Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

This Edition is dedicated to our teachers and mentors in medicine and surgery, pathology, and dermatopathology—too numerous to name individually—whose commitment to the discovery and dissemination of knowledge and patient tutoring at the bedside, bench, and microscope enabled this work to be accomplished.

CONTENTS

Preface to the Tenth Edition *ix*
Preface to the First Edition *xi*
Contributors *xv*

1 Introduction to Dermatopathologic Diagnosis 1
David E. Elder, George F. Murphy, Rosalie Elenitsas, Bernett L. Johnson, Jr., and Xiaowei Xu

2 Biopsy Techniques 5
Rosalie Elenitsas and Michael E. Ming

3 Histology of the Skin 7
Elsa F. Velazquez and George F. Murphy

4 Laboratory Methods 67
Rosalie Elenitsas, Carlos H. Nousari, Elias Ayli, and John T. Seykora

5 Outline of Cutaneous Pathology 83
David E. Elder, Rosalie Elenitsas, Bernett L. Johnson, Jr., George F. Murphy, and Xiaowei Xu

6 Congenital Diseases (Genodermatoses) 133
Bernett L. Johnson, Jr. and Albert C. Yan

7 Noninfectious Erythematous, Papular, and Squamous Diseases 169
Narciss Mobini, Sonia Toussaint, and Hideko Kamino

8 Vascular Diseases 205
Raymond L. Barnhill, Carlos H. Nousari, Xiaowei Xu, and Sarah K. Barksdale

9 Noninfectious Vesiculobullous and Vesiculopustular Diseases 235
Hong Wu, Heather A. Brandling-Bennett, and Terence J. Harrist

10 Connective Tissue Diseases 279
Harry Winfield and Christine Jaworsky

11 Cutaneous Toxicities of Drugs 311
Kim M. Hiatt and Thomas D. Horn

12 The Photosensitivity Disorders 333
Eduardo Calonje and John L.M. Hawk

13 Disorders Associated with Physical Agents: Heat, Cold, Radiation, and Trauma 343
Jacqueline M. Junkins-Hopkins

14 Noninfectious Granulomas 361
Christine J. Ko, Earl J. Glusac, and Philip E. Shapiro

15 Degenerative Diseases and Perforating Disorders 389
Michael K. Miller, Narayan S. Naik, Carlos H. Nousari, Robert J. Friedman, and Edward R. Heilman

16 Cutaneous Manifestations of Nutritional Deficiency States and Gastrointestinal Disease 407
Cynthia Magro, A. Neil Crowson, Molly Dyrsen, and Martin Mihm, Jr.

17 Metabolic Diseases of the Skin 425
John C. Maize, John C. Maize, Jr., and John Metcalf

18 Inflammatory Diseases of Hair Follicles, Sweat Glands, and Cartilage 459
Michael D. Ioffreda

19 Inflammatory Diseases of the Nail 503
Thomas D. Griffin

20 Inflammatory Diseases of the Subcutaneous Fat 509
N. Scott McNutt, Abelardo Moreno, and Felix Contreras

21 Bacterial Diseases 539
Sebastian Lucas

22 Treponemal Diseases 579
A. Neil Crowson, Cynthia Magro, and Martin Mihm, Jr.

23 Fungal Diseases 591
Molly Hinshaw and B. Jack Longley

24 Protozoan Diseases and Parasitic Infestations 621
Klaus Sellheyer and Eckart Haneke

25 Diseases Caused by Viruses 637
Xiaowei Xu, Lori Erickson, Lianjun Chen, and David E. Elder

26 The Histiocytoses 667
Walter H.C. Burgdorf and Bernhard Zelger

27 Pigmentary Disorders of the Skin 689
Carrie L. Kovarik, Richard L. Spielvogel, and Gary R. Kantor

28 Benign Pigmented Lesions and Malignant Melanoma 699
David E. Elder, Rosalie Elenitsas, George F. Murphy, and Xiaowei Xu

29 Tumors and Cysts of the Epidermis 791
Nigel Kirkham

30 Tumors of the Epidermal Appendages 851
Tamer S.S. Ahmed, Joseph Del Priore, and John T. Seykora

31 Cutaneous Lymphomas and Leukemias 911
Mei-Yu Hsu and George F. Murphy

32 Tumors of Fibrous Tissue Involving the Skin 969
Trevor W. Beer, Minh H. Lam, and Peter J. Heenan

33 Vascular Tumors: Tumors and Tumor-like Conditions of Blood Vessels and Lymphatics 1007
Eduardo Calonje

34 Tumors With Fatty, Muscular, Osseous, and/or Cartilaginous Differentiation 1057
Bruce D. Ragsdale

35 Tumors of Neural Tissue 1107
Richard J. Reed and Donald R. Pulitzer

36 Metastatic Carcinoma of the Skin 1151

PREFACE
TO THE TENTH EDITION

This book represents an incremental revision and update of the previous two editions, the first of which constituted a somewhat more extensive revision of the seven editions produced by Walter Lever, MD, beginning in 1949 as a 449-page volume with "221 Illustrations Including 8 Subjects in Color on 4 Plates." Thus, this will be the tenth edition of a book that has been continuously published for 60 years! In this second generation of the work, the principles that made "Lever" such a success for so long continue to be applied. These include, first and foremost, a continued organization of the book along the lines of a traditional clinicopathologic classification of cutaneous disease. This enables us to discuss lesions according to their clinical and etiological relationships, paralleling the organization of the major clinical texts. In some other dermatopathology works, a greater emphasis has been placed on histological patterns of disease as the underpinning of the chapter organization. This has advantages in enabling beginners to develop an appropriate differential diagnosis for a given pattern of disease, but can be confusing in that etiologically and clinically disparate conditions tend to be discussed in juxtaposition to each other, and also in that polymorphous conditions need to be discussed in multiple different places.

We have taken into account the modern emphasis on pattern recognition in several ways. First, within each chapter, the conditions considered are, when appropriate, organized and discussed along pattern lines. Second, we have, as in the past, included a chapter that presents an algorithmic classification of skin diseases according to histologic pattern features. It is intended that this chapter may serve as a means of developing a differential diagnosis from an unknown slide, following which references are provided for discussion of the disorders in other areas of the book. In addition, we have prepared a companion volume "Atlas and Synopsis of Lever's Histopathology of the Skin," now in its second edition. This Atlas has enabled us to greatly extend the number of illustrations including a larger number of clinical images, and is organized completely on the basis of histologic patterns. Unlike some other pattern-based works, this Atlas includes neoplastic disorders among the inflammatory conditions. Thus, it becomes clear to the reader that a lichenoid actinic keratosis or *in situ* melanoma may share features with (and potentially be misdiagnosed as) a plaque of lichen planus or a patch of lupus. This Atlas, which was produced as a companion to the last edition of the "Big Lever," will be continue to be updated and extended to incorporate the new information in successive editions of "Lever."

In another area of emphasis, we have continued the practice of providing clinical review prior to exposition of the histologic features for each group of disorders. This, in our opinion, greatly enhances the value of the work, not only for pathologists and others whose primary training is not in clinical dermatology, but also for dermatologists in training and, no doubt, for some who are more advanced in the field as well. In this present edition, we have included clinical images to enhance this distinctive aspect of the text, recognizing that the clinical morphology is the "gross pathology" of dermatopathology. Indeed, in today's environment of ubiquitous digital cameras and internet connections, we would take this opportunity to encourage clinicians to submit with their biopsies not only detailed clinical differentials, but also clinical images of selected cases, for the benefit of more accurate diagnosis and improved patient care.

At the other end of the spectrum of clinical science, we have continued and updated the classic work's emphasis on "histogenesis" by emphasizing underlying mechanisms of disease. To us, the term *histogenesis* includes mechanisms of development of histological patterns of disease and might equally well be (and sometime is) labeled "pathogenesis." In this edition, more than in any other because of the explosion of knowledge, molecular mechanisms of pathogenesis are presented for perhaps almost a majority of the diseases. However, it is interesting that, in most cases, these molecular mechanisms, while of explanatory interest, have not yet supplanted traditional histopathology and immunohistology as the "gold standard" for diagnosis of most of the conditions discussed in the book.

As in the past, the book does not attempt to be a compendium of all known skin diseases. However, we have tried to make it a reference work for those skin diseases in which histopathology plays an important role in diagnosis. Particular attention has been paid to the index in this edition, which we believe will further enhance the scholarly value of the work. We are grateful for this opportunity and are excited to present another edition of this revered work to a new generation of readers. At the same time, we hope that members of earlier generations who have used "Lever" as their primary skin pathology training and reference source will continue to find this new edition useful in their continuing development and in their daily practices.

David E. Elder
2008

PREFACE
TO THE FIRST EDITION

This book is based on the courses of dermatopathology that I have been giving in recent years to graduate students of dermatology enrolled at Harvard Medical School and Massachusetts General Hospital. The book is written primarily for dermatologists; I hope, however, that it may be useful also to pathologists, since dermatopathology is given little consideration in most textbooks of pathology.

I have attempted to keep this book short. Emphasis has been placed on the essential histologic features. Minor details and rare aberrations from the typical histologic picture have been omitted. I have allotted more space to the cutaneous diseases in which histologic examination is of diagnostic value than to those in which the histologic picture is not characteristic. In spite of my striving for brevity I have discussed the histogenesis of several dermatoses, because knowledge of the histogenesis often is of great value for the understanding of the pathologic process.

Primarily for the benefit of pathologists who usually are not too familiar with dermatologic diseases, I have preceded the histologic discussion of each disease with a short description of the clinical features.

A fairly extensive bibliography has been supplied for readers who are interested in obtaining additional information. In the selection of articles for the bibliography preference has been given, whenever possible, to those written in English.

I wish to express my deep gratitude to Dr. Tracy B. Mallory and Dr. Benjamin Castleman of the Pathology Laboratory at the Massachusetts General Hospital for the training in pathology they have given me. It has been invaluable to me. Their teaching is reflected in this book. Furthermore, I wish to thank Mr. Richard W. St. Clair, who with great skill and patience produced all the photomicrographs in this book.

Walter F. Lever
1949

ACKNOWLEDGMENTS

The Editors acknowledge the many contributions of others to this work in its previous editions, especially those of Walter F. Lever MD and Gundula Schaumberg-Lever MD.

Introduction to Dermatopathologic Diagnosis

Readers of this book in its nine previous editions have relied on it to aid them in making accurate histologic diagnoses of cutaneous disease. A diagnosis is a clinical tool that assists in the process of codifying patients into disease groups that tend to share a common outcome and a common set of responses to therapy. The histologic diagnosis in turn is used by clinicians to aid in the management of patients. The most accurate diagnosis is the one that most closely correlates with clinical outcome and helps to direct the most appropriate clinical intervention. Thus, there is a close relationship between diagnosis and prognostication. By emphasizing certain key observations that have value in identifying particular diseases, this book aids observers to make appropriate histologic diagnoses, and to provide an estimate of prognosis, in most skin biopsies. Where applicable, ultrastructural, immunohistochemical, and molecular aids to diagnosis are discussed. These advances have resulted in increased specificity for many diagnoses. For example, immunofluorescence has long been used to differentiate among vesiculobullous disorders (see Chapter 9). In another example, an amelanotic dermal tumor composed of large, mitotically active cells that are positive in an immunohistochemical reaction for the HMB-45 or Melan-A antigens is almost certainly a malignant melanoma. In the absence of the immunologic criteria, these specific diagnoses could not have been made as reliably (see Chapter 28). In the next several years, it can be expected that molecular criteria will increasingly be used for diagnosis and prognosis. For example, a fusion transcript for EWS-ATF1 detected by reverse-transcriptase polymerase chain reaction (PCR) or potentially by fluorescence *in situ* hybridization (FISH) might be used to distinguish between a primary clear cell sarcoma and a malignant melanoma involving the soft tissue, a distinction that is not always possible to make with certainty by traditional means (1). Despite the incremental advances of molecular techniques in diagnosis and prognosis, it may seem surprising that morphology is still the basis of diagnosis for most neoplasms and many inflammatory dermatoses. Nonetheless, a histologic image represents a true synthesis of all of the molecular events acting in a given microscopic "scene," encompassing not only the concerted expression of genes, including oncogenes and tumor suppressor genes, but also the sum total of all epigenetic effects such as gene methylation, posttranslational modification, and the spatially and temporally segregated interactions of proteins and other gene products. This level of complexity of information cannot be captured by any high-throughput molecular testing that has yet been conceived.

Although histopathology remains the gold standard for most dermatologic diagnoses, it must be recognized that not all lesions are amenable to definitive "specific" histologic diagnosis. As reviewed by Foucar (2–4), specificity, or the "true negativity rate," is the frequency of a negative test result in individuals who actually do not have the disease of interest. Specificity studies are hard to do because they require large-scale studies of normal populations and because of the need for a gold standard for the disease independent of the test under consideration. Most studies in the literature begin with data demonstrating the "sensitivity" or "true positive rate," which is a measure of the frequency of a positive test result in individuals with the disease (2). These data do not, however, indicate that a diagnostic test is perfectly reliable. For example, most melanomas are positive for the immunohistochemical marker S100 (high sensitivity). However, almost all benign melanocytic neoplasms are also positive for the same marker (low specificity). Frequent mitoses in the dermal component of the neoplasm, on the other hand, are common in bulky tumorigenic melanomas but rare in most benign melanocytic neoplasms and are therefore a useful, relatively specific but not pathognomonic marker for melanoma. On the other hand, mitotic figures are absent in most thin nontumorigenic melanomas, so that their sensitivity for the diagnosis of "melanoma," overall, is low (see Chapter 28).

The histologic features of many inflammatory dermatoses in particular are nonspecific or, at best, only suggestive of a specific diagnosis. Even among the more readily characterized papulosquamous dermatoses, such as psoriasis or lichen planus (see Chapter 7), the histologic picture is more typically "compatible with" rather than "diagnostic of" the clinical process. Sometimes, however, the histopathology can contribute by ruling out an important diagnosis, even though an exact diagnosis cannot be made. For example, review of a biopsy of a psoriasiform plaque may rule out mycosis fungoides (see Chapter 31) but may not be able to establish the specific diagnosis of psoriasis (see Chapter 7). The obvious diagnostic limitations of histology extend to infectious and neoplastic processes as well. For example, infectious granulomas of different etiologies are not readily

distinguishable unless the causative organism can be demonstrated. This may not be possible without additional testing such as bacterial or fungal cultures (see Chapters 21 to 23). The same applies to noninfectious inflammatory disorders such as pyoderma gangrenosum in which infection needs to be ruled out as an etiologic possibility (see Chapter 16). Similarly, in the neoplastic realm, histology may not suffice to distinguish between keratoacanthoma and squamous cell carcinoma (5) (see Chapter 29), or between Spitz nevus and melanoma (6) (see Chapter 28).

Some of these "difficult" diagnoses result from the existence of important data that are undetectable by routine histologic methods, such as sparse organisms in a granulomatous process. In other instances, the data might be detectable if sought, but are obscure. For example, many granulomatous processes can be more specifically characterized if more sensitive staining for organisms is done, as in a Grocott or acid-fast stain. If the observer does not think of infection and order the stain, the diagnosis is never made. In many other situations, however, such as the diagnosis of keratoacanthoma versus squamous cell carcinoma or of Spitz nevus versus melanoma, the data may have been assiduously collected by the observer using complex algorithms published for these purposes, and yet the diagnosis may remain obscure and agreement among observers difficult or impossible to obtain. In such cases, there is typically a continuum of the traits that underlie diagnosis, and individual cases in the vicinity of the diagnostic cut-point are more likely to be misclassified than other cases (7).

In an interesting exercise published as a "Tutorial on Melanocytic Lesions" a panel of six experts in pigmented lesion pathology reviewed 71 "difficult" cases (8). Although agreement was substantial for many of the different categories of lesions, the categories of Spitz nevi and other variants of nevi and of nevoid melanoma were more difficult. Unanimity in diagnosis was reached in only 11 of 38 of these cases, and in 6 cases the opinions of the experts were equally divided between benign and malignant. In another category, that of six examples of "pseudomelanomas" in children, agreement on a benign diagnosis was almost unanimous, yet one of these patients had died of metastatic disease. In another study of 30 lesions selected for their difficulty, evaluation of 17 "Spitzean" lesions yielded no clear consensus as to diagnosis: "In only one case did six or more pathologists agree on a single category, regardless of clinical outcome" (9). In addition, some lesions that proved fatal were categorized by most observers as either Spitz nevi or atypical Spitz tumors (9). Thus, agreement on a diagnosis does not necessarily mean that the diagnosis is correct. Therefore, the best opinion that can be rendered about these lesions is that the true diagnosis is unknown, and the likely behavior of these lesions is uncertain.

Following practice in other areas of pathology in which similar problems exist (10–20), such lesions in our opinion are best categorized as "tumors of uncertain malignant potential." In these cases, we always provide a differential diagnosis, and therapy is usually tailored with the "worst-case scenario" taken into consideration. Even this latter assumption is not without potential for controversy, however; it is not at all clear, for example, that therapy devised for routine cases of melanoma should be uncritically applied to melanocytic tumors of uncertain potential (see Chapter 29). In these "borderline" or "difficult" lesions, the clinical usefulness of histology may be aided by effective communication between clinician and pathologist with appropriate attention to the clinical and epidemiologic context of the lesion under study, and also by ancillary testing such as comparative genomic hybridization or FISH for assessment of gene amplification profiles, which have been shown to differ between Spitz nevi and melanomas (21). Even when all of the clinical, histologic, and molecular information is at hand, however, a consensus diagnosis may be impossible, and there is no prospective assurance that any diagnosis is biologically "correct."

Elliott Foucar has elegantly discussed the difficulties inherent in making a histologic diagnosis (and these considerations apply to other forms of diagnosis as well), and the issues have also been well covered by Sackett and his colleagues (3,4,22,23). A major source of difficulty in making an exact diagnosis in pathology, as in clinical medicine, is that the information required to make the diagnosis is frequently incomplete at some level or at multiple levels. At the most fundamental level, there may simply be no standard for a particular diagnosis. For example, histopathology is often taken to be a gold standard for diagnosis of a particular disease. However, if the histopathologic parameters that are considered to define this disease have been determined in a clinically defined series of cases, their independence and specificity could be called into question. A histologic study of nummular dermatitis, however complete and accurate it may be, will not glean any information that reliably distinguishes between this diagnosis and that of another spongiotic dermatitis (see Chapter 7). Patches of early mycosis fungoides biopsied from patients with established plaque stage lesions may well represent examples of "early" mycosis fungoides, yet similar histologic changes in a patient with only a solitary lesion may or may not progress to established disease (see Chapter 31).

Another serious problem in histopathologic diagnosis results from the fact that specificity studies to determine the prevalence of criteria in diagnostically challenging cases are frequently not available. For example, early studies of the HMB-45 antibody determined that it had 100% specificity for melanoma cells in the dermis or deeper tissues (24). After the specificity studies were extended, however, it was recognized that this antigen is expressed not only in melanoma, but also in blue nevi (25) and in other benign lesions (see Chapter 28).

Foucar has pointed out that the diagnostic process is an example of complex decision making that has intrinsic uncertainty, usually resulting from one or more of the following: (a) The large number of variables that can be evaluated in an attempt to solve the problem results in novel combinations of variables that cannot be managed consistently by problem solvers; (b) one or more key variables lack clear definition; or (c) one or more key variables is hidden from the problem solver (22). To the uncertainty inherent in these complex problems can be added (d) the uncertainty (discussed previously) of the specificity of the individual findings and (e) the uncertainty that results from deficiencies in the observer's ability to evaluate and categorize histologic findings. Even the most expert

observers have inherent and often unrecognized deficiencies that result in less than perfect reproducibility of histopathologic observations and thus of diagnoses (26). Furthermore, there are limitations in the ability of even the most expert observers to communicate their diagnostic acumen to others (22).

The diagnostic difficulties that result from uncertainty are compounded when there is also failure to agree on the criteria for diagnosis. In a study of inter- and intraobserver reproducibility for the diagnosis of dysplastic nevi, intraobserver reproducibility was substantial, and interobserver concordance was fair, despite differences in criteria. It was concluded that, although experienced dermatopathologists in this study used different diagnostic criteria for histologic dysplasia, their usage was consistent (27). In another study in which observers agreed to abide by predetermined criteria and were provided reference photomicrographs illustrative of the criteria, agreement was substantial to excellent for the histopathologic diagnosis of 112 melanocytic tumors including typical and dysplastic nevi and melanomas. It was concluded that, with the use of predetermined criteria, melanocytic dysplasia can be reproducibly graded among diverse general dermatopathologists (28). It is also interesting to note that, even when reproducibility is less than what might be considered optimal, a diagnosis can still be meaningful if the association between the diagnostic observation and a biologically important result is sufficiently powerful. For example, in a recent case–control study of the association of histologic melanocytic dysplasia with melanoma risk, a statistically significant and biologically meaningful relative risk of 3.99 was observed despite κ values for agreement among observers that were in the "poor" range (29). In such a situation, there is an opportunity for observers to work together to develop a set of criteria that can achieve better agreement while retaining biological significance.

In another example, the criteria for diagnosis of vertical growth phase in thin melanomas have been rigorously evaluated in two large studies. In one of the studies, 94 slides of malignant melanoma were circulated to six pathologists in two university departments. For each slide, the growth phase of the lesion, the Breslow thickness, and the Clark level were determined by each observer. The aims of the study were "to evaluate agreement among nonspecialist pathologists in identifying the vertical growth phase in malignant melanoma and to compare agreement for the growth phase with agreement for Breslow thickness and the Clark level" (30). It was found that, although overall agreement for the growth phase was moderate, agreement among experienced observers was good (30). Although this was outside of the scope of the study, is it is likely that, with increased experience, the nonspecialist pathologists would attain the same level of agreement. In a similar study, 148 pathologists participated in two circulations of melanoma slides, and the results were compared with those of a national melanoma pathology panel that had developed and evaluated diagnostic criteria. After a first circulation of slides in which only fair agreement was achieved, a second circulation of slides was accompanied by diagnostic criteria and diagrams. In this second circulation, there was a higher level of agreement for overall diagnosis, using the categories benign, melanocytic intraepidermal neoplasia, and melanoma with vertical growth phase ($\kappa = 0.68$). In their conclusions, these authors emphasized the importance of standardized diagnostic criteria to ensure accurate reporting of incidence and correct management of patients (31).

As discussed by Foucar and illustrated in some of the foregoing examples, differences in criteria may result from the use of different assumptions for the development of criteria (22). At the simplest level of diagnosis, an individual pathologist might establish a set of criteria that establish a diagnosis "by definition." Such a definitional diagnosis reduces uncertainty for that individual to a minimum. At a somewhat more advanced level, criteria are used that are considered likely to be acceptable to other pathologists, constituting a "consensus gold standard." At this level of diagnosis, difficulties in communicating a clear definition of the criteria among pathologists introduce uncertainty due to lack of reproducibility, and this uncertainty increases with the number of variables under consideration and the resultant increasing subjectivity of the diagnostic exercise.

The most advanced measure of the level of diagnostic problem solving, according to Foucar, is represented by the attempt to assign a biologically correct label, one that precisely predicts a disease's course (22). Attempts fully to resolve this more difficult level of prediction are likely in many cases, if not most, to be frustrated by the uncertainties enumerated earlier, especially the existence of hidden variables— "host resistance," "virulence," "environmental effects," and so on—that are not evident to the observer of a histologic slide, however expert and diligent he or she may be. Efforts to improve on diagnostic efficacy at this level might, for example, pursue information at the ultrastructural or molecular level. However, the accurate and complete prediction of a particular disease outcome will always prove to be an elusive goal.

Prognostication—the prediction of disease outcome—is an important biological indicator of diagnostic efficacy. In some instances, many of them neoplasms, a histologic diagnosis is predictive of biological behavior, such as the capacity for distant metastasis. Then, follow-up studies of outcome can serve as an appropriate gold standard for validation of diagnostic utility. Indeed, a 100% statistical probability of survival for a given neoplasm could be regarded as equivalent to a diagnosis of benignancy, illustrating a strong relationship between diagnosis and prognosis. Even when such studies are available, however, the prediction of outcome is usually in terms of statistical probabilities, which are not absolute. In addition, the course of the disease is inevitably altered by the diagnostic process; for example, excision of a melanocytic lesion that is diagnosed as a melanoma *in situ* is effective in preventing "malignant" behavior such as persistence, continued growth, and progression to a lesion with capacity for metastasis. The information needed to predict outcome accurately in any given individual case is also frequently not available to the histologic observer. For example, the outcome of a viral infection may depend on the presence or absence of antibodies in the patient's serum, which cannot be determined from observation of histologic sections. Similarly, even the most advanced and seemingly lethal primary malignant

melanoma has a certain probability of survival, even after using the most sophisticated prognostic models (32).

Another advanced measure of the biological relevance of a diagnostic system is through the correlation of traditional diagnostic labels with molecular findings. In the molecular-based studies of Bastian and his colleagues (33–36), nevi have been distinguished from melanomas, a subset of atypical Spitz nevi has been distinguished from among the usual forms of this condition, the acral-lentiginous subset of melanoma has been distinguished from other types, and findings traditionally associated with melanoma classification have been found to relate to underlying genetic abnormalities, all through the use of comparative genomic hybridization or gene sequencing techniques to identify molecular lesions that appear to have specificity for these traditionally defined variants of melanocytic neoplasia (see Chapter 29). In a patient with a suspected infection, a PCR test for "foreign" DNA can be diagnostic of the presence of an infectious agent (see Chapters 20 to 25). These types of correlations can be expected to increase in the future, strengthening the relationship between our present empirically based classification schemas and the underlying biology.

It is likely that the best approximation to the goal of improving diagnostic specificity will be achieved by a detailed correlation of findings at the molecular, histologic, and gross anatomic levels with the physical findings and clinical history, interpreted in the context of the whole patient and his or her environment, with long-term follow-up serving as the gold standard. In the real world of clinical medicine, a histologic description and differential diagnosis for a difficult case is often more likely to be useful than a single "specific" diagnosis that may be correct in its own frame of reference but wrong or misleading in the total clinicopathologic context of a particular patient. The former is the traditional method of clinical practice, which should be aided but not supplanted by the tools of histopathology. The information in this book has been designed to assist in this clinical diagnostic process.

Biopsy Techniques

It has been said that more errors are made from failing to biopsy properly than from performing unnecessary biopsies (1). Biopsy is indicated in suspected malignant neoplasms and to clarify a diagnosis when a limited number of conditions are under consideration. Biopsies submitted without a differential diagnosis are likely to be less successful in supporting a more definitive diagnosis, although of course there are exceptions to this rule. The technique used to obtain a specimen for microscopic evaluation may have a significant impact on the ability of the dermatopathologist to arrive at the correct diagnosis. Commonly used skin biopsy techniques are punch biopsy, superficial and deep shave biopsy, deep incisional biopsy, complete excision, and curettage. The choice of technique depends on many factors, including the clinical differential diagnosis and a mental review of the pathology of each disorder; the anatomic site; the morphology of the lesion, particularly its size and shape; the overall physical health of the patient; and cosmetic concerns. Several reviews of biopsy techniques have been published (1–3).

Selection of the appropriate lesion to biopsy when evaluating an inflammatory disorder is crucial. In most instances, histologic examination of a fully developed lesion will give more information than examination of an early or involuting lesion. However, vesicobullous lesions, ulcers, and pustular lesions are exceptions. For their histologic examination, a very early lesion is optimal; otherwise, secondary changes such as regeneration, degeneration, scarring, or secondary infection may obscure essential features and make recognition of the primary pathologic process impossible. The ideal candidate lesion for biopsy has not been scratched or traumatized and is untouched by topical or systemic therapy, especially antiinflammatory agents. If there are lesions in different stages of evolution, multiple biopsy specimens may be helpful. When considering diagnoses such as connective tissue nevus, anetoderma, atrophoderma, and some pigmentation disorders, the dermatopathologist may wish to compare involved and uninvolved skin. In those cases, one can perform a scalpel biopsy incorporating a portion of the lesion and adjacent normal skin.

When performing scalp biopsies for alopecia, many laboratories prefer two specimens: one for transverse (horizontal) sectioning and one for standard "vertical" sections. The punch instrument should be inserted into the skin parallel to the direction of hair growth, and the biopsy should extend well into the subcutis to be certain that the bulbs of terminal follicles are included (4). In scarring alopecia, it is important that a biopsy be performed in an area of erythema with visible hair shafts; a biopsy of a completely scarred area of alopecia will show only end-stage nonspecific changes.

Punch biopsy is the standard procedure for obtaining samples of inflammatory dermatoses but is often used for neoplasms as well. In most instances, a specimen obtained with a 4-mm punch biopsy is adequate for histologic study. A 3-mm punch biopsy may be preferable for small lesions or biopsies from the face or other areas where cosmesis is a concern. Either a 6-mm punch biopsy or a deep incisional biopsy using a scalpel should be performed if panniculitis is suspected to ensure that adequate amounts of subcutaneous fat are obtained. After the skin specimen has been loosened with the biopsy punch, it should be handled very gently and, above all, should not be grasped with forceps except at the very edge. Crush artifact from forceps makes a specimen of an inflammatory process essentially useless, with lymphoma and leukemic infiltrates being particularly susceptible to crush. Often, a punch biopsy specimen can be squeezed gently out of its socket or carefully speared with the syringe needle that was used for injection of the local anesthetic. Sharp scissors can be used to cut through the subcutaneous fat at the base of the specimen. All punch biopsy specimens for inflammatory disease should extend to the subcutaneous fat because in many dermatoses, characteristic histologic features are found in the lower dermis or in the subcutaneous fat.

Shave biopsies may be either superficial or extend more deeply into the skin, but in general they should extend at least into the papillary dermis. Superficial shave biopsies should be used only for lesions in which characteristic histologic changes are expected to be present in the epidermis or the superficial dermis, such as seborrheic keratoses, solar keratoses, verrucae, benign nevi, and basal cell carcinomas. This method has the advantage of leaving the lower portion of the dermis intact so that, immediately afterward, lesions such as basal cell carcinomas can be fully removed by curettage with or without electrodesiccation. In addition, cosmesis is often improved by using the superficial shave biopsy technique. A variant of the deep shave biopsy is the saucerization technique, in which the blade is introduced at roughly a 45-degree angle. To aid in the control of the size of the tissue to be removed, some physicians score

the skin before performing a shave biopsy. Shave biopsies are inadequate for differentiating between squamous cell carcinoma and keratoacanthoma. A superficial shave biopsy without adequate dermis may be suboptimal if melanoma is included in the differential diagnosis due to concerns that a melanoma might be transected at the base. A transected melanoma specimen may be more difficult to diagnose, and accurate assessment of tumor thickness may be more difficult. Because of the thick stratum corneum, a shave biopsy of acral skin may produce a superficial specimen extending only to the midepidermis or papillary dermis. This is especially important when considering a biopsy of an acral pigmented lesion; in this situation, a punch biopsy or small excision is often the best method.

To carry out a shave biopsy, either the skin is raised as a fold and cut with the blade parallel to the skin surface or a curved razor blade is used. Aluminum chloride is recommended for hemostasis; Monsel's solution (ferric subsulfate) and electrocautery are alternatives, but they may affect the interpretation of subsequent biopsies or reexcisions (5).

Deep incisional biopsies using a scalpel may be helpful when evaluating panniculitis or when assessing deep dermal or subcutaneous nodules. Complete excision is often used to obtain an initial specimen for diagnosis when examining atypical pigmented lesions or when evaluation of margins is necessary. Curettage is the least satisfactory of the foregoing methods of obtaining material for histologic examination because the submitted material usually is scanty and superficial; it has lost its architecture, and it may show crush artifact. Even if curettage is performed well, fragmentation and distortion cannot be avoided. Curettage of a melanoma that clinically resembles a seborrheic keratosis or pigmented basal cell carcinoma may prevent accurate diagnosis and may make assessment of microscopic features such as ulceration or regression more difficult.

The biopsy specimen should be placed in fixative immediately on removal from the patient to prevent autolysis. It should not be allowed to dry, and the dermatologist should check the specimen bottle to ensure that the tissue has not adhered to the side of the bottle or remained inside the punch. Patient information should be placed on the bottle itself, not on the lid, which could be accidentally placed on a different bottle. As fixative, 10% buffered formalin can be used in nearly all instances (see Chapter 4). However, if the specimen is mailed in winter, 10% aqueous formalin, which freezes at −11°C, may allow formation of ice crystals in the specimen. This causes damage and distortion in the specimen, particularly in epithelial cells, and makes adequate histologic evaluation impossible. Freezing can be prevented by the addition to the formalin of 95% ethyl alcohol, 10% by volume. An alternative is to let the specimen stand in the formalin solution at room temperature for at least 6 hours before mailing.

Every specimen submitted for histologic diagnosis should be accompanied by detailed clinical information, including a differential diagnosis. The histopathologist's ability to render an accurate diagnosis often depends on the available clinical information, and clinicopathologic correlation is the key to providing optimal patient care. Previous biopsies at the same site, specific requests (e.g., special stains for infectious organisms), and special handling should also be indicated on the requisition sheet sent to the laboratory with the specimen. If, for instance, a stain for lipids is to be carried out, the specimen must not be processed in the automatic processor (see Chapter 4). Handling of biopsies for immunofluorescence is discussed in Chapter 4.

George F. Murphy

Histology of the Skin

OVERVIEW

Understanding the normal histology of skin is central to recognizing cutaneous pathology. The journey to defining the normal histology of human skin is a relatively short one in terms of spatial dimensions. From an en face view of the skin surface, characterized by desquamating scale, furrows, and evidence of adnexal growth, to the normal ultrastructure of key organelles within underlying cellular constituents, we span a magnification range of 10^5 (1). Over this expanse, the histology of the skin is amazingly complex. Divided into two seemingly separate but functionally interdependent layers (epidermis and dermis) (Figs. 3-1 to 3-5), the skin is composed of cells with myriad functions ranging from mechanical and photoprotection, immunosurveillance, and nutrient metabolism to repair. A third layer, the subcutaneous adipose tissue, is not truly a part of the skin, but because of its close anatomic relationship and its tendency to respond together with the skin in many pathologic processes, it is also discussed in this chapter.

The epidermal layer is composed primarily of keratinocytes (greater than 90%), with minority populations of Langerhans cells, melanocytes, neuroendocrine (Merkel) cells, and unmyelinated axons. In addition, the epidermis also contains specialized cuboidal epithelium that forms the spiraling acrosyringia of eccrine sweat ducts, as well as occasional cells putatively programmed for possible adnexal/glandular differentiation (e.g., Toker cells, as found in nipple epidermis in approximately 10% of individuals) (2,3). Architecturally, the epidermal layer has an undulant undersurface in two-dimensional sections, with downward invaginations termed retes and interdigitating mesenchymal cones termed dermal papillae (not to be confused with follicular papillae of the hair bulb). In reality, three-dimensional reconstruction reveals epidermal rete to form a honeycomb of interconnected ridges, with dermal papillae representing rounded conical invaginations not dissimilar to the undersurface of an egg carton. Separated from the epidermis by a structurally and chemically complex basement membrane zone, the dermis consists of endothelial and neural cells and supporting elements, fibroblasts, dendritic and nondendritic monocyte/macrophages, factor XIIIa–expressing dermal dendrocytes, and mast cells enveloped within a matrix of collagen and gylcosaminoglycan. Adnexae extend from the epidermis into the dermis and consist of specialized cells for hair growth, epithelial renewal (stem cells), and temperature regulation. Adnexal epithelium also appears to provide a safe haven for certain precursor cells (e.g., for melanocytes and dendritic cells) in a tissue niche sequestered from deleterious environmental influences at the skin surface. The subcutis is an underlying cushion formed by cells engorged with lipid and nourished by vessels that grow within thin intervening septae. The developmental anatomy of skin is important not only for understanding the basis for mature structural–functional relationships, but also in relation to certain skin tumors that recapitulate embryologic cutaneous structure.

EPIDERMIS

The epidermis comprises the following cell types:

- Keratinocytes
- Melanocytes
- Langerhans cells
- Merkel cells

Keratinocytes

Embryology

The development of *in utero* skin biopsy techniques gives practical importance to understanding the normal evolutionary histology of fetal skin. The epidermis begins as a single layer of ectodermal cells (4,5). By 5 weeks of gestational age, this has differentiated at least focally into two layers—the basal layer or stratum germinativum and the overlying periderm; by 10 weeks, an intervening layer—the stratum intermedium—develops (Fig. 3-1). Cells forming the periderm are large, bulge from the epidermal surface, and are bathed in amniotic fluid. By 19 weeks, there are several layers of intermediate cells, and the periderm has begun to flatten (Figs. 3-1 and 3-2). Keratinization is well developed by 23 weeks within the stratum intermedium in association with small keratohyaline granules. At this juncture, most of the periderm cells have shed, and the keratinizing cells that remain beneath represent the newly formed stratum corneum (5).

By ultrastructure, the histogenesis of the epidermis involves early formation of immature desmosomes and early hemidesmosomes and distinct basement membrane (6 to 7

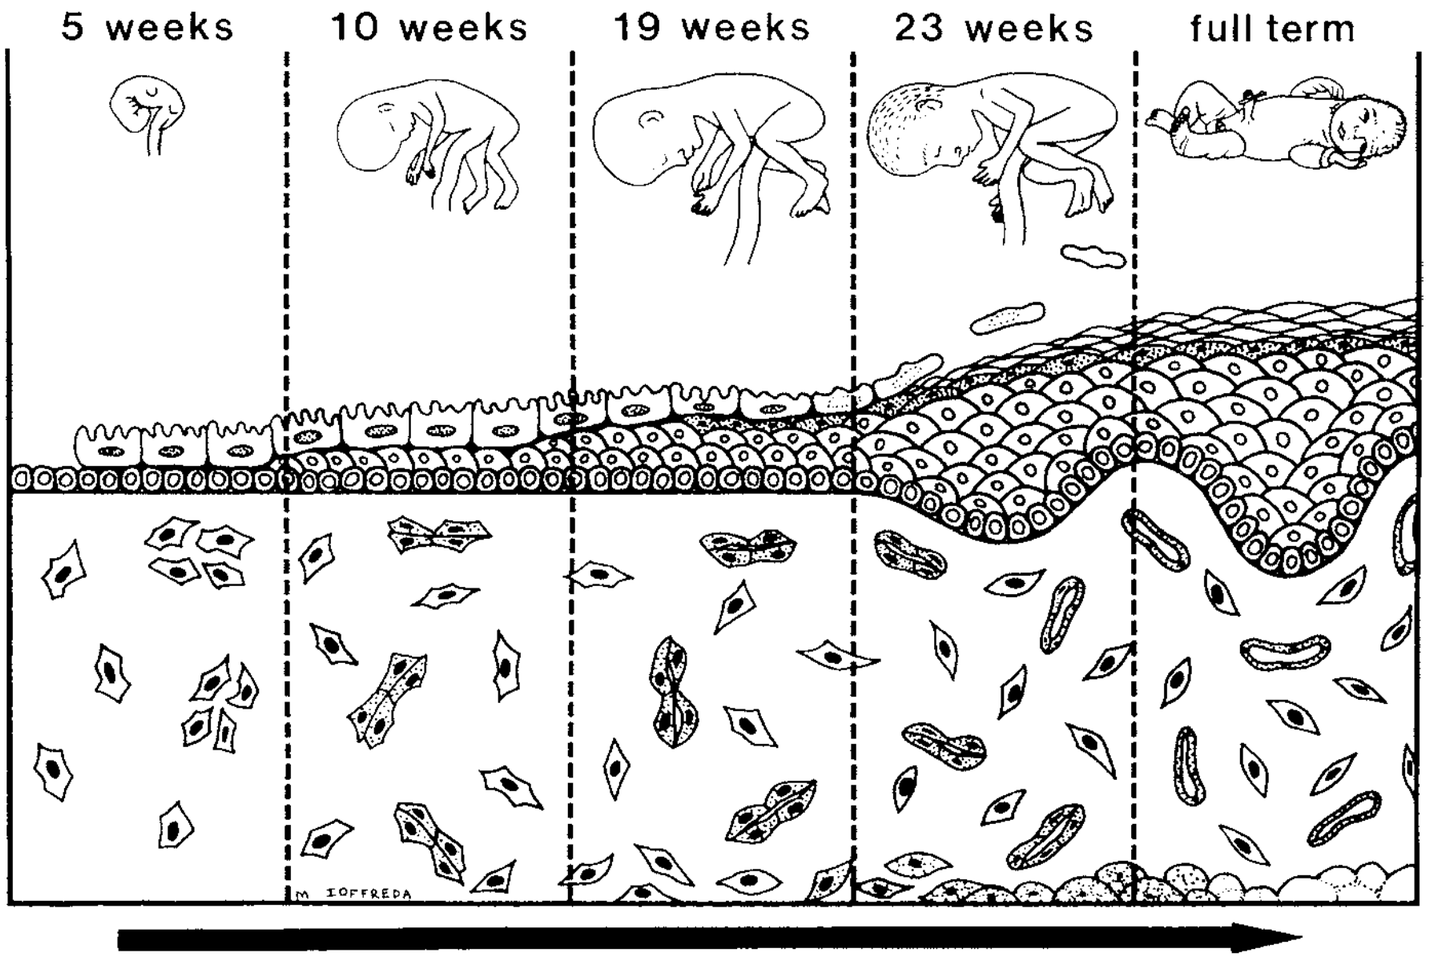

FIGURE 3-1. Schematic overview of embryonic development of human skin. (Courtesy of Dr. Michael Ioffreda).

weeks of gestational age) (6,7). Anchoring filaments are observed several weeks later, and the basement membrane appears structurally mature by the end of the first trimester. The surface cells of the periderm display numerous microvilli and cytoplasmic microvesicles, increasing the area in contact with amniotic fluid and suggesting active interchange between the periderm cells and the amniotic fluid (4). Tonofilaments are sparse until 16 weeks, when dense accumulations are observed in cells of the intermediate layer as evidence of beginning keratinization (5).

Normal Microanatomy

As they differentiate into horny cells, the keratinocytes are arranged in four layers from bottom to top (Figs. 3-6 to 3-12): the basal cell layer (stratum basalis), the squamous cell layer (stratum spinosum), the granular layer (stratum granulosum), and the horny layer (stratum corneum) (Figs. 3-3 and 3-6). An additional layer, the stratum lucidum, can be recognized in

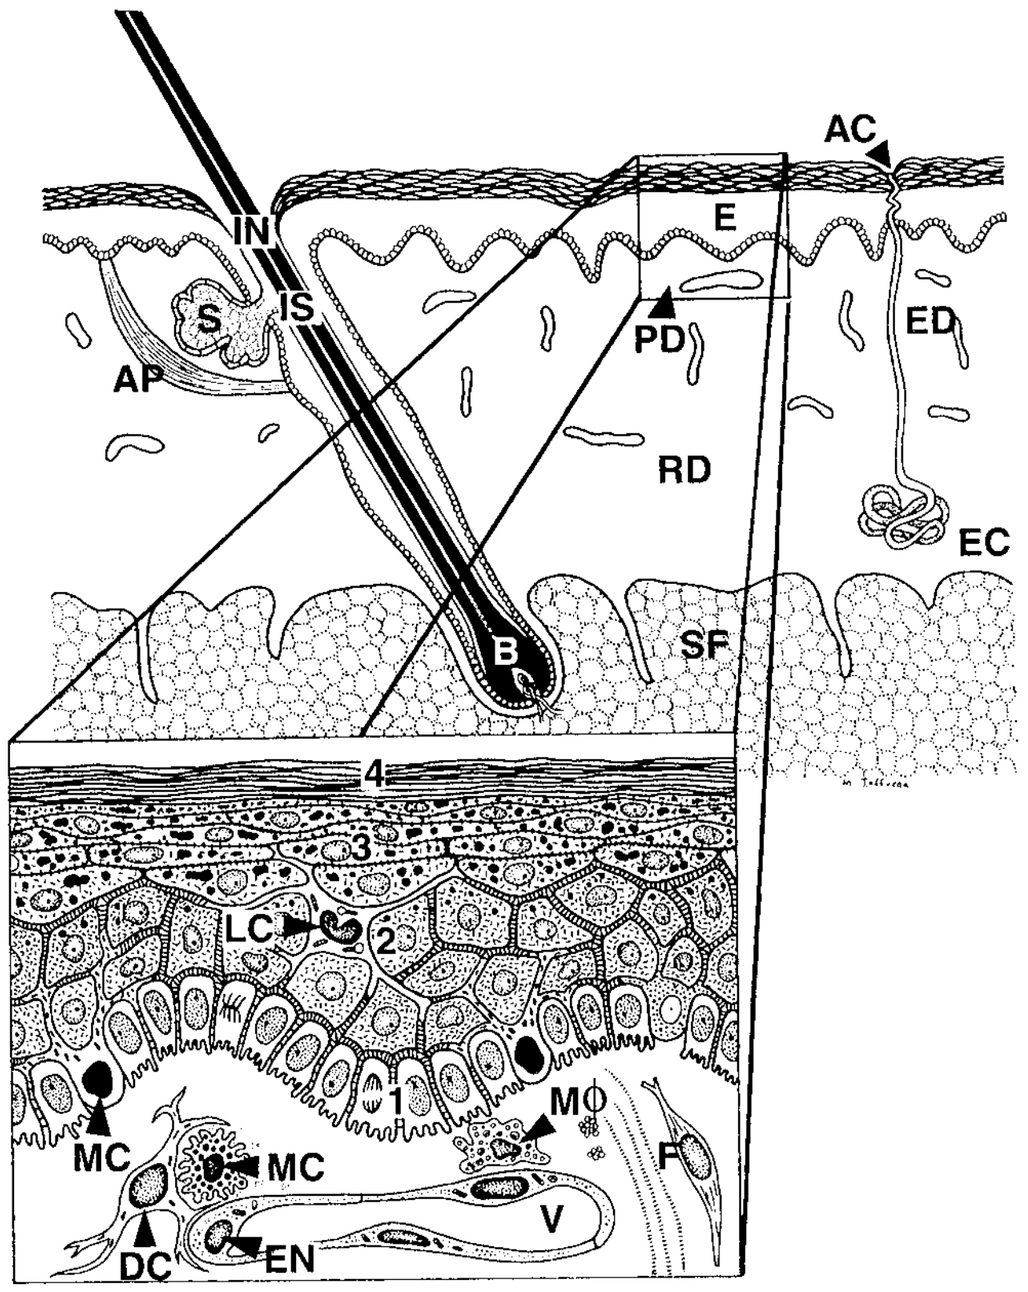

FIGURE 3-3. Schematic overview of the architecture and cytologic constituents of normal human skin. This projection demonstrates the cellular components of the epidermis and superficial dermis in greater detail, with epidermal strata denoted numerically. 1, stratum basalis; 2, stratum spinosum; 3, stratum granulosum; 4, stratum corneum. areas having a thick stratum granulosum and corneum forming the lowest portion of the horny layer, especially on the palms and soles (Fig. 3-7). The keratinocytes differ from the dendritic or clear cells (melanocytes and Langerhans cells) by their larger size, an ample amount of stainable cytoplasm, and the presence of intercellular bridges.

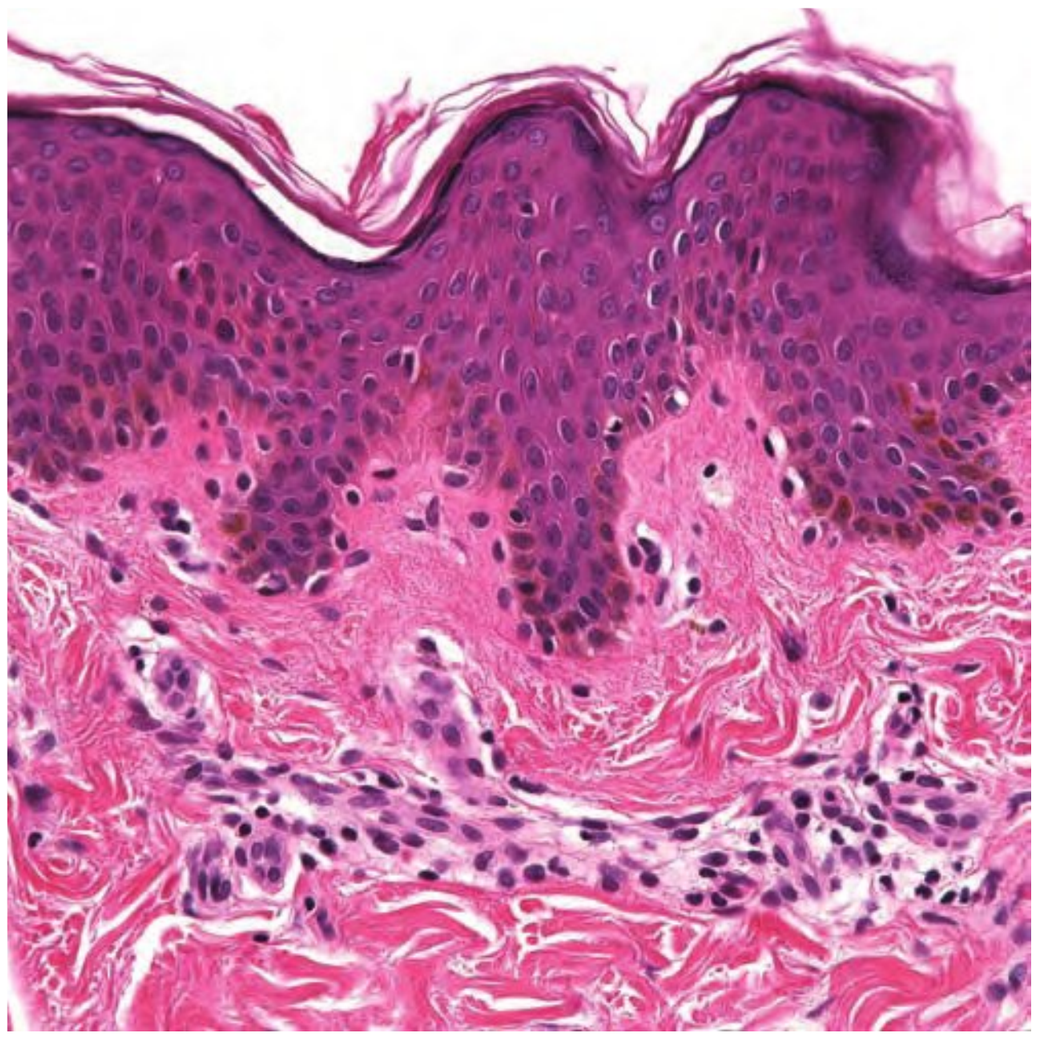

FIGURE 3-5. Histology of normal epidermis and superficial dermis. Note the separation of the delicate papillary dermal collagen from the underlying coarser reticular dermis by the horizontally aligned blood vessel representing a portion of the superficial vascular plexus.

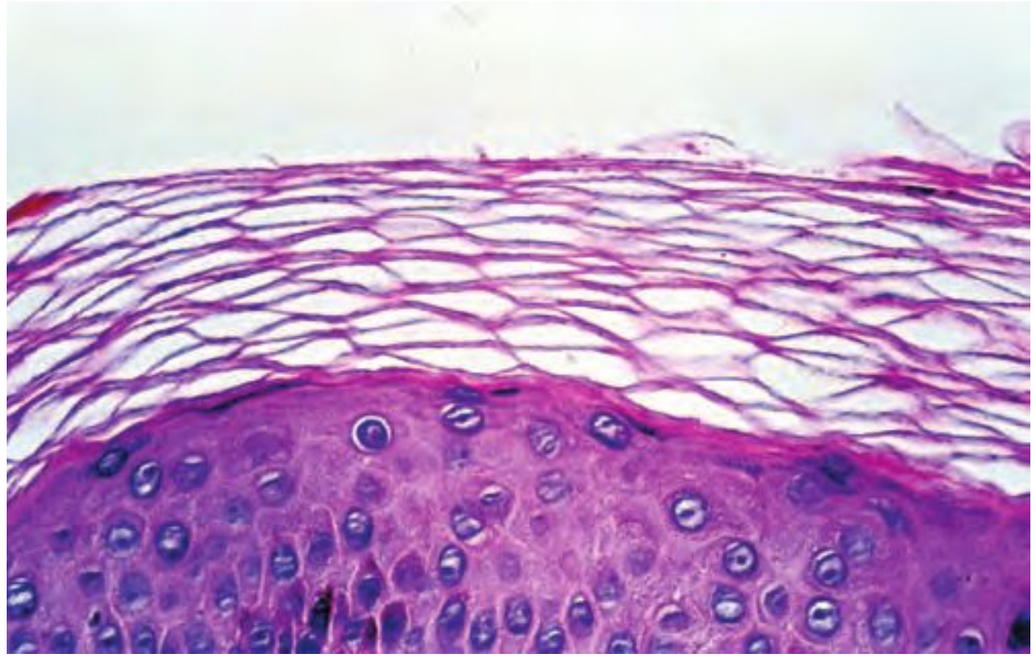

FIGURE 3-6. Histology of normally anucleate stratum corneum, the terminal differentiation product of underlying basal and suprabasal cells. Note the characteristic "basket-weave" architecture typical of nonacral sites.

Stratum Basalis

The basal cells form a single layer, are ovoid in contour, and lie with their long axes perpendicular to the underlying basement membrane. They have a more basophilic cytoplasm than cells of the stratum spinosum, often contain melanin pigment transferred from adjacent melanocytes, and contain dark-staining round to oval nuclei (Fig. 3-5). They are connected with each other and with the overlying squamous cells by intercellular

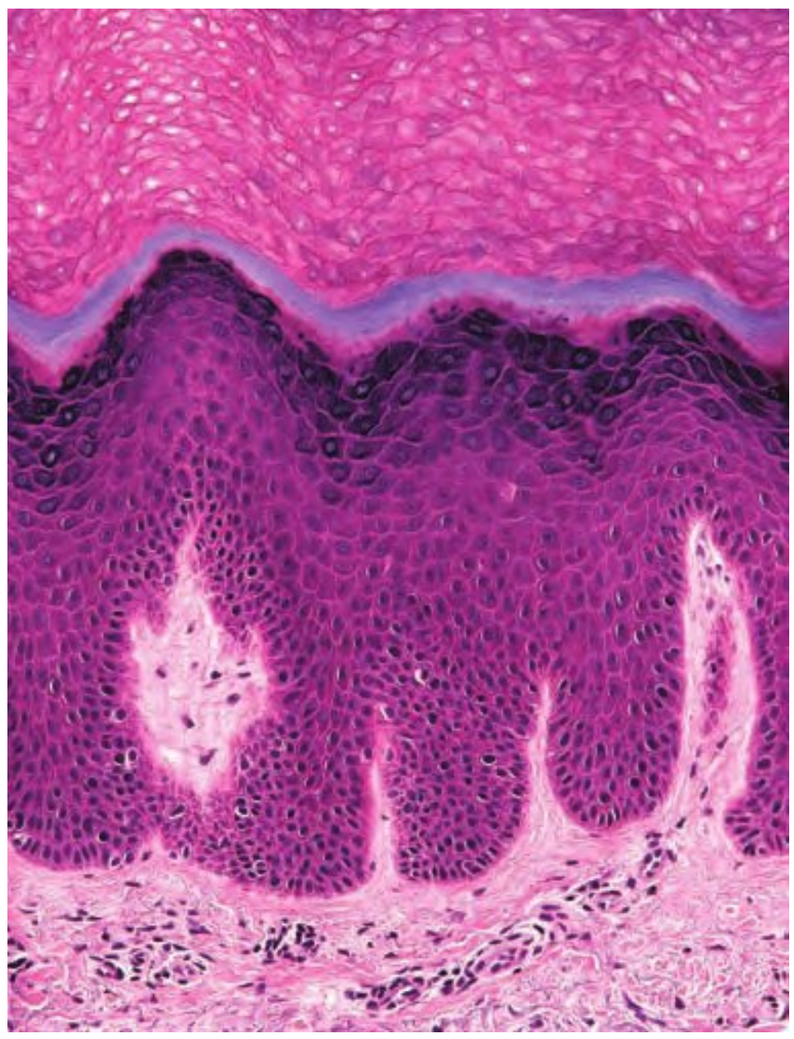

FIGURE 3-7. Histology of normal acral skin illustrating the thick and compact stratum corneum and the presence of a stratum lucidum (gray blue) in the lower portion of the horny layer.

FIGURE 3-8. Ultrastructure of stratum corneum showing transition of intracellular tonofilaments within viable cells to anucleate stratum corneum at the epidermal surface. The darker granules directly beneath the stratum corneum represent keratohyaline granules.

bridges united by desmosomes (discussed in detail later). At their base, the basal cells are attached to the subepidermal basement membrane zone by modified desmosomes, termed hemidesmosomes. Basal cells and overlying squamous cells contain keratin intermediate filaments termed tonofilaments, which form the developing cytoskeleton; these cells and related cytoskeletal proteins ultimately give rise to the anucleate stratum corneum at the epidermal surface (Figs. 3-6 and 3-8).

Most of the mitotic activity in normal human epidermis occurs in the basal cell layer (8). By tritiated-thymidine labeling of cells in the S phase of DNA synthesis, which is approximately seven times longer than the mitotic or M phase, many more tritiated-thymidine–labeled basal cells can be visualized than mitotically active basal cells. Ki-67 labeling is a useful way of determining cycling cells in paraffin sections, and, as with tritiated thymidine, the vast majority of labeled cells in normal skin are within the basal cell layer of the epidermis (Fig. 3-9). Slow-cycling basal cells reside at tips of epidermal rete ridges and have characteristics of stem cells (9). Recent studies have defined similar populations in the bulge region of the hair follicle (10).

Stratum Spinosum

The polyhedral cells of the stratum spinosum overlying the basal cell layer form a mosaic usually 5 to 10 layers thick. They

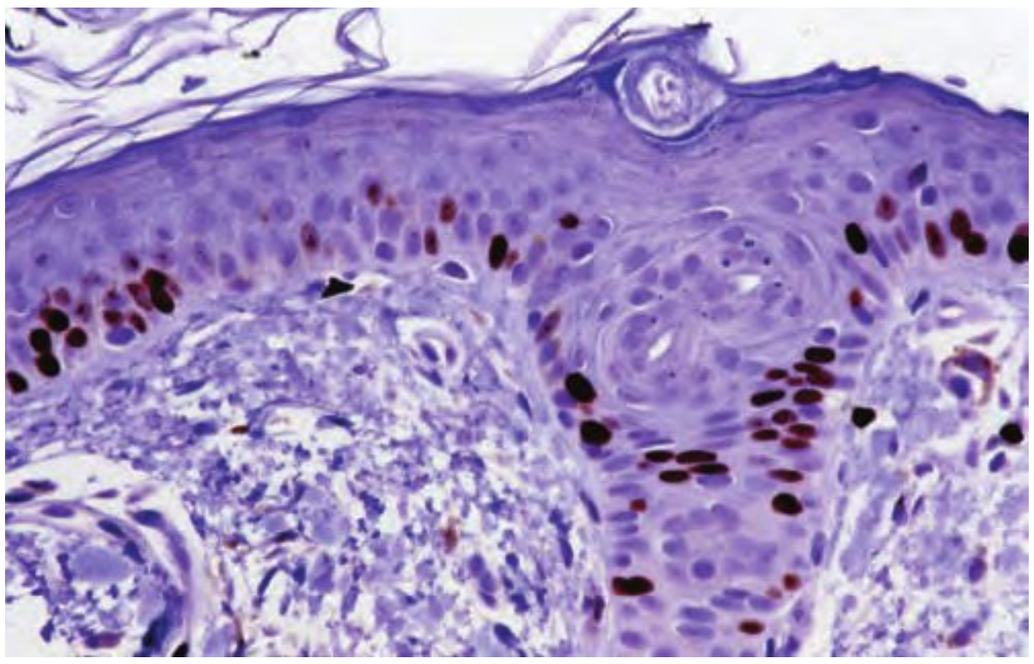

FIGURE 3-9. Evidence of basal cell layer replicative potential by Ki-67 immunostaining. Note the predominance of labeled cells in the basal cell layer of the epidermis and the included portion of a follicular infundibulum.

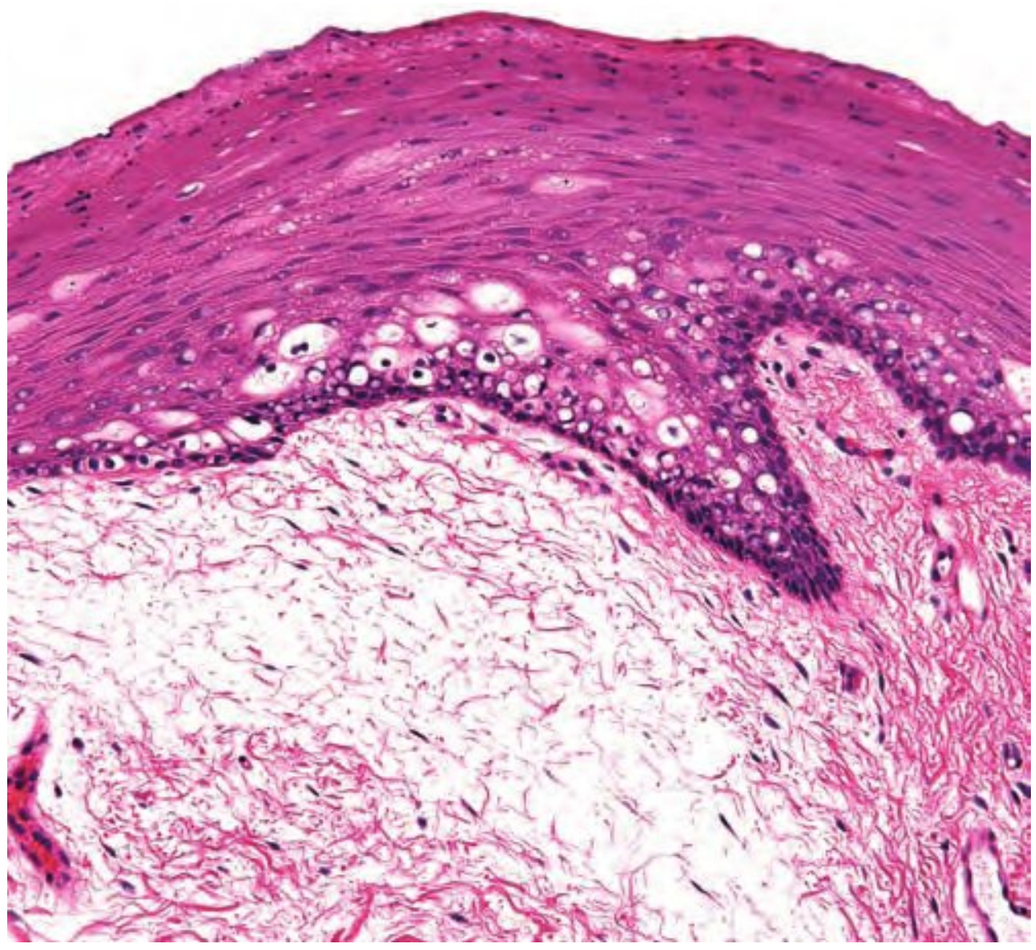

FIGURE 3-10. Mucosal epithelium of the oral cavity showing stratified squamous epithelium without a well-formed granular or cornified layer. Note the cytoplasmic pallor due to glycogenation and delicate underlying connective tissue.

become progressively flattened toward the skin surface (Fig. 3-6). The cells are separated by spaces that are traversed by intercellular bridges united by desmosomes. These intercellular spaces contain neutral mucopolysaccharides and acid mucopolysaccharides (glycosaminoglycans). Hyaluronic acid, an important component of the glycosaminoglycans, is quite abundant in the matrix between keratinocytes, occurring predominantly in the spinous layers but also in the basal layer and the stratum corneum (11). The intercellular cement substance between two adjacent keratinocytes, referred to also as glycocalyx, has a gel-like consistency. On one hand, it provides cohesion between the epidermal cells, and on the other hand, it allows the rapid passage of water-soluble substances through the intercellular spaces; furthermore, it allows the opening up of desmosomes and individual cell movement (12–14).

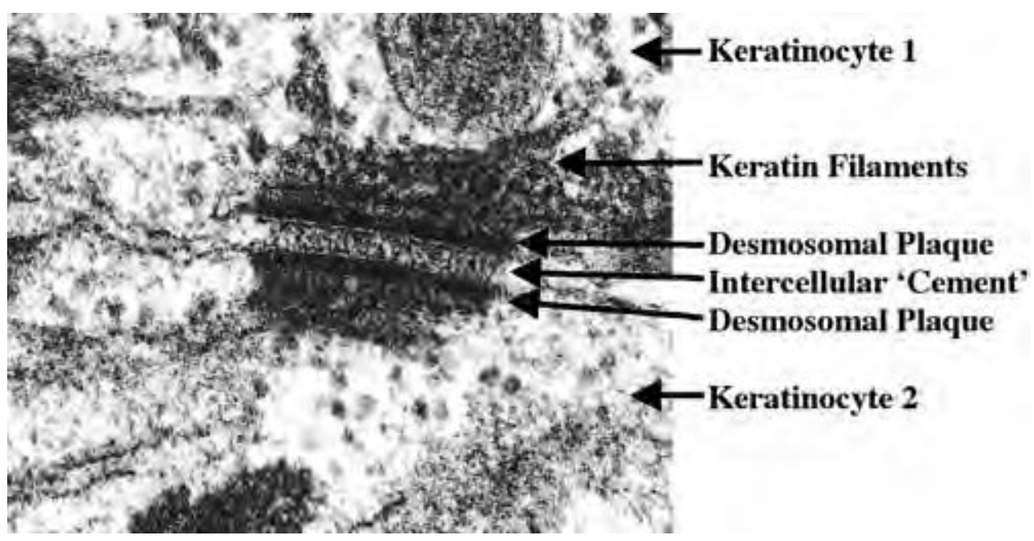

FIGURE 3-11. Ultrastructure of a desmosome. Note the two electron-dense plaques, each located within the cytoplasm of the two keratinocytes that are connected by the desmosome.

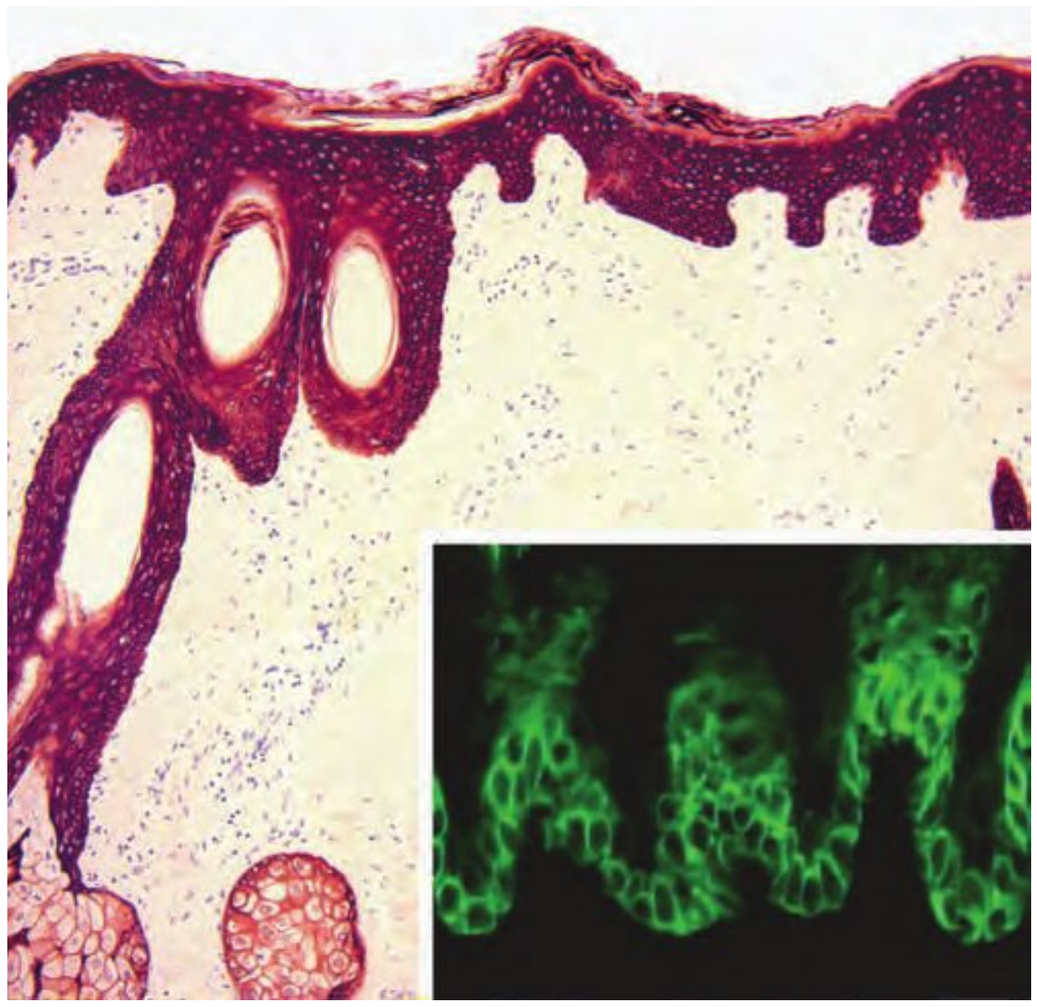

FIGURE 3-12. Immunohistochemistry for a pan-keratin (including low– and high–molecular-weight keratins) showing diffuse expression in the epidermis and adnexal structures. Inset: Preferential expression of keratin 14 by the basal and parabasal layers (immunofluorescence).

The tonofilaments within the cytoplasm of the keratinocytes of the stratum spinosum are loose bundles of electron-dense filaments, each filament measuring 7 to 8 nm in diameter. These structures correlate with keratin proteins, as may be demonstrated by immunohistochemistry (see later discussion on immunohistochemistry) (Fig. 3-12). The tonofilaments at one end are attached to the attachment plaque of a desmosome, and the other ends form the cytoskeleton within the cytoplasm. Electron microscopy shows that the intercellular junctions (desmosomes) consist of two dense plaques 10 to 15 nm thick on adjacent cell membranes. A 30-nm-wide multilayered zone is present between them (Fig. 3-11). The binding of adjacent keratinocytes via interaction of these ultrastructurally complex adjacent desmosomal plaques (12,13) has recently been understood at a molecular level (Fig. 3-11; see also Fig. 3-23). A key family of molecules is the cadherins, derived from multiple genes and representing Ca^{2+}-dependent cell adhesion molecules with a characteristic single-spanning-transmembrane structure (15). Desmosomal cadherins are desmogleins and desmocollins (16) that localize to desmosomes and are linked to intracytoplasmic intermediate filaments by plakoglobin and desmoplakin. Within the desmosome complex, desmogleins within the cell membrane bind to plakoglobin through their cytoplasmic domain. Intermediate keratin filaments anchor at the desmosomal plaque, possibly by way of the carboxy-terminal domain of plakoglobin. The structural importance of these molecules in uniting keratinocyte cytoskeletons within the epidermis is indicated by the disorders pemphigus vulgaris and pemphigus foliaceus, in which autoantibodies to desmoglein 3 and desmoglein 1, respectively, result in clinical blisters due to loss of cell–cell adherence (acantholysis) (see Chapter 9) (17,18). Desmoglein 3 is normally concentrated between immediately suprabasal keratinocytes, whereas desmoglein 1 is distributed preferentially among keratinocytes directly beneath the stratum corneum. Indeed, a remarkable correlation has been established between desmoglein expression in normal skin and pathologic lesions in which specific desmogleins are disrupted with regard to the plane of blister formation due to loss of cell–cell adhesion.

Stratum Granulosum

The cells of the granular cell layer are flattened, and their cytoplasm is filled with keratohyaline granules that are deeply basophilic and irregular in size and shape (Fig. 3-6). The thickness of the granular layer in normal skin is generally proportional to the thickness of the horny layer: It is only 1 to 3 cell layers thick in areas in which the horny layer is thin but measures up to 10 layers in areas with a thick, horny layer, such as the palms and soles (Figs. 3-5 and 3-7). In the process of keratinization, the keratohyaline granules form two structures: the interfibrillary matrix or filaggrin, which cements the keratin filaments together, and the inner lining of the horny cells, the so-called marginal band. Whereas the tonofibrils contain only small amounts of sulfur as sulfhydryl groups, the interfibrillary matrix and the marginal band contain about 10 times the amount of sulfur that is present in the tonofibrils, predominantly as disulfide bonds of cystine (19,20). Consequently, the tonofibrils are soft and flexible, whereas the matrix and marginal band provide necessary strength and stability (20). Thus, the keratin of the epidermis represents "soft" keratin, in contrast to the "hard" keratin of the hair and nails, in which keratohyaline granules are lacking and the tonofibrils themselves harden through the incorporation of disulfide bonds (21). "Soft" keratin desquamates as the result of enzymatic action, but the "hard" keratin of the hair and nails does not and thus requires periodic cutting.

The granular cell layer represents the mature keratin-forming transitional zone of the epidermis, in which the dissolution of the nucleus and other cell organelles is prepared. In contrast to the stratum basalis and stratum spinosum, in which lysosomal enzymes, such as acid phosphatase and aryl sulfatase, are present as only a few granular aggregates, there is diffuse staining for lysosomal enzymes in the granular cell layer. These diffusely staining lysosomal enzymes probably play an important role in the autolytic changes occurring in the granular layer (22).

Stratum Corneum

Unlike the nucleated cells of the other epidermal layers, the cell remnants of the normal stratum corneum are anucleate. Thus the normal horny layer stains eosinophilic. The thickness of the horny layer is often difficult to ascertain in formalin-fixed specimens because the outer cell layers may become

detached. The portion of the horny cytoplasm that contains disulfide bonds of cystine tends to shrink on formalin fixation to form a shell along the cell membrane, resulting in the characteristic basket-weave architecture in routine sections (Fig. 3-6) (23). In contrast, glutaraldehyde fixation used for electron microscopy causes precipitation of the formalin-soluble substances within the horny cells and allows staining of the contents of the horny cells with reagents such as uranyl acetate and lead citrate. With a fluorescent stain it can be shown that the cells of the horny layer are arranged in orderly vertical stacks (24).

Mucosal Epithelium

Skin shows considerable variation among different body sites, and appreciation of such normal differences is critical to accurate diagnostic assessment. Perhaps the most profound differences exist at mucosal and paramucosal sites. For example, with the exception of the dorsum of the tongue and the hard palate, the mucous membrane of the mouth possesses neither a granular nor a horny layer (Fig. 3-10). When these layers are absent, the epithelial cells may appear vacuolated, largely as a result of their glycogen content. Electron microscopic examination reveals that the number of tonofilaments diminishes in the upper layers, and they become dispersed. Large aggregates of glycogen are present in the cells. The epithelial cells of the oral mucosa show only few well-developed desmosomes. Instead, they show numerous microvilli at their borders. They are held together by an amorphous, moderately electron-dense intercellular cement substance, the dissolution of which causes the detachment of the uppermost cells (25).

Specialized Structure and Function

Superficial Cellular Cohesion

The number of tonofilaments in the epidermis increases in the upper portion of the squamous layer. The earliest formation of keratohyaline granules consists of the aggregation of electron-dense ribonucleoprotein particles largely along tonofilaments. The keratohyaline granules increase in size through peripheral aggregation of ribonucleoprotein particles, and they surround more and more tonofilaments (26). By extending along numerous tonofilaments, the keratohyaline granules assume an irregular, often star-shaped outline and may reach a size of 1 to 2 μm. After ultimately ensheathing all tonofilaments, they form in the horny cells the electron-dense interfilamentous protein matrix of mature epidermal keratin. Keratohyaline granules are biochemically complex. One component is a histidine-rich protein called filaggrin precursor (27). When granular cells are converted to cornified cells, filaggrin precursor is broken down into many units of filaggrin. Filaggrin then aggregates with keratin filaments and acts as a "glue" for keratin filaments.

Terminal Differentiation

The transformation of granular cells into horny cells usually is abrupt. By electron microscopy, the cytoplasm of the cells in the lower portion of the horny layer shows relatively electron-lucent tonofilaments, about 8 nm thick, embedded in an interfilamentous substance having the same high degree of electron density as the keratohyaline granules (Fig. 3-8) (28). In the upper portions of the horny layer, however, the cells lose their filamentous structure. Together with the sudden keratinization of the horny cells, an electron-dense, homogeneous marginal band forms in their peripheral cytoplasm in close approximation to the trilaminar plasma membrane. In the lowermost horny layer the trilaminar plasma membrane is preserved outside of the marginal band; in the midportion of the horny layer it becomes discontinuous and then desquamates, so that the marginal band serves as the real cell membrane (25). Immunohistochemistry reveals that involucrin, a structural component of mature squamous epithelium, is incorporated into the marginal band as part of the formation of the protein envelope that characterizes squamous cells immediately prior to terminal differentiation (29). Desmosomal contacts are at first still present in the horny layer but disappear before desquamation of the horny cells.

Barrier Function

Odland bodies, also called membrane-coating, lamellar granules, and keratinosomes are small organelles that are discharged from the granular cells into the intercellular space and have two important functions: They establish a barrier to water loss, and they mediate stratum corneum cell cohesion. Lamellar granules appear first in the perinuclear cytoplasm in the stratum spinosum. Higher up in the epidermis, they rapidly increase in number and size (30). Both within and outside the granular cells, lamellar granules are round or oval, measure approximately 300 to 500 nm in diameter, and possess a trilaminar membrane and a laminated interior. The lamellar granules fuse with the plasma membrane of a granular cell, secreting its contents into the intercellular spaces (31). The lamellar granules fuse and completely fill the intercellular spaces at the level of the granular layer. They contain neutral sugars linked to lipids and/or proteins; hydrolytic enzymes, possibly charged with degrading intercellular materials; and free sterols. The stratum granulosum interstices contain free sterols and sugars; the stratum corneum intercellular spaces stain as a pure neutral lipid mixture with abundant free sterols but no sugars (31). Sugars are cleaved at the granular-cornified layer interface by sugar-specific glycosidases. The lipids formed in these organelles act as hydrophobic material, which is important to the barrier function (32). A similar permeability barrier exists in the oral mucosa. Lamellar granules may also contribute to cohesion between the cells of the lower stratum corneum as a result of the lipids that they contain. The action of enzymes, such as steroid sulfatase, removes the lipids from the upper stratum corneum and brings about desquamation of the cells there (33).

Enzyme Activity

Primary lysosomes that are membrane bound and contain a variety of hydrolytic enzymes, such as acid phosphatase, aryl sulfatase, and β-galactosidase, are seen in small numbers within keratinocytes, largely but not exclusively in the basal cell layer and lower squamous cell layer (14). A great number of

lysosomal enzymes, primarily located free within the cytoplasm, are demonstrable in the granular layer and in the lowermost horny layer. Lysosomal enzymes are found also in the lamellar granules and are located within granular cells and after their discharge into the intercellular space (34). Secondary lysosomes, also called phagolysosomes, are present in the lower epidermis, especially in the basal cells, where they digest phagocytized melanosomes, usually as melanosome complexes (see later discussion). In cases of epidermal injury, such as sunburn or interface dermatitis, numerous phagosomes are observed that contain remnants of organelles from damaged cells (34).

Immune Functions of Keratinocytes

In recent years, the epidermal keratinocyte has been recognized as a potent source of immunogenic molecules. Keratinocytes are capable of producing interleukins (ILs) (IL-1α, IL-1β, IL-6, IL-8); colony-stimulating factors (CSFs) (IL-3, granulocyte-macrophage-CSF, granulocyte-CSF, macrophage-CSF); interferons (IFNs) (IFNα, IFNβ); tumor necrosis factors (TNFs); transforming growth factors (TGFs) (TGFα, TGFβ); and growth factors (platelet-derived growth factor, fibroblast growth factor, melanocyte-stimulating hormone) (35). Some of these substances are expressed constitutively, whereas others are synthesized only after signal transduction initiated by external or systemic cues (36). Accordingly, keratinocytes may play an active role in elaboration of molecular signals that facilitate lymphocyte homing and local activation, enabling certain dermal cells to mature and regulating synthesis of extracellular matrix molecules.

Immunohistochemistry

Immunohistochemical techniques have become an important part of the diagnostic arsenal of pathologists, and the expression of keratin by poorly differentiated tumor cells is considered an important marker of epithelial differentiation. Keratins consist of two families of intermediate filament proteins, with type I and type II members always occurring as pairs (37,38). In humans, keratin genes are clustered as families in two regions of the genome, the type I genes on chromosome 17q21.2 and those encoding type II keratins on chromosome 12q13.13. There are 54 functional keratin genes, 27 in each of these domains (38). Different epithelia express different keratins. In addition, different keratins are expressed by the different layers of the human epidermis, reflecting the variable degree of differentiation in keratinocytes. Keratin 5 (K5) and keratin 14 (K14) are predominantly expressed by basal cells (39) (Fig. 3-12). When these cells differentiate, they downregulate expression of mRNAs encoding these two keratins and induce expression of new sets of keratins specific for individual programs of epithelial differentiation (Fig. 3-12). Moreover, unlike other basal cells that express K14, basal cells in the general region where stem cells reside also express keratin 15, indicating that biosynthetic heterogeneity exists within the basal layer with regard to expression of cytoskeletal elements (40,41). Suprabasal keratinocytes predominantly express keratin 1 and keratin 10. Keratin 2 is expressed by terminally differentiated keratinocytes. Keratin 9 is expressed by suprabasal keratinocytes in palmar and plantar epidermis. The pattern and type of keratin expression is different in the epidermis and adnexal structures. It is important to be familiar with the expression of keratin by normal structures because specific mutations are associated with different conditions (e.g., epidermolysis bullosa simplex variants are associated with mutations in keratin 5 and 14 genes, whereas mutations for keratin 1 and 10 genes are associated with bullous ichthyosiform erythroderma; mutations in the keratin 2 gene result in bullous ichthyosis of Seimens, and mutations of keratin 9 genes are responsible for epidermolytic palmoplantar keratoderma).

A more novel epithelial immunohistochemical marker is p63, a member of the p53 gene family implicated in both the development and maintenance of stratified epithelial tissues, including the epidermis. Increasing data support p63 function in the regenerative capacity of basal keratinocytes by maintaining cell proliferation (42) as well as inducing epidermal commitment of embryonic stem cells (43,44). The critical contribution of p63 to embryonic development is underscored by the severe abnormalities seen at birth in mice null for p63, including lack of epidermis. Mutations in p63 have been linked to ectodermal dysplasia syndromes with a skin phenotype, indicating the relevance of p63 to normal epidermal development in humans (45). In normal human epidermis, in hair follicles, and in stratified epidermal cultures, p63 protein is principally restricted to cells with high proliferative potential and is absent from the cells that are undergoing terminal differentiation. Accordingly, p63 expression is seen in basal/suprabasal cells of the epidermis, outer root sheath, and hair matrix cells of the hair follicle, basal cells situated in the outermost layer of sebaceous glands, and outer layer cells of the ductal portion and myoepithelial cells of the secretory portion of the sweat glands (Fig. 3-13). p63 is overexpressed in the vast majority of squamous

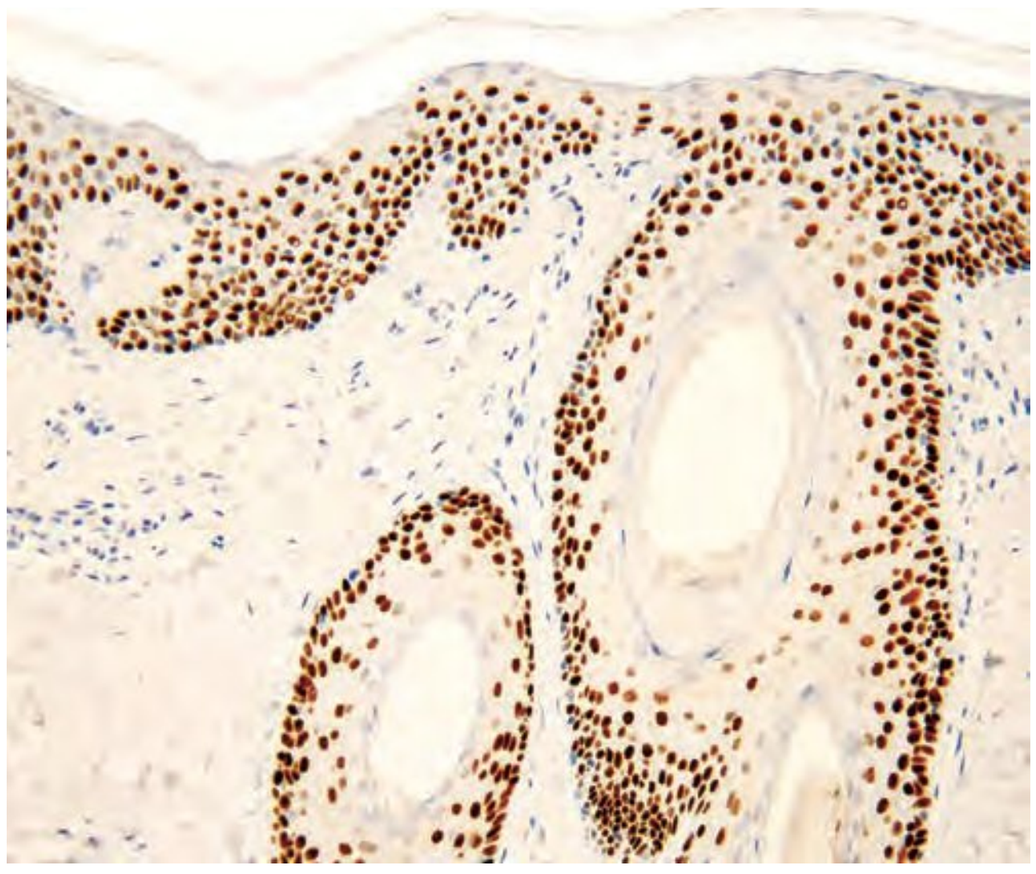

FIGURE 3-13. p63 immunostain shows intense nuclear positivity in all epithelial compartments, including the epidermis and adnexal structures. The staining is more intense in basal and parabasal areas.

cell carcinomas and basal cell carcinomas and appears to be an especially helpful marker for poorly differentiated squamous cell carcinomas, including the sarcomatoid variant (46).

Melanocytes

Embryology

The appearance of melanocytes in the epidermis takes place in a craniocaudal direction, in accordance with the development of the neural crest, from which the melanocytes are derived. By enzyme histochemistry, melanocytes can be identified in the epidermis of the head region during the latter part of the third fetal month; in the more caudal body regions, the earliest-formed melanin can be observed only in the latter part of the fourth month. Because melanocytes are functionally immature during their migration through the fetal dermis, they cannot be identified by histochemical methods until they have reached the epidermis (47). Electron microscopy and immunohistochemical approaches (e.g., stain for HMB-45 protein) allow for an earlier recognition of melanocytes in the epidermis than is possible by light microscopy (48,49).

The tyrosine kinase receptor KIT and its ligand stem cell factor play a critical role in melanocyte physiology, influencing migration, proliferation, differentiation, and survival (50–52). Piebaldism, a genetic disorder, results from KIT receptor defects secondary to mutations of the c-kit proto-oncogene. Patients with piebaldism present at birth with white patches of skin and hair that lack melanocytes, supporting the major role of KIT in melanocyte migration from the neural crest to the skin (53).

Microphthalmia transcription factor (MITF) is a nuclear protein involved in the embryonic development of melanocytes and the regulation of transcription of genes involved in melanin synthesis, such as tyrosinase. The microphthalmia (*mi*) gene is located on chromosome 3p. Since its discovery as a mutant allele producing mice devoid of viable melanocytes, *mi* has emerged as the gene whose mutation is responsible for the human pigmentation condition Waardenburg's syndrome IIa, as well as a variety of cellular defects involving retinal pigment epithelium, osteoclasts, and mast cells (54).

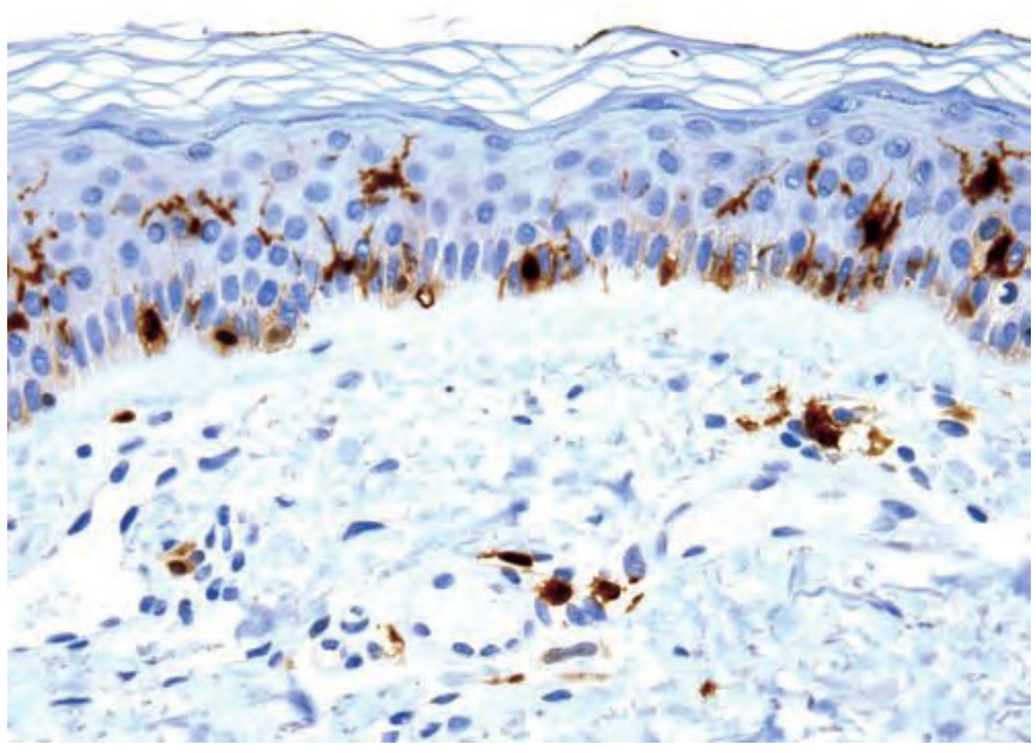

FIGURE 3-14. S100 immunostain is expressed by junctional melanocytes and also by Langerhans cells in the mid epidermis and dermis.

Normal Microanatomy

Mature melanocytes are melanin-synthesizing dendritic cells located within the basal layer of the epidermis, hair bulb, and outer root sheath of hair follicles (Figs. 3-14 to 3-17). In sections stained with hematoxylin-eosin, the dendrites of epidermal melanocytes are usually not seen, and the cells bodies are randomly dispersed within the basal cell layer. They contain round to oval, dark-stained nuclei that are generally smaller than those of basal keratinocytes and what may appear as a clear halo of surrounding cytoplasm, largely as the result of shrinkage during tissue processing. Although the number of

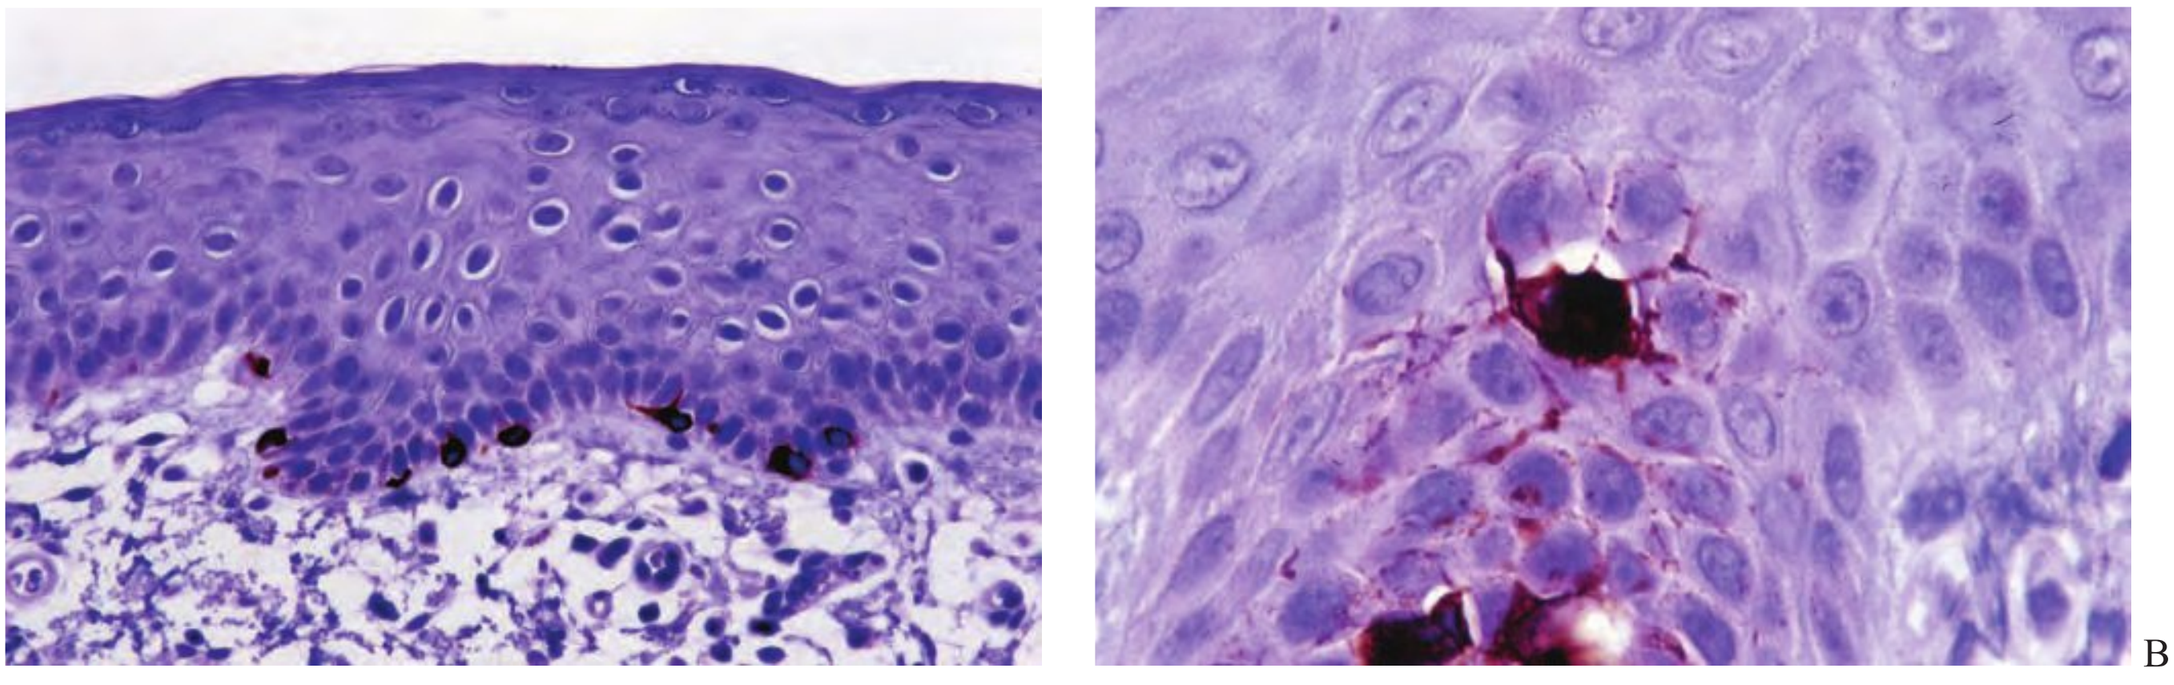

FIGURE 3-15. Melan-A/MART-1 immunostain demonstrates normal melanocytes within the epidermal basal layer. This is a more specific melanocytic marker compared to S100 (A). Note the dendritic extension at higher magnification (B). This melanocyte appears to be suprabasal as a result of the tangential plane of the section.

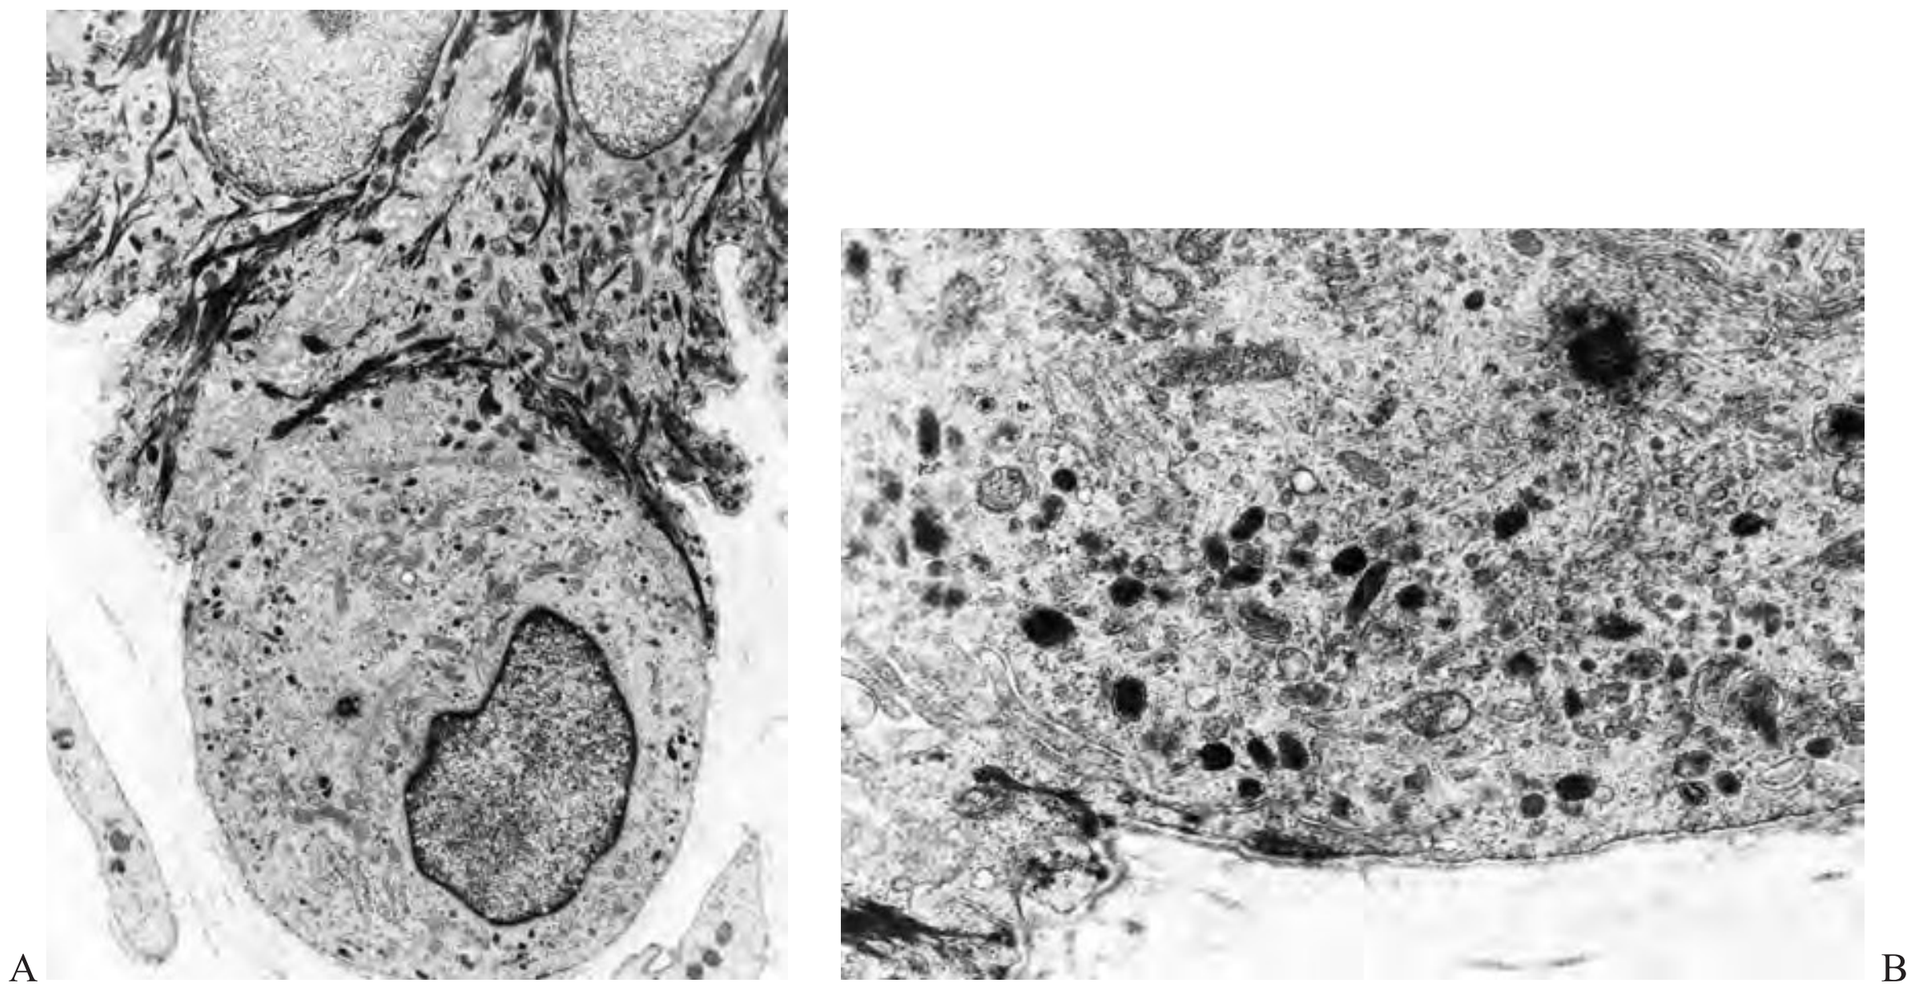

FIGURE 3-16. Ultrastructure of melanocytes. These cells characteristically "hang down" from the basal cell layer and are devoid of tonofilaments of desmosomes (A). They contain characteristic melanosomes in varying stages of melanization (B).

melanocytes in relation to basal cells varies with the body region and increases with repeated exposure to ultraviolet light, the average number of clear cells in hematoxylin-eosin–stained vertical sections is 1 of 10 cells in the basal layer, and a similar ratio was found with immunohistochemical studies (55,56). Melanin is transferred by means of the dendritic processes (Figs. 3-14 and 3-15A, B) from the melanocytes to the basal keratinocytes, where it is first stored and later degraded. As a rule, a greater amount of melanin is present in the basal keratinocytes than in the melanocytes, and often basal cells at the tips of rete ridges are preferentially more melanized. Because only about 10% of the cells in the basal layer are melanocytes, each melanocyte supplies several keratinocytes with melanin, forming with them an epidermal-melanin unit (57).

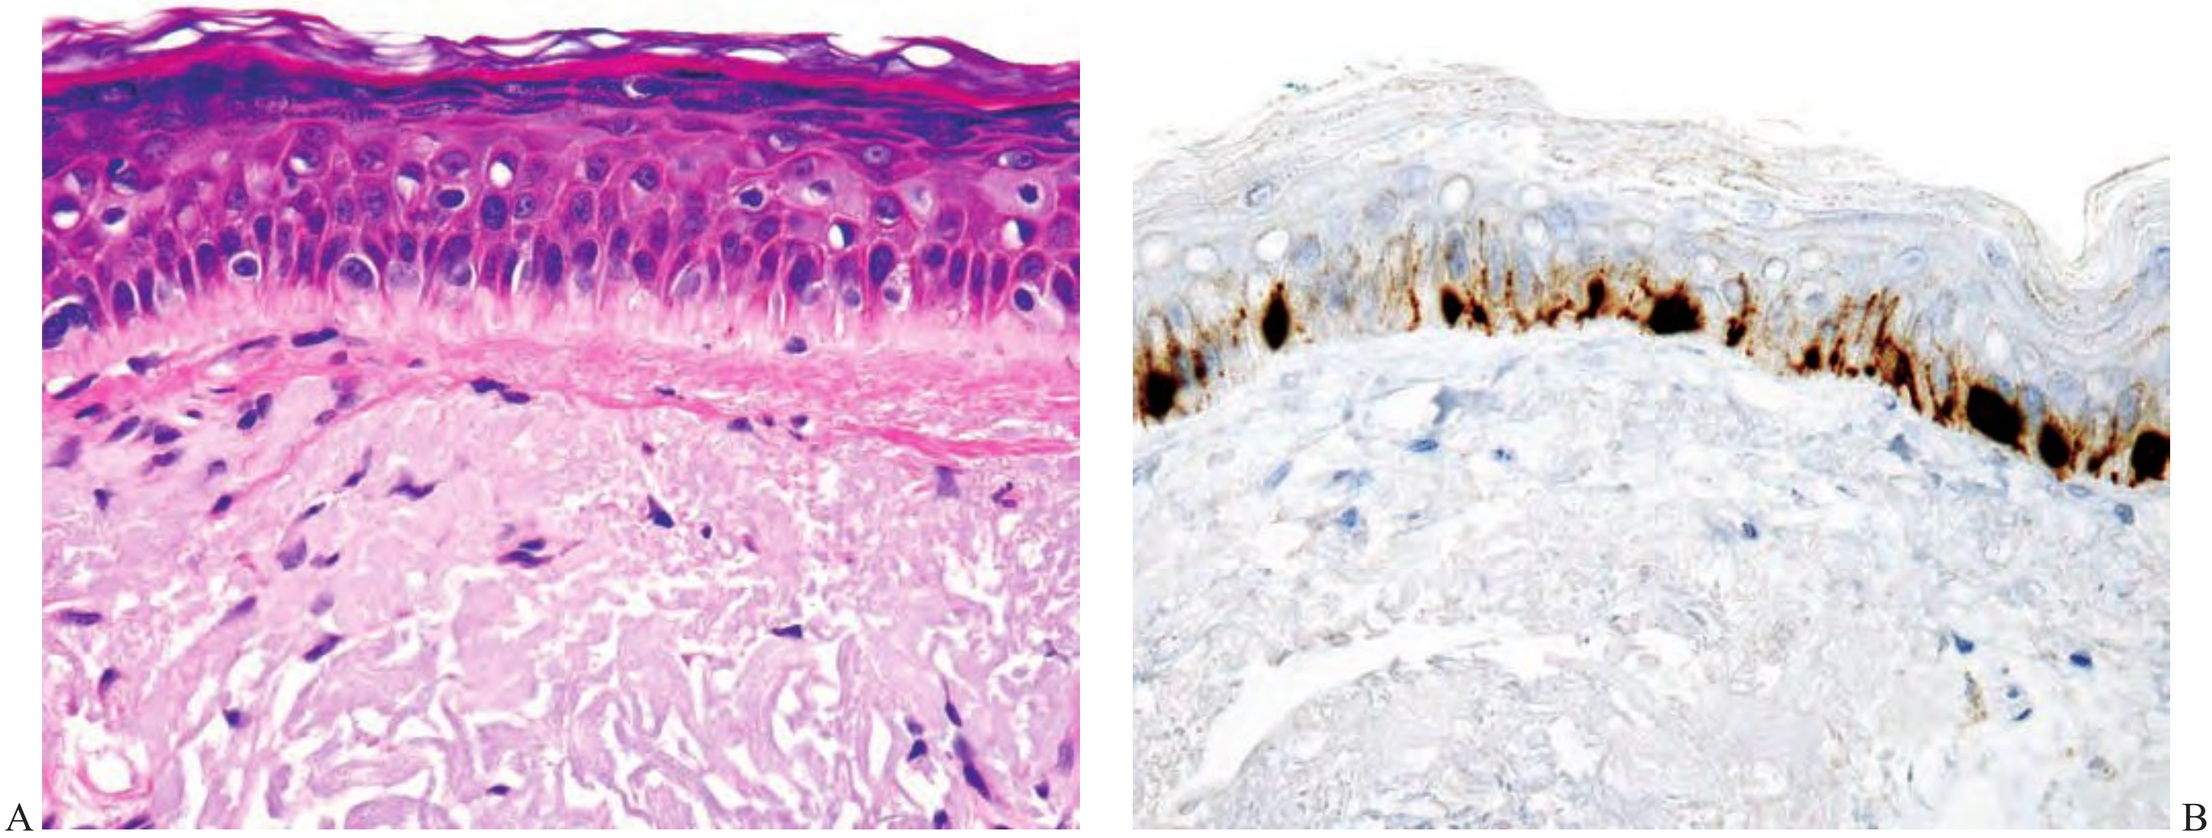

FIGURE 3-17. A: Melanocytes in sun-damaged skin may be increased in number and size as depicted in this microphotograph. Note the marked dermal solar elastosis. B: MART-1 immunostain highlights an increase in melanocyte density in sun-damaged skin.

In persons with a light skin color, staining with hematoxylin-eosin may reveal few or no melanin granules in the basal cell layer. In persons with a dark skin color, especially individuals of African heritage, melanin granules are present in the basal cell layer, as well as throughout the epidermis, including the horny layer, and in some instances in the upper dermis within macrophages, called melanophages. Accordingly, ethnic background and body site are critical in separating normal variations from true pathology.

Special Stains

Melanocytes may be difficult to appreciate on hematoxylin-eosin–stained sections, and there are several special stains that can facilitate their detection by light microscopy. Silver stains indicate the presence of melanin, which is both argyrophilic and argentaffin. Argyrophilia is based on the ability of melanin to be impregnated with silver nitrate solutions, which, on reduction with hydroquinone to silver, stain black. Because melanin is argentaffin, ammoniated silver nitrate may be reduced by phenolic groups in the melanin, forming black silver precipitate (e.g., the Fontana-Masson method). Neither of these methods is entirely specific for melanin, however. Melanin may be bleached by a strong oxidizing agent, such as hydrogen peroxide or potassium permanganate, a method that permits more specific identification (58) and is used in heavily melanized tumors, where pigment may obscure nuclear detail. The dihydroxyphenylalanine (dopa) reaction, which stains melanocytes dark brown to black, imitates physiologic melanin formation, which begins by tyrosinase-dependent hydroxylation of tyrosine to dopa and the oxidation of dopa to dopa-quinone, which is subsequently polymerized into melanin. Thus, the dopa reaction is in essence an assay for tyrosinase activity in melanosomes (58).

The use of immunohistochemical techniques for labeling melanocytes is becoming increasingly important, and several melanocytic markers that work in paraffin-embedded tissues are available (see Table 3-1). Immunohistochemical detection of melanocytes has been classically and most commonly accomplished by polyclonal antibodies to S100 protein. The antigen S100, a family of calcium-binding proteins (molecular weight 21,000), originally isolated from bovine brain extract (59), is present in the cytoplasm and nucleus of a variety of cells, including those of neural melanocytic lineage (60). The function of S100 within melanocytes is unclear, although different subtypes of S100 appear to have different functions in different cell types. The member of the S100 family predominantly expressed in normal melanocytes is S100B (61), whereas S100A subtypes have been reported in various skin lesions. In the skin, in addition to melanocytes, S100 labels Langerhans cells, specialized macrophages, Schwann cells, sweat glands, and adipocytes, and therefore, although it is a sensitive marker, it lacks specificity (Fig. 3-14; see also Figs 3-35F, 3-52C, 3-53A, and 3-54B).

The search for new targets for immunotherapy in patients with melanoma has generated several novel reagents valuable for diagnostic pathology. By using cytotoxic T-cell assays, various antigens that are recognized by autologous cytotoxic T lymphocytes were identified (62). A group of these antigens is referred to as melanocyte differentiation antigens because their expression is restricted to cells of melanocytic lineage. A number of reagents to melanocyte differentiation antigens suitable for analysis of paraffin-embedded material have become available, including the classically used monoclonal antibody HMB-45 and more novel reagents such as monoclonal antibodies to Melan-A/MART-1 (63,64) (Fig. 3-15), tyrosinase, and PNL2. HMB-45 antibody reacts with a cytoplasmic epitope, the premelanosome glycoprotein gp100 (75 to 100 kD), in cells of most but not all melanomas and in a minority of nevi (65,66). HMB-45 is negative in normal epidermal melanocytes in adults; however, it is expressed by melanocytes in fetal skin and stimulated adult melanocytes and is considered a highly specific antibody for the immunocytochemical substantiation of the diagnosis of malignant melanoma.

The advantage of the newer melanocyte differentiation antigens (e.g., Melan-A/MART-1) is a stronger sensitivity

TABLE 3-1 Immunohistochemical Expression of S100 and Most Common Melanocytic Differentiation Markers in Normal Skin

Antigen	Antibody	Positive cells	Antigen location
S100 protein	Anti-S100 protein	Melanocytes, Langerhans cells, macrophages, Schwann cells, adipocytes, myoepithelial cells of sweat glands	Nuclear and cytoplasmic
gp100	HMB-45	Fetal melanocytes, activated melanocytes	Cytoplasmic
Melan-A/MART-1	A103/M2-7C10	Melanocytes	Cytoplasmic
Tyrosinase	T311	Melanocytes	Cytoplasmic
PNL2 Antigen	PNL2 Antibody	Melanocytes, neutrophils	Cytoplasmic
MITF	D5	Melanocytes, macrophages, Schwann cells, smooth muscle cells	Nuclear

MITF, microphthalmia transcription factor.

when dealing with melanocytic neoplasms compared to HMB-45 and stronger specificity when compared with S100. The gene for Melan-A/MART-1 was independently cloned by two groups of scientists, which explains the two different designations (67). This melanocytic differentiation antigen is a small cytoplasmic protein (22 kD) with distinctive nucleotide sequences and genetic organization that is believed to be a melanosomal component. Tyrosinase is a key enzyme in melanin biosynthesis and represents a marker of melanocytic differentiation. T311, a murine monoclonal antibody to tyrosinase, is a reliable marker of melanocytes in paraffin-embedded sections (68). PNL2 is a relatively new monoclonal antibody directed against a fixative-resistant melanocyte antigen. The exact nature of the antigen recognized by PNL2 remains to be defined. The analysis of PNL2 immunostaining on a broad range of normal or malignant human tissues and on various melanocytic lesions revealed its high specificity (69). Despite the advent of these new markers, S100 and HMB-45 remain very important tools when dealing with tumors, and S100 remains the more sensitive (although not very specific marker) for neoplastic melanocytes, especially spindle cell lesions (e.g., desmoplastic melanoma).

Microphthalmia transcription factor, another novel melanocyte differentiation marker, was shown to be less sensitive and not restricted to melanocytes. D5 (monoclonal antibody to microphthalmia transcription factor) was generated from the consensus region shared by various isoforms of MITF. Only one isoform, MITF-M, is melanocyte specific. Other isoforms that are recognized by D5 can be found in various nonmelanocytic cell types (see Table 3-1) (70).

Ultrastructure

Melanocytes differ from keratinocytes by possessing no tonofilaments or desmosomes (Fig. 3-16A). At their base, where they lie in close apposition to the lamina densa, melanocytes show structures resembling, yet smaller than, hemidesmosomes of basal keratinocytes (71). Melanosomes are the most characteristic organelles of the melanocyte, and identification of various stages of their formation within a cell assists in its ultrastructural identification as a melanocyte (in contrast to keratinocytes that contain via transfer only fully melanized organelles) (Fig. 3-16B). Melanosomes are membrane-bound organelles that in their development from stage I to stage IV gradually move from the cytoplasm of the melanocyte into the dendritic processes. As melanosomes mature, their content of melanin increases, and their concentration of melanogenic enzyme decreases (72).

Stage I melanosomes are round, 0.3 μm in diameter, and contain no melanin (73). Stage II-IV melanosomes are ellipsoid and measure approximately 0.5 μm in length. They contain longitudinal filaments that are cross-linked with one another. Enzyme activity is present both on the enveloping membrane and on the filaments. Melanin deposition on the cross-linked filaments begins at stage II. Stage III melanosomes have only little tyrosinase activity but show continued melanin deposition, partially through nonenzymatic polymerization. Stage IV melanosomes are fully melanized and no longer possess tyrosinase activity. Melanin, which is homogeneous and electron dense, fills the entire organelle at this stage, obscuring its internal structure.

Regional and Racial Variation

The highest concentration of melanocytes is found on the face and the male genitals, about 2,000/mm^2, and the lowest on the trunk, about 800/mm^2 (74–76). No significant difference in the density of distribution of melanocytes for any given area of the skin exists between African-American and Caucasoid skin. In the former, the melanocytes are uniformly highly enzymatically reactive, whereas the melanocytes of Caucasoids, when not exposed to sunlight, are highly variable in dopa reactivity (77). In addition, African-American skin contains larger and more highly dendritic melanocytes than does Caucasoid skin (75,76). Finally, transferred melanosomes within keratinocytes of people of African descent tend to be individually distributed, whereas those in keratinocytes of Caucasians are packaged in membrane-enclosed aggregates (78–81).

Melanocytes in Sun-Exposed Areas

Regional variation of melanocyte number and morphology may also be influenced by environmental factors, such as sun exposure. After a single exposure to ultraviolet light *in vivo*, the skin of Caucasoids, when examined with the dopa reaction, shows no increase in the density of the melanocyte population but does show an increase in the size and functional activity of the existing melanocytes (82). Repeated exposure to ultraviolet light, however, causes an increase in the concentration of dopa-positive melanocytes, as well as an increase in their size and functional activity (77,83). Thus, examination of habitually exposed and of unexposed skin from adjacent anatomic sites, such as the lateral and medial aspects of the upper arm, has shown a twofold-higher concentration of melanocytes in the former, and the melanocyte concentration is even higher in areas such as head and neck (84).

Surgical pathologists and dermatopathologists often face the difficulty of having to distinguish melanocyte hyperplasia of sun-damaged skin from melanoma *in situ* (e.g., when evaluating surgical margins in melanoma excisions). It is known that melanocytes increase in number and size in sun-damaged skin (Fig. 3-17A,B). On immunohistochemical studies, long-standing sun-exposed skin has been reported to have an average of 15 to 20 melanocytes per high-power field (in 0.5 mm of skin) (84,85), some degree of contiguous growth (up to nine adjacent melanocytes), and melanocytes extending to hair follicles but not reaching the level of the uppermost portion of sebaceous glands. However, there should not be significant confluence, deep follicular penetration, nesting, or pagetoid spread.

Specialized Structure and Function

Melanogenesis

Enzymatic melanogenesis involves tyrosinase as the melanogenic enzyme (76,86). Tyrosinase is a copper-containing enzyme that

catalyzes the hydroxylation of tyrosine to dopa and the oxidation of dopa to dopa-quinone. However, before tyrosinase can act on tyrosine, two cupric atoms present in tyrosinase must be reduced to cuprous atoms. It is believed that, in addition to being a substrate, dopa activates this reduction, thereby acting as a cofactor in the reaction. The conversion of tyrosine to melanin by tyrosinase is characterized by a variable lag period. When tyrosinase is present in low concentrations, as in epidermal melanocytes of nonirradiated skin, this lag period is markedly prolonged, and no use of tyrosine by tyrosinase is detectable. In contrast, in skin exposed *in vivo* to ultraviolet light, as well as in epidermal sheets and in hair bulbs, tyrosinase activity is detectable with tyrosine as substrate (57,76,87). Because there is no lag period with dopa as substrate, tyrosinase in epidermal melanocytes can be readily demonstrated even in nonirradiated skin when skin sections are incubated in dopa rather than in tyrosine. The enzyme acting on dopa is therefore thought to be tyrosinase rather than dopa-oxidase.

The melanogenic enzyme tyrosinase is synthesized in the Golgi-associated endoplasmic reticulum, in which tyrosinase condenses in membrane-limited vesicles. This process has been observed by electron microscopy in epidermal melanocytes after *in vivo* ultraviolet irradiation with either dopa or tyrosine as substrate (88). Subsequently, these tyrosinase units are transferred to dilated tubules of the smooth endoplasmic reticulum. There, tyrosinase is incorporated into a structural protein matrix containing filaments that have a distinctive periodicity. This then represents a stage I melanosome (89). Few stage I and II melanosomes have acid phosphatase activity, but the proportion of acid phosphatase–positive melanosomes increases in stage III, reaching a maximum in stage IV (90). This enzyme may play a role in the degradation or transfer of melanosomes. Detailed analysis of nonmelanosomal regulatory factors in melanogenesis has revealed coated vesicles to be richest in tyrosinase and catalase, whereas premelanosomes have the highest concentrations of peroxidase (91). Among relevant metal ions, premelanosomes contain higher amounts of copper, zinc, and iron than do coated vesicles.

Melanin Transfer

The transfer of melanosomes from melanocytes to epidermal keratinocytes and to hair cortex cells is the result of active phagocytosis of the tips of melanocytic dendrites by keratinocytes and hair cortex cells as demonstrated in tissue cultures (92) and in epidermal reconstructs seeded with melanocytes (93). Once incorporated into keratinocytes, melanosomes aggregate to form protective parasoles above the keratinocyte nuclei. As previously noted, melanin in Caucasoids is concentrated in basal keratinocytes, whereas in people of African ancestry, distribution is more diffuse within the epidermis (94,95). Both melanin formation and melanin transfer are enhanced by various stimuli, notably by skin exposure to ultraviolet (UV) light. Recent data suggest a central role for p53 in UV-induced skin melanization and potentially certain forms of pathologic hyperpigmentation (96). UV-induced melanization, or sun tanning, requires the induction of α-melanocyte-stimulating hormone (α-MSH) secretion by epidermal keratinocytes. This phenomenon requires α-MSH generation as a cleavage product of pro-opiomelanocortin (POMC). p53 is believed to stimulate the POMC promoter in response to UV exposure, and mice genetically deficient in p53 fail to exhibit the normal tanning response. Accordingly, it is possible that p53 may function as, in addition to an inducer of apoptosis in UV-damaged cells, a sensor/effector of the tanning response, and even potentially as a trigger for certain pathologic forms of melanization.

Merkel Cells

Embryology

Although the origin of Merkel cells is unclear, it seems likely that they are differentiated from stem cells in the epidermis (97,98). The alternative hypothesis is that Merkel cells derive from the neural crest (97,99,100). The favored hypothesis, however, is that they arise between weeks 8 and 12 of gestational age from precursor stages of epithelial cells of early fetal epidermis that still express simple epithelial cytokeratins. *In situ* differentiation from epidermal ectoderm versus immigration of cells from the neural crest is supported by studies of fetal skin without Merkel cells transplanted to nude mice and subsequently found to contain mature Merkel cells within the engrafted tissue (101). Some Merkel cells detach from the epidermis and migrate temporarily into the upper dermis, where some of them associate with small nerves.

Normal Microanatomy

Merkel cells are present within the basal cell layer of the epidermis, oral mucosa, and the bulge region of hair follicles (102). They are quite scarce, irregularly distributed, and occasionally arranged in groups, often at tips of rete ridges (Fig. 3-18A), in eccrine glandular ridges of glabrous skin, in "Haarscheiben" of hairy skin, within beltlike clusters of hair follicles, and in certain mucosal tissues (103). It is assumed that the Merkel cell may represent a rudimentary touch receptor, more important in lower vertebrates (e.g., particularly in relationship to vibrissa hairs). The Merkel cell cannot be recognized in light microscopic sections; however, in silver-impregnated sections, the meniscoid neural terminal that covers the basal portion of each Merkel cell can be seen as a Merkel disk (104). A sensory nerve fiber may terminate at the disk. Immunohistochemistry for low–molecular-weight cytokeratins (CKs) such as CK8, 18, 19, and 20 more typical of simple epithelial cells than keratinocytes permits differential identification of Merkel cells in tissue sections (77). The most useful of these filamentous proteins is CK20, which has been shown to be a highly specific marker for Merkel cells because in human skin no other cell type expressing CK20 exists (103) (Fig. 3-18A).

By electron microscopic examination, Merkel cells usually are located directly above the basement membrane (105). They possess small, electron-dense, membrane-bound neurosecretory-type granules, strands of perinuclear intermediate

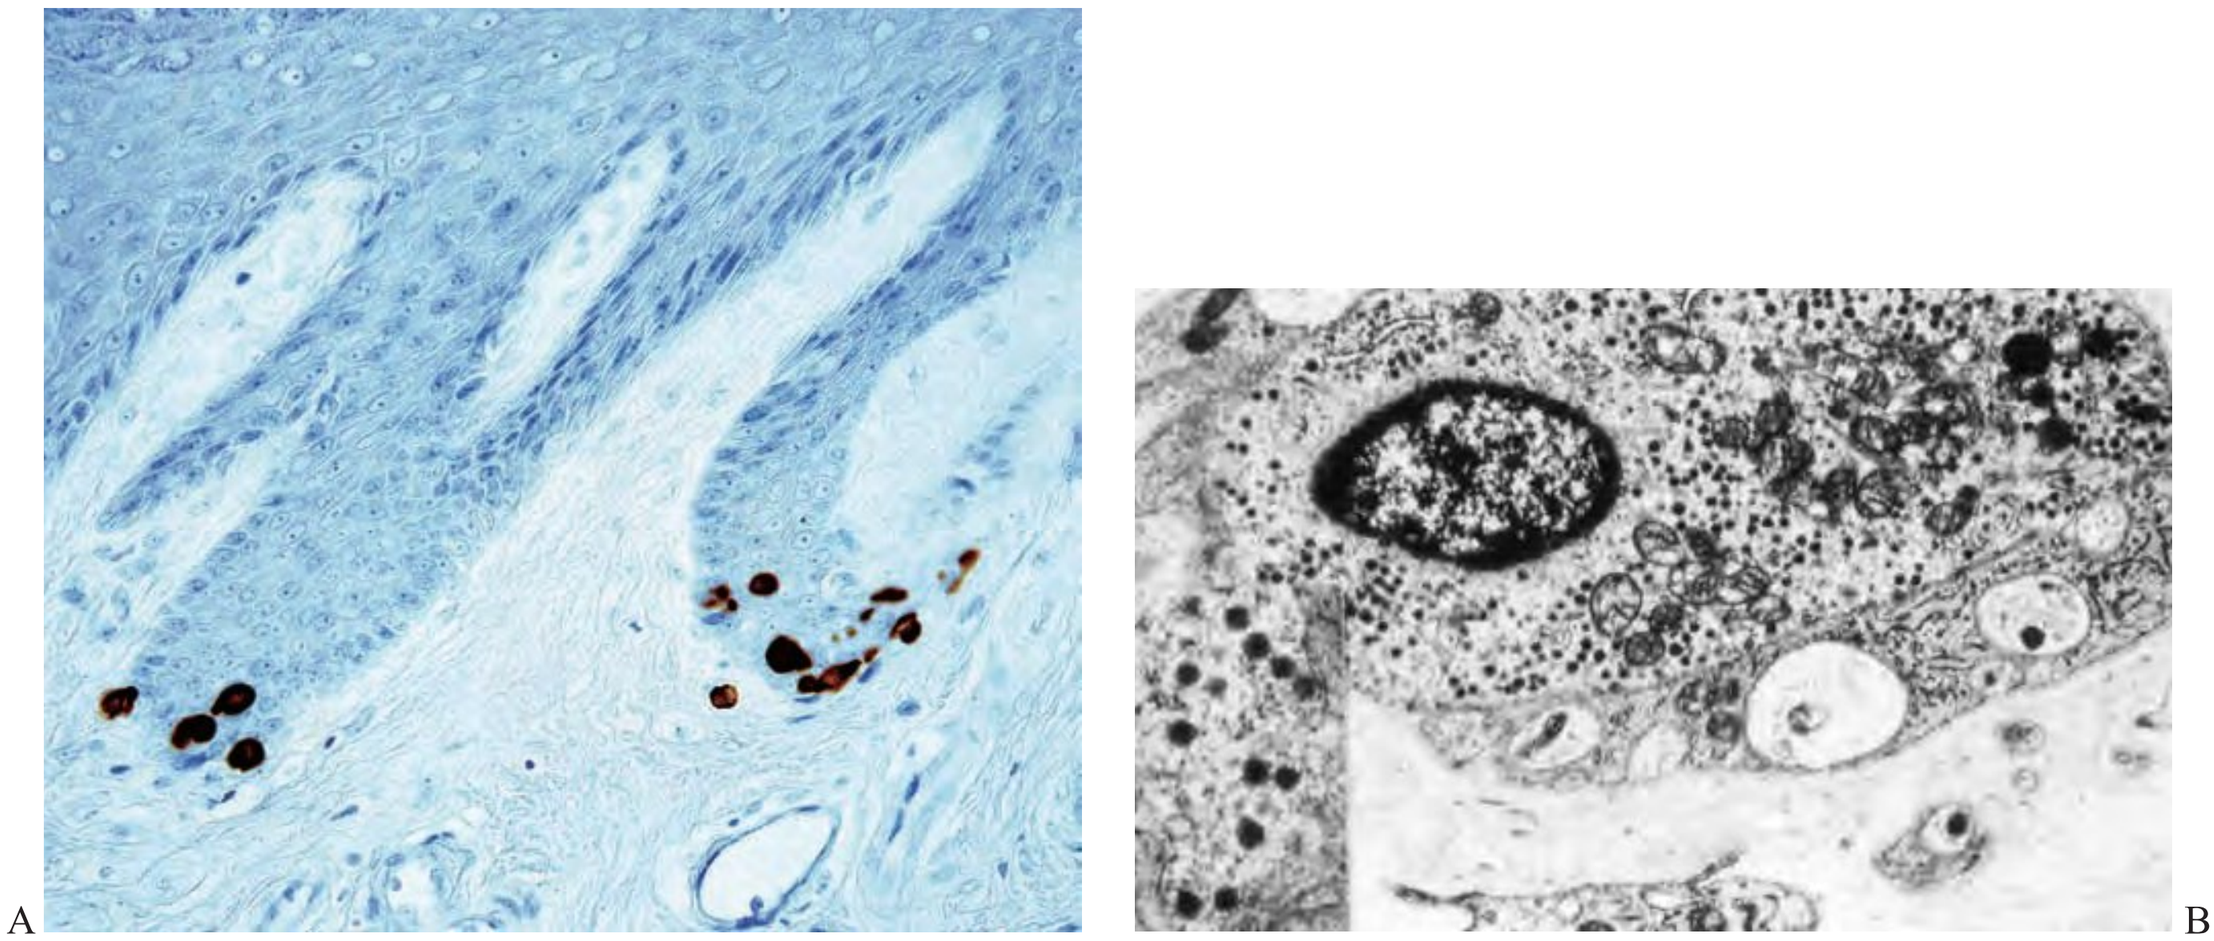

FIGURE 3-18. A: Immunohistochemistry with cytokeratin 20 highlights Merkel cells in the glabrous epithelium of the digit. They are often distributed, forming small groups at the tip of the rete ridges. B: By electron microscopy, Merkel cells contain characteristic neurosecretory granules.

filaments, and occasional desmosomes on their cell membranes connecting them with neighboring keratinocytes (Fig. 3-18B). The electron-dense granules vary in size between 80 and 200 nm and tend to be located at the side of cytoplasm in contact with axon terminals. Intermediate-type junctions are noted between axon terminals and Merkel cells.

Regional Variation

Merkel cells are most heavily concentrated in skin with high hair density and in glabrous epithelium of the digits, lips, regions of the oral cavity, and the outer root sheath of the hair follicle. These cells are present in mammals as so-called "touch-domes," also known as "Haarscheiben," a form of type I mechanoreceptor that surrounds tylotrich (large touch-sensitive) hairs and the rete ridge collars about external root sheaths of hair follicles.

An increase in Merkel cells is seen after chronic sun exposure and has also been described in the epidermal basal layer adjacent to prurigo nodularis, actinic keratoses, and tumors such as basal cell carcinomas (103).

Specialized Structure and Function

Merkel cells are specialized epithelial cells that react with the intermediate filament cytokeratin and desmosomal proteins (106,107). Of note, Merkel cells also express neuroendocrine markers such as chromogranin A, the matrix substance of the dense-core granules, as well as synaptophysin, supporting the view that they are epithelial neuroendocrine cells and that they may possess a neurosecretory function (103,108). Merkel cells also contain neuron-specific enolase and neurofilaments in their cytoplasm (109,110). The characteristic presence of specific cytokeratins (CK20) and neuroendocrine markers in Merkel cells is relevant to the diagnosis of Merkel cell carcinoma (primary neuroendocrine tumor of the skin), perhaps the only practical reason for the diagnostician to know about this mysterious cell type.

In addition to the expression of neuroendocrine markers, a variety of neurosecretory substances, in particular neuropeptides, that are stored within the dense-core granules have been demonstrated in Merkel cells. These neuropeptides include vasoactive intestinal polypeptide, calcitonin gene–related peptide (CGRP), serotonin, and substance P (103). Although some of these neurosecretory substances work as neurotransmitters, others have been demonstrated to promote growth and differentiation of various cutaneous cell types (103). However, any functional significance to their presence in human Merkel cells is unproven.

Langerhans Cells

Embryology

Langerhans cells are bone marrow–derived, dendritic, antigen-presenting cells that appear in the epidermis by 7 weeks of gestation, as documented by their positive staining for adenosine triphosphatase (ATPase) (Fig. 3-19). Although all Langerhans cells at this stage are ATPase positive, they are negative for their more characteristic and specific cell surface glycoprotein CD1a. At a gestational stage of 60 days, Langerhans cells begin to express CD1a reactivity. By 80 to 90 days, the number of CD1a-positive cells increases abruptly, and after 90 days, the expression of CD1a is approximately equivalent to the number of ATPase-positive Langerhans cells (111) (Fig. 3-20A,B).

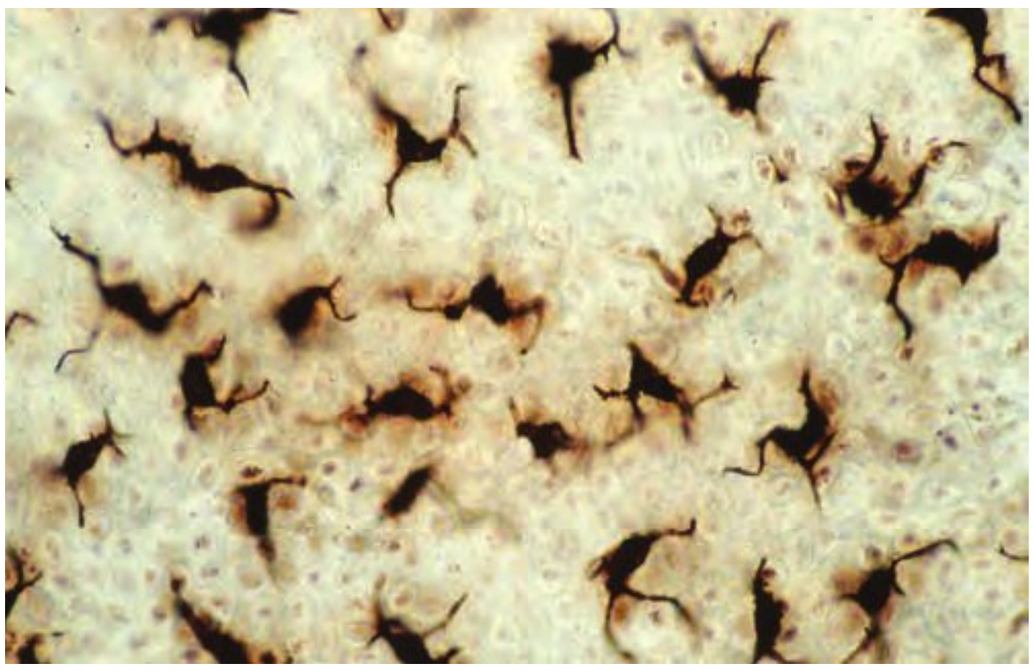

FIGURE 3-19. An epidermal sheet, removed and viewed en face, after adenosine triphosphatase enzyme histochemical staining. Note numerous, evenly distributed dendritic Langerhans cells.

S100 protein is not found in the Langerhans cells of fetal epidermis, but it can be demonstrated within 1 day after delivery (112). By electron microscopy, Langerhans cells can be identified by 10 to 11 weeks of gestation on the basis of the presence of Langerhans granules (Fig. 3-20 C).

Normal Microanatomy

Langerhans cells may be presumptively observed in histologic sections stained with hematoxylin-eosin as clear cells in the suprabasal epidermis. However, they cannot be reliably distinguished from occasional intraepidermal T lymphocytes and macrophages, and their dendritic cytoplasmic processes cannot be resolved. Because Langerhans cell detection is difficult in conventional sections, special stains are generally required for their detection and enumeration. Several enzyme histochemical stains have historically been used to identify Langerhans cells and to differentiate them from melanocytes. These

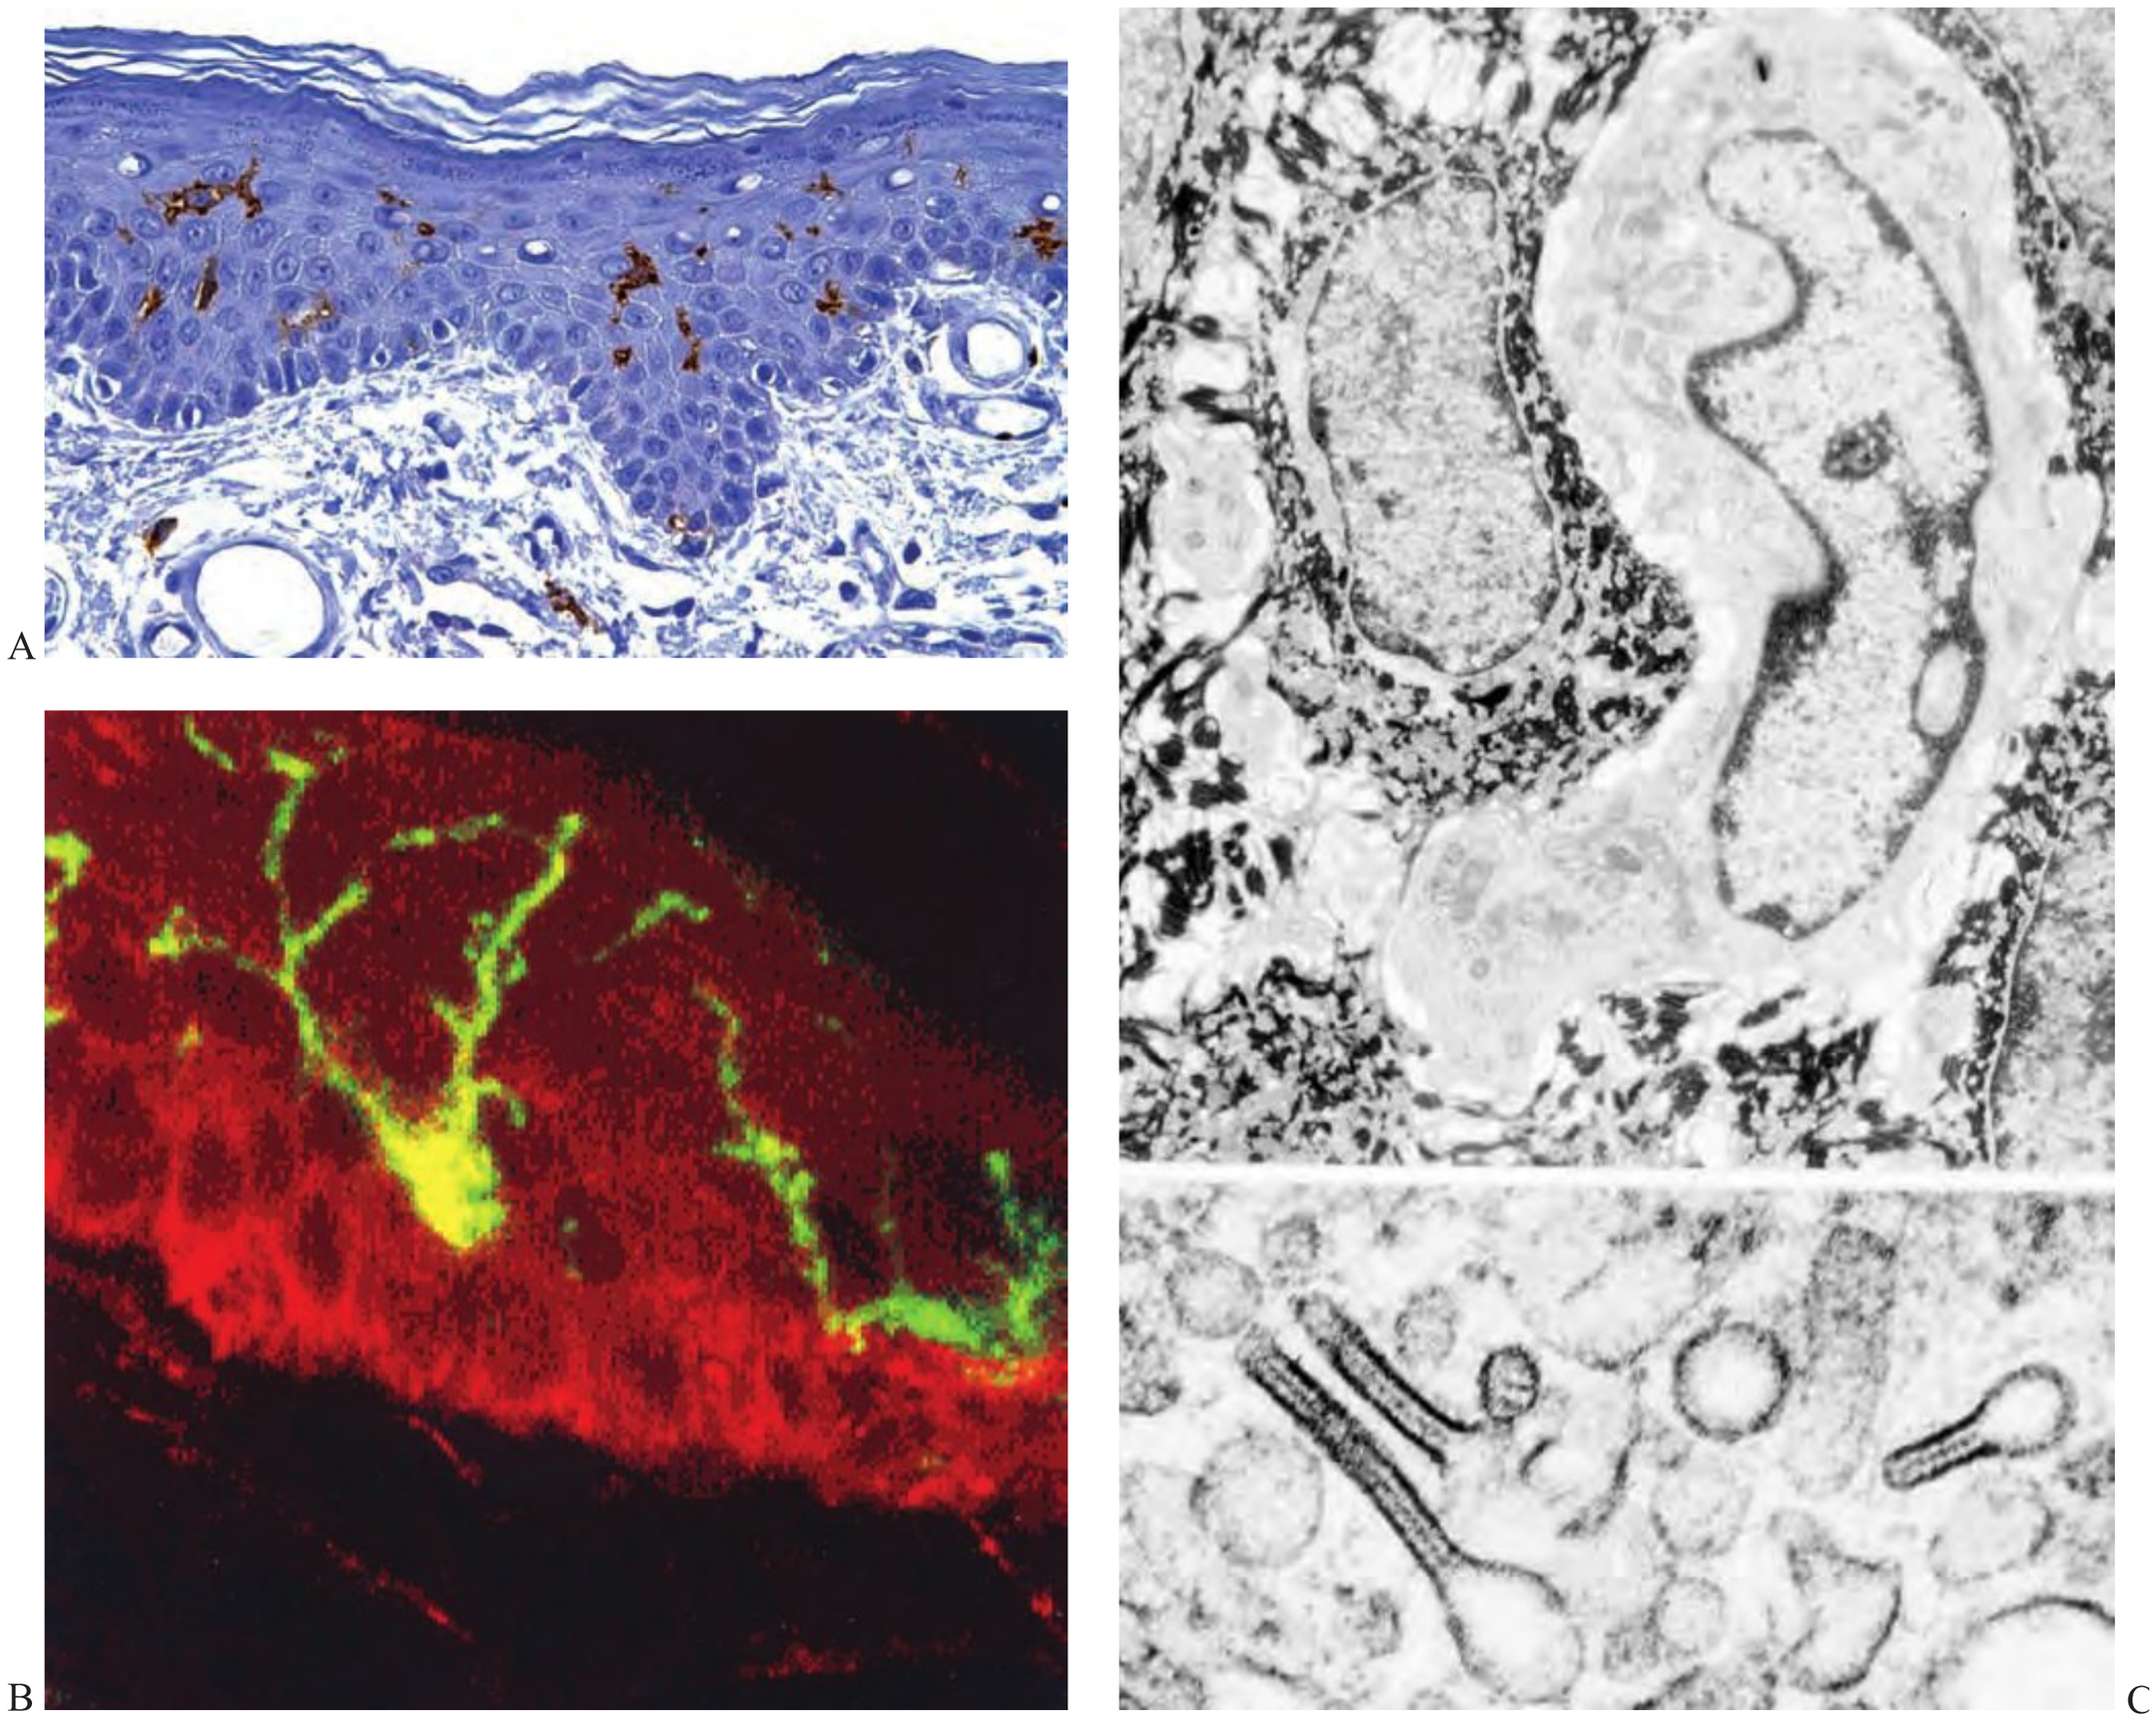

FIGURE 3-20. A: Anatomy of a human Langerhans cell. B: Typical dendritic morphology seen with immunohistochemical stain for CD1a and immunofluorescence detection of CD1a glycoprotein by confocal scanning laser microscopy. C: Transmission electron micrograph of Langerhans cell (top) and characteristic cytoplasmic granules (Birbeck granules) (bottom).

include ATPase (Fig. 3-19) and aminopeptidase (113). Langerhans cells are also positive for HLA-DR antigen and S100 protein, although the former also reacts with cells forming the acrosyringium (114), and the latter is found in melanocytes (Fig. 3-14). Langerhans cells can be demonstrated more specifically with monoclonal antibody to the prothymocyte differentiation cell surface glycoprotein CD1a when the antibody is labeled with either peroxidase or fluorescein (115–117) (Fig. 3-20A, B).

By electron microscopic examination, Langerhans cells show a markedly folded nucleus and no tonofilaments or desmosomes. Melanosomes are only rarely found in them, and, if they are, they always are located within lysosomes, indicating that they have been phagocytized (118). Of great interest is the regular presence of an organelle called the Langerhans or Birbeck granule in the cytoplasm of Langerhans cells (Fig. 3-20 C). The size of these granules varies considerably, from 100 nm to 1 μm (119). The granule has the three-dimensional shape of a disk and often shows a vesicle at one end and occasionally at both ends. A cross section of the disk portion has the appearance of a rod, and, if a vesicle is attached to the rod at one end, the Langerhans granule has the highly characteristic appearance of a tennis racquet. The rod-shaped cross section has a central lamella showing cross striation with a periodicity of 6 nm (119). Langerhans cell granules form as a consequence of endocytotic, clathrin-associated invaginations of the cell membrane of Langerhans cells. This was first recognized on the basis of the presence of intradermally injected peroxidase within the granules of Langerhans cells, even though the peroxidase molecule cannot cross the cell membrane (120). In addition, on incubating Langerhans cells with a gold-labeled antibody directed against the CD1a glycoprotein of the cell membrane of the Langerhans cell it was found that the labeled CD1a was internalized and appeared within Langerhans granules (121). The histiocytes present in the cutaneous and visceral lesions of histiocytosis X contain Langerhans granules. These granules are indistinguishable in their electron microscopic appearance from those seen in epidermal Langerhans cells (122,123). Cells that have the ultrastructural features of Langerhans cells but lack the Langerhans granule have been called indeterminate cells. They react specifically with the monoclonal antibody to CD1a (124,125).

Regional Variation

Langerhans cells are present in the epidermis in a concentration similar to that of melanocytes, between 460/mm^2 and 1,000/mm^2. In contrast to melanocytes, their number does not increase but instead may decrease with repeated exposure to ultraviolet light (113). CD1a-positive Langerhans cells have been found to be less plentiful in trunk skin than extremity skin (126). However, there appears to be considerable site variation among individuals, and the best comparison for determination of site-matched normal Langerhans cell numbers may be uninvolved skin directly adjacent to the lesion under study (126). Langerhans cells are present not only in the skin but also in the oral mucosa, the vagina, lymph nodes, and the thymus; occasionally, they are seen in the dermis (127). Their numbers may vary significantly in pathologic processes, in part as a result of local accumulation or their tendency actually to migrate on stimulation (128).

Specialized Structure and Function

Langerhans cells originate in the bone marrow and are functionally and immunologically related to the monocyte-macrophage-histiocyte series (129). Langerhans cells constitute 2% to 4% of the total epidermal cell population, and they tend to be evenly distributed such that their dendrites extend toward the epidermal surface in a uniform manner (130). A few Langerhans cells are present in the dermis of normal skin. Langerhans cells express immune response–associated antigens class II (HLA-DR in humans, Ia in mice) (131,132), leukocyte common antigen (133) Fc and C3 receptors, CD1a antigen (116–118), CD1c (M241) antigen (134), a membrane-bound ATPase (130), S100 protein, and actin-like and vimentin filaments. These markers are compatible with an active role in cutaneous immunity.

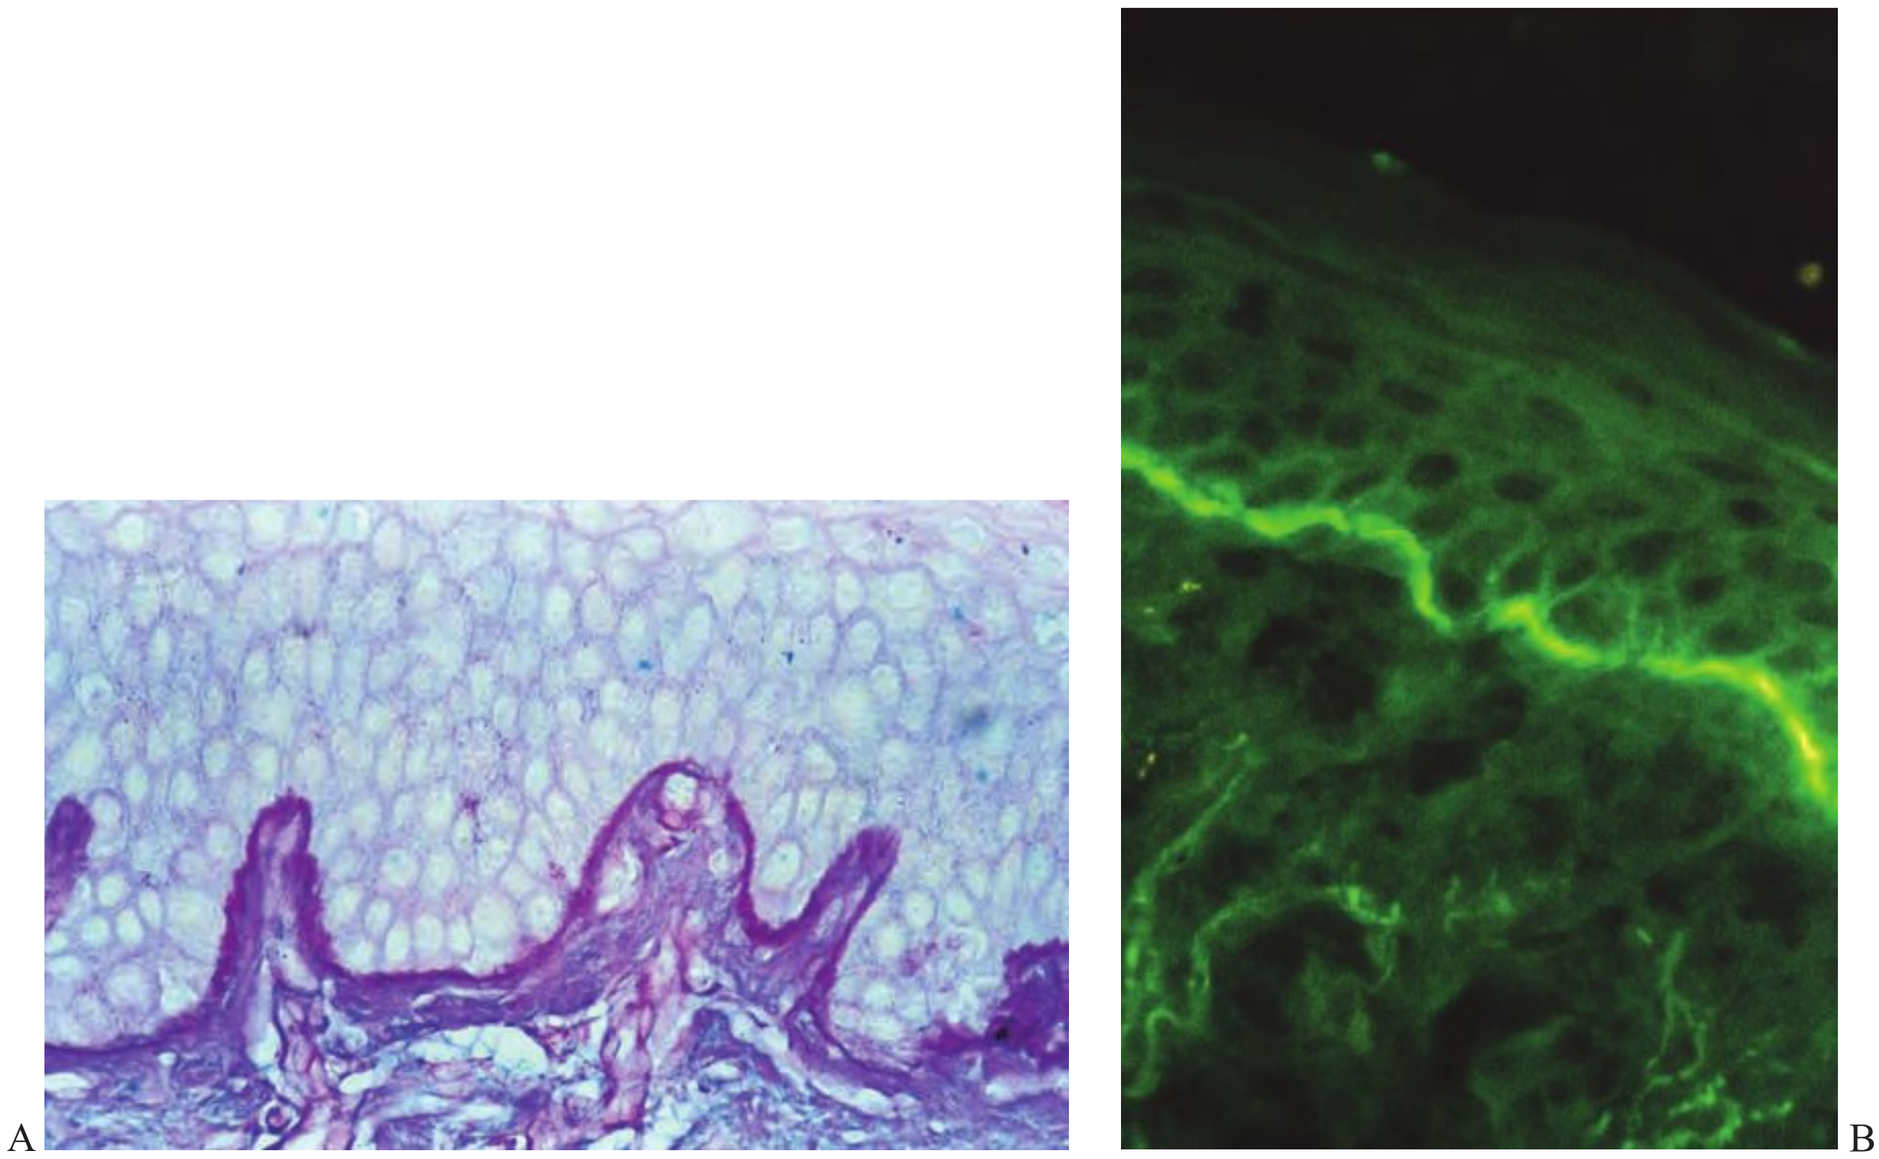
Langerhans cells have antigen-processing and antigen-presenting capacity. The recognition of a soluble protein and haptenized antigens by T lymphocytes requires the initial uptake and processing by an HLA-DR–positive cell like the Langerhans cell, which then presents immunologically relevant signals to the T lymphocytes. This often involves active migration of the antigen-bearing Langerhans cell from the epidermis into the dermis, where transit to draining lymph nodes occurs via lymphatic channels. In the lymph node, naive T cells are plentiful for receipt of the antigenic signals communicated by the Langerhans cells in a class II (HLA-DR)–dependent manner. Such T-cell sensitization results in the formation of memory T cells with the ability to recall and respond to the specific antigenic peptide on reexposure or challenge. This mechanism is believed to provide an important component to normal cutaneous immunosurveillance, as well as the underpinning of the contact hypersensitivity reaction.

Ultraviolet radiation interferes with the antigen-presenting capacity of Langerhans cells. After UV irradiation fewer Langerhans cells could be demonstrated in the skin (135). It is likely that this initial decrease of Langerhans cells is due to a temporary loss of membrane markers rather than to a destruction of the cells. Chronic repeated exposure to UV light may result in actual depletion of cells, contributing to potential for carcinogenesis as a result of impaired immunosurveillance. Similar depletion of Langerhans cells may result from application of potent topical corticosteroids (136) and in the setting of acquired immunodeficiency syndrome (137). With respect to the latter, viral particles have been identified in Langerhans cells (138), which, it is interesting to note, express one of the HIV receptors, CD4 (139). Replenishment of Langerhans cells after depletion has been accomplished by application of topical retinoids (140).

Basement Membrane Zone

Normal Microanatomy, Ultrastructure, and Molecular Structure

The basement membrane is an inconspicuous structure of enormous junctional significance, bonding together the protective epidermal layer and adnexal structures with the adjacent dermis.



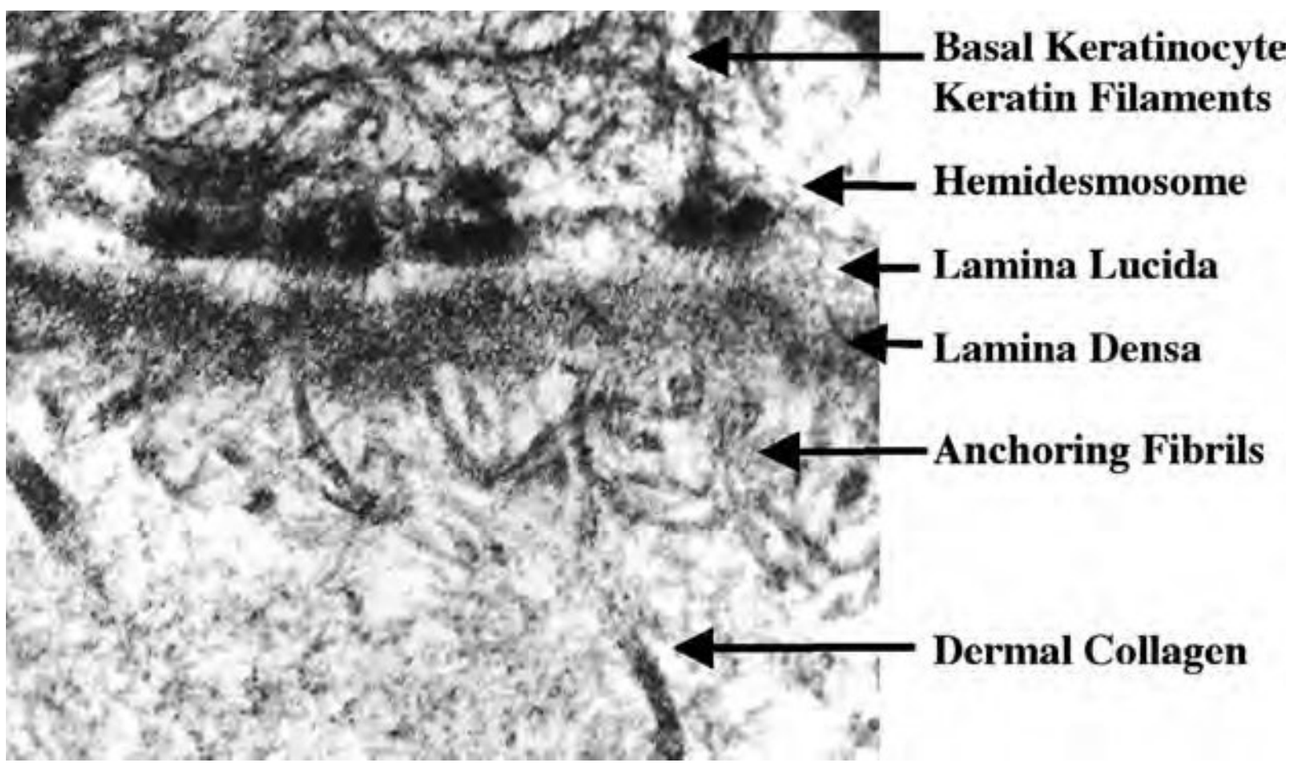


FIGURE 3-21. A: Demonstration of normal basement membrane zone separating epidermal and dermal layers by periodic acid Schiff stain. B: By direct immunofluorescence staining for the basement membrane–associated structural protein bullous pemphigoid antigen, a linear band is observed along the dermal–epidermal junction.

A subepidermal basement membrane zone not visible in sections stained with hematoxylin-eosin is seen on staining with the periodic acid Schiff (PAS) stain or by immunofluorescence as a 0.5- to 1.0-μm-thick homogeneous band (141) (Fig. 3-21). Its positive PAS reaction indicates a relatively large number of neutral mucopolysaccharides in this zone. Furthermore, impregnation with silver nitrate reveals a meshwork of reticulum fibers in the uppermost dermis. Staining with alcian blue, which identifies the band of polysaccharides and the reticulum meshwork, reveals that the band of polysaccharides is located above the reticulum layer (142). The light microscopic PAS-positive subepidermal basement membrane zone appears heterogeneous on electron microscopy (Fig. 3-22). The plasma membrane at the undersurface of basal cells shows hemidesmosomes ("half-desmosomes") possessing only one intracytoplasmic attachment plaque, to which tonofilaments from the interior of the basal cell are attached (Fig. 3-22). The cytoskeletal intermediate filaments within basal keratinocytes that insert into hemidesmosomes are composed predominantly of keratins 14 and 5 (143,144) (Fig. 3-23).

FIGURE 3-22. Transmission electron microscopy of the basement membrane separating the epidermis and dermis. Hemidesmosomes, lamina lucida, lamina densa, and anchoring fibrils can all be seen in this image.

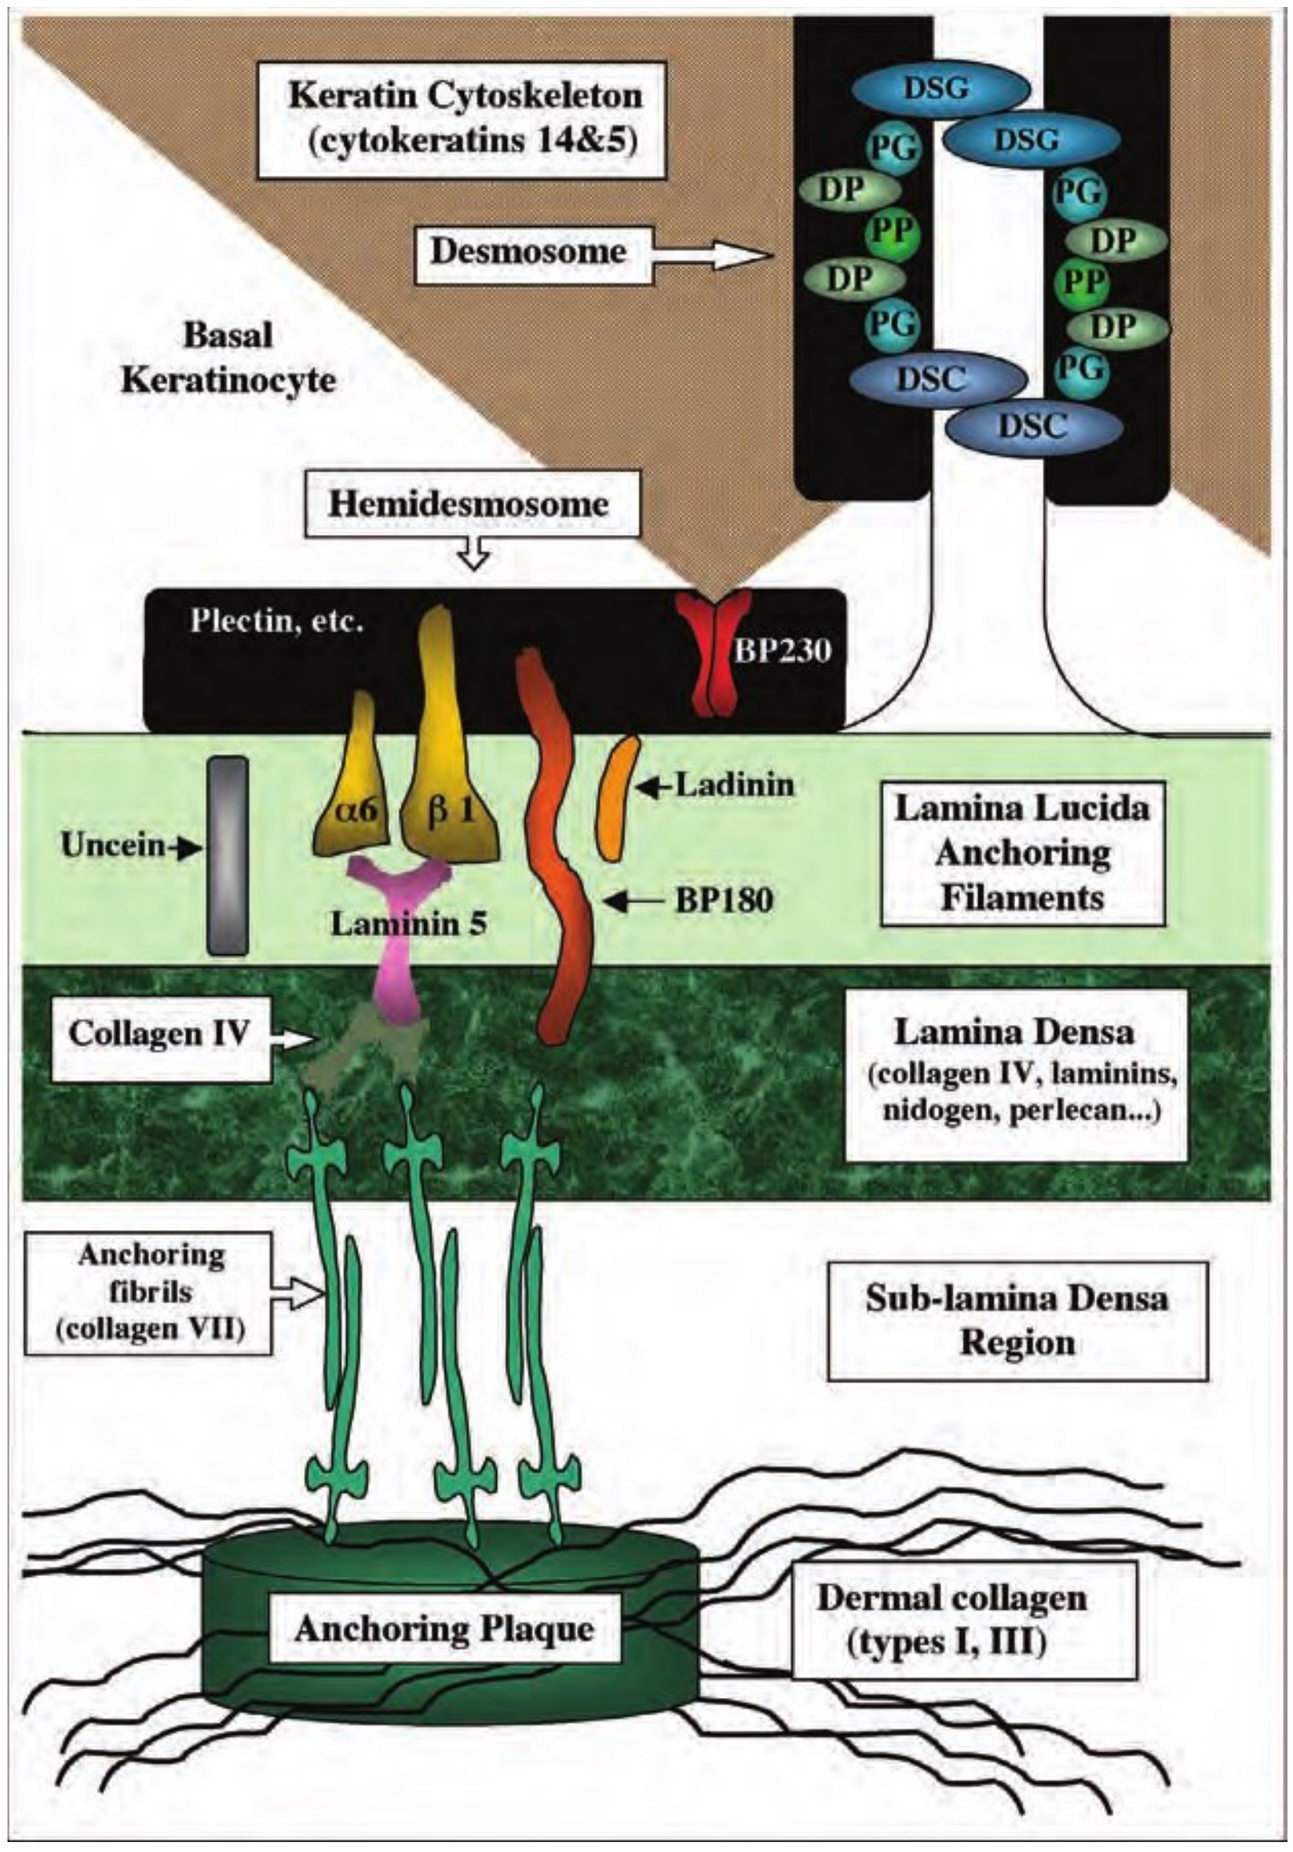

FIGURE 3-23. Diagram illustrating the different components of the desmosome and basement membrane zone. DP, desmoplakin; DSC, desmocollin; DSG, desmoglein; PG, plakoglobin; PP, plakophilin.

Hemidesmosomes contain plaque proteins involved in intermediate filament anchorage including bullous pemphigoid antigen 1 (BPAG1; 230 kD) and plectin, transmembranous proteins including bullous pemphigoid antigen 2 (BPAG2; 180 kD), and integrin α6β4. Additional components of the hemidesmosomes include IFAP300, p200, and other molecules not yet fully characterized. Bullous pemphigoid antigens are easily demonstrated by immunofluorescence as a smooth linear band that separates the epidermal and dermal layers (Fig. 3-21B). Beneath the plasma membrane of the basal cells, a rather electron-lucent zone called the lamina lucida separates the trilaminar plasma membrane, about 8 nm wide, from the more electron-dense component of the basement membrane, or lamina densa (141). Anchoring filaments extend from the basal cell plasma membrane to the lamina densa, traversing the lamina lucida (Fig. 3-23). Anchoring filament components include BPAG2 and α6β4 integrin, which extend from the basal cell membrane into the lamina lucida. BPAG2 exhibits features of a collagen molecule, and it is also referred to as collagen XVII. The 97-kD/120-kD protein ladinin, an important antigen in linear immunoglobulin A (IgA) dermatosis (lamina lucida type), is considered to represent a degradation product of the 180-kD bullous pemphigoid antigen (BPAG2) (145). Other proteins in the lamina lucida that are associated with these anchoring filaments include laminin 5 (also called kalinin, nicein, or epiligrin), uncein (defects in uncein are known to be involved in the recessive junctional type of epidermolysis bullosa), laminin 1, and nidogen (entactin). Although the molecular binding interactions are undoubtedly complex, it is known that α6β4 integrin is a receptor for laminin 1 and 5, and that laminin 5 (epiligrin) is a ligand for α3β1 integrin, which is also expressed by basal keratinocytes. Such adhesive interactions are likely to contribute to the anchoring of basal cells to underlying lamina lucida. Nidogen within the lamina lucida is a 150-kD protein that facilitates adhesion between specific domains of laminin and type IV collagen within the

adjacent lamina densa. Anchoring fibrils are short, curved structures with an irregularly spaced cross-banding of their central portions (146). They fan out at either end, the distal part inserting into the lamina densa and the proximal part terminating in the papillary dermis or looping around and merging in the lamina densa. They insert into amorphous patches containing type IV collagen, which is the main component of the lamina densa (146). The lamina densa itself is anchored to the underlying dermis in part by anchoring fibrils. The anchoring fibrils derive, at least in part, from the dermis and contain type VII collagen (147). The anchoring fibrils connect with islet-like anchoring plaques in the subjacent dermis. These anchoring plaques have a basement membrane–like composition (144). These anchoring structures are interwoven with the dermal interstitial type I and type III collagen fibers, resulting in the adhesion of the basement membrane to the dermis. In addition to anchoring fibrils, elastic fibers consisting of microfibril bundles and individual microfibrils approximately 10 nm in diameter are attached to the undersurface of the lamina densa. Three varieties of elastic tissue exist: oxytalan, elaunin, and elastic fibers (148). The oxytalan fibers consisting of microfibrils form a thin, superficial network perpendicular to the dermoepidermal junction. They originate from a plexus of elaunin fibers located parallel to the dermoepidermal junction in the upper dermis. The elaunin fibers are connected with the thicker elastic fibers of the middle and deep dermis. Effective anchoring of the epidermis to the dermis is a function largely of the anchoring fibrils; anchoring of the basement membrane by oxytalan fibers is quite sparse (149). Defects in basement membrane zone adhesive molecules due to autoantibodies or gene defects may result in disorders characterized by dermal–epidermal separation, as in bullous pemphigoid (BPAG1 and 2 = targets), cicatricial pemphigoid and Herlitz-type junctional epidermolysis bullosa (laminin 5 and uncein = target), and epidermolysis bullosa acquisita, dystrophic epidermolysis bullosa, bullous systemic lupus erythematosus, and some cases of linear IgA disease (type VII collagen = target), discussed further in Chapters 6 and 9.

In addition to their critical adhesive junctions, basement membrane related proteins have recently been shown to subserve other important functions. Certain protein components of the hemidesmosomes have more than just a structural role; for example, integrin $\alpha 6\beta 4$ is able to transduce signals from the extracellular matrix to the interior of the basal cells modulating the organization of their cytoskeleton and their proliferation, apoptosis, and differentiation (150).

Hair Follicles

Embryology

Hair germs, or primary epithelial germs, are first observed in embryos in the eyebrow region and the scalp during the third month of gestation (151). The general development of hair begins in the fourth fetal month in the face and scalp and gradually extends in a cephalocaudal direction. Thus, during the fourth month, while some hair follicles on the head are already well matured and are producing hair, most of those on the trunk are barely differentiated (152). In addition, new primary epithelial germs continue to form adjacent to more-established ones so that, in any section obtained from the beginning of the fifth month up to birth, hair structures in different stages of development are found (153).

Hair germs, or primary epithelial germs, in their earliest stage of development consist of a cluster of tightly aggregated, deeply basophilic cells in the basal cell layer of the epidermis. Subsequently, these develop into buds that protrude into the dermis (Figs. 3-24 and 3-25). Beneath each bud lies a zone of plump mesenchymal cells from which the dermal hair papilla

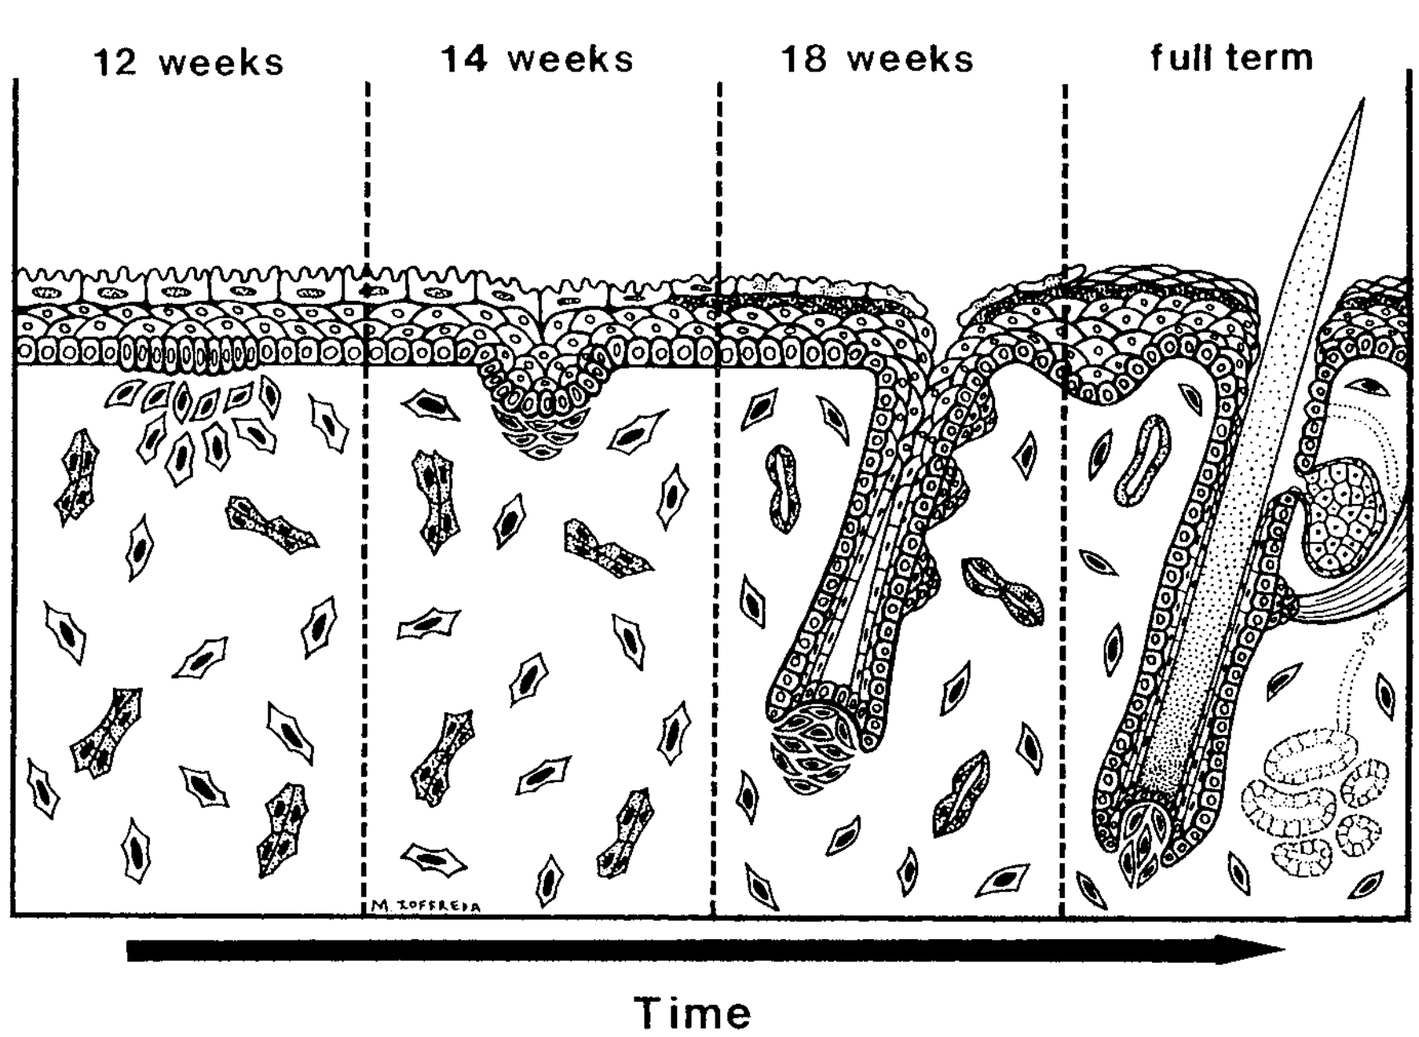

FIGURE 3-24. Schematic overview of embryonic trichogenesis in human skin. (Courtesy of Dr. Michael Ioffreda.)

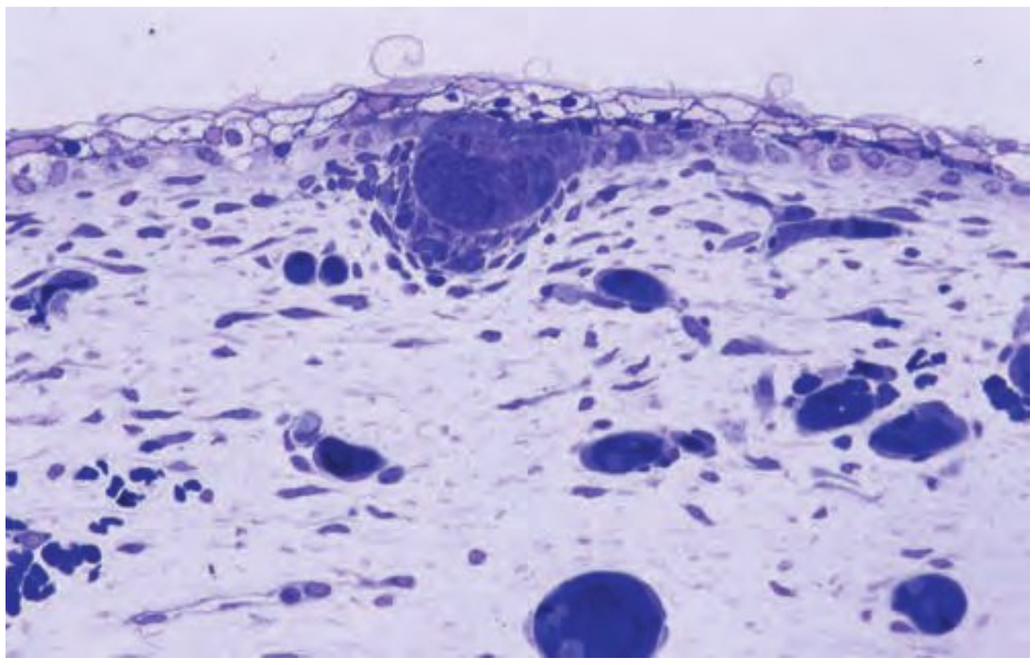

FIGURE 3-25. Histology of early trichogenesis, showing the formation of a primary epithelial germ with associated underlying mesenchymal condensation (1-μm-thick, plastic-embedded section).

is later formed. As the primary epithelial germ grows deeper into the dermis under the inductive influence of the underlying mesenchymal cells, it forms first the hair peg and then, as the hair matrix cells and the dermal hair papilla develop, the bulbous hair peg (154). Ultrastructural observations suggest that the "hair germ mesenchymal cells" pull down the hair germ as they move deeper in the dermal mesenchyme (151).

As the bulbous peg stage is reached, differentiation occurs in the lower and upper portions of the hair follicle and in the overlying epidermis. Differentiation in the lower portion of the follicle leads to the formation of the hair cone and subsequently to the formation of the hair, the cuticle, and the two inner root sheaths. The hair canal in the upper portion of the hair follicle, located at the level of the upper dermis, is formed by the premature death of the central core cells before they have become keratinized. In contrast, the intraepidermal portion of the hair canal is produced by means of premature keratinization and subsequent dissolution of the matrix cells of the cordlike hair canal extending obliquely through the epidermis. By the time the hair cone has reached the upper portion of the hair follicle, the hair canal is already open within the dermis and epidermis (155).

The hair follicles grow at a slant and, in the late hair peg or early bulbous stage, develop two or three bulges on their undersurface. The lowest of the three bulges develops into the attachment for the arrector pili muscle and is associated with the follicular stem cell niche; the middle bulge differentiates into the sebaceous gland. The uppermost bulge, if present, either involutes or develops into an apocrine gland. Apocrine glands develop only in certain regions (156). The intraepidermal portion of the hair canal seems to form by lysosomal digestion of cellular cytoplasm analogous to the formation of the intraepidermal eccrine duct and of the intrafollicular apocrine duct (155).

In sections treated with the dopa reaction or stained with ammoniated silver nitrate, melanocytes are distributed at random in primary epithelial germs and in hair pegs. During the bulbous peg stage, the melanocytes concentrate in the so-called pigment matrix region (the basal cell layer lying on top of the dermal hair papilla) and to a lesser degree in the lower hair bulb located lateral to the dermal hair papilla (153).

Normal Microanatomy

General Anatomic Features

The hair follicle, with its hair in longitudinal sections, consists of three parts: the lower portion, extending from the base of the follicle to the insertion of the arrector pili muscle; the middle portion, or isthmus, a rather short section, extending from the insertion of the arrector pili to the entrance of the sebaceous duct; and the upper portion, or infundibulum, extending from the entrance of the sebaceous duct to the follicular orifice (Figs. 3-26 to 3-33). The lower portion of the hair follicle is composed of five major portions: the dermal hair papilla; the hair matrix; the hair, consisting inward to outward of medulla, cortex, and hair cuticle; the inner root sheath, consisting inward to outward of inner root sheath cuticle, Huxley layer, and Henle layer; and the outer root sheath (Figs. 3-27

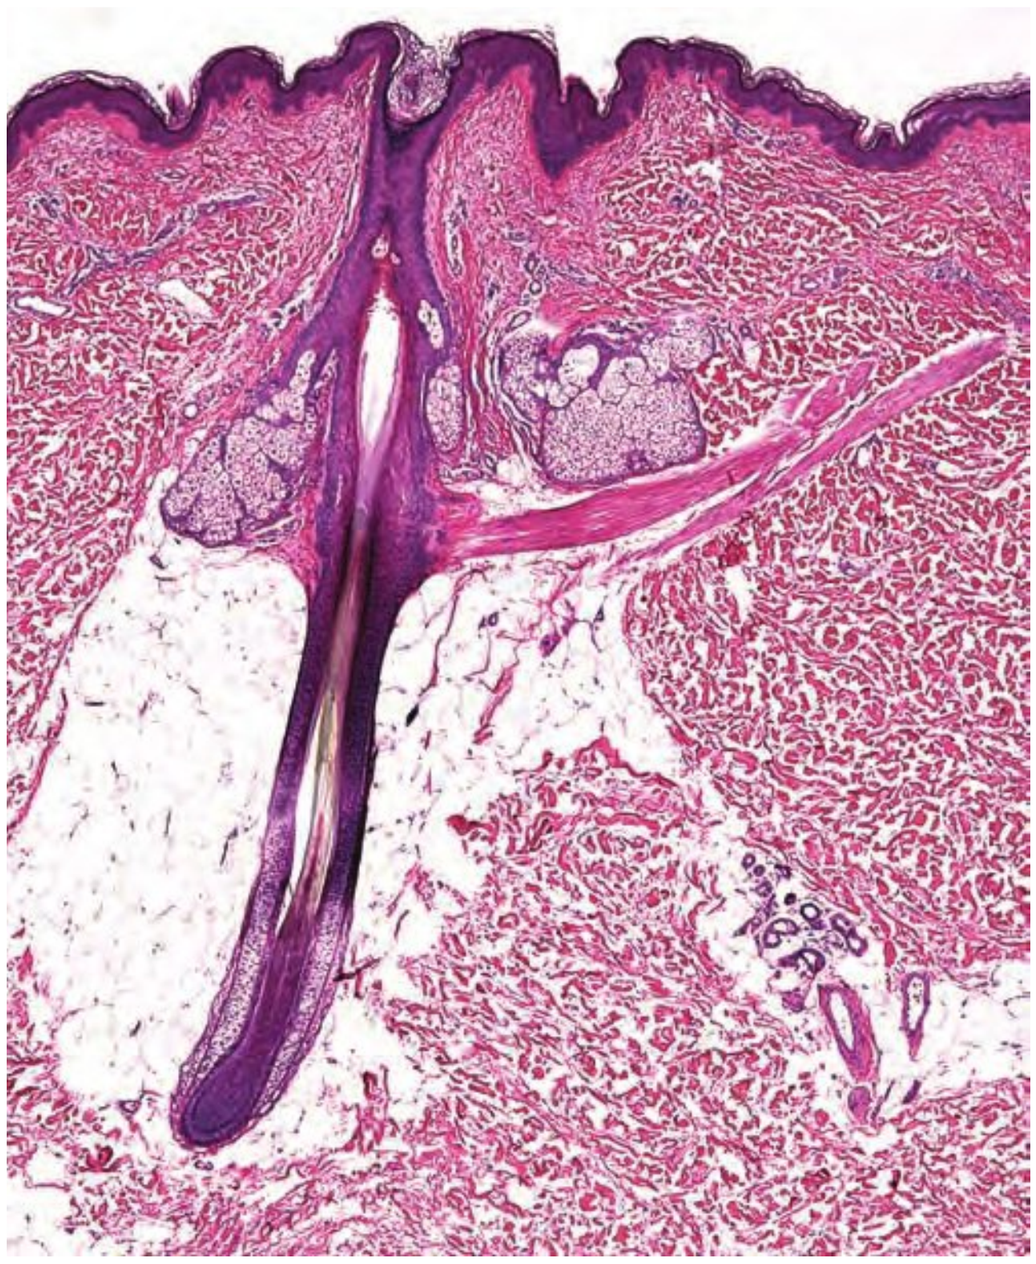

FIGURE 3-26. Low-power view of a hair follicle to illustrate its four zones. From bottom to top: the hair bulb, the suprabulbar zone (at which point the various layers of the follicle start to differentiate), the isthmus (located between the arrector pili muscle and entrance of the sebaceous duct), and the infundibulum (the uppermost zone of the follicle, whose inferior boundary is represented by the entrance of the sebaceous duct).

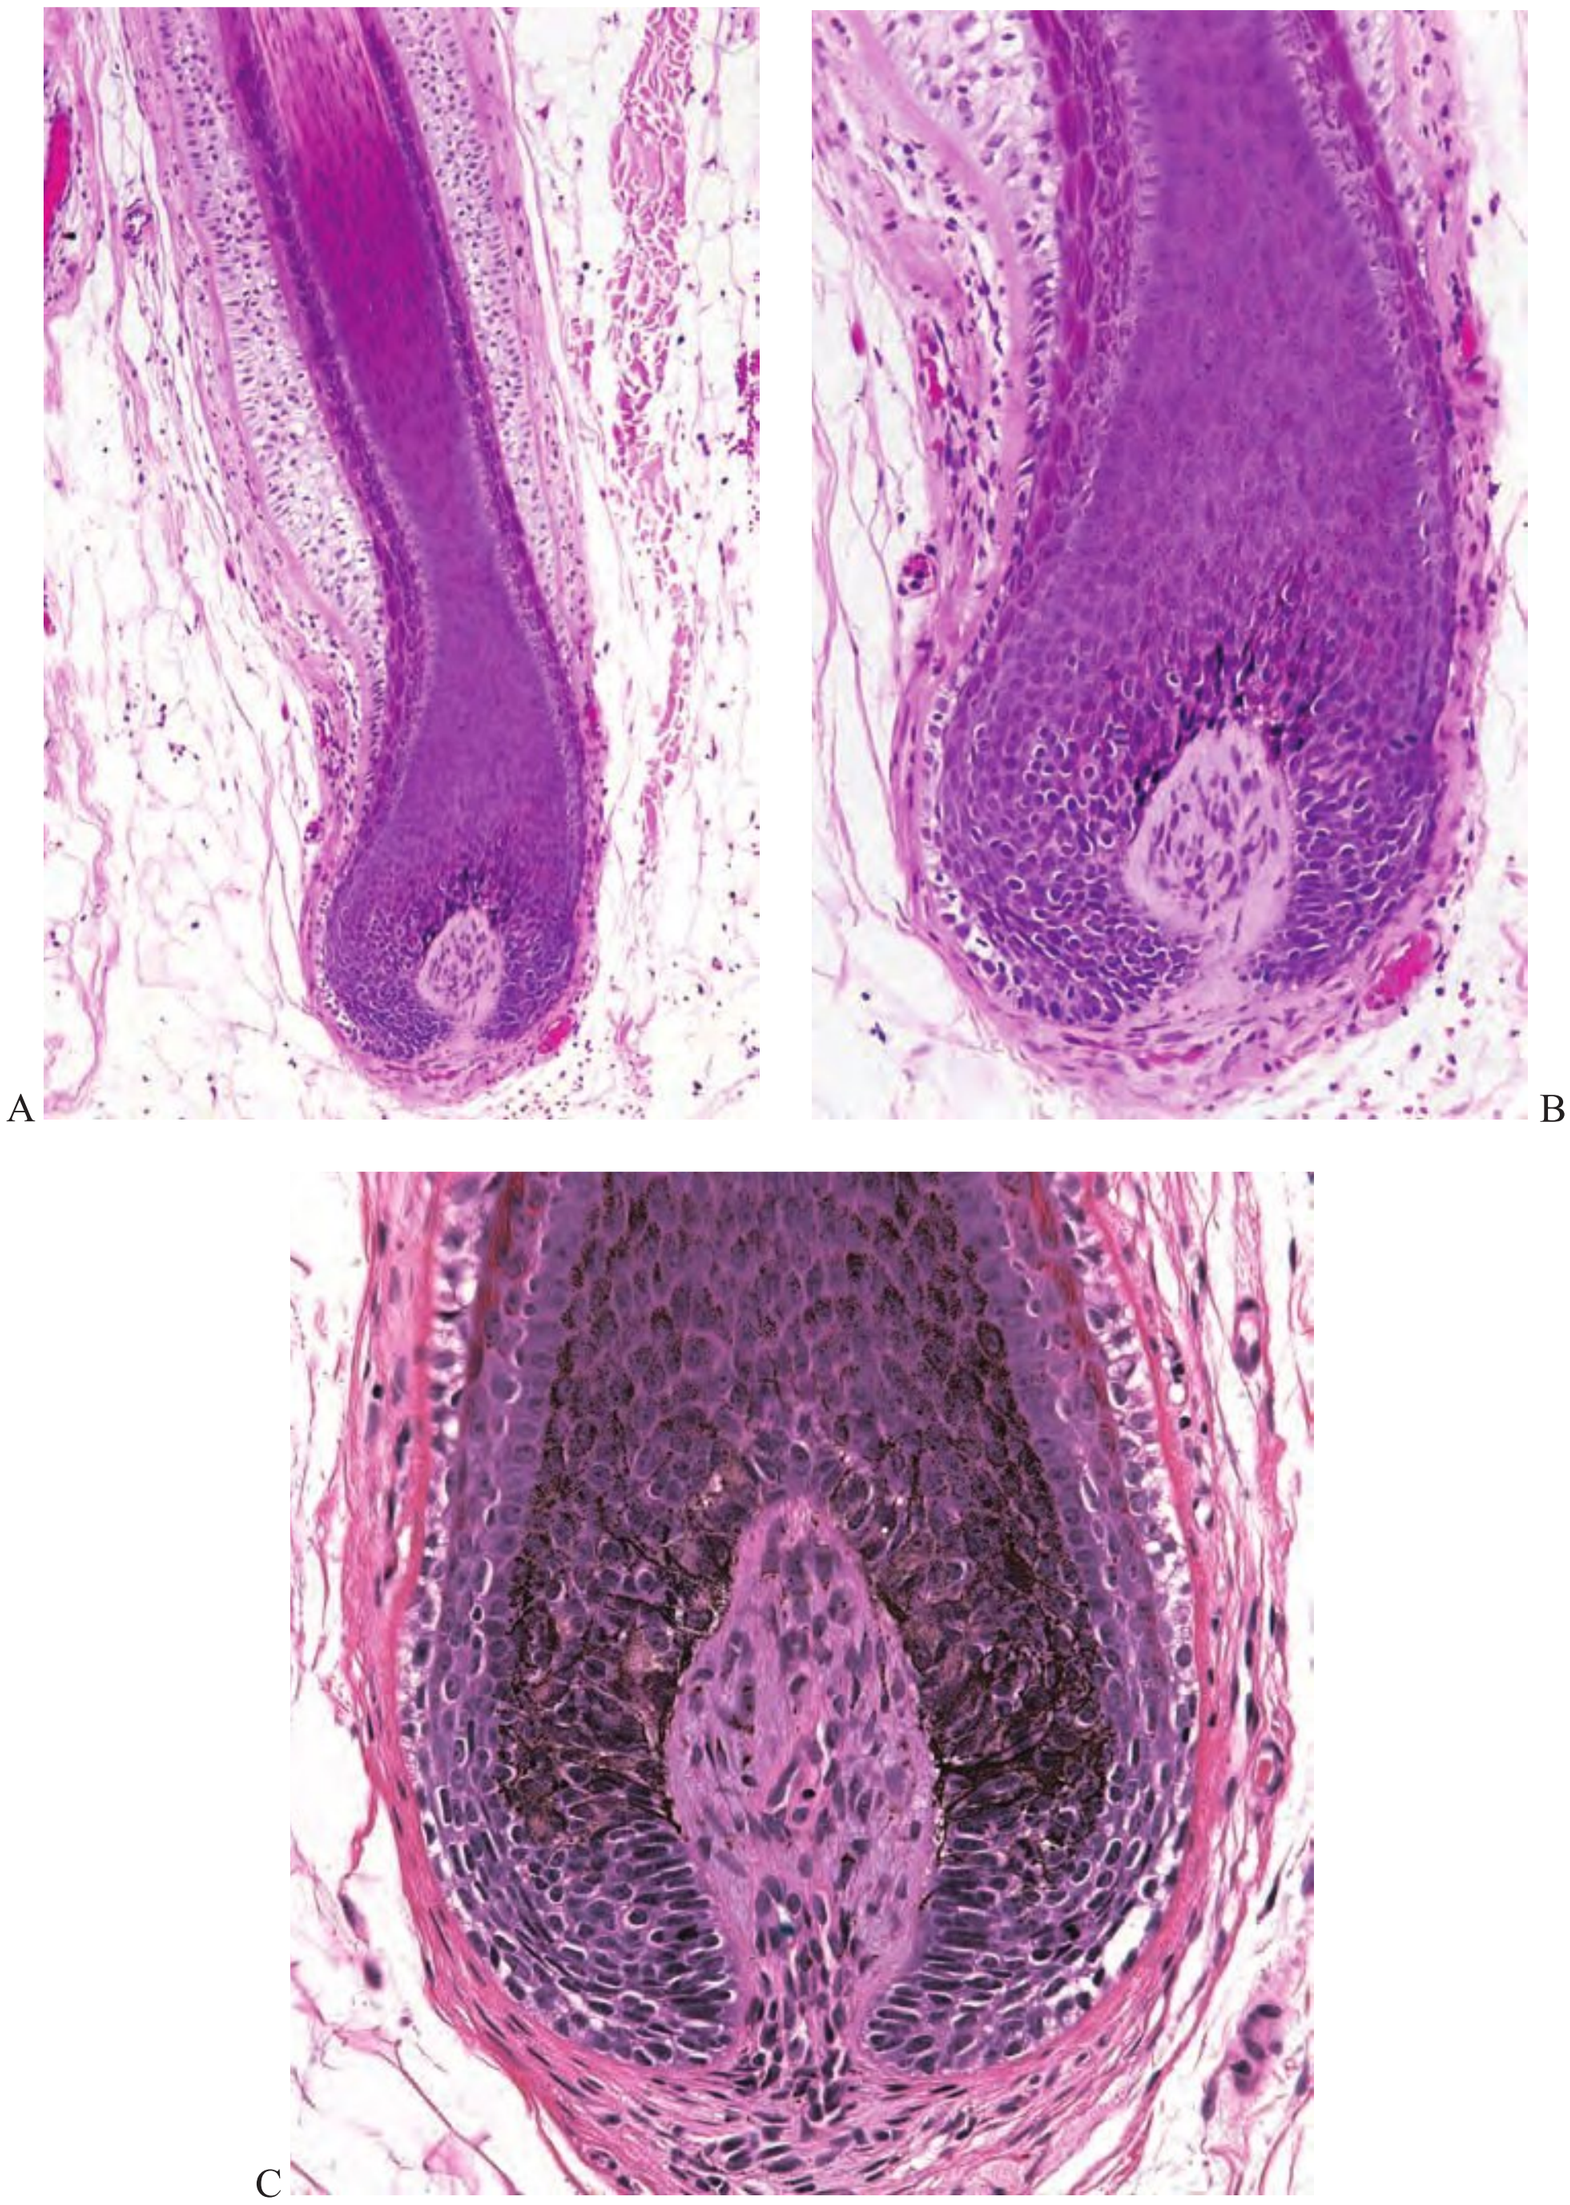

FIGURE 3-27. Histology of the lower portion of the human hair follicle. A: The terminal anagen hair bulb is usually located in the deep dermis or superficial subcutaneous tissue. B: The basophilic hair matrix surrounds the dermal papillae. C: Note the pigmented and dendritic melanocytes in the suprapapillary matrix. The typically mucinous inferior portion of the follicular papilla (stalk) is continuous with the fibrous root sheath.

and 3-28). This bulb region gives rise to the formation of the hair shaft that occupies the overlying follicular canal (Figs. 3-27 and 3-28). The hair shaft is predominantly composed of keratin. The large keratin multigene family comprises the epithelial keratins and the hair keratins, the latter involved in the formation of hard keratinized structures such as hair and nail. Recent studies have found that the human hair keratin family consists of nine type I and six type II members, whose genes are organized as distinct clusters within the type I and type II epithelial keratin gene domains (157,158).

Cycles of Hair Growth

The size of the hair follicles varies from long and thick terminal hairs with their bulbs in the fat to thin, short, and often hypopigmented vellus hairs with bulbs located in the upper dermis (Fig. 3-31). Regardless of size, every follicle goes through the three phases of the "hair cycle." The histologic appearance of the hair follicle changes considerably during the hair cycle, which causes the hair to turn from an anagen hair into a catagen hair, then into a telogen hair, and finally into a new anagen hair (Chapter 18). In the adult scalp, the anagen stage—the

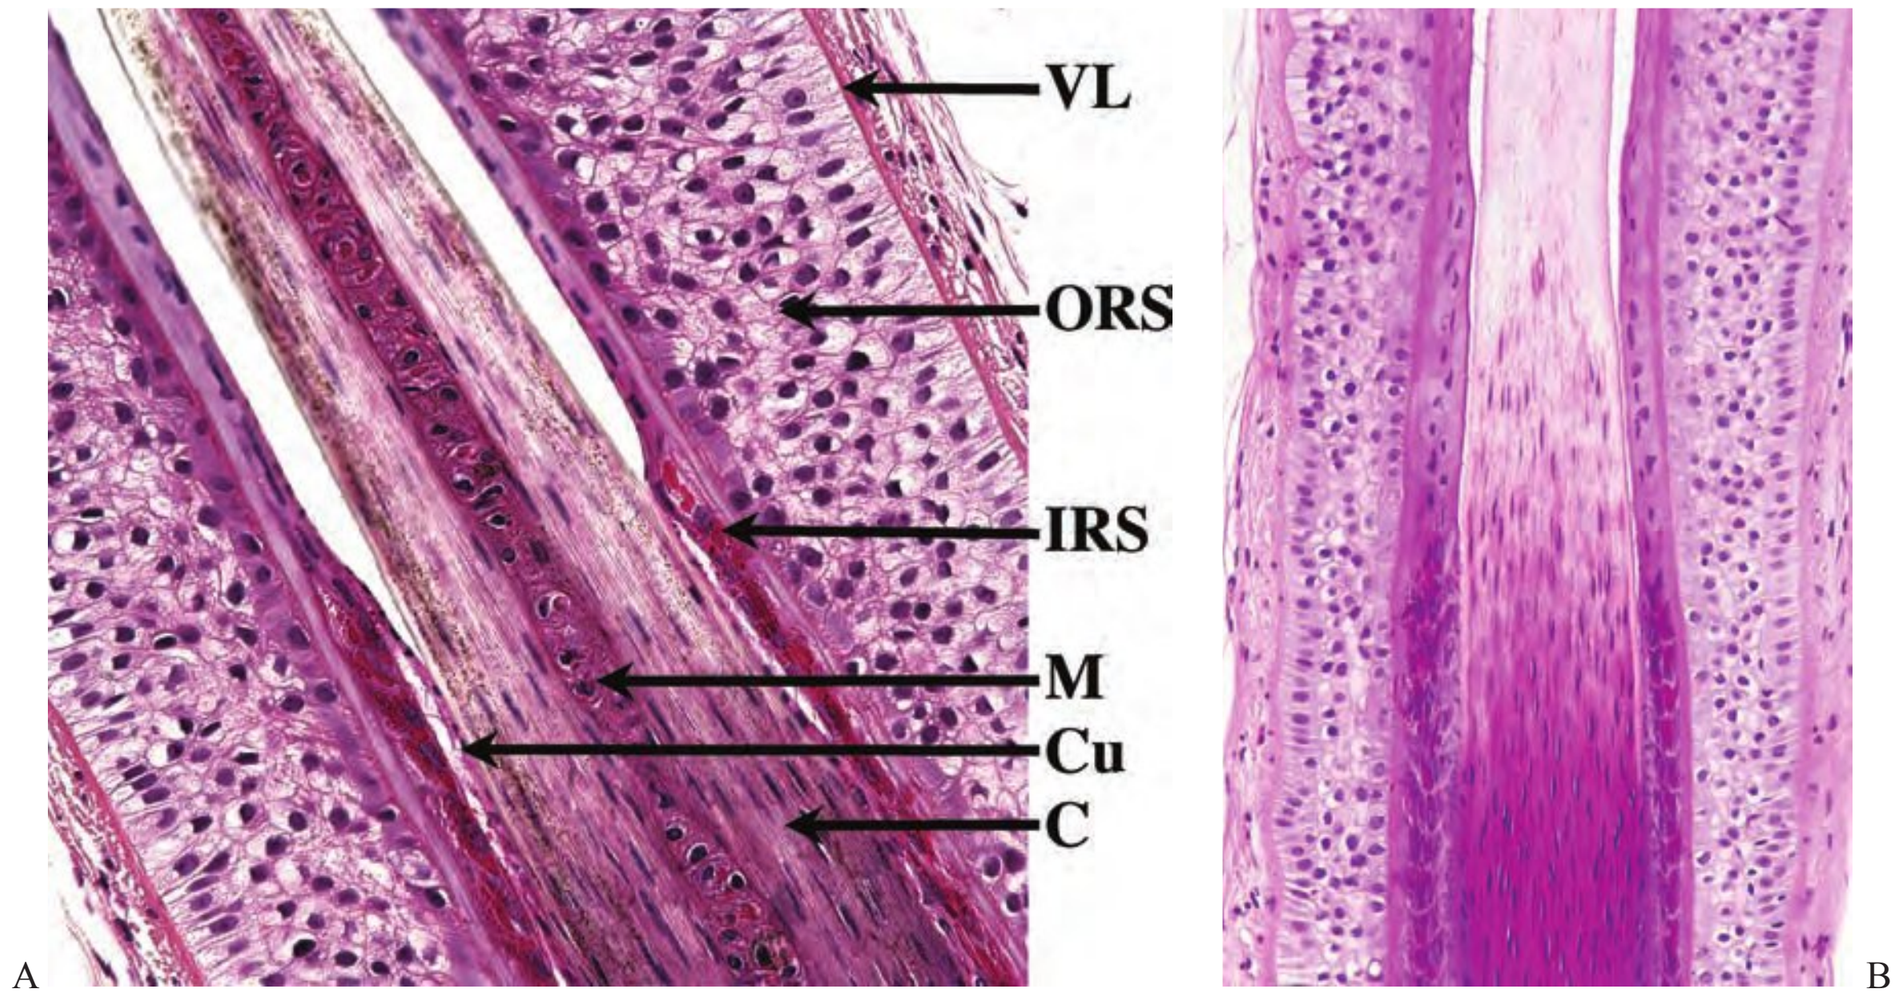

FIGURE 3-28. A: Suprabulbar portion (lower segment) of the hair follicle. The various layers of the anagen hair can be recognized. From the inside to the periphery: the medulla (M) when present, the cortex (C), the cuticle (Cu) that includes the hair shaft cuticle and the cuticle of the inner root sheath (IRS), the Huxley and Henley layers of the IRS, the highly glycogenated outer root sheath (ORS), and the glassy vitreous layer (VL). B: Note the loss of nuclei in the hair shaft and inner root sheath.

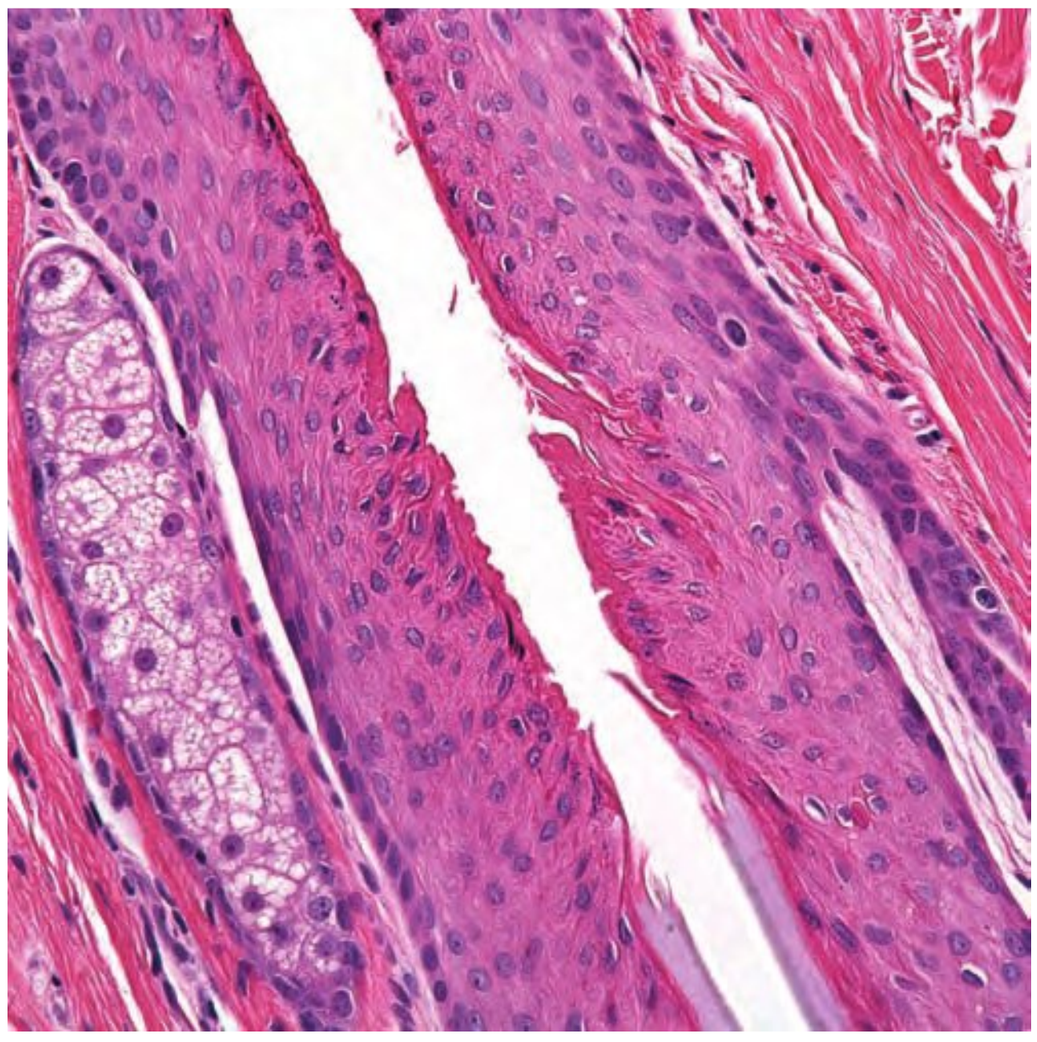

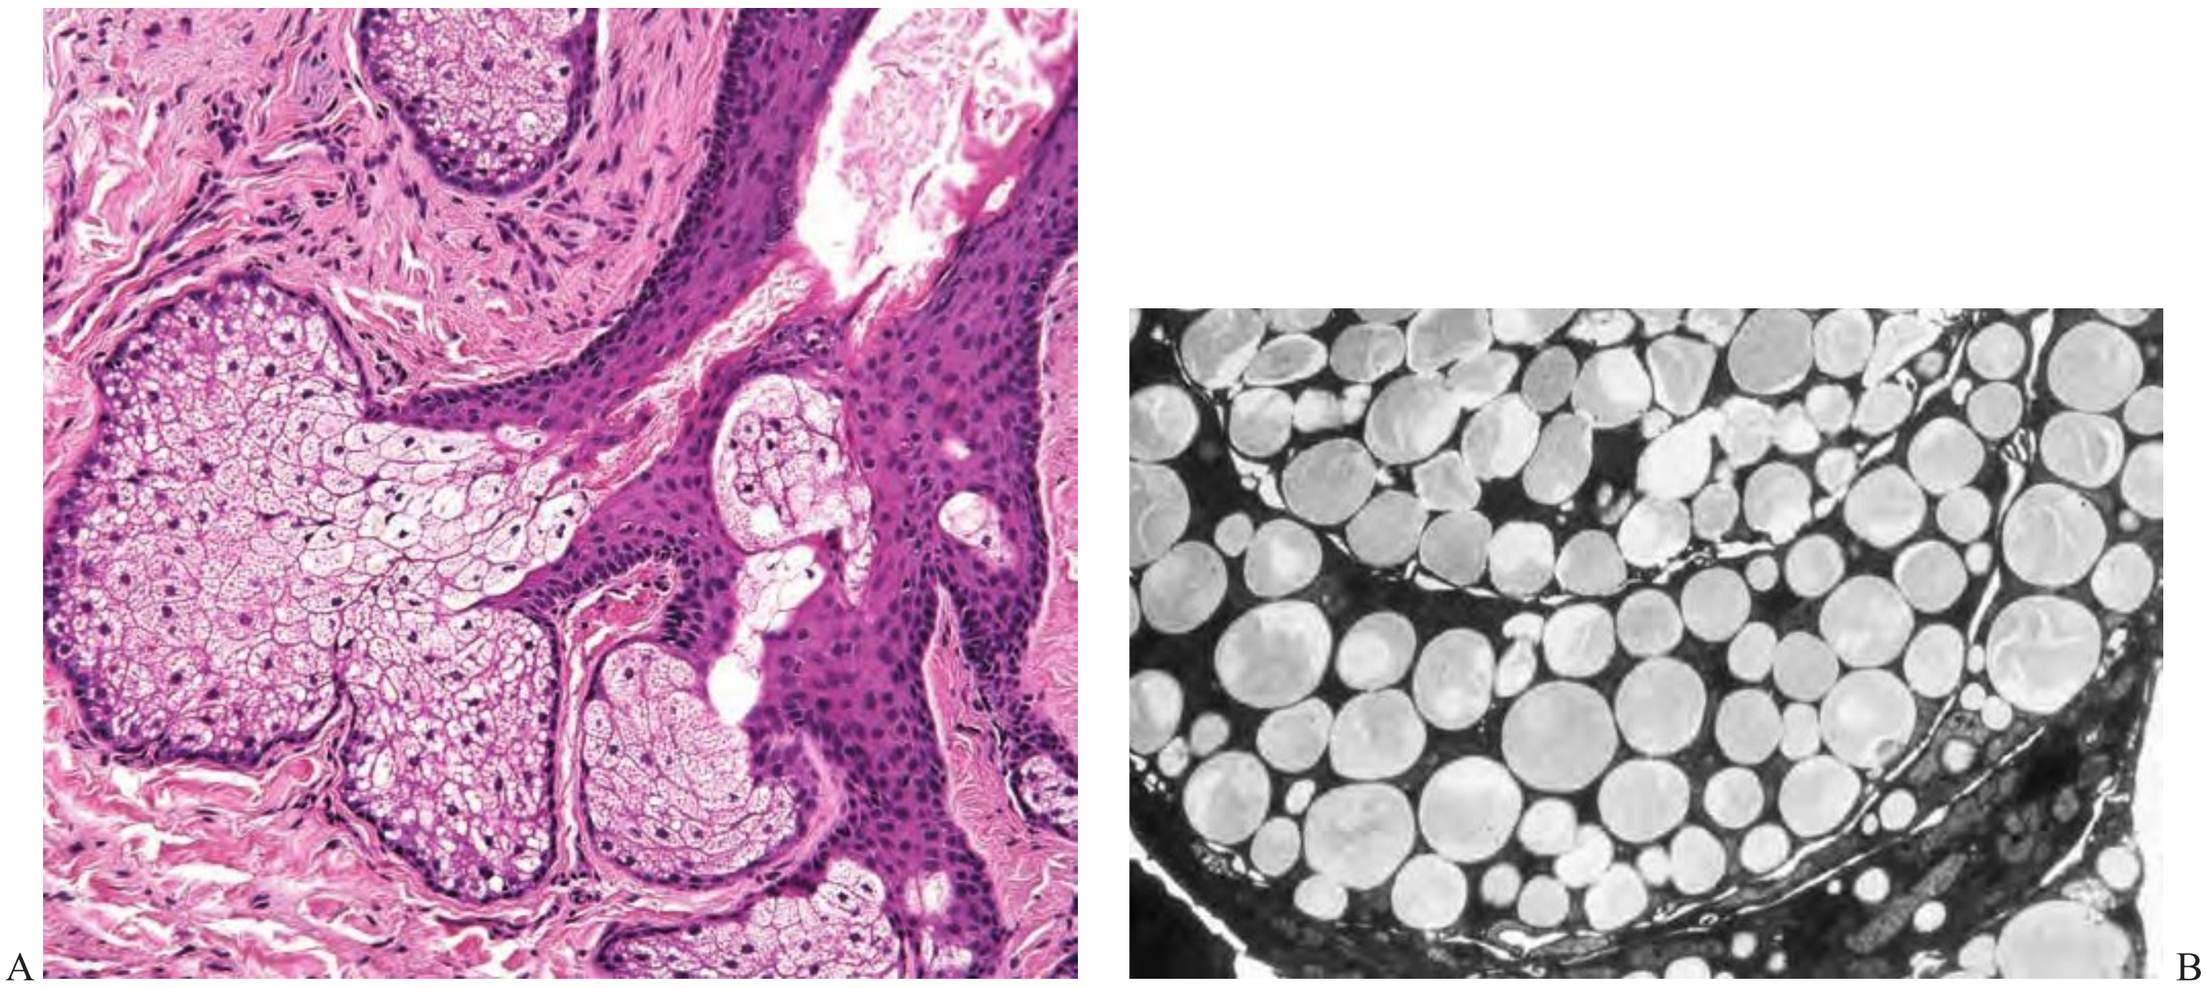

FIGURE 3-29. Isthmus of a hair follicle. Its upper limit is marked by the sebaceous gland opening. In the mid portion of the isthmus, the abrupt desquamation of the inner root sheath (gray blue) takes place. Above it, the outer root sheath cornifies (dark pink) without formation of a granular layer (trichilemmal keratinization).

phase of active growth—lasts at least 3 years; catagen—the phase of regression—lasts about 3 weeks; and telogen—the resting period—lasts about 3 months. At any one time, approximately 84% of scalp hairs are in anagen stage, 2% in catagen, and 14% in telogen (159). These ratios are important in evaluating abnormalities in the hair cycle in biopsies of partially alopecic scalp. The daily hair growth rate averages about 0.4 mm on the scalp.

