelioid and histiocyte-like appearing forms also present. The cells are arranged in disordered fascicles, surrounding but not destroying adnexal structures. An epidermal collarette is often seen, with ulceration frequently present. Scattered inflammatory cells are present, often with focal hemorrhage.

The *spindle cell variant* of AFX consists exclusively of spindle cells with eosinophilic cytoplasm, vesicular nuclei, and prominent nucleoli arranged in fascicles. Some examples of this subtype have a somewhat more regular and bland cytologic appearance, and a plaquelike pattern of growth may be evident (Fig. 32-13A, B) (129,134,138). *Clear cell AFX* is a

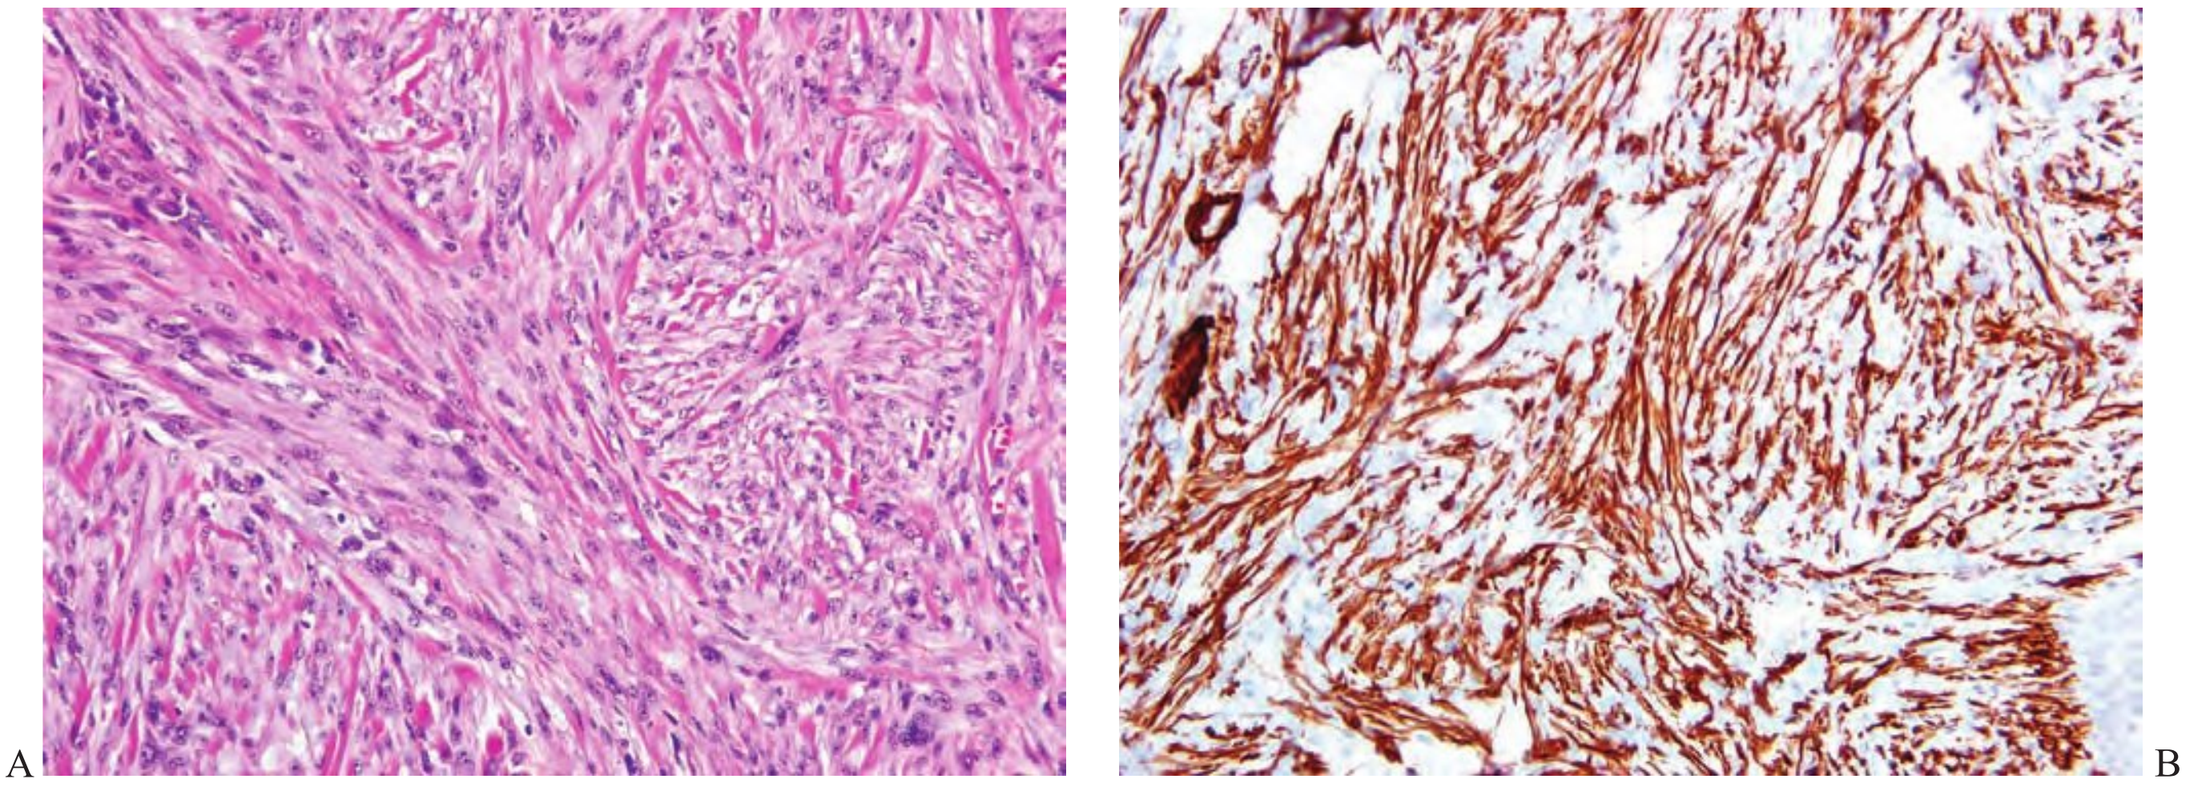

FIGURE 32-13. Spindle cell atypical fibroxanthoma. A: Swathes of pleomorphic spindle cells are present, with some background collagen. Some tumors of this type show relatively monomorphic cytologic features. B: Immunohistochemistry demonstrates strong positivity in the cytoplasm of the spindle cells for smooth muscle actin. Desmin was negative (not shown).

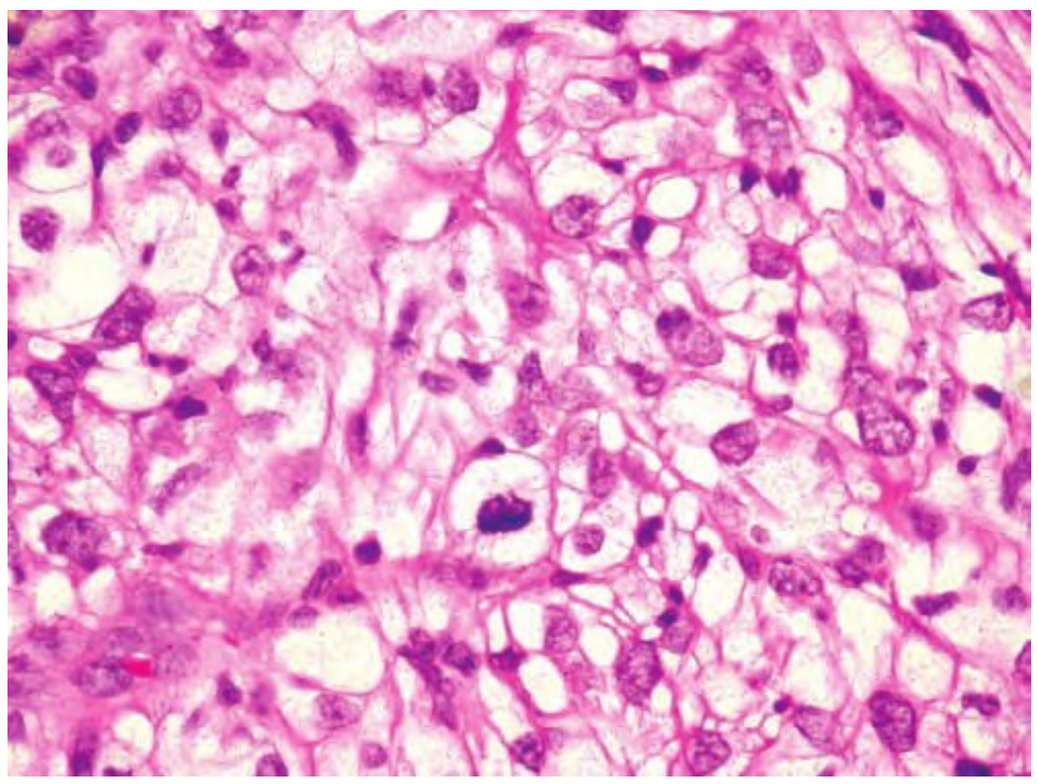

FIGURE 32-14. Clear cell atypical fibroxanthoma. The atypical cells exhibit abundant clear cytoplasm in this variant.

rare variant composed of sheets of large cells with foamy cytoplasm and hyperchromatic, pleomorphic nuclei (Fig. 32-14) (139,140). Occasional tumors are pigmented due to hemosiderin deposition (141). *Granular cell* and *sclerotic* variants have also been reported (142,143).

Histogenesis. Electron microscopic (130,144) and immunohistochemical (106,145) studies suggest that the progenitor cell is an undifferentiated mesenchymal cell capable of showing histiocytic, fibroblastic, and myofibroblastic differentiation.

Differential Diagnosis. Although the features of this tumor are often characteristic, it is important to perform immunohistochemistry to exclude other malignancies, in particular melanoma, leiomyosarcoma, and poorly differentiated squamous cell carcinoma. The possibility of a metastasis should always be considered. In our laboratory, a broad panel of markers is applied, with an expected profile of negative staining for desmin, epithelial, and melanoma markers. Positivity with CD68 is generally present (Fig. 32-15), with quite frequent smooth muscle actin positivity; a negative desmin stain helps to exclude leiomyosarcoma in cases of actin positivity. Desmin positivity has been reported in some cases of AFX, but lesions might be better regarded as leiomyosarcoma if staining is extensive or intense (146). Vimentin, although expected to be positive, has little discriminatory value. Recently CD10 has been shown to be expressed in many cases of AFX (134,147). h-Caldesmon has been reported as negative in AFX but positive in leiomyosarcoma (146), and CD99 is frequently expressed by AFX (134,148).

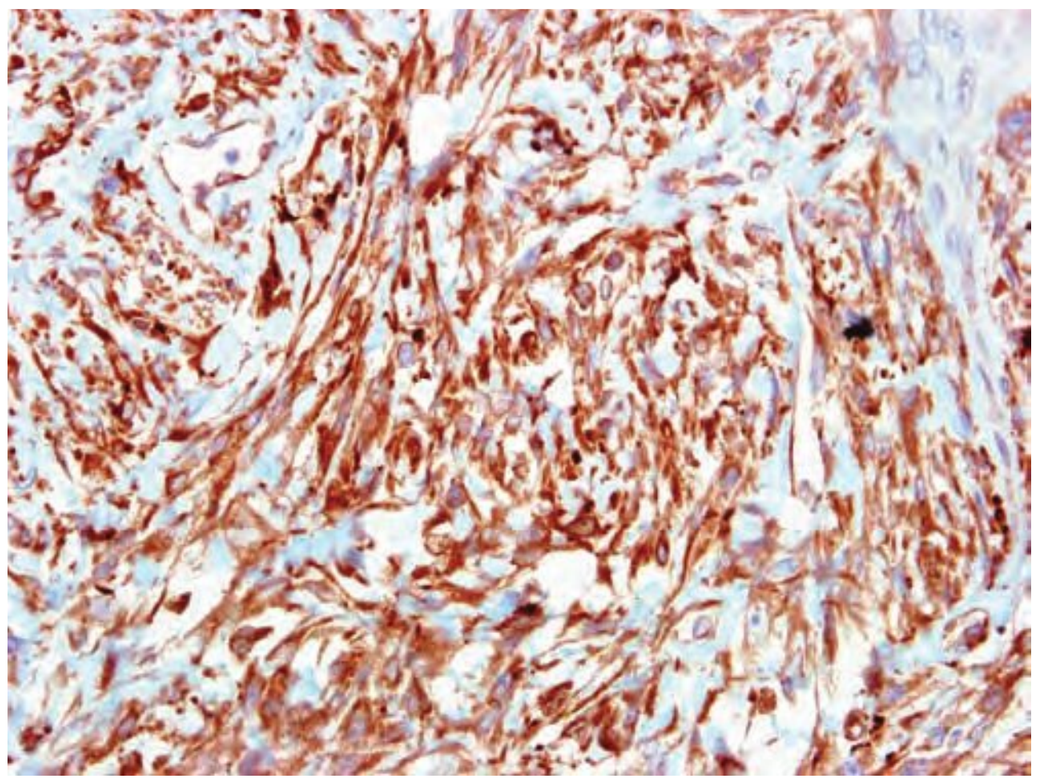

FIGURE 32-15. Clear cell atypical fibroxanthoma (AFX). CD68 is typically positive in all forms of AFX.

Malignant

Malignant Fibrous Histiocytoma

The concept of malignant fibrous histiocytoma (MFH) (149–151) has generally fallen into disrepute, with many authorities considering that the tumor is neither of histiocytic origin nor a specific entity. Based on the use of techniques such as immunohistochemistry, cytogenetics, and electron microscopy, most MFH can be recategorized as other types of sarcoma, melanoma, carcinoma, or even lymphoma (1,128,152–154). The majority of tumors in these categories arise in deep soft tissue, only occasionally reaching the skin by direct growth or metastasis; as such, presentation in the skin is uncommon (155,156).

Despite the best techniques available, a small group of such tumors apparently show no definable line of differentiation, and these are probably best classified for the most part as *undifferentiated pleomorphic sarcomas* (128,153,157). *Myxoid MFH* is generally considered to be a myxoid fibrosarcoma (myxofibrosarcoma), and *giant cell MFH* (158,159) probably often represents a form of osteosarcoma or, perhaps, malignant giant cell tumor of soft tissue (160).

Angiomatoid fibrous histiocytoma was formerly regarded as a subtype of MFH (161) but has been reclassified as a fibrohistiocytic tumor of intermediate grade on the basis of its excellent prognosis (see page 994) (66,162).

FIBROBLASTIC/MYOFIBROBLASTIC TUMORS

Benign

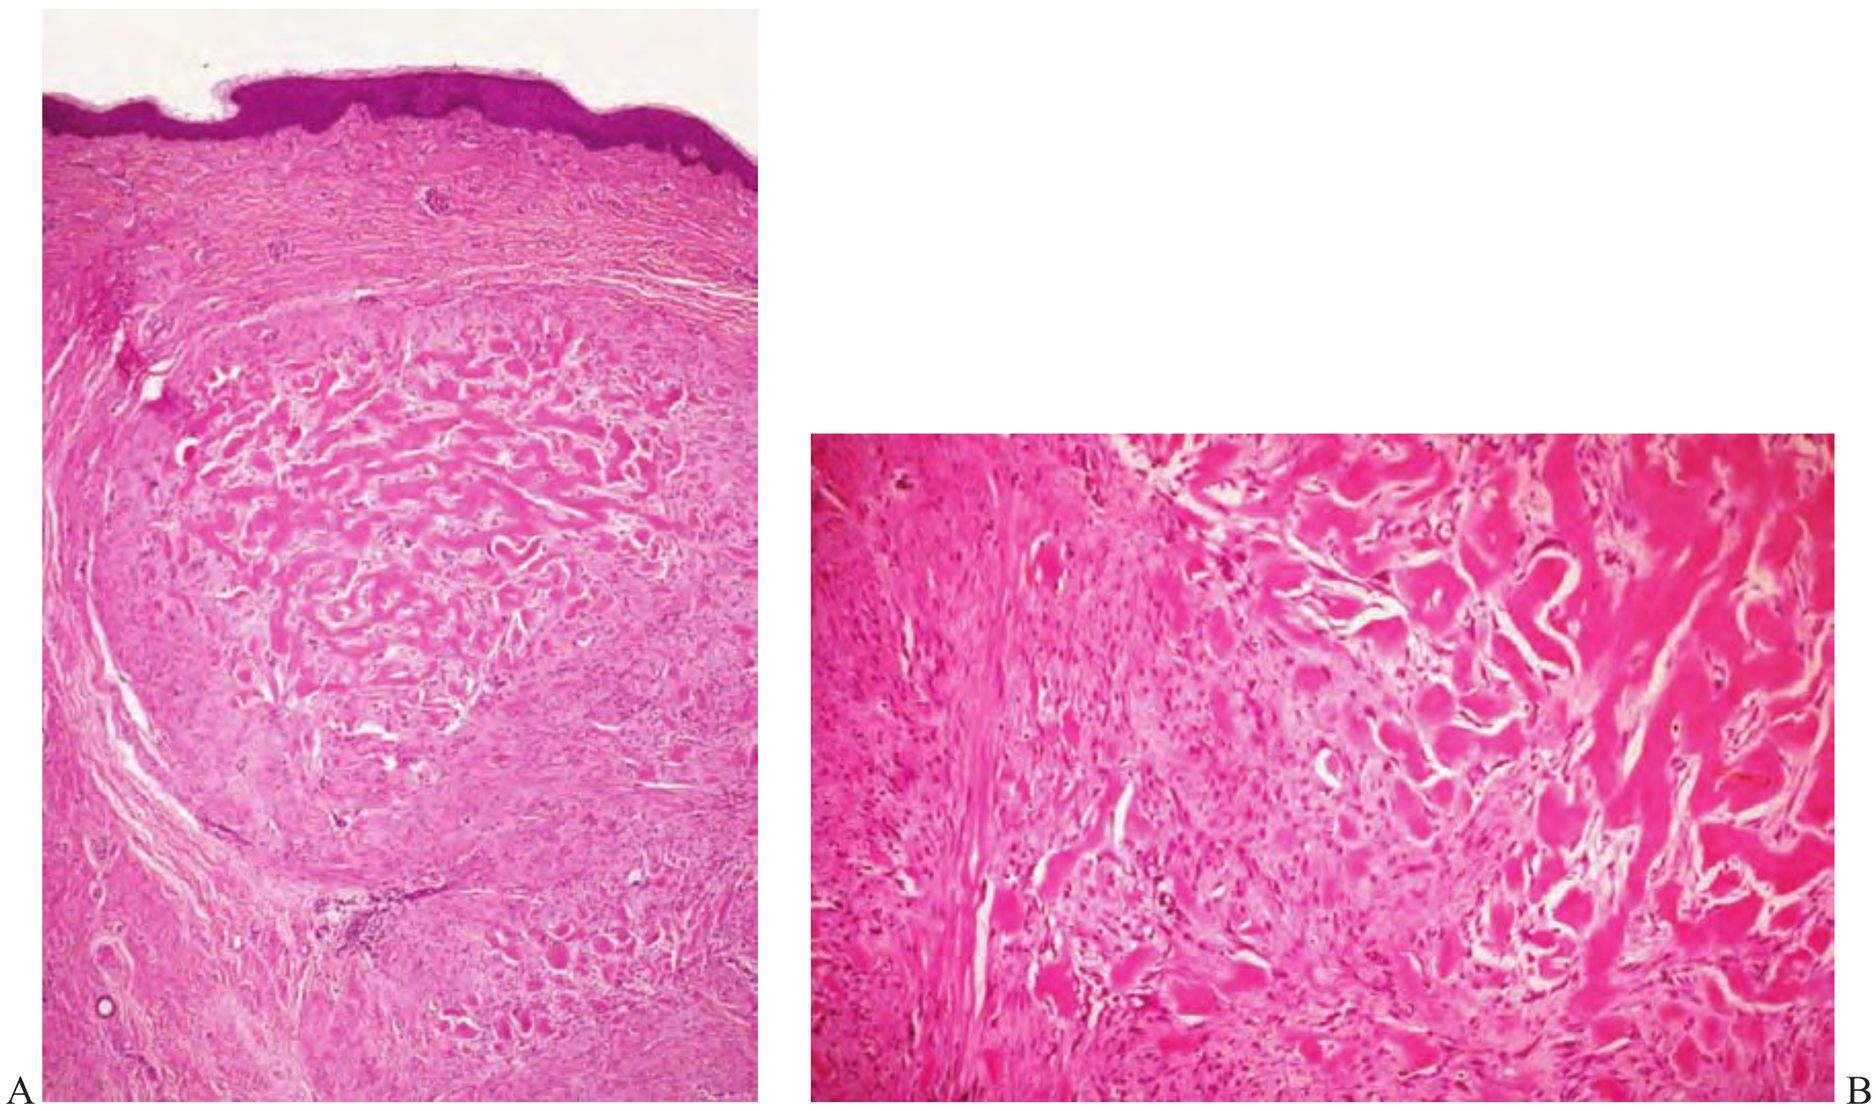
Hypertrophic Scar and Keloid

Excessive fibrous tissue deposited in association with scar formation may lead to a hypertrophic scar or keloid. There are important clinical and pathologic differences between these processes, although it has been suggested that they may form a spectrum of changes (163–165). Keloids become much more prominent than hypertrophic scars and extend beyond the original site of injury, with a high rate of recurrence following

surgical treatment. However, contractures are not a feature of keloid scars, tending to occur mostly in postburn hypertrophic scars. Keloids occur mainly on the upper chest and arms, head and neck, and especially on the ear. They are uncommon in the periocular region and on the palms, soles, penis, and scrotum (166,167). Keloids mostly affect people in the second and third decades of life, and they are more common in wounds that have been infected or under excess tension.

There is frequently a history of prior trauma (such as ear piercing), but some keloids arise spontaneously, especially in the presternal region. Dark-skinned individuals are much more susceptible to keloids, and occasional familial cases have been recorded (167).

Histopathology. Hypertrophic scars and keloids both exhibit excess collagen formation with varying numbers of fibroblastic cells. These tend to form nodular, whorled masses, with vertically aligned vessels in hypertrophic scars and reduced vascularity in keloids (167,168). In keloids, characteristic hypocellular zones of fibrous tissue contain thickened, glassy, eosinophilic collagen bundles, in contrast to the more cellular nodules in hypertrophic scars (Fig. 32-16A, B).



Histogenesis. Keloids have been shown to exhibit abnormal fibroblast activity, with increased hyaluronic acid production and increased levels of transforming growth factor β and other cytokines (169). Decreased apoptosis may also play a role, allowing the keloidal fibroblasts to proliferate and produce more collagen (169). Reduced vascular density in keloids compared to hypertrophic scars and normally healing scars suggests that hypoxia may also play an important role (167).

Dermatomyofibroma

Dermatomyofibroma is an uncommon plaque-like proliferation of fibroblasts and myofibroblasts in the dermis, occurring mainly in young females. The lesions are typically small, with a variety of sites involved, although the shoulder region and neck are most commonly affected (170–172).

Histopathology. Uniform spindle cells in elongated and intersecting fascicles are arranged mainly parallel to the epidermis to form a well-circumscribed plaque. There is occasional involvement to the level of upper subcutis, with sparing of adnexae (Fig. 32-17A, B) (170,173). Overlying epidermal hyperplasia and pigmentation may be seen with increased and fragmented elastin within the lesion. Three cases have recently been reported in adult males on the thigh and trunk that showed red blood cell extravasation associated with dilated capillaries and slit-like spaces giving a resemblance to Kaposi's sarcoma (174).

Histogenesis. Immunohistochemical reactivity for nonspecific muscle actin, variably for α-smooth muscle actin, and the ultrastructural features suggest myofibroblastic differentiation (170,173,175,176).

A B

FIGURE 32-16. Keloid scar. A: Nodules of spindle cells with abundant collagen are present in the dermis with prominent hyalinization. B: Glassy eosinophilic and hyalinized collagen fibers are interspersed with swathes of fibroblasts.

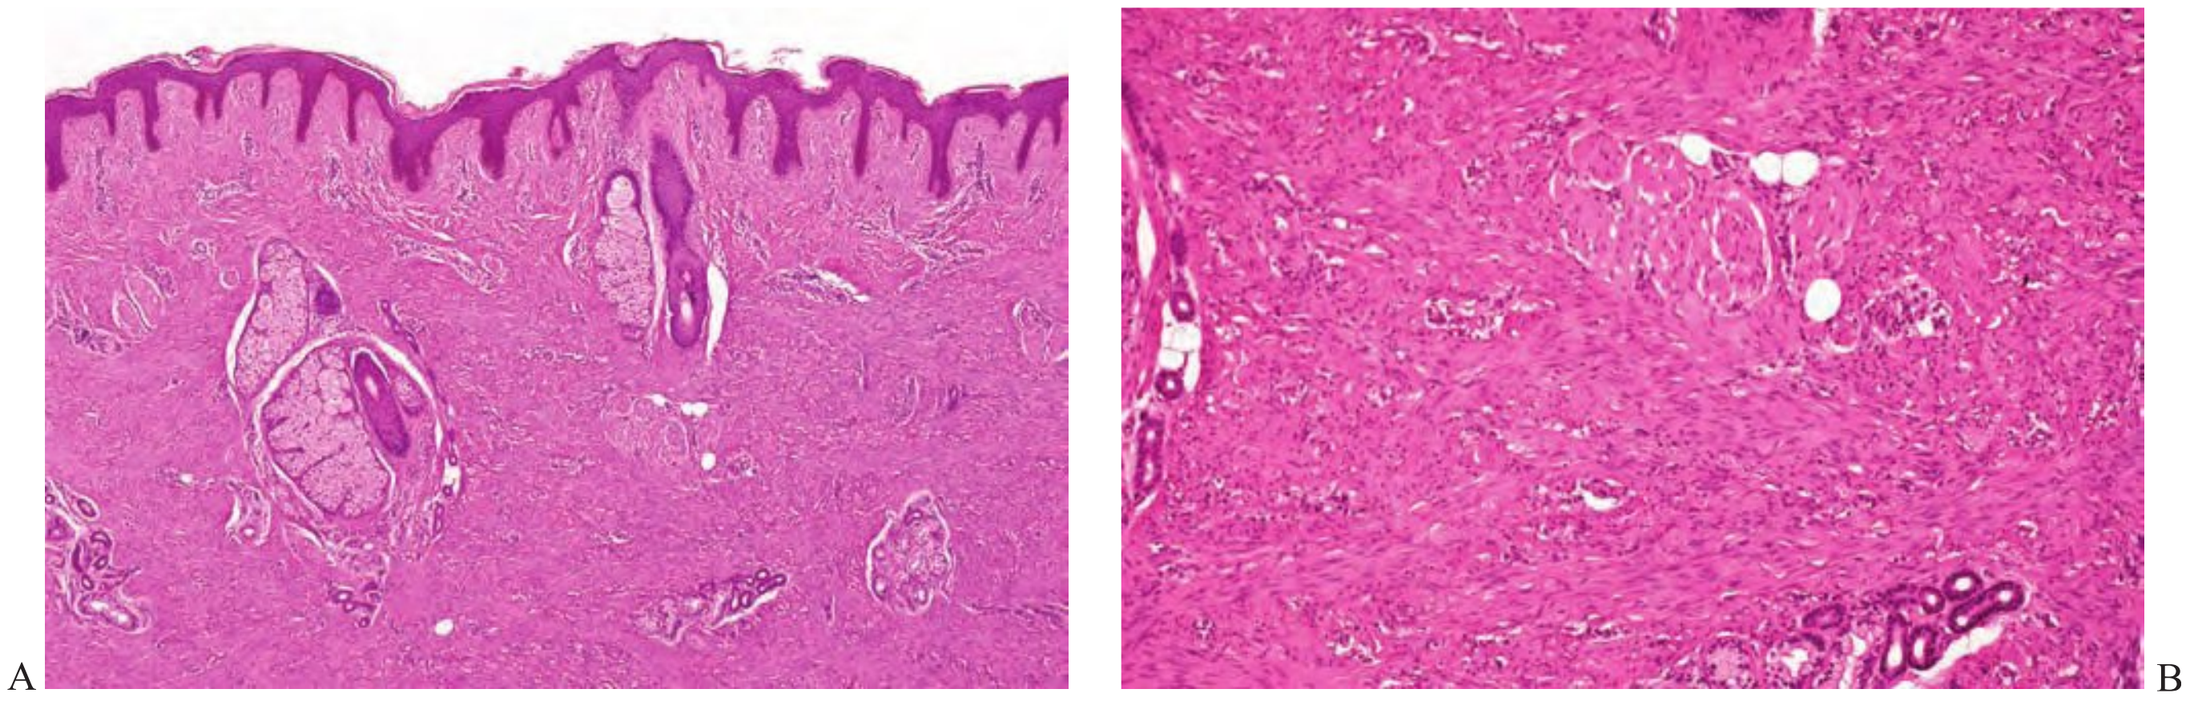


FIGURE 32-17. Dermatomyofibroma. A: The epidermis shows elongated rete ridges overlying a plaque of increased cellularity that surrounds but does not replace appendages. B: At higher power, the lesion is seen to be composed of uniform spindle cells with eosinophilic cytoplasm that efface the dermis, sparing adnexae.

Differential Diagnosis. The orientation parallel to the epidermis of monomorphic spindle cells and their location primarily in the reticular dermis are points of distinction from fibrous histiocytoma. Dermatomyofibroma does not express factor XIIIa, CD34, or h-caldesmon (173,175). Desmin and S100 are also negative.

Soft Fibroma (Fibroepithelial Polyp)

Soft fibromas, also called fibroepithelial polyps, acrochordons, or skin tags, occur as three types: (a) multiple, 1- to 2-mm, furrowed papules, especially on the neck and axillae; (b) single or multiple filiform, smooth growths in varying locations, up to 5 mm long; and (c) solitary, pedunculated or "baglike" growths, usually about 10 mm diameter but occasionally much larger, most often on the lower trunk (177,178).

Several reports have suggested an association between the presence of soft fibroma and colonic polyps (178–181), diabetes (182–184), and acromegaly (185). The association with colonic polyps, however, has not been confirmed by subsequent reports (186–191).

Histopathology. The multiple small furrowed papules usually show papillomatosis, hyperkeratosis, and regular acanthosis. Occasionally horn cysts are also present, giving a resemblance to a pedunculated seborrheic keratosis. The epidermis of the filiform, smooth growths shows slight to moderate acanthosis and occasionally mild papillomatosis. The connective tissue stalk is composed of loose collagen fibers and often contains numerous dilated capillaries filled with erythrocytes. Nevus cells are found in as many as 30% of the filiform growths, indicating that some of them represent involuting melanocytic nevi (192). The larger pedunculated growths generally show a flattened epidermis overlying loose collagen fibers and mature fat cells in the center (187). In some instances, the fat is prominent, indicating lipofibroma formation (193).

Pleomorphic Fibroma

Pleomorphic fibroma typically presents as a slow-growing exophytic nodule most commonly on the trunk or extremities and rarely at other sites, such as the face and subungual location, of middle-aged to older adults (194–196).

Histopathology. The epidermis is flattened, overlying a circumscribed nodule in the dermis composed of plump mononucleate and multinucleate, spindle-shaped or stellate cells with atypical nuclei and occasional mitoses, distributed sparsely in a fibrous stroma (Fig. 32-18A, B).

Histogenesis. The tumor cells are variably smooth muscle actin and CD34 positive, suggesting either myofibroblastic or dermal dendritic cell origin (190,194,195,197).

Differential Diagnosis. Dermatofibromas with monster cells are more cellular, and have areas with typical histologic features of dermatofibroma and often acanthotic pigmented epidermis overlying the lesion. In contrast to dermatofibroma, pleomorphic fibroma expresses CD34 (197). Atypical fibroxanthomas present as rapidly growing, highly cellular lesions composed of pleomorphic, spindle-shaped to epithelioid cells with numerous mitotic figures, which may be atypical.

Sclerotic Fibroma (Storiform Collagenoma or Plywood Fibroma)

This is an uncommon lesion occurring as a small, solitary nodule occasionally as large as 3 cm diameter (199). Multiple lesions are a marker for Cowden's disease (200).

Histopathology. The tumors are circumscribed and composed of interwoven fascicles of laminated eosinophilic collagen with prominent clefting (Fig. 32-19A, B). Cellularity is low, with inconspicuous nuclei. Occasional cases have been reported containing pleomorphic cells, suggesting a relationship to pleomorphic fibroma (198). Giant cells may be conspicuous in

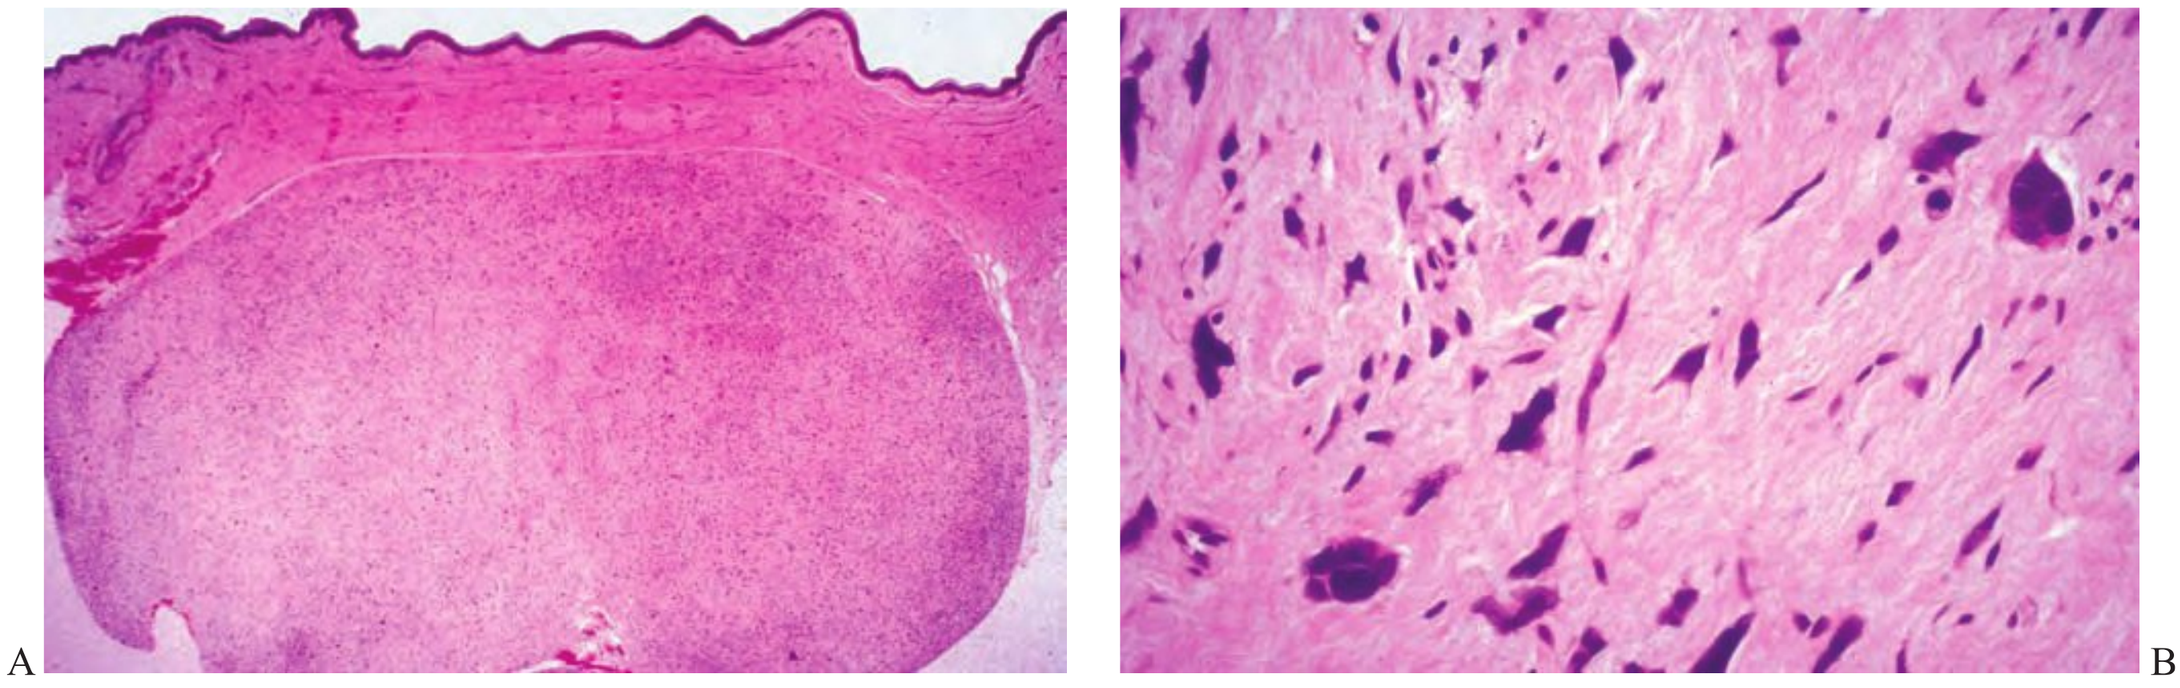

FIGURE 32-18. Pleomorphic fibroma. A: A sharply circumscribed nodule in the dermis and subcutis. B: Spindle cells and giant cells with marked nuclear pleomorphism and hyperchromatism in a pale, hyalinized stroma.

some examples (201). Immunostaining is positive for factor XIIIa, with focal positivity for CD34 (202).

Histogenesis. On the basis of similar fibrotic changes seen in dermatofibroma and in inflammatory lesions, it has been suggested that sclerotic fibromas may have diverse origins (204,205). The demonstration of ongoing collagen synthesis, rare recurrence, and detection of proliferative activity with immunohistochemistry, however, suggests that the lesions are benign fibroblastic neoplasms (202,206,207).

Fibroma of Tendon Sheath

Fibroma of tendon sheath presents as a slow-growing nodule near tendinous structures, most frequently in the hands and wrists. Other less common sites include feet, elbows, and knees. It is uncertain whether fibroma of tendon sheath is a neoplasm or a reactive process. A clonal chromosomal abnormality, t(2;11) (q31-32;q12), has been demonstrated (208). The identical translocation has been described in collagenous fibroma, raising the possibility of a genetic link (209). Treatment is by local excision, with a recurrence rate of 24% (210).

Histopathology. The lesion is characterized by nodules largely composed of interlacing bundles of hyalinized, hypocellular fibrous tissue, with occasional more cellular areas of spindle-shaped, fibroblast-like cells (Fig. 32-20A, B). The more cellular areas may show some degree of pleomorphism, with mitotic figures (211). A characteristic feature is the presence of slit-like vascular channels (212). No foam cells are seen, and multinucleated giant cells are very rare (211).

Histogenesis. The cells of fibroma of tendon sheath express smooth muscle actin. Ultrastructural studies show features of myofibroblastic differentiation (213).

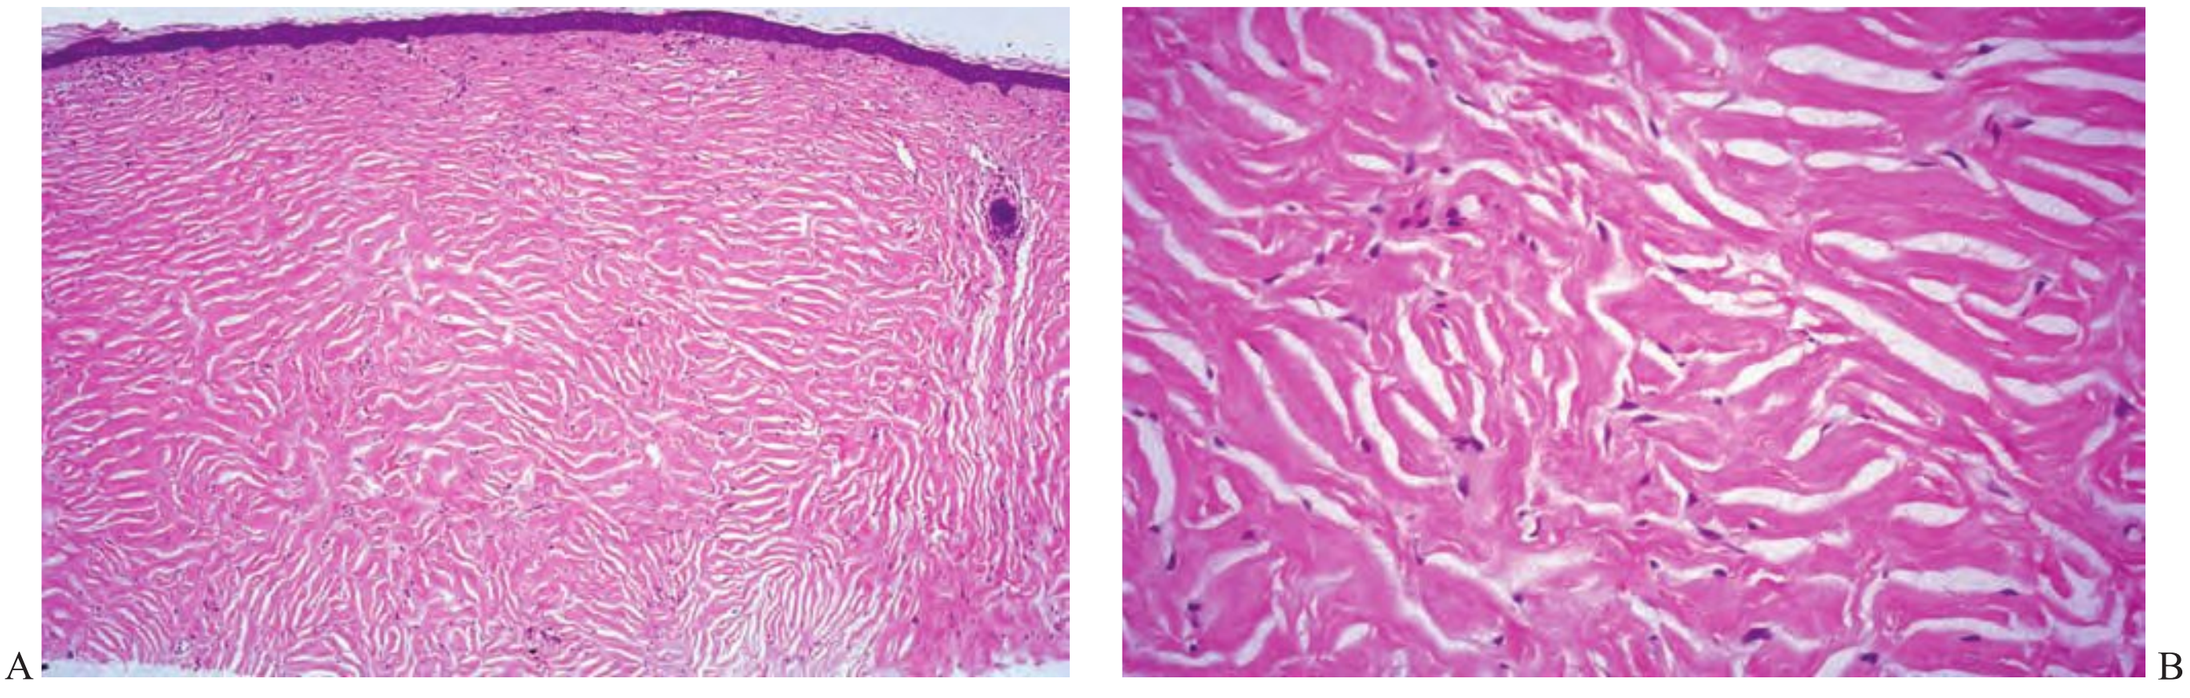

FIGURE 32-19. Sclerotic fibroma. A: A pale, poorly cellular lesion replaces the dermis with some flattening of overlying rete ridges. B: Clefts are prominent between laminated, hyaline, and highly eosinophilic collagen.

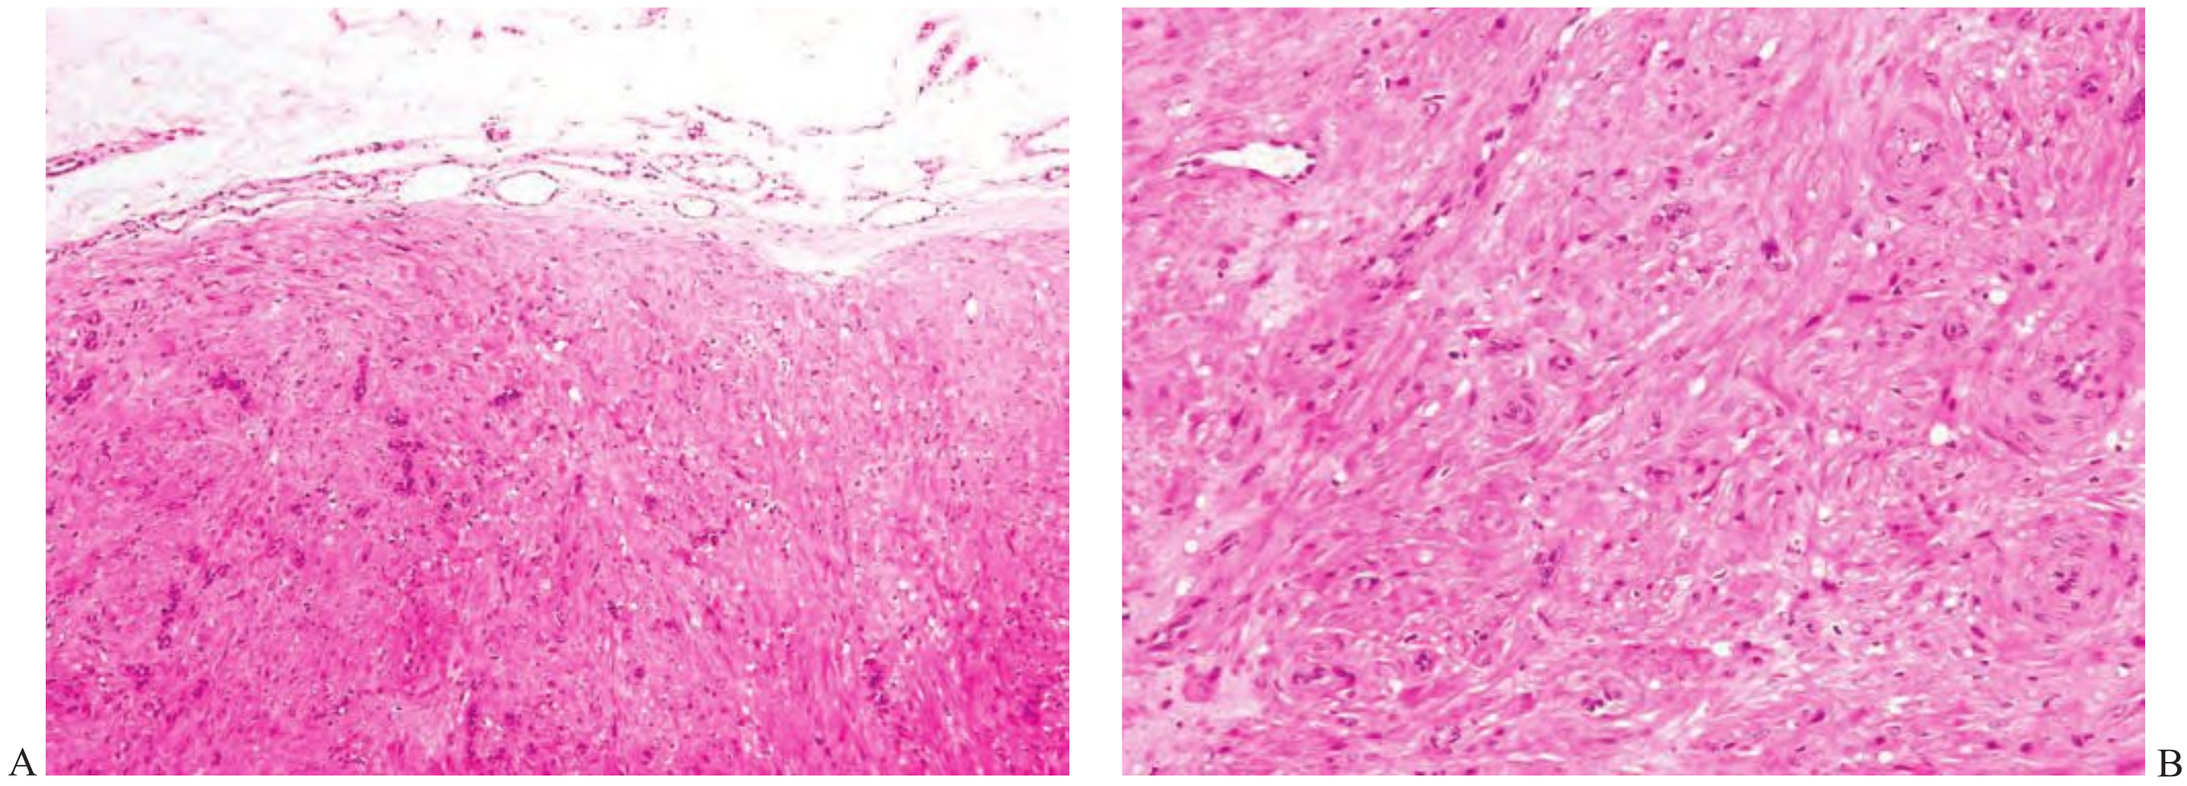

FIGURE 32-20. Fibroma of tendon sheath. A: These lesions are poorly cellular, with ill-defined fascicles of bland, myofibroblast-type cells. B: The spindle cells show a smooth muscle–like appearance and are typically actin positive.

Collagenous Fibroma (Desmoplastic Fibroblastoma)

Collagenous fibroma is a rare benign tumor mainly affecting men. It typically involves subcutis or skeletal muscle, but occasionally it primarily involves the dermis (214–216). Tumors are usually small (1 to 4 cm diameter), but examples up to 20 cm in diameter have been reported (217).

Histopathology. Tumors are circumscribed, ovoid masses that may be lobulated and are composed of dense, paucicellular collagenous tissue with scattered spindle cells without mitotic activity. These show features of myofibroblasts ultrastructurally (218–220). A fascicular growth pattern is absent, and areas reminiscent of a keloid may be seen (Fig. 32-21). Focal myxoid change may be present with inconspicuous blood vessels (217). The tumor cells variably express α-smooth muscle actin and, rarely, keratins AE1/AE3. The cells are negative for desmin, epithelial membrane antigen (EMA), S100 protein, and CD34 (217). Cytogenetic studies performed in a small number of cases have shown a t(2;11) translocation, suggesting a relationship to fibroma of tendon sheath, which shows the same abnormality (221,222).

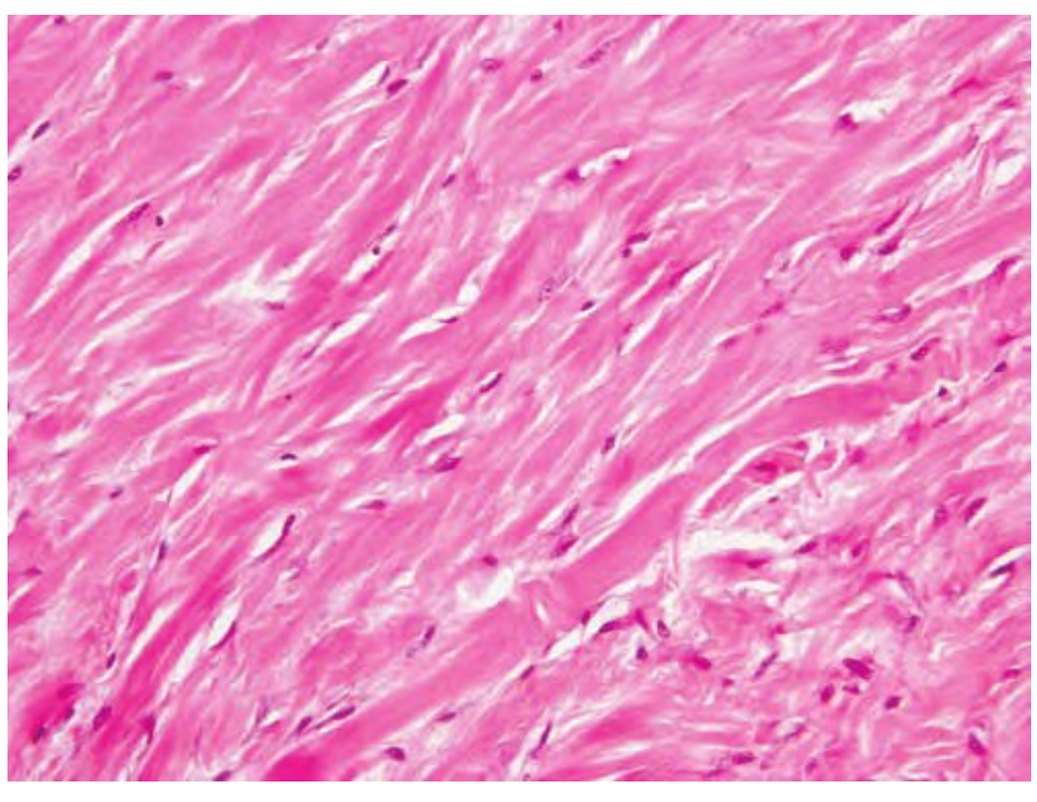

FIGURE 32-21. Desmoplastic fibroblastoma/collagenous fibroma. Thick bands of hyalinized, eosinophilic collagen are present, giving an appearance resembling a keloid.

Nodular Fasciitis

Nodular fasciitis is a rapidly growing benign soft tissue lesion. It usually presents as a solitary, sometimes tender subcutaneous nodule that reaches its ultimate size of 1 to 5 cm within a few weeks. The lesions tend to regress, even if incompletely excised, usually within a few months (223). Although the arm is the most common site, lesions may occur in any subcutaneous area. Nodular fasciitis occurs in all age groups but is more common in young adults, with an equal sex distribution. The cause is unknown. Although trauma does not seem to play a role, the general view is that nodular fasciitis represents a reactive fibroblastic and vascular proliferation.

Histopathology. Nodular fasciitis usually occurs in the subcutis, less often in muscle, and rarely in the dermis. A prominent feature is the infiltrative growth pattern along fibrous septa of the subcutis, resulting in poor demarcation. The nodule consists of immature spindly myofibroblasts and fibroblasts growing haphazardly in vascular, myxoid stroma, presenting a "tissue culture–like" pattern (Fig. 32-22A, B). The vascular component includes well-formed capillaries and slit-like spaces with extravasation of red blood cells. The fibroblasts may show numerous mitoses, which are not atypical. Multinucleate, osteoclast-like giant cells are frequently present. In some instances, degenerate muscle fibers simulate multinucleate

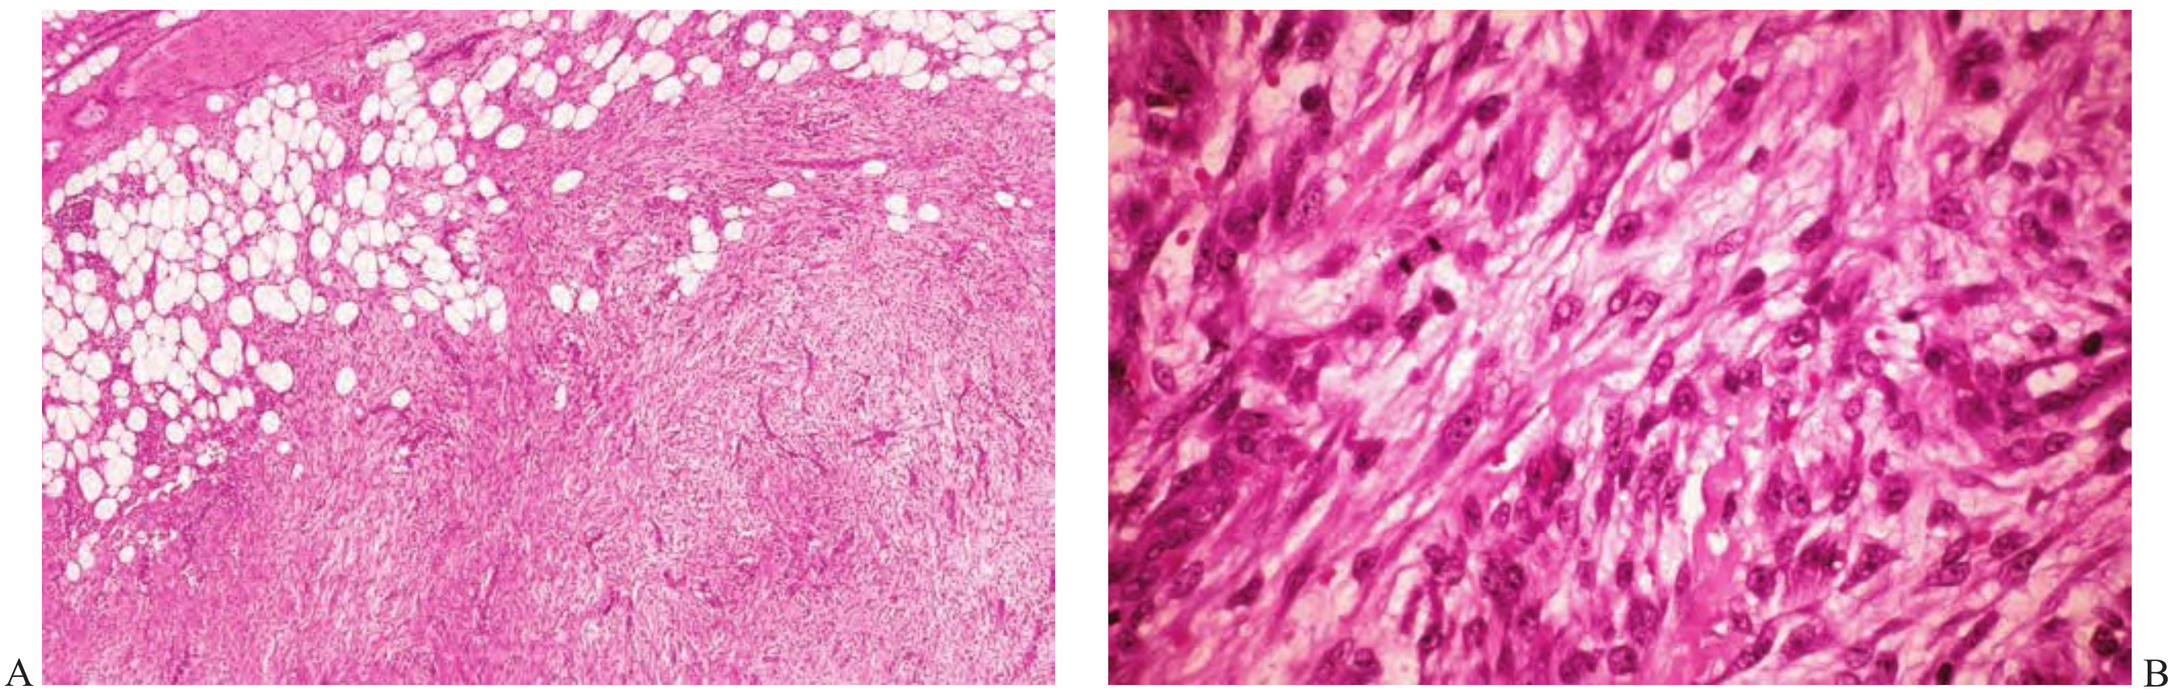

FIGURE 32-22. Nodular fasciitis. A: Plump spindle cells are arranged in varied cellularity in a loosely structured, vascular stroma. B: Plump spindle cells with ovoid, vesicular nuclei and scattered mitoses are embedded in a loosely structured stroma with capillaries and scattered erythrocytes.

giant cells (224). A lymphocytic infiltrate is often present, mainly at the periphery of the nodule (225). In older lesions, the fibroblasts appear more mature, showing a more compact arrangement of spindle cells with increased production of collagen (226).

Dermal fasciitis is a rare variant arising within the dermis, usually occurring in the head and neck region (227–231). *Postoperative/posttraumatic spindle cell nodule* has also been described as the dermal analog of nodular fasciitis (232). Another variant, *intravascular fasciitis* (233), occurs within vessel walls. *Proliferative fasciitis* appears to be related to nodular fasciitis but includes giant cells resembling ganglion cells, similar to those of proliferative myositis. These show abundant, irregularly outlined, basophilic cytoplasm with one or two large vesicular nuclei and a prominent nucleolus (234,235).

Histogenesis. The spindle cells in nodular fasciitis have the ultrastructural features of myofibroblasts (236). As in other myofibroblastic lesions, the cells are immunoreactant for smooth muscle actin and muscle-specific actin but not for desmin (237).

Differential Diagnosis. The presence of numerous large, pleomorphic fibroblasts and the infiltrative type of growth may suggest a malignancy such as sarcoma. In addition to rapid growth and tenderness, however, the combination of fibroblastic and vascular proliferation is the most helpful diagnostic feature of nodular fasciitis. Other findings suggesting the diagnosis are the presence of a mucoid ground substance and an inflammatory infiltrate, especially near the margin of the lesion. Recurrence of a lesion originally diagnosed as nodular fasciitis should spur a careful reappraisal of the clinical and histologic findings (224).

Cranial fasciitis of childhood is considered an unusual variant of nodular fasciitis of uncertain etiology. It occurs in infants and children as a rapidly growing mass in the subcutaneous tissue of the scalp that extends into the underlying cranium. In some cases, the lesion extends through the cranium to involve the dura (238). No recurrence has been reported after excision of the mass with resection or curettage of the underlying bone (238,239). The histologic features closely resemble those of nodular fasciitis. An origin in one of the deep fascial layers of the scalp appears likely (238). Immunohistochemical studies and electron microscopy of the spindle cells demonstrate features of myofibroblasts (238,240).

Ischemic Fasciitis

This condition is also known as atypical decubital fibroplasia and occurs at sites of longstanding pressure, typically in the elderly (241,242). The resultant ischemia is believed to induce formation of a reactive fibroblastic proliferation that may mimic nodular fasciitis or even a sarcoma. The process extends through dermis and into subcutis and underlying tissue, often abutting bony prominences.

Histopathology. Reactive fibroblastic tissue is present associated with foci of necrosis and repair. Atypical reactive fibroblasts are seen with a proliferation of fine vessels, and ulceration may be present (Fig. 32-23A, B) (242).

Myofibroma/Myofibromatosis

Myofibroma is a benign neoplasm that can present as solitary or multiple lesions. The majority of tumors are solitary, measuring between 0.5 and 7.0 cm in size. The nodules are most commonly confined to the dermis, subcutis, and skeletal muscle of the head, neck, and trunk, but any site may be affected. In *infantile myofibromatosis*, multiple tumors may also develop in bones and viscera in addition to skin involvement, causing death in rare cases (243–245). Death may occur in the first few months of life, usually from cardiopulmonary or gastrointestinal complications, but in survivors and in those with superficial

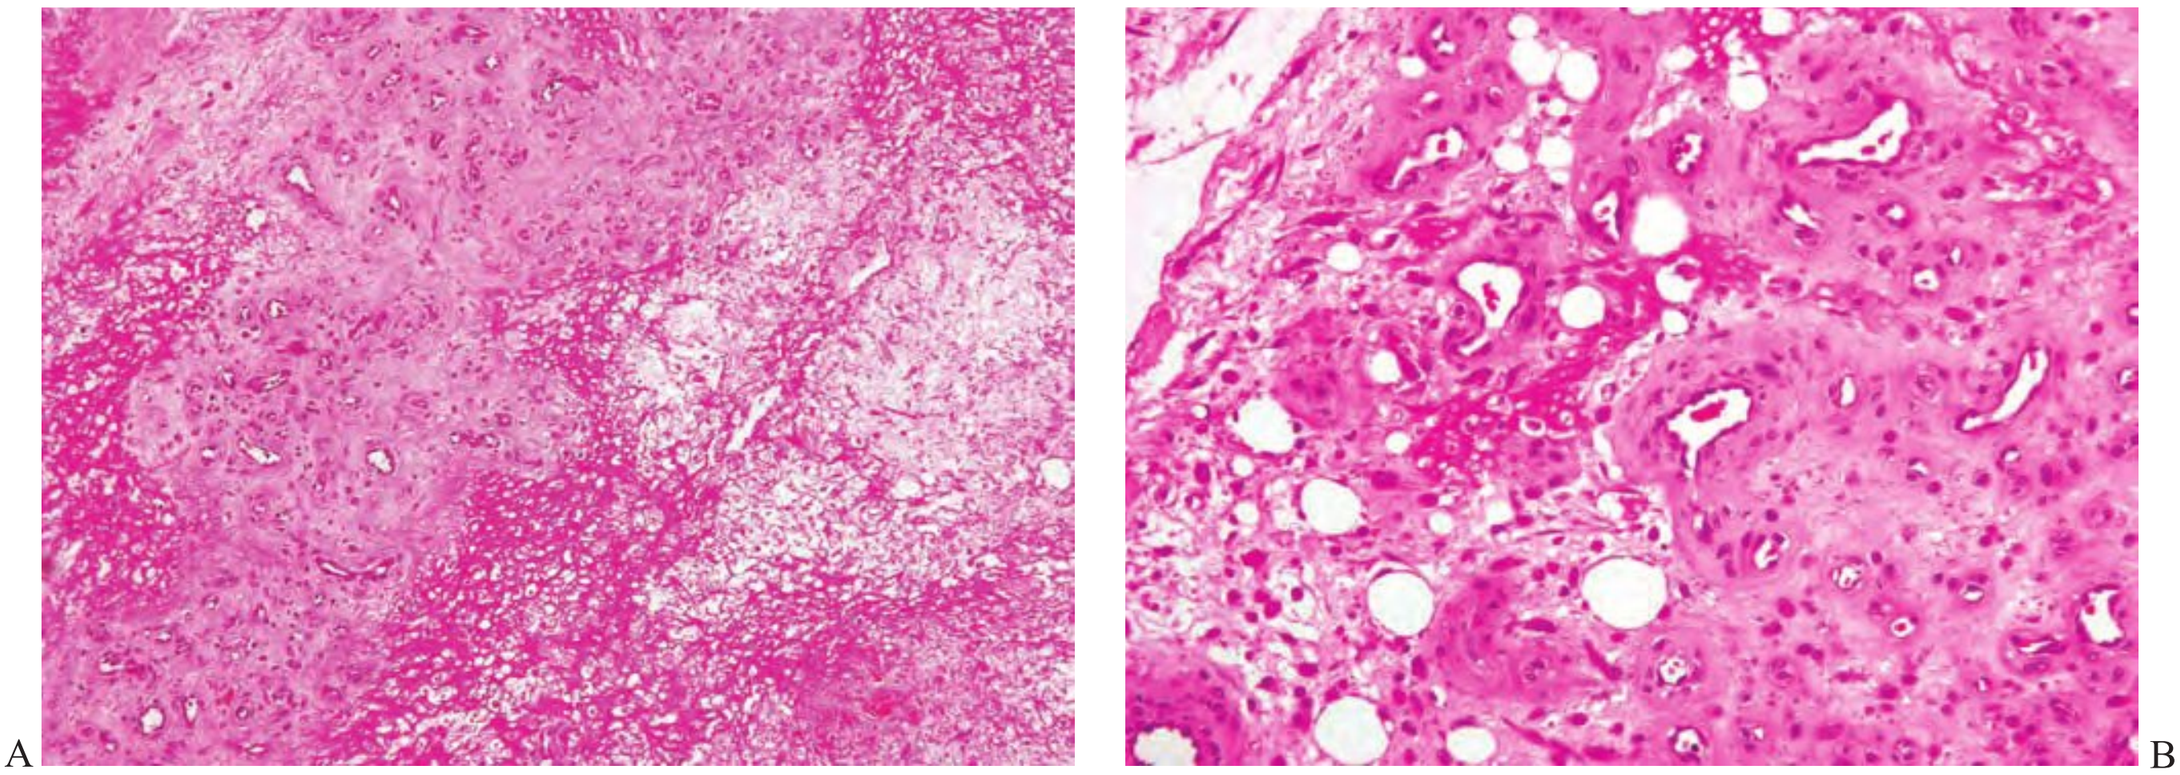

FIGURE 32-23. Ischemic fasciitis. A: Fibrin deposition and granulation tissue are present in this lesion excised from the greater trochanter of an elderly, bed-ridden man. B: Dilated vessels and reactive stromal cells are seen at high power. The degree of atypia may raise the possibility of a sarcoma at times.

myofibromatosis, spontaneous involution of the lesions usually takes place, often within the first year of life. Involution may be mediated by apoptosis or overgrowth of its own vascular supply (246,247). In adults, the tumors are solitary, superficial, and show no tendency to regress (248,249). Familial cases of infantile myofibromatosis are believed to be inherited in an autosomal dominant manner (250).

Histopathology: Most tumors have a characteristic biphasic growth pattern. The lesions consist of nodular dermal aggregates of plump spindle cells resembling smooth muscle cells with pale eosinophilic cytoplasm arranged in short fascicles, sometimes with areas of hyalinization (251) (Fig. 32-24A, B) surrounding a central, hemangiopericytoma-like component where less-differentiated rounded cells with scant cytoplasm

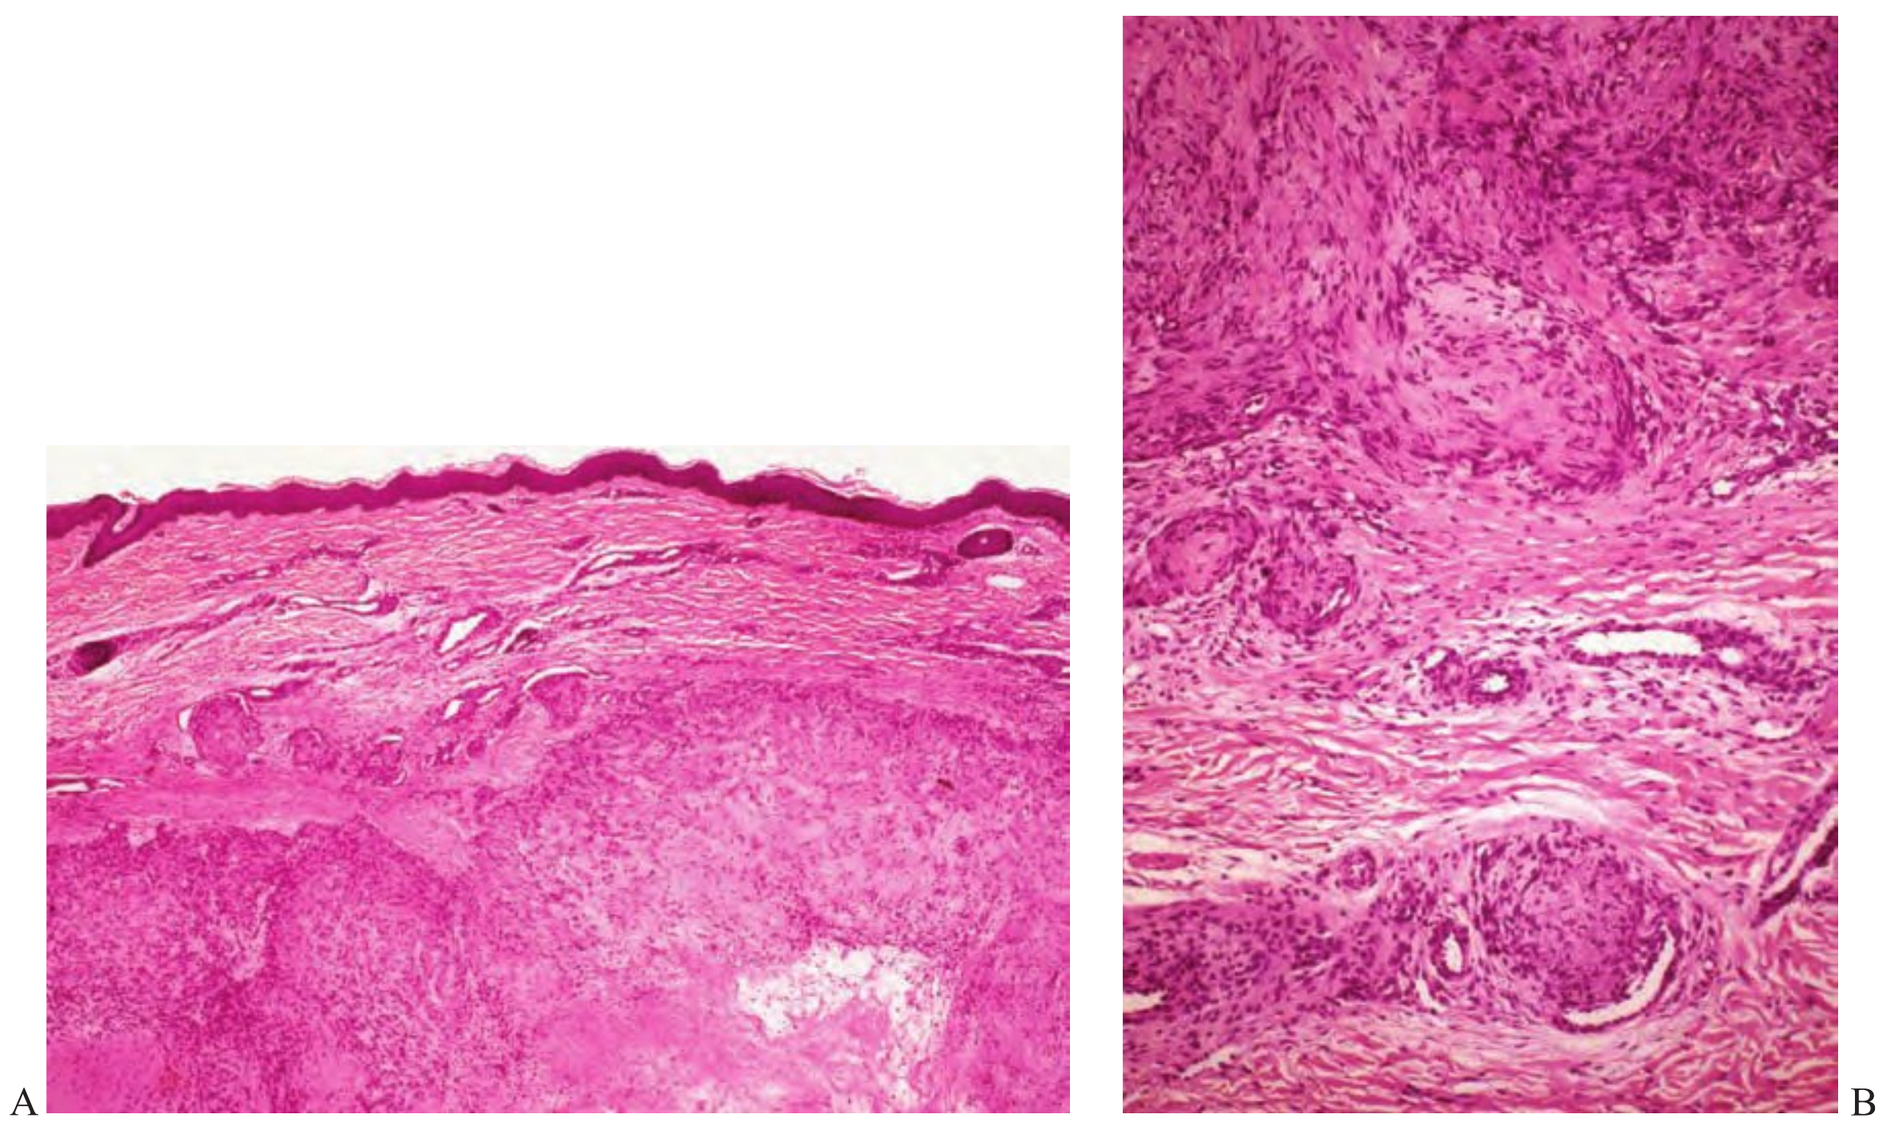

FIGURE 32-24. Myofibroma. A: Circumscribed dermal nodules of varied size, with hyalinization in the center of the largest nodule. B: The nodules consist of fascicles of plump spindle cells with pale eosinophilic cytoplasm, some of which indent the walls of blood vessels.

are arranged around irregularly shaped, thin-walled blood vessels. There is no atypia or pleomorphism. The stroma may appear mucoid in the less cellular areas (252). Foci of necrosis and calcification may be present centrally. In some cases, the distribution of the two components is reversed, that is, the hemangiopericytoma-like areas are situated peripherally. Other lesions may show a predominance of myoid or hemangiopericytomatous elements.

Histogenesis. The spindle cells are immunoreactive for actin but are negative for desmin (248,253,254). The cells are believed to be myopericytic in origin (249,255).

Fibrous Hamartoma of Infancy

Fibrous hamartoma of infancy usually occurs as one or, rarely, two subcutaneous nodules that may be present at birth or develop during the first 2 years of life (256–259). After an initial period of growth, there is no further increase in the size of the nodule. There is a predilection for boys, with male-to-female ratio of up to 2.6:1 (259,260). These lesions present in a wide range of locations, most commonly the axilla, upper arm, upper trunk, inguinal region, and external genitalia (259). Complete local excision is usually curative, and the recurrence rate is low (261). A case with t(2;3) (q31;q21) chromosomal translocation was described (262).

Histopathology. The nodule consists of three distinct tissue components: fibrocollagenous trabeculae composed of bland spindle cells, whorls of immature-appearing spindle mesenchymal cells with scant cytoplasm cells in a mucoid matrix, and mature fat (Fig. 32-25A, B) (256,257). The fibrous component varies in cellularity, pattern, and amount and may resemble granulation tissue, deep fibrous histiocytoma, or fibromatosis in some areas (260). The spindle cells in the fibrous trabeculae express actin (259).

Juvenile Hyaline Fibromatosis

This is a rare, autosomal recessively inherited disorder. It starts in early infancy with flexural contractures and innumerable skin papules and nodules that gradually increase in size, with osteolytic bone lesions and gingival hyperplasia. Wart-like papillomatous lesions may occur in the perianal region. The largest nodules are usually seen on the scalp and around the neck. Juvenile hyaline fibromatosis has been reported in association with skull and encephalic abnormalities and in the hand of an adult (263). *Infantile systemic hyalinosis* is believed to be a severe form of the disease, with widespread visceral involvement and an invariably fatal outcome (264).

Histopathology. The nodules are composed of spindle-shaped or round stromal cells and homogeneous, amorphous eosinophilic ground substance to varying degrees. Small, newly developed tumors are more cellular, whereas larger, older tumors contain more ground substance (265,266). The spindle-shaped cells tend to be arranged in interlacing cords, and the ground substance is periodic acid-Schiff positive and diastase resistant. In paraffin-embedded, formalin-fixed material, empty spaces are seen around the nuclei of stromal cells, giving these cells a chondroid appearance (267,268).

Histogenesis. The stromal cells have the ultrastructural features of fibroblasts (268–270). The perinuclear vacuoles are intracytoplasmic, membrane-bound vesicles filled with fibrillogranular material identical in appearance to the ground substance (268,271).

Infantile Digital Fibromatosis (Inclusion Body Fibromatosis)

Infantile digital fibromatosis occurs as single or multiple nodules on the fingers or toes, excluding the great toe and the thumb. Lesions may be present at birth, but they usually

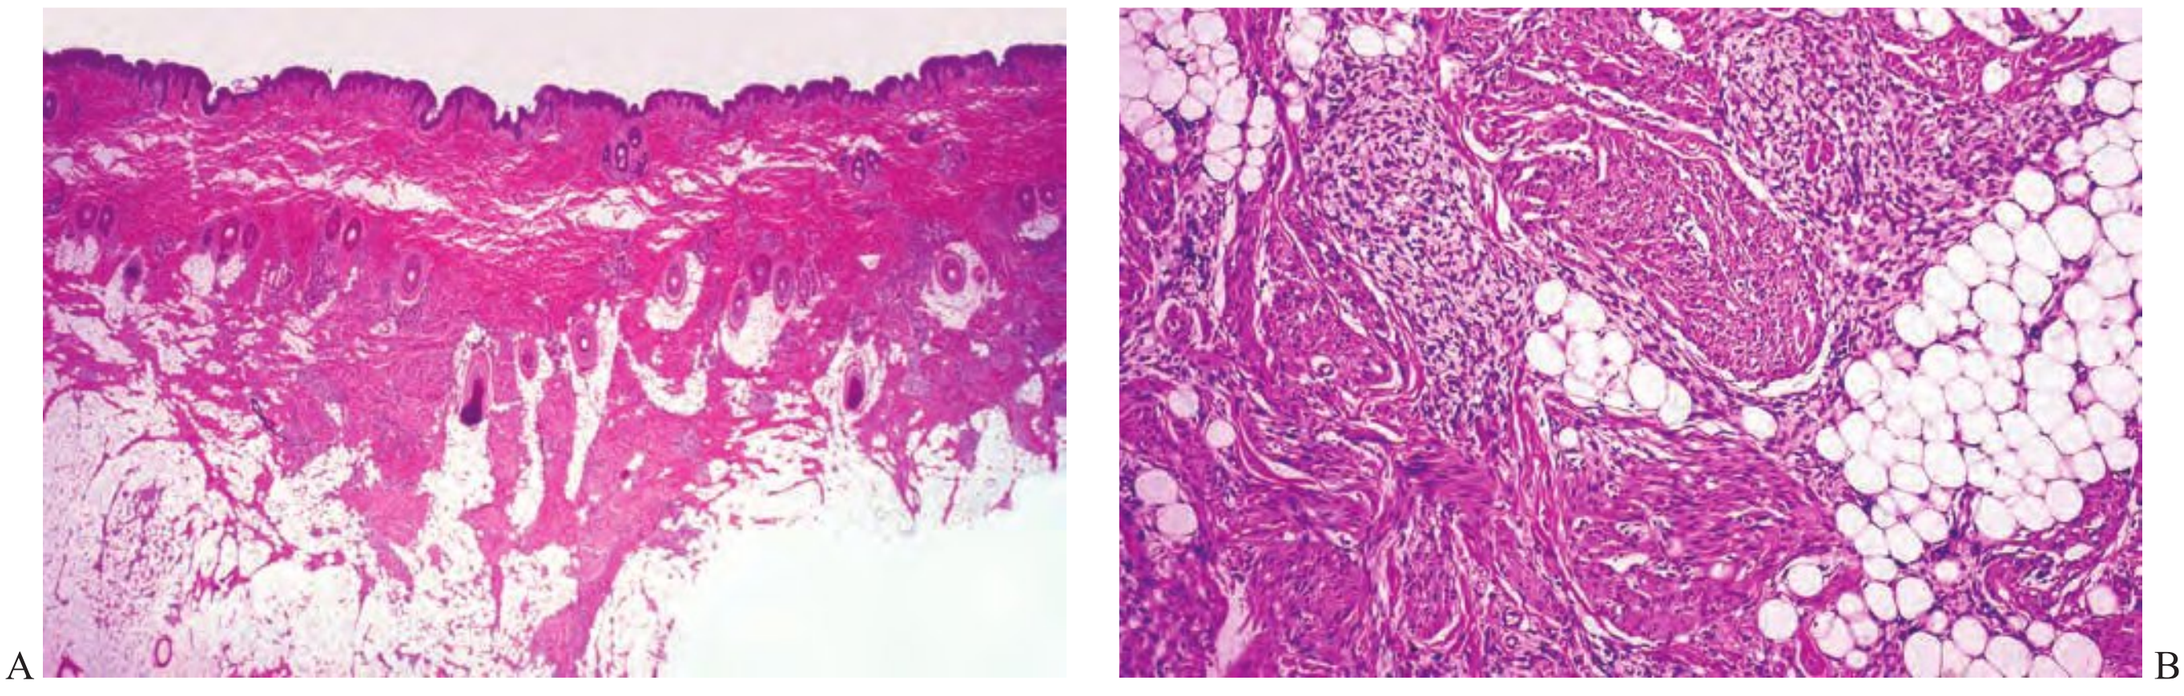

FIGURE 32-25. Fibrous hamartoma of infancy. A: Trabeculae of varied thickness intersect lobules of fat in the subcutis. B: The trabeculae are composed of immature spindle cells arranged in loosely structured myxoid areas and more densely collagenous tissue.

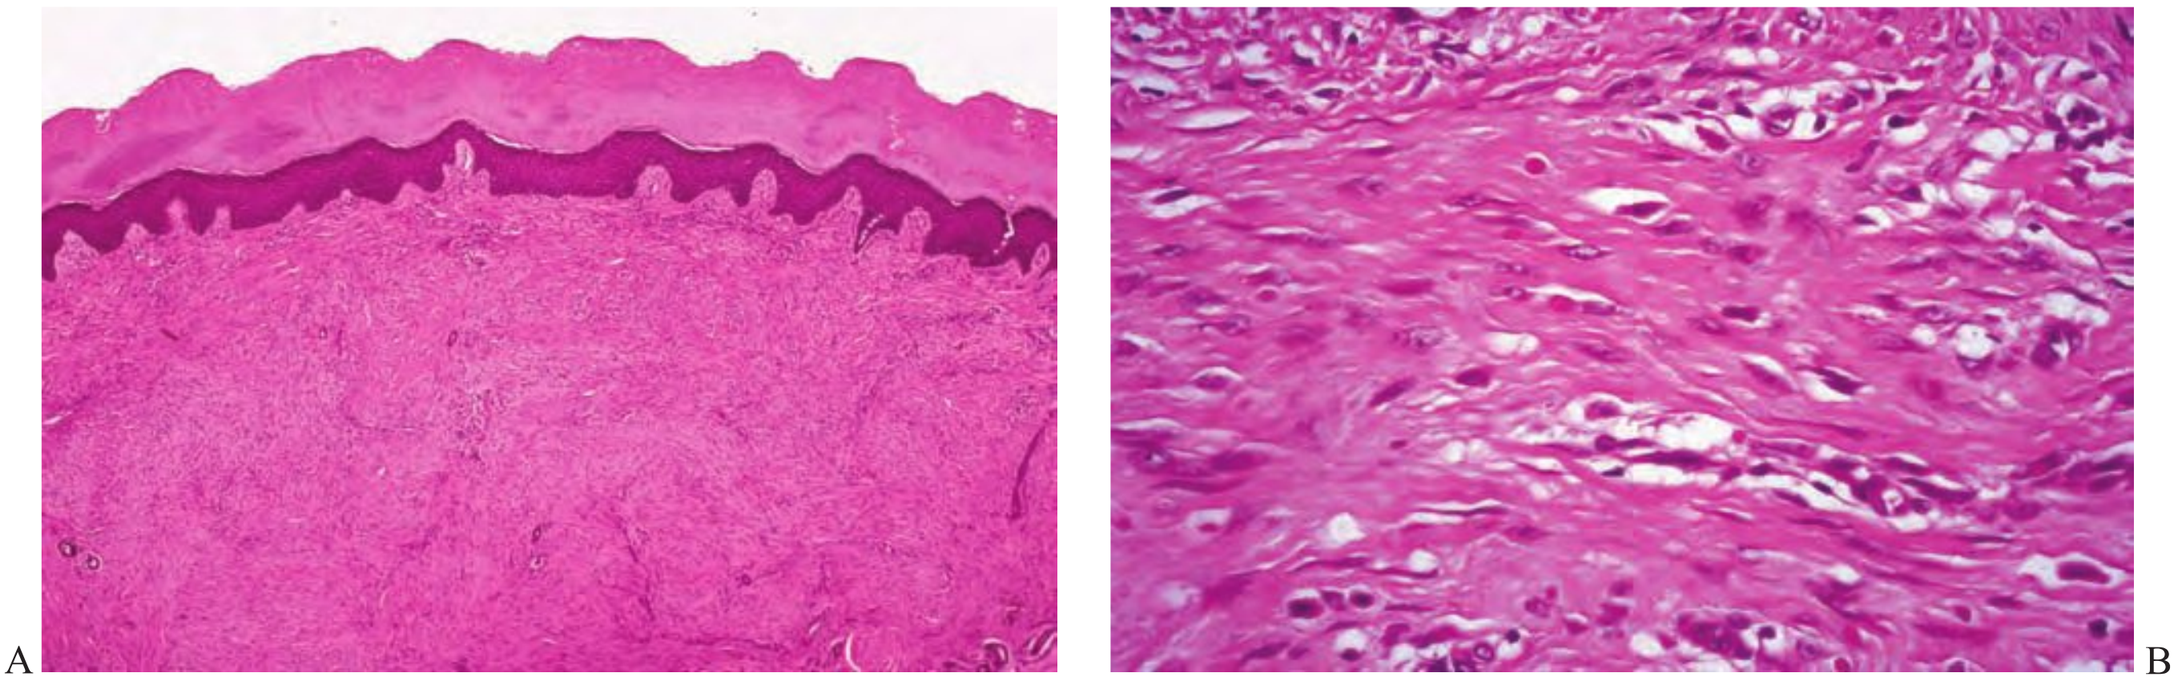

FIGURE 32-26. Infantile digital fibromatosis. A: Intersecting fascicles extend from the papillary dermis into the subcutis. B: Fascicles of spindle cells, some of which contain small round, eosinophilic, cytoplasmic inclusions.

appear during the first year of life and occasionally later in childhood. The nodules rarely exceed 2 cm in diameter and involute spontaneously. In about 75% of the cases, recurrences are observed during early childhood (272).

Histopathology. The dermis is infiltrated by uniform spindle cells and collagen bundles arranged in interlacing fascicles, extending from just below the epidermis into the subcutis (Fig. 32-26A). A characteristic feature is the presence of eosinophilic cytoplasmic inclusions 3 to 10 μm in diameter resembling erythrocytes, often indenting the nucleus (Fig. 32-26B). These inclusions stain deep red with Masson trichrome and purple with phosphotungstic acid–hematoxylin. They express vimentin and actin (203).

Histogenesis. The lesional cells are vimentin and muscle actin positive. Ultrastructurally, the spindle cells show the features of myofibroblasts and contain actin filaments, which extend into and are continuous with the granular intracytoplasmic inclusions.

Elastofibroma Dorsi (Elastofibroma)

This condition appears to be degenerative and occurs most often in older women beneath the scapula. Lesions form a poorly circumscribed connective tissue mass, which may be as large as 15 cm in diameter. Rare cases have been recorded away from the scapula, and some lesions are multiple (273–275). The behavior is benign, with recurrence exceptional.

Histopathology. Irregular zones of poorly cellular collagen extend into the soft tissues with prominent, abnormally formed elastin bundles (Fig. 32-27). Elastin stains show these to have a globular and beaded morphology. CD34 staining is present in some of the spindle cells in the tumors that are negative for S100 and actin (276,277).

Histogenesis. Repeated mild trauma has been suggested as an etiologic factor leading to elastin degeneration. Abnormal elastin production is also a possible cause, with evidence of various chromosomal changes in lesions in a few patients and some genetic predisposition (278,279).

Differential Diagnosis. Once the presence of abnormal elastin is appreciated, the diagnosis is straightforward. Fibromatoses are more-cellular lesions, and nuchal-type fibromas, although occurring in a similar site, typically occur in males and show more dense collagen with only fine elastin bands and sometimes a proliferation of fine nerve twigs.

Angiofibromas

The histologic features of angiofibroma occur in a number of different clinical contexts. Multiple lesions on the face may occur in association with several clinical syndromes, including tuberous sclerosis and multiple endocrine neoplasia type 1 (280).

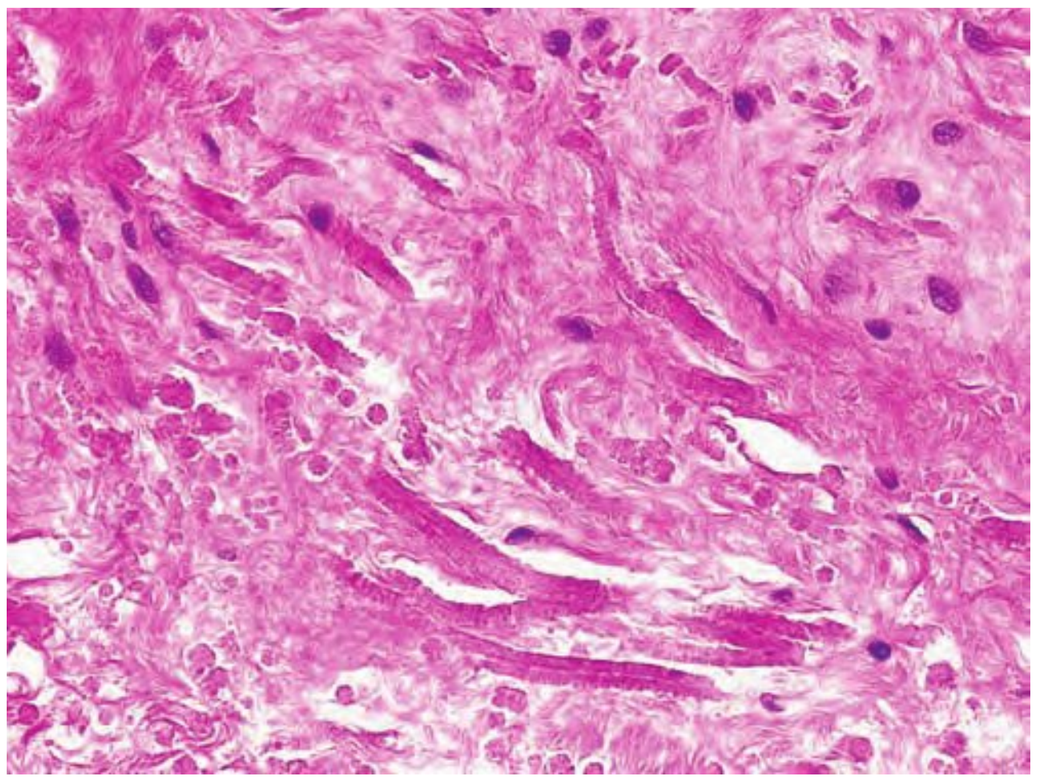

FIGURE 32-27. Elastofibroma. Coarse elastin fibers are prominent in the lesion, with small globular excrescences. (Courtesy of Dr. E.-C Jung, University of California, San Francisco, California.)

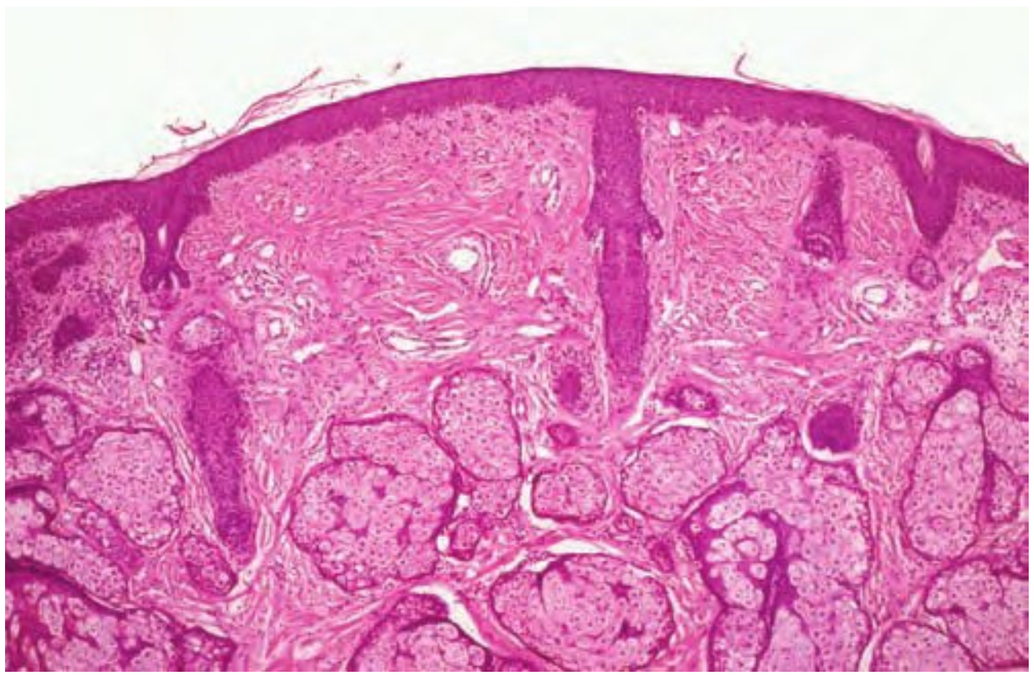

FIGURE 32-28. Angiofibroma (fibrous papule of the face). The epidermis is elevated over a zone of vascular fibroplasia in the superficial dermis.

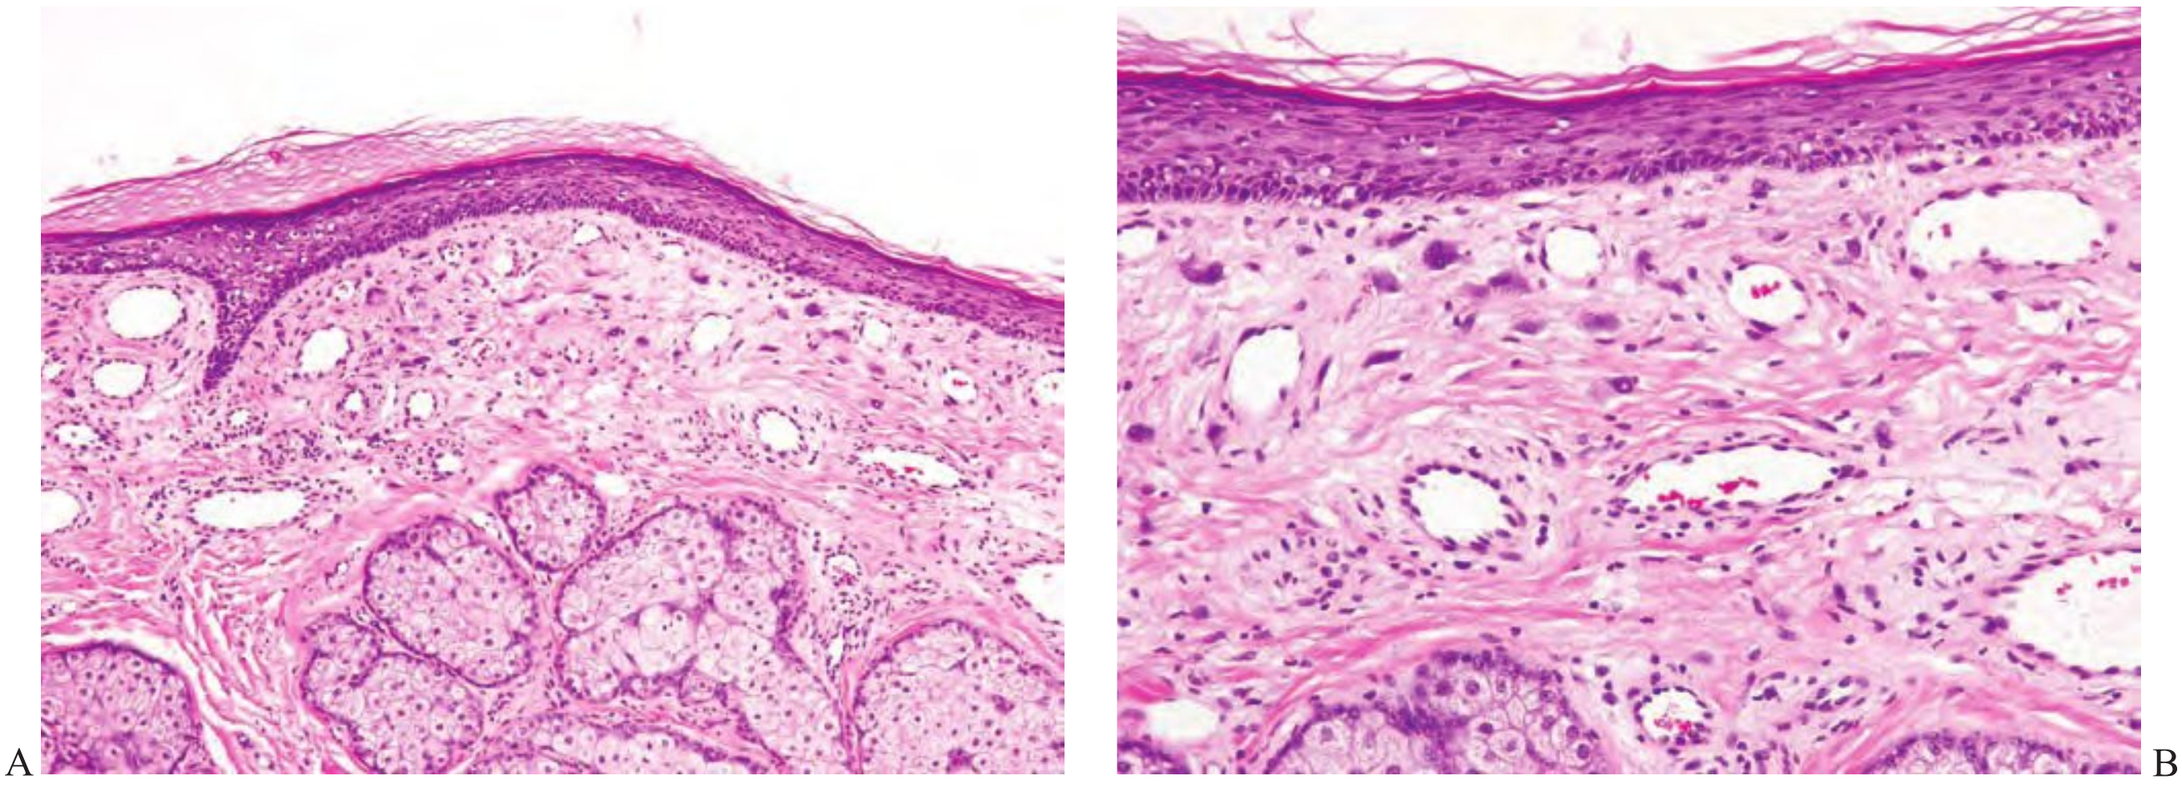
Fibrous Papule of the Face

These common lesions typically occur on the nose or adjacent skin of adults. They present as small, firm, dome-shaped nodules up to 5 mm in diameter. Although originally believed to represent involuting melanocytic nevi (281,282), they are now considered to be a discrete entity (283).

Histopathology. The epidermis is raised, overlying a localized area of fibroplasia and fine vascular proliferation in the upper dermis (Fig. 32-28). There are scattered associated enlarged triangulate or stellate cells, which may be multinucleated (282,284). Atypia may be evident in these cells, with nuclear hyperchromasia, enlargement, and pleomorphism (Fig. 32-29A, B). In some cases, increased melanocytes are seen at the dermoepidermal junction. *Clear cell fibrous papule* appears to be a variant in which the cells show cytoplasmic clearing that is not due to glycogen accumulation (285,286).

Histogenesis. Electron microscopic and immunohistochemical studies indicate that the stromal cells are of fibroblastic or dermal dendrocytic origin rather than melanocytic (287,288). They express factor XIIIa but not S100 protein (289–293).

Cellular angiofibroma appears to be a separate entity that occurs almost exclusively on the vulva. It is a condition of superficial soft tissue origin rather than dermal location and may be related to angiomyofibroblastoma (294). Similarly, *giant cell angiofibroma* appears to be unrelated to dermal angiofibromas, showing features more in common with solitary fibrous tumor (295).



Pearly Penile Papules

These small (1 to 3 mm in diameter), persistent white papules occur mainly on the coronal margin and sulcus of the penis and rarely on the glans in groups or rows in about 10% of young men. They do not appear to be related to human papillomavirus infection (296).

Histopathology. The features are typical of an angiofibroma, without associated hair follicles (297).

Tuberous Sclerosis

Tuberous sclerosis is a rare genetic disorder that may be inherited in an autosomal dominant pattern or present as a new spontaneous mutation (298,299). A variety of cutaneous lesions occur with systemic defects in wide-ranging body systems, including the brain, kidney, eye, and lung (300). The majority of patients develop multiple facial angiofibromas (previously misleadingly termed adenoma sebaceum). These tumors consist of numerous small, red papules in symmetric distribution over the nose, cheeks, and chin. Soft fibromas may also develop on the face and the scalp, with skin tags and subungual and periungual fibromas a frequent finding. Shagreen patches are usually found in the lumbosacral region and consist

A B

FIGURE 32-29. Angiofibroma. This angiofibroma shows prominent atypical stromal cells—a not uncommon finding of no sinister significance.

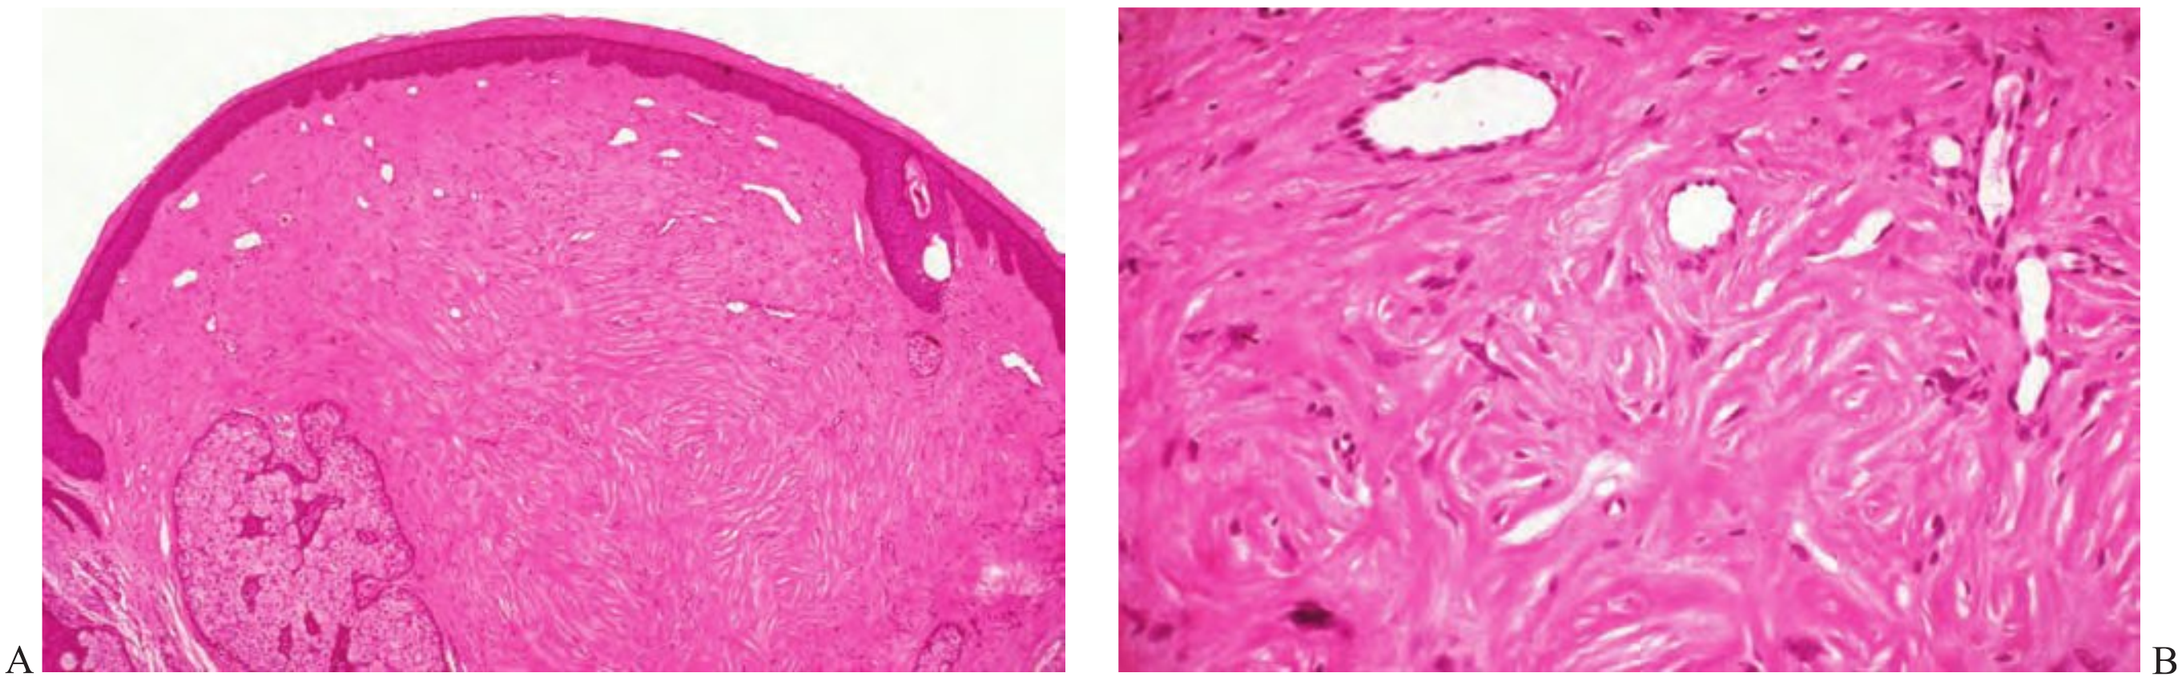


FIGURE 32-30. Angiofibroma arising in tuberous sclerosis. A: The epidermis is raised in a dome-shaped pattern overlying a zone of compact fibroplasia with prominent blood vessels in the upper half. B: The typical features of an angiofibroma are seen with sclerotic, hyalinized stroma, with scattered spindle and stellate cells and telangiectatic blood vessels.

of slightly raised, yellowish, leathery areas of skin. Various hypopigmented skin lesions are present in more than half of patients with tuberous sclerosis; significantly, they may be present at birth or appear at an early age and are often the earliest indication of tuberous sclerosis (301).

Genetic studies show linkage to chromosome 9q34 (TSC1) or to chromosome 16p31 (TSC 2) in many patients with TSC (298,299,302–304). Two thirds of cases are sporadic and are assumed to result from new mutations, many of which are in TSC 2 (304). TSC 2 patients tend to have more severe disease with greater numbers of hypopigmented lesions (298).

Systemic Lesions. Multiple tumors are commonly found in the brain (gliomas, often calcified) (305), retina (gliomas) (306), heart (rhabdomyomas) (307), and kidneys (angiomyolipomas) (308).

Histopathology. The angiofibromas show a fine vascular proliferation in the dermis with associated fibrosis and occasional reactive stromal cells (309). Elastic tissue is absent in these lesions, and compression of adnexae may be seen (Fig. 32-30A, B).

The soft fibromas on the face and scalp show markedly sclerotic collagen arranged in thick, concentric layers around atrophic pilosebaceous follicles. In contrast to the angiofibromas, dilated capillaries are usually absent. Giant angiofibroma (310) and a cluster growth of large nodules (311) have also been reported.

The ungual fibromas show fibrosis, occasionally with capillary dilation. The shagreen patches have the histologic features of connective tissue nevi, with either a dense, sclerotic mass of broad collagen bundles in the dermis, mimicking morphea, or normal collagen bundles interwoven throughout the dermis. The elastic tissue in some instances shows fragmentation and clumping (309) but is generally reduced in amount (312).

The hypopigmented areas show a normal number of melanocytes, with decreased pigmentation. On electron microscopy, the melanosomes within the melanocytes and keratinocytes are smaller and show reduced melanization (301,312).

Differential Diagnosis. The angiofibromas seen in tuberous sclerosis are often histologically identical to solitary angiofibromas (fibrous papules of the face). The shagreen patches of tuberous sclerosis differ from other connective tissue nevi by the reduced amount of elastin present.

Acral Fibrokeratoma (Acquired Digital Fibrokeratoma, Periungual Fibroma)

Acral fibrokeratoma is considered by some authors to fall within the spectrum of angiofibromatous proliferations, although the vascular component may be limited. Lesions normally present as solitary firm, hyperkeratotic projections from the finger or toe but are occasionally sited on the palm or sole (312–314). Some appear to originate from the nail bed (315,316), and there are isolated examples of large size (314,317). Tumors arise in adults, with rare cases of familial multiple acral mucinous fibrokeratoma and multiple acral fibromas associated with familial retinoblastoma, which may represent cutaneous markers of tumor suppressor gene germline mutation (318,319). Some lesions are associated with tuberous sclerosis.

Histopathology. There is hyperkeratosis and acanthosis with broad, often branching rete ridges. In the core are prominent interwoven collagen bundles mostly vertically oriented (Fig. 32-31). Elastic fibers are present but are normally thin and sparse. Many tumors show abundant fine vessels. Recently, a *cellular variant* has been described that shows features similar to DFSP, including CD34 positivity (320). Some authors consider that this may in fact represent a form of superficial acral fibromyxoma (321).

Differential Diagnosis. Rudimentary supernumerary digits may appear similar clinically and histologically. However,

FIGURE 32-31. Digital fibrokeratoma. A polypoid lesion with acanthotic epidermis overlying dense bundles of collagen in the dermis.

rudimentary polydactyly almost always occurs at the base of the fifth finger, is present from birth, and is often bilateral. Histologically, numerous nerve bundles are present, especially at the base of the lesions.

Nuchal-Type Fibroma (Nuchal Fibroma)

Nuchal fibroma is an uncommon lesion typically arising on the posterior neck of adult men (322,323). Similar changes have also been seen at a number of nonnuchal sites, leading to the inclusion of the qualifier "type" into the name. A large proportion of patients have diabetes mellitus, and consideration should be given to the possibility of Gardner's syndrome (see discussion below) (322). Lesions occasionally recur but do not metastasize.

Histopathology. In the dermis and subcutis there is a poorly circumscribed mass containing haphazardly arranged collagen bundles with sparse, bland, spindle-shaped cells (Fig. 32-32). There is frequently entrapment of fat and a proliferation of fine nerves resembling a traumatic neuroma. Inflammation is not a feature, and elastin fibers may be reduced in number (324).

Histogenesis. A fibroblastic origin is proposed, with immunohistochemical staining showing CD34 positivity in the spindle cells in some cases (324).

Differential Diagnosis. *Gardner's fibroma* is considered to be similar, if not identical, histologically, but it occurs in the context of Gardner's syndrome (322,324–326). It may be the presenting feature of that syndrome, which represents a form of familial adenomatous polyposis coli with osteomas and epidermoid cysts (325). Some authors recognize fibromatous proliferations in patients with Gardner's syndrome that have a more diverse appearance than typical nuchal fibroma (326,327). Recurrence of Gardner's fibromas as desmoid tumors has been recorded (325). Elastin fibers are decreased in number, in contrast to elastofibroma (324).

Superficial Acral Fibromyxoma

This uncommon tumor was first described in a series of 37 cases in 2001 (328). The lesions are almost always sited on the toes or fingers, often close to the nail, and average about 2 cm in size (328–331). A few have been reported on the palm (328), and lesions may be of long duration at presentation. A broad range of ages may be affected, but many patients are young adults. The course is benign, with recurrence uncommon.

Histopathology. Tumors are sited in the dermis or subcutis and show a partly circumscribed proliferation of spindle to stellate cells in loose fascicles. There may be mild nuclear atypia and occasional multinucleated stromal cells, but mitoses are sparse. A myxocollagenous matrix bears fine vessels, with mast cells often conspicuous (Fig. 32-33A, B).

Histogenesis. The majority of tumors stain prominently with CD34 and frequently with epithelial membrane antigen and CD99 (328,330). S100, actin, desmin, keratins, and HMB-45 are typically negative.

Differential Diagnosis. The appearances have features in common with a variety of other connective tissue lesions, especially those with a tendency to become myxoid. However, correlating the clinical setting, histology, and immunostaining pattern should lead to the correct diagnosis.

Angiomyofibroblastoma of the Vulva

Angiomyofibroblastoma is a benign tumor that occurs mainly in the vulvovaginal region of middle-aged premenopausal women (332) but has also been rarely described in the inguinoscrotal region of males. It presents as a circumscribed tumor 0.5 to 12 cm in size and is often mistaken clinically for a Bartholin's gland cyst. The tumors do not recur when treated with local excision (333–335).

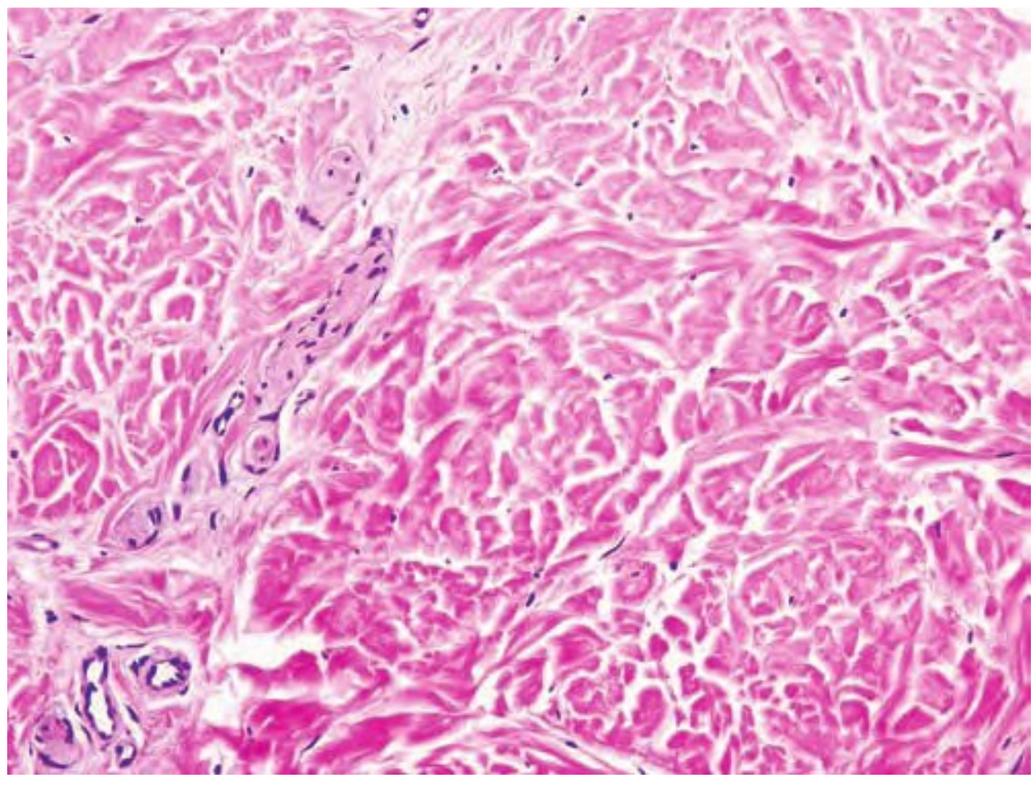

FIGURE 32-32. Nuchal-type fibroma. The tumor is hyalinized and poorly cellular. Note the small nerve twigs within the lesion.

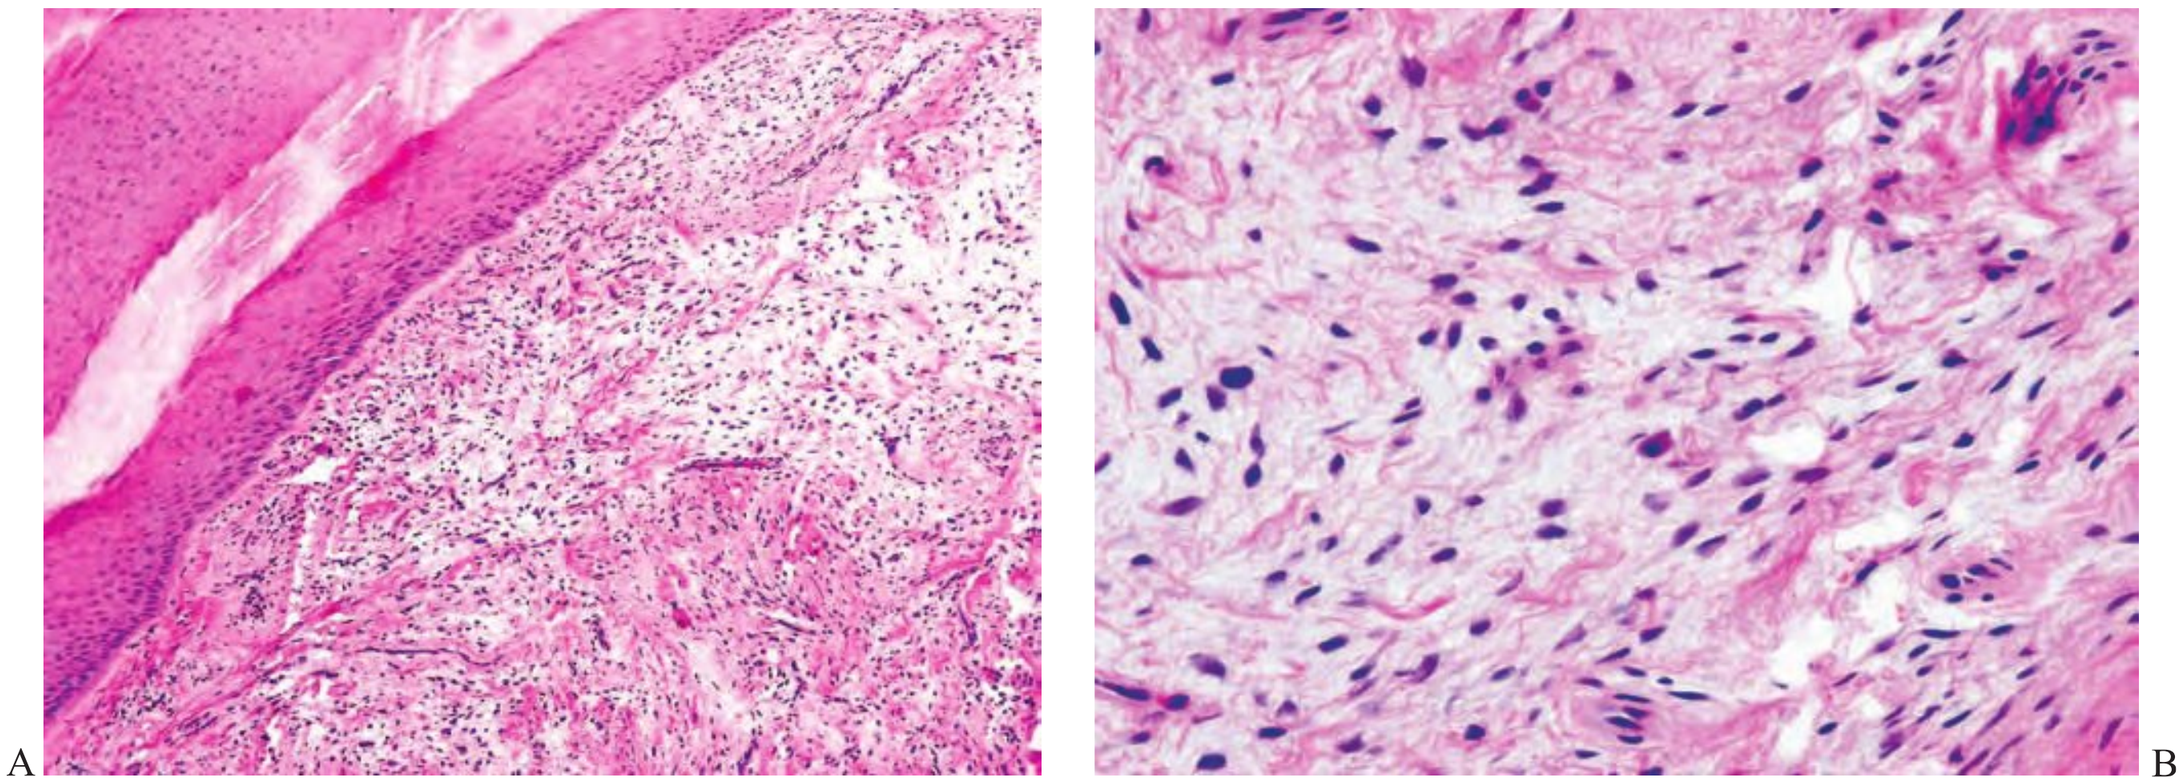

FIGURE 32-33. Superficial acral fibromyxoma. A: This lesion was from under the big toe nail, seen in the upper left of the photograph, a common site of origin. B: Myxoid stroma is present with nondescript, bland, spindle-shaped cells. These were CD34 and epithelial membrane antigen positive on immunohistochemistry.

Histopathology. Angiomyofibroblastomas are well-circumscribed tumors composed of hypercellular and hypocellular areas. There are plump epithelioid or spindle cells with moderate amounts of eosinophilic cytoplasm arranged singly, in clusters, or forming linear arrays around numerous small to medium-sized dilated capillaries within an edematous stroma. Some of the cells may have eccentric nuclei, imparting a plasmacytoid appearance. Multinucleated cells are not uncommon. There is minimal cytologic atypia, and mitoses are generally difficult to find (333–337). An adipose tissue component is present in some cases (338).

Histogenesis. The tumor cells of angiomyofibroblastoma are desmin positive and actin negative in most cases. Occasional cases are smooth muscle actin positive (333–337). The cells also express estrogen and progesterone receptors (33,338,339).

Differential Diagnosis. In contrast to angiomyofibroblastoma, aggressive angiomyxoma has an infiltrating growth pattern, prominent hyalinized vessels, and mucin within the stroma. The cells of aggressive angiomyxoma are actin positive and desmin negative.

Angiofibroblastoma of the Skin

Angiofibroblastoma of the skin is a benign neoplasm that occurs as small, solitary dermal nodules on the extremities of adults (340,341).

Histopathology. There are dome-shaped, circumscribed nodules in the upper dermis composed of stellate and spindle fibroblasts embedded in a fibromyxoid and fibrous matrix. There are focal collections of stellate cells arranged in a whorled pattern with numerous capillary-sized vessels present throughout the lesion. Mitotic figures are not a feature.

Histogenesis. Immunohistochemical and ultrastructural studies of the tumor cells support fibroblastic differentiation. Both stellate and spindle cells show focal positivity for muscle-specific actin but are negative for smooth muscle actin. Factor XIIIa is present only in associated dendritic cells (341).

Differential Diagnosis. Angiofibroblastoma is more cellular than sclerotic fibroma and does not express CD34. Giant cell fibroblastomas develop in infants and consist of cells that express CD34, pseudovascular spaces, and large, multinucleated cells. Myxoid neurofibromas contain S100-positive Schwann cells with wavy nuclei. Angiomyofibroblastomas present in the vulva and are characterized by desmin-positive cells clustered around vessels within edematous stroma. Although perineuriomas also possess spindle cells arranged in a whorled pattern, they are generally EMA positive (341).

Fibromatosis Colli

Fibromatosis colli presents 2 to 4 weeks after birth as a hard, immobile, fusiform swelling in the mid or lower portions of the sternocleidomastoid muscle, causing the head to tilt toward the side of the affected muscle (342). There is a high associated incidence of preceding breech and forceps delivery. However, the lesion develops *in utero* and not as a consequence of birth trauma as was once believed (343). Some cases are associated with congenital musculoskeletal abnormalities, including congenital dysplasia of the hip and rib cage anomalies (344–346). Most cases respond well to conservative treatment (344). Less than 20% require surgical therapy (342). Fine-needle-aspiration cytology has been reported to be a reliable method of diagnosing these tumors (347,348).

Histopathology. There are proliferating fibroblasts of varying cellularity in a collagenous stroma partially replacing the skeletal muscle. There is little or no pleomorphism and a lack of mitotic activity. Atrophic and degenerate skeletal muscle fibers are entrapped with the lesion.

Intermediate Biological Potential (Locally Aggressive)

Desmoid-Type Fibromatosis (Aggressive Fibromatosis, Desmoid Tumor, Musculoaponeurotic Fibromatosis)

Desmoid-type fibromatoses are benign clonal fibroblastic proliferations that arise as firm, nontender masses from muscular aponeuroses and tend to invade the muscle. This infiltrative growth pattern predisposes to local invasiveness and recurrence, but the lesions do not metastasize. Their rate of growth is slow, but the lesions may attain considerable size, as large as 25 cm in diameter (349). Although usually solitary, they may be multiple (350). Desmoid fibromatoses may occur in children, but they are seen mainly in young adults, particularly in women, the most common type arising from the rectus abdominis muscle after pregnancy. The lesions also occur as extraabdominal masses in older adults in equal gender distribution (351).

The association of desmoid fibromatoses with familial adenomatous polyposis and Gardner's syndrome is well documented. The prevalence in familial adenomatous polyposis is between 10% and 25% (352). Adenomatous polyposis coli gene mutation occurs in desmoid-type fibromatosis in patients with familial polyposis and less commonly in sporadic lesions (352–354). Trisomies for chromosomes 8 and 20 also have been demonstrated in some cell subpopulations (355,356).

Histopathology. Desmoid fibromatoses are composed of poorly circumscribed bundles of uniform spindle cells surrounded by abundant collagen with extensive hyalinization, whereas some cases have abundant mucoid matrix. The nuclei are small, regular, and pale staining, with a variable mitotic rate. The lesions frequently infiltrate adjacent striated muscle, entrapping atrophic muscle fibers (Fig. 32-34A, B) (349).

Histogenesis. Ultrastructurally, the spindle cells of desmoid fibromatosis show features of fibroblasts or myofibroblasts (350,357,358). Immunostaining shows variable smooth muscle actin and muscle-specific actin positivity (359).

Palmar Fibromatosis (Dupuytren's Contracture)

Palmar fibromatosis presents as a benign, slow-growing nodule or cordlike thickening on the volar surface of the hands accompanied by flexion contracture of the digits. The incidence rises with increasing age, and bilateral disease is common. There is a higher incidence among patients with epilepsy, diabetes, or alcoholic liver disease and heavy smokers. There is a genetic predisposition, and some studies show an association with manual labor (360–366). *Plantar fibromatosis* is a similar lesion that arises from the plantar aponeurosis and rarely causes flexion contractures of the toes. Palmar and plantar fibromatoses and knuckle pads can develop in the same patient (367,368).

Histopathology. Early lesions consist of multinodular cellular proliferations of uniform plump, spindle-shaped fibroblastic cells within a collagenous stroma (Fig. 32-35). Mitotic figures may be present but are usually infrequent. Longstanding lesions are less cellular and contain increased amounts of dense collagen.

Histogenesis. The cells variably express smooth muscle and muscle-specific actin (369). Ultrastructural studies show features of fibroblasts and myofibroblasts (370,371).

Knuckle Pads

Knuckle pads are uncommon, entirely benign fibroblastic tumors that present as persistent, slow-growing lesions over the extensor surfaces of the proximal interphalangeal and metacarpophalangeal joints (372). The lesions are flesh colored, flat or dome shaped, and freely mobile and mostly arise in men

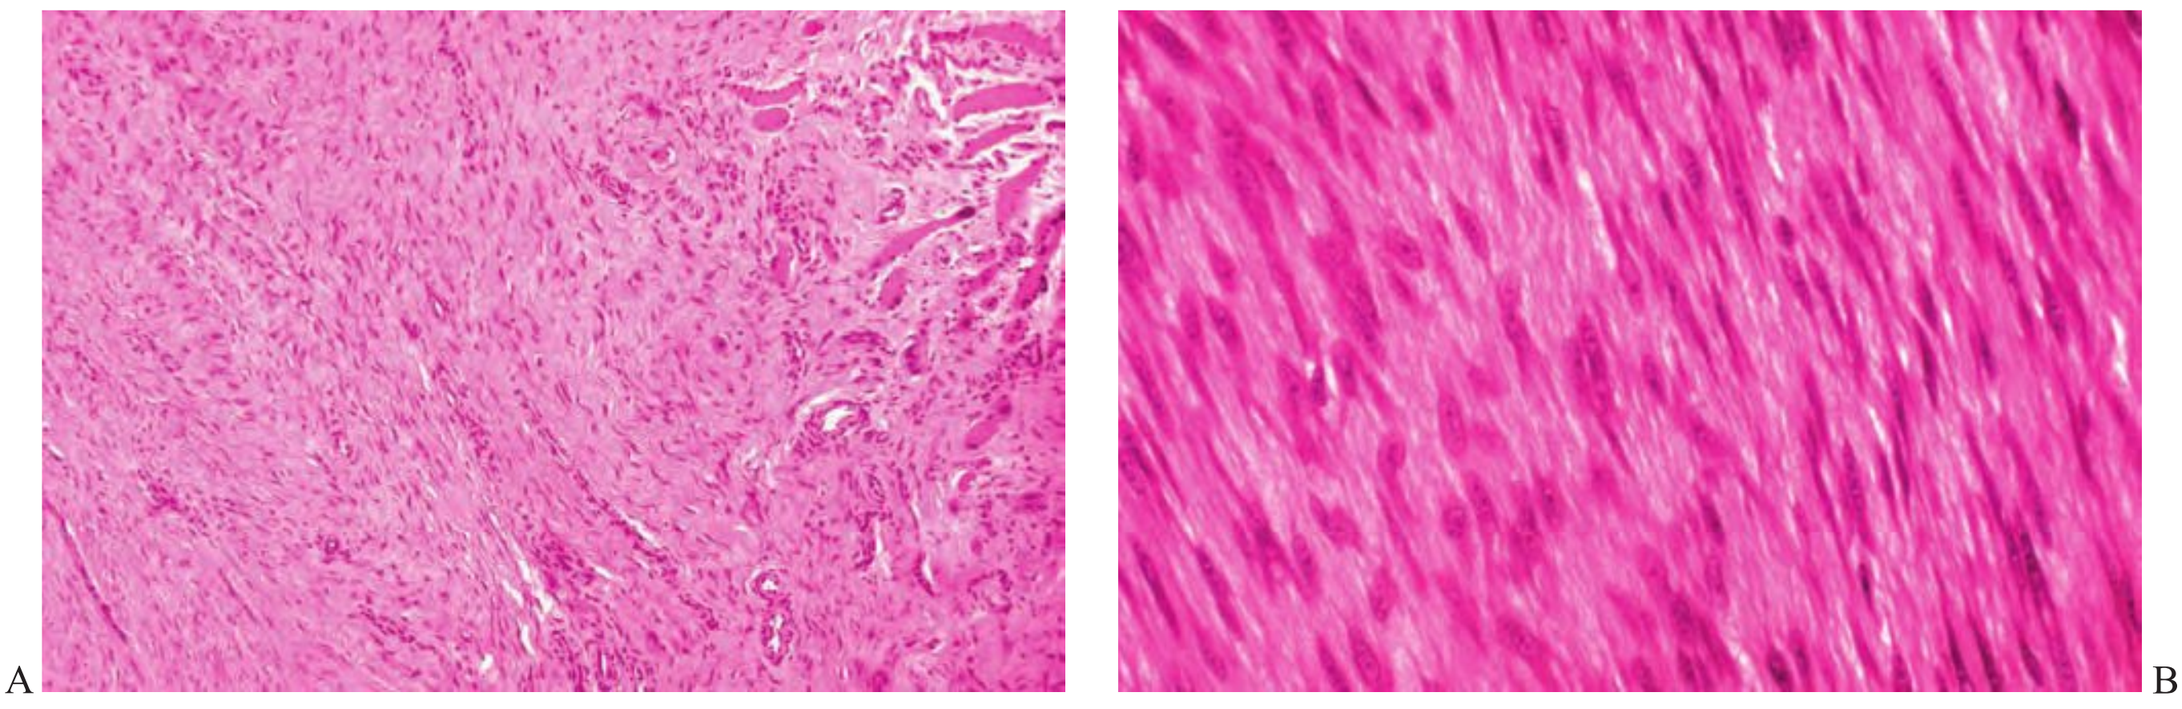

FIGURE 32-34. Desmoid type fibromatosis (desmoid tumor). A: A mass composed of dense bundles of eosinophilic spindle cells is present within striated muscle (right). B: The tumor cells are monomorphic, with regular nuclei and pale eosinophilic cytoplasm.

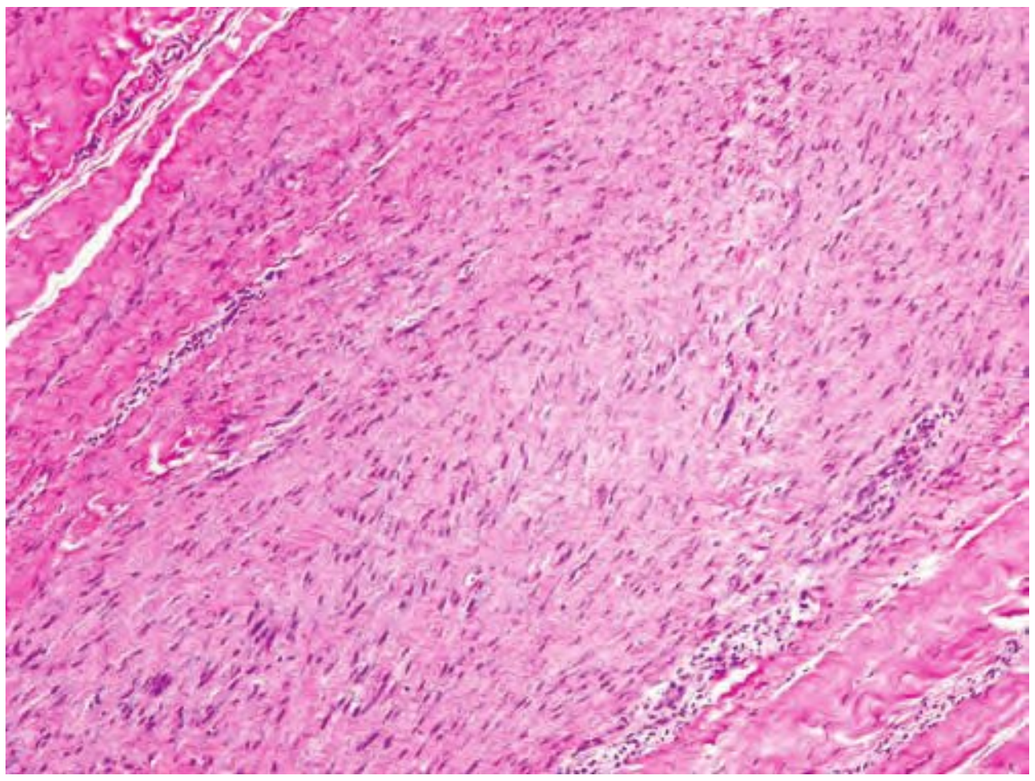

FIGURE 32-35. Palmar fibromatosis (Dupuytren's contracture). Proliferation of uniform fibroblastic cells within a collagenous stroma.

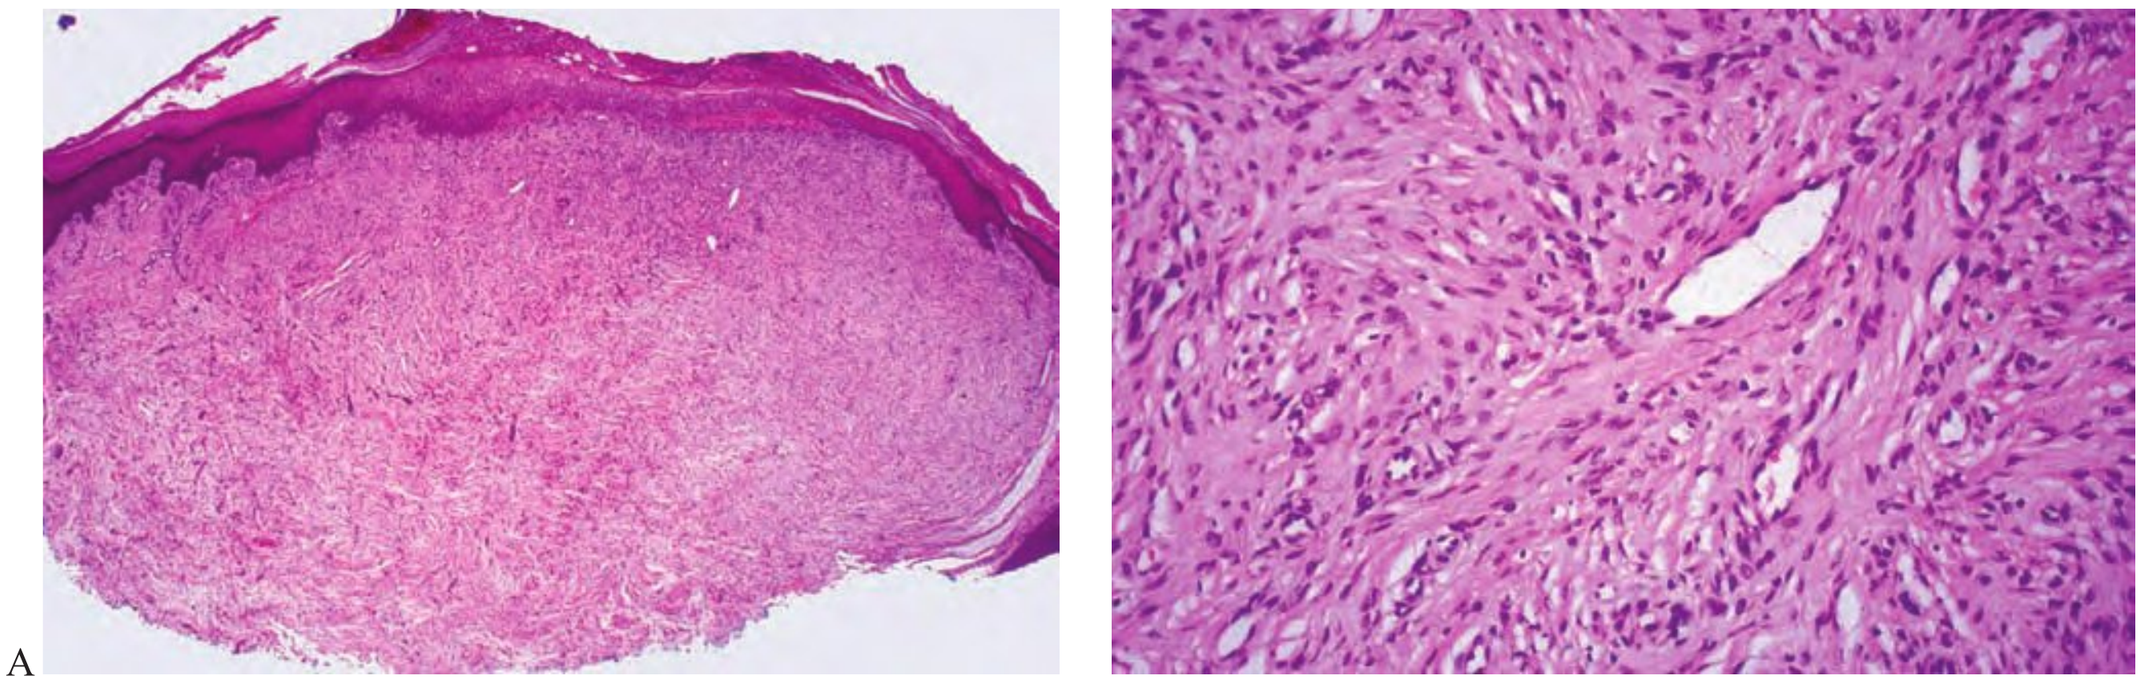
(372). Some patients have coexisting Dupuytren's contractures, and these entities may be related (367).

Histopathology: The histologic features are similar to those of Dupuytren's contracture. There is fibroblastic proliferation, with thickened irregular collagen bundles. The overlying epidermis may show hyperkeratosis and acanthosis (372,373).

Intermediate Biological Potential (Rarely Metastasizing)

Solitary Fibrous Tumor



Solitary fibrous tumor is a rare mesenchymal neoplasm that most commonly involves the pleura but has also been reported in numerous extrapleural locations, including rare cases in the skin (374–377). In the skin, lesions present as a circumscribed nodule, mainly on the head and neck (377,378). Rare metastases from pleural solitary fibrous tumors have been reported, but all documented cutaneous tumors appear to be benign and cured by complete excision (374).

Histopathology: The tumors are circumscribed, unencapsulated nodules involving the dermis, subcutis, and fascia. Lesions are typically described as having a "patternless pattern" with hypercellular and hypocellular areas composed of bland spindle cells with pale vesicular nuclei, inconspicuous nucleoli, and indistinct cell borders. The spindle cells form fascicles or storiform patterns similar to dermatofibrosarcoma protuberans, alternating with a vascular component of ectatic vessels and slit-like staghorn vessels presenting a hemangiopericytoma-like appearance. Abundant hyalinized collagen makes up the less cellular areas (Fig. 32-36A, B), and mitotic activity is inconspicuous. The cells express CD34, CD99, bcl-2, and, focally, factor XIIIa, but they are negative for smooth muscle, neural, and epithelial markers (376,377,379).

Inflammatory Pseudotumor

Inflammatory pseudotumor encompasses a heterogeneous group of lesions also known as inflammatory myofibroblastic tumor and plasma cell granuloma. The tumor was originally described in the lung but has since been reported in other organs, including rare cases in the skin. The exact pathogenesis of inflammatory pseudotumor is unclear. Some lesions probably represent an exaggerated response to an antigenic stimulus such as an infectious agent, whereas others are true neoplasms (380–383). Although tumors in extracutaneous sites can recur and occasionally metastasize, all cases reported in the skin have behaved in an indolent manner, with no reports of recurrence after complete excision (384).

Histopathology: Inflammatory pseudotumors present as circumscribed, unencapsulated lesions confined to the dermis or involving both dermis and subcutaneous fat. Two histologic patterns have been described in the skin (381–386). The first consists of bland spindle cells arranged in fascicle or storiform

A B

FIGURE 32-36. Solitary fibrous tumor. A: A circumscribed dermal nodule is present with some overlying reactive epidermal hyperplasia. B: Prominent vascularity is seen extending between bland "patternless" spindle cells.

pattern admixed with variable numbers of inflammatory cells within myxoid and collagenous stroma. Although mitotic figures are usually present, there is no nuclear pleomorphism. The predominant inflammatory cells are plasma cells and small lymphocytes. Lymphoid follicles with germinal centers, eosinophils, and neutrophils may also be present. The second pattern is characterized by nodules composed of lymphocytes and plasma cells in a background of thick, hyaline collagen bundles arranged in intersecting or onion skin-like pattern without spindle cells. Giant histiocyte-like cells and Reed-Sternberg–like cells were described in one case report (381).

Histogenesis. The spindle cells are smooth muscle actin positive (381,383,384). Ultrastructural studies demonstrate features of myofibroblastic and fibroblastic differentiation (385). Immunoreaction to anaplastic lymphoma kinase (ALK) has been reported in up to 60% of extracutaneous cases, mostly in lesions from the pediatric population and young adults (380,387,388). There have been no reports of ALK in cutaneous lesions. ALK protein is a product of t(2;5) chromosomal translocation, adding support to the belief that some of these tumors are genuine neoplasms of myofibroblasts.

Differential Diagnosis. Nodular fasciitis typically presents as a rapidly developing tumor consisting of plump myofibroblasts within myxoid stroma imparting a "tissue culture" appearance accompanied by a sparse inflammatory infiltrate and red blood cell extravasation. Dermatofibromas are less well circumscribed, are usually associated with epidermal hyperplasia, and lack the prominent lymphoplasmacytic infiltrate.

TUMORS OF UNCERTAIN DIFFERENTIATION

Benign

Multinucleated Cell Angiohistiocytoma

Multinucleated cell angiohistiocytoma is an uncommon lesion that presents in middle-aged to elderly women as grouped red-to-brown or violaceous, circumscribed, dome-shaped tumors. Lesions occur in acral regions, most commonly the lower legs, wrists, and back of the hands and on the face. The tumors have a smooth surface and range from 2 to 10 mm in size. Some of the papules may coalesce to form larger annular lesions. They are benign lesions that progress slowly and persist, although spontaneous regression has been reported in some cases (389–394). One case of generalized multinucleated cell angiohistiocytoma was described (395). The pathogenesis of multinucleated cell angiohistiocytoma is uncertain.

Histopathology. The lesions are characterized by fine vessels with prominent endothelium in a fibrous stroma. There are sparse perivascular lymphocytes, with neutrophils and plasma cells present in some cases. Characteristically, there are increased numbers of large, irregular, bizarre mononuclear or multinucleated cells with hyperchromatic nuclei and scalloped basophilic cytoplasm in the interstitium. The epidermis may be hyperplastic (389–394).

Histogenesis. The mononuclear interstitial cells express lysozyme and factor XIIIa. The multinucleated cells are immunoreactive only for vimentin (389,391,393,394).

Intermediate Biological Potential (Rarely Metastasizing)

Angiomatoid Fibrous Histiocytoma

This tumor is now considered to be of intermediate biological potential (rarely metastasizing) and was previously known as "angiomatoid malignant fibrous histiocytoma" (161,162). The prognosis is generally good, with recurrence seen in some cases, primarily related to incomplete excision (66). Metastases arise in 5% or less of patients and are usually confined to local lymph nodes only, but fatalities occasionally occur (66,161,162,396). This tumor should not be confused with aneurysmal fibrous histiocytoma, which might be better described as dermatofibroma with aneurysmal change (22) (see page 970).

The tumor occurs most often on the extremities of children and young adults as a slowly growing nodular or cystic mass of the dermis or subcutis (66,397). There may be associated pain and systemic symptoms such as anemia, pyrexia, and weight loss.

Histopathology. The tumors show hemorrhagic cystic areas lined by flattened, attenuated tumor cells that are not endothelial. Associated multinodular groups of eosinophilic histiocytoid or myoid cells are present in varying patterns with an infiltrate of lymphocytes and plasma cells (Fig. 32-37A, B) (162). Mitotic activity and atypia are not usually prominent. Stromal desmoplasia may efface much of the tumor in some instances. The overall pattern may suggest a lymph node, with lymphoid tissue with follicles and germinal centers and a thick pseudocapsule.

Histogenesis. The cell of origin of this entity is unclear, with varying results using immunohistochemistry (65,398). Many cases are CD68 positive, but the expression of desmin in some cases has been interpreted as evidence of myoid or myofibroblastic differentiation (65,162). Vascular markers such as CD31 and CD34 are negative in the tumor cells. It should be noted that myogenin and MyoD1 are negative in these cases, in contrast to rhabdomyosarcoma (22). Some cases are epithelial membrane antigen positive (399). Cytogenetic studies have been performed in a few cases, revealing t(12;16) and t(12;22) translocations (400).

Malignant

Synovial Sarcoma

Synovial sarcoma most commonly occurs on the limbs, particularly the thigh, of young and middle-aged adults. Superficial lesions adjacent to the joints of the hand, foot, or knee sometimes present with dermal involvement (401,402). The chromosomal translocation t(X;18) (p11;q11) has been

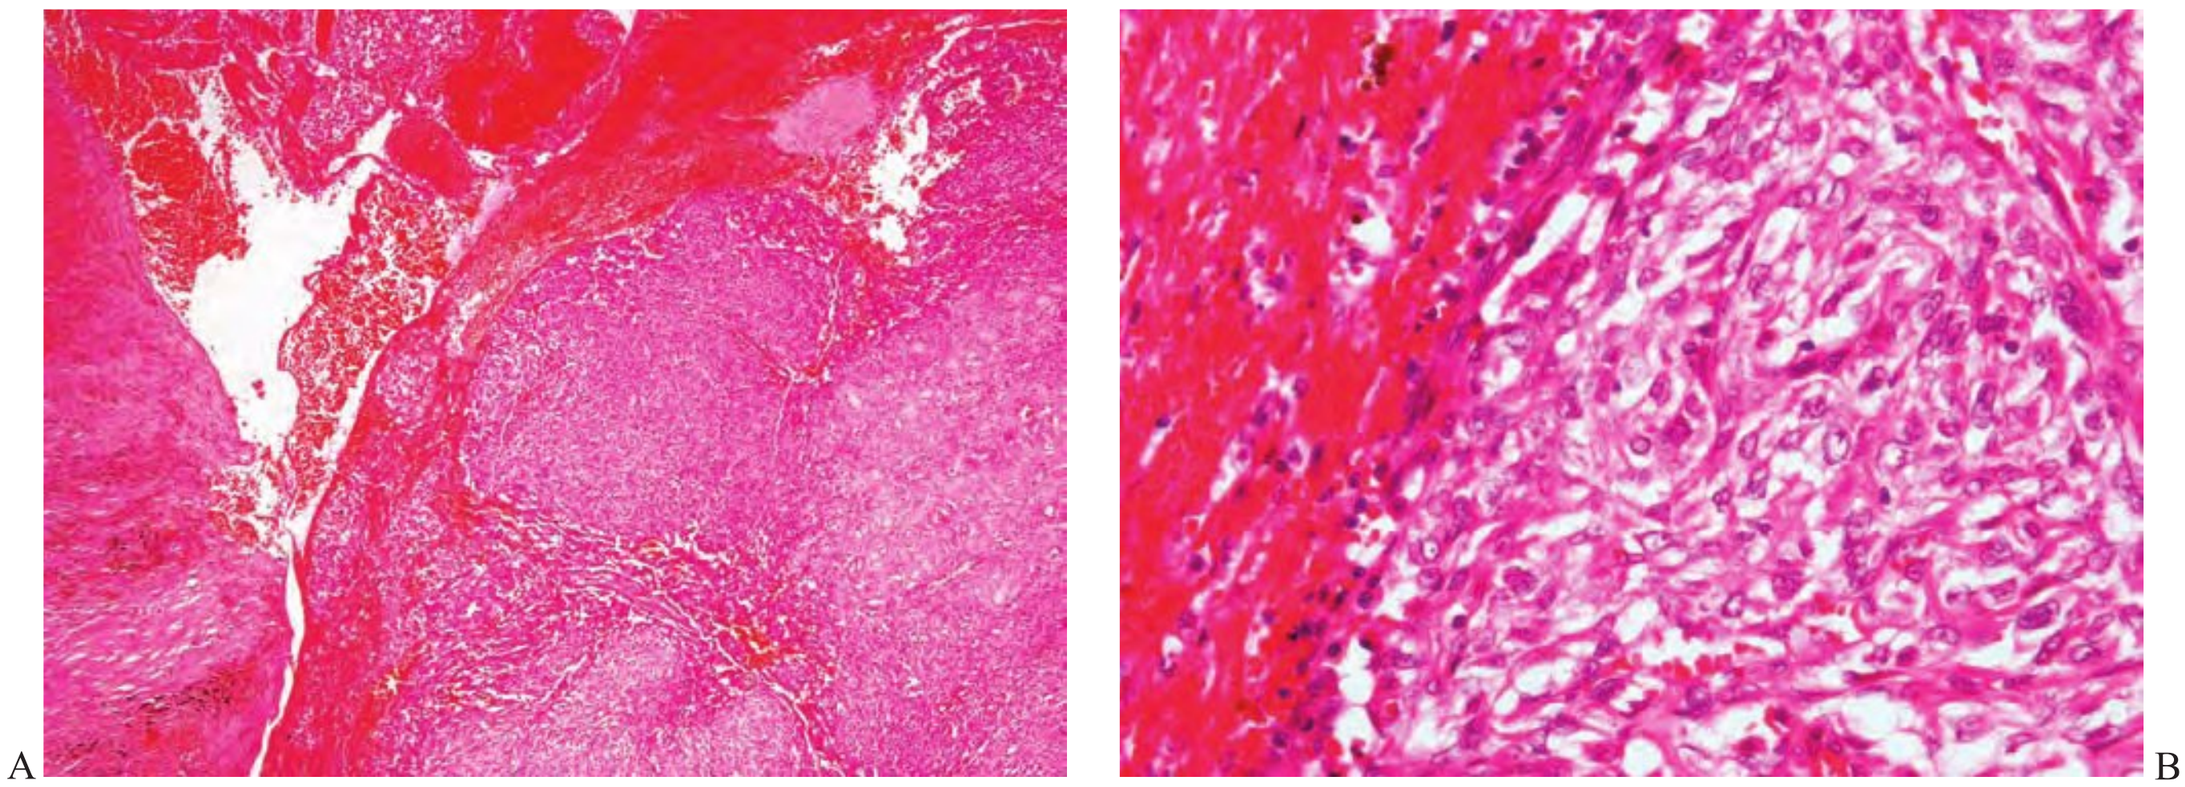


FIGURE 32-37. Angiomatoid fibrous histiocytoma. A: This 20-year-old man had severe anemia associated with this lesion, which was sited on the shoulder. Blood-filled spaces are prominent, with surrounding pale zones of tissue. B: Pale histiocytoid cells are present in the wall of the blood-filled spaces that do not show an endothelial lining.

described in the majority of cases of synovial sarcoma (403,404), but cytogenetic analysis is not considered mandatory for diagnosis (405).

Histopathology. The tumor typically presents a biphasic pattern, including an epithelioid cell component forming glandular spaces and a uniform small, spindle cell component resembling fibrosarcoma (Fig. 32-38). Monophasic synovial sarcoma is composed usually only of spindle cells. Purely glandular monophasic synovial sarcoma theoretically exists but without cytogenetic analysis would be indistinguishable from adenocarcinoma (406). Most tumors express EMA and low and high molecular-weight cytokeratins, including cytokeratins 7 and 19. It is of note that the latter are not found in malignant peripheral nerve sheath tumor or Ewing's sarcoma (406). S100 is stainable in 30% of cases (407).

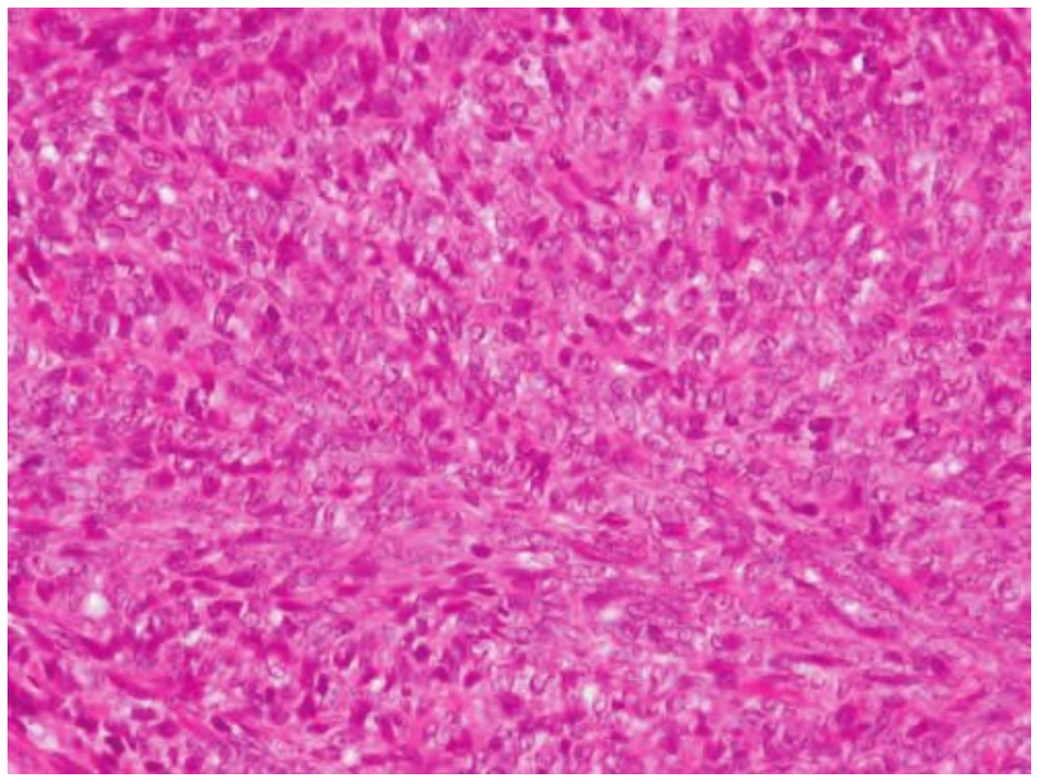

FIGURE 32-38. Synovial sarcoma. A cellular proliferation of fairly monomorphic, ovoid to spindle-shaped cells is seen in this monophasic tumor. Immunohistochemistry showed cytokeratin positivity in these cells.

Histogenesis. Immunohistochemical and ultrastructural features indicate that the tumor is not derived from synovium, leading to suggestions of alternative terms such as connective tissue carcinosarcoma and soft tissue carcinoma (408,409). The distribution of collagens, fibronectin, laminin, and tenascin in synovial sarcoma suggests similarities with the embryonic development of epithelia from mesenchymal cells, supporting the concept that synovial sarcoma is a soft tissue carcinosarcoma (410).

Prognostic factors include tumor size, differentiation, and patient age, with younger patients faring more favorably (411–413).

Epithelioid Sarcoma

Epithelioid sarcoma is a rare, highly malignant soft tissue neoplasm of uncertain histogenesis. It occurs most commonly on the distal limbs of young men as a slowly growing nodule or plaque (Fig. 32-39) (414,415). Occasionally, it also arises at a variety of other sites, including the head, neck, pelvis, and genital region (416–421). Most lesions are sited in subcutis or soft tissue, but occasional examples present primarily in the dermis and upper subcutis. Recurrence and metastasis are frequent, usually to lymph nodes and lung (415). Prognosis is related to tumor size and is more favorable in females (423).

Histopathology. Tumors are composed of nodules of atypical epithelioid cells with pleomorphic nuclei and variable amounts

FIGURE 32-39. Epithelioid sarcoma. Ulcerated nodules on the back of the hand of a 32-year-old. The patient died from systemic metastases 18 months later.

of eosinophilic cytoplasm. These merge with spindle cells and an associated fibrous stroma, in which there may be hemorrhage, hemosiderin, and mucin deposition with a patchy peripheral lymphocytic infiltrate. Variable mitotic activity is seen, with frequent vascular and perineural invasion. Necrosis is characteristically present in the center of tumor nodules, contributing to the granulomatous appearance. Foci of calcification and ossification may be present. The lesions are diffusely invasive and may show overlying ulceration (Fig. 32-40A–C).

Positive immunostaining is seen for cytokeratin, vimentin, EMA, and, frequently, CD34 and actin (424).

A *spindle cell (fibroma-like) variant* of epithelioid sarcoma also occurs, in which the spindle cell pattern predominates without the characteristic epithelioid cells and nodularity (425,426).

Proximal-type epithelioid sarcoma is an aggressive variant occurring predominantly in the pelvis, perineum, and genital tract of older adults. It frequently shows rhabdoid features microscopically, simulating extrarenal rhabdoid tumor (427,428).

Histogenesis. The histogenesis of epithelioid sarcoma is uncertain, but the ultrastructural features of desmosome-like intercellular junctions, numerous microvilli, and whorled arrangements of intermediate filaments (416,429), allied with immunoreactivity for EMA, cytokeratin, vimentin, and, in many cases, CD34 and actin, suggest an origin from primitive mesenchymal cells with the capacity for epithelial differentiation (424). Cytogenetic studies have shown various chromosomal aberrations, including frequent loss of 22q (430). However, no specific, reproducible changes have been identified.

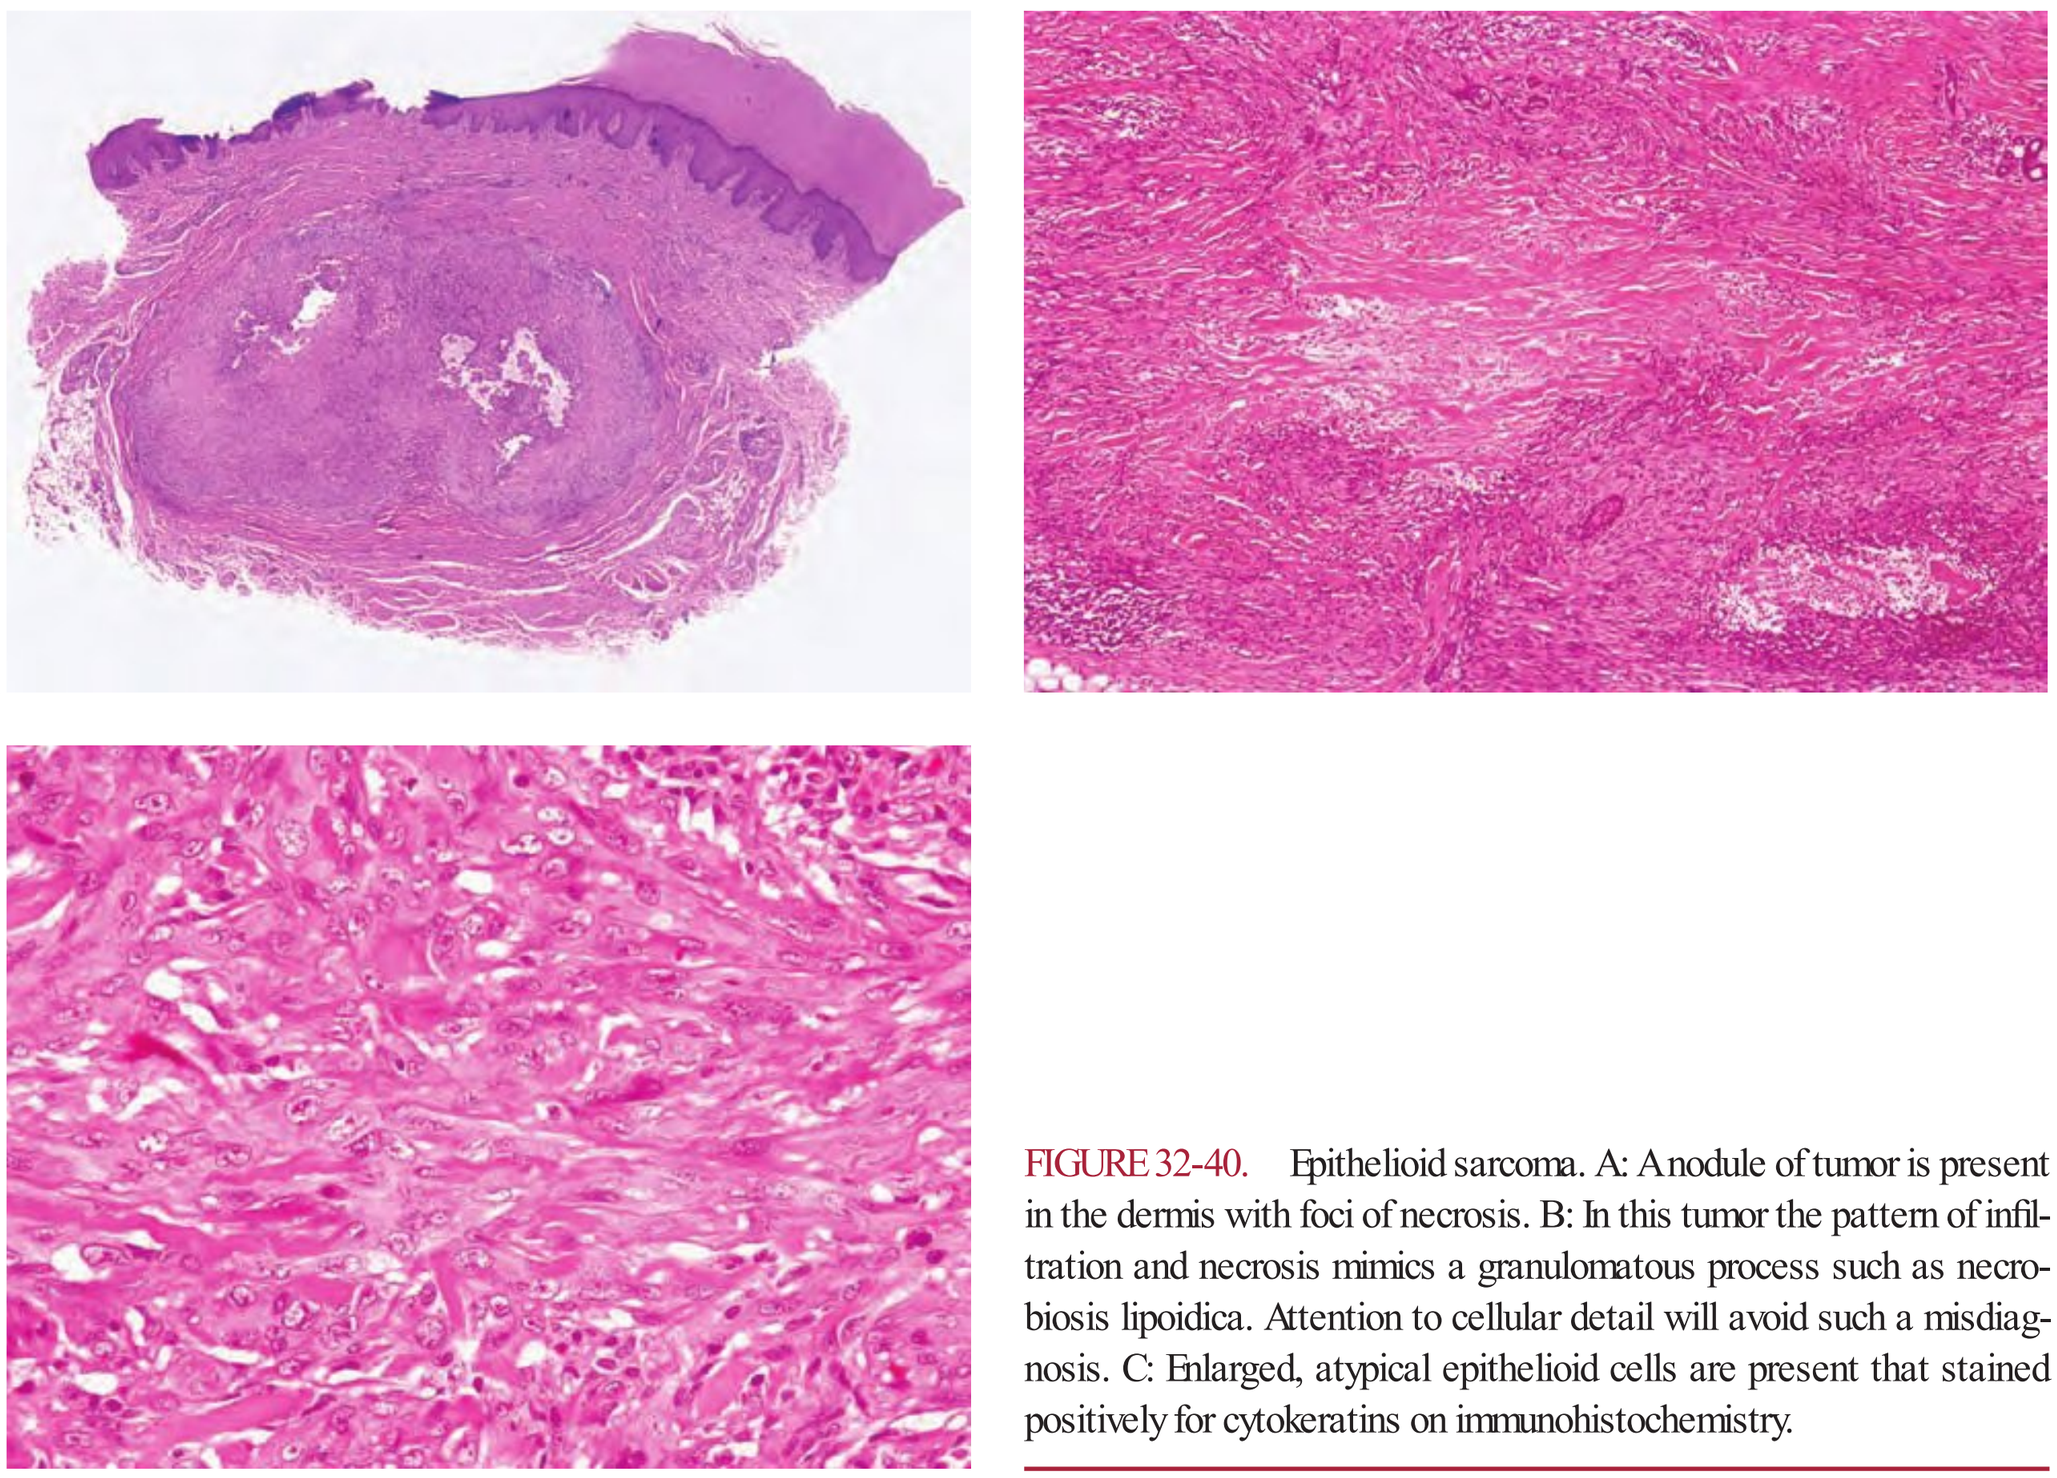

FIGURE 32-40. Epithelioid sarcoma. A: A nodule of tumor is present in the dermis with foci of necrosis. B: In this tumor the pattern of infiltration and necrosis mimics a granulomatous process such as necrobiosis lipoidica. Attention to cellular detail will avoid such a misdiagnosis. C: Enlarged, atypical epithelioid cells are present that stained positively for cytokeratins on immunohistochemistry.

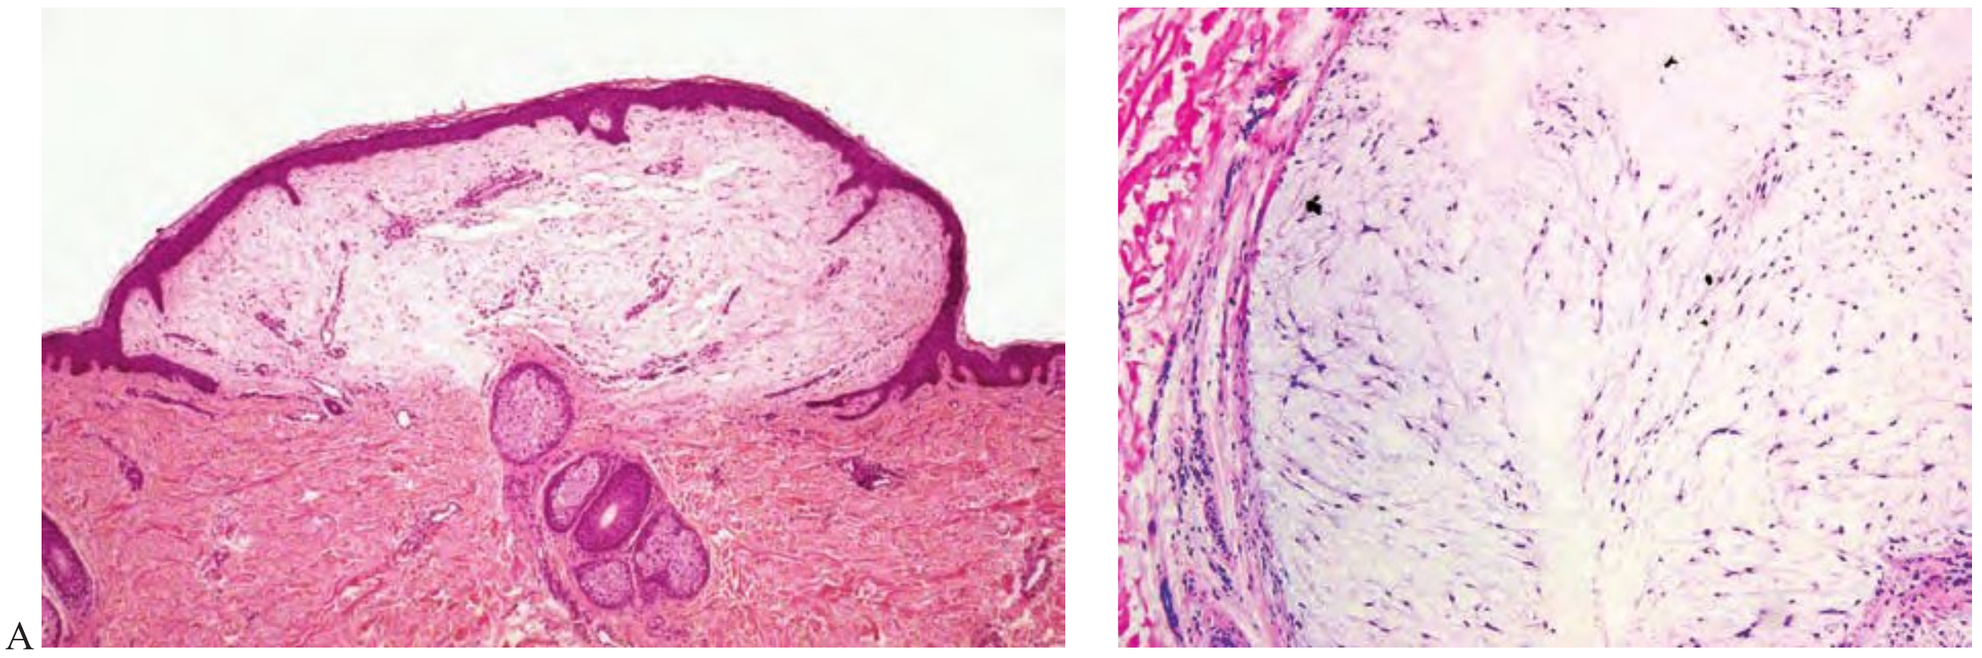

FIGURE 32-41. (A-B) Cutaneous myxoma. The lesion is a sharply circumscribed nodule composed of a vascular mucinous matrix in which spindle cells are scattered.

Differential Diagnosis. At low power, the features often suggest a granulomatous process such as granuloma annulare or rheumatoid nodule. However, cellular atypia, a general lack of mucin, and foci of tumor cell necrosis assist in making the correct diagnosis, even before immunohistochemical stains have been performed (429,431). Although epithelioid sarcoma shows both mesenchymal and epithelial differentiation, it lacks the characteristic biphasic pattern of synovial sarcoma, which does not usually express CD34 (406). Epithelioid sarcoma is negative for cytokeratins 5/6 in most cases, which helps to distinguish it from squamous cell carcinoma, which is consistently positive (432).

MISCELLANEOUS LESIONS

Cutaneous Myxoma

Cutaneous myxomas are sharply demarcated nodules in the dermis or subcutis. They may occur as multiple lesions in association with cardiac and breast myxomas, spotty pigmentation, and endocrine overactivity in Carney's complex (433) or as solitary lesions, usually on the head and neck, trunk, or digits (434–437).

Histopathology. Lesions are sharply circumscribed and sparsely cellular, composed of stellate and spindle-shaped fibroblasts, abundant small, thin-walled vessels, and myxoid matrix (Fig. 32-41A, B). An epithelial component is sometimes present, taking the form of linear strands of epithelium with basaloid features, small keratinous cysts, or follicular induction resembling superficial basal cell carcinoma (433,436,438). *Superficial angiomyxoma* describes tumors with a more prominent associated vascular pattern (436,439).

Differential Diagnosis. Cutaneous myxoma is more sharply circumscribed and more vascular than focal mucinosis (440). The tumor cells in myxomas express vimentin, with variable positivity for CD34 and actin. The cells are usually negative for S100 protein, which is helpful in the distinction from neuroid tumors such as neurothekeoma and myxoid neurofibroma. (441). Neurothekeomas display a multilobular pattern, and the cells in myxoid neurofibromas have wavy nuclei.

Digital Mucous Cyst

It has been suggested that two types of digital mucous cyst exist (442,443). One type is analogous to focal mucinosis. It differs from focal mucinosis only by its location near the proximal nail fold and by its greater tendency to fluctuation. The other type is located on the dorsum of a finger near the distal interphalangeal joint and is due to a herniation of the joint lining, thus representing a ganglion (442). Another view is that digital mucous cyst and digital myxoma are identical and that there is no anatomic connection with the interphalangeal joint (441).

Histopathology. According to the first concept, digital mucous cyst in its early stage has the same histologic appearance as that seen in focal mucinosis, namely, an ill-defined area of mucinous material. Subsequently, multiple clefts form and then coalesce into one large cystic space containing mucin composed largely of hyaluronic acid, which stains with Alcian blue and colloidal iron (444). The cystic space in early lesions is separated from the epidermis by mucinous stroma, but in older lesions it is found in a subepidermal location with thinning of the overlying epidermis. The collagen at the periphery of the cyst appears compressed. No lining of the cyst wall is apparent (Fig. 32-42) (444,445).

Histogenesis. The type analogous to focal mucinosis results from overproduction of hyaluronic acid by fibroblasts (444). In the ganglion type of digital mucous cyst, hyaluronic acid is derived from the joint fluid. This concept is supported by the observation that methylene blue injected into the distal interphalangeal joint can be identified in the cyst (445,446).

Mucous Cyst of the Oral Mucosa/Mucocele

Mucoceles present as solitary asymptomatic lesions, usually on the mucous surface of the lower lip and only rarely elsewhere

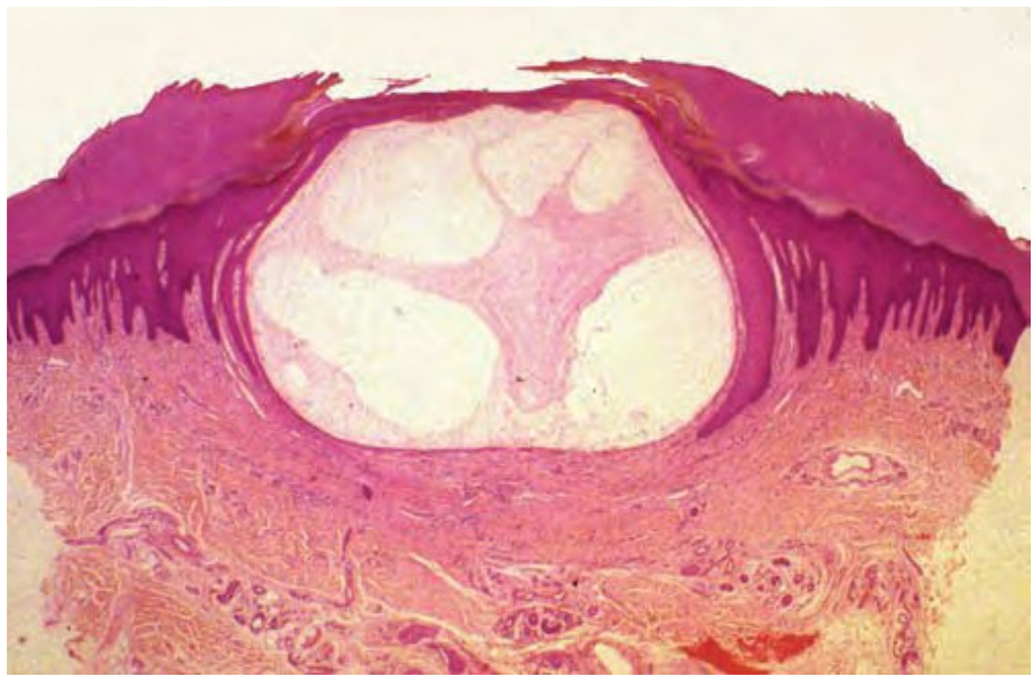

FIGURE 32-42. Digital mucous cyst. The epidermis is raised and attenuated and overlies a circumscribed mucinous cystic nodule, with an epidermal collarette.

on the oral mucosa (447). The cysts usually typically measure less than 10 mm in diameter, appear dome shaped, are translucent, and contain a clear, viscous fluid. Minor trauma causing rupture of a mucous duct appears to initiate the lesion, releasing sialomucin into the tissue. Although most patients with an oral mucous cyst have no preexisting abnormality, mucous cysts of the lower lip may occur in patients with cheilitis glandularis, a condition in which the labial mucous glands and ducts are hyperplastic (448).

FIGURE 32-43. Mucous cyst of the oral mucosa. The squamous epithelium is raised and overlies a cyst containing mucin and inflammatory cells. A segment of salivary gland duct opens into the base of the cyst.

Histopathology. Early lesions consist of multiple small spaces filled with sialomucin surrounded by or intermixed with granulation tissue in the submucosa. Older lesions show either a solitary large cystic space or several large spaces lined by a thick layer of granulation tissue composed of neutrophils, lymphocytes, fibroblasts, muciphages, and capillaries (447). The wall of some cysts shows a ruptured salivary duct opening into the cavity. The sialomucin within the cysts appears as amorphous, slightly eosinophilic material that is periodic acid-Schiff positive and diastase resistant and also stains with Alcian blue and colloidal iron. Minor salivary gland ducts in the underlying stroma provide a clue to the diagnosis (Fig. 32-43) (449).

CHAPTER 33

Eduardo Calonje

Vascular Tumors: Tumors and Tumor-like Conditions of Blood Vessels and Lymphatics

The classification of vascular lesions and in particular benign vascular tumors is far from satisfactory. The division between developmental, reactive, benign (neoplastic), and occasionally malignant vascular tumors is often blurred, and many conditions cannot be neatly classified into a specific category. This often reflects either limited knowledge about the pathogenesis or the presence of overlapping features among different entities. While advances in knowledge and research have undoubtedly led to the improvement of this situation, the classification of many vascular tumors still remains controversial. A few examples include pyogenic granuloma and angiolymphoid hyperplasia with eosinophilia (reactive vs. neoplastic) and, more importantly, Kaposi's sarcoma (neoplastic vs. infectious). The classification of cutaneous vascular tumors proposed in this chapter and in Table 33-1 is partially based on the recent World Health Organization (WHO) classification of vascular tumors (1) and intends only to provide a framework to define and present different vascular tumors in a coherent manner based on recent developments. It does not intend to be definitive, because future changes in our understanding of vascular tumors will undoubtely give way to further modifications.

REACTIVE CONDITIONS

Intravascular Papillary Endothelial Hyperplasia (Masson's Tumor)

Not an uncommon condition, intravascular papillary endothelial hyperplasia, or Masson's tumor, represents an unusual endothelial proliferation in an organizing thrombus that can be misdiagnosed as angiosarcoma (2). Intravascular papillary endothelial hyperplasia arises primarily within a venous channel or secondarily within a preceding angioma or some type of vascular anomaly, including hemorrhoids, as in Masson's original description. Secondary Masson's tumor often occurs in deep-seated hemangiomas. An exceptional case of an extravascular location in association with a hematoma has been reported (3). The lesions are almost always solitary, arising in the skin, subcutaneous tissue, or even muscle with the head and neck region and the upper extremities. The fingers especially are the most common sites. A rare instance of multiple lesions of the lower extremities simulating Kaposi's sarcoma has also been described (4). All ages can be affected, although there is a slight female predominance (5). Primary lesions are usually tender nodules <2 cm in size, whereas secondary lesions occur because some preceding vascular abnormality increases in size.

Histopathology. Often, low-power examination allows recognition of the intravascular nature of the process in a single thin-walled vein (Fig. 33-1) or as part of a preceding angiomatous condition. Extravascular lesions fail to reveal a blood vessel wall despite serial sectioning. The main lesion consists of a mass of anastomosing vascular channels with a variable degree of intraluminal papillary projections (Fig. 33-2). The stroma consists of hyalinized eosinophilic material that may merge with uncanalized thrombus remnants. The infiltrating vascular channels show enlarged and prominent endothelial cells that may be "heaped up" to give rise to intraluminal prominences, but atypia and mitotic activity are slight.

Differential Diagnosis. The occurrence of areas of somewhat atypical endothelial-lined channels apparently showing a "dissection of collagen" appearance can closely simulate a well-differentiated angiosarcoma. However, the stroma is not collagen and thus is not refractile on polarization, and the changes are localized and occur within a preceding vessel or a vascular anomaly. Usually, angiosarcoma shows a much greater degree of nuclear atypia, multilayering, and mitotic activity.

Angioendotheliomatosis

Until the last decade, two distinctive forms of angioendotheliomatosis were recognized: an aggressive variant with systemic involvement and poor prognosis as well as a reactive self-limited form with a benign course usually restricted to the skin. However, with the advent of immunohistochemistry, many studies in recent years have demonstrated that malignant angioendotheliomatosis shows no endothelial differentiation but represents a form of angiotropic lymphoma that has been renamed *intravascular lymphomatosis* (see Chapter 31).

TABLE 33-1 Classification of Cutaneous Vascular Tumors

BENIGN VASCULAR TUMORS
Benign Tumors and Tumor-like Conditions
Papillary endothelial hyperplasia (Masson's tumor)
Reactive angioendotheliomatosis
Glomeruloid hemangioma
Bacillary angiomatosis
Vascular ectasias
Nevus flammeus (salmon patch and port-wine stain)
Angiokeratoma
Generalized essential telangiectasia
Cutaneous collagenous vasculopathy
Unilateral naevoid telangiectasia
Angioma serpiginosum
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu)
Nevus araneus
Venous lake
Congenital hemangiomas
RICH
NICH
Capillary hemangioma
Variants:
Infantile hemangioma
Cherry angioma
Tufted angioma (angioblastoma)
Lobular capillary hemangioma (pyogenic granuloma)
Cavernous hemangioma
Variant: Sinusoidal hemangioma
Verrucous hemangioma
Microvenular hemangioma
Hobnail hemangioma
Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia)
Cutaneous epithelioid angiomatous nodule
Acquired elastotic hemangioma
Arteriovenous hemangioma
Variants:
Superficial (cirsoid aneurysm)
Deep
Angiomatosis
Spindle cell hemangioma
Symplastic hemangioma
INTERMEDIATE VASCULAR TUMORS
Locally Aggressive
Kaposi-like hemangioendothelioma
Giant cell angioblastoma
Rarely Metastasizing
Kaposi's sarcoma
Retiform hemangioendothelioma
Papillary intravascular angioendothelioma (malignant endovascular papillary angioendothelioma, Dabska tumor)
Composite hemangioendothelioma
MALIGNANT VASCULAR TUMORS
Epithelioid hemangioendothelioma
Angiosarcoma
Variants:
Idiopathic (head and neck)
Associated with chronic lymphedema (Stewart-Treves)
Postirradiation
Epithelioid
TUMORS OF LYMPH VESSELS
Lymphangioma
Variants:
Lymphangioma circumscriptum
Cavernous lymphangioma/cystic hygroma
Benign lymphangioendothelioma (acquired progressive lymphangioma)
Lymphangiomatosis
Lymphangiomyoma
Atypical vascular proliferation after radiotherapy
TUMORS OF PERIVASCULAR CELLS
Glomus tumor
Glomangiomatosis
Variant: Infiltrating glomus tumor
Glomangiosarcoma
Myopericytoma

RICH, rapidly involuting congenital hemangioma; NICH, noninvoluting congential hemangioma.

Reactive Angioendotheliomatosis

Reactive angioendotheliomatosis is an uncommon condition that almost exclusively affects the skin and presents in patients of either gender with a wide anatomic distribution and predilection for the limbs. Clinical presentation varies from erythematous or brown macules to papules and/or plaques that can be associated with purpura. A livedo-like pattern is sometimes present. In many cases, an association with systemic disease has been documented including cryoglobulinemia (6); paraproteinemia; renal disease; amyloidosis (7); antiphospholipid syndrome (8); rheumatoid arthritis (9); cirrhosis (9); polymyalgia rheumatica (9); sarcoidosis (10); myelodysplastic syndrome (11); and systemic infections, especially bacterial endocarditis (12). Localized forms of the disease are less frequent and include a variant associated with peripheral vascular atherosclerotic disease described as *diffuse dermal angiomatosis* (13–15). The latter presentation has also been described in association with iatrogenic arteriovenous fistulas (16).

Histopathology: Lesions are predominantly dermal and composed of closely packed, variably dilated vascular spaces (mainly capillaries) (Fig. 33-3) lined by bland but plump endothelial cells surrounded by pericytes. A minority of cases display endothelial cells with focal epithelioid change (9). Small lumina might be apparent, but some are obliterated by endothelial cells or fibrin thrombi. Often, the capillaries appear to proliferate in the lumina of dilated preexisting blood

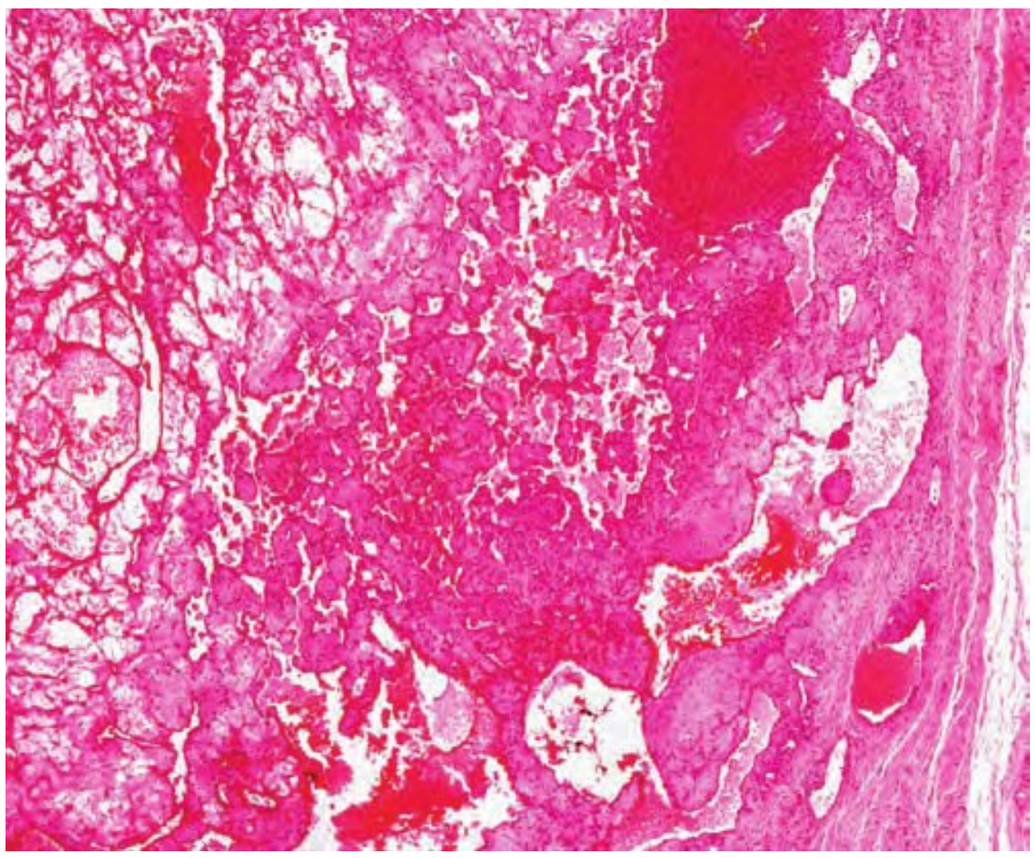

FIGURE 33-1. Primary intravascular papillary endothelial hyperplasia. Part of a markedly dilated vascular channel with prominent papillary structures intermixed with red blood cells and fibrin.

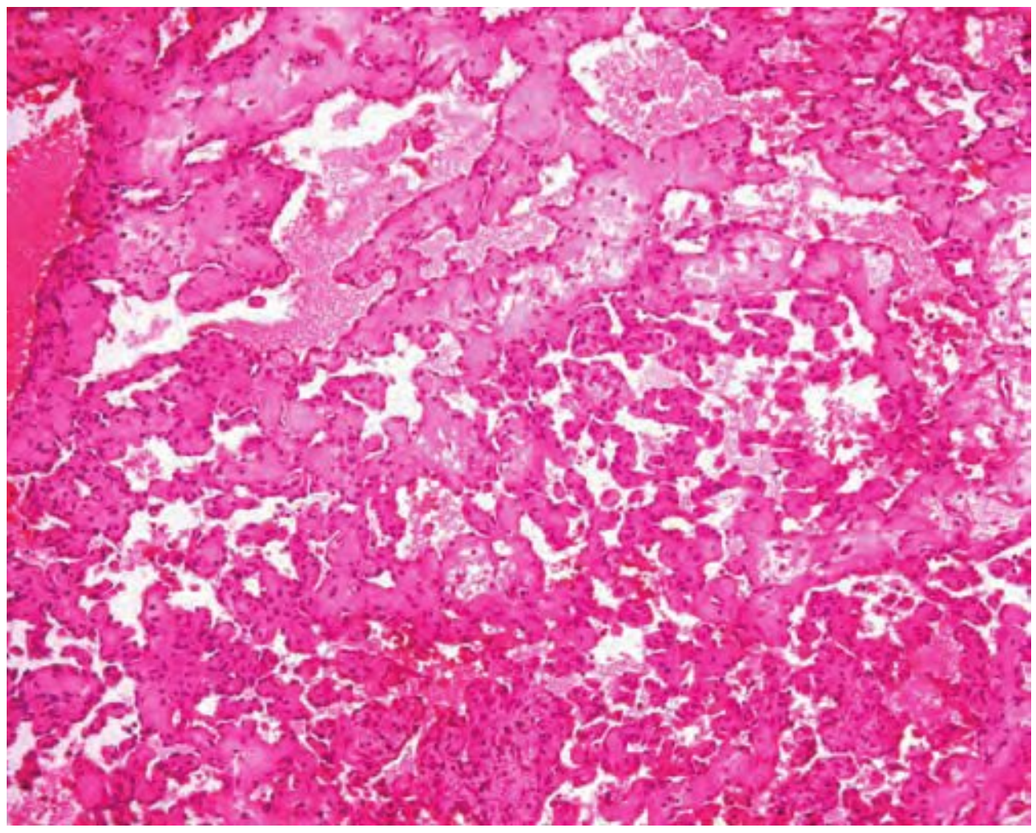

FIGURE 33-2. Intravascular papillary endothelial hyperplasia. Typical hyaline papillary projections lined by endothelial cells focally mimicking a dissection of collagen pattern.

vessels. Hyaline refractile eosinophilic thrombi representing immunoglobulins are present in cases associated with cryoglobulinemia (6) (Fig. 33-4). In diffuse dermal angiomatosis, the proliferating endothelial cells are not present within vascular channels but can be found between dermal collagen fibers. Rare cases of patients presenting with a clinical and histologic picture similar to that of reactive angioendotheliomatosis but showing intravascular cells with a histiocytic immunophenotype have been described. It is not clear whether this represents the early stages of reactive angioendotheliomatosis or a distinctive entity (17).

Histogenesis. Reactive angioendotheliomatosis, in contrast to malignant angioendotheliomatosis, displays universal reactivity for endothelial markers and negativity for leukocyte common antigen, proving that the proliferating cells are endothelial cells (12). It has been proposed that the endothelial cell proliferation is induced by a circulating angiogenic factor or, alternatively, especially in cases associated with cryoglobulinemia or atherosclerotic vascular disease, by occlusion of vascular spaces (6). In many instances, the vascular proliferation is triggered by luminal occlusion, and it is likely that thrombosis plays an important role in the pathogenesis (18).

Differential Diagnosis. The histologic distinction from tufted angioma may be difficult, but the clinical presentation of both

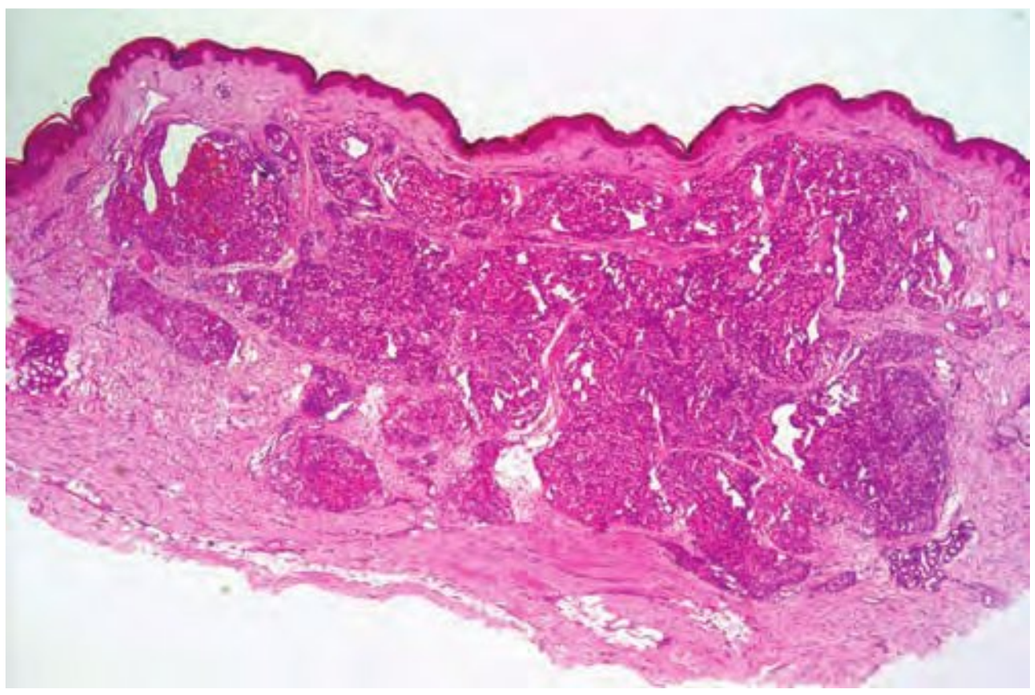

FIGURE 33-3. Reactive angioendotheliomatosis. Numerous closely packed capillaries within preexisting dilated blood vessels are seen throughout the dermis.

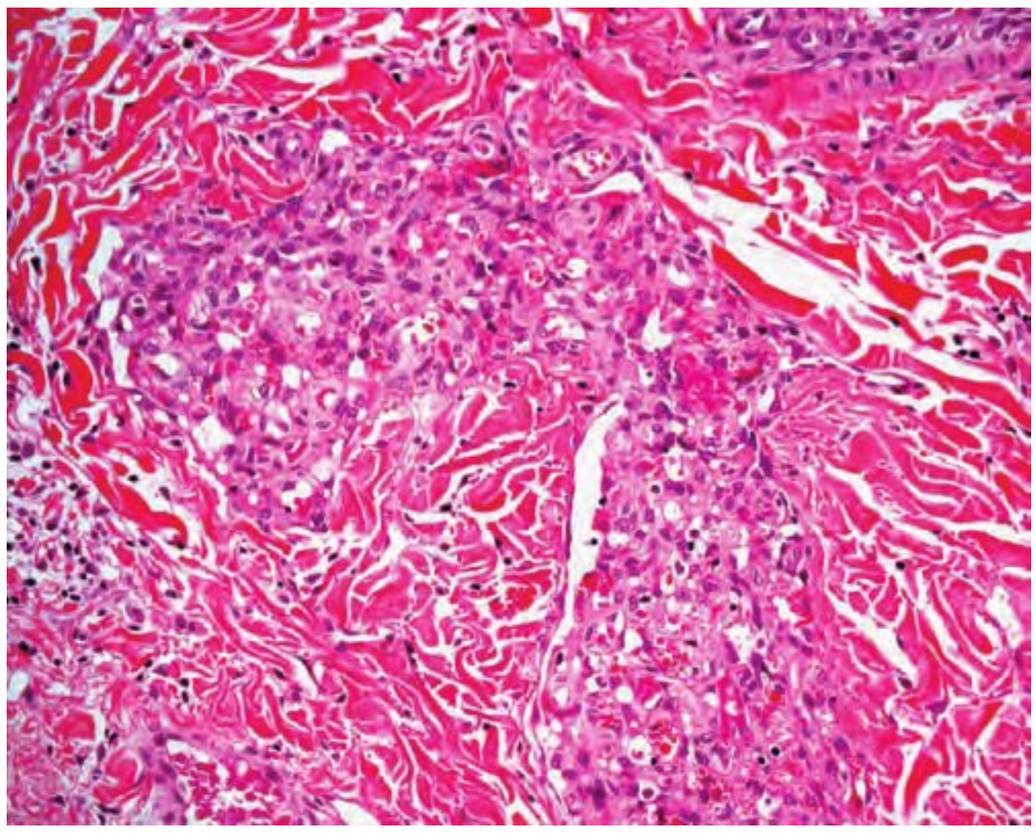

FIGURE 33-4. Reactive angioendotheliomatosis. Plump endothelial cells and intraluminal eosinophilic globules in a case associated with cryoglobulinemia.

entities is different, and tufted angioma shows clusters of capillaries in a typical cannonball distribution throughout the dermis with crescent-like dilated spaces that probably are lymphatic in nature in the periphery of many of the vascular tufts.