During its active growth, or anagen, stage the hair follicle shows at its lower pole a knoblike expansion, the hair bulb, composed of matrix cells and melanocytes. A small, egg-shaped dermal structure, the dermal hair papilla, protrudes into the hair bulb (Fig. 3-27). The papilla induces and maintains the growth of the hair follicle (160). Because of the presence of large amounts of acid mucopolysaccharides in its ground substance, the dermal hair papilla stains positively with alcian blue and metachromatically with toluidine blue. Because positive staining with alcian blue takes place at pH 2.5 and 0.5, it can be concluded that the ground substance of the hair papilla contains nonsulfated acid mucopolysaccharides, such as hyaluronic acid, and sulfated acid mucopolysaccharides, such as chondroitin sulfate (161). In addition, there is considerable alkaline phosphatase activity in the hair papilla during the anagen stage as a result of the presence of large numbers of capillary loops (162,163). In persons with dark hair, large amounts of melanin can be seen in the dermal hair papilla situated within melanophages.

Bulb and Lowermost Portion of the Hair Follicle

The pluripotential cells of the hair matrix present in the hair bulb give rise to the hair and to the inner root sheath. In contrast, the outer root sheath represents a downward extension of the epidermis. The cells of the hair matrix have large vesicular nuclei and a deeply basophilic cytoplasm. Dopa-positive melanocytes are interspersed mainly between the basal cells of the hair matrix lying on top of the dermal hair papilla and, to a lesser degree, between the basal cells of the hair matrix located lateral to the hair papilla (153). Melanin, varying in quantity in accordance with the color of the hair, is produced in these melanocytes and is incorporated into the future cells of the hair through phagocytosis of the distal portion of dendritic processes by future hair cells. This transfer of melanin is analogous to that observed from epidermal melanocytes to keratinocytes.

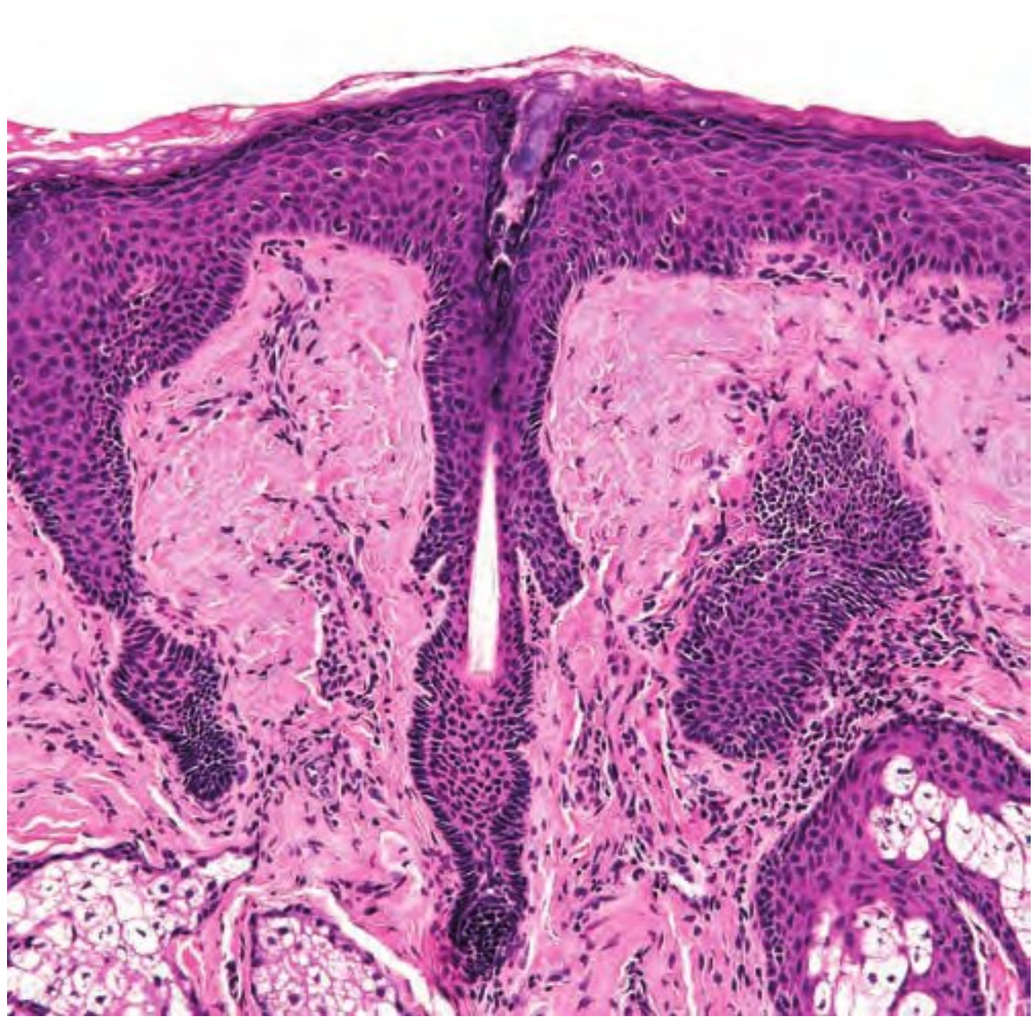

FIGURE 3-31. Vellus hair. The bulb of these small hair follicles is located in the upper dermis. As terminal hairs, vellus hairs go through the entire hair cycle.

As they move upward, the cells arising from the hair matrix differentiate into six different types of cells, each of which keratinizes at a different level. The outermost layer of the inner root sheath, the Henle layer, keratinizes first, thus establishing a firm coat around the soft central parts. The two apposed cuticles covering the inside of the inner root sheath and the outside of the hair keratinize next, followed by Huxley's layer. The hair cortex then follows, and the medulla is last (164).

The hair medulla of human hair is often difficult to find by routine light microscopy because it may be discontinuous or even absent. It is more readily recognizable by polariscopic examination because, unlike the cortex, the only partially keratinized medulla contains hardly any doubly refractile structures (165). If the medulla is seen by light microscopy in human hairs, it appears amorphous because of only partial keratinization.

The hair cortex consists of cells that, during their upward growth from the hair matrix, keratinize gradually by losing their nuclei and become filled with keratin fibrils. The process of keratinization takes place without the formation of keratohyaline granules, as seen in the keratinizing epidermis, or of trichohyaline granules, as seen in the inner root sheath. Thus,

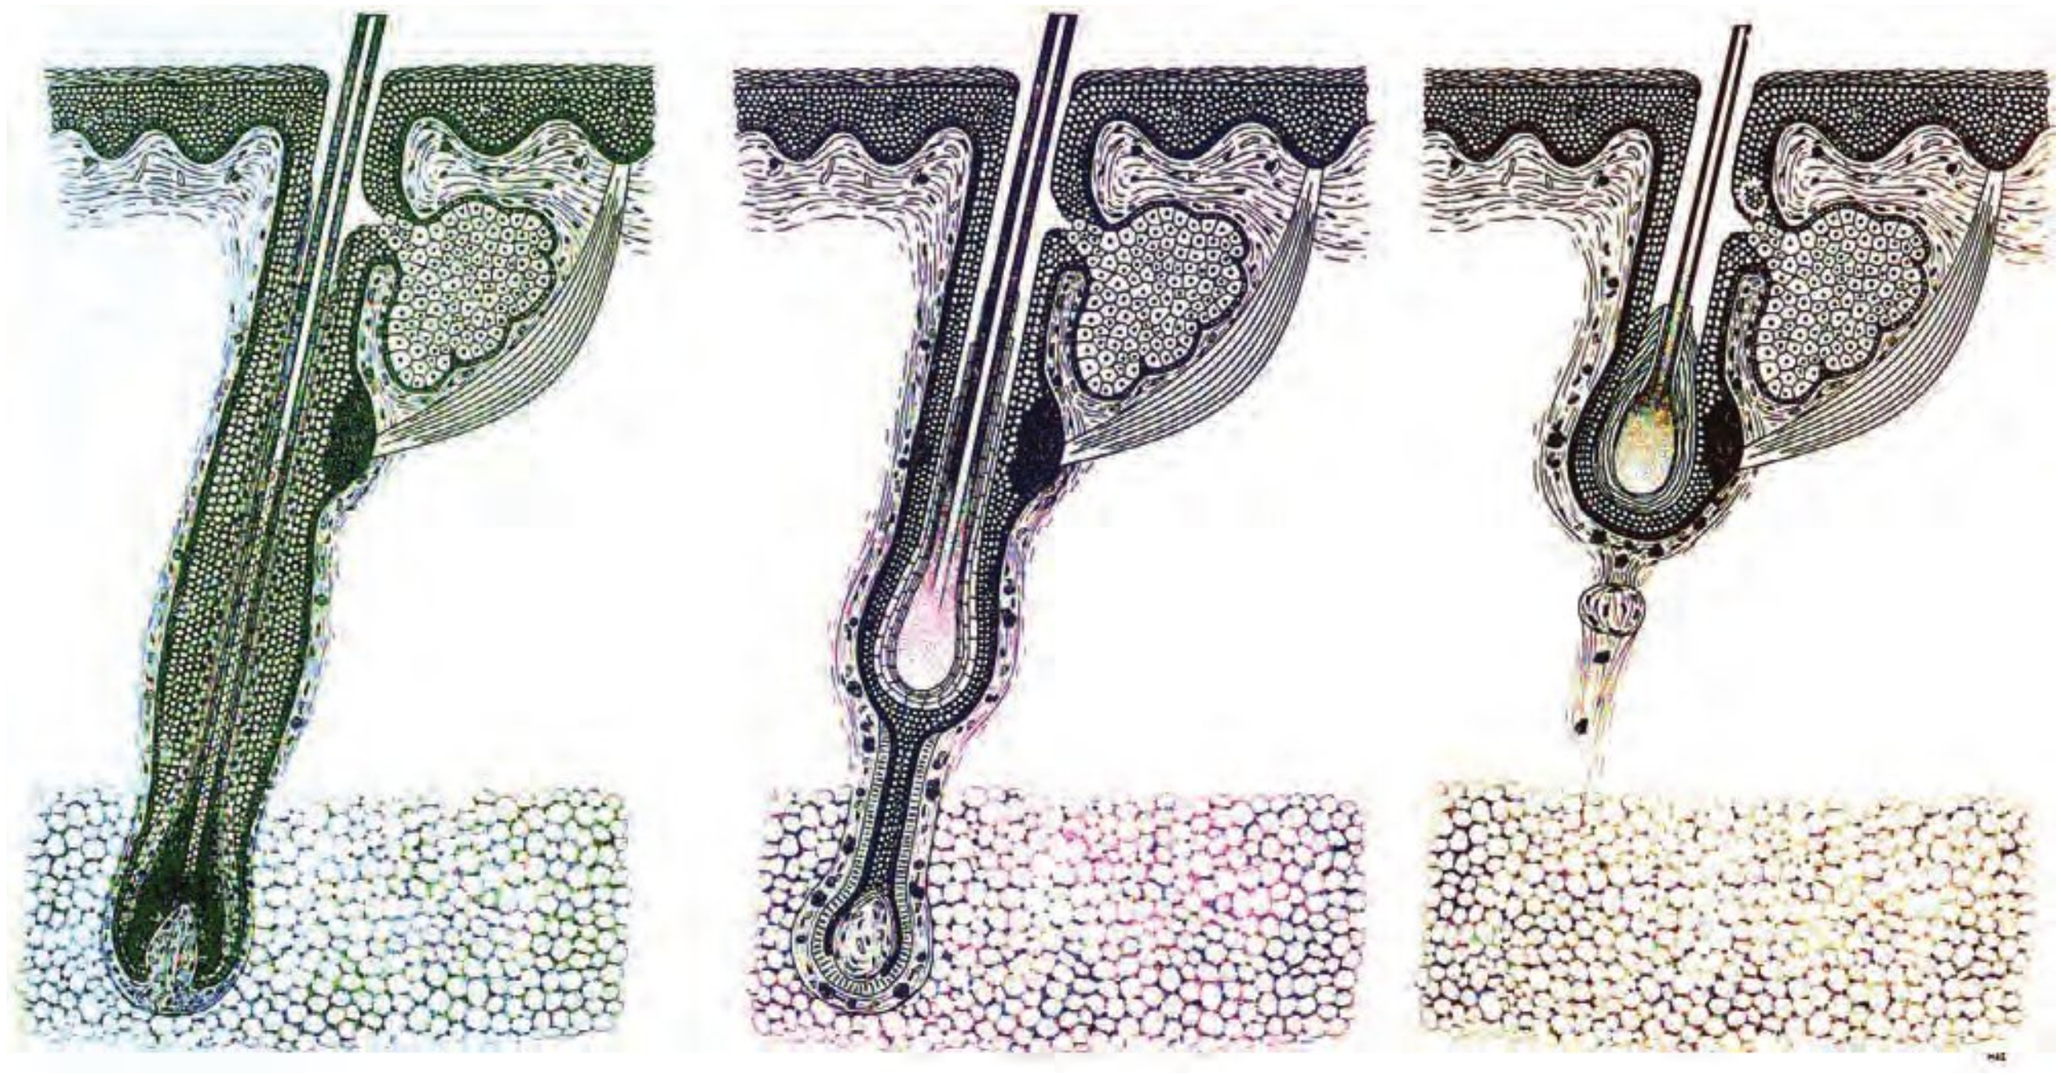

FIGURE 3-32. Diagram of the hair cycle. From left to right: anagen hair, catagen hair, and telogen hair.

the keratin of the hair cortex represents hard keratin, in contrast to the keratin of the inner root sheath, which, like that of the epidermis, represents soft keratin (166).

The hair cuticle (Fig. 3-28), located peripheral to the hair cortex, consists of overlapping cells arranged like shingles and pointing upward with their peripheral portion. The cells of the hair cuticle are tightly interlocked with the cells of the inner root sheath cuticle, resulting in the firm attachment of the hair to its inner root sheath. The hair and the inner root sheath move upward in unison (167).

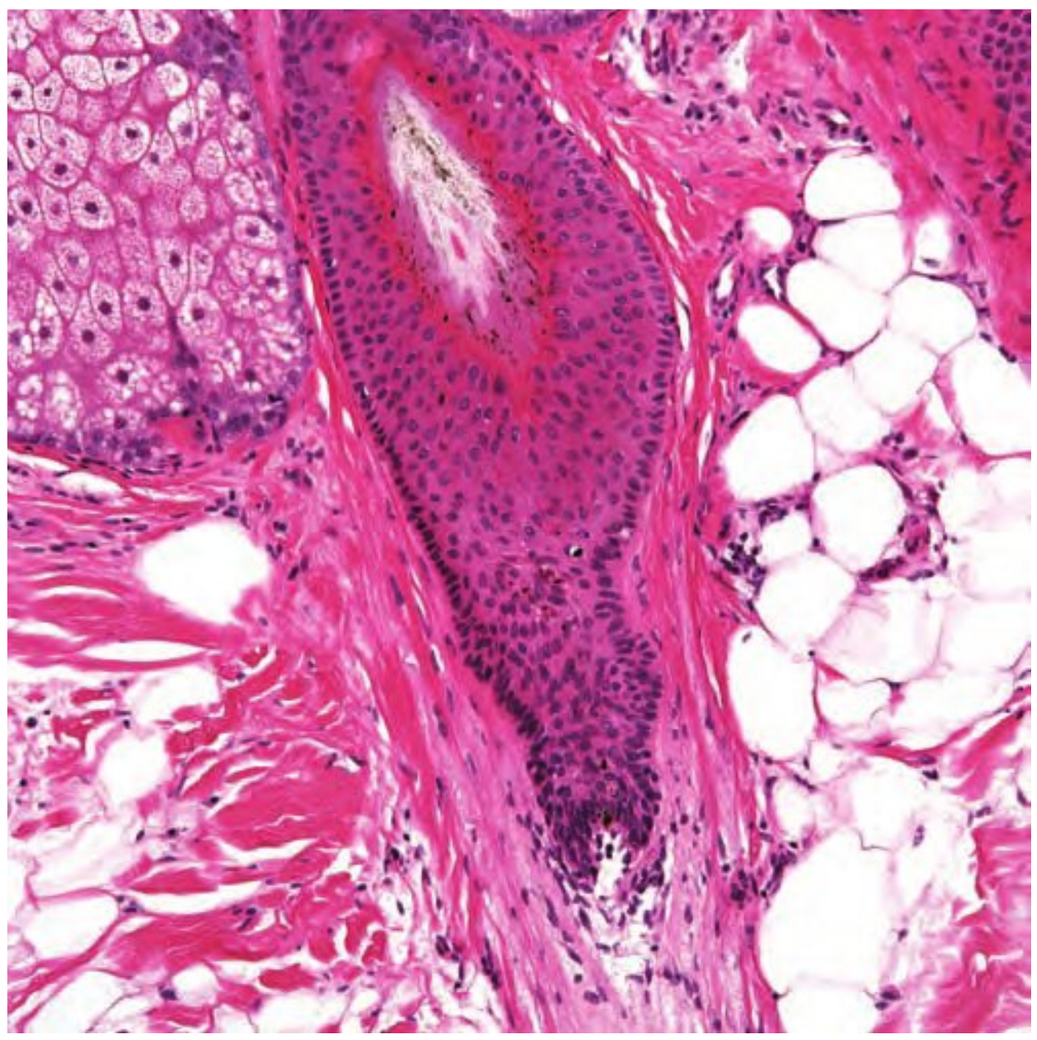

FIGURE 3-33. Section of a catagen/telogen hair. Note the club-shaped cornifying hair shaft with serrated borders. There are numerous apoptotic nuclei in the hair epithelium.

The inner root sheath is composed of three concentric layers; from the inside to the outside, these are the inner root sheath cuticle, the Huxley layer, and the Henle layer (Fig. 3-28). None of these three layers contains melanin. All three layers keratinize, unlike the cells of the hair cortex and of the hair cuticle, by means of trichohyaline granules. These granules resemble the keratohyaline granules of the epidermis, although they stain eosinophilic, in contrast to the basophilic-staining keratohyaline granules of the epidermis. Similar granules may be noted in the pathologic process of epidermolytic hyperkeratosis. Closest to the hair is the single-layered inner root sheath cuticle, consisting of flattened overlapping cells that point downward in the direction of the hair bulb. Because the cells of the hair cuticle point upward, these two types of cells interlock tightly. Trichohyaline granules are few in the inner root sheath cuticle cells. The Huxley layer, which usually consists of two rows of cells, develops numerous trichohyaline granules at the level of the keratogenous zone of the hair. The Henle layer, which is only one cell layer thick and the first layer to undergo keratinization, already has many trichohyaline granules at its emergence from the hair matrix (168) (Fig. 3-27). After having become fully keratinized, the cells of all three layers composing the inner root sheath disintegrate when they reach the isthmus of the hair follicle, which extends from the area of attachment of the arrector pili muscle to the entrance of the sebaceous duct. The cells of the inner root sheath thus do not contribute to the emerging hair (169).

The outer root sheath extends upward from the matrix cells at the lower end of the hair bulb to the entrance of the sebaceous duct, where it changes into surface epidermis, which lines the upper portion, or infundibulum, of the hair follicle. The outer root sheath is thinnest at the level of the hair bulb, gradually increases in thickness, and is thickest in the middle portion of the hair follicle, the isthmus. In its lower portion, below the isthmus, the outer root sheath is covered by the inner root sheath and does not undergo keratinization. The outer root sheath cells have a clear, vacuolated cytoplasm because of the presence of considerable amounts of glycogen (Fig. 3-28). In contrast to the surface epidermis lining the infundibulum, which contains active, melanin-producing melanocytes in its basal layer, the basal layer of the outer root sheath contains only inactive, amelanotic melanocytes demonstrable with toluidine blue. However, these inactive melanocytes can become melanin-producing cells after skin injuries, such as dermabrasion, when they increase in number and migrate upward into the regenerating upper portion of the outer root sheath and into the regenerating epidermis (170).

Follicular Isthmus and Infundibulum

In the middle portion of the hair follicle, the so-called isthmus, which extends upward from the attachment of the arrector pili muscle (so-called bulge region) (Fig. 3-29) to the entrance of the sebaceous duct, the outer root sheath is no longer covered by the inner root sheath, which by then has keratinized and disintegrated. The outer root sheath therefore undergoes keratinization. This type of keratinization, referred to as trichilemmal keratinization, produces large, homogeneous keratinized cells without the formation of keratohyaline granules (Fig. 3-29). Trichilemmal keratinization is found also in catagen and telogen hairs and in trichilemmal cysts and trichilemmal tumors. The bulge region at the site of the arrector pili muscle insertion is poorly defined in human follicles and difficult to detect in routine sections. When it is visualized, it consists of several knobby protuberances and ridges composed of relatively undifferentiated follicular keratinocytes with putative stem cell capability (10).

The upper portion of the hair follicle above the entrance of the sebaceous duct, the infundibulum, is lined by surface epidermis, which, like the sebaceous duct, undergoes keratinization with the formation of keratohyaline granules. The infundibulum contains a number of dendritic nonkeratinocytes on ultrastructural examination, and immunohistochemistry reveals numerous CD1a-positive Langerhans cells within the infundibula of normal adult anagen hairs.

The glassy or vitreous layer forms a homogeneous, eosinophilic zone peripheral to the outer root sheath (Fig. 3-28). Like the subepidermal basement membrane zone, it is PAS positive and diastase resistant, but it differs from the subepidermal basement membrane zone by being thicker and visible with routine stains. It is thickest around the lower one third of the hair follicle. Peripheral to the vitreous layer lies the fibrous root sheath, which is composed of thick collagen bundles.

Sebaceous Glands

The sebaceous glands are well developed at the time of birth, most likely because of maternal hormones. After a few months, they undergo considerable involution. At puberty, as a result of increased androgen output, the sebaceous glands become greatly enlarged (171). This normal cycle may also occur in certain pathologic conditions, such as nevus sebaceus.

A sebaceous gland may consist of only one lobule but often has several lobules leading into a common excretory duct composed of stratified squamous epithelium (Fig. 3-30A). Sebaceous glands, being holocrine glands, form their secretion by decomposition of their cells. In sebaceous glands of the skin, the pilosebaceous follicle into which the sebaceous duct leads may possess a large hair or a vellus hair that may be too small to reach the skin surface. There is no relationship between the size of the sebaceous gland and the size of the associated hair. For example, in the center of the face and on the forehead, where the sebaceous glands are very large, the associated hairs are of the vellus type.

Each sebaceous lobule possesses a peripheral layer of cuboidal, deeply basophilic cells that usually contain no lipid droplets (Fig. 3-30B). The more centrally located cells contain lipid droplets, which can be detected if lipid stains are used on formalin-fixed frozen sections, but in routinely processed sections in which the lipid has been extracted, the cytoplasm of these cells appears as a delicate network of fine cytoplasmic vacuoles. The nucleus is centrally located. In the portion of the lobule located closest to the duct, the cells disintegrate.

The composition of lipids in the sebaceous glands is not uniform. Thus, under polarized light, doubly refractile lipids may be present in small to moderate amounts or may be absent (172). Histochemical examination reveals the presence of triglycerides and small amounts of phospholipids. Esterified cholesterol is present, but there is no free cholesterol. Waxes are also present, but they are not identifiable by histochemical means (172). Evidence of active lipid synthesis and storage may be observed by electron microscopy (173,174).

Lysosomal enzymes bring about the physiologic autolysis that occurs in the holocrine secretion. Histochemical staining of electron microscopic sections for lysosomal enzymes, such as acid phosphatase and aryl sulfatase, reveals an increasing number of lysosomes as the sebaceous cells become more lipidized. In the disintegrating cells located in the preductal region, the acid phosphatase and aryl sulfatase activity is most pronounced, but this activity is largely outside of lysosomes because the lysosomes have released their contents in their function as "suicide bags" (175). Prior to the sudden disintegration of the sebaceous cells an abrupt conversion of –SH to S–S linkages of proteins occurs in sebaceous glands just as in epidermis and hair (176).

Regional Variation

Hair follicles vary considerably in different anatomic regions and according to age and sex. In adults, deep anagen hairs (extending into subcutaneous fat) are typically found on the scalp (see Fig. 3-59) and male beard area, whereas vellus hairs typify the female face and nonbeard-area facial regions of men.

Hair of extremities and trunk generally can be differentiated from scalp by the more superficial location of the bulbs and diminished density. Sebaceous glands are present everywhere on the skin except on the palms and soles. On the skin, they are found in association with hair structures. In addition, free sebaceous glands that are not associated with hair structures occur in some areas of modified skin, such as the nipple and areola of both the male and female breasts. There, they occur over the entire surface of the nipple and in Montgomery's areolar tubercles, each of which contains several sebaceous lobules in association with a lactiferous duct. Free sebaceous glands also may be found on the labia minora and the inner aspect of the prepuce. Modified sebaceous glands called Tyson's glands have been reported to occur on the coronal sulcus of the penis (177). The not infrequent presence of free sebaceous glands on the vermilion border of the lips and on the buccal mucosa is known as Fordyce's condition. The meibomian glands of the eyelids are modified sebaceous glands (see Fig. 3-62A).

Specialized Structure and Function

Hair Cycle

The hair cycle ensures that periodically, entirely new hair shafts are produced, and it also serves as an intrinsic regulator of maximum hair length The hair cycle consists of the involutionary stage (catagen) and the end stage (telogen) of the old hair and its replacement by a young, new hair (early anagen) (Fig. 3-32). At the onset of the catagen stage, mitotic activity and melanin production in the hair bulb cease. Next, the bulb shrinks and becomes separate from the dermal hair papilla (168). As the hair moves upward, the lower portion of the follicle involutes (Fig. 3-33). The reduction in follicle size results from cell deletion by apoptosis, or programmed cell death (178). The lower follicle thus becomes a thin cord of epithelial cells surrounded by the fibrous root sheath, which is wrinkled in thick folds. In addition, as the hair moves upward, growth of the inner root sheath ceases, so that the lower end of the hair shaft becomes surrounded by dense keratin, referred to as trichilemmal keratin, that is formed by the outer root sheath without the interposition of keratohyaline granules. This then represents the club hair of the catagen stage.

Next, the thin cord of epithelial cells retracts upward, faithfully followed by the underlying dermal hair papilla, which also moves upward. The cord of epithelial cells shortens until it forms only a small, nipple-like downward protrusion from the club hair, called the secondary hair germ. Under it lies the dermal hair papilla. With the hair follicle decreased to about one third of its former length, the lowest portion of the hair follicle lies at the level of the attachment of the arrector pili. The lower portion of the hair is encased in trichilemmal keratin and completely surrounded by the outer root sheath. Folds of the fibrous root sheath extend downward from the hair follicle. At this point, the hair has reached the telogen stage (179).

When regrowth of the hair begins, the secondary hair germ where the stem cell cluster is believed to be preserved begins to elongate by cell division and grows down as an epithelial column together with the dermal hair papilla inside of the old, collapsed fibrous root sheath of the previous hair (so-called "bulge activation" stage). As it is growing down, the lower end of the epithelial column becomes invaginated by the dermal hair papilla. A new hair bulb is formed, representing the early anagen stage. By subsequent differentiation, a new hair arises. Thus, the formation of an active hair follicle from the secondary germ recapitulates the embryonic pattern of development of the hair from the primary hair germ (179). Recent experimental data in rodents suggest that the primary site that gives rise to new hair germ during follicular regrowth is the bulge region of the follicle, where a population of normally slow-cycling, relatively undifferentiated cells with features of stem cells reside (10). Stimulation of the bulge region, which persists throughout telogen, then gives rise to new hair germ and the developing anagen follicle (bulge activation hypothesis).

Hair Color

Three types of melanosomes are present in hair. Erythromelanin granules, seen in red hair, are polymorphous and have an irregular internal structure. The other two types of granules, homogeneous eumelanin granules and lamellated pheomelanin granules, are found in varying proportions in blond and dark hair and are round to oval. Dark hair contains more melanosomes than light hair, and the melanosomes are largely of the homogeneous eumelanin type; in light hair, lamellated pheomelanin melanosomes predominate (180).

In gray and white hair, the melanocytes in the basal layer of the hair matrix are greatly reduced in number or are absent. The melanocytes that are present show degenerative changes, especially of their melanosomes (181). Such changes appear to affect melanocyte stem cells, resulting in permanent hair graying (182). The hair shafts contain only detritus of melanin or none at all (180).

Follicular Immunity

The number of CD1a-positive Langerhans cells in normal follicular infundibula raises questions concerning their role in follicular immunity. Such populations could be appropriately sequestered from harmful environmental agents, such as ultraviolet light, and thus serve as a reservoir of antigen-presenting cells, as well as an evolutionary rationale for preservation of hair follicles in *Homo sapiens* no longer in need of the thermal or protective benefits of hair shafts. Such follicle-associated immune tissue has been evidenced in clinical settings of primarily follicular pathology in contact dermatitis, as well as in sequential studies of human, experimentally induced contact allergy, where the first sentinel lymphocytes selectively home to follicular infundibula (183). Chronic UV exposure may deplete epidermal Langerhans cells, whereas follicular Langerhans cells remain intact, resulting in a protected niche that may be stimulated to replenish sun-damaged skin (140).

Eccrine and Apocrine Glands

The apocrine glands differ from eccrine glands in origin, distribution, size, and mode of secretion. The eccrine glands primarily

serve in the regulation of heat, and the apocrine glands represent scent glands. More recently, a third type of sweat gland called the apoeccrine gland has been described in the axillae (184).

Embryology

Eccrine glands are present in mammals, with the exception of anthropoid apes, only on the soles. Their presence in other parts of the skin in humans is a late development from the phylogenetic point of view. Accordingly, the eccrine glands develop in humans earlier on the palms and soles than elsewhere. On the palms and soles, eccrine gland germs are first seen early in the fourth gestational month (185). In the early part of the fifth fetal month, they develop in the axillae, and near the end of the fifth month, they begin to appear over the remainder of the body (152). The eccrine gland germs begin as areas of crowding of deeply basophilic cells in the basal layer of the epidermis. They differ from primary epithelial germs only slightly by being narrower and by showing fewer mesenchymal cells at their base. Like hair follicles, eccrine glands may be seen at one time in different stages of development. In embryos 16 weeks old, some eccrine glands are already beginning to form coils on the palms and soles, while new eccrine gland germs are still forming in the epidermis (186).

At the time of lumen formation, the intradermal duct and the secretory segment show a wall composed of two layers of cells—an inner layer of luminal cells and an outer layer of basal cells. Although the dermal duct continues to consist of these two layers of cells throughout life, the two layers in the secretory segment undergo differentiation: The luminal cells differentiate into tall, columnar secretory cells extending from the basement membrane to the luminal border, and the basal cells differentiate into secretory cells or into myoepithelial cells, which appear as pyramidal, relatively small cells wedged at the base between secretory cells (185). The differentiation into secretory and myoepithelial cells in the secretory segment is well advanced on the palms and soles of embryos 22 weeks old. At the time of birth, the appearance of the eccrine glands resembles that of adult eccrine glands.

In contrast to eccrine glands, apocrine glands develop only in certain areas. Wherever they form, they develop from the upper bulge of hair follicles that are in the early bulbous peg stage and show a hair cone. The formation of apocrine glands begins late in the fourth month and continues until late in embryonic life, as long as new hair follicles develop. In the earliest stage, a solid epithelial cord projects into the perifollicular mesenchyme at a right angle to the long axis of the hair follicle and then grows downward past the developing sebaceous gland and arrector pili bulge. By the time the tip of the epithelial cord has reached the level of the sebaceous gland, the intradermal ductal lumen begins to form, as does the intrafollicular lumen (156). At the time of birth, there is no recognizable myoepithelial layer of cells around the secretory portion of the apocrine glands (152).

Eccrine glands apparently give rise to apoeccrine axillary glands during puberty (184).

Normal Microanatomy

Eccrine glands are composed of three segments: the intraepidermal duct, the intradermal duct, and the secretory portion (Fig. 3-34). The secretory portion makes up about one half of the basal coil, the other half being composed of duct. The basal coil lies either at the border between the dermis and the subcutaneous fat or in the lower one third of the dermis. When located in the lower dermis, it is surrounded by fatty tissue that connects with the subcutaneous fat. Eccrine glands are highlighted by immunohistochemical stains for S100 protein and carcinoembryonic antigen (Fig. 3-35).

The intraepidermal eccrine duct extends from the base of a rete ridge to the surface and follows a spiral course (Fig. 3-34A). The cells composing the duct are different from the cells of the surrounding epidermis in that they are derived from dermal duct cells through mitosis and upward migration (187). For this reason, the intraepidermal eccrine duct has been referred to as acrosyringium or the epidermal sweat duct unit. The intraepidermal eccrine duct consists of a single layer of inner or luminal cells and two or three rows of outer cells. The ductal cells begin to keratinize, as evidenced by the presence of keratohyaline granules, at a lower level than the cells of the surrounding epidermis, in the middle squamous layer, and are fully keratinized at the level of the stratum granulosum of the surrounding epidermis (188). Before keratinization, the intraepidermal lumen is lined by an eosinophilic cuticle.

The intradermal eccrine duct is composed of two layers of small, cuboidal, deeply basophilic epithelial cells (Fig. 3-34B). Unlike the secretory portion of the eccrine gland, the eccrine duct has no peripheral hyaline basement membrane zone, but the lumen of the duct is lined with a deeply eosinophilic, homogeneous cuticle that is PAS positive and diastase resistant.

The secretory portion of the eccrine gland shows only one distinct layer composed of secretory cells (Fig. 3-34C). The presence of only one distinct layer is due to the fact that the cells of the outer layer have become differentiated into either secretory or myoepithelial cells during the sixth to eighth months of embryonic life. The secretory cells lining the lumen consist equally of two types—clear cells and dark cells. The clear cells generally are broader at the base than they are near the lumen, appear somewhat larger than the dark cells, and contain very faint, small granules. The dark cells are broadest near the lumen and contain numerous basophilic granules (189). The clear cells contain PAS-positive, diastase-labile glycogen, and the dark cells contain PAS-positive, diastase-resistant mucopolysaccharides. The clear cells secrete abundant amounts of aqueous material together with glycogen; the dark cells secrete sialomucin. This substance contains both neutral and nonsulfated acid mucopolysaccharides, is positive for PAS and for alcian blue at pH 2.4, and is resistant to diastase and hyaluronidase. Prolonged sweating leads to a depletion of glycogen in the clear cells (190). The myoepithelial cells possess a small spindle-shaped nucleus and long contractile fibrils. The fibrils run in a spiral, their long axes aligned obliquely to the direction of the secretory tubule. Delivery of sweat to the

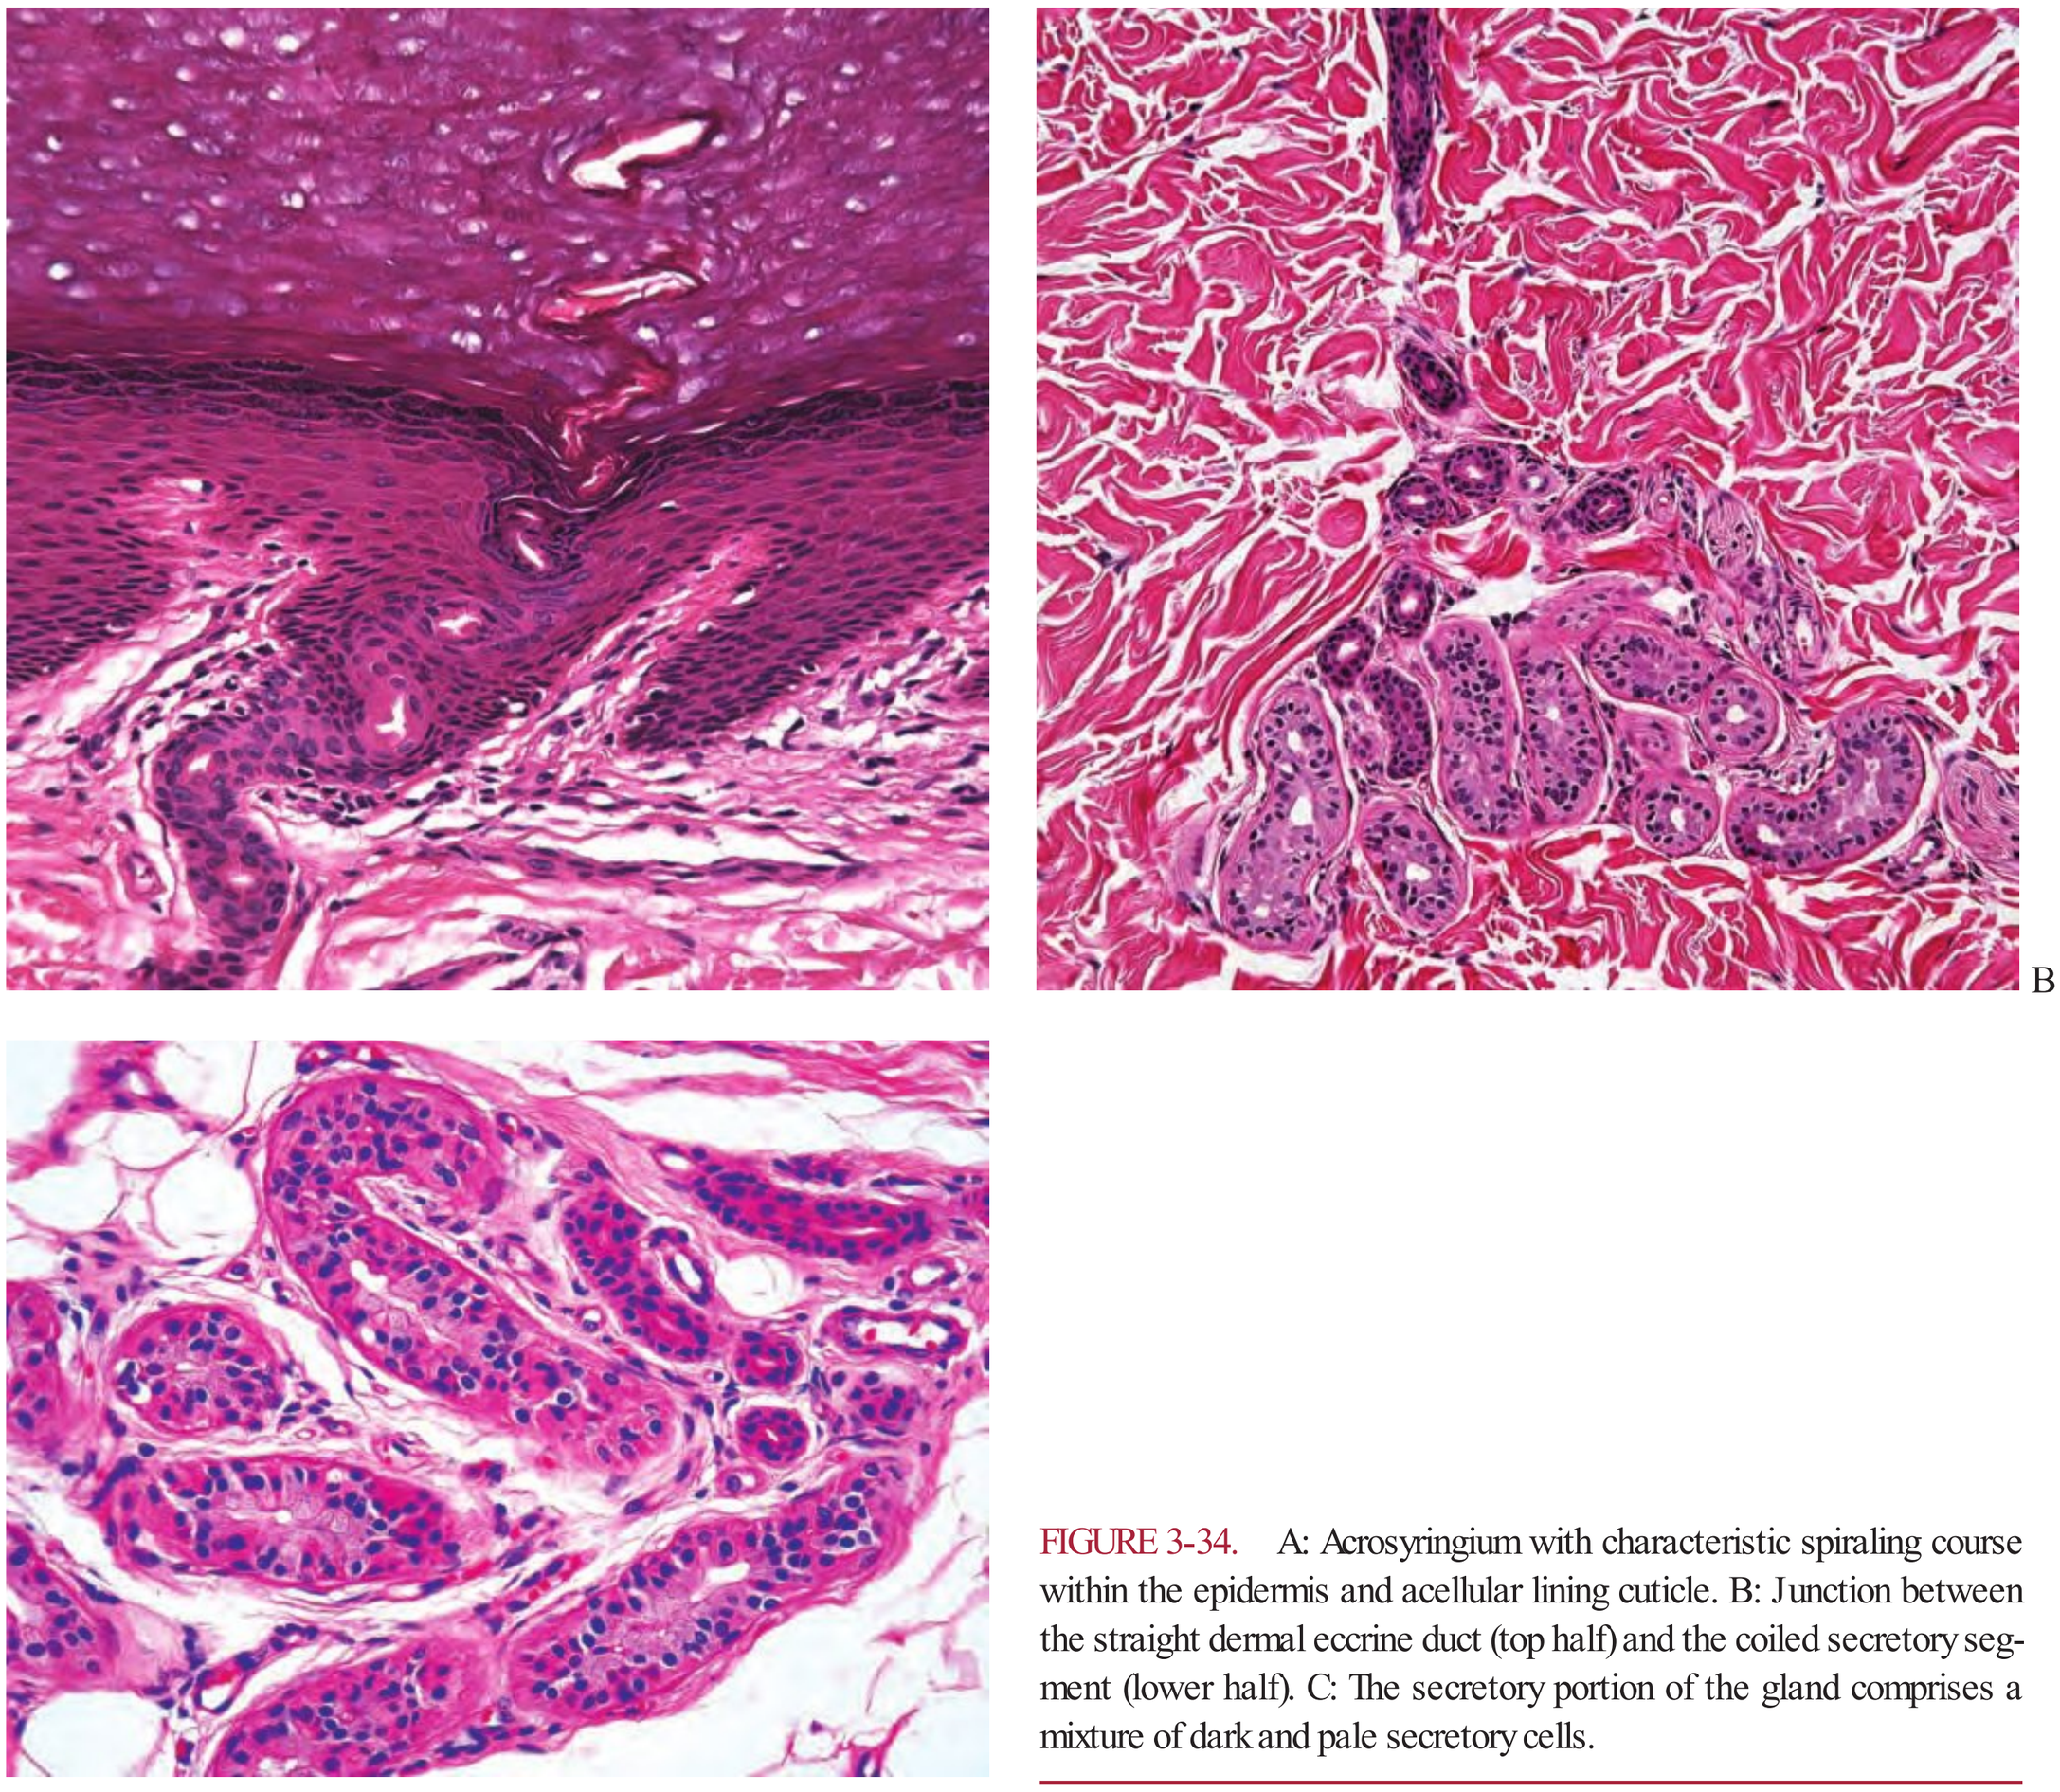

FIGURE 3-34. A: Acrosyringium with characteristic spiraling course within the epidermis and acellular lining cuticle. B: Junction between the straight dermal eccrine duct (top half) and the coiled secretory segment (lower half). C: The secretory portion of the gland comprises a mixture of dark and pale secretory cells.

skin surface is greatly aided by myoepithelial contraction (191). Peripheral to the myoepithelial cells lies a hyaline basement membrane zone containing collagen fibers. The transition from the secretory to the ductal epithelium is abrupt (Fig. 3-34B). The lumen of the secretory portion of the eccrine gland, measuring approximately 20 μm in diameter, is small in comparison with that of the apocrine gland (compare Figs. 3-34C and 3-36). The lumen of the eccrine duct measures about 15 μm across.

Apocrine glands are tubular glands, the secretory cells of which pass through various stages. Schiefferdecker, who in 1917 first described these glands, observed that, during secretion, part of the cell was pinched off and released into the lumen (192). He referred to this process as decapitation secretion. He chose the name apocrine for these glands to indicate that part of the cytoplasm of the secretory cells was pinched off ("apo" = "off").

Apocrine glands, like eccrine glands, are composed of three segments: the intraepidermal duct, the intradermal duct, and the secretory portion. Because apocrine glands originate from the hair germ, or primary epithelial germ, the duct of an apocrine gland usually leads to a pilosebaceous follicle, entering it in the infundibulum, above the entrance of the sebaceous duct. An occasional apocrine duct, however, opens directly on the skin surface close to a pilosebaceous follicle. In contrast to eccrine glands, the basal coil of apocrine glands, which is located in the subcutaneous fat, is composed entirely of secretory cells and contains no ductal cells.

The ductal portion of the apocrine glands has the same histologic appearance as the eccrine duct, showing a double layer of basophilic cells and a periluminal eosinophilic cuticle (Fig. 3-36). The intrafollicular or intraepidermal portion of the apocrine duct is straight and not spiral in appearance, as is the intraepidermal eccrine duct.

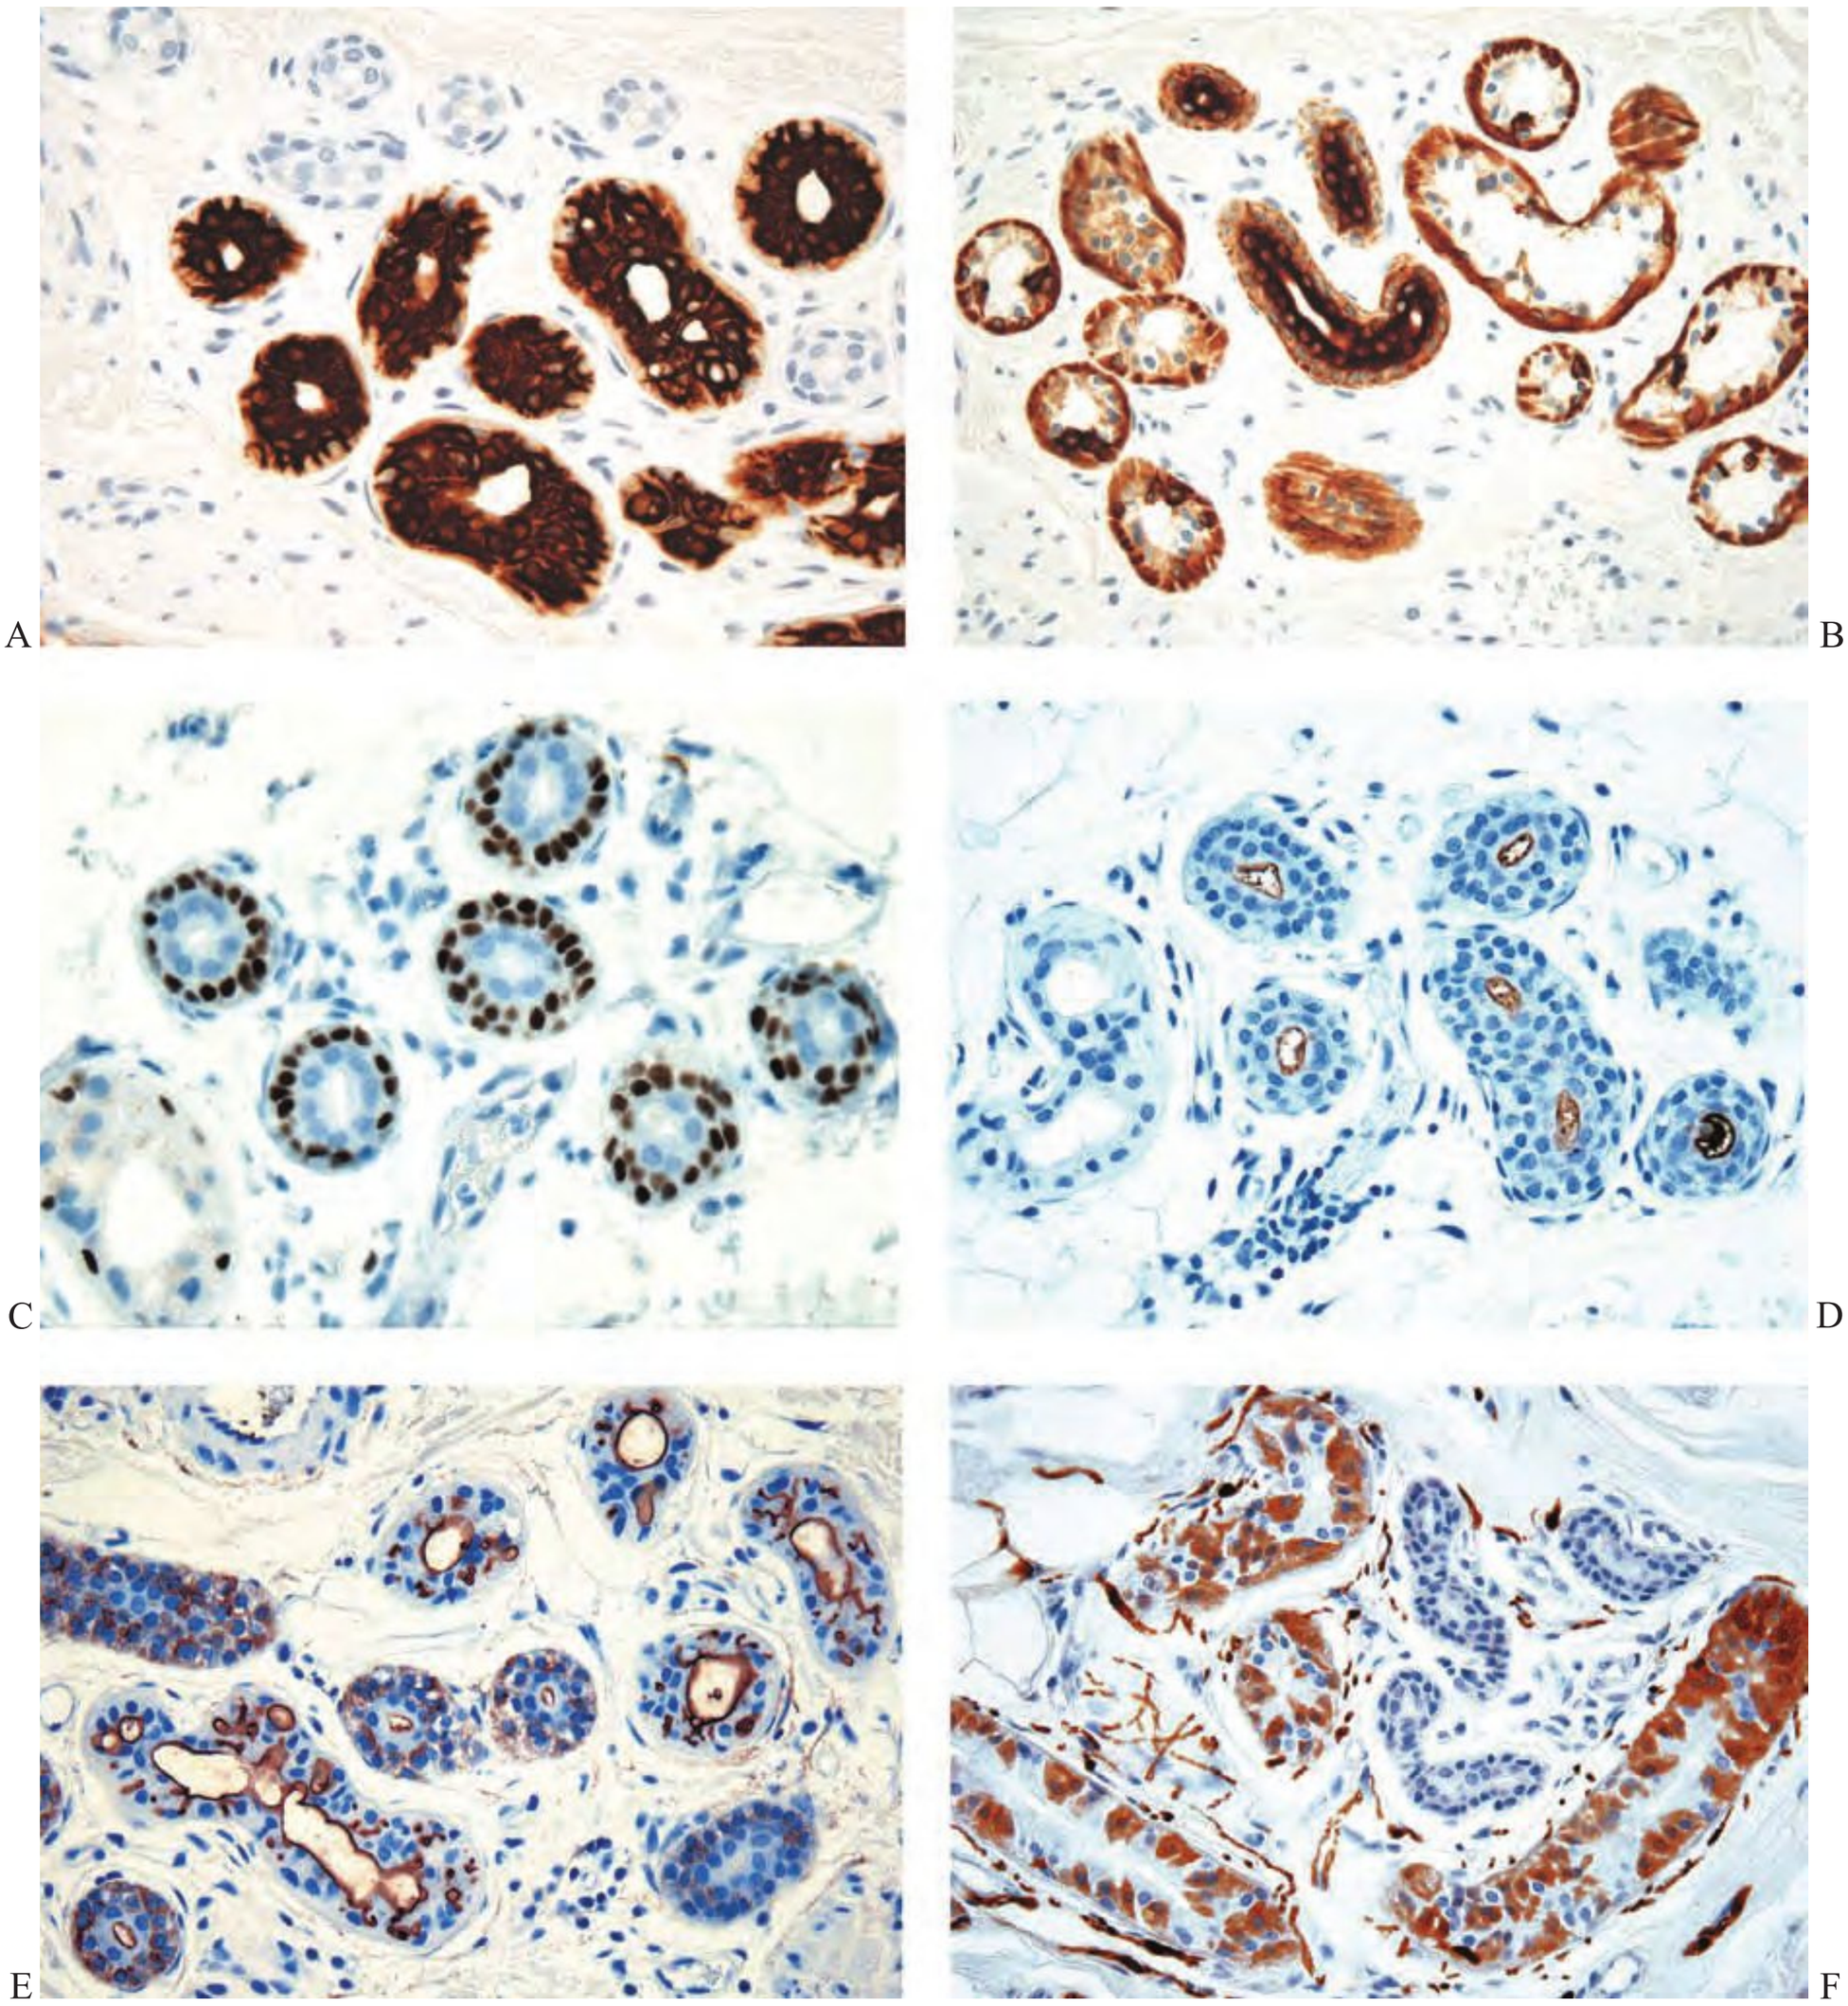

FIGURE 3-35. Immunohistochemistry of eccrine glands. A: Cytokeratin 7 shows strong immunopositivity of the secretory portion, whereas the ductal portion is negative. B: With cytokeratin 34 β E12, there is a preferential staining of the most basally located cells in the secretory portion. The ductal cells are strongly positive. C: p63 immunostain shows strong expression by the most basally located cells in the ductal portion, scattered positive nuclei in the secretory portion of the eccrine glands. D: Carcinoembryonic antigen immunostain shows a classical luminal expression pattern. E: Epithelial membrane antigen immunohistochemistry. Characteristic canalicular pattern. F: S100 protein is expressed by some of the secretory cells. The surrounding stroma contains delicate S100-positive nerves.

The secretory portion of the apocrine gland shows a single layer of secretory cells because the outer layer of cells consists of myoepithelial cells, just as in the eccrine gland. The secretory cells vary greatly in height, depending on the stage of secretion. Variation in height may be seen even in the cross section of the same secretory tubule (193). The secretory cells possess an eosinophilic cytoplasm. Except in the apical portion, they contain in their cytoplasm fairly large, PAS-positive, diastase-resistant granules, which appear much larger than similar granules seen in the dark secretory cells of eccrine glands. In addition, the apocrine

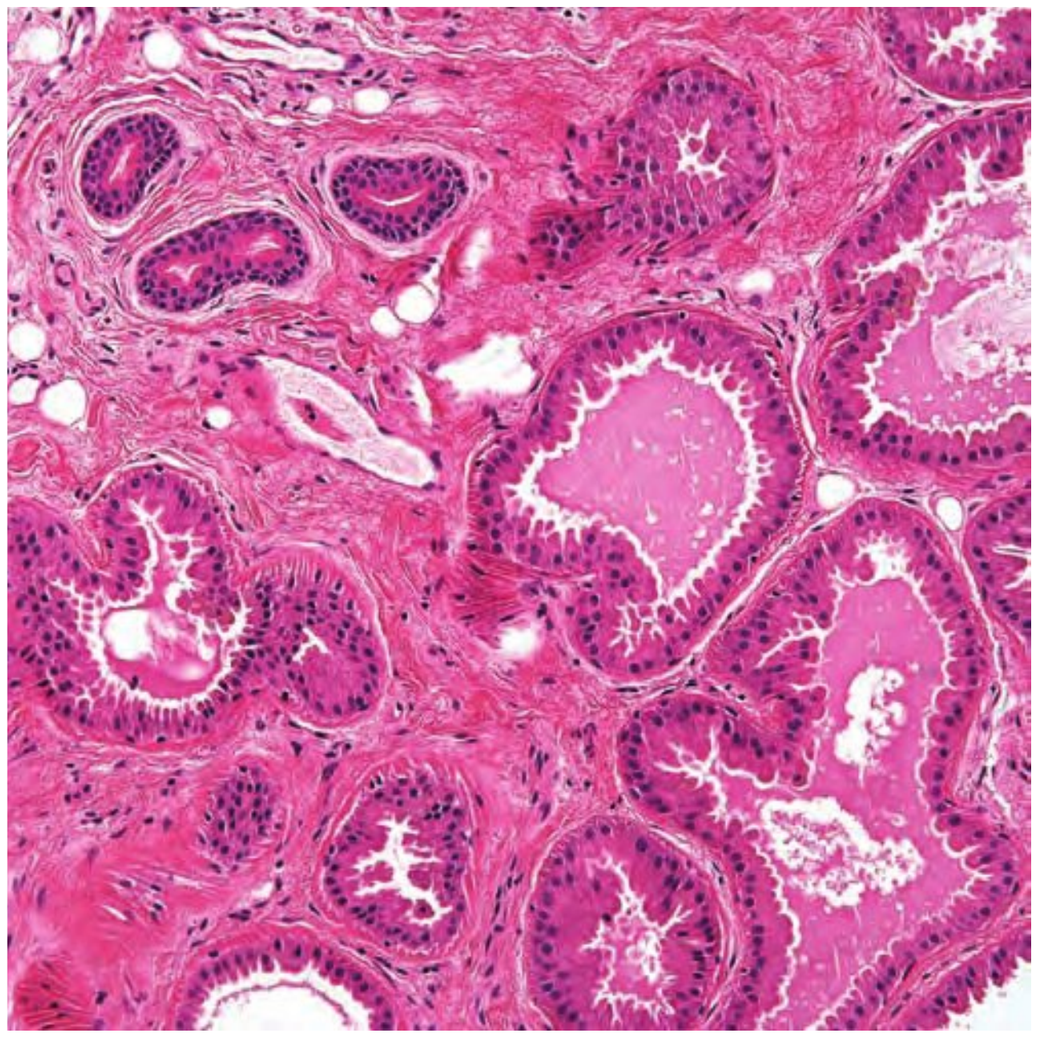

FIGURE 3-36. Apocrine glands. The secretory portion shows typical decapitation-type secretion. The ductal portion is indistinguishable from the ductal portion of the eccrine glands.

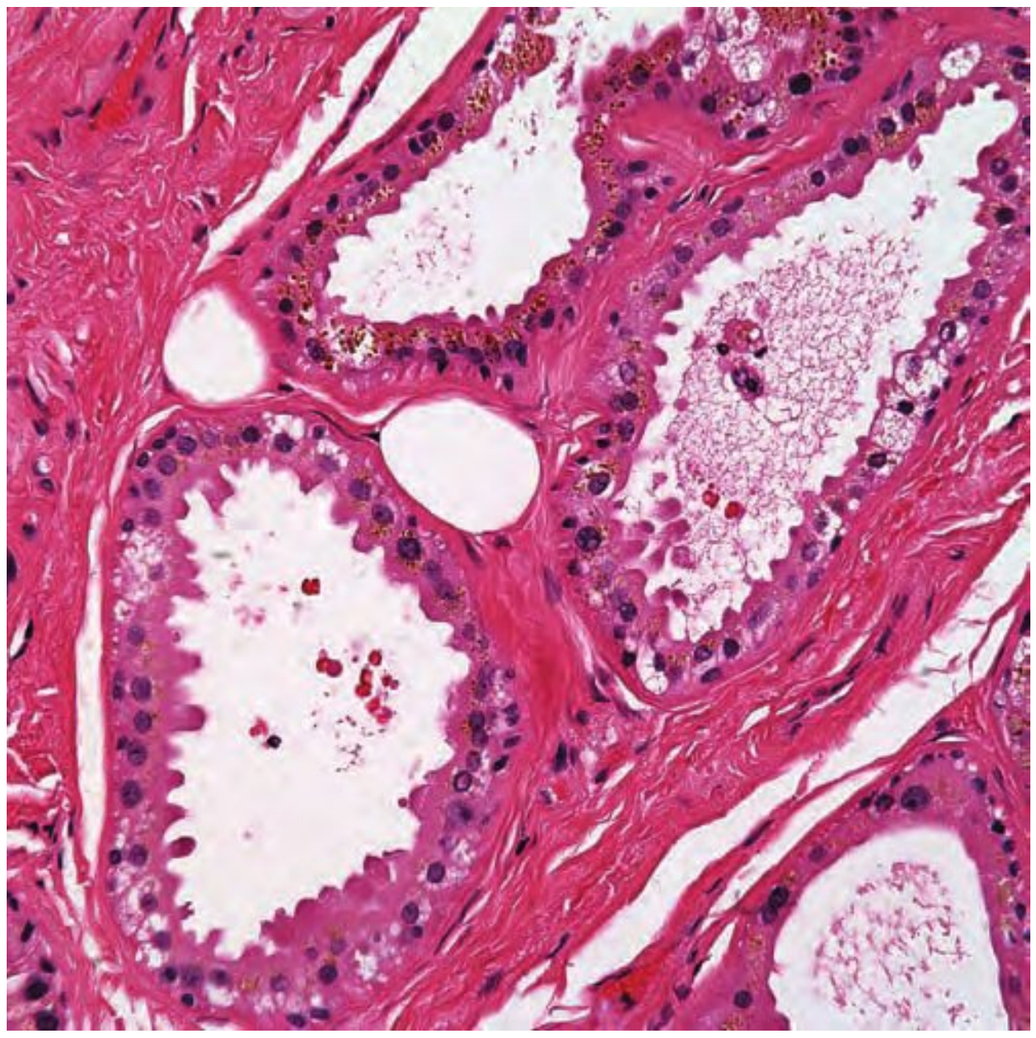

FIGURE 3-37. Ceruminous glands are modified apocrine glands found in the external ear canal. Note the lipofuscin pigment in the cytoplasm of apocrine cells.

granules frequently contain iron. Maturation of the secretory cells is indicated by the formation of a dome-shaped apical cap (Fig. 3-36). The type of secretion occurring in apocrine glands consists of the release of portions of cytoplasm into the lumen. Because of the cytoplasm in the secretion, apocrine secretion, in contrast to eccrine secretion, is visible in histologic sections stained with hematoxylin-eosin. The apocrine secretion contains amorphous, PAS-positive, diastase-resistant material originating from the granules that have dissolved in the apical portion of the secretory cells (194). This PAS-positive material, like the secretion of the dark cells in eccrine glands, consists of sialomucin.

The third type of sweat gland designated as the apoeccrine sweat gland shows a segmental or diffuse, apocrine-like dilation of its secretory tubule but has a long and thin duct that does not open into a hair follicle. The electron microscopy of its dilated segment is often indistinguishable from that of the classical apocrine gland. The less remarkably dilated segment of the apoeccrine gland tends to retain intercellular canaliculi and/or dark cells (184).

Regional Variation

Eccrine glands are present everywhere in the human skin; however, they are absent in areas of modified skin that lack all cutaneous appendages, that is, the vermilion border of the lips, the nail beds, the labia minora, the glans penis, and the inner aspect of the prepuce. They are found in greatest abundance on the palms and soles and in the axillae.

Apocrine glands are encountered in only a few areas: in the axillae, in the anogenital region, and as modified glands in the external ear canal (ceruminous glands) (Fig. 3-37), in the eyelid (Moll's glands) (see Fig. 3-62D), and in the breast (mammary glands). Occasionally, a few apocrine glands are found on the face, in the scalp, and on the abdomen; they usually are small and nonfunctional (195). Apocrine glands develop their secretory portion and become functional only at puberty. Each of the multiple protuberances present in the areola of the female breast and referred to as Montgomery's areolar tubercles contains a lactiferous duct and several superficially located sebaceous lobules whose ducts lead into the lactiferous duct (196,197).

Specialized Structure and Function

The eccrine sweat gland is engineered for temperature regulation (198). With approximately 3 million glands in the human integument weighing 35 μg/gland, the average human boasts about 100 g of eccrine glands capable of producing a maximum of approximately 1.8 L of sweat/hour! The eccrine secretory coil is richly invested in a stroma rich in unmyelinated nerve fibers, which are believed to play an important role in regulation of sweat production. Cholinergic stimulation of eccrine clear cells has been shown to increase cytosolic Ca^{2+} in a biphasic manner. This results in stimulation of both K^+ and Cl^- membrane channels, resulting in a net efflux of KCl along with Na^+ from the cell. Such electrolyte shifts, associated with water loss, underscore major metabolic implications of excessive eccrine sweating. Aside from potentially critical temperature regulation, the eccrine gland may contribute to general cutaneous homeostasis. For example, patients with congenital

anhidrotic ectodermal dysplasia suffer from heat intolerance that cannot be alleviated by simply adding moisture to the skin surface, suggesting that vasodilation associated with sweating may in some way be linked to eccrine function (198). There is abundant biologically active IL-1 in sweat (199), as well as numerous proteolytic enzymes, raising the possibility that eccrine sweat may possess proinflammatory or protective functions.

The mechanisms and rationale for apocrine-type secretion remain elusive. Schaumburg-Lever and Lever found three types of secretion (193): merocrine, apocrine, and holocrine. In the apocrine type of secretion, three stages were observed: formation of an apical cap, formation of a dividing membrane at the base of the apical cap, and formation of tubules above and parallel to the dividing membrane, supplying a new plasma membrane for both the undersurface of the apical cap and the top of the residual cell, bringing about detachment of the apical cap. Convincing proof of the detachment of entire apical caps in apocrine glands was provided through scanning microscopy by Inoue (200), who observed on each secretory cell a cytoplasmic luminal protuberance about 2 μm in diameter. In the early stage of secretion, the protuberance was hemispheric, but it later increased in height to form a linguiform process.

Why apocrine glands undergo the cellular complexities of decapitation secretion and the functional raison d'être for apocrine secretion in humans remain an enigma, although they may simply be an evolutionary vestige (musk glands of the deer and scent glands of the skunk are modified apocrine-type structures). The characteristic odor in human axillary sweat has recently been shown to reside in volatile C_6-C_{11} acids, with the most abundant being 3-methyl-2-hexenoic acid (201). This initially odorless apocrine secretion is formed at the skin surface from protein precursors via saponification or bacteriolysis. Such chemical interactions are similar to those in lower mammals, in which secreted proteins act as carriers of one or more pheromone signals.

Special Stains

Eccrine and apocrine glands and their products can be identified using special histochemical, enzymatic, and immunohistochemical stains (202,203). With PAS stain the clear secretory cells show a dense, globular PAS-positive material when glycogen is present (there is a depletion of glycogen after sweating). The dark cells show a finely granular, PAS-positive and diastase-resistant cytoplasm that is also seen with acid-fast stains. The ductal cells of eccrine and apocrine glands show a more variable staining with PAS (204). PAS stains the basement membrane of both eccrine and apocrine ducts. PAS stains of the secretory apocrine component vary from negative to focally positive; they can show a markedly positive granularity with iron and acid-fast stains. The mucicarmine stain is usually noncontributory. Enzymatic stains in fresh tissue such as amylophosphorylase and succinic dehydrogenase are very rarely used in routine surgical pathology (204).

Immunohistochemical stains (Figs. 3-35A–F) show that carcinoembryonic antigen is expressed in the luminal border of eccrine and apocrine ducts; it is also expressed in the intercellular canaliculi and cytoplasm of some eccrine secretory cells but is usually negative in secretory apocrine cells (Fig. 3-35D). A characteristic canalicular pattern is observed with epithelial membrane antigen (Fig. 3-37E). Cytokeratins of low molecular weight such as CK7 and CAM 5.2 are expressed only by the secretory portion of both eccrine and apocrine glands (Fig. 3-35A); however, they are not expressed by their excretory ducts. Keratin AE1 stains the secretory and ductal cells of both eccrine and apocrine glands. Keratin 34 β E12 is expressed by ductal cells and basal cells of the secretory portion (Fig. 3-35B). p63 is expressed by basal cells (but not luminal cells) of the ductal portion and only scattered cells of the secretory portion (Fig. 3-35C). The expression of S100 protein is seen in some of the secretory cells of the eccrine glands (Fig. 3-35F) but not in apocrine glands. However, in sections of the axilla, some larger glands do show S100 staining; these may represent apoeccrine glands (204). The myoepithelial cells express smooth muscle actins.

Specialized Keratinization: Nails

The nail unit is a region of specialized keratinization of practical importance because dermatosis, infections, and neoplasms may affect this region, prompting histologic sampling (205). The nail unit has six main components (Figs. 3-38 and 3-39): (a) the nail matrix, which gives rise to the nail plate; (b) the nail plate; (c) the cuticular system, consisting of the dorsal component, or cuticle, and the distal component, or hyponychium; (d) the nail bed, which includes the dermis and underlying bone and soft tissue beneath the nail plate; (e) an anchoring system of ligaments between bone and matrix proximally and between distal grooves distally; and (f) the nail folds proximally, laterally, and distally.

The proximal nail fold is a wedge-shaped fold of the skin on the dorsum of the distal digit underneath where the nail

FIGURE 3-39. A: Low-power view of a transverse section of the distal portion of a finger including the nail unit. Overlying the nail bed is a thick, acellular nail plate. The lateral folds can be appreciated on both sides. B: Proximal nail fold forming the roof of the nail groove. Note the presence of granular layer on the dorsal and ventral surfaces. The floor of the nail groove corresponds to the nail matrix. Between the two structures lies the nail plate. C: Nail matrix. Note the lack of granular layer and presence of multilayered germinative basal cells. D: Nail bed. Note the lack of granular layer. The epithelium shows a paucity of germinative basal cells.

plate arises. It consists of two layers of epidermis, both of which show a granular layer. The dorsal surface proximal nail fold contains eccrine but not pilosebaceous units and undergoes epidermal-type keratinization with an intervening granular cell layer, resulting in the production of soft keratin. Its ventral surface or eponychium is devoid of rete ridges and appendages. Keratohyalin granules are present in the epidermis of the ventral proximal nail fold, which produces the semihard keratin of the cuticle. The ventral surface of the proximal nail fold forms the roof of the proximal nail groove. The floor of the proximal nail groove is formed by the nail matrix, and the nail plate lies between the two (Figs. 3-38 and 3-39B).

The nail matrix is responsible for the production of the "hard keratin" of the nail plate. This occurs via a process termed onychokeratinization, and, as in trichilemmal keratinization, it occurs by accretion of tonofilaments without the

formation of intervening keratohyalin granules (206,207). This process involves thickening of the cellular envelope of the keratinizing cells to form a marginal band, analogous to similar changes in the surface epidermis (208). The nail matrix may be divided into two regions—one distal, responsible for the formation of the ventral portion of the nail plate and clinically visible (the lunula), and the other proximal and responsible for the formation of the dorsal surface of the nail plate. The nail thickness is determined predominantly by the matrix, although one study suggested that the nail bed may contribute up to 20% as the nail grows (209). The matrix epithelium contains an upper, broad keratogenous zone containing flattened eosinophilic keratinocytes and a basal compartment with active germinative cells (Fig. 3-39C). Compared to the epidermis, this basal compartment is multilayered (210). Melanocytes are present in the distal portion of the nail matrix (211), and Langerhans cells and Merkel cells have also been identified in this region (206).

The nail bed begins at the distal lunula and ends distally at the hyponychium. It also exhibits onycholemmal-type keratinization. The nail bed epidermis is usually thinner than the matrix epidermis, with less prominent basal layer and no melanocytes (Fig. 3-39D). The surface of the bed typically shows parallel longitudinal grooves that correlate with interdigitation of underlying rete ridges and dermal papillae. Clinically, the onychodermal band signifies the separation of the nail plate from the hyponychium, where the normal volar epidermis and epidermal-type keratinization resumes.

The nail plate consists of closely packed, adherent, interdigitating corneocytes lacking nuclei or organelles. Desmosomal junctions are identified.

Recent immunohistochemical studies revealed two types of tissue compartments in the nail unit—compartments that exclusively express epidermal keratins, and others exhibiting a varying, mixed expression of epidermal and hair keratins (210).

DERMIS

The cellular components (resident cells) of the dermis comprise the following:

- Fibroblasts
- Dermal dendritic cells
- Macrophages
- Mast cells

The extracellular components comprise the following:

- Collagen
- Elastic fibers
- Ground substance

The dermis is a dynamic, supportive connective tissue composed of an extracellular matrix that includes collagen, elastic fibers, and ground substance intimately associated with a cellular component that is mainly composed of fibroblasts, myofibroblasts, macrophages, dermal dendritic cells, and mast cells (Figs. 3-40 to 3-55). Within the dermis, there are also epidermal appendages with their connective tissue sheath, arrector pili muscles, blood vessels and nerves, and their end organs. The dermis consists of two layers: the papillary dermis and the reticular dermis. The papillary dermis represents a thin zone beneath the epidermis (and between the rete ridges) (Figs. 3-5 and 3-47). The reticular dermis, which is thicker, lies between papillary dermis and the subcutaneous adipose tissue (Figs. 3-4 and 3-58). The adventitial dermis combines the papillary and periadnexal dermis. The papillary dermis and the epidermis together form a morphologic and functional unit whose interrelatedness is reflected in their alteration jointly in various inflammatory processes, for example, interface dermatitides such as lichen planus and erythema multiforme (Chapters 7 and 9). An analogous relationship exists between adnexal epithelium and periadnexal connective tissue (the "adventitial dermis") (212).

Dermal Fibroblasts

The dermis of a 2-month-old embryo consists of loosely arranged mesenchymal cells that are embedded in ground substance. During the third month, argyrophilic reticulum fibers appear. As these fibers increase in number and in thickness, they arrange themselves in bundles that no longer can be impregnated with silver and, instead, stain with the methods for collagen. Simultaneously, the mesenchymal cells develop into fibroblasts. Electron microscopic examination of the fetal dermis from week 6 to week 14 reveals, apart from Schwann cells identified by their association with neuraxons, three main types of cells: (a) stellate mesenchymal cells with long processes, (b) phagocytic macrophages of probable yolk-sac origin, and (c) cells containing granules, which could be either melanoblasts or mast precursors. From week 14 on, fibroblasts become numerous. In the normal adult dermis, fibroblasts appear as inconspicuous bipolar spindle cells with elongated ovoid nuclei. They cannot reliably be distinguished from other dermal spindle-shaped and dendritic cells. By electron microscopy, fibroblasts that actively synthesize collagen have a prominent rough endoplasmic reticulum composed of many membrane-lined cisternae with large numbers of attached ribosomes (Fig. 3-40B). The dilated cisternae are filled with an amorphous material produced by the ribosomes lining the cisternae (213). This apparently amorphous material consists of triple-helical procollagen molecules, each molecule being composed of three pro–α-polypeptide chains. The procollagen molecules pass from the cisternae of the rough endoplasmic reticulum to the Golgi area, whence they are excreted into the extracellular space by means of secretory vesicles (214,215). Conversion of procollagen molecules into collagen molecules composed of three α chains then occurs outside the cell (216). Immunohistochemically, fibroblasts express vimentin. CD10 immunoreactivity is normally found in periadnexal fibroblasts. Active, regenerative fibroblasts (e.g., in granulation tissue) disclose ultrastructural and immunohistochemical features of myofibroblasts (217). Myofibroblasts may express, in addition

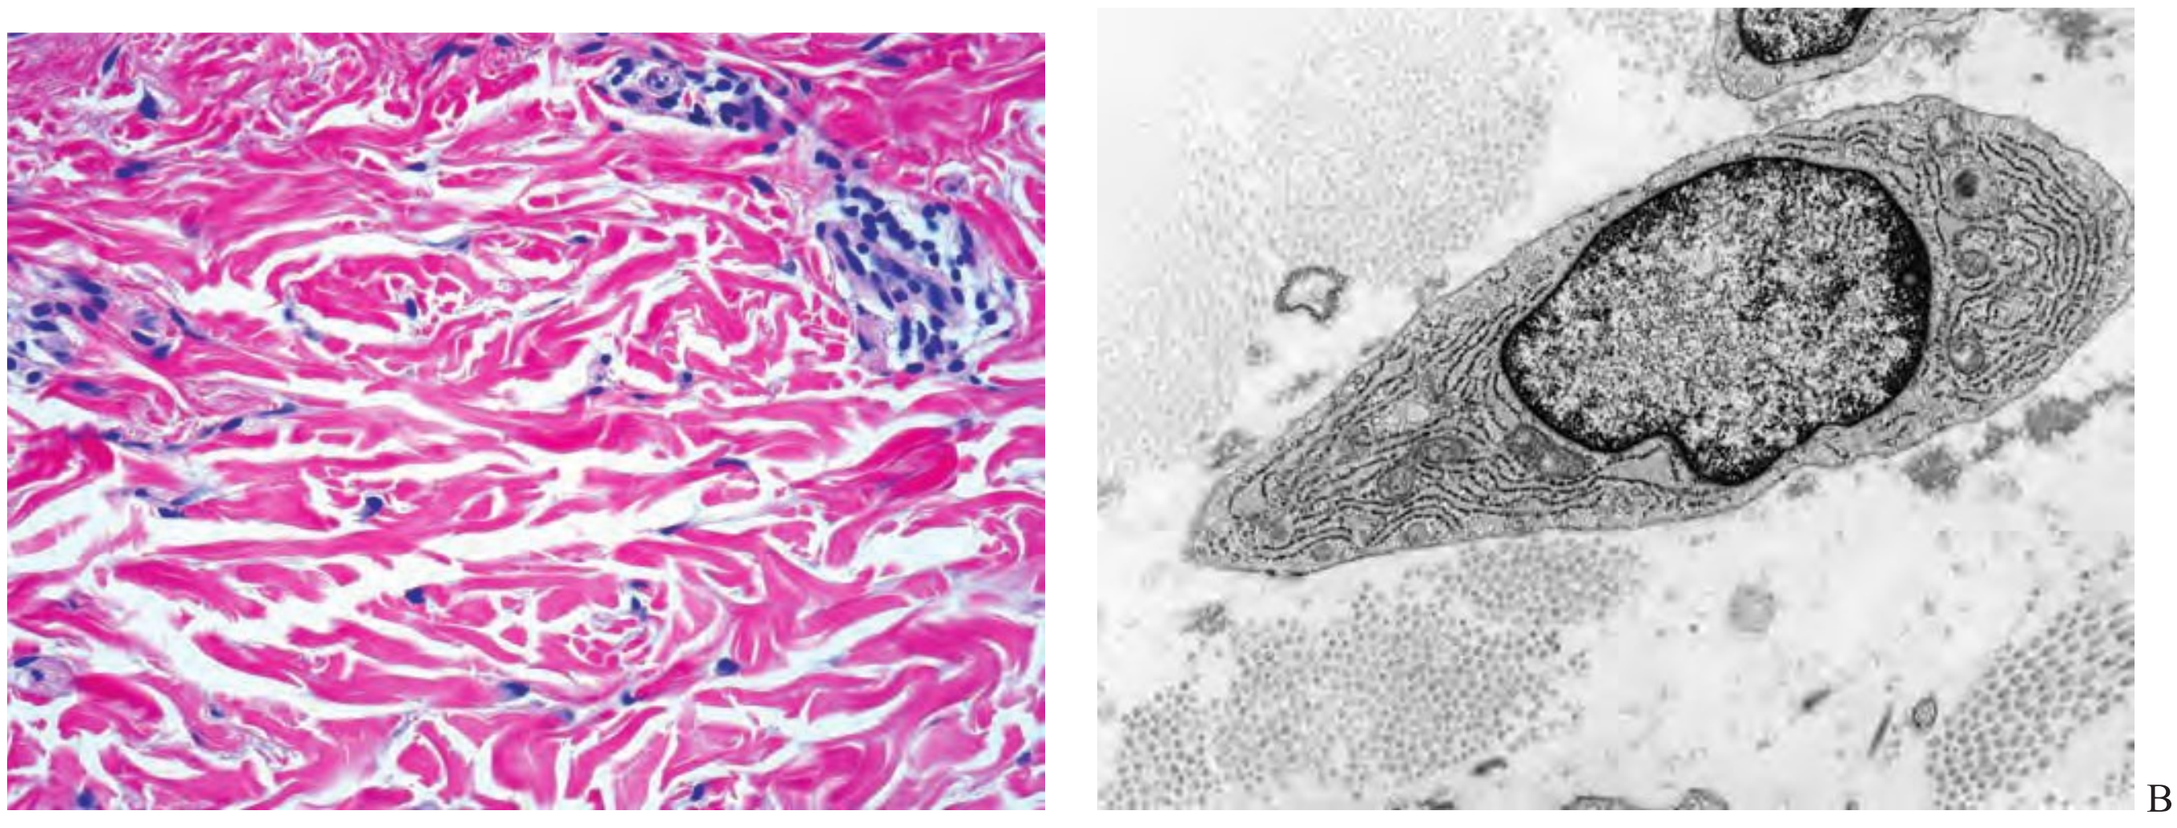

FIGURE 3-40. A: Scattered fibroblasts are present among thick collagen bundles in the reticular dermis. B: Dermal fibroblast viewed by transmission electron microscopy, showing dilated cisternae of rough endoplasmic reticulum and surrounding collagen fibers on cross section.

to vimentin, smooth muscle actin and desmin. Whereas resting fibroblasts may be difficult to differentiate from other dermal spindle cell elements, stimulated fibroblasts may be detected at transcriptional and posttranscriptional levels by probes that identify components involved in active collagen synthesis.

Perivascular and Interstitial Dendritic Cells

In 1986, Headington introduced the term "dermal dendrocyte" to denote newly recognized dendritic cells in the human dermis (218). These cells were primarily but not exclusively perivascular in location and differed from conventional bipolar fibroblasts by their stellate contours. Some of these cells appeared to represent "veil cells," which enshrouded venular walls with thin membrane flaps, as originally described by Braverman et al. (219). Many of these cells were subsequently shown to express the membrane glycoprotein CD1c (220), HLA-DR, and certain macrophage markers as well as the cytoplasmic transglutaminase, factor XIIIa (221) (Fig. 3-41). Heterogeneity of dermal dendrocytes within different dermal strata with regard to their expression of the hematopoietic progenitor antigen, CD34, and FXIIIa has been described (222). Per conventional immunohistochemistry, factor XIIIa–positive cells are predominantly found in perivascular distribution in the papillary dermis and around sweat glands. Although their presence is not specific, factor XIIIa–positive cells have been detected in increased numbers in numerous pathologic conditions, including Kaposi's sarcoma, dermatofibroma, and scar formation. CD34-positive cells are more numerous in the mid and deep dermis and around adnexae (223).

Whereas dermal dendrocytes are dendritic only in cross section, with three-dimensional reconstructions showing elaborate membranous flaps (222), truly dendritic cells also exist in the perivascular space. These cells are Langerhans cell-like, although they generally do not contain Birbeck granules, strongly express HLA-DR, and are believed to be involved in dermal antigen presentation (224). Considerable plasticity among the various subpopulations of dermal perivascular dendritic cells may exist, and alterations in local microenvironment may induce phenotypic transformation from one subtype to another (225).

In general, perivascular dendritic cells are not identifiable as such in routinely prepared and stained sections, although immunohistochemistry for the relevant markers permits the ready identification and classification of these cell types. Dermal dendrocytes may be observed in certain situations in which

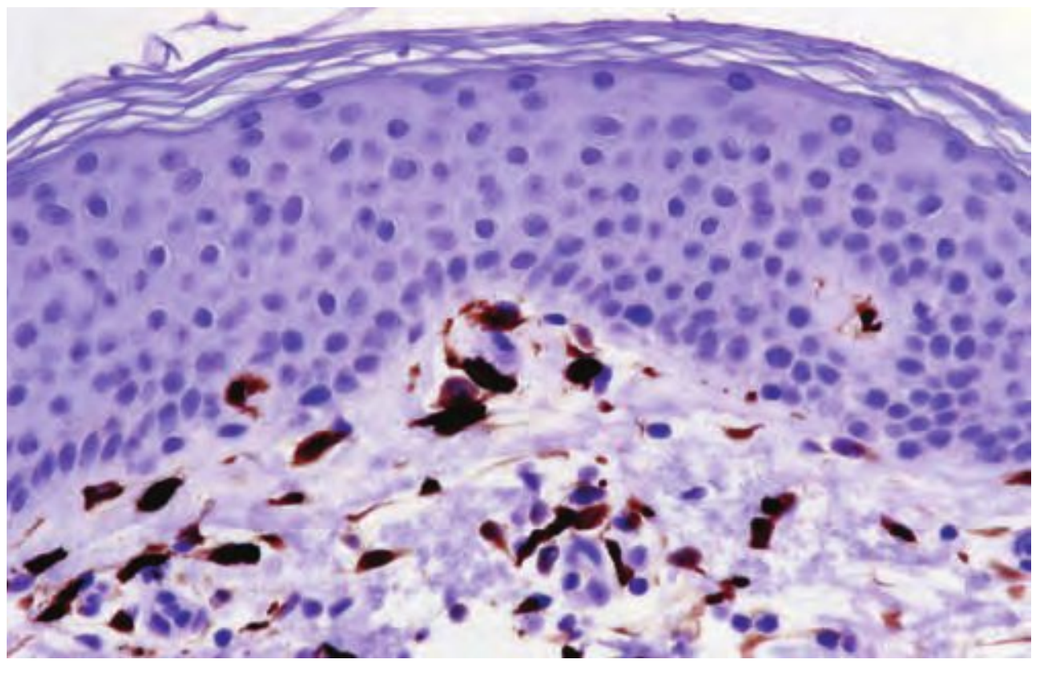

FIGURE 3-41. Factor XIIIa–positive "dermal dendrocytes" concentrated beneath the epidermal layer and about the dermal microvascular unit.

they acquire avid phagocytic potential, taking up hemosiderin, for example. Such phagocytic perivascular dendritic cells have been termed "dendrophages" (226).

Phagocytic Macrophages

Macrophages, also called histiocytes, are of bone marrow origin, circulate in the blood as precursors, and enter the tissue as monocytes (227). On proper stimulation, monocytes can develop into macrophages in the skin, which involves a considerable increase in cell size and changes in cellular composition and architecture, including increases in lysosomal enzymes, such as β-glucuronidase, acid phosphatase, lysozyme, and aryl sulfatase (228). Macrophages may develop further into epithelioid histiocytes and foreign body giant cells. Aggregates of activated macrophages are referred to as granulomas. Macrophages are most often concentrated in the perivascular space of normal skin, although, depending on the nature and location of the stimulus for their activation, may be found anywhere in the dermis (or epidermis).

Macrophages constitute the "mononuclear phagocytic system," a concept that has replaced that of the reticuloendothelial system. The macrophages of the mononuclear phagocytic system, including the alveolar phagocytes in the lungs and the Kupffer cells in the liver, are the "professional" phagocytes, whereas the reticuloendothelial cells, including the dendritic reticulum cells in lymph nodes and the endothelial cells of blood vessels, are merely "facultative" phagocytes and are comparatively inadequate (228). As "professional" phagocytes, macrophages are capable of ingesting large particles and developing a high concentration of lysosomal enzymes, which combine with the particles to form phagolysosomes. In contrast, the facultative phagocytosis carried out by endothelial cells consists merely of pinocytosis of small particles without immune stimulation (228). Macrophages can also be stimulated by immunologic factors having surface receptors for the Fc portion of IgG, for C3, and for immune-associated HLA-DR antigen (human leukocyte antigen-D subregion of the major histocompatibility complex) (229).

Monocytes are indistinguishable by routine histology from lymphocytes because both cells have a small, dark, rounded nucleus and very scanty cytoplasm that cannot be recognized in routine sections. Only slightly larger than lymphocytes, monocytes measure 12 to 15 μm in diameter (229). Monocytes can be differentiated from lymphocytes in histologic sections through staining for lysosomal enzymes, such as acid phosphatase, which are present in monocytes and absent in lymphocytes. In addition, monocytes but not lymphocytes express intracytoplasmic molecules probably associated with lysosomes, such as CD68 and KP1. Such antibodies, however, are generally regarded as organelle rather than cell lineage specific and are not considered exclusive markers of cells of monocyte/macrophage derivation (230). A more recently described monocytic/macrophagic marker is CD163, which is a glycoprotein belonging to the scavenger receptor cysteine-rich superfamily. CD163 is of particular interest because its expression has been shown by *in situ* hybridization, immunofluorescent, and immunohistochemical techniques to be largely restricted to monocytes and tissue macrophages (230). CD68, KP1, and CD163 may be detected immunohistochemically in paraffin sections (231).

Macrophages, because they are activated monocytes, are larger cells than monocytes and measure from 20 to 80 μm in diameter (229). They possess a vesicular, lightly staining, elongated nucleus with a clearly visible nuclear membrane. It is often impossible in routinely stained sections to distinguish macrophages from fibroblasts or from endothelial cells except through their respective locations or phagocytic activities. Macrophages that have ingested melanin are referred to as melanophages and may be observed normally within the papillary dermis of darkly pigmented individuals. Macrophages that have ingested hemosiderin are termed siderophage, and may be suspected due to the characteristic yellow-green color and refractile nature of particulate hemosiderin. Iron stains (e.g., Prussian blue) are confirmatory.

The origin of the tissue monocytes in human skin from blood monocytes has been established in healthy probands through transfusion of tritiated-thymidine–labeled monocytes and their observation 3 hours later in skin window exudates (232). On the other hand, the dermal infiltrate of monocytes and macrophages in patients with chronic dermatitis is largely self-renewing because the monocyte recruitment rate from the blood is low in these patients after the autotransfusion of labeled monocytes (232). Electron microscopic examination reveals in monocytes many primary lysosomes scattered through their cytoplasm as small dense bodies (233). Macrophages, which represent stimulated monocytes, differ from monocytes in that they are larger, show longer processes, and contain a greater number of lysosomes (234) (Fig. 3-42).

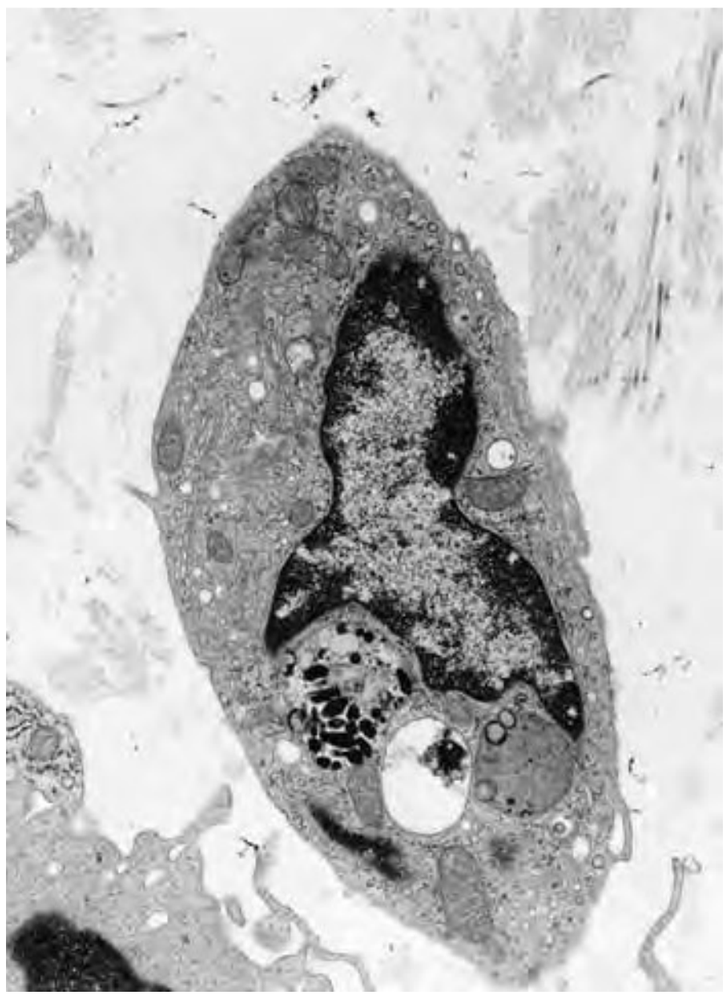

FIGURE 3-42. Ultrastructure of phagocytic macrophage within the dermis. Note the intracytoplasmic lysosomes associated with engulfed cell breakdown products, including a large vacuole containing internalized melanosomes.

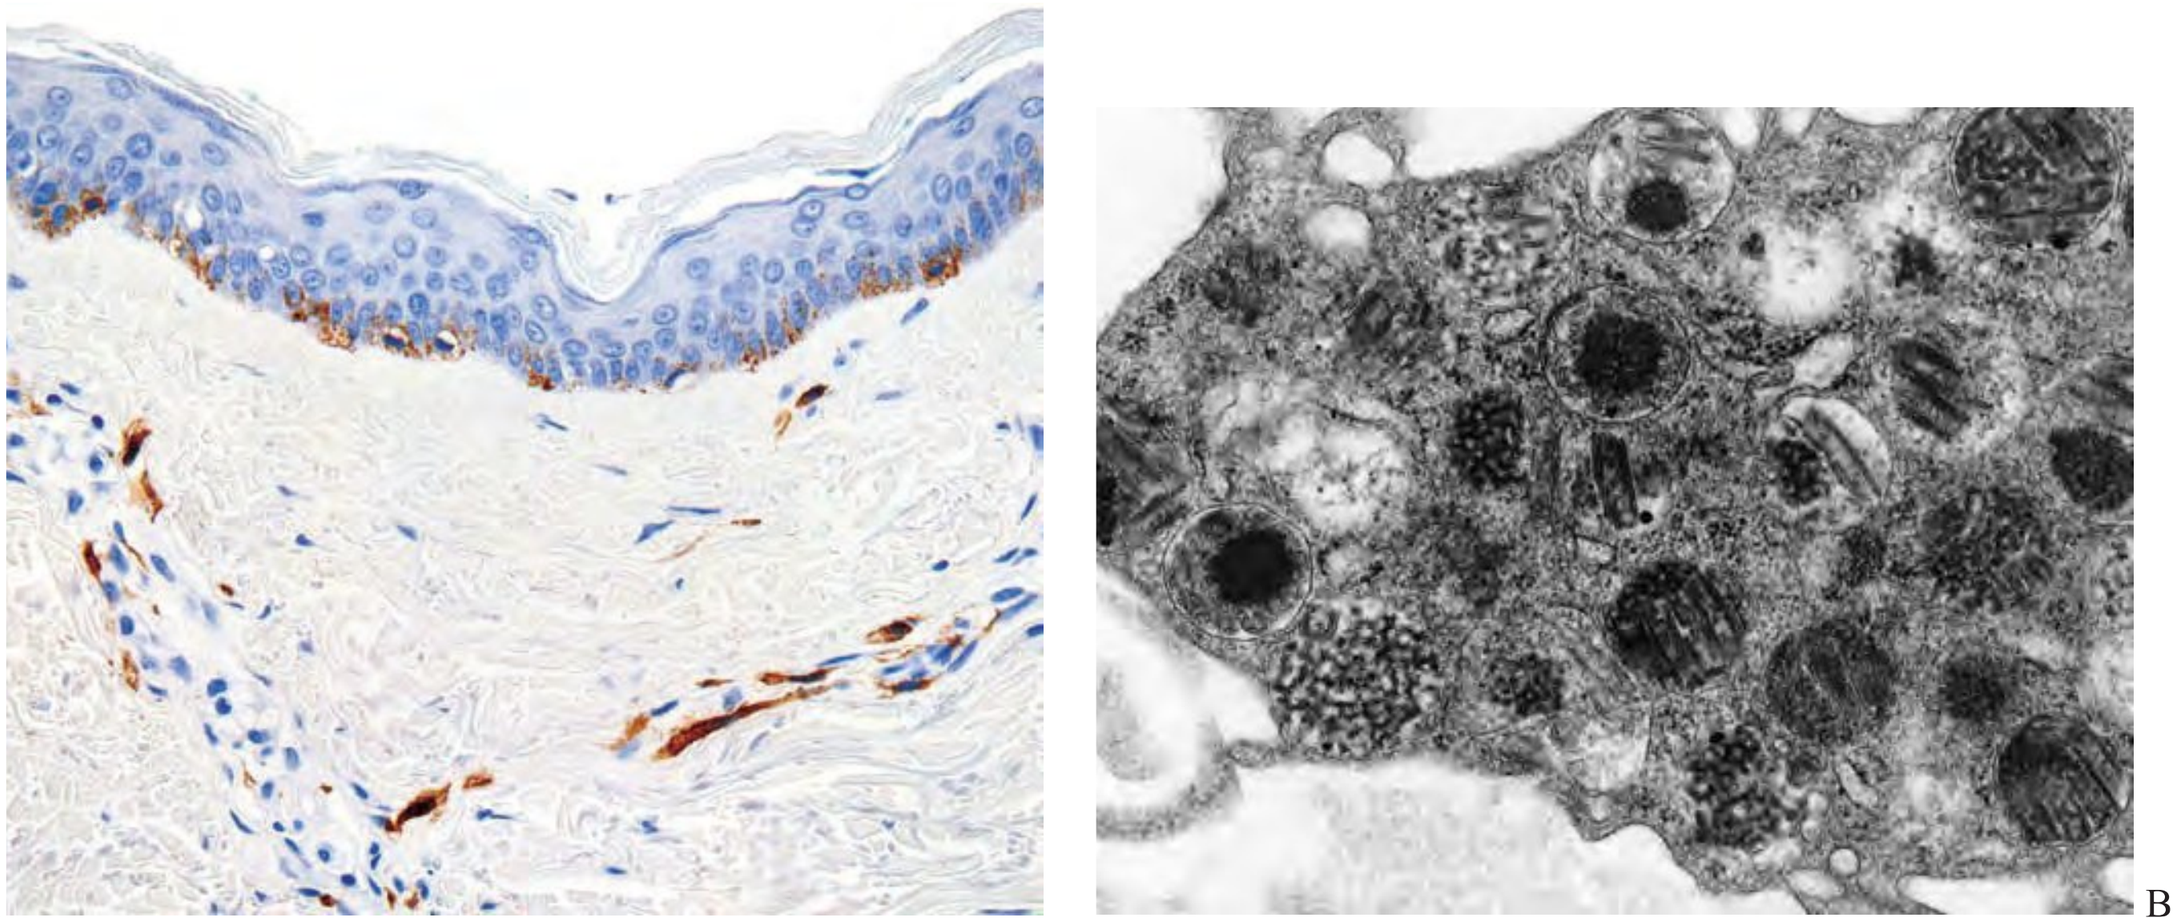

FIGURE 3-43. A: KIT (CD117) highlights dermal mast cells and junctional melanocytes. B: Transmission electron micrograph of a granulated mast cell.

Many macrophages contain phagocytized material within phagosomes, which, through the influx of the contents of primary lysosomes, have become phagolysosomes.

Mast Cells

Mast cells (Fig. 3-43) are bone marrow–derived cells that occur in the normal dermis in small numbers as oval to spindle-shaped cells with a centrally located round to oval nucleus. They are generally concentrated about blood vessels, specifically postcapillary venules (one to three cells per cross-sectional vessel profile). They contain in their cytoplasm numerous granules that do not stain with routine stains like hematoxylin-eosin. Therefore, mast cells in normal skin are not reliably distinguishable from other perivascular cells, although one can occasionally recognize in mast cells a small amount of cytoplasm and the cell membrane. The granules stain with methylene blue, which is present in the Giemsa stain, with toluidine blue, and with alcian blue. They also stain metachromatically with methylene blue and toluidine blue, that is, they stain in a color different from that possessed by the dye and appear purplish red rather than blue.

Electron microscopic examination of mast cells reveals numerous large and long villi at their periphery. The mast cell granules appear as round, oval, or angular-shaped, membrane-bound structures. Mature granules measure up to 0.8 μm in diameter (235) (Fig. 3-43B). They contain two components: lamellae and electron-dense, finely granular material (236). Tangential sectioning of the lamellae reveals paracrystalline lattices as a result of transverse banding. Immunoultrastructural observations indicate that the various granule subcompartments correlate with distribution of serine proteinases tryptase and chymase within granules (237). In addition, mast cells that populate connective tissue environments like dermis tend to contain granules with poorly formed scrolls and express both chymase and tryptase, whereas mast cells found primarily in mucosae and associated lamina propria have granules with well-formed scrolls and express tryptase but not chymase (238,239). Of interest, one of these two granule types may be preferentially expressed in some cases of mastocytosis (240).

Degranulation of mast cells occurs after cross-linking of IgE on the cell surface, exposure to neuropeptides such as substance P, after nonspecific mechanical or thermal stimuli, or after exposure to a variety of exogenous secretagogues (compound 48/80, calcium ionophore, morphine sulfate). Degranulation generally occurs within minutes of exposure of the cell membrane to the secretagogue and usually consists in the extrusion of entire granules, but some granules may undergo intracellular disintegration (235,241,242). Initial stages of degranulation consist in granule swelling with loss of internal substructure and electron density. Extrusion of granules takes place through extensive membrane fusion between the plasma membrane and perigranular membranes and is associated with formation of conduits resulting from fusion of the membranes of multiple granules. This results in extensive labyrinthine channels in the cell through which swollen, less electron-dense granules, all of which have lost their individual surrounding membranes, are released into the extracellular space (236,243). Concomitant with their release into the extracellular space, the granules release their preformed and stored mediators histamine, heparin, serine proteinases, and certain cytokines.

Immediate hypersensitivity reactions can be triggered by mast cells and basophils in "anaphylactically" sensitized persons through the presence on their cell surfaces of specific antibodies of the IgE type. When the specific antigen combines

with these antibodies, an anaphylactic reaction is elicited through the degranulation of mast cells and the release of histamine from the granules (244). Histamine increases the permeability of postcapillary venules and, if released in sufficient amounts, may produce an anaphylactic shock. In delayed hypersensitivity reactions and in experimental allogeneic cytotoxic reactions, mast cells degranulate early, often preceding the initial influx of pioneer lymphocytes (245,246). Part of the reason for this lies in the fact that human mast cells contain TNFα (247), and local release of TNFα as a consequence of mast cell degranulation induces expression of adhesion molecules such as E-selectin in adjacent postcapillary venules (248), with resultant leukocyte binding to the endothelial luminal membrane (249). Cooperation between the mast cell and the endothelial cell is also underscored by the observations that mast cells appear to situate in the laminin-rich perivascular space in association with expression of specific laminin receptors on their membranes (250), and that endothelial cells express mast cell growth factor (also known as c-kit ligand or stem cell factor) (251). CD117 (KIT) is a type III receptor tyrosine kinase operating in cell signal transduction in several cell types. Normally KIT is activated (phosphorylated) by binding of its ligand, the stem cell factor. This leads to a phosphorylation cascade ultimately activating various transcription factors in different cell types. Such activation regulates apoptosis, cell differentiation, proliferation, chemotaxis, and cell adhesion. KIT-dependent cell types in the skin include mast cells, some hematopoietic stem cells, melanocytes, scattered basal keratinocytes, and epithelial cells of skin adnexae (252) (Fig. 3-43A).

Emigrant Inflammatory Cells

Various types of cells, largely derived from the bone marrow, infiltrate the dermis and occasionally also the epidermis in the inflammatory dermatoses. Infiltration is initiated at the level of the dermal microvascular unit, accounting for the observation that on detection, such cells are often partially or exclusively perivascular in location (Figs. 3-44A–D). Such cells may also be present in normal skin in low numbers as part of the skin immune system. It is important for diagnostic purposes to identify the cell types because many diagnostic algorithms for dermatitis classification and identification depend on initial categorization by architecture followed by recognition of inflammatory cell type(s) (see Chapter 5) (253). Three groups of cells are derived from the bone marrow: the granulocytic group; the lymphocytic group, including plasma cells; and the monocytic or macrophagic group (discussed earlier).

Neutrophilic Granulocytes

The neutrophilic granulocyte, also called a neutrophil or polymorphonuclear leukocyte, is 10 to 15 μm in diameter and has a lobated nucleus consisting of several segments that are connected

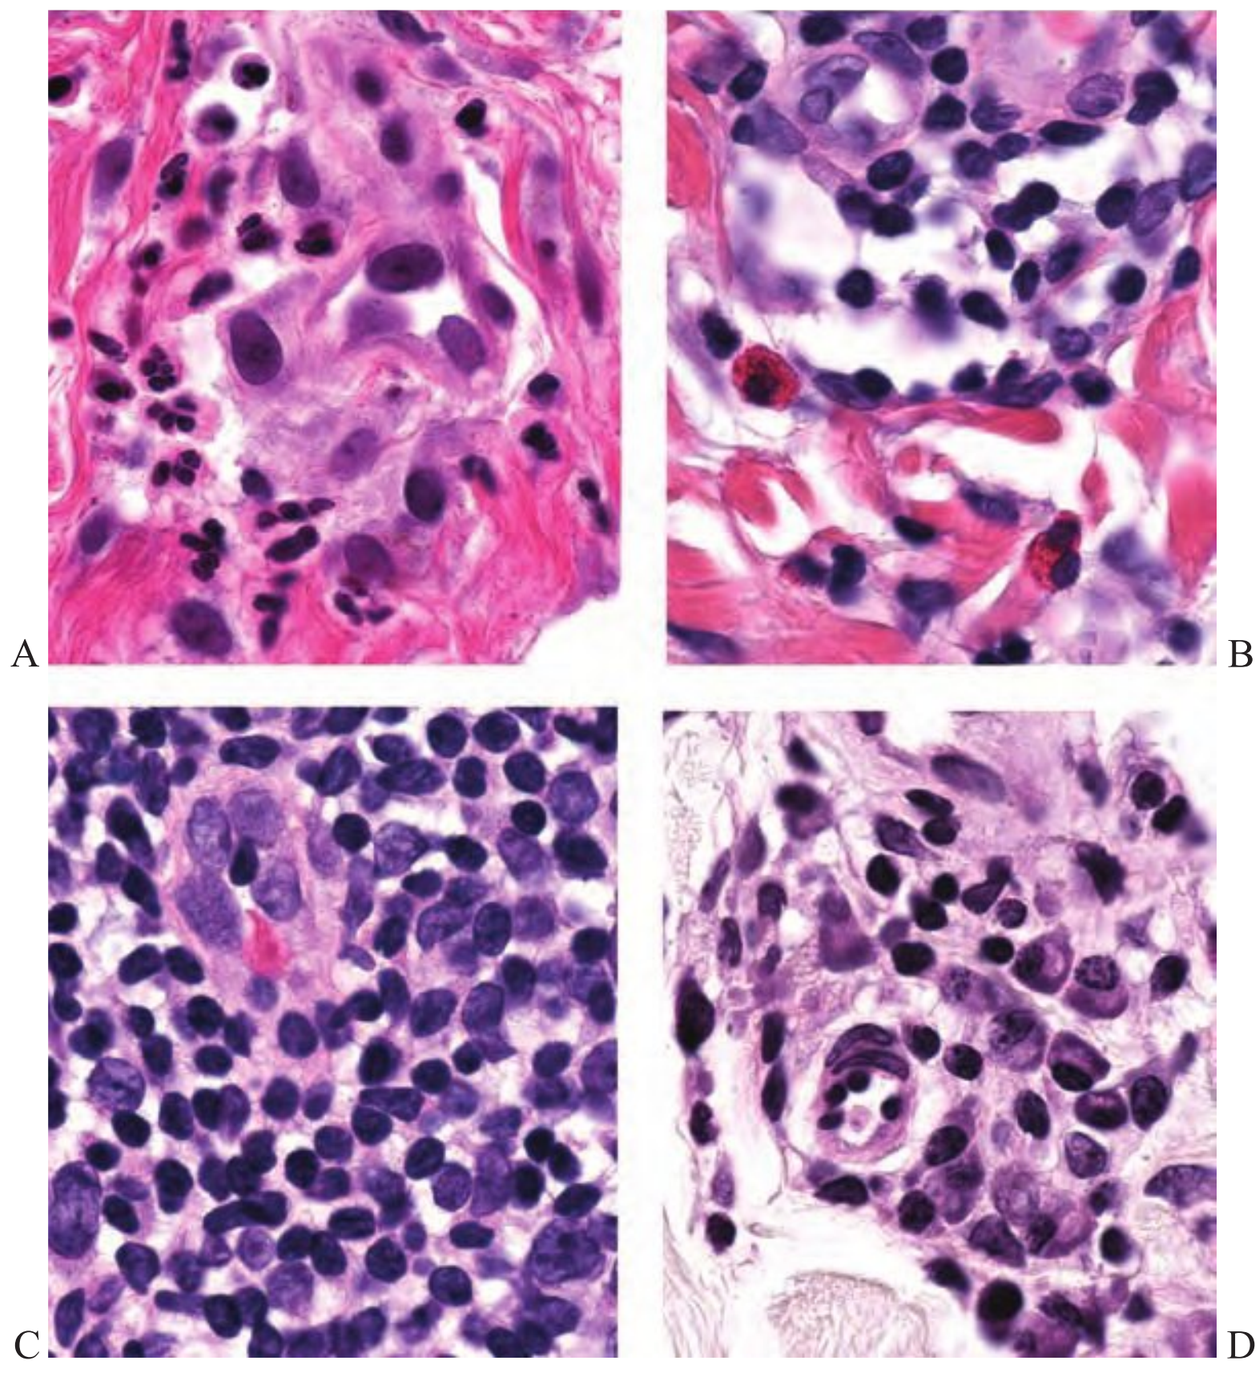

FIGURE 3-44. Emigrant inflammatory cells found in different common dermatitides include neutrophils (A), eosinophils (B), lymphocytes and histiocytes (C), and plasma cells (D).

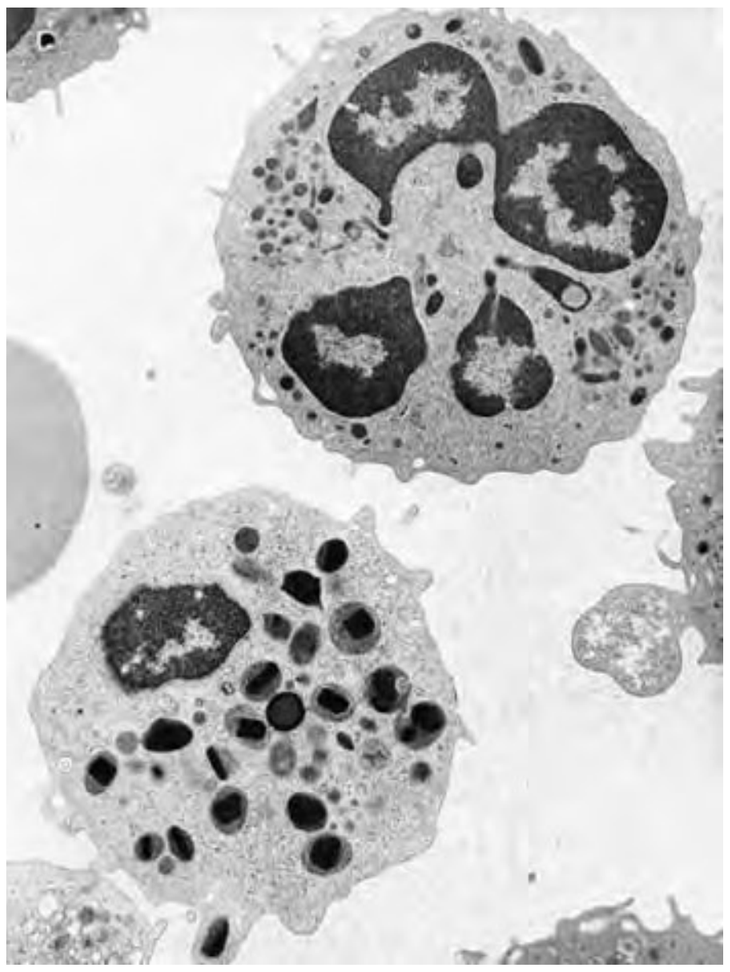

FIGURE 3-45. Ultrastructural comparison between neutrophilic (uppermost cell) and eosinophilic (lowermost cell) granulocytes.

only by narrow bridges of nucleoplasm (Fig. 3-44A). The cytoplasm contains numerous neutrophilic to slightly eosinophilic granules. On histochemical examination, the granules are seen to contain lysosomal enzymes and thus represent primary lysosomes. Two types of membrane-bound cytoplasmic granules or lysosomes are found to be present in neutrophils on electron microscopic examination: azurophilic and specific granules (254) (Fig. 3-45). The azurophilic granules, constituting about 20% of all granules, are relatively dense and large, measuring up to 1 μm in diameter. The more numerous specific granules average 300 nm in diameter. Among other substances, azurophilic granules contain (a) myeloperoxidase, which mediates the formation of hydrogen peroxide, essential for the killing of many microorganisms; (b) acid hydrolases, such as β-glucuronidase and acid phosphatase, capable of degrading dead bacteria and other necrotic material; (c) neutral proteases, such as collagenase and elastase, that may break down collagen and elastin; (d) cationic proteins, which cause an increase in vascular permeability; and (e) lysozyme, an enzyme that degrades and lyses bacterial cell walls. The specific granules also contain lysozyme and, in addition, collagenase, alkaline phosphatase, and lactoferrin, an iron-binding protein with bacteriostatic properties.

Neutrophils are unusual in normal skin but occur typically in a relatively small subset of dermatitides, including various cutaneous infections, urticaria, immune complex–mediated necrotizing vasculitis, and the spectrum of neutrophilic dermatosis (e.g., Sweet's syndrome, pyoderma gangrenosum). Neutrophils may participate, along with other cell types, in other inflammatory processes, such as psoriasis, seborrheic dermatitis, and pityriasis lichenoides et varioliformis acuta. In tissue sections, neutrophils are often recognized by virtue of their "popcorn"-shaped nuclei within pale pink, faintly granular cytoplasm. Nuclear breakdown due to local necrosis or autodigestion results in fragmentation of the multiple nuclear lobes, resulting in the characteristic "nuclear dust" of vasculitis.

Functionally, neutrophilic granulocytes play an important role in (a) certain inflammatory responses (examples were provided earlier), (b) the phagocytosis and killing of microorganisms, and (c) the immobilization and phagocytosis of antigen–antibody complexes in the presence of complement (255). Neutrophils fail to kill bacteria in chronic granulomatous disease, where they are congenitally incapable of oxygen uptake from the surrounding media (256). Phagocytosis of organisms and antigen–antibody complexes by neutrophils is accompanied by their partial or complete degranulation, with associated discharge of lysosomal enzymes (257). Endocytotic uptake of microorganisms by neutrophils results in the formation of intracytoplasmic phagolysosomes, where high enzyme concentrations result in microbial killing. Immune complexes, after activation of complement, may induce the local accumulation of neutrophils via chemotaxis. Phagocytosis of immune complexes by neutrophils and/or neutrophil degranulation may then occur (258). Exocytosis of neutrophil granules containing collagenase and elastase may result in local tissue damage, including necrosis of vessels containing immune complexes in their basement membranes (259).

Eosinophilic Granulocytes

The eosinophil, 12 to 17 μm in diameter, is characterized by strongly eosinophilic granules in the cytoplasm and a characteristically bilobed nucleus (260). Eosinophil granules are larger than the granules of neutrophils. Although visible with routine stains (Fig. 3-44B), these granules stand out more clearly in brilliant red when a Giemsa stain is used. On electron microscopic examination, the granules of eosinophils are seen to be round to oval. They consist of two components—a central, angular-shaped core, often referred to as the crystalloid, and a surrounding matrix. In electron microscopic sections stained with lead compounds, the crystalloid is more darkly stained than the matrix (261) (Fig. 3-45). The granules contain a variety of hydrolytic enzymes, particularly peroxidase and arylsulfatase, and therefore can be classified as lysosomes. The phagocytic potential of eosinophils seems to be limited to immune complexes and mast cell granules. During phagocytosis, which is analogous to that seen in neutrophils, the content of the eosinophilic granules is discharged into phagosomes (262).

Because eosinophils can phagocytize mast cell granules and certain antigen–antibody complexes, tissue eosinophilia in the skin can occur (a) as a result of anaphylactic or atopic hypersensitivity, (b) subsequent to the degranulation of mast cells, and (c) in certain diseases associated with deposits of antigen–antibody complexes in the skin. The tissue eosinophilia appearing in anaphylactic reactions and other forms of "immediate" allergy such as atopy is based on antibodies of the IgE type on the surface of mast cells. The anaphylactic reaction,

classified as type I hypersensitivity reaction (263), occurs after the binding of a specific antigen to a specific antibody on the surface of the mast cells. This leads to degranulation of mast cells and to the release of vasoactive substances, especially histamine. Wherever degranulation of mast cells occurs, eosinophils may appear and phagocytize the released mast cell granules (257). Eosinophils thus may modify an anaphylactic reaction (264). Eosinophils are attracted in an anaphylactic reaction by sensitized mast cells, which release an eosinophil chemotactic factor of anaphylaxis. Eosinophils thus attracted to the site of an anaphylactic reaction accumulate around degranulating mast cells and phagocytize the free mast cell granules (265).

Diseases in which deposition of antigen–antibody complexes is the cause of eosinophilia include pemphigus vulgaris, particularly pemphigus vegetans, pemphigus foliaceus, bullous pemphigoid (see Chapter 9), and granuloma faciale (see Chapter 8). The reasons for the occasional presence of tissue eosinophilia in histiocytosis X (see Chapter 6) and in Hodgkin's disease (see Chapter 31) are not fully apparent. Parasitic infestations often are associated with eosinophilia both in the peripheral blood and in the tissue (see Chapter 24). It is likely that eosinophils function as effector cells in parasite destruction (262). Destruction of parasites, such as those causing schistosomiasis, is accomplished by means of the major basic protein (MBP) of the eosinophils. The MBP is localized in the crystalloid core of the eosinophil granules and accounts for more than 50% of the protein in the granules and for almost 25% of the total protein in the cell. Its toxicity provides a mechanism by which the eosinophil damages parasites. Release of MBP from degranulating eosinophils, however, is not always beneficial to the host. Release of MBP may partly account for the tissue damage seen in chronic hypersensitivity reactions (266).

Basophilic Granulocytes

Although basophils and mast cells have similar or identical functions and supplement each other, they are different cells both in origin and in anatomy (267). Both cells have their origin in the bone marrow, although basophils circulate in the peripheral blood, and mature mast cells are confined to connective tissue and mucosal tissue compartments. Basophils are relatively rare in human dermatitis, although they are active participants in certain forms of dermatitis in rodents (267). The demonstration of basophils in light microscopic sections requires the use of electron microscopic fixation and processing techniques; biopsy specimens must be embedded in plastic resin and sectioned at 1 μm. The sections then are stained with the Giemsa stain. Basophils possess a multilobed nucleus and large, diffusely arranged metachromatic granules, whereas mast cells have a unilobed nucleus and smaller, peripherally located metachromatic granules (268).

Lymphocytes

There are two main types of peripheral lymphocytes—T and B lymphocytes—both of which arise in the bone marrow. One type migrates to the thymus, where it differentiates into a mature lymphocyte and then proceeds to the peripheral lymphoid tissues as a thymus-derived or T lymphocyte. In lymph nodes, T lymphocytes are located predominantly in the interfollicular cortex, also called the paracortical areas. The other type of lymphocyte—the B lymphocyte—matures in the bone marrow (269). The term B lymphocyte, meaning bursa-derived lymphocyte, originally was used because in birds the bursa of Fabricius is held responsible for B-cell maturation (269). In humans, the term B lymphocyte is used to indicate a bone marrow–derived lymphocyte. In lymph nodes, B lymphocytes largely occupy the lymphoid follicles, including their germinal centers. Whereas the T lymphocyte is the effector cell for cellular immunity, the B lymphocyte mediates humoral immunity. T cells can exert important regulating functions on both T cells and B cells in the form of specific functional subsets termed helper T cells and cytotoxic/suppressor T cells (270). The lymph nodes and other lymphoid organs share three principal functions to: (a) concentrate within them antigens from all parts of the body, (b) expose these antigens to naive and antigen-specific lymphocytes that circulate within them, and (c) deliver products of the immune response, namely the antibodies and cells mediating humoral and cellular immunity, respectively, to the blood and peripheral nonlymphoid tissues (269). Tissues that represent significant host–environmental interfaces, like skin and gut, are regular targets for physiologic T-cell trafficking mediated by tissue-specific homing receptors that interact with endothelial adhesion molecules (e.g., T-cell cutaneous lymphocyte-associated antigen and endothelial E-selectin in skin). This intimate homing relationship between central lymphoid organs and tissues like skin, in addition to resident populations of dendritic antigen-presenting cells (Langerhans cells) and effector cells (mast cells, see later discussion) is responsible for the concept of skin-associated lymphoid tissue.

Resting lymphocytes measure on average 8 to 10 μm in diameter and possess a relatively small, round nucleus that appears deeply basophilic because of the presence of numerous chromatin particles (Fig. 3-46). They have only a very narrow rim of cytoplasm that is difficult to delineate by conventional light microscopy. It is also usually not possible by light microscopy to distinguish lymphocytes from monocytes in routinely stained histologic sections. It is therefore preferable to refer to cells with a histologic appearance of lymphocytes as lymphoid cells, and infiltrates likely to contain significant admixtures of both lymphocytes and monocytes are sometimes referred to as involving mononuclear cells. Ultrastructurally, resting lymphocytes contain relatively few organelles within a thin cytoplasmic rim that surrounds a nucleus with coarsely aggregated heterochromatin (Figs. 3-44C and 3-46). Activated lymphocytes, on the other hand, may show enlarged, vesicular nuclei, visible nucleoli, and/or elaborately infolded nuclear contours that may bear some resemblance to Lutzner-Sezary cells.

The patterns of T- and B-cell infiltration in the skin are also of interest. In most inflammatory conditions, T cells are

FIGURE 3-46. Transmission electron micrograph of a mature lymphocyte; note the chromatin-rich nucleus and organelle-poor cytoplasm.

present primarily around blood vessels within the dermis and periadnexal adventitia. Migration into the epidermis (exocytosis) is generally accompanied by related pathologic changes affecting adjacent keratinocytes (e.g., spongiosis, apoptosis). Although interstitial infiltrates of T cells may occur, this pattern is less commonly encountered. B cells, on the other hand, tend not to migrate into the epidermis. When significant dermal B-cell infiltration exists, nodular aggregates replete with actual lymphoid follicles may develop.

Although T and B cells are indistinguishable by light microscopy, they can be differentiated by *in vitro* tests and immunohistochemical studies. Human T lymphocytes have receptors for sheep erythrocytes (E), so that, in the historically important E rosette assay, sheep erythrocytes form rosettes around T lymphocytes (271,272). Antibodies are available for the identification of T cells and B cells in routine paraffin sections [e.g., CD3 for T cells and L26 (CD20) and CD79a for B cells]. Immunohistochemically specific detection of cell surface glycoproteins that correlate with T-cell functional subsets (CD4 for helper/inducer, CD8 for cytotoxic/suppressor) is also possible on paraffin-embedded tissues. The T-cell receptor (TCR) consists of either αβ or γδ heterodimer expressed on the cell surface in association with CD3. The majority of the peripheral T lymphocytes express the αβ TCR and are $CD4^+$ or $CD8^+$. In 1970, Gershon and Kondo (273,274) observed that T cells not only augmented but also dampened immune responses and that this downregulation was mediated by T cells that were different from helper T cells. The phenotype of suppressor T cells corresponded for the most part to $CD8^+$, whereas some of them, in particular those suppressing delayed-type hypersensitivity, were $CD4^+$ cells. More recently, this subset of T lymphocytes has been shown to express CD25 (IL-2 receptor), as well as the Fox P3 marker, in addition to CD4. Such "regulatory" T cells serve to limit/suppress the immune response and may be detected in tissue by conventional immunohistochemical markers (274). It is unclear whether these regulatory T cells ("T regs") represent a subset of the same cells originally described as suppressor T cells (275).

An additional lymphocytic lineage closely related to T cells is composed of the natural killer (NK) cells. These cells represent approximately 10% of the circulating lymphocytes and are reactive to glycolipids presented in the context of the major histocompatibility complex (MHC) class I–like molecule CD1d. NK cells are characterized by the expression of CD56, CD57, and CD16. They lack B-cell markers and surface CD3 but express cytoplasmic CD3ε. They are usually $CD4^-/CD8^-$ but can rarely express CD8. NK cells do not demonstrate rearrangement of immunoglobulin heavy-chain genes or TCR genes (276).

It is important to realize that normal skin will contain small numbers of perivascular T cells with the helper subtype predominating as part of the skin immune system. Recent studies have found that there may be a larger pool of memory T cells in normal skin than originally believed. These T cells can initiate and perpetuate immune reactions in the absence of T-cell recruitment from the blood (277).

T cells play an important role in normal cutaneous immunosurveillance and in delayed hypersensitivity reactions. Initial antigen uptake by Langerhans cells occurs during sensitization. After their migration to draining lymph nodes via dermal lymphatics (see later discussion), Langerhans cells present antigen to naive T cells, which undergo initial clonal expansion to become memory cells. In the challenge reaction, the dermal microvascular unit is activated (possibly in part due to mast cell degranulation stimulated by antigen-specific IgE-like molecules generated during sensitization) (278), resulting in display of leukocyte adhesion molecules on the endothelial luminal surface that facilitate the recruitment of antigen-specific, skin-homing memory T cells. On local antigen presentation at the challenge site, these pioneer memory cells, now capable of antigen recognition, respond by elaboration of a cascade of cytokines that result in recruitment of secondary inflammatory cells.

The B lymphocyte is the effector cell of humoral immunity. On antigenic stimulation, the primary follicles in lymph nodes, composed of small B lymphocytes, develop into secondary follicles, consisting of a germinal center surrounded by a rim of small B lymphocytes (269). In the germinal centers, small B lymphocytes enlarge through an intermediate stage of centrocytes with cleaved nuclei into centroblasts, which are large cells with noncleaved nuclei (279). The centroblasts become immunoblasts as a result of antigenic stimulation and produce a clone of daughter cells that mature into immunoglobulin-secreting plasma cells (280,281). The differentiation of B lymphocytes into plasma cells is facilitated by helper T cells and is suppressed by suppressor T cells (282). The plasma cells collect in the medullary cords of lymph nodes

without entering the bloodstream but secrete immunoglobulins that circulate as "humoral" antibodies. Although these events most commonly occur in lymph nodes, identical alterations may take place in the dermis in response to locally introduced antigen, as is the case in cutaneous lymphoid hyperplasia with prominent germinal center formation (283,284). In clonal neoplasms of B cells, there may be an arrest at any of these differentiation stages, producing a monotonous infiltrate typical of the various categories of lymphoma cutis (see Chapter 31).

Plasma Cells

Plasma cells have an abundant cytoplasm that is deeply basophilic, homogeneous, and sharply defined. The round nucleus is eccentrically placed, and along its membrane it shows coarse, deeply basophilic, regularly distributed chromatin particles, which give the nucleus a cartwheel appearance (Fig. 3-44D). The fact that patients with agammaglobulinemia lack plasma cells was responsible for early recognition of the fact that the plasma cell is the site of formation of all immunoglobulins that circulate as humoral antibodies. The synthesis of immunoglobulins takes place in plasma cells located mainly in the lymph nodes, the spleen, and the bone marrow. Because plasma cells are tissue cells and are not seen in the peripheral circulation, it can be assumed that, if they are present in the dermis, they have developed there from B lymphocytes. Intracytoplasmic immunoglobulins may be demonstrated immunohistochemically in paraffin-embedded tissue. Subclassification of cells according to κ (approximately two thirds of reactive plasma cells) and γ (approximately one third of reactive plasma cells) is also possible and may facilitate in some instances detection of a neoplastic clone where only one of the light chains is produced exclusively. On electron microscopy, plasma cells are characterized by the presence in their cytoplasm of an extensive system of cisternae lined by a ribosome-associated rough endoplasmic reticulum.

Plasma cells are apt to be present in conspicuous numbers in several infectious diseases, such as early syphilis, rhinoscleroma, and granuloma inguinale (see Chapters 21 and 22). In the presence of many plasma cells, but especially in rhinoscleroma, round, hyaline, eosinophilic bodies called Russell bodies may be found inside and outside of plasma cells. They form within plasma cells as the result of a very active synthesis of immunoglobulins and may ultimately completely replace the plasma cells in which they have formed (285). They may possess a size twice that of normal plasma cells, measuring up to 20 μm in diameter. They contain varying amounts of glycoproteins and are as a rule gram positive as well as PAS positive and diastase resistant (286). Russell bodies are initiated by intracisternal secretion, analogous to the secretion of immunoglobulins. When the plasma cell is overloaded with this material, first the nucleus and ultimately the entire cell lyses (285). Immunofluorescence and immunohistochemical stains show the presence of immunoglobulins within the Russell bodies, especially on their surface (287,288).

Dermal Muscle Cells

Smooth Muscle

Smooth or involuntary muscle of the skin occurs as arrectores pilorum, tunica dartos of the external genitals, and in the areola of the nipples. The muscle fibers of the arrectores pilorum arise in the connective tissue of the upper dermis and are attached to the hair follicle below the sebaceous glands (Fig. 3-26). They are situated in the obtuse angle of the hair follicle. Thus, when contracted, they pull the hair follicle into a vertical position and produce the perifollicular elevations of "gooseflesh.""

Smooth muscle is characterized by the absence of striation and by the location of the nucleus in the center of the muscle cell. Typically, the nuclei are cigar shaped with rounded ends, a feature that may be diagnostically helpful in assessing dermal spindle cell proliferations and neoplasms. Argyrophilic reticulum fibers surround each muscle cell. Electron microscopic examination reveals that smooth muscle cells possess a basement membrane peripheral to the plasma membrane. The cytoplasm of the cells is filled with myofilaments 5 nm in diameter that form cytoplasmic and peripheral dense bodies as a result of condensations, just as the myofilaments do in myoepithelial cells, vascular smooth muscle cells, and glomus cells. The rather narrow spaces between the muscle cells are occupied by collagen fibrils and by Schwann cells with associated nonmyelinated axons.

Smooth muscle cells contain vimentin and desmin as intermediate filaments and smooth muscle actin (223).

Striated Muscle

Striated or voluntary muscle is found in the skin of the neck as platysma and in the skin of the face as muscles of expression. The striated muscle bundles take their origin either from a fascia or from the periosteum, or they form a closed ring, as in the musculus sphincter oris. They extend through the subcutaneous tissue into the lower dermis (see Fig. 3-62C). The muscle fibers, like skeletal muscle, show characteristic cytoplasmic cross-striations. Their nuclei are located at the periphery of the fibers immediately beneath the sarcolemma, the limiting membrane of the fibers.

Extracellular Matrix

The extracellular matrix of the dermis consists of collagenous and elastic fibers embedded into ground substance. All three components are formed by fibroblasts.

Collagen Fibers

Collagen represents by far the most abundant constituent of the connective tissue of the dermis. On light microscopy, collagen consists of fibers (Figs. 3-47 to 3-50). The diameter of collagen fibers is quite variable, ranging from 2 to 15 μm. The collagen fibers are present either as a finely woven network or as thick bundles. Collagen as a finely woven meshwork of collagen fibers is found in the papillary layer of the dermis, which includes not only the subepidermal papillae situated between

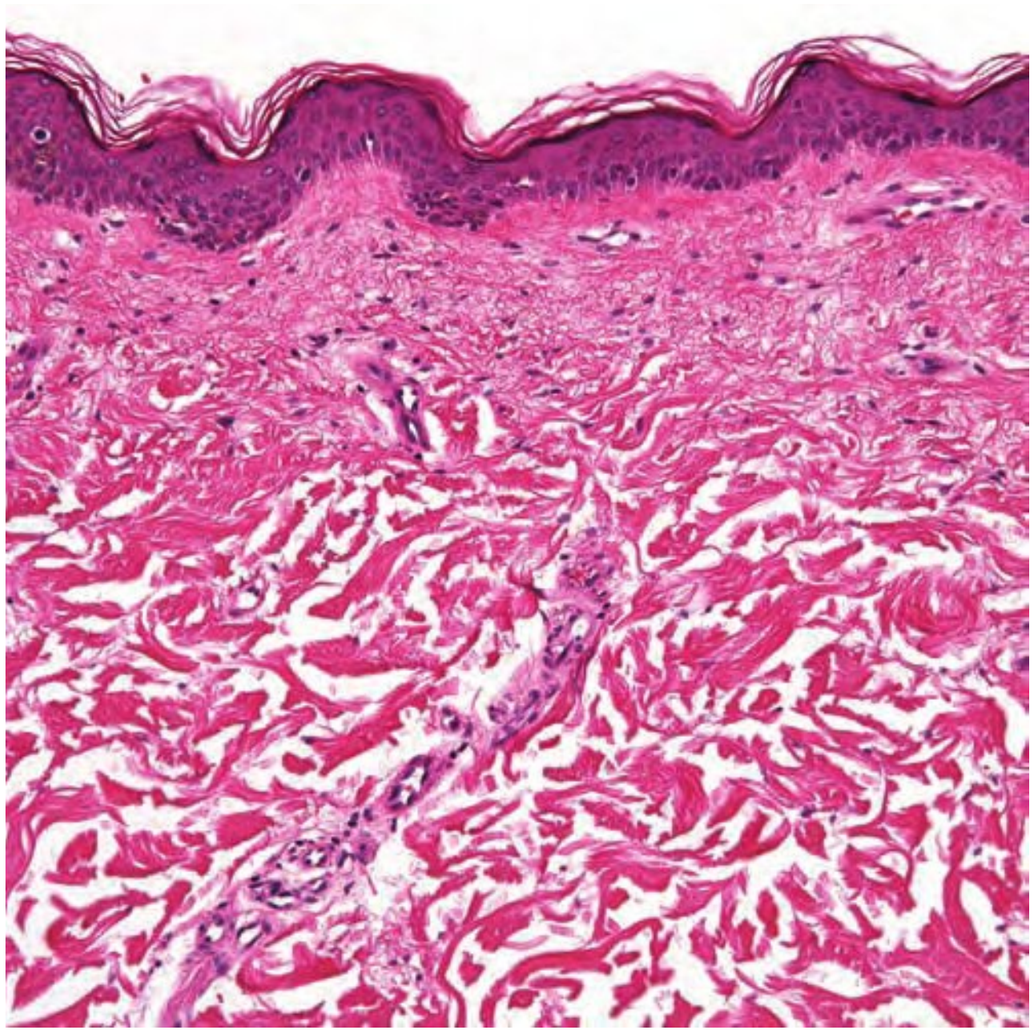

FIGURE 3-47. Conventional histology of the transition between papillary (top) and reticular (bottom) dermis. The dermal collagen in the papillary dermis is more delicate and thin than the thicker collagen bundles in the papillary dermis.

the rete ridges, but also the subpapillary layer forming a narrow ribbon between the rete ridges and the subpapillary blood vessels (Figs. 3-5, 3-47, and 3-50B). This is referred to as the papillary dermis. In addition, the pilosebaceous units and the eccrine and apocrine glands are encircled by a thin meshwork of collagen fibers similar to that present in the papillary dermis. Therefore, the papillary and the periadnexal dermis is regarded as an anatomic unit, the adventitial dermis. The blood vessels of the dermis are also surrounded by a thin layer of fine collagen fibers. Biochemically, the papillary dermis is composed primarily of type III collagen.

The rest of the dermis, constituting by far the largest portion of the dermis and referred to as the reticular dermis, shows the collagen fibers united into thick bundles (Figs. 3-40A and 3-47). These collagen bundles extend in various directions horizontally, and thus some are cut lengthwise and others across in histologic sections. As a rule, collagen bundles that are cut lengthwise appear slightly wavy. Biochemically, reticular dermal collagen is composed primarily of type I collagen.

Reticulum fibers are not recognizable with routine stains, but, being argyrophilic, they can be impregnated with silver nitrate, which, by being subsequently reduced to silver, stains black. Reticulum fibers represent a special type of thin collagen fiber that measures from 0.2 to 1 μm in diameter. The argyrophilia shown by reticulum fibers, in contrast to collagen fibers, probably is related to the fact that reticulum fibers correspond to the distribution of type III collagen rather than type I collagen.

Argyrophilic reticulum fibers are the first-formed fibers during embryonic life and in various pathologic conditions associated with increased fibroblastic activity. In normal skin, even though collagen is being continuously replaced, the formation of new collagen is not preceded by an argyrophilic phase. Instead, all newly formed collagen consists of large fibers. However, there are a few areas in which normally small collagen fibers are present as reticulum fibers without transforming into larger, nonargyrophilic collagen fibers. This occurs above all in the basement membrane zone, the region of the adventitial dermis that lies closest to the epidermis and its appendages. In addition, reticulum fibers are present normally around blood vessels and as a basket-like capsule around each fat cell.

The biosynthesis of collagen begins within the fibroblast by the assembly of three pro–α-polypeptide chains into a triple-helical procollagen molecule (216). After excretion into the extracellular space, the three pro-α chains of each procollagen molecule are shortened by 30% to 40% through removal of the carboxy-terminal and amino-terminal peptide extensions brought about by the action of two enzymes produced by

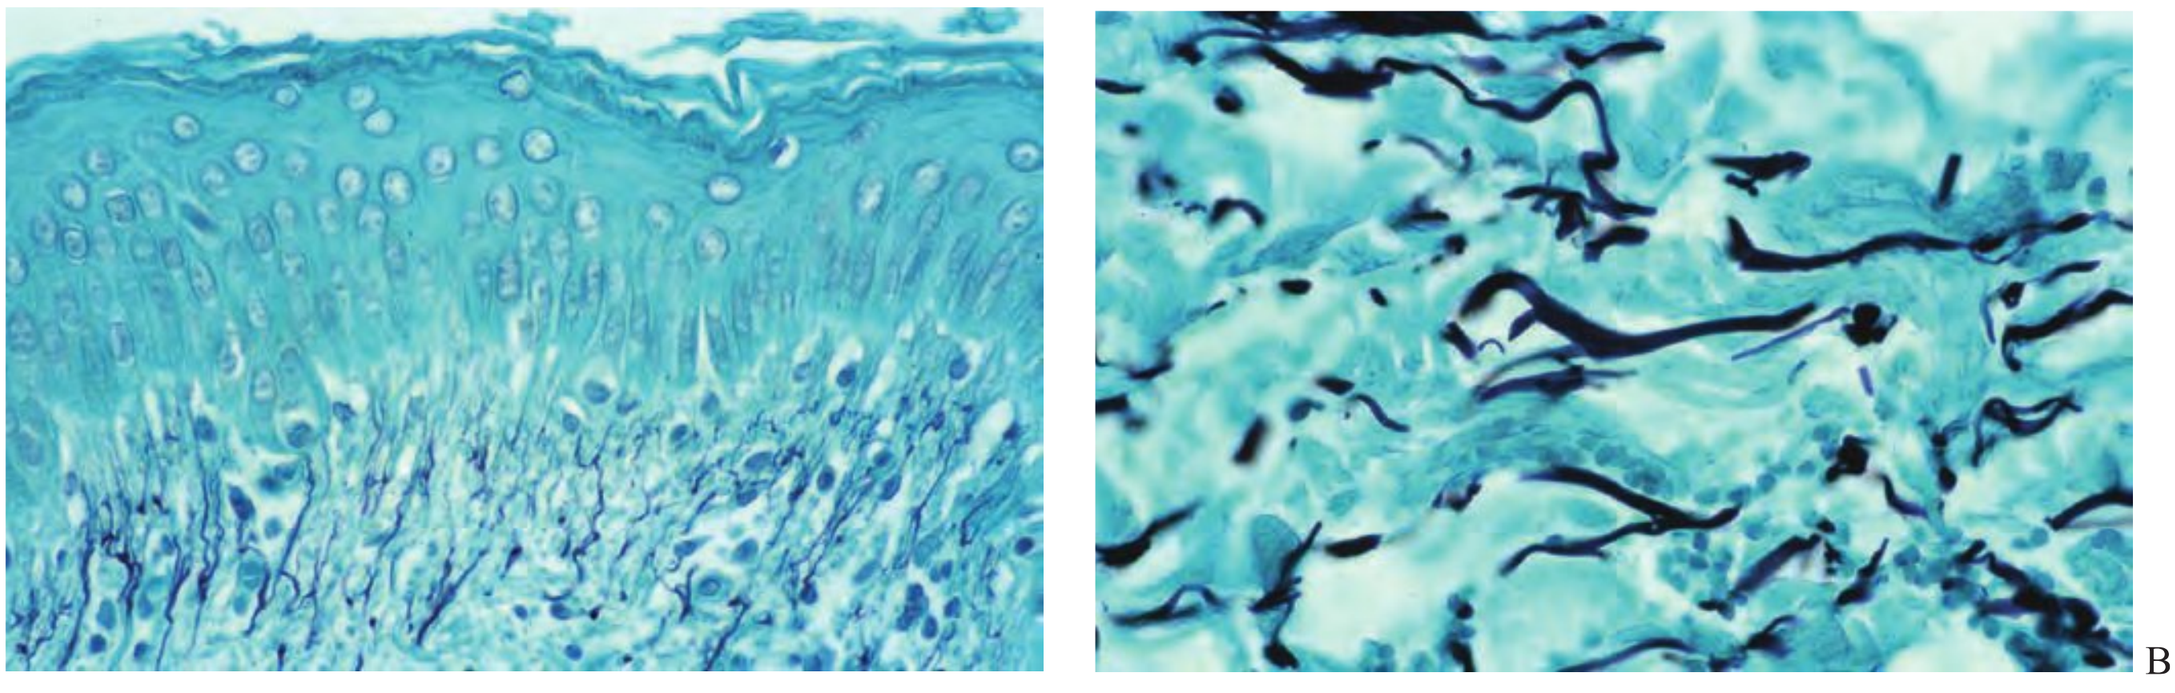

FIGURE 3-48. Histochemical demonstration of elastin fibers within papillary dermis (A) and reticular dermis (B). Silver stain.

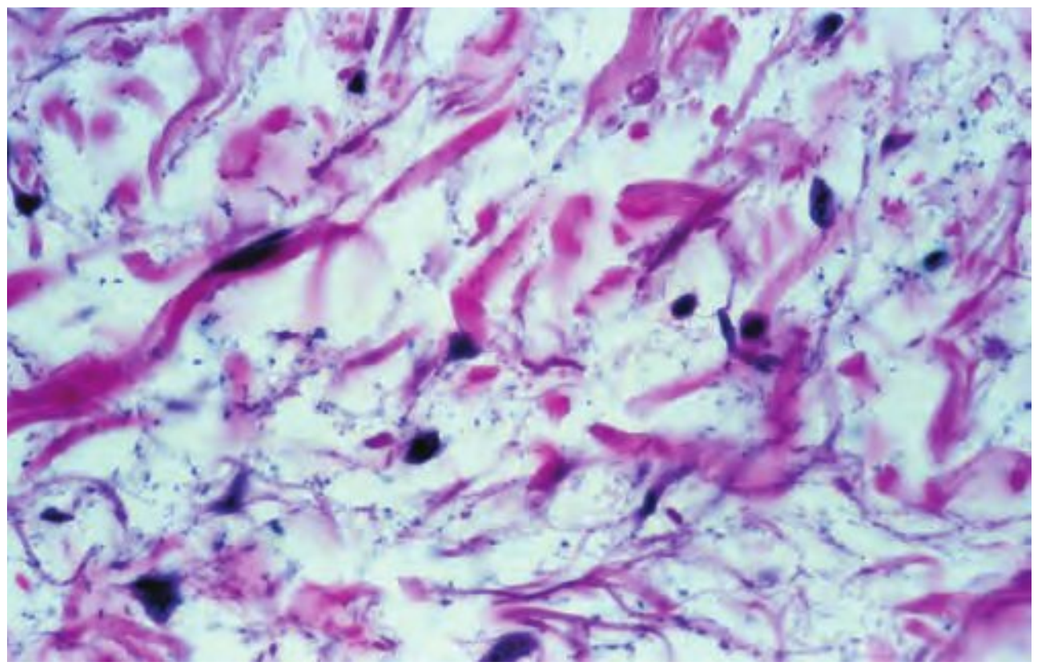

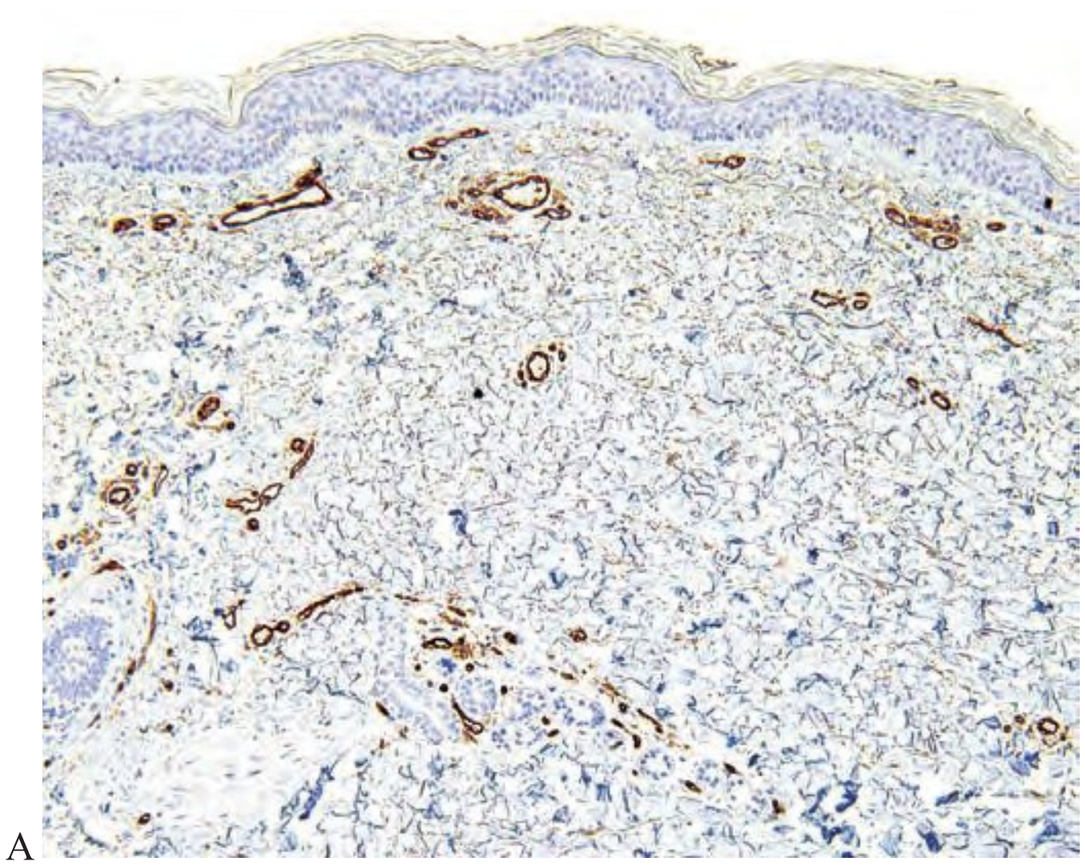

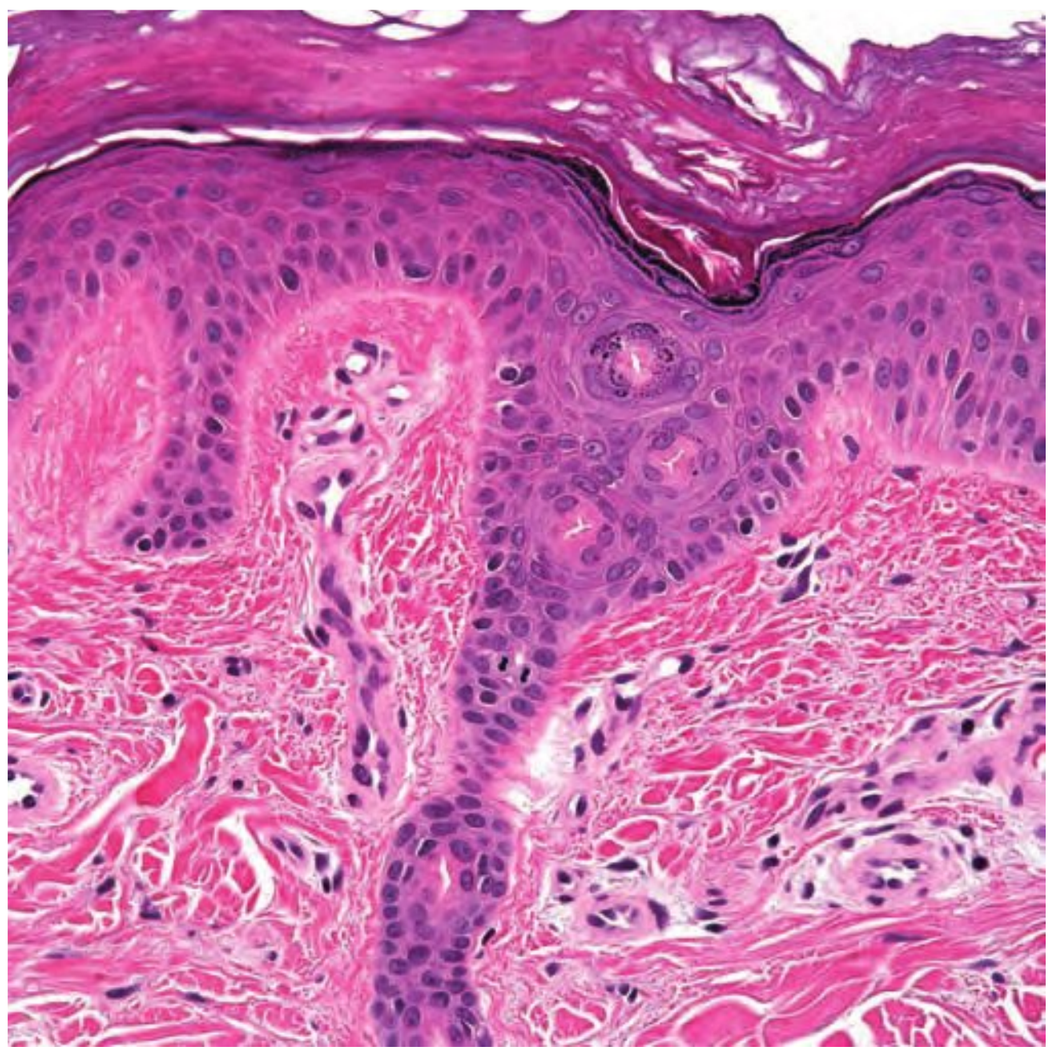

FIGURE 3-49. Ground substance. Although these mucopolysaccharides are normally inconspicuous by conventional light microscopy, in this case they are pathologically increased and thus visible as thin, pale blue-gray strands within widened spaces separating reticular dermal collagen.

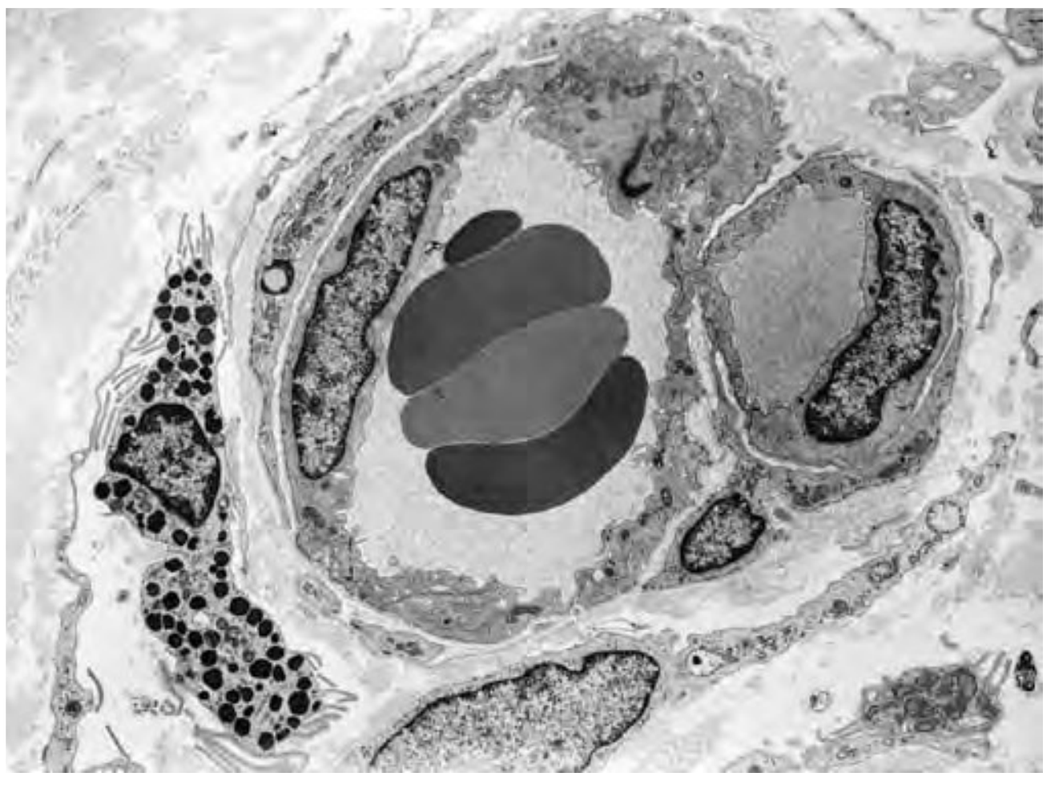
the fibroblast: carboxy-terminal peptidase and amino-terminal peptidase (215). This results in conversion of the procollagen molecule into the collagen molecule. Although the additional peptides present in procollagen keep it soluble and prevent its intracellular polymerization, collagen molecules polymerize readily. The collagen molecule is a rigid rod in which each of the three coiled α chains consists of about 1,000 amino acids (216). The collagen molecule is about 300 nm long and 1.5 nm wide (289–291). Collagen fibrils form by both lateral and longitudinal association of collagen molecules. However, the collagen fibrils vary in diameter as a result of varying degrees of polymerization of collagen molecules, with younger collagen fibrils being thinner than older fibrils. In the normal dermis, the thickness of collagen fibrils ranges from 70 to 140 nm; most of the fibrils are approximately 100-nm thick (292).



Collagen fibrils possess characteristic cross-striations with a periodicity of 68 nm. The periodicity of the cross-striations in the collagen fibrils can be explained as follows. Each collagen molecule possesses along its length of 300 nm five charged regions 68 nm apart, and although neighboring collagen molecules overlap

A

B

C

FIGURE 3-50. A: Immunohistochemical stain with CD31 highlights the vascular pattern in the dermis. B: Histology of a capillary loop originating from underlying superficial vascular plexus and extending into the dermal papilla. C: Transmission electron micrograph of dermal microvascular unit consisting of a plexus of central vessels and surrounding cells that form the junction between the papillary and reticular dermis. Note the endothelial cells lining the central postcapillary venule surrounded by pericytes and dermal immune cells, including granulated mast cells.

each other, they always have their charged regions lying side by side. This parallel alignment of the charged regions produces the cross-striations (290). Reticulum fibrils possess the same 68-nm periodicity of their cross-striations as collagen fibrils but have a smaller diameter than collagen fibrils, varying between 40 and 65 nm rather than between 70 and 140 nm (293). Furthermore, reticulum and collagen differ in the number of fibrils present in the cross section of each fiber and in the amount of ground substance present within and around each fiber. The amount of ground substance around the fibrils and on the surface of the fiber may explain the presence of argyrophilia in reticulum fibers and its absence in collagen fibers (293).

Seven different types of collagen have been recognized that differ in composition and antigenicity. Type I collagen, the predominant collagen in postfetal skin, is found in the large fiber bundles of the reticular dermis. Reticulum fibers are composed of type III collagen. Although type III collagen is the prevalent type of collagen in early fetal life, in postfetal life it is limited to the subepidermal and periappendageal regions, that is, the basement membrane zones and the perivascular region or the "papillary" and "adventitial" dermis (294). Basement membrane collagen (basal lamina collagen) is type IV, and the collagen of cartilage is type II. Type V collagen has been recognized in fetal membranes and vascular tissue (295). Type VII collagen occurs in different basement membranes, including those of the skin, and forms a major structural component of anchoring fibrils (296). The skin of the human fetus contains a large percentage of type III collagen, in contrast to the skin of the adult, which contains a large proportion of type I collagen (297).

Among the differences in composition are the following. In type I collagen, the three α chains in the collagen molecule consist of two different kinds: two identical α chains designated as α-1(I) and a third chain called α-2. In type II collagen, the collagen molecules are composed of three identical, genetically distinct α chains, α-1(II). Type III collagen is also composed of three identical, distinct α chains (215). Type IV collagen consists of procollagen composed of three identical pro-α chains that have retained their nonhelical extensions. Types V and VI collagen have not yet been adequately characterized. Type VII collagen consists of three α chains, with the terminal regions being noncollagenous (296).

Elastic Fibers

Elastic fibers appear in the dermis at 22 weeks, much later than the collagenous fibers. At this time, acid orcein stains show elastic tissue in the reticular dermis either as granular material interspersed with occasional short fibers or as a delicate network of branching fibers. As gestation progresses, elastic fibers increase in quantity. At 32 weeks, a well-developed network of elastic fibers indistinguishable from that seen in term infants is present in both the papillary and the reticular dermis (298). Young elastic fibers, as seen in a 22-week-old fetal dermis, show masses of peripheral microfibrils surrounding a small, amorphous, electron-lucent core representing elastin, with only a few internal microfibrils. As the embryo matures, the amount of elastin and the number of microfibrils within the elastin increase, whereas the number of peripheral microfibrils decreases (299).

In light microscopic sections that are routinely stained, elastic fibers are inconspicuous. With special elastic tissue stains, such as orcein or resorcin-fuchsin, or in plastic-embedded sections they are found entwined among the collagen bundles (Fig. 3-48). Because elastic fibers are thin in comparison with collagen bundles, measuring from 1 to 3 μm in diameter, and are wavy, only a small portion of any fiber is seen in histologic sections, giving even normal elastic fibers a fragmented appearance. The elastic fibers are thickest in the lower portion of the dermis, where they are arranged, like collagen bundles, chiefly parallel to the surface of the skin. Elastic fibers become thinner as they approach the epidermis. In the papillary dermis, they form an intermediate plexus of thinner elaunin fibers running parallel to the dermal–epidermal junction (Fig. 3-48). From this plexus, thin fibers termed oxytalan fibers run upward in the papillary dermis perpendicular to the dermal–epidermal junction and terminate at the PAS-positive basement membrane zone.

The elastic fibers of the dermis consist of two components: the microfibrils and the matrix elastin. The microfibrils are electron dense and measure 10 to 12 nm in diameter. They are aggregated at the periphery of the elastic fiber, giving the fiber its characteristic frayed appearance by ultrastructure. In addition, microfibrils are present within the elastin as strands 15 to 80 nm in diameter extending in a longitudinal direction (300). The microfibril component amounts to only 15% of the elastic fiber, whereas the amorphous, electron-lucid elastin makes up 85% of the fiber (299). It is the elastin that stains with elastic tissue stains, is removable by elastase, and is markedly extensible, whereas the microfibrils are the elastic resilient component of the elastic fiber (300).

Elastic fibers undergo significant changes during life. One change, representing aging, is best studied in nonexposed skin. The other change, elastotic degeneration, is the result of chronic sun exposure and is described in Chapter 15. In young children up to the age of 10 years, the elastic fibers may not be fully matured, so that microfibrils predominate (301). Physiologic aging is a gradual process and usually becomes quite apparent by age 30 to 50 years. There is a gradual decrease in the number of peripheral microfibrils, so that ultimately there may be none; instead, the surface of the elastic fiber appears irregular and granular (301). The microfibrils within the elastin matrix become thicker and show electron-lucent holes of varying sizes (302). In very old persons, fragmentation and disintegration of some of the elastic fibers may be observed. Oxytalan fibers that consist of microfibrils diminish and ultimately disappear in aging skin.

Ground Substance

The ground substance, an amorphous substance that fills the spaces between collagen fibers and collagen bundles, contains glycosaminoglycans, or acid mucopolysaccharides (Fig. 3-49).

These glycosaminoglycans are covalently linked to peptide chains to form high–molecular-weight complexes called proteoglycans (303). Glycosaminoglycans are present in normal skin in such small amounts that they cannot be demonstrated with either routine or special histologic staining methods except in the hair papilla of anagen hair, which contains both nonsulfated and sulfated acid mucopolysaccharides. However, through the study of tissues with an active growth of fibroblasts, as seen in the papillary dermis in dermatofibroma and in the connective tissue around the tumor islands of basal cell epithelioma, it is known that the dermal ground substance consists largely of nonsulfated acid mucopolysaccharides such as hyaluronic acid (161). In healing wounds, however, in which new collagen is laid down, the ground substance contains sulfated and nonsulfated acid mucopolysaccharides (304).

The nonsulfated acid mucopolysaccharides consist largely of hyaluronic acid, are stainable with alcian blue at pH 3.0 but not at pH 0.5, and show metachromasia with toluidine blue at pH 3.0 but not at pH 1.5. The sulfated acid mucopolysaccharides consist largely of chondroitin sulfate, are stainable with alcian blue at pH 0.5 and at pH 3.0, and show metachromasia with toluidine blue at pH 1.5 and at pH 3.0. Both nonsulfated and sulfated acid mucopolysaccharides stain with colloidal iron. Testicular hyaluronidase hydrolyzes hyaluronic acid but not the sulfated acid mucopolysaccharides (161).

Dermal Microvascular Unit

Not long ago, the dermis was considered to be a leathery cutaneous layer primarily responsible for housing and protection of vessels that served to nourish the keratinizing epidermis. Today we realize that the dermis is a dynamic microenvironment containing a repertoire of cells and matrix molecules arguably more complex and sophisticated than the epidermis and its appendages. The dermal microvascular unit is the heart of this new concept of the dermis, for it represents an intricate assemblage of cells responsible not only for cutaneous nutrition, but also for immune cell trafficking, regulation of vessel tone, and local hemostasis.

Endothelial Cells

General Microanatomy

The dermal microvasculature is divided into two important strata. The first, the superficial vascular plexus, defines the boundary between the papillary and the reticular dermis and extends within an adventitial mantle to envelop adnexal structures (Figs. 3-5 and 3-50A). This plexus forms a layer of anastomosing arterioles and venules in close approximation to the overlying epidermis and is normally surrounded by other cellular components of the dermal microvascular unit (see later discussion). Small capillary loops emanate from the superficial vascular plexus and extend into each dermal papilla (Fig. 3-50B, C). The second plexus—the deep vascular plexus—is connected to the first by vertically oriented reticular dermal vessels and separates the reticular dermis from the subcutaneous fat. Many of these vessels are of larger caliber and communicate with branches that extend within fibrous septae that separate lobules of underlying subcutaneous fat.

The small arteries of the deep vascular plexus and the arterioles of the dermis possess three layers: an intima, composed of endothelial cells and an internal elastic lamina that stains for elastic tissue; a media, which contains two or more layers of muscle cells in the small arteries but only a single layer of muscle cells in the arterioles of the lower dermis and a discontinuous layer of muscle cells in the arterioles of the upper dermis; and an adventitia of connective tissue (305) (Fig. 3-51A). The capillaries that are present throughout the dermis but especially in the papillary dermis are composed of a layer of endothelial cells surrounded by an incomplete layer of pericytes. A basement membrane, which stains positive with PAS, is present peripheral to the endothelial cells and surrounds the pericytes. There is alkaline phosphatase activity in the endothelial cells of all capillaries (306). Staining for alkaline phosphatase thus demonstrates well the capillary loop in each subepidermal dermal papilla, with the ascending, arterial limb of the loop staining more heavily than the descending, venous limb. The abundant capillaries present in the hair papillae of anagen hairs also stain heavily (162,306).

The walls of veins generally are thinner than those of arteries and less clearly divided into the three classic layers (Fig. 3-51B). The postcapillary venules resemble capillaries because they consist of endothelial cells, pericytes, and a basement membrane (Fig. 3-50C). The arteriolar and venous segments can be distinguished from each other on the basis of the basement membrane, which has a homogeneous appearance in the former and is multilaminated in the latter. Furthermore, terminal arterioles have elastin and smooth muscle cells in their walls, whereas postcapillary venules have only pericytes in their walls (307). The capillary loops leading from the subpapillary plexus to the dermal papillae and back can be divided into an intrapapillary portion and an extrapapillary portion. The extrapapillary ascending limb and the intrapapillary portion have the characteristics of an arterial capillary, that is, a homogeneous basement membrane, whereas the extrapapillary descending limb has venous characteristics, that is, a multilayered basement membrane (308). Although some investigators have observed areas of fenestration at the tips of the capillary loops between the endothelial cells (309), others have failed to find them (308). Endothelial cells characteristically show a well-developed endoplasmic reticulum, bundles of fairly thick cytoplasmic filaments with a diameter of 5 to 10 nm, and many pinocytotic vesicles at their luminal surface. Frequently, one can observe in endothelial cells a unique structure, the Weibel-Palade body. It is an electron-dense, rod-shaped cytoplasmic organelle measuring approximately 0.1 μm in diameter and up to 3 μm in length. It is composed of a number of small tubules, approximately 15 nm thick and arranged in the long axis of the rod (309). Peripheral to the endothelium lies a basement membrane. The peripheral row of cells—the pericytes—have long cytoplasmic processes and form a discontinuous

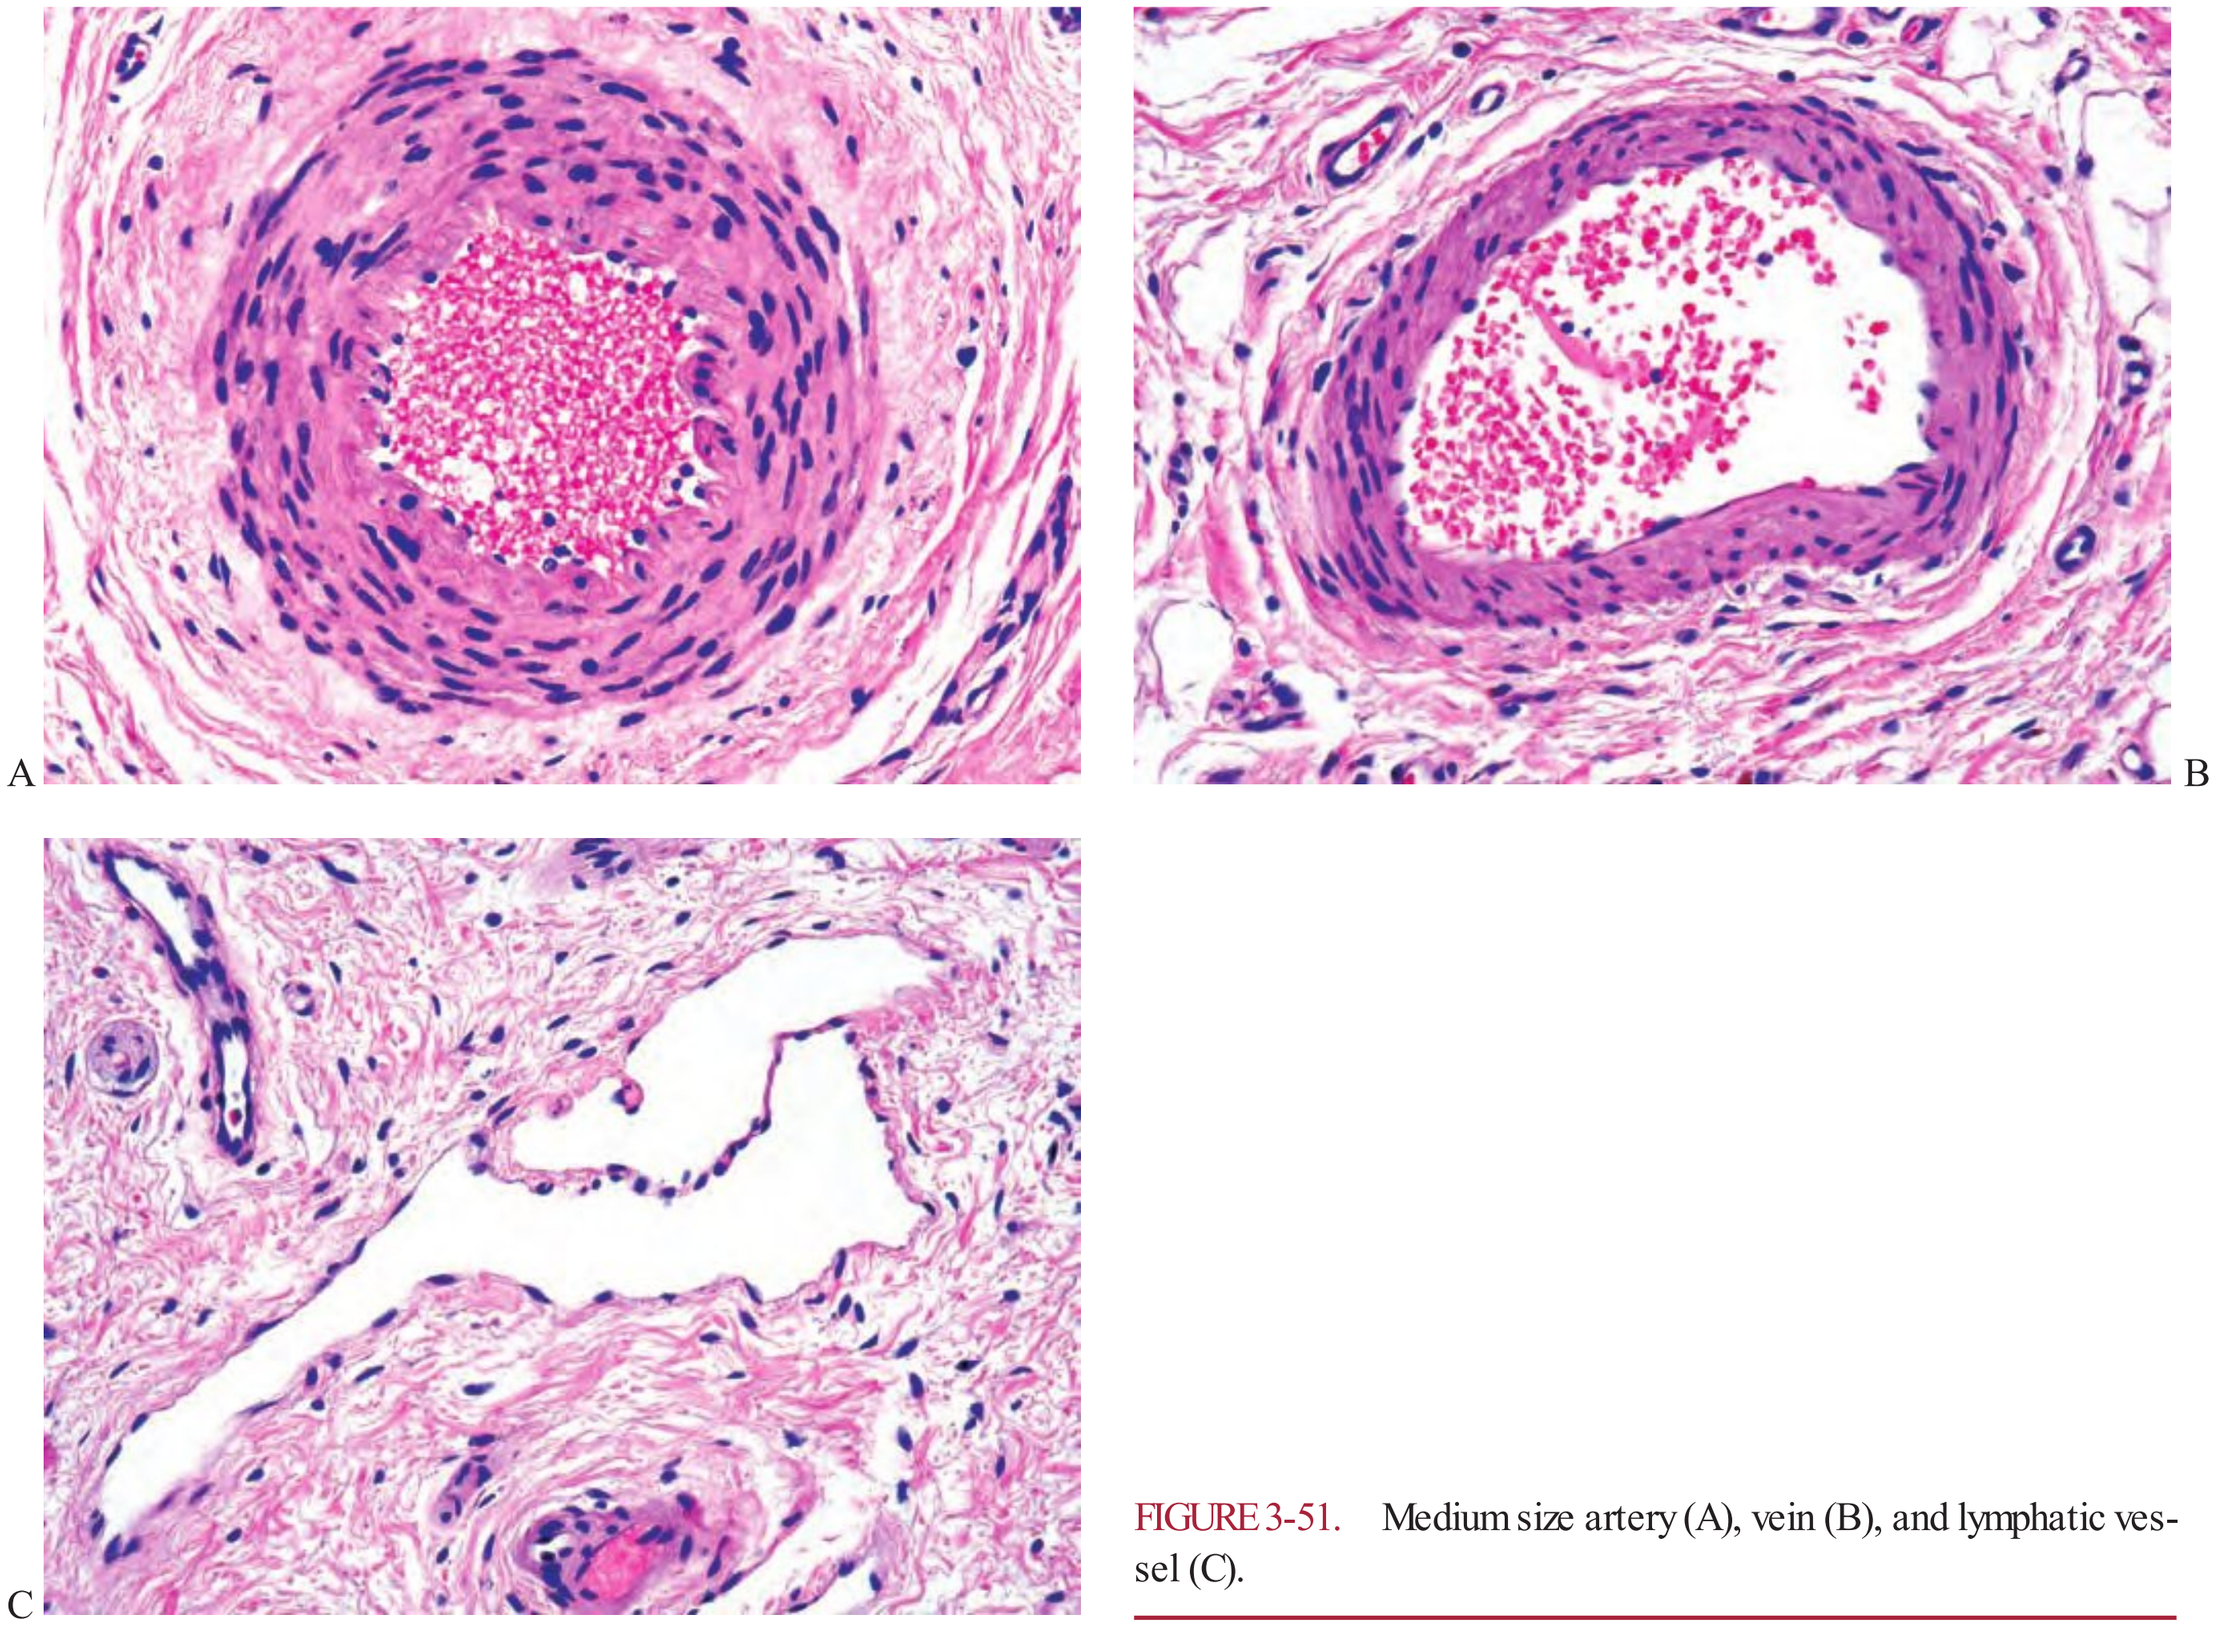


FIGURE 3-51. Medium size artery (A), vein (B), and lymphatic vessel (C).

layer. They are completely surrounded by the capillary basement membrane. In larger capillaries, more than one layer of pericytes may be present, and transitional forms between pericytes and smooth muscle cells may be seen (310).

Endothelial cells of blood capillaries contain α-L-fucose, which can be demonstrated with *Ulex europaeus* (311), and they contain factor VIII–related antigen. *U. europaeus* and an antibody against factor VIII–related antigen are used as endothelial markers for the identification of neoplastic endothelial cells. Endothelial cells also express CD31 (312,313), a marker that may be the most sensitive for normal and neoplastic endothelial cells. In addition, endothelial cells of blood capillaries contain class I antigens (HLA-A, B, C) and class II antigen (HLA-DR) (314). HLA-DR is considered to play a role in antigen presentation and elicitation of an immune response (315), and endothelial cells and perivascular dermal dendritic cells are capable of dermal antigen presentation (see later discussion). Laminin and type IV collagen are present within the vascular basement membranes. Blood capillaries contain vimentin intermediate filaments.

Specialized Structure and Function

Recent evidence indicates that endothelial cells are active participants in transmural shuttling of macromolecules, as well as facilitators of normal and pathologic trafficking of immune cells. The luminal surface of the endothelial cell that lines the superficial postcapillary venule is the primary site of adhesive interactions that initiate subsequent diapedesis of leukocytes. The outer membrane of the Weibel-Palade body contains a glycoprotein termed CD62, which is rapidly transported to the luminal endothelial membrane on exposure to histamine or thrombin (316,317). This molecule mediates the initial loose rolling adhesion between circulating leukocytes and the endothelial surface. Subsequently, other cytokine-inducible glycoproteins are expressed in a cascade (E-selectin, vascular cell adhesion molecule-1, intercellular adhesion molecule-1) on the endothelial surface, resulting in orchestrated and progressively stable leukocyte-endothelial adhesion (318–322). Some luminal molecules that are constitutively and diffusely expressed (e.g., CD31) redistribute to cell–cell junctions on endothelial stimulation, thus creating a situation potentially conducive to

concentrating adherent leukocytes at sites where transmural diapedesis may occur (322). Provocative signals for such events may come from inflammatory cells themselves or from native cells in the perivascular space (see mast cells, earlier discussion).

Glomus Cells

A special vascular structure, the glomus, is located within the reticular dermis in certain areas. Glomus formations occur most abundantly in the pads and nailbeds of the fingers and toes but also elsewhere on the volar aspect of the hands and feet, in the skin of the ears, and in the center of the face (Fig. 3-52A). The glomus is concerned with temperature regulation and represents a special arteriovenous shunt that, without the interposition of capillaries, connects an arteriole with a venule. When open, these shunts cause a great increase in blood flow in the area. Each glomus consists of an arterial and a venous segment. The arterial segment, called the Suquet-Hoyer canal, branches from an arteriole and has a narrow lumen and a thick wall measuring 20 to 40 μm in diameter. The wall shows a single layer of endothelium, surrounded by a PAS-positive, diastase-resistant basement membrane zone, and a media that is densely packed with four to six layers of glomus cells (Fig. 3-52B). These are large cells with a clear cytoplasm resembling epithelioid cells. Although myofibrils cannot be recognized within glomus cells with light microscopic staining methods, these cells have generally been regarded as smooth muscle cells (323). Peripheral to the glomus cells is a zone of loose connective tissue. Staining with silver salts shows many nerve fibers extending to the glomus cells within this zone. The venous segment of the glomus is thin walled and has a wide lumen. This wide collecting venule functions as a reservoir and drains into a dermal venule. As many as four Suquet-Hoyer canals may be found in a single glomus body, which is encapsulated (324).

Electron microscopic study of the Suquet-Hoyer canal reveals the glomus cells to be vascular smooth muscle cells. As such, each glomus cell is surrounded by a basement membrane.

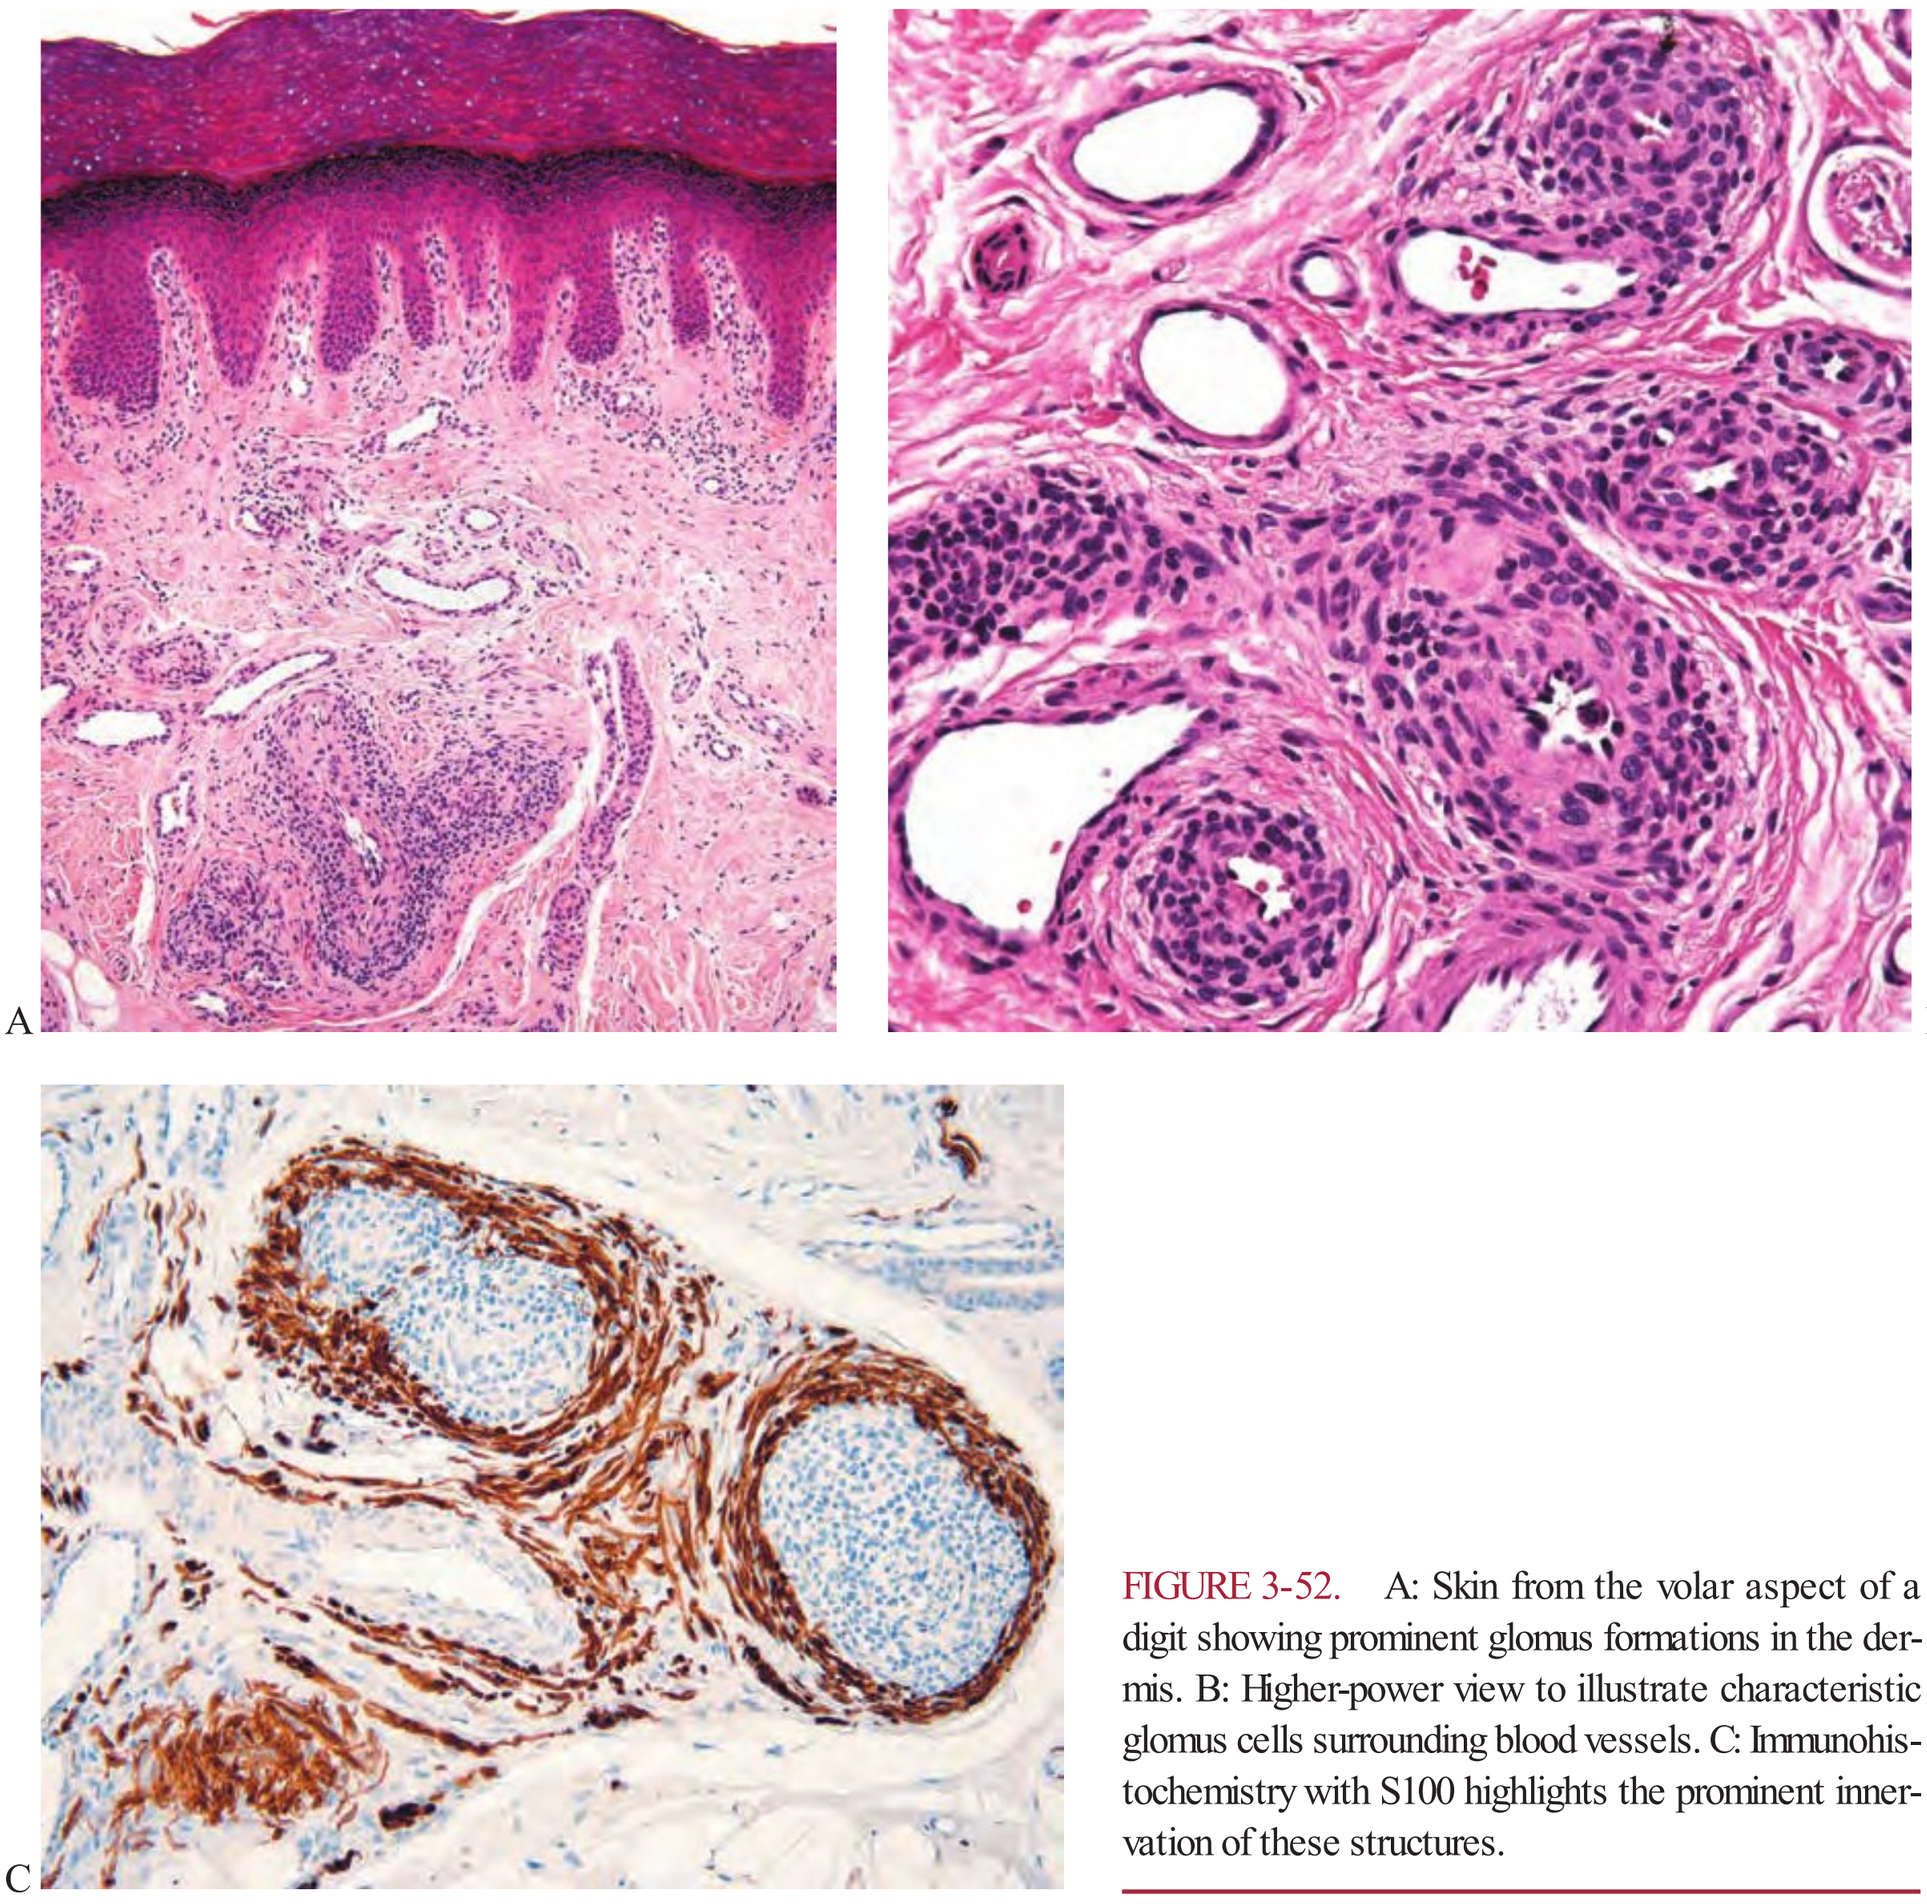

FIGURE 3-52. A: Skin from the volar aspect of a digit showing prominent glomus formations in the dermis. B: Higher-power view to illustrate characteristic glomus cells surrounding blood vessels. C: Immunohistochemistry with S100 highlights the prominent innervation of these structures.

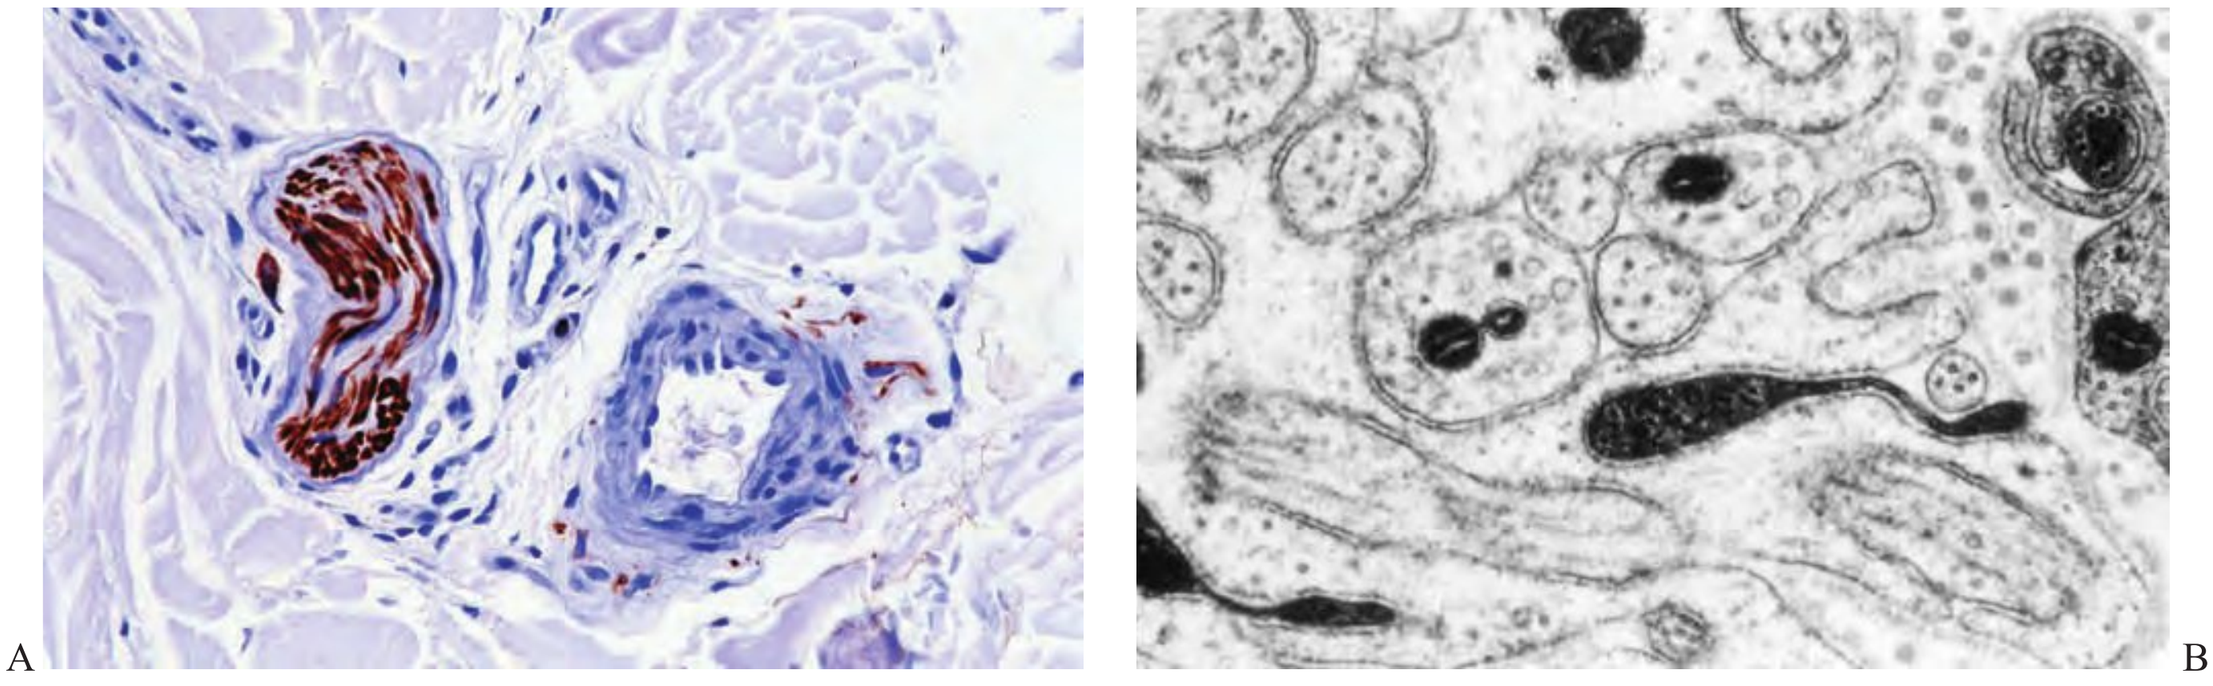

FIGURE 3-53. Dermal nerve fibers demonstrated by S100 immunohistochemical staining (A) and by transmission electron microscopy as individual axons enveloped by Schwann cells (B).

The cytoplasm of the glomus cells is filled with filaments with a diameter of about 5 nm. Cytoplasmic and peripheral dense bodies, 300 to 400 nm in diameter, are present in the glomus cells as a result of condensations of the myofilaments. Numerous nonmyelinated nerves ensheathed by Schwann cells are present peripheral to the glomus cells (325) (Fig. 3-52C).

Dermal Lymphatics

Dermal lymphatics are often inconspicuous in normal skin because they do not have a well-developed wall, as is the case with blood vessels. They are easily detected, however, when they become slightly ectatic as a result of increased lymphatic drainage, as in urticaria. Lymph vessels typically are not rounded in contour, but instead show angulations dictated by the fact that their lining lymphatics are buttressed by adjacent collagen bundles (Fig. 3-51C). In normal skin, the perilymphatic space is relatively devoid of other cells, and the lumen is lined by relatively flattened endothelial cells. Occasional valves may be observed emanating from the endothelial lining. By electron microscopy, the thin layer of endothelium does not contain Weibel-Palade bodies and is devoid of a basement membrane or surrounding pericytes. Lymphatic vessels show a negative or weakly positive reaction when incubated with *U. europaeus* and no reaction with an antibody against factor VIII–related antigen in most instances. They do not contain class I (HLA-A, B, C) or class II (HLA-DR) antigens (314). Endothelial cells of lymphatic vessels contain cytoplasmic filaments (326), which probably represent vimentin filaments. Lymphatic vessels contain podoplanin and can be specifically labeled using an antibody such as D2-40 or LYVE-1 (326).

Neural Network

In sections stained with routine methods, one can recognize only the larger myelinated nerve bundles and the Meissner and Vater-Pacini end organs. The finer nerves require special staining, and accordingly the enormous importance of these structures to cutaneous homeostasis and pathology has been overlooked. Among the staining methods used are impregnation with silver salts (327), vital staining with methylene blue (328), and *in vitro* staining of thick sections with methylene blue (329). More recently nerves have been identified by the S100 technique (Fig. 3-53A) and by using antibodies to specific neurofilaments, neuropeptides, and adhesion molecules (neural cell adhesion molecule-1). Nerves are composed of neuraxons, a cytoplasmic process that conducts neural impulses from cell bodies in the central nervous system, and Schwann cells (sheath cells or neurilemmal cells) enveloping the neuraxons (Figs. 3-53A, B). This primary functioning unit may or may not be myelinated and is surrounded by an endoneurium—a mucinous or fibrous matrix containing fibroblasts—which supports the primary functioning unit. A perineurium composed of elongated, flattened cells surrounds several primary functioning units and their endoneurial matrix (330).

The skin is supplied with sensory nerves and autonomic nerves, which permeate the entire dermis with nerve fibers and show frequent branching. Sensory and autonomic nerves differ in that sensory nerves possess a myelin sheath up to their terminal ramifications, but autonomic nerves do not. The autonomic nerves, derived from the sympathetic nervous system, supply the blood vessels, the arrectores pilorum, and the eccrine and apocrine glands. The sebaceous glands possess no autonomic innervation, and their functioning depends on endocrine stimuli. All autonomic nerves end in fine arborizations. So do the sensory nerves, except in a few areas in which there are, in addition to fine arborizations, special nerve end-organs. Hair follicles, especially large hair follicles, are also surrounded below the entry of the sebaceous duct by a network of sensory nerves that lose their myelin sheaths a short distance from the outer root sheath and end in numerous arborizations of fine nonmyelinated fibers.

The papillary dermis is richly invested in unmyelinated nerve fibers, particularly about the dermal microvascular unit, where axons often terminate in close proximity to mast cells (331). This relationship is of interest inasmuch as small neurosecretory granules within axons contain a variety of mediators,

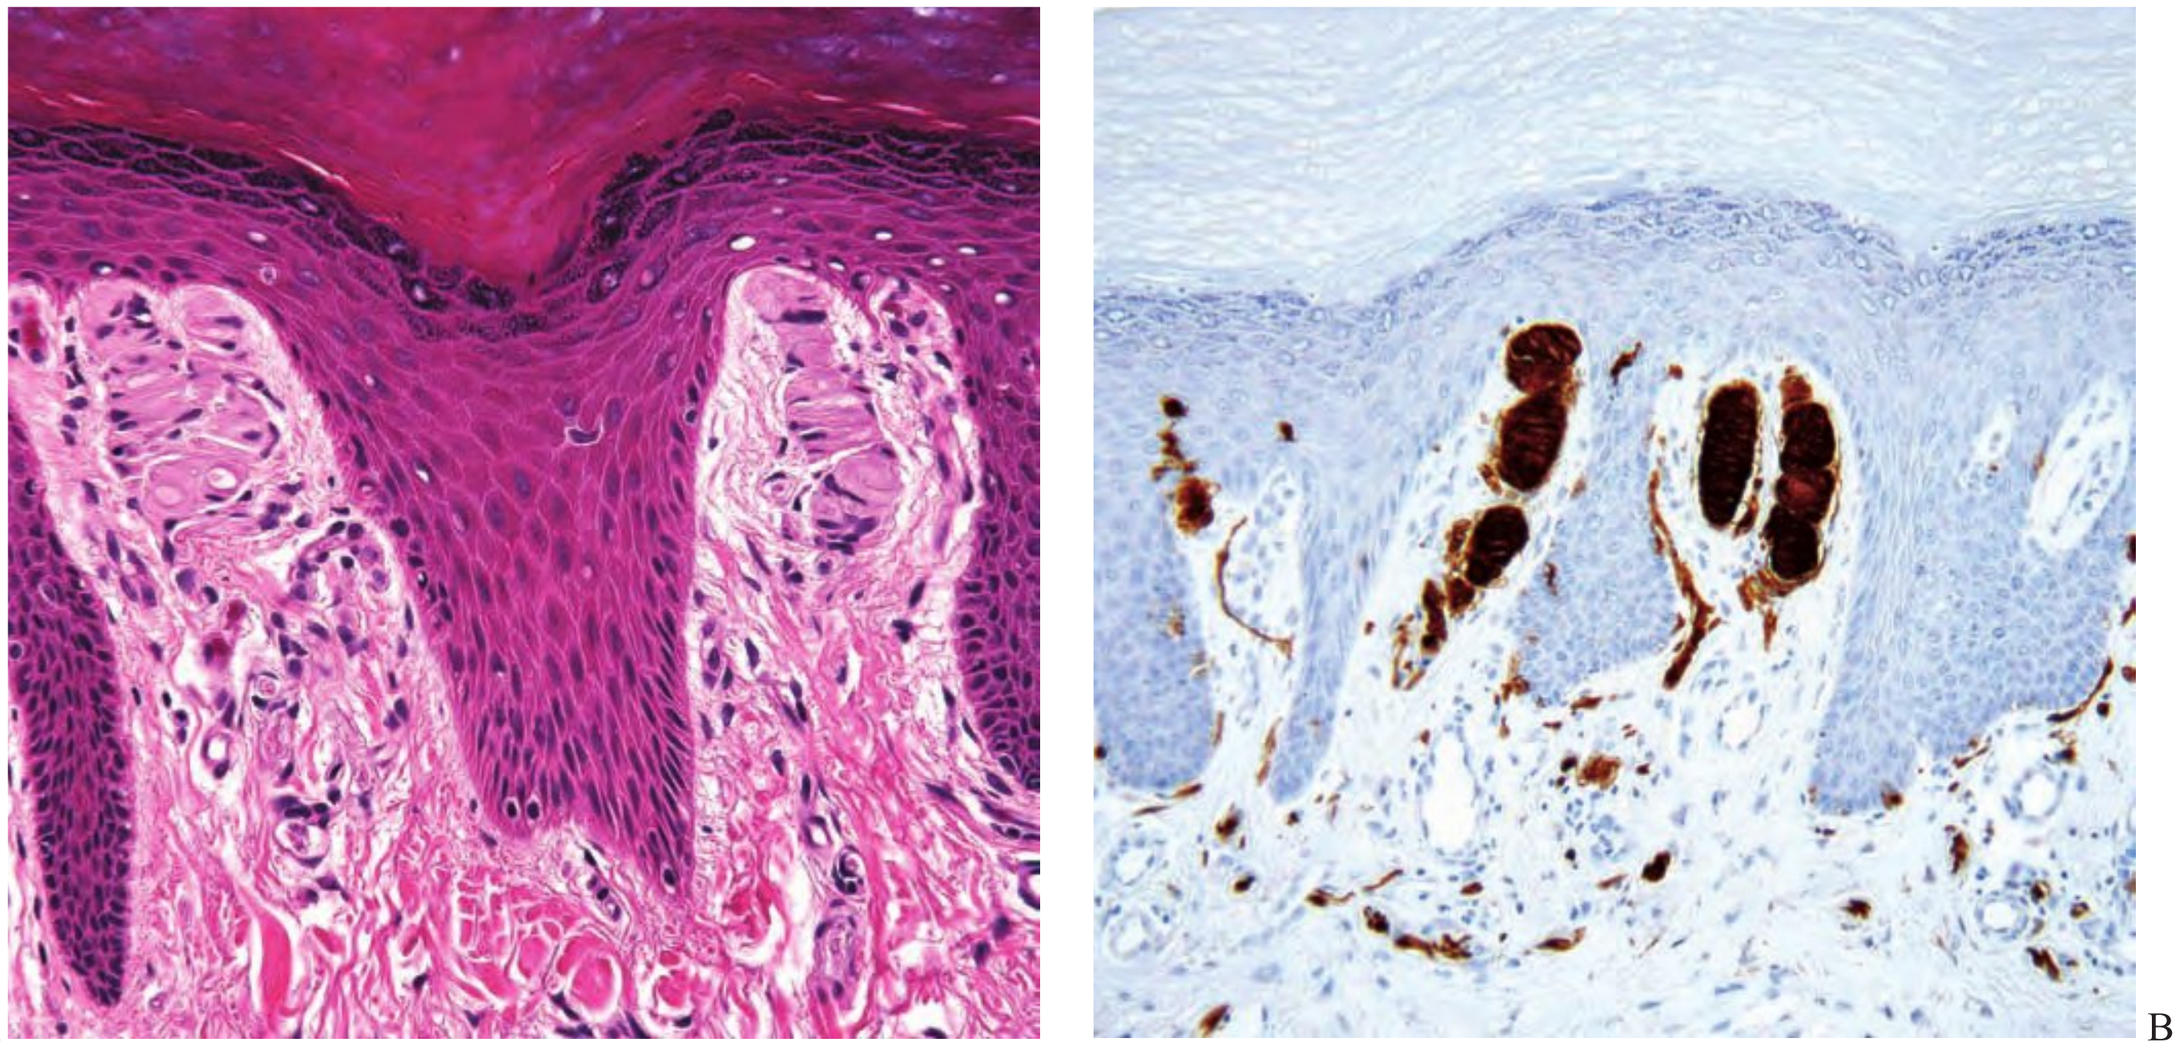

FIGURE 3-54. A: Meissner corpuscle within dermal papillae of human palm skin. B: Meissner corpuscles are strongly positive with S100 immunostain.

including neuropeptides that may serve as mast cell secretagogues, such as substance P. The development of confocal scanning laser microscopy has permitted assessment of complicated spatial relationships between axons and skin cells. Recently, superficial dermal axons containing another neuropeptide, calcitonin gene–related peptide (CGRP), were documented to enter the epidermis and to associate selectively with the cell bodies of Langerhans cells (332). Substance P–induced mast cell degranulation may elicit expression of endothelial-leukocyte adhesion molecules and thus be proinflammatory (333), and CGRP has been shown to diminish antigen presentation by Langerhans cells (334). Thus, the superficial dermal plexus of unmyelinated axons may represent a heretofore-unappreciated influence of normal and perturbed cutaneous immunity.

Special Nerve End-Organs

In the areas of hairless skin on the palms and the soles and in the areas of modified hairless skin at the mucocutaneous junctions, some of the sensory nerves end in special nerve end-organs. They are of three types: mucocutaneous end-organs, Meissner corpuscles (Figs. 3-54A, B), and Vater-Pacini corpuscles (Fig. 3-55). Although it is customary to speak of them as end organs, they actually represent starting organs in a functional sense because nerve impulses start there and are transmitted to the sensory cells of the spinal cord (335).

The mucocutaneous end organs, on the average 50 μm in diameter, are found in the modified hairless skin at the mucocutaneous junctions, namely, the glans, the prepuce, the clitoris, the labia minora, the perianal region, and the vermilion border of the lip. They are in the papillary dermis. They cannot be recognized in routinely stained sections, in contrast to the Meissner corpuscles in the dermal papillae. Impregnation with silver nitrate reveals that from two to six myelinated nerve fibers enter each mucocutaneous end organ and, after losing their myelin sheaths, form many loops of nerve fibers resembling

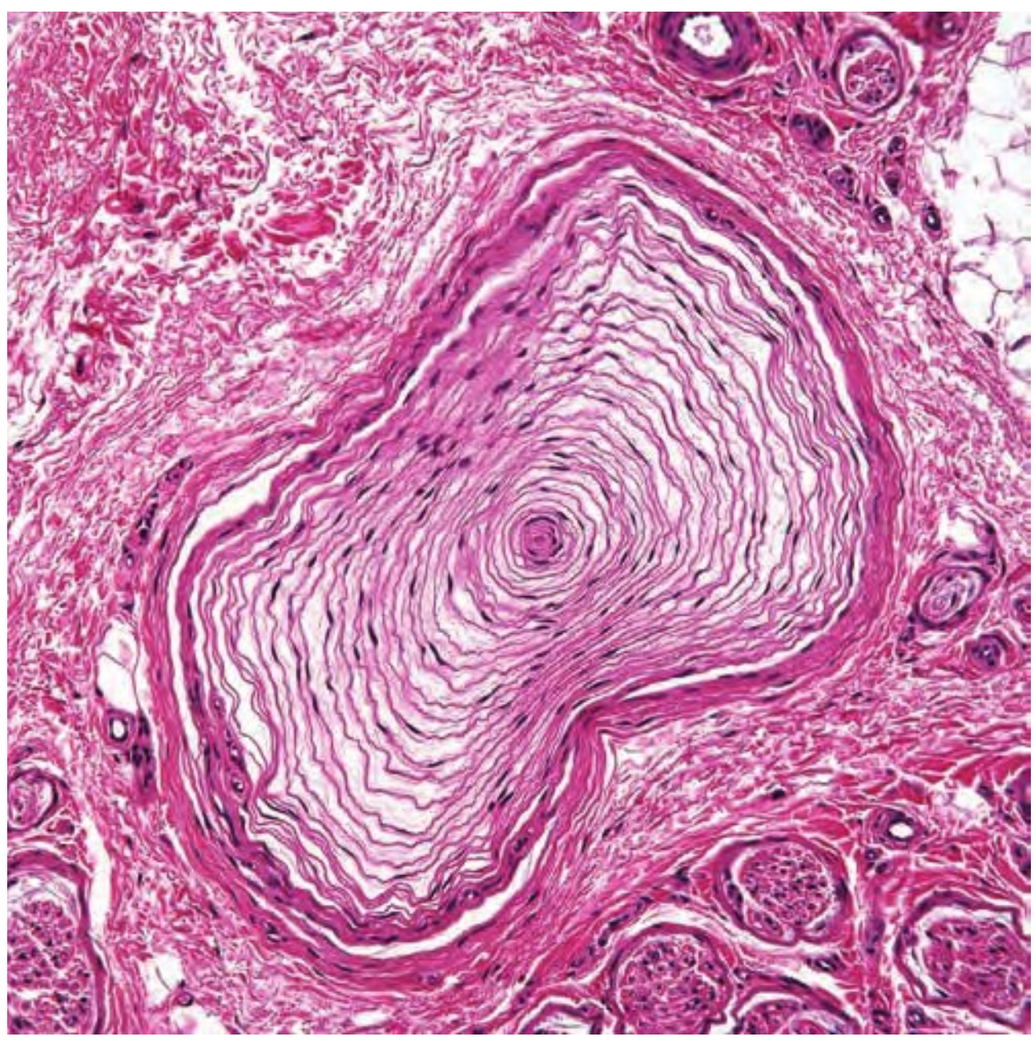

FIGURE 3-55. Vater-Pacini structure with characteristic concentric pattern.

an irregularly wound ball of yarn. The electron microscopic features of mucocutaneous end organs are similar to those of Meissner corpuscles (336), despite minor differences in their light microscopic appearance. They show a subdivision into lobules, each containing a complex arrangement of axon terminals. These axon terminals are surrounded by concentric lamellar processes derived from so-called laminar cells, the nuclei of which are situated toward the periphery of the lobules. It is assumed that the laminar cells represent modified Schwann cells. The mucocutaneous end organs are always separated from the basal layer of the epidermis by a band of papillary dermal collagen.

Meissner corpuscles are located in dermal papillae (Fig. 3-54A, B) and mediate a sense of touch. They occur exclusively on the ventral aspects of the hands and feet, their number increasing distally. There are more Meissner corpuscles on the hands than on the feet. At the site of their greatest concentration, the fingertips, approximately every fourth papilla contains a Meissner corpuscle. The size of the Meissner corpuscles averages 30 by 80 μm in diameter. Owing to their size and their elongated shape, resembling that of a pine cone, they occupy the greater part of the papilla in which they are located. They possess a capsule composed of several layers of flattened Schwann cells that are arranged transverse to the long axis of the corpuscle. Impregnation with silver salts reveals that several myelinated nerves, as they approach the base or the side of the corpuscle, lose their myelin sheaths and then enter it. Within the corpuscle, the nerves take a meandering course upward. Electron microscopic studies reveal that the principal part of the Meissner corpuscle is made up of irregular layers of flattened, greatly elongated laminar cells. The nuclei of the laminar cells are located largely at the periphery of the corpuscle. The axons terminating within the Meissner corpuscle are surrounded by slender processes of the laminar cells. This enveloping of axons by laminar cells or their lamellar processes is analogous to the enveloping of axons by infolding of the plasma membrane of Schwann cells and indicates that the laminar cells are modified Schwann cells (337). The axon terminals and laminar cells are in direct contact with the epidermal basal cells at the upper end of the Meissner corpuscle without interposition of a basement membrane (338).

Vater-Pacini corpuscles are large nerve end organs that are located in the subcutis and mediate a sense of pressure. They measure up to 1 mm in diameter and thus are detected easily by light microscopy (Fig. 3-55). They are found most commonly below the skin of the volar aspects of the palms and soles, showing their greatest concentration at the tips of the fingers and toes. In addition, a few Vater-Pacini corpuscles occur in the subcutis of the nipple and of the anogenital region (336). Vater-Pacini corpuscles vary in shape. Some are ovoid, others have the appearance of a flattened sphere, and still others have an irregular shape. They consist of a stalk and of the body proper, the latter having a small core and a thick capsule. In the stalk, the single thick nerve supplying the Vater-Pacini corpuscle makes several turns and, just after entering the stalk, loses its myelin sheath. The core shows a granular substance surrounding the ascending meandering nerve. The thick capsule consists of 30 or more concentric, loosely arranged lamellae. On electron microscopic examination, the single nerve fiber present in the inner portion of the core retains its Schwann cell cytoplasmic covering for a short distance. The outer portion of the core shows closely packed, greatly elongated laminar cells. The thick capsule consists of at least 30 layers of flattened laminar cells separated from one another by fluid-filled spaces (339). The laminar cells of the Vater-Pacini corpuscle, analogous to those of the Meissner corpuscle, are modified Schwann cells.

SUBCUTANEOUS FAT

Fat cells begin to develop in the subcutaneous tissue toward the end of the fifth month. Histologic examination at that time shows (a) spindle-shaped, lipid-free mesenchymal cells as precursor cells, (b) young-type fat cells containing two or more small lipid droplets, and (c) mature fat cells possessing one large central lipid droplet and a peripherally located nucleus, so-called signet-ring cells. Although some of the cells containing multiple small lipid droplets resemble the multivacuolated mulberry cells present in brown fat and in hibernoma, only few such cells occur in embryonic white fat. Brown and white fat are two separate entities incapable of interconversion (340).

Mature subcutaneous fat consists of lobules composed of adipocytes with cytoplasm markedly expanded by nonvacuolated or membrane-bound lipid that displaces the cell nucleus eccentrically to produce a thin, fusiform contour compressed along the inner plasma membrane. The lipid dissolves in routinely processed specimens, although it is visible in glutaraldehyde-fixed, plastic-embedded specimens. It may be stained histochemically in frozen section obtained from fresh or "wet" tissue retrieved while still in formalin. The lobules that form the subcutis are separated by thin fibrous septae through which small vessels course (Fig. 3-56). The septae provide structural

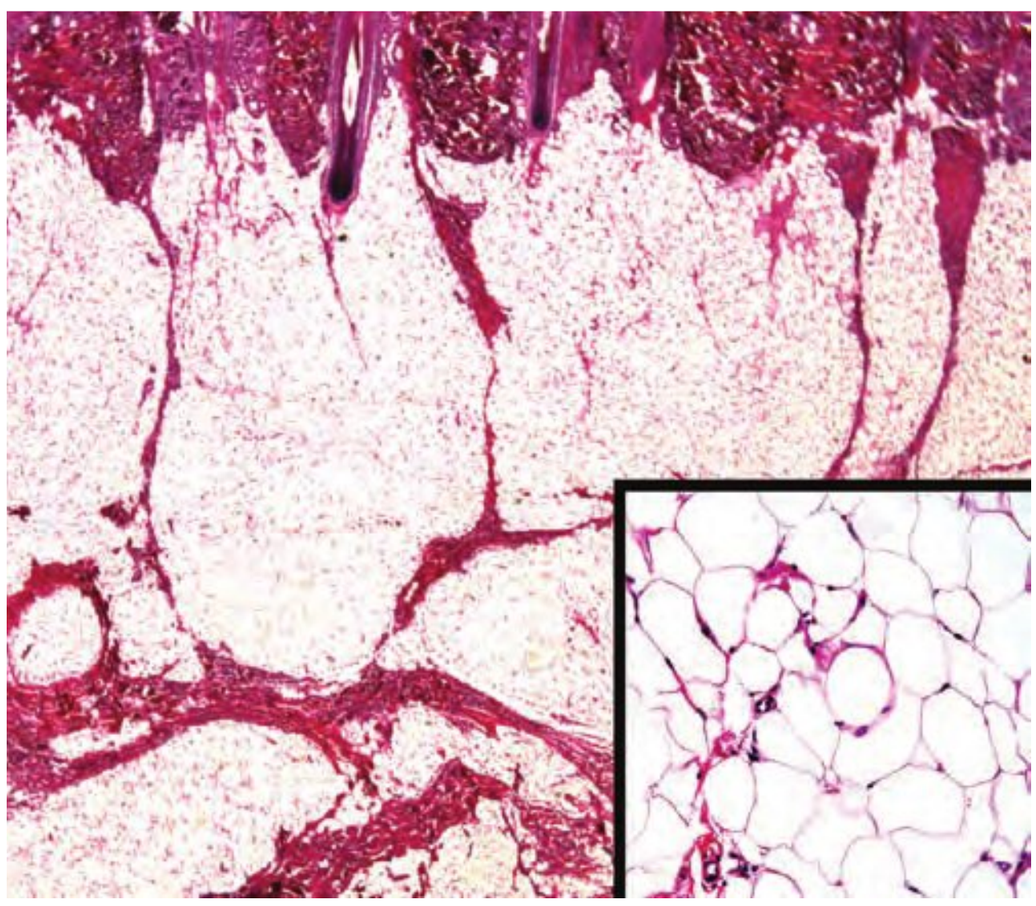

FIGURE 3-56. Low-power view of the subcutaneous tissue. Lobules of adipose tissue are separated by fibrous septa. Inset: A higher-power view of a subcutaneous lobule.

stability to the subcutaneous layer by compartmentalizing it and by connecting the lowermost reticular dermis to the fascial planes that underlie the subcutis.

AGE- AND ENVIRONMENTAL-RELATED VARIATIONS

Structural and functional alterations caused by intrinsic aging and independent of environmental insults are now recognized in the skin of elderly individuals and must be considered a fundamental component of "normal" histology (341). Changes associated with skin aging include a thinner epidermis with flattened dermal–epidermal junction (341–343). The keratinocytes become less adherent to one another and tend to be arranged haphazardly because of the aberrant proliferation of basal cells. The melanocyte density declines slowly, and a reduction in the number of melanosomes leads to reduced pigmentation (343). Although it is conceptually important to distinguish between the effects of true biological aging and environmental factors such as sun exposure, in general the observed changes are a practical consequence of the combined effect of both. Despite the decreased melanocyte density, photoaged skin has irregular or heterogeneous pigmentation. Heterogeneity in skin color in exposed areas of skin is due to uneven distribution of pigment cells. Associated with a local loss of melanocytes are noncontiguous areas where melanocytes are increased in number and size (Figs. 3-17A,B) (344,345). Langerhans cells decrease in number and function with age and chronic sun damage, which partially contributes to age-associated deterioration of the immune system. In general the dermis becomes atrophic, and it is relatively acellular and avascular. Dermal changes involve alteration and reduction of collagen, elastin, and ground substance. There is attenuation in the number and diameter of elastic fibers in the papillary dermis, an increase in number and thickness of the same fibers in the reticular dermis, and a coarsening of collagen fibers, which become thicker and stiffer (342). Fibroblasts, dendritic cells, and mast cells are reduced in number. In chronically sun-damaged skin, however, the dermis may be rich in cells showing some enlarged, angulated fibroblast/myofibroblast (343). The hallmark of sun-damaged skin is the presence of solar elastosis characterized by a fibrillary basophilic material present in the upper dermis (Fig. 3-57). The elastotic material is composed of elastin, fibronectin, fibrillin (microfibrillary proteins), and glycosaminoglycans. The pathogenesis of solar elastosis is complex and not fully understood, but it appears to include both *de novo* synthesis of elastotic material and degradation of previously synthesized dermal matrix proteins (346).

A consistent finding in aged skin everywhere is the dilation of lymphatic channels, and this is especially evident in areas where elastosis has taken place (343) (Fig. 3-57). Eccrine and apocrine glands are reduced in number and function. Sebaceous glands may remain unchanged or may increase in size; they are, however, less active (341). There is a progressive reduction in the density of hair follicles per unit area on the face and scalp and a decline in the rate of growth. The hair

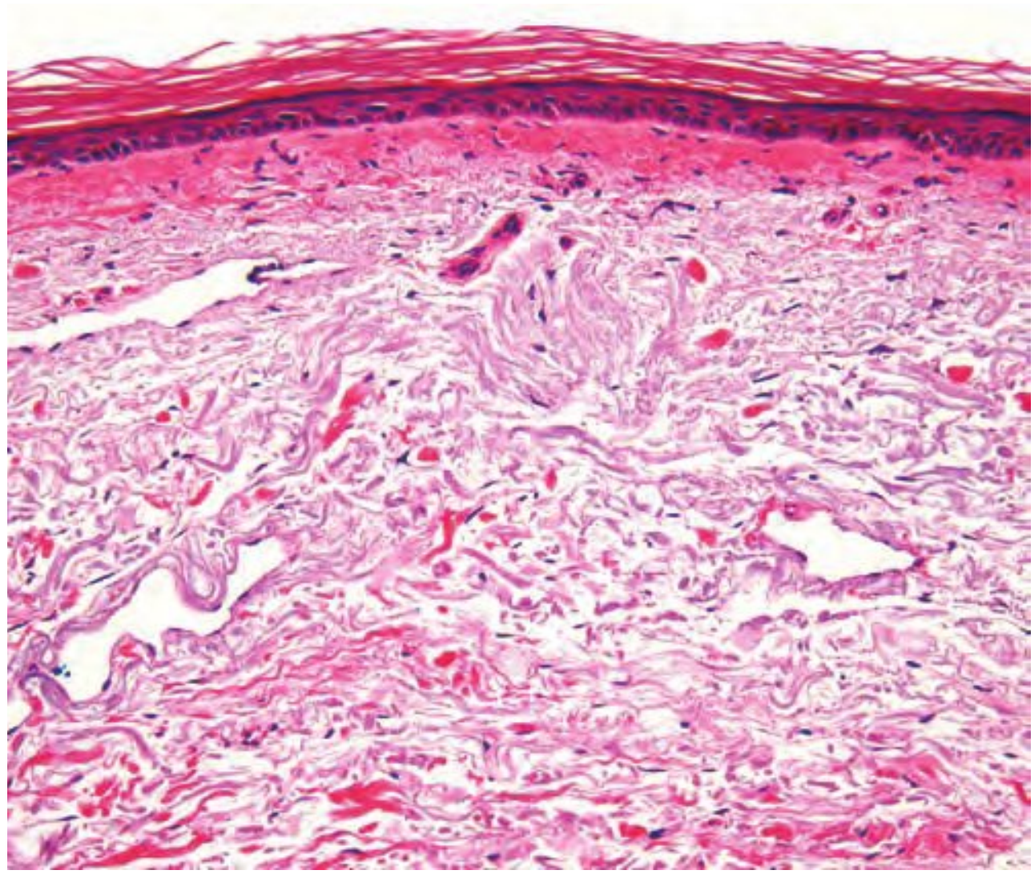

FIGURE 3-57. Changes associated with skin aging include a thinner epidermis with flattened dermal–epidermal junction and telangiectatic dermal vessels associated with marked solar elastosis in the form of bluish-gray fibers, the latter related to chronic sun damage.

shaft diameter is generally reduced, but in some areas, especially the ears, nose, and eyebrows of men and the upper lip and chin in women, it is increased as vellus hairs convert to cosmetically compromising terminal hairs (341).

The subcutaneous tissue is diminished in some areas, especially the face, shins, hands, and feet, whereas in others, particularly the abdomen in men and the thighs in women, it is increased (341).

The nail plate is generally thinned, the surface ridged and lusterless, and the lunula decreased in size; these structural changes are associated with a slowing of the rate of nail growth (341).

REGIONAL VARIATION OF THE SKIN

As a final consideration in the context of the many different components of the skin discussed to this point, it is important to emphasize that although the skin has basically the same components at different anatomic sites, the distribution of these components is variable, so that the skin has different morphology at different sites. The skin of the trunk and especially the back has a significantly thicker reticular dermis compared to other regions (Fig. 3-58), and the skin of the umbilical area also shows a thick and fibrotic dermis. Acral skin from palms and soles has a typical thickened and compact stratum corneum containing a stratum lucidum, numerous eccrine glands, and no pilosebaceous units (Figs. 3-7 and 3-52A). Glomus structures and nerve end organs are seen in the dermis (Figs. 3-52B and 3-54A, B). The scalp is characterized by numerous terminal hair follicles, with most of their bulbs in the subcutaneous tissue (Fig. 3-59). The skin from the face has prominent sebaceous glands in vellus hairs and especially on the nose (Fig. 3-60). Anywhere in hairy skin, but especially in the

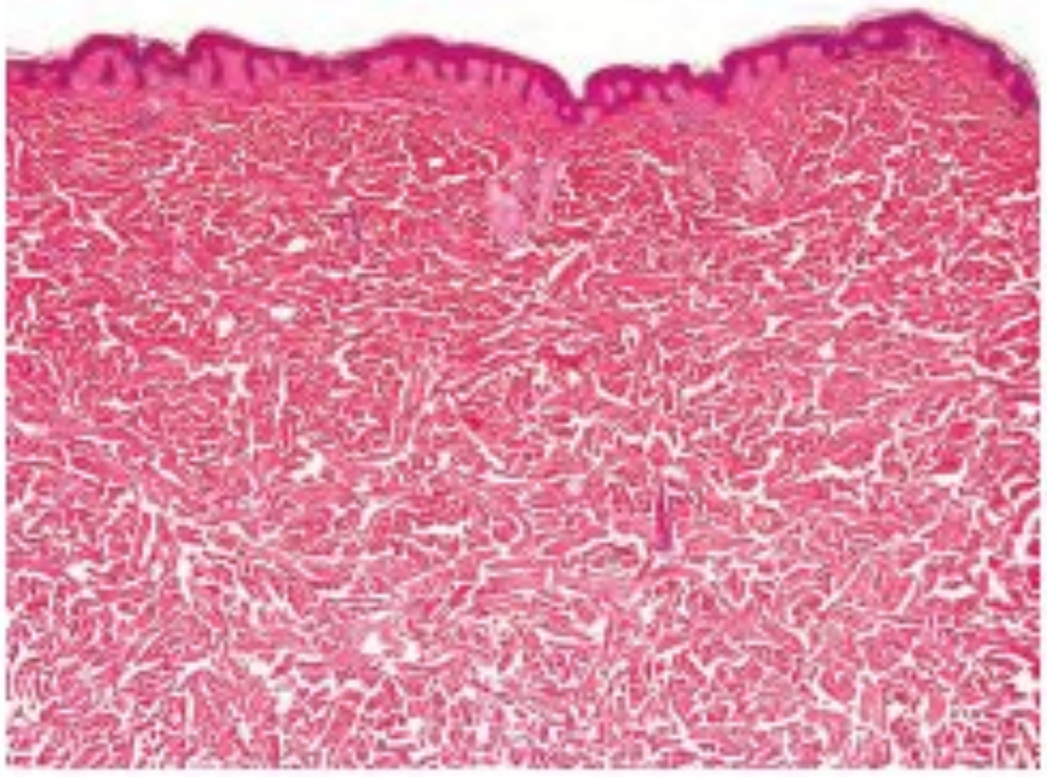

FIGURE 3-58. Skin from the back, showing a significantly thicker reticular dermis compared to most other regions.

beard area, it is possible to find pili multigemini characterized by more than one hair shaft emerging from a single infundibulum. Although classically considered a rare developmental defect of hair, recent studies suggest that they are commonly present in variable numbers in otherwise normal skin (347) (Fig. 3-61). Skeletal muscle is more superficial on the face, including lips and periorbital areas; skeletal muscle fibers may be seen in the dermis in these areas (Fig. 3-62D). Numerous vellous hairs are seen in the ear. The eyelid epidermis is thin (two to three layers thick) with basaloid buds (Fig. 3-62A, B). The basal layer tends to show increased pigmentation and more melanocytes compared with specimens from other anatomic locations from the same person. Modified apocrine glands (Moll's glands) and vellus hairs are seen in the dermis (Fig. 3-62D). The mucosal portion of the eyelid is lined by a nonkeratinizing stratified epithelium with scattered goblet cells (Fig. 3-62C). Smooth muscle fibers are numerous in the

dermis of the areola and nipple and are also seen in the dartos layer (underneath the dermis) in foreskin and scrotum (Fig. 3-63). Skin biopsies from the legs, especially in adults, may show prominent thick-walled blood vessels due to gravity and stasis (Fig. 3-64).

INCIDENTAL FINDINGS IN SKIN SPECIMEN

"Normal" skin is seldom perfect and pristine. As discussed earlier, it must be viewed in the context of alterations implicit to normal aging, unavoidable environmental agents, and anatomic site. In this section, some of the "incidental findings" in normal skin that may be at times confused with pathologic and clinically significant changes are briefly discussed.

Focal Epidermolytic Hyperkeratosis

Incidental (focal) epidermolytic hyperkeratosis is a common, nonspecific finding that may be seen in normal and especially sun-damaged skin (348). It has been also described adjacent or within different unrelated lesions such as seborrheic keratosis, scars, fibrous histiocytomas, actinic keratosis, carcinomas, and melanocytic lesions. Incidental epidermolytic hyperkeratosis is characterized by a focal area showing hyperkeratosis, acanthosis, thickened and abnormal granular layer containing irregular, enlarged, and deeply eosinophilic intracytoplasmic inclusions resembling trichohyaline granules, and suprabasal keratinocytes showing marked intracellular edema (cytolysis). There is no clinical correlate, and the pathogenesis is unclear. Incidental epidermolytic hyperkeratosis should be distinguished from congenital bullous ichthyosiform erythroderma,

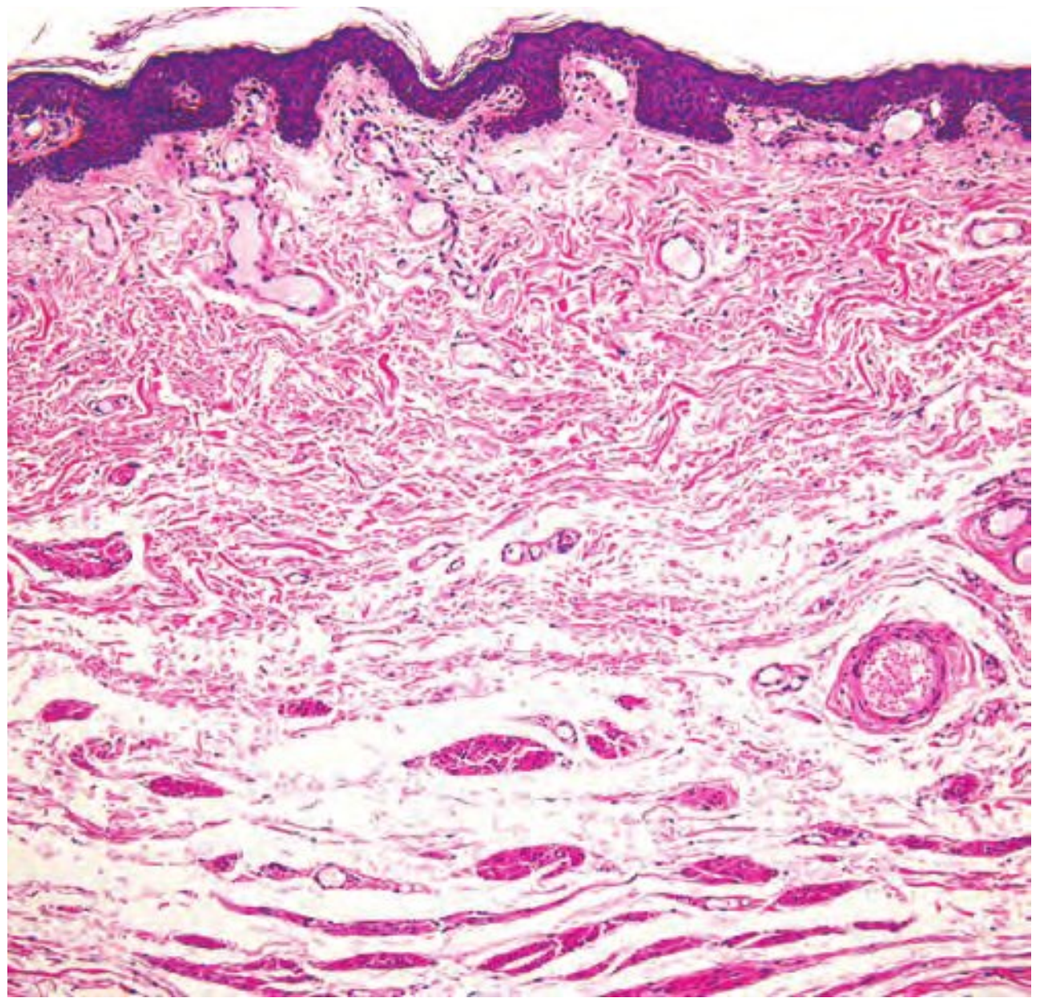

FIGURE 3-63. Smooth muscle fibers are numerous in the dartos layer (underneath the dermis) in foreskin.

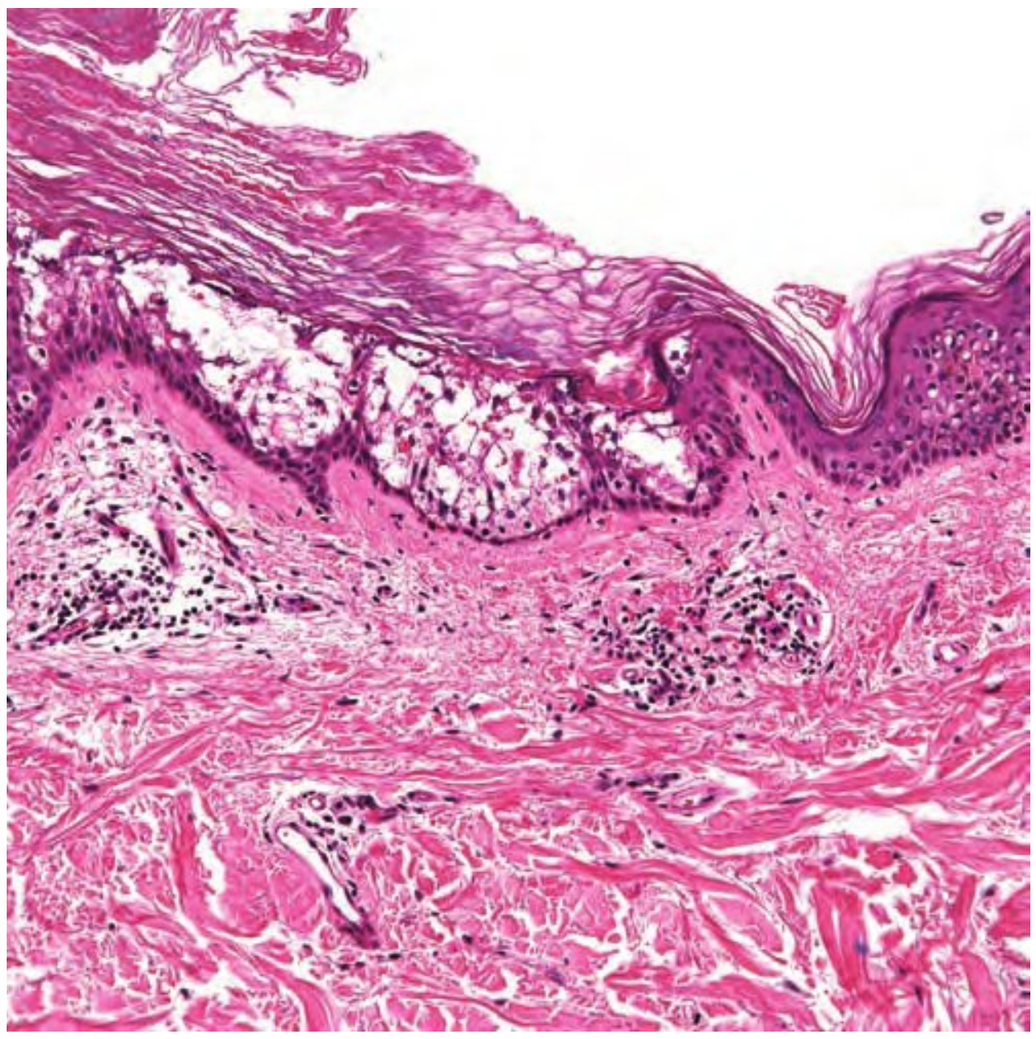

FIGURE 3-65. Incidental (focal) epidermolytic hyperkeratosis is a common, nonspecific finding that may be seen in normal and especially sun-damaged skin.

linear verrucous epidermal nevus, epidermolytic keratoderma, and epidermolytic acanthoma (see Chapter 6). The changes in the incidental form are less extensive and limited to the epidermis (Fig. 3-65).

Focal Acantholytic Dyskeratosis

Another incidental finding that can be seen in normal skin is focal acantholytic dyskeratosis. Like incidental epidermolytic hyperkeratosis, focal acantholytic dyskeratosis is a subclinical condition of unknown pathogenesis frequently identified in normal skin or adjacent to unrelated pathologic conditions including dermatitis, benign tumors, carcinomas, and melanomas (349,350). Histologically, there is a focal area of hyperkeratosis, parakeratosis, and suprabasal cleft formation

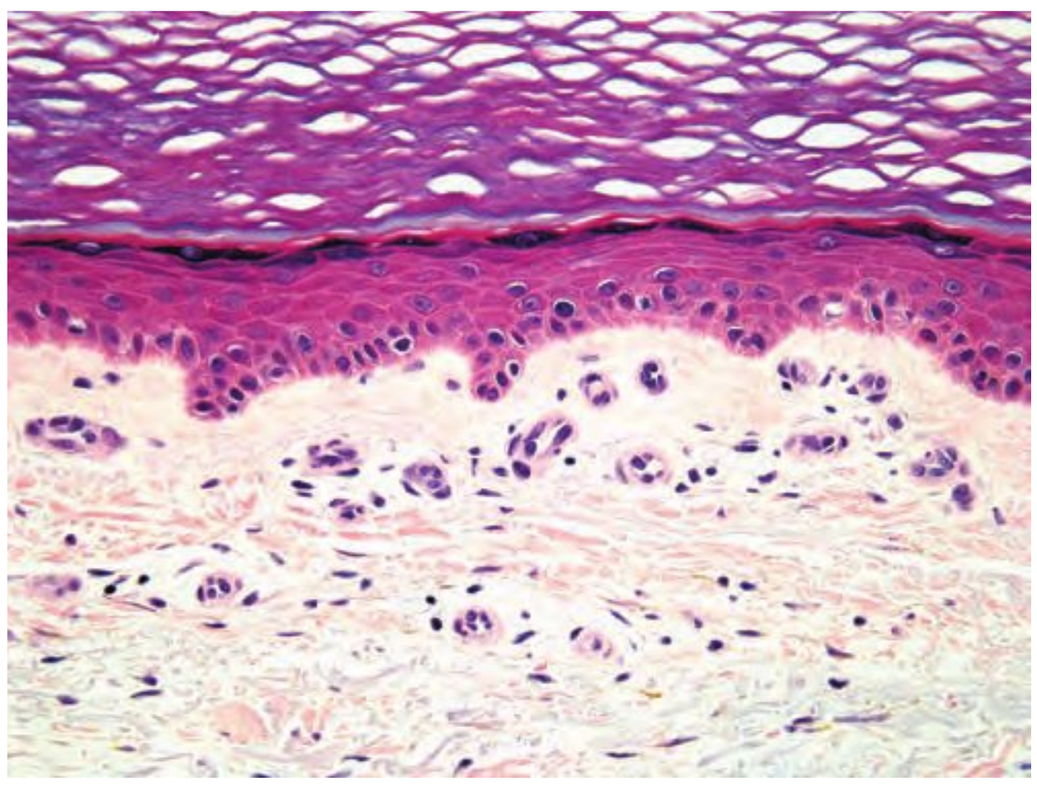

FIGURE 3-64. Skin biopsies from the legs, especially in adults, may show prominent thick-walled blood vessels due to gravity and stasis.

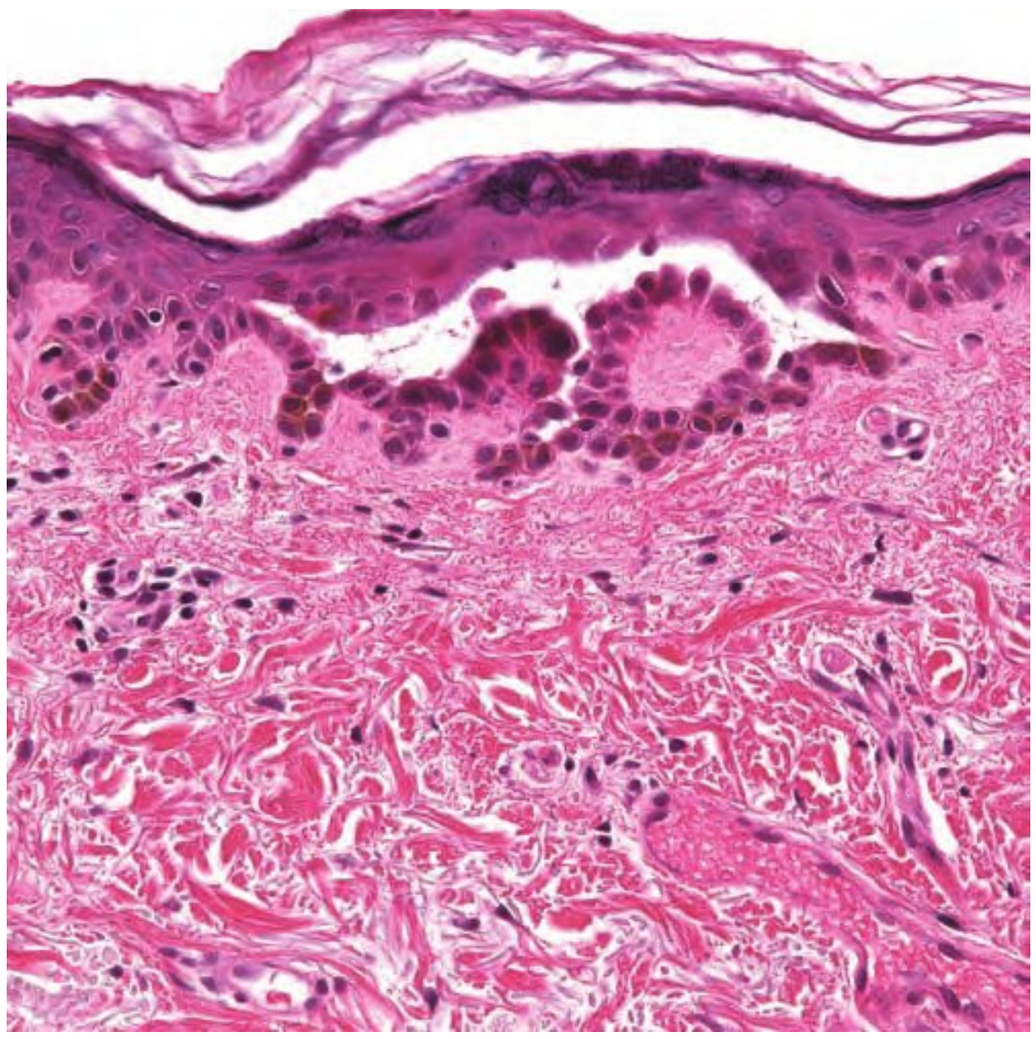

FIGURE 3-66. Focal acantholytic dyskeratosis represents another incidental finding that can be seen in normal skin.

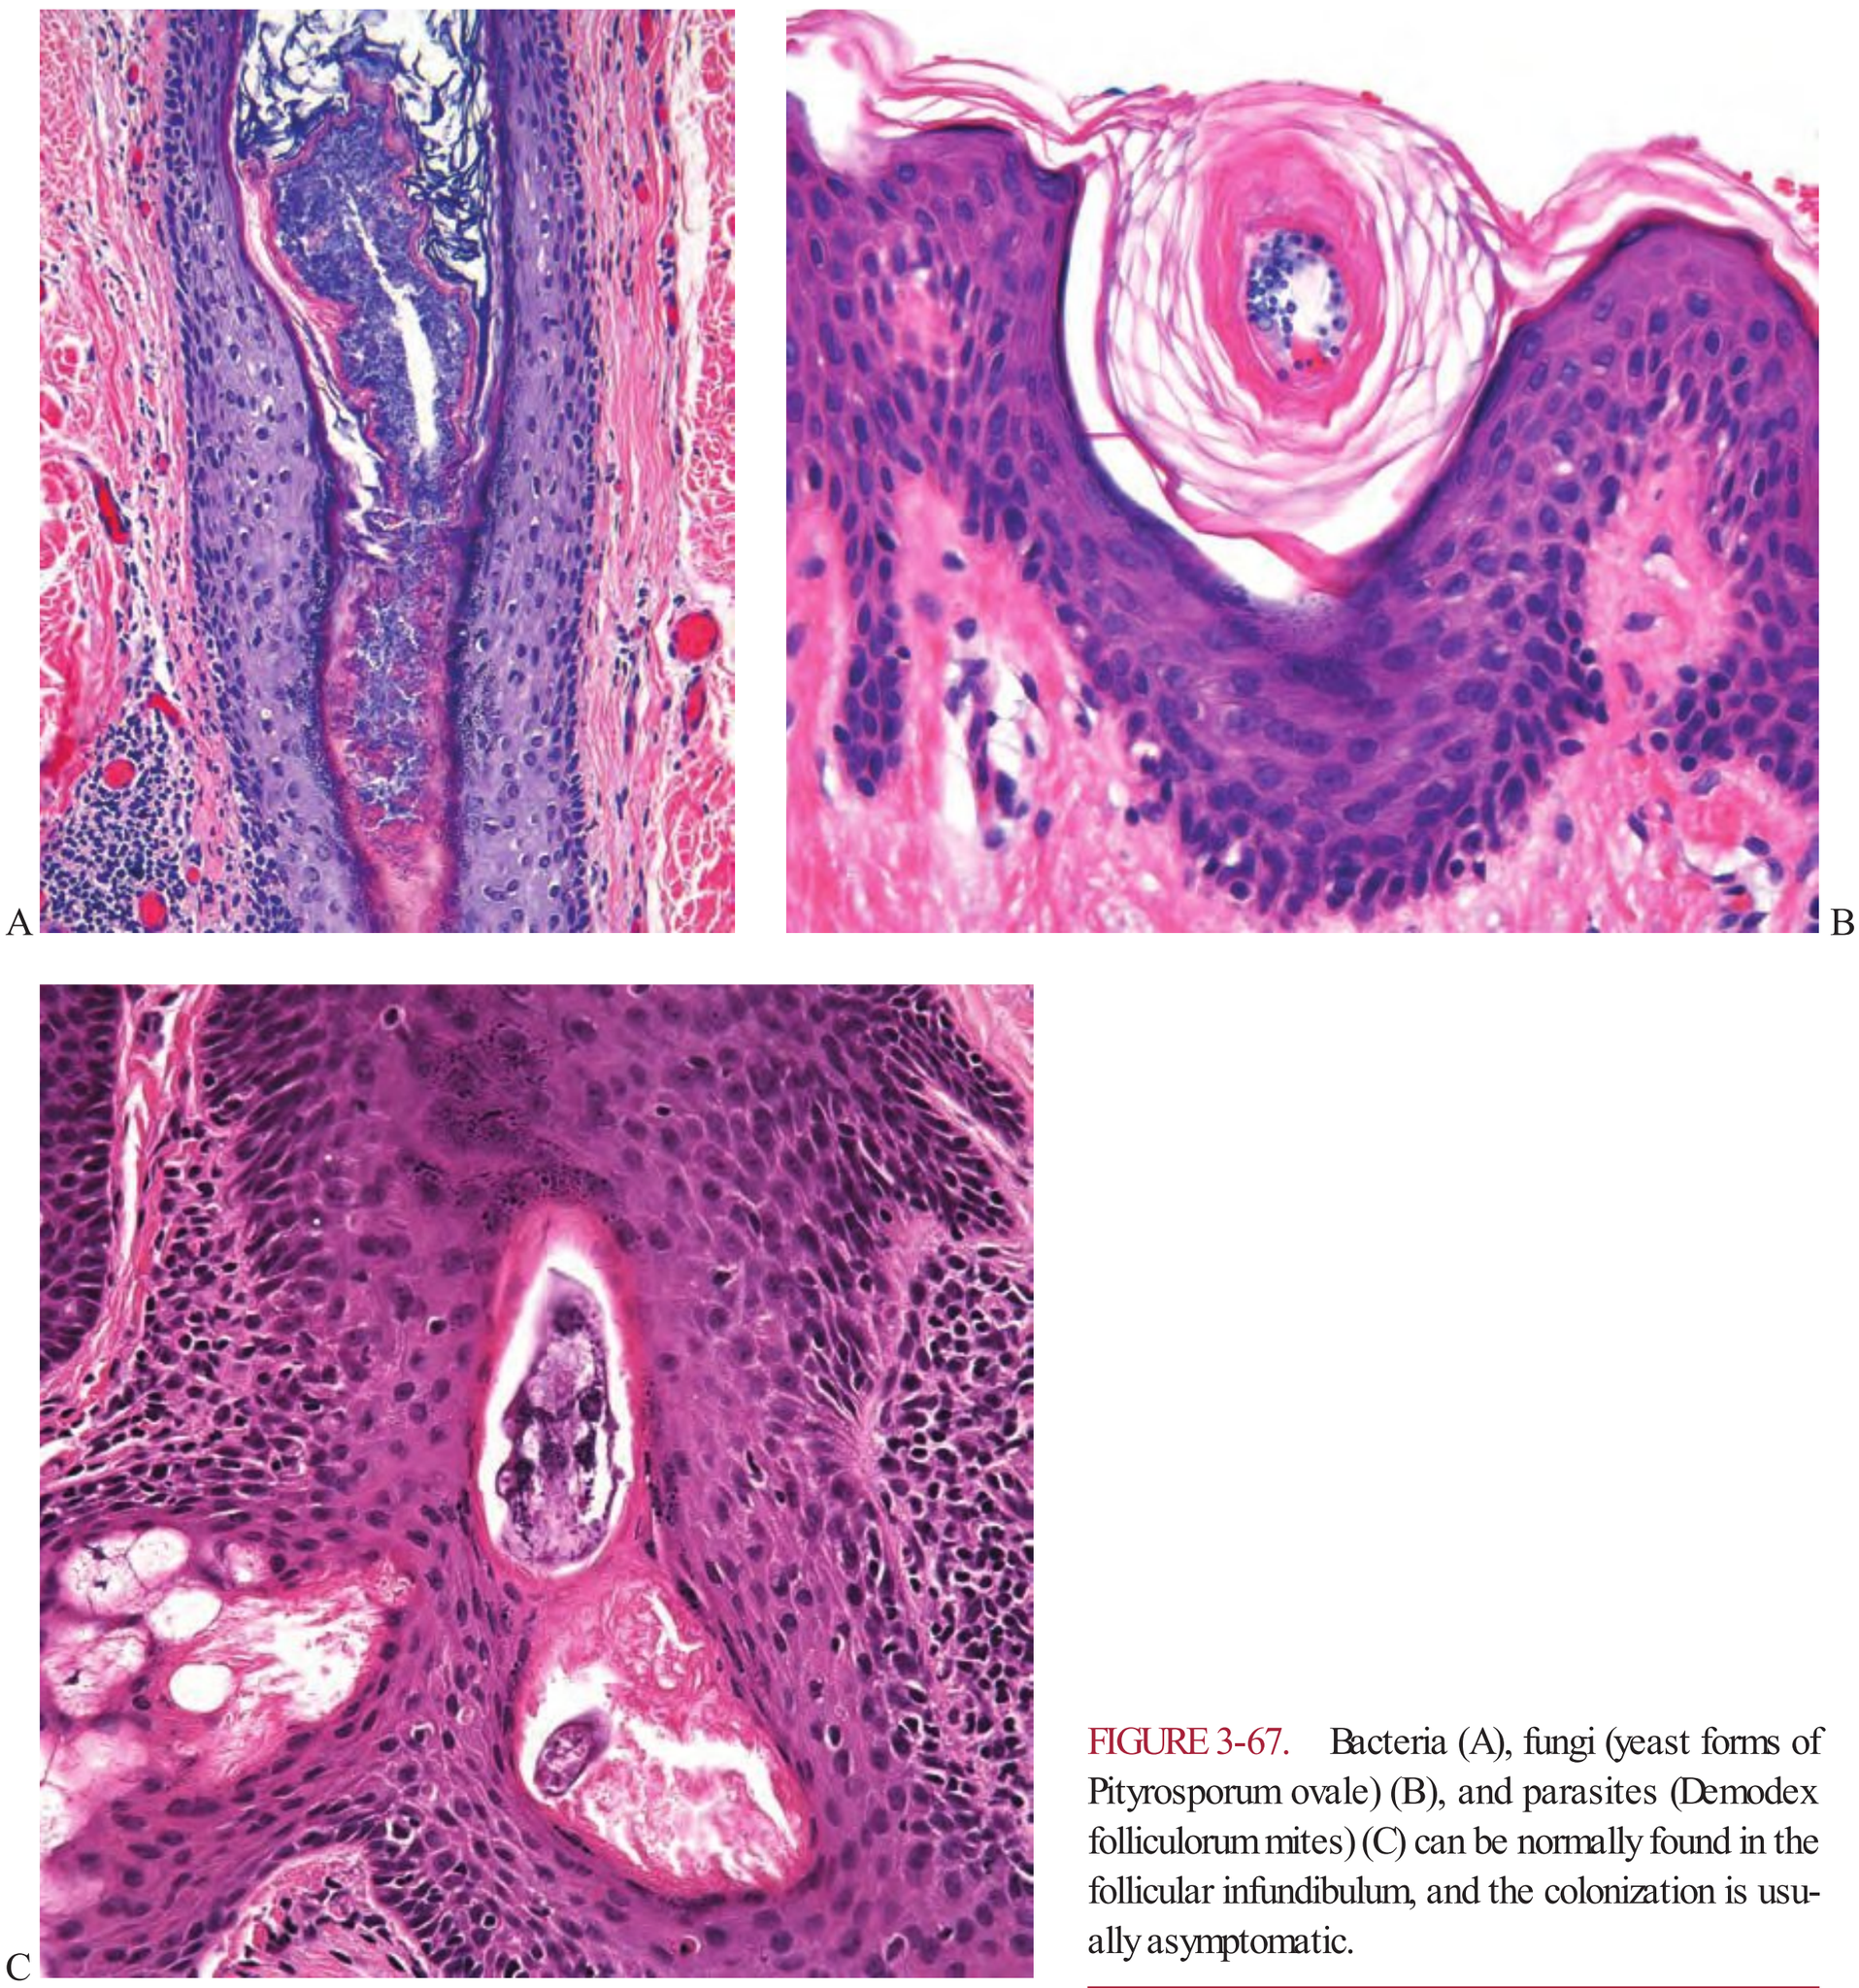

FIGURE 3-67. Bacteria (A), fungi (yeast forms of Pityrosporum ovale) (B), and parasites (Demodex folliculorum mites) (C) can be normally found in the follicular infundibulum, and the colonization is usually asymptomatic.

with dyskeratosis and acantholysis (349) (Fig. 3-66). The differential diagnosis includes Darier's disease, Grover's disease, warty dyskeratoma, acantholytic acanthoma, epidermal nevus, and others.

MICROORGANISMS PRESENT IN NORMAL SKIN

Microorganisms such as *Staphylococcus epidermidis*, yeast forms of *Malassezia furfur* (*Pityrosporum ovale*) (351), and *Demodex folliculorum* mites can be normally found in the follicular infundibulum, and the colonization is usually asymptomatic (Fig. 3-67A–C). The role of *D. folliculorum* in rosacea and other skin disorders is controversial. *Malassezia* yeasts are residents of normal human skin with a fine balance between commensalism and pathogenicity. They may play a role in seborrheic dermatitis and atopic eczema, and a form of *Pityrosporum* folliculitis has been described. They are the cause of tinea versicolor (in this last condition, however, hyphae are found admixed with yeasts in the cornified layer).

Laboratory Methods

There are a number of important steps in preparing histologic sections prior to their interpretation by the dermatopathologist. Failure to handle the tissue properly may make it difficult to provide an accurate diagnosis or appropriate margins.

PREPARATION OF SPECIMENS

Fixation

It is important properly to fix a skin biopsy to stabilize proteins and prevent tissue decay. The specimen should be placed in fixative immediately after it is removed from the patient; artifacts may result if it is allowed to dry. The fixative of choice is a 10% neutral-buffered formalin solution. The volume of formalin should be 10 to 20 times the volume of the specimen. During winter, either 95% ethyl alcohol, 10% by volume, should be added to the formalin solution or the specimen should be allowed to stand in the formalin solution at room temperature for at least 6 hours before mailing.

Adequate time should be allowed for fixation. Fixation time is 1 to 2 hours per millimeter thickness. Large specimens, such as excised tumors, should be cut in the laboratory into slices 4 to 5 mm thick for further fixation, generally overnight. These specimens also require greater volumes of formalin.

Grossing

After fixation, ink should be applied to the deep and lateral margins of an excisional specimen for which examination of margins has been requested. The specimen should be appropriately cut for the examination of margins. Some examples are demonstrated in Fig. 4-1. It is important to remember that these cuts are only representative of the margins because it is almost impossible to evaluate every marginal cell. If a localizing suture has been placed by the surgeon, ink of a different color should be applied to that margin, or some other method of labeling should be used to identify the margins. Both 4- and 6-mm punch biopsies are generally bisected, and specimens less than 3 mm in size should be submitted in toto. If a laboratory does not handle many skin specimens, discussion with the embedding technician may be appropriate to facilitate optimal orientation of the blocks.

Demonstration of Enzyme Activities

With few exceptions, specimens should not be placed in formalin for the demonstration of enzyme activities. Instead, they should be delivered to the laboratory wrapped in water-moistened gauze and placed in a clean container because frozen sections cut on a cryostat are usually used for enzyme staining. Staining for enzyme activities is not routinely done and therefore should not be requested without first checking with the laboratory.

Although immunohistochemistry has largely replaced histochemistry for routine diagnostic use, demonstration of dopa-oxidase activity in melanocytes could potentially aid in distinguishing a malignant melanoma from tumors not composed of melanocytes. In addition, certain enzymes, such as succinic dehydrogenase and phosphorylase (eccrine), and acid phosphatase and β-glucuronidase (apocrine) can be detected in glandular tumors. However, these differentials are not usually significant clinically.

Several enzyme reactions can be carried out on formalin-fixed, paraffin-embedded tissue: (a) demonstration of naphthol AS-D chloroacetate esterase activity, with naphthol AS-D chloroacetate as substrate [present in mature and immature granulocytes, except in myeloblasts (1) and mast cells], and (b) demonstration of lysozyme with the antilysozyme immunohistochemical technique (lysozyme being present in mature and immature granulocytes, even in myeloblasts, and in histiocytes) (see Chapter 31).

In two diseases—scleredema of Buschke and amyloidosis—unfixed frozen sections may show a more conclusive reaction to specific staining methods than is obtainable with formalin-fixed material. It is therefore recommended that in these two diseases only part of the tissue be fixed in formalin and the remainder be used for frozen sections. In scleredema, demonstration of hyaluronic acid with toluidine blue at pH 7.0 may be more intense in unfixed, frozen sections than in formalin-fixed sections; in amyloidosis, the reactions of the amyloid with crystal violet or Congo red may be conclusive only in unfixed, frozen sections (see Chapter 17).

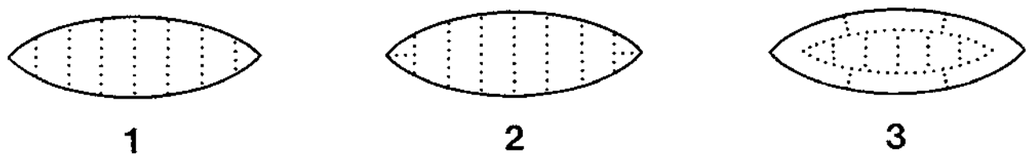

FIGURE 4-1. Preparation of blocks from a skin ellipse. After the margins have been painted with ink, the specimen is sectioned for processing and later embedding. In example 1 the tissue is cut as if one is slicing a loaf of bread; this is one of the most common methods used in dermatopathology laboratories. Example 2 allows for better evaluation of the "tips" of the ellipse; however, embedding of these small pieces is more difficult. Often only the center section of the "tips" is embedded, or the tips may be cut in half and embedded flat, especially for smaller specimens. In example 3, the entire margin is theoretically visualized; however, this method requires the technician meticulously to embed and orient small pieces of tissue and is not recommended for most specimens in most routine laboratories (65).

Processing

The purpose of processing is to remove the extractable water from the skin and to provide a supporting matrix (paraffin) so that the tissue can be cut with minimal distortion. After fixation, routine specimens are processed in an automatic processor. An exception is made for specimens that are to be stained for lipids. Because lipids are extracted by the xylene used for the processing of specimens, frozen sections are cut and postfixed in 10% neutral buffered formalin for lipid staining.

In the automated histology processor, the specimens pass first through increasing concentrations of ethanol for dehydration, then through xylene for lipid extraction and clearing of alcohol. Finally, the tissues are infiltrated with several changes of hot, melted paraffin (or Paraplast) to provide a matrix so that the tissue can be stabilized and cut easily. This processing takes between 4 and 12 hours; in most laboratories, processing is run overnight. Newer methodology includes microwave-assisted tissue processing, an application of microwave irradiation that accelerates tissue fixation and processing, allowing processing times of only 1 to 2 hours (1). This rapid tissue processing, when perfected, has yielded histologic material and immunohistochemical staining comparable in quality to conventional overnight tissue processing (2).

The next morning, the specimens are embedded with the cut surface face down into the cassette base mold, in the liquid paraffin, which is allowed to harden. To prevent tangentially oriented sections, it is important that this cut surface be firmly embedded in the base of this mold. The specimens are then cut on a rotary microtome into sections 5 to 7 μm thick.

Staining

Routine sections are usually stained with hematoxylin-eosin, the most widely used routine stain. With this staining method, nuclei stain blue or "basophilic," and collagen, muscles, and nerves stain red or "eosinophilic." Special stains are employed when particular structures need to be demonstrated (for details, see later discussion and ref. 3).

HISTOCHEMICAL STAINING

Histochemistry, especially immunohistochemistry, at both the light microscopic and electron microscopic level has gained increasing importance in recent years and has been largely responsible for the expansion of histopathology from a purely descriptive science to one that is dynamic and functional. Many enzyme histochemical methods are used only for research and have the limitation of usually requiring fresh tissue in the place of formalin-fixed tissue.

Most histochemical "special" stains can be carried out on formalin-fixed, paraffin-embedded material. Their primary uses in dermatopathology are listed in Table 4-1.

The *periodic acid-Schiff* (*PAS*) *stain* demonstrates the presence of certain polysaccharides, particularly glycogen and mucoproteins containing neutral mucopolysaccharides, by staining them red. The PAS reaction consists in the oxidation of adjacent hydroxyl groups in 1,2-glycols to aldehydes and the staining of the aldehydes with fuchsin-sulfuric acid. The PAS reaction is of value also in the study of basement membrane thickening, such as in lupus erythematosus or porphyria cutanea tarda. Furthermore, because the cell walls of fungi are composed of a mixture of cellulose and chitin and thus contain polysaccharides, fungi stain bright pink-red with the PAS reaction.

For the distinction of neutral mucopolysaccharides and fungi from glycogen deposits, it is necessary to compare two serial sections, one exposed to diastase before staining and the other not. Because glycogen is digested by the diastase and thus is no longer colored red by the PAS reaction, it can be easily distinguished from neutral mucopolysaccharides and fungi that are diastase resistant. Because glycogen is present in outer root sheath cells and eccrine gland cells, demonstration of glycogen may be of diagnostic value in adnexal tumors with outer root sheath or eccrine differentiation. Demonstration of neutral mucopolysaccharides is of value in Paget's disease of the breast and in extramammary Paget's disease.

The *alcian blue reaction* demonstrates the presence of acid mucopolysaccharides by staining them blue. Acid mucopolysaccharides are present in the dermal ground substance but in amounts too small to be demonstrable in normal skin. However, in the dermal mucinoses, there is a great increase in nonsulfated acid mucopolysaccharides, mainly hyaluronic acid, so that the mucin stains with alcian blue (see Chapter 17). In extramammary Paget's disease of the anus with rectal carcinoma (see Chapter 29) and in cutaneous metastases of carcinoma of the gastrointestinal tract containing goblet cells (see Chapter 36), tumor cells in the skin, like their parent cells, secrete sialomucin. Sialomucin contains nonsulfated acid mucopolysaccharides staining with alcian blue, as well as PAS-positive neutral mucopolysaccharides. Whereas nonsulfated acid mucopolysaccharides stain with alcian blue at

TABLE 4-1 Histochemical Stains Used in Dermatopathology

Stain	Purpose of stain	Results
Hematoxylin-eosin	Routine	Nuclei: blue Collagen, muscles, nerves: red
Masson trichrome	Collagen	Collagen: blue or green Nuclei, muscles, nerves: dark red
Verhoeff-van Gieson	Elastic fibers	Elastic fibers: black Collagen: red Nuclei, muscles, nerves: yellow
Pinkus acid orcein	Elastic fibers	Elastic fibers: dark brown
Silver nitrate	Melanin, reticulum fibers (argyrophilic)	Melanin, reticulum fibers: black
Fontana-Masson	Melanin (argentaffin)	Melanin: black
Methenamine silver	Fungi, Donovan bodies, Frisch bacilli (rhinoscleroma), basement membranes	Black
Grocott	Fungi	Fungus cell walls: black
Periodic acid-Schiff/diastase (PAS)	Glycogen, neutral MPS, fungi	Glycogen: red; diastase labile Neutral MPS, fungi: red; diastase resistant
Alcian blue, pH 2.5	Acid MPS	Blue
Alcian blue, pH 0.5	Sulfated MPS	Blue
Toluidine blue	Acid MPS	Blue
Colloidal iron	Acid MPS	Blue
Hyaluronidase	Hyaluronic acid	Hyaluronidase labile
Mucicarmine	"Epithelial" mucin	Red
Giemsa	Mast cell granules, acid MPS, myeloid granules, Leishmania	MCG, acid MPS: metachromatically purple Myeloid granules, Leishmania: red
Fite	Acid-fast bacilli	Red
Perl's potassium ferrocyanide	Hemosiderin (iron)	Blue
Alkaline Congo red	Amyloid	Pink-red, green birefringence in polarized light
Von Kossa	Calcium	Black
Scarlet red	Lipids	Red
Oil red O	Lipids	Red
Dopa (in unfixed tissue)	Tyrosinase in melanocytes	Black dopa-melanin
Naphthol-AS-D-chloroacetate esterase	Mast cells, neutrophils, myelocytes	Granules stain red
Warthin-Starry	Spirochetes	Black
Dieterle and Steiner	Spirochetes, bacillary angiomatosis	Black
Ziehl Neilson	Acid-fast bacilli	Red

MCG, mast cell granules; MPS, mucopolysaccharides.
Note: All stains, except those for lipids, can be carried out on formalin-fixed, paraffin-embedded specimens. The stains for lipids require formalin-fixed frozen sections.

pH 2.5 but not at pH 0.5, strongly acidic sulfated acid mucopolysaccharides, such as heparin in mast cell granules and chondroitin sulfate in cartilage, stain with alcian blue both at pH 2.5 and at pH 0.5.

Several special stains for elastic tissue are available. The most commonly used stains are the Verhoeff-van Gieson stain (Fig. 4-2) or Weigert's resorcin-fuchsin. Additional techniques, such as the Luna stain and the Miller stain, may allow better visualization of elastic fibers than traditional methods (4). These stains are beneficial in the diagnosis of anetoderma, connective tissue nevi, mid-dermal elastolysis, and other alterations of elastic tissue.

The Giemsa stain is frequently used to highlight mast cells. Giemsa contains methylene blue, a metachromatic stain. The granules of a mast cell stain metachromatically purple (Fig. 4-3).

POLARISCOPIC EXAMINATION

Polariscopic examination is the examination of histologic sections under the microscope with polarized light, that is, light from which all waves except those vibrating in one plane are excluded.

For polariscopic examination, two disks made of polarizing plastics are placed on the microscope. One disk is placed below the condenser of the microscope and acts as the polarizer. The second disk is placed in the eyepiece of the

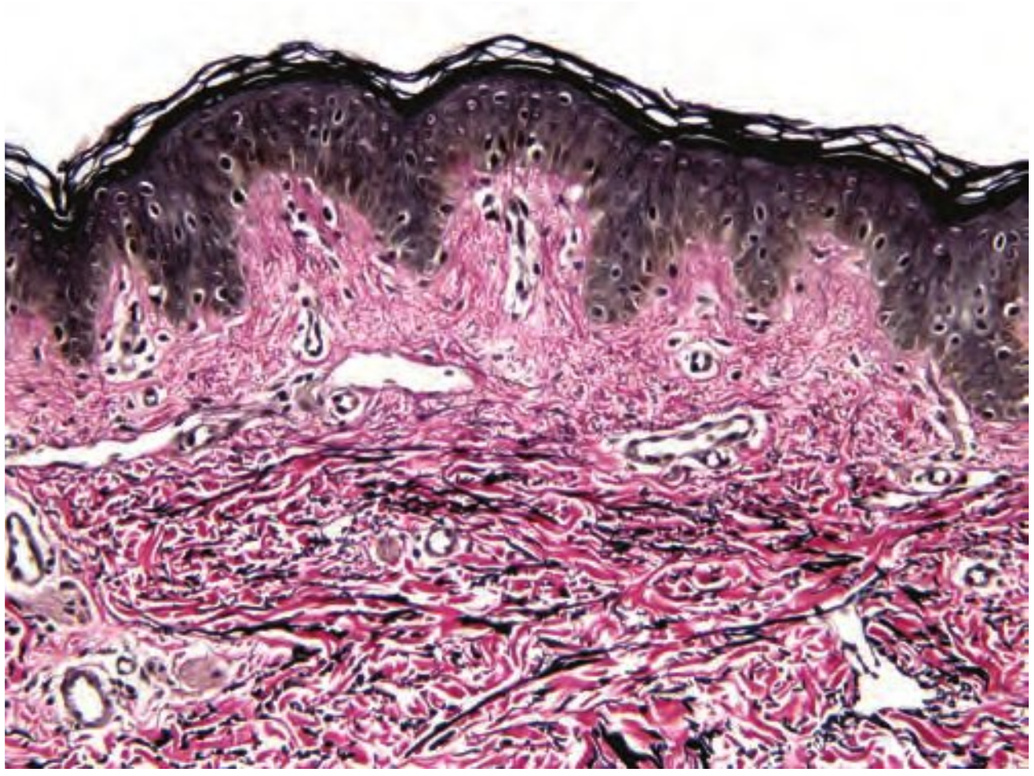

FIGURE 4-2. Elastic fibers. This Verhoeff-van Gieson stain demonstrates the darkly staining normal elastic fibers of the skin.

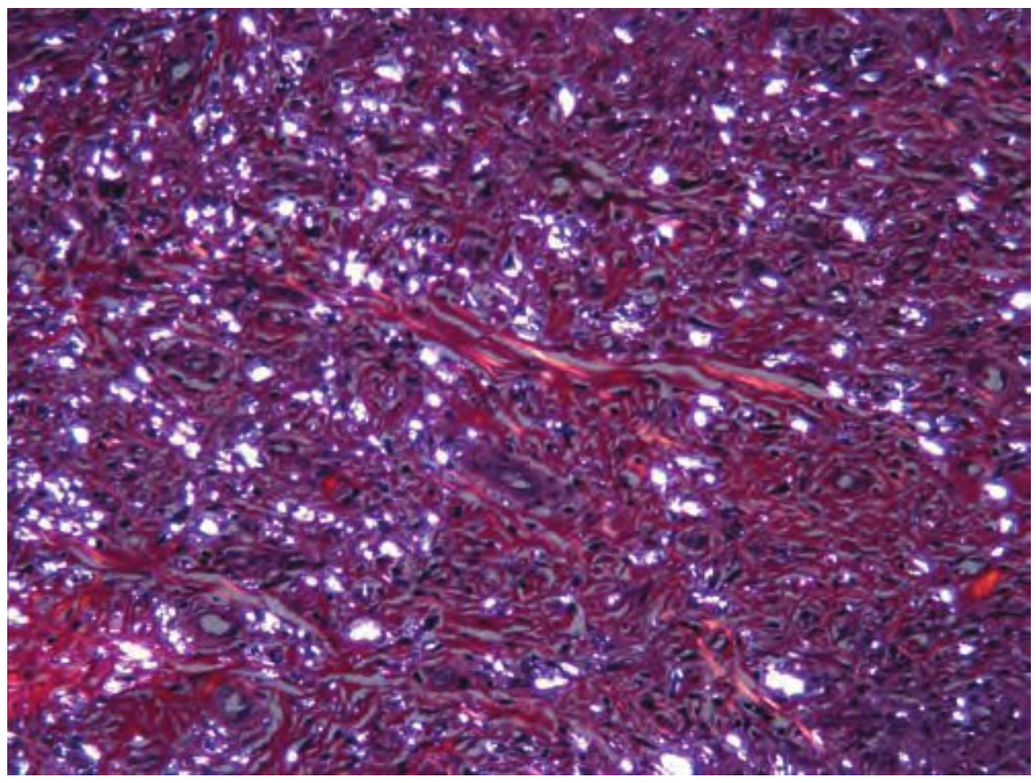

FIGURE 4-4. Polariscopic examination. In this talc granuloma, polariscopy reveals hundreds of refractile foreign bodies within the dermis.

microscope or on top of the glass slide and acts as the analyzer. When one of the two disks is rotated so that the path of the light through the two disks is broken at a right angle, the field is dark. However, when doubly refractile substances are introduced between the two disks, they break the polarization and are visible as bright white bodies in the dark field.

Polariscopic examination is useful in evaluating lipid deposits, certain foreign bodies, gout, and amyloid.

With regard to lipids, it is not fully known why certain lipids are doubly refractile and others are not. In general, cholesterol esters are doubly refractile, but free cholesterol, phospholipids, and neutral fat are not. Only formalin-fixed, frozen sections can be used for a polariscopic examination for lipids.

Doubly refractile lipids are regularly present in the tuberous and plane xanthomas and xanthelasmata (but not always in the eruptive xanthomas) of hyperlipoproteinemia, in the cutaneous lesions of diffuse normolipemic plane xanthoma, and in the vascular walls of angiokeratoma corporis diffusum (Fabry disease) (see Chapter 33). Doubly refractile lipids are present, as long as the cutaneous lesions contain a sufficient amount of lipid, in histiocytosis X (Hand-Schüller-Christian type) (see Chapter 26), in juvenile xanthogranuloma (see Chapter 26), in erythema elevatum diutinum (extracellular cholesterosis) (see Chapter 8), and in dermatofibroma (lipidized "histiocytoma") (see Chapter 32).

Doubly refractile lipids are absent in lipid-containing lesions, as a rule, in necrobiosis lipoidica (see Chapter 14), in hyalinosis cutis et mucosae or lipoid proteinosis (see Chapter 17), and in multicentric reticulohistiocytosis and solitary reticulohistiocytic granuloma (see Chapter 26).

Among foreign bodies, silica causes granulomas showing doubly refractile spicules. These granulomas are caused either by particles of soil or glass (silicon dioxide) or by talcum powder (magnesium silicate) (see Chapter 14). Wooden splinters, suture material, and starch granules are also doubly refractile. An example of polariscopic examination is seen in Fig. 4-4.

Gout tophi show double refraction of the urate crystals if the crystals are sufficiently preserved. They are preserved by the use of alcohol rather than formalin for fixation (see Chapter 17).

Amyloid shows a characteristic green birefringence in polarized light after staining with alkaline Congo red (see Chapter 17).

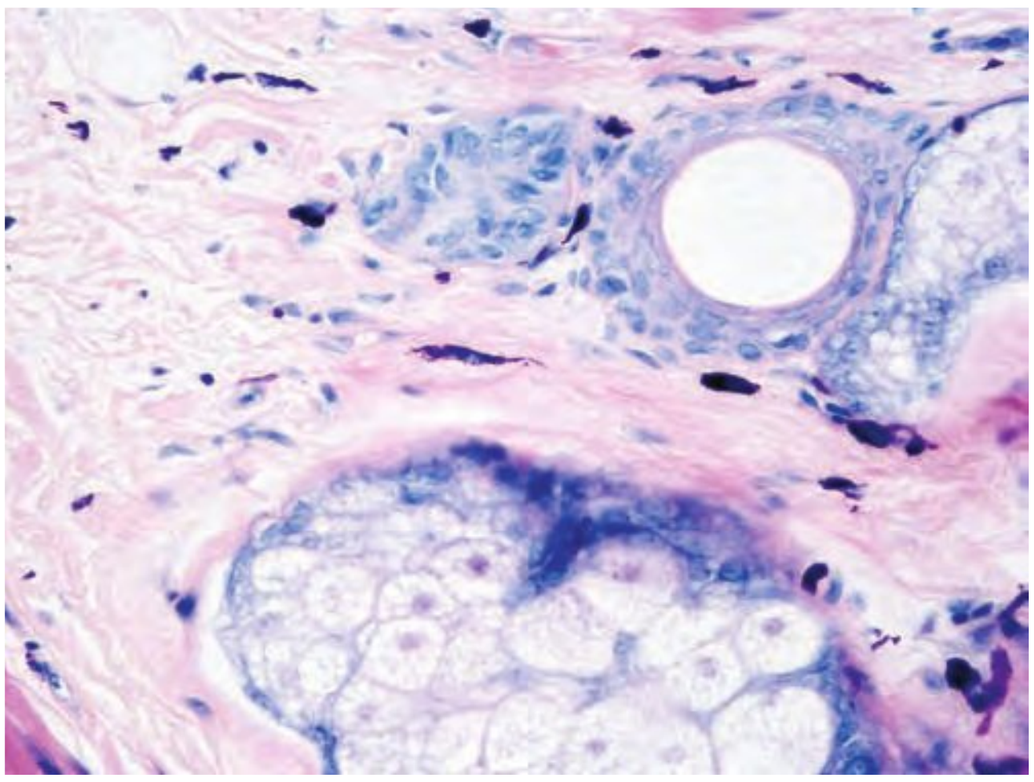

FIGURE 4-3. Giemsa stain. Mast cell cytoplasmic granules are purple.

IMMUNOFLUORESCENCE TESTING

Two immunofluorescence methods are commonly used in dermatology: direct immunofluorescence testing, which probes for immunoreactants localized in patients' skin or mucous membranes, and indirect immunofluorescence testing, which

is used to identify and titer circulating autoantibodies in the patient's serum. A modified indirect immunofluorescence technique using the patient's skin as a substrate, known as immunomapping, is used to determine the site of cleavage or abnormalities in the distribution of mutated proteins in various forms of hereditary epidermolysis bullosa.

DIRECT IMMUNOFLUORESCENCE

Direct immunofluorescence testing has a valuable diagnostic role in several autoimmune and inflammatory mucocutaneous diseases, including autoimmune-mediated blistering diseases, dermatitis herpetiformis, Henoch-Schoenlein purpura [immunoglobulin (Ig) A vasculitis], and cutaneous lupus erythematosus. The role of direct immunofluorescence as a diagnostic procedure is important but not critical in other dermatoses, such as dermatomyositis, cutaneous porphyrias, pseudoporphyria, lichen planus, and vasculitides other than Henoch-Schoenlein purpura (5). Table 4-2 illustrates a stepwise schematic for evaluation of immunofluorescence sections prior to making an immunopathologic diagnosis.

Biopsy Techniques

A 3- to 4-mm punch biopsy is generally adequate. In the group of autoimmune blistering diseases an inflamed but unblistered perilesional area is the ideal specimen. Blistered-lesional sampling is the most common cause of false-negative results. On the other hand, sampling too distant from the blistering also can cause false-negative results. In a few cases of pemphigus, pemphigoid, and epidermolysis bullosa acquisita, false-positive results can occur in blistered lesions. Of note, due to the often focal and skipping nature of the immunoreactants in dermatitis herpetiformis, a shave biopsy often provides a broader surface with which to evaluate dermal papillae than a punch biopsy.

The performance of an adequate perilesional biopsy in mucosal lesions is often not feasible, and thus a high incidence of false negatives and even false positives may occur in these specimens. In patients with desquamative gingivitis secondary to mucous membrane pemphigoid an easy way to obtain sampling is by the so-called "peeling technique," in which rubbing the perilesional affected gingivae with a cotton swab induces a "fresh peeling of the mucosa." In most cases of mucous membrane pemphigoid, the 180- and 230-kD hemidesmosomal antigens are the autoantigens; therefore, the hemidesmosomes will be available for interpretation in the peeled gingivae specimens, and a linear immunostaining with "capping" phenomenon is observed (6).

It has been reported that there is a theoretical higher incidence of false-negative results in bullous pemphigoid lesions from lower extremities; however, this finding has not been confirmed by others.

In asymptomatic dermatitis herpetiformis patients who have strictly adhered to a gluten-free diet for less than 6 months, or even patients that have not done so but remain lesion-free due to dapsone therapy, wide-shaved specimens from the elbows or any other classically affected area will still show the typical IgA deposits at the tips of dermal papillae (7).

In autoimmune and inflammatory disorders other than autoimmune blistering diseases in which direct immunofluorescence plays an important role, the specimens should be taken from lesional areas, including cutaneous lupus erythematosus, dermatomyositis, vasculitides, lichen planus, cutaneous porphyria, and pseudoporphyria.

Transport and Processing of Biopsy Specimens

Tissue for immunofluorescence studies should be obtained fresh and kept moist until it is quickly frozen. Skin specimens can be kept on saline-moistened gauze in a small Petri dish for 24 hours but not longer before processing. For longer delay times the specimens should be put into Michel's transport medium. This medium is composed of 5% ammonium sulfate, the potassium inhibitor *N*-ethylmaleimide, and magnesium sulfate in citrate buffer (pH 7.25). This solution is stable at room temperature but must be kept in a tightly capped container to prevent absorption of CO_2 and acidification. Specimens stored in Michel's medium are stable for at least 2 weeks at room temperature. Specimens stored in Michel's medium and kept in the refrigerator can be preserved for several weeks or even months. This method of transportation has made the direct immunofluorescence technique much more readily applicable. When the specimen is received in a laboratory the ammonium sulfate is washed out and the specimen is oriented and embedded in O.C.T. (Optimal Cutting Temperature) compound and then the specimen is snap frozen. The tissue is then sectioned at 6 μm. The frozen sections are incubated with antihuman antibodies to IgG, IgA, IgM, C3, C5b-9, and fibrinogen. These antibodies are linked to a fluorescent label such

Direct Immunofluorescence Interpretation

Autoimmune Blistering Diseases

Sensitivity of direct immunofluorescence with active autoimmune blistering disease should be close to 100%. If it is not, it is likely due to technical reasons (8). In pemphigus vulgaris and pemphigus foliaceus the IgG immunostaining on the epithelial cell surfaces can be granular and/or linear, giving a characteristic "chicken wire" pattern. Nonspecific patchy granular staining along the basement membrane is not uncommon, especially in mucosal lesions. In paraneoplastic pemphigus the IgG "chicken wire" immunostaining tends to be linear, thick, and homogeneous throughout the epidermis and mucosal specimens, including those from bronchi with or without a concomitant linear basement membrane (9). Lichenoid mucosal and even cutaneous lesions in paraneoplastic pemphigus tend to show focal granular IgG and other immunoreactants along the basement membrane without the typical "chicken wire" pattern. The presence of low titers of circulating autoantibodies may preclude differentiation among the subepithelial autoimmune blistering disorders using indirect immunofluorescence or any other serologic test. In these cases a technique called salt-split direct immunofluorescence often circumvents this problem. This technique consists of thawing the frozen specimen formerly used for routine direct immunofluorescence and incubating it in 1 M NaCl for 48 to 72 hours, allowing for separation of the epidermis from the dermis. This salt cleaves the basement membrane zone through the lamina lucida, leaving the hemidesmosomes on the epidermal side and deeper-seated proteins such as type VII collagen and epiligrin on the dermal side of an artificially induced blister. Therefore, in virtually all cases of bullous pemphigoid the linear IgG immunostaining will be localized on the epidermal side (occasionally epidermal and dermal) and in epidermolysis bullosa acquisita on the dermal side.

Cutaneous Lupus Erythematosus

Direct immunofluorescence has a significant value in the evaluation of patients with active cutaneous connective tissue disease. The intensity of the deposits of immunoreactants along the basement membrane in these patients correlates with the degree of interface/lichenoid dermatitis/mucositis.

In discoid lupus erythematosus the most common immunoreactant visualized with direct immunofluorescence is IgM; in systemic lupus erythematosus and in subacute cutaneous lupus erythematosus it is IgG. Of note, most patients with anti-Ro–positive subacute cutaneous lupus erythematosus may have a characteristic granular IgG speckling pattern along the basement membrane and throughout the epidermis. The lupus band test, described as positive when granular IgG is present along the basement membrane zone in specimens from sun-protected nonlesional areas, is rapidly being abandoned due to its unreliability and the availability of more reliable methods for the early diagnosis and prediction of systemic disease in lupus erythematosus (10,11).

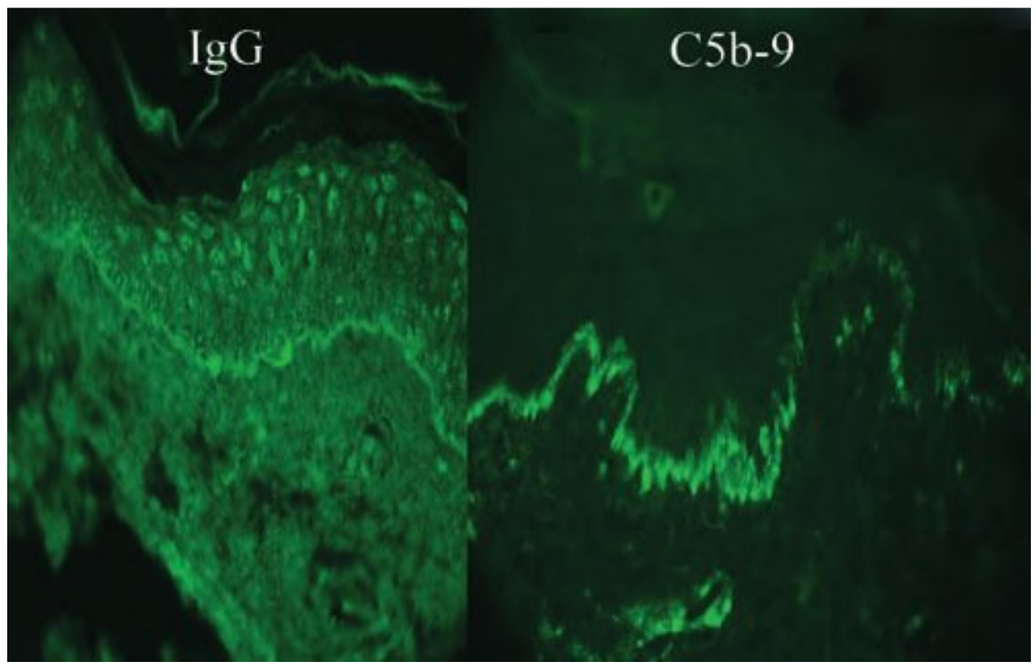

FIGURE 4-5. Cutaneous Ro-positive cutaneous lupus erythematosus (idiopathic or drug induced) and dermatomyositis direct immunofluorescence patterns. Left: Ro-positive cutaneous lupus erythematosus (idiopathic or drug induced). Granular immunoglobulin G speckling "dusting" pattern throughout the epidermis (keratinocyte cytoplasmic) with mild deposits at the basement membrane zone and an often in vivo antinuclear antibody pattern highlighting keratinocyte nuclei. Right: Dermatomyositis. Dense granular C5b-9 (membrane attack complex) deposits along the basement membrane zone and upper dermal vessels.

In cutaneous lesions of dermatomyositis, dense, granular C5b-9 (membrane attack complex) deposition at the basement membrane zone and upper dermal vessels along with that of weaker C3, IgG, and IgM deposits is a quite characteristic immunofluorescence pattern that often helps to distinguish dermatomyositis from lupus erythematosus spectrum, namely in acute phases of these diseases (Fig. 4-5) (12,13).

Cutaneous Vasculitides

Direct immunofluorescence evaluation is a very important diagnostic tool in the workup of cutaneous small vessel vasculitis, especially Henoch-Schoenlein purpura. The best immunofluorescence diagnostic yield in Henoch-Schoenlein purpura is obtained from 1- to 2-day-old lesions. As lesions get older, the IgA deposits get degraded and cleared. Because most patients have older lesions at the time of the evaluation, a high index of suspicion is required and exhaustive search for scant granular IgA deposits in very superficial papillary dermis is mandatory before ruling out Henoch-Schoenlein purpura.

Hypocomplementemic urticarial vasculitis is another small-vessel vasculitis in which direct immunofluorescence plays a critical diagnostic role. In this type of cutaneous vasculitis, granular IgG and C3 deposits are seen in and around small dermal vessels and along the basement membrane zone. The presence of basement membrane granular immunostaining among other clinical and serologic findings in patients with hypocomplementemic urticarial vasculitis have led some

authors to believe that this vasculitis is no more than a subset of systemic lupus erythematosus (14).

Other Autoimmune and Inflammatory Skin Diseases

Lichen planus lesions, mainly the mucosal variant, are characterized by typical yet not pathognomonic, linear and shaggy fibrin deposits and patchy granular IgM and C3 along the basement membrane.

The direct immunofluorescence findings in cutaneous porphyrias are indistinguishable from those seen in pseudoporphyria. These findings are characterized by thick and glassy linear IgG and IgA deposits in superficial dermal vessels in a "doughnut pattern" and along the basement membrane. It is believed that immunoglobulins become trapped and bound to glycoproteins in a thickened basement membrane zone and degenerated blood vessels in this disorder.

INDIRECT IMMUNOFLUORESCENCE

Indirect immunofluorescence is a semiquantitative procedure in which a double immunolabeling is carried out to evaluate the presence and titer of circulating antibodies or specifically to localize antigen in the skin.

Indirect Immunofluorescence in the Evaluation of Circulating Antiepithelial Antibodies

Blood is drawn into a tube without anticoagulant, and the serum is serially diluted. Substrates most commonly used are 6-μm frozen sections of monkey esophagus, human salt-split skin, and murine bladder. The substrate is incubated with serum dilutions for 30 minutes at room temperature and then washed; antibodies bound to the substrates are detected by incubation with fluorescein isothiocyanate–labeled goat anti-human IgG and/or IgA.

Monkey esophagus is probably the best substrate for the evaluation of antiepithelial surface antibodies specifically for pemphigus vulgaris and paraneoplastic pemphigus. Pemphigus foliaceus has a high incidence of false-negative results with this substrate. Low titers of antiepithelial surface antibodies up to 1:80 or even higher can also be seen in control sera (15). In pemphigus vulgaris and foliaceus, antidesmoglein antibodies give a "chicken wire" staining that is more predominant on superficial epithelial cells, whereas in paraneoplastic pemphigus the antiplakin antibodies give a pattern that is consistently homogeneous throughout the epithelium and sometimes is even associated with immunostaining along the basement membrane zone.

Transitional epithelium is a plakin-rich substrate, and thus murine bladder is a common substrate for the screening of circulating antiplakin antibodies in paraneoplastic pemphigus (16). Exceptional cases of pemphigus vulgaris and foliaceus and pemphigoid can have concomitant low-titer antidesmoplakin antibodies (Fig. 4-6).

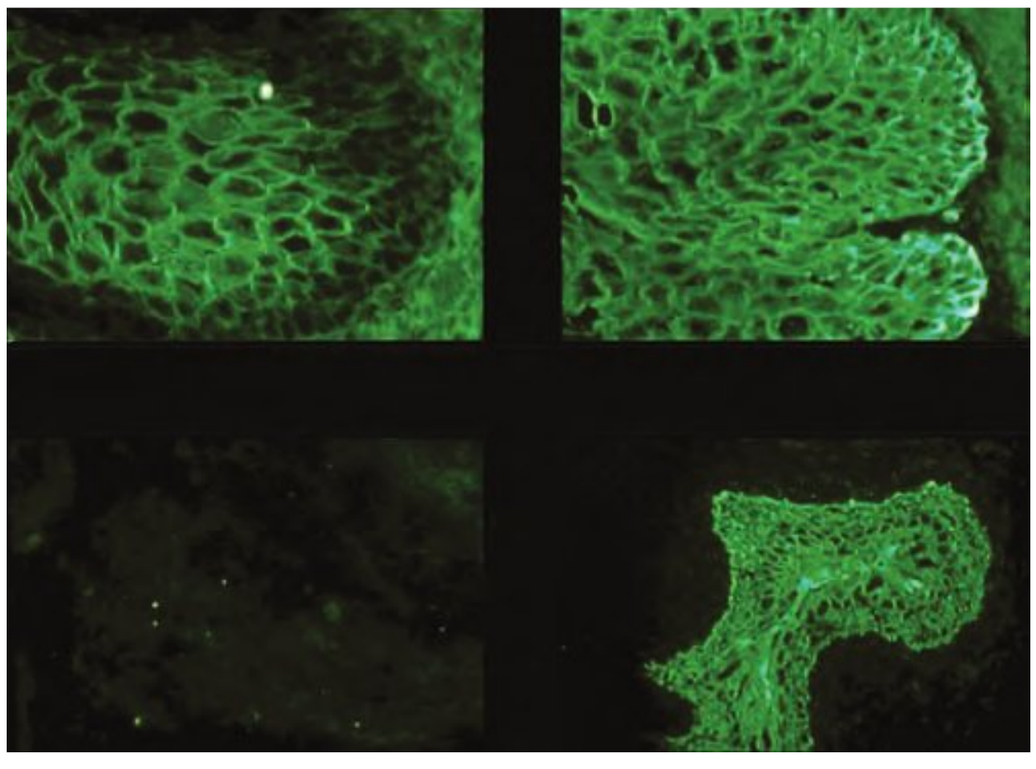

FIGURE 4-6. Differentiation between pemphigus vulgaris and paraneoplastic pemphigus, using indirect immunofluorescence. Left upper quadrant shows pemphigus vulgaris. Indirect immunofluorescence showing immunoglobulin G (IgG) bound to the epithelial cell surface of the stratified squamous epithelium of monkey esophagus. Of note, the "chicken wire" pattern is more prominent in the most superficial aspects of the epithelium. Left lower quadrant shows pemphigus vulgaris. Indirect immunofluorescence showing no IgG bound to the epithelial cell surface of transitional epithelium of murine bladder. Transitional epithelium does not have desmogleins, the autoantigens of pemphigus vulgaris and foliaceus. Right upper quadrant shows paraneoplastic pemphigus. Indirect immunofluorescence showing IgG bound to the epithelial cell surface of the stratified squamous epithelium of monkey esophagus. Of note, the "chicken wire" pattern is consistent throughout the epithelium and also along the basement membrane zone. Plakins, the autoantigens in paraneoplastic pemphigus, are ubiquitous desmosomal and hemidesmosomal proteins present in squamous and nonsquamous epithelia. Right lower quadrant shows paraneoplastic pemphigus. Indirect immunofluorescence showing IgG bound to the epithelial cell surface of transitional epithelium of the bladder. Transitional epithelium is rich in plakins.

Monkey esophagus is also a useful substrate in the indirect immunofluorescence screening for subepidermal autoimmune blistering disease. However, human salt-split skin renders better definition of the subtypes of subepidermal blistering disorders. Disorders characterized by antibodies to hemidesmosomal proteins BP180 and BP230, including those seen in bullous and gestational pemphigoid, some cases of mucous membrane pemphigoid, and linear IgA bullous disease, are associated with a linear immunostaining on the epidermal side (roof) of the salt-split human skin.

On the other hand, patients with circulating antibodies reacting against type VII collagen and antiepiligrin (laminin 5), as is seen in epidermolysis bullosa acquisita and antiepiligrin mucous membrane pemphigoid, respectively, have circulating IgG autoantibodies that bind the dermal side of the salt-split human skin.

More sensitive and specific assays for the evaluation of circulating autoantibodies, including enzyme-linked immunosorbent assay for antidesmoglein and anti-BP180 antibodies, immunoblotting and immunoprecipitation for pemphigoid, epidermolysis bullosa acquisita, and antiepiligrin, and immunoprecipitation for paraneoplastic pemphigus, have been recently incorporated into the diagnostic armamentarium of autoimmune blistering diseases.

Indirect Immunofluorescence for the Evaluation of Site of Cleavage in Hereditary Epidermolysis Bullosa

This technique offers a practical yet useful diagnostic tool in hereditary epidermolysis bullosa by revealing the site of the defect in these mechanobullous disorders. Thus, this technique classifies these disorders into epidermolytic, functional, and dermolytic categories (Table 4-3).

In brief, this technique is performed as follows: A freshly induced blister is obtained by twisting a rubber-ended pencil, and then this artificially induced blister skin specimen is incubated with anti–type IV collagen and anti-BP180 antigen. Then, according to localization of the immunolabeling of these antibodies, the site of cleavage can be deduced.

In some cases of generalized atrophic benign epidermolysis bullosa where the mutated protein is the BP180 antigen the immunostaining in the floor of the induced blister given by the anti-BP180 may be focal or absent. Specific antibodies to the mutated protein are also used for complementary diagnostic purposes. These antibodies include antiplectin antibodies for epidermolysis bullosa simplex with muscular dystrophy, anti-$\alpha 6\beta 4$ for junctional epidermolysis bullosa with pyloric atresia, anti–laminin 5 antibodies for most cases of junctional epidermolysis bullosa, and anti–type VII collagen for most cases of the dystrophic form of hereditary epidermolysis bullosa. These specific antibodies are intended to identify a disrupted linear staining due to an even distribution of the probed mutated protein (17,18). The definite diagnosis of hereditary epidermolysis bullosa is made with electron microcopy and genetic analysis.

TABLE 4-3 Indirect Immunofluorescence for the Evaluation of site of Cleavage in Hereditary Epidermolysis Bullosa (HEB)

Type of HEB	Anti-BP180 immunostaining	Anti–type IV collagen immunostaining

Junctional	Roof	Floor
Dermolytic	Roof	Roof

IMMUNOHISTOCHEMISTRY

Introduction, Techniques

Immunohistochemistry techniques have been available since the early 1970s, but they have been used widely for diagnostic pathology only since the early 1980s. They are mainly used to diagnose poorly differentiated malignant tumors and lymphoma. They can also be beneficial in the diagnosis of bullous diseases (14). With the refinement of techniques, immunohistochemistry methods have achieved the same sensitivity for many antigens in paraffin-embedded tissues as the direct immunofluorescence method in frozen sections. The paraffin-embedded tissues offer the advantage over frozen sections of better preservation of cellular details and permanency of the reaction, so that the specimens can be preserved and stored. Most monoclonal antibodies, especially those necessary for the diagnosis of lymphoma, when first introduced required frozen section studies, but monoclonal and polyclonal antibodies are now available that can be applied to formalin-fixed, paraffin-embedded tissue, such as antibodies for the identification of B cells, T cells, and macrophages and many other cell types.

Sections that will be incubated with polyclonal or monoclonal antibodies should be mounted on glass slides specially coated or charged to ensure better adherence (19).

Certain antibodies, including antibodies against keratins, lysozyme, or chymotrypsin, require protease digestion if formalin-fixed, paraffin-embedded sections are used. Other "antigen retrieval" methods include the use of heat, either by microwaving or steaming the sections, and pretreatment of the sections with acid (HCl).

Immunohistologic Techniques

In most laboratories, immunopathology techniques are well established. Historically, several techniques have been used; the peroxidase–antiperoxidase technique has been replaced by more sensitive techniques, namely, techniques using avidin-biotin-peroxidase complex, alkaline phosphatase/anti–alkaline phosphatase, and streptavidin peroxidase or alkaline phosphatase. In all of these methods, the antibody is used to localize an enzyme (peroxidase or phosphatase) to sites of antigen expression in tissue sections. An appropriate "chromogen" is then added—a reagent that has the property of developing a color that can be visualized at sites of localization of the enzyme-antibody-antigen complex.

The Alkaline Phosphatase/Anti–Alkaline Phosphatase Technique

This is an unlabeled antibody bridge technique that uses three antibodies; the first and third antibodies are from the same species and are monoclonal. The second antibody is polyclonal, from the rabbit, and forms a bridge between the first and third antibodies (20). The third antibody is linked to the enzyme alkaline phosphatase. After applying these antibodies with the linked enzyme, an alkaline phosphatase

substrate is added containing a compatible indole chromogen such as 2-(4-iodophenyl)-3-(4-nitrophenyl)-5-phenyltetrazolium chloride (INT)/5-bromo-4-chloro-3′-indolyl phosphate *p*-toluidine salt (BCIP) (which yields a red color after the phosphatase-catalyzed reaction), naphthol fast red (red color), or nitro-blue tetrazolium chloride (NBT)/BCIP (blue). This method may be useful for pigmented tumors because the blue or red reagents can be distinguished easily from melanin (19).

The Avidin-Biotin-Peroxidase Complex and Streptavidin Peroxidase or Alkaline Phosphatase Techniques

The avidin-biotin technique takes advantage of the strong interaction of avidin with biotin (21,22). Avidin is a glycoprotein found in egg white that has a strong affinity to biotin, a vitamin of low molecular weight. The streptavidin technique is exactly analogous, but achieves sensitivity one to two orders of magnitude greater by using streptavidin in place of avidin. This method is becoming standard. In these techniques, the primary antibody (which may be monoclonal or polyclonal) binds directly with the specific antigen, in or on the cells, to form a stable antigen–antibody complex within the tissue section. A secondary antibody that has been labeled with biotin (biotinylated) and is directed against the same species and immunoglobulin type binds to the primary antibody, leaving the biotinylated end available. A peroxidase or an alkaline phosphatase detection system can be used. In a peroxidase method, the biotinylated complex is detected by avidin or streptavidin that has been conjugated to the peroxidase enzyme. A peroxidase-oriented chromogen is then added, such as diaminobenzidine (yielding a brown color) or aminoethylcarbazole (red color, and therefore useful for pigmented lesions). The alkaline phosphatase-streptavidin method is analogous to the streptavidin peroxidase method, but in this case the biotinylated complex is detected with an alkaline phosphatase–linked streptavidin and requires a compatible chromogen such as the indole reagents INT/BCIP (red color), naphthol fast red (red), or NBT/BCIP (blue). This technique in the authors' experience achieves the greatest sensitivity of all immunohistochemical methods.

The origin of an undifferentiated cell can usually be determined with the application of monoclonal or polyclonal antibodies. A "panel approach" using multiple markers is the best method for evaluating problem neoplasms. Positive and negative controls should be used. If tumor cells unexpectedly do not show a positive reaction with a certain antibody, several possibilities exist, including technical difficulties with the assay. One may encounter nonspecific staining as well as aberrant immunoreactivity (observed staining with a particular antibody where it is theoretically unexpected). Caution should be taken not to make a diagnosis based on immunohistochemistry alone. Unfortunately, there is no antibody that reliably distinguishes between benign and malignant cells.

APPLICATIONS OF IMMUNOHISTOPATHOLOGY

Diagnosis of Tumors (Excluding Lymphomas)

The most important antibodies for routine dermatopathology and their occurrence in certain cells and tissues are listed in Table 4-4. The most frequently used antibodies in dermatopathology are discussed below. The list of available antibodies is extensive; detailed information is available in literature and text reviews (23–27).

Antibodies Against Cytoskeletal Antigens

The cytoskeleton of a cell consists of intermediate filaments measuring 7 to 11 nm in diameter, actin-containing microfilaments, and tubulin-containing microtubules (28–30). Intermediate filaments are smaller than microtubules (25 nm) but larger than microfilaments (6 nm), hence the designation intermediate.

Antibodies against intermediate filaments (IFs) help to identify the origin of an anaplastic cell. Malignant tumors usually retain the intermediate filament type characteristic of the tissue of origin, and metastases generally continue to express these intermediate filaments (31). There are six groups of intermediate filaments. Type 1 and 2 IFs include cytokeratins, which are present in epithelia. Type 3 IFs include vimentin, found in mesenchymal cells and melanocytes; desmin, found in most muscle cells; and glial fibrillary acidic protein, found in glial cells and astrocytes. Type 4 IFs include neurofilaments, which are components of neurons. Nuclear lamins constitute type 5 IFs, and nestin comprises type 6 and is found in some stem cells. In dermatopathology, keratin antibodies are used to differentiate epithelial from nonepithelial (melanocytic, hematopoietic, and mesenchymal) tumors. A mixture of antibodies against low and intermediate keratins such as AE1 and AE3 (AE1/3) is commonly used (32). An additional antibody to low–molecular weight keratins such as CAM 5.2 may be beneficial in poorly differentiated carcinomas (33). The keratin marker CK20 has useful specificity for Merkel cell carcinoma (34).

Atypical spindle cell tumors, for example, are often difficult to diagnose with routine stains. The differential diagnosis for such lesions includes spindle cell squamous cell carcinoma, atypical fibroxanthoma, leiomyosarcoma, and spindle cell malignant melanoma. Table 4-5 lists the most important antibodies to use (35).

Vimentin

Vimentin is an intermediate filament originally isolated from chick embryo fibroblasts. It is found in fibroblasts, endothelial cells, macrophages, melanocytes, lymphocytes, and smooth muscle cells. Antibodies to vimentin are found in both benign and malignant counterparts of these cells (36). There have also been reports of positivity in epithelial tumors (37); however, normal epidermis is negative with this antibody. Because of the nonspecific nature of the antibody, it is useful only as a panel approach to support mesenchymal or melanocytic differentiation.

TABLE 4-4 Common Antigens That Can Be Detected in Formalin-Fixed, Paraffin-Embedded Sections

Antigen	Location
Cytokeratins, including AE1, AE3, CAM 5.2, CK20	Epidermis and its appendages and their tumors
Vimentin	Mesenchymal cells, melanocytes, lymphomas, sarcomas, melanomas
Desmin	Smooth and skeletal muscle, muscle tumors
Leukocyte common antigen (LCA)	Benign leukocytes, lymphoma, leukemia
CD45-RO (UCHL-1)	T lymphocytes
CD20 (L-26)	B lymphocytes
Epithelial membrane antigen (EMA)	Sweat and sebaceous glands, carcinoma, epithelioid sarcoma
Carcinoembryonic antigen (CEA)	Eccrine and apocrine glands and their tumors, Paget cells
S100 protein	Melanocytes, Langerhans cells, eccrine and apocrine glands and their tumors, Schwann cells, nerves, interdigitating reticulum cells, chondrocytes, melanomas, adipose tissue, liposarcomas, Langerhans cell histiocytosis
HMB-45	Melanoma cells, some nevus cells
Chromogranin	Neuroendocrine cells, Merkel cell carcinoma, eccrine gland cells
Synaptophysin	Neuroendocrine cells, Merkel cell carcinoma
Lysozyme	Macrophages, granulocytes, myeloid cells
α1-Antitrypsin, α1-antichymotrypsin	Macrophages, "fibrohistiocytic" neoplasms including malignant fibrous histiocytoma, but nonspecific in most routine practice
Factor VIII–related antigen	Endothelial cells, angiosarcomas, Kaposi's sarcoma
Ulex europaeus agglutinin I	Endothelial cells, keratinocytes, angiosarcomas, Kaposi's sarcoma
CD31	Endothelial cells
CD34	Endothelial cells, bone marrow progenitor cells, cells of dermatofibrosarcoma protuberans
Smooth muscle actin	Smooth muscle cells and tumors, myofibroblastic cells
MART-1/Melan-A	Melanocytes, nevi, melanoma
Factor XIIIa	Dermatofibromas, certain fibrohistiocytic cells (see text)
CD1a	Langerhans cells

Note: Few if any of these reagents are perfectly specific for their target antigens. Every test must be interpreted in the context of all of the available histologic and clinical information.

Carcinoembryonic Antigen and Epithelial Membrane Antigen

Carcinoembryonic antigen (CEA) has been found in normal eccrine and apocrine cells, in benign sweat gland tumors, and in mammary and extramammary Paget's disease of the skin. Incubation with anti-CEA can be helpful in distinguishing Paget cells from atypical melanocytes in melanoma *in situ*. However, reactivity of melanomas with CEA has been reported (see Chapter 28) (38). Carcinoembryonic antigen typically stains adenocarcinomas from most organ systems. Most epithelial tumors react with antibodies against epithelial membrane antigen (EMA), including squamous cell carcinoma, breast carcinoma, and large cell lung carcinoma. EMA will also stain normal sweat and sebaceous glands, although epidermis

TABLE 4-5 Differential Diagnosis of Malignant Spindle Cell Tumors

Diagnosis	Keratin	Vimentin	Desmin	S100	HMB-45	Factor VIII/CD31
Squamous cell carcinoma	+	−	−	−	−	−
Atypical fibroxanthoma	−	+	−	−	−	−
Melanoma	−	+	−	+	+	−
Leiomyosarcoma	−	+	+	−	−	−
Angiosarcoma	−	+/−	−	−	−	+

Note: Few if any of these reagents are perfectly specific for their target antigens. Every test must be interpreted in the context of all of the available histologic and clinical information.

is nonreactive with this antibody. Epithelioid sarcoma is also stained by EMA (see Chapter 32).

Neuron-Specific Enolase

Neuron-specific enolase (NSE) is an acidic enzyme found in neuroendocrine cells, neurons, and tumors derived from them. Merkel cell carcinoma contains NSE; however, NSE can be detected in a variety of other tumors, including malignant melanoma, and therefore has low specificity. The keratin marker CK20 has better specificity for Merkel cell tumor than for melanoma and other neuroendocrine tumors (39).

Chromogranin

The soluble proteins of chromaffin granules are called *chromogranin* (40). Chromogranins consist of three families of acidic proteins: chromogranin A, B, and C. They are normally found in most endocrine cells (e.g., thyroid, parathyroid, anterior pituitary). In the skin, chromogranin A has been found in Merkel cell carcinoma (41). In contrast, nevi and melanoma do not contain chromogranin.

Synaptophysin

Synaptophysin is a 38-kD glycoprotein that participates in calcium-dependent release of neurotransmitters (42). It is a neuroendocrine antigen with a distribution similar to chromogranin. Positive staining with antibodies to synaptophysin is useful in the diagnosis of neuroendocrine tumors such as Merkel cell carcinoma. Of interest, normal Merkel cells are negative with this antibody. Similar to chromogranin, melanocytic tumors do not stain with synaptophysin.

S100 Protein

S100 protein is an acidic protein that binds Ca^{2+} and Zn^{2+}. It was called S100 because of its solubility in 100% ammonium sulfate at neutral pH. It is found in the cytoplasm and in the nucleus. S100 protein can be detected in a large variety of cells: melanocytes, Langerhans cells, eccrine and apocrine gland cells, nerves, muscles, Schwann cells, myoepithelial cells, chondrocytes, adipocytes, and their malignant counterparts. Histiocytes may also stain positively with S100 protein. The polyclonal antibody against S100 works well on paraffin sections. Its high sensitivity contrasts with a low specificity, a feature that supports the concept of a panel approach to immunohistochemistry.

Useful applications of the antibody against S100 protein include (a) diagnosing spindle cell melanoma and desmoplastic melanoma, (b) distinguishing between melanocytes and lymphocytes in halo nevi, (c) differentiating between pigmented actinic keratoses and lentigo maligna, and (d) diagnosing poorly differentiated cutaneous metastases.

HMB-45

HMB-45 is a monoclonal antibody that was initially generated from an extract of metastatic melanoma. Both primary and metastatic melanomas reveal cytoplasmic staining with HMB-45; spindle cell melanomas and desmoplastic melanomas are frequently negative. This antibody reacts with a melanosomal protein, GP-100, which tends to be expressed in immature or proliferating cells. Unfortunately, HMB-45 may react with melanocytes in nevi, including dysplastic nevi and Spitz nevi (39). Therefore, it should not be used for the differential diagnosis between a malignant melanoma and a benign nevus. Most desmosplastic melanomas, as well as some metastatic melanomas, may show negative staining with HMB-45 (43).

MART-1/Melan-A

Melanoma antigen recognized by T cells (MART-1) is a relatively new melanocytic differentiation marker. The antigen is expressed in normal melanocytes, common nevi, Spitz nevi, and malignant melanoma (Fig. 4-7). Monoclonal antibodies to MART-1/Melan-A are commercially available and are suitable for both frozen tissue and formalin-fixed paraffin-embedded tissue. Negative staining is frequently seen in neurotized nevi and desmoplastic melanomas (44). In the skin, Melan-A mRNA has only been found in melanocytic lesions and angiomyolipomas (45). Immunoreactivity can also be seen in the adrenal cortex, Leydig cell of the testes, granulosa cells of the ovary, and tumors derived from these cells. This antibody is a useful addition when evaluating intraepidermal melanocytes (vitiligo, early melanoma *in situ*), as well as amelanotic melanomas.

CD34

CD34 is a heavy glycosylated molecule that is expressed on virtually all human hematopoietic progenitor cells. Expression is normally lost during maturation in the skin. Both benign and malignant vascular tumors express this antigen. In dermatopathology, CD34 positivity in dermatofibrosarcoma protuberans is useful in differentiating these lesions from dermatofibromas, which are CD34 negative and factor XIIIa positive (46). Other cutaneous neoplasms that express CD34

FIGURE 4-7. MART-1/Melan-A immunoperoxidase staining highlights normal melanocytes in the basal layer of the epidermis.

include solitary fibrous tumor, giant cell fibroblastoma, neurofibroma, epithelioid sarcoma, spindle cell lipoma, sclerotic fibroma, and fibrous papule of the nose.

Factor VIII–Related Antigen and Ulex europaeus Agglutinin I

Factor VIII–related antigen (von Willebrand factor) is a large glycoprotein produced by endothelial cells and therefore useful in benign and malignant vascular neoplasms. However, some studies have demonstrated factor VIII positivity in only 50% of hemangiomas and 5% to 25% of malignant endothelial tumors (47,48).

Ulex europaeus agglutinin I (UEA) is a lectin that reacts specifically with α-L-fucose present in endothelial cells, keratinocytes, and most eccrine glands. UEA is a reliable marker for endothelial cells of blood vessels and lymphatics, although it is less specific than factor VIII–related antigen (49).

CD31

CD31 is a marker of endothelial differentiation that is normally expressed in endothelial cells and selected hematopoietic elements (Fig. 4-8) (50). This 130-kD glycoprotein, whose major function is to mediate platelet adhesion in vascular endothelial cells, is also known as platelet endothelial cell adhesion molecule. CD31 is a sensitive marker for vascular tumors, except Kaposi's sarcoma (51). It is a more sensitive marker for cutaneous angiosarcoma than factor VIII–related antigen.

Factor XIIIa

Factor XIIIa, a blood coagulation factor, is responsible for stabilizing newly formed clots by cross-linking fibrin. It is present in fibroblast-like mesenchymal cells, dermal dendrocytes, platelets, megakaryocytes, peritoneal and alveolar macrophages, normal adipose tissue, monocytes, and placenta, uterine, and prostate tissue. As noted earlier, using factor XIIIa in combination with CD34 can be helpful in differentiating dermatofibroma from dermatofibrosarcoma protuberans. Factor XIIIa has also been reported to be positive in a multitude of other lesions, including fibrous papule, atypical fibroxanthoma, xanthogranuloma, multinucleate cell angiohistiocytoma, epithelioid cell histiocytoma, and atypical cells in radiation dermatitis (52–54).

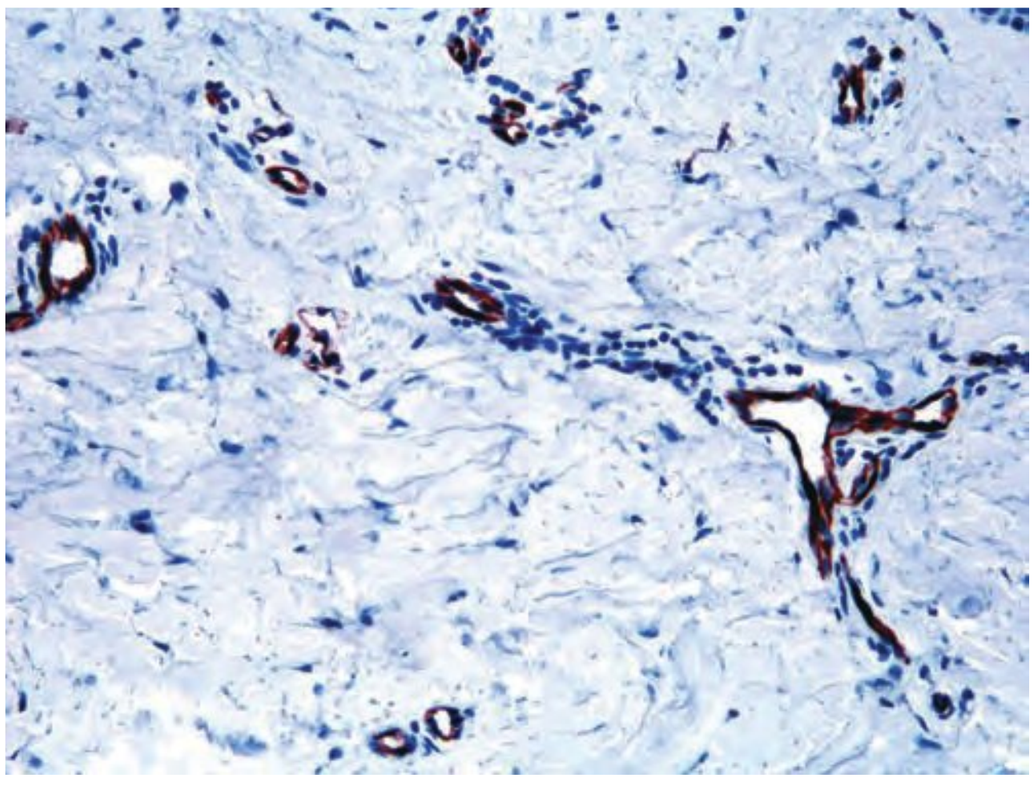

FIGURE 4-8. CD31 staining of vascular endothelium.

Antibodies Against Lysozyme, α_1-Antitrypsin, α_1-Antichymotrypsins

These antibodies have been regarded as markers of mononuclear phagocytic cells. Although once felt to be markers for "fibrohistiocytic" neoplasms, they have also been identified in carcinomas and melanomas, making them less specific.

c-kit (CD117)

The human proto-oncogene c-kit is a member of the type III receptor tyrosine kinase family that includes macrophage growth factor, platelet-derived growth factor, and flt-3/flk-2 receptors. It is present on a number of cell types, including mast cells, melanocytes, hematopoietic stem cells, immature myeloid cells, and myeloid and lymphoid progenitors, and in germ cell lineages, and it plays a crucial role in their activation and growth. Constitutively active c-kit has been implicated in the pathogenesis of a number of disorders, including systemic mastocytosis and gastrointestinal stromal tumors, whereas impairment of kinase activity has been implicated in a number of developmental disorders (55,56). Increased c-kit expression has been seen on malignant cells from many acute myeloid leukemia subtypes and chronic myelogenous leukemia; in addition, a number of solid tumor cells have been shown to express high-affinity c-kit receptors, including breast, lung, and gastric carcinoma, as well as some melanomas, especially of the acral, lentigo maligna, and ocular subtypes.

CD1a

CD1a is a transmembrane glycoprotein, structurally related to major histocompatibility class I, and it is found as a heterodimer associated to β_2-microglobin (57). CD1a is localized to the plasma membrane, with a small fraction of internalized CD1a restricted to the perinuclear recycling vesicles of endosomal sorting machinery. Like other members of the CD1 family, CD1a functions to mediate the presentation of lipid and glycolipid antigens to T cells. In pathology, CD1a has become a marker of Langerhans cells (Fig. 4-9) and blood monocyte–derived dendritic cells. CD1a is also expressed on double-positive ($CD4^+CD8^+$) cortical thymocytes and with less intense expression on CD4 or CD8 single-positive thymocytes. As a diagnostic tool, it has been used together with S100 to define dendritic cell populations in tumors and other tissues, as well as for the diagnosis of Langerhans cell histiocytosis (histiocytosis X) (58).

Antibodies Against Leukocyte Common Antigen (CD45)

This antibody helps to distinguish between undifferentiated lymphomas and carcinomas. Leukocyte common antigen (LCA) is found on all leukocytes, including granulocytes,

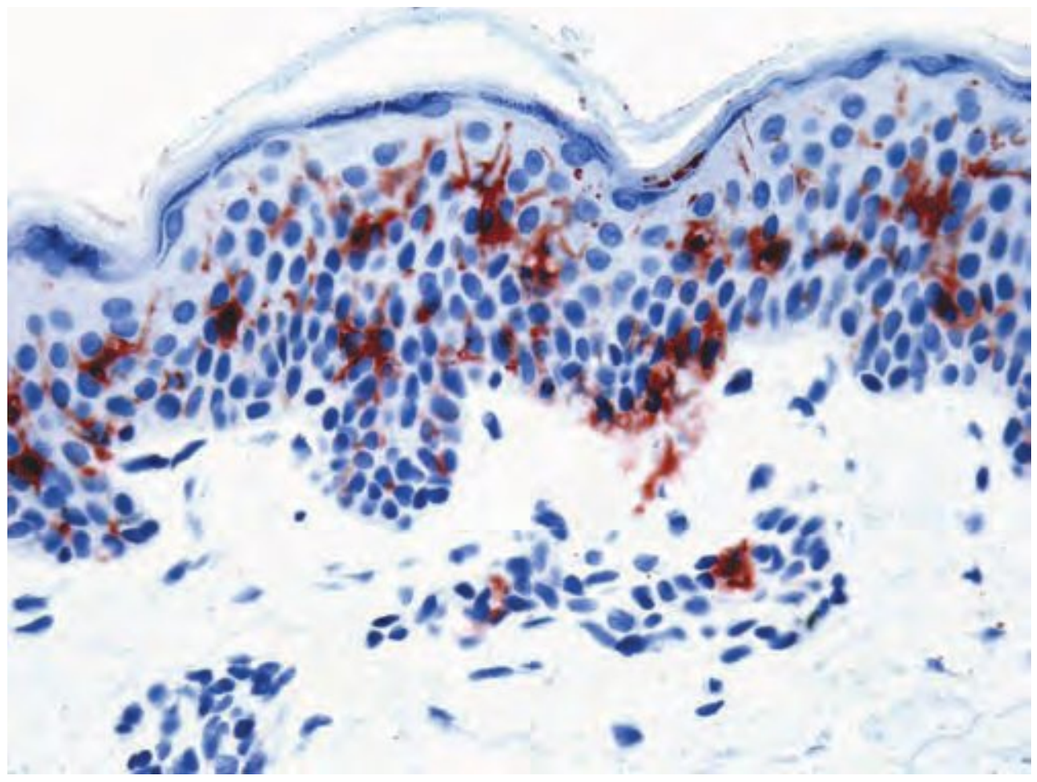

FIGURE 4-9. CD1a immunoperoxidase stain highlights Langerhans cells in the epidermis.

lymphocytes, monocytes, macrophages, mast cells, and Langerhans cells. The lymphomas and leukemias react with the antibody against LCA; carcinomas and melanomas are negative. In addition to LCA, lysozyme and chloroacetate esterase aid in the diagnosis of leukemia cutis (59). LCA is particularly useful in the evaluation of tumors composed of small atypical basophilic cells in the dermis (Table 4-6). Other antigens useful in the analysis of suspected lymphomas include the B- and T-cell markers L-26 (CD20, B cells) or CD79a (B cells) and UCHL-1 (CD45-RO, T cells) (see Chapter 31).

Diagnosis of Lymphomas

The application of monoclonal antibodies for the diagnosis of lymphomas is expanding. However, there is no antibody that distinguishes between benign and malignant lymphocytes. Hence, the difficult distinction between lymphoma and pseudolymphoma remains.

Although many antibodies are best used on frozen sections, an increasing number of commonly available antibodies can be used on formalin-fixed, paraffin-embedded tissue. The quality of certain markers, such as κ and λ light chains, has been variable in paraffin sections and is more reliable on frozen sections or utilizing in situ hybridization. Monoclonal antibodies can determine the cell types in a lymphoma or pseudolymphoma: helper or suppressor T cells, B cells, plasma cells, or macrophages. A confusing issue is that B-cell lymphomas may contain reactive T-cell infiltrates, which can outnumber the B cells. The predominance of a T-helper lymphocytic infiltrate with epidermotropism of the T-helper subtype is highly suggestive of cutaneous T-cell lymphoma. In contrast, a mixture of T-helper and T-suppressor phenotypes is most consistent with a reactive profile (e.g., spongiotic dermatitis). In dense nodular infiltrates, the presence of germinal center formation with B-lymphocyte aggregates surrounded by a mantle of T cells favors lymphocytoma cutis over lymphoma. A detailed discussion of antibodies helpful in the diagnosis of lymphoma is found in Chapter 31.

Molecular studies can provide additional information in the evaluation of atypical lymphoid infiltrates. Detection of a characteristic gene rearrangement coding for B- and T-cell antigen receptors will identify the presence or absence of a clonal population of lymphocytes (60). These applications are an important supplement to routinely available technology; however they must always be interpreted in the context of the clinical presentation and findings on routine histology. Although clonality studies can assist in early detection of cutaneous T-cell lymphoma, nonneoplastic processes such as pityriasis lichenoides, pseudolymphoma, and lichen planus occasionally show T-cell clonality (61–63).

Electron Microscopy

Transmission electron microscopy may be beneficial in the diagnosis of poorly differentiated skin neoplasms for which immunohistochemistry is negative (64). Using electron microscopy, the identification of intercellular junctions (epithelial tumors), melanosomes (melanocytic tumors), or Weibel-Palade bodies (endothelial cells) can provide an important diagnostic aid. Other uses of diagnostic electron microscopy include the subtype determination of epidermolysis bullosa and the diagnosis of metabolic storage diseases (e.g., Fabry disease) or amyloidosis. For optimum results, fresh tissue

Poorly differentiated carcinoma may be keratin negative or only positive with low–molecular weight keratin antibodies.

should be fixed in Karnovsky medium (paraformaldehyde-glutaraldehyde) and stored in the refrigerator until processing; although electron microscopy rarely can be performed from paraffin-embedded tissue, there may be extensive distortion precluding valuable interpretation.

Bernett L. Johnson, Jr.

Outline of Cutaneous Pathology

INTRODUCTION

The diagnosis of disease concerns the ability to classify disorders into categories that predict clinically important attributes such as prognosis and response to therapy. This permits appropriate interventions to be planned for particular patients. Understanding this process involves mastery of the stages of disease, the mechanisms of changes in morphology over time, and the molecular, cellular, gross clinical, and epidemiologic reasons for the differences among diseases.

The process of cutaneous diagnosis at its simplest level might involve the matching of a large number of attributes contained in classical descriptions of skin diseases with the presence or absence of the same attributes in a particular case under consideration. Because there are hundreds of potential diagnostic categories, each having potentially scores of attributes, it is evident that an efficient strategy must be used to enable diagnoses to be considered, dismissed, or retained for further consideration. Observation of an experienced dermatopathologist reveals a rapidity of accurate diagnosis that precludes the simultaneous consideration of more than a few variables. Indeed, the process of diagnosis by an experienced observer is quite different from that employed by the novice and is based on the rapid recognition of combinations or patterns of criteria (1,2). Just as the recognition of an old friend occurs by a process that does not require the serial enumeration of particular facial features, this process of pattern recognition occurs almost instantly and is based on broad parameters that do not, at least initially, require detailed evaluation.

In clinical medicine, patterns may present as combinations of symptoms and signs or even of laboratory values, but in dermatopathology, the most predictive diagnostic patterns are recognized through the scanning lens of the microscope or even before microscopy as the microscopist holds the slide up to the light to evaluate its profile and distribution of colors. Occasionally, a specific diagnosis can be made during this initial stage of pattern recognition by a process of "gestalt"-based or instant recognition, but this should be tempered with a subsequent moment of healthy analytic scrutiny. More often, the scanning magnification pattern suggests a small list of possible diagnoses, a "differential diagnosis." Then, features that are more readily recognized at higher magnification may be used to differentiate among the possibilities. Put in the language of science, the scanning magnification pattern suggests a series of hypotheses, which are then tested by additional observations (1). The tests may be observations made at higher magnification, the results of special studies such as immunohistochemistry, or external findings such as the clinical appearance of the patient or the results of laboratory investigations. For example, a broad, plaquelike configuration of small blue dots near the dermal–epidermal junction could represent a lichenoid dermatitis or a lichenoid actinic keratosis. At higher magnification, the blue dots may be confirmed to be lymphocytes, and one might seek evidence of parakeratosis, atypical keratinocytes, and plasma cells in the lesion, a combination that would rule out lichen planus and establish a diagnosis of actinic keratosis.

Most diagnoses in dermatopathology are established either by the gestalt method or by the process of hypothesis generation and testing (differential diagnosis and investigation) just described, but in either case the basis of the method is the identification of simple patterns recognizable with the scanning lens that suggest a manageably short list of differential diagnostic considerations. This *pattern recognition method* was first developed in a series of lectures given in Boston by Wallace Clark (3) and was refined for inflammatory skin disease by Ackerman (4) and for inflammatory and neoplastic skin disease by Mihm (5). Additional work was done by Murphy (6), Barnhill (7), Maize and colleagues (8), Weedon (9), and McKee (10). These authors published texts based more or less extensively on pattern classification. The present work, however, is organized along more traditional lines, in which diseases are discussed on the basis of pathogenesis (mechanisms) or etiology, as well as on reaction patterns. Such a classification has the advantage of placing disorders such as infections in a common relationship to one another, facilitating the description of their many common attributes. From a histopathologic point of view, however, the novice must learn that some infections, such as syphilis, can resemble disorders as disparate as psoriasis, lichen planus, cutaneous lymphoma, and granulomatous dermatitis.

Because there is a limited number of reaction patterns in the skin, morphologic simulants of disparate disease processes are common in the skin, as elsewhere. For this reason, classification methods based on patterns and those based on pathogenesis are incompatible with each other. To partially circumvent

this problem, the present section of this book presents a pattern-based classification of cutaneous pathology based on *location in the skin, reaction patterns,* and, where applicable, *cell type,* indexed to the more detailed descriptions of the disease entities discussed in other sections of the book. The section is based (with permission) on the original lecture notes prepared by Wallace H. Clark Jr., MD, in 1965, and on the published works cited previously, especially that of Hood et al. (5).

The classification is presented here in tabular form and is redundant, in that a particular disease entity may appear in several positions in the table because of the morphologic heterogeneity of disease processes, which are often based on evolutionary or involutional morphologic changes as a disease waxes and wanes. The order of presentation of particular entities in any given position in the table reflects the authors' rough opinion of the relative frequency of the entities in the list as encountered in a typical dermatopathology practice. For example, lichenoid drug eruption may be more common than lichen planus in most hospital-based practices. However, lichen planus is the "prototypic" lichenoid dermatitis, whereas drug eruptions may adopt any of a number of morphologies as reflected by their appearance in the psoriasiform, lichenoid, perivascular, and bullous categories, as well as elsewhere. The "prototypic" member of each category is italicized for easy reference to the detailed descriptions because such entities constitute the descriptive standard in a given category and they are also the standard against which other entities are evaluated. For example, a "naked" epithelioid cell granuloma may suggest sarcoidosis, whereas the presence of lymphocytes and necrosis in addition to granulomas might suggest tuberculosis, plasma cells might suggest syphilis, and neuritis might suggest leprosy.

The classification tables may be used as the basis of an algorithmic approach to differential diagnosis and as a guide to the descriptions in the other sections of this book. For example, a psoriasiform dermatitis with plasma cells may represent syphilis or mycosis fungoides, whose descriptions are to be found in Chapters 22 and 31, respectively. Terms such as "psoriasiform" and "lichenoid" are defined briefly, and appropriate page references are provided in this section so that the reader may review more specific criteria for the distinctions among morphologic simulants. This system of hypothesis generating and testing not only should lead to more efficient use of this book in the evaluation and diagnosis of an unknown case, but also should facilitate the development of pattern recognition skills as more subtle diagnostic clues are absorbed into the diagnostic repertoire to allow for "tempered gestalt" diagnosis in an increasing percentage of cases. The classification presented here is also the basis of the classification presented in the *Synopsis and Atlas of Lever's Histopathology of the Skin,* which is intended to be a more richly illustrated companion to the present volume, with a more synoptic text relating to the disease entities illustrated (11).

This chapter is intended as a guide to differential diagnosis but should not be construed as an infallible diagnostic tool. Diagnosis should be based not only on the diagnostic considerations presented here, but also on those discussed elsewhere in this book and in the literature, all considered in a clinical and epidemiologic context appropriate to the individual patient.

PART 1. SITE CATEGORIES OF CUTANEOUS PATHOLOGY

In this part, the major categories of cutaneous disease are briefly discussed based on their location in the skin and subcutis.

I. DISORDERS MOSTLY LIMITED TO THE STRATUM CORNEUM

The stratum corneum is usually arranged in a delicate meshlike or "basket-weave" pattern. It may be shed (exfoliated) or thickened (hyperkeratosis) with or without retention of nuclei (parakeratosis or orthokeratosis, respectively). Usually, alterations in the stratum corneum result from inflammatory or neoplastic changes that affect the whole epidermis and, more often than not, the superficial dermis. Only a few conditions, mentioned in this section, show pathology mostly or entirely limited to the stratum corneum.

II. NEOPLASTIC LOCALIZED EPITHELIAL OR MELANOCYTIC PROLIFERATIONS

Localized proliferations may be reactive but are often neoplastic. The epidermis (keratinocytes) may proliferate without extension into the dermis, extend into the dermis, and be squamous or basaloid. Melanocytes within the epidermis may proliferate with or without cytologic atypia (nevi, dysplastic nevi, melanoma *in situ*) in a proliferative epidermis (superficial spreading melanoma *in situ*, Spitz nevi) or an atrophic epidermis (lentigo maligna); they can also extend into the dermis as proliferative infiltrates (invasive melanoma with or without vertical growth phase). There may be an associated variably cellular, often mixed inflammatory infiltrate, or inflammation may be essentially absent.

III. INFLAMMATION OF THE SUPERFICIAL CUTANEOUS REACTIVE UNIT

The epidermis, papillary dermis, and superficial capillary-venular plexus in the superficial reticular dermis react together in many dermatologic conditions and were termed the "superficial cutaneous reactive unit" by Clark. Many dermatoses are associated with infiltrates of lymphocytes around the superficial vessels with or without other cell types. The epidermis in pathologic conditions can be thinned (atrophic), thickened (acanthosis), edematous (spongiosis), and/or infiltrated by inflammatory cells (exocytosis). The epidermis may proliferate in response to chronic irritation or infection (bacterial, yeast, deep fungal, or viral). The epidermis may proliferate in response to dermatologic conditions (psoriasis, atopic dermatitis, prurigo). The papillary dermis and superficial vascular plexus may have a variety of inflammatory cells, can be edematous, may have increased ground substance (hyaluronic acid), or may be sclerotic or homogenized.

IV. ACANTHOLYTIC, VESICULAR, AND PUSTULAR DISORDERS

Keratinocytes may separate from each other, resulting in separation and rounding up of keratinocyte cell bodies (acantholysis). This may occur on the basis of immunologic antigen/antibody–mediated damage, edema and inflammation (spongiosis), infections (impetigo or herpes viral infection), or structural deficiencies of cell adhesion (Darier's disease). These processes produce spaces within the epidermis (vesicles, bullae, pustules).

V. INFLAMMATION OF THE RETICULAR DERMIS

The dermis serves as a reaction site for a variety of inflammatory, infiltrative, and desmoplastic (fibrogenic) processes. These include infiltrations of a variety of cells (lymphocytes, histiocytes, eosinophils, plasma cells, melanocytes, etc.); perivascular and vascular reactions; infiltration with organisms and foreign bodies; and proliferations of dermal fibers and precursors of dermal fibers as reactions to a variety of stimuli. The infiltrates may be characterized as perivascular, diffuse, or granulomatous.

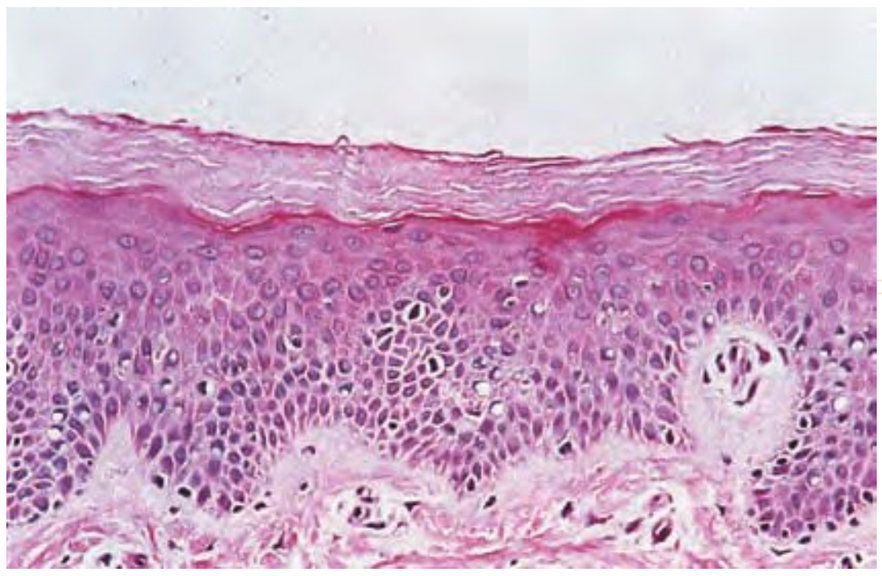
VI. NEOPLASTIC NODULES AND CYSTS OF THE RETICULAR DERMIS

Neoplasms of the reticular dermis may arise from any of the tissues included in the dermis —lymphoreticular tissue, connective tissue, and epithelial tissue of the skin appendages. In addition, metastases commonly present in the dermis.

VII. INFLAMMATORY DISORDERS OF SKIN APPENDAGES

The hair, sebaceous glands, eccrine glands, apocrine glands, and nails may be involved in inflammatory processes (hidradenitis, folliculitis). Some neoplasms may masquerade as inflammatory processes.

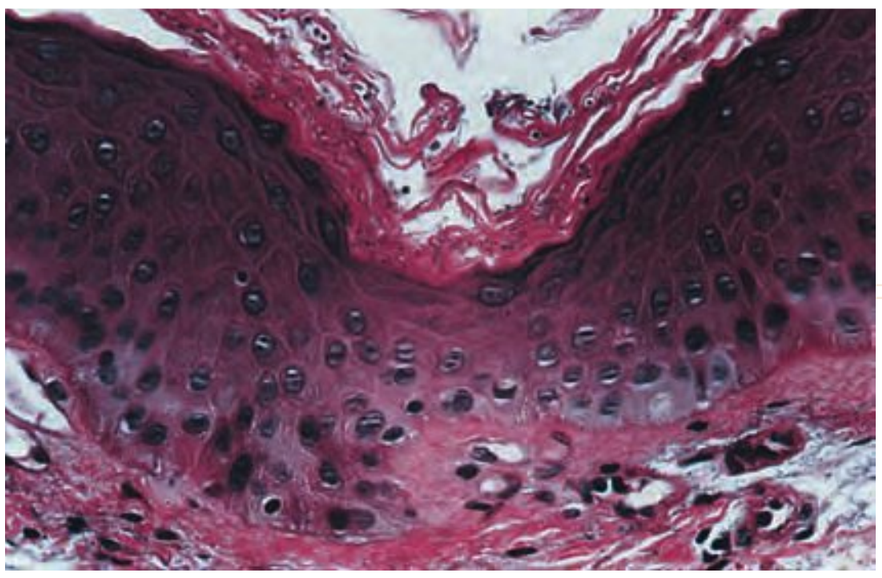
VIII. DISORDERS OF THE SUBCUTIS



The reactions in the subcutis are mostly inflammatory, although neoplastic proliferations of the subcutis do occur (lipoma). Pathologic conditions centered in the dermis may infiltrate the subcutis.

PART 2. SITE, PATTERN, AND CYTOLOGIC CATEGORIES OF CUTANEOUS PATHOLOGY

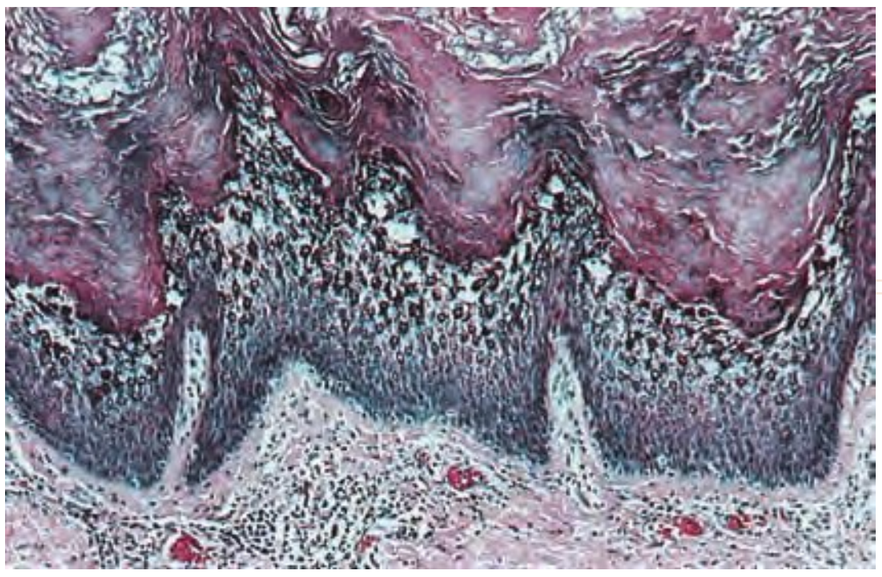
The following listings give the categories of cutaneous disease based on location in the skin (categories I, II, III, etc.), architectural pattern (categories A, B, C, etc.), and cytology (categories 1, 2, 3, etc.). A single prototypic example of each disease category is listed, and a prototypic example of each major pattern category is illustrated.



I. DISORDERS MOSTLY LIMITED TO THE EPIDERMIS & STRATUM CORNEUM

A. Hyperkeratosis with Hypogranulosis

1. No Inflammation
   ichthyosis vulgaris

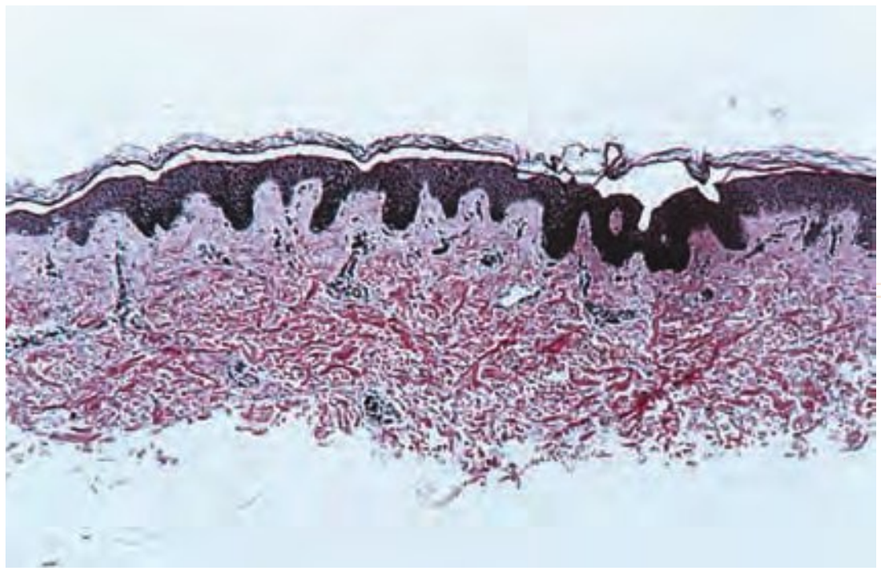


B. Hyperkeratosis with Normal or Hypergranulosis

1. No Inflammation
   lamellar ichthyosis

2. Scant Inflammation
   dermatophytosis

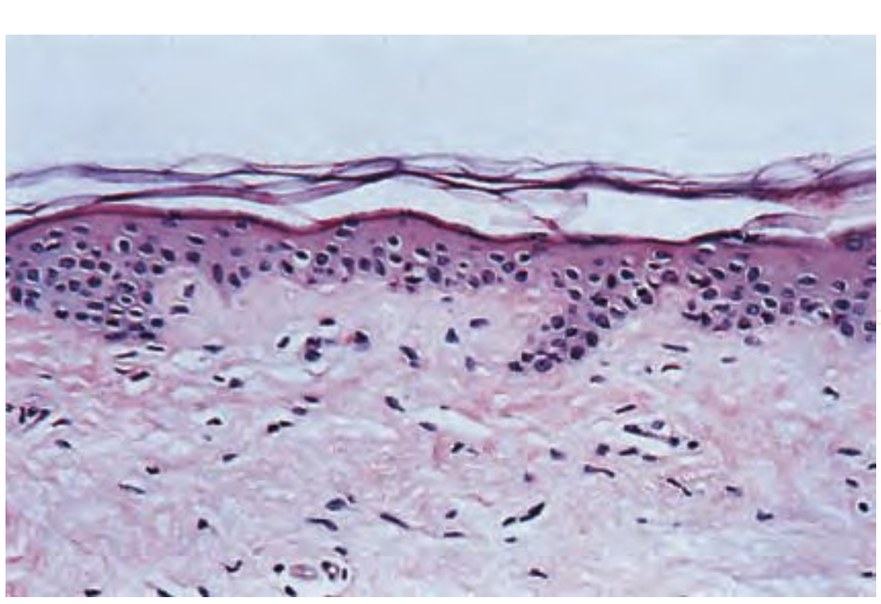
C. Hyperkeratosis with Parakeratosis



1. No Inflammation
   epidermolytic hyperkeratosis

2. Scant Inflammation
   scurvy

3. With Epidermal Pallor or Necrosis (“Nutritional Dermatosis”)
   pellagra



D. Localized or Diffuse Hyperpigmentations

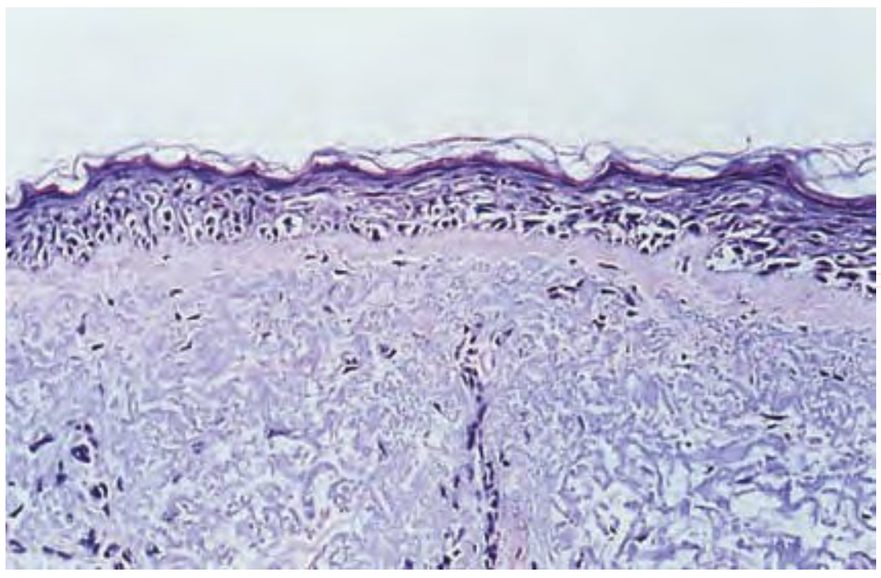
1. No Inflammation
   actinic lentigo

2. Scant Inflammation
   postinflammatory hyperpigmentation

E. Localized or Diffuse Hypopigmentation/ Depigmentation

1. With or Without Slight Inflammation
   vitiligo

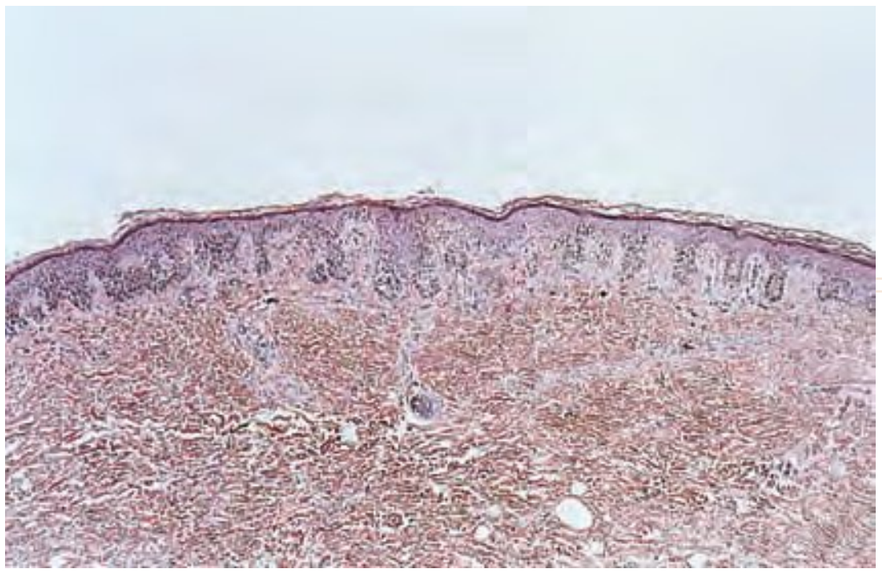
II. LOCALIZED SUPERFICIAL EPIDERMAL OR MELANOCYTIC PROLIFERATIONS



A. Localized Irregular Thickening of the Epidermis

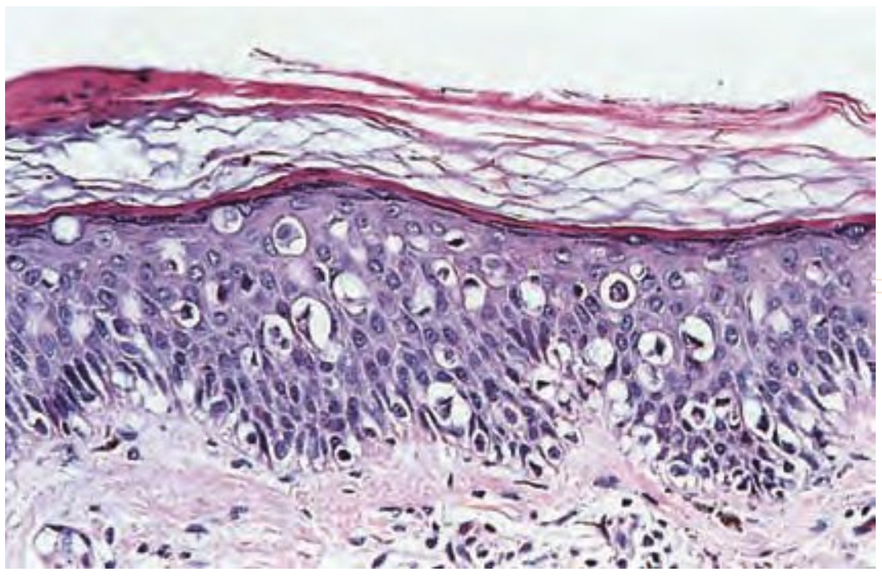
1. Localized Epidermal Proliferations
   seborrheic keratosis

2. Superficial Melanocytic Proliferations
   melanoma *in situ* (superficial spreading type)



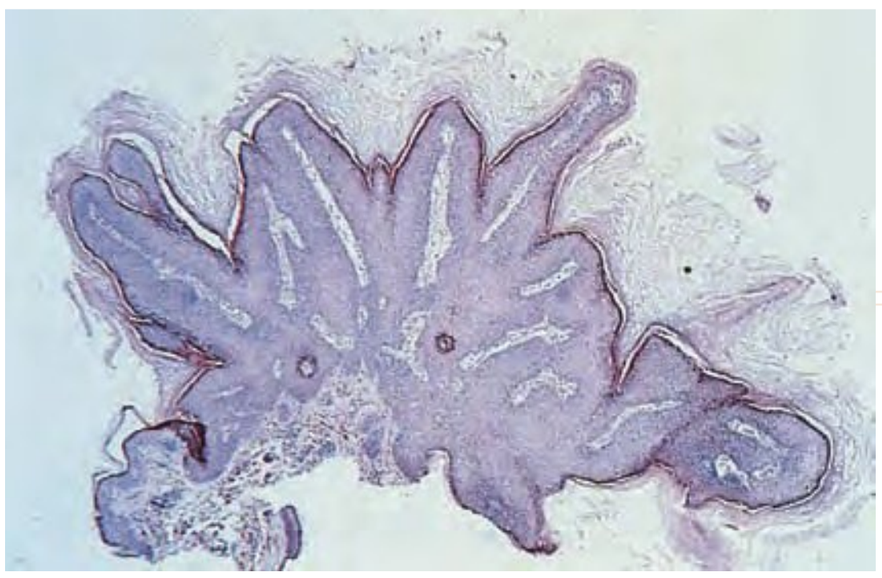
B. Localized Lesions with Thinning of the Epidermis

1. With Melanocytic Proliferation
   melanoma in situ (lentigo maligna type)



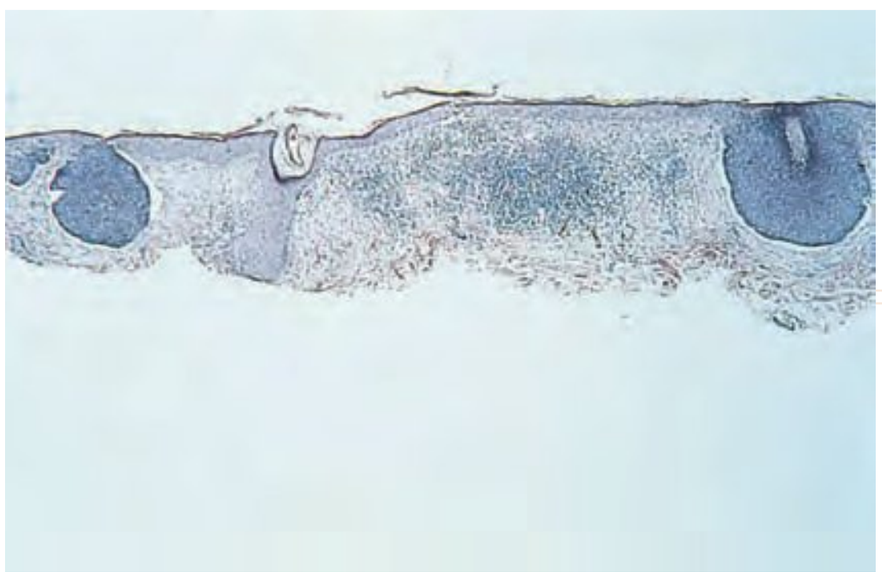
2. Without Melanocytic Proliferation
   actinic keratosis

C. Localized Lesions with Elongated Rete Ridges



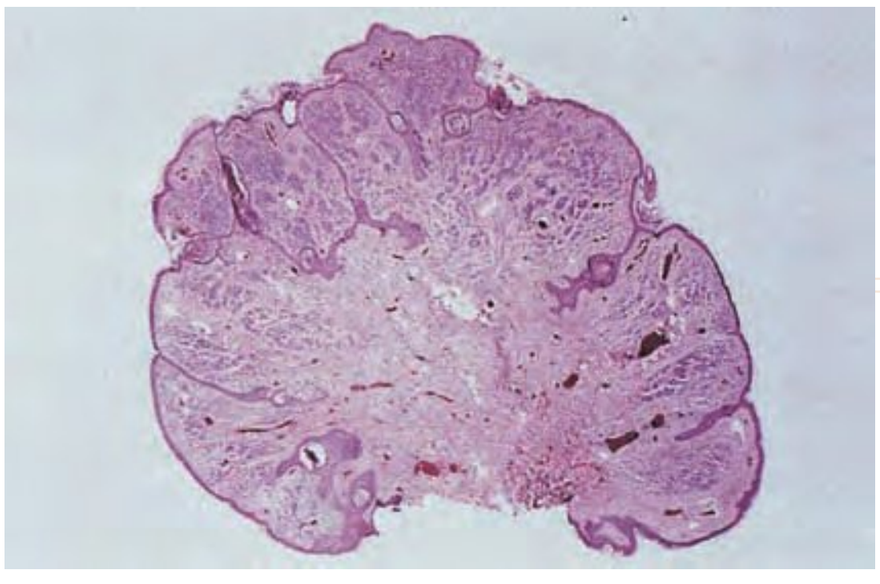
1. With Melanocytic Proliferation
   lentiginous junctional nevus
2. Without Melanocytic Proliferation
   epidermal nevi

D. Localized Lesions with Pagetoid Epithelial Proliferation



1. Keratinocytic Proliferations
   pagetoid squamous cell carcinoma *in situ*
2. Melanocytic Proliferation
   melanoma in situ (superficial spreading type)
3. Glandular Epithelial Proliferations
   Paget's disease (mammary or extramammary)
4. Lymphoid Proliferations
   Pagetoid reticulosis, localized (Woringer-Kolopp)

E. Localized Papillomatous Epithelial Lesions

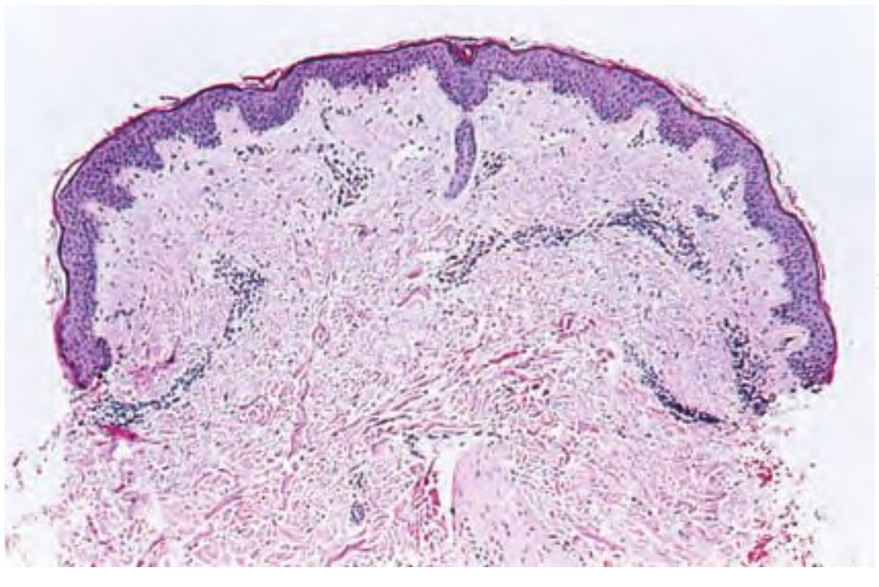


1. With Viral Cytopathic Effects
   verruca vulgaris
2. No Viral Cytopathic Effect
   seborrheic keratosis

F. Irregular Proliferations Extending into the Dermis

1. Squamous Differentiation
   squamous cell carcinoma, superficial
2. Basaloid Differentiation
   basal cell carcinoma, superficial types

G. Superficial Polypoid Lesions



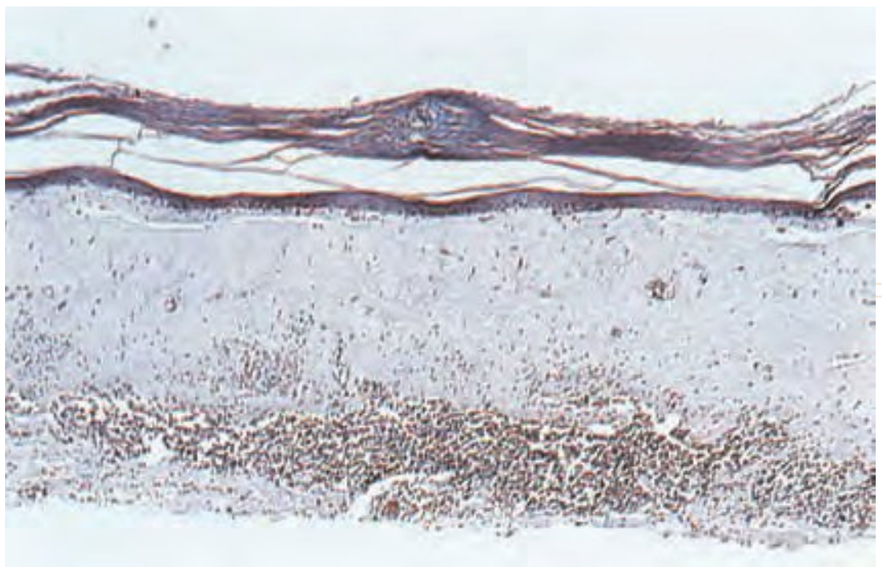
1. Melanocytic Lesions
   polypoid dermal and compound nevi

2. Stromal Lesions
   soft fibroma

III. DISORDERS OF THE SUPERFICIAL CUTANEOUS REACTIVE UNIT

A. Superficial Perivascular Dermatitis

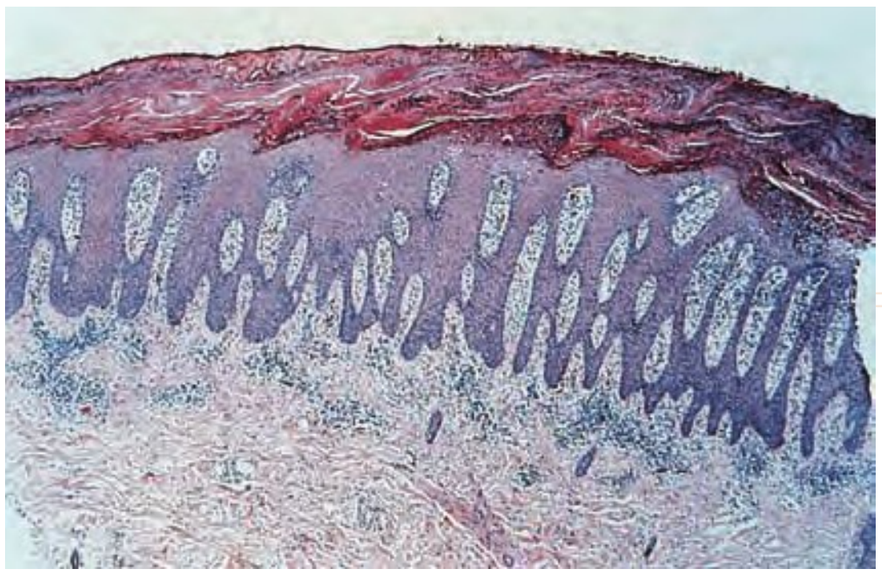
1. Lymphocytes Predominant
   morbilliform viral exanthem
   a. With Eosinophils
      arthropod-bite reaction
   b. With Neutrophils
      erysipelas
   c. With Plasma Cells
      secondary syphilis
   d. With Extravasated Red Cells
      pigmented purpuric dermatosis
   e. Melanophages Prominent
      postinflammatory pigmentation



2. Mast Cells Predominant
   telangiectasia macularis eruptiva perstans

B. Superficial Perivascular Dermatitis with Spongiosis (Spongiotic Dermatitis)

1. Lymphocytes Predominant
   nummular eczema
   a. With Eosinophils
      allergic contact dermatitis
   b. With Plasma Cells
      syphilis, primary or secondary lesions
   c. With Neutrophils
      seborrheic dermatitis

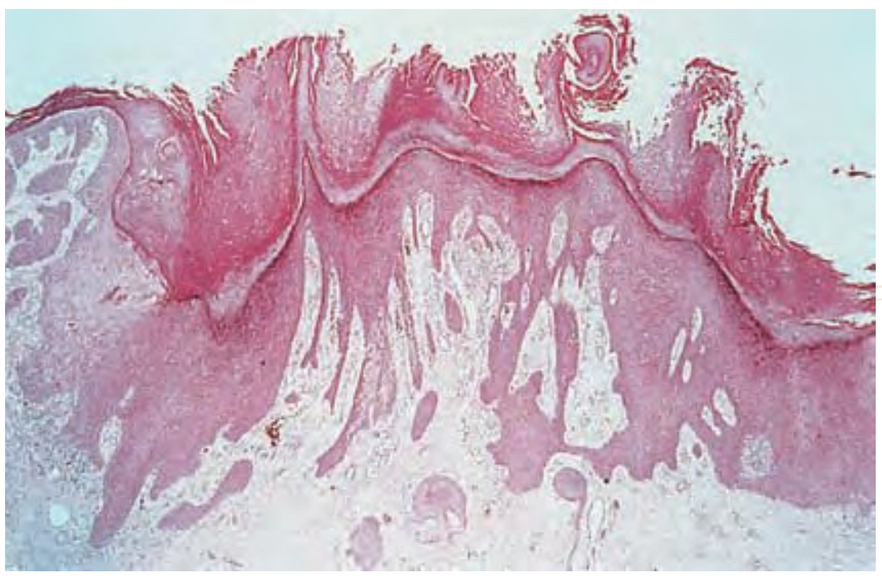


C. Superficial Perivascular Dermatitis with Epidermal Atrophy (Atrophic Dermatitis)

1. Scant Inflammatory Infiltrates
   radiation dermatitis

2. Lymphocytes Predominant
   parapsoriasis/early mycosis fungoides
   a. With Papillary Dermal Sclerosis
      lichen sclerosis et atrophicus

D. Superficial Perivascular Dermatitis with Psoriasiform Proliferation (Psoriasiform Dermatitis)

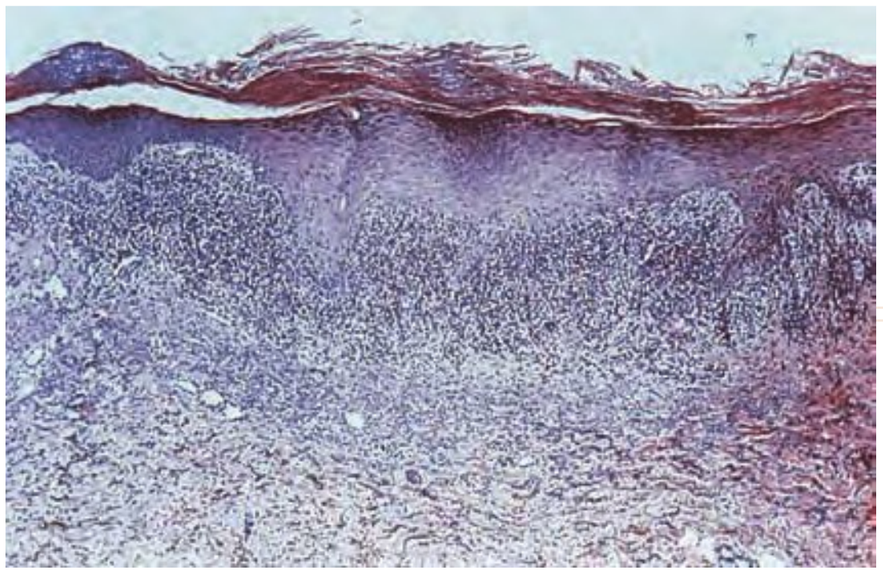


1. Lymphocytes Predominant
   chronic atopic dermatitis
   a. With Plasma Cells
      secondary syphilis
   b. With Eosinophils
      chronic allergic dermatitis

2. Neutrophils Prominent
   psoriasis vulgaris

3. Psoriasiform Epidermal Proliferation, with Epidermal Pallor or Necrosis ("Nutritional Dermatosis")
   pellagra

E. Superficial Perivascular Dermatitis with Irregular Epidermal Proliferation (Hypertrophic Dermatitis)

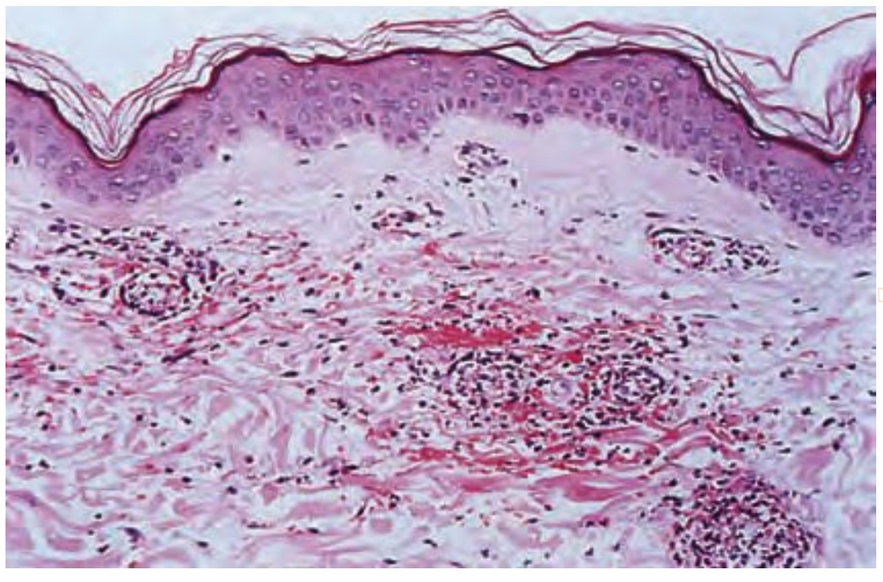


1. Lymphocytes Predominant
   prurigo nodularis
   a. Plasma Cells Present
      rupial secondary syphilis, condyloma lata

2. Neutrophils Prominent
   impetigo contagiosa

3. Neoplastic
   malignant melanoma ("verrucous" pattern)

F. Superficial Dermatitis with Lichenoid Infiltrates (Lichenoid Dermatitis)

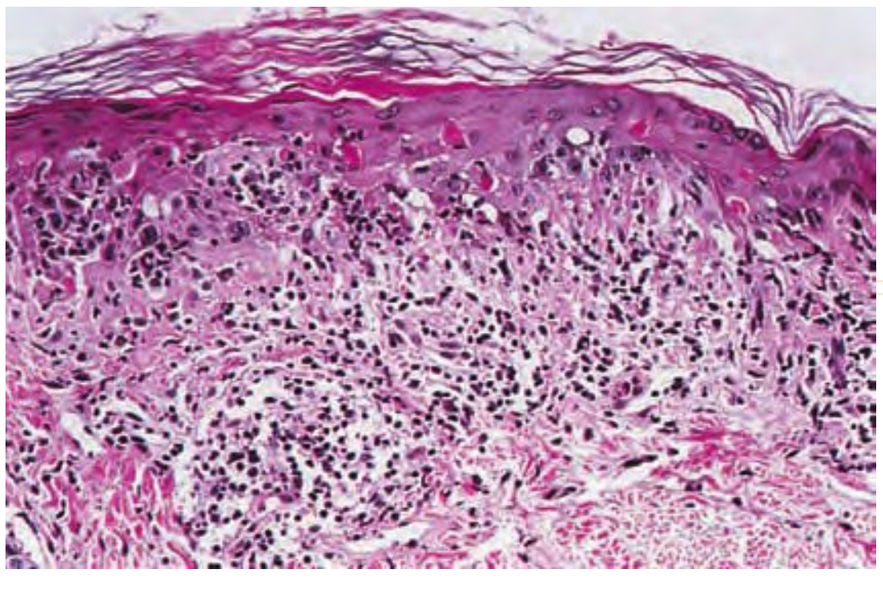


1. Lymphocytes Exclusively
   lichen planus

2. Lymphocytes Predominant
   lichen planus–like keratosis (benign lichenoid keratosis)
   a. Eosinophils Present
      lichenoid drug eruptions
   b. Plasma Cells Present
      secondary syphilis
   c. With Melanophages
      postinflammatory hyperpigmentation
   d. With Lymphocytic Atypia
      mycosis fungoides

3. Histiocytes Predominant
   lichen nitidus

G. Superficial Vasculitis and Vasculopathies



1. Neutrophilic Vasculitis
   cutaneous necrotizing (leukocytoclastic) vasculitis

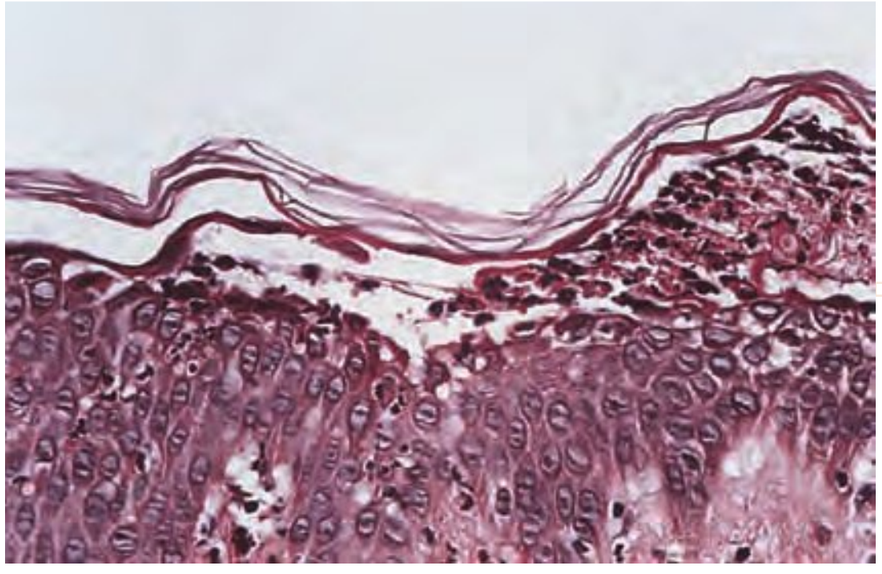
2. Mixed Cell and Granulomatous Vasculitis
   Churg-Strauss vasculitis

3. Vasculopathies with Scant Inflammation
   malignant atrophic papulosis (Degos)

4. Thrombotic, Embolic, and Other Microangiopathies
   disseminated intravascular coagulation

H. Superficial Perivascular Dermatitis with Interface Vacuoles (Interface Dermatitis)

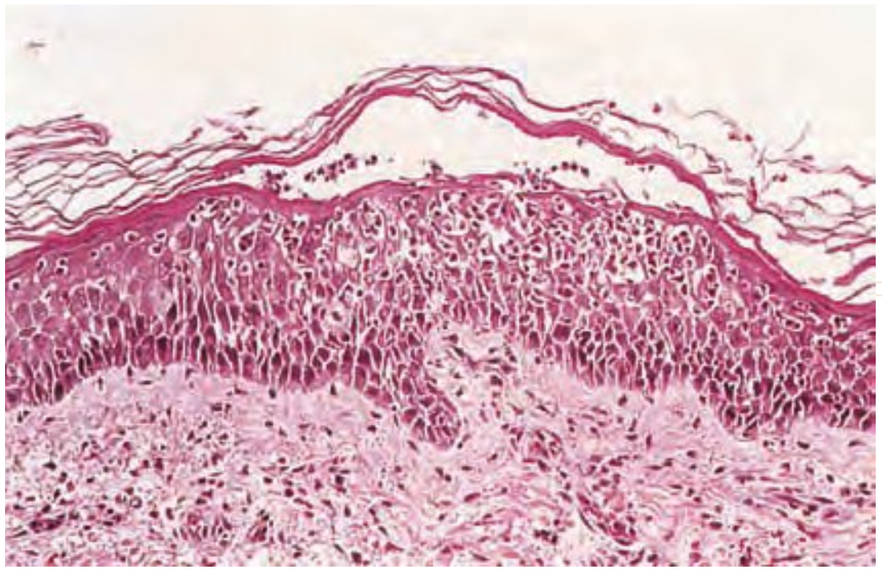
1. Apoptotic Cells Prominent (Cytotoxic Dermatitis)
   erythema multiforme



2. Apoptotic Cells Usually Absent
   dermatomyositis

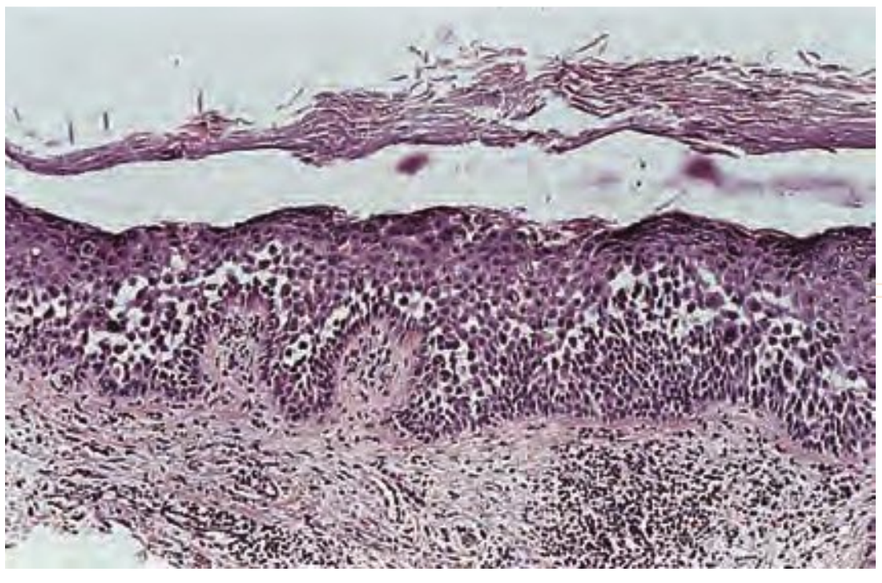
3. Variable Apoptosis
   cytotoxic drug eruptions

4. Basement Membranes Thickened
   lupus erythematosus



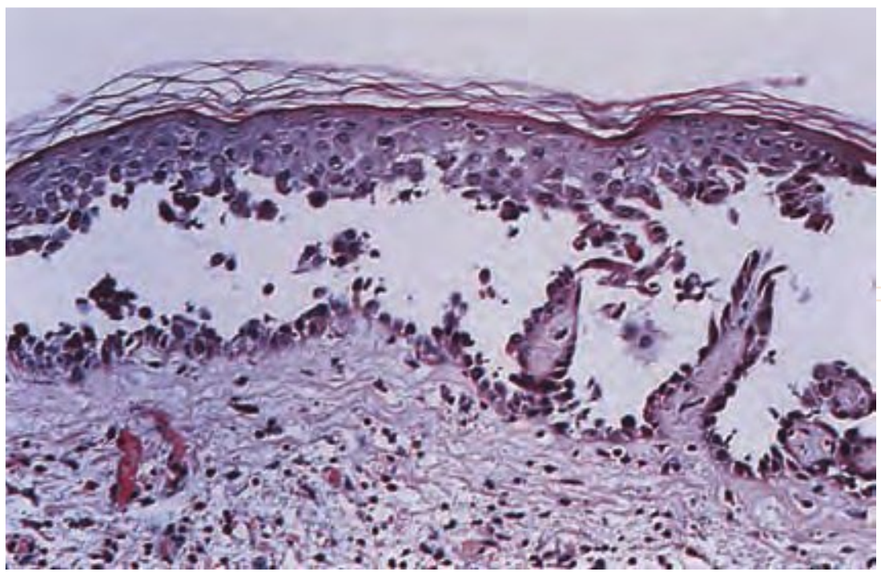
IV. ACANTHOLYTIC, VESICULAR, AND PUSTULAR DISORDERS

A. Subcorneal or Intracorneal Separation



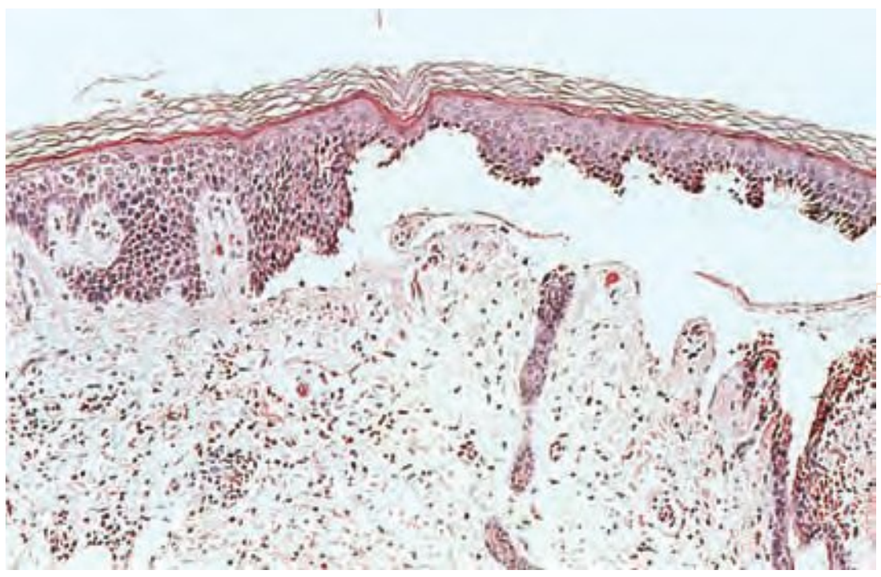
1. Scant Inflammatory Cells
   staphylococcal scalded skin
2. Neutrophils Prominent
   impetigo contagiosa
3. Eosinophils Predominant
   erythema toxicum neonatorum

B. Intraspinous Keratinocyte Separation, Spongiotic



1. Scant Inflammatory Cells
   focal acantholytic dyskeratosis
2. Lymphocytes Predominant
   nummular eczema
   a. Eosinophils Present
      allergic contact dermatitis
3. Neutrophils Predominant
   pustular psoriasis

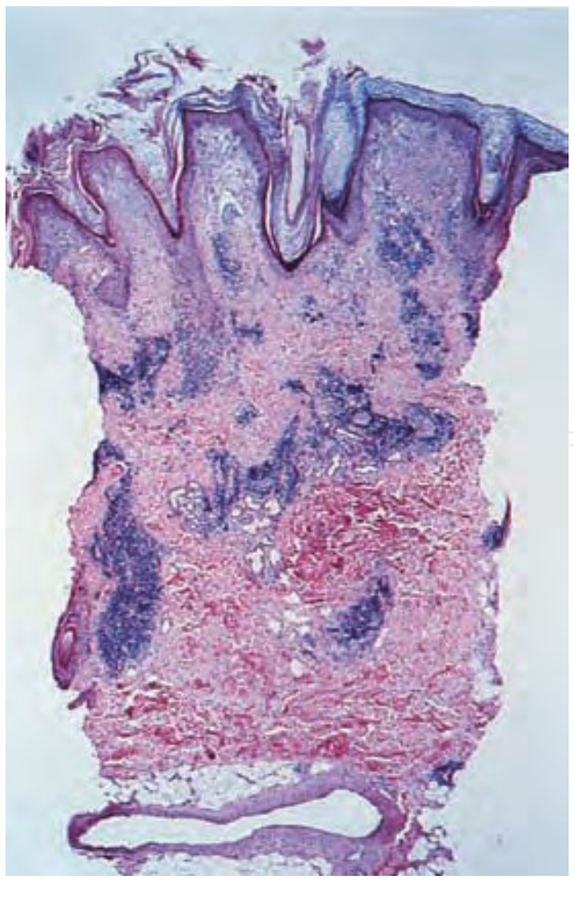
C. Intraspinous Keratinocyte Separation, Acantholytic



1. Scant Inflammatory Cells
   Hailey-Hailey disease
2. Predominant Lymphocytes
   herpes simplex, varicella-zoster
   a. Eosinophils Present
      pemphigus vegetans
3. Mixed Cell Types
   acantholytic solar keratosis

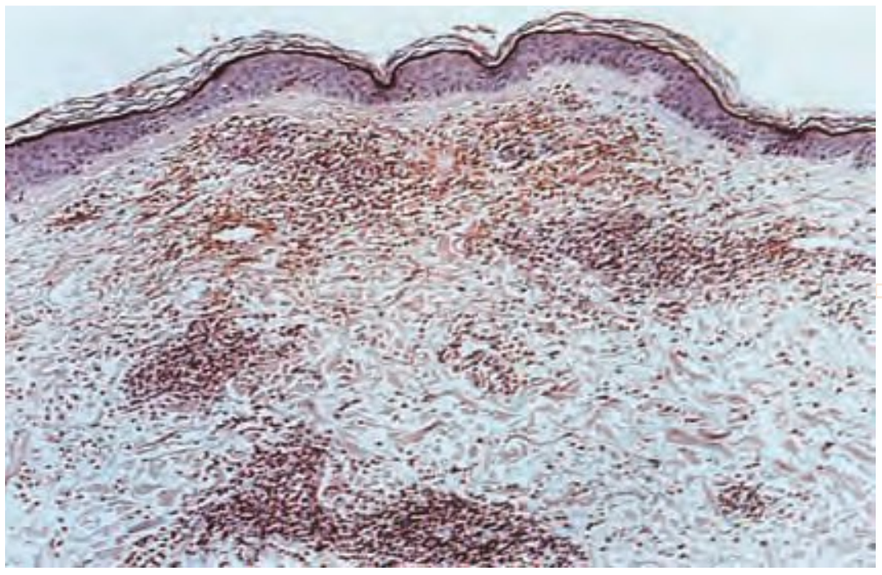
D. Suprabasal Keratinocyte Separation

1. Scant Inflammatory Cells
   transient acantholytic dermatosis (Grover)
2. Lymphocytes and Plasma Cells
   acantholytic solar keratosis
3. Lymphocytes and Eosinophils
   pemphigus vulgaris



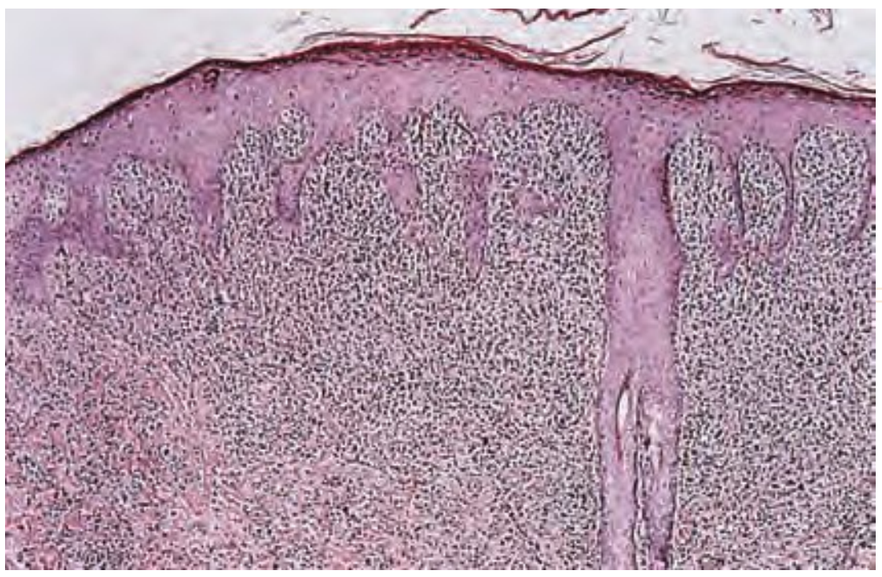
E. Subepidermal Vesicular Dermatitis

1. Scant /No Inflammation
   porphyria cutanea tarda
2. Lymphocytes Predominant
   bullous lichen planus
3. Eosinophils Prominent
   bullous pemphigoid
4. Neutrophils Prominent
   dermatitis herpetiformis
5. Mast Cells Prominent
   bullous mastocytosis



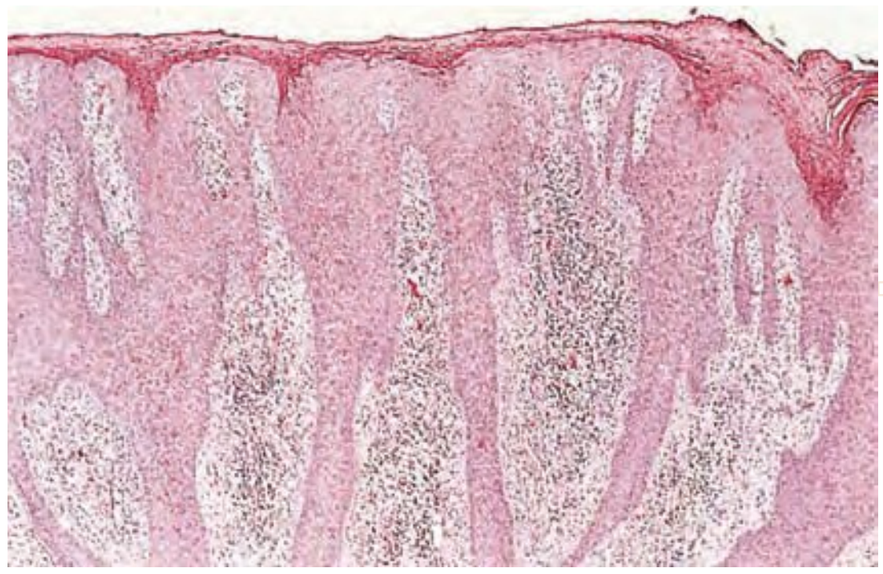
V. PERIVASCULAR, DIFFUSE, AND GRANULOMATOUS INFILTRATES OF THE RETICULAR DERMIS

A. Superficial and Deep Perivascular Infiltrates without Vascular Damage or Vasculitis



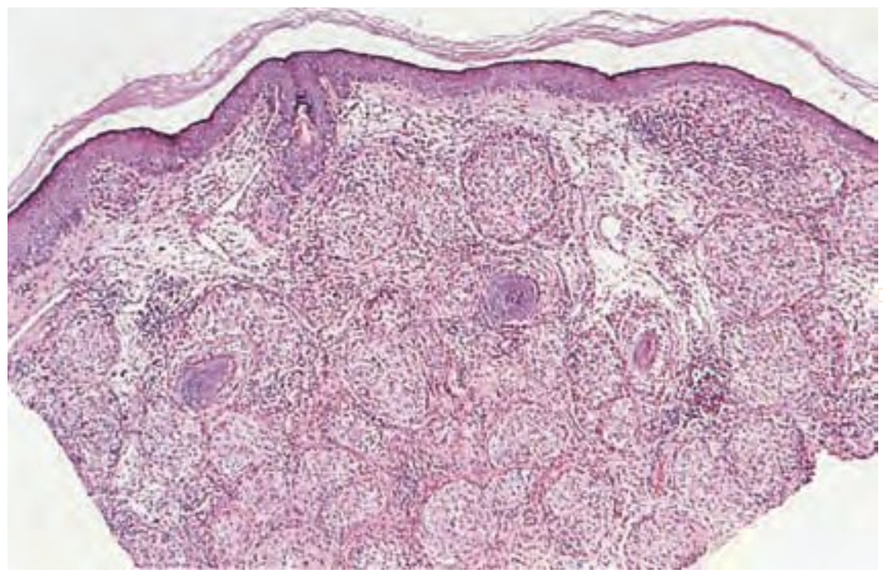
1. Lymphocytes Predominant
   discoid lupus erythematosus (DLE)
2. Neutrophils Predominant
   acute febrile neutrophilic dermatosis (Sweet's syndrome)
3. Lymphocytes and Eosinophils
   papular urticaria
4. With Plasma Cells
   scleroderma/morphea
5. Mixed Cell Types
   erythema chronicum migrans

B. Vasculitis and Vasculopathies



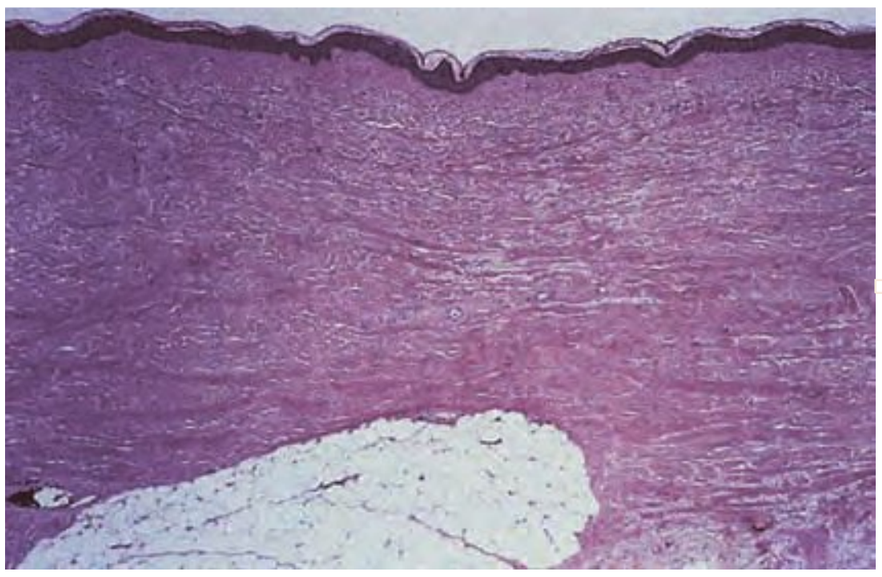
1. Scant Inflammatory Cells
   Degos' disease (malignant atrophic papulosis)
2. Lymphocytes Predominant
   "lymphocytic vasculitis"
3. Neutrophils Prominent
   leukocytoclastic vasculitis
4. Mixed Cell Types and/or Granulomas
   allergic granulomatosis (Churg-Strauss)
5. Thrombotic and Other Microangiopathies
   disseminated intravascular coagulation

C. Diffuse Infiltrates of the Reticular Dermis



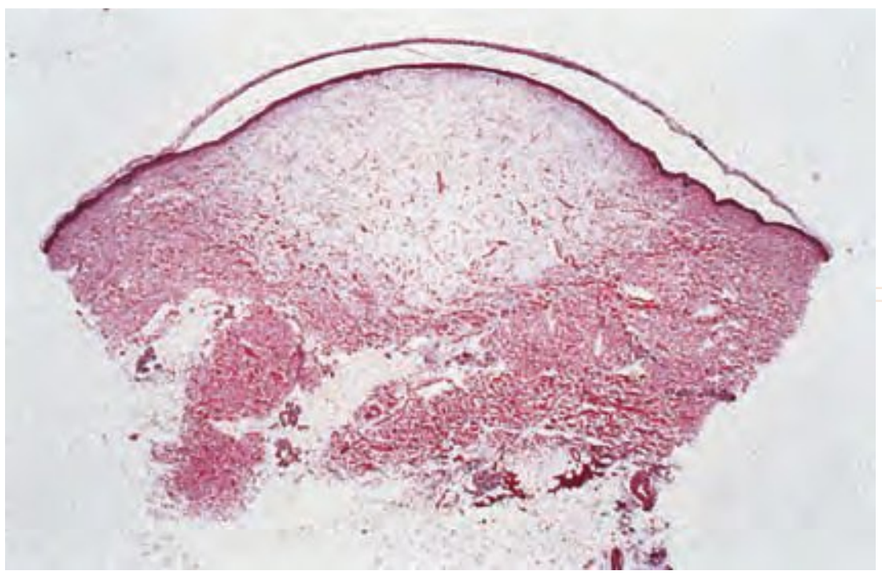
1. Lymphocytes Predominant
   cutaneous lymphoid hyperplasia/lymphocytoma cutis
2. Neutrophils Predominant
   acute neutrophilic dermatosis (Sweet's syndrome)
3. "Histiocytoid" Cells Predominant
   lepromatous leprosy
4. Plasma Cells Prominent
   plasmacytoma, myeloma
5. Mast Cells Predominant
   urticaria pigmentosa
6. Eosinophils Predominant
   eosinophilic cellulitis (Wells' syndrome)
7. Mixed Cell Types
   syphilis, primary, secondary or tertiary
8. Pigment Cells
   nevus of Ota, nevus of Ito
9. Extensive Necrosis
   calciphylaxis

D. Diffuse or Nodular Infiltrates of the Reticular Dermis with Epidermal Proliferation



1. Epidermal Proliferation with Mixed Cellular Infiltrates
   deep fungal infection (pseudoepitheliomatous hyperplasia)

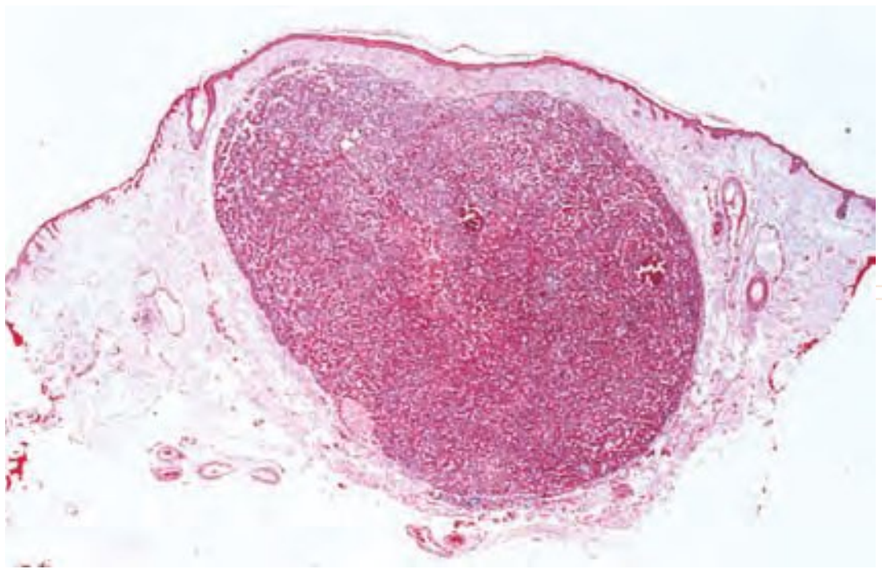
E. Nodular Inflammatory Infiltrates of the Reticular Dermis: Granulomas, Abscesses, and Ulcers



1. Epithelioid Cell Granulomas without Necrosis
   sarcoidosis (lupus pernio and other types)
2. Epithelioid Cell Granulomas with Necrosis
   tuberculosis (lupus vulgaris and other types)
3. Palisading Granulomas
   granuloma annulare
4. Mixed Cell Granulomas
   keratin granuloma (ruptured cyst)
5. Inflammatory Nodules with Prominent Eosinophils
   angiolymphoid hyperplasia with eosinophils
6. Inflammatory Nodules with Mixed Cell Types
   sporotrichosis
7. Abscesses
   acute or chronic bacterial abscesses
8. Inflammatory Nodules with Prominent Necrosis
   aspergillosis
9. Chronic Ulcers and Sinuses
   pyoderma gangrenosum

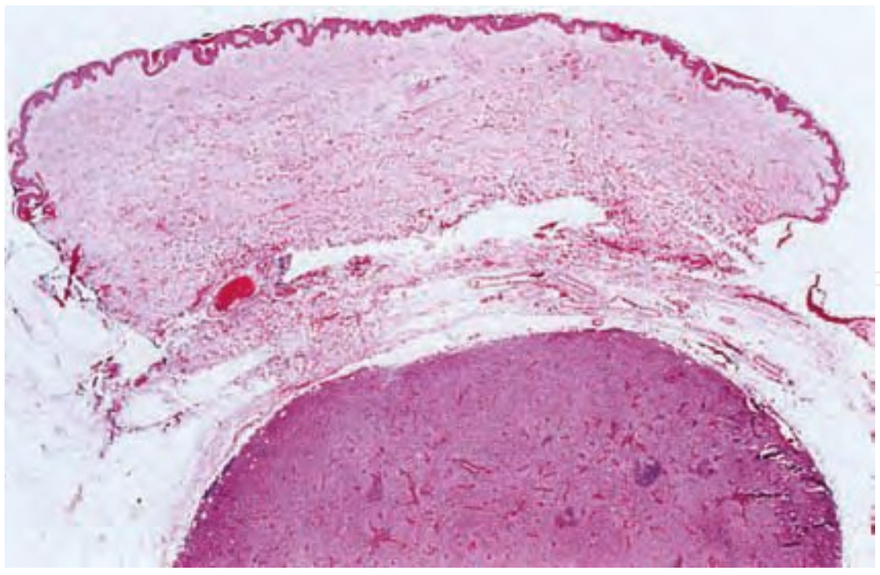
F. Dermal Matrix Fiber Disorders

1. Collagen Increased
   scleroderma/morphea
2. Collagen Reduced
   scleroderma/morphea
3. Elastin Increased or Prominent
   pseudoxanthoma elasticum
4. Elastin Reduced
   cutis laxa
5. Perforating
   elastosis perforans serpiginosa



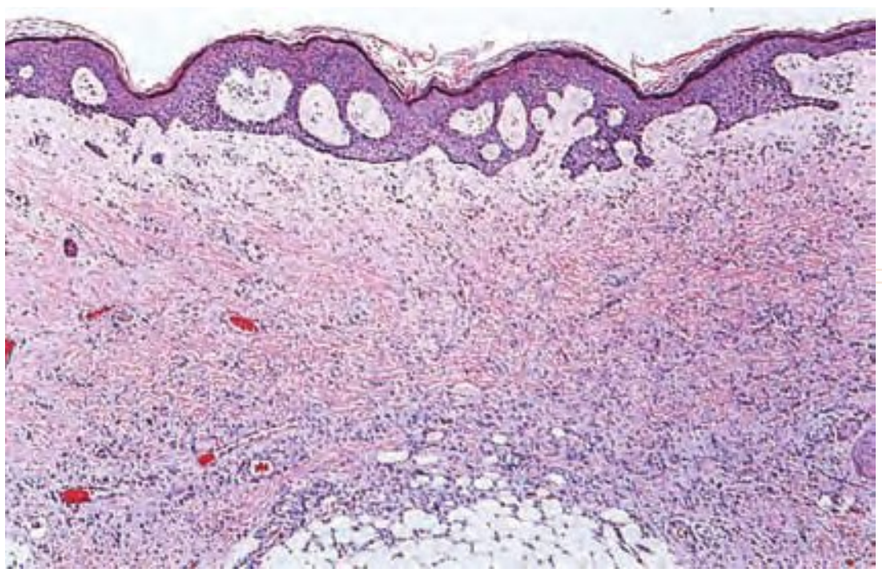
G. Deposition of Material in the Dermis

1. Increased Normal Matrix Constituents
   focal dermal mucinosis
2. Material Not Normally Present in the Dermis
   gout
3. Parasitic Infestations of the Dermis and/or Subcutis
   Myiasis



VI. TUMORS AND CYSTS OF THE DERMIS AND SUBCUTIS

A. Small Cell Tumors



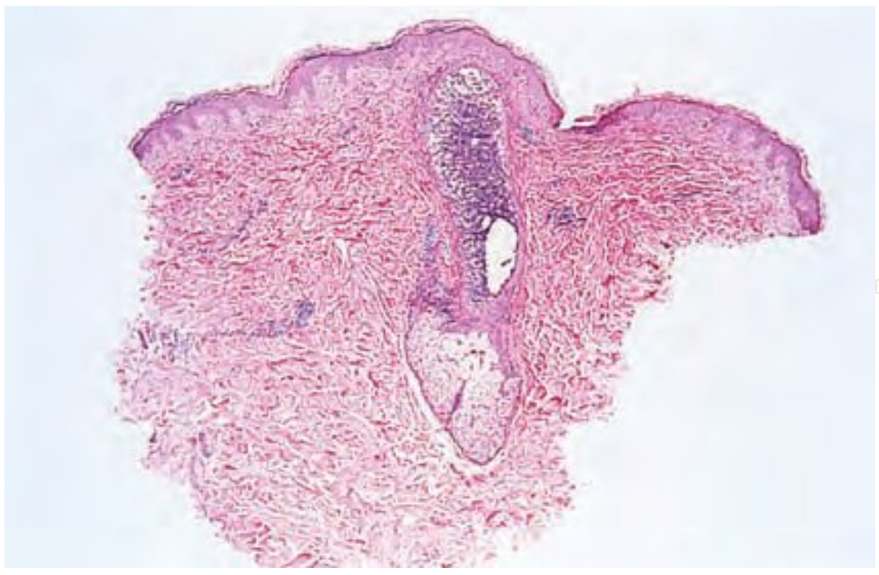
1. Tumors of Lymphocytes or Hemapoietic Cells
   tumor-stage mycosis fungoides
2. Tumors of Lymphocytes and Mixed Cell Types
   cutaneous lymphoid hyperplasia/lymphocytoma cutis
3. Tumors of Plasma Cells
   cutaneous plasmacytoma and myeloma
4. Small Round Cell Tumors
   eccrine spiradenoma

B. Large Polygonal and Round Cell Tumors

1. Squamous Cell Carcinomas
   primary squamous cell carcinoma
2. Adenocarcinomas
   metastatic adenocarcinoma
3. Melanocytic Tumors
   metastatic melanoma
4. Eccrine Tumors
   nodular hidradenoma (eccrine acrospiroma)
5. Apocrine Tumors
   hidradenoma papilliferum
6. Pilar Tumors
   trichoepithelioma
7. Sebaceous Tumors
   sebaceous adenoma and epithelioma
8. "Histiocytoid" Tumors
   xanthomas—eruptive, plane, tuberous, tendon
9. Tumors of Large Lymphoid Cells
   cutaneous anaplastic large cell lymphoma (Ki-1)
10. Mast Cell Tumors
    mastocytosis
11. Tumors with Prominent Necrosis
    epithelioid sarcoma
12. Miscellaneous and Undifferentiated Epithelial Tumors
    undifferentiated carcinoma (large cell, small cell)

C. Spindle Cell, Pleomorphic, and Connective Tissue Tumors

1. Fibrohistiocytic Spindle Cell Tumors
   benign fibrous histiocytoma (dermatofibroma)
2. Schwannian/Neural Spindle Cell Tumors
   neurofibromas
3. Spindle Cell Tumors of Muscle
   leiomyoma
4. Melanocytic Spindle Cell Tumors
   desmoplastic melanoma, including amelanotic
5. Tumors and Proliferations of Angiogenic Cells
   pyogenic granuloma
6. Tumors of Adipose Tissue
   nevus lipomatosus superficialis
7. Tumors of Cartilaginous Tissue
   soft tissue chondroma
8. Tumors of Osseous Tissue
   osteoma cutis



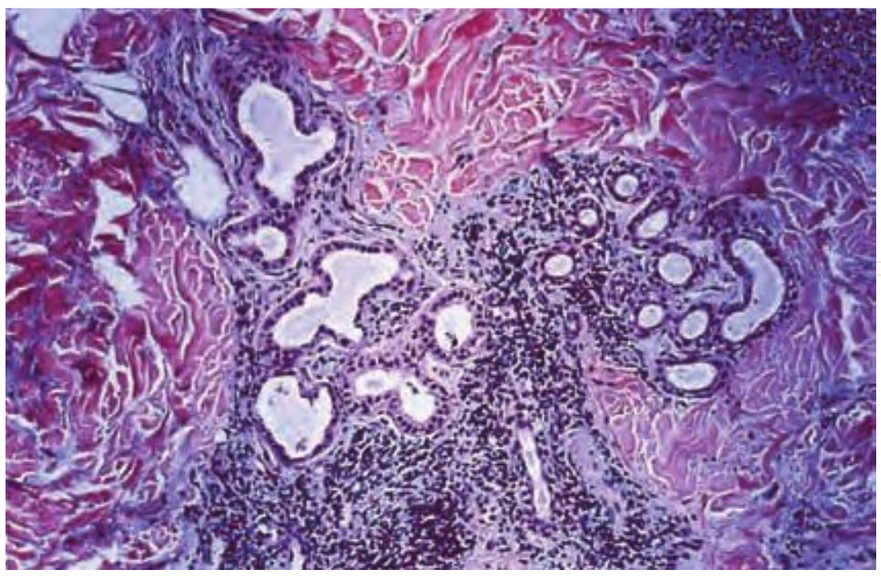
D. Cysts of the Dermis and Subcutis

1. Pilar Differentiation
   epidermal cyst
2. Eccrine and Similar Differentiation
   eccrine hidrocystoma
3. Apocrine Differentiation
   apocrine hidrocystoma

VII. INFLAMMATORY DISORDERS OF SKIN APPENDAGES

A. Pathology Involving Hair Follicles

1. Scant Inflammation
   androgenic alopecia

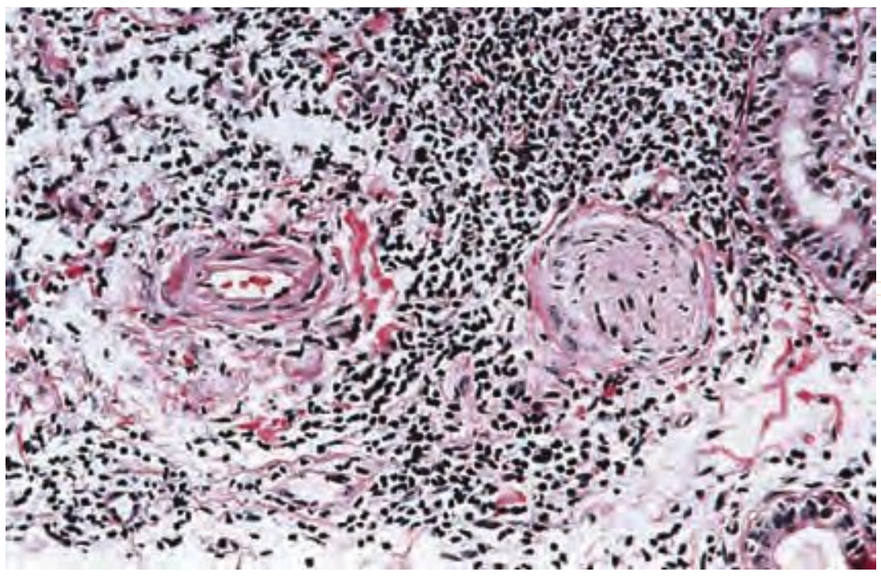


2. Lymphocytes Predominant
   alopecia areata
   a. With Eosinophils Present
      eosinophilic pustular folliculitis

3. Neutrophils Prominent
   acute bacterial folliculitis

4. Plasma Cells Prominent
   acne keloidalis

5. Fibrosing and Suppurative Follicular Disorders
   hidradenitis suppurativa



B. Pathology Involving Sweat Glands

1. Scant Inflammation
   eccrine nevus

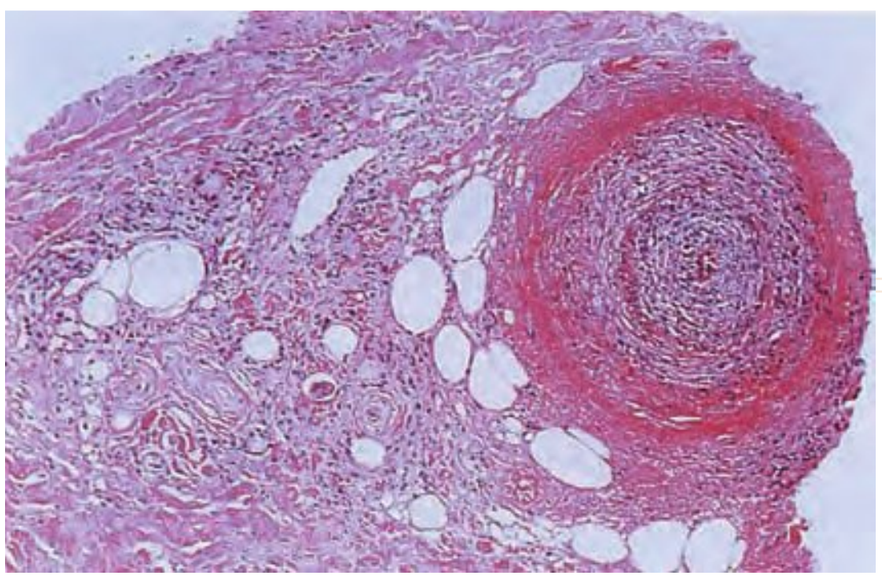
2. Lymphocytes Predominant
   lupus erythematosus
   a. With Plasma Cells
      cheilitis glandularis
   b. With Eosinophils
      insect bite reactions
   c. With Neutrophils
      neutrophilic eccrine hidradenitis

C. Pathology Involving Nerves

1. Lymphocytic Infiltrates
   neurotropic melanoma

2. Mixed Inflammatory Infiltrates
   leprosy

3. Neoplastic Infiltrates
   neurotropic melanoma

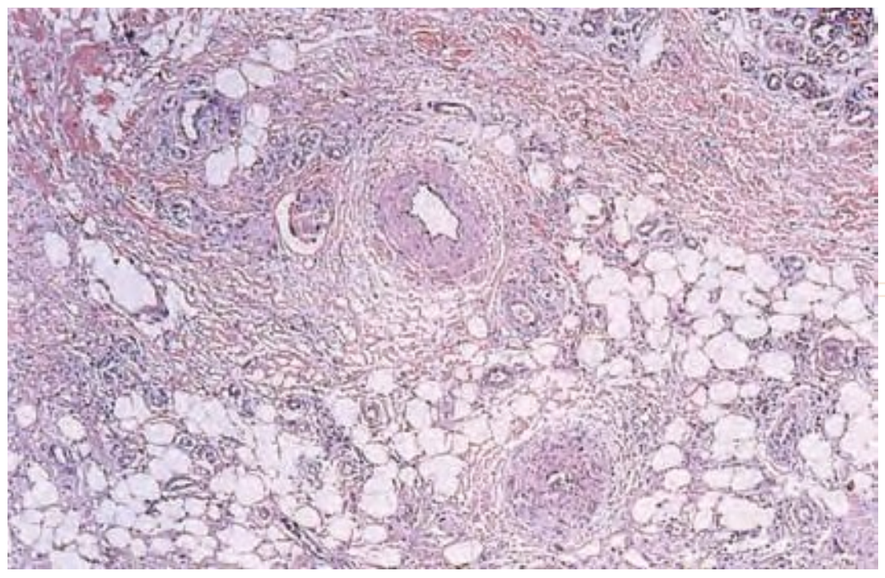


D. Pathology of the Nails

1. Lymphocytic Infiltrates
   melanoma *in situ,* acral-lentiginous type
2. Lymphocytes with Neutrophils
   tinea unguium, onychomycosis
3. Bullous Diseases
   Darier's disease
4. Parasitic Infestations
   scabies

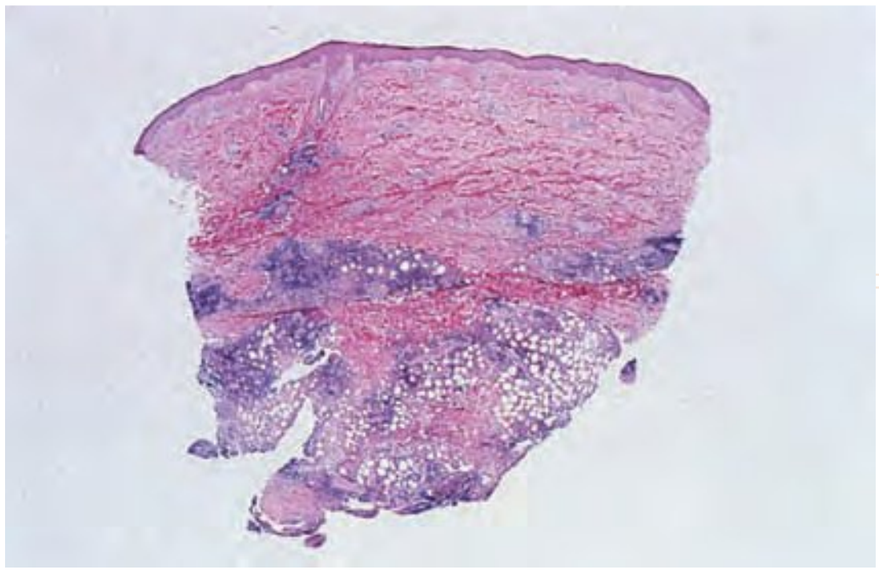
VIII. DISORDERS OF THE SUBCUTIS

A. Subcutaneous Vasculitis and Vasculopathy (Septal or Lobular)



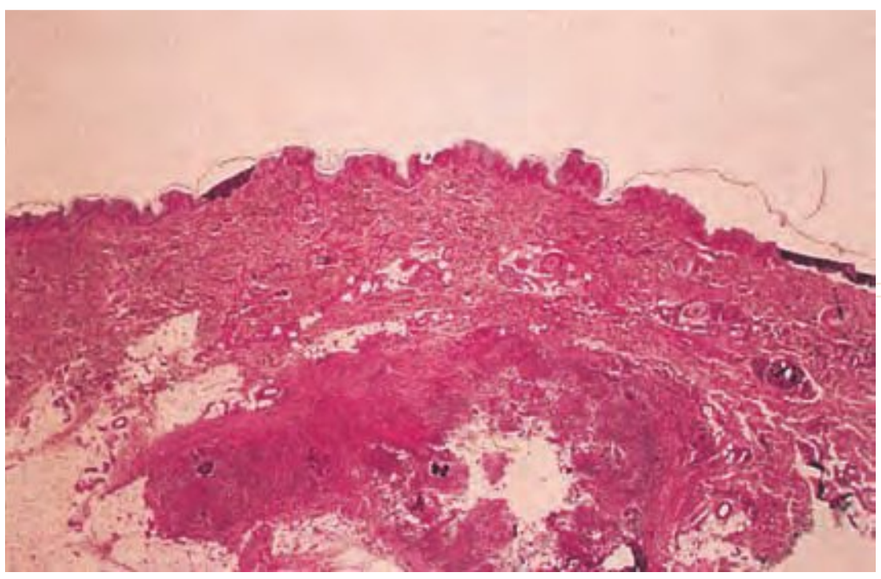
1. Neutrophilic
   subcutaneous polyarteritis nodosa
2. Lymphocytic
   nodular vasculitis
3. Granulomatous
   Churg-Strauss vasculitis

B. Septal Panniculitis without Vasculitis



1. Lymphocytes and Mixed Infiltrates
   erythema nodosum and variants
2. Granulomatous
   subcutaneous granuloma annulare
3. Sclerotic
   scleroderma, morphea

C. Lobular Panniculitis without Vasculitis



1. Lymphocytes Predominant
   lupus panniculitis
2. Lymphocytes and Plasma Cells
   scleroderma
3. Neutrophilic
   infection (cellulitis)
4. Eosinophils Prominent
   eosinophilic fasciitis
5. Histiocytes Prominent
   cytophagic histiocytic panniculitis
6. Mixed with Foam Cells
   Weber-Christian Disease
7. Granulomatous
   subcutaneous sarcoidosis
8. Crystal Deposits, Calcifications
   sclerema neonatorum
9. Necrosis Prominent
   pancreatic panniculitis
10. Embryonic Fat Pattern
    lipoatrophy
11. Miscellaneous
    lipomembranous panniculitis

D. Mixed Lobular and Septal Panniculitis

1. With Hemorrhage or Sclerosis
   traumatic panniculitis
2. With Many Neutrophils
   necrotizing fasciitis (bacterial infection)
3. With Many Lymphocytes
   nonspecific panniculitis
4. With Cytophagic Histiocytes
   histiocytic cytophagic panniculitis (late lesion)
5. With Granulomas
   mycobacterial panniculitis

E. Subcutaneous Abscesses (Courtesy Waine Johnson, MD)

1. With Neutrophils
   deep fungus infection

PART 3. DISEASE LISTINGS CATEGORIZED BY SITE, PATTERN, AND CYTOLOGY

In this section, the cutaneous diseases are listed in categories based on their location in the skin, their architectural patterns, and their cytology. The listings may be used as a basis for differential diagnosis generation and for review of material covered elsewhere in this text.

I. DISORDERS MOSTLY LIMITED TO THE EPIDERMIS AND STRATUM CORNEUM[1]

The stratum corneum is usually arranged in a delicate mesh-like or "basket-weave" pattern. It may be shed (exfoliated) or thickened (hyperkeratosis) with or without retention of nuclei (parakeratosis or orthokeratosis; respectively). The granular layer may be normal, increased (hypergranulosis), or reduced (hypogranulosis). Usually, alterations in the stratum corneum result from inflammatory or neoplastic changes that affect the whole epidermis and, more often than not, the superficial dermis. Only a few conditions, mentioned in this section, show pathology mostly or entirely limited to the stratum corneum.

A. Hyperkeratosis with Hypogranulosis 86

1. No Inflammation 86

ichthyosis vulgaris 133

B. Hyperkeratosis with Normal or Hypergranulosis 86

The stratum corneum is thickened, the granular cell layer is normal or thickened, and the dermis shows only sparse perivascular lymphocytes. There is no epidermal spongiosis or exocytosis.

1. No Inflammation 86

The upper dermis contains only sparse perivascular lymphocytes.

lamellar ichthyosis 135
X-linked ichthyosis 133
epidermolytic hyperkeratosis 793
epidermolytic acanthoma 793
oculocutaneous tyrosinosis (tyrosinemia) 451
acanthosis nigricans 447
large cell acanthoma 799
hyperkeratosis lenticularis perstans (Flegel's disease) 397

[1]In the lists that follow, the term "predominant" is used to describe an infiltrate in which the majority of the cells are of a certain type, usually lymphocytes or neutrophils. Many dermatoses are composed of infiltrates that are predominantly lymphocytic, with only an occasional other cell; these are listed as, for example, "1. Lymphocytes predominant." Many other dermatoses contain a diagnostically significant admixture of other cell type(s) as a minority population; these are listed in subsequent sections as, for example, "a. With Eosinophils," "b. With Plasma Cells," and so on, it being understood that lymphocytes predominate in these dermatoses also. Infiltrates in which there is an approximately equal admixture of multiple cell types are listed as "mixed" infiltrates.

confluent and reticulated papillomatosis (Gougerot and Carteau)

2. Scant Inflammation 86

Lymphocytes are minimally increased about the superficial plexus. There may be a few neutrophils in the stratum corneum.

dermatophytosis 592
lichen amyloidosis 427
tinea versicolor
erythrasma

C. Hyperkeratosis with Parakeratosis 86

The stratum corneum is thickened, the granular cell layer is reduced, and there is parakeratosis. The dermis may show only sparse perivascular lymphocytes, although some of these conditions in other instances may show more substantial inflammation. There is no epidermal spongiosis or exocytosis.

1. No Inflammation 86

The upper dermis contains only sparse perivascular lymphocytes.

epidermolytic hyperkeratosis 793
epidermal nevi 791
porokeratotic eccrine duct nevus 793
cutaneous horn 811
oral leukoplakia 811
leukoplakia of the vulva 816

2. Scant Inflammation 86

Lymphocytes are minimally increased about the superficial plexus. There may be a few lymphocytes and/or neutrophils in the stratum corneum.

scurvy 407
vitamin A deficiency 407, 450
pellagra (niacin deficiency) 451
Hartnup's disease 451
acrokeratosis neoplastica (Bazex's syndrome) 419
dermatophytosis 592
epidermal dysmaturation (cytotoxic chemotherapy: variable keratin alterations) 321

3. With Epidermal Pallor or Necrosis ("Nutritional Dermatosis") 86

There may be psoriasiform epidermal hyperplasia, and there is hyperkeratosis with parakeratosis and with pallor, swelling, or necrosis of superficial keratinocytes.

necrolytic migratory erythema 409
necrolytic acral erythema 409
acrodernmatitis enteropathica 410
pellagra 408

D. Localized or Diffuse Hyperpigmentations 87

Increased melanin pigment is present in basal keratinocytes, without melanocytic proliferation.

1. No Inflammation 87

The upper dermis contains only sparse perivascular lymphocytes.

simple ephelis (ephelide) 705
melanotic macules 705
café-au-lait spot 1111
actinic lentigo 706
pigmented actinic keratosis 811
melasma 690
Becker's melanosis 706
congenital diffuse melanosis 689
reticulated hyperpigmentations 689
Addison's disease 690
alkaptonuric ochronosis 439
hemochromatosis 449

2. Scant Inflammation 87

Lymphocytes are minimally increased about the superficial plexus. There may be a few lymphocytes and/or neutrophils in the stratum corneum. Melanophages may be present in the papillary dermis.

lichen amyloidosis 427
postinflammatory hyperpigmentation 690
erythema dyschromicum perstans 172

E. Localized or Diffuse Hypopigmentations 87

Melanin pigment is reduced in basal keratinocytes, with (vitiligo) or without (early stages of chemical depigmentation) a reduction in the number of melanocytes.