Glomeruloid Hemangioma

Glomeruloid hemangioma is a highly distinctive, rare, reactive vascular proliferation that presents in patients with POEMS syndrome (*P*olyneuropathy, *O*rganomegaly, *E*ndocrinopathy, *M*-protein, and *S*kin changes), usually but not always in association with multicentric Castleman's disease (18–20). The skin changes in POEMS syndrome include hypertrichosis, hyperpigmentation, hyperhidrosis, sclerodermoid features, and multiple small vascular papules on the trunk and limbs. Single or multiple lesions with similar morphology have been described in patients with no evidence of POEMS syndrome (21,22).

Histopathology. Most vascular lesions in POEMS syndrome show the features of cherry angiomas, and only a small number of lesions have the appearance of a glomeruloid hemangioma. Other lesions may display histologic features that do not fit exactly into a definitive diagnostic category. In glomeruloid hemangioma, there are numerous ectatic vascular spaces throughout the dermis that contain in their lumina clusters of small, congested capillaries surrounded by pericytes bearing a striking resemblance to renal glomeruli (Figs. 33-5 and 33-6). Although the endothelial cells are flat, a few scattered cells appear vacuolated and can show periodic acid-Schiff (PAS)-positive hyaline globules that correspond to deposition of immunoglobulins. Staining for human herpesvirus 8 (HHV-8) is negative.

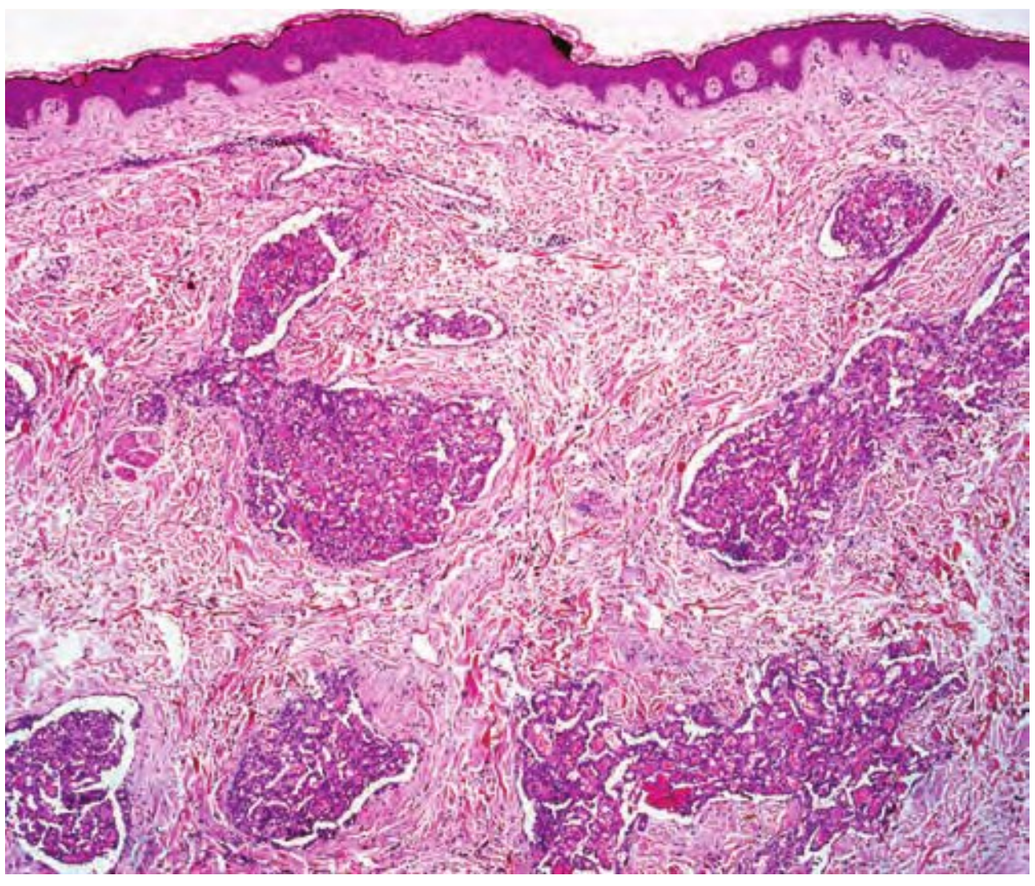

FIGURE 33-5. Glomeruloid hemangioma. Widely dilated preexisting vascular channels filled with smaller blood vessels. Note the low-power resemblance to reactive angioendotheliomatosis.

Histogenesis. Glomeruloid hemangioma probably represents a variant of reactive angioendotheliomatosis. The cause of the vascular proliferation in POEMS syndrome has not been established, but it may be induced by an angiogenic factor, possibly the abnormal immunoglobulin in the vascular spaces.

VASCULAR ECTASIAS

Nevus Flammeus

The term *nevus flammeus* is often used to refer to two different lesions: the *salmon patch* and the *port-wine stain*. Although both lesions are congenital, the former tends to involute in the first years of life and usually has no association with other types of anomalies, while the latter tends to be persistent and is often related to other malformations. The salmon patch is present in up to 50% of newborns of either gender as an ill-defined, red to pale pink macule mainly in the nape of the neck, the glabella, or the eyelids (23,24). The port-wine stain occurs in about 0.3% of newborns as a macular, usually unilateral, red-pink lesion with a predilection for the face (24). Later in life, the lesion becomes darker and raised.

Sturge-Weber syndrome (encephalotrigeminal angiomatosis) is characterized by the presence of a facial port-wine stain, often in the distribution of the trigeminal nerve associated with an ipsilateral leptomeningeal venous malformation, atrophy and calcification of the underlying cerebral cortex, epilepsy, mental retardation, ocular vascular malformations, glaucoma, and contralateral hemiparesis.

In *Klippel-Trenaunay syndrome* (osteohypertrophic nevus flammeus), hypertrophy of the soft tissues and bones of one or several extremities affected with a nevus flammeus are observed. Associated with this are varicosities or arteriovenous fistulas or both and, less commonly, spindle cell hemangioendotheliomas. Cases presenting with arteriovenous fistulas are

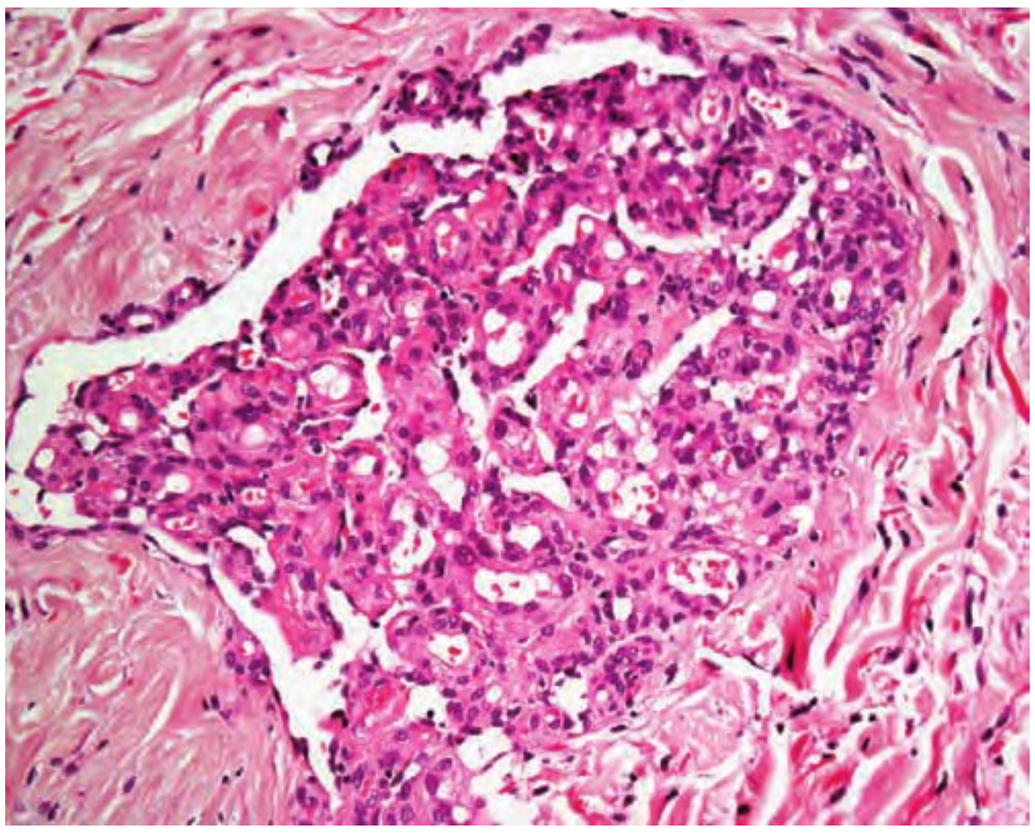

FIGURE 33-6. Glomeruloid hemangioma. Striking resemblance to a renal glomerulus.

sometimes known as Parkes-Weber syndrome. Complications of note are cutaneous ulcers and high-output cardiac failure.

Histopathology. In the *salmon patch*, dilated capillaries are seen in the papillary dermis. In the *port-wine stain*, no telangiectases are apparent histologically until the patient has reached about 10 years of age (25). The capillary ectasias thereafter gradually increase with age. Ultimately, when the lesion is raised or nodular, dilation appears not only the superficial capillaries but also in some of the blood vessels in the deeper layers of the dermis and in the subcutaneous layer. Many ectatic vessels are filled with red blood cells. Lesions with a deep component can be associated with a cavernous hemangioma or an arteriovenous malformation (25).

Histogenesis. Because no histologic abnormalities are present early in life with a port-wine stain, it appears likely that this malformation is the result of a congenital weakness of the capillary walls (25). Thus, the port-wine stain represents a progressive telangiectasia. Antibodies directed against components of the blood vessel wall, collagenous basement membrane protein (type IV collagen), fibronectin, and factor VIII–related antigen have an equivalent distribution and intensity in normal skin and nevus flammeus. Although this does not rule out a structural abnormality of these components, it has been suggested that the alteration may be related to the supporting dermal elements rather than to an intrinsic abnormality in the vessel wall (26). An abnormality in neuromodulation has been proposed as an alternate theory (27).

Angiokeratoma

Four types of angiokeratoma have been described that represent true ectasias of blood vessels of the superficial dermis (28):

1. *Angiokeratoma corporis diffusum.* Patients present with numerous clusters of tiny, red papules in a symmetrical distribution usually in the "bathing-trunk" area. Although often considered synonymous with Fabry's disease, which is an X-linked genetic disorder associated with deficiency of the lysosomal enzyme A-galactosidase, identical clinical appearances have been described in patients with other enzymatic deficiencies, including B-galactosidase, neuraminidase, L-fucosidase, and B-mannosidase (29–31). In exceptional cases, presentation is not associated with detectable biochemical abnormalities, and these cases may be familial (32,33).
2. *Angiokeratoma of Mibelli.* Several dark red papules with a slightly verrucous surface are seen on the dorsa of the fingers and toes. Usually, the lesions appear during childhood or adolescence and measure 3 to 5 mm in diameter (34).
3. *Angiokeratoma of Fordyce.* Multiple vascular papules of 2 to 4 mm in diameter are seen on the scrotum (35). Similar lesions have been described on the vulva (36). They arise in middle or later life. Early lesions are red, soft, and compressible; later, they become blue, keratotic, and noncompressible.

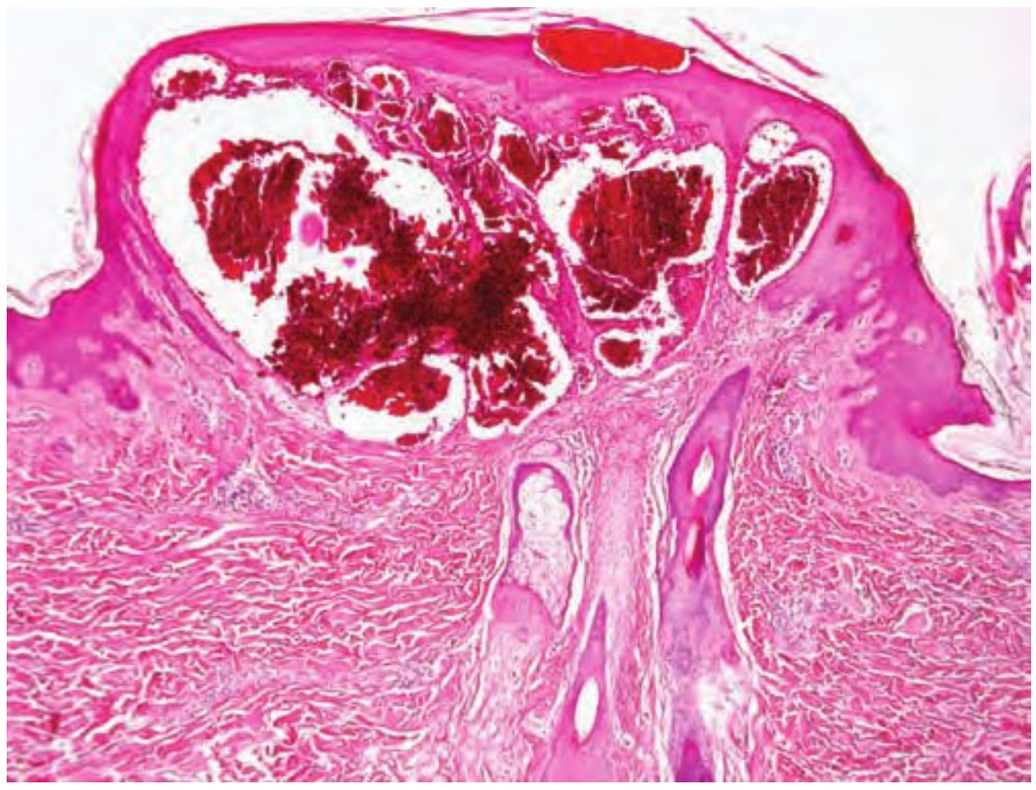

FIGURE 33-7. Angiokeratoma. Note ectatic blood vessels in the papillary dermis with overlying epidermal hyperplasia.

4. *Solitary or multiple angiokeratomas.* Usually one and occasionally several papular lesions arise in young adults, most commonly on the lower extremities. They may be congenital, and when located in a restricted area of the lower limbs, the term *angiokeratoma circumscriptum* is used (37). The lesions range from 2 to 10 mm in diameter. Early lesions appear bright red and soft, but they later become blue to black, firm, and hyperkeratotic (28). Thrombosed lesions are not uncommonly misdiagnosed clinically as malignant melanomas.

Histopathology. The histologic findings are essentially the same in all four above-mentioned types of angiokeratoma and consist of numerous, dilated, thin-walled, congested capillaries mainly in the papillary dermis underlying an epidermis that shows variable degrees of acanthosis with elongation of the rete ridges and hyperkeratosis (28) (Fig. 33-7). In cutaneous lesions of Fabry's disease, cytoplasmic vacuoles representing lipids can sometimes be detected in endothelial cells, fibroblasts, and pericytes.

Generalized Essential Telangiectasia

Widespread linear telangiectases, mainly on the extremities, may gradually develop in adults, predominantly in women (38,39).

Histopathology. Dilated, often congested, vessels are seen in the papillary dermis. The walls of the vessels are composed only of endothelium. The absence of alkaline phosphatase activity suggests that it is the venous portion of the capillary loop that participates in the disease process (38,39).

Cutaneous Collagenous Vasculopathy

This condition is very rare and presents in adults as asymptomatic, progressive, generalized telangiectasia with no involvement of the oral cavity or nails (40).

Histopathology. Superficial, small dermal vessels appear dilated, and their walls are thickened by amorphous hyaline material. This material is positive for PAS and also for colloidal iron. It represents collagen, as demonstrated by electron microscopy; by immunohistochemistry, it is positive for collagen type IV, laminin, and fibronectin. Ultrastructure examination demonstrates that the vessels involved are postcapillary venules.

Unilateral Nevoid Telangiectasia

Although unilateral nevoid telangiectasia may be congenital, in most instances, its onset is related to high estrogen levels associated with pregnancy, puberty, and chronic hepatic disease associated with alcoholism (41). The telangiectases, which are largely punctate and stellate rather than linear, follow a dermatomal distribution, particularly those associated with the trigeminal nerve and cranial nerves III and IV. Rare cases are associated with gastric involvement (42).

Histopathology. Numerous dilated vessels are seen in the upper and middle dermis and, to a lesser extent, in the deeper part of the dermis.

Histogenesis. It has been proposed that the changes seen in this condition are induced by an increase in estrogen receptors in a dermatomal distribution (43).

Angioma Serpiginosum

Angioma serpiginosum is a rare acquired vascular lesion that usually presents in the first two decades of life with a predilection for females. Anatomic distribution is wide, but lesions often present on the lower extremities. The disorder is asymptomatic, and slow progression occurs over the years. Focal spontaneous regression rarely occurs. Most cases are sporadic, but inherited cases have been reported (44). A typical lesion is characterized by deeply red nonpalpable puncta that are grouped closely together in a macular or netlike pattern. Irregular extension at the periphery of the macules may cause them to have serpiginous borders. The deeply red puncta represent dilated capillaries.

Histopathology. Dilated, thin-walled capillaries are seen in some of the dermal papillae and the superficial reticular dermis. Epidermal changes and extravasation of red blood cells does not occur.

Histogenesis. On electron microscopic examination, it is apparent that the thickening of the capillary walls is caused by a heavy precipitate of basement membrane–like material mixed with thin collagen fibers and an increased number of concentrically arranged pericytes (45). In addition, some of the dilated capillaries show slitlike protrusions of their lumina and endothelial lining into the surrounding thickened vessel walls. These findings indicate that angioma serpiginosum is not just a simple telangiectasia but represents a vascular malformation (45).

Hereditary Hemorrhagic Telangiectasia (Osler-Weber-Rendu Disease)

Hereditary hemorrhagic telangiectasia, or Osler-Weber-Rendu disease, is inherited as an autosomal dominant trait. Although epistaxis may already begin in childhood, the characteristic telangiectases on the mucous membranes do not begin to appear until adolescence, and the cutaneous lesions often appear much later in life, particularly involving the upper part of the body. Typical lesions are small, bright red, nonpulsating papules.

Concomitant involvement of other organs including the gastrointestinal tract, liver, brain, lungs, spleen, kidneys, and adrenal glands is common. Associated vascular malformations are often a feature (46). Morbidity and mortality are mainly related to bleeding from internal organs.

Histopathology. Irregularly dilated capillaries and venules lined by flat endothelial cells are seen in the papillary and subpapillary dermis.

Histogenesis. On electron microscopy, the dilated vessels in the skin and oral mucosa are seen to be small postcapillary venules that normally do not possess pericytes. A defect in the perivascular supportive tissue has been found to be responsible for the breakdown of the junctions between endothelial cells and the resultant hemorrhage (47). The presence of a mild perivascular lymphocytic infiltrate has been regarded as important in inducing the pathologic changes (48).

Nevus Araneus (Spider Nevus)

Nevus araneus, or spider nevus, considered the most common form of telangiectasia, presents at any age, especially in children, with a predilection for the face and upper limbs (46). It is characterized by a central, slightly elevated, red punctum from which blood vessels radiate. Occasionally, pulsation can be observed. Although spider nevi often arise spontaneously, pregnancy, the use of oral contraceptives, and liver disease are factors predisposing to their appearance (46). Spontaneous regression is common as children grow older and after pregnancy.

Histopathology. In the center of the lesion is an ascending artery that branches and communicates with multiple dilated capillaries.

Venous Lake

Venous lake is a small, dark blue, slightly raised, soft lesion occurring on the exposed skin of elderly persons. It can usually be emptied of most of its blood by using sustained pressure. Usually, several lesions are present. The face, ears, and lips are the most common sites.

Histopathology. Venous lake represents a telangiectasia. In the upper dermis, close to the epidermis, the lesions show either one greatly dilated space or several interconnected dilated spaces filled with erythrocytes and lined by a single layer of

flattened endothelial cells and a thin wall of fibrous tissue (49). In some instances, in place of fibrous tissue, there is a thin irregular noncontinuous smooth muscle layer (50).

BENIGN TUMORS

Congenital Hemangiomas

The term *congenital hemangioma* was first proposed in 1996 to describe a group of hemangiomas that first appear *in utero* and are fully developed at birth (51). These lesions were probably classified in the past as infantile hemangiomas (52), vascular malformations, and even cavernous hemangiomas. These congenital hemangiomas have been divided into rapidly involuting congenital hemangiomas (RICH) and noninvoluting congenital hemangiomas (NICH). Although they seem to represent distinctive clinicopathologic entities, there is some degree of overlap not only between RICH and NICH but also between RICH and infantile hemangioma (53). This means that accurate diagnosis usually relies on close clinicopathologic correlation. It is still controversial whether these lesions are pathogenetically interconnected or whether they are linked (53).

Rapidly Involuting Congenital Hemangioma

RICH develops fully before birth and tends to regress during the first year of life. The tumor affects males and females equally and has a wide anatomical distribution with some predilection for the head and limbs (54,55).

Histopathology. Lesions are mainly subcutaneous and extend focally into the dermis. The architecture is lobular, and between tumor lobules, there are often bands of fibrosis (Figs. 33-8 and 33-9) with focal inflammation, dystrophic calcification, and hemosiderin deposition. Lobules are composed of variably congested capillaries, each of which is surrounded by a layer of pericytes. The overlying epidermis and adnexal structures usually appear atrophic. Larger vascular channels may be found in the fibrotic areas. Individual lobules may show variable fibrosis. Extramedullary hemopoiesis may be seen, and perineural extension is absent. GLUT-1 staining is usually negative in tumor lobules. However, in rare cases, focal positivity may be present.

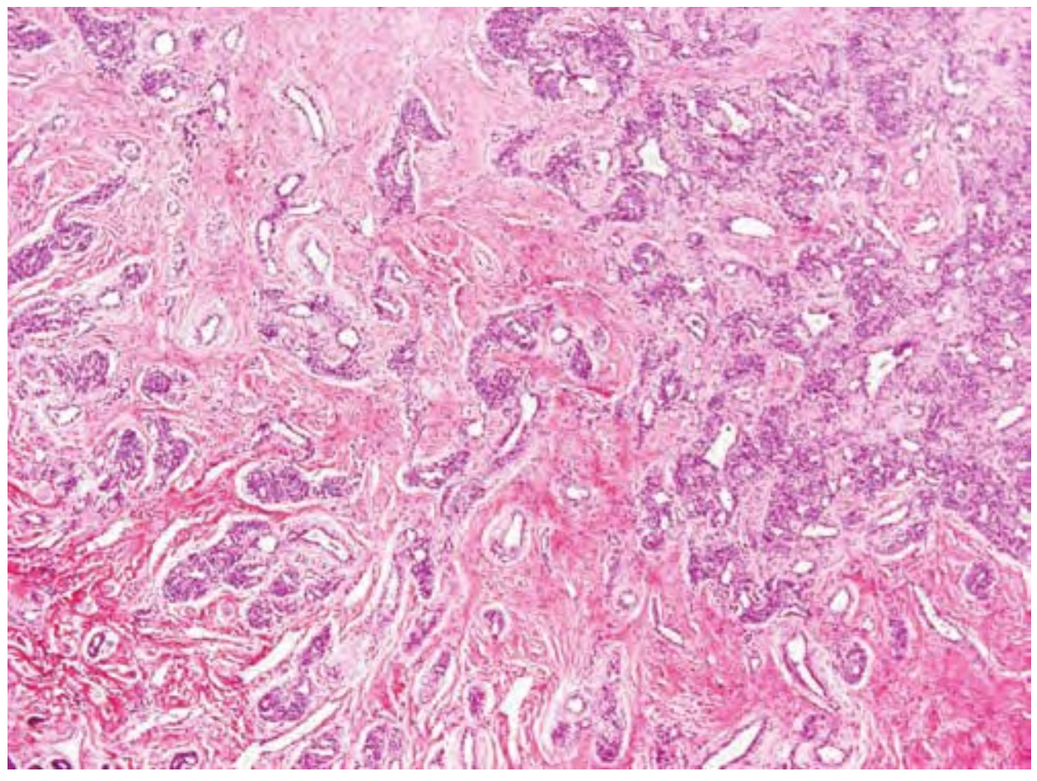

FIGURE 33-8. Rapidly involuting congenital hemangioma. Fibrous tissue is seen not only within individual tumor lobules but also between different tumor lobules. (Courtesy of H. Kozakevich, M.D., Boston, MA.)

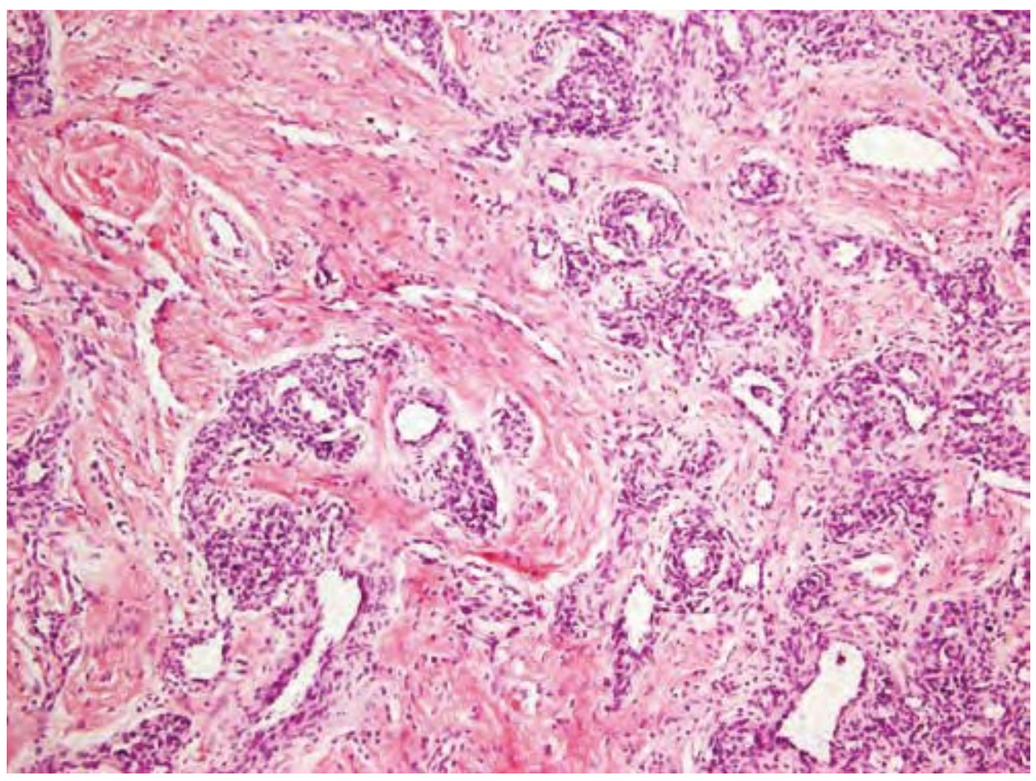

FIGURE 33-9. Rapidly involuting congenital hemangioma. Individual lobules are identical on high power to those seen in infantile hemangioma, but there is fibrosis with the lobules. (Courtesy of H. Kozakevich, M.D., Boston, MA.)

Differential Diagnosis. This is discussed below, under NICH.

Noninvoluting Congenital Hemangioma

NICH is fully developed at birth but shows no signs of regression, and it progresses over time (56). There is an equal sex incidence, and although anatomical distribution is wide, there is predilection for the head and limbs.

Histopathology. Vascular lobules tend to be large and are often composed of capillaries and larger, sometimes thicker blood vessels (Fig. 33-10). Draining larger blood vessels are present in tumor lobules. Surrounding the latter, there are areas of fibrosis containing large blood vessels with features of veins and arteries. Arteriovenous fistulas are also identified, and this closely mimics arteriovenous malformations. Histologic distinction can be very difficult, and close clinicopathologic correlation is often necessary. As opposed to vascular malformations, NICH does not tend to recur. GLUT-1 staining is usually negative.

Differential Diagnosis. The main differential diagnosis of RICH and NICH is infantile hemangioma. The latter typically develops shortly after birth, grows rapidly during the first year of life, and tends to involute over a period of several years. The lobules of RICH and infantile hemangioma are often identical, and it has been proposed that distinction between

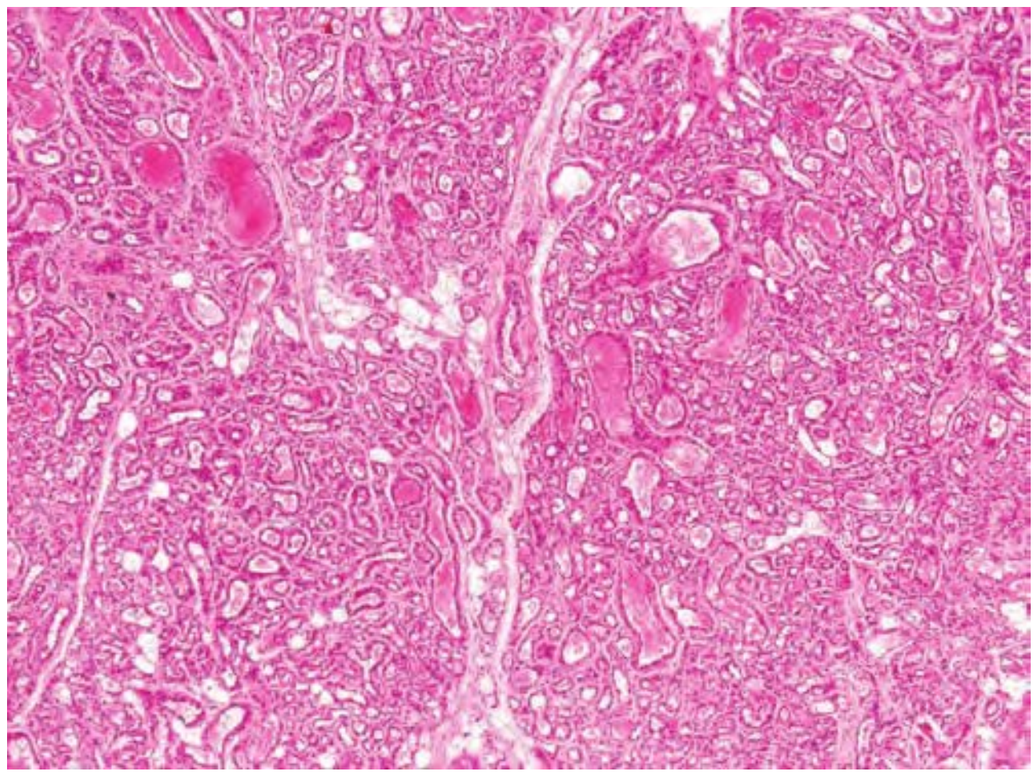

FIGURE 33-10. Noninvoluting congenital hemangioma. Tumor lobules vary more in size and contain a number of larger vascular channels.

both is mainly based in the presence of bands of fibrosis around tumor lobules, presence of atrophy of adnexal structures and epidermis, and lack of GLUT-1 positivity in the former. In practice, however, and especially in small biopsies, distinction may be very difficult and clinicopathologic correlation is paramount. Staining for GLUT-1, the human erythrocyte glucose transporter, is particularly helpful, as infantile hemangioma tends to be diffusely positive for this marker (57) while RICH is usually negative, and if positive, the pattern tends to be focal. Distinction between infantile hemangioma and NICH is easier, as the latter tends to display more variability in the size of vascular channels, GLUT-1 staining is usually negative, and arteriovenous fistulas are identified. The main problem with NICH, RICH, and infantile hemangioma is that there is some degree of overlap between the three entities, as demonstrated by the fact that infantile hemangioma may coexist with either RICH or NICH. The problem is further compounded by the fact that some cases of RICH fail to involute completely and behave more like NICH. In such cases, the histologic appearances overlap with those of RICH and NICH. At present, the pathogenetic relation between these groups of lesions remains obscure.

Capillary Hemangioma Variants

Infantile Hemangioma (Strawberry Nevus, Juvenile Hemangioendothelioma, Juvenile Hemangioma)

Capillary hemangioma, mostly represented by strawberry nevus, constitutes the most common vascular tumor of infancy, affecting as many as 1 in every 100 live births. Overall, it comprises between 32% and 42% of all vascular tumors (58,59). Lesions usually first appear between the third and fifth week of life, increase in size for several months to 1 year, and then start to regress. A typical lesion consists of one or several bright red, soft, lobulated tumors that vary greatly in size and have a wide anatomic distribution with a predilection for the head and neck area. Females are slightly more affected than males. On occasion, lesions can involve deeper soft tissues or even internal organs and can be associated with high morbidity, especially if located near vital structures. Complete spontaneous resolution is common, occurring in about 70% of capillary hemangiomas by the time the patient has reached the age of 7 years.

Contrary to what was believed in the past, capillary hemangiomas are not associated with Kasabach-Merritt syndrome. This syndrome, consisting of thrombocytopenia, microangiopathic hemolytic anemia, and acute or chronic consumption coagulopathy, is mainly seen with kaposiform hemangioendothelioma (see page 1038) and less commonly with cavernous hemangiomas (see page 1019) and tufted angioma (see page 1015).

Histopathology. All tumors have a lobular architecture (Fig. 33-11), but microscopic features change as the lesion evolves. During their period of growth in early infancy, capillary hemangiomas show considerable proliferation of their endothelial cells. The endothelial cells are large, mitotically active, and aggregated predominantly in solid strands and masses in which there are only a few small capillary lumina. Not uncommonly, crystalline intracytoplasmic inclusions can be seen in the endothelial cells. The lumina can be highlighted with the use of a reticulin stain. In maturing lesions, the capillary lumina are wider, and the lining endothelial cells then appear flatter (Fig. 33-12). In mature lesions, some of the lumina may be greatly dilated, focally resembling a cavernous hemangioma. In the involuting phase, there is progressive fibrosis with disappearance of the blood vessels. The vascular nature of the tumor may then be difficult to establish. However, the lobular pattern is often preserved. A worrying but entirely benign feature seen in a number of capillary hemangiomas is the presence of perineural invasion (60).

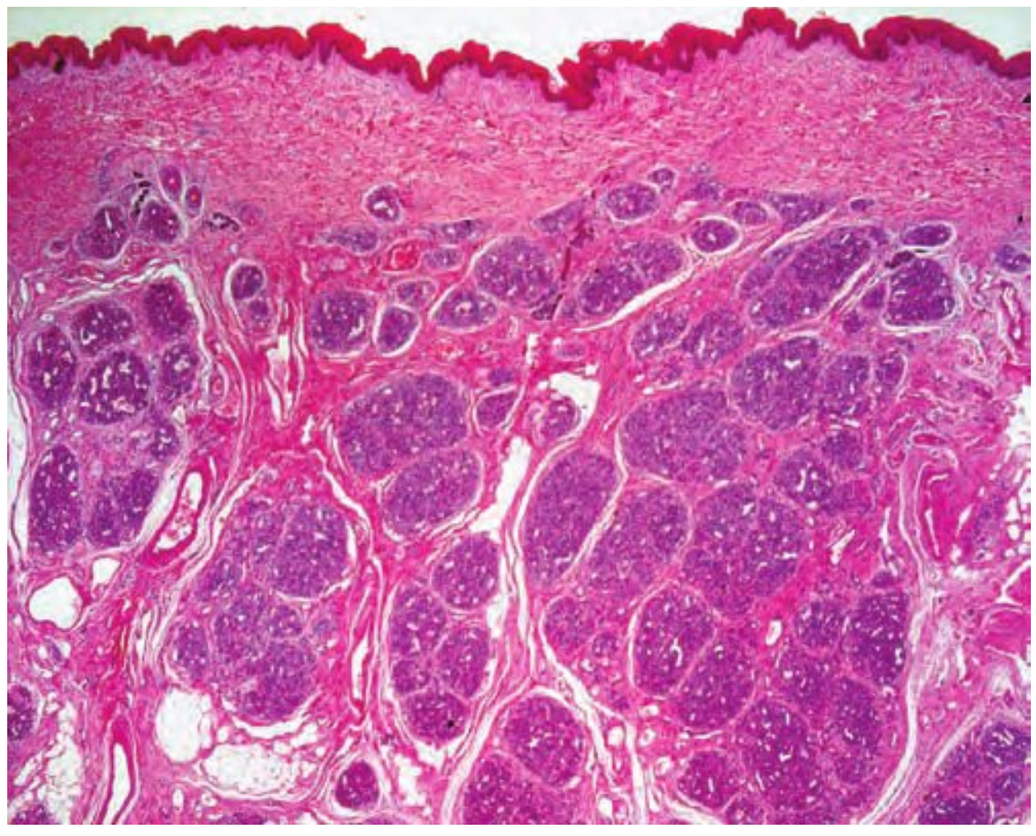

FIGURE 33-11. Infantile hemangioma. Involvement of the dermis and subcutis by multiple lobules composed of capillaries.

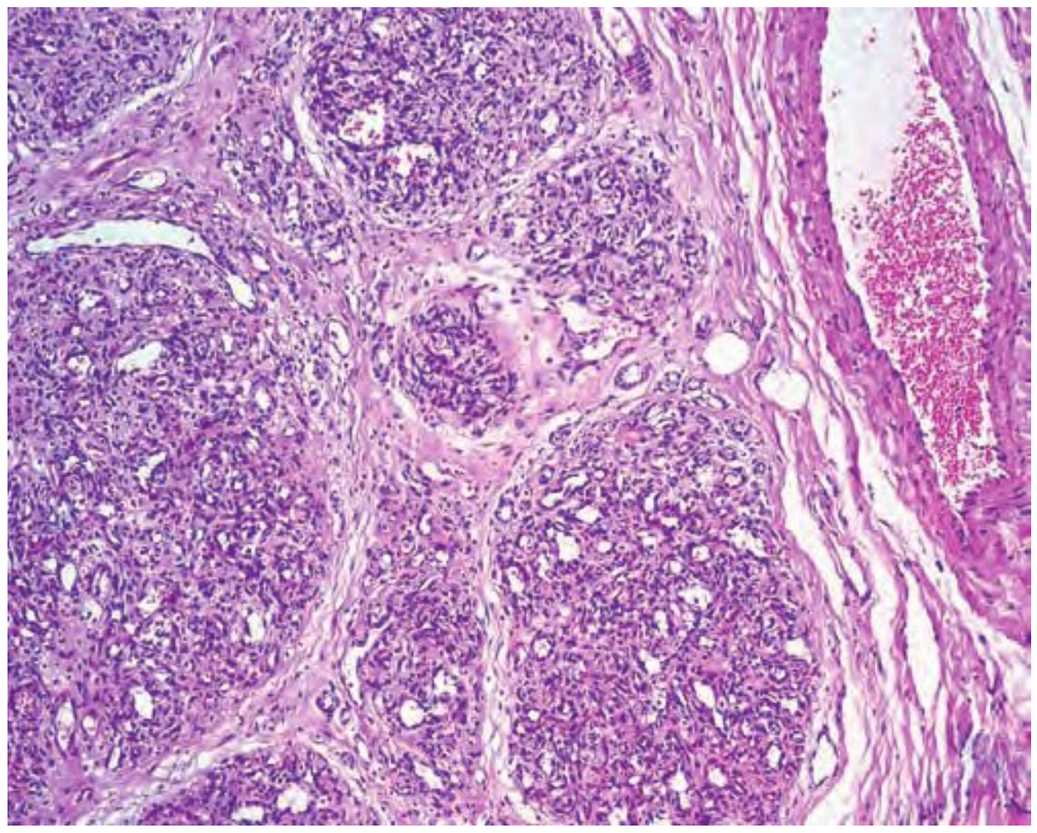

FIGURE 33-12. Infantile hemangioma. Mature lesion with well-formed canalized capillaries and a neighboring feeding vessel.

Pathogenesis. Ultrastructural and immunohistochemical studies of capillary hemangiomas have demonstrated that tumors show remarkable cellular heterogeneity. A large proportion of the cells in a given tumor are endothelial cells and pericytes, but fibroblasts, mast cells, and a population of as yet unidentified factor XIIIa–positive cells have been described (61–63). A complex interaction among these cell populations may modulate the progression and latter evolution of capillary hemangiomas (64). It has recently been described that juvenile hemangiomas share the same unique phenotype with human placenta (64). Immunohistochemical staining for GLUT-1 uniformly stains endothelial cells in infantile hemangioma (57).

Differential Diagnosis. Distinction between infantile hemangioma and RICH and NICH is discussed on pages 1013–1014.

Cherry Hemangioma (Senile Angioma, Campbell de Morgan Spot)

Cherry hemangiomas are bright red lesions varying in size from a hardly visible punctum to a soft, raised, dome-shaped lesion measuring several millimeters in diameter. This very common lesion, often present in large numbers, may start appearing in early adulthood, and the number of lesions increases with age. Cherry hemangiomas may occur anywhere on the skin, but the trunk and the upper limbs are the most common sites.

Histopathology. In the early stage of development, cherry hemangiomas have the appearance of true capillary hemangiomas, being composed of numerous newly formed capillaries with narrow lumina and prominent endothelial cells arranged in a lobular fashion in the subpapillary region. As the lesion ages, the capillaries become dilated. In a fully mature cherry hemangioma, numerous moderately dilated capillaries lined by flattened endothelial cells are observed. The intercapillary stroma shows edema and homogenization of the collagen. The epidermis is thinned and often surrounds most of the angioma as a collarette.

Differential Diagnosis. In its early stage, cherry hemangioma, like granuloma pyogenicum, shows capillary proliferation; however, endothelial proliferation is much less pronounced than in granuloma pyogenicum; thus, solid aggregates of endothelial cells are not seen.

Tufted Angioma (Angioblastoma)

Tufted angioma is a benign angiomatous condition that can be regarded as identical to the angioblastoma reported by Japanese authors (65,66). The angiomas affect the genders equally, usually arising between the ages of 1 and 5 years (67–69); occasionally, the lesions are present at birth (70,71), but they may develop in adults or even in old age (72). There are exceptional instances of angiomas arising in pregnancy, with regression after pregnancy (73), the occurrence in several members of a family (74), and the development of lesions after liver transplantation (75). The most common sites for the angiomatous papules and plaques are the upper trunk, neck, and proximal part of the limbs. Exceptionally, presentation may be in the oral cavity (76). The lesions usually slowly progress for several years and can eventually cover wide segments of the body; some are tender on palpation, and rare lesions regress (77). In rare cases, hypertrichosis may be seen in the skin overlying the lesion (69). Kasabach-Merritt syndrome is a rare association (78,79).

Histopathology. Circumscribed foci of closely set capillaries are found scatttered through the dermis and occasionally reach the subcutis. At lower magnification, these discrete, ovoid angiomatous lobules or tufts have been alluded to as giving rise to a "cannonball" appearance (Fig. 33-13). The vascular nature of the tufts may not be immediately apparent, as vascular lumina are compressed by enlarged endothelial cells and contain few red blood cells. Some of the vascular tufts appear to indent lymphatic-like channels (Figs. 33-14 and 33-15). Mitotic activity and cell atypia are insignificant.

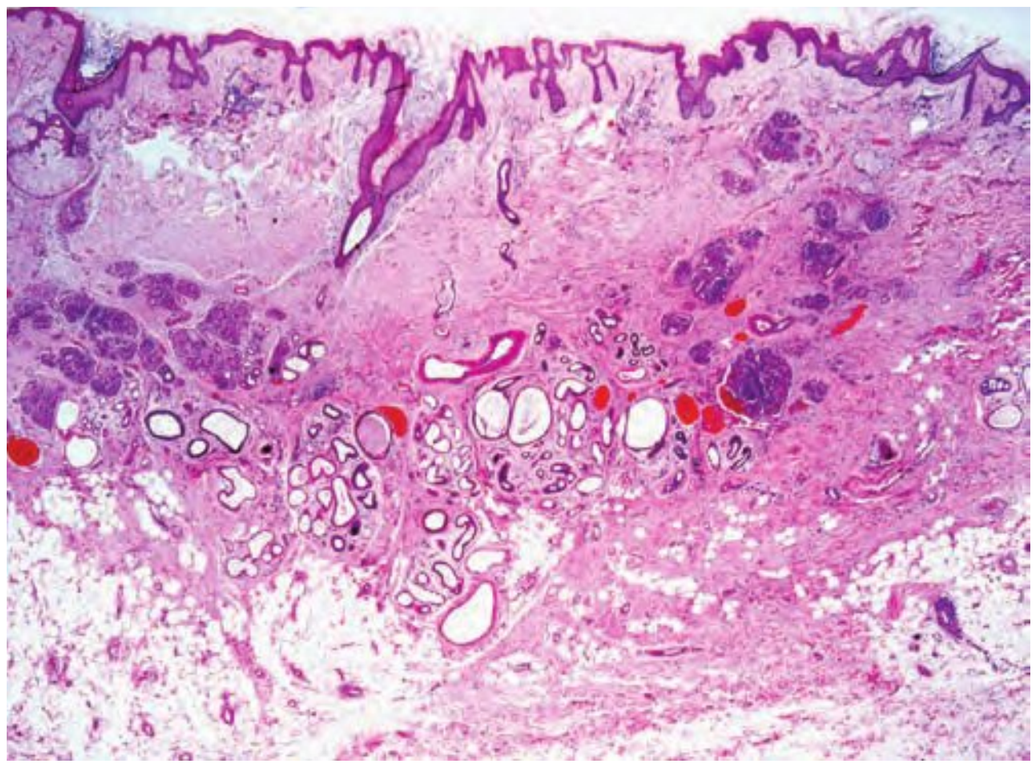

FIGURE 33-13. Tufted angioma. Scattered round or ovoid dermal lobules in a typical "cannonball" distribution.

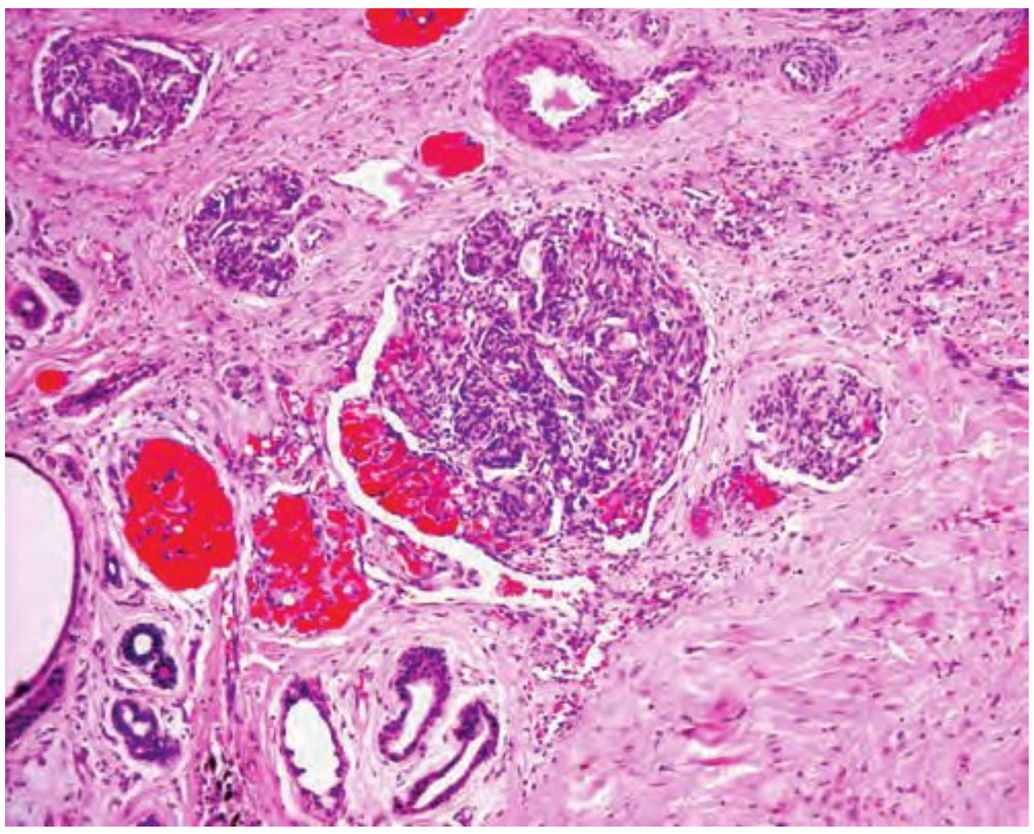

FIGURE 33-14. Tufted angioma. Lobule composed of bloodless capillaries surrounded by dilated crescent-shaped vascular channels.

The presence of strong labeling for actin indicates a prominent pericytic component among the tumor capillaries.

Differential Diagnosis. The main importance of this uncommon angioma, especially if it develops in adults, is the differential diagnosis from *Kaposi's sarcoma* or possibly a low-grade *angiosarcoma*. Endothelial cells in tufted angioma may show slight spindling but not the elongated spindle cells of Kaposi's sarcoma. The discrete focal arrangement of vascular tufts having few red blood cells also differs greatly from the mature lesions of Kaposi's sarcoma. The absence of cell atypia is the main distinguishing feature from angiosarcoma.

The hypertrophic cellular appearance of the tufts is similar to the angiomatous tissue in strawberry nevi, but the angiomatous aggregates are far more massive in the latter, where they tend to replace wide segments of the dermis and fat. It seems likely that tufted angioma is a variant of capillary hemangioma; this is supported by the finding of characteristic cytoplasmic crystalline lamellae in both disorders (80).

Distinction from kaposiform hemangioendothelioma is sometimes difficult, particularly in small biopsies, and it has been suggested that both tumors overlap (81). In difficult cases, immuonhistochemistry for D2-40 may be useful: As in kaposiform hemangioendothelioma, there is positivity for this marker within the tumor lobules, while in tufted angioma, the tufts of capillaries are negative for D2-40, which only stains the endothelium in the channels in the vicinity of the tufts (82).

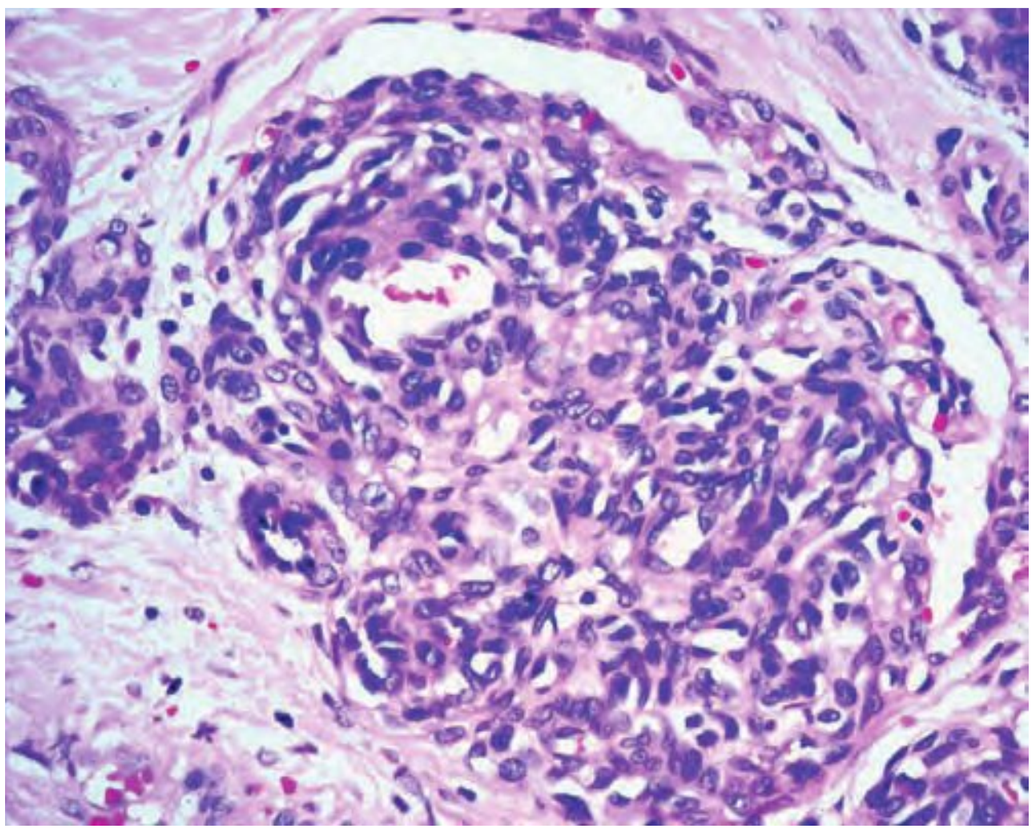

FIGURE 33-15. Tufted angioma. Often, the capillaries appear poorly canalized and pericytes are prominent.

Pyogenic Granuloma (Lobular Capillary Hemangioma)

Pyogenic granuloma, or lobular capillary hemangioma, is a common proliferative lesion that is often related to trauma. Typically, the lesion grows rapidly for a few weeks before stabilizing as an elevated, bright red papule, usually not more than 1 to 2 cm in size (Fig. 33-16); it may then persist indefinitely unless destroyed. Recurrence after surgery or cautery is not rare. Pyogenic granuloma most often affects children or young adults of either gender, but the age range is wide; the hands, fingers, and face, especially the lips and gums, are the most common sites (83,84). Pyogenic granuloma of the gingiva in pregnancy (epulis of pregnancy) is a special subgroup. Lesions may rarely develop within a port-wine stain (85,86).

FIGURE 33-16. Lobular capillary hemangioma (pyogenic granuloma). Ulcerated, polypoid papular lesion.

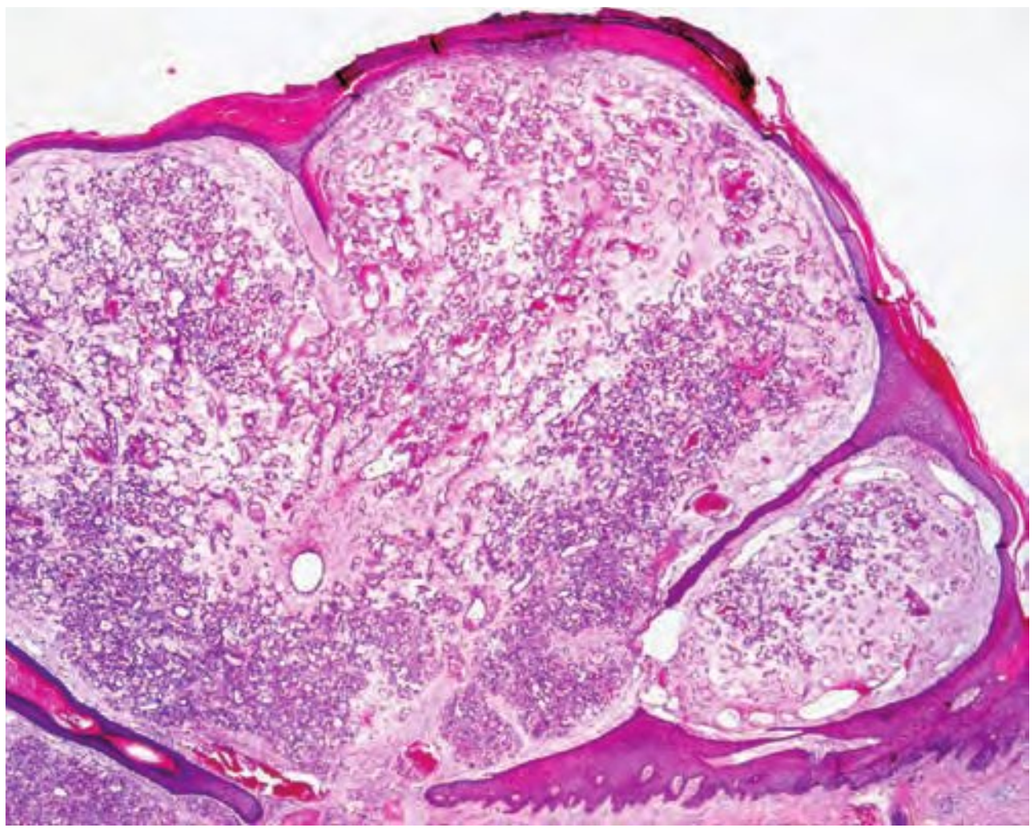

FIGURE 33-17. Lobular capillary hemangioma (pyogenic granuloma). Early, nonulcerated lesion with the typical epithelial collarette.

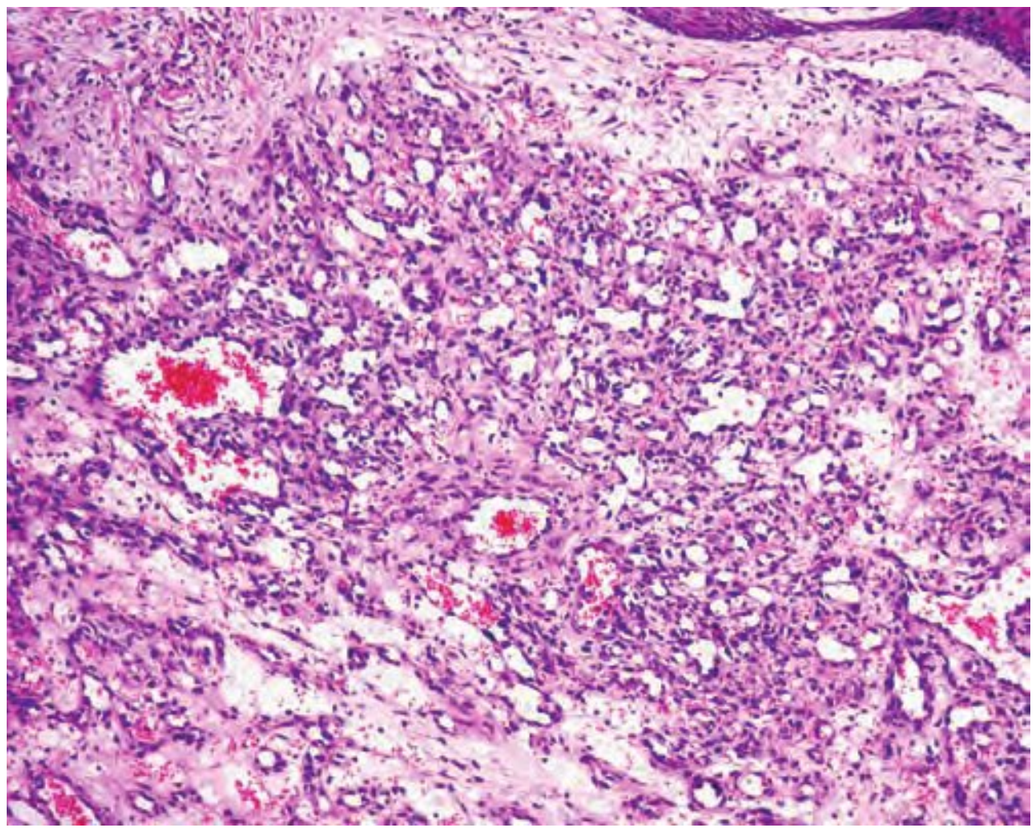

FIGURE 33-18. Lobular capillary hemangioma (pyogenic granuloma). Distinctive lobules of dilated and congested capillaries in an edematous stroma.

A rare and alarming event is the development of multiple satellite angiomatous lesions at and around the site of a previously destroyed pyogenic granuloma (87,88). This usually occurs following lesions on the shoulder or upper trunk in children. Histologically, lesions that are similar to pyogenic granuloma can occur in the deep dermis, the subcutaneous tissue (89), and even within dilated venous channels (90,91). Widely scattered angiomatous lesions resembling pyogenic granulomas have also been described (92–94), sometimes in association with visceral disease.

Histopathology. The typical lesion presents as a polypoid mass of angiomatous tissue protruding above the surrounding skin. It is often constricted at its base by a collarette of acanthotic epidermis (Fig. 33-17). An intact, flattened epidermis may cover the entire lesion, but surface erosions are common. In ulcerated lesions, a superficial inflammatory cell reaction can give rise to an appearance suggestive of granulation tissue, but inflammation does not appear to be an intrinsic feature. Inflammation is usually slight in the deeper part of the lesion and may be absent when the epidermis is intact. The angiomatous tissue tends to occur in discrete masses or lobules, resembling a capillary hemangioma—hence, the preference by Mills and associates (83) for the term *lobular capillary hemangioma* to describe this condition (Fig. 33-18). The angiomatous tissue is surrounded by myxoid stroma containing scattered spindle- and stellate-shaped connective tissue cells and occasional mast cells. The angiomatous tissue is composed of a variably dilated network of blood-filled capillary vessels and groups of poorly canalized vascular tufts. Mitotic activity varies and can be prominent. Feeding vessels often extend into the adjacent dermis, and rare lesions show a deep component in the reticular dermis. Occasionally, foci of intravascular papillary endothelial hyperplasia occur within the larger deep vessels. Focal epithelioid endothelial cells can sometimes be seen. Focal cytologic atypia may be present, particularly in lesions arising in mucosal surfaces such as the mouth (95). The histology of recurrent or satellite lesions is similar, but the angiomatous proliferation can extend more deeply into the dermis. Pyogenic granulomas of the subcutaneous tissue or in veins show similar histologic features but lack an inflammatory component. Intravascular lesions can so distend the veins that the surrounding muscle coat can be thinned and difficult to detect (Fig. 33-19).

Pathogenesis. It was once assumed that granuloma pyogenicum was caused by pyogenic infection. However, the histologic picture of early lesions suggests a capillary hemangioma, and even in eroded lesions that show inflammation,

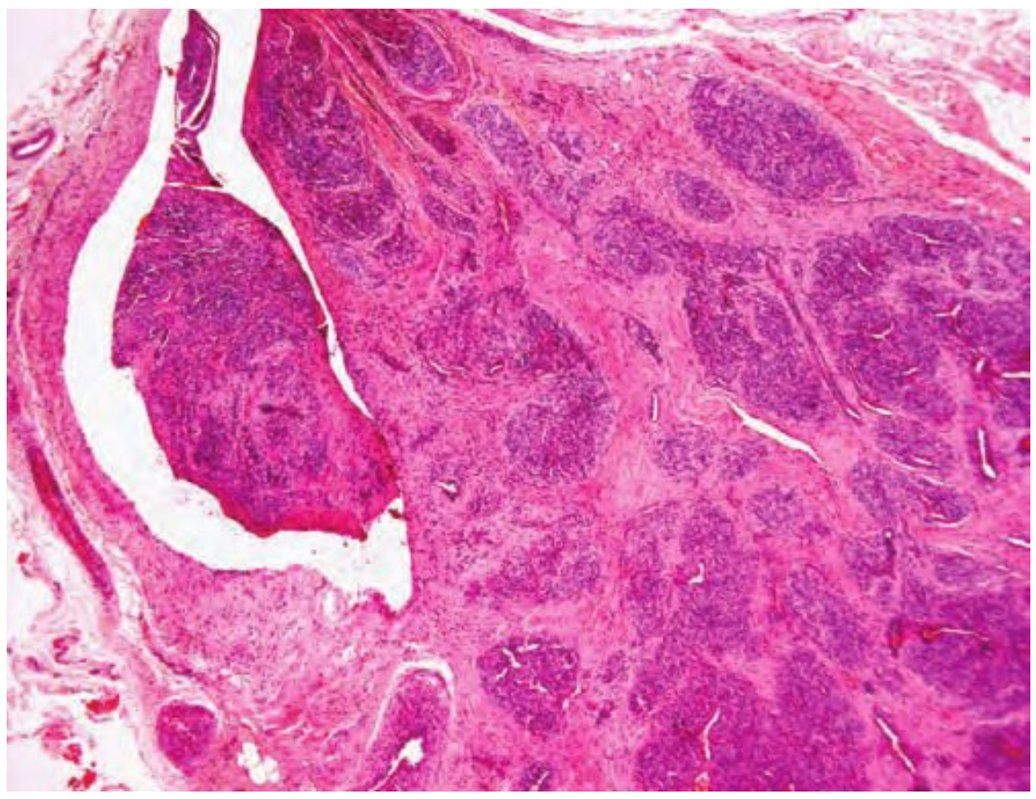

FIGURE 33-19. Intravascular lobular capillary hemangioma (pyogenic granuloma). Some cases occur entirely in an intravenous location.

the appearance mimics that of a capillary hemangioma in its deeper portions. Therefore, the term *lobular capillary hemangioma* has been suggested (83).

Immunohistochemical studies demonstrate positive labeling of endothelial cells for vascular markers, including CD31, and also of pericytes for smooth muscle actin.

Differential Diagnosis. Both Kaposi's sarcoma and angiosarcoma should be considered as part of the differential diagnosis, especially when multiple lesions are present. Elevated polypoid lesions are rare in Kaposi's sarcoma; most show obvious spindle cells woven between delicate vascular spaces, unlike in pyogenic granuloma. A much greater degree of cell atypia with intraluminal spreading of malignant cells characterizes well-differentiated angiosarcomas. Focal areas of intravascular papillary endothelial hyperplasia within a pyogenic granuloma occasionally can simulate angiosarcoma, but, even so, nuclear atypia is slight.

In recent years, a further differential diagnosis of pyogenic granuloma is with bacillary angiomatosis, an infectious, vascular proliferation seen in HIV-infected patients and caused by *Bartonella henselae* or less commonly by *Bartonella quintana*, which are small, gram-negative rods belonging to the family Bartonellaceae (96–98) (see Chapter 21). Bacillary angiomatosis is now rarely seen in the Western world, as HIV-positive patients are treated with HAART and with prophylactic antibiotics. Clinically, and especially histologically, lesions of bacillary angiomatosis can look remarkably similar to a pyogenic granuloma. The low-power architecture in superficial lesions may be almost identical to that seen in pyogenic granuloma (Fig. 33-20). In bacillary angiomatosis, however, the endothelial cells often have

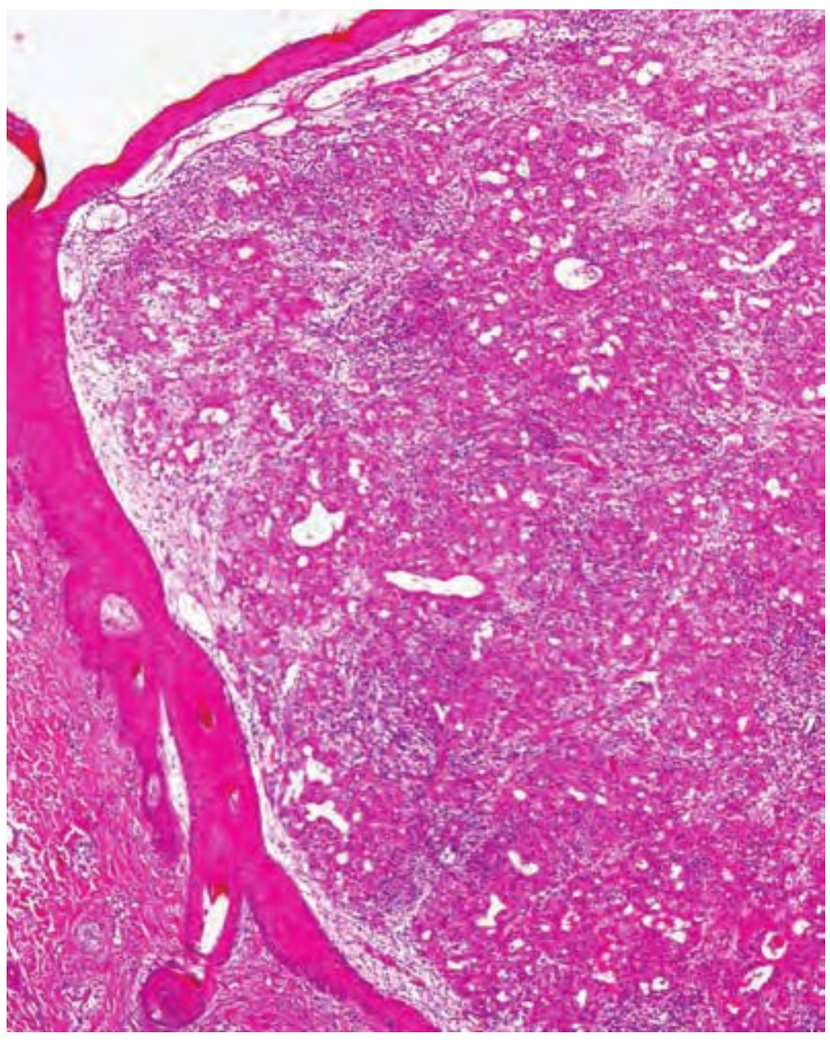

FIGURE 33-20. Bacillary angiomatosis. Similar low-power architecture to lobular capillary hemangioma, but there is more prominent inflammation in the background.

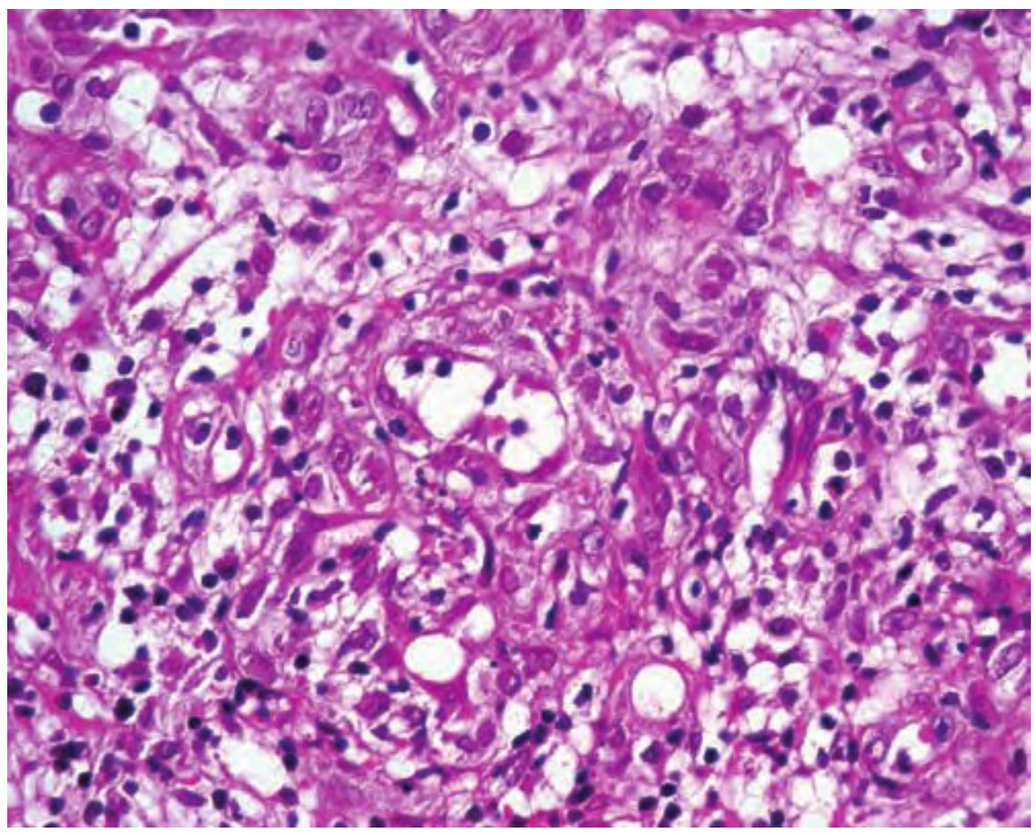

FIGURE 33-21. Bacillary angiomatosis. The vascular channels are lined by pale epithelioid endothelial cells. Often, neutrophils with nuclear dust are seen in the surrounding stroma.

abundant pale cytoplasm (Fig. 33-21), and aggregates of neutrophils are present throughout the lesion, often in relation to clumps of granular basophilic material. This basophilic material shows bacilli when stained with Warthin-Starry (Fig. 33-22) or Giemsa stains. The presence of the organism may also be detected by PCR.

Vascular granulomatous lesions mimicking pyogenic granulomas occasionally arise as a complication of systemic or topical retinoid therapy, but the histology is that of nonspecific vascular granulation tissue lacking a lobular architecture (99–101). Pyogenic granuloma–like lesions have also been described during capecitabine therapy (102).

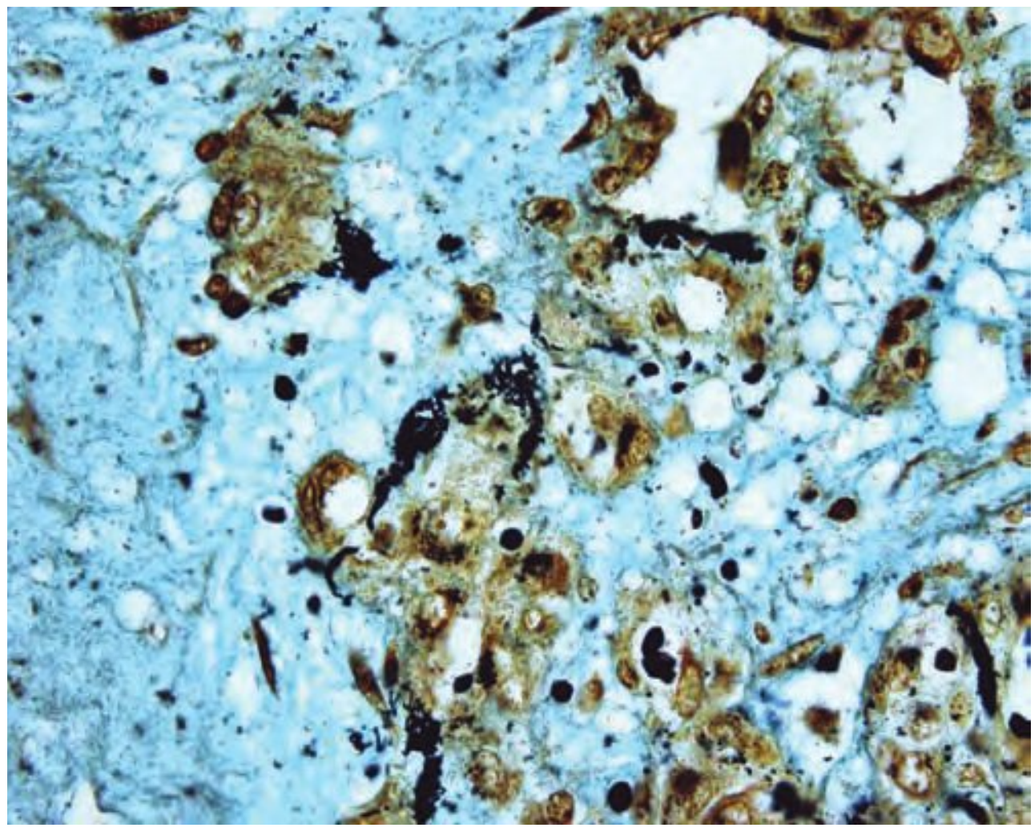

FIGURE 33-22. Bacillary angiomatosis. Warthin-Starry stain showing numerous clumps of bacilli.

Distinction from a nodular lesion of orf or milker's nodule may be difficult, as the low-power architecture may resemble a lobular capillary hemangioma. However, in the former, there is often prominent hyperplasia of the epidermis and the infundibular portion of the hair follicles. The prominent vascular component represents granulation tissue with only a focal lobular architecture, and the keratinocytes often show typical viral inclusions.

Cavernous Hemangioma

Sharing with strawberry nevus the same age, gender, and anatomic distribution, cavernous hemangioma is still less common and tends to be larger, deeper and less well-defined than the former and shows no tendency for spontaneous regression (58,59). Rare cavernous hemangiomas may be associated with an overlying capillary hemangioma. There are two rare conditions in which numerous cavernous hemangiomas occur: Maffucci's syndrome and the blue rubber bleb nevus.

Maffucci's Syndrome

The outstanding features of Maffucci's syndrome are dyschondroplasia resulting in defects in ossification; fragility of the bones, causing severe deformities; and osteochondromas, which may develop into chondrosarcomas (24). In addition, large, compressible subcutaneous cavernous hemangiomas may be present at birth or appear in childhood or early adulthood.

Blue Rubber Bleb Nevus

In the blue rubber bleb nevus, cavernous hemangiomas are present at birth but may subsequently increase in size and number. The hemangiomas have a distinct appearance, and most of them are protuberant, dark blue, soft, and compressible; some are pedunculated. They vary from a few millimeters to 3 cm in diameter. In addition, subcutaneous hemangiomas are felt on palpation. There are also hemangiomas in the oral mucosa, the gastrointestinal tract, and less commonly in other organs (24). Some blue rubber bleb nevi are probably telangiectatic glomangiomas in which the glomus cells are sparse.

Histopathology. Cavernous hemangiomas appear in the lower dermis and the subcutaneous tissue with large, irregular spaces containing red blood cells and fibrinous material (Fig. 33-23). The spaces are lined by a single layer of thin endothelial cells. Not uncommonly, a capillary component is present, especially in the superficial portion of a tumor. Dystrophic calcification is often present.

Variant of Cavernous Hemangioma: Sinusoidal Hemangioma

Sinusoidal hemangioma is a relatively rare variant of cavernous hemangioma (60,103). The lesion presents as a bluish subcutaneous mass, especially in middle-aged adults, and has a predilection for females. Although the anatomic distribution is wide, tumors often present in the breast, and in this setting, angiosarcoma is considered in the differential diagnosis.

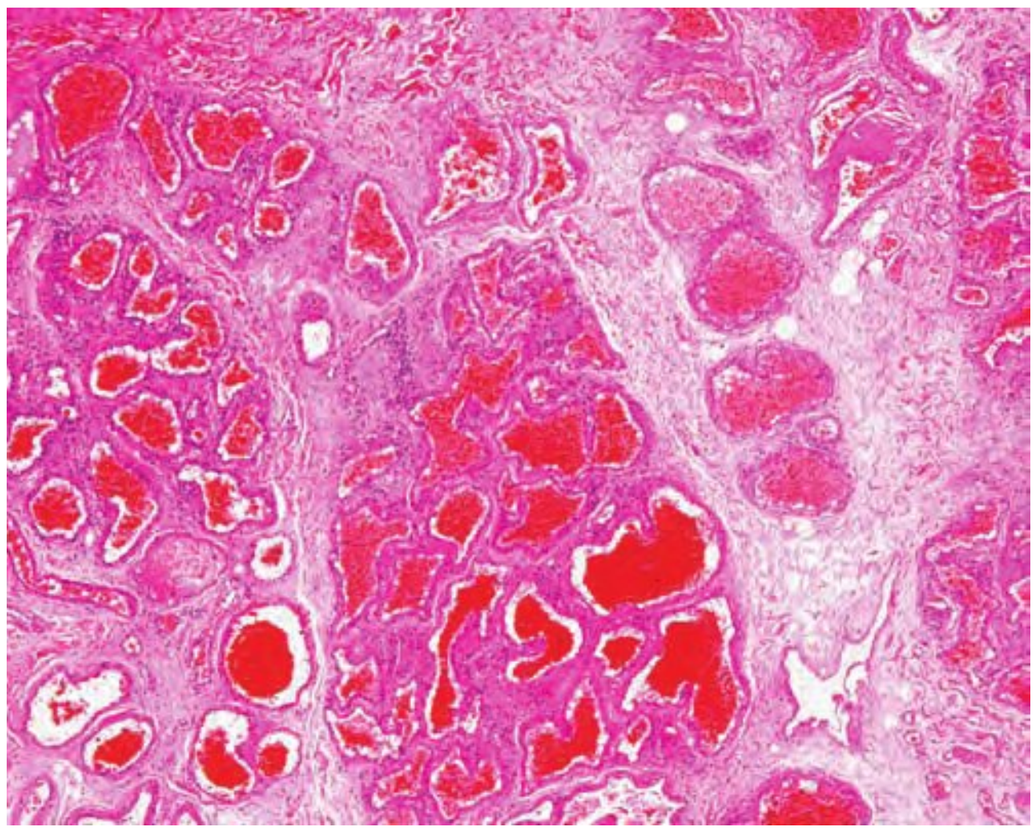

FIGURE 33-23. Cavernous hemangioma. Markedly dilated and congested vascular spaces.

Histopathology. Sinusoidal hemangioma is lobular and focally ill-defined with partial or total replacement of subcutaneous fat lobules. The typical feature is the presence of gaping, markedly dilated and congested, thin walled, back-to-back vascular spaces in a sievelike or sinusoidal arrangement (Fig. 33-24). Pseudopapillary structures due to cross-sectioning of these spaces focally resemble intravascular papillary endothelial hyperplasia (Fig. 33-25). The blood vessels are lined by bland, flat endothelial cells, which can be focally prominent and mildly pleomorphic. Thrombosis, hyalinization, dystrophic calcification, and even areas of infarction can be seen in older lesions. Distinction from a well-differentiated angiosarcoma is based on the presence in the latter of an infiltrative growth pattern, cytologic atypia, and multilayering. In breast lesions, it is

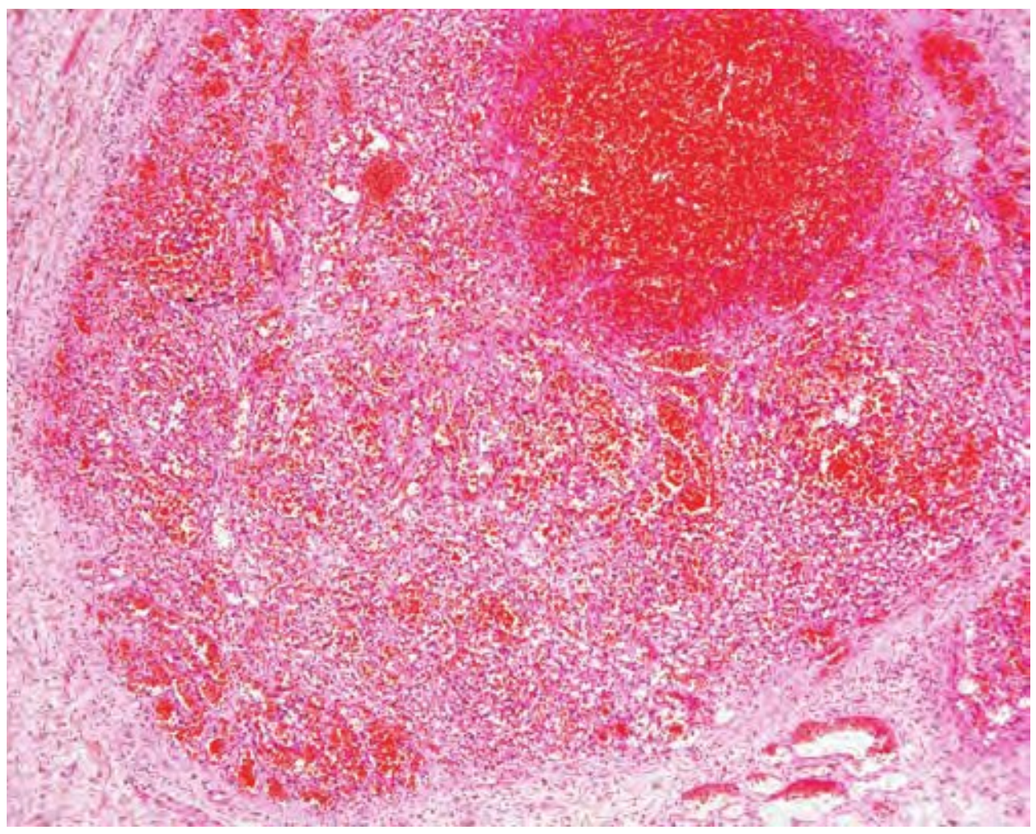

FIGURE 33-24. Sinusoidal hemangioma. Congested anastomosing vascular channels with a sievelike appearance.

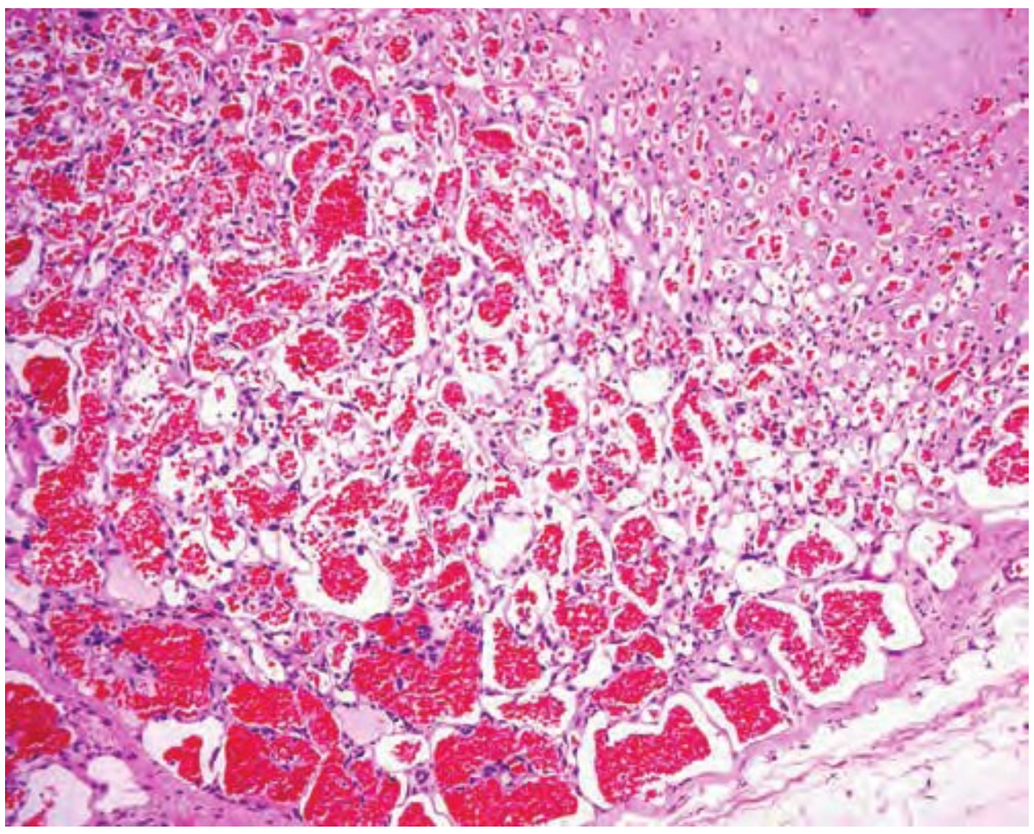

FIGURE 33-25. Sinusoidal hemangioma. Higher magnification reveals a typical sinusoidal appearance.

worth remembering that mammary angiosarcomas are always intraparenchymal.

Verrucous Hemangioma

Verrucous hemangioma is a rare form of vascular malformation that is usually congenital and only rarely presents later in life. Most cases present as wartlike, dark blue papules or nodules with special predilection for the distal lower limbs (Fig. 33-26). Although the majority of cases are solitary, an exceptional case with multiple lesions on different parts of the body has been reported (104). Often, cases are confused clinically and histologically with angiokeratomas, but verrucous hemangiomas always have a deep component, and recurrence after incomplete excision occurs in up to one third of cases (105).

In *Cobb syndrome*, a lesion identical to a verrucous hemangioma presents on the trunk with a dermatomal distribution and in association with an underlying meningospinal hemangioma (106).

Histopathology. The superficial portion of a verrucous hemangioma is indistinguishable from an angiokeratoma. However, a combination of congested capillaries and cavernous-like vascular spaces is seen extending into the deep dermis and subcutaneous tissue (Fig. 33-27). These vascular spaces are lined by flattened endothelial cells and are usually surrounded by a layer of pericytes. A lobular growth pattern is often apparent in the deep component.

FIGURE 33-26. Verrucous hemangioma. Verrucous vascular plaques are typically seen.

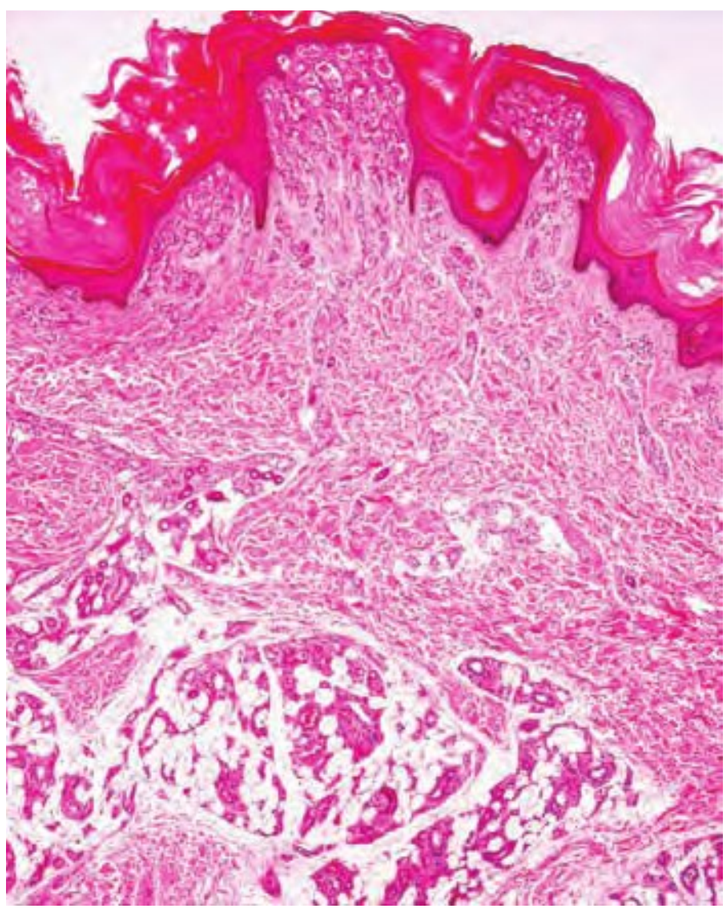

FIGURE 33-27. Verrucous hemangioma. Note the superficial component similar to angiokeratoma but with a deep component extending to the subcutaneous tissue.

Microvenular Hemangioma

This is a relatively rare, acquired vascular lesion that usually arises as a small, reddish lesion in young to middle-aged individuals of either gender (107,108). The arms, trunk, and legs are favored sites. The development of lesions in relationship to pregnancy or a change in the use of oral contraception may suggest a hormonal influence on the disease in women (109).

Histopathology. Histologically, thin, branching capillaries and small venules with narrow or slightly dilated lumina are found widely throughout the dermis (Fig. 33-28). There is no obvious endothelial cell atypia or accompanying inflammation, but slight dermal sclerosis is often present (Fig. 33-29). The collagen bundles around the vascular channels appear somewhat

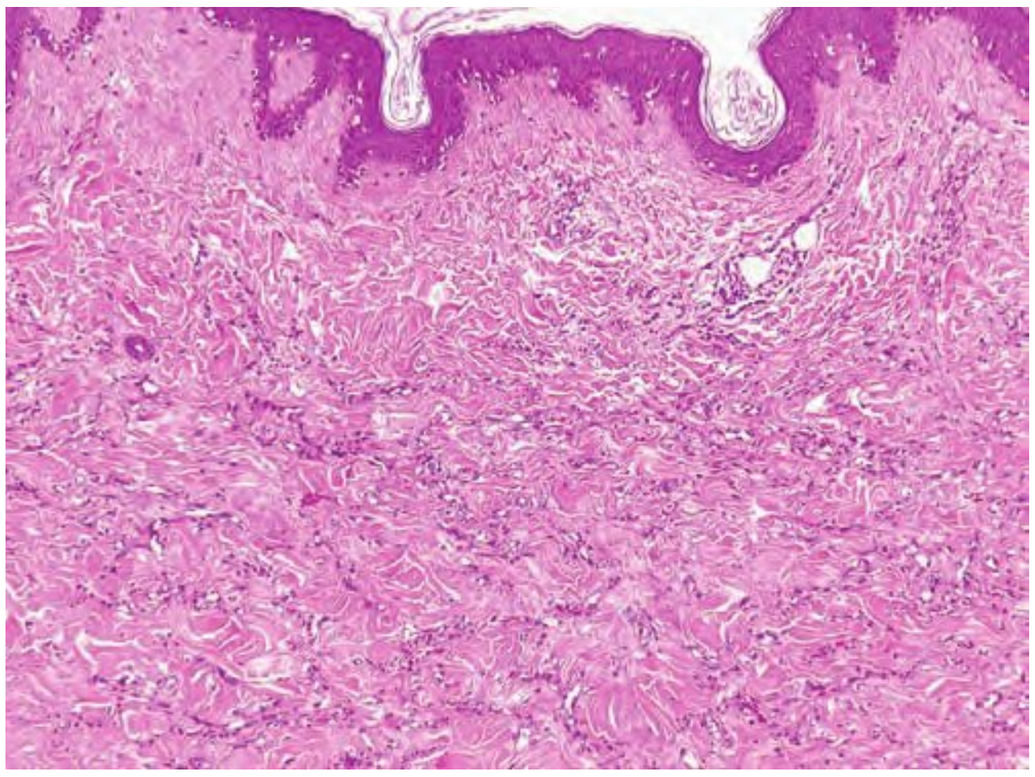

FIGURE 33-28. Microvenular hemangioma. Irregular, branching, thin-walled venules within the dermis.

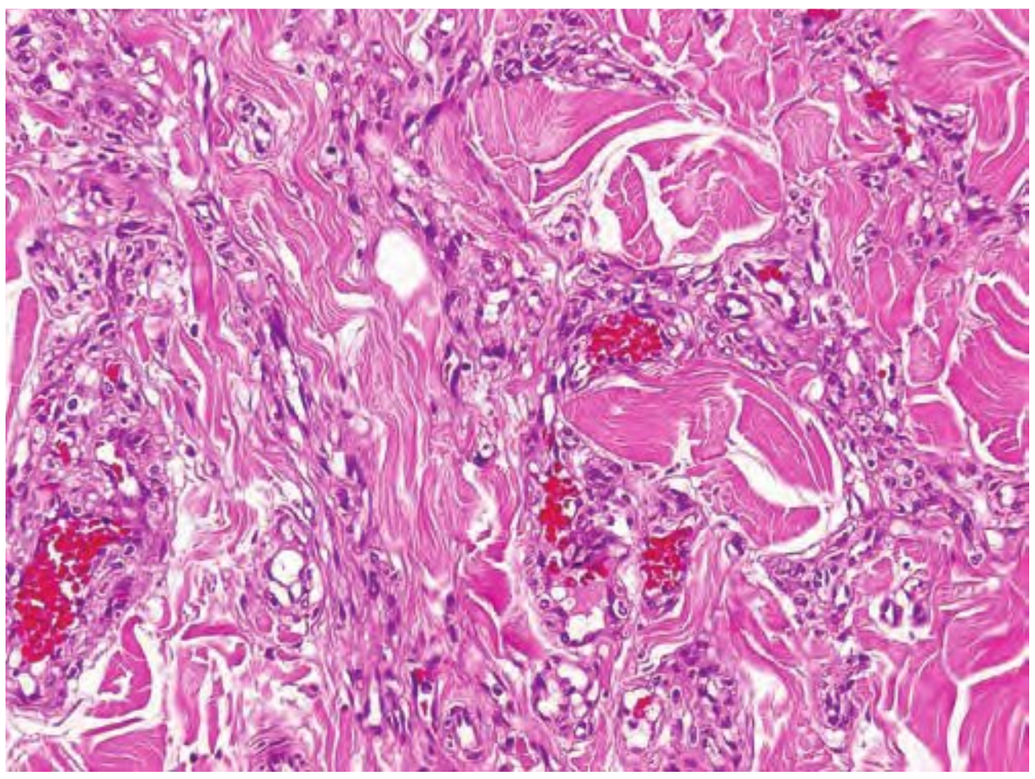

FIGURE 33-29. Microvenular hemangioma. Note small venules surrounded by somewhat hyalinized collagen bundles.

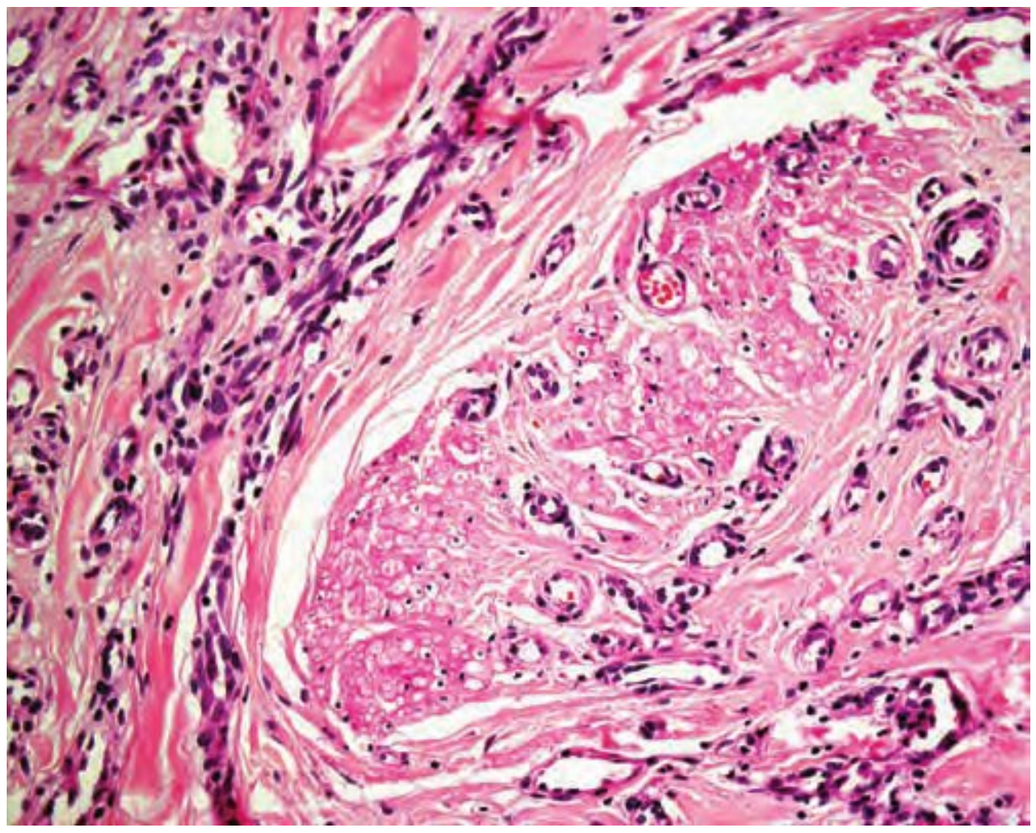

FIGURE 33-30. Microvenular hemangioma. Prominent infiltration of the arrector pili muscle.

sclerotic. A fairly constant feature in many cases is the prominent infiltration of arrector pili muscles by the proliferating vascular channels (Fig. 33-30). The cells lining the vessels are strongly positive for von Willebrand factor and CD34. In two cases, angiomatous tufts in the deeper part of the lesion have suggested a possible relationship with tufted angioma (108).

Differential Diagnosis. The importance of microvenular hemangioma as an acquired vascular anomaly in young persons lies in the differential diagnosis from an early or macular lesion of Kaposi's sarcoma. The lymphangioma-like channels of Kaposi's sarcoma are more delicate, do not contain erythrocytes, show angulated outlines, and tend to wrap around collagen bundles. Furthermore, plasma cells and other inflammatory cells are common in Kaposi's sarcoma but not in microvenular hemangioma. HHV-8 is consistently positive in Kaposi's sarcoma and negative in microvenular hemangioma. Only a single case of HHV-8–positive microvenular hemangioma in a patient with POEMS syndrome has been reported (110).

Hobnail Hemangioma (Targetoid Hemosiderotic Hemangioma)

Hobnail hemangioma, or targetoid hemosiderotic hemangioma, is a relatively uncommon vascular tumor that usually presents in the trunk or extremities of young or middle-aged adults with a male predominance (111–113). Rare cases occur in the oral mucosa. The descriptive name initially given to this tumor reflects a typical clinical appearance characterized by a small solitary lesion consisting of a brown to violaceous papule, 2 to 3 mm in diameter, surrounded by a thin, pale area and a peripheral ecchymotic ring. However, these features are only present in a small percentage of cases, and most often, the clinical appearance is that of a red-blue or brown papule. The alternative name of *hobnail hemangioma*, which emphasizes a more constant special histologic feature, has therefore been proposed (see text following). Interestingly, some lesions in females change during the menstrual cycle, suggesting that there is a direct hormonal influence (114).

Histopathology. In the superficial reticular dermis, there are a number of thin-walled, dilated, and irregular vascular spaces (Fig. 33-31) often lined by bland endothelial cells with scanty cytoplasm and rounded nuclei that protrude into the lumina and closely resemble hobnails (Figs. 33-32 and 33-33). Focally, epithelioid cells are rarely present. Intraluminal papillary projections and fibrin thrombi can be seen in the superficial blood vessels (Fig. 33-33). The vascular channels in the deeper dermis become much less conspicuous and eventually disappear completely. These deeper channels are irregular and angulated, lined by flattened endothelial cells, and dissect between collagen bundles.

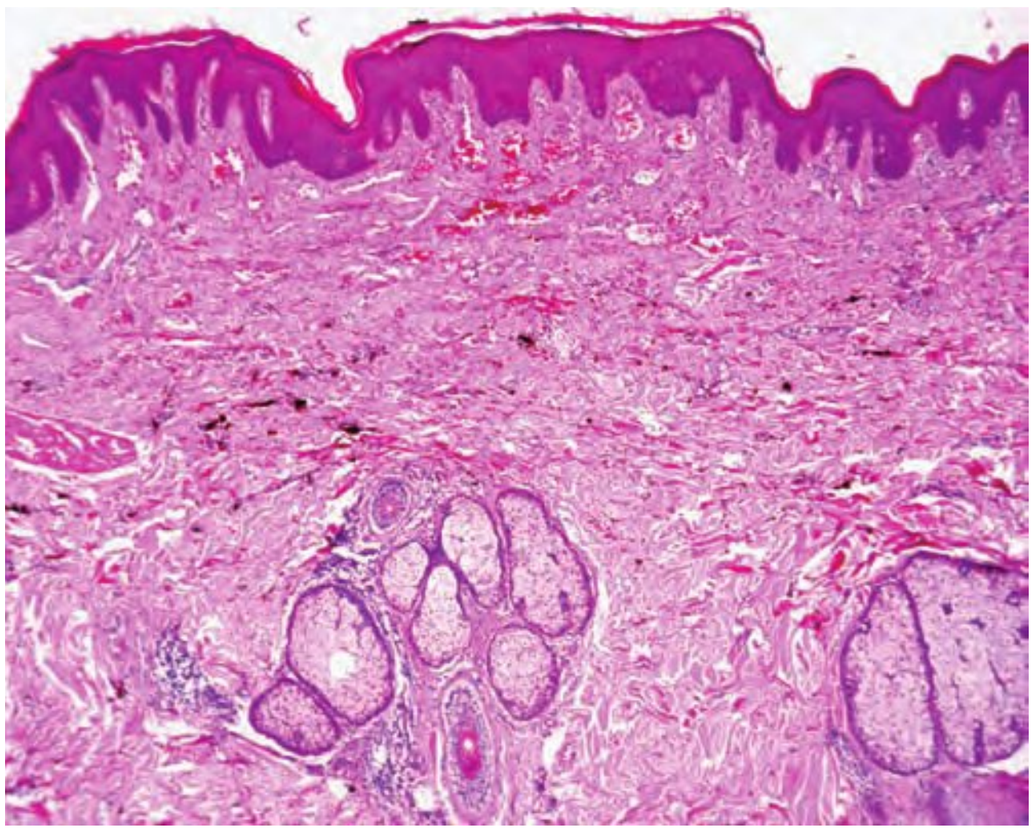

FIGURE 33-31. Hobnail hemangioma. Typical wedge-shaped architecture with a prominent superficial component. Note prominent hemosiderin deposition.

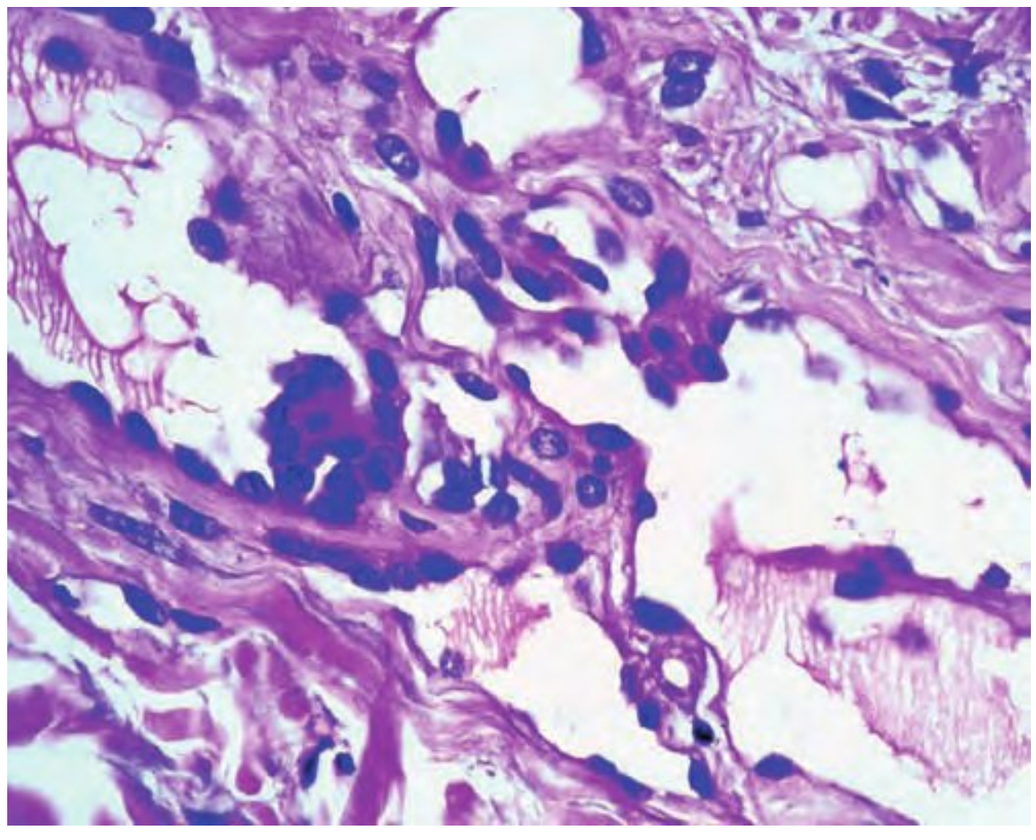

FIGURE 33-33. Hobnail hemangioma. Hobnail endothelial cells and small papillary projections.

Extensive red blood cell extravasation, inflammatory aggregates predominantly of lymphocytes, and, in a later stage, extensive stromal hemosiderin deposition are commonly seen.

Pathogenesis. Because there is a family of vascular tumors characterized by epithelioid endothelial cells, it has been proposed that this tumor represents the benign end of the spectrum of a group of vascular tumors characterized by hobnail endothelial cells that includes *Dabska's tumor* and *retiform hemangioendothelioma* (115). Based on the positivity of the endothelial cells for vascular endothelial growth factor receptor 3 (VEGFR-3), it has been proposed that these tumors display lymphatic differentiation (113). However, it has become apparent that VEGFR-3 is not a specific marker of lymphatic differentiation (116).

Differential Diagnosis. This includes patch-stage Kaposi's sarcoma, retiform hemangioendothelioma, and benign lymphangioendothelioma (see page 1045).

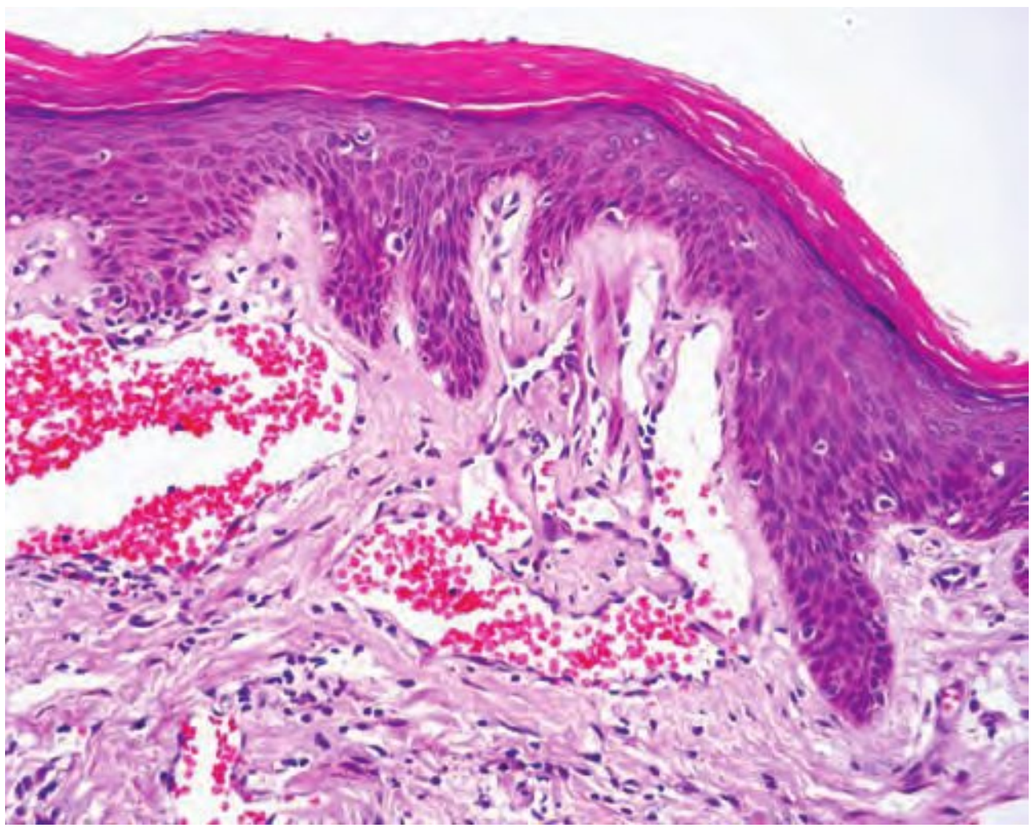

FIGURE 33-32. Hobnail hemangioma. Irregular congested vascular channels, some of which are lined by hobnail endothelial cells.

Epithelioid Hemangioma (Angiolymphoid Hyperplasia With Eosinophilia)

The terms *epithelioid hemangioma* and *angiolymphoid hyperplasia with eosinophilia* highlight the controversy about whether this entity represents a vascular neoplasm or a reactive process consequent to trauma or some other stimulus. Previously, lesions included within this group were referred to as *histiocytoid hemangiomas*, but this name has been abandoned because as originally proposed it included other entities that do not qualify as epithelioid hemangioma (117,118). It is not clear whether this entity represents a reactive proliferation secondary to diverse stimuli including trauma (119) or a neoplastic process, but the latter is favored. Therefore, the term *epithelioid hemangioma* is generally preferred to encompass vascular lesions at the benign end of the spectrum of conditions characterized by endothelial cells that have an epithelioid morphology (117,118).

Clinical Features. Most lesions arise either superficially in the dermis or in the subcutaneous tissue or deeper tissues, although occasionally both superficial and deep tissues are affected together (120). Blood eosinophilia has been reported in up to 15% of patients (118,120). Local recurrence may be seen in up to 30% of cases.

Superficial lesions. Young to middle-aged women are mainly affected with the development of pruritic papules

FIGURE 33-34. Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia). Single or multiple vascular papules often present in the ear.

(Fig. 33-34) and plaques at or around the external ear. The lesions can be numerous but are limited to one side. Typically, the clinical course is chronic over several years despite excision and other treatment modalities. Such superficial lesions were originally referred to as *pseudopyogenic granuloma*. Occlusion of the external auditory canal can bring patients to the attention of ear, nose, and throat specialists. Sometimes, other areas in the head and neck region, especially the occipital region and the vicinity of the temporal artery, are affected.

Lesions of subcutaneous and deeper tissues. Adults are mainly affected, and there is no gender predilection. The typical lesion is a solitary, slowly growing, firm, subcutaneous swelling 2 to 10 cm in size in the head and neck region, with some predilection for the pre- or postauricular sites. Sometimes, more than one lesion arises. Most lesions are asymptomatic except for occasional pruritus. Lymphadenopathy is usually not seen. Occasionally, other body sites are affected, such as the arm, hands, axillae, or inguinal region (120–122). Rare cases have been documented in association with a traumatically induced arteriovenous fistula involving the popliteal artery (123). Origin from the radial artery has also been documented (124). The condition can persist for years, but serious complications do not occur.

Epithelioid hemangioma may also rarely occur in the oral cavity (125), tongue (126), lymph node (127), bone (128), and testis (129). A case has also been reported in an ovarian teratoma (130). Epithelioid hemangiomas occurring at sites different from the skin often lack the inflammatory component.

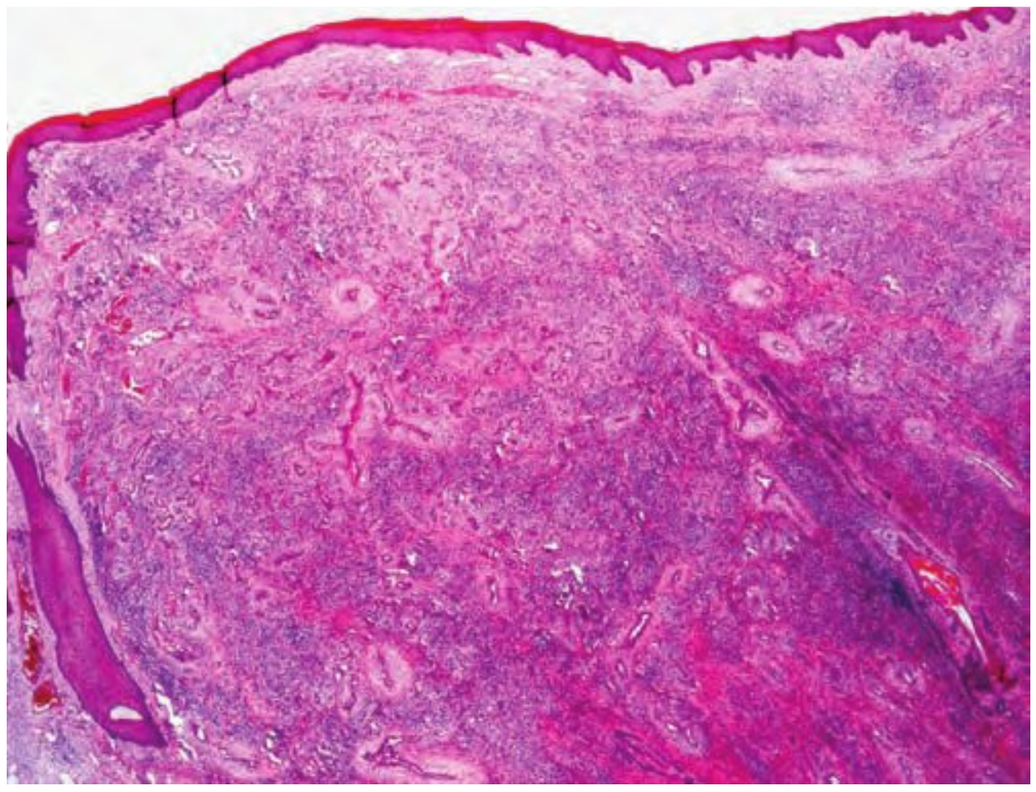

FIGURE 33-35. Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia). Superficial lesion from the ear showing typical lobular architecture and a prominent inflammatory cell infiltrate.

Histopathology. The main components of the pathology include the following:

1. Proliferation of small- to medium-sized blood vessels often showing a lobular architecture (Fig. 33-35). Many of these vascular channels are lined by greatly enlarged (epithelioid) endothelial cells (Figs. 33-36 and 33-37).
2. A perivascular inflammatory cell infiltrate composed mainly of lymphocytes and eosinophils.
3. Nodular areas of a lymphocytic infiltrate with rare follicle formation.
4. Frequent origin from a small artery or a vein. Rarely, the whole lesion is intravascular (Fig. 33-38). The condition

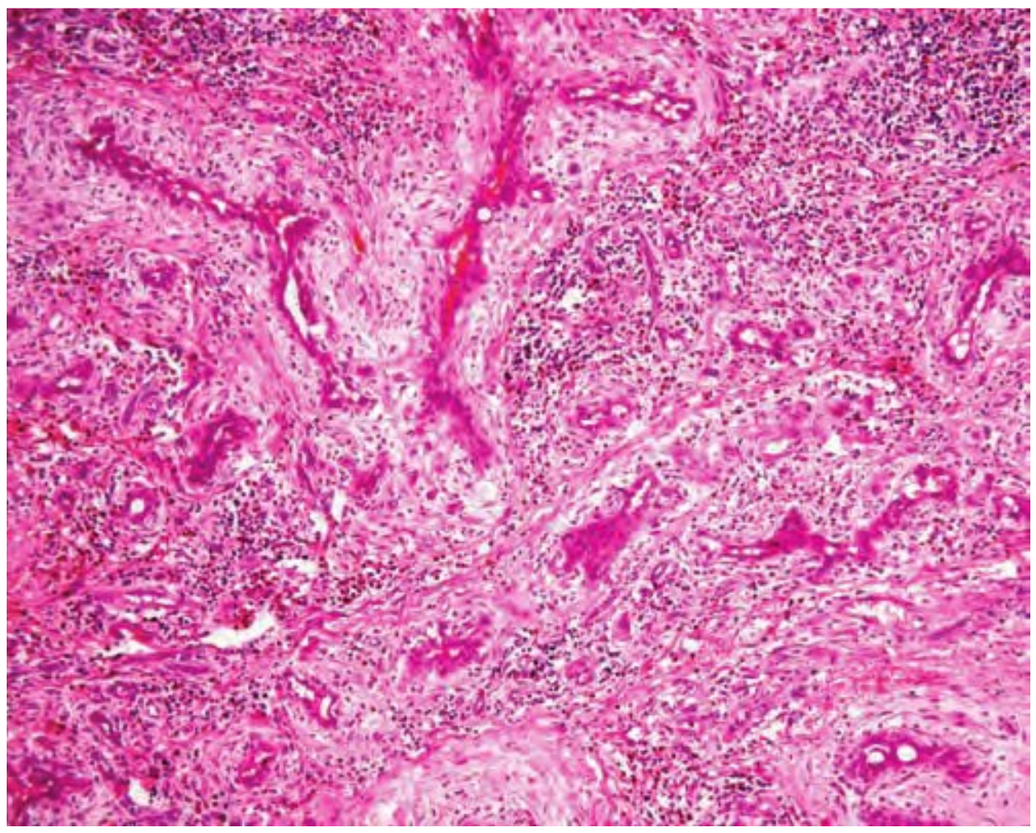

FIGURE 33-36. Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia). Numerous vascular channels lined by prominent large, pink epithelioid endothelial cells and surrounded by inflammation.

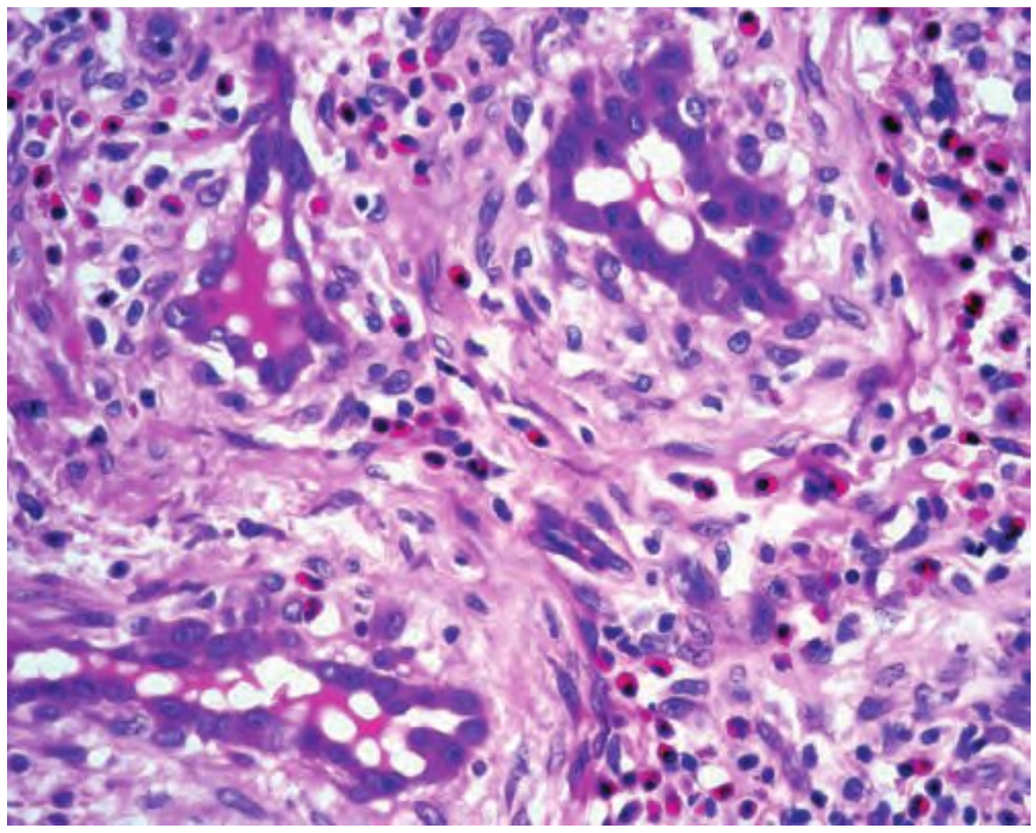

FIGURE 33-37. Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia). Prominent endothelial cells with abundant eosinophilic cytoplasm and numerous eosinophils in the surrounding stroma. Note perivascular fibrosis and numerous eosinophils.

originally described as intravenous atypical vascular proliferation likely represents a variant of intravascular epithelioid hemangioma (131).

In superficial lesions, there is variable degree of vascular hyperplasia that can include areas in which the proliferation is almost angiomatous. A distinctive feature is the "cobblestone" appearance of enlarged endothelial cells that project into the lumina of some vessels. The nucleus of these cells is ovoid and orthochromatic without atypia or evidence of mitotic activity. Affected vessels often show endothelial cells with intracytoplasmic vacuoles, which is a prominent feature of diagnostic value (Fig. 33-37). The most abnormal blood vessels are usually surrounded by stellate and spindle-shaped cells in a mucoid stroma. The associated perivascular inflammatory cell infiltrate is usually loosely scattered around the affected vessel, but it may be almost completely absent in some places. Generally, eosinophils make up 5% to 15% of the cells. Lesions with few inflammatory cells are rarely seen. Inflammatory cells also decrease markedly in late stages when a prominent fibrotic component is often present.

The epidermis above the lesions may show acanthosis or erosions due to superficial trauma. The skin appendages are usually unaffected except for the occasional finding of follicular mucinosis (132).

In subcutaneous lesions, the inflammatory cell infiltrate is usually more massive, with a central, poorly circumscribed nodule that replaces the fat. The nodule is composed of confluent sheets of small lymphocytes and eosinophils in which a network of poorly canalized thick-walled capillaries is embedded. Satellite smaller islands of lymphoid cells with lymphoid follicles usually surround the central nodule. Eosinophils can form up to 50% of the cell population.

In about 50% of cases, evidence of involvement of medium- to large-sized arteries can be found. A variable degree of blood vessel damage occurs, with infiltration of the vessel wall by inflammatory cells and occlusion of the lumen. Partial loss of the internal elastic lamina is often seen.

Histogenesis. The etiology and pathogenesis of angiolymphoid hyperplasia is at present uncertain. Occasionally, trauma (119) or external otitis can precede the onset of the disease. Ultrastructural studies have not confirmed that the enlarged endothelial cells are developing histiocytic properties, as has been suggested. There is no relation to HHV-8, but transient angiolymphoid hyperplasia with eosinophilia and Kaposi's sarcoma have been described after primary infection with HHV-8 in an HIV-positive patient (133,134).

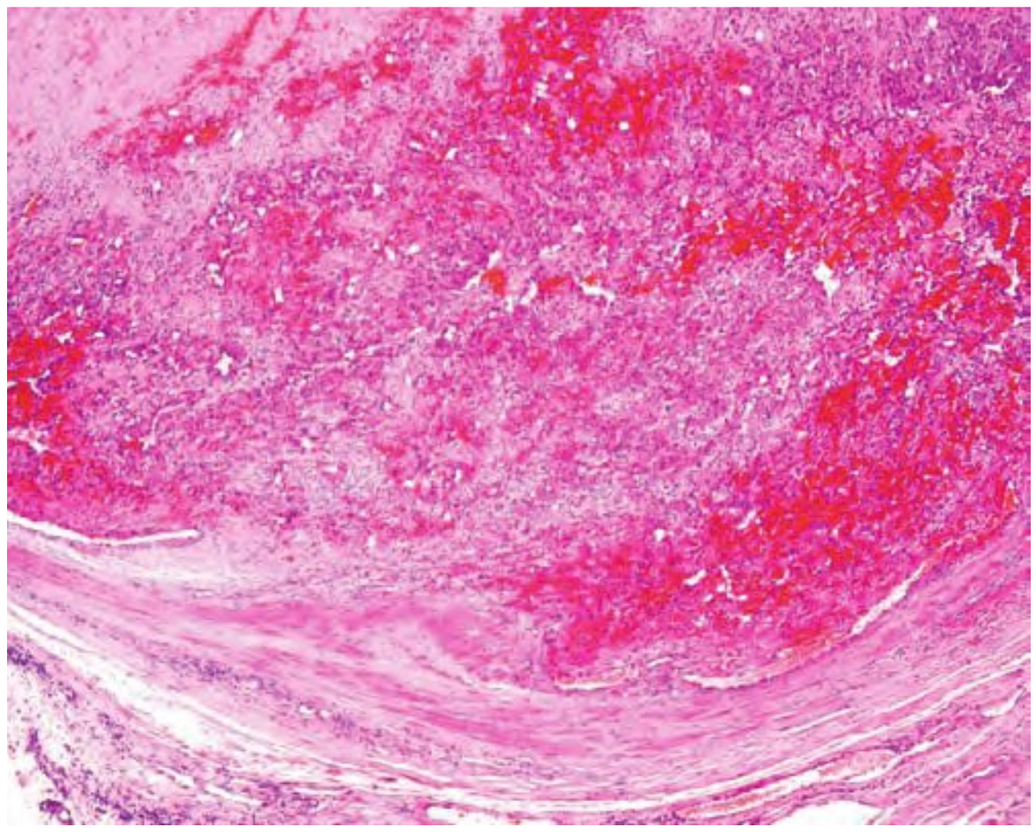

FIGURE. 33-38. Intravascular epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia). Some cases of epithelioid hemangioma are entirely intravascular.

Differential Diagnosis. The proliferation of endothelial-lined channels with large irregular cells can be misinterpreted as angiosarcoma. The latter can be accompanied by a lymphocytic infiltrate, but eosinophils are rarely present. The main distinguishing feature is the presence of nuclear atypia with hyperchromatism, mitotic activity, and dissection of collagen pattern in angiosarcoma but not in epithelioid hemangioma. Distinction from the recently described retiform hemangioendothelioma is easy: Angiolymphoid hyperplasia lacks a retiform growth pattern and does not show tall, narrow endothelial cells with a typical hobnail appearance, as is the case in retiform hemangioendothelioma.

Angiolymphoid hyperplasia can be distinguished from most benign angiomas or ectasias by the absence of an intrinsic inflammatory cell infiltrate in the latter. Greatly enlarged endothelial cells with an eosinophilic cytoplasm rarely feature in benign angiomas, although they can be seen focally in lobular capillary hemangioma (pyogenic granuloma).

Persistent insect-bite reactions can show overlapping histologic features with angiolymphoid hyperplasia, but the

vascular proliferation is rarely as exuberant. A somewhat similar pathology can also arise as a reaction to injected vaccines (135,136). The histology is characterized by a deep lymphoid infiltrate with lymphoid follicles, tissue eosinophilia, and fibrosis. Vascular hyperplasia is, however, less marked than in angiolymphoid hyperplasia, and epithelioid endothelial cells are not a feature. A diagnostic feature is the presence of aluminium-containing histiocytes as demonstrated by solochrome-azurine when aluminium-adsorbed vaccines have been used (135). The presence of aluminium may also be demonstrated by energy dispersive x-ray microanalysis.

When angiolymphoid hyperplasia with eosinophilia was first described in Western Europe, similarities to *Kimura's disease* as reported in the Far East were noted. Indeed, many authors thought that both conditions might be part of one disease spectrum (137). However, more recently, most authorities emphasize differences between the two entities (137–140). Subcutaneous angiolymphoid hyperplasia and Kimura's disease occur most commonly in the head and neck region in adults and both share the histologic features of extensive lymphoid proliferation, tissue eosinophilia, and evidence of vascular hyperplasia. Kimura's disease, however, demonstrates a wider age span, with a male predominance and a tendency for more extensive lesions to occur, often with involvement of salivary tissue and lymph nodes and at sites distant from the head and neck region. Authors from the Far East have stressed the histologic differences, the most important of which are the lesser degree of exuberant vascular hyperplasia, lacking prominent eosinophilic endothelial cells, and the absence of uncanalized blood vessels in Kimura's disease. Other points of difference are eosinophilic abscesses and marked fibrosis around the lesions in Kimura's disease and the absence of lesions centered around damaged arteries. There is an important association between Kimura's disease and renal disease, particularly nephrotic syndrome (141).

Cutaneous Epithelioid Angiomatous Nodule

Cutaneous epithelioid angiomatous nodule is a recently described lesion within the spectrum of vascular tumors with epithelioid endothelial cells (142–144). It is rare and presents in adults as a papule or nodule with predilection for the trunk followed by the limbs and face. Occasionally, multiple lesions may be seen, and there is no tendency for local recurrence.

Histopathology. Scanning maginification shows a superficial, well-circumscribed proliferation (Fig. 33-39) often surrounded by an epidermal collarete. It is composed of sheets of epithelioid endothelial cells with abundant pink cytoplasm, vesicular nuclei, and a single, small nucleolus (Fig. 33-40). Cytologic atypia is absent, and mitotic figures may be focally seen (Fig. 33-41). There is little tendency for formation of vascular channels, but individual endothelial cells often contain intracytoplasmic vacuoles. There is very little stroma between tumor cells, and in the background, scattered mononuclear inflammatory cells and eosinophils may be seen.

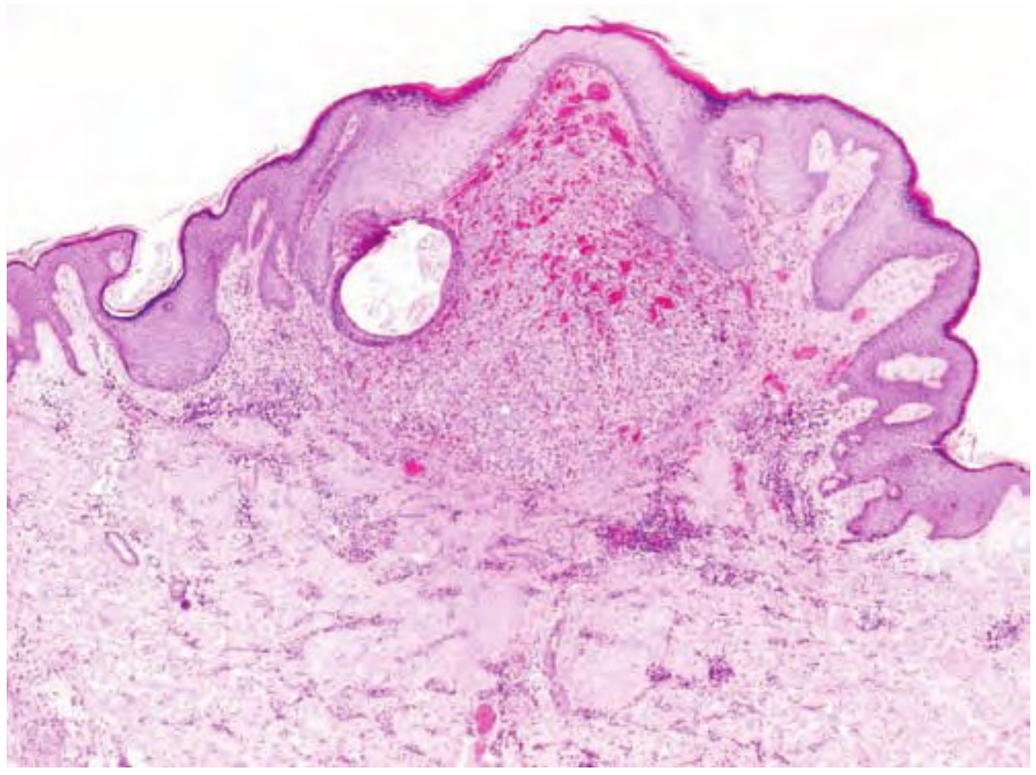

FIGURE 33-39. Cutaneous epithelioid angiomatous nodule. Superficial, well-defined polypoid lesion.

Differential Diagnosis. Distinction from epithelioid hemangioma is easy, as the clinical setting in the latter is different, and lesions are composed of vascular channels lined by epithelioid endothelial cells and not by solid sheets of epithelioid endothelial cells. Bacillary angiomatosis can be distinguished from epithelioid angiomatous nodule, as lesions in the former are usually multiple, and histologically there is formation of vascular channels lined by pale epithelioid endothelial cells and associated amorphous basophilic aggregates and neutrophils indicating the areas where the bacteria are located. Distinction from epithelioid angiosarcoma is based on the infiltrative growth pattern, pleomorphism, and mitotic activity in the latter.

Acquired Elastotic Hemangioma

Acquired elastotic hemangioma is a recently described and distinctive relatively rare vascular lesion that develops in

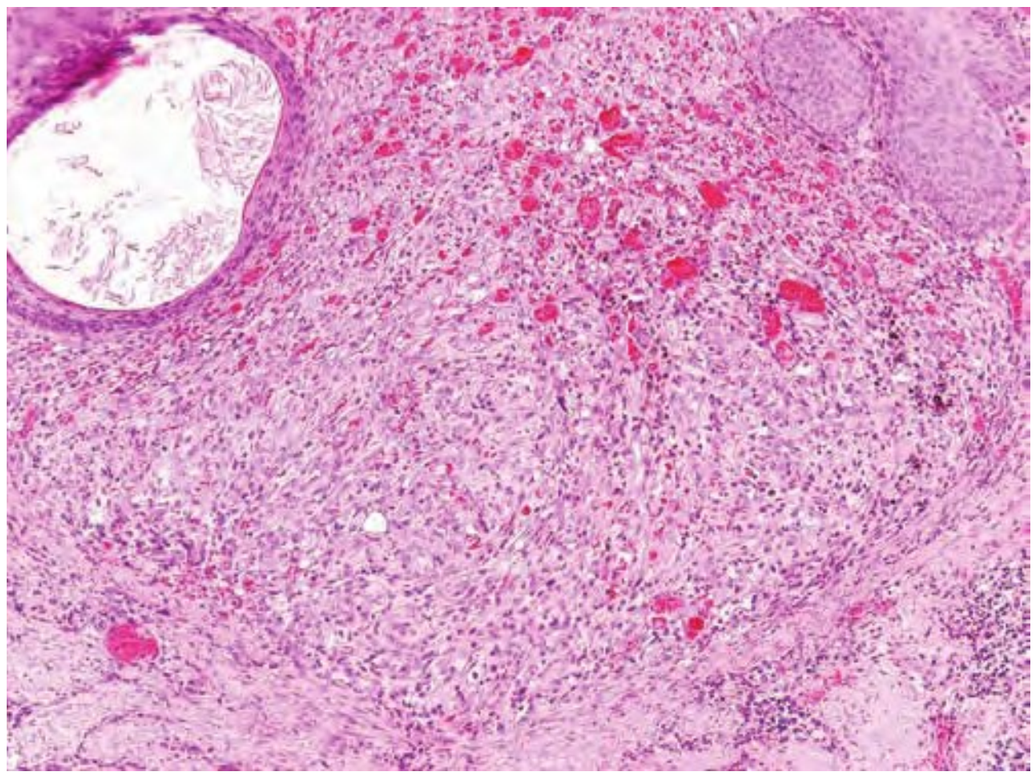

FIGURE 33-40. Cutaneous epithelioid angiomatous nodule. Sheets of epithelioid endothelial cells with focal intracytoplasmic lumina.

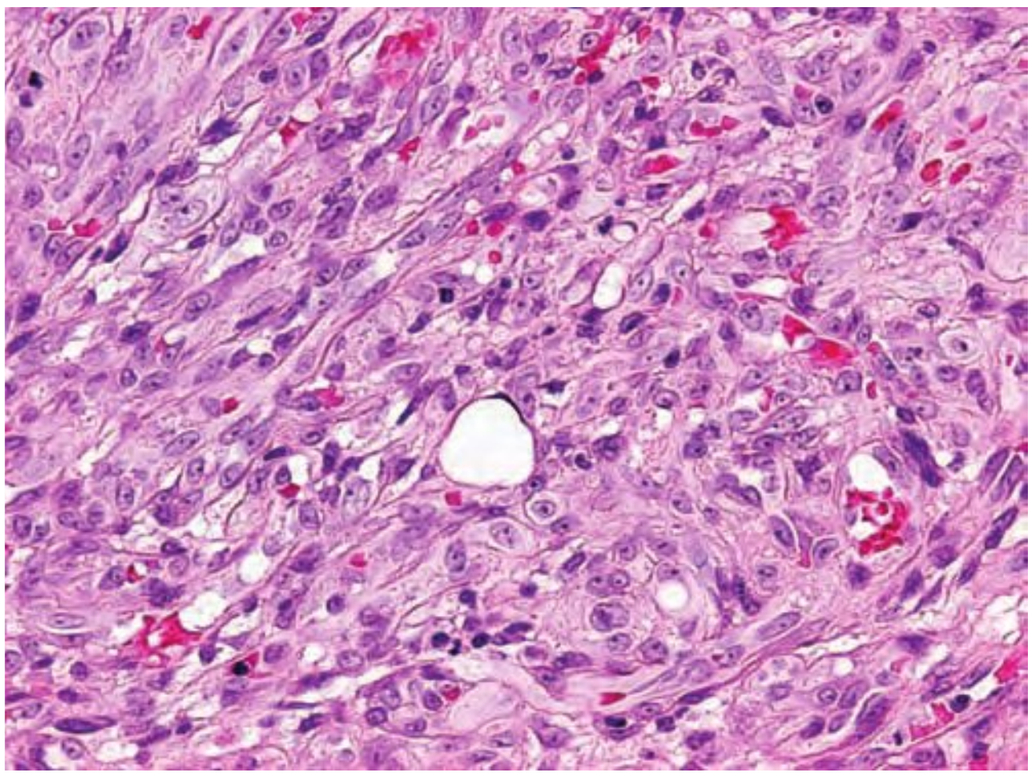

FIGURE 33-41. Cutaneous epithelioid angiomatous nodule. Cytologic atypia is mild or absent, and there are rare mitotic figures.

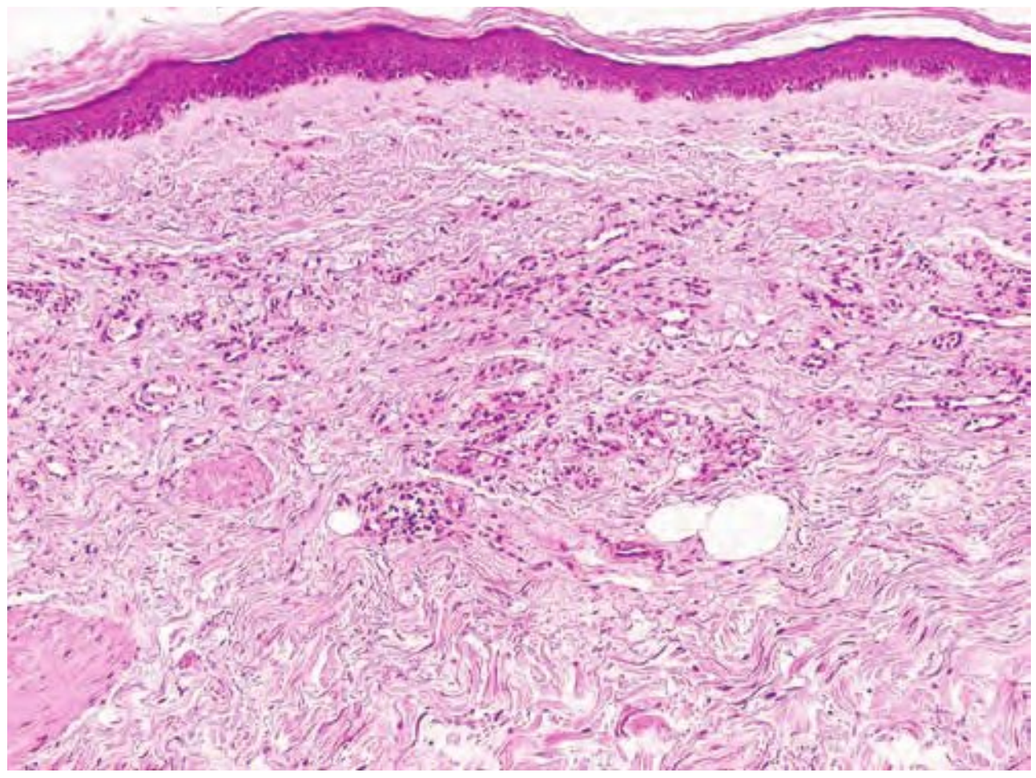

FIGURE 33-42. Acquired elastotic hemangioma. Superficial plaque-like proliferation of small, round vascular channels. (Courtesy of Dr. T. Mentzel, Friedrichshafen, Germany.)

sun-exposed skin, mainly of the forearms and neck of middle-aged to elderly patients, with predilection for females. The clinical presentation consists of a small, red or blue, circumscribed and asymptomatic plaque (145).

Histopathology. Lesions are well circumscribed and consist of a superficial, bandlike proliferation of capillaries in the background of solar elastosis (Figs. 33-42 and 33-43). Each capillary is surrounded by a layer of pericytes.

Arteriovenous (Venous) Hemangioma (Cirsoid Aneurysm)

Arteriovenous (venous) hemangioma, or cirsoid aneurysm, usually occurs as a solitary dark red papule or nodule on the face (especially the lip) or, less commonly, on the extremities of adults, with equal gender incidence (146,147). Rare cases present in the oral cavity (148). Most of the lesions measure <1 cm in diameter.

Histopathology. Within a circumscribed area, usually restricted to the dermis (Fig. 33-44), densely aggregated, thick-walled and thin-walled vessels lined by a single layer of endothelial cells are observed (Fig. 33-45). The walls of the thick-walled vessels consist mainly of fibrous tissue but in most instances also contain some smooth muscle. Internal elastic lamina is found in very few vessels, indicating that most of the blood vessels are veins. Many vessels contain red blood cells, and thrombi are occasionally seen (148). Lesions with similar histologic appearances can be seen in the deeper soft tissues of

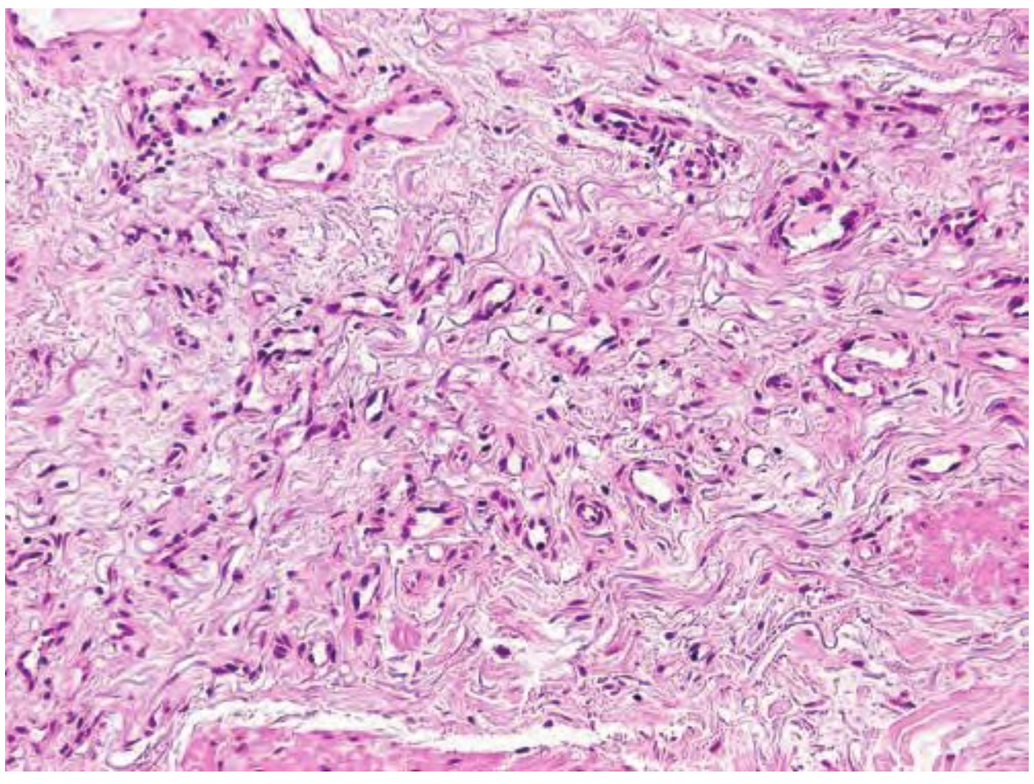

FIGURE 33-43. Acquired elastotic hemangioma. Note solar elastosis in the background. (Courtesy of Dr. T. Mentzel, Friedrichshafen, Germany.)

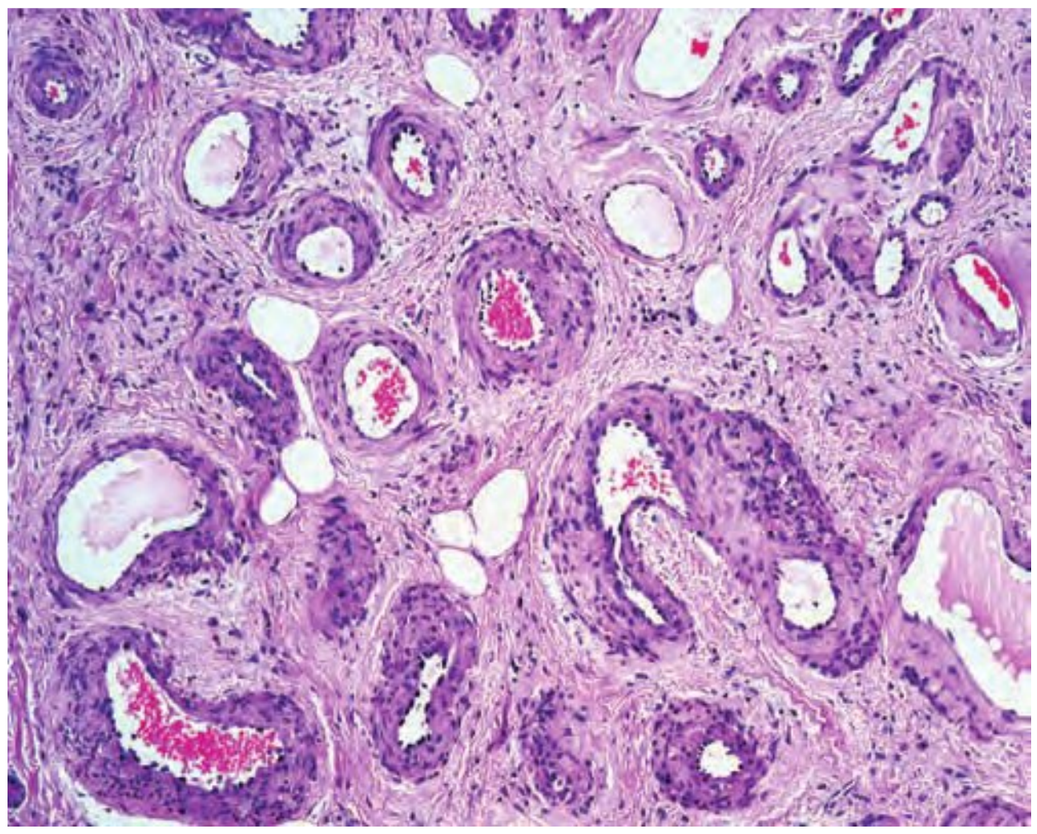

FIGURE 33-45. Cirsoid aneurysm. A combination of small veins and arteries.

younger patients and can be associated with hemodynamic complications due to shunting.

Histogenesis. It seems likely that many of these lesions represent pure venous hemangiomas, some of which have arterialized veins (148).

Angiomatosis

Angiomatosis is an uncommon condition that presents exclusively in children and adolescents and is defined as a diffuse proliferation of blood vessels affecting a large contiguous area of the body (149–151). Anatomic distribution is wide, but there is a preference for limb involvement. A typical case presents with involvement of the skin, underlying soft tissues, and even bones. Associated limb hypertrophy is common. Involvement of parenchymal organs and the central nervous system can be present. Due to extensive involvement, surgical treatment is difficult and recurrences are common.

Histopathology. Most tumors are composed of abundant mature fat intermixed with blood vessels in two histologic patterns (150). The most common pattern is a mixture of veins with irregular walls, cavernous vascular spaces, and capillaries. The veins often show an incomplete muscular layer, and smaller blood vessels can be seen in the walls of larger vessels. The second pattern is composed mainly of capillaries with a focal lobular architecture. Perineural invasion can be a feature in both patterns.

Spindle Cell Hemangioma

Spindle cell hemangioma is a tumor that was first described in 1986 (152) as a form of low-grade angiosarcoma, although mounting evidence in recent years widely favors a nonneoplastic process most likely related to a vascular malformation (see Pathogenesis). Gender incidence is equal, and most lesions arise in the second or third decade of life. It presents as multiple red-blue nodules in the dermis and subcutaneous tissue, most commonly involving the distal aspects of the extremities with a predilection for the hands. Visceral lesions do not occur, and involvement of deeper soft tissues is rare (153). The clinical course is indolent, with multiple new lesions appearing over the years. Spontaneous regression is exceptional. In approximately 10% of cases, associated anomalies include lymphedema, Maffucci's syndrome, Klippel-Trenaunay syndrome, and early-onset varicose veins (152–155).

Histopathology. Tumors tend to be poorly circumscribed and may present totally or partially in an intravascular location, especially involving medium-sized veins. A typical lesion is composed of two elements (Fig. 33-46): irregularly dilated, thin-walled congested cavernous spaces often with organizing thrombi and phleboliths intermixed with more solid areas composed of spindle-shaped cells (Fig. 33-47) generally bland in appearance, although rare cases may show focal degenerative cytologic atypia. Mitotic figures are rare. Commonly, in the solid areas, focal aggregates of epithelioid cells with eosinophilic cytoplasm and bundles of smooth muscle are seen. The epithelioid cells may show vacuolation or intracytoplasmic lumina (Fig. 33-48). Slitlike vascular spaces are common in the solid areas and are accompanied by scattered extravasated red blood cells and hemosiderin-laden macrophages. Focal areas with changes resembing Masson's tumor can be a feature. Irregular, thick-walled vascular spaces reminiscent of those seen in vascular malformations are often seen in the periphery of many lesions. Occasionally, cases show combined features of epithelioid and spindle cell hemangioendothelioma (156,157). However, these cases are likely to represent examples of composite hemangioendothelioma (see page 1037).

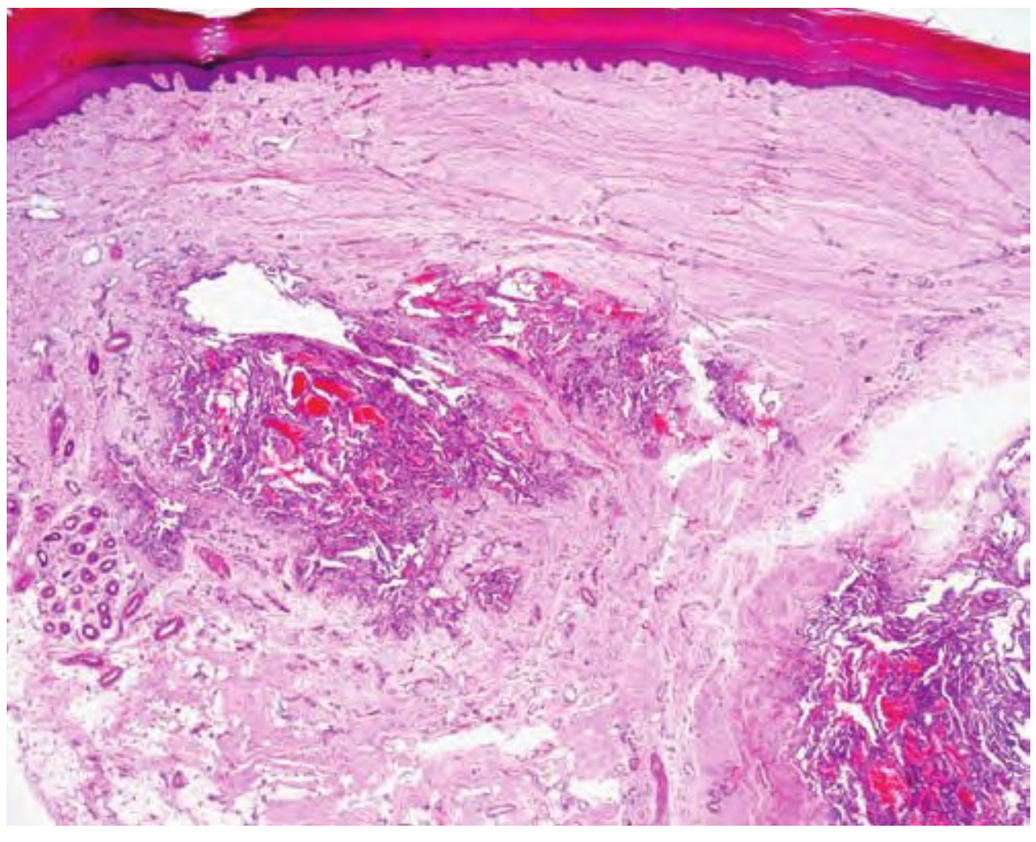

FIGURE 33-46. Spindle cell hemangioma. Multifocal lesions combining dilated and congested vascular spaces and more cellular areas.

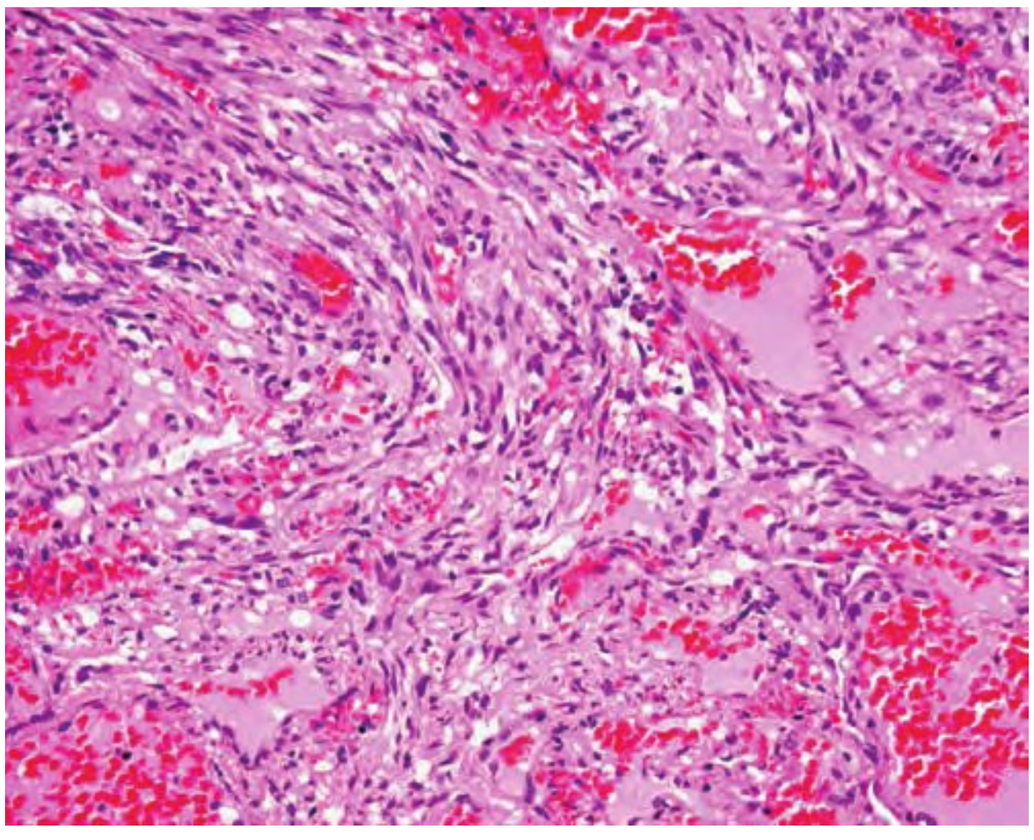

FIGURE 33-47. Spindle cell hemangioma. Thin-walled, dilated vascular spaces and bland spindle-shaped cells.

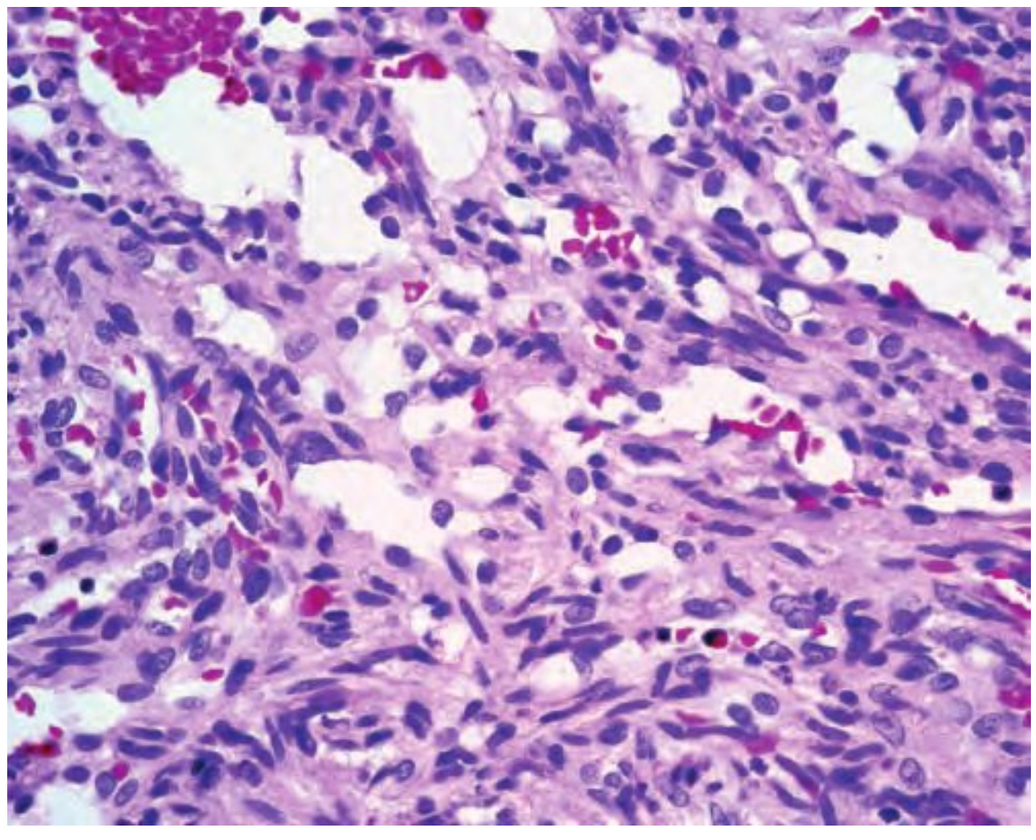

FIGURE 33-48. Spindle cell hemangioma. Spindle-shaped cells and focal epithelioid pale pink vacuolated cells.

Pathogenesis. Original classification of this tumor as a form of low-grade angiosarcoma was based on the development of lymph node metastasis in one of the patients reported (152). However, the patient had been treated with radiotherapy, and it is very likely that the metastasis was from a radiation-induced sarcoma. Further case series in recent years have provided evidence favoring the theory that spindle cell hemangioendothelioma represents a reactive condition or a form of vascular malformation (154,158–160).

By immunohistochemistry, the endothelial cells lining the vascular spaces and the epithelioid cells in the solid areas stain variably with endothelial markers. The spindle cells stain focally with actin and less commonly with desmin.

Differential Diagnosis. The main differential diagnosis is with nodular stage Kaposi's sarcoma, as discussed below (page 1035).

Symplastic Hemangioma

Symplastic hemangioma is not a distinctive variant of hemangioma but rather represents extensive degenerative changes in a preexisting hemangioma closely mimicking malignancy (161–163). Very few cases have been reported, but from personal experience with a limited number of cases, the preexisting hemangioma is often not identifiable or it represents a cirsoid aneurysm.

Histopathology. Lesions are often polypoid and well circumscribed and do not tend to be ulcerated (Fig. 33-49). Dilated and congested thin- to thick-walled vascular spaces are surrounded by a variable cellular stroma that is often myxoid and hemorrhagic. Stromal cells and smooth muscle cells within the vessel walls display variable cytologic atypia consisting of nuclear enlargement and hyperchromatism (Fig. 33-50). The endothelial cells lining the vascular spaces do not show cytologic atypia (Fig. 33-51). Other cells have a bizarre appearance, and multinucleation is not uncommon. Mitotic figures may be found but are not common. Very occasional atypical mitotic figures may also be seen.

Differential Diagnosis. The main differential diagnosis to consider is angiosarcoma. However, in symplastic angioma, the endothelial cells lining the vascular channels are bland, with no mitotic acitivity or multilayering. A further differential diagnosis is with pleomorphic hyalinizing angiectatic tumor of soft parts (164). The latter is an infiltrative tumor that mainly occurs in the subcutis or deeper soft tissues and is characterized by thin-walled dilated vascular spaces with prominent perivascular hyalinization and pleomorphic stromal cells with low mitotic activity and frequent intranuclear inclusions.

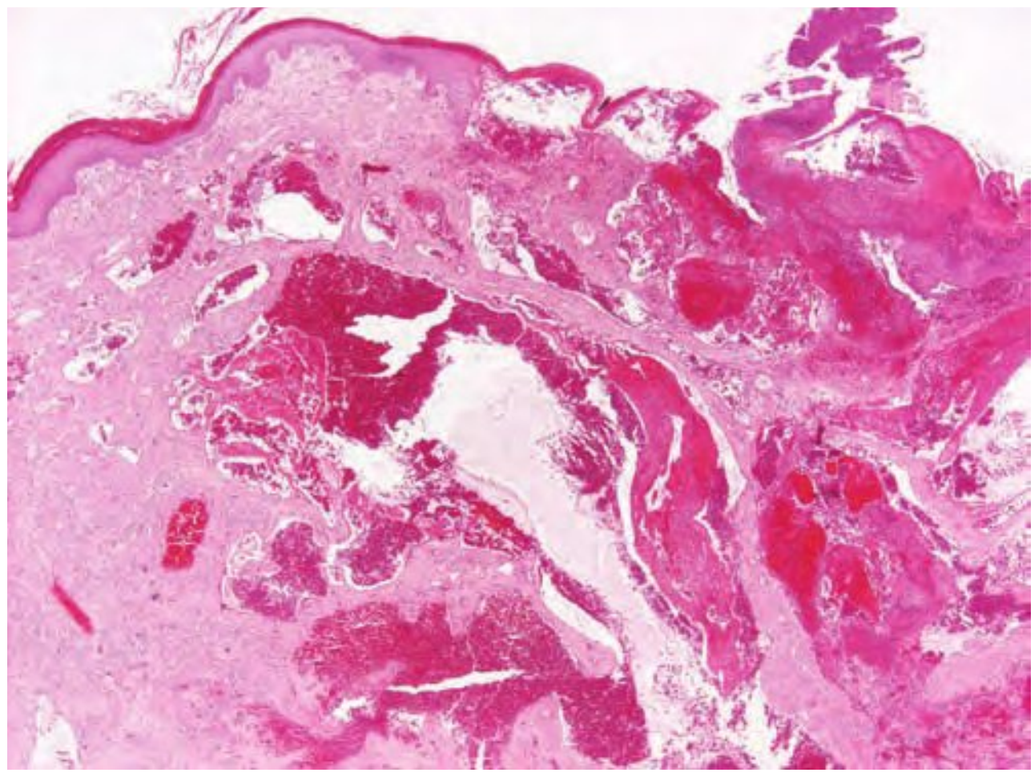

FIGURE 33-49. Symplastic hemangioma. Lesions are often polypoid, and their vascular nature is apparent at scanning magnification.

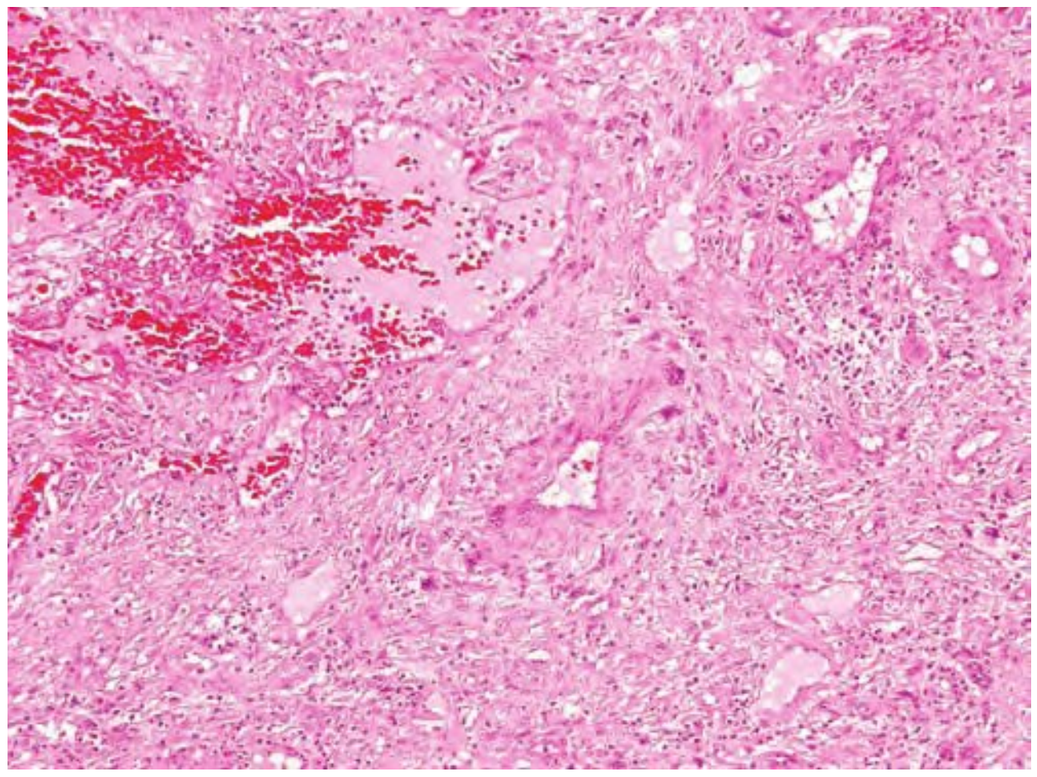

FIGURE 33-50. Symplastic hemangioma. Atypical cells both within the stroma and in the blood vessel walls.

VASCULAR TUMORS OF INTERMEDIATE MALIGNANCY

Malignant tumors of endothelial cell origin can be broadly divided into intermediate and high-grade malignancy. Strictly used, the term *intermediate malignancy* refers to a tumor that has potential for aggressive local behavior with a tendency for local recurrence and low or negligible potential for metastatic spread. There is a tendency to designate malignant vascular tumors with true potential for metastatic spread as angiosarcomas and low-grade tumors as hemangioendotheliomas. However, some authors use the terms interchangeably, and progress in understanding of some of these tumors has led to certain neoplasms being either upgraded as fully malignant (e.g., epithelioid hemangioendothelioma) or downgraded as benign (e.g., spindle cell hemangioma). It must also be remembered that the term *hemangioendothelioma* was used in the past to refer to some benign vascular tumors, especially strawberry nevus in children. The category of vascular tumors of intermediate malignancy also includes lesions like Kaposi's sarcoma, a generally indolent process in which a truly neoplastic origin has not clearly been demonstrated.

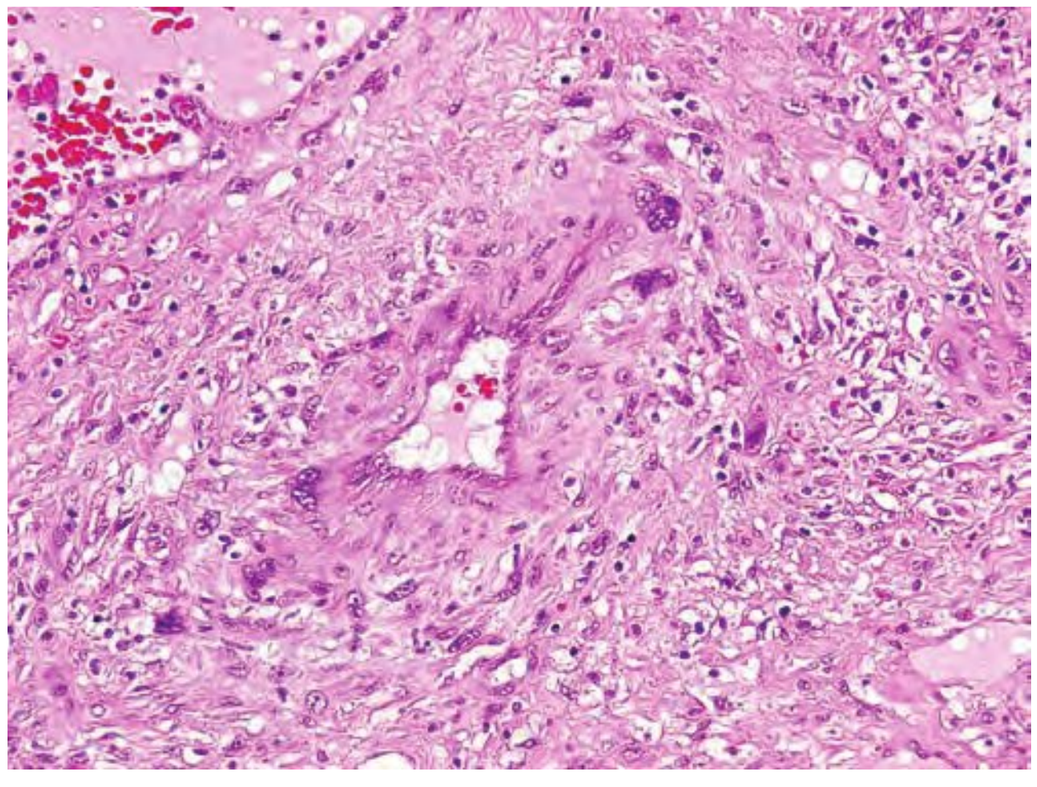

FIGURE 33-51. Symplastic hemangioma. Endothelial cells show no atypia or mitotic activity.

Kaposi's Sarcoma

Until the late 1960s, Kaposi's sarcoma was described as an uncommon, slowly progressive, multifocal tumor arising mostly in elderly male patients of eastern and southern European descent, a clinical pattern now referred to as the *classic* form of the disease. During the last two decades of the last century, intense interest developed as Kaposi's sarcoma became a prime marker of AIDS. Although with the advent of highly active antiretroviral therapy (HAART) the incidence of Kaposi's sarcoma in HIV/AIDS has decreased dramatically in the Western world, the same is not true in Third World countries, particularly in Africa, where access to HAART is still very limited. In addition, Kaposi's sarcoma can arise in association with other causes of immunodeficiency, especially when drug induced, particularly in the setting of organ transplantation and less commonly in different forms of inherited immune deficiency. Despite recent great advances in knowledge regarding the etiology and pathogenesis of Kaposi'sarcoma, there remain many unusual facets about the disease that as yet defy adequate scientific explanation. Although it has been demonstrated that all types of Kaposi's sarcoma are associated with a novel variant of herpesvirus, HHV-8, it is still controversial whether Kaposi's sarcoma is a multifocal reactive process or a neoplastic condition.

Clinical Features. Nearly all cases of Kaposi's sarcoma can be classified into four groups (165–171):

1. *Classic Kaposi's sarcoma.* This arises 10 to 15 times more commonly in men than women, affecting mainly patients of eastern European, Jewish, and Mediterranean origin (172). The disease mainly arises in patients over the age of 50 years with the slow development of angiomatous nodules and plaques on the lower extremities (Fig. 33-52). Chronic lymphedema is not an infrequent association. Affected patients may survive 10 to 20 years; even at late stages with widespread skin nodules, visceral disease is unusual, although asymptomatic involvement of lymph nodes, lungs, or gastrointestinal tract can often be found at necropsy. Occasionally, before the advent of AIDS, an aggressive type of Kaposi's sarcoma occurred in young adults or children with early lymph node involvement (168).
2. *Endemic African Kaposi's sarcoma.* In the 1960s, it was realized that Kaposi's sarcoma was quite common among native blacks in Central Africa, representing the most common tumor in pathology departments in Uganda and parts of what was known as Zaire (now the Democratic Republic

FIGURE 33-52. Clinical Kaposi's sarcoma. Typical endemic case with plaques and nodules on an acral location.

of Congo). In South Africa, it has been estimated that Kaposi's sarcoma is ten times more common in blacks than whites (Fig. 33-53). In Africans, the disease can run a similar indolent course as in classic Kaposi's sarcoma, but a higher proportion of young people are affected, with a more aggressive disease manifested by widespread tumors, deep infiltrative or elevated fungating lesions, and bone involvement. A distinctive childhood type of Kaposi's sarcoma occurs with massive lymph node involvement and early death. Mucocutaneous lesions are usually a late or minor clinical feature in this lymphadenopathic form (168). The male-to-female ratio in these children is approximately 3:1. Most cases of Kaposi's sarcoma that have occured in sub-Saharan Africa in the last 25 years are in patients with HIV/AIDS (169–171).

3. *AIDS-associated Kaposi's sarcoma.* In the early 1980s, reports of groups of young homosexual males in New York and California who were developing Kaposi's sarcoma was one of the keys in establishing the existence of AIDS. Originally, about 40% of patients with AIDS had concomitant Kaposi's sarcoma, but this high percentage has gradually and dramatically fallen in the United States (165,168) and Europe since the advent of HAART (173). Collected data from the Centers for Disease Control and Prevention in the United States has suggested that Kaposi's sarcoma was at least 201,000 times more common with AIDS than in the general population (165). The risk of Kaposi's sarcoma occurring with AIDS is much greater in active homosexuals than in heterosexual males or females, such as hemophiliacs who receive contaminated blood products or drug abusers who share needles.

   The clinical features of AIDS-related Kaposi's sarcoma differ from the classic disease in the rapid evolution of the lesions, their atypical distribution affecting the trunk, and the mucosal involvement (167) (Fig. 33-54). Visceral involvement is very common at autopsy (174,175), but such internal lesions are often unapparent clinically during life. Visceral involvement may be present without any skin lesions. In patients on HAART and according to the degree of restoration of the immune system, lesions may regress, and if they develop during treatment, they are usally limited in number and extent.
4. *Kaposi's sarcoma and iatrogenic immunosuppression.* Drug-induced immunosuppression to prevent rejection of transplanted organs greatly increases the risk of developing lymphomas and other tumors, including Kaposi's sarcoma (176,177). In a large retrospective study over 23 years, Kaposi's sarcoma developed in 3.9% of cases of kidney transplant patients (176). A peculiarity of this type of Kaposi's sarcoma is the frequent regression or apparent cure on discontinuation of immunosuppressive therapy. The male-dominant gender ratio is much smaller in this group.

   Kaposi's sarcoma can also occur in other causes of immunosuppression, including genetic diseases (178).

Histopathology. The histopathology of fully developed nodules of Kaposi's sarcoma in all types of the disease is distinctive

FIGURE 33-53. Clinical Kaposi's sarcoma. In endemic African cases, associated lymphedema is often seen.

FIGURE 33-54. Kaposi's sarcoma. Oral lesions are often seen in HIV/AIDS, particularly in patients not on HAART.

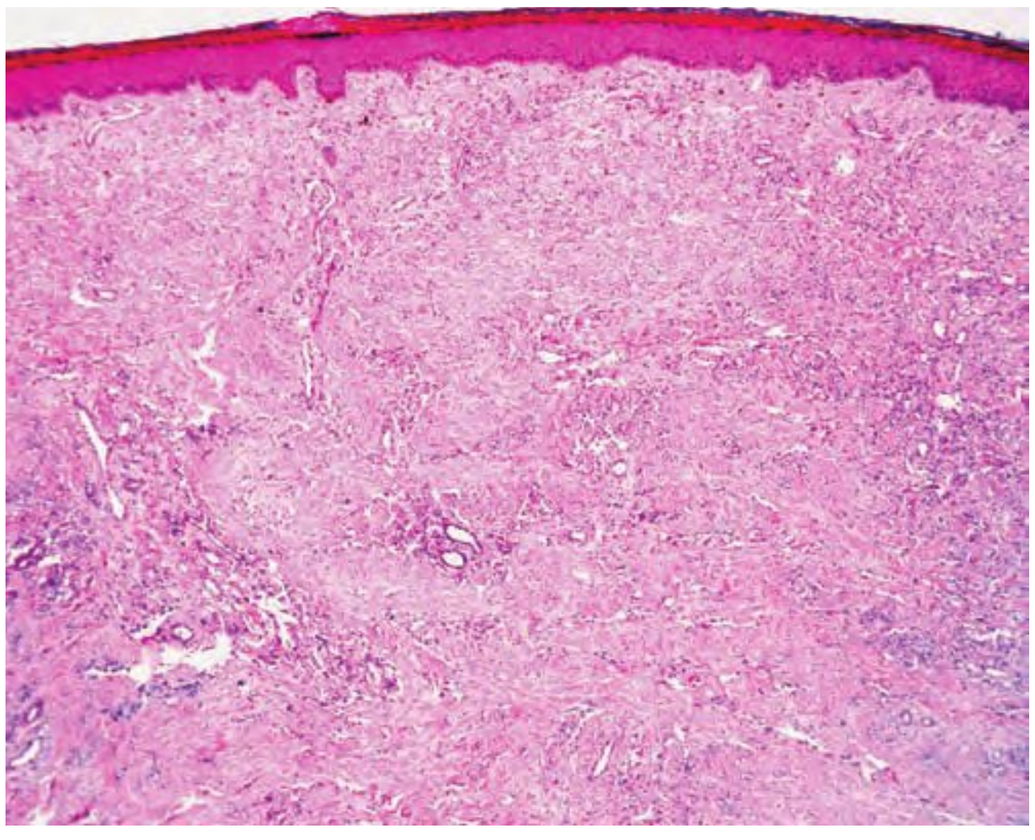

FIGURE 33-55. Patch-stage Kaposi's sarcoma. Numerous slitlike spaces throughout the dermis in the background of hemorrhage.

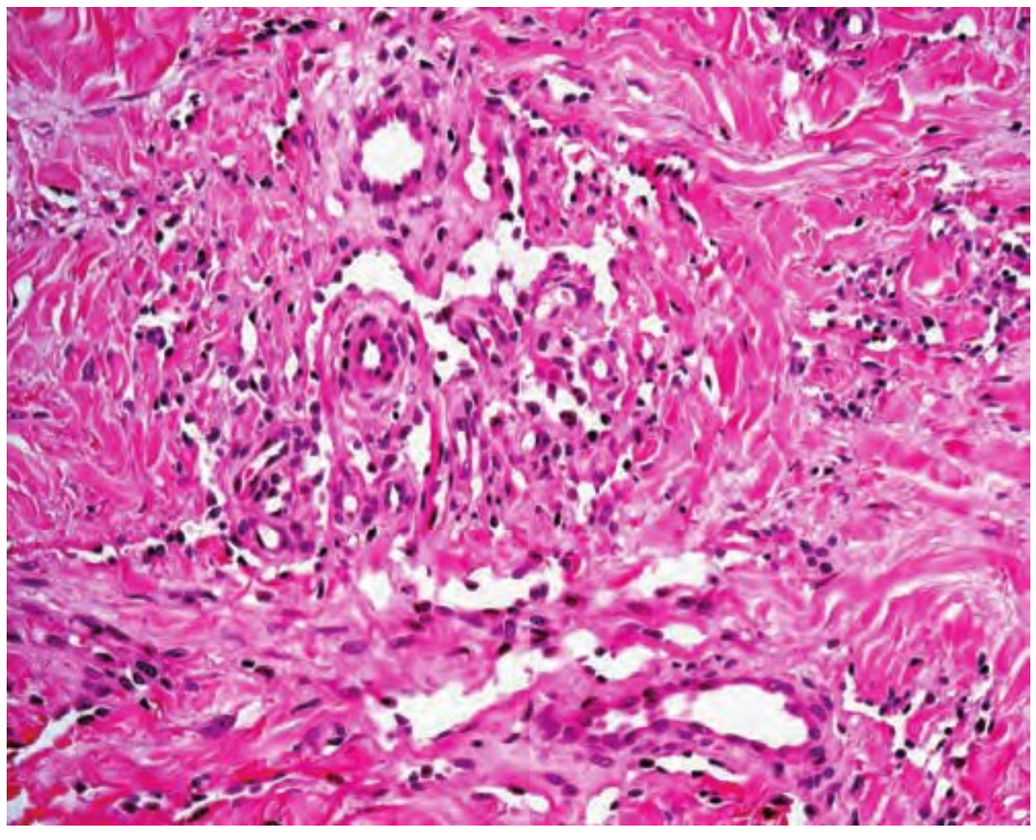

FIGURE 33-57. Patch-stage Kaposi's sarcoma. A normal blood vessel protruding into newly formed blood vessels ("promontory sign") lined by bland endothelial cells.

and should rarely cause problems for pathologists. The diagnostic pitfalls lie mainly in the early macular lesions, where misinterpretation as banal inflammation or some form of minor angiomatous or lymphatic anomaly is easy to make. Despite the name of sarcoma, cytologic atypia is minimal in tumor cells in all stages of evolution of Kaposi's sarcoma.

For descriptive convenience, the histologic spectrum can be divided into stages roughly corresponding to the clinical type of lesion: early and late macules, plaques, nodules, and aggressive late lesions. In reality, there is overlap between stages and multiple biopsies taken at the same time, or even a single biopsy may show features of different histologic stages. There are no differences in the pathology of the disease in the different risk groups.

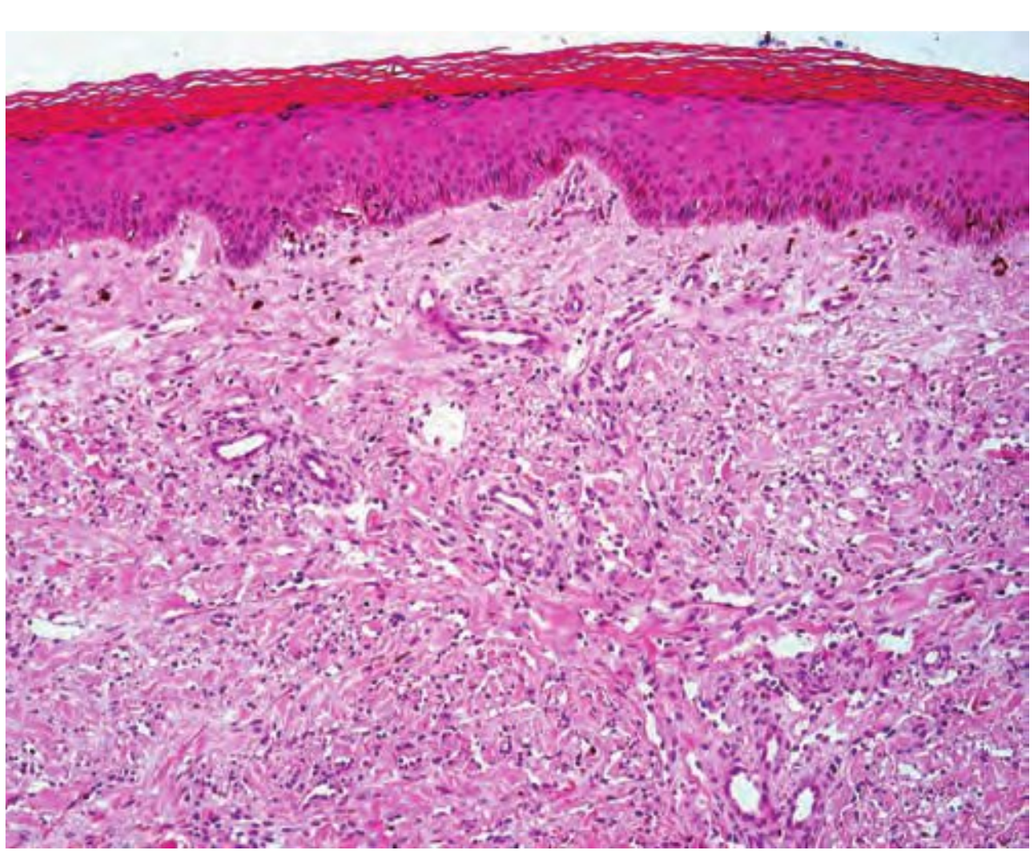

FIGURE 33-56. Patch-stage Kaposi's sarcoma. Irregular, jagged, thin-walled small vascular channels in association with hemosiderin deposition and focal inflammation.

1. *Macular (patch stage).* In early macules, there is usually a patchy, sparse, dermal perivascular infiltrate consisting of lymphocytes and plasma cells. Narrow cords of cells, insinuated between collagen bundles, may at first suggest histiocytes or connective tissue cells, but close inspection should reveal evidence of luminal differentiation or connection with discernable small vessels (Fig. 33-55). Usually, a few dilated irregular or angulated lymphatic-like spaces lined by delicate, bland endothelial cells are also present. Vessels with "jagged" outlines tending to separate collagen bundles are especially characteristic (Fig. 33-56). Normal adnexal structures and preexisting blood vessels often protrude into newly formed blood vessels (Fig. 33-57). This finding, known as the *promontory sign*, is commonly present but is not specific to Kaposi's sarcoma. In late macular lesions, there is a more extensive infiltrate of vessels in the dermis: "jagged" vessels and cords of thicker-walled vessels similar to those in granulation tissue. Some of these vessels may in part be reactive rather than an intrinsic part of the tumor. At this stage, red blood cell extravasation and the presence of siderophages may be encountered. In some lesions, ramifying variably dilated bloodless lymphatic-like spaces dissect out collagen to give an appearance that suggests a well-differentiated angiosarcoma or progressive lymphangioma. This exaggerated lymphangioma-like appearance has led some authors to designate this as a special variant of the disease (179) (Fig. 33-58). Occasional fascicles of spindle-shaped cells may occur independent of blood vessels. In some cases, dilated, congested, thin-walled vascular channels with a sievelike (Fig. 33-59) appearance mimicking a hemangioma are seen.

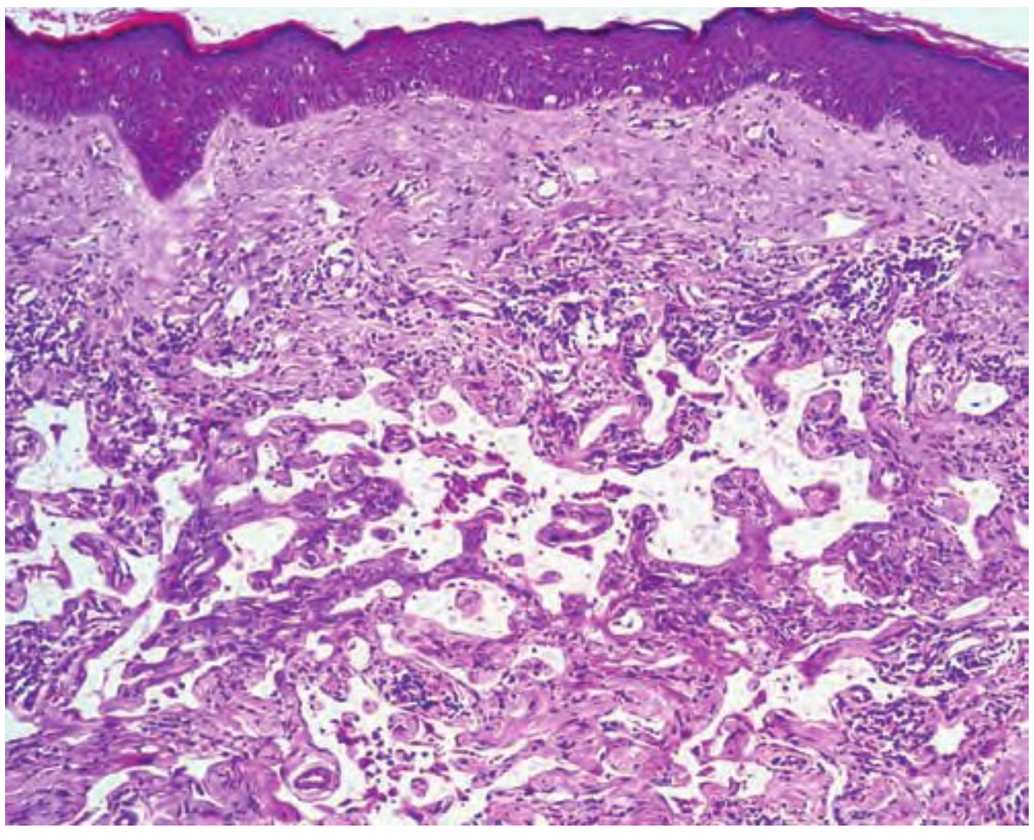

FIGURE 33-58. Lymphangiomatous Kaposi's sarcoma. Numerous, irregular, dilated, bloodless vascular channels with a striking lymphangioma-like appearance.

2. *Plaque stage.* In this stage, a diffuse infiltrate of small blood vessels extends through most parts of the dermis and tends to displace collagen (Fig. 33-60). The vessels show variable morphology, with some occurring as poorly canalized cords, some as blood-containing ovoid vessels, and some showing lymphatic-like features. Loosely distributed spindle cells, arranged in short fascicles, are also encountered (Fig. 33-61). Intracytoplasmic hyaline globules (180) may be found in areas with a denser infiltrate.

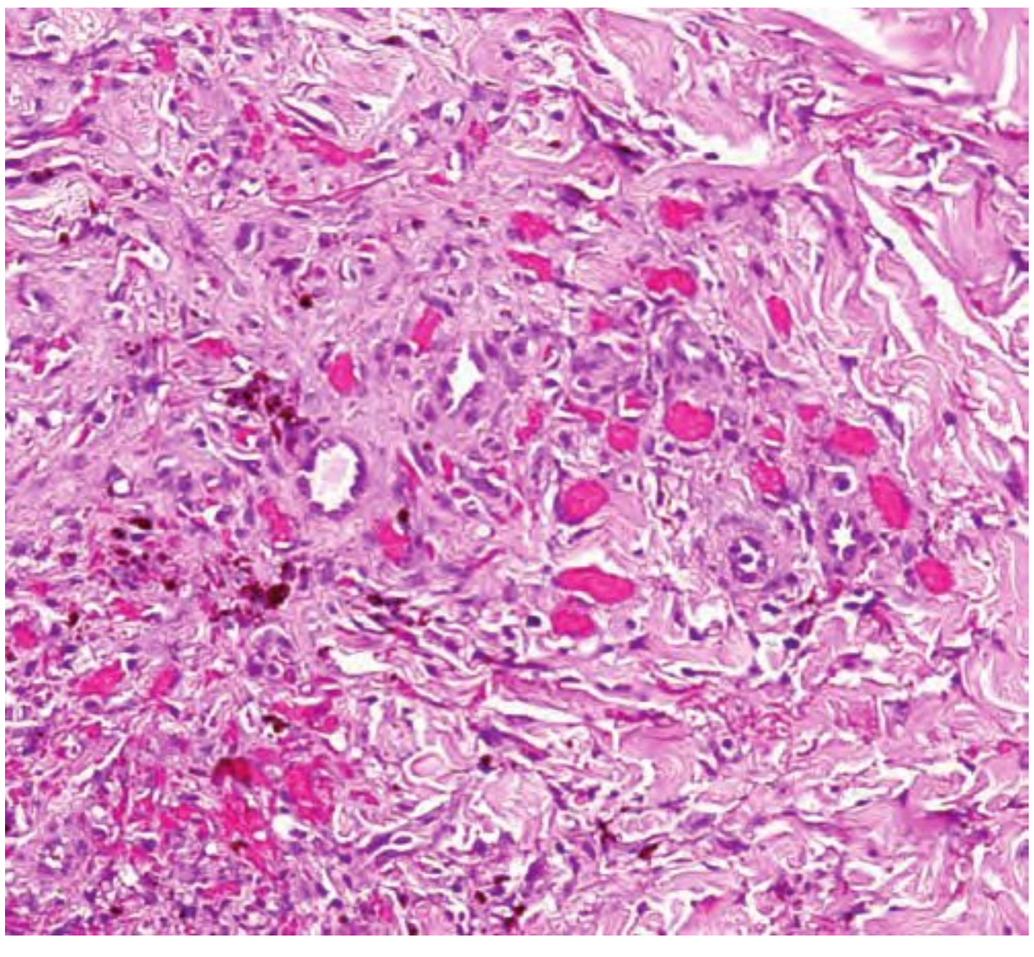

FIGURE 33-59. Angiomatous Kaposi's sarcoma. Congested small vascular channels in a focal sievelike pattern.

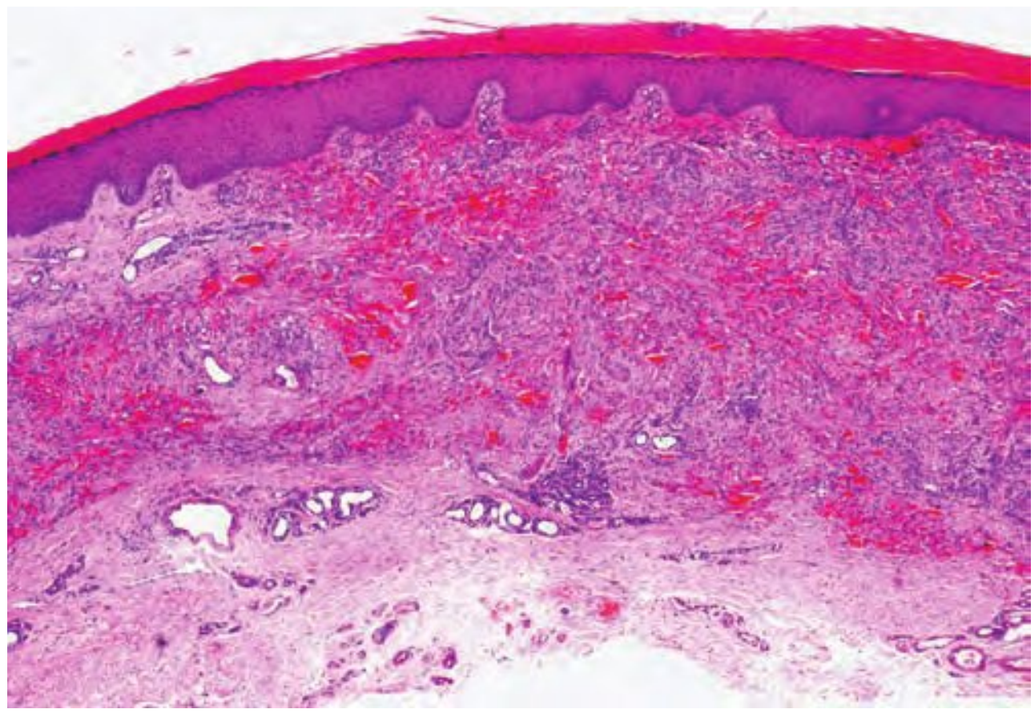

FIGURE 33-60. Plaque-stage Kaposi's sarcoma. A more cellular dermis with extensive hemorrhage.

These hyaline globules are seen more often in lesions from patients with AIDS.

3. *Nodular stage.* In the tumor stage, well-defined nodules composed of vascular spaces and spindle cells replace dermal collagen (Fig. 33-62). These tumor nodules tend to be compartmentalized by dense bands of fibrocollagenous tissue. Dilated lymphatic spaces can also be seen between tumor aggregates. The characteristic feature is a honeycomb-like network of blood-filled spaces or slits that are closely associated with interweaving spindle cells (Fig. 33-63). Although generally vascular spaces and fascicles of spindle cells are present, either element can focally predominate. The vascular lumina in the angiomatous tissue are so

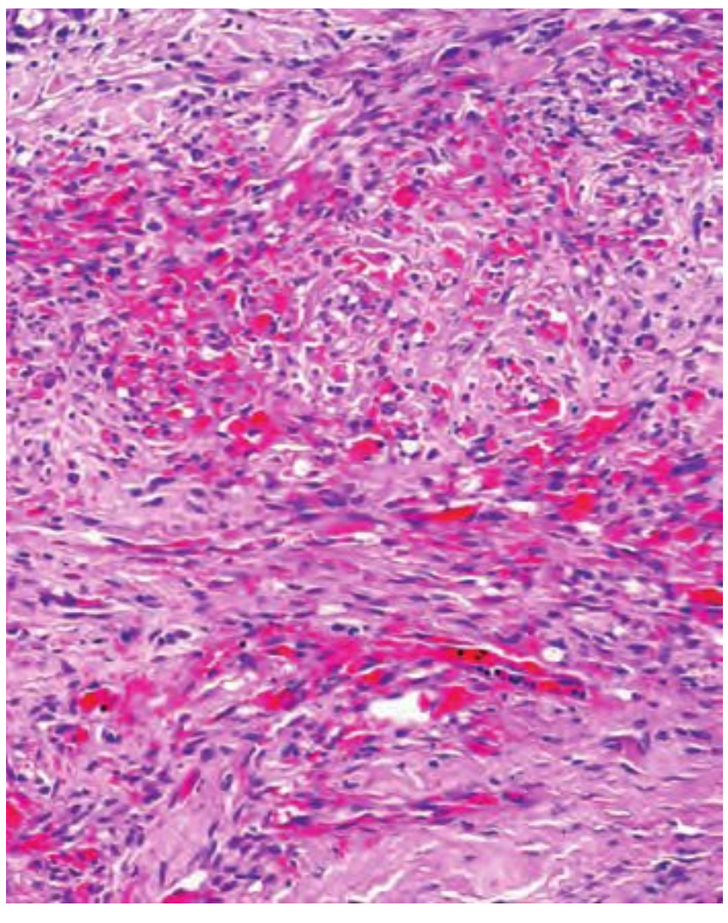

FIGURE 33-61. Plaque-stage Kaposi's sarcoma. Bland spindle-shaped cells with focal formation of cleftlike spaces containing red blood cells.

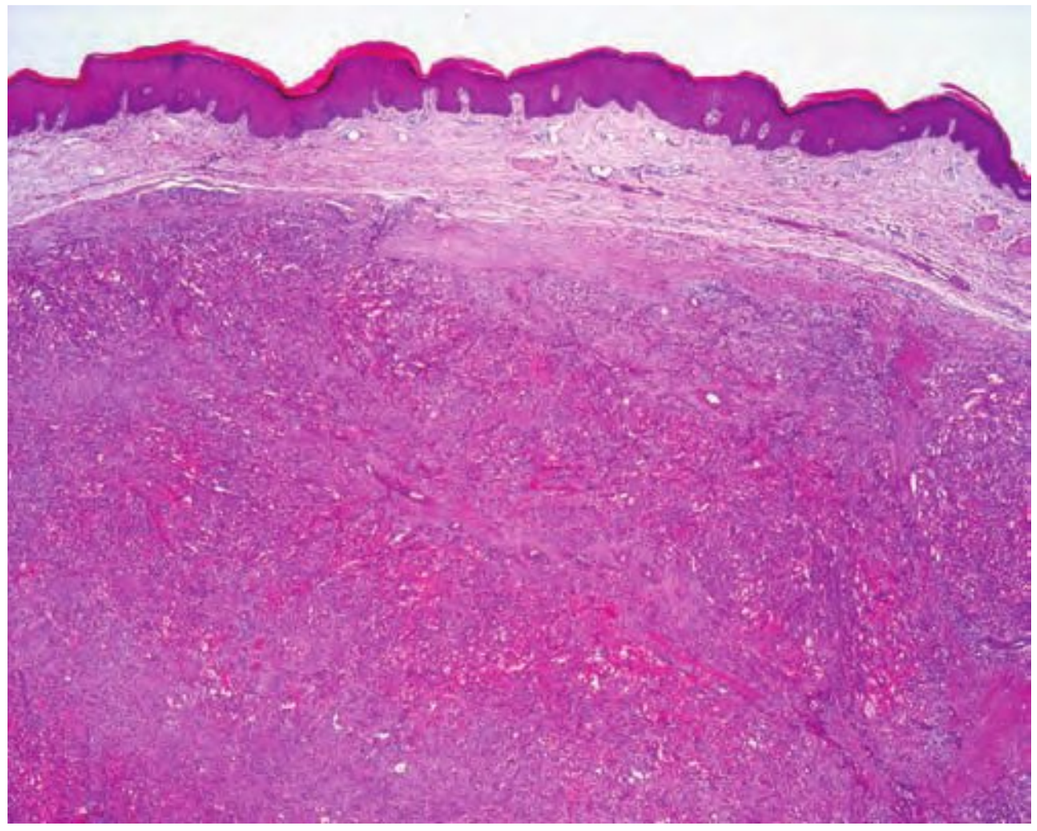

FIGURE 33-62. Nodular-stage Kaposi's sarcoma. Fairly well-circumscribed dermal nodule.

closely set that they lie next to each other in a "back-to-back" arrangement. Delicate, flattened endothelial cells lining the vascular clefts are hardly discernable with routine stains but are easily seen with the immunocytochemical markers CD31 and CD34. The vascular slits in the nodules appear to be in direct contact with spindle cells, leading to the suggestion that they are pseudovascular spaces. The presence of a closely set honeycomb-like pattern of vascular spaces is perhaps the single most important diagnostic feature of Kaposi's sarcoma. In the vascular spaces of pyogenic granuloma and most angiomas, the endothelial cells of the capillary walls are more prominent, and the vessels are set farther apart by intervening stroma. Around the nodules, varying numbers of thicker-walled vessels are encountered that may represent reactive or "feeder" vessels and are not a basic component of the tumor. Blood pigment–containing macrophages are nearly always prominent adjacent to the nodules, especially in lesions at dependent sites.