1. With or Without Slight Inflammation 87

Lymphocytes may minimally increase about the dermal–epidermal junction, as in the active phase of vitiligo, or may be absent, as in albinism.

vitiligo 694
chemical depigmentation 691
idiopathic guttate hypomelanosis 691
albinism 693
tinea versicolor 596
piebaldism 693
Chediak-Higashi syndrome 694
postinflammatory hypopigmentation

II. LOCALIZED SUPERFICIAL EPIDERMAL OR MELANOCYTIC PROLIFERATIONS

Localized proliferations may be reactive but are often neoplastic. The epidermis (keratinocytes) may proliferate without extension into the dermis or extend into the dermis and may be squamous or basaloid. Melanocytes within the epidermis may proliferate with or without cytologic atypia (nevi, dysplastic nevi, melanoma *in situ*), in a proliferative epidermis (superficial spreading melanoma *in situ*, Spitz nevi) or an atrophic epidermis (lentigo maligna); they can also extend into the dermis as proliferative infiltrates (invasive melanoma with or without vertical growth phase). There may be an associated variably cellular, often mixed, inflammatory infiltrate, or inflammation may be essentially absent.

A. Localized Irregular Thickening of the Epidermis 87

Localized irregular epidermal proliferations are usually neoplastic.

1. Localized Epidermal Proliferations 87

The epidermis is thickened secondary to a localized proliferation of keratinocytes (acanthosis). The proliferation can be cytologically atypical, as in squamous cell carcinoma *in situ*, or bland, as in eccrine poroma.

a. No Cytologic Atypia 87

seborrheic keratosis 795
dermatosis papulosa nigra 799
stucco keratosis 799
large cell acanthoma 799
clear cell acanthoma 799
epidermal nevi 791
eccrine poroma 885
hidroacanthoma simplex 886
oral white sponge nevus 794
leukoedema of the oral mucosa 794
verrucous hyperplasia of oral mucosa (oral florid papillomatosis) 813

b. With Cytologic Atypia 87

actinic keratosis 807
arsenical keratosis 816
squamous cell carcinoma *in situ* 809
Bowen's disease 813
erythroplasia of Queyrat 815
erythroplakia of the oral mucosa 812
bowenoid papulosis 656

c. Pseudoepitheliomatous Hyperplasia 822

halogenodermas (Halogen Eruptions) 326
deep fungal infections 604
epidermis above granular cell tumor 1130
Spitz nevus 718
verrucous melanoma 756

2. Superficial Melanocytic Proliferations 87

The epidermis may be thickened (acanthosis) and is associated with a proliferation of single or nested melanocytic cells. The proliferation can be malignant, as in superficial spreading melanoma, or benign, as in nevi.

junctional nevi 699
recurrent melanocytic nevi 732
Spitz nevi 718
compound or dermal nevi, papillomatous 714
junctional or superficial compound dysplastic nevi 733
melanoma in situ 738

B. Localized Lesions with Thinning of the Epidermis 87

A thinned epidermis is characteristic of aged or chronically sun-damaged skin. The epidermis is thinned secondary to diminished number and to decreased size of keratinocytes.

1. With Melanocytic Proliferation 87

The epidermis is thinned (atrophic), and there is proliferation of single or small groups of atypical melanocytes, resulting in the localization of melanocytes in contiguity with one another, in the basal layer of the epidermis.

melanoma in situ (lentigo maligna type) 738

2. Without Melanocytic Proliferation 87

The epidermis is thinned without proliferation of keratinocytes or melanocytes. Each melanocyte is separated from the next by several keratinocytes.

actinic keratosis. 807
porokeratosis 139
lichen sclerosus et atrophicus 303

C. Localized Lesions with Elongated Rete Ridges 88

Elongation of the rete ridges without melanocytic proliferation is termed "psoriasiform hyperplasia" because this pattern is seen in psoriasis. Elongated rete with melanocytic proliferation and predominance of single cells over nests is termed a "lentiginous" pattern. The prototype of this pattern, also seen in a more exaggerated form in dysplastic nevi and in the "lentiginous" melanomas, is lentigo simplex.

1. With Melanocytic Proliferation 88

The epidermal rete ridges are elongated, and within the rete is melanocytic proliferation.

lentigo simplex 708
nevus spilus 708
lentiginous junctional nevus 711
junctional nevus 711
dysplastic nevus 733
acral-lentiginous melanoma 747
mucosal-lentiginous melanoma 749

2. Without Melanocytic Proliferation 88

The epidermis is thickened (acanthotic). Melanocytes are normal as are keratinocytes. The only change is acanthosis.

epidermal nevi 791
psoriasis 174
lichen simplex chronicus 174, 242
acanthosis nigricans 447

D. Localized Lesions with Pagetoid Epithelial Proliferation 88

A neoplastic proliferation of one cell type distributed as single cells or nests within a benign epithelium is termed "Pagetoid" after Paget's disease of the breast (mammary carcinoma cells proliferating in skin of the nipple).

1. Keratinocytic Proliferation 88

The epidermis has atypical keratinocytes scattered within mature epithelium at all or multiple levels; there is loss of normal maturation. Mitoses are increased, and there may be individual cell necrosis.

pagetoid squamous cell carcinoma in situ 815
intraepithelial epithelioma (Borst-Jadassohn) 832
clonal seborrheic keratosis 832

2. Melanocytic Proliferation 88

Atypical melanocytes are seen at all levels within the otherwise mature but often hyperplastic epidermis.

melanoma in situ (superficial spreading type) 738

3. Glandular Epithelial Proliferations 88

Atypical large clear cells with glandular differentiation (mucin production, occasionally lumen formation) proliferate in a normally maturing epidermis.

Paget's disease (mammary or extramammary) 838

4. Lymphoid Proliferations 88

Atypical, large, clear lymphoid cells proliferate in a normally maturing epidermis.

a. Pagetoid reticulosis 88

localized (Woringer-Kolopp) 940
disseminated (Ketron-Goodman) 940

E. Localized Papillomatous Epithelial Lesions 88

A "papilla" may be likened to a "finger" of stroma with a few blood vessels, collagen fibers, and fibroblasts covered by a "glove" of epithelium, which may be reactive or neoplastic, benign or malignant.

1. With Viral Cytopathic Effects 88

The epidermis is acanthotic with vacuolated cells often having enlarged and somewhat irregular nuclei (koilocytes), the granular cell layer is usually thickened with enlarged keratohyaline granules, and there is parakeratosis in tall columns overlying the thickened epidermis at the tops of the papillae. Large inclusions are seen in molluscum contagiosum.

verruca vulgaris 650
orf 637
condyloma acuminatum 654

molluscum contagiosum 659
bowenoid papulosis 656

2. No Viral Cytopathic Effect 88

The epidermis proliferates. The cells may be basophilic or "basaloid" in type (seborrheic keratoses). There may be increased stratum corneum and elongation of the dermal papillae (squamous papilloma), or there may be basilar keratinocyte atypia (actinic keratosis).

seborrheic keratosis 795
acanthosis nigricans 447
confluent and reticulated papillomatosis 449
actinic keratosis, hypertrophic 808
nonspecific squamous papilloma 649, 791
epithelial nevus/epidermal nevus 791
hyperkeratosis of the nipple and areola 792
verruciform xanthoma 685
verrucous melanoma 756

F. Irregular Proliferations Extending into the Dermis 88

Irregular or asymmetric proliferations of keratinocytes extending into the dermis are usually neoplastic. The differential diagnosis includes reactive pseudoepitheliomatous hyperplasia, which may be seen around chronic ulcers or in association with other inflammatory conditions.

1. Squamous Differentiation 88

The epidermis is irregularly thickened, the maturation is abnormal, and there may be keratinocyte atypia (squamous cell carcinoma). The proliferation is often associated with a thick parakeratotic scale.

lichen simplex chronicus 182, 242
squamous cell carcinoma, superficial 817
keratoacanthoma 835
prurigo nodularis 173
actinic prurigo 335
inverted follicular keratosis 795
verrucous carcinoma 656, 822
of oral mucosa 813
of anogenital region (giant condyloma of Buschke and Lowenstein) 656, 822
of plantar skin (epithelioma cuniculatum) 822
pseudoepitheliomatous hyperplasia 822
deep fungal infection 604
halogenoderma 326
chronic ulcers 539, 604, 625
granular cell tumor 1131
Spitz nevus 718
verrucous melanoma 756

2. Basaloid Differentiation 88

The proliferation is of basal cells from the epidermis, extending into the dermis. The epidermis can be thickened, normal, or atrophic.

basal cell carcinoma, superficial types 817
dermatofibroma with basaloid induction 969

G. Superficial Polypoid Lesions 89

A polyp is any lesion that protrudes from a surface. Whereas a papilloma consists of elongated papillae representing a "finger" of stroma covered by a "glove" of epithelium, a polyp is more like a hand within which the papillae ("fingers") may be elongated or, more usually, normal or attenuated. Thus, polypoid lesions may also be papillomatous, or not. Many of the neoplasms listed in Section VI may also present as polypoid neoplasms.

1. Melanocytic Lesions 89

polypoid dermal and compound nevi, including Spitz nevi 756
polypoid melanoma 756

2. Stromal Lesions 89

neurofibroma 1109
soft fibroma (fibroepithelial polyp, acrochordon, skin tag) 981

3. Other Neoplasms 89

See Section VI on tumor and cysts of the dermis and subcutis.

III. DISORDERS OF THE SUPERFICIAL CUTANEOUS REACTIVE UNIT

The epidermis, papillary dermis, and superficial capillary-venular plexus react together in many dermatologic conditions and were termed the *superficial cutaneous reactive unit* by Clark. Many dermatoses are associated with infiltrates of lymphocytes, with or without other cell types, around the superficial vessels. The epidermis in pathologic conditions can be thinned (atrophic), thickened (acanthosis), edematous (spongiosis), and/or infiltrated (exocytosis). The epidermis may proliferate in response to chronic irritation or infection (bacterial, yeast, deep fungal, or viral). The epidermis may proliferate in response to dermatologic conditions (psoriasis, atopic dermatitis, prurigo). The papillary dermis and superficial vascular plexus may have a variety of inflammatory cells, can be edematous, may have increased ground substance (hyaluronic acid), or may be sclerotic or homogenized.

A. Superficial Perivascular Dermatitis 89

Many dermatoses are associated with infiltrates of lymphocytes around the vessels of the superficial capillary-venular plexus with or without other cell types. The vessel walls may be quite unremarkable, or there may be slight to moderate endothelial swelling. Eosinophilic change ("fibrinoid necrosis"), a hallmark of true vasculitis, is not seen. The term "lymphocytic vasculitis" may encompass some of the conditions mentioned here, but is of doubtful validity in the absence of vessel wall damage. The epidermis is variable in its thickness, amount, and type of exocytotic cells and in the integrity of the basal cell zone (liquefaction

degeneration). In some of the entities listed here, the perivascular infiltrate may in some examples also involve vessels of the mid and deep vessels. These conditions are also listed in Section V.

1. Superficial Perivascular Dermatitis, Lymphocytes Predominant 89

Lymphocytes are seen about the superficial vascular plexus. Other cell types are rare or absent.

morbilliform viral exanthem 659
papular acrodermatitis (Gianotti-Crosti) 184, 418
stasis dermatitis 1034
pityriasis lichenoides et varioliformis acuta (PLEVA), early 196
Jessner's lymphocytic infiltrate 291
candidiasis 597
superficial gyrate erythemas 171
lupus erythematosus, early 287
mixed connective tissue disease 292
dermatomyositis 293
early herpes simplex, zoster 638
morbilliform drug eruption 311
cytomegalovirus inclusion disease 644
polymorphous drug eruption 314
progressive pigmented purpura 169, 952
parapsoriasis, small-plaque type (digitate dermatosis) 182
mucocutaneous lymph node syndrome (Kawasaki's disease) 184
secondary syphilis 579

a. Superficial Perivascular Dermatitis with Eosinophils 89

In addition to lymphocytes, eosinophils are present in varying numbers, with both a perivascular and interstitial distribution.

arthropod-bite reaction 634
allergic urticarial reaction (drug) 311
bullous pemphigoid, urticarial phase 256
erythema toxicum neonatorum 267
Wells' syndrome 467
mastocytosis/telangiectasia macularis eruptiva perstans 159
angiolymphoid hyperplasia with eosinophilia 1007
Kimura's disease 1025
Langerhans cell histiocytosis (early lesions) 668

b. Superficial Perivascular Dermatitis with Neutrophils 89

In addition to lymphocytes, neutrophils are present in varying numbers, with both a perivascular and interstitial distribution.

cellulitis
erysipelas
urticaria
Still's disease
if vasculitis is present, refer to Section III.G

c. Superficial Perivascular Dermatitis with Plasma Cells 89

Plasma cells are seen about the dermal vessels as well as in the interstitium. They are most often admixed with lymphocytes.

secondary syphilis 579
arthropod-bite reaction 634
Kaposi's sarcoma, nonspecific patch stage 1031
actinic keratoses and Bowen's disease 815
Zoon's plasma cell balanitis circumscripta 815
erythroplasia of Queyrat 815

d. Superficial Perivascular Dermatitis, with Extravasated Red Cells 89

A perivascular lymphocytic infiltrate is associated with extravasation of erythrocytes, without fibrinoid necrosis of vessels.

pityriasis rosea 184
lupus erythematosus, subacute 283
lupus erythematosus, early 289
postinflammatory hyperpigmentation 691
stasis dermatitis 1034
Kaposi's sarcoma, patch stage 1031
pityriasis lichenoides et varioliformis acuta (PLEVA) 196
pityriasis lichenoides chronica 196
pigmented purpuric dermatoses (Schamberg's) 225

e. Superficial Perivascular Dermatitis, Melanophages Prominent 89

There is a perivascular infiltrate of lymphocytes with an admixture of pigment-laden melanophages, indicative of prior damage to the basal layer and "pigmentary incontinence." Some degree of residual interface damage may also be evident.

postinflammatory hyperpigmentation 691
postchemotherapy hyperpigmentation 322
chlorpromazine pigmentation 319
amyloidosis 425
regressed pigmented lesion
resolved lichenoid reaction including fixed drug eruption

2. Superficial Perivascular Dermatitis, Mast Cells Predominant 89

Mast cells are the main infiltrating cells seen in the dermis. Lymphocytes are also present, and there may be a few eosinophils.

urticaria pigmentosa, nodular type 158
telangiectasia macularis eruptiva perstans (TMEP), adult mast cell disease 159

B. Superficial Dermatitis with Spongiosis (Spongiotic Dermatitis) 89

Spongiotic dermatitis is characterized by intercellular edema in the epidermis. In mild or early lesions, the intercellular space is increased with stretching of desmosomes but the integrity of the epithelium is intact. In more severe spongiotic conditions, there is separation of keratinocytes to form spaces (vesicles). For this reason, the spongiotic dermatoses are also discussed later in Section IV.

1. Spongiotic Dermatitis, Lymphocytes Predominant 89

There is marked intercellular edema (spongiosis) within the epidermis. In the dermis, perivascular lymphocytes are predominant.

eczematous dermatitis 236
atopic dermatitis 242
allergic contact dermatitis 242
photoallergic drug eruption 318, 241
irritant contact dermatitis 240
nummular dermatitis (eczema) 241
dyshidrotic dermatitis 240
parapsoriasis, small-plaque type (digitate dermatosis) 182
polymorphous light eruption 333
lichen striatus 193
chronic actinic dermatitis (actinic reticuloid) 333
actinic prurigo, early lesions 335
"id" reaction 241
seborrheic dermatitis 243
stasis dermatitis 243
erythroderma 244
miliaria 244
pityriasis rosea 183
Sézary's syndrome 944
papular acrodermatitis (Gianotti-Crosti) 184, 418

a. Spongiotic Dermatitis, with Eosinophils 89

There is marked intercellular edema (spongiosis) within the epidermis. In the dermis, lymphocytes are predominant. Eosinophils can be found in most examples of atopy and allergic contact dermatitis and are numerous in incontinentia pigmenti.

spongiotic (eczematous) dermatitis 237
atopic dermatitis 242
allergic contact dermatitis 242
photoallergic drug eruption 318
incontinentia pigmenti, vesicular stage 161
eczematous nevus (Meyerson's nevus) 730
erythema gyratum repens 171
scabies 626
erythema toxicum neonatorum 267

b. Spongiotic Dermatitis with Plasma Cells 89

There is marked intercellular edema (spongiosis) within the epidermis. In the dermis, perivascular lymphocytes are predominant, and plasma cells are present.

syphilis, primary or secondary lesions 579
pinta, primary or secondary lesions 584
seborrheic dermatitis in HIV infection 243

c. Spongiotic Dermatitis with Neutrophils 89

There is marked intercellular edema (spongiosis) within the epidermis. Lymphocytes are present in the dermis. There is focal and shoulder parakeratosis, with a few neutrophils in the stratum corneum.

dermatophytosis 592
seborrheic dermatitis 243
toxic shock syndrome 546

C. Superficial Dermatitis with Epidermal Atrophy (Atrophic Dermatitis) 90

Most inflammatory dermatoses are associated with epithelial hyperplasia. Only a few chronic conditions exhibit epidermal atrophy.

1. Epidermal Atrophy, Scant Inflammatory Infiltrates 90

The epidermis is thinned—only a few cell layers thick. There is a scanty lymphocytic infiltrate about the superficial capillary-venular plexus.

aged skin 691
chronic actinic damage 691
radiation dermatitis 348
porokeratosis 139
acrodermatitis chronica atrophicans 586
malignant atrophic papulosis 232
poikiloderma atrophicans vasculare 295

2. Epidermal Atrophy, Lymphocytes Predominant 90

The epidermis is thinned but not as marked as in aged or irradiated skin. In the dermis there are many lymphocytes about the superficial capillary-venular plexus.

parapsoriasis/early mycosis fungoides 182, 944
lupus erythematosus 279
mixed connective tissue disease 292
pinta, tertiary lesions 584
dermatomyositis 293

a. Epidermal Atrophy with Papillary Dermal Sclerosis/Matrix Changes 90

The epidermis is thinned, and there can be hyperkeratosis. The dermis is homogenized and edematous; inflammation is minimal.

lichen sclerosus et atrophicus 296
thermal burns 274, 345
parapsoriasis/early mycosis fungoides 183, 944
poikiloderma vasculare atrophicans 295
radiation dermatitis

D. Superficial Dermatitis with Psoriasiform Proliferation (Psoriasiform Dermatitis) 90

Psoriasiform proliferation is a form of epithelial hyperplasia characterized by uniform elongation of rete ridges. Although the surface may be slightly raised to form a plaque, the epidermal proliferation tends to extend downward into the dermis, in contrast to a papillomatous pattern, in which the rete ridges are elongated upward above the plane of the epidermal surface and a papilloma (such as a wart) is formed. The prototype is psoriasis, in which the suprapapillary plates are thinned. In most other psoriasiform conditions, the suprapapillary plates are thickened but not as much as the elongated rete. Because of the increased epithelial turnover, there is often associated hypogranulosis and parakeratosis.

1. Psoriasiform Epidermal Proliferation, Lymphocytes Predominant 90

The epidermis is evenly and regularly thickened in a psoriasiform pattern, spongiosis is variable (rare to absent in psoriasis, common in seborrheic and inflammatory dermatoses). There is an infiltrate of lymphocytes about dermal vessels.

chronic spongiotic dermatitis 237
atopic dermatitis 242
seborrheic dermatitis 243
nummular dermatitis (eczema) 241
lichen simplex chronicus 173, 242
prurigo nodularis 173
psoriasis 174
psoriasiform drug eruptions 322
pityriasis rosea 183
exfoliative dermatitis 175
pityriasis rubra pilaris 195
parapsoriasis/early mycosis fungoides 182, 944
verrucous hyperkeratotic mycosis fungoides 936
inflammatory linear verrucous epidermal nevus (ILVEN) 194
pellagra 408
necrolytic migratory erythema (chronic lesions) 409
acrodermatitis enteropathica 410
kwashiorkor 410
reticulated hyperpigmentations (e.g., Dowling-Degos disease) 689

a. Psoriasiform Epidermal Proliferation, with Plasma Cells 90

The epidermis is evenly thickened and may be spongiotic. There may be exocytosis of lymphocytes. The stratum corneum is variable, often parakeratotic. Plasma cells are found about the superficial vessels in varying numbers admixed with lymphocytes.

arthropod-bite reactions 634
secondary syphilis 579
cutaneous T-cell lymphoma (mycosis fungoides) 936
prurigo nodularis 173

b. Psoriasiform Epidermal Proliferation, with Eosinophils 90

The epidermis is evenly thickened and may be spongiotic, and there may be exocytosis of inflammatory cells, including eosinophils. Eosinophils are easily identified in the dermis and may be numerous in some conditions (e.g., incontinentia pigmenti).

chronic spongiotic dermatitis
chronic allergic dermatitis 237
chronic atopic dermatitis 237
exfoliative dermatitis 175
cutaneous T-cell lymphoma 935
incontinentia pigmenti, verrucous stage 160

2. Psoriasiform Epidermal Proliferation, Neutrophils Prominent (Neutrophilic/Pustular Psoriasiform Dermatitis) 90

The epidermis is evenly thickened, and there is exocytosis (migration of inflammatory cells through the epidermis) of neutrophils. These may collect into abscesses in the epidermis at the level of the stratum corneum (Munro microabscess). The stratum corneum is thickened and parakeratotic and contains neutrophils.

psoriasis vulgaris 174
pustular psoriasis 174
Reiter's syndrome, keratoderma blenorrhagicum 181
pustular drug eruption 326
acute generalized exanthematous pustulosis 314
geographic tongue (lingua geographica) 187, 795
candidiasis 597
pustular secondary syphilis (rare) 582
dermatophytosis 592

3. Psoriasiform Epidermal Proliferation, with Epidermal Pallor or Necrosis ("Nutritional Dermatosis") 90

There may be psoriasiform epidermal hyperplasia, and there is hyperkeratosis with parakeratosis and with pallor, swelling, or necrosis of superficial keratinocytes.

necrolytic migratory erythema 409
necrolytic acral erythema 409
acrodermatitis enteropathica 410
pellagra 408

E. Superficial Dermatitis with Irregular Epidermal Proliferation (Hypertrophic Dermatitis) 90

Irregular thickening and thinning of the epidermis is seen in some reactive conditions, but the possibility of squamous cell carcinoma should also be considered. As in other conditions

associated with increased epithelial turnover, there may be hypogranulosis and parakeratosis.

1. Irregular Epidermal Proliferation, Lymphocytes Predominant 90

The epidermis is irregularly thickened, with areas of normal thickness, acanthosis, and thinning. Lymphocytes are the predominant inflammatory cell about the dermal vessels.

lichen simplex chronicus 173, 242
inflammatory linear verrucous nevus (ILVEN, psoriasiform category) 194
prurigo nodularis 173
incontinentia pigmenti, verrucous stage 160
pellagra (niacin deficiency) 451
Hartnup's disease 451

a. Irregular Epidermal Proliferation, Plasma Cells Present 90

The epidermis is irregularly acanthotic. Plasma cells are found about the dermal vessels admixed with lymphocytes.

squamous cell carcinoma *in situ* (Bowen's disease) 813
erythroplasia of Queyrat 815
rupial secondary syphilis, condyloma lata 582
yaws, primary or secondary 583
pinta, primary or secondary lesions 584
actinic keratosis 807
pseudoepitheliomatous hyperplasia 822
pemphigus vegetans 245

2. Irregular Epidermal Proliferation, Neutrophils Prominent 90

The epidermis has focal areas of acanthosis, and neutrophils can be seen as exocytotic cells and are found in the dermis in abscesses and about dermal vessels without there being a primary vasculitis.

deep fungal infections (superficial biopsy; see later) 604
halogenodermas (Halogen Eruptions) 326
botryomycosis 573
keratoacanthoma 835
impetigo contagiosa 539
granuloma inguinale 570

3. Irregular Epidermal Proliferation, Neoplastic 90

The epidermis is irregularly acanthotic. There is an associated neoplastic infiltrate in the epidermis or dermis or in both.

squamous cell carcinoma
malignant melanoma ("verrucous" pattern) 738
granular cell tumor 1130

F. Superficial Dermatitis with Lichenoid Infiltrates (Lichenoid Dermatitis) 91

Lichenoid inflammation is a dense, "bandlike" infiltrate of small lymphocytes clustered about the dermal–epidermal junction and obscuring the interface. The epidermis is variable in its thickness, amount of exocytotic lymphocytes, and integrity of the basal cell zone (liquefaction degeneration). Hypergranulosis due to delayed epidermal maturation is a commonly associated feature. For the same reason, there may be orthokeratotic hyperkeratosis. Apoptotic or necrotic keratinocytes are often present. In lichen planus, these are called Civatte bodies. Pigmentary incontinence (melanin-laden macrophages in the papillary dermis) is common, as in any condition in which there is destruction of basal keratinocytes.

1. Lichenoid Dermatitis, Lymphocytes Exclusively 91

The bandlike infiltrate is composed almost exclusively of lymphocytes. Eosinophils and plasma cells are essentially absent.

lichen planus–like keratosis (benign lichenoid keratosis) 186
lichen planus 185
pityriasis lichenoides chronica
lupus erythematosus, lichenoid forms 279
mixed connective tissue disease 292
acrodermatitis chronica atrophicans 586
poikiloderma atrophicans vasculare 295
pigmented purpuric dermatitis, lichenoid type (Gougerot-Blum) 226
graft-versus-host disease (GVHD), lichenoid stage 270
erythema multiforme 268
pityriasis lichenoides et varioliformis acuta (PLEVA), early lesions 196
parapsoriasis/mycosis fungoides, patch/plaque stage 182, 936
Sézary's syndrome 944

2. Lichenoid Dermatitis, Lymphocytes Predominant 91

The bandlike lichenoid infiltrate is composed almost exclusively of lymphocytes. A few plasma cells and eosinophils may also be present.

lichen planus–like keratosis (benign lichenoid keratosis) 186
parapsoriasis/mycosis fungoides, patch/plaque stage 182, 936
Sézary's syndrome 944
paraneoplastic pemphigus 254
secondary syphilis 579
halo nevus 730
lichenoid tattoo reaction 361
lichen striatus 193

a. Lichenoid Dermatitis, Eosinophils Present 91

Eosinophils are found in the lichenoid dermal infiltrate, about the dermal vessels, and in some instances around the adnexal structures.

lichenoid drug eruptions 313
lichenoid actinic keratoses 187
lichen planus, hypertrophic 185
arthropod-bite reactions 634
cutaneous T-cell lymphoma, mycosis fungoides, patch/plaque stage 182, 936
histiocytosis X (Letterer-Siwe) 668
mastocytosis/telangiectasia eruptiva macularis perstans 159

b. Lichenoid Dermatitis, Plasma Cells Present 91

Plasma cells are found in the lichenoid infiltrate; their number is variable, but they do not as a rule comprise the major portion of the dermal infiltrate.

lichenoid actinic keratosis 808
lichenoid keratosis (lichen planus–like keratosis) 187
Bowen's disease 813
erythroplasia of Queyrat 815
keratosis lichenoides chronica 192
secondary syphilis 579
pinta, primary or secondary lesions 584
arthropod-bite reaction 634
cutaneous T-cell lymphoma, mycosis fungoides, patch/plaque stage 182, 936
zoon plasma cell balanitis 815
lichen striatus 193

c. Lichenoid Dermatitis, with Melanophages 91

Most of the conditions listed as lichenoid dermatoses may be associated with release of pigment from damaged basal keratinocytes into the papillary dermis—"pigmentary incontinence." If a specific dermatosis cannot be identified, the appearances may be classified as postinflammatory hyperpigmentation.

postinflammatory hyperpigmentation 689

3. Lichenoid Dermatitis, Histiocytes Predominant 91

Histiocytes are the predominant cell type in the dermal infiltrate.

lichen nitidus 192
actinic reticuloid/chronic actinic dermatitis 338
histiocytosis X (Letterer-Siwe, Hand-Schüller-Christian) 669
granulomatous slack skin 936

G. Superficial Vasculitis and Vasculopathies 91

Endothelial swelling, eosinophilic degeneration of the vessel wall ("fibrinoid necrosis"), and infiltration of the vessel wall by neutrophils, with nuclear fragmentation or leukocytoclasia resulting in "nuclear dust," define true vasculitis. There are extravasated red cells in the vessel walls and adjacent dermis. If the vasculitis is severe, ulceration or subepidermal separation ("bullous vasculitis") can occur. "Lymphocytic vasculitis" in which there is no vessel wall damage is a controversial term and is discussed under lymphocytic infiltrates. A "vasculopathy" includes any abnormality of the vessel wall that does not meet the foregoing criteria for vasculitis, such as fibrosis or hyalinization of the vessel wall without inflammation or necrosis.

1. Neutrophilic Vasculitis 91

In the dermis, vessels are necrotic, fibrinoid is present, and there are perivascular and intravascular neutrophils with leukocytoclasia and nuclear dust.

cutaneous necrotizing (leukocytoclastic) vasculitis 205
Henoch-Schönlein purpura 218
cryoglobulinemia 219
connective tissue associated (rheumatoid arthritis, lupus erythematosus) 220
septicemia, especially meningococcemia/gonococcemia 546
urticarial vasculitis 169, 219
erythema elevatum diutinum 221
miscellaneous 228
polyarteritis nodosa 209
vasculitis in exanthemic pustulosis (drug induced) 315

2. Mixed Cell and Granulomatous Vasculitis 91

There is vessel wall damage and a mixed infiltrate in the dermis that includes eosinophils, plasma cells, histiocytes, and giant cells.

Churg-Strauss vasculitis 213
Wegener granulomatosis 214
giant-cell arteritis 207
granuloma faciale 222
Buerger's disease 209

3. Vasculopathies with Scant Inflammation 91

There is fibrosis or hyalinization of the vessel walls, with few inflammatory cells.

atrophie blanche (segmental hyalinizing vasculitis) 231
malignant atrophic papulosis (Degos) 232
Mondor's disease 209
pigmented purpuric dermatoses (Majocchi-Schamberg-Gougerot-Bloom) 225

4. Thrombotic, Embolic, and Other Microangiopathies 91

There are thrombi or emboli within the lumens of small vessels. In other microangiopathies, the vessel walls may be thickened with compromise of the lumen (amyloidosis, calciphylaxis).

disseminated intravascular coagulation 228
thrombotic thrombocytopenic purpura 228

cryoglobulinemia/macroglobulinemia 219
antiphospholipid syndrome 288
lupus anticoagulant and antiocardiolipin syndromes 288
connective tissue disease (rheumatoid, mixed) 220, 286
calciphylaxis 435
amyloidosis 425
porphyria cutanea tarda and other porphyrias 432
cholesterol emboli 230

H. Superficial Dermatitis with Interface Vacuoles (Interface Dermatitis) 91

1. Vacuolar Dermatitis, Apoptotic/Necrotic Cells Prominent 91

Lymphocytes approximate the dermal–epidermal junction. Vacuolar degeneration is present in the basal cell zone. Apoptotic keratinocytes are found in the epidermis in variable numbers, visualized as round, eosinophilic anuclear structures. The dermis usually has perivascular lymphocytes and may show pigment incontinence.

erythema multiforme 268
toxic epidermal necrolysis (Lyell) 268
Stevens-Johnson syndrome 268
fixed drug eruption 314
phototoxic drug eruption 318
radiation dermatitis 270, 348
sunburn reaction 692
thermal burn 343
pityriasis lichenoides et varioliformis acuta (PLEVA) 196
graft-versus-host disease (GVHD), acute 270
eruption of lymphocyte recovery 272
bullous vasculitis 205

2. Vacuolar Dermatitis, Apoptotic Cells Usually Absent 91

There is basilar keratinocyte vacuolar destruction; apoptotic cells are rare or absent. The dermis has perivascular lymphocytes and may show pigment incontinence.

dermatomyositis 293
morbilliform viral exanthem 659
poikiloderma vasculare atrophicans 295
paraneoplastic pemphigus 254
erythema dyschromicum perstans 172
pinta, tertiary stage 584

3. Vacuolar Dermatitis, Variable Apoptosis 91

Vacuolar degeneration is associated with variable numbers of apoptotic cells in the epidermis. The dermis may have increased ground substance, and there may be pigmentary incontinence.

cytotoxic drug eruptions 318
lupus erythematosus 279
drug-induced lupus 318, 287

4. Vacuolar Dermatitis, Basement Membranes Thickened 91

Vacuolar degeneration is associated with variable numbers of apoptotic cells in the epidermis. The basement membrane zone is thickened by deposition of eosinophilic hyaline material.

lupus erythematosus 279

IV. ACANTHOLYTIC, VESICULAR, AND PUSTULAR DISORDERS

Keratinocytes may separate from each other on the basis of immunologic antigen/antibody–mediated damage, resulting in separation and rounding up of keratinocyte cell bodies (acantholysis) on the basis of edema and inflammation (spongiosis) or perhaps on the basis of structural deficiencies of cell adhesion (Darier's disease). These processes produce intraepidermal spaces (vesicles, bullae, pustules).

A. Subcorneal or Intracorneal Separation 92

There is separation within or just below the stratum corneum. Inflammatory cells may be sparse or may consist predominantly of neutrophils.

1. Sub/Intracorneal Separation, Scant Inflammatory Cells 92

There is separation within or just below the stratum corneum, associated with scant inflammation, usually lymphocytic.

staphylococcal scalded skin 539
bullous impetigo 539
miliaria crystallina 244
exfoliative dermatitis 178
pemphigus foliaceus 250
pemphigus erythematosus 252
necrolytic migratory erythema 409
pellagra 408
acrodermatitis enteropathica 410

2. Sub/Intracorneal Separation, Neutrophils Prominent 92

There is separation in or just below the stratum corneum. Neutrophils are prominent in the stratum corneum and in the superficial epidermis and can often be found in the dermis.

impetigo contagiosa 539
epidermis adjacent to folliculitis 542
impetiginized dermatitis 539
candidiasis 597
subcorneal pustular dermatosis (Sneddon-Wilkinson) 267
immunoglobulin A pemphigus 253
secondary syphilis 579
acropustulosis of infancy 267
transient neonatal pustular melanosis 267

3. Sub/Intracorneal Separation, Eosinophils Predominant 92

There is separation in or just below the stratum corneum, with (pemphigus) or without acantholytic keratinocytes. Eosinophils are present in the epidermis, and occasionally there is eosinophilic spongiosis. The separation is associated with a dermal infiltrate that contains eosinophils.

erythema toxicum neonatorum 267
pemphigus foliaceus 250
pemphigus erythematosus 252
immunoglobulin A pemphigus 253
eosinophilic pustular folliculitis 466
incontinentia pigmenti, vesicular 160
exfoliative dermatitis, drug induced 320

B. Intraspinous Keratinocyte Separation, Spongiotic 92

There are spaces within the epidermis (vesicles, bullae). There may be dyskeratosis or acantholysis, and a few eosinophils may be present in the epidermis.

1. Intraspinous Spongiosis, Scant Inflammatory Cells 92

The infiltrate in the dermis is scant, and lymphocytic or eosinophilic.

early spongiotic dermatitis 237
epidermolytic hyperkeratosis 793
epidermolytic acanthoma 793
miliaria rubra 244
transient acantholytic dermatosis 273
bullous dermatitis of diabetes and of uremia 273
coma bulla 316
friction blisters 274

2. Intraspinous Spongiosis, Lymphocytes Predominant 92

In the dermis, lymphocytes predominate. Eosinophils can be found in most examples of atopy and allergic contact dermatitis.

spongiotic (eczematous) dermatitis 237
atopic dermatitis 242
allergic contact dermatitis 273
photoallergic drug eruption 318, 241
irritant contact dermatitis 240
nummular dermatitis (eczema) 318
dyshidrotic dermatitis 240
"id" reaction 241
seborrheic dermatitis 243
stasis dermatitis 243
erythroderma 244
miliaria rubra 244
pityriasis rosea 183

a. Intraspinous Spongiosis, Eosinophils Present 92

The number of eosinophils seen is variable, from many in incontinentia pigmenti and pemphigus vegetans to few in atopic dermatitis.

spongiotic (eczematous) dermatitis 237
atopic dermatitis 242
allergic contact dermatitis 273
photoallergic drug eruption 318
incontinentia pigmenti, vesicular stage

3. Intraspinous Spongiosis, Neutrophils Predominant 92

Neutrophils are seen in the epidermis, stratum corneum, and dermis. Aggregations of neutrophils in the superficial spinous layer constitute the spongiform pustules of Kogoj that are characteristic of psoriasis.

pustular psoriasis 174
Reiter's syndrome 181
immunoglobulin A pemphigus 253
subcorneal pustular dermatosis (Sneddon-Wilkinson) 267
exanthemic pustular drug eruptions 314
impetiginized dermatosis 539
dermatophytosis 592
rupial secondary syphilis 482
seborrheic dermatitis 243
epidermis adjacent to folliculitis 542
impetigo contagiosa 539
hydroa vacciniforme 337
mucocutaneous lymph node syndrome (Kawasaki's disease, pustular variant) 184
if vasculitis is present, refer to Section III.G or Section V.B

C. Intraspinous Keratinocyte Separation, Acantholytic 92

There are spaces within the epidermis (vesicles, bullae). The process of separation is acantholysis. Keratinocytes within the spinous layer detach or separate from each other or from basal keratinocytes. There may be dyskeratosis, and a few eosinophils may be present in the epidermis. The infiltrate in the dermis is variable, composed of lymphocytes with or without eosinophils.

1. Intraspinous Acantholysis, Scant Inflammatory Cells 92

The infiltrate in the dermis is scant, and lymphocytic or eosinophilic.

epidermolytic hyperkeratosis 793
epidermolytic acanthoma 793
Darier's disease 149
isolated keratosis follicularis (warty dyskeratoma) 794
Hailey-Hailey disease 148
transient acantholytic dermatosis 273
focal acantholytic dyskeratosis 794
acantholytic actinic keratosis 808
pemphigus erythematosus 252
pemphigus foliaceus 250
friction blister (cytolytic blister) 274

2. Intraspinous Acantholysis, Predominant Lymphocytes 92

In the dermis, lymphocytes are predominant. In erythema multiforme and related lesions, there is necrosis of individual cells (apoptosis) that may become confluent.

erythema multiforme (with vacuolar and apoptotic changes) 268
Stevens-Johnson syndrome 268
toxic epidermal necrolysis (TEN) 268
herpes simplex, varicella-zoster 637
hydroa vacciniforme (epidermal necrosis) 337
cowpox 646
hand-foot-and-mouth disease (coxsackievirus) 658
orf 647
paraneoplastic pemphigus 254

a. Intraspinous Acantholysis, Eosinophils Present 92

The number of eosinophils seen is variable, from many in incontinentia pigmenti and pemphigus vegetans to few in atopic dermatitis.

pemphigus vegetans 250
pemphigus vulgaris 247
drug-induced pemphigus 253, 317
paraneoplastic pemphigus 254

3. Intraspinous Separation, Neutrophils or Mixed Cell types 92

Inflammatory cells in the dermis include lymphocytes and plasma cells, with or without eosinophils, neutrophils, mast cells, and histiocytes.

acantholytic actinic keratosis 808
acantholytic squamous cell carcinoma 810
hydroa vacciniforme (epidermal necrosis) 337
immunoglobulin A pemphigus 253
herpesvirus infection

D. Suprabasal Keratinocyte Separation 93

There is separation between the keratinocytes of the basal layer and those of the spinous layer.

1. Suprabasal Vesicles, Scant Inflammatory Cells 93

The suprabasal separation may be associated with scant inflammation and frequently with dyskeratotic or atypical keratinocytes.

transient acantholytic dermatosis (Grover) 794
benign familial pemphigus (Hailey-Hailey) 148
Darier's disease (keratosis follicularis) 149
acantholytic actinic keratosis 808
acantholytic squamous cell carcinoma 810
focal acantholytic dyskeratosis

2. Suprabasal Separation, with Keratinocytes Atypia, Lymphocytes, and Often Plasma Cells 93

Suprabasal separation is associated with keratinocyte atypia.

acantholytic actinic keratosis 808
acantholytic squamous cell carcinoma 810

3. Suprabasal Vesicles, Lymphocytes, Eosinophils 92

There is suprabasal separation with eosinophils in the epidermis (eosinophilic spongiosis) and in the dermis.

pemphigus vulgaris 247
pemphigus vegetans 250

E. Subepidermal Vesicular Dermatitis 93

A subepidermal blister refers to separation of the epidermis from the dermis. The roof of the blister is composed of an intact or (partially) necrotic epithelium.

1. Subepidermal Vesicles, Scant/No Inflammation 93

The infiltrate in the dermis in most of these conditions is scant (few lymphocytes, eosinophils, neutrophils).

porphyria cutanea tarda and other porphyrias 432
drug-induced pseudoporphyria 320
bullous pemphigoid, cell poor 256
epidermolysis bullosa simplex 145
epidermolysis bullosa letalis 145
epidermolysis bullosa acquisita (classic) 261
graft-versus-host disease (GVHD), acute 187
acute radiation dermatitis 630
bullous dermatosis of diabetes 273, 395
bullous dermatosis of uremia 435
electrical burn (polarized epidermis) 274
thermal burn (epidermal necrosis) 274, 343
suction blister 275
Vibrio vulnificus septicemia (necrotic bullae) 548

2. Subepidermal Vesicles, Lymphocytes Predominant 93

The epidermis is separated from the dermis, predominantly due to liquefaction of the basal cell layer. In polymorphous light eruption, massive papillary dermal edema is the cause. The infiltrate in the dermis is primarily lymphocytic.

bullous lichen planus (more often histologic than clinical) 185
erythema multiforme 268
fixed drug eruption 314
lichen sclerosus et atrophicus 303
bullous lupus erythematosus, mononuclear type 279
graft-versus-host disease 270
polymorphous light eruption 333
epidermolysis bullosa acquisita (usually neutrophils) 261

3. Subepidermal Vesicles, Eosinophils Prominent 93

The subepidermal blister is associated with a dermal infiltrate rich in eosinophils. Eosinophils may extend into the overlying epidermis.

bullous pemphigoid 235
cicatricial pemphigoid 259
bullous drug eruption 317
herpes gestationis 260
bullous insect-bite reaction 634
dermatitis herpetiformis
(certain old bullae) 259

4. Subepidermal Vesicles, Neutrophils Prominent 93

A neutrophilic infiltrate is seen often in dermal papillae at the dermal–epidermal junction adjacent to the subepidermal blister or in the blister.

dermatitis herpetiformis 259
bullous lupus erythematosus,
neutrophilic type 261, 279
bullous vasculitis 205
linear immunoglobulin A dermatosis
(adult, childhood, drug associated) 236
epidermolysis bullosa acquisita (inflammatory) 261
vesiculopustular eruption of hepatobiliary disease 266
toxic shock syndrome 546
cutis laxa 157

5. Subepidermal Vesicles, Mast Cells Prominent 93

The epidermis is separated from the dermis. There is an infiltrate in the superficial dermis composed almost entirely of mast cells, with or without a few eosinophils. This may be associated with separation of the epidermis from the dermis.

bullous mastocytosis 158

V. PERIVASCULAR, DIFFUSE, AND GRANULOMATOUS INFILTRATES OF THE RETICULAR DERMIS

The dermis serves as a reaction site for a variety of inflammatory, infiltrative, and desmoplastic processes. These include infiltrations of a variety of cells (lymphocytes, histiocytes, eosinophils, plasma cells, melanocytes, etc.); perivascular and vascular reactions; infiltration with organisms and foreign bodies; proliferations of dermal fibers and precursors of dermal fibers as reactions to a variety of stimuli.

A. Superficial and Deep Perivascular Infiltrates without Vascular Damage or Vasculitis 93

In some of the diseases considered here, the infiltrates are predominantly in the upper reticular dermis (urticarial eruptions), whereas others are both superficial and deep (gyrate erythemas). Most of these also involve the superficial plexus. A few diseases are mainly deep (e.g., lupus erythematosus, scleroderma).

1. Perivascular Infiltrates, Lymphocytes Predominant 93

In the dermis there is no vasculitis, only a perivascular surround of lymphocytes as the predominant cell.

pityriasis lichenoides et varioliformis
acuta (PLEVA) 196
stasis dermatitis 1034
acne rosacea 462
discoid lupus erythematosus (DLE) 280
polymorphous light eruption 333
deep gyrate erythemas 171
erythema annulare centrifugum 191
erythema chronicum migrans 926
Jessner's lymphocytic infiltrate 291
reticulated erythematous
mucinosis (REM) 444
perioral dermatitis 462
papular acrodermatitis
(Gianotti-Crosti) 184, 418
leprosy, indeterminate 550
"tumid" lupus erythematosus 280
perniosis (chilblains) 526

2. Perivascular Infiltrates, Neutrophils Predominant 93

Neutrophils are seen in perivascular or perivascular and diffuse patterns in the dermis. Edema is prominent in some instances (Sweet's syndrome).

acute febrile neutrophilic dermatosis
(Sweet's syndrome) 223
cellulitis/erysipelas 541
necrotizing fasciitis 541
pyoderma gangrenosum (early) 411
ecthyma gangrenosum 547
neutrophil-rich urticaria 169
solar urticaria 340
rheumatoid neutrophilic dermatosis
if vasculitis is present, refer to Section V.B

3. Perivascular Infiltrates, Lymphocytes and Eosinophils 93

Lymphocytes and eosinophils are mixed in the infiltrate. Lymphocytes are always seen; eosinophil numbers may vary, being greatest in bite reactions and often (though variable and sometimes very few) in eosinophilic fasciitis.

urticaria/angioedema 169
pruritic and urticarial papules and
plaques of pregnancy (PUPPP) 170
prurigo simplex 173
papular urticaria 634
morbilliform drug eruption 311

photoallergic reaction 338
eosinophilic fasciitis/scleroderma 295
angiolymphoid hyperplasia with eosinophilia (AHLE) 1022
insect-bite reaction 634
if vasculitis is present, refer to Section V.B

4. Perivascular Infiltrates, with Plasma Cells 93

In addition to lymphocytes, plasma cells are found in the dermal infiltrate.

primary syphilitic chancre 580
erythema chronicum migrans 586
acne rosacea 463
perioral dermatitis 462
scleroderma/morphea 295
secondary syphilis 581
Kaposi's sarcoma, early lesions 1029

B. Vasculitis and Vasculopathies 94

True vasculitis is defined by eosinophilic degeneration of the vessel wall ("fibrinoid necrosis"), infiltration of the vessel wall by neutrophils, with neutrophils, nuclear dust, and extravasated red cells in the vessel walls and adjacent dermis. Some of the conditions mentioned here lack these prototypic findings and may be termed "vasculopathies" (e.g., Degos' disease)

1. Vascular Damage, Scant Inflammatory Cells 94

Although there is significant vascular damage, there is little early inflammatory response.

Degos' disease (malignant atrophic papulosis) 232
atrophie blanche 231

2. Vasculitis, Lymphocytes Predominant 94

The term "lymphocytic vasculitis" is controversial, but there are some conditions in which perivascular and intramural lymphocytes may be associated with some degree of vasculopathy, not usually including frank fibrinoid necrosis. Most of these conditions are discussed elsewhere as "perivascular lymphocytic infiltrates." In angiocentric lymphomas, the cells infiltrating the vessel walls are neoplastic, but the process may be mistaken for an inflammatory reaction.

"lymphocytic vasculitis" 224
lupus erythematosus 279
lymphomatoid papulosis 935
pityriasis lichenoides et varioliformis acuta (PLEVA) 196
pityriasis lichenoides chronica 196
purpura pigmentosa chronica 225
morbilliform viral infections 659
Lyme disease 585
perniosis (chilblains) 526
angiocentric mycosis fungoides 936
angiocentric T-cell lymphoma/lymphomatoid granulomatosis 933
cytomegalovirus inclusion disease 644
Behçet's syndrome 412

3. Vasculitis, Neutrophils Prominent 94

Neutrophils are prominent in the infiltrate, with fibrinoid necrosis and nuclear dust; eosinophils and lymphocytes are also found.

small-vessel leukocytoclastic vasculitis 215
neutrophilic dermatoses 333
Sweet's syndrome 223
granuloma faciale 221
bowel-associated dermatosis-arthrosis syndrome 224, 412
septic/embolic lesions of gonococcemia/meningococcemia 548
Rocky Mountain spotted fever (*Rickettsia rickettsii*) 568
polyarteritis nodosa 209
erythema elevatum diutinum 221
Behçet's syndrome 412
papulonecrotic tuberculid 554
mixed cryoglobulinemia

4. Vasculitis, Mixed Cell Types and/or Granulomas 94

Histiocytes and giant cells are a part of the infiltrate. Lymphocytes and eosinophils can also be found, depending on the diagnosis. Giant cell arteritis is a true inflammation of the artery wall (true arteritis), although there is no fibrinoid necrosis.

allergic granulomatosis (Churg-Strauss syndrome) 213
Wegener granulomatosis 214
giant cell arteritis (temporal arteritis) 207
erythema chronicum migrans 586
erythema nodosum leprosum 564
some insect-bite reactions 234
"secondary vasculitis" at the base of ulcers of diverse etiology 205
Behçet's syndrome 412
Granuloma faciale 222

5. Thrombotic and Other Microangiopathies 94

The dermal vessels contain fibrin, red cells, and platelet thrombi and/or eosinophilic protein precipitates.

septicemia 221
disseminated intravascular coagulation 228
coumarin necrosis 228
amyloidosis 425
porphyria cutanea tarda and other porphyrias 431
calciphylaxis 230, 543
thrombophlebitis and superficial migratory thrombophlebitis 209
Lucio reaction 565
cryoglobulinemia, type I
anticardiolipin antibodies

C. Diffuse Infiltrates of the Reticular Dermis 94

Diffuse infiltrates of the reticular dermis may show some relation to vessels or to skin appendages or may be randomly distributed in the reticular dermis.

1. Diffuse Infiltrates, Lymphocytes Predominant 94

Lymphocytes are seen almost to the exclusion of other cell types.

cutaneous lymphoid hyperplasia/ lymphocytoma cutis 915
Jessner's lymphocytic infiltrate 291
leukemia cutis (lymphocytic lymphoma, chronic lymphocytic leukemia) 957

2. Diffuse Infiltrates, Neutrophils Predominant 94

Neutrophils are the main infiltrating cell although lymphocytes can be found.

cellulitis 541
dermis adjacent to folliculitis 542
abscess 542
acute neutrophilic dermatosis (Sweet's syndrome) 223
rheumatoid neutrophilic dermatosis 223
granuloma faciale 222
pyoderma gangrenosum 411
neutrophilic dermatosis of the dorsal hands 223
cutaneous reaction to cytokines especially granulocyte colony-stimulating factor 322
bowel arthrosis dermatosis syndrome 412
erythema elevatum diutinum 221
Behçet's syndrome 412

3. Diffuse Infiltrates, "Histiocytoid" Cells Predominant 94

Histiocytes or histiocytoid cells are found in great numbers in the dermal infiltrate. Some may be foamy; others may contain organisms. The leukemic cells of myeloid leukemia may be easily mistaken for histiocytes and may have histiocytic differentiation (myelomonocytic leukemia).

xanthelasma, xanthomas (usually nodular) 681
atypical mycobacteria
Mycobacterium avium-intracellulare (MAI) 555
deep fungus infection
cryptococcosis 609
histoplasmosis 611
paraffinoma 374
silicone granuloma 374
talc and starch granuloma 375
annular elastolytic giant cell granuloma (actinic granuloma) 364
"histiocytoid" Sweet's syndrome 223
lepromatous leprosy 560
histoid leprosy 562
cutaneous leishmaniasis 621
rhinoscleroma (*Klebsiella rhinoscleromatis*) 570
histiocytosis X 667
leukemia cutis (myeloid, myelomonocytic) 958
anaplastic large cell lymphoma (Ki-1) 952
reticulohistiocytic granuloma 948
malakoplakia 549
Rosai-Dorfman disease 678

4. Diffuse Infiltrates, Plasma Cells Prominent 94

Plasma cells are found in the diffuse dermal infiltrate, although they may not be the predominant cell type.

insect-bite reaction 634
plasmacytoma, myeloma 922
circumorificial plasmacytosis 922
syphilis, secondary or tertiary 579
yaws, primary or secondary 583
acne keloidalis nuchae 544

5. Diffuse Infiltrates, Mast Cells Predominant 94

Mast cells compose almost the entire dermal infiltrate. There may be an admixture of eosinophils.

urticaria pigmentosa 158

6. Diffuse Infiltrates, Eosinophils Predominant 94

Eosinophils are prominent, although they are not the only infiltrating cell type. Lymphocytes are also found, and plasma cells may also be present.

eosinophilic cellulitis (Wells' syndrome) 467
insect-bite reaction 634
granuloma faciale 222

7. Diffuse Infiltrates, Mixed Cell Types 94

The diffuse infiltrate contains plasma cells, lymphocytes, histiocytes, and a variety of acute inflammatory cells.

syphilis, primary, secondary, or tertiary 579
acrodermatitis chronica atrophicans 586
cutaneous reactions to cytokines 322
chronic actinic dermatitis (actinic reticuloid) 333
rhinosporidiosis 615
rhinoscleroma 622
histoplasmosis 611
dermal hematopoiesis (extramedullary hematopoiesis) 956
cutaneous leishmaniasis 621
granuloma inguinale 570
granuloma gluteale infantum 381
persistent nodular scabies 627

8. Diffuse Infiltrates, Pigment Cells 94

The diffuse infiltrate contains bipolar, cuboidal, or dendritic cells with brown cytoplasmic pigment.

Mongolian spot 699
nevus of Ota, nevus of Ito 700
dermal melanocytic hamartoma 700

9. Diffuse Infiltrates, Extensive Necrosis 94

Vascular and dermal necrosis is found secondary to vascular occlusion or to destruction by organisms.

tertiary syphilis 583
sporotrichosis 612
deep fungus 591
atypical mycobacteria 549
infarcts 230
vasculitis and deep vasculitis 205
thrombi and deep thrombi 205
calciphylaxis (cutaneous necrosis/
calcification syndrome) 230, 435
gangrenous ischemic necrosis 230

D. Diffuse or Nodular Infiltrates of the Reticular Dermis with Epidermal Proliferation 95

Ill-defined nodules or diffuse infiltrates of inflammatory cells, usually including lymphocytes, plasma cells, and neutrophils, are present in the dermis, and the epidermis is irregularly thickened.

1. Epidermal Proliferation with Mixed Cellular Infiltrates 95

squamous cell carcinoma 817
pseudoepitheliomatous hyperplasia 822
halogenodermas (Halogen Eruptions) 326
deep fungus infections
North American blastomycosis 603
paracoccidioidomycosis 605
chromoblastomycosis 607
coccidioidomycosis 608
rhinosporidiosis 615
protothecosis 615
verrucous cutaneous leishmaniasis 621
verrucous lupus vulgaris 551
tuberculosis verrucosa cutis 551
Mycobacterium marinum 555
granuloma inguinale
(*Calymmatobacterium* granulomatis) 570
pyoderma vegetans 546
verruciform xanthoma 685
verrucose sarcoidosis 370
granuloma gluteale infantum 381
verrucous lupus erythematosus 280

E. Nodular Inflammatory Infiltrates of the Reticular Dermis: Granulomas, Abscesses, and Ulcers 95

A granuloma is defined as a collection of histiocytes, which may have abundant cytoplasm and confluent borders ("epithelioid histiocytes"), often with Langhans type giant cells. Granulomas may be associated with necrosis or may palisade around areas of necrobiosis, may be mixed with other inflammatory cells, may include foreign-body giant cells, and may contain ingested foreign material or pathogens (acid-fast bacilli, fungi). An abscess is a localized area of suppurative necrosis containing abundant neutrophils mixed with necrotic debris and usually surrounded by a reaction of granulation tissue and fibrosis.

1. Epithelioid Cell Granulomas without Necrosis 95

Large epithelioid histiocytes are common in the infiltrate, as are giant cells. The infiltrate may also contain a few plasma cells as well as lymphocytes.

sarcoidosis (lupus pernio and other types) 370
lichen scrofulosorum 554
granulomatous granuloma annulare 361
foreign-body granulomas 365
syphilis, secondary or tertiary 581
granulomatous rosacea 463
cheilitis granulomatosa
(Miescher-Melkersson-Rosenthal) 380
tuberculoid leprosy 563
tuberculosis
lupus vulgaris 551
Crohn's disease 415
allergic granulomatous reactions to chemical
agents (silica, zirconium, aluminum,
beryllium granulomas) 373
collagen implant granuloma 378
granulomatous mycosis fungoides 941
chronic cutaneous leishmaniasis 623

2. Epithelioid Cell Granulomas with Necrosis 95

The presence of necrosis in an epithelioid cell granuloma of the skin strongly suggests tuberculosis except in lesions of the face. Epithelioid sarcoma may simulate a necrotizing granuloma.

tuberculosis 550
tuberculosis verrucosa cutis 551
miliary tuberculosis 551
lupus vulgaris (necrosis usually
slight or absent) 551
nontuberculosis mycobacteria 555
lupus miliaris disseminatus faciei 465
granulomatous rosacea 373
tertiary syphilis 583
epithelioid sarcoma 995
cryptococcosis 609
histoplasmosis 611

3. Palisading Granulomas 95

There are foci of altered collagen ("necrobiosis") surrounded by histiocytes and lymphocytes. Histiocytic giant cells may also be seen in the infiltrate. The lesions of epithelioid sarcoma are associated with true tumor necrosis but may superficially resemble rheumatoid nodules.

granuloma annulare 361
rheumatoid nodule 367
necrobiosis lipoidica 365
subcutaneous granuloma annulare 361

annular elastolytic giant-cell granuloma
(actinic granuloma) 364
rheumatic nodule 368
epithelioid sarcoma 995
occasional examples of deep fungus infections 363
necrobiotic xanthogranuloma 683
palisading necrotizing granuloma 213
palisaded neutrophilic and
granulomatosis (PNGD) 368

4. Mixed Cell Granulomas 95

Lymphocytes and plasma cells are present in addition to epithelioid histiocytes, which may form loose clusters, and giant cells, which may be quite inconspicuous. Organisms are found in many of these granulomatous infiltrates. Keratin granuloma is the most common mixed granuloma. Flakes of keratin may be appreciated as fibers, often gray rather than pink, in the cytoplasm of giant cells.

keratin granuloma
ruptured cyst 373, 801
folliculitis with rupture 542
sporotrichosis 612
persistent arthropod bite 634
syphilis, secondary and tertiary 581
cryptococcosis 609
candidal granuloma 598
nontuberculosis mycobacteria 555
cat-scratch disease 571
North American blastomycosis 603
South American blastomycosis 605
chromomycosis 607
phaeohyphomycosis 601
coccidioidomycosis 608

5. Inflammatory Nodules with Prominent Eosinophils 95

The nodular dermal infiltrates contain many eosinophils, often admixed with lymphocytes.

angiolymphoid hyperplasia with eosinophils 1022
Kimura's disease 1025
scabietic nodule 626

6. Inflammatory Nodules with Mixed Cell Types 95

There is a variety of cells in the infiltrate, including neutrophils, histiocytes, plasma cells, giant cells, and lymphocytes.

chronic bacterial infections 555
keratin granuloma
ruptured cyst 373, 801
folliculitis 542
sporotrichosis 612
rhinoscleroma (*Klebsiella rhinoscleromatis*) 570
atypical mycobacteria 549
Mycobacterium avium-intracellulare 555
Mycobacterium marinum 555
nocardiosis 574
lobomycosis 606
protothecosis 615

7. Inflammatory Nodules with Necrosis and Neutrophils (Abscesses) 95

Inflammatory nodules are characterized by central suppurative necrosis, with neutrophils adjacent to the necrosis and often with granulation tissue, mixed inflammatory cells including epithelioid histiocytes and giant cells, and fibrosis at the periphery.

acute or chronic bacterial abscesses 567
deep fungal infections 604
phaeohyphomycotic cyst 602
North American blastomycosis 603
chromoblastomycosis 607
cutaneous alternariosis 603
paracoccidioidomycosis 605
coccidioidomycosis 608
sporotrichosis 612
botryomycosis 573
actinomycosis 574
nocardiosis 574
cat-scratch disease 571
erythema nodosum leprosum
(type 2 leprosy reaction) 564
scrofuloderma 552
tuberculous gumma 552
protothecosis 615

8. Inflammatory Nodules with Prominent Necrosis 95

Necrosis is a striking feature along with variable but sometimes sparse infiltrates of inflammatory cells, which may include plasma cells, epithelioid histiocytes, neutrophils, lymphocytes, and hemorrhage. Organisms may be demonstrable. Epithelioid sarcoma may simulate an inflammatory lesion.

tertiary syphilis 583
tertiary yaws 584
aspergillosis 599
zygomycosis (mucormycosis) 599
tuberculosis 550
atypical mycobacteria 549
infarcts 230
deep vasculitis 205
deep thrombi 205
calciphylaxis 230, 435
frostbite 352
necrobiotic xanthogranuloma with
paraproteinemia 367, 683
gangrenous ischemic
necrosis 230
epithelioid sarcoma 995

9. Chronic Ulcers and Sinuses Involving the Reticular Dermis 95

A chronic ulcer is characterized by central suppurative necrosis, with neutrophils adjacent to the necrosis and often with granulation tissue, fibrosis, and reactive epithelium at the periphery. A sinus extends deeper into the dermis than most ulcers, in a serpentine fashion. A fistula is an abnormal communication between two epithelial-lined surfaces. The histologic architecture of fistulas and sinuses is similar to that of chronic ulcers.

pyoderma gangrenosum 411
ecthyma gangrenosum 547
deep fungal infection
North American blastomycosis 603
eumycetoma 614
tuberculosis cutis orificialis 553
enterocutaneous fistula 415
chondrodermatitis nodularis helicis 492
ecthyma 541
papulonecrotic tuberculid 554
Buruli ulcer (*Mycobacterium ulcerans*) 556
chancroid (*Haemophilus ducreyi*) 569
granuloma inguinale
(*Calymmatobacterium granulomatis*) 570
lymphogranuloma venereum
(*Chlamydia trachomatis*) 571
follicular occlusion disorder
pilonidal sinus 545
hidradenitis suppurativa 544
acne conglobata 544
perifolliculitis capitis abscedens et suffodiens
(dissecting cellulitis of the scalp) 544
anthrax (*Bacillus anthracis*) 567
tularemia (*Francisella tularensis*) 568
cutaneous leishmaniasis 621
necrotizing sialometaplasia of the hard palate 813
eosinophilic ulcer of the tongue 813

F. Dermal Matrix Fiber Disorders 96

The dermis serves as a reaction site for a variety of inflammatory, infiltrative, and desmoplastic processes. These may include accumulations or deficiencies of dermal fibrous and nonfibrous matrix constituents as reactions to a variety of stimuli.

1. Fiber Disorders, Collagen Increased 96

Dermal collagen is increased with production at the dermal–subcutaneous interface. Inflammation is seen at this site. The inflammatory cells are lymphocytes, plasma cells, and eosinophils. In some instances fibroblasts are increased.

scar, keloid 979
scleroderma/morphea 295
phytonadione-induced pseudoscleroderma 316
necrobiosis lipoidica 365
eosinophilic fasciitis 303
radiation fibrosis 349
nephrogenic systemic fibrosis (nephrogenic
fibrosing dermopathy) 301, 316
fibroblastic rheumatism 307
sclerodermoid graft-versus-host
disease (GVHD) 270
acrodermatitis chronica atrophicans 586
facial hemiatrophy 588
chronic lymphedema 527, 1029
necrobiosis lipoidica 365
acro-osteolysis 401

2. Fiber Disorders, Collagen Reduced 96

Collagen may be reduced focally or diffusely as part of an inborn error of collagen fiber metabolism or as an acquired phenomenon.

Ehlers-Danlos syndrome 155
Marfan's syndrome 394
penicillamine-induced atrophy 325
striae distensae 398
aplasia cutis 142
focal dermal hypoplasia (Goltz) 142
atrophoderma (Pasini and Pierini) 301
relapsing polychondritis (type II collagen
degeneration of cartilage) 493

3. Fiber Disorders, Elastin Increased or Prominent 96

Abnormal elastic fibers are increased focally in the dermis and may become calcified (pseudoxanthoma elasticum), or there may be diffuse elastosis in the superficial reticular dermis of sun-exposed skin.

pseudoxanthoma elasticum 152
penicillamine-induced elastosis perforans 325
solar elastosis 390
erythema ab igne 347
annular elastolytic giant cell granuloma
(actinic granuloma) 364

4. Fiber Disorders, Elastin Reduced 96

Elastin may be reduced focally or diffusely as part of an inborn error of metabolism or as an acquired phenomenon.

cutis laxa 157
anetoderma 399
middermal elastolysis 399
annular elastolytic giant cell granuloma
(actinic granuloma) 364

5. Fiber Disorders, Perforating 96

Abnormal elastin or collagen fibers may be extruded through the epidermis, which may form channels that extend down into the dermis.

elastosis perforans serpiginosa 393
Kyrle's disease 392
perforating folliculitis 392
reactive perforating collagenosis 395
perforating disorder of renal failure
and diabetes 395

perforating calcific elastosis 396
perforating granuloma annulare 361

G. Deposition of Material in the Dermis 96

The dermis serves as a reaction site for a variety of inflammatory, infiltrative, and desmoplastic processes, which may include accumulations of matrix molecules that may be indigenous to the normal dermis or foreign to it.

1. Increased Normal Nonfibrous Matrix Constituents 96

Ground substance (hyaluronic acid) is increased, associated with a varying inflammatory infiltrate that can include lymphocytes, plasma cells, and eosinophils.

granuloma annulare 361
pretibial myxedema 441
generalized myxedema 441
juvenile cutaneous mucinosis 445
papular mucinosis (lichen myxedematosus) 441
scleromyxedema 444
reticular erythematous mucinosis (REM) 444
scleredema 445
focal dermal mucinosis 997
digital mucous cyst/myxoid cyst 997
cutaneous myxoma 997
mucocele, mucinous mucosal cyst 997
lupus erythematosus 279
hereditary progressive mucinous histiocytosis 677
nephrogenic systemic fibrosis (nephrogenic fibrosing dermopathy) 301

2. Deposition of Material Not Normally Present in the Dermis 96

Materials not present in substantial amounts in the normal dermis are deposited as crystals (gout), amorphous deposits (calcinosis), hyaline material (colloid milium, amyloidosis, porphyria), or pigments.

gout 438
colloid milium 429
calcinosis cutis 299, 435
calcinosis universalis, circumscripta (scleroderma) 436
tumoral calcinosis 437
idiopathic calcinosis of the scrotum 437
subepidermal calcified nodule 437
amyloidosis 425
dermal pigments 319
minocycline 324
argyria 327
chrysiasis 327
mercury pigmentation 327
hemochromatosis 449
endogenous ochronosis (alkaptonuria) 439
calcaneal petechiae (hemoglobin) 356
lipoid proteinosis (hyalinosis cutis et mucosae, Urbach-Wiethe) 430
cryoglobulinemia 219
porphyria cutanea tarda 432
foreign material: dirt, glass, paraffin, grease, etc. 373
tattoo reactions 377
silicone, talc, starch 374
cactus, sea urchin, hair granulomas 375
intralesional steroids 380
vaccines, aluminum 376
Hunter's syndrome (lysosomal granules) 447

3. Parasitic Infestations of the Dermis and/or Subcutis 96

Macroscopically visible parasitic agents may infest the dermis and subcutis.

subcutaneous dirofilariasis 628
onchocerciasis 629
strongyloidiasis 628
schistosomiasis 631
subcutaneous cysticercosis 632
myiasis 632

VI. TUMORS AND CYSTS OF THE DERMIS AND SUBCUTIS

Neoplasms in the reticular dermis may arise from any of the tissues included in the dermis—lymphoreticular tissue, connective tissue, and epithelial tissue of the skin appendages. In addition, metastases commonly present in the dermis and subcutis.

A. Small Cell Tumors 96

A neoplastic nodule is a circumscribed collection of neoplastic cells in the dermis. Abscesses, granulomas, and cysts may also present as nodules. Cysts are considered separately. In general, neoplastic nodules can be differentiated from reactive and inflammatory nodules by the presence of a monotonous population of cells consistent with a clonal proliferation, whereas inflammatory nodules are composed of inflammatory cell types (lymphocytes, neutrophils, histiocytes, etc.), generally in a heterogeneous mixture.

1. Tumors of Lymphocytes or Hemapoietic Cells 96

Nodular infiltrates or extensive diffuse infiltrates of normal and/or atypical lymphocytes are found in the dermis.

cutaneous T-cell lymphoma
lymphoblastic lymphoma, T-cell type 955
tumor-stage mycosis fungoides 936
adult T-cell leukemia/lymphoma 953
cutaneous B-cell lymphoma
lymphoblastic lymphoma, B-cell type 922
small lymphocytic lymphoma 925
immunocytoma (lymphoplasmacytoid lymphoma) 925

primary cutaneous follicle center lymphoma 917
diffuse large B-cell lymphoma (centroblastic/immunoblastic) 930
leukemia cutis 957
drug-induced pseudolymphoma 320
aluminum granuloma 376
pseudolymphomatous tattoo reaction 377

2. Tumors of Lymphocytes and Mixed Cell Types 96

Nodular infiltrates or extensive diffuse infiltrates of normal lymphocytes are found in the dermis. Other reactive cell types (plasma cells, histiocytes) are admixed.

cutaneous lymphoid hyperplasia/lymphocytoma cutis 915
Lennert's (lymphoepithelial) lymphoma 951
chronic myleogenous leukemia 957
angioimmunoblastic lymphadenopathy 952
borrelial lymphocytoma cutis 588

3. Tumors of Plasma Cells 96

Nodular plasma cell infiltrates, with scattered lymphocytes.

cutaneous plasmacytoma and myeloma 923

4. Small Round Cell Tumors 96

Tumors of small cells with scant cytoplasm and with small dark nuclei constitute a group of tumors that can usually be distinguished from one another with appropriate immunohistochemical investigations in conjunction with light microscopic and clinical information. Some of these tumors arise in the deep soft tissue, but they may rarely present in a deep skin biopsy.

primitive neuroepithelial tumors (PNET)
peripheral neuroblastoma/neuroepithelioma . .1139
Ewing's sarcoma 995
cutaneous small cell undifferentiated carcinoma (CSCUC/Merkel's cell tumor) 1138
melanotic neuroectodermal tumor of infancy 1141
lymphoma/leukemia 911
rhabdomyosarcoma 1084
metastatic neuroectodermal carcinoma 1158
small cell melanoma 749
small cell carcinoma (squamous or adenocarcinoma) 1153
eccrine spiradenoma 888
lymphoepithelioma-like carcinoma 819

B. Large Polygonal and Round Cell Tumors 97

1. Squamous Cell Carcinomas 97

Proliferations of atypical cells with more or less abundant cytoplasm, contiguous cell borders, evidence of keratinization, and/or desmosomes occupy the dermis as nodular masses. Most primary squamous cell carcinomas show evidence of epidermal origin, often with associated squamous cell carcinoma *in situ*.

primary squamous cell carcinoma. 817
metastatic squamous cell carcinoma 1154

2. Adenocarcinomas 97

Proliferations of atypical cells with more or less abundant cytoplasm and with evidence of gland formation and/or mucin production occupy the dermis as nodular masses. The possibility of metastatic adenocarcinoma must be considered and differentiated from the possibility of a primary cutaneous adenocarcinoma of skin appendages (refer to the eccrine, apocrine, pilar, and sebaceous tumor sections that follow).

primary adenocarcinoma of skin adnexal origin (see later discussion) 896
mucin-producing squamous cell carcinoma simulating adenocarcinoma 821
mucoepidermoid carcinoma 821
adenosquamous carcinoma 821
metastatic adenocarcinoma 1155

3. Melanocytic Tumors 97

The proliferations in the dermis are melanocyte derived, pigmented or amelanotic, benign, atypical, or malignant. Superficial lesions may involve the epidermis (junctional component). There may be a fibrous and inflammatory host response. S100 and HMB-45 stains may be of value in recognizing melanocytic differentiation in amelanotic tumors.

superficial melanocytic nevi
compound melanocytic nevus 712
dermal melanocytic nevus, acquired type 714
dermal recurrent melanocytic nevus 717
dysplastic nevi, compound 717
nevus of genital skin 717

satellites and in-transit metastatic
melanoma 768
dermal and subcutaneous metastatic
melanoma 767

4. Eccrine Tumors 97

Proliferations of eccrine ductal (small, dark cells usually forming tubules at least focally) or glandular tissue or both occur in a hyalinized or sclerotic dermis. The inflammatory infiltrate is mainly lymphocytic.

circumscribed, symmetric
eccrine nevus 883
papillary eccrine adenoma 890
clear cell (nodular) hidradenoma
(eccrine acrospiroma) 891
syringoma 884
chondroid syringoma 893
eccrine spiradenoma 888
cylindroma (some consider apocrine) 881
eccrine syringofibroadenoma 888
mucinous syringometaplasia 888
infiltrative, asymmetric
microcystic adnexal carcinoma (sclerosing
sweat duct carcinoma) 896
malignant chondroid syringoma 894
malignant clear cell (nodular) hidradenoma
(malignant acrospiroma) 891
malignant eccrine spiradenoma 890
malignant eccrine poroma
(porocarcinoma) 887
eccrine adenocarcinoma 896
mucinous eccrine carcinoma 898
adenoid cystic eccrine carcinoma 899
aggressive digital papillary adenoma/
adenocarcinoma 899
syringoid eccrine carcinoma 831, 896

5. Apocrine Tumors 97

Tumors in the dermis are composed of proliferations of apocrine ductal and glandular epithelium (large, pink cells with decapitation secretion). The stroma is sclerotic and well vascularized, and the inflammatory cells are mainly lymphocytes.

circumscribed, symmetric
apocrine nevus 876
tubular apocrine adenoma
('tubulopapillary hidradenoma") 880
cylindroma (some consider eccrine) 881
hidradenoma papilliferum 878
syringocystadenoma papilliferum 878
apocrine hidrocystoma 877
infiltrative, asymmetric
apocrine adenocarcinoma 895
malignant cylindroma 883
erosive adenomatosis of the nipple
(florid papillomatosis) 881

6. Pilar Tumors 97

The dermal infiltrating tumor is composed of epithelium that differentiates toward hair or is a proliferation of portions of the follicular structure and its stroma. The inflammatory cell infiltrate is mainly lymphocytic, and the dermis is fibrocellular.

follicular infundibular neoplasms
dilated pore of Winer 855
pilar sheath acanthoma 855
trichilemmoma 867
tumor of the follicular infundibulum 869
branching and lobular pilosebaceous neoplasms
trichofolliculoma 854
trichoepithelioma 857
tumor of follicular infundibulum 869

tumors of pilosebaceous mesenchyme
trichodiscoma 856
fibrofolliculoma 856
tumors of the arrector pili muscle 1075

infiltrative, asymmetric
pilomatrix carcinoma (malignant pilomatricoma) 864
trichilemmal carcinoma 870
basal cell carcinoma with follicular differentiation 832

7. Sebaceous Tumors 97

The dermal masses are proliferations of the germinative epithelium and of mature sebocytes. The admixture of these cells varies from one tumor to another. The dermis is fibrocellular.

symmetric, circumscribed
sebaceous hyperplasia 465, 872
Fordyce's condition (ectopic sebaceous glands in mucosae) 872
rhinophyma 463
nevus sebaceous 853
sebaceous adenoma 873
sebaceous epithelioma 873
sebaceous trichofolliculoma 855
infiltrative, asymmetric
sebaceous carcinoma 875
basal cell carcinoma with sebaceous differentiation 831

8. "Histiocytoid" Tumors 97

"Histiocytes" may have foamy cytoplasm reflecting the accumulation of lipids or may have eosinophilic or amphophilic cytoplasm surrounding an ovoid nucleus with open chromatin. Some nonhistiocytic lesions whose cells may simulate histiocytes are also included here.

foamy histiocytes
xanthomas: eruptive, plane, tuberous, tendon 680
verruciform xanthoma 685
xanthelasma 681
cholestanolemia, phytosterolemia 680
xanthoma disseminatum 675
diffuse normolipemic plane xanthoma 684
papular xanthoma 673
eruptive normolipemic xanthoma 684
progressive nodular histiocytosis (superficial) 677
Langerhans cell histiocytosis (rare xanthomatous type) 669
lepromatous leprosy 560
dermatofibroma with xanthomatous change
nonfoamy histiocytes
dermatofibroma/histiocytoma
Langerhans cell histiocytosis 669
congenital self-healing reticulohistiocytosis 669
indeterminate cell histiocytosis 678
granuloma annulare 361
eruptive histiocytomas 678
benign cephalic histiocytosis 677
sinus histiocytosis with massive lymphadenopathy 678
juvenile xanthogranuloma 672
epithelioid cell histiocytoma
giant cells prominent
juvenile xanthogranuloma 672
multicentric reticulohistiocytosis 675
giant cell reticulohistiocytoma 675
necrobiotic xanthogranuloma with paraproteinemia 683
xanthoma disseminatum 675
histiocytic simulants
pleomorphic large cell lymphoma (Ki-1, usually T cells) 952
epithelioid sarcoma 995
leukemia cutis 957

9. Tumors of Large Lymphoid Cells 97

Large lymphoid cells may be mistaken for carcinoma or melanoma cells but can be distinguished morphologically by their tendency to exhibit less cohesive growth in large sheets, by the absence of epithelial or melanocytic differentiation, and by immunopathology.

pleomorphic peripheral T-cell lymphoma 950
cutaneous anaplastic large cell lymphoma (CD30 [Ki-1] lymphoma, regressing atypical histiocytosis) . . .952
leukemia cutis 957
cutaneous Hodgkin's disease 933

10. Mast Cell Tumors 97

Mast cells predominate in a nodular dermal infiltrate, with scattered eosinophils.

mastocytosis 158

11. Tumors with Prominent Necrosis 97

Necrosis is a striking feature in epithelioid sarcoma, which as a result may be mistaken for a granulomatous process. In addition, many advanced malignancies, often metastatic, have prominent necrosis.

epithelioid sarcoma 995
some metastatic carcinomas, sarcomas, melanomas 1154
occasional advanced primary malignant tumors 749, 791, 892

12. Miscellaneous and Undifferentiated Epithelial Tumors 97

Proliferations of atypical cells with more or less abundant cytoplasm and contiguous cell borders occupy the dermis as nodular masses.

undifferentiated carcinoma (large cell, small cell) 1154
granular cell nerve sheath tumor (granular cell tumor/schwannoma) 1130

plexiform granular cell nerve
sheath tumor 1131
malignant granular cell tumor 1130
neuroendocrine tumor 1124
cephalic brain-like hamartoma (nasal glioma) 1141
encephalocele 1141
cutaneous meningiomas 1141
epithelial simulants
pleomorphic large cell lymphoma
(Ki-1, usually T cells) 952
epithelioid sarcoma 995
epithelioid angiosarcoma 1043
cellular neurothekeoma (immature
nerve sheath myxoma) 1127
ganglioneuroma 1140

C. Spindle Cell, Pleomorphic, and Connective Tissue Proliferations 98

There is a proliferation of elongated, tapered "spindle cells" in the dermis that may be of fibrohistiocytic, muscle, neural (schwannian), melanocytic, or unknown origin. Immunohistochemistry can be essential in making these distinctions.

1. Fibrohistiocytic Spindle Cell Proliferations 98

There is a proliferation of spindle to pleomorphic cells that may synthesize collagen or be essentially undifferentiated. In the absence of specific markers for fibroblasts, immunohistochemistry is of little diagnostic utility except to rule out nonfibrous spindle cell tumors. Morphology is critical for accurate diagnosis.

benign fibrous histiocytoma (dermatofibroma) 969
aneurysmal fibrous histiocytoma 1035
fibrous papule (angiofibroma) 987
hypertrophic scar, keloid 979
atypical fibroxanthoma 978
juvenile xanthogranuloma, spindle
cell variant 673
dermatofibrosarcoma protuberans 974
nephrogenic fibrosing dermopathy (not a tumor)
fibromatoses
desmoid tumor 992
recurrent infantile digital fibromatosis 986
juvenile hyaline fibromatosis 986
giant cell tumors
giant cell fibroblastoma 976
giant cell tumor of tendon sheath 974
proliferative lesions of the fascia
nodular fasciitis 983
cranial fasciitis of childhood 984
myxoid spindle cell infiltrate
cutaneous myxoma 997
digital mucous cyst 997
mucocele of oral mucosa 997
pseudocyst of the auricle 1100
sarcomas
malignant fibrous histiocytoma 979
angiomatoid fibrous histiocytoma 994
synovial sarcoma 994
fibromas
fibroma of tendon sheath 982
follicular fibroma 989
acquired digital fibrokeratoma 989
elastofibroma 987
dermatomyofibroma 980
progressive nodular histiocytoma
(deep fibrous type) 677
plexiform fibrohistiocytic tumor 977

2. Schwannian/Neural Spindle Cell Tumors 98

These tumors are composed of elongated, narrow spindle cells that tend to have serpentine, S-shaped nuclei and to be arranged in "wavy" fiber bundles. Immunohistochemistry for S100 is useful but not specific.

neurofibromas 1109
sporadic cutaneous neurofibroma
(common neurofibroma) 1109
extraneural (common neurofibroma) 1109
intraneural 1111
neurofibromatosis 1110
plexiform neurofibroma 1110
diffuse neurofibroma 1113
fibrolamellar nerve sheath tumor 1132
storiform nerve sheath tumor 1132
pacinian neurofibroma 1133
neurilemmomas (schwannomas) 1116
cellular schwannoma 1118
atypical schwannoma 1119
transformed (borderline)
schwannoma 1121
epithelioid schwannoma 1119
glandular schwannoma 1120
plexiform schwannoma 1120
infiltrating fascicular schwannoma
of infancy 1121
malignant schwannomas, intraneural
or extraneural 1119
malignant nerve sheath tumor 1122
psammomatous melanotic
schwannoma 1121
epithelioid malignant schwannoma 1121
mature (myxoid) neurothekeoma,
nerve sheath myxoma 1126
perineurioma 1132
extraneural neuromas 1135
traumatic neuroma 1135
intraneural neuromas 1135
palisaded and encapsulated
neuroma (PEN) 1135
intraneural plexiform neuroma 1136
mucosal neuroma syndrome 1137
linear cutaneous neuroma 1137

impingement neurofasciitis (Morton's neuroma) . . .1143
accessory digit 1135
ganglioneuroma 1140

3. Spindle Cell Tumors of Muscle 98

Smooth muscle cells have more abundant cytoplasm than fibroblasts or Schwann cells. The cytoplasm is trichrome positive and reacts with the muscle markers desmin and muscle-specific actin. The nuclei tend to have blunt ends. In neoplasms, the cells tend to be arranged in whorled bundles.

leiomyoma 1076
angioleiomyoma 1076
superficial leiomyosarcoma 1080
infantile myofibromatosis 984
solitary myofibroma 984
dermatomyofibroma 980
benign mixed mesodermal proliferations 1094
malignant mesenchymal tumors
of uncertain origin 1075
smooth muscle hamartoma 1075
rhabdomyosarcoma 1084

4. Melanocytic Spindle Cell Tumors 98

Melanocytic spindle cell tumors may have many attributes of the schwannian tumors described earlier. S100 is positive and HMB-45 is often negative in spindle cell melanomas. Diagnosis of melanoma then depends on recognizing melanocytic differentiation—pigment synthesis—or a characteristic intraepidermal *in situ* or microinvasive component.

desmoplastic melanoma, including amelanotic 753
cellular blue nevus, amelanotic 702
blue nevus, amelanotic 702
desmoplastic Spitz nevus 722
spindle cell metastatic melanoma 755

5. Tumors and Proliferations of Angiogenic Cells 98

There is a dermal proliferation of vascular endothelium. Factor VIII staining may be helpful in demonstrating endothelial differentiation. The many variants of benign hemangiomas should be carefully considered in the differential diagnosis of Kaposi's sarcoma and angiosarcoma.

angiomas 1013
juvenile hemangioendothelioma
(strawberry nevus) 1014
cherry hemangioma 1015
glomeruloid hemangioma 1010
tufted angioma (angioblastoma) 1015
angiokeratoma 1011
cavernous hemangioma 1019
sinusoidal hemangioma 1019
verrucous hemangioma 1020
microvenular hemangioma 1020
targetoid hemosiderotic (hob-nail)
hemangioma 1021
cirsoid aneurysm (arteriovenous
hemangioma) 1026
epithelioid hemangioma 1022
lymphangiomas 1043
cavernous lymphangioma and cystic
hygroma 1044
lymphangioma circumscriptum 1044
progressive lymphangioma (benign
lymphangioendothelioma) 1045
lymphangiomatosis 1045

bacillary angiomatosis 572
intravascular papillary endothelial hyperplasia 1007
telangiectases 1011
hereditary hemorrhagic telangiectasia 1012
spider nevus 1012
venous lakes 1012
vascular malformations 1010
angioma serpiginosum 1012
glomus tumors
glomus tumor, glomiangioma,
glomangiomyoma 1047
infiltrating glomus tumor 1048
glomangiosarcoma 1047
vascular lipomas
angiomyolipoma 1060
angiolipoma 1064
angiosarcomas 1040
epithelioid angiosarcoma 1043
Kaposi's sarcoma 1029
Kaposi's sarcoma simulants (see also angiomas)
aneurysmal fibrous histiocytoma 1035
spindle cell hemangioendothelioma 1027
Kaposi-like infantile
hemangioendothelioma 1038
acroangiodermatitis (pseudo-
Kaposi's sarcoma) 1035
multinucleate cell angiohistiocytoma 1035
bacillary angiomatosis 1018
angiomatosis 1027
hemangioendotheliomas
epithelioid hemangioendothelioma 1039
retiform hemangioendothelioma 1035
malignant endovascular papillary
angioendothelioma (Dabska's tumor) 1036
spindle cell hemangioendothelioma 1027
Kaposi-like infantile
hemangioendothelioma 1038
hemangiopericytoma 1049
angiolymphoid hyperplasia with eosinophilia 1022
intravascular lymphoma (malignant
angioendotheliomatosis) 932
reactive angioendotheliomatosis 933, 1008

6. Tumors of Adipose Tissue 98

nevus lipomatosus superficialis 1058

lipomas
spindle cell lipoma 1066
pleomorphic lipoma 1066
chondroid lipoma 1067
angiolipoma 1064
liposarcomas
well differentiated 1071
atypical lipomatous tumor 1072
myxoid 1072
round cell 1074
pleomorphic 1074
hibernoma 1068
benign lipoblastoma 1070

7. Tumors of Cartilaginous Tissue 98

chondroid lipoma 1067
soft tissue chondroma 1094
chondrosarcoma 1097

8. Tumors of Osseous Tissue 98

Albright's hereditary osteodystrophy 1086
osteoma cutis 1087
metaplastic ossification 1089
subungual exostosis 1090

D. Cysts of the Dermis and Subcutis 98

A cyst is a space lined by epithelium; its contents are usually a product of its lining. Some cysts are inclusion or retention cysts of normal structures (e.g., hair follicle–related cysts). Others are benign neoplasms. Some malignant neoplasms may be cystic. These tend to be larger and asymmetric, with a poorly circumscribed and infiltrative border. Their epithelial lining is proliferative, with cytologic atypia.

1. Pilar Differentiation 98

Cystic proliferations are present in the dermis; these show spaces surrounded by epithelium of follicular origin and differentiation. Keratin is usually seen in the cystic cavity. Associated cells may be sparse or may include lymphocytes and plasma cells.

epidermal cyst 801
milia 802
trichilemmal cyst 802
steatocystoma multiplex 803
pigmented follicular cyst 804
dermoid cyst 804
bronchogenic and thyroglossal duct cysts 805
eruptive vellus hair cyst 806
pilar sheath acanthoma 855
dilated pore of Winer 855

2. Eccrine and Similar Differentiation 98

Cystic proliferations are present in the dermis; these show spaces surrounded by eccrine epithelium (small, dark epithelial cells). The epithelium of ciliated and bronchogenic cysts is not eccrine but may resemble that of an eccrine cyst.

eccrine hidrocystoma 884
cutaneous ciliated cyst 805
bronchogenic and thyroglossal duct cysts 805
median raphe cyst of the penis 805
cutaneous endometriosis 890

3. Apocrine Differentiation 98

Cystic proliferations are present in the dermis; these show spaces surrounded by apocrine epithelium (large, pink cells with decapitation secretion). There may be lymphocytes and plasma cells (syringocystadenoma).

hidradenoma papilliferum 852
syringocystadenoma papilliferum 878
apocrine hidrocystoma 877

VII. INFLAMMATORY AND OTHER BENIGN DISORDERS OF SKIN APPENDAGES

The hair, sebaceous glands, eccrine glands, apocrine glands, and nails may be involved in inflammatory processes (hidradenitis, folliculitis). Some neoplasms may masquerade as inflammatory processes.

A. Pathology Involving Hair Follicles 99

Inflammatory processes may present as alopecia or as follicular localization of inflammatory rashes. Acne and related conditions present as dilation of follicles, which are filled with keratin.

1. Scant Inflammation 99

There is follicular alteration with a sparse infiltrate of cells, mainly lymphocytes.

follicular maturation disorders
androgenetic alopecia 479
telogen effluvium 478
trichotillomania 476
scurvy 407
vitamin A deficiency (phrynoderma) 407, 450
follicular keratinization disorders
keratosis pilaris 469
lichen spinulosus 469
trichorrhexis invaginata (Netherton's syndrome) 489
trichostasis spinulosa 470
acne vulgaris 459
Favre-Racouchot syndrome (nodular elastosis with cysts and comedones) 390
nevus comedonicus 793
Bazex's syndrome (follicular atrophoderma) 823

2. Lymphocytes Predominant 99

There is follicular alteration with an inflammatory infiltrate, mainly of lymphocytes.

alopecia areata 470
discoid lupus 280, 468
alopecia mucinosa/follicular mucinosis 467, 936
folliculotropic mycosis fungoides 939
lichen planopilaris 470
Fox-Fordyce disease 492
syringolymphoid hyperplasia with alopecia 490
lichen striatus 193
chronic folliculitis 544
rosacea 463
perioral dermatitis 462
disseminated and recurrent
infundibular folliculitis 459
acne varioliformis (acne necrotica) 543

a. With Eosinophils Present 99

Eosinophils are prominent in the infiltrate and may infiltrate the follicular structures.

eosinophilic pustular folliculitis 466
erythema toxicum neonatorum 267, 467
Ofuji's syndrome 466
fungal folliculitis 591

3. Neutrophils Prominent 99

There is a follicular alteration with an inflammatory infiltrate containing neutrophils, which may result in disruption of the follicle.

superficial folliculitis
acute bacterial folliculitis 543
impetigo of Bockhart 542
Pseudomonas folliculitis 542
acne vulgaris 459
alopecia of secondary syphilis 582
deep folliculitis
furuncle, carbuncle 543
folliculitis barbae, decalvans 544
pseudofolliculitis of the beard 544
pyoderma gangrenosum 411
follicular occlusion disorders
dissecting cellulitis/perifolliculitis capitis abscedens
et suffodiens 544
hidradenitis suppurativa 544
acne conglobata 544
fungal folliculitis
Majocchi granuloma (*Trichophyton rubrum*) 593
favus (*Trichophyton schoenleinii*) 593
Pityrosporum folliculitis 596
viral folliculitis 638
acne fulminans 459
Behçet's syndrome, acneiform lesions 412

4. Plasma Cells Prominent 99

Plasma cells are seen in abundance in the infiltrate. In most instances they are admixed with lymphocytes.

acne keloidalis 544
fungal folliculitis 591
alopecia of secondary syphilis 582

5. Fibrosing and Suppurative Follicular Disorders 99

In follicular occlusion disorders and acne keloidalis there is extensive fibrosis of the dermis, often with keratin tunnels of follicular origin and with embedded hairs with associated foreign-body inflammation. Neutrophils and plasma cells are seen in abundance in the infiltrate in addition to lymphocytes. In scarring alopecias the follicles are replaced by a delicate fibrous track.

acne keloidalis 549
follicular occlusion disorders
pilonidal sinus 545
hidradenitis suppurativa 544
acne conglobata 544
perifolliculitis capitis abscedens et suffodiens
(dissecting cellulitis of the scalp) 544
deep folliculitis
folliculitis barbae, decalvans 544
scarring alopecias . . . . . .
pseudopelade of Brocq 483
follicular degeneration syndrome 482
folliculitis decalvans 487
tufted folliculitis 487
central centrifugal scarring alopecia 482
postmenopausal frontal fibrosing
alopecia 488

B. Pathology Involving Sweat Glands 99

The sebaceous glands, eccrine glands, and apocrine glands may be involved in inflammatory processes (hidradenitis).

1. Scant Inflammation 99

Sweat glands are abnormal in color or size and number but there is little or no inflammation.

argyria 327
syringosquamous metaplasia 322
eccrine nevus 883
eccrine angiomatous hamartoma 883
coma blister 273

2. Lymphocytes Predominant 99

There is a predominantly lymphocytic infiltrate in and around the sweat glands.

lupus erythematosus 279
syringolymphoid hyperplasia with
alopecia 490
lichen striatus 193
morphea/scleroderma 295
syringotropic mycosis fungoides
(cutaneous T-cell lymphoma) 939
Fox-Fordyce disease (apocrine miliaria) 492

a. With Plasma Cells 99

There is a predominantly lymphocytic infiltrate in and around the sweat glands. Plasma cells are also present as a minority population.

lupus erythematosus 279
secondary syphilis 581
cheilitis glandularis 380
morphea/scleroderma

b. With Eosinophils 99

There is an inflammatory infiltrate with eosinophils in and around the sweat glands.

arthropod assault reactions 634

c. With Neutrophils 99

There is an inflammatory infiltrate with neutrophils in and around the sweat glands.

insect-bite reactions 634
neutrophilic eccrine hidradenitis 314, 491
palmoplantar hidradenitis 491
secondary syphilis 581

C. Pathology Involving Nerves 99

Specific inflammatory involvement of nerves is uncommon in dermatopathology.

1. Lymphocytic Infiltrates 99

Neurotropic spread of neoplasms, especially neurotropic melanoma, may be associated with a dense lymphocytic infiltrate that may tend to obscure a subtle infiltrate of neoplastic spindle cells. Certain infections may also be associated with inflammation of nerves.

neurotropic melanoma 755
leprosy 558

2. Mixed Inflammatory Infiltrates 99

There is a mixed inflammatory infiltrate involving nerves.

leprosy 558
erythema chronicum migrans 586

3. Neoplastic Infiltrates 99

Many neoplasms may occasionally involve nerves. The involvement by carcinomas (basal cell, squamous cell, metastatic) is commonly in the perineural space, whereas involvement by neurotropic melanoma tends to occupy the endoneurium and to be associated with a dense lymphocytic infiltrate that may tend to obscure a subtle infiltrate of neoplastic spindle cells.

neurotropic melanoma 755
neurotropic tumors 1144

D. Pathology of the Nails 100

Several inflammatory dermatoses more often seen elsewhere in the skin may present incidentally or exclusively in the nails. The reaction patterns may vary from those seen elsewhere because of the unique responses of the nail unit to injury.

1. Lymphocytic Infiltrates 100

spongiotic dermatitis 503
lichen planus 185

2. Lymphocytes with Neutrophils 100

psoriasis 174, 504
tinea unguium, onychomycosis 504, 595

3. Bullous Diseases 100

Darier's disease 506
pemphigus 506
erythema multiforme 506
toxic epidermal necrolysis 506
epidermolysis bullosa 506

4. Parasitic Infestations 100

scabies 508, 626

VIII. DISORDERS OF THE SUBCUTIS

The reactions in the subcutis are mostly inflammatory, although tumors (proliferations) of the subcutis do occur (lipoma). Pathologic conditions arising in the dermis may infiltrate the subcutis.

A. Subcutaneous Vasculitis and Vasculopathy (Septal or Lobular) 100

True vasculitis is defined by the presence of necrosis and inflammation in vessel walls. Other forms of vasculopathy include thrombosis and thrombophlebitis, fibrointimal hyperplasia, and neoplastic infiltration of vessel walls.

1. Neutrophilic 100

Neutrophils and disrupted nuclei are present in the wall of the vessel, with associated eosinophilic "fibrinoid" necrosis.

leukocytoclastic vasculitis 215
subcutaneous polyarteritis nodosa 209
superficial migratory thrombophlebitis 515
erythema nodosum leprosum 564

2. Lymphocytic 100

The concept of "lymphocytic vasculitis" is controversial. Many disorders characterized by lymphocytes within the walls of vessels are best classified as lymphocytic infiltrates. The term "vasculitis" may be appropriate when there is vessel wall damage, as in nodular vasculitis, even in the absence of neutrophils and "fibrinoid."

nodular vasculitis 519
perniosis 526
angiocentric lymphomas 913
superficial migratory thrombophlebitis 209

3. Granulomatous 100

The inflammatory infiltrate in the vessel walls is composed of mixed cells including more or less epithelioid histiocytes and giant cells. Other cell types, including lymphocytes and plasma cells, and sometimes neutrophils and eosinophils, also are commonly present.

erythema induratum/nodular vasculitis
(inconspicuous vasculitis) 519
erythema nodosum leprosum
(type 2 leprosy reaction) 564
Wegener granulomatosis 214
Churg-Strauss vasculitis 113
Crohn's disease 415

B. Septal Panniculitis without Vasculitis 100

1. Septal Panniculitis, Lymphocytes, and Mixed Infiltrates 100

The inflammation predominantly involves the subcutaneous septa, although there may be "spillover" into the fat lobules. The infiltrate is mainly lymphocytic, although other cells can be found, including plasma cells and acute inflammatory cells.

erythema nodosum and variants 511
Crohn's disease 415
morphea 295, 531

2. Septal Panniculitis, Granulomatous 100

Subcutaneous granulomas may present as ill-defined collections of epithelioid histiocytes, as well-formed epithelioid-cell granulomas, and as palisading granulomas in which histiocytes are radially arranges around areas of necrosis or necrobiosis.

palisaded granulomas
subcutaneous granuloma annulare 361
rheumatoid nodules 367
necrobiosis lipoidica 363
sarcoidosis 370
lichen scrofulosorum 554
Crohn's disease 514
subcutaneous infections
syphilis 579
tuberculosis 550

3. Septal Panniculitis, Sclerotic 100

Sclerosis of the panniculitis may begin as a septal process and extend into the lobules.

scleroderma, morphea 516
eosinophilic fasciitis 186
ischemic liposclerosis 510
toxins 510

C. Lobular Panniculitis without Vasculitis 101

The inflammation is mainly confined to the lobules, although there may be some septal involvement.

1. Lobular Panniculitis, Lymphocytes Predominant 101

Lymphocytes are the primary infiltrating cells.

lupus panniculitis 521
nodular vasculitis/erythema induratum,
inapparent vasculitis 519
poststeroid panniculitis 530
subcutaneous lymphoma-leukemia 911

2. Lobular Panniculitis, Lymphocytes, and Plasma Cells 101

Lymphocytes and plasma cells are the primary infiltrating cells.

lupus profundus 521
morphea profunda 535

3. Lobular Panniculitis, Neutrophilic 101

Lymphocytes and neutrophils are the primary infiltrating cells.

infection (cellulitis) 527
ruptured follicles and cysts 803
pancreatic fat necrosis 531
necrotizing panniculitis 516
Weber-Christian disease 523

4. Lobular Panniculitis, Eosinophils Prominent 101

Lymphocytes and eosinophils are the primary infiltrating cells.

eosinophilic fasciitis 303
eosinophilic panniculitis 515
arthropod bites 634
parasites 621

5. Lobular Panniculitis, Histiocytes Prominent 101

Lymphocytes and histiocytes are the primary infiltrating cells.

cytophagic histiocytic panniculitis 532
Rosai-Dorfman disease 534

6. Lobular Panniculitis, Mixed with Foam Cells 101

Lymphocytes, plasma cells, and a variety of infiltrating cells can be seen, including giant cells and foamy histiocytes.

α-1-antitrypsin deficiency panniculitis 516
Weber-Christian disease 523
traumatic fat necrosis 530
cold panniculitis 526
injection granuloma 525
factitious panniculitis 525
necrobiotic xanthogranuloma with
paraproteinemia 683

7. Lobular Panniculitis, Granulomatous 101

Lymphocytes and histiocytes are the primary infiltrating cells.

erythema induratum/nodular vasculitis
(if vasculitis is inapparent) 519
palisaded granulomas

subcutaneous granuloma annulare/
pseudorheumatoid nodule 361
rheumatoid nodules 367
subcutaneous sarcoidosis 370
tuberculosis 550

8. Lobular Panniculitis, Crystal Deposits, and Calcifications 101

Crystalline deposits derived from free fatty acids or other precipitated salts are present in the fat lobules.

sclerema neonatorum 529
subcutaneous fat necrosis of the newborn 529
gout 438
oxalosis 510
calcifying panniculitis 530

9. Lobular Panniculitis, Necrosis Prominent 101

There is fat necrosis with a resulting infiltrate that is mixed.

pancreatic panniculitis 528
erythema induratum, inapparent vasculitis 519
necrobiotic xanthogranuloma with
paraproteinemia 683
infarct 230
abscess 555

10. Lobular Panniculitis, Embryonic Fat Pattern 101

Due to atrophy or to failure of normal morphogenesis, immature small fat cells are present in the lobules.

lipoatrophy 526
lipodystrophy 526

11. Lobular Panniculitis, Miscellaneous 101

Lymphocytes, plasma cells, and a variety of infiltrating cells can be seen, including giant cells and histiocytes.

lipomembranous panniculitis 531
lipogranulomatosis of Rothmann-Makai 524
granulomatous panniculitis in
light-chain disease 524
early stages of pyoderma gangrenosum 517
necrobiotic xanthogranuloma

D. Mixed Lobular and Septal Panniculitis 102

Neoplastic infiltrates and inflammation due to trauma or infection do not respect anatomic compartments of the subcutis.

1. With Hemorrhage or Sclerosis 102

Inflammation due to trauma is likely to be associated with hemorrhage, neutrophilic inflammation, and sclerosis in late lesions.

traumatic panniculitis 525
cold panniculitis 526
injections, including factitial panniculitis 525
blunt trauma: sclerosing lipogranuloma 514
lipomembranous panniculitis/
lipodermatosclerosis 531
lupus panniculitis/profundus 521

2. With Many Neutrophils 102

Neutrophilic inflammation diffusely involves the subcutis.

necrotizing fasciitis (bacterial infection) 541
abscesses 555
North American blastomycosis 603
pyoderma gangrenosum (involves dermis also) 411
ecthyma gangrenosum 547
α-1-antitrypsin deficiency 516
infection (cellulitis) 527, 541
dissecting cellulitis of the scalp (perifolliculitis
abscedens et suffodiens) 544
hidradenitis suppurativa 544
ruptured follicles and cysts 801
Weber-Christian disease 523
miscellaneous necrotizing panniculitis 516
e.g., nodular vasculitis, pyoderma gangrenosum,
inflammatory reaction near ulcers or abscesses
of all causes, bacterial or fungal infection, etc.

3. With Many Lymphocytes 102

Lymphocytic infiltrates diffusely involve the subcutis.

lupus panniculitis (also with plasma
cells and sclerosis) 280, 522
chronic lymphocytic leukemia 925
subcutaneous T-cell lymphoma 948
histiocytic cytophagic panniculitis (early lesion) . . .948

4. With Cytophagic Histiocytes 102

Histiocytes with phagocytized erythrocytes diffusely infiltrate the subcutis.

α-1-antitrypsin deficiency (late lesion) 516
histiocytic cytophagic panniculitis (late lesion) 948
Rosai-Dorfman disease 678

5. With Granulomas 102

There is granulomatous inflammation diffusely involving the subcutis.

gummatous tertiary syphilis 583
erythema nodosum leprosum 564
chronic erythema nodosum 511
mycobacterial panniculitis 549
subcutaneous sarcoidosis 370

E. Subcutaneous Abscesses 102

A collection of neutrophils in the subcutis, usually surrounded by granulation tissue and fibrosis.

1. With Neutrophils 102

The center of the abscess contains pus, which is viscous because of the presence of DNA fragments derived from neutrophils and dead organisms.

acute or chronic bacterial
abscesses 567
deep fungal infections 604
phaeohyphomycotic cyst 602
North American blastomycosis 603
chromoblastomycosis 607
cutaneous alternariosis 603
paracoccidioidomycosis 605
coccidioidomycosis 608
sporotrichosis 612
protothecosis 615
mycobacterial panniculitis 549

CHAPTER 6

Congenital Diseases (Genodermatoses)

ICHTHYOSIS

A classification of ichthyosis includes four major and three minor forms. In addition, there are a number of syndromes that are associated with ichthyosis.

Ichthyosis Vulgaris

Ichthyosis vulgaris is a common disorder caused by mutations in filaggrin and inherited in an autosomal dominant fashion. It develops a few months after birth. The skin shows scales that are large and adherent on the extensor surfaces of the extremities, resembling fish scales, and are small elsewhere. The flexural creases are spared. Keratosis pilaris is often present, and the palms and soles may show hyperkeratosis.

An acquired, noninherited form of the disease may appear in patients with lymphoma, particularly Hodgkin's disease (1), but this form has been reported also in association with carcinoma (2) and sarcoidosis. The expression of profilaggrin is reduced in this disorder. Profilaggrin mRNA in keratinocytes cultured from subjects with ichthyosis vulgaris is unstable and has a shorter half-life compared with that in normal cells. Therefore, a stabilizing factor may be absent or functionally inactive (3).

Histopathology. The characteristic finding is the association of a moderate degree of hyperkeratosis with a thin or absent granular layer (Fig. 6-1). The hyperkeratosis often extends into the hair follicles, resulting in large keratotic follicular plugs. The dermis is normal.

Histogenesis. Labeling with tritiated thymidine shows a normal rate of epidermal proliferation (4). The hyperkeratosis is regarded as a retention keratosis resulting from increased adhesiveness of the stratum corneum. The reason for this, as seen by electron microscopy, is a delay in the dissolution of the desmosomal disks in the horny layer. Keratohyaline granules are regularly seen on electron microscopy, in contrast to light microscopy. The stratum granulosum, however, consists of only a single layer, and the keratohyaline granules appear small and crumbly or spongy, which is evidence of defective synthesis. The reason for the inadequate formation of keratohyaline granules lies in a defect in the synthesis of filaggrin, a histidine-rich protein (4). Defective profilaggrin expression in ichthyosis vulgaris may be a result of selectively impaired posttranscriptional control (5). In noninherited ichthyosis vulgaris associated with neoplasia, the keratohyaline granules have been described as being small but showing a normal structure, indicating a reduced but not an abnormal synthesis (6).

Differential Diagnosis. Although the noninflamed but dry skin of patients with atopic dermatitis clinically resembles ichthyosis vulgaris, on histologic examination it does not show the features of ichthyosis vulgaris but rather increased epidermal thickness, patchy parakeratosis, and slight hypergranulosis in places, as seen in chronic dermatitis (6).

X-Linked Ichthyosis

X-linked ichthyosis is recessively inherited, with about 90% caused by gene deletion. It is only rarely present at birth. Although female heterozygotes are frequently affected, males have a more severe form of the disorder. The thickness of the adherent scales increases during childhood (7). In contrast to ichthyosis vulgaris, the flexural creases may be involved.

Histopathology. In hyperkeratosis, the granular layer is normal or slightly thickened but not thinned as in dominant ichthyosis vulgaris. The epidermis may be slightly thickened (6).

Histogenesis. X-linked ichthyosis, like ichthyosis vulgaris, shows a normal rate of epidermal proliferation. The disorder is a retention hyperkeratosis characterized by delayed dissolution of the desmosomal disks in the horny layer. In contrast to that of ichthyosis vulgaris, the synthesis of keratohyaline granules in X-linked ichthyosis is not defective, and the rate of synthesis is slightly increased (8). The cause of the retention hyperkeratosis in X-linked ichthyosis is the virtual absence of steroid sulfatase activity. This was first recognized in skin fibroblasts (9) but was found subsequently also in the entire epidermis and in leukocytes (10). X-linked ichthyosis is caused by an extensive deletion of the steroid sulfatase gene (11). Steroid sulfatase normally acts on cholesteryl sulfate, a product of the Odland bodies that is discharged with them from the granular cells into the intercellular space and provides cell cohesion in the lower stratum corneum. Failure of steroid sulfatase to remove cholesteryl sulfate results in persistent cell cohesion even in the upper stratum corneum and interferes with the normal process of desquamation (12).

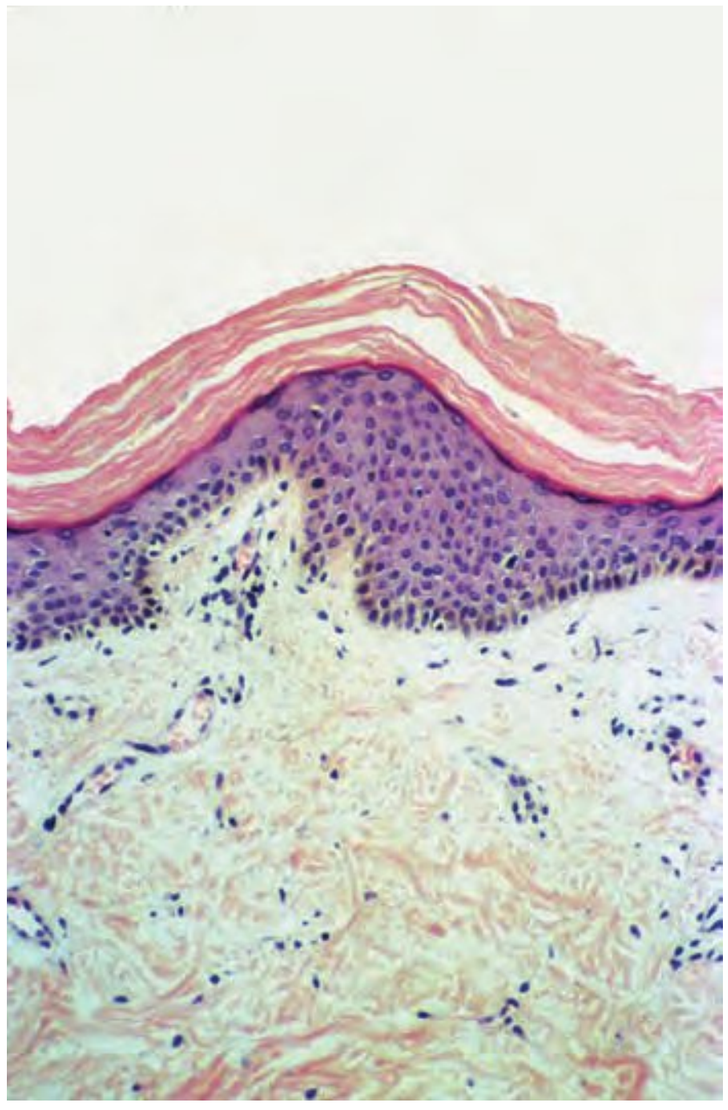

FIGURE 6-1. Ichthyosis vulgaris. Hyperkeratosis with a diminished and focally absent granular cell layer (original magnification ×100).

FIGURE 6-2. Epidermolytic hyperkeratosis. Generalized erythema, scaling, and a re-epithlialized right axilla (previously denuded).

Epidermolytic Hyperkeratosis

Epidermolytic hyperkeratosis, an autosomal dominantly inherited disease also known as *bullous congenital ichthyosiform erythroderma*, shows generalized erythema from the time of birth (Fig. 6-2). Within a few days after birth, there is thick, brown, verrucous scaling (Fig. 6-3). The flexural surfaces of the extremities show marked involvement, often consisting of furrowed hyperkeratosis. Vesicles and bullae and erosions are usually encountered only during the first few years.

Histopathology: A characteristic histologic picture is seen in the epidermis (Fig. 6-4) and is referred to either as *epidermolytic hyperkeratosis* (7) or as *granular degeneration* (13). It is present in bullous as well as in nonbullous areas. There are variously sized clear spaces around the nuclei in the upper stratum spinosum and in the stratum granulosum. Peripheral to the clear spaces, the cells show indistinct boundaries formed by lightly staining material or by keratohyaline granules. A markedly thickened granular layer containing an increased

FIGURE 6-3. Epidermolytic hyperkeratosis. Erythema and thick "scales" in older child.

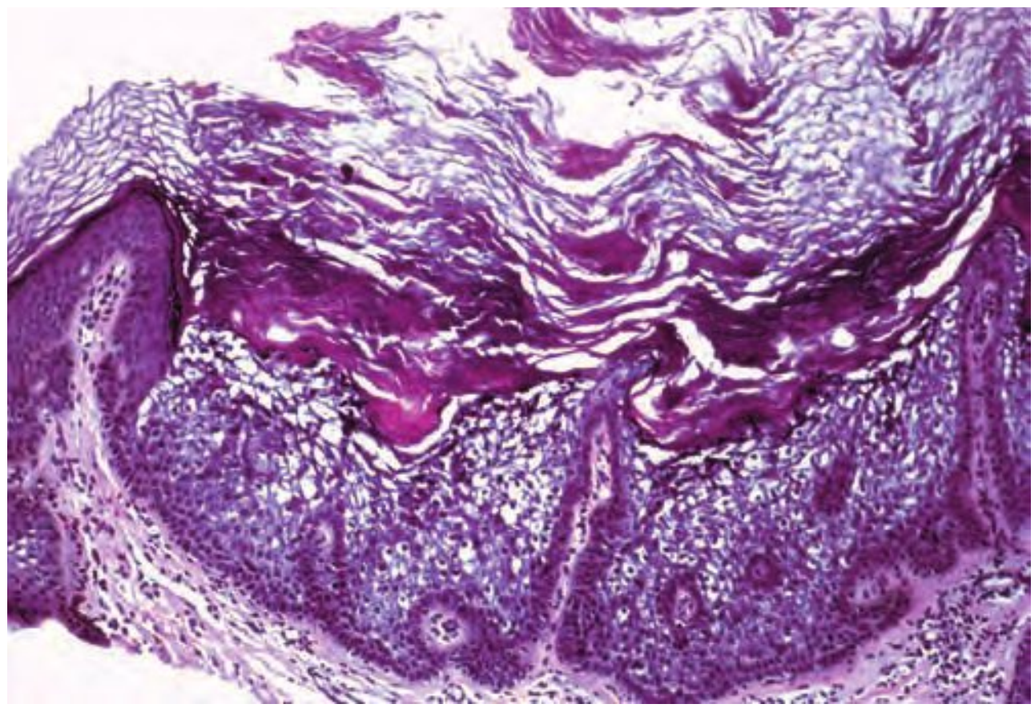

FIGURE 6-4. Epidermolytic hyperkeratosis. There is vacuolization of the upper and mid-spinus layer. There is hyperkeratosis with large keratohyaline granules in the vacuolated expanded granular cell layer (original magnification ×100).

number of irregularly shaped keratohyaline granules and compact hyperkeratosis is observed (14). When bullae form, they arise intraepidermally through separation of edematous cells from one another (15). The upper dermis shows a moderately severe, chronic inflammatory infiltrate. Mitotic figures are five times more numerous than in normal epidermis (7).

Pathogenesis. Defects in keratin genes (KRT1 and KRT10) (16) are now known to be associated with this disorder. Mutations have been found in the carboxy terminal of the rod domain of keratin 1 and the aminoterminal of the rod domain of keratin 10 (17). The essential electron microscopic features are excessive production of tonofilaments and excessive and premature formation of keratohyaline granules; thus, at the periphery of the cells, numerous keratohyaline granules are embedded in thick shells of irregularly clumped tonofilaments (18,19). The desmosomes appear normal, but the association of tonofilaments and desmosomes is disturbed, so many desmosomes are attached to only one keratinocyte instead of connecting two neighboring keratinocytes. Because of this disturbance in desmosomal attachment, blister formation takes place and real acantholysis occurs (16). Labeling with tritiated thymidine reveals greatly increased proliferative activity in the epidermis (7). It can be concluded that keratinization is both excessive and abnormal.

Differential Diagnosis. Although the histologic picture of epidermolytic hyperkeratosis is diagnostic for the type of ichthyosis called *epidermolytic hyperkeratosis*, it is not specific for it. Hyperkeratosis is found also in several other seemingly unrelated conditions (20,21): epidermolytic keratosis palmaris et plantaris, solitary epidermolytic acanthoma, disseminated epidermolytic acanthoma, and linear epidermal nevus, usually of the systematized type. This latter entity was thought to be an entirely different condition than epidermolytic hyperkeratosis but with similar histologic findings. However, it is now known that epidermal nevi of the epidermolytic hyperkeratotic type are a mosaic genetic disorder of suprabasal keratin (i.e., point mutations of 10k alleles of epidermal cells in keratinocytes from lesional skin) that can be transmitted to offspring producing generalized epidermolytic hyperkeratosis (21). Epidermolytic hyperkeratosis can be an incidental finding in a variety of conditions (22,23).

Autosomal Recessive Ichthyosis

In many instances, it is possible to subdivide recessive ichthyosis into two types. A less severe type, *congenital ichthyosiform erythroderma*, shows fine white scales with fairly pronounced erythroderma and has a tendency to improve at the time of puberty. The more severe type, *lamellar ichthyosis*, shows large, platelike scales and severe ectropion but only slight erythroderma. In both forms, the flexural surfaces and the palms and soles are involved (10,24). Several pathogenetic mechanisms have been identified for this condition, including transglutaminase acylation defects (25), defects in lamellar body secretion (26), and abnormalities in the processing of LOX gene products (27). The condition results from deleterious mutations in the transglutaminase 1 (TGM1) gene. However, the disease is genetically heterogeneous due to some families who were found to be unlinked to TGM1 and 2q33-3J (28). In some of these instances, mutations in ABCA12 have been identified. In rare instances, autosomal recessive ichthyosis is associated with storage of neutral lipid in multiple tissues, the Chanarin-Dorfman syndrome (29). It is easily recognized by the presence of lipid vacuoles in leukocytes.

Histopathology. The histologic findings in both congenital ichthyosiform erythroderma and lamellar ichthyosis are nonspecific. As a rule, however, congenital ichthyosiform erythroderma shows only mild thickening of the stratum corneum with foci of parakeratosis, whereas lamellar ichthyosis has a markedly thickened stratum corneum without areas of parakeratosis (30).

In the Chanarin-Dorfman syndrome, lipid stains reveal prominent neutral lipid droplets in some of the epidermal cells (29).

CHILD Syndrome

CHILD syndrome is a rare but clinically striking dermatosis that shows from birth unilateral ichthyosiform erythroderma and ipsilateral underdevelopment of the limbs (Fig. 6-5). It is known under the acronym **C**ongenital **H**emidysplasia with **I**chthyosiform erythrodermal and **L**imb **D**efects (31). Because nearly all published cases have been female, it is likely that the disease is the result of an X-linked dominant gene defect that is lethal in the hemizygote male fetus. Peroxisomal abnormalities have been found in fibroblasts from involved skin in these children (32). More recently, this disorder has been shown to result from mutations in genes encoding enzymes involved in sequential steps in the conversion of lanosterol to cholesterol (33).

Histopathology. On a thickened epidermis, a pronounced hyperkeratosis with prominent parakeratotic foci is observed (34).

FIGURE 6-5. CHILD syndrome. Note unilateral erythema, scaling, and underdevelopment of limbs.

Harlequin Ichthyosis

Harlequin ichthyosis is a rare condition that is frequently but not invariably fatal. It is probably of autosomal recessive inheritance, as in one family, five siblings have the disease. At birth, the child is encased in a thick, horny cuirass with deep fissures. Marked ectropion and eclabium are present. Fetal skin biopsy is the only available method for prenatal diagnosis.

Histopathology. There is usually a massive hyperkeratosis, the stratum corneum being 20 to 30 times thicker than the stratum malpighii (35). The appearance of the stratum granulosum is variable; it may be normal, or it may be flattened to absent. A stain for fat has shown small droplets of neutral fat distributed uniformly throughout the cornified cells. Some cases have shown papillomatosis in addition to the massive hyperkeratosis or areas of parakeratosis.

Pathogenesis. An abnormality in lamellar body formation and secretion (36) exists as a result of deleterious mutations in ABCA12, which leads to an inadequate delivery of desmosomal proteases to the stratum corneum (37), a failure to degrade corneodesmosomes and, therefore, massive hyperkeratosis (38).

Erythrokeratodermia Variabilis

A rare, dominantly inherited disorder, erythrokeratodermia variabilis starts in infancy rather than at birth. It has two morphologic components. First, areas of erythema expand centrifugally and coalesce into circinate figures. These lesions fluctuate, sometimes rapidly, in their configuration and extent and thus are "variable." Second, persistent hyperkeratotic plaques develop both within the areas of erythema and in areas of apparently normal skin (39). In rare cases, referred to as *progressive symmetric erythrokeratodermia*, only persistent erythematous hyperkeratotic plaques are present, and they are limited to the extremities (40).

Histopathology. The changes are nonspecific. In the hyperkeratotic plaques, they consist of hyperkeratosis with moderate papillomatosis and acanthosis. The granular layer appears normal, being two to three cell layers thick (39).

Pathogenesis. Labeling with tritiated thymidine shows a normal rate of proliferation. It is likely that the hyperkeratosis is due to decreased shedding of horny cells and is of the retention type (39). Mutations in the genes gjb3 and gjb4, which affect connexins 31 and 30.3, have been described (41).

Ichthyosis Linearis Circumflexa

Ichthyosis linearis circumflexa, a recessive disorder that is present at birth or starts shortly thereafter, manifests as extensive migratory polycyclic lesions of erythema and scaling (42). At their periphery, some of the areas show a distinctive "double-edged" scale. The presence of extensive erythema causes a resemblance to psoriasis. The dermatosis persists through life. In more than half of the reported cases, hair anomalies have been present in the scalp, usually trichorrhexis invaginata, as part of Netherton's syndrome (43).

Histopathology. The areas of erythema and scaling show nonspecific changes with some resemblance to psoriasis, such as elongation of the rete ridges and hyperkeratosis, as well as parakeratosis (44).

The double-edged scale frequently shows in the upper stratum malpighii intracellular edema and irregular spongiosis, resulting in multilocular vesicles or vesiculopustules within the horny layer (45). In other cases, focal accumulations of PAS-positive, diastase-resistant, homogeneous material representing exuded serum protein are seen within a parakeratotic stratum corneum (46). The presence of such exudative changes, however, is not specific or characteristic for ichthyosis linearis circumflexa, as has been claimed (47).

Pathogenesis. Electron microscopic examination has shown the presence of multilocular vesicles that are filled with an amorphous substance compatible with serum protein (48).

Syndromes Associated with Ichthyosis

There is an expanding list of syndromes that combine ichthyosis with neuroectodermal and mesodermal defects (49). Some of the syndromes described in the literature may be chance associations (50). Among the well-established syndromes are the *Sjögren-Larsson syndrome*, which is characterized by lamellar ichthyosis in association with mental retardation and spastic paresis (51)—skin fibroblasts and leukocytes from these patients are deficient in activity of the enzyme fatty alcohol and NAD oxidoreductase (52) and are due to a gene defect in FALDH (53); *Rud's syndrome*, showing generalized ichthyosis with hypogonadism, mental deficiency, and epilepsy (54); and *Conradi-Hunermann syndrome*, an X-linked form of chondrodysplasia punctata in which ichthyosis with a whorled pattern is associated with skeletal and ocular abnormalities (55), with a gene defect in emopamil binding protein affecting delta 8, delta 7 sterol isomerase (56). Some forms are associated with peroxisome abnormalities (57). *Netherton's syndrome* consists of a combination of either ichthyosis linearis circumflexa or, less commonly, lamellar ichthyosis, a predisposition to atopic dermatitis, with trichorrhexis invaginata; *IBIDS syndrome*, which is icthyosis associated with brittle hair, impaired intelligence, decreased fertility, and short stature (52); and *PIBIDS syndrome*, showing photosensitivity and IBIDS. Patients with these syndromes have sulfur-deficient, sparse hair. Also included are *KID syndrome*, keratitis associated with ichthyosis and deafness (58); *neutral lipid storage disease*, ichthyosis with cataracts, deafness, ataxia, and lipid droplets in many circulating cells (59); and *multiple sulfatase deficiencies*, a combination of ichthyosis, neurodegeneration, organomegaly, and skeletal dysplasia (includes steroid sulfatase deficiency). The only syndrome showing specific histologic changes in the skin is *Refsum's syndrome*.

Refsum's Syndrome

An autosomal recessive disorder, Refsum's syndrome is characterized by generalized ichthyosis, cerebellar ataxia, progressive paresis of the extremities, and retinitis pigmentosa.

Histopathology. The skin shows hyperkeratosis, hypergranulosis, and acanthosis. In the basal and suprabasal cells of the epidermis are variably sized vacuoles that on staining for lipids are seen to contain lipid accumulations (60).

Pathogenesis. The primary metabolic defect in Refsum's syndrome is an accumulation of phytanic acid, which results from a deficiency of alpha-phytanic acid alpha-hydroxylase (61). Refsum's disease is caused by mutations in the phytanol-CoA hydroxylase gene (62).

KERATOSIS PALMARIS ET PLANTARIS

Three major autosomal dominant forms and two autosomal recessive forms of keratosis palmaris et plantaris exist. Evidence is accruing that indicates abnormalities in intracellular structural proteins (e.g., loricrin, keratins), desmosomal proteins, gap junction components (e.g., connexins), and enzymes (e.g., cathepsins) lead to the varying palmoplantar keratodermas. Gene defects causing many types of hereditary palmoplantar keratodermas have been discovered (63). The three dominantly inherited forms include the following:

1. *Keratosis palmaris et plantaris of Unna-Thost*, showing either diffuse or localized, occasionally linear hyperkeratosis of the palms and soles (Fig. 6-6). A division into two types—a circumscribed type with limitation to the palms and soles and an extending type with gradual progression to the dorsa of the hands and feet, the ankles and wrists, and the elbows and knees—is not tenable, because both types may occur in the same family (64).
2. *Epidermolytic keratosis palmaris et plantaris*, although clinically indistinguishable from the Unna-Thost type, histologically shows epidermolytic hyperkeratosis. This form appears to be quite common (65). This variant has been associated with mutations in keratin type 9 localized within the keratin gene cluster on chromosome 17q 12-q21 and keratin type 1 on chromosome 12q13 (66).
3. *Keratosis palmoplantaris punctata* (or *papulosa*) has multiple keratotic plugs.

The two recessively inherited forms include the following:

1. *Keratosis palmaris et plantaris of the Meleda type*, showing diffuse involvement of the palms and soles and a marked tendency toward progression to the dorsa of the hands and feet, the ankles and wrists, and the elbows and knees (67).
2. The *Papillon-Lefèvre syndrome* shows the clinical characteristics of the Meleda type in association with periodontosis resulting in the loss first of the deciduous teeth and later of the permanent teeth (68). Abnormalities in cathepsin C localized to chromosome 11q14.1 has been found as well as keratins 6b,9,16,17 on 12q13 and 17q12-q21 and connexin 30 on 13q12 (69).

In addition, keratosis palmaris et plantaris occurs in three syndromes: (a) pachyonychia congenita, (b) hidrotic ectodermal dysplasia, and (c) the Richner-Hanhart syndrome associated with tyrosinemia (tyrosine tyrosinase on 16q22,1-q22.3) (69).

FIGURE 6-6. Keratosis palmeris et plantaris of Unna-Thost. Thickened palms and soles of the father, whose child has similar findings.

Histopathology. In keratosis palmaris et plantaris of the Unna-Thost type and the Meleda type, as well as in the Papillon-Lefèvre syndrome, the histologic picture is nonspecific, consisting of considerable hyperkeratosis, hypergranulosis, acanthosis, and a sparse inflammatory infiltrate of lymphocytes in the upper dermis (67,68).

In epidermolytic keratosis palmaris et plantaris, the histologic picture is identical with that seen in epidermolytic hyperkeratosis. Many cells in the middle and upper stratum malpighii appear vacuolated, and scattered cavities are present as a result of ruptured cell walls. Keratohyaline granules are numerous and large (70–72).

In keratosis palmoplantaris punctata, there is massive hyperkeratosis over a sharply limited area, with depression of the underlying malpighian layer below the general level of the epidermis. There is an increase in the thickness of the granular layer. The dermis is free of inflammation (73). In two cases reported as punctate keratoderma, a cornoid lamella was seen in the center of the hyperkeratotic plug; these cases represent punctate porokeratosis with the lesions limited to the palms and soles, rather than keratosis palmoplantaris punctata (74,75).

ACROKERATOELASTOIDOSIS

Acrokeratoelastoidosis is a rare, autosomal dominantly inherited condition in which firm, shiny papules are seen at the periphery of the palms and soles with extension to the dorsa of the fingers and the sides of the feet (76,77) (Fig. 6-7).

Histopathology. The essential histologic feature in the papules consists of diminution and fragmentation of the elastic fibers, especially in the deeper portions of the dermis (76,77). Some of the fragmented elastic fibers appear thickened and tortuous (78).

Histogenesis. On electron microscopic examination, the elastic fibers in the reticular dermis appear disaggregated, with fragmentation of the microfibrils (77,79).

Differential Diagnosis. In *focal acral hyperkeratosis,* the lesions have the same clinical appearance as in acrokeratoelastoidosis.

FIGURE 6-7. Acrokeratoelastoidosis. Firm papules at side of foot.

There may or may not be a familial predisposition, but the elastic tissue stains fail to reveal any abnormalities (80,81). In *degenerative collagenous plaques of the hands,* the lesions develop late in life; there is no involvement of the feet and no familial predisposition. These histologic changes consist of basophilic degeneration of the elastic tissue (82,83).

PACHYONYCHIA CONGENITA

A disorder with autosomal dominant inheritance, pachyonychia congenita is characterized by the following triad: (a) subungual hyperkeratosis with accumulation of hard, keratinous material beneath the distal portion of the nails (Fig. 6-8), lifting the nails from the nail bed; (b) keratosis palmaris et plantaris with thick callosities, especially on the soles, that are tender and often associated with blister formation; and (c) thick white areas on the oral mucosa (Fig. 6-9) that resemble those seen in white sponge nevus and possess no tendency toward malignant degeneration (84). Follicular hyperkeratosis may occur, mainly on the elbows and knees. Several clinical variants have been described. Type I shows prominent palmoplantar hyperkeratosis and extensive follicular hyperkeratosis that also involves the trunk. Type II (most common) manifests scalloped tongue and oral leukokeratosis. Type III develops corneal thickenings and cataracts. Type IV (Jackson-Lawler variant) develops cysts of the head, neck, and chest at puberty. They may also manifest hidradenitis suppurativa and milia. A late onset type may also exist.

Histopathology. The nail bed shows marked hyperkeratosis. As in a normal nail bed, there is no granular layer (84). The blisters that may be seen beneath and around the plantar callosities arise in the upper layers of the stratum malpighii through increasing intracellular edema and vacuolization. Unlike friction blisters, they show no areas of necrosis (85). The oral lesions show thickening of the oral epithelium with extensive intracellular vacuolization, exactly as seen in white sponge nevus, and without evidence of dyskeratosis (86).

FIGURE 6-8. Pachyonychia congenita. Thickened nails in infant with this syndrome.

Pathogenesis. A defect in keratin synthesis in types I and II is suggested by mutations of K6b, K9, K16, and K17 mapped to chromosome 12q13 or 17q12-q21 (87,88).

DYSKERATOSIS CONGENITA

Dyskeratosis congenita usually is inherited as an X-linked recessive disorder, most likely location Xq28, occurring only in males; but in some instances, it is transmitted in an autosomal dominant fashion, in which case females also may be affected (89). It is characterized by the following triad: (a) dystrophy of the nails, with failure of the nails to form a nail plate; (b) white thickening (leukokeratosis) of the oral and occasionally also of the anal mucosa; and (c) extensive areas of netlike pigmentation of the skin suggestive of poikiloderma atrophicans vasculare but with less atrophy and telangiectasia. In the X-linked form, testicular atrophy is also common. Carcinoma may develop in areas of buccal and anal leukokeratosis. In many cases, a Fanconi

FIGURE 6-9. Pachyonychia congenita. Note whitened mucosa at back of tongue.

type of anemia develops that may begin with leukopenia and thrombocytopenia but ends in severe pancytopenia (90).

Histopathology. In dyskeratosis congenita, the areas of netlike pigmentation show melanophages in the upper dermis as their only constant feature (91). In contrast to poikiloderma atrophicans vasculare, atrophy of the epidermis, vacuolization of basal cells, and inflammatory infiltration of the upper dermis are either absent (92) or are mild and thus not diagnostic (91). Oral biopsies may show squamous cell carcinoma *in situ* or invasive squamous cell carcinoma.

Pathogenesis. The gene responsible for X-linked dyskeratosis congenita (DKC1) encodes a protein called *dyskerin*, which is essential for ribosome biogenesis and telomerase RNP assembly. X-linked and autosomal dyskeratosis congenita have reduced telomere lengths but normal telomerase activity (93,94).

FIGURE 6-10. Porokeratosis. Linear hyperkeratosis along the feet and legs.

POROKERATOSIS

Porokeratosis has a wide variety of manifestations, but with the exception of the punctate type, it is characterized by a distinct peripheral keratotic ridge that corresponds histologically to the cornoid lamella (Fig. 6-10). Porokeratosis is inherited in an autosomal dominant pattern. Five different forms can be distinguished (95).

The *plaque type*, as originally described by Mibelli, shows a single or a few lesions several centimeters in diameter. Rarely, there are numerous lesions (96). The border often consists of a raised wall, having on its top a furrow filled with keratotic material. The lesions have a tendency toward peripheral extension.

Disseminated superficial actinic porokeratosis, the most common type, shows lesions that often are most pronounced in sun-exposed areas and may be exacerbated by exposure to the sun (97). However, the term *actinic* cannot be applied to all cases. In some instances, the lesions are distributed mainly in areas not exposed to the sun (98), and in some cases, immunosuppression has been the eliciting factor (99). The extensor surfaces of the extremities are the most common site of involvement. The lesions in disseminated superficial porokeratosis are small and are surrounded only by a narrow, slightly raised, hyperkeratotic ridge without a distinct furrow (97).

Linear porokeratosis may involve only a segment of the body or may have a generalized distribution. The lesions clinically resemble those of linear verrucous epidermal nevus (100,101).

Porokeratosis plantaris, palmaris, et disseminata is characterized by the appearance in adolescence or early adult life of many lesions on the palms and soles and subsequently by the involvement of other areas of the body with large numbers of small superficial lesions (102–104).

Punctate porokeratosis, limited to the palms and soles, shows numerous punctate, 1- to 2-mm seedlike keratotic plugs without tendency to centrifugal enlargement. They may be moderately tender to pressure (105).

Development of a squamous cell carcinoma or of Bowen's disease within lesions of porokeratosis has been repeatedly reported in patients with solitary lesions (106) and in persons with disseminated lesions (102) or linear lesions (107). In one reported instance with many lesions and multiple squamous cell carcinomas, visceral metastases resulted in death (96).

Histopathology. It is essential that the specimen for biopsy be taken from the peripheral, raised, hyperkeratotic ridge. On histologic examination, the ridge then shows a keratin-filled invagination of the epidermis. In the plaque type of porokeratosis, the invagination extends deeply downward at an angle, the apex of which points away from the central portion of the lesion. In the center of this keratin-filled invagination rises a parakeratotic column, the so-called cornoid lamella, representing the most characteristic feature of porokeratosis of Mibelli (108) (Fig. 6-11). Within the parakeratotic column, the horny cells appear homogeneous and possess pyknotic nuclei. In the epidermis beneath the parakeratotic column, the keratinocytes are irregularly arranged and have pyknotic nuclei with perinuclear edema. In the upper stratum malpighii, some cells possess an eosinophilic cytoplasm as a result of premature keratinization (109). Usually, no granular layer is found at the site at which the parakeratotic column arises, but elsewhere, the keratin-filled invagination of the epidermis has a well-developed granular layer.

The histologic changes in the other forms of porokeratosis are similar to those seen in the plaque type but less pronounced, the central invagination being rather shallow, especially in disseminated superficial actinic porokeratosis. The shallow parakeratotic invagination then stands out by showing homogeneous cells rather than the basket weave pattern seen in the surrounding orthokeratotic stratum corneum (Fig. 6-12).

Because the peripheral raised ridge in porokeratosis slowly moves centrifugally, it stands to reason that the invagination is not bound to a definite structure, such as the sweat pore, as originally assumed by Mibelli. Although the invagination occasionally may be seen within a sweat pore or a pilosebaceous

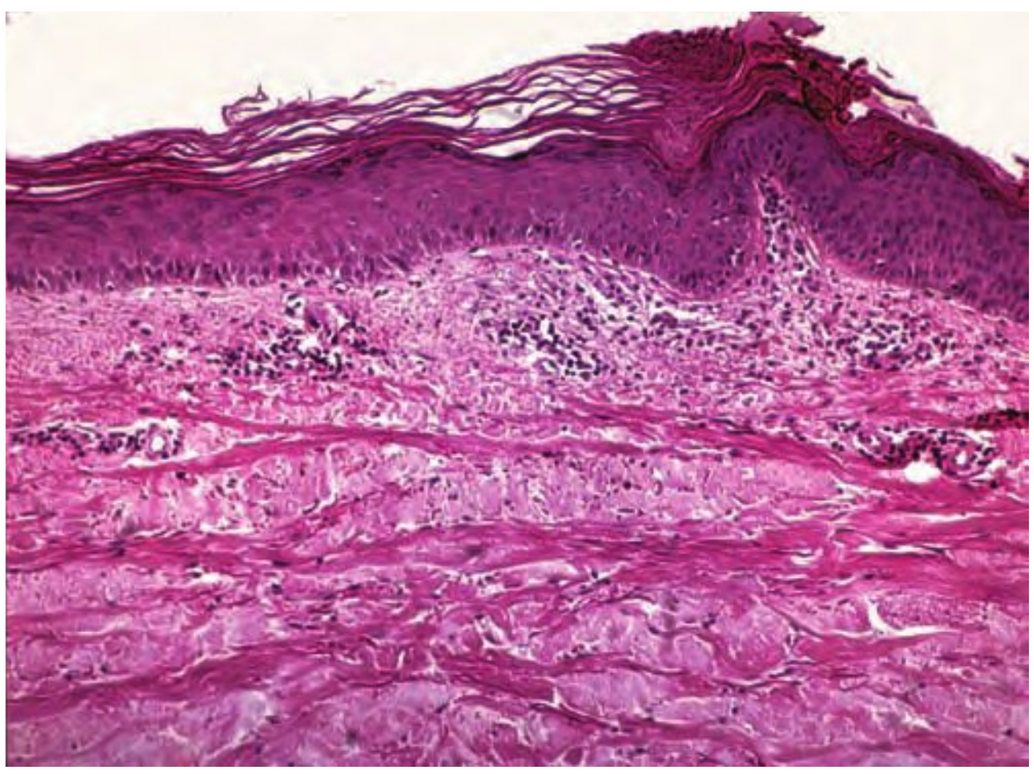

FIGURE 6-11. Porokeratosis of Mibelli. Stacked parakeratosis in an area of delled epidermis. The underlying granular cell layer is diminished to absent (original magnification ×200).

follicle, it is found most commonly in the epidermis independent of these cutaneous appendages (110). Overexpression of the P53 tumor suppressor protein has been found in porokeratosis (111). The epidermis overlying the central portion of a lesion of porokeratosis may be either flattened or normal in thickness or, rarely, acanthotic. A nonspecific perivascular infiltrate of chronic inflammatory cells is present in the dermis.

Pathogenesis. The presence of a clone of abnormal epidermal cells located at the base of the parakeratotic column explains the lesions of porokeratosis. As a result of a gradual centrifugal movement of this clone, the furrow is slanted, its apex pointing away from the center of the lesion (110).

Electron microscopic examination reveals that in the epidermis beneath the parakeratotic column, many keratinocytes show signs of degeneration. They show a pyknotic nucleus, large perinuclear vacuoles that are separated from one another by cytoplasmic strands, and condensation of tonofilaments at their periphery (112). At the base of the parakeratotic column, dyskeratotic cells composed of nuclear remnants and aggregated tonofilaments are seen (113). The parakeratotic column is composed chiefly of cells with a pyknotic nucleus and a cytoplasm possessing high electron density because of the presence of many partially degraded organelles. In addition, a few dyskeratotic cells are present (114).

Differential Diagnosis. Even though cornoid lamellation is a typical finding for porokeratosis, it is found in a variety of other conditions (115), especially in verruca vulgaris and solar

Witmer.)

keratosis. A histologic distinction of punctate porokeratosis from plantar or palmar warts may be impossible, and clinical data such as age of onset, inheritance, and number and size of lesions may be needed. For discussion of porokeratotic eccrine duct nevus, see the section on nevus comedonicus.

XERODERMA PIGMENTOSUM

In xeroderma pigmentosum, an autosomal recessive disorder, excessive solar damage to the skin develops at an early age. Consequently, the lesions occur chiefly in areas of the skin that habitually are exposed to sunlight. Three stages are recognized. In the first stage, which usually starts when the child is 1 or 2 years old, slight diffuse erythema is associated with scaling and small areas of hyperpigmentation resembling freckles. In the second stage, atrophy of the skin, mottled pigmentation, and telangiectases give the skin an appearance similar to that of a chronic radiodermatitis. Solar keratoses arise in areas of scaling. In the third stage, which usually starts in adolescence but sometimes much earlier in the patient's life, various types of malignant tumors of the skin appear, often causing death. They include squamous cell carcinoma, basal cell carcinoma, and, rarely, fibrosarcoma. In about 3% of patients with xeroderma pigmentosum, malignant melanomas arise. In some patients, they show no tendency to metastasize; however in others, they metastasize rapidly (116). Multiple malignant melanomas have been observed (117). The eyes also are affected, showing conjunctivitis and often keratitis with corneal opacities.

A very rare form of xeroderma pigmentosum is the *De Sanctis-Cacchione syndrome*, which in addition to severe skin lesions shows neurologic manifestations, especially microcephaly, retarded growth, and cerebellar ataxia (118).

Histopathology. In the first stage, the histopathologic appearance is not specific, but the diagnosis is suggested by a combination of changes that normally are not seen in the skin of young persons. They are hyperkeratosis; thinning of the stratum malpighii, with atrophy of some of the rete ridges and elongation of others; a chronic inflammatory infiltrate in the upper dermis; and irregular accumulations of melanin in the basal cell layer, with or without an increase in the number of melanocytes.

In the second stage, the hyperkeratosis and irregular hyperpigmentation already present in the first stage are more pronounced. The epidermis shows atrophy in some areas and acanthosis in others. There may be disorder in the arrangement of the epidermal nuclei, and in some areas the epidermis may show atypical downward growth, so the histologic picture in such areas is identical with that of solar keratosis. The upper dermis shows basophilic degeneration of the collagen and solar elastosis, as also is seen in solar degeneration.

In the third, or tumor, stage, histologic evidence of the various malignant tumors mentioned earlier is found.

Pathogenesis. In patients with xeroderma pigmentosum (with the exception of those who have the so-called XP variant; see below), cells of the skin in tissue culture show a decrease in their ability to repair the damage induced by sunlight to their deoxyribonucleic acid (DNA). This repair is brought about by *excision repair*, a system whereby damaged single-strand regions of DNA are excised and replaced with new sequences of bases (119). The reason for the inadequate excision repair is that the DNA–endonuclease that initiates the excision process is deficient. *In vitro* testing of skin fibroblasts from different patients with xeroderma pigmentosum shows considerable variation in the excision defect, with the extent of repair replication varying between 0% and 90% of normal. Affected siblings are usually similar to each other in degree of repair replication. However, no correlation exists between the level of repair replication and the severity of clinical symptoms (120).

There are at least five patients known in whom excision repair is normal but the cells are defective in a DNA repair mode referred to as *postreplication repair*. This represents the so-called XP variant form. In cells of this variant form, the rate of conversion from low– to high–molecular weight DNA is defective (121). Mutated genes in this condition include XP(A-G) and h RAD 30 with affected protein function complementation group A-G and DAN polymerase (122).

In pigmented areas, electron microscopic examination of the epidermis has revealed marked pleomorphism and a definite increase in the number of melanosomes. In some cases, very large melanosomes, referred to as *giant melanosomes*, are present in both melanocytes and keratinocytes (123). Even epidermis that is protected from light and shows no clinical abnormalities exhibits significant cellular alterations.

ECTODERMAL DYSPLASIA

The ectodermal dysplasias share abnormalities of the hair, nails, teeth, and sweat glands. Additionally, other abnormalities including mental retardation are described. Over 170 different clinical conditions have been reported as ectodermal dysplasias, many of which have clinical overlap. For the purpose of simplification, *hidrotic* and *anhidrotic* (now called *hypohidrotic*) forms will be discussed (124).

The *hidrotic* form, which has an autosomal dominant inheritance, is primarily a disorder of keratinization that is characterized by hypotrichosis, dystrophic nails, and palmoplantar hyperkeratosis. It is sometimes associated with dental hypoplasia (125). The degree of alopecia varies from slight to total (126). A mutated gene gap junction protein beta-b (GJB6) on chrosome 13q12, which encodes connexin 30, has been described (127).

The *anhidrotic* (hypohidrotic) form is an X-linked recessive disorder occurring in its full expression only in males. Mutations in the genes for ectodysplasin, its receptor, or mediating proteins (EDA or dL or EDARADD, respectively) cause these forms of ectodysplasia (128) and are localized to Xq12-q13.1. Females, as heterozygotes, may be mildly affected, with reduced sweating and faulty dentition. Males affected with anhidrotic ectodermal dysplasia show the tetrad of anhidrosis or hypohidrosis—hypotrichosis, dental hypoplasia, and a characteristic facies (129)

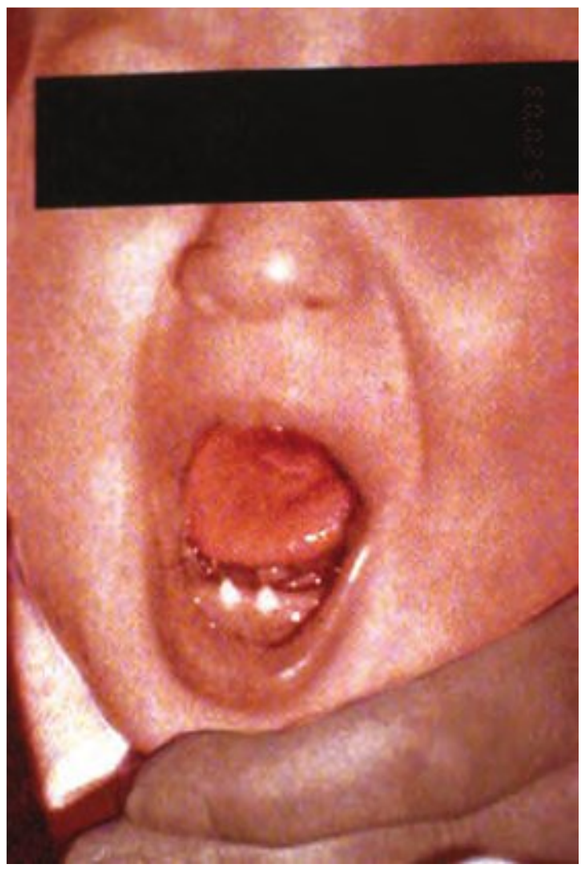

FIGURE 6-13. Hypohidrotic ectodermal dysplasia. Characteristic pegged teeth.

(Fig. 6-13). Frequently, there is also dystrophy of the nails (129). The greatly reduced or absent function of the eccrine glands results in intolerance to heat. The face shows prominent frontal bosses and a depressed nasal bridge (Fig. 6-14). In addition, the mucous glands of the mouth and respiratory tract may be absent (130). The lack of mammary glands and nipples has been noted (131).

Histopathology. Both the hidrotic and the anhidrotic forms show hypoplasia of the hair and the sebaceous glands, with a decrease in their number, size, and degree of maturation (125,131).

In the anhidrotic form, there is, in addition, either a total absence or severe hypoplasia of the eccrine glands. In the case of hypoplasia, eccrine glands are present in only a few areas, especially the axillae and palms, but even in these areas, they are sparse and poorly developed. The secretory cells may be small and flat, so that they resemble endothelial rather than epithelial cells, and the excretory ducts may be composed of a single instead of a double layer of epithelial cells (132). The apocrine glands of the axillae are present in some patients with the anhidrotic form; in others, these glands are hypoplastic and cannot be distinguished from hypoplastic eccrine glands; in still others, both eccrine and apocrine glands are absent.

FIGURE 6-14. Hypohidrotic ectodermal dysplasia. In addition to frontal bossing and a flat nasal bridge, this infant demonstrates hyperpigmentation of the eyelids and surrounding skin as well as patulous lips.

FOCAL DERMAL HYPOPLASIA SYNDROME

The focal dermal hypoplasia syndrome, or Goltz syndrome, is probably due to an X-linked dominant gene that is lethal in homozygous males. Mutations in PORCN, which are involved in the Wnt signaling pathway, have been identified as causal in Goltz syndrome (133). Therefore, the syndrome occurs largely in females. Its occasional occurrence in males had been considered to be the result of a new mutation, but recent evidence reveals that all affected males may be mosaic for mutations in PORCN. The mode of inheritance thus is similar to that of incontinentia pigmenti (IP).

The cutaneous manifestations of the focal dermal hyperplasia syndrome include widely distributed linear areas of hypoplasia of the skin resembling striae distensae; soft, yellow nodules, often in linear arrangement; and large ulcers due to congenital absence of skin that gradually heal with atrophy. It is important to remember that there are varied presentations of this syndrome (134). Frequent additional abnormalities include lack of a digit, which may be associated with syndactyly and results in the very characteristic "lobster-claw deformity"; colobomata of the eyes, or microphthalmia, or agenesis of an eye (135); and hypoplasia of hair, nails, or teeth (136). The presence of fine, parallel, vertical striations in the metaphysis of long bones on radiography, referred to as osteopathia striata, is a reliable diagnostic marker of Goltz's syndrome (137).

Histopathology. The linear areas of hypoplasia of the skin show a marked diminution in the thickness of the dermis, with the collagen being present as thin fibers not united into bundles. The soft, yellow nodules represent accumulations of fat that largely replace the dermis; thus, the subcutaneous fat extends upward to the epidermis in some areas (136,138) (Fig. 6-15). Thin fibers of collagen and even some bundles of collagen resembling those of normal dermis may be located between the subepidermal adipose tissue and the subcutaneous fat (137).

Pathogenesis. Electron microscopic examination shows, in addition to collagen fibrils 70 nm or more in diameter, many fine filamentous structures measuring 5 to 70 nm in diameter. There are two types of fat cells, one unilocular and the other multilocular, the latter representing young lipocytes (139).

Differential Diagnosis. Fat cells are seen in the dermis and also in the nevus lipomatosus of Hoffmann and Zurhelle, but the extreme attenuation of the collagen that occurs in some areas of

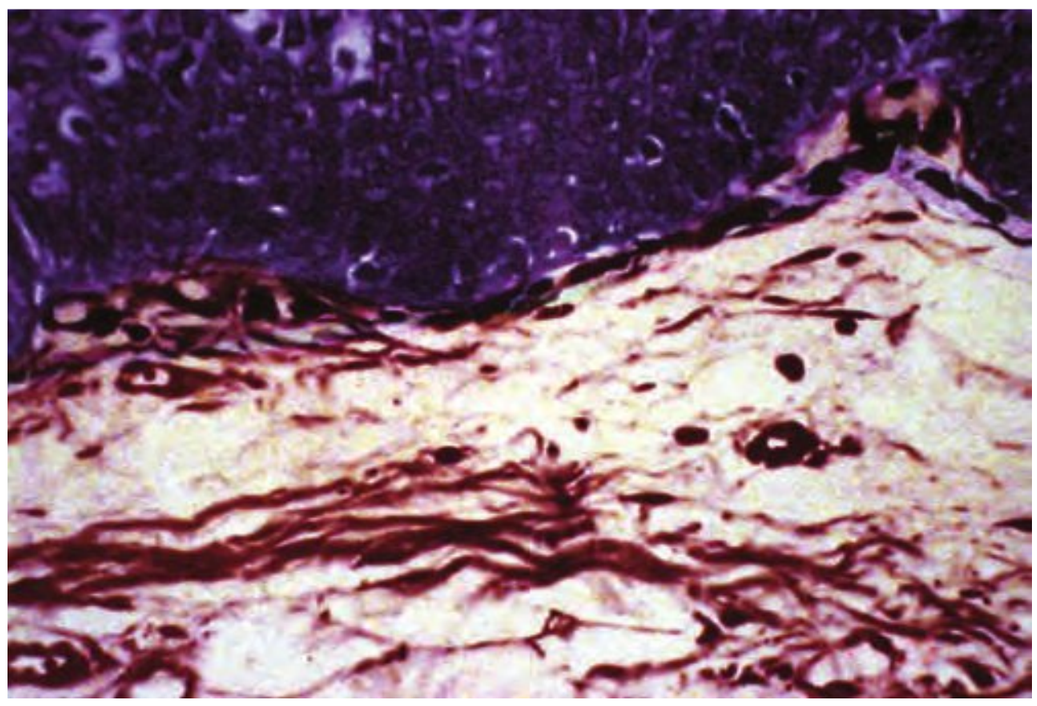

FIGURE 6-15. Focal dermal hypoplasia. Adipose tissue is present very near the epidermis, separated from it by only a few collagen fibers (original magnification ×200).

the skin in patients with focal dermal hypoplasia syndrome is not seen in nevus lipomatosus. Several females with deletions of the distal short arm of X(Xp22.3–p22.2) have recently been described who have lapping features of this syndrome.

APLASIA CUTIS CONGENITA

Aplasia cutis congenita consists of a localized absence of skin at the time of birth (Fig. 6-16) and may be membranous or nonmembranous. Most commonly, one observes a single ulcer or several ulcers on the scalp that measure only 1 to 3 cm in diameter and heal uneventfully. In some instances, intrauterine healing has occurred. Occasionally, large defects of the skin are present; but even then, as a rule, healing takes place within several months (140,141). The condition includes a diverse group of disorders in which localized absence of skin occurs alone or in association with a wide variety of abnormalities (142).

FIGURE 6-16. Aplasia cutis congenita. Two areas of congenitally absent skin (scarred and hairless).

Histopathology. Ulcers extend through the entire thickness of the dermis, exposing the subcutaneous fat (143). Healed areas show, besides a flattened epidermis, fibrosis in the dermis and complete absence of adnexal structures (140).

Differential Diagnosis. Aplasia cutis should not be confused with congenital absence of the skin, where only epidermis is absent. This is a variant of *epidermolysis bullosa (EB) (Bart's syndrome)* (144).

POIKILODERMA CONGENITALE (ROTHMUND-THOMSON SYNDROME)

Poikiloderma congenitale is inherited in an autosomal recessive pattern due to mutations in the DNA helicase gene RECQLA on gene map locus 8q24.3 (145). It begins a few months after birth with erythema on the face (Fig. 6-17) and subsequently extends to the dorsa of the hands and feet and occasionally also to the arms, legs, and buttocks. Later on, slight atrophy develops with telangiectases and mottled hyper- and hypopigmentation, so the appearance is that of poikiloderma atrophicans vasculare (Fig. 6-18). Exposure to light aggravates the lesions. Most patients show dwarfism and hypogonadism. In about 40% of patients, cataracts develop between the ages of 4 and 7 years (146). Recent evidence suggests that children with this syndrome have a reduced DNA repair capacity (147).

Histopathology. During the early phase occurring in infancy and early childhood, there is hydropic degeneration of the basal layer leading to "pigment incontinence" with presence of melanophages in the upper dermis (131). A mild chronic inflammatory infiltrate is intermingled with the melanophages and may show a bandlike arrangement close to the flattened

FIGURE 6-17. Poikiloderma congenitale. An older child with pokiloderma, atrophy, and hyperpigmentation.

FIGURE 6-18. Poikiloderma congenitale. Older child with poikilodermatous changes of the cheek and ear.

FIGURE 6-20. Bloom's syndrome. Erythema of the shoulders with photodistributed skin changes on the back.

epidermis (146) (Fig. 6-19). The histologic changes thus may be identical with those seen in the early stage of poikiloderma atrophicans vasculare. In later childhood and adult life, the epidermis is flattened, and dilated capillaries as well as melanophages are present in the upper dermis, but there is no longer any inflammatory infiltrate.

BLOOM'S SYNDROME (CONGENITAL TELANGIECTATIC ERYTHEMA)

Bloom's syndrome, with autosomal recessive inheritance due to mutations in the gene encoding DNA helicase RecQ protein-like 2 on gene map locus 15q26.1 (148), resembles poikiloderma congenitale by showing (a) telangiectatic erythema of the face starting in infancy and often extending to the forearms and hands, (b) sensitivity to sunlight, (c) café au lait macules in over 50% of patients (149), and (d) growth retardation (Fig. 6-20). It differs from poikiloderma congenitale by (a) the lack of netlike hyper- and hypopigmentation (150); (b) the absence of hypogonadism (testicular atrophy and sterility are common in male patients) and cataracts; (c) the occasional presence of immunoglobulin deficiencies, especially of IgA and IgM (151,152); (d) a high incidence of nonspecific chromosomal breakage (152) and a great increase in the frequency of another type of chromosome instability, sister chromatid exchanges (153); and (e) an increased risk for malignant disease, especially leukemia, lymphoma, and carcinoma of the alimentary tract (154).

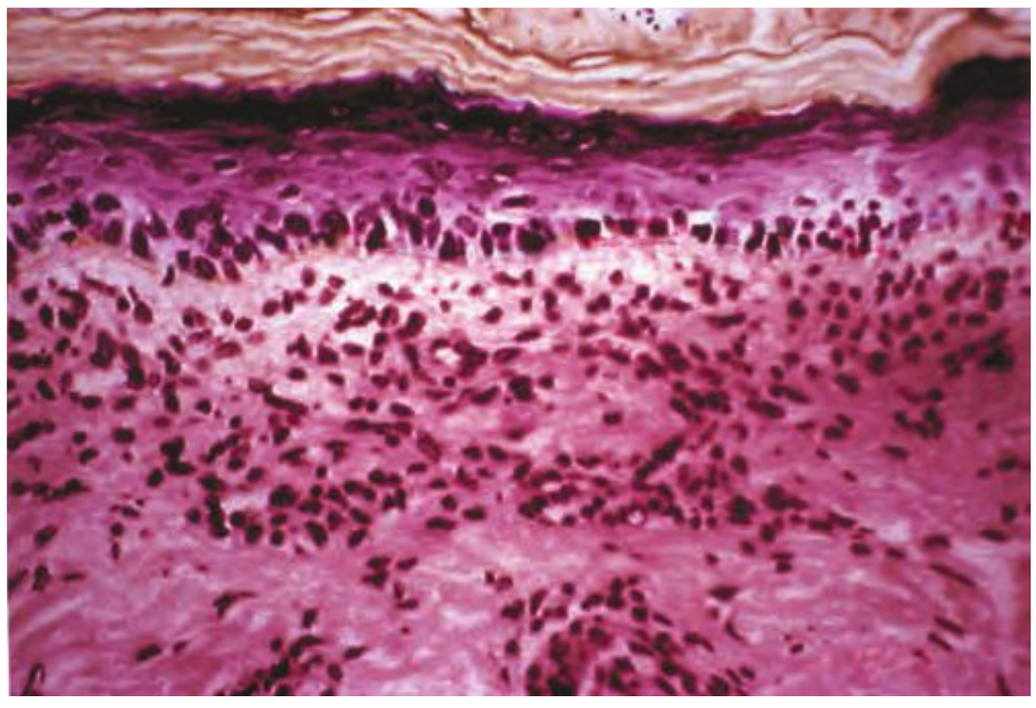

FIGURE 6-19. Poikiloderma congenitale (Rothman-Thompson), early. This section from a young child shows flattening of the epidermis, hydropic degeneration of the basal layer, and a bandlike inflammatory infiltrate in the upper dermis (original magnification ×200).

Histopathology. The epidermis is flattened and may show hydropic degeneration of the basal cell layer (153). There is dilatation of the capillaries in the upper dermis, which may be associated with a perivascular mononuclear infiltrate (149,153); however, there may be absence of any infiltrate (150).

Pathogenesis. Bloom's syndrome shows impairment of both cellular and humoral immunity, although this is not as pronounced as in *ataxia-telangiectasia* (see later). Evidence of impaired cellular immunity is the occasional absence of delayed hypersensitivity reactions (152) and the tendency toward development of malignant disease. Evidence of impaired humoral immunity is the occasional presence of immunoglobulin deficiencies. However, in contrast to ataxia-telangiectasia, susceptibility to infections is not pronounced.

Differential Diagnosis. Pigmentary incontinence is not pronounced in Bloom's syndrome, as it is in poikiloderma congenitale. The presence of hydropic degeneration of the basal cell layer and of a perivascular infiltrate may cause difficulties in differentiation from lupus erythematosus. However, no linear deposits of immunoglobulin are seen at the dermal–epidermal junction in Bloom's syndrome (153).

ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia is transmitted in an autosomal recessive mode. The ataxia is evident already in infancy, whereas the telangiectases do not appear until childhood. They usually appear first on the bulbar conjuntivae, with subsequent extension to the cheeks, ears, and neck and often also to other areas, such as the buttocks and extremities. A marked susceptibility to infections, particularly sinopulmonary infections, exists. Death from chronic respiratory infection or lymphoma-leukemia is common in the second or third decade of life (155).

Histopathology. The upper dermis shows numerous markedly dilated vessels that belong to the subpapillary venous plexus (156).

Pathogenesis. All patients have severe defects in both humoral and cellular immunity. In approximately 75% of patients, there is an absence or extreme deficiency of the serum IgA; in about 80%, there is a great IgE deficiency (157). Autopsies have established maldevelopment of the thymus as an integral part of ataxia-telangiectasia (158). Increased number of T cells with gamma/delta chains in the T-cell receptors rather than alpha/beta chains may produce defects in immunity (159). Chromosomal breakage is common, but there is no increased rate of sister chromatid exchanges (156). Mutations in the ATM gene, which affects protein kinase, have been mapped to gene locus 11q22.3 (160).

PROGERIA OF THE ADULT (WERNER'S SYNDROME)

Werner's syndrome, which has an autosomal recessive mode of inheritance, does not manifest itself until the second or third decade of life. The subcutaneous fat and the musculature of the extremities undergo atrophy, so the patient exhibits thin arms and legs. The skin of the extremities gradually becomes taut, and ulcers may develop on the legs. As signs of premature senility, patients show graying of the hair, cataracts, and atherosclerosis in early adult life. Diabetes of the late-onset type (161) and hypogonadism due to interstitial fibrosis of the testes (162) are common. Death usually occurs in the fifth decade of life because of atherosclerosis.

Histopathology. On the arms and legs, where the skin is taut, the epidermis is thin and devoid of rete ridges, and the dermis shows fibrosis with or without hyalinization of the collagen. The pilosebaceous structures degenerate. The subcutaneous fatty tissue is largely replaced by newly synthesized, hyalinized collagen that merges with the collagen of the overlying dermis (163).

Pathogenesis. Poor growth and decreased life span of cultured skin fibroblasts have been found (164). The cause is due to mutation in the RECQL2 gene, which encodes a homolog of the *Escherichia coli* RecQ DNA helicase on gene map locus 8p12-11.2 (148).

Differential Diagnosis. Differentiation from a late lesion of scleroderma may be difficult, because fibrosis and hyalinization of the collagen are seen also in scleroderma (161). In its late stage, scleroderma may also show no inflammatory infiltrate, so that differentiation has to be made on the basis of the patient's history and clinical manifestations.

EPIDERMOLYSIS BULLOSA

On the basis of clinical, histologic, and electron microscopic findings, three groups of EB are recognized: epidermal, junctional, and dermal (Table 6-1).

In all types of EB, the blisters form as a result of minor trauma. Because of the great differences in prognoses, identification of the type of EB is often very important. In families with the potential of having an infant born with one of the frequently or potentially fatal forms of EB, such as *EB letalis*

TABLE 6-1 Comparison of the Clinical Features and Prognosis in Epidermolysis Bullosa

Type	Epidermolysis Bullosa	Distribution	Inheritance	Oral	Scarring	Prognosis
Epidermal	EB simplex	Generalized	Dominant	+	−	Good
	EB Cockayne	Feet, hands	Dominant	−	−	Good
	EB Dowling–Meara (Herpetiform)	Generalized	Dominant	+	Atrophy	Improves by school age
Junctional	EB letalis	Generalized	Recessive	+	−	Usually fatal
	EB benign	Generalized	Recessive	±	Atrophy	Good
Dermal	EB dystr-dom	Extremities	Dominant	±	+	Good
	EB dystr-rec	Generalized	Recessive	++	+++	Poor
	EB dystr-rec	Localized	Recessive	+	+	Good
	EB dystr-inversa	Mainly trunk	Recessive	+	+, late	Good
	EB acquisita	Generalized	—	+	+	Good

EB, epidermolysis bullosa; dystr-dom, dystrophica-dominant; dystr-rec, dystrophica-recessive; dystr-inversa, dystrophica-inversa.

FIGURE 6-21. Junctional epidermolysis bullosa. Erosions of the face, arm, and trunk.

FIGURE 6-23. Epidermal epidermolysis bullosa. Herpetiform blistering on the leg.

(Fig. 6-21) or generalized *EB dystrophica-recessive* (Fig. 6-22), a prenatal biopsy at 18 to 20 weeks of gestation is recommended. On electron microscopy, EB letalis shows abnormalities of the hemidesmosomes while generalized EB dystrophica-recessive shows absence of anchoring fibrils.

There is more variability in the clinical course in some forms of EB than was previously appreciated (165). For example, within the epidermal type of EB, which usually has a good prognosis, some cases of *EB herpetiformis*, which is known also as the *Dowling-Meara variant*, may show generalized blistering that at times is associated with mortality during early infancy (166) (Fig. 6-23). Also, the junctional form of EB can result in scarring as *cicatricial junctional EB* (167). Occasionally, dermal EB may be transient and heal within a few months (168,169). It is likely that the majority of cases published as Bart's syndrome, which was originally described as congenital absence of the skin (170), belong in this group (171,172).

FIGURE 6-22. Recessive dystrophic epidermolysis bullosa. Child with mitten deformity of hands as well as generalized blisters and scarring.

Histopathology. If a fresh blister is available, a specimen for biopsy may be taken from its edge. However, it is advisable to carry out a biopsy also on an induced blister because it will show a blister free of secondary changes. In an existing blister, the location of the blister may have changed as the result of regeneration of keratinocytes at the base of the blister or degeneration of the keratinocytes over the blister. The mode of artificially producing a blister depends on the degree of vulnerability of the skin. However, in most instances, gentle friction with a cotton swab or a pencil eraser is used. The preferred type of biopsy is either a shave or an ellipse. The use of a punch is not recommended because the applied torsion will frequently cause total separation and even loss of the epidermis (173).

Even though electron microscopic examination (discussed later) is informative, the light microscopic features seen in the various forms of EB are of diagnostic value.

In *epidermal EB*, which includes EB simplex, EB of feet and hands of Weber and Cockayne (174), and EB herpetiformis (Dowling-Meara) (175,176), the primary separation in experimentally induced blisters always occurs within the basal cell layer. Spontaneously arising blisters may be found subepidermally as the result of complete disintegration of the basal cell layer; in bullae of more than 1 day's duration, the cleavage may be found intraepidermally or subcorneally as a result of epidermal regeneration (174). In sections stained with the PAS technique, the PAS–positive basement membrane zone is located on the dermal side of the blister (177).

In *junctional EB*, the trauma of having a specimen taken for biopsy generally is sufficient to induce separation. This separation is located between the epidermis and the dermis, with

the PAS–positive basement membrane zone usually remaining with the dermis (178). In some cases of EB letalis, autopsy has revealed extensive subepithelial separation also in the gastrointestinal, respiratory, and urinary tracts (178,179). There are no morphologic or enzymatic abnormalities to distinguish the atrophic benign form of junctional EB from EB letalis (180).

In *EB dystrophica-dominant* and *EB dystrophica-recessive*, light microscopy shows dermal–epidermal separation. A PAS stain is of little help in ascertaining the exact level of cleavage because the PAS–positive basement membrane zone often appears hazy (178). If recognizable, it is seen in contact with the detached epidermis or appears split. In EB dystrophica-dominant, scarring is mild. However, in generalized EB dystrophica-recessive, extensive erosions may occur, resulting in ulcerations and severe scarring. Severe oral involvement can lead to esophageal stenoses (181). In especially severe cases, death may occur. The ulcers and scars of the skin, mouth, and esophagus may give rise to squamous cell carcinomas, which tend to metastasize (182).

EB acquisita is not a genodermatosis but an autoimmune disorder (see also chapter 9).

Pathogenesis. If possible, all specimens of artificially induced blisters should be subjected to electron microscopic examination and immunofluorescence mapping (178). The latter procedure consists of exposing cryostat sections to specific antisera against type IV collagen (localized in the lamina densa or basal lamina), against laminin (localized in the lower portion of the lamina lucida), and against bullous pemphigoid antigen (localized in the upper portion of the lamina lucida in the vicinity of the hemidesmosomes). For the latter test, bullous pemphigoid antibodies contained in many bullous pemphigoid sera are used.

In the epidermal types of EB, electron microscopic examination shows that cleavage is the result of degenerative cytolytic changes occurring in the lower portion of the basal cells between the dermal–epidermal junction and the nucleus (EM 4). Immunofluorescence mapping shows that all three antigens (type IV collagen, laminin, bullous pemphigoid antigen) are located beneath the cleavage. Studies in several families with the Dowling-Meara form of EB have revealed point mutations of keratin genes for KRT5 and KRT14 on chromosome 12 and 17, respectively (183). Different mutations in the KRT5 gene can lead to the Koebner type of EBS or the Weber-Cockayne type.

In the junctional types of EB, electron microscopic examination often shows the hemidesmosomes to be abnormal, especially in EB letalis. They may be reduced in size or number and may lack their subbasal cell-dense plaque (184). However, there are exceptions. In one fatal case of EB letalis, the hemidesmosomes were structurally and numerically normal. Also, one patient with nonlethal junctional EB showed similar abnormalities of the hemidesmosomes, as seen in the majority of patients in the lethal group (185). It is possible that the abnormalities of the hemidesmosomes are a secondary phenomenon and that the basic cause of the junctional types of EB is a biochemical disorder of a lamina lucida constituent. In favor of this theory is the fact that normal skin shows separation at the dermal–epidermal junction when cultured with blister fluid of patients with EB letalis (186). Immunofluorescence mapping shows type IV collagen and laminin on the floor of the blister; bullous pemphigoid antigen is present mainly on the blister roof but also in a more spotty distribution and to a much lesser extent on the blister floor (178). Mutations have been found in any of three polypeptides of laminin-5: alpha-3 (LAMA3), BETA-3 (LAMB3), and GAMMA-2 (LAMC2). The gene is responsible for encoding a portion of laminin 5. This mutation may have significance in reducing adhesion between the epidermis and dermis (187). A newly found mutation of the gene encoding $beta_4$ integrin has been found in the subset of EB letalis with pyloric atresia (186).

The dermal types of EB, on electron microscopy, show abnormalities in regard to their anchoring fibrils. Generalized recessive dystrophic EB shows absence of the anchoring fibrils even in nonlesional unscarred skin. On the other hand, in both dominant dystrophic EB and in localized recessive dystrophic EB, structurally normal anchoring fibrils are present but in significantly reduced number (188). The complete absence of anchoring fibrils in generalized recessive dystrophic EB could be established through the lack of a reaction with monoclonal antibodies to anchoring fibrils (189). Because type VII collagen is a major structural component of the anchoring fibrils, immunofluorescence staining with polyclonal antibodies to type VII collagen reveals complete absence of staining, even in the unaffected skin of patients with severe dystrophic recessive EB (190). Similarly, there was no reaction with periodic acid-thiosemicarbazide-silver proteinate, which stains anchoring fibrils selectively (191). Mutations in the gene encoding type VII collagen (COL 7A1) located at chromosome band 3p21 have been reported to cause these abnormal findings in the dystrophic forms of EB (192,193). Immunofluorescence mapping shows all three basement membrane zone constituents—bullous pemphigoid antigen, laminin, and type IV collagen—on top of the cleavage (178).

Epidermolysis Bullosa Acquisita

EB acquisita starts in childhood or adult life (196) with blisters at sites of trauma resulting in atrophic scars that in some cases are not pronounced (Figs. 6-24 and 6-25). Milia may not appear until the disorder has been present for many years. Oral lesions are seen occasionally. A significant proportion of patients with EB acquisita have circulating IgG antibodies (194).

Histopathology. The bullae are located beneath the epidermis and thus are indistinguishable in their location from those seen in bullous pemphigoid. The prevalence of eosinophils in the infiltrate of bullous pemphigoid often helps in distinguishing the two diseases. However, because the findings by light microscopic immunofluorescence are identical in the two diseases, patients with EB acquisita have been misdiagnosed frequently as having bullous pemphigoid before the recognition of the

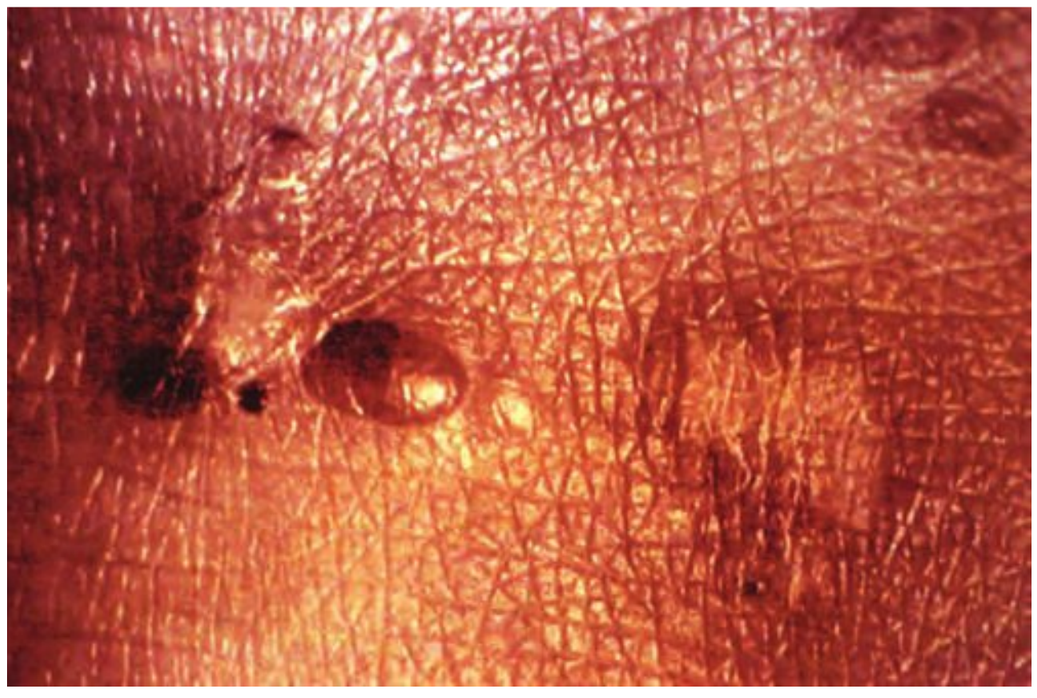

FIGURE 6-24. Epidermolysis bullosa acquisita. A blister surrounded by two scars.

different location of the respective antibodies on immunoelectron microscopy. "Salt-split" skin combined with immunofluoresence has proven to be an aid in distinguishing EB acquisita from bullous pemphigoid. Early studies demonstrated EB acquisita antibodies on the dermal side (floor) of the salt-split skin and bullous pemphigoid antibodies on the epidermal side (roof) (195,196). Later studies have found bullous pemphigoid as well as EB acquisita antibodies on the floor of the salt split (197). Despite these latter studies, this technique still has value in differentiating these two conditions.

Histogenesis. Since EB acquisita on direct immunofluorescence shows subepidermal deposits of IgG and C3 and on indirect immunofluorescence often shows circulating antibodies against IgG, a misdiagnosis of bullous pemphigoid has been made in some cases (198), or in the case of pronounced scarring, a misdiagnosis of cicatricial pemphigoid (199). Immunoelectron microscopy, however, has shown a different location of the IgG deposits in these two disease groups: in bullous pemphigoid and cicatricial pemphigoid, they are located in the lamina lucida (200); in EB acquisita, they are found in the upper dermis just beneath or contiguous to the lamina densa (194). Similarly, whereas type IV collagen and laminin are located at the floor of the blister in bullous pemphigoid, they are seen on the roof of the blister in EB acquisita. Because antibody to human type IV collagen functions also in formalin-fixed, paraffin-embedded tissue sections, standard immunoperoxidase methods have revealed type IV collagen to be associated with the blister roof in EB acquisita and with the blister base in bullous pemphigoid and cicatricial pemphigoid (201).

FAMILIAL BENIGN PEMPHIGUS (HAILEY-HAILEY DISEASE)

Familial benign pemphigus is inherited as an autosomal dominant trait, with a family history obtainable in about two thirds of patients. Genetic studies have localized the key mutations to the ATP2C1 gene on chromosome 3q (202), specifically 3q21-q24, the area responsible for ATP-dependent calcium transport (203). It is characterized by a localized, recurrent eruption of small vesicles on an erythematous base. By peripheral extension, the lesions may assume a circinate configuration. The sites of predilection are the intertriginous areas, especially the axillae and the groin. Only very few instances of mucosal lesions have been reported, of the mouth (204,205), the labia majora (205), and the esophagus (206).

Histopathology. Although, as in *Darier's disease,* early lesions may show small suprabasal separations, so-called lacunae, fully developed lesions show large separations, that is, vesicles and even bullae, in a predominantly suprabasal position (Fig. 6-26). Villi, which are elongated papillae lined by a single layer of basal cells, protrude upward into the bulla, and in some cases,

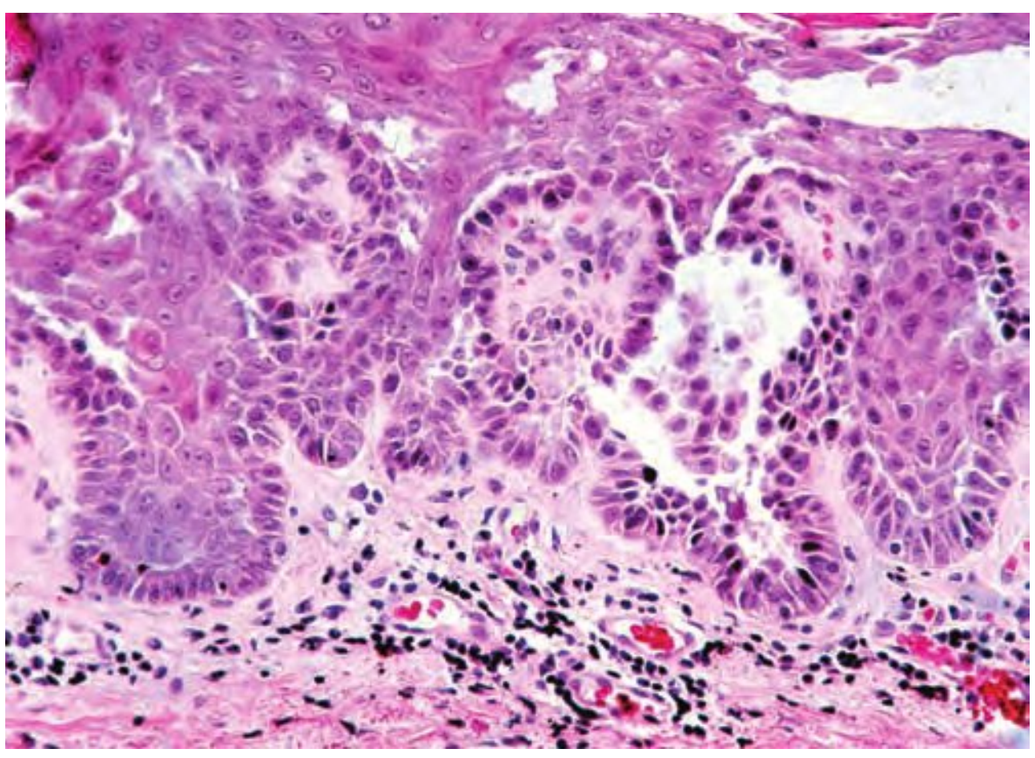

FIGURE 6-26. Familial benign pemphigus (Hailey-Hailey). The bulla is largely in a suprabasal position. The extensive loss of intercellular bridges with partial coherence of cells gives the detached epidermis the appearance of a dilapidated brick wall. On the right side within the granular layer, a corps rond can be seen (original magnification ×40).

narrow strands of epidermal cells proliferate downward into the dermis. Many cells of the detached stratum malpighii show loss of their intercellular bridges; thus, acantholysis affects large portions of the epidermis. Individual cells and groups of cells usually are seen in large numbers in the bulla cavity. Despite the extensive loss of intercellular bridges, the cells of the detached epidermis in many places show only slight separation from one another, because a few intact intercellular bridges still hold them loosely together. This quite typical feature gives the detached epidermis the appearance of a dilapidated brick wall.

Many of the cells of the stratum malpighii that have lost all or most of their intercellular bridges show a fairly normal cytoplasm and a normal nucleus in which mitotic activity has even been observed (207,208). Some of the acantholytic cells, however, have a homogenized cytoplasm, suggesting premature partial keratinization. In some instances, such acantholytic cells with premature keratinization resemble the grains of Darier's disease. Occasionally, a few corps ronds are present in the granular layer (207–209) (Fig. 6-26).

Differential Diagnosis. Histologically, familial benign pemphigus shares certain features with both Darier's disease and pemphigus vulgaris. In all three diseases, one finds predominantly suprabasal separation of the epidermis caused by acantholysis and resulting in lacunae or bullae and villi formation.

Differentiation of familial benign pemphigus from Darier's disease as a rule is not very difficult, because in Darier's disease, (a) the suprabasal separations usually are smaller, thus appearing as lacunae rather than as bullae; (b) acantholysis is less pronounced, being limited to the lower epidermis, especially the suprabasal region; and (c) dyskeratosis consisting of the formation of corps ronds and grains is much more evident.

Pemphigus vulgaris often resembles familial benign pemphigus to a striking degree, and in some specimens, histologic differentiation of these two diseases may be impossible. As a rule, however, there is less extensive acantholysis in pemphigus vulgaris, limited largely to the suprabasal region, so the detached epidermis appears normal and lacks the appearance of a dilapidated brick wall, and more severe degeneration of the acantholytic cells within and near the bulla cavity. The presence of eosinophils in the bulla points toward a diagnosis of pemphigus vulgaris, but their absence does not rule it out. In case of doubt, immunofluorescence will decide the issue.

There used to be much discussion as to whether familial benign pemphigus represents a vesicular variant of Darier's disease. Two points in favor of the basic unity of the two diseases were stressed: the alleged simultaneous presence of both diseases in the same patient and the occurrence of corps ronds in both diseases. However, it has become apparent that patients described as having both diseases were either cases of Darier's disease with vesicular lesions (210) or cases of familial benign pemphigus with the presence of corps ronds (211,212). Evidence against a relationship is also shown by the fact that in affected families, always only one of the two diseases occurs and the genetic basis of the two diseases has been elucidated and are clearly different though related—the ATP2C1 gene on chromosome 3q is mutated in Hailey-Hailey (202), while Darier's disease is due to a mutation in the the ATP2A2 gene on chromosome 12 (206).

KERATOSIS FOLLICULARIS (DARIER'S DISEASE)

Darier's disease is usually transmitted in an autosomal dominant pattern. It has been found to be due to mutations in the ATP2A2 gene on chromosome T2, which encodes the sarcoplasmic/endoplasmic reticulum calcium pumping ATPase SERCA2 (206). The gene is 12q23-24.1. In typical cases, there is a more or less extensive, persistent, slowly progressive eruption consisting of hyperkeratotic or crusted papules often showing a follicular distribution. By coalescence verrucous, crusted areas may form. The so-called seborrheic areas are the sites of predilection. The oral mucosa is involved occasionally (213). In some cases of Darier's disease, keratotic papules that resemble those seen in *acrokeratosis verruciformis of Hopf* are found on the dorsa of the hands and feet (214).

Special clinical variants of keratosis follicularis are a hypertrophic type, a vesiculobullous type, and a linear or zosteriform type. In the hypertrophic type, widespread, markedly thickened, and hyperkeratotic lesions are seen, especially in the intertriginous areas (215). In the vesiculobullous type, vesicles and small bullae are seen in addition to papules (216,217). In the linear or zosteriform type, usually limited to one side, there are either localized or widespread lesions that may be present at birth (218) but in most cases have arisen in infancy, childhood, or adult life (219). The question has been raised as to whether this type of lesion represents a linear epidermal nevus with acantholytic dyskeratosis rather than Darier's disease (218), and the designation *acantholytic dyskeratotic epidermal nevus* has been suggested (219). It is quite likely that some of the cases with scattered papular lesions of limited extent arising in adult life and diagnosed as acute, eruptive Darier's disease (220) or acute adult-onset Darier-like dermatosis in reality represented transient acantholytic dermatosis. A recent review on the clinical aspects of this condition has been written (221).

Histopathology. The characteristic changes in Darier's disease include the following: (a) a peculiar form of dyskeratosis resulting in the formation of corps ronds and grains; (b) suprabasal acantholysis leading to the formation of suprabasal clefts or lacunae; and (c) irregular upward proliferation into the lacunae of papillae lined with a single layer of basal cells, so-called villi (Fig. 6-27). There are also papillomatosis, acanthosis, and hyperkeratosis. The dermis shows a chronic inflammatory infiltrate. In some cases, there is downward proliferation of epidermal cells into the dermis.

The corps ronds occur in the upper stratum malpighii, particularly in the granular and horny layers; grains are found in the horny layer and as acantholytic cells within the lacunae. Corps ronds possess a central homogeneous, basophilic,

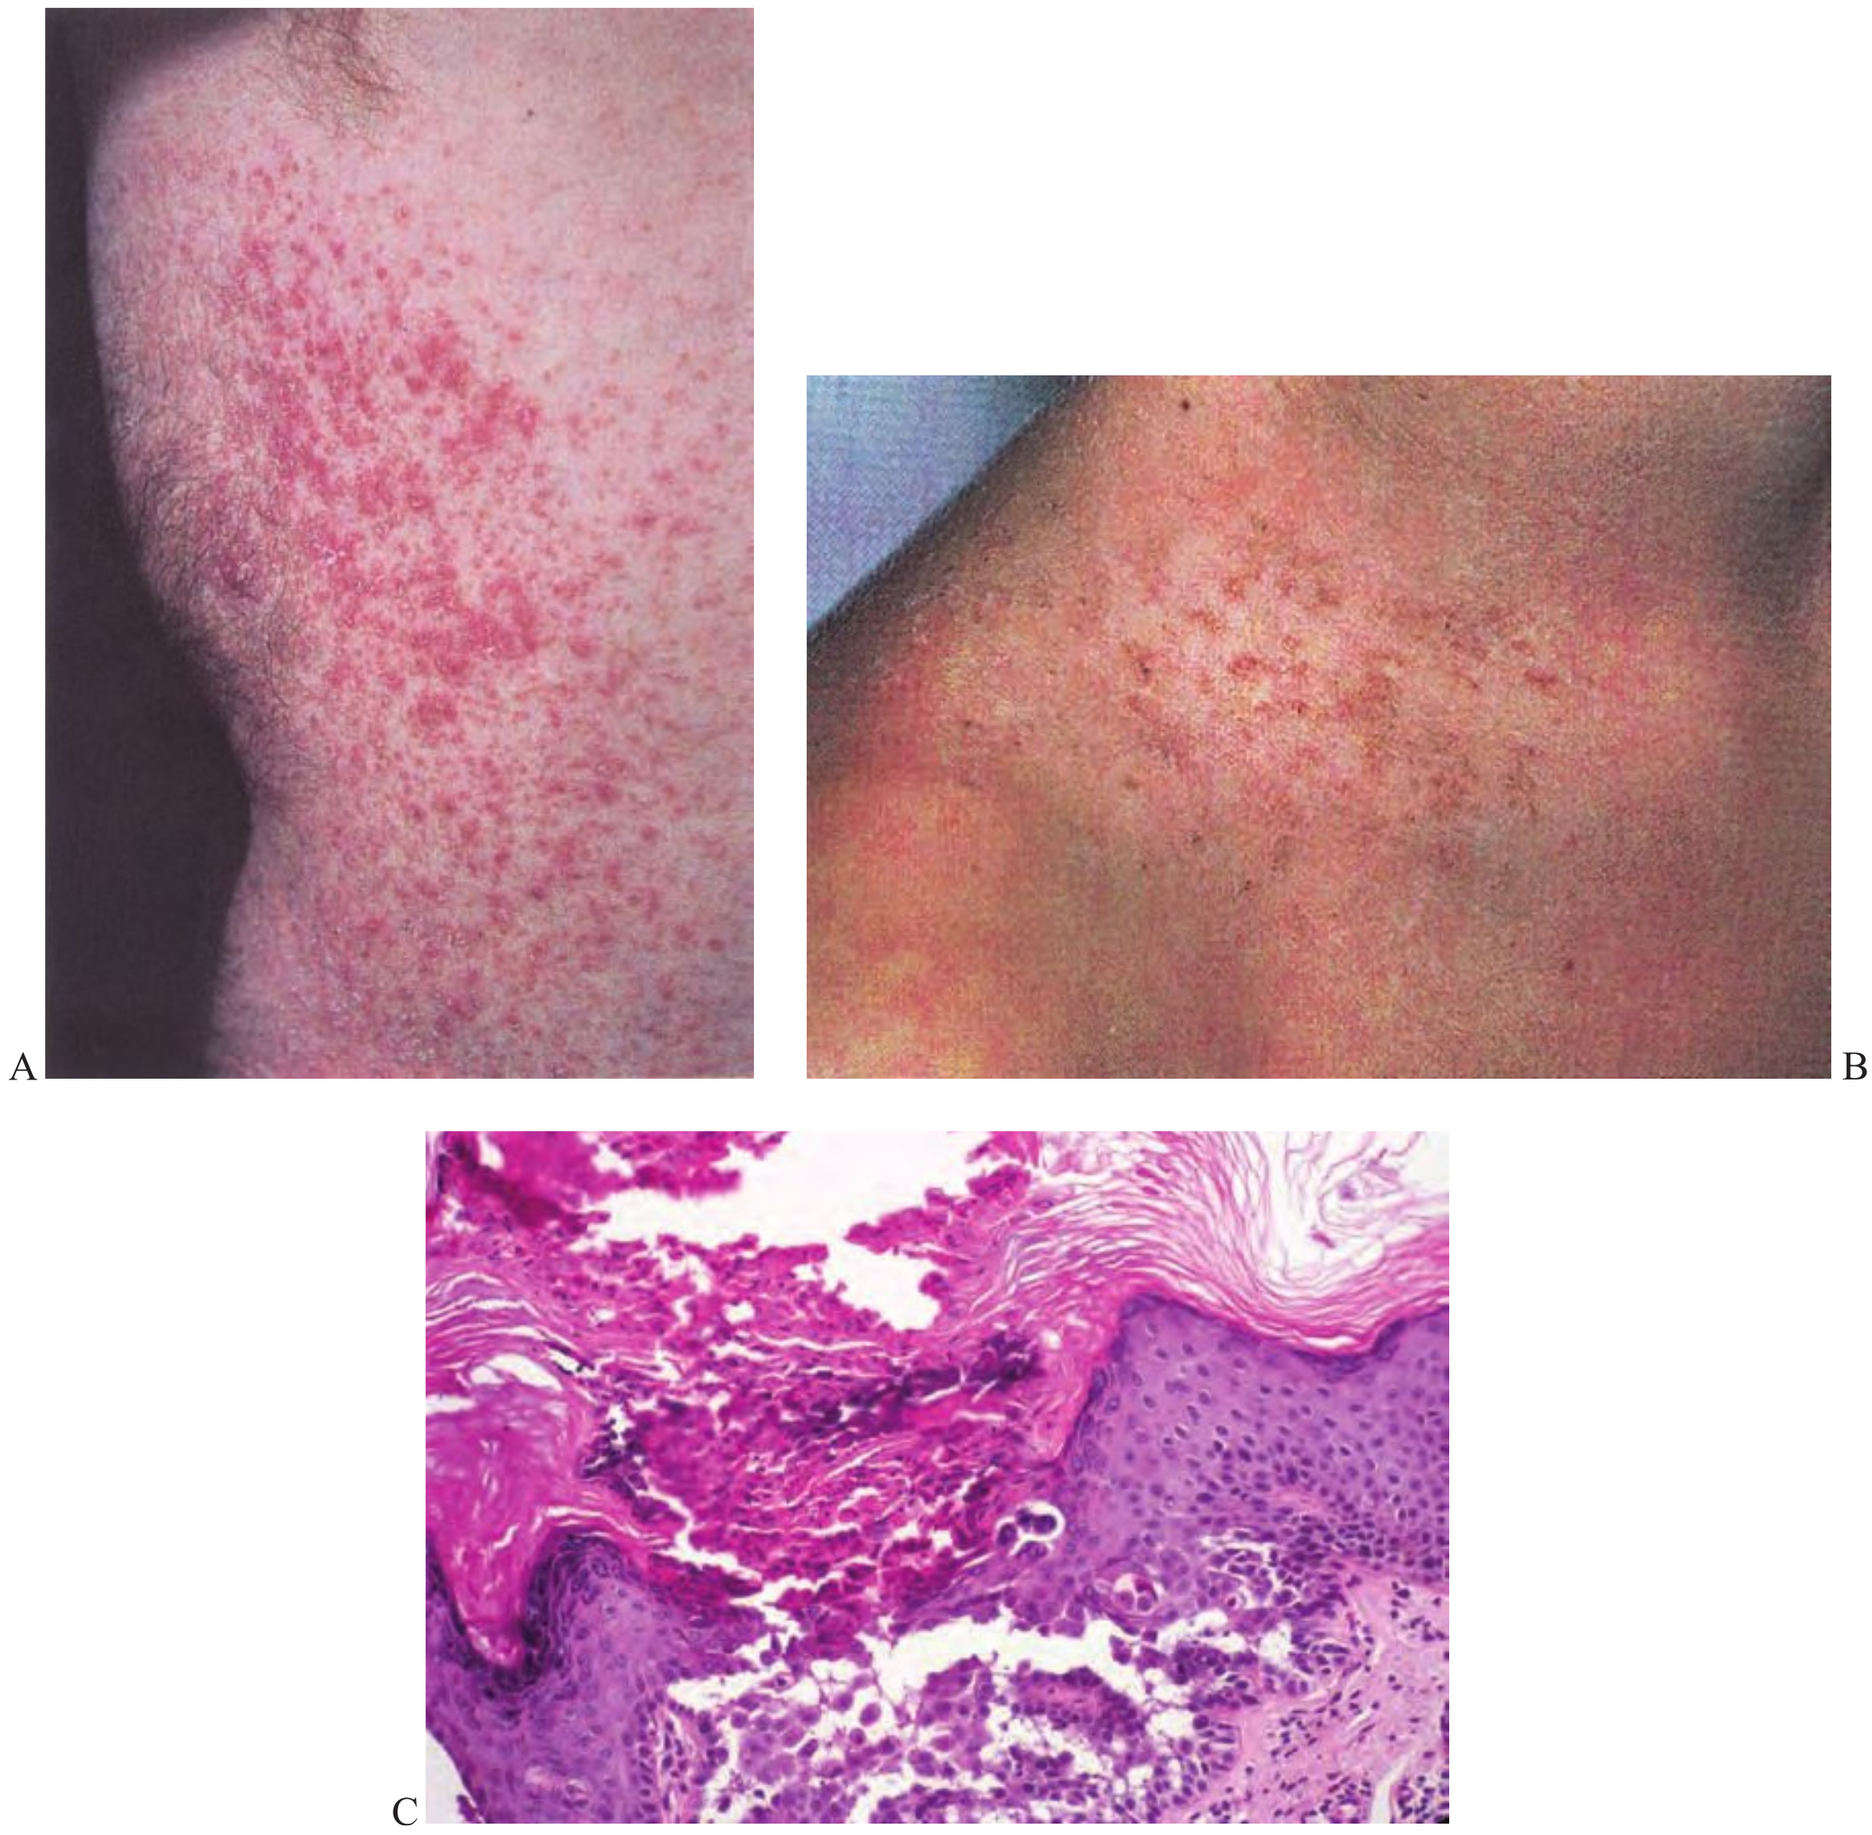

FIGURE 6-27. A: Darier's disease. Multiple tiny hyperkeratotic papules that coalesce into plaques present on the trunk. B: Crusted papules in a follicular distribution at the base of the neck and upper chest. C: Darier's disease, low magnification. Hyperkeratosis and papillomatosis are evident. Numerous lacunae are present. On the left are elongated papillae lined by a single layer of cells, so-called villi. Corps ronds are present in the granular layer, and grains are seen in the horny layer. The lacunae contain desquamated cells (original magnification ×100).

pyknotic nucleus that is surrounded by a clear halo. By virtue of size and the conspicuous halo, corps ronds stand out clearly (Fig. 6-28). Peripheral to the halo lies basophilic dyskeratotic material as a shell (222). The nonstaining halo in some instances is partially replaced by homogeneous, eosinophilic dyskeratotic material (223). Compared with the corps ronds, the grains are much less conspicuous. They resemble parakeratotic cells but are somewhat larger. The nuclei of grains are elongated and often grain shaped and are surrounded by homogeneous dyskeratotic material that usually stains basophilic but may stain eosinophilic. The lacunae represent small, slitlike intraepidermal vesicles most commonly located directly above the basal layer. They contain acantholytic cells and show premature partial keratinization. Because of shrinkage, some of them are elongated, and these then appear identical with the grains in the horny layer. The villi projecting into the lacunae may be quite tortuous, so on histologic examination, some of them appear in cross section as rounded dermal structures lined by a solitary row of basal cells (see Fig. 6-27).

Hyperkeratosis and papillomatosis may cause the formation of keratotic plugs, which often fill the pilosebaceous follicles but are found also outside of follicles. That Darier's disease is not exclusively a follicular disorder is also proved by the fact

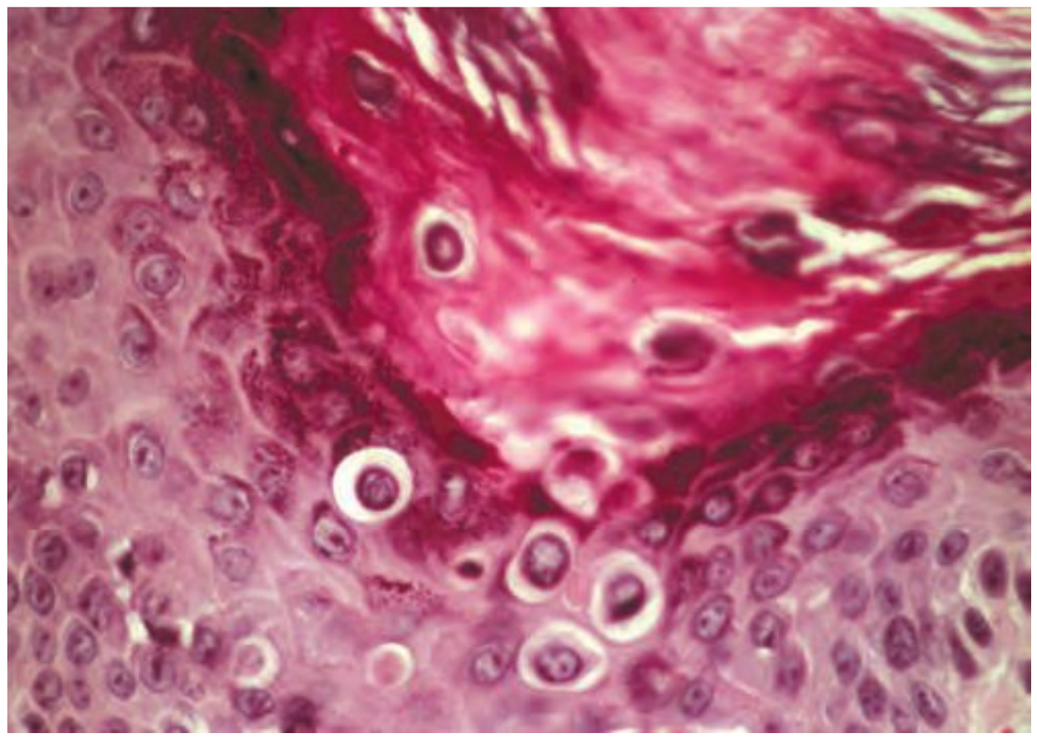

FIGURE 6-28. Darier's disease. Hyperkeratosis corps ronds are in the thickened stratum corneum and epidermis. Suprabasalar acantholysis is present (original magnification ×400).

that areas devoid of follicles, such as palms, soles, and the oral mucosa, may be affected.

In hypertrophic lesions of Darier's disease, considerable acanthosis may occasionally be observed, either as proliferations of basal cells or as pseudocarcinomatous hyperplasia. Proliferations of basal cells consist of long, narrow cords composed of two rows of basal cells separated by a narrow lacunar space (224).

The vesiculobullous lesions, which occur in rare instances, differ from lacunae merely in size; they contain numerous shrunken cells with the appearance of grains (216,217).

The keratotic papules that may occur on the dorsa of the hands and feet and that clinically resemble those seen in acrokeratosis verruciformis of Hopf in most instances, on serial sectioning, show mild dyskeratotic changes and often suprabasal clefts as well (214). They are a manifestation of Darier's disease and not of acrokeratosis verruciformis.

The lesions on the oral mucosa are analogous in appearance to those observed on the skin and thus show lacunae and dyskeratosis, although definite well-formed corps ronds generally are absent (225).

The occasional reports of patients having both Darier's disease and familial benign pemphigus or a transition from one of these two diseases to the other are discussed in the differential diagnosis of familial benign pemphigus.

Pathogenesis. Whereas histologically a distinction between Darier's disease and familial benign pemphigus is generally possible, with dyskeratosis being the predominating factor in Darier's disease and acantholysis in familial benign pemphigus, this distinction is not as clearly evident in electron microscopic examination. The reason for this is that for electron microscopy, only a small specimen can be processed, which in either of the two diseases shows predominantly acantholysis in some instances and dyskeratosis in others and only rarely shows both. In both diseases, however, acantholysis precedes dyskeratosis.

Acantholysis has been thought by some authors to be due to the loss of the intercellular contact layer within desmosomes, both in Darier's disease (226,227) and in familial benign pemphigus (228). The two halves of the desmosomes then pull apart, after which the tonofilaments become detached from them. Another group of authors believes that there is some basic defect in the tonofilament—desmosome complex in Darier's disease (223,229) and in familial benign pemphigus (230)—resulting in separating of tonofilaments from the attachment plaques of desmosomes and subsequently leading to the disappearance of desmosomes and thus to acantholysis. It is likely that both processes take place simultaneously in both Darier's disease (222) and familial benign pemphigus (231).

The cause for the acantholysis in Darier's disease and familial benign pemphigus is not yet definitely known. Faulty synthesis of the intercellular substance has long been suspected. It seems likely that mutations underlying Darier's disease and Hailey-Hailey disease would affect structural components but both disorders mapped to chromosome regions devoid of any known candidate gene. Furthur studies have suggested that intercellular communication is crucial for epidermal differentiation. This was corroborated when mutations found in ATP2A2 caused Darier's disease and disclosed a role for the SERCA2 pump in the calcium signaling pathway that regulates cell to cell adhesion and differentiation of the epidermis (232).

In association with the loss of desmosomes, excessive amounts of tonofilaments form within the keratinocytes around the nucleus as thick, electron-dense bundles. A defect of the tonofilaments would best explain the dyskeratotic features of both Darier's disease and familial benign pemphigus. In Darier's disease, in which the dyskeratosis is much more pronounced than in familial benign pemphigus, thick bundles of tonofilaments, often in association with large keratohyaline granules, form large aggregates of homogenized dyskeratotic material. The corps ronds, on electron microscopic examination, are characterized by extensive cytoplasmic vacuolization (233). They show in their center an irregularly shaped nucleus surrounded by a halo of autolyzed electron-lucid cytoplasm and at their periphery a shell of tonofilaments (EM 16) (222,226). On electron microscopic examination, the grains are seen to consist of nuclear remnants surrounded by dyskeratotic bundles of tonofilaments.

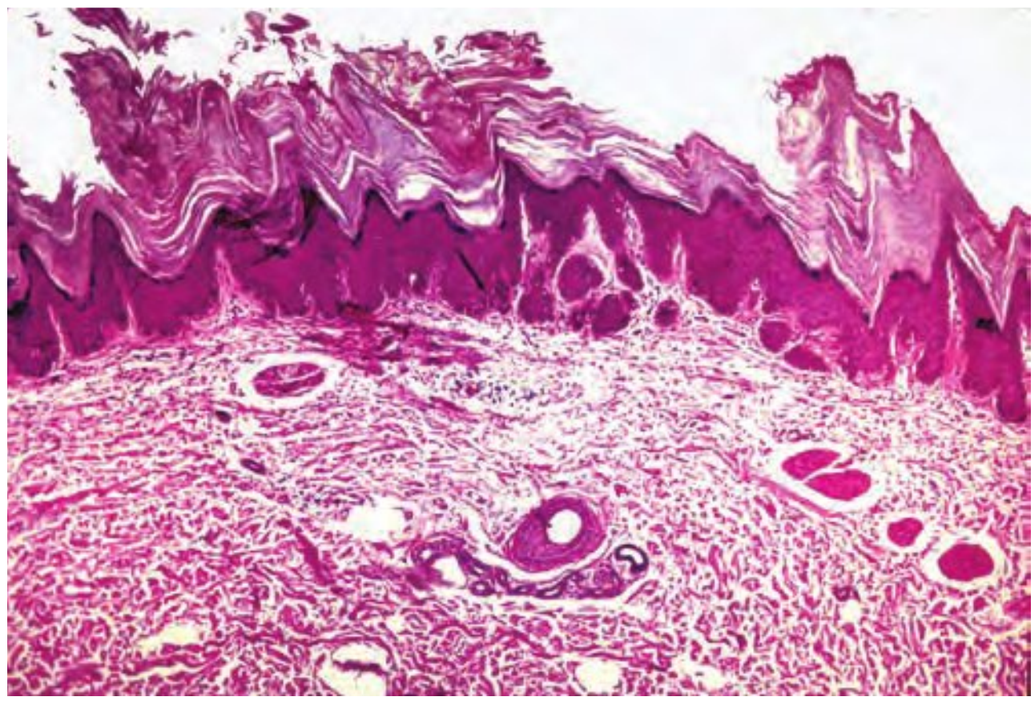
In familial benign pemphigus, too, after loss of the desmosomes, excessive amounts of tonofilaments form within the keratinocytes and aggregate around the nucleus as thick, electron-dense bundles, often in a whorling configuration; however, even though dyskeratosis is present, it is less pronounced than in Darier's disease, and most of the keratinocytes keratinize normally, with only very few becoming grains or corps ronds as the result of dyskeratotic degeneration.

On intralesional injection of tritiated thymidine, one group (234) observed labeling of many acantholytic keratinocytes in familial benign pemphigus but not in Darier's disease, suggesting that in familial benign pemphigus, the epidermal cells participated in the renewal of the epidermis but

did not do so in Darier's disease, probably because these cells were undergoing keratinization. However, another group (235) could not confirm this observation.

Differential Diagnosis. Although acantholytic dyskeratosis in association with corps ronds is highly characteristic of Darier's disease, it occurs also in several other conditions (229): in warty dyskeratoma, a solitary lesion with a deep central invagination; in transient or persistent acantholytic dermatosis, in which the lesions consist of discrete papules; in focal acantholytic dyskeratoma, manifesting itself as a solitary papule; and as an incidental small focus in a variety of unrelated lesions. Occasionally, a few corps ronds are seen also in familial benign pemphigus (see preceding text).

ACROKERATOSIS VERRUCIFORMIS OF HOPF



In acrokeratosis verruciformis, an autosomal dominant disorder, numerous flat, hyperkeratotic, occasionally verrucous papules are present on the distal part of the extremities, predominantly on the dorsa of the hands (Fig. 6-29A) and feet (236).

Histopathology. The papules show considerable hyperkeratosis, an increase in thickness of the granular layer, and acanthosis. In addition, there is slight papillomatosis, which is frequently but not always associated with circumscribed elevations of the epidermis resembling church spires (237,238) (Fig. 6-29B). The rete ridges are slightly elongated and extend to a uniform level.

Histogenesis. A possible relationship between acrokeratosis verruciformis and Darier's disease has been repeatedly discussed. On the one hand, there is no question that acrokeratosis verruciformis usually occurs as an independent entity, often in several family members (239) and occasionally even in many family members (240) but also as a solitary incidence (238). On the other hand, a relationship to Darier's disease is suggested by several observations: (a) patients with Darier's disease not infrequently show lesions that are indistinguishable from acrokeratosis verruciformis both clinically and histologically (237,241); (b) some of the lesions of presumed acrokeratosis verruciformis occurring in patients with Darier's disease show dyskeratosis and lacunae as seen in Darier's disease, whereas others do not; and (c) patients with apparent histologic lesions of acrokeratosis verruciformis may later develop histologic lesions of Darier's disease. Admittedly, there can be considerable clinical resemblance between the acral lesions of both diseases, but if multiple specimens for biopsy are taken and serial sections carried out, clear histologic evidence of Darier's disease is obtained only in those patients who have Darier's disease (249). It seems that there is only one instance in which both diseases were seen in different members of the same family (242), and this may well have been coincidence. Rather than taking the view that the two diseases result from a single dominant defect with variable expressivity (242), it is best to regard acrokeratosis verruciformis as an independent entity.

A

B

FIGURE 6-29. A: Acrokeratosis verruciformis of Hopf. B: A well-circumscribed lesion shows hyperkeratosis and papillomatosis. The latter is associated with elevations of the epidermis resembling church spires (original magnification ×100).

Differential Diagnosis. Although elevations of the epidermis with the configuration of church spires are quite typical of acrokeratosis verruciformis, they may be absent and are not specific for that disease. Particularly, they are present in the hyperkeratotic type of seborrheic keratosis. Even though seborrheic keratoses usually are larger than the lesions of acrokeratosis verruciformis, clinical data may be necessary for the differentiation of these two conditions. Also, acrokeratosis verruciformis may resemble verrucae clinically, but it differs from verruca plana by the absence of vacuolization in the cells of the upper epidermis and from verruca vulgaris by the absence of parakeratosis.

PSEUDOXANTHOMA ELASTICUM

In this disorder, genetically abnormal elastic fibers with a tendency toward calcification occur in the skin and frequently also in the retina and within the walls of arteries, particularly the gastric mucosal arteries, coronary arteries, and large peripheral

arteries. The inheritance is usually autosomal recessive but is occasionally autosomal dominant. It seems that two recessive and two dominant forms exist. Struk predicted that allelic heterogeneity with different variants of a single disease gene residing on 16p13.1 accounts for both recessive and dominant forms of pseudoxanthoma elasticum, and subsequent work by Ringpfeil and Struk have documented that mutations in the ABC-C6 gene are responsible for cases of pseudoxanthoma elasticum (243,244). The classic disorder in this classification is recessive type 1. In the dominant type 1, the cutaneous and internal manifestations are more severe than in recessive type 1, whereas in dominant type 2 they are less severe. The very rare recessive type 2 shows only cutaneous involvement, which, however, is extensive (245). The accuracy of the Pope classification has been disputed, leading to a new classification (246).

The cutaneous lesions usually appear first in the second or third decade of life and are generally progressive in extent and severity. They consist of soft, yellowish, coalescing papules, and the affected skin appears loose and wrinkled. The sides of the neck, the axillae, and the groin are the most common sites of lesions (Fig. 6-30). In the eyes, so-called angioid streaks of the fundi may cause progressive impairment of vision. Involvement of the arteries of the gastric mucosa may lead to gastric hemorrhage; involvement of coronary arteries may result in attacks of angina pectoris, although myocardial infarction is rare; and involvement of the large peripheral arteries may cause intermittent claudication (247). Radiologic examination in such cases reveals extensive calcification of the affected peripheral arteries (248).

In rare instances, the coexistence of pseudoxanthoma elasticum with elastosis perforans serpiginosa has been reported, with perforation and transepidermal elimination present only in the lesions of elastosis perforans serpiginosa (249). Calcific elastosis, which has been referred to also as *perforating pseudoxanthoma elasticum* or *localized acquired pseudoxanthoma elasticum*, is not related to pseudoxanthoma elasticum. The absence of skin lesions should not be used to exclude pseudoxanthoma elasticum in patients with an inherited predisposition and suspicious manifestations, such as angioid streaks or gastric bleeding. In these patients, biopsies of scars or of flexural skin may show the characteristic changes of pseudoxanthoma elasticum in the deep dermis (246).

FIGURE 6-30. Pseudoxanthoma elasticum. Yellow coalescing papules at the side of neck.

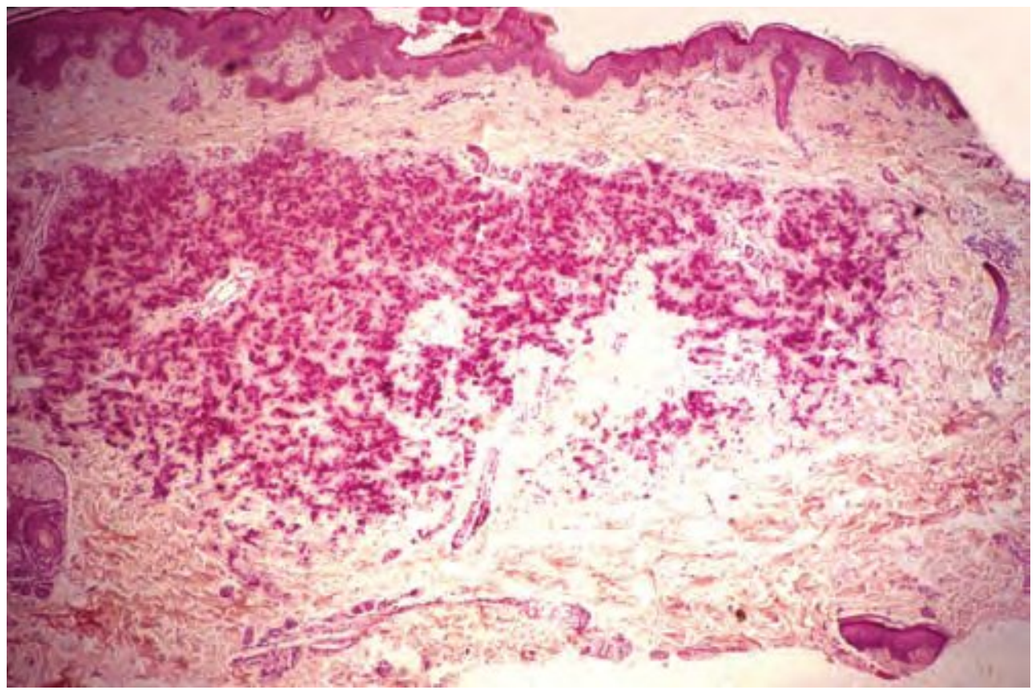


FIGURE 6-31. Pseudoxanthoma elasticum. Low magnification, H&E stained tissue showing calcified altered elastic fibers in the midreticular dermis (original magnification ×100).

Histopathology. Histologic examination of the involved skin reveals considerable accumulations of swollen and irregularly clumped fibers staining like elastic fibers in the middle and lower thirds of the dermis; that is, they stain deeply black with orcein or Verhoeff's stain (Figs. 6-31 and 6-32). Although normally elastic fibers do not stain with routine stains such as hematoxylin-eosin, the altered elastic fibers in pseudoxanthoma elasticum stain faintly basophilic because of their calcium imbibition. Staining for calcium with the von Kossa method also shows these fibers well.

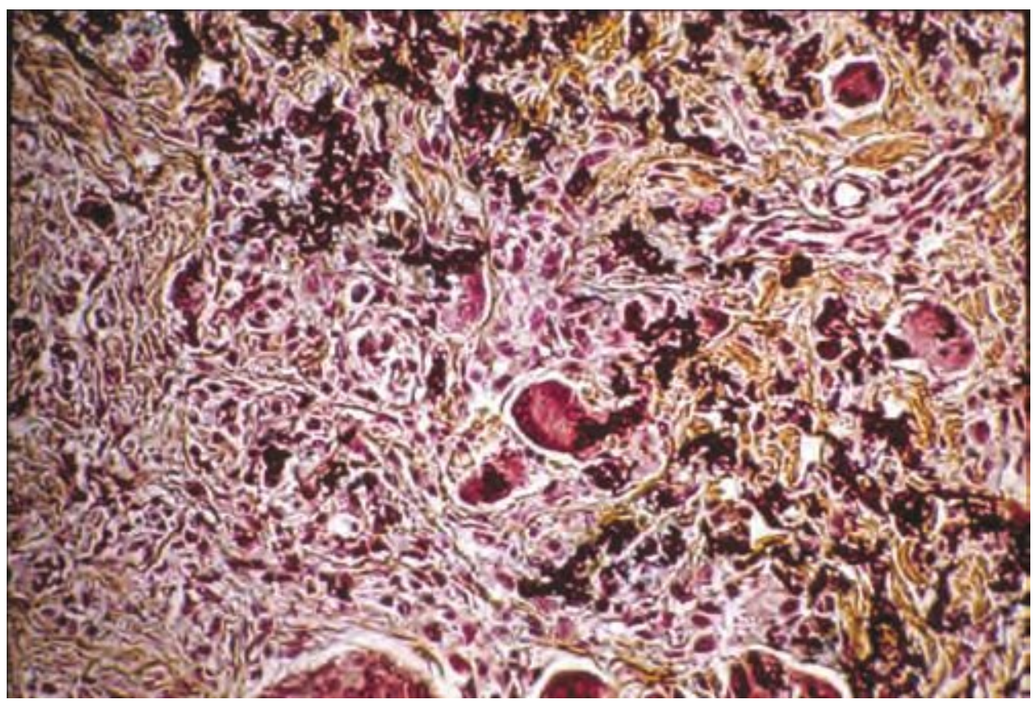

FIGURE 6-32. Pseudoxanthoma elasticum, high magnification, elastic tissue stain. The elastic fibers show marked degeneration (original magnification ×100).