The spindle cells in the nodules are elongated and fusiform with a well-defined cytoplasm. The nuclei are ovoid and somewhat flattened with finely granular chromatin in the long axis of the cells. The nucleoli are generally inconspicuous, and nuclear atypia is absent or slight. Mitotic figures are not prominent. Prominent and consistent positivity for CD34 is seen in the spindle cell population.

Intra- and extracellular hyaline globules occur more frequently than in plaque-stage lesions. They present in groups as faintly eosinophilic spheres 1 to 7 μm in size and are PAS positive and diastase resistant. The globules probably represent partially digested erythrocytes. Usually, the epidermis and skin appendages remain intact.

Lesions of Kaposi's sarcoma, particularly in the nodular stage, may be partially or completely intravascular (181). The vessels involved are usually veins.

A variant of classic Kaposi's sarcoma presenting with a micronodular pattern has been described (182).

HIV-positive patients presenting with Kaposi's sarcoma in lymphedematous skin may show focal fibroma-like lesions that may represent an early stage in the evolution of Kaposi's sarcoma (183).

4. *Aggressive late-stage lesions.* Mostly in Africans but sometimes with other types of Kaposi's sarcoma, "infiltrating" lesions show a more obviously sarcomatous character with reduction or loss of the vascular component. The spindle cells demonstrate a greater degree of cytologic atypia with regard to size, shape, and nuclear features, with mitosis becoming frequent. In such lesions, phagocytozed erythrocytes and the presence of hyaline globules may provide clues about the tumor's origin. Very rarely, angiosarcoma is mimicked by the development of vascular spaces lined by grossly atypical endothelial cells. This variant of Kaposi's sarcoma is vanishingly rare.

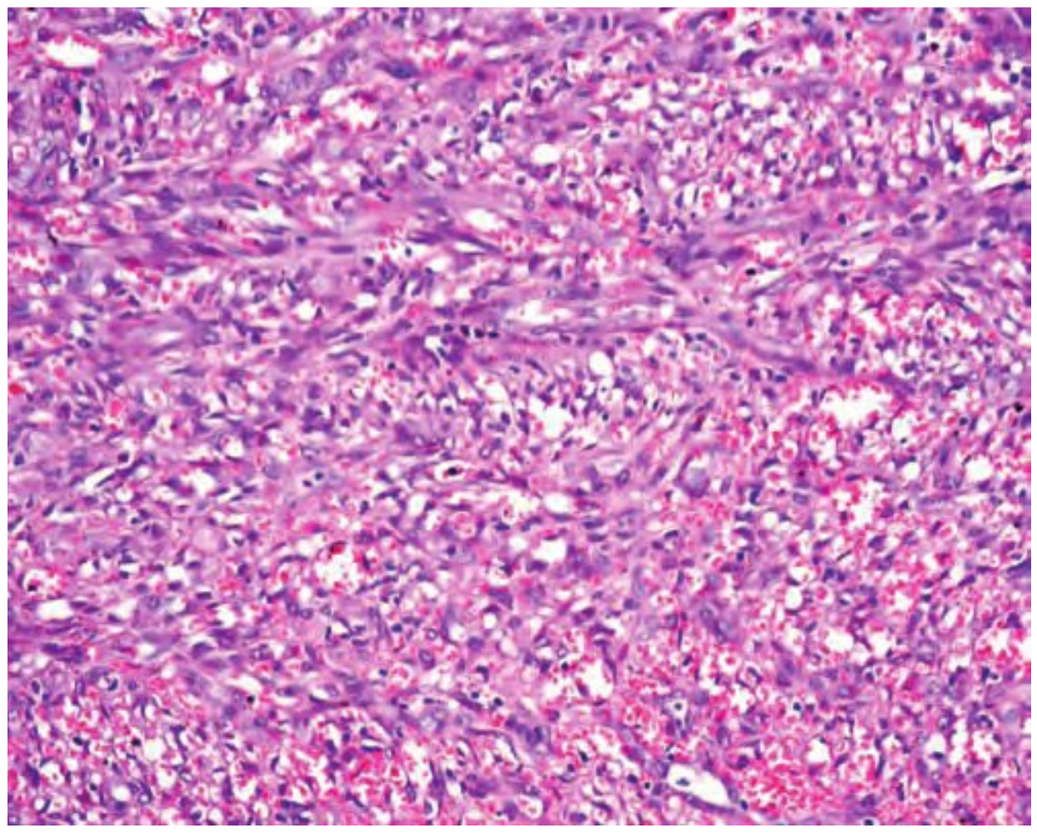

FIGURE 33-63. Nodular Kaposi's sarcoma. Bland spindle cells forming slitlike spaces occupied by red blood cells.

A useful diagnostic tool is the demonstration of HHV-8 in samples from patients with all clinical subsets of Kaposi's sarcoma. All variants of this tumor are etiologically related to this novel virus. Until recently, demonstration of the virus was only possible by *in situ* hybridization. This has been simplified by the development of a commercially available monoclonal antibody against the latent nuclear antigen (LNA-1) of the virus that can be used in routine practice. Positive cases demonstrate granular nuclear staining (184,185) (Fig. 33-64).

The histology of lesions of Kaposi's sarcoma that have regressed after chemotherapy or with angiogenesis inhibitors including Col-3 can be difficult to interpret (186). Regression may be partial or complete. In completely regressed lesions, there is absence of spindle-shaped cells; increase in the number of capillaries in the superficial dermis; a superficial, perivascular

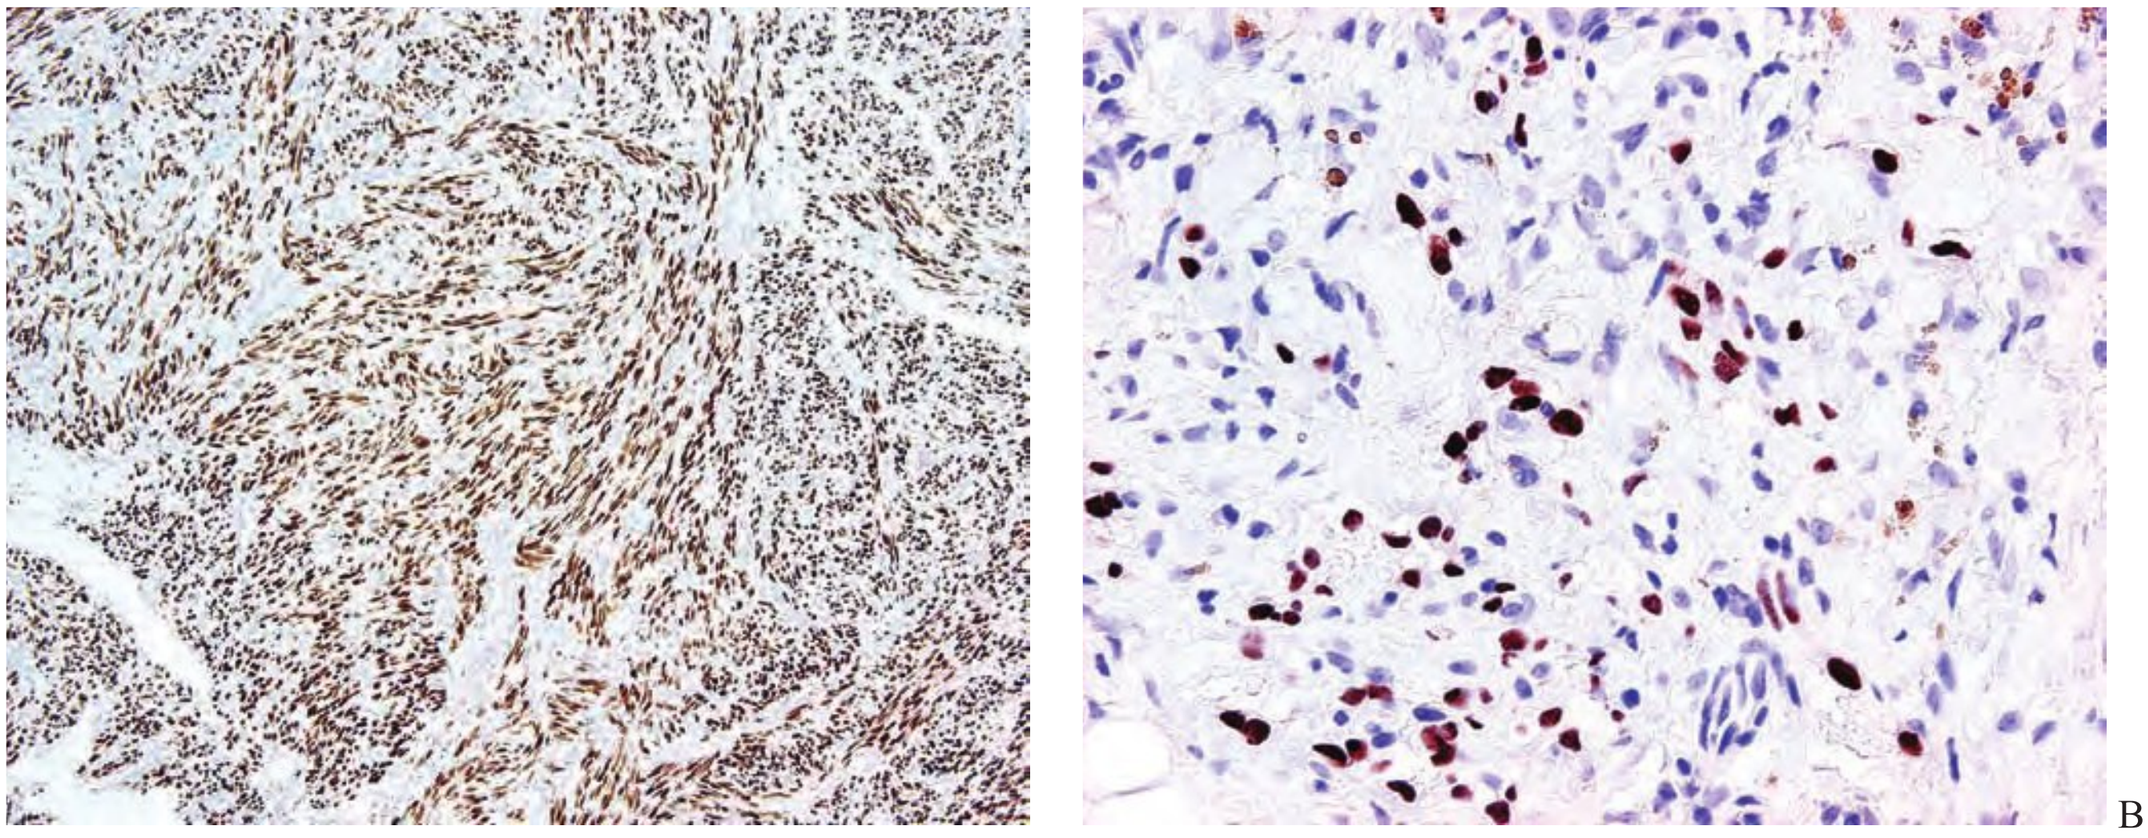

FIGURE 33-64. A: Staining of the nuclei of tumor cells with an antibody against the LAN-1 of HHV-8 using the ABC method. B: High power of another example.

lymphohistiocytic inflammatory cell infiltrate; and variable numbers of siderophages. Partially regressed lesions show prominent decrease in the number of spindle-shaped cells, focal inflammation, and siderophages. The residual spindle-shaped cells tend to be arranged around superficial and mid-dermal capillaries. These changes are correlated with prominent decrease in the expression of LNA-1.

Pathogenesis. The peculiar epidemiologic aspects of Kaposi's sarcoma have stimulated research for many years on whether viruses other than HIV or some other transmissible agent help to induce the disease. Initial studies of the fine structure of tumor cells in Kaposi's sarcoma have revealed tuboreticular structures and cylindrical-confronting cisternae, suggestive of a cellular reaction to a viral infection. In the last decade of the 20th century, the riddle of the association between Kaposi's sarcoma and a virus was resolved. Chang and colleagues (187) described a new human gammaherpesvirus associated with Kaposi's sarcoma. This virus is closely associated to Epstein-Barr virus, has been named *HHV-8*, and it is etiologically associated with Kaposi's sarcoma (188–190). DNA sequences of this virus have been detected consistently in all variants of the disease, including AIDS-related Kaposi's sarcoma, African endemic Kaposi's sarcoma induced by iatrogenic immunosuppresion, and Mediterranean Kaposi's sarcoma. The virus can be found in the blood of patients before lesions of Kaposi's sarcoma develop (191).

For many years, it was suspected that the proliferating cell in Kaposi's sarcoma is lymphatic in origin. This has recently been substantiated by the development of antibodies specific for lymphatic endothelium, including Lyve-1, podoplanin, D2-40, and Prox-1 (192,193).

The multifocal development, slow evolution of the classic form of the disease, regression when immunosuppression is reduced or stopped, and histology of inflammation and cells lacking cytologic atypia have led many to suggest that at least initially Kaposi's sarcoma is a reactive condition and not a neoplastic process (166,169). Initial reports demonstrating the presence of clonality have lended support to the latter (194). However, a number of more recent studies have suggested that the disease starts as a reactive angioproliferative and inflammatory process that progresses to become a monoclonal neoplastic process (195,196). This is a result of close, complex interactions between inflammatory cytokines, angiogenic factors, HHV-8, and, in HIV-positive patients, the HIV virus (197). In the latter setting, it has been demonstrated that the HIV-1 transactivating protein Tat-1 promotes the development of lesions by increasing the activity of different cytokines and angiogenic factors (198).

Differential Diagnosis. The differential diagnosis is wide, with the most difficulties encountered with either early macular or late aggressive lesions. Vascular proliferations in stasis and multinucleate-cell angiohistiocytoma are discussed here in more detail because they are not described elsewhere in this chapter. All of the different lesions described below in this section are usually negative for HHV-8, while Kaposi's sarcoma in all stages should be positive for this marker.

In *early macular lesions*, an inflammatory condition or a cell-poor (atrophic) histiocytoma may be suspected since the vascular nature of vessels with collapsed lumina may not be apparent. Appropiate cell markers may clarify the vascular nature of the underlying lesion. In late macular lesions, the differential diagnosis includes a well-differentiated angiosarcoma, progressive lymphangioma, targetoid hemosiderotic hemangioma, and microvenular hemangioma. Angiosarcoma shows not only a "dissection" of collagen infiltrative pattern but also endothelial cell atypia with hyperchromatism and intraluminal shedding of malignant cells. Histologically, progressive lymphangioma is almost indistinguishable from Kaposi's sarcoma

with prominent lymphangioma-like features, but inflammatory cells, especially plasma cells, tend to be absent in the former. When the clinical features are taken into account, distinction is not difficult. In hobnail hemangioma, lymphangioma-like channels are mainly confined to the upper dermis; in some places, plump "hobnail" endothelial cells invaginate vascular spaces, inflammatory cells are rare, and hemosiderin deposition is prominent, unlike early Kaposi's sarcoma. Microvenular hemangioma differs by showing blood-containing vessels, many of which are surrounded by pericytes or smooth muscle cells (positive for smooth muscle actin) suggestive of venular differentiation.

Spindle cell hemangioma, kaposiform hemangioendothelioma, and moderately differentiated angiosarcomas with spindle cell differentiation are the most important histologic simulants of *nodular Kaposi's lesions*.

Spindle cell hemangioma differs by showing cavernous or widely dilated vascular spaces and collections of epithelioid cells with or without intracytoplasmic lumina.

Kaposiform hemangioendothelioma is mainly a disease of children that usually affects deep soft tissues, although the skin can be affected (199). Histologically, the tumor shows intermediate features of capillary hemangioma and Kaposi's sarcoma and has a lobular growth pattern that is absent in Kaposi's sarcoma. Furthermore, the capillaries at the periphery of tumor lobules in kaposiform hemangioendothelioma often show focal thrombosis, there may be focal epithelioid endothelial cells, and eosinophilic globules are absent.

Sometimes spindle cell differentiation is prominent in angiosarcoma, but usually markedly atypical cells are present, allowing differentiation from Kaposi's sarcoma.

Other acquired vascular conditions that can cause problems from the clinical and histologic point of view are bacillary angiomatosis and pyogenic granuloma, especially if complicated by satellite lesions and tufted angioma. Spindle cell fascicles with a bland cytologic appearance do not feature as a prominent component of any of these entities.

Aneurysmal benign fibrous histiocytoma is a nonvascular, highly cellular spindle cell lesion with pseudovascular spaces and hemosiderin deposition that can be confused with nodular Kaposi's sarcoma (200). The variability of pathology, the presence of peripheral areas similar to common dermal fibrous histiocytoma, and immunohistochemistry should prevent error in diagnosis.

In *aggressive late-stage lesions*, many malignant spindle cell tumors can come into the differential diagnosis, especially if clinical details are unavailable. The most important differential diagnoses are fibrosarcoma, leiomyosarcoma, monophasic synovial sarcoma, malignant cellular blue nevus with sparse melanin deposition, and desmoplastic malignant melanoma. Accurate diagnosis may be impossible unless reliable immunohistochemistry is available. CD31 and CD34 are particularly helpful in suggesting a vascular derivation, even in poorly differentiated Kaposi's lesions.

Hypostasis and high venous pressure gives rise to vascular proliferation (pseudo–Kaposi's sarcoma and acroangiodermatitis). Angiomatous papules and plaques near the ankles that are secondary to high venous pressure result from incompetent veins and are common causes of Kaposi-like lesions (201). Less commonly, high venous pressure can arise due to congenital or acquired arteriovenous anomalies (202). Histologically, there is expansion of the whole capillary bed throughout the dermis. In the papillary dermis, there is reduplication and corkscrewing of thick-walled capillaries, which increase in size and become angiomatous in appearance. Similarly, venules and deeper, vertically small veins become hypertrophied and tortuous. Erythrocyte extravasation, fibrosis with horizontally oriented spindle cells, and numerous siderophages are additional features. The angiomatous capillaries appear separated from each other by an edematous matrix, and they do *not* lie "back-to-back" as in Kaposi's sarcoma. To complicate matters, hypostatic vascular proliferation can coexist with Kaposi's sarcoma. A key difference between Kaposi's sarcoma and pseudo–Kaposi's sarcoma is that in the latter, vascular hyperplasia results from hyperplasia of the preexisting vasculature, whereas in the former, the vascular proliferation is mainly independent.

Multinucleate-cell angiohistiocytoma arises as slowly developing grouped vascular papules usually on the legs (203) but also at other sites including the face and hands (204). Most patients are older women. Histologically, an increased number of capillaries and venules with few inflammatory cells are found throughout the dermis, but the extent of the proliferation does achieve angiomatous proportions. Increased numbers of histiocytes and scattered multinucleate cells are usually found, although not in every biopsy. Blood pigment deposition is generally insignificant.

Immunohistochemical demonstration of HHV-8 is of great help in the histologic differential diagnosis of Kaposi's sarcoma, as all of the vascular and nonvascular entities previously discussed are usually not associated with this virus.

Retiform Hemangioendothelioma

Retiform hemangioendothelioma is a rare variant of low-grade angiosarcoma that is characterized by indolent clinical behavior (115,205,206). There is a predilection for young adults, and it presents as a slowly growing nondistinct tumor with equal gender incidence and a predilection for the extremities, especially the distal lower limbs. Rare cases can be associated with radiotherapy or chronic lymphedema. A single case with multiple primary tumors has been documented (207). Multiple recurrences are common, but metastasis has so far been reported in only two cases. One case metastasized to a regional lymph node, and a second case presented with a soft tissue metastasis close to the primary tumor (207). Retiform hemangioendothelioma is part of the spectrum of a family of vascular tumors that are characterized by endothelial cells with a distinctive hobnail appearance. This includes a benign tumor originally described as targetoid hemosiderotic hemangioma (hobnail hemangioma) and another low-grade malignant lesion, Dabska's tumor.

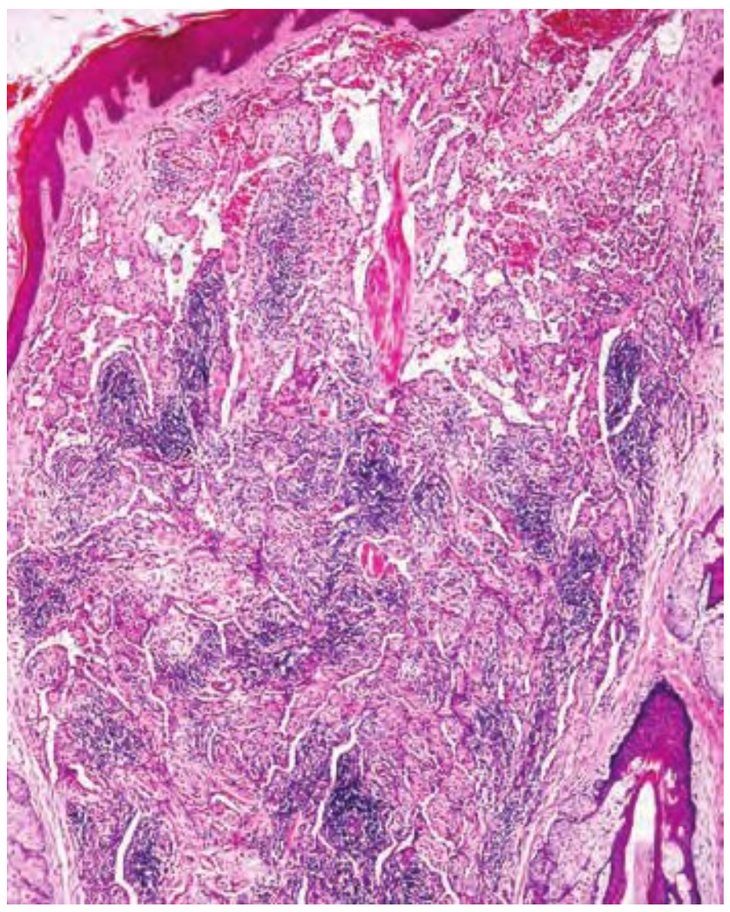

FIGURE 33-65. Retiform hemangioendothelioma. Branching blood vessels and a prominent lymphocytic inflammatory cell infiltrate.

Histopathology. Tumors are ill-defined and involve the reticular dermis with frequent extension into the subcutis. In most cases, there is a striking low-power resemblance to the normal rete testis conferred by the presence of elongated, arborizing blood vessels (Fig. 33-65) lined by monomorphic bland endothelial cells with prominent apical nuclei and scanty cytoplasm. These cells have been described as having a "matchstick" or hobnail appearance (Fig. 33-66). A lymphocytic inflammatory cell infiltrate is frequently seen not only in the stroma but also in the vascular lumina (though not invariably present). The intravascular lymphocytes commonly appear in close contact with the hobnail endothelial cells. Occasional intravascular papillae with hyaline cores can be seen (Fig. 33-66). In most tumors, there are solid areas composed of bland spindle cells or epithelioid cells that stain for endothelial markers. Some lesions present a mini-retiform pattern that may be more difficult to recognize on low-power examination. A sclerotic stroma is seen in some cases.

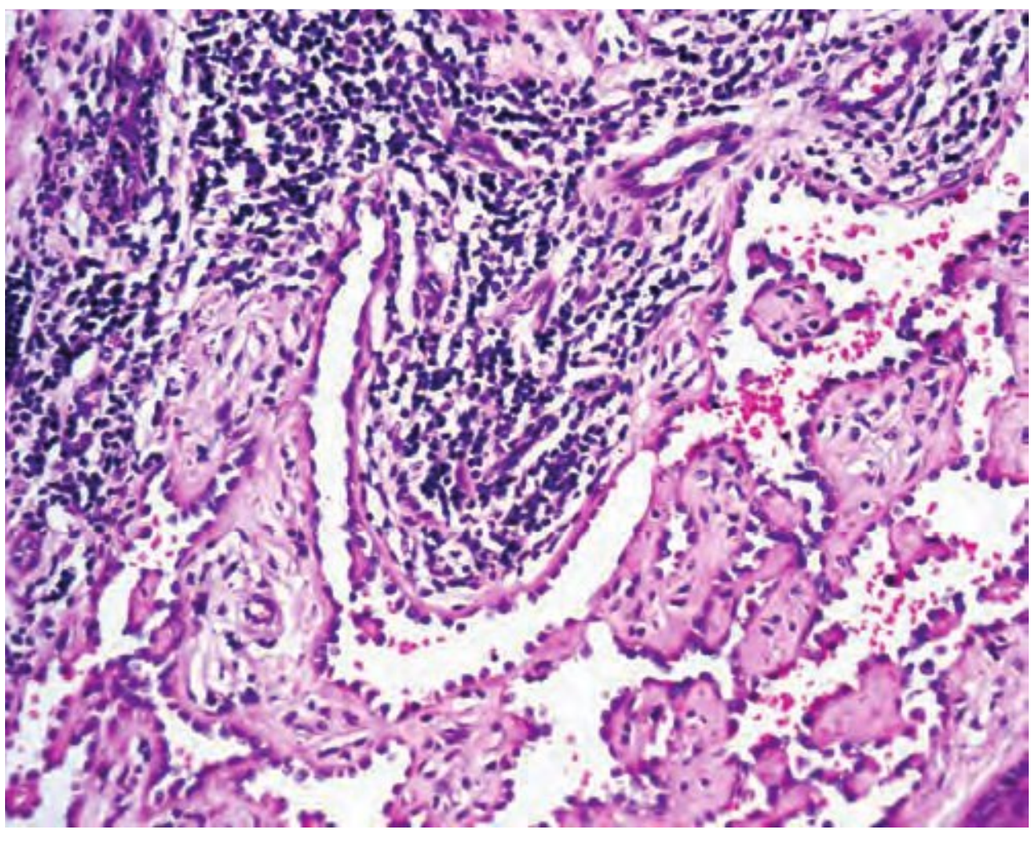

FIGURE 33-66. Retiform hemangioendothelioma. Typical bland hobnail endothelial cells and focal papillary projections.

Differential Diagnosis. Retiform hemangioendothelioma shares clinical and histologic features with Dabska's tumor. However, in Dabska's tumor, cavernous vascular spaces resembling lymphatics predominate, there is no retiform architecture, and intravascular papillae with collagenous cores are a striking feature. Hobnail hemangioma (targetoid hemosiderotic hemangioma) is more superficial, lacks a retiform architecture, and has hobnail endothelial cells that are mainly seen in vessels near the surface. Angiosarcoma often presents in a different clinical setting and shows cytologic atypia, mitoses, and absence of hobnail endothelial cells.

Papillary Intralymphatic Angioendothelioma (Malignant Endothelial Papillary Angioendothelioma, Dabska's Tumor)

Papillary intralymphatic angioendothelioma (PILA) is a very rare tumor that was first described in 1969 as malignant endolymphatic angioendothelioma. Until recently, only very few additional cases had been reported in the literature, and there seemed to be a lack of consensus regarding its specific histologic features. However, a recent series has delineated the histologic features of this tumor more accurately, and the alternative name of PILA has been proposed (208). Tumors present mainly in infants and children, but around 25% of patients are adults. Males and females are equally affected, and most cases involve the limbs. Clinical presentation is that of a slowly growing, solitary, asymptomatic nodule or plaque. This tumor is classified among tumors with low-grade malignant potential based on reports of local recurrence and rare regional lymph node metastasis in the original series. However, follow-up in 8 of the 12 cases recently reported showed no evidence of either local recurrence or distant spread (208). It is therefore likely that these tumors are benign, although confirmation of these findings is required in larger series with longer follow-up. Until this happens, complete excision of these tumors is advised.

Histopathology. Low-power examination reveals a dermal and often subcutaneous tumor composed of markedly dilated, thin-walled vascular channels resembling a cavernous lymphangioma (Fig. 33-67). These vascular channels are lined by bland hobnail endothelial cells with protruding nuclei and very scanty cytoplasm. A prominent intra- and extravascular lymphocytic inflammatory cell infiltrate is often present, and intravascular papillae with collagenous cores are a frequent finding (Fig. 33-68). Commonly, the lymphocytes appear to be in close apposition to the endothelial cells. Tumor cells stain for vascular markers including CD31, CD34, and von Willebrand factor.

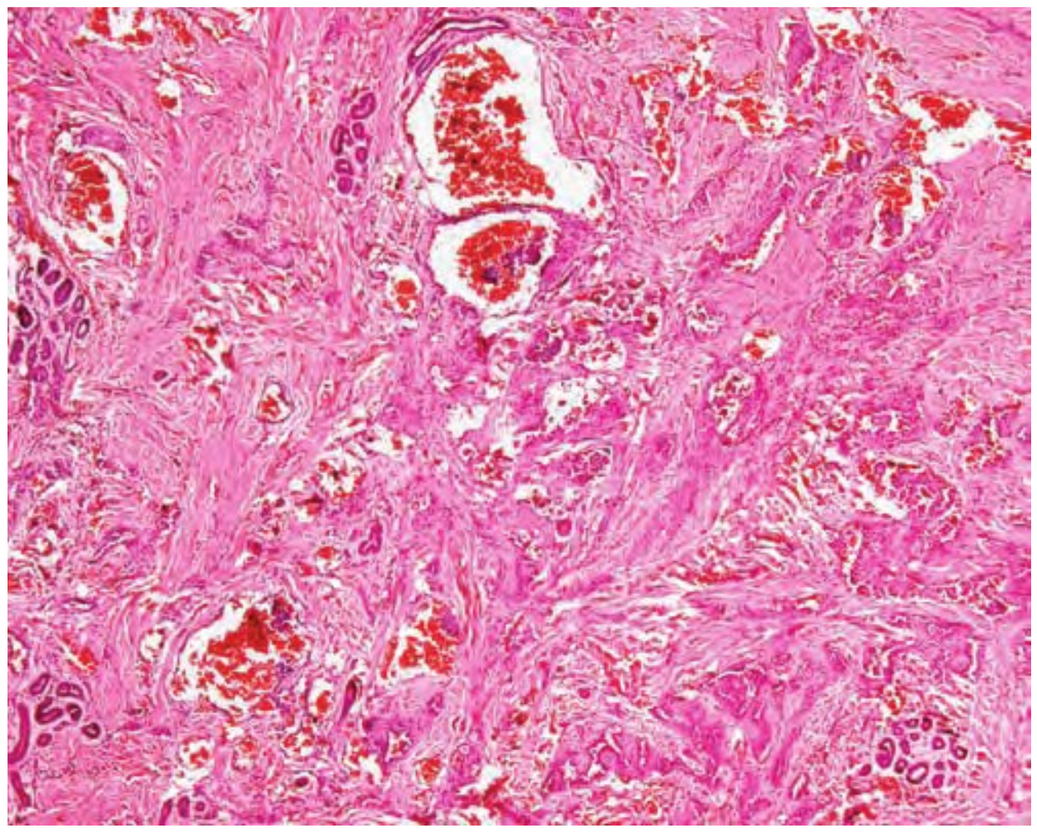

FIGURE 33-67. Papillary intralymphatic angioendothelioma. Cavernous lymphangioma–like vascular spaces and intravascular papillae.

Pathogenesis. Based on the close interaction between lymphocytes and endothelial cells in Dabska's tumor, it has been proposed that the hobnail endothelial cells differentiate toward high endothelial cells, which are normally responsible for the selective homing of lymphocytes in lymphoid organs (209). A similar theory can be proposed for retiform hemangioendothelioma, which shares some histologic features with Dabska's tumor. The strong expression of vascular endothelial growth factor receptor-3 (VEGFR-3) by tumor cells has led to suggestions that these tumors display lymphatic differentiation (209). However, the specificity of this marker as an indicator of lymphatic differentiation is doubtful.

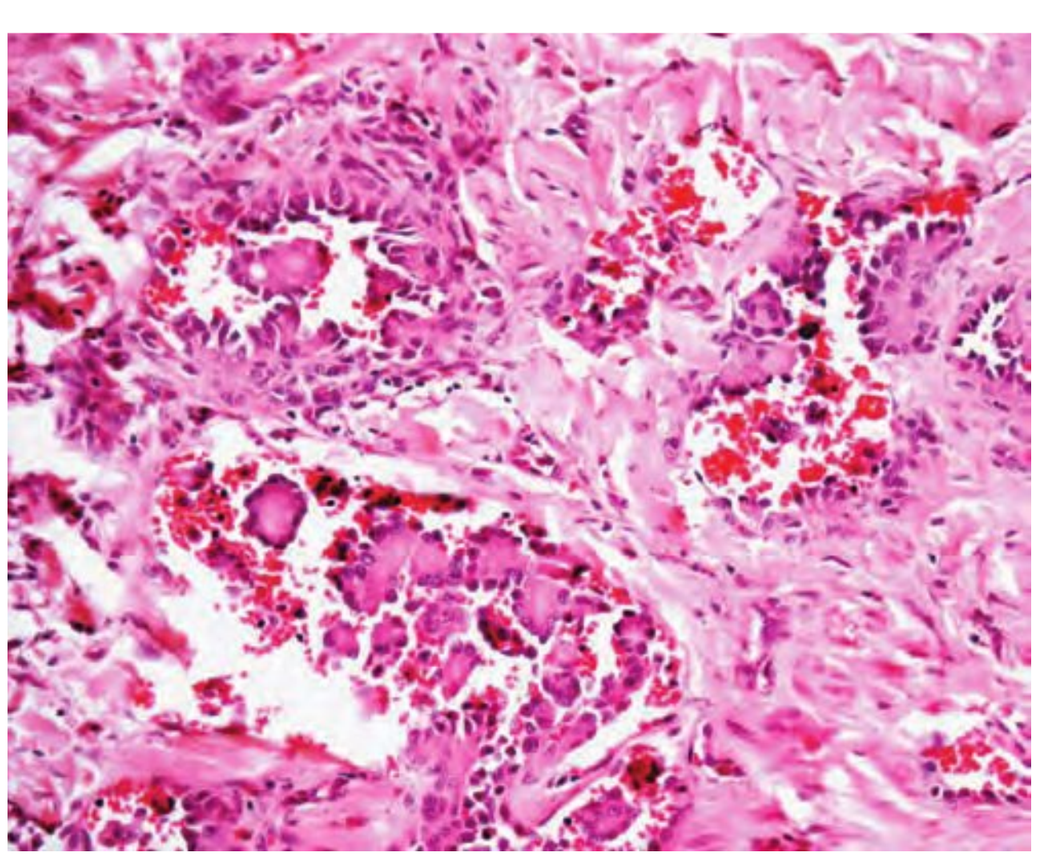

FIGURE 33-68. Papillary intralymphatic angioendothelioma. Bland hobnail endothelial cells and formation of numerous papillary projections with collagenous cores.

Differential Diagnosis. Refer to the differential diagnosis for retiform hemangioendothelioma, previous page.

Composite Hemangioendothelioma

Composite hemangioendothelioma is a recently described low-grade malignant vascular tumor with a tendency for local recurrence but very low metastatic potential. It is defined as a neoplasm containing a mixture of histologic patterns including benign, intermediate, and/or malignant (210). It is a very rare tumor presenting mainly in adults and only exceptionally in children (210–212). There is no sex predilection, and most tumors occur in the extremities with a predilection for the hands and feet. In 25% of patients, tumors arise in association with lymphedema and lesions present as long-standing red-blue nodules or plaques. The rate of local recurrence is around 50%, and this may occur years after excision of the primary tumor. Only a single case originating in the tongue has been reported to metastasize to a regional lymph node and to the soft tissues of the thigh.

Histopathology. Composite hemangioendothelioma is poorly circumscribed, with an infiltrative growth pattern and involvement of the dermis and subcutaneous tissue. The different components vary from tumor to tumor and may include retiform hemangioendothelioma (Fig. 33-69), epithelioid hemangioendothelioma, spindle cell hemangioma, conventional angiosarcoma (low and even high grade), lymphangioma circumscriptum, and areas simulating an arteriovenous malformation. The prognosis is likely to be dictated by the component with the highest histologic grade, but this should be estimated in larger series of cases with adequate follow-up. Immunohistochemistry displays positive staining for vascular markers including CD31, CD34, and von Willebrand factor.

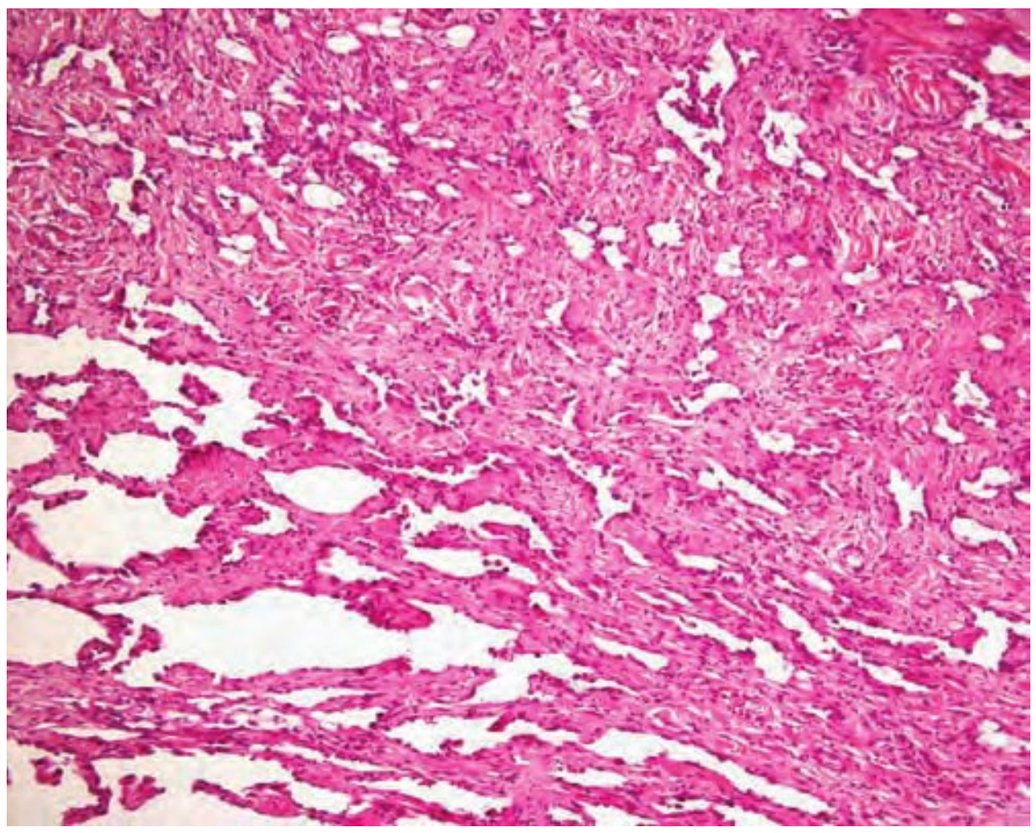

FIGURE 33-69. Composite hemangioendothelioma. Areas of retiform hemangioendothelioma and well-differentiated angiosarcoma. Elsewhere, the tumor contains areas resembling an epitheliod hemangioendothelioma.

Kaposi-like Infantile Hemangioendothelioma

Although Kaposi-like infantile hemangioendothelioma has only been described recently, individual cases of the same condition were reported in the past under different names (199,213–217). It is a rare vascular tumor that usually presents in the retroperitoneum or deep soft tissues of infants. Occasionally, congenital multifocal lesions have been described (218). A high number of cases are associated with Kasabach-Merritt syndrome (up to half of cases or more) or lymphangiomatosis. It is classified as a low-grade malignant vascular tumor because of its locally aggressive growth. Although exceptional regional perinodal soft tissue involvement has been reported, metastases have not been described (214). Cutaneous and superficial soft tissue tumors are relatively rare (219). Lesions with a superficial location tend to behave in a benign fashion except when associated with Kasabach-Merritt syndrome.

Histopathology. Low-power examination shows a tumor with a lobular and focally infiltrative growth pattern (Fig. 33-70). Bands of collagen separate tumor lobules. These lobules are composed of a mixture of congested capillaries surrounded by fascicles of bland spindle-shaped endothelial cells and pericytes (Fig. 33-71). Slitlike vascular spaces are often a feature. Focal areas with epithelioid cells containing abundant pale pink cytoplasm are often seen. In many areas, the tumor resembles a capillary hemangioma. Toward the periphery of the tumor lobules, small vascular channels frequently show intraluminal thrombi (Fig. 33-72). Hemosiderin deposition and hemorrhage are additional findings. It has been suggested that this tumor consists of vascular and lymphatic components. The latter is reflected by the presence of dilated, irregular, lymphatic-like spaces in the stroma between tumor lobules. Some tumors have areas resembling tufted angioma, and it has been suggested that there is an overlap between both entities (220).

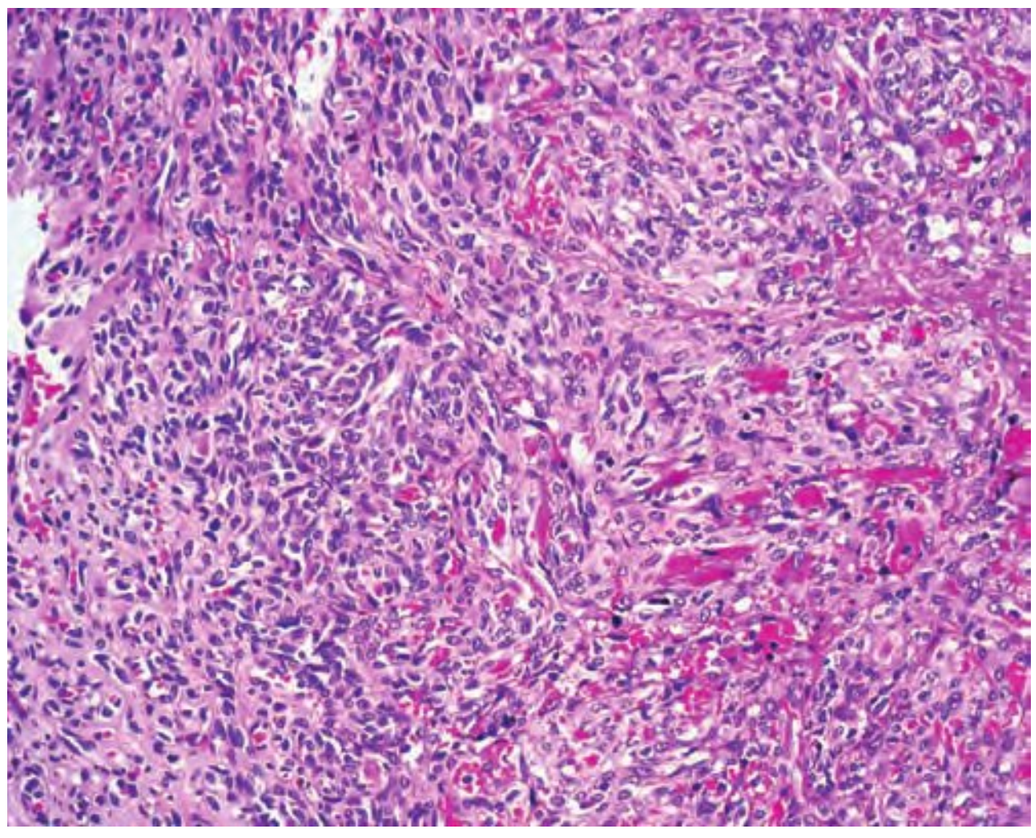

FIGURE 33-71. Kaposiform hemangioendothelioma. Capillaries intermixed with bland spindle-shaped cells.

Lesions are always negative for HHV-8. Regression does not tend to occur in patients who survive the Kasabach-Merritt phenomenon (221).

Distinction from Kaposi's sarcoma is discussed on page 1035.

Giant Cell Angioblastoma

Giant cell angioblastoma (222,223) is very rare, with only a handful of cases reported so far in the literature. Although it is briefly mentioned in the WHO book on classification of tumors of soft tissue and bone (1), it was not formally included in the final classification until more and larger series provide a

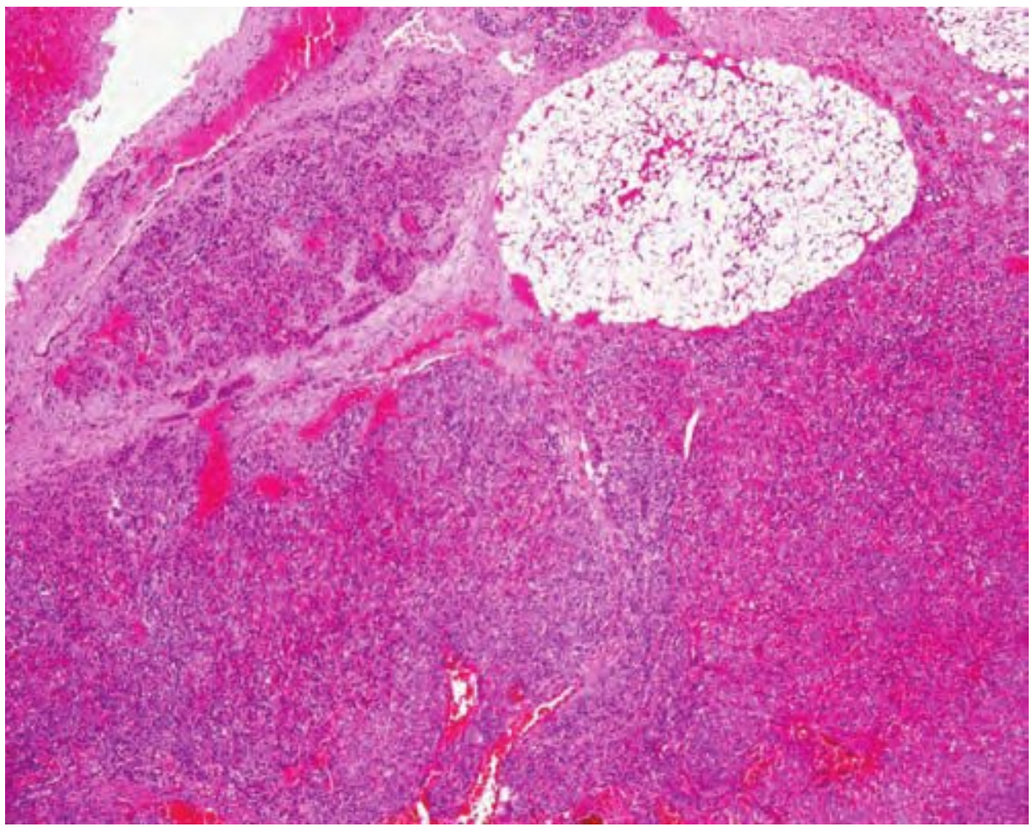

FIGURE 33-70. Kaposiform hemangioendothelioma. Typical lobular and infiltrative growth pattern with replacement of the subcutaneous tissue.

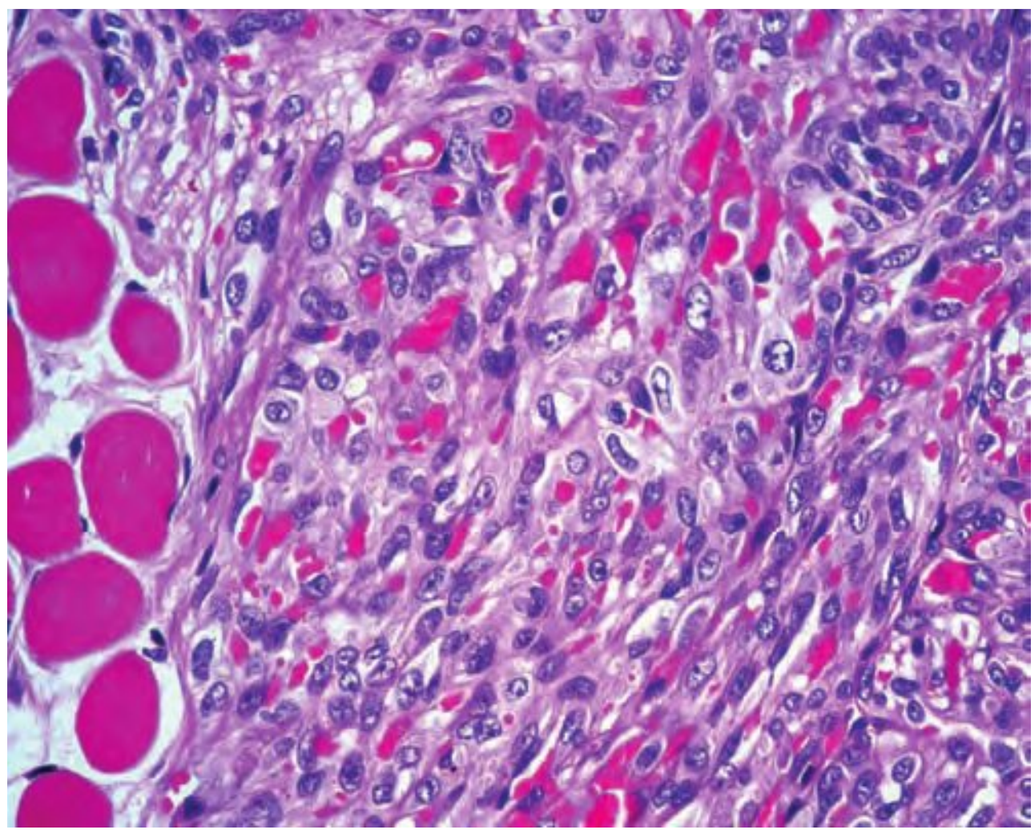

FIGURE 33-72. Kaposiform hemangioendothelioma. Note infiltration of skeletal muscle and frequent microthrombi within the capillaries.

better definition of the entity particularly, as it is not clear whether the line of differentiation of these tumors is truly endothelial.

Tumors are locally destructive and have been described on the hand, forearm, scalp, and palate of infants as hemangioma-like lesions. No metastases have been reported.

Histopathology. Characteristically, tumors display a distorted attempt at producing vascular walls, and many of its features simulate a fibrohistiocytic tumor. There is involvement of the mucosa, dermis, subcutis, and deep soft tissue by nodular, linear, and plexiform granuloma-like aggregates of bland histiocyte-like cells and giant cells with no mitotic activity. These cells are distributed in a concentric onionskin pattern around capillary-sized vessels lined by plump endothelial cells with no atypia. The background shows a loose focally myxoid stroma and a moderate mononuclear inflammatory cell infiltrate. Perineural and intraneural involvement by small vessels can be seen. Smooth muscle actin is strongly positive in most histiocyte-like cells, suggesting a vascular smooth muscle origin while CD68 and KP1 stain the multinucleated giant cells.

Differential Diagnosis. The differential diagnosis includes plexiform fibrous histiocytoma (PFH), myofibroma, and giant cell fibroblastoma (GCF). PFH has a characteristic plexiform biphasic growth pattern with nodules of histiocyte-like cells and small numbers of multinucleated giant cells intermixed with bundles of myofibroblast-like cells. Myofibroma also usually shows a biphasic growth pattern with immature round cells distributed around branching vascular channels in a hemangiopericytoma-like arrangement alternating with bundles of mature myofibroblasts with focal hyalinization. GCF differs in showing CD34-positive, fleurette-type multinucleated cells and pseudoangiomatoid spaces and sinusoidal focally lined by giant cells.

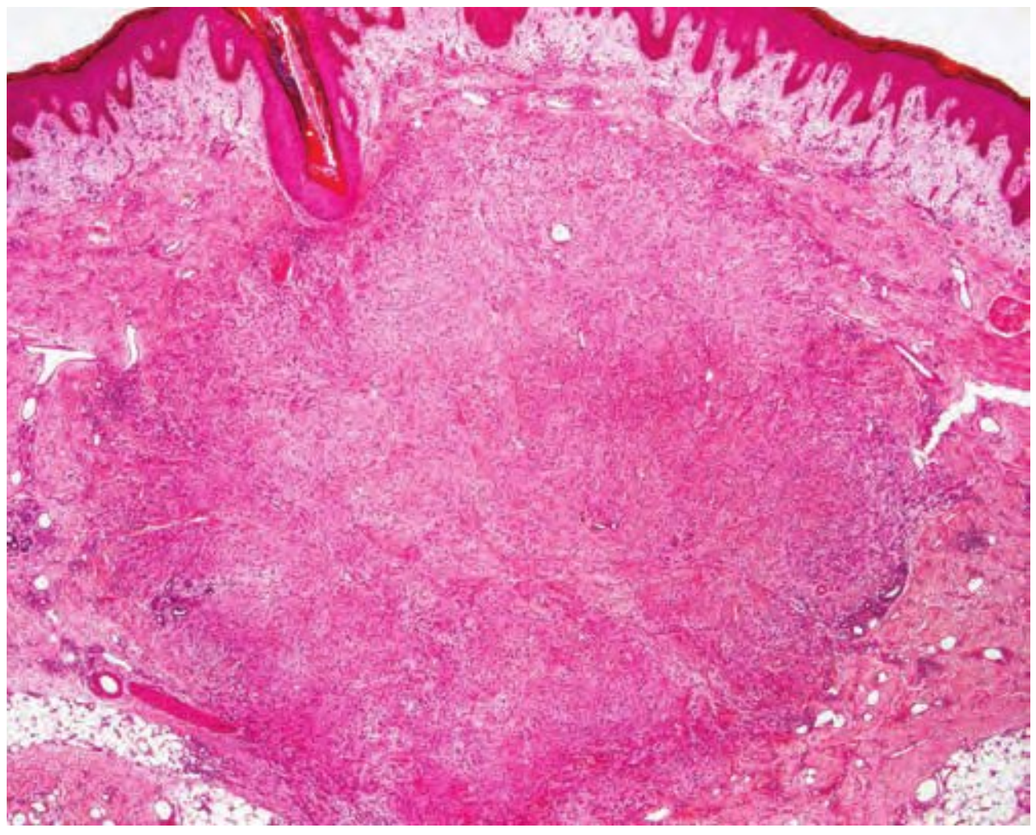

FIGURE 33-73. Epithelioid hemangioendothelioma. Purely cutaneous tumors often present as a fairly circumscribed nodule with hyalinization or myxoid change.

MALIGNANT TUMORS

Epithelioid Hemangioendothelioma

Epitheliod hemangioendothelioma is a neoplasm that was initially described in 1982 as a low-grade tumor of vascular endothelial origin (224). Epithelioid hemangioendothelioma, however, is associated with high morbidity and mortality and should therefore be regarded as a neoplasm with full malignant potential (225). It mainly arises in the superficial and deep soft tissue and muscle of the extremities (226). The tumor can also arise at internal sites and in the viscera (especially the liver, lungs, and bone). Many of such tumors were described previously by different names (224,226). Middle-aged patients, with an equal gender distribution, are mainly affected, but the tumor has a wide age distribution. In about half the cases, the tumor apparently arises from a medium-sized vein or, less often, an artery (224,225). Multicentricity is common in visceral lesions, particularly those affecting the lungs, liver, and bones. Skin involvement is uncommon and usually associated with an underlying soft tissue or bone lesion or with multicentric disease (226–228). Rare cases present with pure cutaneous involvement (229,230). Metastases develop in about 30% of cases involving superficial soft tissues, with a mortality rate of 17% (225). The prognosis is worse for internal sites (226).

Histopathology. Typically, epithelioid hemangioendothelioma shows an infiltrative growth pattern. However, purely cutaneous tumors often consist of a fairly circumscribed dermal tumor (Fig. 33-73). Tumor cells are ovoid, cuboidal, or short and spindle shaped with prominent eosinophilic cytoplasm. The nucleus is vesicular, showing variable or no atypia, and the nucleolus lacks prominence (Fig. 33-74). Cells tend to be

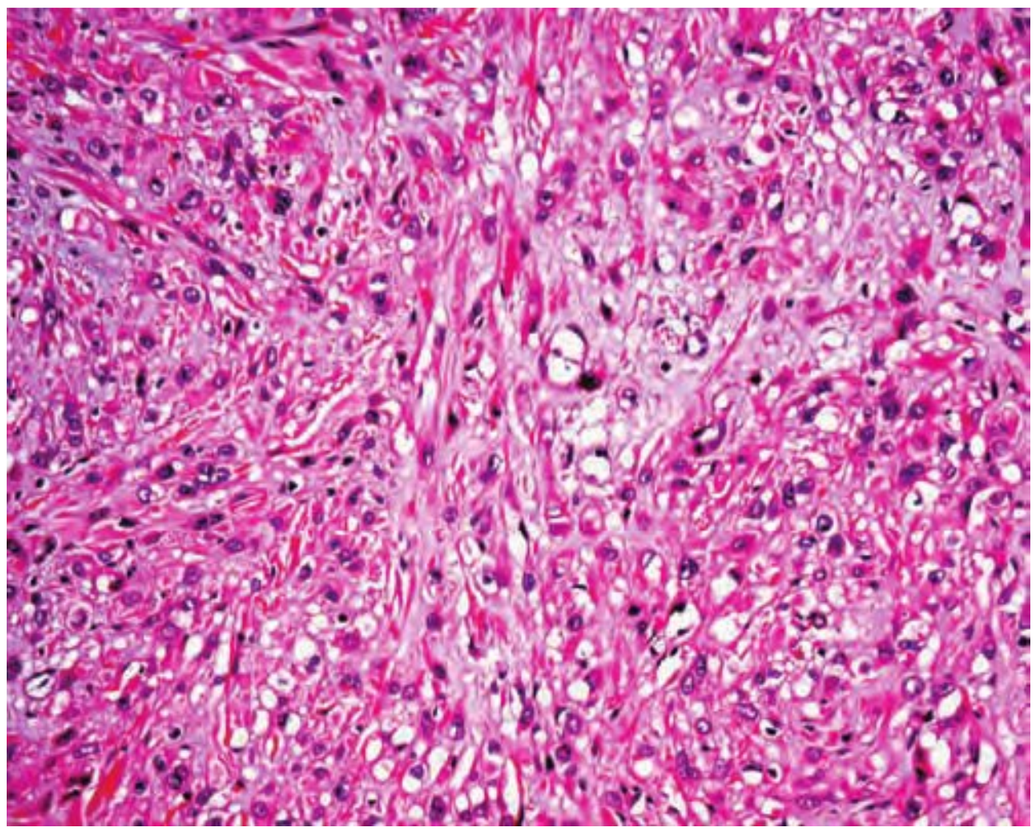

FIGURE 33-74. Epithelioid hemangioendothelioma. Epithelioid cells with variable atypia organized in short strands or individual units. Notice formation of intracytoplasmic lumina.

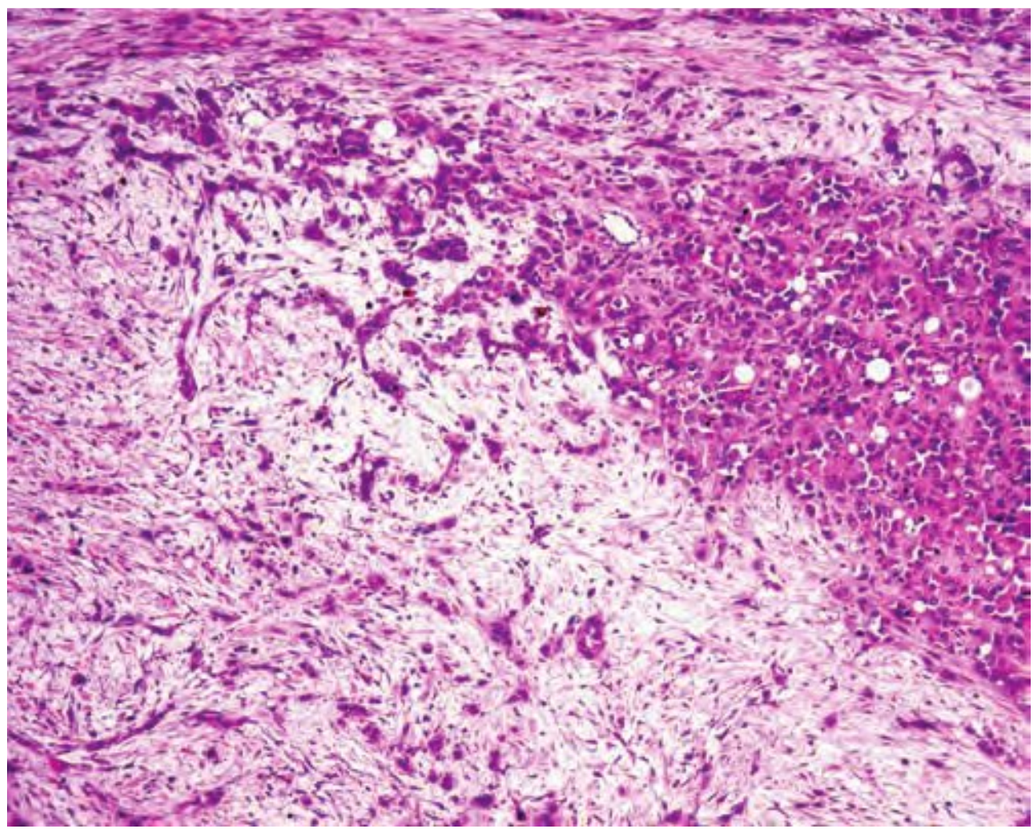

FIGURE 33-75. Epithelioid hemangioendothelioma. Transition between classic epithelioid hemangioendothelioma and solid, more pleomorphic areas with features of an epithelioid angiosarcoma.

arranged in short fascicles, small nests, or in an "Indian file" pattern, often set in a distinctive hyalinized or mucoid stroma rich in sulphated acid mucopolysaccharides. There is often a chondroid appearance. Obvious vascular channels are generally lacking, but intracytoplasmic vacuoles, sometimes containing erythrocytes, are usually present (Fig. 33-74). Infiltration through large-vessel walls and evidence of endothelial origin may be found. A subset of the tumor with a more aggressive clinical course shows prominent cytologic atypia and a high mitotic rate, overlapping histologically with epithelioid angiosarcoma (225) (Fig. 33-75). Some cases are associated with a prominent osteoclast-like giant cell reaction (231,232). Although lesions with cytologic atypia and mitoses are associated with a poorer prognosis, the behavior of tumors with bland morphology is difficult to predict.

Tumor cells often stain for endothelial markers including CD31, CD34, and von Willebrand factor. Positivity for pankeratin can be focally found in up to 20% to 30% of cases (225,233). Staining for epithelial membrane antigen is usually negative.

Cytogenetic analysis in two cases revealed a t(1;3) (p36.3;q25) (234). Analysis of a further case showed a complex translocation 7;22 (235).

Differential Diagnosis. The differential diagnosis includes epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia), which often has a lobular architecture, prominent inflammation, and numerous well-formed blood vessels; metastatic adenocarcinoma, which is negative for endothelial markers and positive for mucin stains; myxoid chondrosarcoma, which has a lobular growth pattern, S-100–positive cells, and absence of intracytoplasmic lumina; and myoepithelioma, which usually lacks intracytoplasmic lumina and has cells that are variably positive for keratin, smooth muscle actin, epithelial membrane antigen, and S-100.

Angiosarcoma

Most angiosarcomas of the skin arise in the following clinical settings: (a) angiosarcoma of the face and scalp in the elderly, (b) angiosarcoma (lymphangiosarcoma) secondary to chronic lymphedema (Stewart-Treves syndrome), and (c) angiosarcoma as a complication of chronic radiodermatitis or arising from the effects of severe skin trauma or ulceration (236).

An aggressive variant known as *epithelioid angiosarcoma* (237) regarded as distinctive from the variants mentioned before has been described. This tumor is difficult to diagnose histologically without the help of immunohistochemistry because of the exclusive epithelioid morphology and the limited formation of vascular channels (see text following).

Apart from these circumstances, cutaneous angiosarcomas are extremely rare. Exceptional case reports include angiosarcoma arising in preceding benign vascular tumors including vascular malformations (238), in a large blood vessel (239), in association with a plexiform neurofibroma in neurofibromatosis (240), in a schwannoma (241), in a malignant peripheral nerve sheath tumor (242,243), in xeroderma pigmentosum (244), in a gouty tofus (245), in association with vinyl chloride exposure (246), in association with immunosuppression in organ transplantation (247), and as the mesenchymal component in a metaplastic carcinoma (248). A case of "cutaneous-type" angiosarcoma has been described arising in a mature teratoma of the ovary (249). Angiosarcoma in children is extremely rare (250). An exceptional case of an angiosarcoma producing granulocyte colony-stimulating factor and inducing a leukemoid reaction has been described (236). With the exception of epithelioid angiosarcoma, the histologic spectrum of angiosarcomas is similar regardless of the clinical setting.

1. *Angiosarcoma of the scalp and face of the elderly.* This is almost invariably a fatal tumor that usually arises innocuously as erythematous or bruiselike lesions on the scalp or middle and upper face with a predilection for men (251–254). Subsequent plaques, nodules, or ulcerations develop (Fig. 33-76); metastasis to nodes or internal organs (mainly lungs, liver, and brain) usually arises as a late complication, with many patients dying as a result of extensive local disease. This sarcoma has only rarely been reported in black patients; the disease mainly affects whites and sometimes Asians. Only a very small percentage of patients, with smaller lesions usually less than between 5 and 10 cm in diameter at presentation, can be successfully treated with radical wide field radiotherapy and surgery (251,254). Combined series of idiopathic angiosarcoma of the face and scalp, other cutaneous angiosarcomas, and angiosarcomas occurring in internal organs report 5-year survival rates varying between 24% and 34% (253–256). The best chance of survival resides in wide surgical excision followed by radiotherapy (257).
2. *Angiosarcoma following lymphedema (postmastectomy lymphangiosarcoma or the Stewart-Treves syndrome).* Typically, the tumor presents in women who have had severe, long-standing lymphedema of the arm following breast surgery (258–260). In most cases, lymphedema is present for about

FIGURE 33-76. Idiopathic angiosarcoma of the face. Hemorrhagic, ulcerated nodule with bruiselike lesions in a multifocal pattern in surrounding skin.

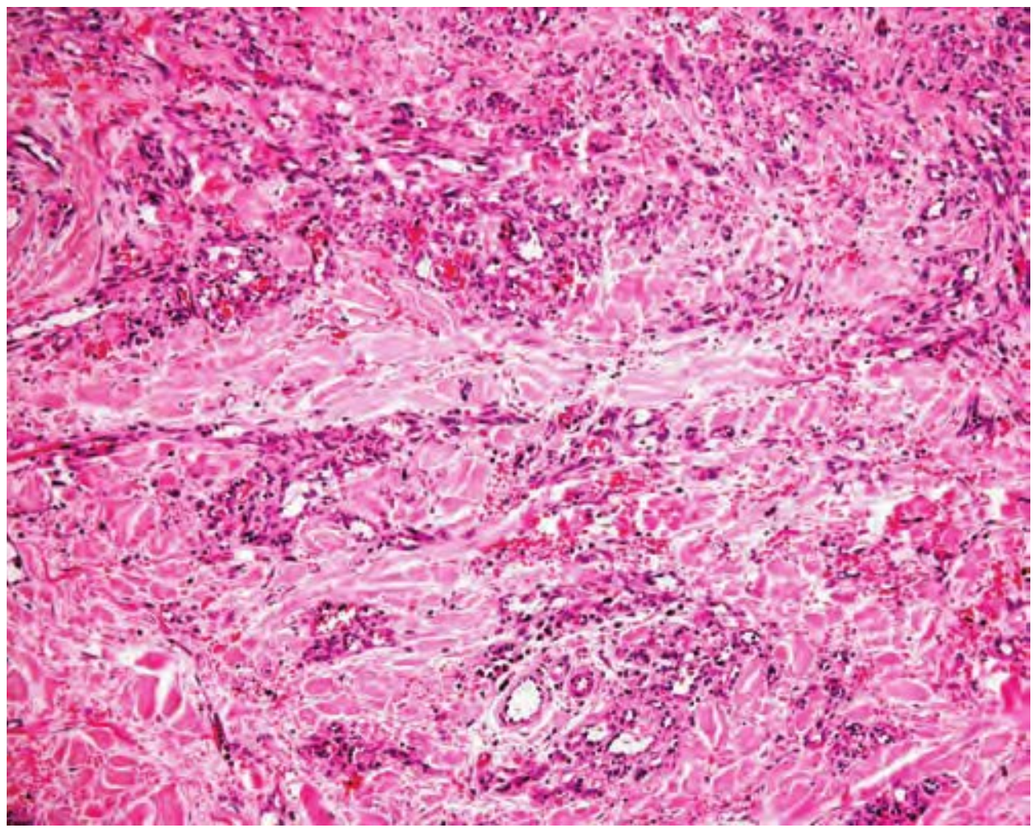

FIGURE 33-78. Well-differentiated angiosarcoma. Irregular and congested vascular channels infiltrating between collagen bundles.

10 years before the tumor arises, usually in the inner portion of the upper arm. Radiotherapy can usually be excluded as an etiologic factor, because the sarcoma nearly always develops beyond the areas of chronic radiodermatitis. Lymphedema-induced angiosarcoma has also been described in men and in a lower extremity (260) from causes other than cancer surgery, including congenital lymphedema (261) and tropical lymphedema due to filarial (262). The prognosis despite radical surgery is extremely poor. Exceptionally, a low-grade angiosarcoma with lesions simulating lymphangioma circumscriptum has been described as complicating chronic lymphedema after surgery (263).

3. *Postirradiation angiosarcoma.* There are many reports of angiosarcoma arising in the skin after radiotherapy for internal cancer. The most common sites are the breast or chest wall (264–268) and the lower abdomen after therapy for breast or gynecologic cancer (268).

Histopathology. Usually, the tumor extends well beyond the limits of the apparent clinical lesion, and multifocality is frequent. As a rule, the tumor shows varied differentiation in different biopsies, even within different fields in a single biopsy (Fig. 33-77). In well-differentiated areas, irregular anastomosing vascular channels lined by a single layer of somewhat enlarged endothelial cells permeate between collagen bundles (Figs. 33-77 and 33-78). Isolation and enclosure of collagen bundles, figuratively referred to as *dissection of collagen* is a characteristic feature (Fig. 33-79). Nuclear atypia is always

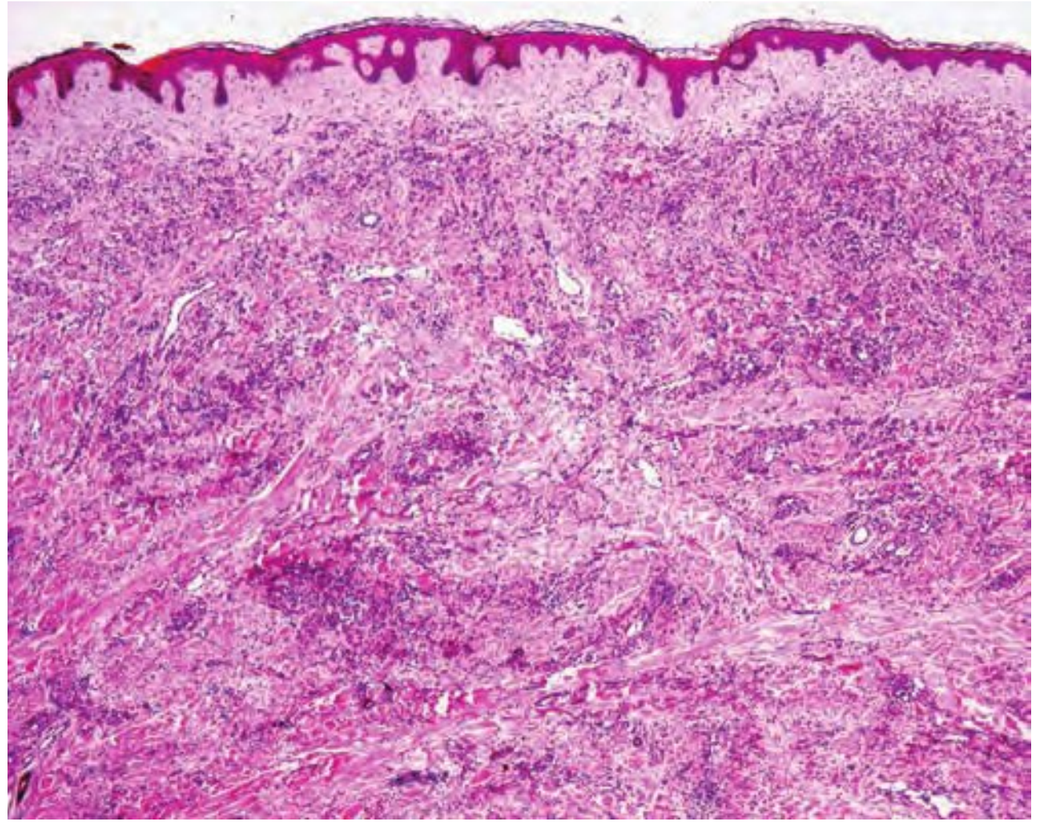

FIGURE 33-77. Well-differentiated angiosarcoma. Low-power view mimicking plaque-stage Kaposi's sarcoma.

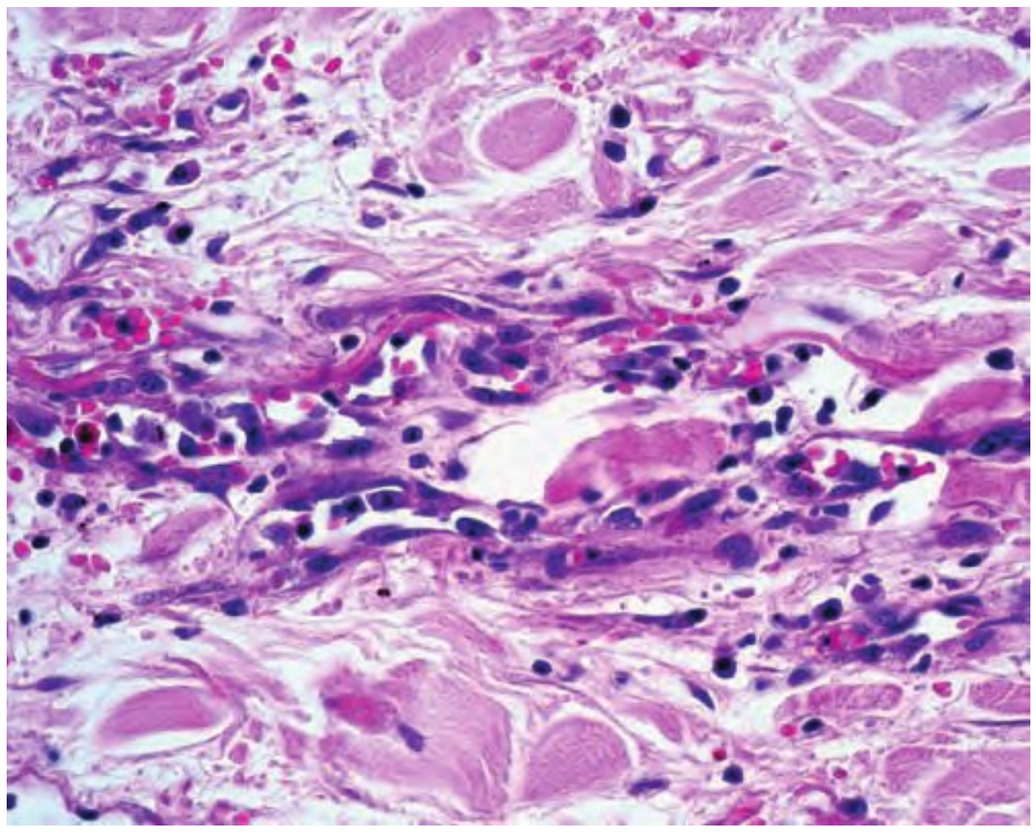

FIGURE 33-79. Well-differentiated angiosarcoma. Dissection of collagen pattern. Marked cytologic atypia and multilayering.

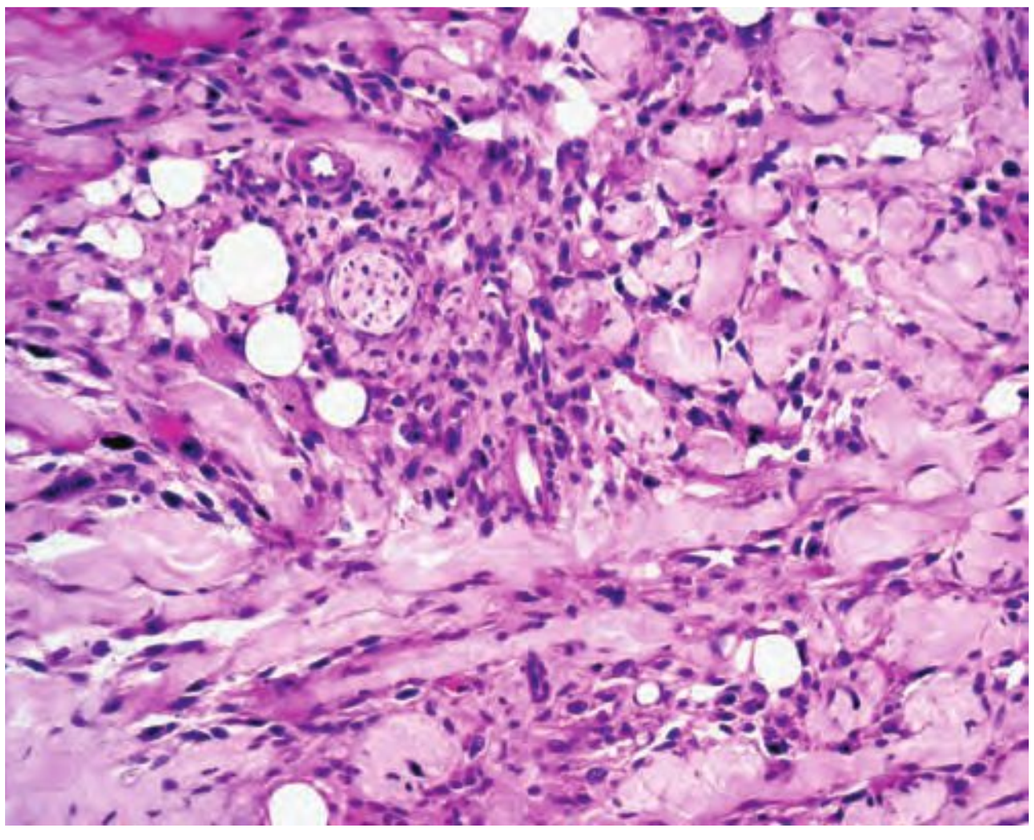

FIGURE 33-80. Moderately differentiated angiosarcoma. More cellular tumor with less evident vascular differentiation and more cytologic atypia.

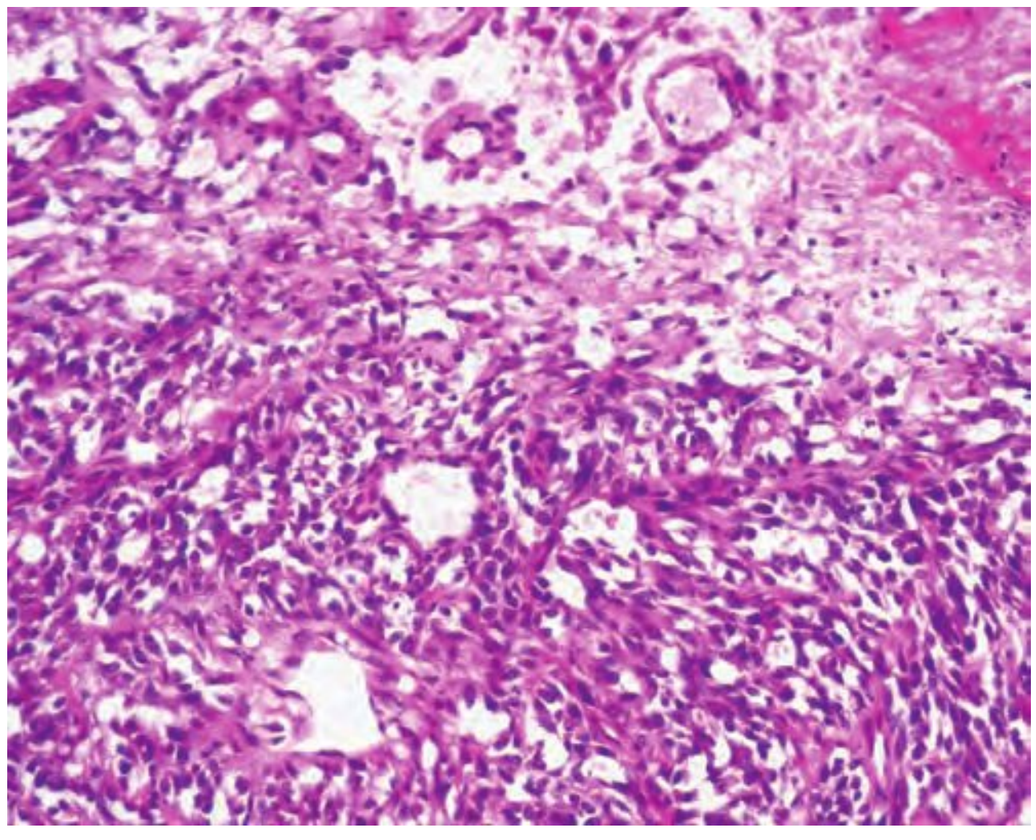

FIGURE 33-81. Poorly differentiated angiosarcoma. Highly cellular tumor composed of pleomorphic spindle-shaped cells and only focal suggestion of vascular differentiation.

present and may be slight to moderate, but occasional large hyperchromatic cells may be encountered. At this stage, the vascular lumens are generally bloodless, but they may contain free-lying shed malignant cells. Mitotic figures are invariably present, and it has been suggested that a high mitotic rate correlates with a poor prognosis (254,269). Other factors that are associated with poor prognosis include depth of invasion and positive tumor margins along with a tumor diameter >5 cm (254).

In less well-differentiated areas, endothelial cells increase in size and number (Fig. 33-80), forming intraluminal papillary projections where there is enhanced mitotic activity. In poorly differentiated areas, solid sheets of large pleomorphic cells with little or no evidence of luminal differentiation can resemble metastatic carcinoma or melanoma. Focally, areas showing epithelioid cells are not uncommon. The presence of an epithelioid component in the three variants of angiosarcoma described herein should not lead to the classification of a tumor, as epithelioid angiosarcoma such as this represents a distinctive variant of angiosarcoma (see next page). Other areas of tumors may simulate a poorly differentiated spindle cell sarcoma (Fig. 33-81). Interstitial hemorrhage and widely dilated blood-filled spaces may sometimes develop. Rare cases are composed of granular cells (270). In exceptional cases, tumors may be extensively infiltrated by lymphocytes or macrophages. In the former setting, distinction from a lymphoma may be difficult (271,272).

The histopathology of angiosarcomas secondary to lymphedema and radiotherapy shows a similar range of well-differentiated to poorly differentiated neoplasms as idiopathic angiosarcoma of the face and scalp. There are no reliable histologic differentiating features, although sometimes evidence of chronic lymphedema or chronic radiation dermatitis may be apparent in the tissue adjacent to the sarcoma.

Histogenesis. Sarcomas of probable lymphatic origin cannot be distinguished histologically from those of presumptive vascular endothelial origin; hence, there is a tendency to disregard the term *lymphangiosarcoma* in favor of *angiosarcoma*. For many years, a number of putative specific markers of lymphatic endothelium have been described, many of which have been a disappointment. However, a few appear to be specific, and these include LYVE-1, podoplanin, D2-40, and Prox-1 (273–276). By using D2-40, it has been shown that a percentage of cases but by no means all angiosarcomas display lymphatic differentiation (275).

von Willebrand factor is the most specific but least sensitive vascular marker, and it is generally negative even in well-differentiated tumors. However, patchy, weak, diffuse staining may be found focally in less well-differentiated tumors that require caution in interpretation. CD34 and especially the more specific CD31 are much more reliable as sensitive markers of tumors of endothelial cell origin for use in routine biopsies. It is important to remember, however, that CD34 is a very poorly specific marker and that CD31 stains macrophages, and this may represent a pitfall in tumors with prominent numbers of macrophages (277). Recently, an antibody against the carboxy terminal of the Fli-1 protein, a nuclear transcription factor member of the ETS family of DNA-binding transcription factors, has been shown to be a fairly specific marker of endothelial cells (278,279). As opposed to other markers of endothelial cell differentiation, the staining with this marker is nuclear. On electron microscopic examination, well-differentiated tumors may show the ovoid laminated organelle-like Weibel-Palade bodies characteristic of vascular endothelial cells, but they are absent in most tumors.

Cytogenetics studies of soft tissue and cutaneous angiosarcoma are limited to a few case reports. Most analyzed cases have shown complex cytogenetic aberrations (280–282). In a

single case of an angiosarcoma arising within a cavernous hemangioma, trisomy 5 and loss of the Y chromosome was the only abnormality demonstrated (283).

Differential Diagnosis. Well-differentiated angiosarcomas, if cell atypia is slight, may closely resemble early macular lesions of Kaposi's sarcoma and benign lymphangioendothelioma, because all of these conditions can demonstrate to a greater or lesser extent a "dissection of collagen" pattern. The major differences in clinical presentation of the disorders (absence of mitosis and the bland appearances of the endothelial cells in macular lesions of Kaposi's sarcoma and benign lymphangioendothelioma) should prevent any difficulties. Focal dissection of collagen pattern is also mimicked in intravascular papillary endothelial hyperplasia by new vessels invading thrombotic material. In poorly differentiated angiosarcomas, it is usually possible to find evidence of channel formation in peripheral areas that allows diagnosis. However, the use of endothelial markers, especially CD31, is an important aid in diagnosis. CD31 is the most specific and sensitive marker of endothelial cell differentiation, but it is important to remember that this marker also stains macrophages, and this may represent a diagnostic pitfall. Finally, occasionally adenoid squamous carcinomas or sarcomatoid squamous cell carcinoma, with or without intratumor hemorrhage, can simulate angiosarcoma (284–286). Immunohistochemistry is useful in these cases, since only angiosarcomas with epithelioid morphology are usually positive for cytokeratin, but these also show staining for CD31 and CD34. Angiosarcomas are consistently negative for HHV-8 (287).

Epithelioid Angiosarcoma

Epithelioid angiosarcoma is a rare form of angiosarcoma that usually arises in deep soft tissues (237) but may also occur in the skin and internal organs, including the thyroid and adrenal gland (288,289). Personal experience indicates that cutaneous lesions are more common than previously thought, and it is likely that such lesions were diagnosed in the past as epithelial or melanocytic neoplasms. There is wide anatomic distribution, and cases present in adults with a slight predilection for males. Some examples are multifocal, and it is difficult to establish the source of the primary tumor. Epithelioid angiosarcoma occurring in internal organs may rarely metastasize to the skin (290). Rare examples have been associated with radiation therapy (237), an arteriovenous fistula (291), and a foreign body (292). The outlook is extremely poor, although a slow course has been described for some skin tumors (289). However, the latter is based on a small number of cases with short follow-up, and cutaneous tumors appear to be aggressive.

Histopathology. Tumors are composed of sheets of pleomorphic large cells with prominent eosinophilic cytoplasm, a large nucleus, and an eosinophilic nucleolus, usually with little evidence of vascular differentiation other than the occasional presence of intracytoplasmic vacuoles sometimes containing red blood cells (Fig. 33-82). This angiosarcoma can easily be mistaken for a carcinoma deposit or even malignant melanoma (Fig. 33-83). Usually, the tumor cells demonstrate consistent

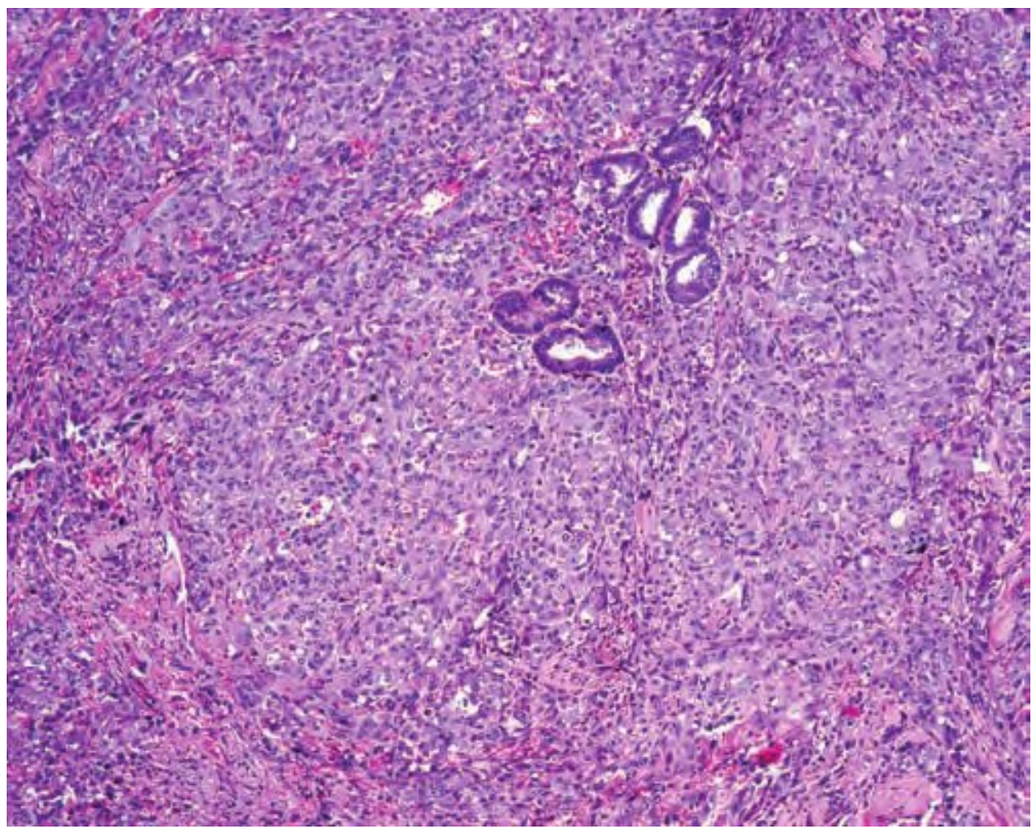

FIGURE 33-82. Epithelioid angiosarcoma. Solid proliferation of atypical epithelioid cells replacing the dermis.

positivity for von Willebrand factor, CD34, Fli-1, and CD31. However, cytokeratin positivity is present in up to 50% of cases, and rare cases are focally positive for epithelial membrane antigen; this might be a source of confusion with metastatic carcinoma and epithelioid sarcoma, which are negative for endothelial markers. However, epithelioid sarcoma is positive for CD34 in up to 60% of cases.

TUMORS OF LYMPHATIC VESSELS

Lymphangiomas constitute only about 4% of all vascular tumors and about 26% of benign vascular tumors in children (59).

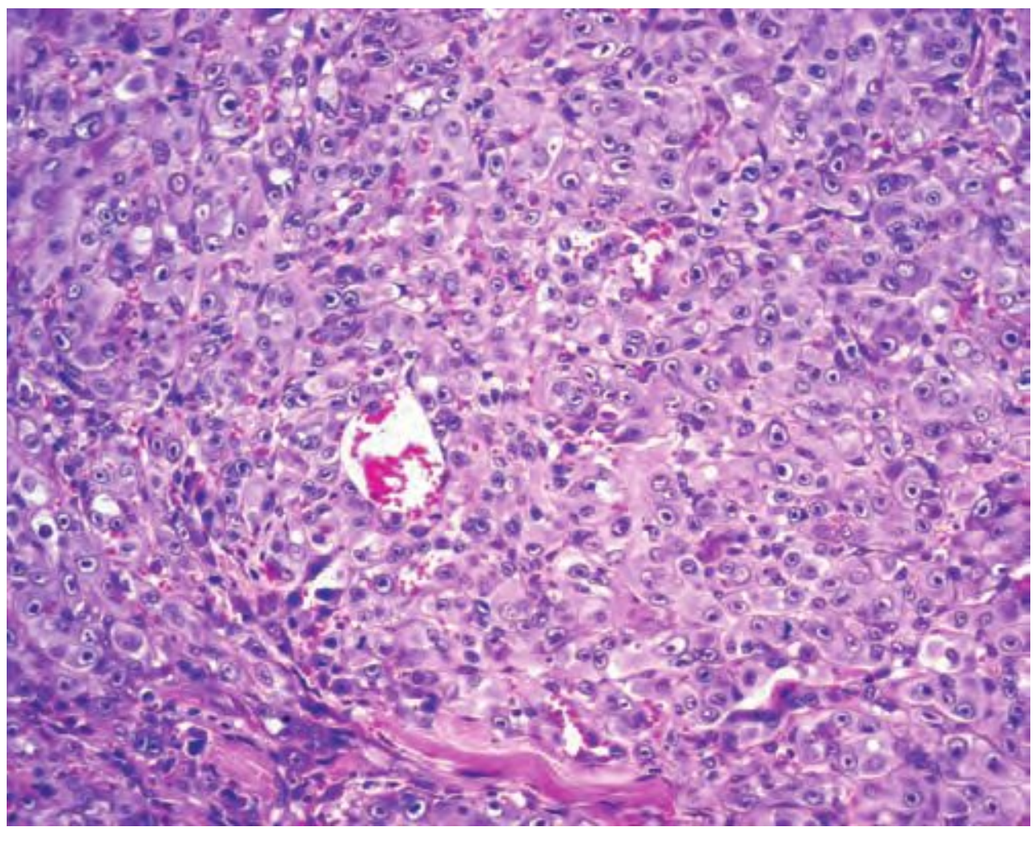

FIGURE 33-83. Epithelioid angiosarcoma. Large epithelioid cells with abundant pink cytoplasm, vesicular nuclei, and a single prominent eosinophilic nucleolus. Note the resemblance to melanoma cells and the hemorrhage in the background.

They can be classified into four types: (a) cavernous lymphangioma, (b) cystic hygroma, (c) lymphangioma circumscriptum (293), and (d) acquired progressive lymphangioma or benign lymphangioendothelioma (294–296). In addition, lesions of lymphangiectasia, which are indistinguishable from classic lymphangioma circumscriptum, may occur, although rarely, in association with congenital or acquired lymphedema (297). Although traditionally cavernous lymphangioma and cystic hygroma have been considered independent entities, it is likely that the latter is an ectatic variant of the former, which arises in areas of loose connective tissue; therefore, they will be discussed under the same heading (298). The existence of capillary lymphangioma is doubtful and will not be considered further.

Histogenesis. The great majority of tumors of lymphatic vessels are benign, and most of them appear to represent developmental abnormalities rather than true neoplasms. Although in hemangiomas the endothelial cells stain positively for factor VIII–related antigen, the endothelial cells in lymphangiomas are for the most part negative for this marker (299). The presence of fragmented basal lamina and anchoring filaments in hemangiomas is a more reliable ultrastructural feature to use to distinguish lymphatics and blood vessels. However, distinction between angiomas and lymphangiomas is not always clear even when light microscopy is combined with immunohistochemistry and electron microscopy (300).

Cavernous Lymphangioma and Cystic Hygroma

Cavernous lymphangioma usually presents at birth or during the first 2 years of life with an equal gender incidence (301,302). The most common locations are the head and neck area (particularly the oral cavity) and, less often, the extremities. It presents as a large, diffuse, subcutaneous, often fluctuant soft mass. Recurrences are common after limited excision.

Cystic hygroma has a similar age and gender distribution, and lesions tend to affect the neck, axillae, and groin (301). Tumors tend to be better circumscribed than cavernous lymphangiomas, but there is also a tendency for local recurrence unless a wide excision is performed. Cystic hygroma of the neck is commonly associated with Turner's syndrome (301,303).

Histopathology. Cavernous lymphangioma shows large, irregularly shaped spaces in the dermis and subcutaneous tissue lined by a single layer of bland endothelial cells (Fig. 33-84). The surrounding stroma can be loose or fibrotic and shows a lymphocytic inflammatory cell infiltrate with scattered lymphoid follicles. An incomplete layer of smooth muscle can be seen in the walls of some vessels. The vascular lumina show pink proteinaceous fluid with lymphocytes, but erythrocytes can also be seen. Large cavernous lymphangiomas, particularly in areas of the lip or tongue, may extend between the muscle bundles, separating them from one another (293).

In cystic hygroma, microscopic features are similar to those of cavernous lymphangioma except for the presence of numerous cystically dilated thin-walled lymphatic spaces.

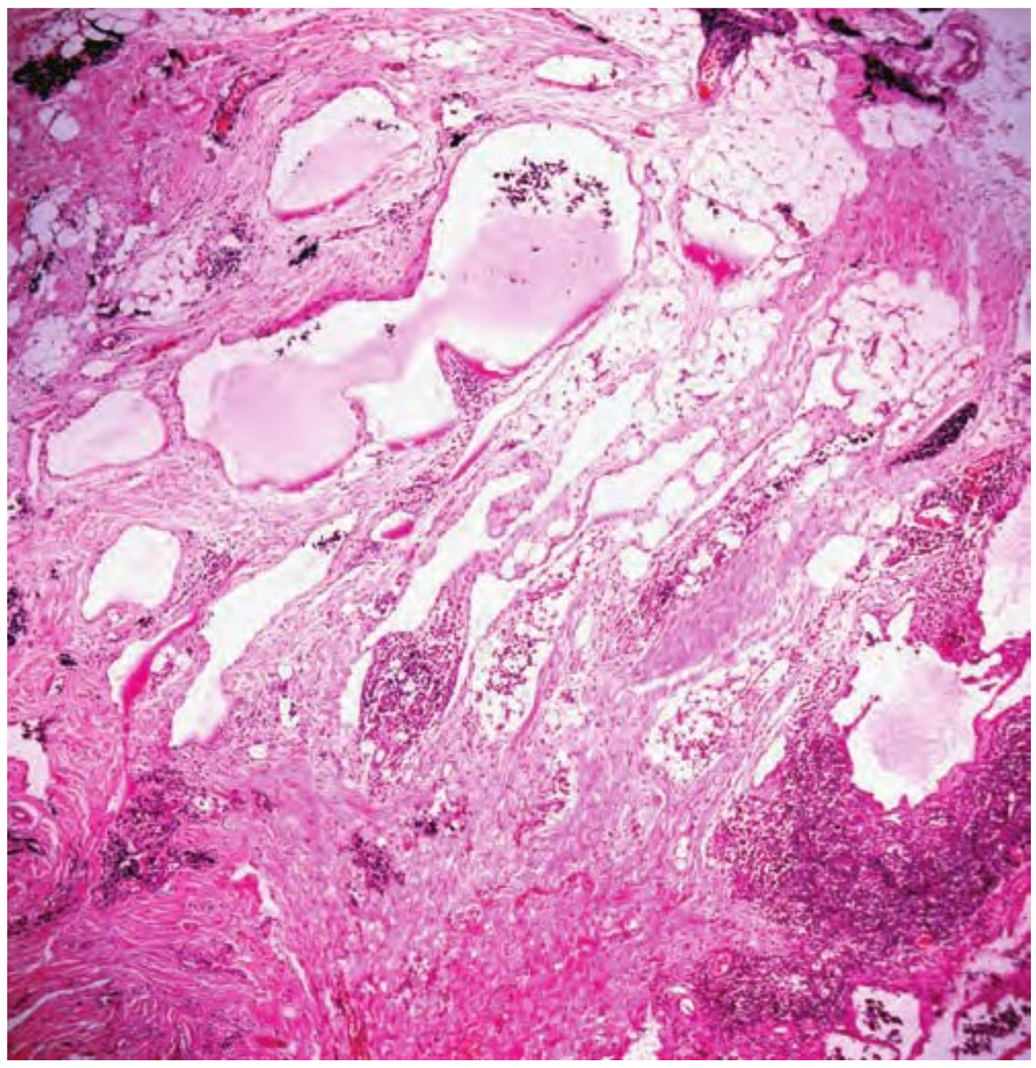

FIGURE 33-84. Cavernous lymphangioma. Dilated lymphatic channels and aggregates of lymphocytes in the stroma.

Differential Diagnosis. Distinction from cavernous hemangioma can be impossible, since the vascular channels in both conditions can show red blood cells in their lumina. The presence of lymphoid aggregates in the stroma tends to favor the diagnosis of lymphangioma.

Lymphangioma Circumscriptum

Lymphangioma circumscriptum is predominantly a developmental malformation of infancy with an equal gender incidence, but it may arise at any age (294,304). Similar acquired lesions arising in adults in relation to chronic lymphedema or radiotherapy are best regarded as *lymphangiectasia* (298). The anatomic distribution is wide, but the proximal portions of the limbs and limb girdle are most frequently affected. Association with cavernous lymphangioma, cystic hygroma, and even lymphangiomatosis is common. A typical lesion consists of collections of numerous papules with vesicle-like lesions containing clear fluid and, less commonly, blood (Fig. 33-85). Due to the presence of a deep component (see text following), lesions arising in infancy tend to recur after simple excision.

Histopathology. Lymphangioma circumscriptum is composed of numerous dilated lymphatics in the superficial and papillary dermis (Fig. 33-86). There is clear fluid and, less frequently, red blood cells in their lumina. In the overlying epidermis, there is some degree of acanthosis and hyperkeratosis. The surrounding stroma shows scattered lymphocytes. Lesions developing in infancy often show a large-caliber, muscular lymphatic space in the subcutaneous tissue, which

FIGURE 33-85. Lymphangioma circumscriptum. Localized, plaque-like lesion with multiple slightly warty papules.

has to be ligated at the time of excision to avoid recurrence (Fig. 33-87).

Progressive Lymphangioma (Benign Lymphangioendothelioma)

Progressive lymphangioma (benign lymphangioendothelioma) is a benign rare tumor that has a tendency to present in middle-aged to elderly adults and evolve slowly over years. Males and females are equally affected, and although the anatomic distribution is wide, there is preferential involvement of the limbs (295–297). Clinically, a typical lesion is a solitary well-circumscribed erythematous macule or plaque. Recurrence after simple excision is exceptional, and occasional lesions can show focal or complete spontaneous regression (305). A case has been described after femoral arteriography (306).

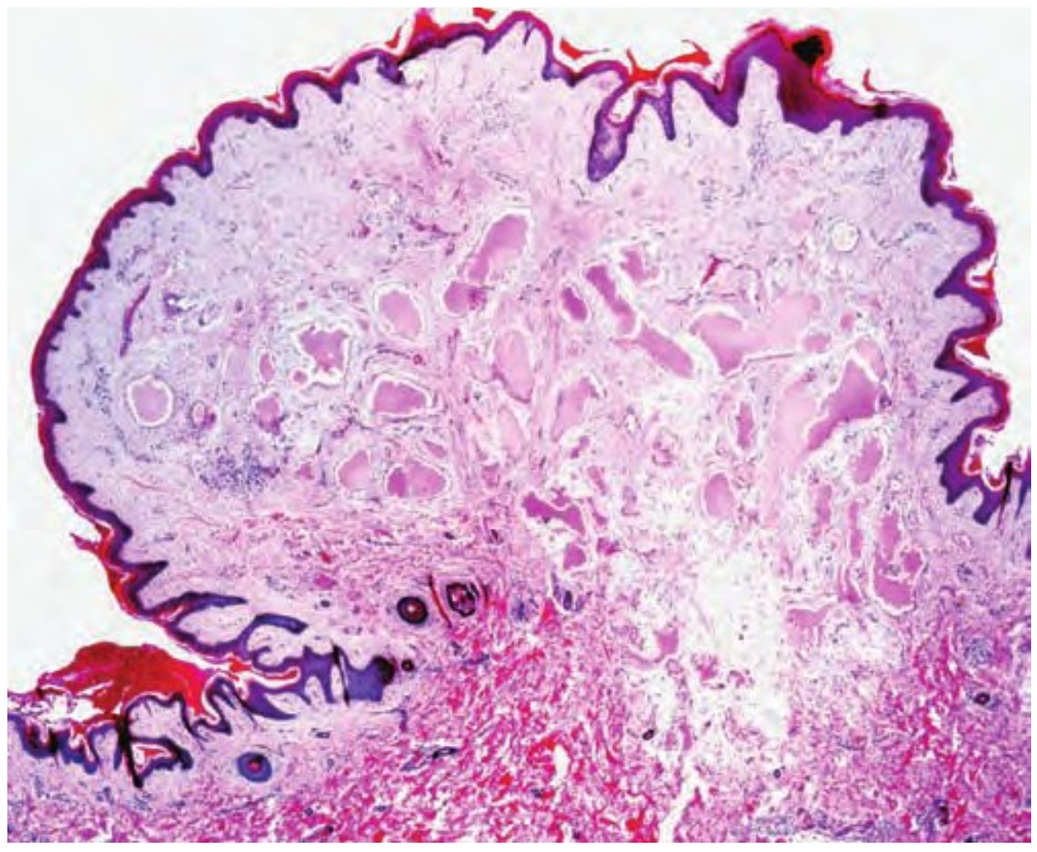

FIGURE 33-86. Lymphangioma circumscriptum. Numerous dilated lymphatic channels expand the papillary dermis.

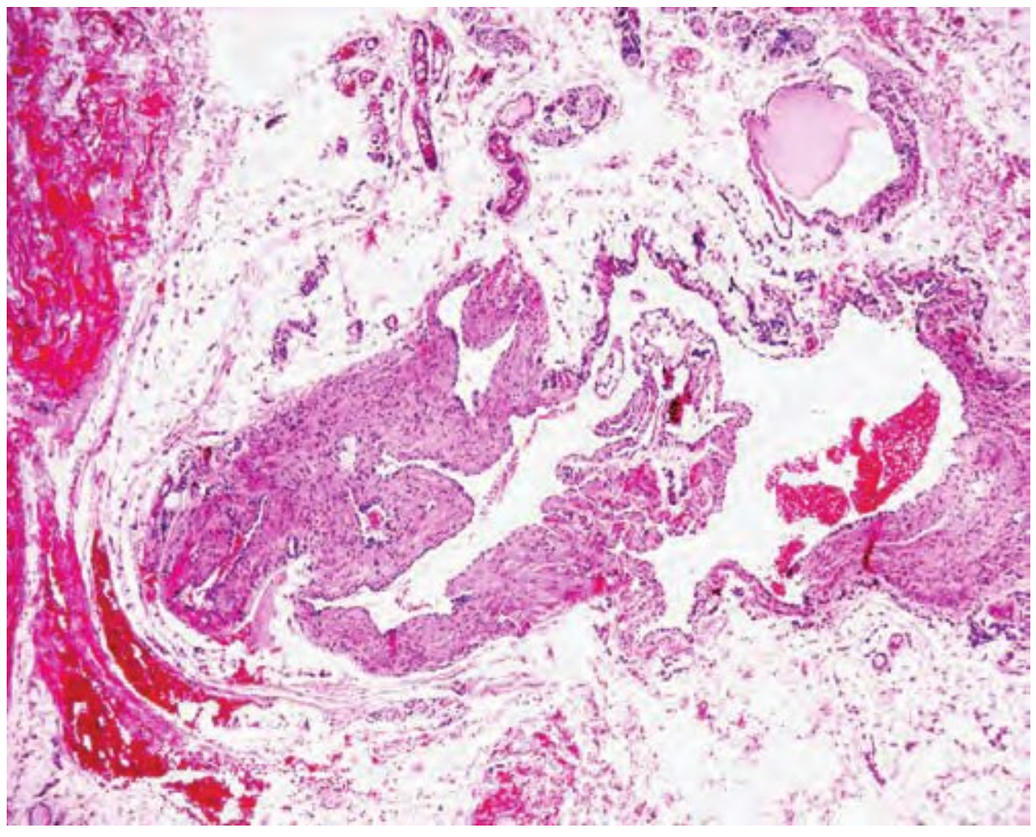

FIGURE 33-87. Lymphangioma circumscriptum. Deep muscular lymphatic. If this vessel is not ligated, the lesion will recur.

Histopathology. Most lesions predominantly involve the superficial dermis, but extension into the dermis and subcutis can be present (295,297). Irregular, horizontal, thin-walled vascular channels lined by a single layer of bland endothelial cells are seen dissecting collagen bundles (Fig. 33-88). Endothelial cell atypia and mitotic figures are absent. The vascular channels appear empty or have scanty proteinaceous material and/or a few red blood cells.

Differential Diagnosis. The main differential diagnosis is with well-differentiated angiosarcoma and patch-stage Kaposi's sarcoma. Although sharing with angiosarcoma the presence of extensive dissection of collagen bundles, the latter conditions occur in completely different settings, and in angiosarcoma, there is usually, at least focally, cytologic atypia and mitotic figures. Patch-stage Kaposi's sarcoma often presents clinically with multiple lesions, and histologically, the abnormal blood vessels tend to cluster around normal preexisting blood vessels. There is hemosiderin deposition with an inflammatory cell infiltrate with lymphocytes and plasma cells.

Lymphangiomatosis

Lymphangiomatosis is a rare developmental abnormality that affects children with an equal gender incidence. Although most cases appear to be congenital, the disease is often not diagnosed until childhood. The majority of cases involve soft tissues, skin, bone, and parenchymal organs. When vital organs are affected, the prognosis is very poor (307,308). Cases with involvement limited to skin and soft tissues of a limb (with or without bone involvement) have been described and are associated with a better prognosis (308). Rare cases can present in association with kaposiform hemangioendothelioma of

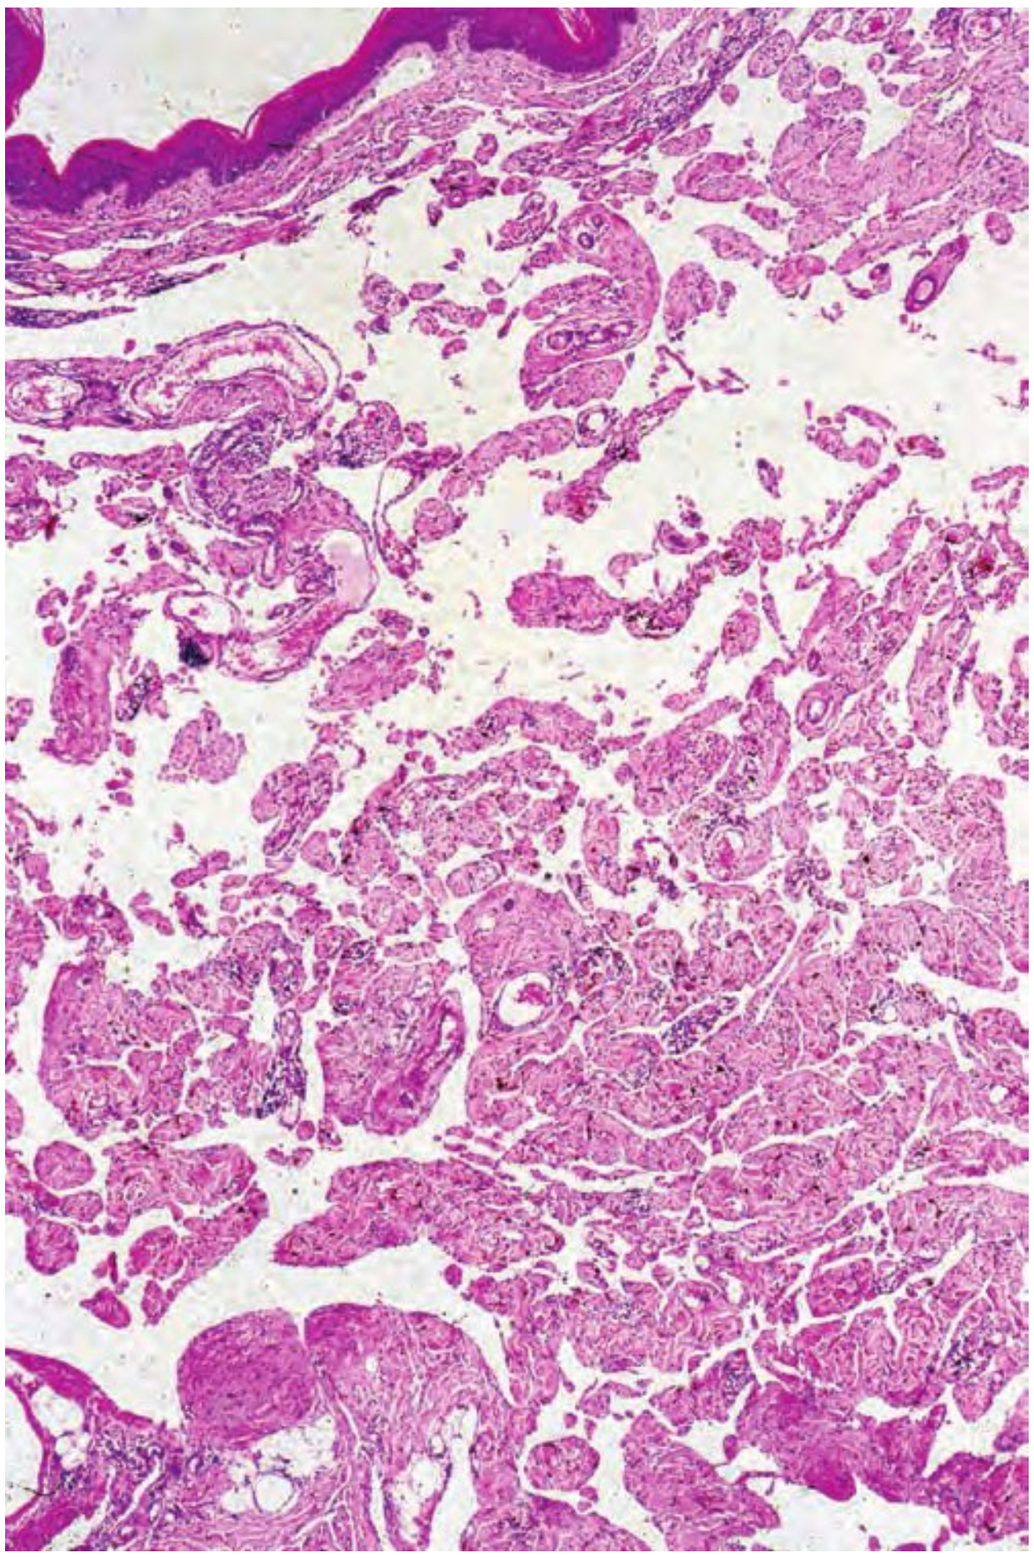

FIGURE 33-88. Progressive lymphangioma. Extensive dissection of collagen bundles by irregular vascular channels lined by bland, flat endothelial cells.

infancy and childhood. Lymphangiomatosis is the lymphatic counterpart of angiomatosis. In some instances, distinction between them can be difficult, although lymphangiographic studies can be very helpful in establishing the difference.

Histopathology. The appearance of lymphangiomatosis is very similar to that of progressive lymphangioma, but the changes in lymphangiomatosis are more extensive and diffuse with involvement of deeper soft tissues, fibrosis in long-standing cases, and stromal hemosiderin deposition.

Atypical Vascular Proliferation After Radiotherapy

Lesions related to atypical vascular proliferation usually develop a few months or years after radiotherapy for breast cancer, but they may also appear in irradiated skin after treatment for ovarian and endometrial carcinoma (309–313). The clinical presentation is not distinctive and varies from skin-colored to red macules and papules. Occasional cases may mimic

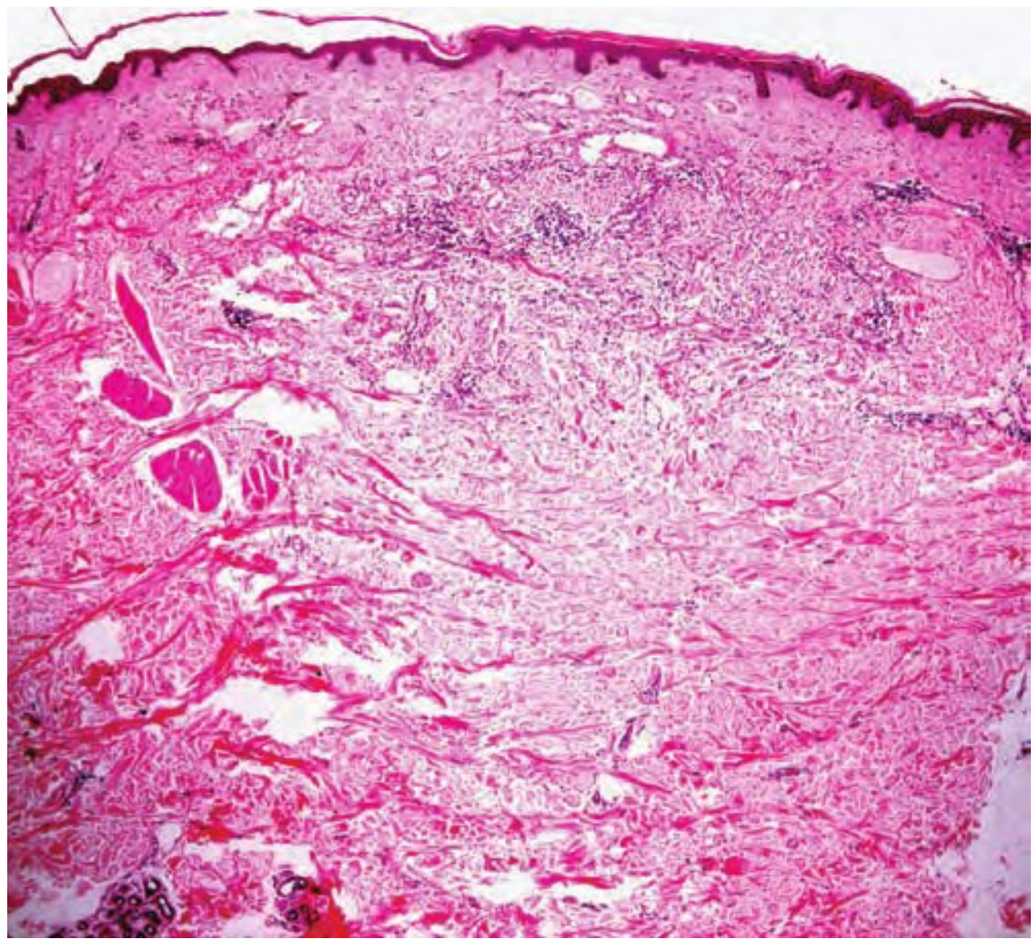

FIGURE 33-89. Atypical vascular proliferation after radiotherapy. Fairly localized superficial dermal vascular proliferation.

lymphangioma circumscriptum. The behavior appears to be benign, with occasional local recurrences. However, it has been suggested that there is a spectrum between these proliferations and postradiation angiosarcoma (312,313). This contention has been challenged by a recent study from the French Sarcoma Group, but unfortunately, the follow-up in their reported cases is limited (314). In view of the controversy and also due to the fact that histologic diagnosis may be difficult, these lesions should therefore be treated with complete excision, and patients should be followed-up closely.

Histopathology. Irregular lymphatic-like vascular channels lined by a single layer of endothelial cells are present focally in the superficial and/or deep dermis. An infiltrative growth pattern is lacking, and lesions are usually fairly circumscribed (Fig. 33-89). The cells lining the channels often have a hobnail appearance, and papillary projections may occasionally be seen. There is no cytologic atypia, multilayering, or mitotic figures (Fig. 33-90). Interestingly, dermal changes secondary to radiotherapy are not usually seen.

Differential Diagnosis. The differential diagnosis includes a well-differentiated angiosarcoma, hobnail hemangioma, and Kaposi's sarcoma. As opposed to hobnail hemangioma, the lesion is not symmetrical, and the vascular channels do not have a predominant superficial dermal location. The clinical setting, the absence of inflammation, and the presence of hobnail endothelial cells with focal papillary projections should allow distinction from Kaposi's sarcoma. Careful examination of multiple sections is recommended to make sure that there are no mitotic figures and cytologic atypia to distinguish it from a well-differentiated angiosarcoma. This distinction can be very difficult, especially in small biopsies.

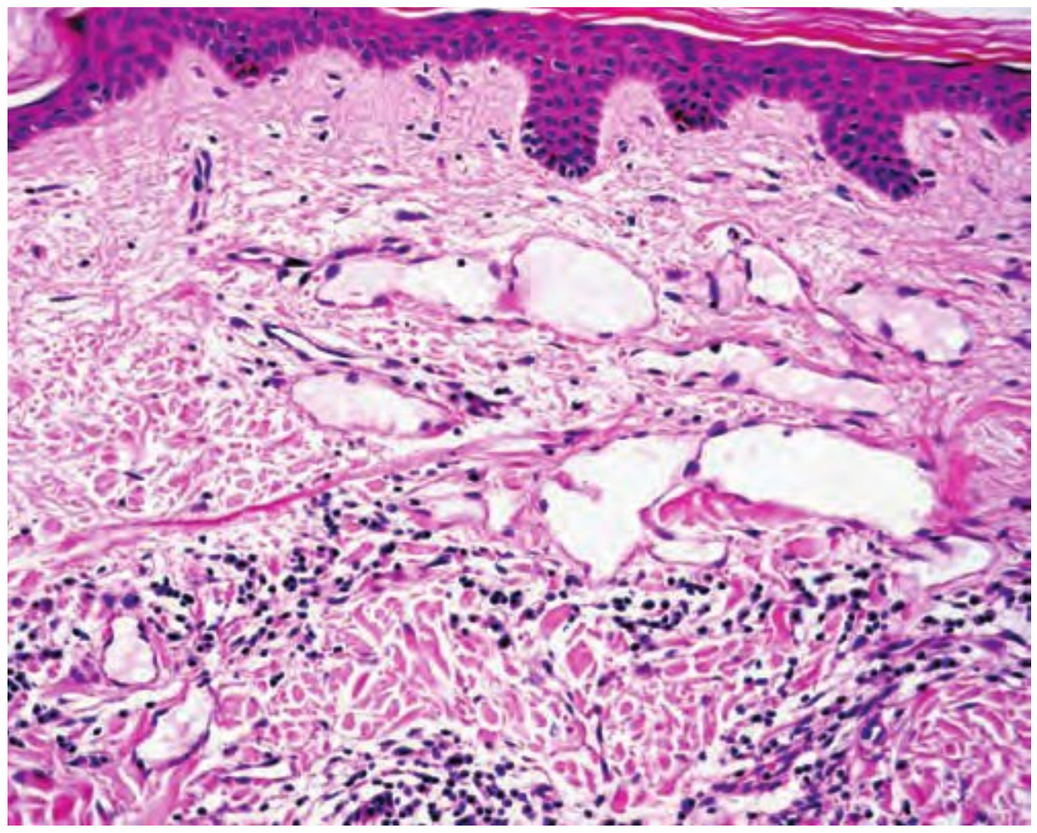

FIGURE 33-90. Atypical vascular proliferation after radiotherapy. Irregular vascular channels lined by slightly hyperchromatic endothelial cells, some of which have a hobnail appearance.

FIGURE 33-91. Glomangiomas. Multiple bluish dermal lesions.

TUMORS OF PERIVASCULAR CELLS

Glomus Tumor

Glomus tumors are relatively rare lesions that usually present in young adults between the third and fourth decade of life with no gender predilection except for subungual tumors, which have a marked female predilection (315). The hand (particularly subungual region and palm) is the most commonly affected site, followed by the foot and forearm. Lesions, however, can occur with a wide anatomic distribution, not only on the skin but also rarely in mucosa and internal organs. The latter include the stomach (316), lung (317), trachea (318), bone (319), small bowel (320), pterygoid fossa (321), and mediastinum (322). Most tumors classically present as solitary, small (<1 cm), blue-red nodules that are characteristically associated with paroxysmal pain often elicited by changes in temperature (especially cold) or pressure. Subungual glomus tumors have been associated with neurofibromatosis type I (323–325).

A very small proportion of glomus tumors are multiple (in up to 10% of patients) (Fig. 33-91). As opposed to solitary glomus tumors, the latter usually arise in children, tend to be asymptomatic, are rarely subungual, and are thought to be inherited in an autosomal dominant fashion (326). The gene for multiple inhereted glomangiomas (also known as *glomuvenus malformations*) has been linked to chromosome 1p21-22 (327–330). Clinically, multiple glomangiomas can be confused with lesions of the blue rubber bleb nevus syndrome, and it is likely that cases of this condition reported in the past represented examples of multiple glomangiomas or glomangiomyomas. They can also be confused with venous malformations (331). Histologically, multiple glomus tumors are predominantly glomangiomas (see text following).

The glomus coccygeum is a prominent glomus body measuring up to several millimeters and located near the tip of the coccyx. Awareness of its existence is important, because when found incidentally in biopsies, it may be confused with a neoplasm (332).

Local recurrence is uncommon and when seen is usually in deep-seated tumors with an infiltrative growth pattern (so-called infiltrating glomus tumor; see text following) (333). Glomangiomatosis is defined as lesions with clinical features of angiomatosis displaying histologic evidence of glomus cells around the vascular channels (334). Exceptionally, glomus tumors originate within a blood vessel (335,336) or nerve (337). Malignant glomus tumor or glomangiosarcoma is very rare and usually arises in deep soft tissues. It comprises around 1% of all glomus tumors (338). Glomangiosarcoma appears to be an aggressive tumor with a metastasis rate of 40% (338). Exceptionally, a glomangiosarcoma arising in an internal organ may present with metastases to the skin (339).

Histopathology. Glomus tumors show varying proportions of glomus cells, blood vessels, and smooth muscle and are classified accordingly into *solid glomus tumor* (25% of cases), *glomangioma* (60% of cases), and *glomangiomyoma* (15% of cases). Most cases of glomus tumor are well circumscribed, and a classic solid lesion (Fig. 33-92) is composed of sheets of uniform cells with pale or eosinophilic cytoplasm, well-defined cell margins (highlighted distinctively by PAS stain), and round or ovoid punched-out central nuclei (Fig. 33-93). Small blood vessels are uniformly distributed in the tumor but may not be apparent without the use of special stains. The stroma is

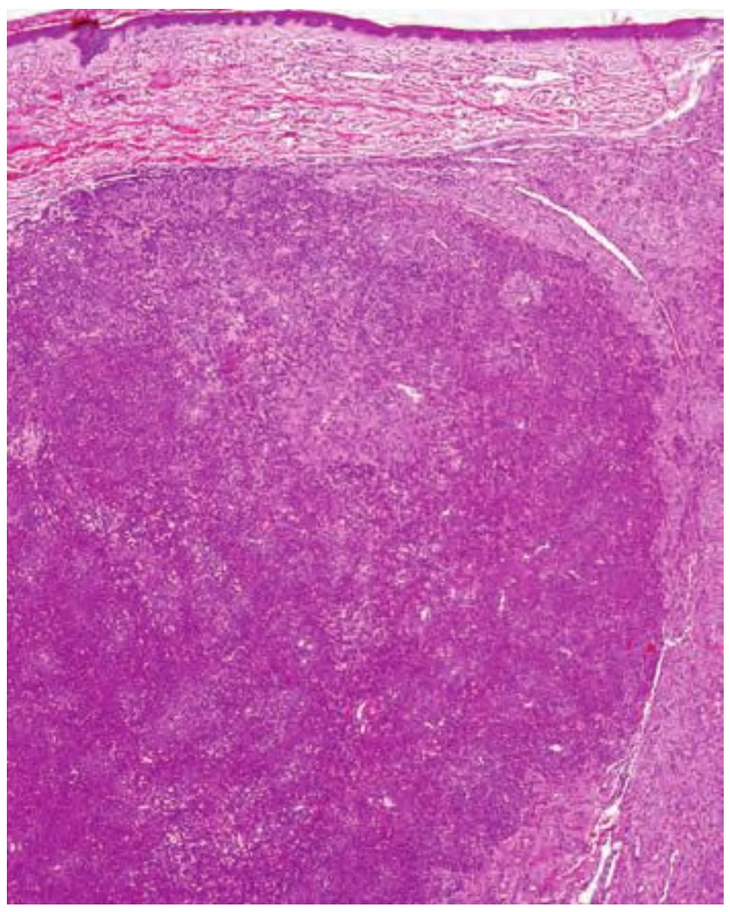

FIGURE 33-92. Solid glomus tumor. Well-circumscribed dermal nodule with only tiny vascular channels in the background.

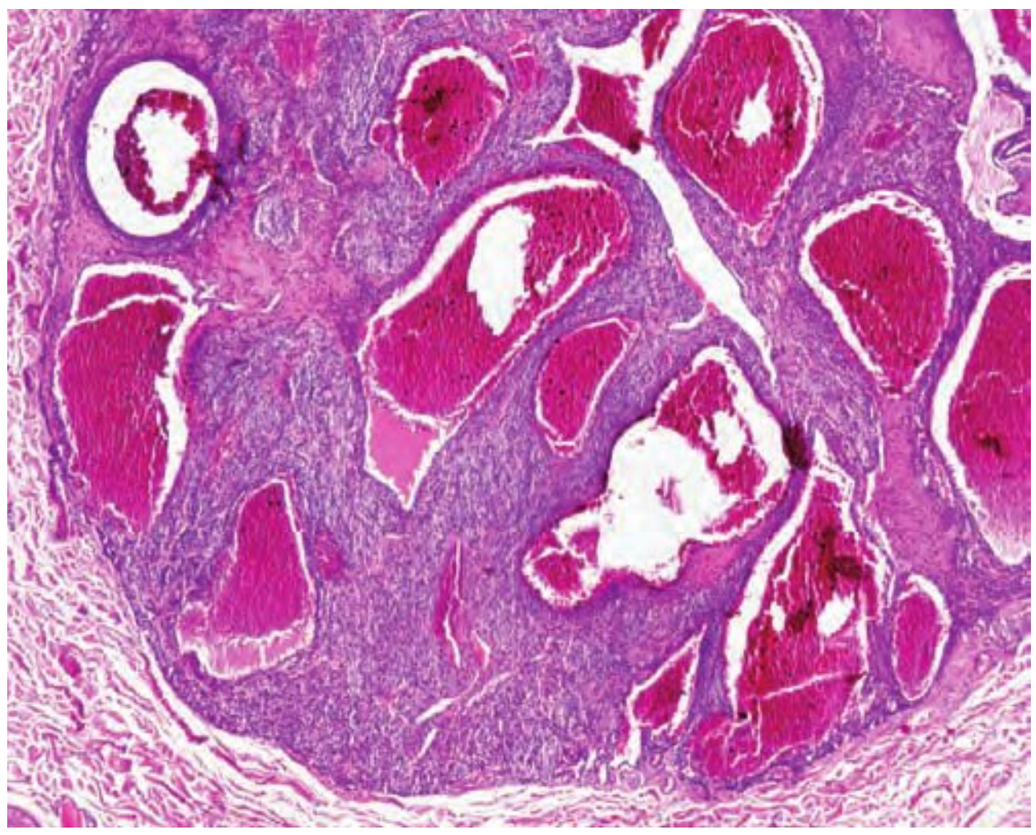

FIGURE 33-94. Glomangioma. Cavernous vascular spaces surrounded by layers of glomus cells.

often edematous, and extensive myxoid change may be present. Normal mitotic figures may be conspicuous in some cases, but cytologic atypia is usually absent. Numerous stromal nerve fibers may be highlighted with special stains. Exceptional cases show extensive oncocytic change (340). Tumor cells with epithelioid morphology have also been described (341). In glomangioma, there are numerous dilated, cavernous-like, thin-walled vascular spaces surrounded by one or a few layers of glomus cells (Fig. 33-94). In glomangiomyoma, there is an important number of spindle-shaped smooth muscle cells, which tend to be distributed near the vascular spaces and blend with the adjacent collections of glomus cells (Fig. 33-95).

Infiltrating glomus tumor is a very rare variant that occurs in deep soft tissues and is characterized by solid nests of glomus cells with an infiltrative growth pattern (333). It is associated with a high recurrence rate.

The histologic diagnosis of glomangiosarcoma is difficult because of the few cases reported in the literature (333,338). Only recently, criteria for the histologic diagnosis of glomangiosarcoma have been delineated and include (338) (a) size >2 cm and subfascial or visceral location, (b) atypical mitotic figures, or (c) moderate to marked nuclear atypia and five or more mitotic figures per 50 high-power fields. A preexisting benign component is common but not invariably present.

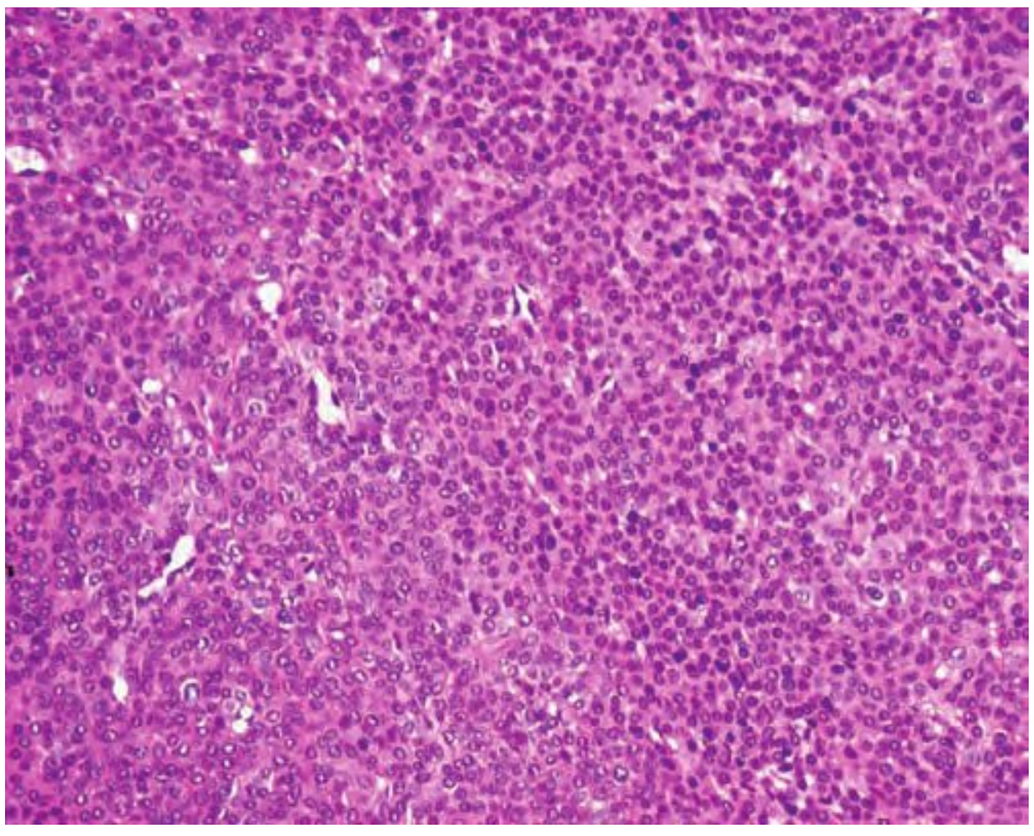

FIGURE 33-93. Solid glomus tumor. Monomorphic round cells with eosinophilic cytoplasm and central punched-out nuclei.

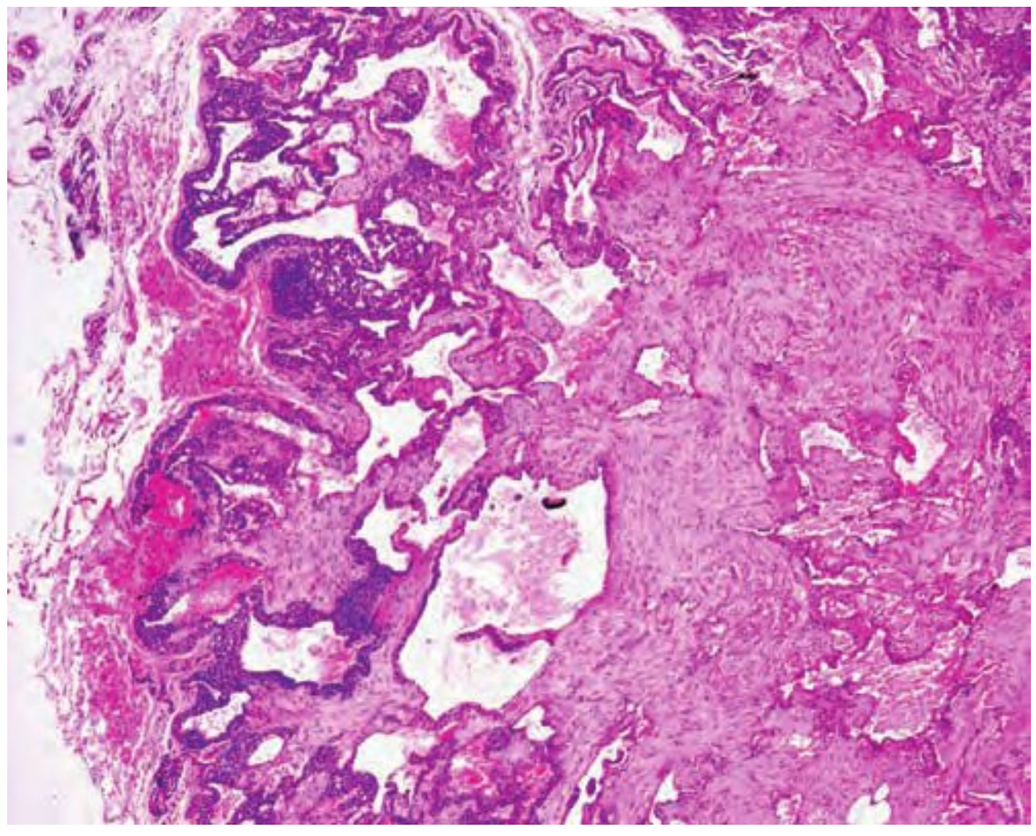

FIGURE 33-95. Glomangiomyoma. Spindle-shaped cells with pink cytoplasm combined with glomus cells.

Tumors arising *de novo* have architectural features resembling a glomus but consist of cells with prominent atypia. In such cases, the diagnosis should be confirmed by positive immunohistochemical stain for smooth muscle actin and for collagen type IV (in a pericellular distribution) (338). Tumors with focal cytologic atypia but no evidence of other features suggestive of malignancy are classified as symplastic glomus tumors. Glomus tumors of uncertain malignant potential are regarded as those that do not fulfill the criteria for the diagnostics of malignant glomus tumor or symplastic glomus tumor but have frequent mitotic activity and superficial location only, deep location only, or large size only.

Histogenesis. Glomus tumors closely resemble the modified smooth muscle cells of a segment of a specialized arteriovenous anastomoses (Sucquet-Hoyer canal) that is involved in the regulation of temperature, the *glomus body*. Glomus bodies are usually found in acral skin, particularly on the hands. However, many glomus tumors arise from sites where glomus bodies are not known to exist. In view of this, it is likely that some glomus tumors arise from differentiation of pluripotential mesenchymal cells or ordinary smooth muscle cells. On immunohistochemical examination, glomus tumor cells stain for smooth muscle actin, H-caldesmon, muscle-specific actin, and myosin (342,343). Staining for collagen type IV shows prominent pericellular positivity. Staining for desmin is only occasionally focally positive. CD34 may also be positive in glomus tumors (344).

Differential Diagnosis. Solid glomus tumor can be distinguished from eccrine spiradenoma by the presence in the latter of two populations of cells, focal ductal differentiation, and positivity for epithelial markers. Occasionally, intradermal nevus with pseudovascular spaces resembles a glomus tumor, but in the former, there is always evidence of nesting, maturation, and positivity of lesional cells for S-100 (345).

Multiple glomus tumors differ from lesions of the blue rubber bleb nevus by the presence of glomus cells in nearly all tumors. It is likely that some, if not all, previously reported cases of blue rubber bleb nevus have actually represented examples of multiple glomangiomas.

Myopericytoma

Traditionally, tumors thought to differentiate toward perivascular myoid cells or pericytes have been divided into two main categories: infantile hemangiopericytoma and adult hemangiopericytoma. Both variants, however, appear to have very little in common except for the histologic presence of a pericytomatous vascular pattern. Moreover, with the combination of immunohistochemistry and electron microscopy, most tumors classified as adult hemangiopericytoma on light microscopy show other lines of differentiation (346). These include synovial sarcoma, mesenchymal chondrosarcoma, solitary fibrous tumor, and deep benign fibrous histiocytoma. The few cases for which the line of differentiation remains obscure are the "true" adult hemangiopericytomas, but it is likely that they arise from an undifferentiated mesenchymal cell. These rare examples of "true" adult hemangiopericytomas do not usually occur in the skin and will not be discussed further in this chapter.

In recent years, the concept of myopericytoma has been introduced to describe a spectrum of tumors composed of short, oval- to spindle-shaped cells with a myoid appearance and a distinctive concentric perivascular growth (347). These tumors tend to occur mainly in the deep dermis and subcutaneous tissue and include lesions classified in the past as glomangiopericytoma, myopericytoma, myofibroma, and myofibromatosis in adults. Infantile hemangiopericytoma and infantile myofibromatosis represent identical entities, and the only term used now to denote the entity is the latter (347–349).

Infantile myofibroma/myofibromatosis usually presents at birth or in the first years of life as single or multiple dermal or subcutaneous nodules. Local recurrence is common, and distant spread has been described, but it is likely that spread represents multicentricity rather than true metastasis (350,351).

Myopericytoma most commonly occurs in middle-aged adults with a predilection for the limbs, especially the distal lower limb. Lesions are small (<2 cm in diameter), long-standing, usually asymptomatic, and may be single or, less frequently, multiple. Tumors rarely are painful. In the setting of multiple myopericytomas, these often develop simultaneously with a predilection for a single anatomic site. Recurrence is rare and frequently represents either persistence or the development of a new tumor. Very rare malignant examples of myopericytoma have been described (352).

Histopathology. Infantile myofibroma/myofibromatosis lesions are multinodular and show, at least focally, a biphasic growth pattern (Fig. 33-96). Hemangiopericytomatous areas composed of small, round hyperchromatic cells blend with areas composed of bundles and nodules of more mature spindle-shaped cells with eosinophilic cytoplasm resembling myofibroblasts

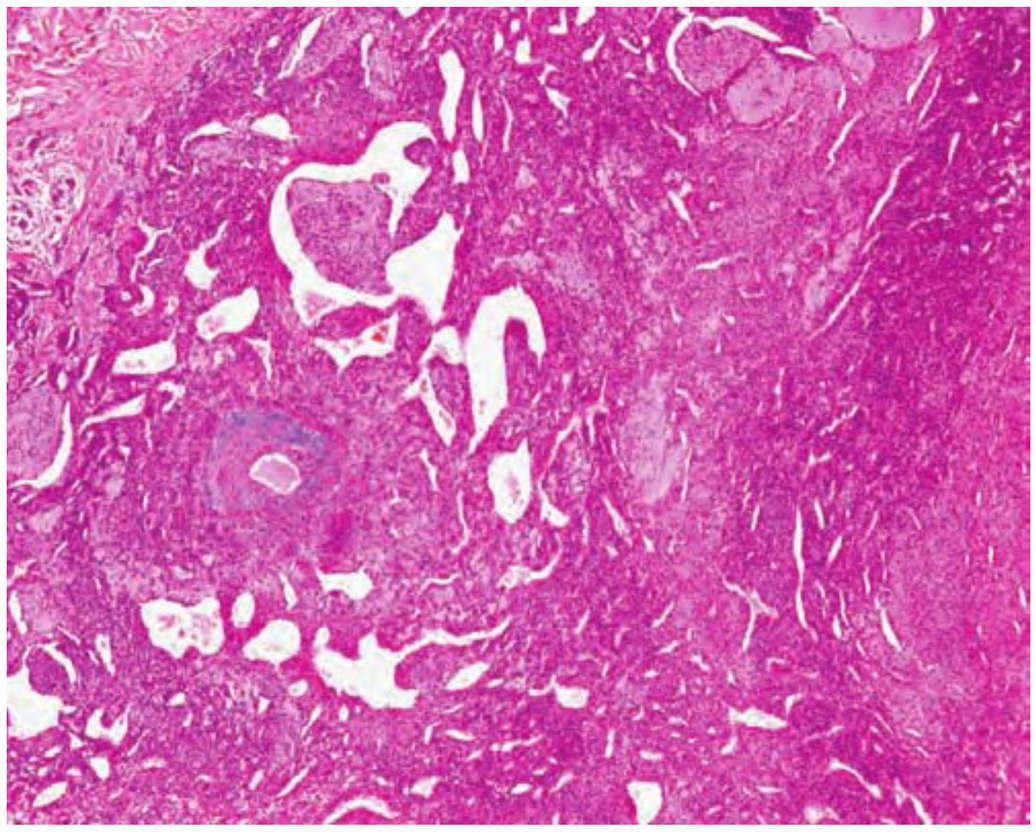

FIGURE 33-96. Infantile myofibroma. Biphasic tumor with numerous branching blood vessels.

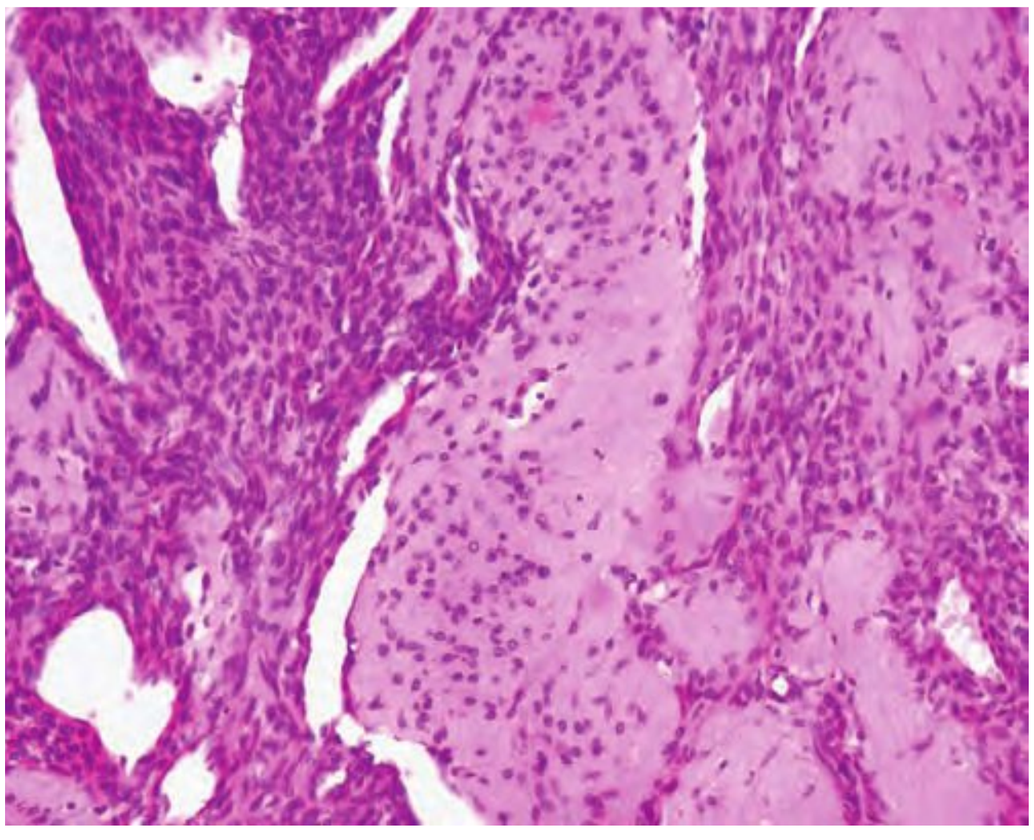

FIGURE 33-97. Infantile myofibroma. Typical biphasic pattern showing immature round cells with scanty cytoplasm (left) alternating with bundles of spindle cells with a myofibroblastic appearance (right).

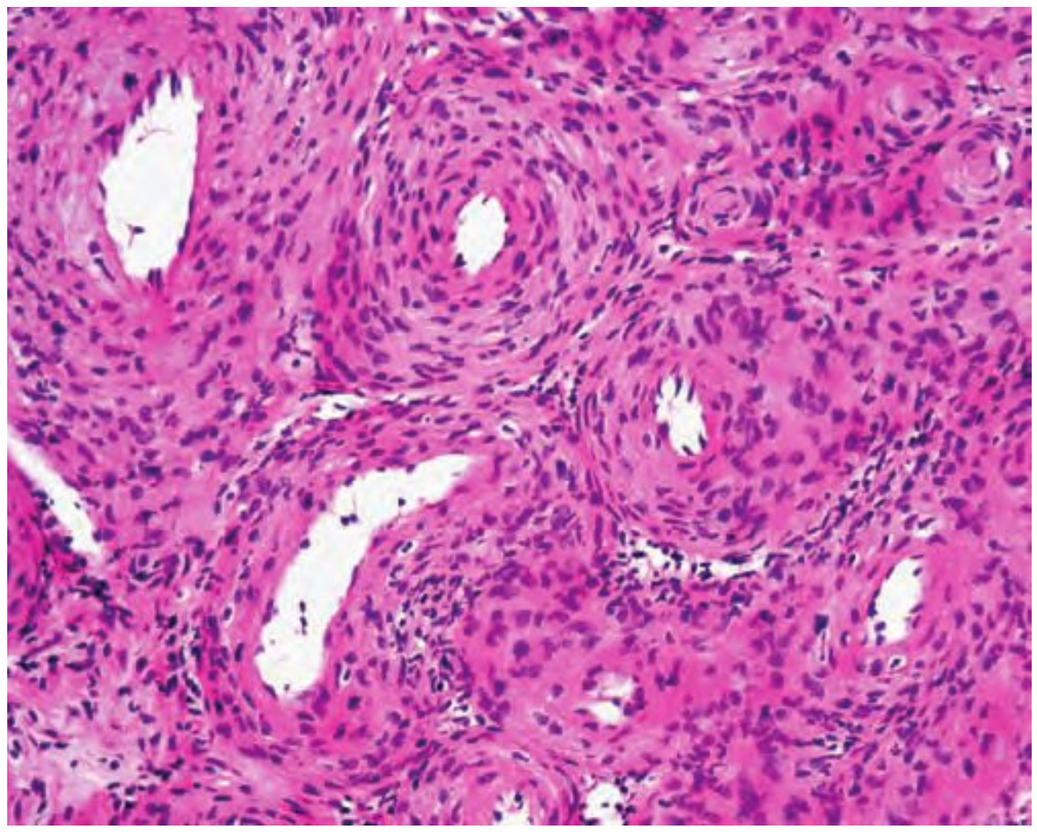

FIGURE 33-99. Myopericytoma. Bland spindle-shaped pericytes arranged in a concentric manner.

(Fig. 33-97). This zoning phenomenon is identical to, although less pronounced than, that seen in infantile myofibromatosis (see Chapter 32, page 984). Mitosis, necrosis, and vascular invasion are common features.

In infantile hemangiopericytoma, the darker, less mature cells in the pericytomatous areas usually do not stain for any markers, whereas the more mature spindle-shaped cells resembling myofibroblasts stain for alpha-smooth muscle actin. Identical features are seen in infantile myofibromatosis, and it is believed that the two entities are part of the same spectrum.

The histologic spectrum of myopericytoma is very wide and varies from lesions that are very similar to myofibromatosis to tumors that closely resemble glomus tumors and even an angioleiomyoma. Tumors are well circumscribed and composed of a mixture of solid cellular areas intermixed with variable numbers of vascular channels (Fig. 33-98). The latter are often elongated and display prominent branching resulting in a stag-horn appearance (hemangiopericytoma like). The cells in the solid areas are round or short and spindle shaped with eosinophilic or amphophilic cytoplasm and vesicular nuclei. Cytologic atypia is not usually a feature, and mitotic figures are very rare. A common and striking feature is the presence of concentric layers of tumor cells around vascular channels resulting in a typical onion ring appearance (Fig. 33-99). Myxoid change may be focally

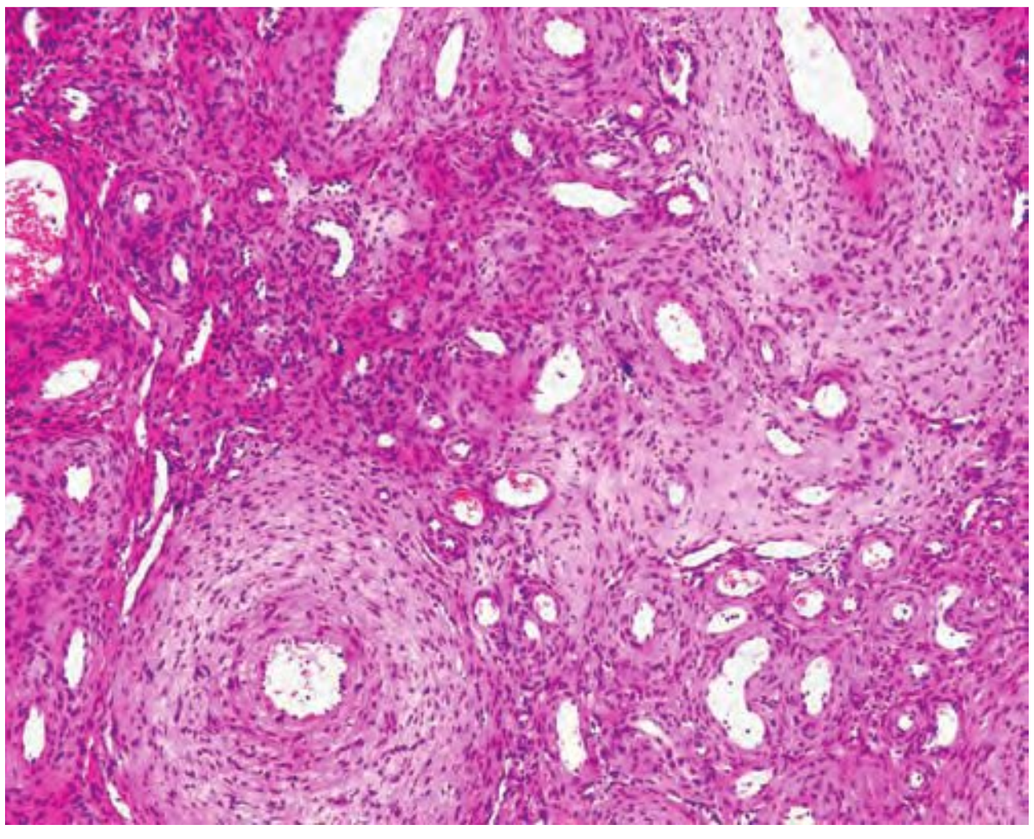

FIGURE 33-98. Myopericytoma. Biphasic pattern and prominent whirling of tumor cells around blood vessels.

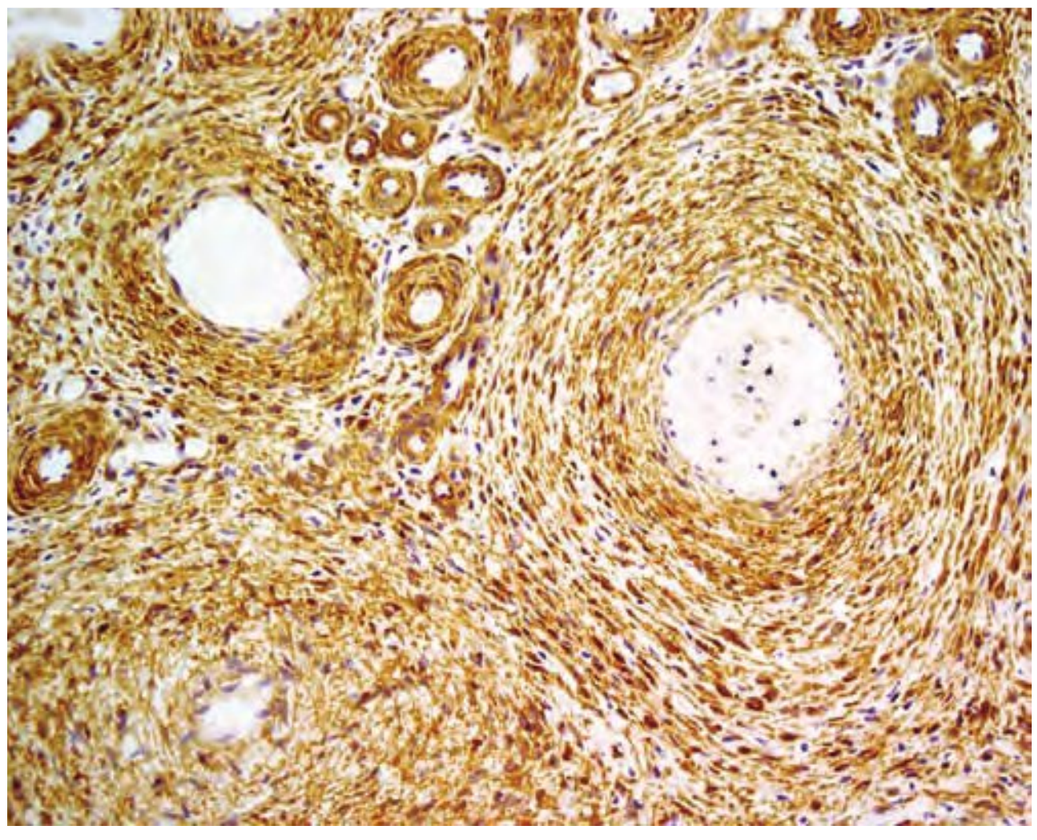

FIGURE 33-100. Myopericytoma. Diffuse staining of tumor cells with alpha-smooth muscle actin by the ABC method.

prominent. Occasional findings include hyalinization, cystic degeneration, and bone formation. Nodules of tumor cells may protrude into the lumina of vascular channels. Rare examples are entirely intravascular (353). In some cases, tumor cells closely resemble glomus cells and are characterized by round punched-out central nuclei and pale eosinophilic cytoplasm. These cases are referred to as *glomangiopericytomas*.

Glomangiopericytoma cells stain diffusely for smooth muscle actin (Fig. 33-100) and are only very rarely focally positive for desmin. Focal staining for CD34 may also be seen.

Differential Diagnosis. Some authors regard angioleiomyoma as part of the spectrum of myopericytoma. Angioleiomyoma, however, is composed of uniform smooth muscle cells, which stain diffusely for both smooth muscle actin and desmin. Furthermore, concentric arrangement of tumor cells around vascular channels is not present.

CHAPTER 34

Bruce D. Ragsdale

Tumors With Fatty, Muscular, Osseous, and/or Cartilaginous Differentiation

INTRODUCTION

Dermatoradiology

It is axiomatic in dermatopathology that correlation of histopathology with the clinical configuration of skin lesions is the surest route to an accurate and therapeutically relevant diagnosis. However, lesions covered in this chapter often appear merely as dome-shaped elevations of otherwise normal skin. For these, the best "clinical photo" is a radiologic study. These will depict location that bears on origin and adjacent structures at risk, size, character of margins that predicts biologic potential and the necessary extent of surgery, and the presence or absence of mineralization to judge adequacy of the biopsy. Magnetic resonance imaging (MRI) predicts composition (fat vs. other soft tissue +/– cystic change and necrosis). There are many syndromes with simultaneous skin and bone expression. Correlation with available films can avoid misdiagnosis. Radiology contributes to dermatopathology in these and other ways (Table 34-1).

Differentiation

In tumors, clonality does not always translate into morphologic uniformity. While most sarcomas exhibit only one line of histologic differentiation, a minority may display a strikingly diverse phenotype in addition to the main lineage. This phenomenon not only presents a diagnostic problem but also raises questions about the commitment of tumor cells toward a specific phenotype. Diagnostically, it is crucial to recognize the "primary" sarcoma in such tumors correctly and distinguish it from the "secondary" divergent elements. Even though it may be difficult to explain the pathogenesis of divergent differentiation, divergence still illustrates that the phenotype of a tumor cell is not set in stone but can be modulated or switched by a number of factors (1), particularly body location and character of the vascular supply.

Modifiers

The usual bewildering array of uniquely pathologic adjectives are applied to the tumors discussed in this chapter, such as myxoid, histiocytoid, epithelioid, angiomatoid, atypical, bizarre, pleomorphic, giant cell, pseudosarcomatous, dedifferentiated, plexiform, storiform, inflammatory, desmoplastic, round cell, clear cell, granular cell, lipomatous, and the like, and their use is a sure route to acceptance of a case report.

THE BASIC SCIENCE OF FAT RELEVANT TO LIPOCYTIC TUMORS

Adipose tissue can be divided into two types: brown and white. In adults, most fat is the white, univesicular variety. White fat serves as the depot for stored lipid, which is an efficient energy reserve, and protects against external trauma. Obesity, formerly a status symbol of wealth, is now known to be detrimental to health and associated with a wide variety of dermatologic conditions (2).

With hematoxylin and eosin (H&E) staining, only the cell membrane and possibly an eccentric nucleus with or without vacuoles or pseudoinclusions of cytoplasmic fat (*lochkern*, German for "hole in the nucleus") are seen. The red-brown to tan color of brown adipose tissue results from cytochrome pigment in the numerous mitochondria of its finely vacuolated cells. Brown fat has been considered an immature or fetal stage in the development of white fat, but most evidence now substantiates the unique identity of brown fat and its role in basal metabolism and nonshivering thermogesis. In humans, brown fat is more prevalent in the newborn period than later in life, but it persists throughout adulthood in the neck, axilla, and mediastinum, as well as elsewhere, embedded within the common white fat that, over time, tends to replace it.

Most investigators agree that perivascular cells resembling pericytes and fibroblasts play an important transition role in the development of benign and malignant lipoblasts. Both white and brown fat cells modulate (Fig. 34-1A) from these primitive fat organ precursors through multivesicular stages easily mistaken for histiocytes, to preadipocytes in which lipid inclusions coalesce and glycogen decreases, and finally to univacuolar adipocytes (3) (Fig. 34-1B) that are variably S-100 positive. The multivacuolar stage is observed in various tumors and is likely to reappear with involution following fat injury. In these settings, the cells with foamy cytoplasm are commonly mistaken for histiocytes—for example, the CD68-negative foam cells in the subcutis following biopsy. This is the source of much nosologic confusion, particularly with regard to some of the lesions termed *histiocytomas* (4).

TABLE 34-1 Utility of Radiologic Studies in Dermatopathology ("Dermatoradiology")

1. Serves as the "clinical photo" for subsurface lesions that are otherwise merely dome-shaped elevations.
   - Dermal, subcutaneous, and deeper lesions
2. To unequivocally demonstrate site of origin and extent.
   - Subungual exostosis versus fibro-osseous pseudotumor (myositis ossificans) versus osteochondroma in a digit
   - Calvarial osteoma versus mineralized/ossified subcutaneous cyst and others
   - Intracranial extension of occult meningoceles and encephaloceles
   - Scalp hemangioma versus sinus pericranii
3. A cross-check on adequacy of biopsy sampling or removal.
   - Diagnostic mineralized portions of soft tissue masses
   - MRI predicts tissue composition and degree of cystic change
4. To detect recurrence.
   - Subcutaneous metastasis beneath a surgical site versus hematoma, foreign body, etc.
5. Ancillary evidence for diagnosis.
   - Sarcoidosis (chest film), psoriasis (hip arthritis), congenital syphilis (periostitis)
   - Pachydermoperiostosis (thickened corticies), metastatic renal cell carcinoma (kidney tumor)
   - Sterile lytic bone lesions with palmoplantar pustulosis, acne fulminans, and Sweet's syndrome
6. To diagnose syndromic associations.
   - Maffucci's syndrome
   - McCune-Albright syndrome
   - POEMS syndrome
   - Buschke-Ollendorff syndrome
7. An aesthetic dimension and confirmation of early cases.
   - Calciphylaxis
   - Dystrophic mineralization in scleroderma

Normal fat has scattered CD34-positive dendritic cells and small factor XIIIa–positive dendritic cells, more numerous near vessels and within fibrovascular septae. Subsets of them proliferate together in mesenchymal areas of spindle cell lipomas, pleomorphic lipomas, myxoid lipomas, and atypical lipoma/well-differentiated liposarcomas (5).

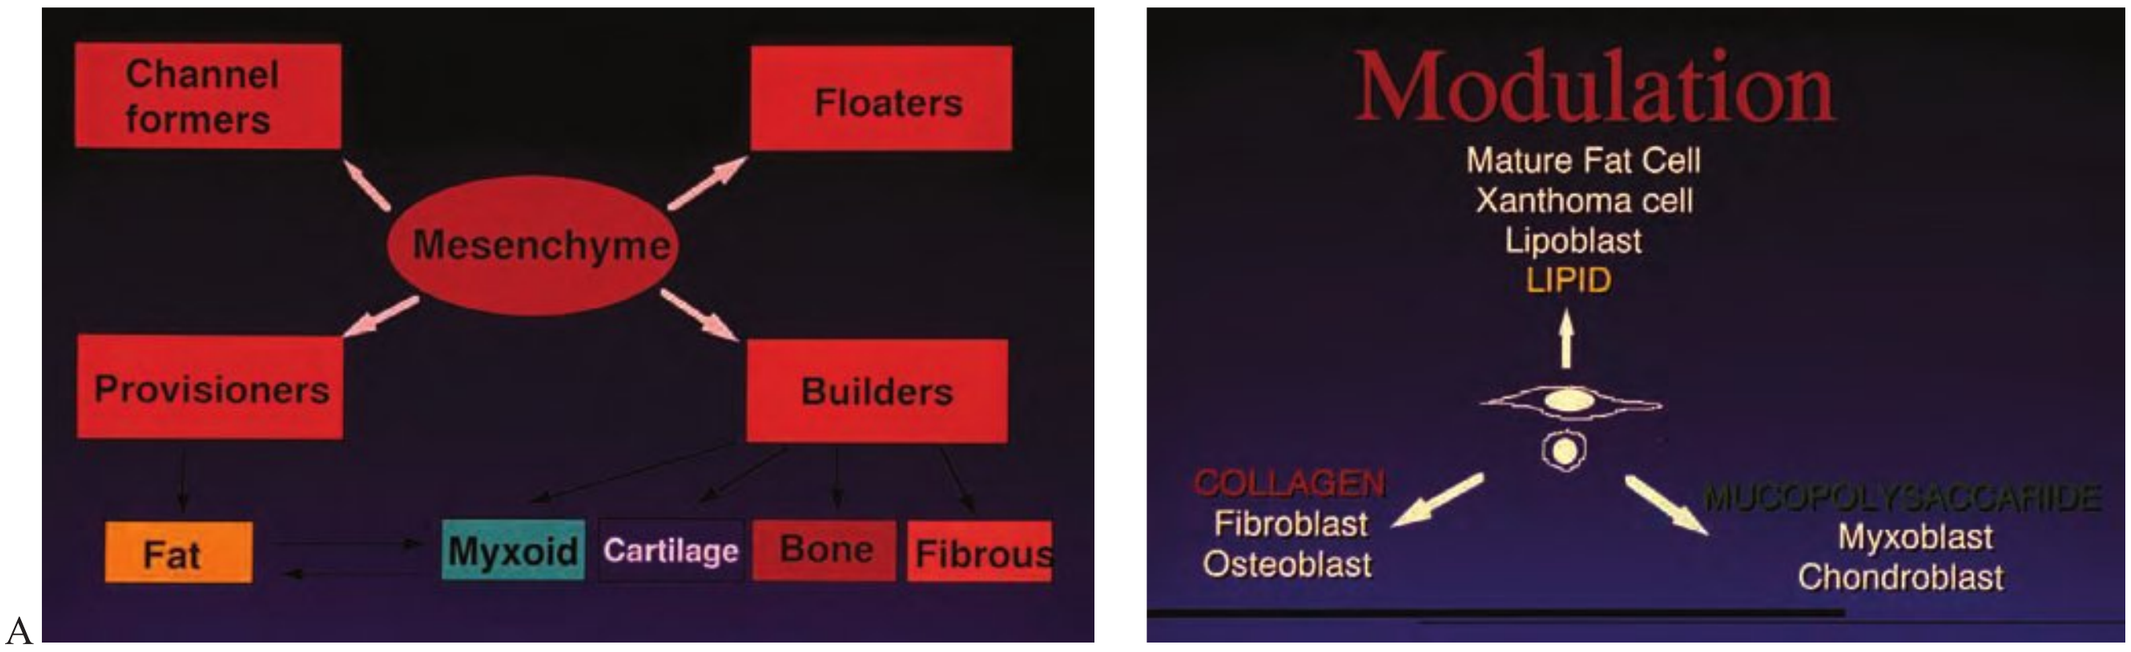
Fatty tumors of dermatologic interest are common and are generally situated in subcutaneous position (6). Purely *cutaneous* lipogenic tumors are exceptionally rare and have different specific clinicopathologic features in comparison with more deeply located tumors (7). This fact, as with many other subsets of soft tissue tumors, makes correlation of histopathologic opinions with history and radiologic studies the surest route to accurate diagnoses.

NEVUS LIPOMATOSUS SUPERFICIALIS

Nevus lipomatosus superficialis is a fairly uncommon lesion showing groups of soft, flattened papules or nodules that have smooth or wrinkled surfaces and are skin colored or pale yellow. Characteristically, the lesions are linearly distributed on one hip or buttock (nevus lipomatosus superficialis of Hoffman and Zurhelle) (8) (Fig. 34-2), from where they may overlap onto the adjacent skin of the back or the upper thigh. Other areas, such as the thorax or the abdomen, are only rarely affected. The lesions may be present at birth or may begin in infancy (nevus angiolipomatosus of Howell) (9), in which case the replacement of hypoplastic dermis may cause pseudotumorous yellow protrusions and be associated with skeletal and other malformations, but they develop most commonly during the first two decades of life and occasionally later. Multiple lesions may coalesce.

Solitary lesions that may not appear until after the fifth decade predilect the trunk and have been diagnosed as nevus lipomatosus superficialis, but it seems preferable to regard them instead as solitary, baglike, soft fibromas (see Chapter 33), polypoid fibrolipomas, or pedunculated lipofibromas (10).

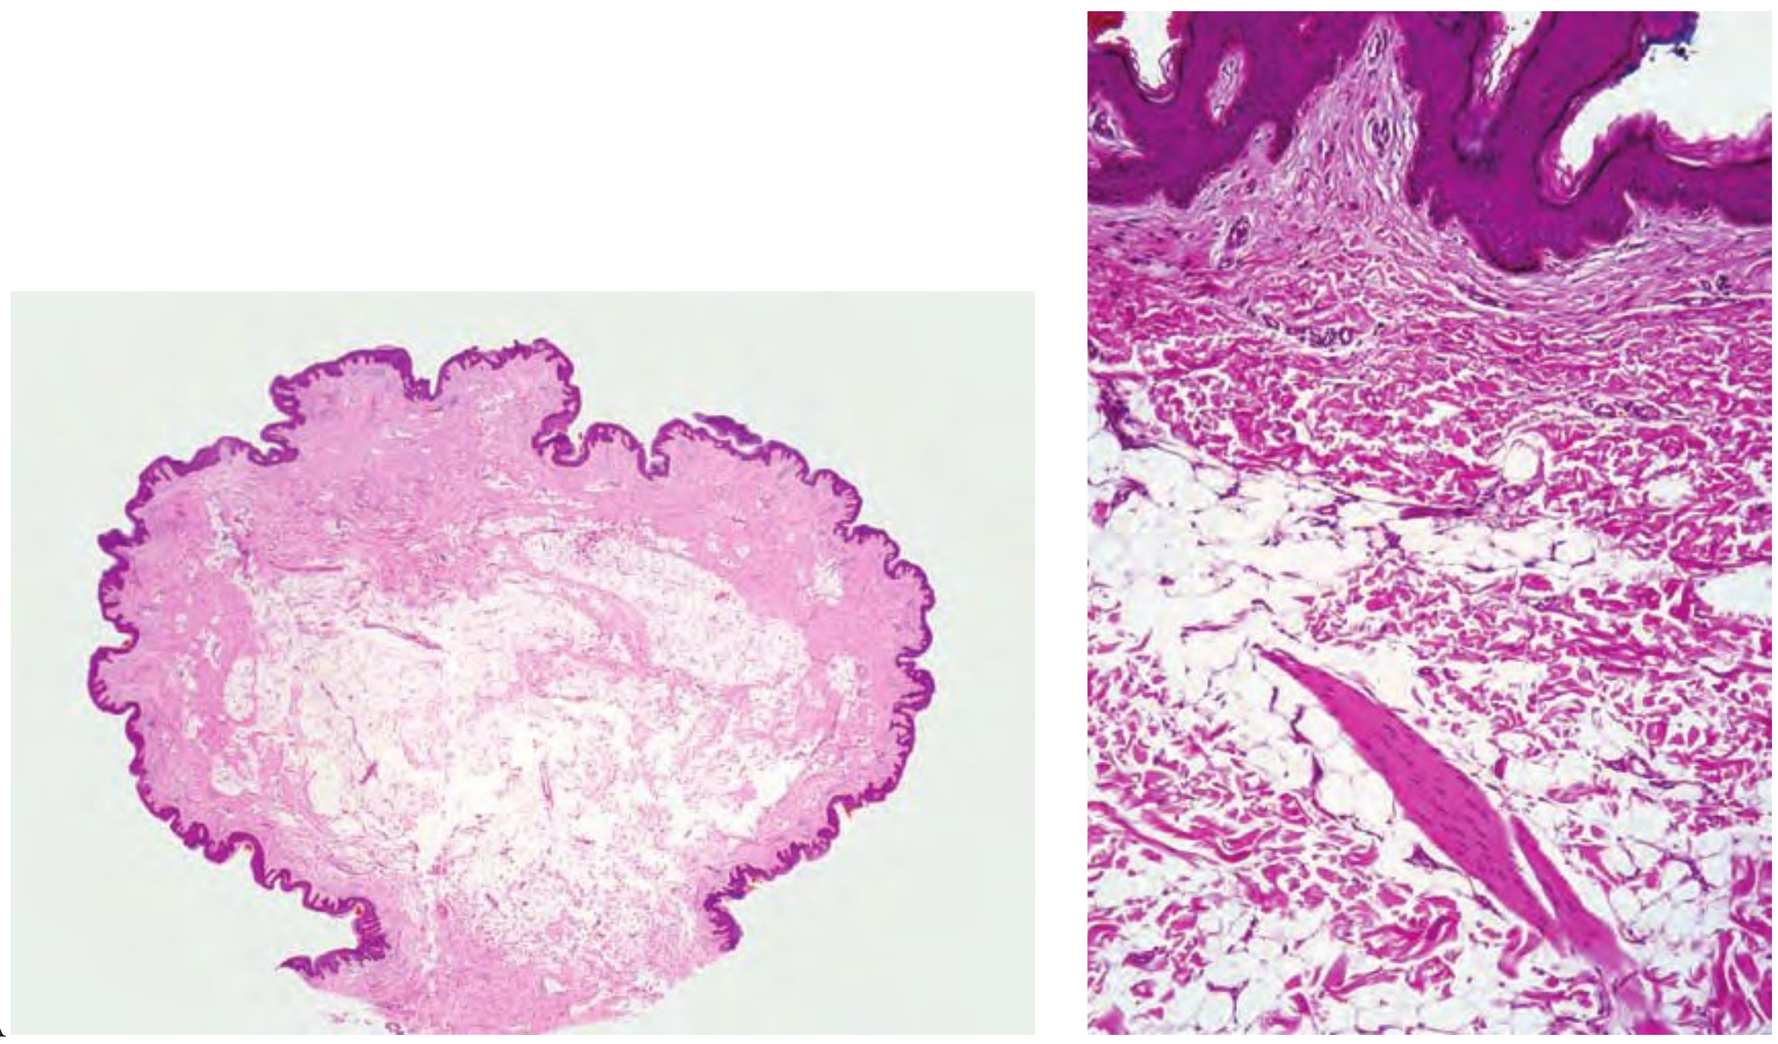
Histopathology. Groups and strands of fat cells are found embedded among the collagen bundles of the dermis, often as high as the papillary dermis (Fig. 34-2B). The proportion of fatty tissue varies greatly, from >50% of the dermis to <10%. In cases with only small deposits, the fat cells are apt to be situated in small foci around the subpapillary vessels. In instances with relatively large amounts of fat, the fat lobules are irregularly distributed throughout the dermis, and the boundary between the dermis and the hypoderm is ill-defined or lost. The fat cells may all be mature, but in some instances an occasional small, incompletely lipidized cell may be observed.



Aside from the presence of fat cells, the dermis may be entirely normal, but in some instances the density of the collagen bundles, number of fibroblasts, and vascularity are greater than in normal skin (8).

Pathogenesis. It is generally agreed that nevus lipomatosus represents, as the name implies, a nevoid anomaly. The ectopic fat cells in the dermis are derived from the perivascular mesenchymal tissue. This view has found support in electron microscopic studies of nevus lipomatosus superficialis, which in some instances showed, in the vicinity of capillaries, immature lipocytes containing numerous small lipid droplets and a centrally located nucleus (11).

Differential Diagnosis. In focal dermal hypoplasia, fat cells are also present in the dermis, often in close proximity to the epidermis but with concomitant extreme attenuation of collagen (see Chapter 6). The rather common presence of fat cells within long-standing intradermal melanocytic nevi represents an involutionary phenomenon rather than an association of a nevus lipomatosus with a melanocytic nevus (see Chapter 28).



FOLDED SKIN WITH LIPOMATOUS NEVI

Multiple, symmetric, deep, gyrate skin folds involving trunk and similar circumferential lesions on extremities since birth

A B

FIGURE 34-1. Mesenchymal modulation diagrams. A: Uncommitted mesenchyme is the product of differentiation, distinct from ectoderm and endoderm. Further adoption of specific function and corresponding cell structure (phenotype) is modulation, resulting in components of the circulatory system ("channel formers"), lymphohematopoietic cells ("floaters"), structural connective tissue ("builders"), and fat-storing cells ("provisioners"). This normal panoply has its frequent neoplastic parallel in the multiple tissue types that can be found in mesenchymal tumors. B: Extracellular matrix products can be collagen dominant (fibrous or osseous) or mucopolysaccharide dominant (chondroid or myxoid). A signet-ring fat cell represents the end result of internal product storage rather than export (i.e., accumulation of cytoplasmic fat), a process that begins as multiple small vacuoles. The structure and function of some fully modulated mesenchymal cells can change with altered systemic or local influences in the realms of metabolic, mechanical (e.g., trauma, friction, etc.), and/or circulatory (increased arterial flow vs. venous congestion) factors. Initially, in this process, regression leads to spindle or round cells that can be easily mistaken for fibroblasts or lymphocytes. This is followed by cytoplasmic reorganization and acquisition, making possible new functions. Also, more than one modulational potential may be seen in mesenchymal tumors as they grow (e.g., Figs. 34-8 and 34-9). (11a) (After Lent C. Johnson, AFIP, Washington, DC.)

A B

FIGURE 34-2. Nevus lipomatosus (45-year-old man; 2-cm lesion from buttock). A: A polypoidal projection of crenated epidermis has a fatty core. B: Mature signet-ring fat cells displace dermal collagen. A pilar muscle is surrounded by lesional fat.

are seen in the Michelin tire baby syndrome. Look for the characteristic round face with hypertelorism; depressed nasal bridge; thin, down-turned vermillion border of upper lip; and short neck (12).

Newborns, phenotypically likened to the "Michelin man" of tire fame (13), have excessive symmetric, circumferential folds of skin with underlying nevus lipomatosus affecting the neck, forearms, and lower legs and resolving spontaneously in childhood (14). Smooth muscle hamartoma (15) and multiple anomalies may coexist (16).

Histopathology. In some areas, hypertrophic fat lobules extend close to the epidermis, as in nevus lipomatosus superficialis, and surround adnexal structures (17). In other areas, the dermis is of normal thickness, but excessive amounts of adipose tissue are beneath the dermis and around adnexal structures. Several bands of fibrous tissue penetrate the subcutaneous fat. An increase in smooth muscle fibers of the deeper dermis is reported (18) as well as fragmented elastic fibers (19).

Differential Diagnosis. Folded skin has also been reported overlying smooth muscle hamartoma (14).

PIEZOGENIC PAPULES

Fat pad thickness and septal integrity are both important to the mechanical characteristics of the heel fat pad. In various diseases (e.g., rheumatoid arthritis and diabetes) and aging, the load-carrying ability of the heel pad is impaired (20). Septal wall fragmentation and increased width is noted in atrophic heel fat pads from patients with peripheral neuropathies (21). Nonneoplastic *piezogenic papules* due to the herniation of fat into the dermis present as multiple small papulonodules on the heels (22) or wrist (23), with or without pain. Piezogenic papules are primarily a problem of athletes (24) and tend to retract when unburdened. They can be seen in the Ehlers-Danlos syndrome, possibly due to structural defects in the connective tissue with resultant poor compartmentalization of the fat (25).

Histopathology. The normally small fat compartments in lower dermis and subcutis coalesce due to loss of thin fibrous septations (23).

Differential Diagnosis. In bilateral congenital adipose plantar nodules (or congenital fibrolipomatous hamartoma) (26), well-defined lobules of mature fat occur in the mid and deep dermis, mostly around adnexa (27).

LIPOMAS

Common lipomas consist of mature fat cells throughout (Fig. 34-3) and are the most common neoplasms of mesenchyme. Lipomas are subclassified according to the anatomic site into dermal, subcutaneous, and subfascial, also inter- or intramuscular, or tumors directly related to bone, synovium, or nerve. Most lipomas (98%) occur as single or multiple subcutaneous growths that are soft, rounded or lobulated, and movable against the overlying skin. They often grow insidiously, displaying an initial growth phase followed by a period of quiescence. They come to clinical attention only if they reach inordinate size (Fig. 34-3A) or are perceived as blemishes in need of cosmetic removal. Approximately 6% of all cases are multifocal. The patient commonly presents with an asymptomatic, slowly growing round mass having a gelatinous or cystic consistency. Well-circumscribed lipomas are easily "shelled out" and only rarely regrow, generally when initially incompletely encapsulated or infiltrative. Deep-seated variants of ordinary lipomas tend to be less well circumscribed than their superficial counterparts, often sending out pseudopod-like processes within fascial planes, engulfing aponeuroses, and potentially compressing local structures. Large, even giant size, defined as >10 cm diameter in at least one dimension (28), rapid growth, deep location, fixation, pain, and thigh or retroperitoneal location are features that suggest the wisdom of preoperative radiographic characterization and a cautious surgical approach to exclude a more significant lesion before enucleation that could preclude limb-sparing surgery for a more aggressive lesion.

Some lipomas are characterized by specific clinical presentation and location. Location on the forehead (29) (Fig. 34-3B) is a rather common dermatologic specimen. *Perineural lipoma* involves the median nerve in 9 out of 10 cases and may be associated with macrodactyly. *Lumbosacral lipomas* frequently occur in conjunction with spina bifida and intraspinal lipoma. *Lipomas of tendon sheath and joint synovium* are centered on the named structures. *Lipoma arborescens (diffuse articular lipomatosis, synovial lipomatosis, Hoffa disease)* is a rare intra-articular lesion of unknown etiology where benign papillomatous intra-articular fatty expansions usually in the knee joint have a tendency for repeated regrowth (30).

Intramuscular lipomas, in contrast to *intermuscular lipomas*, infiltrate muscle and tend to recur unless completely excised (31). *Myolipomas of soft tissue* are rarely subcutaneous (32).

The *cutaneous angiomyolipoma*, also known as *cutaneous angiolipoleiomyoma*, is seen most often in adult male patients and in an acral location. Like its more common renal counterpart, it is composed of an admixture of blood vessels, smooth muscle, and adipose tissue. While the renal lesions are often seen in the setting of tuberous sclerosis and its pulmonary lymphangiomyomatosis, not those in skin, work-up for tuberous sclerosis should not be pursued (33). Smooth muscle cells in cutaneous angiomyolipomas stain negatively for HMB-45, in contrast to renal and extrarenal angiomyolipoma (7,34). It is proposed that cutaneous angiomyolipomas should be termed *angioleiomyoma with fat* to avoid confusion with unrelated noncutaneous angiomyolipomas that are HMB-45 negative and require investigation for tuberous sclerosis (35).

The *adenolipoma* is a dermal or subcutaneous variant of the common lipoma that does not deviate appreciably in presentation or gross appearance but microscopically has inclusions of sweat gland apparatus (7), likely passively enveloped as in "glandular" neurofibroma.

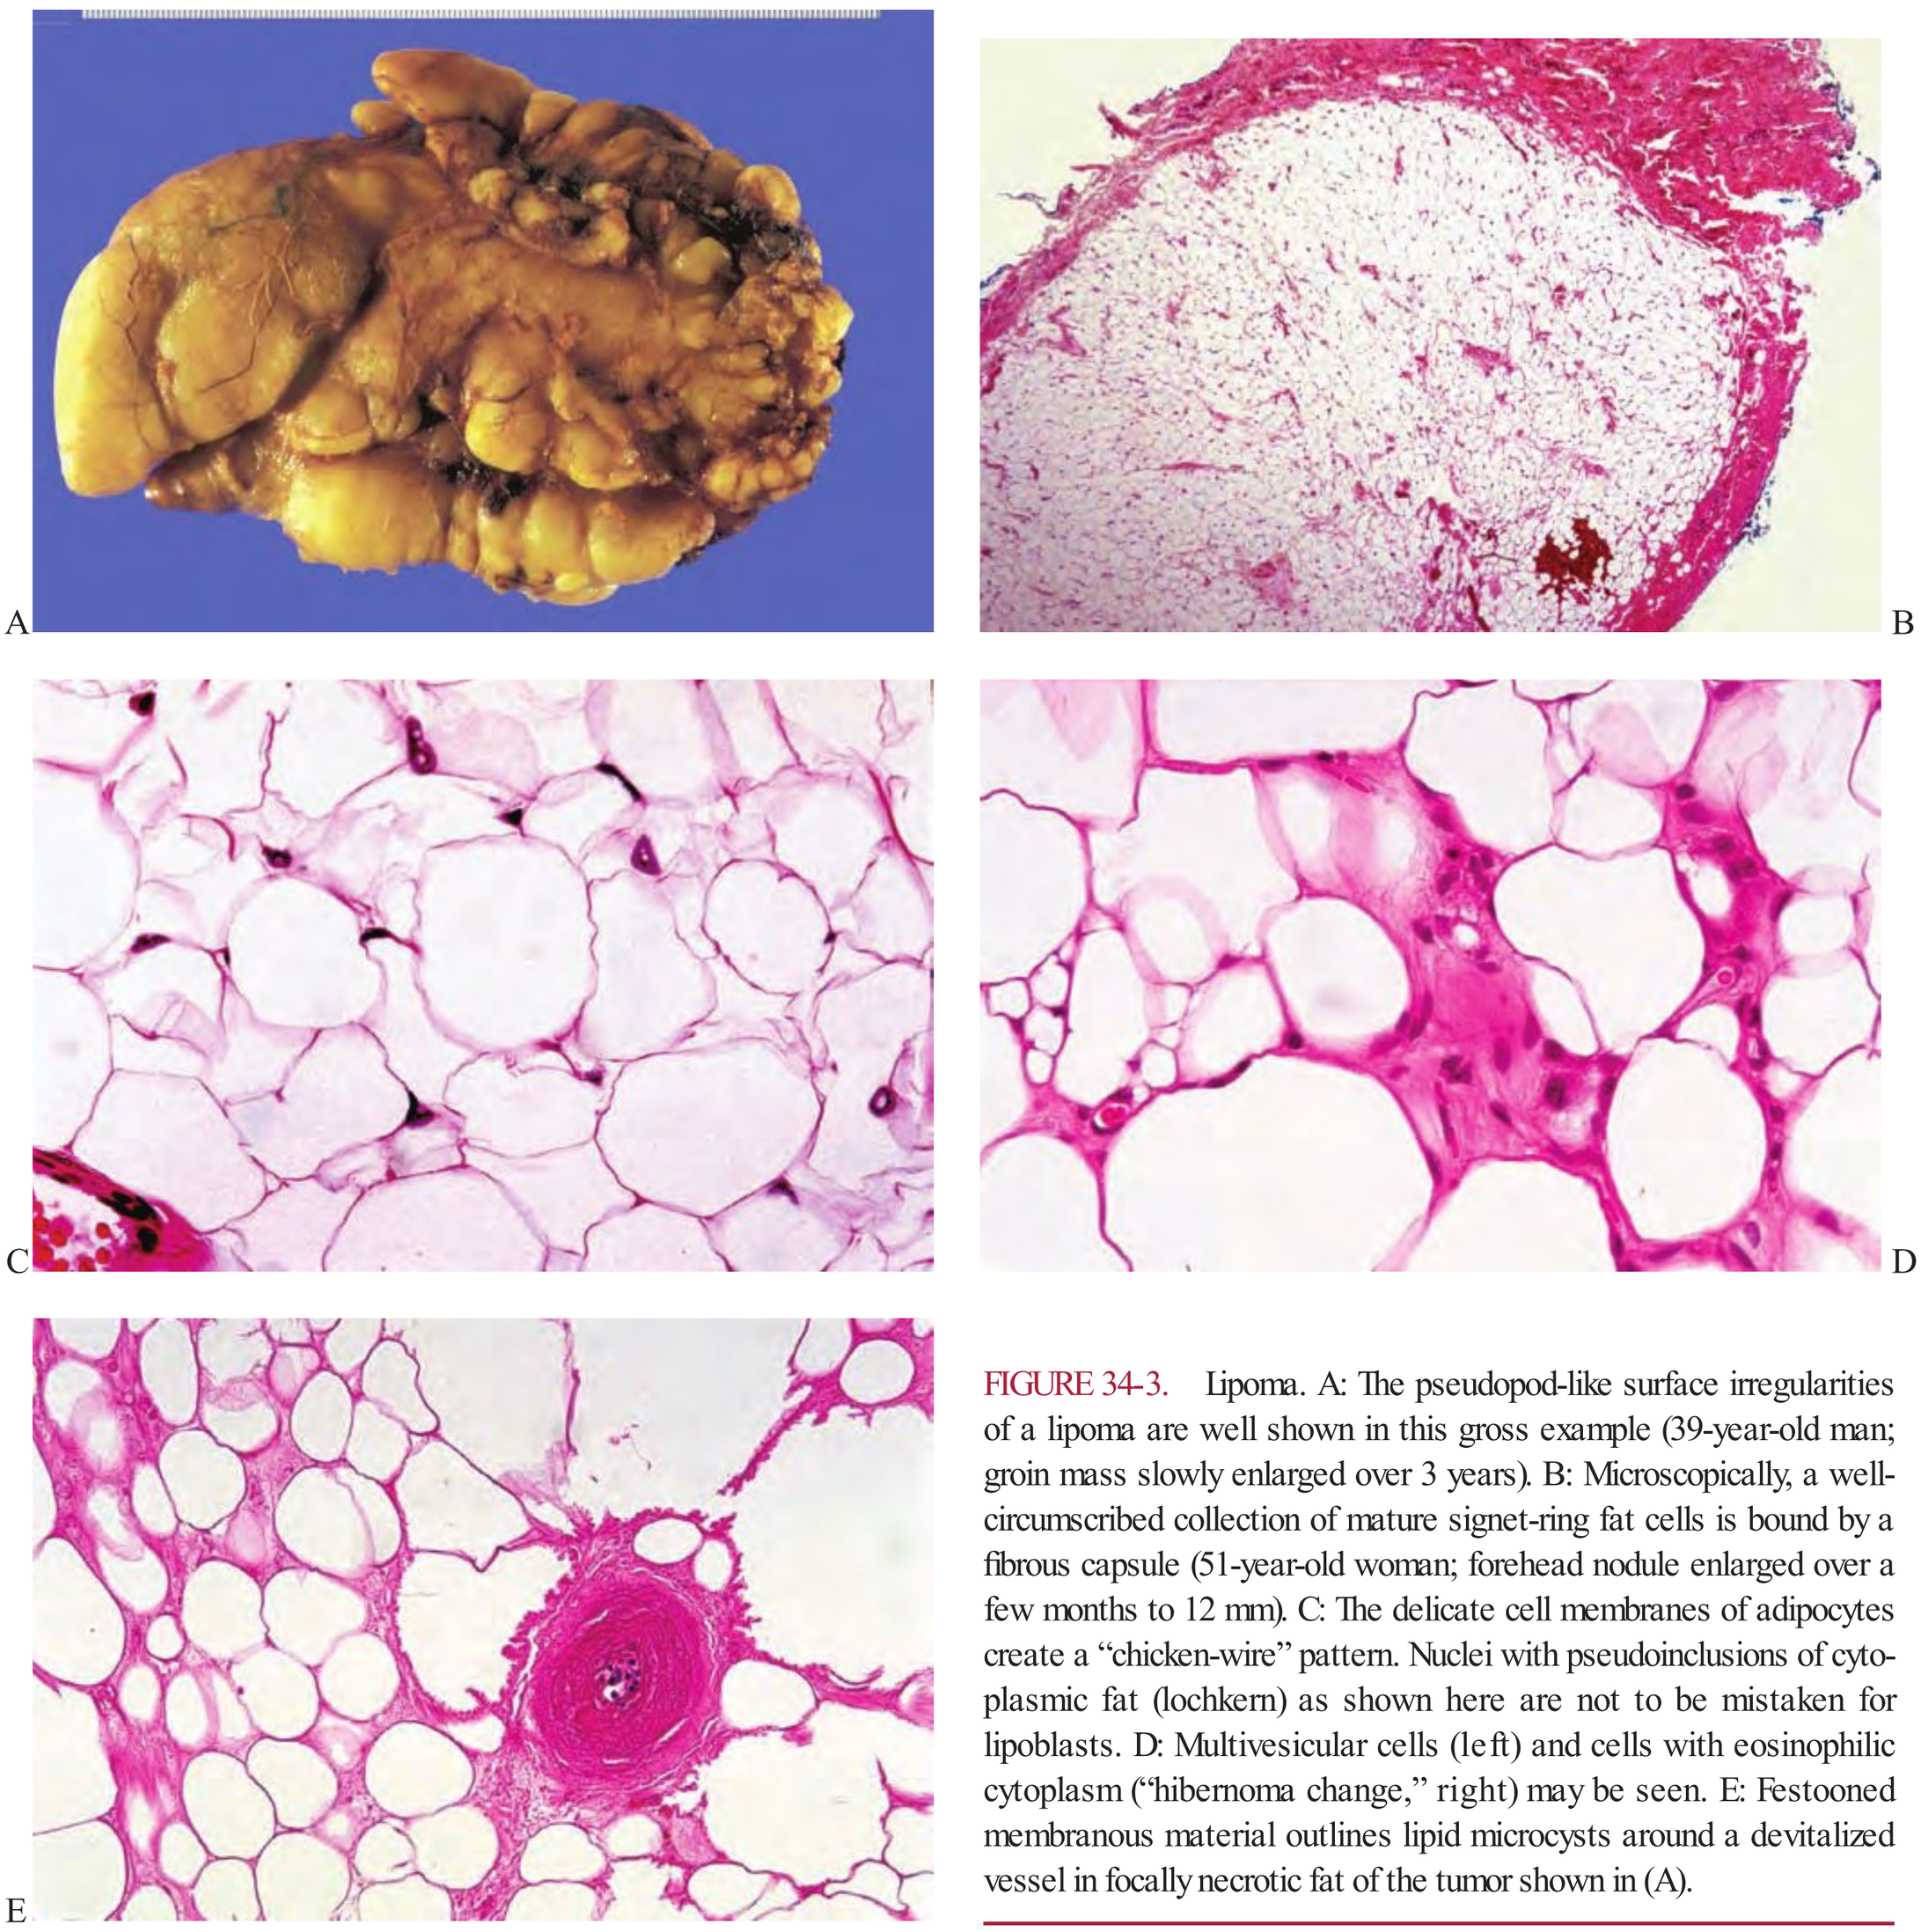


FIGURE 34-3. Lipoma. A: The pseudopod-like surface irregularities of a lipoma are well shown in this gross example (39-year-old man; groin mass slowly enlarged over 3 years). B: Microscopically, a well-circumscribed collection of mature signet-ring fat cells is bound by a fibrous capsule (51-year-old woman; forehead nodule enlarged over a few months to 12 mm). C: The delicate cell membranes of adipocytes create a "chicken-wire" pattern. Nuclei with pseudoinclusions of cytoplasmic fat (lochkern) as shown here are not to be mistaken for lipoblasts. D: Multivesicular cells (left) and cells with eosinophilic cytoplasm ("hibernoma change," right) may be seen. E: Festooned membranous material outlines lipid microcysts around a devitalized vessel in focally necrotic fat of the tumor shown in (A).

Instances of malignant transformation of ordinary lipomas are anecdotal at best.

In two rare conditions, multiple lipomas composed of mature fat cells arise in adult life. In Dercum's disease (adiposis dolorosa, lipomatosis dolorosa morbus Dercum) (36), there are tender, circumscribed, or diffuse fatty deposits, with a predilection for the upper arms, legs, abdomen, and buttocks (37). Postmenopausal women are selectively affected. Paresthesia in the overlying skin is common. Lipomas about the joints cause mechanical arthralgia. The diagnosis, which is often delayed, rests on ultrasonography and, above all, MRI. The portrait painted of Dercum's disease is very complicated, with many other disorders seen associated with the disease. There are no clear pathologic mechanisms known, although it is suspected that there is either a metabolic or autoimmune component involved. A combination of medications, surgery, and psychiatric care is usually needed. The treatment aims at relieving the pain and restoring a normal appearance.

Multiple or *benign symmetric lipomatosis (Madelung's disease)* is a rare disease of undetermined cause characterized by symmetric deposits of painless, diffuse, subcutaneous adipose tissue on the suboccipital area, cheeks, neck (in "horse collar"

distribution), shoulders, and upper trunk. Lipomas are present especially on the back and upper trunk (38). It is most common in countries bordering the Mediterranean. The patients are usually middle-aged male alcoholics (39). Although lesions can initially mimic a head and neck malignancy, management is essentially symptomatic, with conservative removals done as indicated clinically or for cosmesis.

Familial multiple lipomatosis has hundreds of slowly growing subcutaneous (forearm, trunk, and thigh) masses and deep or visceral lipomas that appear in the third decade (40,41). This as well as Dercum's disease can be inherited as an autosomal dominant trait. Children presenting with lipomas need a complete physical examination to look for other signs of Bannayan-Riley-Ruvalcaba syndrome, which is a dominant autosomal disorder characterized by cutaneous lipomas, intestinal polyps, developmental delay associated with PTEN gene mutations and in some instances hemangiomas, and macrocephaly, because they may need further follow-up for tumor screening in adulthood (42).

Diffuse lipomatosis features infiltrating masses of mature adipose tissue in part of an extremity or the trunk before age 2 years, possibly with concurrent tuberous sclerosis (43). *Nevus psiloliparus* (44) is the cutaneous component of subcutaneous scalp lipomas with overlying alopecia in *encephalocraniocutaneous lipomatosis* (45). Similarly, hamartomatous, *infiltrating lipoma of the face* (46) is another variant of it. A thickened and soft scalp that may present as alopecia, *lipedematous scalp*, is a thickening of the subcutaneous fat (47). Multiple lipomas and hemangiomas occur in *Cowden's syndrome*. *Fröhlich's syndrome* exhibits multiple lipomas, obesity, and sexual infantilism. The *Proteus syndrome* features multiple lipomatous lesions, including pelvic lipomatosis and fibroplasia of the feet and hands, skeletal hypertrophy, exostoses and scoliosis, and pigmented skin lesions. This rare overgrowth disorder is generally progressive, with subcutaneous lipomas and cerebriform connective tissue nevi progressively increasing in size, and in most patients, additional lesions developed at new locations (48).

Use of protease inhibitors for HIV-1 can be associated with fat abnormalities including subcutaneous lipomas (49), angiolipomas (50), peripheral lipodystrophy, and benign symmetrical lipomatosis (51).

Histopathology. By definition, lipomas contain mature adipocytes as a principal component. They tend to be surrounded by a thin connective tissue capsule and are composed, often entirely, of normal fat cells that are indistinguishable from the fat cells in the subcutaneous tissue (Fig. 34-3C). Occasional "hibernoma-like" cells or multivesicular cells (Fig. 34-3D) around foci of necrosis should not be misinterpreted as lipoblasts, which differ in having coarse vacuoles and irregular nuclei. Membranous fat necrosis is a rare occurrence in lipomas of larger size (Fig. 34-3E) and has the typical staining reactions of ceroid pigment. Traumatic or ischemic causation is postulated (52).

Intramuscular (infiltrating) lipomas consist of mature fat cells that infiltrate muscle, splaying fibers but showing no nuclear atypia (Fig. 34-4). Be skeptical of this diagnosis on the face where mature fat is normally admixed with facial muscles of expression (Fig. 34-5). In some lipomas, what is found is more or less of a connective tissue framework than in the normal subcutaneous fat. Those containing considerable proportions of fibrous connective tissue are called *fibrolipomas* (Fig. 35-6) or *sclerotic lipoma* if a prominent sclerotic stroma is in a storiform arrangement (53). Substantial basophilic mucopolysaccharide may fill regions of the tumor and the term *myxolipoma* is recommended (Fig. 34-7). Focal chondroid (Fig. 34-8) and/or osteoid production (Fig. 34-9) have no significance other than underscoring the modulational potential of functional mesenchymal cells (see below).

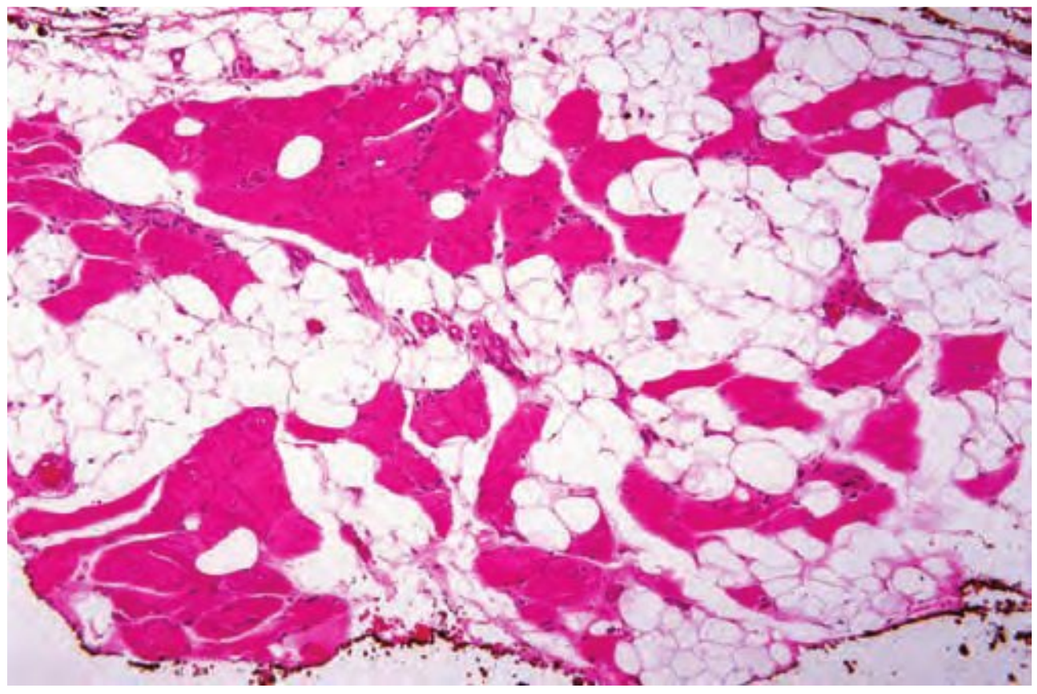

FIGURE 34-4. Intramuscular (infiltrating) lipoma (28-year-old woman; 11-month history of a 1.5-cm shin nodule). Mature fat cells splay individual skeletal muscle fibers.

Myolipomas are comprised of variable amounts of benign smooth muscle and mature adipose tissue. The smooth muscle component of a cutaneous *angiomyolipoma* comprised of mature adipose tissue, smooth muscle fascicles, and medium-

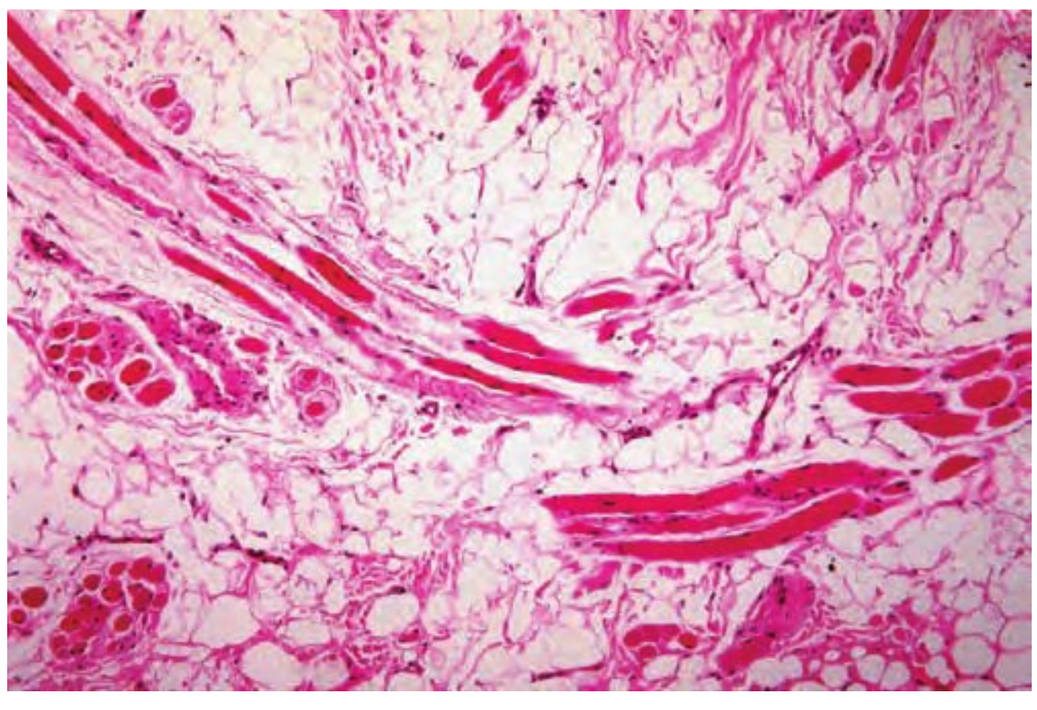

FIGURE 34-5. Normal subcutaneum, face. Skeletal muscle bundles are normally surrounded by mature fat on the face, and this is not to be mistaken for infiltrating lipoma.

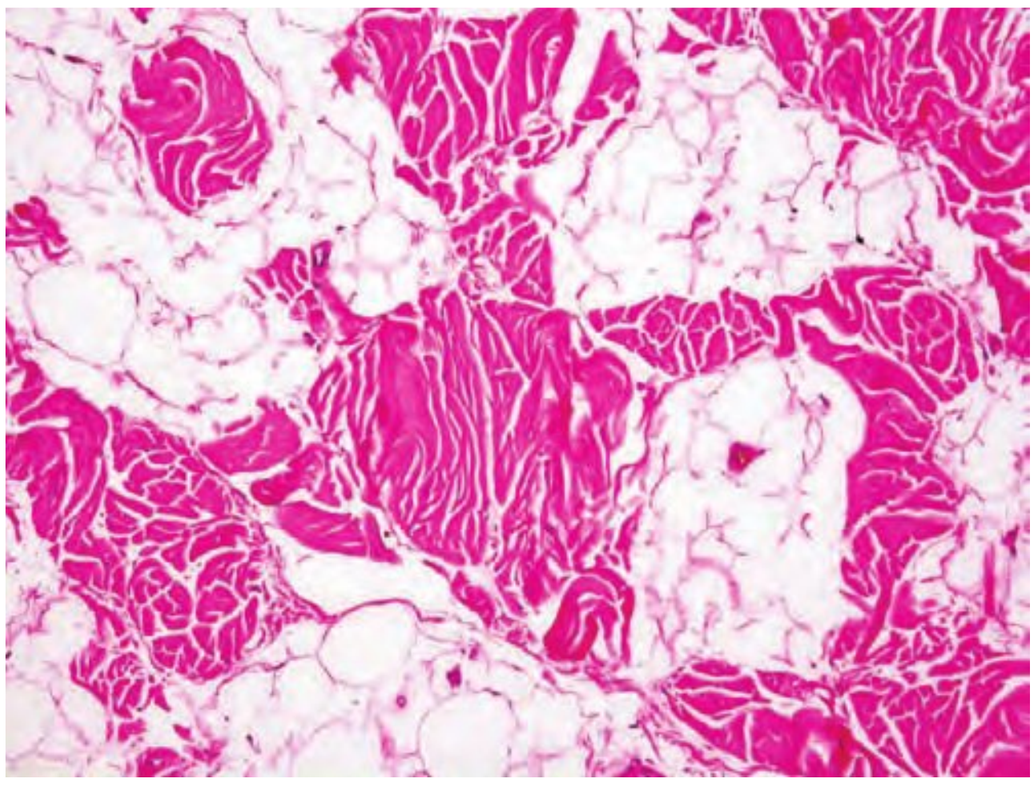

FIGURE 34-6. Fibrolipoma. Strands of collagenous, fibrous connective tissue can be seen within a tumor composed of mature adipocytes. In other cases, the nodule may be predominantly fibrous with little fat.

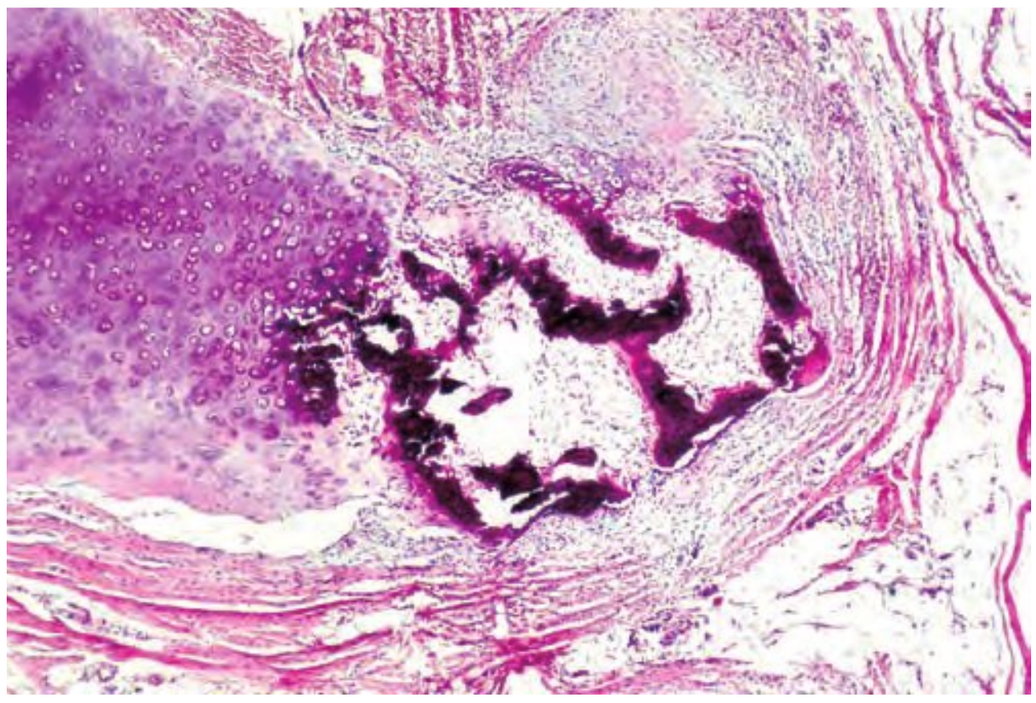

FIGURE 34-8. Ossifying chondromyxoid lipoma. Within a fatty and myxoid background are areas of chondrification (right) and ossification (center). The contact between the bone and cartilage to the left of center indicates that part of the bone was formed through the enchondral mechanism, analogous to longitudinal bone growth at the growth plate. A portion of the bone has formed directly from the fibrous background (intramembranous ossification). This lesion manifests all three directions of modulation outlined in Figure 34-1B.

sized blood vessels (Fig. 34-10) may show pronounced cellular and nuclear pleomorphism and hyperchromatism, as is common in the renal tumor of the same name (54). The distinctive feature of an *adenolipoma* (Fig. 34-11) is an admixture of displaced and distorted sweat glands within the fatty background.

In *adiposis dolorosa* (Dercum's disease), most authors have found the lipomas to be indistinguishable histologically from ordinary lipomas. In some cases, the histologic appearance is that of an angiolipoma, a tumor that is often painful (see text following). In other cases, granulomas of the foreign body type have been noted within the fatty tissue. In *benign symmetric lipomatosis* (Madelung's disease), the lipomas have the histologic appearance characteristic of ordinary lipomas.

Metaplastic formation of cartilage and bone is only rarely seen in lipomas. Ossifying lipomas, independent of bone tissue and with concurrent cartilage in about half, is rarely reported in the dermatopathologic literature (55). It has the same excellent prognosis as simple lipoma after excision. Focal chondroid (Fig. 34-8) and/or osteoid production (Fig. 34-9) have no significance other than underscoring the modulational potential of functional mesenchymal cells. Mechanical stress, trophic disturbances, character of local vascular flow, the conspicuously frequent contact with periosteum, and still unknown factors may be the causes for the metaplastic transformations (56).

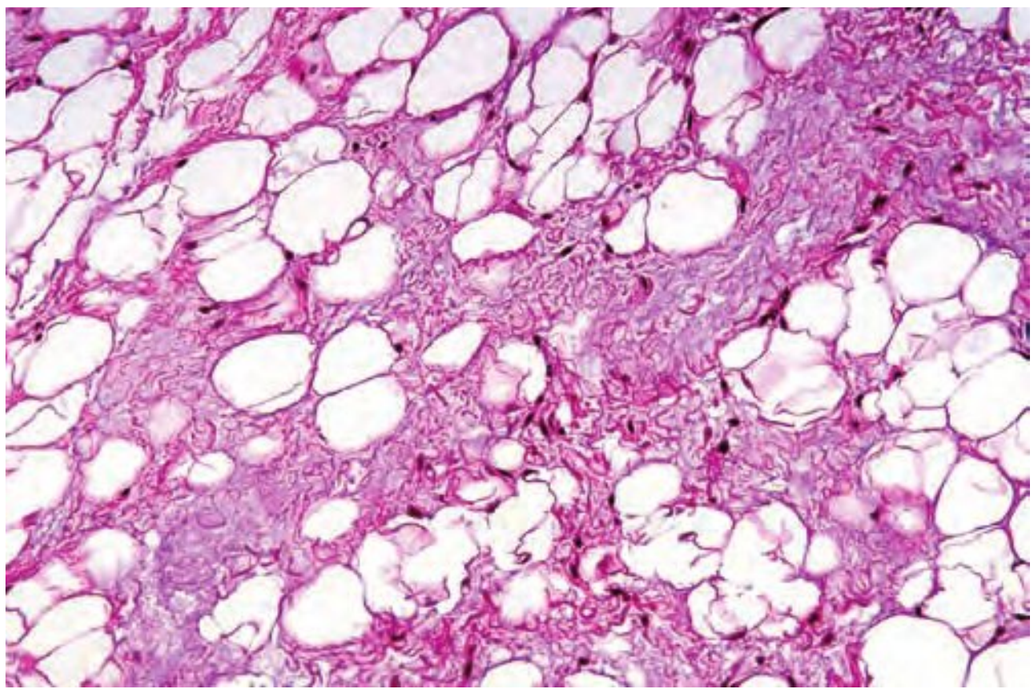

FIGURE 34-7. Myxolipoma (65-year-old woman; small dorsal hand mass for 7 years, enlarging in the last several months to 2.8 cm). Basophilic myxoid substance between mature adipocytes is sparcely populated by nonatypical stellate- and spindle-shaped cells.

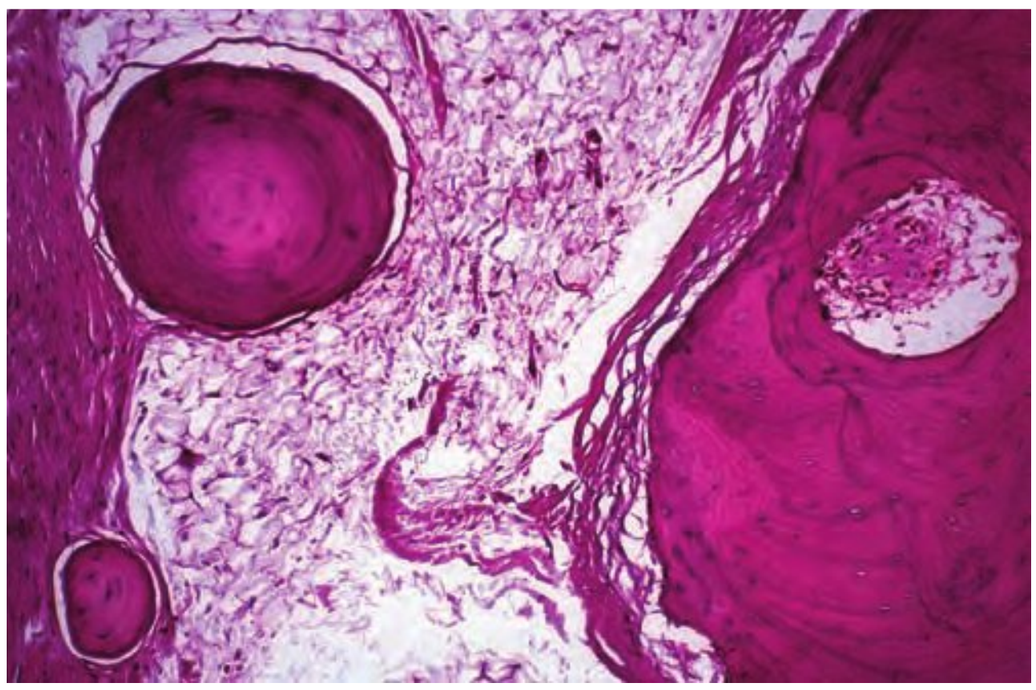

FIGURE 34-9. Osteolipoma (63-year-old man with "cyst" on forehead for many years). Rounded islands of bone are visible within a fibrofatty background in this mass. The largest ossicle (right) is undergoing haversianization.

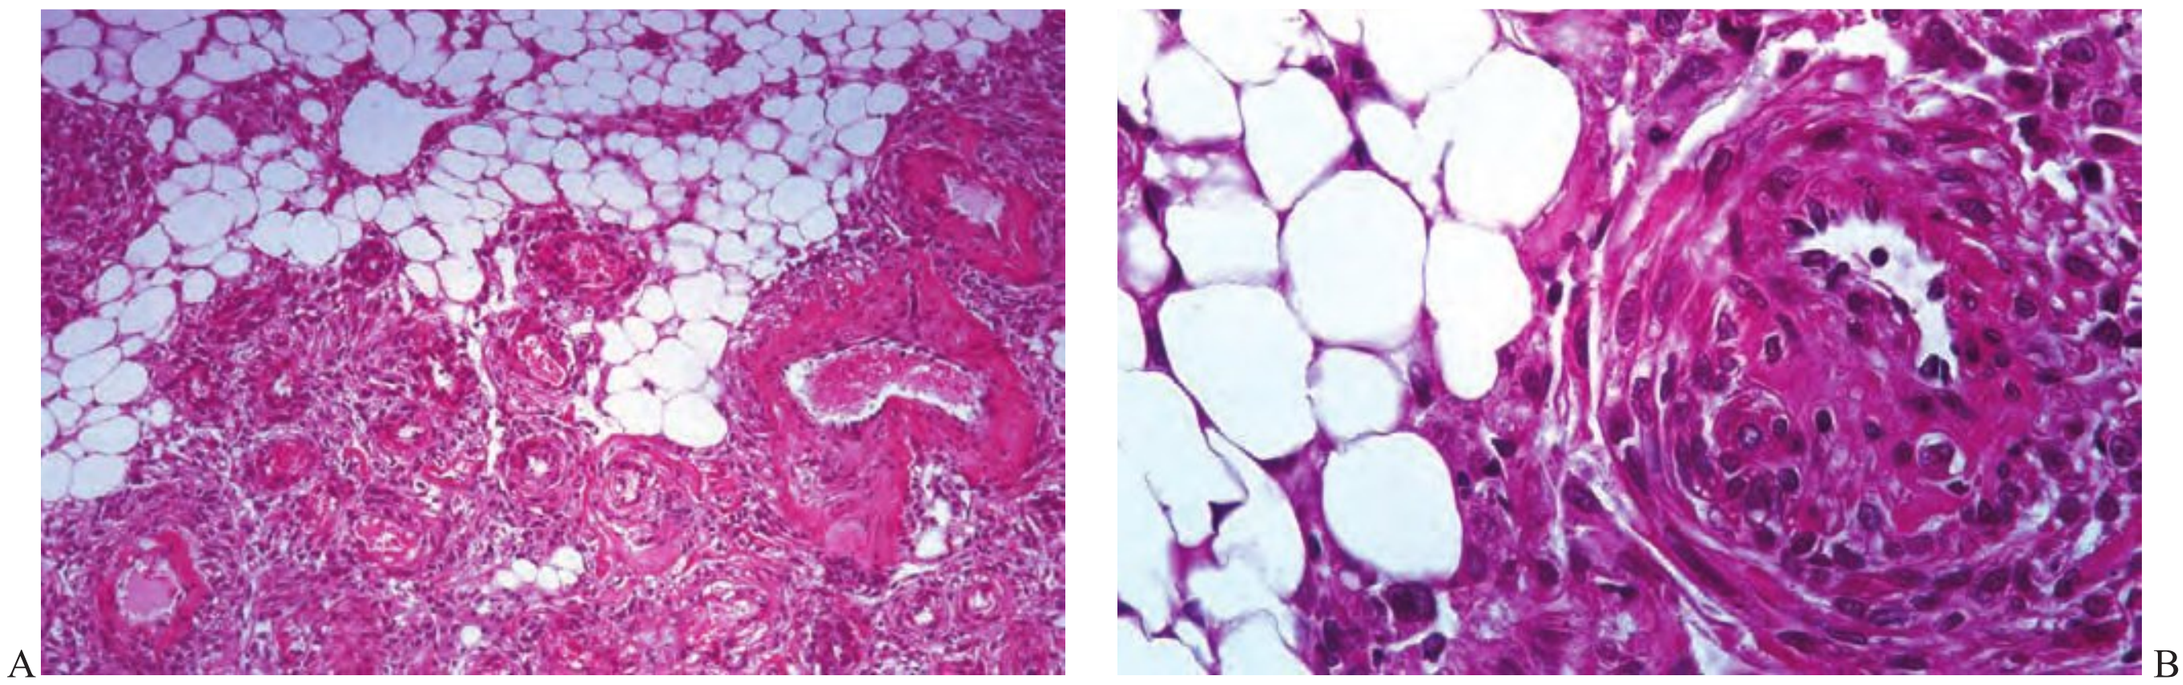

FIGURE 34-10. Angiomyolipoma. A: The basic components of this tumor are mature adipose tissue and thick-walled, medium-sized vascular channels from which sheets of plump, smooth muscle cells appear to be derived. B: Plump cells with features of smooth muscle appear to derive from the wall of a vessel within a fatty background. Moderate pleomorphism of the fatty and smooth muscle components is expected and does not connote malignancy.

Efforts to distinguish true adipocyte neoplasms from lipomatous hamartomas and localized overgrowth of fat have been limited by the lack of reproducible markers for adipose neoplasms. Identification of a (12:16)(q13p11) translocation in myxoid liposarcomas, and of a similar translocation in lipomas with breakpoints at 12q14 (57), makes future prospects of resolving these issues of pathogenesis seem bright. For the present, lipomatous tumors are still classified morphologically (Table 34-2).

Differential Diagnosis. Growth pattern and size may suggest well-differentiated liposarcoma, but superficial (dermal or subcutaneous) liposarcomas are extremely rare. Lipomas do not contain diagnostic lipoblasts. This fact and the absence of the characteristic delicate capillary network distinguish lipomas with focal or substantial basophilic mucopolysaccharide from myxoid liposarcomas. Intramuscular (infiltrating) lipoma lacks the lipoblasts of well differentiated (lipoma-like) liposarcoma and the lobulation and multiple muscle involvement of the pediatric lipoblastoma. Deeply situated myolipomas can be confused with well-differentiated liposarcomas (32).

ANGIOLIPOMA

Angiolipomas usually occur as encapsulated subcutaneous lesions. As a rule, they arise in young adults. The forearm is the single most common location for this tumor, which comprises 10% of tumors of fat (58). Clinically, angiolipomas resemble lipomas, although they have a greater tendency to be multiple. Size of these yellow to yellow-red, circumscribed lesions is from 0.5 to 4.0 cm. They are often tender or painful when pressured or moved (59).

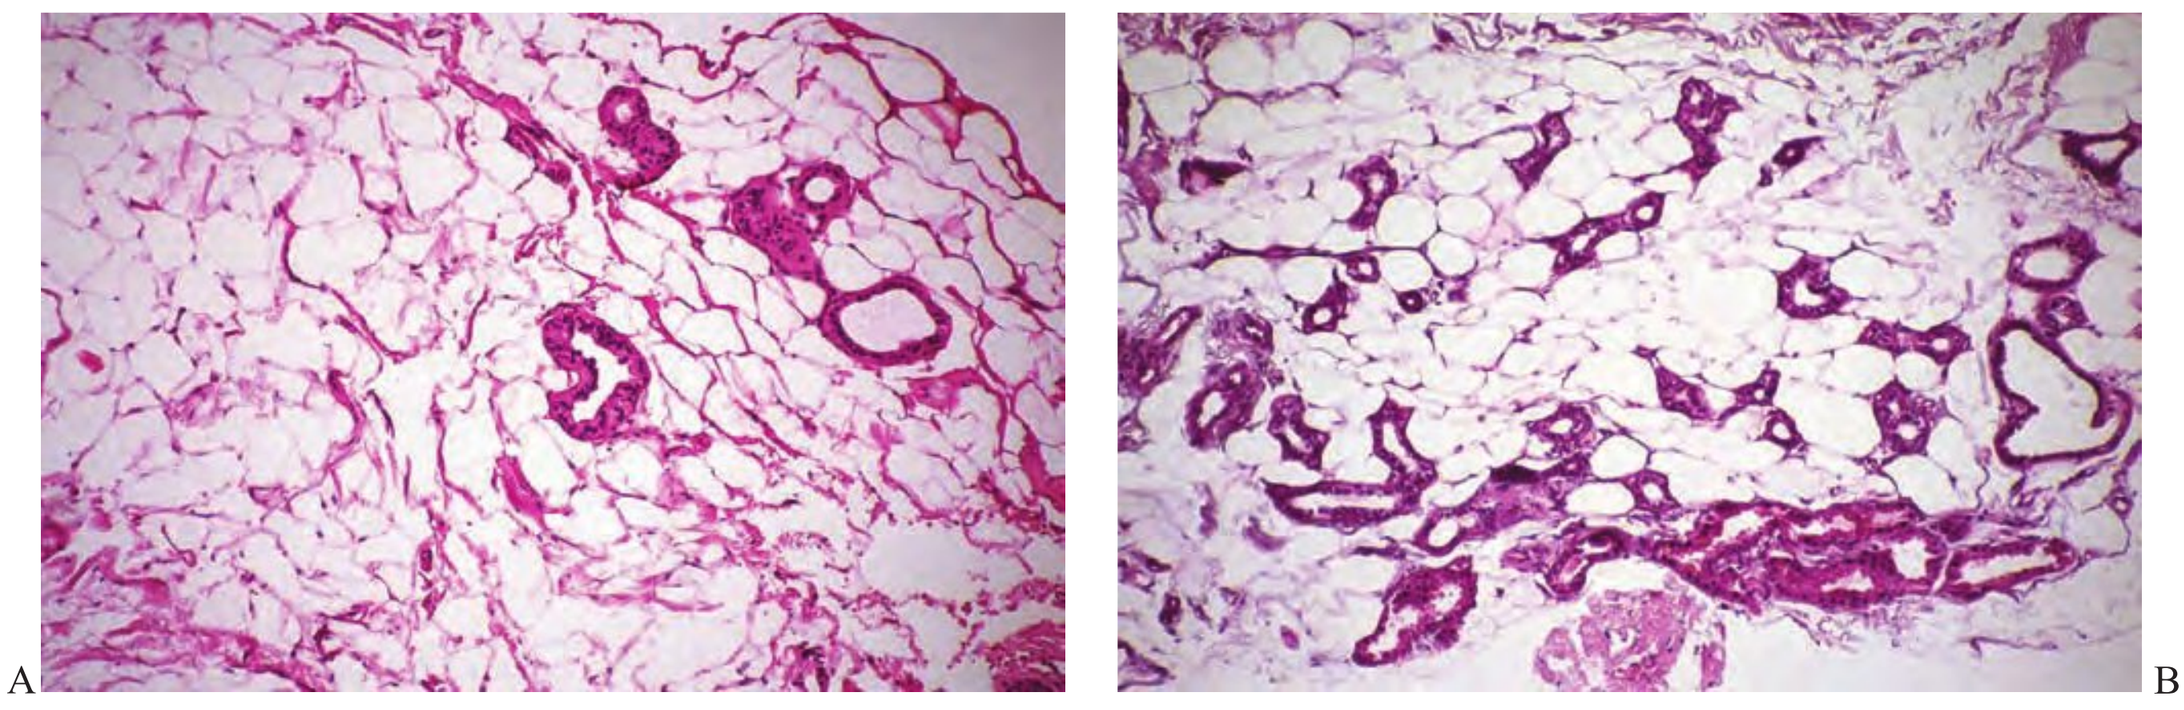

FIGURE 34-11. Adenolipoma. A: Excess mature fat in this medium-magnification view surrounds sweat gland coils and tubules (52-year-old man; 2-cm left neck nodule). B: Apocrine glandular elements (bottom) can be seen with sweat gland elements in a background of mature fat (62-year-old woman; small axillary mass).

TABLE 34-2 Benign Lipomatous Tumors of Skin and Soft Tissue

Hamartomas
Nevus lipomatosus cutaneous superficialis
Folded skin with lipomatous nevus
Congenital lipomatosis:
  Proteus syndrome
Benign neoplasms of white fat
  Homogeneous:
    Mature lipoma
  With heterogeneous mesenchymal elements:
    Fibrolipoma
    Myxolipoma
    Ossifying lipoma
    Angiolipoma
    Myolipoma
    Angiomyolipoma
  With specific clinicopathogenic settings:
    Perineural lipoma
    Lipoma of tendon sheath and synovium
    Multiple lipoma syndromes
    Adiposis dolorosa (Dercum's disease)
    Benign symmetric lipomatosis
    Familial multiple lipomatosis
  Pseudosarcomatous benign adipose tumors:
    Spindle cell lipoma
    Pleomorphic lipoma
    Chondroid lipoma
    Lipoblastoma and lipoblastomatosis
    Inter- and intramuscular lipoma
    Cervical symmetrical lipomatosis
    Pelvic lipomatosis
    Diffuse lipomatosis
Benign neoplasm of brown fat:
  Hibernoma

Histopathology. Inapparent at the gross level, angiolipomas microscopically show sharp encapsulation, numerous small-caliber vascular channels containing characteristic microthrombi, and variable amounts of mature adipose tissue (Fig. 34-12). These thrombi are well demonstrated by phosphotungstic acid–hematoxylin staining and are likely artifacts of removal because they show no organization. The degree of vascularity is quite variable, ranging from only a few small angiomatous foci to lesions with a predominance of dense vascular and stromal tissue (57). The angiomatous foci are composed in part of well-formed, dilated capillaries engorged with erythrocytes. Other capillaries appear tortuous and have poorly formed lumina and prominent proliferation of pericytes. Perivascular fibrosis may be prominent. Fat cells are sparse, and small vessels predominate in the cellular variant (60). With myxoid stroma, the term *angiomyxolipoma* (61) can be used. Scattered mast cells are expected. A normal karyotype implies hamartomatous pathogenesis.

Differential Diagnosis. Lesions with prominent perithelial fibrocytes may bring to mind spindle cell lipoma, which, however, lacks the conspicuous capillary channels with fibrin thrombi. Nearly all angiolipomas contain fibrin thrombi within their capillaries, often to a considerable degree. Cellular angiolipomas composed almost entirely of vascular channels and prominent spindle cells are sometimes confused with Kaposi's sarcoma or angiosarcoma. Subcutaneous position, encapsulation, septation, small size, diminutive nonatypical endothelial cells, microthrombi, and clinical presentation in healthy individuals help to exclude a malignant diagnosis (62). The term *infiltrating angiolipoma*, as used by Dionne and Seemayer (63) and by Puig and associates (64), is synonymous with *intramuscular angioma* (65), a vascular tumor with copious mature fat that is not acknowledged in its name. Its vessels are larger, and this lesion has a significant recurrence rate.

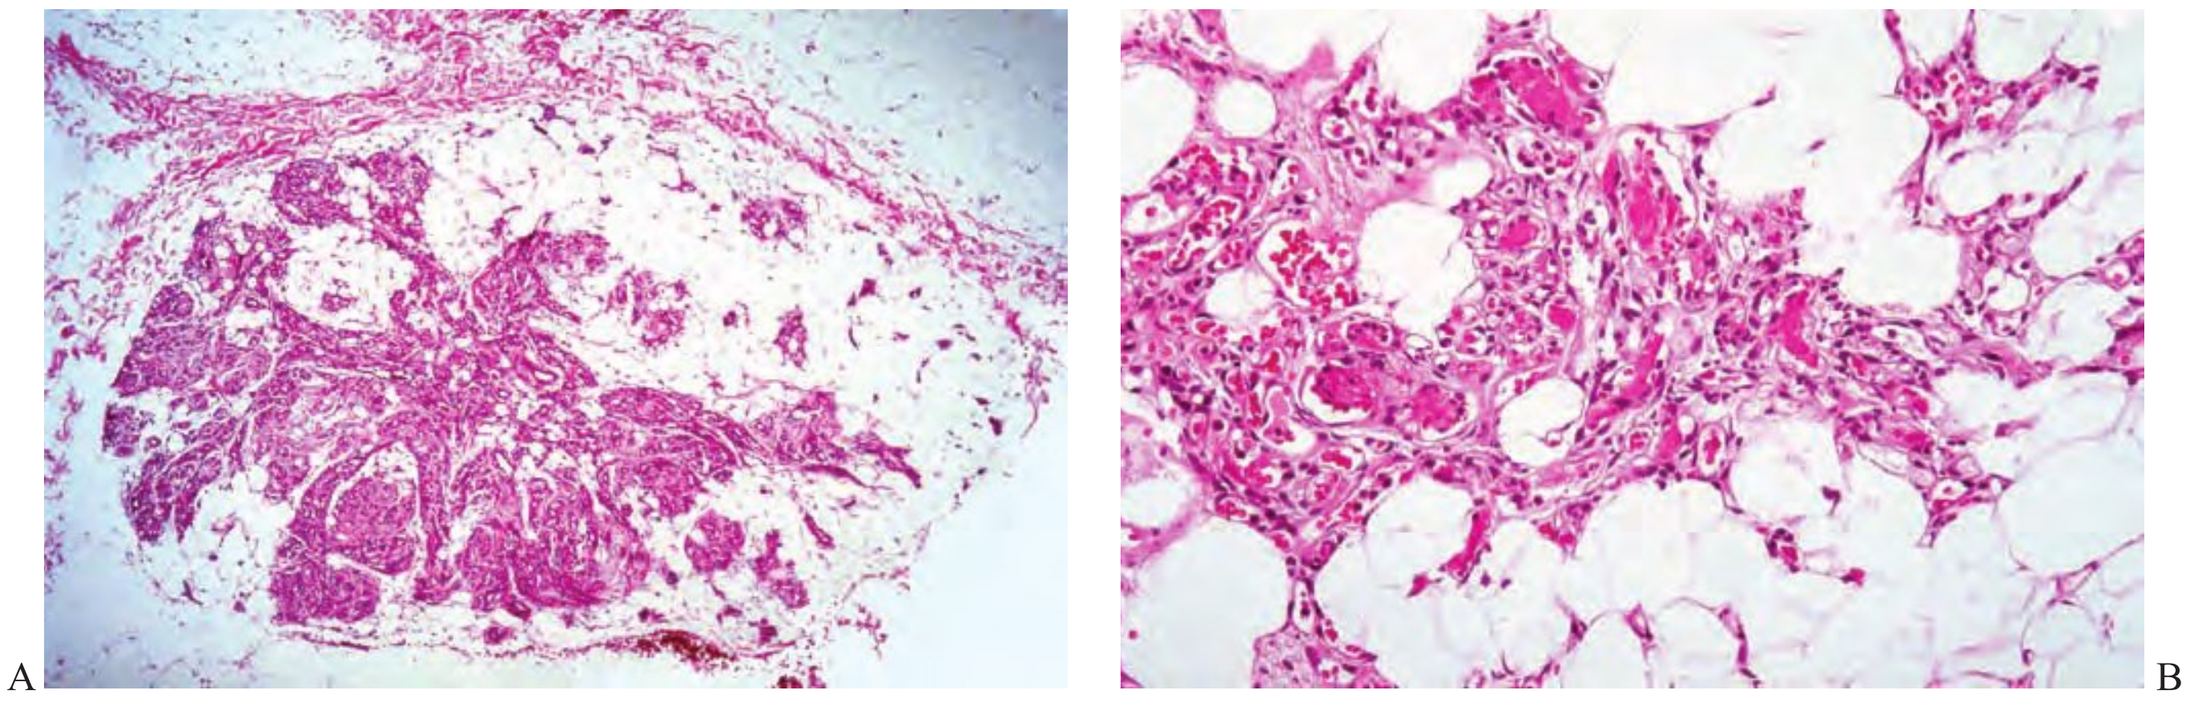

FIGURE 34-12. Angiolipoma. A: Prominent vessels radiate through a fibrous background into mature fat (incidental finding in a melanoma resection specimen). Prominent vascularity can impersonate a primary vascular neoplasm. B: At higher magnification, fibrin thrombi without organization occur in capillary lumina.

Nodular-cystic fat necrosis, also called *mobile encapsulated lipoma* (66), *encapsulated angiolipoma*, and *encapsulated necrosis*, can be shifted laterally, perhaps by several inches, and cause pain. They are most often in the subcutis of the elbow or hip. The pathogenesis seems to be ischemic changes secondary to trauma. They have no permanent attachment to a blood supply. Histologically, the fully developed lesions are thinly encapsulated, rounded nodules with well-preserved outlines of nonnucleated adipocytes devoid of inflammation or saponification but may calcify. Diffuse formation of pseudomembranes may make diagnosis difficult, leading to consideration of a wide range of potential diagnostic possibilities. This entity should be distinguished histologically from lipoma, angiolipoma, alpha 1-antitrypsin deficiency-associated panniculitis, membranous fat necrosis, and pancreatic fat necrosis (67).

SPINDLE CELL LIPOMA

A generally solitary, slowly growing subcutaneous tumor, spindle cell lipoma exhibits a predilection for the posterior neck and shoulder girdle region in men in their fifth to seventh decades. Clinically, the tumor is a slowly growing, painless nodule centered in the dermis or subcutis and measuring from 1 to 13 cm and potentially "massive" (68). This tumor does not recur or metastasize. Cytogenetics finds monosomy 16 or partial loss of 16q, a difference from liposarcoma (69). Abnormalities of chromosome 13 are reported (70).

Histopathology. Although the lesion is well circumscribed, it is seldom encapsulated. It is comprised of mature fat cells and uniform, slender spindle cells within a mucinous matrix (71). Spindle cell lipoma is polymorphous as a result of variations in cellularity, collagen content, and the ratio of spindle cells to mature adipocytes. In some areas, the neoplasm consists of a pure spindle cell population, often arranged in thick bundles, without fat cells. In other areas, the spindle cells are intermingled with scattered groups of mature fat cells (Fig. 34-13). The spindle cells, functioning as fibroblasts, produce varying amounts of collagen. If abundant, the diagnosis is fibrous spindle cell lipoma (72). Numerous mast cells are scattered throughout the tumor. Some tumors also show a prominent admixture of blood vessels ranging from capillaries to thick-walled vessels containing smooth muscle bundles to prominent sinusoidal channels that divide the tumor into irregular lobules. Irregular branching spaces between villiform, vascularized tumor projections constitute the *pseudoangiomatous* variant (73). Osseous or cartilaginous metaplasia is rare. The spindle cells are positive for CD34 and vimentin but not S-100. Some factor XIIIa–positive stromal cells are present. Ultrastructurally, they have abundant rough endoplasmic reticulum similar to fibroblasts and nonmembrane-bound lipid vacuoles (74). The cytogenetics parallels pleomorphic lipoma with loss of 16q material and less frequently 13q (75). A number of variants have been reported, including spindle cell lipoma with pseudoangiomatous change, composite spindle cell lipoma-hibernoma, and composite spindle cell lipoma/pleomorphic lipoma.

About 10% are the "low-fat" and "fat-free" spindle cell lipoma variants easily confused with nerve sheath tumors (76).

Differential Diagnosis. Nuclear palisading may be reminiscent of a neural tumor. Myxoid change and hypocellularity may bring myxoma to mind. A prominent hemangiopericytoma-like vascular pattern may be seen or a plexiform vascular pattern that may resemble myxoid liposarcoma. The diagnosis of liposarcoma or fibrosarcoma can usually be excluded without difficulty because of the uniformity of the proliferated spindle cells and the absence of multivacuolated lipoblasts, nuclear atypia, or atypical mitotic figures in spindle cell lipoma (71). Larger unvacuolated cells with some atypia, with or without floret giant cells, constitute transitional features to pleomorphic lipoma. Consider also mammary type and extramammary myofibroblastoma and solitary fibrous tumor (77).

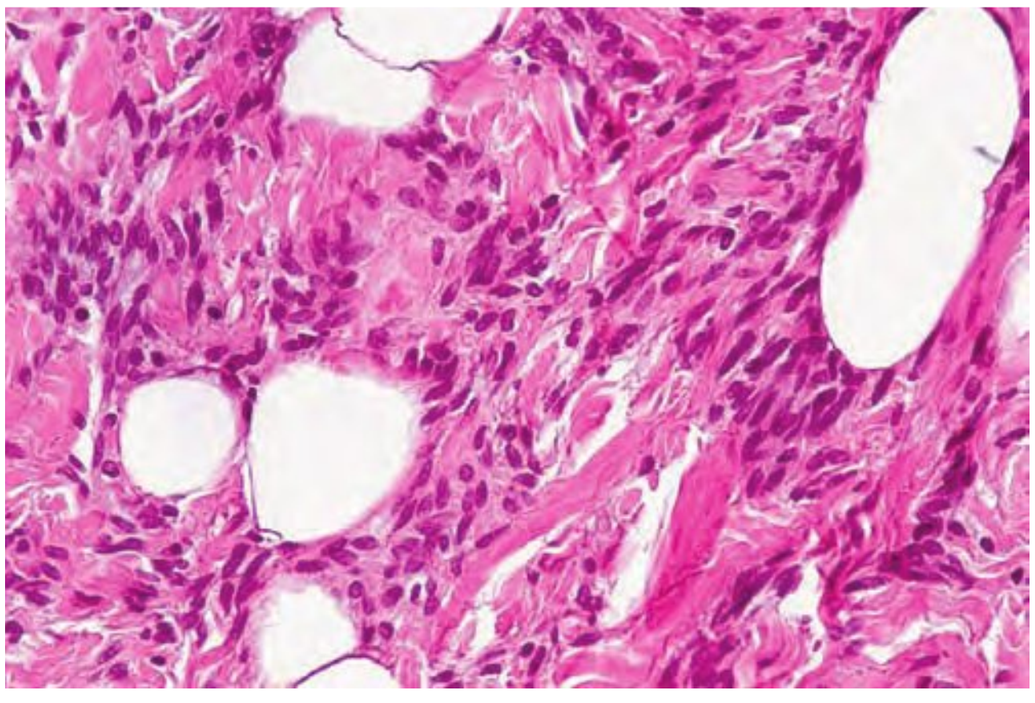

FIGURE 34-13. Spindle cell lipoma (62-year-old man; small back nodule). Uniform collagen-forming spindle cells expand the space between mature fat cells.

PLEOMORPHIC LIPOMA

Like spindle cell lipomas, the great majority of pleomorphic (giant cell) lipomas are solitary tumors of the shoulder girdle and neck in men in the fifth to seventh decade. The rare cutaneous spindle lipomas and pleomorphic lipomas, in contrast to subcutaneous forms, are more common in females and have a wider anatomic distribution (7). The lesion presents as a slowly growing, well-circumscribed dermal or subcutaneous mass averaging 5 cm, grossly resembling an ordinary lipoma (78) save for possible gelatinous gray areas on the cut surface. Like spindle cell lipoma, there is loss of chromosome 16q material (69).

Histopathology. The well-circumscribed tumor displays a wide morphologic spectrum. Although areas of mature fat cells are present, some of them show enlarged, hyperchromatic nuclei (79). In addition, most fat cells show marked variation in size. About half of the tumors contain occasional multivacuolated cells that have the appearance of lipoblasts (78). The mature and immature fat cells are situated singly and in groups in a

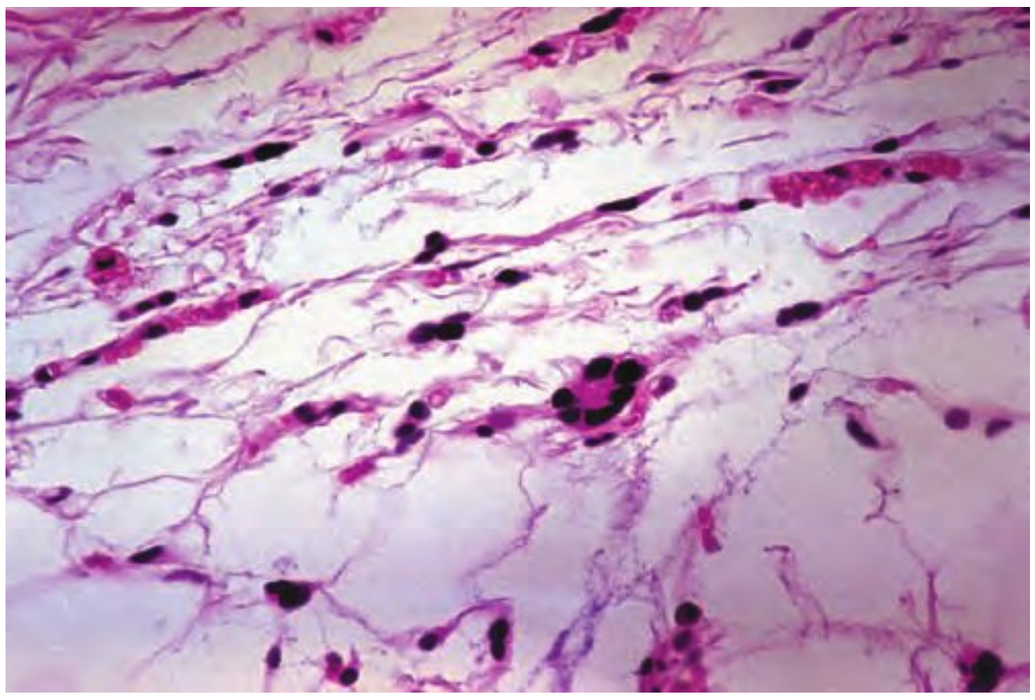

FIGURE 34-14. Pleomorphic lipoma with local regrowth (59-year-old man; interscapular local regrowth that had regained its original size of 9 cm 8 years after initial surgery). A characteristic floret-type giant cell with multiple peripherally placed nuclei and deeply eosinophilic cytoplasm is near center.

mucinous stroma traversed by dense collagen bundles. Pseudopapillary structures as in the pseudoangiomatous spindle cell lipoma may be seen (80). A very helpful feature in the diagnosis of pleomorphic lipoma is the presence of characteristic multinucleated giant cells, which are found in most but not all cases (79). These giant cells exhibit, within an eosinophilic cytoplasm, multiple, marginally placed, and often overlapping hyperchromatic nuclei. This peculiar arrangement is not unlike that of the petals of a small flower, and these giant cells are therefore referred to as *floret-type giant cells* (78) (Fig. 34-14). Rarely, pleomorphic lipoma histology comprises a sharply demarcated nodule within an otherwise ordinary lipoma. Also, small foci of spindle cell lipoma may be encountered in some pleomorphic lipomas (78). Some pleomorphic lipomas have inflammatory cells, including lymphocytes, plasma cells, mast cells, and occasional histiocytes in a perivascular or diffuse stromal distribution. Mitoses are rare.

Differential Diagnosis. Pleomorphic lipoma microscopically may resemble a liposarcoma (81). However, it is a slow-growing and well-circumscribed lesion with a benign behavior. Despite occasional lipoblast-like cells and atypical mitotic figures, local excision should be curative. No single feature confirms the diagnosis of pleomorphic lipoma and excludes liposarcoma. Only a multivariate analysis leads to the correct diagnosis, and such an analysis should consider the age and sex of the patient, anatomic location, size, epicenter of growth (deep or superficial), degree of local invasion, and histologic appearance. Liposarcomas differ from pleomorphic lipomas by their infiltrative growth, greater cellularity, more nuclear atypicality including atypical mitoses, more numerous multivacuolated lipoblasts, prominent necrosis, and absence of thick collagen bundles. Floret-type giant cells are rarely seen in liposarcomas and then only in small numbers (78).

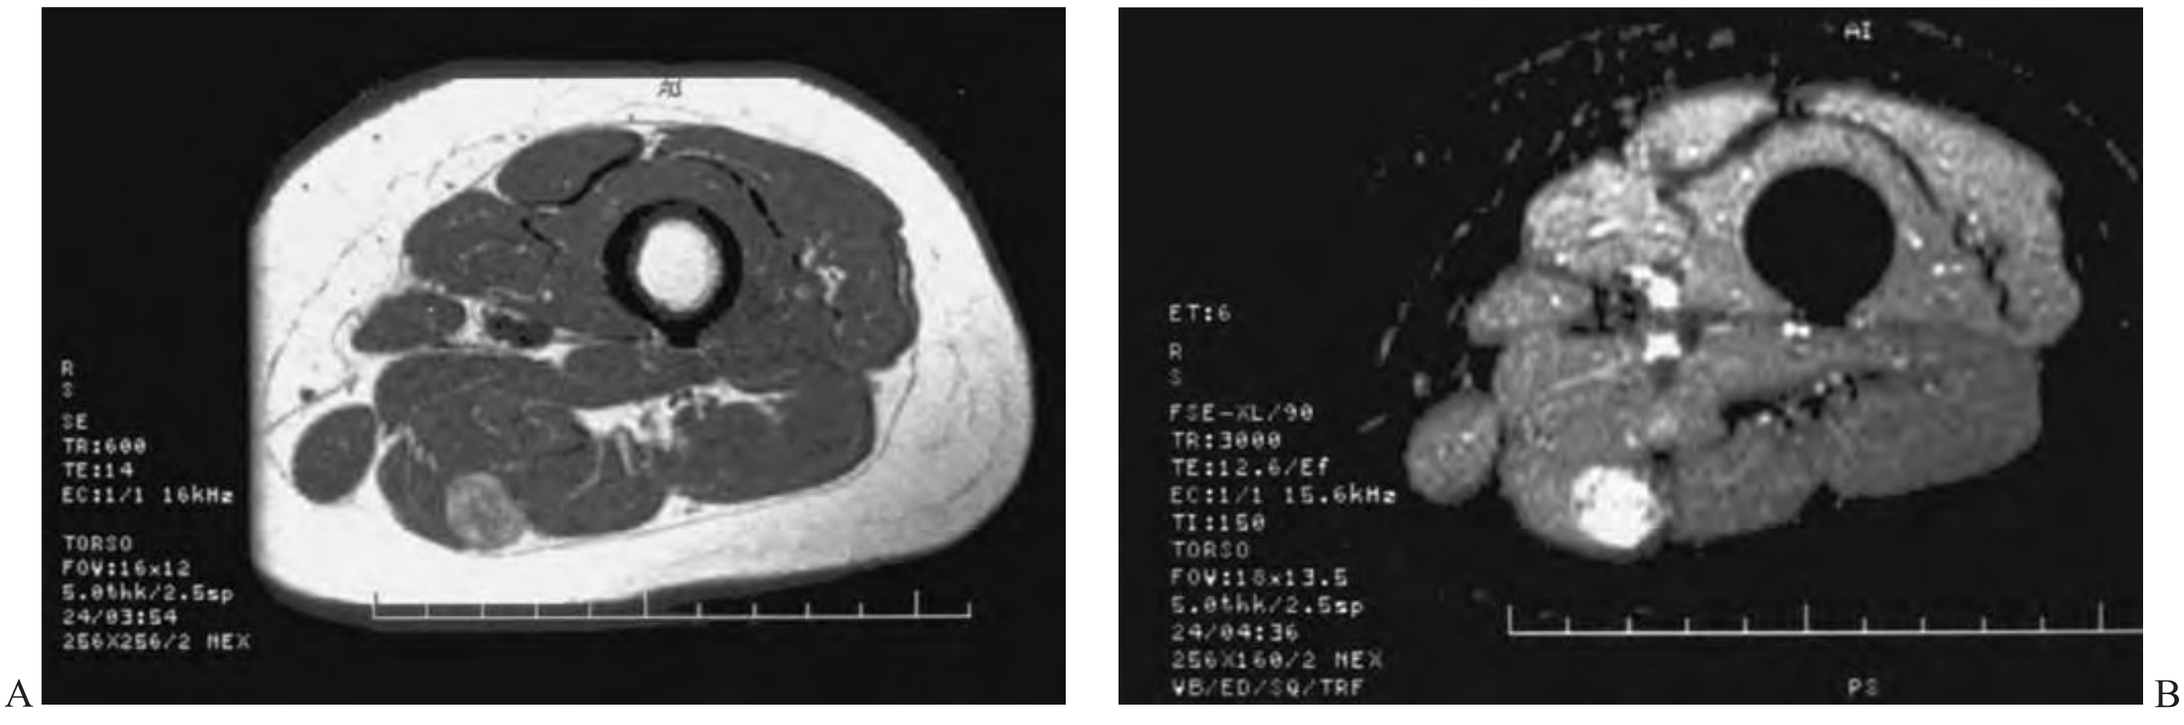
CHONDROID LIPOMA

Chondroid lipoma is an uncommon firm, yellow tumor, averaging 3 to 5 cm, generally encountered in adults, comprised of vacuolated fat cells similar to brown fat in a chondromucinous stroma. Based on 20 cases (82), the age range is 14 to 70 years, with a 4:1 female predominance and predilection for the limbs and limb girdles. These nonpainful masses of weeks' or years' duration range from 1.5 to 11.0 cm in diameter, with a median of 4.0 cm. Perhaps half of these well-demarcated, encapsulated, yellow-to-white or gray-tan masses are in the subcutis or involve the superficial fascia of the skeletal muscle (Fig. 34-15A, B). The remainder are more deeply situated, possibly within muscles. The lower extremity is the most common location. This lesion, almost invariably mistaken for a sarcoma, especially myxoid liposarcoma or myxoid chondrosarcoma, is nonaggressive and has a benign clinical course without local regrowth or metastases in the original 12 cases with follow-up (82). A three-way translocation between chromosomes 1, 2, and 5 together with an 11;16 translocation with a breakpoint in 11q13 is reported (83).

Histopathology. In chondroid lipoma, a variable background of mature adipose tissue is associated with a predominant, partially fibrinous to hyalinized myxoid matrix (Fig. 34-15C). Within this matrix are nests, strands, and sheets of eosinophilic and vacuolated cells, which contain glycogen and fat droplets, resembling brown fat cells, lipoblasts, and chondroblasts. The eosinophilic cells frequently contain one or several clear lipid vacuoles and an appearance similar or indistinguishable from lipoblasts. Vacuolated cell forms (hibernoma-like cells) simulate lipoblasts or chondroblasts. These cells lack pleomorphism and mitoses and adopt a lacunar appearance when surrounded by the prominent myxoid or hyalin matrix (Fig. 34-15D). The characteristic reaction panel is positivity for S-100 protein, CD68, and KP1. Chondroid lipoma can be diagnosed by fine-needle aspiration biopsy (84), but more confidently in cell block sections where immunochemistry and special stains can be brought to bear (85). The sulfated stroma is strongly metachromatic with toluidine blue at pH 4.0, Alcian blue positive, hyaluronidase resistant, and aldehyde fuchsin positive at pH 1.7.

Differential Diagnosis. The differential diagnosis includes primarily extraskeletal myxoid chondrosarcoma (where myxoid matrix obscures the mature fatty component), soft tissue chondroma (mainly hands and feet), myxoid liposarcoma, hyaline variant of chondroid syringoma, and occasionally myoepithelial tumors. The plexiform, capillary-like vasculature and myxoid matrix allow recognition of myxoid liposarcoma (82).

Pathogenesis. Electron microscopy reveals that the tumor cells have abundant intracytoplasmic lipid and glycogen as well as numerous pinocytotic vesicles characteristic of adipocytes rather than chondroblasts. This favors the view that chondroid lipoma is a tumor of pure white adipocytes with a hyalinized extracellular matrix that resembles cartilage under light microscopy (86).



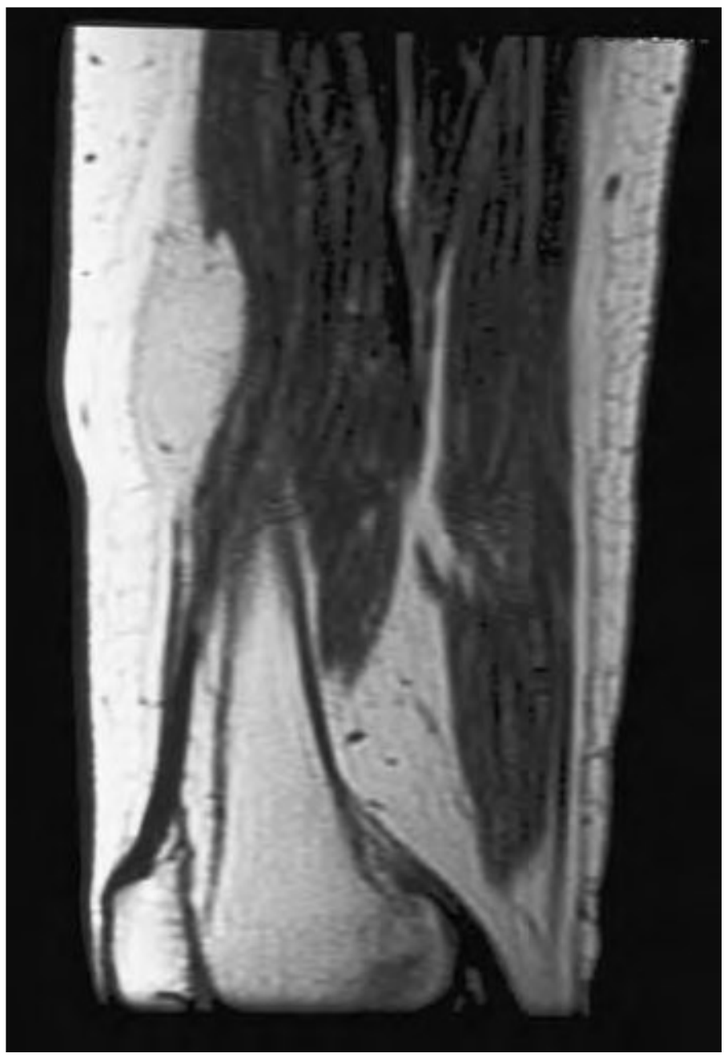


FIGURE 34-15. Chondroid lipoma (60-year-old woman; 6-month history of posterior leg nodule). A: A T1-weighted MRI of proximal thigh reveals a well-demarcated intramuscular mass with areas of high and low to intermediate signal consistent with fat. B: In a short tau inversion recovery (STIR) image, the foci of high T1 signal suppress, indicating fat. The bulk has high signal consistent with increased water content (myxoid) and cartilage. C: Chondroid lipoma is a lobular, well-circumscribed tumor comprised of strands and nests of rounded or polygonal eosinophilic cells in a stroma of mature fat, myxoid and chondroid material, and partly hyalinized fibrous tissue. D: The eosinophilic tumor cells have lipid vacuoles and grossly simulate lipoblasts. They contain neutral fat and glycogen and stain positively with oil red O and PAS stains. They are positive for vimentin and S-100 protein.

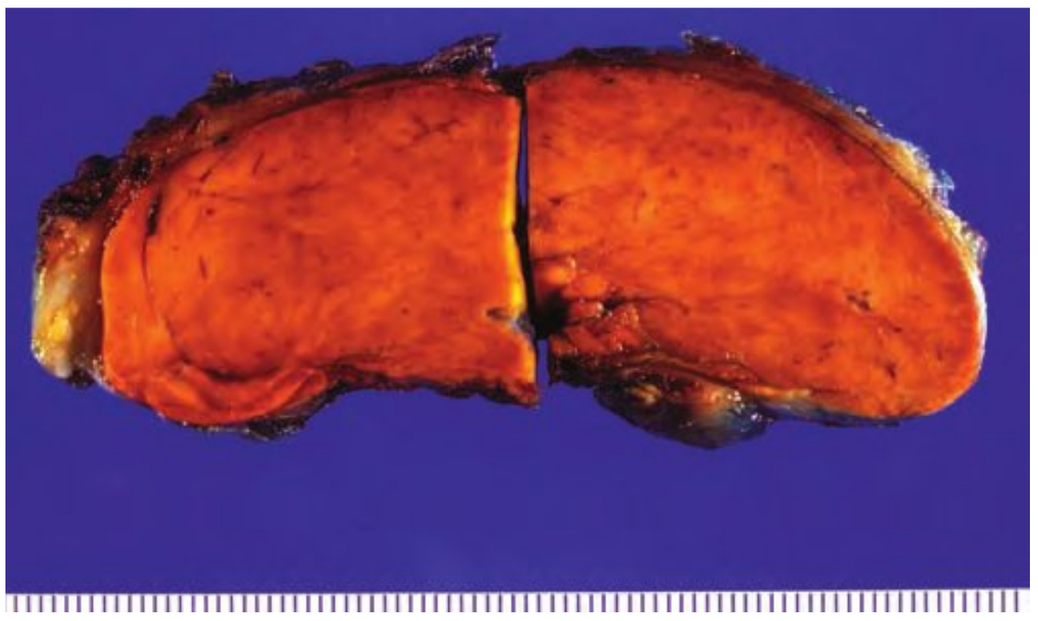
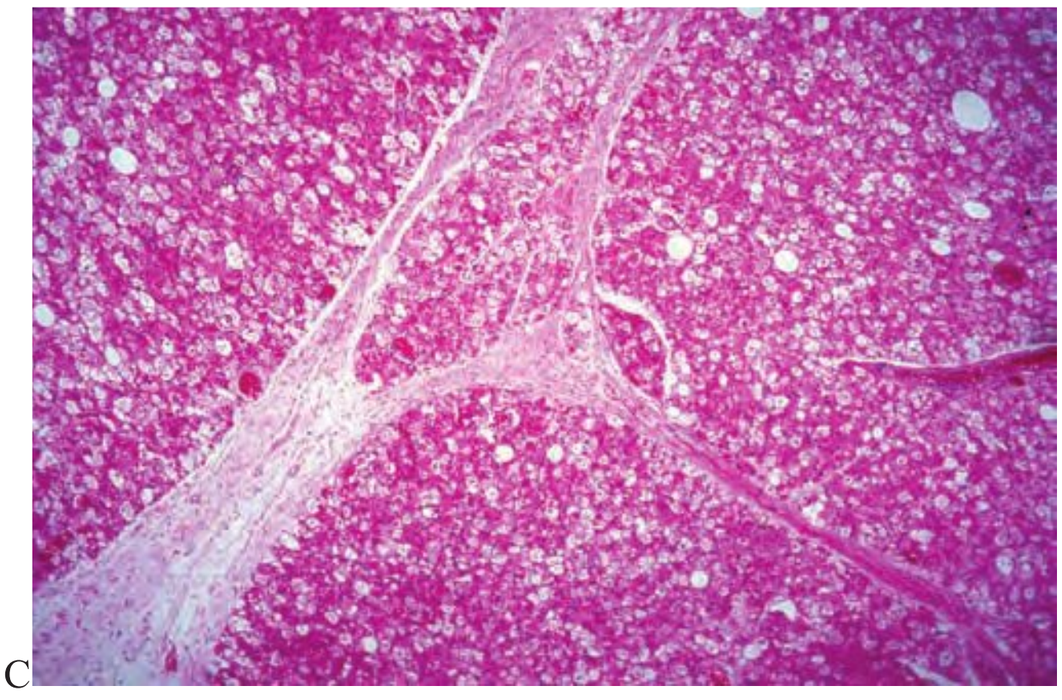
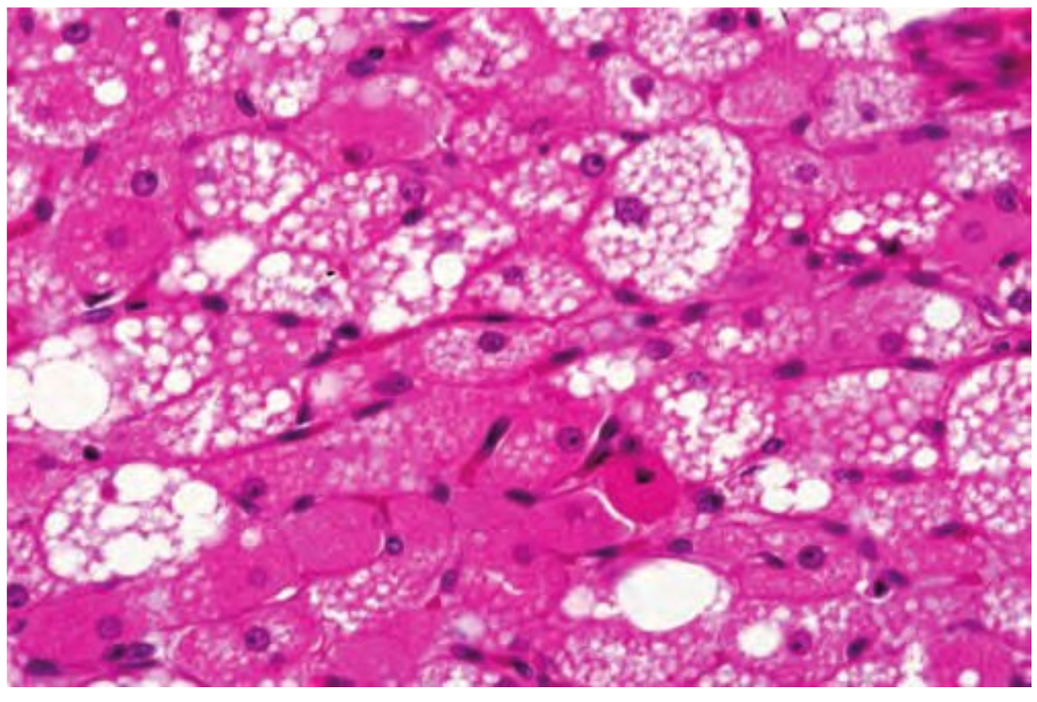


Another view is that the cells have features of embryonal fat and embryonal cartilage (87). Female predominance raises the possibility of hormonal factors in pathogenesis (82).

HIBERNOMA



Hibernomas may appear in childhood and slowly increase in size but occur chiefly in adults, with a peak incidence during the third decade of life—on average, considerably younger than those with ordinary (mature) lipoma. This rare tumor arises most frequently at the few sites in which brown fat is encountered in adults—for example, in the subcutis of the shoulder girdle, posterior neck, axilla (88), and mediastinum (89). Vestigial remnants of brown adipose tissue are impugned (90). However, some hibernomas occur at rarer sites such as abdomen, retroperitoneum, thigh, popliteal fossa, neck, chest wall, inguinal area, larynx, parotid region, mammary, and intradural–extramedullary spinal. The tumor is rarely described in the dermatology literature because locations where a dermatologist would likely be consulted, such as pertaining to the scalp (91) or forehead (92), are virtually unique. Clinically, hibernomas are indistinguishable from common lipomas. They are slowly growing and painless, typically occurring in the subcutis or rarely in muscle, and often noted several years before excision. Although usually asymptomatic, they are occasionally tender. Overlying skin may have increased warmth (93). This benign, moderately firm, solitary, subcutaneous, tan or red-brown tumor is generally from 5 to 10 cm in diameter, although examples up to 20 cm have been reported. The MRI finding of a lesion that is diffusely slightly hypointense to surrounding subcutaneous fat should prompt consideration of hibernoma in the differential diagnosis (94) (Fig. 34-16A).



A

B

C

D

FIGURE 34-16. Hibernoma (69-year-old woman; 2- to 3-year history of slowly growing thigh mass). A: A longitudinal MRI of the thigh discloses a fusiform tumor between subcutaneous fat and muscle with less T1 signal than mature fat. B: The characteristic brown color of this hibernoma contrasts with the pale yellow color of attached pericapsular white fat on each end of it. It results from the prominent vascularity and many mitochondria in tumor cells. C: A low-magnification view displays the distinct lobular pattern characteristic of hibernoma. D: At higher magnification, hibernoma cells show varying degrees of complete modulation to signet-ring fat cells. These cells range from uniform round to oval granular eosinophilic cells to multivacuolated cells with multiple small oil red O–positive lipid droplets and centrally placed nuclei to intermixed univacuolar cells with one or more large lipid droplets and peripherally placed nuclei (lipocytes).

On gross cross-section, the well-circumscribed, somewhat lobulated mass varies from tan to a deep red-brown. The distinct brown color of the gross cut surface (Fig. 34-16B) is due to prominent vascularity and a profusion of mitochondria in the granular tumor cells. Adequate treatment consists of complete excision (91,95) sparing vital structures. Like lipomas, hibernomas have little tendency to recur locally after excision, although continued enlargement has been reported after 70% removal of an 11-cm infraclavicular tumor (96). A malignant counterpart of hibernoma (97) remains speculative. An intensely FDG-avid lesion on positron emission tomography/computed tomography (CT) examination can mimic a metastasis (e.g., melanoma) (98).

Histopathology. Histologic examination reveals that the tumor is divided into numerous lobules by well-vascularized connective tissue (Fig. 34-16C). In contrast to ordinary lipoma of white fat, the highly vascular nature of the tumor is readily

apparent in most sections. Hibernoma's constituent cells resemble those of brown fat tissue, which is present in the human fetus and newborn infants but gradually diminishes in quantity throughout adult life. The tumor cells are round or polygonal and are closely apposed to one another within the lobules (Fig. 34-16D). Three principal types of cells in varying proportions can be recognized (90): (a) a small cell (average, 37 μ) with granular, eosinophilic cytoplasm and with or without rare, multiple small oil red O–positive lipid droplets and centrally placed nuclei and distinct cellular membranes; (b) a larger, multivacuolated fat cell (average, 54 μ) with scanty granular, eosinophilic cytoplasm, referred to as a *mulberry cell*; and (c) a still larger, univacuolated fat cell (average, 64 μ) with peripherally placed nucleus, variably present and perhaps predominating, making distinction from ordinary lipoma difficult. The nuclei of the granular and multivacuolated cells are usually centrally located, and the nuclei of the univacuolated fat cells are peripheral. Cells of the three principal types, with transitional forms, usually are dispersed randomly throughout the lobules. In most tumors, multivacuolated mulberry cells predominate. Some tumors, however, contain a few lobules, particularly at their peripheries, that are composed entirely of univacuolated cells (90). The vacuoles in both the multivacuolated and univacuolated cells stain positively with Sudan black or oil red O. Nuclear pleomorphism or hyperchromatism and lobate nuclei are rarely seen (97), and mitoses are absent. Based on the nature of the stroma and the appearance of the multivacuolated cells, four categories of hibernomas are described: typical, lipoma-like, myxoid, and spindle cell. The myxoid variant is very rare (99).

Ultrastructure. Each tumor cell is invested by a basal lamina. There is an inverse relationship between lipid droplet size and the number of mitochondria per unit of cytoplasm that conspicuously lacks membrane systems. Pleomorphic mitochondria have dense matrices and transverse lamellar cristae, micropinocytotic vesicles, and periodic short plasmalemmal densities.

Pathogenesis. The term *hibernoma* reflects the fact that these tumors are composed of cells that resemble the brown fat of hibernating animals. The incomplete modulation of the mulberry cells may be attributable to underdevelopment of enzyme systems. Like many other benign lipomatous tumors, hibernoma has a characteristic cytogenetic abnormality, specifically, abnormalities of the long arm of chromosome 11 (11q13-21) (100) and 10q22 (101).

Differential Diagnosis. Rhabdomyoma and granular cell tumor should be thought of before diagnosing hibernoma. Immunohistochemically, rhabdomyomas are strongly positive for myogenic markers (desmin, actin, and myoglobin) but negative for S-100, while hibernoma and granular cell tumor strongly express S-100. Hibernomas are to be distinguished from granular cell tumors that have no lipid vacuoles and from myxoid and round cell liposarcoma, which usually contain diagnostic multivacuolar lipoblasts. The larger, univacuolated fat cell may predominate, making distinction from ordinary lipoma difficult.

LIPOFIBROMATOSIS

Lipofibromatosis is a rare pediatric neoplasm that has been variously interpreted as a type of infantile or juvenile fibromatosis, a variant of fibrous hamartoma of infancy, and a fibrosing lipoblastoma. Although it is likely that this tumor comprises part of the spectrum of what has been referred to in the literature as *infantile/juvenile fibromatosis*, its clinicopathologic features and, in particular, its distinctive tendency to contain fat as an integral component, warrant separate classification as a *lipofibromatosis*. Males predominate in a ratio of 2:1. The patients present with a soft tissue mass from 1 to 7 cm involving the hand, arm, leg, foot, trunk, or head that may be evident at birth. Histologically, the adipose tissue has a spindled fibroblastic element with focal fascicular growth, typically has limited mitotic activity, and chiefly involves the septa of fat and skeletal muscle, generally without extensive architectural effacement of fat as is common with conventional fibromatoses. The primitive nodular fibromyxoid component of fibrous hamartoma of infancy is absent. The fibroblastic element exhibits cytologic atypia and occasional mitoses. Small collections of univacuolated cells are often present at the interface between some of the fibroblastic fascicles and the mature adipocytes. The tumors entrap vessels, nerves, skin adnexa, and skeletal muscle. Focal immunoreactivity is present in some tumors for CD99, CD34, alpha-smooth muscle actin, and BCL-2 and, less frequently, S-100 protein, muscle actin (HUC 1-1), and EMA. However, no reactivity is detected for desmin (D33 and D-ER-1 clones), keratins, or CD57. Follow-up data for 25 individuals (median follow-up period, 6 years and 7 months) found regrowth of the tumor or persistent disease documented in 17 (72%), correlating with congenital onset, male sex, hand and foot location, incomplete excision, and mitotic activity in the fibroblastic element (102).

BENIGN LIPOBLASTOMA

Lipoblastoma and lipoblastomatosis (103) are rare benign neoplasms of fetal white fat that occur almost exclusively in infants and children (104) and typically as a stable or slowly to rapidly enlarging, asymptomatic soft lobular mass in the superficial or deep layers of soft tissue on the trunk or extremities, especially lower. Other sites of occurrence include the head, neck, retroperitoneum, trunk, back, extremities, heel (105), buttock, inguinal canal, scrotum, retroperitoneum, peritoneal cavity, and lung (106). In a child younger than 3 months of age, images showing a predominantly fatty but inhomogeneous soft tissue mass are suggestive of lipoblastoma (107). Two basic forms of benign lipoblastoma occur. The variant called *lipoblastomatosis* is deeply situated and poorly circumscribed, presenting as a superficial mass that extends from the subcutis

to the underlying muscle (108), mostly, but not entirely, of fat on MRI (109). Lipoblastoma is relatively superficial and encapsulated. Each form commonly presents as a painless nodule or mass, affecting boys twice as frequently as girls. Circumscribed lipoblastoma is more common than diffuse infiltrative lipoblastomatosis. Sizes range from 1 to >20 cm in greatest dimension. They may cause dysfunction of other organ systems due to mass effect. Lipoblastomas occurring on the back can have intraspinal extension (110). Complete resection is the only definitive treatment and should not be delayed when impingement on surrounding structures is imminent. These neoplasms have no malignant potential but have a tendency to recur despite presumed complete excision up to 25% of the time (111). Patients with diffuse lipoblastoma (lipoblastomatosis) are likely to have recurrent disease (usually within 2 years) and should undergo close follow-up (112) for a minimum of 5 years. Cellular maturation has been reported in serial biopsies over time. A "wait and see" approach may be justified, at least in infants with huge invasive lesions requiring a mutilating excision, since complete spontaneous resolution of a diffuse lipoblastoma in the thigh has been shown in a 2-day-old male at 1 year by MRI (113).

Histopathology. Peripheral immature lipoblasts with fat vacuoles of various sizes and central mature fat cells containing single, large fat vacuoles are characteristic (Fig. 34-17) whether the tumor is deeply or superficially situated. The lipoblasts vary in size. Most of them contain single vacuoles that are variable in size but smaller than those found in mature fat cells. These vacuoles displace the nuclei against the cytoplasmic membrane. A few small lipoblasts contain two, three, or occasionally more vacuoles. Some benign lipoblastomas also show lipoblasts with finely vacuolar cytoplasm and centrally placed nuclei resembling hibernoma cells. Nonvacuolated cells that are spindle shaped or stellate are observed in the mucinous stroma with a fine vascular network that is strikingly similar to myxoid liposarcoma and from which it may be indistinguishable. Fibrous septa partition lobules in the circumscribed form.

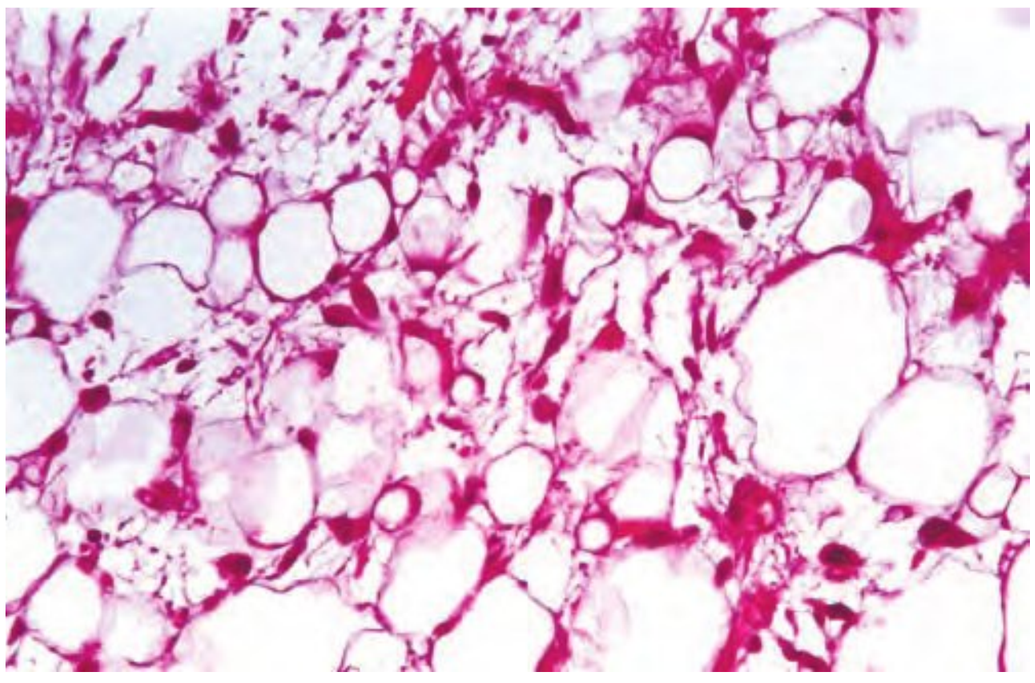


FIGURE 34-17. Lipoblastomatosis. The tumor is comprised of partly differentiated lipoblasts and has a prominent capillary vascular pattern with areas of mucoid matrix. Cells with large hyperchromatic nuclei are absent.

Differential Diagnosis. Only the age of the patient, the abundance of lipoblasts, the absence of atypical mitoses, and a sometimes subtle lobularity distinguish it from liposarcoma—especially the myxoid type (103). Although liposarcomas occur very rarely in infants and young children, the distinction may be impossible by light microscopy alone. Therefore, when performing a biopsy of a childhood adipose tumor with unusual features, such as progressive or invasive growth, fresh tissue should be submitted for cell culture. The tumor karyotype will in most cases aid in differentiating lipoblastoma from myxoid liposarcoma (114). Rearrangements of chromosome 8 q11-q13 region leading to rearrangement of the PLAG1 gene are a discriminative marker that distinguishes lipoblastoma and lipoblastomatosis from myxoid liposarcoma (104). Fluorescent *in situ* hybridization can serve as a decisive tool in the differential diagnosis of lipoblastoma and lipoma-like liposarcoma apart from its role in the distinction between lipoblastomas and myxoid/round cell liposarcoma (115). Confusion with typical lipoma may occur. In fact, lipoblastoma's early occurrence, its ability to mature into a simple lipoma, its cellular composition of mainly mature adipocytes, and its benign course suggest that it may more accurately be termed an *infantile lipoma* (116).

LIPOSARCOMA

Liposarcomas, constituting 15% to 20% of all soft tissue sarcomas, are generally deep-seated tumors most likely in the retroperitoneum or the deep soft tissues in or below buttocks (117). Most commonly, they originate in the intermuscular fascial planes, with a special predilection for the thighs (118). From a fascial plane, they can extend to subcutaneous tissue. Liposarcomas are slightly more prevalent in males and tend to occur on the right side of the body more commonly than on the left. Infrequently, liposarcomas may be multicentric. Liposarcoma can occur in subcutaneous location and rarely in dermis. As with most other dermal sarcomas, local recurrence is a more frequent problem than distant metastases (119).

Liposarcomas arise as such and for practical purposes do not develop from lipomas. The average age of onset is 50 years. Occasionally, liposarcomas arise in children from 10 to 15 years of age, comprising 4% of childhood soft tissue sarcomas (120) but are exceedingly rare, if not nonexistent, in children younger than 10 years (121).

The morphologic classification of liposarcoma is into three main groups: (a) well-differentiated liposarcoma (including adipocytic or "lipoma-like," sclerosing, inflammatory, spindle cell, and their dedifferentiated variants), characterized by ring or long marker chromosomes derived from the long arm of chromosome 12; (b) myxoid and round cell (poorly differentiated myxoid) liposarcoma, characterized in most cases by a reciprocal translocation t(12;16)(q13;p11); and (c) pleo-

morphic liposarcoma, characterized by complex karyotypes (liposarcoma) (122). In some tumors, more than one type can be recognized. The well-differentiated and myxoid types have better prognoses than the round cell and pleomorphic types. Myxoid variants are more common in the young, whereas well-differentiated and pleomorphic subtypes are more often encountered in older patients.

Well-differentiated liposarcomas are low grade and may regrow locally but do not metastasize. The clinical outcome of well-differentiated lipoma-like liposarcoma is best predicted by anatomic location (123). In the subcutis, they are usually cured by local excision, rarely regrow, and do not metastasize. Therefore, the term *atypical lipoma* was been introduced for the subcutaneous form of well-differentiated liposarcoma (79). Great debate has been generated by the introduction of that term, with most now agreeing that well-differentiated liposarcoma and atypical lipoma should be considered synonyms that describe lesions identical both morphologically and karyotypically (122). This is the form of liposarcoma most likely to be biopsied by the dermatologist. Because of this benign course, Evans (124) later suggested an even less committal designation for this neoplasm, *atypical lipomatous tumor*. It has been recommended that this term be restricted to subcutaneous tumors, especially those of small size with minimal atypical changes, and the term *well-differentiated liposarcoma* for the same histology at other sites (125).

For the more aggressive liposarcomas, circumscription of the lesion may offer false hope of eradication by simply shelling out the tumor. In reality, liposarcomas extend microscopic pseudopod-like extensions that commonly insinuate between fascial planes. Occasionally, small satellite nodules become separated from the lobulated sarcomatous mass, leading to an erroneous impression of multicentricity. Biopsy and resection should be carefully planned, guided by MRI and radiographic findings in a manner that eliminates prior biopsy tracts and any plane potentially contaminated by surgical exposure or spreading hematoma. The depth of atypical and malignant neoplasms showing lipomatous differentiation correlates with the tendency for local recurrence that is especially uncommon in subcutaneous location (123). Metastases are common, especially in round cell and pleomorphic liposarcomas where increased numbers of mitoses, in either in the primary tumor or a local recurrence, predict metastases (123). The lungs and liver are the most common sites. Myxoid and round cell liposarcoma sarcoma have marked propensity to involve intra-abdominal sites, other soft tissue areas (especially the neck), and bone. Therefore, abdominal CT and bone scan are recommended in the initial evaluation as well as follow-up of high-risk patients with larger, locally recurrent or high-grade tumors of any size (117). Myxoid liposarcoma metastasizes preferentially to serosal surfaces (e.g., pleura, pericardium, pelvic sidewall). If found in a trunk biopsy, an occult primary tumor in an extremity should be sought (126).

Histopathology. Liposarcoma is diagnosed only when there is convincing evidence of synthesis and storage of fat by the tumor cells (117), the hallmark of which is the lipoblast. For a cell to be designated as a lipoblast, it must show the ability to synthesize and accumulate nonmembrane-bound lipid in the cytoplasmic matrix. Acceptable malignant lipoblasts are quite variable, because they may recapitulate any stage in the normal maturation sequence. Their common morphologic denominator is well-demarcated cytoplasmic lipid that displaces or indents one or more irregular hyperchromatic nuclei. The nucleus conforms to the contours of the lipid droplet, creating an apparent delicate scalloping of the nuclear membrane. Hyperchromaticity and variability from lipoblast to lipoblast support a malignant diagnosis. Despite these criteria, the distinction between malignant lipoblast and "atypical lipocyte" is at times subjective, especially in the more well-differentiated lipoma-like variants of liposarcoma. A "true" lipoblast is defined not only by a multivacuolated or univacuolated fat cell with indented or scalloped nucleus but also by its histologic context (82). Benign fat necrosis, myxoid changes in structural fat, lipogranulomas, lymphomas with signet-ring changes, and carcinomas can contain vacuolated cells that mimic lipoblasts. Lesions such as pleomorphic lipomas and lipoblastomas illustrate that even unequivocal lipoblasts do not always signal malignancy.

The cells of liposarcoma bear a close resemblance to different stages in the development of fat and are found in variable proportions as a function of histologic subtype but show a much greater individual variability.

In *well-differentiated lipoma-like liposarcoma*, the tumor is composed predominantly of univacuolated fat cells of various sizes. The nuclei of the fat cells are slightly pleomorphic, and some of them are hyperchromatic.

Well-differentiated liposarcoma (*atypical lipoma*) histologically features distended fat cells that vary slightly in size and shape, with occasional interspersed lipoblasts. Broad, fibrous septa containing cells with enlarged hyperchromatic atypical nuclei are a characteristic feature (Fig. 34-18). Foci of well-differentiated smooth muscle may be found but do not influence the behavior (127). The emergence of a high-grade sarcoma pattern within a well-differentiated liposarcoma or in recurrence is known by the biologically imprecise term *dedifferentiation* and is limited for practical purposes to these tumors when they are located in body spaces, especially the retroperitoneum (128).

Spindle cell liposarcoma represents an uncommon variant of well-differentiated liposarcoma that tends to recur locally and may "dedifferentiate". Morphologically, it is composed of a fairly bland neural-like spindle cell proliferation set in a fibrous and/or myxoid background and is associated with an atypical lipomatous component (122).

Myxoid liposarcoma (Fig. 34-19) is the most common type of liposarcoma and displays various quantities of four elements: (a) proliferating lipoblasts, (b) delicate plexiform capillaries, (c) myxoid matrix, and (d) acid mucopolysaccharide lakes (Fig. 35-19A). Mitotic figures are conspicuously absent. These tumors have been subdivided into a well-differentiated type with little tendency to metastasize and a poorly differentiated type that commonly metastasizes (118). A well-differentiated myxoid liposarcoma contains, in addition to lipoblasts with spindle-shaped nuclei and several lipid vacuoles, more highly differenti-

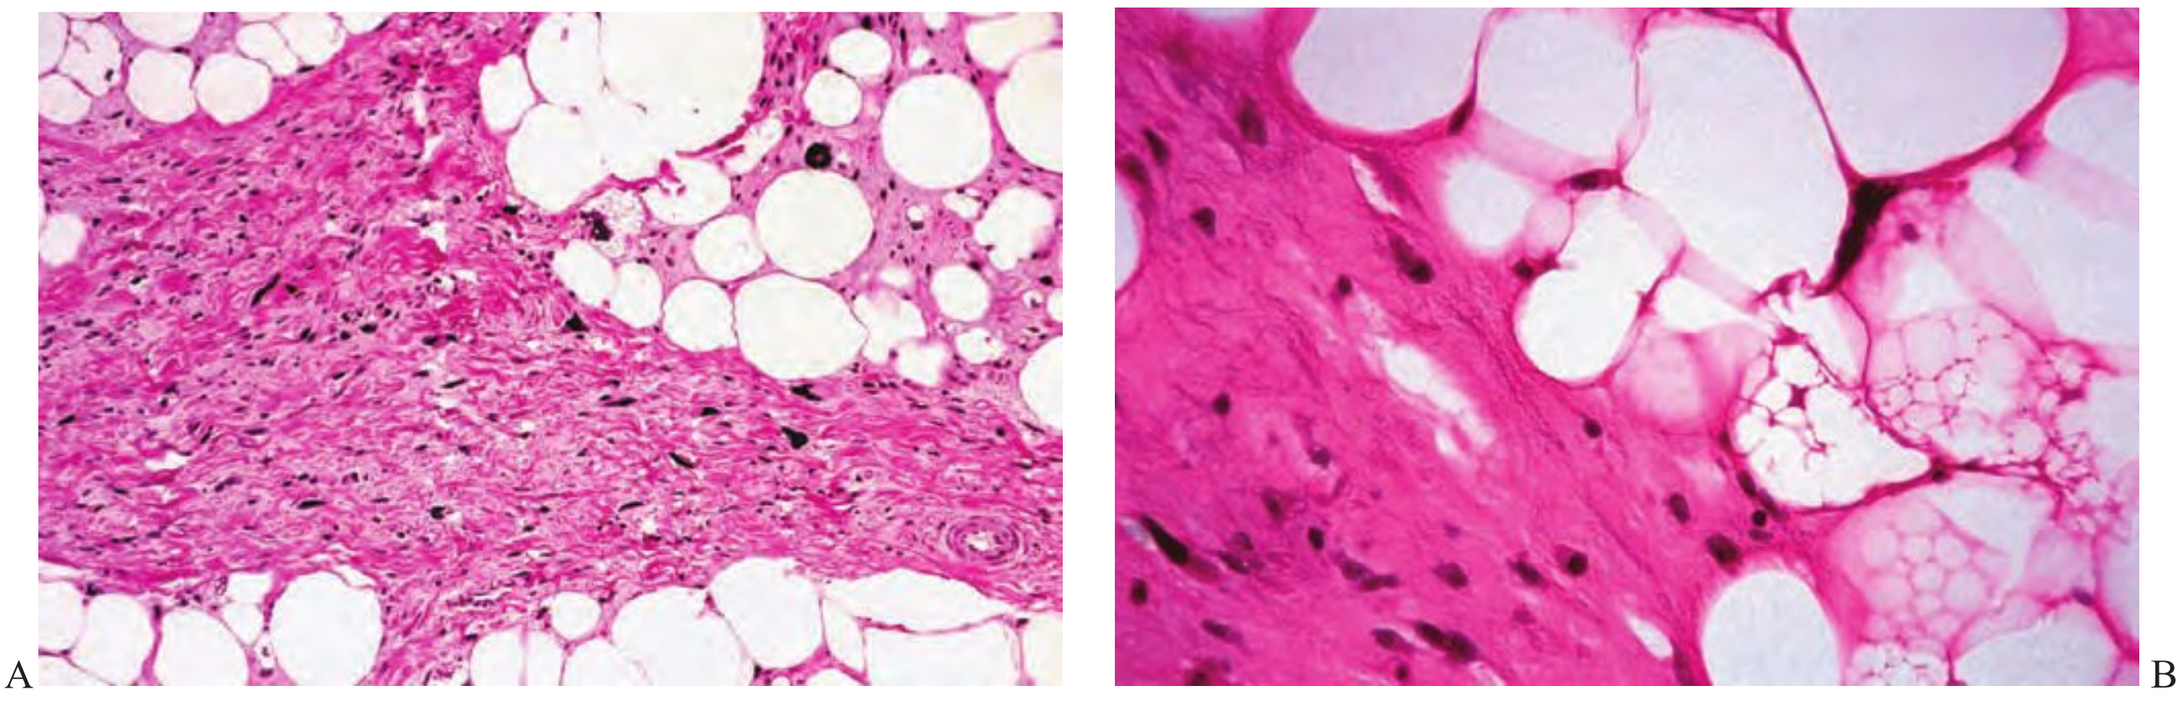

FIGURE 34-18. Well-differentiated lipoma-like liposarcoma (atypical lipoma). A: A broad, fibrous septum containing cells with atypical hyperchromatic nuclei partitions a tumor of fat-filled rounded cells, some of which are lipoblasts. (Courtesy of Andrew E. Rosenberg.) B: A higher magnification shows hyperchromatic nuclei in the fibrous septum and a dark-staining triangular lipoblast nucleus in adjacent fat (compare with Fig. 34-4). Prolonged searching may be required to find enlarged, irregular, hyperchromatic nuclei (some indented by clear lipid vacuoles) in atypical lipoma.

ated fat cells, such as so-called *signet-ring* cells (Fig. 35-19B), which have single large vacuoles occupying a major portion of the cytoplasm, and even mature fat cells. The tumor cells are arranged loosely in a myxoid stroma. In a poorly differentiated myxoid liposarcoma, the spindle-shaped lipoblasts have large, atypical nuclei and usually only small numbers of lipid droplets. Depending on the amount of myxoid stroma, there is considerable resemblance to either a myxosarcoma or an undifferentiated fibrosarcoma, because the latter may also have a certain amount of myxoid stroma.

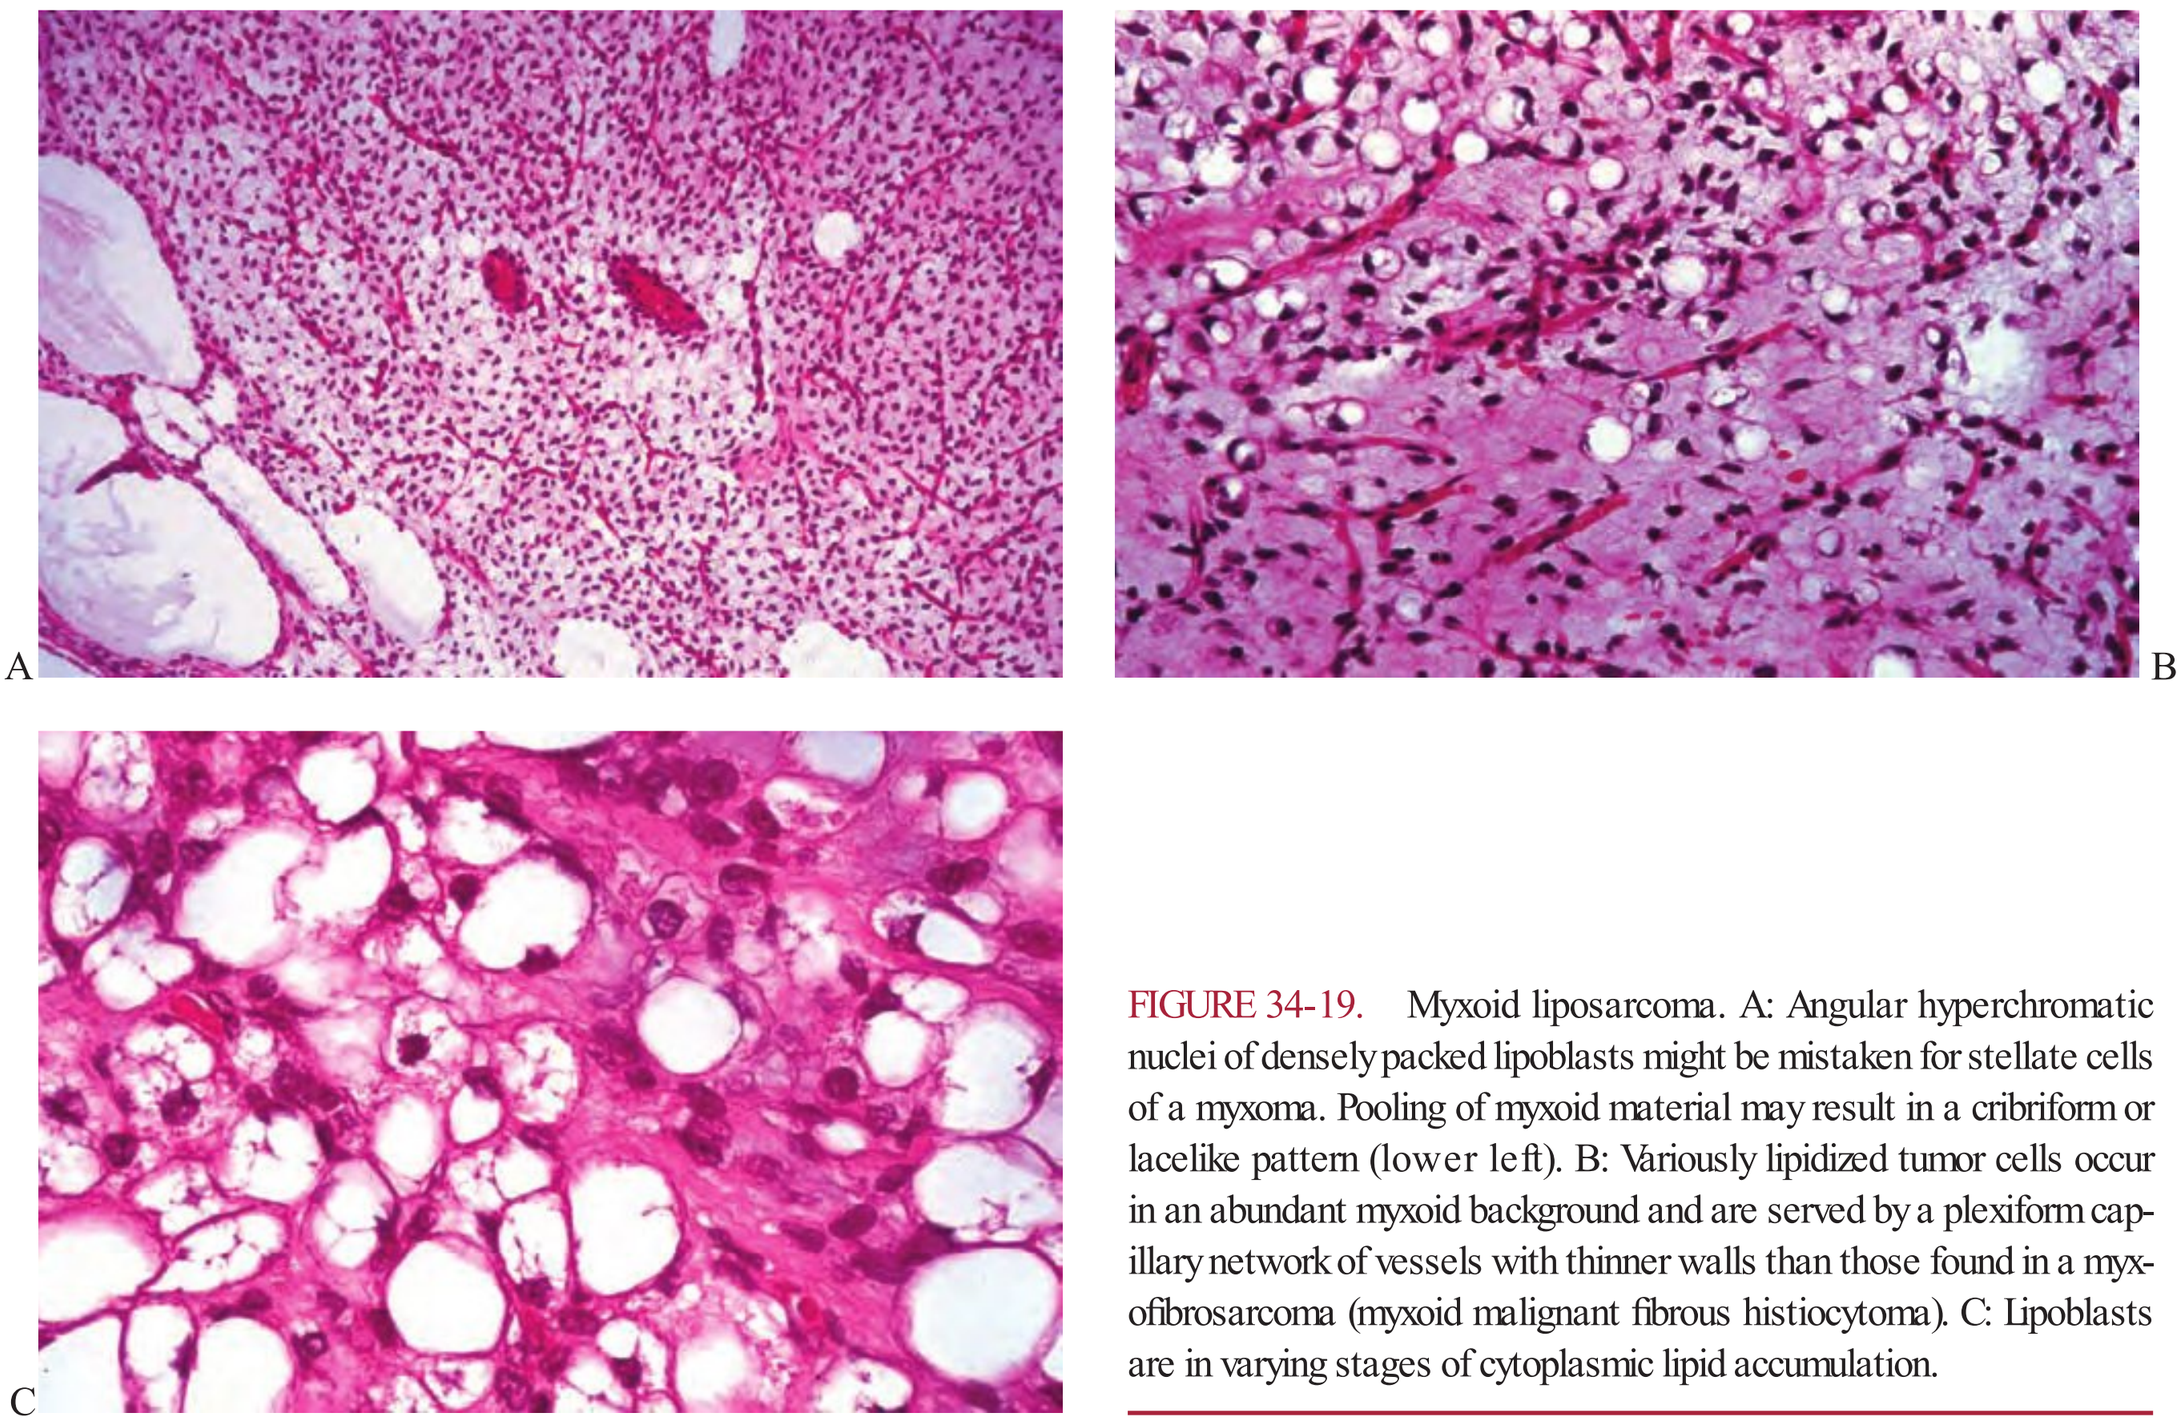

FIGURE 34-19. Myxoid liposarcoma. A: Angular hyperchromatic nuclei of densely packed lipoblasts might be mistaken for stellate cells of a myxoma. Pooling of myxoid material may result in a cribriform or lacelike pattern (lower left). B: Variously lipidized tumor cells occur in an abundant myxoid background and are served by a plexiform capillary network of vessels with thinner walls than those found in a myxofibrosarcoma (myxoid malignant fibrous histiocytoma). C: Lipoblasts are in varying stages of cytoplasmic lipid accumulation.

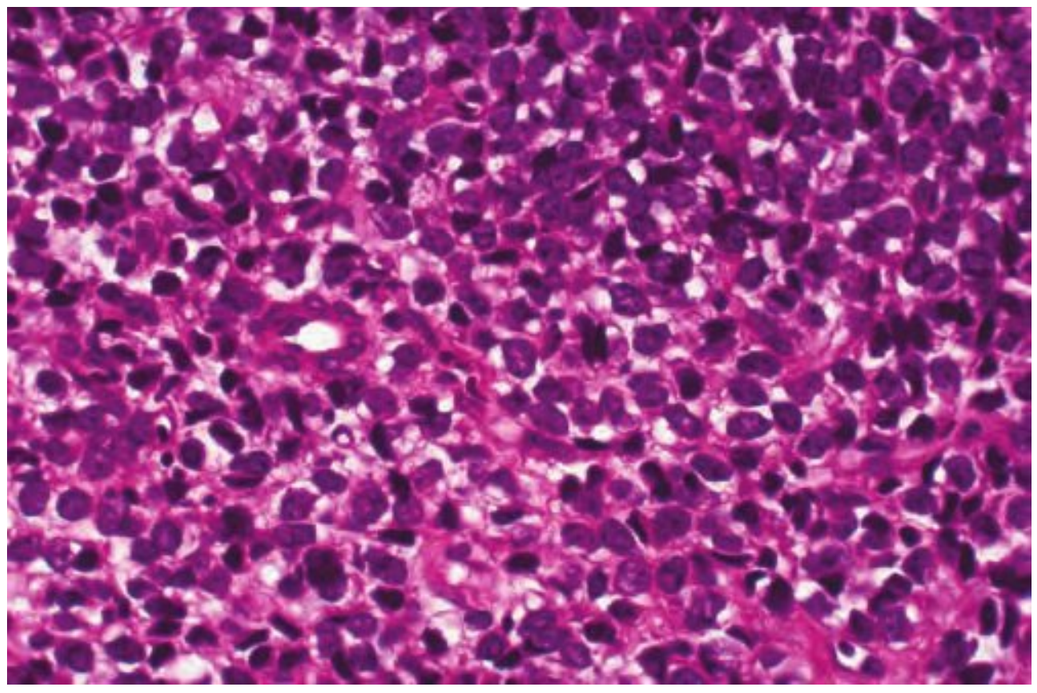

FIGURE 34-20. Round cell liposarcoma. Small, dark-staining tumor cells have little or no lipid accumulation. Because glycogen is involved in lipogenesis, these cells are PAS positive, and this should not be taken as evidence for Ewing's sarcoma.

Because of the more aggressive behavior of *round cell liposarcoma*, accurate diagnosis is important. As indicated by its name, round cell liposarcoma is characterized by an excessive proliferation of uniform, closely packed, rounded or oval cells, some of which contain no lipid. Others contain only small cytoplasmic vacuoles or a thin rim of clear cytoplasm (Fig. 34-20). These cells are vaguely reminiscent of Ewing's sarcoma (and, similarly, may contain glycogen), malignant lymphoma, or small cell anaplastic carcinoma. Their association with other patterns of liposarcoma points to their liposarcomatous nature. Multivacuolated lipoblasts are few in number. Most tumor cells have hyperchromatic and atypical nuclei, with frequent mitoses. This tumor can be thought of as a less-differentiated modification of liposarcoma in which the cells are largely incapable of lipid accumulation. At least focal transition toward the myxoid variant, or, less frequently, a well-differentiated or pleomorphic subtype, is always present. As indicated previously, these transitions are central to the correct diagnosis of round cell liposarcoma.

Myxoid and round cell liposarcoma account for about 30% to 35% of all liposarcomas and, even if still classified by the World Health Organization as two distinct subtypes, share both clinical and morphologic features. Lesions combining both patterns are frequent, and wide agreement exists in considering round cell liposarcoma as the high-grade counterpart of myxoid liposarcoma (122). Furthermore, myxoid and round cell liposarcoma share the same characteristic chromosome change represented most frequently by a reciprocal translocation t(12;16)(q13;p11) that fuses the CHOP gene with the TLS gene (129).

Clinically, myxoid and round cell liposarcoma tend to occur in the limbs, with a peak incidence ranging between the third and the fifth decade. In general, when more than 25% of the cellular elements are round cells, the diagnosis of round cell liposarcoma should be made. However, any more than 5% round cell component in a myxoid liposarcoma portends a higher risk of metastasis or death from disease (130). A peculiar tendency to metastasize to the soft tissue is observed that should not be interpreted as multicentricity (129).

Pleomorphic liposarcoma, an unlikely prebiopsy diagnosis (131), is characterized by a disorderly growth pattern, an extreme degree of cellular pleomorphism, and bizarre giant cells. Pleomorphic liposarcoma is a high-grade pleomorphic sarcoma, containing multivacuolated lipoblasts, which usually develops during late adult life. It usually occurs in the deep soft tissues and uncommonly arises in the subcutis, the dermis representing an exceedingly rare site of occurrence (132). Despite high-grade morphology, the intradermal tumor shows a relatively favorable prognosis (7). Diagnostic considerations include pleomorphic lipoma, clear cell atypical fibroxanthoma, balloon cell melanoma, and metastatic clear cell carcinoma of renal origin.

Two histologic variants of pleomorphic liposarcoma have been described. The majority of pleomorphic liposarcomas display limited numbers of lipoblasts admixed with smaller, polygonal, round or spindle-shaped cells with eosinophilic cytoplasm. Mitotic figures are usually rare. In any given microscopic field lacking a lipoblast, the separation of this entity from the pleomorphic storiform variant of malignant fibrous histiocytoma is difficult if not impossible. A less common variant contains giant lipoblasts. These extremely large cells have numerous cytoplasmic lipid droplets of variable size (Fig. 34-21). Multinucleation and amphophilia of the cytoplasm causes these cells to have the appearance of atypical mulberry cells; thus, the tumor is suggestive of a "malignant" hibernoma. No myogenic (skeletal or smooth) ultrastructural features as well as positivity for vimentin but not for desmin or alpha-smooth muscle actin are expected (133).

Whereas it is accepted that liposarcoma rarely occurs in the subcutaneous soft tissue, the dermis seems to represent an

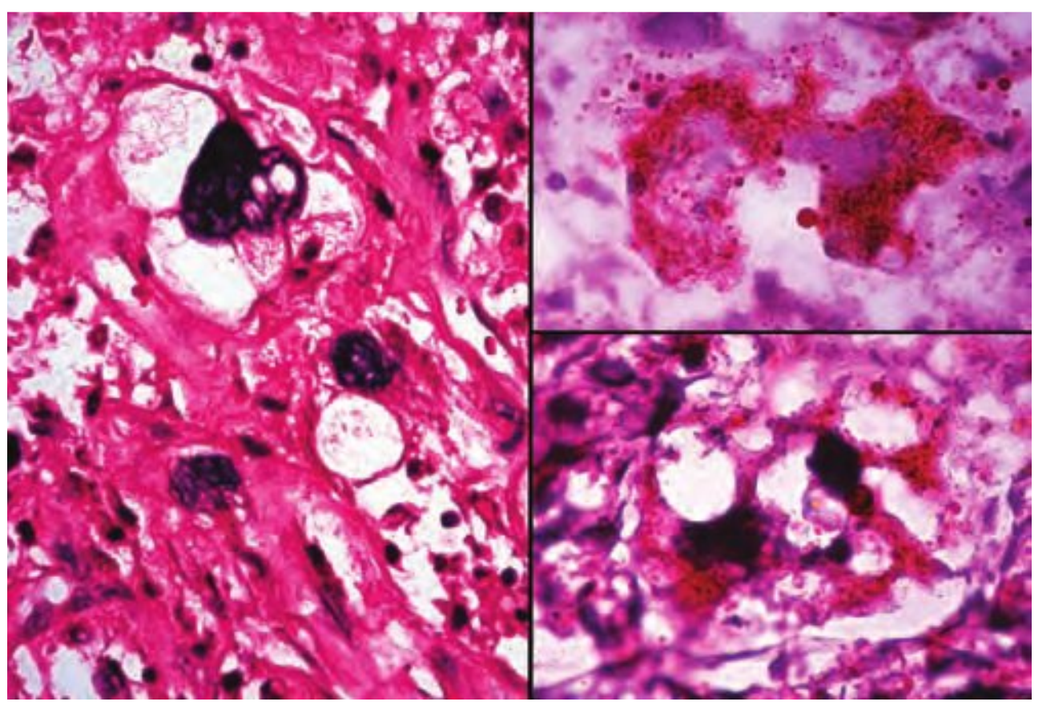

FIGURE 34-21. Pleomorphic liposarcoma. Multivacuolar lipoblasts have large, irregular hyperchromatic nuclei (left panel). The cytoplasmic lipid content of lipoblasts (lost in routine processing) can be demonstrated by frozen sections on fresh (top right panel) or formalin-fixed (bottom right panel) tissues stained with oil red O.

exceedingly rare site of occurrence (119). Exceptionally, liposarcoma occurs primarily in the skin, presenting clinically as a dome-shaped or polypoid lesion that despite an apparent tendency to show high-grade morphologic features seems to exhibit relatively indolent clinical behavior in this location (132).

A subtype of pleomorphic liposarcoma in which transition from low-grade to high-grade nonlipogenic morphology within a well-differentiated liposarcoma is observed (122) is known by the pathobiologically imprecise designation *dedifferentiated liposarcoma*. The interface between the two zones is usually abrupt. A peculiar biology is displayed, which at least in most cases shows neither "anaplasia" nor "dedifferentiation" but most likely "transdifferentiation" of part of the neoplastic cells to a cellular phenotype of a different mesenchymal differentiation lineage (134). A well-differentiated (lipoma-like) or myxoid liposarcoma (135) component has superimposed nonlipogenic areas resembling high-grade fibrosarcoma or malignant fibrous histiocytoma with the full range of potential patterns from storiform pleomorphic and myxoid to the less common giant cell and inflammatory forms. Less common are undifferentiated large round cells resembling carcinoma or melanoma, meningothelial-like whorls, (136,137) or myofibroblastic, rhabdomyosarcomatous, leiomyosarcomatous, even osteoblastic, differentiation. Dedifferentiated liposarcoma rarely exhibits heterologous (most often myoid) differentiation. A peculiar "neural-like whorling pattern" of dedifferentiation also has been described. Recently, it also has been proposed that dedifferentiated liposarcoma should be further classified into low and high grade. Surprisingly, the clinical outcome of dedifferentiated liposarcoma is less aggressive than in other high-grade pleomorphic sarcomas, but genetic as well as molecular data exist that may partially justify such a discrepancy (122).

The histologic subgroups of pleomorphic liposarcoma have not been shown to have prognostic value, perhaps because of the limited number of cases available for study. Its karyotype is complex (138). DNA flow analysis shows benign and low-grade liposarcomas to be diploid and high-grade tumors to be generally aneuploid, regardless of histogenetic type (139).

Differential Diagnosis. A poorly differentiated myxoid liposarcoma may contain very little lipid material. A lipid stain then often aids in the diagnosis. The demonstration of neutral lipid in cells with special stains (e.g., Sudan black, oil red O) on frozen sections of tumor tissue is insufficient for a diagnosis of liposarcoma unless lipoblasts are also found. Many other mesenchymal tumors and some carcinomas (e.g., of the kidney and adrenal) routinely contain fat, as do tumors injured by ischemia or radiation. The differential diagnosis of myxoid liposarcoma includes benign lesions, such as myxoid spindle cell lipoma, intramuscular myxoma, and lipoblastoma, and malignant ones, such as low-grade myxofibrosarcoma (a.k.a. myxoid malignant fibrous histiocytoma) and extraskeletal myxoid chondrosarcoma.

The main utility of immunohistochemistry in the diagnosis of liposarcoma is one of exclusion, because no specific or useful immunohistochemical marker has been found for malignant fatty tumors. Immunohistochemistry can be quite helpful in revealing the true identities of various sarcomas that may contain vacuolated bizarre cells, such as malignant schwannoma (S-100 protein), rhabdomyosarcoma (myoglobin), and leiomyosarcoma (desmin). But smooth muscle and even rhabdomyosarcomatous differentiation (140) can be found in primary liposarcoma. Alpha-1-antitrypsin and alpha-1-antichymotrypsin can be demonstrated in "malignant fibrous histiocytoma," regardless of subtype, and are constant and diagnostically useful characteristics. However, these markers may also be present in other spindle cell malignant tumors. By electron microscopy, cytoplasmic lipid is not membrane bound in liposarcoma, unlike in malignant fibrous histiocytoma (117). Late granulomatous reactions from silicone injection can cause an incorrect diagnosis of liposarcoma (141).

TUMORS OF SMOOTH MUSCLE

Smooth muscle in the skin serving as the substrate for tumors consists of arrector pili muscles, mural muscle of blood vessels, and specialized muscle in genital sites (i.e., scrotum [dartos], vulva, and nipple [areolar]).

SMOOTH MUSCLE HAMARTOMA

Smooth muscle hamartoma usually presents as a single patch that is several centimeters in diameter, on the extremities or trunk, most commonly in the lumbar region, and rarely scrotal (142). It may be present at birth or may arise in childhood or early adulthood (143). Usually, there are small, follicular papules throughout the patch, although the entire lesion may be slightly elevated and/or linear (144). Transient elevation (pseudo-Darier sign) can often be elicited on rubbing (145). Associated vermiform movements are rarely seen, suggesting that the lesion is acting as an innervated functional (although abnormal) unit (143). The patch shows hyperpigmentation and hypertrichosis in some patients (146) but not in others (147). If hyperpigmentation and hypertrichosis are present, an association with Becker's melanosis (see Chapter 28) exists (148). These two entities represent different poles of the same developmental spectrum of hamartomatous change (146). There is no known associated systemic involvement beyond being a potential component of the Michelin tire syndrome (see page 1060) or malignant transformation (143). Induration, hyperpigmentation, and localized hypertrichosis diminish with time (149).

Histopathology. Numerous thick, long, straight, well-defined bundles of smooth muscle fibers are scattered throughout the dermis and extend in various directions (Fig. 34-22) without the circumscription of a cutaneous leiomyoma. Smooth muscle bundles can be readily distinguished from collagen bundles by the trichrome stain, which stains smooth muscle red and collagen green or blue. The overlying basal layer is often pigmented,

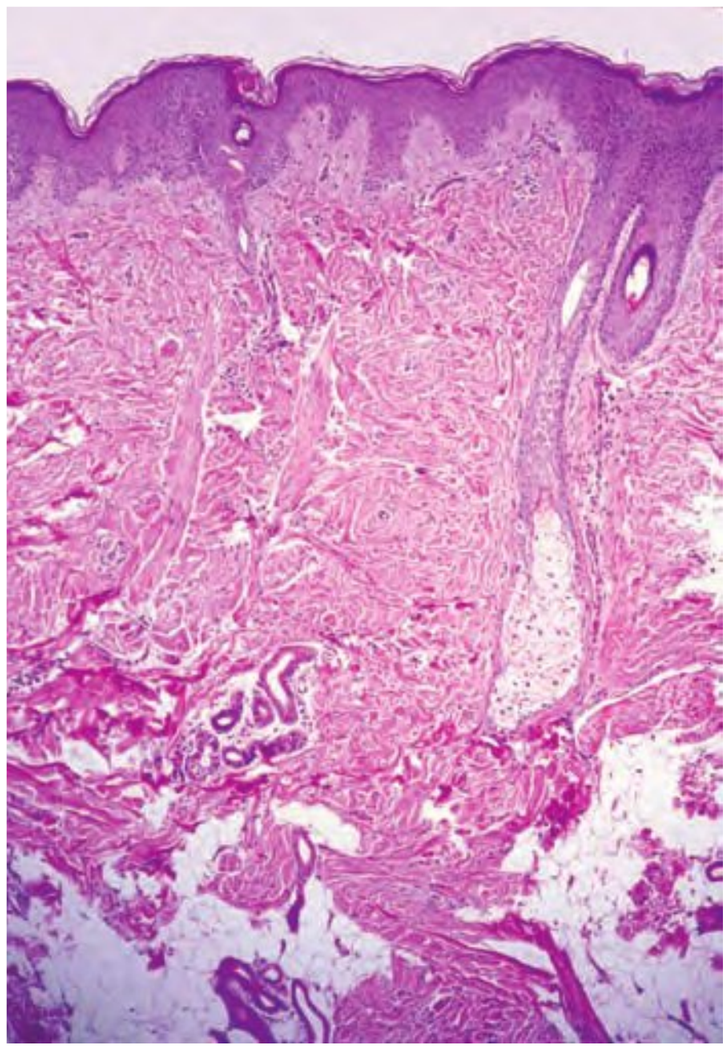

FIGURE 34-22. Smooth muscle hamartoma. Numerous thick, long, straight, well-defined bundles of smooth muscle fibers extend in various directions throughout the dermis.

and above that, hyperkeratosis and papillomatosis (143). Hypertrichosis, if present, is due to increased hair shaft diameter and length, not increased hair density (143). Some of the smooth muscle bundles show connections with large hair follicles (148).

Differential Diagnosis. The arrangement of the smooth muscle bundles in the dermis differs from that observed in piloleiomyoma, in which the smooth muscle bundles form a large aggregate.

Pathogenesis. In fetal life, hair muscles originate in a diffuse metachromatic zone of the mesoderm, near but not part of the fibroepithelial hair germ. Overproduction in these pilar fields may lead to stable hamartomatous overgrowths or progressive neoplasms (150). Intermediate lesions support the hypothesis that congenital smooth muscle hamartoma is one end of a spectrum of dermal smooth muscle proliferative disorders, with Becker's melanosis at the other end. However, the former is present at birth and the latter acquired beginning in the first or second decade, with hyperpigmentation preceding hypertrichosis (143).

LEIOMYOMA

The five types of leiomyomas of the skin are (a) multiple piloleiomyomas and (b) solitary piloleiomyomas, both arising from arrectores pilorum muscles; (c) solitary genital leiomyomas, arising from the dartoic, vulvar, or mammillary muscles; (d) solitary angioleiomyomas, arising from the muscles of veins; and (e) leiomyomas with additional mesenchymal elements.

Multiple piloleiomyomas, by far the most common type of leiomyoma, are small, firm, red or brown intradermal nodules arranged in a group or linear pattern, primarily affecting the trunk and extremities but may occur on the face and neck and rarely in the mouth (151). Lesions may run into the hundreds and cluster to form plaques, zosteriform groups, or, in symmetrical distribution (152,153), nevus leiomyomatosus systematicus (154). Often, two or more areas are affected. Usually, but not always, the lesions are tender and give rise to occasional painful paroxysms (150). Pain can be spontaneous or triggered by exposure to cold, pressure, trauma, or emotion (151). When multiple, excision of larger lesions and analgesics for pain, even oral nitroglycerin, phenoxybenzamine, nifedipine, and calcium channel-blocking drugs can be tried, either alone or in combination (151).

Uterine leiomyomas or erythropoietic activity are rare associations. Hereditary leiomyomatosis and renal cell carcinoma is an autosomal dominant familial syndrome characterized by the development of cutaneous and uterine leiomyomas as well as renal tumors, most often of the papillary type (155). The mutation of this condition has been identified in the fumarate hydratase (FH, 1q42.3-q43) gene. These renal tumors have a characteristic large nucleus with a very prominent inclusion-like orangophilic or eosinophilic nucleolus surrounded by a clear halo and are associated with poor prognosis (155), often with early metastasis despite small primary tumor size (156).

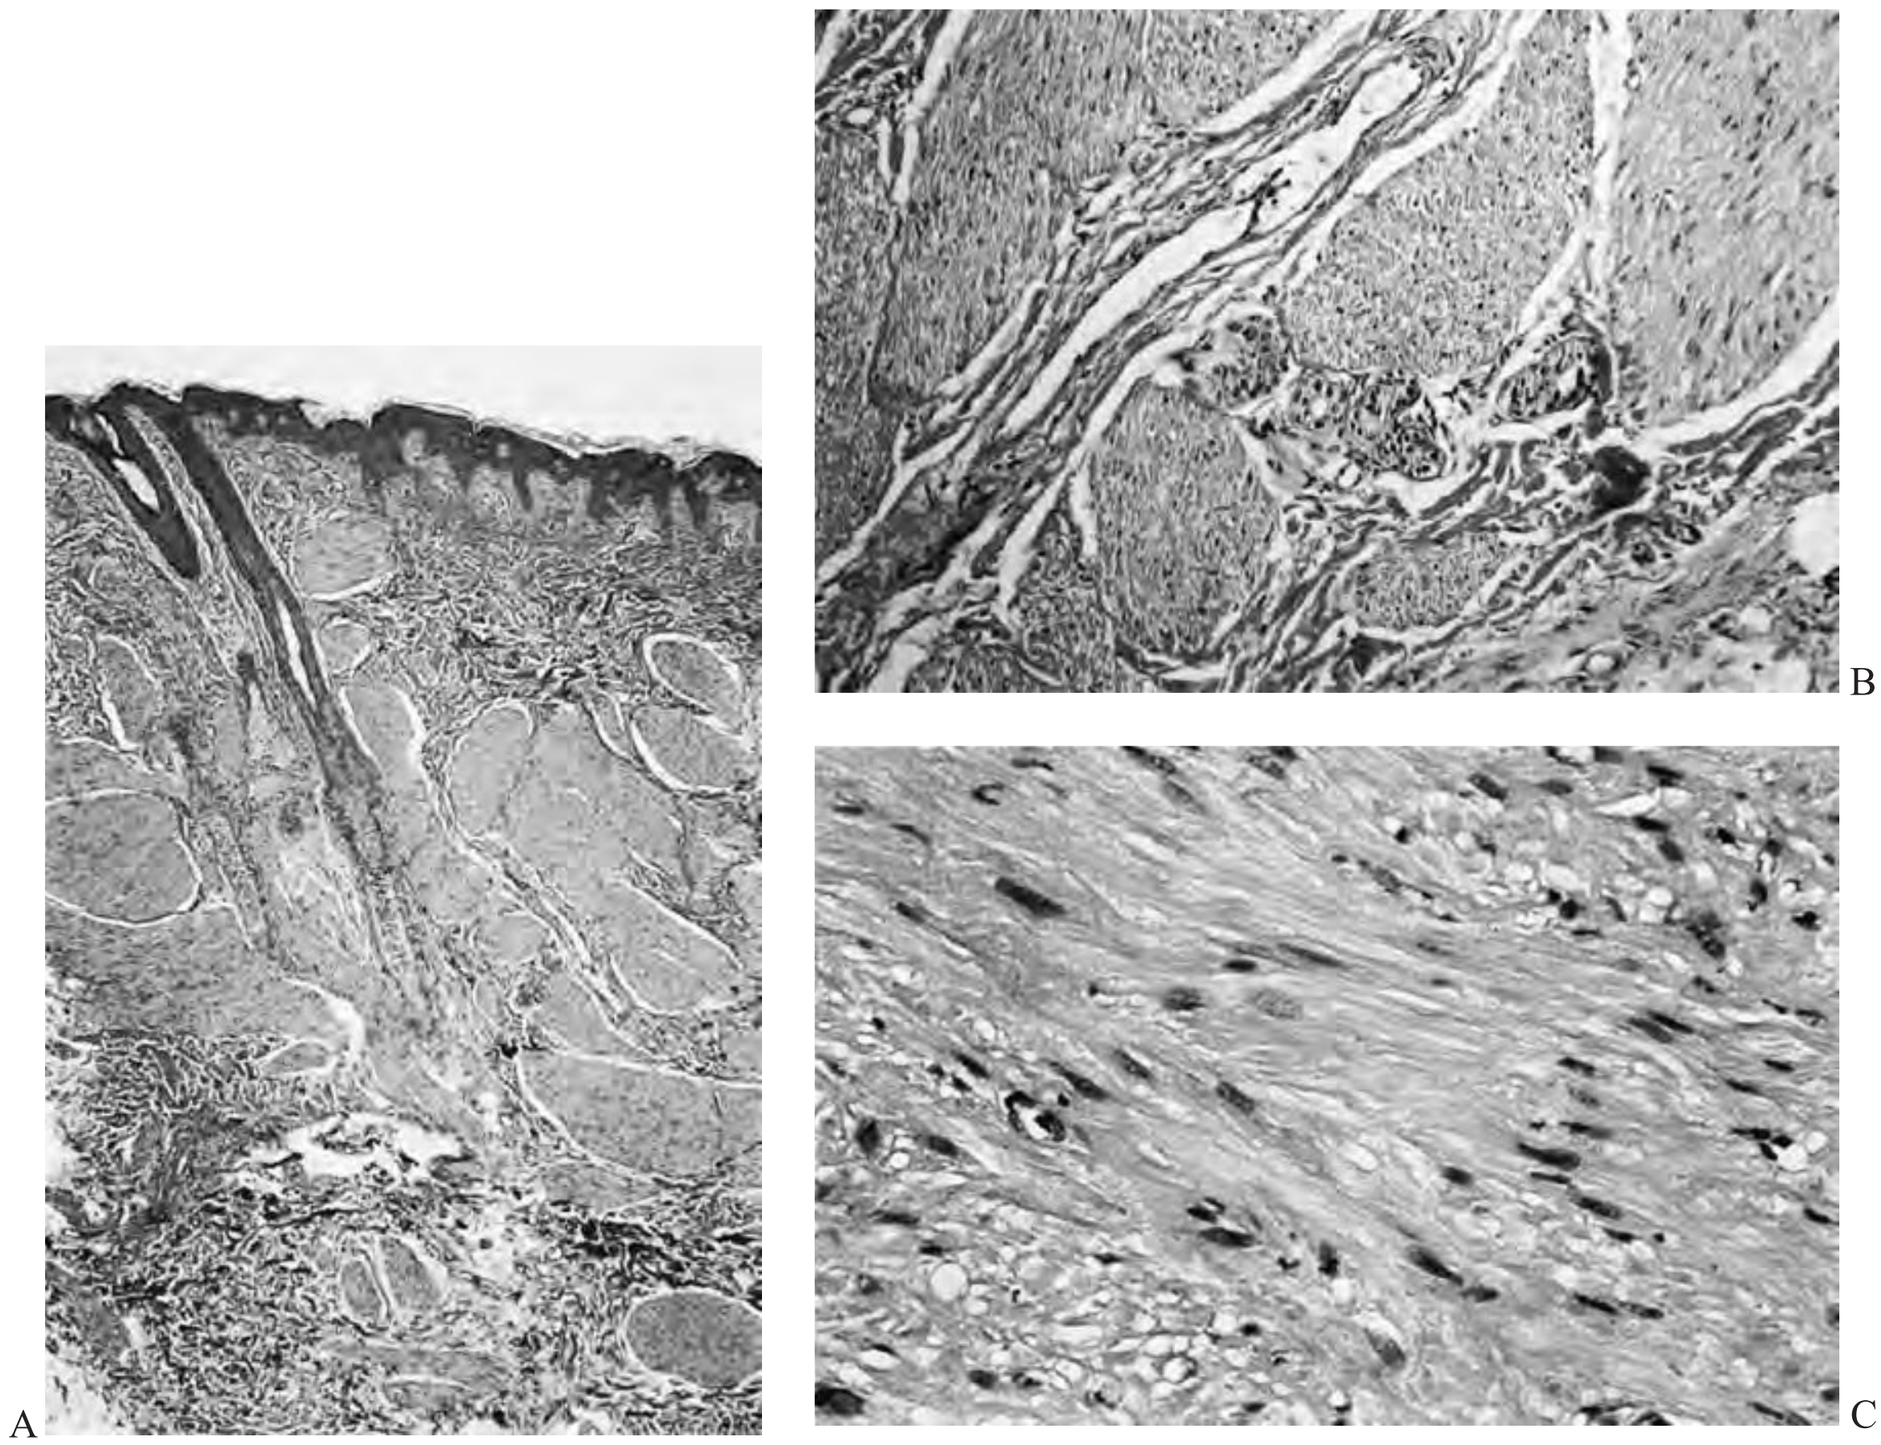
Solitary piloleiomyomas (157) are intradermal nodules that are usually larger than those of multiple piloleiomyomas, measuring up to 2 cm in diameter. Females predominate. Congenital occurrence is rare. Most of them are tender and also occasionally painful (158). Simple excision may suffice for one or a few lesions (151).

Genital leiomyomas originate from the dartoic, vulvar, or mammary smooth muscle (159). Solitary genital leiomyomas are located on the scrotum, labia majora (160,161), or, rarely, nipples (160). Supernumerary breasts (polymastia) and supernumerary nipples (polythelia areolaris) are not uncommon along the course of the embryologic milk line. This extends from the anterior axillary fold to the inner thigh on either side of the midline. Supernumerary breast tissue (160) or aberrant areolae (159) located outside the milk line are extraordinary. Genital leiomyomas are intradermal, and in contrast to the other leiomyomas, most are asymptomatic (158).

Solitary angioleiomyomas are usually subcutaneous and only rarely intracutaneous in location. As a rule, they do not exceed 4 cm in diameter. The lower extremities are the most common site. Pain and tenderness are evoked by most, but not all, angioleiomyomas (150).

The rare *cutaneous angiolipoleiomyoma* is an acquired asymptomatic tumor and always acral. The lesion has a strong male rather than female predilection (162). Unlike the renal counterpart, there is no association with tuberous sclerosis. Recurrence after surgery is not anticipated.

Histopathology. Piloleiomyomas, whether multiple or solitary, and genital leiomyomas are similar in histologic appear-



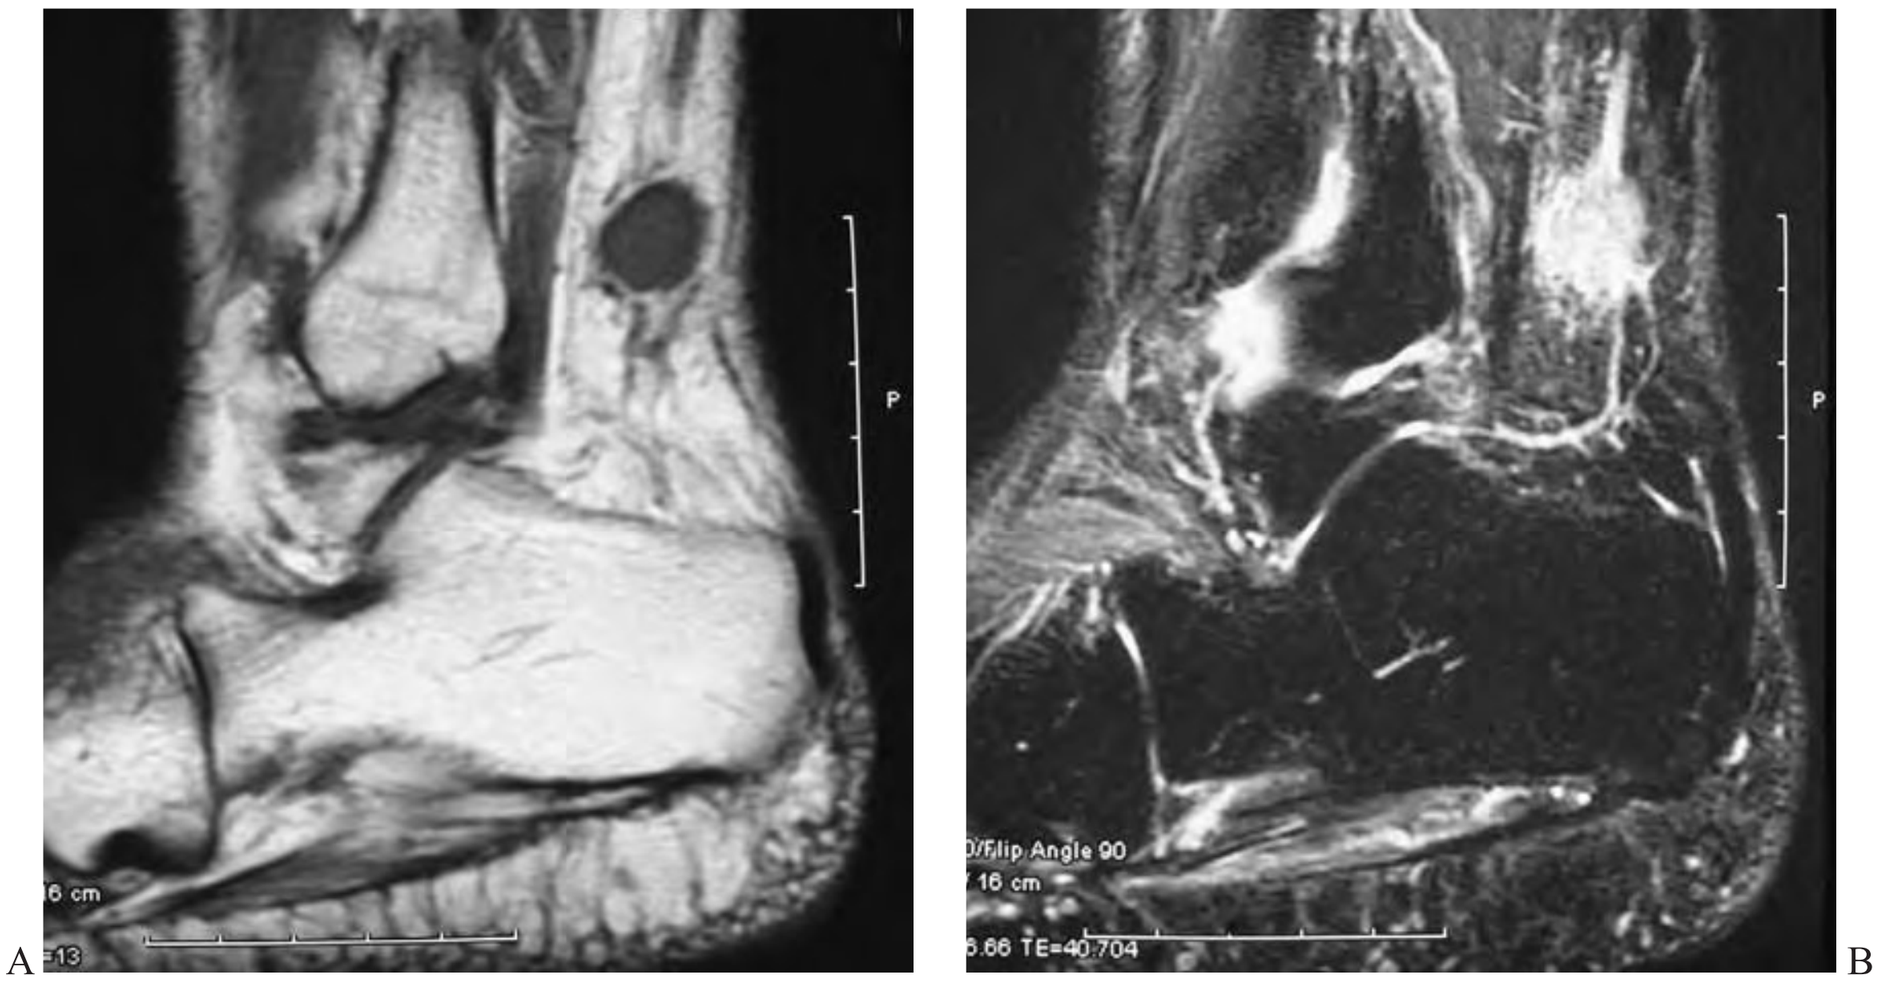


FIGURE 34-23. Piloleiomyoma. A: Bundles of smooth muscle interlace around follicular structures in the dermis. B: Well-defined smooth muscle bundles resembling pilar muscles surround sweat gland coils. C: Benign smooth muscle cells have some variation in nuclear size and chromaticity, blunt nuclear ends, and no conspicuous mitotic activity.

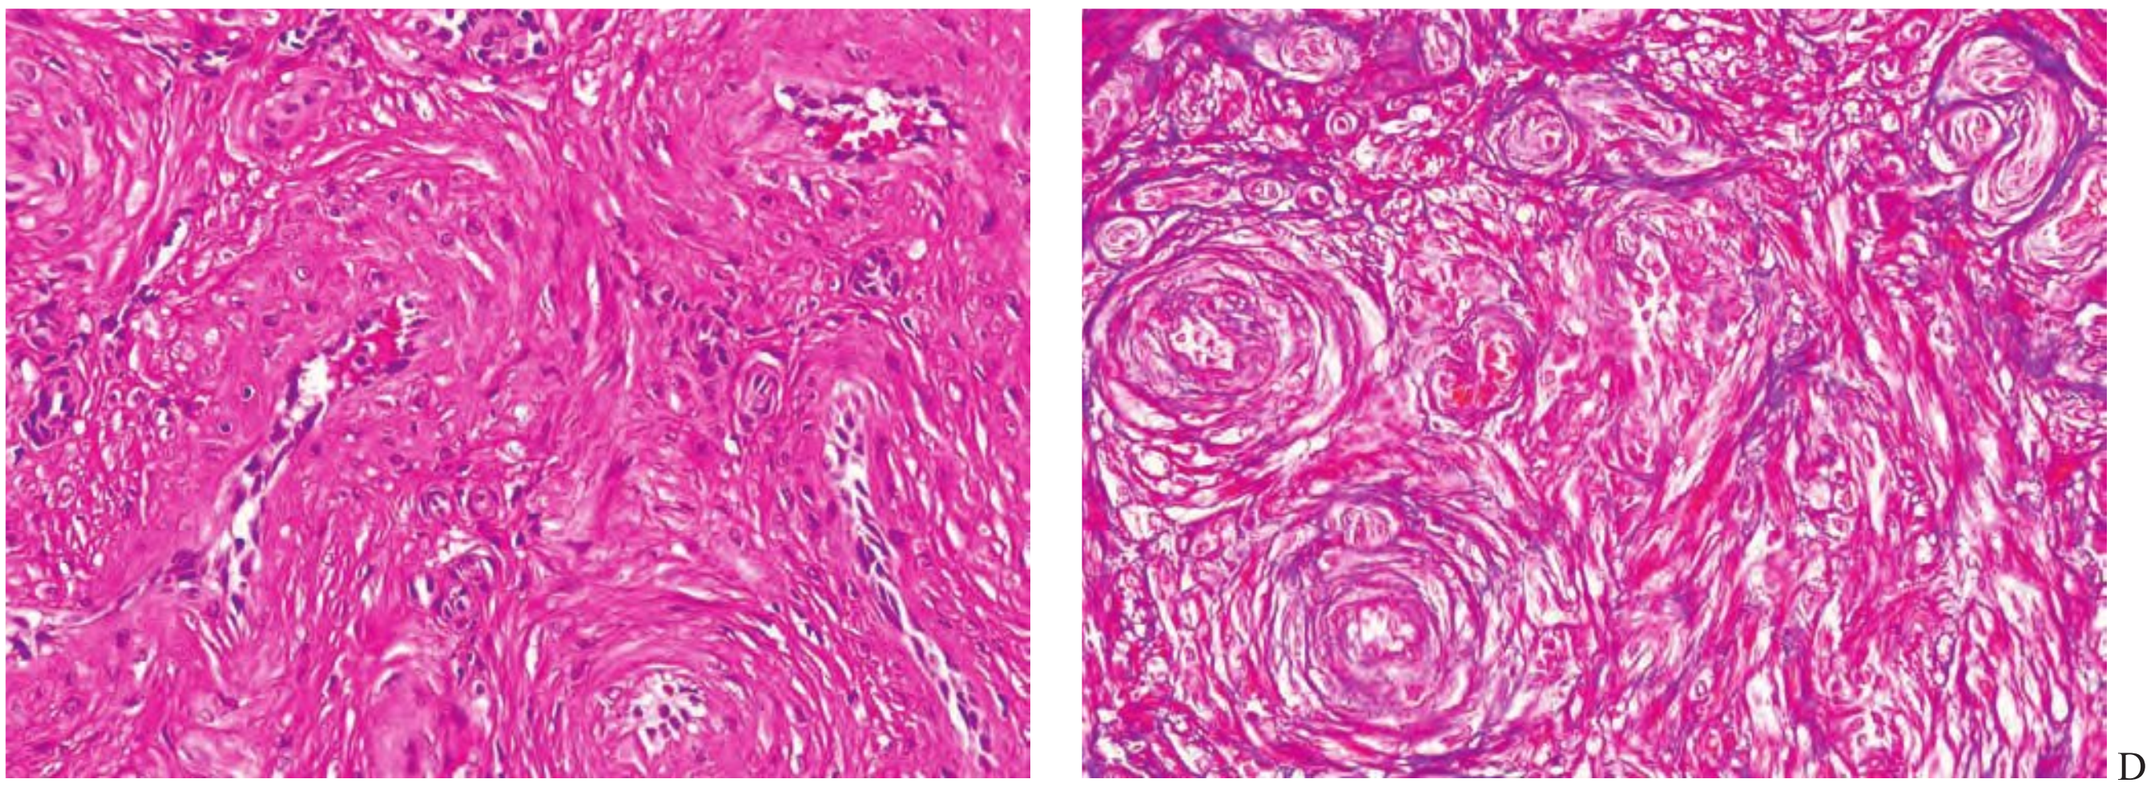

ance (158). They are poorly demarcated and are composed of interlacing bundles of smooth muscle fibers with which varying amounts of collagen bundles are intermingled (Fig. 34-23). The muscle fibers composing the smooth muscle bundles are generally straight, with little or no waviness; they contain centrally located, thin, very long, blunt-edged, "eel-like" nuclei. Overlying epidermal hyperplasia is seen in about half. Hair follicles may persist in the lesion (163). Rare variants show granular (164) or clear cell (165) change.

Leiomyomas of arrector pili origin may exhibit a low mitotic activity of <1 per 10 high-power field (HPF), and this does not adversely affect the prognosis for these patients (166). Pleomorphic multinucleated tumor giant cells can occur in cutaneous "symplastic" leiomyomas (167) and pleomorphic angioleiomyoma (168), but more commonly in the uterus. Vulval leiomyomas express estrogen and progesterone receptors, unlike pilar tumors (169).

Angioleiomyoma presents as a painful mass in approximately 60% of cases. One distinct clinical feature is the increase in size of the swelling with physical activity of the involved part, especially in the hand. It should be considered in the differential diagnosis of painful nodular lesions of the extremity (170). *Angioleiomyomas* differ from the other types of leiomyomas in that they are encapsulated and contain numerous vessels (Fig. 34-24). As a rule, they contain only small amounts of collagen (Fig. 34-24D). The numerous veins that are present vary in size and have muscular walls of varying thickness. On this basis, angioleiomyomas have been subdivided into a capillary or solid type, a cavernous type, and a venous type (171). In the capillary type, the vascular channels are numerous but small. Tumors of the cavernous type are composed of dilated vascular channels with small amounts of smooth muscle. Tumors of the venous type exhibit veins with thick muscular walls. In venous tumors, smooth muscle cells extend tangentially from the peripheries of the veins and merge with the intervascular tumor substance (Fig. 34-24C). The veins usually have a rounded or slitlike lumen, but some, because of contraction of their muscular tissue, have a stellate lumen. The veins have no elastic lamina. Areas of mucinous alteration are often present, especially in large angioleiomyomas. The smooth muscle may exhibit pleomorphism (171). An intravascular variant is rare (172).

A B

C D

FIGURE 34-24. Angioleiomyoma (posterior ankle mass in a 73-year-old man diagnosed by correlation of a needle biopsy specimen with MRI). A: A T1-weighted sagittal MRI highlights high signal tissue (fat) but not the nodule behind distal fibula, anterior to the Achilles tendon, excluding lipoma. B: A STIR-weighted image, fat suppression sequence highlights fluid content and therefore the blood in a vein that is interrupted by the high signal (i.e., well-vascularized) nodule. C: Smooth muscle of vessel walls merges without borders into intervening muscle. D: Myoplasm is bright red in a Masson trichrome stain, while modest blue-staining collagen outlines vessel walls.

Lipoleiomyomas comprise long, intersecting bundles of bland, smooth muscle mixed with the additional mesenchymal element of nests of mature fat cells (173). *Cutaneous angiolipoleiomyoma* could arguably be considered an angioleiomyoma with fat cell modulation (Fig. 34-25). However, elastic laminae completely or partially rim the vascular channels and are absent in angioleiomyomas. These subcutaneous, well-circumscribed tumors are composed of benign smooth muscle, vascular spaces, connective tissue, and mature fat, which may predominate. Masson trichrome will separate the muscular from fibrous components that are invariably present. The smooth muscle cells have a more mature fascicular arrangement than in the renal analog. Blood vessels in these subcutaneous well-circumscribed tumors intermittently have an elastic lamina (Fig. 34-25C) (162). Cutaneous angiolipoleiomyomas are unreactive for HMB-45, in contrast to renal and extrarenal angiomyolipoma (162,164,174), yet have been reported under the term *angiomyolipoma* (174,175).

The muscle bundles of various leiomyoma variants stain pink with H&E, just as collagen does, but can be distinguished from collagen bundles by the following differences in appearance. The nuclei of the fibroblasts located in the collagen are

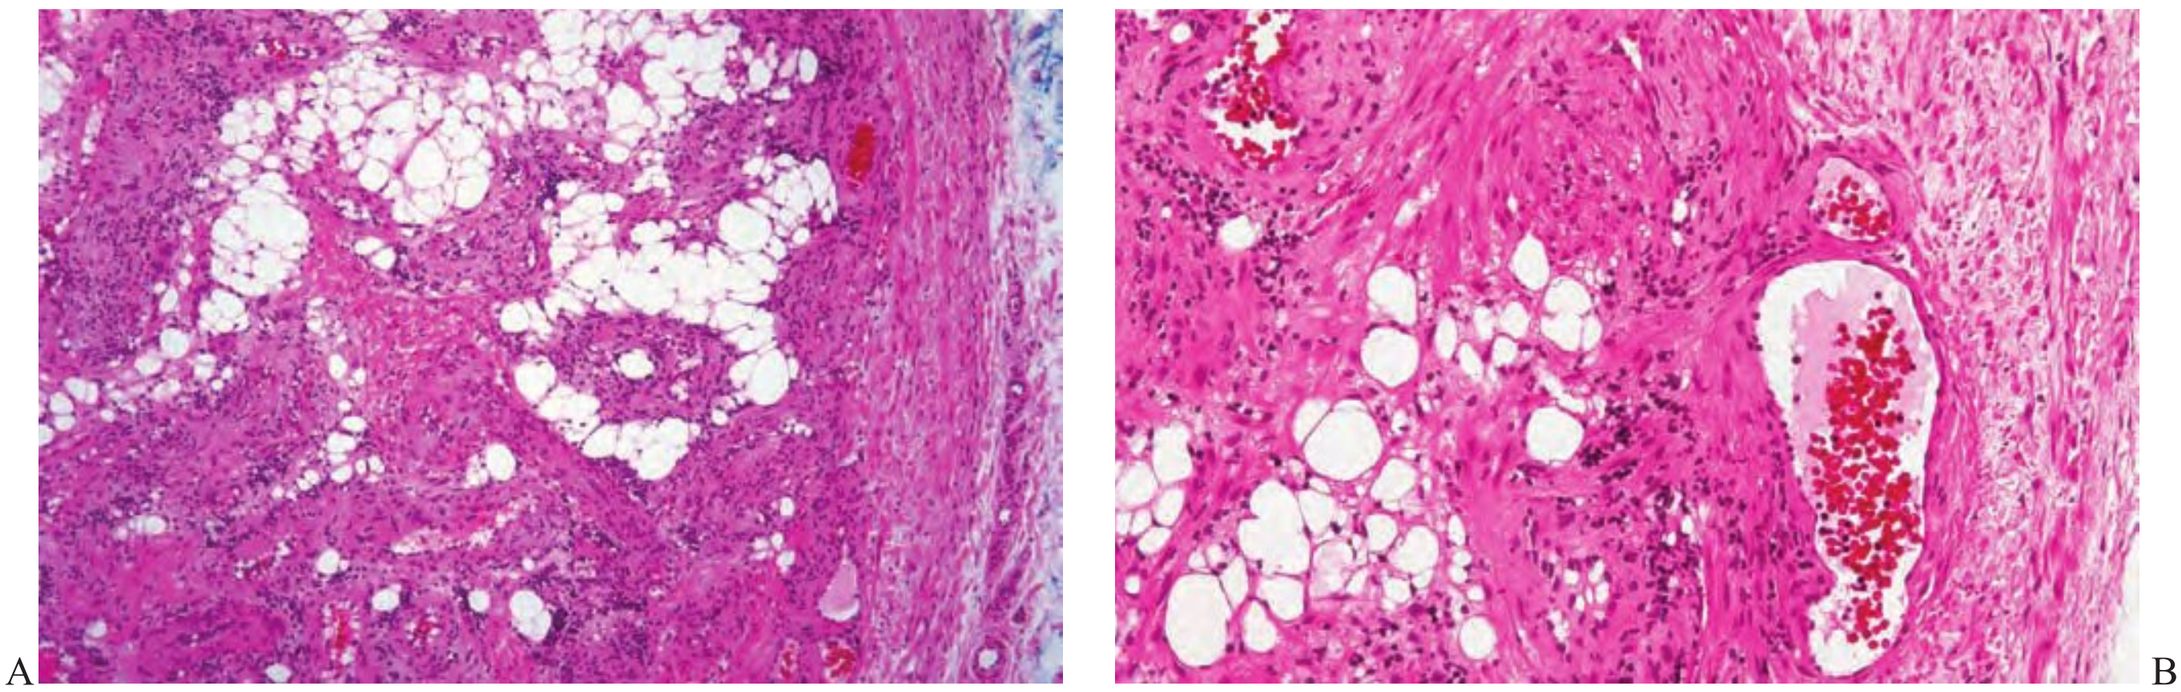

FIGURE 34-25. Angioleiomyoma with fat (51-year-old man; nonpainful 1.5-cm knee "cyst" present 10 years but enlarging). A: A well-circumscribed nodule has prominent vascular spaces, redundant smooth muscle, and much mature fat. B: The smooth muscle cells have a fascicular arrangement. C: Elastic lamina partly rim a representative vascular channel (elastic tissue stain).

shorter than the nuclei located in the smooth muscle fibers and show tapering at their ends, whereas smooth muscle nuclei tend to have blunt ends; the cytoplasm of the smooth muscle cell is more conspicuous than in quiescent fibroblasts. In contrast to collagen bundles, smooth muscle bundles usually show slight vacuolization, especially in cross-sections, as a result of a perinuclear clear zone. Reliable differentiation between muscle and collagen bundles is possible with the aid of one of the collagen stains, such as the aniline blue stain or the trichrome stain. With the aniline blue stain, muscle stains red and collagen blue; with the trichrome stain, muscle stains dark red and collagen green or blue. The Masson technique is superior to that of Gamori. Longitudinal intracytoplasmic myofibrils often can be visualized as striations in H&E sections and can be more easily resolved if stained with phosphotungstic acid–hematoxylin, where they appear as purple threads.

Differential Diagnosis. The discrete bundles set in dermal collagen of smooth muscle hamartoma are unlike the circumscription of most cutaneous leiomyomas and the scant intralesional collagen common in the multiple papular variant of pilar leiomyoma (176). The differential diagnosis of angiolipoleiomyoma includes angiolipoma with fibrosis (lacks muscle on Masson trichrome), angioleiomyoma (usually lacks elastic laminae and has female predominance), arteriovenous hemangioma (but it is uncircumscribed and without a fibrous pseudocapsule, fascicles of smooth muscle and intermixed lipocytes), and even cavernous hemangioma (but with larger vascular spaces having thinner walls and no surrounding fascicles of smooth muscle or fibrous pseudocapsule) (162). The histologic differential diagnosis of lesions with an intravascular growth pattern includes intravascular angioleiomyoma, intravascular pyogenic granuloma, papillary endothelial hyperplasia, reactive angioendotheliomatosis, intravascular nodular fasciitis, hemangiopericytoma, and intravascular glomus tumor (172). *Palisaded angioleiomyoma*, a histopathologic variant of angioleiomyoma with prominent Verocay body formation, should be added to the ever-expanding list of tumors that demonstrate nuclear palisades, along with neurilemoma, but immunohistochemistry gives positive reactions for actin and desmin and is negative for S-100 (177).

Pathogenesis. Arrectores pilorum gives rise to smooth muscle tumors. Electron microscopic examination has shown that piloleiomyomas are composed of normal-appearing smooth muscle cells. Each of these cells has a central nucleus surrounded by an area containing endoplasmic reticulum and mitochondria and, peripheral to this area, numerous myofilaments arranged in bundles. Both cytoplasmic and marginal dense bodies are present. The cause of the frequent pain or tenderness has not been satisfactorily determined. Some authors have observed, by electron microscopy, ultrastructural damage to nerve fibers through distortion and disruption of the myelin sheath (178), and only scanty unmyelinated nerve fibers (179) are postulated factors. It

is probable, therefore, that the pain is a result of muscular contractions. Familial cases of multiple piloleiomyomas have been reported in autosomal dominant–incomplete penetrance mode (151). Since cutaneous leiomyomas show no positive staining for ER-1D5 or PGR-1A6 antibodies, the tumorigenesis of cutaneous leiomyomas does not appear to be related to estrogen or progesterone receptor-mediated effects (169).

LEIOMYOSARCOMA

Among 26,758 soft tissue sarcomas, leiomyosarcomas have accounted for 23.9%, malignant fibrous histiocytomas 17.1%, liposarcomas 11.5%, dermatofibrosarcomas 10.5%, rhabdomyosarcomas 4.6%, and angiosarcomas 4.1%. Almost half (47.9%) of the sarcomas arose in the soft tissues, *14.0% in the skin* and 7.0% in the uterus (180). Cutaneous leiomyosarcoma is a rare soft tissue sarcoma with negligible metastatic potential, but local recurrence rates after surgical excision have ranged from 14% to 42% (181). Unlike other sarcomas, guidelines for the optimal surgical excision margin of cutaneous leiomyosarcoma are not clearly defined in the existing literature (181).

Leiomyosarcomas, malignant nonepithelial tumors with smooth muscle differentiation, are generally deemed to be derived from mural smooth muscle cells of vessels or in viscera such as the uterus or stomach, the urogenital system, or in the retroperitoneal space. Leiomyosarcomas of the dermis and subcutaneous tissues are rare, accounting for $<$5% of all soft tissue sarcomas in adults. Superficial leiomyosarcomas are most common in the fifth and sixth decades of life, and reports differ as to whether there is (182) or is not (183) a male predominance.

Cutaneous leiomyosarcomas (Fig. 34-26) exhibit a predilection for proximal extremity extensor surface location (184), which coincides with the areas of greatest hair distribution. They are believed to derive from the arrector pili muscles, from smooth muscle that surrounds sweat glands in the nearby adipose tissue, or from vessel walls (183). Clinically, a solitary red-pink nodule may be painful or tender (150) but only rarely ulcerates. In some cases, several nodules are present, but this should arouse suspicion of metastases, for example, from a retroperitoneal, uterine, or alimentary tract primary (185), which favor the scalp and back. Leiomyosarcoma has been reported in an ectopic areola (186). Radiation dermatitis (187), trauma, lupus vulgaris, and origin in an angioleiomyoma (188) are other associations for leiomyosarcoma.

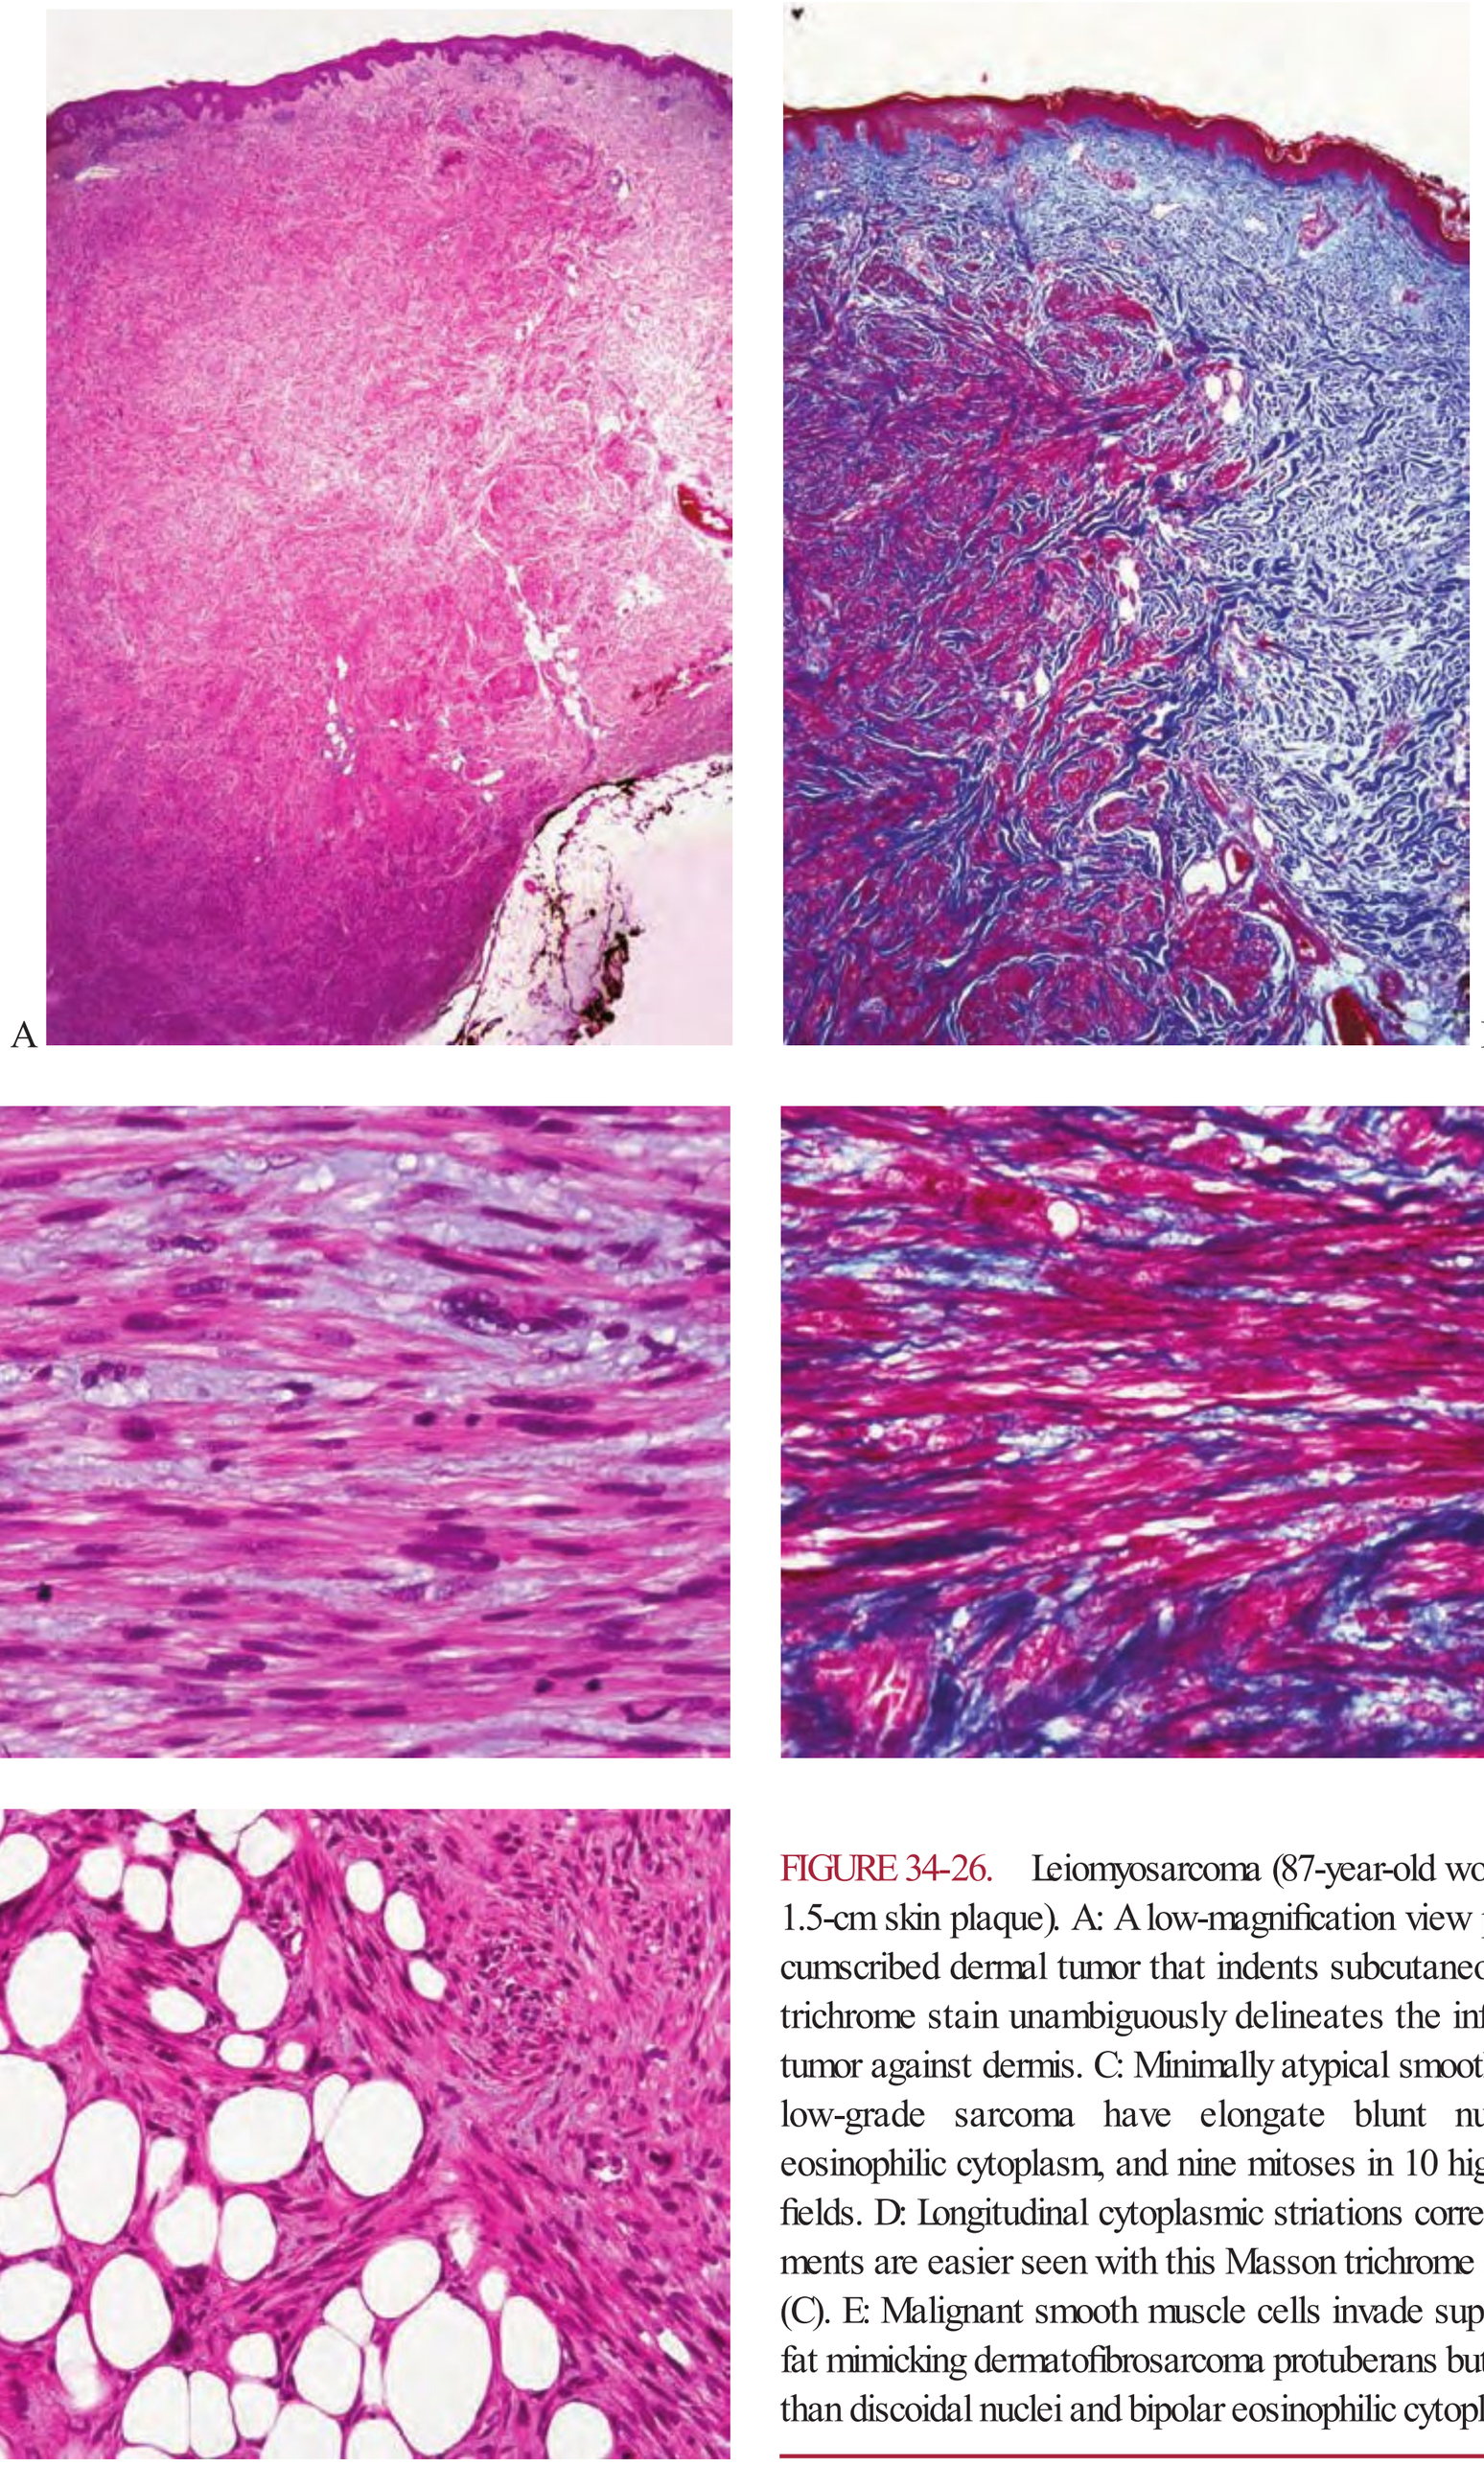
Subcutaneous leiomyosarcomas (189) are deemed to be vascular in origin and analogous to angioleiomyomas. Radiation dermatitis may be a substrate here as well (187). They are subcutaneous nodules or diffuse swellings over which the nondiscolored skin usually is freely movable. They cause pain of a local or radiating nature in only a few patients. Wide surgical excision of leiomyosarcoma with close follow-up is recommended (183), as local recurrence is common (40%–60%), with inadequate excision as the presumed risk factor (181). They are relatively radioresistant, according to a small number of treated cases (182,190).

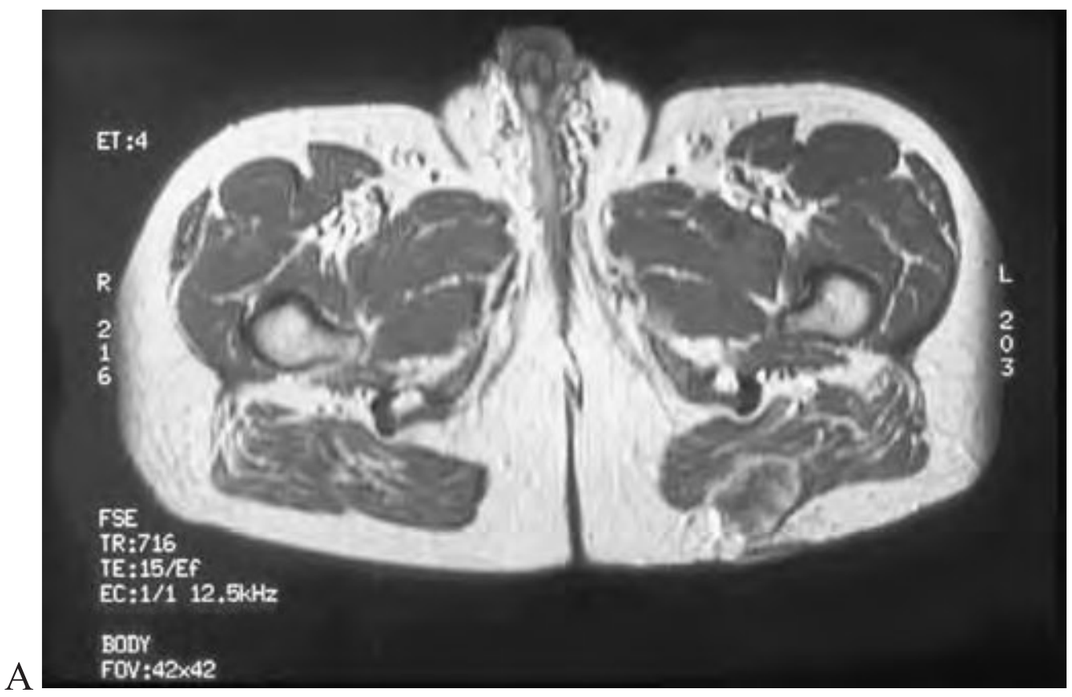
The division of superficial leiomyosarcoma into two distinctly different histogenetic and prognostic categories (cutaneous and subcutaneous) (191) is more significant in predicting metastatic potential than is mitotic activity (182). Cutaneous leiomyosarcomas have a good prognosis. When confined to the dermis, the sarcoma may recur in up to half of all cases. Metastases to regional lymph nodes may occur, but they are not usually fatal (181). In at least one reported instance, however, distant metastases ultimately led to the death of the patient (185). Subcutaneous leiomyosarcomas are more aggressive, exhibiting a higher growth rate, greater recurrence (40%–60%), metastatic potential (30%–60%), and ultimately fatal outcome (30%–40%) than their cutaneous counterparts (181). Subcutaneous leiomyosarcoma may cause hematogenous metastases, usually to the lungs (182) but only rarely to lymph nodes, and lead to death in about one third of patients (182). Aneuploid tumors are more prone to metastasize than diploid (192).

Purely subcutaneous leiomyosarcomas must be differentiated from leiomyosarcomas involving skeletal muscle or fascia, which can present as a skin or subcutaneous tumor (Fig. 34-27) and are often fatal (193). In assessing depth, remember that subcutaneous leiomyosarcoma may invade the dermis and that cutaneous leiomyosarcoma generally is contained within the dermis, although larger lesions may extend into the adjacent subcutis and epidermis (181). MRI may be helpful in the distinction (Fig. 34-27A).

Vulvar and *scrotal leiomyosarcomas* tend to be larger and better circumscribed than those in skin or subcutaneous locations. Their traditional inclusion under the general heading of cutaneous leiomyosarcoma has been challenged (191,193). Vulvar smooth muscle tumors that manifest three or all of the four following features should be considered sarcomas: (a) $\geq$5 cm in greatest dimension, (b) infiltrative margins, (c) $\geq$5 mitotic figures per 10 HPF, and (d) moderate to severe cytologic atypia. Those that have only one of these characteristics should be diagnosed as leiomyoma, and those that exhibit only two of these features should be considered benign but atypical leiomyomas (194). The sarcomas should be excised with wide negative margins; the leiomyomas and the atypical leiomyomas should be excised conservatively, with long-term, careful follow-up.

Histopathology. Cutaneous leiomyosarcomas (Fig. 34-26) vary from moderately well to poorly delimited, nodular or diffuse (195) intradermal tumors that may extend into the subcutaneous tissue. In the center, the tumor shows nodular aggregates and densely packed, interlacing bundles of smooth muscle cells. At the margin of the tumor, strands of smooth muscle cells extend between collagen bundles. Cutaneous leiomyosarcomas, with their fascicular, infiltrative, peripheral growth pattern, presumably are derived from arrectores pilorum muscles (182). Minimal criteria for malignancy in a well-differentiated lesion include crowded cellularity, some plump and hyperchromatic nuclei constituting cellular atypia, irregular extension into dermis, and a few mitoses (Fig. 34-26C). Areas of lesser differentiation are present in all tumors, although to varying degrees. They show numerous irregularly shaped, anaplastic nuclei and usually also atypical giant cells with bizarre nuclei (182) (Fig. 34-27).





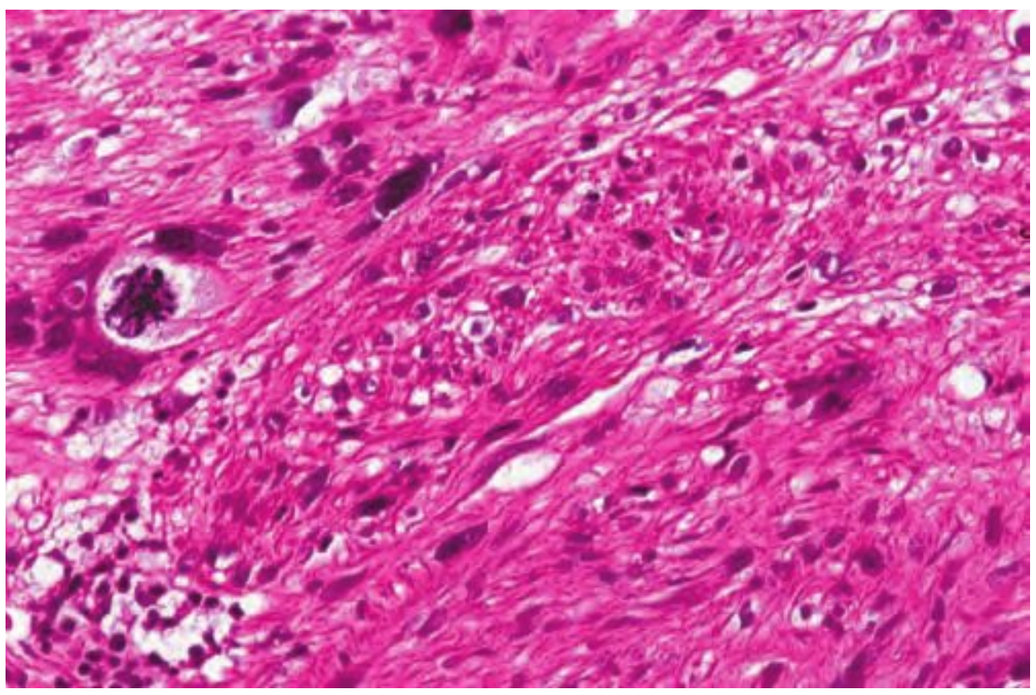


FIGURE 34-26. Leiomyosarcoma (87-year-old woman; rapidly growing 1.5-cm skin plaque). A: A low-magnification view presents a poorly circumscribed dermal tumor that indents subcutaneous fat. B: A Masson trichrome stain unambiguously delineates the infiltrative front of this tumor against dermis. C: Minimally atypical smooth muscle cells of this low-grade sarcoma have elongate blunt nuclei, conspicuously eosinophilic cytoplasm, and nine mitoses in 10 high-power microscopic fields. D: Longitudinal cytoplasmic striations correlating with actin filaments are easier seen with this Masson trichrome stain than in the H&E (C). E: Malignant smooth muscle cells invade superficial subcutaneous fat mimicking dermatofibrosarcoma protuberans but have elliptical rather than discoidal nuclei and bipolar eosinophilic cytoplasmic extensions.

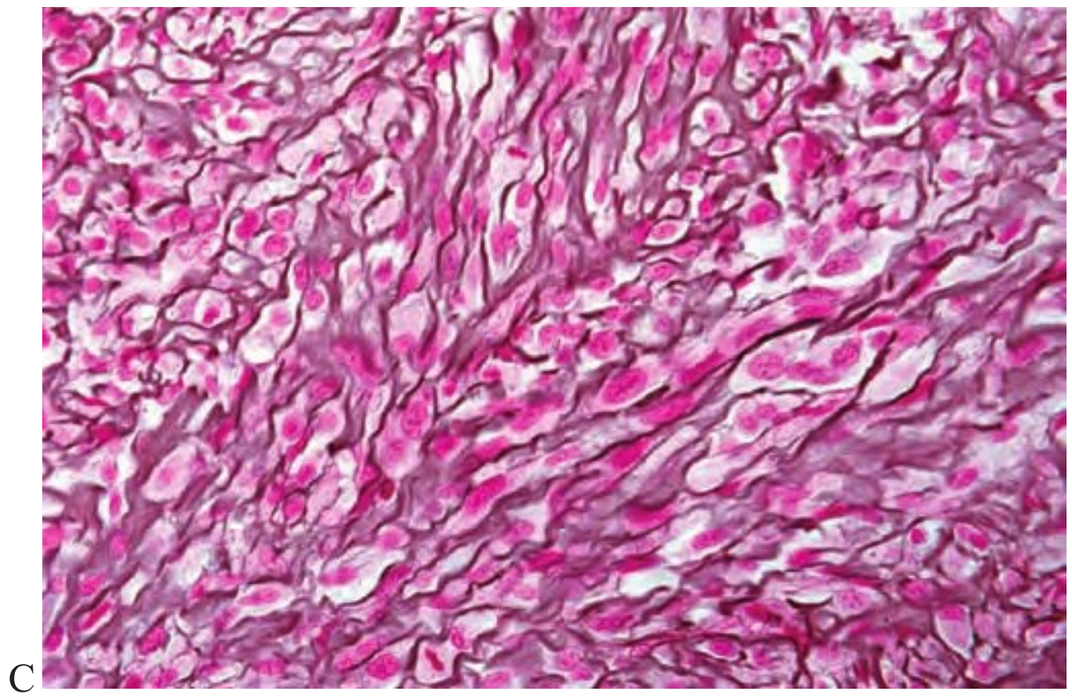

Still, the nature of the sarcoma usually can be established even in rather anaplastic tumors, because in some areas, there are bundles of fairly well-differentiated smooth muscle cells in which delicate myofibrils can be revealed by staining with phosphotungstic acid–hematoxylin (80) or trichrome. Epithelioid leiomyosarcoma, mainly occurring in the uterus, can rarely occur in the extremity soft tissue, skin, superficial veins and venules of the skin, and subcutis (196). Granular cell (197), inflammatory (198), and desmoplastic (199) leiomyosarcoma are other rare variants.

A

B

C

FIGURE 34-27. Intramuscular leiomyosarcoma (45-year-old male; nodule on buttocks noted on sitting; within 2 years of excision and local irritation, he had removal of 2 lung metastases and is alive with no evidence of disease now 5 years and 3 months after the original excision). A: Two thirds of an oval 4 × 5-cm buttock mass is within skeletal muscle, favoring its origin there, with secondary extension to subcutaneous fat where a biopsy might be mistaken for a superficial tumor. B: Substantial atypia and bizarre mitoses characterize this high-grade leiomyosarcoma that manifests brightly eosinophilic cytoplasm. C: A delicate reticulin network envelopes each tumor cell (reticulin stain).

The number of mitoses may be high in anaplastic areas even when there will be no metastases. A given leiomyosarcoma may have "mitotic hot spots" that might not be represented in single samples. Percentage of S-phase cells correlates with mitotic count but, like absence of desmin reactivity, is not predictive of patient survival (192). Although notable mitotic rate remains the main criterion for leiomyosarcoma (e.g., three or more per 10 HPF) (200), other histopathologic features of the tumor are important, as with uterine leiomyosarcoma (201), including atypical smooth muscle cells with peripheral extension into the surrounding tissue, pleomorphism, giant cells, and necrosis (182). Antidesmin positivity is found in 47% to 85% of superficial leiomyosarcomas and less common in higher-grade tumors. For those rare tumors in which routine histology and immunohistochemistry fail to provide a classification, electron microscopy offers another means for diagnosis (192).

Subcutaneous leiomyosarcomas may be well circumscribed and partially surrounded by a compressed rim of connective tissue. Irregular aggregates of more or less atypical smooth muscle cells can be seen intertwining haphazardly without the fascicular pattern characteristic of cutaneous leiomyosarcomas. Subcutaneous leiomyosarcomas show endothelium-lined, thin-walled blood vessels with variously shaped but often large lumina surrounded by smooth muscle cells (182). Vascular invasion is an adverse finding (202). Mitoses should be easily found. Osteoclast-like giant cells (203) or myxoid change (204) should not deter diagnosis. No correlation seems to exist between the degree of histologic malignancy of the tumor and metastases, which occur in up to 40% of cases (193). DNA content, as determined by flow cytometry, was a strong predictor of metastatic potential in one study (192). Involvement of underlying muscular fasciae or skeletal muscle is a likely harbinger of metastases (193).

Pathogenesis. Immunohistochemical staining of deparaffinized sections shows expression of desmin in all cutaneous leiomyosarcomas and of muscle-specific actin in the great majority (185). Only about half of the subcutaneous leiomyosarcomas show significant numbers of tumor cells that are positive for desmin and actin (193). These smooth muscle markers may be demonstrated in "myofibroblastic" lesions and therefore are not absolute diagnostic criteria. Some hold that ultrastructural study is a more reliable means for definite identification. Positivity for cytokeratin may be found and is attributed to "phenotypic shift" in terms of vimentin and cytokeratin expression for the supposed muscle of origin (205). Losses in the 13q4-21 region are the most frequent abnormality (206).

Electron microscopic examination has shown that the tumor cells have the characteristics of smooth muscle cells even when there is marked nuclear atypicality. Thus, the tumor cells show skeins of intermediate filaments punctuated by dense bodies, subplasmalemmal plaques, pinocytotic vesicles, and

external pericellular lamina (184,194). However, in some instances, the basal lamina is discontinuous (185).

Differential Diagnosis. The presence of bizarre giant cells in cutaneous leiomyosarcomas may cause a resemblance to malignant fibrous histiocytoma and atypical fibroxanthoma. However, at least in some areas, there are greatly elongated, thin, blunt-ended nuclei characteristic of smooth muscle cells. Also, demonstration of the enhancement of longitudinal striation due to myofibrils by staining with trichrome or phosphotungstic acid–hematoxylin will aid in the differentiation. The same holds true for subcutaneous leiomyosarcomas, in which the presence of endothelial-lined vessels may suggest a hemangiopericytoma. The more extended histologic differential diagnosis includes fibrosarcoma, rhabdomyosarcoma, dermatofibroma, dermatofibrosarcoma protuberans, malignant schwannoma, nodular fasciitis, and synovial sarcoma.

RHABDOMYOMATOUS MESENCHYMAL HAMARTOMA OF SKIN (STRIATED MUSCLE HAMARTOMA)

Rhabdomyomatous mesenchymal hamartoma of the skin, or striated muscle hamartoma, is a rare lesion that principally occurs in the face and neck of newborns but can present in adults as well (207). The typical presentation is as a small, solitary, dome-shaped papule or a polypoid pedunculated lesion, from a few millimeters to 1 to 2 cm. There is a strong male predominance. Hamartomas containing skeletal muscle have rarely been reported outside of the head and neck region (208).

Histopathology. Single or small groups of mature-appearing skeletal muscle fibers lie in the dermis and subcutaneous tissue below the normal epidermis. Mature fat, nerves, and adnexal structures may be admixed, and central calcification or ossification may be noted (209).

Differential Diagnosis. Fibrous hamartoma of infancy will have fat but not skeletal muscle fibers. Benign Triton tumor (neuromuscular choristoma), a rare subcutaneous, peripheral nerve-associated lesion, is composed of mature skeletal muscle and neural tissue. Juvenile rhabdomyoma has round and polygonal cells. A cutaneous embryonal rhabdomyosarcoma will show much less differentiation.

RHABDOMYOMA

Rhabdomyomas are extremely rare benign tumors of striated muscle (210) that are divided into cardiac and extracardiac types, which are then further subtyped on the basis of clinical and morphologic differences. *Adult-type rhabdomyomas* are slowly growing lesions that nearly always occur in the head and neck areas of older persons (Fig. 34-28). *Fetal-type rhabdomyomas*

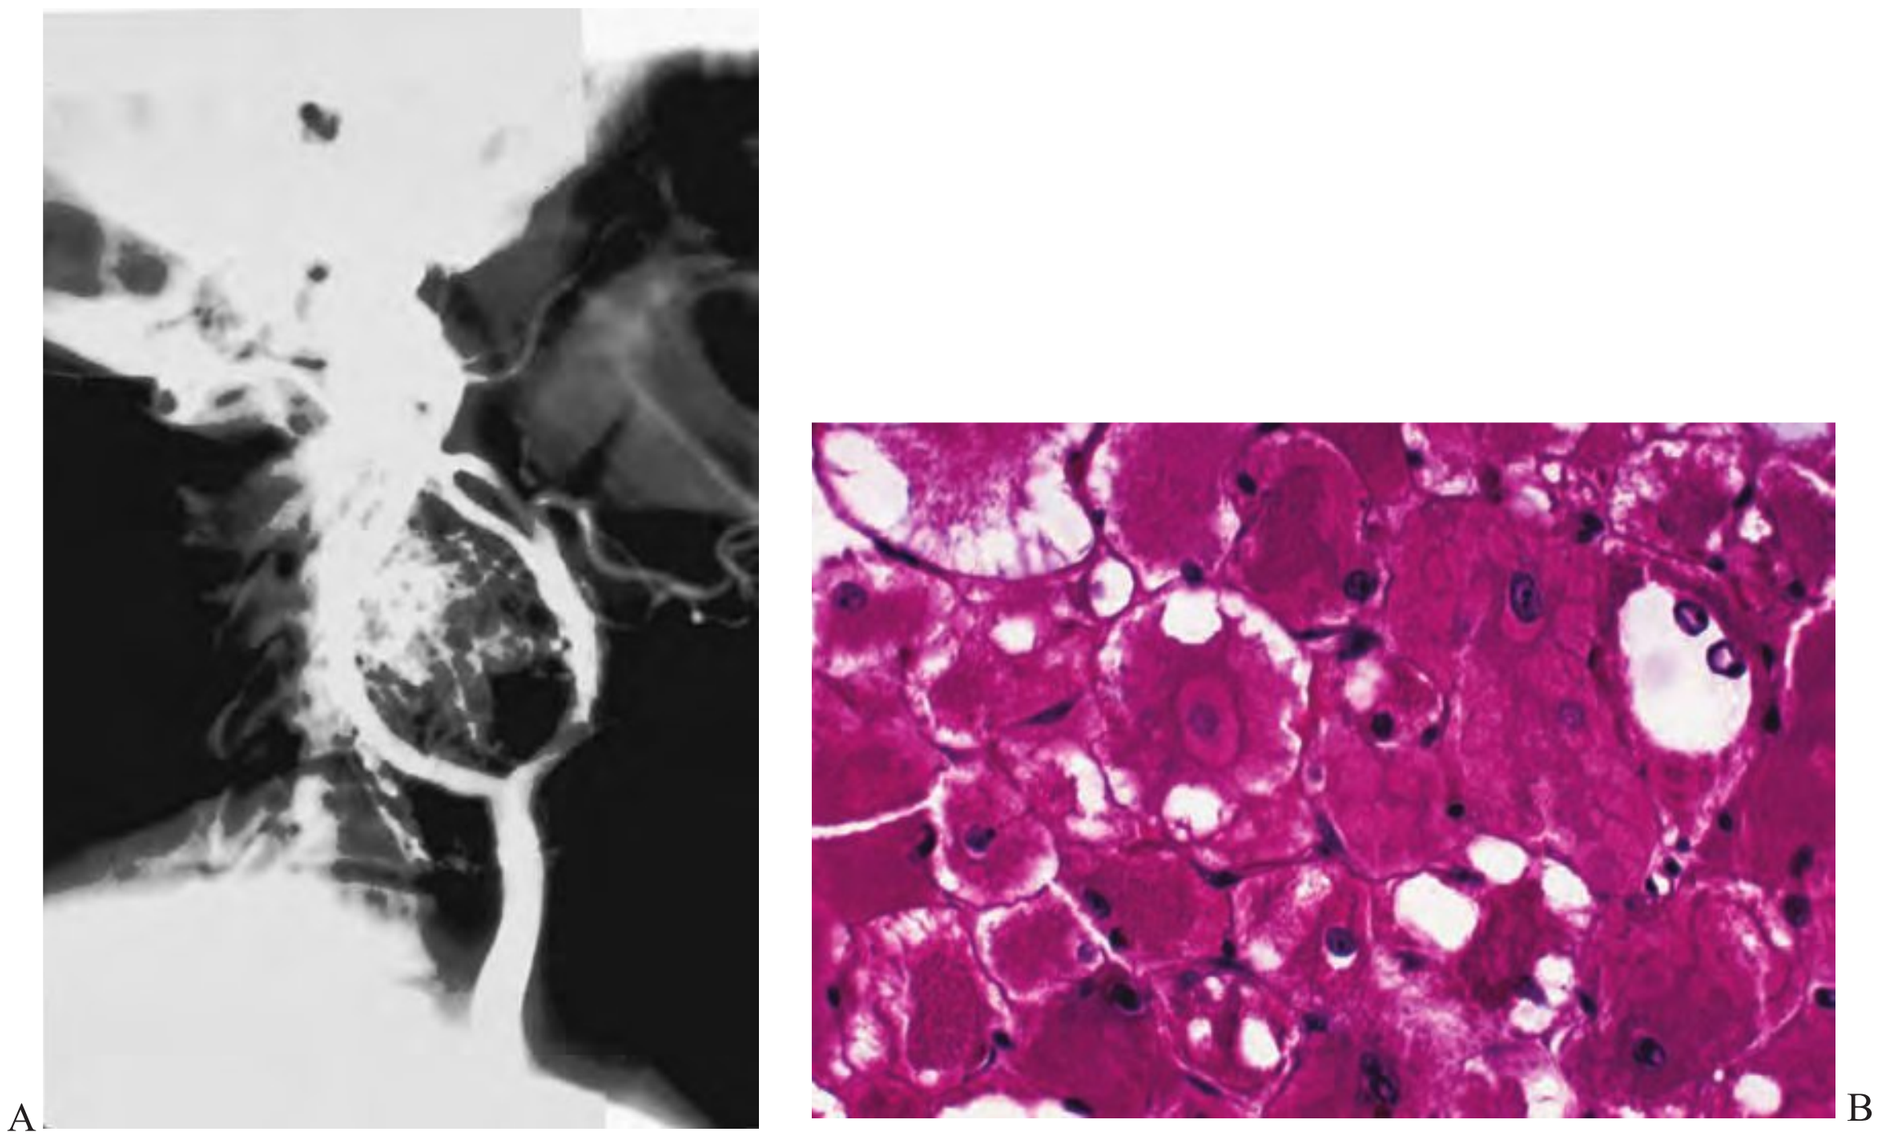

FIGURE 34-28. Adult-type rhabdomyoma (55-year-old man; 4-cm lateral neck mass). A: A hypervascular mass splays the carotid bifurcation in this carotid angiogram. B: Variably sized, deeply eosinophilic polygonal cells comprising this tumor have peripherally situated nuclei. Cytoplasmic cross-striations may be seen. Tissue processing removes intracellular glycogen and results in the pronounced vacuolated appearance of many of the cells. This lesion should not be mistaken for a granular cell tumor.

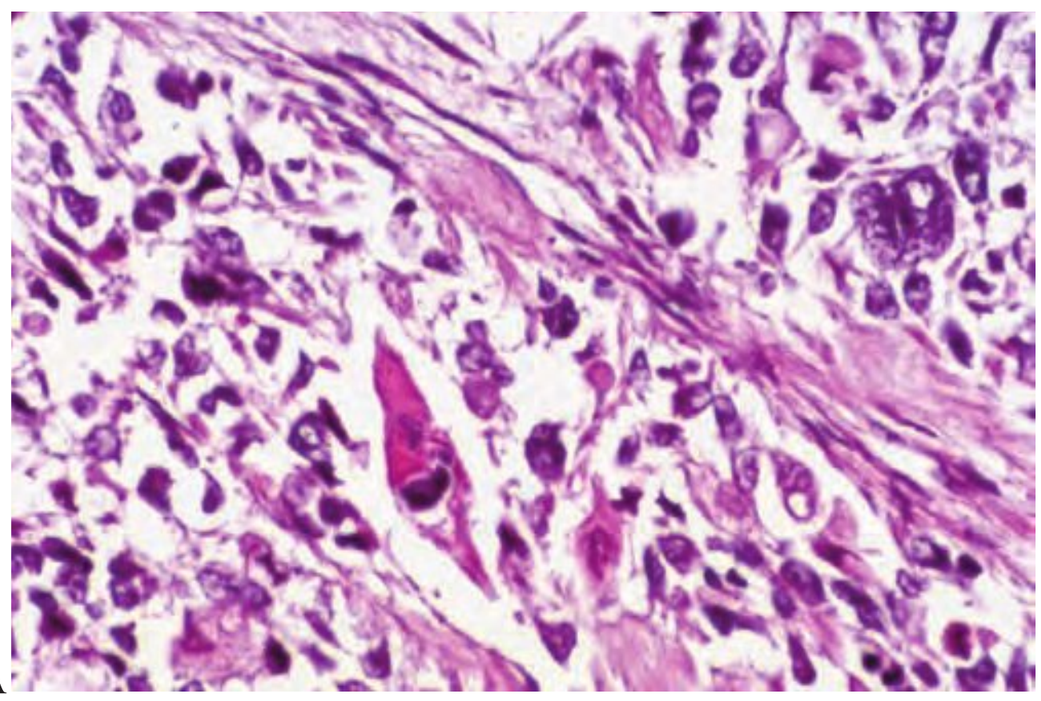
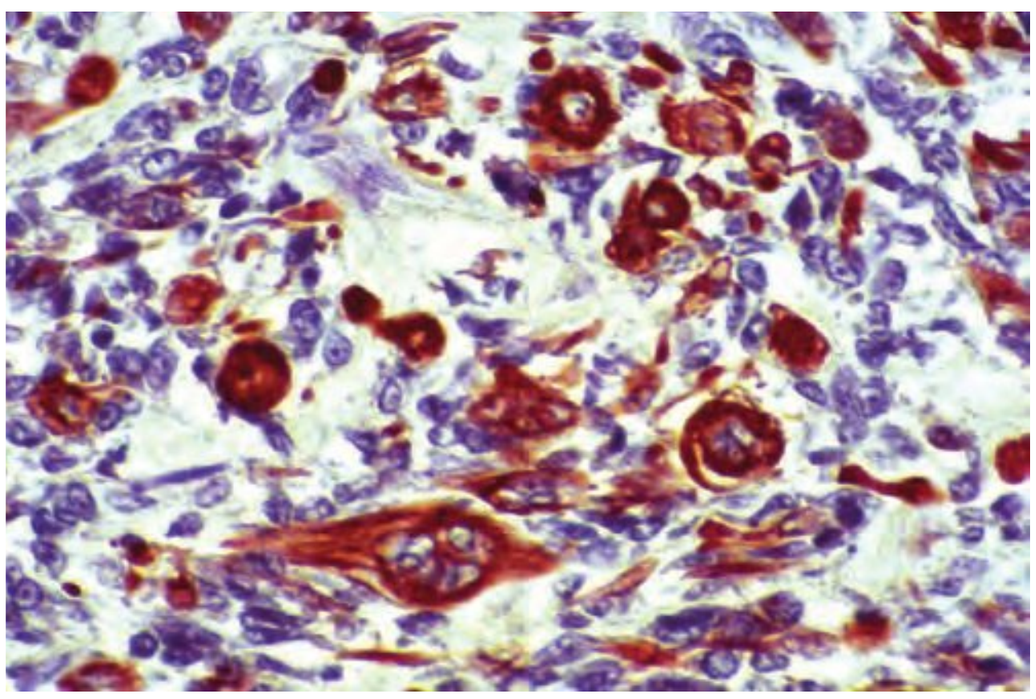
occur in the head and neck areas of children and adults. *Genital-type rhabdomyomas* are polypoidal tumor masses in the vagina and vulva of middle-aged women.



Histopathology. *Adult rhabdomyomas* contain cells with cytoplasmic vacuoles due to glycogen content but without easily observable cross-striations on H&E staining (Fig. 34-28B). Residual strands of cytoplasm between the vacuoles define "spider web cells" (211). The *fetal type* consists of immature skeletal muscle fibers. *Genital rhabdomyomas* contain interlacing fascicles or bundles of polymorphous cells, many with cross-striations, bland nuclei, and no mitoses. Immunohistochemical reactions identify positivity for desmin, myoglobin, actin, and myosin (212) and possibly weak S-100 staining (213). The tumor cells are surrounded by basement membrane laminin and type IV collagen (214).



Differential Diagnosis. Both adult rhabdomyoma and fetal rhabdomyoma show polygonal eosinophilic cells with peripherally or centrally localized nuclei and cross-striations, while in hibernoma, multivacuolated cells with centrally localized nuclei are detected. In granular cell tumor, polygonal eosinophilic cells with granular periodic acid-Schiff–positive cytoplasm are found (215). Immunohistochemically, rhabdomyomas are strongly positive for myogenic markers (desmin, actin, and myoglobin) but negative for S-100, while hibernoma and granular cell tumor strongly express S-100. Also exclude a supernumerary (216), accessory, or hypertrophic (217) muscle presenting as a tumor-like mass.

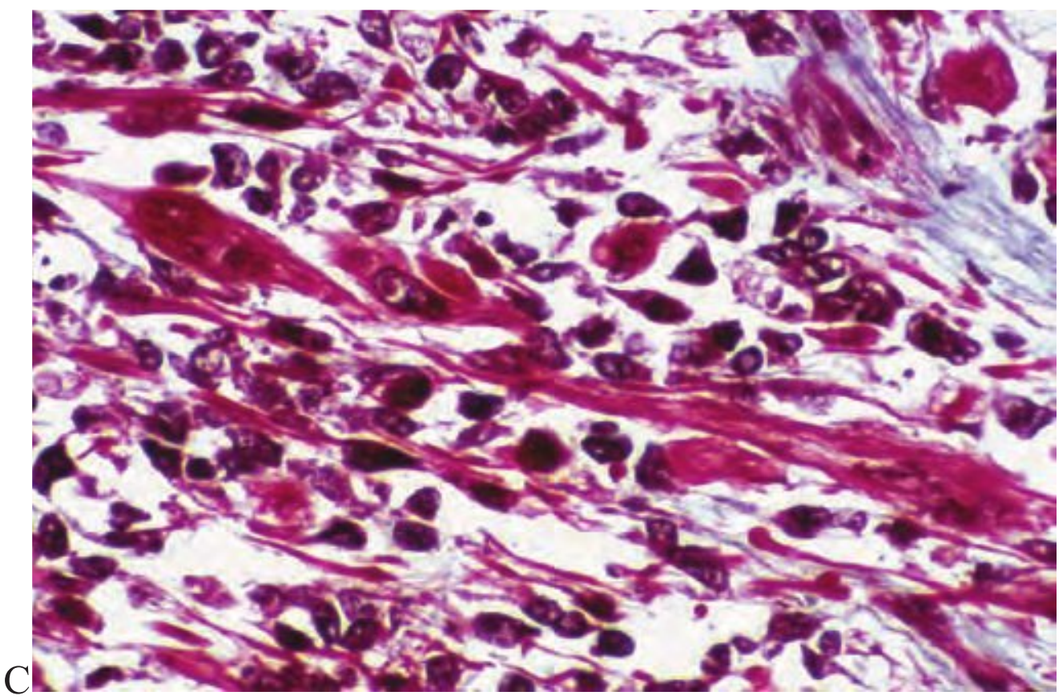
RHABDOMYOSARCOMA

Although rare in adults, rhabdomyosarcomas are the most common soft tissue sarcomas in children. Most of these tumors are located in intramuscular locations or the genitourinary tract, usually deep to the introitus, most often in the vagina and less so in the vulva and perineum (218). Involvement of the skin is rare (219). Five primary and two metastatic rhabdomyosarcomas with primary presentation in the skin accounted for only 0.7% of the 682 cases of rhabdomyosarcoma collected at two large institutions with a main interest in soft tissue tumors (220). Only a few rhabdomyosarcomas have presented as dermal nodules (221). Subcutaneous indurations, congenital rashes (222), or multiple cutaneous metastases are other presentations. Rarely, rhabdomyosarcoma has arisen within congenital melanocytic nevi (223). The finding of both rhabdomyoblastic and melanocytic differentiation within the same lesion lends support to the hypothesis of their derivation from common pluripotential stem cells or neural crest cells.