In the vicinity of the altered elastic fibers, there may be accumulations of a slightly basophilic mucoid material, which stains strongly positive with the colloidal iron reaction or with Alcian blue (250). The number of collagen bundles is reduced in such areas, and numerous reticulum fibers are seen on impregnation with silver (251). In some cases with pronounced elastic tissue calcification, a macrophage and giant cell reaction may be present (252).

The angioid streaks occur in Bruch's membrane, which is located between the retina and the choroid and possesses numerous elastic fibers in its outer portion, the lamina elastica. Calcification of these fibers causes fissures to form in the lamina elastica. These fissures result in repeated hemorrhages and exudates, which in turn cause degenerative changes in the retina consisting of scar formation and pigment shifting (252,253).

Gastric bleeding is the result of calcification of elastic fibers in the thin-walled arteries located immediately beneath the gastric mucosa. The internal elastic lamina is particularly affected. In muscular arteries, such as the coronary arteries and the large peripheral arteries, calcification begins in the internal and external elastic laminae, leading to their fragmentation, and subsequently extends to the media and intima (247). Calcification of the elastic fibers in the endocardium is a common occurrence but is clinically silent (254).

Histogenesis. Electron microscopic examination shows that the calcification occurs in normal-appearing elastic fibers (251,254–257). In some patients, especially in young persons, only some of the elastic fibers in the lower dermis are calcified, and the calcification is variable in degree. However, in adult patients, most elastic fibers show considerable calcification and, as a result, degeneration. Early calcification of elastic fibers consists either of diffuse granular deposits throughout the elastic fiber or of dense aggregates that may be located in the center or near the margin of the fiber (EM 5). With progression of the calcification, the elastic fibers ultimately become fully calcified, showing marked swelling and bizarre distortions. In addition, heavy calcium deposits may be seen in the ground substance adjacent to elastic fibers and free in the ground substance. The presence of calcified material outside of elastic fibers can be explained by the disintegration of completely calcified elastic fibers (257).

Besides varying numbers of normal collagen fibrils, irregularly twisted collagen fibrils and granulofilamentous aggregates are present. It appears unlikely that the process of calcification begins in the granulofilamentous material, as maintained by some authors who regard this material as an abnormal precursor of elastic fibers (256,258). It is probable that this misinterpretation has resulted from the examination of advanced lesions containing disintegrated calcified elastic fibers within the granulofilamentous material (254). In favor of a primary location of the calcification within elastic fibers is the important observation that in decalcified sections of endocardial lesions, the internal structure of the calcified segments of elastic fibers is very similar to that of the adjacent noncalcified segments.

Differential Diagnosis. Solar elastosis, like pseudoxanthoma elasticum, shows abnormal elastic tissue. However, in solar elastosis, this material is located in the upper third of the dermis and is present as dense masses rather than as individual altered fibers. Furthermore, these dense masses always show negative staining for calcium. If associated with a perforation, calcific elastosis is easily distinguished from pseudoxanthoma elasticum. In the absence of a perforation, the two are indistinguishable, and clinical data are necessary for differentiation.

CONNECTIVE TISSUE NEVUS

The connective tissue nevus represents a hamartoma in which the amount of collagen is increased, but the amount of elastic tissue may be increased, normal, or decreased. The lesions consist of slightly elevated, slightly indurated nodules that may be grouped together in one or several plaques or may be widely disseminated (Fig. 6-33). A connective tissue nevus can occur without alterations in other organs and without being genetically determined (259); occur without alterations in other organs, being inherited as an autosomal dominant trait (260); or occur with osteopoikilosis, being inherited in an autosomal dominant pattern (261). The shagreen patches of tuberous sclerosis do not strictly belong in the category of connective tissue nevi, since they always consist only of excessive amounts of collagen and thus are "collagen nevi" rather than connective tissue nevi (262).

Connective tissue nevi associated with osteopoikilosis are also referred to as *Buschke-Ollendorff syndrome,* because these authors first recognized the frequent simultaneous occurrence of these two types of lesions. The skin lesions in this syndrome consist of firm, pale papules and plaques in asymmetric distribution with a tendency to grouping (261,263). Individual members of affected families may have skin lesions without bone lesions and vice versa. The bone lesions of osteopoikilosis are asymptomatic and on x-ray examination consist of round or oval densities 2 to 10 mm in diameter in the long bones and in the bones of the hands, feet, and pelvis.

Histopathology. A clear separation of collagenoma and elastoma is not always possible, because in many instances both

FIGURE 6-33. Connective tissue nevus. Grouped slightly raised nodules producing an irregular surface on the lower posterior chest.

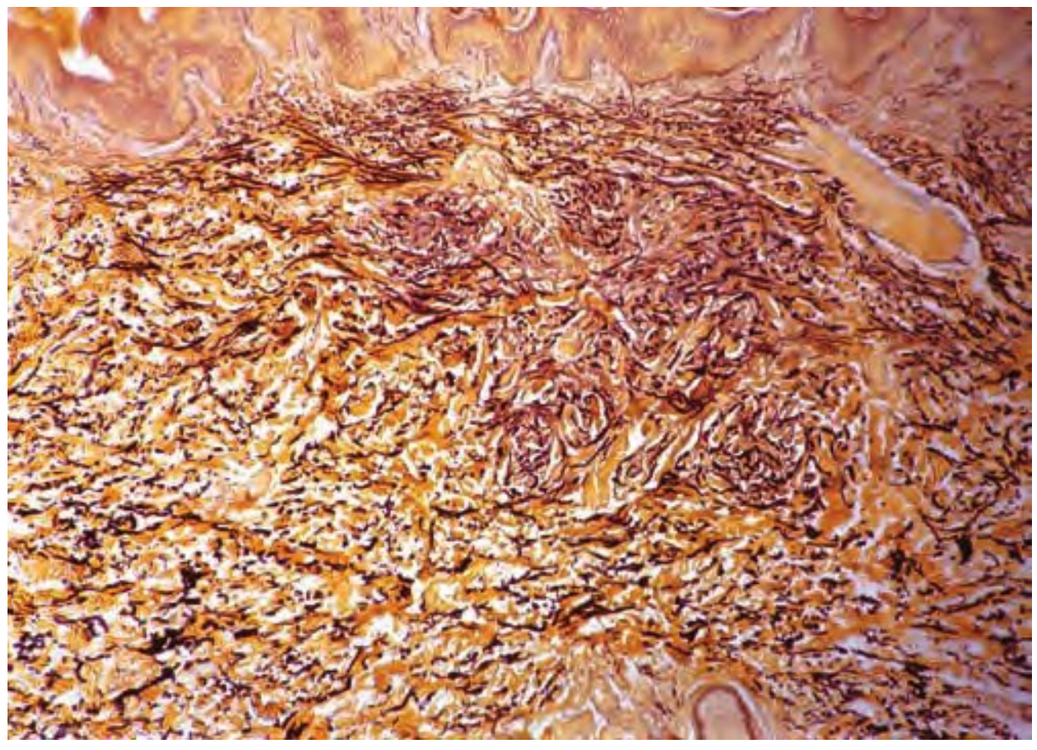

FIGURE 6-34. Connective tissue nevus. The elastic fibers are markedly increased in number and size without showing signs of degeneration (original magnification ×100).

collagenous and elastic fibers are increased, as indicated by the fact that most lesions of connective tissue nevus feel firm to the touch. The increase in the amount of collagen may be difficult to ascertain if the collagen bundles are normal in appearance. In some lesions of collagenoma (260) and lesions of the connective tissue nevus–osteopoikilosis syndrome (263), the collagen bundles are thickened and homogenized.

Most cases of the connective tissue nevus–osteopoikilosis syndrome clearly show a marked increase in the amount of elastic fibers, which are present as broad, interfacing bands, without showing signs of degeneration (264,265) (Fig. 6-34).

Pathogenesis. On electron microscopic examination, connective tissue nevi show a variable picture. In some cases, the elastic fibers appear thick and are surrounded by a thready material (259). In the Buschke-Ollendorff syndrome (266), the elastic fibers lack their microfibrillar component, so only electron-lucent elastin is present (267).

Differential Diagnosis. Pseudoxanthoma elasticum is the major differential disease. The connective tissue nevus does not show elastic tissue fragmentation and calcification as does pseudoxanthoma elasticum.

LINEAR MELORHEOSTOTIC SCLERODERMA

Melorheostosis is characterized by linear hyperostosis of an extremity. It may be associated with thickening and hypertrichosis of the overlying skin. Although not familial, its start in infancy suggests a congenital disorder (268).

Histopathology. The skin shows thickening of the dermis caused by the extension of normal-appearing collagen and elastic tissue in strands and lobules into the subcutaneous fat (269).

Pathogenesis. Hyperplasia of the skin is related to the underlying cortical hyperostosis. The normal appearance of the thickened dermis indicates that the process does not represent localized scleroderma (269).

WINCHESTER SYNDROME

A rare autosomal recessive disorder described only in the offspring of consanguinous parents, Winchester syndrome is characterized by dwarfism, small-joint destruction, corneal opacities, thickening and hypertrichosis of the skin, and hypertrophic lips and gingivae and is related to mutations in the matrix metalloproteinase 2 gene (270,271). The condition is related to nodulosis-arthropathy-osteolysis (NAO) syndrome, which is allelic with Winchester syndrome.

Histopathology. In the early stage, the skin shows proliferation of fibroblasts in the lower portions of the dermis with extension into the subcutaneous tissue. At a later stage, the collagen appears homogenized and contains only few fibroblasts. Some areas may show an increase in both the number of fibroblasts and the density of the collagen bundles (272).

Pathogenesis. Abnormal functioning of the fibroblasts is the likely cause for all manifestations. Electron microscopic examination has shown dilated and vacuolated mitochondria in the fibroblasts (271).

EHLERS-DANLOS SYNDROME

Ehlers-Danlos (E-D) syndrome (EDS) has been divided into more than 10 types on the basis of clinical, genetic, and biochemical information (273). The common clinical features are hyperextensibility of the skin; fragility of the skin with impaired wound healing, resulting in the formation of atrophic scars; and hypermobility of the joints, which may lead to dislocations (Fig. 6-35). Occasionally, raisin-like pseudotumors that are raised and soft and have a wrinkled

FIGURE 6-35. Ehlers-Danlos syndrome. Hyperelasticity of the skin.

surface are observed at sites of traumatic hematomas. In some cases, firm, spheroid subcutaneous nodules form at sites of traumatic fat necrosis.

E-D types I, II, and III, the most common forms of this syndrome, are inherited in an autosomal dominant pattern and are distinguished by the extent and severity of the symptoms, type I being the gravis type, type II the mitis form, and type III the benign hypermobile type. No biochemical defect has been detected. Absence of the inferior labial frenulum and the lingual frenulum has recently been described in EDS II and EDS III (274). EDS I and II are allelic with mutations in pro-alpha-1 (V) collagen chains (COL5A1) causing both types (275). Type II EDS can also be caused by a missense mutation in the COL5A2 gene (276). Mutations in more than one gene can lead to type III phenotype (277).

E-D type IV, the arterial form, is inherited as an autosomal dominant or recessive trait. The skin of persons with this disorder is thin and fragile. Ecchymoses are very common. Patients rarely live beyond the second decade of life because of ruptures of large arteries or of the gastrointestinal tract (278). This tendency toward rupture is explained by the fact that there is a deficiency of type III collagen (COL3A1 gene) in the skin and in other tissues. Even though cultured fibroblasts are capable of normal synthesis of collagen type III, they show poor secretion of it into the medium (279).

E-D type V has an X-linked recessive inheritance pattern and clinical features similar to those of type I. The fibroblasts produce only 15% to 30% of the normal amount of lysyl oxidase. This deficiency results in deficient intramolecular cross-linking in the collagen molecule (282). An abnormality in the expression of COL5A1 may be the issue here (280).

E-D type VI, the ocular type, with autosomal recessive inheritance, is characterized by severe scoliosis and intraocular bleeding. There is a deficiency in lysyl hydroxylase in this form of the disorder. The gene for this enzyme maps to 1p36.3. p36.2 (277).

E-D type VII, the arthrochalasis type, also with autosomal dominant or recessive inheritance, shows marked looseness of joints resulting in multiple joint dislocations. The skin and tendons of patients with this form of E-D contain collagen polypeptides with a length intermediate between pro-alpha (procollagen) chains and alpha (collagen) chains. This is due to a structural mutation in the pro-alpha 2 chain that prevents the normal enzymatic removal of the aminopropeptide from it (281). A mutation at one of at least two loci COL1A1 and COL1A2 can produce this autosomal dominant phenotype (280). The autosomal recessive subtype may be due to mutations in the ADMTS2 gene (282).

E-D type VIII, the periodontal type, inherited as an autosomal dominant trait, is characterized by severe periodontitis and moderate skin fragility. Its biochemical defect is thought to be due to decreased production of type III collagen.

E-D type IX, the occipital horn syndrome (X-linked cutis laxa), with X-linked recessive inheritance, shows moderate skin extensibility, joint hypermobility, bladder diverticula, herniae, and rhizomelic limb shortening. The defect is due to abnormal copper metabolism caused by a mutation in the Cu^{++} transporting ATPase alpha peptide and a decrease in lysyl oxidase. This disorder may be allelic with Menkes' syndrome (283).

E-D type X, the fibronectin type, with autosomal recessive inheritance, shows stria, moderate skin extensibility, joint hypermobility, and a platelet aggregation defect caused by dysfunction of the plasma fibronectin (284) gene map locus 2q34.

Histopathology. Except for areas of the skin that have been altered secondarily by trauma, most patients with types I to III show no abnormalities either in the thickness of the skin or in the appearance of the collagen or of the elastic fibers. Only an exceptional patient shows thin collagen fibers that are not united to collagen bundles. In these cases, the skin may also be reduced in thickness and show a relative increase in amount of elastic fibers. These changes are more pronounced in the type I (gravis) than in the types II and III and are more evident when a large excision biopsy is carried out rather than a punch biopsy. They are often seen best in the collagen bundles of the connective tissue septae of the hypodermis, with the collagen bundles appearing thin and rare (285).

E-D type IV shows the most pronounced degree of dermal thinning of all types, usually to half or three quarters of normal thickness. There is a relative abundance of elastic fibers that appear shortened and fragmented. This probably is secondary to changes in collagen fiber morphology (286).

The raisin-like pseudotumors that arise at the site of hematomas show fibrosis and numerous capillaries; they may also show accumulations of foreign body giant cells (287). The spheroid subcutaneous nodules consist of partially necrotic adipose tissue that may contain areas of dystrophic calcification and that is surrounded by a thick layer of dense collagen (288).

Histogenesis. The enzyme deficiencies observed in the various types of the EDS suggest a disturbance in collagen biosynthesis. In several electron microscopic studies, no abnormalities were observed in the normal skin of patients with EDS (289,290); however, other studies have reported abnormalities. In a study comparing healing experimental wounds in a patient with EDS with those in normal persons, the fibroblasts of the patient with EDS showed a paucity of rough-surfaced endoplasmic reticulum, and the bundles of collagen appeared small and sparse (291). Similar abnormalities were observed also in the normal-appearing skin of five patients with various types of EDS. The fibroblasts were smaller than in the skin of normal control persons, the endoplasmic reticulum was underdeveloped, and ribosome content was diminished. In addition, some collagen fibrils possessed an irregular outline, and lateral aggregation of the fibrils into bundles was reduced (291,292). Scanning electron microscopic examination in various types of EDS has revealed thinner collagen bundles than normal and, within the bundles, gross disorganization of the collagen fibers (290). Scanning electron microscopy has shown that the hyperextensibility in EDS is due to defective "wicker work" of the collagen fiber bundles.

CUTIS LAXA (ELASTOLYSIS)

Cutis laxa, also called *dermatochalasis* and *generalized elastolysis*, is characterized by loose, pendulous skin resulting in a prematurely aged appearance (Fig. 6-36). There are two types: congenital occipital horn syndrome (see page 156, type IX EDS) and acquired. In the congenital type, the usual mode of inheritance is autosomal recessive (293), although autosomal dominant transmission due to a mutation in the elastin gene has been described in a few relatively mild cases (294). The occipital horn syndrome is X-linked (293). The acquired type has no genetic background (295).

In both the congenital and acquired types, internal organs are frequently involved. There may be pulmonary emphysema causing death in infancy in some of the congenital cases (293,296) or later in life in some of the acquired cases (295). The congenital form may show wormian bones of the lambdiodal suture and osteoporosis. The deficiency in lysyl oxidase is due to a mutation on the encoding gene located on chromosome 5q (297). In addition, there may be diverticula in the gastrointestinal tract or in the bladder. Also, rectal prolapse and inguinal, umbilical, and hiatal hernias have been observed (293). About half of the cases of acquired cutis laxa are preceded or accompanied by a cutaneous eruption showing urticaria (298), erythematous plaques (299), or a vesicular eruption (300). The occipital horn syndrome is discussed in the section on EDS and should be categorized as a disorder of copper metabolism.

Histopathology. In cases without an inflammatory infiltrate, the changes are limited to the elastic fibers and depend on the stage and the severity of the disease. In the early stage, the elastic fibers are diminished either throughout the dermis or largely in the upper dermis or the lower dermis (301). Those elastic fibers that are present may be considerably thickened in their midportion and may taper to a point at either end. Their borders may be indistinct, and they may stain unevenly, showing a granular appearance (Fig. 6-37). Ultimately, no intact elastic fibers may be identifiable. Instead, fine, dustlike orceinophilic granules may be scattered in the dermis.

FIGURE 6-36. Cutis laxa. Child with pendulous skin.

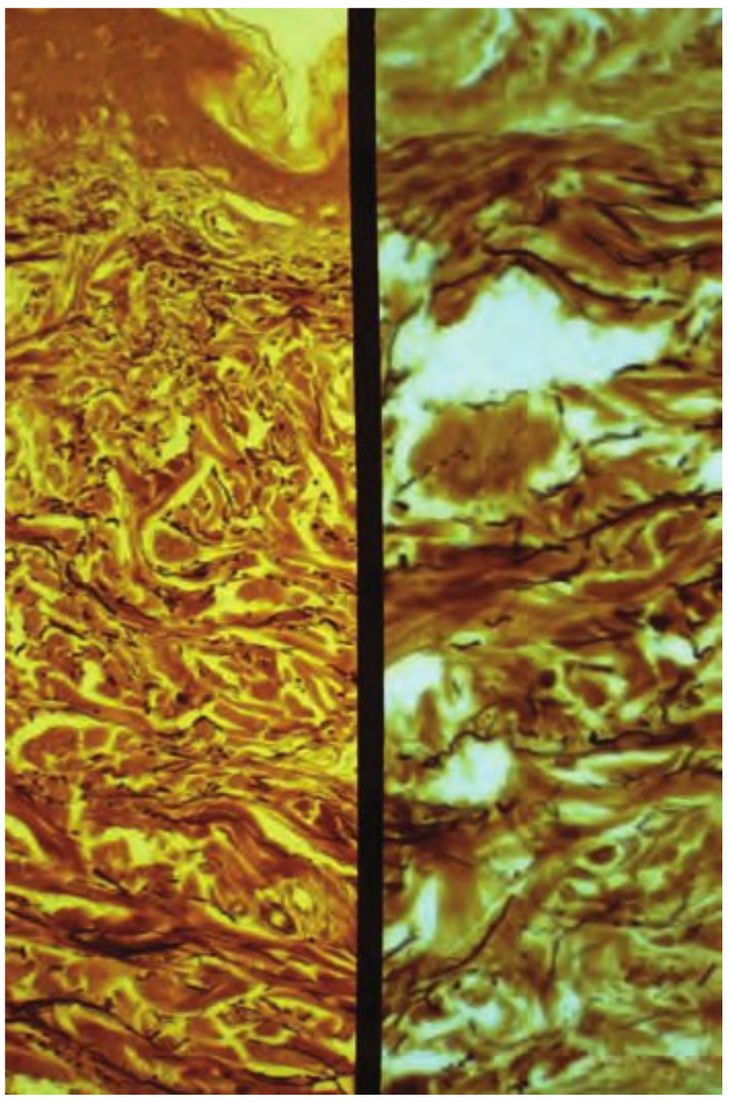

FIGURE 6-37. Cutis laxa, elastic tissue stain. The degenerated elastic fibers stain unevenly, resulting in a granular appearance and indistinct border. (Split views 100×/4,000×.)

In cases in which an inflammatory infiltrate is present, it may consist of a nonspecific chronic inflammatory infiltrate of lymphocytes and histiocytes. However, it may also contain neutrophils. If vesicles are present, they are subepidermal in location and may show papillary microabscesses composed of neutrophils and eosinophils suggestive of dermatitis herpetiformis.

In patients with involvement of internal organs, the lungs and gastrointestinal tract show the same granular changes in the elastic fibers as seen in the skin.

Histogenesis. Electron microscopic examination shows degenerative changes in the elastic fibers that vary somewhat from case to case. In some instances, the elastic fibers show normal microfibrils but a deficiency of the amorphous, electron-lucent elastin (296,302); in other instances, the elastin is preserved and the microfibrils are absent. In most electron microscopic examinations, the most significant finding is the presence of electron-dense amorphous or granular aggregates in the vicinity of the elastic fibers (303). The presence of this electron-dense material outside of elastic fibers suggests that instead of a primary elastolysis, as generally assumed, a defect in the synthesis of elastic fibers causes the disease (296,299).

Another controversy concerns the role of the cutaneous eruption that precedes or accompanies many of the reported cases of acquired cutis laxa. The traditional view has been that the inflammatory infiltrate is in some way responsible for the damage to the elastic fibers (304). However, in one reported case, sequential biopsies seemed to indicate that the changes in the elastic fibers induced the inflammatory infiltrate, and the

possibility therefore exists that the inflammatory infiltrate is a consequence of changes in the fibers.

PACHYDERMOPERIOSTOSIS

An idiopathic and an acquired form of pachydermoperiostosis exist, the latter being secondary to carcinoma of the lung. The idiopathic form is transmitted as an autosomal dominant trait, with males being more severely affected than females (305). The manifestations include (a) clubbing of the digits, with periosteal proliferation of the bones of the hands and feet; (b) hyperplasia of the soft parts of the forearms and legs, with periosteal proliferation of the corresponding bones; and (c) thickening and furrowing of the skin of the face and scalp (cutis verticis gyrata). In abortive forms, there may be only clubbing of the fingers with periosteal proliferation of the bones of the hands and forearms (306).

Histopathology. The skin of the face shows thickening of the dermis, with thick fibrous bands extending into the subcutaneous tissue (307). In addition to an increase in the amount and size of the collagen bundles in the dermis, there is an increase in the number of fibroblasts and in the amount of ground substance. The latter stains with colloidal iron, and because it is composed largely of hyaluronic acid, it stains with Alcian blue at pH 2.5 but not at pH 0.45.

URTICARIA PIGMENTOSA (MASTOCYTOSIS)

Urticaria pigmentosa, although occasionally showing an autosomal dominant mode of transmission (308,309) with a possible relationship to mutations in the KIT gene (310), in most instances occurs without a family history. It can be divided into four forms: (a) urticaria pigmentosa arising in infancy or early childhood without significant systemic lesions (311), (b) urticaria pigmentosa arising in adolescence or adult life without significant systemic lesions (312), (c) systemic mast cell disease, and (d) mast cell leukemia.

In the first form, the cutaneous lesions often improve or even clear at puberty (313). Systemic lesions are absent as a rule and if present usually are few in number. Progression into systemic mast cell disease is very rare (see later). In the second form, urticaria pigmentosa arising in adolescence or adult life, systemic lesions are often present but as a rule are rather static in their course (314,315). However, spontaneous regression has never been documented in adults, in contrast to children (316). In only a few patients is there progression to the third form, systemic mast cell disease, which shows extensive and progressive involvement of internal organs (see section on systemic lesions). The fourth form, mast cell leukemia, is very rare. It is characterized by the presence of cytologically malignant mast cells in many organs of the body, especially in the bone marrow and the peripheral blood, and is a rapidly fatal disease (327). Usually, there are no skin lesions (317).

Patients with extensive mast cell infiltration of the skin or the internal organs commonly have attacks of flushing, palpitation, or diarrhea as a result of degranulation of mast cells and the release of histamine.

Five types of cutaneous lesions are seen in urticaria pigmentosa (313). Two types can occur in both the infantile and the adult forms. First is the maculopapular type, the most common type, consisting usually of dozens or even hundreds of brown lesions that urticate on stroking (Fig. 6-38A); the second type exhibits multiple brown nodules or plaques and on stroking shows urtication and occasionally blister formation (Fig. 6-38B). The third type, seen almost exclusively in infants, is characterized by a usually solitary, large cutaneous nodule, which on stroking often shows not only urtication but also large bullae. In rare instances, solitary nodules have been described as arising in adults without giving rise to bullae (318). The fourth type, the diffuse erythrodermic type, always starts in early infancy and shows generalized brownish red, soft infiltration of the skin, with urtication on stroking. Multiple blisters may form during the first 2 years of life on stroking and also spontaneously. If bullae are a predominant clinical feature, the term *bullous mastocytosis* has been applied (319,320). Although visceral lesions are common in the diffuse erythrodermic type,

A

B

FIGURE 6-38. A: Urticaria pigmentosa. Multiple papular lesions of urticaria pigmentosa. B: Blister formation.

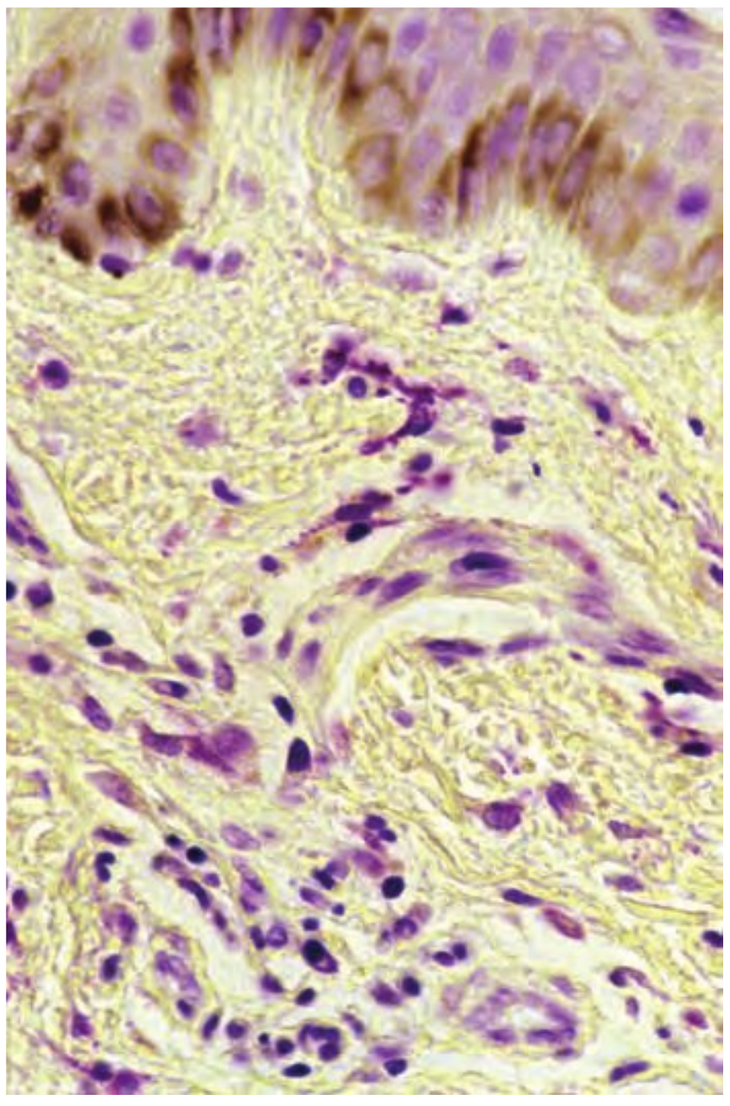

FIGURE 6-39. Urticaria pigmentosa, maculopapular (adult type). Scattered mast cells are seen, some cuboidal in shape. The greatest numbers are about dermal vessels. The epidermis is hyperpigmented (original magnification ×100).

they usually improve and only very rarely progress to fatal systemic mast cell disease. On rare occasions, death occurs in early infancy, apparently as a result of histamine shock with no or with only insignificant mast cell infiltration of visceral organs (321). The fifth type of lesion, telangiectasia macularis eruptiva perstans, which usually occurs in adults, consists of an extensive eruption of brownish red macules showing fine telangiectasias, with little or no urtication on stroking (322).

Histopathology. In all five types of lesions, the histologic picture shows an infiltrate composed chiefly of mast cells, which are characterized by the presence of metachromatic granules in their cytoplasm. These granules are not visible with routine stains but can be seen well after staining with a Giemsa stain or with toluidine blue. Also, the method using naphthol AS-D chloroacetate esterase, often called *Leder's method,* makes mast cell granules appear red and thus quite conspicuous (323).

In the maculopapular type and in telangiectasia macularis eruptiva perstans, the mast cells are limited to the upper third of the dermis and are generally located around capillaries. In some mast cells, the nuclei may be round or oval, but in most mast cells, they are spindle shaped (Fig. 6-39). Because the mast cells may be present only in small numbers, and because in sections stained with hematoxylin-eosin their nuclei resemble those of fibroblasts or pericytes, the diagnosis may be missed unless special staining is employed (324).

In cases with multiple nodules or plaques or with a solitary large nodule, the mast cells lie closely packed in tumor-like aggregates (Figs. 6-40 and 6-41). The infiltrate may extend

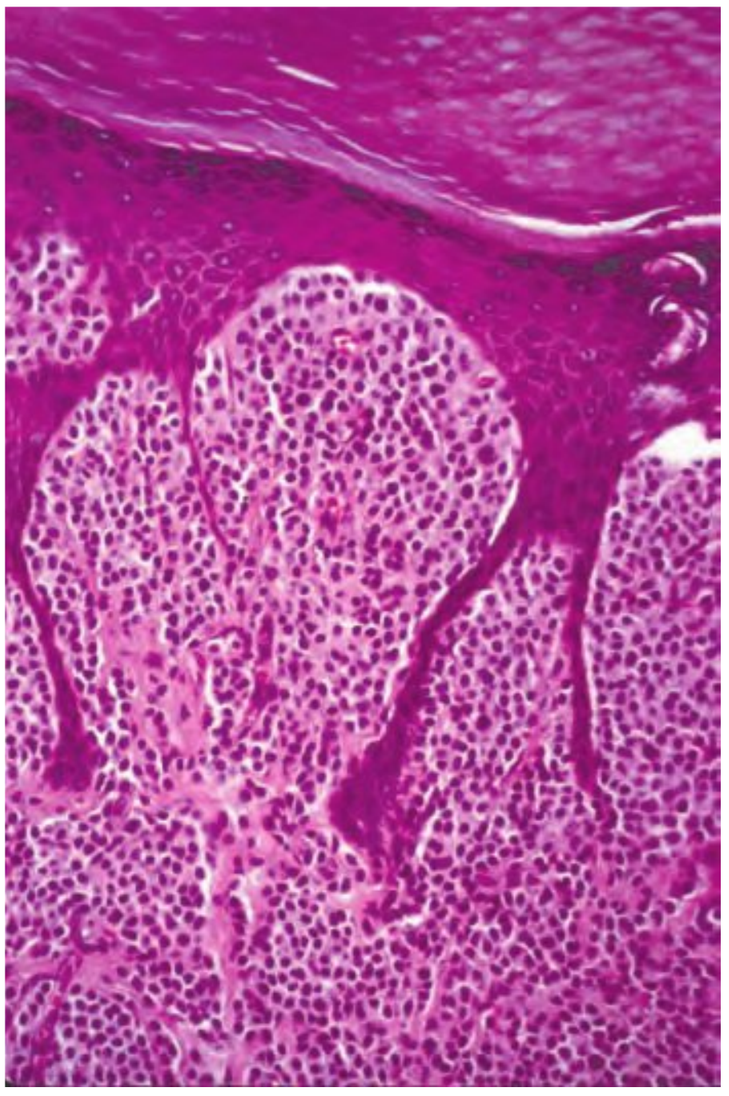

FIGURE 6-40. Urticaria pigmentosa, nodular type. Mast cells fill the expanded papillary dermis (H&E stain, original magnification ×100).

through the entire dermis and even into the subcutaneous fat (325). Whenever the mast cells lie in dense aggregates, their nuclei are cuboidal rather than spindle shaped, and they show ample eosinophilic cytoplasm and a well-defined cell border. Because of the shape of their nuclei and ample cytoplasm, they have a rather distinctive appearance, so the diagnosis usually can be made even before special staining has been carried out.

In the diffuse, erythrodermic type, a dense, bandlike infiltrate of mast cells with a rather uniform appearance showing round to oval nuclei and a distinctly outlined cytoplasm is observed in the upper dermis (326).

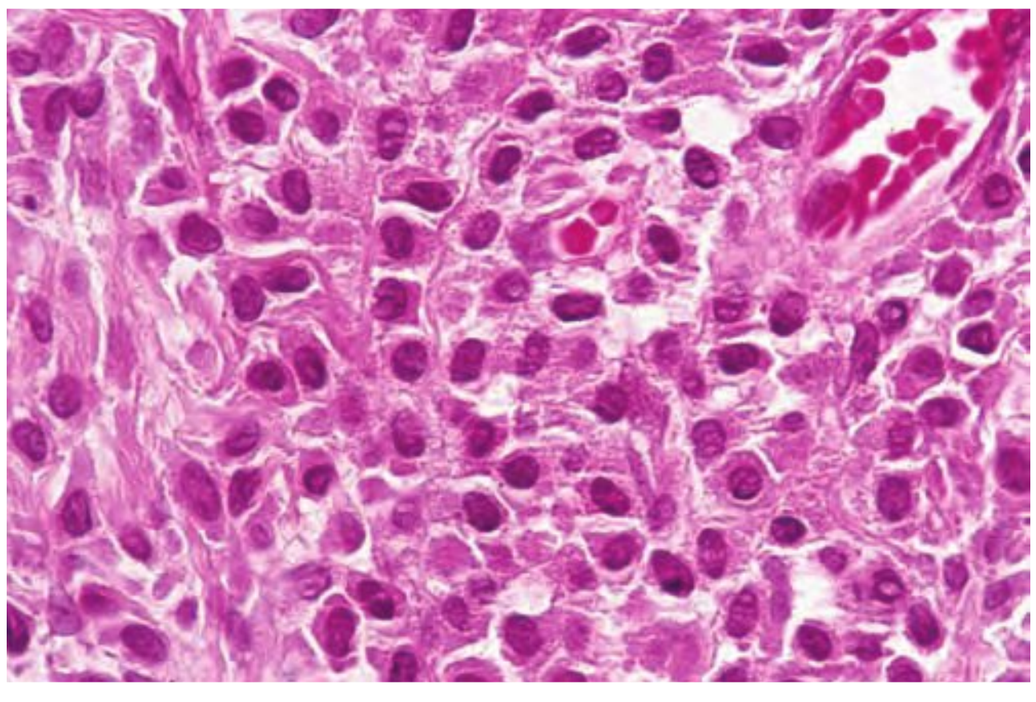

FIGURE 6-41. Urticaria pigmentosa, nodular type. Cuboidal mast cells that fill and expand the papillary dermis. These cells closely resemble nevus cells. Special stains will differentiate (original magnification ×400).

Eosinophils may be present in small numbers in all types of urticaria pigmentosa with the exception of telangiectasia macularis eruptiva perstans, in which eosinophils are generally absent because of the small numbers of mast cells within the lesions. If a biopsy is taken shortly after the lesion has been stroked, an increased number of eosinophils and extracellular mast cell granules are observed, which is an indication that granules have been released by the cells (327).

The bullae that may occur in infants with multiple or solitary nodules or with the diffuse erythrodermic type arise subepidermally (328). Because of regeneration of the epidermis at the base of the bulla, older bullae may be located intraepidermally. The bullous cavity often contains mast cells as well as eosinophils (329). The pigmentation of lesions of urticaria pigmentosa is due to the presence of increased amounts of melanin in the basal cell layer and occasionally also of melanophages in the upper dermis.

Systemic Lesions

It is important to distinguish between asymptomatic systemic involvement of limited degree and true systemic mast cell disease, in which the lesions are symptomatic, widespread, and progressive.

Asymptomatic systemic involvement of a limited degree may occur in urticaria pigmentosa of children, but it is not common. It occurs most commonly in the erythrodermic and nodular types and consists of bone and bone marrow involvement or of hepatosplenomegaly. In urticaria pigmentosa of adults, systemic lesions are more common. For instance, in routinely carried out bone marrow biopsies, as many as 75% of adult patients show mast cell infiltration of bone marrow in contrast to only 18% of children; radiologic survey of the skeleton has revealed bone changes in 44% of adult patients with urticaria pigmentosa but in only 5% of children (330). On radiologic examination, bones with mast cell infiltration may show areas of increased lucency intermingled with areas of increased density owing to the fact that mast cell aggregates in the bone marrow can cause focal bone resorption as well as reactive bone formation (331).

In true systemic mast cell disease, massive infiltration of the bones may cause collapse of several vertebrae or a fracture of long bones (332). Myelofibrosis may occur, resulting in anemia, leukopenia, and thrombocytopenia (313). Pancytopenia may cause death. Systemic mastocytosis, besides involving the bone marrow and bones, generally involves various groups of lymph nodes and the liver and spleen, resulting in hepatosplenomegaly. In some cases, the gastrointestinal tract, lungs, and meninges are also infiltrated with mast cells (326). Mature mast cells may be found in the peripheral blood.

Histogenesis. As seen by both light microscopy and electron microscopy, the mast cells of urticaria pigmentosa do not differ from normal mast cells either in structure or in mode of degranulation (333,334). Because mast cells contain histamine and release it during degranulation, chemical analysis of cutaneous lesions of urticaria pigmentosa reveals a considerably higher level of histamine than is found in normal skin (335).

The increased melanin pigmentation in lesions of urticaria pigmentosa is the result of stimulation of epidermal melanocytes by mast cells. It is not caused by any substance present within the mast cells. In one case of nodular urticaria pigmentosa, however, some mast cells showed dual granulation containing both mast cell granules and melanosomes as well as granules representing intergrades between mast cell granules and melanosomes (336).

Differential Diagnosis. Even if numerous mast cells are present, an absolutely reliable diagnosis of urticaria pigmentosa requires the demonstration of mast cell granules with the Giemsa stain, Leder's method, or toluidine blue stain. On routine staining, the mast cells in macular lesions may resemble fibroblasts or pericytes, but those in nodular or erythrodermic lesions may resemble the histiocytes that are seen in Letterer-Siwe disease or in eosinophilic granuloma. Differentiation of urticaria pigmentosa from these two diseases on routine staining can be particularly difficult because in all three diseases, the infiltrate may contain eosinophils. In contrast with Letterer-Siwe disease, the cells of urticaria pigmentosa have no tendency to invade the epidermis. Occasionally, the cuboidal mast cells in nodular urticaria pigmentosa resemble nevus cells, but they show no tendency to lie in nests and show no junction activity.

The macular type of urticaria pigmentosa, especially telangiectasia maculosa eruptiva perstans, occasionally may be difficult to diagnose even with the Giemsa stain because the number of mast cells may be so small that it does not differ significantly from the number normally present (330). Some inflammatory dermatoses, such as atopic dermatitis, lichen simplex chronicus, and lichen planus, may contain a high percentage of mast cells in their inflammatory cell infiltrates (337). However, in urticaria pigmentosa, the infiltrate consists exclusively of mast cells, except for a slight admixture of eosinophils as a result of the degranulation of some of the mast cells.

INCONTINENTIA PIGMENTI

Incontinentia pigmenti (IP) is an X-linked dominantly inherited disorder. Females with the abnormal gene on only one of their two X chromosomes are heterozygous for this condition and are not severely affected, but males with the abnormal gene on their single X chromosome are hemizygous for this condition and hence are so severely affected that they typically die *in utero*. This explains the predominance of female patients with this disorder (338). To date, over 40 male patients with IP have been reported (339). Male patients may survive either through hypomorphic mutations, as in cases of genetic mosaicism, or through the presence of a compensatory X chromosome, as in cases of 47,XXY or Klinefelter syndrome (340,341). The familial form of this disorder, IP2 (or classical incontinentia pigmentosa), is localized to the Xq28 region (342). It is due to a mutation in the IKK-gamma gene as part of the NEMO complex.

The disorder has four stages. The first stage, consisting of erythema and bullae arranged in lines, either is present at birth or starts shortly thereafter. The extremities are predominantly affected. There is also marked blood eosinophilia. In the second stage, which occurs after about 2 months, the vesicular lesions gradually are superseded by linear, verrucous lesions that persist for several months. As the verrucous lesions subside, widely disseminated areas of irregular, spattered, or whorled pigmentation develop. This pigmentation, representing the third stage, is most pronounced on the trunk (Fig. 6-42A). It diminishes gradually after several years and may even clear completely. The fourth stage is seen in adult females. Subtle, faint, hypochromic or atrophic lesions in a linear pattern are most apparent on the lower extremities.

In about 80% of the cases, IP is associated with various congenital abnormalities, particularly of the central nervous system, eyes, and teeth. Partial alopecia at the vertex is also often seen (343).

Histopathology. The vesicles seen during the first stage arise within the epidermis and are associated with spongiosis. They are of the type seen in dermatitis (344). However, they differ from the vesicles of dermatitis by the numerous eosinophils within them and around them in the epidermis (eosinophilic spongiosis) (Fig. 6-42B and C). The epidermis between the vesicles often shows single dyskeratotic cells and whorls of squamous cells with central keratinization. Like the epidermis, the dermis shows an infiltrate containing many eosinophils and some mononuclear cells.

The alterations in the second stage consist of acanthosis, irregular papillomatosis, and hyperkeratosis. Intraepidermal keratinization, consisting of whorls of keratinocytes and of scattered dyskeratotic cells, is often more pronounced than in the first stage. The basal cells show vacuolization and a decrease in their melanin content. The dermis shows a mild, chronic inflammatory infiltrate intermingled with melano-phages. This infiltrate extends into the epidermis in many places.

The areas of pigmentation seen in the third stage show extensive deposits of melanin within melanophages located in the upper dermis. Usually, this dermal hyperpigmentation is found in association with a diminution of pigment in the basal layer, the cells of which show vacuolization and degeneration (345). In some cases, however, the cells of the basal layer contain abundant amounts of melanin (346,347).

A different pattern has recently been described on the skin of the legs of an infant in whom the vesiculation had produced superficial scarring and depigmentation. The light-colored skin lacked melanocytes and appendages as the result of scarring, and the darker skin showed a normal degree of pigmentation without incontinence of pigment (348).

Pathogenesis. The fact that the first two stages of IP are seen predominantly on the extremities and the third stage mainly on the trunk has led to the assumption by some authors that

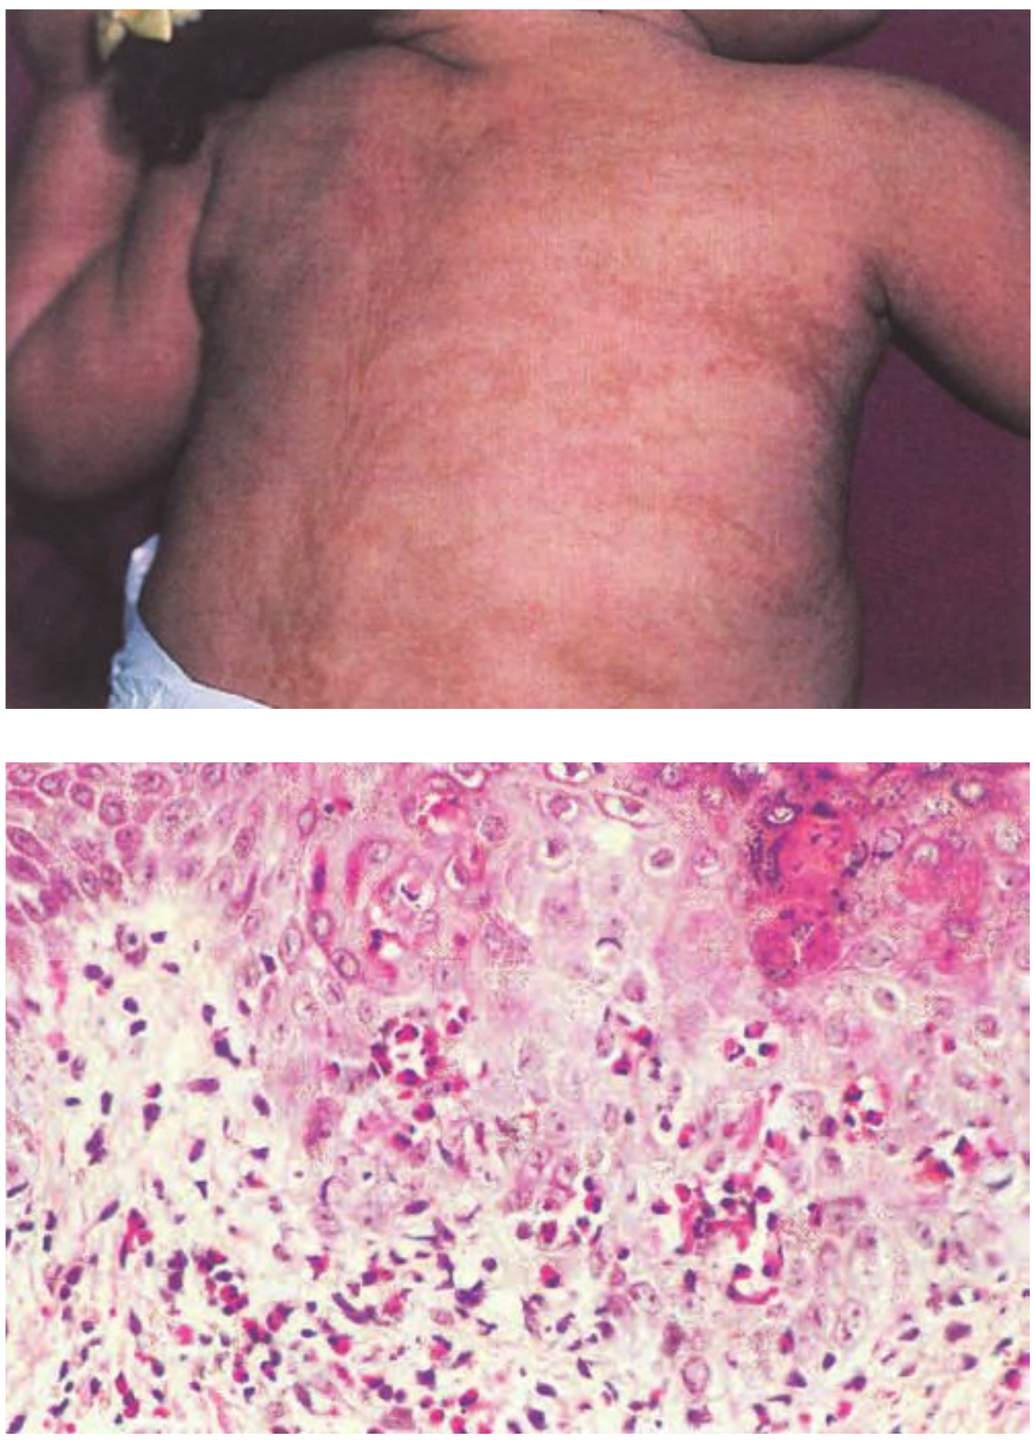

FIGURE 6-42. A: Incontinentia pigmenti. Streaking and whorling pigmentation on the trunk. B: The transition stage between vesicular and acanthotic. Many eosinophils are seen in the dermis and in the focally acanthotic and spongiotic epidermis. C: High magnification of Fig. 6-42B, showing eosinophilic spongiosis and acanthosis.

the pigmentary changes of the third stage occur independently of the bullous and verrucous lesions of the first two stages and represent some sort of nevoid anomaly. However, electron microscopic studies have revealed common features, albeit to varying extents, in all three stages of IP and thus suggest that the three stages are related to each other (349–351). Even in the first stage, many keratinocytes and melanocytes show degenerative changes resulting in the migration of macrophages to the epidermis, where they phagocytize dyskeratotic keratinocytes and melanosomes. Subsequently, the macrophages return to the dermis (EM 6). The macrophages seen in the dermis in the second and third stages contain many melanosome complexes and thus are easily recognizable as melanophages even by light microscopy, whereas the macrophages in the first stage contain only few melanosome complexes and therefore can be identified as melanophages only in the electron microscope (349). The phagocytosis of melanin by dermal macrophages in the first stage of the disease (350) and the presence of dyskeratotic keratinocytes in the epidermis during all three stages of the disease have been confirmed.

The presence of eosinophils in epidermal and dermal infiltrates can be explained by the presence in the early vesicular stage of basophils, which release eosinophil chemotactic factor of anaphylaxis (352). Eosinophil chemotactic activity has been demonstrated in patients with IP in the blister fluid (353) and in eluates of crusted scales overlying the lesions (354).

HYPOMELANOSIS OF ITO

Hypomelanosis of Ito was originally called *incontinentia pigmenti achromians*, but because the disorder shows no pigmentary incontinence, this term has been largely abandoned. However, it is now felt that hypomelanosis of Ito is not an entity but a symptom of many different states of mosaicism and is due to an X/autosome translocation involving Xp11 (355).

The hypomelanosis seen in this disorder may be present at birth. However, it usually develops during the first year of life. In some instances, the loss of pigment does not begin until childhood. There is a tendency for the pigmentary loss to become more pronounced at first but to be followed by partial repigmentation in adult life. The pattern and distribution of the hypopigmentation in hypomelanosis of Ito is similar to the pattern of hyperpigmentation seen in IP (Fig. 6-43). Although first reported in Japanese patients, hypomelanosis of Ito has since been observed in many races.

Congenital abnormalities are found in 50% of the cases (355). Most common are mental retardation and seizure disorders, but there also may be abnormalities of the eyes, hair, teeth, or the musculoskeletal system (356). Abnormal chromosomal constitutions are common (357).

Histopathology. In the hypopigmented areas, a Fontana-Masson stain shows a decrease in the amount of melanin granules in the basal cell layer, with a complete absence of melanin in some areas (358). With the dopa reaction, the hypopigmented areas are seen to contain fewer and smaller melanocytes than normal, with sparse, short dendrites (359).

FIGURE 6-43. Hypomelanosis of Ito. Streaking hypopigmentation on trunk.

Pathogenesis. The electron microscopic findings show a significant decrease in the number of melanosomes within melanocytes and keratinocytes (356,359). In addition, some melanocytes show degenerative changes and an absence of melanosomes (360).

Noninfectious Erythematous, Papular, and Squamous Diseases

URTICARIA

Urticaria is characterized by the presence of abrupt-onset transient and recurrent wheals, which are raised erythematous and edematous areas of skin that are often pruritic. When large wheals occur and the edema extends to the subcutaneous or submucosal tissues, the process is referred to as angioedema (1). Recently, a large survey of nearly 1,000 patients revealed that angioedema can occur without urticarial flares (2). Acute episodes of urticaria generally last only several hours. When episodes of urticaria last up to 24 hours and recur over a period of at least 6 to 8 weeks, the condition is considered chronic urticaria. When urticaria and angioedema occur simultaneously, the condition tends to have a chronic course.

In approximately 15% to 25% of patients with chronic urticaria, an eliciting stimulus or underlying predisposing condition can be identified (3). The various causes of urticaria include soluble antigens in foods, drugs, and insect venom; contact allergens; physical stimuli such as pressure, vibration, solar radiation, or cold temperature; occult infections and malignancies; and some hereditary syndromes such as familial cold urticaria and Muckle-Wells syndrome (amyloidosis, nerve deafness, and urticaria), which are both inherited as an autosomal dominant trait and linked to chromosome 1q44. Schnitzler's syndrome is characterized by a chronic urticaria and a monoclonal gammopathy with evolution in 15% of patients to lymphoplasmacytic neoplasms (4).

Recent evidence suggests that at least 30% to 50% of chronic idiopathic urticarias may have an autoimmune basis for their condition (5,6) (see pathogenesis discussion).

In *hereditary angioedema,* a rare form of dominantly inherited angioedema, recurrent attacks of edema involve not only the skin, but also the oral, upper respiratory, and gastrointestinal tracts. Itching is absent, and there is no associated urticaria. However, lesions may be painful. Attacks are commonly precipitated by trauma, such as dental extraction or emotional stress. Hereditary angioedema manifesting in late middle age after angiotensin-converting enzyme inhibitor therapy has been reported (7). Patients may later manifest autoimmune disorders such as systemic or discoid lupus erythematosus.

Urticarial vasculitis is a syndrome consisting of recurrent episodes of urticarial lesions often associated with arthralgia and abdominal pain and rarely with glomerulonephritis and obstructive pulmonary disease (8). The individual skin lesions tend to persist for 1 to 3 days and may resolve with purpura or hyperpigmentation (9). Lesions in urticarial vasculitis are not necessarily acral in distribution. Urticarial vasculitis should be suspected when individual lesions persist for more than 24 hours and produce burning or stinging sensations (10). Urticarial vasculitis may be normo- or hypocomplementemic. The latter is less frequent and can occur in up to 30% of the cases (11). Organ involvement is more common in hypocomplementemic urticarial vasculitis than in the normocomplementemic form (9). Urticarial vasculitis is usually idiopathic but may be associated with infectious mononucleosis, infectious hepatitis, serum sickness, systemic lupus erythematosus, Sjögren's syndrome, mixed cryoglobulinemia, polycythemia rubra vera (12), and B-cell lymphoma (13). Urticarial vasculitis may antedate other manifestations of collagen vascular disease by months or years (14). Accordingly, the appropriate serologic studies should be performed and periodically monitored. Other associations with urticarial vasculitis include drugs, especially selective serotonin reuptake inhibitors (15,16).

Histopathology. In *acute urticaria* one observes interstitial dermal edema, dilated venules with endothelial swelling, and a paucity of inflammatory cells. In *chronic urticaria* interstitial dermal edema and a perivascular and interstitial mixed-cell infiltrate with variable numbers of lymphocytes, eosinophils, and neutrophils are present (17) (Figs. 7-1 and 7-2).

In *angioedema* the edema and infiltrate extend into the subcutaneous tissue. In *hereditary angioedema* there is subcutaneous and submucosal edema without infiltrating inflammatory cells (18).

In *urticarial vasculitis* the dermis shows an early leukocytoclastic vasculitis characterized by (a) an infiltrate predominantly within and around the walls of small blood vessels composed largely of neutrophils, some of which show fragmentation of their nuclei (leukocytoclasis); (b) minimal deposits of fibrin in the vessel walls; and (c) slight to moderate extravasation of erythrocytes (19).

Pathogenesis. Electron microscopic examination reveals mast cell and eosinophil degranulation in common urticaria. In chronic urticaria, immunoglobulin G (IgG) autoantibodies cross-link the α chain of the high-affinity receptor for IgE on

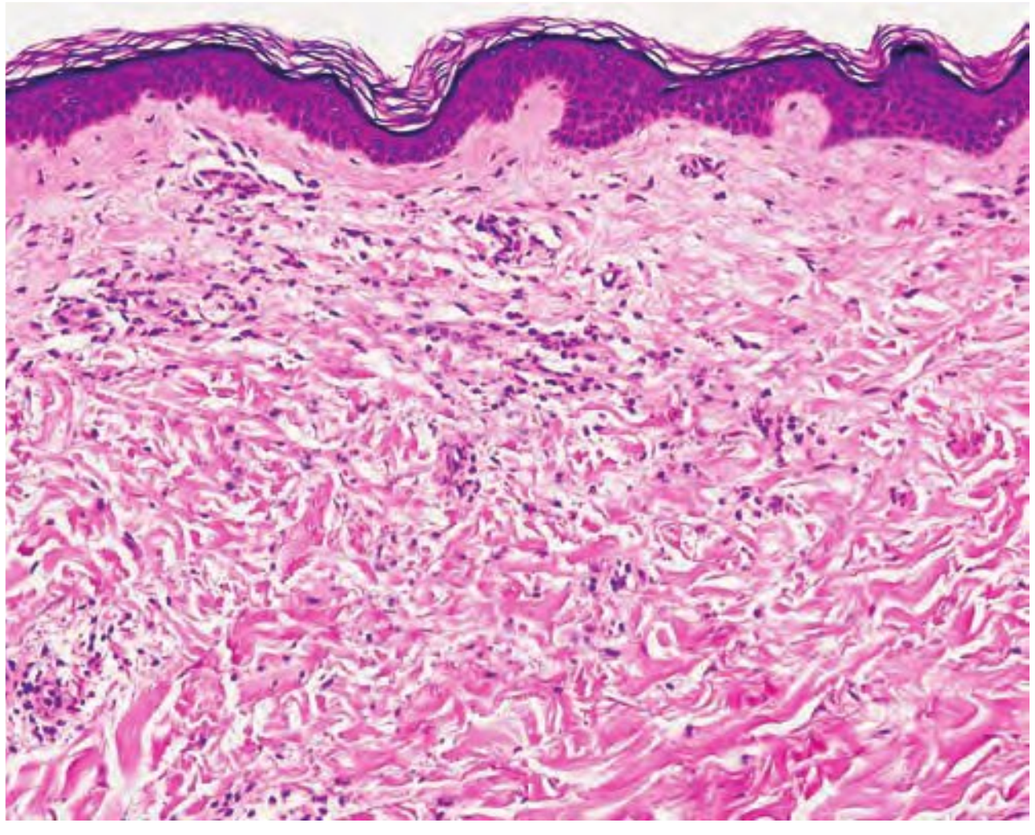

FIGURE 7-1. Urticaria. Sparse superficial perivascular and interstitial inflammatory infiltrate.

mast cells (FcεRI), which results in histamine release. It appears that complement, especially C5a, augments histamine release (20,21). In addition, recent studies have shown that CD203c is a basophil activation marker that is upregulated by cross-linking of the FcεRI α-receptor and may serve as a useful marker to identify patients with chronic urticaria (22). In addition, chemotactic mediators are released from mast cells that induce a sequential upregulation of endothelial adhesion molecules (P-selectin, E-selectin, intercellular adhesion molecule-1 [ICAM-1], and vascular cell adhesion molecule-1) and of β2-integrins on leukocytes (23). The presence of these autoantibodies against the FcεRI α-subunit of the IgE receptor or IgE itself is detected in approximately 30% to 40% of patients with chronic urticaria (22).

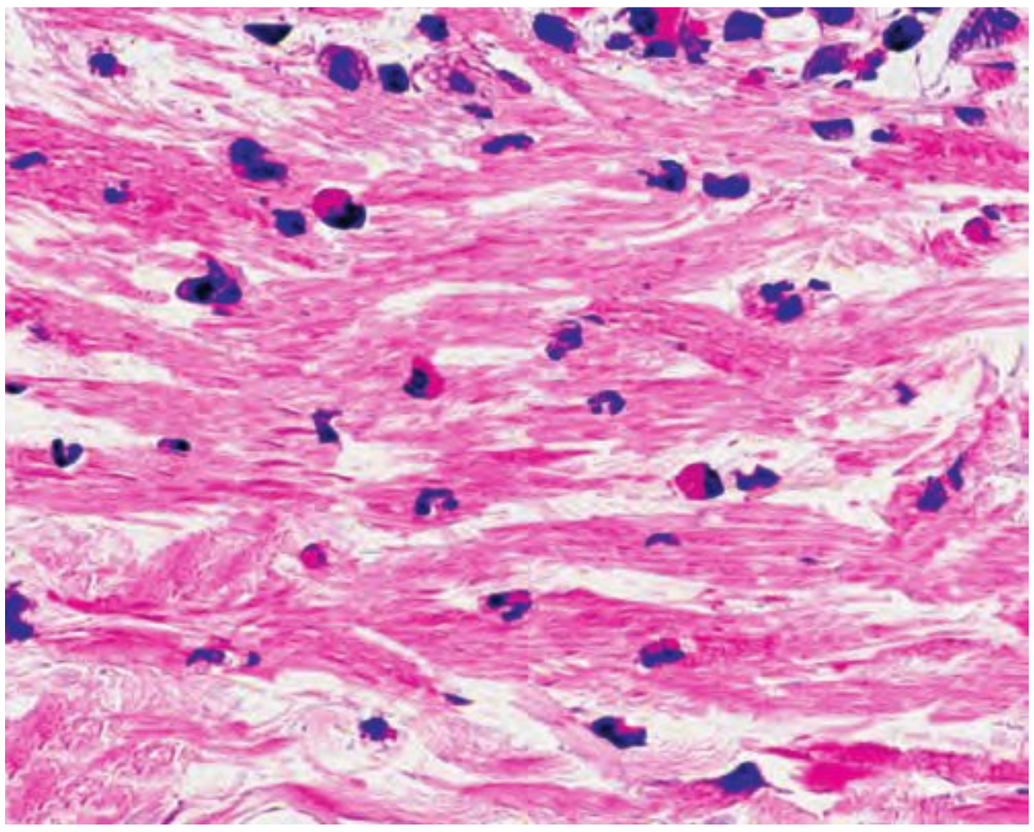

FIGURE 7-2. Urticaria. Interstitial infiltrate of eosinophils, neutrophils, and lymphocytes.

Most patients with hereditary angioedema have a low serum level of the esterase inhibitor of the first component of complement (C1-INH). Exhaustion of this inhibitor allows activation of C1. This leads to activation of C4 and C2, with the generation of a C2 fragment possessing kinin-like activity and causing increased vascular permeability (3). A smaller proportion of patients with hereditary angioedema have a deficit in functional C1-esterase inhibitor.

In urticarial vasculitis, circulating immune complexes are found in about one half of the patients. By direct immunofluorescence testing, strong granular deposits of immunoreactants are seen along the dermoepidermal junction and perivascular areas (14,24). Positive immunofluorescence findings are more common in patients with the hypocomplementemic form of urticarial vasculitis (10). Renal biopsy in patients with hypocomplementemia frequently shows glomerulonephritis (8).

PRURITIC URTICARIAL PAPULES AND PLAQUES OF PREGNANCY

Pruritic urticarial papules and plaques of pregnancy (PUPPP) is a fairly common entity first described in 1979 by Lawley et al. (25) The condition has a predilection for primigravidas in the third trimester of pregnancy. The rash usually starts on the abdomen and is composed of intensely pruritic erythematous urticarial papules, which may be surmounted by vesicles. The proximal parts of the extremities are also affected. There is no increased incidence of the rash in subsequent pregnancies (26). The rash usually involutes spontaneously after delivery. Fetal outcome appears to be unaffected. Unusual clinical presentations have recently been reported as involvement of palmoplantar surfaces and also initial manifestation of the disease in the postpartum period (27,28).

Histopathology. Microscopic findings most commonly show a superficial and middermal perivascular lymphohistiocytic infiltrate with variable numbers of eosinophils and neutrophils together with edema of the superficial dermis. Epidermal involvement is variable and consists of focal spongiosis, parakeratosis, and mild acanthosis (25,26,29).

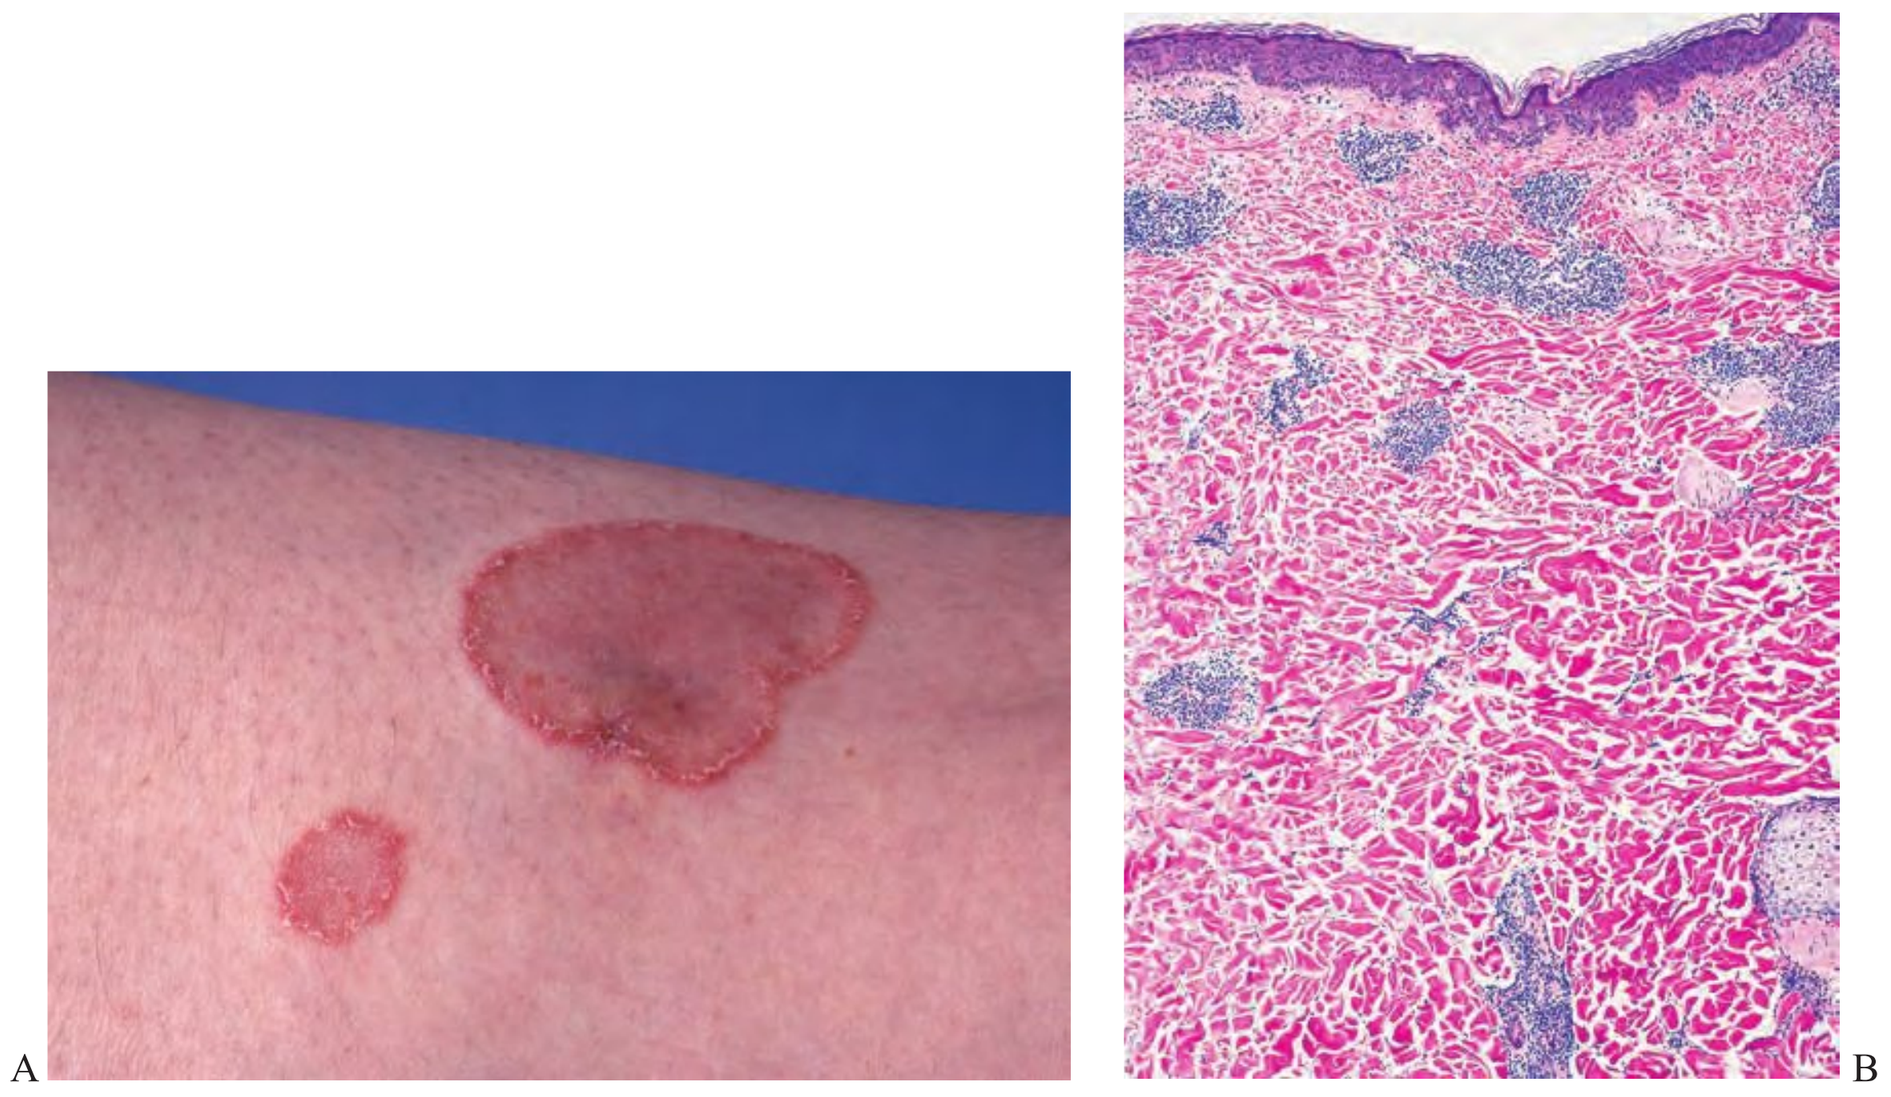
Pathogenesis. A possible correlation has been proposed between susceptibility to develop PUPPP and increased maternal weight gain and twin/triplet pregnancies (30,31). In cultures of human keratinocytes, lesional epidermis of PUPPP has shown positive progesterone receptor (PR) expression detected by immunohistochemistry and reverse transcriptase polymerase chain reaction (RT-PCR). Nonlesional epidermis, however, has not revealed any PR positivity (32). In addition, a paternal factor hypothetically generated or expressed by the fetal portion of the placenta has been invoked as the cause of PUPPP in two families with unusual conjugal patterns (33). Direct immunofluorescence studies may be negative or show nonspecific immunoreactants on dermal blood vessels or at the dermoepidermal junction (34).

ERYTHEMA ANNULARE CENTRIFUGUM

Erythema annulare centrifugum is also known as gyrate erythema and represents a hypersensitivity reaction manifesting as arcuate and polycyclic areas of erythema. The condition has been categorized into superficial and deep variants. The deep form was originally described by Darier and is characterized by annular areas of palpable erythema with central clearing and absence of surface changes (35). The superficial variant differs only by the presence of a characteristic trailing scale—a delicate annular rim of scale that trails behind the advancing edge of erythema (36,37) (Fig. 7-3A). Small vesicles may occur.

The lesions may attain considerable size (up to 10 cm across) over a period of several weeks, may be mildly pruritic, and have a predilection for the trunk and proximal extremities. Most cases resolve spontaneously within 6 weeks; however, the condition may persist or recur for years. In a recent study of 66 patients with erythema annulare centrifugum, the lower extremities were the most frequently involved area and the superficial variant was more common than the deep form, 78% versus 22%, respectively (38).

Histopathology. In the superficial variant of gyrate erythema, there is a superficial perivascular tightly cuffed lymphohistiocytic infiltrate with endothelial cell swelling and focal extravasation of erythrocytes in the papillary dermis. In addition, there is focal epidermal spongiosis and focal parakeratosis (36,37).



In the classic deep form or indurated type, a superficial and deep perivascular lymphocytic infiltrate characterized by a tightly cuffed "coat-sleeve–like" pattern is present in the mid and deep dermis (39) (Figs. 7-3B and 7-4). Occasionally, focal vacuolar alteration of the basal layer keratinocytes may be noted in the deep variant (40).

Pathogenesis. The exact pathogenesis of erythema annulare centrifugum is not clear. It has been associated with occult infections, dermatophytosis, candidiasis, medications, and, rarely, an underlying malignancy (41–43). The rash responds poorly to topical steroids. Treatment of any underlying disorder, if identifiable, is indicated.

Differential Diagnosis. The rather striking coat-sleeve—like perivascular arrangement of the infiltrate seen in the deep form of gyrate erythema is encountered also in secondary syphilis. However, in secondary syphilis numerous plasma cells and histiocytes are usually present, and the endothelial cells are swollen. The presence of increased deposits of connective tissue mucin distinguishes tumid lupus erythematosus from deep gyrate erythema.

ERYTHEMA GYRATUM REPENS

Erythema gyratum repens is a very rare but clinically highly characteristic dermatosis that was originally reported in 1952 by Gammel (44). It mostly represents a paraneoplastic

syndrome that is associated with an internal malignancy in 82% of patients (45). The most common associated malignancies include lung/bronchial, esophageal, and breast carcinomas. Occurrence of erythema gyratum repens as a nonparaneoplastic phenomenon has also been described (46). The eruption typically is very pruritic and is composed of concentric and parallel bands of erythema and scale producing a "wood-grain" pattern on the skin. The trunk and extremities are preferentially involved; however, the entire integument may be affected. The rash of erythema gyratum repens constantly migrates at a fairly rapid rate (up to 1 cm/day). Ichthyosis and palmar/plantar hyperkeratosis have been observed concomitantly in 16% and 10% of patients, respectively (47). The condition is known to remit with treatment and eradication of the associated malignancy.

Histopathology. The histologic picture usually shows mild acanthosis, spongiosis, focal parakeratosis, and a superficial perivascular lymphohistiocytic infiltrate that may also include eosinophils, neutrophils, and melanophages (47,48).

Pathogenesis. Several authors have described granular deposition of C3, C4, or IgG at the basement membrane zone on direct immunofluorescence, suggesting that erythema gyratum repens may have an immunologic basis (49–51). In particular, Caux et al., using immunoelectron microscopy, noted that the deposits are located in the sublamina densa region (51).

ERYTHEMA DYSCHROMICUM PERSTANS

Erythema perstans, also called ashy dermatosis, is an extensive asymptomatic eruption. It begins with disseminated macules showing an elevated red active border, which by peripheral extension and coalescence form large patches with a polycyclic outline (Fig. 7-5). Although the macules may at first be erythematous before assuming their characteristic bluish gray color, they often appear blue-gray from the very beginning. The disease progresses slowly, and the discoloration persists. The most common areas of involvement are the trunk, arms, and face. Most patients with this disorder are Latin Americans (52). A genetic susceptibility to develop the disease in Mexican mestizo patients has been associated with the HLA-DR4 DRB1(*)0407 allele (53).

Histopathology. In the early active stage or in the erythematous active border, there is vacuolar alteration of the basal layer. The papillary dermis shows a mild to moderate perivascular infiltrate of lymphocytes and histiocytes intermingled with melanophages (54,55). There may also be exocytosis of lymphocytes into the basal layer, and occasional necrotic keratinocytes or colloid bodies resembling those seen in lichen planus may be present (56). Late lesions show aggregates of melanophages in the papillary dermis (54).

Pathogenesis. Electron microscopic examination reveals many vacuoles delimited by a membrane within the affected keratinocytes as the ultrastructural counterpart of the vacuolar alteration. This is associated with widening of the intercellular spaces and retraction of desmosomes to either one cell or the other. Additional findings include discontinuities in the subepidermal basement membrane and the presence in the dermis of melanophages containing aggregates of melanosomes enclosed by a lysosomal membrane (57). It can be assumed that the vacuolar alteration of basal keratinocytes is the cause of the pigmentary incontinence and of the formation of the colloid bodies.

Direct immunofluorescence studies have shown IgG deposition on necrotic keratinocytes at the dermal—epidermal junction. Immunohistochemical studies have revealed that in

early lesions, the dermal inflammatory infiltrate is composed primarily of T lymphocytes, both $CD4^+$ (helper-inducer) and $CD8^+$ (cytotoxic-suppressor) subtypes (58).

It has been shown that the expression of ICAM-1 and HLA-DR on basal layer keratinocytes is increased. The activation molecule AIM/CD69 and the cytotoxic cell marker CD94 have been seen to be expressed in the inflammatory cell infiltrate (59). Damage and necrosis of the basal keratinocytes resulting in formation of colloid bodies and pigmentary incontinence suggests a possible relationship of erythema dyschromicum perstans to lichen planus pigmentosus, also called lichen planus actinicus or subtropicus (56,60,61). However, lichen planus pigmentosus shows a different clinical presentation, characterized by dark brown macules located predominantly on exposed areas and flexural folds. Histologically, it shows a more pronounced lichenoid distribution of the infiltrate (55,62). Erythema dyschromicum perstans coexisting with lichen planopilaris has been reported (63).

Differential Diagnosis. Erythema dyschromicum perstans may show similarities with the inflammatory infiltrate and pigmentary incontinence seen in interface drug reactions, especially in the late stage of fixed-drug eruption (54).

PRURIGO SIMPLEX

Prurigo simplex is characterized by intensely pruritic, erythematous urticarial papules that are seen in symmetric distribution, especially on the trunk and extensor surfaces of the extremities of middle-aged patients. Some patients may have an atopic background or may exhibit dermographism (64). In contrast with dermatitis herpetiformis, which prurigo simplex may resemble in clinical appearance, there is no grouping of lesions (65). In other cases, prurigo simplex greatly resembles arthropod bites (papular urticaria).

Histopathology. The histologic picture of the early papules shows mild acanthosis, spongiosis with an occasional small spongiotic vesicle, and parakeratosis. The upper dermis contains a mild lymphocytic inflammatory infiltrate in a largely perivascular arrangement (66). An admixture of eosinophils is present in some cases (65,67). Excoriated papules show partial absence of the epidermis, and they are covered with a crust containing degenerated nuclei of inflammatory cells (65). On serial sectioning, most of the histologic changes may be found to be located around hair follicles, which then show spongiosis and exocytosis of lymphocytes in the follicular infundibulum, and a perifollicular infiltrate (68). In other instances, there is distinct sparing of the follicular structures (67).

Differential Diagnosis. The diagnosis of dermatitis herpetiformis is easily excluded by the absence in prurigo simplex of neutrophilic microabscesses at the tips of dermal papillae and of neutrophils, eosinophils, and nuclear dust in the dermal infiltrate. A negative direct immunofluorescence study of perilesional skin excludes dermatitis herpetiformis or urticarial bullous pemphigoid (64). The histologic picture of prurigo simplex resembles that of a subacute eczematous dermatitis, except that the extent of its papular lesions is much more limited. Histologic differentiation from papular urticaria is not possible (65).

PRURIGO NODULARIS

Prurigo nodularis is a chronic dermatitis characterized by discrete, raised, firm hyperkeratotic papulonodules, usually from 5 to 12 mm in diameter but occasionally larger. They occur chiefly on the extensor surfaces of the extremities and are intensely pruritic. The disease usually begins in middle age, and women are more frequently affected than men (69). Prurigo nodularis may coexist with lesions of lichen simplex chronicus, and there may be transitional lesions (70).

The cause is unknown, but local trauma, insect bites, atopic background, and metabolic or systemic diseases have been implicated as predisposing factors in some cases (70–73).

Histopathology. One observes pronounced hyperkeratosis and irregular acanthosis. In addition, there may be papillomatosis and irregular downward proliferation of the epidermis and adnexal epithelium (74) approaching pseudoepitheliomatous hyperplasia (75) (Fig. 7-6). The papillary dermis shows a predominantly lymphocytic inflammatory infiltrate and vertically oriented collagen bundles. Occasionally, prominent neural hyperplasia may be observed (75); however, this is an uncommon finding and is not considered to be an essential feature for the diagnosis of prurigo nodularis (76). In some cases, silver stains or cholinesterase stains demonstrate the increased number of cutaneous nerves (69).

Eosinophils and marked eosinophil degranulation may be seen more frequently in patients with an atopic background (71). Dermal Langerhans cells are shown to be increased in prurigo nodularis compared to normal controls (77). The

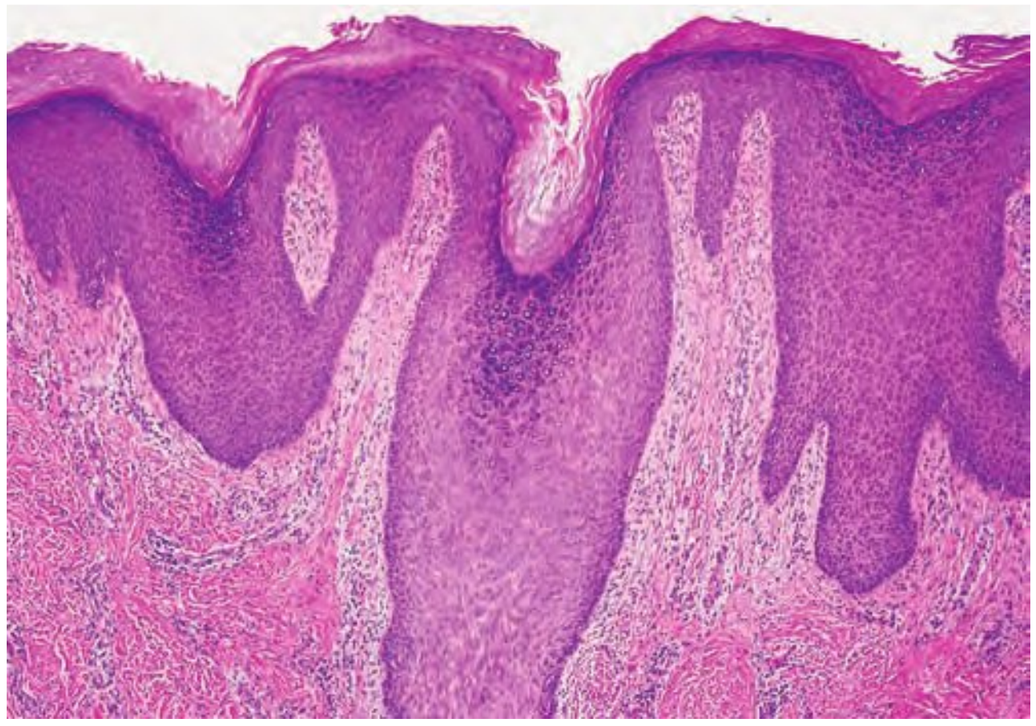

FIGURE 7-6. Prurigo nodularis. Marked irregular acanthosis, focal hypergranulosis, and compact orthokeratosis with parakeratosis.

identification of enlarged dendritic mast cells containing fewer cytoplasmic granules within the lesional dermis has recently been described (78).

Pathogenesis. It is generally assumed that the neural proliferation in prurigo nodularis is a secondary phenomenon due to chronic trauma by scratching. Still, it may be that the extreme pruritus is related to the increased number of dermal nerves (75). A recent study showed that nerve growth factor (NGF) and its receptors are overexpressed in lesional skin of prurigo nodularis compared to normal controls, with the inflammatory cell infiltrate being the source of NGF with resulting neural hyperplasia (79).

Calcitonin gene–related peptide and substance P are markedly increased in prurigo nodularis compared to normal skin. These neuropeptides may mediate the pruritus in prurigo nodularis (80). On electron microscopic examination, it is evident that the neural proliferation involves both axons and Schwann cells (75). Many nerve fibers are also demonstrable with immunostains for S100 protein (81), neurofilament, and myelin basic protein (82). Immunohistochemical analysis has confirmed that they are mostly sensory nerves by demonstrating the presence of sensory neuropeptides (83). In addition, Merkel cells are reported to be increased in number in the basal cell layer of the affected interfollicular epidermis, suggesting that these specialized sensory receptors interacting with the neural fibers may participate in the pathogenesis of the disease (84).

Differential Diagnosis. Lichen simplex chronicus may have a similar histologic picture, although less exuberant and less circumscribed (76). Multiple keratoacanthomas, which often show less of a central crater than solitary keratoacanthomas, may be difficult to distinguish from prurigo nodularis because both show marked epidermal and epithelial hyperplasia (85).

PSORIASIS

Psoriasis may be divided into psoriasis vulgaris, generalized pustular psoriasis, and localized pustular psoriasis.

Psoriasis Vulgaris

Clinical Features

Psoriasis vulgaris is a common chronic inflammatory skin disorder that affects approximately 1.5% to 2% of the population in the Western countries. It is characterized by pink to red scaly papules and plaques (Fig. 7-7). The lesions are of variable size, sharply demarcated, dry, and usually covered with layers of fine, silvery scales. As the scales are removed by gentle scraping, fine bleeding points are usually seen—the so-called Auspitz sign. The scalp, sacral region, and extensor surfaces of the extremities are commonly involved, although in some patients the flexural and intertriginous areas are mainly affected (inverse psoriasis). An acute variant—guttate or eruptive psoriasis—is often seen in younger patients and is characterized by

FIGURE 7-7. Psoriasis vulgaris. Sharply demarcated erythematous scaly papules and plaques on the upper extremity. (Courtesy of Department of Dermatology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.)

an abrupt eruption of small lesions associated with acute group A β-hemolytic streptococcal infections (86). Involvement of the nails is common; the most frequent alteration of the nail plate surface is the presence of pits (87). In severe cases, the disease may affect the entire skin and present as generalized erythroderma. Pustules are generally absent in psoriasis vulgaris, although pustules on palms and soles occasionally occur. Rarely, one or a few areas show pustules, and this is referred to as "psoriasis with pustules." Also rarely, severe psoriasis vulgaris develops into generalized pustular psoriasis. Oral lesions such as stomatitis areata migrans (geographic stomatitis) and benign migratory glossitis (geographic tongue) may be seen in psoriasis vulgaris as well as in generalized pustular psoriasis (88,89).

Psoriatic arthritis characteristically involves the terminal interphalangeal joints, but frequently the large joints are also affected, so that a clinical differentiation from rheumatoid arthritis is often difficult. However, the rheumatoid factor is generally absent.

Generalized Pustular Psoriasis

Clinical Features

Generalized pustular psoriasis includes (a) acute generalized pustular psoriasis (von Zumbusch type and acute exanthematous type), (b) generalized pustular psoriasis of pregnancy (impetigo herpetiformis), (c) infantile and juvenile pustular psoriasis, and (d) subacute annular or circinate pustular psoriasis (90).

This cutaneous eruption is characterized by the presence of variable numbers of sterile pustules appearing in erythematous and scaly lesions associated with moderate to severe constitutional symptoms (91). Several exacerbations may occur, and lesions of ordinary psoriasis may be seen in the intervals between them.

The four variants of generalized pustular psoriasis show considerable resemblance and overlapping in their clinical picture and also have a similar histologic appearance. They differ

mainly in the mode of onset and the distribution of the lesions. Frequently, all four diseases show oral pustules, particularly on the tongue (92).

Acute generalized pustular psoriasis of von Zumbusch is generally diagnosed when the pustular eruption occurs in patients with preexisting psoriasis, either of the plaque type (93) or of the erythrodermic type (94). Frequently, the eruption occurs after systemic steroid therapy withdrawal (90,95). The *exanthematous type of generalized pustular psoriasis* refers to a group of patients with later onset of psoriasis, atypical distribution of the lesions, and a rapid and apparently spontaneous pustular eruption (96).

Generalized pustular psoriasis of pregnancy is a rare pustular eruption that appears during the last trimester of pregnancy. It starts with flexural lesions of psoriasis followed by a generalized pustular eruption. It may occur repeatedly during successive pregnancies (97). Some authors have considered it to be the same disease as *impetigo herpetiformis* (90), but others claim that they stand as separate entities (98,99).

In some instances of *subacute annular pustular psoriasis* the annular or gyrate lesions show a clinical resemblance to subcorneal pustular dermatosis (100,101). Figurate lesions are more frequently seen in subacute or chronic forms of generalized pustular psoriasis (90). Annular pustular psoriasis, although usually generalized, in some instances may be localized (102).

Very rarely, children develop generalized pustular psoriasis, also known as *infantile and juvenile pustular psoriasis*. In these patients the disease has a benign course with frequent spontaneous remissions (103).

Localized Pustular Psoriasis

Clinical Features

There are three types of localized pustular psoriasis: (a) "psoriasis with pustules" (95,96), in which only one or a few areas of psoriasis show pustules and the tendency to change into a generalized pustular psoriasis is low; (b) localized acrodermatitis continua of Hallopeau, which occasionally evolves into generalized acrodermatitis continua; and (c) pustular psoriasis of the palms and soles, with two variants: the chronic palmoplantar pustulosis, also called pustulosis palmaris et plantaris, and the acute palmoplantar pustulosis, or "pustular bacterid." Both are occasionally seen in association with psoriasis vulgaris (90). The relationship of Reiter's disease to psoriasis is discussed in the description of Reiter's disease.

Acrodermatitis continua of Hallopeau is the term used when the pustular eruption involves the distal portions of the hands and feet. In the localized type of acrodermatitis continua, these are the only areas affected, whereas in the generalized type of acrodermatitis continua, extensive areas of the skin in addition to the acral portions of extremities are involved (96). Atrophy of the skin and permanent nail loss may occur on the fingers and toes.

Pustulosis palmaris et plantaris is a chronic, relapsing disorder occurring on the palms, soles, or both (Fig. 7-8). Crops of small, deep-seated pustules are seen within areas of erythema and scaling. In the earliest stage, the lesions may appear as vesicles or vesiculopustules. During the subsiding stage, the pustules appear as brown macules. The sites of predilection are the midpalms and thenar eminences of the hands and the heels and insteps of the feet (104). In pustulosis palmaris et plantaris, in contrast to acrodermatitis continua of Hallopeau, the acral portions of the fingers and toes are spared. An acute variant called "pustular bacterid" (105) describes a rare eruption of large and sterile pustules on hands and feet.

FIGURE 7-8. Pustular psoriasis (palmar pustulosis). Confluent pustules on erythematous scaly skin of the palm. (Courtesy of Department of Dermatology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.)

Psoriasis and Acquired Immunodeficiency Syndrome

Clinical Features

The association between psoriasis and human immunodeficiency virus (HIV) infection is commonly seen. The prevalence of psoriasis is reported to be 1.3% to 2.5% in HIV-positive patients (106,107). Clinically, psoriasis may have a more severe course with sudden exacerbations and may be refractory to treatment (106,108). Extensive erythrodermic psoriasis may occur (109). Palmoplantar involvement, flexural (inverse) psoriasis, and psoriatic arthritis were found to be more frequent in patients who developed psoriasis after HIV infection (107). Although a direct relation between the stage of HIV infection and the severity of psoriasis has not been found, a trend of low peripheral T-cell $CD4^+$ (helper-inducer) counts and a more severe clinical course have been noted (107).

Psoriasis Vulgaris

Histopathology

The histologic picture of psoriasis vulgaris varies considerably with the stage of the lesion and usually is diagnostic only in early, scaling papules and near the margin of advancing plaques.

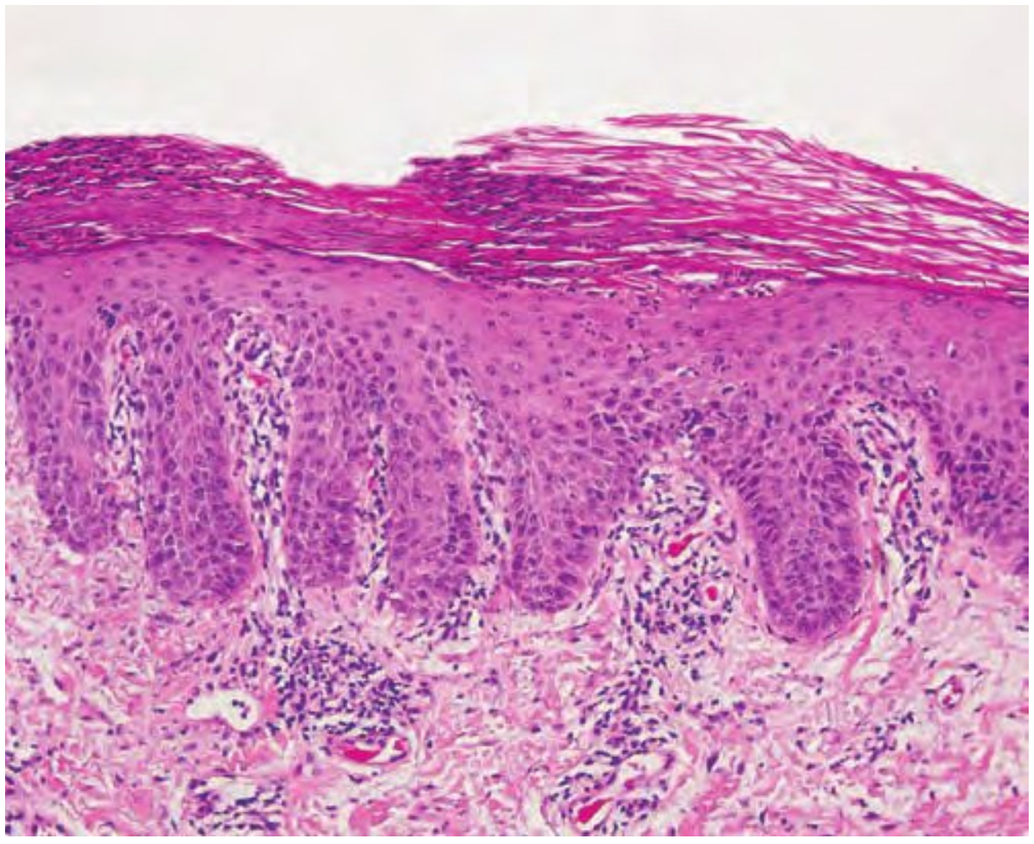

FIGURE 7-9. Early psoriasis. Mounds of parakeratosis with neutrophils, thin granular layer, moderate acanthosis, focal spongiosis, increased mitotic figures, dilated blood vessels at the tip of the dermal papillae, and perivascular infiltrate of lymphocytes and a few neutrophils.

The earliest pinhead-sized macules or smooth-surfaced papules show subtle histologic changes with a preponderance of dermal changes (110,111). At first, there is capillary dilation and edema in the papillary dermis, with a lymphocytic infiltrate surrounding the capillaries. The lymphocytes extend to the lower portion of the epidermis, where slight spongiosis develops. Then focal changes occur in the upper portion of the epidermis, where granular cells become vacuolated and disappear, and mounds of parakeratosis are formed. Neutrophils are usually seen only at the summits of some of the mounds of parakeratosis and appear scattered through an otherwise orthokeratotic cornified layer (Fig. 7-9). These mounds of parakeratosis with neutrophils represent the earliest manifestation of Munro microabscesses (111). At this stage, which is characterized clinically by an early scaling papule, a histologic diagnosis of psoriasis can often be made. In some cases, when there is marked exocytosis of neutrophils, they may aggregate in the uppermost portion of the spinous layer to form small spongiform pustules of Kogoj. Lymphocytes remain confined to the lower epidermis, which, as more and more mitoses occur, becomes increasingly hyperplastic. The epidermal changes are at first focal, but later become confluent, leading clinically to plaques.

In the fully developed lesions of psoriasis, as best seen at the margin of enlarging plaques, the histologic picture is characterized by (a) acanthosis with regular elongation of the rete ridges with thickening in their lower portion; (b) thinning of the suprapapillary epidermis with the occasional presence of small spongiform pustules; (c) pallor of the upper layers of the epidermis; (d) diminished to absent granular layer; (e) confluent parakeratosis; (f) the presence of Munro microabscesses;

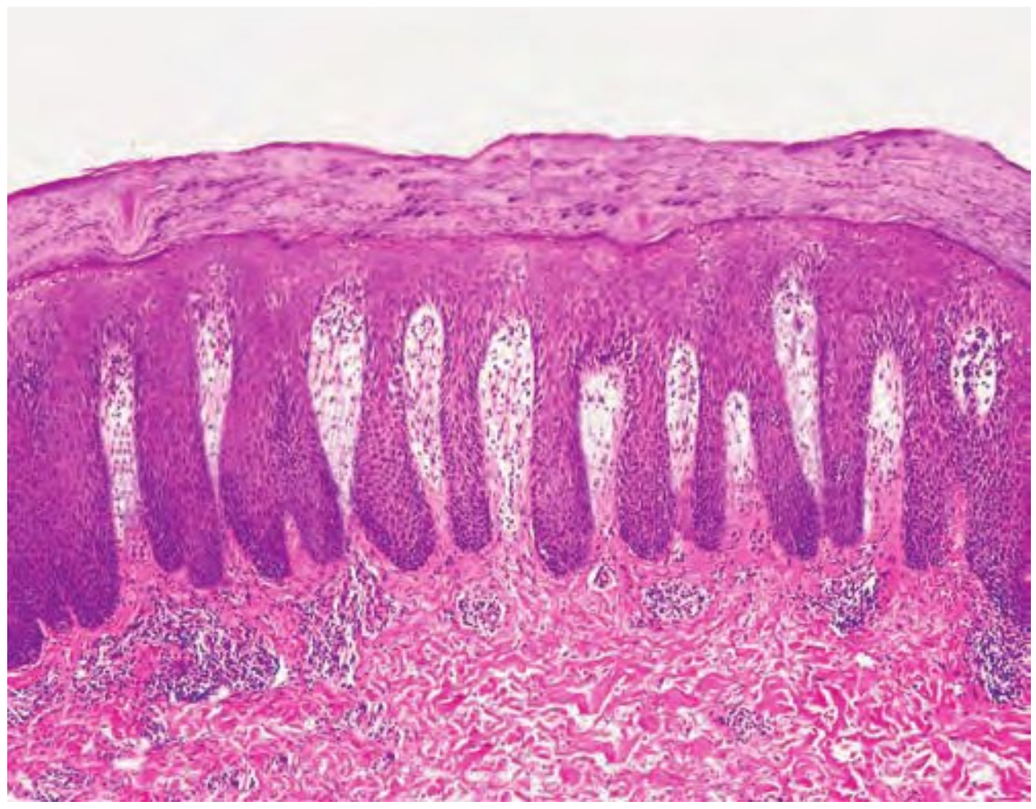

FIGURE 7-10. Psoriasis, well-developed plaque. Markedly elongated rete ridges, absent granular layer, parakeratosis with neutrophils, and dilated tortuous vessels in the dermal papillae.

(g) elongation and edema of the dermal papillae; and (h) dilated and tortuous capillaries (Fig. 7-10).

Of the listed features, only the spongiform pustules of Kogoj and Munro microabscesses are truly diagnostic of psoriasis, and, in their absence, the diagnosis can rarely be made with certainty on a histologic basis. The changes in active psoriasis are discussed in detail later.

The rete ridges show considerable elongation and extend downward to a uniform level, resulting in regular acanthosis (Fig. 7-11). They are often slender in their upper portion but

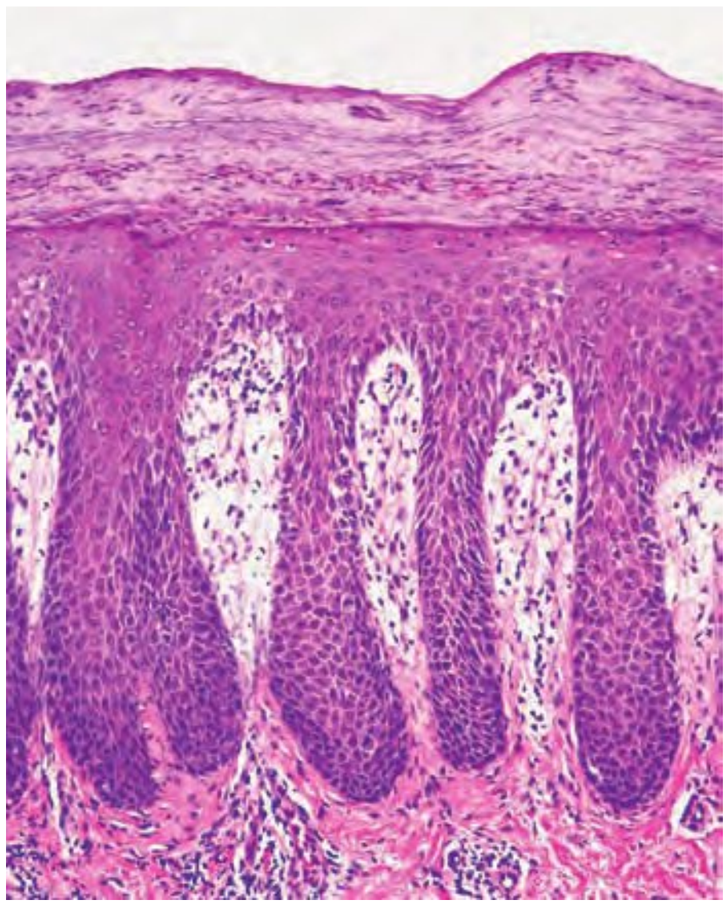

FIGURE 7-11. Psoriasis, well-developed plaque. Acanthosis with club-shaped rete ridges of even length, suprabasal mitoses, thin suprapapillary epidermal plates, absent granular layer, pallor of the upper epidermis, and confluent parakeratosis with collections of neutrophils.

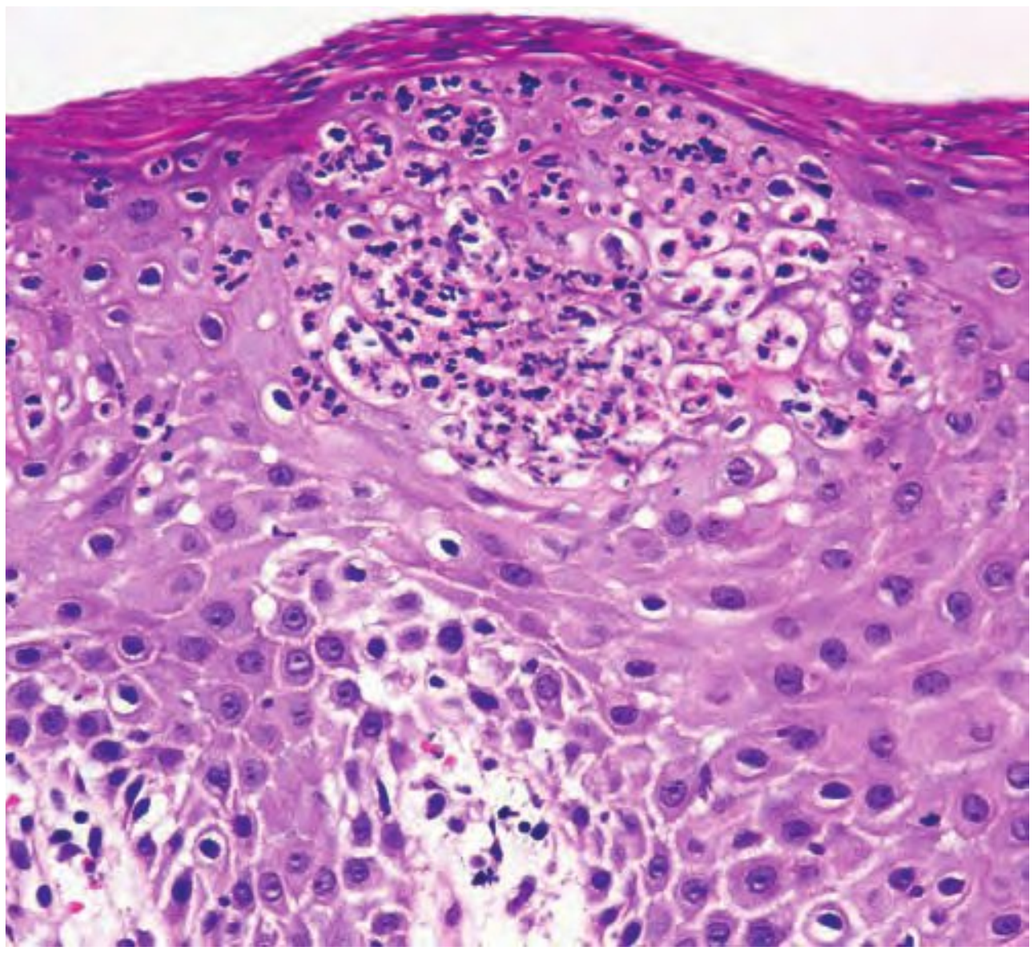

FIGURE 7-12. Psoriasis. Closer view of a spongiform pustule of Kogoj formed by collections of neutrophils in the spinous and granular layers.

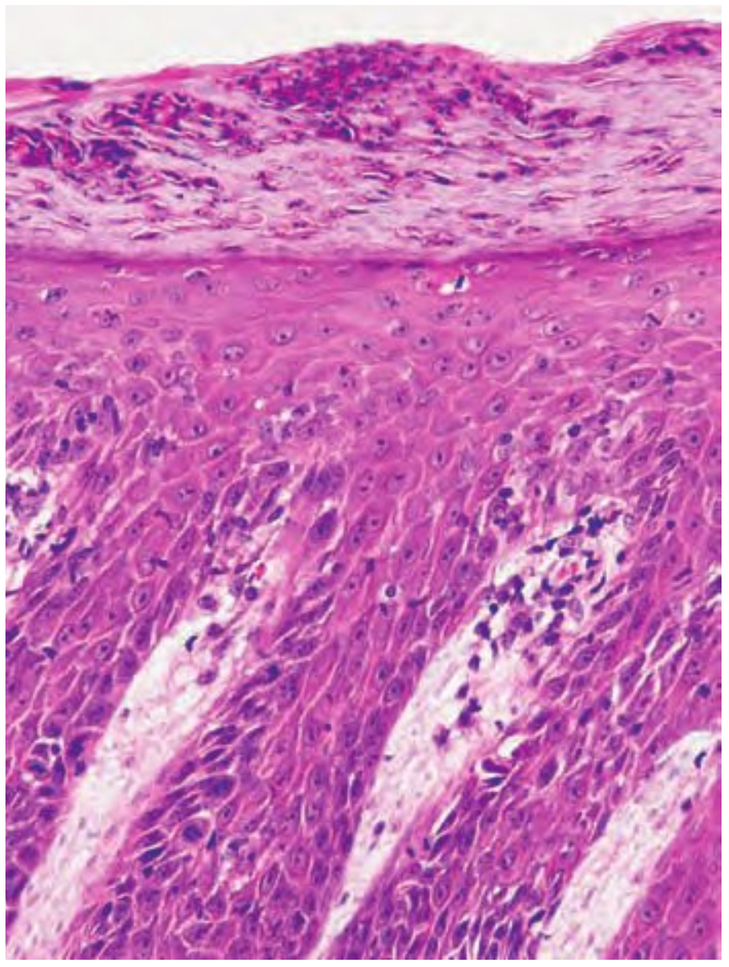

FIGURE 7-13. Psoriasis, plaque lesion. Closer view of the neutrophilic collections within the parakeratotic cornified layer (Munro microabscess). Note the thin suprapapillary epidermal plates and dilated blood vessels in the dermal papillae.

show thickening ("clubbing") in their lower portion. Not infrequently, adjacent rete ridges seem to coalesce at their bases due to tangential sectioning. Usually, intercellular and intracellular edema is absent in the rete ridges, and keratinocytes located well above the basal layer show deep basophilia. In addition, mitoses are not limited to the basal layer as in normal skin but are also seen above the basal layer. This, together with a considerable lengthening of the basal cell layer due to elongation of the rete ridges, results in a marked increase in the number of mitoses. This increase has been calculated to be 27 times the number of mitoses in uninvolved skin (112).

The suprapapillary epidermis appears relatively thin in comparison with the markedly elongated rete ridges, and the cells in the upper layers of the epidermis may appear enlarged and pale stained as a result of intracellular edema and hypogranulosis. Keratinocytes beneath the parakeratotic cornified layer may be intermingled with neutrophils (113). The histologic picture is then that of a small spongiform pustule of Kogoj (Fig. 7-12). Although it is only a micropustule, it is nevertheless of the same type as the much larger macropustules seen in pustular psoriasis. Such a spongiform pustule, highly diagnostic for psoriasis and its variants, shows aggregates of neutrophils within the interstices of a spongelike network formed by degenerated and thinned epidermal cells (114).

In some instances the cornified layer consists entirely of confluent parakeratosis forming a platelike scale with a concomitant absence or diminution of the granular layer. However, occasional focal orthokeratosis with preservation of the underlying granular cells is present.

Munro microabscesses are located within the parakeratotic areas of the cornified layer (Fig. 7-13). They consist of accumulations of neutrophils and pyknotic nuclei of neutrophils that have migrated there from capillaries in the papillae through the suprapapillary epidermis. As a rule, Munro microabscesses are easily found in early lesions but are few in number or absent in longstanding lesions (115).

The dermal papillae, in accordance with the elongation and basal thickening of the rete ridges, are elongated and club shaped. They show edema, and the capillaries within them appear dilated and tortuous. A relatively mild inflammatory infiltrate is present in the upper dermis and the papillae. It consists of lymphocytes, except in early lesions, in which neutrophils are also present in the upper portion of the papillae (116).

An entirely typical histologic picture as described earlier is not always found, even if the biopsy specimens are taken from clinically typical lesions of psoriasis (117). Orthokeratosis often appears intermingled with parakeratosis. In such cases, one may see vertically adjoining areas of orthokeratosis and parakeratosis, focal parakeratosis, or, occasionally, alternating layers of orthokeratosis and parakeratosis. The last-named pattern indicates a fluctuation in the activity of the psoriasis.

The bleeding points that may be produced by gentle scraping of the skin (Auspitz sign) correspond to the tips of dermal papillae. They are attributable to the following histologic changes: parakeratosis, intracellular edema of keratinocytes in the suprapapillary epidermis, thinning of the suprapapillary plates, and dilation of the capillaries in the upper portion of the papillae.

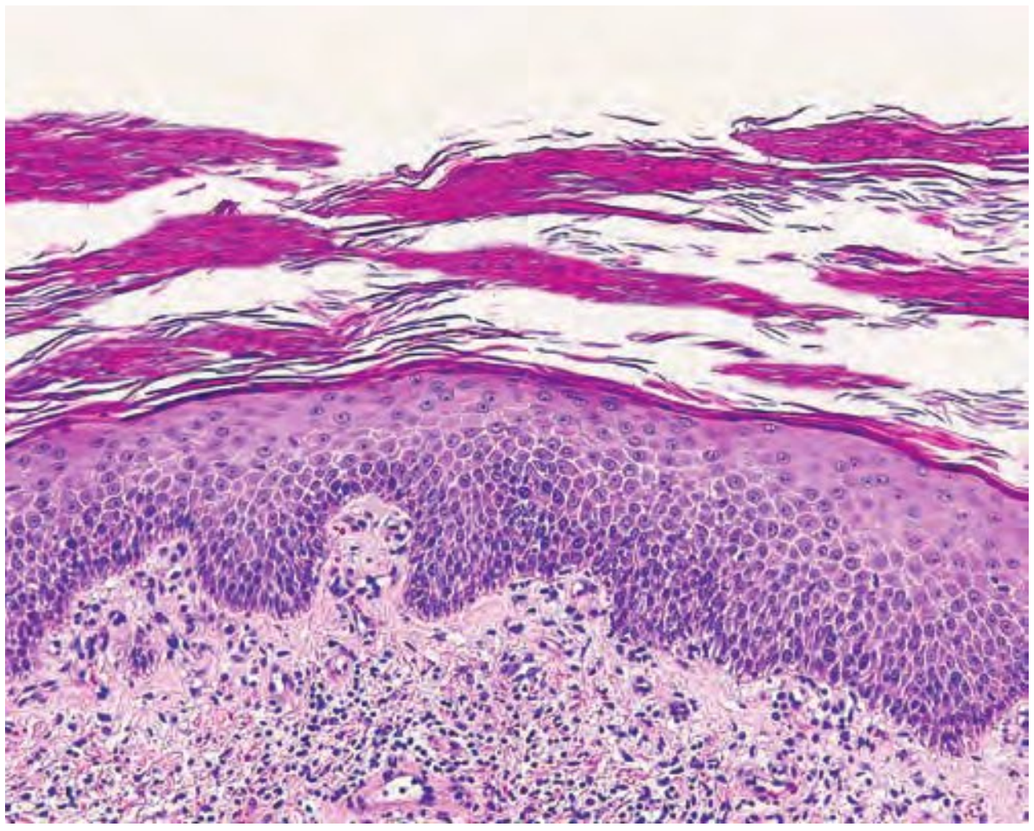

FIGURE 7-14. Eruptive psoriasis. Multilayered mounds of parakeratosis admixed with basket-weave orthokeratosis, slight acanthosis, and dilated blood vessels in the dermal papillae.

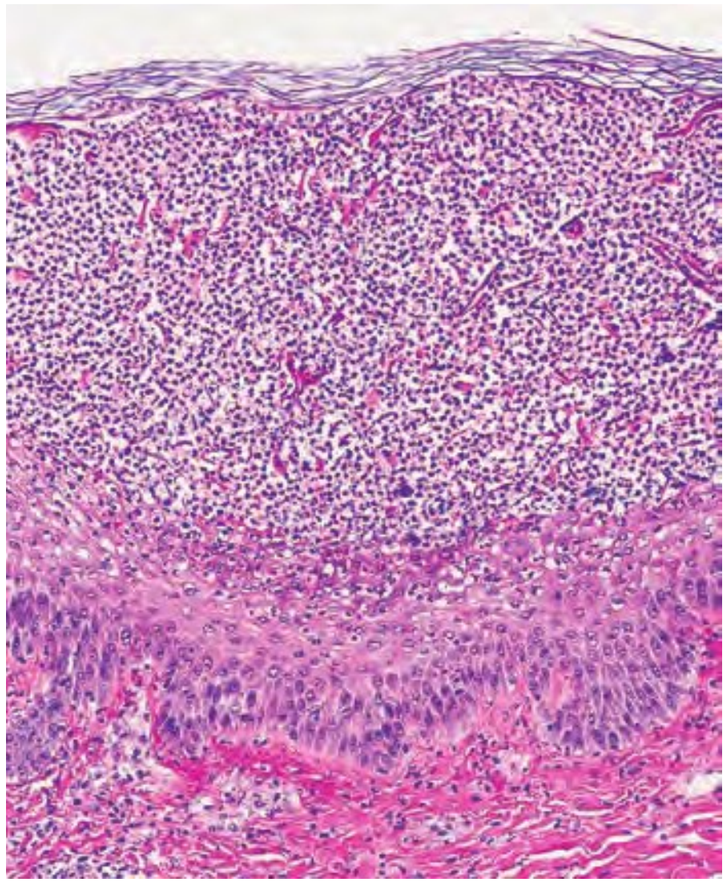

FIGURE 7-15. Pustular psoriasis. Large collections of neutrophils with spongiosis in the upper spinous layer and granular layer.

Guttate or eruptive psoriasis shows the histologic features of an early or active lesion of psoriasis, where there is more pronounced inflammatory infiltrate and less acanthosis as compared with a well-developed chronic plaque of psoriasis. Because of its acute onset, one may observe the remaining normal basket-weave orthokeratotic cornified layer overlying the mounds of parakeratosis with neutrophils, which, in turn, may appear loosely arranged (Fig. 7-14).

The histologic picture of *erythrodermic psoriasis* in some instances shows enough of the characteristics of psoriasis to allow this diagnosis. Frequently, however, the histologic appearance is indistinguishable from that of a chronic eczematous dermatitis (118).

Generalized Pustular Psoriasis

Histopathology

Whereas in ordinary psoriasis the spongiform pustule of Kogoj is a very small micropustule and is seen only in early, active lesions, it occurs as a macropustule in all variants of generalized pustular psoriasis and represents their characteristic histologic lesion. The spongiform pustule forms through the migration of neutrophils from the papillary dermal capillaries to the upper layer of epidermis, where they aggregate within the interstices of a spongelike network formed by degenerated and thinned epidermal cells (114). As the size of the pustule increases, the epidermal cells in the center of the pustule undergo complete cytolysis so that a large single cavity forms (Fig. 7-15). At the periphery of the pustule, however, the network of thinned epidermal cells persists for a much longer time. As the neutrophils of the spongiform pustule move up into the cornified layer, they become pyknotic and assume the appearance of a large Munro abscess (93,119).

In addition to the large spongiform pustules, the epidermal changes in generalized pustular psoriasis are very much like those seen in psoriasis vulgaris, consisting of parakeratosis and elongation of the rete ridges. The upper dermis contains an infiltrate of lymphocytes, and neutrophils can often be seen migrating from the capillaries in the papillae into the epidermis (120). The oral lesions show the same spongiform pustule formation as those seen on the skin (92).

In the healing stage, the lesions of all types of generalized pustular psoriasis may present the same histologic appearance as ordinary psoriasis (93).

Localized Pustular Psoriasis

Histopathology

In the variants of localized pustular psoriasis "psoriasis with pustules" (95,96) and localized annular pustular psoriasis, the histologic picture is the same as that described for generalized pustular psoriasis.

In localized acrodermatitis continua of Hallopeau, the nail bed is mainly affected, showing marked epithelial hyperplasia with variable numbers of spongiform pustules, hypogranulosis, and hyperkeratosis with mounds of parakeratosis with neutrophils. The nail matrix is only occasionally involved (121).

In pustulosis palmaris et plantaris there is a fully developed large intraepidermal unilocular pustule. It is elevated only slightly above the surface but presses onto the underlying dermis. Many neutrophils are present within the cavity of the pustule. The epidermis surrounding the pustule shows slight acanthosis, and an inflammatory infiltrate can be seen beneath the pustule (122). In many instances one can observe typical, although small, spongiform pustules in the epidermal wall of

the pustule, most commonly at the junction of the lateral walls and the overlying epidermis (122–126). These spongiform pustules are identical to those seen in the walls of the pustules of generalized pustular psoriasis.

Very early lesions may show spongiosis and exocytosis of lymphocytes in the lower epidermis overlying the tips of dermal papillae (125). This may be followed by the formation of a small intraepidermal vesicle containing mostly lymphocytes (122,125). Subsequently, there is a massive exocytosis of neutrophils, which penetrate the intercellular spaces of the vesicle wall, where the histologic picture of spongiform pustules is then seen (122). In the acute form, pustular bacterid, leukocytoclastic vasculitis has been described (127).

Psoriasis and Acquired Immunodeficiency Syndrome

Histopathology

The histologic picture in most cases is similar to that of psoriasis. In others, the histologic sections may show acanthosis without thinning of the suprapapillary epidermis, slight spongiosis, rare necrotic keratinocytes, and a superficial perivascular infiltrate of lymphocytes and histiocytes that occasionally contains some plasma cells (128). As in other dermatitides related to AIDS, eosinophils may be present in the inflammatory infiltrate.

Pathogenesis of Psoriasis Vulgaris

Although the cause of psoriasis is unknown, there is increasing evidence of a complex interaction among altered keratinocytic proliferation and differentiation, inflammation, and immune dysregulation.

Electron Microscopy

The earliest recognizable morphologic events in psoriasis have been investigated in lesions that cleared with corticosteroid under occlusion and then were allowed to relapse. The earliest indications of relapse, as seen by electron microscopy, are swelling and intercellular widening of endothelial cells. This is followed by the appearance around postcapillary venules of mast cells showing degranulation. Hours later, activated macrophages migrate into the lower epidermis, where there is loss of desmosome-tonofilament complexes. Only then are lymphocytes and neutrophils seen (129). Ultrastructurally, in well-developed lesions, psoriatic keratinocytes from the suprabasal layers of the epidermis show significant abnormalities. The tonofilaments are decreased in number and in diameter and lack their normal aggregation. The size and number of keratohyaline granules are greatly reduced, and occasionally these are absent (130,131). The cornified cells possess thin tonofilaments and often retain organelles and a nucleus as parakeratotic cells. They often fail to form a marginal band and to lose their outer plasma membrane (132). Basal keratinocytes may show cytoplasmic processes protruding into the dermis through gaps in the basal lamina. These are more numerous in active and untreated lesions and are absent in completely resolved and uninvolved psoriatic skin (133). The intercellular spaces between all epidermal cells are widened because of a deficiency in the glycoprotein-rich cell surface coat, so that intercellular adhesion is limited to the desmosomes (132,134). Electron microscopic studies have confirmed the view that the keratinocytes in psoriasis are defective and not just immature owing to accelerated epidermal proliferation. Although a correlation exists in psoriasis between an increased rate of mitosis and parakeratosis, rapid proliferation of the epidermis does not cause parakeratosis (135).

Ultrastructural studies of the spongiform pustule of Kogoj, one of the most characteristic histologic structures encountered in psoriasis, reveal that it is located in the uppermost portion of the spinous and granular layers, where neutrophils lie intercellularly in a multilocular pustule in which the spongelike network is composed of degenerated and flattened keratinocytes (114).

The ultrastructure of the capillary loops in the dermal papillae shows them to be different from normal capillary loops. In psoriasis, the capillaries show a wider lumen, bridged fenestrations and gaps between endothelial cells, edematous areas in the cytoplasm of endothelial cells, pericytes and myocytes, extravasation of red blood cells and inflammatory cells, and a thickened multilayered basement membrane (136). This finding may be a result of the deposition of amorphous substances and accumulation of collagen fibrils in the basement membrane zone (137).

Epidermal Cell Cycle Kinetics

The rate of epidermal cell replication is markedly accelerated in active lesions of psoriasis, as shown by the higher than normal number of basal and suprabasal mitotic figures and the greater number of premitotic cells labeled by tritiated thymidine (138). The mitotic activity within different lesions of psoriasis and even within the same lesion can vary considerably and seems to be correlated with the degree of parakeratosis. Thus, psoriatic epidermis with 91% to 100% parakeratosis shows on average five times as many mitotic figures as psoriatic epidermis with only 0% to 20% parakeratosis (117). The frequent finding in psoriasis of alternating layers of orthokeratosis and parakeratosis suggests that epidermal growth activity fluctuates in the lesions (117). Step sections of early "punctate" papules show a mitotically very active parakeratotic center surrounded by a zone of a thickened granular layer with a relatively low mitotic rate (139).

Early calculations made it appear likely that in psoriatic lesions there was a great acceleration of the transit time of cells from the basal cell layer to the uppermost row of the squamous cell layer, from approximately 53 days in normal epidermis to only 7 days in the epidermis of active psoriatic lesions (138).

Further investigations (140) have found that (a) the germinative cell cycle is shortened from 311 to 36 hours, indicating that psoriatic keratinocytes proliferate approximately eightfold faster than do normal keratinocytes, (b) there is a doubling of the proliferative cell population in psoriasis from 27,000 to 52,000 cells/mm^2 of epidermal surface area, and (c)

100% of the germinative cells of the epidermis enter the growth fraction instead of only 60% for normal subjects. However, in another study (141), it was shown that the germinative cell cycle time is around 200 hours in normal epidermis and about 100 hours in psoriatic epidermis, a twofold rather than an eightfold acceleration.

The source of the cycling cells in the suprabasal layers of the epidermis is not well defined. They could be an expanded population of basal keratinocytes or could be recruited from the transient-amplifying cells (TAC)—suprabasal keratinocytes committed to terminal differentiation—that might undergo rounds of amplifying divisions above the basal layer (142). Based on keratin studies, it is believed that proliferating keratinocytes may result from recruitment of TAC (142) because they express K1/K10 and predominantly K6/K16 keratins and not K5/ K14 as basal keratinocytes do (143).

Recent studies suggested that psoriatic epidermis shows aberrant expression of apoptosis-related molecules representing suppressed apoptotic process, which might be related to proliferative characteristic of the epidermis in this disease (144).

Keratinocyte Differentiation

Keratinocytes undergo the process of differentiation as they migrate upward through the epidermis from the basal layer to the cornified layer. During this process, different structural proteins are synthesized. One such protein family is the keratins, which are intermediate filaments found in the cytoplasm of all epithelial cells. Studies revealed that the keratin pair K5/K14 is expressed in basal keratinocytes (145) and keratins K1/K10 are found in the suprabasal layers. Involucrin, one of the major precursor proteins of the cornified cell envelope, is detected higher in the granular and cornified layers (146). In psoriatic skin, basal keratinocytes continue to express K5/K14; however, keratins K1/K10 are replaced by the so-called hyperproliferation-associated keratins K6 and K16. In addition, involucrin is expressed prematurely in the lower suprabasal layers (143,147). Keratin 17, normally expressed in the deep outer root sheath of the hair follicle, has been found also in the upper suprabasal keratinocytes within the interfollicular psoriatic epidermis (143).

Immunopathology

Immunologic factors play a very important role in the pathogenesis of psoriasis. Psoriasis is now regarded as a T-cell—mediated disorder. It has been shown that both $CD4^+$ and $CD8^+$ T lymphocytes are found in the papillary dermis and the epidermis of the psoriatic lesions. $CD8^+$ T cells seem to be dominant in the epidermis, whereas the $CD4^+$ T lymphocytes are the predominant subset in the dermis. Presence of $CD8^+$ T cells within the epidermis is believed to be a key event in the pathogenesis of psoriasis (148), with up to one third of them expressing the activation markers (149). Recent data suggest that lesions of psoriasis exhibit clonal expansion of epidermal T lymphocytes. Recurrent lesions also show the recruitment of the identical expanded T-cell clones. Nonlesional skin did not show the presence of the same T-cell receptor rearrangements. These findings suggest that a stable antigen-specific pathogenic T-cell response may play a role in disease perpetuation in psoriasis (150–152). The activation of T lymphocytes may be due to bacterial superantigens such as group A β-hemolytic streptococci. It is suggested that amino acid sequences from streptococcal M-protein share sequences with keratin 17, and therefore an epitope on keratin 17 or keratin 6 may be a target for autoreactive lymphocytes in psoriasis (153,154). Group A streptococcal–reactive $CD8^+$ and to a lesser extent $CD4^+$ T cells in psoriatic epidermis may play a role in the pathogenesis of both poststreptococcal guttate psoriasis (155) and chronic plaque psoriasis (156). Activated $CD4^+$ T cells produce a variety of cytokines, including interleukin-2 (IL-2), tumor necrosis factor-α (TNFα), and γ-interferon (γIFN), which is also produced by $CD8^+$ T lymphocytes (157).

Keratinocytes stimulated by TNFα may produce IL-8, which is a potent T-lymphocyte and neutrophil chemoattractant present in increased amounts in psoriatic epidermis. This cytokine may be involved in the formation of Munro microabscesses (158).

γIFN is believed to play an important role in the initiation of psoriatic lesions as demonstrated by the induction of pinpoint lesions of psoriasis at sites of γIFN injection in previously uninvolved skin (159).

γIFN induces the expression of the ICAM-1 in keratinocytes and endothelial cells. This molecule mediates the adhesion and trafficking of lymphocytes into the epidermis by binding to its ligand lymphocyte function-associated antigen-1 (LFA-1) expressed on lymphocyte membranes (158). In addition, γIFN-inducible protein (IP-10) is overexpressed by keratinocytes in psoriatic lesional skin (160). IP-10 is detected in epidermis during cellular immune responses and may have chemotactic as well as mitogenic properties. Psoriatic keratinocytes are shown not to be responsive to the growth inhibition effects of γIFN, leading to their hyperproliferative state in the disease (161).

Increased expression of p53 and downregulation of Bcl-2, consistent with the dynamics of psoriasis, have been shown (162). In addition, aberrant cytokine expression has been proposed as an underlying cause of psoriasis, with IL-23 being considered as a master regulator cytokine in the pathogenesis of the disease (163).

Pathogenesis of Localized Pustular Psoriasis

A relationship of pustulosis palmaris et plantaris with psoriasis is not generally accepted, although two facts favor a close relationship: the relatively common occurrence of psoriasis in patients with pustulosis palmaris et plantaris, reported in 19% to 48% of patients (164–166), and the common presence of spongiform pustules in the walls of the pustules of pustulosis palmaris et plantaris. In addition, a leukotactic factor identical to that noted in psoriasis has been found in pustulosis palmaris et plantaris (167).

Pathogenesis of Psoriasis and AIDS

There is evidence of the role of both $CD8^+$ and $CD4^+$ T lymphocytes and γIFN in the pathogenesis of psoriasis in AIDS

(128,168). Paradoxically, as T-helper cell counts decline, it appears that psoriatic lesions exacerbate until a preterminal stage, when the dermatitis improves. The latter event is probably a consequence of a decreased local production of γIFN due to the increasing number of infected T-helper lymphocytes or a diminished number of dermal lymphocytes available to produce this cytokine (115). However, in a recent study, it was shown that γIFN serum levels were much higher in HIV-positive psoriatic patients than HIV-negative subjects (169).

The immunodysregulation resulting from HIV infection may trigger psoriasis in those genetically predisposed by carrying the HLA-Cw□0602 allele. HLA-Cw□0602 could act as a cross-reactive target for cytotoxic T lymphocytes responding to peptides from microorganisms. Human retrovirus-5 has been implicated in the pathogenesis of psoriatic arthropathy but not psoriasis (168). Immunohistochemical studies showed similar proportions of T-lymphocyte subtypes in psoriasis of HIV-positive patients and in psoriasis of immunocompetent hosts (170). Furthermore, there is evidence of identical keratinocyte expression of γIFN-induced IP-10 in both groups (128). These two findings suggest that the cellular immune reactions involved in the pathogenesis of psoriasis may be similar in AIDS and non-AIDS patients (170).

Differential Diagnosis

Two histologic features are of great value in the diagnosis of psoriasis vulgaris: (a) mounds of parakeratosis with neutrophils at their summits (Munro microabscesses) and (b) spongiform micropustules of Kogoj in the uppermost layers of the spinous layer. Dilation and tortuosity of capillaries in the papillae may also help in the diagnosis. All other features, such as acanthosis with elongation of the rete ridges and parakeratosis, can be found also in chronic eczematous dermatitis, such as *atopic dermatitis*, *nummular dermatitis,* or *allergic contact dermatitis*, which then may appear to be "psoriasiform." However, the elongation of rete ridges is uneven. Although mild spongiosis may be seen in psoriasis, the presence of marked spongiosis and especially of coagulated serum as evidence of crusting in the cornified layer are features speaking against psoriasis, except in psoriasis on volar skin, in which spongiosis may be prominent. In addition, eosinophils, which are commonly found in allergic contact dermatitis and mainly in HIV-positive patients, are rarely seen in the psoriatic infiltrate. Difficulties may arise in treated lesions of psoriasis and in those with superimposed allergic contact dermatitis secondary to topical treatments. *Lichen simplex chronicus* is considered in the differential diagnosis of fully developed psoriatic plaques. In contrast to psoriasis, it shows a prominent granular layer, more irregular acanthosis, and fibrosis of the papillary dermis with collagen bundles aligned perpendicular to the skin surface. *Seborrheic dermatitis* may be very difficult to distinguish from psoriasis vulgaris, especially if overlap occurs. Accentuated spongiosis, mounds of parakeratosis with neutrophils predominantly at the follicular ostia, and more irregular acanthosis are histologic features suggestive of seborrheic dermatitis. *Pityriasis rubra pilaris* shares some histologic features with psoriasis, namely, acanthosis and parakeratosis. However, it could be differentiated from well-developed lesions of psoriasis by the presence of thick suprapapillary plates, broader and shorter rete ridges, and a preserved granular layer and alternating ortho- and parakeratosis. It also lacks Munro microabscesses and neutrophils in the infiltrate (171). Although the Kogoj spongiform pustule is highly diagnostic of the psoriasis group of diseases, including Reiter's disease, histologically typical spongiform pustules may occur also in *pustular dermatophytosis*, *bacterial impetigo*, *pustular drug eruptions*, and *candidiasis*, particularly if pustules are clinically present (172). Periodic acid-Schiff (PAS) and Gram stains are useful for identifying the infectious microorganisms. Aggregates of neutrophils with pyknotic nuclei within areas of parakeratosis may occur in conditions other than psoriasis, but they generally differ from Munro microabscesses by being larger and less well circumscribed and by often showing crusting.

Because of the clinical and, particularly, the histologic resemblance of the tongue lesions in pustular psoriasis with those seen in geographic tongue, it has been suggested that geographic tongue represents an abortive form of pustular psoriasis (173).

REITER'S DISEASE

Reiter's disease is a sterile arthritis associated in most cases with a distant infection causing enteritis or urethritis. Reiter's disease predominantly affects young men and consists of the triad of urethritis, arthritis, and conjunctivitis. Although as a rule the arthritis occurs in attacks and is followed by recovery, it progresses in some cases to cause permanent damage to the affected joints (174,175). Cutaneous lesions occur in about half of affected patients. Lesions have a predilection for glans penis (balanitis circinata), palms and soles (keratoderma blennorrhagicum), and the subungual regions (Fig. 7-16).

FIGURE 7-16. Reiter's disease. Confluent erythematous scaly papules and plaques on the dorsum of feet and toes, with nail dystrophy. (Courtesy of Department of Dermatology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.)

In uncircumcised men, balanitis circinata presents as superficial crusted erosions forming a serpiginous pattern. In circumcised men the condition presents as erythematous hyperkeratotic and coalescent papules on the glans. Lesions on the palms and soles are erythematous, mollusk-like plaques with central keratotic excrescences. Pustular lesions may also develop. The subungual lesions consist of hyperkeratosis with opacification of the nail plate, and eventual shedding of the nail plate may occur. The prevalence of Reiter's disease in HIV-infected individuals is less than 1%; however, the disease appears to be more severe in immunocompromised patients (176).

Histopathology. Early pustular lesions on the palms or soles show a spongiform macropustule in the upper epidermis (174,177). In addition, one observes parakeratosis and elongation of the rete ridges.

As the lesions age, the parakeratotic cornified layer thickens considerably, which correlates with the keratotic excrescences seen clinically. The parakeratotic cornified layer is intermingled with the pyknotic nuclei of neutrophils. In old lesions, spongiform pustules are no longer seen, and the histologic picture shows acanthosis and orthokeratosis with only a few areas of parakeratosis, but occasionally the histologic picture resembles that of psoriasis (174).

Pathogenesis. Most cases of Reiter's disease are probably caused by microorganisms that infect the urogenital or gastrointestinal systems, such as *Chlamydia trachomatis*, *Ureaplasma urealyticum*, and *Shigella*, *Salmonella*, *Campylobacter*, *Cyclospora*, and *Yersinia* species. *Chlamydia trachomatis* has been cultured from urethral samples in nearly half of the patients and is believed to be capable of triggering Reiter's syndrome in susceptible men (178). Although joint cultures are negative for bacteria in Reiter's disease, hybridization studies have detected chlamydial RNA in synovial specimens (179). The occurrence of Reiter's syndrome after bacille Calmette-Guérin immunotherapy for bladder cancer has been reported (180). Eighty percent of Reiter's disease patients are HLA-B27 positive (176); however, the precise role of this major histocompatibility class I antigen in the development of this disease is unclear.

A close relationship to psoriasis has been assumed for the cutaneous lesions because of their clinical resemblance to psoriasis and the presence of spongiform pustules (174). Similarly, the arthritis of Reiter's disease resembles that of psoriasis not only clinically but also by the absence of rheumatoid factor (175).

Differential Diagnosis. The early spongiform pustule seen in Reiter's disease is indistinguishable from the spongiform pustule seen in pustular psoriasis. Slightly older lesions often can be identified as representing Reiter's disease, in contrast to psoriasis, by the presence of a markedly thickened cornified layer.

PARAPSORIASIS

There are three entities described as parapsoriasis: small-plaque parapsoriasis, large-plaque parapsoriasis, and parapsoriasis variegata.

Large-plaque parapsoriasis and *parapsoriasis variegata* are best considered as early stages of cutaneous T-cell lymphoma/mycosis fungoides (181). These are discussed further in Chapter 31.

The *small-plaque parapsoriasis* is also known as xanthoerythrodermia perstans of Crocker (182) and as digitate dermatosis (183). Pink-to-yellow, slightly scaly, oval or elongated, often fingerprint-like patches 1 to 5 cm in diameter are symmetrically distributed over the trunk and the proximal portions of the extremities following the tension lines of the skin (184). The eruption is usually asymptomatic, has a chronic course, and tends to persist. In some instances, cases diagnosed originally as small-plaque type later showed reticulate pigmentation and atrophy and were reclassified as the large-plaque type (185).

Histopathology. The small-plaque parapsoriasis shows focal epidermal involvement consisting of slight spongiosis, exocytosis of lymphocytes, mild acanthosis, and parakeratosis (183,186). Elongated mounds of parakeratosis with collections of plasma above a basket-weave cornified layer is a characteristic finding (Fig. 7-17). In the papillary dermis, there is a mild superficial perivascular lymphocytic infiltrate that in some instances is more pronounced and resembles that seen in the large plaque type; such cases require inclusion in the large-plaque category (185,187). It must be conceded that, in some instances, a clinical or histologic distinction of small-plaque parapsoriasis from large-plaque parapsoriasis is difficult, so that only the subsequent course decides the issue (185).

Pathogenesis. The inflammatory infiltrate in small-plaque parapsoriasis is dominated by $CD4^+$ (helper-inducer) T lymphocytes with a small proportion of the $CD8^+$ (cytotoxic-suppressor)

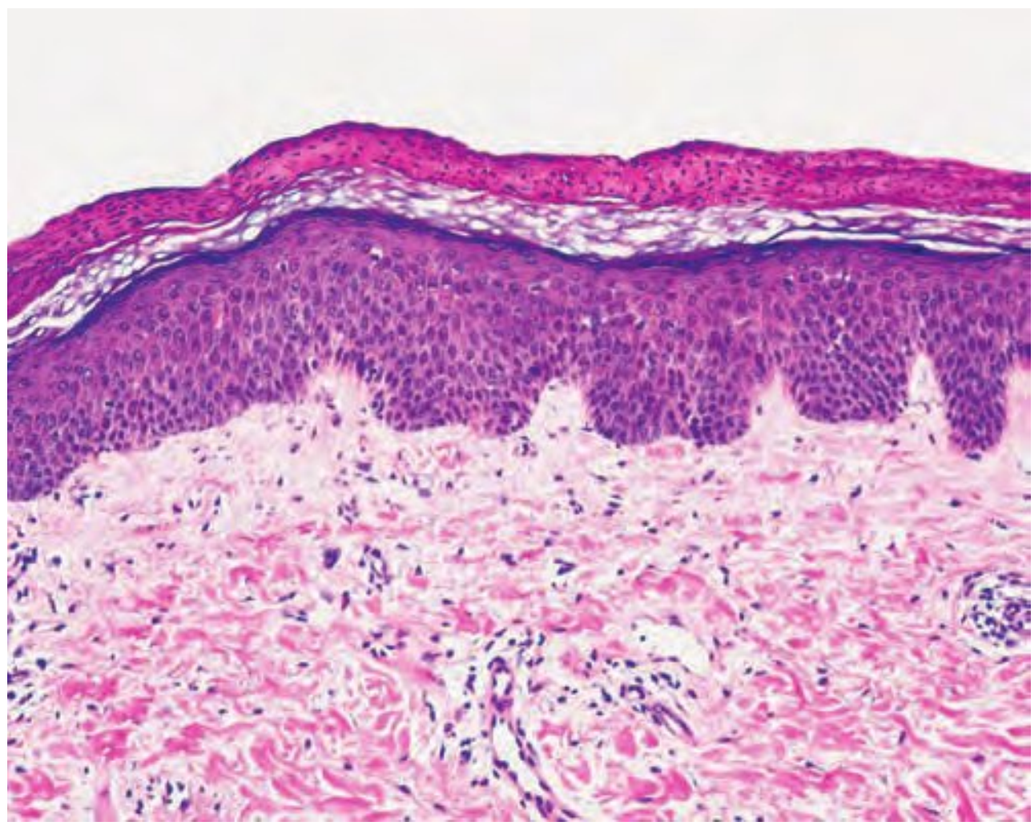

FIGURE 7-17. Digitate dermatosis (small-plaque parapsoriasis). Characteristic elongated mound of parakeratosis with collections of plasma above a basket-weave cornified layer, preserved granular layer, and minimal acanthosis. There is a sparse superficial perivascular lymphocytic infiltrate.

T lymphocytes subset. Langerhans cells are increased in the epidermis and dermis (188).

Relationship to Lymphoma. Although it is generally accepted that small-plaque parapsoriasis, or digitate dermatosis, is a benign disorder without the potential for transformation into mycosis fungoides (181,183,185,189,190), it has been shown that in some cases there is a dominant clonal rearrangement of the infiltrating T lymphocytes (188). Accordingly, some authors hypothesize that small-plaque parapsoriasis could be placed into the category of "abortive lymphomas," which includes conditions in which clonality can be demonstrated but conversion into a systemic lymphoma does not occur (191). However, some believe that small-plaque parapsoriasis is a form of mycosis fungoides (192), and in a retrospective cohort study of more than 100 patients in a 26-year follow-up period, 10% of those diagnosed with small-plaque parapsoriasis and 35% of those diagnosed with the large-plaque variant developed histologically confirmed mycosis fungoides (193). Another study detected a clonal T-cell proliferation in the peripheral blood but not in the skin of patients with small-plaque parapsoriasis, suggesting that this disorder is not strongly related to mycosis fungoides, where there is clonal T-cell proliferation in both peripheral blood and skin (194).

FIGURE 7-18. Pityriasis rosea. Round to oval, salmon-colored patches following the lines of cleavage on the trunk. (Courtesy of Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, New York.)

PITYRIASIS ROSEA

Pityriasis rosea is a self-limited dermatitis usually lasting from 4 to 7 weeks. It frequently starts with a herald patch, followed by a disseminated eruption. The lesions, found chiefly on the trunk, neck, and proximal extremities, consist of round to oval salmon-colored patches following the lines of cleavage and showing peripherally attached thin, cigarette paper—like scales (Fig 7-18). Several typical and atypical clinical variants have been described, including papular, vesicular, urticarial, purpuric, and recurrent forms (195,196).

Histopathology. The patches of the disseminated eruption show a superficial perivascular dermal infiltrate that consists predominantly of lymphocytes, with occasional eosinophils and histiocytes. Lymphocytes extend into the epidermis (exocytosis), where there is spongiosis, intracellular edema, mild to moderate acanthosis, areas of decreased to absent granular layer, and focal parakeratosis with plasma (197–199). Intraepidermal spongiotic vesicles (197,198) and a few necrotic keratinocytes (200) are found in some cases. A common feature is the presence of extravasated erythrocytes in the papillary dermis, which sometimes extend into the overlying epidermis (200,201) (Fig. 7-19). Occasionally, multinucleated keratinocytes in the affected epidermis can be seen (201). Late lesions from the disseminated eruption are more likely to have a psoriasiform pattern (197) and a slight increased number of eosinophils in the inflammatory infiltrate (199). The herald patch may have, in addition to the histopathologic changes described earlier, more pronounced acanthosis, deeper and

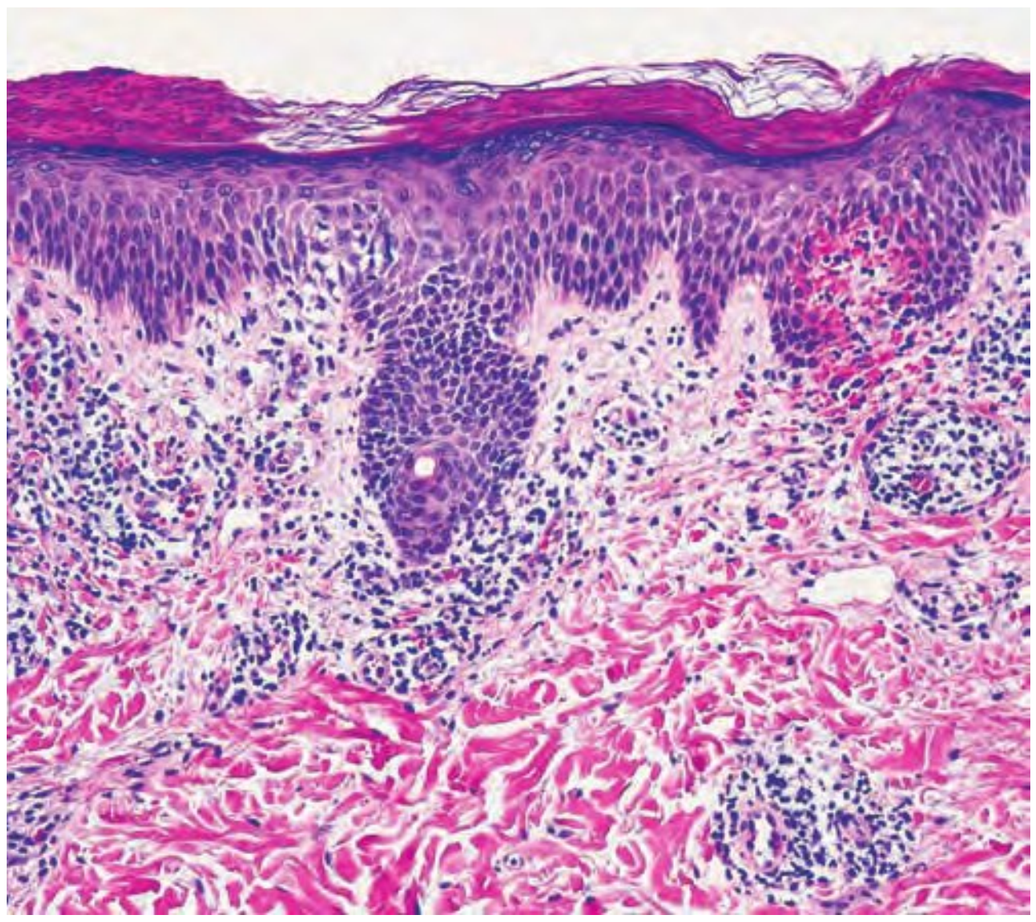

FIGURE 7-19. Pityriasis rosea. Superficial perivascular infiltrate of lymphocytes and extravasated erythrocytes that extend to the epidermis, where there is moderate acanthosis, spongiosis, decreased granular layer, and mounds of parakeratosis.

denser perivascular inflammatory infiltrate, and papillary dermal edema (201).

Pathogenesis. The cause of pityriasis rosea is unknown, although a viral etiology such as human herpesvirus 7 is highly suspected (202). Enterovirus infection has also been proposed as a possible cause of the disease (203). Several drugs have produced pityriasis rosea–like reactions that on their withdrawal have subsided (204). Cell-mediated immunity may be involved in the pathogenesis of pityriasis rosea due to the presence of activated helper-inducer T lymphocytes ($CD4^+$/HLA-DR^+) in the epidermal and dermal infiltrate (205) in association with a highly increased number of Langerhans cells ($CD1a^+$) (206) and the expression of HLA-DR^+ antigen on the surface of keratinocytes located around the area of lymphocytic exocytosis (207).

Differential Diagnosis. The differential diagnosis includes superficial gyrate erythema and small-plaque parapsoriasis (digitate dermatosis). The histopathologic picture in superficial gyrate erythema could be identical to that seen in milder forms of pityriasis rosea. Elongated mounds of parakeratosis with plasma, sparse superficial perivascular lymphocytic infiltrate, minimal exocytosis, and spongiosis are features of small-plaque parapsoriasis (186).

GIANOTTI-CROSTI SYNDROME (PAPULAR ACRODERMATITIS OF CHILDHOOD AND PAPULOVESICULAR ACROLOCATED SYNDROME)

Papular acrodermatitis of childhood was first described by Gianotti in 1955 (208). It is clinically characterized by a nonpruritic, symmetric eruption of monomorphic erythematous papules on the face, extremities, and buttocks lasting about 3 weeks. It was originally described in association with lymphadenopathy and hepatitis B viral infection (209). However, in recent years, it has become apparent that similar acral papular eruptions may occur with several other viruses, such as Epstein-Barr virus, coxsackie virus, parainfluenza virus, vaccine-related virus, and cytomegalovirus, among others (210–213). In such cases, there is often no hepatitis or lymphadenopathy. These eruptions were classified by Gianotti (209) in a separate category as "papular or papulovesicular acrolocated syndrome." However, further studies (213,214) failed to identify repeatable clinical differences between papular acrodermatitis of childhood and papulovesicular acrolocated syndrome. The term Gianotti-Crosti syndrome now applies to all self-limited, acrolocated, papular eruptions that occur in association with an underlying viral infection (215). Atopic background has recently been shown to have a significant association with this syndrome (216).

Histopathology. There is a superficial and middermal perivascular infiltrate of lymphocytes and histiocytes with some lymphocytes extending to the overlying epidermis, where there is focal spongiosis and parakeratosis. In some cases, there is associated papillary dermal edema and extravasation of erythrocytes. In some instances, true lymphocytic vasculitis has been described with lymphocytes in the vessel walls and extravasated erythrocytes into the upper dermis (210). Gianotti-Crosti syndrome associated with Epstein-Barr virus is reported to have marked papillary dermal edema with minimal spongiosis and rare eosinophils in the dermal infiltrate (217). The inflammatory pattern may also present as a lichenoid interface dermatitis (218).

Pathogenesis. Immunohistochemical stains have shown that the inflammatory infiltrate is composed predominantly of $CD4^+$ (helper-inducer) T lymphocytes and about 20% of $CD8^+$ (suppressor-cytotoxic) T lymphocytes. There is also an increased number of Langerhans cells in the epidermis. A virus-induced type IV hypersensitivity reaction has been proposed (219). The surface antigen of the hepatitis B virus is detectable in the sera of all cases of papular acrodermatitis of childhood due to hepatitis B virus by radioimmunoassay. Cases in which serologic studies for hepatitis B virus are negative require studies for other viruses by means of throat swabs and stool samples and by testing for antibodies (211).

MUCOCUTANEOUS LYMPH NODE SYNDROME (KAWASAKI'S DISEASE)

The mucocutaneous lymph node syndrome, first reported in 1967 (220), is most common in Japanese or Korean children younger than 5 years of age, although it can occur in all races (221) either sporadically or epidemically. A definitive diagnosis is established by the presence of unexplained fever lasting 5 or more days and of at least four of five clinical criteria: (a) bilateral conjunctivitis; (b) erythematous oral mucosa, injected or dry fissured lips, and "strawberry tongue"; (c) erythema and indurated edema of hands and feet, often followed by periungual desquamation; (d) polymorphous skin rash; and (e) cervical nonsuppurative lymphadenopathy (222). Measles and group A β-hemolytic streptococcal infections may closely resemble Kawasaki's disease and must be excluded (223).

The course of the disease could be divided in three clinical phases: acute, subacute, and convalescent. The first phase is the febrile period, in which all the diagnostic signs may be seen (224). The rash appears around the third to fifth day of illness and may have different morphologic patterns, such as maculopapular, morbilliform, scarlatiniform, or urticarial (225). It involves the trunk and extremities and in some cases has a peculiar perineal distribution (226).

Recently a psoriasiform skin eruption that occurs during either the acute or convalescent phase has been described, with some lesions being pustular (227,228). There are many other associated systemic manifestations, but cardiovascular complications account for the death of 2% of the children with the disease (220). Twenty percent of untreated patients may develop coronary artery aneurysms (229), and myocardial infarction secondary to aneurysmal thrombosis is the principal cause of death (230). A rare and serious complication is the development of peripheral ischemia and gangrene (231).

Histopathology. The histologic changes in the skin consist of a sparse perivascular infiltrate of lymphocytes and histiocytes

(220), marked papillary dermal edema, and dilation of blood vessels (232). Mild exocytosis of lymphocytes can be seen (233). An uncommon pustular variant of Kawasaki's disease shows sterile intraepidermal spongiform pustules with neutrophils (234).

Pathogenesis. Electron microscopic studies have revealed swelling and focal degenerative changes of endothelial cells from the superficial and deep vascular plexuses of the skin (232). Immunohistochemical stains have shown that the inflammatory infiltrate has predominantly $CD4^+$ (helper-inducer) T lymphocytes and $CD13^+$ macrophages, with only a few $CD8^+$ (suppressor-cytotoxic) T lymphocytes and no $CD20^+$ B lymphocytes. There is also expression of HLA-DR by keratinocytes and endothelial cells (233). In the acute stage of the disease, IL-1α and TNFα can be detected in the epidermis. TNFα is also found on blood vessel walls (233). All of these findings support the hypothesis of a cell-mediated immune reaction in the pathogenesis of the disease, possibly triggered by a virus (235), conventional antigen (236), or superantigen (237). It has been suggested that vascular endothelial growth factor, also known as vascular permeability factor, together with hepatocyte growth factor might play an important role in the pathophysiology of Kawasaki's disease, and their serum levels could be a powerful predictor for the development of coronary artery lesions (238). The detection of autoantibodies against a 70-kD protein from vascular smooth muscle cells may also contribute to the coronary and systemic vasculitis in Kawasaki's disease (239).

LICHEN PLANUS

Lichen planus is a subacute or chronic dermatosis that may involve skin, mucous membranes, hair follicles, and nails (240).

In glabrous skin, the eruption is characterized by small, flat-topped, shiny, polygonal, violaceous papules that may coalesce into plaques. The papules often show a network of white lines known as Wickham's striae (Fig. 7-20). Pruritus is usually

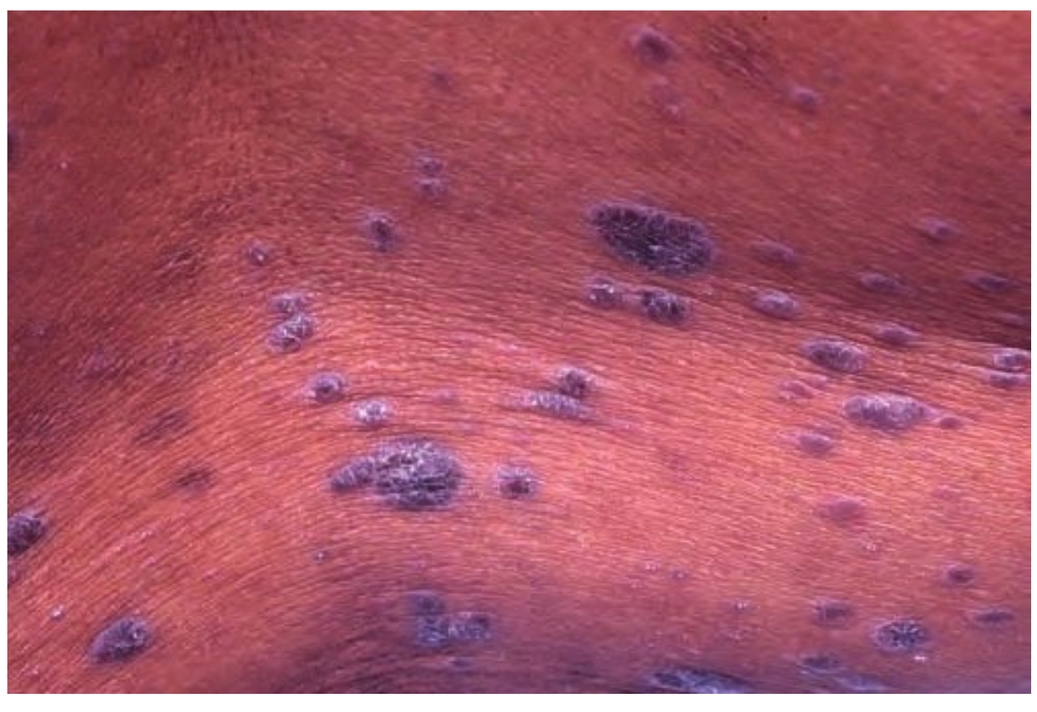

FIGURE 7-20. Lichen planus. Flat-topped, shiny, violaceous papules with white Wickham's striae. (Courtesy of Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, New York.)

FIGURE 7-21. Oral lichen planus. Lacy reticular network of white coalescent papules involving the buccal and labial mucosa. (Courtesy of Department of Dermatology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.)

pronounced. The disease has a predilection for the flexor surfaces of the forearms, legs, and glans penis. The eruption may be localized or extensive, and Koebner's phenomenon is commonly seen (241).

The oral lesions of lichen planus are frequently seen as either sole manifestation of the disease or associated with cutaneous involvement (242). They usually involve the buccal and glossal mucosa and most often consist of a lacy reticular network of white coalescent papules (Fig. 7-21) (243). Besides the reticular type, other lesional patterns have been described, such as plaquelike, atrophic, papular, erosive, and bullous (240,244).

The nails are involved in about 10% of cases and show roughening, longitudinal ridging, and, rarely, thinning with destruction (245). Pterygium formation is a frequent finding.

A common variant is *hypertrophic lichen planus*, which is usually found on the shins and consists of thickened, often verrucous plaques. In contrast, *vesicular lichen planus* is rare. It shows vesicles situated only on some of the preexisting lesions (246). It is different from the so-called *lichen planus pemphigoides* in which the eruption is more disseminated and the bullae are more extensive, arising from the papules of lichen planus or from normal-appearing skin (247–250). Lichen planus pemphigoides manifesting exclusively in the oral mucosa has recently been reported (251). Although lichen planus pemphigoides and bullous pemphigoid manifest in different ways clinically, the same antigen may be involved in the immunopathogenesis of these two diseases (see pathogenesis discussion).

Lichen planopilaris designates the folliculotropic variant of lichen planus, which predominantly involves the scalp. Initially, there may only be follicular papules or perifollicular erythema; however, with progressive hair loss, irregularly shaped atrophic patches of scarring alopecia develop on the scalp. The axillae and the pubic region may also be affected, and the alopecia in these areas may be cicatricial (252). Hyperkeratotic follicular papules may also be seen on glabrous skin. The association of scarring alopecia of hair-bearing areas and hyperkeratotic follicular papules on glabrous skin is known as

Graham-Little syndrome. Lichen planopilaris may also coexist with typical lesions of lichen planus on skin, mucous membranes, or nails. Linear lichen planopilaris of the face resolving with scarring has also been described (253).

Ulcerative lichen planus, a rare but quite characteristic variant of lichen planus, shows bullae, erosions, and painful ulcerations on the feet and toes resulting in atrophic scarring and permanent loss of the toenails. It is usually associated with patches of atrophic alopecia of the scalp and with cutaneous and oral lesions of lichen planus (254,255).

Lichen planus actinicus, or *pigmentosus*, occurs mainly in Middle Eastern countries, where between 20% and 30% of the cases of lichen planus are of this type (256,257). It tends to be more common in children or young adults. The lesions develop in spring and summer on sun-exposed areas, especially the face. Three different forms have been described: annular (the most common type), pigmented (resembling melasma) (258), and dyschromic (259). The lesions are typically annular plaques with central slate blue to light brown pigmentation and well-defined, slightly raised hypopigmented borders. Pruritus is minimal or absent.

The *overlap syndrome*, or *lichen planus/lupus erythematosus,* refers to a heterogeneous group of patients bearing at the same time skin lesions with clinical, histologic, and/or immunologic features typical of both diseases (260). The cutaneous findings in these unusual cases consist of erythematous to purplish scaly patches and plaques, some of which show central atrophy, with a predilection for photodistributed areas or acral portions of extremities (260,261).

Twenty-nail dystrophy may be encountered in adults as well as children. The nails have longitudinal ridging and distal notching and splitting. With time, they become thin and roughened. Clinically, the nail changes resemble those seen in lichen planus (262,263). Other manifestations of lichen planus are usually absent. In children, the nail changes tend to involute spontaneously after a few years. In familial cases, it tends to have an unremitting course. Congenital cases have been described (264). Twenty-nail dystrophy may be idiopathic or may be associated with alopecia areata, atopic dermatitis, lichen planus, or psoriasis.

The coexistence of *lichen nitidus* with lichen planus is frequent enough that some authors have suggested that both entities are variants of the same disease (265).

Malignant transformation of cutaneous lichen planus occurs in less than 1% of cases (266). In hypertrophic lichen planus of the leg, development of squamous cell carcinoma, verrucous carcinoma, or keratoacanthoma is an exceptional occurrence (267–269). There have been reports of squamous cell carcinoma arising occasionally on long-standing lesions of lichen planus situated on mucous membranes or the vermillion border (270,271). The incidence of carcinoma evolving in oral lichen planus is about 0.5% (272), with a range of 0.3% to 3%. Development of carcinoma in ulcers of the feet in ulcerative lichen planus has been reported to occur rarely in lesions that had not been previously grafted (273).

Histopathology. Typical papules of lichen planus show (a) compact orthokeratosis, (b) wedge-shaped hypergranulosis, (c) irregular acanthosis, (d) vacuolar alteration of the basal layer, and (e) a bandlike dermal lymphocytic infiltrate in close approximation to the epidermis (Fig. 7-22). This constellation of findings is sufficiently diagnostic that a histologic diagnosis can be rendered in more than 90% of the cases (274).

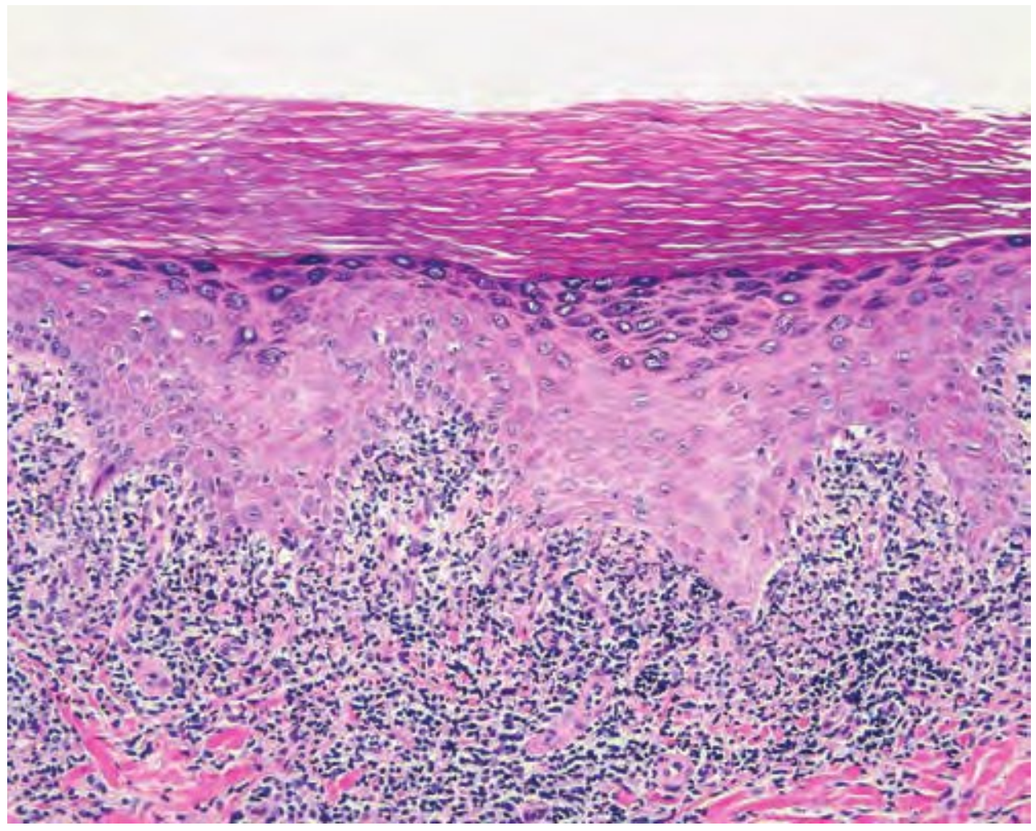

FIGURE 7-22. Lichen planus. Dense, bandlike infiltrate predominantly of lymphocytes in the papillary dermis that extends to the epidermis, where there is vacuolar alteration of the basal layer, necrotic keratinocytes, irregular acanthosis, wedge-shaped hypergranulosis, and compact orthokeratosis.

The cornified layer shows compact orthokeratosis and contains very few, if any, parakeratotic cells, a fact that is important for the diagnosis. The thickening of the granular layer is uneven and wedge shaped. The granular cells appear increased in size and contain coarse and more abundant keratohyaline granules. On step sectioning, the areas of wedge-shaped hypergranulosis are found to be contiguous to intraepidermal adnexal structures, namely acrosyringia and acrotrichia (275). Wickham's striae are believed to be caused by focal increase in the thickness of the granular layer and the entire epidermis (276).

The acanthosis in lichen planus is irregular and affects the spinous layer and the suprapapillary plates. Keratinocytes of the spinous layer often appear larger and eosinophilic, possibly because of advanced keratinization. The rete ridges show irregular lengthening, and some are pointed at their lower end, giving them a saw-toothed appearance. The dermal papillae between elongated rete ridges are often dome shaped (277).

The basal layer keratinocytes are not clearly visible in early lesions because the dense dermal infiltrate obscures the dermal–epidermal junction with vacuolar alteration and necrosis of these cells. In fully developed lesions, the basal layer keratinocytes appear as flattened squamous cells.

The infiltrate in the upper dermis is bandlike and sharply demarcated at its lower border and is composed almost entirely of lymphocytes intermingled with macrophages. A few eosinophils and/or plasma cells may be seen. Melanophages are seen in the upper dermis, often in considerable number, as a result of damage to the basal cells with subsequent pigment

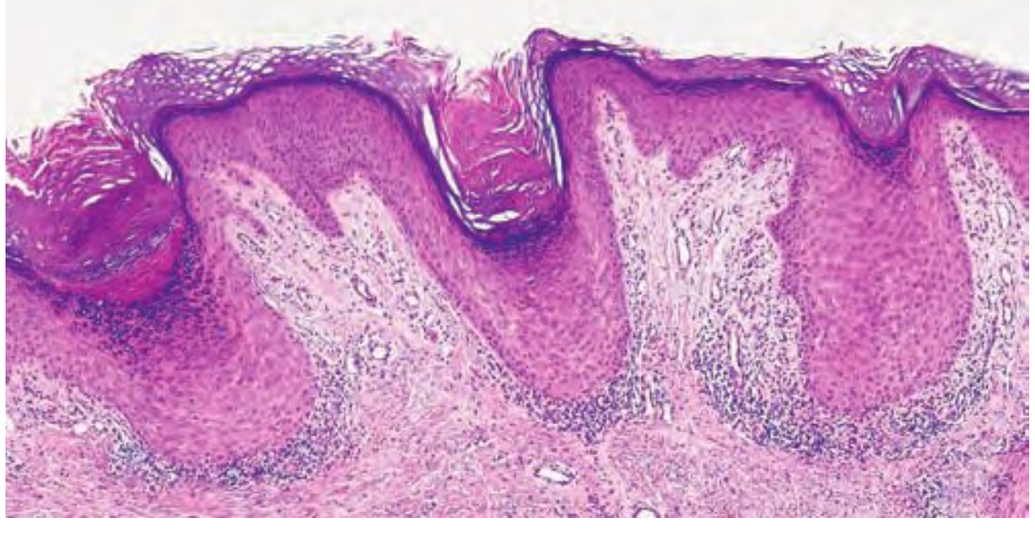

FIGURE 7-23. Hypertrophic lichen planus. Marked irregular acanthosis, hypergranulosis, and compact orthokeratosis. The vacuolar alteration and the lymphocytic inflammatory infiltrate are accentuated at the base of the rete ridges.

incontinence. In some instances, the dermal lymphocytic infiltrate is seen in juxtaposition to the acrosyringium, and vacuolar alteration of the acrosyringeal basal cell layer is a prominent finding (*acrosyringeal lichen planus*) (278).

In old lesions, the cellular infiltrate decreases in density, but the number of melanophages increases. In areas in which a basal cell layer has regenerated, the dermal infiltrate no longer lies in close approximation to the epidermis. *Hypertrophic lichen planus* shows considerable acanthosis, papillomatosis, hypergranulosis, and hyperkeratosis (Fig. 7-23). The interface vacuolar changes are discrete and often limited to the base of the rete ridges.

Necrotic keratinocytes are present in most of the cases in the lower epidermis and especially in the papillary dermis. They are also referred to as colloid, hyaline, cytoid, or Civatte bodies. They average 20 μm in diameter and have a homogeneous, eosinophilic appearance (Fig. 7-24). They are PAS positive and

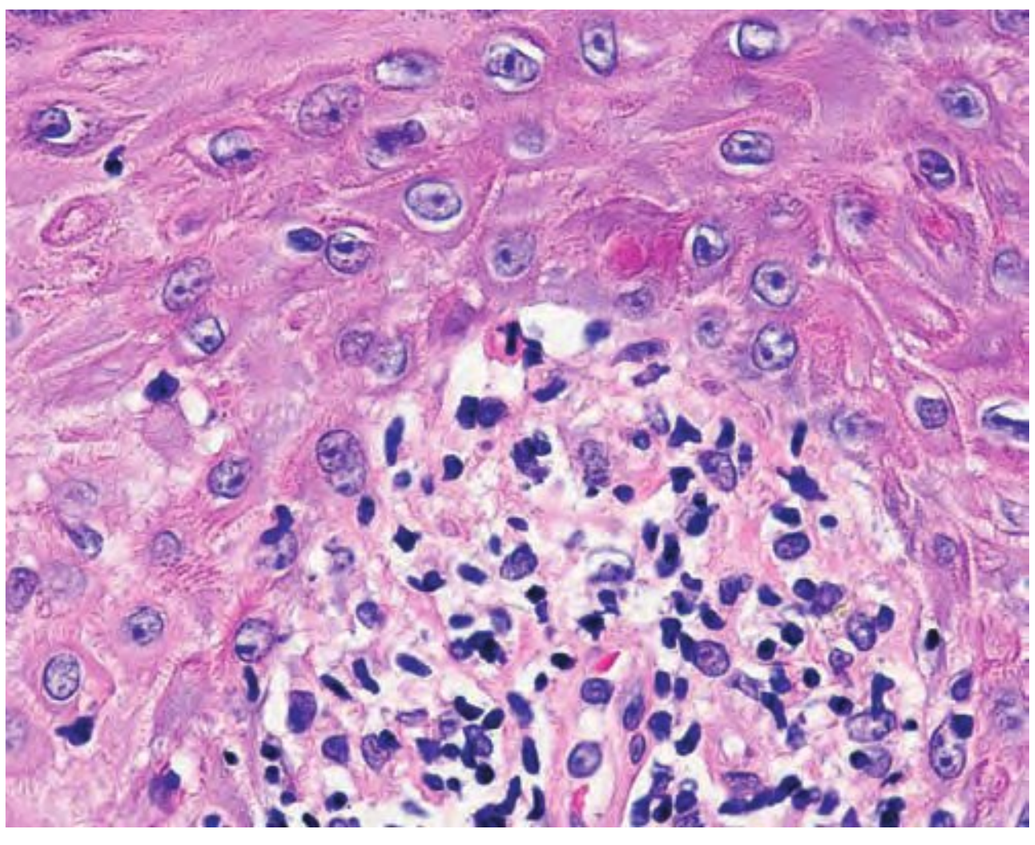

FIGURE 7-24. Lichen planus. Closer view shows lymphocytes and melanophages in the papillary dermis, vacuolar alteration of the basal layer, necrotic keratinocytes (Civatte bodies), and enlarged keratinocytes with eosinophilic cytoplasm.

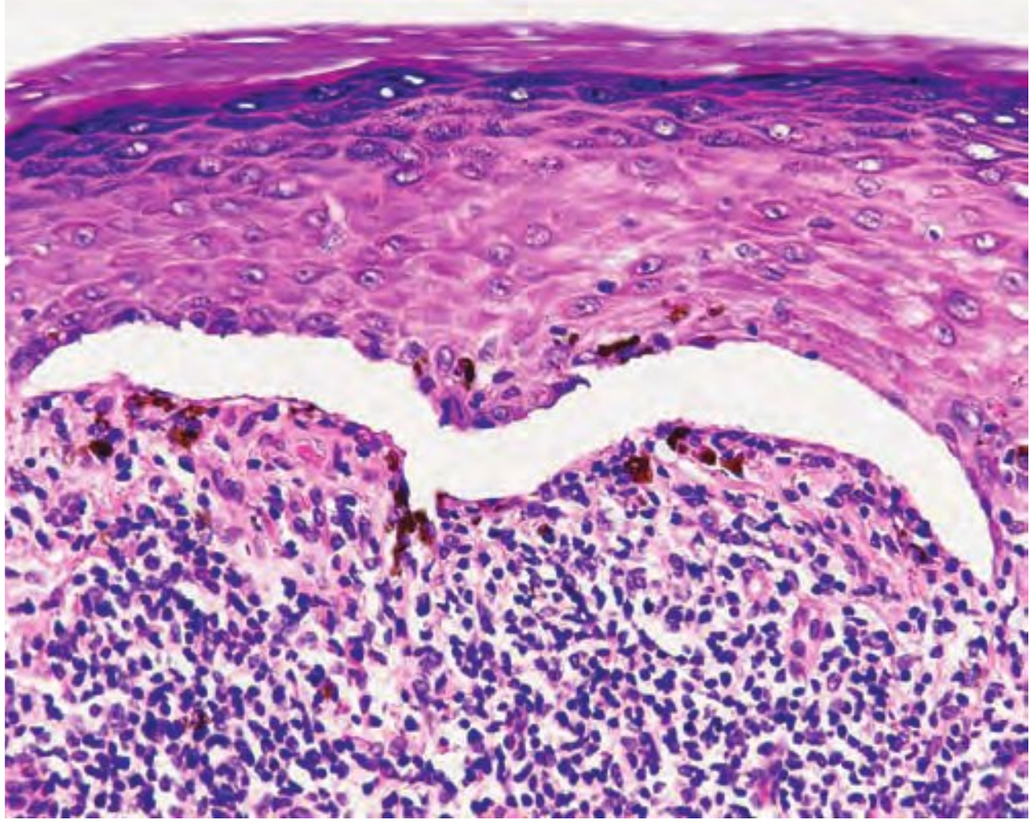

FIGURE 7-25. Lichen planus. Artifactual cleft between the epidermis and the lichenoid infiltrate known as the Max-Joseph space.

diastase resistant. Even though necrotic keratinocytes are found most commonly in lichen planus, they may occur in any interface dermatitis in which damage to the basal cells occurs, including graft-versus-host disease, lichen nitidus, lupus erythematosus, and drug reactions, as well as in inflamed keratoses such as lichenoid actinic keratosis and lichen planus–like keratosis. They may even be seen in normal skin (279). In lichen planus, the number of necrotic keratinocytes may be so large that they are seen lying as clusters in the uppermost dermis (260). Their aggregation may result in the perforation of the epidermis with subsequent transepidermal elimination (280).

Occasionally, small areas of artifactual separation between the epidermis and the dermis, known as Max-Joseph spaces, are seen (274) (Fig. 7-25). In some instances, the separation occurs *in vivo* and subepidermal blisters form (*vesicular lichen planus*). These vesicles develop as a result of extensive damage to the basal cells (246,247).

Oral Lichen Planus

The oral lesions of lichen planus differ in their histologic appearance from those of the skin, as one would expect, because the oral mucosa normally shows parakeratosis without the presence of a granular layer. Thus, the lesions of the oral mucosa often show parakeratosis rather than orthokeratosis without a granular layer, although alternating areas of both types of keratinization with the presence of a granular layer may also be observed (244) (Fig. 7-26). In addition, rather than showing acanthosis, the epithelium is often atrophic. Ulcerations may develop either through the rupture of vesicles or as a result of necrosis of the atrophic epithelium.

Lichen Planopilaris

Most early lesions of lichen planopilaris show a focally dense, bandlike perifollicular lymphocytic infiltrate at the level of the

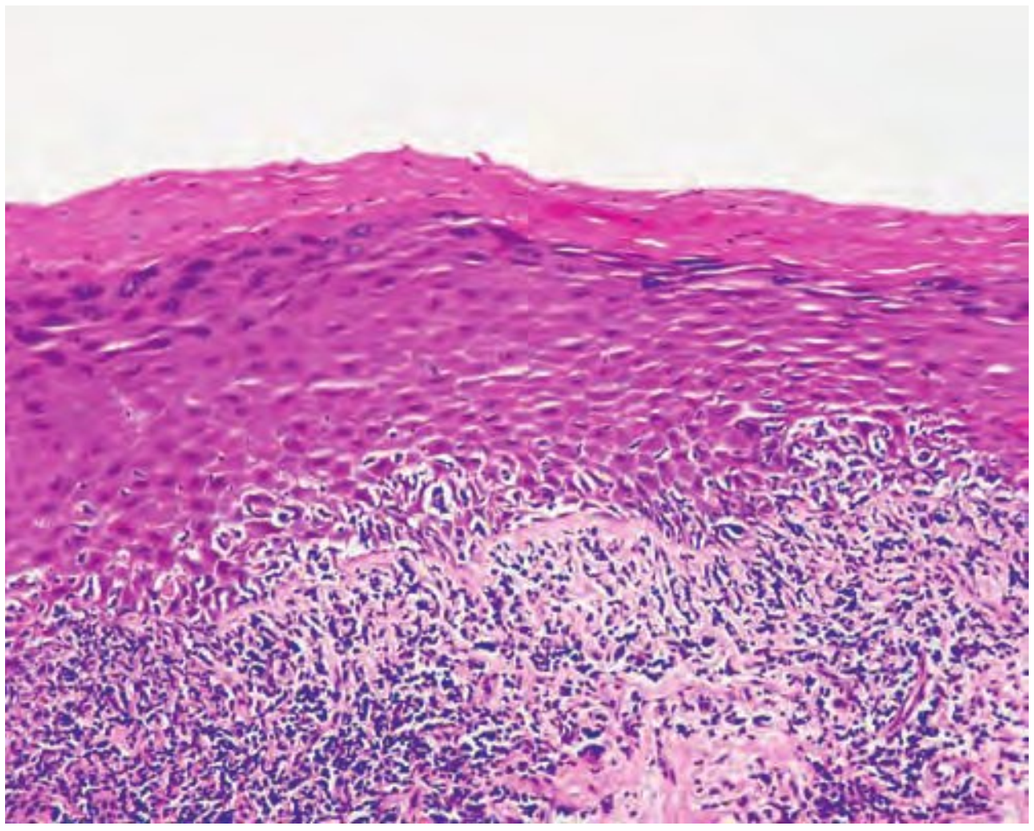

FIGURE 7-26. Oral lichen planus. Similar lichenoid inflammatory pattern as seen in the skin except for less hypergranulosis and confluent parakeratosis.

infundibulum and the isthmus where the hair "bulge" is located. Initially, the inferior segment of the hair follicle is spared. Vacuolar changes of the basal layer of the outer root sheath and necrotic keratinocytes are often seen. In addition, orthokeratosis, follicular plugging, and wedge-shaped hypergranulosis of the infundibulum are observed (Fig. 7-27). Interfollicular epidermis is often spared, but it can occasionally be involved (281). In more developed lesions, perifollicular fibrosis and epithelial atrophy at the level of the infundibulum and isthmus are characteristic findings and give rise to an hourglass

FIGURE 7-27. Lichen planopilaris. Follicular plugging, hypergranulosis, and dense, bandlike perifollicular lymphocytic infiltrate that obscures the infundibular epithelium.

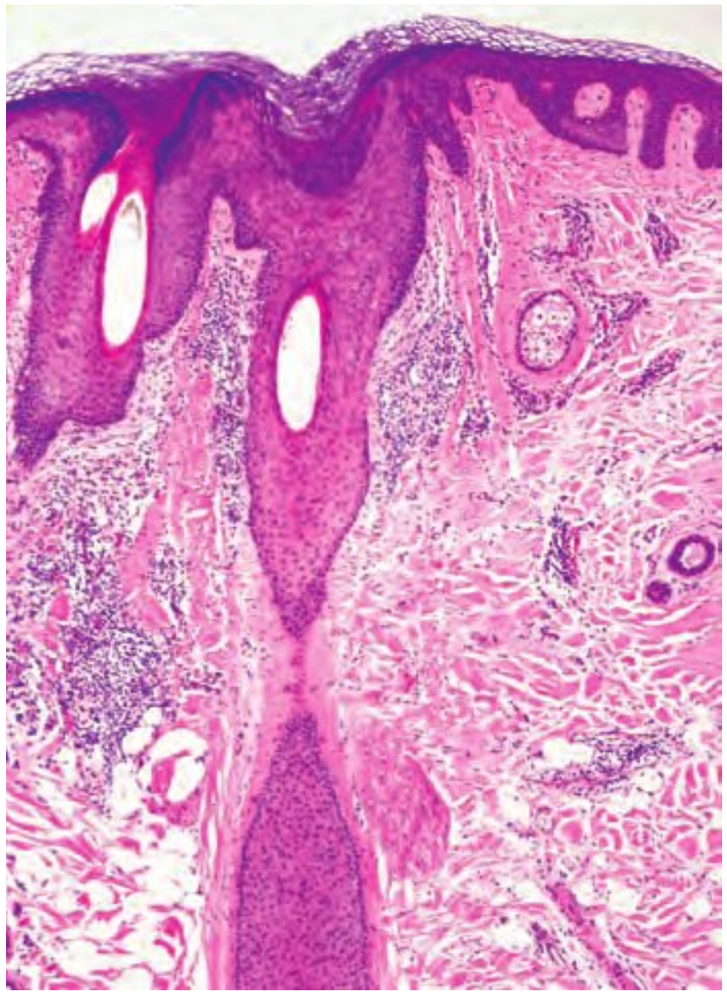

FIGURE 7-28. Lichen planopilaris, developed lesion. Perifollicular fibrosis and inflammation with epithelial atrophy at the infundibuloisthmic portion give rise to an hourglass configuration.

configuration (Fig. 7-28). It is hypothesized that damage to the hair bulge, where the stem cells of the hair follicle supposedly reside, results in permanent scarring alopecia (282). Advanced cases show alopecia with vertically oriented fibrotic tracts containing clumps of degenerated elastic fibers that had replaced the destroyed hair follicles. This end-stage scarring alopecia in which no visible hair follicles remain is called pseudopelade of Brocq (283).

The hyperkeratotic follicular papules that are occasionally seen on glabrous skin in association with lichen planopilaris of the scalp exhibit similar changes; however, perifollicular fibrosis is usually slight, and the process does not eventuate in scarring (284).

Ulcerative Lichen Planus

In ulcerative lichen planus, samples taken from the skin adjacent to the ulcer generally show changes of an established lichen planus (254).

Lichen Planus Actinicus

In some instances, the histologic picture of lichen planus actinicus is similar to that of the typical lichen planus but with a tendency toward thinning of the epidermis at the center of the lesion and more evident pigmentary incontinence in the upper dermis (55,257). Because of the histologic resemblance in some cases, a relationship between lichen planus actinicus and erythema dyschromicum perstans has been postulated (285); however, they have significant clinical differences (55).

Overlap Syndrome–Lichen Planus/Lupus Erythematosus

In some cases of the overlap syndrome, the histologic features and direct immunofluorescence findings are more consistent with lichen planus. In others, the immunofluorescence testing favors lupus erythematosus (261), and still in another subset of patients, there are lesions of lichen planus that coexist rather than overlap with those of lupus erythematosus (286).

Twenty-Nail Dystrophy

Histologic data on twenty-nail dystrophy are available in only a few cases. Twenty-nail dystrophy is a manifestation of diverse underlying processes; therefore, its histology varies (263,264). Biopsies may show typical lichen planus involving the nail matrix (262). However, spongiosis may be prominent as in cases associated with atopic dermatitis.

Lichen Planus Pemphigoides

In lichen planus pemphigoides, biopsies taken from blisters arising from uninvolved skin show subepidermal bullae with an infiltrate that is not bandlike and that contains eosinophils (287).

Pathogenesis

The eosinophilia of the keratinocytes and the increase in thickness of the granular and cornified layers suggest a decreased epidermal turnover. However, in spite of severely damaged basal cells, measurements of cell proliferation in lichen planus with tritiated thymidine have shown an increase in cell proliferation (288).

Electron Microscopy

On electron microscopy, the basal keratinocytes in lichen planus, together with their desmosomes and hemidesmosomes, show degenerative changes (289). Whereas the tonofilaments in the basal cells are decreased in early lesions, they are increased in later lesions (290). Because of the presence of degenerated and necrotic keratinocytes in the basal layer, it is assumed that the basal cells in later lesions are largely regenerated cells. The dermal infiltrate, extending to the epidermis, causes damage to the lamina densa such as fragmentation (EM 12). This may be followed by duplication and irregular folding of the lamina densa (291). The dermal infiltrate contains mainly lymphocytes, but it also contains macrophages. Some of the lymphocytes have hyperconvoluted nuclei and appear indistinguishable from Sézary cells.

Necrotic keratinocytes or colloid bodies are located largely in the papillary dermis but also in the lowermost epidermis (EM 12). They can be seen to develop from damaged keratinocytes through filamentous degeneration. This is followed by their discharge into the dermis. Necrotic keratinocytes consist of aggregates of filament bundles, with each filament measuring approximately 10 nm in diameter. The use of antikeratin immune sera has resulted in their intense staining (292). Necrotic keratinocytes often still contain cell organelles, such as melanosomes and mitochondria, but only rarely contain nuclear material (293). Fibrin deposits in the upper dermis are a common finding in electron microscopy studies (EM 12).

In the vesicular lesions of lichen planus, electron microscopic examination shows cytolysis of basal keratinocytes; therefore, the blister cavity is situated below the spinous layer (294).

Immunofluorescence

In lichen planus, fibrinogen deposition can be demonstrated by direct immunofluorescence as shaggy deposits at the dermal–epidermal junction (295). Only occasionally are there granular deposits of IgM (296) or linear deposits of C3 (297), or both IgG and C3 (298) in the basement membrane zone. Necrotic keratinocytes are demonstrable in lichen planus by direct immunofluorescence staining in about 87% of the cases (295). They stain mainly for IgM but often also for IgG, IgA, C3, and fibrin. Although necrotic keratinocytes are found occasionally in many other conditions with damage to the basal cell layer, such as lupus erythematosus, they are highly suggestive of lichen planus if they are present in large numbers or arranged in clusters. Their staining for IgM facilitates their recognition (279).

In lichen planopilaris, direct immunofluorescence in many specimens shows deposition of IgM and/or IgA, IgG, and, rarely, C3 at the level of the infundibulum and isthmus (299). The necrotic keratinocytes may react with anti-IgM antibody. There is often deposition of fibrinogen in a shaggy pattern surrounding the affected follicles. The dermal–epidermal junction is virtually always negative for deposition of immunoreactants (281).

In lichen planus pemphigoides, direct immunofluorescence of perilesional skin shows the presence of IgG and C3 in a linear arrangement along the basement membrane zone (287,300), and on immunoelectron microscopy, C3 is seen to be localized within the lamina lucida, analogous to its location in bullous pemphigoid (248). It has been shown that circulating IgG autoantibodies are directed against the bullous pemphigoid antigen 180 (BP180, type XVII collagen), a transmembrane hemidesmosomal glycoprotein of the basal keratinocytes that spans the lamina lucida (301,302). Immunoelectron microscopic studies have also confirmed that the location of the antigen is at the same site as the bullous pemphigoid antigen, the basal cell hemidesmosomes on the epidermal side of salt-split skin (303). However, it is suggested that the immunoglobulin subclass of the autoantibody and/or the epitope that is recognized may be different in these two diseases (301). One study has shown that in addition to BP180 antigen, the autoantibodies were also directed against a 200-kD antigen (304).

In the overlap syndrome lichen planus/lupus erythematosus, some patients show immunofluorescence testing consistent with lichen planus; yet another group demonstrates deposition of immunoglobulins and C3 at the dermal–epidermal junction in a linear granular pattern as in cutaneous lupus erythematosus (261).

Immunohistochemistry

The infiltrating cells in lichen planus are predominantly T lymphocytes with very few B lymphocytes. More than 90% are activated T lymphocytes expressing HLA-DR antigen and some interleukin-2 receptor (305). The identification of various subtypes of T lymphocytes has given contradictory results with regard to the predominance of $CD4^+$ helper-inducer T lymphocytes and $CD8^+$ suppressor-cytotoxic T lymphocytes in the infiltrate (306–308). It is likely that both subsets participate in the immunologic reaction. It has been shown that in older lesions of oral lichen planus, the suppressor T lymphocytes predominate. The epitheliotropic lymphocytes have also been shown to be of the same subtype, supporting a cell-mediated cytotoxic mechanism against epithelial cells (307,309). In the epidermis adjacent to the infiltrate, basal keratinocytes express HLA-DR surface antigen and ICAM-1 (310), both of which are implicated in the enhancement of the interaction between lymphocytes and their epidermal targets resulting in keratinocyte destruction (308). It is probable that these surface antigens are induced by cytokines (γIFN and TNFα) released by lymphocytes from the infiltrate (311,312). Immunophenotyping studies on T lymphocytes extracted from specimens of lichen planus have shown that the majority of clones were $CD8^+$ T lymphocytes, displayed suppressor activity, and expressed $\alpha\beta$ T-cell receptor (313) or a distinctive $\gamma\delta$T-cell receptor (314). Clonal expansion of $\alpha 2\beta 3$ T-cell receptor of the V-gene family has been reported, suggesting that a superantigen could be involved in the pathogenesis of the disease (315).

The number of Langerhans cells in the epidermis is increased very early in the disease, especially near keratinocytes expressing $HLA\text{-}DR^+$ antigen (275,316). Immunoelectron studies have shown close contacts of lymphocytes with Langerhans cells and macrophages. Specific conjugations between $CD4^+$ T lymphocytes and dendritic ($HLA\text{-}DR^+$) cells and between $CD8^+$ T lymphocytes and degenerated basal keratinocytes have been observed in lesional epithelium of oral mucosa. These cell-to-cell interactions suggest that a cell-mediated immune mechanism is operative (317). Recent studies have shown that lesional type I interferons produced by plasmacytoid dendritic cells play an important role in chronic cytotoxic inflammation of lichen planus by recruiting cytotoxic effector lymphocytes via IP10/CXCR3 interactions (318).

Differential Diagnosis

It should be borne in mind that parakeratosis is not a feature of lichen planus of the skin and that if more than focal parakeratosis is present, a diagnosis of lichen planus should not be made on histologic grounds.

Focal parakeratosis and adjacent solar lentigines in an otherwise typical histologic picture of lichen planus should be regarded as lichen planus–like keratosis, even more so if there is a solitary and nonpruritic lesion (319). Lichenoid drug eruptions may be differentiated from lichen planus by the presence of focal parakeratosis with concomitant absence of the granular layer, necrotic keratinocytes in the basal and spinous layers, exocytosis of lymphocytes to the upper layers of the epidermis, and a deeper inflammatory infiltrate with numerous eosinophils (320).

Differentiation from lichenoid lupus erythematosus is based on (a) atrophy of the epidermis in addition to acanthosis, (b) absence of eosinophilia of the keratinocytes in the spinous layer, (c) a superficial bandlike infiltrate with a superficial and deep perivascular and periadnexal infiltrate, (d) the presence of a thickened, PAS-positive basement membrane, and (e) dermal mucin deposits. Direct immunofluorescence findings may also be helpful; in lupus erythematosus linear or granular deposits of immunoglobulins and C3 predominate in lesional skin, whereas in lichen planus clusters of necrotic keratinocytes with absorbed immunoglobulins and complement are found. Langerhans cells are decreased in number in discoid and systemic lupus erythematosus; in contrast, they are increased in early lichen planus (308). The epidermal changes in chronic graft-versus-host disease may be similar to those in lichen planus; however, the inflammatory infiltrate tends to be perivascular instead of bandlike. In addition, the number of Langerhans cells in graft-versus-host disease is decreased, and nearly all intraepidermal lymphocytes are cytotoxic-suppressor T cells (321). In long-standing hypertrophic lichen planus, the basal layer may show hardly any residual damage and the infiltrate may no longer be bandlike, rendering differentiation from lichen simplex chronicus at times difficult. However, in hypertrophic lichen planus, deeper sections still may show areas of damage to the basal layer at the base of the rete ridges.

On the lips and in the mouth, the differentiation of lichen planus from early squamous cell carcinoma *in situ* ("dysplastic leukoplakia") may cause difficulties clinically as well as histologically. Both diseases may show hyperkeratosis and an inflammatory infiltrate close to the epidermis/epithelium. However, thorough microscopic study reveals more atypical keratinocytes in squamous cell carcinoma *in situ*. Furthermore, squamous cell carcinoma *in situ* is more apt than lichen planus to show irregular downward proliferation of the rete ridges and numerous plasma cells.

Lichen planopilaris of the scalp must be differentiated in its early phase from discoid lupus erythematosus, which affects the hair follicles as well as the interfollicular epidermis. Lupus erythematosus shows vacuolar alteration of the basal cells both in the epidermis and in the hair follicles without disappearance of basal cells. In addition, it also shows a thickened basement membrane and an interfollicular superficial and deep perivascular infiltrate. There is also an increase in connective tissue mucin. In their late stages, both lichen planopilaris and lupus

erythematosus may result in permanent scarring alopecia, which is known as pseudopelade of Brocq (283).

LICHEN PLANUS–LIKE KERATOSIS

Lichen planus–like keratosis (LPLK), also known as "benign lichenoid keratosis," was originally described in 1966 as "solitary lichen planus" (322) and as "solitary lichen planus–like keratosis" (323). It is a common lesion that occurs predominantly on the trunk and upper extremities of adults between the fifth and seventh decades. Occurrence on the face and lower extremities has also been reported (324–327). LPLK consists of a nonpruritic papule or slightly indurated plaque that is nearly always solitary, although cases with more than one skin lesion have been reported (328). It usually measures 5 to 20 mm in diameter, and its color varies from bright red to violaceous and brown. Its surface may be smooth or slightly verrucous. Lichen planus–like keratosis probably represents the inflammatory stage of involuting solar lentigines (329).

Histopathology. Histologic examination shows, at least in a part of the lesion, a lichenoid pattern that may be indistinguishable from lichen planus (319,322,323). As in lichen planus, there is vacuolar alteration of the basal cell layer and a bandlike lymphocytic infiltrate that obscures the dermal–epidermal junction. Necrotic keratinocytes are commonly seen and may be numerous. As in lichen planus, the epidermis often shows increased eosinophilia, hypergranulosis, and hyperkeratosis (330). In contrast to lichen planus, parakeratosis is fairly common (Fig. 7-29) and ranges from focal to prominent (319,325). In addition, eosinophils and plasma cells in the infiltrate are more frequently found in some cases of LPLK, as opposed to lichen planus, in which they are rarely seen (319). A residual solar lentigo at the edge of the lesion supports the diagnosis of LPLK (331). Regressed LPLK represents the involuted and late-stage lesion with atrophic epidermis, patchy lymphocytic infiltrate in the papillary dermis, and pigment incontinence, associated with dermal fibrosis. Bullous LPLK has also been described as a histopathologic variant (328). Immunohistochemical studies have shown that LPLK has significantly fewer Langerhans cells in the epidermis compared to lichen planus (332). The epidermal and dermal lymphocytes were shown to mainly consist of $CD8^+$ T cells and partly $CD20^+$ B cells with only scarce $CD4^+$ T cells. However, epidermal lymphocytes in lichen planus are mainly $CD8^+$ T cells and dermal lymphocytes are $CD4^+$ or $CD8^+$ T cells. In addition, in lichen planus, $CD20^+$ B cells are scarcer than in LPLK. Memory T cells express a skin homing receptor called cutaneous lymphocyte associated antigen. This antigen is strongly expressed in lichen planus but not in LPLK, suggesting that in lichen planus, disease-related lymphocytes infiltrate the epidermis, whereas in LPLK, the lymphocytes may be nonspecific infiltrating cells (327).

Direct immunofluorescence studies have revealed the linear deposition of IgM at the basement membrane zone (333). Even though some keratinocytes may show pyknotic hyperchromatic nuclei, no definite nuclear atypia is seen. If marked keratinocytic atypia is found in association with a lichenoid inflammatory pattern, a lichenoid actinic keratosis should be considered in the differential diagnosis.

Pathogenesis. LPLK has been noted to involute spontaneously (334). LPLK may be the inflammatory stage of regressing solar lentigines and reticulated seborrheic keratoses (329,331). These precursor lesions could be the targets of an immune cell–mediated reaction (319).

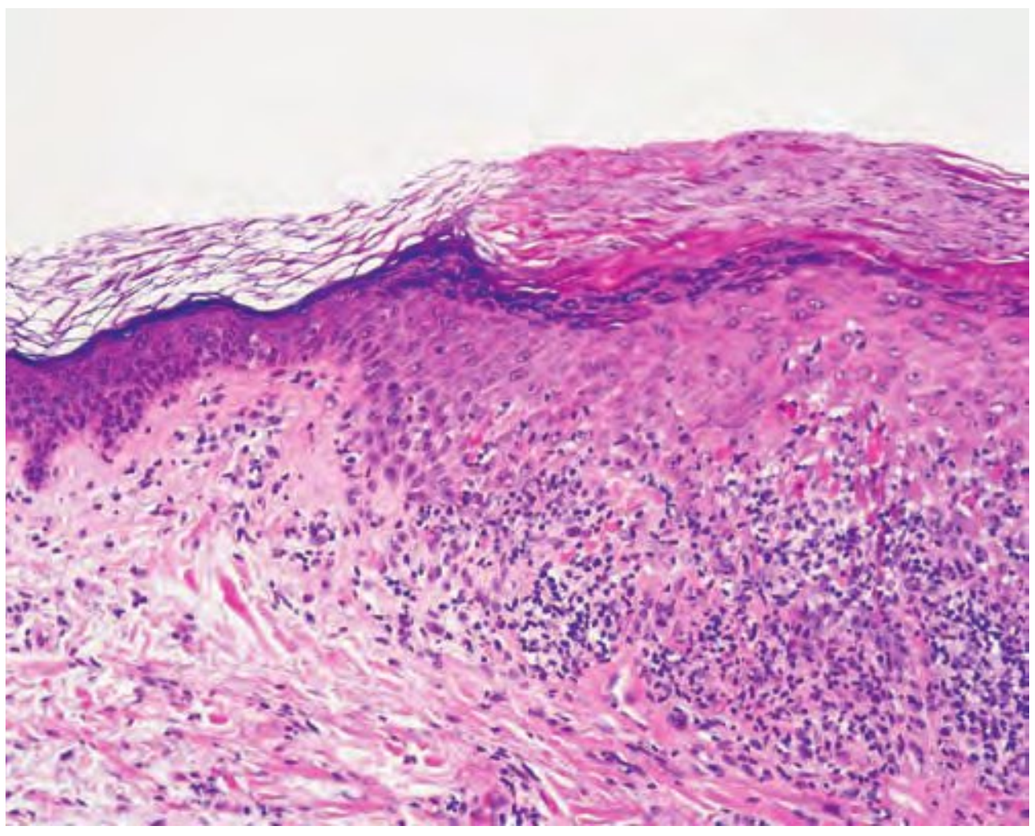

FIGURE 7-29. Lichen planus–like keratosis. Lichenoid inflammatory pattern with numerous necrotic keratinocytes, granular layer of uneven thickness, orthokeratosis, and parakeratosis with a residual solar lentigo.

KERATOSIS LICHENOIDES CHRONICA

A rare asymptomatic dermatosis, keratosis lichenoides chronica was first described by Kaposi in 1895 as "lichen ruber acuminatus verrucosus et reticularis" (335) and received its present name in 1972 (336). It usually begins in adulthood between 20 and 50 years of age and is extremely rare in children (337). There is an extensive, symmetrically distributed eruption predominantly on the dorsal aspects of extremities and trunk. It mainly consists of red to violaceous papulonodules covered with a thick, adherent scale and arranged often in a characteristic linear and occasionally reticular pattern. The lesions may coalesce to form erythematous scaly or hyperkeratotic plaques (338,339). Very frequently there is associated seborrheic dermatitis–like eruption of the face, palmoplantar hyperkeratosis (338), and, in some cases, nail changes with warty hypertrophy of the periungual tissues, which has been described as a distinctive feature of the disease (340). Mucosal membrane involvement is common and includes oral ulcers, nodular infiltration of the epiglottis and

larynx, blepharitis, and keratoconjunctivitis, among others (336,338,339). Although the disease is characterized by a chronic and progressive course, spontaneous resolution has been reported (341).

The disease has been reported in association with lymphoma (342), following trauma (343), and after a drug-induced erythroderma (344).

Histopathology. In most cases, there is a lichenoid inflammatory infiltrate comprised of lymphocytes, histiocytes, and numerous plasma cells that obscures the dermal–epidermal junction with vacuolar alteration of the basal cell layer and necrotic keratinocytes (338,345). The epidermis shows areas of acanthosis as well as atrophy covered by a hyperkeratotic cornified layer with focal parakeratosis and follicular plugging (346). Prominent dilated dermal capillaries are seen in cases with associated telangiectasias (347).

Differential Diagnosis. Although the histologic picture may closely resemble that of lichen planus, the presence of parakeratosis, alternating areas of atrophy and acanthosis, numerous plasma cells, and a heavier infiltrate than is usually seen in lichen planus may help in the differentiation. In addition, the clinical appearance of keratosis lichenoides chronica is quite different from that of lichen planus.

LICHEN NITIDUS

Lichen nitidus is a chronic and usually asymptomatic dermatitis that commonly begins in childhood or early adulthood (348). It is characterized by round, flat-topped, flesh-colored papules 2 to 3 mm in diameter that may occur in groups but do not coalesce (Fig. 7-30). The lesions appear frequently as a localized eruption affecting predominantly the arms, trunk, or penis. Rarely, the eruption may become generalized, and Koebner's phenomenon may be observed (265,349,350). Purpuric generalized variant has also been reported (351). In addition, lesions occurring on the palms, soles, nails, and mucous membranes have been described (352). The clinical course is unpredictable, and spontaneous resolution may be seen (348).

FIGURE 7-30. Lichen nitidus. Cluster of round, flat-topped, flesh-colored papules of a few millimeters in diameter. (Courtesy of Ronald O. Perelman Department of Dermatology, New York University School of Medicine, New York, New York.)

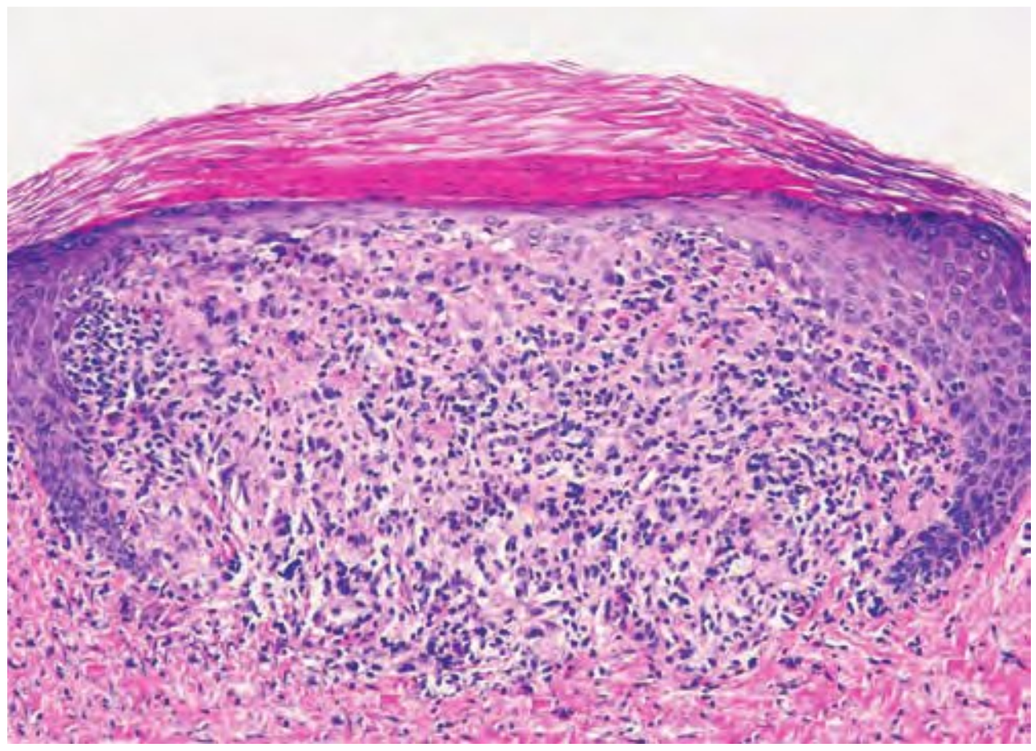

FIGURE 7-31. Lichen nitidus. Dense infiltrate of lymphocytes and histiocytes in an expanded dermal papilla, thin suprapapillary epidermis with vacuolar alteration of the basal layer, and focal parakeratosis.

Histopathology. Each papule of lichen nitidus consists of a well-circumscribed mixed-cell granulomatous infiltrate that is closely attached to the lower surface of the epidermis and confined to a widened dermal papillae. The infiltrate is composed of lymphocytes and mono- and a few multinucleated epithelioid histiocytes. The dermal infiltrate often extends slightly into the overlying epidermis, which is flattened and shows vacuolar alteration of the basal cell layer, focal subepidermal clefting, diminished granular layer, and focal parakeratosis (348). Transepidermal perforation of the infiltrate through the thinned epidermis may occur (353). At each lateral margin of the infiltrate, rete ridges tend to bend downward and inward and seem to clutch the infiltrate in the manner of a "claw clutching a ball" (Fig. 7-31). The palmar lesions have the infiltrate mostly disposed around the bases of the rete ridges, similar to that found in hypertrophic lichen planus (354). Follicular involvement in lichen nitidus has also been described (355).

Relationship Between Lichen Planus and Lichen Nitidus

There are controversial facts regarding the relationship that might exist between lichen planus and lichen nitidus. The view that lichen nitidus represents a variant of lichen planus has been supported by several authors because the two diseases are occasionally present simultaneously (265), ultrastructural findings are similar (356), and, in some cases of lichen planus, small miliary papules may have a histologic appearance consistent with lichen nitidus (357). However, the subsequent

evolution is different; in lichen nitidus, the papule remains small and develops parakeratosis with epidermal flattening, whereas in lichen planus, the papule develops acanthosis and hyperkeratosis (265). Occasional deposits of fibrinogen can be observed by direct immunofluorescence in lichen nitidus, in contrast to lichen planus, where most of the lesions have globular deposits of immunoglobulins at the dermal–epidermal junction (358). Furthermore, immunohistochemical studies have revealed different cell populations in the inflammatory infiltrate of each disease. Lichen nitidus has a significantly smaller proportion of $CD4^+$ (helper-inducer) and HECA-452^+ (skin-homing receptor) T lymphocytes than lichen planus, suggesting different immunologic pathways (359).

LICHEN STRIATUS

Lichen striatus is a fairly uncommon dermatitis that, as a rule, occurs in children from 5 to 15 years of age but may be seen in adults (360). It usually manifests as a unilateral eruption along Blaschko's lines on the extremities, trunk, or neck as either a continuous or an interrupted band composed of minute, slightly raised erythematous papules, which may have a scaly surface (361) (Fig. 7-32). The lesions appear abruptly and usually involute within a year. They are occasionally pruritic (362). Hypopigmented lesions may be seen in dark-skinned patients (363). A few cases with associated onychodystrophy, rare cases of multiple or bilateral presentations, and simultaneous occurrence of lichen striatus in siblings have been reported (364–368).

Histopathology. Although lichen striatus has been recognized by its variable histologic picture (360,363,369), some constant microscopic findings may be present (370). There is usually a superficial perivascular inflammatory infiltrate of lymphocytes admixed with variable number of histiocytes. Plasma cells and eosinophils are rarely seen (360) (Fig. 7-33). Focally, in the papillary dermis, the infiltrate may have a bandlike distribution with extension into the lower portion of the epidermis, where there is vacuolar alteration of the basal layer and necrotic keratinocytes. In these areas, the papillary dermis occasionally contains melanophages (360,369). Additional epidermal changes consist of spongiosis and intracellular edema often associated with exocytosis of lymphocytes and focal parakeratosis (Fig. 7-34). Less frequently, there are

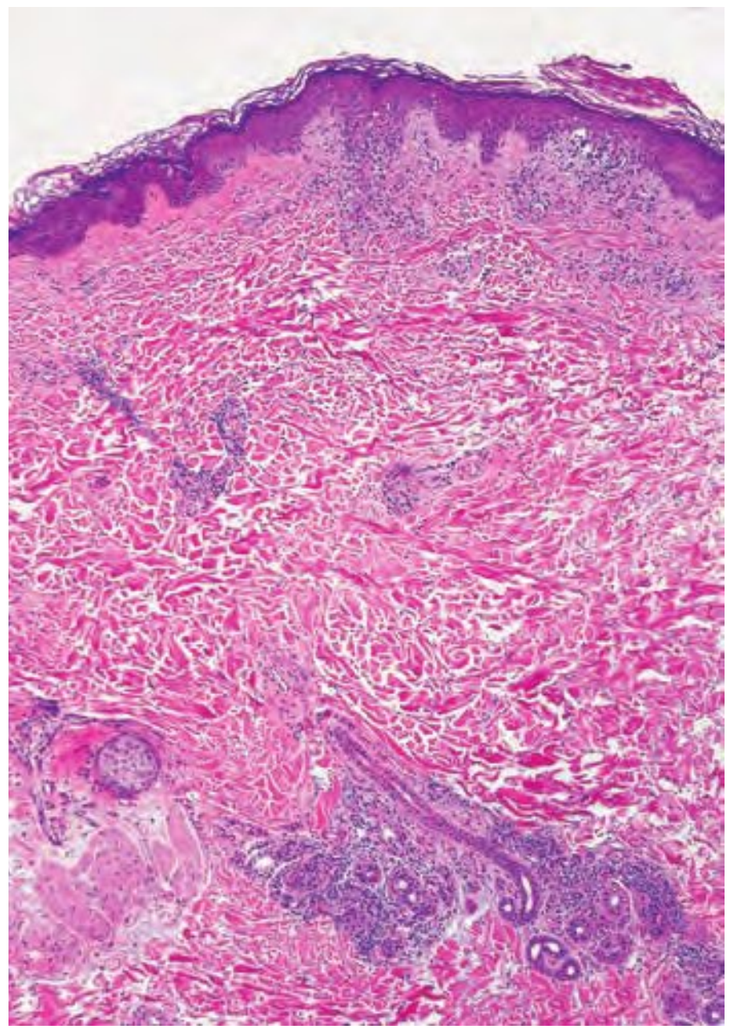

FIGURE 7-33. Lichen striatus. Superficial and deep perivascular, perieccrine, and perifollicular infiltrate of lymphocytes and histiocytes that extends to the epidermis, which shows acanthosis and spongiosis.

FIGURE 7-32. Lichen striatus. Linear band of confluent small papules following a Blaschko's line. (Courtesy of Department of Dermatology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.)

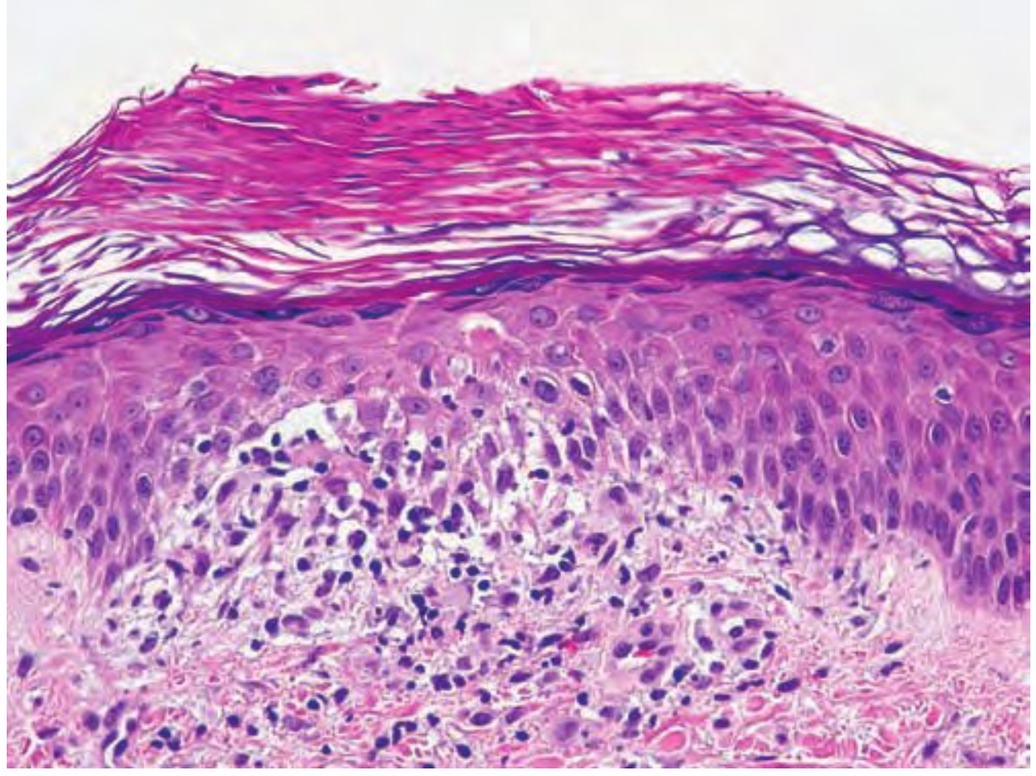

FIGURE 7-34. Lichen striatus. Closer view shows an infiltrate of lymphocytes and histiocytes, exocytosis of lymphocytes, acanthosis, spongiosis, and focal parakeratosis.

scattered necrotic keratinocytes in the spinous layer as well as subcorneal spongiotic vesicles filled with Langerhans cells (370). A very distinctive feature is the presence of inflammatory infiltrate in the reticular dermis around hair follicles and eccrine glands (Fig. 7-33) (360,370). An unusual perforating variant of lichen striatus has been described, which shows transepidermal elimination of clusters of necrotic keratinocytes (371).

Pathogenesis. It has been demonstrated in lichen striatus that the inflammatory cells reaching the epidermis are $CD8^+$ T lymphocytes (370,372) with the Langerhans cell population in the epidermis being either decreased or increased. These findings suggest a cell-mediated immunologic mechanism in which cytotoxic events against keratinocytes could be taking place during the evolution of the disease (370).

Differential Diagnosis. Lichen striatus may show histologic features similar to those of other interface dermatitides such as lichen planus, lichen nitidus, or graft-versus-host disease. In contrast to lichen striatus, the inflammatory infiltrate of lichen nitidus is only focally present in a widened dermal papillae and contains more histiocytes. The presence of epidermal spongiosis and a deeper dermal inflammatory infiltrate around adnexal structures are features rarely seen in lichen planus. In secondary syphilis, the infiltrate mainly comprises plasma cells.

INFLAMMATORY LINEAR VERRUCOUS EPIDERMAL NEVUS

Inflammatory linear verrucous epidermal nevus (ILVEN) presents as a persistent, linear, intensely pruritic lesion. It is composed of erythematous, slightly verrucous, scaly papules arranged in one or several lines. Although the usual time of onset is early childhood, the disease may arise in adults (373). The most common location is on a lower extremity. On rare occasions the lesions are bilateral (374).

ILVEN in association with arthritis (375) and lichen amyloidosus (376) has been reported. ILVEN is considered to be a variant of epidermal nevi; however, it is described and included in the papulosquamous disorders due to its clinical and histologic similarities to psoriasis and lichen striatus.

Histopathology. There is hyperkeratosis with foci of parakeratosis, moderate acanthosis, elongation and thickening of the rete ridges with a "psoriasiform" appearance, papillomatosis, and, occasionally, slight spongiosis with exocytosis of lymphocytes (377).

Frequently, a rather characteristic histologic feature is a sharply demarcated alternation of orthokeratosis and parakeratosis in the cornified layer (Fig. 7-35). The parakeratotic areas are slightly raised, lack a granular layer, and show a compact eosinophilic cornified layer with nuclear preservation. The orthokeratotic areas instead are slightly depressed with underlying hypergranulosis (374,378,379). Underneath the parakeratotic areas, there is mild exocytosis of lymphocytes and slight spongiosis (380). The papillary dermis shows a mild to moderate perivascular inflammatory infiltrate of lymphocytes and histiocytes.

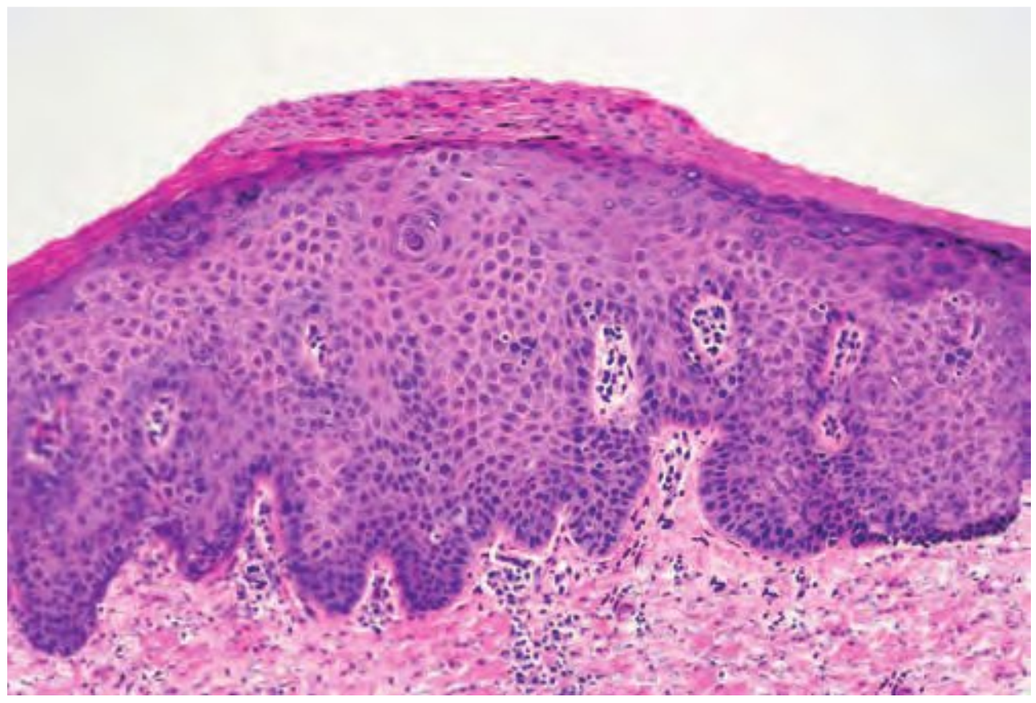

FIGURE 7-35. Inflammatory linear verrucous epidermal nevus. Moderate acanthosis with elongated rete ridges and alternating elevated foci of parakeratosis with absent granular layer and depressed foci of orthokeratosis with preserved granular layer.