Histopathology. Rhabdomyosarcomas often exhibit a low degree of differentiation, so their identification requires immunohistochemical studies (Fig. 34-29). Only some of these

A

B



C

FIGURE 34-29. Embryonal rhabdomyosarcoma pattern (14-year-old boy; 3-month history of a mass, ultimately 11 × 7 cm, partly cystic and hemorrhagic, along the spermatic cord with additional unfavorable histology including both alveolar and anaplastic features; patient is disease-free 8 years after removal of the tumor and ipsilateral iliac nodal metastases, plus radiation and chemotherapy.) A: Cytologically malignant round and elongate tumor cells occur together. B: The tumor cells are reactive for actin (but were negative for desmin) by immunoperoxidase technique. C: Myoplasm stains bright red in this Masson trichrome preparation.

tumors contain cells recognizable as rhabdomyoblasts by virtue of their cytoplasm exhibiting cross-striation that is best revealed by phosphotungstic acid–hematoxylin staining. Round cells of the *embryonal variant*, unlike those of lymphoma, neuroblastoma, cutaneous neuroendocrine (trabecular or Merkel cell) carcinoma, and Ewing's sarcoma, tend to have cytoplasmic rims that are stained red by trichrome (Fig. 34-29C). The *botryoid type*, a gross, morphologic descriptor meaning "grapelike," is a variant of the embryonal type found mainly in mucosa-lined hollow organs, but a few may be encountered in skin-covered surfaces such as the eyelid or anal region (219). Some tumors show alveolar spaces lined with small, round, dyshesive neoplastic cells, with tumor giant cells floating within these spaces (*alveolar rhabdomyosarcoma*) (224) (Fig. 34-30A). A *mixed form*, such as embryonal rhabdomyosarcoma with focal alveolar features, is not uncommon and for staging and prognostic purposes are classified as the alveolar type (219) that has a more aggressive clinical course. Pleomorphic cytologic features may be encountered in pediatric tumors still properly classified as embryonal or alveolar. Cells with elongated eosinophilic cytoplasm, so-called "strap cells," are suggestive but not diagnostic of rhabdomyosarcoma (224) (Fig. 34-30B) and may be found in the *pleomorphic type* (Fig. 34-30C). A sclerosing variant has cords of small, round malignant cells embedded in a densely hyalinized matrix having both a chondroid and osteoid-like appearance (225).

Histogenesis. Immunohistochemical studies of deparaffinized tissue may show undifferentiated cells to be positive only for vimentin, indicating a mesenchymal origin. More differentiated cells may be positive for desmin and myoglobin, which is indicative of muscular differentiation (224).

Differential Diagnosis. In younger patients, poorly differentiated round and spindle cell sarcomas should be excluded. Immunostains for muscle markers lack complete specificity. Rhabdomyosarcomatous differentiation can be seen in other sarcomas (e.g., "dedifferentiated" chondrosarcoma and malignant peripheral nerve sheath [malignant Triton] tumor) and in less expected settings such as cutaneous neuroendocrine (Merkel cell) carcinoma (226). Benign reactive lesions such as proliferative myositis and skeletal muscle regenerative giant cells in scars are to be excluded.

MALIGNANT EXTRARENAL RHABDOID TUMOR

Rhabdoid sarcoma (malignant rhabdoid sarcoma), comprising 2% of renal tumors, has a phenotype-characterized histopathology by the presence of eosinophilic cytoplasmic inclusions corresponding to masses of intermediate filaments on electron

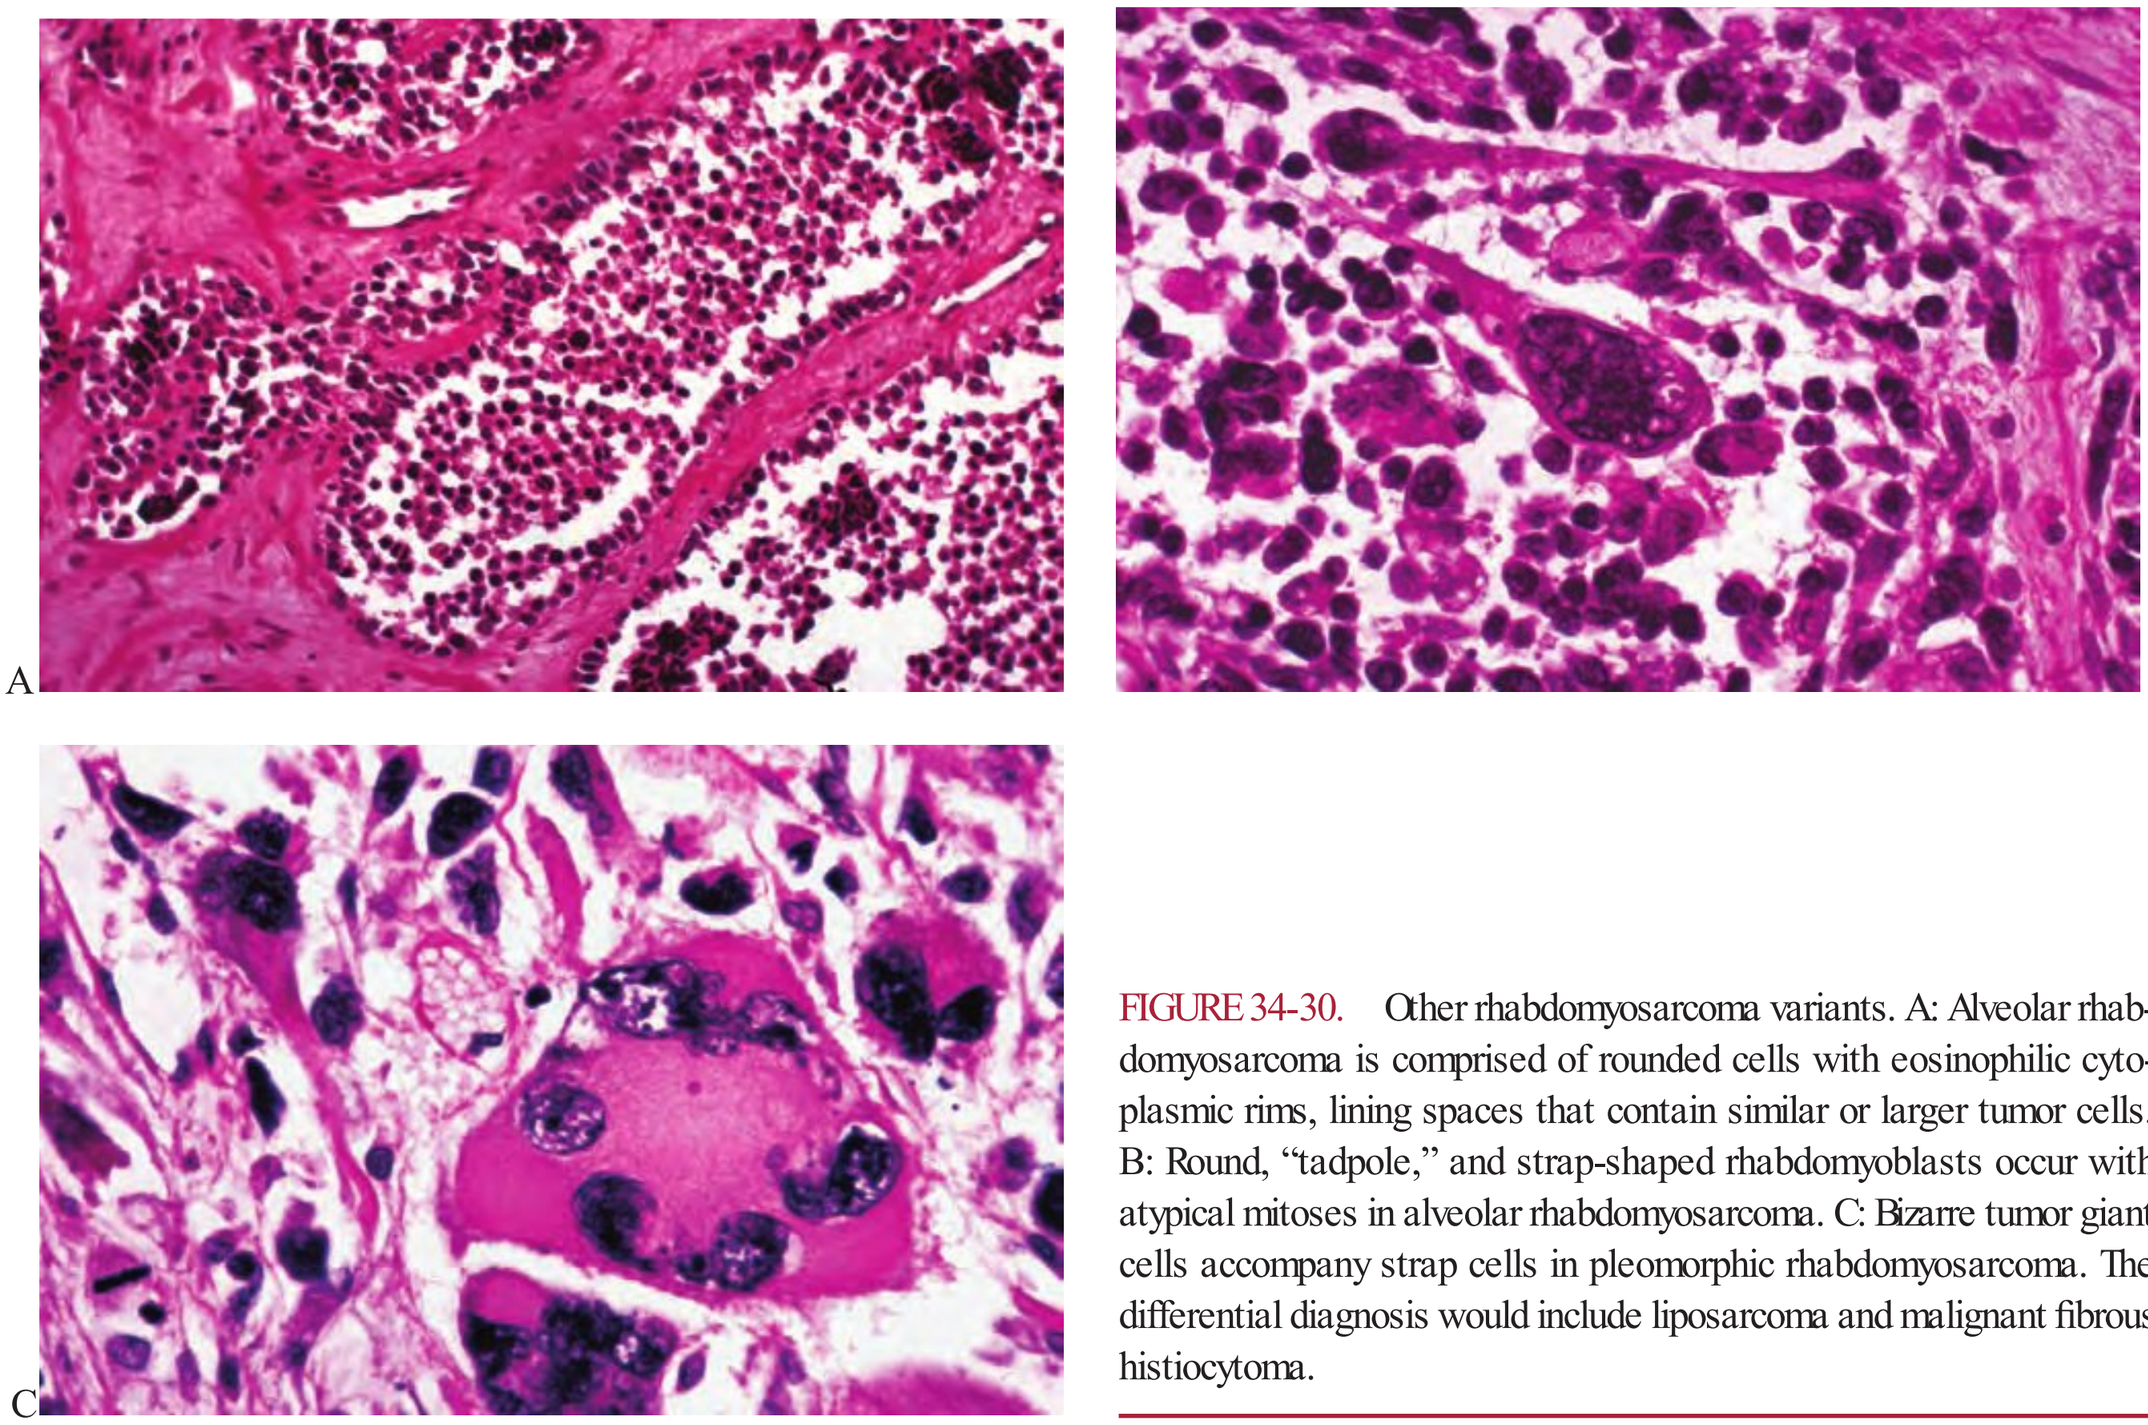


FIGURE 34-30. Other rhabdomyosarcoma variants. A: Alveolar rhabdomyosarcoma is comprised of rounded cells with eosinophilic cytoplasmic rims, lining spaces that contain similar or larger tumor cells. B: Round, "tadpole," and strap-shaped rhabdomyoblasts occur with atypical mitoses in alveolar rhabdomyosarcoma. C: Bizarre tumor giant cells accompany strap cells in pleomorphic rhabdomyosarcoma. The differential diagnosis would include liposarcoma and malignant fibrous histiocytoma.

microscopy that can arise in subcutaneous sites (227), congenitally, or in adults (228). Metastatic skin disease has been reported only in infants (229). The PAS-D- and vimentin-positive eosinophilic round cytoplasmic inclusions are negative for muscle-specific antigens. Prognosis is poor (230).

Differential Diagnosis. Carcinomas of various types including Merkel cell carcinoma (231), melanoma (232), and lymphoma (233) may have rhabdoid features.

Pathogenesis. It is arguable whether the rhabdoid phenotype may represent a "final common pathway" that many tumors take in escalating grade and aggressivity (234) or a clinicopathologic entity in its own right. Previously reported cases of rhabdoid tumors in adults support the contention that such tumors, although of distinctive morphologic phenotype, are of heterogenous lineage differentiation and do not represent a distinct clinicopathologic entity. A variety of lineage differentiation was shown by immunohistochemistry and electron microscopy, the lesions representing leiomyosarcoma, gastric carcinoma, epithelioid sarcoma, Merkel cell carcinoma, and desmoplastic small round cell tumor (235). Deletions and/or translocations of chromosomes 11p15 and 22q11 are found (236).

CUTANEOUS CHONDRO-OSSEOUS LESIONS

Extraskeletal osseous and cartilaginous tumors and tumor-like conditions of the extremities can often be differentiated radiologically; for those that cannot, knowledge of the spectrum of lesions will allow a suitably ordered differential diagnosis. Of the osseous lesions (myositis ossificans, fibro-osseous pseudotumor, fibrodysplasia (myositis) ossificans progressiva [FOP], soft tissue osteoma, and extraskeletal osteosarcoma), all but myositis ossificans are relatively rare. The differential diagnosis for these extraskeletal osseous and cartilaginous lesions includes soft tissue sarcoma, calcified tophi in gout, melorheostosis, pilomatricoma, and tumoral calcinosis (237).

CUTANEOUS OSSIFICATION

Cutaneous bone formation may be primary or secondary. If it is primary, there is no preceding cutaneous lesion; if it is secondary, bone forms through metaplasia within a preexisting lesion. Primary cutaneous ossification can occur in Albright's hereditary osteodystrophy (AHO) and as osteoma cutis. Aggressive, systemic forms of heterotopic ossification exist, generating lesions that often resist surgical treatment and producing a high rate of recurrence. These entities typically manifest during infancy as genetic syndromes such as fibrodysplasia ossificans progressiva or progressive osseous heteroplasia (POH) (238).

Albright's Hereditary Osteodystrophy

In AHO, first described in 1952 (239), multiple areas of subcutaneous or intracutaneous ossification are often encountered

FIGURE 34-31. Heterotopic ossification in pseudohypoparathyroidism. A plain film of a juvenile's thigh features irregular branching spicules and cords of bone in dermis and subcutaneous tissue medial to the femur.

(Fig. 34-31) in infancy and childhood, and its significance should not be overlooked, even in the normocalcemic patient (240). Early recognition of the skin manifestations of this syndrome and careful follow-up are important to prevent the deleterious effects of hypocalcemia. No definite area of predilection seems to exist; areas of ossification have been described on the trunk (241), extremities, and scalp. The areas of ossification may be so small as to be hardly perceptible or as large as 5 cm in diameter. Those located in the skin may cause ulceration, and bony spicules may be extruded through the ulcer. In addition to cutaneous and subcutaneous osteomas, bone formation may be observed in some cases along fascial planes.

AHO includes the syndromes of pseudohypoparathyroidism (PHP) and pseudopseudohypoparathryoidism. Patients with the former condition have hypocalcemia with a failure to respond to parathyroid hormone, whereas patients with the latter syndrome fail to respond to parathyroid hormone but have normal serum calcium values. PHP is described as AHO when a specific phenotype is present: short stature, round facies, and multiple skeletal abnormalities, such as curvature of the radius and shortening of some of the metacarpal bones (242). As a result of this shortening, some knuckles are absent when the fists are clenched, and depressions or dimples are apparent there instead (the Albright dimpling sign). Additional manifestations include basal ganglia calcification and mental retardation.

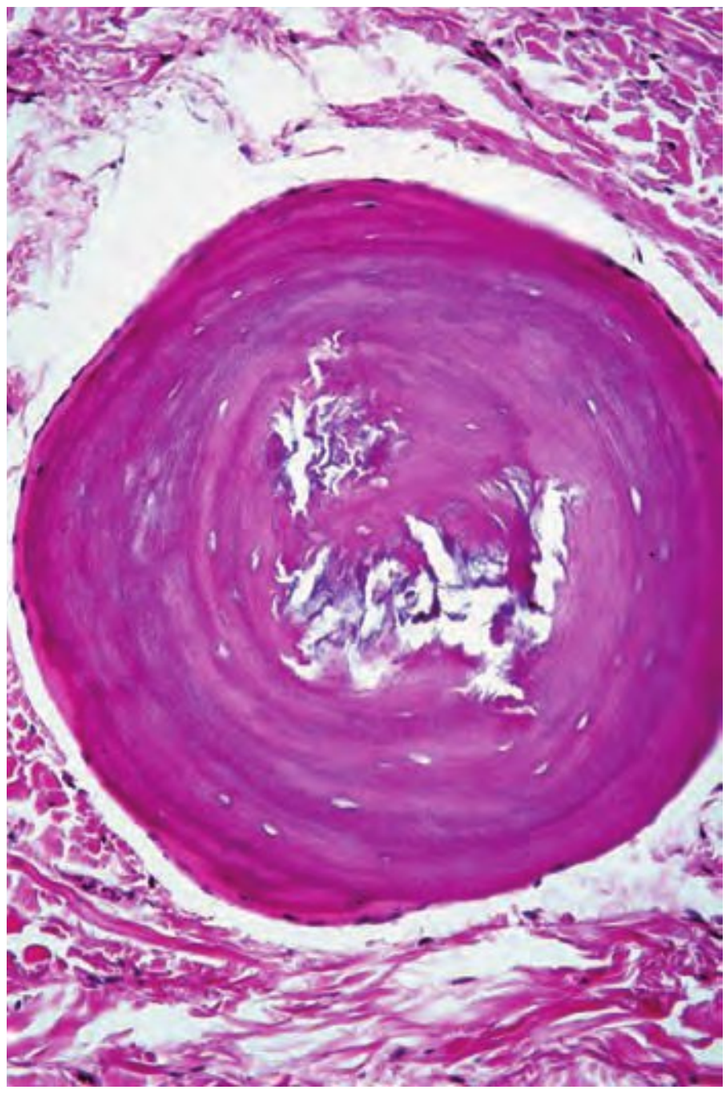
Pathogenesis. An autosomal dominant condition, AHO results from heterozygous inactivation of G(s)alpha, encoded by the

GNAS1 locus on the distal long arm of chromosome 20. Small insertions and deletions or point mutations of GNAS1 are found in approximately 80% of patients with AHO. The remainder may be accounted for by larger genomic rearrangements (243).

Histopathology. Spicules of bone of various sizes may be found within the dermis (244) or in the subcutaneous tissue. The bone contains fairly numerous osteocytes as well as cement lines that are best revealed with a strong (e.g., Harris) hematoxylin or in polarized light. In addition, osteoblasts with elongated nuclei can usually be seen along the edges where new bone is being laid down. The osteoblasts that form bone in all forms of primary cutaneous ossification originate in preexisting fibrous connective tissue, and thus their product is termed *intramembranous* rather than *enchondral* bone. Osteoclasts, if present, are cells with multiple large nuclei resembling multinucleated foreign body giant cells but are distinguished by their attachment to a bone surface. They excavate surface pits called *Howship's lacunae* into the bone substance as the initial step in remodeling. Osteons with haversian canals containing blood vessels and connective tissue are produced through internal remodeling and indicate the passage of significant time. The spicules of bone may enclose, either partially or completely, areas of mature fat cells, which represent the maturation of the lesion with establishment of a medullary cavity. Hematopoietic elements, however, are observed only rarely among the fat cells.

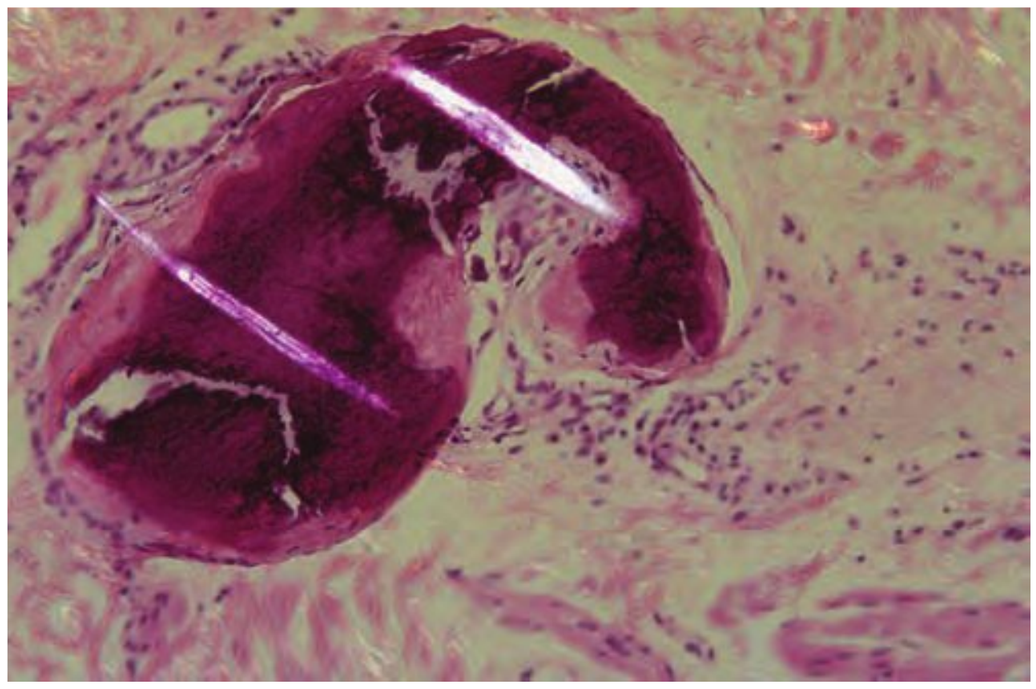
The incidence of cutaneous ossification in AHO is fairly high, estimated at 42% of patients with PHP and in 27% of those with pseudopseudohypoparathyroidism (244). However, the reason for the bone formation is not clear. Because the association of AHO with cutaneous ossification was not recognized until 1965 (245), the question arises as to how many cases of primary cutaneous ossification reported before then occurred in association with AHO. In a review examining this question (242), several cases originally reported as primary osteoma of the skin were recognized as showing evidence of AHO. Although the conclusion that most cases of primary osteoma cutis are associated with AHO seems somewhat exaggerated, it is nevertheless apparent that patients with extensive foci of ossification usually have AHO.

Differential Diagnosis. POH is a rare autosomal dominant condition of mesenchymal differentiation in females characterized by dermal ossification during infancy and progressive heterotopic ossification of cutaneous, subcutaneous, and deep connective tissues during childhood (246). Recently, paternally inherited inactivating mutations in the GNAS1 gene on chromosome 20q13 have been implicated in the pathogenesis, although sporadic cases have also been reported (247). It is clinically distinguishable from AHO and FOP, which can present as fibrous scalp nodules (248). The initial skin involvement tends to be a plaquelike or papulovesicular rash or reddened induration, with dermal ossification. The disorder can be distinguished from FOP by the presence of cutaneous ossification, the absence of congenital malformations of the skeleton, the absence of inflammatory tumor-like swellings, the asymmetric mosaic distribution of lesions, and the absence of predictable regional patterns of heterotopic ossification. Also, in FOP, cartilage production precedes ossification of deeper tissues (enchondral ossification), whereas the predominant pathway of bone formation in POH and AHO is intramembranous. POH can be distinguished from AHO by the progression of heterotopic ossification from skin and subcutaneous tissue into skeletal muscle, the presence of normal endocrine function, and the absence of a distinctive habitus associated with AHO. The genetic basis of POH is unknown; it may lie at one end of a clinical spectrum of ossification disorders mediated by abnormalities in GNAS1 expression and impaired activation of adenylyl cyclase (246).



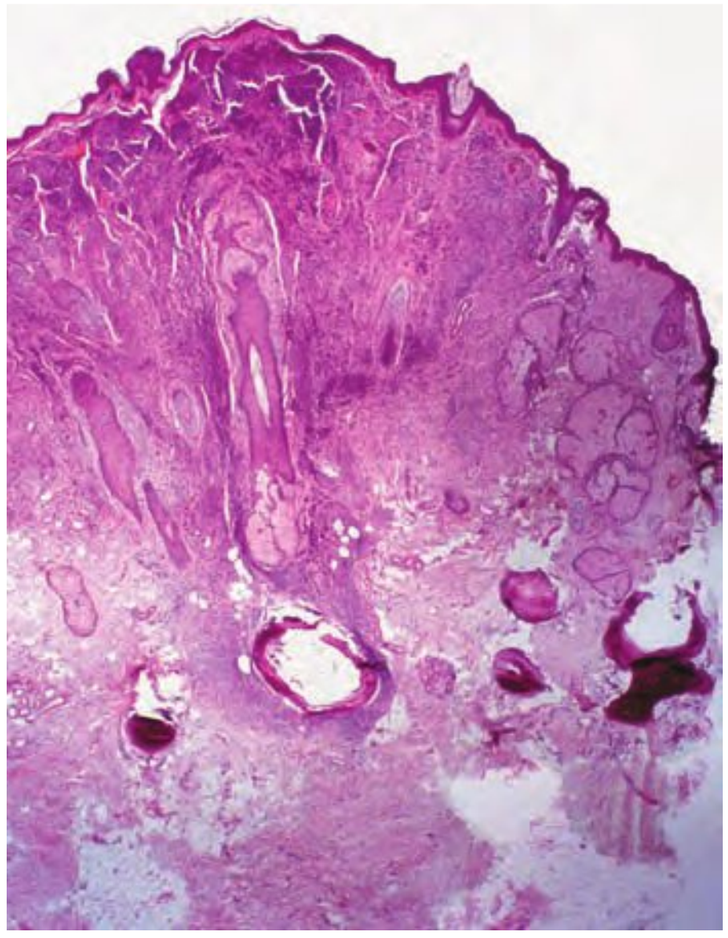
Osteoma Cutis

The term *osteoma cutis* is applied to cases of primary cutaneous ossification in which there is no evidence of AHO in either the patients or their families (249). Congenital osteomas occur in Gardner's syndrome and AHO or in patients presenting with numerous, spontaneous osteoma cutis lesions without systemic manifestations or disease (250). Multiple miliary osteoma cutis, a disfiguring disorder, can occur unassociated with AHO (251).

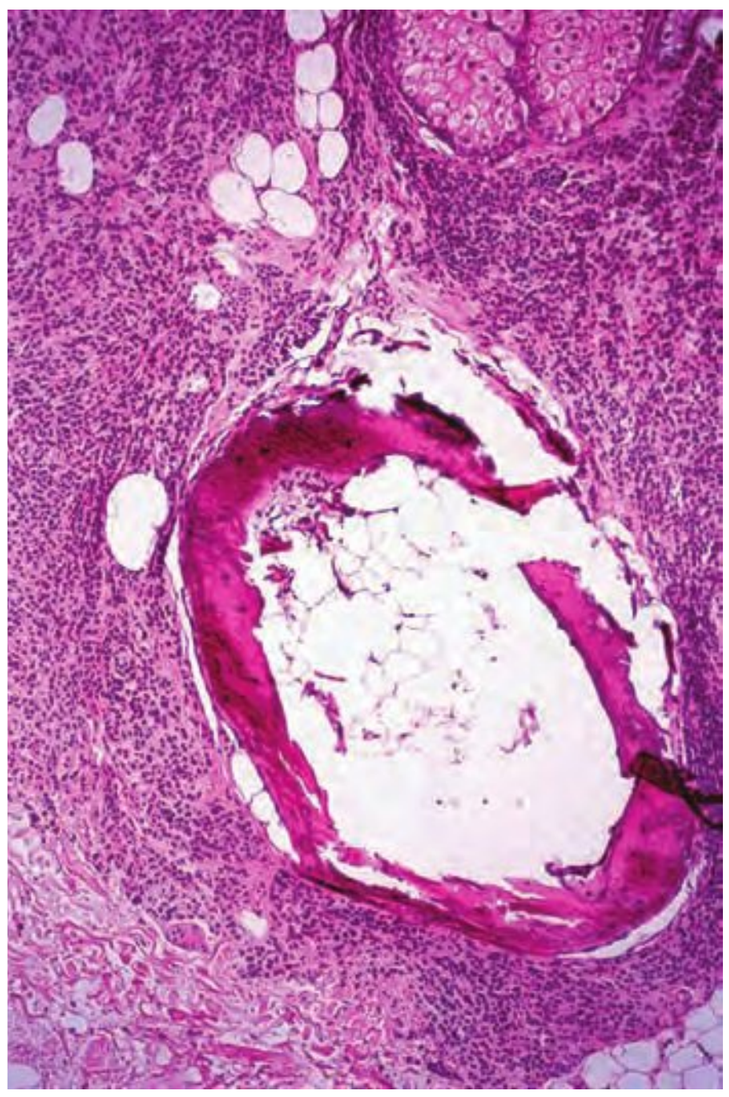


Less noticeable facial osteoma cutis is likely more common than reported, since in a series of randomly selected patients with histories of long-term acne vulgaris, three of seven patients had x-ray evidence of multiple cutaneous radiopaque deposits on the face (252).

The four groups of patients with osteoma cutis have osteomas limited in extent in all but the first group: (a) patients with *widespread osteomas* since birth or early life but without evidence of AHO; (b) patients with *single, large, plaquelike or platelike osteomas* present since birth either in the skin of the scalp (253) or in the skin or subcutaneous tissue of an extremity (254); (c) patients with *single, small osteomas* arising in later life in various locations (254); and (d) patients with *multiple miliary osteomas of the face.* In some instances of the latter, all of them women, the osteomas do not appear until late in life (255). In others, they are observed in young women in association with long-standing acne vulgaris; in these, the miliary osteomas have been interpreted as metaplastic ossification within acne scars (256). However, the absence of acne vulgaris among the patients in the older age group and the presence in one case of miliary osteomas also in the scalp, where acne does not occur (255), raise the possibility that the acne vulgaris is coincidental.



Histopathology. The histologic findings in osteoma cutis are the same as in primary cutaneous ossification occurring in conjunction with AHO. Small, generally spherical spots of ossification within the dermis often start initially against a speck of amorphous mineralization or demonstrably around extravasated keratin debris (Fig. 34-32A), hair shafts (Fig. 34-32B), or in the stroma of another lesion such as a melanocytic nevus (Fig. 34-32C, D). This bone is formed by the activities of flattened osteoblasts that appear to be derived through modulation from dermal fibroblasts (Fig. 34-32E). A



A

B

C

D

FIGURE 34-32. Osteoma cutis. A: A spherical osteoma cutis has resident osteocytes in oval lacunae of its laminations about a central nidus of mature squames (keratin flakes) that were likely extruded from a follicle or cyst (80-year-old woman; shoulder). B: A polarized light view highlights two hair shafts crossing an irregular osteoma cutis (70-year-old man; mid-back). C: Five rounded ossifications are in the base of this compound nevus (44-year-old woman; cheek). D: Fat is in the central chamber of one of the osteomas shown in (C). (continued)

minority of the formative cells persist in the osseous product as resident osteocytes. Osteomas undergo a high rate of remodeling (250), enlarging by continued bone application on outer surfaces with eventual central hollowing out by osteoclastic erosion (Fig. 34-32F). A circular outline is commonly achieved, with central space for fatty marrow and, rarely, trilineage hematopoietic marrow. They are at risk for all of the disorders of genuine skeletal members. In cases with transepidermal elimination, some patients show fragments of bone within channels lined by epidermis and leading to the surface (Figs. 34-32G, H), as with a foreign body, and others show such fragments within breaks in the epidermis. A sinus tract draining an underlying osteomyelitis or septic joint should enter the differential.

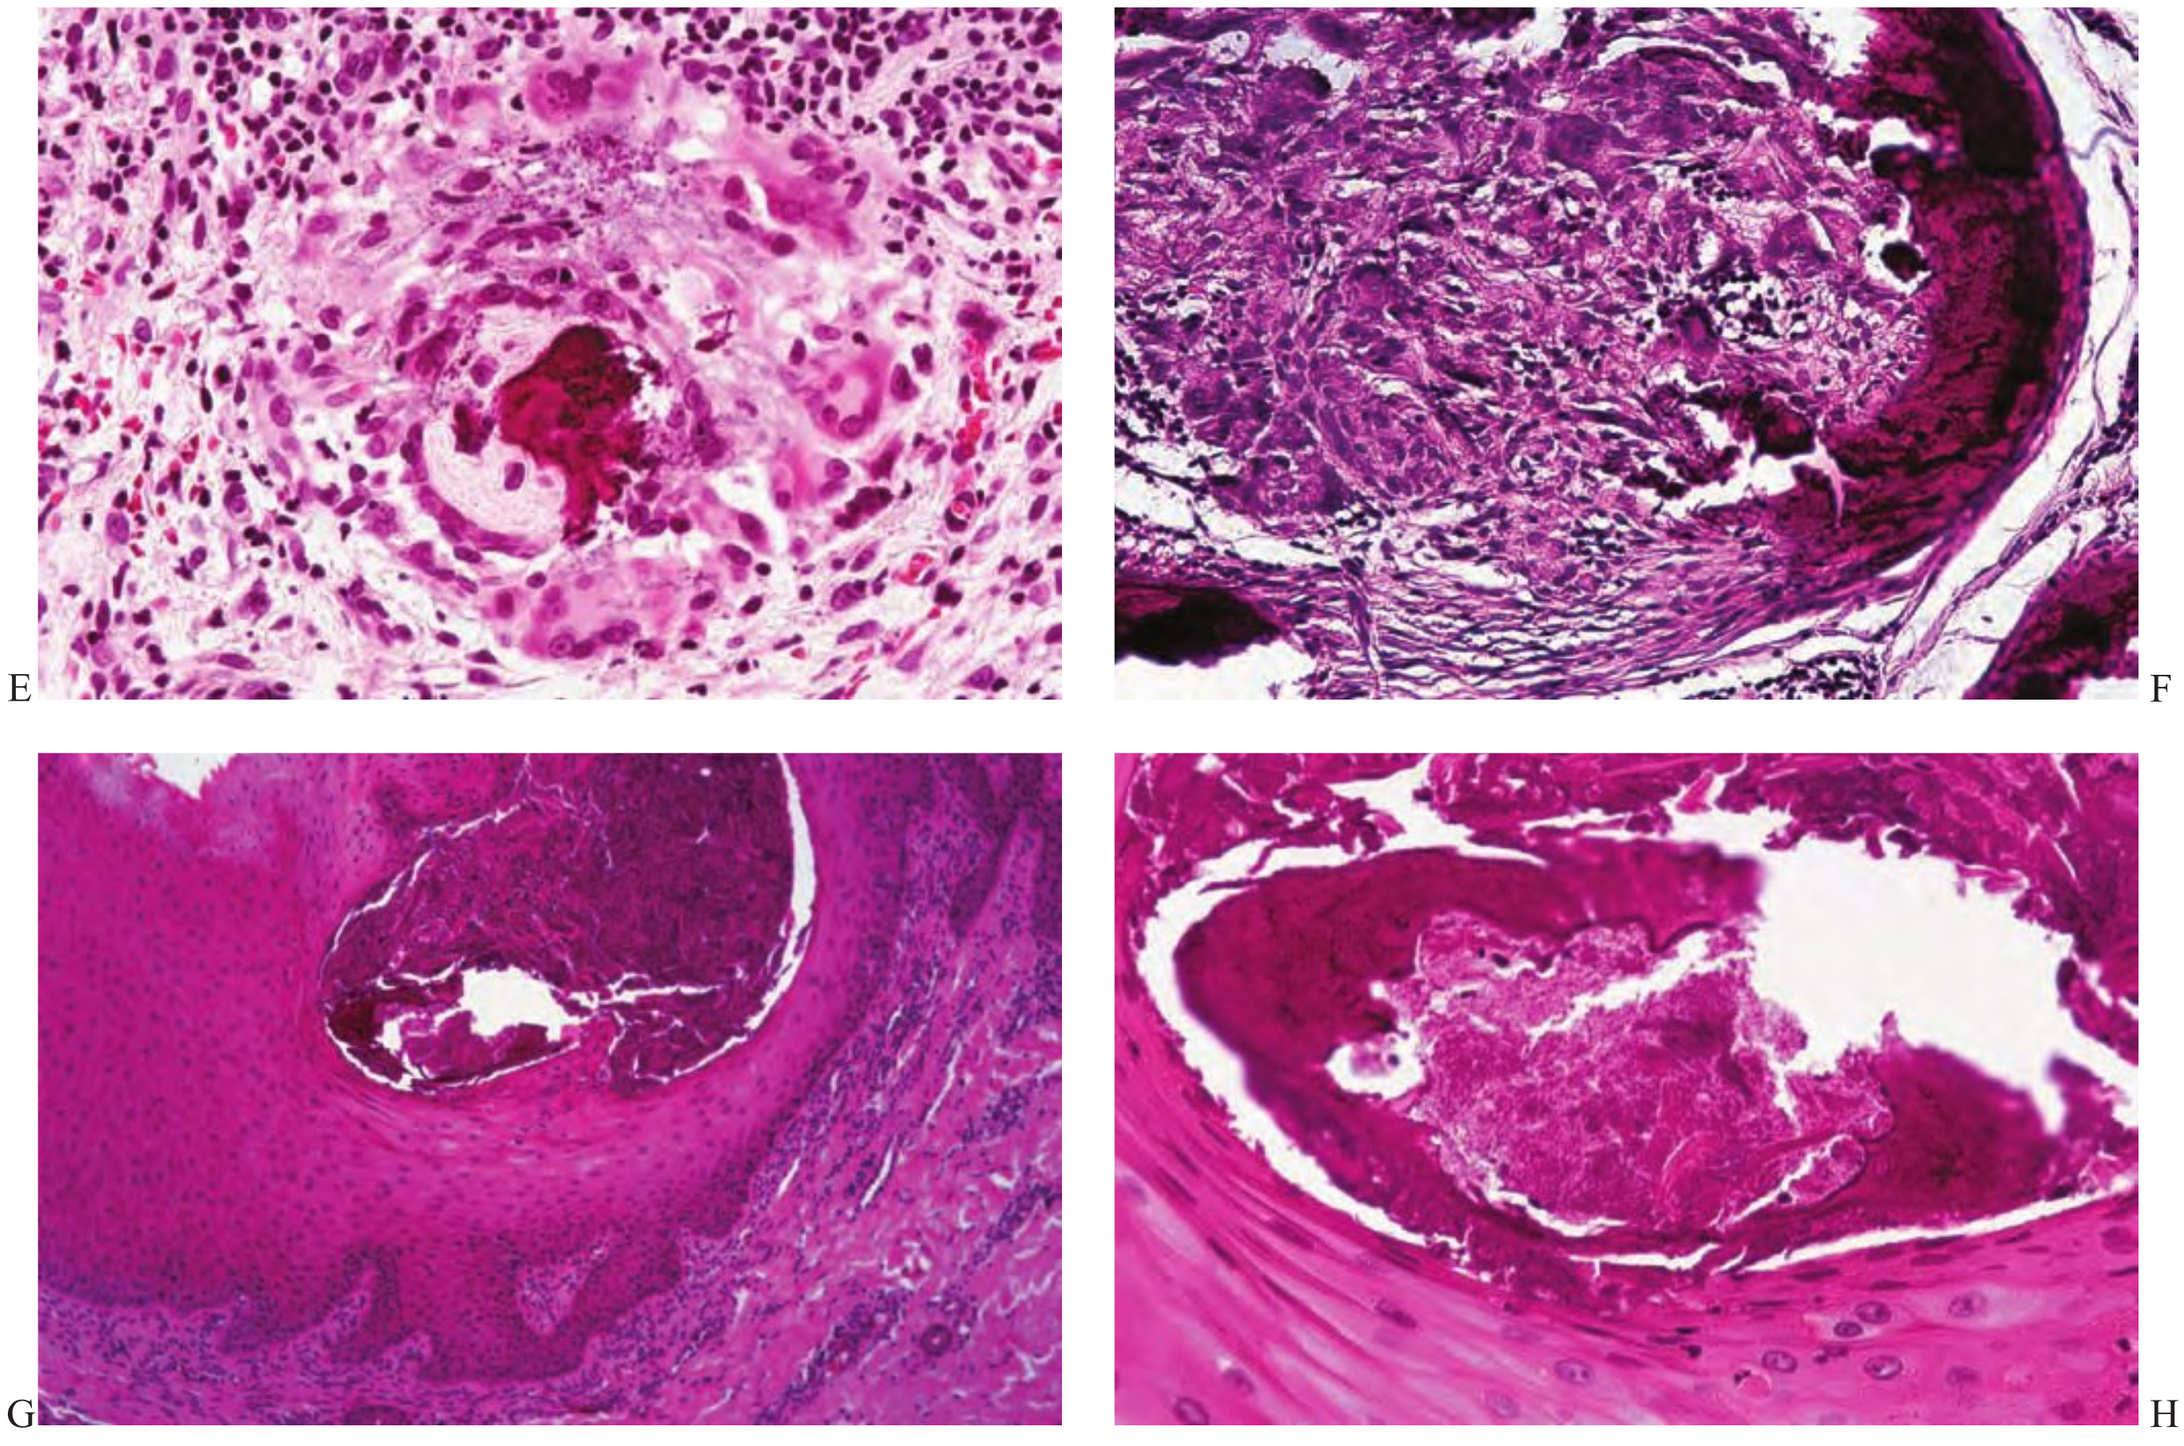


FIGURE 34-32. Continued. E: A very early stage in osteogenesis is depicted as it occurred near ruptured folliculitis (43-year-old man; back). F: Exuberant osteoclasia is hollowing out this osteoma that occurred in a nevus (36-year-old woman; face). G: An epidermal-lined channel is evacuating a small osteoma, no longer in dermis (74-year-old man; toe). H: A high-power view of the osteoma from (G) depicts osteoclastic erosions (Howship's lacunae) and autolysis of associated inflammatory exudate.

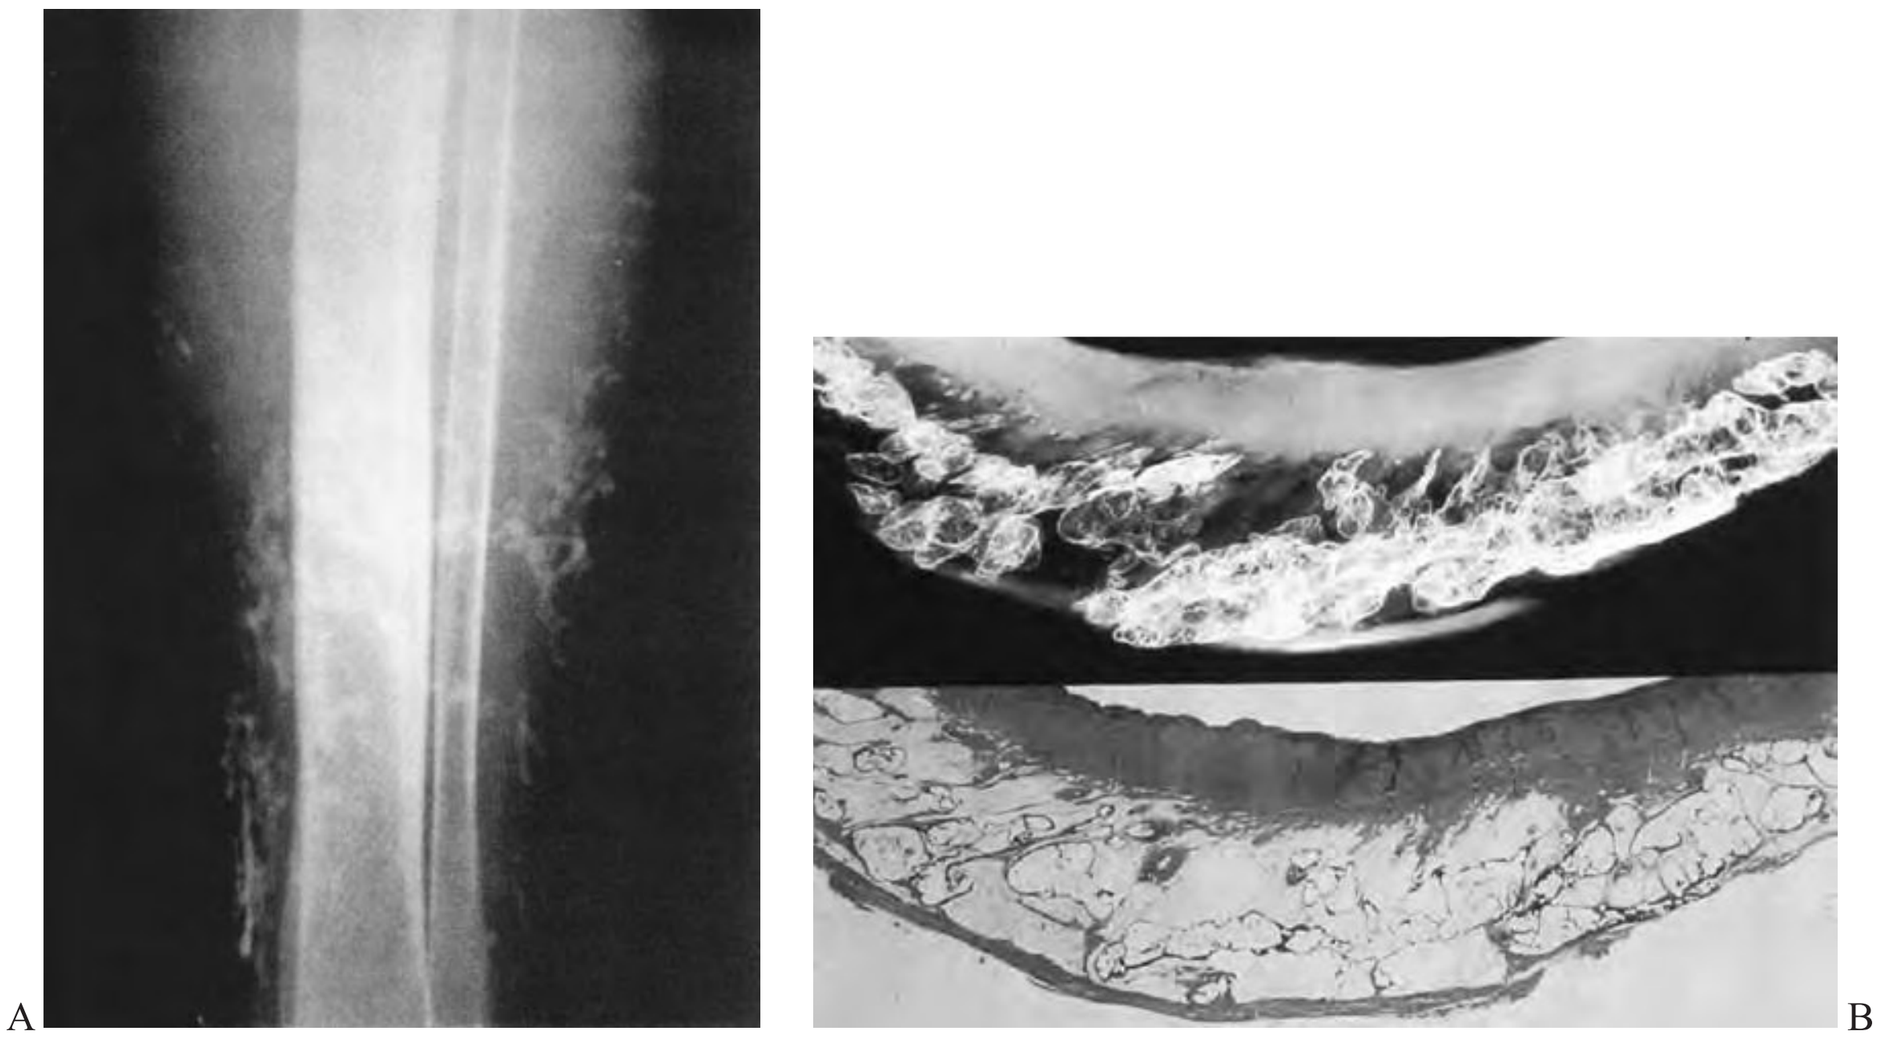
Pathogenesis. Postulation of "embryonal cell nests" or "primitive mesenchymal cells" as the source for osteoblasts (257) is unnecessary, since in the genesis of osteoma cutis, dermal fibroblasts have the ability to differentiate into osteoblasts (258). Cultured cells from the adult human hair follicle dermis can be directed toward adipogenic and osteogenic differentiation (259). They actively deposit type I collagen, as in mature bone, but also 80% to 85% of collagen in the skin. *In situ* hybridization techniques further indicate that given appropriate stimulation, indigenous fibroblasts have the ability to modulate into osteoblastic cells (see discussion of myositis ossificans) that have the same properties as those of osteoblasts, such as high alkaline phosphatase activity and a high expression of osteonectin (249). Osteogenesis by dermal fibroblasts cultured *in vitro* has been verified in a rabbit model (260). Dermal "fibroblasts" can be viewed with new respect. No (stem) cell rides idly. In multiple miliary osteoma cutis, a dynamic bone study using a tetracycline double- labeling technique demonstrated a high rate of internal remodeling (261).

Metaplastic or Secondary Ossification

Metaplastic or secondary ossification occurs within a preexisting lesion. A simple prerequisite seems to be some antecedent relatively rigid substrate. Virtually any process that calcifies may secondarily ossify (262).



Histopathology. The tumor that most commonly shows metaplastic ossification is pilomatricoma (calcifying epithelioma of Malherbe) (see Chapter 30), in 14% to 20% of patients (263). Calcification of shadow cells attracts osteoclastic giant cells. Osteoclastic erosion of mineralized epithelium is followed by ("coupled to") osteoblastic deposition of osteoid against remnants of the shadow cell islands. The process is therefore similar to enchondral ossification, wherein mineralized cartilage is the inducing factor and can lead to a fat-filled

cancellous network with thin cortex resembling a normal rib cross-section. Ossification is also rarely found in basal cell carcinoma, where it takes place usually in the stroma but sometimes around mineralizing keratin microcysts. Basal cell carcinomas rarely have ossification (263), even including those in the nevoid basal cell carcinoma syndrome (264). In intradermal nevi, ossification usually follows folliculitis. In desmoplastic malignant melanoma, fibroplasia may be accompanied by cement production resulting in bone formation (265). Rare melanomas in which there is osteoid synthesis by S-100–positive tumor cells have been termed *osteogenic melanomas* (266). Metaplastic ossification is exceptional in scars, burns (267), venous stasis (Fig. 34-33), nephrogenic systemic fibrosis (268), cutis laxa–like pseudoxanthoma elasticum (269), and in inflammatory processes of the skin such as morphea, systemic scleroderma, dermatomyositis (270), and toxic epidermal necrolysis that resulted in multiple joint contractures (271).

Postinjury Ossification

Myositis ossificans (Fig. 34-34) results from a postinjury modulation of osteoblasts and can occur in a sufficiently superficial location to come to the attention of dermatology (272). The characteristic radiologic appearance is that of a mass with a peripheral rim of radiodensity correlating with the most advanced and mature bony parts of the lesion as well as a relatively lucent, maximally injured, and somewhat ischemic central area. Other nonneoplastic soft tissue processes with bone formation such as pseudomalignant osseous tumor of soft tissues (273) (Fig. 34-35), florid reactive periostitis (274), and bizarre parosteal osteochondromatous proliferation (275) occur more commonly in acral location than myositis ossificans. A differential diagnosis of these lesions includes periosteal and parosteal osteosarcoma, periosteal chondroma, and osteomyelitis.

Subungual exostosis (Fig. 34-36), first described by Dupuytren (276), is a fairly common benign bony projection that occurs on a distal phalanx beneath or beside the nail, often leading to nail deformity (277). It has also been reported as *subungual osteochondroma* (278), a term correctly applied only to the common anomalous tumor of epiphyseal cartilage generally seen in the growth years (279). The great toe is the most common site, but other toes and fingers can be affected. Although the nodule usually measures only a few millimeters in diameter, it can be larger and cause swelling of the entire distal phalanx, possibly with ulceration that is treated for a time as an ingrown nail with infection. There is frequently an association with trauma (280), and these anecdotes argue persuasively for traumatic induction. Radiographs reveal a bony projection from the edge of the terminal phalangeal tuft (Fig. 34-36A) and are indispensable in avoiding assigning an incorrect alternative diagnosis

A B

FIGURE 34-33. Heterotopic subcutaneous ossification associated with chronic venous stasis (60-year-old woman; chronic venous stasis of lower legs). A: In this plain film radiograph, irregular bony deposits unrelated to veins can be seen in the absence of fat necrosis or abnormal serum calcium or phosphorus. B: A specimen radiograph (top) correlates well with the large-format histologic section (bottom) showing the distribution of irregular lobulated ossific plates in and around subcutaneous fat. The ossification seems to have taken place in interlobular septa. In the histologic view, fibrosis markedly thickens dermis. Thick-walled veins are in subcutaneous fat (e.g., left of center).

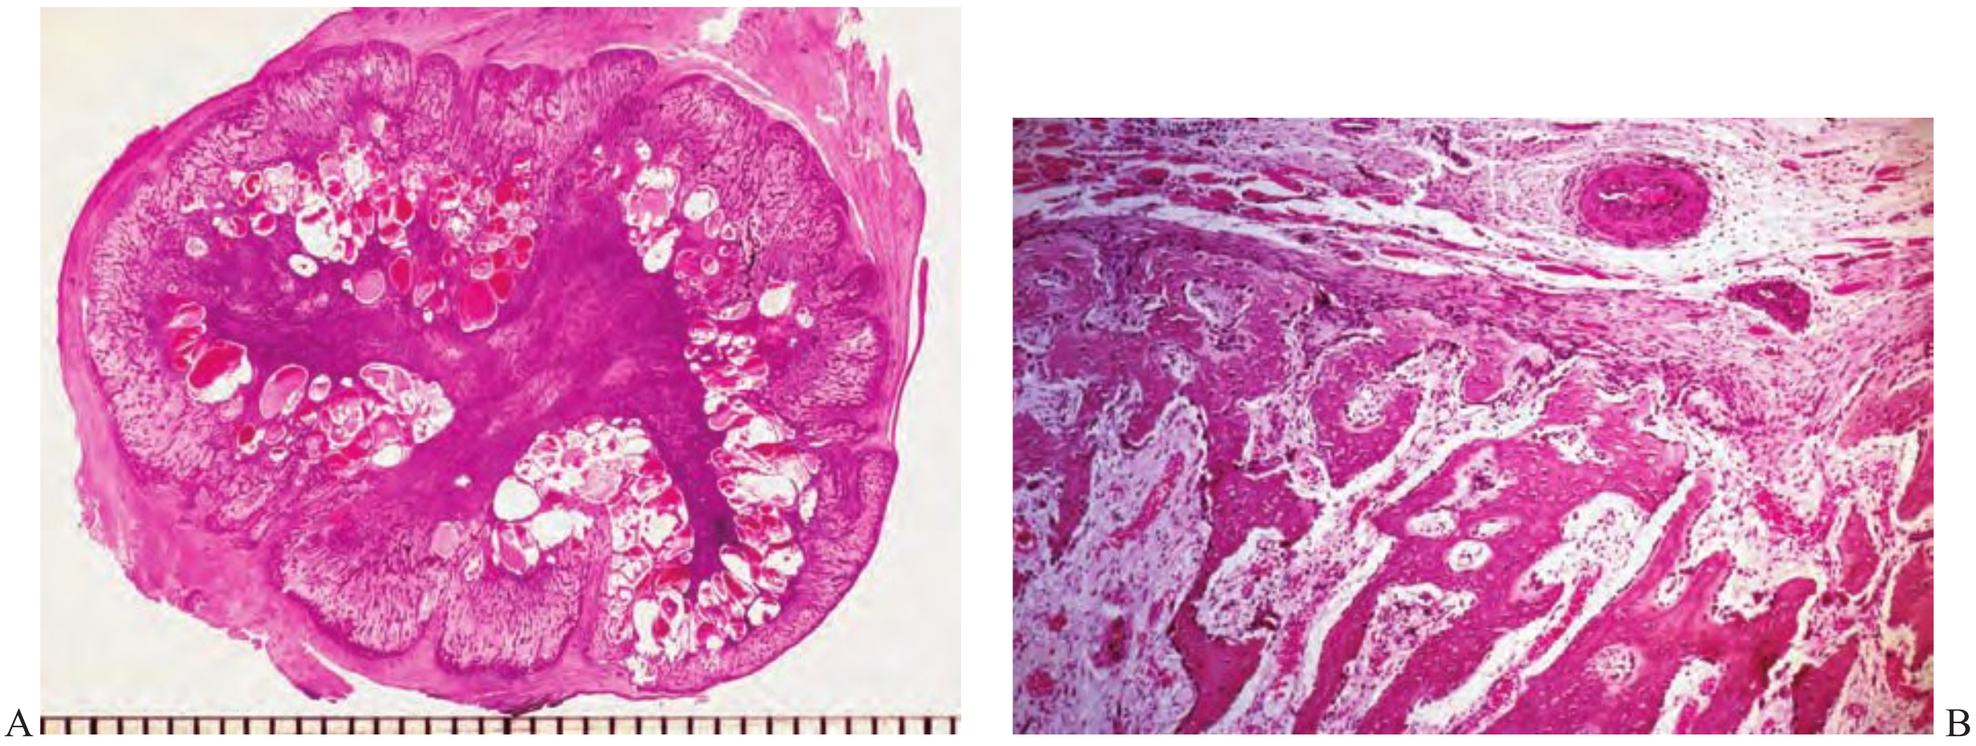


FIGURE 34-34. Myositis ossificans. A: A rounded 3-cm mass has central cellular bands without ossification and cancellous bone forming in the periphery. B: Involuting skeletal muscle fibers in what could be called a periosteum around the mass leave no doubt that interstitial connective tissue cells in injured muscle are the modulating osteogenic cells condensing to form the bone.

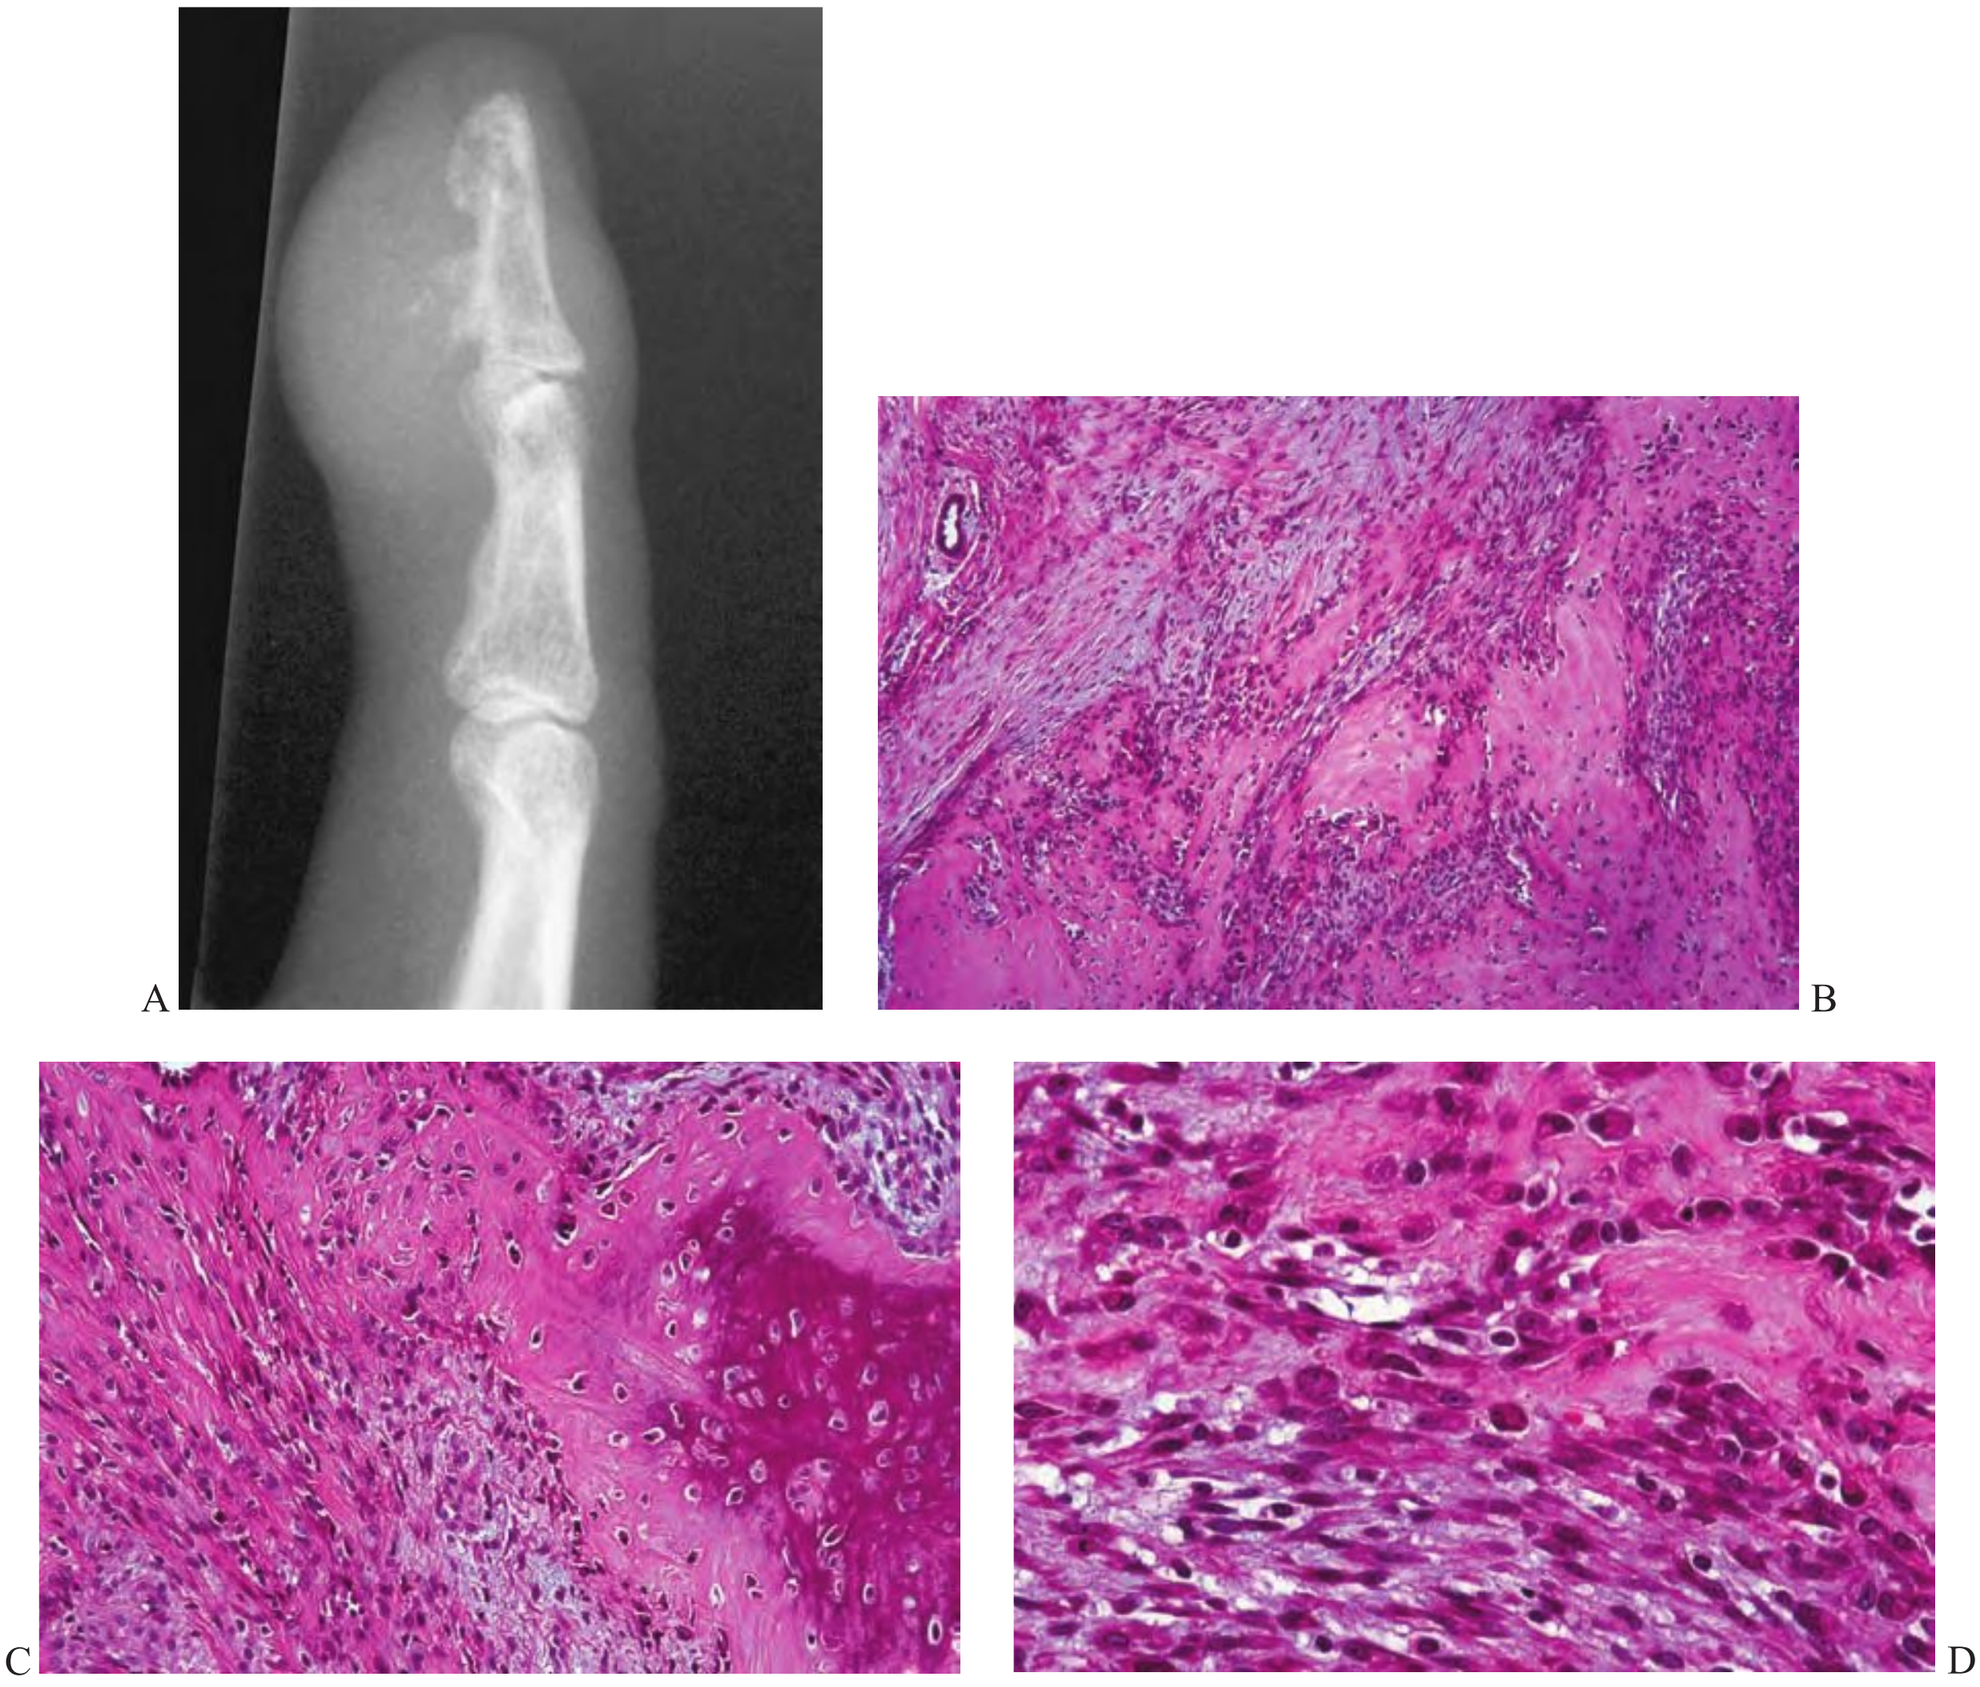

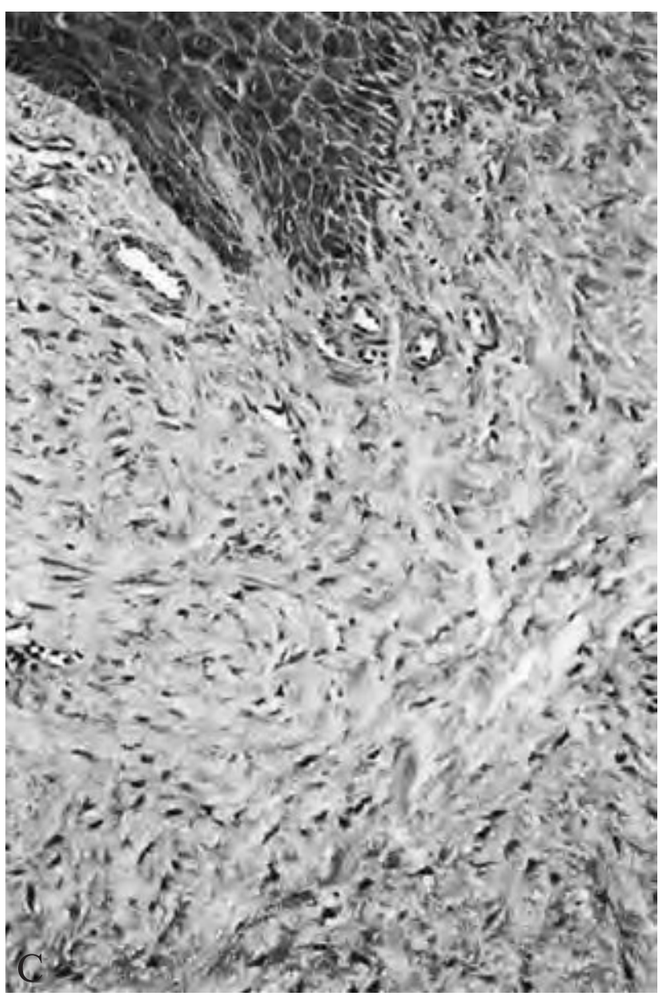

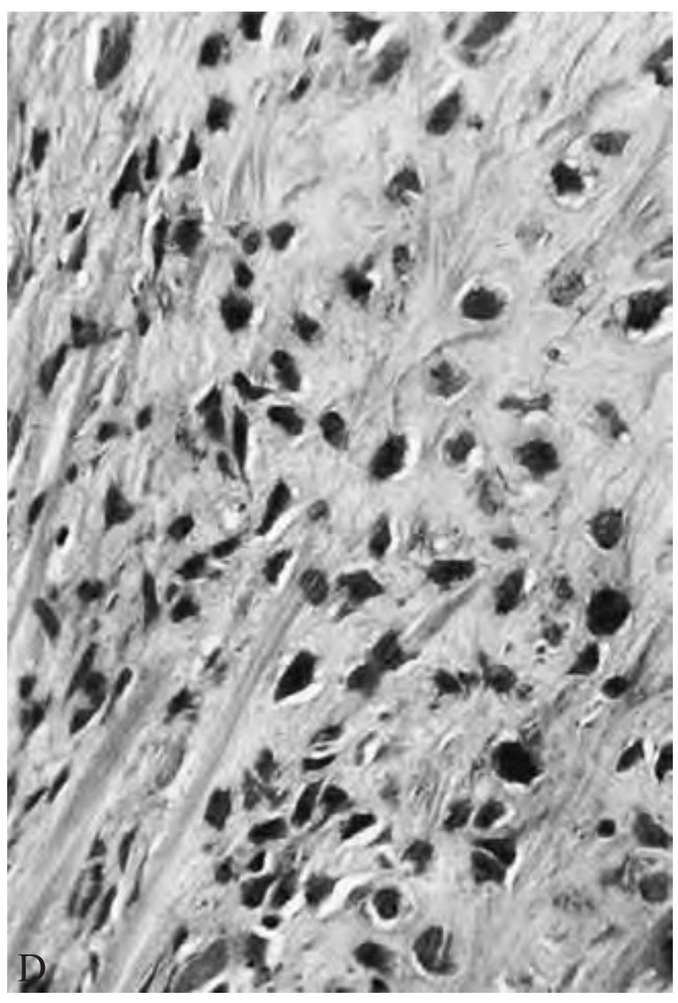

FIGURE 34-35. Fibro-osseous pseudotumor of digit (42-year-old man; rapidly enlarging fingertip with no recalled history of trauma). A: The terminal phalange of the fifth finger in this plain film radiograph has undergone bulbous enlargement and has some internal ossific density that may partly extend from the periosteal surface. B: A chaotic pattern of osteoid is emerging in an active spindle cell background. A sweat gland duct is at upper left. C: A medium-power view of this highly cellular reactive lesion shows basophilic mineralization of part of the osteoid product (right). D: The cellularity lacks the pleomorphism and abnormal mitoses of osteosarcoma.

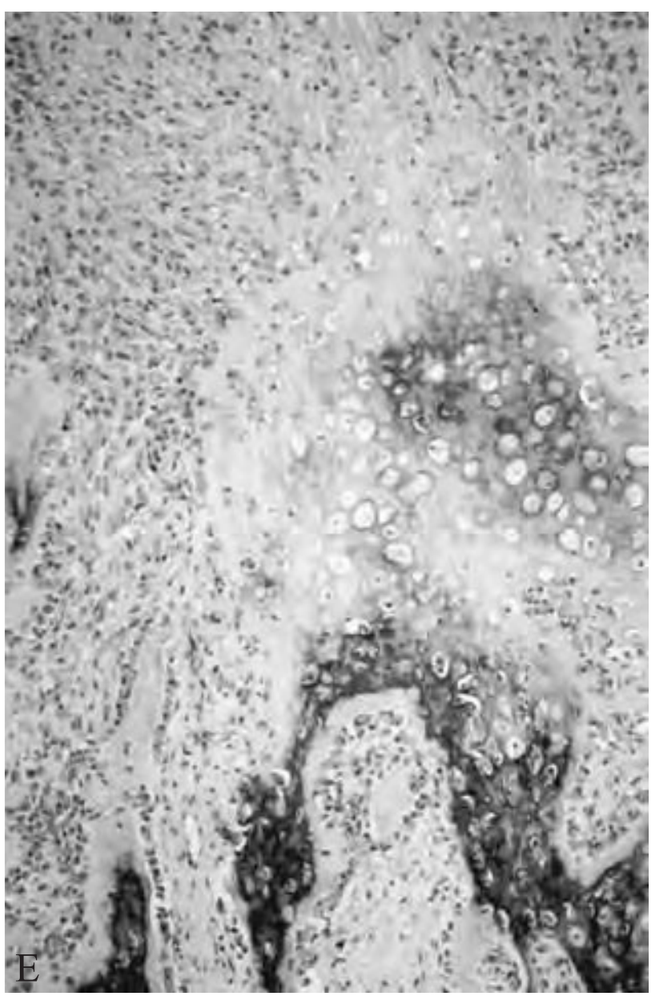
D

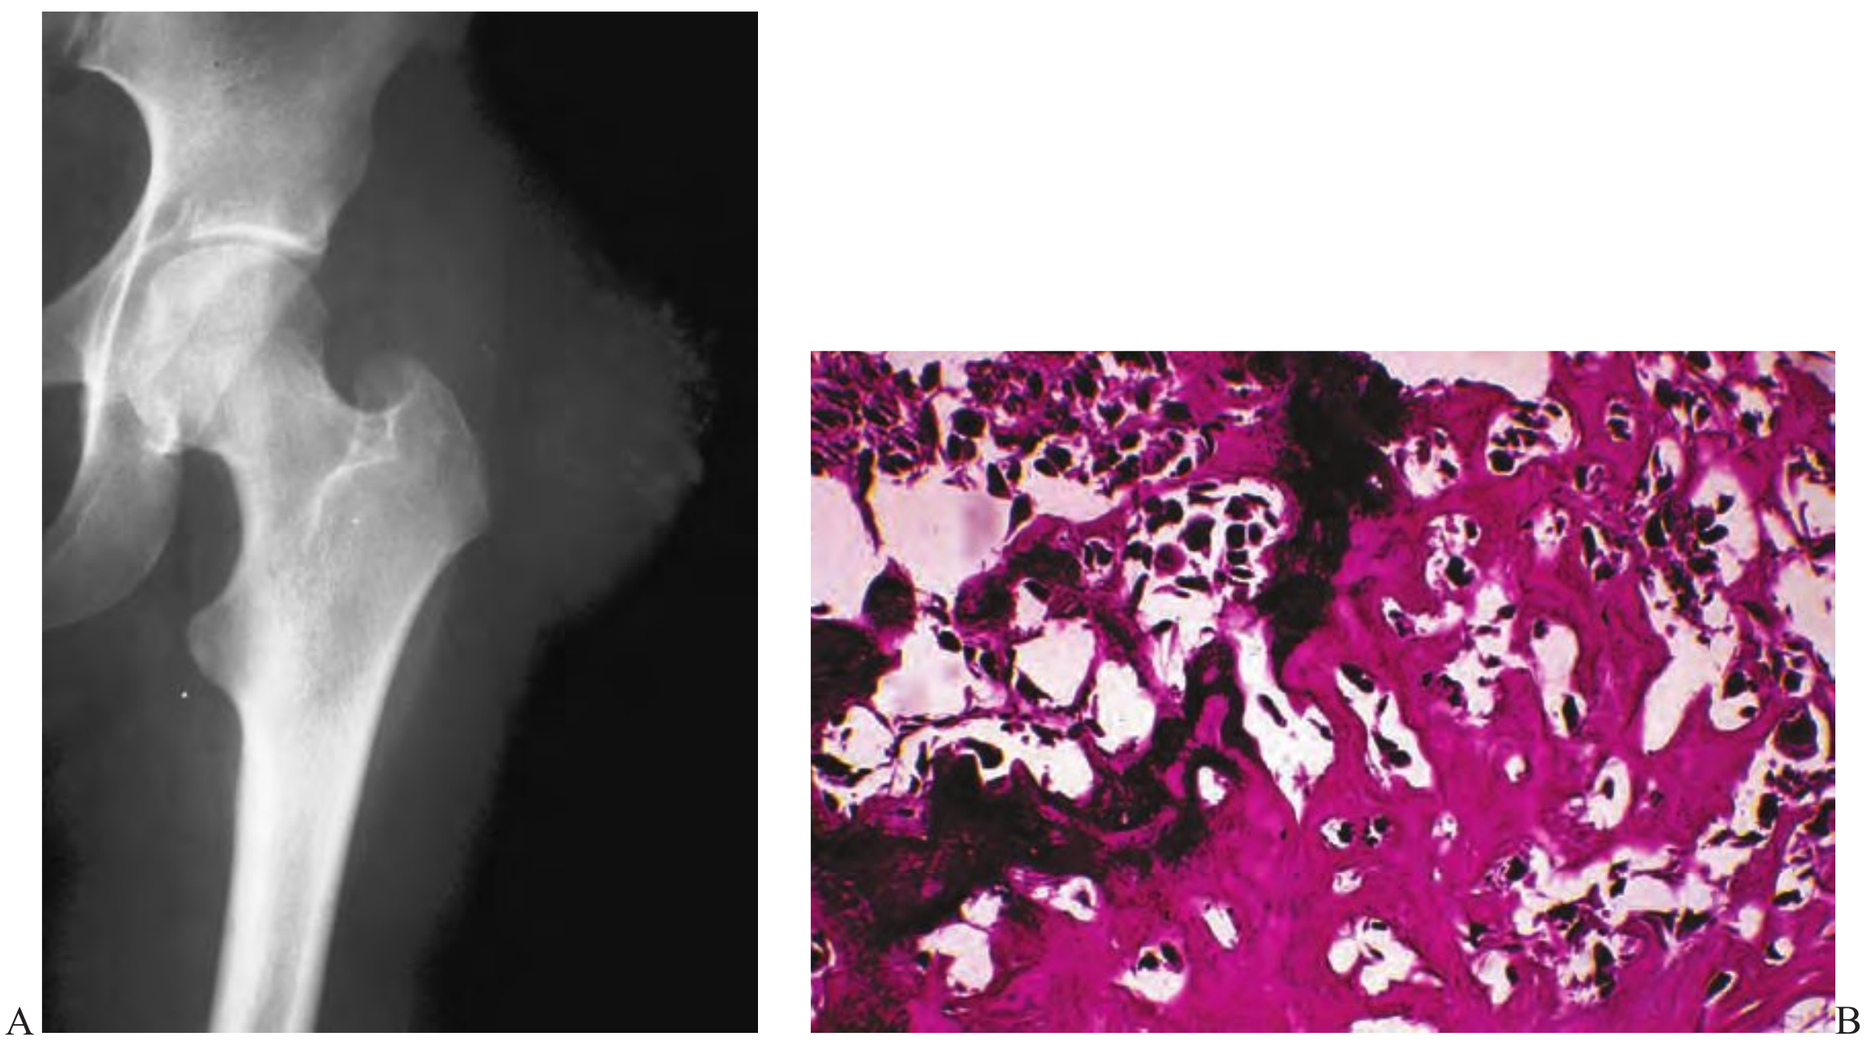


E

FIGURE 34-36. Subungual exostosis (14-year-old girl; 4 months previously, a horse stepped on her great toe). A: A polypoid bony projection extends from the tuft of terminal phalanx beneath the nail. An osteocartilaginous exostosis (osteochondroma) would be expected to be attached to the metaphyseal (more proximal) region of the phalanx, not to the tip. B: The excised exostosis consists of a cartilaginous cap (top) emerging from dermis beneath stretched epidermis and nail bed epithelium. This cartilage overlies a cancellous bony stalk built largely through the process of enchondral ossification. C: The earliest stage in the progressive enlargement of a subungual exostosis is the elaboration of myxoid material between dermal fibroblasts (bottom). D: With time, the myxoid material assumes the solidity of hyaline cartilage, and the intervening cells occupy lacunae within it. Deletion by osteoclastic erosion and substitution of bone tends to follow. E: Exuberant and reactive/reparative chondro-osseous tissue, as illustrated from another case, can be histologically disconcerting.

(281). The length and radiologic density are proportional to duration. The treatment is surgical.

Histopathology. *Myositis ossificans* and its subcutaneous counterpart, *panniculitis ossificans*, in early postinjury stages can mimic a cellular, mitotically active spindle cell sarcoma in its early posttrauma growth but lacks the abnormal mitoses and extreme pleomorphism of malignancy and manifests uniform nuclear chromaticity. Later, greater density and maturity of the bony product in the periphery around the still disturbingly cellular central zones is less of a diagnostic challenge since it is reverse of the architecture of soft tissue osteosarcoma and would not be seen in nodular fasciitis.



The earliest change in an *exostosis* (Fig. 34-36B) is mucopolysaccharide and osteoid elaboration by periosteum and modulated fibroblasts in the closely approximated contiguous dermis (Fig. 34-36C), eventuating in a gradational continuum of chondroid and osteoid that can be alarmingly cellular (Fig. 34-36E). As the cartilage achieves solid hyalin qualities, it becomes focally eroded along its deep surface by osteoclastic giant cells, followed immediately by enchondral bone deposition on any chondral remnant. In this way, a cancellous bony stalk is built out from original cortex at the expense of cartilage. The process continues, aggravated perhaps from ongoing irritation by footwear and as long as dermal fibroblasts continue to modulate into matrix-producing cells (281).

Bone formation in midline scars (282) is rare, and its etiology remains obscure. The lesion may not be discovered for a long period of time after it occurs, and the patient, except in rare circumstances, is asymptomatic (283). Clinically, it should be differentiated from scar recurrence following surgery for abdominal malignancy.

Button osteomas on the calvarium are usually approached surgically with a preoperative palpation diagnosis of cyst. They are common in modern (37.6%) and archaeologic (41.1%) populations and correlate with age (284). In one third of cases, there are two or more. The demographic characteristics of button osteoma, mainly its high frequency among ancient and modern populations, its independence of sex and race, its scarcity in other primates, and the fact that its macro- and microstructure with parallel lamella of compact bone, sometimes partly haversianized and best appreciated under polarized light, favor a hamartoma and not a neoplastic osteoma, although posttraumatic exostosis remains an attractive hypothesis.

Extraskeletal Osteosarcoma

This aggressive tumor, characterized by atypical mesenchymal cells synthesizing osteoid (Fig. 34-37), is extremely rare, especially in the skin (285). It can occur in the skin with no associated predisposing conditions (286), in an old burn scar (287), and under a previously electrodessicated actinic keratosis (288). There should be no connection to deeper structures and no demonstrable primary bone lesion (289). Other extraskeletal sites for primary osteosarcoma that may come to the attention of dermatologists include the penis (290) and tongue (291). Origin in antecedent myositis ossificans is possible (292). When osteosarcoma is concurrent with a distinct carcinoma pattern, such as that found in basal cell carcinoma, the term *carcinosarcoma* can be used. Alkaline phosphatase stain-

FIGURE 34-37. Extraskeletal osteosarcoma. A: In this plain film, an oval mass lateral to the hip joint has irregular central bony density, unlike the peripheral ossification of myositis ossificans. B: Cytologically, malignant cells are forming osteoid. (Compare with Fig. 34-35D.)

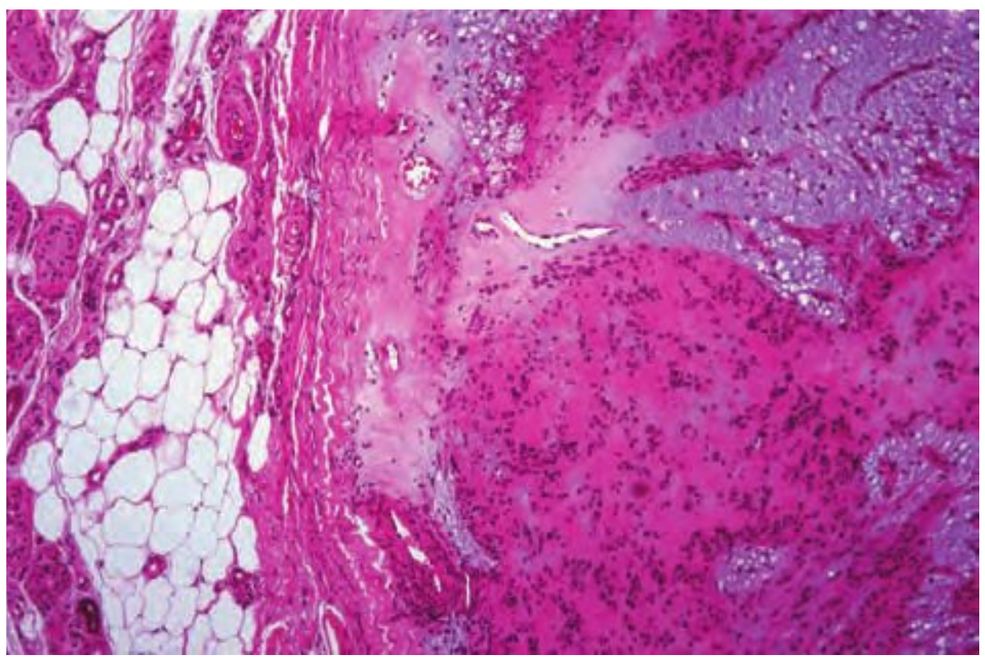
ing compared with immunohistochemistry has proved to be superior in the differentiation from other pleomorphic sarcomas (291).

Differential Diagnosis. Metaplastic and reactive ossification may occur in and around various tumors with specific identity such as the ossifying fibromyxoid tumor of soft tissue (293), sarcomatoid (osteogenic) malignant melanoma (294), and "fibrohistiocytic" tumors such as dermatofibroma (295), atypical fibroxanthoma (296), so-called malignant fibrous histiocytoma, and peripheral nerve sheath tumors (e.g., malignant triton tumor). Merkel cell carcinoma may demonstrate "divergent" differentiation into bone, cartilage, or myogenous tissue (297). Follow-up data suggests an excellent prognosis for polypoid and exophytic sarcomatoid basal cell carcinoma after complete surgical resection (298). Electron microscopy can assist in detecting this deception of tumors with differing biologic behaviors. *Fibro-osseous pseudotumor* typically occurs in the digits of the hand and is characterized histopathologically by a fibroblastic proliferation with foci of osseous differentiation lacking the well-defined zonal pattern of myositis ossificans (299) (Fig. 34-35B). Because of its rapid growth and aggressive histopathologic appearance, this lesion can be mistaken for extraskeletal or parosteal osteosarcoma (294). A 2007 review of *cutaneous metastasis from osteosarcoma* found only eight cases and added one (300).

BENIGN CARTILAGENOUS TUMORS OF SKIN AND SOFT TISSUE

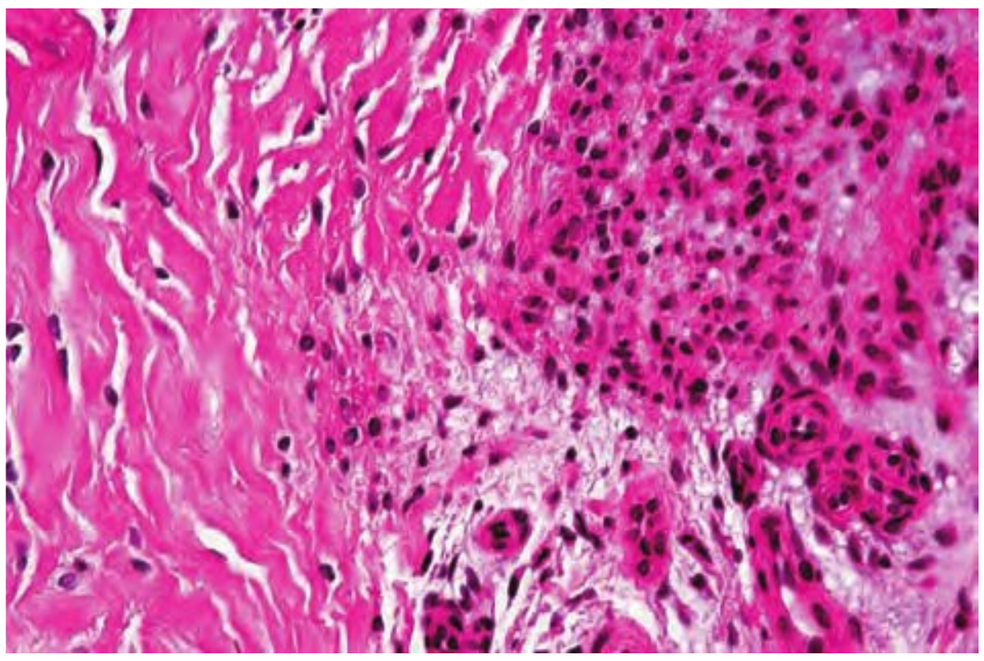
Soft Tissue Chondromas

The hallmark of all differentiated chondrogenic tumors is the presence of neoplastic chondrocytic cells responsible for the formation of the characteristic cartilaginous tumor matrix (134). Benign cartilage nodules and masses independent of bone, including cutaneous cartilage tumors, are variously regarded as neoplastic, metaplastic, or anomalous. Generically referred to as *soft part* or *extraskeletal chondromas* (Fig. 34-38), most of these nodules are located in the hands and feet, especially in the fingers of middle-aged adults, but other sites (e.g., the back) (301) and ages, and even infants (302), are not immune. Most are solitary and may attach to tendons, tendon sheaths, or joint capsules (303) (Fig. 34-38A). These slowly enlarging nodules are seldom painful or tender and rarely exceed 3 cm in diameter. Soft tissue chondroma may present as a painful finger (304), an acute inflammatory episode (305), trigger finger (306), and compression neuropathy (307). Few recur locally. True *cutaneous chondromas*, primarily located in the dermis, are rarely described in the dermatologic literature (308) but can be familial (309).



Synovial chondroma (intracapsular and periarticular) and multiple purely cartilaginous (chondromatosis) or chondro-osseous (osteochondromatosis) nodules in tenosynovium or joint synovium are metaplastic changes of subsynovial fibrous tissue that may create a mass around a joint or along a tendon. When near a joint, intracapsular and para-articular chondromas are to be differentiated from *synovial chondromatosis* (310) (Fig. 34-39). *Extraskeletal osteochondromas* are painless, slow-growing masses of mature hyaline cartilage, with extensive enchondral ossification (311). Tenosynovial osteochondroma independent of bone can cause carpal tunnel syndrome (312). Because of location, these tumors come to the attention of the dermatopathologist only rarely. Primary synovial chondrosarcoma is anecdotally rare (313).

Enchondromas are benign intraosseous hyaline cartilage tumors whose location in the distal phalanx (in contrast to more proximal bones) is rare but may be responsible for nail dystrophy (314).



Histopathology. Soft tissue chondromas appear to develop and grow at their periphery by the metaplastic enlargement of fibroblasts into plump cells that inflate the preexisting structural fibrous tissue with mucopolysaccharides, creating hyalin cartilage (Fig. 34-38C). The plump chondrocytes frequently have distinctive reniform and elongated nuclei rather than the expected round shape in most cartilage (Fig. 34-38D). A minority exhibit central or peripheral (315) secondary stippled or heavy deposits of calcium pyrophosphate dihydrate (316) and hydroxyapatite crystals. The well-circumscribed, solid-appearing cartilage may exhibit focal fibrosis, enchondral ossification (soft tissue osteochondroma), myxoid change (myxochondroma), cystification, and/or hemorrhage. Hyaline globules, spherical intracytoplasmic eosinophilic droplets deemed secretory products of probable glycoprotein nature, are in a minority of soft tissue chondromas. Ultrastructurally, these are spherical, nonmembrane-bound bodies having complex architectural features associated with profiles of rough endoplasmic reticulum with electron probe x-ray microanalytic peaks of sulphur and calcium (317). Hypercellular soft tissue chondromas composed of enlarged chondrocytes within a variable amount of chondroid matrix that often demonstrate delicate calcifications and contain numerous osteoclast-like multinucleated giant cells closely resemble chondroblastoma of bone (318). There may be a granulomatous reaction ("chondrogranuloma") (319) with multinucleated giant cells along the margins and interlobular vascular channels (Fig. 34-38E). Interpretation should ignore substantial atypia in what is radiologically or clinically a small lesion to avoid unnecessarily disfiguring surgery. Plump, immature-appearing chondrocytes that are bi- or multinucleated are not uncommon and, as in bone lesions, do not necessarily connote malignancy (Fig. 34-38D); lesions associated with them behave no differently from the well-differentiated forms. Aspiration cytology of soft tissue chondroma presents myxofibrillary material and pleomorphic cells, the clinical, radiologic, and cytologic triad being critical for the correct cytologic diagnosis of soft tissue chondroma despite worrisome cell atypia (320). Immunohistochemically, most of the tumor cells except for multinucleated giant cells are positive for vimentin. Cells positive for S-100 protein will be scattered throughout the tumor. Ultrastructurally, the chondroblastic cells have a characteristic microvillous cell border (319).

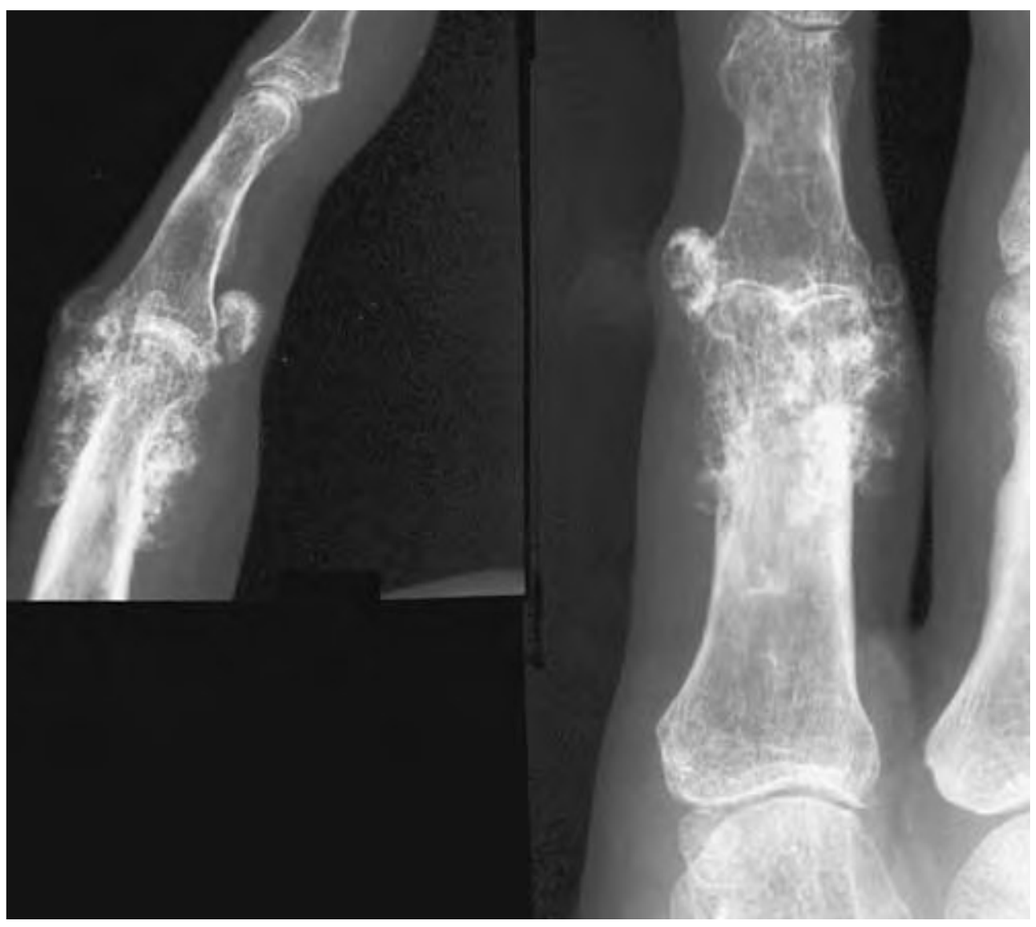
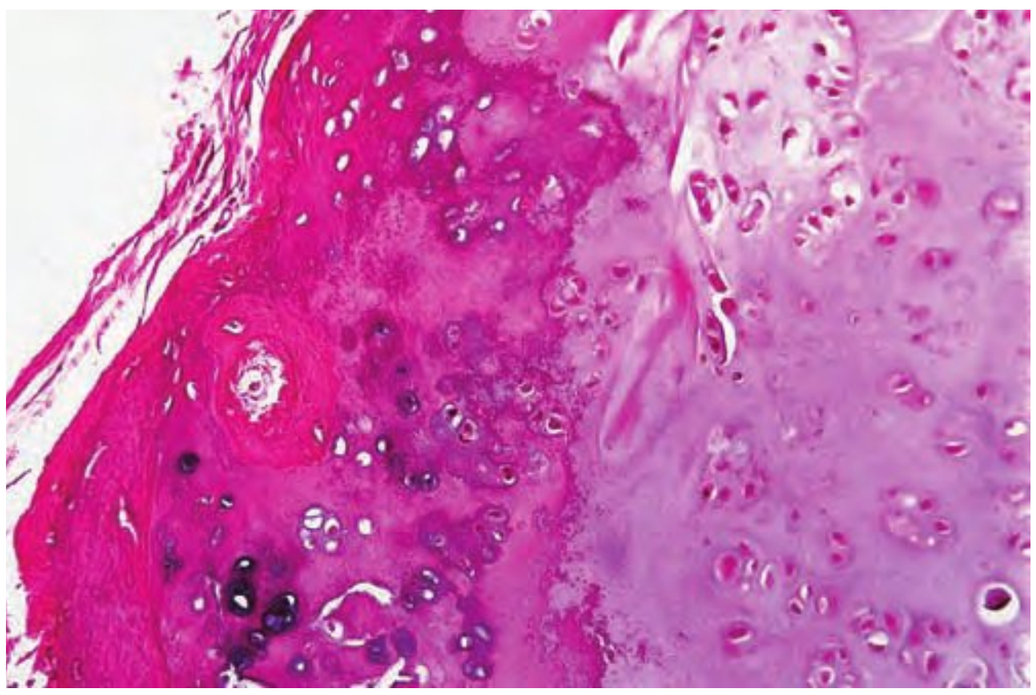
FIGURE 34-38. Extraskeletal (soft tissue) chondroma (62-year-old man; toe pain and swelling for 18 years). A: The plain film radiograph submitted with the specimen shows pressure erosion of all but 2 mm of the proximal end of the distal phalanx, which abuts a 1.4-cm diameter rounded unmineralized soft tissue mass at the tip of the toe. B: The tumor consists of a rounded mass of variably cellular, myxoid and hyaline cartilage. C: The gradual emergence of lesional chrondroid tissue from surrounding fibrous tissue suggests an in situ transformation of "fibroblasts," through the stage of chondroblasts, to become quiescent chondrocytes in lacunae. D: Chondrocytes in lacunae often have oblong nuclei, unlike the round nuclei of synovial and intraosseous chondromas. Nuclear size variation and binucleate cells are commonplace in this benign lesion. E: Particulate mineralizations and lacy basophilic mineral deposits around tumor cells in the matrix correlate with the speckled radiographic densities from another case that are seen in one third of these tumors.



Differential Diagnosis. Chondromas of soft tissue are defined by an asymptomatic and harmless clinical course, lack of connection between the tumor and the underlying bone, slow tumor development, absence of age and sex predominance, and their characteristic tumor histologic picture (321). Extraskeletal chondromas are to be distinguished from developmental cartilaginous rests of branchial origin (usually in the lateral neck in children or infants). A superficial biopsy might retrieve a bit of hyalin cartilage from digital synovial (osteo)chondromatosis (Fig. 34-39). Several soft tissue processes may contain histologically disconcerting cartilage including mixed tumors (apocrine or eccrine), juvenile aponeurotic fibroma (Fig. 34-40), giant cell tumor of tendon sheath, fibromatosis, metaplastic cartilage in occasional lipoma varieties, (teno)synovial (osteo)chondromatosis, cartilage produced in myositis ossificans and fracture callus, metaplastic cartilage in and around tophaceous pseudogout, and soft tissue recurrence of a bone tumor (e.g., chondromyxoid fibroma) (322). Heavily calcified chondromas show granular areas with giant cell reaction resembling tumoral calcinosis or tenosynovial giant cell tumors. Radiographs can distinguish tumors extending from bone, such as osteochondroma or subungual exostosis (323). Extraskeletal chondromas with mineralization of the chondroid matrix will show on plain film radiographs (324), and the remainder can be imaged by MRI (325) or sonography (326).

Pathogenesis. Cytogenetic analyses of soft tissue chondroma report aberrations of chromosomes 6, 11, and 12q13-q15 (327).



Calcifying (Juvenile) Aponeurotic Fibroma

Calcifying (juvenile) aponeurotic fibroma (CAF) is a rare benign tumor clinically presenting as a painless, mobile solitary mass with a strong predilection for the distal portion of the distal hands and feet of children and young adults (328). Uncommonly, it can occur in extraacral sites such as lumbosacral (329), back, knee region, thigh, forearm, elbow, and arm (330). Minute calcific foci may be evident grossly and on plain films (Fig. 34-40C). Often adherent to dense fibrous connective tissue (e.g., tendon, fascia, or periosteum), CAFs are 1 to 5 cm in maximum dimension, lobulated, and poorly circumscribed with a dense fibrous consistency. Histologically, in the periphery of each chondroid island (Fig. 34-40A) is the transition from rounded mononuclear and fibroblastic cells to chondrocytic cells. The intervening fibromatosis-like areas (Fig. 34-40B) consist of spindle-shaped fibroblastic cells and occasional myofibroblasts. The morphologic pattern of the tumor somewhat mimics embryonal chondrogenesis, and the fibromatosis-like areas may represent an overgrowth of the fibrous layer of the "perichondrium" around some chondroid islands. CAF may represent the cartilage analog of fibromatosis. It is possible to regard this as an organoid tumor having a capacity for bidirectional differentiation into cartilage and fibrous tissue.

CAF has been diagnosed by fine needle aspiration where cytologic examination reveals benign-appearing spindled cells, chondroid cells, multinucleated giant cells, and calcific debris (331). Immunoreactivity always finds vimentin positivity and

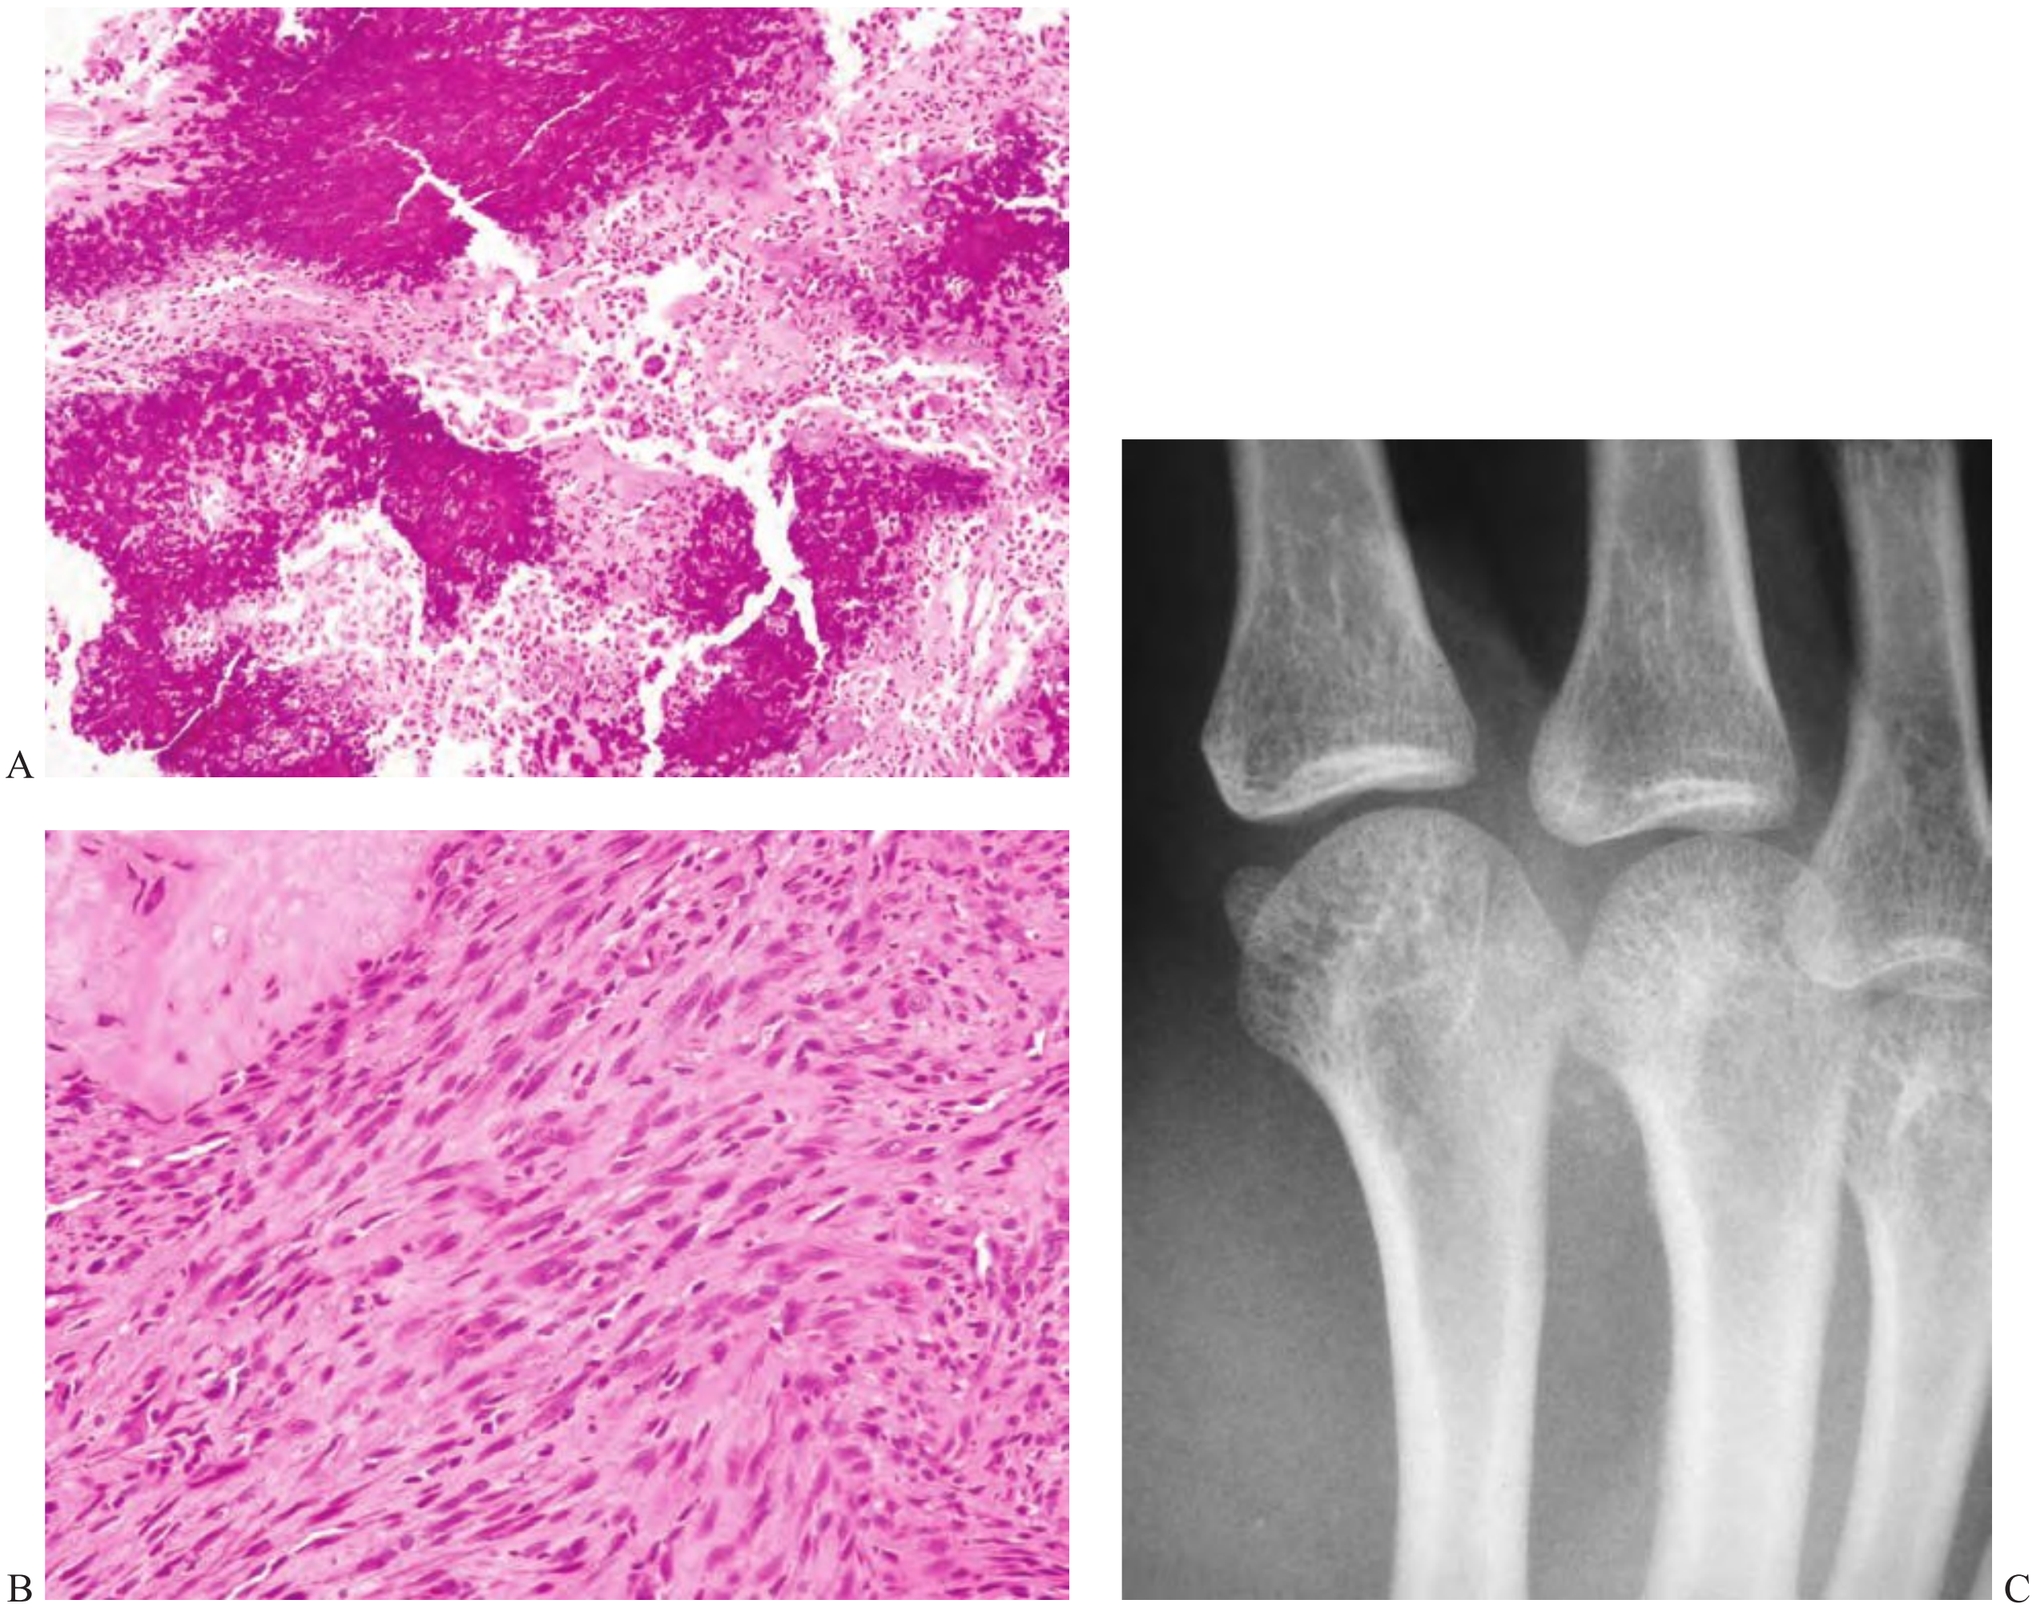

FIGURE 34-40. Calcifying (juvenile) aponeurotic fibroma (27-year-old man; palm). Cartilage islands with characteristic calcification (A) set in a fibromatosis-like background (B) explain the speckled densities in the plain film (C).

possibly also reactivity for muscle-specific actin, smooth muscle actin, CD99, CD34, EMA, S-100 protein, and CD68 (332).

According to Wick and colleagues (333), "[s]urgical management should be conservative for all tumors with the typical appearance of a CAF. In fact, excision and re-excision, if necessary, appear preferable to radical or mutilating surgical procedures to maintain function of the extremity." Fifty percent develop one or more recurrences. Rapidity of growth seems to slow down with increasing age. Various references state that no instances of metastasis have been reported, although others allude to rare malignant transformation (332).

Differential Diagnosis. Familiarity with this entity should help to avoid confusion with other processes, including infantile and extra-abdominal fibromatoses, chondroma of soft parts, and fibrous hamartoma of infancy (330). Unlike mesenchymal chondrosarcoma, which is a high-grade spindle cell sarcoma with islands of hyaline cartilage, mitoses are not obvious in the spindle cell component of the tumor, and a Ki-67 (proliferating cell antigen) reaction should label very few cells.

CHONDROSARCOMA

Extraskeletal Myxoid Chondrosarcoma

Extraskeletal myxoid chondrosarcoma is uncommon and known also as *chordoid sarcoma* because of the resemblance to chordoma (333). It usually affects adult males with a median age at the time of diagnosis in the fifth decade of life (334–336). Only a small minority have been reported in children (334,337,338). The tumor frequently arises in the deep soft tissues, especially of the lower extremity (334). A gradually enlarging mass may or may not be associated with pain (334). Radiographically, the neoplasm is a nodular, radiolucent mass rich in water. Most extraskeletal myxoid chondrosarcomas are

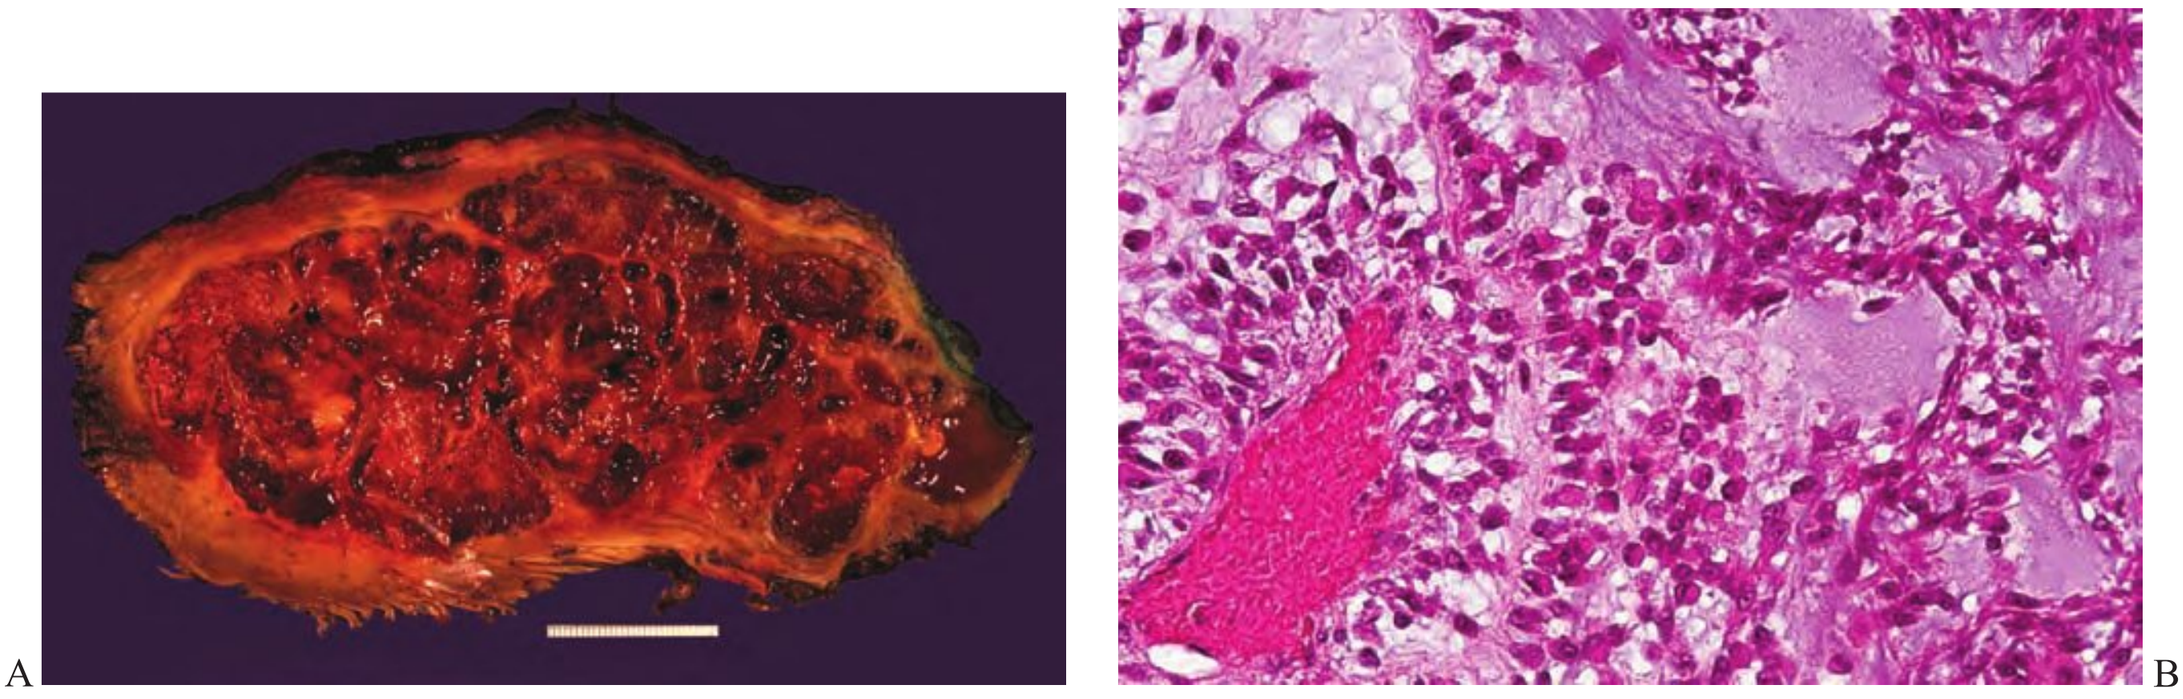

FIGURE 34-41. Extraskeletal myxoid chondrosarcoma (63-year-old man; 17 × 8 × 8-cm anterior thigh mass; death unrelated to tumor 28 months postoperative.) A: The tumor has a glistening myxoid and hemorrhagic cut surface. B: Ovoid and stellate tumor cells form perivascular arrays and cords in a basophilic myxoid background.

large, ovoid, pseudoencapsulated, well-circumscribed tumors with a lobular architecture. The cut surface is tan, gelatinous, and frequently hemorrhagic (Fig. 34-41A).

Histopathology. Extraskeletal myxoid chondrosarcoma is characterized by a proliferation of ovoid and bipolar cells that are enmeshed in a prominent myxoid matrix rich in chondroitin and keratin sulfate (334,339) (Fig. 34-41B). It has a repetitive lobular pattern and chains of neoplastic cells that seem to progress from the periphery toward the center of lobules. Hemorrhage and hemosiderin in the fibrous tissue surrounding the nodules is characteristic. The tumor cells have little to moderate amounts of eosinophilic cytoplasm, and the nuclei are uniform and not pleomorphic. Occasionally, individual tumor cells are surrounded by lacunar spaces; however, the formation of well-developed hyaline cartilage is uncommon. Mitoses are not numerous, and multinucleated giant cells are absent. There may be marked collagenization, spindling of tumor cells, and matrix-poor regions in which the tumor cells grow in solid sheets. Ultrastructurally, the tumor cells of myxoid chondrosarcoma resemble chondroblasts. They are round to elongate and frequently have microvilli. The cytoplasm contains abundant dilated rough endoplasmic reticulum, glycogen, free ribosomes, well-developed Golgi complexes, and mitochondria. Aggregates of microtubules within the rough endoplasmic reticulum are a distinguishing feature (340). The cells may connect by desmosome-like intercellular junctions or those of the macula adherens type (333). The extracellular matrix is rich in amorphous material, small electron-dense particles, and scattered collagen fibers. The neoplastic cells usually stain with antibodies to vimentin and S-100 protein (333,339–341). Some studies have shown that they also may be positive for Leu-7 and EMA. Uniformly, they have been negative for keratin. Extraskeletal myxoid chondrosarcoma is a unique entity defined by the presence of a fusion gene between the orphan nuclear receptor, CHN/NOR1, and a promiscuous partner, most commonly EWSR1 (342). Based on the types of collagen synthesized, the cellular phenotype of extraskeletal myxoid chondrosarcoma is not chondrocytic or prechondrocytic but rather is composed of primitive mesenchymal cells with focal, multidirectional differentiation (343).

Differential Diagnosis. Myxoid tumors of soft tissue encompass a heterogeneous group of lesions characterized by a marked abundance of extracellular mucoid (myxoid) matrix, with marked differences in biologic potential that generate diagnostic challenges for the clinician and pathologist alike (344). The differential diagnosis of extraskeletal myxoid chondrosarcoma is broad and includes many reactive processes and epithelial and mesenchymal neoplasms, chief among them, intramuscular myxoma, juxta-articular myxomas, neural neoplasms, cutaneous and soft tissue myoepitheliomas (345), benign polymorphous mesenchymal tumor of soft parts (346), myxoid liposarcoma, myxofibrosarcoma (myxoid malignant fibrous histiocytoma), metastatic carcinoma, metastatic melanoma with myxoid stroma, and chordoma. Myxoid chondrosarcoma does not have the vascular pattern typical of myxoid liposarcoma and lacks lipoblasts. Immunohistochemistry will help to sort it out.

Pathogenesis. Cytogenetic studies are few but so far have shown reciprocal translocations involving chromosomes 9 and 22 (347) and translocations between chromosomes 2 and 13. Behavior is as a low-grade sarcoma.

Mesenchymal Chondrosarcoma

Mesenchymal chondrosarcoma (348) represents the prototypic neoplasm of prechondrogenic undifferentiated cells undergoing multifocal chondrocytic differentiation (134) and can involve the skin (349). Chondroid-type calcifications and foci of low signal intensity within enhancing lobules reflect its dual histopathologic morphologic characteristics of differentiated

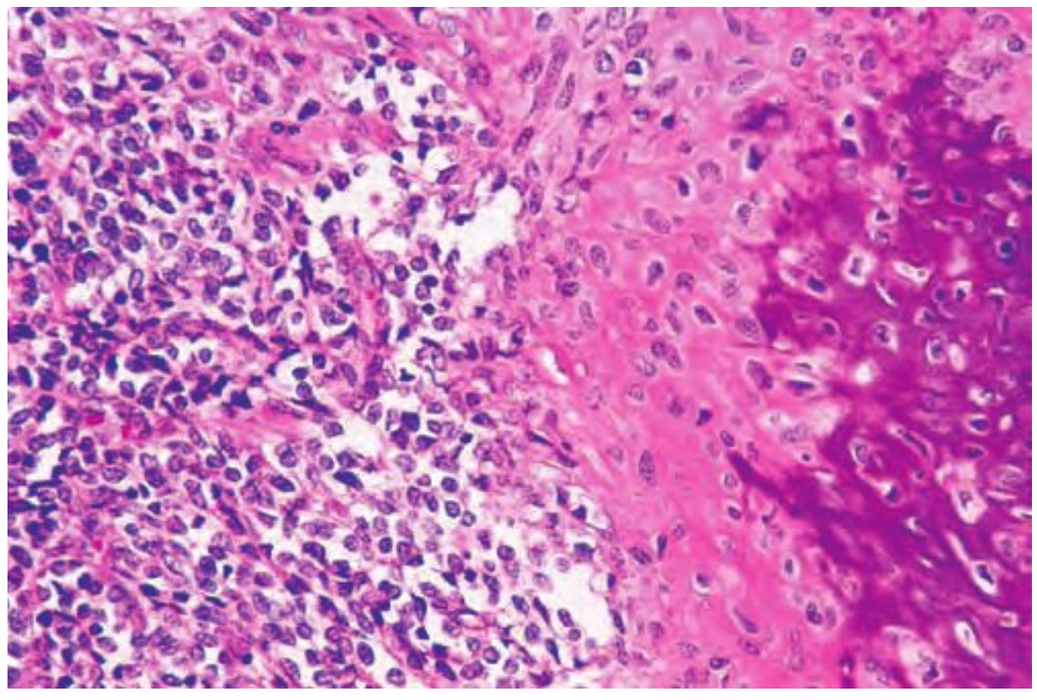

FIGURE 34-42. Mesenchymal chondrosarcoma. Small, round, undifferentiated cells (left) might easily be mistaken for Ewing's sarcoma or lymphoma were it not for the sporadic island of cartilaginous product (right).

cartilage islands interspersed within highly cellular undifferentiated mesenchyme (Fig. 34-42) (350). The cartilaginous areas are S-100 positive and exhibit strong CD99 reactivity in more than 50% of the small round blue cells with a distinct membrane pattern of staining (351). The expression of p30/32 (MIC2) is typically restricted to the small cell component. Positivity of small cells for desmin and/or smooth muscle actin may be seen; and in rare cases, more diffuse rhabdomyoblastic differentiation indicating mesenchymal chondrosarcoma is another primitive neoplasm with polyphenotypic differentiation and features that overlap those of other small cell malignancies of bone and soft tissue (352).

Differential Diagnosis. The cellular areas of mesenchymal chondrosarcoma can mimic fibrosarcoma, Ewing's sarcoma, malignant hemangiopericytoma, peripheral neuroectodermal tumor, and synovial sarcoma.

Pathogenesis. An identical robertsonian translocation involving chromosomes 13 and 21 [der(13;21)(q10;q10)] was detected in two cases of mesenchymal chondrosarcoma, possibly representing a characteristic rearrangement for this histopathologic entity (353).

OSSEOUS AND CHONDROID LESIONS, RARER STILL

Embryonic tissue and organ development are initiated from three embryonic germ layers: ectoderm (skin and neuron), mesoderm (blood, bone, muscle, cartilage, and fat), and endoderm (respiratory and digestive tracts). In former times, it was believed that cell types in each germ layer were specific and did not cross from one to another throughout life. A new finding is that one tissue lineage can differentiate across to another tissue lineage, and this is termed *transdifferentiation* (354). For example, skin-derived precursor cells (ectoderm) can transdifferentiate to osteoblastic cells (mesoderm), explaining the potential of skin appendage tumors to contain mesenchymal elements. Ossification in chondroid syringomas or mixed tumors of the skin employs the enchondral mechanism.

The appearance of cutaneous lesions in a patient with a prior history of chondrosarcoma should alert the clinician to the rare possibility of a *metastatic chondrosarcoma* (355). Such metastases preceding the diagnosis of primary chondrosarcoma are anecdotal. These metastases can be either single or multiple, with a slight predilection for the head and neck region (356).

Metaplastic carcinoma (a.k.a. carcinosarcoma, sarcomatoid carcinoma, malignant mixed tumor) is a biphasic tumor comprising malignant epithelial and heterologous mesenchymal elements (357). Mere vimentin reactivity alone is not enough. Leiomyosarcomatous areas have been the basis for a designation of metaplastic carcinoma (primary "carcinosarcoma") in a very few cases (357,358); better to hold out for a tumor product visible without immunohistochemistry (i.e., production of chondroid, osteoid or fat). In view of recent developments and progress in the understanding of the possible histogenesis of such tumors, *biphasic sarcomatoid carcinoma* or *metaplastic carcinoma* rather than carcinosarcoma are the most appropriate terms (357). Many conclude that the sarcomatous component of the tumor is best regarded as a metaplastic transformation of the carcinomatous component.

Primary carcinosarcoma of the skin is uncommon, and the count of exactly how many cases have been reported varies, even in three separate reports, all of which were published in 2005: Only 20 cases of primary cutaneous carcinosarcoma have been described in the world literature according to Ram and associates (359), 23 in the English literature according to Bigby and colleagues (358), and 38 according to Tran and coworkers (360). Most of these tumors were seen on the head and neck region of older individuals, both male and female. Microscopically, the more common carcinoma component is a squamous cell carcinoma followed by basal cell carcinoma, whereas the most common sarcoma component is osteosarcoma.

Tran's literature review in 2005 (360) identified 38 cases of cutaneous carcinosarcoma that could be broadly classified into two distinct groups. Epidermal-derived (basal or squamous cell carcinoma epithelial component with a sarcomatous component) carcinosarcomas arose on the sun-damaged skin of the head and neck of elderly males (mean age 72 years) and had a 70% 5-year disease-free survival. In contrast, adnexal carcinosarcomas (spiradenocarcinoma, porocarcinoma, proliferating trichilemmal cystic carcinoma, or matrical carcinoma) occurred in younger patients (mean age 58 years), showed recent growth in a long-standing nodule, and had a 25% 5-year disease-free survival. Malignant heterologous malignant mesenchymal elements included osteosarcoma, chondrosarcoma, leiomyosarcoma, and rhabdomyosarcoma. In contrast to metaplastic carcinomas arising in visceral sites, those primarily arising in the skin do not appear to behave in a very aggressive manner.

Although *dedifferentiated* is a concise term of which generations of pathologists have been exposed, it is not reflective of

actual tumor biology, nor is it entirely correct when applied to epithelial tumors, because the so-called dedifferentiated component is still recognizable as carcinoma and usually is an adenocarcinoma. In fact, this term is one of the most widely used misnomers in pathology jargon, because it merely reflects a type of tumor progression—a subpopulation of tumor cells within a low-grade tumor fails to differentiate along expected lines rather than transforming in a retrograde fashion toward a more protean morphology. Hence, high-grade transformation is a more appropriate description of this phenomenon (361).

Breast carcinoma is the most common origin of cutaneous metastasis in women but is usually a ductal or lobular histologic type. *Sarcomatoid (metaplastic) carcinoma* of the breast, although a well-established aggressive neoplasm, is very uncommon. Its metaplastic elements, derived from carcinomatous elements, span all types of mesenchymal differentiation. Skin metastasis from such lesions is extremely rare but can be chondrosarcomatous (362).

Malignant mesenchymoma, defined as a sarcoma with three or more lines of differentiation, can occur in skin (e.g., a tumor in an abdominal incision scar composed of leiomyosarcoma, chondrosarcoma, and osteosarcoma) (363).

Malignant melanomas showing foci of osteocartilaginous differentiation are extremely rare, with only 18 cases reported as of 1998 (364), a review that added two primary mucosal malignant melanomas (vagina and oral cavity). Chondroid change in the absence of osteogenic differentiation is extremely rare in malignant melanoma, but melanoma should be considered in the differential diagnosis of primary cutaneous neoplasms exhibiting cartilaginous differentiation (364). Oral mucosal melanomas with osteocartilaginous differentiation are to be distinguished from malignant change in a pleomorphic adenoma, sarcomatoid carcinoma, osteogenic sarcoma, and mesenchymal chondrosarcoma. Primary vaginal melanoma with cartilaginous differentiation must be distinguished from primary malignant mixed müllerian tumor (363).

Atypical fibroxanthoma can contain areas of chondroid differentiation that resemble chondrosarcoma and have S-100 positivity (366).

A gastrointestinal carcinoma metastasis is reported in cutaneous osseous metaplasia (367).

Pseudocyst of the auricle is a benign condition that presents as a fluctuant swelling of the ear, most commonly in young Asian males (368). Histologically, there is an intracartilaginous cyst with no epithelial lining, often with a sparse lymphocytic inflammatory response (Fig. 34-43).

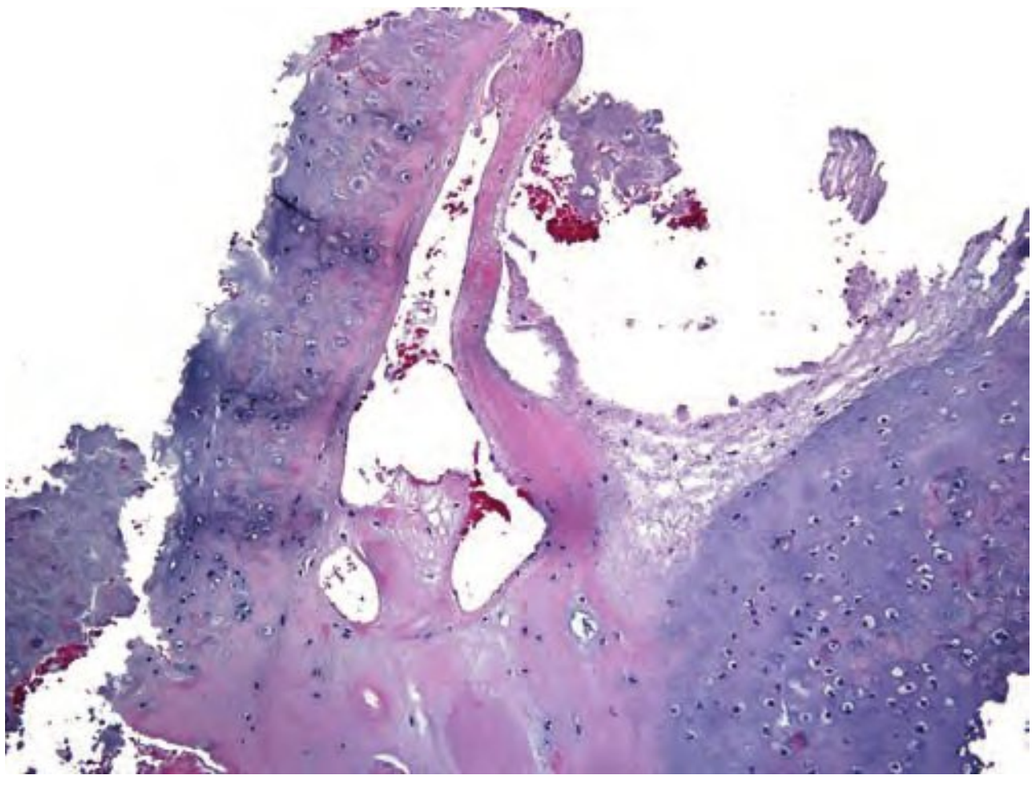

FIGURE 34-43. Pseudocyst of the auricle. There is a space in the auricular cartilage lined by chondroid tissue with a sparse inflammatory response. There is no epithelial lining, which is consistent with a pseudocyst.

CHAPTER 35

Richard J. Reed
Donald R. Pulitzer

Tumors of Neural Tissue

GENERAL ANATOMIC RELATIONSHIPS STRUCTURAL COMPONENTS

A *nerve*, an anatomic unit, is composed of nerve fibers, endoneurium, and perineurium. *Nerve fibers*, the functioning elements, are aggregated to form axial bundles (parallel arrays of nerve fibers with longitudinal symmetry). Individually, each fiber consists of an axon, or axons, and related *Schwann cells* (1–4). *Axons* are cytoplasmic extensions from the perikaryon of *neurons* in the central nervous system or from ganglion cells in sympathetic ganglia. The peripheral portion of an axon, along its entire length from its origin to terminus, is enclosed by enveloping Schwann cells. Along nonmyelinated nerve fibers, a single Schwann cell encloses segments of several axons in cytoplasmic invaginations. Along myelinated nerve fibers, a single Schwann cell encloses a segment of an axon in concentric layers of its cytoplasmic membrane; where neighboring Schwann cells abut, end to end, a node of Ranvier is formed. In sympathetic ganglia, neurons are rimmed by satellite cells; Schwann cells are substituted for satellite cells along axons. Ultrastructurally, microfilaments, specialized intermediate (neural) filaments, and microtubules are components of axons. Schwann cells have complex cytoplasmic processes; they are surrounded by continuous basal lamina and contain densely packed intermediate filaments (4).

The *perineurium*, a tubular fibrous sheath, delimits each nerve. It extends from the pia-arachnoid of the central nervous system to the terminus of each nerve or to specialized sensory receptors. Slender, bipolar or tripolar cells (*perineurial cells*) are isolated among the concentric fibrous lamellae of the perineurium. Ultrastructurally, discontinuous basal lamina, numerous pinocytotic vesicles, and tight intercellular junctions are characteristics of the perineurial cells (4). The perineurium is a relatively impervious barrier.

The *endoneurium*, a delicate, mucinous matrix, is confined by the perineurium; it provides a cushion for the axial collection of nerve fibers. Components of the endoneurium include fibroblasts ($CD34^+$), mast cells, collagen, a myxoid matrix, and capillaries.

In proximal (axial) locations, several large nerves in bundles are encased in a dense fibrous matrix, the *epineurium* (a fibrous sheath that, at the junction of the spinal nerves with the central nervous system, is continuous with the dura mater). Individual nerves, at some place along their course, leave the bundles to continue without an epineurium. Near the terminus of each nerve, nerve fibers extend beyond an open-ended perineurium into the mesenchyme; naked axons even extend into epithelium. Ensheathed receptors of the skin include mucocutaneous corpuscles and the corpuscles of Vater-Pacini, Meissner, and Merkel. Meissner corpuscles are ovoid structures in which an axon is sinuously enclosed in stacks of distinctive cells. Pacinian corpuscles are spherical structures in soft tissue. In them, concentrically laminated, distinctive cells and fibrous lamellae are arranged around a centrally located axon (Fig. 35-1). The ultrastructural features of the laminated cells of both Meissner and pacinian corpuscles are perineurial cell-like, with the exception of the innermost cells that ensheathe the central axon (5).

ONTOGENY AND REACTIONS TO INJURY AS RELATED TO THE INTERPRETATION OF PHENOTYPIC EXPRESSIONS OR PATTERNS IN NEOPLASIA

Neurosustentacular cells of peripheral nerves, related cells of the peripheral ganglia, melanocytes, and even cells of some cranial mesenchyme are all of neurocristic origin.

In reactions of peripheral nerves to injury, reserve cells of neural origin proliferate; they subsequently express either a schwannian or a perineurial phenotype. Expressions of phenotype are fortuitous; the environs in which uncommitted reserve cells find themselves influence the expressions. The available options probably include a capacity to function facultatively as endoneurial fibroblasts (6).

Histologic interpretations are based on images, both real and virtual; the virtual images are evoked from the pathologist's mental stores; the richness of the stores is a reflection of the experience of the pathologist. Virtual images, once recalled and compared with real images, form the basis for histologic interpretations. Various patterns, some relating to the structural components of peripheral nerves, some to the embryologic development of their neurocristic precursors, and some to the reactions of normal nerves to injury, provide clues for the interpretation of the puzzling histologic patterns of nerve sheath tumors. In turn, the interpretations, often with an

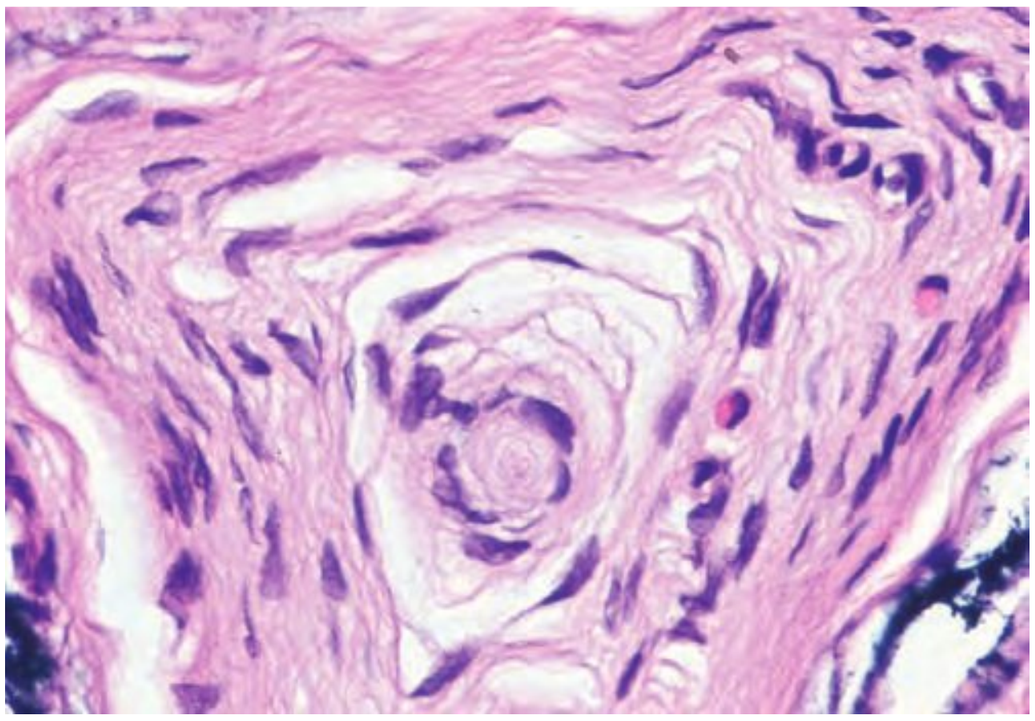

FIGURE 35-1. Pacinian corpuscle. This pacinian body has a distorted outline. At the periphery, there is a well-formed dense fibrous membrane. Elongated spindle cells are compressed among the compactly arranged collagen fibers. At the center, an acidophilic punctum is representative of a single axon. Cytoplasmic processes of sheath cells are clustered about the axon. There is an intermediate zone in which spindle cells are loosely spaced in a clear matrix. Regardless of the results of immunoreactions, the loosely spaced spindle cells have the morphologic features of perineurial cells. There is a morphologic continuum from periphery to, but not including, axon.

element of luck, can lead to the structuring of a proper histologic diagnosis. For example, the structure of Meissner corpuscles is recapitulated in the tactile corpuscle–like structures (tactoid bodies) of diffuse (extraneural) neurofibromas (3). Some of the features of wallerian degeneration (Fig. 35-2) are recapitulated in a most distorted manner in granular cell nerve sheath tumor. The intravaginal hyaline nodules of Renaut (3) may provide a model for the patterns manifested in nerve sheath myxomas.

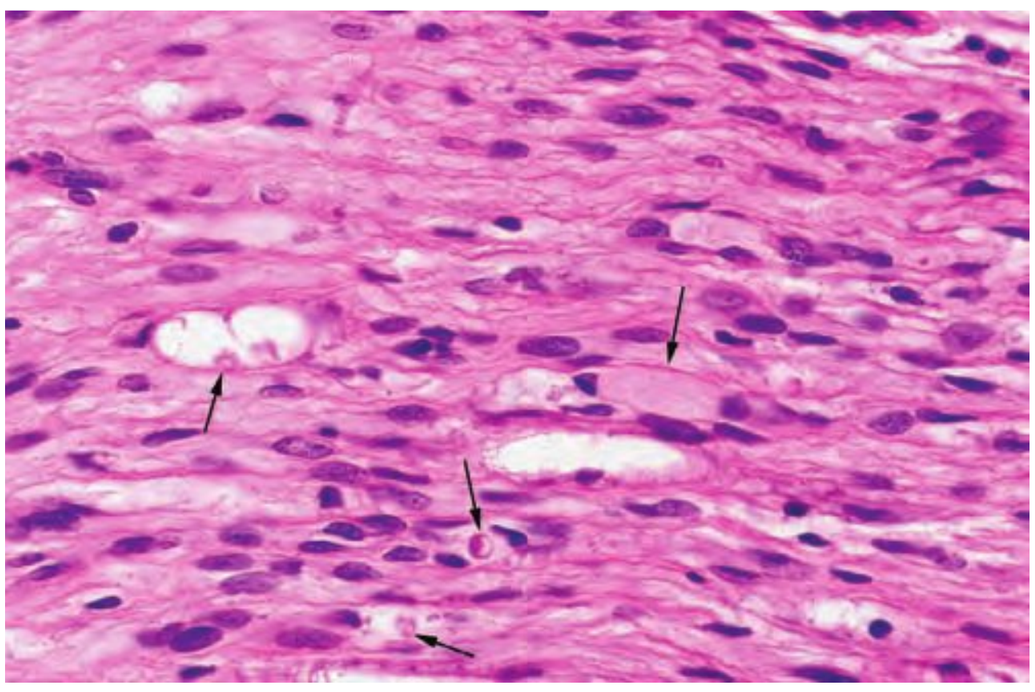

FIGURE 35-2. Wallerian degeneration. This peripheral nerve, bordering the site of an injury, shows poorly defined myelin sheaths; as a result, reticular fibers (basement membranes) of individual Schwann cells are more closely spaced. Scattered microcystic areas are representative of sites in which myelin sheaths have been disrupted. In some of the defects, there are globular deposits, some of which are concentrically laminated (black arrows); these "myelin figures" are collections of lipid membranes. Some of the Schwann cells are swollen and have pale, faintly granular cytoplasm.

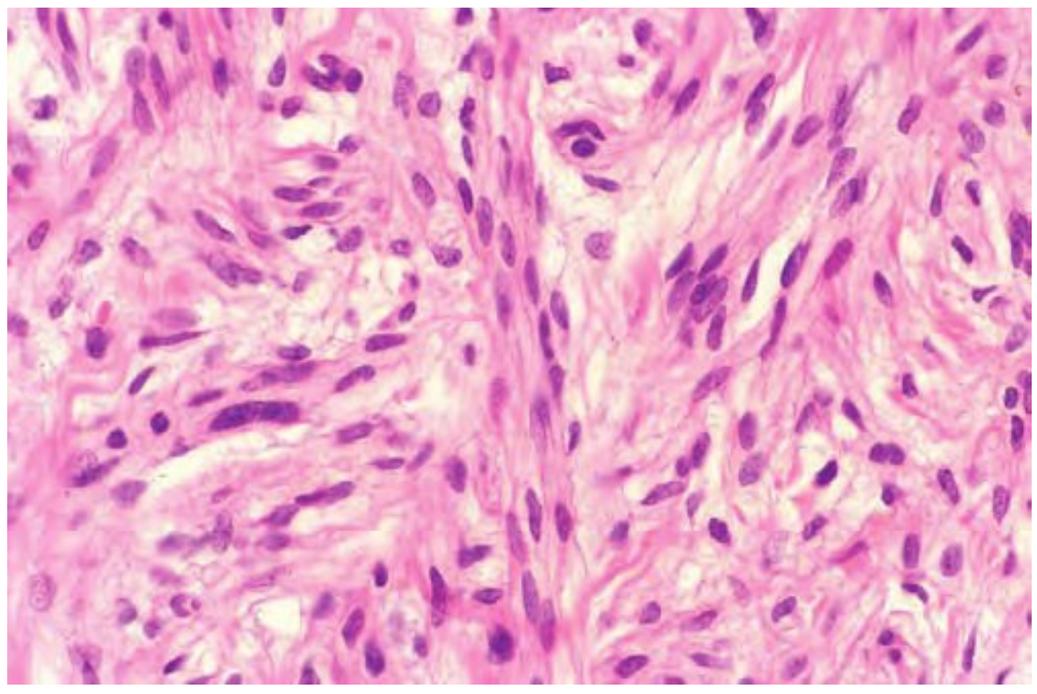

FIGURE 35-3. Extraneural neuroma. In this extraneural neuroma, Schwann cells cluster to form thin fascicles among collagen bundles of the preexisting soft tissue. Proliferating axons, as they extend in the process of repair into the fibrous tissue, provide a scaffold for proliferating Schwann cells.

When damaged, axons form multiple, sproutlike extensions (6). In the ensuing reparative process, newly formed Schwann cells accompany newly formed axons (Fig. 35-3). These patterns are incompletely recapitulated in spontaneous, intraneural neuromas. The distorted patterns that are manifested in intraneural neurofibromas, and even in some small schwannomas, may relate to a (temporary?) local excess of thin, nonmyelinated axons.

PHENOTYPES AND HISTOCHEMICAL AND IMMUNOHISTOCHEMICAL REACTIONS

Neurosustentacular cells, melanocytes, and even some mesenchymal cells, being of neurocristic origin, share a common progenitor. In tumors of peripheral nerves, the structural qualities of either Schwann cells or perineurial cells are commonly expressed, but the expression of either histologic cell type may, in turn, be associated with an immunohistochemical marker of a conflicting type. For example, the cells of tactile corpuscles mark with antibodies for S100 protein (as do Schwann cells) but have the ultrastructural features of perineurial cells.

S100 protein is a lightly acidic, calcium-binding protein of glial cells but also is expressed in a variety of other cells, including melanocytes, lipocytes, chondrocytes, some cells of sweat glands, and Schwann cells. Neuron-specific enolase (NSE) is a cytoplasmic product common to a variety of cells, including Schwann cells, and both neurons and their axons. An immunoreaction for the demonstration of neural filaments

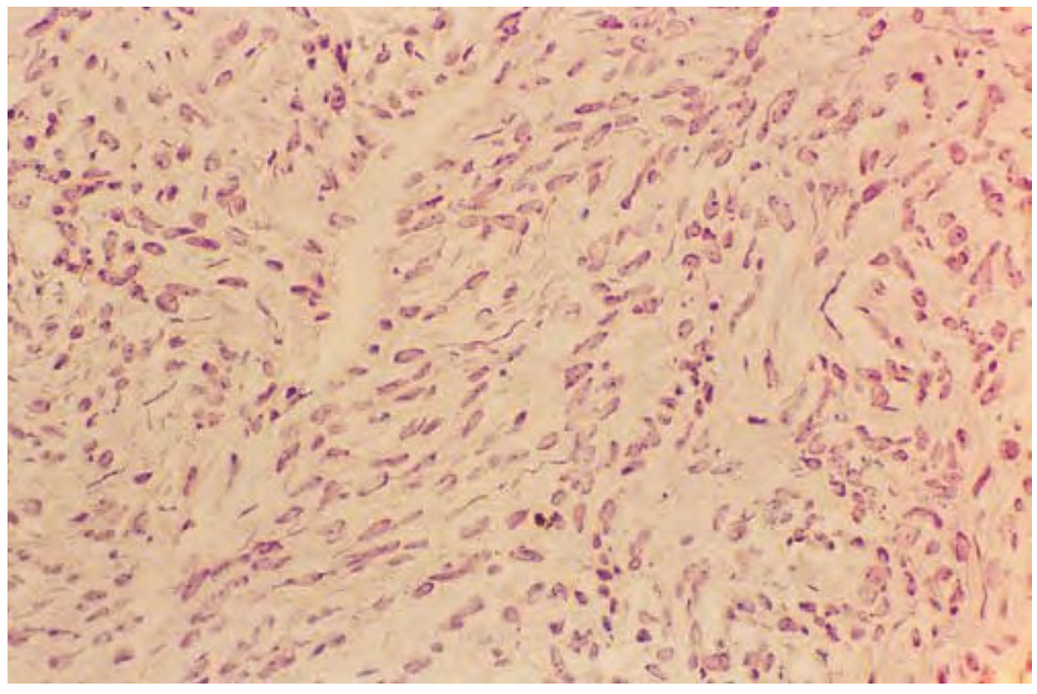

FIGURE 35-4. Extraneural neuroma (Bodian stain). The loosely spaced, delicate fibers are axons; axons are argyrophilic.

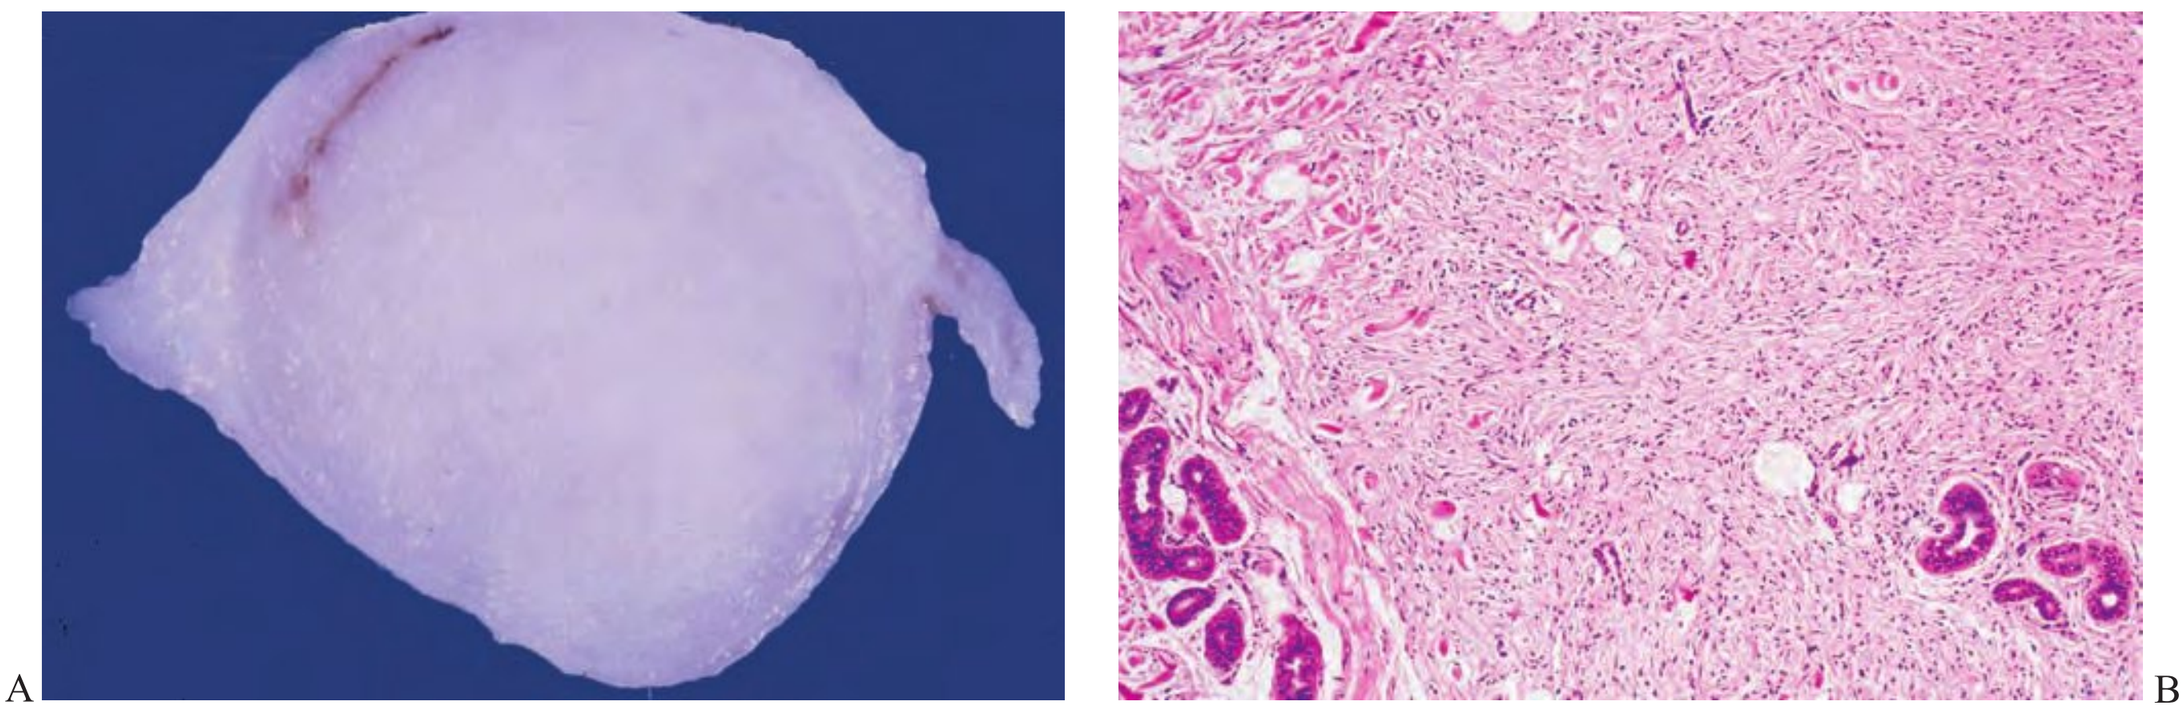

provides a pure demonstration of the reaction of axons. Silver impregnation techniques are the time-honored method of demonstrating axons (Fig. 35-4) but are less sensitive than immunohistochemical reactions; fewer axons are demonstrated. The Luxol-fast blue stain and antibodies for either myelin basic protein (MBP) or CD57 (Leu-7) antigen demonstrate myelin products. An immunoreaction for glial fibrillary acidic protein (GFAP) is positive in glial cells; it is also positive in some of the cells in some tumors of salivary glands. In some large schwannomas of soft tissue, neoplastic Schwann cells are immunoreactive for GFAP. Epithelial membrane antigen (EMA) is a cytoplasmic antigen commonly expressed in a variety of normal and neoplastic tissue, including cells of the perineurium and sebaceous cells.

Structural peculiarities take precedence over immunohistochemical findings; the commonness of a reaction for S100 protein does not take precedence over the morphologic distinctions between schwannoma and neurofibroma. The commonness of a reaction for EMA should not be the basis for a grouping of morphologically dissimilar lesions in a category of "perineurioma," a currently popular practice.

NEUROFIBROMAS (HAMARTOMAS WITH PHENOTYPIC DIVERSITY)

Extraneural sporadic cutaneous neurofibromas (ESCNs) (the common, sporadic neurofibromas) are soft, polypoid, and skin colored or slightly tan; they are small (rarely larger than 1 cm in diameter) (Fig. 35-5A). They usually arise in adulthood. The identification of as many as four small cutaneous neurofibromas in a single patient, in the absence of other confirmatory findings, would not qualify as stigmata of neurofibromatosis.

Histopathology: Under low magnification, most examples of ESCN are faintly eosinophilic. These small tumors of the reticular dermis are circumscribed but not encapsulated (Fig. 35-5B); they are extraneural (3,4). Thin spindle cells with elongated, wavy nuclei are regularly spaced among thin, wavy collagenous strands (Fig. 35-6). The strands are either closely spaced (homogeneous pattern) or loosely spaced in a clear matrix (loose pattern) (1); the two patterns often are intermixed in a single lesion. Rarely, ESCNs are composed of widely spaced spindle and stellate cells in a myxoid matrix. The regular spacing of cutaneous adnexa is relatively preserved in cutaneous neurofibromas (Fig. 35-5B). Small nerves that extend into a common cutaneous neurofibroma occasionally are

A B

FIGURE 35-5. A: Extraneural sporadic cutaneous neurofibroma. This symmetrically rounded, circumscribed tumor bulges into the subcutaneous fat. The cut surface is white and homogeneous. B: Extraneural sporadic cutaneous neurofibroma. A circumscribed, nonencapsulated tumor of the dermis is composed of loosely spaced spindle cells and wavy collagenous strands. Near the margin, collagen bundles of the dermis are entrapped in the lesion. A cluster of sweat glands also is present within the tumor; in this relationship, a defect in dermal mesenchyme has been inlaid with a neurocristic derivative.

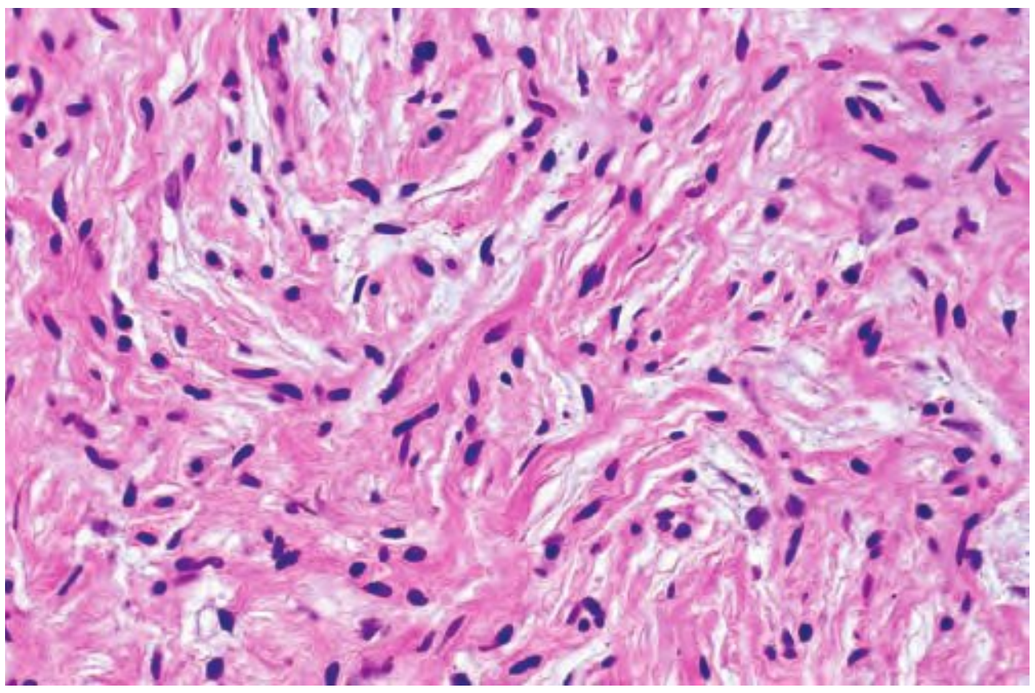

FIGURE 35-6. Extraneural sporadic cutaneous neurofibroma. Thin spindle cells are associated with thin, wavy collagen bundles. The cells and collagen bundles are loosely spaced in a clear or mucinous matrix.

enlarged and hypercellular. Tactoid (tactile corpuscle–like) bodies and pigmented, dendritic melanocytes are most uncommon (3).

Histogenesis. With silver impregnations (Bodian or Bielschowsky stain), only a few axons, mostly in small, embedded nerves, are demonstrable. Immunohistochemically, axons are more uniformly and generously represented. With monoclonal antibodies for NSE, the reaction of the axons of a cutaneous neurofibroma is intense; it is either punctate or fiber-like in a background of diffuse, but faint staining of the cytoplasm of the enveloping Schwann cells. A similar response, but without diffuse cytoplasmic staining, characterizes the reaction for neural filaments. Both of these immunochemical reactions and ultrastructural features have utility in the documentation of the schwannian (neurosustentacular) nature of the tumor cells in ESCN.

Differential Diagnosis. A schwannoma is intraneural (encapsulated); it usually does not contain axons (as demonstrated by antibodies to neurofilaments).

In a neurotized nevus, nests and fascicles of nevocytic cells usually can be identified in scattered foci. Tactile corpuscle–like bodies are common in neurotized nevi; they are rare in ESCN.

In the absence of an intraneural component, some cutaneous neurofibromas of neurofibromatosis are histologically indistinguishable from ESCN; cutaneous neurofibromas of neurofibromatosis, which in histologic patterns resemble sporadic variants, usually are larger than sporadic variants.

Some sporadic, cutaneous neurofibromas, including subcutaneous variants, differ in patterns from ESCN. Confined, at least in part, by the perineurium of the nerve of origin, they are circumscribed and variable intraneural (1–4). Their intraneural patterns are indistinguishable from the patterns variously manifested in the intraneural components of plexiform neurofibromas.

On rare occasions, the pattern of a dermatofibroma or that of a subcutaneous, spindle cell lipoma might be mistaken for that of a nerve sheath tumor.

NEUROFIBROMATOSIS (PHENOTYPIC DIVERSITY EXPRESSED IN GENETICALLY DETERMINED HAMARTOMAS AND NEOPLASMS)

Multiple cutaneous neurofibromas are characteristic of most, but not all, examples of neurofibromatosis (von Recklinghausen's disease). Other important stigmata include plexiform (intraneural) and deep, diffuse (extraneural) neurofibromas; multiple periareolar neurofibromas (Fig. 35-7); intraocular Lisch nodules; and macular, cutaneous hyperpigmentations (e.g., café-au-lait spots and bilateral axillary freckling) (7,8).

Neurofibromatosis type I (NF1) can arise as an autosomal dominant condition, but in nearly half of the patients, it arises by spontaneous mutation (9). In NF1, cutaneous neurofibromas usually appear first in late childhood or in adolescence; the disease progresses by showing gradual increases in the size and number of neurofibromas.

For NF1, the gene, which is huge, has been localized to the pericentromeric region of the long arm of chromosome 17 (10). A high spontaneous mutation rate, an attribute of huge genes, would account for the high incidence of sporadic cases. The gene shows functional and structural homology with guanosine triphosphatase–activating protein, which controls the ras oncogene. In turn, the role of the ras oncogene in growth, development, and differentiation may be aberrantly expressed in the NF1 phenotype (10). The protein product of the gene is called neurofibromin (11).

In NF1, superficial peripheral nerves, deep peripheral nerves, nerve roots, and the autonomic nerves of viscera and blood vessels may be affected. Large, pendulous plexiform neurofibromas have the flabby texture of a "bag of worms." Deep, diffuse neurofibromas are poorly defined at their limits with the adjacent soft tissue (3). Changes sometimes associated with large neurofibromas of the skin and subcutaneous fat provide an elephantiasic quality. Spinal nerve root tumors may cause compression of the spinal cord (9). Tumors of the central nervous system occur in 5% to 10% of the patients (7). A neurofibroma that is adjacent to bone or is intraosseous may erode the bone. Lesions that are variably associated with neurofibromatosis include

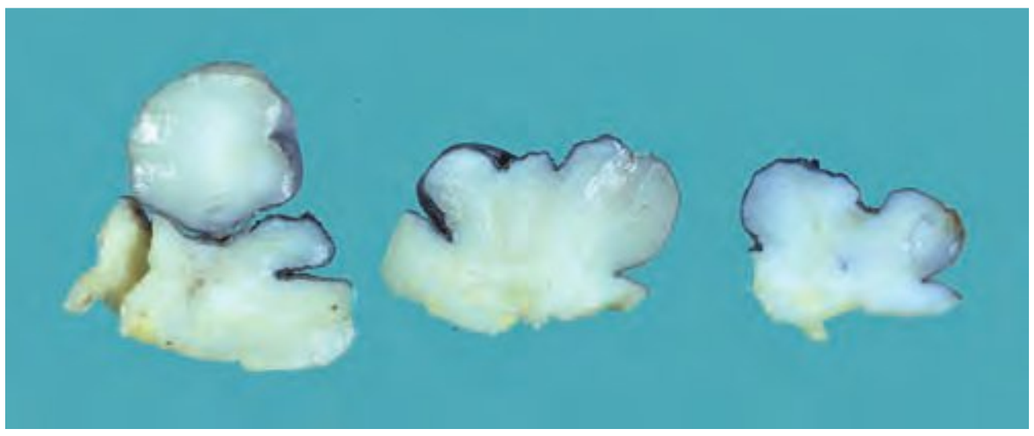

FIGURE 35-7. Periareolar neurofibroma. The lesion has been breadloafed. Multiple polypoid components project above the skin surface. The cut surface is white and glistening. The lesion diffusely involves the dermis and protrudes irregularly into the subcutaneous fat.

FIGURE 35-8. A: Acoustic neuroma (schwannoma involving the VIIIth cranial nerve and meningiomas). The schwannoma is expansile and white. Portions of a meningioma are also represented along the base of the brain; other portions had been surgically removed. The patient had neurofibromatosis. B: Acoustic nerve schwannoma (cut surface of brainstem at the level of the pons). On the right, an acoustic neuroma (schwannoma) involves the VIIIth cranial nerve. The cut surface focally is hemorrhagic. In other areas, the cut surface is tan, a coloration often seen in association with hemosiderin deposits.

kyphoscoliosis and an increase in the length of long bones. NF1, diffuse intestinal ganglioneuromatosis, and multiple endocrine neoplasia (MEN) type 2b are unpredictably associated (12,13). Gastrointestinal stromal tumors are more common in NF1 than in the general population (14). An association among juvenile xanthogranuloma, juvenile chronic myelogenous leukemia, and NF1 has been observed (15).

In localized or segmental neurofibromatosis, cutaneous neurofibromas are few in number, and the family history is negative (16–18).

In *neurofibromatosis type 2* (NF2) (a genetically distinct variant), café-au-lait spots, neurofibromas, schwannomas, and a variety of intracranial tumors, including bilateral schwannomas of the acoustic nerves, are manifestations (11) (Fig. 35-8). Meningioangiomatosis has been reported in association with NF2 (19). The gene locus has been linked to chromosome 22q11-q13. The protein gene product, called merlin, is similar to a group of cytoskeleton-linked proteins (11).

The syndrome of *multiple schwannomas* (schwannomatosis or neurilemmomatosis) (20) is characterized by multiple schwannomas and plexiform schwannomas. It has been characterized as a clinical entity, distinct from NF2 (21).

Café-au-lait spots occur in nearly all patients with neurofibromatosis. In the sequence in which clinical findings first appear, they usually precede cutaneous tumors (8). Although a few café-au-lait spots are occasionally seen in patients without neurofibromatosis, the presence of more than six spots, each exceeding 1.5 cm in diameter, is indicative of neurofibromatosis (7,9).

Histopathology. The histologic spectrum of neurofibromas in NF1 is broad. Cutaneous, extraneural variants (as manifested in ESCN), cutaneous or deep, circumscribed (intraneural) variants, plexiform (intraneural) variants (Fig. 35-9), deep, diffuse (extraneural) variants, and various combinations thereof are manifested in an array of histologic patterns.

In many deep, circumscribed (intraneural) neurofibromas and in most plexiform (intraneural) neurofibromas, axial bundles (which are composed of symmetrically arranged nerve fibers) are remnants of the axial bundle of the nerve of origin (Figs. 35-9 and 35-10) (3,4,22) Their role in the histogenesis of NF is uncertain. The axial bundle retains its symmetry in a field of distorted and asymmetric patterns (Fig. 35-10). In some axial bundles, Schwann cells are hyperplastic and tightly packed. In areas, these remnants of the nerve of origin focally evolve into micronodules composed of interlacing fascicles of Schwann cells; the micronodules qualify as *microscopic schwannomatosis* (3). Many of these cellular nidi (micronodules) may be independent of a true axial bundle, but all seem to function as growth centers (Fig. 35-11). Cells and collagenous strands stream from the periphery of these nidi (growth centers); they extend asymmetrically into the expanded, mucinous, endoneurial matrix. In some intraneural variants, similar patterns of streaming cells and collagenous strands blend with (or arise from) the perineurium; in such lesions, the perineurium appears to contribute to the tumor; the cells that stream from the perineurial components cytologically resemble perineurial cells.

In the evolution of a neurofibroma, the contributions from each anatomic component of a peripheral nerve are variable. The cells of *perineurial variants* are bipolar or tripolar with rigid processes; they are loosely spaced in either a myxoid or fibrous matrix (Figs. 35-12 and 35-13). *Endoneurial (schwannian) variants* are characterized by a thickened perineurium, one or several axial bundles, and isolated cells in an

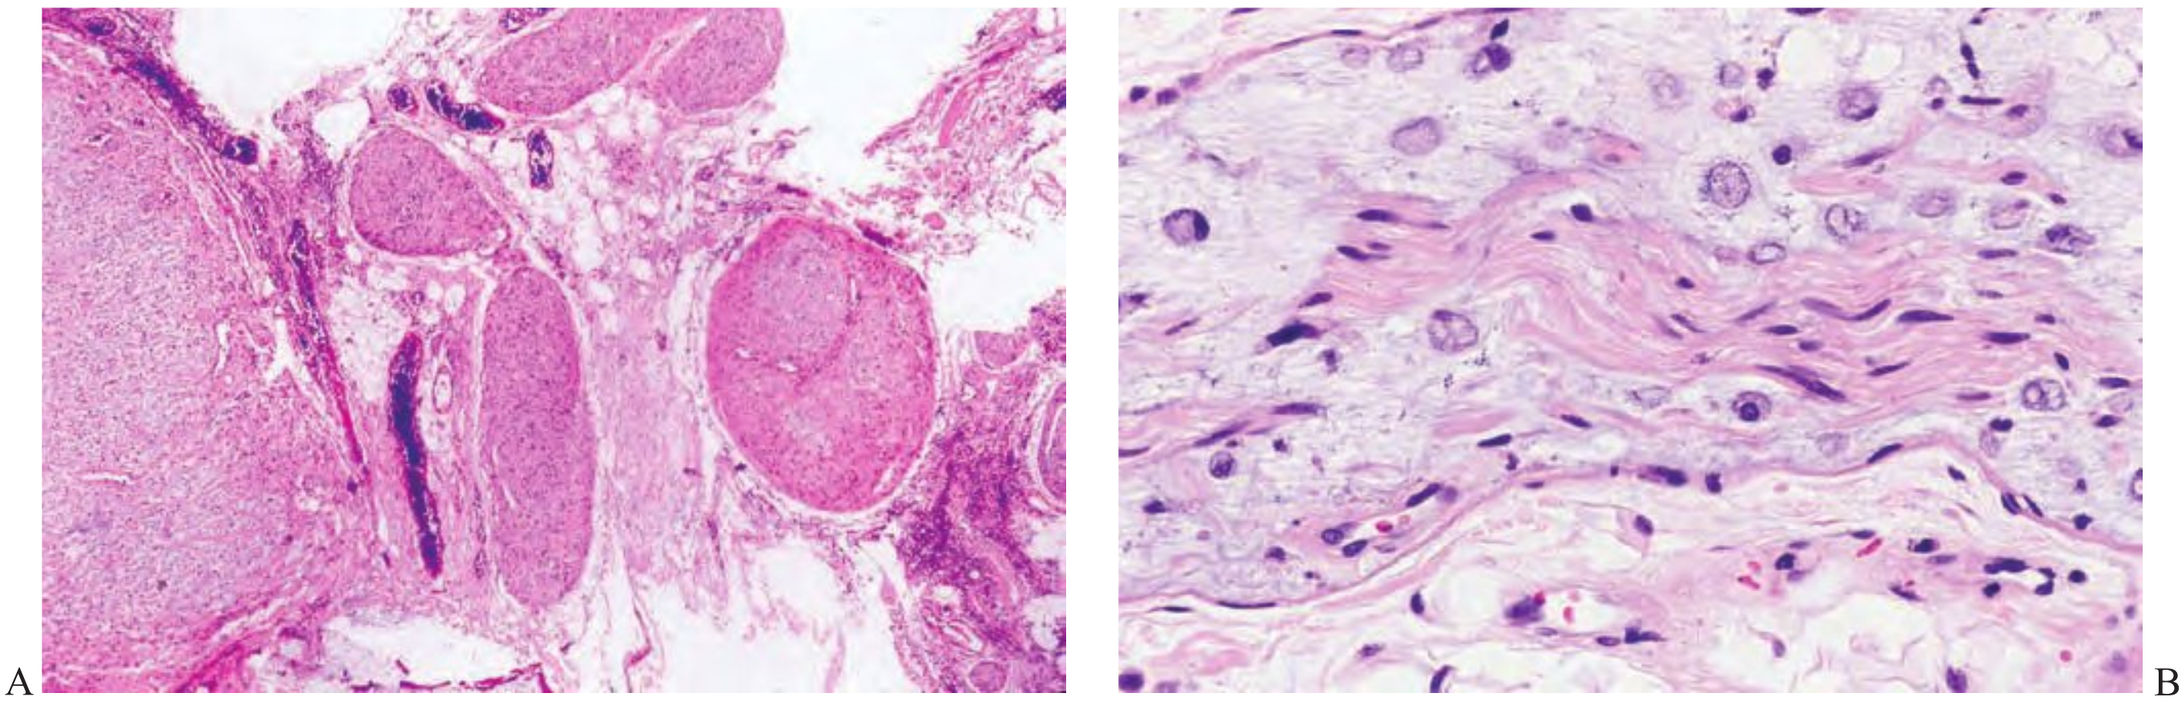

FIGURE 35-9. A: Components of a cutaneous, plexiform, intraneural neurofibroma. For the most part, components of the plexus in this field are cut in cross section. The tumor is intraneural; it sits in fibrofat without an extraneural component. Each component of the plexus is confined by a thickened perineurium. B: Plexiform intraneural neurofibroma; mucinous endoneurial type. This small branch of a large, cutaneous, plexiform neurofibroma shows a well-defined, central bundle of Schwann cells (an axial bundle). In this central bundle, Schwann cell fascicles of the preexisting nerve are symmetrically arranged along the long axis of the nerve. The endoneurial space is widened and mucinous. In it, distinctive rounded cells (endoneurial mucocytes) are loosely spaced. The expanding mucinous matrix has displaced some of the Schwann fascicles of the axial bundle away from their neighbors. The muciparous cells resemble the "cellules godronné" as seen in the "intravaginal hyaline system" of Renaut (6). The perineurium is delicate; it is a single layer of flattened cells.

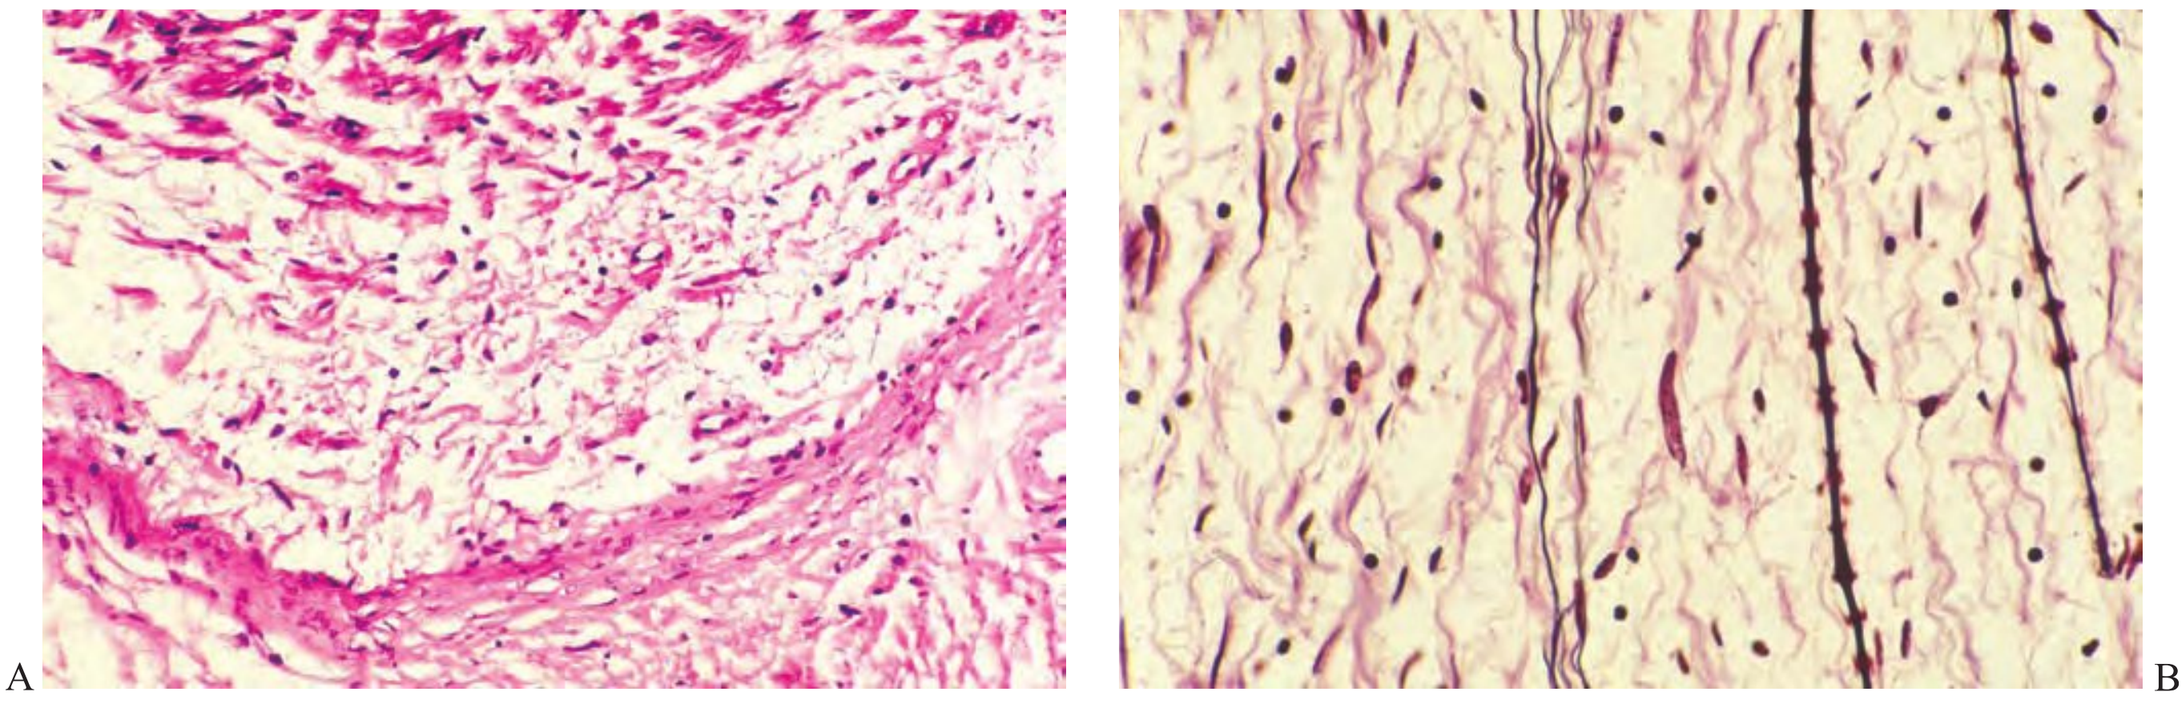

FIGURE 35-10. A: Intraneural neurofibroma; schwannian pattern of differentiation. A thickened perineurium forms a concave band near the bottom of the field; it defines the limits of the tumorous component at the interface with the adjacent soft tissue. At the top of the field, a distorted axial bundle (a remnant of the nerve of origin) is represented. The tumor is represented in the space between the perineurium and the distorted axial bundle; thin, pale collagen bundles are loosely and randomly spaced in a stringy, myxoid matrix. Thin spindle cells with elongated, wavy nuclei are closely associated with some of the collagen bundles. The fibrous component of the lesion is asymmetric in its relationships with both the long axis of the involved nerve and the central axial bundle. B: Intraneural neurofibroma; remnant of axial bundle (Bodian stain). Argyrophilic, myelinated and nonmyelinated axons are parallel; they have axial symmetry and are a remnant of the axial bundle. Wavy collagen bundles of the tumor are more asymmetric in orientation and distribution.

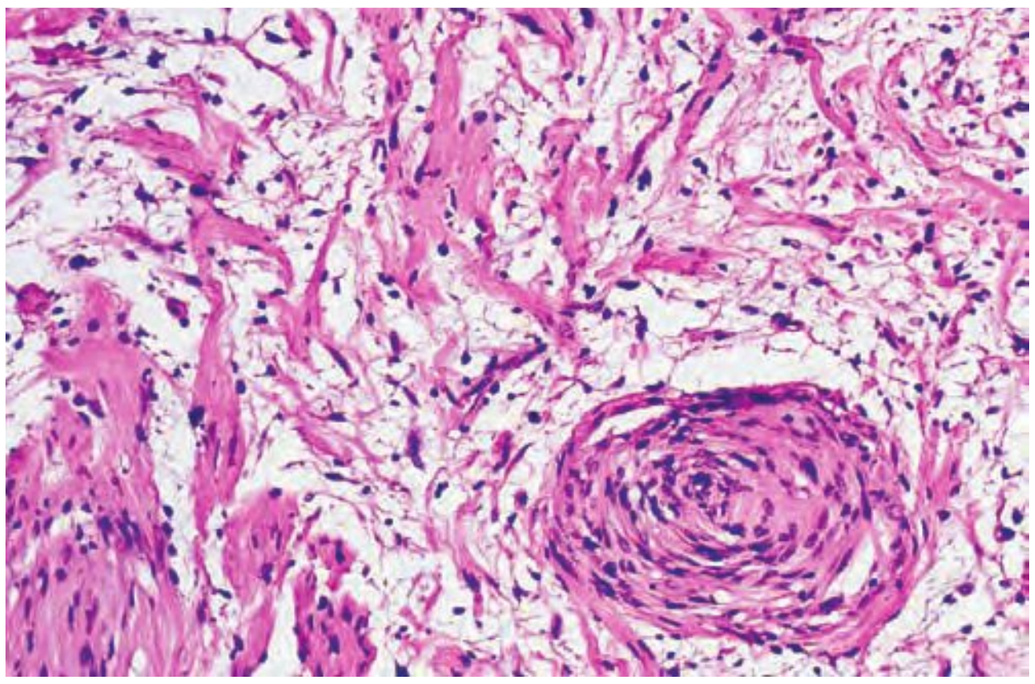

FIGURE 35-11. Intraneural neurofibroma; focal, microscopic schwannomatosis. Coarse collagen bundles are asymmetrically arranged in a loosely cellular, myxoid matrix. Near the right lower corner, collagen bundles and cells form a whorl; the whorl, as a nidus, is an example of microscopic schwannomatosis.

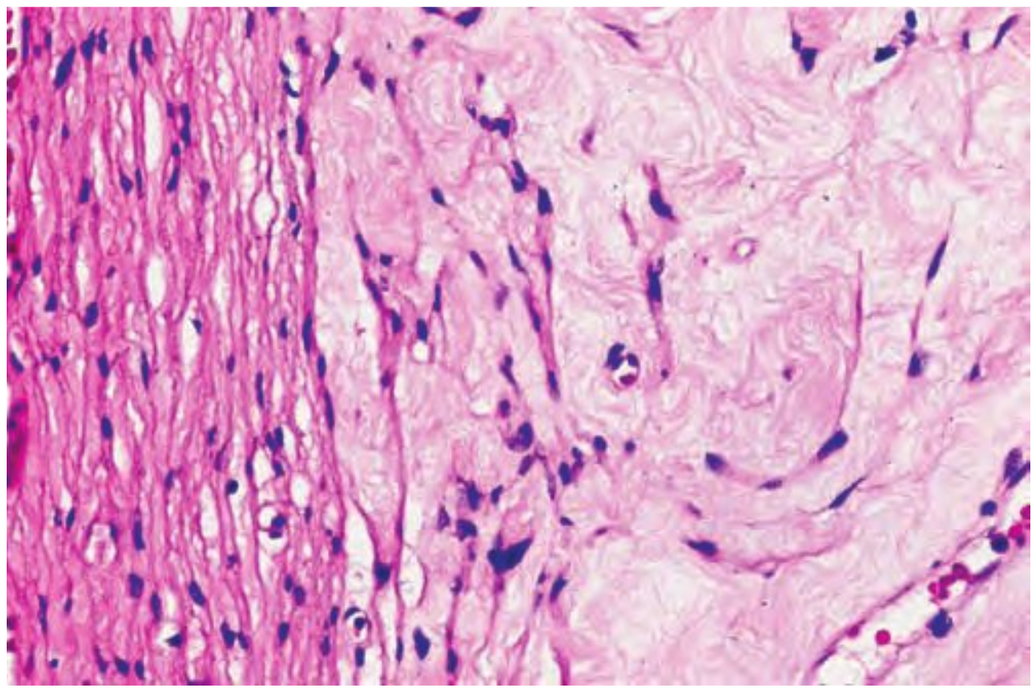

FIGURE 35-13. Intraneural neurofibroma; perineurial cell differentiation near the capsule of the tumor. The membrane to the left of the field is a thickened perineurium (capsule). In the fibrous matrix to the right of the perineurium, distinctive cells are loosely spaced; some blend with the inner surface of the perineurium. The loosely spaced cells have the morphologic features of perineurial cells.

expanded, mucinous endoneurial component (Fig. 35-14). In some examples, some of the cells in an expanded, mucinous matrix resemble the "cellules godronné" of Renaut [round cells with portions of the mucinous matrix that are either enclosed within the cytoplasm or focally partitioned (encircled and sequestered) by cytoplasmic processes] (Fig. 35-9B) (1,3,4,23). One or several axial bundles may be found among asymmetric collagen bundles of the tumor. In the expanded endoneurial component of both perineurial and endoneurial (schwannian) variants, the matrix is myxoid; it is rich in hyaluronic acid (Figs. 35-14 and 35-15) (3).

In a lesion in which the patterns of neurofibroma are otherwise preserved and mitotic activity is not a feature, spottily scattered cells with enlarged, atypical nuclei are not a significant finding (Figs. 35-14 and 35-16); as a variable to be assessed, cytologic atypia, in the absence of mitotic activity and necrosis, is comparable to the "ancient" (atypical) nuclear changes of some schwannomas (3,4).

At the interface of *extraneural (diffuse) neurofibromas* with soft tissue, margins are poorly defined (Fig. 35-17), and lipocytes are often present in the fibrous matrix of the tumor (4,24). The matrix of extraneural neurofibroma is either delicately fibrous

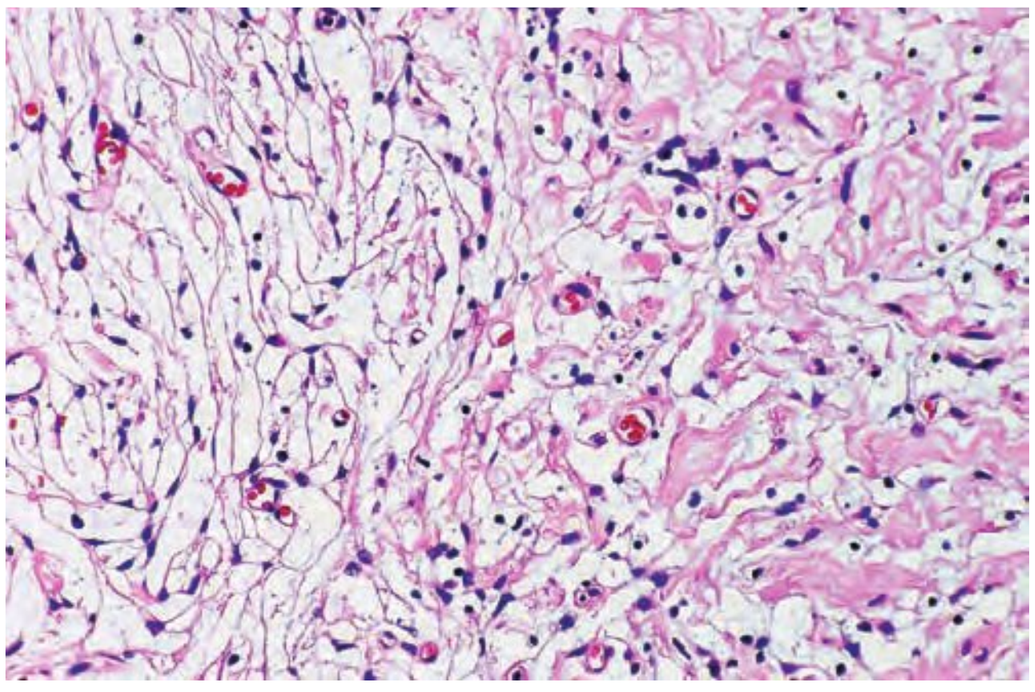

FIGURE 35-12. Intraneural neurofibroma; biphasic (perineurial and schwannian) patterns. To the right, wavy collagen bundles are loosely spaced; spindle cells are closely associated with the collagen bundles (schwannian pattern). To the left, distinctive bipolar and tripolar cells are loosely spaced in a clear or myxoid matrix; these distinctive cells have perineurial qualities.

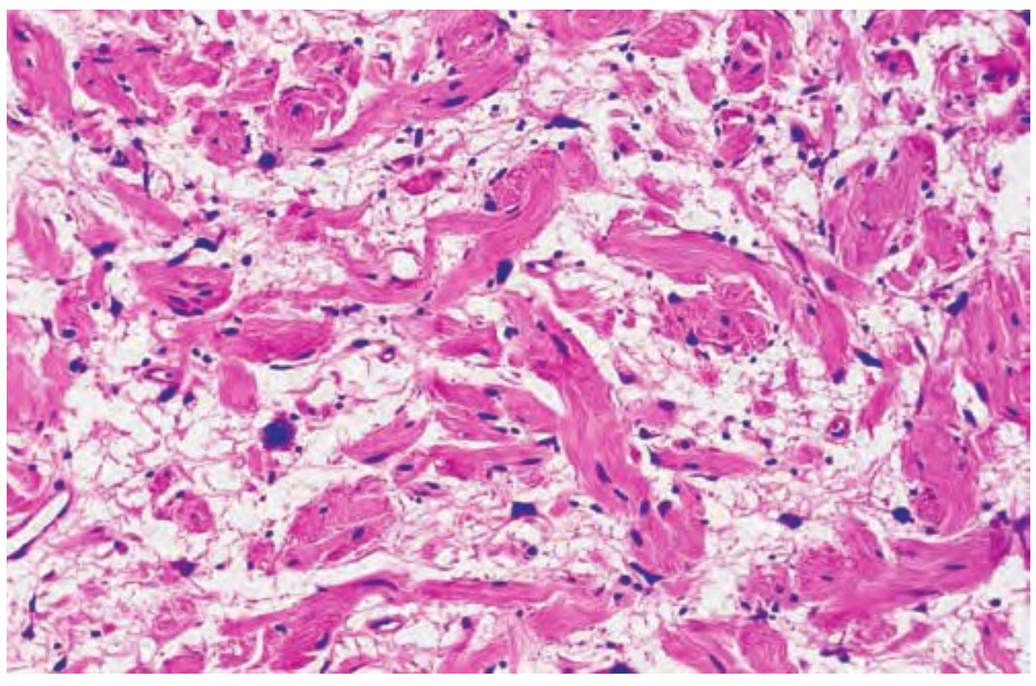

FIGURE 35-14. Intraneural neurofibroma; cytologic atypia. Coarse collagen bundles are loosely and randomly spaced in a myxoid matrix. Spindle cells are closely associated with the collagen bundles. Spindle and stellate cells are present among the collagen bundles in the myxoid matrix. Some of the cells in the myxoid matrix show nuclear atypism; they show variations in nuclear size and outline.

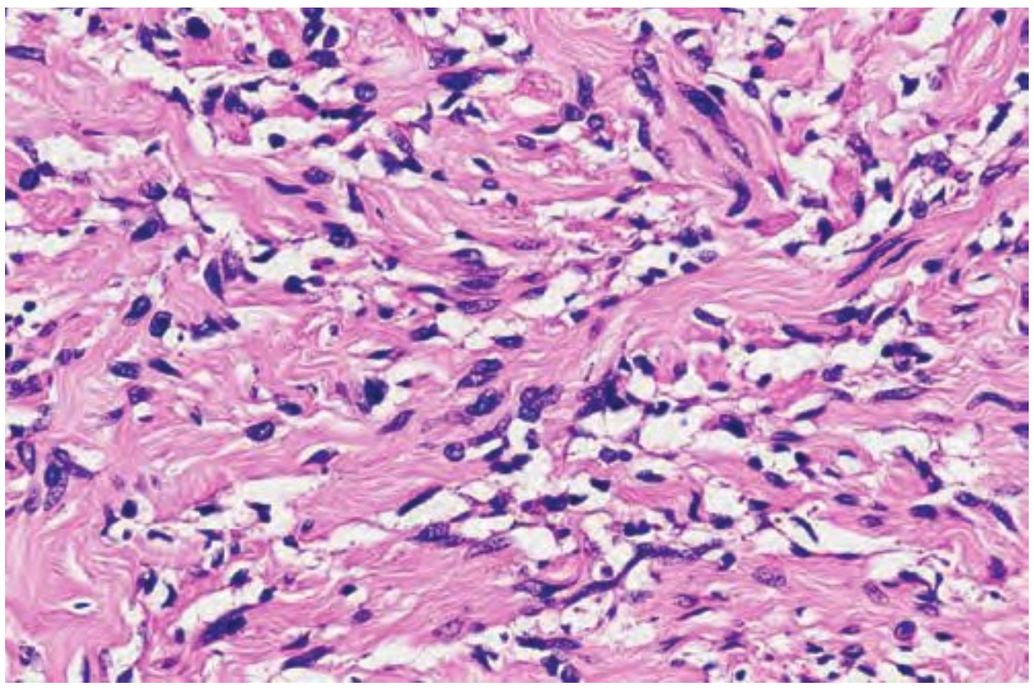

FIGURE 35-15. Intraneural neurofibroma; cellular pattern. Spindle cells are increased in number among the collagen bundles; focally, they are present within the collagen bundles. The cells have enlarged, wavy nuclei and scanty cytoplasm.

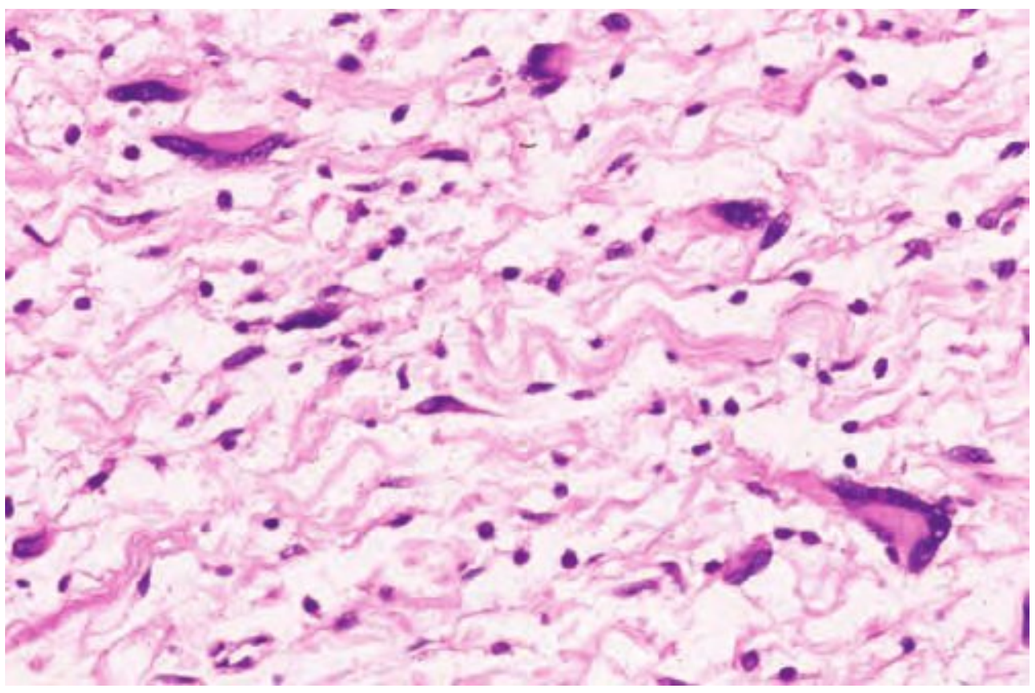

FIGURE 35-16. Intraneural neurofibroma; cellular atypia. Some of the cells among the collagen bundles are cytologically atypical; some of the atypical cells are multinucleated.

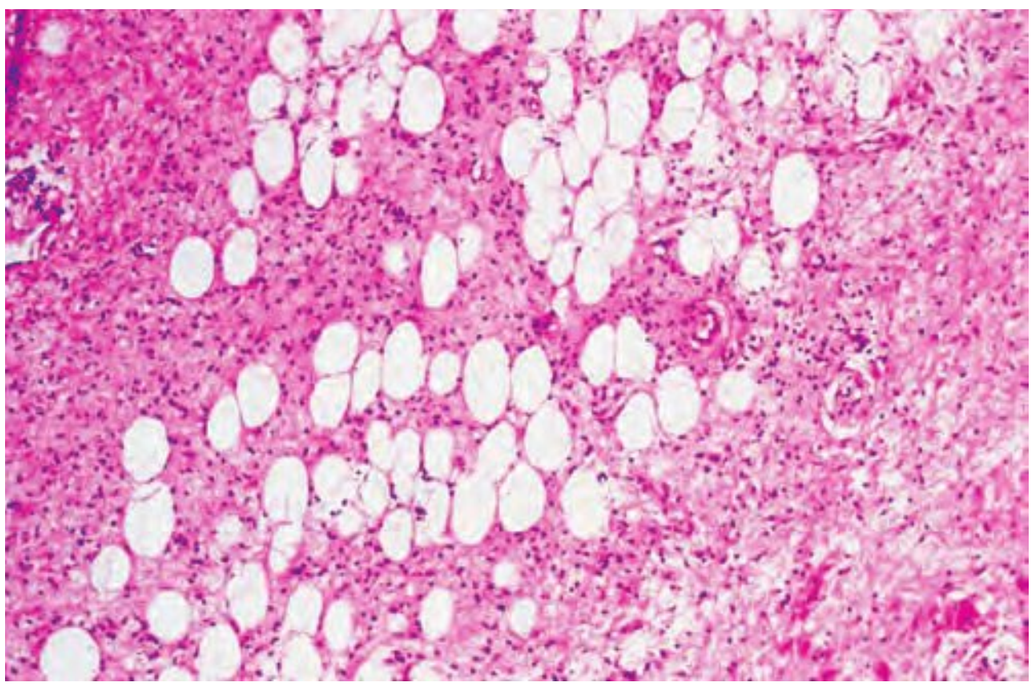

FIGURE 35-17. Extraneural (diffuse) neurofibroma. A delicately fibrous matrix is loosely cellular. The cells have scanty cytoplasm; they appear as naked nuclei. Lipocytes are entrapped.

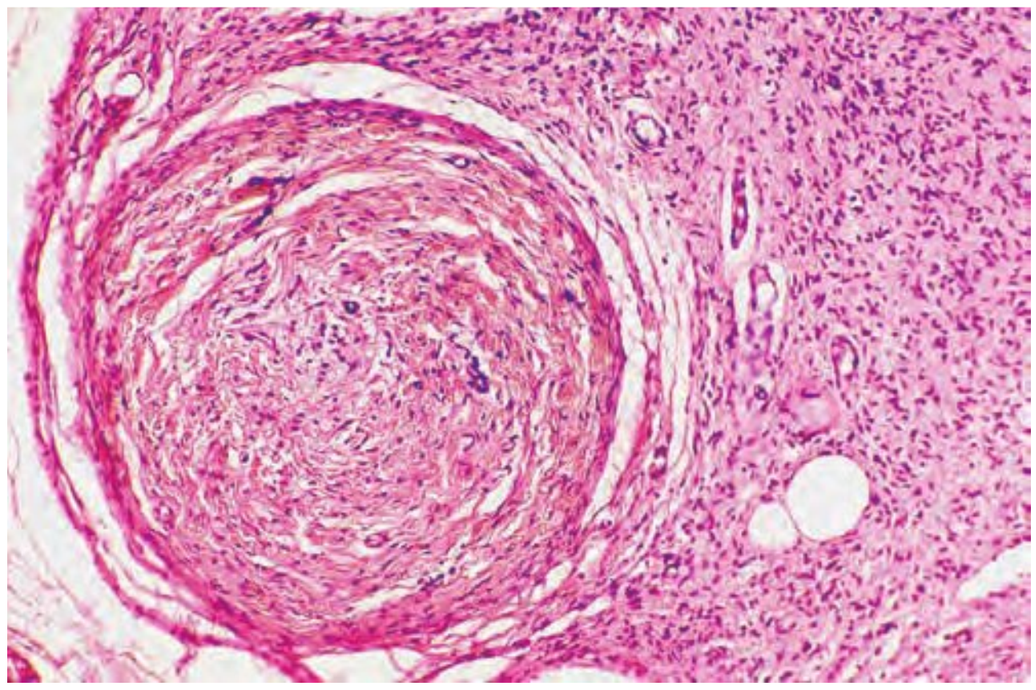

FIGURE 35-18. Diffuse and plexiform neurofibroma (paraneurofibroma). The round nodule to the left is a portion of an intraneural plexiform neurofibroma; it has been cut in cross section. The delicate fibrous matrix to the right is a portion of a diffuse (extraneural) component.

and faintly acidophilic or more coarsely fibrous and brightly acidophilic. In the absence of plexiform components, nerves within diffuse neurofibromas usually are small, internally symmetric, and hypercellular; perineuria of such nerves often are hyperplastic. In cross section, these nerves might be mistaken as evidence of pacinian corpuscle–like differentiation (25). Patterns of both a plexiform (intraneural) neurofibroma and a diffuse (extraneural) neurofibroma are combined in *paraneurofibroma* (Figs. 35-18 and 35-19) (3). Focal collections of structures resembling tactile corpuscles (tactoid bodies) (Fig. 35-20) and pigmented, dendritic melanocytes [a relatively

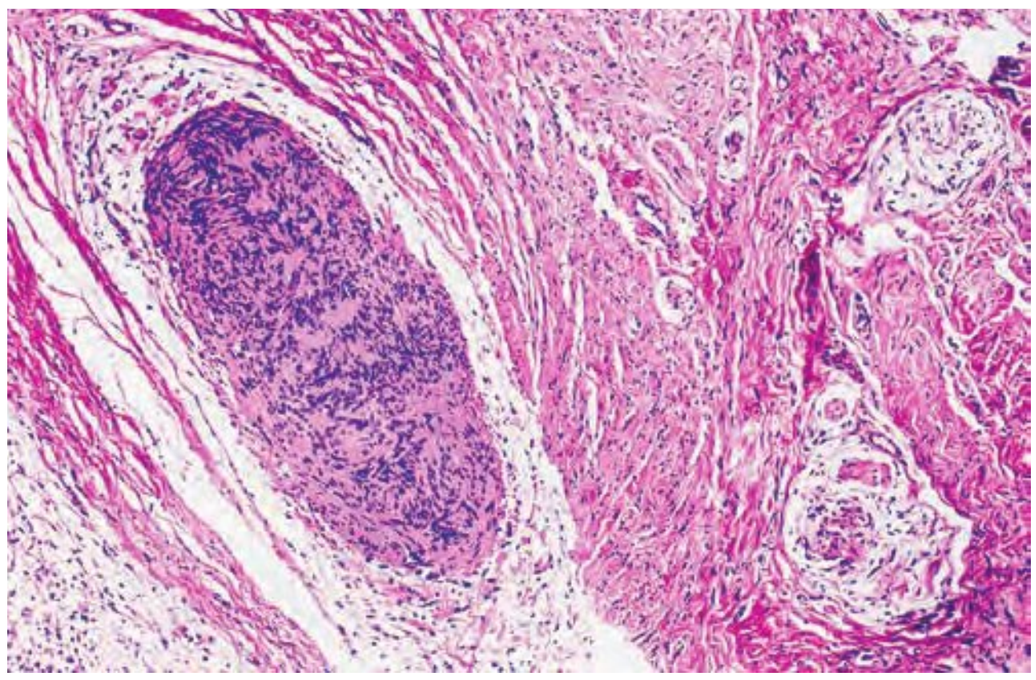

FIGURE 35-19. Diffuse and plexiform neurofibroma (paraneurofibroma) with focal microscopic schwannomatosis. The intraneural portions are pale, rounded, and faintly basophilic; in these components, wavy collagen bundles are loosely spaced. The extraneural component is a uniformly cellular fibrous matrix. Near the center of the field, a cellular nodule is confined within the intraneural matrix; in this cellular nodule, nuclei are arranged in palisades. The nodule is an example of microscopic schwannomatosis. The patterns of Verocay bodies are represented.

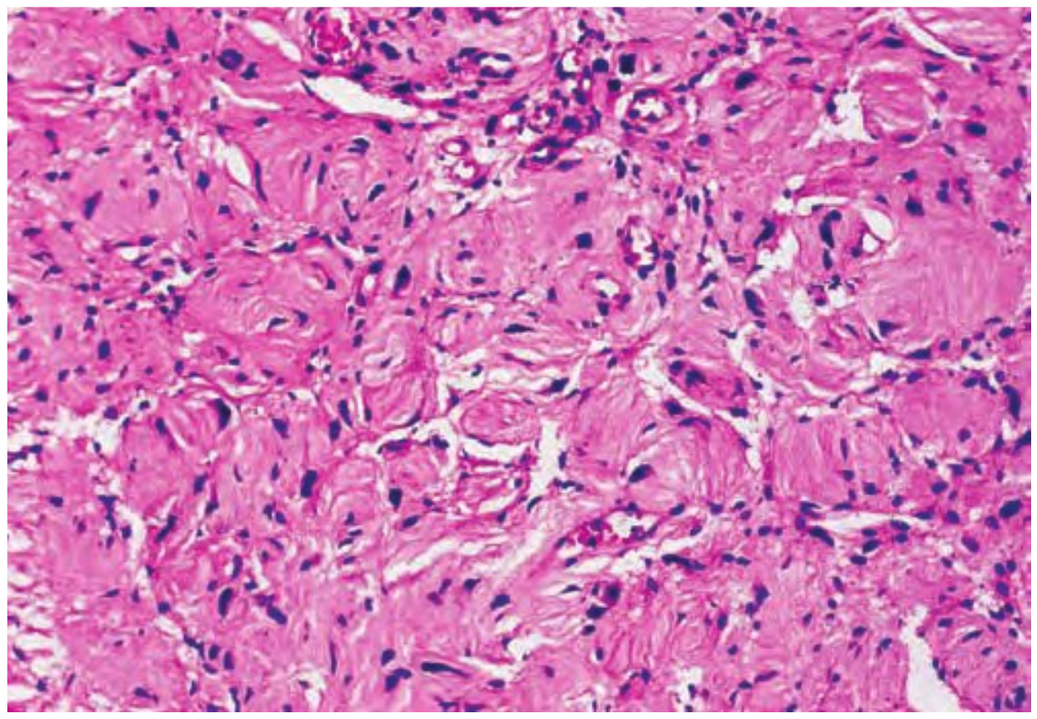

FIGURE 35-20. Extraneural neurofibroma; tactile corpuscle–like patterns. As a regional variation in this extraneural neurofibroma, spindle cells, in stacked lamellae, form tactile corpuscle–like structures.

common feature of deep, extraneural (diffuse) neurofibromas] are rare in the intraneural components of plexiform, or circumscribed, intraneural neurofibromas (3).

Ultrastructurally, the cells of neurofibromas (including those of tactoid bodies) mostly resemble perineurial cells (26), but cells with the characteristics of Schwann cells, as well as endoneurial fibroblasts, also have been identified; a morphologic continuum of neurosustentacular cells is manifested (3,27). Endoneurial fibroblasts, like common mesenchymal fibroblasts, do not have basal lamina. The average diameter of their collagen fibrils lies well below that of dermal collagen fibrils, which is about 100 nm (28).

Histogenesis. The immunohistochemical profile of neurofibroma is as follows: S100 protein (+), with variable expression of CD57 (Leu-7) antigen (+) and myelin basic protein (+). In extraneural cutaneous neurofibromas, axons, as demonstrated with NSE, or with antibodies to neurofilaments, are fairly uniform in distribution among collagen bundles. This finding is less consistent in deep, intraneural neurofibromas. Endoneurial fibroblasts are $CD34^{+}$ (29).

The ultrastructural features of neurofibromas [i.e., a preponderance of cells that resemble perineurial cells (26)] and the respective immunohistochemical findings (i.e., $S100^{+}$ and EMA^{-}) are discordant qualities.

Schwann cells with enclosed axons, as demonstrated with monoclonal antibodies for either NSE or neural filaments, are variably distributed in cutaneous neurofibromas. They have been characterized as an integral part of neurofibromas or simply as a consequence of the entrapment of uninvolved nerve fibers (26). Nonplexiform but circumscribed neurofibromas of von Recklinghausen's disease contain abundant, peptide-rich nerve fibers (30). Similar associations undoubtedly exist in plexiform variants. The innervation of neurofibromas of NF1 apparently is much richer than was appreciated in the past.

The extraneural distribution of the common dermal neurofibroma may be a manifestation of the extension of tumor through the open-ended terminal of perineurial sheaths or through the thin perineurium of small dermal nerves (22). Deep, extraneural neurofibroma may represent a diffuse, neurocristic dysplasia that is expressed in mesenchymal patterns (3,31). In this approach, the presence of lipocytes within such a tumor may be evidence of mesenchymal differentiation rather than simple entrapment.

Hybrid peripheral nerve sheath tumors have been described (32). In this study, in which certain lesions were classified as schwannoma-perineurioma or neurofibroma-perineurioma, histopathologic and immunohistochemical findings were emphasized; the characterization for one case was supplemented with ultrastructural findings. In one case, a point mutation was detected in exon 15 of the NF2 gene (32).

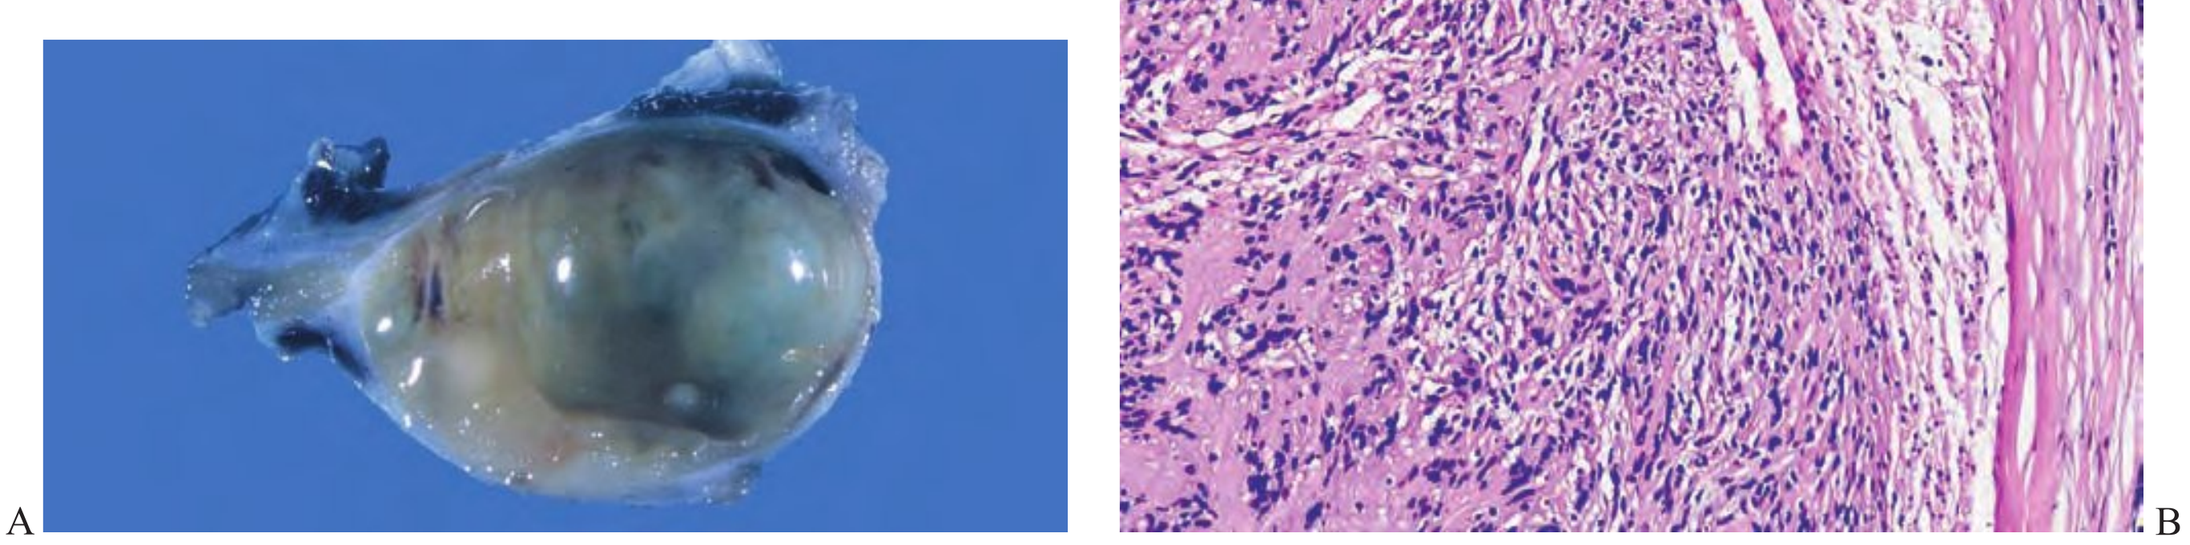
Differential Diagnosis. Plexiform (and pseudoplexiform) lesions of the skin and subcutaneous tissue include plexiform schwannoma (3), plexiform neuroma (33), the neuromas of the mucosal neuroma syndrome (34), nerve sheath myxoma (1,35), and plexiform fibrous histiocytoma (36). A plexiform variant of perineurioma (all of its current guises apparently being insufficient) has been described (37). Currently, there is a tendency to classify fasciculated melanocytic tumors as "plexiform" lesions.

Dendritic cell neurofibroma with pseudorosettes is a poorly documented, benign, "plexiform" lesion of the skin (38,39). Two cell types are represented: large dendritic cells and small, dark cells. The dark cells tend to cluster in palisades about the large dendritic cells. The tumor cells are immunoreactive for S100 protein. The large cells are not neurons. In a reply to a letter to the editor, Michal et al. provided additional photomicrographs (40). Their Fig. 1A shows a tumor that is both extraneural and intraneural (both diffuse and plexiform). With these photomicrographs as an aid, one can see that the lesion has the qualities of a variant of a plexiform and diffuse neurofibroma. As photographically documented, the dendritic cells are intraneural. The large dendritic cell is sheltered from the small-cell component by a complex of cell processes; as represented in the illustrations, the complex resembles neuropil. The histologic features of the population of small cells can be compared to those of the small cells in some examples of "epithelioid" small-cell populations in some variants of schwannoma. These variant schwannomas are of the type associated with zones of radial sclerosis. In neither category of nerve sheath tumor do the small cells have the cytologic features of a population of "blast" cells. To borrow an old designation, but to alter its definition, the patterns of differentiation in the small cell population might qualify as "neuroglial" differentiation. Having made such a concession, it would be difficult to define features that might qualify the "dendritic cell neurofibroma" as an example of a malignant small blue cell tumor, thus legitimizing the rubric "neuroblastoma-like."

Subcutaneous, extraneural (diffuse) neurofibromas may be confused with the deep component of *dermatofibrosarcoma*

protuberans. The confounding patterns account for the characterization of pigmented dermatofibrosarcoma protuberans as *pigmented storiform neurofibroma* (25,41). In infancy, "plexiform" fibrous hamartoma also might be considered in the differential diagnosis of an extraneural neurofibroma.

The nodular myxoid components of a low-grade *malignant myxoid fibrous histiocytoma* might be misinterpreted as the pattern of a "plexiform" nerve sheath tumor.



Mucinous and proliferative endarteritis and aneurysms are occasional features in the setting of NF1; they affect mainly muscular renal vessels, but similar changes can be manifested in other sites (3,42,43). Aneurysmal changes have been a prominent feature of muscular vessels in some examples of extraneural neurofibromas of the skin and soft tissue, particularly in the distribution of the trigeminal nerve (3). Such lesions clinically may be mistaken for *hemangioma*.

TRUE NEOPLASMS OF SCHWANN CELLS (ULTRASTRUCTURALLY DISTINCTIVE CELLS THAT ARE IMMUNOREACTIVE FOR S100 PROTEIN), SCHWANNOMAS

Schwannomas (neurilemmomas; anaxonal, intraneural, Schwann cell tumors; "peripheral neurogliomas") are benign, expansile neoplasms (1,26,44). The cells of schwannomas mostly have the characteristics of Schwann cells. Schwann cells are specialized sustentacular cells normally distributed as a single layer about and along one or more axons. In a sense, the insulation that they provide along normal nerve fibers favors proper propagation of nerve impulses. In schwannomas, the population of Schwann cells exists independent of a plexus of axons. As solitary, skin-colored tumors along the course of peripheral or cranial nerves, their usual size is between 2 and 4 cm; their usual location is the head or the flexor aspect of the extremities (Fig. 35-21). Schwannomas are rare in the subcutaneous tissue; they are even less common in the dermis. In deep soft tissue, they may be large (45). In the central nervous system, the VIIIth cranial nerve is the favorite site. Internal viscera (46) and bones may be involved. When small, most schwannomas are asymptomatic, but pain, localized to the tumor or radiating along the nerve of origin, can be a complaint.

Histopathology. Schwannomas, with the exception of infiltrating, fascicular variants, are intraneural and symmetrically expansile; they are confined by the perineurium of the nerve of origin (Fig. 35-21B). Most of the symmetrically bundled nerve fibers of the nerve of origin are displaced eccentrically; if identified in a histologic section, they usually are found between the tumor and the perineurium (Fig. 35-21B) (3,44). At the interface with the nerve of origin, some of the nerve fibers may extend from the compressed, eccentric axial bundle into the tumor. The observations of Russell and Rubinstein (47) contradict the dictum that schwannomas are universally devoid of axons. Loosely and randomly spaced nonmyelinated axons have been observed in small peripheral schwannomas and in small and medium-sized acoustic nerve schwannomas (47).

Two variant patterns, namely *Antoni A* and *Antoni B* types, have been described (4,48). In the Antoni type A tissue, uniform spindle cells are arranged back to back (Fig. 35-22); each cell is outlined by delicate, rigid, reticular fibers (basement membranes). The cells tend to cluster in stacks, and the respective nuclei often form palisades. Two neighboring palisades, the intervening cytoplasms of Schwann cells, and associated reticular

A B

FIGURE 35-21. A: Schwannoma. The lesion is circumscribed and encapsulated. The lesion bulges over a portion of the cut surface,. B: Schwannoma and nerve of origin. This schwannoma is uniformly cellular; the Schwann cells focally form nuclear palisades and Verocay bodies. To the right, a thickened perineurium, at its interface with the neighboring soft tissue, defines the limits of the tumor. The loosely cellular zone between the perineurium and the tumor is a compressed nerve of origin; the nerve maintains its identity at the periphery of the tumor; it is not enclosed within the substance of the tumor.

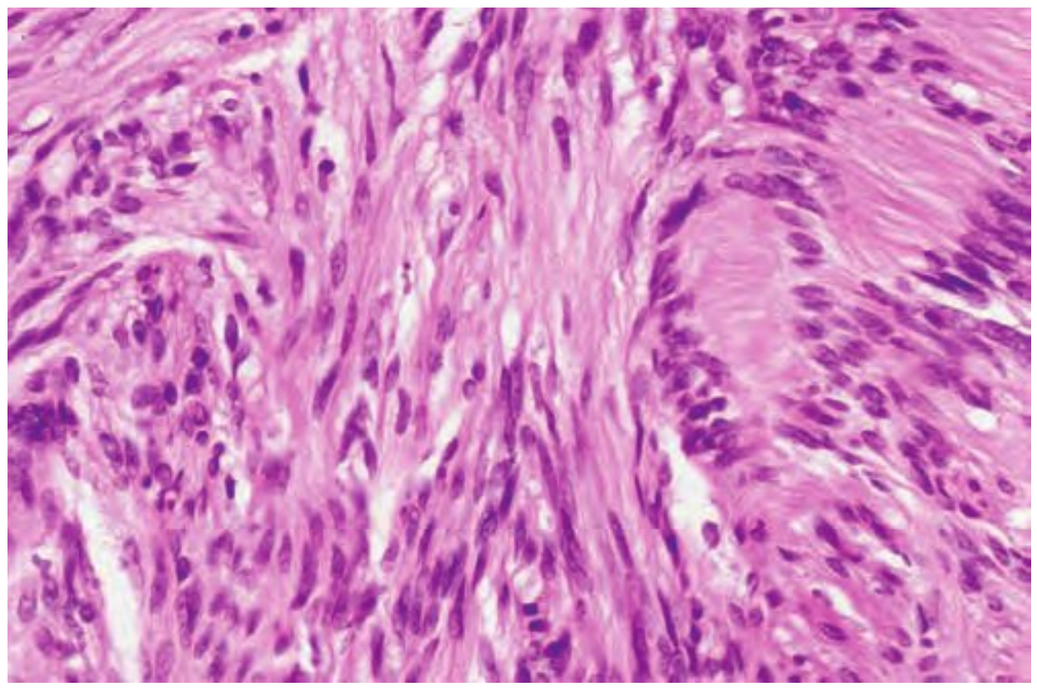


FIGURE 35-22. Schwannoma; Antoni A patterns. Pale spindle cells with elongated, wavy nuclei are arranged in fascicular patterns. To the right of the field, nuclear palisades are regularly spaced; two nuclear palisades and the enclosed cytoplasmic processes comprise a Verocay body. Cellular components of this type qualify as Antoni A tissue.

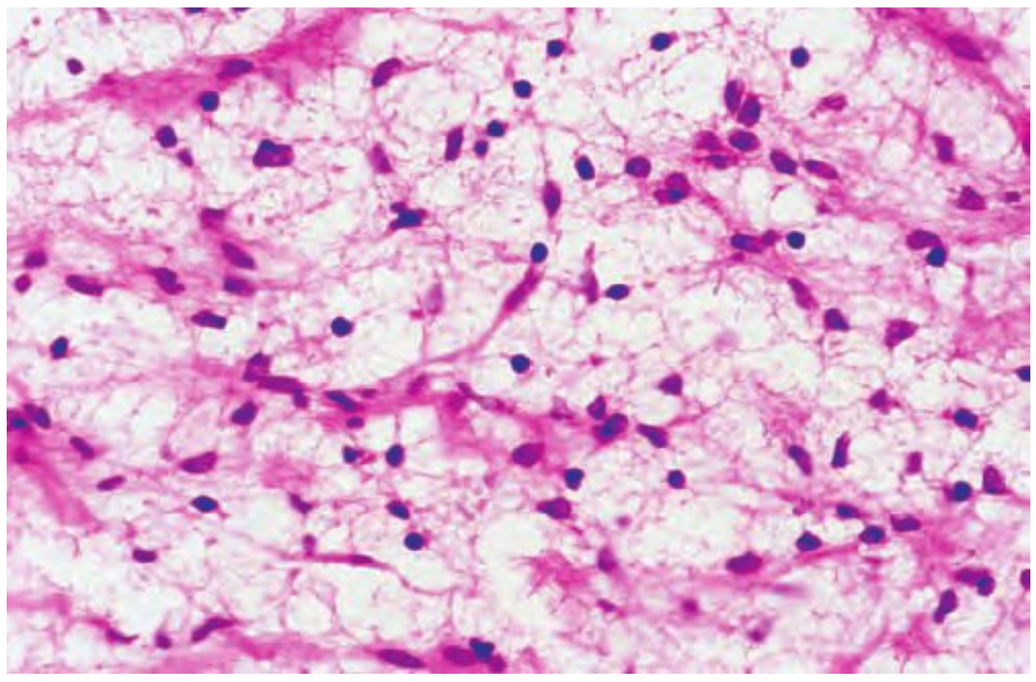

FIGURE 35-24. Schwannoma; Antoni B patterns. In this example, the cells of an Antoni B component are small with complex, delicate cytoplasmic processes. The cytologic features have a glial cell–like quality.

fibers, all in combination, constitute a *Verocay body* (Figs. 35-22 and 35-23).

In Antoni type B tissue, files of elongated "Schwann" cells arranged end to end and individual "Schwann" cells are loosely spaced in a clear, watery, or myxoid matrix (Figs. 35-23 to 35-25) (1,49); in some examples, the cells somewhat resemble glial cells; in other examples, they resemble perineurial cells.

Clusters of dilated, congested vessels are a characteristic feature (4). Fibrinoid necrosis or hyalinization, thrombi, and subendothelial collections of foam cells, in various combinations, often are features of the thick-walled vessels (Fig. 35-26) (49). The vascular changes can be found in both Antoni A and Antoni B tissue. Cystic changes (Fig. 35-27) (3,49), extravasated erythrocytes, and hemosiderin deposits are variable features.

Ultrastructurally, the tumor cells of a schwannoma manifest the features of Schwann cells (26). Axons usually are not a component. Long-spacing collagen may be represented (48).

The patterns in Antoni type B tissue are degenerative in nature; at the level of the light microscope, they have been characterized as "ancient change" (49). "Ancient change" also characterizes the nuclear atypia often seen in some schwannomas (4). Ultrastructurally, tumor cells are widely separated by an electron-lucid, homogeneous matrix containing strands of fibrin and detached segments of basement membrane. Autophagic lysosomes, some containing myelin figures, are seen in many cells (i.e., a "histiocytic" quality). The cellular changes include extensive loss of basement membrane, disruption of cell membrane, and nuclear degenerative changes (50).

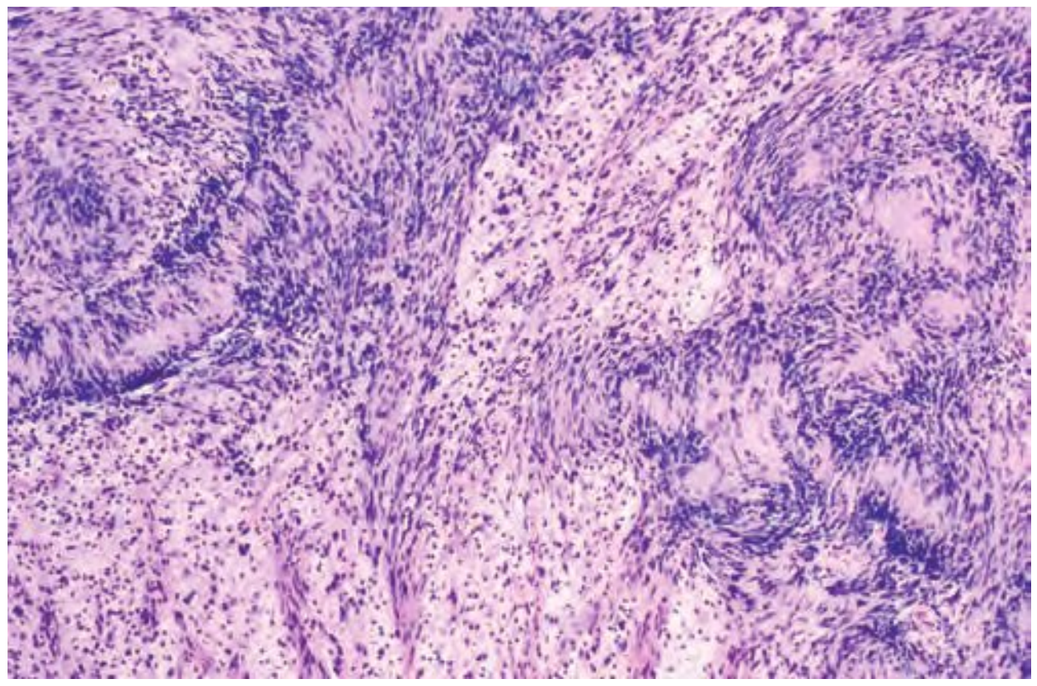

FIGURE 35-23. Schwannoma; mixed Antoni A and Antoni B patterns. The Antoni A component is cellular; Verocay bodies are a prominent feature. The loosely cellular, pale zones are Antoni B patterns. In the Antoni B component, there is some variation in nuclear size and staining.

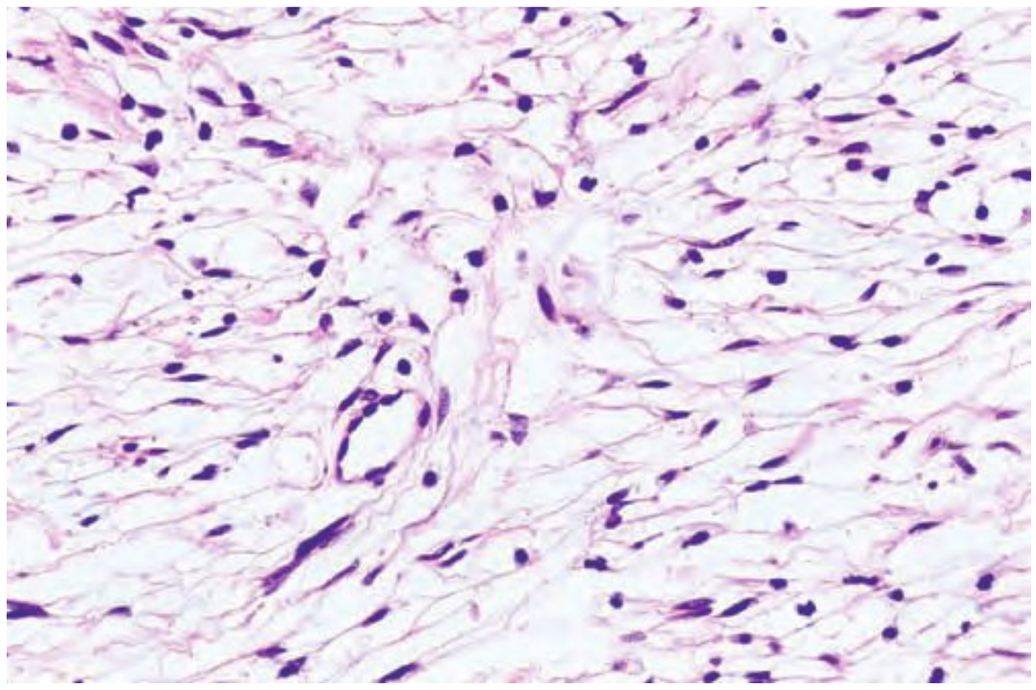

FIGURE 35-25. Schwannoma; Antoni B Patterns. In this example, the cells of an Antoni B component are bi- or tripolar; the cytoplasmic processes are elongated and straight; the cells cytologically resemble perineurial cells.

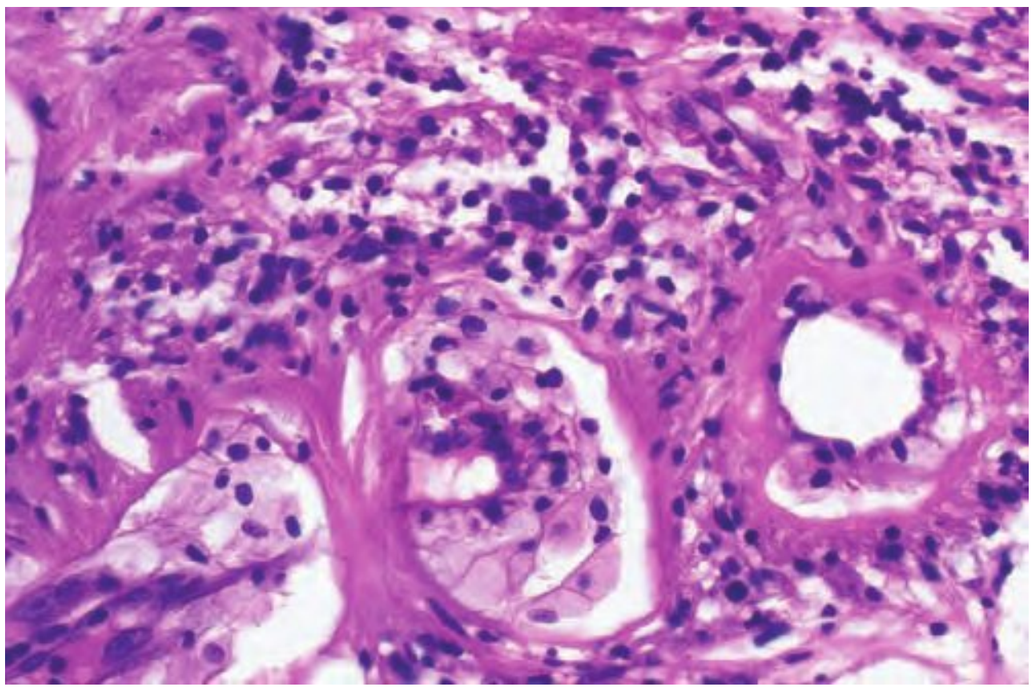

FIGURE 35-26. Schwannoma; Antoni B component, vascular changes. In this Antoni B component, several vessels are loosely clustered. They have thickened, hyalinized walls. There are prominent, subintimal collections of foam cells. Loose infiltrates of lymphoid cells are adjacent to the vessels and among the foamy histiocytes. In part, the hyalin represents a stage in the organization of fibrinoid; fibrinoid degeneration and thrombosis are common vascular changes in some schwannomas.

Histogenesis. The immunohistochemical profile is positive for S100 protein and collagen type IV and laminin. In the capsule, cells are EMA$^+$. A Bodian stain and an immunoreaction for the demonstration of neural filaments reveal few or no axons, except in and near the peripherally displaced axial bundle.

Apoptosis is a deletion of selected cells in both physiologic and pathologic processes (51,52). A modification of apoptosis may be operative in the expression of Antoni B patterns in a schwannoma.

Differential Diagnosis. If a nerve sheath tumor involves a significant sensory or motor nerve, the distinctions between intraneural neurofibroma and schwannoma become important considerations for a surgeon. For a functionally significant nerve, the intact but displaced symmetric axial bundle (Fig. 35-21) of a schwannoma (4) often can be preserved during surgical dissections. On the other hand, excision of an intraneural neurofibroma requires sacrifice of the nerve of origin (i.e., the axial bundle, being confined within the tumor, must be sacrificed).

Palisaded and encapsulated neuroma (PEN) should be considered in the differential diagnosis of schwannoma. A demonstration of axons within the fascicles of tumor cells is sufficient evidence from which the distinctions between PEN and schwannoma can be made.

Variant Types of Schwannomas

Cellular Schwannoma

In cellular schwannoma (CS), as defined by Harkin and Reed (4), the cellular arrangements mostly resembled those of Antoni A type tissue; Schwann cells were closely aggregated with scanty intercellular matrix. If other common features were preserved, scattered cells having large, hyperchromatic nuclei (Fig. 35-28) were of no significance. Increased cellularity per unit area, a preponderance of type A patterns, and a low mitotic rate were, in part, requisites for the diagnosis of "cellular schwannoma" (Fig. 35-29). Areas of atypia were acceptable in the definition. The definition of "cellular schwannoma" recently has been expanded (1). In this expanded definition, a wide range of features, some of which overlap with those of malignant peripheral nerve sheath tumor (MPNST), are acceptable. The criteria that currently are being promoted for the diagnosis of "cellular schwannoma" are of a type that generally would define borderline categories in other neoplastic systems. The designation has found a degree of legitimacy in several retrospective studies in which a "favorable" prognosis

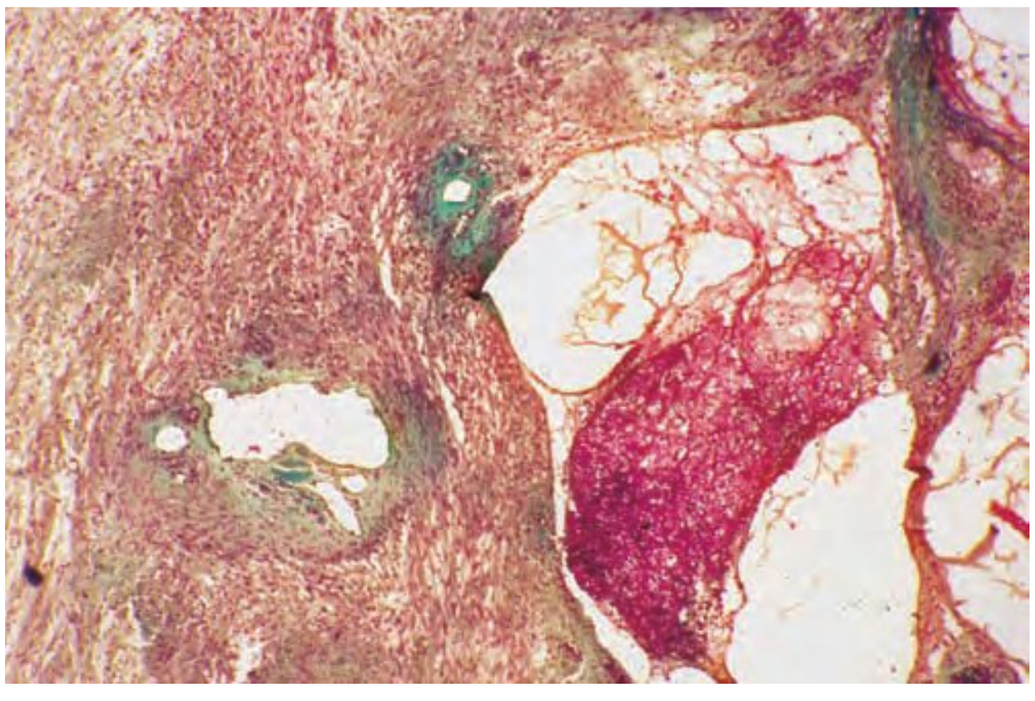

FIGURE 35-27. Schwannoma; microcystic and vascular changes. With this connective tissue stain, cells have a reddish tinge and connective tissue is green. Vessels are dilated; their walls are fibrous and irregularly thickened. To the right, multiple small cysts contain a loose meshwork of fibrin.

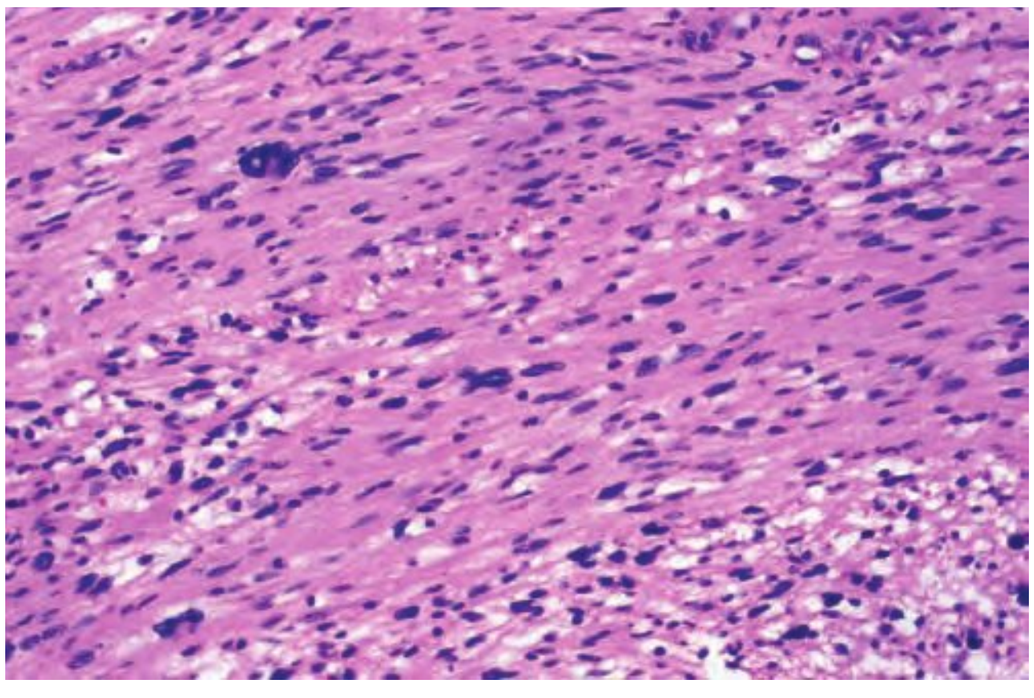

FIGURE 35-28. Schwannoma; cytologic atypia (ancient change of cytologic type). Spindle cells form interlacing fascicles. The cells show variations in nuclear size, staining, and outlines; in many of the nuclei, chromatin is dense and smudgy. Mitoses are not a feature of "ancient change."

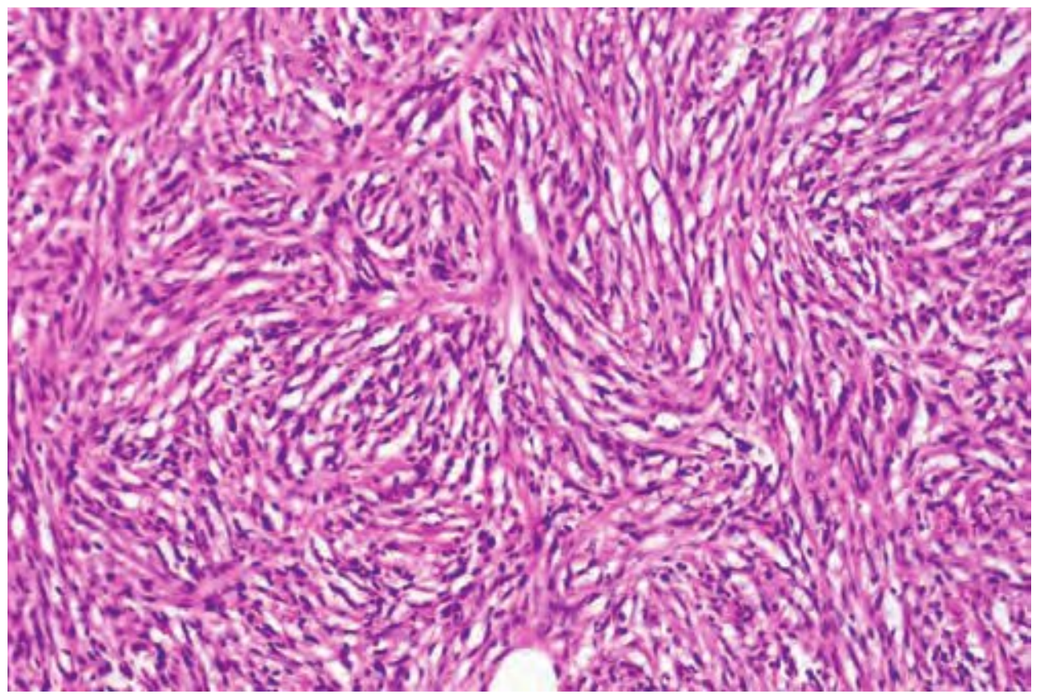

FIGURE 35-29. Schwannoma; cellular variant (CS1). In this schwannoma, patterns are uniformly cellular (Antoni A type). Uniform spindle cells are arranged in the pattern of interlacing fascicles. In this example, mitotic activity is not a significant feature.

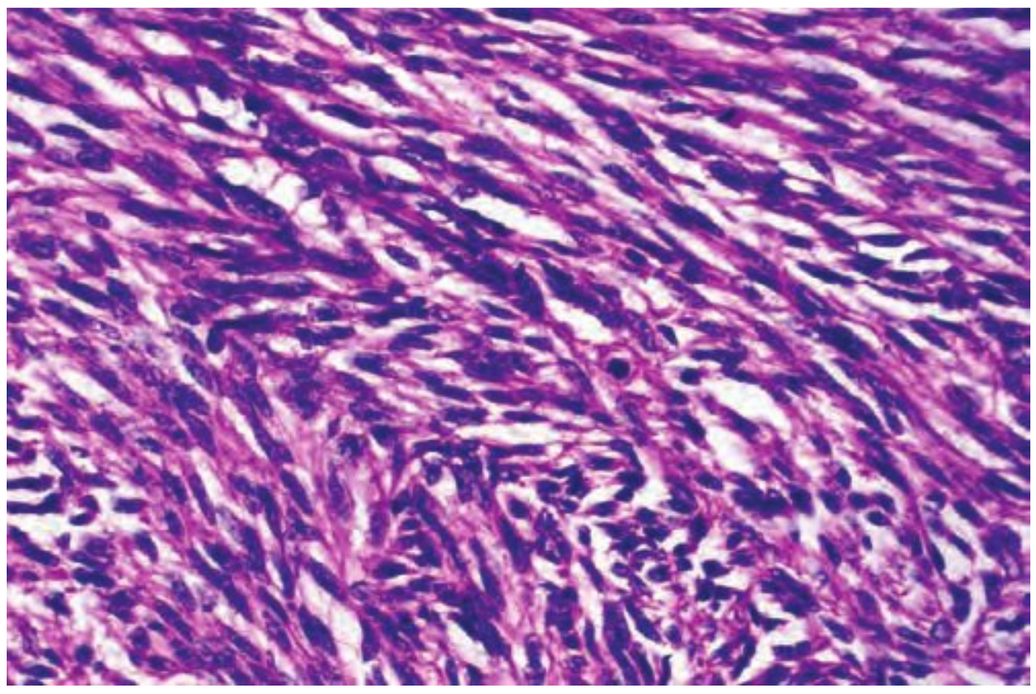

FIGURE 35-30. Schwannoma; cellular variant with mitotic activity (CS2). In this example of cellular schwannoma, the fascicles are hypercellular; nuclei are enlarged and show hyperchromatism. There are scattered mitotic figures.

has been documented (1). The dichotomy in the approaches to "cellular" schwannoma is given recognition herein by the definition of two classes: CS1 and CS2.

In *CS1* [a restricted application of the designation in the manner of Harkin and Reed (4)], most examples are large tumors of the retroperitoneum and mediastinum (and may incidentally show immunoreactivity for GFAP) (53,54). The lesions of CS1 are mostly cellular with patternless areas in which cells form solid sheets alternating with areas in which intersecting fascicles of spindle cells (Fig. 35-29) produce storiform patterns (4). The basic patterns of a variant of schwannoma, such as those of a common schwannoma or an epithelioid schwannoma, are preserved, but in some examples most of the cells are cytologically atypical (Fig. 35-30). Cellular pleomorphism is acceptable. In some examples, nuclear atypia is uniform and extensive. By definition, mitoses are infrequent (less than 2 per 10 high-power fields [hpf]). A background population of small lymphocytes also may contribute to the cellularity (3). Nuclear palisades, Verocay bodies, and Antoni type B components tend to be inconspicuous (4); zones of necrosis in palisaded patterns are not included in the definition.

In *CS2* [*cellular schwannoma* of Woodruff et al. (55); *transformed schwannoma* of Reed and Harkin (3)], some features are histologically worrisome. Increased cell density, storiform patterns, mitotic activity (even up to 20 or more mitoses per 10 hpf), zones of necrosis, and cytologic atypia might be cited as worrisome features (1,54–59). Some have argued that these lesions are unequivocally benign, but the prospective studies, which would certify CS2 as something other than a low-grade, intraneural malignant schwannoma [transformed schwannoma of Reed and Harkin (3)], are not available. The patterns are of a type that, in other organ systems, would be consistent with a transition from benignancy to low-grade malignancy (Fig. 35-30). In practice, most of these lesions are amenable to local surgery. In making a distinction between these lesions and infiltrating low-grade malignant schwannomas, confinement by the perineurium of the nerve of origin may be prognostically and therapeutically important (55).

Differential Diagnosis. The differential diagnosis of CS1 includes *leiomyoma*, low-grade *leiomyosarcoma*, and *gastrointestinal stromal tumor*. In the evaluation of a problematic lesion, an intense reaction for S100 protein and a negative reaction for both smooth muscle antigen (SMA) and desmin would offer support for a diagnosis of schwannoma. Smooth muscle cells, in turn, react with antibodies to SMA and desmin. In gastrointestinal stromal tumors, divergent phenotypes may be expressed, but CD117 (c-kit) is the commonly expressed antigen. Immunoreactivity for CD117 has been noted in MPNST (60). Variants of soft tissue sarcoma must be included in the differential diagnosis of CS1 and CS2.

Epithelioid Schwannoma

In the rare *epithelioid schwannoma* (with or without radial sclerosis) (3,61–63), spindle and round cells are clustered in epithelioid patterns; the nuclei often are round (Figs. 35-31 and 35-32). Nuclear atypia and dense nuclear chromatin are common features. In some examples, the cells have acidophilic cytoplasm. In one variation, in which cells have round nuclei and scanty cytoplasm, some of the cells are radially arranged in palisades around distinctive zones of sclerosis (3,64–67). In the zones of sclerosis, fibrous lamellae are radially oriented; they interdigitate with cytoplasmic projections of the surrounding tumor cells (67). Such lesions have been characterized as epithelioid schwannoma with radial sclerosis (3), "collagenous spherulosis" in a schwannoma (66), rosetoid schwannoma (67), and "neuroblastoma-like" epithelioid schwannoma (64,65). The designation neuroblastoma-like schwannoma gives recognition to a lymphocyte-like pattern; the nuclei of the small, blue tumor cells resemble those of lymphocytes in

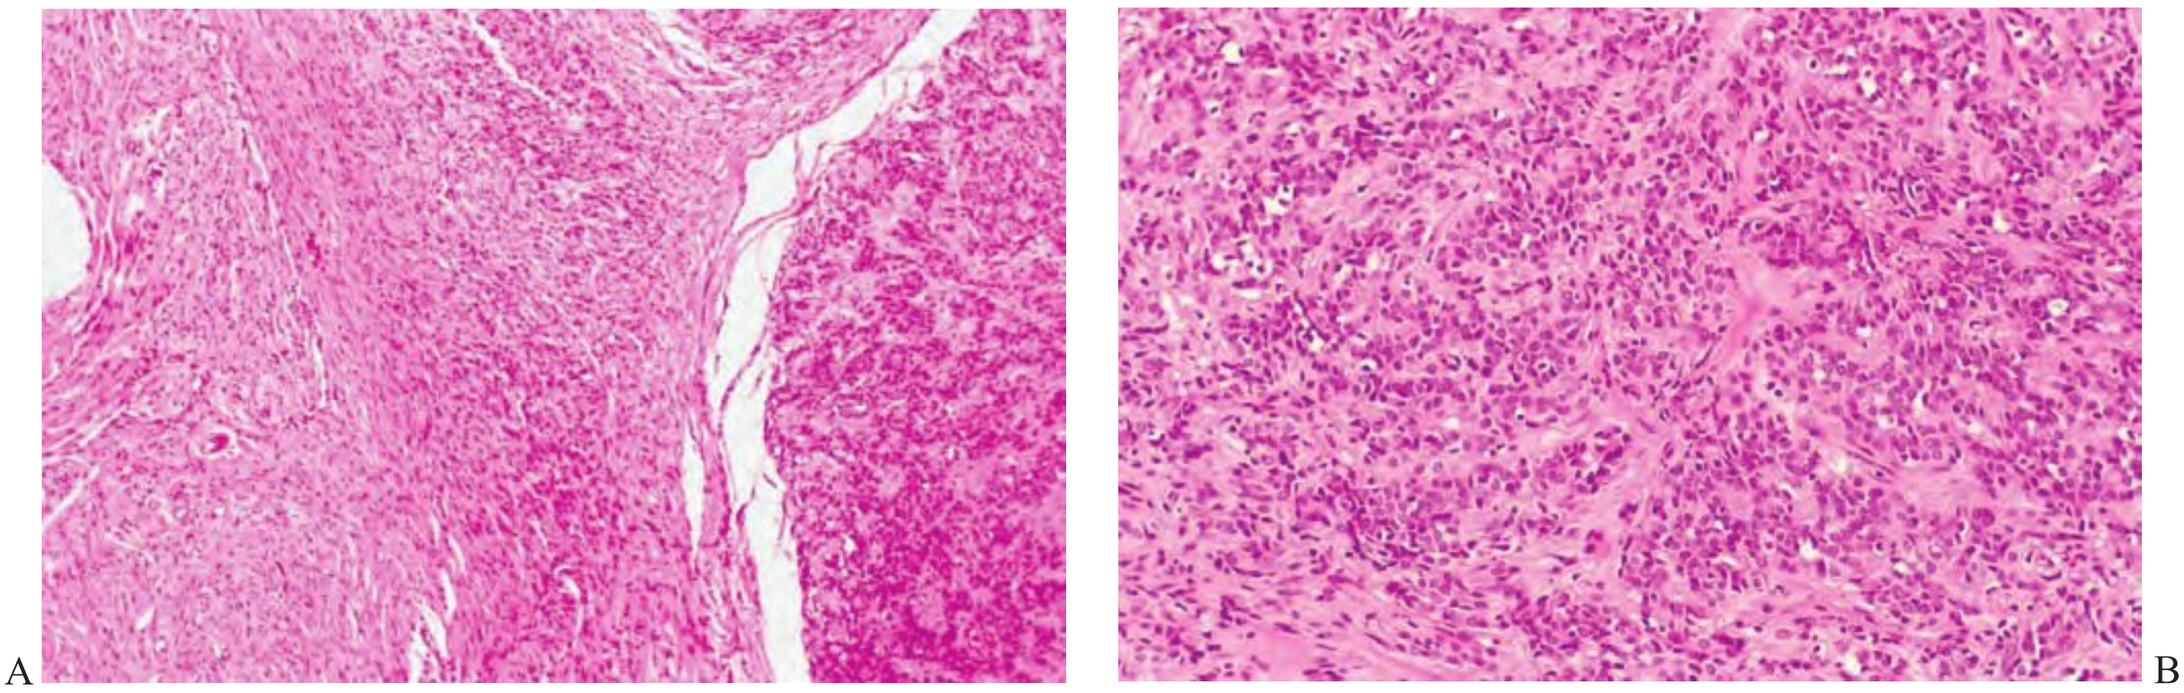

FIGURE 35-31. Plexiform epithelioid schwannoma, arising in extraneural neurofibroma. A: To the right, a portion of a plexiform lesion presents a sharp interface with an extraneural (diffuse) neurofibroma. Fascicles of uniform, epithelioid cells are loosely and regularly spaced in the plexiform component. B: At higher magnification, the fascicles of uniform, small epithelioid cells are loosely spaced in a fibrous matrix.

size and staining. The small-cell component may be extensive or a focal variation in what is otherwise a typical schwannoma. The small cells tend to cluster in rosette-like patterns about vessels and spherical zones of radial sclerosis. Neither the histologic patterns and the cytologic features nor the clinical behavior of these lesions justifies a characterization of the small, dark cells about radial zones of sclerosis as "neuroblastoma-like" (67). Collagenous spherulosis, as originally defined for breast lesions, is distinct from the patterns of radial sclerosis, as manifested in nerve sheath tumors (68). Some examples of epithelioid schwannoma have been characterized as cellular. Some epithelioid schwannomas are also plexiform (Figs. 35-31 and 35-32).

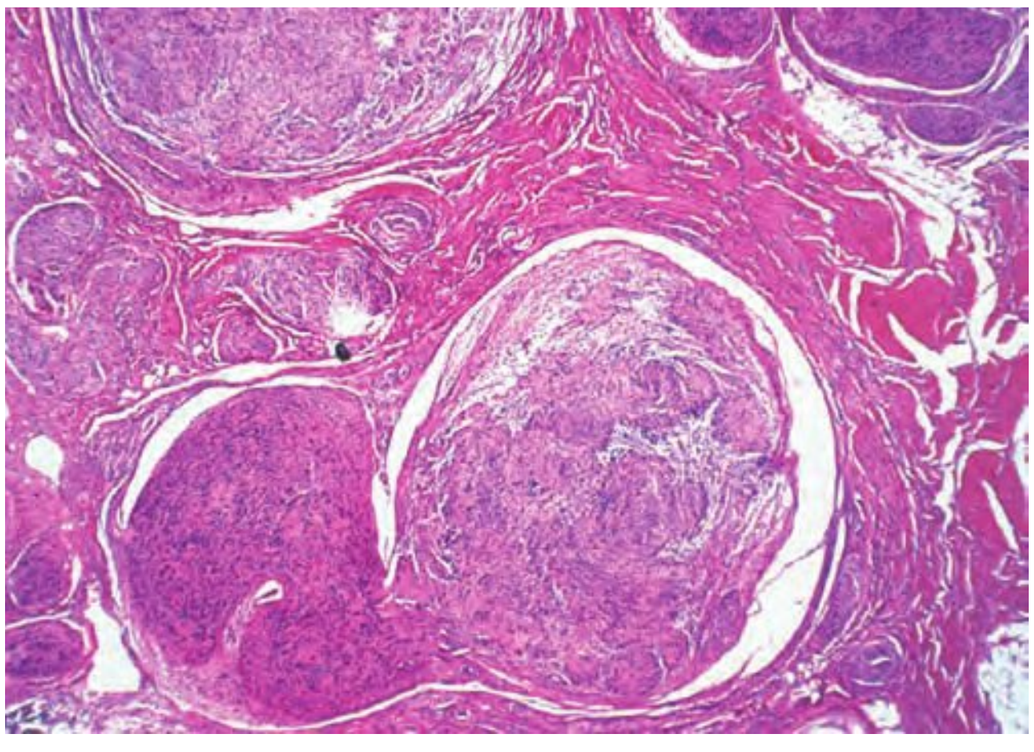

FIGURE 35-32. Plexiform schwannoma. Components of the plexus are mostly cut in cross section; they are supported by a dense fibrous matrix. Within some of the components, both Antoni A and Antoni B patterns are represented.

Glandular Schwannoma

Glands having the features of sweat glands are occasionally found within subcutaneous schwannomas (69–72). A demonstration of a component of myoepithelial cells has fostered a proposal that the glands are nothing more than entrapped sweat glands (70–72). Yoshida and Toot (71) proposed *divergent differentiation* as an alternate explanation for the glandular inclusions. Glandular patterns of a different type are a feature of some malignant schwannomas; they also have been observed in a benign neurofibroma (70). Cysts that contain mucoid material are a feature of some schwannomas; they are outlined by palisades of Schwann cells. Such lesions have been classified as pseudoglandular schwannomas (73).

Plexiform Schwannoma

Plexiform schwannomas occur mostly in the subcutaneous tissue; they rarely are confined to the dermis (3,21,74–80). They may be a feature of the syndrome of *multiple schwannomas* (clinical schwannomatosis or neurilemmomatosis) (77,81), or they may be solitary (79). The gene of NF2 and that of multiple schwannomas may be identical (82,83).

Histopathology. Plexiform schwannoma is intraneural. Spindle cells, often in solid Antoni A patterns, fill the expanded endoneurial space of a limited segment of a neural plexus; each column and nodule of the tumor is surrounded by perineurium. The vascular changes and Antoni type B tissue of a common schwannoma are variable features. Cystic changes are uncommon. In some examples, fascicles of Schwann cells extend for a short distance beyond the confines of the perineurium into the neighboring mesenchyme. These limited patterns, when encountered in the adjacent soft tissue, resemble those of a small, circumferential, extraneural neuroma (75).

Some plexiform schwannomas are "cellular;" some are epithelioid. Plexiform schwannomas of the deep soft tissue

frequently show the worrisome histologic features of CS2 (84). In one series, the atypical features included increased cellularity, pleomorphism, and mitotic activity; tumor necrosis and myxoid change were less common. Females were more commonly affected than males; none of the patients had stigmata of neurofibromatosis. Two of six patients with follow-up had two local recurrences, and one patient had one local recurrence. At last follow-up, all six patients were free of disease (84).

The category of plexiform schwannoma may be heterogeneous. In a single case, Kao et al. (79) documented a relationship between neurofibroma and plexiform schwannoma. In our experience, plexiform schwannoma may be associated with a background of diffuse neurofibroma (Figs. 35-31 and 35-32).

Schwannoma Arising in Neurofibroma (With Emphasis on Relationships With Intraneural Microscopic Schwannomatosis)

Schwannomas in continuity with neurofibromas have been documented (85,86). *Intraneural microscopic schwannomatosis* (Figs. 35-11 and 35-19) (3), a proliferative change affecting axial bundles of nerve fibers in intraneural neurofibromas, might, with progression, become *schwannoma ex neurofibroma* (18). Rarely, remnants of an intraneural neurofibroma are found at the periphery of a cellular schwannoma (CS1).

Borderline Variants

Infiltrating (Extraneural) Fascicular Schwann Cell Tumor of Infancy and Childhood

Infiltrating (extraneural) fascicular Schwann cell tumor (IFSCT) [*plexiform malignant peripheral nerve sheath tumor of infancy and childhood* (87); *congenital hamartoma of nerve*] is a rare Schwann cell neoplasm most often affecting an extremity (88). In contrast to all variants of schwannoma, IFSCT is chiefly extraneural. True plexiform patterns (intraneural by definition) are not a prominent feature. In common usage, a schwannoma is a benign, intraneural (encapsulated) tumor of Schwann cells. IFSCT is obviously something other than a variant schwannoma. It also lacks the organoid qualities of a hamartoma.

Histopathology. Uniform spindle cells form tortuous, interlacing fascicles; the fascicles vary in size. In some of the thin fascicles, spindle cells tend to cluster in palisades; anuclear collections of cytoplasm separate the neighboring palisades. The lesion infiltrates skin and soft tissue and, in some examples, erodes bone.

Histogenesis. The most characteristic feature of IFSCT is its extraneural invasion of soft tissue in fascicular patterns. The tumor cells of IFSCT are clearly identifiable, both immunohistochemically and ultrastructurally, as Schwann cells.

Prognosis. In one published collection, four of the six patients with follow-up had local recurrences (87). In addition, one patient, who had an invasive lesion of the orbit, died. Woodruff et al. reported six cases (89). The patients ranged in age from 2 to 15 months. There was no association with NF1. Three of the tumors were well circumscribed; the lesions were not encapsulated. All of the tumors recurred locally. With the exception of one case that was lost to follow-up, all of the children were alive and free of disease. Rapid growth, locally aggressive behavior, hypercellularity, and increased mitotic activity are worrisome features.

The documented behavior of reported examples has not convincingly established the nature of the lesion. The histologic patterns, if not the cytologic features, overlap with those of infiltrating and fascicular epithelioid malignant schwannoma (IFEMS, page 1124); they even share some features with neurotropic melanoma.

The nature of IFSCT is controversial. To assign IFSCT, in the face of controversy, to the category of malignant nerve sheath tumor would only mask its undefined biological nature. A malignant nerve sheath tumor unequivocally behaves in a malignant fashion, with a predictable capacity for local recurrence and metastasis. Assignment of IFSCT to the category of either cellular or plexiform schwannoma would be an unwarranted extension of what is already too broadly defined. In the category of cellular schwannoma, as defined by Woodruff et al. (55), some examples share the histologic features of malignant peripheral nerve sheath tumor, but in the available retrospective studies, all examples, *by definition*, have been biologically benign (examples with local recurrences excluded). IFSCT should be characterized as a borderline lesion of indeterminate malignant potential until its nature is better documented.

Psammomatous Melanotic Schwannoma

This uncommon tumor may be either sporadic or a stigma of a complex (i.e., *Carney's complex*). The complex includes some or all of the following: myxomas (including trichogenic and cardiac variants) (90), spotty pigmentation, pigmented adrenal cortical hyperplasia, large-cell calcifying Sertoli cell tumor (91), and endocrine overactivity (including Cushing's syndrome) (92,93). Some examples of psammomatous melanotic schwannoma (PMS) have behaved in a malignant fashion (94).

Histologically, psammoma bodies and pigmented, dendritic melanocytes are features. Most examples of PMS are quite distinctive, but some examples show nuclear palisades and Verocay bodies (92,95). Zhang et al. studied 13 cases of nonpsammomatous melanotic schwannoma (94). Positive immunohistochemical staining includes S100, Leu-7, HMB-45, Melan-A, and vimentin. The product, in linear patterns, of immunoreactions for laminin and collagen IV correlate with the Schwann cell nature of the tumor cells. Ultrastructural features also are those of Schwann cells (94).

Transformed (Borderline) Schwannoma (CS2)

This borderline lesion of uncertain malignant potential is, like its benign counterpart, intraneural (confined by an expanded perineurium) (3). Its internal patterns, but not its setting, are reminiscent of patterns seen in minimal-deviation (low-grade) malignant schwannomas (MPNST) of neurofibromatosis (a lesion that is not confined by the perineurium of the nerve of origin). Some examples of transformed (borderline) schwannoma (TBS) contain scattered globular deposits of melanotic pigment (3).

TBS, as defined by Reed and Harkin (3), shares many features with cellular schwannoma as defined by Woodruff et al. (55). Herein, *cellular schwannoma of Woodruff* is identified as cellular schwannoma, class 2 (CS2).

Malignant transformation of benign schwannoma is a rarely documented event (96–98). In one report, only histologically "high-grade" variants were represented (99). "High-grade," transformed malignant schwannomas, in contrast to TBS, show a greater degree of cellular atypia and pleomorphism and a higher mitotic rate. They may show infiltrative growth beyond the confines of the perineurium (99), a quality that excludes TBS.

MALIGNANT PERIPHERAL NERVE SHEATH TUMOR OF COMMON TYPE

Malignant peripheral nerve sheath tumor of common type (*neurofibrosarcoma*; *malignant schwannoma*; *MPNST*; *neurogenic sarcoma*) is expressed in a variety of phenotypes but, most commonly, the immunohistochemical profile is that of $S100^+$. These lesions may be sporadic, they may be associated with neurofibroma, or they may be associated with NF 1.

Malignant peripheral nerve sheath tumor of the common type is the characteristic malignancy arising in neurofibromatosis type 1 (Fig. 35-33). Related malignancies may be *de novo* or may be transformations in other neurocristic neoplasms, such as schwannoma or ganglioneuroma. The criteria for the diagnosis of MPNST include some, or all, of the following: origin from, or continuity with, a major nerve or neurofibroma; association with classic stigmata of neurofibromatosis; identification of characteristic histologic patterns and demonstration of immunohistochemical profile of $S100^+$; or ultrastructural features of Schwann cells (and/or perineurial cells) (100). It has been argued that, because most "malignant schwannomas" arise in association with neurofibromas of neurofibromatosis and malignant schwannoma ex schwannoma is rare, the designation "malignant schwannoma" has limited application. The designation "malignant peripheral nerve sheath tumor," an alternative lacking discrimination, provides no distinctions between the common malignancy of neurofibromatosis and an uncommon lesion such as peripheral neuroepithelioma (primitive neuroectodermal tumor). It provides no distinctions between Schwann cell variants and perineurial variants. Epithelioid variants and mesenchymal variants are not distinguished in the promotion of the designation "malignant peripheral nerve sheath tumor."

MPNST (*sheath* or *Schwann cell type*: $S100^+$) is the common malignant tumor of peripheral nerves (1,3,4,26,101–107). Its association with neurofibromatosis 1 is established, but it is uncommon even in this setting. In a series of 678 patients with neurofibromatosis, MPNST was observed in only 21 (3.1%) of the patients (104). In only 2 of the 678 patients did MPNST primarily involve the skin and subcutaneous fat. Allison et al. reviewed the clinicopathologic features of five examples of MPNST involving the skin or subcutaneous tissue (106). Four of the lesions occurred in women. One patient had a diagnosis of type 1 neurofibromatosis. Four of the lesions were associated with a cutaneous neurofibroma; for the remaining case the tumor involved a superficial peripheral nerve. Four of the cases were of a common type, whereas the remaining case was an epithelioid variant. There were no local recurrences, but three patients died of metastatic disease.

MPNST usually arises contiguous to either an extraneural or intraneural component of a neurofibroma: In turn, it may be intraneural or extraneural. In the deep soft tissue, involvement of a large nerve trunk, such as a femoral, tibial, or intercostal

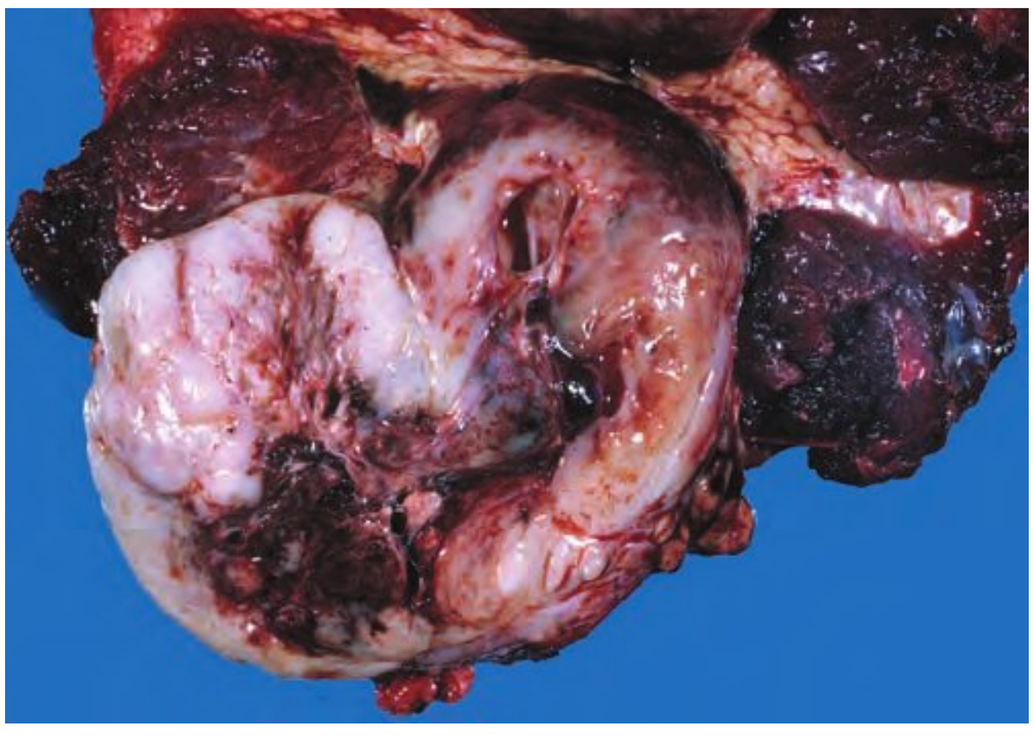

FIGURE 35-33. Malignant peripheral nerve sheath tumor. The tumor is expansile and circumscribed. The cut surface has a fish-flesh quality. A central, degenerative cyst contains blood clot.

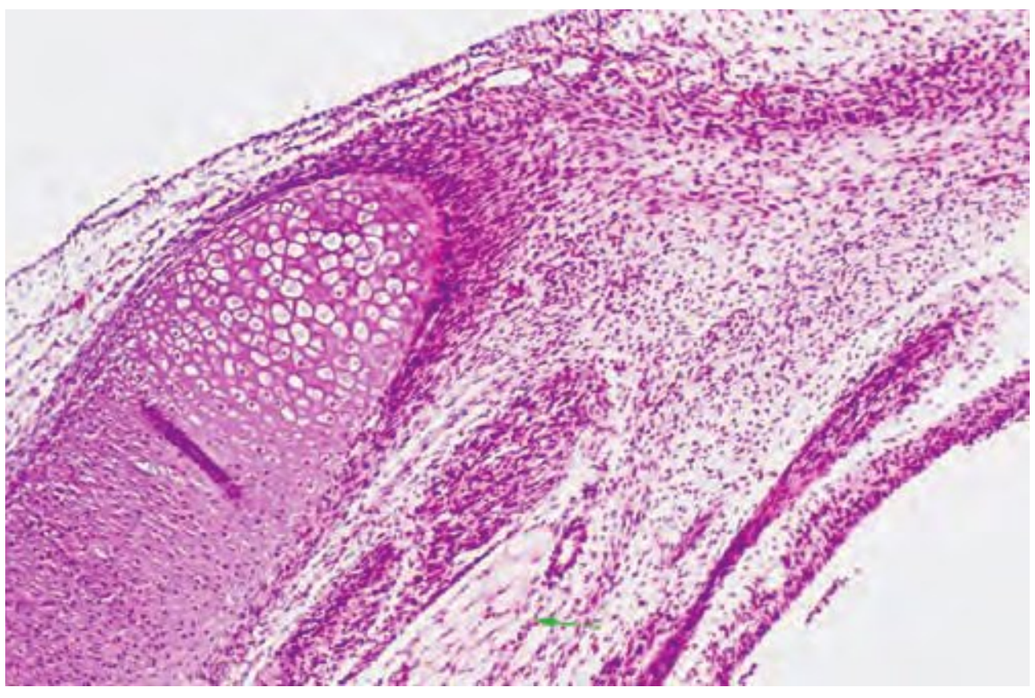

FIGURE 35-34. Fetal mesenchyme. Fetal mesenchyme shows varying patterns of differentiation. An island of immature cartilage is represented. In the neighboring mesenchyme, there are patterns of alternating light and dark fascicles. One fascicle of developing skeletal muscle fibers (green arrow) is represented in the myxoid matrix at the bottom of the field. These patterns are recapitulated, in neoplastic distortions, in many examples of malignant peripheral nerve sheath tumor.

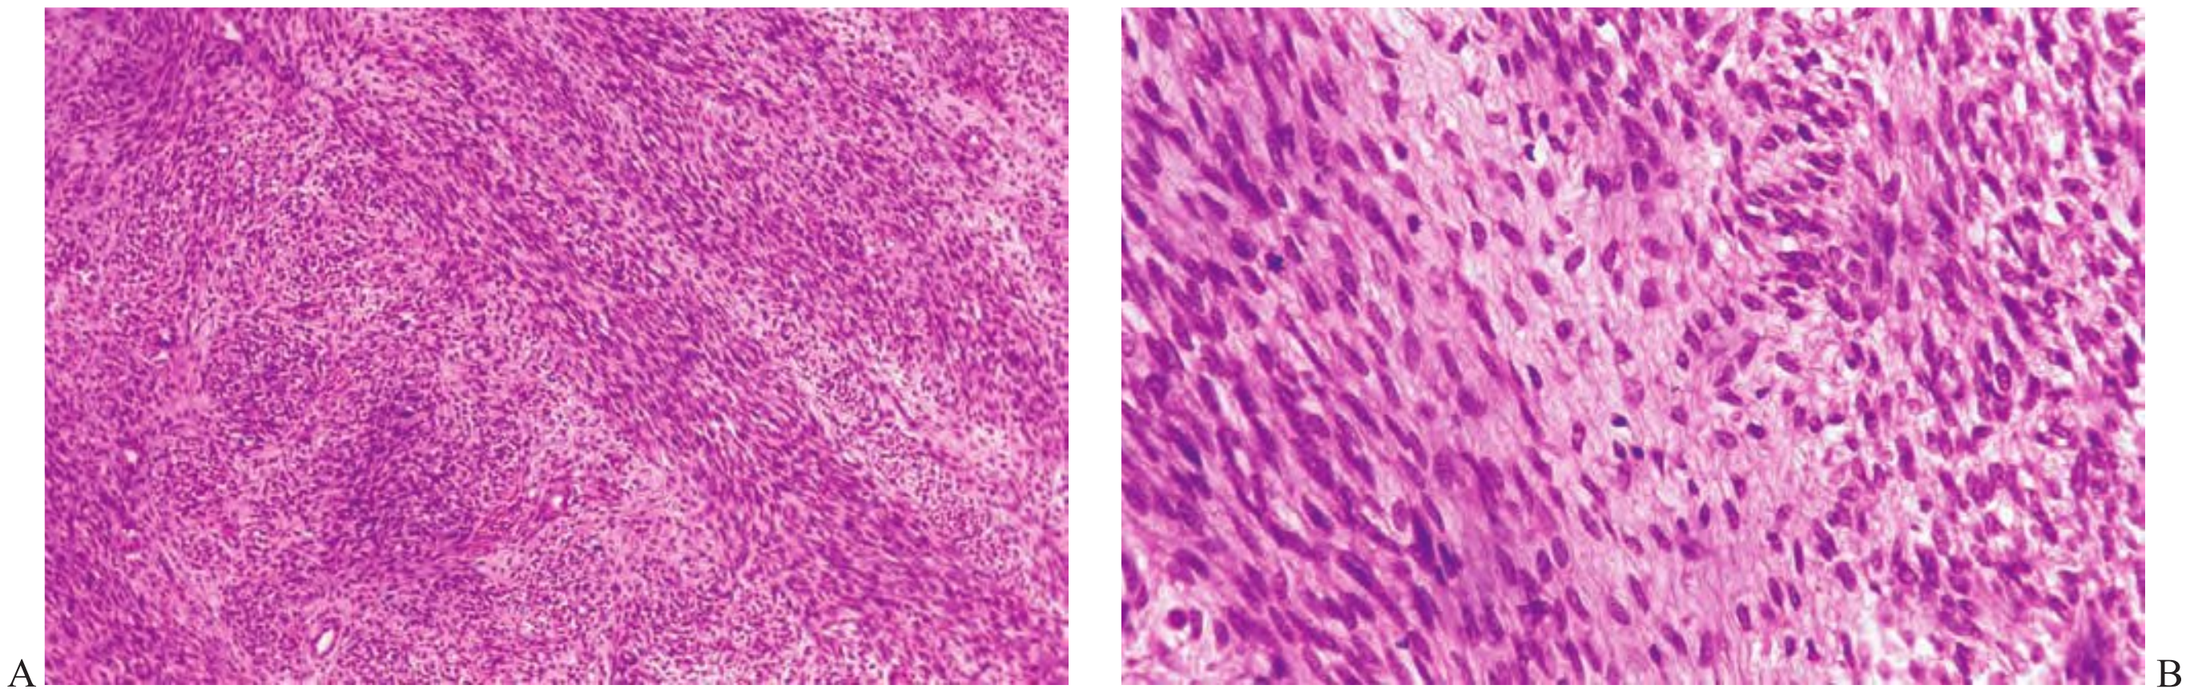

FIGURE 35-35. Malignant peripheral nerve sheath tumor; spindle cell variant. A: Atypical spindle cells form intersecting fascicles; the fascicles alternately are light and dark. B: At higher magnification, spindle cells are cytologically atypical, but cytologic features are uniform.

nerve, is characteristic, but in some instances no such connections are apparent. MPNST also can arise as a sporadic or *de novo* lesion (i.e., not associated with neurofibromatosis) (105). An origin in a benign schwannoma rarely has been reported as a documented phenomenon (99). For many examples of MPNST (sheath cell type), the patterns are expressive of the patterns of differentiation in embryonic mesenchyme (Fig. 35-34). The expressions can include, singly or in various combinations, fascicles of cells, often alternatingly light and dark (Fig. 35-35A, B), or elements such as chondroid matrix, osteoid (Fig. 35-36A), and rhabdomyoid cells (Fig. 35-36B) (107,108). MPNST of perineurial type has been promoted as a variant, with the predictable proposal that such a lesion is a malignant perineurioma, but without evidence that there is a relationship between any of the benign "perineurioma" variants and MPNST of any type (109–111). The biological potential of the perineurial variants has not been adequately defined.

Histopathology. The variable patterns of differentiation in MPNST include mesenchymal [fibrosarcomatous, osteosarcomatous, and chondrosarcomatous (3), rhabdomyosarcomatous (1,107,108), and even liposarcomatous] patterns; glandular (entodermal) patterns (70); epithelioid patterns in which individual spindle and round cells often have acidophilic cytoplasm (3,112,113) and are closely spaced in nests, fascicles, and sheets; and neuroepithelioma-like patterns (114).

Histologically, *mesenchymal patterns* are preponderant in the setting of MPNST that arise in patients with neurofibromatosis (4). Thin spindle cells are arranged in interlacing fascicles in a fibromyxoid matrix. The fascicles are straight, enabling an

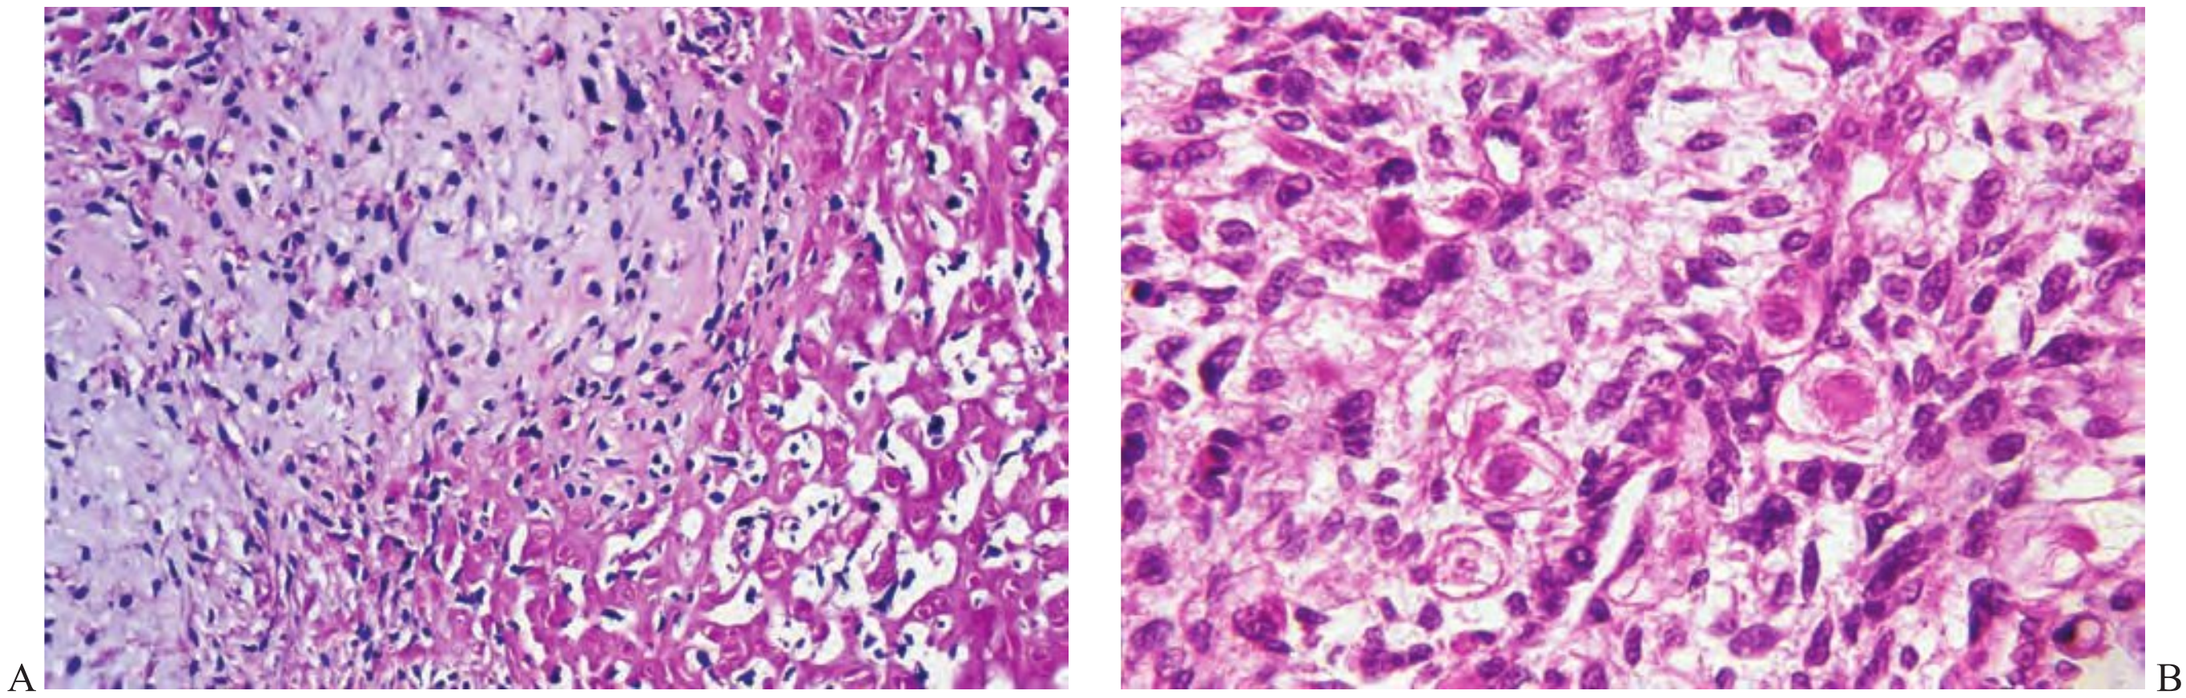

FIGURE 35-36. Mesenchymal differentiation in malignant peripheral nerve sheath tumor. A: Chondro-osseous differentiation. Chondroid differentiation is represented to the left of the center of the field; to the right, the patterns are those of neoplastic osteoid. B: Rhabdomyoblastic differentiation. In this field of undifferentiated small cells, there are scattered, rounded cells with plump, round nuclei; these round cells show concentrically arranged cytoplasmic myofibrils.

observer to trace them across low-power fields. They are alternatingly light (pale) and dark (more intensely stained). Often the spindle cells are remarkably uniform (Fig. 35-35A, B). Neoplastic cells tend to be concentrically or radially arranged about vessels, particularly near areas of necrosis. Having identified these basic features, an additional search for, and the identification of, specific expressions of mesenchymal differentiation provide strong support for a diagnosis of MPNST (Fig. 35-36A, B). Patterns of specific mesenchymal differentiation, when found, usually are spotty in distribution. Having identified one specific pattern of mesenchymal differentiation, it is often possible for the observer to then find others. The mitotic rate provides a correlate for the diagnosis of MPNST. It is not a prime determinant of biological potential. In the setting of neurofibromatosis, rates may be low (fewer than 10 per 10 hpf) or high (more than 50 per 10 hpf), and the outcome for either category may be poor, depending on other factors, such as the size and location of the lesions and the age of the patient.

Epithelioid patterns are a variant expression of MPNST in the setting of neurofibromatosis (4). *De novo* malignant schwannomas (105) and "high-grade" MPNST arising in benign schwannomas (*malignant transformed schwannoma*) (99) tend to be intraneural in origin and be manifested in "epithelioid" patterns (112,113). The study of Hruban et al. does not support this generalization but is compromised by including, as *de novo* variants, examples of both neuroepithelioma and MPNST arising in neurofibroma (114).

In epithelioid variants, plump tumor cells in nests and sheets are closely spaced with scanty intercellular matrix (Figs. 35-37 and 35-38) (112,113). Nuclei are large and often rounded. In pleomorphic variants, tumor giant cells are common. Specific patterns of mesenchymal differentiation are variant features. In some examples, the cells form nests and cords in a sparsely cellular, myxoid or hyaline matrix. The "purely epithelioid" (epithelial) MPNST, a lesion with no "sarcomatous" component, is rare (115). In some "epithelial" examples, plump, acidophilic tumor cells manifest a striking cytoplasmic argyrophilia (Fig. 35-39) (3); such examples may represent large-cell neuroendocrine carcinoma.

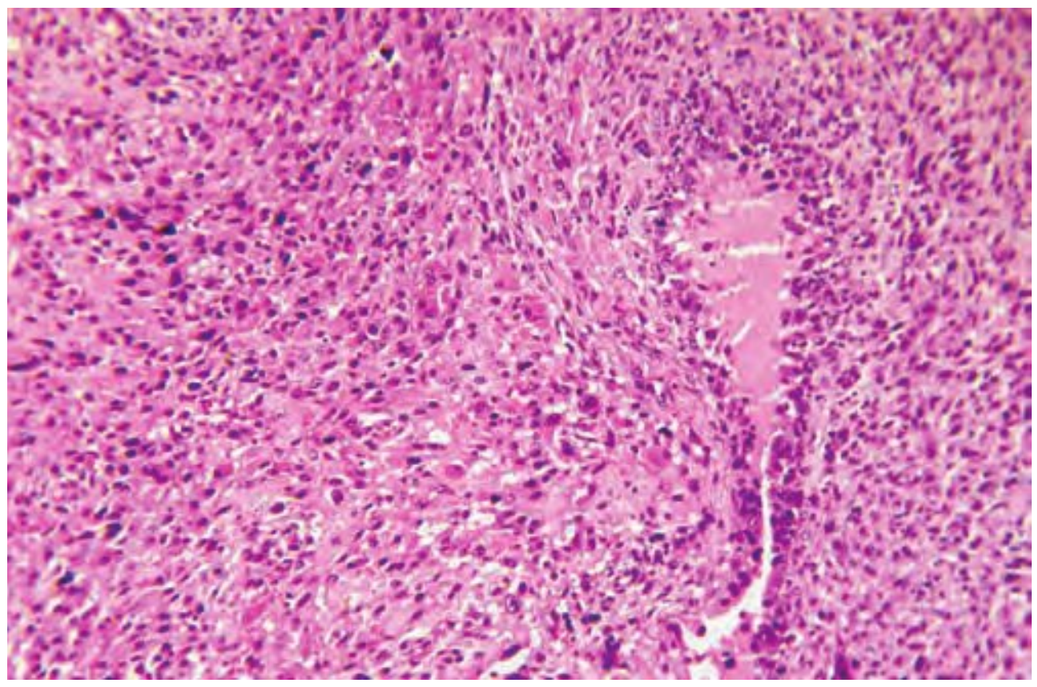

FIGURE 35-38. Epithelioid malignant peripheral nerve sheath tumor. Plump, rounded cells are arranged in patterns of ill-defined nests. Nuclei show variations in size and staining. A cleft to the right of the center of the field is outlined by palisades of tumor cells.

Malignant epithelioid peripheral nerve sheath tumors, some of which appear to have had their origin from, and are in continuity with, a peripheral nerve, may manifest extraneural, infiltrating, and fascicular patterns (25,112); they qualify as infiltrating and fascicular epithelioid malignant schwannoma (IFEMS). In the skin and subcutis, such a lesion, in recurrences, might be histologically indistinguishable from desmoplastic and neurotropic melanoma (Fig. 35-40).

The designation MPNST without additional qualifications constitutes a category without discrimination; in the epithelioid category, the designation MPNST of epithelioid sheath cell type is more appropriate.

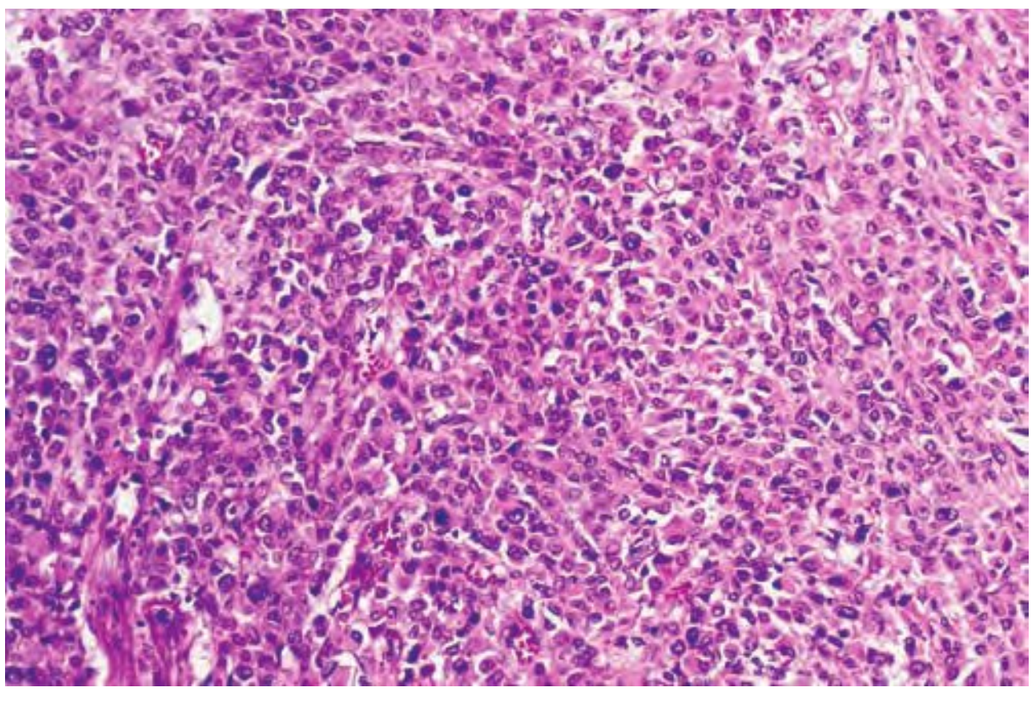

FIGURE 35-37. Epithelioid malignant peripheral nerve sheath tumor. Plump, atypical, spindle and epithelioid cells form solid sheets. Intercellular matrix is scanty.

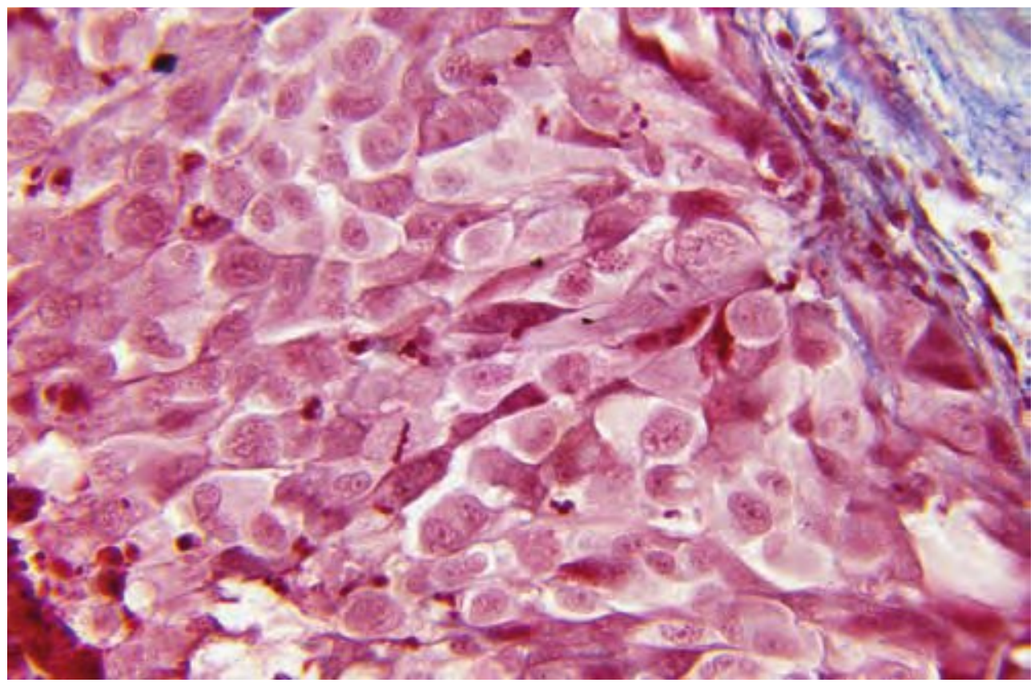

FIGURE 35-39. Neuroendocrine malignant peripheral nerve sheath tumor (Masson trichrome stain). Large atypical cells are closely clustered; they form distinct nests in a fibrous matrix. The preponderant cells have pale cytoplasm. Dark cells with dendritic processes are compressed among the pale cells. The dark cells are argyrophilic.

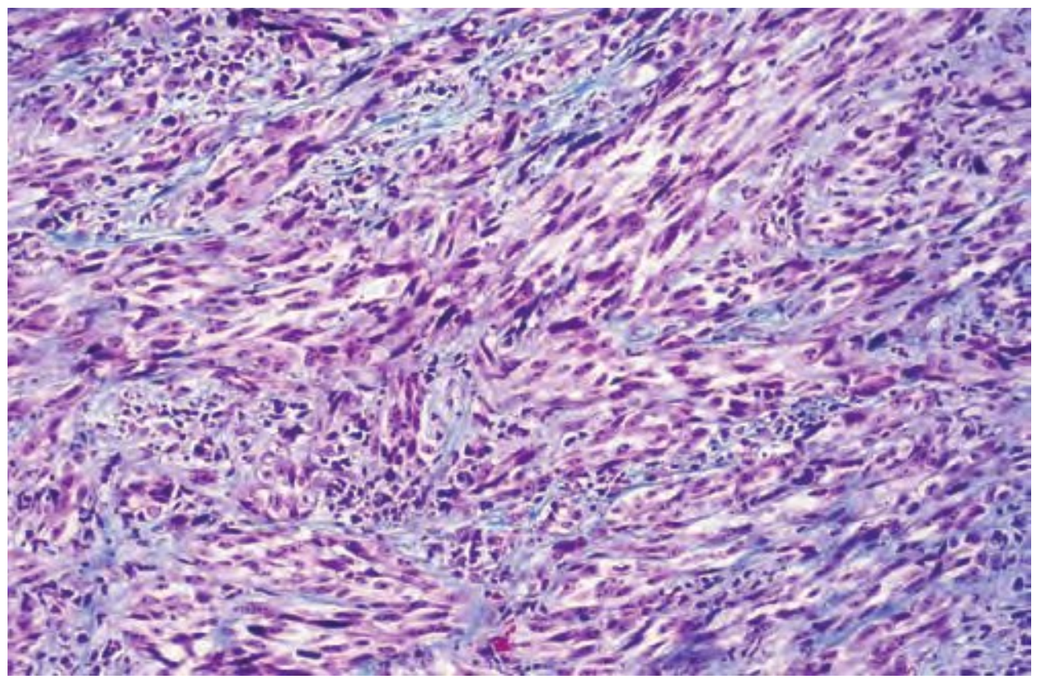

FIGURE 35-40. Fasciculated, malignant epithelioid peripheral nerve sheath tumor (both melanoma-like and neurotropic). Broad fascicles of atypical spindle cells infiltrate a fibrous matrix; portions of this soft tissue lesion were intraneural.

Zones of necrosis with peripheral palisades of tumor cells, a feature of both mesenchymal and epithelioid variants (4), are reminiscent of patterns in high-grade gliomas of the central nervous system.

For both the *de novo* variants and the transformed variants, attempts to predict an association with neurofibromatosis made simply on the basis of histologic findings in the malignant component usually are defeated by common expressions of overlaps in patterns of differentiation in the *de novo* and the transformed categories.

Of the many peripheral stigmata in neurofibromatosis, neurofibromas are the most predisposed to malignant transformations.

Ultrastructure. A light microscopic diagnosis of MPNST of sheath (Schwann) cell type is supported by a variety of features. Slender, overlapping cytoplasmic processes that envelop other processes or cell bodies may be connected by intercellular junctions. Granular, flocculent material, preferably along and parallel to the plasma membrane, may occasionally assume the linear form of basal lamina. Fine intracytoplasmic filaments should be absent or relative scanty (100).

Histogenesis. In this section, the figures reflect the whims of authors as they select or reject examples of "MPNST" for their studies. In 40% to 80% of cases of MPNST (25,115,116), the tumor cells are immunoreactive for S100 protein. CD57 can be detected in 30% to 40% of the cases (116). Myelin basic protein is less commonly detected (10%) (117). Laminin and collagen type IV are found in about 25% to 30% of cases. A high Ki67 labeling index (LI) has been correlated with a reduced survival rate; in addition, a significant correlation between Ki67 LI and the immunohistochemical expression of p53 or MDM2 has been reported (118). A positive reaction for S100 protein has taken on the aura of primacy in the classification of nerve sheath tumors. In turn, a malignant peripheral nerve sheath tumor ($S100^{+}$) might then be characterized as malignant schwannoma.

Patterns of diverse differentiation have been noted in MPNSTs (102). In the latter study, immunohistochemistry and ultrastructure were emphasized in documenting evidence of diverse differentiation; schwannian, perineurial and endoneurial, and mesenchymal categories were defined. Some MPNSTs had a high component of cells immunoreactive for S100 protein; for this group, perineurial and mesenchymal features were not associations. In a second category, less than 50% of tumor cells were reactive for S100 protein, and, in a third category, the cells did not react for S100 protein; for these two groups, patterns of heterologous (mesenchymal) and/or perineurial differentiation were observed.

Differential Diagnosis. In the absence of discernible stigmata of neurofibromatosis, differentiation of MPNST from fibrosarcoma is difficult. Patterns of interlacing fascicles that are alternately light and dark are characteristic of malignant schwannoma. In a mesenchymal variant of MPNST with patterns of specific differentiation but with no history or stigmata of neurofibromatosis, a diagnosis of malignant mesenchymoma would be a consideration.

Monophasic synovial sarcoma should be considered in the differential diagnosis (119). Its genetic profile includes t(X;18). For MPNST, the common changes are a loss of NF1 locus and a loss of the band containing gene p53; the changes are not specific. In 50% of monophasic synovial sarcomas, the cells are immunoreactive for cytokeratins and EMA. With the exception of one study, MPNSTs are t(X;18) (SYT-SSX)–negative "sarcomas" (119).

For deep epithelioid variants of MPNST, malignant fibrous histiocytoma (120), rhabdomyosarcoma, leiomyosarcoma, and malignant melanoma are considerations.

If one is confronted with infiltrating and fascicular patterns in a tumor of the skin, it might be impossible to distinguish between neurotropic melanoma (3,121) and cutaneous primary infiltrating and fascicular epithelioid MPNST in the absence of lentiginous and junctional, melanocytic patterns in the overlying or adjacent epidermis. Fortunately, the distinction as to whether such a lesion is one or the other has no major therapeutic or prognostic implications: The management is similar for both lesions. Patterns of radial sclerosis, as seen in rare epithelioid schwannomas, occasionally are a feature of dermal lesions in this overlap category of malignant fascicular epithelioid schwannoma and neurotropic melanoma.

Infiltrating fascicular Schwann cell tumor of infancy, in its histologic but not its cytologic patterns, shows overlaps with the patterns of both IFEMS and neurotropic melanoma (121).

Glandular, entoderm-like patterns (Fig. 35-41) may be more commonly associated with epithelioid than with mesenchymal variants of MPNST. If glandular patterns are represented in a problematic lesion, then carcinosarcoma might be a consideration. Entoderm-like glandular patterns, in the absence of sarcomatous components, rarely are encountered in the soft tissue in the setting of neurofibromatosis; a lesion showing such patterns may represent a primary neuroendocrine carcinoma (122).

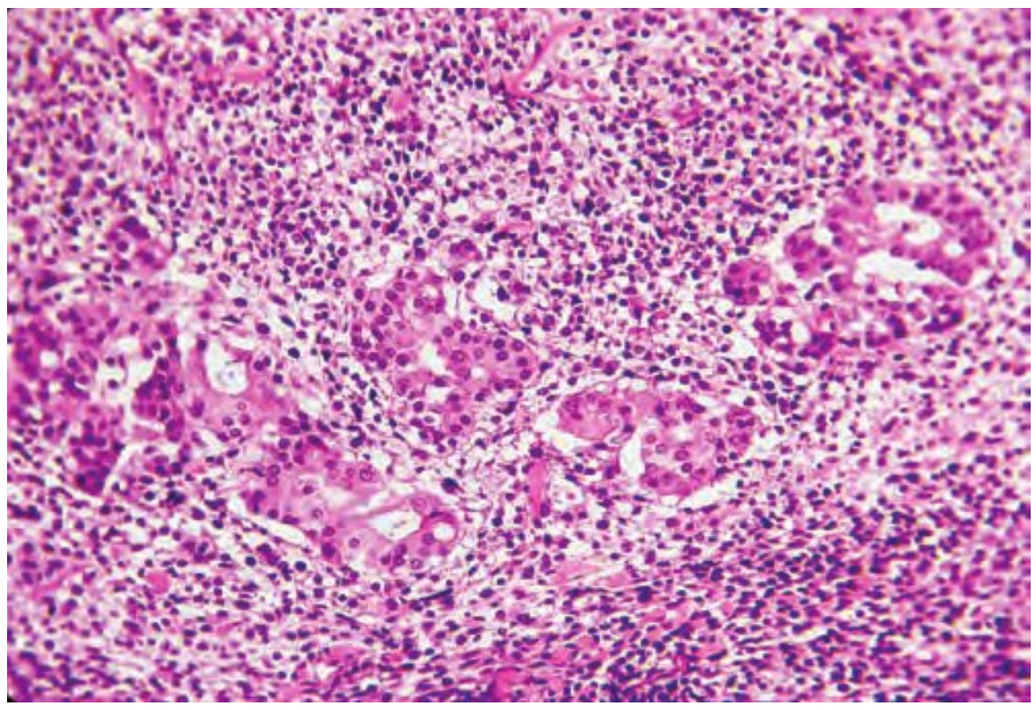

FIGURE 35-41. Small epithelioid cell malignant peripheral nerve sheath tumor; divergent glandular differentiation. Plump, columnar cells form solid nests and glandular patterns; the cells have small, round nuclei with uniform nuclear characteristics. The glandular spaces contain basophilic mucin. The glandular component is a random manifestation in an epithelioid malignant peripheral nerve sheath tumor.

Ganglioneuroma of the deep soft tissue has been the rare site of origin for a MPNST (31,123,124).

Prognostication and Treatment. A moderate increase in cellularity, focal storiform patterns, mild nuclear atypia, and the presence of mitoses (fewer than 10 per 10 hpf) may be the only features that distinguish low-grade MPNST from neurofibroma (3,57,125,126). Such examples qualify as *minimal deviation variants of indeterminate malignant potential*; local surgery is an option in treatment.

In the setting of neurofibromatosis, MPNST, in its many guises, generally has a poor prognosis. High-grade tumors show high mitotic rates (as many as 50 per 10 hpf), dense cellularity, scanty stroma, marked nuclear atypia, pleomorphism, and palisaded zones of necrosis. For intraneural, high-grade MPNST ex schwannoma (confined by the perineurium of the nerve of origin), confinement favorably modifies the significance of the "high grade." In one series of epithelioid MPNST, superficial location (skin and subcutis) and small size were favorable prognostic parameters (112). In general, adverse prognostic factors include large tumor size, age greater than or equal to 7 years, tumor necrosis greater than or equal to 25%, and von Recklinghausen's disease (127,128). A high mitotic rate and the need for resection by amputation have also been cited as factors related to a poor prognosis (114). Aggressive surgical treatment is required for high-grade tumors with extensive spread along the involved nerve (129).

TUMORS OF UNCERTAIN NATURE WITH NERVE SHEATH–LIKE FEATURES

Nerve sheath myxoma was originally defined by Harkin and Reed (3). Gallager and Helwig, under the designation *neurothekeoma,* described a series of tumors that they interpreted as nerve sheath tumors; the histologic patterns of neurothekeomas shared some general features with those of nerve sheath myxoma (130). As a result, there has been confusion regarding a relationship between the two categories.

Herein, the designation *nerve sheath myxoma* (NSM) (a myxoid and loosely cellular lesion that mostly appears micronodular) recognizes the classic nerve sheath myxoma as defined by Harkin and Reed (3,4). A larger group, the *neurothekeomas* of Gallager and Helwig (NTK) (130), includes both a cellular, or epithelioid and fascicular, neurothekeoma and a variant of neurothekeoma in which epithelioid and myxoid patterns are mixed (131,132).

NSM has an "immunohistochemical profile" that more clearly identifies nerve sheath qualities (i.e., $S100^{+}$); immunohistochemical distinctions have come to define the apparent separateness of NSM and NTK. In the face of immunohistochemical properties, which are of value in defining neural tumors but are weak or negative in NTK, attempts to find definitive immunohistochemical neural markers for NTK have found only brief support—witness the initial enthusiasm for PGP 9.5 in NTK (133).

In all variations, NSM and NTK are mostly neoplasms of the dermis. Similar lesions are rarely encountered in the soft tissue. NSM, in all its expressions, has been benign, although in cases of incomplete removal, rare examples have recurred. Neither neurofibromatosis nor multiple mucosal neuroma syndrome has been a documented association of either NSM or NTK.

Mature Nerve Sheath Myxoma

The relationship, if any, between nerve sheath myxoma (NSM) and neurothekeoma is controversial. In 1985, Pulitzer and Reed (134) expanded the concept of NSM and, in the process, fed the controversy. In 2005, Fetsch et al. (135) analyzed their material with emphasis on those cases that would immunohistochemically and clinicopathologically correspond to classic NSM. Their results offer strong support for the neural character of classic NSM. The nature of classic neurothekeoma has remained a mystery, although some of the findings, which initially had been cited as offering support for a neural origin, now could also be interpreted as favoring a fibrohistiocytic origin (136).

Classic (micronodular) NSM (Pulitzer and Reed) is most common in middle-aged adults, with a male-to-female ratio of approximately 1:2 (3,4,134,135); mean age has been variously reported as 21.6 and 36 years. Characteristically, it is an asymptomatic, soft, skin-colored or translucent papule or nodule ranging from 0.5 to 1.0 cm in diameter (35,134). It is typically located on the face and the upper extremities but can occur anywhere on the body; in the material from the Armed Forces Institute of Pathology, acral locations were preponderant (135).

Histopathology. Symmetrically expansile, myxoid micronodules are loosely clustered in a fibrous matrix in the reticular

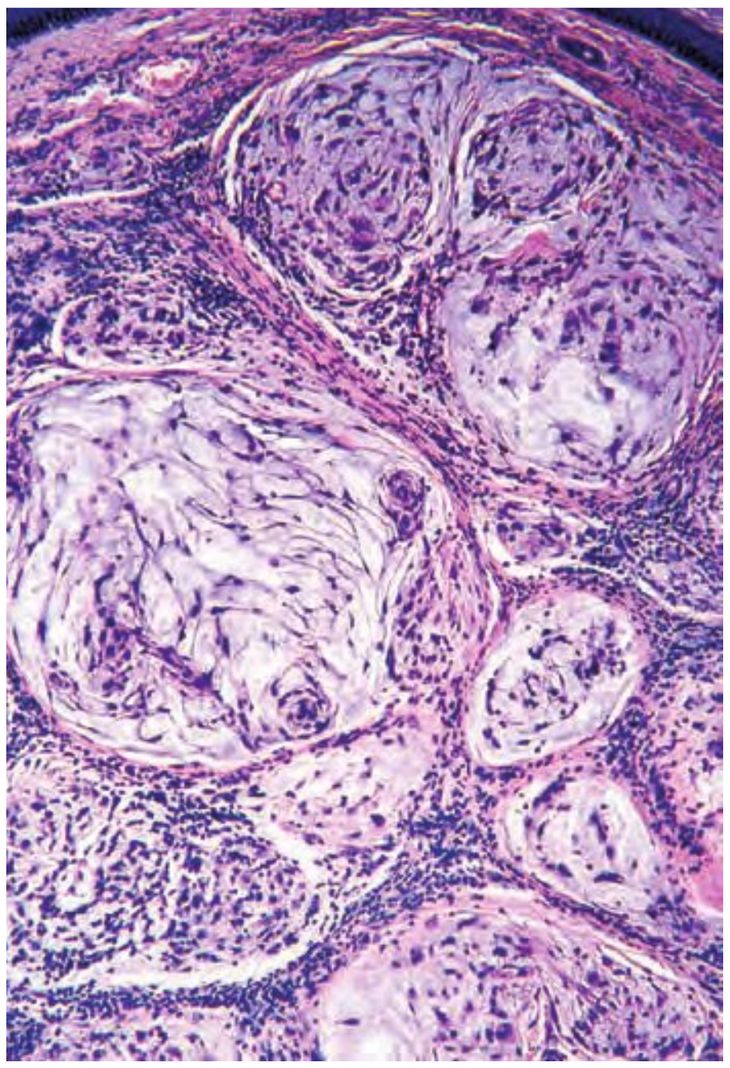

FIGURE 35-42. Mature nerve sheath myxoma. The lesion is plexiform; fascicles are represented in both longitudinal and cross sections. Some of the fascicles are outlined by thin sheaths of condensed fibrous tissue. Tumor cells are loosely spaced in a prominent myxoid matrix. Some of the tumor cells have thin polar extensions of cytoplasm; they morphologically resemble perineurial cells. Some are plump and epithelioid. Some of the thin cells form whorls about blood vessels of the fascicles. In this example, lymphoid infiltrates are prominent in the stroma.

dermis; they vary in size. In aggregate, they form a multilobulated mass that is often poorly circumscribed and not always symmetric (Fig. 35-42). The myxoid matrix is rich in acid mucopolysaccharides (sulfated glycosaminoglycans). In it, bipolar and tripolar cells are widely and fairly regularly spaced (Fig. 35-43). Nuclei are elongated and often angulated, with inconspicuous nucleoli and uniformly distributed, dense chromatin. Cytoplasms are pale, and cell membranes are sharply defined. Centrally in the micronodules, cells tend to be arranged in loose whorls. Each micronodule is partially or completely outlined, in perineurium-like patterns, by a thin condensation of fibrous tissue. Continuity with adjacent nerves is rarely identified (3,130,134,135).

Ultrastructurally in lesions of NSM, a continuous basal lamina outlines most cells, but in some reports, discontinuous basal lamina and pinocytotic vesicles have been features (134,137). Engulfment of collagen fibers in the manner of Schwann cells has been observed. Fibroblasts and mast cells are also represented.

Histogenesis. The most consistent immunohistochemical profile is S100$^+$, collagen type IV$^+$, GFAP$^+$, and vimentin$^+$ (35,136). A smaller number of cells are EMA$^+$ (35).

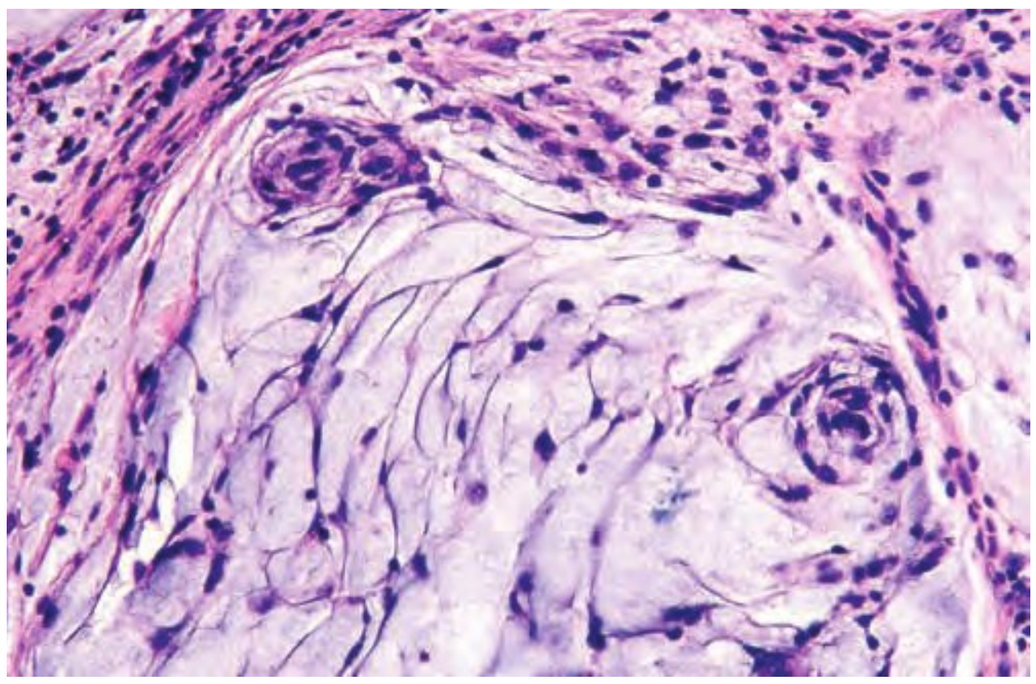

FIGURE 35-43. Mature nerve sheath myxoma. At higher magnification, many of the tumor cells have "perineurial cell–like" qualities. Some of the distinctive cells form whorls about vessels.

Neurothekeoma [Cellular, Epithelioid, and Fascicular (Nerve Sheath Tumor–Like) Neoplasm, Questionably of Nerve Sheath Origin: Cellular Neurothekeoma; NTK]

The lesions of this category should be classified as *neurothekeoma* (NTK); the designation *cellular neurothekeoma* was and is, in large part, a political accommodation that has been rendered superfluous. The category includes two variants. For one variant (*NTKA*), the patterns are uniformly cellular and fasciculated. For the second variant (*NTKB*), cellular and fascicular patterns are admixed with myxoid components (i.e., focal histologic qualities that might be confused with those of classic nerve sheath myxoma).

In NTK, the mean age is 24 years, but examples have been reported in children. The upper body is the favored site. Women are more commonly affected (136). The lesions are firm, pink, red-brown papules or nodules measuring 0.5 to 3.0 cm; some may produce symptoms (137).

Histopathology. In the variant *NTKA*, fascicles of cells tend to be rather uniform in diameter, and their margins are poorly defined. They are arranged in infiltrating (dissecting) patterns among collagen bundles of the reticular dermis or are supported by a fibrous matrix (Fig. 35-44A, B); they often extend into the subcutis. Exclusive of the fascicular component, individual tumor cells and small, irregular clusters of tumor cells may infiltrate the reticular dermis; they may even extend into arrector muscles. In the fascicles, the cells are closely spaced; they tend to be polygonal, but in rare examples they are plump and spindle shaped. Cytoplasm is conspicuous and tends to be acidophilic. Rigid cytoplasmic processes are prominent. The nuclei are plump and rounded or elongated and somewhat irregular in outline. Nuclear chromatin is stippled, and nuclear membranes are heavy.

In the variant *NTKB*, some of the aggregates become locally expanded to form broad fascicles and nodules in which

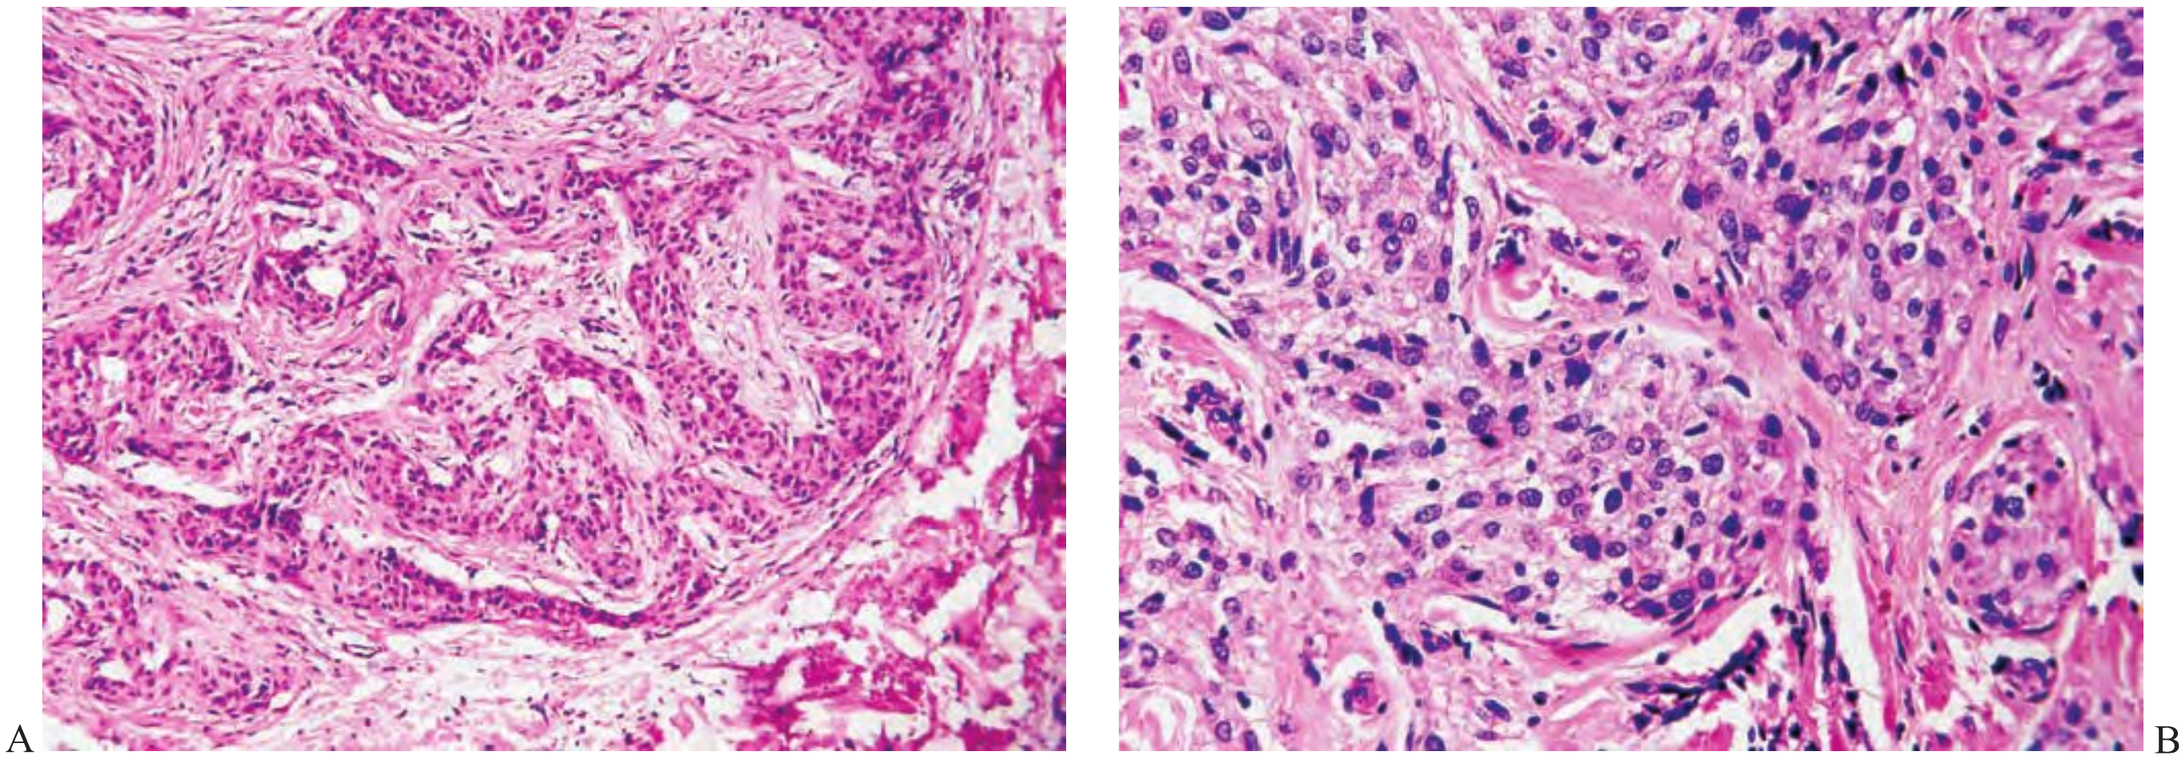

FIGURE 35-44. Neurothekeoma. A: Pale, acidophilic epithelioid cells from tortuous, interconnected fascicles in a well-defined fibromyxoid matrix; the lesion is sharply circumscribed. In the fascicles, myxoid matrix is scanty. B: At higher magnification, the epithelioid cells of the fascicles are loosely attached to their neighbors. Defects among the tumor cells contain a mucinous matrix. The tumor cells show regular, round nuclei with well-defined nuclear membranes and stippled chromatin; nuclei are small.

both cellular and myxoid patterns are represented (Fig. 35-45). In the myxoid zones, stellate cells are loosely spaced: Their cytoplasmic processes are broader and more irregular in diameter than those of the cells of classic NSM. The myxoid patterns tend to be represented at the periphery of broad fascicles and nodules. Compact whorls of cells are focally prominent in all variations of NTK. Spotty, incomplete condensations of fibrous tissue are observed at the periphery of the broad fascicles and nodules.

In some examples of NTK, the stroma consists of a sclerotic, fibrous matrix with no preservation of the interwoven fiber patterns of the reticular dermis (Fig. 35-44A).

Mitoses are not a prominent feature in most examples of both variants of NTK. Atypical variants are characterized by nuclear atypia and pleomorphism with scattered mitoses (Figs. 35-46 and 35-47), some of which may be atypical (134,138).

In some examples of NTK, histiocytic, multinucleated giant cells are represented among the tumor cells. In lesions showing a component of such cells, the patterns somewhat overlap with those of plexiform fibrous histiocytoma (Fig. 35-48).

Rarely in lesions of NTK, cells of the tumor can be found within small nerves in the adjacent dermis.

Ultrastructurally, NTKA and NTKB are composed preponderantly of undistinguished cells. Focal densities of the cell

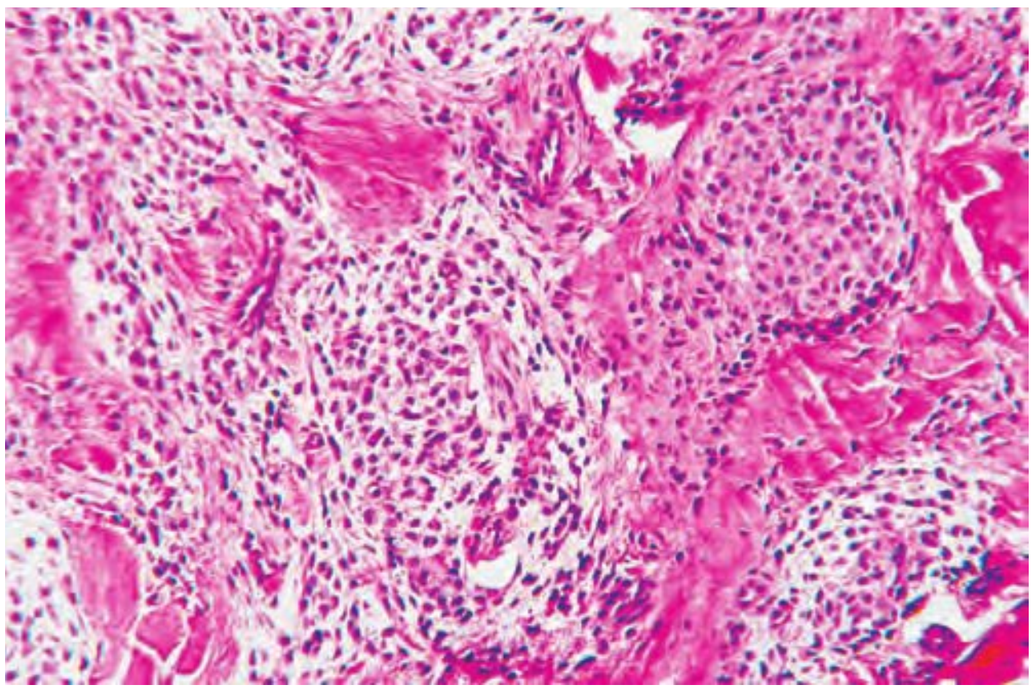

FIGURE 35-45. Neurothekeoma; intermediate variant. In this example, cellular zones merge with myxoid zones; the lesion is fasciculated; the fascicles extend among collagen bundles of the reticular dermis without inducing a tumor stroma.

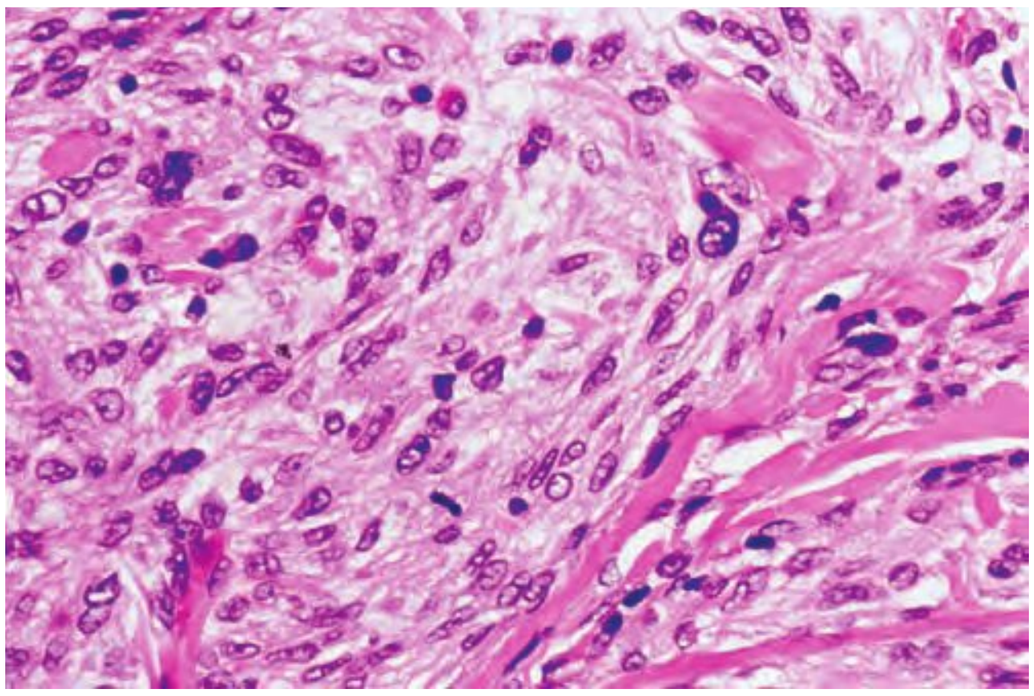

FIGURE 35-46. Atypical neurothekeoma. Tumor cells of this atypical nerve sheath myxoma vary in size and outline; some are hyperchromatic. A mitotic figure is represented to the left and below the center of the field.

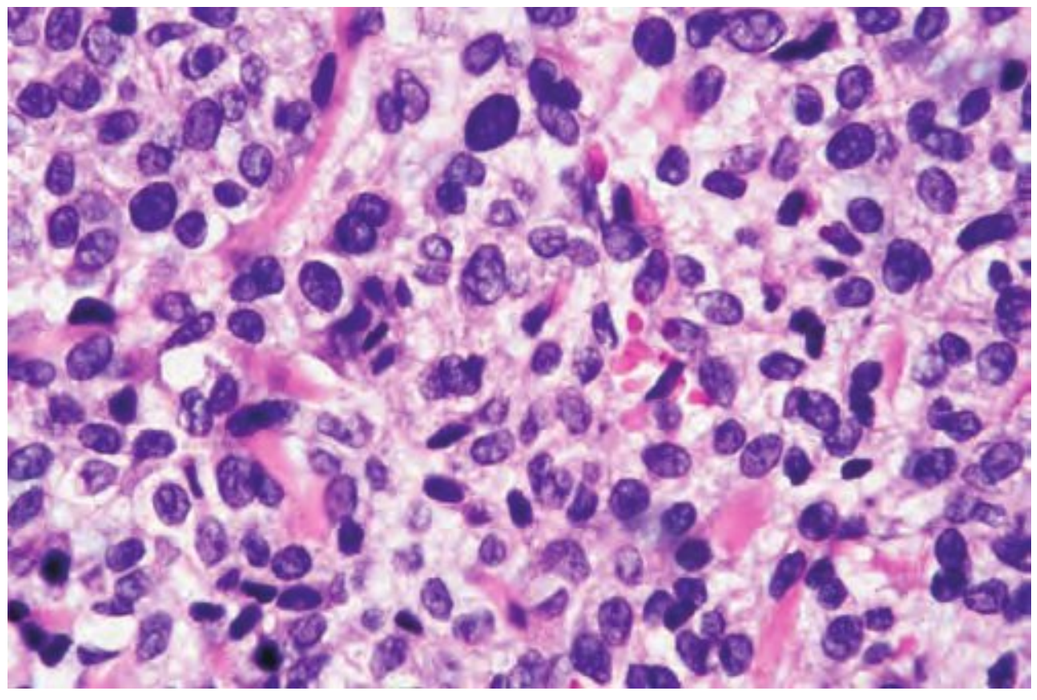

FIGURE 35-47. Atypical neurothekeoma. Cells have scanty cytoplasm. Enlarged, hyperchromatic nuclei vary in size and outline; some show prominent nucleoli.

membranes, which are suggestive of attachment plaques, and focal, poorly formed, basal lamina–like material have been described (139). Some of the cells contain phagolyosome-like structures, irregularly arranged microfilaments, and rare microfilament-attached dense bodies (140). Fibroblasts are common. In a single case, perineurial cell–like features were described (137).

Histogenesis. Immunohistochemically, the cells of NTK exhibit a variable and inconsistent phenotype. They are positive for vimentin, CD10 (140), and PGP 9.5 but do not often stain for S100 protein or epithelial membrane antigen (136,141,142). Weak and variable expressions of smooth muscle–specific actin, collagen type IV, NK1/C3, and CD57 have been reported (35,132–143).

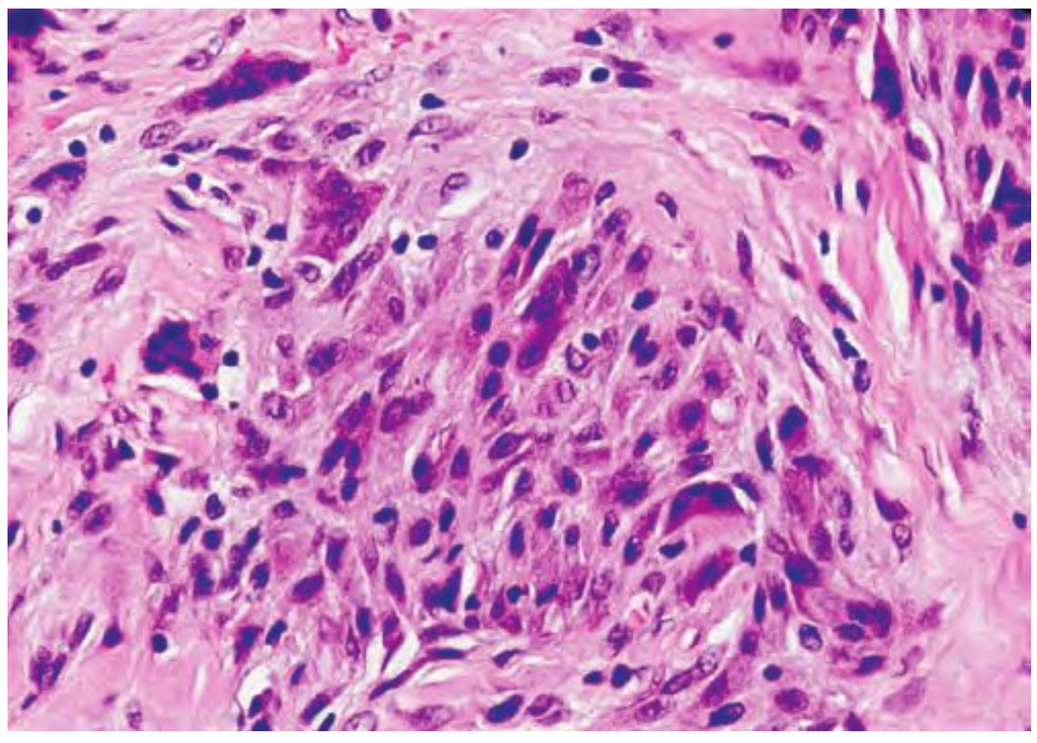

FIGURE 35-48. Neurothekeoma with multinucleated giant cells. The basic pattern of this "plexiform" lesion suggested a variant of nerve sheath myxoma. Focally, as in this field, the patterns overlap with those of plexiform fibrous histiocytoma.

PGP 9.5 recently has been found to be a rather nonspecific marker in the practice of surgical pathology (144). NK1/C3, although having been cited as a marker that distinguishes cellular neurothekeoma from other dermal tumors (145), was found to be positive in a spectrum of neoplastic tissues; it was also positive in many dermal tumors of possible histiocytic origin (146).

Differential Diagnosis. Intraneural neurofibromas are rare in the dermis and only slightly more common in the subcutis. Immunoreactive axons, a feature of intraneural neurofibroma, are not a feature of NSM.

Cellular myxomas of the skin, including *angiomyxomas* (147) and *trichogenic myxomas* (90), are rare; some are poorly documented. They are solid, uniform lesions; neither the micronodular qualities of NSM nor the fascicular and nodular qualities of NTKA and B are represented. In cellular myxomas, immunoreactions for S100 protein are negative (35). Examples of cellular myxoma appear to have been included in some reports of NSM. Zelger et al. suggested that some reported examples of NSM were perineuriomas (37).

Spindle cell nevus of the Spitz type, particularly dermal variants, might be confused with NTK. A strong and uniform reaction for S100 protein would favor a variant of Spitz nevus or some other variant of nevus, such as a cellular blue nevus with prominent fascicular components. The pigmentation of deep penetrating nevus is not a feature of NTK.

In rare examples, minimal deviation *neurotropic melanoma* would be a consideration. Most spindle cell melanomas are S100 protein positive. Not all desmoplastic and neurotropic melanomas are immunoreactive for HMB-45, but a positive reaction would exclude NTK. *Neurothekeoma A* might be mistaken for a metastatic malignant melanoma (a lesion lacking a primary configuration). A positive reaction for S100 protein and HMB-45 would strongly favor a diagnosis of malignant melanoma.

The immunohistochemical distinctions between NSM and NTK provide evidence that "cellular neurothekeoma" could well be something other than a nerve sheath tumor (136). Zelger et al. proposed that "cellular neurothekeoma" is a variant of dermatofibroma (148), but it is difficult to accommodate the fascicular patterns of NTK in the category of dermatofibroma.

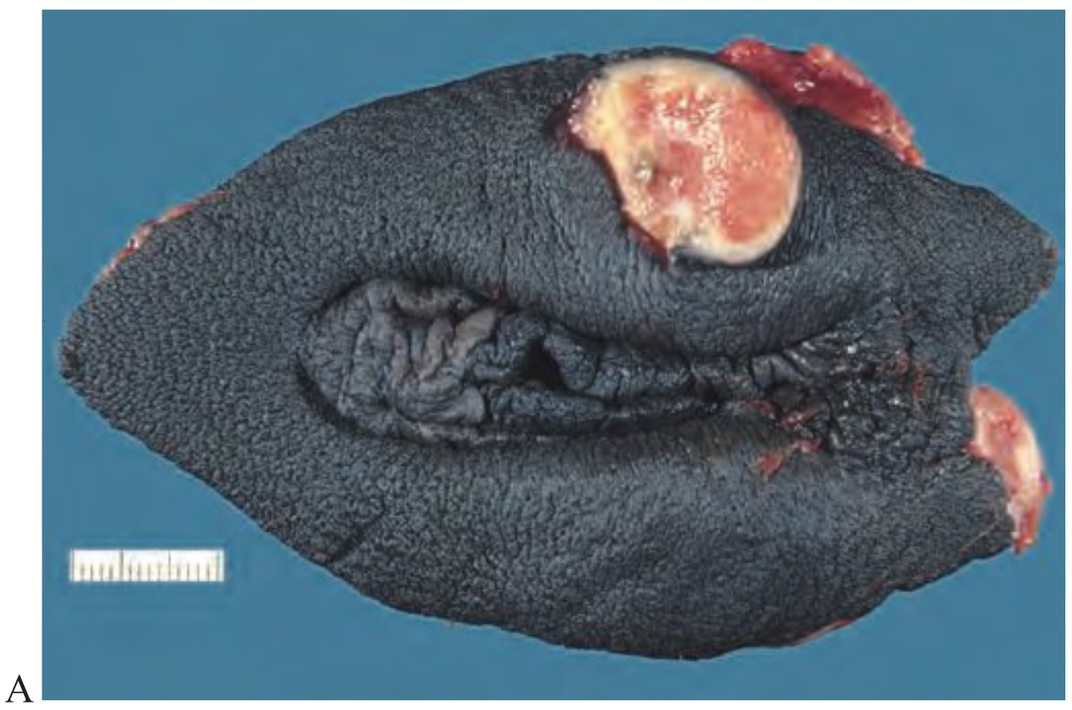
The commonness of many of the histologic patterns in the groups NSM and NTK could depend on the degree of differentiation or the functional status of Schwann cells. In the latter promotion, NK1/C3 positivity could be evidence of the ability of Schwann cells to function as histiocytes. It has been argued that "cellular neurothekeoma" is a variant of dermatofibroma or fibrous histiocytoma (136); in this promotion, NK1/C3 positivity is evidence of the "histiocytic" nature of the tumor cells, and the lesion could then be assigned to the "fibrohistiocytic" category. Positivity for CD10 could be offered in support of the "histiocytic" nature of "cellular neurothekeoma," but this type of positivity has also been observed in myelin sheaths (149) and wallerian degeneration. It is too

soon to assign cellular neurothekeoma to the "fibrohistiocytic" category. The "fibrohistiocytic" category is perhaps more poorly defined than when A. P. Stout proposed the concept of the "facultative" fibroblast.

Some examples of NTKB with involvement of the subcutis and with representation of numerous giant cells would be difficult to distinguish from plexiform fibrous histiocytoma of children and young adults (Fig. 35-48) (36). In the nodular portions of plexiform fibrous histiocytoma, the cells are closely spaced and often are admixed with multinucleated giant cells. Plexiform fibrous histiocytoma has a close association with fascia. A myxoid matrix is not prominent but focally may be a feature. The fascicular ("plexiform") qualities of NTK have complicated attempts to assign this lesion to its proper category (150). It has been suggested that NTK and plexiform fibrous histiocytoma might be one and the same lesion. Such an approach would not necessarily require that priority be assigned to the fibrous histiocytoma category.

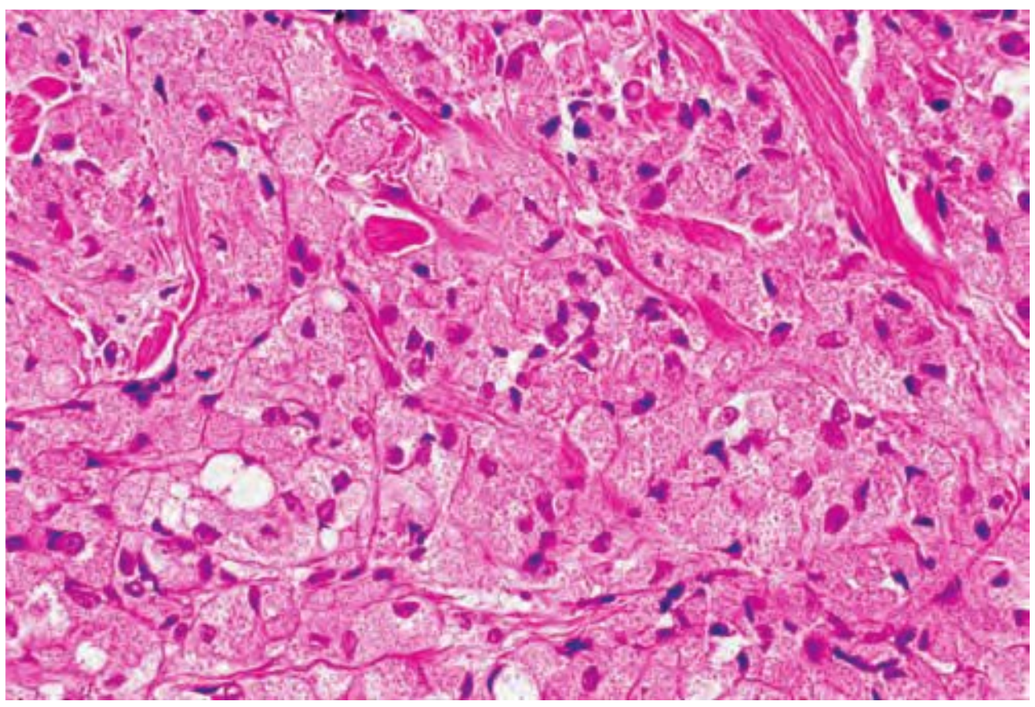
Sclerosing myofibroblastomas, as well as rare myxoid or epithelioid pilar leiomyomas, of the skin should be considered in the differential diagnosis (151). Cells of the cellular portions of myxoid leiomyomas clearly are smooth muscle in type. In some examples of NTKA, in which some of the cells are immunoreactive for smooth muscle actin, the tumor cells are consistently negative for desmin (35).

Epithelioid fibrous histiocytoma (EFH) (*epithelioid cell histiocytoma*, *adventitial cellular myxofibroblastoma*) (152,153), a lesion favoring acral sites, tends to be polypoid; it is mostly confined to a widened papillary dermis. Some examples are mostly myxoid. Large, vacuolated cells with muciparous qualities are occasionally a feature. Many of the dendritic histiocytes that are found among tumor cells of EFH are reactive for factor XIIIa, and some are reactive for S100 protein. Examples of EFH can be identified in some reports of NSM.



Granular Cell Tumors

Granular Cell Nerve Sheath Tumor



Granular cell nerve sheath tumor (GCNST) (*granular cell myoblastoma, granular cell schwannoma, granular cell tumor*) usually is solitary. In about 10% of the cases, lesions are multiple; they may be multifocal. Forty percent of the cases involve the tongue (154), but the skin and the subcutaneous tissue also are common sites (Fig. 35-49A). Other reported sites include the esophagus, stomach, appendix, larynx, bronchus, pituitary gland, uvea, and skeletal muscle (155).

GCNSTs of the skin are well circumscribed, raised, firm, and nodular. Some examples are verrucoid at the surface. Generally, lesions range from 0.5 to 3.0 cm in diameter. The cut surface often is faintly yellow and homogeneous. Tenderness or pruritus has been an occasional complaint.

Histopathology. Most GCNSTs are extraneural; rare examples have been intraneural, at least in part. Broad fascicles of tumor cells infiltrate the dermis among the collagen bundles (Fig. 35-49B). Extension of fascicles of tumor into the subcutis is common. The tumor cells are large and polygonal (Fig. 35-49B); cell membranes are distinct. Faintly eosinophilic, uniform, small granules that are periodic acid-Schiff (PAS) positive and diastase resistant fill the cytoplasms. Scattered, laminated, cytoplasmic globules with peripheral halos (residual bodies) (Fig. 35-50) are also represented. Nuclei usually are small and centrally located. They tend to be round to oval in outline but, in some examples, are plump, irregular, and hyperchromatic

A

B

FIGURE 35-49. Granular nerve sheath tumor. A: This granular cell tumor involves a labia majora of the vulva. The cut surface of the tumor is exposed; it is yellow-tan and somewhat granular. The specimen is the product of a vulvectomy. B: In this example, the cells are plump and polygonal; fine granules, uniform in size, fill the cytoplasm of each cell. In this category, nuclear characteristics are variable from case to case; in this example, there is some variability in nuclear size and outline. An occasional nucleus contains an inclusion of cytoplasm. Nucleoli are variable in size.

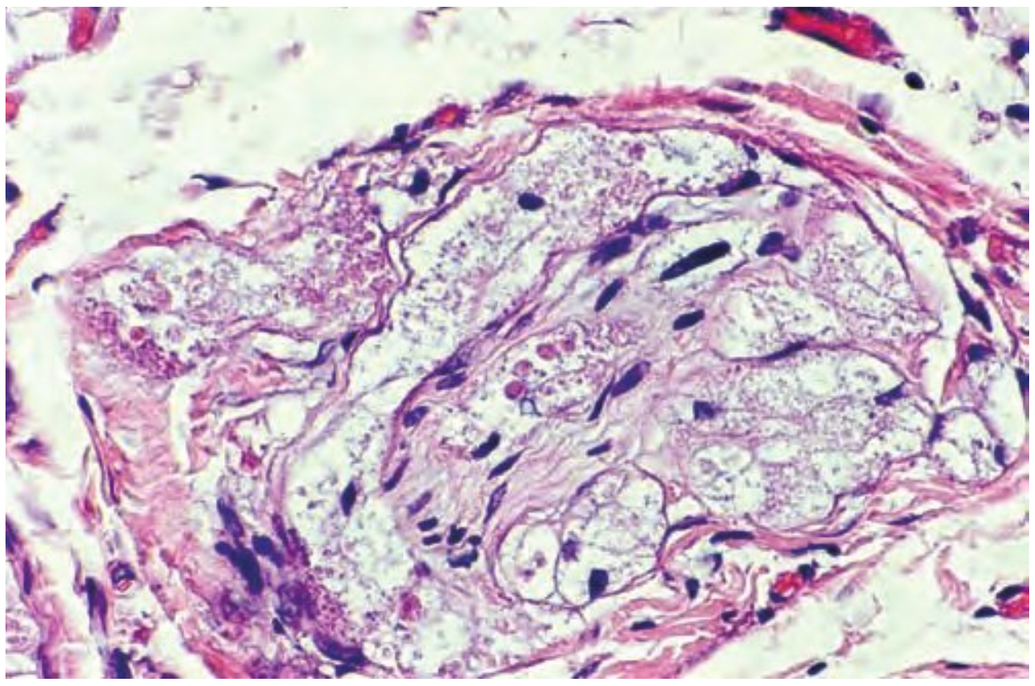


FIGURE 35-50. Granular cell nerve sheath tumor, neurotropism. Granular cells infiltrate the perineurium and the endoneurial space of this small nerve. In the cytoplasm of some of the cells, in addition to fine, uniform granules, there are larger, rounded, acidophilic bodies that are "residual body like."

with a central nucleolus. Mitoses are uncommon. Some clusters of tumor cells are surrounded by PAS-positive, diastase-resistant membranes, strands of collagen fibers, and occasional flattened, satellite cells (154). Interstitial spindle cells have fibroblast-like qualities (25). Rarely, fascicles of tumor cells are entrapped in a dense fibrous matrix (sclerosing variant).

Neurotropic spread along peripheral nerves both within and at the advancing margins of the tumor is often a feature (Fig. 35-50). Rarely, deep GCNSTs have an intraneural component that expands the involved nerve.

The histologic features of some GCNSTs are of a type that, in other neoplastic systems, might be characterized as indicative of a malignancy (156). Mitoses are an acceptable feature of GCNST; they are not a marker for malignant transformation. GCNST infiltrates locally; it should be completely excised. Recurrences are common after incomplete excision.

Infiltration of skeletal muscle is a common feature of GCNST involving the squamous mucosae; in such areas, regenerating and degenerating muscle fibers are entrapped among fascicles of tumor cells. *Plexiform GCNST* is characterized by perineural extensions of tumor along the neural plexus of the dermis in the absence of a discrete mass (157).

Ultrastructurally, tumor cells are outlined by basal lamina (158,159). The preponderant cytoplasmic granules are largely phagolysosomes. They appear as membrane-bound vacuoles measuring 200 to 900 nm in diameter. Some of the larger cytoplasmic bodies have the appearance of residual bodies or myelin figures (154,158,159). The peripheral satellite cells of the fascicles are outlined by a discontinuous basal lamina (160). Interstitial cells of the tumor contain angulate bodies (25).

Histogenesis. The granular cell category is heterogeneous. Not all examples mark as nerve sheath tumors; some of the immunohistochemically divergent lesions are also cytologically atypical (161). The classic immunohistochemical profile is positive for S100 protein, peripheral nerve myelin proteins, such as P2 protein and PO protein (162), PGP 9.5 (163), NSE, and vimentin.

Differential Diagnosis. A *xanthoma* is excluded by the identification of cytoplasmic granules (rather than vacuoles). A fascicular arrangement of cells favors GCNST.

Angulated, elongated columns of bland squamous cells occasionally extend from the epidermis into GCNST among the fascicles of tumor cells (*pseudoepitheliomatous hyperplasia*). On biopsy specimens from tumoral lesions of the tongue, genitalia, or the mucous membranes of the upper respiratory tract, esophagus, or anus, such patterns should be interpreted with caution. If one is confronted with such patterns on a superficial biopsy specimen, a careful search for a component of granular cells might avoid a mistaken diagnosis of carcinoma and, in turn, needless aggressive surgery.

Tumor cells with cytoplasmic granular-cell qualities are occasionally a feature of *granular cell lesions of diverse lineage*, such as basal cell carcinoma (164) and dermatofibroma (165). The granules of rare granular squamous cell carcinomas, in contrast to those of other benign and malignant granular cell tumors, are PAS negative, and desmosomes are seen on electron microscopy (166). In the jawbones, a granular cell variant of ameloblastoma has been described. Granular cell change has been noted in smooth muscle tumors (167).

The *primitive polypoid granular cell tumor* (*dermal non-neural granular cell tumor*) presents as a painless nodule, mainly on the extremities or face (168). Lesions are both polypoid and endophytic. The tumor cells are immunoreactive for NKI-C3 and are negative for S100 protein, smooth muscle actin, Melan-A, CD34, desmin, and cytokeratin. The reported cases have behaved in a benign fashion (168).

Granular Cell Epulis of Infancy

Granular cell epulis of infancy is a polypoid tumor of the gingiva of the newborn, with a predilection for girls (169). It shares the basic histologic features of GCNST but is immunohistochemically distinctive. The immunohistochemical profile is NSE^{+}, vimentin^{+}, S100^{-}, GFAP^{-}, CD57^{-}, MBP^{-}, lysozyme^{-}, a1-ACT^{-}, and laminin^{-}. Interstitial cells are positive for S100 protein; they do not contain angulate bodies (170).

Malignant Granular Cell Tumor

Malignant granular cell tumor (MGCT) is uncommon. Most of the reported cases have occurred on the skin or in the subcutaneous tissue (171). As in benign GCNST, a few cases have been reported from other areas, such as the sciatic nerve (172) and the viscera. A variety of malignant tumors may masquerade in granular cell patterns. In all instances, an acceptance of the diagnosis MGCT is predicated on circumspection.

In the skin and subcutaneous tissue, MGCT, a rapidly growing, poorly defined nodule or mass, may reach considerable size and undergo ulceration (172). Extensive metastases to viscera, skin, and skeletal musculature occur, with or without

regional lymph node metastases (173). Some lesions, even in the absence of demonstrable metastases, have been characterized as MGCT (174).

Histopathology. There are two types of MGCT (175). In one type, in spite of the clinically malignant course, the histologic appearance of the primary lesion, and even of the metastases, is that of a benign GCNST, except for occasional mitotic figures and mild cellular pleomorphism with nuclei that are slightly larger than those seen in most benign GCNSTs (173,175,176). In the general category of GCNST, these cytologic features are too common to provide a reliable identification of lesions with the potential for metastasis. In evaluating the malignant potential of histologically benign or indeterminant granular cell tumors, clinical data, such as large size of the tumor, rapid growth, ulceration, and invasion into adjacent tissue, are of greater diagnostic value than the histologic features (177). The average diameter of "histologically benign, clinically malignant" granular cell tumors has been found to be 9 cm, as compared with 1.85 cm for the benign variety (175,177).

In the second type of MGCT, both the primary lesion and the metastases are histologically malignant; they show transitions from typical granular cells through pleomorphic granular cells to pleomorphic, nongranular spindle and giant cells with numerous mitotic figures (178,179).

In benign GCNST, immunohistochemical tests for S100 protein, NSE, and vimentin are regularly positive. In MGCT, the same tests often are negative.

Fibrolamellar Nerve Sheath Tumor

Fibrolamellar nerve sheath tumor (FNST) is a solitary tumor of the dermis (180). In a recently reported example, a 25-year-old man had a solitary rubbery nodule of the right cheek (181).

Histopathology. FNST is nonencapsulated but sharply defined in the dermis. Coarse, rigid, eosinophilic lamellae are arranged in parallel arrays in stacks of four or more. Neighboring stacks are random in orientation, one to the other, but in some areas the patterns that result from the abutment of neighboring stacks have storiform qualities. Some examples are mostly myxoid; in them, the fibrous lamellae are more delicate and widely spaced. Tumor cells, each with a small nucleus, scanty perikaryon, and rigid, thin, polar extensions of cytoplasm, resemble perineurial cells. They are isolated in clear or mucinous matrix among the fibrous lamellae. Rarely, a few loosely clustered, pigmented dendritic melanocytes have been a feature.

FNST is histologically distinctive but may be simply an exaggeration of perineurial-like patterns that are occasionally manifested in cutaneous neurofibromas.

FNST shares features with *sclerotic fibroma*, as manifested either sporadically or in the setting of *Cowden's disease*. A demonstration of immunoreactivity for S100 protein by some of the tumor cells strongly favors the diagnosis of FNST.

TUMORS OF PERINEURIAL CELLS ("PERINEURIOMAS")

Storiform Perineurial Cell Fibroma, Soft Tissue type

Storiform perineurial cell fibroma, soft tissue type (SPCF; *storiform perineurial fibroma*; *"soft tissue perineurioma"*) is a solitary, symmetrically expansile, and well-circumscribed tumor; it most commonly affects the subcutis (3,182–184), but the deep soft tissue and even viscera may be involved. The clinical features are not well established. The lesion is a fibroma whose component cells express the phenotype of perineurial cells. In the series reported by Hornick and Fletcher (185), there was a slight preponderance of females. A painless mass in the subcutis was the most common clinical presentation; for slightly more than one fourth of Hornick and Fletcher's cases, the deep soft tissue was affected. Most of their cases were well circumscribed; 12 cases microscopically showed focal, infiltrative margins; 14 cases were classified as atypical perineuriomas; only 2 tumors recurred locally; and there were no metastases. In recognizing an atypical variant of perineurioma, the possibility that some atypical examples might be precursors of MPNST of perineurial type mostly has been dismissed. MPNST of perineurial type has been set apart from atypical perineurioma; it is grouped in the general category of MPNST. The atypical forms are being promoted as benign lesions in which atypia is dismissed as "degenerative" ("ancient") change. In the series reported by Hornick and Fletcher (185), mitotic activity ranged from 1 to more than 5 mitoses per hpf. Among the atypical perineuriomas, mitoses ranged from 0 to 7 per 30 hpf. The conceptual approach to atypical, mitotically active perineuriomas is the same as the cavalier approach to atypical, mitotically active "cellular schwannoma."

Histopathology. SPCF is circumscribed. At its periphery, the interface with soft tissue is defined by a thin capsule consisting of several loosely spaced, delicate fibrous lamellae. Beneath the capsule, thin collagen fibers form a delicate, fibrous matrix. Cells with plump, angulated nuclei and rigid, polar, cytoplasmic extensions are loosely spaced (Fig. 35-51). Fascicles in storiform patterns are variably represented. In most examples, small nerves are embedded in, or may be traced into, the tumor. The tumor cells tend to form thin, concentric layers around entrapped small nerves, blood vessels, and collagen bundles. Small stacks of hyalinized (skeinoid?) fibrous lamellae, somewhat similar to those of fibrolamellar nerve sheath tumor, occasionally are a focal variation in such lesions (Fig. 35-51).

Histogenesis. The cytologic features are perineurial cell like. In some examples, tumor cells are immunoreactive for vimentin and EMA (183). The latter reaction may be weak or patchy; it is most likely to be best developed in cells in or near the capsule. In other examples, scattered aggregates of tumor cells in more central locations are reactive for S100 protein. Claudin-1, a tight-junction–associated protein, was recently reported as a common expression in membranous,

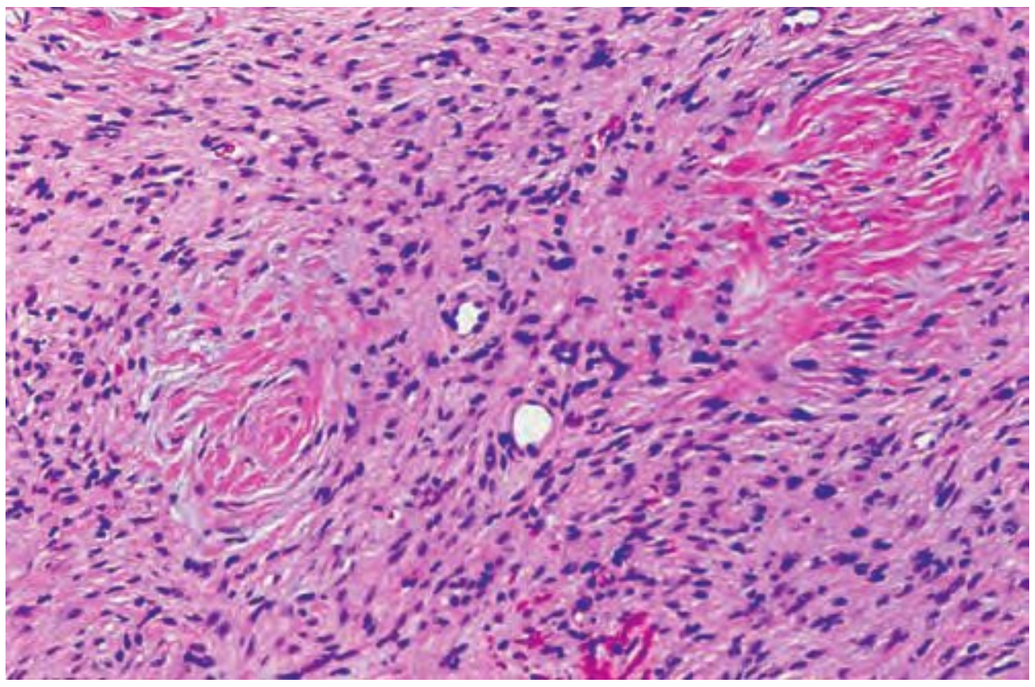

FIGURE 35-51. Storiform perineurial cell nerve sheath tumor (soft tissue "perineurioma"). Spindle cells are individually isolated in a delicate fibrous matrix. There are two collections of stacked, acidophilic fibrous lamellae.

granular patterns in perineuriomas (186). An abnormality of chromosome 22 was reported (187). One example of soft tissue perineurioma in a patient with neurofibromatosis type 2 was reported (188).

Differential Diagnosis. Storiform patterns appear to be variations that are expressed in a variety of nerve sheath tumors. Perhaps variants of both schwannomas and neurofibromas have been included in this category of "perineurioma." The evidence that SPCF is purely perineurial in character is unconvincing. For some problematic lesions, "cellular" schwannoma would be a diagnostic consideration.

Fibrous histiocytoma of the subcutaneous fat and dermatofibroma also are considerations in the differential diagnosis.

Dermatofibrosarcoma protuberans (DFSP), in its nodular, well-differentiated components, might be confused with SPCF. It has been variously classified as a fibroblastic, fibrohistiocytic, or neurocristic tumor. The pigmented variant of DFSP (*Bednar tumor*) has been characterized as pigmented storiform neurofibroma. The nature of pigmented dermatofibrosarcoma is controversial but, in one study, perineurial cell–like qualities were observed (189). The cells of DFSP, like some cells of nerve sheath tumors, are immunoreactive for CD34 (190). DFSP is described in detail elsewhere (Chapter 32).

Acral Perineuriomas

Pacinian Neurofibroma

The designation *pacinian neurofibroma* has been assigned to a variety of lesions. The nature of this lesion has not been carefully examined by immunohistochemical studies (191,192).

Intraneurial Perineurioma

Intraneurial perineurioma (*intraneural, symmetrically concentric perineurial cell tumor; hypertrophic interstitial neuritis; hypertrophic mononeuropathy; ISCPCT*) is an intraneural, solitary, segmental and cylindrical enlargement of a nerve (193–195). Sensorimotor defects are characteristic.

Histopathology. In the characterization of this lesion, distinctions are required between onion bulbs and pseudo–onion bulbs. Pseudo–onion bulbs are composed of cells that are immunoreactive for EMA. If the cells of a concentrically arranged cluster are Schwann cells ($S100^+$), the collection qualifies as an onion bulb pattern; if the concentrically arranged cells are mostly perineurial cells (EMA^+), the collection qualifies as a pseudo–onion bulb pattern. In ISCPCT, cells with both the structural qualities and the immunoreactivity of perineurial cells form concentric sheaths (pseudo–onion bulbs) around affected nerve fibers (Fig. 35-52) and even around small clusters of pseudo–onion bulbs (193). Collagen bundles and vessels may be similarly embraced. A specific and concentric orientation of cells about axons is a symmetric quality. Demyelination and degeneration of axons are associated phenomena; in the center of the clusters, axons may appear enlarged and irregular in outline.

Histogenesis. In ISCPCT, the concentrically arranged cells immunoreact with antibodies for EMA (193). They have the ultrastructural features of perineurial cells.

A defect in the integrity of the perineurial barrier has been proposed as the primary alteration. Delamination of the perineurium and migration of perineurial cells into the endoneurium have been offered as an explanation for the origin of pseudo–onion bulbs (194).

ISCPCT is intraneural; the concentric ensheathing of nerve fibers is a symmetric quality; the ensheathing cells have perineurial cell–like qualities.

In common with descriptions of the clonal chromosomal abnormalities in benign and malignant schwannomas, neurofibromas, meningiomas, and gliomas, monosomy of 22q and deletion of 22q11.2-qter have been described in PSCPCT (193); deletion of 22q11 is cited as a finding favoring neoplasia (193).

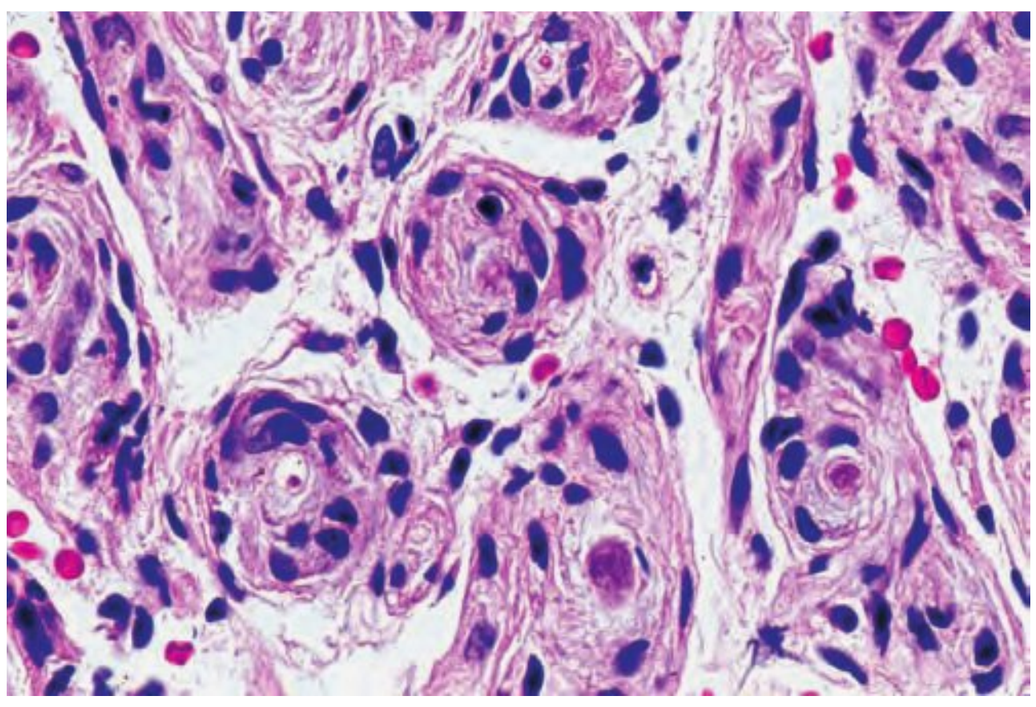

FIGURE 35-52. Perineurioma, intraneural variant. Axons are surrounded by concentric layers of spindle cells; the spindle cells are layered in onionskin patterns. The lesion is intraneural; axial symmetry is preserved.

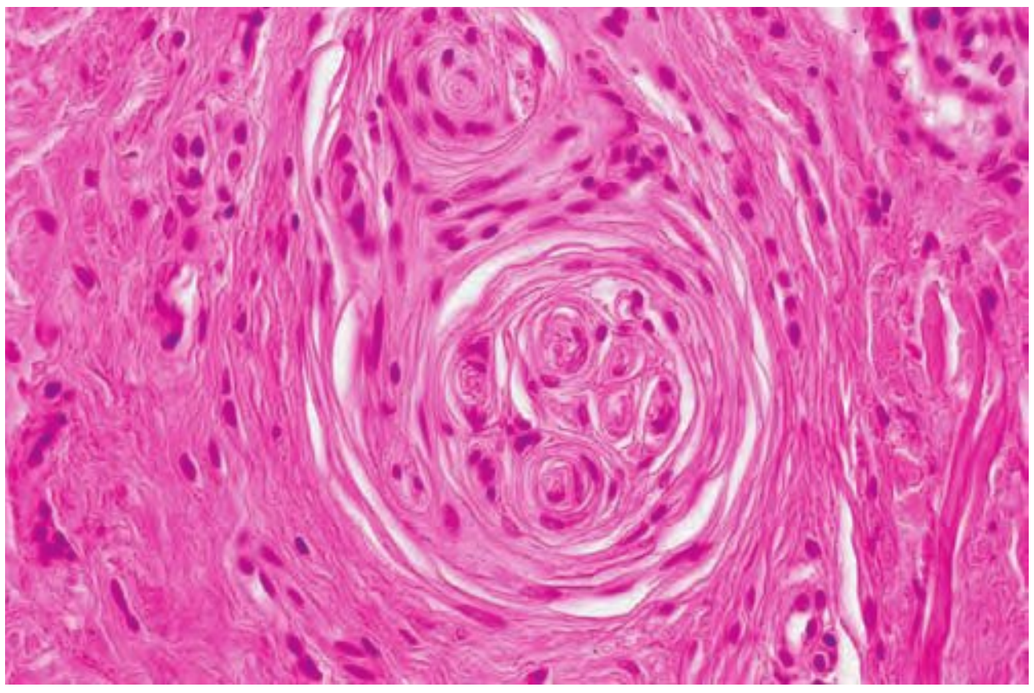

FIGURE 35-53. Hypertrophic neuropathy. In the center of the field, a small nerve is cut in cross section. The perineurium is thickened. Spindle cells are arranged concentrically about nerve fibers (onionskin pattern). Some of the spindle cells blend with the thickened perineurium.

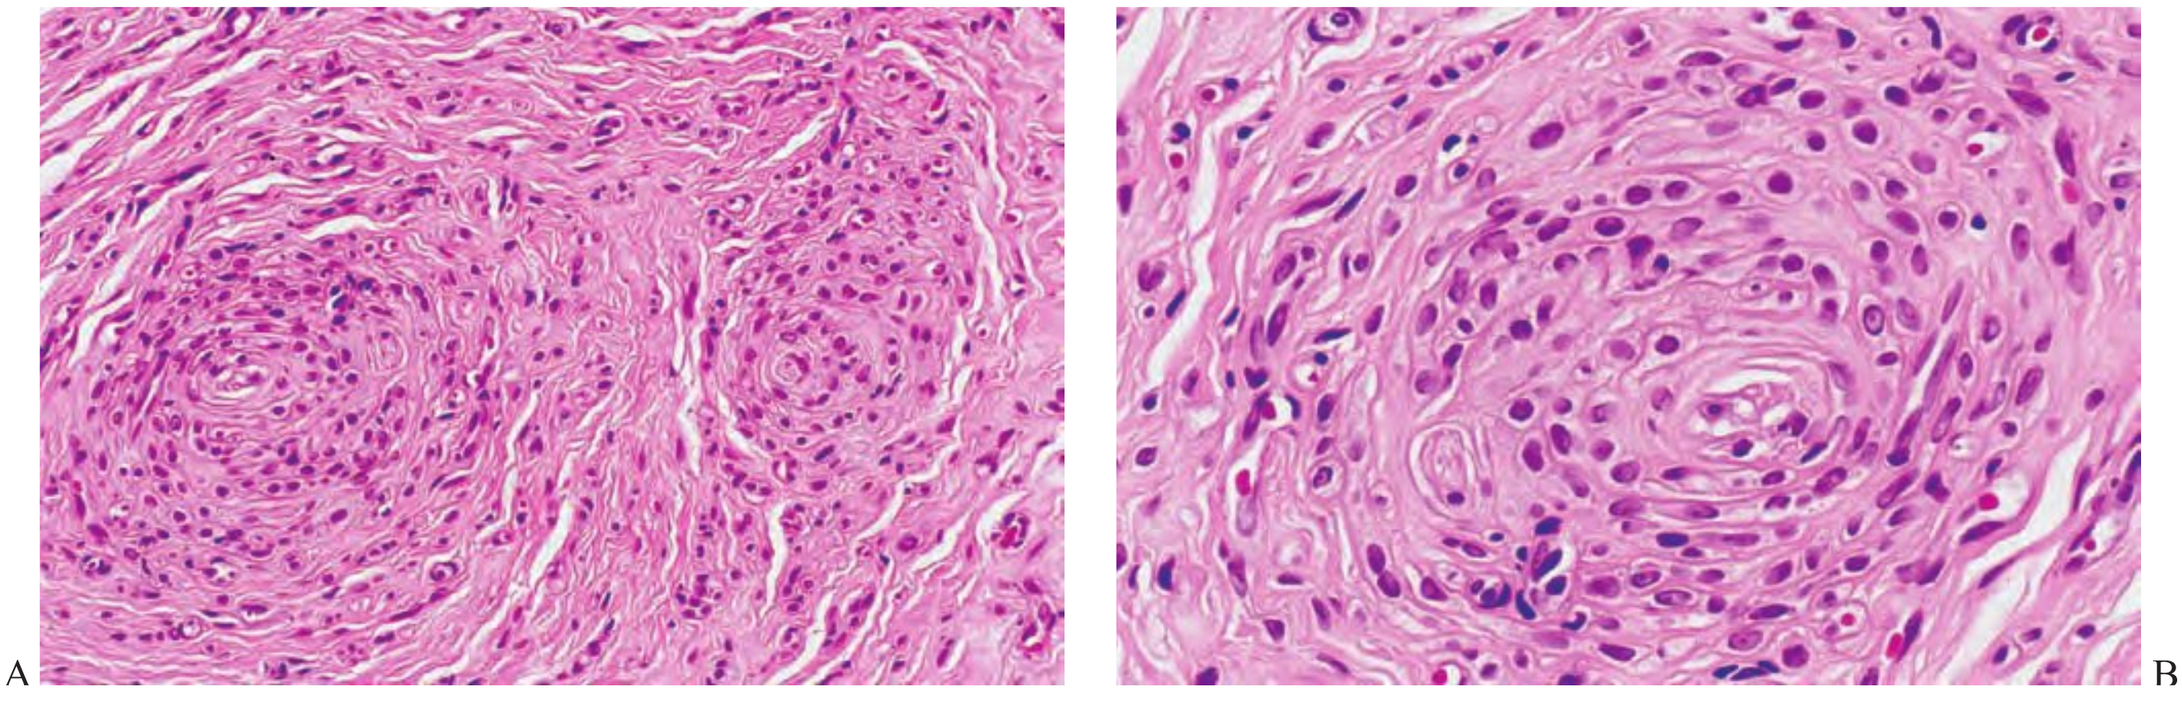
Differential Diagnosis. The *hereditary degenerative neuropathies* are not localized and segmental (196). In addition, they are characterized by concentric hyperplasia of Schwann cells (onion bulbs) (Fig. 35-53).



Pacinian Perineurial Cell Fibroma, Acral Type [Subcutaneous (Sclerosing) or Dermal (Fibrous) Perineurioma, PPCF]

An uncommon, small, benign tumor found mainly on the hands has been characterized as either *fibrous (dermal) perineurioma* (197) or *sclerosing (subcutaneous) perineurioma* (198,199). It should be noted that most, if not all, of the lesions in this category could, in the past, have been easily accommodated in the category of *pacinian neurofibroma*. The pacinian features should be given recognition in the designation; *pacinian perineurial cell fibroma* is a more appropriate designation. The categories of fibrous perineurioma and sclerosing perineurioma express the penchant of some observers for new designations; it additionally expresses a currently popular penchant to group dissimilar lesions in the category of perineurioma.

These small tumors are basically fibrous lesions with focal areas of increased cellularity; they are fibromas whose component cells express the phenotype of perineurial cells. They are additionally distinguished by distribution; they mostly are acral in location. They tend to be oval in outline, with the long axis perpendicular to the surface of the skin. The lesions reported by Skelton et al. had a configuration at low magnification that resembled that of a cutaneous neurofibroma (197). Some of the lesions have ill-defined margins; some are circumscribed, particularly along the deep margin, with cellularity being greatest in the area of circumscription. The cells are spindle shaped or ovoid; they have round nuclei with uniformly distributed chromatin; they have pale or clear cytoplasm. Some of the cells appear to be outlined by a delicate membrane (reticulum?). In areas, the cells form thin, interconnected ribbons (retiform patterns). In some examples, small spindle and round cells form whorls in patterns strongly suggestive of the arrangement of cells in a pacinian corpuscle (199).

An additional variant of "perineurioma," *retiform (reticular) perineurioma* (200), is a soft tissue lesion sharing some of the features of the subcutaneous or dermal variants. It should be obvious that the category of "perineurioma" has been compromised by this willingness to be extravagant in the application of the designation (Fig. 35-54A, B).

The cells are immunoreactive for EMA; claudin-1 has also been identified as a marker for perineurial cells and perineuriomas (186). Some of the tumor cells are immunoreactive for

A B

FIGURE 35-54. Sclerosing perineurial cell nerve sheath tumor (fibrous or sclerosing "perineurioma"). A: In two foci, bland, small cells with pale cytoplasm are arranged in whorls among delicate collagen fibers; the cells are round or slightly spindle shaped; some appear to be isolated by basement membranes. The bland cytologic features are reminiscent of glomus cells. The concentric whorls are reminiscent of cellular arrangements in pacinian corpuscles. In the background, the lesion is sclerotic with small spindle cells among collagen bundles. B: At higher magnification, the cells form whorls about a central nidus. The cytologic features are more epithelioid than perineurial.

muscle-specific actin and CD 99. The tumor cells show ultrastructural features of perineurial cells.

The differential diagnosis includes glomus tumor. In the past, before the era of immunohistochemistry, some lesions of this type must have been characterized as some type of pacinian neurofibroma. PPCF, in certain aspects, such as concentric symmetry about nerve fibers, shares important features with intraneural perineurioma.

NEUROMAS

Neuromas are hyperplasias of axons and associated nerve sheath cells. In most but not all cutaneous neuromas, Schwann cells and axons are arranged in interlacing (tortuous) fascicles. Axons are easily demonstrated with silver impregnation techniques. They are also easily demonstrated with monoclonal antibodies, such as those for neurofilaments, but neither silver impregnation stains nor immunoreactions in themselves distinguish between the innervated fascicles of a neuroma and those of cutaneous neurofibroma.

Neuromas can be divided into four types: extraneural (traumatic or acquired) neuromas; intraneural (isolated and spontaneous, solitary or multiple) neuromas; intraneural (multiple mucosal) neuromas, including those occurring in multiple endocrine neoplasia, type 2b; and abnormalities of sensory receptors.

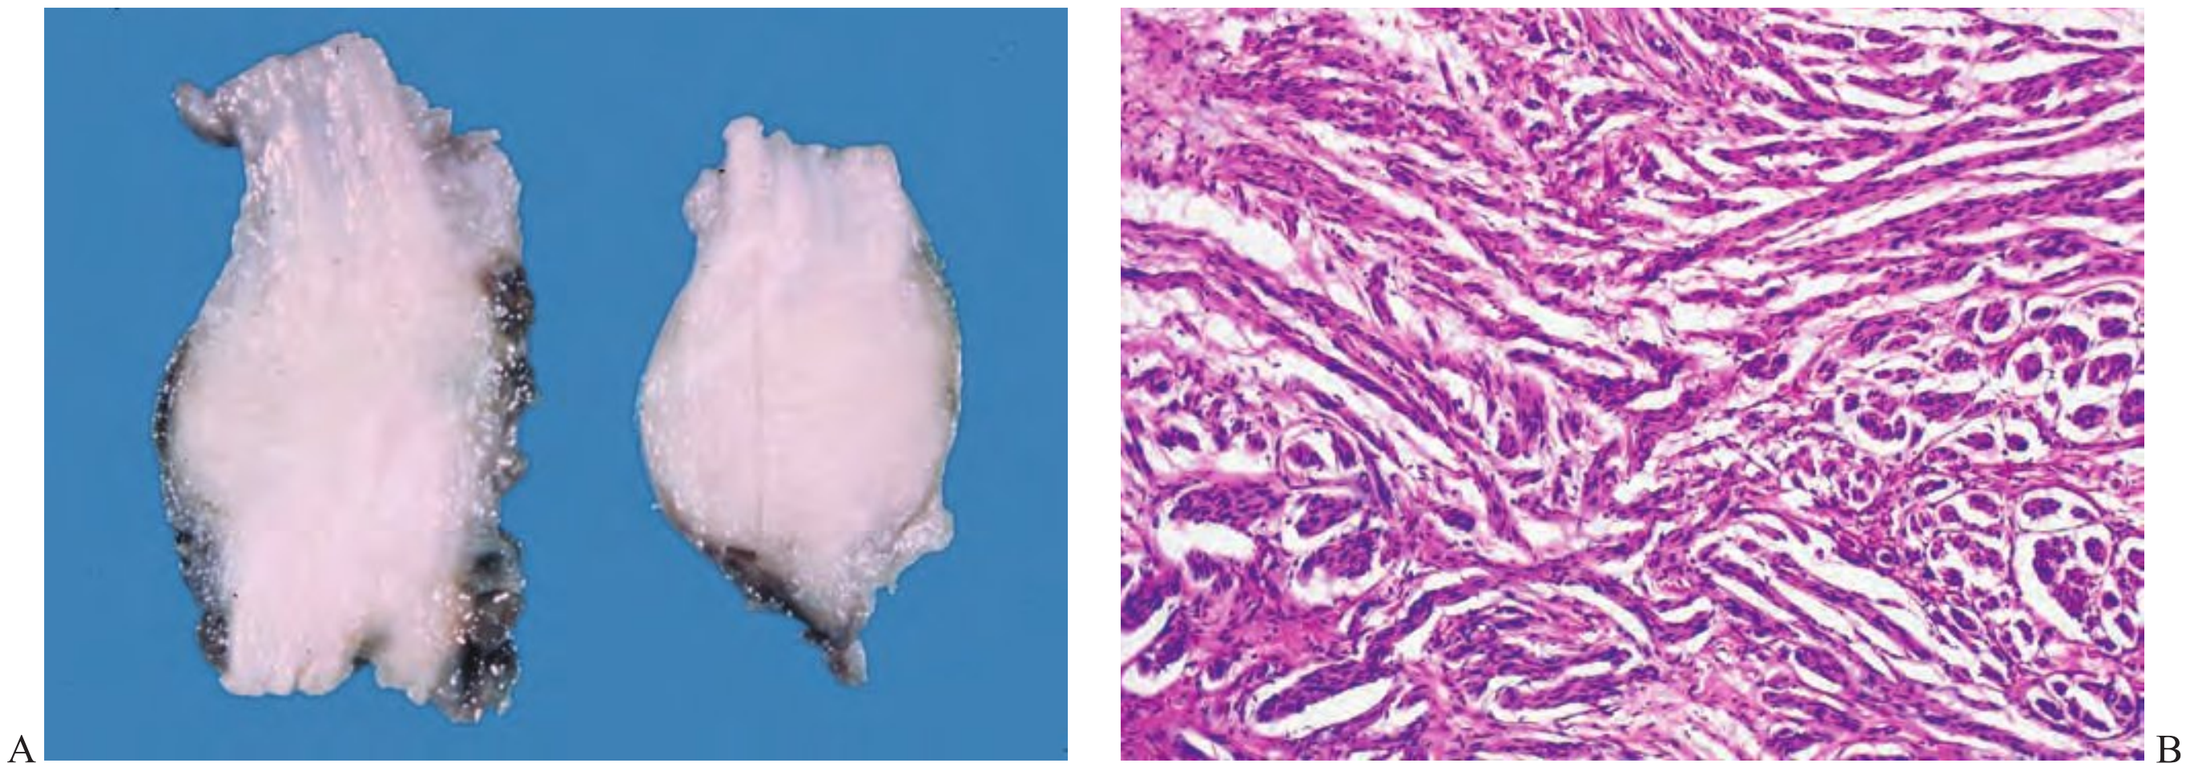
Extraneural Neuromas

Acquired (Traumatic) Neuroma

Traumatic neuromas are usually solitary, firm papules or nodules at the sites of scars after local trauma (Fig. 35-55A); if they extend to the skin surface, they are skin colored or pink. In mature neuromas, a lancinating type of pain might be elicited in response to local pressure.

Histopathology. Interlacing fascicles of regenerating nerve fibers extend from the proximal end of a damaged nerve; they extend through an acquired defect in the perineurium and then into the neighboring mesenchyme. They insinuate in asymmetric patterns among collagen bundles (Fig. 35-55B). With maturation, perineuria form around each of the extraneural fascicles. Tangled fascicles in a scar form the tumor. The distal end of a severed nerve does not contribute significantly to the neuroma. In pretumorous stages, nerve fibers of both the proximal and distal segments of the disrupted nerve show wallerian degeneration (Fig. 35-2).

Rudimentary Supernumerary Digits



These usually are asymptomatic, smooth or verrucous papules. Like supernumerary digits, they usually occur at the base of the ulnar side of the fifth finger. They are assumed to represent the residua of either autoamputation *in utero* or postnatal destruction of a supernumerary digit (201).

Histopathology. Much of what comprises a rudimentary digit shows the histologic pattern of an acquired neuroma. Some of the nerve fibers of the neuroma, among those that are located close to the epidermis, terminate in closely spaced Meissner corpuscles (201).

Intraneural Neuromas

Palisaded and Encapsulated (Sporadic and Spontaneous) Neuroma

Palisaded and encapsulated (sporadic and spontaneous) neuroma (PEN) is a firm, rubbery, skin-colored or pink papule or nodule (202–205). It commonly affects the "butterfly area" of

A B

FIGURE 35-55. Extraneural (traumatic neuroma). A: This neuroma has been bisected along the long axis of the specimen. The neuroma is centrally placed; the cut surface in the region of the neuroma is homogeneous and white. Proximal and distal portions of the involved nerve are attached to the tumor. B: Fascicles of Schwann cells are arranged haphazardly in a fibrous matrix. A thin perineurium has formed at the periphery of some of the fascicles; the thin perineuria are separated from the respective Schwann cell fascicles by a clear space.

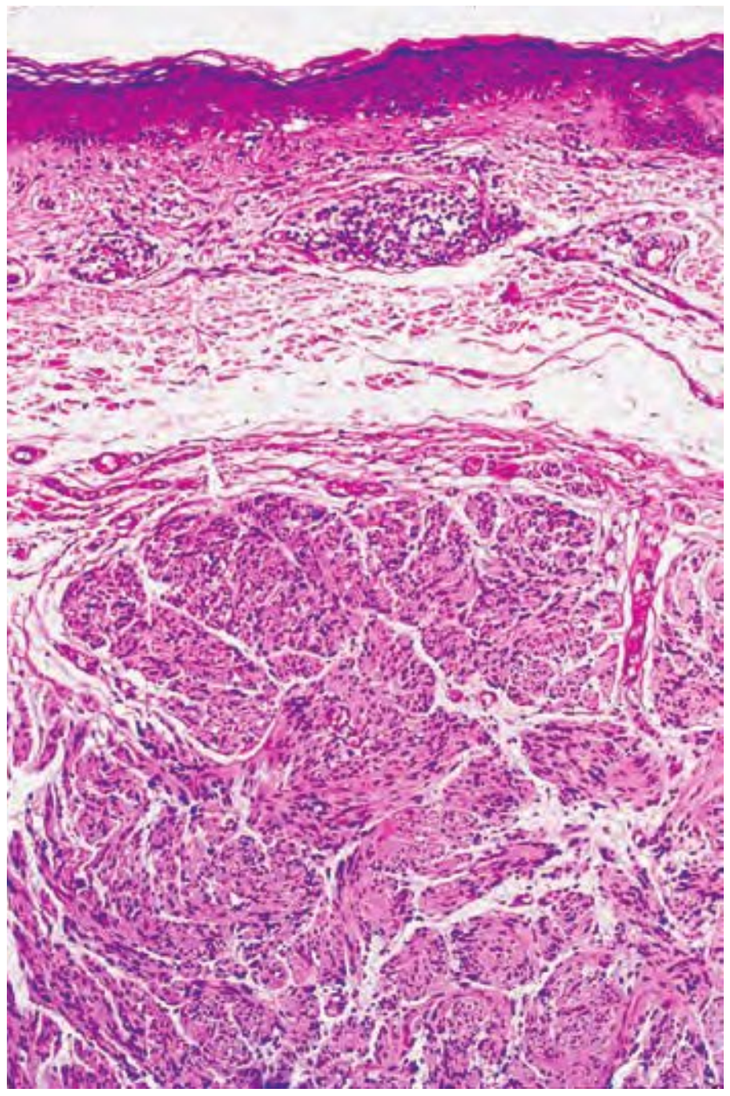


FIGURE 35-56. Palisaded and encapsulated (intraneural) neuroma. The lesion is encapsulated. Fascicles of Schwann cells are arranged in interlacing patterns; the fascicles are supported by a scanty clear or myxoid matrix. Focally, within some of the fascicles, the nuclei of the Schwann cells form ill-defined palisades.

the face. Solitary examples may arise in either early childhood or adulthood (mean age, 45.5 years). In adulthood, sporadic neuromas can be multiple. Both solitary and multiple cutaneous intraneural neuromas usually are asymptomatic. In neither presentation are the lesions associated with the stigmata of MEN. During biopsy, a lesion of PEN often is enucleated from its dermal bed and then submitted to the pathologist with little, if any, surrounding skin.

Histopathology. PEN is a bulbous expansion of a peripheral nerve, appearing as a well-circumscribed, ovoid or rounded nodule in the dermis (Fig. 35-56). Intraneurally, Schwann cells form uniform, broad (often consisting of as many as four or five cell layers), interlacing fascicles that are spaced in a clear or mucinous matrix (Fig. 35-57). Nuclear palisades are ill defined. Nuclear pleomorphism and mitoses are not features. PEN is confined by a thin, expanded perineurial sheath. In many examples, the sheath is attenuated along the surface that approximates the epidermis. This variation might be a consequence of the anatomy of a nerve; the perineurial sheath is open ended in this site. At some site along the periphery, it is usually possible to identify, as in-continuity extensions, tumor within the endoneurial space of small neighboring nerves.

The fascicles, with silver stains (Fig. 35-58) (204) and with immunoreactions for both neuron-specific enolase (Fig. 35-59) and neural filaments, are rich in axons. (205). A weak,

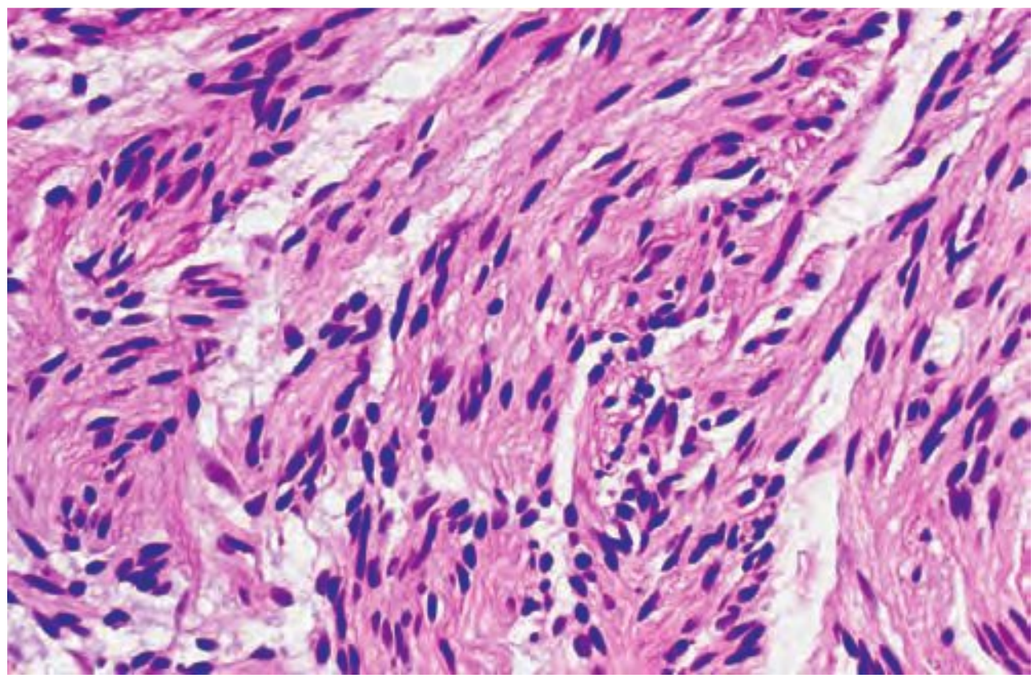

FIGURE 35-57. Palisaded and encapsulated (intraneural) neuroma. The Schwann cells form broad fascicles, which are loosely spaced in a myxoid matrix. There are scattered nuclear palisades. In cross section, the small vacuoles in the cytoplasm of some of the cells are of the type that is produced by nonmyelinated axons. Myelinated fibers also are commonly found in the fascicles.

sometimes discontinuous, reaction for EMA is a feature in the capsule of PEN (205). The presence of axons sets PEN apart from schwannoma, including all the variants. In PEN, axon representation in the fascicles is variable from lesion to lesion (204). Axon density, as evaluated by an immunoreaction to peripherin, may not be comparable to the relative density of axons with a Bodian stain (206).

Intraneural Plexiform Neuroma

Plexiform neuroma is an uncommon intraneural tumor of the dermis and subcutis. It has been characterized as a variant of PEN (33), but some examples might represent incipient plexiform schwannoma.

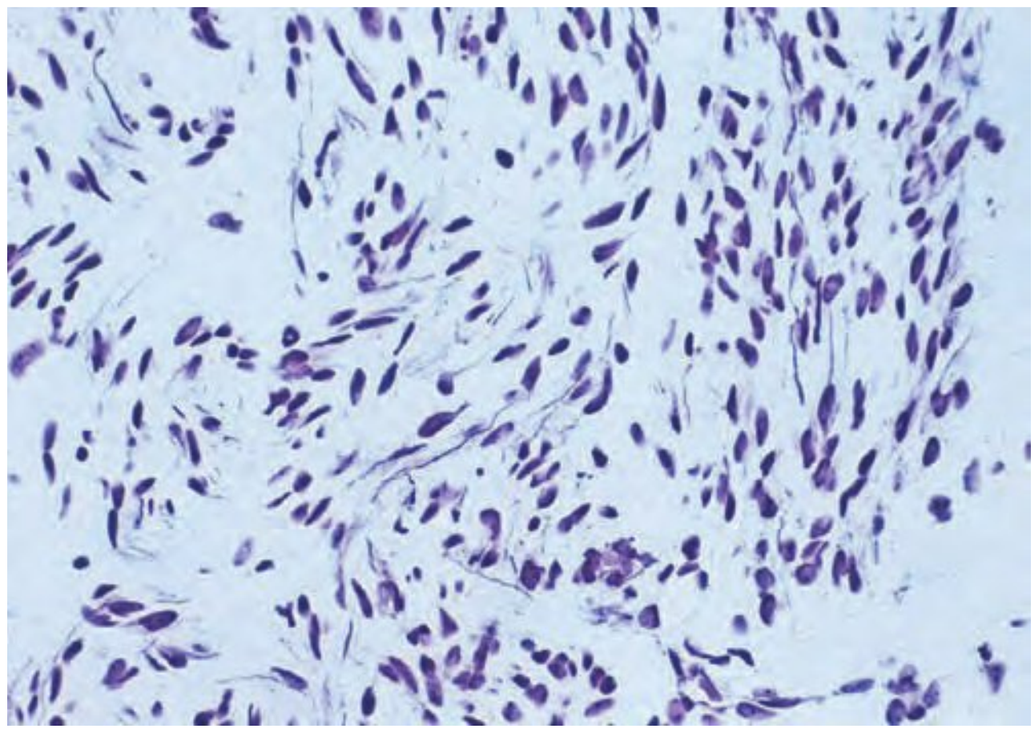

FIGURE 35-58. Palisaded and encapsulated (intraneural) neuroma (Bodian silver stain). The lesion is axon rich.

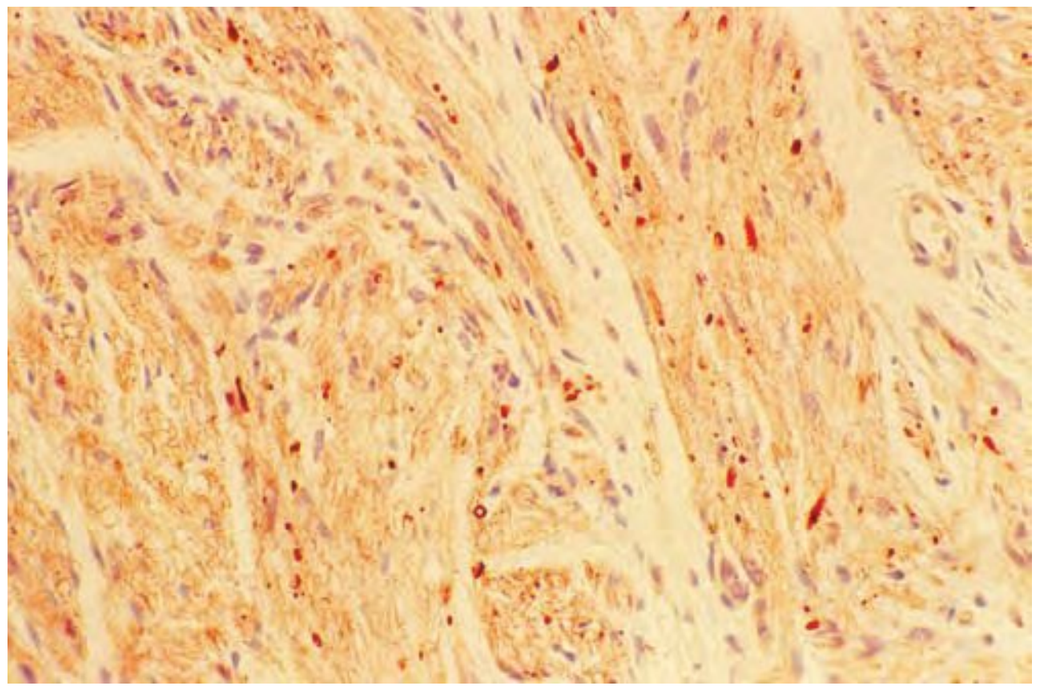

FIGURE 35-59. Palisaded and encapsulated (intraneural) neuroma (immunohistochemical reaction for neuron-specific enolase). With a reaction for neuron-specific enolase, axons are represented in large part as puncta.