Pathogenesis. Electron microscopy and immunohistochemical studies have shown that keratinocyte differentiation is altered in the parakeratotic areas.

Ultrastructurally, keratinocytes have prominent Golgi apparatus and vesicles in their cytoplasm. The intercellular spaces in upper layers of the epidermis are widened by deposits of an electron-dense homogeneous substance. The cytoplasm of parakeratotic corneocytes contains remnants of nucleus and membrane structures and a few lipid droplets. The marginal band formation inside the plasma membrane is incomplete, suggesting a deficient keratinization process (380).

Involucrin expression has a very characteristic pattern in ILVEN. The orthokeratotic epidermis shows increased involucrin expression, whereas the parakeratotic areas are almost negative for involucrin staining (380). This pattern differs from that of psoriasis, in which involucrin is expressed prematurely in most of the suprabasal keratinocytes (381).

More than 90% of the mononuclear cells in the dermal infiltrate are $CD4^+$ T lymphocytes; in contrast, the majority of the epidermal infiltrating T lymphocytes are CD4 negative (382).

Differential Diagnosis. The clinical appearance of lichen striatus and that of ILVEN may be indistinguishable. However, ILVEN, in contrast to lichen striatus, is pruritic and persistent. Histologically, lichen striatus tends to have a lichenoid pattern and ILVEN a psoriasiform pattern. Furthermore, careful search of step sections will usually reveal in ILVEN alternate areas of orthokeratosis with a thickened granular layer and of parakeratosis without a granular layer.

Since alternating orthokeratosis and parakeratosis can be seen in psoriasis and occasionally Munro microabscesses can be

found in ILVEN, the differential diagnosis of these two entities could be sometimes difficult, and a clinicopathologic correlation is necessary (383).

PITYRIASIS RUBRA PILARIS

Pityriasis rubra pilaris is an erythematous squamous disorder characterized by follicular keratotic papules and perifollicular erythema that coalesce to form orange-red scaly plaques that frequently contain islands of normal-appearing skin (384) (Fig. 7-36). As the erythema extends, the follicular component is often lost, but it persists longest on the dorsal aspect of the proximal phalanges. The lesions spread caudally and may progress to a generalized erythroderma (385). Other clinical findings are palmoplantar keratoderma and scaling of the face and scalp. Five types can be recognized (385). Only three types, however, are common enough to deserve mention. *Type I classical adult type* and *type III classical juvenile type* are seen in 55% and 10% of the patients, respectively. They are considered to be the same disease in different age groups (386). In both groups, the majority of the patients clear within 3 years (386,387). *Type IV*, the *circumscribed juvenile type*, accounts for approximately one fourth of the patients. It affects children and is characterized by sharply demarcated areas of follicular hyperkeratosis and erythema on the knees and elbows. It may improve in the late teens (386). There is a familial form of pityriasis rubra pilaris inherited as an autosomal dominant trait (388).

Pityriasis rubra pilaris has been reported to occur in association with malignancies (389–391) and arthritis/arthropathy (392,393). A few cases of pityriasis rubra pilaris with oral involvement have been described (394).

Histopathology. The histologic picture of a fully developed erythematous lesion shows acanthosis with broad and short rete ridges, slight spongiosis, thick suprapapillary plates, focal or confluent hypergranulosis, and alternating orthokeratosis and parakeratosis oriented in both vertical and horizontal directions (171) (Fig. 7-37). In the dermis there is a mild superficial perivascular lymphocytic infiltrate and moderately dilated blood vessels (171,395).

Areas corresponding to follicular papules show dilated infundibula filled out with an orthokeratotic plug and often display perifollicular shoulders of parakeratosis and a mild perifollicular lymphocytic infiltrate (396) (Fig. 7-38). Erythrodermic lesions have a thinned or absent cornified layer with overlying plasma exudate and a diminished granular zone (171).

Differential Diagnosis. Even though pityriasis rubra pilaris and psoriasis bear a similar clinical appearance, they are not alike histologically. Psoriasis differs from pityriasis rubra pilaris

FIGURE 7-36. Pityriasis rubra pilaris. Confluent orange-red scaly plaques with islands of normal-appearing skin. (Courtesy of Department of Dermatology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.)

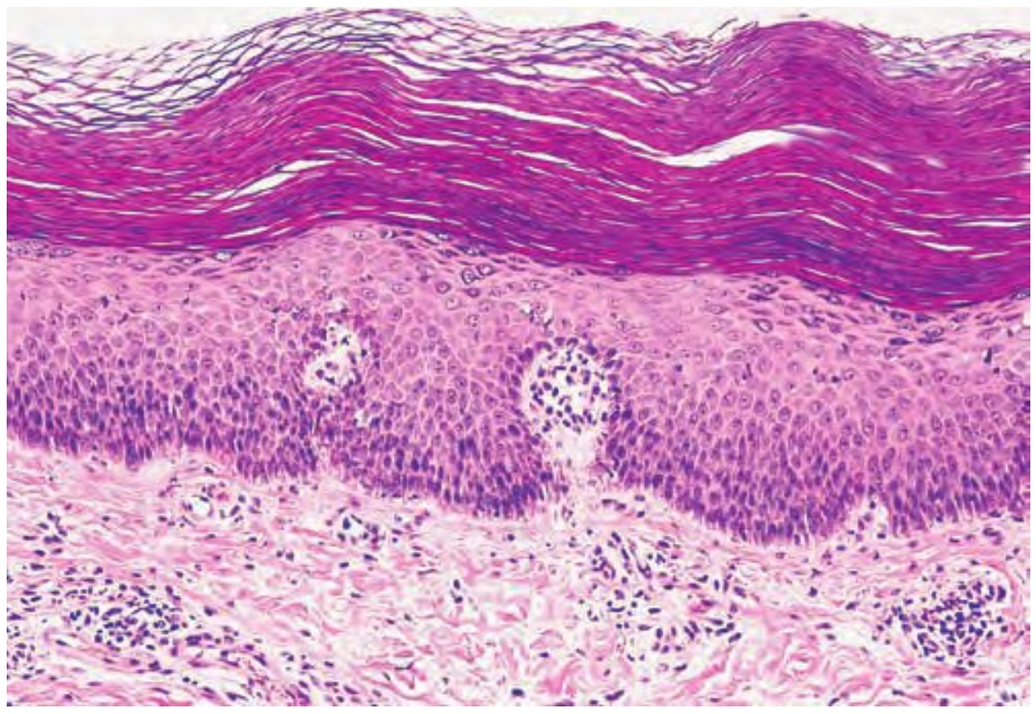

FIGURE 7-37. Pityriasis rubra pilaris. Moderate acanthosis with short and broad rete ridges, focally thin granular layer, and alternating vertical and horizontal foci of orthokeratosis and parakeratosis.

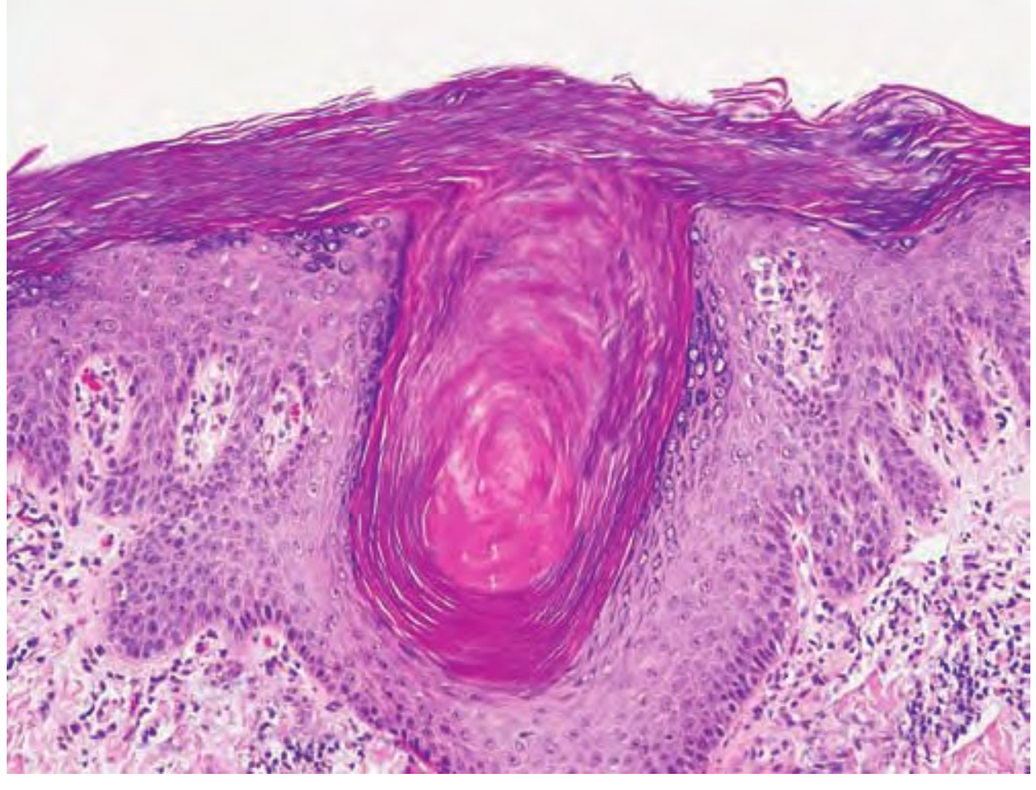

FIGURE 7-38. Pityriasis rubra pilaris, follicular lesion. Dilated follicular infundibulum with hyperkeratotic plug.

by the presence of neutrophils and Munro microabscesses, more pronounced parakeratosis in mounds, thin suprapapillary plates, elongated rete ridges, and tortuous blood vessels (395). Pityriasis rubra pilaris has a more prominent granular layer with less epidermal spongiosis and inflammatory infiltrate (171). Moreover, it has been demonstrated that pityriasis rubra pilaris has a lower keratinocyte proliferation rate than psoriasis, suggesting differences in cell kinetic characteristics (395,397,398).

Pathogenesis. The cause of pityriasis rubra pilaris is unknown. There is evidence that suggests an abnormal epidermal differentiation based on the presence of suprabasal staining with monoclonal antibody against keratin AE1 and the detection of cytokeratins K6 and K16, which are not expressed in normal skin (388).

PITYRIASIS LICHENOIDES

Pityriasis lichenoides is an uncommon cutaneous eruption usually classified in two forms that differ in severity. Simultaneous appearance of the two types and transitions between them often occur, suggesting that they are variants of the same disease (392–401). Both are rarely pruritic or painful, with crops of self-healing lesions affecting mainly young adults and occasionally children (399,400,402,403).

The milder form, called *pityriasis lichenoides chronica*, is characterized by recurrent crops of brown-red papules 4 to 10 mm in size, mainly on the trunk and extremities, that are covered with a scale and generally involute within 3 to 6 weeks with postinflammatory pigmentary changes (186).

The more severe form, called *pityriasis lichenoides et varioliformis acuta* (PLEVA), also referred to as Mucha-Habermann disease, consists of a fairly extensive eruption, present mainly on the trunk and proximal extremities. It is characterized by erythematous papules that develop into papulonecrotic, occasionally hemorrhagic or vesiculopustular lesions that resolve within a few weeks, usually with little or no scarring. Occasionally, some lesions increase in size to necrotic ulcers 1 to 2 cm in diameter, which heal with an atrophic or varioliform scar. Although the individual lesions follow an acute course, the disorder is chronic, extending over several months or even years with development of new lesions and variable periods of remission. Cases of PLEVA occurring during pregnancy and affecting the vagina/cervical mucosa with resultant premature rupture of the membranes and/or premature labor have been reported (404,405). Very rarely, patients with PLEVA have a sudden, severe flare-up of their disease, characterized by innumerable coalescent necrotic ulcerations associated with high fever and systemic manifestations (406–408). Pityriasis lichenoides occurring concurrently with idiopathic thrombocytopenic purpura in childhood has been reported (409).

Histopathology. In pityriasis lichenoides chronica—the mild form—one observes a superficial perivascular and lichenoid infiltrate composed of lymphocytes that extends into the epidermis, where there is vacuolar alteration of the basal layer, mild spongiosis, a few necrotic keratinocytes, and confluent parakeratosis. Melanophages and small numbers of extravasated erythrocytes are commonly seen in the papillary dermis (186,400).

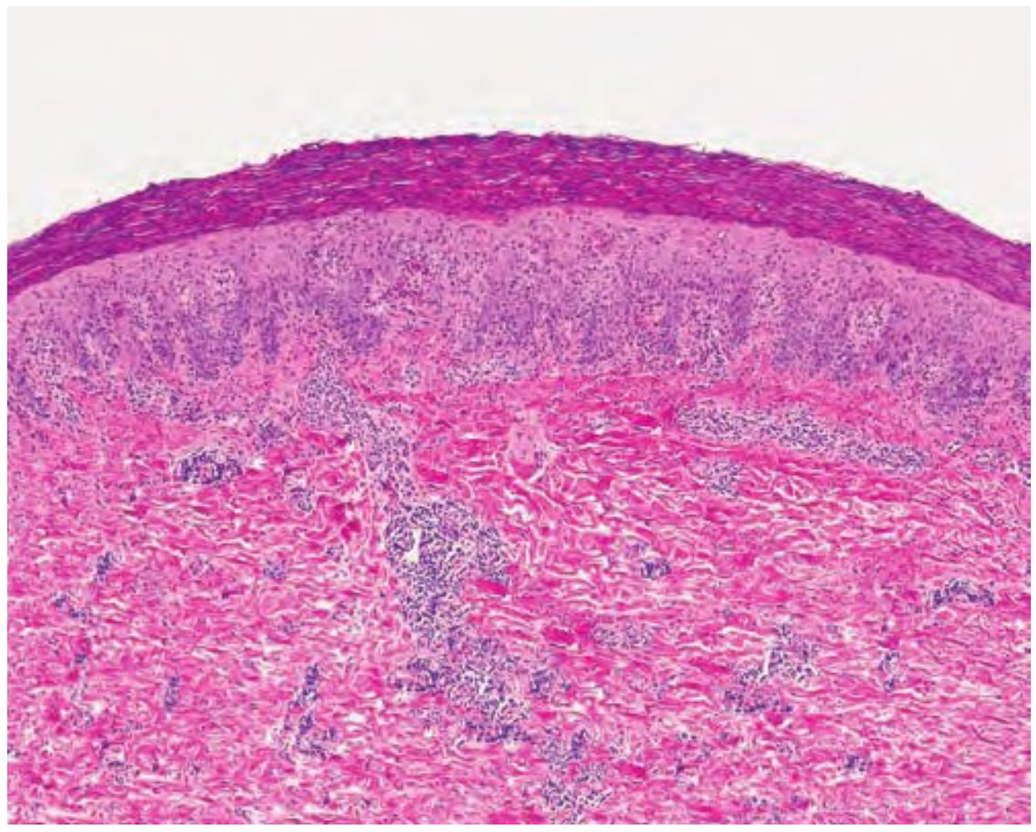

FIGURE 7-39. Pityriasis lichenoides et varioliformis acuta. Lichenoid inflammatory pattern with a superficial and deep perivascular lymphocytic infiltrate.

In PLEVA—the more severe form—there is a perivascular and dense, bandlike, predominantly lymphocytic infiltrate in the papillary dermis that extends into the reticular dermis in a wedge-shaped pattern (Fig. 7-39). The infiltrate obscures the dermal–epidermal junction with pronounced vacuolar alteration of the basal layer, marked exocytosis of lymphocytes and erythrocytes, and intercellular and intracellular edema leading to variable degree of epidermal necrosis (Fig. 7-40). Ultimately,

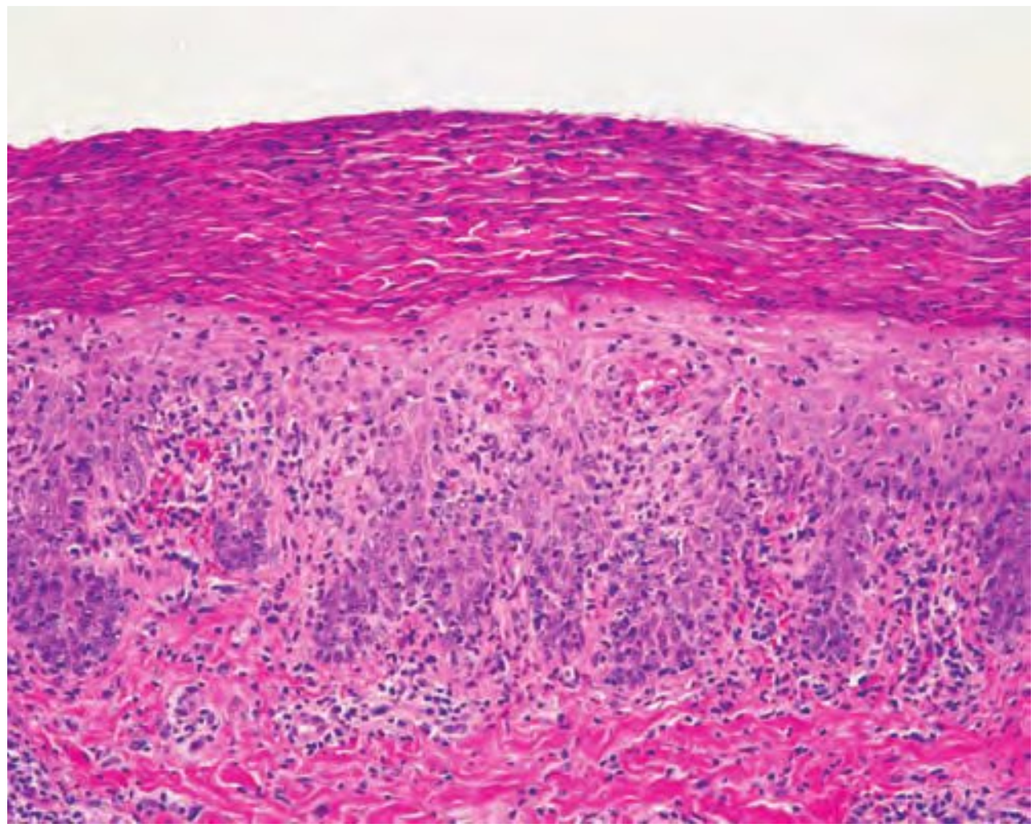

FIGURE 7-40. Pityriasis lichenoides et varioliformis acuta. Closer view reveals lichenoid inflammatory pattern with an infiltrate of lymphocytes, extravasated erythrocytes, irregular acanthosis, pallor of the upper layers of the epidermis, spongiosis, necrotic keratinocytes, and confluent mounds of parakeratosis with plasma, neutrophils, and lymphocytes.

erosion or even ulceration may occur. The overlying cornified layer shows parakeratosis and a scaly crust with neutrophils in the more severe cases (400,410).

Variable degrees of papillary dermal edema, endothelial swelling, and extravasated erythrocytes are seen in the majority of cases. Although occasionally small deposits of fibrin are present within the vessel walls, severe vascular damage is rarely found (400), except in the severe febrile ulceronecrotic variant of PLEVA, in which lymphocytic vasculitis with leukocytoclasis is a fairly common feature (406,408).

Differential Diagnosis. Occasionally, the histologic picture of PLEVA can be mimicked by other diseases such as pityriasis rosea, vesicular insect bites, and subacute eczematous dermatitis. The presence of a deeper inflammatory infiltrate, extensive epidermal necrosis, and the absence of intraepidermal spongiotic microvesicles may help to distinguish PLEVA from pityriasis rosea and subacute eczematous dermatitis. Numerous eosinophils in a vertically oriented dermal infiltrate is more commonly seen in insect bites (411).

Pathogenesis. Most of the cells in the inflammatory infiltrate are activated T lymphocytes (HLA-DR$^+$/CD3$^+$) (401,410,412) that express CD7 and rarely lack other T-cell antigens (CD2, CD5) (401,413). Two constant findings in PLEVA are the predominance of CD8$^+$ (cytotoxic-suppressor) T cells over CD4$^+$ (helper-inducer) T lymphocytes in the infiltrate and the expression of HLA-DR on the surrounding keratinocytes (401,410–412), suggesting a direct cytotoxic immune reaction in the pathogenesis of epidermal necrosis. Recent studies have suggested that PLEVA is a clonal T-cell disorder (414–416). Some cases of pityriasis lichenoides chronica, although less frequent than PLEVA, also exhibited a clonal T-cell receptor gene rearrangement (414,417). Malignant transformation in pityriasis lichenoides is controversial. It does not appear that cases of clonal PLEVA have a higher risk of developing malignant lymphoma (414,418). However, there are a few reports of cases with pityriasis lichenoides that have been associated with cutaneous lymphoma (419–422). It is proposed that pityriasis lichenoides represents an indolent T-cell dyscrasia (423). In conclusion, it is suggested that monoclonal expansion of T cells results most likely from a cellular host immune response to an as-yet-unidentified antigen, perhaps a viral one such as human parvovirus B19 (414,424,425).

CHAPTER 8

Raymond L. Barnhill
Carlos H. Nousari
Xiaowei Xu
Sarah K. Barksdale

Vascular Diseases

This chapter discusses vasculitides, vasculopathies, and several other disease processes with vascular injury that can affect the skin. The spectrum of clinical manifestations of such diseases is broad and depends on several factors, including the number, size, and type of vessels involved (arterial vs. venous); the extent of vascular damage; the presence or absence of inflammation; the type of inflammatory infiltrate (neutrophilic vs. lymphocytic); the distribution of the infiltrate (superficial dermis vs. deep dermis or subcutis); and other parameters (1–13).

In general, severe vascular damage with vascular occlusion leads to ischemic damage and may result in necrosis, blister formation, and/or ulceration. Nonocclusive vascular disease may be associated with damage to the structural integrity of the vessel wall and may lead to leakage of blood, resulting in dermal hemorrhage and edema. Dermal hemorrhage is clinically seen as purpura. Hemorrhages less than 3 mm in diameter are called petechiae, and larger lesions are called ecchymoses. If an inflammatory infiltrate is present, purpura may become palpable.

CRITERIA FOR VASCULITIS

Considerable controversy surrounds the criteria for vasculitis. The essential difficulty is the dynamic nature of vascular injury. The appearance of the injured vessels and the inflammatory cells present change as lesions evolve. Furthermore, the degree of vascular injury varies depending on the severity of the insult. The spectrum of vascular reaction to injury ranges from endothelial cell swelling and leakiness to frank fibrinoid necrosis and fibrin deposition. Thus, criteria for recognizing microvascular injury are somewhat arbitrary.

Although the minimum criteria for vasculitis are controversial, in general, vasculitis must have two components: (a) an inflammatory cell infiltrate and (b) evidence of vascular injury (Table 8-1). Vasculitis is an inflammatory process, and thus the absence of inflammation precludes the diagnosis even though vascular alterations may be present. However, in the late, healing state, the inflammatory cell infiltrate may be minimal. The inflammatory cells involved may include neutrophils, eosinophils, lymphocytes, or monocytes/macrophages. The type of infiltrating cell may correlate to some extent with the chronology of the process, but not always.

Evidence of vascular injury is the second major component of vasculitis. Criteria for vascular injury have included (a) evidence of vessel leakiness such as edema and extravasation of erythrocytes, (b) evidence of vessel destruction such as necrosis of endothelium and deposition of fibrinoid material within the vascular lumina or vessel walls, and (c) evidence of inflammatory compromise of the vascular walls, including infiltration by inflammatory cells and leukocytoclasis of the surrounding inflammatory cell infiltrate (Fig. 8-1). As mentioned, there is a continuum of injury. However, for several years pathologists have required a certain degree of injury, as manifested by deposition of fibrinoid material and/or necrosis of the vessel itself, as a primary indicator of a true vasculitis. Certain changes, including edema, extravasation of erythrocytes, infiltration of vessel walls, leukocytoclasis, and thrombosis, may occur with minimal evidence of vascular injury. Pathologists should strive not to overinterpret such changes as vasculitis when definitive evidence of vessel injury is lacking. For instance, leukocytoclasis also may result from necrosis of a neutrophilic infiltrate itself without fibrinoid necrosis of vessels. Similarly, fibrin thrombi may be present in noninflamed vessels in the setting of hypercoagulable states.

Secondary Vasculitis, Incidental Vasculitis, Vasculopathy, Pseudovasculitis

The development of terminology to describe whether vascular injury or vasculitis is primary or secondary (incidental), the degree of vascular injury present, or conditions or disorders mimicking vasculitis indicates the difficulty of interpreting signs of vascular injury and vasculitis (2–13). Primary vascular injury implies that the vascular insult is the predominant disease process. Secondary or incidental vascular injury indicates that another disease process outside the vessels is the primary pathologic process. An example of the latter is vascular alteration noted near cutaneous ulceration. In many instances, distinguishing clearly between a primary and a secondary vascular insult is not possible. However, secondary vascular injury is often variable, with sparing of some vessels within the zone of tissue injury. Other indications of secondary vascular injury include deposition of fibrinoid material at the periphery of the vessel wall and focal thrombosis without significant infiltration by inflammatory cells.

TABLE 8-1 Definitions of Vascular Injury

Primary vascular injury
Vasculopathy
Fibrinoid deposition, thrombosis with limited to no inflammation
Infiltration of vessel wall by inflammatory cells with otherwise minimal alteration
Leukocytoclasis of tissue infiltrate with minimal alteration of vessel, that is, swelling only, absence of fibrinoid necrosis
Vasculitis
Perivascular inflammatory cell infiltrate* (neutrophilic, eosinophilic, lymphocytic, histiocytic, or mixed)
Fibrinoid necrosis*: necrosis of vessel wall with deposition of fibrinoid material
Other changes often present but not essential: edema, extravasation of erythrocytes, leukocytoclasis, infiltration of vessel wall by inflammatory cells, swelling of endothelial cells, luminal thrombosis
Secondary vascular injury†
Vasculopathy or vasculitis
Secondary to another insult such as external trauma or ulceration
Variable vascular alterations with sparing of some vessels
Peripheral perivascular fibrinoid deposition

*Essential for diagnosis.
†Distinguishing between primary and secondary vasculitis is often not possible.

The term *vasculopathy* or *pseudovasculitis* may be used to describe certain degrees of vascular alteration and injury that fail to satisfy the criteria for vasculitis, may closely mimic vasculitis, or both (Table 8-1). Such histopathologic alterations might include hemorrhage, vascular thrombosis (hypercoagulable states), embolic phenomena with little additional evidence of vascular injury (Fig. 8-2), deposition of fibrinoid material with little or no inflammation, minimal infiltration of vessel walls with little or no leukocytoclasis, pathologic alterations of the vessel wall, vasospasm, and repetitive vascular trauma (2–13).

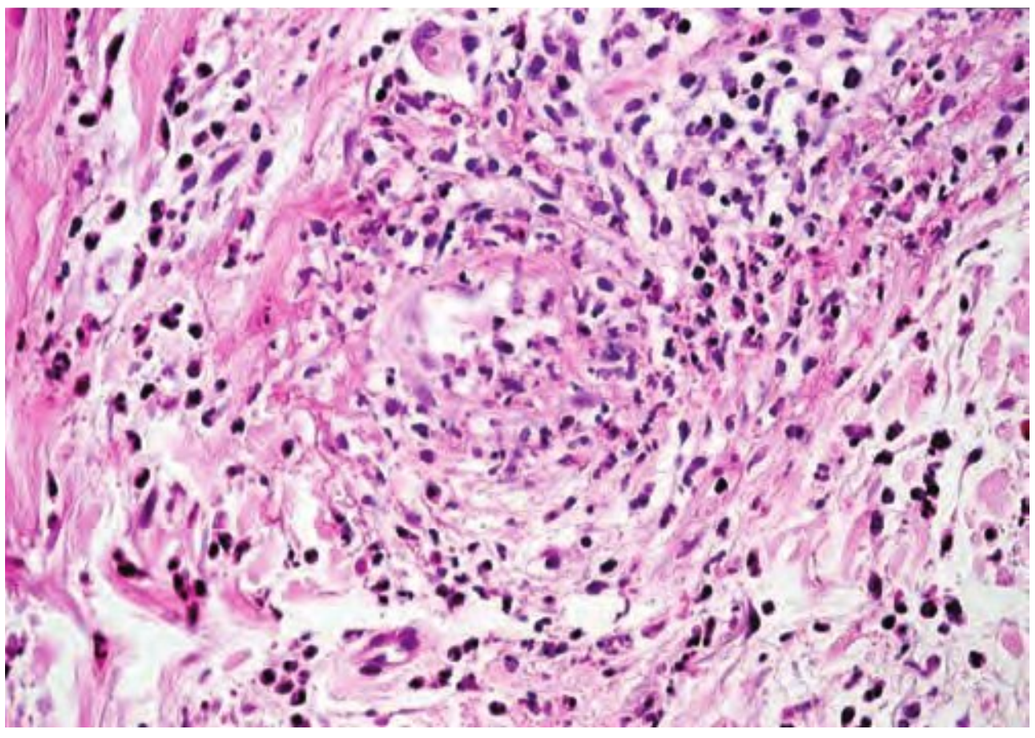

FIGURE 8-1. Hypersensitivity vasculitis showing an upper dermal small blood vessel with full-blown features of neutrophil-rich vasculitis. The specimen was obtained from a 2-day-old purpuric papule.

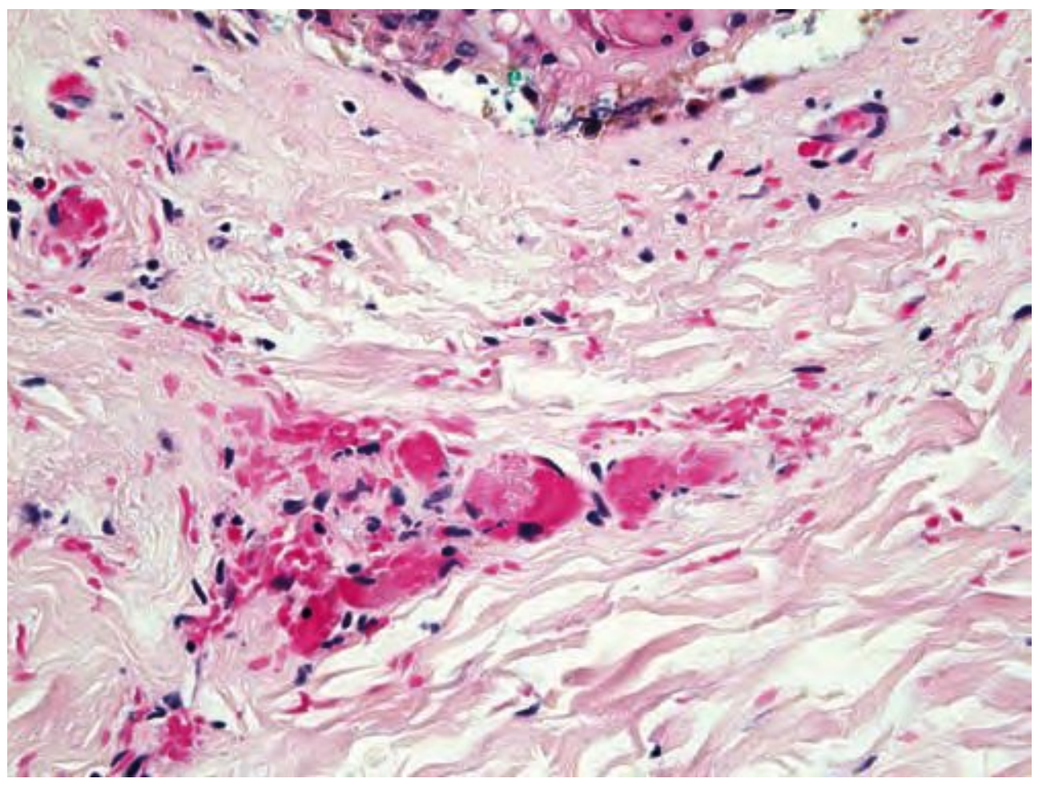

FIGURE 8-2. Vasculopathic reaction, disseminated intravascular coagulation. Pink fibrin thrombi are present within vessels that do not show evidence of damage or inflammation in their walls.

EVALUATION OF VASCULITIS

The classification of inflammatory vascular reactions—specifically that of vasculitides—is difficult for a variety of reasons (1–13). Clinically different entities lack histologic specificity, and the same disease process may show a spectrum of histologic changes depending on the stage of the disease, the level of activity, and the type of treatment that might have modified its course. In an attempt to standardize nomenclature for vasculitides, an international conference proposed a system primarily based on vessel size (3,4,14,15). Large vessels are considered to include the aorta and large named arteries and veins. Medium-sized vessels include the medium-sized and small arteries and veins. These vessels in dermatopathology specimens are located in the subcutis or near the dermal subcutis junction in the skin. Small vessels include arterioles, venules, and capillaries. Most of the vessels in the dermis belong to this group. Classification based on vessel size is helpful because there is some correlation with the clinical presentation. Purpura, palpable purpura, urticaria, vesicles and bullae, and splinter hemorrhages typically reflect small-vessel injury. Cutaneous nodules, ulcers, livedo reticularis, and digital gangrene suggest the involvement of medium-sized arteries. However, classification based on vessel size alone is of limited value in dermatopathology because most cutaneous vasculitides affect primarily small dermal vessels.

A practical approach (Table 8-2) for the histopathologist in evaluating small-vessel inflammatory reactions is first to decide whether clear-cut vascular damage is present and sufficient for a designation as vasculitis, then to assess the composition of

TABLE 8-2 Approach to Vasculitis

1. Determine whether vasculitis or vasculopathy is present or absent
2. Primary or secondary
3. Size of vessel and type
   a. Large
   b. Medium
   c. Small
4. Composition of infiltrate
   a. Neutrophilic/leukocytoclastic
   b. Eosinophilic
   c. Lymphocytic
   d. Histiocytic/granulomatous
5. Evaluation for infection
6. Serologic and immunopathologic evaluation
   a. Evaluation for antineutrophil cytoplasmic antibodies, antinuclear antibodies, rheumatoid factor, cryoglobulins
   b. Immunofluorescence and other studies for the detection of immune complexes, for example, immunoglobulin A-fibronectin aggregates
7. Clinical context
   a. Cutaneous involvement only
   b. Extent of systemic involvement

the inflammatory infiltrate (neutrophilic/leukocytoclastic vs. eosinophilic vs. lymphocytic vs. granulomatous), its distribution (superficial, superficial and deep, or deep only) and to look for associated findings, such as microorganisms, that might narrow the differential diagnosis. The context of the histologic findings is important—for example, vasculitic changes may merely be secondary events in the setting of nonvasculitic causes, such as adjacent to an ulcer, herpes virus infection, or trauma. Lesions also have life spans, and a leukocytoclastic vasculitis may evolve into a predominantly lymphocytic or even granulomatous process.

Histopathology alone is inadequate to classify a vasculitic disease process. Integration of data from other laboratory tests, clinical findings, and even arteriography may be critical to arrive at a diagnosis. In particular, clinical and radiographic findings are needed to assess the degree of systemic involvement and range in size of arteries involved. Infection must be excluded via special stains, cultures, and other laboratory studies. Specific systemic diseases that may be associated with vasculitis such as collagen vascular diseases must be excluded.

Antineutrophil cytoplasmic antibodies (ANCAs) are serologic markers that have allowed a new classification of certain vasculitides. These markers may reflect biologic relationships between disease processes (14–18). ANCAs are best demonstrated by a combination of indirect immunofluorescence of normal peripheral blood neutrophils followed by enzyme linked immunoasorbent assay (ELISA) to detect specific autoantibodies. Indirect immunofluorescence assays reveal two staining patterns: cytoplasmic (c-ANCA) and perinuclear (p-ANCA). ELISAs show that the majority of c-ANCAs are autoantibodies to proteinase 3, and most p-ANCAs are specific for myeloperoxidase (MPO).

TABLE 8-3 Antineutrophil Cytoplasmic Antibody (ANCA)–Positive Vasculitides

Disease Process	Antimyeloperoxidase (p-ANCA)	Antiserine Proteinase (c-ANCA)
Wegener's syndrome	Rare (5%)	Common (80%)
Microscopic polyangiitis (polyarteritis)	Common (50%–60%)	Common (45%)
Churg-Strauss syndrome	Common (70%)	Rare (7%)

c-ANCA, cytoplasmic ANCA; p-ANCA, perinuclear ANCA.

These antibodies are especially helpful, in combination with clinical features, in the differential diagnosis of three small-vessel vasculitides: Wegener's syndrome (WG), Churg-Strauss syndrome (CSS), and microscopic polyarteritis (MPA). WG is usually associated with c-ANCA, MPA with either p- or c-ANCA, and CSS with p-ANCA (see following discussion and Table 8-3). These three syndromes are termed "pauci-immune vasculitides" because vascular injury is not associated with immunoglobulin deposition in vessel walls, in contrast to the immune complex–mediated small-vessel injury seen in entities such as Henoch-Schönlein purpura. The role of ANCAs in these disease processes is unclear. ANCAs may induce vasculitis by activating circulating neutrophils and monocytes, making them adhere to vessels and degranulate, and releasing toxic metabolites, thereby causing vascular injury. On the other hand, ANCA may be an epiphenomenon unrelated to the pathogenesis of these diseases.

The following sections discuss the histologic features and clinical differential diagnoses of inflammatory vascular reactions affecting the skin. Vasculitides are categorized first by vessel size. Large-vessel vasculitides with cutaneous or subcutaneous findings include temporal (giant cell) arteritis and Takayasu's arteritis (19–22). Vasculitis affecting medium-sized and small arteries and, in particular, small-vessel vasculitides are discussed in more detail. Small-vessel vasculitides are classified according to the composition of the inflammatory infiltrate: neutrophilic/leukocytoclastic versus lymphocytic versus granulomatous vasculitis.

VASCULITIS OF LARGE AND MEDIUM-SIZED VESSELS: TEMPORAL (GIANT CELL) ARTERITIS

Giant cell arteritis of the elderly primarily affects large or medium-sized arteries in the temporal region. Although the etiology of temporal arteritis is unknown, in some cases actinic degeneration of the internal elastic lamina may provoke granulomatous inflammation in a reaction similar to actinic granuloma.

The arteritis may be unilateral or bilateral and associated with involvement of other cranial arteries—in particular, retinal arteries. The clinical presentation may include pain and

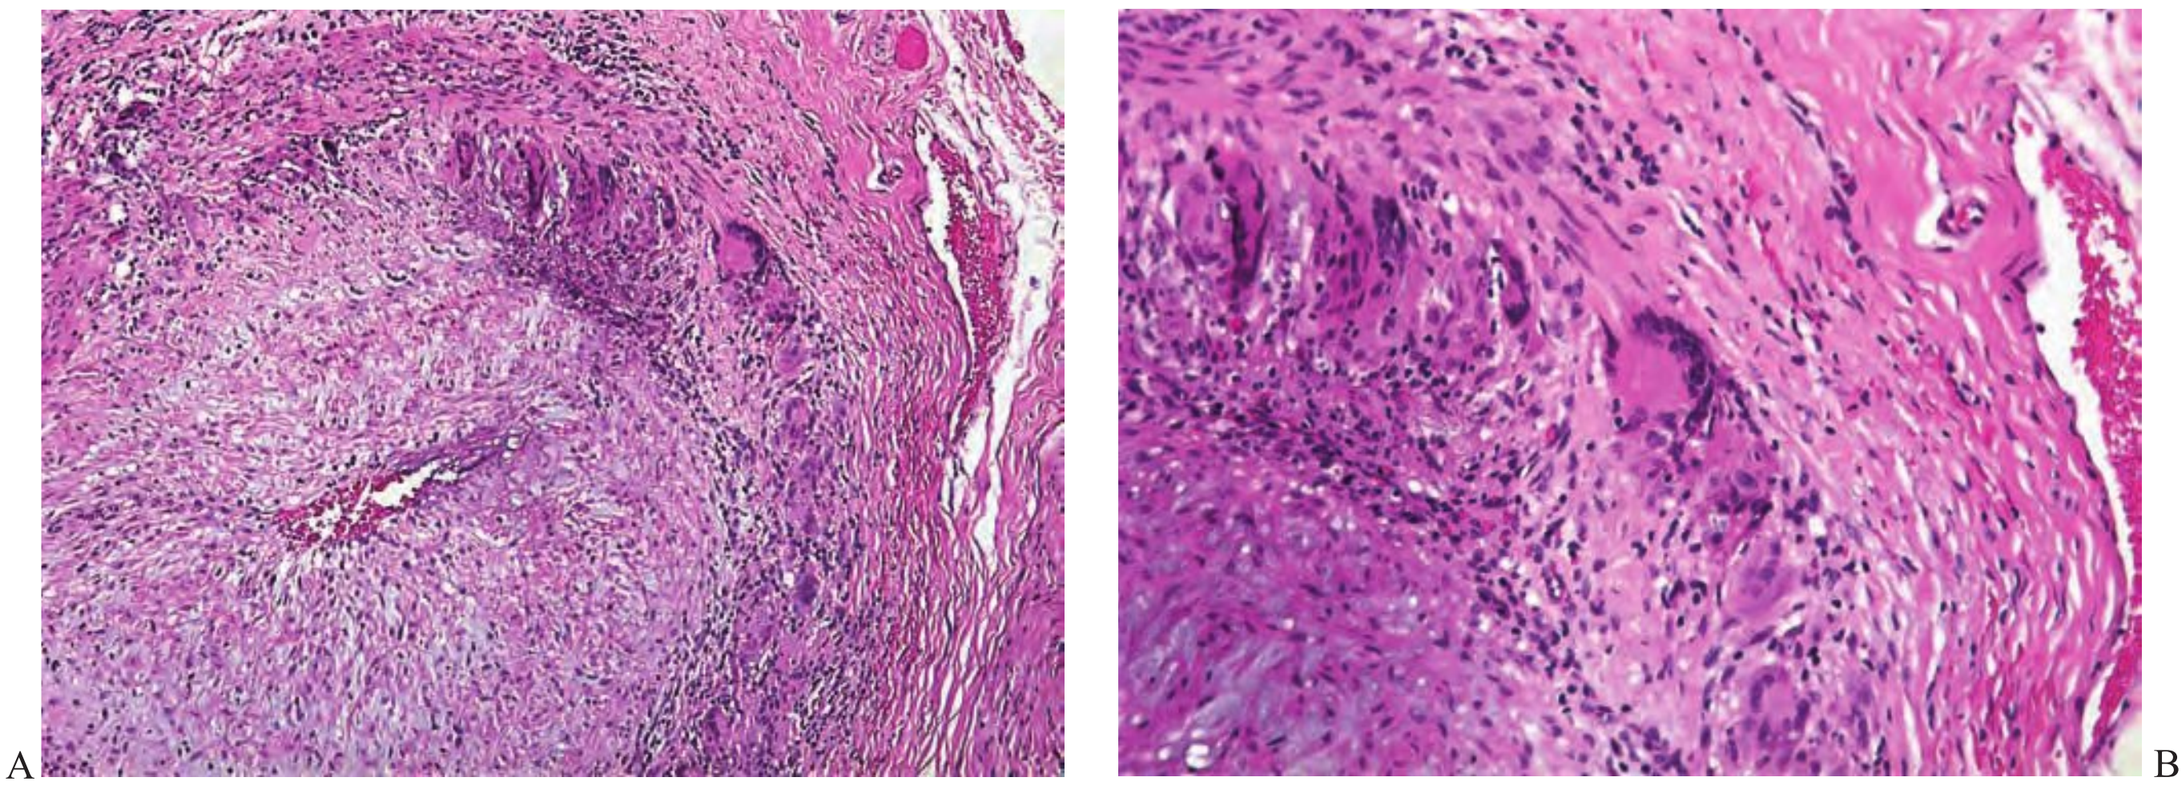

FIGURE 8-3. Giant cell arteritis. (A) and (B) Biopsy of the temporal artery shows a predominantly mononuclear cell infiltrate with a few giant cells in the region of the internal elastic lamina.

tenderness of the forehead and possible sudden visual impairment. Erythema and edema of the skin overlying the involved arteries are commonly seen, and occasionally the scalp may ulcerate (19). The involved artery may be palpable. Clinical laboratory data include a significantly elevated erythrocyte sedimentation rate.

Although the clinical presentation is strongly suggestive of the diagnosis, a biopsy is often performed for confirmation prior to the initiation of systemic steroid therapy. However, results of diagnostic tests are not always positive.

Histopathology. Involved arteries show an inflammatory process of mainly lymphocytes and macrophages that may extend throughout the entire arterial wall (Fig. 8-3). Classically, fragmentation of the lamina elastica and elastophagocytosis by multinucleated giant cells are seen. However, depending on the stage of the disease process, giant cells may not be present, and the inflammatory infiltrate is often unevenly distributed. Step sections may be needed to reveal diagnostic features. In some instances, neutrophils may be present, but this finding should not impede the diagnosis. An elastica van Gieson stain greatly facilitates the evaluation of elastic fibers. Disruption of the internal elastic lamina is not sufficient for diagnosis because this is nonspecific. In late stages, thickening of the intima by deposits of fibrin-like material and myofibroblastic proliferation with subsequent luminal narrowing may be the only findings.

Differential Diagnosis. Not all cases of arteritis involving the temporal artery represent examples of temporal arteritis. Infection-related vasculitis, connective tissue disease, and polyarteritis nodosa might enter into the differential diagnosis. The latter processes often show necrotizing neutrophilic vasculitides (depending on the stage), and diagnosis depends on serologic studies, the absence of infection, and clinical findings.

Takayasu's Arteritis

A large-vessel chronic and fibrosing vasculitis primarily involving the aorta, Takayasu's arteritis (TA) may rarely have cutaneous involvement (21,22). The principal clinical manifestations, usually in women younger than 40 years, include erythematous nodules often of the lower extremities, suggesting erythema nodosum or erythema induratum, or pyoderma gangrenosum–like ulcers (22).

Histopathology. Small and medium arteries of the subcutaneous fat usually show a necrotizing panarteritis with fibrinoid necrosis and sparse inflammatory infiltrates containing lymphocytes and neutrophils. Additional findings may include granulomatous vasculitis, fibrin thrombi without vasculitis, neutrophilic abscesses, and septal and lobular panniculitis.

Differential Diagnosis. Polyarteritis nodosa, pyoderma gangrenosum, and erythema nodosum may be histologically indistinguishable. Additional clinical findings and angiography should facilitate differentiation of TA from other entities.

VASCULITIS AFFECTING MEDIUM-SIZED AND SMALL VESSELS

Vasculitides affecting medium-sized vessels include Kawasaki's syndrome, Takayasu's arteritis, infections, Buerger's disease, polyarteritis nodosa, MPA, WG, CSS, rheumatoid and lupus vasculitis, and giant cell (temporal) arteritis. As noted earlier, there are several methods of classifying vasculitides. WG, MPA, and CSS can be categorized as ANCA-associated vasculitides. Temporal arteritis, WG, and CSS can also be classified as vasculitides associated with granulomatous inflammation.

Kawasaki's Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki's disease is a necrotizing arteritis that usually affects young children, with a peak age incidence at 1 year (20). Mucocutaneous findings are common and include a polymorphous exanthematous macular rash, conjunctival congestion, dry, reddened lips, "strawberry tongue," oropharyngeal reddening, and swelling of the hands and feet—especially the palms and soles.

Typically a nonpurulent cervical lymphadenopathy is associated. Desquamation of the skin of the fingers typically occurs after 1 to 2 weeks, often followed by thrombocytosis. The most serious clinical complications are related to arteritis and thrombosis of coronary arteries.

Histopathology. Cutaneous vasculitis is rare. The macular rash is usually accompanied by nonspecific histologic changes. Characteristic arteritis is typically found in visceral sites, such as the coronary arteries (see Chapter 7).

Superficial Thrombophlebitis

Superficial thrombophlebitis (STP) of small to medium-sized veins is a common condition usually involving the lower extremities and presents as a painful or tender erythematous cordlike structure or nodule (23). Affected individuals often have predisposing factors such as varicose veins, a hypercoagulable state, ingestion of oral contraceptives, or an underlying malignancy. Variants of STP include Mondor's disease and superficial septic thrombophlebitis (usually secondary to peripheral venous infusion).

Histopathology. Small and medium-sized veins of the lower dermis and subcutaneous fat are involved by an acute vasculitis and thrombosis that occludes the vessel lumina. Early lesions demonstrate dense inflammatory infiltrates primarily composed of neutrophils within the vessel wall. The venous wall is significantly thickened by this influx of leukocytes and edema fluid. In later stages one may observe other inflammatory cells, including lymphocytes, histiocytes, and multinucleate giant cells within the walls of veins. Recanalization of the affected veins ultimately occurs with resolution of the process. Gram stain is indicated for the assessment of septic STP.

Differential Diagnosis. Polyarteritis nodosa (PAN) is the principal entity to be distinguished. PAN affects medium-sized arteries rather than veins, is more inflammatory and less thrombogenic than STP, that is, thrombi are usually absent in PAN, and finally PAN shows conspicuous fibrinoid necrosis, whereas STP usually does not. An elastic tissue stain to demonstrate the presence of an internal elastic lamina in an arterial vessel versus its usual absence (not always) in a vein may facilitate the differentiation of PAN and STP.

Mondor's Disease

Mondor's disease is a thrombophlebitis of the subcutaneous veins of the chest region or dorsal vein of the penis (formerly termed sclerosing lymphangiitis) and is often manifested clinically by a cordlike induration (23,24). Generalized symptoms are usually not a feature, and resolution within weeks is the norm.

Histopathology. In early lesions, a polymorphonuclear infiltrate may be present. However, most biopsied lesions show subcutaneous veins with organizing thrombi and fibrous thickened walls that give them a cordlike appearance at scanning magnification.

Pathogenesis. In the majority of cases, the etiology is unknown; however, local interference with venous flow may be a factor. Trauma, connective tissue disease, breast carcinoma (in rare cases), and a variety of other conditions have been associated.

Thromboangiitis Obliterans (Buerger's Disease)

Buerger's disease is a distinctive condition characterized by a segmental, thrombosing inflammatory process affecting intermediate and small arteries and sometimes veins and may be closely related to STP (23). The vessels of the upper and lower extremities are most commonly involved. The condition almost exclusively affects smokers. Cutaneous findings are manifestations of ischemic injury.

Histopathology. Active lesions are characterized by luminal thrombotic occlusion and a mixed inflammatory cell infiltrate of the vessel wall, characteristically with microabscesses. Later, the thrombus is organized and its lumen may be recanalized (Fig. 8-4). A granulomatous reaction may be present as well.

Differential Diagnosis. The histologic findings in Buerger's disease have been believed to be characteristic. The prevalent current opinion is that these findings are nonspecific and probably occur in other processes, including nonspecific thrombosis and inflammation of intermediate-sized arteries and veins.

Polyarteritis Nodosa

In 1866, Kussmaul and Maier reported the case of a 27-year-old man with fever, abdominal pain, muscle weakness, peripheral neuropathy, and renal disease (25). They termed the fatal illness *periarteritis nodosa*, referring to nodular protuberances along the course of medium-sized muscular arteries, which histologically were characterized by inflammation predominantly at the periphery of the vessel walls, with vessel-wall destruction. Ferrari noted in 1903 the more characteristic presence of inflammatory cells within all levels of the affected vessels and suggested the term *polyarteritis* instead of *periarteritis* (26). The term PAN is believed to subsume three entities: (a) classic systemic PAN, (b) cutaneous PAN, and (c) MPA (27,28). Classic PAN is a multisystem disorder characterized by inflammatory vasculitis involving arterioles and small and medium-sized arteries. According to some authors, cutaneous PAN is the only variety of PAN consistently involving the deep dermis and subcutaneous fat with diagnostic features of arteritis. Some authors maintain that if there is no evidence of systemic involvement by (skin-limited) PAN at the time of initial diagnosis, then the condition will remain confined to the skin, despite a potentially prolonged clinical course with multiple recurrences (29).

Clinical Features. PAN is more common in men than women and usually occurs between the ages of 20 and 60 years. Clinical manifestations may be dramatic and protean. Fever, malaise, weight loss, weakness, myalgias, arthralgias, and anorexia are common symptoms, reflecting the systemic nature of the disease. Other findings may reflect infarction of specific organs. Renal involvement, present in about 75% of patients, is the most common cause of death. Hematuria, proteinuria, hypertension, and azotemia may result from both infarction owing to disease of renal arteries and sometimes focal, segmental necrotizing

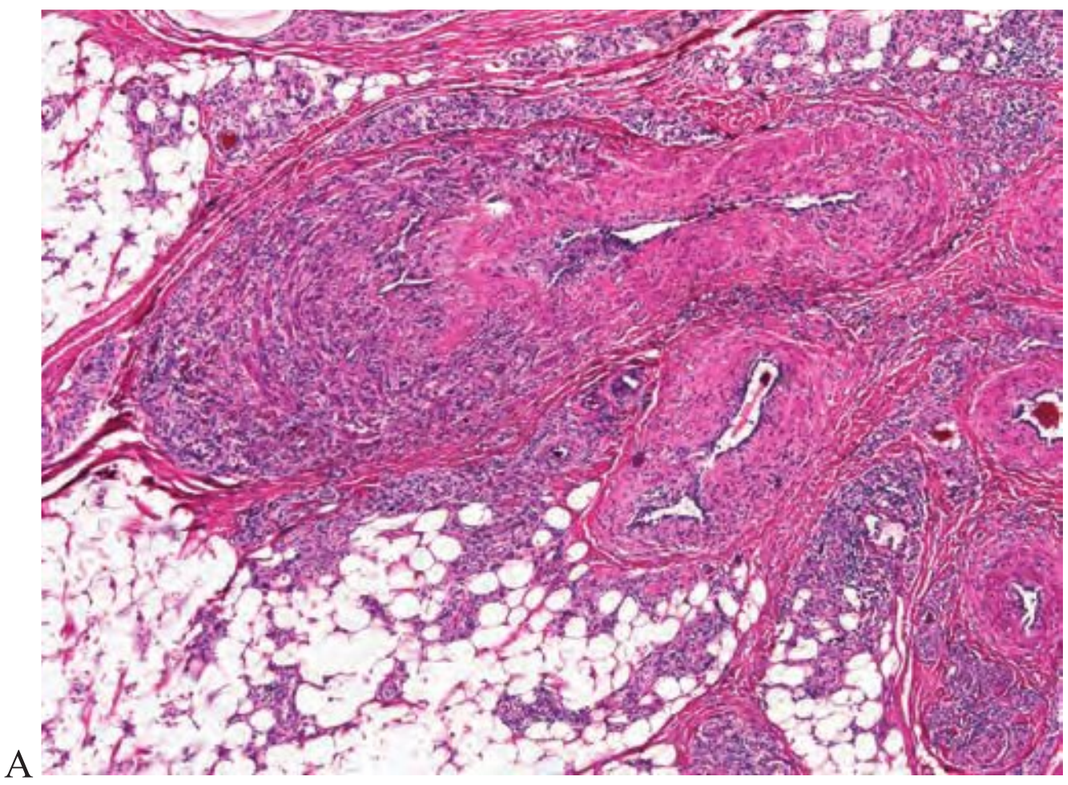

FIGURE 8-4. Thromboangiitis obliterans (Buerger's disease). A mixed inflammatory infiltrate is present in the wall of a large vein, and its lumen is recanalized in a 35-year-old man (A, B) with associated ischemic ulceration in the distal extremity (C).

glomerular lesions suggesting involvement of small vessels. Acute abdominal crises, strokes, myocardial infarction, and mononeuritis multiplex result from involvement of the relevant arteries. Arteriography of visceral arteries often shows multiple aneurysms that are highly suggestive of PAN. ANCAs are generally absent in patients with predominately medium-sized vessel involvement. Symptoms such as asthma, Löffler's syndrome, and rashes may be related to the hypereosinophilia sometimes seen in these patients. Cutaneous manifestations include subcutaneous nodules that may pulsate or ulcerate, ecchymoses, and gangrene of fingers and toes (Fig. 8-5A). Livedo reticularis, bullae, papules, scarlatiniform lesions, and urticaria occur in some patients. A limited form of PAN without visceral involvement may exist, but this concept is controversial (27–29). The so-called cutaneous polyarteritis nodosum may not be limited to the skin but may also affect muscle, peripheral nerve, and joints. The course of disease is described as benign but protracted with steroid dependence.

Histopathology. The characteristic lesion of classic PAN is a panarteritis involving medium-sized and small arteries (Fig. 8-5B, C). Even though in classic PAN the arteries show the characteristic changes in many visceral sites, affected skin often shows only small-vessel disease, and arterial involvement is typically focal. The changes affecting cutaneous small vessels are usually those of a necrotizing leukocytoclastic vasculitis. If there is a clinical presentation of cutaneous nodules, panarteritis similar to visceral lesions is usually detected. In classic PAN, the lesions typically are in different stages of development (i.e., fresh and old). Early lesions show degeneration of the arterial wall with deposition of fibrinoid material. There is partial to complete destruction of the external and internal elastic laminae. An infiltrate present within and around the arterial wall is composed largely of neutrophils, showing evidence of leukocytoclasis, although it often contains eosinophils. At a later stage, intimal proliferation and thrombosis lead to complete occlusion of the lumen with subsequent ischemia and possibly ulceration. The infiltrate also may contain a significant number of lymphocytes, histiocytes, and some plasma cells, which may extend far into the surrounding perivascular tissue and may be predominant at a certain stage. In the healing stage, there is fibroblastic proliferation extending into the perivascular area. The small vessels of the middle and upper dermis often exhibit a nonspecific lymphocytic perivascular infiltrate.

Differential Diagnosis. Vasculitis indistinguishable from PAN may be observed in infections (bacterial, e.g., pseudomonas;

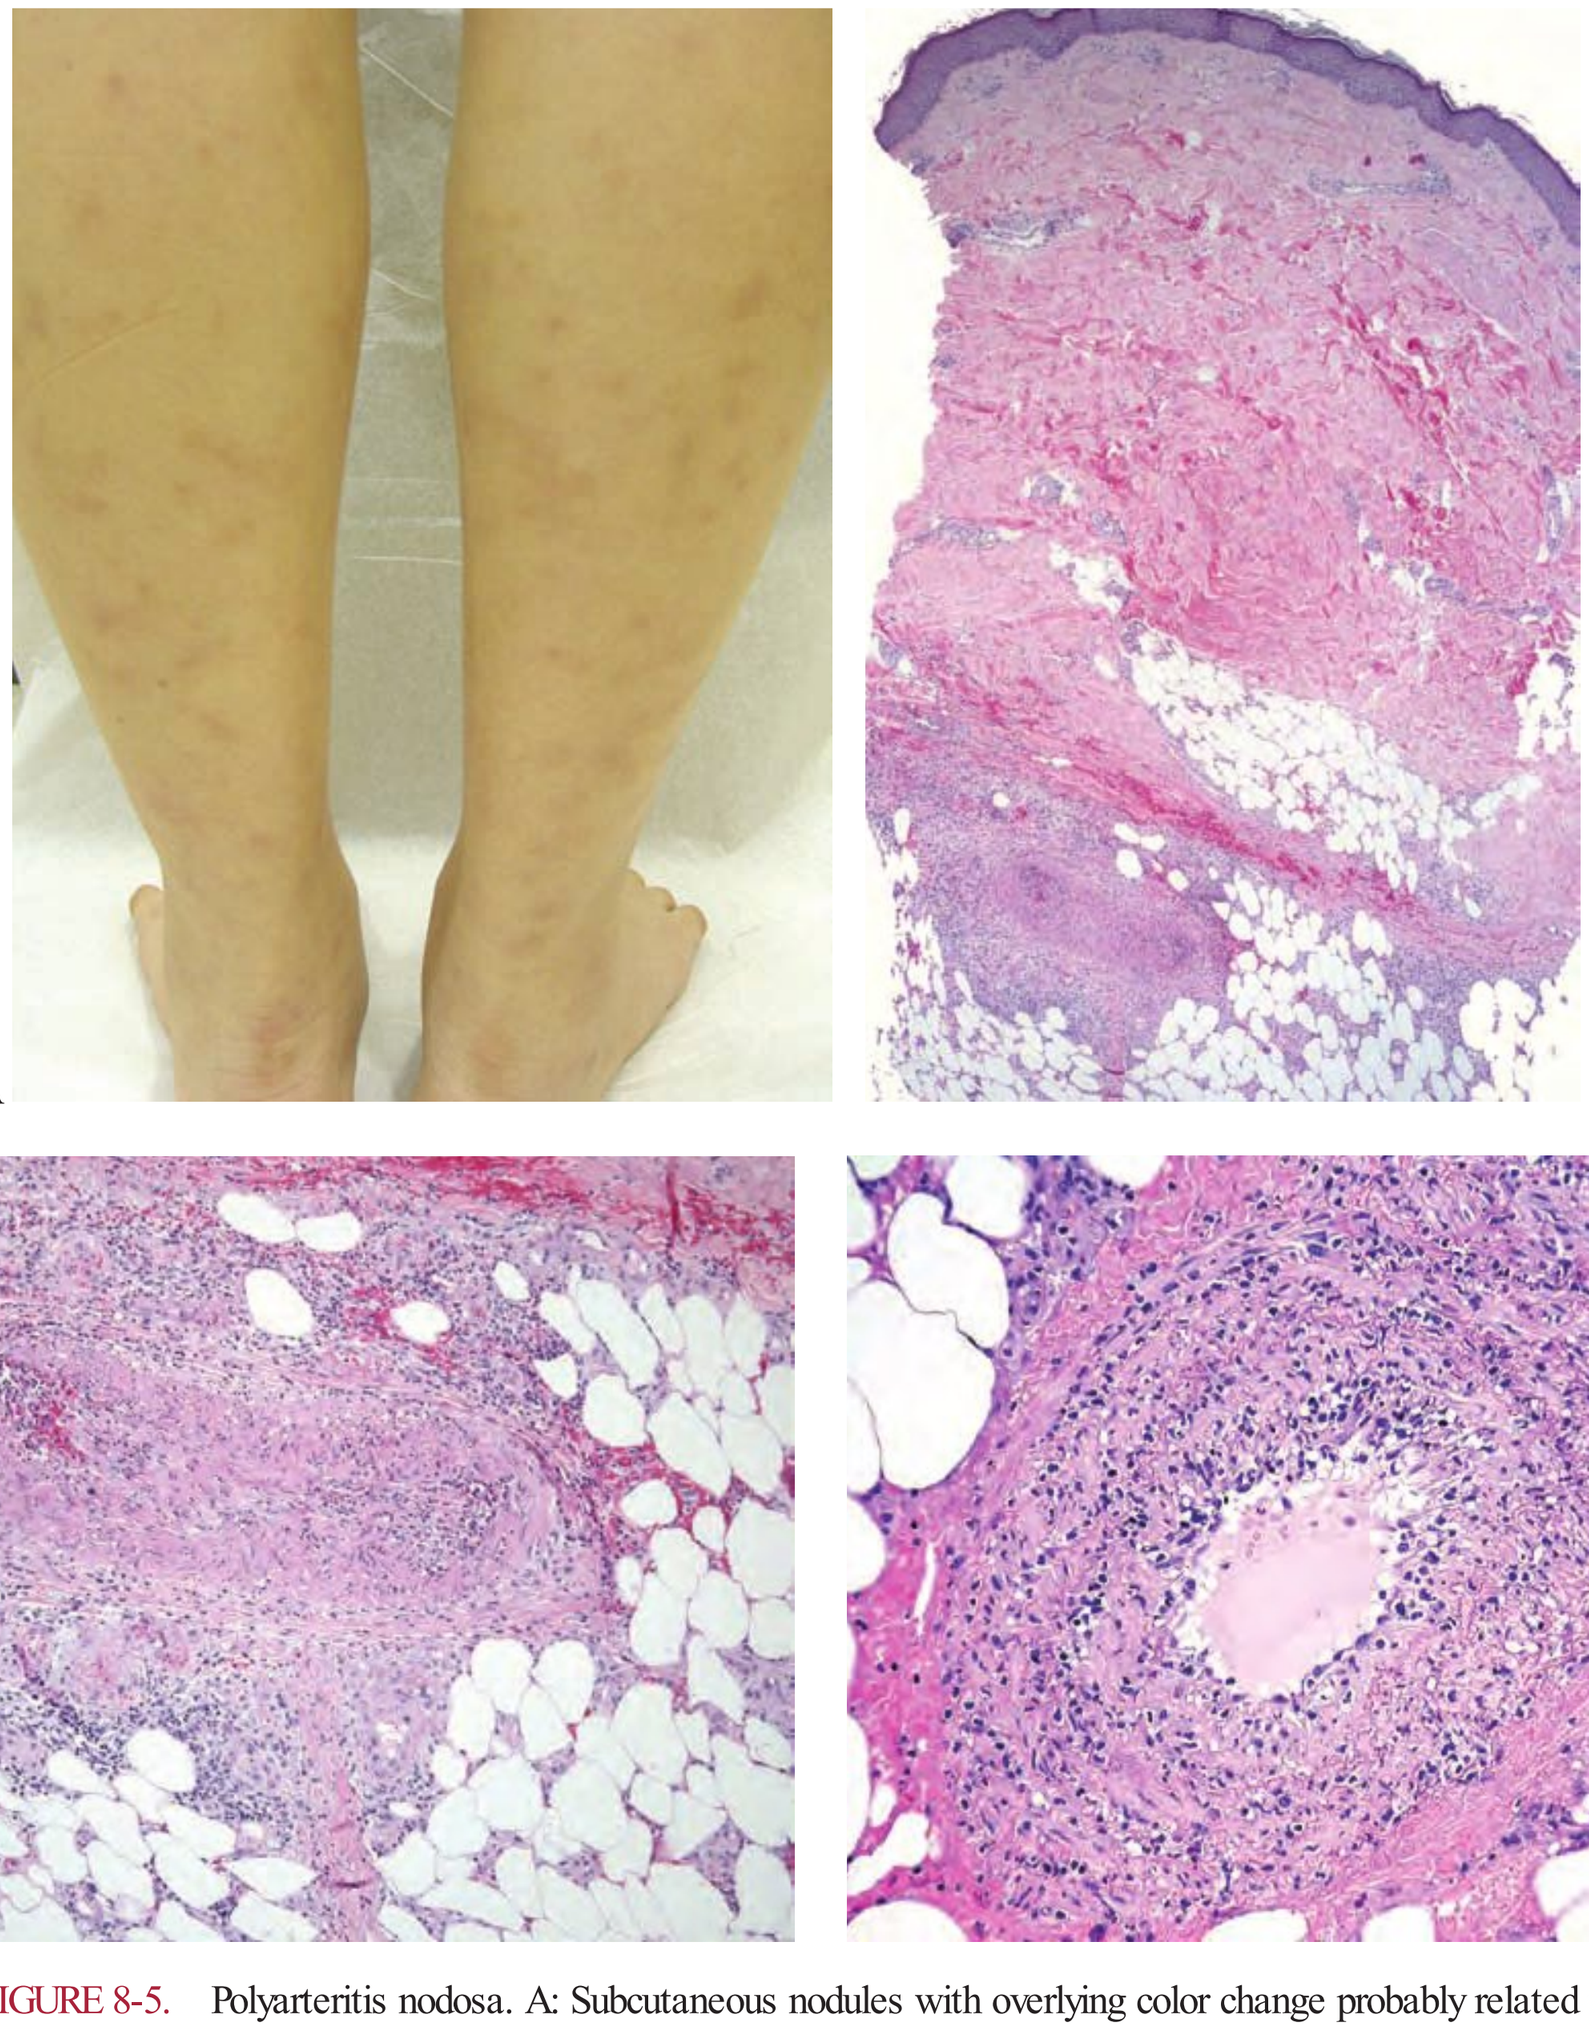

FIGURE 8-5. Polyarteritis nodosa. A: Subcutaneous nodules with overlying color change probably related to telangiectasias and/or hemorrhage. B: A small artery in the subcutis is surrounded and partially obliterated by a cellular inflammatory infiltrate. C: Necrotizing leukocytoclastic vasculitis, with eosinophilic change of the vessel wall, neutrophilic infiltration, and leukocytoclasia. D: Another example of neutrophil-rich, medium-sized vasculitis with focal necrotizing features in a subcutaneous vessel in a patient with polyarteritis nodosa.

viral, e.g., hepatitis B or HIV), in connective tissue diseases (lupus erythematosus, rheumatoid arthritis), in TA, WG, and CSS, and in other settings—for example, acute myelogenous leukemia—without explanation. MPA can overlap considerably with PAN, as discussed later.

Pathogenesis. The pathogenesis of classic PAN is poorly understood. Direct immunofluorescence testing of skin lesions of PAN shows some immune deposits in dermal vessels. However, they may reflect a secondary event after vascular injury from another cause. ANCAs are generally absent in patients with predominately medium-sized vessel involvement and thus are not involved in the pathogenesis of these cases of PAN.

Microscopic Polyangiitis

Davson et al. distinguished classic and microscopic polyarteritis nodosa (30). *Classic polyarteritis nodosa* is to a greater degree a disease of medium-sized vessels, so that ischemic glomerular

lesions are common but glomerulonephritis is rare. *Microscopic polyarteritis nodosa*, on the other hand, refers to a systemic small-vessel vasculitis primarily affecting arterioles and capillaries that is typically associated with focal necrotizing glomerulonephritis with crescents and serum myeloperoxidase-antineutrophil cytoplasmic autoantibodies. Involvement of the small vessels of the kidneys, lungs, and skin gives MPA a particular clinical picture and separates MPA from classic polyarteritis nodosum (30–36).

Clinical Features. The majority of patients with MPA are men and older than 50 years of age. Prodromal symptoms include fever, myalgias, arthralgias, and sore throat. The most common clinical feature is renal disease, manifesting as microhematuria, proteinuria, or acute oliguric renal failure. Although cutaneous involvement is rare in classic PAN, at least 30% to 40% of patients with MPA have skin changes. These include erythematous macules (100% in one study), livedo reticularis, palpable purpura, splinter hemorrhages, and ulcerations. Tender erythematous nodules are exceedingly rare in MPA. Pulmonary involvement without granulomatous tissue reaction occurs in approximately one third of patients. Other organ systems (e.g., gastrointestinal tract, central nervous system, serosal and articular surfaces) also may be affected, but this is less common. Serious clinical complications usually arise from renal and pulmonary disease.

Histopathologic Features. A leukocytoclastic vasculitis primarily affecting arterioles, venules, and capillaries is observed. Necrotizing vasculitis of medium-sized arteries typical of classic PAN is present on occasion. Cutaneous palisading granulomatous inflammation may be seen rarely.

Differential Diagnosis. MPA and classic PAN may not be distinguishable in every case, practically speaking. Glomerulonephritis, typical skin signs, ANCA positivity, and lack of arteriography findings (aneurysms and stenoses reflecting medium-sized vessel involvement) favor MPA over classic PAN (31). MPA also tends not to be associated with viral hepatitis, in contrast to some cases of classic PAN. Biopsy findings are less useful in distinguishing between these two syndromes because the size of diseased vessels detected is highly dependent on biopsy site, size of specimens, and number of tissue samples. Thus, lack of medium-size vessel involvement in a biopsy by no means excludes classic PAN. Conversely, detection of small-vessel involvement also does not exclude classic PAN, which may show small-vessel disease. A number of cases of vasculitis show overlapping features, leading to the introduction of the term "overlapping syndrome of vasculitis" to encompass vasculitis affecting both small and medium-sized arteries (31). The differential diagnosis also includes Wegener's vasculitis and other small-vessel vasculitides that are occasionally ANCA-positive, such as certain drug reactions. The granulomatous inflammation of WG should be lacking in MPA; however, these two entities share many features, and some researchers believe that the distinction of MPA from WG is largely artificial (33).

GRANULOMATOUS VASCULITIS AND GRANULOMATOUS VASCULAR REACTIONS

Over the life spans of many inflammatory reactions involving blood vessels, histiocytes may predominate at a certain stage and form granulomas (Fig. 8-6) (1,4). Granuloma formation

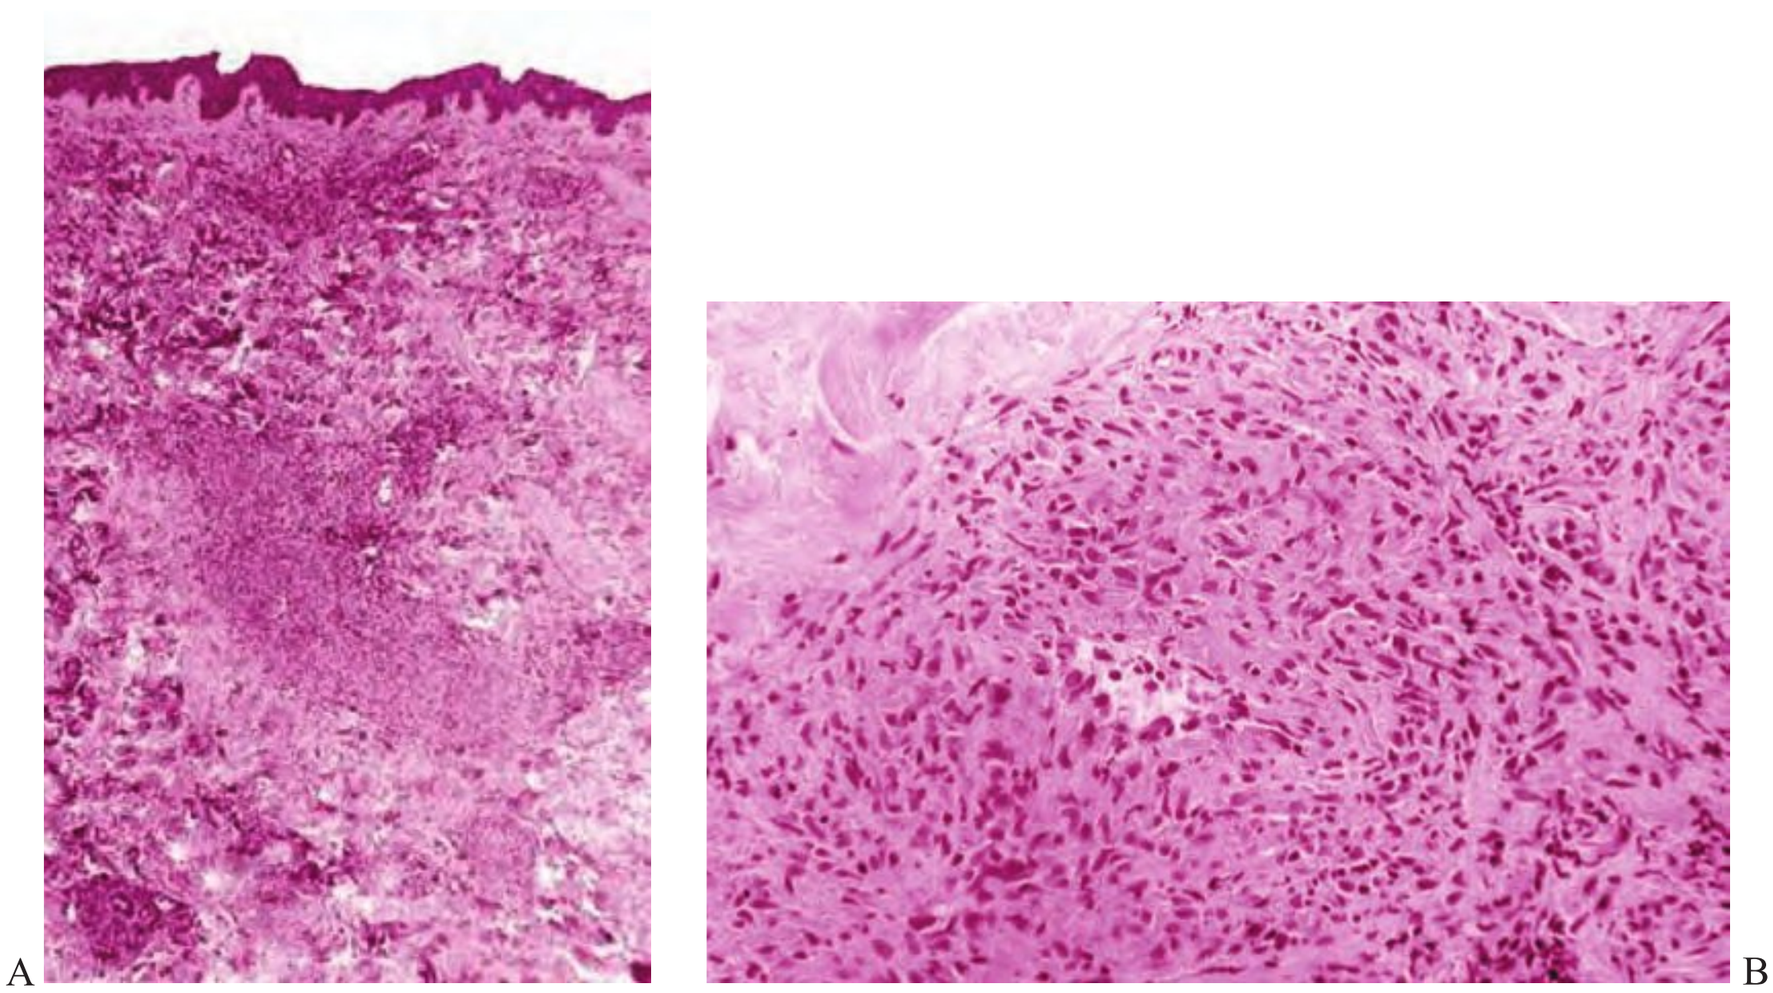

FIGURE 8-6. Granulomatous vasculitis. Note perivascular histiocytic/granulomatous infiltrate (A) and focal vascular damage (B).

Erythema nodosum and erythema nodosum–like reactions

may occur with no or minimal vascular wall damage or may be associated with fibrinoid degeneration of the vessel wall. In the latter situation, a granulomatous vasculitis is present. The main disease processes that need to be considered in the differential diagnosis of a granulomatous vascular reaction are listed in Table 8-4.

The two main disease processes in which granulomatous vasculitis has been described as prominent and fairly characteristic, although nonspecific, are Wegener's granulomatosis and Churg-Strauss syndrome, which are discussed in more detail here. However, the most common cutaneous histologic finding in both diseases is leukocytoclastic vasculitis. The granulomatous inflammation seen in the skin usually is not angiodestructive. Other disease processes that enter the differential diagnosis are also mentioned.

Churg-Strauss Syndrome

The classic clinicopathologic syndrome of Churg-Strauss is characterized by asthma, fever, hypereosinophilia, eosinophilic tissue infiltrates, necrotizing vasculitis, and extravascular granuloma formation. Short of an autopsy, the classic pathologic triad of necrotizing vasculitis, eosinophilic tissue infiltration, and extravascular granulomas is extremely difficult to demonstrate because of the focality of the process (36). A broader definition of CSS requiring asthma, hypereosinophilia greater than 1.5×10^9/L, and systemic vasculitis involving two or more extrapulmonary organs has been suggested. Considerable overlap with other systemic vasculitides and with other inflammatory disorders associated with eosinophils, such as eosinophilic pneumonitis, has brought the legitimacy of the CSS into question.

Clinical Features. Despite multiple reports, CSS appears to be rare. Between 1950 and 1995, only 120 cases were identified at the Mayo clinic (37). The incidence of CSS is similar in males and females. It typically presents in the third or fourth decade of life. Patients tend to display several phases of disease development, from nonspecific symptoms of asthma and allergic rhinitis (prodromal phase) to a phase of hypereosinophilia with eosinophilic pneumonitis or gastroenteritis (second phase) and, finally, to systemic vasculitis (third phase). The internal organs most commonly involved are the lungs, the gastrointestinal tract, and, less commonly, the peripheral nerves and the heart. In contrast to PAN, renal failure is rare. The three disease phases do not always occur sequentially but may on occasion present simultaneously. There is also a limited form of allergic granulomatosis, in which, in addition to preexisting asthma, the lesions are confined to the conjunctiva, the skin, and subcutaneous tissue.

Two types of cutaneous lesions occur in about two thirds of all patients: (a) hemorrhagic lesions varying from petechiae to palpable purpura to extensive ecchymoses, sometimes accompanied by necrotic ulcers and often associated with areas of erythema (similar to Henoch-Schönlein purpura), and (2) cutaneous-subcutaneous nodules. The most common sites of skin lesions are the extremities, but the trunk may also show involvement. In some instances, the petechiae and ecchymoses are generalized. Other skin manifestations include urticaria, erythematous macules, and livedo reticularis.

Diagnostically helpful laboratory findings include an elevated peripheral eosinophil count. CSS is also associated with ANCA. Serum samples from patients with CSS obtained during an active phase of the disease contain anti-MPO (p-ANCA) in the majority of cases (approximately 70%). The levels of anti-MPO have been found to correlate with disease activity. Anti-MPO is found less often in patients with limited forms of the disease. Antiserine proteinase antibodies (c-ANCA) may infrequently be found in patients with CSS (approximately 7%).

Histopathology. The areas of cutaneous hemorrhage typically show leukocytoclastic vasculitis (LCV). However, eosinophils may be conspicuous. In some instances, the dermis shows a granulomatous reaction called palisading necrotizing granuloma composed predominantly of radially arranged histiocytes and, frequently, multinucleated giant cells centered around degenerated collagen fibers (Fig. 8-7). The central portions of the granulomas contain degenerated collagen fibers and disintegrated cells, particularly eosinophils, in great numbers—the so-called "red" palisading granulomas. These palisading granulomas can be embedded in a diffuse inflammatory exudate rich in eosinophils. In the subcutaneous tissue, the granulomas may attain considerable size through expansion and confluence, giving rise to the clinically apparent cutaneous-subcutaneous nodules. Initially believed to be characteristic histologic features, these granulomas were referred to as Churg-Strauss granulomas. However, they are not always present and are not a prerequisite for the diagnosis. Moreover, more recent studies have shown that similar findings can also be observed in other disease processes, such as connective tissue diseases (rheumatoid arthritis and lupus erythematosus), Wegener's granulomatosis, PAN, lymphoproliferative disorders, subacute bacterial endocarditis, chronic active hepatitis, and inflammatory bowel disease (Crohn's disease and ulcerative colitis) (38). Despite the

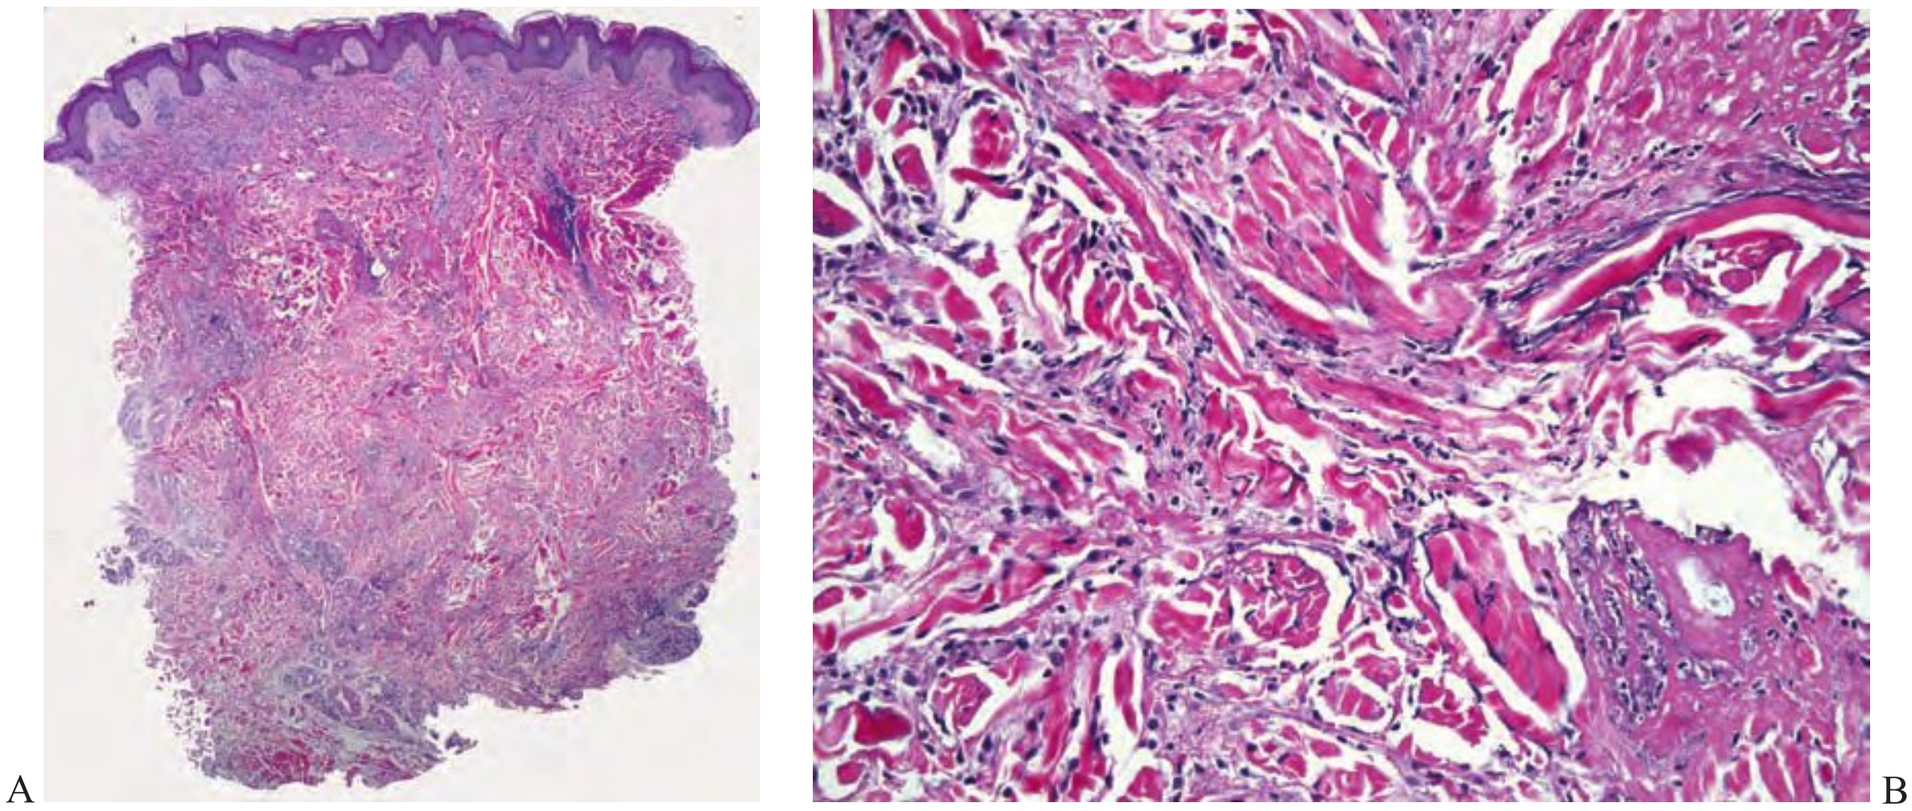

FIGURE 8-7. Palisading necrotizing granuloma. A: Scanning magnification shows a moderately dense cellular infiltrate with an ill-defined palisading pattern around areas of collagen degeneration. B: The infiltrate comprises mainly histiocytes, and collagen degeneration is prominent. C: Degenerating cells including eosinophils are present in some foci. This lesion, formerly called Churg-Strauss granuloma, is not diagnostic of any particular entity, and, in addition to Wegener's syndrome, may also be seen in connective tissue diseases, polyarteritis nodosa, lymphoproliferative disorders, subacute bacterial endocarditis, chronic active hepatitis, and inflammatory bowel disease (see text).

common occurrence of LCV and CS granulomas in CSS, granulomatous arteritis may also be observed (39).

Differential Diagnosis. CSS is a clinicopathologic entity. As such, a diagnosis of CSS depends on the clinical picture of respiratory disease, particularly a history of asthma, p-ANCA positivity, and histology compatible and supportive of this diagnosis, especially granulomatous inflammation, necrotizing angiitis, and eosinophilia. The principal differential diagnosis is from PAN, MPA, WG, and the conditions mentioned previously that may show extravascular necrotizing granulomas. There appears to be significant overlap with WG and PAN. Particular patients may shift from one disease category to another over time.

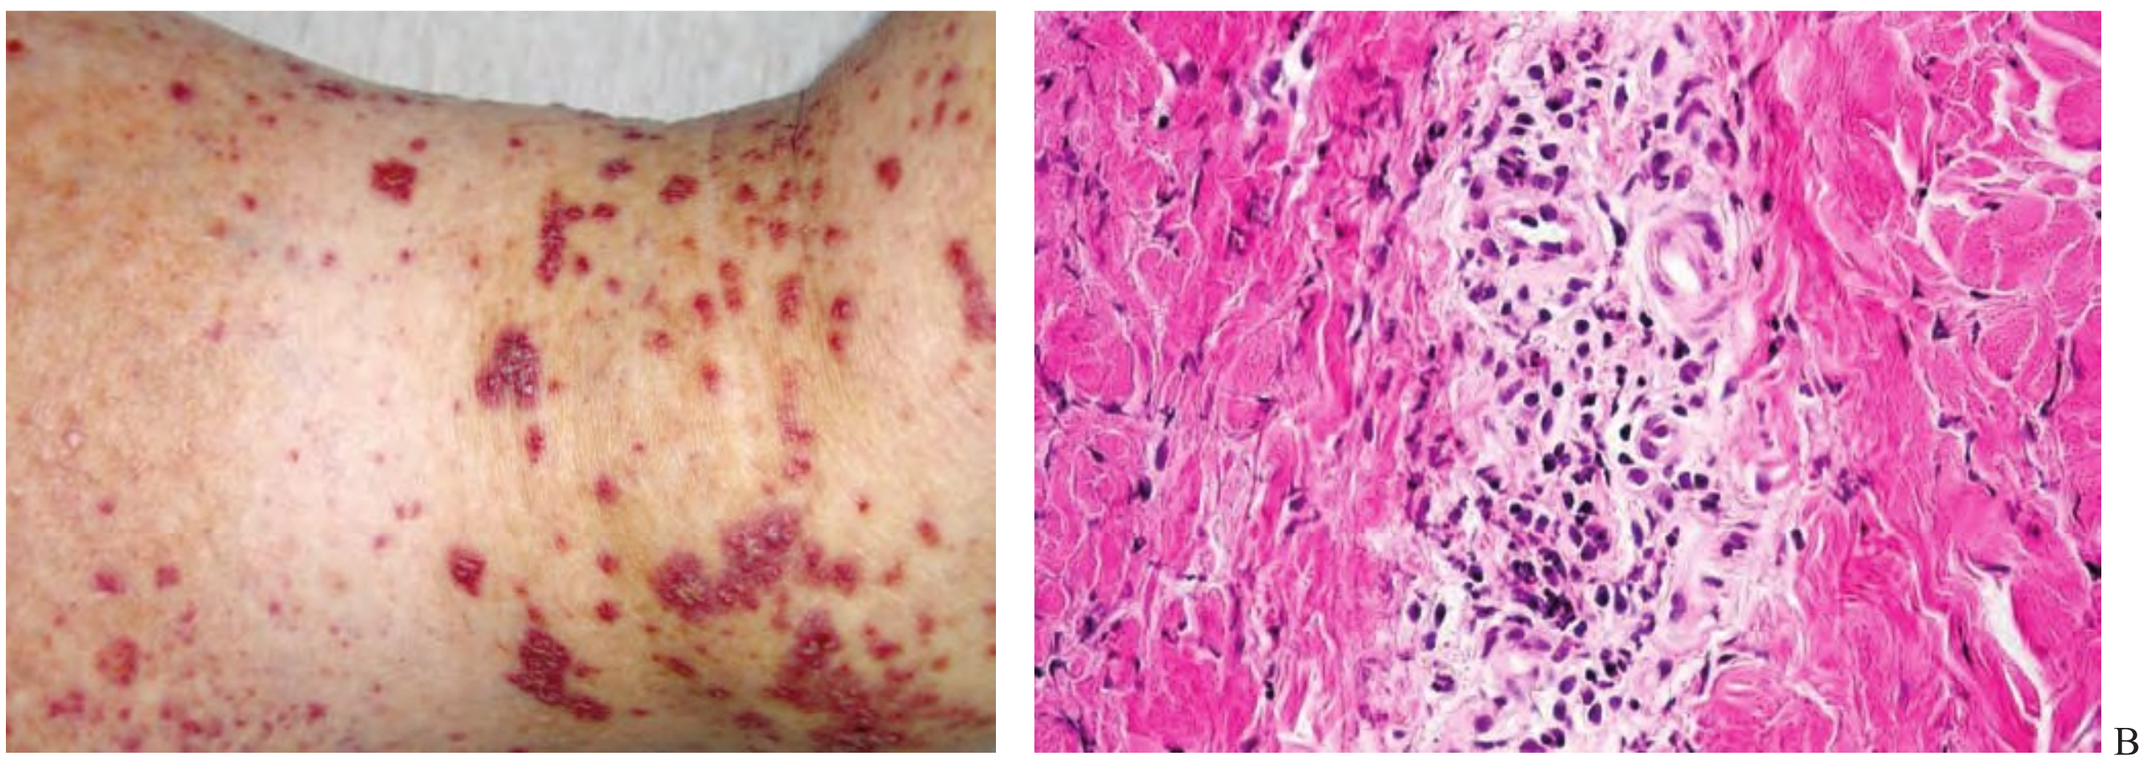
Wegener's Granulomatosis

Wegener's granulomatosis was first recognized as a distinct clinicopathologic disease process in 1936, when Wegener reported three patients with a "peculiar rhinogenic granulomatosis." Goodman and Churg summarized postmortem studies in 1954, from which evolved the classic triad of this clinicopathologic complex characterized by (a) necrotizing and granulomatous inflammation of the upper and lower respiratory tracts, (b) glomerulonephritis, and (c) systemic vasculitis (40). Liebow and Carrington (36) and later Deremee et al. (41) described limited variants of the disease involving the respiratory tract only.

With the recognition of an association between ANCAs and WG, the concept of WG has been modified and the necessity of demonstrating granulomatous inflammation as a prerequisite for the diagnosis of WG has been challenged. A less restrictive definition was proposed in the Third International Workshop on ANCA in 1991 (3) as *Wegener's vasculitis*. Subsumed under this less restrictive category are ANCA-positive patients with clinical presentations of WG, such as sinusitis, pulmonary infiltrates, and nephritis, and documented necrotizing vasculitis, but without biopsy-proven granulomatous inflammation. Both classic WG and Wegener's vasculitis are considered different manifestations of *Wegener's syndrome*, a more generic term.

Two thirds of patients with WG are male, and the mean age of diagnosis is 35 to 54 years. The vast majority of patients

are white. The clinical presentation is extremely variable, ranging from an insidious course with a prolonged period of nonspecific constitutional symptoms and upper respiratory tract findings to abrupt onset of severe pulmonary and renal disease. The most commonly involved anatomic sites include upper respiratory tract, lower respiratory tract, and kidneys. Other organ systems that are commonly affected include joints and skin. Migratory, polyarticular arthralgia of large and small joints is found in up to 85% of patients with WG. Cutaneous involvement is extremely variable in different series, ranging from about 10% to more than 50% of patients. Skin involvement presents most commonly as palpable purpura. Other cutaneous manifestations include macular erythematous eruptions, papules, papulonecrotic lesions, subcutaneous nodules with and without ulceration, and pyoderma gangrenosum–like ulcerations. Occasionally cutaneous lesions are the first manifestation of WG. However, because of their nonspecific appearance, they are infrequently recognized as presentations of WG.



The development of assays for ANCA has greatly facilitated the diagnosis of WG and the monitoring of disease activity. In a series of 106 patients with WG, sera from 88% of the patients with active disease and 43% of the patients in remission were positive for antiserine proteinase (c-ANCA) (41).

Histopathology. The majority of skin biopsies in patients with WG show nonspecific histopathology, and not all of them are directly related to the pathophysiology of WG (42–44). Such nonspecific reaction patterns include perivascular lymphocytic infiltrates. However, in about 25% to 50% of patients, cutaneous lesions have fairly characteristic histopathologic findings. The more frequent distinct reaction patterns include necrotizing/leukocytoclastic small-vessel vasculitis and granulomatous inflammation. Minute foci of tissue necrosis are surrounded by histiocytes and are similar to lesions described in open lung biopsies from WG patients. The palisading granulomas resembling those of Churg-Strauss syndrome may occur, except that the center of the WG granuloma contains necrobiotic collagen and basophilic fibrillar necrotic debris admixed with neutrophils (the "blue" palisading granulomas) (Fig. 8-7). True granulomatous vasculitis appears to be rare.

Differential Diagnosis. Other conditions causing LCV and granulomatous reactions include CSS, metastatic Crohn's disease, rheumatoid arthritis, and sarcoidosis. Granulomatous vascular reactions may also be a manifestation of T-cell lymphomas such as angiocentric T-cell lymphoma or panniculitic T-cell lymphoma. The distinction between CSS and WG relies primarily on the clinical findings. In contrast to WG, CSS is associated with asthma, lacks lesions in the upper respiratory tract, rarely shows severe renal involvement, and typically is accompanied by eosinophilia or eosinophilic infiltrates and p-ANCA positivity. The distinction between MPA and WG may be difficult clinically; however, MPA should lack granulomatous inflammation.

SMALL-VESSEL NEUTROPHILIC/ LEUKOCYTOCLASTIC VASCULITIS

A large number of different disease processes can be accompanied by small-vessel vasculitis with predominantly neutrophilic infiltrates. The clinical and histologic manifestations are thus fairly nonspecific (Fig. 8-8). The main diseases to be considered are listed in Table 8-5 (3–14,45,46).

A B

B: Hypersensitivity vasculitis showing an upper dermal small blood vessel with neutrophil-rich vasculitis and other adjacent postcapillary venules with a perivascular mononuclear cell infiltrate without features of vasculitis. The specimen was obtained from a 6-day-old purpuric macule.

TABLE 8-5 Differential Diagnosis of Cutaneous Neutrophilic Small-Vessel Vasculitis, Categorized on the Basis of Proposed Pathogenic Mechanisms

- Infection
  - Bacterial (gram-positive/gram-negative organisms, mycobacteria, spirochetes)
  - Rickettsial
  - Fungal
  - Viral
- Immunologic injury
  - Immune complex mediated
    - Henoch-Schönlein purpura
    - Urticarial vasculitis
    - Cryoglobulinemia
    - Serum sickness
    - Connective tissue diseases
  - Autoimmune diseases
    - Infection-induced immunologic injury (e.g., hepatitis B or C, streptococcal)
  - Drug induced
  - Paraneoplastic processes
  - Behçet's disease
    - Erythema elevatum diutinum
  - Antineutrophil antibody associated
    - Wegener's granulomatosis
    - Microscopic polyangiitis
    - Churg-Strauss syndrome
    - Some drug-induced vasculitis
  - Unknown
    - Polyarteritis nodosa

Histopathology of Neutrophilic Small-Vessel Vasculitis. Neutrophilic small-vessel vasculitis is a reaction pattern of small dermal vessels, almost exclusively postcapillary venules, characterized by a combination of vascular damage and an infiltrate composed largely of neutrophils (Fig. 8-8). Because there is often fragmentation of nuclei (karyorrhexis or leukocytoclasis), the term *leukocytoclastic vasculitis* is frequently used. Depending on its severity, this process may be subtle and limited to the superficial dermis or be pandermal and florid and associated with necrosis and ulceration. If edema is prominent, a subepidermal blister may form. If the neutrophilic infiltrate is dense and there is pustule formation, the term *pustular vasculitis* may be applied (Fig. 8-9). In a typical case of LCV, the dermal vessels show swelling of the endothelial cells and deposits of strongly eosinophilic strands of fibrin within and around their walls. The deposits of fibrin and the marked edema together give the vessel walls a "smudgy" appearance referred to as *fibrinoid degeneration*. Actual necrosis of the perivascular collagen, however, is seen only rarely in conjunction with ulcerative lesions. If the vascular changes are severe, luminal occlusion of vessels may be observed. The cellular infiltrate is present predominantly around the dermal blood vessels or within the vascular walls, so that the outline of the blood vessels may appear indistinct. The infiltrate consists mainly of neutrophils and of varying numbers of eosinophils and mononuclear cells. The infiltrate also is scattered throughout the upper dermis in association with fibrin deposits between and within collagen bundles. Extravasation of erythrocytes is commonly present.

As with any inflammatory process, the appearance of the reaction pattern depends on the stage at which the biopsy is taken. In older lesions, the number of neutrophils may be decreased and the number of mononuclear cells increased so that mononuclear cells may predominate, and a designation of a lymphocytic or even granulomatous vasculitis or vascular reaction might be made.

Pathogenesis. Many disease processes may exhibit LCV. The major causes of vasculitis are infection and immune-mediated inflammation. Table 8-5 categorizes vasculitides on the basis of suggested pathogenetic mechanisms. Although T-cell–mediated inflammation has been implicated in large-vessel vasculitides, antibody-mediated inflammation seems to play a prominent role in small-vessel vasculitis. Its final common pathway typically involves neutrophil and monocyte activation with adherence to endothelial cells, infiltration of the vessel wall, and release of lytic enzymes and toxic metabolites. This final pathway of vascular injury may be initiated by (a) the deposition of immune complexes, (b) direct binding of antibodies to antigens in vessel walls, and (c) activation of leukocytes by antibodies with specificity for leukocyte antigens (ANCAs).

For example, hepatitis C virus (HCV) is directly linked to a subset of mixed cryoglobulinemia, which is an immune complex–mediated vasculitis (46). HCV particles and nonenveloped nucleocapsid protein participate in the formation of immune complexes. Clonal expansion of rheumatoid factor–synthesizing B lymphocytes is fundamental to the development of mixed cryoglobulinemia. Such B-cell clonal expansion primarily takes place in the liver and correlates directly with intrahepatic HCV viral load, indicating the critical role of HCV in the pathogenesis of such B-cell clonality.

However, it must be stressed that an immune complex etiology has been invoked much too often to explain all forms of vasculitis and particularly small-vessel vasculitis. In many instances, immune complexes are not the primary events in vascular injury but are simply epiphenomena.

Diagnostic Approach to Neutrophilic Small-Vessel Vasculitis. As already mentioned, the clinical and histologic manifestations are fairly nonspecific for this category of vasculitis. For example, palpable purpura may be the clinical appearance of dermal leukocytoclastic small-vessel vasculitis secondary to infection (e.g., gonococcal sepsis), immune complex–mediated vasculitis (e.g., cryoglobulinemia or Henoch-Schönlein purpura), ANCA-associated vasculitis (e.g., WG), allergic vasculitis (e.g., reaction to a drug), vasculitis associated with connective tissue, or a paraneoplastic phenomenon. It is important, therefore, to interpret the histologic findings only in the context of clinical

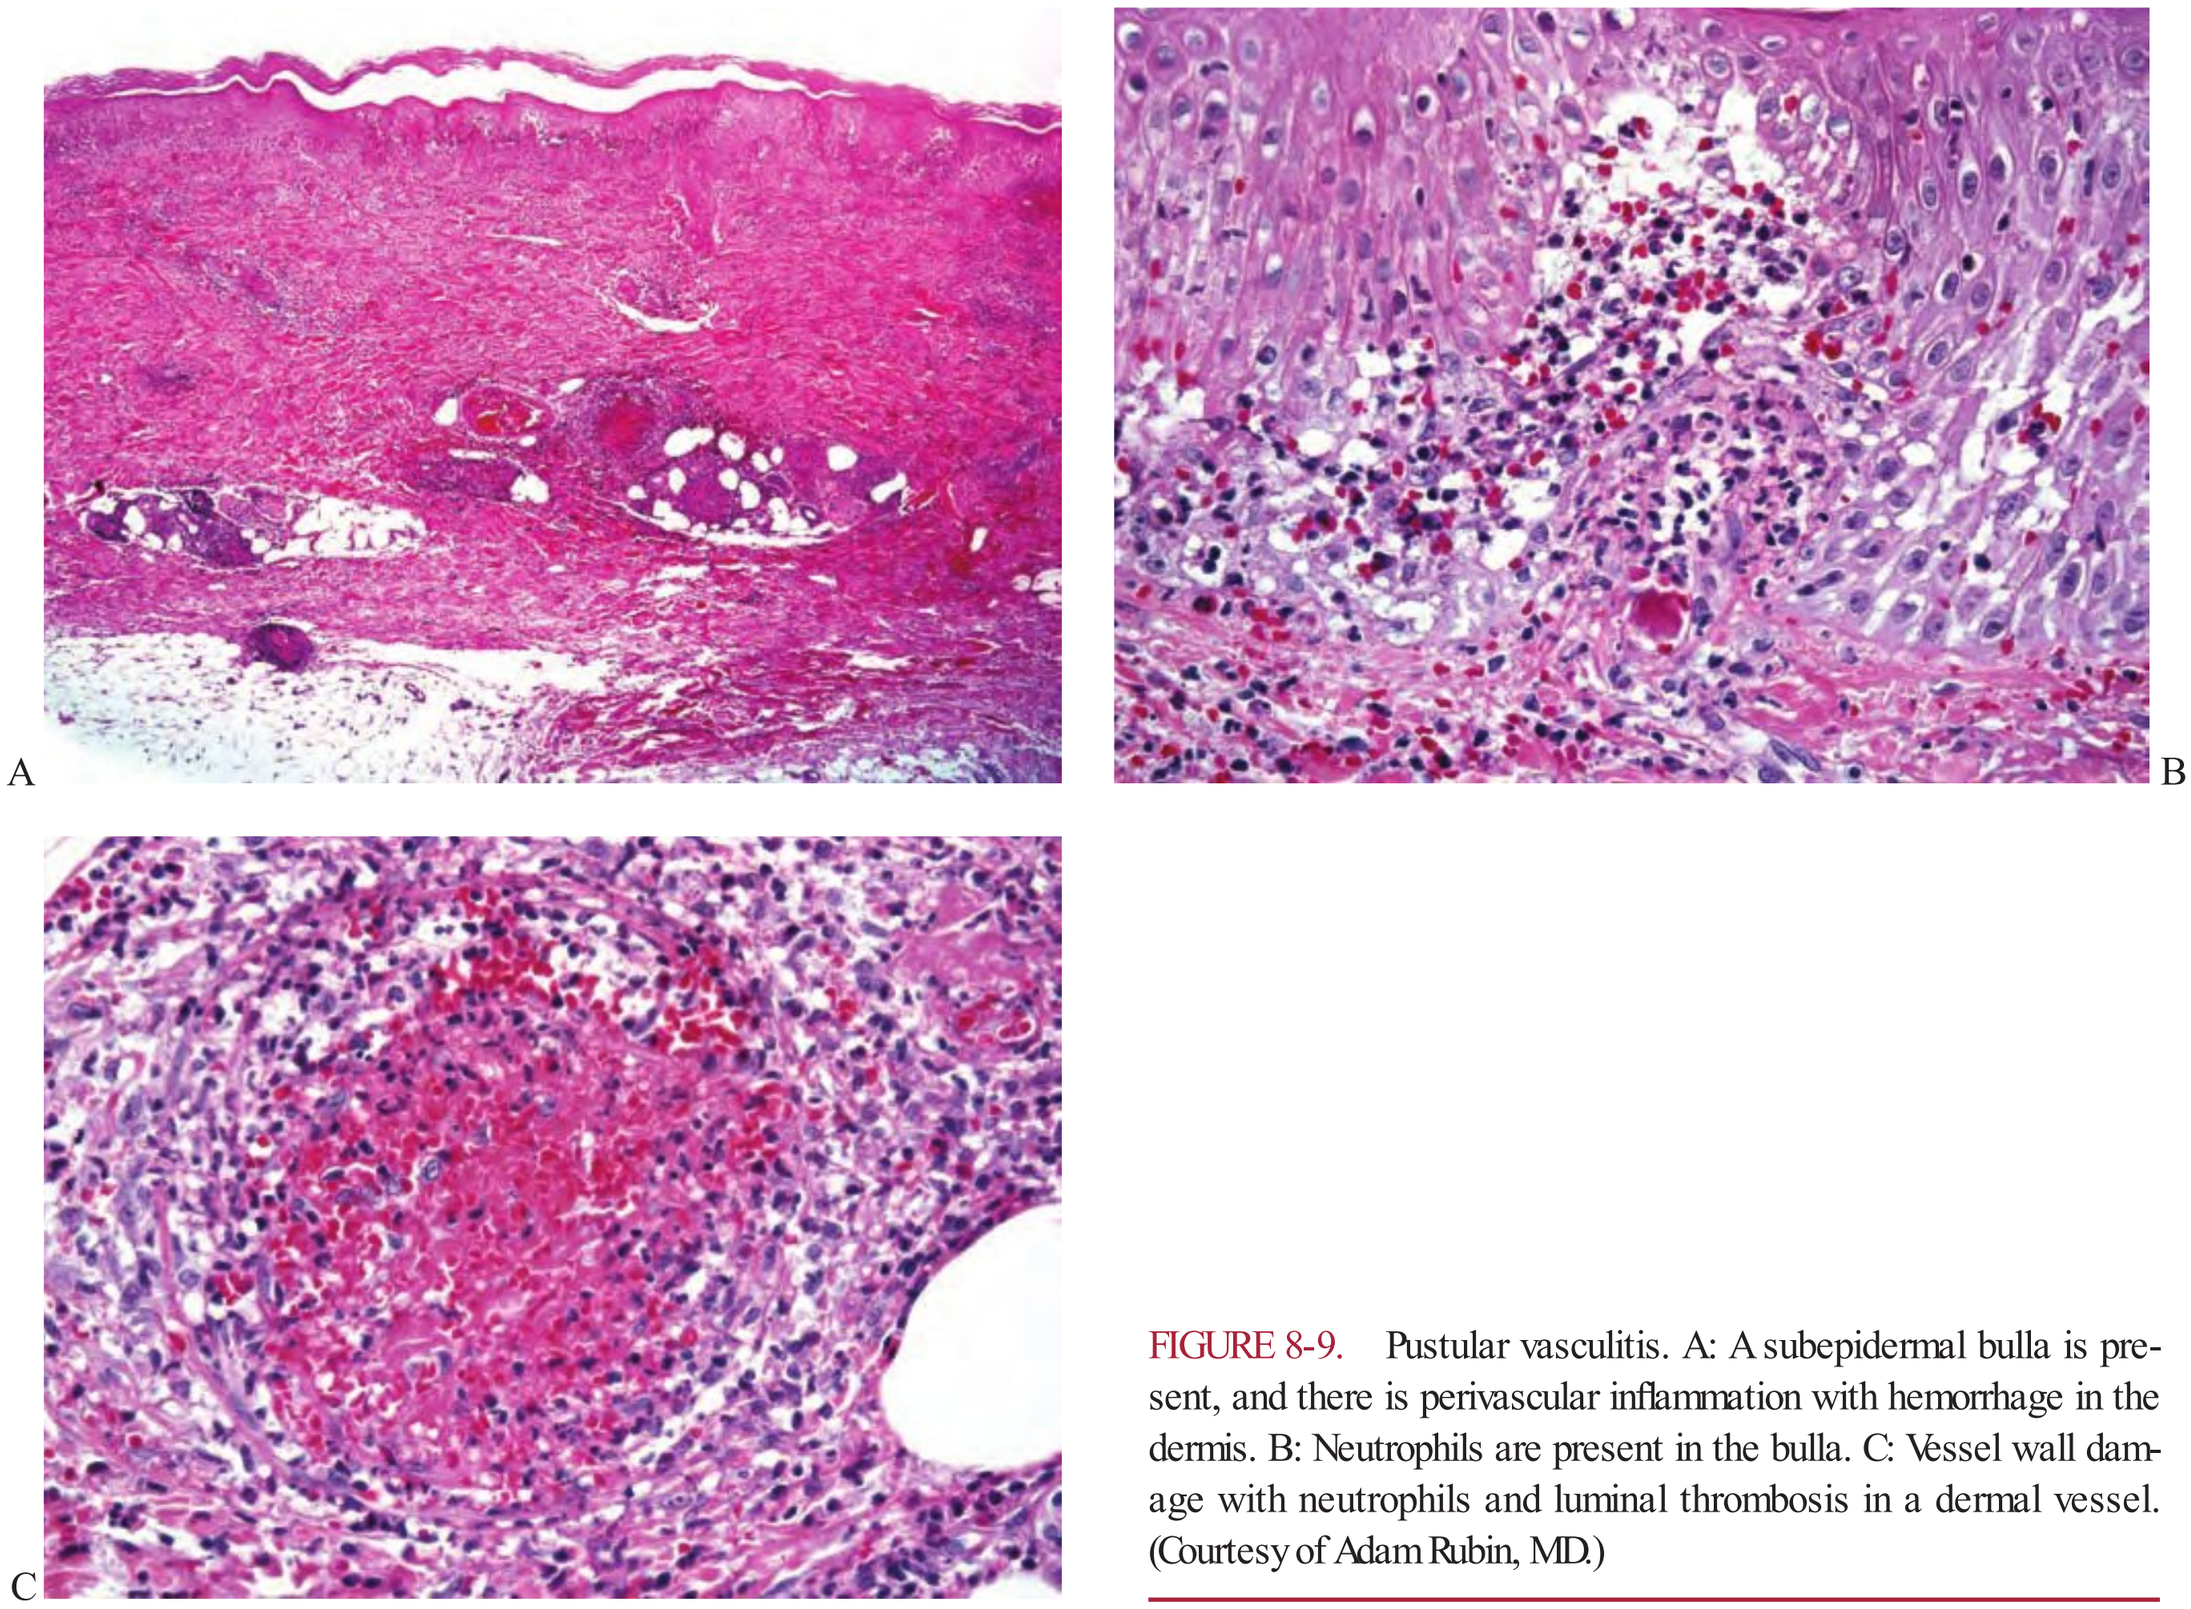


FIGURE 8-9. Pustular vasculitis. A: A subepidermal bulla is present, and there is perivascular inflammation with hemorrhage in the dermis. B: Neutrophils are present in the bulla. C: Vessel wall damage with neutrophils and luminal thrombosis in a dermal vessel. (Courtesy of Adam Rubin, MD.)

information to reach an appropriate diagnosis. Often, additional laboratory data, such as from microbiologic cultures, special stains for organisms, or immunofluorescence or serologic studies, are needed. Because the treatment for infectious vasculitides is so radically different from the treatment for immune-mediated diseases, the most important diagnostic step in the evaluation of a vasculitis is to rule out an infectious process. If noninfectious vasculitis is suspected, evidence for systemic vasculitis must be sought. Clinical findings—such as hematuria, arthritis, myalgia, enzymatic assays for muscle or liver enzymes, and serologic analysis for ANCAs, antinuclear antibodies, cryoglobulins, hepatitis B and C antibodies, IgA-fibronectin aggregates, and complement levels—are important to further delineate the disease process. Exposure to a potential allergen, such as a drug, that might have elicited a hypersensitivity reaction should be sought. Evidence of an allergic pathogenesis is reassuring because it suggests that the vasculitic process may be self-limited and not associated with systemic vasculitis. As mentioned previously, it is also important to address the possibility that the histologic findings of vasculitis may be a secondary phenomenon, for example, in ulceration from localized trauma.

The following subsections discuss the main clinical settings in which LCV occurs.

Infectious Vasculitis

An infectious process needs to be ruled out early in the evaluation of an LCV (1,4). Microorganisms may invade vessels directly or damage them by an immune-mediated mechanism (47). *Neisseria meningitides* is a common cause of infectious cutaneous leukocytoclastic vasculitis. Meningococci may be found within endothelial cells and neutrophils at sites of vascular inflammation. However, other gram-positive or gram-negative bacteria and fungi also may cause cutaneous small-vessel vasculitis (Fig. 8-10). Staphylococcal sepsis can lead to neutrophilic vasculitis with purpura or nodular lesions, which may contain microabscesses. Rickettsial infections, such as Rocky Mountain spotted fever (RMSF), are characterized by invasion of endothelial cells by organisms causing vascular damage. Inflammation, however, is often minimal in RMSF. Direct immunofluorescence microscopy may demonstrate the organism. Clinically, the spectrum of changes ranges from small macules to papules and purpura. Acid-fast organisms can also cause vasculitis. Lucio's

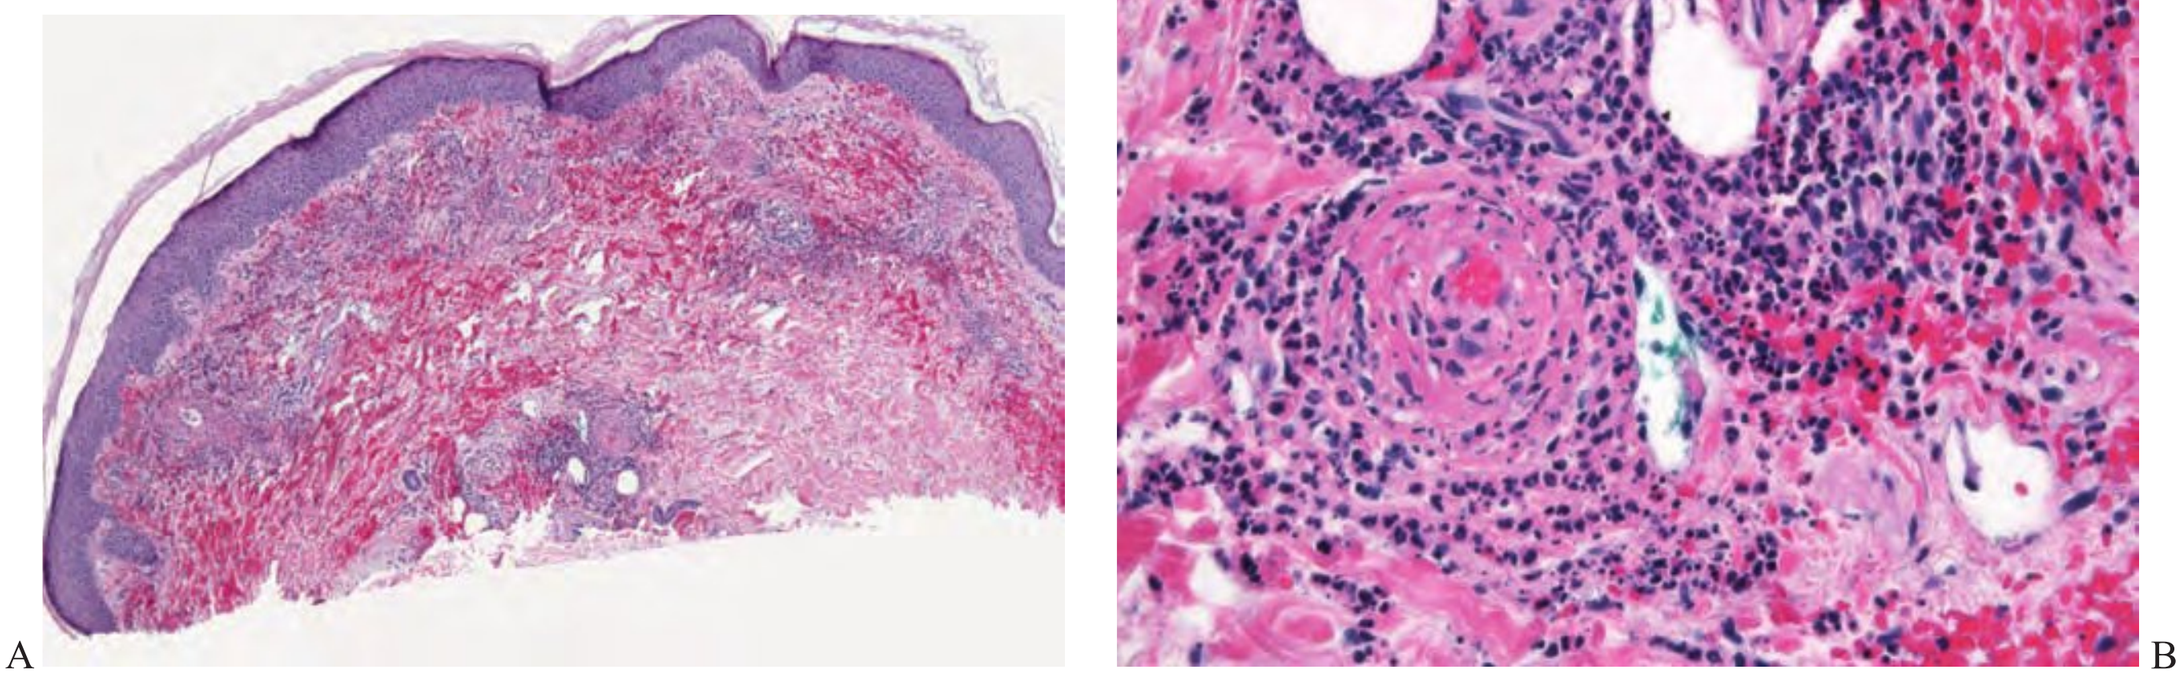

FIGURE 8-10. Septic vasculitis. A: Multiple vessels are surrounded by a dense inflammatory infiltrate and/or contain eosinophilic thrombotic material. It is associated with marked purpuric hemorrhage. B: A small vessel contains fibrin in its lumen and shows fibrinoid change of its wall, with a prominent neutrophilic infiltrate in the wall and in the adjacent tissue. Culture was positive for Pseudomonas. Organisms are difficult to appreciate in the figure.

phenomenon (erythema necroticans) and erythema nodosum leprosum are syndromes that may arise during the course of lepromatous leprosy. In both cases, biopsies show vascular damage, including LCV. Histologically, Lucio's phenomenon shows necrotizing small-vessel vasculitis, and Fite-Faraco staining reveals large aggregates of acid-fast bacilli within the vascular walls and endothelium and throughout the dermis. Ischemia and necrosis of the epidermis, dermis, and adnexal structures often with ulceration are seen. Some researchers have suggested that the massive endothelial mycobacterial burden in Lucio's phenomenon may directly lead to vascular damage (47,48).

Many viral organisms, such as hepatitis C, herpesvirus, and parvovirus B19 (49), may result in LCV on occasion.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (H-SP) is clinically characterized by palpable purpura of the buttocks and lower extremities, abdominal pain, and hematuria (50) (Fig. 8-11A). Retiform or patterned purpura is considered characteristic of H-SP. It typically affects children after streptococcal upper respiratory tract infections and is usually self-limited, with a resolution expected

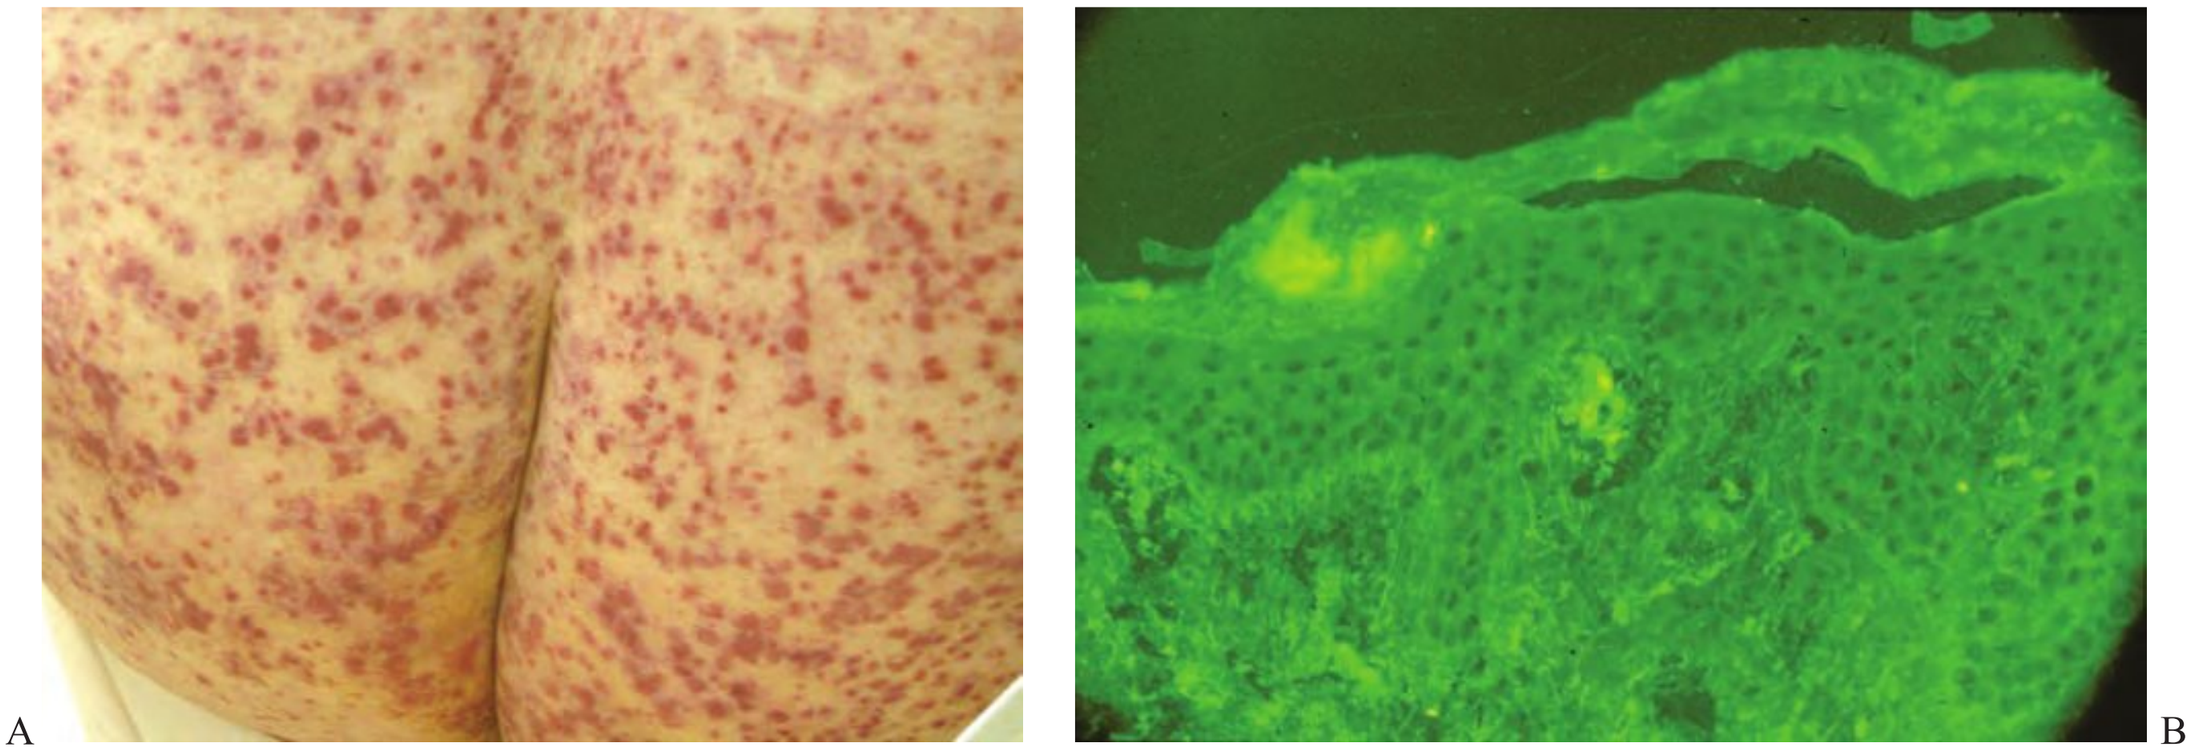

FIGURE 8-11. A: Palpable purpura of sudden onset affecting the buttocks and lower extremities. (Courtesy of Rahat S. Azfur, MD.) B: Direct immunofluorescence showing granular immunoglobulin A (IgA) deposits in very superficial dermal vessels. This immunofluorescence finding is diagnostic for IgA vasculitis (Henoch-Schönlein purpura). Other immunoreactants were negative or significantly weaker.

6 to 16 weeks after the onset of symptomatology. Complications generally arise from renal involvement that may even necessitate kidney transplantation. IgA myeloma has also resulted in HSP-like manifestations (51,52).

Acute infantile hemorrhagic edema (AHE) is an uncommon benign form of cutaneous vasculitis occurring in children younger than 2 years of age and is considered by some to be a variant of HS-P. AHE often presents with striking inflammatory edema and ecchymotic purpura with a targetoid or cockade appearance. Recently, rotavirus infection has been implicated in one case (53).

Histopathology. Henoch-Schönlein purpura cannot be distinguished histologically from other forms of LCV, although the degree of vascular damage is often not as great as that usually observed in typical LCV. Immunofluorescence studies typically demonstrate the deposition of IgA in capillaries (Fig. 8-11). Such a limited extent of vascular damage is also commonly observed in urticarial vasculitis (see text following), and clinical findings may be necessary for distinction of H-SP from urticarial vasculitis. IgA-associated vasculitis may occur outside of the symptom complex of H-SP (52). However, serologic detection of IgA-fibronectin aggregates may be associated with greater likelihood of renal or systemic disease in patients with cutaneous LCV (54).

Urticarial Vasculitis

Persistent wheals (lasting more than 24 hours by convention) with faint purpura are a typical clinical finding of urticarial vasculitis (55–57). Residual purpura is often seen after resolution of the urticarial lesions. Urticarial vasculitis (UV) is not a specific disease but rather a manifestation of a vasculitis that is associated with increased vascular permeability. The course of UV is generally benign and episodic, lasting several months. However, urticarial vasculitis sometimes occurs in lupus erythematosus and may be the initial clinical manifestation of that disease. Approximately one third of all patients with vasculitic urticaria have decreased complement levels (hypocomplementemic vasculitis) (Fig. 8-12). They may have systemic findings, such as arthralgias and adenopathy, and may be more likely to have underlying systemic lupus erythematosus (56). Low complement levels and positive anti-C1q antibodies may indicate greater likelihood of more severe systemic disease.

Histopathology. The histology of urticarial vasculitis is characterized by scant perivascular and interstitial neutrophilic infiltrates and ranges from mild to fully developed LCV (Fig. 8-13). The minimal essential criteria for UV include nuclear debris or fibrinoid alteration of microvessels, with or without extravasation of erythrocytes.

Cryoglobulinemias and Other Small-Vessel Vasculitides Associated with Paraproteins

Small-vessel vasculitis may be associated with paraproteins—that is, abnormal serum proteins (1,58,59). Such paraproteins include cryoglobulins, cryofibrinogens, macroglobulins, and

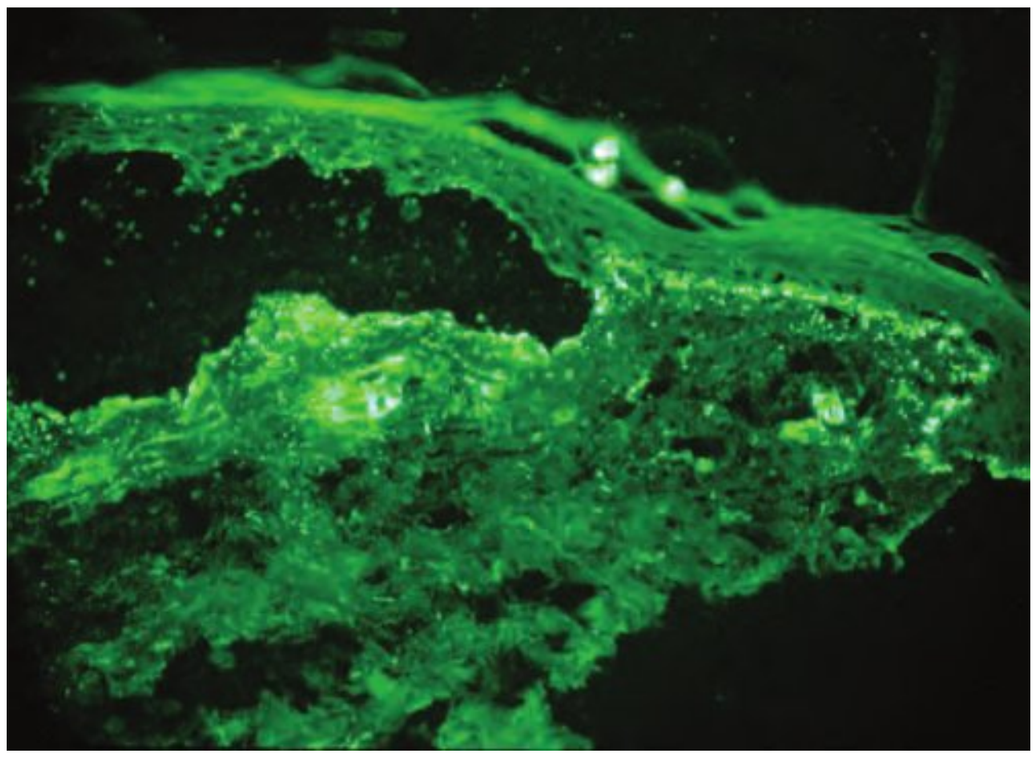

FIGURE 8-12. Direct immunofluorescence showing granular immunoglobulin G deposits in superficial dermal vessels and along the basement membrane zone. This combined vasculitic and lupus type of immunofluorescence finding is characteristic of hypocomplementemic urticarial vasculitis.

gamma heavy chains. Cryoglobulins are serum immunoglobulins that precipitate when the serum is cooled and redissolve on rewarming. There are three major types of cryoglobulinemia: In type I cryoglobulinemia, monoclonal IgG or IgM cryoglobulins are found, often associated with lymphoma, leukemia, Waldenström's macroglobulinemia, or multiple myeloma, or without known underlying disease. In type II cryoglobulinemia, the cryoprecipitate consists of both monoclonal and polyclonal cryoglobulins, with one cryoglobulin acting as an antibody against the other. These cryoglobulins are circulating immune complexes. The most common combination is IgG-IgM (Fig. 8-14). In type III cryoglobulinemia, the immunoglobulins are polyclonal. Type II and III or mixed

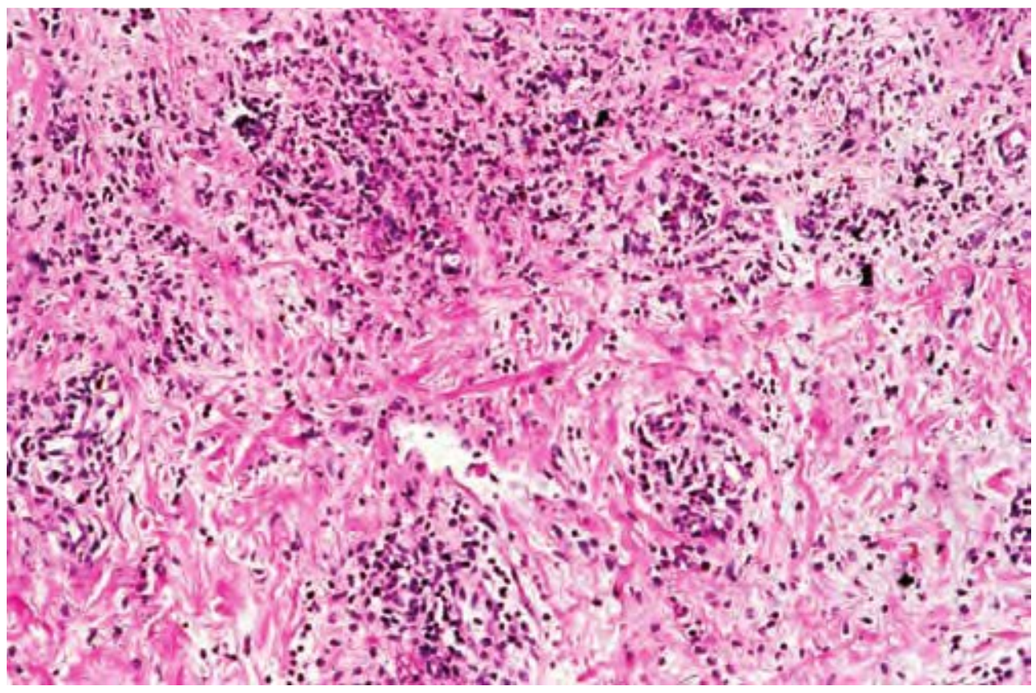

FIGURE 8-13. Neutrophil-rich small-vessel vasculitis of upper and middermal vessels associated with interstitial spillage of neutrophils from a patient with hypocomplementemic urticarial vasculitis.

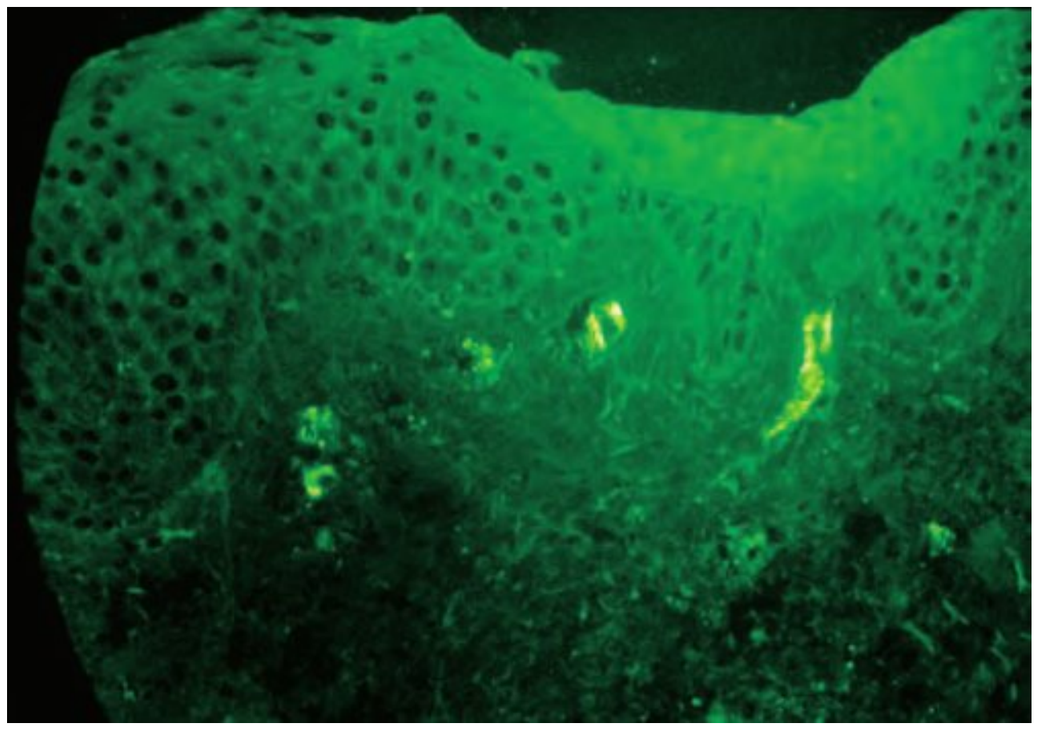

FIGURE 8-14. Direct immunofluorescence showing dense granular immunoglobulin M deposits in superficial small vessels in a patient with cryoglobulinemia type 2. This specimen also showed concomitant dense granular C3 in the same blood vessels.

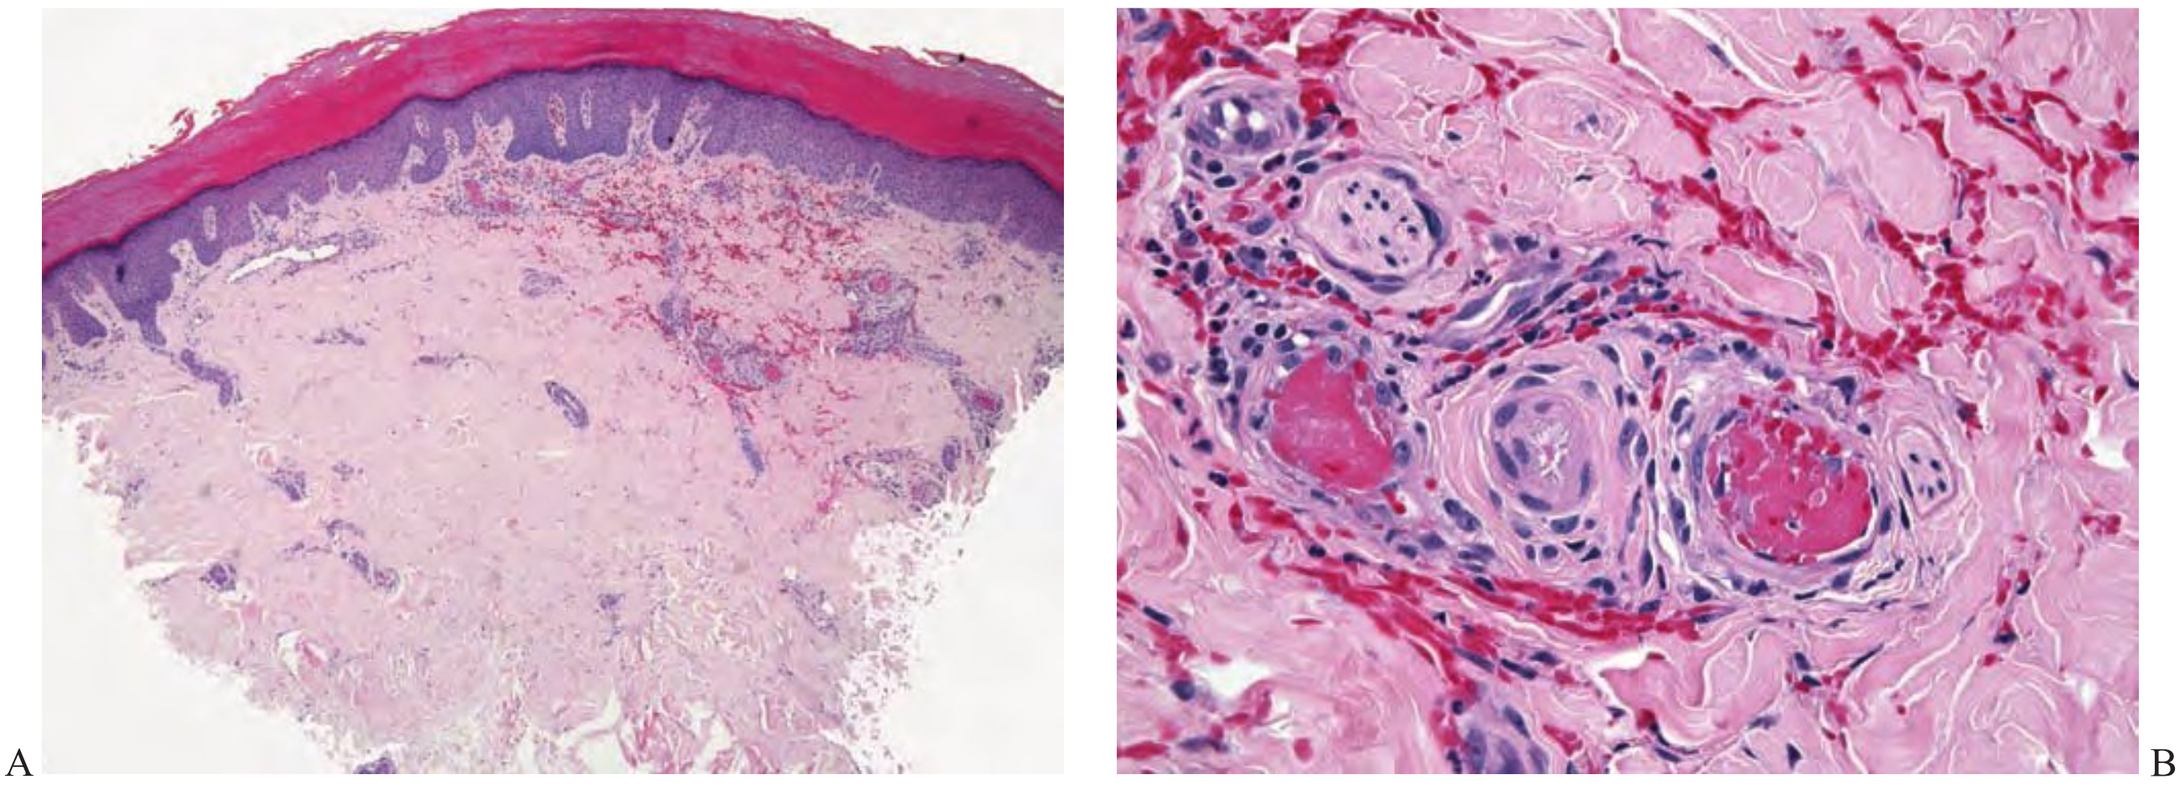
cryoglobulinemias are frequently associated with hepatitis C infection or connective tissue disorders, such as lupus erythematosus, rheumatoid arthritis, and Sjögren's syndrome, or may be related to infection—in particular, hepatitis C infection. Idiopathic forms of type II and III cryoglobulinemias are also termed essential mixed cryoglobulinemia.

Clinically, cutaneous lesions in patients with cryoglobulinemia may manifest as chronic palpable purpura, urticaria-like lesions, livedo reticularis, PAN-like lesions, leg ulcers, splinter hemorrhages, palmar erythema, acrocyanosis, and digital gangrene. Raynaud's phenomenon is common. Systemic manifestations may include arthralgia, hepatosplenomegaly, lymphadenopathy, and glomerulonephritis.

Histopathology. In type I cryoglobulinemia, amorphous material (precipitated cryoglobulins) is deposited subjacent to endothelium and throughout the vessel wall as well as within the vessel lumen, resulting in a thrombus-like appearance (Fig. 8-15). These precipitates stain pink with hematoxylin and eosin and bright red with PAS stain, as opposed to less intense staining of fibrinoid material. Some capillaries are filled with red blood cells, and extensive extravasation of erythrocytes may be present. An inflammatory infiltrate is usually lacking, in contrast to mixed cryoglobulinemia, which typically shows an LCV (Fig. 8-16). PAS-positive intramural and intravascular cryoprecipitates may be found also in mixed cryoglobulinemia, although less frequently than in type I cryoglobulinemia.



Other small-vessel vasculitides with the histologic pattern of an LCV may be found in association with Waldenström's hyperglobulinemia (hyperglobulinemic purpura) and in Schnitzler's syndrome, which manifests as chronic urticaria with macroglobulinemia (usually monoclonal IgM) and other paraproteinemias.

Serum Sickness

This syndrome of a morbilliform urticarial eruption, fever, and lymphadenopathy occurs 7 to 10 days after a primary antigen exposure or 2 to 4 days after a repeat exposure. The antigen may be a drug, from an arthropod sting or a previous infection, or therapeutic serum globulins (60). Serum sickness is usually a self-limited condition. The LCV of serum sickness has no distinctive histologic features.

Connective Tissue Disease

Rheumatoid arthritis, lupus erythematosus, and other diseases in the spectrum of connective tissue disease may develop LCV (61–64). Leukocytoclastic vasculitis may also occur in patients with antiphospholipid antibody syndrome (65). Clinical and

A B

serologic information is critical to the correct interpretation of the cutaneous findings in these clinical settings.

Autoimmune Diseases

Primary Sjögren's syndrome is not associated with connective tissue disease but may present with purpura in addition to ocular and glandular involvement (1). The histologic reaction pattern is often an LCV or lymphocytic vasculitis.

ANCA-Associated Vasculitis

The pauci-immune vasculitides associated with ANCA were discussed in more detail earlier. MPA, WG, and Churg-Strauss syndrome may all be associated with cutaneous LCV.

Drug-Induced Vasculitis

A hypersensitivity reaction to a drug may result in an LCV (1,4). Penicillin, thiazides, and sulfonamides are the most common drugs used to induce LCV. Drugs also may induce the pattern of pustular vasculitis. Increased tissue eosinophil counts (5.2 vs. 1.05 per 10 high-power fields) have recently been shown to correlate with drug-induced versus non–drug-induced LCV (66).

Paraneoplastic Vasculitis

A wide spectrum of vasculitic processes has been associated with neoplastic disorders (67,68). Sixty patients with cancer-related vasculitis demonstrated the following vasculitic patterns: 45% LCV, 36.7% PAN, 6.7% WG, 5% MPA, and 5% H-SP. The distribution of malignancies among these patients was as follows: 63.1% with hematologic (including 32.3% with myelodysplastic syndromes and with 29.2% lymphoid neoplasms) and 36.9% with solid malignancies. Common associations include polyarteritis nodosa with hairy cell leukemia and cutaneous small-vessel vasculitis with lymphoproliferative disorders and some carcinomas.

Behçet's Disease

Behçet's disease is a multisystem disease characterized by oral aphthous lesions and at least two of the following criteria: genital aphthae, synovitis, posterior uveitis, cutaneous pustular vasculitis, and meningoencephalitis (69,70). This HLA-B51–associated disease is common in the Middle East and Japan but rare in northern Europe and the United States. The clinical presentation is extremely variable and so is the vascular involvement, which can range from active inflammatory lesions to aneurysms, arterial or venous occlusions, or varices.

Histopathology. The histopathologic spectrum of mucocutaneous inflammatory vascular lesions includes, depending on the stage and activity of the lesion, neutrophilic, lymphocytic, and granulomatous vascular reactions. Biopsy specimens of early lesions typically show a neutrophilic vascular reaction, and Behçet's disease is sometimes classified as a neutrophilic dermatosis/neutrophilic vascular reaction. However, fully developed necrotizing leukocytoclastic vasculitis may develop. If the neutrophilic infiltrate is very dense, the pattern of pustular vasculitis may be found (see Fig. 8-9).

Pathogenesis. The etiology of Behçet's disease is unknown. The vascular injury is presumably immune mediated because immune complex deposition has been demonstrated in vessel walls. Disorders of neutrophils are also being discussed with regard to the etiology of this disease. However, the occurrence of cutaneous vasculitis together with the vascular injury seen in other organ systems suggests that Behçet's disease is best classified as a systemic vasculitis (70).

Localized Fibrosing Small-Vessel Vasculitis

Erythema elevatum diutinum (EED), granuloma faciale (GF), and some examples of cutaneous inflammatory pseudotumor are very similar chronic fibrosing conditions that show evidence of vascular damage (71,72). Sometimes, they may be classified with the neutrophilic dermatoses. These entities are hypothesized to be reactions to localized persistent immune complex deposition or hypersensitivities to a persistent antigen. EED- and GF-like reactions may occasionally be seen in clinical settings atypical for either entity (71).

Erythema Elevatum Diutinum

This rare condition is characterized by persistent, initially red to violaceous and later brown to yellow papules, nodules, and plaques (73–75). The lesions, typically distributed symmetrically on the extensor surfaces of the extremities, are initially soft and then evolve into fibrous nodules.

Histopathologic Features. In the early stage of EED, nonspecific LCV is observed. In later stages, granulation tissue and fibrosis form with a diffuse mixed-cell infiltrate showing a predominance of neutrophils. The capillaries may still show deposits of fibrinoid material or merely fibrous thickening. Fully developed lesions of EED may be indistinguishable from neutrophilic dermatoses discussed later, Behçet's disease, or neutrophilic drug reaction. Granuloma faciale may also resemble

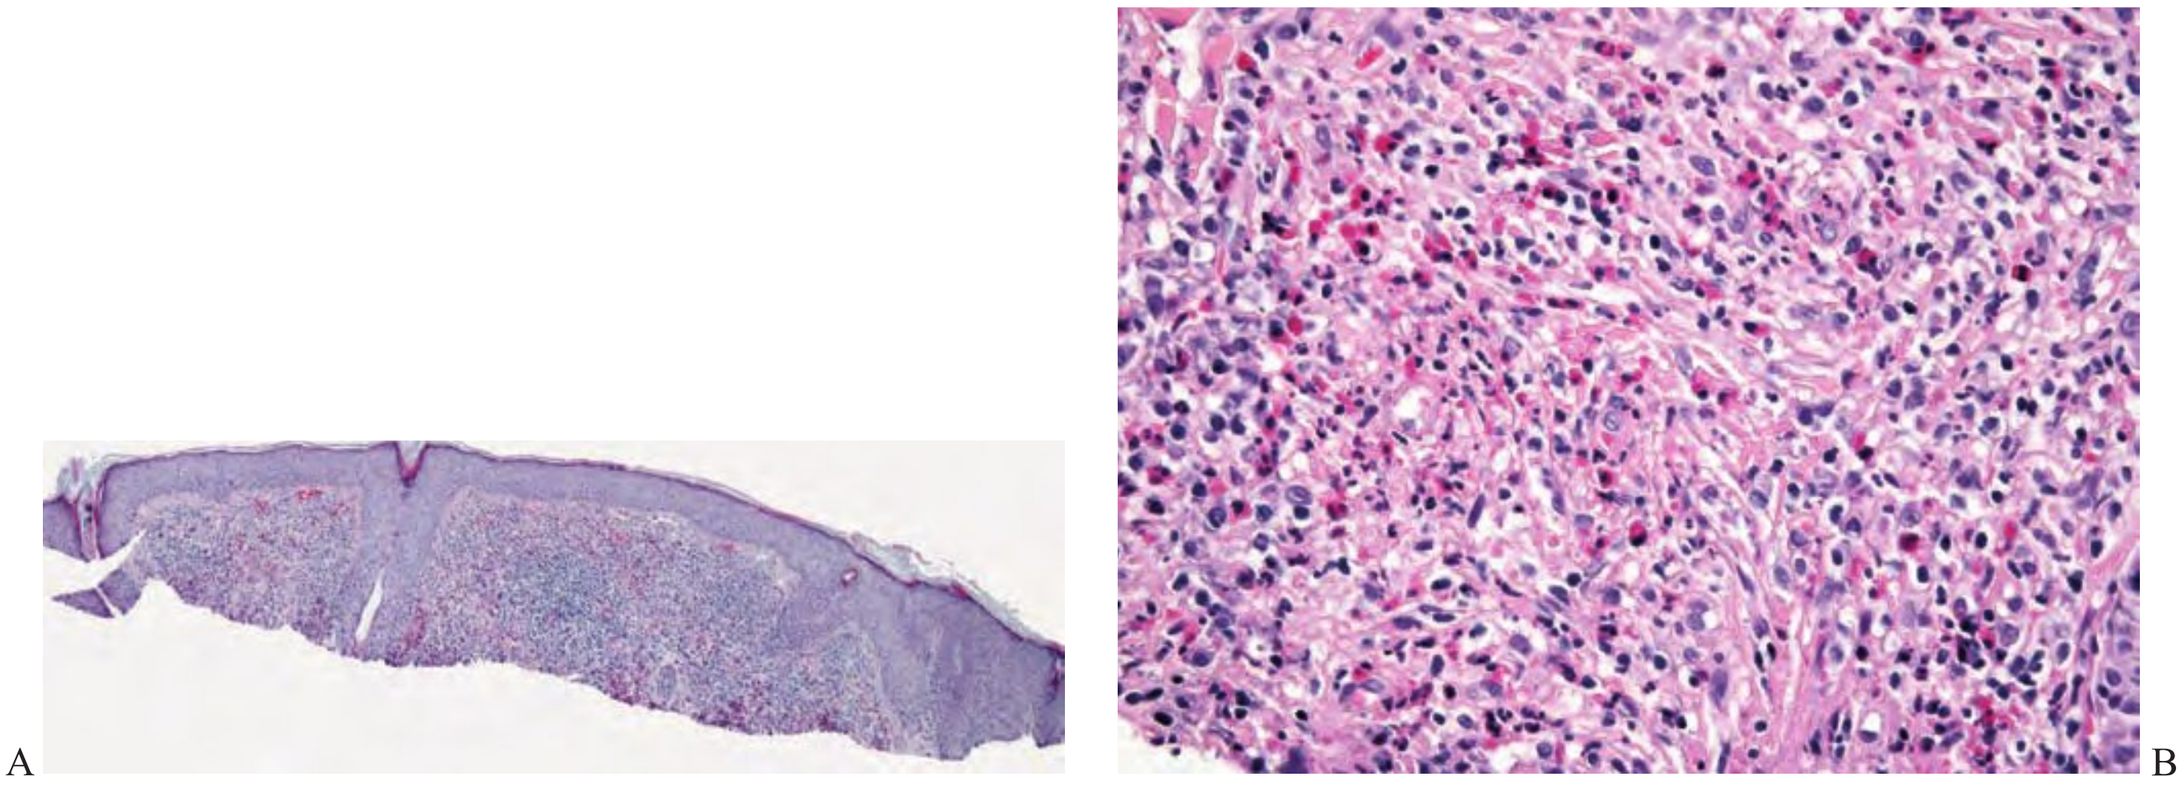

FIGURE 8-17. Granuloma faciale. A: There is a cellular infiltrate in the dermis, separated from the epidermis by an uninvolved or grenz zone. B: The infiltrate contains numerous neutrophils and eosinophils. Vascular damage is minimal.

EED but is distinguished by clinical localization to the face, sparing of the superficial papillary dermis (a grenz zone), and prominence of eosinophils and plasma cells in addition to neutrophils. Occasional cases show neutrophilic microabscesses in the tips of dermal papillae that might suggest dermatitis herpetiformis (74). In old, fibrotic lesions of EED there is an orderly array of spindle cells and collagen bundles often parallel to the skin surface with vertically arranged capillaries similar to a scar. Lipid material also may be present as cholesterol clefts. Serial sections may be required to demonstrate vascular damage in late lesions. These older lesions of EED must be differentiated from Kaposi's sarcoma, dermatofibroma, or granuloma annulare. Neutrophils, nuclear dust, and fibrin owing to persistent vascular damage may be present, helping to distinguish these lesions from dermatofibromas or scars. The irregularly arranged, jagged vascular spaces of Kaposi's sarcoma are absent, and many of the spindle cells have the immunohistochemical and electron microscopic features of macrophages. Focal areas of basophilic collagen caused by nuclear dust in EED can resemble the mucin seen in granuloma annulare but do not stain with Alcian blue.

Pathogenesis. EED probably is not a distinct disease entity but rather a clinicopathologic reaction pattern, most often developing in either a monoclonal or polyclonal gammopathy, in particular IgA hyperglobulinemia. Inflammatory bowel disease, rheumatoid arthritis, and systemic lupus erythematosus may also be associated with EED. HIV-infected patients also develop EED, which can clinically mimic Kaposi's sarcoma (75).

Granuloma Faciale

Clinically, granuloma faciale presents as one or several asymptomatic, soft, brown-red, slowly enlarging papules or plaques, almost always on the face of older individuals. Rare upper respiratory tract forms have been described (76).

Histopathologic Features

A dense polymorphous infiltrate is present mainly in the upper half of the dermis but may extend into the lower dermis and occasionally even into the subcutaneous tissue. Quite characteristically, the infiltrate does not invade the epidermis or the pilosebaceous appendages but is separated from them by a narrow grenz zone of normal collagen (Fig. 8-17). The pilosebaceous structures tend to remain intact. The polymorphous infiltrate consists primarily of neutrophils and eosinophils, but mononuclear cells, plasma cells, and mast cells also are present. Vascular damage in GF is seen but often is limited, and thus perhaps GF is best termed a neutrophilic vascular reaction (78). Frequently, the nuclei of some of the neutrophils are fragmented, especially in the vicinity of the capillaries, thus forming nuclear dust. Often, there is some evidence of vasculitis with deposition of fibrinoid material within and around vessel walls. Occasionally, some hemorrhage is noted. Foam cells and fibrosis frequently are observed in older lesions.

Differential Diagnosis. Granuloma faciale can appear similar to erythema elevatum diutinum, although a grenz zone and prevalence of eosinophils and plasma cells favors granuloma faciale. Other neutrophilic dermatoses can be distinguished from granuloma faciale by the lack of a grenz zone and clinical features. Frank leukocytoclastic vasculitis should not be seen in granuloma faciale. In acneiform lesions and folliculitides, pilosebaceous units are invaded by inflammatory cells and may be destroyed or disrupted.

Pathogenesis. Vascular damage may be important to the pathogenesis of this lesion because direct immunofluorescence data suggest an immune complex–mediated event with deposition of mainly IgG in and around vessels.

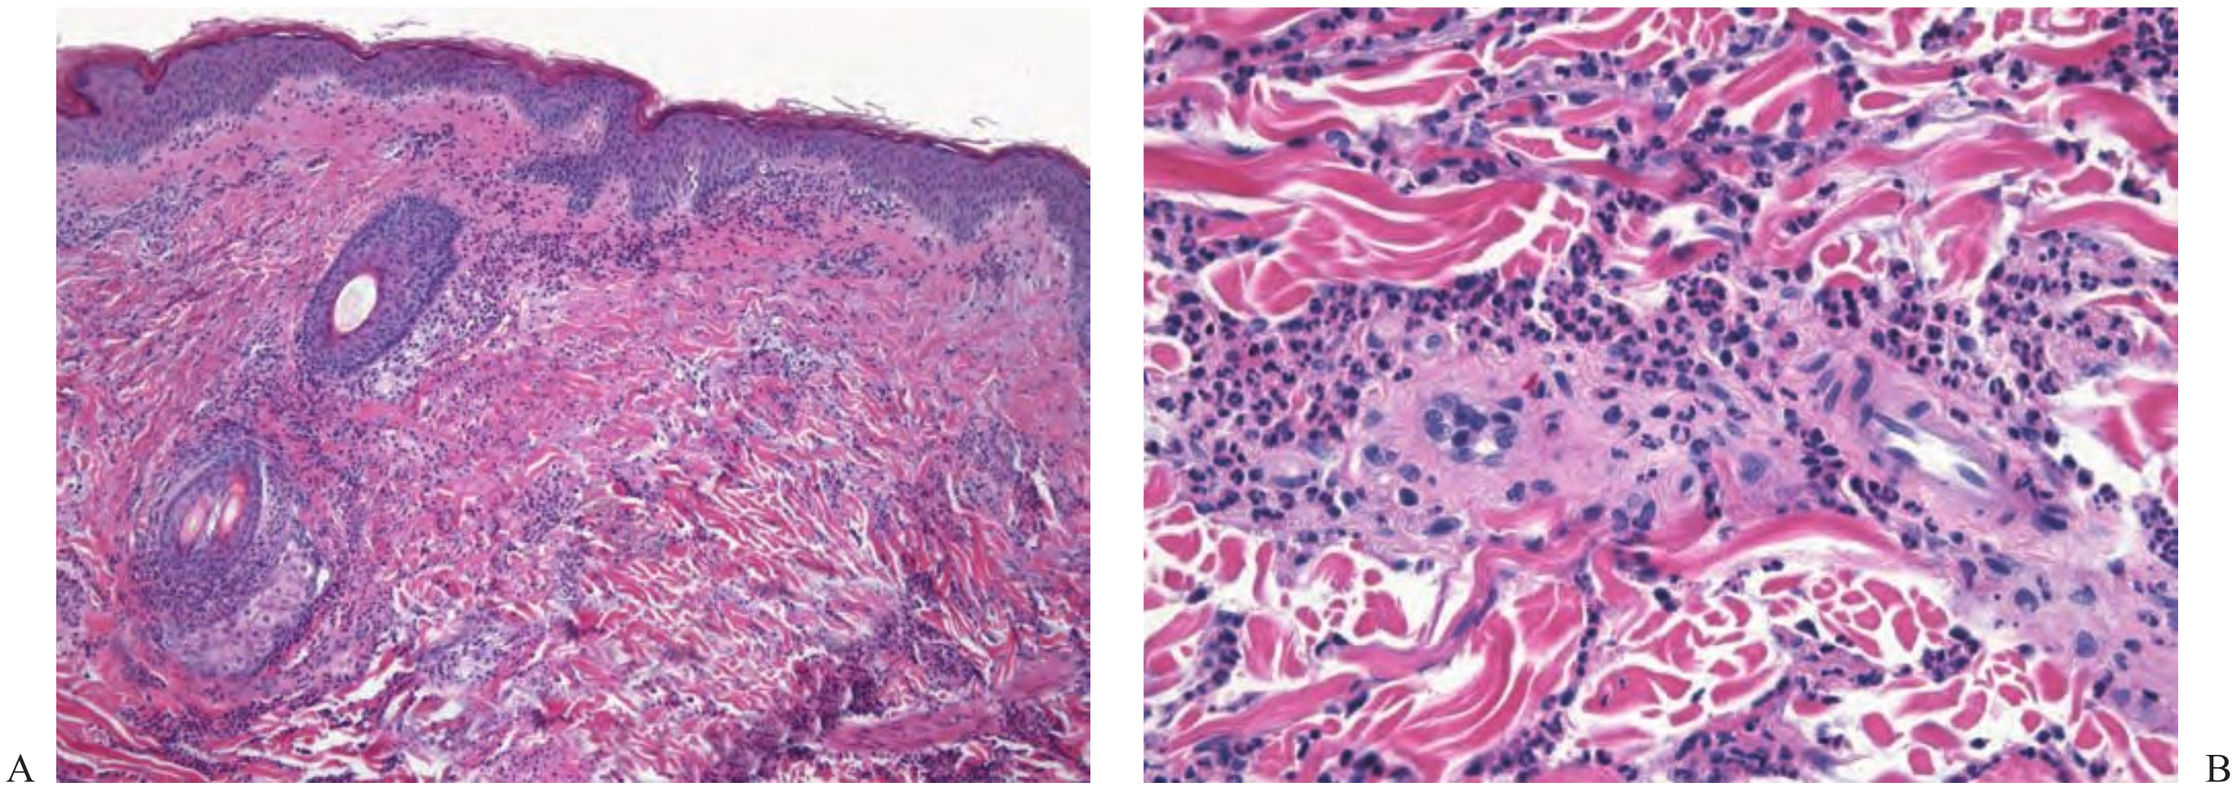

FIGURE 8-18. Sweet's syndrome. A: There is a dense infiltrate in the upper dermis, consisting mainly of neutrophils, without leukocytoclasia. B: Vascular damage is slight.

NEUTROPHILIC DERMATOSES

The histopathologist occasionally encounters lesions consisting of a neutrophilic infiltrate, sometimes even with leukocytoclasis, and some degree of vascular damage in up to one third of cases (69). Microvascular injury is most likely secondary to the dense neutrophilic infiltrates; the extent of vascular damage is insufficient for necrotizing vasculitis—that is, fibrinoid necrosis is lacking. Occasionally such a histologic picture may be seen in an early lesion of vasculitis. However, several clinical conditions characterized by neutrophilic infiltrates rarely develop necrotizing vasculitis and need to be distinguished from vasculitis. These entities are categorized as neutrophilic dermatoses and are characterized by (a) a neutrophilic infiltrate histologically, (b) a lack of microorganisms on special stains and cultures, and (c) clinical improvement on systemic steroid treatment (78). Vascular damage has been observed in these conditions, but it remains unclear whether the vascular injury plays an etiologic role or is merely an epiphenomenon. A relationship between these entities may be indicated by their occasional cooccurrence in patients with predisposing conditions.

Acute Febrile Neutrophilic Dermatosis (Classic Sweet's Syndrome and Sweet's-Like Neutrophilic Dermatosis)

Dr. R. D. Sweet described in 1964 a disease process, which he termed "acute febrile neutrophilic dermatosis," that was characterized by abrupt onset of fever, leukocytosis, and erythematous plaques infiltrated by neutrophils (78,79). This condition typically occurs in middle-aged women after nonspecific infections of the respiratory or gastrointestinal tract. The lesions tend to be found on the face or extremities and only rarely involve the trunk and respond to steroid treatment. Despite the numerous neutrophils, the lesions are sterile. Vesicles and pustules may also arise. Involvement of noncutaneous sites, such as eyes, joints, oral mucosa, and visceral sites (lungs, liver, kidneys), has been reported. A variety of disorders have been associated with neutrophilic dermatoses similar to those seen in Sweet's syndrome (Sweet's-like neutrophilic dermatosis). About 20% of cases are associated with malignancy. Cutaneous eruptions with inflammatory vascular reactions, which on occasion simulate the lesions of Sweet's syndrome, may also occur in association with hereditary periodic fever, which comprises several syndromes including familial Mediterranean fever, the hyper-IgD syndrome, and the tumor necrosis factor receptor–associated periodic syndrome (80).

Histopathology. Typically, a dense perivascular infiltrate composed largely of neutrophils is seen assuming a bandlike distribution throughout the papillary dermis (Fig. 8-18). Some of the neutrophils may show nuclear fragmentation (leukocytoclasis). In addition, the infiltrate may contain scattered lymphocytes and histiocytes and occasional eosinophils. The density of the infiltrate varies and may be limited in a small proportion of cases. Vasodilation and swelling of endothelium with moderate erythrocyte extravasation and prominent edema of the upper dermis are characteristic. In some instances, subepidermal blister formation may result. Extensive vascular damage is not a feature of Sweet's syndrome. The histologic appearance varies depending on the stage of the process. In later stages, lymphocytes and histiocytes may predominate. Sweet's-like neutrophilic dermatoses often show a similar histologic picture. However, the reaction pattern may on occasion be quite different, for instance, manifesting as deep subcutaneous localized suppurative panniculitis. The infiltrate of Sweet's syndrome is not characteristic enough to exclude infection on histologic findings alone. As always, to arrive at the correct interpretation of a neutrophilic infiltrate, cultures need to be obtained and special stains need to be performed to exclude an infectious etiology.

Pathogenesis. Sweet's syndrome's etiology is unknown but is thought to be a hypersensitivity reaction. The three major concepts that have been discussed are immune complex vasculitis, altered T-cell activation, and altered function of neutrophils. All lack, however, sufficient experimental support. The vascular alterations seen in Sweet's syndrome may be secondary to the massive extravasation of activated neutrophils. Direct immunofluorescence studies are generally negative in Sweet's syndrome (78).

Bowel-Associated Dermatosis-Arthritis Syndrome

This syndrome was initially described in patients after jejunoileal bypass surgery. Subsequently, however, the spectrum of the syndrome has expanded to include other disease processes with typical cutaneous findings and associated bowel disease (1). Patients may have inflammatory bowel disease or a blind loop after peptic ulcer surgery. The cutaneous lesions are characterized by initial small macules that develop through a papular phase into pustules on a purpuric base. The evolution usually occurs within a 2-day period. The lesions typically reach a size of 0.5 to 1.5 cm. They are typically distributed on the upper part of the body, especially the arms, rather than on the dependent sites of the legs. Cutaneous lesions often occur in crops and are episodic (1 to 2 weeks), with a tendency to recur within months. Fever, myalgias, and arthralgias may accompany the disease process.

Histopathology. The histopathologic changes are usually those of neutrophilic vascular reactions with little or none of the vascular damage observed in Sweet's syndrome and other neutrophilic dermatoses. However, frank necrotizing small-vessel vasculitis may occasionally be noted. In fully developed lesions, the neutrophilic infiltrate and papillary dermal edema may be florid, and subepidermal pustule formation is seen. If vascular damage is observed in such a context, the term "pustular vasculitis" is applied.

Pathogenesis. One suggested etiology involves antigens derived from intestinal bacteria triggering an immune complex–mediated reaction with vascular insults (81).

Pyoderma Gangrenosum

Pyoderma gangrenosum (PG) is included in this chapter as well as in Chapter 16 because in these and other authors' opinions, it represents a clinicopathologic manifestation that falls within the spectrum of neutrophilic dermatoses (1). As with other neutrophilic dermatoses, infection must be excluded to arrive at the correct diagnosis.

Several clinical types have been described: ulcerative PG with an undermined border; pustular PG with discrete, painful pustules; painful bullae with progression to a superficial ulceration; and vegetative PG with a painless ulcer and a nonundermined exophytic border (Fig. 8-19A). (82). Classically, lesions begin as tender papulopustules or folliculitis that eventually may ulcerate. In the fully developed stage, the lesions have a distinctive raised, undermined border with a dusky purple hue. Again, as with neutrophilic dermatoses in general, pyoderma gangrenosum may occur as an isolated cutaneous phenomenon or may be a cutaneous manifestation associated with various systemic disease processes, such as inflammatory bowel disease, connective tissue diseases, and lymphoproliferative lesions.

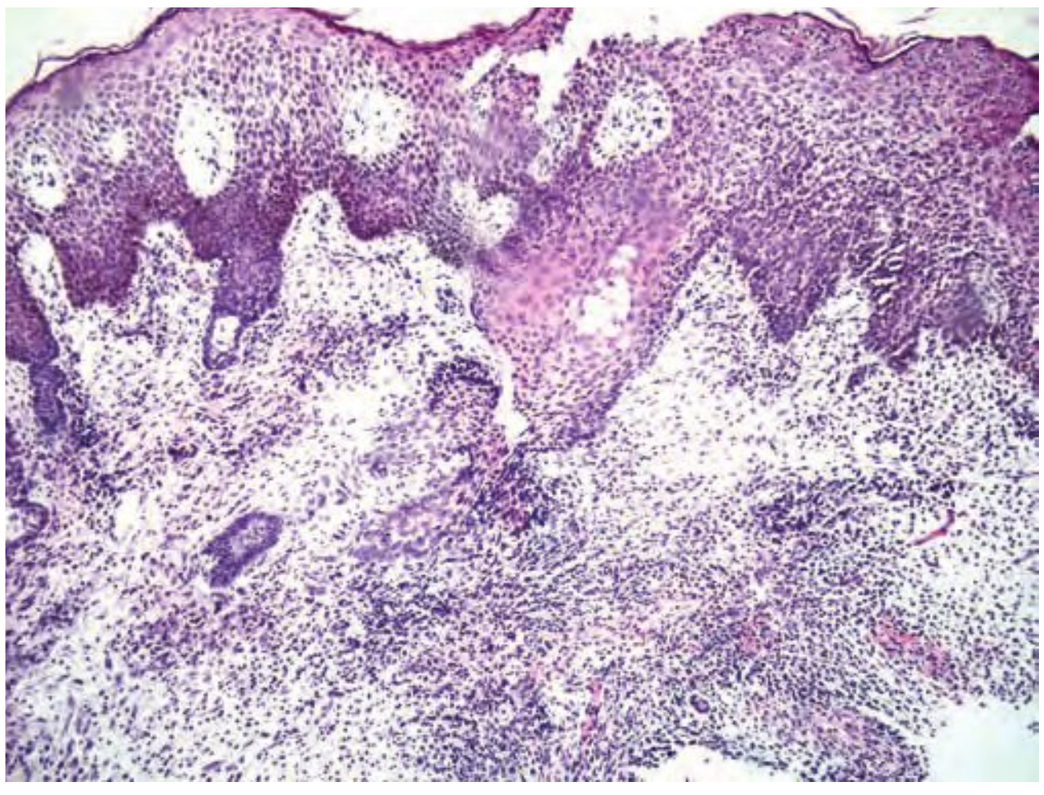
Histopathology. The histologic findings are nonspecific, and the diagnosis is primarily clinical. Most authors studying early lesions have reported a primarily neutrophilic infiltrate, which frequently involves follicular structures (83). Others, however, have stated that the lesions begin with a lymphocytic reaction (84). Degree of vessel involvement ranges from none to fibrinoid necrosis. In the majority of biopsied lesions, a neutrophilic infiltrate is present with some, but limited, vascular damage. Outright vasculitis has been reported and has led to speculations about its possible role in the etiology of pyoderma gangrenosum. Focal vasculitis is often observed in fully developed lesions but appears secondary to the inflammatory process. The infiltrate tends to be deeper and more extensive than that in classic Sweet's syndrome. The pattern of pustular vasculitis may be present. Fully developed lesions exhibit ulceration, necrosis, and a mixed inflammatory cell infiltrate (Fig. 8-19). Involvement of the deep reticular dermis and subcutis may exhibit primarily mononuclear cell and granulomatous inflammatory reactions.

LYMPHOCYTIC SMALL-VESSEL VASCULITIS

A histologic diagnosis of a lymphocytic vasculitis may be made if there is sufficient evidence of vascular damage and the inflammatory infiltrate is predominantly lymphocytic (Fig. 8-20). Often, the vascular damage is subtle, and in many cases there may be disagreement among dermatopathologists on whether the term "vasculitis" is warranted (85). Clear-cut evidence of vasculitis is indisputable if an inflammatory infiltrate is present together with fibrinoid necrosis of the vascular wall. However, these findings are rarely or only focally present in the majority of conditions that have been said to manifest lymphocytic vasculitis.

The disease processes in which lymphocytic vasculitis is commonly observed are listed in Table 8-6. Lymphocytic vasculitis may also be seen in a stage of an otherwise leukocytoclastic or granulomatous vasculitis or in a process that at other times may even be noninflammatory and manifested perhaps as a vasculopathy (e.g., atrophie blanche).

Lymphomatoid Vasculitis and Vascular Reactions



The terms "lymphomatoid vasculitis" and "lymphomatoid vascular reaction" may be used if there is a lymphocytic vasculitis or lymphocytic vascular reaction with significant cytologic atypia of the lymphoid cells (Table 8-7). Although lymphoid nuclear irregularities of some degree may be present in many lymphocytic vascular reactions, probably as a reflection of an activated state of the lymphocytes, lymphoid atypia tends to be particularly well developed in lymphomatoid papulosis and some viral processes. The differential diagnosis includes vascular

damage in the context of cutaneous lymphoma, such as angiocentric T-cell lymphoma and other lymphomas (86).

Pigmented Purpuric Dermatitis

Historically, four variants of purpura pigmentosa chronica have been described: purpura annularis telangiectoides of Majocchi, progressive pigmentary dermatosis of Schamberg, pigmented purpuric dermatitis of Gougerot and Blum, and eczematoid-like purpura of Doucas and Kapetanakis. These entities are all closely related and often cannot be reliably distinguished on clinical and histologic grounds (87). In practice, subclassification may not be necessary. Lichen aureus is a closely related localized variant. The general terms "pigmented purpuric dermatitis," "chronic purpuric dermatitis," and "purpura pigmentosa chronica" appear suitable for this disease spectrum.

Clinically, the primary lesion consists of discrete puncta. Gradually, telangiectatic puncta may appear as a result of capillary dilation, with pigmentation as a result of hemosiderin deposits. In some cases, telangiectasia (Majocchi's disease) predominates; in others, pigmentation (Schamberg's disease) predominates. In Majocchi's disease, the lesions are usually irregular in shape and occur predominantly on the lower legs.

A B

FIGURE 8-20. Lymphocytic vasculitis. A: A small vessel in the reticular dermis is surrounded by an inflammatory infiltrate. B: The infiltrate is composed of lymphocytes. There is damage to the vessel wall.

In some cases, the findings may mimic those of stasis. Not infrequently, clinical signs of inflammation are present, such as erythema, papules, and scaling (Gougerot-Blum disease) or papules, scaling, and lichenification (eczematoid-like purpura). The disorder is often limited to the lower extremities, but it may be extensive. Mild pruritus may be present. There are no systemic symptoms related to this disease process. A localized variant of pigmented purpuric dermatitis (PPD) is lichen aureus, in which one or a few patches are present, most commonly on the legs (88). The patches are composed of closely set, flat papules of a rust, copper, or orange color. In some cases, petechiae are present within the patches. Lichen aureus shows a male predilection and a peak incidence in the fourth decade. The lesions of lichen aureus tend to persist. They typically occur on the lower legs but may affect many other sites.

Histopathology. The basic process is a lymphocytic perivascular infiltrate limited to the papillary dermis (Fig. 8-21). Epidermal alterations may include slight acanthosis and basal layer

Hemosiderin pigment is not prominent in this example.

vacuolopathy. There is also some variability in the pattern of the dermal infiltrate. In some instances, the infiltrate may assume a bandlike or lichenoid pattern, particularly in the lichenoid variant of Gougerot-Blum disease, and may involve the reticular dermis in a perivascular distribution. Evidence of vascular damage may be present, and the reaction pattern may then be termed lymphocytic vasculopathy, vasculitis, or capillaritis. However, the extent of vascular injury is usually mild and often insufficient to justify the term "vasculitis." Vascular damage commonly consists only of endothelial cell swelling and dermal hemorrhage. Extravasated red blood cells and subtle deposits of hemosiderin are usually found in the vicinity of the capillaries. However, less commonly fibrinoid material is deposited in vessel walls. In some instances, the infiltrate involves the epidermis and may be associated with mild spongiosis and patchy parakeratosis, particularly in some cases of pigmented purpuric lichenoid dermatitis of Gougerot and Blum and eczematoid-like purpura of Doucas and Kapetanakis. The pattern of the infiltrate often is both perivascular and interstitial, infiltrating the papillary dermis between vessels.

In old lesions, the capillaries often show dilation of their lumen and proliferation of their endothelium. Extravasated red blood cells may no longer be present, but one frequently finds hemosiderin, although in varying amounts. The inflammatory infiltrate is less pronounced than in the early stage.

In lichen aureus, a dense lymphohistiocytic infiltrate is present in the superficial dermis, typically distributed in a bandlike fashion and often associated with an increase in dermal capillaries. Exocytosis of mononuclear cells into the epidermis may be seen. Scattered within the infiltrate are hemosiderin-laden macrophages (Fig. 8-22). The absence or near absence of Civatte bodies or basal layer vasculopathy facilitates the differential diagnosis from lichenoid dermatitides, such as lichen planus or lichen striatus.

Differential Diagnosis. PPD may resemble stasis dermatitis because inflammation, dilation of capillaries, extravasation of erythrocytes, and deposits of hemosiderin occur in both. However, in stasis dermatitis, the process extends much deeper into the dermis, and more pronounced epidermal changes and fibrosis of the dermis are usually present. Changes of intravascular red blood cell sludge and some fibrin deposits also may be seen in stasis, indicating a low flow state. As mentioned earlier, the histologic pattern of PPD may resemble or possibly be

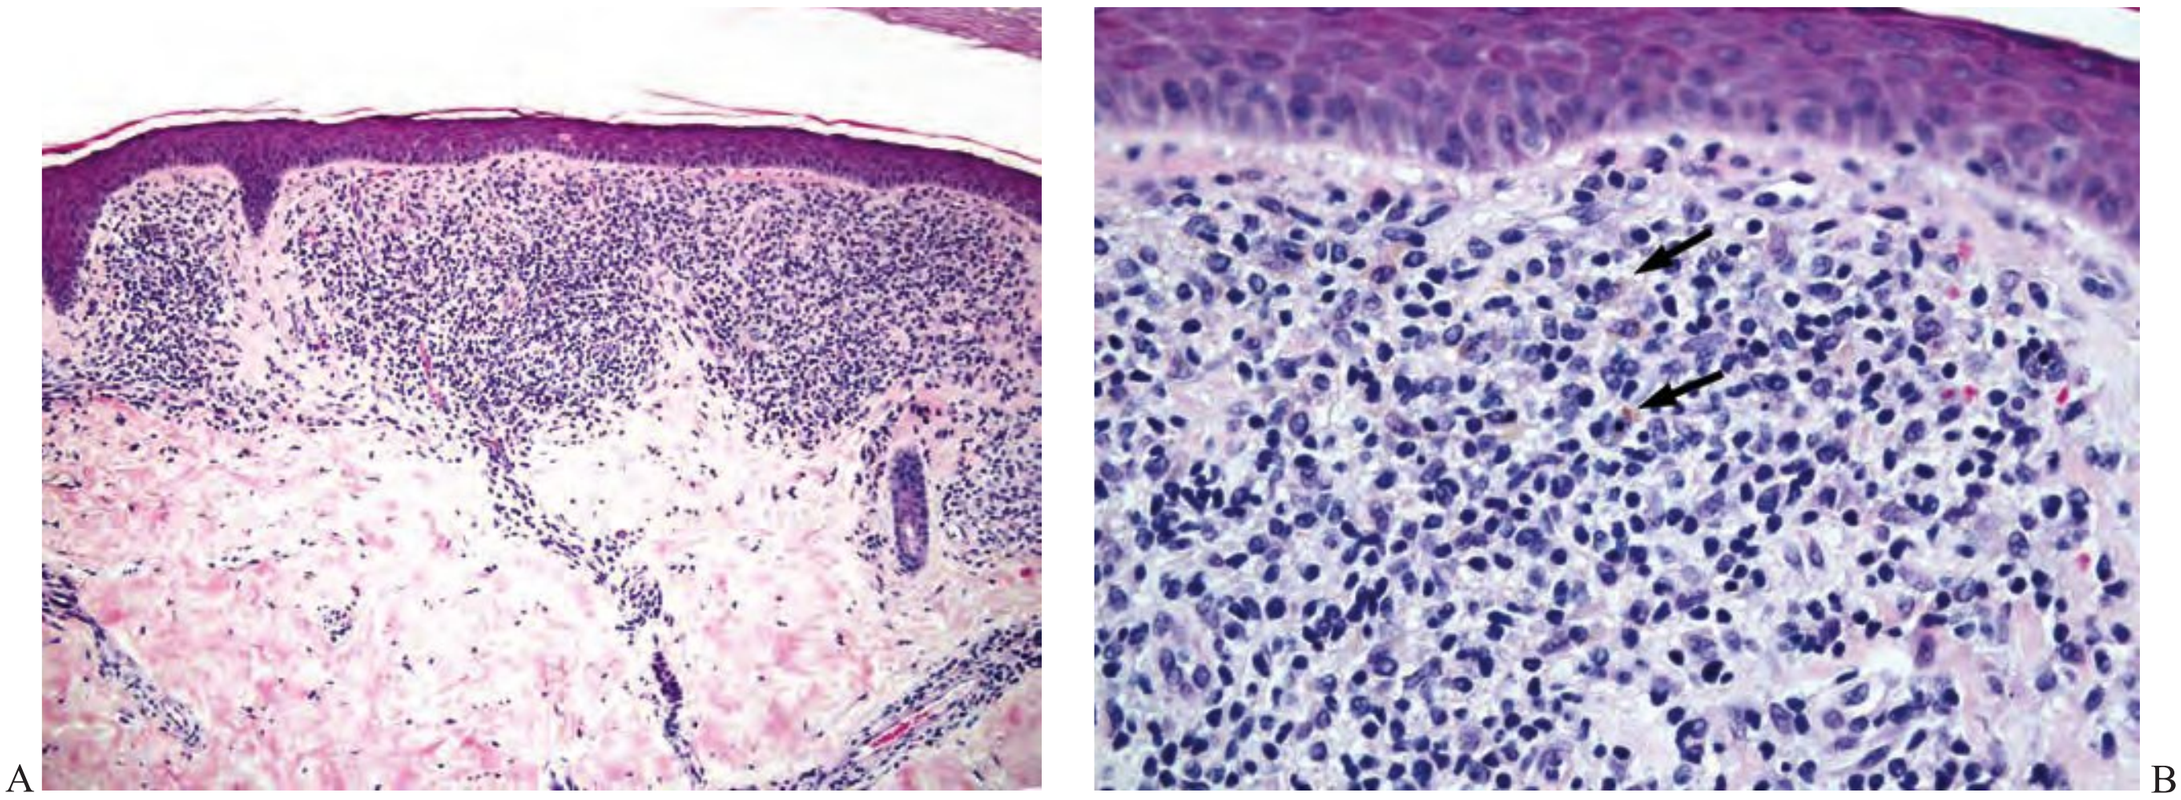

FIGURE 8-22. Lichen aureus. A dense lichenoid infiltrate in the papillary dermis (A), with hemosiderin-laden macrophages (B) (arrows), accounting for the golden clinical color of these lesions.

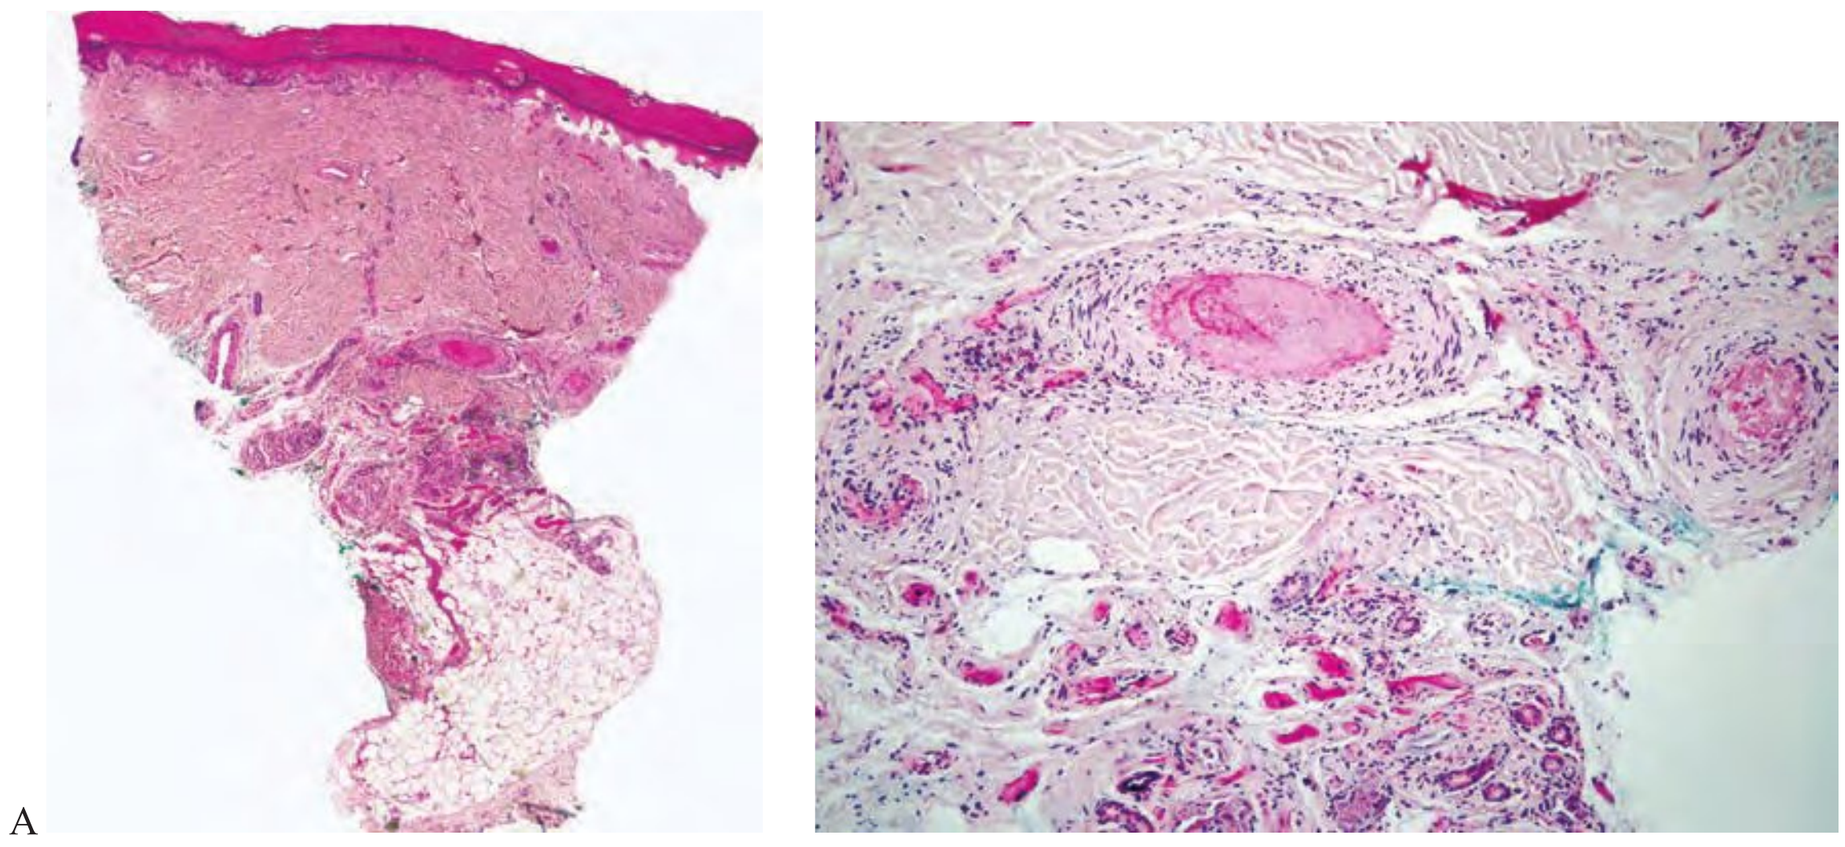
an abnormal T-cell process. Evidence of T-cell clonality may even be demonstrated in some examples of PPD that otherwise lack sufficient criteria for T-cell lymphoma. Careful evaluation of the lesion for epidermotropism and lymphoid atypia and (of particular importance) good clinicopathologic correlation are needed to arrive at the correct diagnosis. However, suspicious or equivocal lesions require monitoring and possibly further evaluation for possible progression to cutaneous T-cell lymphoma.

Pathogenesis. The etiology of PPD is essentially unknown, and there are probably several different factors involved. Some cases of chronic purpuric dermatitis may be related to a hypersensitivity reaction to drugs. However, in the majority of cases, the etiology of this process is unclear. Stasis changes are seen in some individuals with PPD, suggesting that venous insufficiency may be a contributing factor (84). Eruptions with the clinical and histologic appearance of a pigmented purpuric dermatitis have also been associated with subsequent development of a T-cell lymphoproliferative disorder in some patients. Thus, it is possible that some PPD may be the initial manifestation of T-cell lymphoproliferative disease (88,89).

VASCULOPATHIC REACTIONS AND PSEUDOVASCULITIS

Vasculopathic processes, as defined in Table 8-8, refer to the histologic finding of vascular damage in the absence of vasculitis. As already mentioned, the term pseudovasculitis has been used to describe a closely related group of conditions that mimic or exhibit some attributes of vasculitis. Vasculopathic reactions (and pseudovascultis) may be associated with (a) coagulopathies, (b) pathologic alterations of the vessel wall, (c) embolic phenomena, (d) structural deficiencies of the perivascular connective tissue, or (e) miscellaneous other disease processes, including drug-induced vasospasm and repetitive vascular injury.

Coagulopathies and Vascular Thrombosis



Any coagulopathy may be accompanied by vasculopathic changes. The extent of vascular damage is variable. Vascular damage may occur in the setting of altered platelet counts, such as in idiopathic thrombocytopenic purpura, in coagulation factor deficiencies (e.g., inherited or acquired protein C and S deficiencies), coagulopathies associated with connective tissue disease (e.g., lupus anticoagulant, antiphospholipid antibody syndrome; Fig. 8-23) and platelet thrombosis in heparin-induced skin necrosis. Extensive vascular damage with luminal occlusion by thrombotic material may develop in coumarin/warfarin-induced skin necrosis, in thrombotic thrombocytopenic purpura, and in disseminated intravascular coagulation—specifically in the setting of purpura fulminans (90).

In mild forms, the clinical manifestations may be subtle and limited to petechiae. In severe forms of coagulopathies, large areas of ecchymosis may be present, typically located on the extremities. Large hemorrhagic bullae may overlie the ecchymoses, and some of the ecchymotic areas may undergo necrosis. Retiform purpura (a livedoid pattern of cutaneous hemorrhage) in palpable plaques is characteristic of antiphospholipid antibody syndrome, heparin-induced skin necrosis, Coumadin/warfarin-induced skin necrosis, and calciphylaxis (91).

Histopathology. The histologic features are nonspecific for any particular disorder. In mild forms of coagulopathies, the only histologic manifestation may be dermal hemorrhage—that is, extravasation of red blood cells into perivascular connective tissue. With increasing severity of the disease process, intravascular fibrin thrombi may be found (Fig. 8-2). In severe forms (e.g., thrombotic thrombocytopenic purpura, coumarin necrosis, and

TABLE 8-8 Vasculopathic Reactions and Pseudovasculitis

Mechanism	Condition
Coagulopathies	Idiopathic thrombocytopenic purpura Coagulation factor deficiencies (e.g., protein C and S deficiencies) Antiphospholipid antibody syndrome Thrombotic thrombocytopenic purpura Coumadin/warfarin-induced skin necrosis Heparin-induced skin necrosis Calciphylaxis Purpura fulminans Disseminated intravascular coagulation Monoclonal gammopathy Sickle cell disease Livedo vasculopathy

Repetitive vascular trauma	Hypothenar hammer syndrome

A B

FIGURE 8-23. Antiphospholipid syndrome. A: A vessel in the deep dermis contains an eosinophilic fibrin thrombus. The affected vessels are commonly more superficial in this condition. B: The thrombus is not associated with inflammation of the vessel wall. Other small vessels in the vicinity are also affected.

purpura fulminans), thrombotic vascular occlusion may lead to hemorrhagic infarcts, epidermal and dermal necrosis, or subepidermal bulla formation. In severe systemic intravascular coagulation, internal organs may also show widespread thrombosis of small vessels and hemorrhagic necrosis.

Calciphylaxis

Calciphylaxis is an uncommon complication of renal failure usually in combination with secondary or tertiary hyperparathyroidism. Obesity, female gender, and poor nutritional status are putative risk factors. Painful violaceous lesions that may be indurated often develop in areas of livedo reticularis on the trunk and extremities and can rapidly progress to form bullae, ulcers, eschars, and gangrene. The prognosis is extremely poor, especially for proximal disease, even with aggressive treatment by parathyroidectomy (92). Fulminant sepsis may develop from infection of necrotic or gangrenous tissue.

Histopathologic Features. The principal histologic findings include (a) calcification of soft tissue and small vessels, (b) nonspecific intimal proliferation of small vessels, often resulting in luminal narrowing, (c) variable fibrin thrombi, and (d) frequent ischemic necrosis of skin and subcutis (Fig. 8-24). The small vessels involved by this process cannot be identified as either arterial or venous. Foreign body giant cell reaction to calcium and mixed inflammatory cell infiltrates that are neutrophil-rich may be seen.

Cutaneous calcium deposits may be seen in a number of other conditions, especially cutaneous calcinosis and metastatic calcifications. Calcinosis usually lacks prominent vascular involvement. Other crystal-induced inflammatory diseases such as gout, pseudogout, or oxalosis that are associated with a giant cell reaction to crystal deposits and surrounding fibrosis may resemble calciphylaxis. Histopathologically, pancreatic panniculitis may suggest calciphylaxis. However, the polymorphous infiltrate and ghostlike cells seen in panniculitis are absent in calciphylaxis (93). If a biopsy of calciphylaxis lacks significant calcium deposits due to sampling error, the findings may be limited to ischemic damage or mimic a coagulopathy.

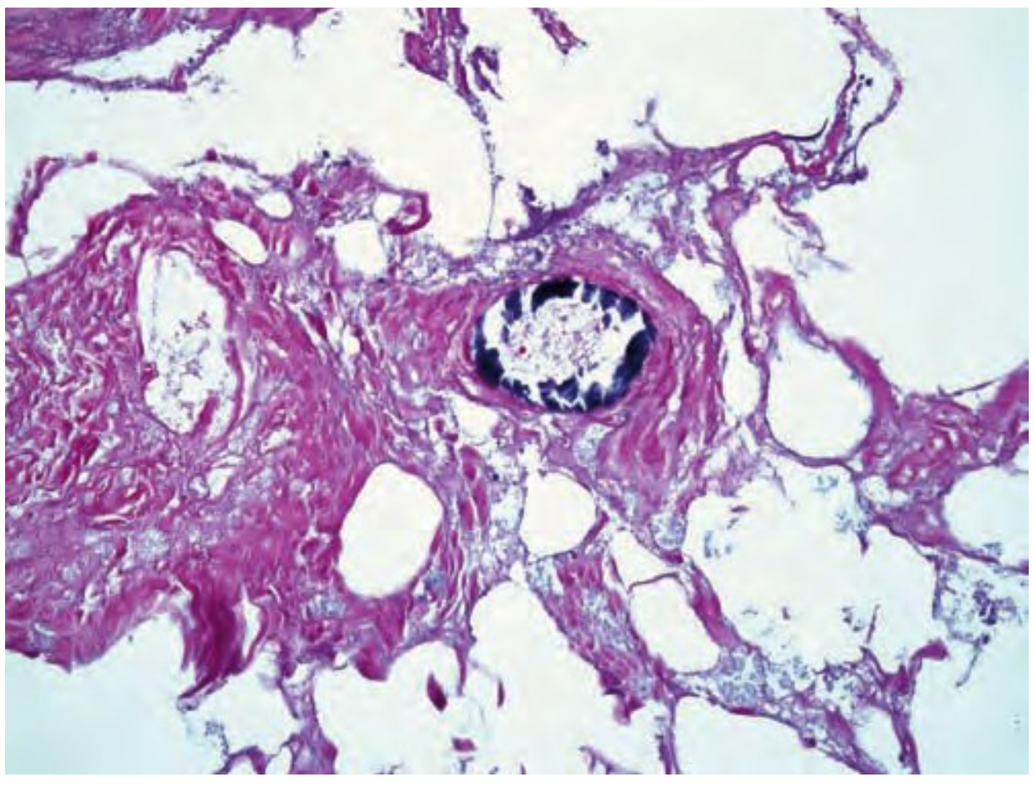

FIGURE 8-24. Calciphylaxis. There is calcification of the media of a small vessel in the panniculus, with delicate fibroplasia of the intima. There may be interstitial deposition of calcium as well.

Pathogenesis. The relationships among the calcification, thrombosis, and ischemic necrosis in calciphylaxis are unclear. Although vascular calcification is common in uremic patients, calciphylaxis is rare. Elevation of the calcium and phosphorous product along with a poorly defined precipitating or challenging event or agent is hypothesized to be necessary for calcium deposition in cutaneous tissues. However, the list of putative sensitizing agents is long, and the calcium and phosphorus product may be within normal limits. The development of a hypercoagulable state may be an additional important element in the pathogenesis of this entity but is not present in all cases (94). Finally, calciphylaxis may mimic vasculitis clinically (95,96).

Pathologic Alterations of the Vessel Wall Including Metabolic Vasculopathies

Vasculopathies may arise also from metabolic disorders. Deposition of endogenously produced material, as in diabetes mellitus, amyloidosis, or porphyria, may lead to vessel fragility. Hemorrhage and ischemic damage to the area of skin supplied by the affected vessels is seen. The basic histologic vascular alteration in the aforementioned disorders is the deposition of amorphous material in the walls of dermal capillaries. The details of the histopathology of these disorders are discussed in more detail in other chapters of this book.

Atherosclerosis is by far the most common form of vasculopathy. However, atherosclerosis is primarily a disease of large vessels supplying visceral organs, and thus it is not discussed here in detail. Cutaneous changes are usually rare and are secondary manifestations of peripheral ischemia. Luminal occlusion may result from intimal thickening and lipid deposition, superimposed thrombosis, or, less frequently, cholesterol emboli. Because cholesterol microemboli can cause cutaneous findings mimicking vasculitis, this phenomenon is discussed in more detail in the next subsection.

Embolic Phenomena

Cutaneous Cholesterol Embolism

Cholesterol crystal embolization is usually a disease of the elderly with significant atherosclerosis (97,98). Atheromatous plaque material may erupt or detach spontaneously. However, more commonly, plaque material is dislodged by an invasive procedure, such as arterial catheterization. Microemboli or cholesterol crystals typically lead to ischemic changes. Cutaneous manifestations are common, often affect the lower extremities, and include livedo reticularis, purple discoloration, gangrene of toes, and small, painful ulcerations on the legs. Occasionally, a few nodules or indurated plaques may occur. A typical clinical sign is adequate distal pulsation, indicating that the ischemia is arteriolar rather than arterial.

Histopathology. Cholesterol emboli may be found as needle-shaped clefts within the lumina of small vessels. The intravascular clefts, which are in effect dissolved cholesterol crystals, may be single or multiple and are commonly associated with amorphous eosinophilic material, macrophages, or foreign body giant cell reactions. Vascular walls exhibit intimal fibrosis and often obliteration of lumina in older lesions. In many instances, only fibrin thrombi are observed. Often a deep biopsy and multiple sections of biopsy material are needed to reveal such emboli, which are distributed focally and therefore are difficult to find.

Vasculopathies Resulting from Deficiencies in Connective Tissue

Finally, structural deficiencies in the perivascular connective tissue may cause vascular fragility and lead to dermal hemorrhage. Such alterations underlie the hemorrhages that accompany senile purpura and scurvy.

Histopathology. In senile purpura, extravasation of red blood cells is encountered in atrophic skin with solar elastosis and normal-appearing capillaries. In scurvy, dermal hemorrhage is found predominantly in the vicinity of hair follicles without evidence of capillary changes. Hemosiderin-laden macrophages are usually noted (99). Other findings associated with scurvy include intrafollicular keratotic plugs and coiled hair.

Other Clinical Presentations Associated with Vasculopathic Reactions

Livedo Reticularis

Livedo reticularis is persistent red-blue mottling of the skin in a netlike pattern and differs from cutis marmorata by not subsiding with warming of the skin. This condition is a nonspecific sign of sluggish blood flow from any cause. Associations include vasculitis or vasculopathy in the context of several different systemic or localized disease processes, such as infection, atrophie blanche, cholesterol emboli, and connective tissue disease. Frequently, however, the condition is idiopathic and limited to the lower extremities. Generalized livedo reticularis has also been described as part of a potentially severe arterio-occlusive syndrome (Sneddon's syndrome) that is often complicated by cerebrovascular disease (100).

Histopathology. A biopsy specimen taken from an erythematous area may be normal, whereas a biopsy specimen from a white area may show a vessel with a thickened wall and the lumen occluded by a thrombus. In other cases, deeply situated dermal arterioles have shown obliterative changes. Other changes observed in livedo reticularis are intravascular aggregates of red blood cells, suggesting a low flow state.

Atrophie Blanche

Atrophie blanche is a common condition that usually affects middle-aged or elderly women (101). Synonymous terms are *livedoid vasculitis*, *livedo reticularis with seasonal ulceration*, and *segmental hyalinizing vasculitis*. Typically located on the lower portions of the legs, particularly on the ankles and the dorsa of the feet, this condition begins as purpuric macules and papules, which develop into small, painful ulcers with a tendency to recur. Healing of the ulcers results in the white atrophic areas that have given the disease its name. A fully developed case of atrophie blanche shows irregularly outlined, whitish atrophic areas with peripheral hyperpigmentation and telangiectasia. Many of the patients have associated livedo reticularis. The condition also may be seasonal, with the greatest disease activity in the summer and winter months.

Histopathology. The histologic findings are nonspecific and vary with the stage of the lesion. However, in all stages, vascular changes are present. In early lesions, fibrinoid material may be noted in the vessel wall or vessel lumen (Fig. 8-25). Infarction

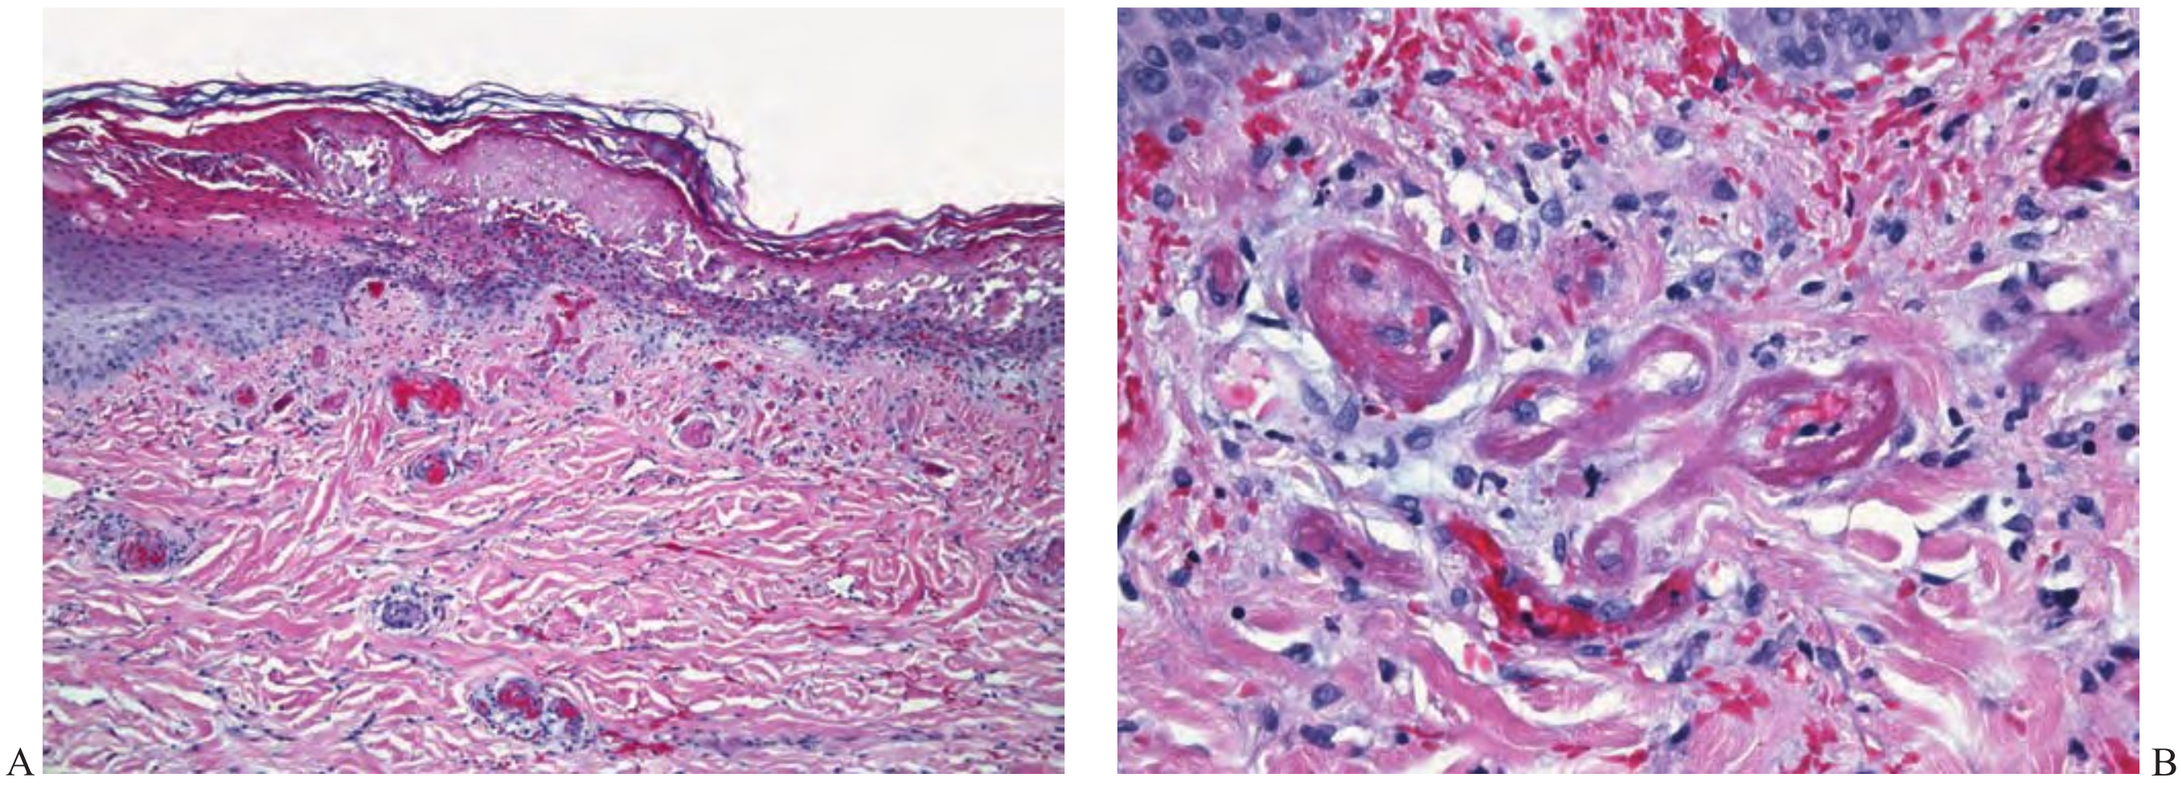

FIGURE 8-25. Atrophie blanche. A: An early lesion characterized by an area of epidermal necrosis with underlying vasculopathy. B: The superficial portion of the epidermis is necrotic. Vessel walls are thickened and contain fibrinoid/thrombotic material.

with hemorrhage and an inflammatory infiltrate may be present as well. In late atrophic lesions, the epithelium is thinned and the dermis is sclerotic, with little if any cellular infiltrate. The walls of the dermal vessels may show thickening and hyalinization of the intima. Luminal occlusion by intimal proliferation and/or fibrinoid material and sometimes recanalized thrombotic vessels may be seen. In some cases, the vessels in the superficial dermis are predominantly affected; in others, the vessels in the middle and even deep dermis are mostly affected.

Pathogenesis. The etiology of atrophie blanche is unknown. Immune complex deposits that have been observed in late lesions are likely secondary changes (102). A primary disturbance of fibrinolysis in the endothelium of affected microvessels has been postulated (103).

Degos' Syndrome

Degos had initially described a cutaneointestinal syndrome in which distinct skin findings ("drops of porcelain") were associated with recurrent attacks of abdominal pain that often ended in death from intestinal perforations (104). The skin lesions of this syndrome arise in crops of asymptomatic, slightly raised, yellowish red papules that gradually develop an atrophic porcelain-white center. These papules tend to affect the trunk and proximal extremities. Degos chose the name *malignant atrophic papulosis* (MAP) for these lesions to emphasize the serious clinical course of the cutaneointestinal disease he was describing. At that time, the cutaneous lesions were then thought to be specific and pathognomonic for this unique disease entity (Degos' disease). However, skin-limited forms of Degos' disease have been described (105–107), and currently such skin lesions are considered to be a clinicopathologic reaction pattern that can be associated with a number of conditions (108). Lesions similar if not identical to MAP have been noted in connective tissue diseases such as lupus erythematosus, dermatomyositis, and progressive systemic sclerosis, in atrophie blanche, and in Creutzfeldt-Jakob disease (109).

Histopathology. The classic lesion shows a wedge-shaped area of altered dermis covered by atrophic epidermis with slight hyperkeratosis. Dermal alterations may include frank necrosis. More common, however, are edema, extensive mucin deposition, and slight sclerosis (Fig. 8-26). A sparse perivascular lymphocytic

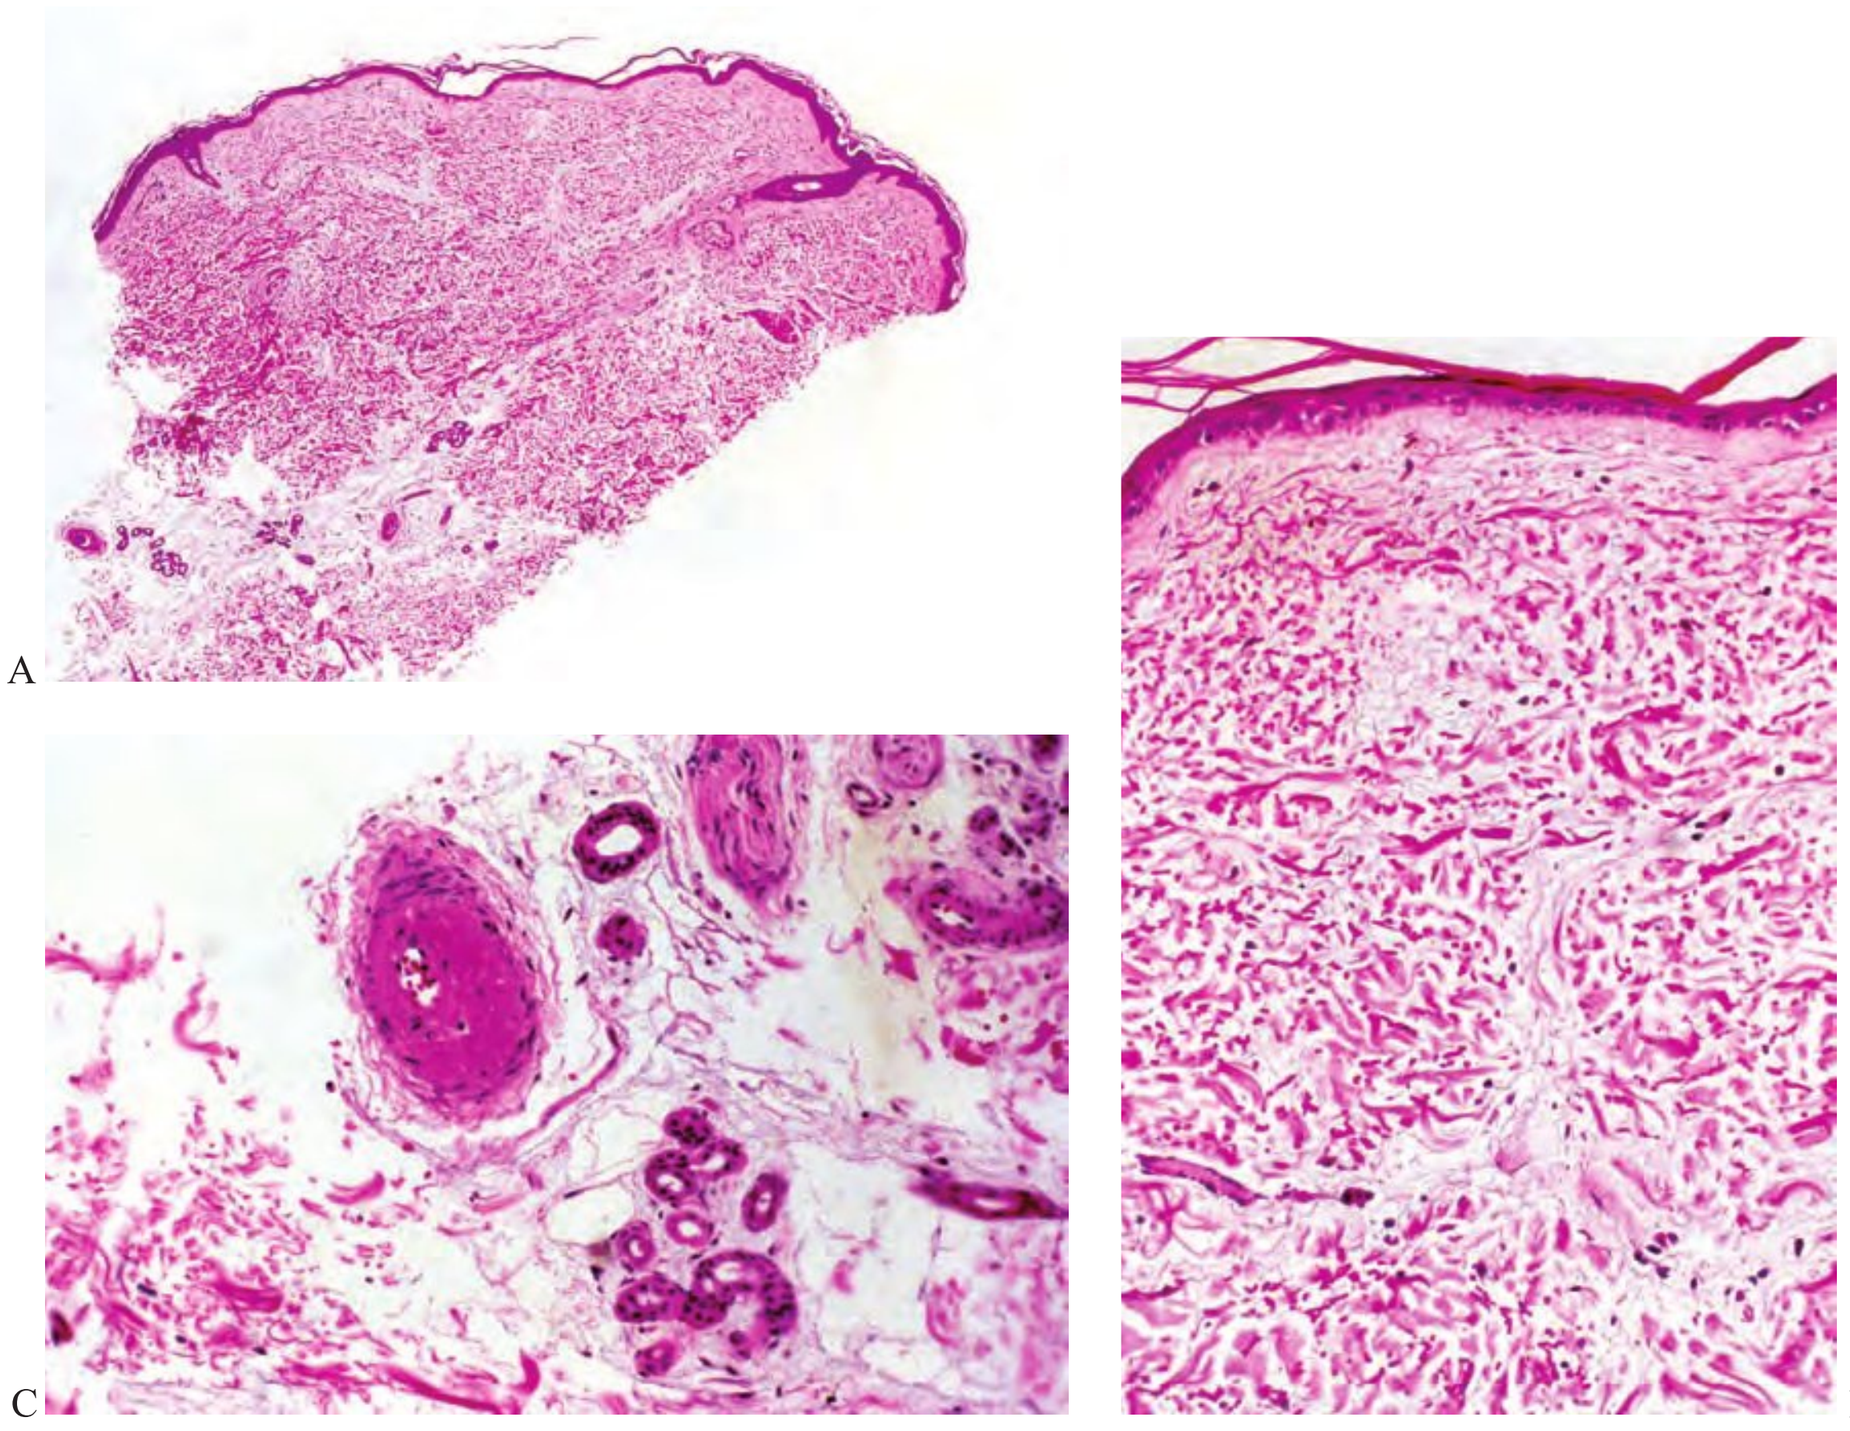

FIGURE 8-26. Degos' lesion. Atrophic epidermis overlies a wedge-shaped area of dermis (A) with mucin deposition (B) and a thrombosed vessel at the base (C). This Degos' lesion was observed in a patient with dermatomyositis.

infiltrate may be seen, although the dermis is largely acellular. Typically, vascular damage is noted in the vessels at the base of the "cone of necrobiosis." Vascular alterations may be subtle and manifest as endothelial swelling or demonstrate lymphocytic vasculitis. However, more characteristically, intravascular fibrin thrombi may be noted, suggesting that the dermal and epidermal changes result from ischemia. Altered vessels may lack an inflammatory infiltrate. The histopathology observed may vary with the evolution of the lesions. Early lesions may be more mucinous and mimic tumid lupus, whereas more evolved lesions are more sclerotic and suggest lichen sclerosus et atrophicus (105).