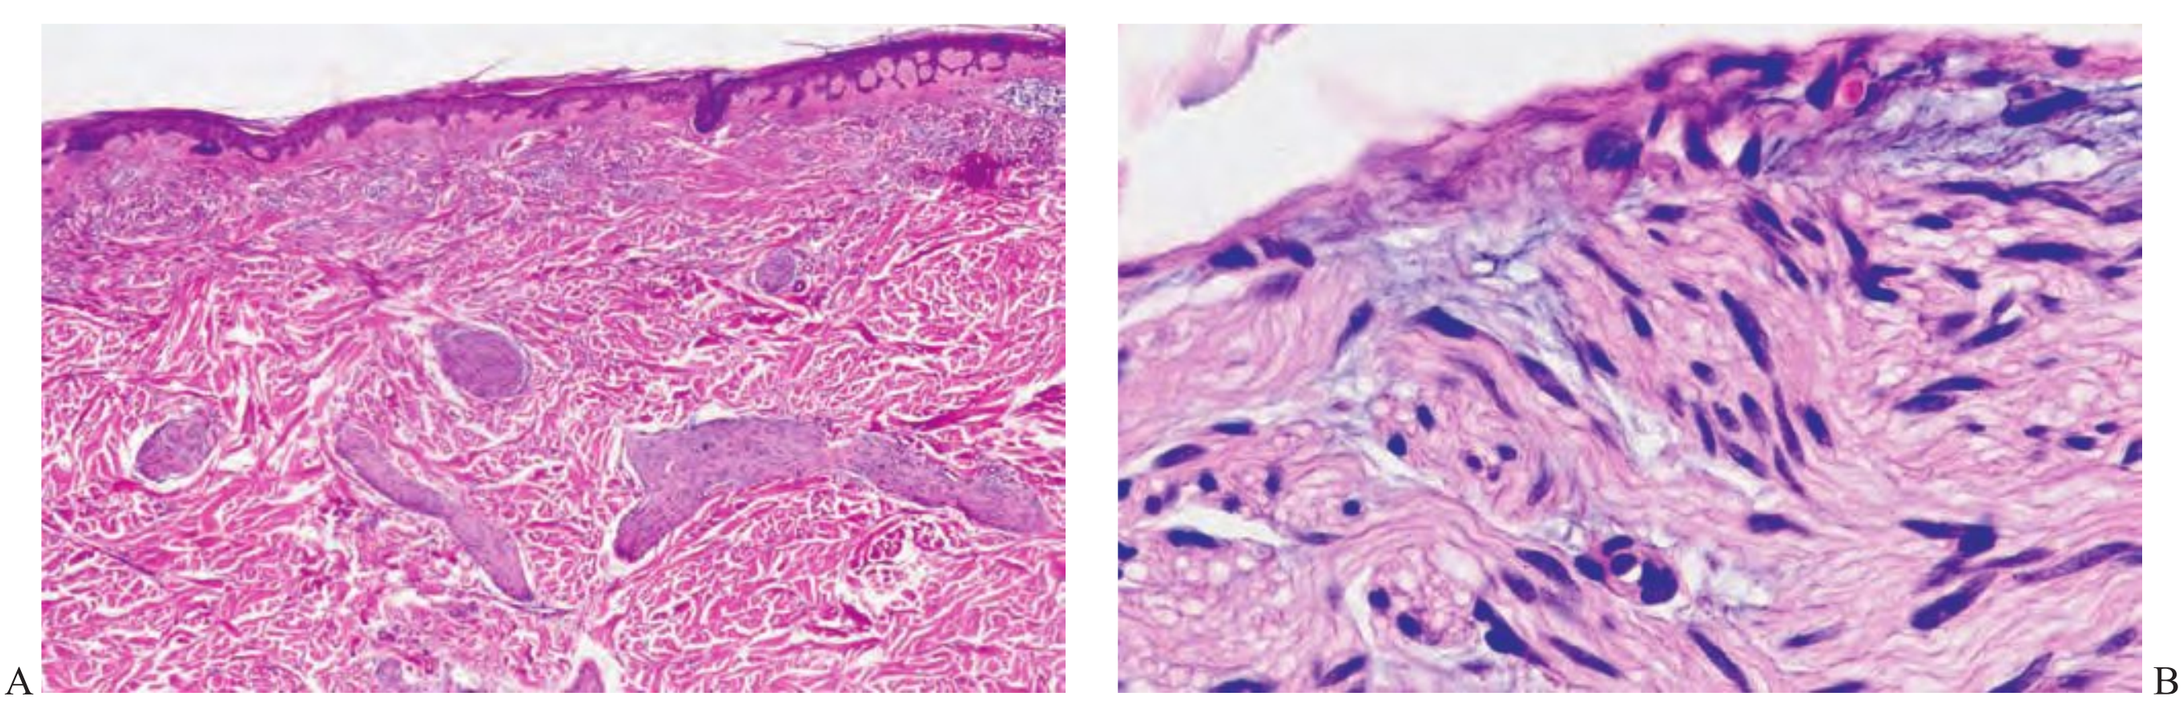
Histopathology. Nodules and broad cords are circumscribed by the perineurium of the involved segment of nerve. The internal patterns of all the nodules and broad cords are basically those of PEN.

Clustered, dilated vessels with sclerotic walls and subendothelial collections of foam cells are features in common with schwannoma.

In contrast to fully developed plexiform schwannoma, plexiform neuroma, with both silver stains and immunoreactions for neural filaments, is rich in axons.

Mucosal Neuroma Syndrome

Multiple endocrine neoplasia, type 2b, first described in 1968 (34), is the only one of three types (i.e., types 1, 2, and 2b) to show mucosal and cutaneous neuromas (*mucosal neuroma syndrome* [MNS]). *Multiple* (*intraneural*) *neuromas*, many of which are periorificial, are often its earliest manifestation. First appearing in early childhood, they are seen as small nodules, often in large numbers, on the mucosa of the lips, tongue, oral cavity (207,208), the conjunctiva, and the sclera. Some patients show small, nodular neuromas, usually only in small numbers, on the skin of the face (208). Lesions occasionally are represented in large numbers on and about the nose and on the eyelids. Quite frequently, the lips are thick, fleshy, and protruding (209). Marfanoid features and skeletal abnormalities may be present (209).



MEN, type 2b, may be inherited as an autosomal dominant trait (209). *Medullary thyroid carcinoma*, *bilateral pheochromocytoma* (208), and *diffuse alimentary tract ganglioneuromatosis* are associated disorders of variable frequency (210).

Histopathology. The neuromas of MNS are intraneural and plexiform. Characteristically, the involved nerves are slender. Many are uniform in diameter, but bulbous expansions also are a feature. Within the confines of the perineurium, fascicles that are fairly uniform in diameter and composed of two or more nerve fibers are interlaced in asymmetric patterns; they are closely spaced back to back in a clear or mucinous (endoneurial) matrix. The fascicles of nerve fibers in the mucosal and cutaneous lesions are richly innervated.

Multiple mucocutaneous neuromas may be encountered in the absence of other stigmata of MEN (211,212).

Linear cutaneous neuroma (*dermatoneurie en strie*), a sporadic variant of an intraneural neuroma, is manifested clinically as a group of raised linearities (213,214). It differs from the mucosal neuroma syndrome in clinical presentation and in the size of the altered nerves in the dermis. It has been proposed that linear cutaneous neuromas are a manifestation of MEN, type 2b (213).

Histologically, nerves of the dermis and subcutis are slightly enlarged and hypercellular (Fig. 35-60A, B). Internally, Schwann cells are increased in number, and nerve fibers are

A B

FIGURE 35-60. Linear (intraneural) neuroma (hyperneury). A: Nerves of the dermis are enlarged; they show Schwann cell hyperplasia; the cross-sectional diameter is increased. B: At higher magnification, interlacing fascicles of innervated Schwann cells form asymmetric patterns; they are confined by a perineurium.

tortuous. This combination of features results in loss of axial symmetry in the affected segments (Fig. 35-60B).

Ensheathed neuroma is a dermal microscopic lesion. Hypercellular nerves of the dermis are ensheathed by benign squamous epithelium (215). This type of reaction occasionally is encountered in the site of a recent biopsy.

Special Stains (Applicable to All Neuromas). With Luxol-fast blue stain, some of the fibers in all forms of neuroma may be myelinated.

Electron Microscopy (Applicable to All Neuromas). Ultrastructurally, fascicles that are composed of both myelinated and nonmyelinated nerve fibers are the chief feature of both extraneural (214) and intraneural neuromas. Those of a mature, extraneural neuroma are ensheathed by multiple lamina of perineurial cells (216). Generally, perineurial cells do not outline the individual, asymmetric fascicles of intraneural neuromas.

Histogenesis (Applicable to All Neuromas). The immunohistochemical profile is positive for S100 protein, collagen type IV, vimentin, and NSE and neural filaments.

In mature traumatic neuroma, the majority of the individual nerve fascicles are surrounded by cells that are immunoreactive for EMA, indicating perineurial differentiation (203). Collagens type I and III are deposited among the fascicles. The nerve fibers of the newly formed fascicles are supported by a matrix that is rich in acid mucopolysaccharides (203).

In spontaneous intraneural neuromas, such as PEN and those of the mucosal neuroma syndrome, the local proliferation of axons within the confines of the perineurium has not been adequately explained.

Pacinian Neuroma

Pacinian neuroma is an occult, painful lesion (217). It is found in the same anatomic sites as pacinian corpuscles (217).

Histopathology. Pacinian corpuscles form a localized cluster but are otherwise unremarkable. The corpuscles may vary in size.

If a cluster of corpuscles is continuous with an extraneural neuroma, it would be difficult to attribute the symptomatology to the cluster of corpuscles.

Patterns in which cells and fibers are concentrically layered are common in the setting of nerve sheath tumors. Some examples of nerve sheath tumors with such patterns have been characterized as "pacinian neurofibroma." Some of these lesions are being characterized as "fibrous" or "sclerosing" perineurioma (197,198).

SMALL BLUE ROUND CELL TUMORS

This category includes *primary, cutaneous, small-cell undifferentiated carcinoma* (*Merkel cell tumor*); *primitive neuroectodermal tumors* (PNETs), such as *Ewing's sarcoma* and *neuroepithelioma*; *neuroblastoma*; *primitive mesenchymal tumors*, such as *small-cell osteosarcoma* and *embryonal* and *alveolar rhabdomyosarcoma*; rare *melanomas of infancy* that arise in the setting of *giant congenital nevus* (*melanoblastoma of infancy*) (218); and *melanotic neuroectodermal tumor of infancy* (219). On hematoxylin-eosin–stained sections, the tumor cells of all these lesions have few distinguishing characteristics, other than scanty cytoplasm and closely spaced, "dark" nuclei. The primitive patterns provide a challenge in differential diagnosis; lesions with these characteristics have been grouped as "primitive neuroectodermal tumors." In this category, some of the lesions share certain basic features, but mostly they are distinguished by patterns of divergent differentiation as manifested morphologically or as demonstrated immunohistochemically (220). Small blue round cell tumors are more common in soft tissue or bone (221,222). In the skin, cutaneous small (Merkel) cell undifferentiated carcinoma is most frequent.

Cutaneous Small (Merkel) Cell Undifferentiated Carcinoma

Cutaneous small-cell undifferentiated carcinoma (*CSCUC*; *Merkel cell*, *neuroendocrine*, or *trabecular carcinoma*) (223–231) is an uncommon tumor. It mostly occurs as a solitary nodule, usually on the head or on the extremities (229). Multiple lesions have been observed, either localized to one area or widely distributed. The tumors are usually few in number but occasionally are multitudinous. CSCUCs have a high rate of recurrence and metastasis (230).

The lesions of CSCUC are firm and red-pink. They usually are nonulcerated and range in size from 0.8 to 4.0 cm in diameter.

Histopathology. Tumor cells with scanty cytoplasm and round or irregular nuclei are closely spaced in trabecular patterns and sheets (Figs. 35-61 and 35-62) (231,232); less commonly, they are arranged in ribbons and festoons. Pseudorosettes are an

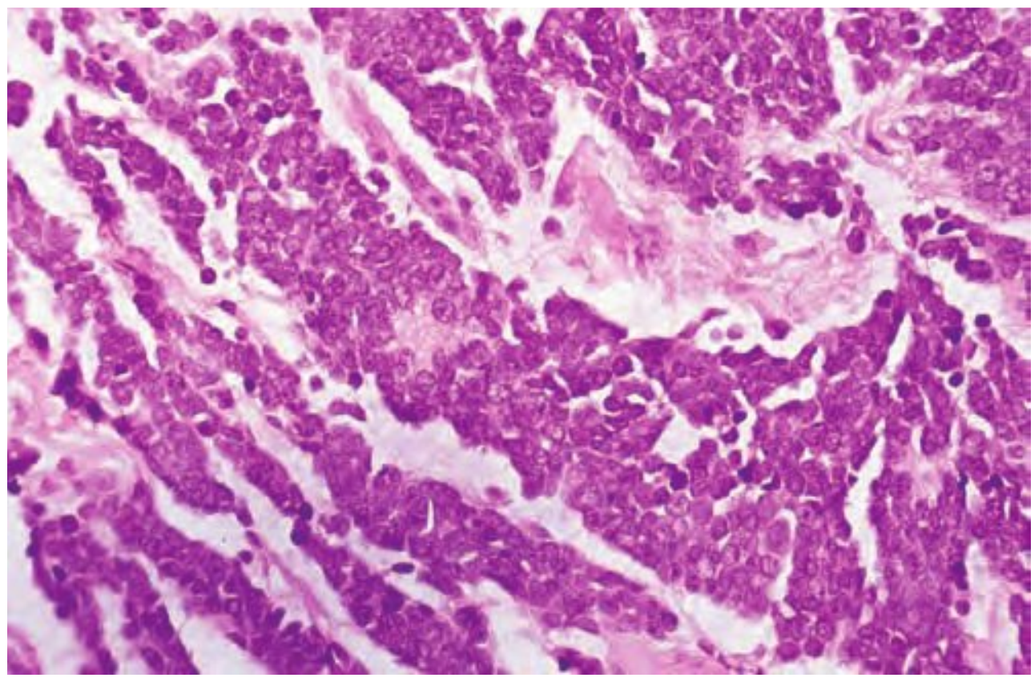


FIGURE 35-61. Merkel cell tumor. Atypical but uniform small blue cells form fascicles that vary in size. The cells have scanty cytoplasm; nuclei are crowded. Chromatin is delicate but uniformly distributed. Nucleoli are inconspicuous. There are scattered pyknotic nuclei. Each fascicle is outlined by a mucinous sheath that abuts on a fibrous matrix.

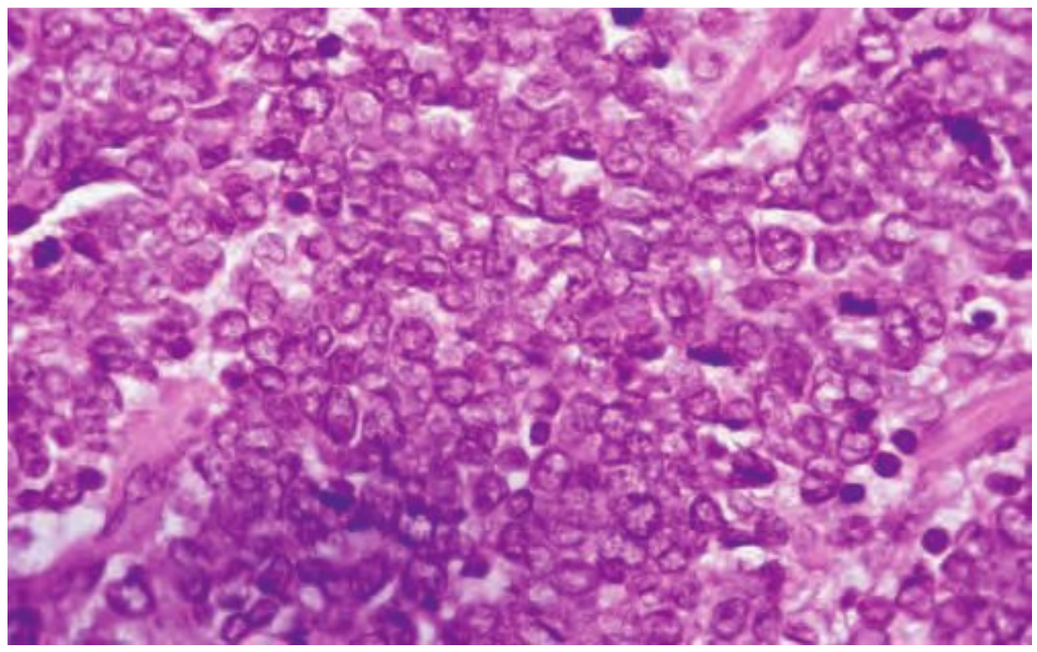

FIGURE 35-62. Merkel cell tumor. In this field, there is some central clearing of nuclear chromatin. The nuclei contain one or several nucleoli. There are scattered mitotic figures.

occasional feature (233). Nuclear chromatin often is dense and uniformly distributed. In some examples, nuclei, focally or uniformly, show margination of chromatin. Nucleoli generally are inconspicuous. Nuclear molding may be a feature. Mitoses and nuclear fragments are regular features (223). For some CSCUC, the nests of cells are supported by scant, delicate, and paucicellular stroma. Lymphoid infiltrates are common at the margin and focally in the stroma. Contact with the epidermis is rare, but if a lesion invades the epidermis, the patterns may include intraepidermal collections of tumor cells (234,235). Patterns of keratinocytic dysplasia in the overlying epidermis and even islands of squamous cell differentiation in the dermal nests are uncommon features (226,229,236). At the interface between the tumor and the epidermis and at the margins of the tumor, dilated, thin-walled vessels commonly contain tumor cells.

The immunohistochemical profile is positive for NSE (238), protein gene product, chromogranins, Ber-EP4 (237), and CD57 (239). A single punctate zone of cytoplasmic immunoreactivity for cytokeratins, especially CK20, or neurofilaments is most characteristic (240). EMA is expressed in 75% to 80% of CSCUC (241). A reaction for CK20 has been offered as a finding against the diagnosis of metastatic small-cell carcinoma of the lung (241). Thyroid transcription factor-1 (TTF-1) is specific for pulmonary small-cell undifferentiated carcinoma of the lung (PSCUC) in situations in which the differential diagnosis includes PSCUC and CSCUC (242).

Ultrastructurally, cytoplasmic, membrane-bound, round, dense-core granules of neuroendocrine type measure 100 to 200 nm in diameter (225,233). Perinuclear bundles or whorls of intermediate filaments that are 7 to 10 nm wide (243) and small desmosomes are regularly present. Tonofilaments attached to the desmosomes have been only found in a few cases (244).

Histogenesis. The origin of the CSCUC is controversial. Divergent differentiation is expressed in neuroendocrine, squamous, adnexal (241,245), and melanocytic phenotypes (246).

CSCUC shares genetic changes with tumors of neural crest origin, such as melanoma, pheochromocytoma, and neuroblastoma (247).

Differential Diagnosis. Cutaneous metastases from atypical carcinoids or small-cell undifferentiated carcinoma (oat cell carcinoma) of the lung may be confused with primary CSCUC (248).

The nuclear characteristics of the cells of CSCUC differ from those of the cells of most lymphomas. Immunohistochemical studies are an aid in the differential diagnosis. If lymphoma remains a problem, even in the face of a negative reaction for leukocyte common antigen, reactions for the antigens L-26 and CD3 may provide more definitive information (249).

Primary small-cell undifferentiated carcinomas have been observed in most organ systems. They are not peculiar to the skin, but those in the skin often have distinguishing characteristics. Small-cell undifferentiated carcinomas of both the skin and lung are neuroendocrine carcinomas, but the former designation (i.e., small-cell undifferentiated carcinoma) has a greater degree of specificity; it gives recognition to basic patterns that are expressed in distinctive primary neoplasms in a variety of organ systems. The nuclei of PSCUC are irregular; they often have a pointed extremity. Patterns of squamous cell and glandular differentiation are variable features of PSCUC. Clinicopathologic correlations are an aid in the differential diagnosis.

The primary basaloid carcinomas and undifferentiated carcinomas of the skin appendages, including lymphoepithelial variants, also must be considered in the differential diagnosis (250).

Tumors that are histologically similar to CSCUC have been observed as isolated lesions in lymph nodes (251).

Peripheral Neuroblastoma

Neuroblastoma, as a primary soft tissue tumor, is a diagnosis of exclusion. The skin is a most unlikely site. In infancy, the differential diagnosis of undifferentiated, small-cell malignancies of the skin and soft tissue includes metastatic neuroblastoma. A thorough workup to rule out a metastasis from an occult site, such as the adrenal gland or paravertebral ganglia, is required. The clinical features of metastatic neuroblastoma in infancy include the patterns of blueberry muffin baby (252) and blanching subcutaneous nodules (253). Adult neuroblastomas have been documented (254,255).

Histopathology. Neuroblastomas are undifferentiated, small-cell malignancies. Solid sheets of undifferentiated cells often are the preponderant patterns, but septation, neuropil, differentiation as manifested by variation in cytologic features, and Homer Wright rosettes (often characterized as pseudorosettes), if identified, are an aid in diagnosis. Neuroblasts are distinguished by the formation of cell processes. The designation *neuropil* gives recognition to a matrix of cytoplasmic processes, including those of neurons, Schwann cells, and glial cells. It

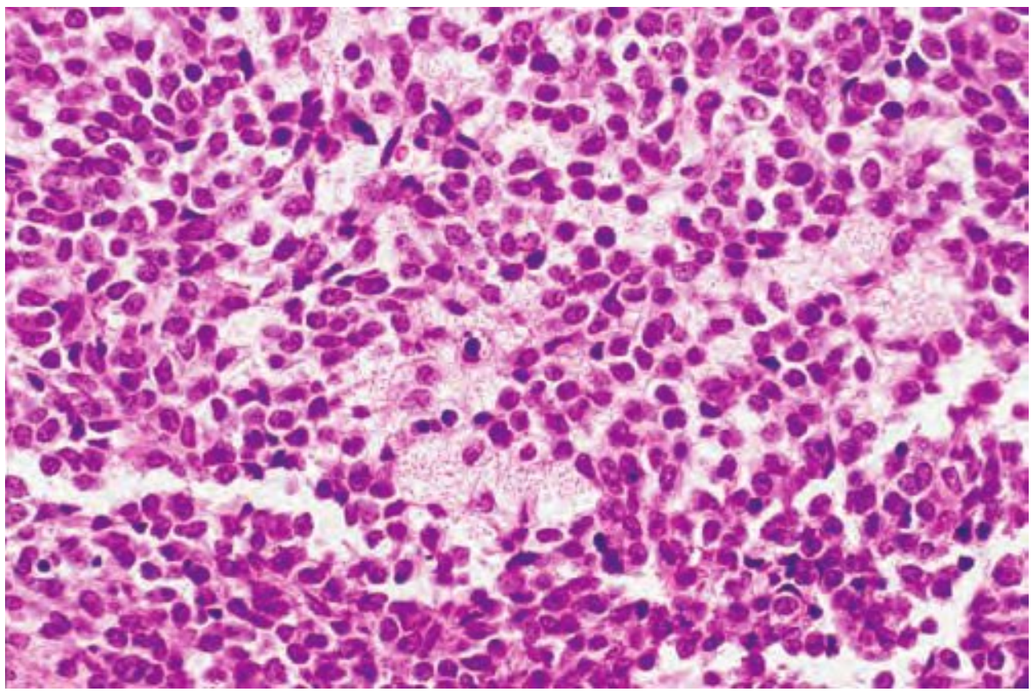

FIGURE 35-63. Differentiating neuroblastoma. Uniform, atypical small blue cells form sheets. In areas, the diffuse patterns are interrupted by pale, rounded collections of delicate fibrils (neuropil).

gives recognition to patterns of "matrical" differentiation in neuroectodermal tumors (Fig. 35-63). Larger cells with slightly eccentric, round nuclei, prominent central nucleoli, and marginated chromatin provide evidence of neuronal differentiation (Fig. 35-64); such cells, when identified, usually are sprinkled about among the more primitive cells.

Depending on the degree of differentiation, the immunohistochemical profile is positive for neural filaments, NSE, S100 protein, and synaptophysin. Other neuroendocrine markers may be positive (256).

Metastatic neuroblastoma possesses an innate tendency for maturation (differentiation). As a consequence, metastases from a neuroblastoma may present as immature or mature ganglioneuroma (257). Problems are complicated by the rare case in which a primary neuroblastoma of the adrenal gland, with distant metastases, undergoes complete regression in the primary site.

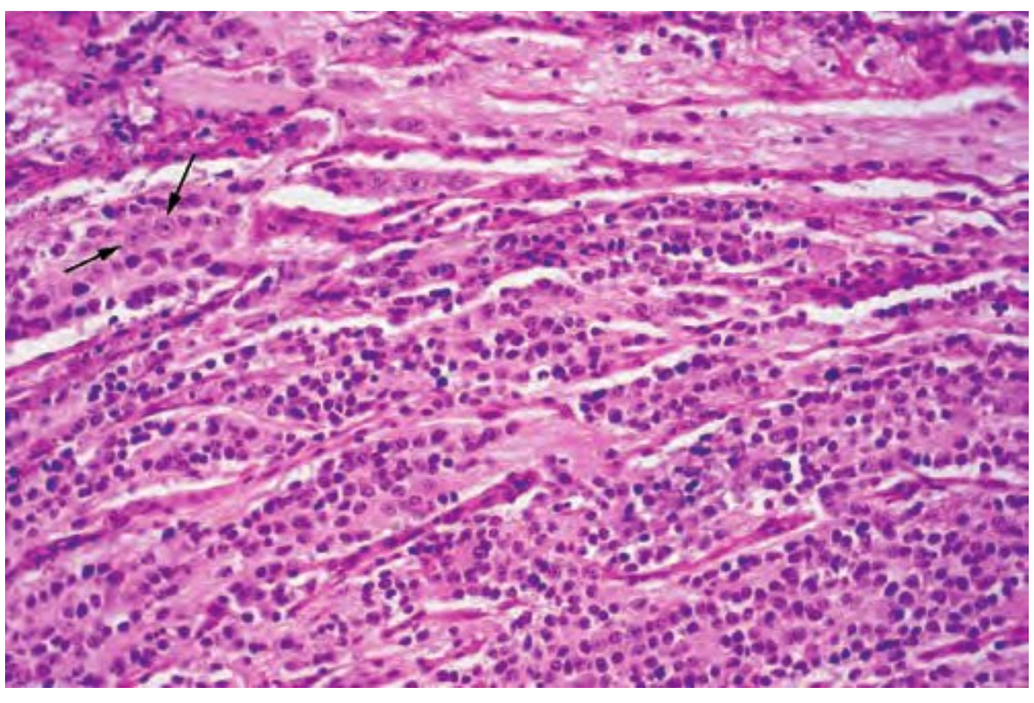

FIGURE 35-64. Differentiating neuroblastoma. The lesion is partitioned by delicate fibrous septa. Tumor cells are clustered among the septa; the hypocellular, fibrillated matrix among the cells is neuropil. Scattered cells have plump, round nuclei with a central nucleolus (arrow); these distinctive cells are differentiating ganglion cells.

Ganglioneuroma

Ganglioneuroma is exceedingly uncommon in the skin (258–260). Rare examples appear to be in the nature of heterotopias (260). Other examples may represent divergent differentiation of phenotypically pluripotent neurocristic cells. Still others may represent metastatic neuroblastoma that has matured into a ganglioneuroma.

Histopathology. The basic pattern of a ganglioneuroma is that of a neuroma in which characteristic ganglion cells are either clustered or individually isolated (260). Small, primary ganglioneuromas of the skin may be characterized by numerous, mature ganglion cells and an inconspicuous background of neurosustentacular cells (261). A desmoplastic variant has been reported (262).

Histogenesis. Schwann cells are reactive with immunoperoxidase stain for S100 protein (263). Schwann cell fascicles of a ganglioneuroma, like those of all neuromas, are innervated. Ganglion cells are reactive for NSE and chromogranins. Immaturity, as manifested by foci of small, dark cells, spongy neuropil, and lymphoid infiltrates, signals the need for additional studies to rule out a differentiating metastatic neuroblastoma. In immature ganglioneuroma, the neurons may not be associated with satellite cells.

PRIMITIVE NEUROECTODERMAL TUMORS

Ewing's Sarcoma and Peripheral Neuroepithelioma

Originally, the designation, *primitive neuroectodermal tumor* served as a taxonomic convenience when confronted with the histologic pattern of a poorly differentiated, small, round cell neoplasm showing some evidence of neuroectodermal differentiation. The designation has been attributed to A. P. Stout, but there is no mention of this designation in the commonly cited reference. The designation has supplanted that of neuroepithelioma, acquiring some degree of specificity.

Ewing's sarcoma (EWS) and *peripheral neuroepithelioma* are PNETs; they are members of the category of small, round cell tumors. EWS, including an atypical variant (264), is a rare malignant neoplasm of bone and soft tissue. *Peripheral neuroepithelioma* (PNE) (the "primitive neuroectodermal tumor") generally is a tumor of the deep soft tissue, with rare examples in bone. It has been reported in internal viscera. *Askin's tumor* of the chest wall is also cited as an example of PNET. Some examples of PNETs have had their origin in a peripheral nerve (265) or have been a component of MPNST (malignant schwannoma) (114).

Histopathology. Primitive neuroectodermal tumors are tumors composed of small blue cells (266). In Ewing's category, the cells tend to be glycogen rich. Nuclear characteristics are uniform;

chromatin patterns tend to be open (266). In the neuroepithelioma category, the cells focally form pseudorosettes.

Histogenesis. Useful but variably positive reactions include NSE, CD57, and synaptophysin. In EWS and peripheral neuroepithelioma, tumor cells are immunoreactive for CD-99 (MIC2) (267–270); the reaction is sensitive but not specific; a positive reaction provides a distinction between PNET (positive) and neuroblastoma (negative).

Both EWS and PNE are characterized by the presence of chromosomal translocation t(11;22) (q24;q12), and the EWS gene has recently been identified at the breakpoint on chromosome 22 (271).

Differential Diagnosis. Neuroepithelioma-like patterns may be encountered as a regional variation in MPNST (114) and in the setting of cutaneous small-cell undifferentiated carcinoma (233).

Melanotic Neuroectodermal Tumor of Infancy

Melanotic neuroectodermal tumor of infancy affects the tissues of the oral cavity but also may be found in other sites (272–275). Expressions of neural and epithelial markers, melanogenesis, and occasional glial and rhabdomyoblastic differentiation are variably represented. The patterns of melanotic neuroectodermal tumor of infancy have been compared to those of the retina at 5 weeks' gestation (275).

HETEROTOPIAS

Cephalic brain–like heterotopias (CBHs) (nasal gliomas) are found most commonly in the skin near the root of the nose (276–282), but they may be intranasal (40%) or extranasal (60%). Extranasal CBHs, ranging in size from 1 to 5 cm, are smooth, firm, noncompressible, and skin colored. They do not pulsate or transilluminate. On the external surface of the nose, they usually are not midline. Intranasally, CBHs present as a firm, smooth, red-to-purple protrusion and usually measure 2 to 3 cm in diameter. They may resemble a hemangioma. Some examples are both intranasal and extranasal, with the two components being connected through a defect in the nasal bone (277). Other common bony defects that are associated with CBH involve the fonticulus frontalis, the cribriform plate, and the space between nasal bone and cartilage (277). Some examples are connected by a fibrous cord to the dura. Other sites of involvement include the scalp, oropharynx, nasopharynx, tongue, and subcutaneous tissue overlying T-12 (278).

Histopathology. CBHs are not encapsulated. They are disorganized and commonly show admixtures of glial tissue (Fig. 35-65), randomly distributed, mature neurons, increased vascularity, focal calcification, and fibrous tissue (281). Strands of neural tissue and fibrous tissue are interwoven (280). Fibrillary and gemistocytic astrocytes, activated oligodendrocytes, and giant astrocytes are variably represented. Astrocytes are the most conspicuous cellular component. In some examples, the astrocytic component may resemble a low-grade astrocytoma. Neurons usually are small; for some examples, they are absent, but, for others, they are focally prominent (281). Ependymal and retinal epithelium and even choroid plexus–like components have been observed (282). Focal areas of oligodendroglial differentiation may be prominent; in such areas, the neuropil may be immunoreactive for both NSE and synaptophysin. The degree of differentiation in these heterotopias may reflect the age of the patient at the time of excision. Some examples are remarkable for the diversity of cell types, all of which are representative of neuroectodermal differentiation. An oligodendroglioma arising in ectopic brain tissue of the nasopharynx was reported (283).

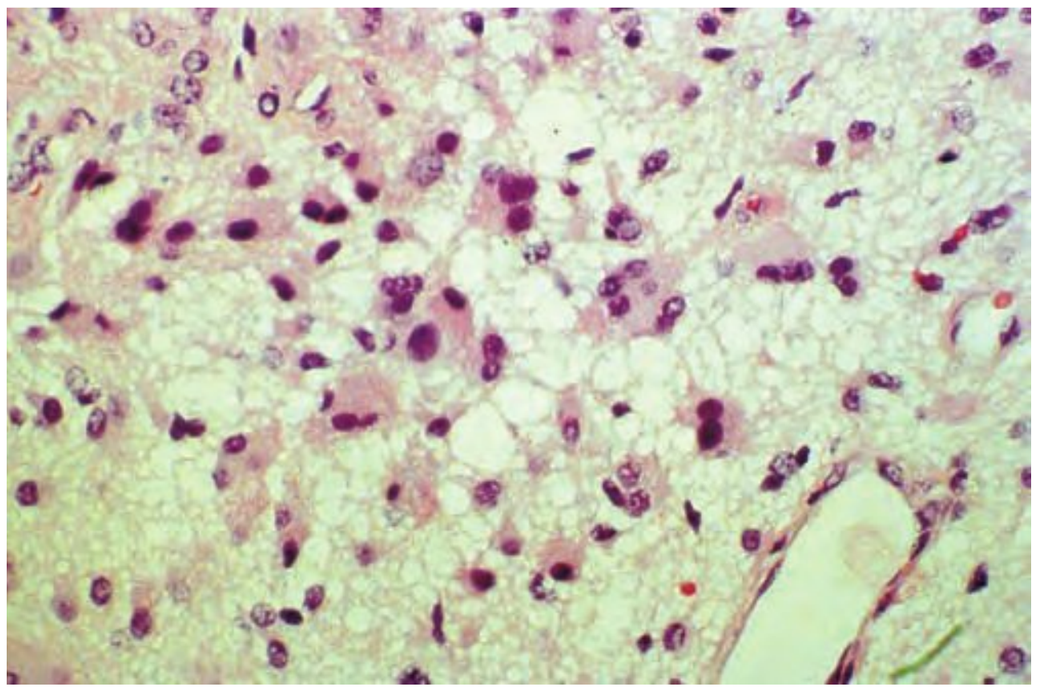

FIGURE 35-65. Parapharyngeal cephalic brain–like heterotopia. Astrocytes are supported by neuropil.

Immunohistochemically, neurons react for NSE and neural filaments. Astrocytes and ependymal cells are, and oligodendroglial cells are not, immunoreactive for GFAP. Oligodendroglial cells share some immunoreactions with Schwann cells.

Differential Diagnosis. *Encephaloceles* (extracranial protrusions of brainlike tissue that are in continuity with the subarachnoid space) may show a high degree of organization (284). CBH and encephaloceles of the same anatomic sites have similar clinical features. A distinction between CBH and encephalocele is not always possible, but encephaloceles are connected to the subarachnoid space by a sinus tract, thus making an ordinary biopsy inadvisable. A rhinorrhea with leakage of spinal fluid and even septic encephalitis may ensue following a biopsy. Computerized tomography (284) and neurosurgical consultation should precede any operative intervention of either CBH or encephalocele (280).

CUTANEOUS MENINGIOMAS AND MENINGOTHELIAL HETEROTOPIAS

Beyond the confines of the central nervous system, cells with the features of meningothelial cells may be encountered in skin

and soft tissue (285). They may be represented in patterns of a neoplasm (and properly characterized as *ectopic* meningioma). They may be represented in patterns similar to those manifested in the coverings of *meningoceles*, *meningomyeloceles*, and *meningoencephaloceles* (and properly characterized as heterotopia or dysplasia).

Definitions of various pathways and an understanding of developmental phenomena provide an explanation for the presence of meningothelial cells in the skin and soft tissue:

1. Precursors of meningothelial cells may be displaced into the dermis and subcutis during embryogenesis. Such remnants, located mainly in subcutaneous tissue of the scalp, forehead, and paravertebral regions of children and young adults (285–288), may develop into congenital meningeal heterotopias. They are relatively restricted in distribution along the lines of closure of the developing neural tube. Some of these lesions qualify as acelic meningeal heterotopias (rudimentary meningoceles) (287). For such examples, occult connections with the central nervous system may become apparent only at the time of surgery; a leakage of spinal fluid into the surgical defect will provide the evidence. Histologic patterns include features of those of both the dura and the leptomeninges.

2. True ectopic meningiomas, distributed along the course of cranial nerves of the sensory organs of the face and head, tend to occur in adults; they arise from extensions of arachnoidal lining cells along peripheral nerves (288). Some ectopic meningiomas arise in sites that are far from the axial skeleton. The histologic patterns of benign ectopic meningiomas recapitulate those of the meningiomas of the central nervous system.

3. Large, intracranial meningiomas may extend in direct continuity through foramina or old operative defects into the neighboring soft tissue; they qualify as *perforating* meningiomas. Their histology corresponds to that of the primary intracranial lesion and, once defined, is predictive of their behavior.

4. *Anaplastic* (*malignant*) *meningiomas* (including sarcomatous variants) and *papillary and hemangiopericytomatous variants* may aggressively invade bone, soft tissue, and scalp. They also may be associated with intracranial seeding and extracranial, mostly pulmonary metastases. Histologically benign meningiomas rarely have seeded the brain surface or metastasized (289).

Histopathology. Heterotopias are not well circumscribed (289). Cells of such lesions are cytologically bland and loosely attached to their neighbors. They commonly outline thin, angulated clefts, a feature that may be mistaken as evidence of vascular differentiation (Fig. 35-66) (288,290). Whorls of cells and psammoma bodies, if identified, are an aid in diagnosis. The supporting fibrous matrix is loosely fissured.

The complexities of the classification of true meningiomas (whether intracranial, ectopic, or metastatic) and the details of the corresponding histopathology preclude a presentation in this section. The basic features include sheets and nests of polygonal or spindle cells, whorls of cells, psammoma bodies (Fig. 35-67), intranuclear inclusions of cytoplasm, immunoreactivity for EMA, and scanty, condensed stroma or thin clefts at the interface between nests.

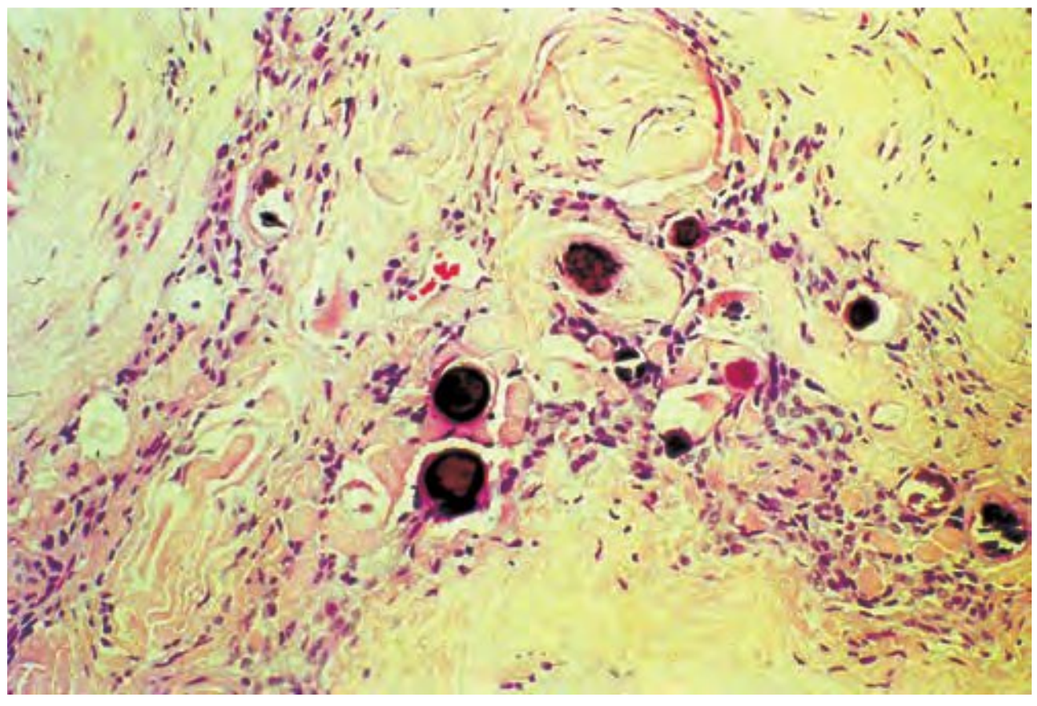

FIGURE 35-66. Meningeal heterotopia. Spindle cells with angulated, uniform nuclei form traceries among collagen bundles. There are clefts in some of the thin nests of spindle cells. The rounded, basophilic structures are psammoma bodies.

Anaplastic (malignant) meningiomas are characterized by dense cellularity, nuclear atypia, mitoses, necrosis, and invasion of the brain and even soft tissue. The basic patterns of common meningiomas usually are preserved, but some examples are frankly sarcomatous.

Ultrastructurally, poorly formed basal lamina, rare desmosomes, abundant mitochondria, and elaborate interdigitating, cytoplasmic processes are all features of meningothelial cells.

Histogenesis. Like intracranial meningiomas, the cells of ectopic meningiomas and meningeal heterotopias react immunohistochemically for vimentin and EMA (291–294).

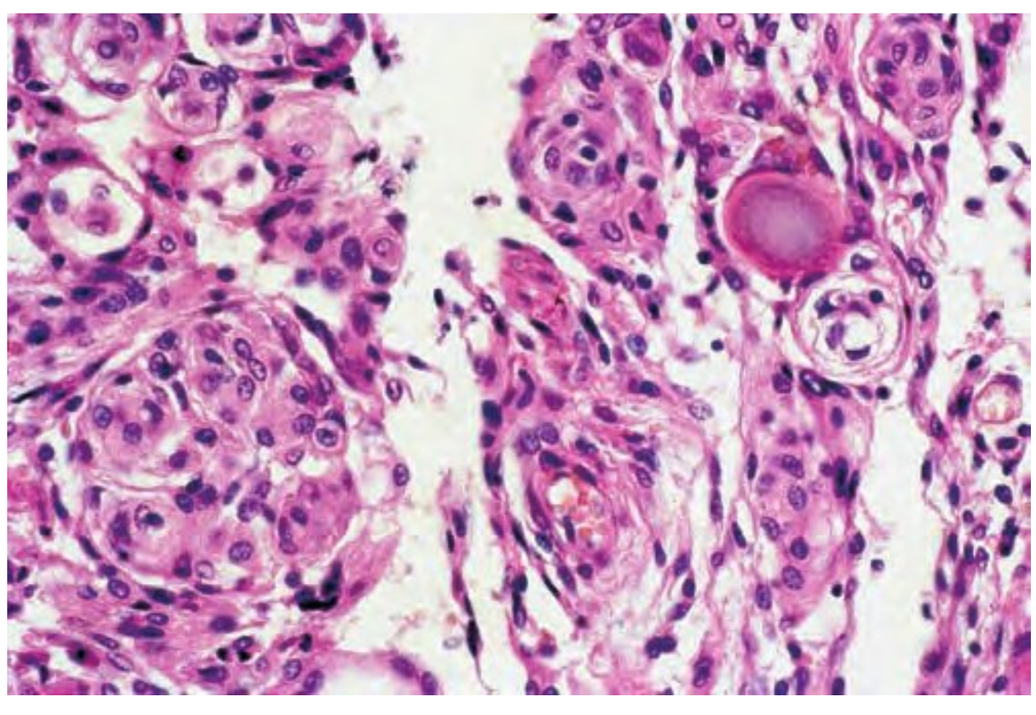

FIGURE 35-67. Cutaneous meningioma. Small, uniform spindle and epithelioid cells are arranged in nests and whorls; there are clefts among the nests. A psammoma body is represented.

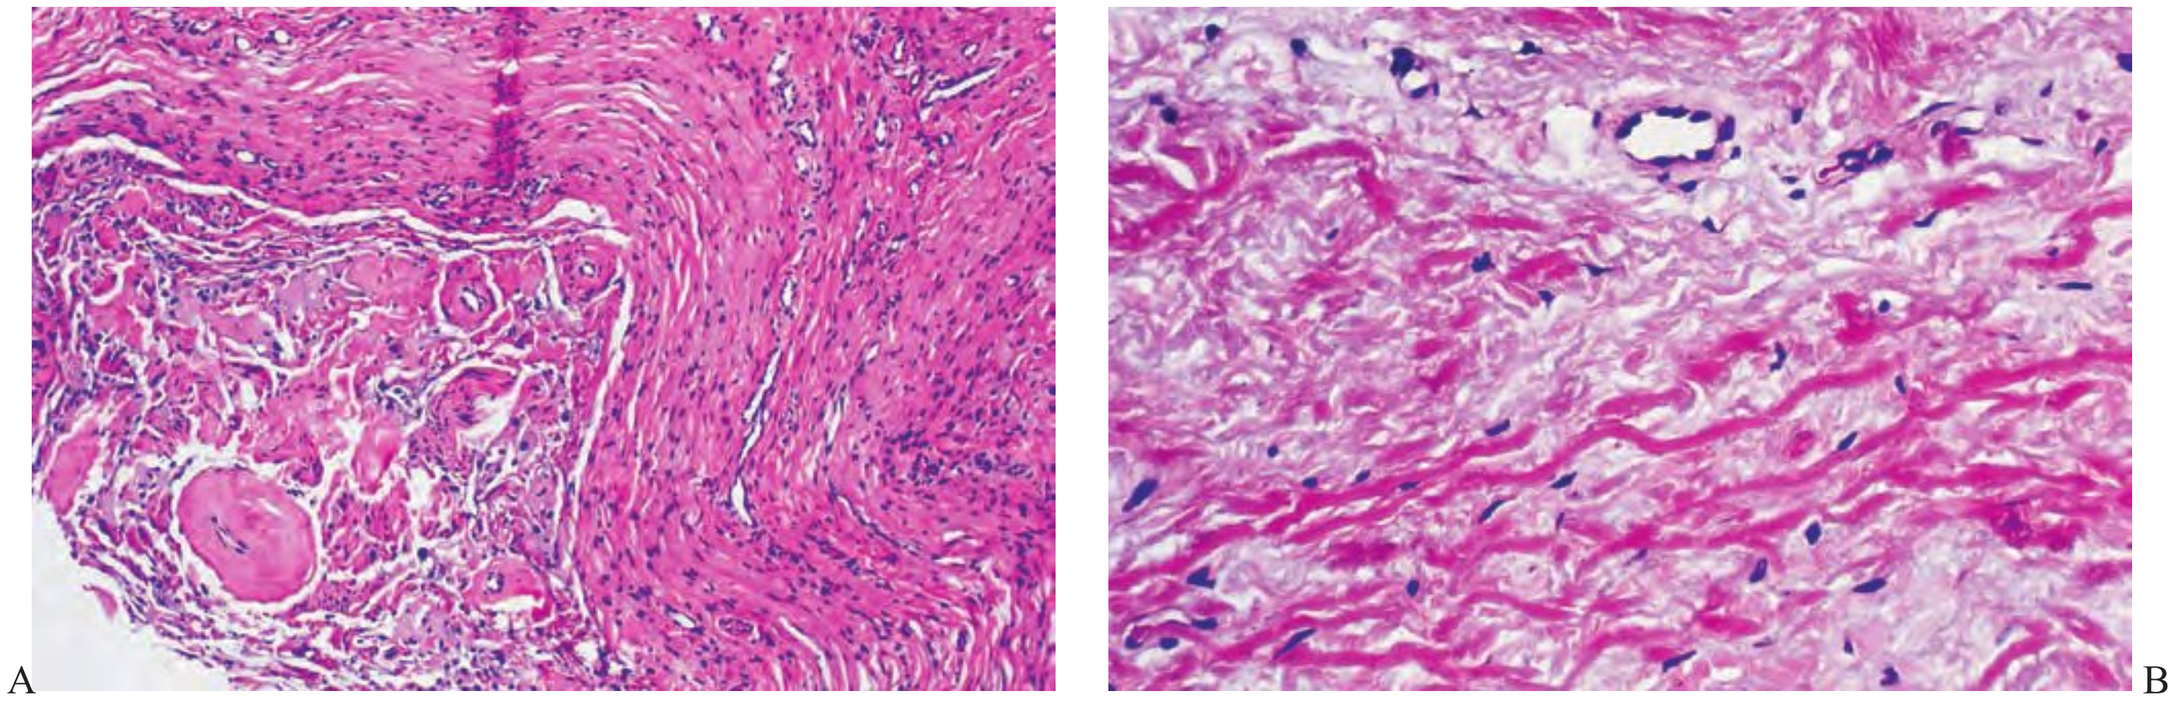

FIGURE 35-68. Impingement neuropathy (Morton's neuroma). A: To the left and extending to the bottom of the field, a nerve is cut in cross section; the perineurium is thickened and fibrotic. Individual nerve fibers and small clusters of nerve fibers are loosely spaced in a myxoid matrix. There are scattered hyaline deposits in the endoneurial space. Vessels of the endoneurium are cut in cross section; they have thickened, hyalinized walls. B: The connective tissue adjacent to an affected nerve shows hyperelastosis; the elastic fibers are increased in diameter. Often in Morton's neuroma, the changes in the adjacent connective tissue are similar to those of elastofibroma dorsi.

Depending on the histologic subtype, the expression of certain antigens, especially cytokeratins and S100 protein, is variable (288–294).

Differential Diagnosis. Meningoceles, meningomyeloceles, and meningoencephaloceles, like meningeal heterotopias, present along the lines of closure of the neural tube. Arachnoidal components are associated with both dense and loosely laminated, vascularized fibrous tissue. If there is an associated encephalocele (or myelocele), then tissue of the central nervous system, other than its coverings, will also be represented.

Ependymal rests also may be found in the sacrococcygeal region. Some are organized in patterns that resemble microscopic myxopapillary ependymomas (295). Such rests may provide an explanation for the origin of rare *ectopic ependymomas* in the sacrococcygeal region (296).

NEURAL TUMORS OF A DEGENERATIVE NATURE

In *impingement neurofasciitis* (*Morton or interdigital "neuroma"*), the compression of nerves and soft tissue between bony or other hard surfaces may induce degenerative changes. The responses include demyelination and endoneurial fibrosis, mucinous and fibrinous degeneration of soft tissue (fascia), deposition of preelastin over the surfaces of elastic fibers (in patterns resembling those seen in lesions of elastofibroma dorsi), and fibrinous bursitis (Fig. 35-68A, B) (297). In the excised specimen, nerve, related vessels, soft tissue, and a portion of synovium often are represented (Fig. 35-69). All of these phenomena, manifested in the interdigital area of so-called Morton neuroma, have nothing in common with the neuromas. In the altered nerves, localized, oval zones of mucinous or fibrous matrix may focally displace the nerve fibers. In them, spindle and stellate cells are loosely arranged in whorls. Similar epiphenomena, which were characterized by Renaut as an "intravaginal hyaline system," are often encountered as an incidental finding in normal nerves (4).

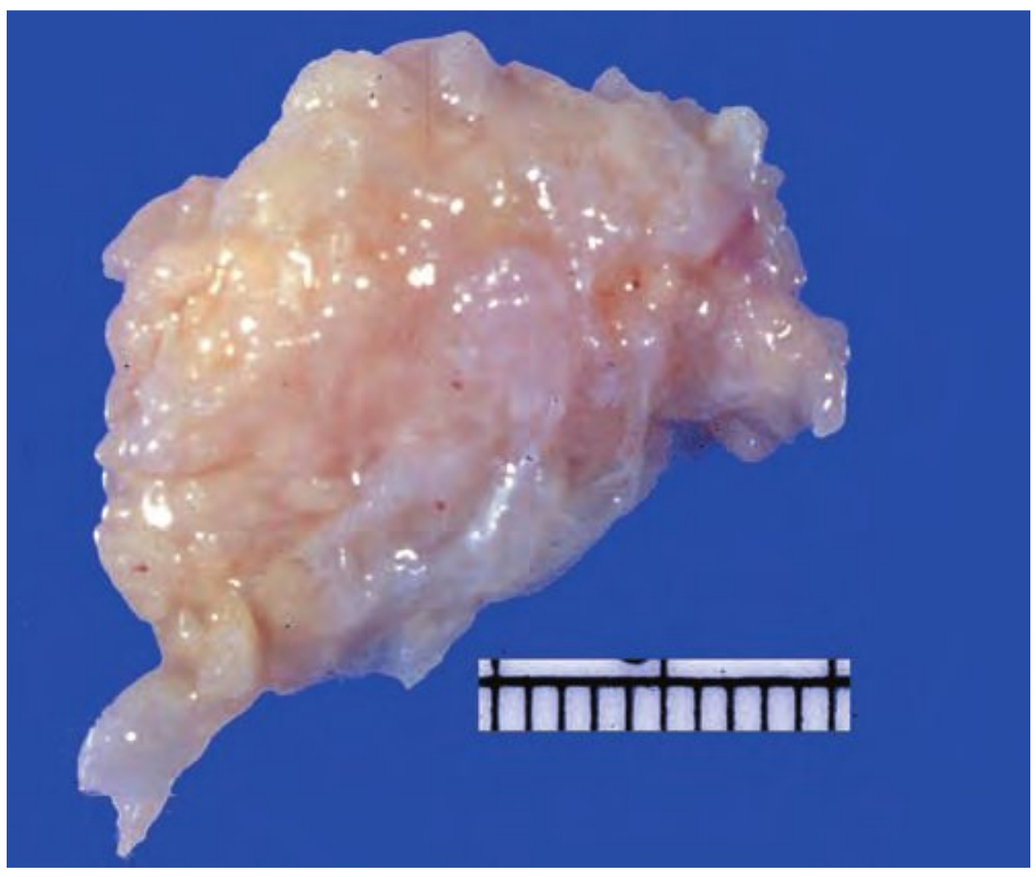

FIGURE 35-69. Morton's neuroma. A portion of a small nerve enters and exits a tumor. The tumor is not a neoplasm; it is an inflammatory process. The inflammatory process involves the interdigital nerve, soft tissue, and associated vessels. A portion of inflamed synovium often is included as part of the excised specimen.

Ganglion cyst of nerve is an uncommon tumor of a degenerative nature. In preferential sites, a superficial nerve impinges on a bony protuberance.

Initially, the perineurium and endoneurium are mucinous, expanded, and paucicellular. In one or more sites, cystic changes ensue. The end result is a mucinous cyst that expands the endoneurial space, compresses the axial bundle, and distends the perineurial sheath. A condensation of fibrous tissue forms the wall of the cyst.

Ganglion cyst of nerve is distinguished from periarticular ganglion cyst by location.

NEUROTROPIC GROWTH: GENERAL COMMENTS

Neurotropic growth of tumor is common in the skin. Generally, the identification of this phenomenon is sufficient to characterize any related primary neoplasm of the skin as aggressive [e.g., neurotropic melanoma (121), epidermoid carcinoma (298), and keratoacanthoma]. Rarely, benign invasion of nerve sheaths by squamous epithelium has been noted in reexcision specimens after a biopsy (299), and the cells of benign blue nevi and related lesions, and of congenital nevi, may occasionally be seen within nerves. Ensheathed neuroma is characterized by hyperplastic nerves that are ensheathed by benign squamous epithelium in the absence of a history of local trauma (300).

Primary malignant lymphoma, as a solitary tumor of peripheral nerve, is rare. Misdraji et al. reported a series of four cases (301). The lesions were all diffuse, large B-cell lymphomas. The involved sites included sciatic nerve (two cases), radial nerve (one case), and sympathetic chain and T2 spinal nerve (one case). At the time of the report, two of the patients had died of their disease. One patient at autopsy had evidence of neurolymphomatosis. The second patient had evidence of disseminated disease, including lymphomatous meningitis.

CHAPTER 36

Waine C. Johnson

Metastatic Carcinoma of the Skin

INCIDENCE AND DISSEMINATION

Cutaneous metastases are of diagnostic importance because they may be the first manifestation of an undiscovered internal malignancy or the first indication of metastasis of a supposedly adequately treated malignancy. The site of the primary tumor, if unknown, may be suspected by the histopathology and appropriate immunoperoxidase studies. Cutaneous metastases are generally uncommon but have been reported more frequently in recent years. In a study of 7,316 patients with internal cancer, Lookingbill and colleagues (1) found 367 (5%) to have skin involvement. Of 4,020 patients with metastatic disease, Lookingbill and associates (2) reported that 420 (10%) had cutaneous metastases. Nine percent of 7,518 patients with internal cancer who were autopsied at Roswell Park Memorial Institute had skin metastases (3). The incidence of various tumors that are metastatic to the skin correlates well with the frequency of occurrence of the primary malignant tumor in each gender.

A review of 724 patients with cutaneous metastases in 1972 by Brownstein and Helwig (4) showed that in women, commensurate with the greater frequency of carcinoma of the breast, 69% of all cutaneous metastases originated in the breast. Carcinoma of the large intestine accounted for 9% of cutaneous metastases, and carcinoma of the lungs and ovaries accounted for 4%. In recent years, the incidence of cutaneous metastasis from carcinoma of the lungs in women has significantly increased, and carcinoma of the lungs has become the most frequent cause of cancer deaths in women (as it is in men) (5,6). The study by Brownstein and Helwig (4) of cutaneous metastases in men revealed the following incidences of primary carcinoma: lungs, 24%; large intestine, 19%; oral cavity, 12%; and kidney and stomach, each 6%. Metastatic melanoma was found in 13% (4) (see Chapter 28).

Due to the relative rarity of carcinomas of the thyroid gland (7,8), pancreas (9), liver, gallbladder, urinary bladder (10), endometrium, prostate (11,12), testes, and neuroendocrine system, cutaneous metastases of these tumors are also relatively rare. A review by Schwartz (13) reported cutaneous metastatic disease as the first sign of internal cancer most commonly seen with cancer of the lung, kidney, and ovary.

Dissemination may take place through the lymphatics or the bloodstream. In carcinomas of the breast and oral cavity, metastases reach the skin largely through lymphatic channels and are often located in the overlying skin. In contrast, cutaneous metastatic lesions in other carcinomas are often the result of hematogenous dissemination and may appear in any area of the skin (14). Cutaneous metastases are more likely to be found in older individuals. Rare metastases found in the young are usually derived from a neuroblastoma or, less commonly, a rhabdomyosarcoma (15).

Cutaneous metastases usually appear as multiple, discrete, painless, and freely movable papules or nodules of sudden onset (Fig 36-1). Cutaneous metastases occur in about 10% of cases of metastases (2). The nodules are usually 1 to 3 cm in diameter, but much larger lesions have been reported (16). Metastases tend to occur on cutaneous surfaces near the site of the primary tumor, but exceptions to this include the scalp, which may be as frequent as 5% of all cutaneous metastases. Metastasis to the umbilicus is relatively common, and the underlying primary tumor is usually an adenocarcinoma of the stomach, ovaries, endometrium, or breast (11,17). A zosteriform pattern of skin metastasis has been reported to occur on the chest wall and abdominal wall, and the most frequent site of the primary was the breast, ovary, lung, prostate, bladder, or stomach (18,19).

Distinction of a primary carcinoma of the skin from a metastatic lesion can be a problem when dealing with a solitary lesion (Fig. 36-2). Some examples include primary mucinous adenocarcinoma of skin (20–22), adenocarcinoma of the mammary-like glands of the vulva (23), cutaneous signet-ring carcinoma (24), primary carcinoids (25,26), and adnexal carcinomas (27).

To establish a diagnosis of a primary mucinous carcinoma of the skin, the presence of a peripheral myoepithelial layer, if present, is helpful (21). Immunoperoxidase positivity with CD15, CK5/6, and 34BE12 (22) favor a primary lesion. A number of studies have shown that p63 staining of a tumor favors a primary tumor over a metastatic lesion (27). Except for sebaceous tumors, there is rare reactivity for primary adnexal carcinoma of the skin with CD10 in comparison with metastatic carcinoma, especially metastatic renal cell carcinoma (28).

Although metastatic lesions can occur at any site, the scalp, head, and umbilicus are more frequent. Finding of the primary tumor or the presence of serum chromogranin (25) would indicate a metastatic carcinoid.

FIGURE 36-1. Metastatic carcinoma of stomach origin to the face. Multiple dermal and subcutaneous nodules are seen on the face and neck.

FIGURE 36-2. Metastatic ovarian carcinoma to the inguinal area. A single nodule of recent onset.

Some immunoperoxidase studies that are helpful in distinguishing primary tumors from metastatic lesions are shown in Table 36-1.

CARCINOMA OF THE BREAST

Cutaneous metastases that occur predominantly by lymphatic dissemination include inflammatory carcinoma, carcinoma en cuirasse, telangiectatic and nodular carcinoma, and carcinoma of the inframammary crease. Alopecia neoplastica and mammary carcinoma of the eyelid are probably caused by hematogenous spread (13).

Inflammatory breast carcinoma is characterized by an erythematous patch or plaque with an active spreading border that resembles erysipelas and usually affects the breast and nearby skin (13). Rarely, inflammatory metastatic carcinoma may arise from primary involvement of other organs. The inflammatory appearance and warmth are attributed to capillary congestion.

En cuirasse metastatic carcinoma is characterized by a diffuse morphea-like induration of the skin and rarely involves skin from other primary carcinomas. It usually begins as scattered papular lesions coalescing into a sclerodermoid plaque without inflammatory changes.

Telangiectatic metastatic breast carcinoma is characterized by violaceous papulovesicles resembling lymphangioma

TABLE 36-1 Immunoperoxidase Studies

Adnexal carcinoma	+/−	−/+	−	−	+/−	−	−

+, almost all are positive; −, almost all are negative; −/+, most are negative; +/−, most are positive.

circumscriptum (13). A violaceous hue, which is often present, is caused by blood in dilated vascular channels.

The nodular form appears as multiple firm nodules that may show ulceration. An exophytic nodule may occur in the inframammary crease resembling a primary squamous cell or basal cell carcinoma and occurs more frequently in women with large breasts.

Alopecia neoplastica occurs as oval plaques or patches of the scalp and may be confused clinically with alopecia areata or a scarring alopecia. Metastatic mammary carcinoma in the eyelid clinically presents as a painless swelling with induration or as a discrete nodule (13).

Histopathology. In inflammatory carcinoma, histologic examination of the skin reveals extensive invasion of the dermal and often the subcutaneous lymphatics by groups and cords of tumor cells. The tumor cells are similar to those in the primary growth and atypical in character with large, pleomorphic, hyperchromatic nuclei. There is marked capillary congestion, which is the reason for the clinical appearance of erythema and warmth (13). Often, there is interstitial edema and a slight perivascular lymphoid infiltrate. The extensive lymphatic dissemination is caused by retrograde lymphatic spread into the skin secondary to blockage of the deep lymphatics and lymph nodes. Fibrosis is not a significant feature. Some studies indicate that only 1% to 4% of patients with metastatic breast carcinoma present with the inflammatory or erysipeloid type and that most of these patients have intraductal breast carcinoma (29).

In carcinoma en cuirasse, also referred to as *scirrhous carcinoma*, the indurated areas show fibrosis and may contain only a few tumor cells. The tumor cells may be confused with fibroblasts. The tumor cells have elongated nuclei similar to fibroblasts, but the nuclei are larger, more angular, and more deeply basophilic. The tumor cells often lie singly; however, in some areas, they may form small groups or single rows between fibrotic and thickened collagen bundles (Fig. 36-3). This latter feature of "Indian filing" is of particular diagnostic importance and may be seen in any histologic variety.

In telangiectatic carcinoma, the tumor cells tend to be located more superficially in the dermis within dilated lymphatic vessels than those in inflammatory carcinoma. The blood vessels are congested with red blood cells, as in inflammatory carcinoma, but usually also contain aggregates of neoplastic cells. The presence of many dilated blood vessels immediately beneath the epidermis gives rise to the clinical appearance of hemorrhagic vesicles.

In nodular carcinoma, there are variably sized groups of tumor cells in the dermis, and these nodular areas are surrounded by fibrosis. Depending on the tumor type, some cells may show a glandular arrangement, which may be quite ill-defined (Fig. 36-4). Sometimes, a nodule may be pigmented and clinically suggestive of a melanoma or pigmented basal cell carcinoma. The pigment results from melanin accumulation within the cytoplasm of neoplastic cells and in the stroma (30).

Carcinoma of the inframammary crease has been described as islands of epithelial cells with hyperchromatic nuclei extending contiguously with the epidermis from the dermis (31).

In hematogenous metastases, the histologic picture varies with clinical presentation. In alopecia neoplastica, the features resemble those of the en cuirasse type, with single files of tumor cells between thickened collagen bundles. Metastatic mammary carcinoma involving the eyelid has been described in 13 patients, and in 8 of them, the microscopic features had a prominent histiocytoid appearance (32).

Epidermotropic involvement from metastatic breast carcinoma may mimic malignant melanoma and/or Paget's disease (33).

The signet-ring cell histologic pattern of breast carcinoma (Fig. 36-5) may also be seen in carcinoma of the gastrointestinal tract and urinary bladder (34). This may be confused with a primary cutaneous signet-ring cell carcinoma that occurs most frequently in middle-aged men on the eyelid and less frequently in the axilla (34). A primary mucinous carcinoma of

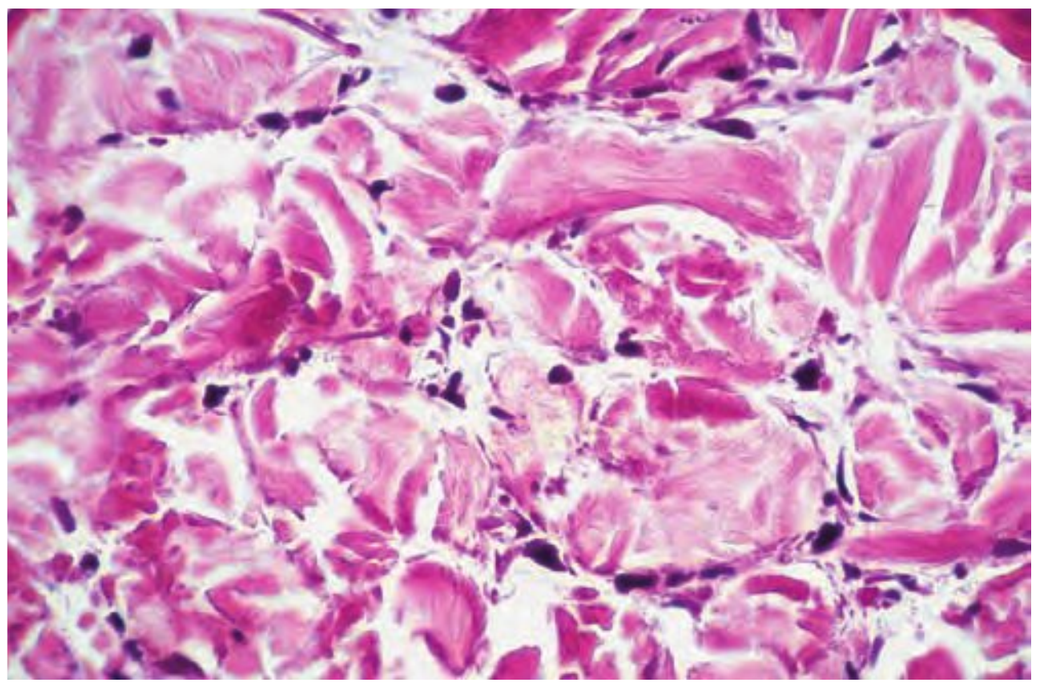

FIGURE 36-3. Metastatic breast carcinoma. Individual atypical tumor cells are seen between fibrotic collagen bundles.

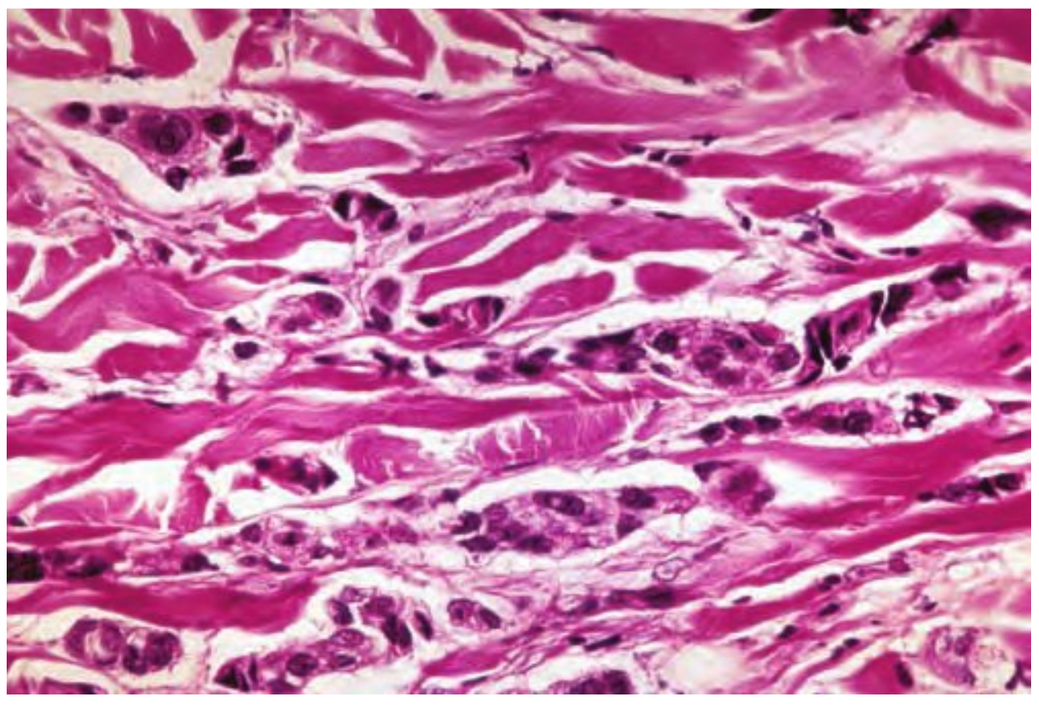

FIGURE 36-4. Metastatic breast carcinoma. Cords of atypical cells with ill-defined attempts at acinus formation infiltrating between collagen bundles.

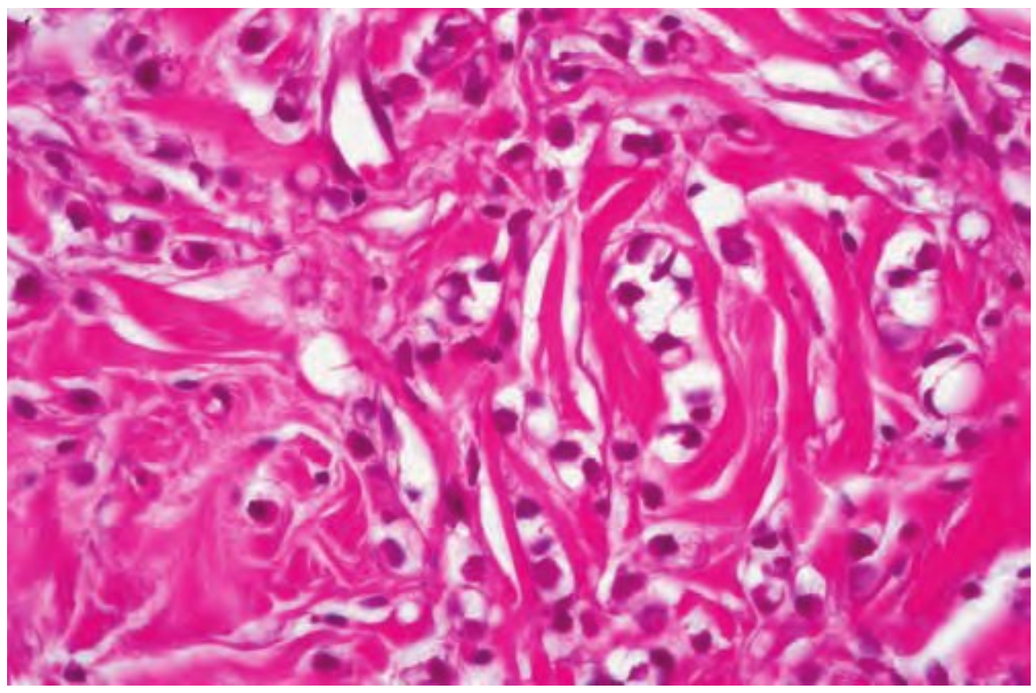

FIGURE 36-5. Metastatic breast carcinoma. This tumor demonstrates a signet-ring cell pattern.

the skin also may require distinction from metastatic lesions from the breast or colon (15). Rarely, a granular cell histologic pattern is seen.

Immunoperoxidase Studies. Cutaneous metastases are positive with most cytokeratins, except for CK20 (15), and often are positive with epithelial membrane antigen (EMA) and carcinoembryonic antigen (CEA). Reactivity with S-100 protein has been reported in as many as 84% of cases of primary and metastatic breast carcinoma (35). The presence of melanin granules and melanosomes within tumor cells that give a positive HMB-45 is rare and probably occurs secondarily to phagocytosis or melanocyte colonization of the tumor cells (30). In lesions in which there are cells positive with S-100 or HMB-45, strong reactivity with keratins or reactivity with EMA and/or CEA would rule out melanoma. A positive androgen receptor marker might be helpful in supporting metastatic breast cancer when estrogen receptors and progesterone receptors are negative (36). Primary signet-ring carcinoma of the skin has been reported to be positive with CK7 and CK20, and this would aid in distinction from the breast, which is usually negative with CK20 (34).

Mucinous carcinoma of the skin, which is generally thought to derive from the sweat glands, is positive with numerous cytokeratins but is negative with CK20. This would allow distinction from a metastatic mucinous adenocarcinoma of the colon, which would be positive with CK20 (37).

Expression of CK7 was found in the majority of cases of carcinoma, with the exception of those arising from the colon, prostate, kidney, thymus, carcinoid tumors of the lung and gastrointestinal tract, and Merkel cell tumors of the skin.

CARCINOMA OF THE LUNG

Metastasis to the skin is more common in men, but the incidence of lung carcinoma in women is increasing (5,6). In 56 patients reported with skin metastasis from lung carcinoma, 7% had a skin nodule before the diagnosis of the primary tumor, and 16% had a nodule at the same time (38). In 11 of 21 patients with cutaneous metastasis, the skin was the first extranodal site (1). Metastases may occur on any cutaneous surface, but the most common sites are the chest wall and posterior abdomen (13). Oat cell carcinoma shows predilection for the skin of the back (2). Most lesions present as a localized cluster of cutaneous papules or nodules or as a solitary nodule.

Histopathology. Cutaneous metastases were undifferentiated in approximately 40% and adenocarcinoma and squamous cell carcinoma in approximately 30% each (4). The undifferentiated tumors were often of the small cell type with hyperchromatic nuclei and scant cytoplasm, also known as *oat cell carcinomas* (4). Carcinoid tumors of the lung are derived from the bronchus and consist of solid islands and nests of uniform cells (Fig. 36-6). Other sources of carcinoid tumors include the stomach, small and large intestine, and primarily the skin (39,40). The closely packed tumor cells may suggest a malignant lymphoma. Immunoperoxidase studies are extremely helpful in making this distinction. Larger cells require consideration of metastatic amelanotic melanoma and, again, immunoperoxidase studies may be required for distinction.

Squamous cell carcinomas that are metastatic to skin are usually poorly or moderately differentiated (4). They can usually be distinguished from primary squamous cell carcinoma by the absence of proliferation from the surface epidermis and seldom show an orderly pattern of differentiation from basaloid to prickle cells with centers of keratinization. They may show occasional whorls of squamoid cells with imperfect keratinization and individually keratinized cells and sometimes have large, bizarre forms with frequent mitotic figures (4). In larger tumors, areas of central necrosis are often present. Most cutaneous metastatic squamous cell carcinomas arise in the

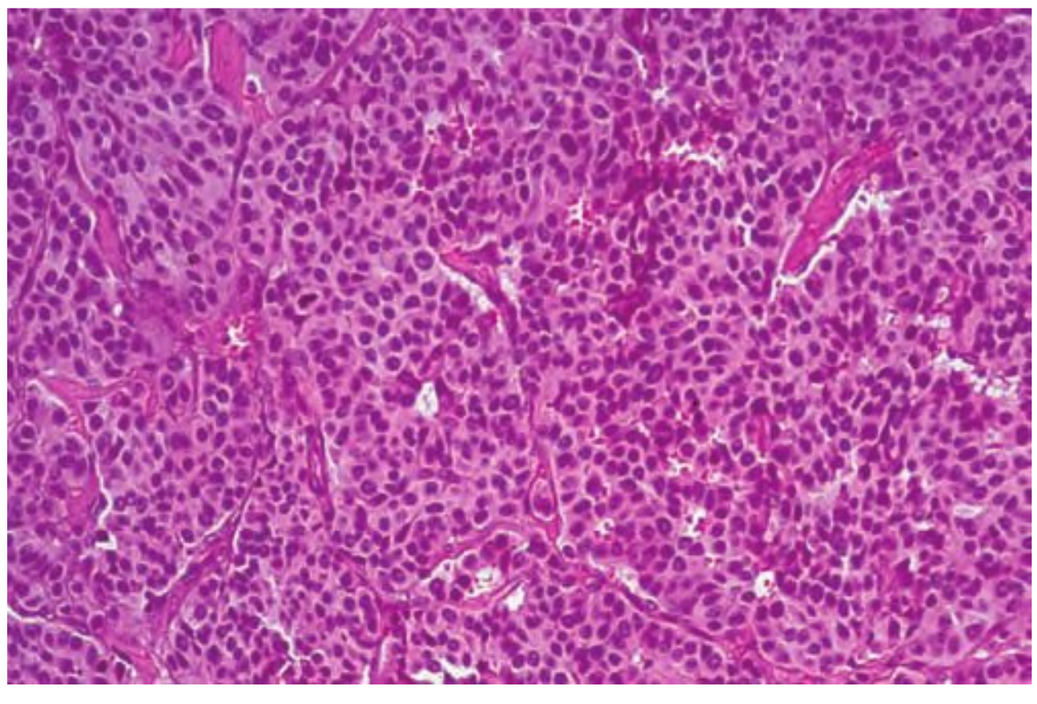

FIGURE 36-6. Metastatic carcinoid tumor from the lung. Uniform small cells without high-grade atypia, forming nests in a typical pattern of a carcinoid tumor.

lung, oral cavity, or esophagus. Tumors from the oral cavity tend to be more differentiated and nearly always appear on the head or neck. Squamous carcinoma metastatic from the esophagus shows essentially similar features to that from the lung (4).

Adenocarcinomas metastatic to the skin from the lung are often moderately differentiated, but some show well-formed, mucin-secreting, glandular structures. Individual tumor cells sometimes contain abundant cytoplasmic mucin but usually lack large pools of mucin, which is more characteristically seen from gastrointestinal metastatic adenocarcinomas (4).

Immunoperoxidase Studies. In addition to keratins that are positive in most metastatic carcinomas, most metastatic adenocarcinomas are positive with EMA and CEA. It has been stated that a positive reaction with CEA (seen in 50% of secondary neuroendocrine carcinomas) may be most helpful in differentiating between primary and secondary lesions (41). A rare exception to this consideration is the presence of ductlike structures in two instances of Merkel cell carcinoma, and these were CEA positive. This was assumed to be eccrine differentiation. Merkel cell carcinomas usually show a CK20, perinuclear dot, and/or diffuse activity, and this is rarely seen in metastatic neuroendocrine carcinomas (42). They may show reactivity to one or more of the following: protein gene product, chromogranin-A, CD56 antigen (Leu-7), and synaptophysin (41). Negative reactions with lymphocyte common antigen (LCA) and other lymphoid markers are most helpful in ruling out malignant lymphomas (43). Thyroid transcription factor 1 (TTF-1) is positive in thyroid carcinoma and small cell lung carcinoma and is negative in most cases of Merkel cell carcinoma (42,44).

GASTROINTESTINAL CARCINOMA

Carcinoma of the colon and rectum is the second most common type of primary cancer in men (13). Cutaneous lesions usually appear after the primary tumor has been recognized and occur more commonly on the abdomen or perineal areas, although the head and neck areas are sometimes involved. Metastases from gastric carcinoma may occur at any distant site, but the umbilical region is perhaps most common.

Histopathology. Most cutaneous metastases from the large intestine and all from the stomach as reported by Brownstein and Helwig (45) were adenocarcinomas (Fig. 36-7). A mucinous carcinoma pattern with small groups of tumor cells that lie in large pools of mucin is common in lesions from the large intestine. Signet-ring cell differentiation is not usually seen in lesions from the large intestine but may be present in lesions from the stomach (4). The stomach metastases are usually anaplastic, infiltrating carcinomas with variable cellularity, a loose stroma, and varying proportions of signet-ring cells. The mucin present in metastatic carcinoma from the gastrointestinal tract as well as in mucinous carcinomas from the breast and lung is a nonsulfated, hyaluronidase-resistant, sialic acid–type of mucosubstance (46–48). Histochemical

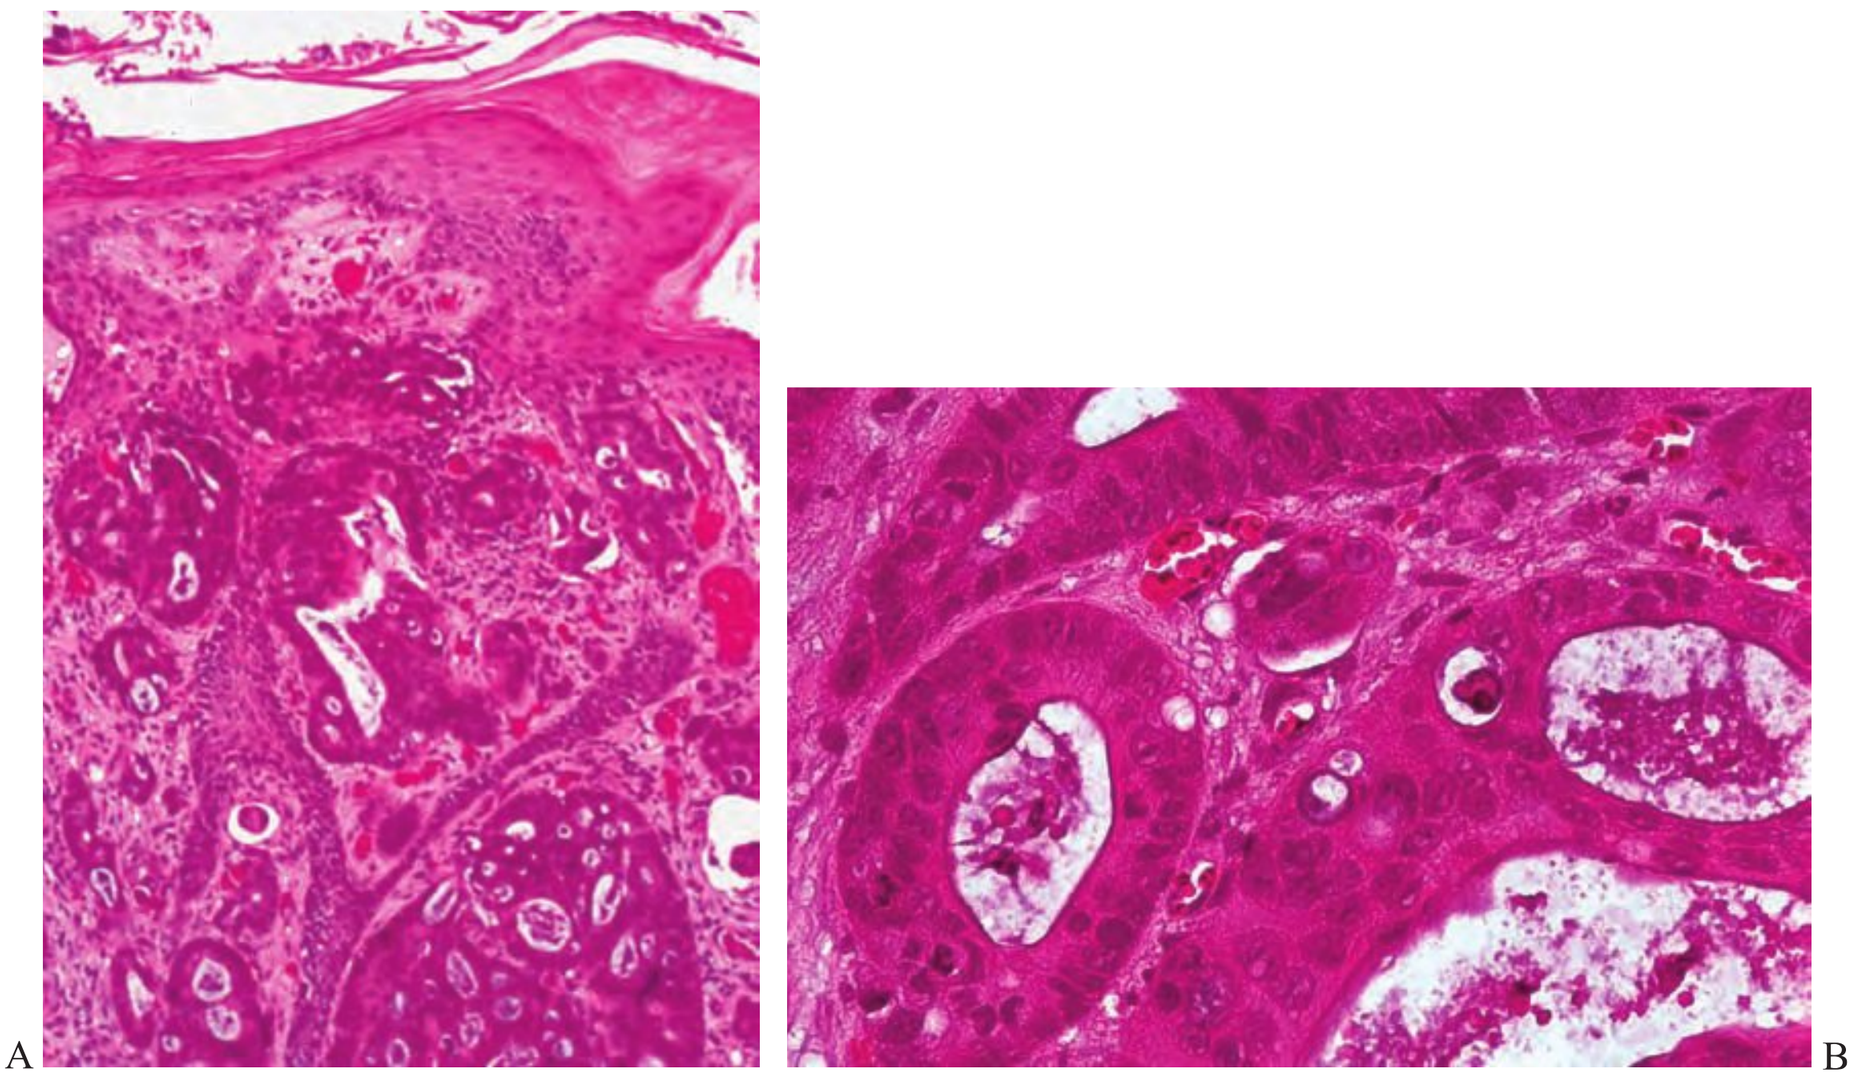

FIGURE 36-7. Metastatic carcinoma from the colon. This tumor shows secondary epidermal involvement (A) and is comprised of somewhat irregular but relatively well-formed glands (A,B).

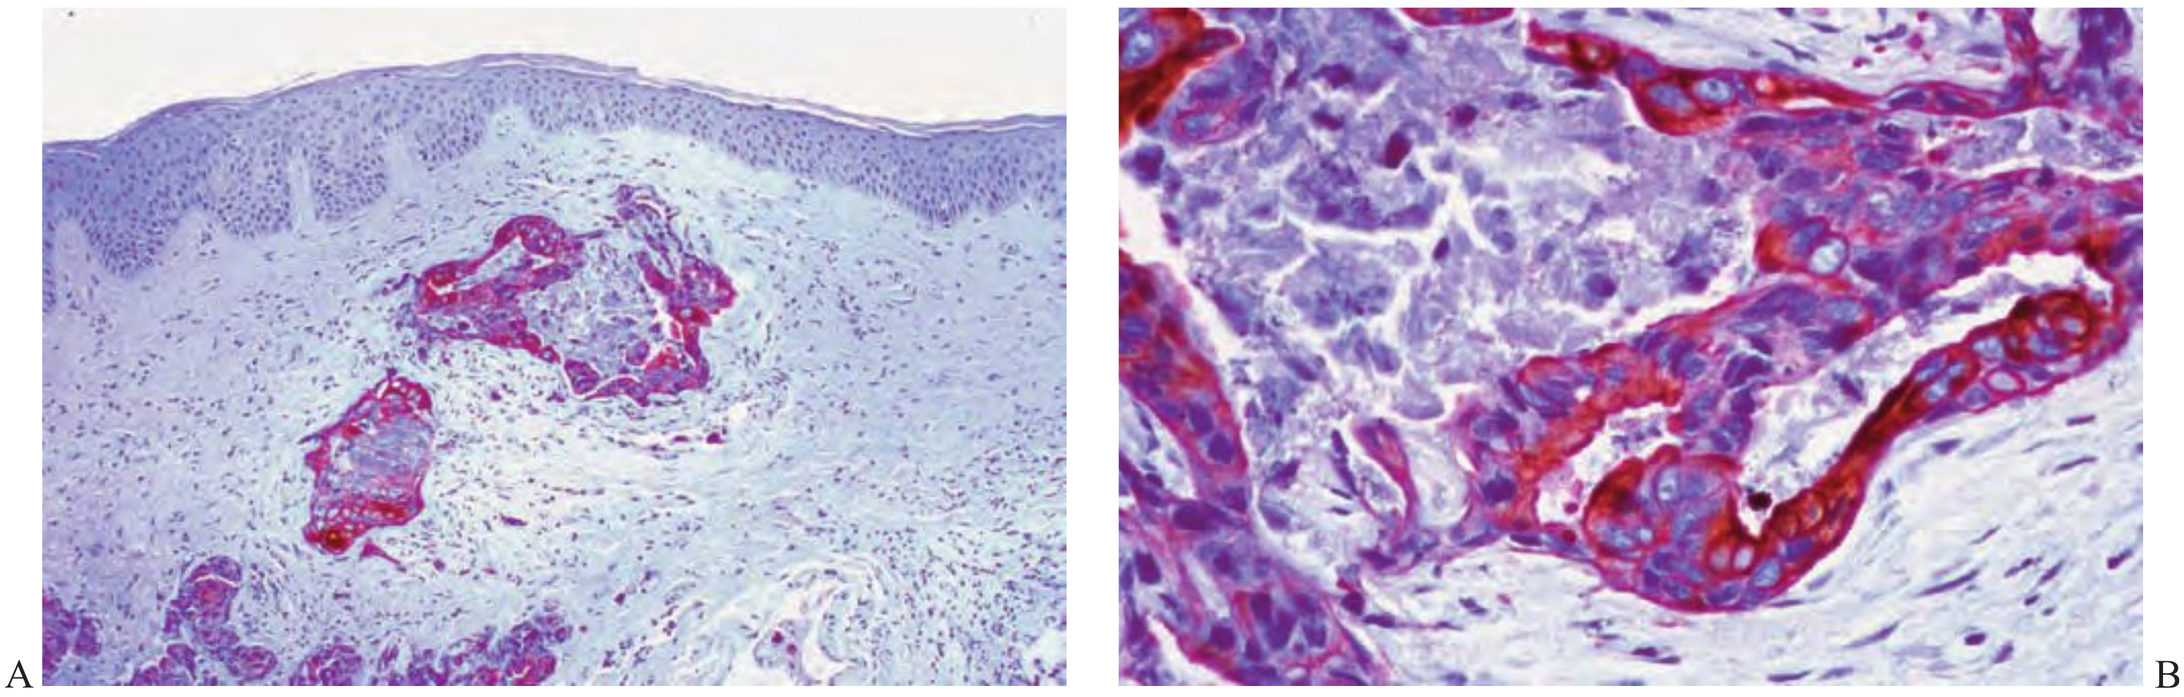

FIGURE 36-8. Metastatic carcinoma from colon, cytokeratin-20. A, B: CK20 reactivity, usually studied in coordination with that of CK7, helps to distinguish this lesion from a nongastrointestinal tract adenocarcinoma. Bladder and mucinous ovarian carcinomas may also be positive.

procedures show this mucin to be positive with colloidal iron, hyaluronidase resistant, Alcian blue positive at pH 2.5 and negative at pH 0.4, and aldehyde-fuchsin positive at pH 1.7 and negative at pH 1.0. It shows metachromasia with toluidine blue at pH 3.0, and is negative at pH 2.0, is PAS positive and diastase resistant, and is mucicarmine positive (49). In contrast, histochemical studies of adenoid squamous cell carcinoma show the mucin to be predominantly hyaluronic acid. Also, distinction from adenoid basal cell carcinoma and adenocystic carcinoma from lacrimal and salivary glands can be made based on the fact that these latter tumors contain a predominance of sulfated acid mucosaccharides (49). The differential diagnosis for metastatic carcinoma includes carcinomas of cutaneous adnexae such as sweat gland carcinomas.

Immunoperoxidase Studies. A study by Chu and associates (50) showed CK20 positivity in almost all colorectal carcinomas (Fig. 36-8) and Merkel cell tumors, pancreatic carcinomas (62%), gastric carcinomas (50%), cholangiocarcinomas (43%), transitional cell carcinomas (29%) and was nearly absent in carcinomas from other organ systems and in malignant mesotheliomas.

ORAL CAVITY CARCINOMA

Most lesions metastasizing from carcinomas of the oral cavity are spread by lymphatic invasion and are located on the face or neck (4). They usually appear as multiple or solitary nodules and sometimes are ulcerated.

Histopathology. The lesions are almost always squamous cell in type and are usually moderately or well differentiated (4). They are located usually in the deeper dermis and subcutaneous tissue with sparing of the superficial cutis. In examples with ulceration and involvement of the upper corium, distinction from primary squamous cell carcinoma of skin may not be possible (4).

RENAL CELL CARCINOMA

In renal cell carcinoma, tumors are most commonly located in the head and neck area, although any site may be involved (13,51). They often present as solitary or a few nodules and may be skin colored, reddish, or violaceous. They may occur as the first sign of internal cancer or as late as 10 years after diagnosis of the primary. They occur almost always in men.

Histopathology. The histologic features are usually those of a clear cell adenocarcinoma. They are often localized intradermal nodules and may stretch the overlying epidermis (4) (Fig. 36-9A). The tumor cells show oval nuclei with abundant, clear cytoplasm and often are in a glandular configuration (Fig. 36-9B). The stroma is vascular, and extravasated red blood cells are frequent. Intracytoplasmic glycogen is uniformly present, as demonstrated by staining with PAS and diastase-labile intracytoplasmic material. Frozen sections stained with oil red O show the presence of lipid droplets in many tumor cells (51). The histologic differential diagnosis includes adnexal tumors and especially eccrine acrospiroma (nodular hidradenoma). In contrast to the usual unilobular and hemorrhagic renal cell carcinoma, the eccrine acrospiroma tends to be multilobular and nonhemorrhagic, and often distinct ductal structures are present. Sebaceous cell tumors also may be confused, but the markedly vascular stroma and hemorrhagic nature of the renal cell cancer is fairly distinctive.

Immunoperoxidase Studies. In most cases, the tumor cells are reactive with pankeratin, AE1/AE3, CAM5.2, EMA, and CD10 (28). They are usually negative with CK7 and CK20, and about 60% in one study were positive with vimentin

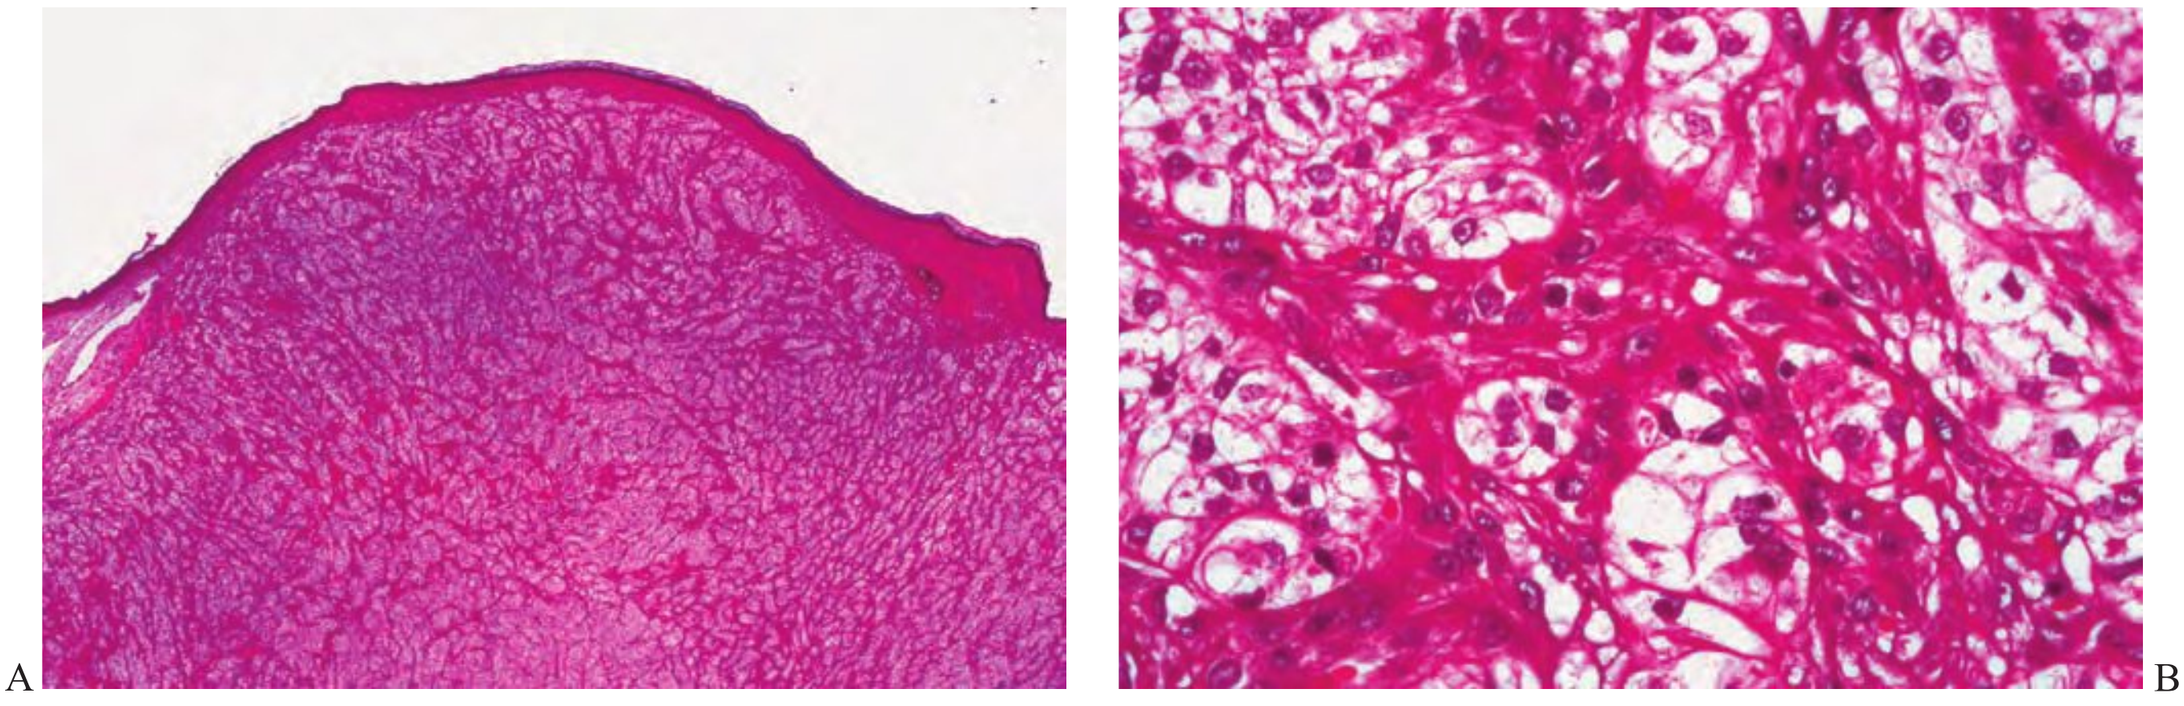

FIGURE 36-9. Metastatic carcinoma from kidney. A dermal tumor pressing on and elevating the overlying epidermis (A) and comprised of clear cells with prominent capillaries in the stroma (B).

(52,53). Renal cell carcinoma marker (RCC-Ma) is positive (54).

CARCINOMA OF THE OVARY

In carcinoma of the ovary, the most frequent sites involved are the abdomen, including the umbilicus, vulva, or back (13). Lesions of the abdomen may be in the scar sites from surgery or diagnostic procedures (2).

Histopathology. The features are usually of a moderately or well-differentiated adenocarcinoma, often having a papillary configuration and containing psammoma bodies (4). In 724 patients studied by Brownstein and Helwig (4), psammoma bodies in cutaneous masses were found only in metastases from the ovary (but might also be seen in papillary carcinomas from other sites including, for example, the thyroid).

Immunoperoxidase Studies. Papillary ovarian tumors were all CK7 positive and CK20 negative. Mucinous ovarian carcinomas (Fig. 36-10) were CK7 positive, and a few were CK20 negative (55).

CARCINOID AND NEUROENDOCRINE CARCINOMAS

Tumors in carcinoid and neuroendocrine carcinomas are assumed to be derived from the neural crest tissues and have been classified as amine precursor uptake and decarboxylase system tumors. Lesions appear as solitary or multiple cutaneous papules or nodules and may occur at any site. Primary carcinoids giving rise to cutaneous metastases (Fig. 36-6) occur most frequently in the bronchi but have been reported in various sites including the small intestines, sigmoid, colon, pancreas, stomach, thymus, and thyroid (40). In addition to carcinoid tumors, cutaneous metastases from neuroendocrine carcinomas of a variety of sites including the uterus, vulva, gallbladder, and fallopian tubes have been reported (13,56). Neuroblastoma, which is the most common cancer identified at birth, has been reported to metastasize to the subcutaneous tissue in 32% of patients with congenital neuroblastoma (13). Clinically, they have a fairly specific appearance, which has been described as like a "blueberry muffin." This term has also been used to describe some cases of congenital leukemia. Cutaneous neuroblastoma is very rare in adults, and it is impossible to distinguish between primary and metastatic lesions except for finding an internal primary tumor (57).

Histopathology. Carcinoid metastases in the skin and subcutaneous tissue consist of solid islands, nests, and cords of tumor cells (Fig. 36-6). As a rule, the cells appear quite uniform in size and shape; have small, rounded nuclei; and abundant, clear, or eosinophilic cytoplasm occasionally containing numerous eosinophilic granules (40). However, in some

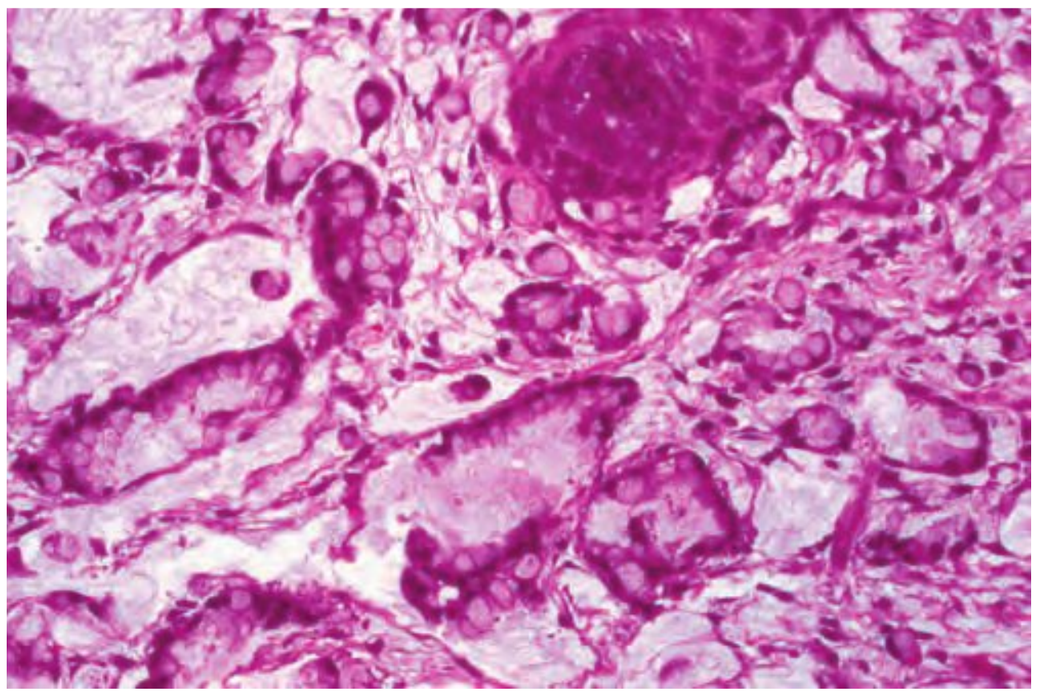

FIGURE 36-10. Metastatic mucinous ovarian carcinoma. Infiltrating acinar structures with scattered signet cells.

instances, the nuclei are hyperchromatic, and there may be areas in which the nuclei show anaplasia by being irregularly shaped, large, and hyperchromatic. Carcinoids of the bronchus usually contain argyrophil granules in contrast to those of the small intestine, which usually contain argentaffin granules, which can be demonstrated by the Fontana-Masson stain (58). Cutaneous metastases of bronchial carcinoids may have either argyrophil or argentaffin granules (59). Yet, diagnosis today is usually made with the support of immunohistochemical studies, as discussed in the next section (60). The histologic differential diagnosis may include sweat gland carcinoma or glomus tumor because of their arrangement in well-defined islands, as well as metastases from noncarcinoid neuroendocrine tumors, and primary Merkel cell carcinoma. The latter usually show more immature cells or greater cellular atypism, a greater number of mitotic figures, and a "trabecular" pattern. The presence of an intraepidermal component would also favor a primary Merkel cell carcinoma. Involvement of the deep dermis and multiple skin sites favor a metastatic lesion (56). Primary or metastatic neuroblastomas (peripheral neuroectodermal tumor) show identical features of undifferentiated, small, hyperchromatic cells with frequent rosettes of the Homer-Wright type and numerous mitoses (57). Some examples of undifferentiated lesions may not show rosettes. The histologic differential diagnosis includes other small cell carcinomas that sometimes show rosette-like structures, extraskeletal Ewing's sarcoma, lymphoma, and leukemia. Merkel cell carcinoma tends to display a trabecular arrangement, but this is not always specific.

Immunoperoxidase and Electron Microscopy Studies. Immunoperoxidase studies are of great value in distinguishing a primary Merkel cell carcinoma of the skin from a metastatic neuroendocrine carcinoma. Merkel cell carcinomas are usually positive with CK20 (60) and are negative with TTF-1 and CK7 (42,44). If the lesion is positive for CEA in nonductal or nonglandular sites, this would strongly favor a metastatic lesion (41). The presence of a positive reaction with nonspecific esterase (NSE) and EMA is not necessarily helpful, since these can be reactive in primary or secondary neuroendocrine carcinomas as well as sweat gland carcinomas. Reactivity with CK20 favors a Merkel cell tumor. If the tumor is positive with S-100, this favors an eccrine sweat gland carcinoma, metastatic breast carcinoma, or malignant melanoma. If the tumor is positive with LCA, this identifies the lesion as a malignant lymphoma. A rare exception to this rule was published by Nandedkar and colleagues (61). Calcitonin has been demonstrated in cutaneous metastasis of medullary carcinoma of the thyroid (62). Electron microscopic studies of carcinoid, neuroendocrine, and primary Merkel cell carcinomas show "neurosecretory" membrane-bound, dense-core granules measuring 100 to 250 nm in diameter (34,55,59,63). These granules do not distinguish among members of this group. Immunoelectron microscopic studies confirm the presence of cytokeratin (AE1/AE3) arranged in paranuclear areas, while cytoplasmic synaptophysin and chromogranin positivity over dense-core granules tend to confirm light microscopic immunohistochemical studies (63). Neuroblastoma has been reported to be positive with NSE but often is negative with other commonly reactive antigens of neuroendocrine tumors such as EMA, chromogranin-A, and synaptophysin (57). Electron microscopy shows membrane-bound, dense-core granules concentrated in the cytoplasmic processes. Desmosomes and microtubules are usually seen in more differentiated tumors.

MISCELLANEOUS CARCINOMAS

In metastatic carcinoma from the liver, the arrangement of malignant hepatocytes in irregular columns is fairly distinctive, and if there are acinar structures containing bile, the diagnosis is definite (64).

In choriocarcinoma, the cutaneous metastases show the two types of cells that arise from the fetal trophoblast: cytotrophoblasts and syncytiotrophoblasts. The cytotrophoblasts usually grow in clusters, and the cells appear cuboidal with large, vesicular nuclei and a pale cytoplasm. The syncytiotrophoblasts, which have large and irregular nuclei and a basophilic cytoplasm, grow around the clusters of cytotrophoblasts in a plexiform pattern resembling chorionic villi (65). The syncytiotrophoblasts have been reported to be strongly positive for human chorionic gonadotropin (HCG) antigen (66).

Metastatic carcinoma of the prostate to the skin is rare and usually occurs in the inguinal area, lower abdomen, or thighs, but distant sites of the scalp and face have been reported (13). Reactivity with prostate-specific antigen establishes the diagnosis (67).

Pancreatic cancer metastatic to the skin is rare, and the most common site is the umbilical area (13,68). Histologically, it usually represents an adenocarcinoma. Immunoperoxidase with a carbohydrate antigen (CA19-9) may be positive (68).

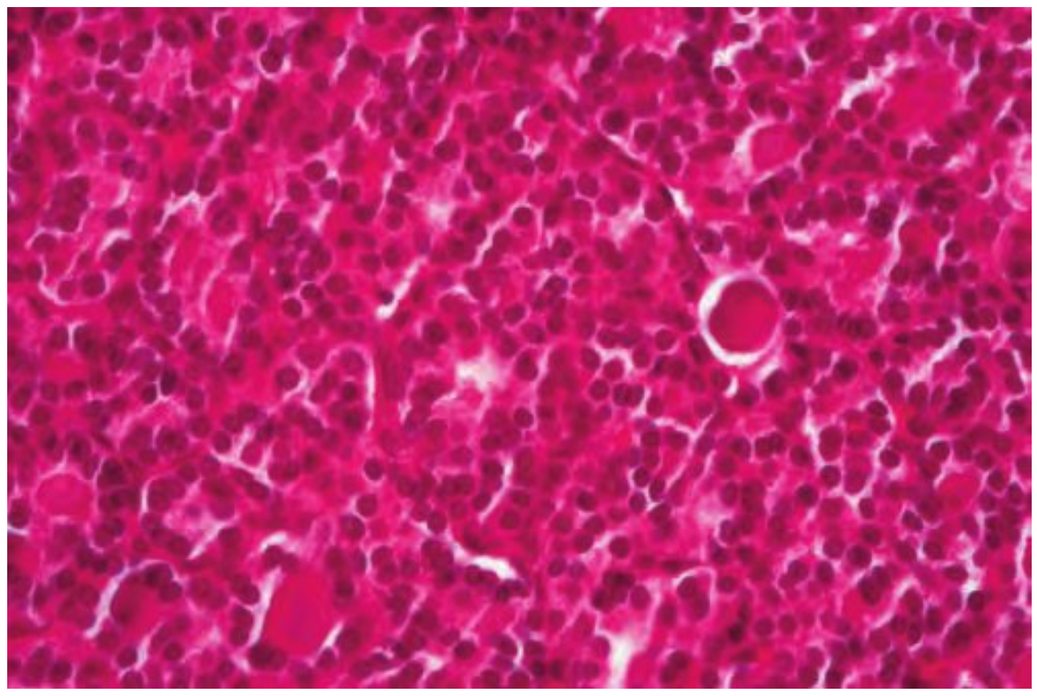

FIGURE 36-11. Metastatic carcinoma from thyroid. In this example of a metastatic follicular carcinoma, comprised of small epithelial cells forming ill-defined follicles containing pink colloid, there is little atypia, and the lesion could not be distinguished from a follicular adenoma except for its metastatic location.

This antigen is commonly present in adenocarcinoma of the pancreas but is not specific. It is usually negative in adenocarcinomas of the breast.

Cutaneous metastases from thyroid carcinoma tend to involve the abdominal skin or the head area (13). Medullary, follicular, and papillary thyroid carcinomas may retain their histologic patterns in the cutaneous metastases (Fig. 36-11). Immunoperoxidase studies often show a positive reaction to antithyroglobulin antibody (69) and TFF-1 (42).

Electron Micrographs

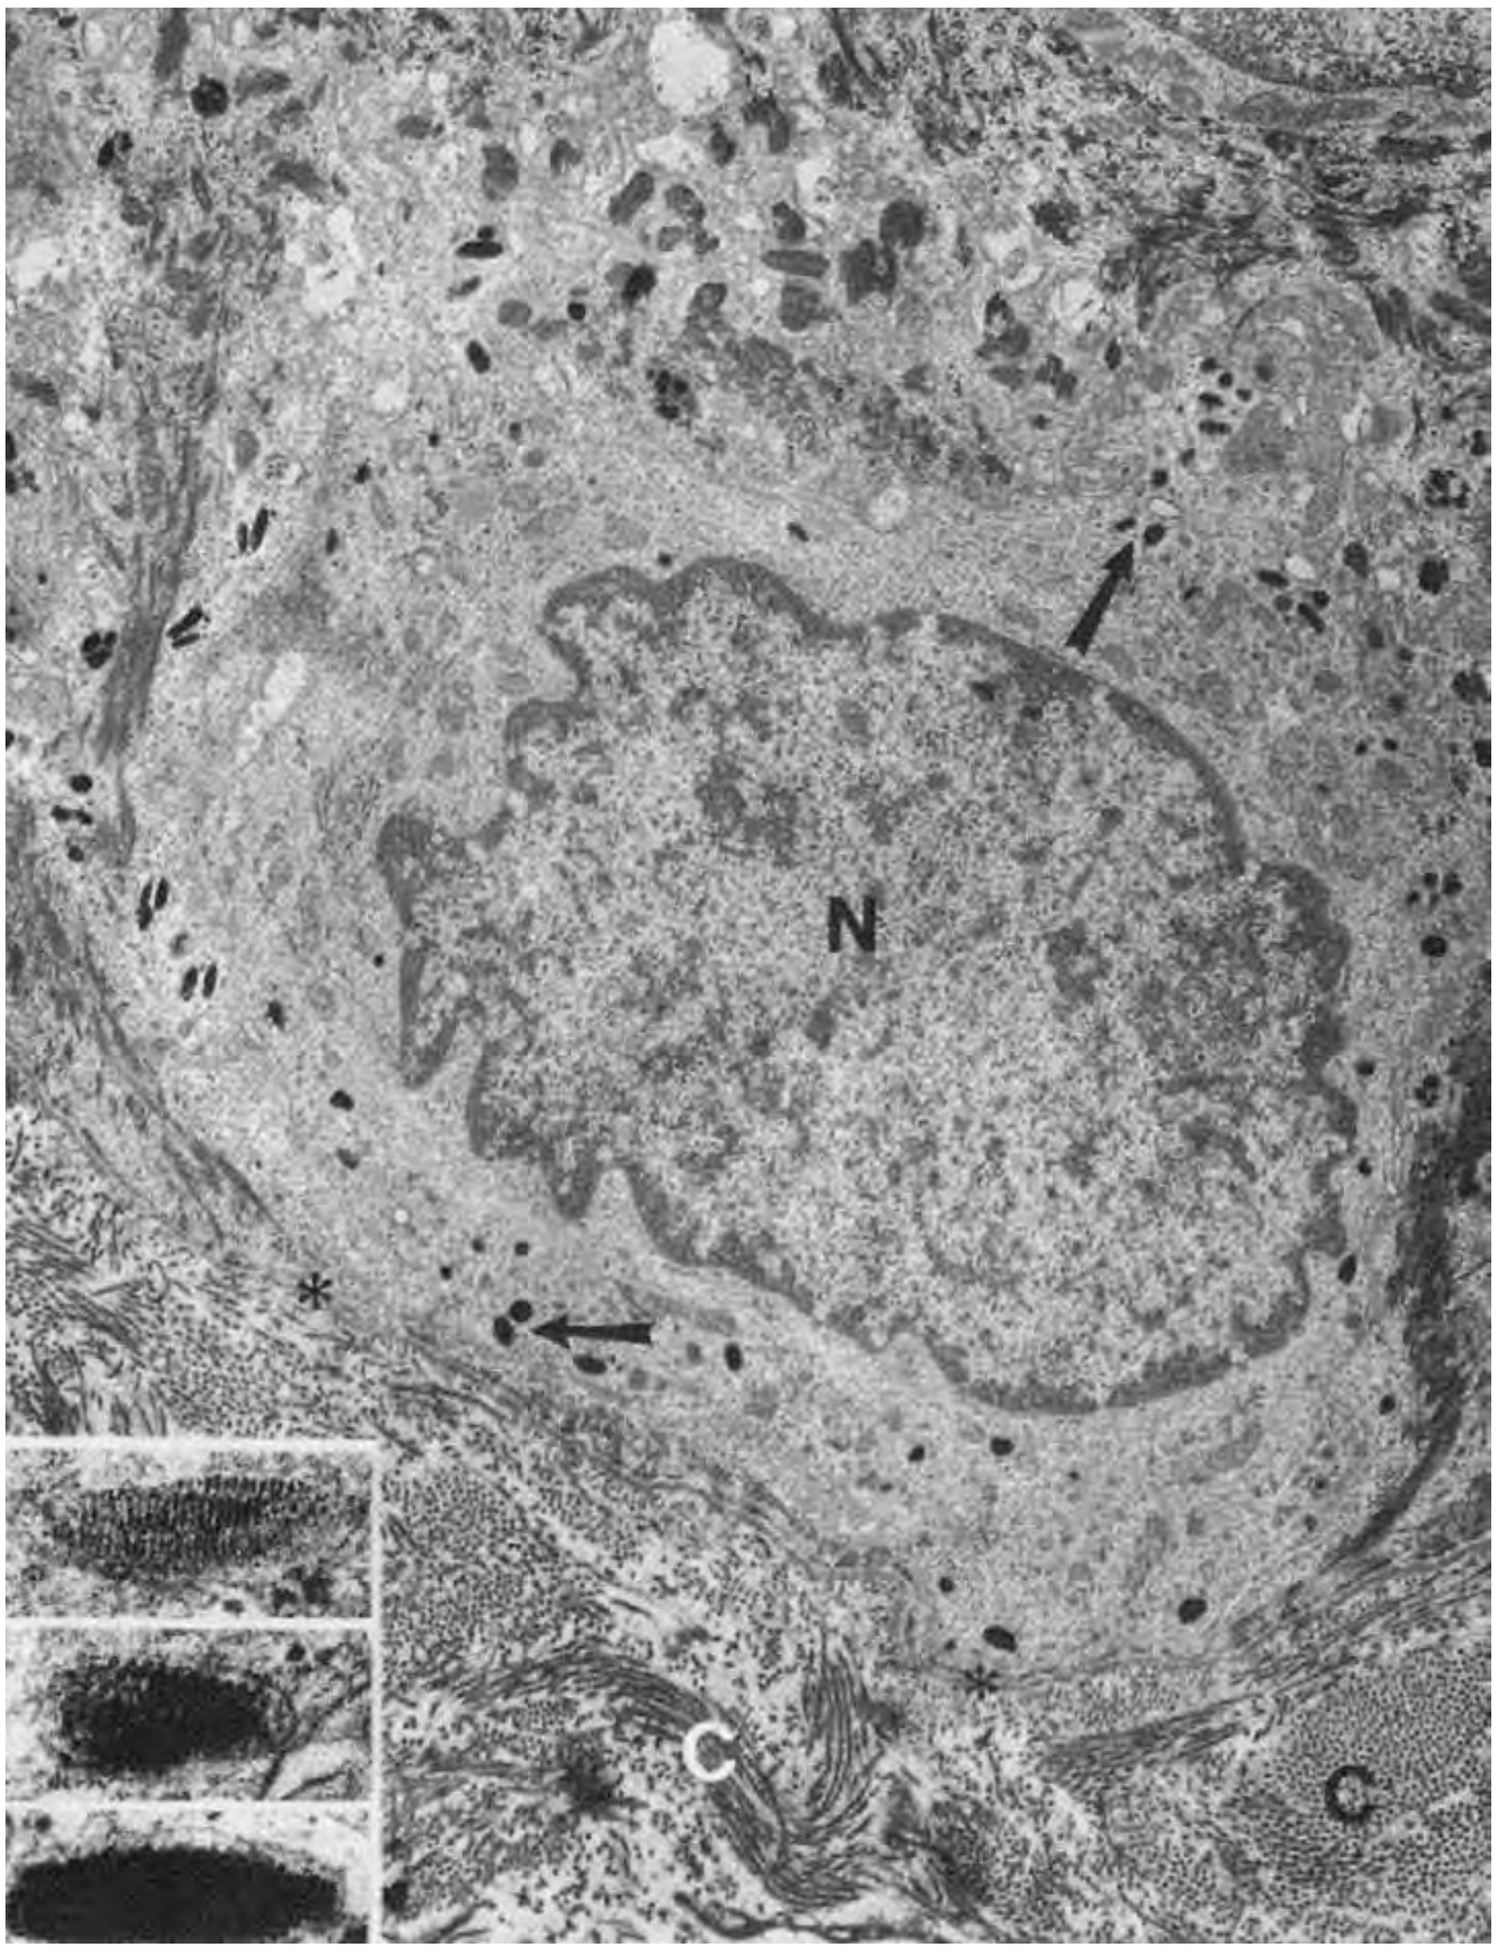

FIGURE EM-1. Melanocyte. Inset: Melanosomes. N, nucleus of melanocyte; arrows, melanosomes; C, collagen in the dermis; asterisk, basal lamina. Insets: Melanosomes in different stages of development: stage II (upper), stage III (middle), and stage IV (lower).

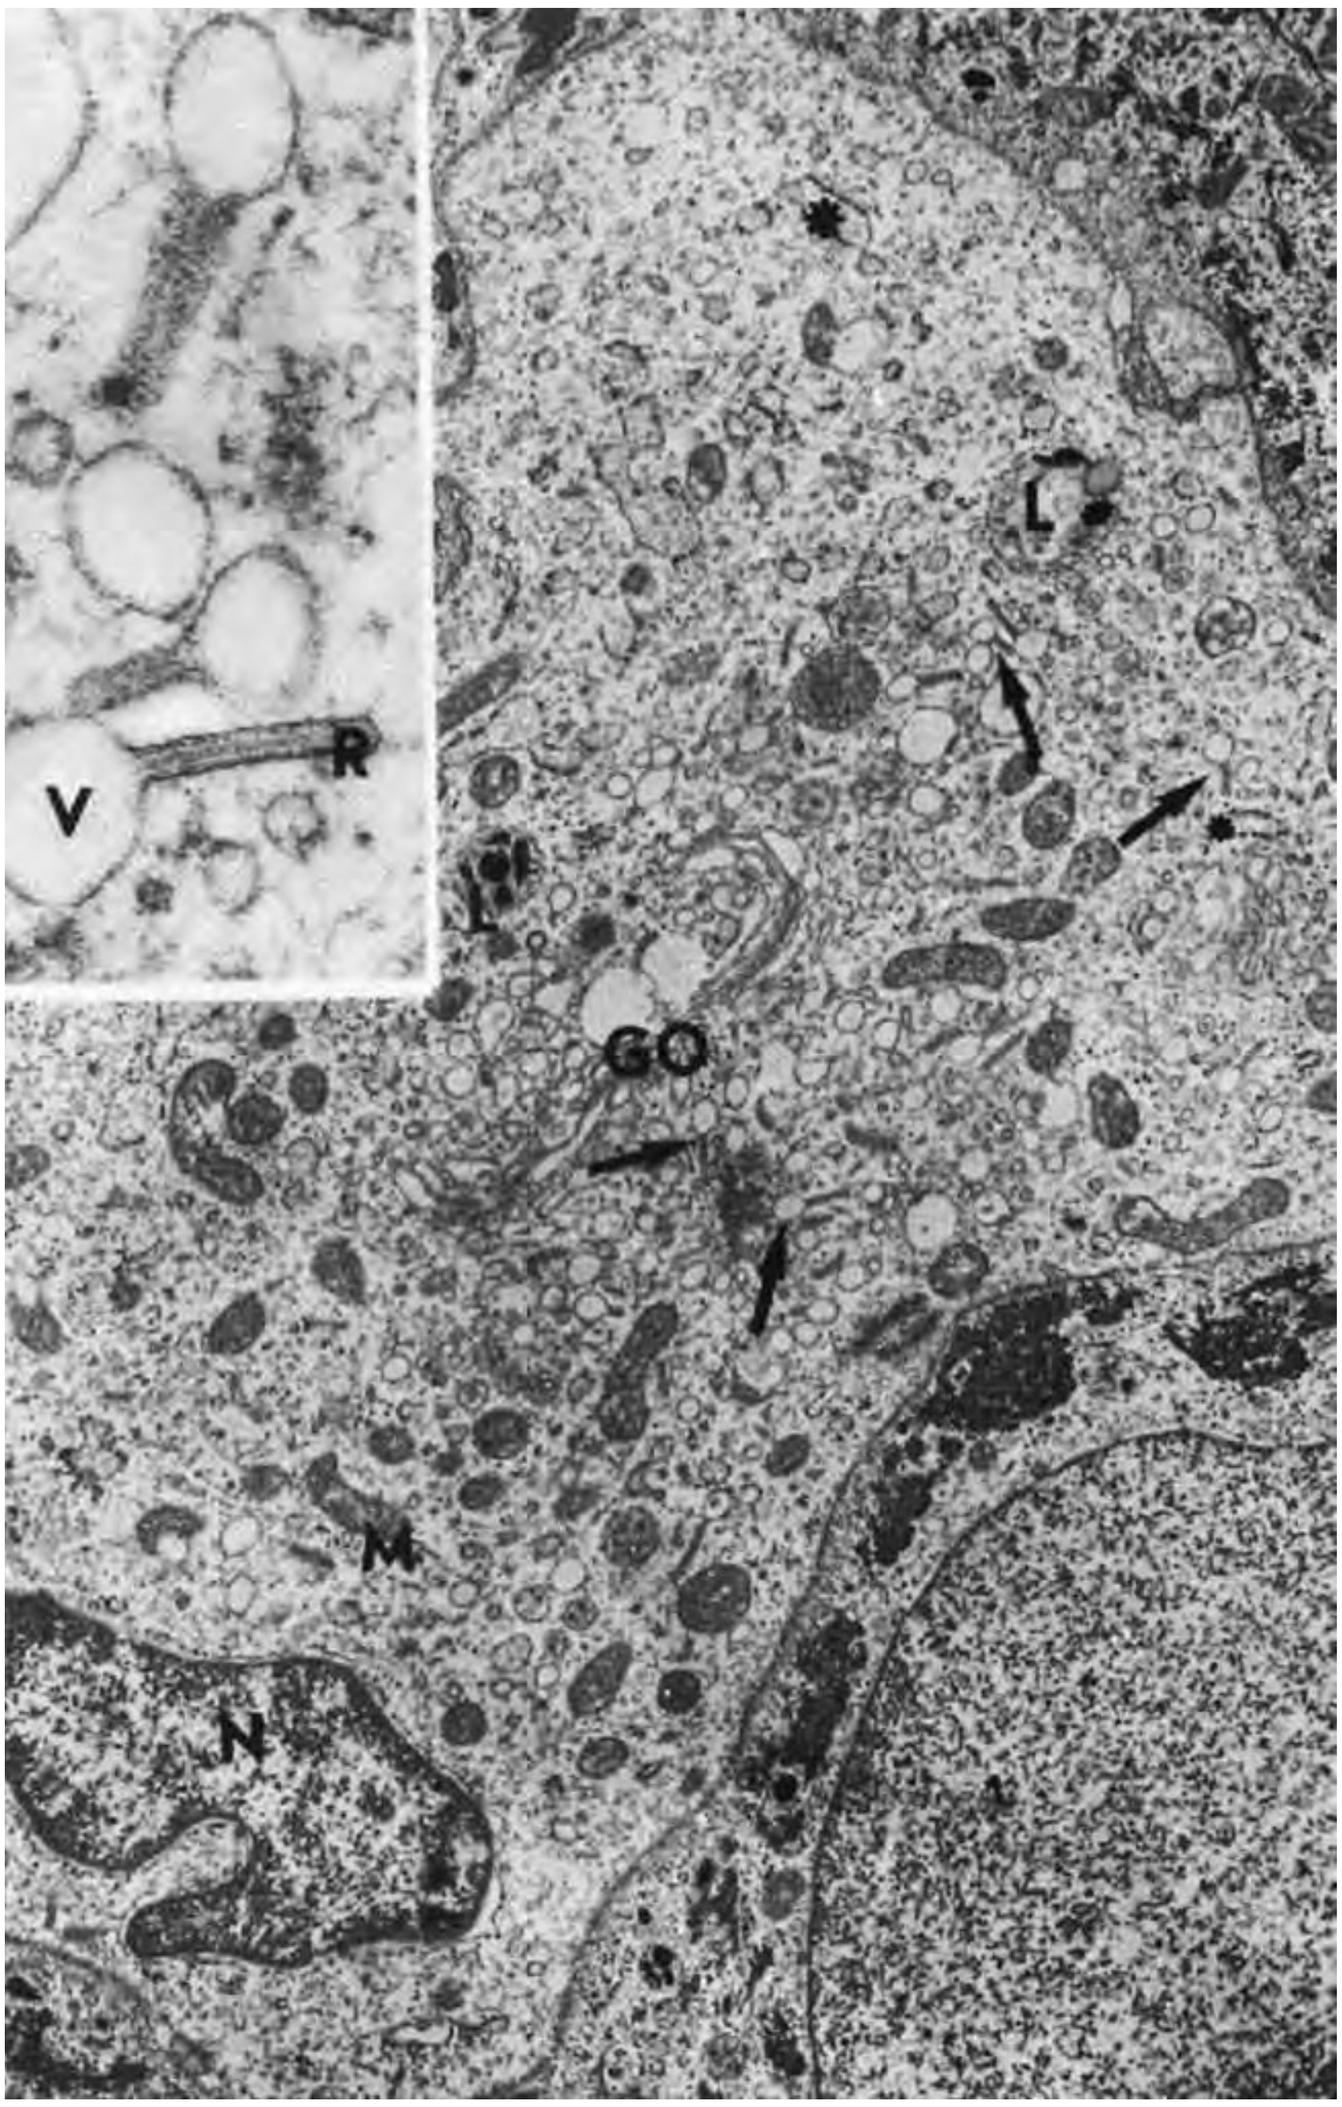

FIGURE EM-2. Langerhans cell. Inset: Langerhans granules. N, nucleus of Langerhans cell; L, lysosomes containing melanosomes; GO, Golgi complex; M, mitochondrium; asterisk, rough endoplasmic reticulum; arrows, Langerhans granules. Inset: Langerhans granules at higher magnification consisting of a vesicle (V) and a rod (R), both giving the appearance of a tennis racquet.

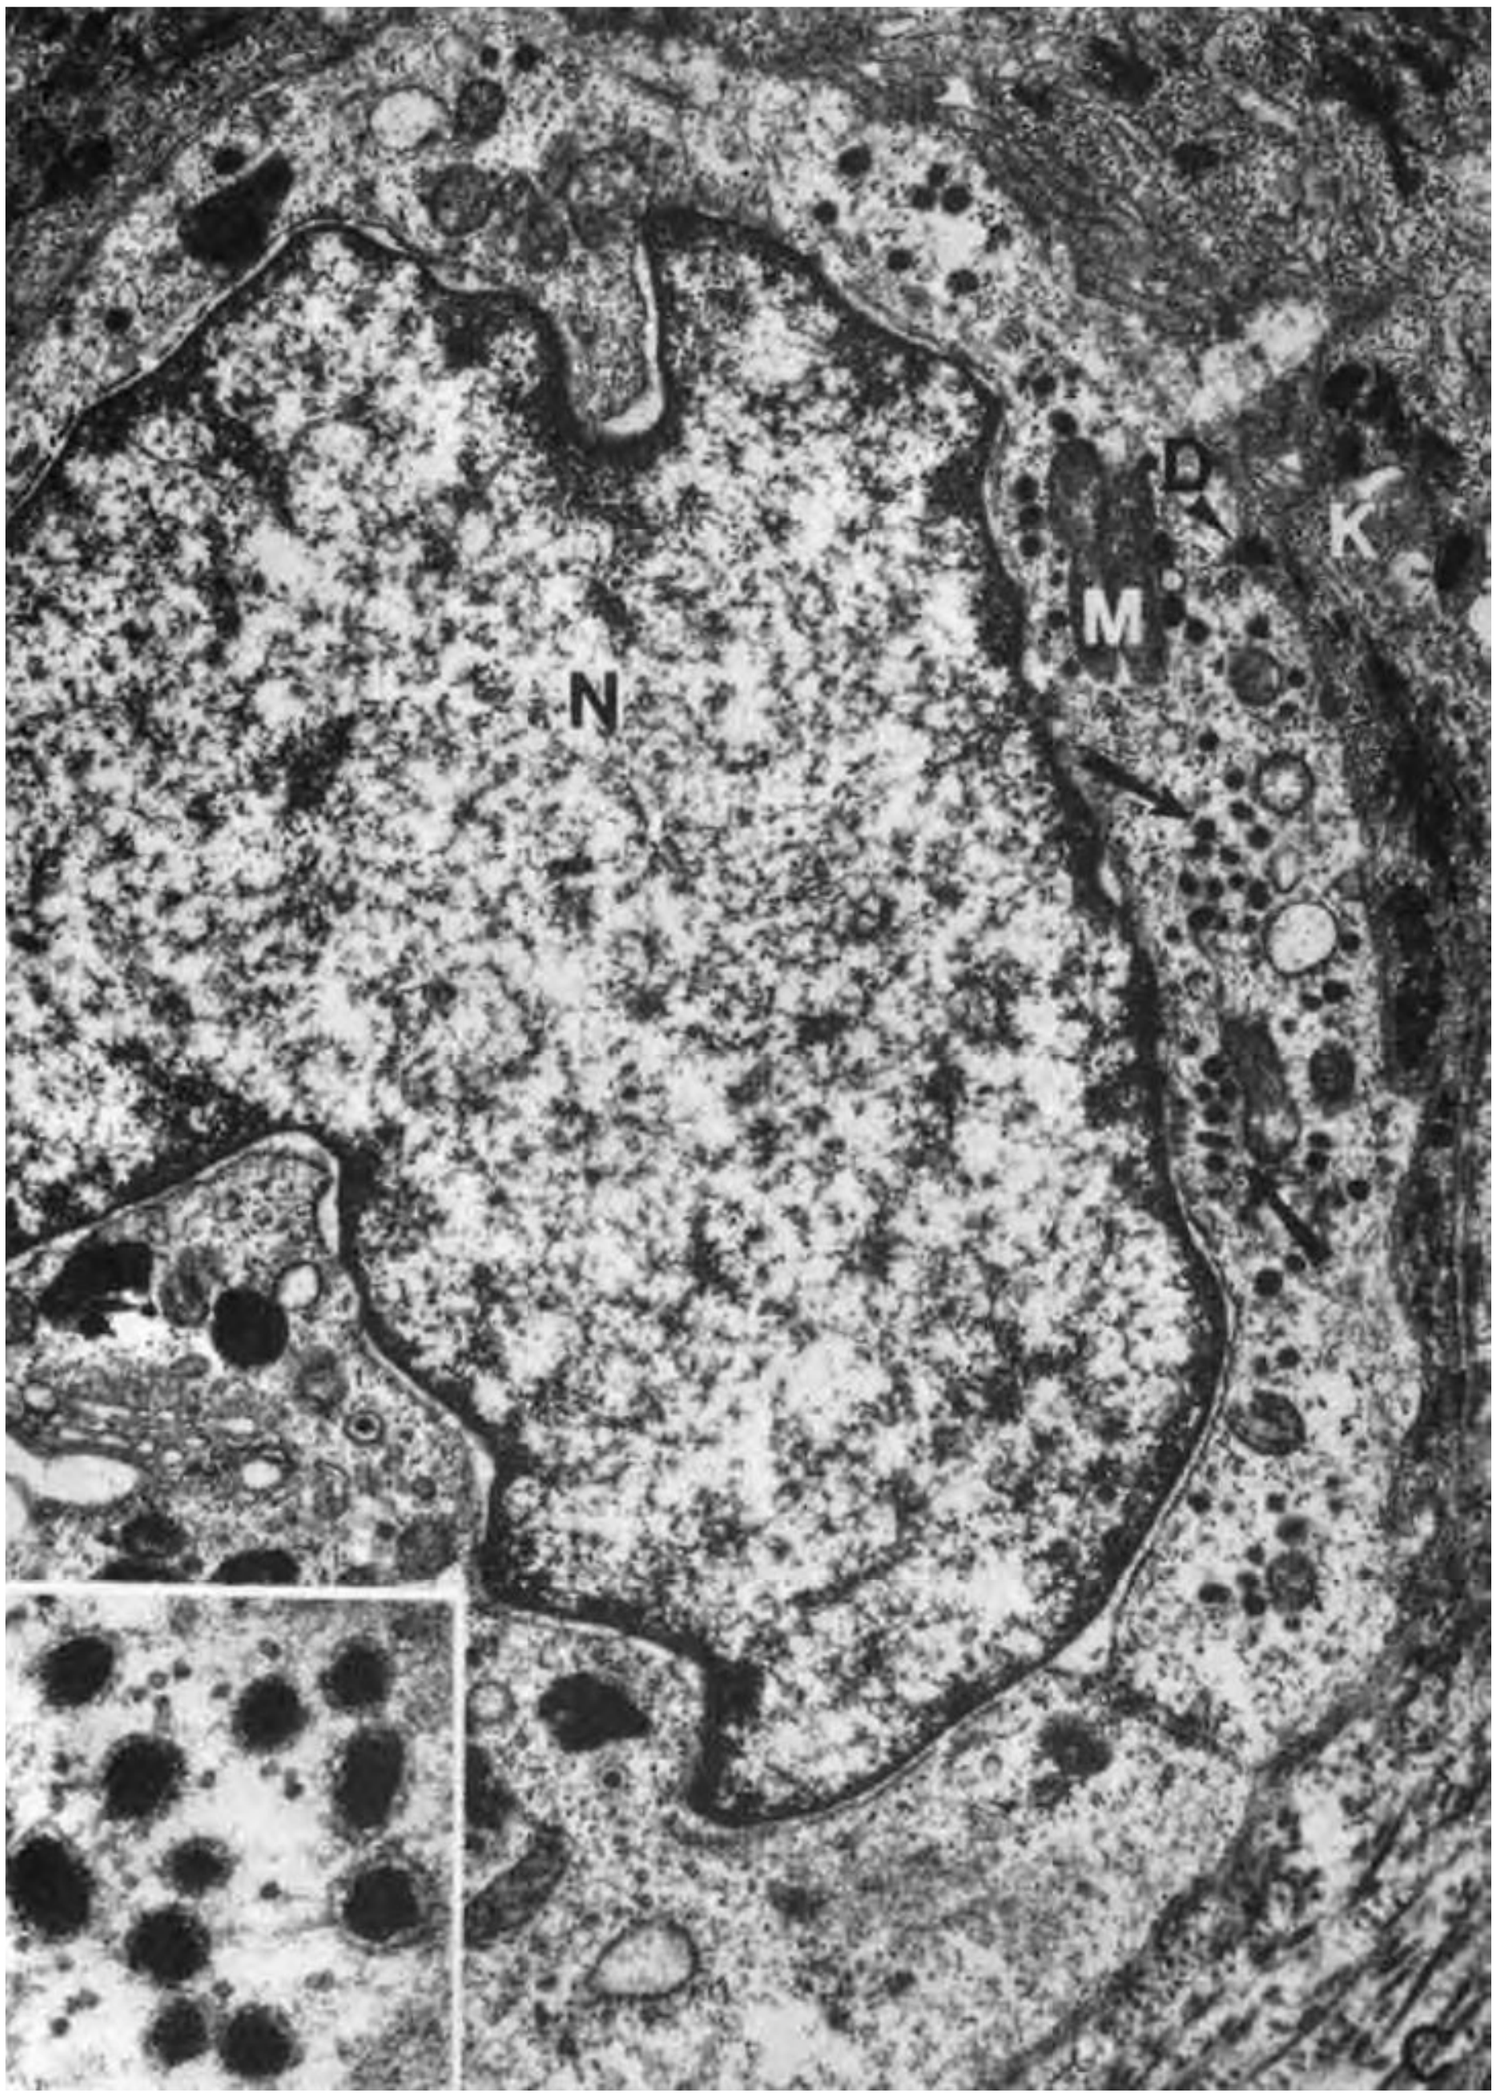

FIGURE EM-3. Merkel cell. Inset: Merkel granules. N. nucleus of Merkel cell; asterisk, on basal lamina; M, mitochondria; arrows, specific granules of the Merkel cell; D with pointer, desmosome between Merkel cell and keratinocyte (K); C, collagen with cross striation. Inset: Specific membrane-bound granules at higher magnification.

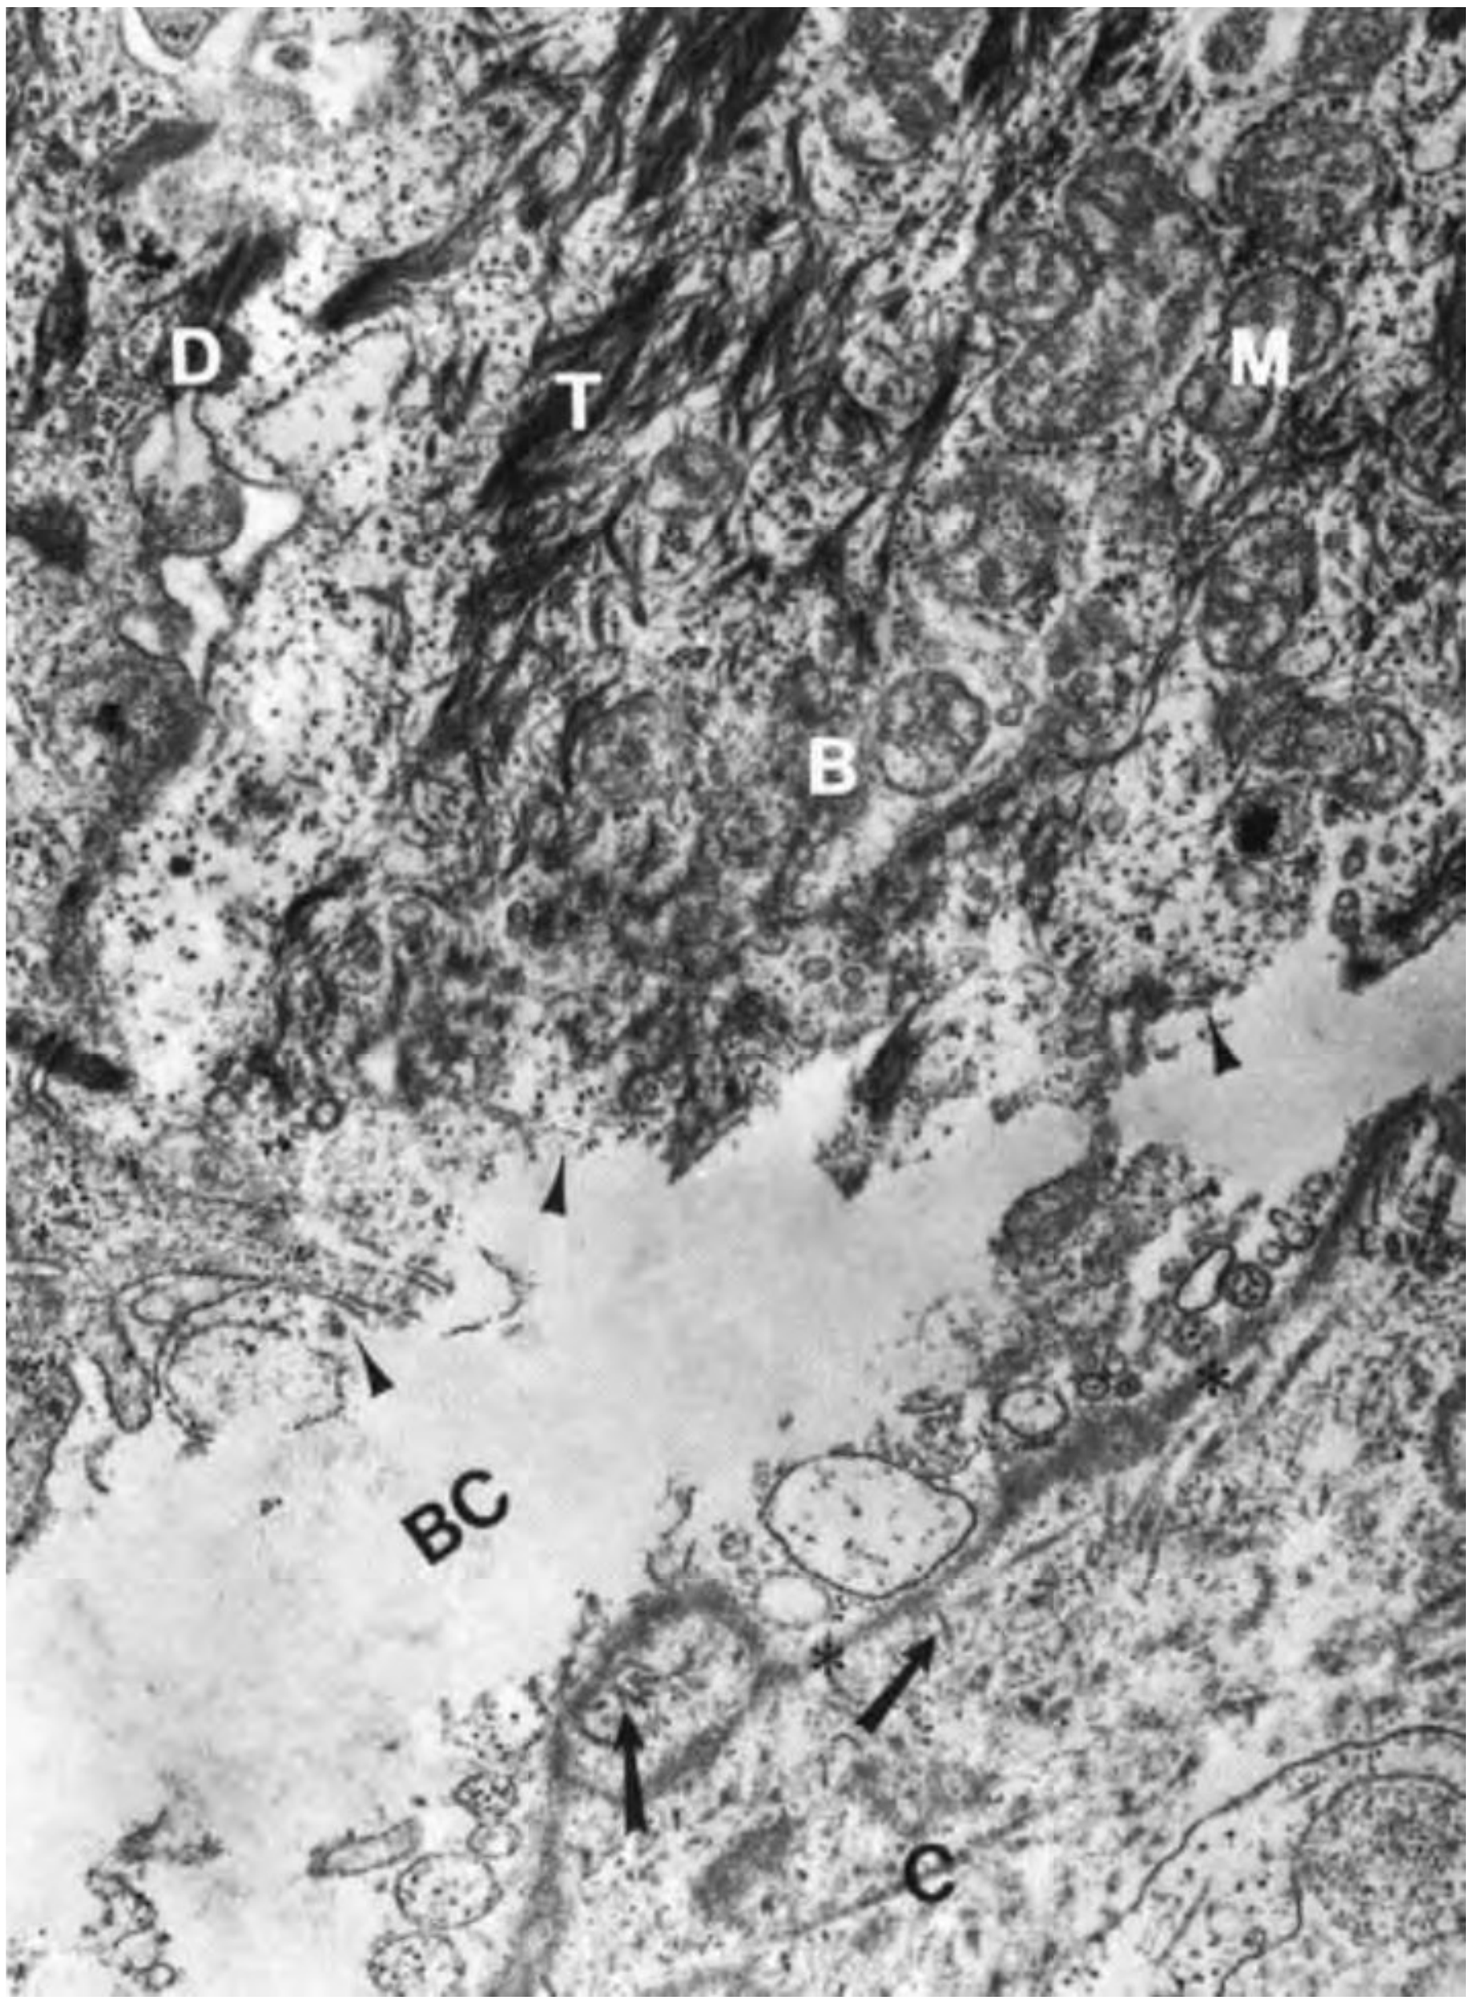

FIGURE EM-4. Epidermolysis bullosa simplex. The blister formed as the result of degenerative, cytolytic changes in the basal cells (B). The bulla cavity (BC) is situated above the basement membrane (asterisk). The basal cells are severely damaged, lacking a plasma membrane (pointers). T, tonofilaments; M, mitochondria; D, desmosome.

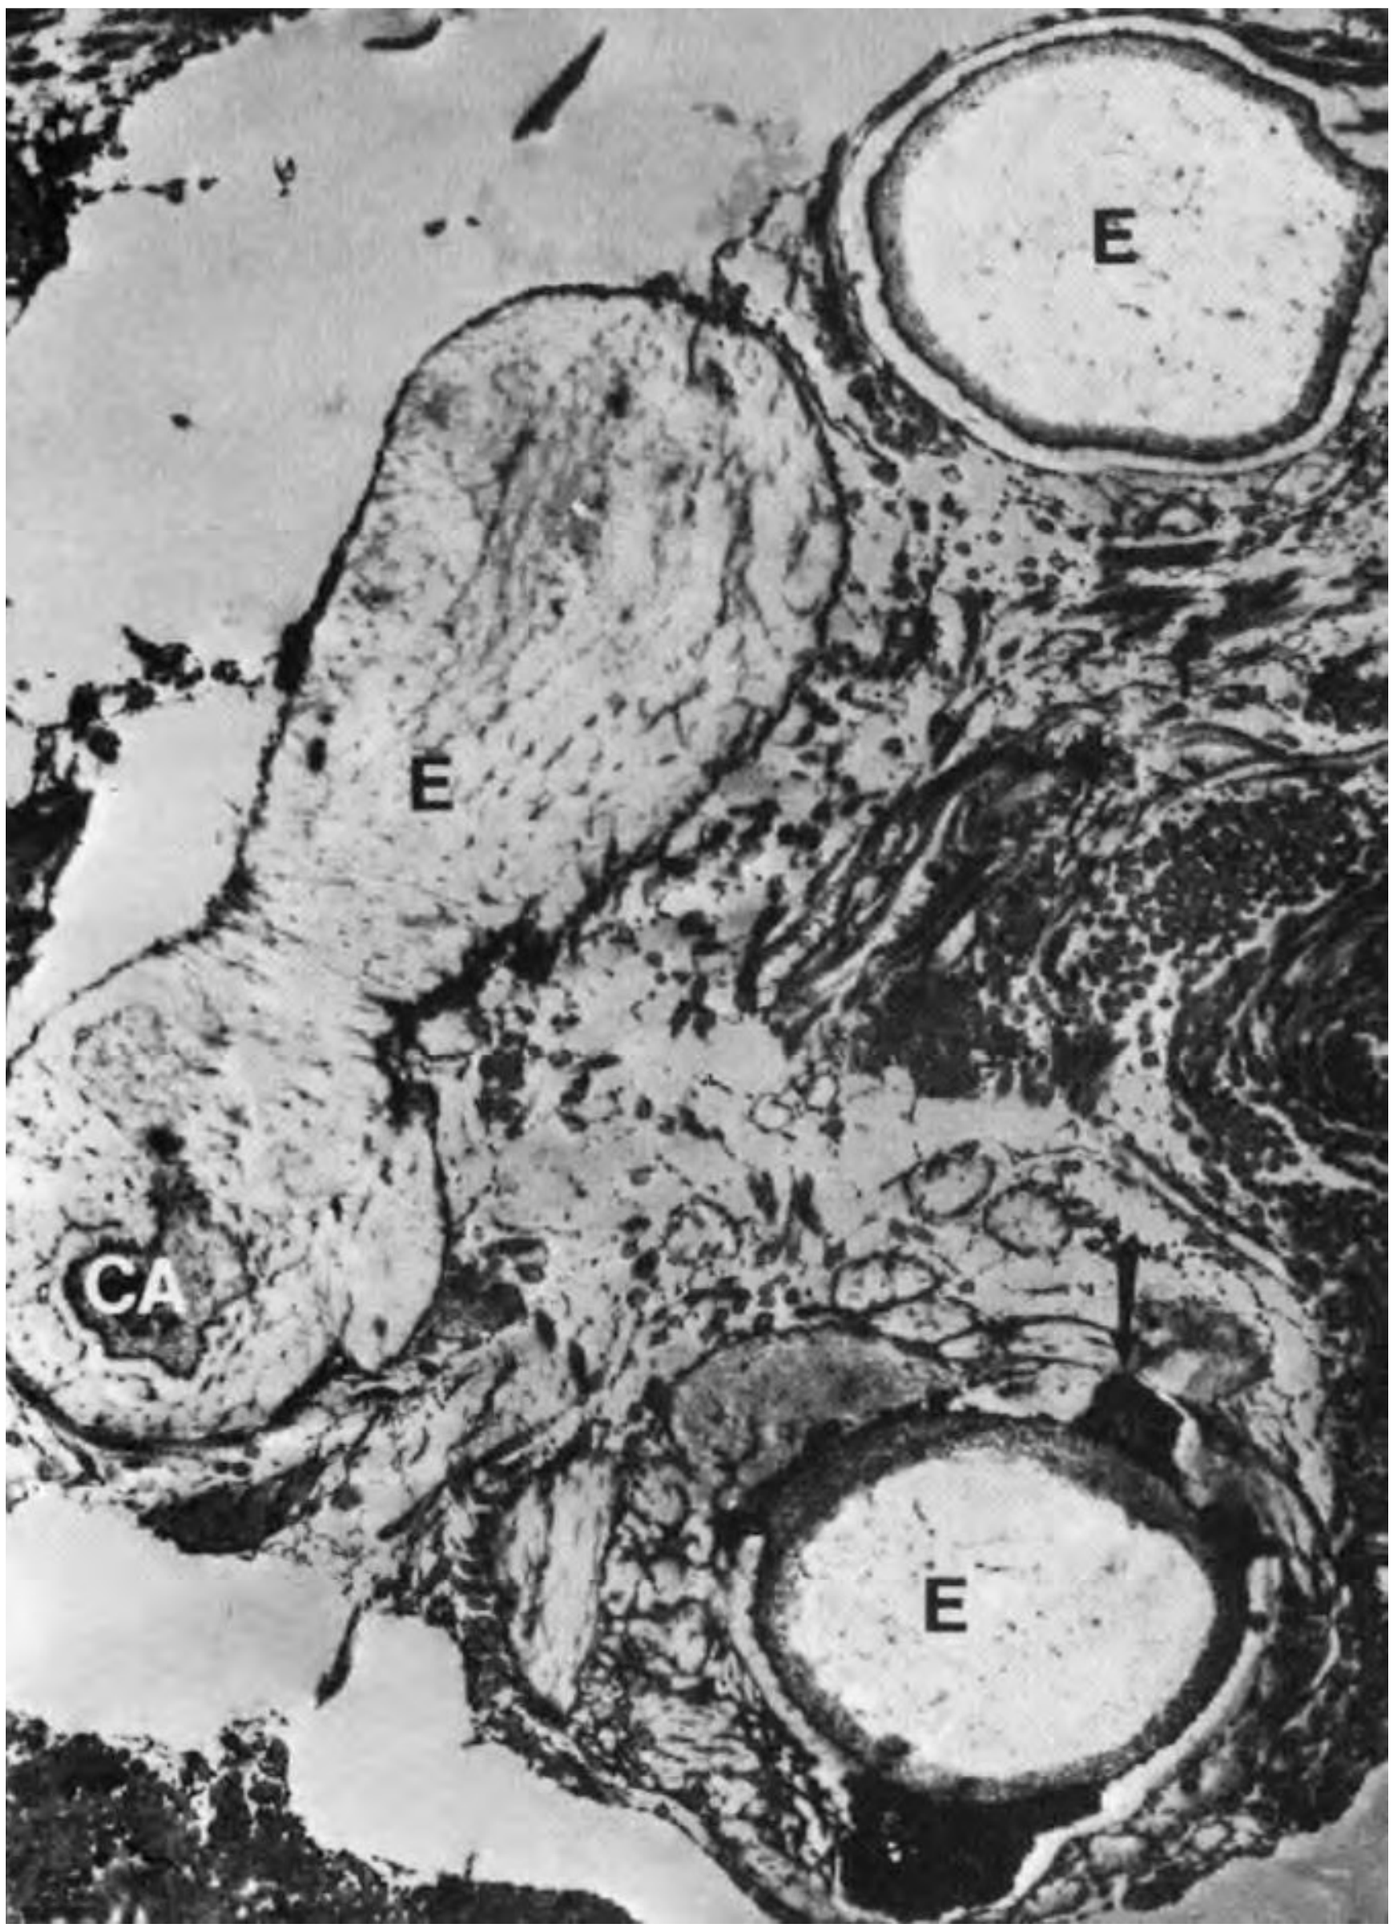

FIGURE EM-5. Pseudoxanthoma elasticum. The elastic fibers (E) are bizarrely shaped. Calcium (CA, arrows) is deposited on or around elastic fibers.

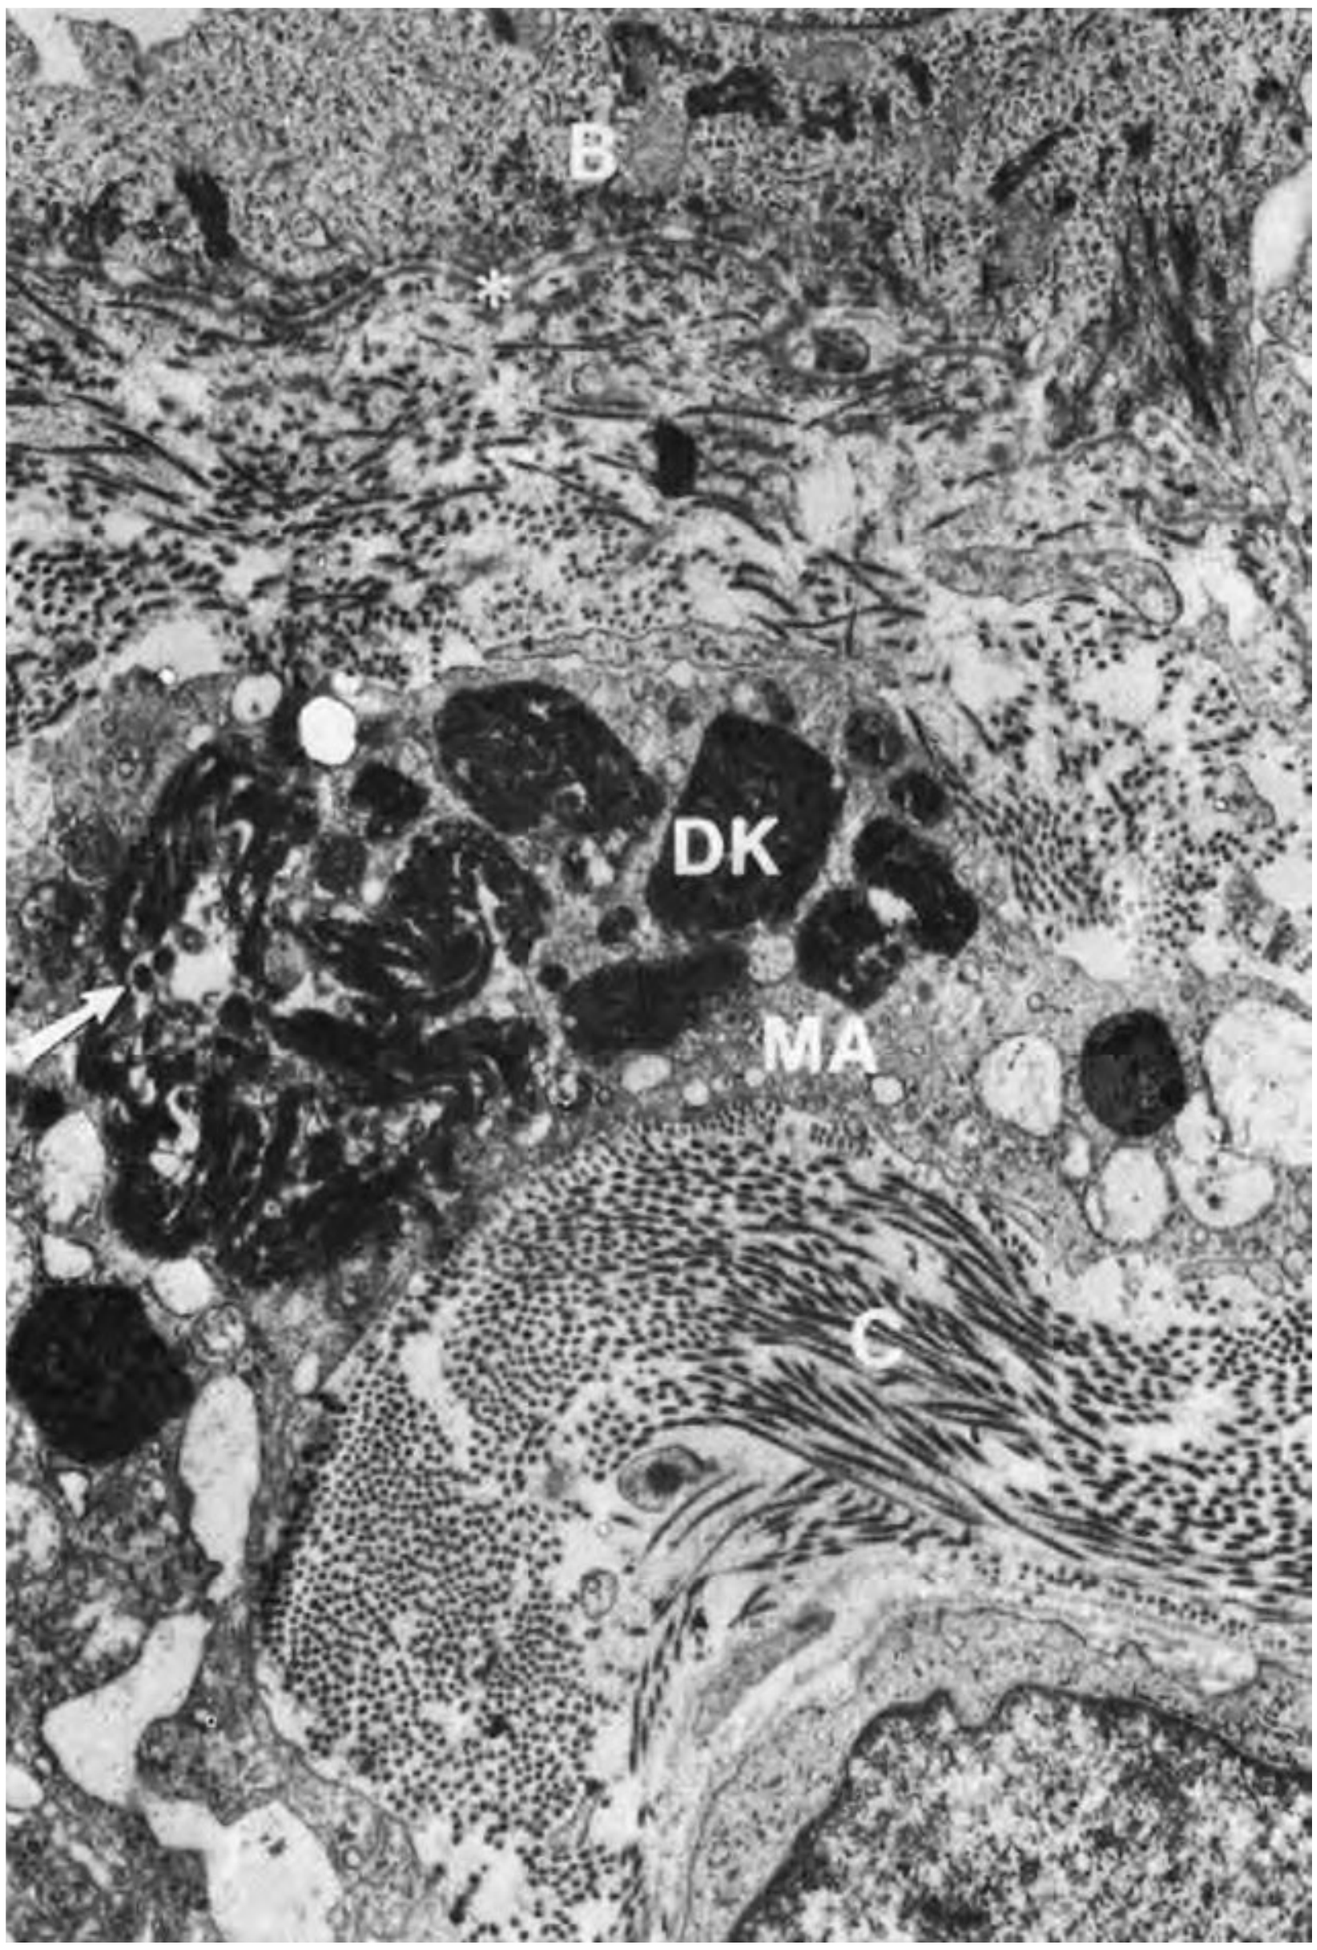

FIGURE EM-6. Incontinentia pigmenti. In this disease, dyskeratotic cells are found in the epidermis. Macrophages migrate into the epidermis, phagocytize these dyskeratotic cells as well as melanosomes, and subsequently return to the dermis. MA, macrophage containing dyskeratotic material (DK) and melanosomes (arrow); B, basal cell; asterisk, basal lamina; C, collagen.

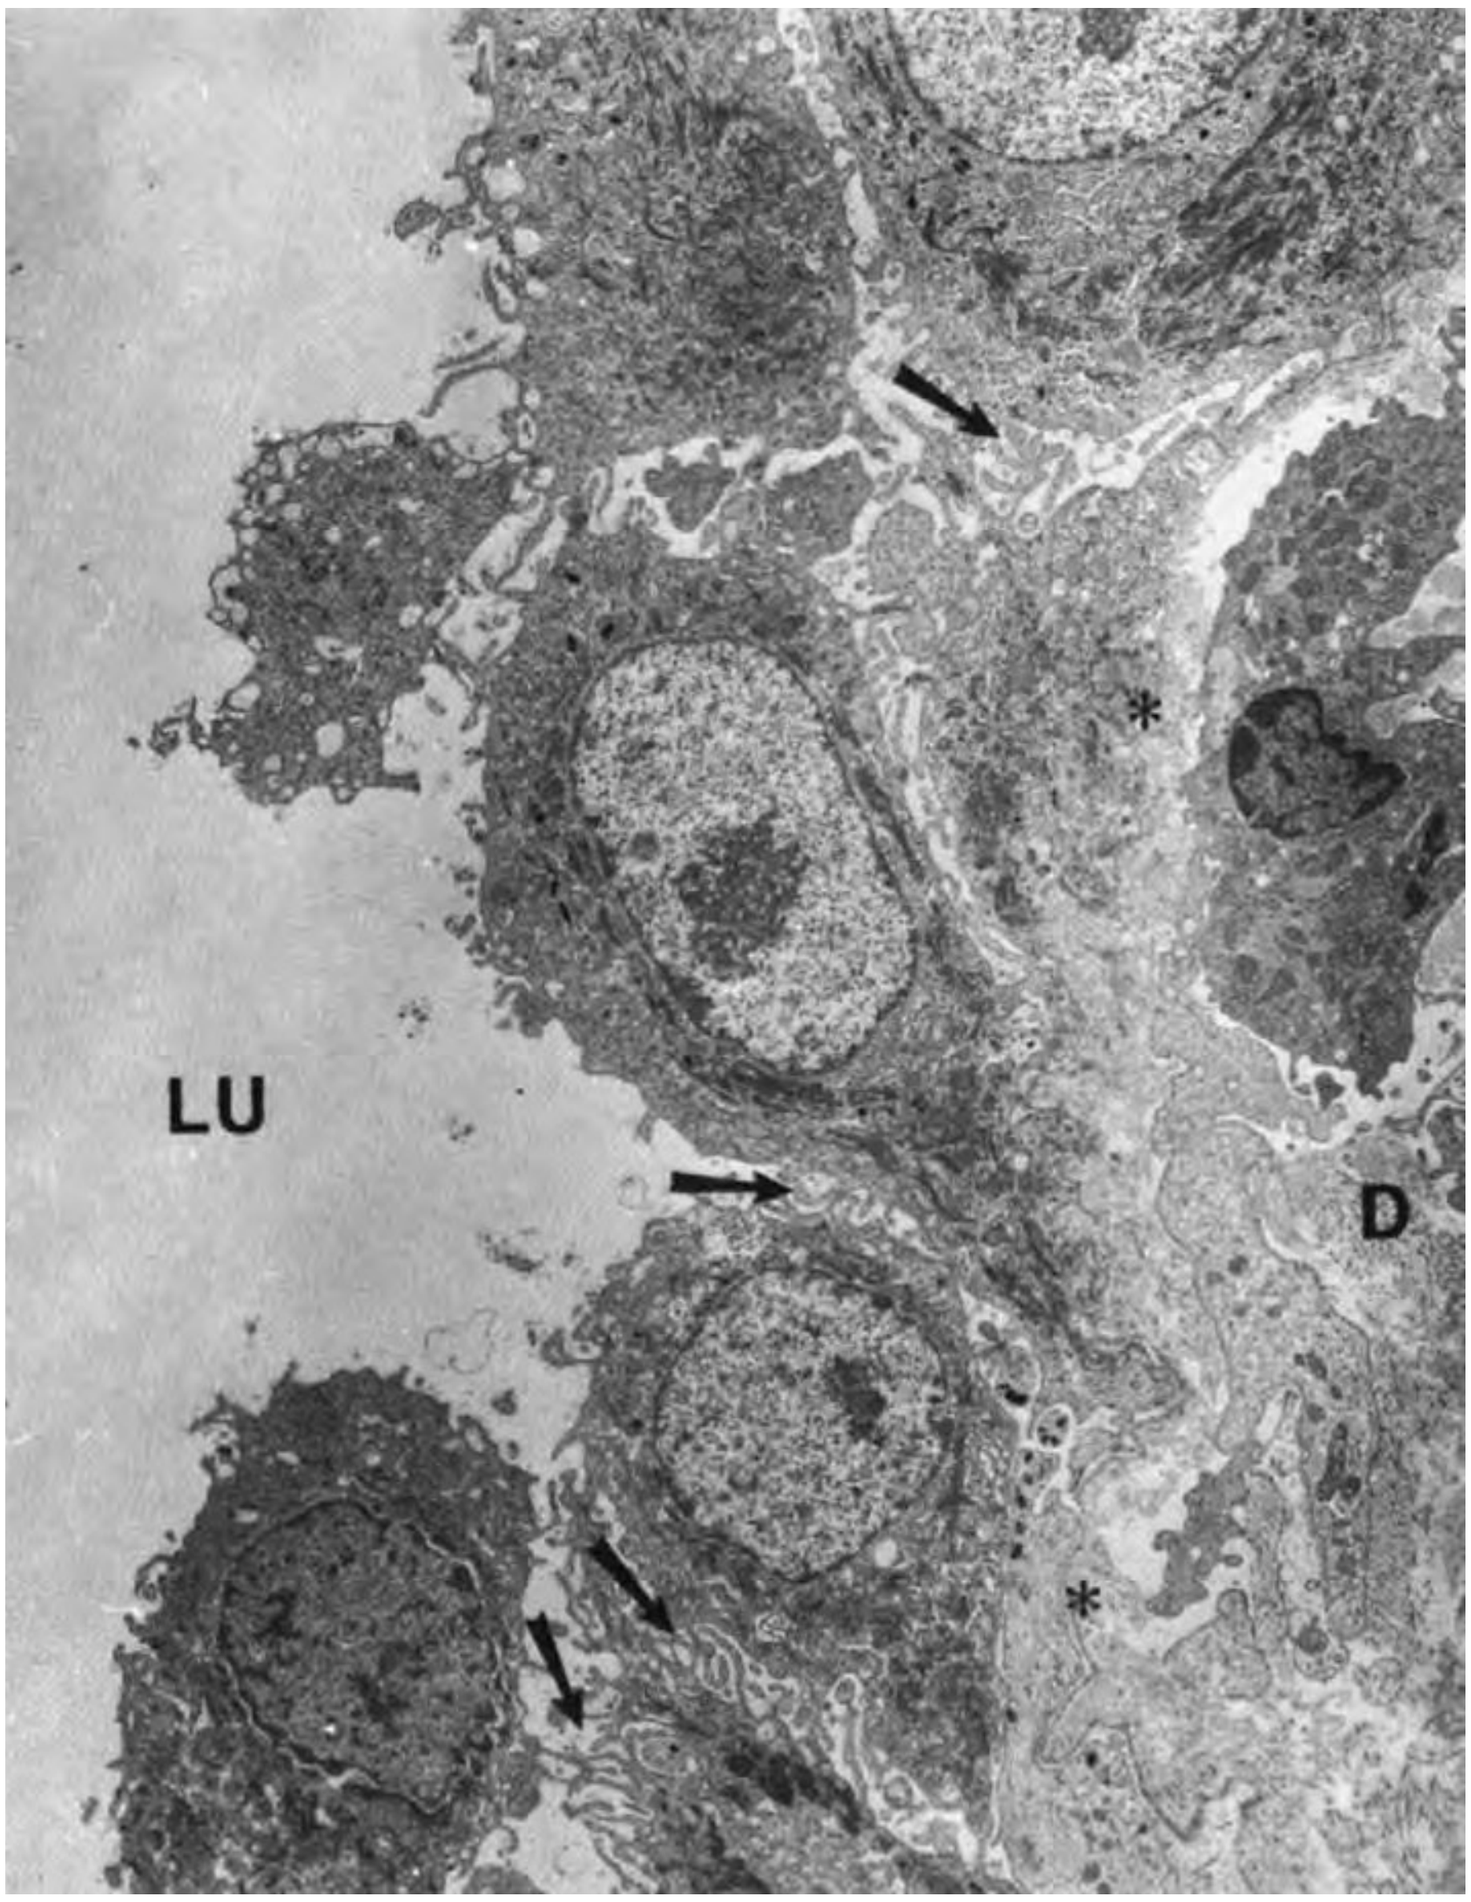

FIGURE EM-7. Pemphigus vulgaris, tombstone row. The dissolution of the intercellular cement led to the formation of a blister. At the base of the blister, one or two rows of keratinocytes are left. The cohesion of the basal cells with the dermis is well preserved. LU, blister lumen; asterisks, basement membrane; arrows, microvilli of keratinocytes; D, dermis.

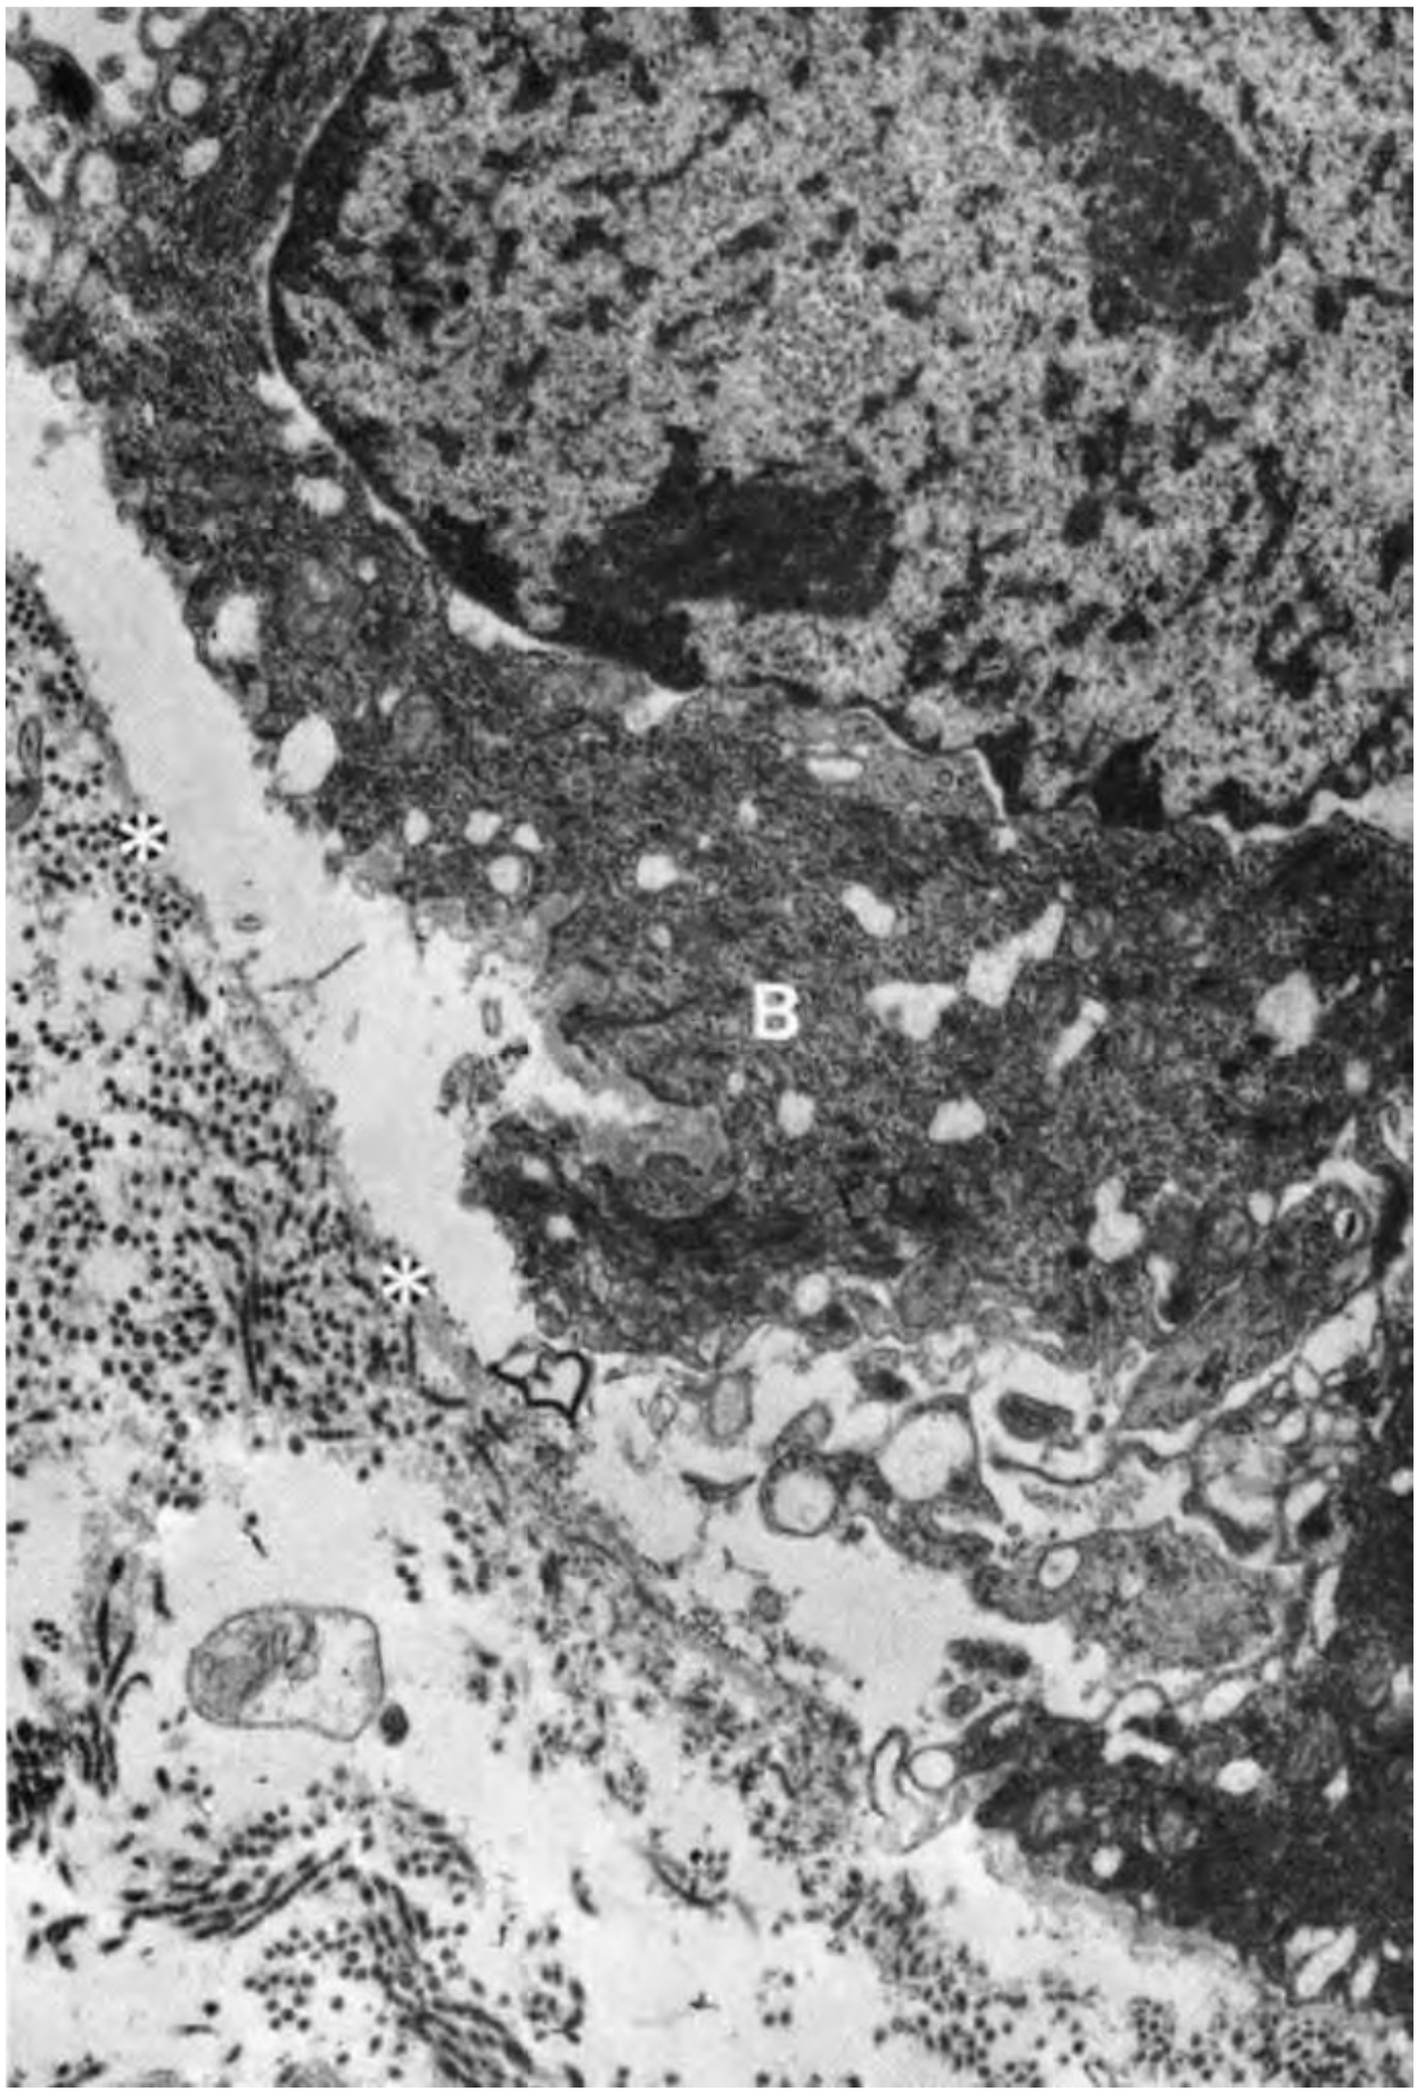

FIGURE EM-8. Bullous pemphigoid, noninflamed type. In this type of bullous pemphigoid, the blister forms between the basal cell (B) and the basement membrane (asterisks).

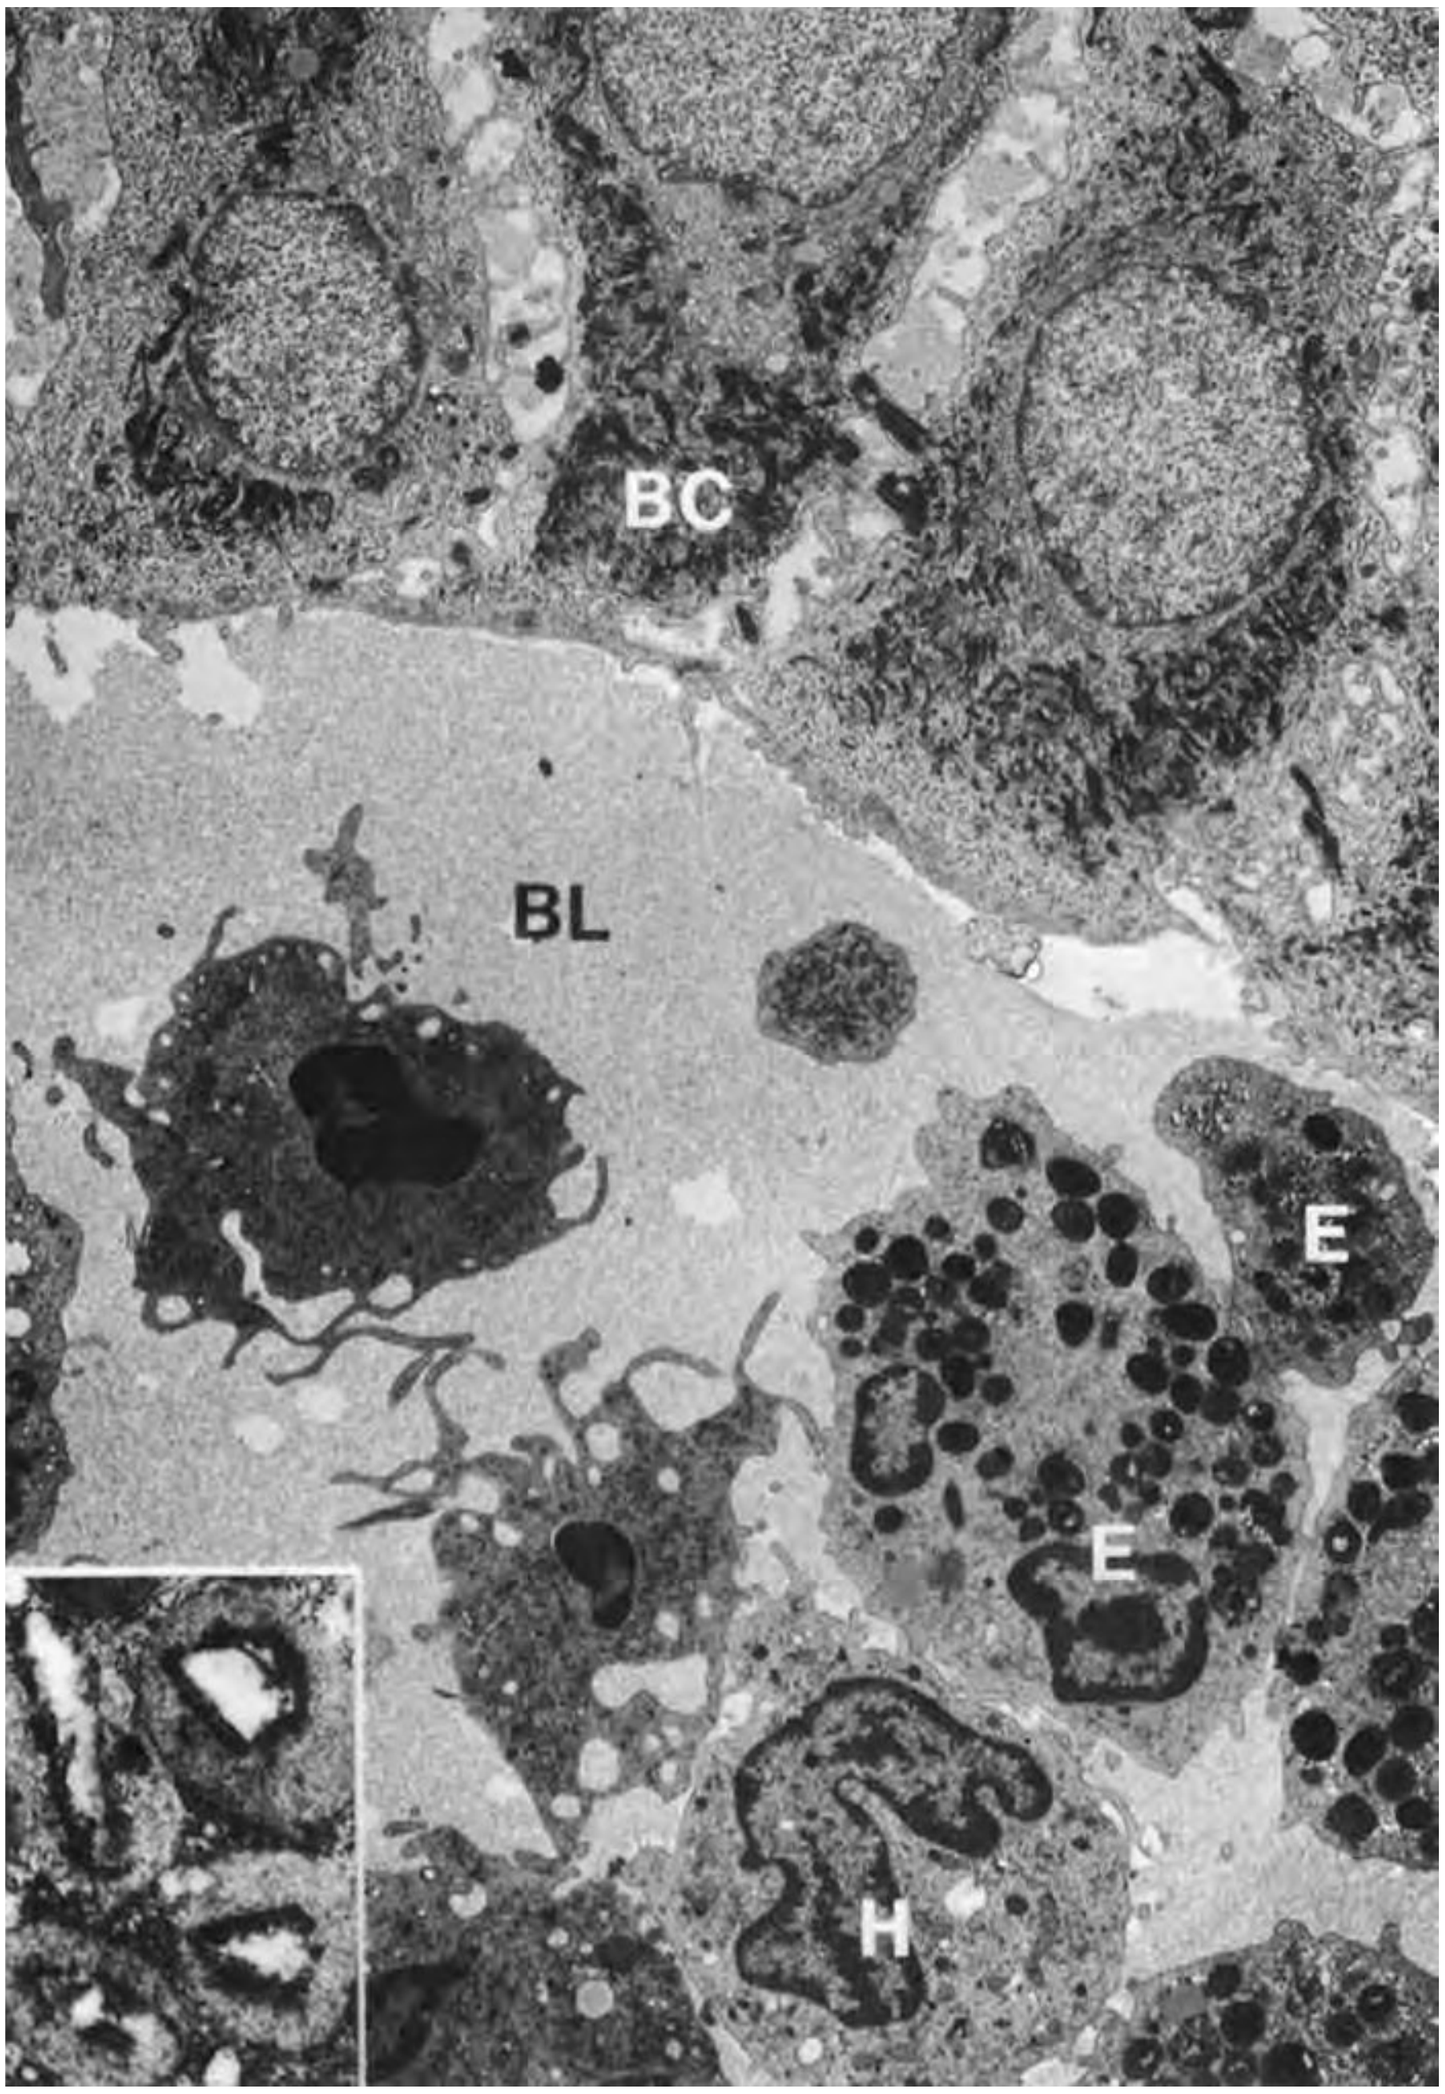

FIGURE EM-9. Bullous pemphigoid inflamed type. Inset: Granules of eosinophils. The blister (BL) contains several histiocytes (H) and eosinophils (E). The basement membrane has disappeared. The basal cells (BC) at the top of the blister are well preserved. Inset: Eosinophilic granules at higher magnification show a "crystal" at their center.

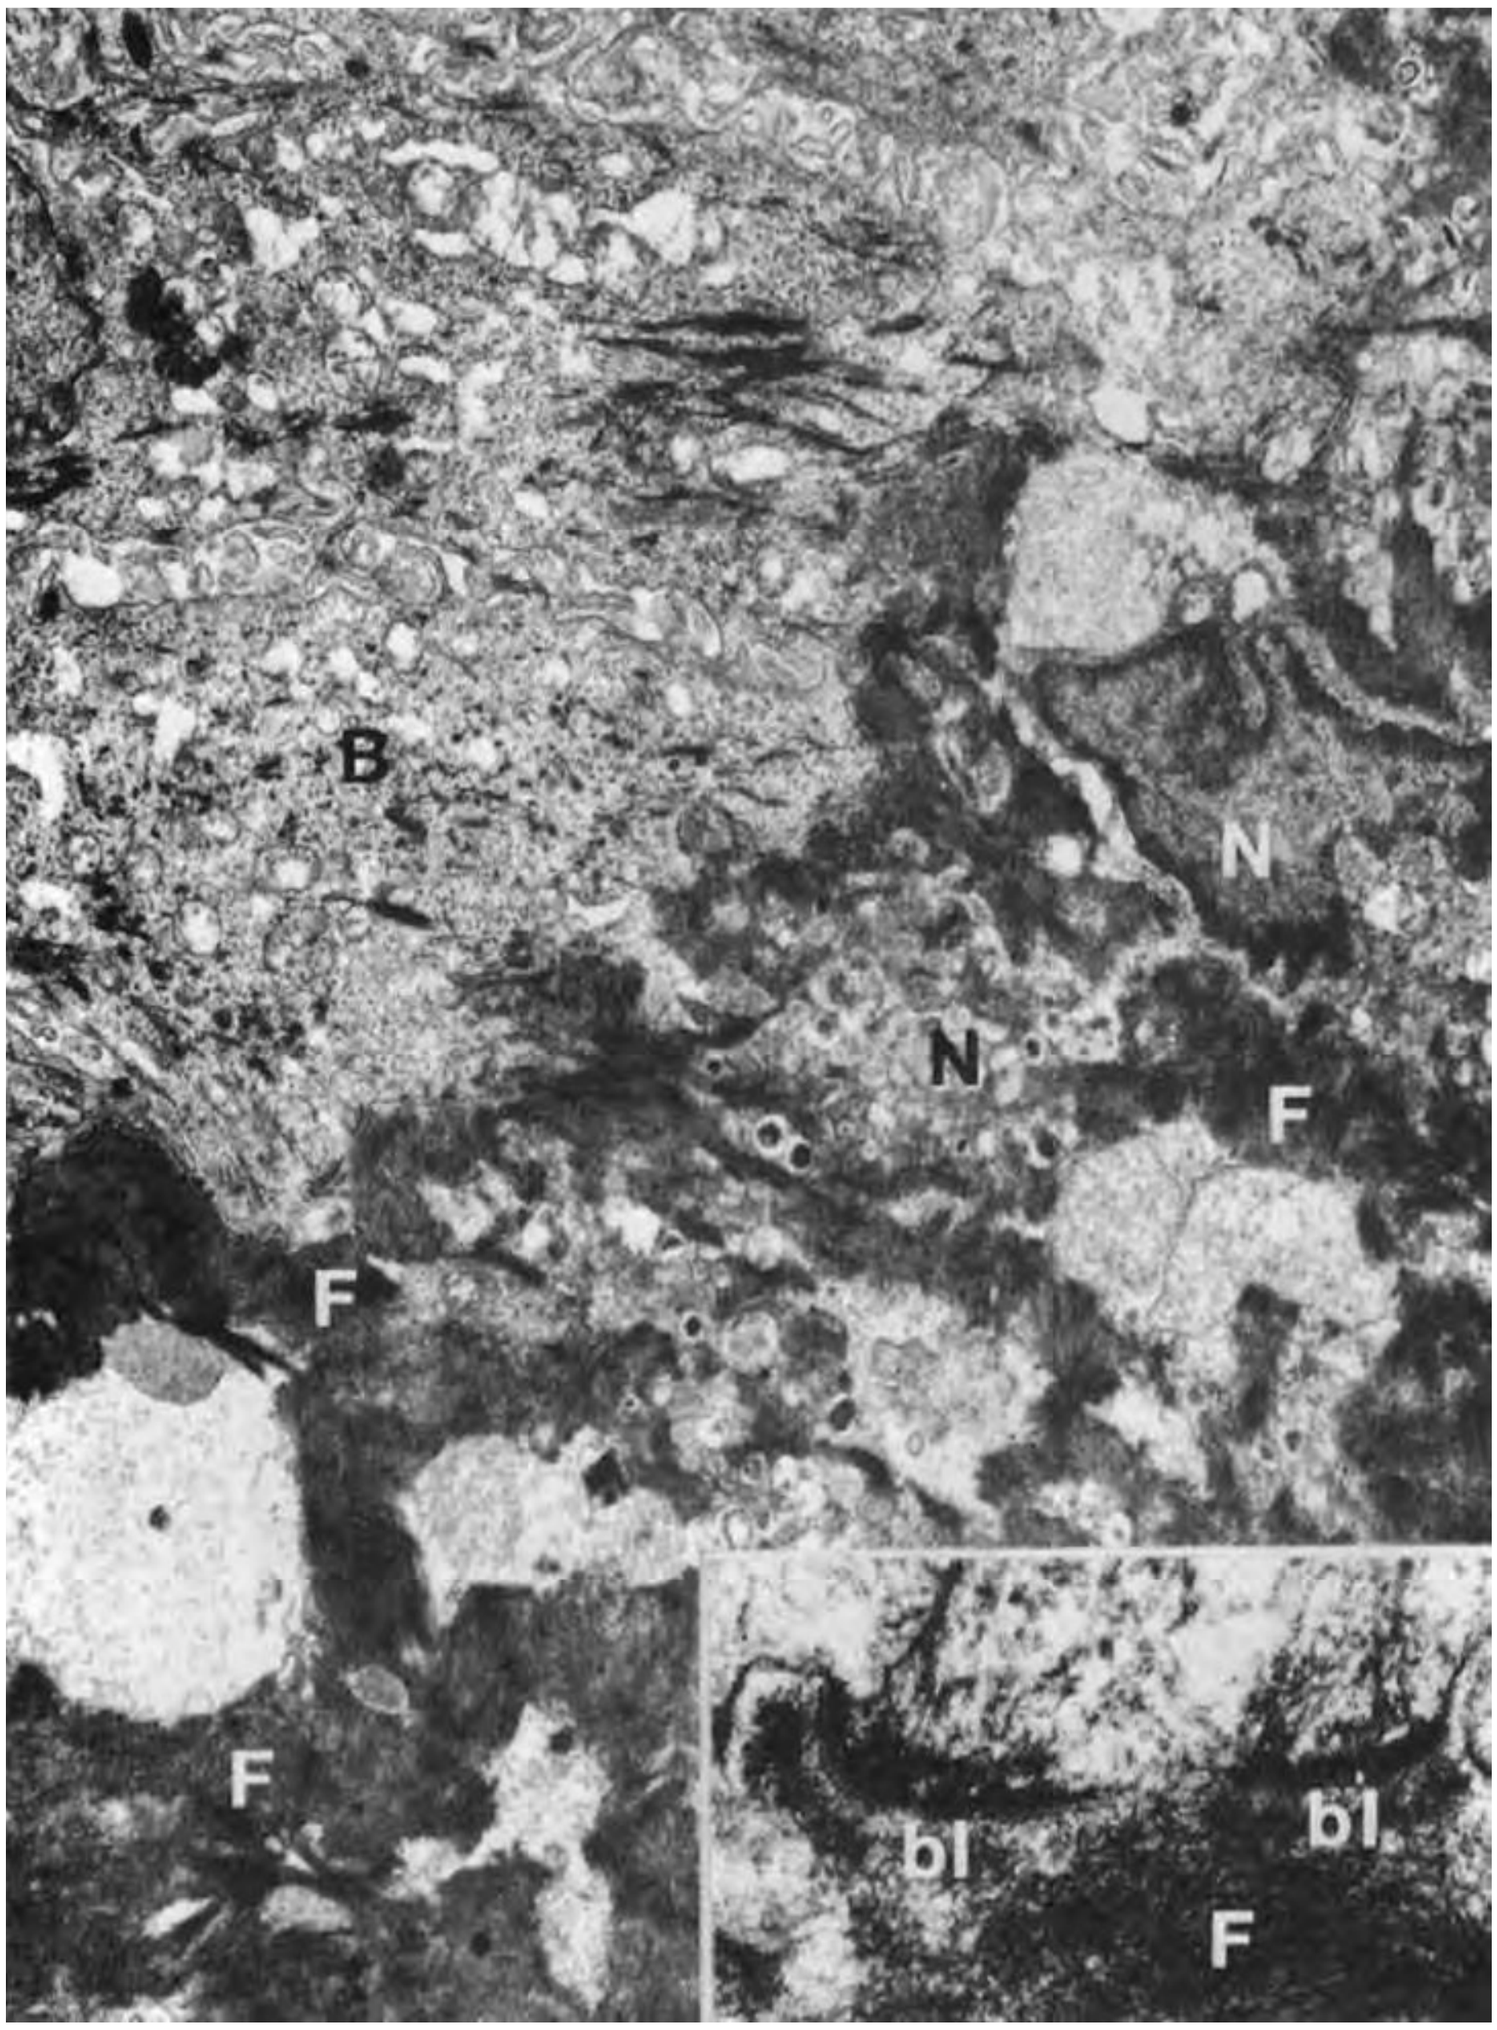

FIGURE EM-10. Dermatitis herpetiformis. Inset: Fibrin. The dermal papillae contain abundant amounts of fibrin (F). Between the meshes of fibrin, fragments of neutrophilic leukocytes (N) can be seen. B, basal cell. Inset: The fibrin (F) is attached to the dermal side of the basement membrane or basal lamina (bl). The basement membrane shows discontinuities.