Pathogenesis. The etiology of Degos' syndrome is unclear. The findings have been ascribed to a coagulopathy, vasculitis, or mucinosis. However, convincing evidence to support any single causal factor is lacking.

Noninfectious Vesiculobullous and Vesiculopustular Diseases

CLASSIFICATION OF BLISTERS

Definition

A blister is a fluid-filled cavity formed within or beneath the epidermis. The fluid consists of tissue fluid and plasma. A variable component of inflammatory cells may also be present. Blisters may occur in many dermatoses. At first glance, this observation seems to imply that blistering is too general or nonspecific for use in clinical gross evaluation. However, the character of blisters in a given disorder tends to be uniform and to have reproducible characteristics. One useful distinction is the categorization of blisters into *vesicles* (blisters $<$0.5 cm in diameter) and *bullae* (blisters $>$0.5 cm in diameter). For example, vesicles characteristically occur in dermatitis herpetiformis as opposed to pemphigoid, in which bullae are most commonly observed.

Mechanisms of Blister Formation

The mechanisms observable in routine sections for some diseases are shown in Table 9-1. *Spongiosis* is the accumulation of extracellular fluid within the epidermis with resultant separation of the keratinocytes. Pronounced spongiosis gives the keratinocytes a stellate appearance and subsequently leads to disruption of desmosomes and blister formation. Thus, the epidermis has a "spongy" appearance microscopically, and the increasing accumulation of fluid leads to a vesicle and, in some instances, to a bulla. Marked spongiosis may terminate in reticular degeneration (see below). Spongiosis is almost always associated with an infiltrate of lymphocytes within the epidermis and around superficial vessels. However, spongiosis is a passive event associated with increased permeability of the superficial vascular plexus, particularly the postcapillary venules. Spongiotic keratinocytes are viable cells.

Acantholysis results from the loss of appropriate keratinocyte cell-cell contact. Histologic evidence of acantholysis includes the presence of rounded keratinocytes with condensed cytoplasm and large nuclei with peripheral condensation of chromatin and prominent nucleoli. Acantholytic keratinocytes are viable. The rounded keratinocytes of acantholysis differ strikingly from the stellate keratinocytes of spongiotic dermatitis.

Reticular degeneration results from ballooning degeneration (intracellular edema) with secondary rupture and death of the keratinocytes. The remaining desmosomal attachments often connect strands of ruptured keratinocytic membranes and cytoplasm to intact keratinocytes, giving the epidermis an irregular meshwork appearance.

Cytolysis is the disruption of keratinocytes. It occurs in the normal epidermis when the structural (keratin) matrix and desmosomal plaques of the keratinocyte are overwhelmed by high levels of physical agents such as friction and heat. Friction (mechanical energy applied parallel to the epidermis) leads to the shearing of keratinocytes one from another and of the keratinocytes themselves, giving the characteristic clear fluid-filled blisters. Minimal friction may lead to cytolysis in subjects whose keratinocytes do not have normal structural matrix and desmosomes, such as in epidermolysis bullosa (EB) simplex and EB of the Cockayne-Weber type.

Basement membrane zone disruption or destruction results from primary structural deficiencies as well as from both humoral and cellular immunologically mediated damage. When blisters arise at the epidermal basement membrane zone, any of the specific subanatomic compartments can be affected: (a) the basal keratinocytes, in particular their lower portions; (b) the lamina lucida, an electron lucid area immediately subjacent to the plasma membrane; (c) the lamina densa, composed principally of type IV collagen; and (d) the sublamina densa zone.

Pathologic Evaluation

When blisters are encountered microscopically, systematic analysis can lead to diagnosis in most cases. The critical interpretive assessments to be approached in sequence are as follows: (a) the blister separation plane (Table 9-2); (b) the mechanism(s) of blister formation (Table 9-1); and (c) the character of the inflammatory infiltrate, including its presence or absence, its pattern, and the specific cell types involved (Table 9-3).

Six principal problems are encountered when using this algorithm. The first is that the separation plane may change as blisters age. Spongiotic microvesicles may move into the stratum corneum as crust. The epidermal blister roofs may become necrotic, not allowing assessment of the original blister plane. However, the basal keratinocytes may retain their columnar appearance in the blister roof (or base), allowing for

separation into either suprabasal or subbasal blister formation. Also, basal keratinocytes are the most melanized cells in the epidermis. Search for the melanized basal keratinocytes (i.e., the basal unit), even if they are necrotic, may allow assessment of the original blister plane. Immunohistochemical stain for type IV collagen is sometimes useful in sublamina densa blistering disorder because type IV collagen may be detectable on the base of subepidermal blister roofs even when the blister roof is necrotic. Some blister roof may be viable for a week or so; in this case, the viable keratinocytes may become elongated and line the base of the blister roof. Similarly, the re-epithelialized subepidermal or suprabasal blister bases are initially lined by flat squamous keratinocytes rather than columnar or cuboidal keratinocytes. When re-epithelialization first occurs, there is no normal rete and the flat squamous keratinocytes migrate on a matrix of fibrinogen, not normal papillary dermis. Second, microscopic slitlike spaces occur within the epidermis in the group of clefting diseases—Darier's disease, Hailey-Hailey disease, and Grover's disease—mimicking true blisters. However, these clefts are small and do not contain fibrin and tissue fluid. Furthermore, this group of disorders only rarely presents clinically with blisters. Third, evaluation of routine histologic preparations may not allow accurate assessment of the specific mechanism of blister formation. This is particularly true in the subepidermal vesiculobullous disorders. Fourth, the cell types infiltrating the lesions in the vesiculobullous diseases change as the lesions age. Fifth, the histologic descriptions of many of the subepidermal blistering disorders are not accompanied by the rigorous immunologic evaluation required today. For example, many cases originally reported as bullous pemphigoid and cicatricial pemphigoid are now known to be better classified as epidermolysis bullosa acquisita (EBA) and linear IgA bullous dermatosis. Many of the subepidermal blistering disorders may strikingly mimic each other clinically, leading to inappropriate diagnosis and making the histologic descriptions in the literature suspect. Finally, in order to rapidly improve the rash and symptomology of the patient, clinicians often embark on therapeutic regimens for the presumed clinical diagnosis. The therapy often consists of topical or systemic steroids and inhibitors of inflammation. Histopathologic examination of a biopsy is only pursued when the therapeutic response is nil or partial, calling into question the clinical diagnosis. Many submit biopsies without notifying the dermatopathologist of the therapy. Such therapy often suppresses the inflammatory infiltrate, the epidermal response, the "triple response of Lewis," and other histopathologic changes. The evolution and temporal relationship of histologic changes of dermatitides under various therapies are NOT sufficiently

documented to allow optimal or perhaps even accurate diagnostic study. Biopsies should be taken of virgin disease and not of therapeutically altered skin if at all possible. If therapy has been instituted, it should be stopped, if possible, at least a week before biopsy.

With these points in mind, the specific disorders and groups of disorders will be discussed.

SPONGIOTIC DERMATITIS

Definition and Evaluation

Spongiotic dermatitis may be acute, subacute, or chronic. The process is dynamic, and each specific type of dermatitis may progress from the acute to the chronic phase. Although the term *spongiotic dermatitis* is occasionally used interchangeably with *eczema*, the word *eczema* lacks specific meaning. *Spongiosis* refers to the accumulation of edema fluid between keratinocytes, in some cases progressing to vesicle or even bulla formation.

In *acute spongiotic dermatitis*, the stratum corneum is normal and the epidermis is of normal thickness. The degree of spongiosis is variable, extending from slight to marked, with intraepidermal vesiculation in the latter instance. The surrounding keratinocytes may be stellate, surrounded by clear spaces representing the site of fluid collection (Fig. 9-1). Papillary dermal edema is present, correlating with the degree of spongiosis. A lymphohistiocytic infiltrate is present around the superficial plexus, with exocytosis of lymphocytes into spongiotic foci.

In *subacute spongiotic dermatitis*, there is usually mild to moderate spongiosis, occasionally with microvesiculation. The epidermis is moderately acanthotic. The parakeratotic stratum corneum may contain aggregates of coagulated plasma and scattered lymphocytes and neutrophils, forming a crust (Fig. 9-2). There is a superficial perivascular lymphohistiocytic infiltrate, which is less prominent than in the acute phase. Impetiginization by gram-positive cocci (Staphylococci and Streptococci) may lead to neutrophilic crust.

In *chronic dermatitis*, there is hyperkeratosis with areas of parakeratosis, often wedge-shaped hypergranulosis, and moderate to marked acanthosis. Spongiosis may be present focally, often minimal in degree. The inflammatory infiltrate is often sparse, and papillary dermal fibrosis may be a prominent feature. The degree of spongiosis and quantity of the infiltrate reflect the present activity of the underlying dermatitis. The other changes reflect lichen simplex chronicus (Fig. 9-3) with its vertical streaking of thick papillary dermal collagen.

Specific Types of Spongiotic Dermatitis

Allergic Contact Dermatitis

The prototype of acute spongiotic dermatitis is allergic contact dermatitis, secondary to exposure to poison ivy. Usually between 24 and 72 hours after exposure to the antigen, the

TABLE 9-3 Principal Infiltrating Inflammatory Cells in Some Vesiculobullous Dermatoses*

Dermatosis	Principal cell type	Infiltrate
Porphyria Variegate Cutanea tarda	—	Absent
EBA (classic)	—	Absent
Bullous pemphigoid (cell poor)	Eosinophils	Minimal
Spongiotic dermatitis	Lymphocytes	Present
EM	Lymphocytes	Present
Bullous pemphigoid (cell rich)	Eosinophils	Present
Herpes gestationis	Eosinophils	Present
Dermatitis herpetiformis	Neutrophils	Present
LAD	Neutrophils	Present
EBA (inflammatory)	Neutrophils or Mixed neutrophils and eosinophils	Present
Anti-p200 pemphigoid	Neutrophils or Mixed neutrophils and eosinophils	Present
Bullous SLE	Neutrophils Interface dermatitis	Present
Cicatricial pemphigoid	Mixed neutrophils and eosinophils Lymphocytic, bandlike (mucosa only) Eosinophils	Present
Paraneoplastic pemphigus	Lymphocytes—interface dermatitis (lichen planus or EM-like)	Present

EBA, epidermolysis bullosa acquisita; EM, erythema multiforme; LAD, linear IgA dermatosis; SLE, systemic lupus erythematosus.
*These descriptions are accurate in the vast majority of the cases in each dermatosis; however, occasionally the cell types may differ, rendering IF testing mandatory. Other inflammatory cells may be present as a minor component but on occasion are of significant number. The inflammatory cells in old or healing lesions often are not cells that are characteristic of the specific primary disease but represent the inflammatory cells present in healing or responding to secondary effects of the vesiculobullous disorder.

patient develops pruritic, edematous, erythematous papules and plaques and, in some cases, vesicles. Linear papules and vesicles are common in allergic contact dermatitis to poison ivy, reflecting the points of contact between the plants or the antigen-contaminated hands and the skin. Other common causes of allergic contact dermatitis (Fig. 9-1A) include nickel, paraphenylenediamine, rubber compounds, fragrances, and preservatives in cosmetics. The degree of histologic alterations to these antigens may be less striking than that secondary to poison ivy.

Histopathology. Early lesions are acute spongiotic dermatitis. If vesicles develop, they may contain clusters of Langerhans cells, some flask-shaped. There is a superficial dermal infiltrate of lymphocytes, macrophages, and Langerhans cells with accentuation around the small vessels. Eosinophils may be present in the dermal infiltrate as well as within areas of spongiosis (Fig. 9-1B, C). In patients with continued exposure to the antigen, the biopsy may show a subacute or, later, a chronic spongiotic dermatitis, often with lichen simplex chronicus due to rubbing.

Pathogenesis. Allergic contact dermatitis represents a type IV cell-mediated delayed hypersensitivity reaction. The immunologic reaction consists of an afferent limb, the sensitization or induction phase, and an efferent limb, the elicitation phase. The allergen is usually of low molecular weight (a hapten) and lipid soluble. After penetrating the skin, the hapten binds to a carrier protein to form a complete antigen, which is processed by antigen-presenting cells, principally the epidermal Langerhans cells, and possibly other cutaneous dendritic cells. These cells then migrate to the draining lymph nodes, where they present the antigen to T lymphocytes. The process triggers antigen-specific commitment and production of memory and effector T cells. Following subsequent exposure of the sensitized subject to the same allergen, an accelerated and more aggressive secondary immune response will be elicited. Both $CD4^+$ and $CD8^+$ subtypes of T lymphocytes participate in

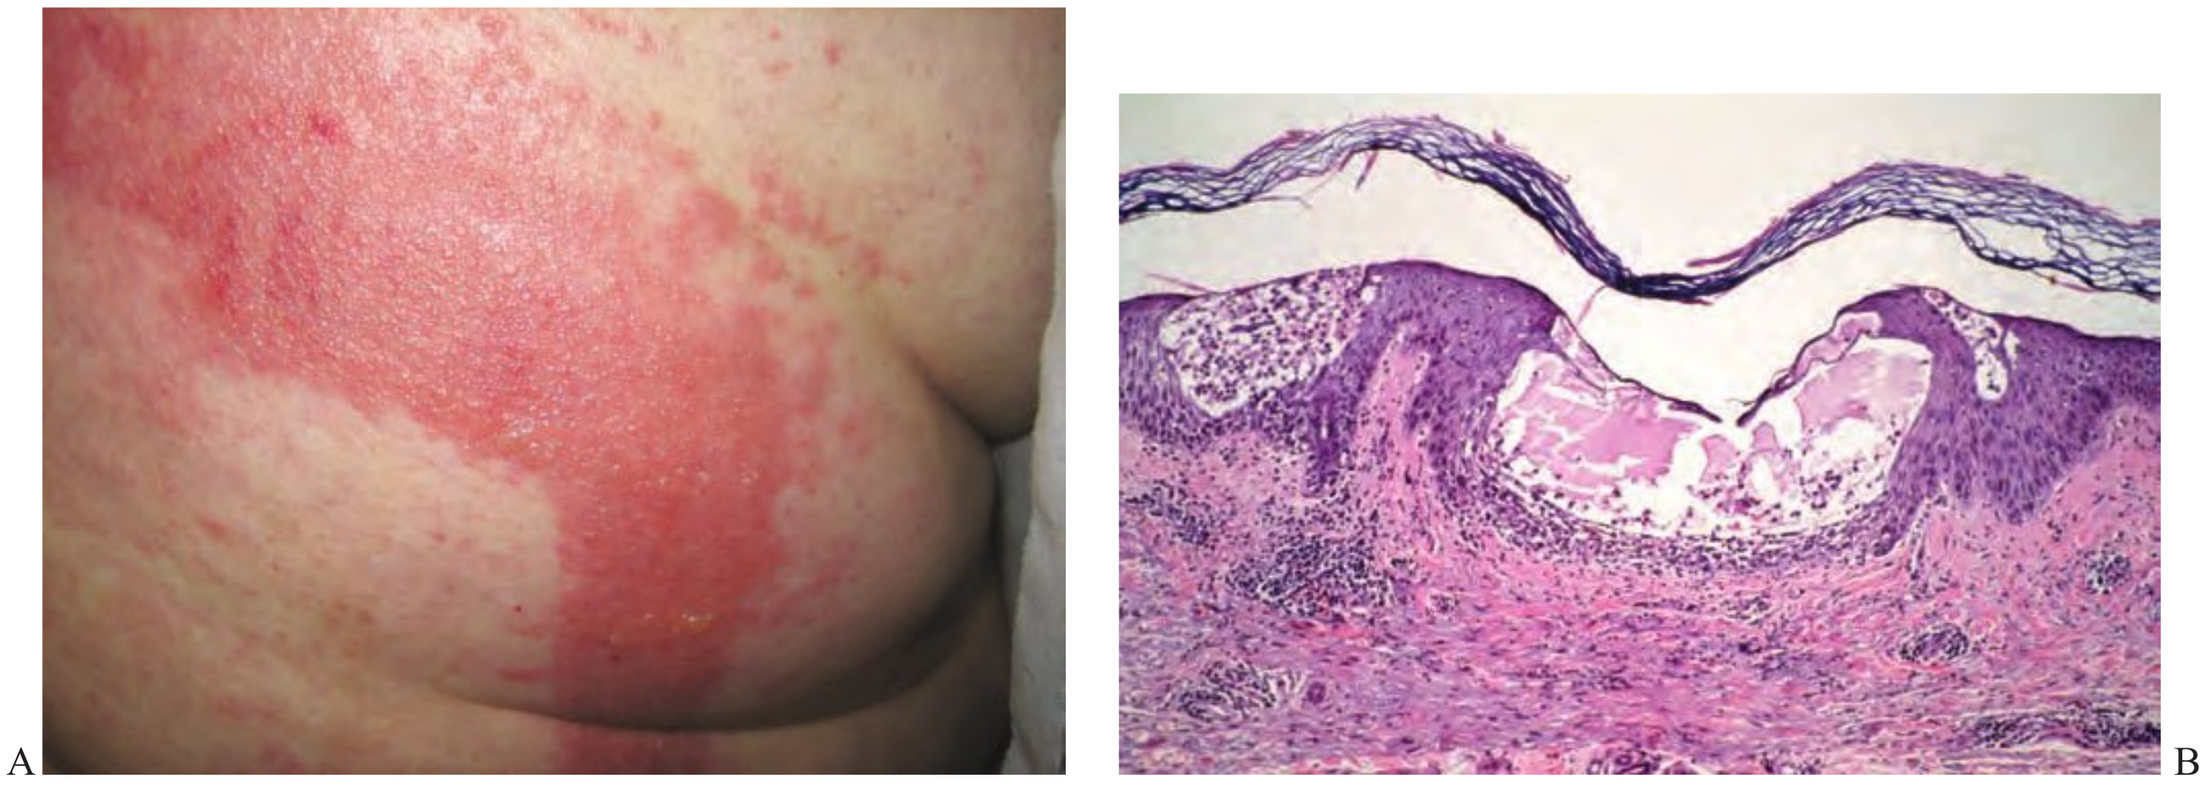

FIGURE 9-1. Acute dermatitis: allergic contact dermatitis. A: Geometric erythematous plaque with overlying vesicles on the back of a patient with allergic contact dermatitis to adhesive tape. B: Spongiosis with vesicles containing fluid and inflammatory cells. C: Exocytosis of lymphocytes and eosinophils into the spongiotic epidermis.

contact hypersensitivity reactions (1). The homing of lymphocytes to the antigen in exposed skin requires various cell adhesion molecules, such as lymphocyte function–associated antigen-1 (LFA-1) (2). Lymphocytes liberate various cytokines in the affected area of skin, including interleukins (ILs), IFN-γ and TNF-α, leading to a further influx of inflammatory cells, particularly nonsensitized lymphocytes and eosinophils. Chemokines appear to be crucial regulators of both induction and expression of allergic contact dermatitis.

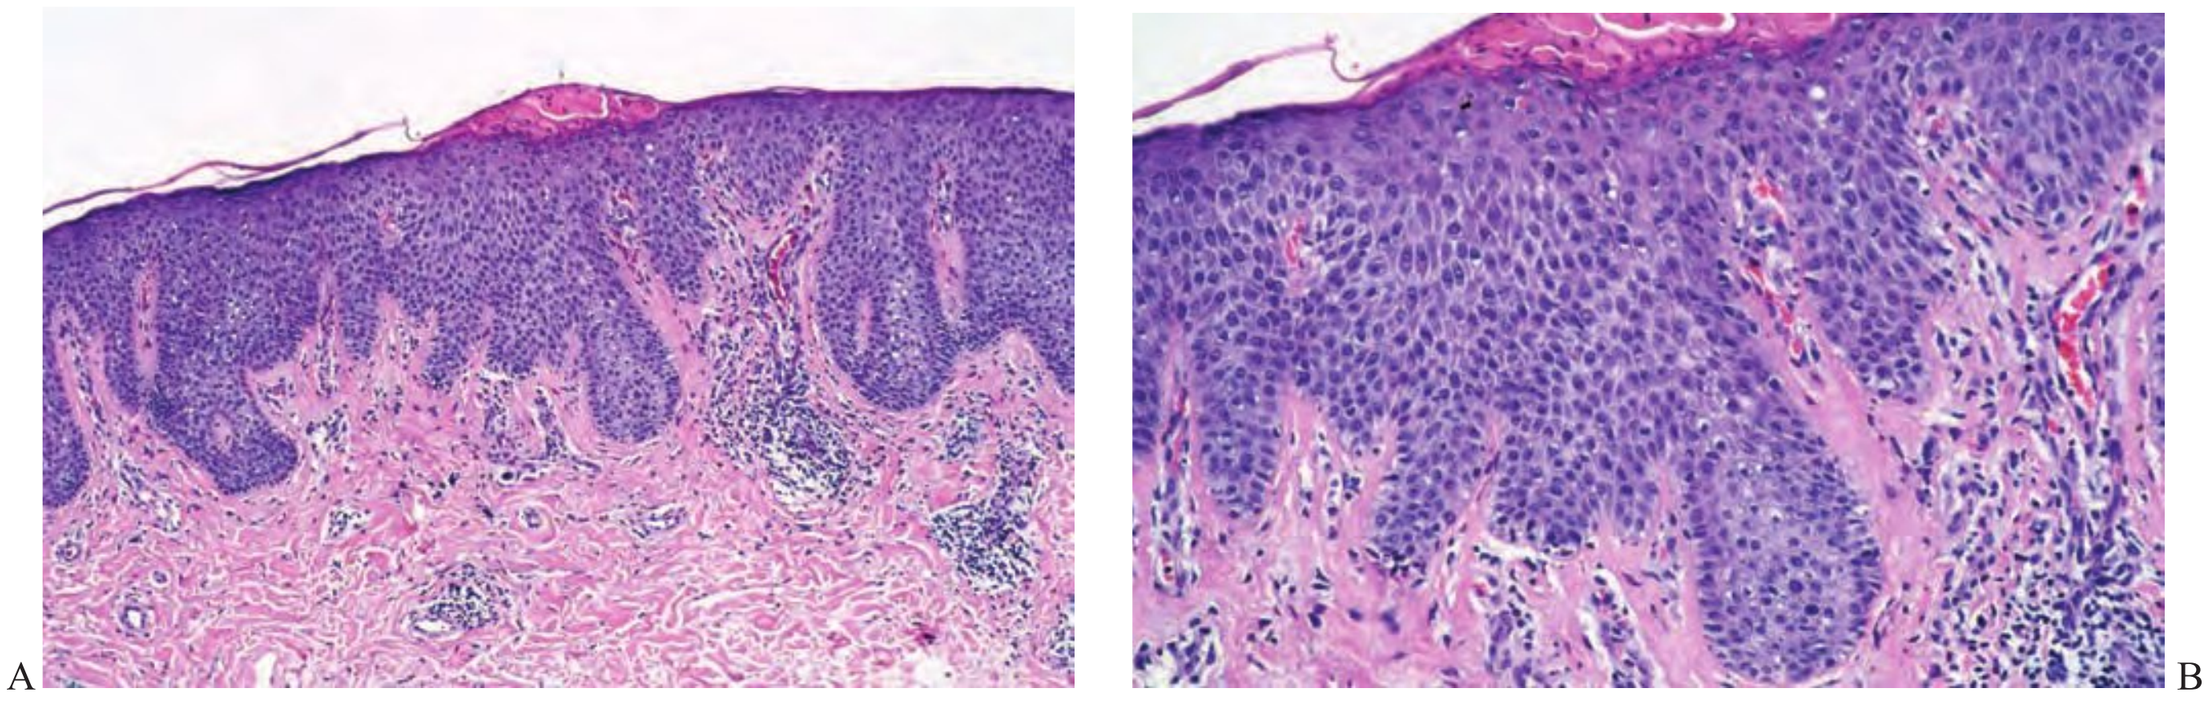

FIGURE 9-2. Subacute spongiotic dermatitis: nummular dermatitis. A: There is irregular acanthosis, spongiosis, and superficial perivascular inflammatory infiltrate. Parakeratosis containing plasma is also present. B: Spongiosis is accompanied by exocytosis of inflammatory cells.

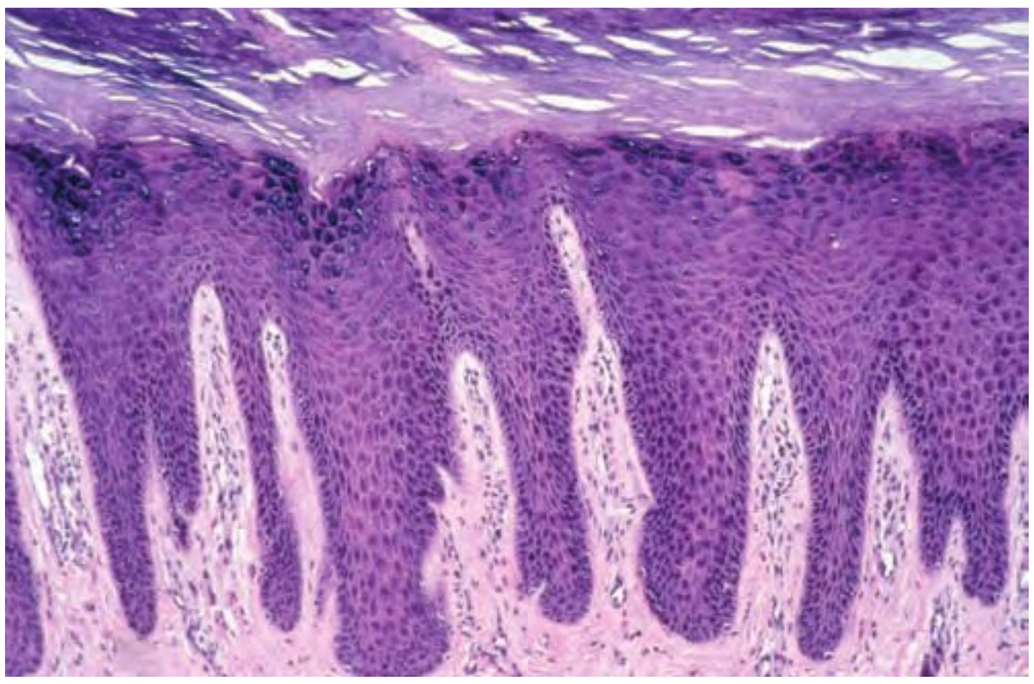

FIGURE 9-3. Lichen simplex chronicus. There is hyperkeratosis, hypergranulosis, and irregular psoriasiform acanthosis with minimal spongiosis. Vertically oriented collagen in the papillary dermis is characteristic.

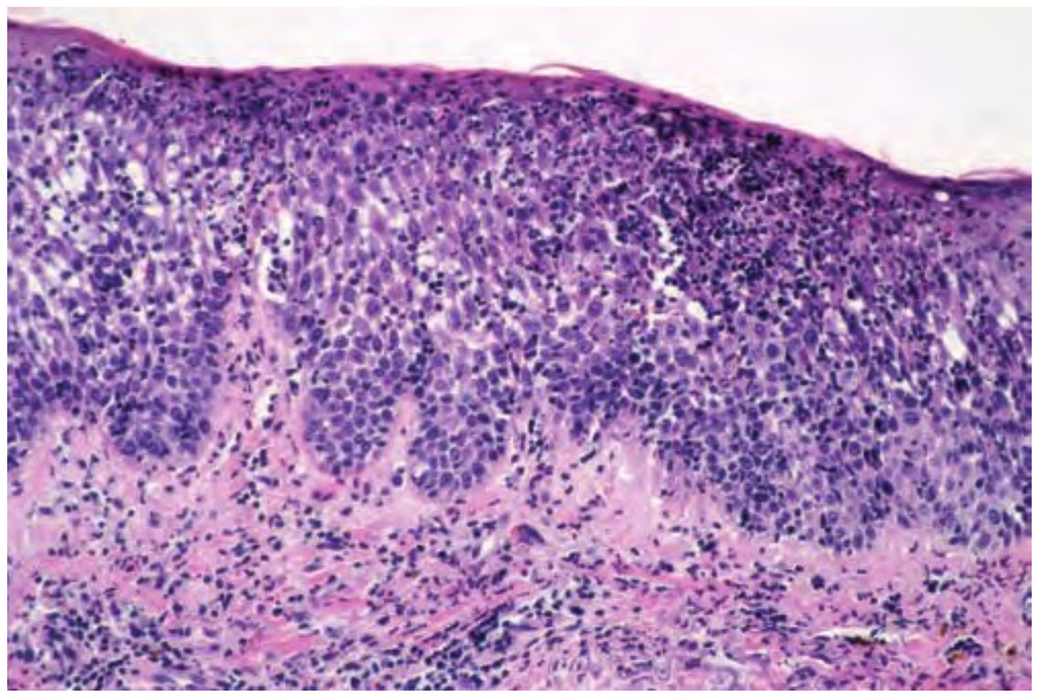

FIGURE 9-4. Irritant dermatitis. There is superficial epidermal necrosis together with spongiosis and infiltrate of neutrophils.

Irritant Contact Dermatitis

This inflammatory reaction occurs after exposure to an irritant, a toxic compound that causes a reaction in most individuals who come into contact with it. Common irritants include alkalis, such as soaps, detergents, lye, and ammonia-containing compounds. The irritant response is determined by the type of chemical, its concentration, the mode of exposure, the body site, the barrier function locally, and the age of the patient. Atopy is a predisposing factor. The clinical morphology varies. Sometimes it is indistinguishable from allergic contact dermatitis.

Chemical burns, usually caused by strong alkalis and acids, lead to immediate painful erythema progressing to vesiculation, necrosis, and, if severe, ulceration. Acute irritant reactions produce a monomorphic picture with scaling, redness, vesicles, pustules, or erosions and are caused by such mild irritants as detergents and water with additives. Agents producing this pattern include tretinoin, benzalkonium chloride, dithranol, adhesive tapes, and cosmetics. Dryness, chapping, and absence of vesicles characterize chronic irritant contact dermatitis. This reaction pattern is produced by repetitive contact to water, detergent, and solvents.

Histopathology. The histologic picture varies from extensive ulceration to simply diffuse hyperkeratosis or parakeratosis with congestion and ectasia to a spongiotic pattern essentially identical to allergic contact dermatitis. The variable features reflect the protean factors discussed above. Some correlations are worthy of note. In some instances, there is significant necrosis with nuclear karyorrhexis and cytoplasmic pallor. In severe reactions, the necrosis may extend into the dermis. Some irritants such as cantharidin and trichloroethylene produce acantholysis and neutrophilic infiltration in the epidermis (3) (Fig. 9-4). Other contactants may specifically target vascular endothelium. However, some reactions may be entirely spongiotic, such as those due to weak irritants, strong irritants in low concentration, and those in the "irritable skin syndrome." Because of these observations and those made in positive patch test sites, routine histopathologic changes do not reliably separate irritant from allergic contact reactions, although necrosis, neutrophilic infiltration, and acantholysis are more frequent in the former. In the recovery phase of irritant dermatitis, mild epidermal hyperplasia, sometimes psoriasiform, is often present. Psoriasiform hyperplasia may develop in chronic irritant reactions. In other words, most common irritants lead to subacute and chronic spongiotic dermatitis—histologic features that are identical to those of allergic contact reactions. Some contact reactions may manifest as only hypekeratosis and minimal spongiosis.

Pathogenesis. The pathogenesis at the cellular and molecular level of irritant contact dermatitis is not completely understood. Mechanisms of damage are variable with different irritants; these include keratin denaturation, damage of the permeability barrier through removal of surface lipid and water-holding substances, disruption of cell membranes, and direct cytotoxic effects. Recent studies indicate that very complex reaction patterns involving immunologic components occur in the irritant response. There are surprisingly more similarities than differences between irritant contact dermatitis and allergic contact dermatitis in morphology, clinical manifestation, chemokine expression, and involvement of T cells (4–6).

Dyshidrotic Dermatitis

Dyshidrotic dermatitis is characterized by recurrent, severely pruritic, deep-seated vesicles that classically involve the lateral aspects of the fingers and, in some cases, the toes. Episodes may be precipitated by infections, "id" reactions, contact reactions, and emotional stress. In chronic cases, there may be more extensive involvement of the palms and soles. Although the eruption develops acutely, it may become chronic with erythema, lichenification, and fissuring. Secondary impetiginization is common.

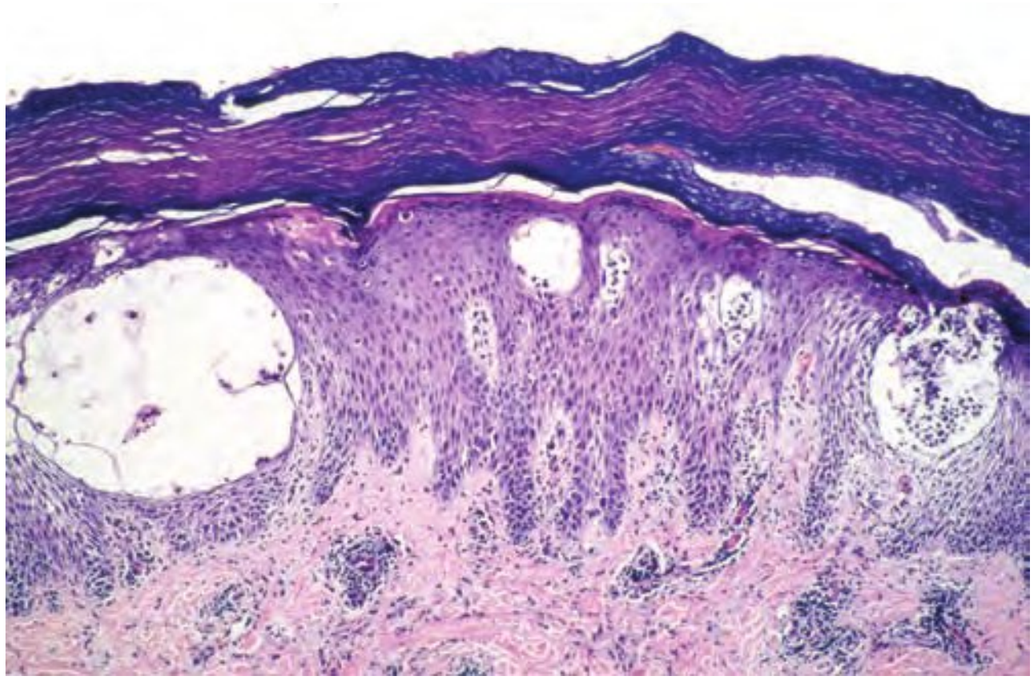

FIGURE 9-5. Dyshidrotic dermatitis. In acral skin, large intraepidermal vesicles are held intact by the thick stratum corneum.

Histopathology. Spongiosis and intraepidermal vesiculation occur in acute lesions (Fig. 9-5). There is a superficial perivascular lymphohistiocytic infiltrate with exocytosis of lymphocytes into spongiotic zones. The infiltration is usually mild. In acute lesions, the compact, thickened stratum corneum of acral skin remains intact, and the epidermal thickness is normal. With chronicity, spongiosis diminishes; acanthosis and parakeratosis predominate with variable crusting. Difficulty in differential diagnosis with pustular psoriasis may occur because of the formation of vesiculopustules in older lesions. A periodic acid-Schiff (PAS) stain should always be performed on vesicular lesions of the palms and soles, because tinea manus/pedis may mimic dyshidrotic dermatitis histologically.

Autoeczematization or Id Reaction

A sudden generalized or localized vesicular dermatitis developing in association with a defined local dermatitis or infection is known as an *id reaction*. The lesions are pinhead-sized, acuminate or flat-topped, papules. The patient most often has bullous tinea pedis or kerion, thus the name, *dermatophytid*. In some cases, patients have a severe localized dermatitis, such as stasis dermatitis, with subsequent development of widespread papulovesicular lesions (7). Other forms of id reaction exist.

Histopathology. The features are those of acute spongiotic dermatitis, often with micro- or macrovesiculation. Eosinophils may be present. There is often some edema of the superficial papillary dermis with some large lymphocytes (presumably activated) in the upper dermis (8). The infiltrating cells are T cells—those within the epidermis are principally $CD8^+$, and those within the dermis are principally $CD4^+$.

Pathogenesis. Id reactions have been postulated to represent hypersensitivity dermatitis to an autoantigen; however, this has never been proven. Several other possibilities exist. First, the reaction may represent a conditioned hyperirritability or responsiveness precipitated by the local infection or dermatitis. Acute local chemical irritation may lower the threshold for an irritant reaction to the same chemical at remote sites. Second, localized dermatitis leads to local production of cytokines by keratinocytes. If the cytokines are hematogenously disseminated, they may lead to distant skin hyperirritability. Circulating activated T lymphocytes may play a role in id reaction associated with allergic contact dermatitis. Lastly, dissemination of antigen (but not of whole infectious agents) from the local site may occur with a secondary response developing at a site of distant deposition. Microbial antigens have been identified in an id reaction in a patient with tuberculoid leprosy (9).

Photoallergic Dermatitis

Photoallergy is increased reactivity of skin to ultraviolet and visible light and is brought about by a chemical agent on an immunologic basis (10). The eruption of photoallergic dermatitis may be due to topical application of, or oral ingestion of, a photosensitizing agent, resulting in a photocontact dermatitis or photodrug eruption, respectively. Agents that may elicit photocontact dermatitis include soaps and cleansers (containing halogenated salicylanilide), perfumes (such as musk ambrette), topical sulfonamides, sunscreens, benzocaine, and diphenhydramine. Common causes of photodrug eruption include thiazide diuretics, oral hypoglycemics, and phenothiazines. The eruption is pruritic and composed of erythematous papules and confluent plaques on sun-exposed skin, usually the face, dorsal aspect of the arms, and the "V" of the neck.

Histopathology. The features are similar to that of an acute allergic contact dermatitis, showing variable spongiosis, in some cases with vesiculation, and a superficial perivascular lymphohistiocytic infiltrate with exocytosis. A deeper perivascular infiltrate and eosinophils are more common in photoallergic dermatitis induced by systemic ingestion of medications. With chronic exposure to the antigen, there is progression to chronic dermatitis, with diminished spongiosis, less intense inflammation, and more acanthosis. Phototoxic reactions are "sunburn" reactions with epidermal apoptosis and necrosis with intraepidermal to subepidermal blisters—the changes paralleling the degree of damage. Neutrophils may be prominent.

Nummular Dermatitis

In nummular dermatitis, the eruption is characterized by pruritic, coin-shaped (nummular), erythematous, scaly, crusted plaques. The lesions tend to develop on the extensor surfaces of the extremities.

Histopathology. Nummular dermatitis is the prototype of subacute spongiotic dermatitis (Fig. 9-2). There is mild to moderate spongiosis, usually without vesiculation. Irregular acanthosis with some exocytosis of inflammatory cells is usually present. The parakeratotic stratum corneum contains aggregates of coagulated plasma, forming a crust. Mild papillary dermal edema and vascular dilatation may be present.

There is superficial perivascular infiltrate of lymphocytes, some eosinophils, occasional neutrophils, and plasma cells.

Pathogenesis. The etiology of this entity is unknown. The routine and ultrastructural changes in nummular dermatitis resemble those of contact dermatitis. Intercellular edema is the most conspicuous finding. There is shearing and loss of desmosomes as spongiosis becomes marked.

Atopic Dermatitis

The eruption in atopic dermatitis is characterized by areas of severe pruritus, erythema, scaling, and excoriation, with chronicity, lichenification, and lichen simplex chronicus. Many of the cutaneous changes are due to chronic rubbing and scratching. Most patients are diagnosed in childhood, with approximately one third of cases diagnosed before 1 year of age (11). There is a female predominance, and many patients have other atopic disorders such as allergic rhinitis or asthma. Increased incidence of contact dermatitis is also noted among patients with atopic dermatitis. In infants, the lesions predominate on the face and extensor surfaces of the extremities, but they later affect the flexural surfaces. The classically involved sites in older children and adults are the popliteal and antecubital fossae and the sides of the neck. Secondary bacterial infection is common.

Histopathology. In early phases, there is mild spongiosis, exocytosis of lymphocytes, and parakeratosis. Lymphocytes and scattered histiocytes are present around the superficial vascular plexus. In long-standing lesions, the rete ridges are regularly elongated, with less prominent spongiosis and cellular infiltrate. Hyperkeratosis and wedge-shaped hypergranulosis with areas of parakeratosis develop. There appear to be an increased number of small vessels with thickened walls. Eosinophils are less conspicuous than in allergic contact or nummular dermatitis. With time, the changes may be those of lichen simplex chronicus.

Pathogenesis. The current understanding of the disease remains incomplete. Atopic dermatitis develops as a result of complex interactions of genetic, environmental, and immunologic factors. Allergic reactions appear to play a role in some patients, but in other patients, factors such as disturbance of skin function, infection, and stress may be more important. Atopic dermatitis can be exacerbated by fungal, bacterial, and viral skin infections. In particular, *Staphylococcus aureus* may exacerbate or maintain skin inflammation in atopic dermatitis by secreting a group of toxins known to act as superantigens (12).

Factors identified as being involved in the pathogenesis of atopic dermatitis include the differentiation of helper T cells, increased life span of eosinophils, multiple roles of IgE, the pattern of local cytokine expression, infectious agents, and superantigens (13).

The initiation of atopic dermatitis appears to be driven by allergen-induced activation of type 2 T-helper cells (Th-2 cells), leading to increased levels of IL-4, -10, and -13. Elevated IgE ensues. IgE contributes to the inflammatory cell infiltrate by several mechanisms, including immediate/late-phase reaction, allergen presentation by IgE-bearing Langerhans cells, and allergen-induced activation of IgE-bearing macrophages.

The mononuclear cell infiltrate in the lesions probably reflects a combination of both IgE-dependent mast cell/basophil degranulation and Th-2 cell-mediated responses elicited during acute exposure to allergens, including ingestants, inhalants, or contact aeroallergens such as human dander, grass pollens, and house dust mites (14).

The pattern of local cytokine expression plays an important role in modulating tissue inflammation and depends on the activity and/or duration of the lesion. Acute skin inflammation is associated with a predominance of IL-4 and IL-13 expression, and little interferon-gamma (INF-γ) But in chronic lesions, there are increased INF-γ producing cells (15,16).

No specific single gene is a unique marker for atopic dermatitis. Genome screens of families with atopic dermatitis have implicated chromosomal regions that overlap with other skin diseases, including inflammatory and autoimmune skin disease (17). The dysfunctional skin barrier genes, which include loss of functional filaggrin (18), increase of protease activity, and lack of protease inhibitor, predispose the patients to the harmful effects of environmental agents (19). Chromosome 5q31 contains the IL-4 gene cluster family. Because IL-4 is central to the induction of IgE synthesis by B cells, it has been suggested that polymorphisms in the chromosome 5q31 region may be linked to the gene controlling total serum IgE in atopic individuals. Another possible candidate gene found on chromosome 11q13 is the high-affinity IgE receptor (20,21).

Lichen Simplex Chronicus

The vast majority of patients with pruritus who chronically rub the skin may develop lichen simplex chronicus. It often develops in the setting of atopic dermatitis or allergic contact dermatitis. Thick plaques often with excoriation, the normal skin markings accentuate producing the finding known as *lichenification*. Uncommonly, some patients develop macular or lichen amyloidosis. Some patients, due to the character of their underlying disease such as dermatitis herpetiformis, only rarely develop lichen simplex chronicus. Lastly, skin with severe chronic dermatoheliosis does not develop typical lichen simplex chronicus.

Histopathology. Lichen simplex chronicus is the prototype for chronic dermatitis (Fig. 9-3). There is hyperkeratosis interspersed with areas of parakeratosis, acanthosis with irregular elongation of the rete ridges, wedge-shaped hypergranulosis, and broadening of the dermal papillae. Slight spongiosis may be observed, but vesiculation is absent. Minimal papillomatosis is sometimes present. Excoriations, which are punctate ulcerations lined by necrotic superficial papillary dermis, fibrin, and neutrophils, are often present; however, they are often present in many pruritic dermatoses. There may be a sparse superficial perivascular infiltrate without

exocytosis. In the papillary dermis, there are an increased number of fibroblasts and vertically oriented collagen bundles. As rubbing increases in intensity and chronicity, epidermal hyperplasia becomes more florid and the fibrosis more marked. Searching for features of dermatitis associated with chronic rubbing and scratching may give a hint as to the initial underlying dermatitis.

Seborrheic Dermatitis

Clinically, patients develop erythema and greasy scale on the scalp, ears, eyebrows, nasolabial areas, and central chest. Rarely, patients with seborrheic dermatitis develop generalized lesions. In infants, the scalp ("cradle cap"), face, and diaper areas are often involved. It is said to be a rare cause of erythroderma. Seborrheic dermatitis is seen with increased frequency in patients with Parkinson's disease, epilepsy, congestive heart failure, chronic alcoholism, zinc deficiency, and HIV infection. Patients with HIV infection often have severe refractory disease and atypical distribution (22).

Histopathology. The histopathologic features are a combination of those observed in psoriasis and spongiotic dermatitis. Mild cases may exhibit only slight subacute spongiotic dermatitis. The stratum corneum contains focal parakeratosis, with a predilection for the follicular ostia, a finding known as *shoulder parakeratosis* (Fig. 9-6). Occasional pyknotic neutrophils are present within parakeratotic foci (neutrophilic parakeratosis), sometimes with fluid (neutrophilic crust). There is moderate acanthosis with regular elongation of the rete ridges, mild spongiosis, and focal exocytosis of lymphocytes. The dermis contains a sparse mononuclear cell infiltrate. In HIV-infected patients, the epidermis contains apoptotic keratinocytes, and the dermal infiltrate usually contains plasma cells.

Pathogenesis. The pathogenesis is unknown; the role of *Malassezia* sp. (*Pityrosporum*) in the etiology is controversial even though many patients have a good response to oral or topical ketoconazole (23,24).

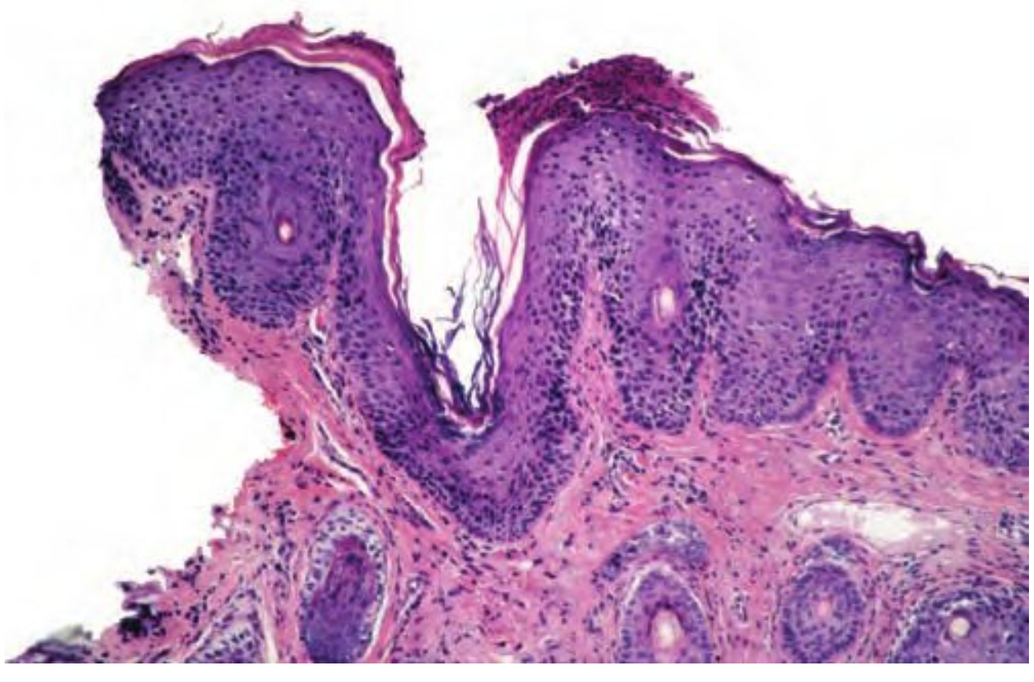

FIGURE 9-6. Seborrheic dermatitis. There is neutrophilic parakeratosis on the follicular ostial shoulder. The epidermis is hyperplastic. Spongiosis is minimal in this biopsy.

Stasis Dermatitis

Patients with long-standing venous insufficiency and lower extremity edema may develop pruritic, erythematous, scaly papules and plaques on the lower legs, often in association with brown pigmentation and hair loss. Ulceration is a frequent complication of long-standing stasis dermatitis.

Histopathology. The variable epidermis may be hyperkeratotic with focal parakeratosis, acanthotic to atrophic, and with focal spongiosis. There is proliferation of small blood vessels in the papillary dermis, forming lobular aggregates (glomeruloid proliferation). The proliferation may be florid, mimicking Kaposi's sarcoma (acroangiodermatitis) (25). There is a superficial perivascular lymphocytic infiltrate that surrounds thickened capillaries and venules. The reticular dermis is often fibrotic. Extravasated erythrocytes and hemosiderin are usually present superficially, but they may be identified about the deep vascular plexus as well. Fibrin thrombi may be observed in the small vessels, likely reflecting flow disruption and anoxia. They do not indicate a concurrent coagulopathy. Endothelial necrosis and neutrophils may be present as well, reflecting similar changes, and do not indicate a leukocytoclastic vasculitis.

Differential Diagnosis of Spongiotic Dermatitis

Acute spongiotic dermatitis may be seen histologically in pityriasis rosea, guttate parapsoriasis, spongiotic drug eruptions, arthropod bite reactions, and dermatophyte infections. Lesions of pityriasis rosea contain discontiguous suprapapillary areas of spongiosis, exocytosis of lymphocytes, and overlying mounds of (lenticular) parakeratosis. The spongiosis varies from micro- to macrovesicular. In addition, extravasated erythrocytes may be present in the involved papillae and overlying epidermis. Guttate parapsoriasis is similar to pityriasis rosea, but it lacks the intraepidermal erythrocytes and has less lymphohistiocytic infiltrate. Spongiotic drug eruptions tend to have a deeper infiltrate with eosinophils than other forms of acute spongiotic dermatitis. They usually do not vesiculate. In arthropod bite reactions, the epidermal changes are focal, corresponding to the site of attack, and the infiltrate is wedge shaped. Bite or sting parts are often not found. A PAS stain is necessary to exclude dermatophyte infection.

Pityriasis lichenoides, dermatophyte infection, spongiotic drug eruption, or an arthropod bite reaction may show histopathologic features similar to *subacute spongiotic dermatitis.* In pityriasis lichenoides et varioliformis acuta, the lesions are sharply circumscribed. Apoptotic keratinocytes, dry neutrophil-rich scale, bandlike interface dermatitis, areas of epidermal necrosis, and a deeper perivascular infiltrate are present. Dermatophyte infections characteristically have neutrophils within the stratum corneum, along with fungal hyphae; however, PAS stain is often necessary to identify the fungal hyphae.

Conditions that reveal a *chronic dermatitis* include pellagra and other nutritional deficiencies, mycosis fungoides, and psoriasis, particularly if altered by therapy. In the nutritional deficiencies, upper epidermal pallor, necrosis, and neutrophilic infiltrate are characteristic. In mycosis fungoides, psoriasiform epidermal hyperplasia may be present, but the lymphocytes have nuclear atypia and cerebriform morphology with epidermotropism in the absence of spongiosis. Lesions of psoriasis may resemble lichen simplex chronicus, but thinning of the suprapapillary plates, confluent parakeratosis, neutrophils within the stratum corneum and upper epidermis, and dilated tortuous capillaries are distinctive.

Other Disorders with Spongiotic Dermatitis

Erythroderma and Generalized Exfoliative Dermatitis

Erythroderma is characterized by generalized erythema and scale, often in association with fever. The eruption is nonspecific and may be caused by a variety of underlying conditions. In one study, 74.4% were associated with a preexisting dermatosis, 14.6% were idiopathic, and 5.5% were related to drugs and malignancy (26). Psoriasis is the most common preexisting dermatosis; others include spongiotic dermatitis, pityriasis rubra pilaris, photosensitivity syndromes, and, rarely, stasis dermatitis, dermatophytosis, pemphigus foliaceus, and even bullous pemphigoid. Many drugs have been incriminated, such as phenytoin, thiazides, nonsteroidal anti-inflammatory drugs (NSAIDS), and recombinant cytokines. A small percentage of erythroderma is associated with lymphoma, most frequently cutaneous T cell lymphoma, in the form of Sézary syndrome or erythrodermic mycosis fungoides. The "red man syndrome" is erythroderma without knowing underlying causes. Some cases may progress to mycosis fungoides after many years.

Histopathology. A careful search for histologic features of any of the above listed etiologies must be undertaken; however, the nature of the underlying dermatosis is not always discernible in the erythrodermic phase, and the changes are often those of nonspecific subacute or chronic spongiotic dermatitis. Erythrodermic lesions associated with underlying psoriasis (27) resemble early lesions of psoriasis with only mild epidermal hyperplasia, mild spongiosis, mounds of parakeratosis with a few neutrophils, and red cell extravasation in the papillary dermis. Blood vessels in the upper dermis are usually dilated. In cases of erythroderma related to mycosis fungoides, atypical cells with cerebriform nuclei are present in the infiltrate. Eosinophils may be present. Drug-related cases might simulate mycosis fungoides with exocytosis, lymphocytic atypia, and the presence of eosinophils. The presence of rare apoptotic keratinocytes may be a clue to the drug etiology.

The histopathologic findings are helpful in establishing the etiologic diagnosis in only about 40% of cases (28). Repeat biopsies and hematologic studies at regular intervals are recommended in patients without definitive diagnosis.

Miliaria

Miliaria develops when sweating is associated with obstruction of the intraepidermal sweat duct. There are three types: miliaria crystallina, miliaria rubra, and miliaria profunda.

Miliaria crystallina develops when the sweat duct is obstructed within the stratum corneum. Asymptomatic, small, superficial, noninflammatory vesicles resembling dewdrops develop, mainly on the trunk, after severe sunburn or with profuse sweating during a febrile illness. The vesicles rapidly subside when sweating ceases or the horny layer overlying the vesicles exfoliates. In some cases, the eruption may be present at birth (29).

Miliaria rubra (prickly heat) ensues when the sweat duct is obstructed within the deeper layers of the epidermis. It generally develops during and after excessive sweating in skin covered by clothing. It may also occur after prolonged covering of the skin by occlusive polyethylene wraps. Anhidrosis and heat intolerance result, particularly when the trunk is occluded. The lesions consist of pruritic small papulovesicles surrounded by erythema. Pustules may develop.

Miliaria profunda usually develops after recurrent episodes of miliaria rubra, particularly in tropical climates. The sweat duct is occluded at the dermal–epidermal junction. Lesions are nonpruritic, flesh-colored papules and can result in widespread anhidrosis.

Histopathology. In *miliaria crystallina*, intracorneal or subcorneal vesicles that are in continuity with the underlying sweat duct are observed. A sparse to moderate infiltrate of neutrophils is seen at the periphery of the vesicle. The surrounding epidermis is spongiotic, and there is papillary dermal edema and sparse superficial perivascular inflammation.

In *miliaria rubra*, spongiotic vesicles are found in the stratum malpighii. Serial sectioning shows these vesicles to be in continuity with a sweat duct. Periductal lymphocyte infiltration and spongiosis are seen, as is an infiltrate in the underlying dermis (Fig. 9-7). In many instances, the distal, intraepidermal sweat duct is filled with amorphous "casts" that are PAS positive and diastase resistant.

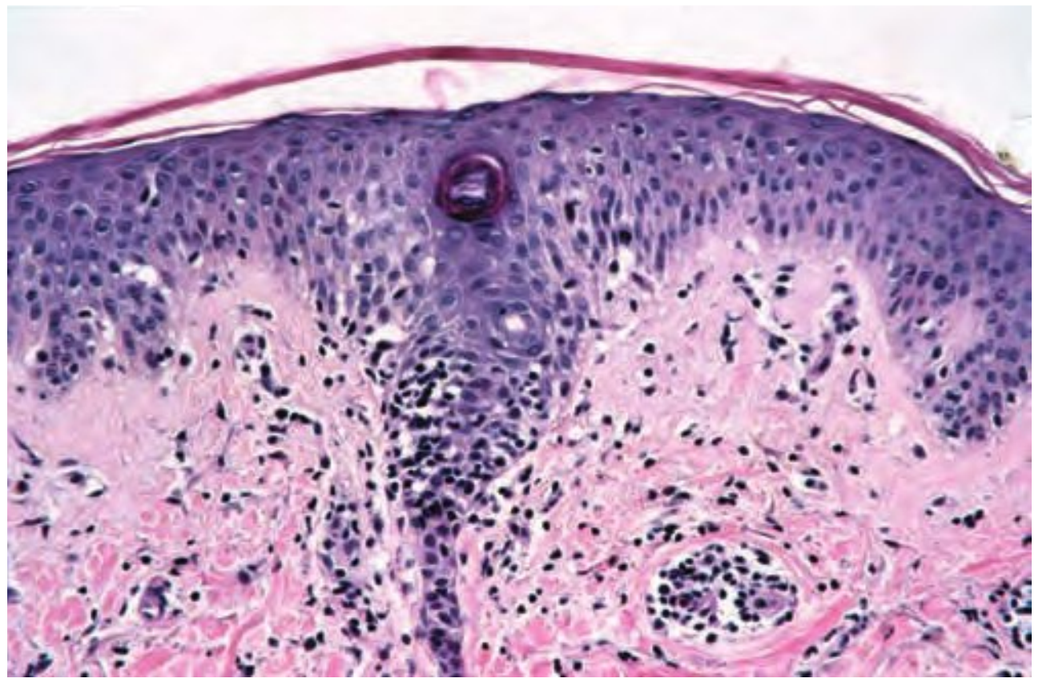

FIGURE 9-7. Miliaria rubra. There is spongiosis about and within the epidermal eccrine duct. Lymphocytes are present in the areas of spongiosis.

In *miliaria profunda*, the features are similar to those of miliaria rubra, but the inflammatory changes involve the lower epidermis and superficial dermis.

Pathogenesis. In *miliaria crystallina*, the obstruction of the sweat duct within the stratum corneum is caused either by mild damage to the epidermis from a preceding sunburn or by excessive hydration of the stratum corneum. In neonates, excess hydration of the stratum corneum *in utero* in combination with immature eccrine ducts may cause swelling of the ductal epithelial cells and occlusion of the duct (29).

In *miliaria rubra*, increased environmental temperature plays an important role (30). Aerobic bacteria are thought to contribute to the obstruction of the acrosyringium. In favor of this view are the frequent presence of *S. aureus* within the sweat ducts and the fact that the development of miliaria rubra under an occlusive polyethylene film can be prevented by application of antibacterial solutions.

The PAS-positive, diastase-resistant, amorphous plug within the acrosyringium may occur as a result of injury to the luminal cells, inflammation, and ductal and periductal spongiosis. These changes occur after 48 hours of occlusion and resolve after 14 days, when old, damaged stratum corneum is desquamated. Tape stripping can restore sweating, which supports a reversible, high-level blockage.

Immunologic Deficiency Diseases Associated with Spongiotic Dermatitis

Familial Leiner's Disease

In familial Leiner's disease, infants develop generalized seborrheic dermatitis, severe diarrhea, recurrent local and systemic infections, and marked wasting. Death is usually due to septicemia. A dysfunction of the fifth component of complement (C5) exists in addition to other cellular and humoral immune defects.

Hyperimmunoglobulin E Syndrome (Job's syndrome)

In hyperimmunoglobulin E syndrome, patients have recurrent pyogenic infections, atopic dermatitis, extreme elevation of serum IgE, and defective neutrophil chemotaxis due to decreased production of INF-γ (31). The infectious complications include recurrent cold staphylococcal abscesses, furunculosis, otitis, sinusitis, and staphylococcal pneumonia.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked recessive disorder that affects males and is characterized by recurrent, systemic bacterial and viral infections; purpura due to thrombocytopenia; and an atopic dermatitis–like eruption because of progressive depletion of nodal and circulating T cells, death due to infection, or lymphoma ensuing in the first decade of life.

Chronic Granulomatous Disease

Chronic granulomatous disease is an X-linked recessive disorder affecting males, beginning in infancy with perioral dermatitis. The dermatitis often progresses to granulomatous lesions accompanied by cervical adenitis. Suppurative and granulomatous infections develop in the skin, lungs, bone, and liver, most commonly due to *S. aureus*. Death occurs in most cases in childhood or adolescence. The defect lies in decreased capacity of neutrophils to generate hydrogen peroxide and kill catalase-positive bacteria and fungi. *In vitro*, neutrophils are unable to reduce nitroblue tetrazolium dye after phagocytosis, which is a useful screening test for the disease.

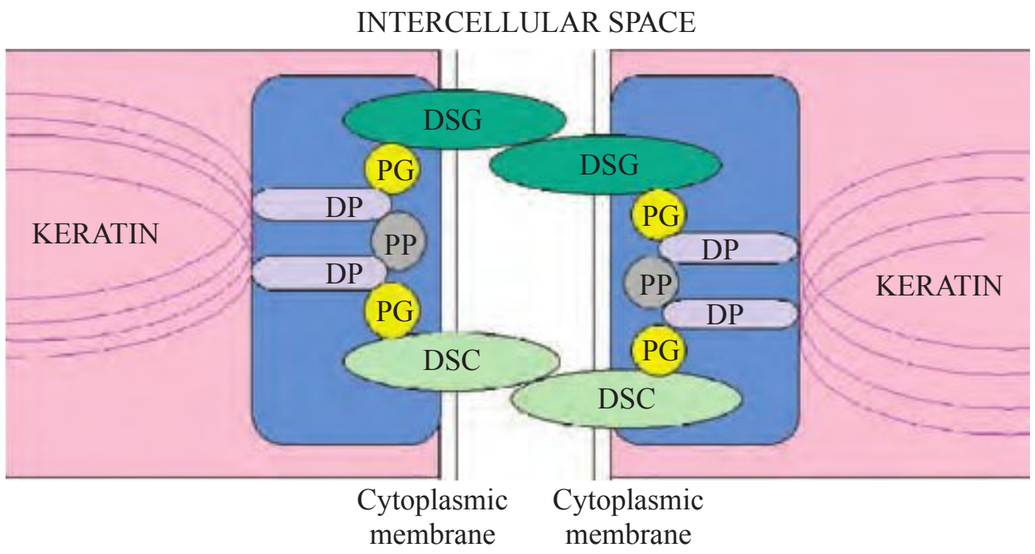
PEMPHIGUS GROUP

As first demonstrated in 1943, acantholysis is the characteristic feature of the bullae of pemphigus. The acantholysis results from *in vivo*–bound antibodies first discovered in 1964 (32). Pemphigus is now characterized as an autoimmune blistering disease presenting clinically with flaccid intraepithelial blisters, erosions, and ulcerations of the skin and mucous membranes; histologically with acantholysis; and immunologically with *in vivo*–bound and circulating autoantibodies against the cell membrane components of keratinocytes important in cell-cell adhesion. Circulating autoantibodies are present in about 80% of patients with active disease, and their titer usually correlates with disease activity. These antibodies are demonstrable by direct immunofluorescence (DIF) testing of skin and indirect immunofluorescence (IIF) testing of serum. The use of these techniques is now the accepted practice in the diagnosis of all antibody-mediated primary vesiculobullous disorders (see Table 9-4). Pemphigus can be divided into five types: (a) pemphigus vulgaris, with its reactive state, pemphigus vegetans; (b) pemphigus foliaceus, with its lupus-like variant, pemphigus erythematosus, and its endemic variant, Fogo selvagem; (c) drug-induced pemphigus; (d) IgA pemphigus; and (e) paraneoplastic pemphigus (PNP). Rarely, IgM mediated pemphigus may occur secondary to IgM production by B cell lymphoproliferative disease.

Pathophysiology of Pemphigus

The target antigens of pemphigus (Table 9-5) are located in the desmosomes, which are the most prominent adhesion junctions in stratified squamous epithelium. The desmosome complex contains desmogleins and desmocollins as transmembrane constituents and plakoglobin, plakophilin, and desmoplakin as cytoplasmic constituents (Fig. 9-8). Desmogleins and desmocollins are members of the cadherin supergene family (33,34), a group of calcium-dependent proteins that play an important role in the formation and maintenance of tissue integrity. The cadherin molecules form dimers as their functional unit, with the extracellular domain from one cell binding to an opposing cell. The cytoplasmic domain of the cadherin associates with plakoglobin, which links intermediate filaments (i.e., keratins) to the desmosome through desmoplakin. The extracellular epitopes of the desmogleins and desmocollins are targets of the pathogenic antibodies. Of these, desmoglein 1 and desmoglein 3 are the best characterized. Desmoglein 1 is a 160-kD molecule that is expressed primarily in the upper layers of the

TABLE 9-4 Direct Immunofluorescence in Vesiculobullous Dermatoses*



Dermatosis	Principal immunoreactant	Site	Pattern
Pemphigus, all variants except:	IgG	ICS	Lacelike, dotlike

ICS, squamous intercellular substance; BMZ, epidermal basement membrane zone; EBA, epidermolysis bullosa acquisita; SLE, systemic lupus erythematosus; LAD, linear IgA dermatosis; EM, erythema multiforme.
*Other immunoglobulins may be present, but they are less intense when present and less frequently observed.

TABLE 9-5 Target Antigens in Pemphigus

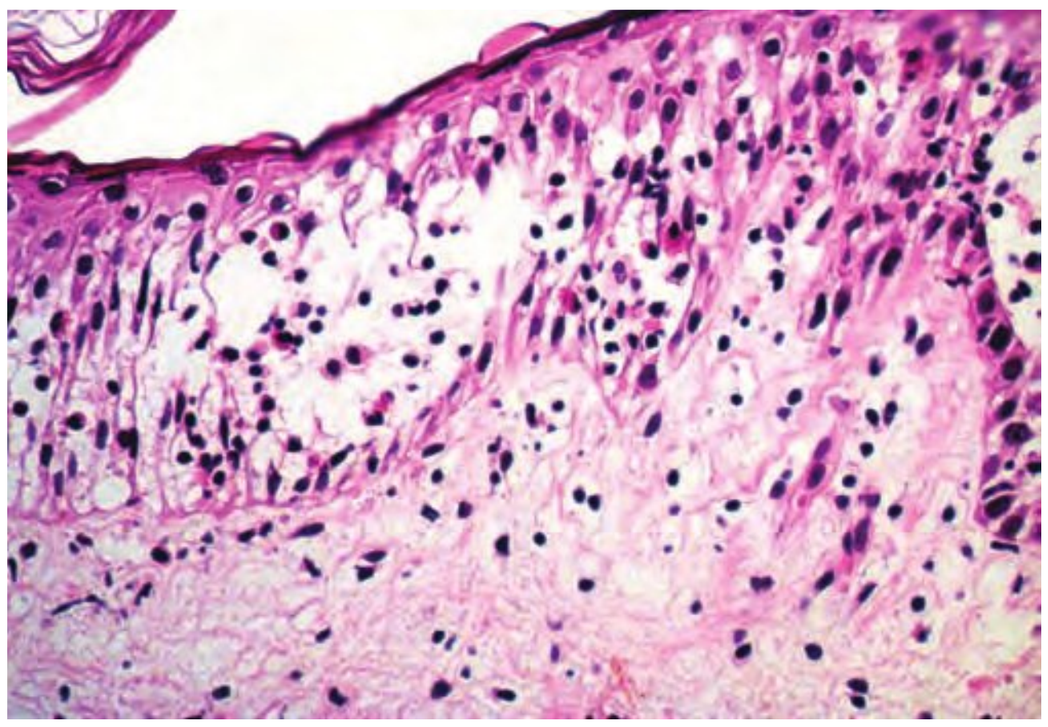
Diseases	Autoantibodies	Antigens	Location of antigens
Pemphigus vulgaris			
Mucosal mainly	IgG	Desmoglein 3 (130 kD)	Desmosomes
Mucocutaneous	IgG	Desmoglein 3 (130 kD) Desmoglein 1 (160 kD)	
Pemphigus foliaceus	IgG	Desmoglein 1 (160 kD)	Desmosomes
Paraneoplastic pemphigus	IgG	Desmoglein 1 (160 kD) Desmoglein 3 (130 kD) Desmoplakin I (250 kD) Envoplakin (210 kD) Periplakin (190 kD) Plectin (500 kD) BPAg1 (230 kD) γ-Catenin (plakoglobin- 82 kD)	Desmosomes or hemidesmosomes
Drug-induced pemphigus (autoimmune variant)	IgG	Desmoglein 3 (130 kD) Desmoglein 1 (160 kD)	Desmosomes
Drug-induced pemphigus (toxic variant)	—	—	—
IgA pemphigus			
SPD type	IgA	Desmocollin 1 (110/100 kD)	Desmosomes
IEN type	IgA	Desmoglein 1 (160 kD) Desmoglein 3 (130 kD)	

BPAg1, bullous pemphigoid antigen; SPD, subcorneal pustular dermatosis; IEN, intraepidermal neutrophilic.

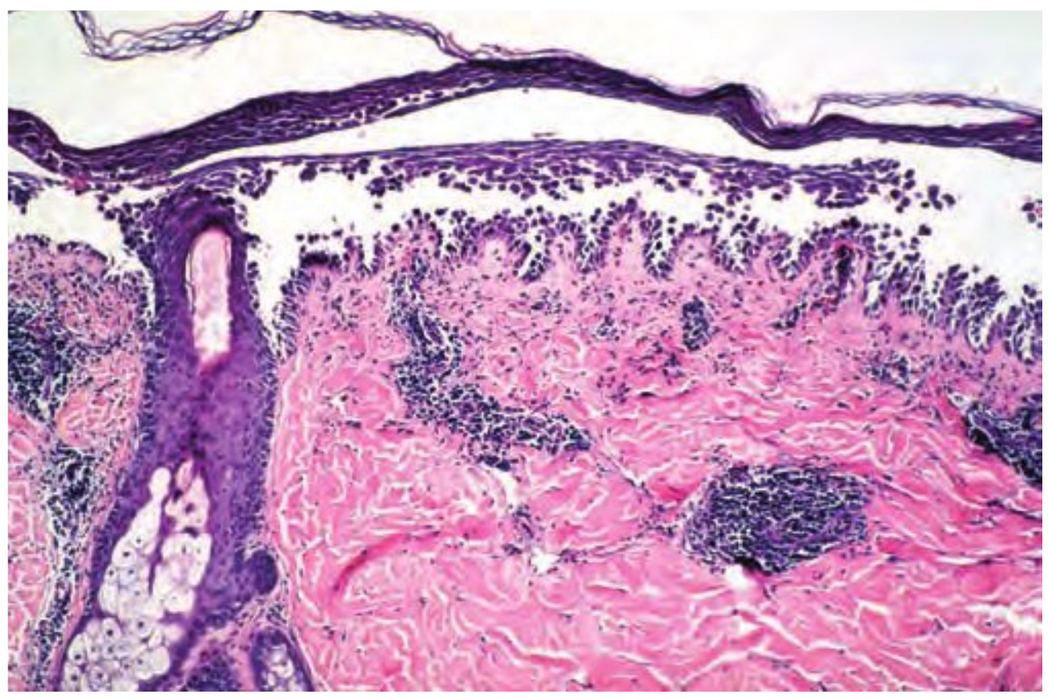
DSG - Desmoglein DSC - Desmocollin PG - Plakoglobin DP - Desmoplakin PP - Plakophilin

FIGURE 9-8. The desmosome. The desmosome complex includes desmogleins and desmocollins as transmembrane components and plakoglobin, plakophilin, and desmoplakin as cytoplasmic components. The cytoplasmic domains of desmoglein and desmocollin associate with plakoglobin, which links intermediate filaments (keratin) to the desmosome through desmoplakin.

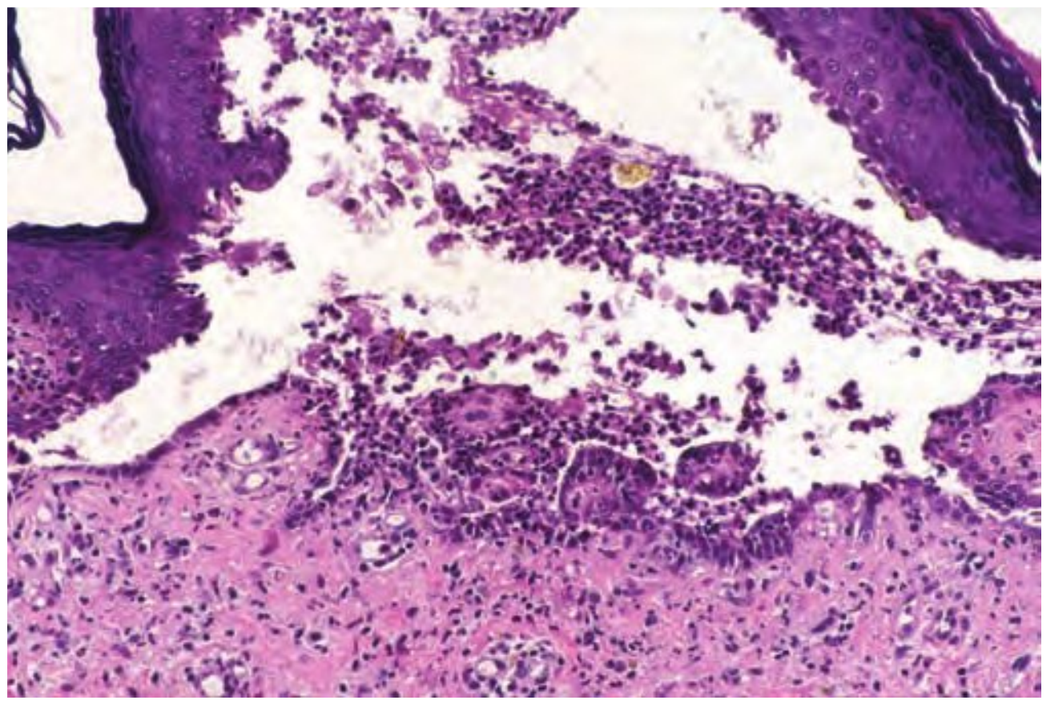
epidermis. It is the target antigen in pemphigus foliaceus. Desmoglein 3 is a 130-kD molecule that localizes primarily in the deeper layer of epidermis and mucous membrane. It is the target antigen in pemphigus vulgaris (35). Since mucosal epithelium expresses mainly desmoglein 3 but skin expresses both desmoglein 1 and 3, damage by antibodies to desmoglein 3 alone results in oral lesions with or without skin lesions. If both desmoglein 3 and desmoglein 1 antibodies are present, cutaneous lesions as well as mucosal lesions appear, and the disease tends to be more severe (36). Less is known about the desmocollins. Some cases of IgA pemphigus have had autoantibodies to the desmocollins.



Pemphigus Vulgaris



Pemphigus vulgaris develops primarily in older individuals, presenting with large and flaccid bullae. They break easily and leave denuded areas that tend to increase in size by progressive peripheral detachment of the epidermis, leading in some cases to widespread cutaneous involvement. The lesions characteristically involve the oral mucosa, scalp, midface, sternum, groin, and pressure points. Oral lesions (Fig. 9-9A) are almost invariably present and may be the first manifestation of the disease (10% of cases) (37). Before corticosteroids became available, the mortality of this disease was high because of fluid loss and superinfection.



Histopathology. It is important that early blisters, preferably small ones, are selected for biopsy. Care should be given to keeping the epidermis attached to the dermis because the torque applied in punch biopsies may separate the blister roof from the blister base. Therefore, a refrigerant spray may be used before excising the blister with a punch biopsy, or it may be excised with a scalpel. If no recent blister is available, an old one may be moved into the neighboring skin by gentle vertical pressure with a finger (positive Asboe–Hansen sign). The newly created cleavage will reveal early and specific histologic changes.

The earliest recognized change may be either eosinophilic spongiosis rarely or, more commonly, "spongiosis" in the lower epidermis (Fig. 9-9B). This spongiosis may actually represent the earliest manifestation of acantholysis rather than true spongiosis as defined earlier. Acantholysis leads first to the formation of clefts and then to blisters in a predominantly suprabasal location (Fig. 9-9C, D). The intraepithelial acantholysis may extend into adnexal structures or occasionally be higher in the stratum spinosum. The basal keratinocytes, although separated from one another through the loss of attachment, remain firmly attached to the dermis like a "row of tombstones." Within the blister cavity, the acantholytic keratinocytes, singularly or in clusters, have rounded condensed cytoplasm about an enlarged nucleus with peripherally palisaded chromatin and enlarged nucleoli. In some patients, there are varying quantities of antidesmoglein 1 and antidesmoglein 3 antibodies, leading to variable planes of acantholysis. There is little inflammation in the early phase of blister formation. If present, it is usually a sparse, lymphocytic perivascular infiltrate accompanied by dermal edema. However, if eosinophilic spongiosis is apparent, numerous eosinophils may infiltrate the dermis. The phenomenon of eosinophilic spongiosis occurs occasionally in other blistering diseases, particularly in their early phases, including acute contact dermatitis, pemphigus foliaceus, bullous pemphigoid, herpes gestationis, drug eruptions, spongiotic arthropod bite reactions, and transient acantholytic dermatosis. Several important changes ensue as the lesions age. First, a mixed inflammatory cell reaction consisting of neutrophils, lymphocytes, macrophages, and eosinophils may develop. Because of the instability of the blister roof, erosion and ulceration may occur. Older blisters may also have several layers of keratinocytes at the blister base because of keratinocyte migration and proliferation. Last, there may be considerable downward growth of epidermal strands, giving rise to so-called villi (Fig. 9-9D). The evaluation of patients with only oral lesions is difficult, because intact blisters are rarely encountered due to the trauma of mastication, and biopsies may show only erosion and ulceration. Indeed, it is best to sample the edge of a denuded area with intact mucosa in an attempt to demonstrate the typical pathologic changes. Clinicians frequently cannot distinguish between an ulcer and the intact mucosa, as both are often white and shaggy. In patients with only oral lesions, biopsies of intact oral mucosa for DIF testing are more sensitive than biopsies of lesions for routine light microscopic evaluation. Therefore, biopsy from the normal maxillary and upper buccal mucosa is necessary when there is extensive ulceration. Cytologic examination using a Tzanck preparation is useful for the rapid demonstration of acantholytic epidermal keratinocytes in the blisters of pemphigus vulgaris. For this purpose, a smear is taken from the underside of the roof and from the base of an early, freshly opened bulla. Giemsa stain is applied with subsequent rinsing and air-

C: An intraepidermal acantholytic blister has a suprabasal cleavage plane. Acantholysis may extend into adnexal structures and stratum spinosum. D: The suprabasal blister contains acantholytic cells, neutrophils, and eosinophils. Note the dermal papillae lined by a single layer of basal keratinocytes, so-called villi. E: There is lacelike squamous intercellular space deposition of IgG in the lower epidermis (DIF).

drying. Because acantholytic keratinocytes are occasionally seen in various nonacantholytic vesiculobullous or pustular diseases as a result of secondary acantholysis, cytologic examination represents merely a preliminary test and should not supplant histologic examination.

Immunofluorescence (IF) Testing. The edge of a blister with intact surrounding normal skin, uninvolved skin adjacent to a blister, or adjacent erythematous skin should be supplied for study. The tissue may be snap-frozen or transported in Michel's medium. DIF testing is a very reliable and sensitive diagnostic test for pemphigus vulgaris, in that it demonstrates lacelike IgG in the squamous intercellular/cell surface areas in up to 95% of cases, including early cases and those with very few lesions, and in up to 100% of cases with active disease (Fig. 9-9E). It remains positive, often for many years after clinical disease has subsided. In late lesions, when acantholysis is well developed, the lacelike intercellular/cell surface pattern of IgG may become dotlike, paralleling electron microscopic findings and correlating with aggregation of desmosomes on the cell surface. Negative DIF findings when the patient is in

remission may be a good prognostic indicator (38). At this time, DIF testing is incorrectly thought by most to be free of false positives; however, false positives may occur. On occasion, it may be difficult to distinguish intercellular staining of pemphigus from nonspecific staining; for example, spongiotic dermatitis, psoriasis, bullous impetigo, and epidermis adjacent to ulcers secondary to a number of disorders may have squamous intercellular substance IgG due to the presence of serum in the intercellular substance. Often, IgM, IgA, fibrinogen, and albumin are present as well, indicating nonspecific trapping in the false-positive tests. Immunoperoxidase methods have achieved roughly the same sensitivity as the IF method, but they have not replaced IF testing as the prime diagnostic tool. For IIF testing, unfixed frozen sections of guinea pig esophagus, monkey esophagus, or normal human skin are used as substrate. In general, monkey esophagus is the best substrate for IIF tests. Circulating IgG autoantibody is demonstrated in the squamous intercellular substance in 80% to 90% of cases (39), and the titer correlates with disease activity. False-positive IIF tests occur. In a series of 1,500 patients with circulating pemphigus antibodies, approximately 1% had no evidence of clinical disease. Antibodies that mimic or may give *in vitro* deposition in stratified squamous epithelium in the absence of pemphigus have been reported in burns, penicillin allergy, toxic epidermal necrolysis (TEN), systemic lupus erythematosus (SLE), myasthenia gravis, bullous pemphigoid, cicatricial pemphigoid, and lichen planus and in patients with antibodies directed against blood groups A and B. Such antibodies are present in low titer and are thought to be nonpathogenic. Antidesmoglein autoantibodies are sometimes found in patients with no bullous disease. For example, they have been found in patients with silicosis (40) and in relatives of patients with pemphigus vulgaris (41).

Pathogenesis. Compelling evidence has accumulated that IgG autoantibodies against desmoglein 3 and desmoglein 1 are pathogenic and play a primary role in inducing the blister formation in pemphigus. Affinity-purified IgG from pemphigus vulgaris sera recognizes the extracellular domain of desmoglein 3 and causes suprabasal acantholysis when injected into neonatal mice (42). Furthermore, when anti-desmoglein 3 IgG from pemphigus vulgaris is immunoabsorbed with the extracellular domains of desmoglein 3, those sera no longer have the ability to cause blisters in neonatal mice (43). Although the pathogenic role of anti-desmoglein 3 autoantibodies in blister formation is assured, the exact sequence of events that occur after antibody binding is not totally understood. Conformational epitope mapping of desmoglein 3 in pemphigus vulgaris suggests that the amino terminal residue 1-161 is the target of autoantibodies (44). This segment is in the extracellular domain that is essential for cell-cell adhesion. One possibility is that these antibodies interfere directly with the adhesive interaction of desmogleins between cells by steric hindrance. Another possibility is that the disruption of cell-cell adhesion is mediated by signal transduction. Proteinases, likely induced by pemphigus antigen-antibody union, are thought to play an important role in acantholysis. Although complement fixation by pemphigus antibodies may promote acantholysis, acantholysis occurs in experimental systems in the absence of complement. The stimulus for the formation of autoantibodies is unknown, although drugs, viral infection, trauma, ionizing radiation, and PUVA therapy have been implicated because they have preceded the onset of pemphigus. Pemphigus vulgaris is rarely associated with internal cancer, Castleman's disease, thymoma, myasthenia gravis, localized scleroderma, Grave's disease, and SLE.

Ultrastructural Study. The intercellular cement substance, or glycocalyx, is partially or entirely lysed in lesions with early acantholysis. There is widening of the intercellular spaces with intact desmosomes. As the intercellular space is widened, there is separation of the two opposing attachment plaques of the desmosomes; thus, single attachment plaques, with adherent tonofilaments, are seen at the periphery of keratinocytes. As acantholysis progresses, the desmosomes gradually disappear and the keratinocytes develop numerous cytoplasmic processes that often interdigitate with one another. All of the early ultrastructural changes in pemphigus vulgaris are extracellular. Only subsequent to the dissolution of the desmosomes does retraction of the tonofilaments to the perinuclear area develop with ultimate degeneration of the acantholytic cells. The cohesion of the basal keratinocytes with the basement membrane zone is not affected in pemphigus vulgaris because of the preservation of structures connecting the basal keratinocytes with the dermis. Immunoelectron microscopy shows that the immunoglobulins are deposited on the surface of the keratinocytes in a discontinuous globular pattern in the extracellular domains of desmosomes (45).

Differential Diagnosis. In early blisters that are free of secondary changes, such as the degeneration or regeneration of epidermal cells, the histopathology of pemphigus vulgaris is characteristic. Important differential diagnoses include Hailey-Hailey disease and transient acantholytic dermatosis. Hailey-Hailey disease has full-thickness ("dilapidated brick wall") acantholysis, epidermal hyperplasia, and an impetiginized scale crust. The acantholysis does not extend down follicles as it does in pemphigus. Transient acantholytic dermatosis may exhibit small foci of intraepidermal acantholysis, but these are only a few rete wide in contrast to the uniform widespread acantholysis observed in biopsies of pemphigus vulgaris. Disorders such as Darier's disease that are characterized by acantholytic dyskeratosis are readily separated from pemphigus vulgaris by the presence of abnormal granular keratinocytes and parakeratotic cells, so-called corps ronds and corps grains. Although light microscopic examination of pemphigus lesions is important, positive DIF is the gold standard in diagnosis at this time and must be pursued in all cases in which pemphigus vulgaris is considered.

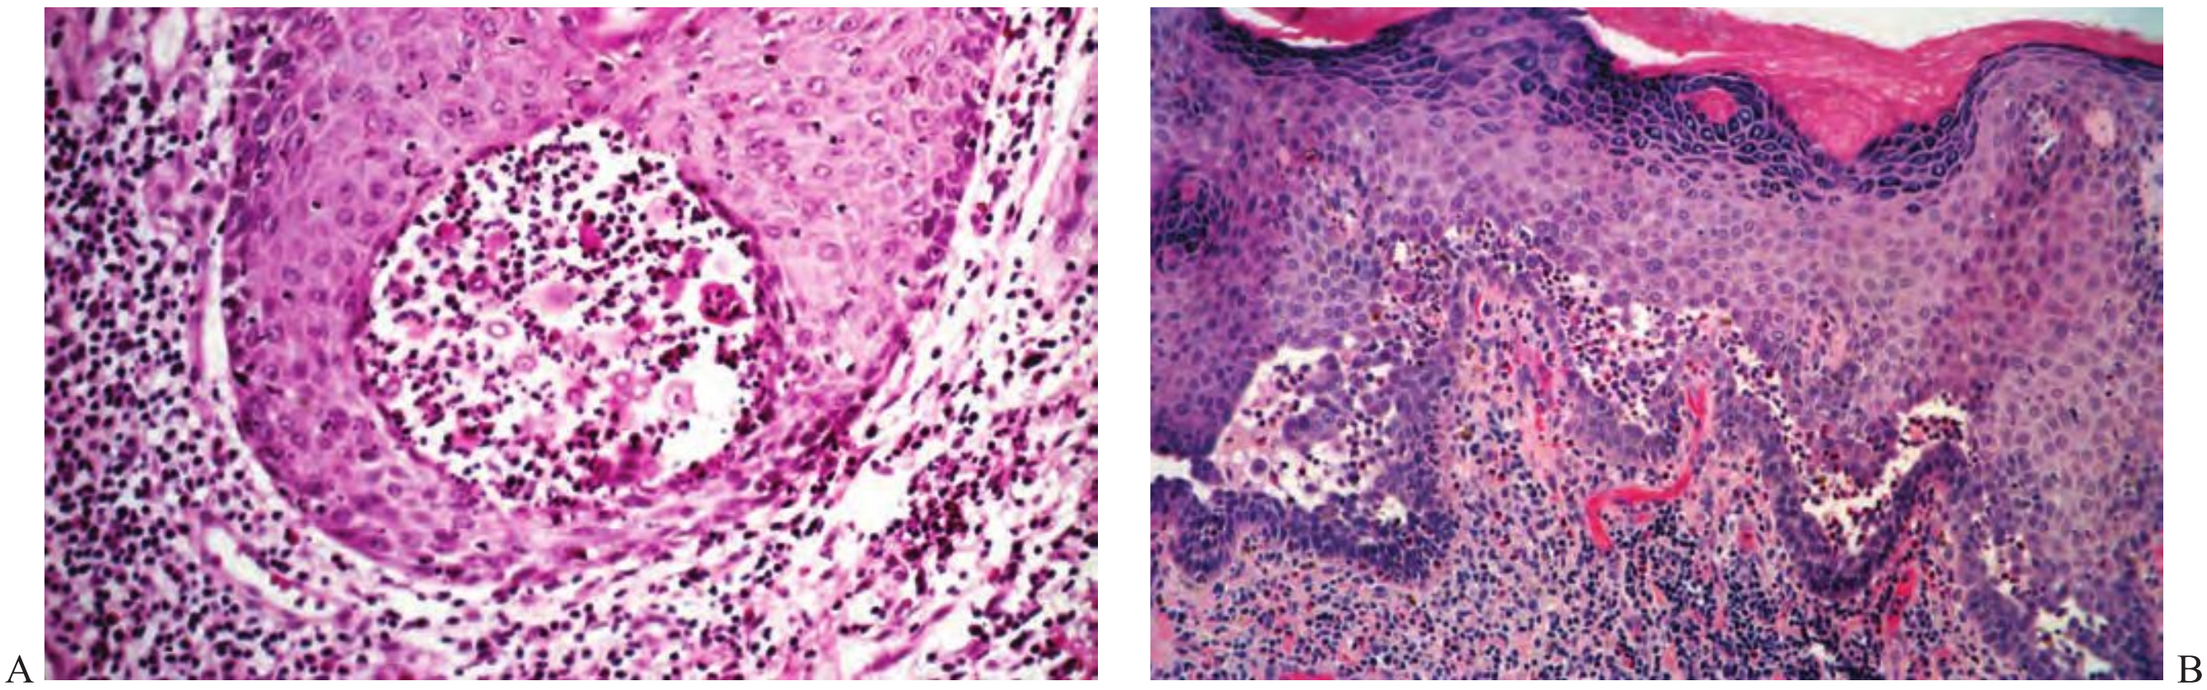

FIGURE 9-10. Pemphigus vegetans. A: Intraepidermal abscesses are composed of eosinophils and a few acantholytic keratinocytes. B: There is marked acanthosis and suprabasal clefts containing eosinophils.

Pemphigus Vegetans

Pemphigus vegetans is an uncommon variant of pemphigus vulgaris, comprising only 1% to 2% of cases (39). Historically, pemphigus vegetans has been divided into the Neumann type and Hallopeau type. In the more severe Neumann type, the disease begins and ends as pemphigus vulgaris, but many of the denuded areas heal with verrucous vegetations that may contain small pustules in early stages. The Hallopeau type is relatively benign, having pustules as the primary lesions instead of bullae. Their development is followed by the formation of gradually enlarging verrucous vegetations, especially in intertriginous areas.

Histopathology. In the Neumann type, the early lesions consist of bullae and denuded areas that have the same histologic picture as that of pemphigus vulgaris. As the lesions age, however, there is formation of villi and verrucous epidermal hyperplasia. Numerous eosinophils are present within the epidermis and dermis, producing both eosinophilic spongiosis and eosinophilic pustules (Fig. 9-10A). Acantholysis may not be present in older lesions. In the Hallopeau type, the early lesions consist of pustules arising on normal skin with acantholysis and formation of small clefts, with many in a suprabasal location. The clefts are filled with numerous eosinophils and degenerated acantholytic epidermal cells (Fig. 9-10B). Early lesions may reveal more eosinophilic abscesses than in the Neumann type. The subsequent verrucous lesions are histologically identical to the Neumann type.

IF Testing. DIF examination reveals squamous intercellular IgG in all reported cases.

Pathogenesis. Pemphigus vegetans is a variant of pemphigus vulgaris in which verrucous vegetations develop. It is unclear why such vegetations develop in some cases of pemphigus vulgaris and not in others. However, they tend to develop in areas of relative occlusion and maceration with subsequent bacterial infection, suggesting a response to superinfection.

Differential Diagnosis. The principal differential diagnosis is pyoderma vegetans, a condition often associated with inflammatory bowel disease, particularly ulcerative colitis. It can mimic pemphigus vegetans clinically and histologically (46). In pyoderma vegetans, neutrophils are more commonly found, and intraepidermal eosinophilic abscesses and acantholysis are rare. DIF is negative in pyoderma vegetans (46). Halogenoderma and blastomycosis-like pyoderma must be excluded as well (see Chapters 11 and 23).

Pemphigus Foliaceus

Usually developing in middle-aged individuals, pemphigus foliaceus may have a chronic generalized course or may rarely present as an exfoliative dermatitis. Patients may present with flaccid bullae that usually arise on an erythematous base or as scaly, crusted erosions without evident blisters (Fig. 9-11A). Because of their superficial location, the blisters break easily, leaving shallow erosions rather than the denuded areas seen in pemphigus vulgaris. Oral lesions do not occur. The Nikolsky sign is positive, and Tzanck preparation reveals acantholytic granular keratinocytes. Fogo selvagem (endemic pemphigus foliaceus) is clinically, histologically, and immunologically indistinguishable from pemphigus foliaceus (47). It develops in those who live or visit areas close to rivers and streams in Brazil, with the peak incidence being at the end of the rainy season. The cause of fogo selvagem is unknown, but substantial epidemiologic evidence suggests that it is precipitated by an environmental factor. A case control study found that farmers exposed to black fly (*Simulium pruinosum*) bites were much more likely to develop fogo selvagem than farmers who were not bitten (48). Sunlight may exacerbate the condition (49).

Histopathology. The earliest change consists of acantholysis in the upper epidermis, within or adjacent to the granular layer, leading to a subcorneal bulla in some instances (Fig. 9-11B, C). More commonly, enlargement of the cleft leads to detachment

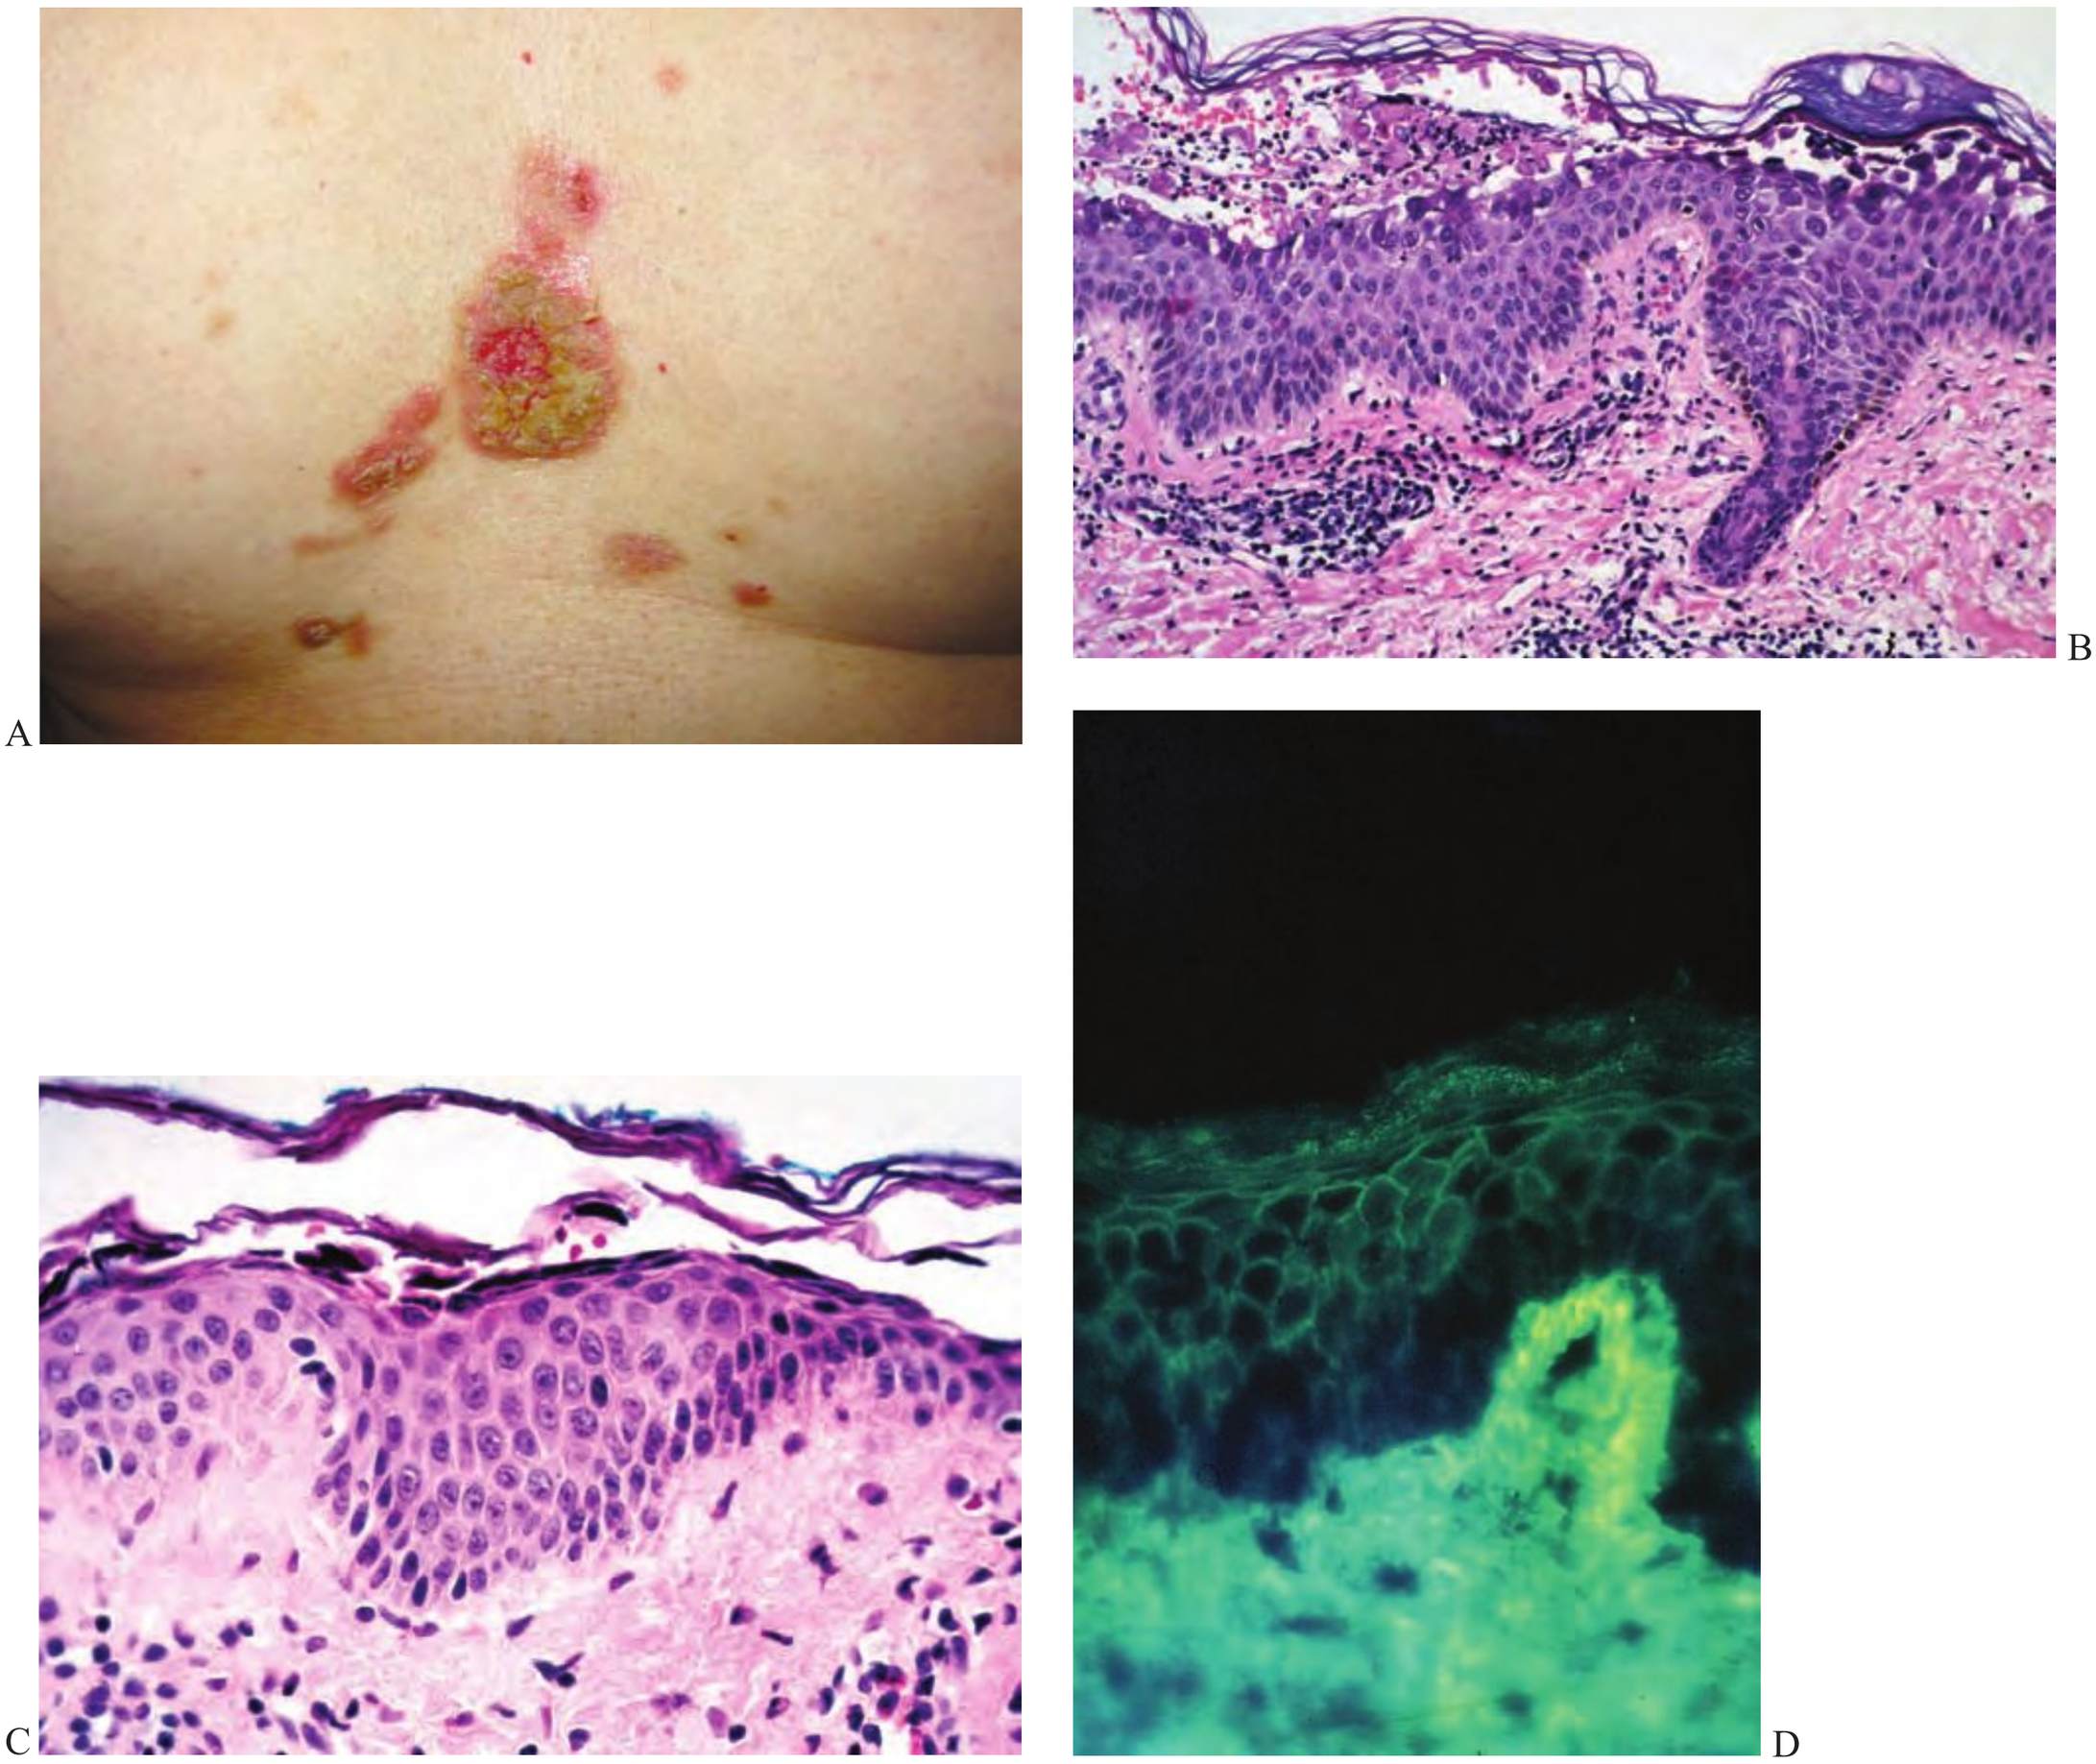

FIGURE 9-11. Pemphigus foliaceus. A: Erosions with thick crusts on the central chest. (Courtesy of Peter Lio, M.D.) B: A subcorneal blister with acantholytic cells and neutrophils in the cavity. C: In the setting of a subcorneal blister, these dyskeratotic acantholytic granular cells are diagnostic of pemphigus foliaceus. D: The intercellular IgG is deposited in the intercellular spaces throughout the epidermis. Rarely, as in this case, the IgG is present in greater quantity in the superficial layers.

of the stratum corneum without bulla being seen. The number of acantholytic keratinocytes is usually small, often requiring a careful search to identify them. Secondary clefts may develop, leading to detachment of the epidermis in its mid level. These clefts may extend to above the basal layer, rarely giving rise to limited areas of suprabasal separation. In the setting of a subcorneal blister, dyskeratotic granular keratinocytes are diagnostic for this disorder. Eosinophilic spongiosis may be prominent with intraepidermal eosinophilic pustules. Thus, the histologic features of pemphigus foliaceus may have three patterns: (a) eosinophilic spongiosis; (b) a subcorneal blister, often with few acantholytic keratinocytes; and (c) a subcorneal blister with dyskeratotic granular keratinocytes (Fig. 9-11C), diagnostic of this disorder. The character of the inflammatory infiltrate is variable and depends on the age of the lesion, whether a blister is present, whether the superficial portion of the epidermis has been detached, and whether there is impetiginization or necrosis of the blister roof.

IF Testing. DIF testing of perilesional skin is positive in the vast majority of cases. Two patterns of pemphigus antibody deposition have been described. In most cases, there is full-thickness squamous intercellular substance deposition of IgG. Rarely, IgG may be localized only to the superficial portion of the epidermis (Fig. 9-11D). IIF testing of serum reveals

squamous intercellular substance deposition of IgG in 80% to 90% of cases.

Pathogenesis. As in pemphigus vulgaris, the autoantibodies of pemphigus foliaceus are pathogenic. During the course of the disease, the antibody levels fluctuate and have some correlation with disease activity. The pemphigus foliaceus antigen, desmoglein 1, is expressed more intensely in the upper layers of the epidermis (35,36), which explains the superficial cleavage plane of pemphigus foliaceus. Interestingly, in staphylococcal scalded skin syndrome (SSSS), and its localized form bullous impetigo, the exfoliative exotoxin produced by *S. aureus* specifically binds and cleaves desmoglein 1, resulting in blister formation at identical levels of the epidermis as pemphigus foliaceus (50,51). In addition, desmoglein 1 is concentrated in the upper torso and is less prominent in the buccal mucosa, scalp, and lower torso, correlating with lesion distribution (52).

Ultrastructural Study. There is early loss of intercellular cement substance within the lower epidermis associated with a decrease in the number of desmosomes and formation of tortuous microvilli from the keratinocyte surface. However, acantholysis is most pronounced in the upper layers of the epidermis. In the mid epidermis, many keratinocytes have perinuclear arrangement of the tonofilaments and homogenization of the perinuclear tonofilament bundles as evidence of dyskeratosis. Marked dyskeratosis distinguishes pemphigus foliaceus from pemphigus vulgaris.

Differential Diagnosis. The differential diagnosis includes SSSS, impetigo, and subcorneal pustular dermatosis (SPD; Sneddon-Wilkinson disease). IF testing may be required to separate SSSS from pemphigus foliaceus, since a small number of acantholytic cells may be observed in SSSS. The lesions of pemphigus foliaceus may become impetiginized and secondarily altered, producing pustules as in impetigo and SPD. Pemphigus foliaceus contains more acantholytic keratinocytes than do the other two disorders, and pustules are the primary lesions in SPD. Because the lesions of pemphigus foliaceus may become superinfected, the finding of bacteria does not confirm a diagnosis of bullous impetigo; therefore, IF testing is critical. SPD usually produces large dome-shaped subcorneal pustules rather than the flaccid flat pustules of pemphigus foliaceus.

Pemphigus Erythematosus

Also known as *Senear-Usher syndrome*, pemphigus erythematosus is a variant of pemphigus foliaceus that gets its name from its lupus erythematosus–like clinical appearance, in which the erythematous plaques and patches are in a butterfly distribution. They may remain localized to this area or may become generalized. No oral lesions are observed.

Histopathology. The light microscopic features are identical to those of pemphigus foliaceus (Fig. 9-12). Interface dermatitis may also be apparent in rare cases, making distinction from lupus erythematosus difficult.

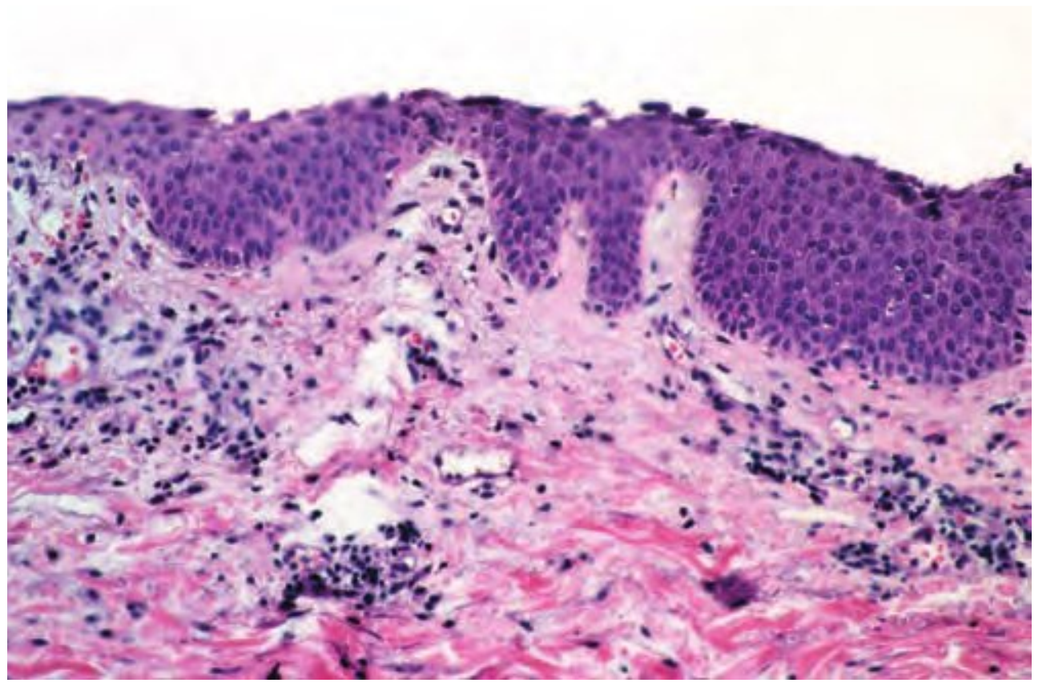

FIGURE 9-12. Pemphigus erythematosus. The histologic appearances are identical to those of pemphigus foliaceus. In this biopsy, the roof of the blister is eroded, which is a frequent event, leaving a diminished but acantholytic granular layer.

IF Testing. DIF testing of perilesional skin reveals squamous intercellular substance deposition of IgG in >75% of cases and granular deposition of IgM and IgG (i.e., a positive lupus band test) at the dermal–epidermal junction. IIF study using monkey esophagus as substrate reveals squamous intercellular substance deposition of IgG in 80% of cases. Antinuclear antibodies are observed in 30% to 80% of cases.

Ultrastructural Study. Pemphigus erythematosus is identical to pemphigus foliaceus in its ultrastructural alterations.

Differential Diagnosis. The differential diagnosis is the same as in pemphigus foliaceus. The presence of interface dermatitis in some cases leads to confusion with lupus erythematosus and PNP. Subcorneal acantholysis is not a feature of lupus erythematosus.

Pemphigus Herpetiformis

Pemphigus herpetiformis combines the clinical features of dermatitis herpetiformis with the immunologic and histologic features of pemphigus, usually the foliaceus type (53). This variant deserves recognition only because of its clinical presentation. Patients present with pruritic, erythematous, vesicular, or papular lesions, often in herpetiform pattern. Mucous membranes are uncommonly involved.

Histopathology. There is eosinophilic spongiosis with or without acantholysis. Variable numbers of neutrophils may be present, leading to neutrophilic spongiosis or subcorneal pustules with both eosinophils and neutrophils.

IF Testing. Because the clinical presentation and histologic findings are often atypical, the most reliable basis for diagnosis of pemphigus herpetiformis is immunopathology. DIF on perilesional skin shows the deposition of IgG on the surface of keratinocytes primarily in the upper epidermis (53). IIF has demonstrated circulating IgG antiepithelial cell surface

autoantibodies in most patients with pemphigus herpetiformis. Most cases have circulating antibodies to desmoglein I, the pemphigus foliaceus antigen. A few cases with antibodies to the pemphigus vulgaris antigen, desmoglein 3, have been reported (54).

Drug-induced Pemphigus

Although immunologic features identical to those of idiopathic pemphigus are reported in most cases of drug-induced pemphigus (55), evidence indicates that some drugs may induce acantholysis without production of antibodies (56). The offending drugs, most frequently penicillamine, captopril, and penicillin derivatives, often contain sulfhydryl groups (57). The earliest clinical manifestation is that of a nonspecific morbilliform or urticarial eruption. In penicillamine-induced pemphigus, the eruption is characteristic and has been labeled "toxic prepemphigus rash" (56). Subsequently, the characteristic lesions of pemphigus develop. On cessation of drug therapy, the rash regresses in those patients who do NOT have pemphigus antibodies in contrast to those patients with pemphigus antibodies, in whom the rash frequently persists. This latter subset has the clinical waxing and waning course of pemphigus.

Histopathology. The findings in the early eruption are nonspecific, consisting of spongiosis, parakeratosis, and a variable dermal infiltrate. Well-developed lesions are essentially identical to those of pemphigus foliaceus or pemphigus vulgaris. Eosinophilic spongiosis may be prominent.

IF Testing. DIF testing is positive in approximately 90% of patients with drug-induced pemphigus (56). IIF study of serum reveals circulating squamous intercellular substance IgG antibodies in 70% of cases. The antibody titers are usually low and do not appear to correlate with the severity of disease.

Pathogenesis. In those cases in which there is antibody production with subsequent acantholysis, the pathogenesis appears to be identical to that of idiopathic pemphigus. Because the pemphigus antigens have disulfide bonds, sulfhydryl-containing drugs may bind to them. These drugs have been shown to localize in high concentration in the epidermis. Therefore, the drug appears to directly affect the keratinocyte adhesion molecules, interferes with their function, and causes subsequent acantholysis, explaining those cases of drug-induced pemphigus that do not have pemphigus antibodies.

IgA Pemphigus

IgA pemphigus is a pruritic pustular eruption characterized by squamous intercellular IgA deposits and intraepidermal neutrophils. It occurs in primarily middle-aged and elderly individuals, but several cases have been described in children (58,61). The clinical findings are similar to those in pemphigus foliaceus or SPD. There are flaccid pustules that arise on an erythematous base. They often appear in an annular arrangement. The most common sites of involvement are the axilla and groin, but trunk, proximal extremities, and lower abdomen can also be involved. Mucous membrane involvement is rare. Mild leukocytosis, eosinophilia, and IgA paraproteinemia may be present (59).

IgA pemphigus is a clinically heterogeneous group reflecting differences in the autoantigens involved (60). In general, patients may develop one of two types: an SPD type or an intraepidermal neutrophilic (IEN) dermatosis type (58,61,62). The presence of cases with overlap features supports the notion that this is one disease with variable expression.

Histopathology. Two patterns are observed that parallel the two clinical presentations (Fig. 9-13). In the SPD type, there are subcorneal vesicopustules or pustules with minimal acantholysis. In the IEN type, there are intraepidermal vesicopustules or pustules containing small to moderate numbers of neutrophils. One case of IgA pemphigus, which

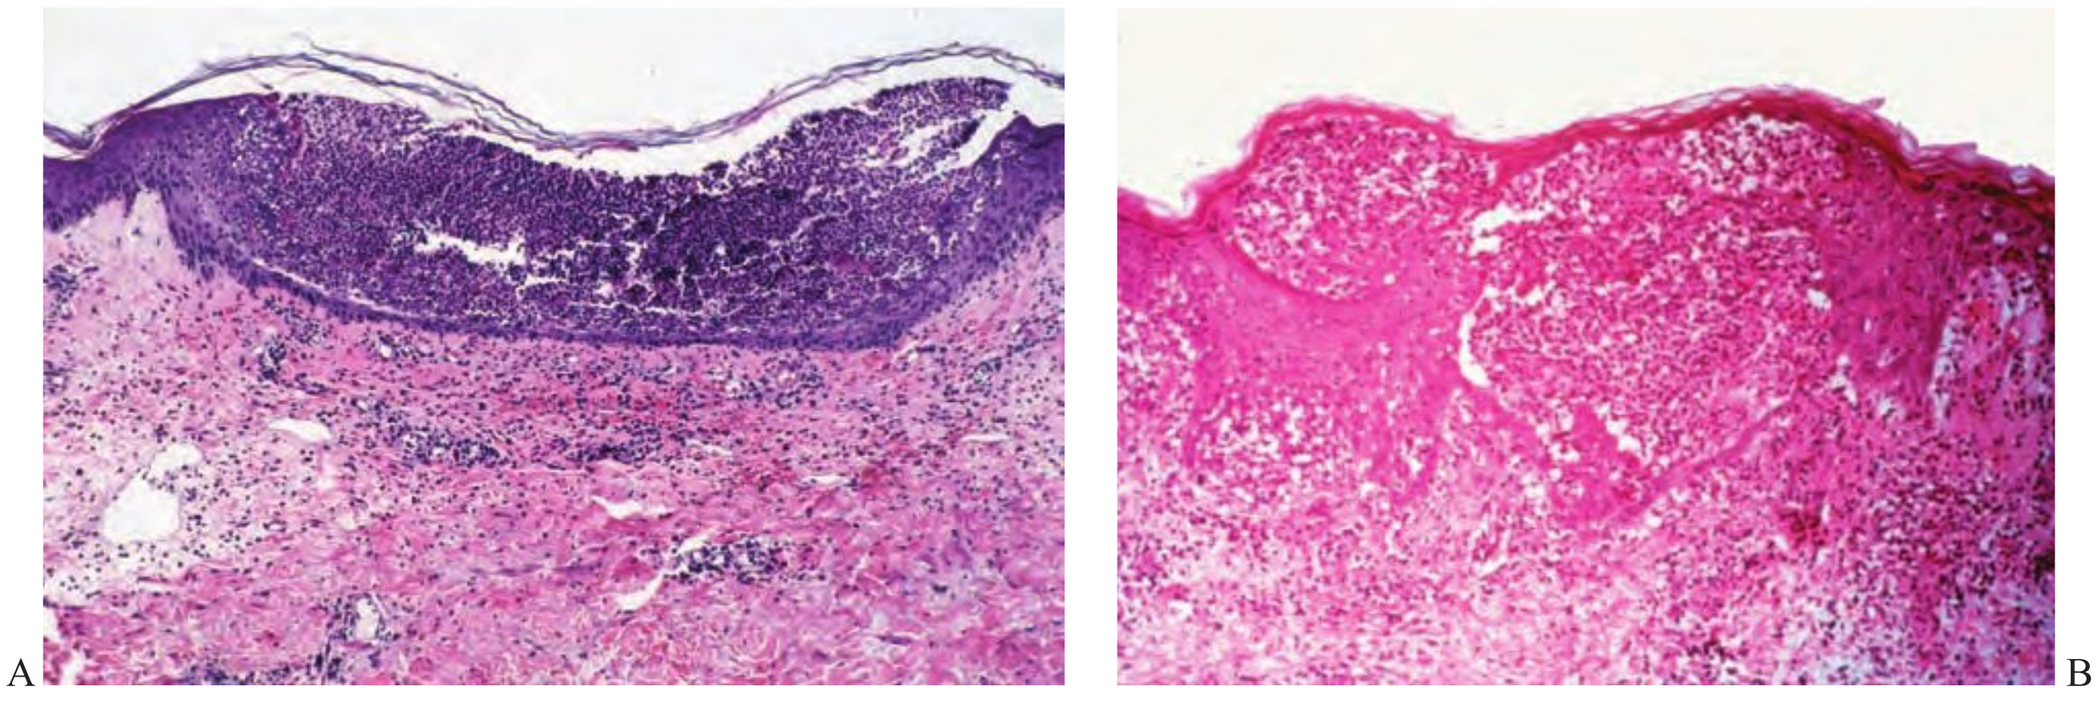

FIGURE 9-13. IgA pemphigus. A: In the SPD type, intraepidermal pustule with numerous neutrophils is seen subcorneally. B: In the IEN type, the neutrophils are in the suprabasal and stratum spinosum.

resembled pemphigus foliaceus without neutrophil infiltration, has been described (63).

IF Testing. DIF testing reveals IgA deposition in the squamous intercellular substance throughout the epidermis with increased intensity in the upper layers in some cases of the subcorneal pustular type. Complement and other immunoglobulins are usually not present (58). However, some cases may have both IgG and IgA present and thus may make a specific diagnosis difficult (i.e., pemphigus vulgaris vs. IgA pemphigus) unless evaluation for antigen specificity is available (64). IIF results are positive in <50% of reported cases. In the SPD type, IgA autoantibodies have been shown to recognize desmocollin 1 (65). In the IEN type, the autoantigens remain to be identified; the antibodies have been variously characterized as reacting to desmoglein 1 or desmoglein 3 in a subset of patients (59,60,66).

Differential Diagnosis. The SPD variant is identical to Sneddon-Wilkinson disease. Indeed, many cases reported as Sneddon-Wilkinson disease, in which IF testing was not performed, likely represent the SPD variant of IgA pemphigus. Pustular psoriasis, bullous impetigo, and pemphigus vulgaris are the principal differential diagnoses. Pustular psoriasis may not be distinguishable on routine light microscopic study; therefore, IF testing may be required.

Paraneoplastic Autoimmune Multiorgan Syndrome: Paraneoplastic Pemphigus

Paraneoplastic autoimmune multiorgan syndrome (PAMS), first described as paraneoplastic pemphigus (PNP), is an autoimmune vesiculobullous and erosive mucocutaneous disease associated with an underlying malignancy. The most commonly associated neoplasms include non-Hodgkin's lymphoma (42%), chronic lymphocytic leukemia (29%), Castleman's disease (10%), thymoma (6%), spindle cell sarcoma (6%), and Waldenström's macroglobulinemia (6%) (67). The age of onset is variable, although the majority of patients are between 45 and 70 years of age.

Cutaneous lesions are quite polymorphic. The most consistent clinical feature of PNP is the presence of intractable stomatitis, which presents as erosions and ulcerations that affect all surfaces of the oropharynx and characteristically extend onto the lips mimicking Stevens-Johnson syndrome (SJS). Multiple organ systems may be involved, and the high rate of mortality often stems from constrictive bronchiolitis obliterans. Autoantibodies are deposited in the kidneys, bladder, muscle, heart, lung, mucous membrane, and skin. The extent and diversity of the clinical presentations and immunopathologic mechanisms have led to the suggestion that PNP, a disease of epithelial adhesion, represents one manifestation of PAMS, which is a heterogeneous autoimmune syndrome (68). At least six different clinical variants are recognized: bullous pemphigoid–like, cicatricial pemphigoid–like, pemphigus-like, erythema multiforme (EM)-like, graft-versus-host disease (GVHD)-like, and lichen planus–like (68–73).

Histopathology. The histologic features are variable, depending on the various clinical presentations. The lesions show a unique combination of EM-like, lichen planus–like, pemphigus vulgaris–like, and pemphigoid-like features. The principal findings are suprabasal acantholysis with basal apoptosis in association with vacuolar interface dermatitis (EM-like) with or without lichenoid inflammation (lichen planus–like) (Fig. 9-14A, B) (74). PNP may present exclusively with lichenoid interface dermatitis in the absence of acantholysis (75). In pemphigoid-like lesions, a subepidermal blister is present.

IF Testing. DIF testing of perilesional skin and mucosa reveals IgG in the squamous intercellular substance in concert with immune reactant deposition at the dermal–epidermal junction (Fig. 9-14C). At the dermal–epidermal junction, granular deposition of complement is noted most frequently (70). Linear deposition of complement, IgG and IgM, as well as granular deposition of complement and IgG have been identified in one case each (69). When present, basement membrane zone staining helps to distinguish PNP from other forms of pemphigus in which basement membrane zone immunoglobulin and complement deposition are generally not present (76). Whereas circulating PNP antibodies bind to squamous keratinocytes in routine substrates in the majority of cases, the antibodies bind to rat bladder epithelium in all cases.

Pathogenesis. Patients with PNP develop IgG autoantibodies against multiple antigens (Table 9-5). It appears that all the members of the plakin family, as well as desmogleins, have been reported to be targeted by IgG autoantibodies in PNP. While antidesmoglein antibodies play a role in inducing the loss of cellular adhesion of keratinocytes and blister formation, the pathophysiologic relevance of the antiplakin autoantibodies is unclear. In addition to the humoral autoimmunity, mounting evidence suggests that cytotoxic T cells play a prominent role. Cases with clinical features of PNP in the absence of detectable autoantibodies have been reported (77). In those patients, the affected areas have high levels of $CD8^+$ cytotoxic T cells, which mediate damage, including interface dermatitis with dyskeratosis (78). IL-6, which activates $CD8^+$ T cells and $CD56^+$ natural killer (NK) cells, has been reported to be significantly increased in the blood of PNP patients (79). The association of PNP with bronchiolitis obliterans provides additional evidence that cytotoxic T cells may play a critical role in PNP.

SUBEPIDERMAL BULLOUS DISEASE

Subepidermal bullous diseases are disorders in which a blister forms along the dermal–epidermal junction. This group of diseases includes conditions with different clinical presentations, histologic findings, and pathogenesis. Both inherited and acquired alterations in key adhesion proteins at or in the dermal–epidermal junction result in blister formation. In the subgroup of autoimmune subepidermal bullous diseases, major target antigens bound by autoantibodies from patients have

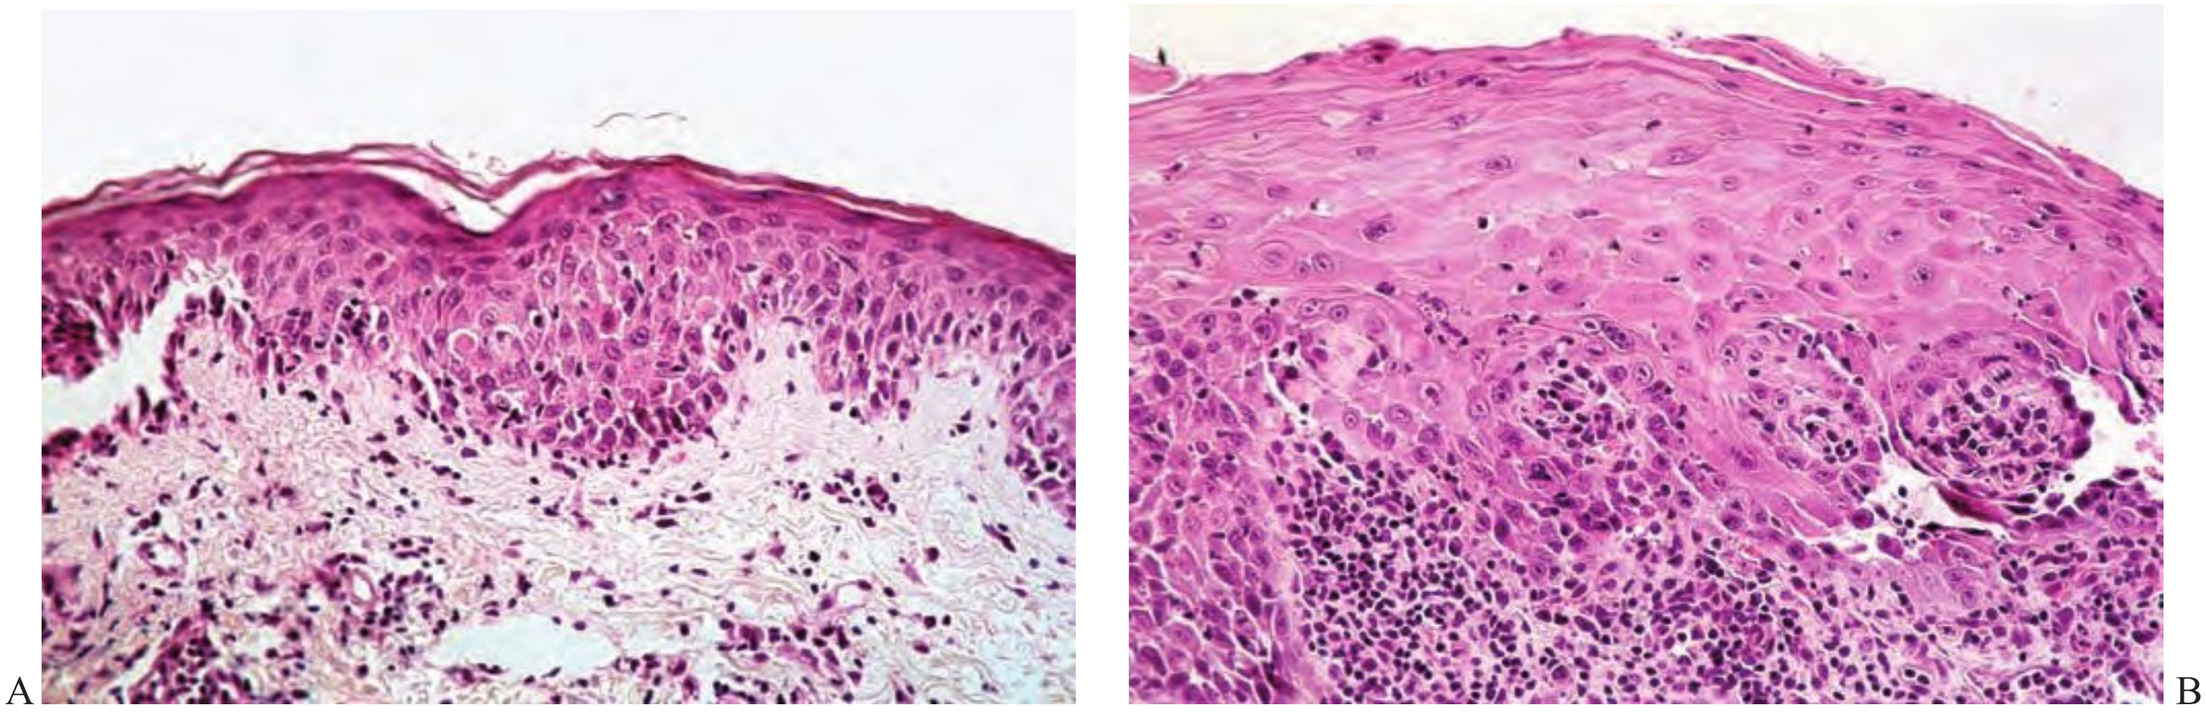

FIGURE 9-14. Paraneoplastic pemphigus. A: EM-like pattern. There is a cell-poor interface dermatitis with apoptosis of keratinocytes. There are also pemphigus vulgaris–like changes with a suprabasal blister. B: Lichen planus–like pattern. There is a cell-rich lichenoid dermatitis associated with a suprabasal blister. C: There are both intercellular and basement membrane staining with IgG by DIF.

been characterized (Table 9-6). Importantly, some of the genes encoding these autoantigens harbor mutations responsible for various mechanobullous diseases (i.e., epidermolysis bullosa [EB]). To understand subepidermal bullous disease, it is essential to have some knowledge of the epidermal basement membrane zone and the various target proteins associated with it (Fig. 9-15).

Proceeding from the epidermis to the dermis, there are four distinct structural components of the epidermal basement membrane:

TABLE 9-6 Targets Common to Autoimmune and Inherited Blistering Diseases*

Protein target	Structural target	Autoimmune disease	Genetic disease
BPAg1 (BP230)	HD	BP	None identified
BPAg2 (BP180, type XVII collagen)	HD-anchoring filament complexes	BP, PG, CP, LABD	GABEB
α6β4 integrin, Subunit β4	HD-anchoring filament complexes	Ocular CP	Junctional EB with pyloric atresia
Laminin 5 (epiligrin)	Lamina lucida–lamina densa interface	Antiepiligrin CP	Junctional EB–Herlitz
P200	Lower lamina lucida	Anti-p200 pemphigoid	None identified
Type VII collagen	Anchoring fibrils	EBA	Dystrophic EB
		Bullous SLE	

BPAg, bullous pemphigoid antigen; HD, hemidesmosome; BP, bullous pemphigoid; PG, pemphigoid gestationis; CP, cicatricial pemphigoid; LABD, linear IgA bullous dermatosis; GABEB, generalized atrophic benign epidermolysis bullosa; EB, epidermolysis bullosa; SLE, systemic lupus erythematosus.
*The targets are bound by antibody in autoimmune disease; however, in genetic disease, the target compounds are absent or aberrantly synthesized.

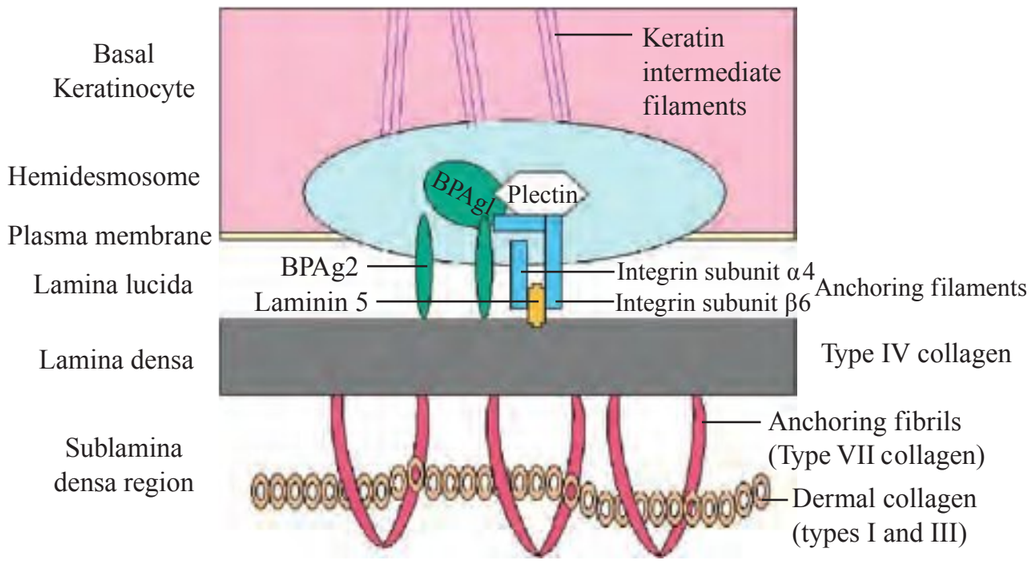

FIGURE 9-15. Schematic model of the dermal–epidermal junction. Along the basal surface of the keratinocytes, keratin intermediate filaments attach to hemidesmosomes on the basal plasma membrane. Major intracellular components of hemidesmosomes include the bullous pemphigoid antigen (BPAg1) and plectin. The transmembrane components of the hemidesmosomes include $\alpha 6\beta 4$ integrin and the bullous pemphigoid antigen (BPAg2). Both extend to the lamina lucida at the site where anchoring filaments are located. The anchoring filaments straddle the lamina lucida between hemidesmosomes and the lamina densa. Multiple antigens are associated with the lamina lucida, including laminin 5 (epiligrin). The lamina densa is an electron-dense layer that lies parallel to and contiguous to the lamina lucida. The main component is type IV collagen. In the sublamina densa region, the lamina densa and the overlying epidermis are tethered to the papillary dermis by anchoring fibrils. Type VII collagen is the major component of anchoring fibrils.

- The intermediate filaments, hemidesmosomal plaques, and plasma membranes of the basal keratinocytes.
- The lamina lucida, which contains delicate anchoring filaments connecting hemidesmosomes in basal keratinocytes to the underlying lamina densa.
- The lamina densa, which provides the basement membrane with much of its strength. The main component is type IV collagen.
- The sublaminar densa region, which contains anchoring fibrils (type VII collagen), anchoring plaques, and filamentous proteins of the papillary dermis.

Along the basal surface of the keratinocytes at the dermal–epidermal junction, keratin intermediate filaments (keratin 5 and 14) attach to hemidesmosomes. Major intracellular components of hemidesmosomes include the 230-kD bullous pemphigoid antigen (BPAg1) and plectin. The transmembrane components of the hemidesmosomes include $\alpha_6\beta_4$ integrin and the 180-kD bullous pemphigoid antigen (BPAg2) or collagen XVII (80). Both extend to the lamina lucida at the site where anchoring filaments are located. The anchoring filaments straddle the lamina lucida between hemidesmosomes and the lamina densa. Antibodies to the BPAg1 are of the most common autoimmune subepidermal bullous disease, bullous pemphigoid. BPAg2 is targeted by autoantibodies from patients with bullous pemphigoid, pemphigoid gestationis, cicatricial pemphigoid, and a subgroup of linear IgA bullous dermatosis (81–83). Some patients with generalized atrophic benign EB have a congenital deficiency of BPAg2. Mutation of the β_4 subunit of $\alpha_6\beta_4$ integrin leads to junctional EB associated with pyloric atresia (84). Patients with one form of ocular cicatricial pemphigoid have autoantibodies directed against the β_4 subunit (85).

The lamina lucida is the weakest link in the dermal–epidermal junction, and it is the cleavage plane in the salt-split skin test. Multiple antigens are associated with the lamina lucida, particularly the anchoring filaments. The antigens include laminin 5, laminin 6, uncein, nidogen, and P200 (86,87). Autoantibodies to epiligrin, the α_3 subunit of laminin 5, result in antiepiligrin of cicatricial pemphigoid. Nonsense mutation of the laminin 5 gene is associated with the Herlitz subtype of junctional EB (88).

The lamina densa is an electron-dense layer that lies parallel to and contiguous to the lamina lucida. The main component is type IV collagen, which is thought to provide the basement membrane with much of its strength. Other antigenic components are laminin 1, nidogen, and heparan sulfate proteoglycans.

In the sublamina densa region, the lamina densa and the overlying epidermis are tethered to the papillary dermis by anchoring fibrils, which is a series of looping elements along the underside of the lamina densa that serve as attachment sites for collagens in the papillary dermis. Type VII collagen is the major component of anchoring fibrils. Autoantibodies against type VII collagen have been identified in EBA, bullous SLE, and some variants of linear IgA disease (IgA-mediated EBA) (89). Nonsense mutation of the type VII collagen gene (COL7A1) is associated with dystrophic EB.

Bullous Pemphigoid

First described in 1953 by Lever, bullous pemphigoid affects primarily elderly patients with large tense bullae arising on urticarial erythematous bases or on nonerythematous skin (Fig. 9-16A) (90). In contrast to pemphigus, the Nikolsky sign is negative. The lesions involve the trunk, the extremities, and the intertriginous areas, with the oral mucosa involved in about one third of cases. Bullous pemphigoid may start as a nonspecific eruption suggestive of urticaria or dermatitis, which can persist for weeks or months. Rarely, bullous pemphigoid may present as erythroderma.

Histopathology. In early lesions, papillary dermal edema in combination with a cell-poor or cell-rich perivascular lymphocytic and eosinophilic infiltrate is present (Fig. 9-16B). The blister arises at the dermal–epidermal junction (90). In the cell-rich pattern, which correlates clinically with blisters arising on erythematous skin (Fig. 9-16C), eosinophilic papillary abscesses may develop with numerous perivascular and interstitial eosinophils intermingled with lymphocytes and neutrophils in the superficial and deep dermis. Early lesions may have the histologic features of eosinophilic cellulitis (Well's syndrome). Eosinophilic spongiosis may occur. The cell-poor pattern is observed

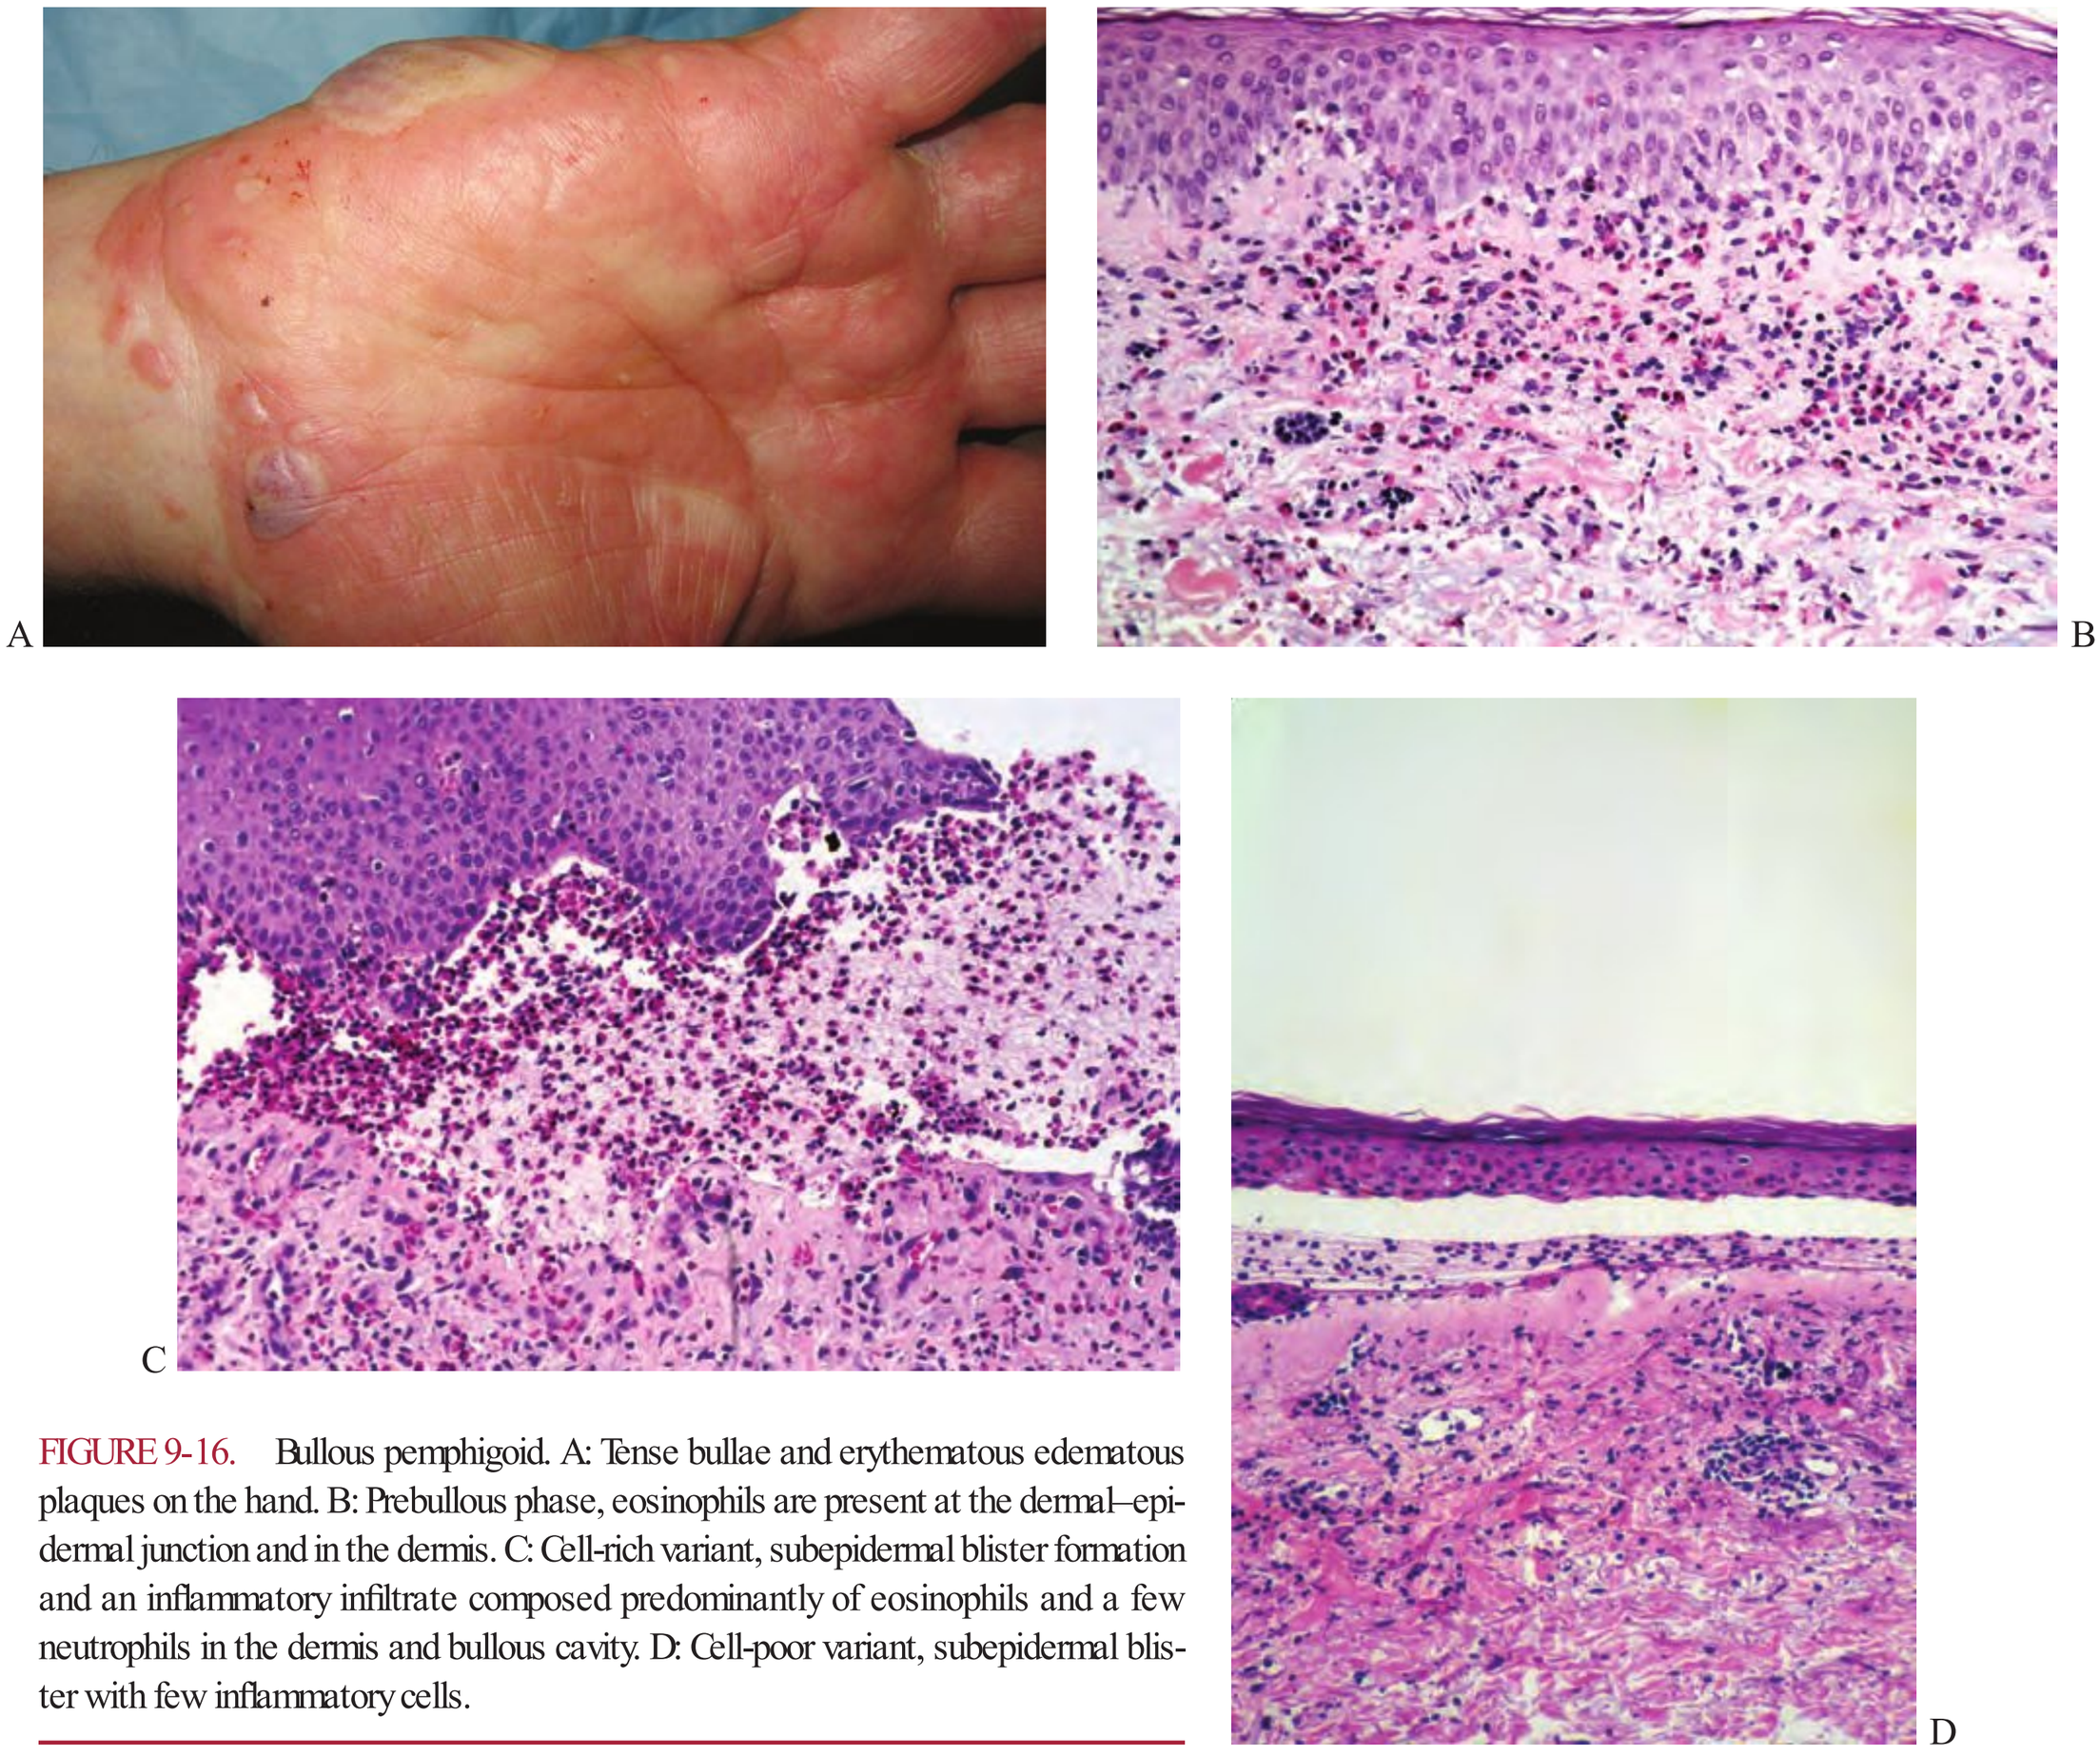

FIGURE 9-16. Bullous pemphigoid. A: Tense bullae and erythematous edematous plaques on the hand. B: Prebullous phase, eosinophils are present at the dermal–epidermal junction and in the dermis. C: Cell-rich variant, subepidermal blister formation and an inflammatory infiltrate composed predominantly of eosinophils and a few neutrophils in the dermis and bullous cavity. D: Cell-poor variant, subepidermal blister with few inflammatory cells.

when blisters develop on relatively normal skin (Fig. 9-16D), in which there is usually a scant perivascular lymphocytic infiltrate with few eosinophils, some scattered throughout the dermis and others near the epidermis. The blister contains few inflammatory cells. Epithelial migration and regeneration may result in an intraepidermal split in older blisters. Similar to pemphigus vegetans, a hyperplasia of the epidermis, subepidermal bullae, and accumulations of eosinophils and lymphocytes may be seen.

IF Testing. DIF testing of perilesional skin has shown linear C3 deposition (Fig. 9-17A and Table 9-4) at the dermal–epidermal junction in virtually 100% of cases and IgG in 65% to 95%. IIF studies reveal circulating anti–basement membrane zone IgG antibodies in 70% to 80%. Similarly deposited IgA and IgM are observed in about 25% of cases. No correlation exists between the antibody titer and the clinical severity of the disease. The IgG is located within the lamina lucida, where it appears to be bound specifically to the hemidesmosomes.

Salt-split skin IF studies are an important diagnostic tool. The technique was first developed in 1984, in which normal human skin was used as a substrate and patient serum as a test (indirect salt-split skin technique) (91). Incubation of normal or patient skin in 1 mol/L NaCl results in a split of the epidermis in the lamina lucida. Pemphigoid antibodies bind solely to the lower aspect of the basal keratinocytes (the blister roof) in 80% of cases; in about 20% of cases, the antibodies bind to both the lower basal keratinocytes (the roof) and the superior aspect of the dermis (the blister floor) (Table 9-7). It must be made clear that the antigenic specificity of the IgG binding to the base or roof is unknown. The IgG cannot be said to be directly against BPAg 1, 2, or other antigen. As time goes on, it is likely that it will be found that a number of cases have different antigenic specificity and should be labeled as different diseases.

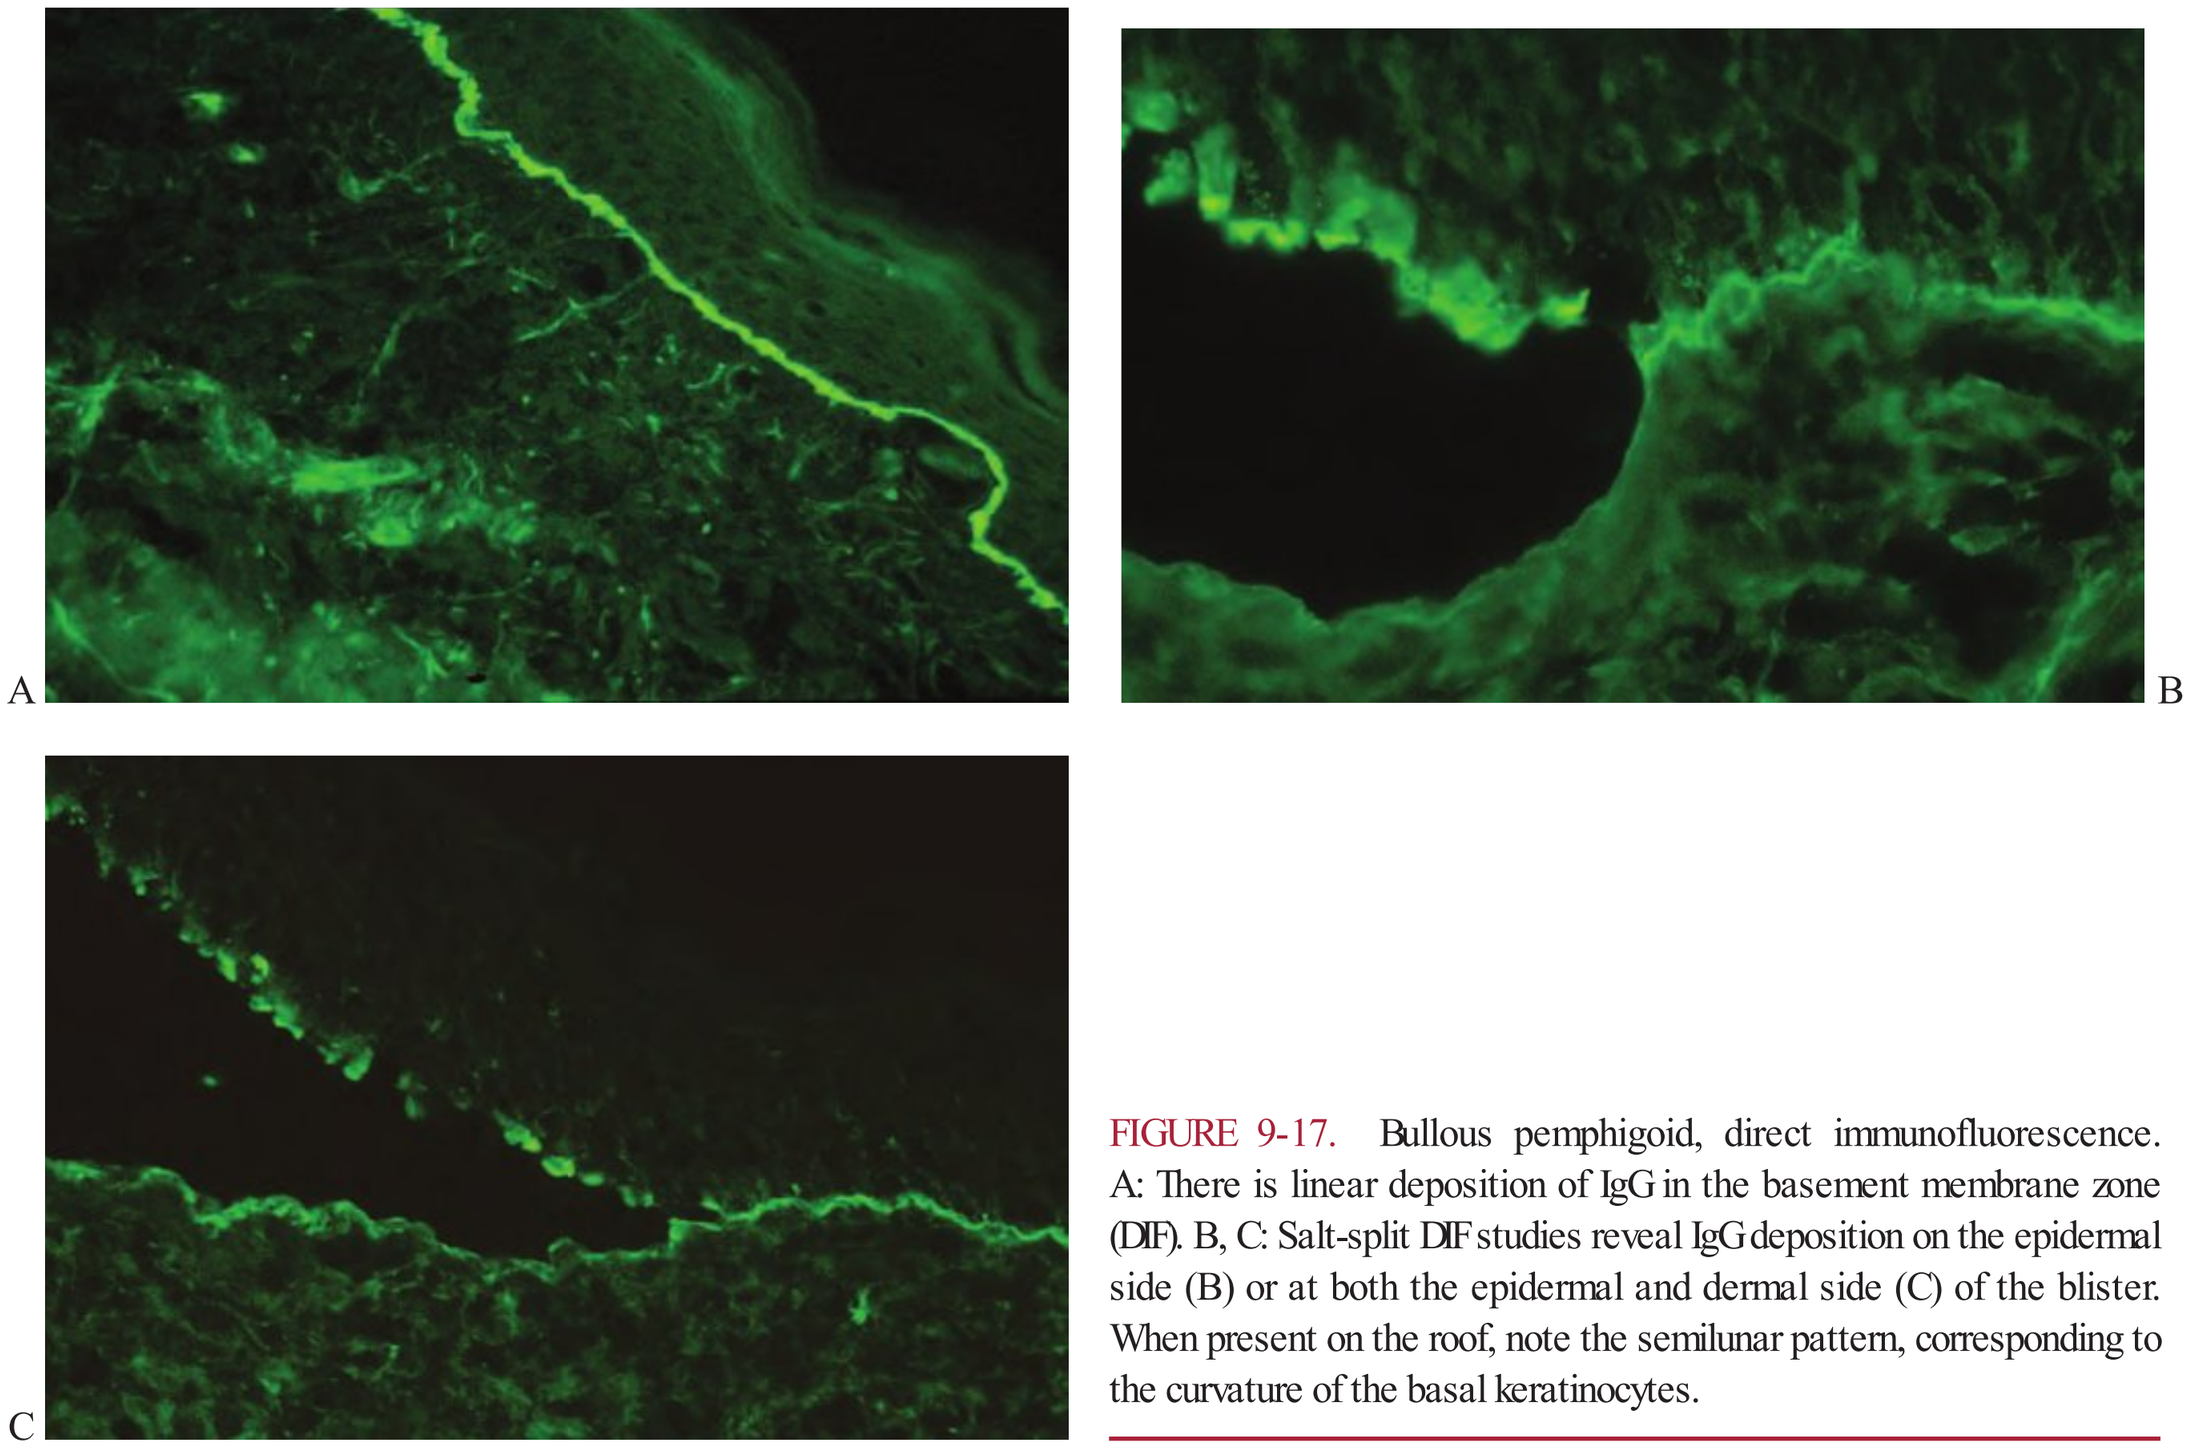

FIGURE 9-17. Bullous pemphigoid, direct immunofluorescence. A: There is linear deposition of IgG in the basement membrane zone (DIF). B, C: Salt-split DIF studies reveal IgG deposition on the epidermal side (B) or at both the epidermal and dermal side (C) of the blister. When present on the roof, note the semilunar pattern, corresponding to the curvature of the basal keratinocytes.

Perilesional skin submitted for DIF examination may also be salt split (direct salt-split skin technique) (92,93). When this technique is used in pemphigoid, IgG is present on the roof or on the roof and the floor (Fig. 9-17B, C). Localization to only the dermal base is characteristic for EBA (see also Fig. 9-20C, page 262) and anti-P200 pemphigoid.

Pathogenesis. Pemphigoid antibodies bind to two antigens, a 230-kD protein (BPAg1) and a second 180-kD protein (BPAg2) (94,95). The principal antigen, BPAg1, is associated with the cytoplasmic attachment site of hemidesmosomes and is largely within the basal keratinocyte. BPAg2 is transmembrane collagen that extends through the lamina lucida. The distribution of these antigens within the skin correlates with lesion location. A blistering disorder clinically similar to pemphigoid has antibodies that recognize a 105-kD protein synthesized by both keratinocytes and fibroblasts (96,97).

Given the known data, a sequence of pathogenetic events may be proposed. Pemphigoid antibodies bind with BPAg1 and BPAg2, activating the complement cascade. The anaphylatoxins, C3a and C4a, are elaborated, activating mast cells. Mast cell activation may be augmented by pemphigoid IgG4, which has homocytotropic properties for mast cells. The mast

cells degranulate, releasing a variety of inflammatory mediators, including eosinophil chemotactic factor, neutrophil chemotactic factor, leukotriene B4, proteolytic enzymes, and eosinophil stimulating factor. Eosinophil infiltration ensues with subsequent degranulation and release of major basic protein and other proteolytic enzymes. The vessels are hyperpermeable, probably because of the release of vascular permeability factor by keratinocytes (98). Lamina lucida separation develops from injury of basal keratinocytes, disruption of hemidesmosomes, and proteolysis (99). The role of infiltrating lymphocytes that are predominantly $CD4^+$ is unclear. IL-1 and IL-2, as well as INF-γ, have been identified in blister fluids (100).

Ultrastructural Study. Pemphigoid antibodies bind within the lamina lucida, in particular, to the hemidesmosomes. The blister arises within the lamina lucida in both the cell-poor and cell-rich lesions. In cell-poor lesions, there is disruption of the anchoring filaments without lamina densa fragmentation. In contrast, inflammatory lesions of bullous pemphigoid with numerous eosinophils and mononuclear cells in the dermis result in greater local destruction or blister formation in the lamina lucida with fragmentation of the lamina densa.

Clinical Variants

Drug-associated Bullous Pemphigoid

Furosemide, phenacetin, and various penicillins have been associated with bullous pemphigoid (101). It is possible that drug hypersensitivity may not be a cause of pemphigoid, but that the patients had subclinical pemphigoid with a superimposed drug eruption, which produces damage to the dermal–epidermal junction. The combination hits the threshold of basal damage necessary to produce subepidermal blister formation.

Pemphigoid Localized to the Lower Extremities

Some patients, usually women, present with tense bullae localized to the lower extremities. Histologically, these reveal a cell-poor pattern and have positive IF findings less frequently (50%) than routine bullous pemphigoid. At least in one instance, it has been shown that the IgG is directed against BPAg1 (102). The exact nosology of the DIF-negative cases is unclear. In our estimation, they likely represent subepidermal blisters in ischemic lower extremities secondary to chronic stasis dermatitis or other causes of chronic ischemic dermatitis such as diabetic microangiopathy, due to the high metabolic activity of basal keratinocytes and inhibition of hemidesmosome formation and maintenance. The hemidesmosome turnover rate is quite rapid, 4 to 6 hours.

Vesicular Pemphigoid

Vesicular pemphigoid is worthy of designation only because of its clinical similarity to dermatitis herpetiformis with small grouped blisters, which may lead to misdiagnosis.

Differential Diagnosis. Histologic differentiation of bullous pemphigoid from pemphigus vulgaris is not difficult because of the difference in cleavage planes and the mechanism of blister formation. Bullous pemphigoid is frequently indistinguishable from herpes gestationis; however, herpes gestationis may have greater quantities of infiltrating neutrophils and more basal keratinocyte damage. EBA (inflammatory variant) may have greater numbers of infiltrating neutrophils, but differentiation may be impossible on routine hematoxylin and eosin stain. Dermatitis herpetiformis is characterized by a subepidermal infiltrate of neutrophils with papillary microabscesses. Similarly, linear IgA dermatosis (LAD) is characterized, in the vast majority of cases, by a neutrophil-rich infiltrate. EM is an interface dermatitis characterized by basal vasculopathy, basal apoptosis, and a tagging lymphohistiocytic infiltrate along the dermal–epidermal junction. Diabetic blisters are noninflammatory, subepidermal in location, and often associated with fibrosis. Some patients with pemphigoid may present only with a superficial perivascular lymphoeosinophilic infiltrate without migration of eosinophils to the dermal–epidermal junction. This histologic reaction pattern is most commonly associated with morbilliform drug eruptions. Rarely, the changes of eosinophilic cellulitis (Well's syndrome) may also herald the presence of pemphigoid. Bullous drug eruptions may present with subepidermal vesicles and eosinophils, and later lesions of dermatitis herpetiformis may contain eosinophils. IF study is necessary to make a specific diagnosis.

Cicatricial Pemphigoid

Cicatricial pemphigoid is a bullous disorder characterized by a chronic course, scarring, and predilection for mucosal surfaces. Most patients are elderly, and there is a male predilection. Oral blisters are present in virtually all cases, and ocular involvement is observed in 75%, with cutaneous involvement in 33%. The oral lesions are usually small blisters that subsequently erode and ulcerate. Other mucosal surfaces, including the larynx, esophagus, nose, vulva, and anus, may also be involved. Scarring is less evident in these locations than in the conjunctiva, where erythema, without blisters and ulceration, and subsequent scarring are the rule. Unilateral blindness occurs in up to 20% of cases. The cutaneous lesions are of two types: (a) an extensive eruption of bullae that heals without scarring, and (b) areas of erythema mainly on the face and scalp in which bullae erupt intermittently followed by atrophy and scarring. Both types of lesions may be present in the same patient. In the Brunsting-Perry variant, there are no mucosal lesions, but rather one to several circumscribed erythematous patches on which recurrent crops of blisters appear with atrophic scarring. The patches are usually confined to the head and neck area. Other clinical variants include a widespread nonscarring bullous eruption in which scarring lesions develop only on the head and widespread bullae that heal with atrophic scars.

Histopathology. In cutaneous lesions, a subepidermal blister develops that may extend down adnexa (Fig. 9-18). Neutrophils, histiocytes, and lymphocytes predominate in the inflammatory infiltrate. Eosinophils may or may not be

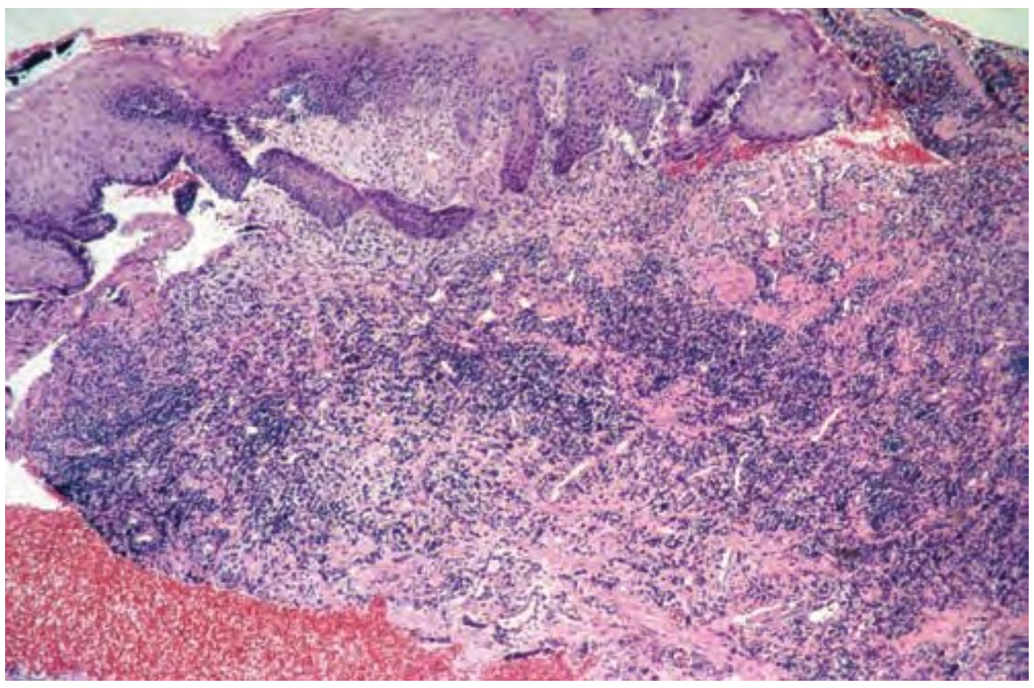

FIGURE 9-18. Cicatricial pemphigoid. There is fibrosis beneath the subepidermal blister containing fibrin. There is often a cell-rich lichenoid infiltrate.

numerous. Lamellar fibrosis beneath the epidermis is a hallmark but may not be present in the initial lesions. Mucosal lesions generally have a lichenoid lymphocytic infiltrate in which neutrophils or eosinophils or both may be present. The changes are often nonspecific in both mucosal and cutaneous lesions, but the above features should lead to consideration of cicatricial pemphigoid.

IF Testing. DIF studies reveal linear IgG and C3 in lesional and perilesional skin in approximately 80% of cases. In most cases, IgG and C3 are present, occasionally in association with IgA or IgM. Rarely, only C3 is present. In that past, cases labeled as cicatricial pemphigoid were found to have only linear IgA deposits, these cases are now best considered linear IgA bullous dermatosis.

IIF testing of serum yields variable results depending on the substrate used (monkey esophagus, guinea pig esophagus, normal human skin, salt-split skin). It appears that circulating antibodies in this disorder may be more readily demonstrated when salt-split human skin is used as substrate, in which IgG may be localized only to the roof or, as in the antiepiligrin subgroup, to the base of the induced separation (see Table 9-7).

The difference in clinical presentation, as well as the localization of the immunoreactants, may be explained by differing antigenic specificity of the antibodies. The known autoantigens include the following: (a) epiligrin (103), also known as *laminin 5*, which is associated with the disease previously termed *antiepiligrin cicatricial pemphigoid*; (b) β4 subunit of the α6β4 integrin, which is predominantly associated with ocular cicatricial pemphigoid (104); and (c) BPAg2 (105) and BPAg1 (95). It is noteworthy that autoantibodies from patients with cicatricial pemphigoid tend to target the C-terminus of BPAg2, whereas those from patients with BP, pemphigoid gestationis, and lamina lucida type linear IgA bullous dermatosis typically target the NC16A domain of BPAg2. All of these antigens occur within the lamina lucida, with epiligrin present in the lower lamina lucida. This may explain the localization of the antibody to the artifactually created blister base in salt-split skin preparations (see Table 9-7). Currently, cicatricial pemphigoid is best considered not one disease but several diseases with a similar clinical phenotype of scarring, predilection for mucosal and conjunctival surfaces, and subepidermal bullae. Many cases in the literature labeled cicatricial pemphigoid without adequate immunologic study may be better classified as linear IgA disease or EBA involving principally mucosal surfaces.

Ultrastructural Study. Electron microscopic examination revealed in two studies that the oral and cutaneous lesions possess an intact basement membrane zone at the base of the blister. In another study of both the oral and cutaneous lesions, the basement membrane zone was destroyed.

Herpes Gestationis

Herpes gestationis is a blistering disorder that usually develops during the second to third trimester in pregnant women. It is estimated to occur in 1 in 50,000 pregnancies. Intensely pruritic, urticarial lesions usually develop on the abdomen, with subsequent involvement of the extremities, hands, and feet. They usually progress to tense vesicles and bullae, some herpetiform. The disorder may recur with subsequent pregnancies, menstrual periods, or the use of birth control pills. The course for the mother is benign. There was a debate concerning the possibility of an increased incidence and risk of fetal morbidity and mortality. However, data obtained in the 1990s indicates that no such risk can be confirmed (106). There is an association with prematurity and small-for-gestational-age weights (107). The infant may be born with a mild, transient, vesiculobullous eruption secondary to transplacental transfer of the mediating antibody.

Histopathology. In zones of erythema and edema, there is a perivascular infiltrate composed of lymphocytes and eosinophils. There is marked papillary dermal edema. As well, there may be spongiosis, which may be eosinophilic in type. Focal necrosis of the basal keratinocytes, which has been emphasized by some authors, leads to a subepidermal blister (Fig. 9-19).

IF Testing. DIF testing reveals linear deposition of C3 in perilesional skin in virtually all patients. IgG is similarly deposited in 30% to 40%. Immunoelectron microscopic study has revealed that IgG and C3 reside within the lamina lucida. Using routine IIF studies of serum, it is uncommon to demonstrate circulating anti–squamous basement membrane zone antibody. Using *in vitro* complement fixation, a circulating anti–basement membrane zone IgG is demonstrable in most cases. At this point in time, the use of the label *HG factor* for these IgG antibodies is of historical interest only. The BPAg2 is the principal antigen, but the BPAg1 is recognized in some patients as well (108).

FIGURE 9-19. Herpes gestationis. A subepidermal blister with eosinophils and neutrophils. The epidermis shows focal spongiosis.

Ultrastructural Study. The epidermis at the periphery of bullae shows significant damage, most pronounced in basal keratinocytes, with resultant complete or partial necrosis of epidermal cells. Despite the fact that basal keratinocytes show severe damage, the basal cell plasma membrane and the lamina densa are well preserved and are present at the floor of the blister. The hemidesmosomes may be intact in some areas.

VESICULOBULLOUS DERMATOSES WITH AUTOIMMUNITY TO TYPE VII COLLAGEN

Epidermolysis Bullosa Acquisita

Classically, EBA is a noninherited disorder of acquired skin fragility. This presentation of EBA was the only one recognized until later. Blisters develop on noninflammatory bases with a predilection for acral areas. Scarring and milia formation ensue. A characteristic nail dystrophy and alopecia are noted. This presentation is associated with malignant lymphoma, amyloidosis, and colitis or enteritis. Some patients with EBA may have significant involvement of oral and conjunctival mucosa and therefore may be *cicatricial pemphigoid–like*. However, acral lesions are prominent and nail dystrophy may be noted In this type, biopsy from mucosal lesions reveals inflammatory, subepidermal bullae with scarring and milia similar to cicatricial pemphigoid.

In 1984, five EBA patients with clinical and histologic features of bullous pemphigoid were described (109). They had generalized pruritic, erythematous macules and papules on which bullae arose. There was less tendency for the lesions to develop acrally and greater involvement of flexural surfaces than in the previously described forms of EBA. At presentation, neither scarring nor milia were discerned; however, delicate scars developed later at the sites of blister formation.

Histopathology. The *bullous pemphigoid–like* presentation described above is the most common form of EBA. The subepidermal blisters are inflammatory. The predominant infiltrating cells are lymphocytes and neutrophils in perivascular and focal interstitial array. Eosinophils are present in variable numbers (Fig. 9-20A). In the classic form, the subepidermal blisters are noninflammatory (Fig. 9-20B); fibrosis and milia formation are often present.

IF Testing. Examination of perilesional skin using DIF reveals linear deposition of complement at the basement membrane zone in the vast majority of cases. IgG is by far the most common immunoglobulin found, but IgM and IgA may be present as well. Increasing numbers of immunoglobulin subclasses noted at the dermal–epidermal junction favor a diagnosis of EBA over bullous pemphigoid. The presence of linear C3 at the dermal–epidermal junction alone favors bullous pemphigoid over EBA. However, use of routine DIF cannot reliably distinguish between bullous pemphigoid and EBA. IIF reveals circulating anti–basement membrane zone antibodies in up to 50%.

The use of the salt-split skin technique leads to the appropriate diagnosis in most cases (110). The antibodies in EBA have specificity for the globular carboxyl terminus of type VII collagen and are deposited beneath the lamina densa. Therefore, on salt-split skin studies, IgG is on the floor and not on the roof of the split (Fig. 9-20C).

Bullous Systemic Lupus Erythematosus

Vesicles and bullae may develop in patients with SLE. In contrast to dermatitis herpetiformis, the lesions are not symmetrical and do not have a predilection for extensor surfaces of arms, elbows, or scalp; they may be photodistributed or widespread and are not pruritic. These patients rarely have classic lesions of discoid, systemic, or subacute cutaneous lupus erythematosus when they develop blisters. In cases from the literature, the vast majority of patients have had a previous history of lupus erythematosus, and most authors have required definitive American Rheumatologic Association criteria before making the diagnosis in those patients with bullous lesions. Uncommonly, patients (who later developed other stigmata of lupus) have presented with a blistering eruption but without previous signs or symptoms of connective tissue disease. Bullous lupus erythematosus is most common in women, particularly black women. Most of these cases were exquisitely sensitive to dapsone therapy, with rapid involution of the lesions. No correlation with clinical activity of lupus erythematosus was apparent. Some patients with EBA will progress to SLE. (See also Chapter 10.)

Histopathology. Three histologic patterns have been identified in such lesions. The first is striking basal layer vacuolization with subsequent blister formation. The second is vasculitis with subepidermal blister and pustule formation (Fig. 9-21A, B). The third and most common is a dermatitis herpetiformis–like histologic pattern. Approximately 25% of

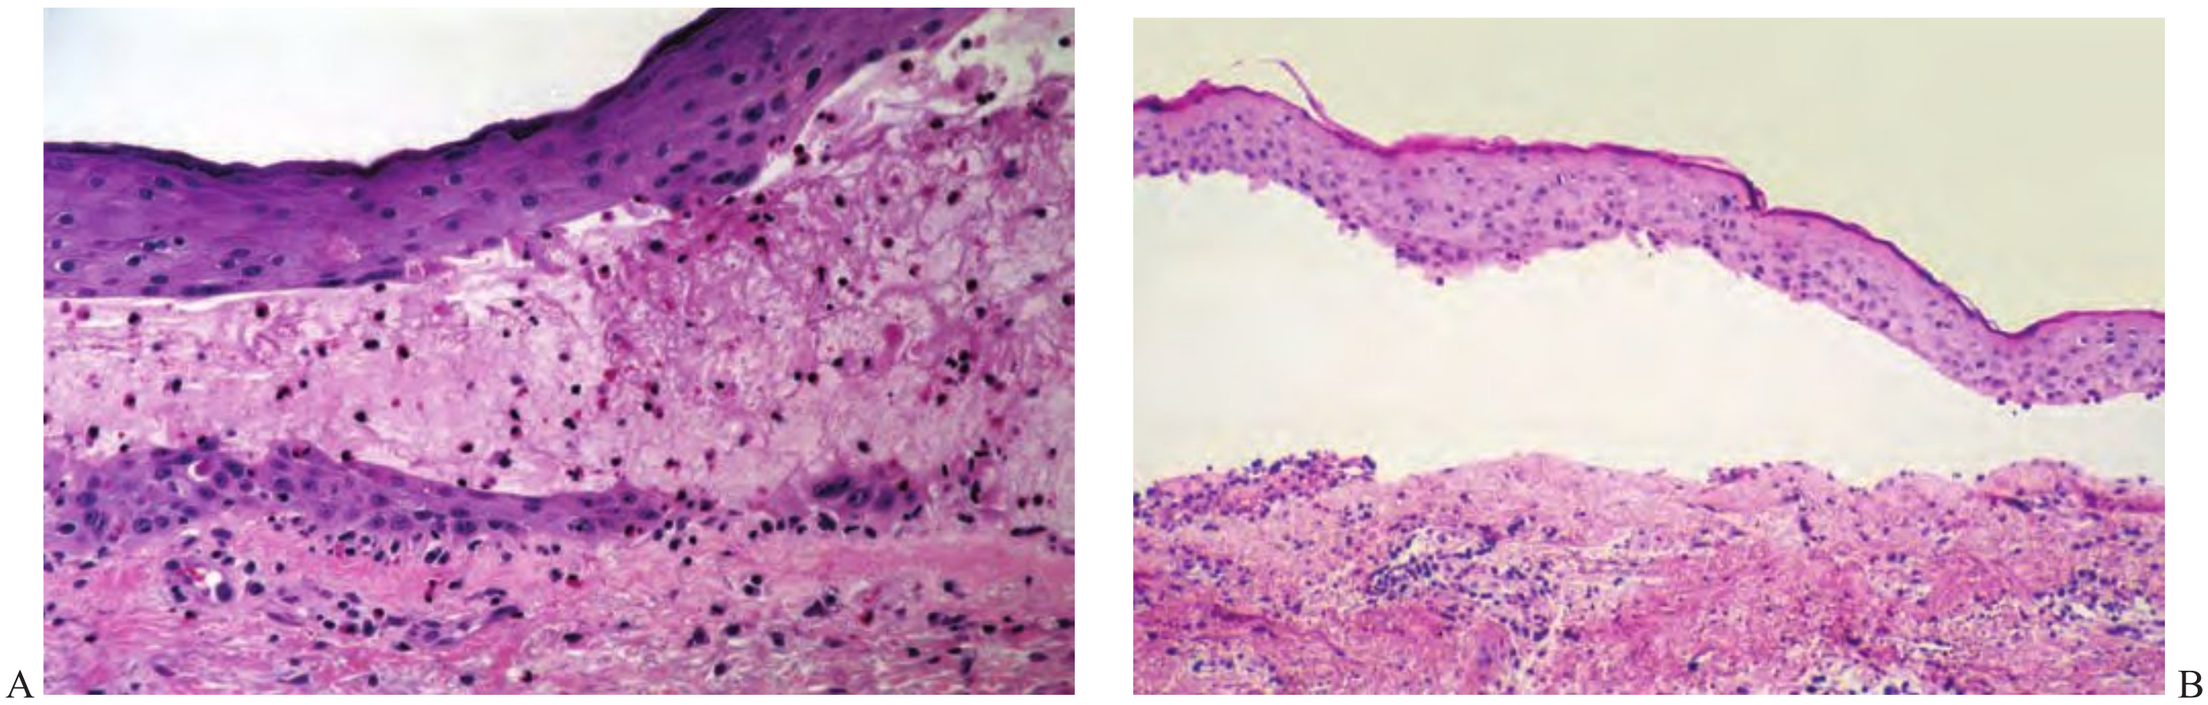

FIGURE 9-20. Epidermolysis bullosa acquisita. A: In the inflammatory type, some neutrophils and eosinophils are in the blister cavity and the superficial dermis. The blister is partially re-epithelialized. B: Non-inflammatory type with a subepidermal blister. C: Salt-split DIF reveals linear deposition of IgG in the blister base.

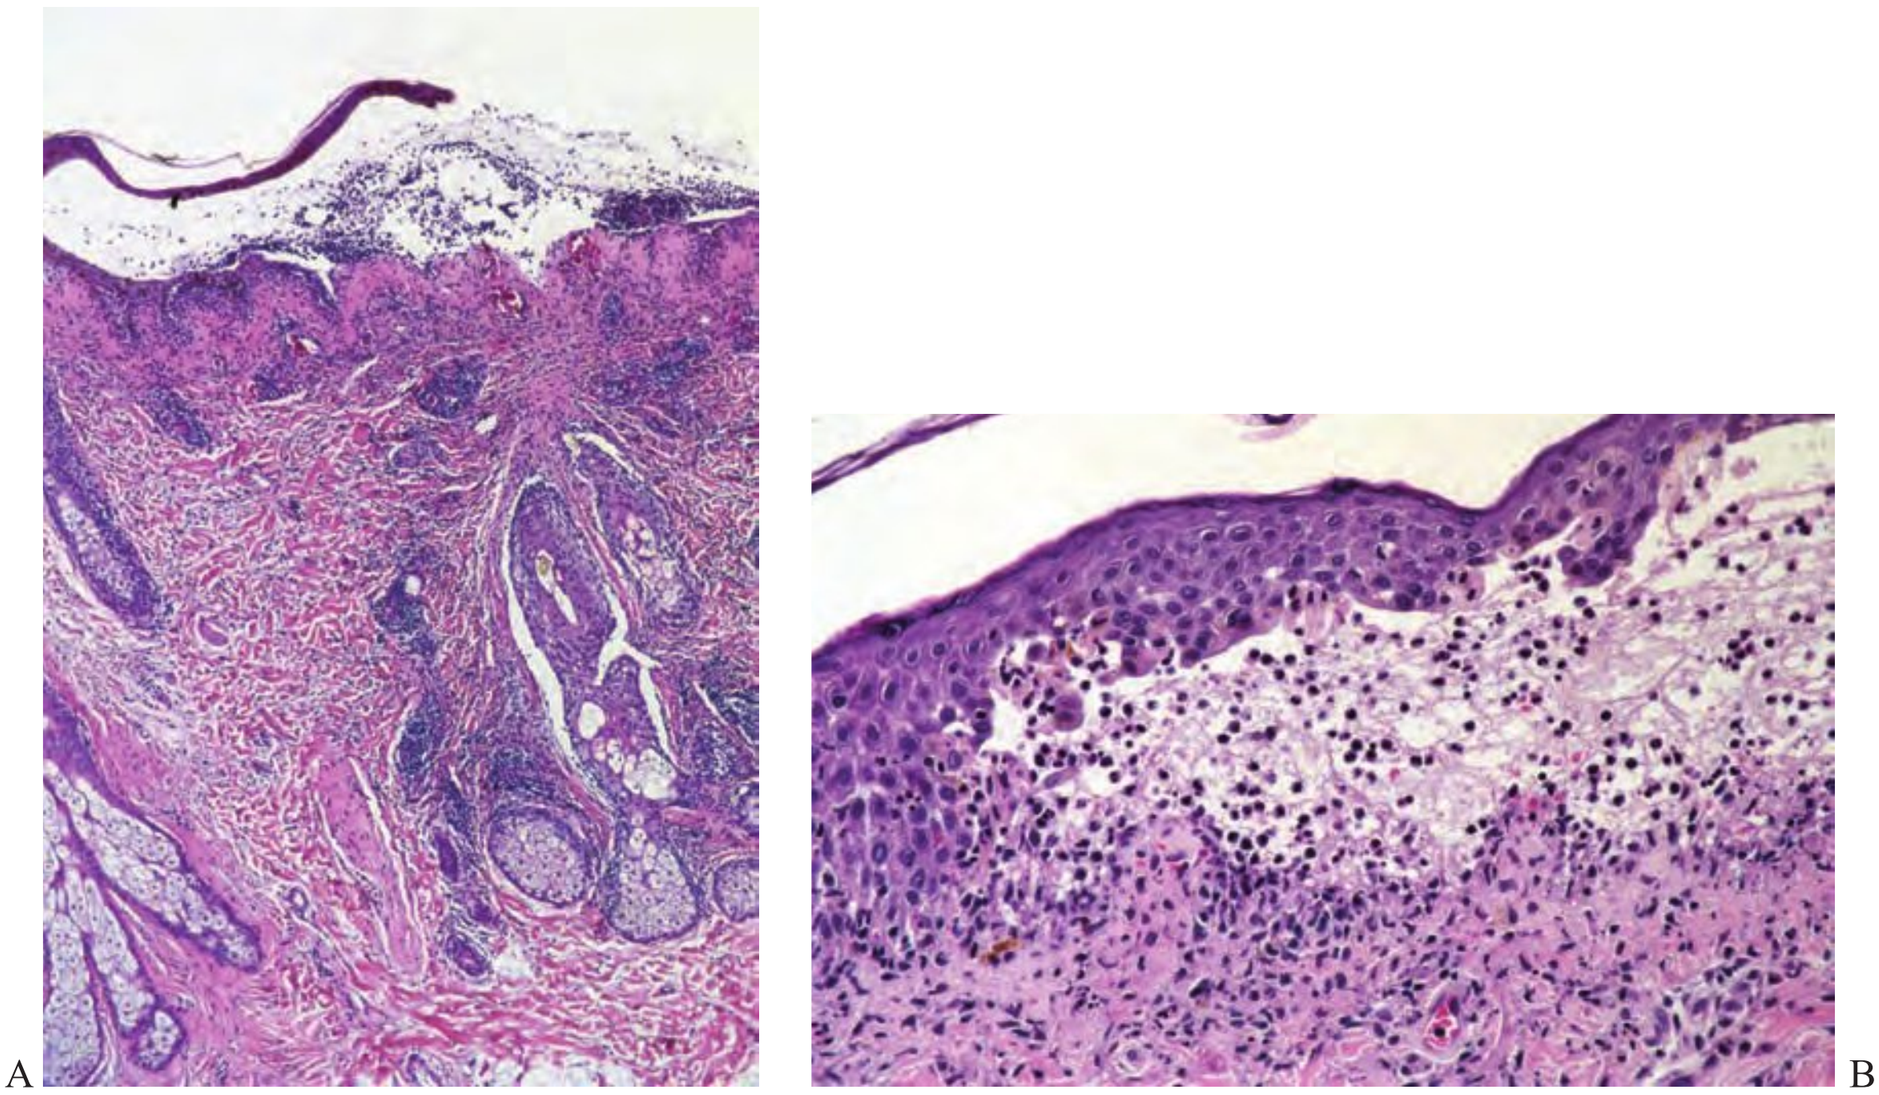

FIGURE 9-21. Bullous systemic lupus erythematosus. A: There is a subepidermal blister and perifollicular inflammatory cell infiltrate. B: The neutrophils are predominant in the blister and superficial dermis.

cases are said to have a small-vessel, neutrophil-rich leukocytoclastic vasculitis beneath the blister. Histologic features more routinely identified with lupus erythematosus are not present. Another histologic finding that is not emphasized in most case reports is the presence of dermal mucin and hyaluronic acid as defined by Alcian blue stain at pH 2.5 (111). The frequency of mucin deposition is unknown.

IF Testing. In all reported cases, IgG and C3 are deposited at the epidermal basement membrane zone. The pattern was linear in more than 50% and was referred to as "granular bandlike" in approximately 25%. IgM and IgA were present in approximately 50% and 60% of cases, respectively. The conflicting pattern of immune reactant deposition is difficult to explain. In these reports, the pattern varies from a "thick band" to a "fine ribbon-like" or "tubular" pattern. The ribbon-like or linear pattern represents antibodies that are bound to rigid, anatomically compartmentalized antigens such as in bullous pemphigoid or EBA. In general, granular patterns represent deposition of circulating immune complexes *in situ* or *in situ* binding of antigen and antibody in non-compartmentalized zones. Therefore, perhaps some of the cases represent tubular or linear deposition obscured by confluent granular bands (positive lupus band test). IIF study of serum rarely reveals circulating anti–squamous basement membrane zone antibodies that are detected against type VII collagen. It should be noted, however, that salt-split skin preparations might be a more sensitive substrate than whole-skin mounts.

A salt-split skin preparation using patient serum reveals localization to the split floor, as in EBA (Table 9-7). As well, Western immunoblot reveals binding to 290-kD or 145-kD dermal proteins, which are components of type VII collagen. However, antibodies to type VII collagen are not present in all cases.

Ultrastructural Study. Immunoelectron microscopic examination reveals electron-dense deposits of IgG at the lower edge of the basal lamina and immediately subjacent dermis in an identical location to the antibody in EBA.

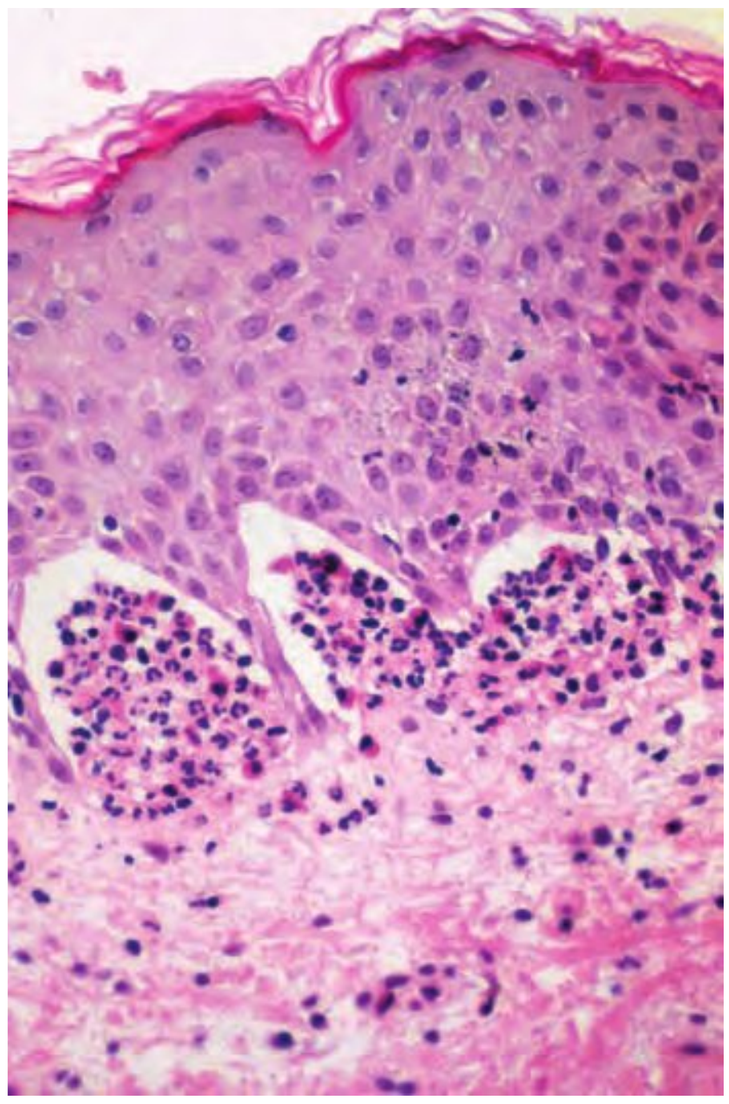
Anti-p200 Pemphigoid

Patients with anti-p200 pemphigoid usually present with a generalized eruption composed of urticarial papules and plaques in combination with tense blisters, closely mimicking BP. In Asian patients, an association with coexisting psoriasis has been reported (86). Mucosal involvement has been observed (87). Since the original description in 1996, about 30 cases of anti-p200 pemphigoid have been reported (112). The real incidence of this disease is probably much higher. It is important to recognize the entity because it shares similar histologic features and immunofluorescence pattern with EBA. In contrast to EB, anti-p200 pemphigoid runs a self-limiting course and rapidly resolves without scarring under immunosuppressive treatment. Unless further immunoblot studies are performed, anti-p200 pemphigoid is indistinguishable from EBA.

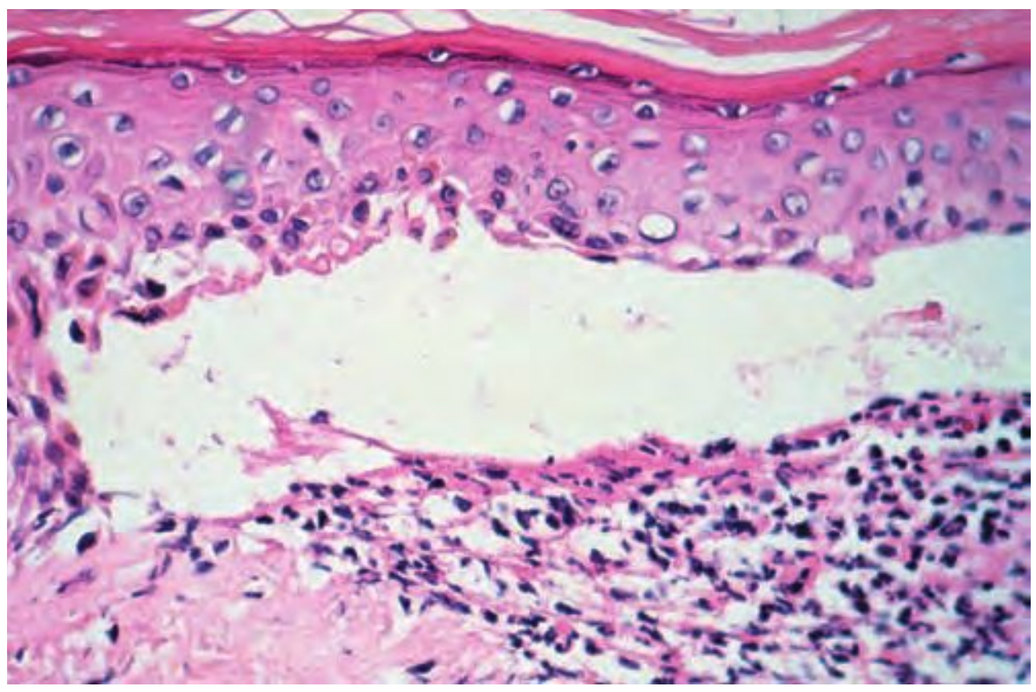
P200 is a glycoprotein localized to the lower lamina of the basement membrane zone. Although the exact identity of the adhesion molecule remains unknown, it has been shown to be distinct from all known autoantigens of the dermal–epidermal junction.

Histopathology. The lesions are characterized by subepidermal blistering and a superficial inflammatory infiltrate, usually of neutrophils but occasionally containing significant numbers of eosinophils. Microabscess formation in the papillary dermis adjacent to the blister cavity, as well as eosinophilic or neutrophilic spongiosis, may be observed. A moderate to dense inflammatory infiltrate in the upper dermis is usually present (113).

IF Testing. DIF shows linear IgG and C3 deposition at the basement membrane zone, whereas IIF study of patient sera demonstrates IgG labeling exclusively on the dermal side (floor) of salt-split human skin. By indirect immunogold electron microscopy, immunoreactants are localized to the lower lamina lucida.



SUBEPIDERMAL IgA-MEDIATED VESICULOBULLOUS DERMATOSES



Dermatitis Herpetiformis

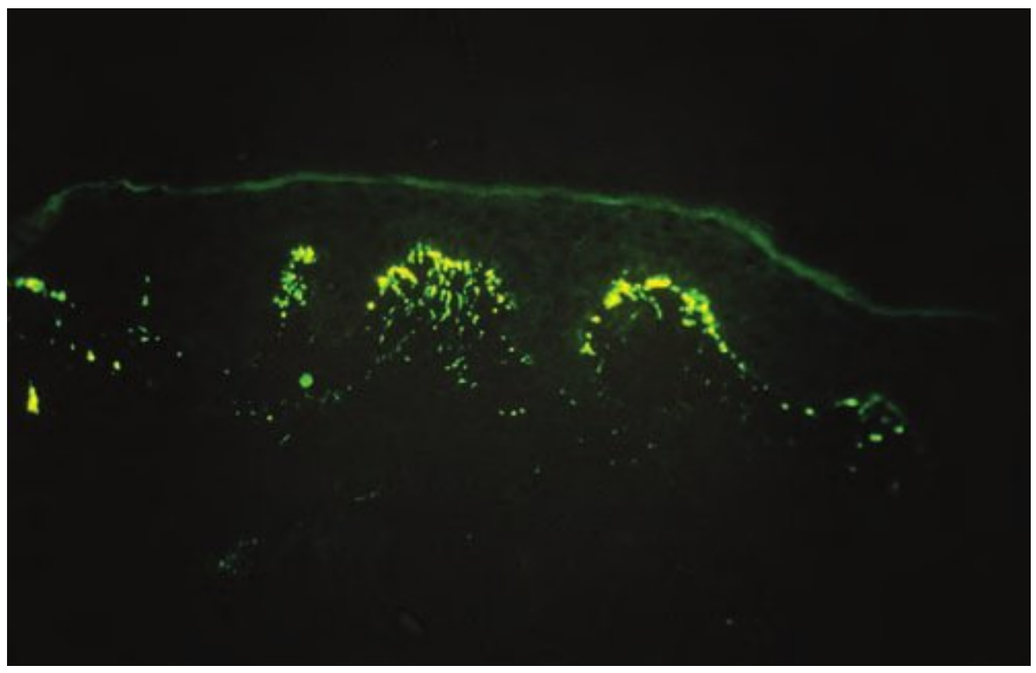
Dermatitis herpetiformis is an intensely pruritic, chronic recurrent dermatitis that has a slight male predilection. The lesions usually develop in young to middle-aged adults as symmetrical grouped erythematous papulovesicles, vesicles, or crusts (Fig. 9-22A). Oral lesions are absent. The elbows, knees, buttocks, scapula, and scalp are commonly involved. There is a high incidence (about 90%) of gluten-sensitive enteropathy and an increased but rare risk of lymphoma (114). Dermatitis herpetiformis in association with SLE has also been reported.

Histopathology. The typical histologic features are best observed in erythematous skin adjacent to early blisters. In these zones, neutrophils accumulate at the tips of dermal papillae. With an increase in size to microabscesses, a significant admixture of eosinophils may be noted. As microabscesses form, a separation develops between the tips of the dermal papillae and the overlying epidermis; thus, the early blisters are multiloculated (Fig. 9-22B). The presence of fibrin in the papillae may give them a bluish appearance. Within 1 to 2 days, the rete ridges lose their attachment to the dermis, and the blisters then become unilocular (Fig. 9-22C) and clinically apparent. At this time, the characteristic papillary microabscesses may be observed at the blister periphery. For this reason, the inclusion of perivesicular skin in the biopsy specimen is of

A

B

C



D

FIGURE 9-22. Dermatitis herpetiformis. A: Erythematous excoriated papulovesicles on the extensor forearms. (Courtesy of Kenneth Tsai, M.D., Ph.D.) B: Dermal papillary neutrophilic microabscesses are characteristic. C: A fully developed subepidermal blister is no longer multilocular; most of the infiltrating cells are neutrophils. D: There is granular and thready IgA predominantly at the tips of dermal papillae (DIF).

utmost value. The papillary dermis beneath the papillae may have a relatively intense inflammatory infiltrate of neutrophils and some eosinophils. Many neutrophils may exhibit leukocytoclasis. Subjacent to this, a perivascular infiltrate composed of lymphocytes, neutrophils, and eosinophils may be apparent. The diagnostic finding of papillary microabscesses may not be present in all patients. Apoptotic keratinocytes may be noted above the papillary microabscesses.

IF Testing. In 1967, Cormane described the presence of granular deposits of IgA within the dermal papillae in both lesional and nonlesional skin. IgA is found alone or in combination with other immune reactants in over 95% of cases when uninvolved skin of the forearm or buttock is tested (Fig. 9-22D). Fibrillary IgA deposits may also be present. Early in the course of the disease, IgA deposits may be absent and repeat DIF is necessary. Some recommend that biopsies be taken from clinically normal skin immediately adjacent to

erythema, because false-negative results may occur when blistered or inflamed skin is evaluated. The presence of IgA within the skin is not altered by dapsone therapy. After as long as 2 years, a gluten-free diet results in the disappearance of IgA from the skin. Negative results of DIF testing of two appropriately selected biopsy sites are a strong indication that the patient does not have dermatitis herpetiformis.

Circulating IgA antibodies that react against reticulin, smooth muscle endomysium, the dietary antigen gluten, bovine serum albumin, and β-lactoglobin may be present. Only the presence of IgA endomysial antibodies is of diagnostic importance, but their presence is not specific or very sensitive. Using monkey or pig gut as substrate, IIF has been used to detect antiendomysial antibodies, which are present in 52% to 100% of patients.

Pathogenesis. Three important findings must be considered in the pathogenesis of dermatitis herpetiformis. First, the disease is associated with a gluten-sensitive enteropathy; second, granular IgA is deposited in the skin; and third, patients have a high frequency of certain HLA antigens. HLA-B8, DR3, and Dqw2 have been identified in high frequency in patients with dermatitis herpetiformis and celiac disease. The majority of patients show focal celiac spruelike changes on jejunal biopsy. Patients with celiac disease develop IgA autoantibodies to tissue transglutaminase, which degrades gliadin. Antitissue transglutaminase antibodies and antiendomysial antibodies are detected in patients with dermatitis herpetiformis (115). Papillary dermal-bound IgA immune precipitates in dermatitis herpetiformis have been shown to contain epidermal transglutaminase (116).

The IgA deposition results in activation of the complement system followed by chemotaxis of neutrophils into the papillary dermis (117). Enzymes released from these neutrophils degrade laminin and type IV collagen, contributing to blister formation.

Ultrastructural Study. The changes in dermatitis herpetiformis resemble those observed in the inflammatory bullae of bullous pemphigoid. Neutrophils are the major inflammatory cell in the former, whereas eosinophils predominate in the latter. Fibrin appears earlier and in greater amount in dermatitis herpetiformis, particularly in dermal papillae. While it has been shown immunohistochemically that the early blister forms above the apparently intact lamina lucida (118), in more advanced lesions the lamina densa has been destroyed, as is noted in the "inflammatory bullae" of bullous pemphigoid.

Linear IgA Dermatosis

A group of bullous disorders mediated by IgA antibodies with differing specificities for epidermal basement membrane zone antigens has been labeled as LAD. The first and second relatively definitive clinical phenotypes are based on patient age and clinical features—adult LAD and childhood LAD (chronic benign bullous dermatosis of childhood). They differ slightly in their clinical presentations but have identical immunopathologic features. Third, a clinical phenotype similar to cicatricial pemphigoid has been described. Fourth, a subset of patients has been described with drug-induced LAD. On the basis of immunoelectron microscopic localization of the IgA deposition, there are at least two distinct types of LAD: a lamina lucida type and a sublamina densa type. Some of the sublamina densa types of LAD are best classified as IgA EBA.

Adult Type

Vesicles and bullae usually develop in patients >40 years of age, with a slight female predilection. The lesions are less symmetrical and less pruritic than those in dermatitis herpetiformis but may be distributed in similar locations. Ocular and oral lesions may be present in up to 50% of cases. Plantar and palmar bullae may develop in contrast to dermatitis herpetiformis. Cutaneous lesions in LAD are heterogeneous and may mimic other bullous diseases. LAD has been associated with an increased risk of lymphoma (119). Ulcerative colitis has been correlated with LAD in various studies, one of which found ulcerative colitis in 7.1% of LAD patients (120). A rare association with SLE has been reported (121).

Histopathology. The features are similar, if not identical, to dermatitis herpetiformis (Fig. 9-23A, B). According to some, there is less tendency for papillary microabscess formation and greater tendency for uniform neutrophil infiltration along the entire dermal–epidermal junction and rete in inflamed skin. Rarely, a principally lymphocytic infiltrate may be observed, sometimes with numerous neutrophils (121).

IF Testing. As this test defines the disease, DIF reveals linear IgA along the basement membrane zone in perilesional skin in 100% of cases (Fig. 9-23C). In the lamina lucida type of LAD, IgA antibodies bind to the epidermal side of salt-split skin, whereas in the sublamina densa type, such as IgA-mediated EBA, IgA antibodies bind to the dermal side of salt-split skin (Table 9-7).

In the vast majority of cases, IgA1, but rarely IgA2, is present. When IgG and IgA are present, some detailed immunologic study may be needed to allow differential diagnosis with bullous pemphigoid (122). It has been suggested that if the IgA deposits are more intense than the IgG deposits and C3 deposition is strong, then LAD is the best diagnosis. However, it is best considered a distinct disorder labeled as *linear IgA/IgG dermatosis* until more data are available. One patient presented with linearly deposited IgG initially and only subsequently developed linear IgA deposits. Low titers of circulating anti–squamous basement membrane zone IgA have been identified in only 20% to 30% of cases (123). Another study, however, has noted such antibodies in up to 75% of patients.