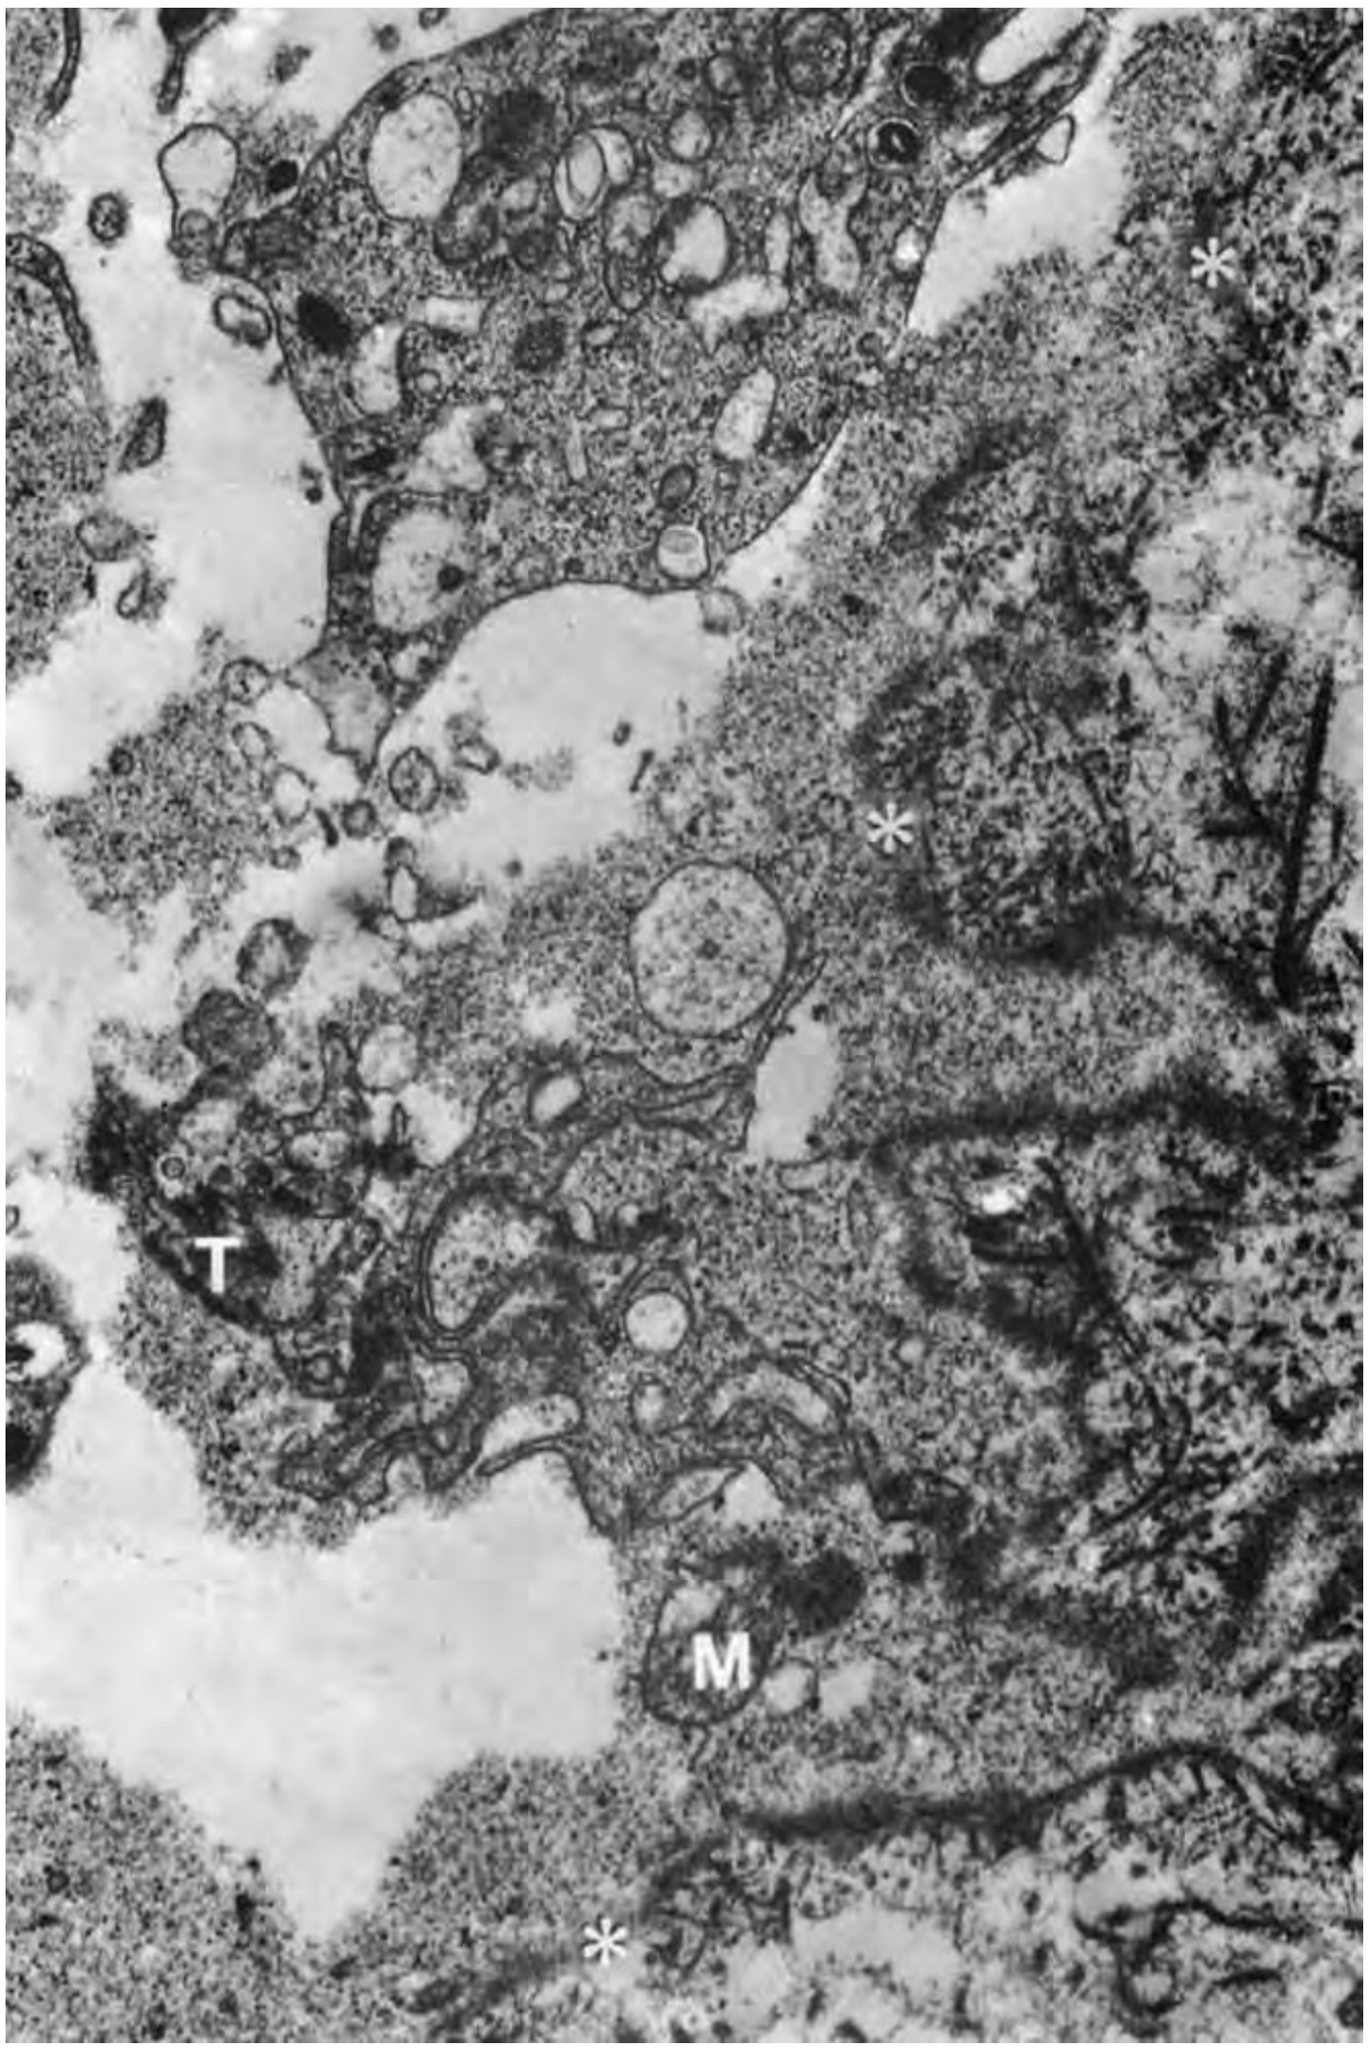

FIGURE EM-11. Herpes gestationis. In this disease, the blister forms either between basal cells and the basement membrane or, subsequent to dissolution of basal cells, between squamous cells and the basement membrane. A disintegrated basal cell containing tonofilaments (T) and mitochondria (M) and the basement membrane (asterisks) form the floor of the blister.

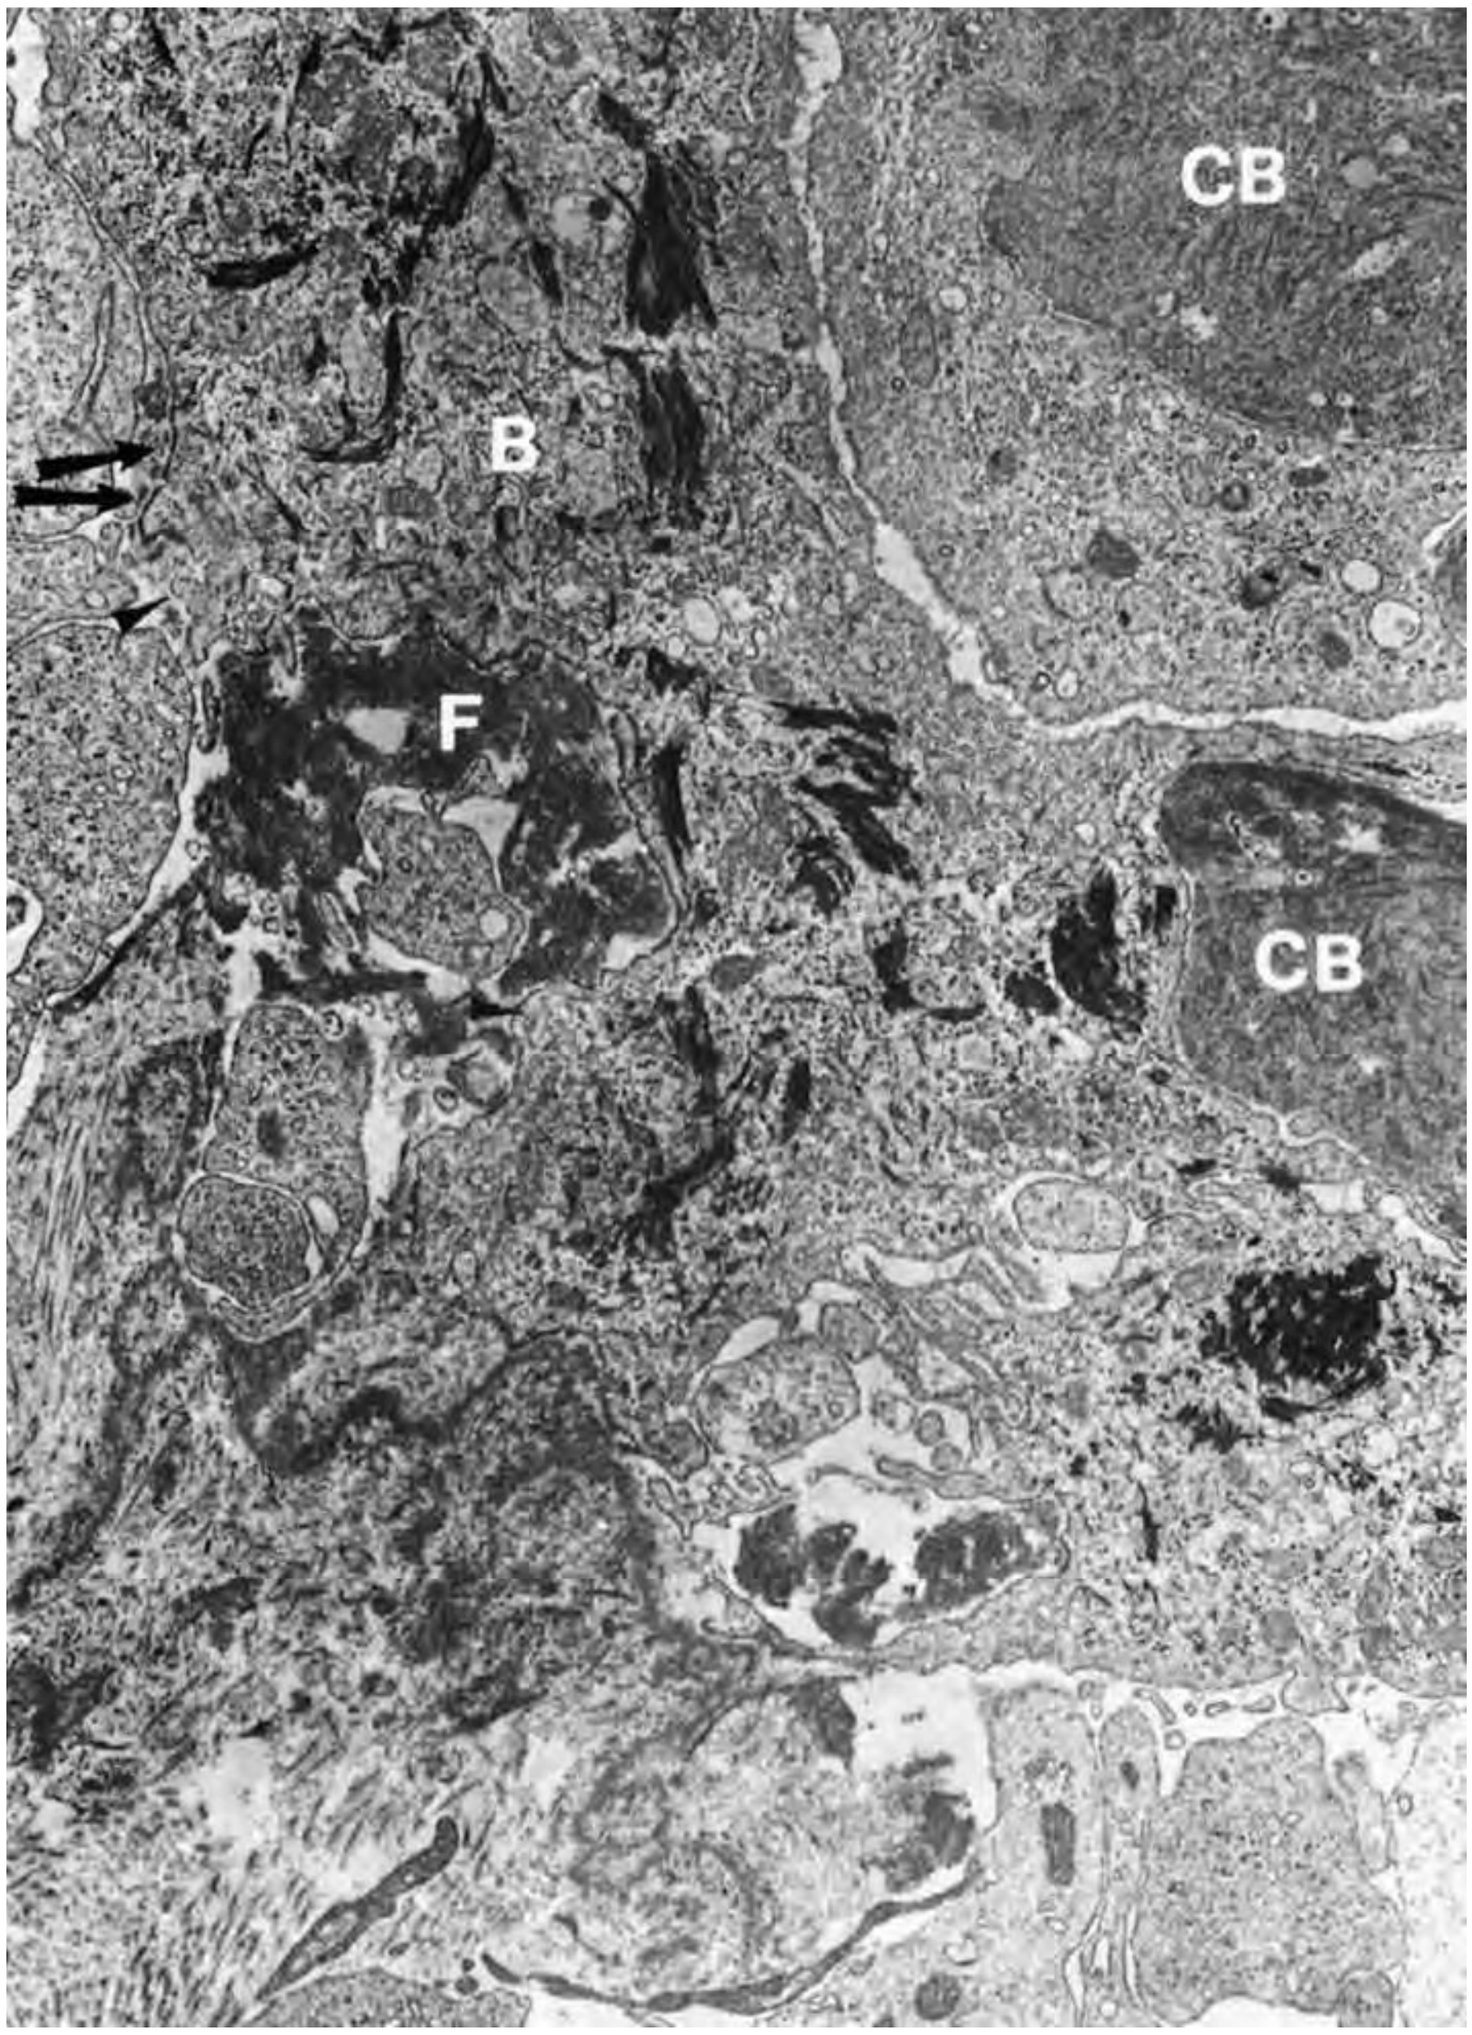

FIGURE EM-12. Lichen planus. The basement membrane is split up in some areas (arrows) and has disappeared in others (pointers). The lower epidermis contains colloid bodies (CB) consisting of numerous filaments and remnants of organelles. F, fibrin beneath the basal cell (B).

FIGURE EM-13. Solar degeneration. The elastic fiber contains in its amorphous matrix (asterisk) numerous electron-dense inclusions (/). Extensive amorphous material (A) can be seen around the elastotic fiber and among the collagen fibrils (C).

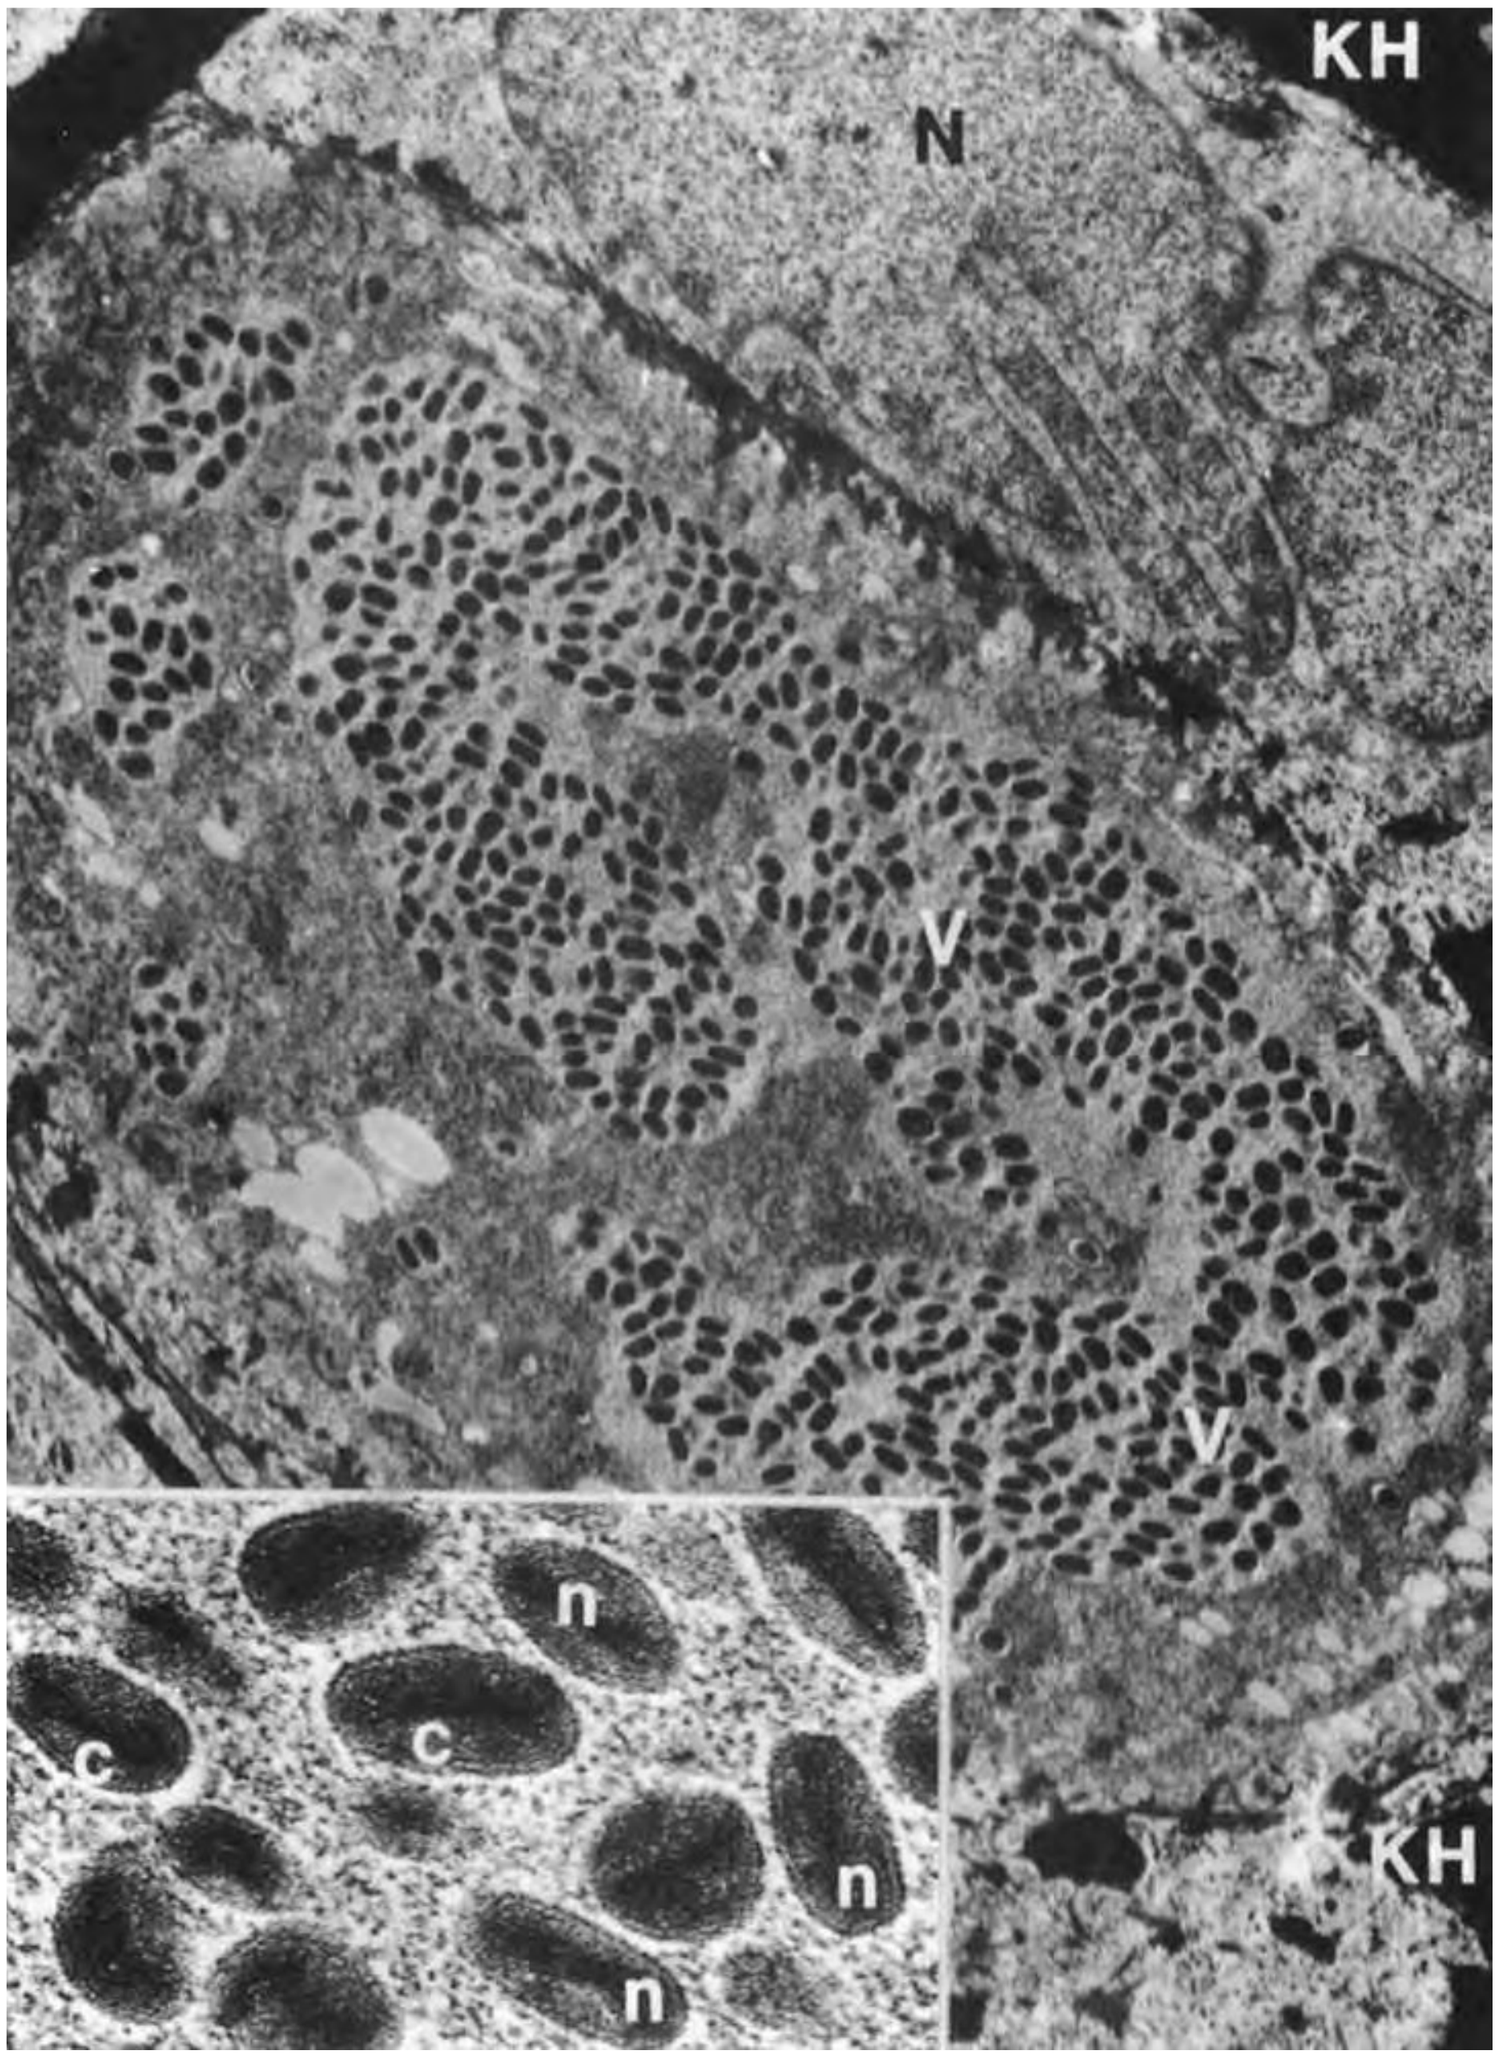

FIGURE EM-14. Molluscum contagiosum. Inset: High magnification of viruses. The granular cell contains an inclusion body consisting of numerous molluscum contagiosum viruses (V). The nucleus (N) of the cell has been displaced to the periphery of the cell. KH, keratohyaline granules. Inset: The virus consists of the dumbbell-shaped nucleoid (n) surrounded by the capsid (c).

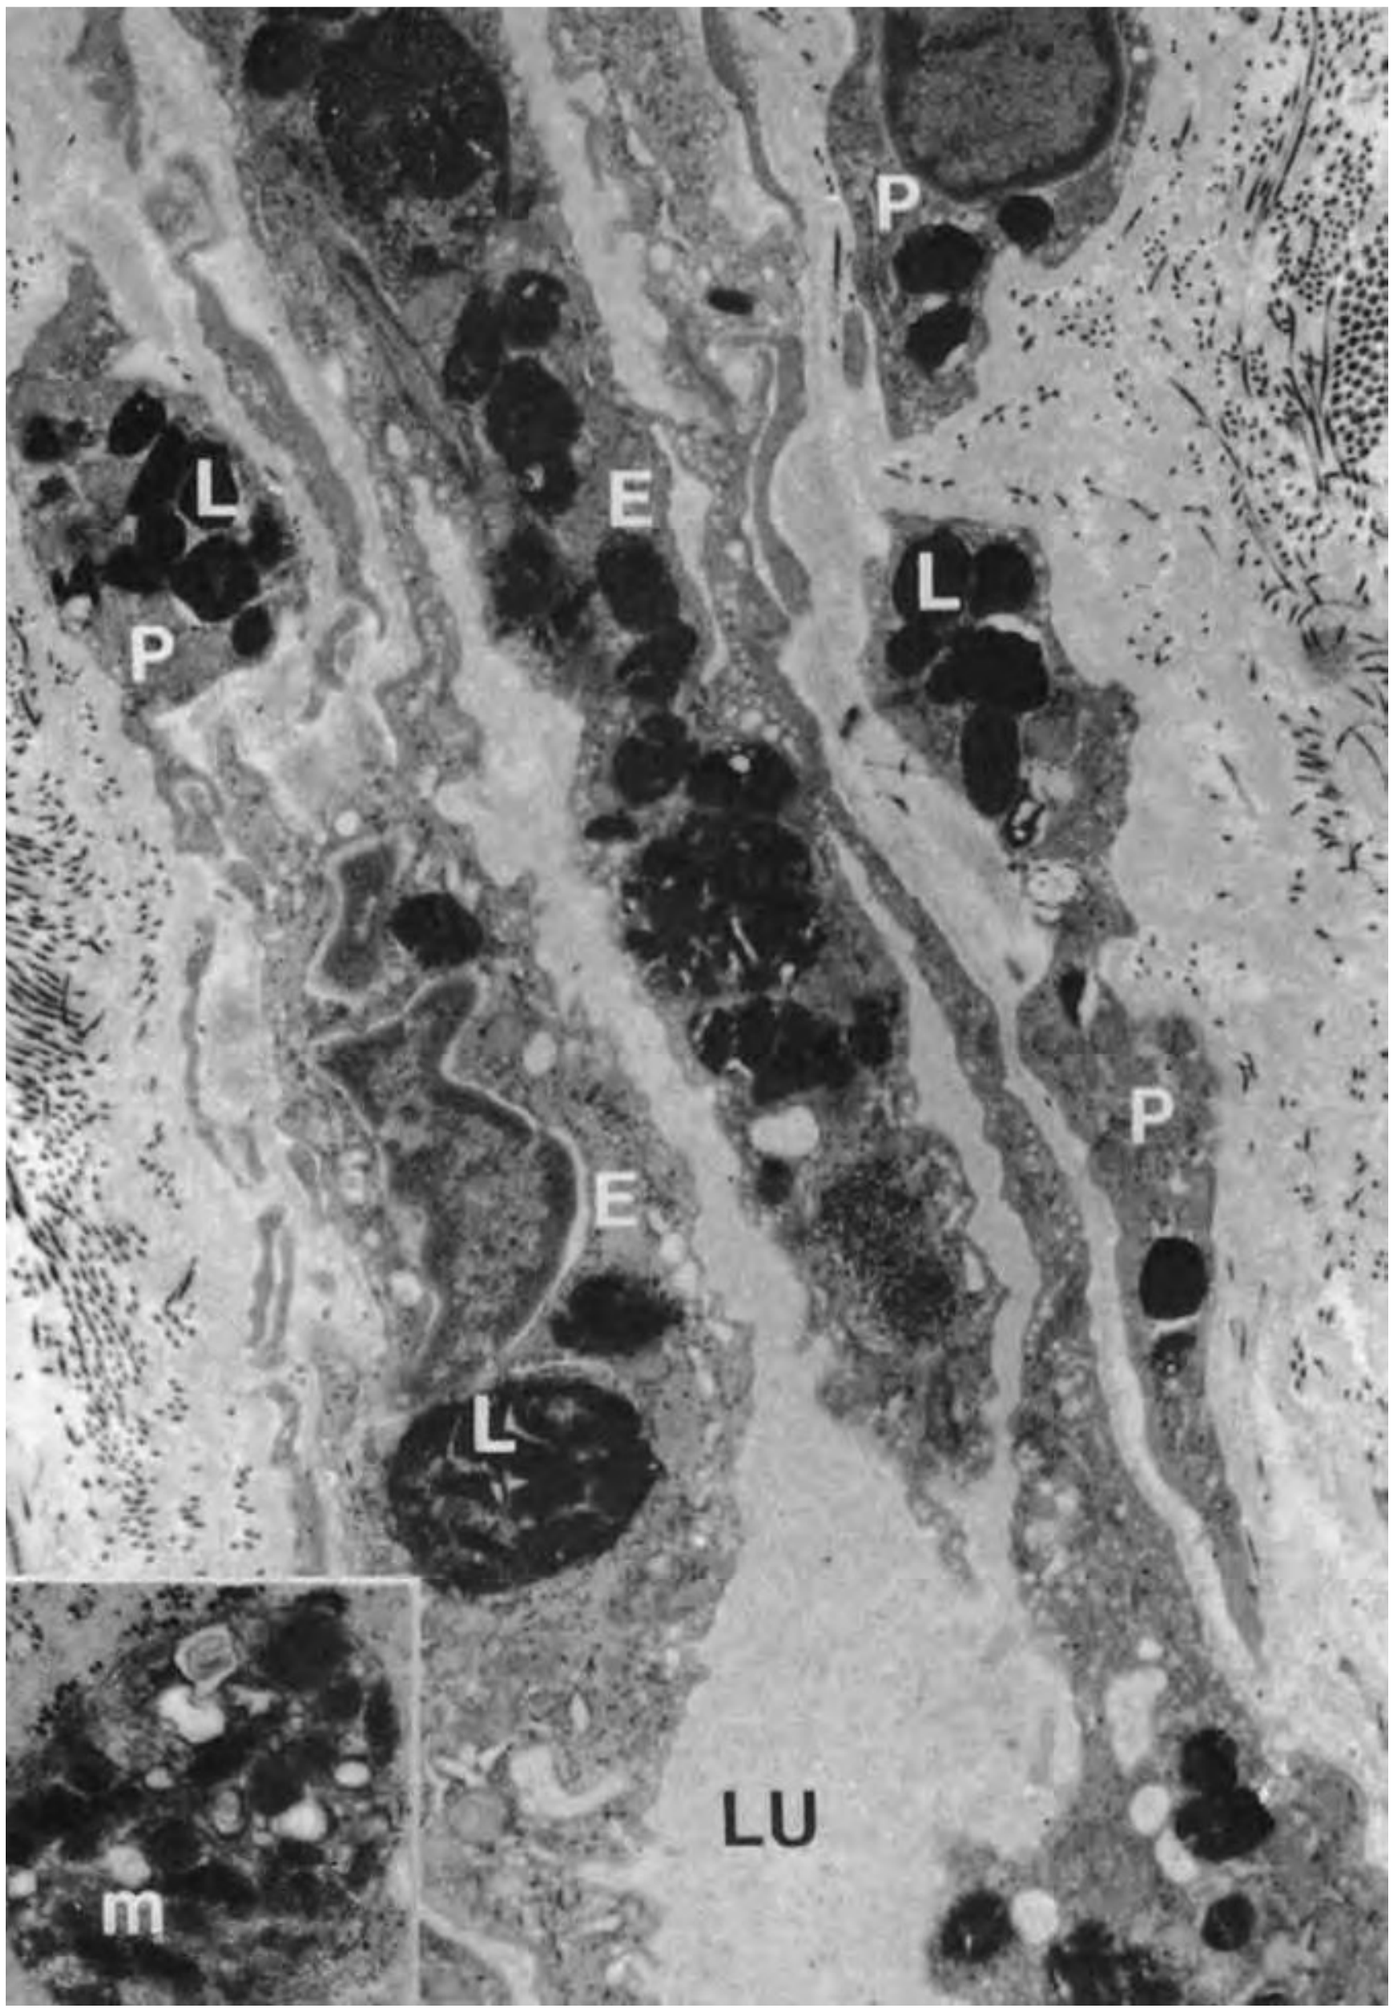

FIGURE EM-15. Angiokeratoma corporis diffusum (Fabry's disease). Inset: Lysosomal residual body. Endothelial cells (E) and pericytes (P) contain lipid deposits (L) within greatly enlarged lysosomes. LU, lumen of capillary. Inset: A large matured lysosome as a residual body shows laminated myelin figures (m).

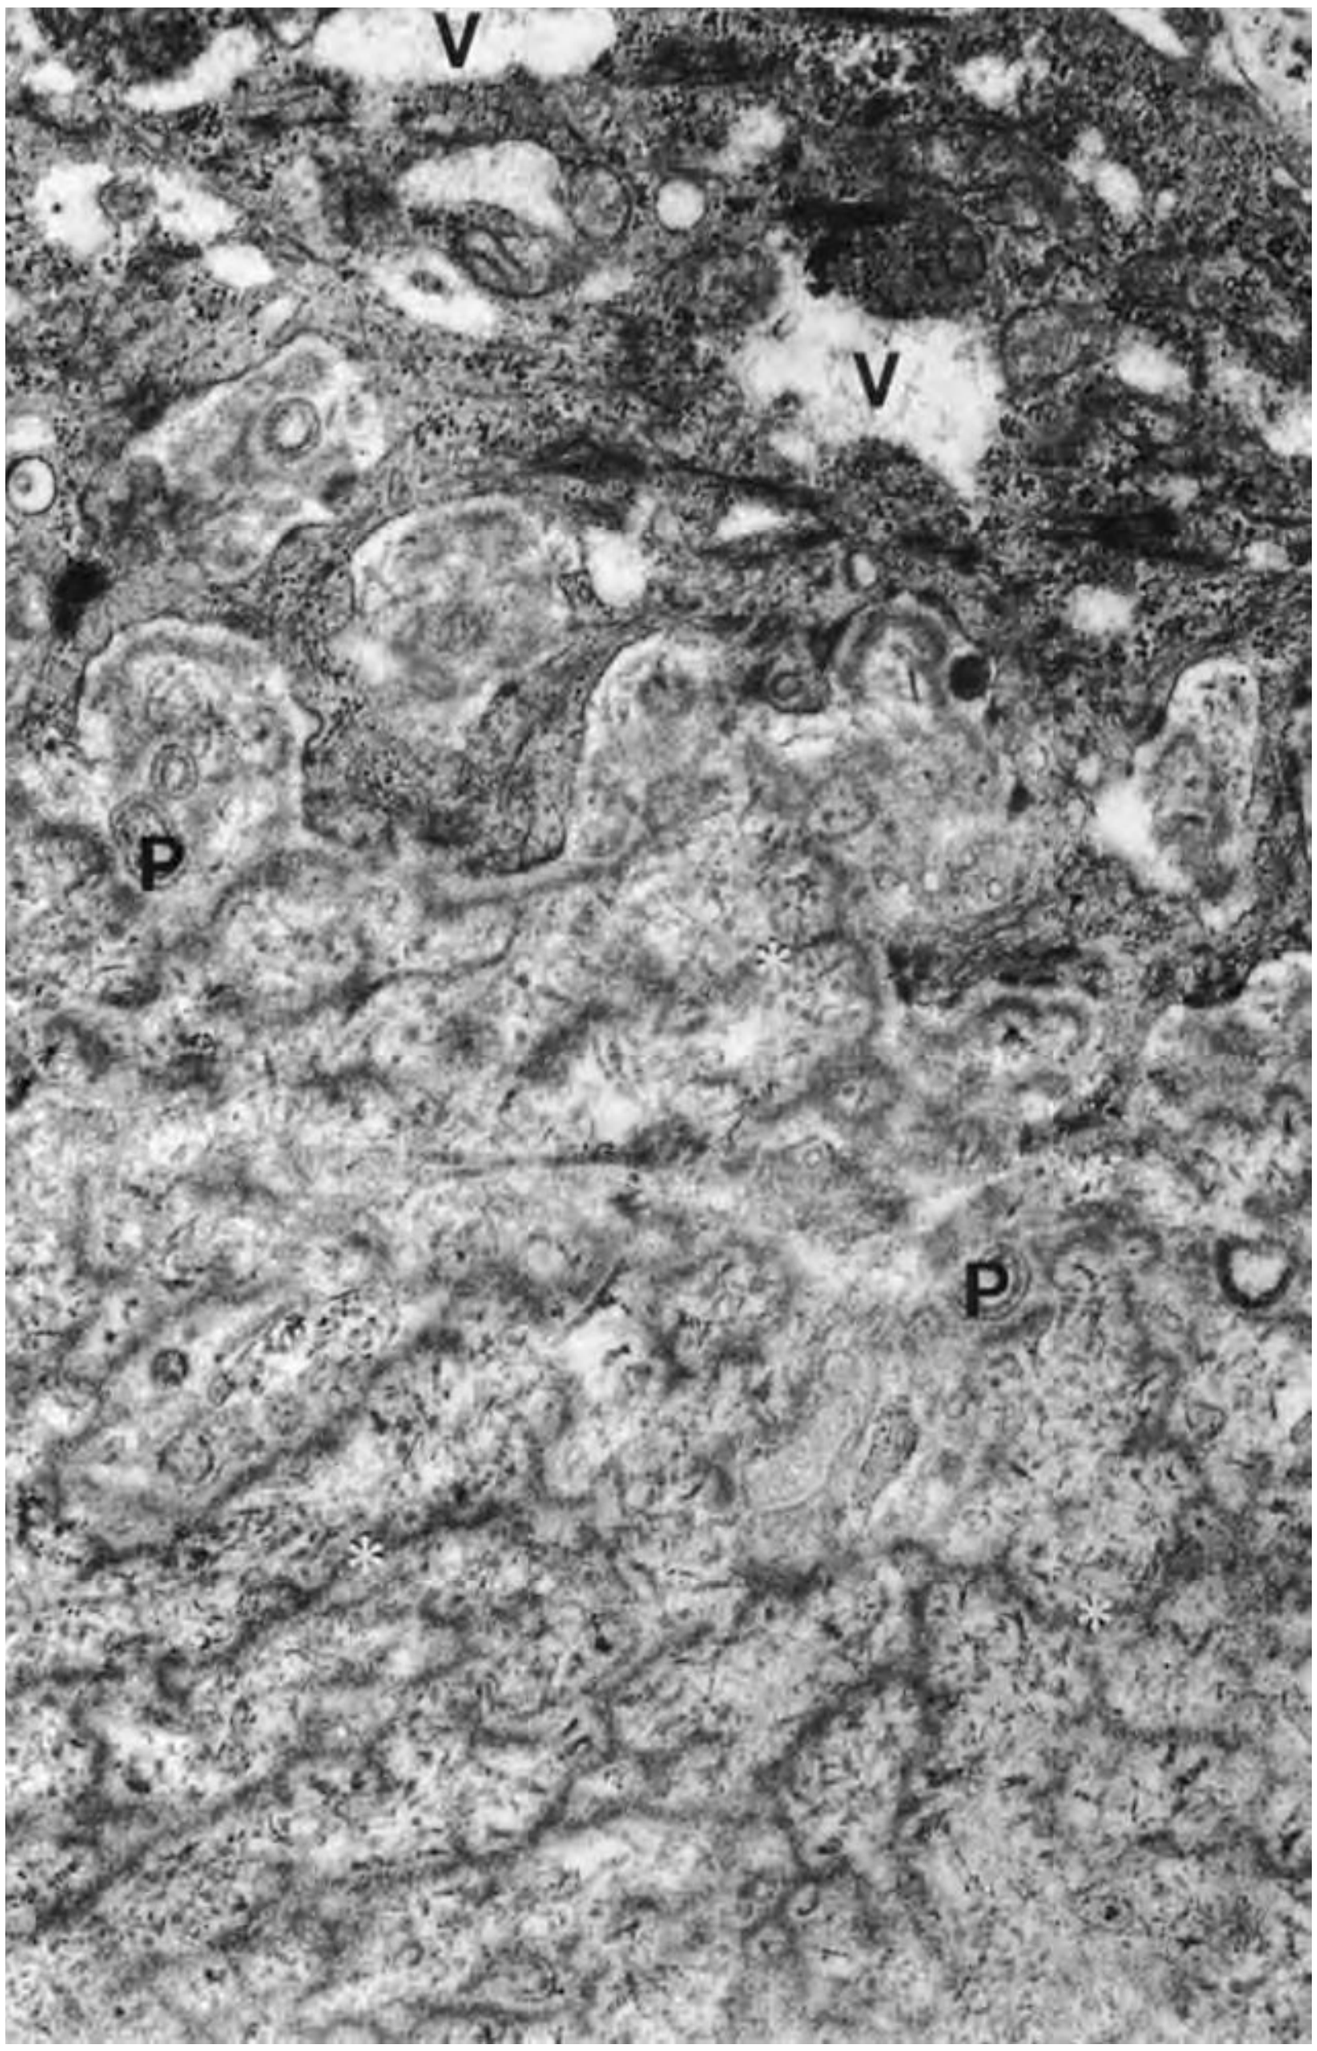

FIGURE EM-16. Discoid lupus erythematosus. The basal cell contains several vacuoles (V), which ultimately may cause disintegration of the cell. Many cross-sectioned projections (P) of the basal cell into the dermis can be seen, as can a greatly increased amount of basal lamina material (asterisks).

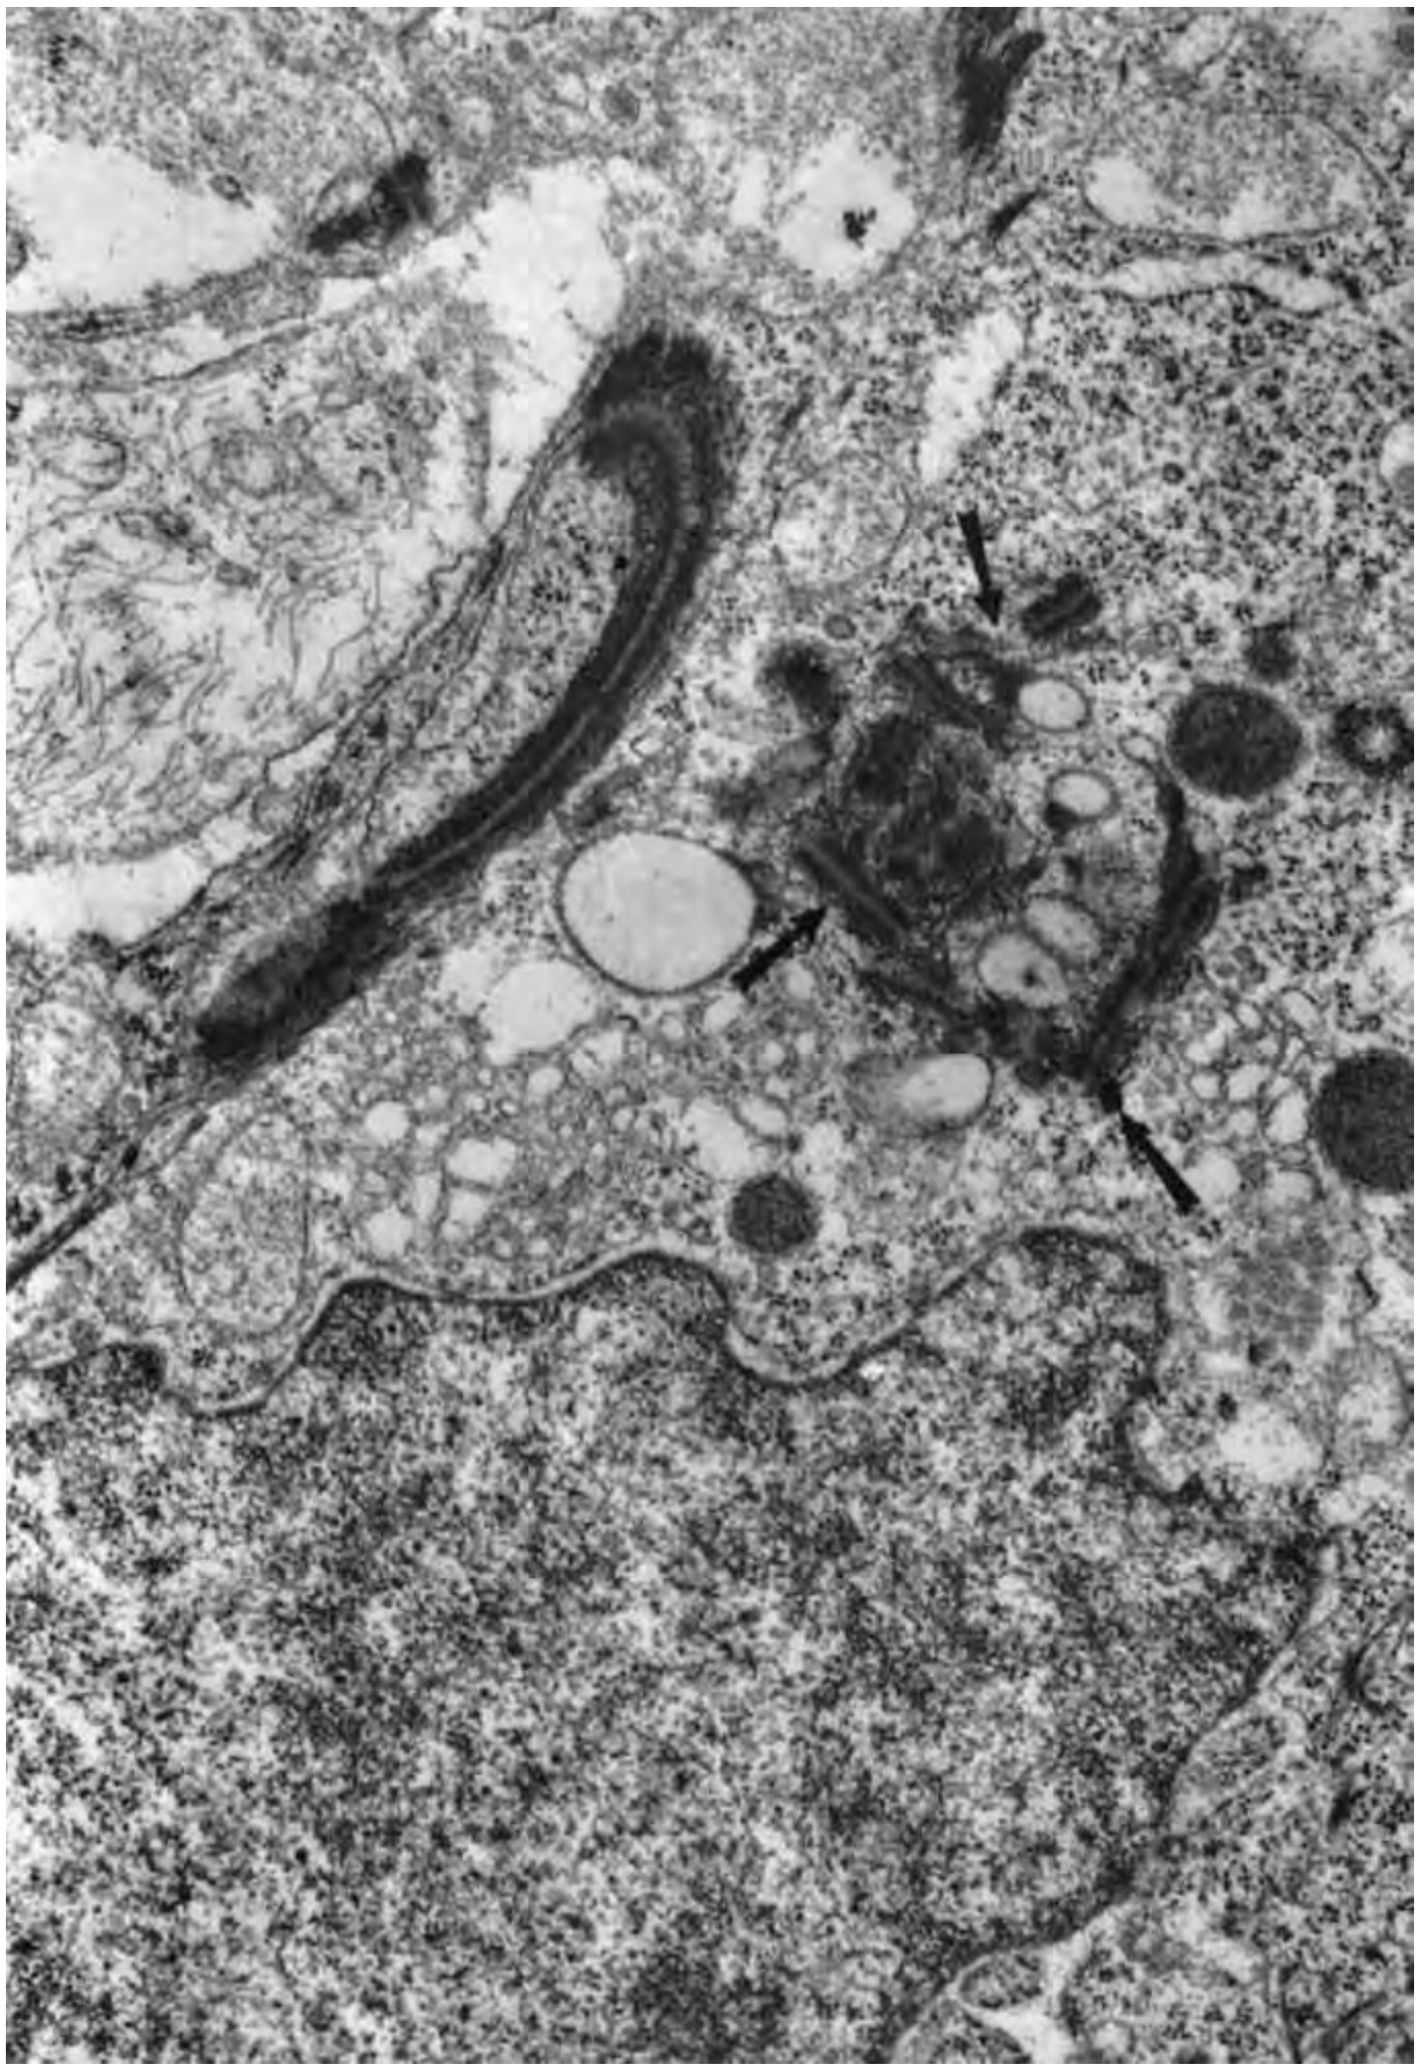

FIGURE EM-17. Squamous cell carcinoma. Desmosomes attached to tonofilaments (arrows) can be seen within the cytoplasm of the tumor cell.

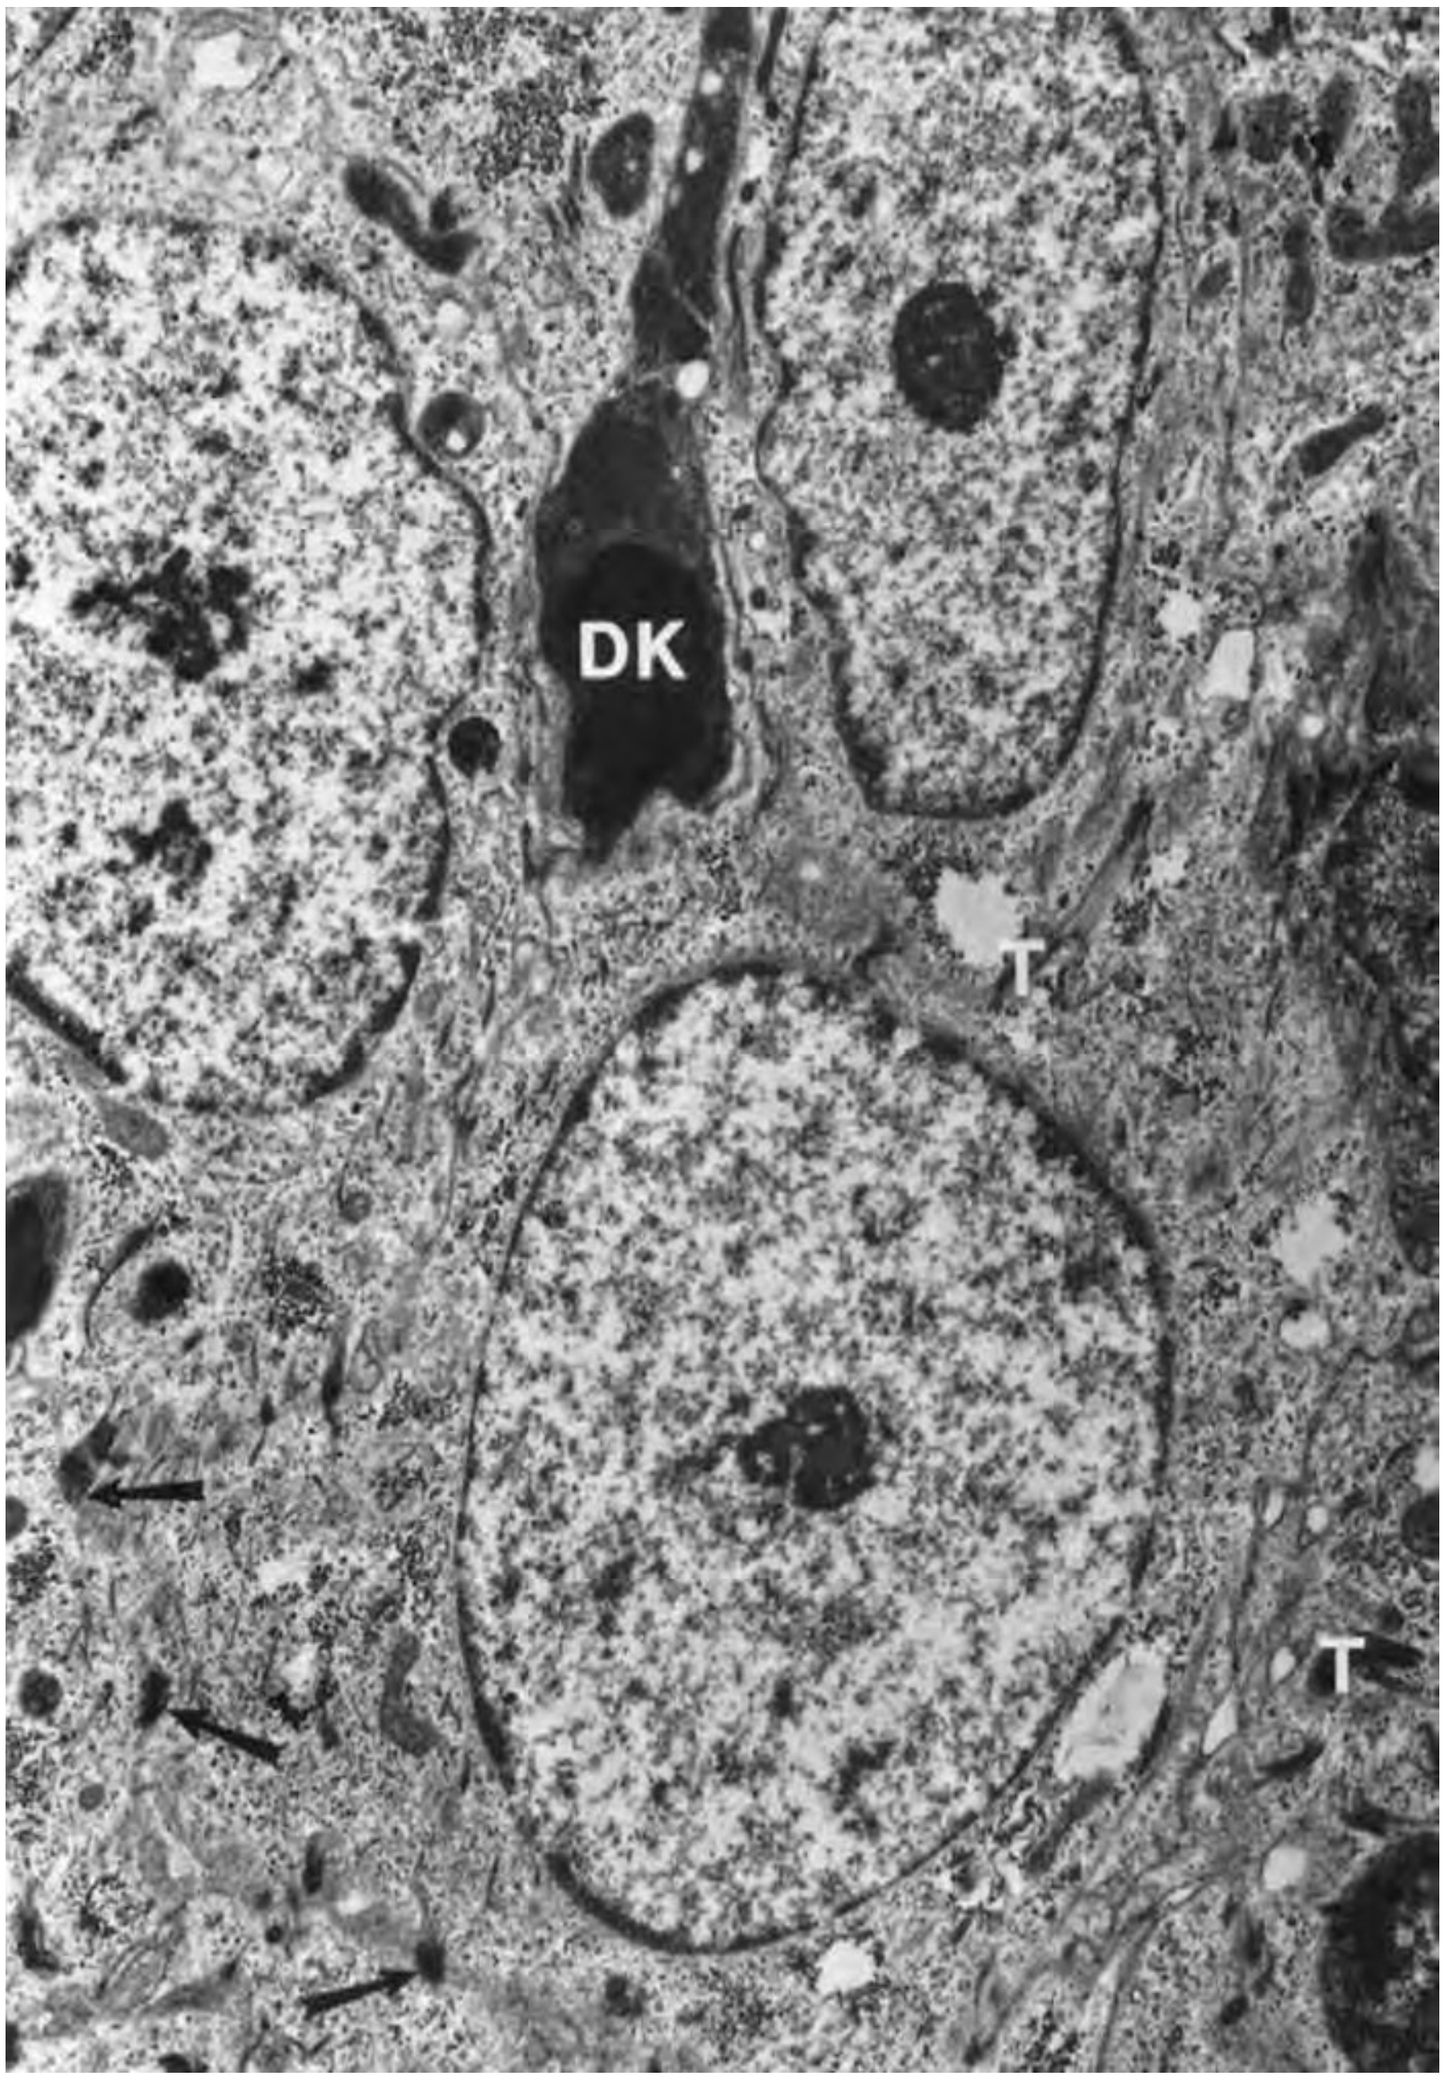

FIGURE EM-18. Basal cell epithelioma. The cells show evidence of keratinization. In addition to tonofilaments (T) and desmosomes (arrows), some dyskeratotic material (DK) is present.

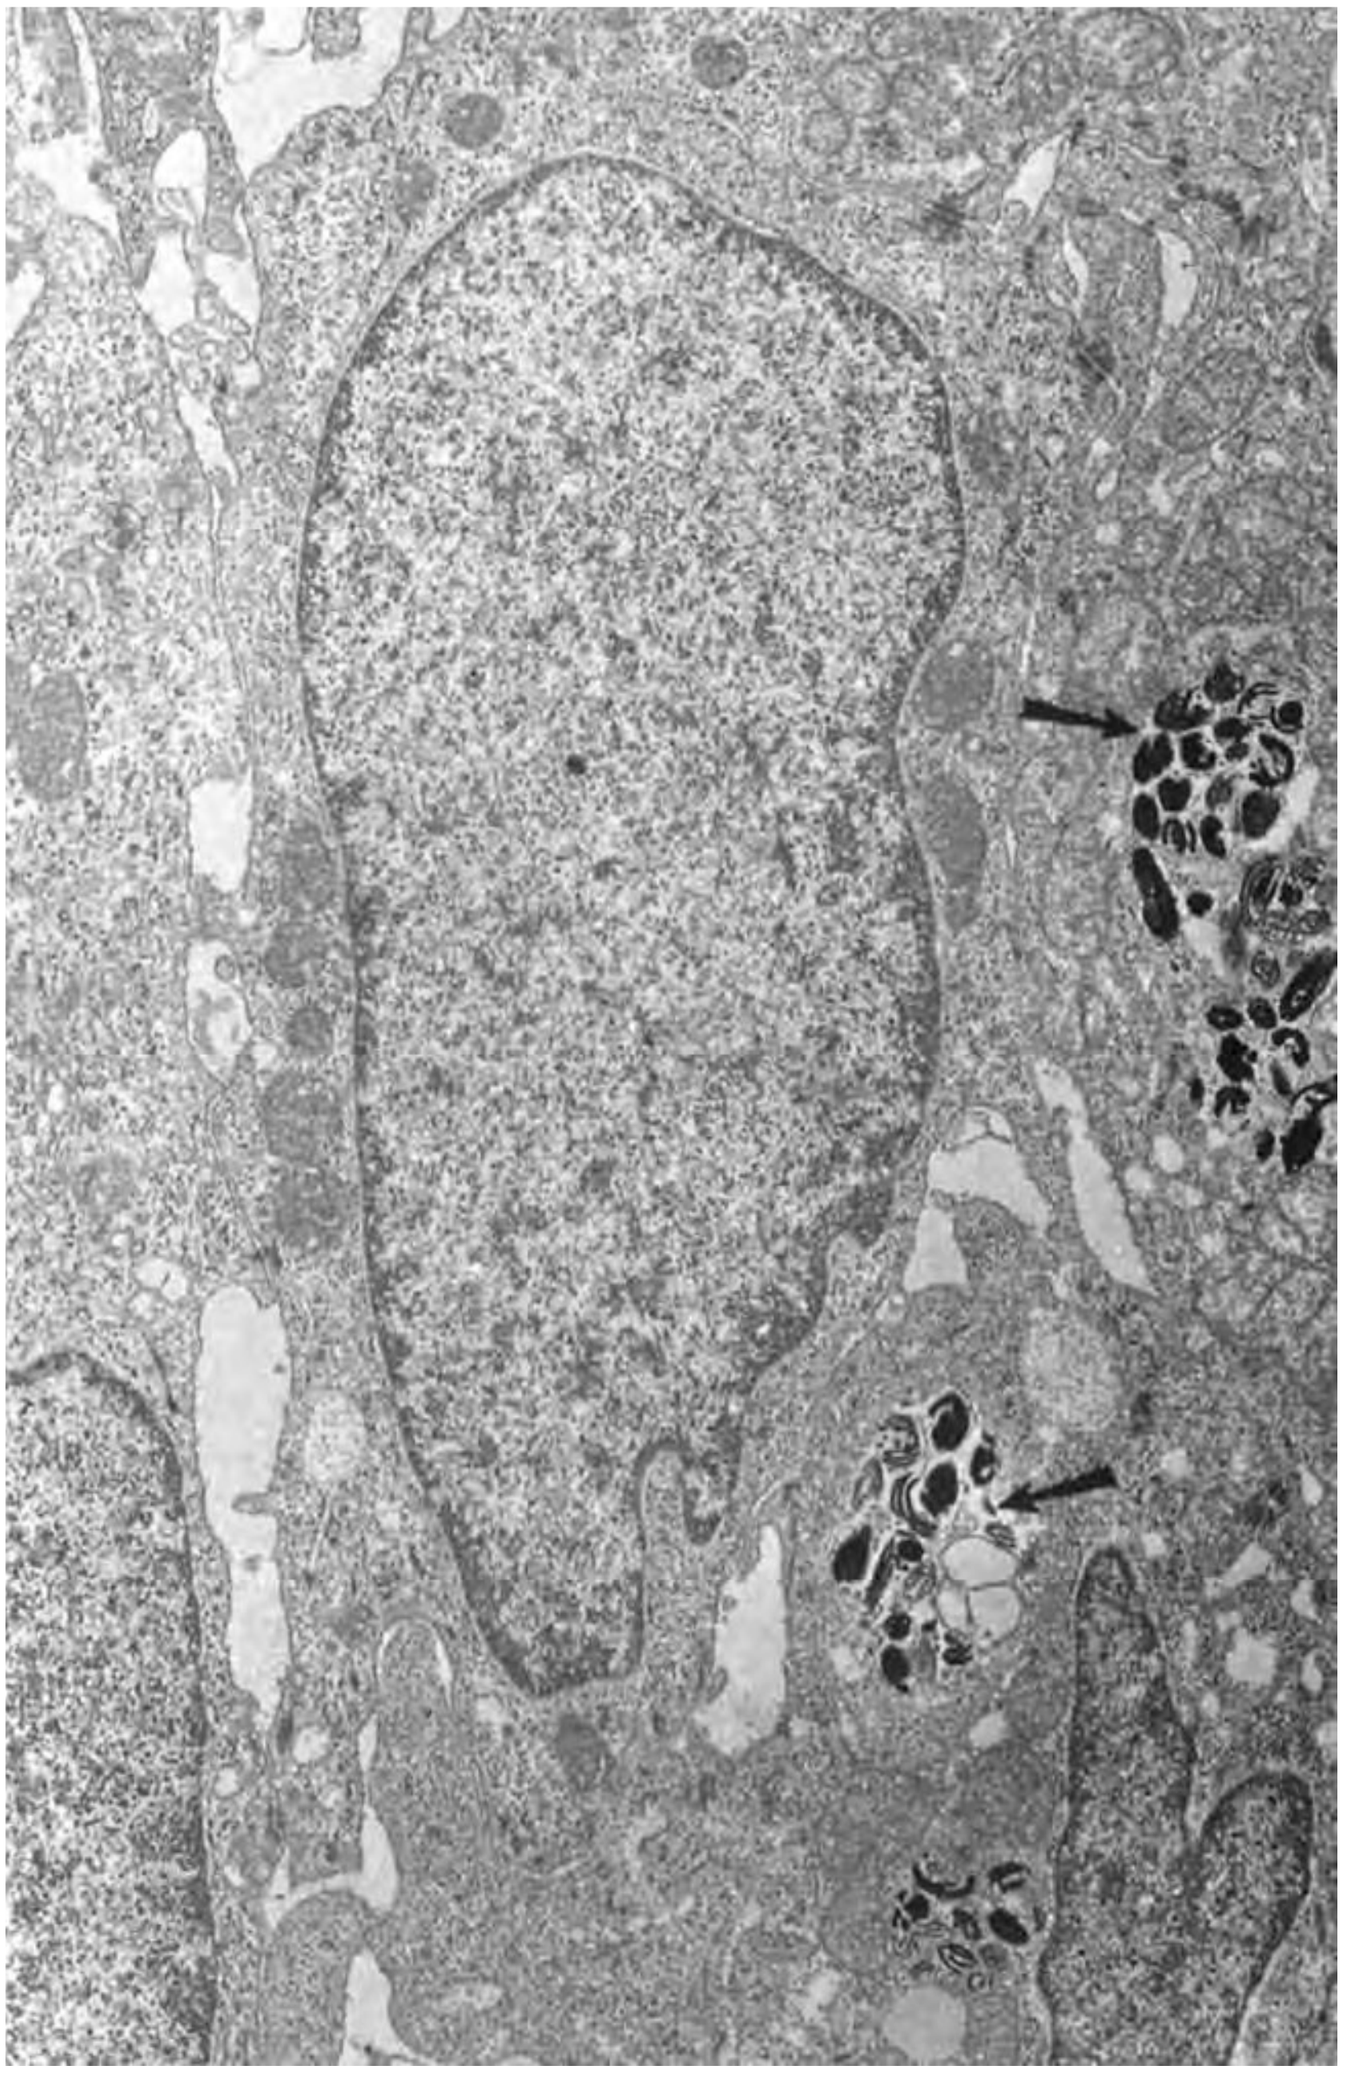

FIGURE EM-19. Pigmented basal cell carcinoma. Some of the tumor cells contain melanosome complexes located within lysosomes (arrows).

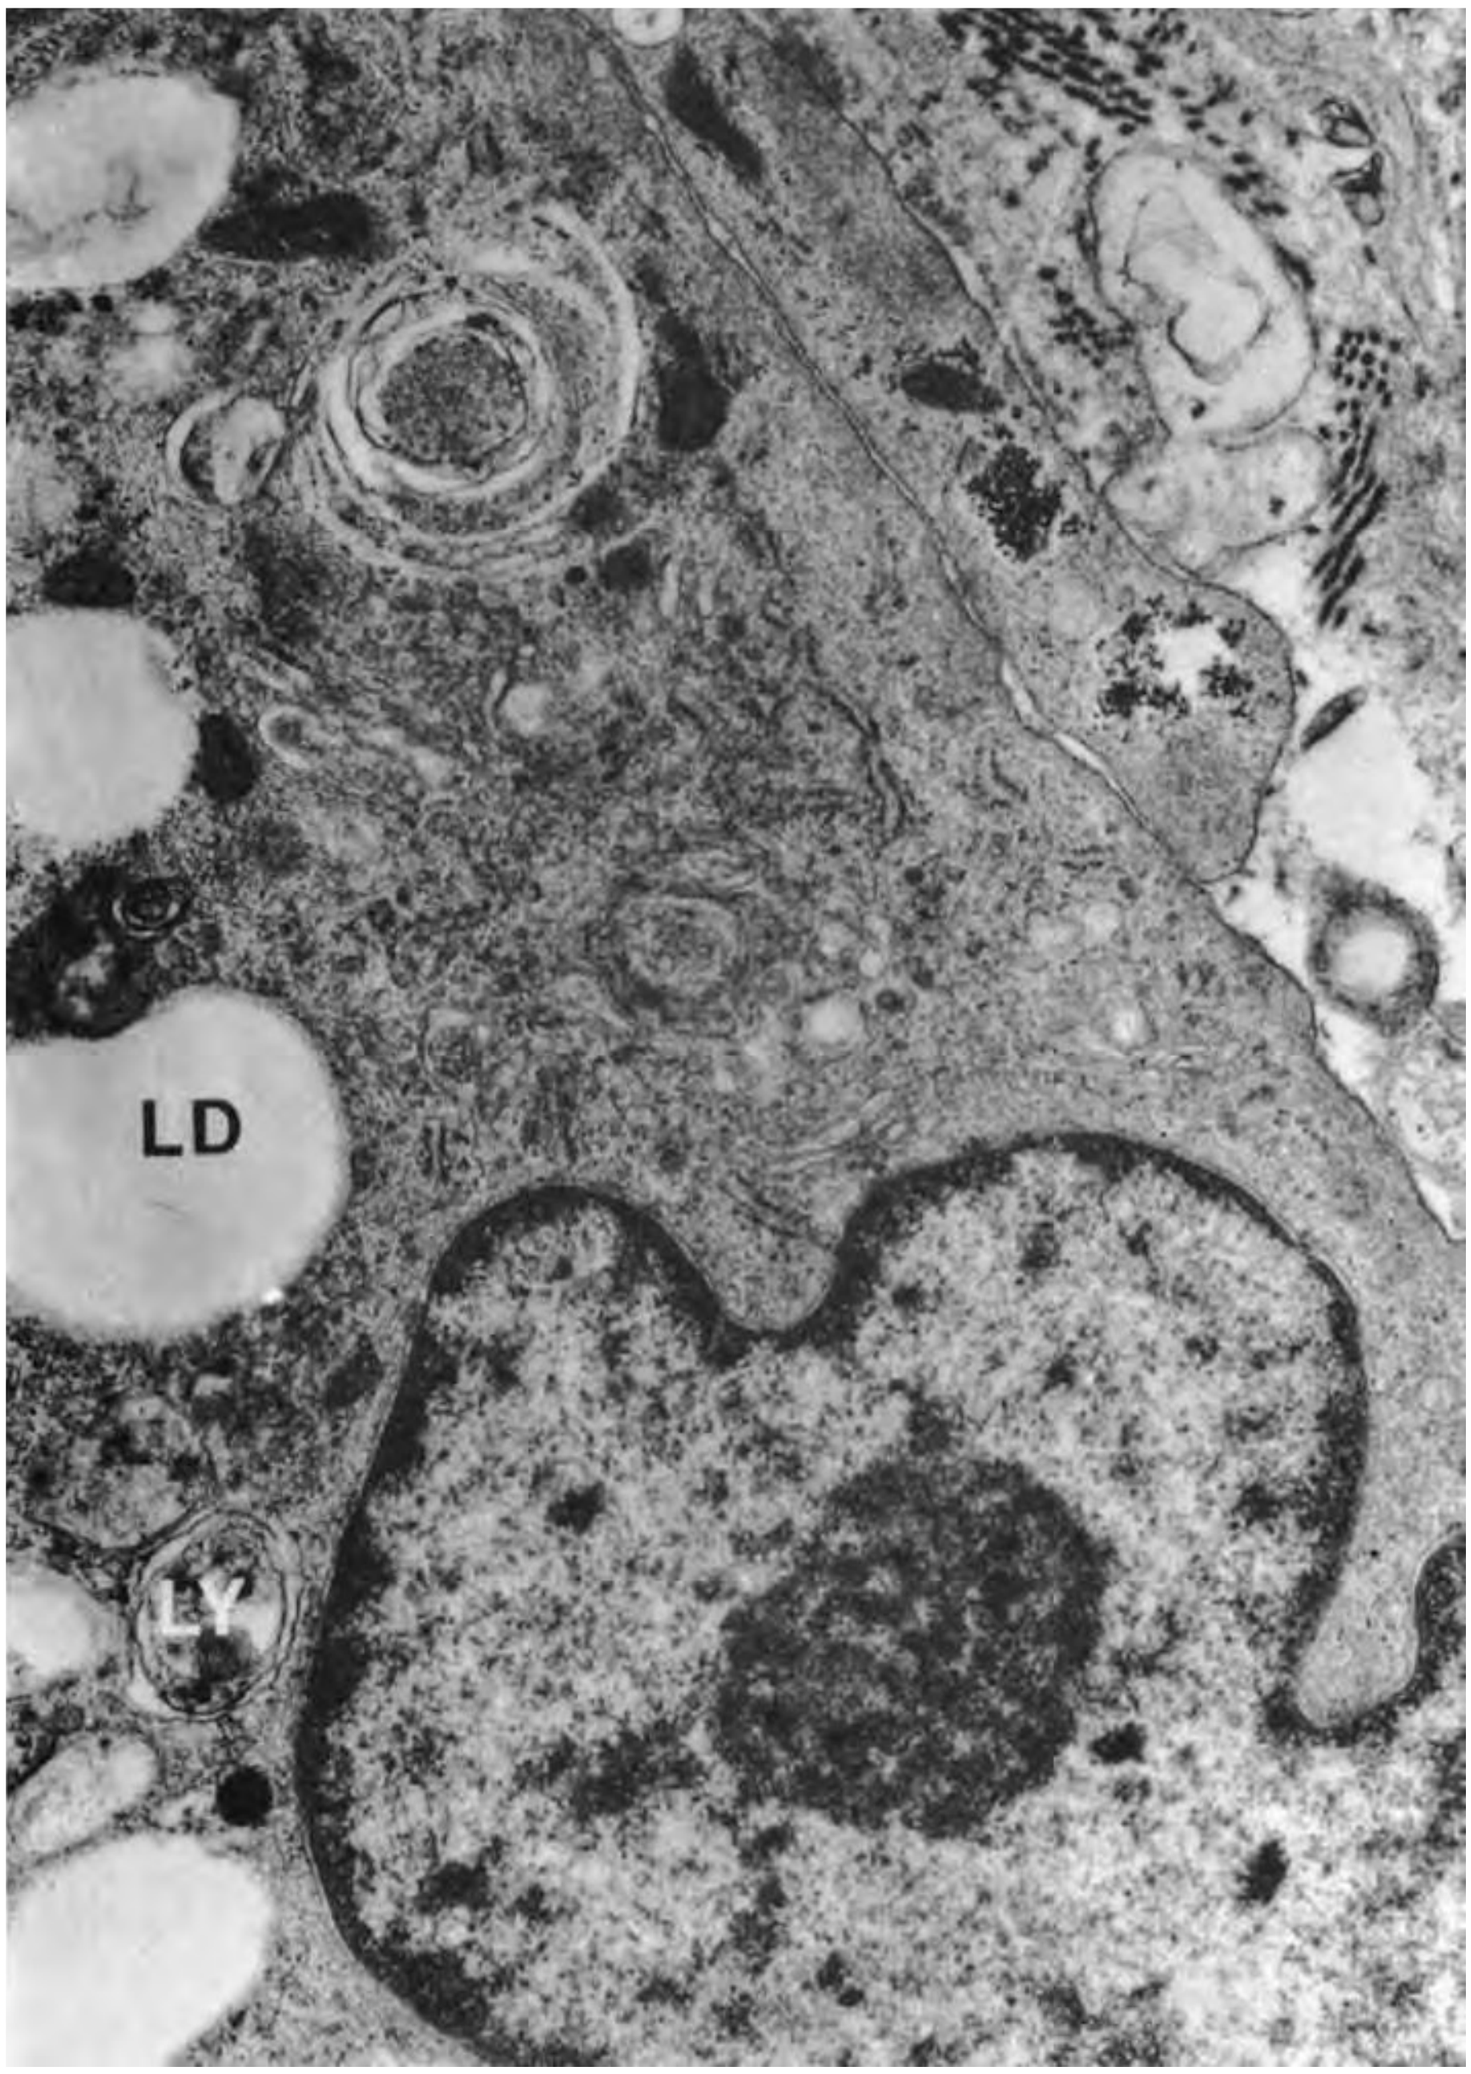

FIGURE EM-20. Dermatofibroma. The essential cells are fibroblasts, which, in addition to producing collagen, are engaged in phagocytosis and storage of lipid. LY, lysosome; LD, lipid droplets. (Courtesy of Dr. B. Mihatsch-Konz.)

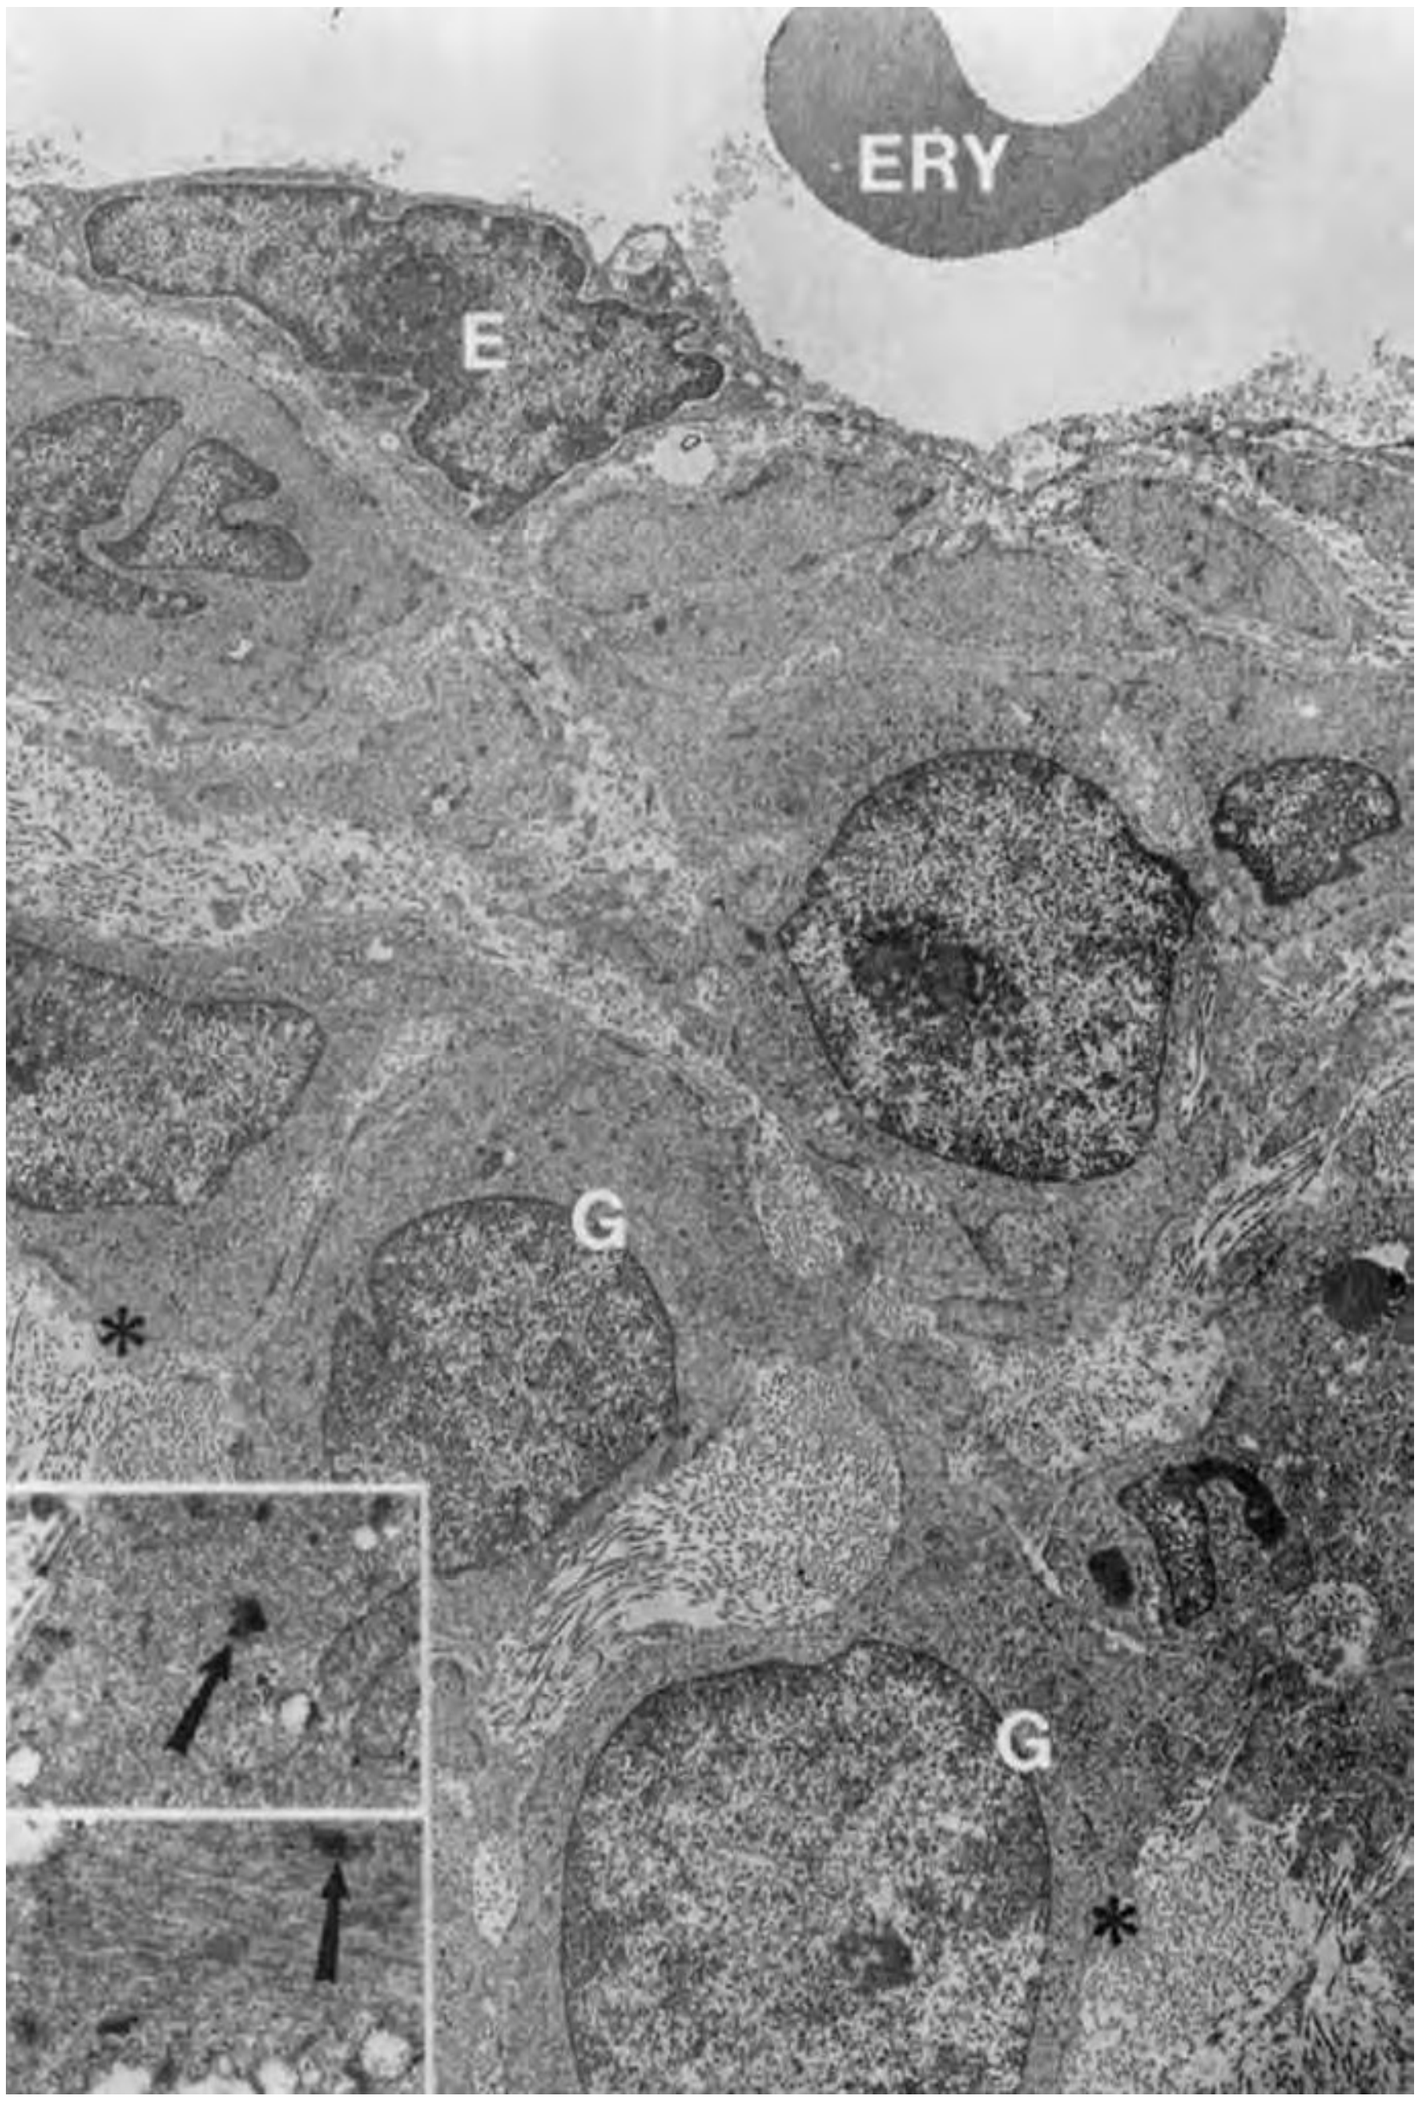

FIGURE EM-21. Glomus tumor. Inset: Myofilaments. The glomus cells are smooth muscle cells. Each glomus cell is surrounded by a basal lamina (asterisk). E, endothelial cell of capillary; G, glomus cell; ERY, erythrocyte within capillary lumen. Insets: The upper inset shows the myofilaments in cross-section, the lower inset in longitudinal section. Arrows point to so-called dense bodies.

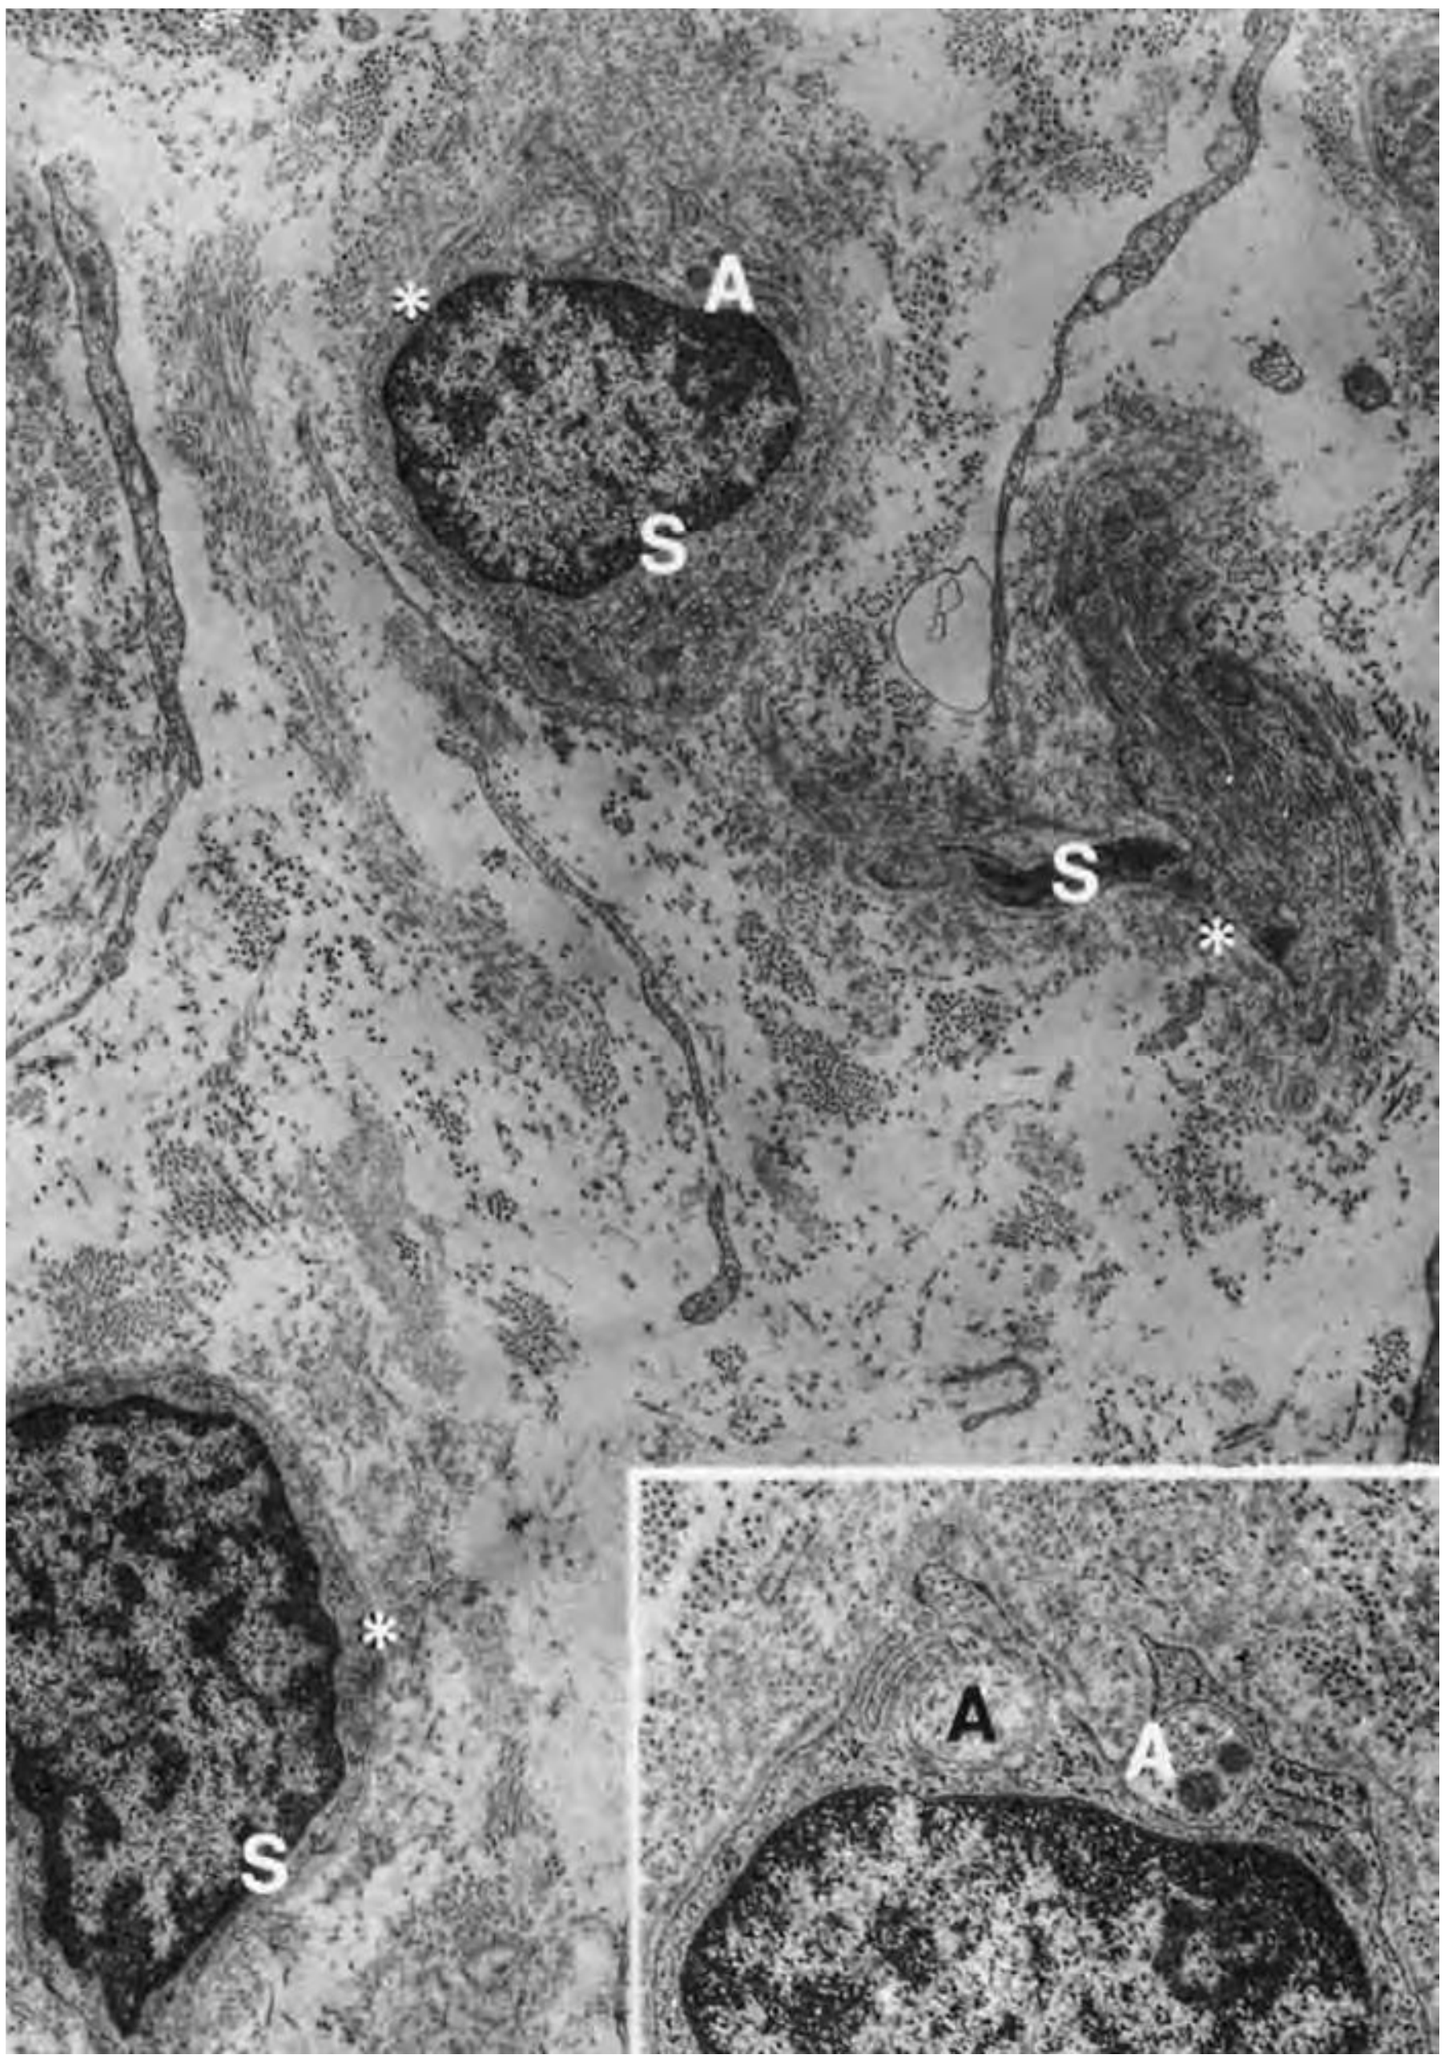

FIGURE EM-22. Neurofibroma. Inset: Axons in Schwann cell. The main cell type is the Schwann cell (S). Each cell is surrounded by a basal lamina (asterisks). Schwann cells contain axons (A) in their cytoplasm. Inset: Two axons (A) of the upper Schwann cell are shown at higher magnification.

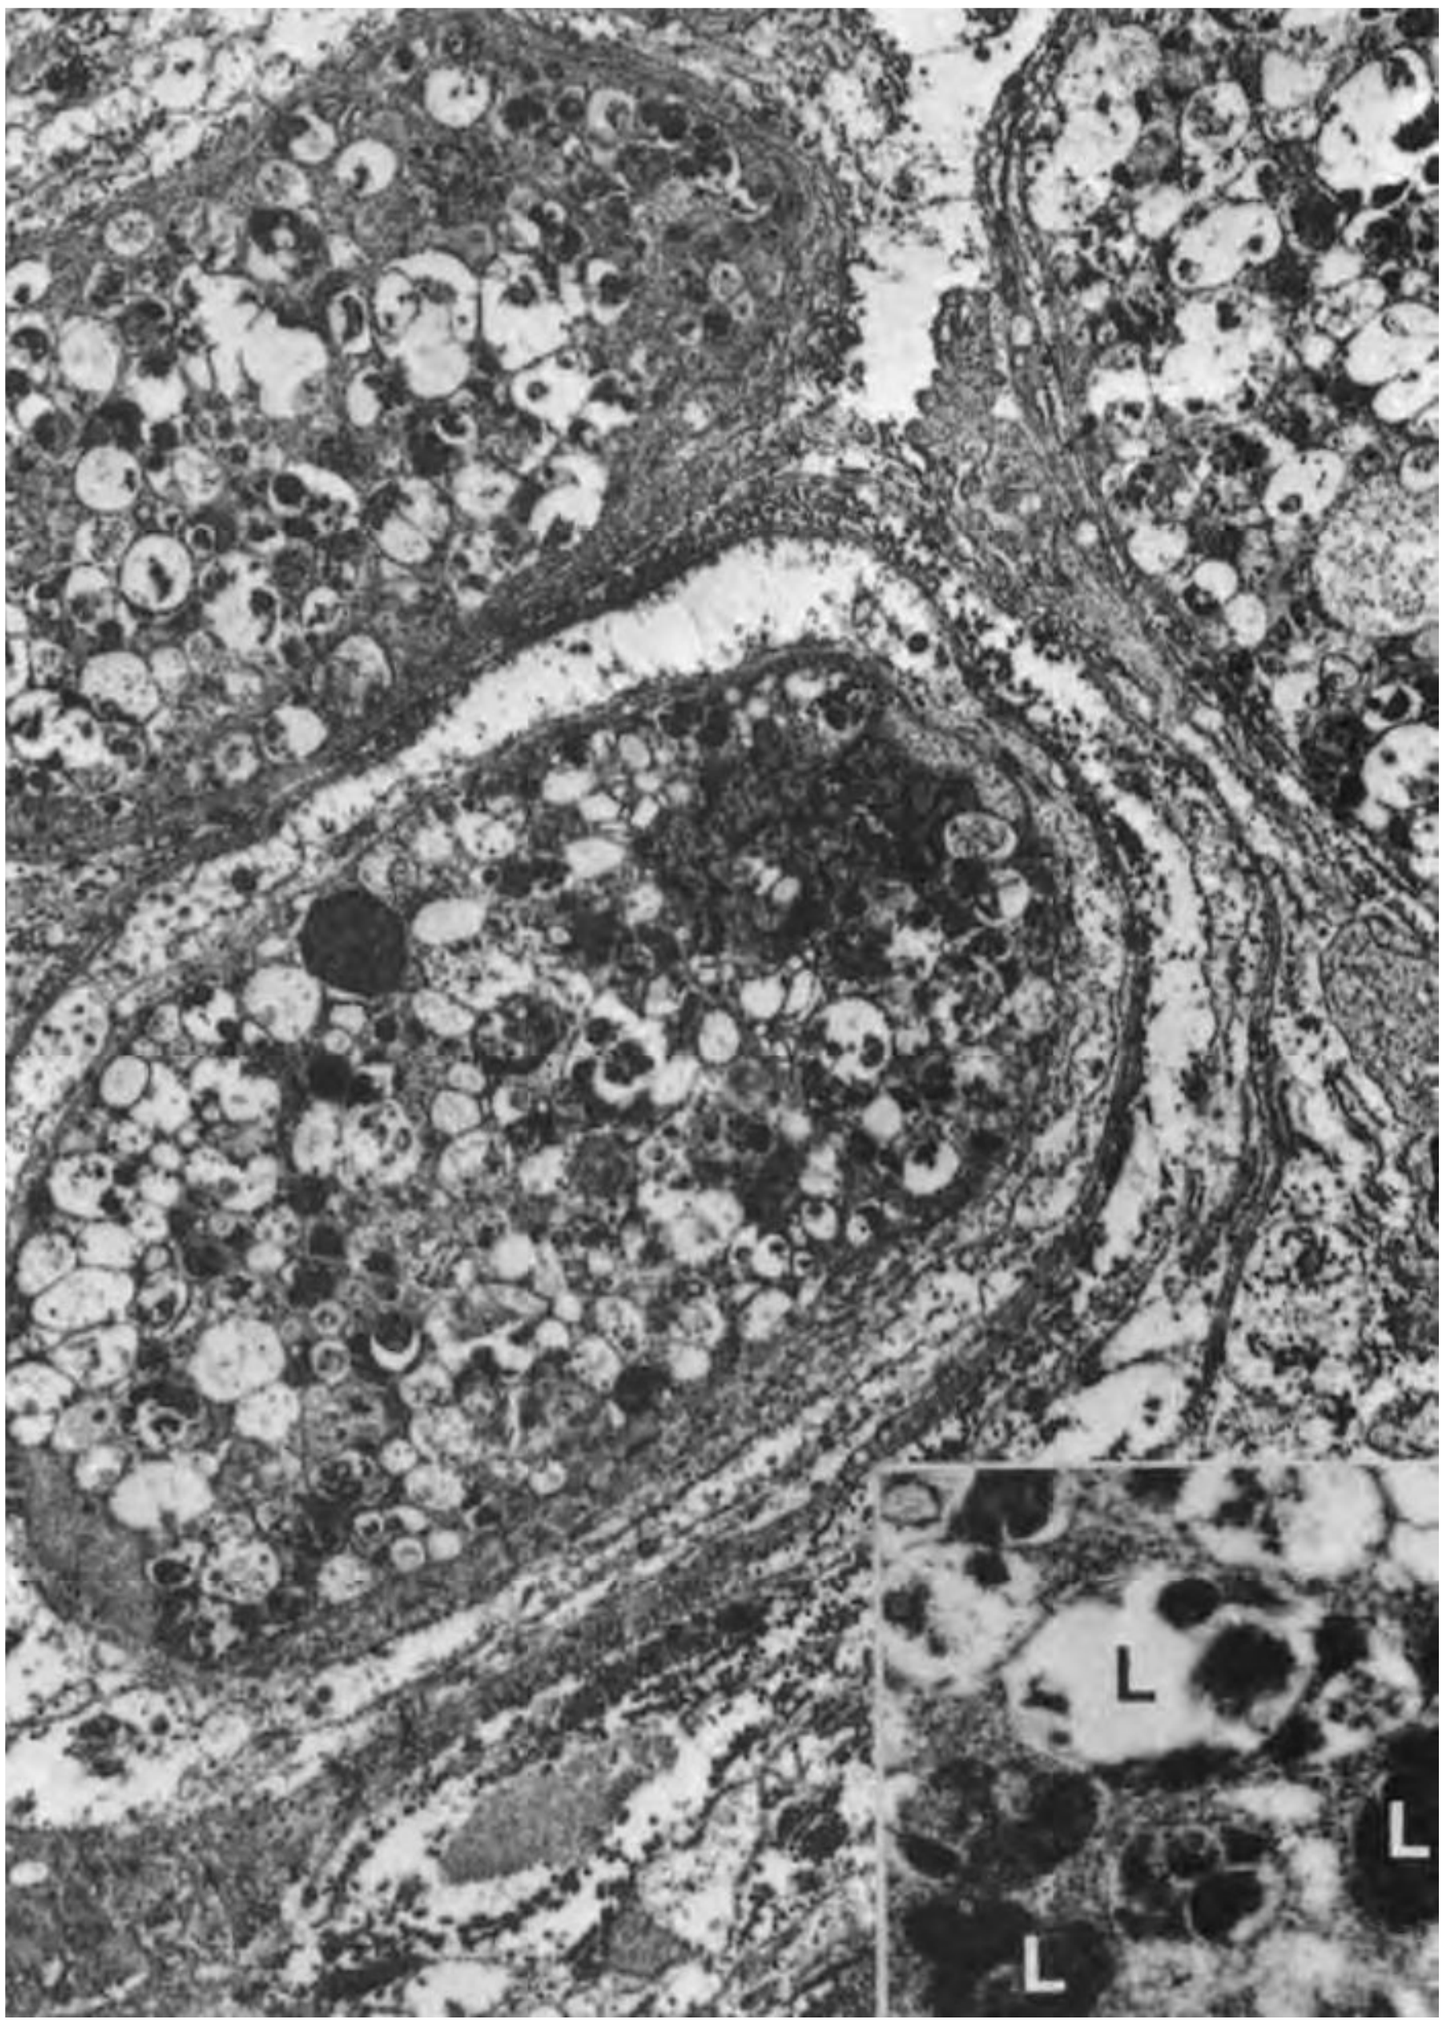

FIGURE EM-23. Granular cell tumor. Inset: Cytoplasmic granules. The cells contain numerous cytoplasmic granules, which are lysosomes. Inset: The lysosomes (L) are shown at higher magnification.

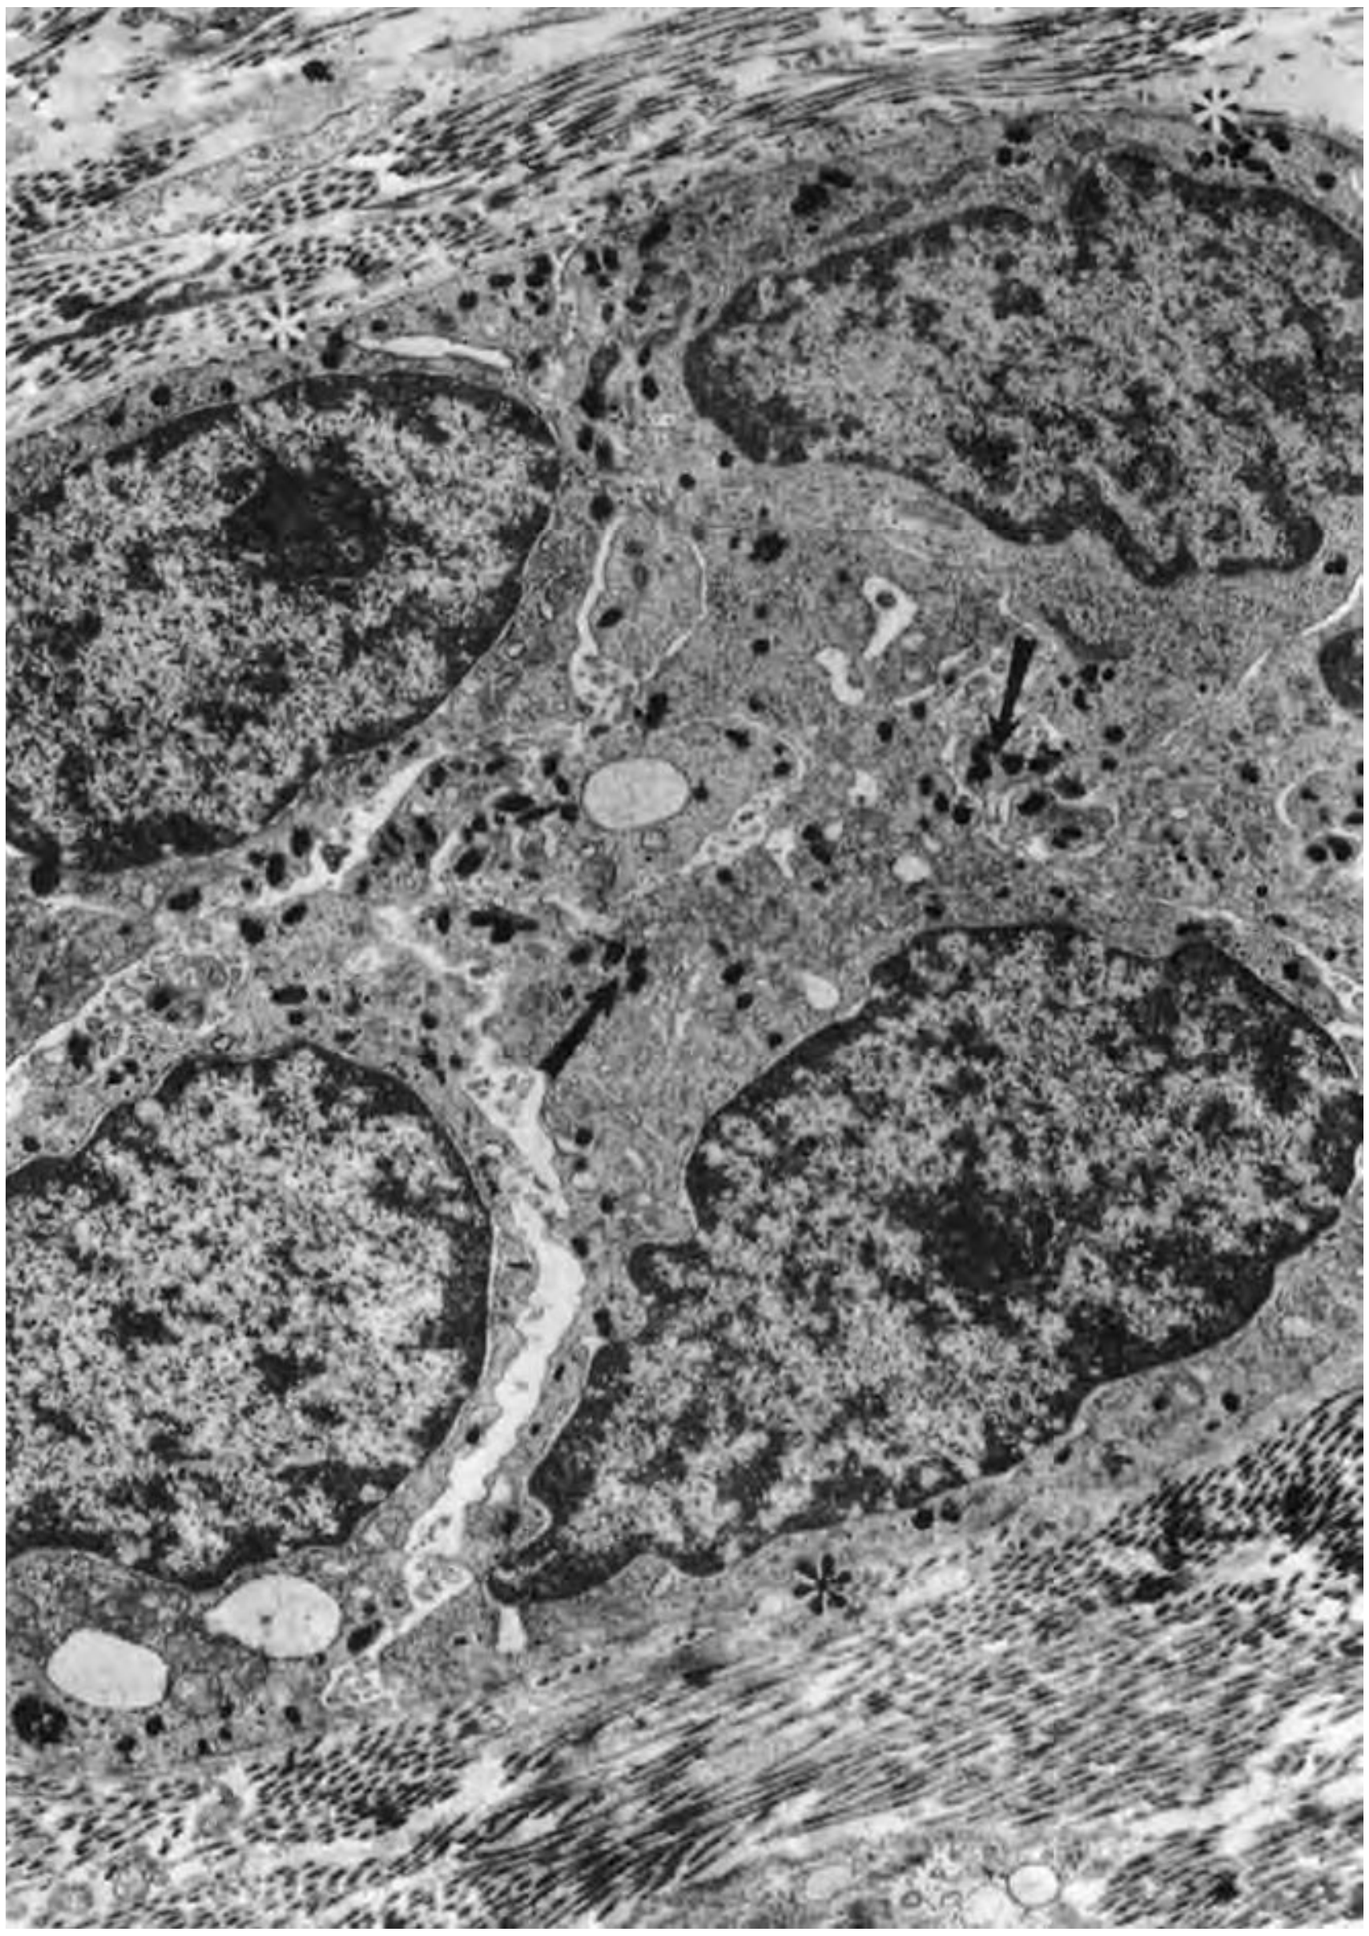

FIGURE EM-24. Intradermal nevus cell nest. The nevus cell nest is surrounded by a basal lamina (asterisk). There are no desmosomes between adjacent nevus cells. The nevus cells contain numerous melanosomes (arrows).

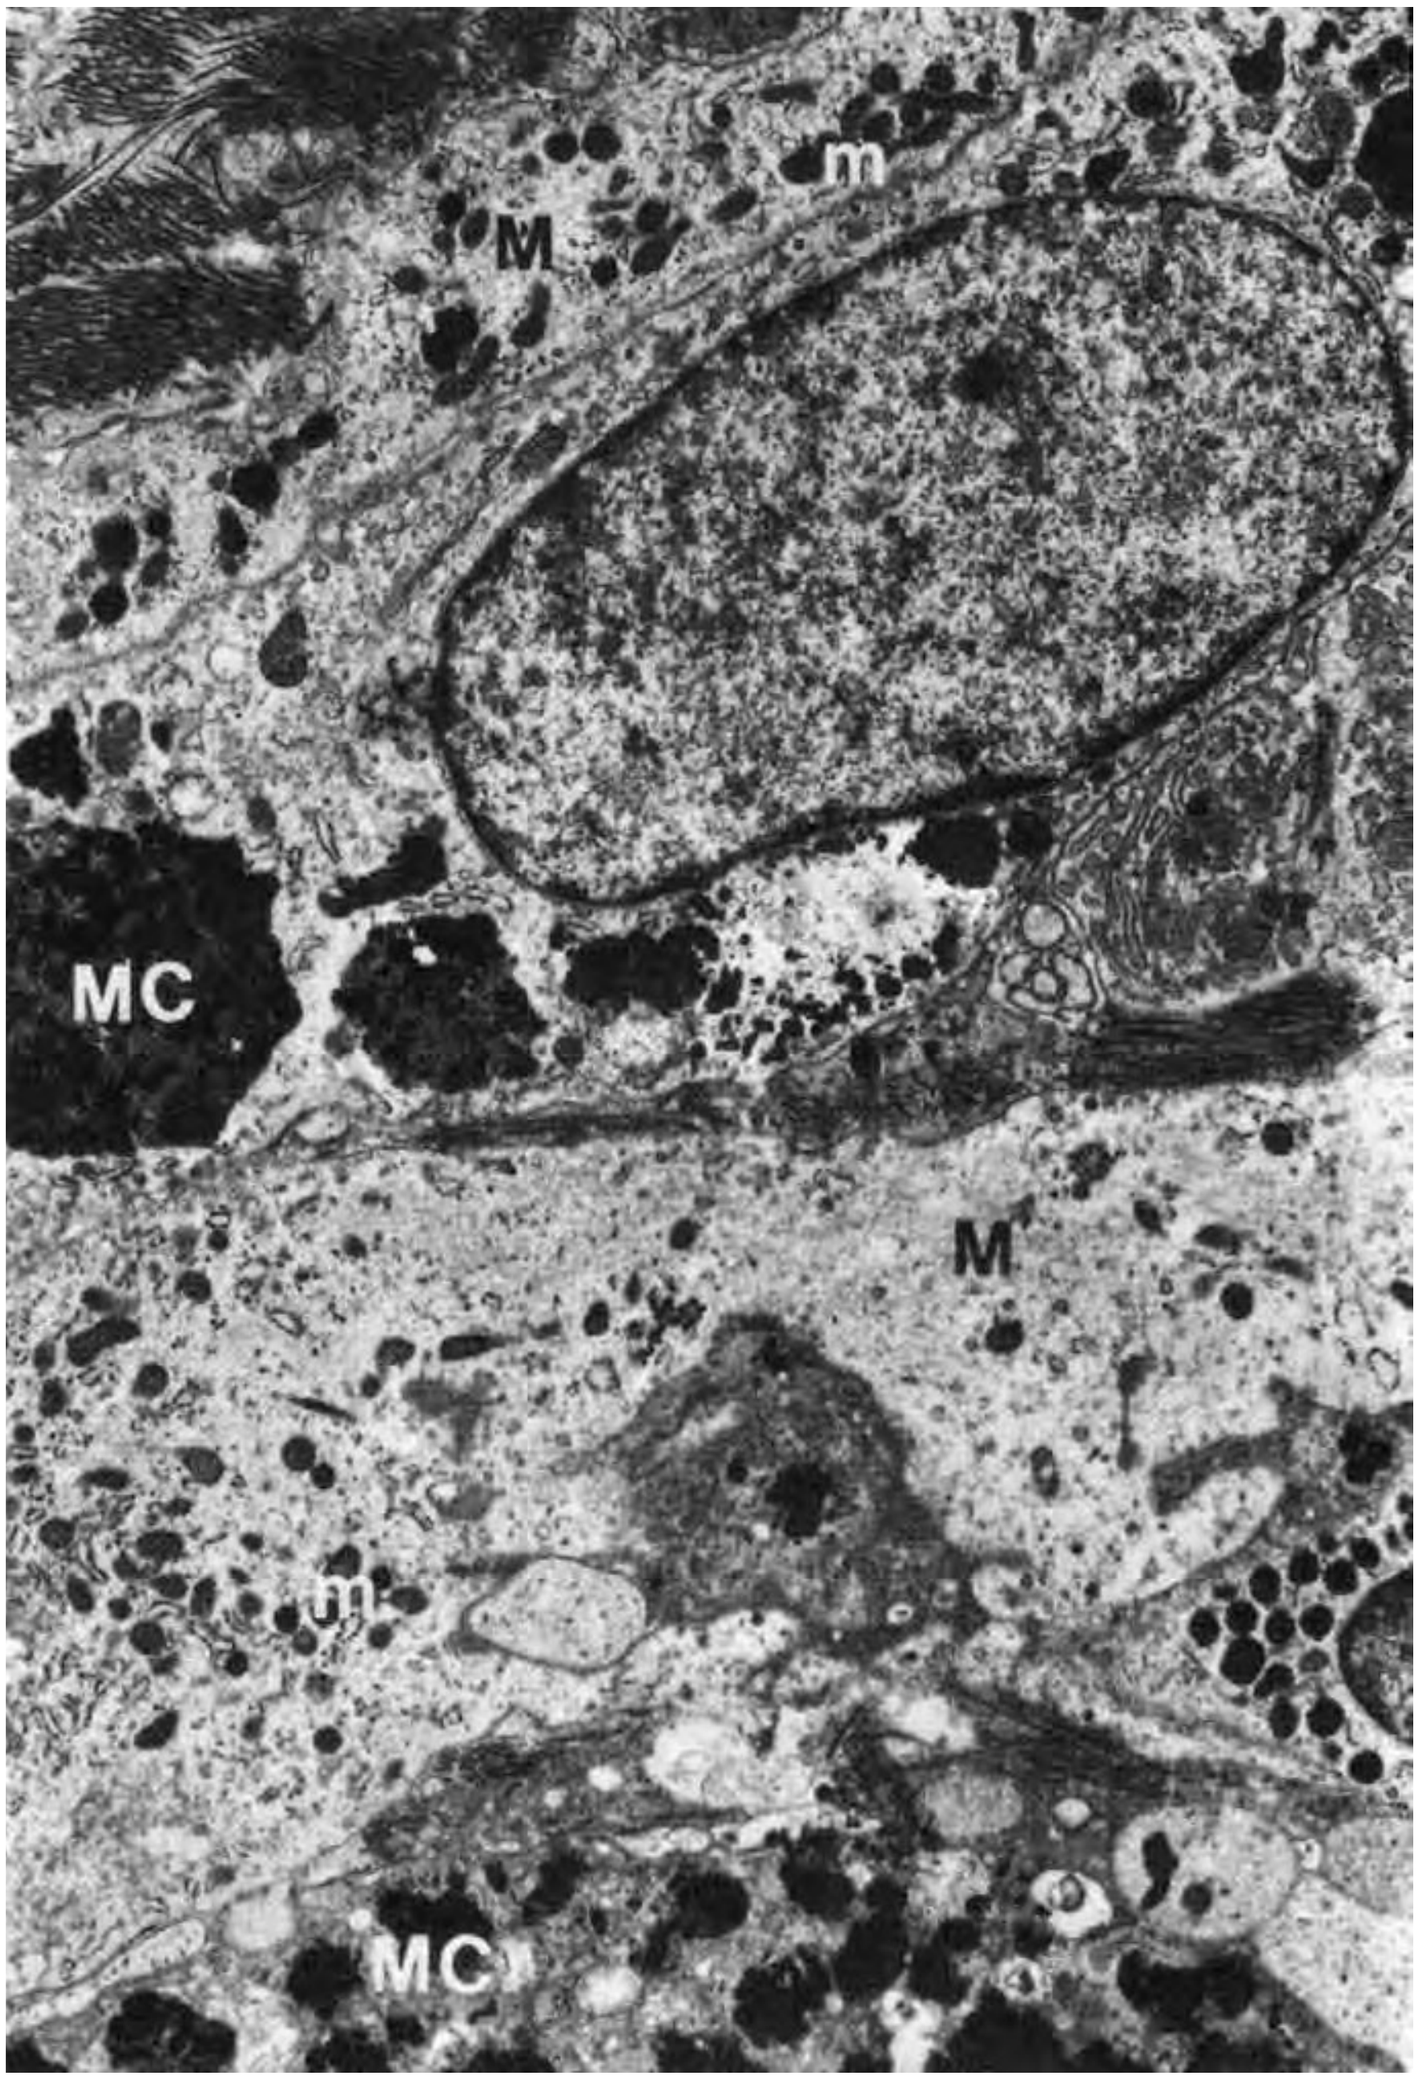

FIGURE EM-25. Malignant melanoma. In addition to malignant spindle-shaped melanocytes (M) containing an abundance of melanosomes (m), melanophages with melanosome complexes (MC) are found.

  collagenous and elastotic marginal plaques of the hands v., 391
Acrokeratosis neoplastica, 419
  histopathology of, 103, 419
Acrokeratosis verruciformis of Hopf, 152, 152*f*
  Darier's disease v., 149, 151–152
  differential diagnosis of, 152
  histogenesis of, 152
  histopathology of, 152, 152*f*
  hyperkeratotic seborrheic keratosis v., 798
Acromegaly, soft fibroma and, 981
Acro-osteolysis, 401
  histogenesis of, 401
  histopathology of, 120, 401
Acropigmentation symmetrica of Dohi, 689
Acropustulosis of infancy, 267
  differential diagnosis of, 267
  histopathology of, 112, 267
  pathogenesis of, 267
Acrosclerosis
  dystrophic calcinosis cutis and, 436–437
  mixed connective tissue disease with, 292
  systemic scleroderma and, 299
Acrosyringeal lichen planus, 187
Acrosyringeal nevi, eccrine syringofibroadenoma v., 888
Actin, in epithelioid sarcoma, 996
Actinic comedonal plaques, 391
  histopathology of, 391
Actinic granuloma. *See also* Annular elastolytic giant cell granuloma
  histopathology of, 117, 120
Actinic keratosis, 807–811, 807*f*. *See also* Solar keratoses
  acantholytic squamous cell carcinoma from, 821
  cutaneous horn and, 811, 811*f*
  differential diagnosis of, 810–811
  histopathology of, 87, 87*f,* 104–107, 110, 808–810, 808*f*–810*f*
  pathogenesis of, 810
  solar lentigines v., 708
  squamous cell carcinoma v., 820–821
Actinic lentigo. *See also* Solar lentigo
  histopathology of, 87, 87*f,* 104
Actinic prurigo (AP), 335–336, 335*f*
  differential diagnosis of, 336
  histopathology of, 106, 108, 335–336, 335*f*–336*f*
  pathogenesis of, 336
  polymorphic light eruption v., 335
Actinic reticuloid syndrome. *See also* Chronic actinic dermatitis
  histopathology of, 111
  neutrophilic eccrine hidradenitis and, 491
Actinomyces israelii, 574
Actinomycetoma, 614
Actinomycosis, 574, 574*f*–575*f*
  histopathology of, 119, 574, 574*f*–575*f*
Acupuncture, silicone granuloma and, 374
Acute bacterial folliculitis, histopathology of, 128
Acute deep folliculitis, 543, 544*f*
  histopathology of, 543
Acute disseminated LCD, 668–669, 671
Acute febrile neutrophilic dermatosis
  histopathology of, 93, 93*f,* 115, 223, 223*f*
  pathogenesis of, 224
Acute generalized exanthematous pustulosis (AGEP), 314–315, 315*f*
  bowel-associated dermatosis-arthritis syndrome v., 412
  histopathology of, 109
Acute generalized pustular psoriasis of von Zumbusch, 175
Acute infantile hemorrhagic edema (AHE), Henoch-Schönlein purpura and, 219
Acute lymphoid, pyoderma gangrenosum with, 411
Acute meningococcemia, 546–547
  histopathology of, 546–547
  pathogenesis of, 547
Acute mucocutaneous candidiasis, 597–598, 597*f,* 598*t*
  histopathology of, 597–598
  pathogenesis of, 598
Acute myeloid leukemia, 957–958
  clinical features of, 957, 958*f*
  differential diagnosis of, 958
  histogenesis of, 958, 959*f*
  histopathology of, 958, 958*t,* 959*f*
Acute neutrophilic dermatosis, histopathology of, 94, 94*f,* 117
Acute pustular bacterid, bowel-associated dermatosis-arthritis syndrome v., 412–413
Acute radiation dermatitis, 348–352, 349*f*–351*f*
  histopathology of, 349
Acute septicemia, 546–548, 547*f*
  acute meningococcemia, 546–547
  Pseudomonas septicemia, 547–548, 547*f*
  Vibrio vulnificus septicemia, 548
Acute spongiotic dermatitis
  definition and evaluation of, 237, 239*f*
  differential diagnosis of, 243
Acute strongyloidiasis, 628
Acute superficial folliculitis, 542–543, 543*f*
  impetigo Bockhart, 542
  Pseudomonas folliculitis, 542–543
Acute ultraviolet burn, 346, 346*f*
Acute urticaria, 169
Acute weeping stage, of parapoxvirus infections, 648
Adalimumab, drug-induced lupus erythematosus with, 318
Addison's disease
  histogenesis of, 690
  histopathology of, 104, 690
  hyperpigmentation with, 690
  macular atrophy and, 400
Adenocarcinoma
  histopathology of, 122
  of mammary-like glands of the vulva, 1151
  metastatic, histopathology of, 97, 97*f,* 122
  primary, histopathology of, 122

  histopathology of, 126, 1041–1042, 1041*f*–1042*f*
  intravascular large B-cell lymphoma v., 933
  intravascular papillary endothelial hyperplasia v., 1007
  Kaposi's sarcoma v., 1034
  postirradiation, 1041
  progressive lymphangioma v., 1045
  pyogenic granuloma v., 1018
  radiation-induced, 351–352
  retiform hemangioendothelioma v., 1036
  of the scalp and face, 1040, 1041*f*
  sinusoidal hemangioma v., 1019
  spindle cell hemangioma v., 1028
  symplastic hemangioma v., 1028
  tufted angioma v., 1016
Angiotensin-converting enzyme inhibitors, T-cell lymphomatoid hyperplasias and, 936
Angiotensin-converting enzyme test, for sarcoidosis, 372
Angiotropism, melanoma prognosis and, 768
Angular cheilitis, macular atrophy and, 400
Anhidrotic ectodermal dysplasia, eccrine glands and, 35–36
Animal-type melanoma, 757
  pigmented epithelioid melanocytoma and, 757
Annular elastolytic giant cell granuloma, 364–365, 364*f*–365*f*
  differential diagnosis of, 364–365
  histopathology of, 117, 119–120, 364, 364*f*–365*f*
  necrobiosis lipoidica v., 367
Annular plaques, of acquired perforating dermatosis, 396
Anogenital cancer
  giant condyloma acuminata of Buschke and Loewenstein in, 656
  human papillomavirus in, 650
Anogenital region, apocrine glands of, 35
Anogenital warts. *See* Condyloma acuminatum
Anorectal mucosa, mucosal lentiginous melanoma of, 749
Anorexia nervosa, pellagra and, 408, 451
Anorexia, polyarteritis nodosa and, 209
Anthill warts, 652
Anthrax, 567, 567*f*
  histopathology of, 120, 567, 567*f*
Antiarrhythmics, systemic lupus erythematosus and, 286–287, 286*t*
Antibiotics
  for acne vulgaris, 461
  acute generalized exanthematous pustulosis with, 314
  acute mucocutaneous candidiasis with use of, 597
  adverse reactions to, 660
  aspergillosis with use of, 599
  for bacillary angiomatosis, 573
  for blastomycosis-like pyoderma, 546
  for confluent and reticulated papillomatosis, 449
  herpetic folliculitis response to, 638
  infectious mononucleosis with, 644
  for Lyme disease, 585
  methicillin-resistant *Staphylococcus aureus* skin infections with use of, 542
  Pseudomonas septicemia with use of, 547
  radiation recall dermatitis and, 352
  for rickettsial infections, 568
  systemic lupus erythematosus and, 286–287, 286*t*
  toxic epidermal necrolysis and, 269
  toxicities of, 311
  ultraviolet recall and, 346
  for yaws, 584
Antibodies
  to cartilage, 494
  to melanocytes, 694
Anti-BP180 antibodies, assays for, 74, 74*t*
Anticardiolipin antibodies
  histopathology of, 116
  macular atrophy and, 400
α_1-antichymotrypsins, antibodies against, 76*t,* 78
Anticonvulsants
  interstitial granulomatous drug reaction and, 381
  pellagra and, 408
  systemic lupus erythematosus and, 286–287, 286*t*
  T-cell lymphomatoid hyperplasias and, 936
  toxic epidermal necrolysis and, 269
Antidepressants
  interstitial granulomatous drug reaction and, 381
  T-cell lymphomatoid hyperplasias and, 936
Antidesmoglein antibodies, assays for, 73–74
Antidesmoplakin antibodies, assays for, 73, 73*f*
Antiepileptics, toxicities of, 311
Antiepiligrin, assays for, 74
Antiepithelial antibodies, circulating, indirect immunofluorescence testing for, 73–74
Antifungal therapy, 596
  herpetic folliculitis response to, 638
Antigens
  for PAMS, 246*t,* 254
  of pemphigus, 245, 246*t*
  tumor detection of, 75, 76*t*
Antihistamines, interstitial granulomatous drug reaction and, 381
Antihistone antibodies, systemic scleroderma and, 301
Antihyperlipidemics, interstitial granulomatous drug reaction and, 381
Antihypertensive drugs
  interstitial granulomatous drug reaction and, 381
  lichenoid drug eruption and, 313
  systemic lupus erythematosus and, 286–287, 286*t*
Antimalarials, drug-induced pigmentary alterations of, 692
Antimony compounds, erythema nodosum with, 515
Antimycotics, 595
  for blastomycosis, 604
Antineoplastic chemotherapeutic drugs
  cutaneous reactions to, 321–322, 321*f*–322*f*
    histogenesis of, 322
    histopathology of, 321–322, 321*f*–322*f*
  drug-induced pigmentary alterations of, 692
Antineutrophil cytoplasmic antibodies (ANCAs), 207, 207*t*
  Churg-Strauss syndrome and, 213
  leukocytoclastic vasculitis and, 216
  Wegener's granulomatosis and, 214–215
Antinuclear antibodies (ANAs)
  drug-induced lupus erythematosus with, 318
  eosinophilic fasciitis and, 303
  systemic lupus erythematosus and, 288
  systemic scleroderma and, 301
Anti-p200 pemphigoid, 263
  histopathology of, 263
  immunofluorescence testing for, 263
Antiphospholipid antibodies, macular atrophy and, 400
Antiphospholipid syndrome
  chilblains v., 353
  histopathology of, 112
  with reactive angioendotheliomatosis, 1008
  systemic lupus erythematosus with, 288, 289*f*
Antiplakin antibodies, 73
Antiplectin antibodies, 74
Antiretroviral therapy, cutaneous manifestations of, 324
Antithyroid drugs, systemic lupus erythematosus and, 286–287, 286*t*
α_1-Antitrypsin, antibodies against, 76*t,* 78
α_1-Antitrypsin deficiency panniculitis, histopathology of, 130–131

Antituberculous medication, 552, 554
  radiation recall dermatitis and, 352
Anti-type IV collagen, assays for, 74, 74*t*
Anti-U1 ribonucleoprotein antibodies, mixed connective tissue disease with, 292–293
Antivirals, adverse reactions to, 660
Antoni A, schwannomas, 1116–1117

Brunsting-Perry variant, of cicatricial pemphigoid, 259
Buerger's disease, 209, 210*f*
  differential diagnosis of, 209
  histopathology of, 111, 209, 210*f*
Bulbous diseases, verruciform xanthomas with, 685
Bullae
  of bullous impetigo, 539–540
  in coma, 316–317, 316*f*–317*f*
  definition of, 235
  with erythema ab igne, 347
  morphea and, 299
  polyarteritis nodosa and, 210
  urticaria pigmentosa and, 160
Bullous congenital ichthyosiform erythroderma. *See also* Epidermolytic hyperkeratosis
  epidermolytic hyperkeratosis in, 793
  hypertrophic actinic keratosis and, 809
Bullous dermatitis, histopathology of, 113
Bullous dermatosis of diabetes, histopathology of, 114
Bullous dermatosis of uremia, histopathology of, 114
Bullous disease
  drug-induced, 317–318, 317*t*
    histopathology of, 317
    pathogenesis of, 317–318
  immunohistochemistry for, 74
  of the nail, 506
Bullous drug eruption, histopathology of, 115
Bullous impetigo, 539–541
  differential diagnosis of, 541
  histopathology of, 112, 540
  pathogenesis of, 540
Bullous insect bite reaction, histopathology of, 115
Bullous lichen planus, histopathology of, 93, 93*f,* 114
Bullous lupus erythematosus, histopathology of, 114–115
Bullous mastocytosis, 158
  histopathology of, 93, 93*f,* 115
Bullous pemphigoid, 256–259, 257*f*–258*f,* 258*t,* 1169*f*–1170*f*
  clinical variants of, 259
    drug-associated, 259
    in lower extremities, 259
    vesicular pemphigoid, 259
  direct immunofluorescence and, 71, 257–258, 257*f,* 257*t*
  eosinophils and, 44
  histopathology of, 93, 93*f,* 107, 114–115, 256–257, 257*f*
  milia and, 802
  with nail unit, 506
  pathogenesis of, 258–259
  ultrastructural study of, 259
  vesicular pemphigoid v., 259
Bullous pemphigoid antigen 1 (BPAG1)
  of hemidesmosomes, 23
  herpes gestationis and, 260–261
Bullous pemphigoid antigen 2 (BPAG2)
  cicatricial pemphigoid and, 260
  of hemidesmosomes, 23
  herpes gestationis and, 260–261
Bullous systemic lupus erythematosus, 261–263, 262*f,* 286
  histopathology of, 261–263, 262*f,* 287, 287*f*–288*f*
  immunofluorescence testing for, 263
  ultrastructural study of, 263
Bullous vasculitis, histopathology of, 112, 115
Bullous/vesicular mycosis fungoides, 942
Bunostomum phlebotomum, 627
Bupropion, SJS and TEN with, 313
Burkitt lymphoma
  diffuse large B-cell lymphoma v., 931
  mantle cell lymphoma v., 929
  precursor B-cell lymphoblastic lymphoma v., 924*f,* 925
Burns. *See also* First-degree burns; Second-degree burns; Third-degree burns
  acute ultraviolet burn, 346, 346*f*
  basal cell carcinoma and, 824
  burn scar-associated malignancy, 346
  histopathology of, 343–346, 344*f*–345*f*
  radiation dermatitis v., 352
  squamous cell carcinoma from, 817
  ultraviolet recall, 346–347
Burrows
  of hookworm-related cutaneous larva migrans, 627, 627*f*
  of scabies, 626
Buruli ulcer, 556–558, 557*f*
  histopathology of, 120, 557, 557*f*
  pathogenesis of, 558
Buschke-Loewenstein tumor, 655*f,* 656
Buschke-Ollendorff syndrome. *See* Connective tissue nevus
Busulfan, drug-induced pigmentary alterations of, 692
Buttocks
  dermatitis herpetiformis and, 263
  lupus erythematosus profundus/panniculitis and, 283
Button osteomas on the calvarium, 1093

Cactus granuloma
  foreign-body reactions and, 374–375
  histopathology of, 375
CAD. *See* Chronic actinic dermatitis
N-Cadherin, desmoplastic melanoma and, 755
Cadherins, of desmosomes, 11
Cadmium selenide, tattoo reactions and, 377
CAF. *See* Calcifying aponeurotic fibroma
Café-au-lait spot
  histopathology of, 104
  of melanotic macules of Albright's syndrome, 705
  with neurofibromatosis, 1111
Calcaneal petechiae, 356, 356*f*
  histopathology of, 121, 356, 356*f*
Calcific elastosis, pseudoxanthoma elasticum v., 154
Calcification
  with dermatomyositis, 293
  of elastic fibers, 153–154
  with lipoid proteinosis, 430
  with metastatic calcinosis cutis, 435
  perforating calcific elastosis and, 397
  systemic scleroderma and, 300
Calcifying aponeurotic fibroma (CAF), 1096–1097, 1097*f*
  differential diagnosis of, 1097
Calcifying panniculitis, 530–531
  clinical features of, 530–531, 531*f*
  histopathology of, 131, 531, 531*f*
  pathogenesis of, 531
Calcineurin inhibitors
  for actinic prurigo, 335
  for chronic actinic dermatitis, 338
Calcinosis circumscripta, dystrophic calcinosis cutis and, 436–437
Calcinosis cutis, 435–438
  dystrophic, 436–437, 437*f*
  histopathology of, 121, 436–437, 436*f*
  idiopathic, 437
  metastatic, 435–436, 436*f*
  subepidermal calcified nodule, 437–438, 438*f*
Calcinosis universalis
  dystrophic calcinosis cutis and, 436, 437*f*
  histopathology of, 121
Calciphylaxis, 230, 230*f*
  calcifying panniculitis with, 531
  histopathology of, 94, 94*f,* 112, 116, 118–119, 230, 230*f*
  metastatic calcinosis cutis with, 435–436
  pathogenesis of, 230
Calcitonin gene-related peptide (CGRP)
  in dermis, 54
  Merkel cells and, 19
  prurigo nodularis and, 174
Calcium
  calciphylaxis and, 230
  dystrophic calcinosis cutis and, 436
  eccrine glands and, 35
  metastatic calcinosis cutis and, 435–436
  in pilomatricoma, 865
  in subcutaneous fat necrosis, 529–530, 530*f*
  subepidermal calcified nodule and, 438
Calcium channel blockers, T-cell lymphomatoid hyperplasias and, 936
C-ALCL. *See* Cutaneous anaplastic large cell lymphoma
Callus, of deep palmoplantar warts, 652
Calvarium, button osteomas on, 1093
Calymmatobacterium granulomatis, 570, 570*f*
  histopathology of, 120
  leishmaniasis v., 622
Campylobacter, Reiter's disease and, 182
c-ANCAs. *See* Cytoplasmic antineutrophil cytoplasmic antibodies
Candida albicans, 593, 598, 604

Chemokines, allergic contact dermatitis and, 239
Chemotherapeutic agents
  acute mucocutaneous candidiasis with use of, 597
  for diffuse large B-cell lymphoma, 930
  drug-induced pigmentary alterations of, 692
  herpes zoster with use of, 643
  for histiocytic cytophagic panniculitis, 533
  for leprosy, 559, 561, 563–564
  neutrophilic eccrine hidradenitis and, 491–492
  nontuberculosis mycobacteria infections with, 555
  radiation recall dermatitis and, 352
  ultraviolet recall and, 346
Cherry hemangioma, 1015
  differential diagnosis of, 1015
  histopathology of, 126, 1015
Chest, lupus erythematosus profundus/panniculitis and, 283
Chicken pox. *See* Varicella
Chilblain lupus erythematosus. *See* Chilblains
Chilblains, 352–355, 353*f*–354*f*
  differential diagnosis of, 355
  histopathology of, 115–116, 353, 353*f*–354*f*
  polymorphic light eruption v., 335
CHILD syndrome. *See* Congenital hemidysplasia with ichthyosiform erythrodermal and limb defects
Childbirth, telogen effluvium and, 478
Childhood diabetes mellitus, scleroderma and, 296
Childhood granulomatous periorificial dermatitis, 462–463
  histopathology of, 462
  pathogenesis of, 463
CHL. *See* Classical Hodgkin's lymphoma

Chlamydia infection, erythema nodosum with, 514
Chlamydia trachomatis, 571
  histopathology of, 120
  Reiter's disease and, 182
Chlorambucin, for dermatomyositis, 294
Chloramphenicol
  pellagra and, 408
  for rickettsial infections, 568
Chlorine, eccrine glands and, 35
Chloroma, myeloid sarcoma v., 957
Chloroquine
  lichenoid drug eruption and, 313
  for reticular erythematous mucinoses, 444
Chlorothiazide, photoallergic drug eruption and, 318
Chlorpromazine
  drug-induced lupus erythematosus with, 318
  photoallergic drug eruption and, 318
  photodistributed hyperpigmentation and, 319, 319*f*–320*f*
Chlorpromazine pigmentation, histopathology of, 107
Cholangiocarcinomas, 1156
Cholestanolemia, histopathology of, 124
Cholestasis, palmar xanthomas with, 680
Cholesterol
  sebaceous gland and, 30
  in xanthomas, 682–683
Cholesterol clefts
  in necrobiosis lipoidica, 366–367
  of necrobiotic xanthogranuloma with paraproteinemia, 683
  in xanthomas, 682, 682*f*
Cholesterol emboli, histopathology of, 112
Cholinergic stimulation, of eccrine glands, 35
Chondroblasts, in chondroid lipoma, 1067
Chondrocytes
  S100 protein in, 77
  of soft tissue chondromas, 1094
Chondrodermatitis nodularis helicis (CNH), 492–493, 493*f*
  acanthoma fissuratum v., 357
  histopathology of, 120, 492–493, 493*f*
  pathogenesis of, 493
Chondroid lipoma, 1067–1068, 1068*f*
  differential diagnosis of, 1067
  histopathology of, 127, 1067, 1068*f*
  pathogenesis of, 1067–1068
Chondroid syringoma, 893–894
  additional studies of, 894
  differential diagnosis of, 894
  histopathology of, 123, 893–894, 893*f*–894*f*
  with nevus sebaceus, 871
Chondroitin sulfate, PAS and, 69, 69*t*

    postinjury ossification, 1090–1093, 1091*f*–1092*f*
  extraskeletal myxoid chondrosarcoma, 1097–1098, 1098*f*
    in chondroid lipoma, 1067
    differential diagnosis of, 1098
    histopathology of, 1098, 1098*f*
    pathogenesis of, 1098
  mesenchymal chondrosarcoma, 1098–1099, 1099*f*
    differential diagnosis of, 1099
    myopericytoma and, 1049
    pathogenesis of, 1099
  osseous and chondroid lesions, 1099–1100, 1100*f*
Chondrosarcoma
  extraskeletal myxoid chondrosarcoma, 1097–1098, 1098*f*
  histopathology of, 127
  mesenchymal chondrosarcoma, 1098–1099, 1099*f*
  radiation-induced, 351
Chordoid sarcoma, 1097
Choriocarcinoma, 1158
Chorionic gonadotropin antigen, 1158
Chorioretinitis, with onchocerciasis, 630
Choroid, melanoma of, 700
Chrome green, tattoo reactions and, 377
Chromoblastomycosis, histopathology of, 118–119, 132
Chromogranin A, Merkel cells and, 19
Chromogranin, antibodies against, 76*t,* 77
Chromomycosis, 600*t,* 601, 607–608, 607*f*
  histopathology of, 119, 607, 607*f*
  pathogenesis of, 608
Chronic actinic damage, histopathology of, 108
Chronic actinic dermatitis (CAD), 338–340, 338*f*–340*f*
  histopathology of, 108, 111, 117
  in HIV, 660
Chronic allergic dermatitis, histopathology of, 109
Chronic atopic dermatitis, histopathology of, 90, 90*f,* 109
Chronic bullous dermatosis of childhood. *See* Linear IgA dermatosis, childhood type
Chronic cutaneous leishmaniasis, 621, 623–624
  differential diagnosis of, 624
  histopathology of, 623–624
Chronic cutaneous lupus erythematosus, 280–283, 281*f*–282*f,* 284*f*
  discoid lupus erythematosus, 280–283, 281*f*–282*f*
  lupus erythematosus profundus/panniculitis, 283, 284*f*
  tumid lupus erythematosus, 283, 284*f*
  verrucous lupus erythematosus, 282*f,* 283
Chronic deep folliculitis, 544
  histopathology of, 544
Chronic eczema, actinic prurigo v., 336
Chronic erythema nodosum, histopathology of, 131
Chronic fibrosing alveolitis, ulcerative colitis with, 416
Chronic focal LCD, 669
Chronic gonococcemia, 548–549
  histopathology of, 548–549
  pathogenesis of, 549
Chronic granulomatous disease, 245
Chronic lymphocytic leukemia (CLL), 925–926
  clinical features of, 925
  differential diagnosis of, 919*t,* 926
  histogenesis of, 925–926
  histopathology of, 925, 926*f*
  paraneoplastic autoimmune multiorgan syndrome and, 254
  primary cutaneous follicle center lymphoma v., 919
  with relapsing polychondritis, 493
Chronic meningococcemia, 548, 548*f*
  histopathology of, 548, 548*f*
Chronic mucocutaneous candidiasis (CMC), 598
  histopathology of, 598
Chronic multifocal LCD, 669
Chronic myelogenous leukemia, histopathology of, 122
Chronic myeloid leukemia, 957–958
  clinical features of, 957, 958*f*
  differential diagnosis of, 958
  histogenesis of, 958, 959*f*
  histopathology of, 958, 958*t,* 959*f*
Chronic radiation dermatitis, 348–352, 349*f*–351*f*
  differential diagnosis of, 352
  histopathology of, 349–351, 349*f*–350*f*
Chronic septicemia, 548–549, 548*f*
  chronic gonococcemia, 548–549
  chronic meningococcemia, 548, 548*f*
Chronic spongiotic dermatitis
  definition and evaluation of, 237, 240*f*
  differential diagnosis of, 244
  histopathology of, 109
Chronic strongyloidiasis, 628
Chronic subcutaneous zygomycosis, 601
Chronic superficial folliculitis, 543
  histopathology of, 543
Chronic ulcerative herpes simplex, 639, 641
Chronic ulcers
  graft-*versus*-host disease and, 271
  histopathology of, 106
Chronic urticaria, 169
  celiac disease and, 417
  with strongyloidiasis, 628
Chrysiasis, 327
  histogenesis of, 327
  histopathology of, 121, 327
CHS1/LYST gene, 695
Churg-Strauss granuloma. *See also* Palisaded neutrophilic and granulomatosis

  histopathology of, 120, 347*f*, 348
Erythema annulare centrifugum
  chilblains v., 355
  differential diagnosis of, 171
  erythema chronicum migrans v., 586
  histopathology of, 115, 171, 171*f*–172*f*
  lymphocytoma cutis v., 588
  pathogenesis of, 171
Erythema chronicum migrans, 586, 586*f*
  with borrelial lymphocytoma cutis, 588
  differential diagnosis of, 586
  histopathology of, 93, 93*f*, 115–116, 129, 586, 586*f*
Erythema chronicum perstans, erythema ab igne v., 348
Erythema dyschromicum perstans, 172–173, 172*f*
  differential diagnosis of, 173
  histopathology of, 104, 112, 172
  pathogenesis of, 172–173
Erythema elevatum diutinum (EED), 221–222
  granuloma faciale v., 222
  histopathology of, 111, 116–117, 221–222
  pathogenesis of, 222
  relapsing polychondritis with, 494
Erythema gyratum repens, 171–172
  histopathology of, 108, 172
  pathogenesis of, 172
Erythema induratum, 519–521, 519*f*–520*f*, 553
  clinical presentation of, 519, 519*f*
  differential diagnosis of, 521
  erythema nodosum v., 515
  histopathology of, 130–131, 131, 519–521, 519*f*–520*f*
  lupus erythematosus panniculitis v., 523
  pancreatic disease v., 529
  pathogenesis of, 521
Erythema infectiosum, 662, 662*f*
Erythema multiforme (EM), 268–270, 269*f*–270*f*, 312, 312*f*
  acute generalized exanthematous pustulosis v., 314–315
  chilblains v., 355
  coccidioidomycosis with, 608
  Crohn's disease with, 415
  differential diagnosis of, 270
  fixed drug eruptions v., 314
  granuloma annulare and, 362
  hepatitis and, 419
  hepatitis C with, 661
  herpes simplex associated with, 639
  histopathology of, 91, 91*f*, 110, 112, 114, 129, 269, 270*f*, 312, 312*f*
  human recombinant proteins with, 322–323
  immunofluorescence testing for, 270
  with nail unit, 506
  parvovirus B19 in, 662
  pathogenesis of, 270
  postinflammatory pigmentary alteration with, 690
  SJS and TEN v., 268–269, 269*f*
  ultrastructural study of, 270
Erythema nodosum, 511–515, 550
  Behçet's syndrome and, 413
  celiac disease and, 417
  clinical presentation of, 511, 511*f*
  Crohn's disease with, 415
  differential diagnosis of, 515
  eosinophilic panniculitis and, 515
  erythema induratum v., 519, 521
  hepatitis C with, 661
  histopathology of, 100, 100*f*, 130, 511–514, 512*f*–514*f*
  lipomembranous panniculitis with, 531
  mycobacterial panniculitis v., 534
  pancreatic disease v., 529
  pathogenesis of, 514–515
  sarcoidosis with, 370
  Takayasu's arteritis v., 208
  tattoo reactions and, 378
  Weber-Christian disease v., 524
Erythema nodosum leprosum (ENL), 564–567, 565*f*
  histopathology of, 116, 119, 129–131, 130, 131
Erythema nodosum migrans, 511, 514
Erythema toxicum neonatorum, 267
  differential diagnosis of, 267
  eosinophilic pustular folliculitis and, 467
  histopathology of, 92, 92*f*, 107–108, 113, 128, 267
  pathogenesis of, 267
  transient neonatal pustular melanosis v., 267
Erythematous macules, microscopic polyarteritis and, 212
Erythematous papule
  of endemic syphilis, 585
  of pinta, 584
  of yaws, 583

  in mycosis fungoides, 937
  xanthogranuloma cells from, 671
Mononeuritis multiplex, Behçet's syndrome and, 413
Mononuclear cells, of indeterminate cell histiocytosis, 678
Mononuclear phagocytic system, macrophages of, 40
Mononuclear variant, of juvenile xanthogranuloma, 672, 673*f*
Mononucleosis, erythema nodosum with, 514
Monophasic synovial sarcoma, Kaposi's sarcoma v., 1035
Monsel's solution
  for shave biopsy, 6
  tattoo reactions and, 378, 379*f*
Monsel's tattoo, 379*f*
Montgomery giant cells, chronic actinic dermatitis and, 339, 339*f*
Montgomery's areola tubercles, sebaceous glands and, 31
Montgomery's tubercles, 872–873
  histopathology of, 872–873, 873*f*
Morbilliform drug eruption, histopathology of, 107, 115
Morbilliform viral exanthem, histopathology of, 89, 89*f,* 107, 112
Morbilliform viral infections, histopathology of, 116
Morphea, 296–299, 297*f*–298*f,* 299*t*
  atrophoderma of Pasini and Pierini v., 303
  burns v., 346
  chronic radiation dermatitis v., 352
  differential diagnosis of, 299, 299*t*
  eosinophilic fasciitis v., 303
  histopathology of, 130, 297–299, 297*f*–298*f*
  lichen sclerosus et atrophicus and, 304–305, 307
  lipomembranous panniculitis with, 531
  with Lyme disease, 587–588
  lymphocytoma cutis v., 588
  nephrogenic systemic fibrosis and, 301
  panniculitis with, 534–535
  subacute cutaneous lupus erythematosus with, 283
  systemic scleroderma v., 299–300
Morphea profunda. *See also* eosinophilic fasciitis
  histopathology of, 130
Morphea-like basal cell carcinoma, 825, 825*f,* 829*f*
  desmoplastic trichoepithelioma v., 860
Morphine, drug-induced scleroderma with, 316
Morton's neuroma, 1143, 1143*f*
  histopathology of, 126
Mosaic warts, 650
Mosquitoes
  as myiasis vector, 632–633
  reactions to bites of, 634–635, 634*f*
Mother yaws, 583
Mouth, lichen planus and, 190

α-MSH. *See* α-Melanocyte-stimulating hormone
Mucin deposition
  in adenoid cystic carcinoma, 899
  follicular mucinosis and, 467–469
  granuloma annulare and, 361–362
  in lichen myxedematosus, 443
  in lipedematous alopecia, 489
  in mucinoses, 441
  in mucinous eccrine carcinoma, 898
  in necrobiosis lipoidica, 366
  palisaded granulomatous panniculitis with, 525
  palisaded neutrophilic and granulomatosis with, 369
  polymorphic light eruption and, 335
  in reticular erythematous mucinoses, 445
  with self-healing juvenile cutaneous mucinoses, 445

Mucinoses, 441–447. *See also* Follicular mucinosis
  generalized myxedema, 441
  lichen myxedematosus, 442–444, 443*f*
  pretibial myxedema, 441–442, 441*f*–442*f*
  reticular erythematous, 444–445, 444*f*–445*f*
  scleredema, 445–447, 446*f*
  self-healing juvenile cutaneous, 445
Mucinous eccrine carcinoma, 898
  additional studies of, 898
  histopathology of, 123, 898, 898*f*
Mucinous mucosal cyst, histopathology of, 121
Mucinous syringometaplasia, 888
  histopathology of, 123, 888
Mucin-producing squamous cell carcinoma, 818, 821–822
  histopathology of, 122, 821–822
Muciphages, in mucous cyst of the oral mucosa, 998
Muckle-Wells syndrome, urticaria and, 169
Mucoblasts, pretibial myxedema and, 442
Mucocele, histopathology of, 121
Mucocele of oral mucosa, histopathology of, 125
Mucocutaneous end-organs, in dermis, 54–55
Mucocutaneous leishmaniasis, 621, 622*t,* 624
  histopathology of, 624
Mucocutaneous lymph node syndrome, 184–185, 208–209
  histopathology of, 107, 113, 184–185, 209
  pathogenesis of, 185
Mucoepidermoid carcinoma, 898–899
  histopathology of, 122
  mucin-producing squamous cell carcinoma and, 821
Mucoid stroma, epithelioid hemangioma and, 1024
Mucopolysaccharides. *See also* Acid mucopolysaccharides
  PAS and, 68, 69*t*
  soft tissue chondromas and, 1094
Mucopolysaccharidosis (MPS), 447
  histogenesis of, 447
  histopathology of, 447
Mucor infection, 599
Mucorales infection, 599
Mucormycosis, 599–601, 600*t,* 602*f*
  histopathology of, 119
  in HIV, 659
Mucosa-associated lymphoid tissue (MALT) lymphoma, PCMZL of, 920–921
Mucosal epithelium, 10*f,* 12
Mucosal lentigines, 705–706, 710*t*
  differential diagnosis of, 706
  histopathology of, 705–706
  pathobiology of, 706
Mucosal lentiginous melanoma, 749
  classification of, 738, 739*f*
Mucosal melanotic macules. *See* Mucosal lentigines
Mucosal neuroma syndrome (MNS), 1137–1138
  histogenesis of, 1138
  histopathology of, 125, 1137–1138, 1137*f*
Mucosal-lentiginous melanoma, histopathology of, 105, 123
Mucous cyst of the oral mucosa, 997–998
  histopathology of, 998, 998*f*
Muir-Torre syndrome, 875
  genetics of, 875
  histopathology of, 875
  sebaceous adenoma with, 873
  sebaceous carcinoma and, 875
  solitary keratoacanthoma in, 836
Mulberry cell, in hibernoma, 1070
Multibacillary patients, 560
Multicentric Castleman disease, human herpesvirus in, 646
Multicentric reticulohistiocytosis (MRH), 675–676, 676*f*
  doubly refractile lipids in, 70
  histopathology of, 124
Multifocal systemic sporotrichosis, 613
Multinucleate cell angiohistiocytoma
  factor XIIIa and, 78
  histopathology of, 126
Multinucleate giant cells, 675
Multinucleated cell angiohistiocytoma, 994
  histogenesis of, 994
  histopathology of, 994
Multinucleated keratinocytes, of Bowenoid papulosis of genitalia, 656
Multiple angiokeratoma, 1011
Multiple benign cystic epithelioma. *See* Trichoepithelioma
Multiple endocrine neoplasia (MEN), 1111
Multiple hamartoma syndrome. *See* Cowden's disease
Multiple keratoacanthoma. *See* Keratoacanthoma, multiple
Multiple leiomyoma, 1076
Multiple lentiginosis syndrome, 708–709, 710*t*
  histopathology of, 709
Multiple miliary osteoma cutis, 1087
Multiple myeloma
  diffuse normolipemic plane xanthoma with, 684
  primary systemic amyloidosis relationship with, 426
Multiple schwannoma, 1111
  plexiform schwannoma of, 1120
Multiple self-healing keratoacanthoma, 837
Multiple sulfatase deficiencies, 137
Multiple symmetric lipomatosis, 1061–1062
Multiple trichoepithelioma, 857–858
  histopathology of, 858–859, 858*f*
Multivariable prognostic models, for malignant melanoma, 762
Munro abscesses, generalized pustular psoriasis, 178
Munro microabscesses
  formation of, 180
  psoriasis vulgaris and, 176–177
Murine bladder, for antiepithelial antibody evaluation, 73
Musca domestica, as myiasis vector, 632
Muscle cells. *See* Dermal muscle cells
Musculoaponeurotic fibromatosis. *See* Desmoid-type fibromatosis
Myalgias
  drug-induced lupus erythematosus with, 318
  microscopic polyarteritis and, 212
  polyarteritis nodosa and, 209
Myasthenia gravis, alopecia areata and, 475
Mycelium, of fungi, 591, 592*t*
Mycobacterial infections, 549–550. *See also* Leprosy; Nontuberculosis mycobacteria; Tuberculosis
Mycobacterial panniculitis, 534, 534*f*
  histopathology of, 102, 102*f,* 131–132
Mycobacterium abscessus, 558
Mycobacterium avium-intracellulare (MAI), 555, 555*f*–556*f*
  histopathology of, 117, 119
  leprosy v., 567
Mycobacterium bovis, 555
Mycobacterium chelonei, 558

  electron microscopy of, 565
  pathogenesis of, 566
  staining of, 559–560
Mycobacterium marinum, 555–556, 556*f*
  differential diagnosis of, 556
  granuloma annulare v., 363
  histopathology of, 118–119, 556, 556*f*
  sporotrichosis v., 614
Mycobacterium tuberculosis
  Behçet's syndrome and, 414
  erythema induratum and, 521
  lupus miliaris disseminatus faciei and, 466
  sarcoidosis and, 372
  in tuberculosis, 550–555, 551*f*–554*f*
Mycobacterium ulcerans, 556–558, 557*f*
  histopathology of, 120
Mycophenolate, for chronic actinic dermatitis, 338
Mycophenolate mofetil, for dermatomyositis, 294
Mycoplasma pneumoniae
  erythema nodosum with, 514
  Stevens-Johnson syndrome and, 268
Mycoses, 591
Mycosis fungoides (MF), 936–944. *See also* Acanthosis nigricans-like mycosis fungoides; Adnexotropic mycosis fungoides; Bullous/vesicular mycosis fungoides; Folliculotropic mycosis fungoides; Granulomatous mycosis fungoides; Granulomatous slack skin; Hyperpigmented mycosis fungoides; Hypopigmented mycosis fungoides; Ichthyosiform mycosis fungoides; Mycosis fungoides palmaris et plantaris; Poikiloderma vasculare atrophicans; Psoriasiform mycosis fungoides; Pustular mycosis fungoides; Solitary pagetoid reticulosis; Syringotropic mycosis fungoides; Verrucous/hyperkeratotic mycosis fungoides
  adult T-cell leukemia/lymphoma v., 955
  angiocentric, histopathology of, 116
  chronic spongiotic dermatitis and, 244
  clinical features of, 936–937, 936*f*
  differential diagnosis of, 939*t,* 944
  drug-induced pseudolymphoma syndrome and, 320
  early, histopathology of, 90, 90*f,* 108–109
  follicular mucinosis and, 467–468
  granuloma annulare v., 363
  granulomatous, histopathology of, 118
  histogenesis of, 942–944, 943*f*
  histopathology of, 91, 91*f,* 96, 96*f,* 108, 110–111, 937–942, 937*f*–941*f*
  Kaposi's varicelliform eruption with, 641
  Leser-Trélat sign with, 799
  peripheral T-cell lymphoma v., 952
  pigmentary presentations of, 692–693
  poikiloderma atrophicans vasculare and, 295, 296*f*
  primary cutaneous aggressive CD8-positive T-cell lymphoma v., 950
  primary cutaneous CD4-positive small-/medium-sized pleomorphic T-cell lymphoma v., 950
  scurvy v., 407
  Sézary syndrome v., 944
  small-plaque parapsoriasis and, 183
  subtypes of, 939–942
  xanthomas with, 686
Mycosis fungoides palmaris et plantaris, 942
Myeloblastic leukemia, with follicular mucinosis, 468
Myeloblasts
  extramedullary hematopoiesis and, 956
  myeloid leukemias with, 958
Myelodysplastic syndrome
  eosinophilic pustular folliculitis and, 466
  necrolytic migratory erythema and, 409
  with reactive angioendotheliomatosis, 1008
  with relapsing polychondritis, 493
Myelogenous leukemia, neutrophilic eccrine hidradenitis and, 491
Myeloid cells, in skin, 911
Myeloid leukemias. *See also* Acute myeloid leukemia; Chronic myeloid leukemia
  myeloid sarcoma v., 957
  pyoderma gangrenosum with, 411
Myeloid sarcoma, 957
  clinical features of, 957
  differential diagnosis of, 957

histogenesis of, 957
histopathology of, 957

  storiform perineural cell fibroma v., 1133
  variant types of, 1118–1122
    cellular, 1118–1119, 1118*f*–1119*f*
    epithelioid, 1119–1120, 1120*f*–1121*f*
    infiltrating fascicular, 1121
    plexiform, 1120–1121, 1120*f*
    psammomatous melanotic, 1121
    transformed, 1121–1122
Schweninger-Buzzi anetoderma, 399–400
Scirrhous carcinoma, 1153
Scl-70 antibodies, systemic scleroderma and, 301
SCLE. *See* Subacute cutaneous lupus erythematosus
Scleredema, 445–447, 446*f*
  differential diagnosis of, 446–447
  histopathology of, 121, 446, 446*f*
  lipedema v., 527
  pathogenesis of, 446
  systemic lesions of, 446
Scleredema adultorum. *See* Scleredema
Scleredema of Buschke, staining methods for, 67
Sclerema neonatorum, 529
  clinical features of, 529
  differential diagnosis of, 529
  histopathology of, 101, 101*f,* 131, 529
  pathogenesis of, 529
  subcutaneous fat necrosis v., 530
  systemic lesions of, 529
Sclerodactyly, fibroblastic rheumatism and, 307
Scleroderma, 295–301
  acro-osteolysis v., 401
  Behçet's syndrome v., 414
  burns v., 346
  chronic radiation dermatitis v., 352
  drug-induced, 315–316
  graft-*versus*-host disease v., 273
  histopathology of, 101, 101*f,* 116, 121
  lymphocytoma cutis v., 588
  morphea, 296–299, 297*f*–298*f,* 299*t*
  panniculitis with, 534–535
  pseudopelade of Brocq v., 483
  systemic, 299–301, 300*t*
Scleroderma/morphea, histopathology of, 93, 93*f,* 96, 96*f,* 100, 100*f,* 116, 120, 128–130

Scleromyxedema, 444
  histopathology of, 121
  lichen myxedematosus and, 442–443
  lipedema v., 527
  nephrogenic systemic fibrosis v., 301
  pathogenesis of, 444
Sclerosing cholangitis, 417–418, 418*f*
  histopathology of, 417, 418*f*
  pathogenesis of, 417–418
  pyoderma gangrenosum with, 411
Sclerosing disorders, of Lyme disease, 587–588, 587*f*
  histopathology of, 588
Sclerosing epithelial hamartoma. *See* Desmoplastic trichoepithelioma
Sclerosing hemangioma. *See* Dermatofibroma
Sclerosing lesions, of Lyme disease, 586–587, 587*f*
Sclerosing lipogranuloma. *See also* Paraffinoma
  histopathology of, 131
Sclerosing myofibroblastoma, neurothekeoma v., 1130
Sclerosis, porphyria cutanea tarda with, 433
Sclerotic fibroma, 981–982
  angiofibroblastoma v., 991
  histogenesis of, 982
  histopathology of, 981–982, 982*f*
Sclerotic lipoma, histopathology of, 1062, 1063*f*
Sclerotic variant of atypical fibroxanthoma, 979
Scolex, of *Taenia solium* larva, 632
Scoliosis, Ehlers-Danlos syndrome and, 156
Scopulariopsis sp., 593
  nail unit and, 506–507
Scrofuloderma, 550, 552
  histopathology of, 119, 552
  pseudocarcinomatous hyperplasia and, 822
Scrotal leiomyosarcoma, 1080
Scrotum, idiopathic calcinosis cutis of, 437
Scurvy, 407
  connective tissue deficiencies and, 231
  differential diagnosis of, 407
  histopathology of, 86, 86*f,* 103, 127, 407
  pathogenesis of, 407
Scutula, 593
Scyballa, 627
Scytalidium (Hendersonula) infections, 593
Sea urchin granuloma, 374–376
  histopathology of, 375
  pathogenesis of, 376
Sea-urchin spines, foreign-body reactions and, 374
Sebaceoma, 873–874
  differential diagnosis of, 874
  histopathology of, 874, 874*f*
  rippled-pattern sebaceoma, 874
Sebaceous adenoma, 873
  differential diagnosis of, 873
  histopathology of, 97, 97*f,* 124, 873, 873*f*
  with Muir-Torre syndrome, 875
  sebaceoma v., 874
Sebaceous carcinoma, 875–876
  additional studies of, 876
  differential diagnosis of, 876
  histopathology of, 124, 874*f*–876*f,* 875–876
  with nevus sebaceus, 871–872
Sebaceous cells
  in sebaceoma, 874
  in sebaceous adenoma, 873, 873*f*
Sebaceous cysts. *See* Pilar cysts
Sebaceous duct, hair follicle and, 30
Sebaceous epithelioma. *See also* Sebaceoma
  histopathology of, 97, 97*f,* 124
  sebaceous adenoma v., 873
Sebaceous glands
  acne vulgaris and, 459–461
  in dermoid cyst, 804
  formation of, 25, 30
  function of, 30
  inflammatory processes of, 85
  necrosis in coma, 317
  nevus comedonicus in, 793
  of nose, 56, 57*f*
  regional variation of, 31
  rosacea and, 464
  sensory nerves to, 53
  in steatocystoma multiplex, 804
  in trichofolliculoma, 854
  tumors of, 97, 97*f,* 124
  vitamin A deficiency and, 407–408
Sebaceous hyperplasia, 872
  additional studies of, 872
  differential diagnosis of, 872
  histopathology of, 124, 872, 872*f*
  sebaceous adenoma v., 873
Sebaceous trichofolliculoma, 855
  differential diagnosis of, 855
  histopathology of, 124, 855
Sebaceus epithelioma, with nevus sebaceus, 871
Sebaceus glands, tumors with differentiation toward, 870–876
  Fordyce's spots and Montgomery's tubercles, 872–873, 873*f*
  Muir-Torre syndrome, 875
  nevus sebaceus, 870–872, 871*f*
  sebaceoma, 873–874, 874*f*
  sebaceous adenoma, 873, 873*f*
  sebaceous carcinoma, 875–876, 875*f*–876*f*
  sebaceous hyperplasia, 872, 872*f*
Sebocytes, in sebaceous hyperplasia, 872
Seborrheic dermatitis, 243
  androgenetic alopecia and, 481
  clear cell acanthoma v., 799
  disseminated epidermolytic acanthoma v., 793
  eczema herpeticum with, 638
  histopathology of, 89, 89*f,* 108–109, 113, 243, 243*f*
  in HIV, 243, 659–660
  Kaposi's varicelliform eruption with, 641
  keratosis lichenoides chronica with, 191
  Malassezia furfur in, 596
  microorganisms and, 60
  neutrophils and, 43
  pathogenesis of, 243, 243*f*
  perioral dermatitis v., 462
  psoriasis vulgaris v., 181
  Sézary syndrome v., 944
Seborrheic keratosis, 795–798, 795*f*
  acanthosis nigricans-like mycosis fungoides v., 942
  acanthotic type, 798
  adenoid or reticulated type, 797–798
  clonal type, 798
  cutaneous horn and, 811, 811*f*
  eccrine poroma v., 887
  histopathology of, 87–88, 87*f*–88*f,* 104, 106, 795–797, 795*f*–797*f*
  hyperkeratotic type, 798
  irritated type, 795, 796*f*–797*f*
  Leser-Trélat sign with, 799
  linear epidermal nevus v., 791–792, 792*f*
  melanoacanthoma, 798
  solar lentigines v., 707
  superficial spreading melanoma v., 743
  tumor of the follicular infundibulum v., 870
  verrucous trichoadenoma v., 863
  vulvar, 656
Sebum, acne vulgaris and, 459–461
Secondary B-cell lymphoproliferative disease, 922–935
  chronic lymphocytic leukemia/small lymphocytic lymphoma, 925–926, 926*f*
  diffuse large B-cell lymphoma, 930–932, 931*f*
  Hodgkin's lymphoma, 933–935, 934*f,* 934*t*
  intravascular large B-cell lymphoma, 932–933, 932*f*
  lymphomatoid granulomatosis, 933, 933*f*
  mantle cell lymphoma, 928–930, 929*f*
  nodal follicular lymphoma, 926–928, 927*f*
  precursor B-cell lymphoblastic lymphoma, 922–925, 924*f*
Secondary cutaneous oxalosis, Crohn's disease with, 415
Secondary lesion
  of endemic syphilis, 585
  of pinta, 585
  of yaws, 584
Secondary myeloid neoplasms, 957–960
  acute and chronic myeloid leukemia, 957–958, 958*f*–959*f,* 958*t*
  precursor plasmacytoid dendritic cell lineage, 959–960
Secondary ossification, 1089–1090
  histopathology of, 1089–1090, 1090*f*
Secondary syphilis, 579, 581–583, 581*f*–582*f*
  differential diagnosis of, 583
  histogenesis of, 583
  in HIV, 659
Secondary systemic amyloidosis, 427
  histopathology of, 427
  pathogenesis of, 427
Secondary T-/NK-cell lymphoproliferative disease, 951–956
  adult T-cell leukemia/lymphoma, 953–955, 954*f*
  anaplastic large cell lymphoma, 952–953, 953*f*
  angioimmunoblastic T-cell lymphoma, 952
  peripheral T-cell lymphoma, 951–952, 951*f*
  precursor T-lymphoblastic leukemia/lymphoblastic lymphoma, 955
  T-cell prolymphocytic leukemia, 955–956
Secondary yaws, 583
Second-degree burns, 274–275, 343, 345, 345*f*
Secretagogue, mast cells and, 41
Secretory portion, 33*f*
  of apocrine glands, 34–35, 35*f*
  of eccrine glands, 32–33, 33*f*
Segmental hyalinizing vasculitis, histopathology of, 111
Segmental lentigines, 708
Segmental morphea. *See* Morphea
Selective lymphadenectomy, for melanomas, 770–771
Selective serotonin reuptake inhibitors, erythema multiforme with, 312
Self-healing juvenile cutaneous mucinoses, 445
  histopathology of, 445
Senear-Usher syndrome. *See* Pemphigus erythematosus
Senescence, compound nevus and, 713
Senescent alopecia, 489
  histopathology of, 489
  pathogenesis of, 489
Senile lentigines. *See* Solar lentigo
Senile purpura, connective tissue deficiencies and, 231
Sensitivity, of diagnosis, 1
Sentinel lymph node dissection, 770–771
  melanocytic tumors of uncertain malignant potential and, 773
Septae, of subcutaneous fat, 55–56
Septal panniculitis
  mixed with lobular, 102, 102*f*
  relapsing polychondritis with, 494
  without vasculitis, 100, 100*f*
Septicemia. *See also* Acute septicemia; Chronic septicemia
  histopathology of, 111, 116
Serologic approach, to virus detection, 637–638
Serositis
  drug-induced lupus erythematosus with, 318
  systemic lupus erythematosus with, 288
Serotonin, Merkel cells and, 19
Serpiginous urticarial lesions, of strongyloidiasis, 628

Serratia marcescens, neutrophilic eccrine hidradenitis and, 491
Serum amyloid A (SAA), secondary systemic amyloidosis and, 427
Serum sickness, 220
Serum sickness-like syndrome, 661
Sestamibi, erythema multiforme with, 312
Severe dysplasia, dysplastic nevus and, 736
Sex hormones, acne vulgaris and, 459
Sexually transmitted diseases
  chancroid, 120, 569–570, 569*f*
  condyloma acuminatum, 654–656, 655*f*
  granuloma inguinale, 46, 110, 117–118, 120, 570, 570*f*
  HSV-2, 638
  lymphogranuloma venereum, 120, 514, 571
  molluscum contagiosum, 649, 649*f*
Sézary syndrome, 944–945
  adult T-cell leukemia/lymphoma v., 955
  clinical features of, 944
  differential diagnosis of, 944–945
  with follicular mucinosis, 468
  histogenesis of, 944
  histopathology of, 108, 110, 944, 945*f*
  Kaposi's varicelliform eruption with, 641
  T-cell prolymphocytic leukemia v., 955
Shadow cells, pilomatricoma and, 865–866, 865*f*
Shagreen patches, in tuberous sclerosis, 988–989
Shave biopsy
  application of, 5–6
  for direct immunofluorescence, 71
  for keratoacanthoma, 836
  of melanoma, 762
  for recurrent nevus, 732
  technique for, 6
Shigella, Reiter's disease and, 182
Shingles. *See* Herpes zoster infection
Shock, with acute meningococcemia, 546–547
Shoulder parakeratosis, seborrheic dermatitis and, 243
Sialidase, for mucin-producing squamous cell carcinoma, 821
Sialomucin
  from dark cells, 32
  in mucinous eccrine carcinoma, 898
  in mucous cyst of the oral mucosa, 998
  PAS and, 68, 69*t*
Siderophages, in aneurysmal fibrous histiocytoma, 970
Siderosis, hemochromatosis and, 450
Sign of Leser-Trélat, acanthosis nigricans and, 448
Signet cell melanoma, 749, 757
Signet ring cell
  of breast carcinoma, 1153
  carcinoma of, 1153–1154
Sildenafil, lichenoid drug eruption and, 313
Silica granuloma, 70, 374, 376, 376*f*
  Crohn's disease v., 416
  histopathology of, 376, 376*f*
  pathogenesis of, 376
Silicone
  panniculitis with, 525
  reactions to, 379
  scleroderma and, 296
Silicone granuloma, 374–375, 375*f*
  histopathology of, 117, 121
Silicone mammoplasty, middermal elastolysis and, 399
Silk, foreign-body reactions and, 373, 373*f*
Silver staining, of syphilis, 580, 581*f,* 582
Simple ephelis, histopathology of, 104
Simulium, as onchocerciasis vector, 629
Simvastatin
  eosinophilic fasciitis and, 303
  radiation recall dermatitis and, 352
Sinus histiocytosis
  histopathology of, 124
  with massive lymphadenopathy. *See* Rosai-Dorfman disease
Sinusoidal hemangioma, 1019–1020
  histopathology of, 126, 1019–1020, 1019*f*–1020*f*
Sjögren-Larsson syndrome, 136, 221
  Behçet's syndrome v., 414
  drug toxicities of, 311
  macular atrophy and, 400
  subacute cutaneous lupus erythematosus with, 283
Sjögren's syndrome
  lymphocytoma cutis v., 588
  with relapsing polychondritis, 493
SJS. *See* Stevens-Johnson syndrome
Skeletal deformities
  mucopolysaccharidosis and, 447
  with nevus sebaceus, 871
Skeletal muscle, eosinophilic fasciitis and, 303
Skin
  absence of, 143
  adenocarcinoma of, 1151
  age- and environmental-related variations, 56, 56*f*
  aged, histopathology of, 108
  angiofibroblastoma of, 991
  basement membrane zone of, 21–24, 22*f*–23*f*
  cold injury to, 352–355
  dermal fibroblasts of, 38–46, 39*f*–43*f,* 45*f*
    dermal muscle cells, 46
    emigrant inflammatory cells, 42–46, 42*f*–43*f,* 45*f*
    mast cells, 41–42, 41*f*
    perivascular and interstitial dendritic cells, 39–40, 39*f*
    phagocytic macrophages, 40–41, 40*f*
  dermal microvascular unit, 50–55
    dermal lymphatics, 51*f,* 53
    endothelial cells, 50–52, 51*f*
    glomus cells, 52–53, 53*f*
    neural network, 53–55, 54*f*
  dermis of, 38–55
    dermal fibroblasts, 38–46, 39*f*–43*f,* 45*f*
    dermal microvascular unit, 50–55
    extracellular matrix, 46–50, 47*f*–48*f*
  eccrine and apocrine glands of, 31–36
    embryology of, 32
    normal microanatomy of, 32–35, 33*f*–35*f*
    regional variation, 35, 35*f*
    special stains, 34*f*–35*f,* 36
    specialized structure and function, 35–36
  epidermis of, 7–38
    basement membrane zone, 21–24, 22*f*–23*f*
    eccrine and apocrine glands, 31–36
    hair follicles, 24–31, 24*f*–29*f*
    keratinocytes, 7–14, 8*f*–11*f,* 13*f*
    Langerhans cells, 19–21, 20*f*
    melanocytes, 14–18, 14*f*–15*f,* 16*t*
    Merkel cells, 18–19, 19*f*
    nails, 36–38, 36*f*–37*f*
  extracellular matrix of, 46–50, 47*f*–48*f*
    collagen fibers, 46–49, 47*f*–48*f*
    elastic fibers, 49
    ground substance, 49–50
  extramedullary hematopoiesis in, 956–957
  hair follicles of, 24–31, 24*f*–29*f*
    embryology, 24–25, 24*f*–25*f*
    normal microanatomy, 25–30, 25*f*–29*f*
    regional variation, 30–31
    sebaceous glands, 28*f,* 30
    specialized structure and function, 31
  histology of, 7, 8*f*–9*f*
  incidental findings in, 58–60
    focal acantholytic dyskeratosis, 59–60, 59*f*
    focal epidermolytic hyperkeratosis, 58–59, 59*f*
  keratinocytes of, 7–14
    embryology, 7–8, 8*f*
    normal microanatomy of, 8–12, 9*f*–11*f*
    specialized structure and function, 11*f,* 12–14, 13*f*
  Langerhans cells of, 19–21, 20*f*
    embryology, 19–20, 20*f*
    normal microanatomy, 20–21, 20*f*
    regional variation, 21
    specialized structure and function, 21
  major functions of, 911
  melanocytes of, 14–18
    embryology, 14
    normal microanatomy, 14–16, 14*f*–15*f*
    regional and racial variation, 17
    specialized structure and function, 17–18
    in sun-exposed areas, 15*f,* 17
    ultrastructure, 15*f,* 17
  Merkel cells of, 18–19, 19*f*
    embryology of, 18
    normal microanatomy of, 18–19, 19*f*
    regional variation of, 19
    specialized structure and function of, 19
  metabolic diseases of, 425–452
    acanthosis nigricans, 447–448, 448*f*–449*f*
    amyloidosis, 425–429
    calcinosis cutis, 435–438
    colloid milium and nodular colloid degeneration, 429–430, 430*f*
    gout, 438–439, 438*f*–439*f*
    lipoid proteinosis, 430–431, 431*f*
    mucinoses, 441–447
    mucopolysaccharidosis, 447
    ochronosis, 439–441, 440*f*
  metastatic carcinoma of, 1151–1159
    of the breast, 1152–1154, 1153*f*–1154*f*
    carcinoid and neuroendocrine carcinomas, 1157–1158
    gastrointestinal, 1155–1156

Viral infections, 637–662
  Bowenoid papulosis of genitalia, 656–657, 657*f*
  cytomegalovirus, 644–646, 645*f*–646*f*
    Epstein-Barr virus, 644–645, 646*f*
    human herpesvirus-6, -7, -8, 645–646
  erythema nodosum with, 514
  hepatitis B, 660–661, 661*f*
  hepatitis C, 661
  Herpesviridae, 637–646, 638*f*–640*f,* 642*f*–643*f,* 645*f*–646*f*
    herpes simplex, 638–639, 638*f*
    herpes zoster infection, 640*f,* 642–644, 643*f*
    Kaposi's varicelliform eruption, 638, 638*f,* 641–642
    varicella, 640*f,* 642–643, 642*f*
measles, 662
oral focal epithelial hyperplasia, 657, 657*f*
Papillomaviridae, 649–656, 651*f*–655*f*
  condyloma acuminatum, 654–656, 655*f*
  deep palmoplantar warts, 652–653, 652*f*
  epidermodysplasia verruciformis, 653–654, 654*f*
  giant condyloma acuminata of Buschke and Loewenstein, 655*f,* 656
  verruca plana, 653, 653*f*
  verruca vulgaris, 650–652, 651*f*
parvovirus B19, 661–662, 662*f*
Picornaviridae, 637, 658–659, 658*f*
  hand-foot-and-mouth disease, 658, 658*f*
  hepatitis A virus, 659
Poxviridae, 637, 646–649, 648*f*–649*f*
  human cowpox infection, 647
  molluscum contagiosum, 649, 649*f*
  parapoxvirus infections, 647–648, 648*f*
  vaccinia virus, 647
  variola, 647
  Retroviridae, 659–660
    acquired immunodeficiency syndrome, 659–660
  rubella, 662
  verrucous carcinoma and, 822
Virchow cells, 561
Virologic approach, to virus detection, 637–638
Virulence, in histopathological diagnosis, 3
Visceral carcinoma, with arsenic, 816–817
Visceral leishmaniasis, 621, 622*t,* 624–625
  histopathology of, 625
Viscerotropic leishmaniasis, 621, 622*t,* 625
Visible light
  chronic actinic dermatitis and, 340
  photoallergic dermatitis and, 241
  solar urticaria and, 340
Visible tract
  of hookworm-related cutaneous larva migrans, 627*f,* 628
  of strongyloidiasis, 628
Vitamin A deficiency, 407–408, 450–451
  differential diagnosis of, 408, 451
  histopathology of, 103, 127, 407–408, 450–451
  scurvy v., 407
Vitamin C deficiency. *See* Scurvy
Vitiligo, 694, 695*f*
  alopecia areata and, 475
  histogenesis of, 694, 695*f*
  histopathology of, 87, 87*f,* 104, 694
  primary biliary cirrhosis with, 417
Vogt-Koyanagi-Harada syndrome, 694
Vomiting, Behçet's syndrome and, 413
von Kossa method
  for calcium deposits, 436
  for pseudoxanthoma elasticum, 154
von Willebrand factor
  angiosarcoma, 1042
  composite hemangioendothelioma and, 1037
  epithelioid angiosarcoma, 1043
  epithelioid hemangioendothelioma, 1040
  microvenular hemangioma, 1021
Voriconazole, drug-induced pseudoporphyria with, 320
Vulva
  angiomyofibroblastoma of, 990–991
  cicatricial pemphigoid and, 259
  extramammary Paget's disease of, 839
  lichen sclerosus et atrophicus and, 303–304
  mucosal lentigines of, 705
  sebaceous hyperplasia in, 872
Vulvar intraepithelial neoplasia (VIN), 816
  Bowenoid papulosis of genitalia v., 656–657
  histopathology of, 816
Vulvar leiomyosarcoma, 1080
Vulvar lentigo, 705
Vulvar nevi, 717
Vulvar seborrheic keratoses, 656
Vulvitis circumscripta plasma-cellularis, 815–816
VX. *See* Verruciform xanthoma
VZV infection, 642–644, 642*f*–643*f*

Waardenburg syndrome IIa, 14, 693–694
Wade-Fire stain, of *Mycobacterium leprae,* 561, 561*f*–562*f*
Waldenström's macroglobulinemia, paraneoplastic autoimmune multiorgan syndrome and, 254
Waldeyer ring, nodal follicular lymphoma of, 927
Warble, 633
Warthin-Starry stain, of syphilis, 580–582
Warts, 649–656, 651*f*–655*f*
  Bowenoid papulosis of genitalia, 656–657, 657*f*
  condyloma acuminatum, 654–656, 655*f*
  deep palmoplantar warts, 652–653, 652*f*
  epidermodysplasia verruciformis, 653–654, 654*f*

giant condyloma acuminata of Buschke and Loewenstein, 655*f,* 656
granuloma annulare and, 362
verruca plana, 653, 653*f*
verruca vulgaris, 650–652, 651*f*
verrucous melanoma v., 756
Warty dyskeratoma, 806–807
histopathology of, 113, 806–807, 806*f*–807*f*
pathogenesis of, 807
Wasps, reactions to stings of, 634–635, 634*f*
Waterhouse-Friderichsen syndrome, 547
Weakness
polyarteritis nodosa and, 209
with self-healing juvenile cutaneous mucinoses, 445
Weber-Christian disease, 523–524
clinical presentation of, 523, 523*f*
differential diagnosis of, 524
histopathology of, 101, 101*f,* 130–131, 523–524, 523*f*
lupus erythematosus panniculitis v., 522
pancreatic disease v., 529
pathogenesis of, 524
Wegener's granulomatosis (WG), 214–215
Behçet's syndrome v., 414
c-ANCA for, 207, 207*t*
Churg-Strauss syndrome v., 214
Crohn's disease v., 416
differential diagnosis of, 215
granulomatous vasculitis and, 213
histopathology of, 111, 116, 130, 215
microscopic polyarteritis v., 212
palisaded neutrophilic and granulomatosis v., 370
parvovirus B19 in, 662
ulcerative colitis with, 416
Wegener's syndrome, 214
Wegener's vasculitis, 214
Weibel-Palade body, of dermal microvasculature, 50–51
Weigert's resorcin-fuchsin, for elastic tissues, 69, 69*t*
Weight loss
with angioimmunoblastic T-cell lymphoma, 952
polyarteritis nodosa and, 209
Well-differentiated liposarcoma, 1072
histopathology of, 1072, 1073*f*
Well's syndrome. *See also* Eosinophilic cellulitis
eosinophilic panniculitis and, 515
eosinophilic pustular folliculitis v., 467
histopathology of, 107, 117
Werner's syndrome, 145
scleroderma and, 295–296
WG. *See* Wegener's granulomatosis
White fibrous papulosis of the neck, papillary dermal elastolysis v., 399
White macules, with idiopathic guttate hypomelanosis, 691
White plaques, of acute mucocutaneous candidiasis, 597
White sponge nevus, oral focal epithelial hyperplasia v., 657
Wickham's striae, lichen planus and, 185, 185*f*
Winchester syndrome, 155
Wind exposure, cheilitis glandularis and, 381
Wiskott-Aldrich syndrome, 245
Wood, foreign-body reactions and, 374, 374*f*
Woringer-Kolopp disease. *See* Solitary pagetoid reticulosis
World Health Organization Melanoma Program, 763
Worms. *See also* Nematodes
of onchocerciasis, 630–631, 630*f*
subcutaneous cysticercosis, 632, 632*f*
subcutaneous dirofilariasis, 621, 628–629, 629*f*
Wound myiasis, 632–633
Wuchereria bancrofti, 630

Xanthelasma, 672, 675, 680–682, 683*f*
histopathology of, 117, 124
Xanthoerythrodermia perstans of Crocker. *See* Small-plaque parapsoriasis
Xanthogranuloma family, 671–678, 672*f*–677*f,* 672*t*
benign cephalic histiocytosis, 677–678, 677*f*
factor XIIIa and, 78
generalized eruptive histiocytosis, 678
juvenile xanthogranuloma, 672–673, 673*f*
papular xanthoma, 673–674, 674*f*
progressive nodular histiocytosis, 676*f,* 677
reticulohistiocytosis, 675–676, 676*f*
scalloped cell xanthogranuloma, 674, 674*f*
spindle cell xanthogranuloma, 676, 676*f*
xanthoma disseminatum, 674*f*–675*f,* 675
Xanthoma
balloon cell melanoma v., 756
granuloma annulare v., 363
histopathology of, 97, 97*f,* 117, 124
with LCD, 669
leprosy v., 567
in lipid abnormalities, 680–683, 680*t,* 681*f*–683*f*
histopathology of, 681–682, 681*f*–683*f*
pathogenesis of, 682–683
miscellaneous, 686
normolipemic, 683–686, 684*f*–685*f*
polariscopic examination for, 70
Xanthoma disseminatum, 674*f*–675*f,* 675
histopathology of, 124, 675, 675*f*
Xanthomatous reactions, in LCD, 669–671
Xeroderma pigmentosum, 141
Xerophthalmia, vitamin A deficiency and, 407
Xerosis
in HIV, 660
radiation dermatitis and, 348
X-linked ichthyosis
histogenesis of, 133
histopathology of, 103, 133

Yangtze fever, 631
Yaws, 583–584, 584*f*
differential diagnosis of, 584
histopathology of, 584, 584*f*
primary, 583
histopathology of, 110, 117
secondary, 583
histopathology of, 110, 117
tertiary, 584
histopathology of, 119
Yeasts, 591, 592*t*
candidiasis, 597–599, 597*f,* 598*t*
cryptococcosis, 600*t,* 609–611, 610*f*
histoplasmosis, 600*t,* 611–612, 612*f*
Malassezia furfur, 596–597, 596*f,* 598*t*
Yellow cadmium sulfide, tattoo reactions and, 377
Yellow-mutant OCA, 693
Yersinia enterocolitica, erythema nodosum with, 514
Yersinia, Reiter's disease and, 182

Zebra-like hyperpigmentation, 690
Ziehl-Neelsen stain, of *Mycobacterium leprae,* 559
Zinc deficiency. *See* Acrodermatitis enteropathica
Zinc granuloma, 377
histopathology of, 377
Zinc-beryllium silicate, berylliosis and, 377
Zirconium granuloma, 374, 376
Crohn's disease v., 416
histopathology of, 376
pathogenesis of, 376
Zirconium lactate, zirconium granuloma and, 376
Zirconium oxide, zirconium granuloma and, 376
Zoon's plasma cell balanitis circumscripta, histopathology of, 107, 111
Zoster sine herpes, 643
Zoster-related granulomas, 381
histopathology of, 381
Zygomycosis, 599–601, 600*t,* 602*f*
histopathology of, 119, 601, 602*f*