Pathogenesis. In the lamina lucida type of LAD, the antigens against which the IgA is directed include a 97-kD and a 120-kD protein that may be found in epidermal and dermal extracts (124). Both of them are part of the cleaved ectodomain of the 180-kD bullous pemphigoid antigen (BPAg2) (125,126). In the sublamina densa type, the antigen in many instances is unknown. In some cases, the antigen is

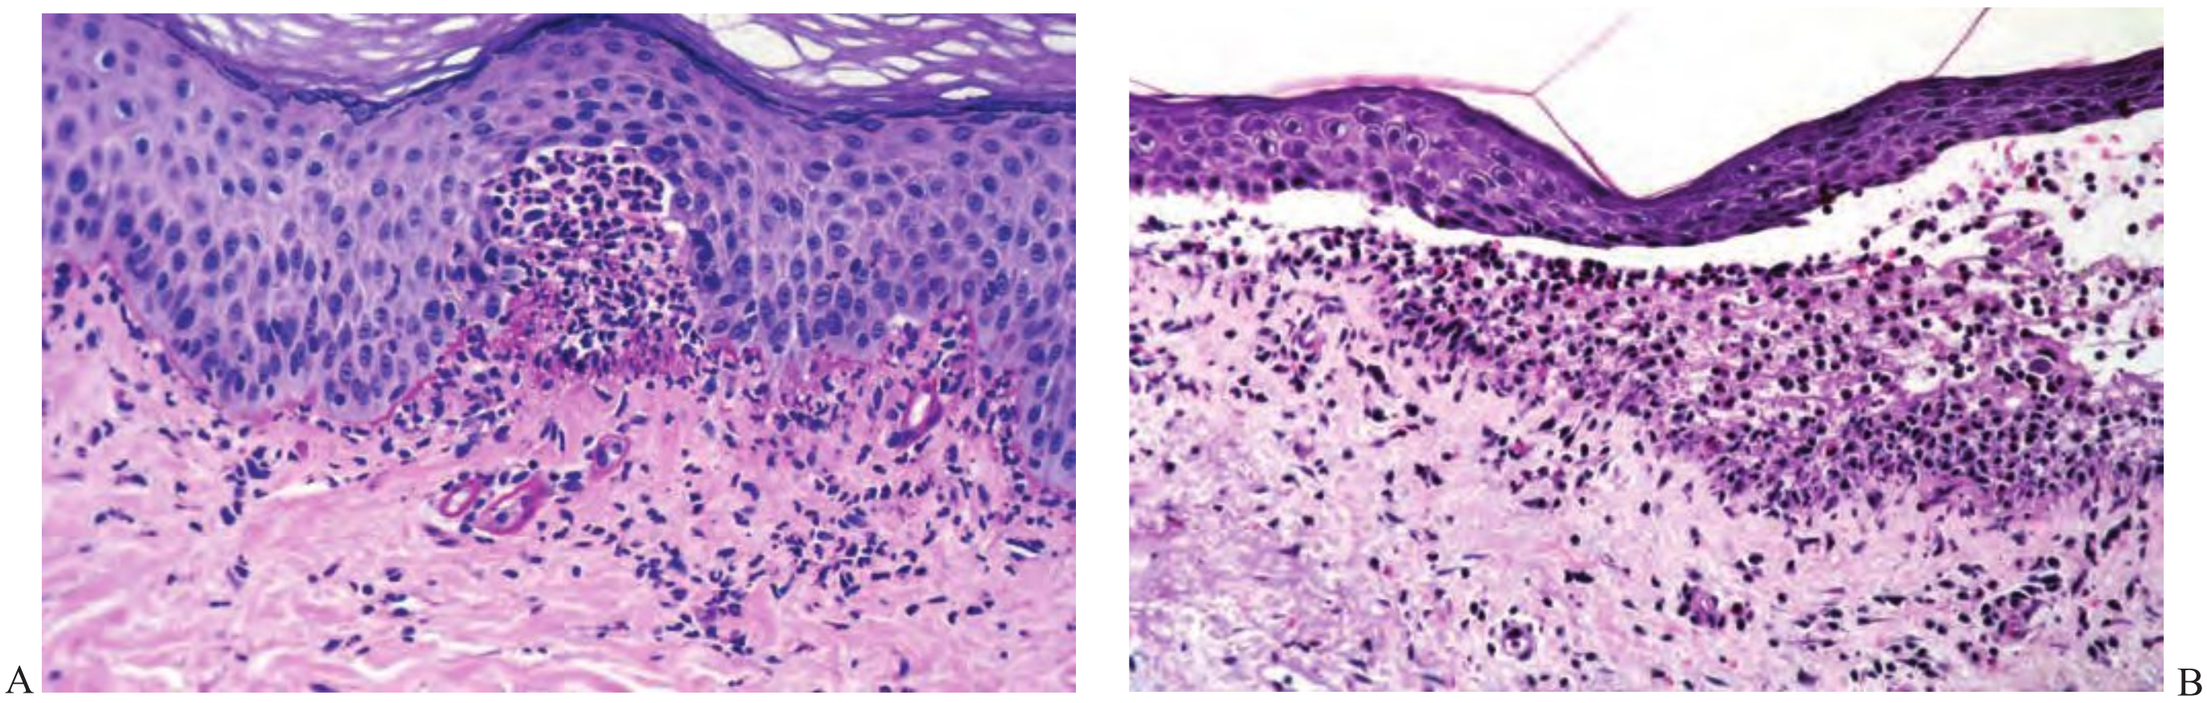


FIGURE 9-23. Linear IgA bullous dermatosis. A: An earlier lesion, where the neutrophils are along the dermal–epidermal junction and are concentrated in the dermal papillae. B: There is a subepidermal blister with inflammatory cells and fibrin in the lumen and in the base. Most of the inflammatory cells are neutrophils. A few eosinophils are also present. C: DIF study reveals deposition of IgA in a linear pattern along the basement membrane zone.

type VII collagen, specifically the NC-1 domain, which is the immunodominant epitope for EBA (127). The events of the inflammatory cascade in IgA-mediated diseases are not well understood.

Ultrastructural Study: The antibodies are deposited principally within the lamina lucida and less commonly beneath the lamina densa (IgA-mediated EBA).

Drug-associated Linear IgA Dermatosis

It is important to note that it is not infrequent for adult-type LAD to be associated with drug therapy. Vancomycin, lithium, diclofenac, captopril, cefamandole, and somatostatin have been associated with such presentations (128). Histologically, the changes are identical to idiopathic LAD in most cases. In some cases, there is an associated lymphoeosinophilic infiltrate in combination with the interface neutrophilic infiltration.

Childhood Type

Originally known as *chronic bullous dermatosis of childhood*, this disorder presents in prepubertal, often preschool, children and rarely in infancy. Vesicles or bullae develop on an erythematous or normal base, occasionally giving rise to a so-called "string of pearls," a characteristic lesion in which peripheral vesicles develop on a polycyclic plaque (Fig. 9-24). They involve the buttocks, lower abdomen, and genitalia and characteristically have a perioral distribution on the face. Oral lesions may occur. The disorder usually remits by 6 to 8 years of age, but 12% in one series experienced persistent disease.

Histopathology: The features are similar to those of the adult-type disease. Some cases, however, resemble bullous pemphigoid because of the presence of eosinophils.

FIGURE 9-24. Childhood linear IgA dermatitis. Crusted erosions on the scrotum. (Courtesy of Kenneth Tsai, M.D., Ph.D.)

IF Testing. DIF testing reveals linearly deposited IgA in virtually 100% of cases. At this time, the targeted antigens are thought to be identical to those noted in the adult-type disease. The sublamina densa type is uncommon in children (129).

NONINFECTIOUS VESICULOPUSTULAR DERMATOSES

Erythema Toxicum Neonatorum

A benign, asymptomatic eruption affecting about 40% of term infants usually within 12 to 48 hours after birth, erythema toxicum neonatorum lasts 2 to 3 days and consists of blotchy macular erythema, papules, and pustules that tend to develop at sites of pressure. The eruption is occasionally associated with blood eosinophilia.

Histopathology. The macular erythema is characterized by sparse eosinophils in the upper dermis, largely in a perivascular location, and mild papillary dermal edema.

The papules show an accumulation of numerous eosinophils and some neutrophils in the area of the follicle and overlying epidermis. Papillary dermal edema is more intense and eosinophils more numerous.

Mature pustules are subcorneal and are filled with eosinophils and occasional neutrophils. The pustules form as a result of the upward migration of eosinophils to the surface epidermis from within and around the hair follicles.

Pathogenesis. The etiology is unknown. However, two hypotheses have been offered. The first is that high-viscosity ground substance in the newborn because of osmotic changes at birth causes tissue dilution and inflammation with minor trauma (130). Second, the eruption has been suggested to be a minor acute graft-versus-host reaction caused by maternal–fetal transfer of lymphocytes during delivery (131).

Differential Diagnosis. Eosinophilic pustular folliculitis is similar to erythema toxicum neonatorum histologically but has completely different clinical features as well as a predilection for the scalp. The subcorneal pustules of impetigo and transient neonatal pustular melanosis are not follicular in origin and contain primarily neutrophils rather than eosinophils. A smear of a pustule is helpful to characterize the predominant inflammatory cell. Although many eosinophils are present in the vesicles of incontinentia pigmenti, the vesicle is intraepidermal rather than subcorneal, and spongiosis is present. In addition, necrotic keratinocytes may be prominent in incontinentia pigmenti but are absent in erythema toxicum neonatorum.

Transient Neonatal Pustular Melanosis

In transient neonatal pustular melanosis, affecting 4.4% of black newborns and 0.6% of white newborns, flaccid vesicopustules with a predilection for the face, trunk, and diaper area develop at birth. These easily rupture, leaving hyperpigmented macules with collarettes of scale. The development of typical lesions of erythema toxicum neonatorum has been observed days later (132). Perhaps the two eruptions represent the same disease in different phases, or their coexistence may be on the basis of the frequent occurrence of erythema toxicum neonatorum.

Histopathology. The vesicopustules consist of intracorneal or subcorneal aggregates of neutrophils with an admixture of eosinophils. Fragmented hair shafts may reside within the blister cavity (132). Within the dermis is an inflammatory infiltrate with some neutrophils and eosinophils. The macules show focal basal hypermelanosis. There is no melanin in the dermis.

Acropustulosis of Infancy

In infantile acropustulosis, intensely pruritic vesicles or pustules that are 1 to 3 mm in diameter occur most commonly on the palms and soles in recurrent crops. The condition more commonly affects darker skin types, and onset is at birth or during the first year of life. The lesions heal with hyperpigmentation and resolve in most cases by 2 to 3 years of age. Rare cases have been reported in older children (133). Scabies infestation must be considered on the differential diagnosis, and acropustulosis may be a postscabetic phenomenon.

Histopathology. The intraepidermal or subcorneal vesicopustules contain neutrophils and sparse eosinophils. There is mild papillary dermal edema and a sparse, mixed, superficial perivascular infiltrate.

Pathogenesis. The etiology of infantile acropustulosis is unknown. The disease may be associated with atopic dermatitis and elevated serum IgE levels. DIF and IIF studies have been negative.

Differential Diagnosis. Impetigo, SPD, candidiasis, and transient neonatal pustular melanosis may be histologically identical to acropustulosis of infancy, so clinical data are necessary for differentiation. Special stains are necessary to rule out an infectious etiology.

Subcorneal Pustular Dermatosis

SPD (Sneddon-Wilkinson disease) is a chronic disorder that was first described in 1956 and is characterized by superficial sterile pustules that have a predilection for flexural surfaces and the axillary and inguinal folds. Many cases have been shown to be a variant of IgA pemphigus (134,135). It usually spares the face and mucous membranes. The pustules develop in an annular or polycyclic arrangement. Pus characteristically accumulates in the lower half of large pustules.

SPD may be associated with a monoclonal gammopathy, which most commonly is an IgA paraproteinemia. Some of these cases eventuate in an IgA myeloma (136) and may have IgA squamous intercellular substance deposits.

Histopathology. The pustules are subcorneal and contain neutrophils, with only an occasional eosinophil (Fig. 9-25).

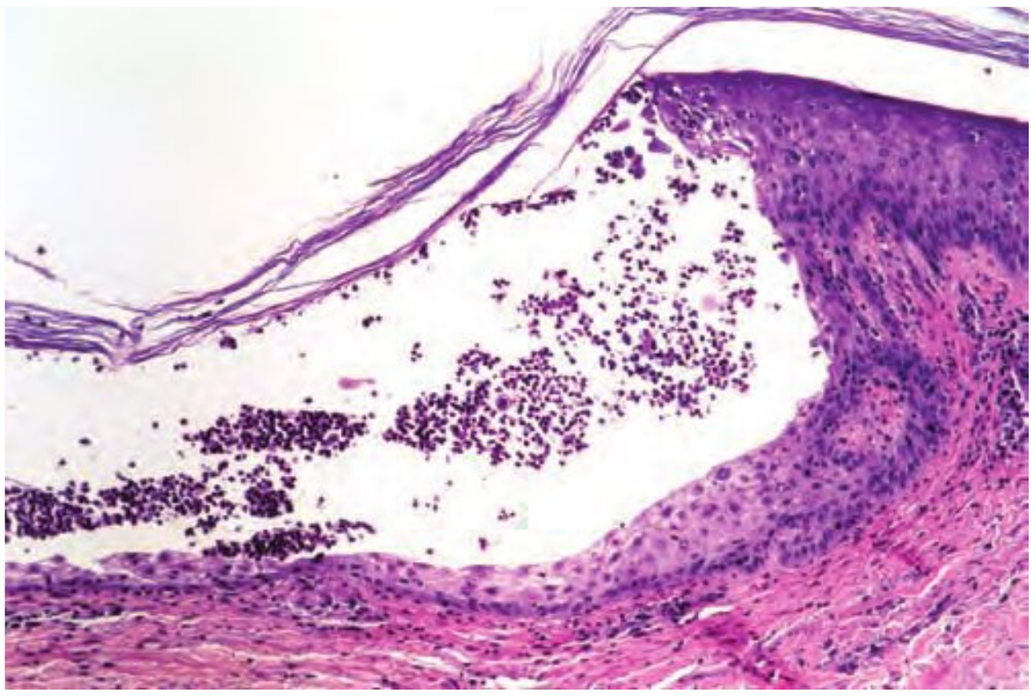

FIGURE 9-25. Subcorneal pustular dermatosis. There is a subcorneal vesicle filled with neutrophils. A few acanthotic keratinocytes are mixed with numerous neutrophils. Only a few spongiform pustules are formed.

The underlying slightly edematous stratum malpighii contains a small number of neutrophils. Only a few spongiform pustules are formed. In some instances, a few acantholytic cells are found in the base of the pustule, most likely because of proteolytic enzymes present in the pustular contents. They may be partially attached to the epidermis or may lie free in the pustule among the neutrophils. The dermal papillae contain dilated capillaries and a perivascular infiltrate composed of neutrophils and a few eosinophils and mononuclear cells.

IF Testing. While most original DIF studies were reported as negative, as more cases accumulate, many cases have squamous intercellular IgA, indicating that they are best considered to be IgA pemphigus (intraepidermal IgA pustulosis) (134).

Pathogenesis. The squamous intercellular substance IgA leads to neutrophilic infiltration. In some patients, elevated levels of tumor necrosis factor-α in the serum and pustules may be responsible for neutrophil activation (137).

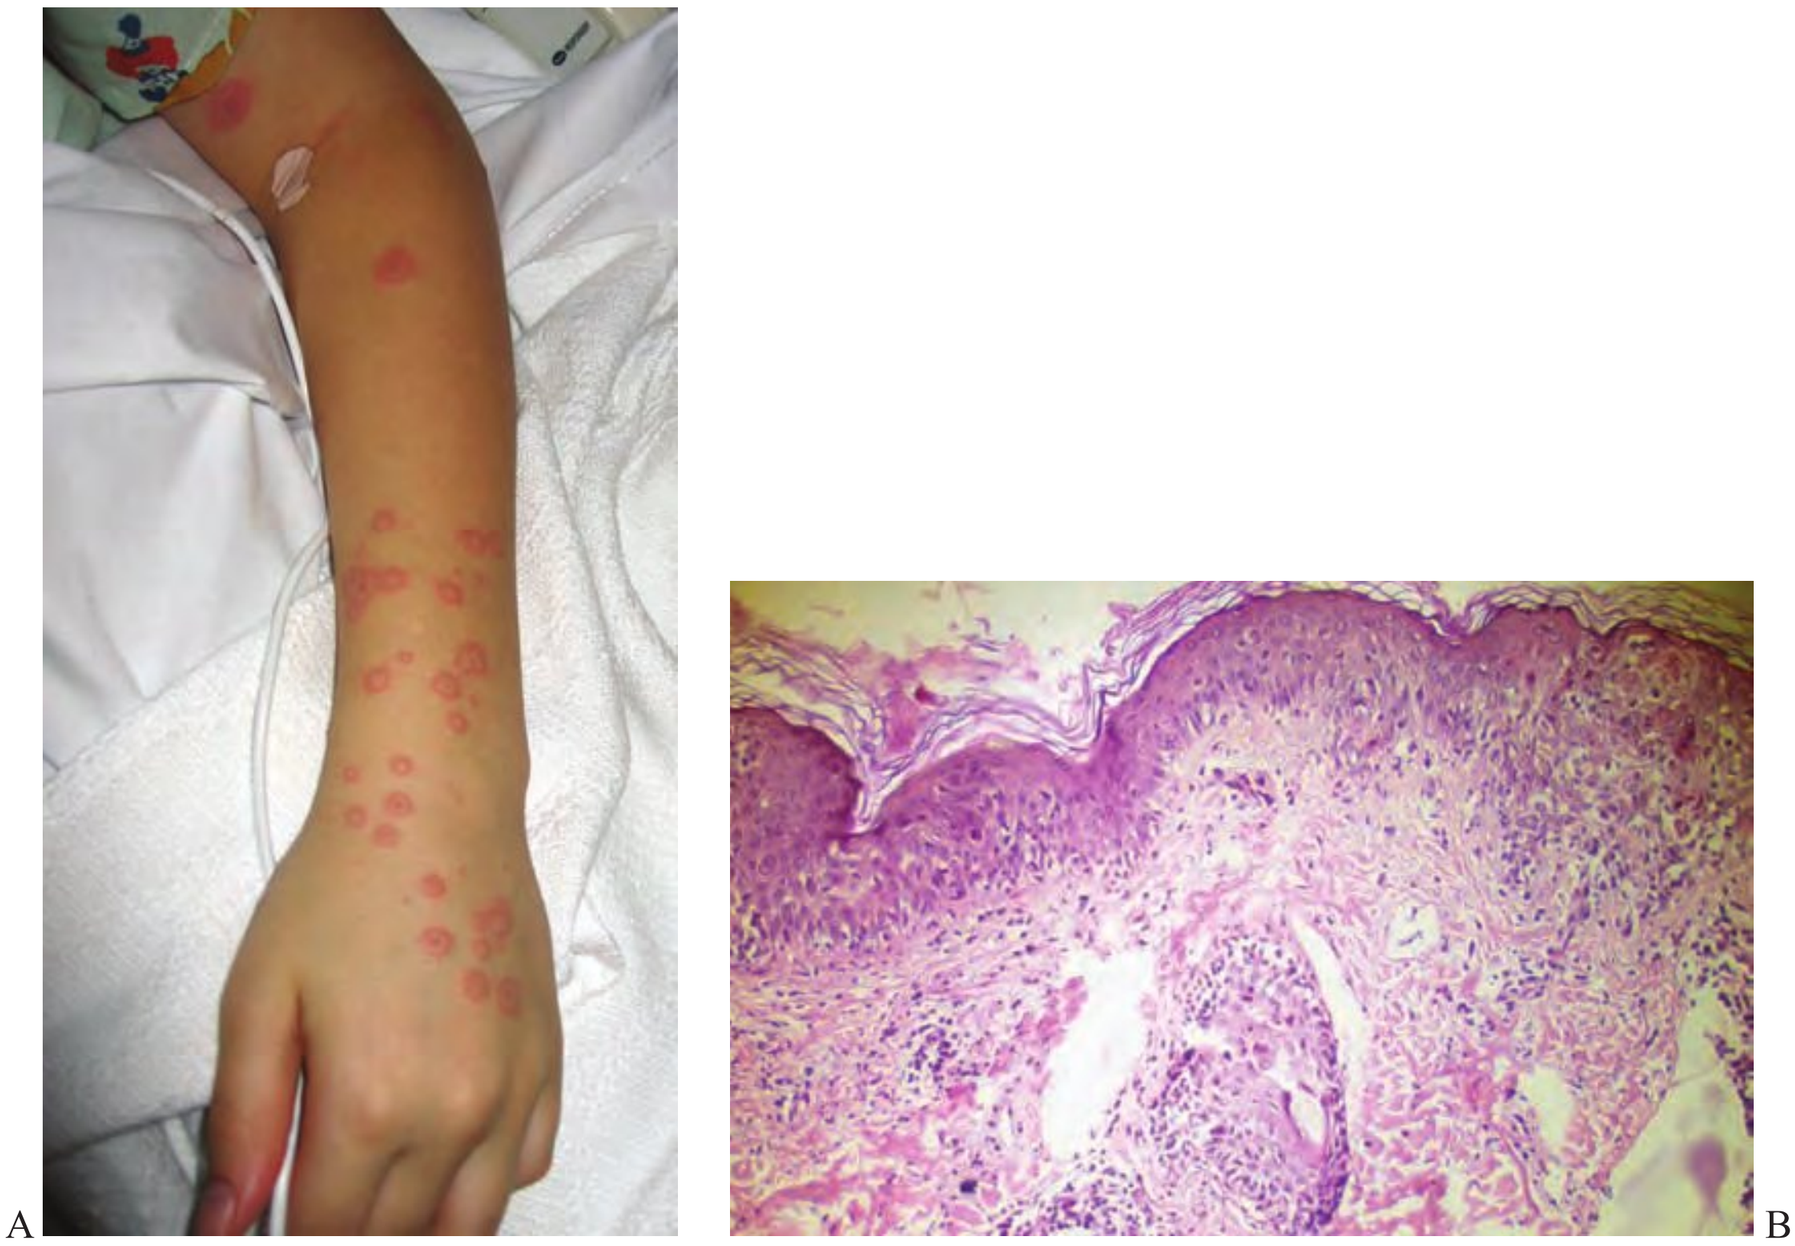
Ultrastructural Study. The edge of the pustules shows cytolytic changes in the upper epidermis, especially in the granular layer. Dissolution of the plasma membrane and of the cytoplasm of granular cells causes the formation of a subcorneal split. The transepidermal migration of neutrophils and their subcorneal accumulation are regarded as events secondary to the cellular destruction in the stratum granulosum seen in one study.

Differential Diagnosis. The differential diagnosis includes other entities that show subcorneal pustules. Histologic differentiation from impetigo may be impossible unless bacteria can be demonstrated with a Gram stain. Cultures may be necessary for diagnosis. Histologic differentiation from pemphigus foliaceus or pemphigus erythematosus may also be difficult, as both diseases show subcorneal blisters with acantholysis, although the acantholysis tends to be more pronounced in pemphigus than in SPD. Clinical information, IF testing, and a therapeutic trial of sulfones may be necessary for definitive diagnosis.

Although subcorneal pustules occur in both pustular psoriasis and SPD, spongiform pustules occur only in pustular psoriasis. Some authors regard SPD as a variant of pustular psoriasis, but with the association to IgA gammopathies and squamous intercellular substance deposits of IgA, this view is discredited.

Erythema Multiforme/Stevens-Johnson Syndrome/Toxic Epidermal Necrolysis

There has been controversy in the literature regarding the clinical definitions of EM, SJS, and TEN and whether they are distinct entities or represent a spectrum of one disease process. While EM major and SJS were once considered synonymous, many now consider EM and SJS to be separate diseases (138). SJS and TEN are widely but not universally regarded as a continuum.



EM, as classically described by von Hebra, is a benign, self-limited condition with symmetric, fixed lesions, some of which evolve into typical targets composed of three concentric rings. The lesions are located primarily on the extremities (Fig. 9-26A). Bullous EM is a more severe form, which was defined by an international consensus group in 1993 as having typical targets or raised atypical targets with <10% of body surface area detachment (139).

Patients with SJS often present with fever and malaise and develop a cutaneous eruption consisting of "flat atypical targets," or erythematous or purpuric macules, many with central epidermal necrosis or blister formation. The lesions usually start on the trunk and spread centrifugally. Again, epidermal detachment is <10% of the body surface area (138).

TEN, also referred to as *Lyell's syndrome*, is characterized by widespread, full-thickness epidermal necrosis involving >30% of the body surface area (Fig. 9-27A). These patients also have systemic symptoms and may initially present with diffuse erythema and skin tenderness, followed by the development of large, flaccid bullae and detachment of the epidermis in sheets (140). SJS/TEN overlap is used to refer to patients with epidermal detachment between 10% and 30% of the body surface area (138). TEN has a high mortality rate because of fluid loss and sepsis.

Mucosal involvement (oral, ocular, and/or genital) is common in all of these severe acute bullous diseases and is a serious cause of morbidity. *Mycoplasma pneumoniae* infection has been associated with severe mucositis without skin lesions, which has been referred to by some as *atypical SJS* (141,142), while others argue that the classification of SJS requires cutaneous involvement (143).

EM, which may be recurrent, is most commonly associated with herpes simplex infection (144,145). Other infections, (Epstein-Barr virus [146], cytomegalovirus [147], and Lyme disease [148]), and rarely drugs, have been implicated in EM. SJS is most commonly drug-induced (138), except in

A B

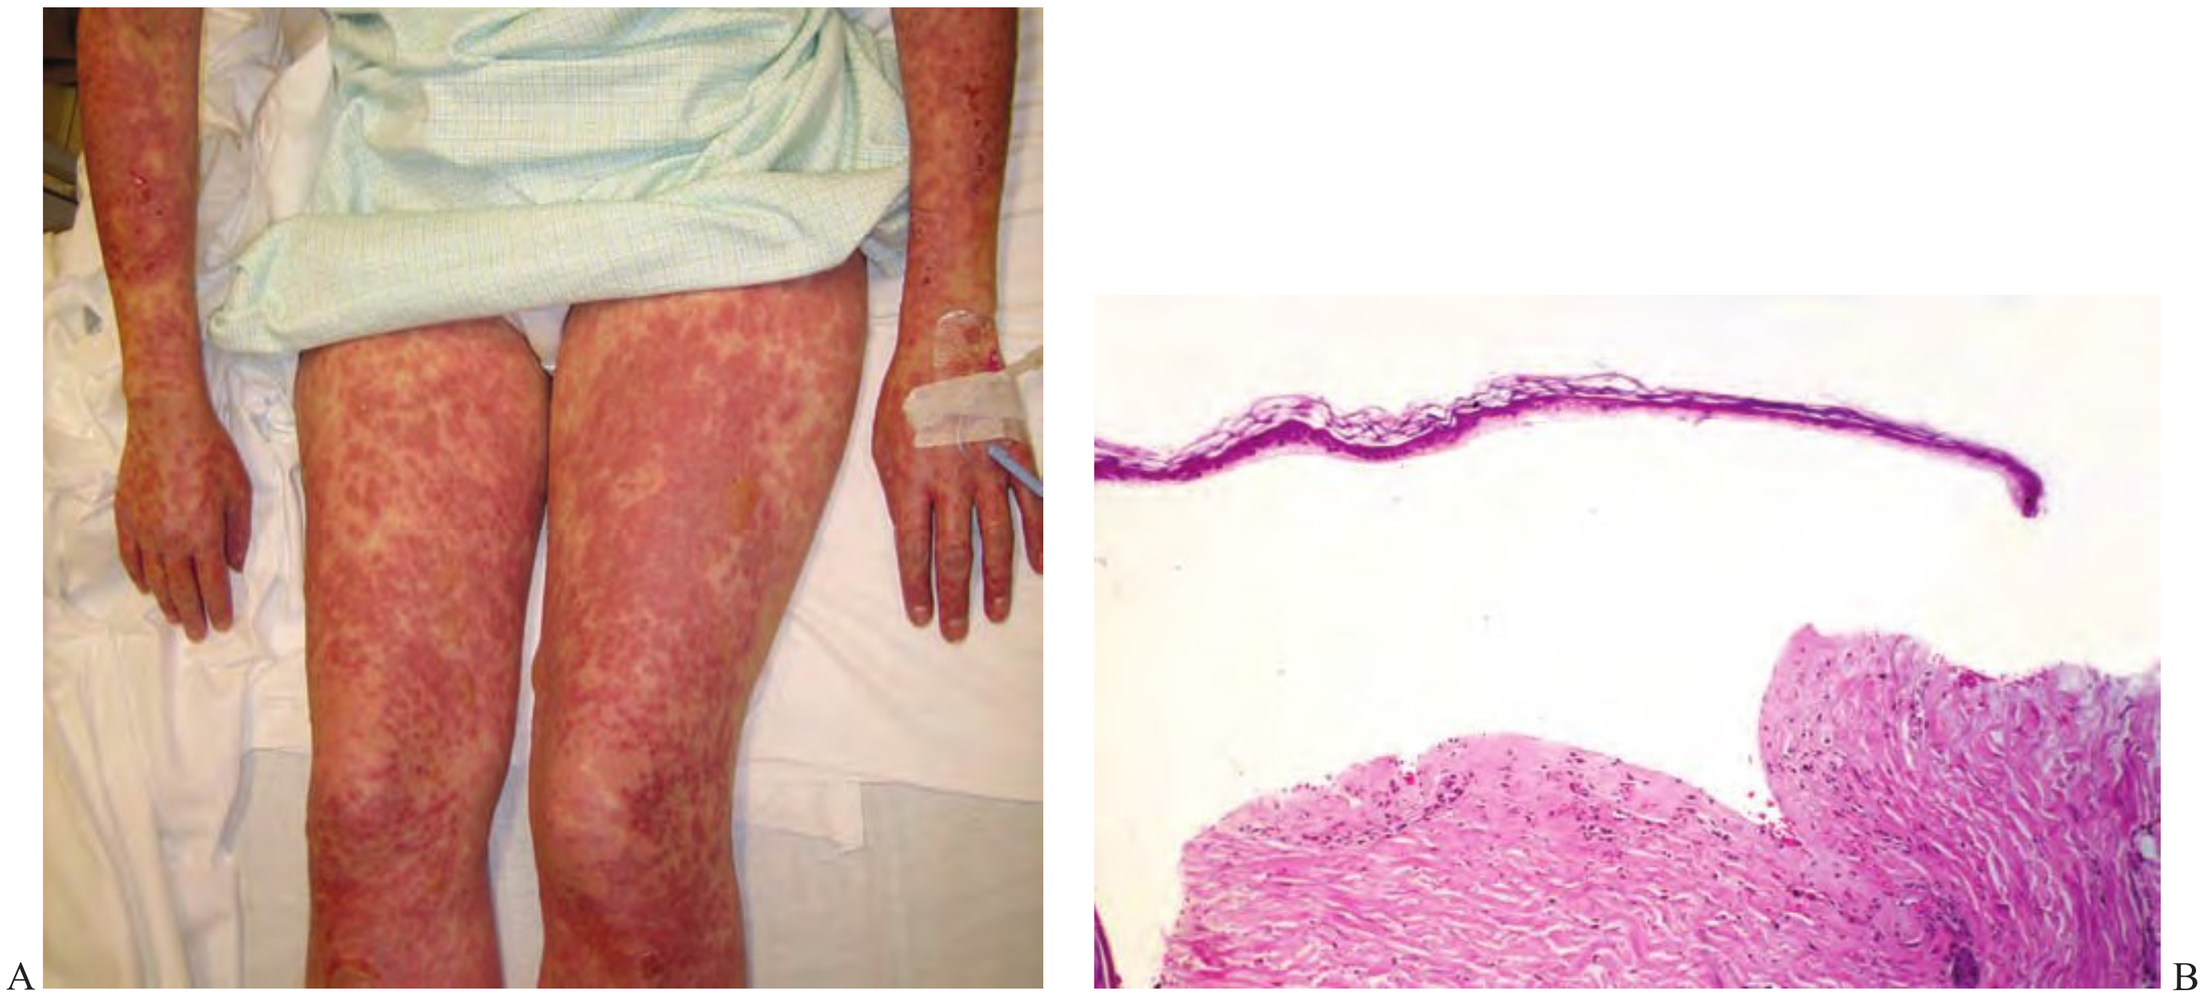


FIGURE 9-26. Erythema multiforme. A: Target lesions on the arm of a young boy. (Courtesy of Peter Lio, MD.) B: There is a superficial perivascular and interface dermatitis with apoptotic keratinocytes. Lymphocytes are "tagging" along the dermal–epidermal junction with apoptotic keratinocytes, which have eosinophilic cytoplasm and pyknotic nucleus. The stratum corneum is normal.

children where the majority of cases have been associated with infection, notably *M. pneumoniae* (149). Immunizations are another etiology to consider. TEN is almost always attributed to drugs, and only rare cases have been thought to have an infectious etiology (150). The most commonly implicated drugs include NSAIDs, sulfonamides and other antibiotics, anticonvulsants, antiretrovirals, and allopurinol (151,152).

Histopathology. EM is considered the prototype of the vacuolar form of interface dermatitis (153). The early changes include vacuolization of the basal cell layer; tagging of lymphocytes along the dermal–epidermal junction; and a sparse, superficial, perivascular lymphoid infiltrate (Fig. 9-26B). Necrosis of individual keratinocytes in the basal unit occurs, which is the hallmark of EM. Because of its acute nature, there is an orthokeratotic stratum corneum. Mild spongiosis, papillary dermal edema, and extravasation of red blood cells are seen. As the lesion becomes more developed, there is a moderate lichenoid infiltrate of lymphohistiocytes at the dermal–epidermal junction with exocytosis. More apoptotic keratinocytes within and above the basal epidermal layer are present. The intensity of epidermal necrosis varies from vacuolated individual keratinocytes surrounded by lymphocytes (satellite cell necrosis) at the basal unit to confluent necrosis in association with intraepidermal and subepidermal vesicles. The dermal infiltrate comprises lymphocytes and histiocytes. Eosinophils may also be present. Although one study has noted a significant number of eosinophils in drug-induced EM, this has not been noted by others. In the authors' estimation, a generous number of eosinophils exclude EM. One study has found that an acrosyringium concentration of apoptotic keratinocytes in EM is a clue to a drug etiology (154).

In early lesions of SJS/TEN, apoptotic keratinocytes are observed scattered in the basal layer of the epidermis. In established lesions, there are numerous necrotic keratinocytes, even full-thickness epidermal necrosis, and a subepidermal bulla. The dermal inflammatory infiltrate is sparser in TEN than in EM (Fig.9-27B). Extravasated erythrocytes are commonly found within the blister cavity. Melanophages within the papillary dermis occur in late lesions. Eccrine epithelium shows a variety of changes from basal cell apoptosis to necrosis of the duct.

In general, EM shows less epidermal necrosis, more dermal inflammation, and exocytosis, whereas SJS and TEN reveal more epidermal necrosis, less dermal inflammation, and exocytosis. However, due to the overlapping histologic features among EM, SJS, and TEN, histologic examination—while important for recognizing the spectrum of disorders—is not reliable for classifying the disease. Correlation with clinical presentation is essential.

A B

FIGURE 9-27. Toxic epidermal necrolysis. A: Diffuse coalescing erythematous macules and patches with dusky centers and multiple bullae in a patient recently started on several new medications. B: There is a cell-poor subepidermal blister and epidermal necrosis. The dermal inflammatory infiltrate is sparse.

IF Testing. In many patients with EM, deposits of IgM and C3 are found in the walls of the superficial dermal vessels. Granular deposits of C3, IgM, and fibrinogen may also be present along the dermal–epidermal junction. Nonspecific deposition of immune reactants in apoptotic or necrotic keratinocytes may be observed in other disorders with apoptosis, lymphocyte satellite necrosis, and epidermal necrosis.

Pathogenesis. EM appears to result from a cell-mediated immune reaction. In the case of herpes simplex, polymerase chain reaction and *in situ* hybridization have detected herpes simplex virus (HSV) DNA within lesions of EM (155). The virus remains in the skin for up to 3 months after the lesions have healed (156). Some authors hypothesize that disease development begins with deposition and expression of HSV genes, leading to recruitment of HSV-specific $CD4^+$ T cells with production of INF-γ. This step initiates an inflammatory cascade that includes increased infiltration of leukocytes, monocytes, NK cells, and T cells (157). The infiltrate consists largely of $CD4^+$ (helper) lymphocytes in the dermis and $CD8^+$ (cytotoxic) cells in the epidermis. The mononuclear cells that are associated with necrotic keratinocytes in the process referred to as *satellite cell necrosis* are largely $CD8^+$ cytotoxic lymphocytes similar to those occurring in GVHD. The pathogenesis of TEN remains unclear but is thought to be mediated by cytotoxic T lymphocytes. As is EM, mainly $CD8^+$ cells are found in the epidermis and blister fluid, while $CD4^+$ cells are in the dermis. Macrophages are also thought to play an important role, along with cytokines such as tumor necrosis factor-α (TNF-α). *In vitro* studies suggests Fas-FasL and other death receptors, as well as perforin/granzyme trigger apoptosis in TEN (158,159).

Ultrastructural Study. The basal lamina is located on the floor or the roof of the blister. The basal cells show marked intracytoplasmic damage with a loss of organelles. Neutrophils and macrophages, which are rich in lysosomes, are present in the lower epidermis phagocytizing the damaged keratinocytes. In the mid-epidermis, large, electron-dense, dyskeratotic bodies correspond to the cells with eosinophilic necrosis seen by light microscopy. The damaged epidermal cells often contain few or no organelles. Large granular lymphocytes have been identified within the epidermis in close contact with keratinocytes, a finding that supports cell-mediated cytotoxic injury to keratinocytes (160).

Differential Diagnosis. Necrotic keratinocytes are also a characteristic feature in drug eruption, especially fixed drug eruptions, pityriasis lichenoides, connective tissue disease, subacute radiation dermatitis, phototoxic dermatitis, acute GVHD, and viral exanthems. Clinicopathologic correlation will help in their distinction. In patients with widespread desquamation or detachment, the clinical differential diagnosis includes TEN and SSSS. Whereas the former involves subepidermal separation, the latter results from separation of the epidermis subcorneally or within the granular layer. Frozen section evaluation of the blister roof is a rapid diagnostic tool to determine the level of the split.

Graft-Versus-Host Disease

GVHD occurs in situations in which donor immunocompetent T cells transferred into allogenic hosts are incapable of rejecting them. The sources of the T cells include primarily peripheral blood stem cell and bone marrow transplants and,

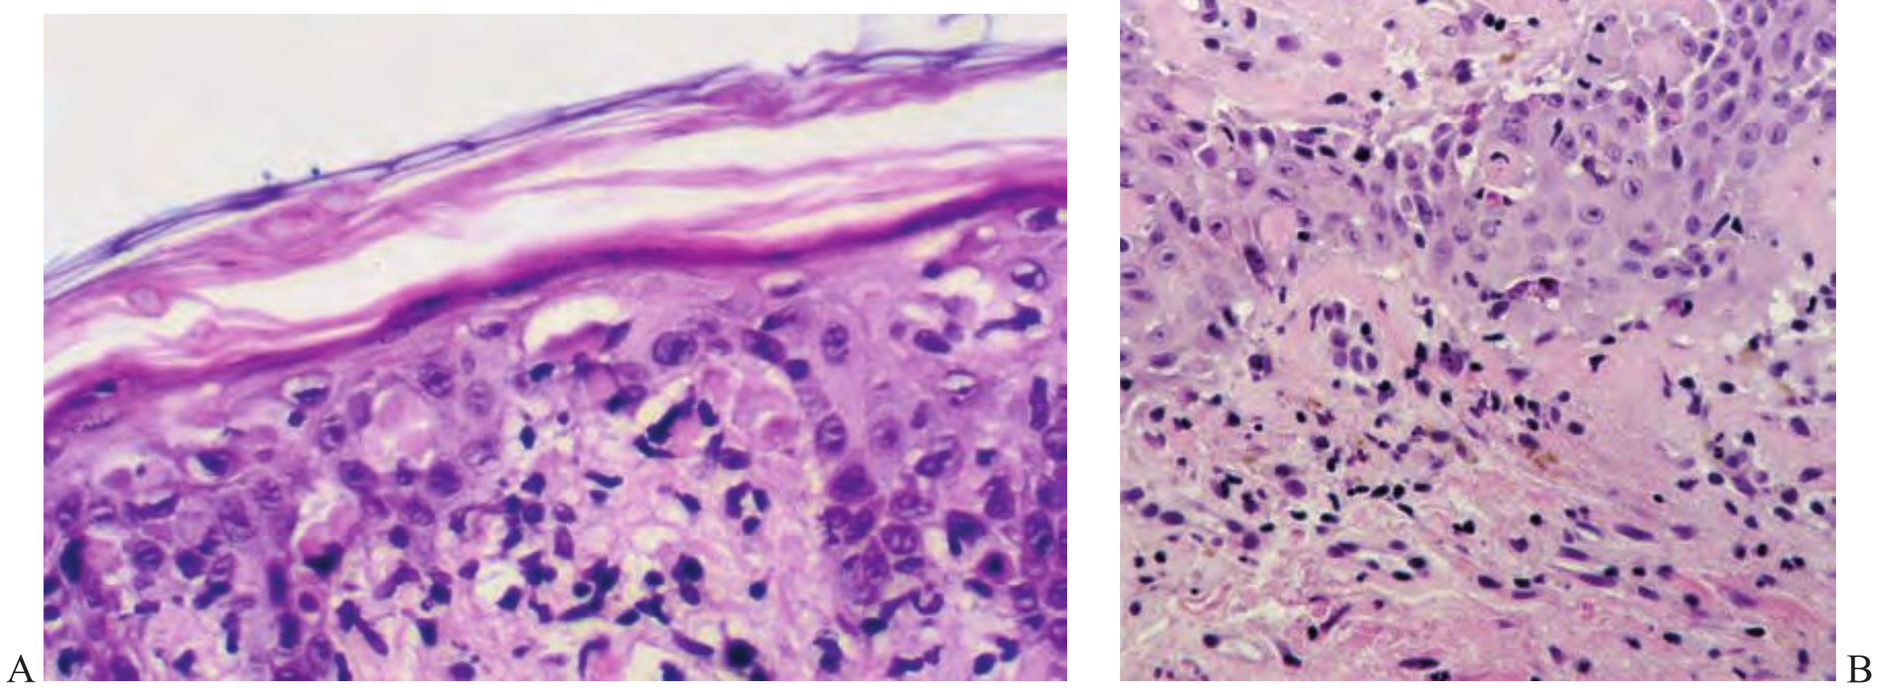
infrequently, unirradiated blood products (161), solid organ transplants (162), and maternal–fetal lymphocyte engraftment. Graft-versus-host–like reaction has been reported in patients with a thymoma or lymphoma (163,164).

The disease can be divided into an acute and a chronic phase. Acute GVHD typically occurs between 7 and 21 days after transplantation but may be seen as late as 3 months; chronic GVHD arises after a mean of 4 months but may occur as soon as 40 days posttransplantation. The two phases were originally defined on the basis of time of presentation (165,166). However, the use of donor lymphocytes and the withdrawal of immunosuppression in relapsed patients have obscured these time-based divisions. In addition, many patients have both phases, either merging with one another or separated by an asymptomatic period. The frequency of acute GVHD depends on the disparity of HLA antigens (167). The risk of chronic GVHD is 11 times greater if the patients had prior acute GVHD.

In the *acute phase*, the classic triad includes skin lesions, hepatic dysfunction, and diarrhea. The clinical severity is judged on the extent of the cutaneous eruption, total bilirubin, and stool volume. The eruption is characterized by extensive macular erythema, a morbilliform eruption, purpuric lesions, violaceous scaly papules and plaques, bullae, or in rare cases a TEN-like epidermal detachment. There is a predilection for the cheeks, ears, neck, upper chest, and palms and soles. Occasionally, follicular papules are seen simulating a folliculitis. Oral lesions may be present. About 30% of patients die from complications of acute GVHD. The overall clinical stage, during the first 40 days after transplantation, is useful in identifying patients with progressive and fatal disease (165). Cutaneous GVHD may be due to a synergistic effect from local irradiation (168).

In the *chronic phase*, an early lichenoid stage and a late sclerodermoid stage can be distinguished. Each stage can occur without the other. Although usually generalized, the involvement is in rare instances localized to a few areas. In the lichenoid stage, both the cutaneous and oral lesions may be clinically similar to those in lichen planus. In addition, the skin may show extensive erythema and irregular hyperpigmentation. A poikiloderma phase may precede the eventual sclerodermoid stage (Fig. 9-28). Other late manifestations include a lupus erythematosus–like eruption, cicatricial alopecia, chronic ulcerations, pyogenic granuloma, and angiomatous lesions (169).

FIGURE 9-28. Chronic graft-versus-host disease. Sclerodermatous skin with dyspigmentation. (Courtesy of Kenneth Tsai, MD, PhD.)



Histopathology. The early changes in the acute phase consist of focal basal vacuolation and sparse superficial perivascular lymphocytic infiltrate with exocytosis of individual cells into the epidermis and follicular epithelium. The number of lymphocytes correlates positively with the probability of developing more severe acute GVHD (170). In association with the perivascular infiltrate, there is marked endothelial cell swelling and narrowing of the vascular lumen. Established lesions show more pronounced vacuolation, focal spongiosis, lymphocytic infiltration, and dyskeratosis at all levels of epidermis. The *acute phase* has been divided into four histopathologic grades (171). In grade 1 disease, there is focal or diffuse vacuolization of the basal cell layer. In grade 2 lesions, spongiosis and dyskeratotic keratinocytes are identified (Fig. 9-29A), with some accompanied by two or more epidermal lymphocytes, a phenomenon known as *satellite cell necrosis*. The necrotic keratinocytes contain a pyknotic nucleus and eosinophilic cytoplasm. Grade 3 lesions are characterized by subepidermal cleft formation. In grade 4, there is complete loss of the epidermis. In cases with follicular papules, the involved follicles show degenerate changes in the cells of the follicular epithelium similar to those in the epidermis. In rare cases, basal vacuolization and dyskeratosis of the follicular epithelium may be the only changes (172).

In the *chronic phase*, the early lichenoid stage may still show evidence of satellite cell necrosis within the epidermis (Fig. 9-29B). The overall histologic picture greatly resembles that of lichen planus with hyperkeratosis, hypergranulosis, acanthosis, apoptotic keratinocytes, and a mononuclear cell infiltrate immediately below the epidermis with pigmentary incontinence. As in lichen planus, apoptotic keratinocytes may "drop" into the upper dermis. There may be areas of separation of the basal cell layer from the dermal papillae resembling the clefts seen in severe lichen planus. A rare manifestation is so-called columnar epidermal necrosis, characterized by small foci of total epidermal necrosis accompanied by a lichenoid tissue reaction (173).

In the late sclerodermoid phase, the epidermis is atrophic, with the keratinocytes being small, flattened, and hyperpigmented. Basal layer vacuolization, inflammation, and colloid body formation are rare or absent. The dermis is thickened, with sclerosis extending into the subcutaneous tissue resulting in septal hyalinization. The adnexal structures are destroyed (174). Subepidermal bullae were present in one reported case.

IF Testing. Epithelial basement membrane zone granular IgM and complement deposition is present in 39% of patients with the acute form and in 86% of patients with the chronic form of GVHD. In addition, IgM and C3 have been found in the walls of dermal vessels.

Pathogenesis. Acute and chronic forms of the disease have a different pathogenesis. In acute GVHD, it is believed that preparative regimen before the infusion of the graft causes extensive tissue damage, which releases inflammatory cytokines and exposes recipient major histocompatibility complex (MHC) antigens. Recognition of the host antigen by donor T cells and activation and proliferation of them is crucial in the initial phase.

A B

FIGURE 9-29. Graft-versus-host disease. A: An acute lesion with interface changes and apoptosis of keratinocytes. B: There is lichenoid dermatitis with basal vasculopathy and apoptosis. There is fibrosis of the papillary dermis.

The greater the disparity between donor and recipient MHC, the greater the T-cell response. In identical pairs, the donor T cells recognize minor antigen difference. Infiltration of both $CD4^+$ and $CD8^+$ T cells or with either one of them predominating has been reported (171,175–177). γδ T cells represent a minority of infiltrates (178,179). B cells are not found.

The inflammatory cytokines (ILs, GM-CSF, TNF-α IFN-γ) produced by activated T cells and by tissue damage during the preparative regimen also activate mononuclear phagocytes and NK cells (180). Both Fas/FasL-dependent apoptosis and perforin/granzyme-dependent killing are important in GVHD-induced damage (181). In skin, young rete ridge keratinocytes, follicular stem cells (182), and Langerhans cells are preferred targets. However, the exact mechanisms by which the skin, liver, and gastrointestinal tract are targeted are not clear.

Less is understood about the pathophysiology of chronic GVHD. The role of donor T cells against the recipient's tissue has been demonstrated. In addition, autoreactivity has also been suggested. Most immunohistochemical studies have shown that $CD8^+$ T cells predominate. Tumor necrosis factor-α and IL-1α are constantly produced by keratinocytes in the lesional skin (183).

Ultrastructural Study. The necrotic keratinocytic cytoplasm is filled with numerous aggregated tonofilaments. Granule-producing cytotoxic lymphocytes, NK-like cells, have been identified in direct cytolytic attack on epithelial cells undergoing apoptosis.

Differential Diagnosis. The acute phase of GVHD is similar to EM, with scattered necrotic keratinocytes and the formation of subepidermal clefts through hydropic degeneration of basal cells. In severe cases, the fulminant lesions resemble TEN. These patients are also at increased risk for drug eruptions, chemotherapy-induced eruptions, and radiation dermatitis, all of which may be indistinguishable from acute GVHD. If there is follicular dyskeratosis, the diagnosis is much more likely to be acute GVHD. The presence of eosinophils is not necessarily in favor of drug reaction, as eosinophils are occasionally observed in GVHD. Epidermal changes identical to acute GVHD may be seen in bone marrow transplant patients without cutaneous lesions.

The *eruption of lymphocyte recovery* occurs predominantly in patients after receiving cytoreductive therapy (without bone marrow transplant) for acute myelogenous leukemia. The eruption is typically morbilliform and develops between 6 and 21 days of chemotherapy, correlating with the earliest recovery of lymphocytes to the circulation. In contrast to patients with GVHD, these patients do not develop diarrhea or liver abnormalities. Resolution occurs over several days. Histopathologically, a superficial perivascular mononuclear cell infiltrate, basal vacuolization, spongiosis, and rare dyskeratotic keratinocytes are present. The changes may be indistinguishable from those of early allogeneic or autologous GVHD, and clinical information is essential (184). The systemic administration of recombinant cytokines prior to marrow recovery leads to a relatively heavy lymphocytic infiltrate with nuclear pleomorphism and hyperchromasia (185).

Distinguishing between the lichenoid lesions of GVHD and lichen planus is often impossible. However, late sclerotic lesions can be differentiated from scleroderma by the marked atrophy of the epidermis. Active synthesis of collagen takes place largely in the upper third of the dermis; in scleroderma, collagen is synthesized mainly in the lower dermis and in the subcutaneous tissue.

Diabetic Bullae

Diabetic bullae (bullosis diabeticorum) is an uncommon condition associated with diabetes mellitus. It usually presents as sudden and spontaneous blisters on the distal extremities. The most frequent locations are the feet, lower legs, hands, forearms, and rarely the trunk. The lesions arise on a noninflamed base, are tense, and vary in diameter from 0.5 cm to several centimeters. A mild burning sensation may be present. The blisters heal in several weeks, usually without scarring.

The cause of diabetic bullae is unknown. The reported histopathologic features have been variable and include subcorneal, intraepidermal, and subepidermal bullae. However, further investigation reveals that the level of cleavage is subepidermal and that the intraepidermal blisters represent older lesions undergoing reepithelialization of the blister base. The bullae contain fibrin and a few inflammatory cells. There may be diabetic microangiopathy with thickening of the walls of small dermal vessels. There is usually only a sparse perivascular lymphotic infiltrate.

DIF is negative for specific reactants at the dermal–epidermal junction. But nonspecific findings such as vascular deposition of fibrin and C3 along with glassy thick wall staining for IgG that correlate with the underlying diabetic microangiopathy may be present.

Coma Blisters

Classically described in patients with barbiturate overdose, coma blisters have been described in comatose patients in the setting of overdose of other medications, infections, metabolic disturbances, and neurologic disease. Tense bullae develop on normal-appearing skin, most commonly at sites of pressure.

Histopathology. Blisters are usually subepidermal, sometimes intraepidermal, with a variable degree of epidermal necrosis and a sparse inflammatory cell infiltrate (186,187). Eccrine gland necrosis is a characteristic finding (188).

Pathogenesis. The exact pathogenesis of these blisters is unknown. Pressure, friction, and local hypoxia have all been implicated as causative factors. In cases involving drug overdose, a direct toxic effect has been postulated to explain the eccrine gland necrosis and blister formation.

Edema Blisters

Tense bullae can occur in the setting of acute edema, most commonly on the lower extremities of an elderly patient with an acute exacerbation of chronic edema. Bullae can range in sizes of up to several centimeters and are usually filled with clear or serous fluid. They resolve with marked treatment of the underlying swelling (189).

Histopathology. There is marked epidermal spongiosis. The dermis is edematous with dilated blood vessels and a mild lymphohistiocytic infiltrate. In some cases, subepidermal blisters can be found. DIF and IIF studies are negative.

Transient Acantholytic Dermatosis (Grover's Disease)

First described in 1970, transient acantholytic dermatosis is characterized by pruritic, discrete papules and papulovesicles on the chest, back, and thighs. In rare instances, vesicles and even bullae are seen. Most patients are middle-aged or elderly men. Although the disorder is transient in the majority of patients, lasting from 2 weeks to 3 months, it can persist for several years. The condition has been reported coexisting with other dermatosis, such as asteatotic eczema, allergic contact dermatitis, atopic eczema, psoriasis, and pemphigus foliaceus. There have been reports of patients with transient acantholytic dermatosis and malignancy, most commonly lymphoproliferative and genitourinary neoplasms (190–192).

Histopathology. Focal acantholysis and dyskeratosis (focal acantholytic dyskeratosis) are present. Because these foci are small, they are sometimes found only when serial sections are obtained. The acantholysis may occur in four histologic patterns, resembling Darier's disease (Fig. 9-30), Hailey-Hailey disease, pemphigus vulgaris, or spongiotic dermatitis. Two or more of these patterns may be found in the same specimen. There is usually a superficial dermal infiltrate of lymphocytes and sometimes eosinophils.

IF Testing. In general, IF results are often said to be negative. However, nonspecific granular basement membrane zone staining of C3 alone or in combination with IgM may be found.

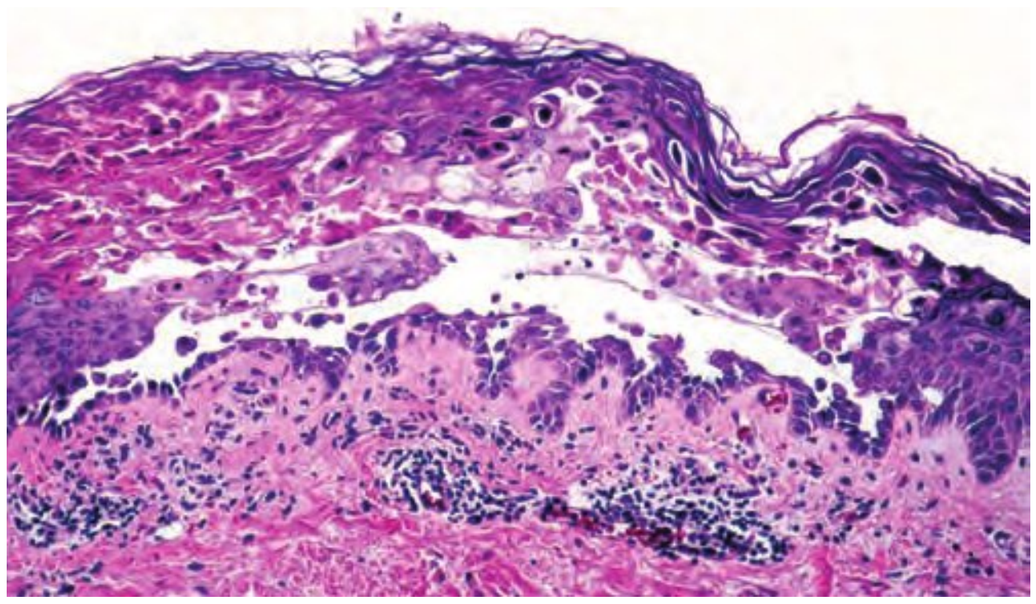


FIGURE 9-30. Transient acantholytic dermatosis. There is hypergranulosis with acantholytic dyskeratotic keratinocytes. The clefts extend to a suprabasal location.

Pathogenesis. Despite the histologic similarity to Darier's disease, Grover's disease does not share an abnormality in the ATP2A2 gene (193), which encodes a keratinocyte Ca^{2+} pump. Mutation of ATP2A2 is responsible for Darier's disease. Although the pathogenesis of Grover's disease remains unknown, there appears to be a relationship to excessive sweating, fever, and bed confinement. Some authors have hypothesized that heat or sweat urea that leaks from the intraepidermal portion of the sweat duct into the surrounding epidermis causes acantholysis. Others dispute this theory and have found the sweat duct to be intact. Finally, IL-4 may be responsible for acantholysis, either by induction of plasminogen activator or by stimulation of antibody production (194). The expression of syndecan-1, a proteoglycan important for keratinocytes intercellular adhesion, is markedly decreased in Grover's disease. The same phenomenon also occurs in other acantholytic conditions such as pemphigus and herpes simplex infection, suggestive of decreased intercellular adhesion and characteristic of these lesions (195).

Ultrastructural Study. In the pemphigus-like zones, there is intradesmosomal separation, fewer desmosomes, and perinuclear aggregation of tonofilament bundles. In the Darier type, features similar to those of Darier's disease are present.

Differential Diagnosis. The features that help to differentiate transient acantholytic dermatosis from the four diseases that it resembles are the focal nature of the histologic changes and the mixture of patterns. The presence of eosinophils in the superficial dermal infiltrate of Grover's disease serves as a distinguishing feature from Darier's disease, in which they are usually absent. It may be important to have clinical information for a definitive diagnosis. IF studies are rarely necessary to exclude pemphigus.

DERMATOPATHIES PRODUCED BY EXTERNAL ENERGY

Friction Blisters

Friction blisters develop mainly on the soles as a result of prolonged walking and on the palms and the palmar surfaces of the fingers as a result of repetitive actions required in certain occupations or sports. They may occur also as self-inflicted artifacts.

Histopathology. In both naturally occurring and experimentally produced friction blisters, intraepidermal cleavage develops as a result of cytolysis and necrosis of keratinocytes in the upper stratum malpighii (Fig. 9-31). The roof of the blister is composed of the stratum corneum, stratum granulosum, and amorphous cellular debris. Most of the degenerated keratinocytes are pale and are located at the floor of the cleft. The deeper part of the epidermis consists of undamaged cells. In severe cases, the cytolysis may extend through the basal layer leading to hemorrhagic blisters.

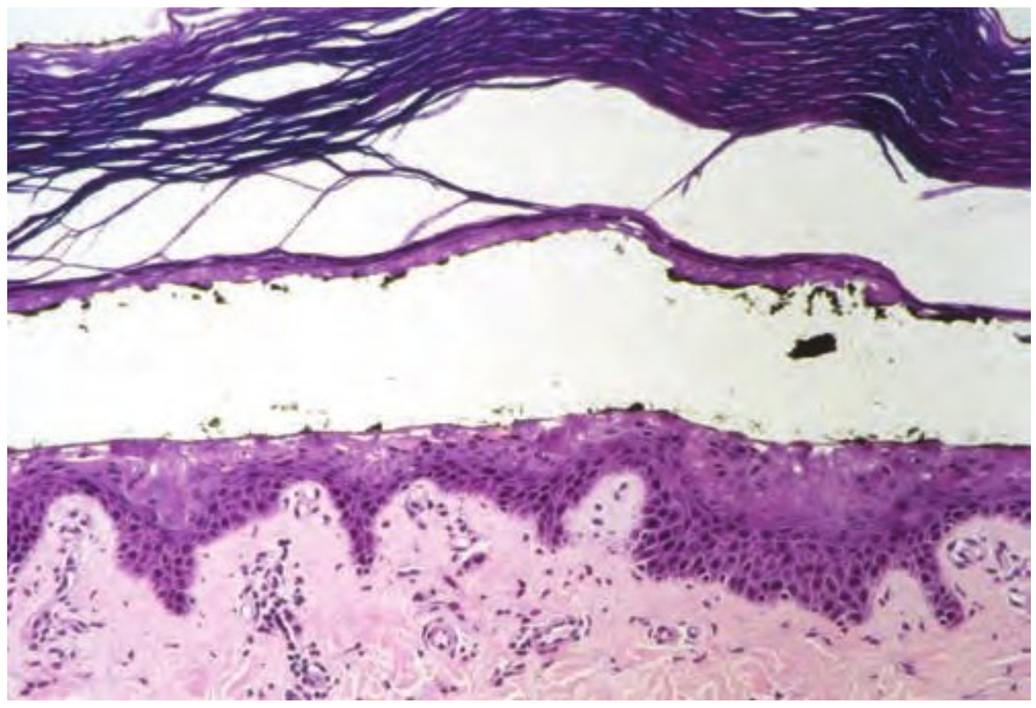

FIGURE 9-31. Friction blister. The intraepidermal blister splits at the level just beneath the stratum granulosum. A thin layer of amorphous cellular debris is present on both sides of the blister.

Pathogenesis. Shearing forces within the epidermis cause friction blisters. They form only where the epidermis is thick and firmly attached to the underlying tissue.

Ultrastructural Study. Electron microscopy reveals clumped tonofilaments, intracellular edema, small vacuoles at the cell periphery, and areas devoid of organelles.

Electric Burns

It is important that dermatopathologists be familiar with the cutaneous effects of electric current as they are used during electrodesiccation and electrocautery.

Histopathology. Electrodesiccation and electrocautery cause a separation of the epidermis from the dermis. A diagnostic histologic feature is the fringe of elongated, degenerated cytoplasmic processes that protrudes from the lower end of the detached basal cells into the subepidermal space (Fig. 9-32). The nuclei of the basal cells appear to be stretched vertically. In addition, the upper dermis is homogenized because of coagulation necrosis.

Thermal Burns

In the evaluation of thermal burns, the depth of penetration is of great importance because first- and second-degree burns heal readily, whereas third-degree burns require grafting.

Histopathology. *First-degree burns* are those in which the lower epidermis, particularly the basal cell layer, remains viable and only the upper epidermis is affected by heat coagulation. In the affected areas, the nuclei may appear pyknotic and contain perinuclear halos. In a more advanced stage, the nuclei stain faintly eosinophilic or not at all, like "architectural ghosts."

Second-degree burns often show subepidermal blisters and are characterized by partial-thickness dermal necrosis. The lower portion of the cutaneous appendages remains intact, allowing re-epithelization to occur. Superficial second-degree

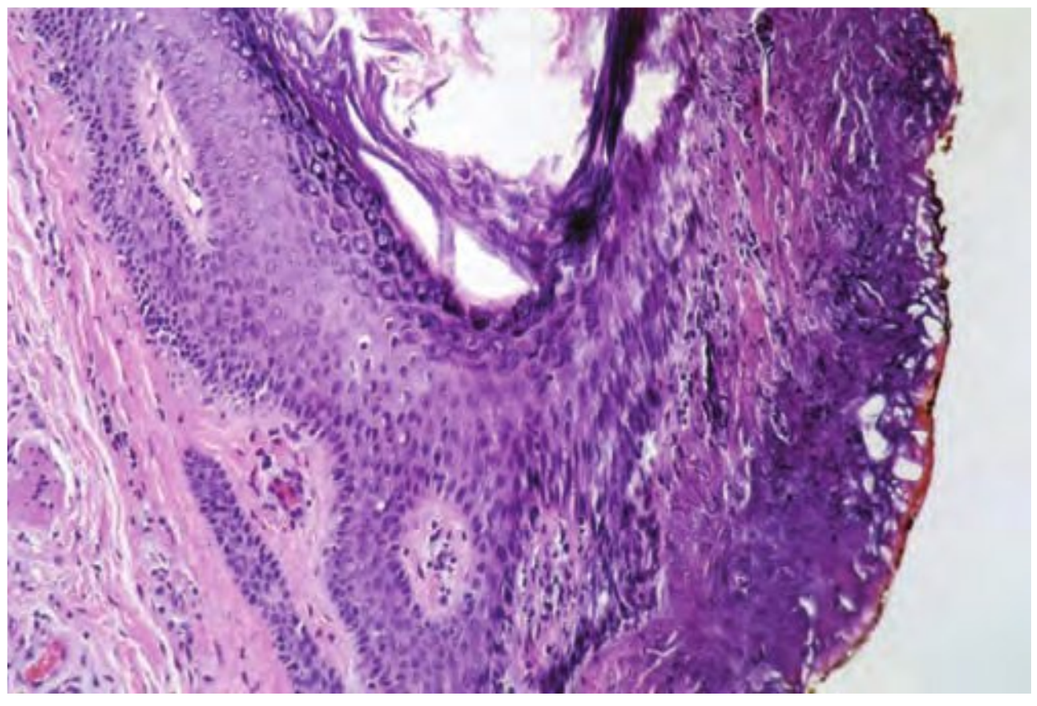

FIGURE 9-32. Electrodesiccation. The keratinocytes are elongated with nuclear pyknosis and cytoplasmic eosinophilia. The collagen is more basophilic compared with that of the unaffected tissue on the left.

burns are associated with necrosis of the surface epidermis and of only a small amount of superficial dermal collagen; in deep second-degree burns, much of the dermal collagen and the cutaneous appendages is injured. In partial-thickness dermal necrosis, the depth of epithelial damage in the cutaneous appendages is a good indicator of the depth of irreversible damage to the collagen. The border between heat-coagulated and normal epithelium is sharp. At a later stage, an inflammatory reaction develops at the junction of the viable and nonviable tissue.

Third-degree burns show full-thickness dermal necrosis with destruction of all cutaneous appendages. The coagulation necrosis may extend to the subcutaneous tissue and to the underlying muscle.

Suction Blisters and Purpura

Negative pressure applied over a circumscribed area may form a subepidermal blister that arises in the lamina lucida. A second reaction, noninflammatory purpura, may also result. The changes may be secondary to overcoming the adhesive forces in the lamina lucida and in vessels (196).

Connective Tissue Diseases

LUPUS ERYTHEMATOSUS

Lupus erythematosus is a disease that affects multiple organ systems. Its clinical manifestations range from an isolated cutaneous eruption to fatal systemic illness. Cutaneous forms of lupus erythematosus occur two to three times more commonly than systemic lupus, and they, therefore, represent an important subcategory of the disease. Cutaneous disease is the presenting symptom in 23% to 28% of cases of systemic lupus, and 72% to 82% of systemic lupus patients manifest at least one cutaneous symptom through the course of their illness (1).

A combination of clinical and laboratory data was used to devise the Criteria for the Classification of Systemic Lupus Erythematosus set forth by the American Rheumatism Association (ARA) in 1972. Since then, there have been slight modifications of laboratory criteria to reflect the changes in diagnostic technology (2,3). Recent evaluation of the 1982 revised criteria noted that the current criteria do not include subacute cutaneous lupus erythematosus as a recognized skin manifestation. A recent position paper on the revision of the 1982 criteria for systemic lupus erythematosus recommends skin biopsy, but not of alopecia or oral lesions, and comprehensive antibody studies including SSA and SSB in the workup of lupus erythematosus (1).

The initial ARA criteria were developed primarily for the distinction of patients with systemic lupus erythematosus from those with other rheumatic diseases. Thus, the control populations used were not normal individuals but cohorts of other connective tissue disease patients. Despite this, these criteria are still widely used to diagnose patients with lupus erythematosus. This classification is based on 11 criteria, which are not meant to be either restrictive or exclusive to the diagnosis of systemic lupus erythematosus:

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Oral ulcers, usually painless
5. Arthritis, nonerosive, involving two or more peripheral joints, with tenderness, swelling, or effusion
6. Serositis (pleurisy or pericarditis)
7. Renal disorder (persistent proteinuria exceeding 0.5 g/day or cellular casts)
8. Neurologic disorders (seizures or psychosis)
9. Hematologic disorders (hemolytic anemia; leukopenia of less than 4,000/mm^3; lymphopenia of less than 1,500/mm^3; or thrombocytopenia of less than 100,000/mm^3)
10. Immunologic disorder (positive lupus erythematosus cell preparation; anti-DNA in abnormal titer; antibody to Sm nuclear antigen; or false-positive serologic test for syphilis)
11. Antinuclear antibody

A person is judged to have systemic lupus erythematosus (SLE) if any 4 or more of the 11 criteria are present serially or simultaneously. Furthermore, a diagnosis of SLE is indicated in any patient who has at least three of the following four symptoms: (a) a cutaneous eruption consistent with lupus erythematosus, (b) renal involvement, (c) serositis, or (d) joint involvement (4). Although there is no single serologic gold standard test to detect SLE, the diagnosis does require some serologic abnormality.

Even though the prognosis of SLE has been greatly improved by early diagnosis and current treatment modalities, the mortality rate of the disease is between 15% and 25% (5). Death usually results from infection or severe nephritis (6). A recent meta-analysis of lupus patients showed that patients with systemic lupus erythematosus are at increased risk of lymphomas, specifically non-Hodgkin's lymphoma, independent of the risk associated with chronic immunosuppressive therapy (7).

The importance of adequate laboratory data for evaluation of the seriousness of the illness and its prognosis has long been recognized. Histologic examination of affected tissues in conjunction with serologic and immunofluorescence studies is essential for proper evaluation of a patient with LE.

Cutaneous changes of lupus erythematosus may be subdivided according to the morphology of the clinical lesion and/or its duration (acute, subacute, or chronic). Differentiation between LE subtypes is based on the constellation of clinical, histologic, and immunofluorescence findings (8). Histologic findings alone may not be sufficient to classify correctly the subtype of the eruption (9). Not every case of lupus erythematosus can be assigned with certainty to a category because intermediate forms and transitions from one type to another occur.

Chronic Cutaneous Lupus Erythematosus: Discoid Lupus Erythematosus, Verrucous Lupus Erythematosus, Tumid Lupus Erythematosus, Lupus Erythematosus Panniculitis/Profundus

Discoid Lupus Erythematosus

Characteristically, lesions of discoid lupus erythematosus (DLE) consist of well-demarcated, erythematous, slightly infiltrated, "discoid" plaques that often show adherent thick scales and follicular plugging. Early and active lesions usually display surrounding erythema (Fig. 10-1A). Old lesions often appear atrophic and have hypo- or epidermal hyperplasia. Occasionally lesions may show verrucous epidermal hyperplasia especially at their periphery (10). Hypopigmentation within previously affected areas is frequent. Rarely, neoplasms have been reported in lesions of lupus erythematosus and have included basal cell carcinoma, squamous cell carcinoma, and atypical fibroxanthoma (11).

In many instances, the discoid cutaneous lesions are limited to the face, where the malar areas and the nose are predominantly affected. In addition, the scalp, ears, oral mucosa, and vermilion border of the lips may be involved. In patients with involvement of the head and neck unaccompanied initially by systemic lupus erythematosus, conversion of DLE to SLE is rare (5% to 10%) (12).

In patients with *disseminated discoid lupus erythematosus,* discoid lesions are seen predominantly on the upper trunk and upper limbs, usually, but not always, in association with lesions on the head (13). SLE may eventually develop in up to 20% of these patients (14). Although discoid cutaneous lesions are typical of DLE, they are also seen in as many as 14% of the patients with SLE (15).

Histopathology. In most instances of *discoid lesions*, a diagnosis of lupus erythematosus is possible on the basis of a combination of histologic findings (Fig. 10-1B–E). Changes may be apparent at all levels of the skin, but all need not be present in every case. The findings are summarized as follows:

1. Stratum corneum: hyperkeratosis with follicular plugging
2. Epithelium: thinning and flattening of the stratum malpighii, hydropic degeneration of basal cells, dyskeratosis and squamatization of basilar keratinocytes
3. Basement membrane: thickening and tortuosity, correlating with deposition of immune reactants (Fig. 10-2)
4. Stroma: a predominantly lymphocytic infiltrate arranged along the dermal–epidermal junction, around hair follicles and other appendages, and in an interstitial pattern; interstitial mucin deposition; edema, vasodilation, slight extravasation of erythrocytes
5. Subcutaneous: possible slight extension of the inflammatory infiltrate

The stratum corneum is usually hyperkeratotic. Parakeratosis is not conspicuous, and it may be absent. Keratotic plugs are found mainly in dilated follicular openings (Fig. 10-1B, C), but they may occur in the openings of eccrine ducts as well. Follicular channels in the dermis may contain concentric layers of keratin instead of hairs.

The most significant histologic change in lupus erythematosus is hydropic degeneration of the basal layer, also referred to as liquefaction degeneration. This change is characterized by vacuolar spaces beneath and between basilar keratinocytes (Fig. 10-1C). In its absence, a histologic diagnosis of lupus erythematosus should be made with caution and only when other histologic findings greatly favor such a diagnosis. In addition to liquefaction degeneration, basilar keratinocytes may show individual cell necrosis (apoptosis) and acquire elongate contours like their superficial counterparts rather than retain their normal columnar appearance (squamatization). Frequently, the undulating rete ridge pattern is lost and is replaced by a linear array of squamatized keratinocytes (Fig. 10-1C) (9).

The epidermal changes vary with the clinical character of lesions; there may be thinning and flattening of the stratum malpighii. A clinically verrucous lesion shows a hyperplastic, papillomatous epidermis with hyperkeratotic scale that simulates a hypertrophic solar keratosis or even a superficially invading squamous cell carcinoma (Fig. 10-3A, B) (16). In lesions of DLE that clinically do not show adherent scaling or keratotic plugging, the epidermis may show few or no changes and, in particular, no hydropic changes in the basal layer (17).

The basement membrane, normally delicate and inconspicuous, appears thickened and tortuous in longstanding lesions (Fig. 10-1E). This change becomes more apparent with periodic acid- Schiff (PAS) stains (PAS positive, diastase-resistant), and may be found not only at the dermal–epidermal interface, but also along follicular–dermal junctions. These findings correlate with locations of immunoreactant deposits found on direct immunofluorescence testing of affected skin (Fig. 10-2). By contrast, in areas of pronounced hydropic degeneration of the basal cells, the PAS-positive subepidermal basement zone may be fragmented and even absent (18). Capillary walls may also show thickening, homogenization, and an increase in the intensity of the PAS reaction.

The inflammatory infiltrate in the dermis is usually lymphocytic admixed with plasma cells (Fig. 10-1C, D). Its distribution is a clue to the diagnosis of LE. In active lesions, the infiltrate can be found approximating the dermal–epidermal junction associated with hydropic degeneration. In hair-bearing areas, the infiltrate is located around hair follicles and the sebaceous glands (Fig. 10-1C). Frequently, one can observe hydropic changes in the basal layer of the hair follicles, which may be of diagnostic value in the absence of dermal–epidermal changes. By impinging on pilosebaceous units, the infiltrate causes their gradual atrophy and disappearance. A patchy inflammatory infiltrate also may be present in the upper dermis in an interstitial pattern and around eccrine coils. Occasionally, the infiltrate extends into the subcutaneous fat.

The dermis shows edema and often small foci of extravasated erythrocytes. In dark-skinned persons, melanin is frequently seen within melanophages in the upper dermis because hydropic degeneration in the basal cells causes these

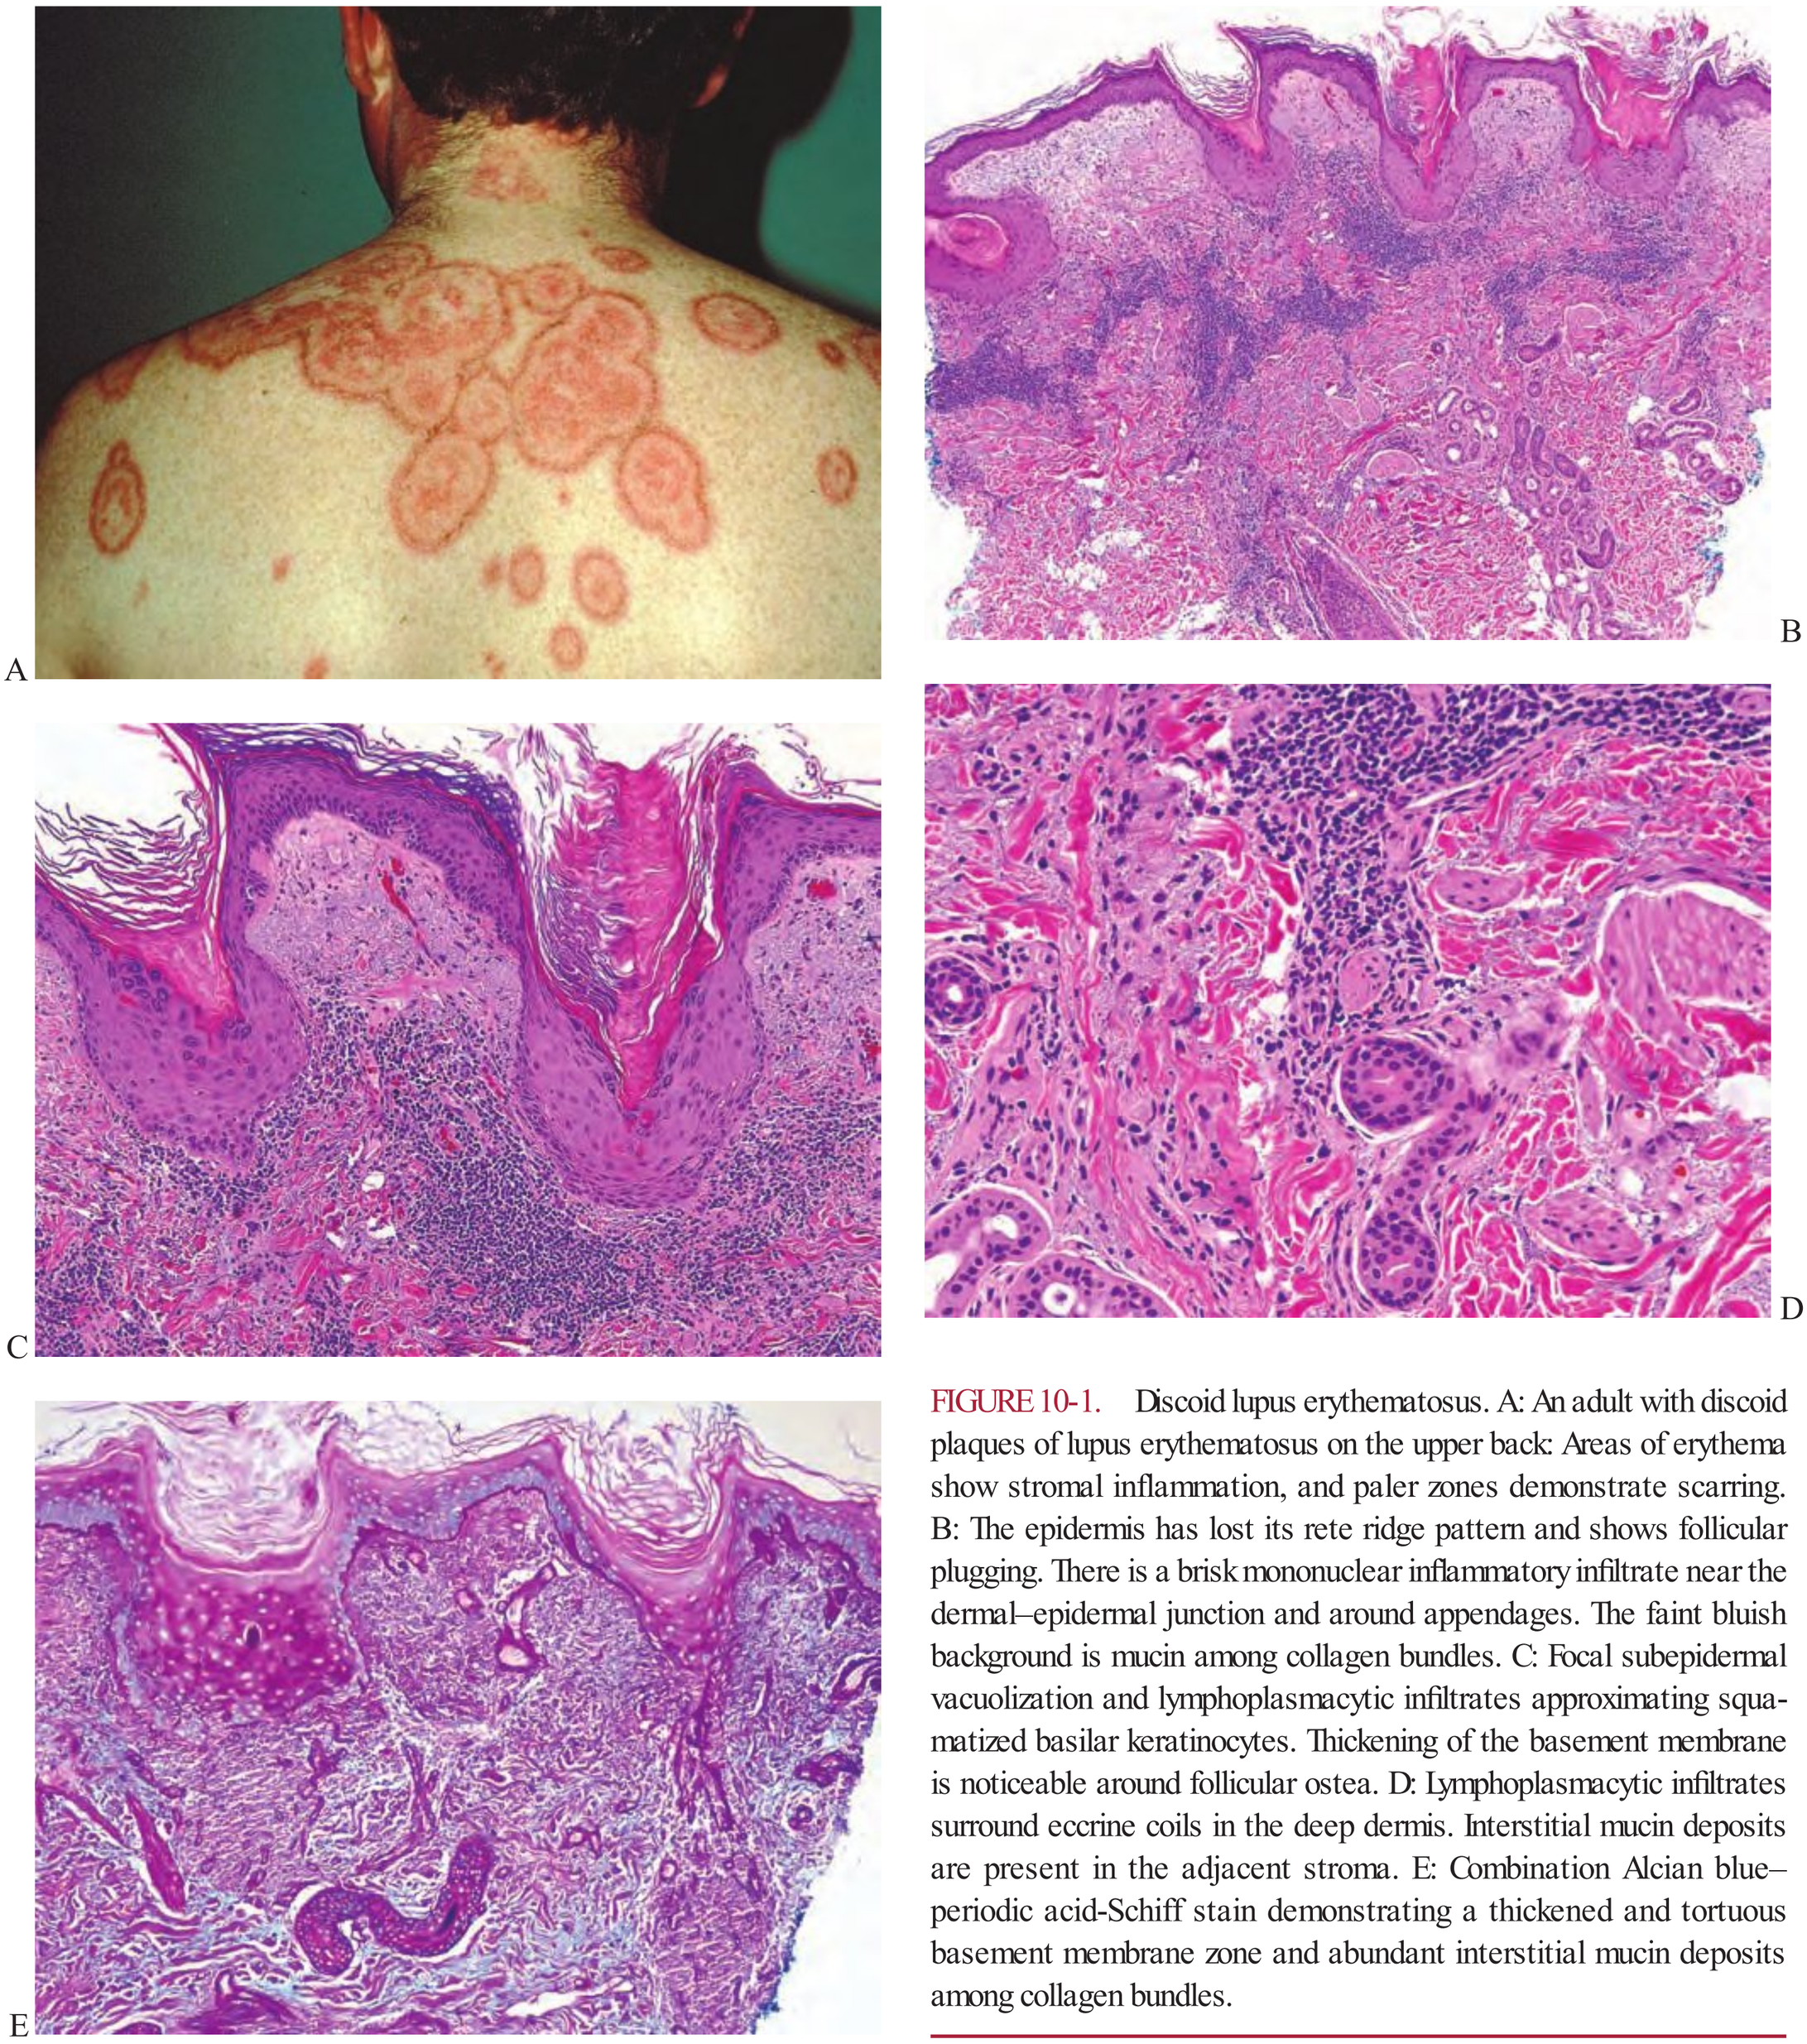

FIGURE 10-1. Discoid lupus erythematosus. A: An adult with discoid plaques of lupus erythematosus on the upper back: Areas of erythema show stromal inflammation, and paler zones demonstrate scarring. B: The epidermis has lost its rete ridge pattern and shows follicular plugging. There is a brisk mononuclear inflammatory infiltrate near the dermal–epidermal junction and around appendages. The faint bluish background is mucin among collagen bundles. C: Focal subepidermal vacuolization and lymphoplasmacytic infiltrates approximating squamatized basilar keratinocytes. Thickening of the basement membrane is noticeable around follicular ostea. D: Lymphoplasmacytic infiltrates surround eccrine coils in the deep dermis. Interstitial mucin deposits are present in the adjacent stroma. E: Combination Alcian blue–periodic acid-Schiff stain demonstrating a thickened and tortuous basement membrane zone and abundant interstitial mucin deposits among collagen bundles.

cells to lose their melanin (pigmentary incontinence). Vascular channels may be dilated and surrounded by edema. Obliterative and proliferative changes are absent. An increase in the ground substance—hyaluronic acid—is common in the middle and lower dermis and is best demonstrated with colloidal iron or Alcian blue stains (Fig 10-1E) (19). Fibrinoid deposits in the dermis are encountered only rarely in discoid lesions, and then only in early discoid lesions.

Colloid bodies, referred to in lichen planus as Civatte bodies, are apoptotic keratinocytes that present as round-to-ovoid, homogeneous, eosinophilic structures. They may be seen in lesions of DLE but also in other inflammatory

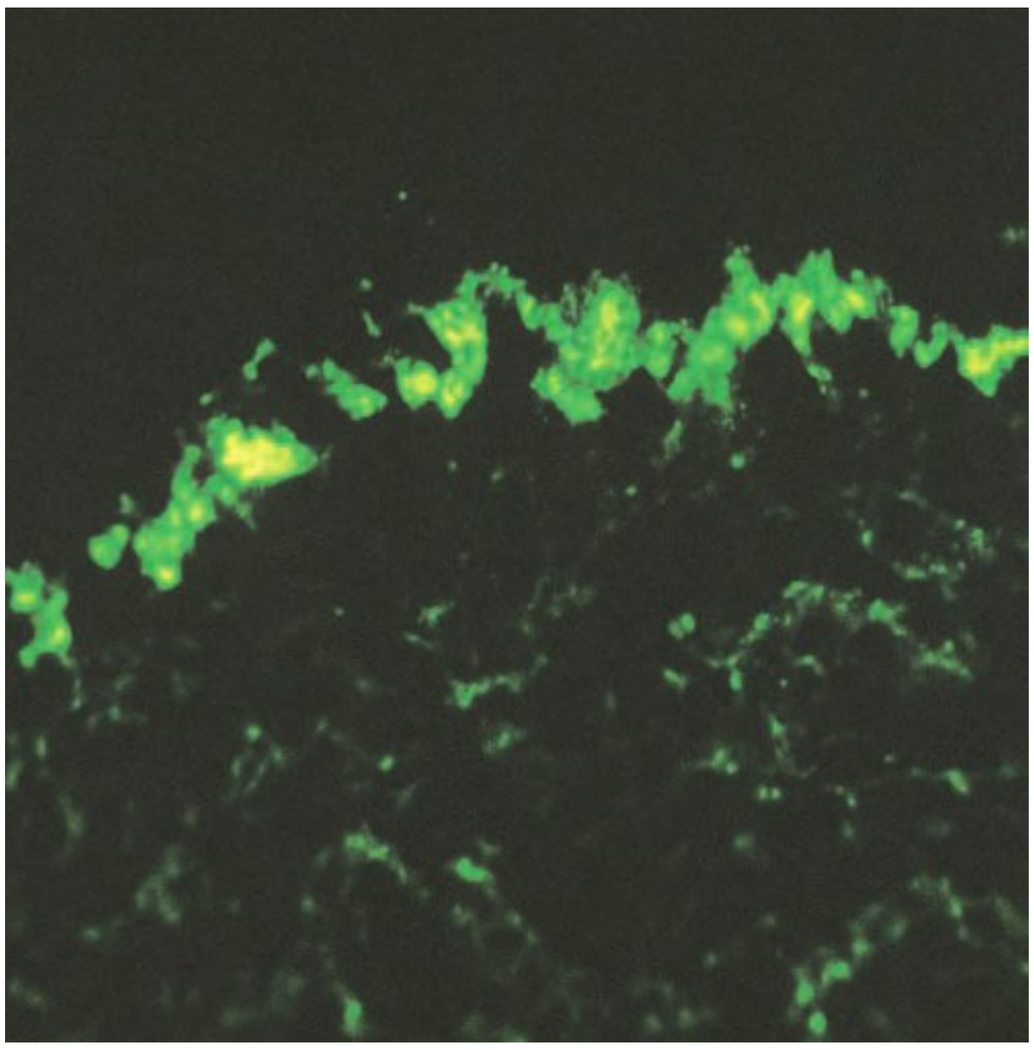

FIGURE 10-2. Positive lupus band test. Granular deposits of immunoglobulin G in the basement membrane zone on direct immunofluorescence of lesional skin.

processes where there is damage to basilar keratinocytes (poikiloderma, lichen planus, fixed drug eruptions, lichenoid keratoses). They measure approximately 10 μm in diameter and are present in the lower epidermis or in the papillary dermis. When located in the dermis, colloid bodies are PAS positive and diastase resistant and, on direct immunofluorescence staining, often are found to contain immunoglobulins (Igs) (IgG, IgM, IgA), complement, and fibrin. This staining does not represent an immunologic phenomenon but is the result of passive absorption.

Differential Diagnosis. The epidermal changes seen in DLE must be differentiated from lichen planus because both diseases may show hydropic degeneration of the basal cell layer. In lichen planus, there is wedge-shaped hypergranulosis and triangular elongation of rete ridges described as "saw-toothing," which are not observed in DLE; in DLE, the epidermis frequently appears flattened. In addition, in lichen planus the infiltrate is superficial (not superficial and deep) and stromal mucin deposition is not seen. (For a discussion of the overlap syndrome lichen planus and lupus erythematosus, see Chapter 7.)

Patchy dermal lymphocytic infiltrates may be seen in five disorders that begin with the letter L (called the five L's). They are lupus erythematosus, lymphocytic lymphoma, lymphocytoma cutis, polymorphous light eruption of the plaque type, and lymphocytic infiltration of the skin of Jessner. Some may also add lues (syphilis) and Lyme disease.

In the absence of significant subepidermal vacuolization, LE must be differentiated from the other six diseases:

- In *lymphocytic lymphoma*, atypical lymphocytes are present, are tightly packed, have an interstitial distribution ("Indian filing"), and do not surround pilosebaceous units as in LE.
- In *lymphocytoma cutis* (see Chapter 31), the infiltrate usually is heavier than in lupus erythematosus, may have an interstitial component, shows no tendency to arrange itself around

A B

FIGURE 10-3. Hypertrophic or verrucous lupus erythematosus. A: A woman with hyperkeratotic scaly plaques on an erythematous base in a photo distribution. B: A hyperplastic epidermis with hypergranulosis and a brisk lichenoid mononuclear infiltrate, histologically mimicking lichen planus.

pilosebaceous structures, and often contains an admixture of larger, paler lymphocytes arranged in lymphoid follicles, mimicking germinal center formation.

- In the plaque type of *polymorphous light eruption* there is often a prominent band of papillary dermal edema. The infiltrate is more intense in the superficial than deep dermis and is occasionally admixed with neutrophils. It does not have a folliculocentric arrangement and is not usually accompanied by stromal mucin deposition (see Chapter 12).
- In *Jessner's lymphocytic infiltration of the skin*, the dermal infiltrate may be indistinguishable from that seen in early, nonscarring, or purely dermal lesions of lupus erythematosus. The presence of increased numbers of B lymphocytes in the infiltrate may help distinguish this from LE (see later text) (20).
- In *lues*, lichenoid lymphoplasmacytic infiltrates are not associated with mucin deposits. Confirmatory antitreponemal antibody immunohistochemical stains or silver stains, such as a Steiner stain, are positive in lues and negative in lupus. Serologic studies assist in distinguishing the two disorders.
- In *Lyme disease*, there are lymphoplasmacytic infiltrates around dermal vessels. Silver and immunohistochemical stains should reveal spirochetal organisms, although they are sparse and difficult to detect.

Verrucous Lupus Erythematosus

An exaggerated proliferative epithelial response, which occurs in approximately 2% of patients with chronic cutaneous LE, manifests as verrucous-appearing lesions (Fig. 10-3A). Clinically, two types of lesions have been reported in this subset of LE. Lesions may simulate lichen planus or keratoacanthomas. They occur on the face (nose, chin, lips), arms, dorsal aspects of the hands, and occasionally the back. The presence of lesions typical of DLE elsewhere is a helpful clue to the diagnosis.

Histologically, the epidermis is papillomatous, hyperplastic, and surmounted by hyperkeratotic scale. Large numbers of dyskeratotic keratinocytes are usually noted in the lower portion of the epithelium, associated with a bandlike mononuclear infiltrate along the dermal–epidermal junction (Fig. 10-3B). Older lesions display a thickened basement membrane zone. A second pattern consists of a cup-shaped, keratin-filled crater surrounded by an acanthotic epidermis with elongate rete ridges and a sparse mononuclear infiltrate. These changes, in the presence of a deep dermal perivascular, periappendageal, and interstitial infiltrate and mucin deposition, suggest a diagnosis of hypertrophic or verrucous lupus erythematosus.

Tumid Lupus Erythematosus

The dermal form of LE without surface/epithelial changes is known as tumid LE. Clinically, affected patients display indurated papules, plaques, and nodules without erythema, atrophy, or ulceration of the surface (Fig. 10-4A). Histologically, superficial and deep dermal perivascular, interstitial, and periappendageal lymphocytic infiltrates associated with stromal mucin deposits are observed (Fig. 10-4B, C) (21). Unlike discoid lupus, in which discoid lesions may coexist with systemic lupus erythematosus, the diagnosis of tumid lupus typically excludes the presence of systemic lupus erythematosus (22).

Lupus Erythematosus Profundus/Panniculitis

Lupus erythematosus may show changes in adipose tissue associated with the chronic cutaneous or systemic forms. Two thirds of affected patients have discoid LE lesions. Women are affected three to four times more often than men. Typically, multiple discrete, firm, deep nodules arise on the face, arms (particularly the deltoid area), chest, and/or buttocks. The legs and back may be affected as well. The overlying skin may be normal, erythematous, or atrophic. The panniculitis resolves, leaving depressed atrophic scars. Several observers believe that lupus erythematosus profundus may represent a lymphoproliferative disease related to connective tissue disease, which has an indolent biological behavior (23).

Subcutaneous adipose tissue may be involved with or without inflammation in the dermis or dermal–epidermal junction. Salient histologic findings include a predominantly lobular lymphohistiocytic infiltrate often with plasma cells, occasionally forming germinal centers. Vascular changes include endothelial prominence, thrombosis, calcification, or perivascular fibrosis ("onion-skin" appearance). Fat necrosis with fibrin deposition often eventuates in hyalinization of adipose lobules (Fig. 10-5A, B). Stromal mucin deposition may be prominent in well-established lesions. The intensity of the infiltrates may lessen over time as the hyalinization progresses.

Subacute Cutaneous Lupus Erythematosus

Subacute cutaneous lupus erythematosus (SCLE) represents about 9% of all cases of lupus erythematosus. It is characterized by extensive, erythematous, symmetric nonscarring and nonatrophic lesions that arise abruptly on the upper trunk, extensor surfaces of the arms, and dorsa of the hands and fingers. This eruption has two clinical variants: (a) papulosquamous lesions and (b) annular to polycyclic lesions (Fig. 10-6A). Frequently both types of lesions are seen. In some instances, vesicular and discoid lesions with scarring may coexist.

Patients with SCLE may have mild systemic involvement, particularly arthralgias. Approximately 50% fulfill criteria for SLE. Conversely, 10% to 15% of SLE patients exhibit cutaneous lesions of SCLE (24). Severe SLE, with renal or cerebrovascular disease, develops in only 10% of SCLE cases (25,26). Serologic studies show 70% of affected patients to have the anti-Ro (SSA) antibody. Patients with SCLE often bear the HLA-DR2 and HLA-DR3 phenotype. SCLE may occur asynchronously with other connective tissue diseases such as Sjögren's syndrome and morphea.

Histopathology. See the histopathology section of neonatal lupus erythematosus and Fig. 10-6B.

Neonatal Lupus Erythematosus

Neonatal lupus erythematosus has clinical and histologic skin changes and serologic findings similar to those of SCLE.

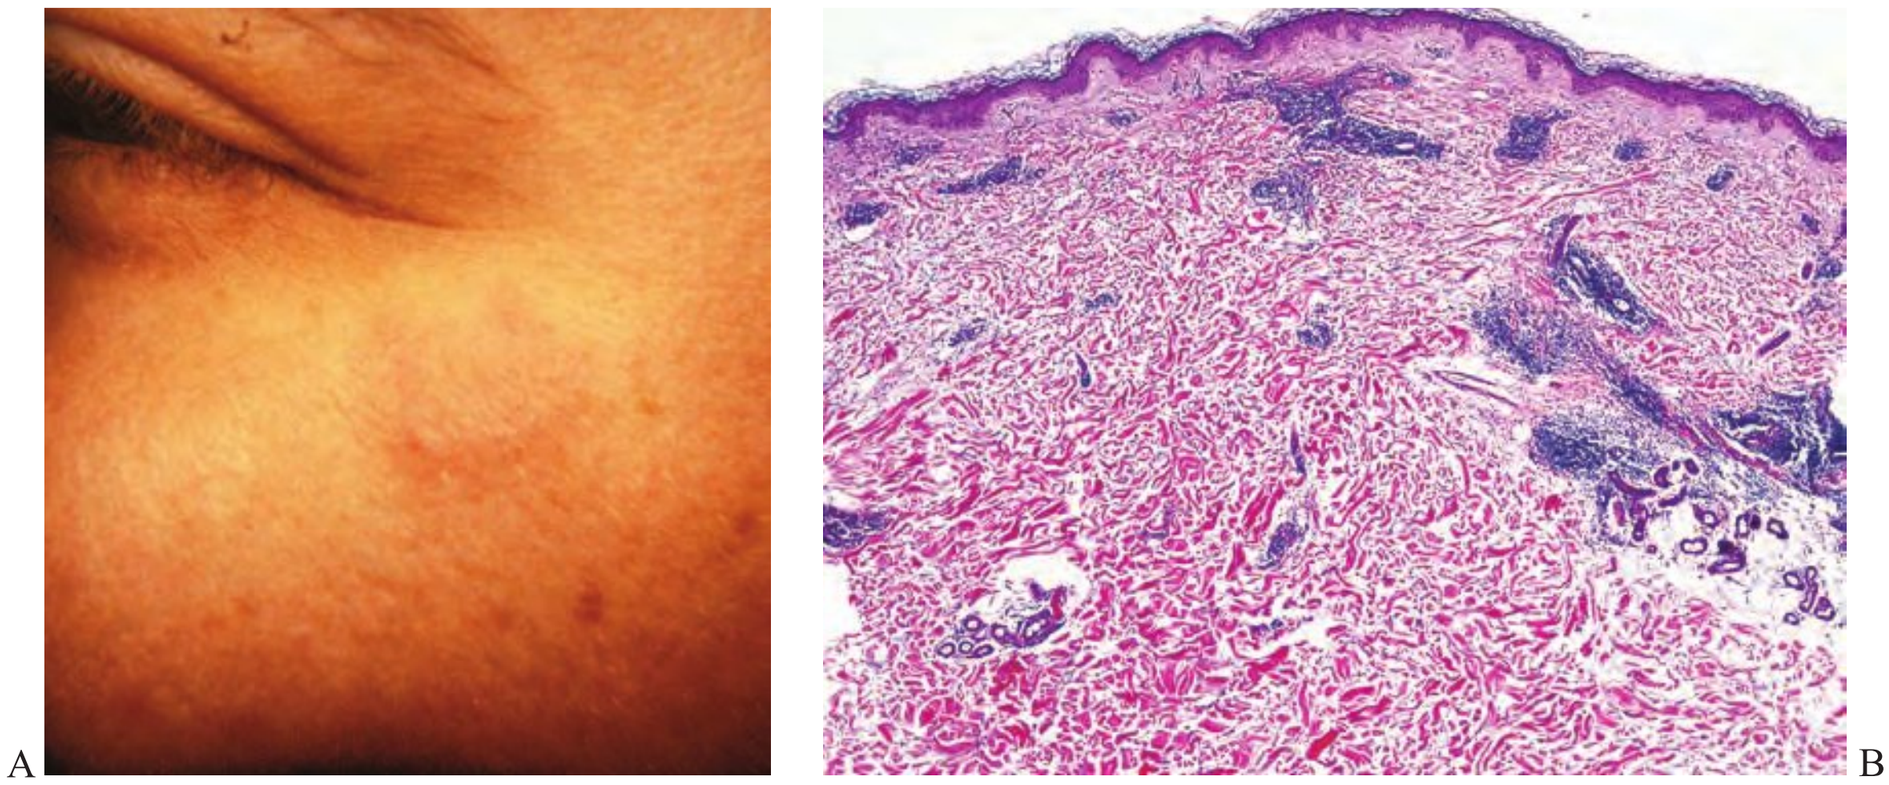

FIGURE 10-4. Tumid lupus erythematosus. A: A barely raised, slightly hyperpigmented plaque on the cheek, without significant scaling, erythema, or atrophy. B: An angiocentric and periappendageal dermal inflammatory infiltrate. The dermal–epidermal junction of this specimen fails to show interface alterations. C: A lymphocytic infiltrate admixed with plasma cells surrounds and separates eccrine glands and adjacent collagen bundles. The faint bluish hue of the matrix is indicative of mucin deposition.

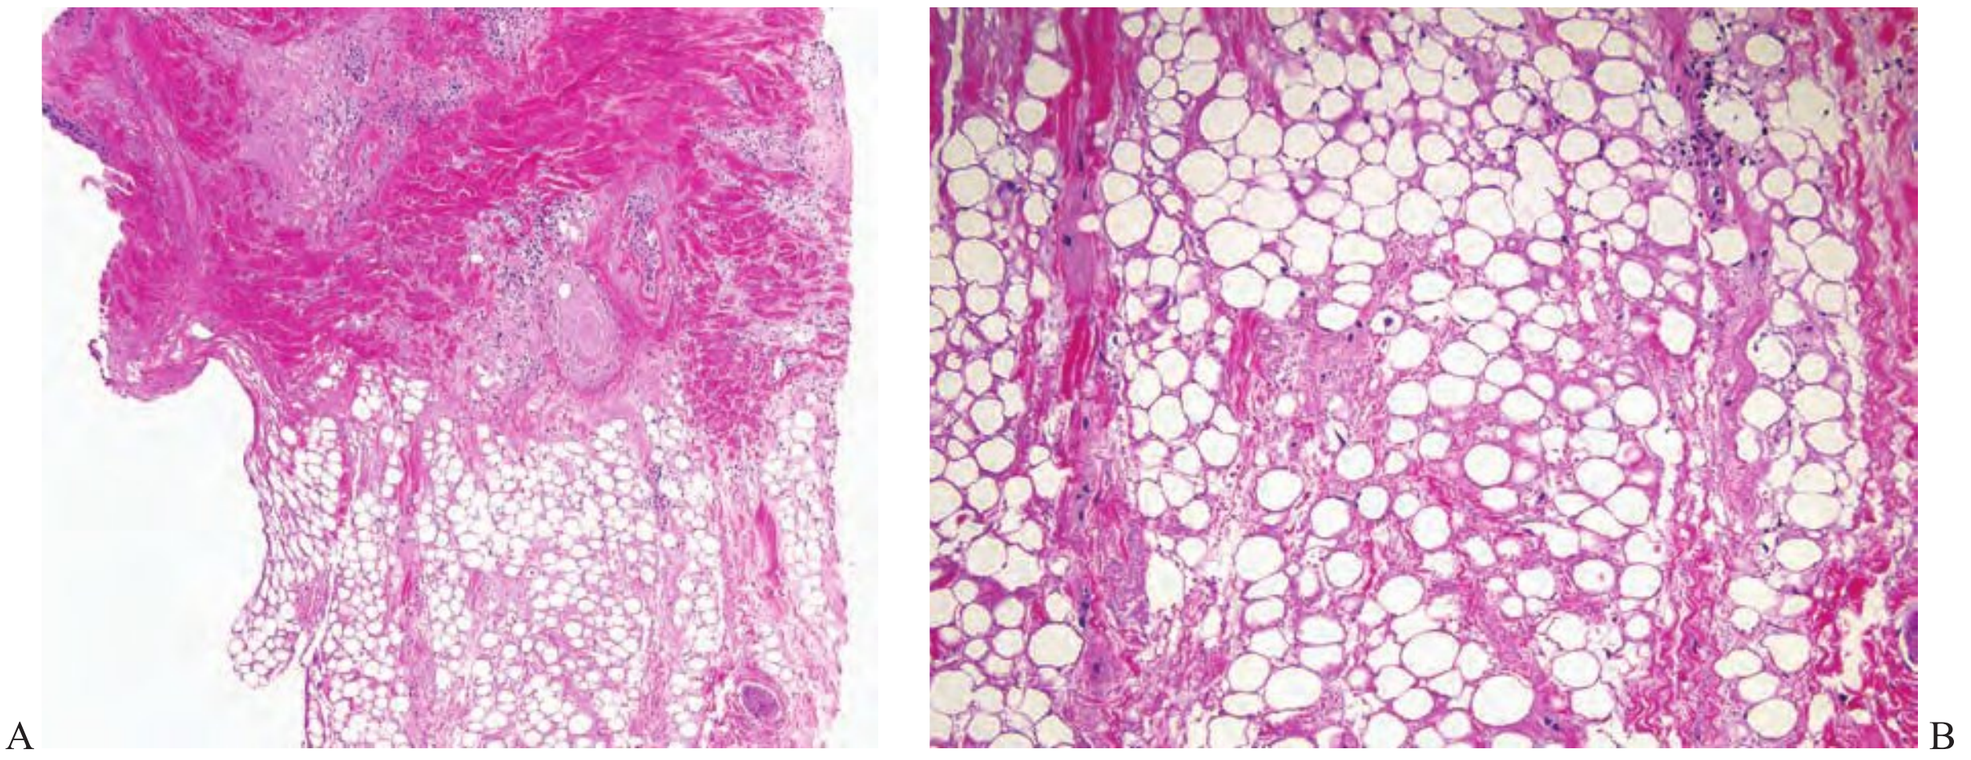

FIGURE 10-5. Lupus panniculitis. A: A perivascular and perifollicular inflammatory infiltrate is present in the deep dermis and extends into adipose tissue in an interstitial pattern. B: Adipocytes vary in size and are embedded in a hyalinized matrix. Longstanding lesions show minimal inflammation and prominent hyalinization.

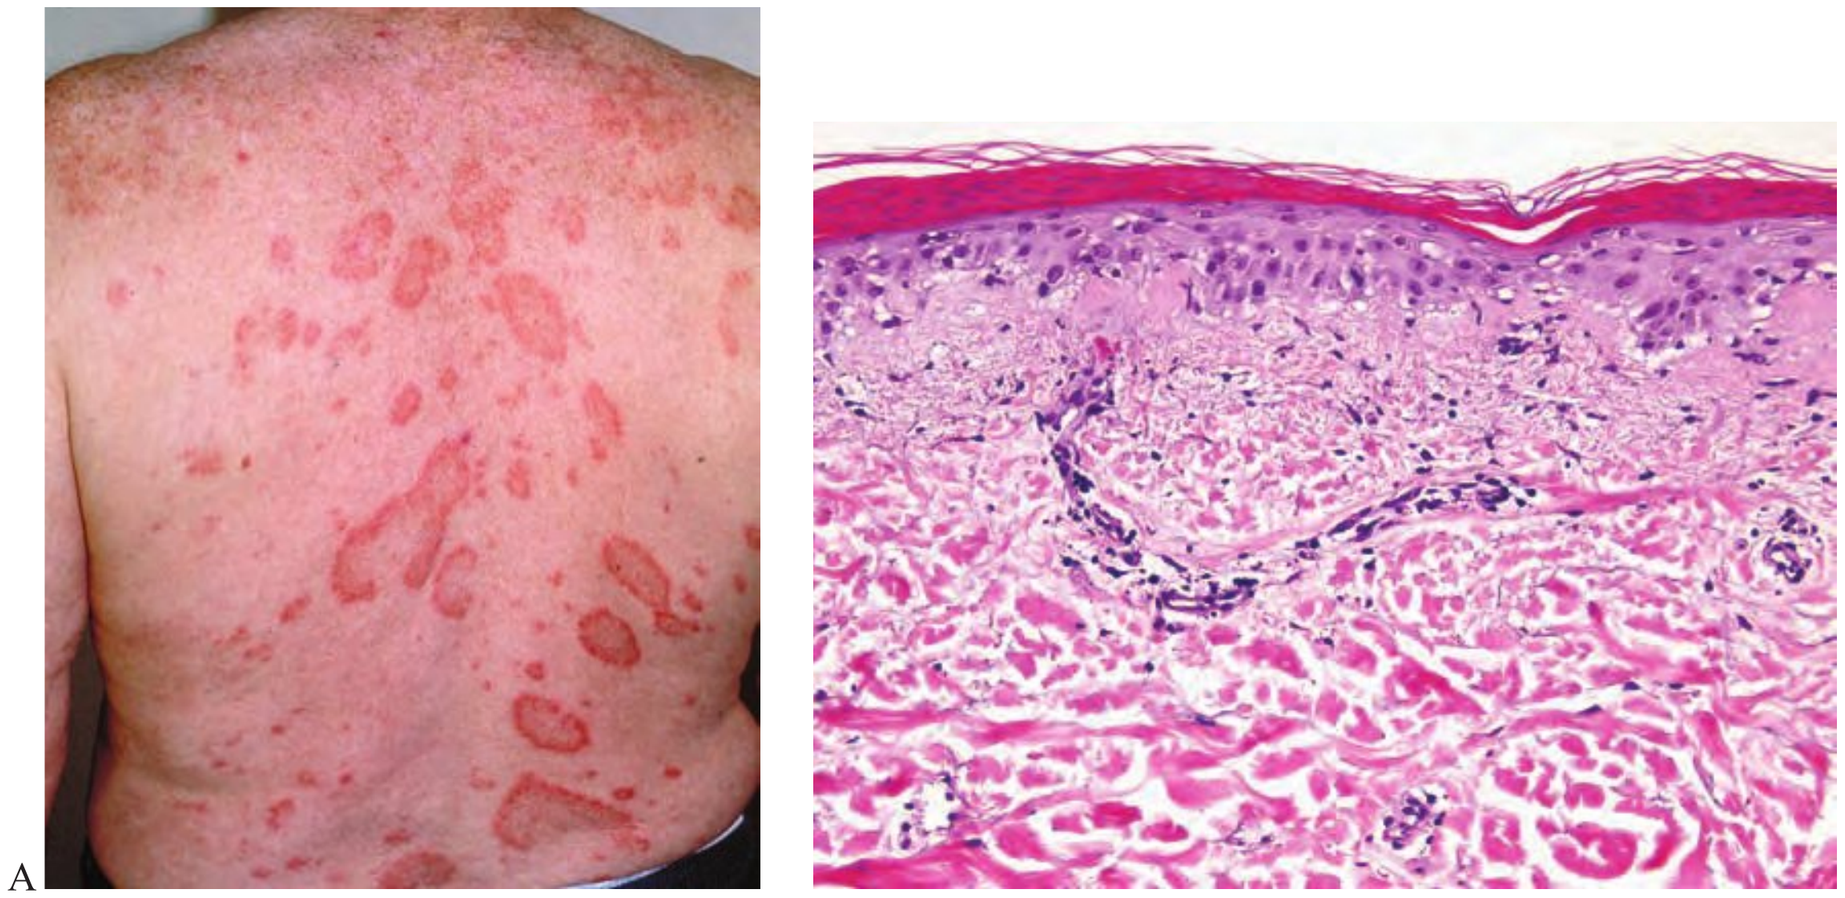

FIGURE 10-6. Subacute lupus erythematosus. A: Variably sized annular scaly patches on the upper back. Scarring and atrophy, as commonly seen in discoid/chronic cutaneous lupus, are uncommon. B: A sparse mononuclear inflammatory infiltrate in the upper dermis associated with pronounced dermal edema. There is continuous subepidermal vacuolization, focal hemorrhage, and slight mucin deposition.

Children of mothers with active SLE may develop LE-like symptoms in the neonatal period related to passage of maternal IgG antinuclear antibodies (particularly anti-Ro/SSA, anti-La/SSB, or anti-U1RNP autoantibodies) through the placenta. Anti-Ro/SSA are the predominant autoantibodies and are found in approximately 95% of cases. This may result in a transient syndrome characterized by widespread polycyclic, annular, usually nonscarring lesions. There is associated photosensitivity, transient thrombocytopenia, mild hemolytic anemia, leukopenia, and congenital heart block. These changes have their onset at birth to 2 months and usually resolve in the first 6 months of life with decreasing levels of maternal antibodies. The heart block occurs in approximately 50% of affected infants, usually without associated skin lesions, and may be fatal. Of interest, individuals affected with transient neonatal LE may develop SLE as young adults (21).

Histopathology. Histologic changes in SCLE (and neonatal LE) differ in degree from those in the discoid lesions and are most intense at the dermal–epidermal interface (Fig 10-6B). They consist of the following:

1. Hydropic degeneration of the basilar epithelial layer, sometimes severe enough to form clefts and subepidermal vesicles
2. Colloid bodies in the lower epidermis and papillary dermis (common)
3. Edema of the dermis, which is more pronounced than in discoid lesions
4. Focal extravasation of erythrocytes and dermal fibrinoid deposits (common)
5. Less prominent hyperkeratosis and inflammatory infiltrate than in discoid lesions (27)

In comparison with chronic, particularly discoid LE, it is not always possible correctly to categorize lesions based on histology alone because there is overlap. Pilosebaceous atrophy is helpful as a discriminating feature and correlates with DLE rather than SCLE.

Systemic Lupus Erythematosus

In SLE, the cutaneous manifestations usually appear less suddenly than in SCLE and are less pronounced, such that the signs and symptoms of systemic disease usually overshadow the often subtle form of skin involvement. Usually systemic manifestations, especially joint manifestations, precede the cutaneous lesions. Only 20% of SLE patients demonstrate prominent cutaneous features at the onset of their disease, but approximately 80% will exhibit cutaneous lesions in the course of their disease (28,29).

The cutaneous manifestations commonly consist of malar erythema, photosensitivity, palmar erythema, periungual telangiectases, diffuse hair loss as a result of telogen effluvium, and urticarial vasculitis and/or bullous lesions. The erythematous lesions of SLE consist of erythematous, slightly edematous patches without significant scaling and without atrophy. As a rule, the patches are not sharply demarcated. The most common site of involvement is the malar region, but any area of the skin may be involved, particularly the palms and fingers. Occasionally, lesions show a petechial, vesicular, or ulcerative component. Rarely, in the late stage, some of the lesions may assume the appearance of poikiloderma atrophicans vasculare.

Well-defined "discoid" lesions with atrophic scarring, as seen typically in DLE, occur in about 15% of the patients with

SLE. They may precede all other clinical manifestations of SLE. A relatively benign course characterizes SLE in most patients with preceding DLE (30); however, many patients usually have had persistent multiple abnormal laboratory findings from the beginning. This is in contrast to cases of simple DLE, in which most abnormal laboratory findings, if present at all, are transient.

Two variants of SLE, *SLE with genetic deficiency of complement components* and *bullous LE*, bear mention. In the former, the onset of SLE occurs in early childhood and often affects several siblings because of the autosomal recessive mode of transmission (31). Deficiencies of C2 and C4 result in strikingly similar clinical pictures of extensive lesions similar to DLE, with marked scaling, atrophy, and scarring associated with sensitivity to sunlight. In addition, there can be central nervous system involvement and glomerulonephritis, which may be fatal (32).

In *bullous SLE* subepidermal blisters may arise in previously involved or uninvolved areas. They may form large hemorrhagic bullae to herpetiform vesicles, arise suddenly, and show clinical resemblance to lesions of bullous pemphigoid or dermatitis herpetiformis.

Rowell's syndrome is a distinct clinical presentation of lupus with erythema multiforme–like lesions. Patients have speckled antinuclear and anti-La antibodies and test positive for rheumatoid factor (33).

The coexistence of SLE and systemic scleroderma or dermatomyositis has been repeatedly described. It is known as overlap syndrome and refers to the coexistence of two related but separate diseases. Similarly, there are reports of systemic lupus and coexistent eosinophilic fasciitis (34,35). Such instances of overlap are in contrast to *mixed connective tissue disease*, which is recognized as a separate disease entity.

Many drugs are associated with induction of lupus erythematosus, the majority of which induce predominantly systemic symptoms such as arthritis, serositis, lymphadenopathy, and fever. A few are associated with specific cutaneous manifestations. They are listed in Table 10-1, and are discussed

TABLE 10-1 Drugs Related to Induction of Lupus Erythematosus

Antiarrhythmics	Procainamide	Anticholesterol	Statins
	Quinidine		Gemfibrozil
	Tocainide	Biological agents	Interleukin-2
Antihypertensive	Hydralazine		Etanercept
	Methyldopa		Infliximab†
	Beta blockers		Interferon-α
	Hydrochlorthiazide*		Efalizumab*
	Calcium channel blockers	Hormones	Estrogen
	Angiotensin-converting enzyme inhibitors		Lefunomide*
		Other	Sulfasalazine
	Clonidine		Penicillamine
Antibiotics	Isoniazid		Fluorouracil agents†
	Minocycline		Gold salts
	Penicillin		Sertraline†
	Streptomycin		Ticlodipine*
	Tetracycline		Buproprione*
	Griseofulvin		Lansoprazole*
	Terbinafine		Doxetacel*
	Ciprofloxin		Reserpine
	Rifampicin		Lithium
Antithyroid	Propylthiouracil		Clonidine
	Methimazole		Hydroxyurea
	Thiamazole		Clozapine
Anticonvulsants	Carbamazepine		Zafirlukast
	Ethosuxamide		
	Phenytoin*		
	Valproate		

*Associated with subacute cutaneous lupus–like syndrome.
†Associated with chronic cutaneous lupus–like syndrome.

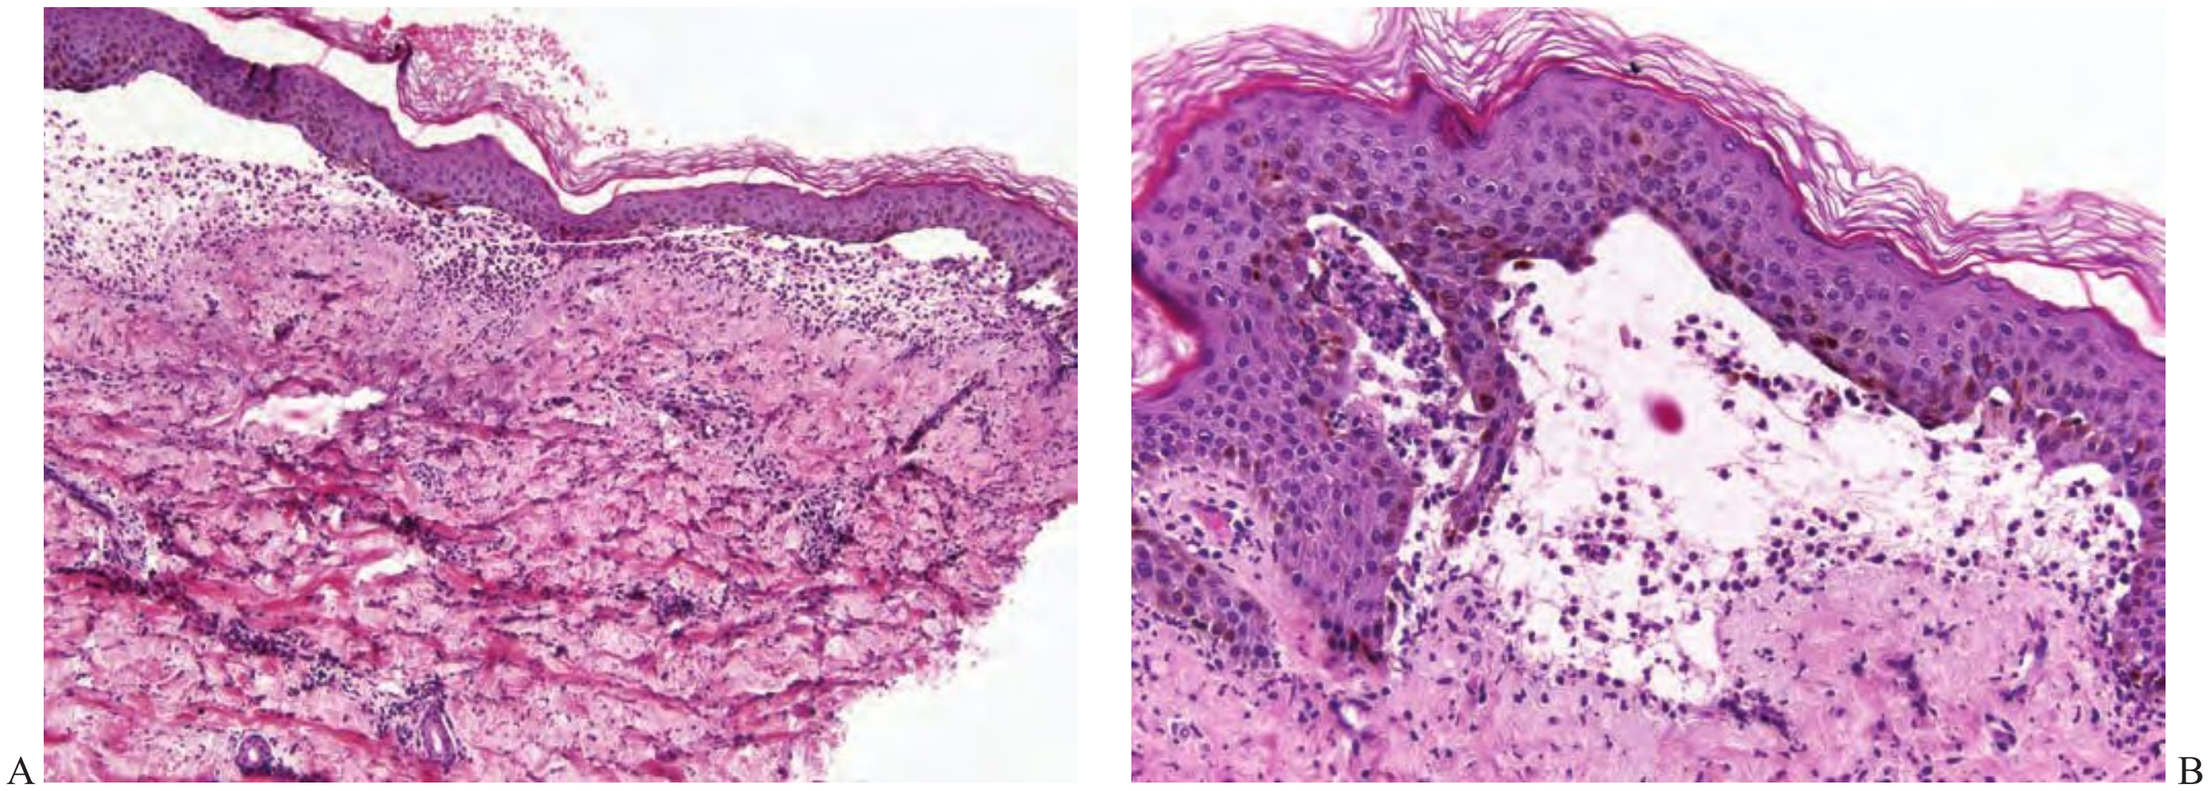

FIGURE 10-7. Bullous lupus erythematosus, neutrophilic. A: There are broad-based subepidermal blisters associated with marked papillary dermal edema and large numbers of neutrophils. Neutrophils are also present around vessels and among collagen bundles throughout the dermis. Faint interstitial mucin deposits and nuclear dust are present. B: The papillary dermal abscesses simulate findings of dermatitis herpetiformis. The dermal changes as noted in panel A, however, would not be seen in dermatitis herpetiformis.

further in the section on drug-induced lupus erythematosus in Chapter 11.

Histopathology. Early lesions of SLE of the erythematous, edematous type may show only mild, nonspecific changes. In well-developed lesions, the histologic changes correspond to those described for subacute cutaneous LE (Fig. 10-6B): Hydropic degeneration of the basal cell layer occurs in association with edema of the upper dermis and extravasation of erythrocytes. Fibrinoid deposits in the connective tissue of the skin are often seen in erythematous, edematous lesions, especially in patients with SLE. Such fibrinoid deposits consist of precipitation of fibrin in the ground substance. They appear as granular, strongly eosinophilic, PAS-positive, diastase-resistant deposits between collagen bundles, in the walls of dermal vessels, in the papillary dermis, or beneath the epidermis in the basement membrane zone. Fibrinoid deposits are not specific for LE. They are seen in association with vascular injury, particularly in leukocytoclastic vasculitis.

Subcutaneous fat is often involved in SLE. Changes similar to those in lupus profundus may be seen but are usually milder: There may be focal mucin deposition associated with a predominantly lymphocytic infiltrate. Adiopocytes may be separated by edema and fibrinoid deposits. These histologic changes in subcutaneous fat produce no clinically apparent lesions.

Occasionally, palpable purpuric lesions in SLE patients show a leukocytoclastic vasculitis histologically indistinguishable from leukocytoclastic vasculitis of other causes: There is endothelial cell swelling, a neutrophilic inflammatory infiltrate, nuclear dust formation, perivenular fibrin deposition, and stromal hemorrhage. Urticaria-like lesions may occur and show either a leukocytoclastic vasculitis or a perivascular mononuclear infiltrate not diagnostic of lupus erythematosus (36). In addition, white atrophic lesions may occur in SLE that both clinically and histologically resemble those of malignant atrophic papulosis of Degos (37).

Bullous SLE shows two histologic inflammatory patterns: One is neutrophilic, and the other is mononuclear. The neutrophilic type simulates dermatitis herpetiformis or linear IgA bullous disease with the formation of papillary microabscesses (Fig. 10-7A, B) (38). Nuclear dust is seen in the papillary microabscesses and in the upper dermis around and within the walls of blood vessels. Direct immunoelectron microscopic studies have localized immunoreactant deposits to beneath the lamina densa; they consist of IgG with or without IgM, and often IgA in a linear or granular pattern. Some patients may also have circulating anti–basement zone antibodies and antibodies directed against type VII collagen. The latter antibodies are similar but not identical to those in epidermolysis bullosa acquisita (39).

The subepidermal blister associated with a mononuclear inflammatory infiltrate arises in longstanding lesions of cutaneous lupus erythematosus (Fig. 10-8A, B). It likely corresponds to an altered dermal–epidermal interface resulting from inflammation and immunocomplex deposition. This type of change is a part of the spectrum of LE rather than a distinct entity.

Systemic Lesions. Although the etiology of SLE is obscure, it is evident that much of the tissue damage results from deposition of antibody–antigen complexes in affected organ systems. These immune complexes are demonstrable in renal glomeruli, blood vessels, skin, and the choroid plexus of the brain.

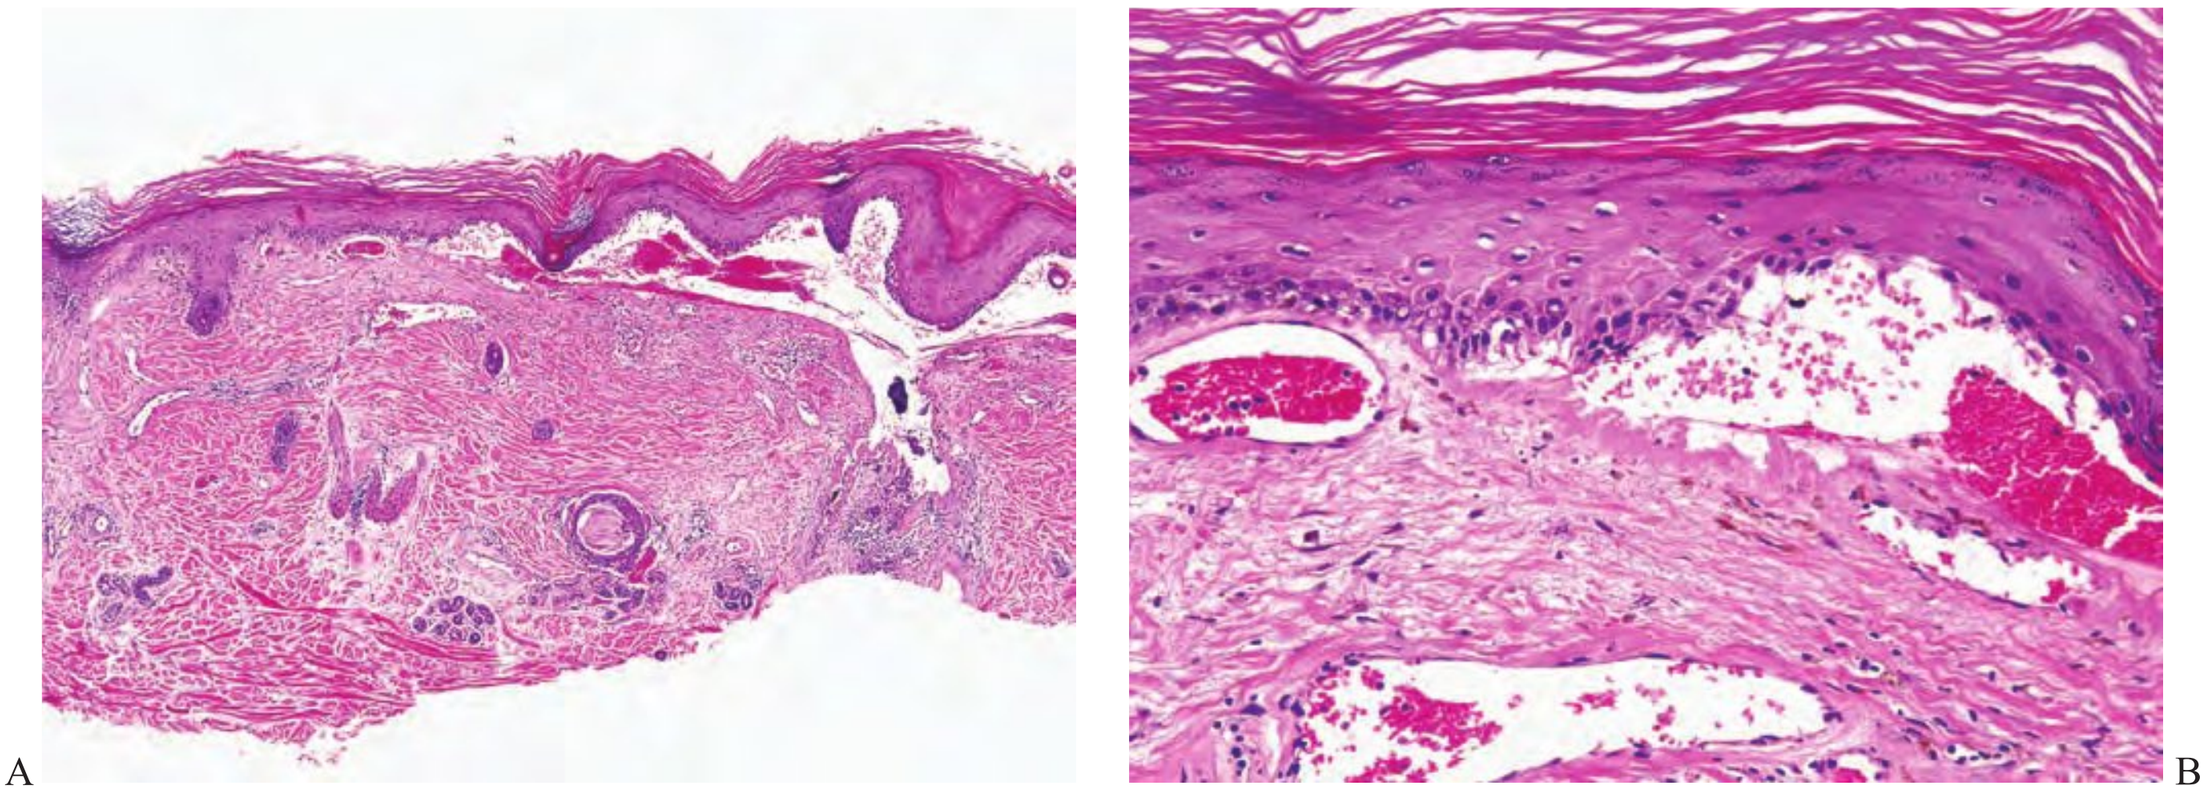

FIGURE 10-8. Bullous lupus erythematosus, mononuclear. A: A broad subepidermal cleft is present beneath an epidermis that has lost its rete ridge pattern and is surmounted by hyperkeratotic scale. The stroma contains perivascular and periappendageal inflammatory infiltrates. B: Adjacent to the zone of dermal–epidermal separation is a thickened eosinophilic basement membrane zone. Melanophages are scattered in the superficial dermis.

Arthritis occurs most often; however, renal changes are the most important because they are the most common cause of death in SLE. Percutaneous renal biopsy allows determination of the type and degree of histologic changes in the kidneys, which are of prognostic significance regardless of the absence or severity of clinical renal disease (40). As in skin, immunoglobulin and complement (immunoreactant) deposits are detectable with immunofluorescence and electron microscopic studies.

A detailed presentation of the classifications of glomerulonephritides is beyond the scope of this section but can be found in the review by Dooley et al. (41).

Serositis involving the pleura, epicardium, and peritoneum may show submucosal mononuclear inflammatory infiltrates associated with fibrinoid deposits. In the spleen, periarterial fibrosis around the follicular arteries is common and is highly characteristic of SLE. Thick, concentrically layered rings of sclerotic collagen fibers surround the arteries.

The *verrucous endocarditis of SLE*, so-called Libman-Sacks endocarditis, occurs mainly on the mitral and tricuspid valves. In the subendothelial connective tissue there are collections of necrotic debris, fibrinoid material, and inflammatory cells forming small vegetations on the valve leaflets (42).

Antiphospholipid syndrome occurs in patients with SLE and other autoimmune diseases who develop immunoglobulins that can prolong phospholipid-dependent coagulation tests. These immunoglobulins occur in association with SLE and other autoimmune diseases but are found unassociated with them as well. One of these is a lupus anticoagulant and occurs in about 10% of SLE patients. Affected patients are at greater risk for thromboembolic disease, including deep venous thrombosis, pulmonary emboli, and other large-vessel thrombosis. Other associated findings are recurrent fetal wastage, renal vascular thrombosis, thrombosis of dermal vessels (Fig. 10-9A, B), and thrombocytopenia. Anticardiolipin antibody, a second type of antiphospholipid antibody, occurs five times more often than lupus anticoagulant antibody. It is associated with recurrent arterial and venous thrombosis, valvular abnormalities, cerebrovascular thromboses, and essential hypertension (Sneddon's syndrome) (43). Other cutaneous findings include livedo reticularis, necrotizing purpura, disseminated intravascular coagulation, and stasis ulcers of the ankles (44).

Pathogenesis and Laboratory Findings. The etiology of lupus erythematosus is considered to be multifactorial (Table 10-2). Studies have demonstrated numerous defects in different arms of the immune system. These abnormalities include but are not limited to abnormal responses to ultraviolet radiation, abnormal antigen-presenting-cell function, numerous HLA associations, polymorphisms in tumor necrosis factor-α promoters, abnormal keratinocyte apoptosis, and polymorphisms in the genes coding for interleukin-1 (IL-1) receptor antagonist and IL-10 promoter sequence (45). In addition, research has shown that aberrant stimulation of Toll-like receptors (TLRs), specifically TLR7 and TLR9, by endogenous antigens may play a crucial role in the autoimmune feedback loop between T cells and B cells (46).

The serologic hallmark of lupus erythematosus is the production of autoantibodies. There are a wide variety of antibodies against different cellular targets. The initial screening test for antinuclear antibodies (ANAs) is indirect immunofluorescence, which provides limited but clinically useful information. Many other assays are available for more specific characterization of ANAs and include immunodiffusion, enzyme-linked immunosorbent assays, immunoprecipitation, and immunoblots.

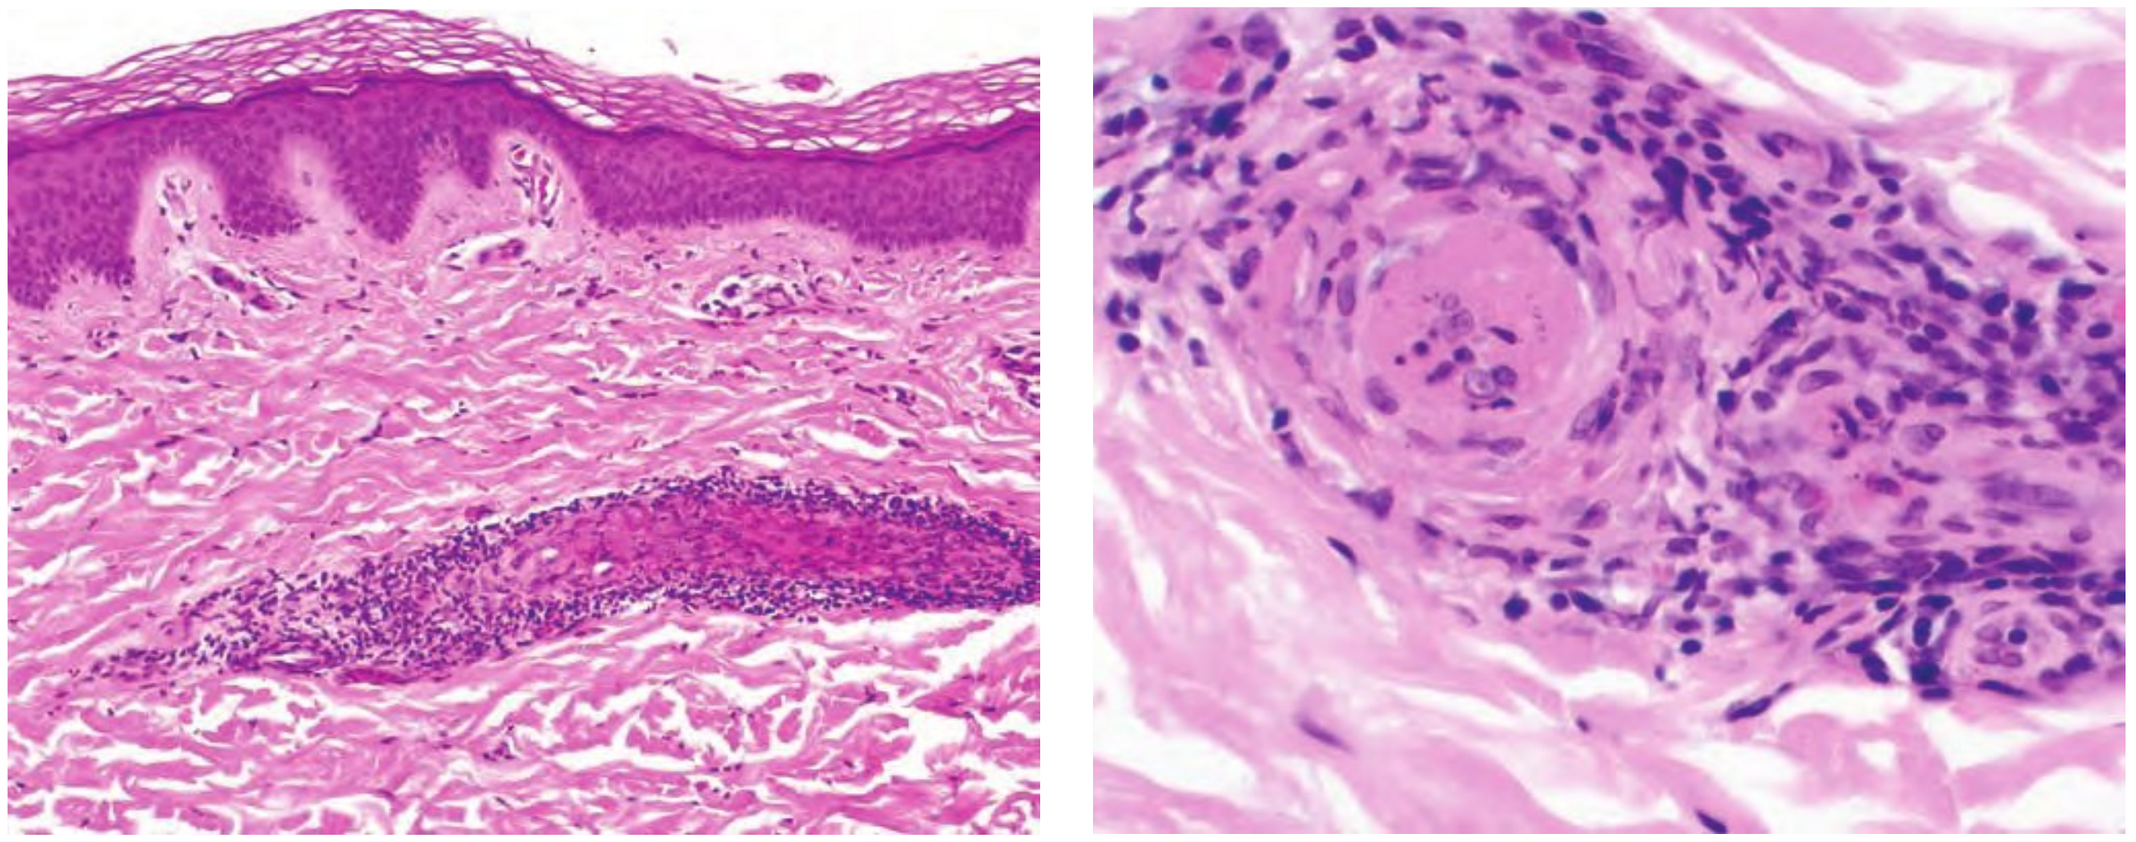

FIGURE 10-9. Lupus anticoagulant syndrome. A: A superficial dermal vessel is surrounded by lymphocytes. B: High magnification of pale eosinophilic intravascular thrombus.

TABLE 10-2 Lupus Erythematosus: Etiologic Factors

Genetic	HLA-DR2	Mothers with newborns with neonatal LE
		Patients positive for anti–Ro/SSA
		Older patients with SLE
	HLA-DR3	Younger SLE patients with anti–native DNA antibodies
	HLA-B8	Increased frequency in:
	HLA-DR3	Mothers with newborns with neonatal LE
	HLA-DQ23	Female patients with primary Sjögren's syndrome
	HLA-DRw52	Female patients with Sjögren's syndrome/LE
Environmental precipitants	Drugs	See Table 10.1
	Ultraviolet light	
	Possibly diet	
Hormonal influences	Predisposition of women in childbearing years	
Autoimmunity	Every aspect of immune system affected:	
	B cells	Abnormal B-lymphocyte maturation and activation
		Hypergammaglobulinemia
	T cells	Decreased peripheral T lymphocytes
		T-cell hyperactivity
		Increased percentage of $CD29^+$ (memory helper) T cells
		Preferential loss of CD4, $CD45R^+$ (suppressor inducer) cells in active LE
		Defective T-suppressor function
	Natural killer (NK) cell	Normal number of NK cells but decreased NK-cell activity (deficient in active cytotoxicity)
	Antilymphocyte antibody	Lymphocytotoxic antibodies in sera of 80% of SLE patients
	Antinuclear antibodies	Nuclear membrane targets
		Chromatin targets
		Ribonucleoprotein targets
	Abnormal feedback loop	Abnormal stimulation of TLR7 and TLR9 by endogenous antigens

TABLE 10-3 Antinuclear Antibodies

Appearance	Pattern	Target site	Associated antibodies	Associated disorder
	Homogeneous	Chromatin	Antihistone	SLE
			Anti-DNA	False + SLE
				Drug-induced LE
	Rim	Chromatin	Anti-DNA	SLE
		Nuclear membrane	Antilaminin (rare)	
	Fine speckled	Nuclear RNP	Anti-Sm	SLE, often with nephritis
			Anti-Ro/SSA	SLE, Sjögren's syndrome
			Anti-La/SSB	
			Anti-U1RNP	SLE, mixed CTD
		Chromatin	Anti-Ku	SLE, scleroderma myositis
			Antitopolsomerase 1 (SCL-70)	Scleroderma
	Discrete speckled	Chromatin	Anticentromere	CREST
	Nucleolar	Nucleolar RNP	Anti-U3RNP	Scleroderma
		Nucleolar components	Anti–RNA polymerase I	
			Anti–Pm-Sci	

CREST, calcinosis cutis, Raynaud's phenomenon, involvement of the esophagus with dysphagia, sclerodactyly, and telangiectases; CTD, connective tissue disease; RNP, ribonucleoprotein.

Indirect immunofluorescence detects nuclear, homogeneous, rim, speckled, and nucleolar patterns (Table 10-3). The fluorescence ANA test can be regarded as a specific marker for SLE in a rim pattern with a titer of 1:160 or higher and is often indicative of the presence of anti–native or double-stranded (ds) DNA antibodies. Although anti-dsDNA has generally been regarded as the most specific marker of SLE, the lack of sensitivity makes a negative test unhelpful. Other markers that have been examined include antinucleosome antibodies, which may be more prevalent in SLE patients and may develop earlier than anti-dsDNA antibodies. This assay, however, is not widely available and has not been rigorously evaluated (47). At a titer of 1:20, about 20% of patients with DLE, most patients with systemic scleroderma, and as many as 5% of normal persons may have a positive reaction. The presence of anti-Sm is indicative of associated lupus nephritis. Antibodies against single-stranded DNA are nonspecific and are found in a variety of diseases. Anti-nRNP antibodies are of diagnostic significance only at high titers because they then indicate mixed connective tissue disease. ANA-negative sera should be examined for the presence of anti-Ro/SSA and La/SSB antibodies, characteristic of subacute and neonatal LE and SLE with genetic deficiency of complement components.

The LE cell test is of historical significance. It consisted of incubating a patient's serum with normal white blood cells. In the presence of antibody to whole nucleoprotein (LE factor), damage to the nuclei of leukocytes incited phagocytosis of affected nuclei by unaffected white blood cells. If a smear of the incubated white blood cells is made and stained with Wright's stain, the phagocytized nuclear material can be observed within some of the neutrophils as a large, round, amorphous, smoky, basophilic body of such a large size that it presses the nucleus of the neutrophil against the cell membrane. This represents the LE cell.

Direct immunofluorescence studies detect immunoreactant deposits in affected tissues, particularly the skin and kidneys. A skin biopsy (3- to 4-mm punch) is submitted in saline-impregnated gauze or phosphate-buffered saline, snap frozen, sectioned, and incubated with fluorescein-conjugated antisera to IgA, IgM, IgG, and the third component of complement (C3). In a positive test there is continuous granular deposition of usually two or more immunoreactants (in a band) along the dermal–epidermal junction (Fig. 10-2). Variables that affect test results are the site of the biopsy (sun exposed vs. sun protected), duration of the lesion (acute, subacute, chronic), and preceding therapy. The frequency and implications of positive results in DLE and SLE are summarized in Table 10-4 (48–50).

Cautious sampling and interpretation of findings are necessary to avoid false-positive and false-negative results. The presence of only one type of immunoreactant, particularly in an intermittent distribution, may be seen in chronically sun-exposed skin or with underlying disorders such as rosacea. False-negative results are often found in acute or subacute lesions and treated lesions. Optimally, an established lesion, present for 3 months or longer, that has not been treated is submitted for study (51).

TABLE 10-4 Direct Immunofluorescence in Lupus Erythematosus

Site		Result: Discoid LE	Result: Systemic LE
Sun exposed (e.g., dorsal forearm)	Involved	Positive in >90% of untreated lesions	Positive in 80%–90% of untreated lesions
Sun exposed (e.g., volar forearm)	Uninvolved	Almost always negative	Positive in >80% of untreated SLE
Non–sun exposed (e.g., buttock)	Uninvolved	Negative	With active LE: positive in >91% With inactive SLE: positive in 33% Positive result may indicate renal involvement

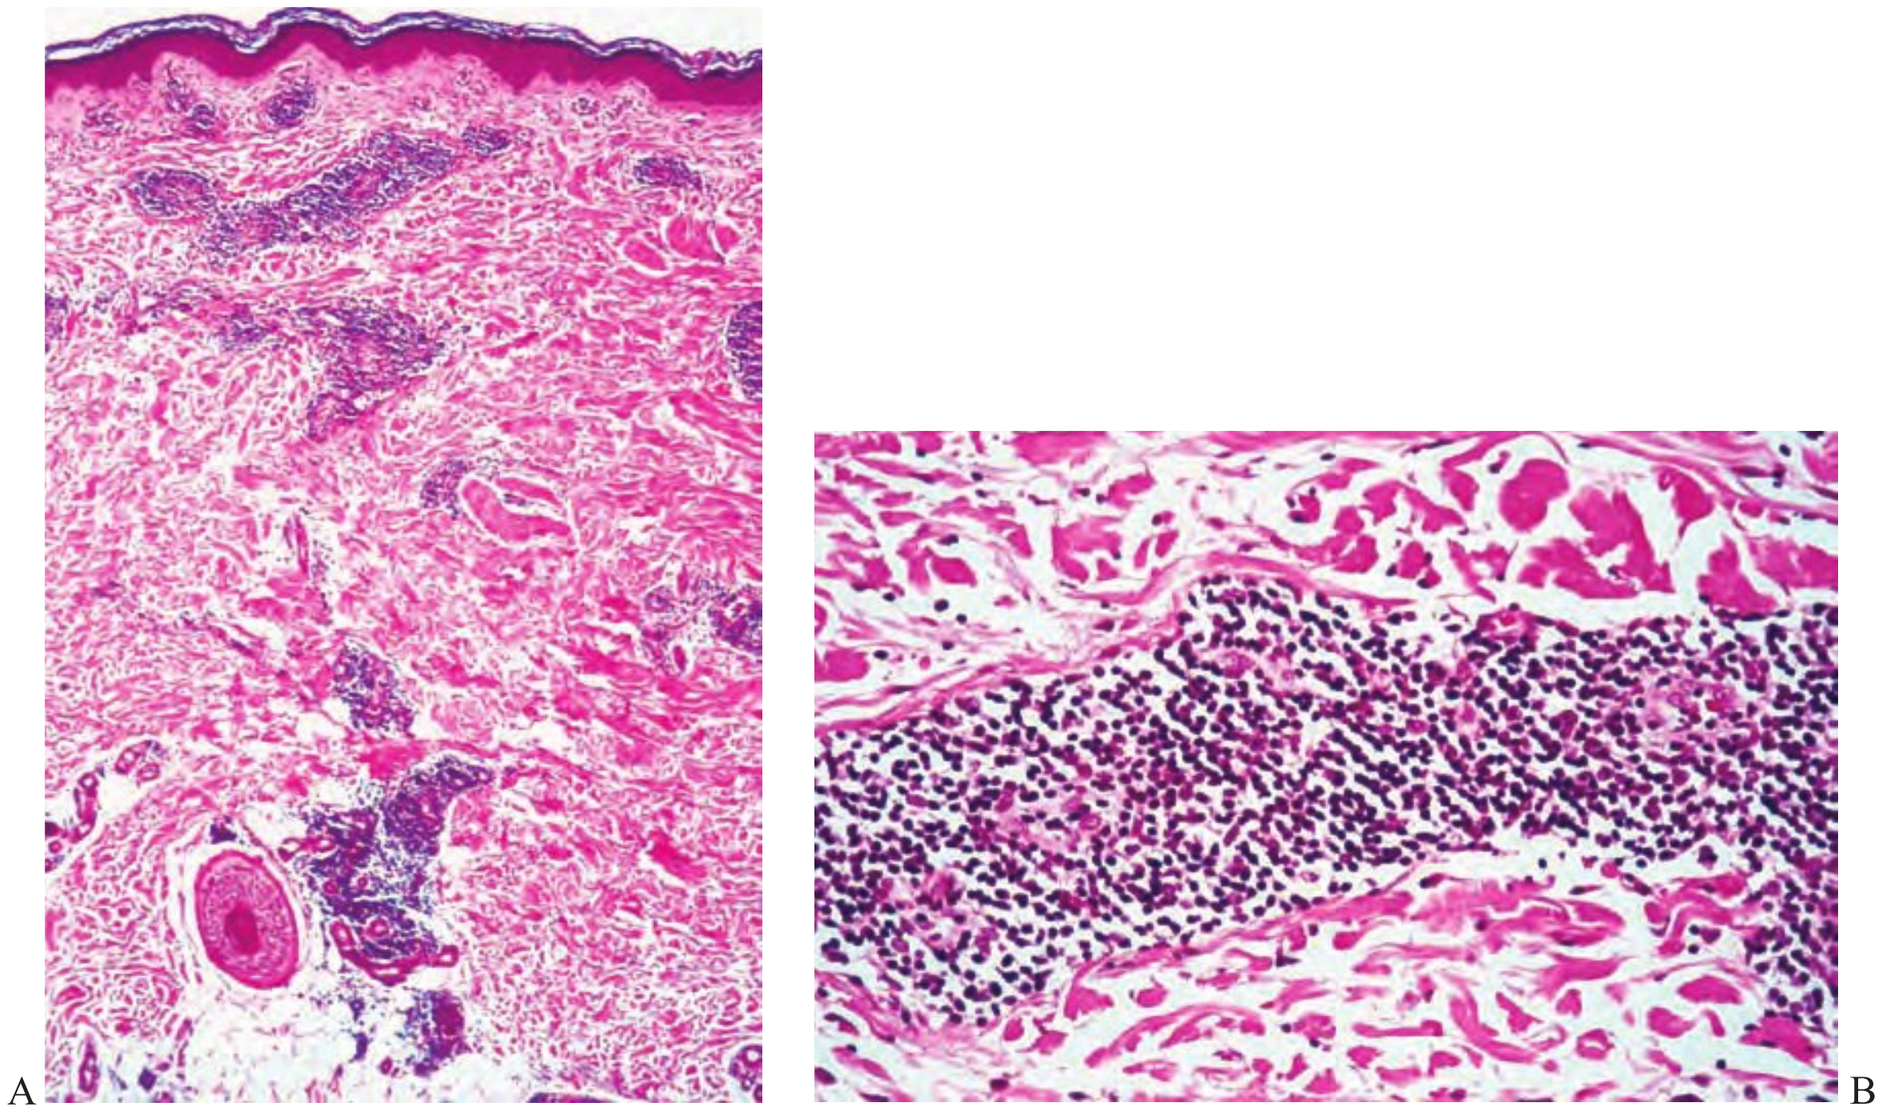
Electron microscopic examination of the cutaneous lesions of both DLE and SLE shows marked changes in the basal cells and the lamina densa. The basal cells show vacuolization of their cytoplasm, which may progress to necrosis and disintegration of the cytoplasm. The colloid or Civatte bodies that may be seen in the epidermis and in the dermis are similar in appearance on electron microscopy to those observed in lichen planus. They are finely filamentous to amorphous granular in appearance and do not possess a delimiting membrane.

The antigen–antibody complexes have been localized with immunoelectron microscopy to beneath the lamina densa. They are seen as irregular aggregates in the uppermost portion of the dermis in the ground substance and occasionally on collagen fibrils. In some instances, small amounts of reaction product are seen within the lamina densa and the lamina lucida. Localization of immune complexes in lupus erythematosus thus differs from their localization in bullous pemphigoid, in which they are situated entirely within the lamina lucida near the basal cells (see Chapter 9). In bullous SLE, direct immunoelectron microscopy of perilesional skin also shows the reaction product in a continuous bandlike distribution below the lamina densa and a separation plane in the dermis below this band, indicating early bulla formation (52).

The presence of intracytoplasmic tubuloreticular structures has been reported in the cutaneous and renal lesions of SLE and in lesions of DLE. They bear a superficial resemblance to tubuloreticular structures and internal nucleoproteins of paramyxovirus. They are a nonspecific result of cell injury related to increased interferon-α levels in lupus patients and are not specific for lupus erythematosus (52).

Jessner's Lymphocytic Infiltration of the Skin

Jessner's lymphocytic infiltration of the skin, first described in 1953 (53), is not a well-understood entity. It is characterized by asymptomatic papules or well-demarcated, slightly infiltrated red plaques, which may develop central clearing. In contrast to lesions of chronic lupus erythematosus, the surface shows no follicular plugging or atrophy. Lesions arise most often on the face but may also involve the neck and upper trunk (54). Although this disorder has been reported to occur in childhood (55), affected patients are usually middle-aged men and women.



Variable numbers of lesions (one to many) often persist for several months or several years. They may disappear without sequelae or recur at previously involved sites or elsewhere. The eruption may be precipitated or aggravated by sunlight. Antimalarial drugs and/or corticosteroids are useful in controlling this disorder.

Histopathology. The epidermis may be normal but often appears slightly flattened. In the dermis, there are moderately dense perivascular and diffuse infiltrates composed of small, mature lymphocytes admixed with occasional histiocytes and plasma cells (Fig. 10-10A, B). The infiltrate may extend around folliculosebaceous units and into subcutaneous adipose tissue.

The histologic differential diagnosis of lymphocytic infiltration of the skin includes the other six of the seven Ls: lupus erythematosus, polymorphous light eruption, lymphocytoma cutis, lues, Lyme disease, and lymphoma. Jessner's lymphocytic infiltrate is limited to sun-exposed skin and lacks the hyperkeratosis, atrophy, interface changes, mucin, and direct immunofluorescence findings noted in lupus. Therefore, lupus should be excluded with serologic and direct immunofluorescence studies. Serologic studies and the clinical distribution of lesions allow separation of lues and Lyme disease from Jessner's lymphocytic infiltrates.

Approximately 10% of cases of lupus that lack interface alterations and that show negative direct immunofluorescence studies may initially be placed into the holding category of "lymphocytic infiltrates of the skin." Polymorphous light eruptions usually show prominent papillary dermal edema; however, plaque-type polymorphous light eruption may histologically overlap with lymphocytic infiltration of the skin. Clinical features may sometimes separate these two entities.

A poorly understood entity histologically similar to Jessner's lymphocytic infiltrate is palpable migratory arciform erythema. This entity differs clinically in that it is slightly pruritic and tends to involve the trunk and proximal extremities. It waxes and wanes over days to weeks rather than weeks to months. Differences in histology have been reported but have not been thoroughly evaluated by multiple studies (56).

A B

FIGURE 10-10. Jessner's lymphocytic infiltrate. A: The epidermis is normal. The dermis contains tightly cuffed lymphocytic infiltrates following blood vessels and focally surrounding appendages. B: Higher magnification shows a purely lymphocytic infiltrate around vascular channels.

Immunohistochemical cell marker studies indicate that the predominant component of lymphocytic infiltration of the skin is a mature T lymphocyte. Phenotyping studies show predominantly $CD4^+$ T helper cell (57). Other studies have suggested a $CD8^+$ cytotoxic phenotype (58). Rearrangement of the T-cell receptor gene has not been detected in the limited number of cases studied. The relative paucity of B lymphocytes may assist in separation of this entity from lymphocytoma cutis, which usually displays larger B-cell components with or without associated germinal center formation. Lymphoma cutis may be distinguished with cell-marker analysis, which may show a high proportion of B lymphocytes with a less mature phenotype than expected in skin, or cells with aberrant expression of surface antigens.

Pathogenesis. Opinion varies as to whether Jessner's lymphocytic infiltrate of the skin is a distinct entity. The following four views have been expressed: (a) clinical, histologic, and immunohistochemical findings warrant its distinction as a separate entity (59); (b) although some cases represent an entity, others are DLE; (c) all cases are DLE; and (d) it represents an abortive or initial phase of any of the four other diseases with a patchy dermal infiltrate—that is, discoid lupus erythematosus, the plaque type of polymorphous light eruption, lymphocytoma cutis, and lymphocytic lymphoma. The last view appears to be the most likely (60). Isolated reports of Jessner's lymphocytic infiltrate have been reported in association with angiotensin-converting enzyme inhibitor, enalapril, and a synthetic polypeptide, glatiramer acetate, used to treat multiple sclerosis (61,62). Isolated familial cases have also been reported (60).

The diagnosis of lymphocytic infiltration of the skin depends on clinicopathologic correlation and on longitudinal follow-up. It may be used as a preliminary diagnostic term until a more definitive diagnosis is possible.

MIXED CONNECTIVE TISSUE DISEASE

Overlapping findings of SLE, scleroderma, and polymyositis associated with the presence of high titers of anti-U1 ribonucleoprotein (RNP) antibodies have been recognized since 1972 as the syndrome of *mixed connective tissue disease* (MCTD) (63). The first clue to the diagnosis is usually a positive, high-titer speckled ANA. The clinical presentation includes, but is not limited to, edema of the hands, acrosclerosis, Raynaud's phenomenon, synovitis of one or more joints, and myositis that is documented with biopsy or serum elevations of muscle enzymes. Esophageal hypomotility and pulmonary disease may be seen as well. The diagnosis of MCTD may not be made at the outset because symptoms may present in an asynchronous fashion.

Cutaneous lupus erythematosus lesions are found in approximately half of the patients, about as often as "sausage fingers" or sclerodactyly. They cover the entire spectrum of cutaneous lupus erythematosus. Most commonly there are diffuse,

nonscarring, poorly demarcated subacute lesions, but some patients show acute malar eruptions as seen in SLE or persistent scarring lesions as seen in DLE.

Patients with high-titer anti-U1 RNP antibodies have a low prevalence of serious renal disease and life-threatening neurologic complications. Although the prognosis of MCTD compares favorably to that of SLE, death may occur from progressive pulmonary hypertension and cardiac complications (64).

Histopathology. If cutaneous lesions of lupus erythematosus are present, the histologic findings correspond to the type of lesion described in the section on DLE and SLE.

Histogenesis. MCTD, in contrast with most cases of SLE, has no antibodies to DNA. The absence of such antibodies accounts for the rarity of renal disease.

Indirect immunofluorescence studies show the presence of very high titers of serum antibodies directed against extractable ribonuclease-sensitive antigens known as small nuclear ribonucleoproteins (snRNPs). They characterize MCTD but are not specific for it. They produce a fine speckled ANA pattern at high dilutions. This speckled pattern corresponds to the widespread distribution of snRNP in the nucleus at sites of active gene transcription, where messenger RNA is being processed.

Direct immunofluorescence staining of normal skin shows deposition of IgG in a speckled (particulate) pattern in epidermal nuclei. Although this finding is typical of MCTD, it is found occasionally also in patients with SLE and other connective tissue diseases (65). In addition, patients with MCTD may show a subepidermal lupus band in normal skin. Such a band has been observed in normal sun-exposed skin in about 20% of the cases.

DERMATOMYOSITIS

Dermatomyositis manifests as an inflammatory myopathy with characteristic cutaneous findings. In the absence of cutaneous findings, the diagnosis of polymyositis is applied. Cutaneous findings alone, without muscular involvement, have been termed *amyopathic dermatomyositis* or *dermatomyositis sine myositis* (66).

Both dermatomyositis and polymyositis are uncommon diseases that have a similar incidence. Both have two peaks of occurrence: one in childhood and one between the ages of 45 and 65 years (51). In some instances, the cutaneous eruption precedes the development of muscular weakness by many months or even several years.

The four systemic and single cutaneous diagnostic criteria for dermatomyositis are symmetric proximal muscle weakness, elevated muscle enzymes, an abnormal electromyelogram in the absence of neuropathy, consistent muscle biopsy changes, and cutaneous findings (67). Involvement of the skeletal muscles causes progressive weakness, vague muscular pain, and, later, muscle atrophy. The proximal muscles of the extremities and the anterior neck muscles often are the first to be involved. Involvement of the pharynx may result in dysphagia and aspiration of food, and involvement of the diaphragm and the intercostal muscles may lead to respiratory failure. Arthritis and arthralgias may occur in up to 25% of cases. Other, less common systemic manifestations, such as interstitial pneumonitis, dysphagia, dysphonia, and cardiac conduction abnormalities, portend a worse prognosis.

Two distinctive cutaneous lesions are found in dermatomyositis. One is violaceous, slightly edematous periorbital patches that primarily involve the eyelids, known as the *heliotrope rash*. The other is discrete red-purple papules over the bony prominences, particularly the knuckles, knees, and elbows, known as *Gottron's papules*. These may evolve into atrophic plaques with pigmentary alterations and telangiectasia and are then known as *Gottron's sign*.

Other cutaneous findings include periungual telangiectasia, hypertrophy of cuticular tissues associated with splinter hemorrhages, photosensitivity, and poikiloderma. Often lesions resembling the erythematous-edematous lesions seen in subacute cutaneous or systemic lupus erythematosus may be found. Subcutaneous and periarticular calcification may be found, particularly in affected children. Calcinosis is usually seen centered in the proximal muscles of the shoulders and pelvic girdle. Childhood onset may also be associated with lipodystrophy and insulin resistance (68). Other uncommonly reported cutaneous findings include gingival telangiectasia, angiokeratomas, panniculitis, flagellate erythema, scleromyxedematous lesions, and pityriasis rubra pilaris–like lesions (69–72).

Controversy exists over the association of dermatomyositis with malignancy (73). Interpretation of reports with incidences of 6% to 50% is hampered by the asynchronous development of malignancy in relation to the dermatomyositis. Some series fail to show a significant difference between affected patients and the control population. If malignancy arises with dermatomyositis, it usually occurs in the adult form. Some sources indicate that this association is also present in the childhood form, whereas others view such reports with skepticism. Various tumors have been reported, with ovarian carcinoma perhaps being most frequent (74). Larger population-based studies have suggested an incidence of carcinoma at between 20% and 25% (75). Although ovarian carcinoma is still considered the most common associated malignancy, other tumors reported include lung, prostatic, pancreatic, and gastrointestinal carcinomas. In younger males, testicular carcinoma is more prevalent. In Asians, there is an increased association with nasopharyngeal carcinoma (76).

As with lupus erythematosus, the pathogenesis of the disease is uncertain. Associated antibodies include PM1, Jo1 (correlates with pulmonary fibrosis), Ku (associated with sclerodermatomyositis), and M2. Other recently reported markers include autoantibodies to 155kd, and Se antigens have been reported to be associated with amyopathic dermatomyosis. (77). A single case of a cutaneous eruption mimicking dermatomyositis after treatment with imatinib mesylate has

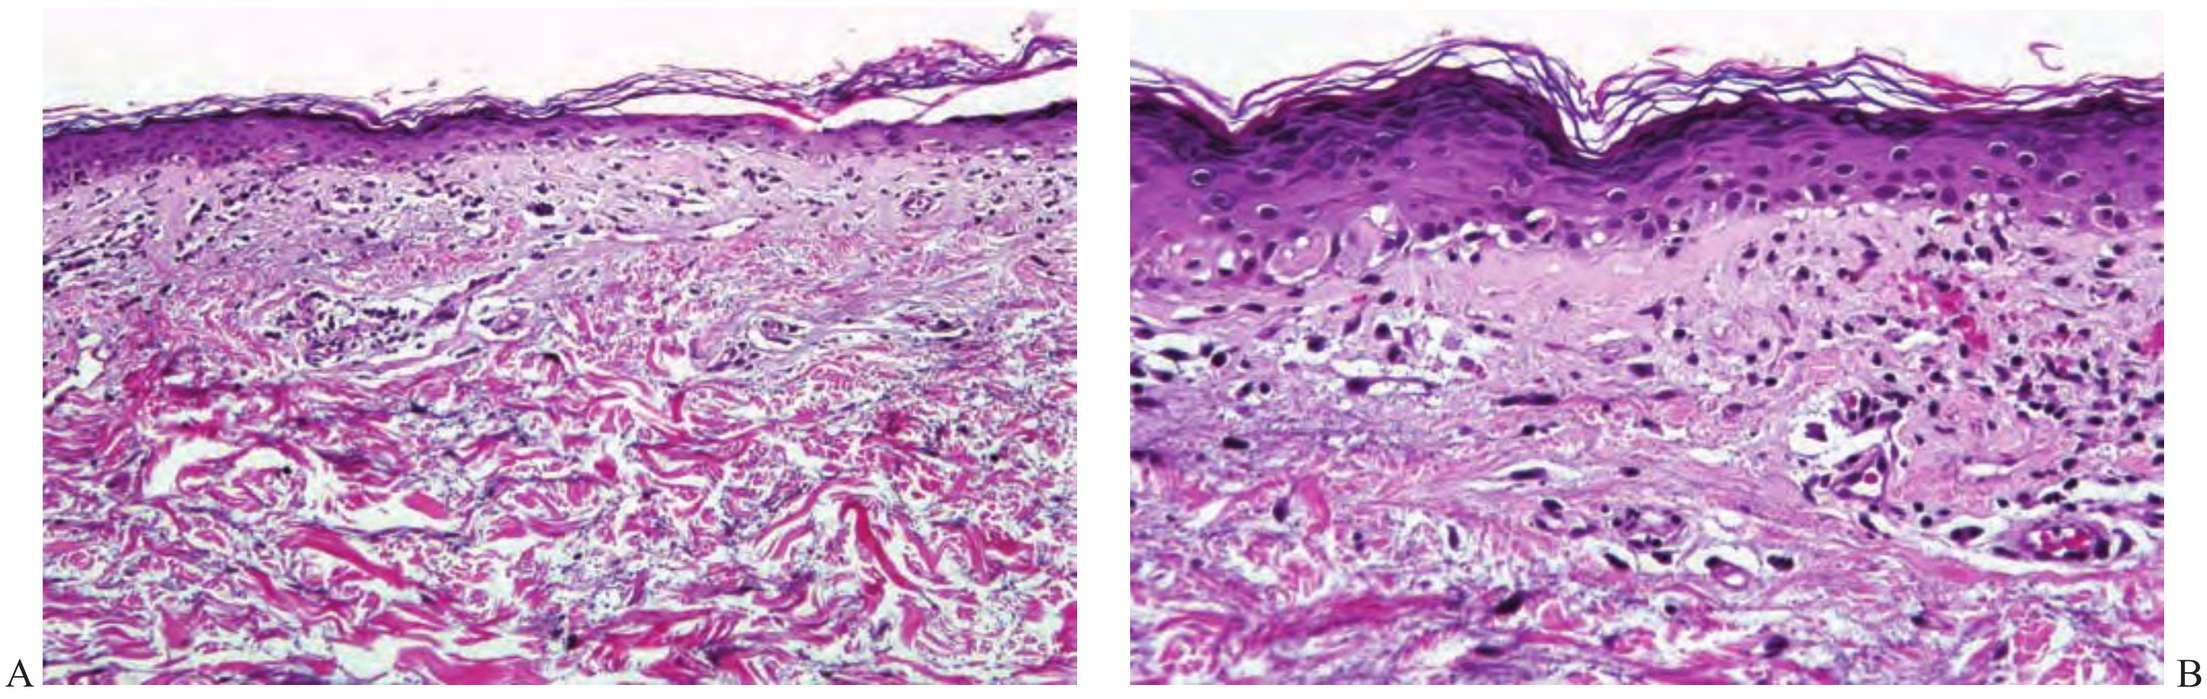


FIGURE 10-11. Dermatomyositis. A: An atrophic epidermis shows marked vacuolar alteration of basilar keratinocytes associated with a sparse lymphocytic inflammatory infiltrate around superficial dermal vessels. B: Marked vacuolar alteration of basilar keratinocytes associated with sparse lymphocytic infiltrates and papillary dermal melanophages.

been reported (78). Medications including hydroxyurea, quinidine, nonsteroidal antiinflammatory agents, d-penicillamine, isoniazid, and 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors have been reported to exacerbate dermatomyositis.

On the whole, the prognosis of dermatomyositis is favorable, especially when treatment with corticosteroids is used. Other therapeutic agents include methotrexate, azathioprine, cyclophosphamide, mycophenolate mofetil, chlorambucil, and cyclosporine. The mortality has been reported to be approximately 14% in some series, with metastatic malignancy a frequent cause of death (79).

Histopathology. The erythematous-edematous lesions of the skin in dermatomyositis may show only nonspecific inflammation. However, quite frequently the histologic changes are indistinguishable from those seen in SLE. There is epidermal atrophy, basement membrane degeneration, vacuolar alteration of basilar keratinocytes, a sparse lymphocytic inflammatory infiltrate around blood vessels, and interstitial mucin deposition (Fig. 10-11A, B) (80). With severe inflammatory changes, there may be associated subepidermal fibrin deposition. Although immune complexes are not detected at the dermal–epidermal junction as in lupus erythematosus, it should be remembered that up to 50% of subacute cutaneous lupus biopsies can also have a negative direct immunofluorescence.

Old cutaneous lesions with the clinical appearance of poikiloderma atrophicans vasculare usually show a bandlike infiltrate under an atrophic epidermis with hydropic degeneration of the basal cell layer (see also the section on poikiloderma atrophicans vasculare). The Gottron's papules overlying the knuckles also show vacuolization of the basal cell layer but acanthosis rather than epidermal atrophy (81). Subcutaneous tissue may show focal areas of panniculitis associated with mucoid degeneration of fat cells in early lesions. Extensive areas of calcification may be present in the subcutis at a later stage (see calcinosis cutis, Chapter 17).

Magnetic resonance imaging permits noninvasive assessment of muscle inflammation and may serve as a guide in locating a site for muscle biopsy. Tender proximal muscles of an extremity yield more useful information than atrophic, weak muscles, which show end-stage changes. Three types of changes may be observed in active disease: (a) interstitial inflammatory infiltrates composed of lymphocytes and macrophages, (b) segmental muscle fiber necrosis (loss of skeletal muscle transverse striation, hyalinization of the sarcoplasm, fragmentation and/or phagocytosis of degenerated muscle fragments), or (c) vasculopathy (82). The latter entity may be seen in the childhood form and shows immunocomplex deposition in vessel walls (83). Old lesions usually show a rather nonspecific picture of atrophy of the muscle fibers and diffuse interstitial fibrosis with relatively little inflammation.

Systemic Lesions. Changes in organs other than the skin and the striated muscles occur only rarely in dermatomyositis, in contrast to SLE and systemic scleroderma. The myocardium may show changes identical to those in the skeletal muscle but less severe. Ulcerative lesions in the gastrointestinal tract, caused by vascular occlusions, have also been described (84).

Histogenesis. On electron microscopic examination the degenerative changes include focal disintegration of myofilaments and myofibrils, vacuolization, and accumulation of lipid and lysosomes within muscle fibers. As in lupus erythematosus, nonspecific intracytoplasmic tubuloreticular structures may be found in skin and muscles.

Differential Diagnosis. Differentiation of the cutaneous lesions of dermatomyositis from those of subacute cutaneous or systemic lupus erythematosus may be impossible on a histologic basis. It may also be impossible on clinical grounds in cases in which muscular weakness is mild or absent, as it may be in the early stage of dermatomyositis. In such cases, laboratory tests are of great value. The most important is the

lupus band test, which is always negative in lesions of dermatomyositis (85), whereas in lesions of lupus erythematosus it is positive in 90% of the cases. Other tests that are usually negative in dermatomyositis and often positive in lupus erythematosus include urinalysis and renal function tests, as well as tests for antinuclear antibodies, anti–native DNA antibodies, and antibodies to ribonucleoprotein. Rarely, patients with dermatomyositis demonstrate a positive Ro antibody titer. Patients with active myositis show an elevation of serum creatine kinase and aldolase.

POIKILODERMA ATROPHICANS VASCULARE

Poikiloderma atrophicans vasculare may be seen in three different settings: (a) in association with three genodermatoses, (b) as an early stage of mycosis fungoides, and (c) in association with dermatomyositis and, less commonly, lupus erythematosus.

The three genodermatoses in which the cutaneous lesions have the appearance of poikiloderma atrophicans vasculare are (a) poikiloderma congenitale of Rothmund-Thomson (see Chapter 6), with the lesions of poikiloderma present largely on the face, hands, and feet, and occasionally also on the arms, legs, and buttocks; (b) Bloom's syndrome (see Chapter 6), with poikiloderma-like lesions on the face, hands, and forearms; and (c) dyskeratosis congenita (see Chapter 6), in which there may be extensive netlike pigmentation of the skin suggestive of poikiloderma atrophicans vasculare.

Poikiloderma-like lesions as features of early mycosis fungoides may be seen in one of two clinical forms: either as the large plaque type of parapsoriasis en plaques, also known as poikilodermatous parapsoriasis (see Chapter 7), or as parapsoriasis variegata, also called parakeratosis variegata, which, in its early state, shows papules arranged in a netlike pattern (see Chapter 7). Although these two types of parapsoriasis represent an early stage of mycosis fungoides, not all cases progress clinically into fully developed mycosis fungoides (86). Cases in which no progression toward mycosis fungoides is observed have been described also as *idiopathic poikiloderma atrophicans vasculare* (87).

The third group of diseases in which lesions of poikiloderma atrophicans vasculare occur are represented by dermatomyositis and SLE. Dermatomyositis is much more commonly seen as the primary disease than lupus erythematosus, and the association with dermatomyositis often is referred to as poikilodermatomyositis. In contrast to mycosis fungoides, in which poikilodermatous lesions are seen in the early stage, the lesions found in dermatomyositis and SLE generally represent a late stage.

Clinically, the term poikiloderma atrophicans vasculare is applied to lesions that, in the early stage, show erythema with slight, superficial scaling, a mottled pigmentation, and telangiectases. In the late stage the skin appears atrophic and the erythema is less pronounced than in the early stage, but the mottled pigmentation and the telangiectases are more pronounced. The clinical picture then resembles that of chronic radiodermatitis.

Histopathology. In its early stage poikiloderma atrophicans vasculare, without respect to its cause, shows moderate thinning of the stratum malpighii, effacement of the rete ridges, and hydropic degeneration of the basal cells. In the upper dermis there is a bandlike infiltrate, which in places invades the epidermis. The infiltrate consists mainly of lymphoid cells, but it also contains a few histiocytes. Melanophages filled with melanin as a result of pigmentary incontinence are found in varying numbers within the infiltrate. In addition, there is edema in the upper dermis, and the superficial capillaries are often dilated. In the late stage the epidermis is apt to be markedly thinned and flattened, but the basal cells still show hydropic degeneration. Melanophages and edema of the upper dermis are still present, and telangiectasia may be pronounced.

The amount and type of dermal infiltrate vary with the underlying cause. In poikiloderma atrophicans vasculare associated with one of the genodermatoses the mononuclear infiltrate is mild and may be absent in the late stage (88). Similarly, in the late stage of poikiloderma seen in association with dermatomyositis or SLE there is only slight dermal inflammation (80). In contrast, the amount of inflammatory infiltrate seen in poikiloderma associated with early mycosis fungoides increases rather than decreases with time (Fig. 10-12). In addition, cells with large, hyperchromatic nuclei, so-called mycosis cells, are likely to be present, and there is often marked epidermotropism of the infiltrate, which may result in Pautrier microabscesses. Cell-marker analysis of such cases has shown most cells to be T-helper/inducer ($CD4^+$) lymphocytes that lack Leu-8 (CD7) and/or Leu-9 expression, as seen in cutaneous T-cell lymphoma (89).

SCLERODERMA

Scleroderma (from the Greek *skleros*, hard, and *derma*, skin) is a connective tissue disorder characterized by thickening and fibrosis of the skin. Two types of scleroderma exist: circumscribed scleroderma (*morphea*) and systemic scleroderma (*progressive systemic sclerosis*). They are somewhat analogous to the purely cutaneous form of lupus erythematosus (DLE) and the cutaneous plus visceral involvement in systemic lupus erythematosus. Rarely, morphea and systemic scleroderma may coexist. In such instances, the manifestations of morphea arise first and are extensive, whereas those of systemic scleroderma are mild and nonprogressive (90). Rarely, the manifestations of systemic scleroderma precede those of morphea (91).

There are also two variants of morphea: (a) atrophoderma of Pasini and Pierini and (b) eosinophilic fasciitis of Shulman. The latter disease differs sufficiently from morphea, and so it will be discussed separately.

Hardening of the skin (sclerodermoid changes) may also arise in association with genetic, metabolic, neurologic, and immunologic disorders, with occupational or chemical exposures, in association with malignancy, or as a sequela of infection (92). Genetic disorders that may show sclerodermatous

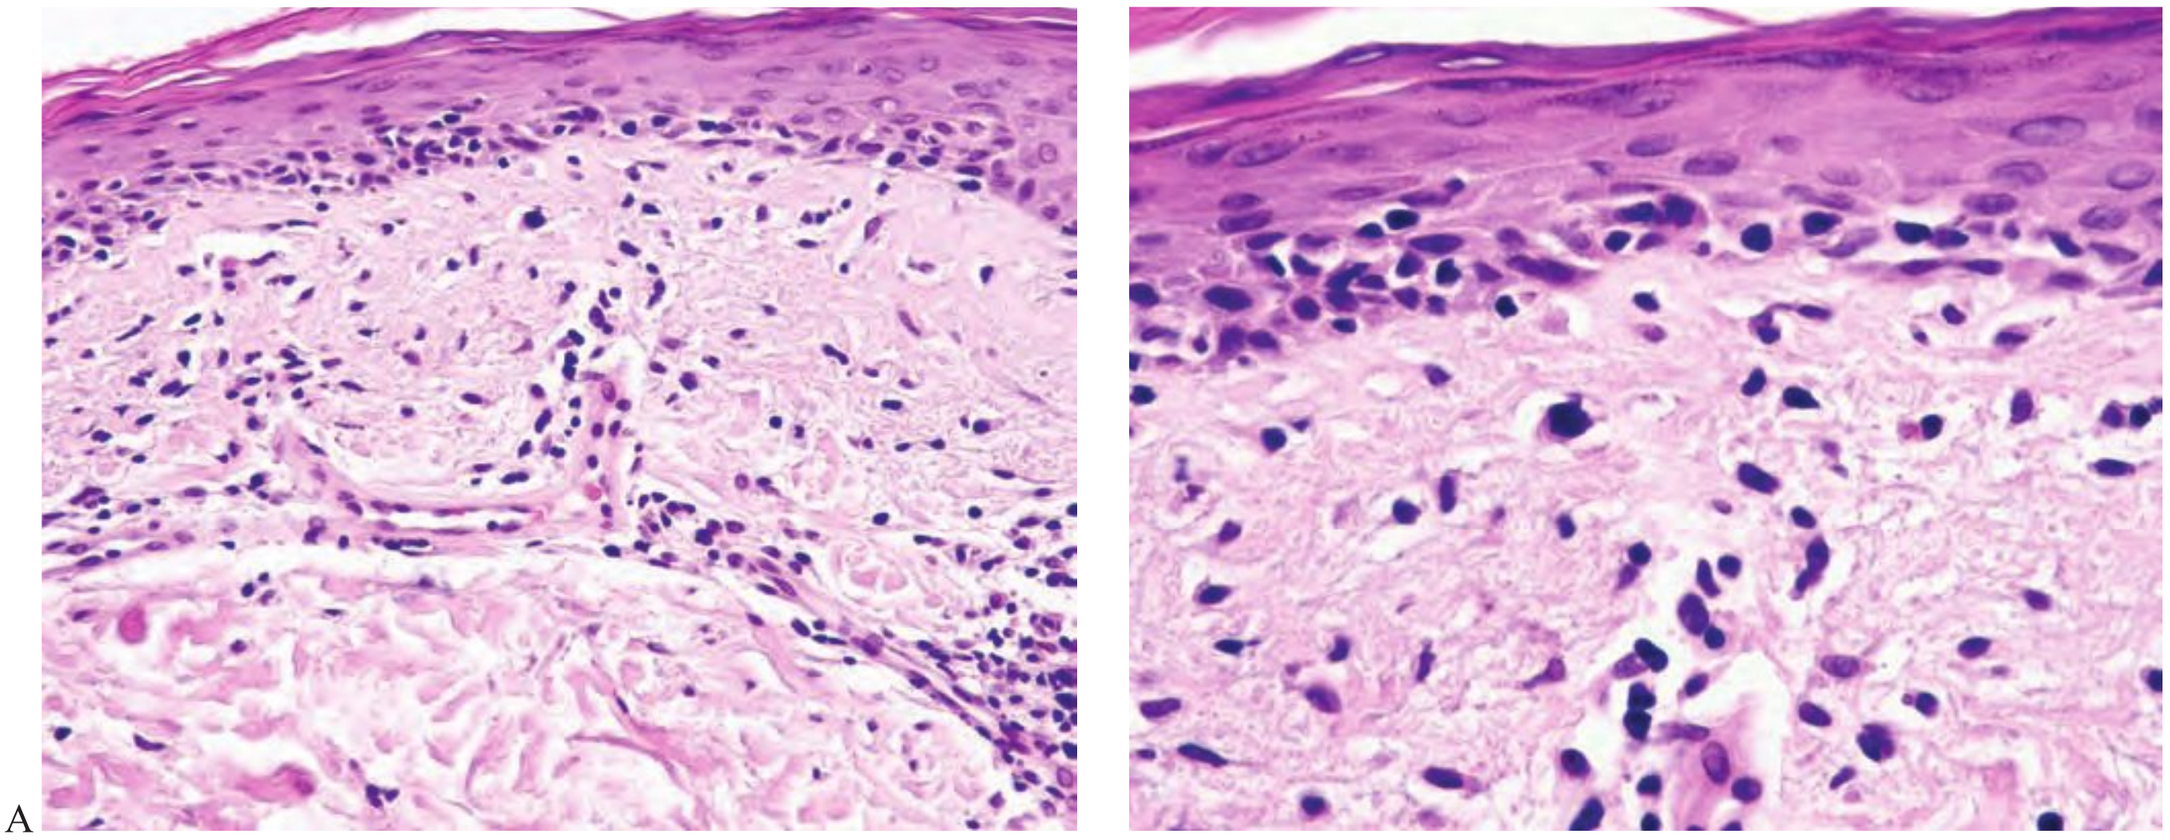

FIGURE 10-12. Poikiloderma. A: The epidermis appears flattened and shows hydropic degeneration of basal cells. B: The upper superficial contains a bandlike infiltrate, which in places extends into the epidermis.

cutaneous changes include phenylketonuria, progeria, Rothmund-Thomson syndrome, and Werner's syndrome. Individuals at risk are jackhammer and chain saw operators and those exposed to polyvinyl chloride, silica, and epoxy resins. Patients with metabolic disorders such as porphyria cutanea tarda, primary systemic amyloidosis, Hashimoto's disease, carcinoid syndrome, and childhood diabetes mellitus may show similar cutaneous changes. Chronic graft-versus-host disease frequently shows sclerodermatous changes, and scattered reports in the literature indicate such changes may arise subsequent to silicone and paraffin injections for cosmetic procedures (93). Chemical agents have been known to induce thickening and hardening of the skin. Specific compounds include polyvinyl chloride, bleomycin, pentazocine, L-5 hydroxytryptophan and carbidopa (94), Spanish rapeseed oil (95), and L-tryptophan (eosinophilia-myalgia syndrome) (96).

Morphea

In morphea, or circumscribed scleroderma, the lesions usually are limited to the skin and to the subcutaneous tissue beneath the cutaneous lesions. Occasionally, however, the underlying muscles and rarely the underlying bones are also affected.

Morphea may be divided according to morphology and distribution of lesions into six types: guttate, plaque, linear, segmental, subcutaneous, and generalized. Eosinophilic fasciitis, even though it is the fascial component of subcutaneous morphea, is discussed separately because of its somewhat different clinical and histologic appearance.

Guttate lesions occur almost always in association with lesions of the plaque type. Guttate lesions are small and superficial; they resemble the lesions of lichen sclerosus et atrophicus but do not show hyperkeratosis or follicular plugging.

Lesions of the plaque type—the most common manifestation of morphea—are round or oval but through coalescence may assume an irregular configuration. They are indurated, have a smooth surface, and show an ivory color. As long as they are enlarging, they may show a violaceous border, the so-called lilac ring.

Lesions of the linear type occur predominantly on the extremities and on the anterior scalp. When one or several extremities are involved, there is often, in addition to induration of the skin, marked atrophy of the subcutaneous fat and of the muscles, resulting in contractures of muscles and tendons and ankyloses of joints. In children it may result in impaired growth of the affected limb (97). On the anterior portion of the scalp and on the forehead, linear morphea often has the configuration of the stroke of a saber (*coup de sabre*) (72).

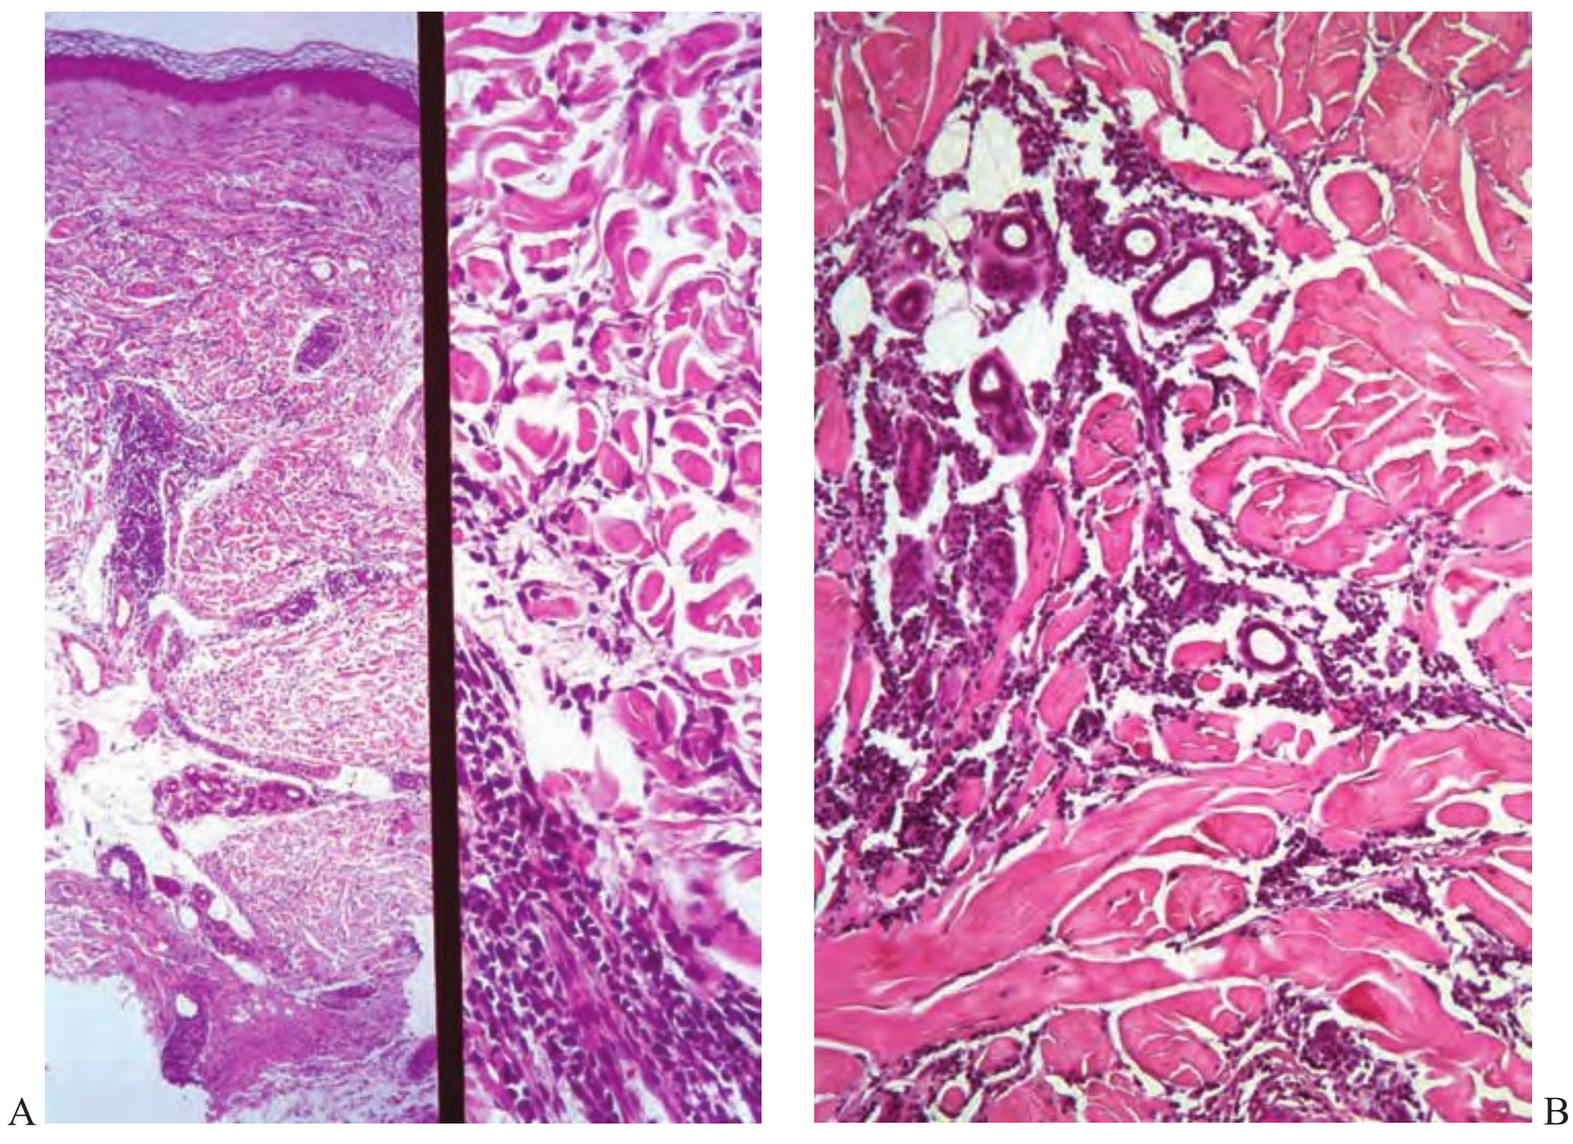
Segmental morphea occurs on one side of the face, resulting in hemiatrophy. Occasionally, morphea en coup de sabre and facial hemiatrophy occur together (98). This manifestation of morphea typically occurs in children and can often be associated with neurologic deficits (99). Due to a high incidence of overlap between the two conditions and the similar histopathology, some authors feel that they represent slightly different manifestations of the same process. Retrospective studies have estimated the coincidence of the conditions at between 36% and 42% (100,101).

In subcutaneous morphea (morphea profunda) the involved skin feels thickened and bound to the underlying fascia and muscle. The involved plaques are ill defined, and the skin of these plaques is smooth and shiny (102).

Generalized morphea comprises very extensive cases showing a combination of several of the five types just described. Although it is seen mainly in children, in whom it has been described as disabling pansclerotic morphea (90), it

can also occur in adults. Rarely, bullous lesions are seen in patients with generalized morphea (103).

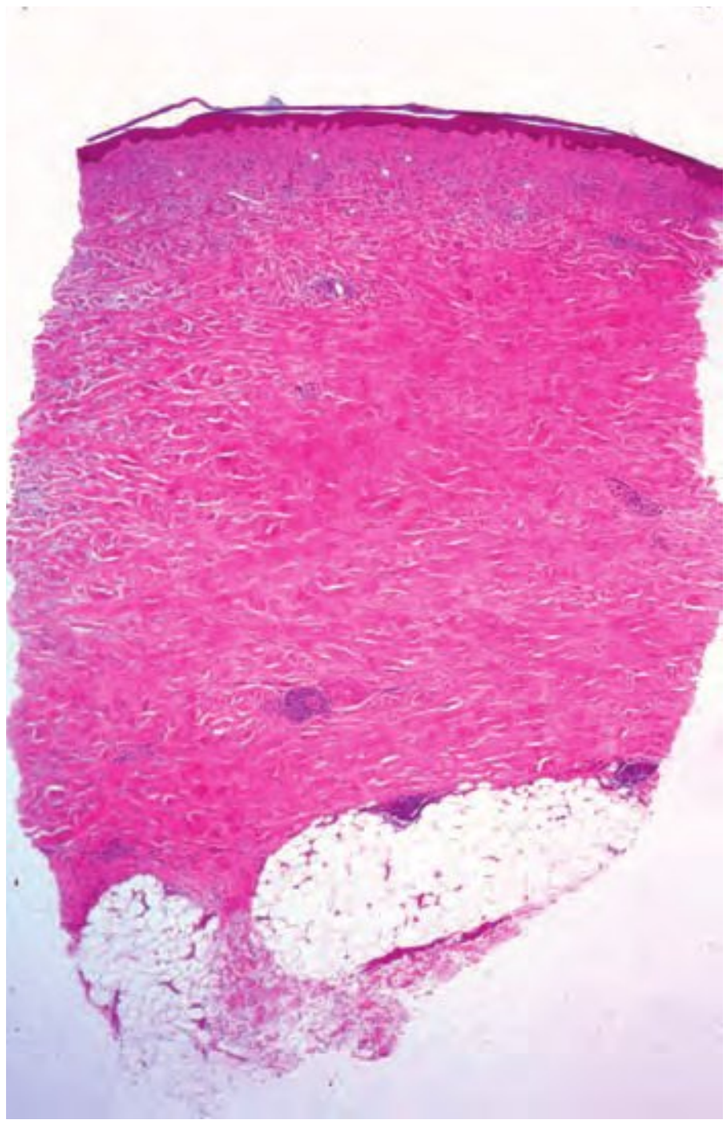
There are several reported cases of morphea that involve the superficial reticular dermis (superficial morphea) as contrasted with its usual involvement of the deep reticular dermis (104). The clinical impact of the depth of involvement is unclear. The coexistence of lesions of morphea and lichen sclerosus et atrophicus is worthy of note.



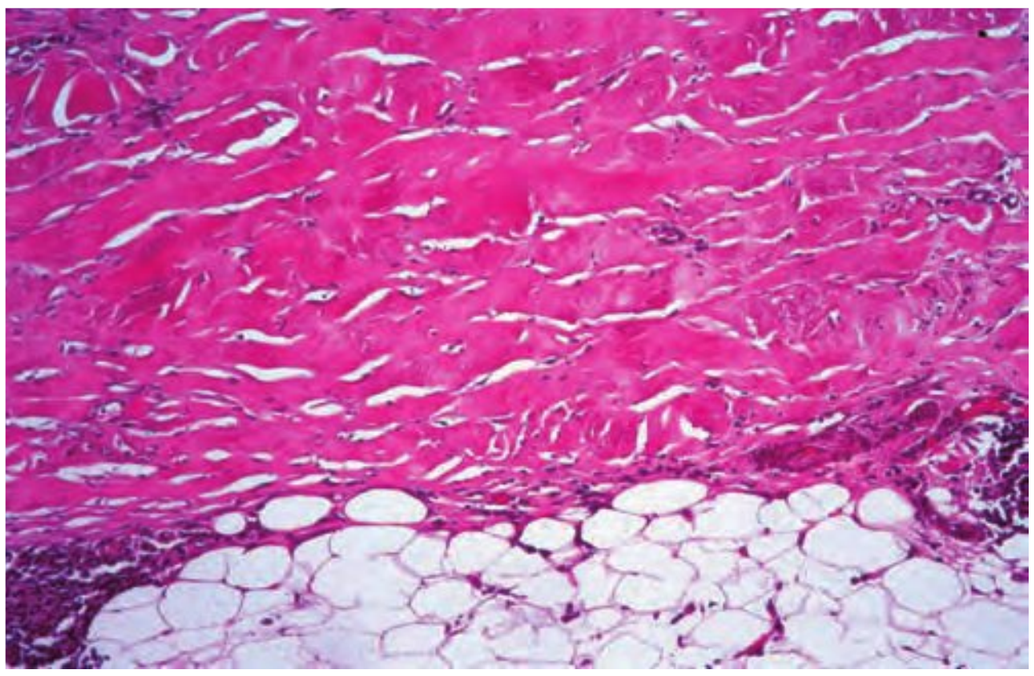
There is conflicting data regarding *Borrelia burgdorferi* infection in cases of morphea. Studies indicating that such a relationship exists are primarily from Europe (105). Studies in North America and some from Europe have resulted in negative findings (106).

Histopathology. The different types of morphea cannot be differentiated histologically. Rather, they differ in regard to severity and depth of involvement of the skin. Therefore, it is of great importance that the biopsy specimen include adequate subcutaneous tissue because most of the diagnostic alterations are seen in the lower dermis and in the subcutis.

Early inflammatory, intermediate, and late sclerotic stages exist. In the early inflammatory stage, found particularly at the violaceous border of enlarging lesions, the reticular dermis shows interstitial lymphoplasmacytic infiltrates with or without eosinophils among slightly thickened collagen bundles (Fig. 10-13A). As lesions become established, the inflammatory infiltrates surround eccrine coils and are associated with hypocellular collagen bundles and reduced numbers of surrounding adipocytes (Fig. 10-13B). A much more pronounced inflammatory infiltrate than that seen in the dermis often involves the subcutaneous fat and extends upward toward the eccrine glands. Trabeculae subdividing the subcutaneous fat are thickened because of the presence of an inflammatory infiltrate and deposition of new collagen. Large areas of subcutaneous fat are replaced by newly formed collagen, which is composed of fine, wavy fibers rather than bundles and stains only faintly with hematoxylin-eosin (107). Vascular changes in the early inflammatory stage generally are mild both in the dermis and in the subcutaneous tissue. They may consist of endothelial swelling and edema of the walls of the vessels (108).



In the late sclerotic stage, as seen in the center of old lesions, the inflammatory infiltrate has disappeared almost completely, except in some areas of the subcutis. The epidermis is normal. The collagen bundles in the reticular dermis often appear thickened, closely packed, and hypocellular and stain more deeply eosinophilic than in normal skin (Fig. 10-13C, D). In the papillary dermis, where the collagen normally consists of loosely arranged fibers, the collagen may appear homogeneous.



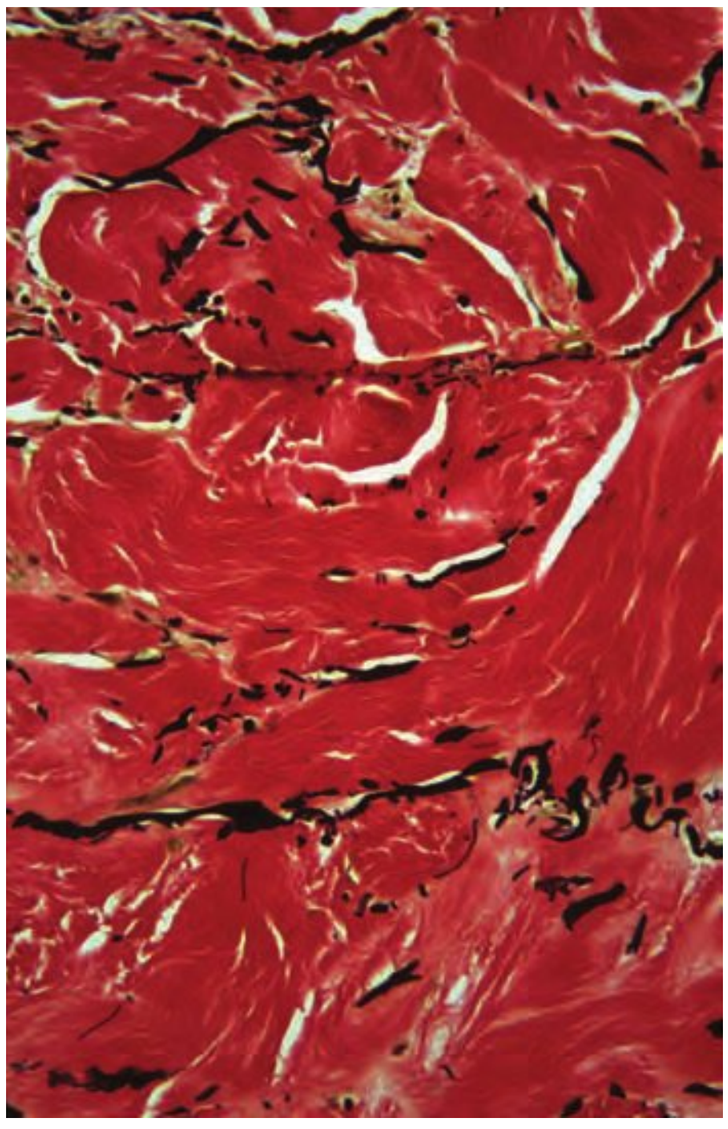
The eccrine glands appear markedly atrophic, have few or no adipocytes surrounding them, and appear surrounded by newly formed collagen (Fig. 10-13B). In addition, instead of

A B

FIGURE 10-13. Morphea. A: The early inflammatory phase of morphea, where there is an interstitial lymphoplasmacytic infiltrate distributed among deep dermal collagen bundles. Collagen bundles are minimally swollen. B: Over time, collagen bundles become thickened, hypocellular, and swollen. Lymphoplasmacytic inflammatory infiltrates separate such collagen strands, surround eccrine coils in the deep dermis, and are associated with loss of adipocytes around eccrine apparatus. (continued)

C 

D



E

FIGURE 10-13. (continued) C: An established lesion of morphea: a "square" appearance in a punch biopsy. Note that appendages such as pilar apparatus are absent. Inflammation is sparse and localized at the dermal–subcutaneous interface. D: The trabeculae subdividing the subcutaneous fat are thickened and there is a patchy lymphoplasmacytic infiltrate. Pale, thickened collagen bundles appear arranged parallel to each other. E: Elastic stains demonstrate thick, coarse elastic fibers separated by collagen. They have a somewhat parallel array.

lying near the dermal–subcutaneous junction as in normal skin, they seem to lie higher in the dermis as a result of the replacement of most of the subcutaneous fat by newly formed collagen. This collagen consists of thick, pale, sclerotic, homogeneous, or hyalinized bundles with only few fibroblasts (hypocellular). Few blood vessels are seen within the sclerotic collagen; they often have a fibrotic wall and a narrowed lumen. Elastic stains show thick elastic fibers arranged parallel to hypocellular collagen strands and parallel to the epidermal surface (Fig. 10-13E) (109).

The fascia and striated muscles underlying lesions of morphea may be affected in the linear, segmental, subcutaneous, and generalized types. The fascia shows fibrosis and sclerosis similar to that seen in subcutaneous tissue. The muscle fibers appear vacuolated and separated from one another by edema and focal collections of inflammatory cells (110).

TABLE 10-5 Contrasting Features of Morphea and Lichen Sclerosus Et Atrophicus

	Morphea	Lichen sclerosus et atrophicus
Epidermis	Relatively normal	Thinning of rete
	No follicular plugging	Follicular plugging
Dermal–epidermal junction	No hydropic degeneration	Hydropic degeneration of basilar cells
	Subepidermal separation infrequent	Often subepidermal bullae
Dermis	Appears homogenized	Marked edema
	Papillary dermal collagen and elastic fibers present	Elastic fibers absent
Subcutis	Inflammation	No inflammation or fibrosis
	Fibrosis	

Bullae, seen only on rare occasions in generalized and in subcutaneous morphea, arise subepidermally, probably as a result of lymphatic obstruction, causing subepidermal edema.

Differential Diagnosis. Contrasting features of morphea and lichen sclerosus et atrophicus are summarized in Table 10-5. They include relatively little epidermal change in morphea, as compared with thinning of the rete ridges, follicular plugging, and interface alterations of lichen sclerosus. The reticular dermal changes of fibrosis and inflammation in morphea contrast with the edema and loss of elastic tissue in lichen sclerosus. Histologic differentiation of the late stage of morphea from lichen sclerosus et atrophicus may cause difficulties, particularly in view of the fact that the two conditions may coexist.

Systemic Scleroderma

In systemic scleroderma, in addition to involvement of the skin and the subcutaneous tissue, visceral lesions are present, leading to death in some patients. The indurated lesions of the skin are not sharply demarcated or "circumscribed," as in morphea, although a few well-demarcated morphea-like patches may occasionally be seen.

Cutaneous involvement usually starts peripherally on the face and hands, gradually extending to the forearms. Facial changes include a masklike, expressionless face, inability to wrinkle the forehead, a beaklike nose, and tightening of the skin around the mouth associated with radial folds. The hands show nonpitting edema involving the dorsa of the fingers, hands, and forearms. Gradually the fingers become tapered, the skin becomes hard, and flexion contractures form. These changes are referred to as acrosclerosis and are associated with Raynaud's phenomenon, which may precede other manifestations by months or even years. Microscopic examination of the nail fold capillary beds shows tortuosity and redundancy of capillary loops with dilation of the arterioles and venules. Such abnormalities may occasionally be seen in patients with localized scleroderma and herald coexisting or evolving systemic sclerosis (111).

Systemic sclerosis with limited scleroderma, known as CREST syndrome, is associated with Raynaud's phenomenon in virtually all affected patients. This variant of acrosclerosis, which frequently but not invariably has a favorable prognosis, consists of several or all of the following manifestations: calcinosis cutis, Raynaud's phenomenon, involvement of the esophagus with dysphagia, sclerodactyly, and telangiectases. Death from visceral lesions is rather infrequent in the CREST syndrome (112).

In about 5% of the cases, the cutaneous lesions first appear on the trunk as so-called *diffuse systemic scleroderma*, often sparing the peripheral portions of the extremities. Raynaud's phenomenon is absent in such patients. There are, however, transitional forms starting out as acrosclerosis with Raynaud's phenomenon but then extending to the proximal portions of the arms and to the trunk. In both forms of systemic scleroderma, the skin in the involved areas is diffusely indurated and, as a result of diffuse fibrosis of the subcutaneous fat, becomes firmly bound to the underlying structures. The skeletal musculature is affected, resulting in weakness and atrophy. Contractures of the muscles and tendons and ankyloses of the joints may develop.

Occasional manifestations pertaining to the skin include diffuse hyperpigmentation, which is seen mainly in diffuse systemic scleroderma. Macular telangiectases on the face and hands, calcinosis cutis located on the extremities, and ulcerations, especially on the tips of the fingers and over the knuckles, occur predominantly in acrosclerosis. In addition, vascular ulcers on the lower extremities resembling those seen in atrophie blanche may occur in patients with acrosclerosis.

Histopathology. The histologic appearance of the skin lesions in systemic scleroderma is similar to that of morphea, so that histologic differentiation of the two types is not possible. One small study stated that the two conditions may be differentiated based upon the pattern of the inflammatory infiltrate and presence or absence of papillary dermal involvement (113). In early lesions of systemic scleroderma the inflammatory reaction is less pronounced than in morphea, so that only a mild inflammatory infiltrate is present around the dermal vessels, around the eccrine coils, and in the subcutaneous tissue. The vascular changes in early lesions are slight, as in morphea (114). In contrast, in the late stage,

systemic scleroderma shows more pronounced vascular changes than morphea, particularly in the subcutis. These changes consist of a paucity of blood vessels, thickening and hyalinization of their walls, and narrowing of the lumen. Even in the late stage of systemic scleroderma, the epidermis appears normal, only occasionally showing disappearance of the rete ridges. Aggregates of calcium may also be seen in the late stage within areas of sclerotic, homogeneous collagen of the subcutaneous tissue (see also calcinosis cutis, Chapter 17).

Systemic Lesions. Internal organs are often affected in scleroderma, but their involvement varies greatly in extent and degree. Involvement does not necessarily imply functional compromise, and in many affected patients systemic scleroderma ultimately comes to a standstill. The clinical symptoms produced by reduced pliability, vascular compromise, and subsequent loss of function can be found in the gastrointestinal tract, lungs, heart, and kidneys, as well as the skin. In the gastrointestinal tract submucosal fibrosis and replacement of the muscularis by fibrosis with intimal thickening of blood vessels give rise to difficulties in swallowing, regurgitation, and malabsorption and eventually ileus. In the lungs interstitial fibrosis, degeneration of alveolar spaces, and intimal thickening of arteries result in dyspnea and cor pulmonale. Cases of pulmonary carcinoma (predominantly bronchoalveolar) have been observed and are associated with the presence of pulmonary fibrosis (115). The most serious consequences arise in the kidneys. Adventitial fibrosis may affect interlobar, arcuate, and interlobular arteries, and mucoid degeneration affects arcuate and interlobular arteries. Uremia occurs more frequently than rapidly evolving renal failure and hypertension. The latter entity, termed scleroderma renal crisis, is associated with "onion-skin" hyperplasia of arterial walls and may be fatal (116).

Pathogenesis and Laboratory Findings. The pathogenesis of systemic scleroderma, as with lupus erythematosus, is uncertain and may be multifactorial. Histogenetic factors are essentially the same in morphea and systemic scleroderma; they differ only in degree and extent.

The triad of vascular compromise, collagen matrix aberrations, and presence of serologic autoimmune indicators contributes in variable degrees to symptoms and clinical findings in scleroderma and morphea (Table 10-6). Although a relationship to retroviral disease has been suggested, it is speculative and may reflect molecular mimicry of viral antigens (117).

Microvascular Changes. Involved vessels are primarily precapillary arterioles. Changes in the microvasculature have been noted in clinically normal skin. Perivascular edema and functional changes in endothelial cells can be detected early (118). Precapillary arterioles then show endothelial proliferation and mononuclear inflammatory infiltrates, followed by intimal proliferation and luminal narrowing (119). Corresponding electron microscopic findings include vacuolization and destruction of endothelial cells, reduplication of the basement membrane, enlargement of the rough endoplasmic reticulum in pericytes and fibroblasts, and perivascular fibrosis. There are some data to suggest that hyperplasia of the pericytic cells at the peripheral superficial aspect of the advancing border of the sclerosis may play an role in the fibrosing process through synthesis of collagenous matrix material and recruitment of fibroblasts through release of cytokines (120). Although widespread arteriolitis may be present in early stages, only rarely does it progress to a necrotizing arteriolitis and eventuate in periarteritis nodosa (121).

A role for adhesion molecules in the evolution of lesions of scleroderma has been suggested: They are believed to bind mononuclear cells to endothelial cells and facilitate diapedesis of inflammatory cells into the connective tissue. Interactions with connective tissue components may lead to the release of cytokines and growth factors, resulting in upregulation of matrix production by fibroblasts and changes in fibroblast phenotype, eventuating in fibrosis (122).

Collagen Matrix Aberrations. Analysis of collagen in affected skin has shown excess production of connective tissue components normally present in the dermis, including types I, III, V, VI, and VII collagen, fibronectin, and proteoglycans (123,124). Other studies suggest that fibroblasts in localized and systemic scleroderma express markers of smooth muscle differentiation (myofibroblasts), which may account for their different biological behavior (125). Some observers have found

TABLE 10-6 Pathogenic Factors in Scleroderma

Vascular aberrations	Raynaud's phenomenon
	Intimal hyperplasia of blood vessels
	Adventitial fibrosis
	Vascular abnormalities in other visceral organs
	Microvascular abnormalities
	Enlargement and tortuosity of capillary loops
	Capillary loop dropout
	Thickened and reduplicated basement membrane
	Loss of endothelium
Immunologic factors	T-helper cell ($CD4^+$) infiltrates
	Reduction in T-suppressor ($CD8^+$) cells
	Increased soluble interleukin-2 receptors correlate with disease progression and mortality
	Decreased interleukin-1 production by peripheral mononuclear cells
Serologic markers	ANA^+ in more than 90% of patients
	Low/absent anti–native (double-stranded) DNA, anti-Sm, rare anti-nRNP
	Speckled ANA pattern correlates with anticentromere antibody on HEp-2 cells and CREST and a relatively favorable prognosis
	Anti–DNA topolsomerase 1 (Sci-70)

ANA, antinuclear antibody; CREST, calcinosis cutis, Raynaud's phenomenon, involvement of the esophagus with dysphagia, sclerodactyly, and telangiectases.

loss of $CD34^+$ dendritic cells in affected areas, a finding of uncertain significance (126).

Serologic/Immunologic Markers. Most patients with systemic sclerosis (greater than 90%) and approximately 50% of those with localized scleroderma (morphea) have a positive ANA. The pattern may be homogeneous, speckled, or nucleolar. When using the human laryngeal carcinoma cell line HEp-2, more than 90% of patients with morphea or acrosclerosis have a detectable anticentromere antibody. In patients with systemic sclerosis this antibody is not usually detected. Instead, 20% to 40% of them have antibodies to Scl-70. This antigen has been identified as DNA topoisomerase I, an intracellular enzyme involved in the uncoiling of DNA before it is transcribed. Antibodies to this enzyme hinder its function. The presence of antibodies to Scl-70 correlates with systemic sclerosis, whereas the presence of anticentromere antibodies correlates with morphea or CREST and suggests a more favorable prognosis (127). Antihistone antibodies have been shown to be positive in cases of morphea, particularly in generalized morphea and linear scleroderma. Although not particularly sensitive, anti–single-stranded DNA is considered very specific for linear scleroderma (128).

In some cases of systemic scleroderma, epidermal nucleolar IgG deposition is seen even in clinically normal skin as a result of high serum concentrations of antibody to nucleolar antigen (129). Although subepidermal and vascular deposits are regularly absent in the skin in scleroderma, kidney biopsies in patients with renal involvement show diffuse vascular deposits of immunoglobulins, predominantly IgM, or of complement in the intima of the interlobular and arcuate arteries, which by light microscopy often exhibit fibromucinous alterations (130).

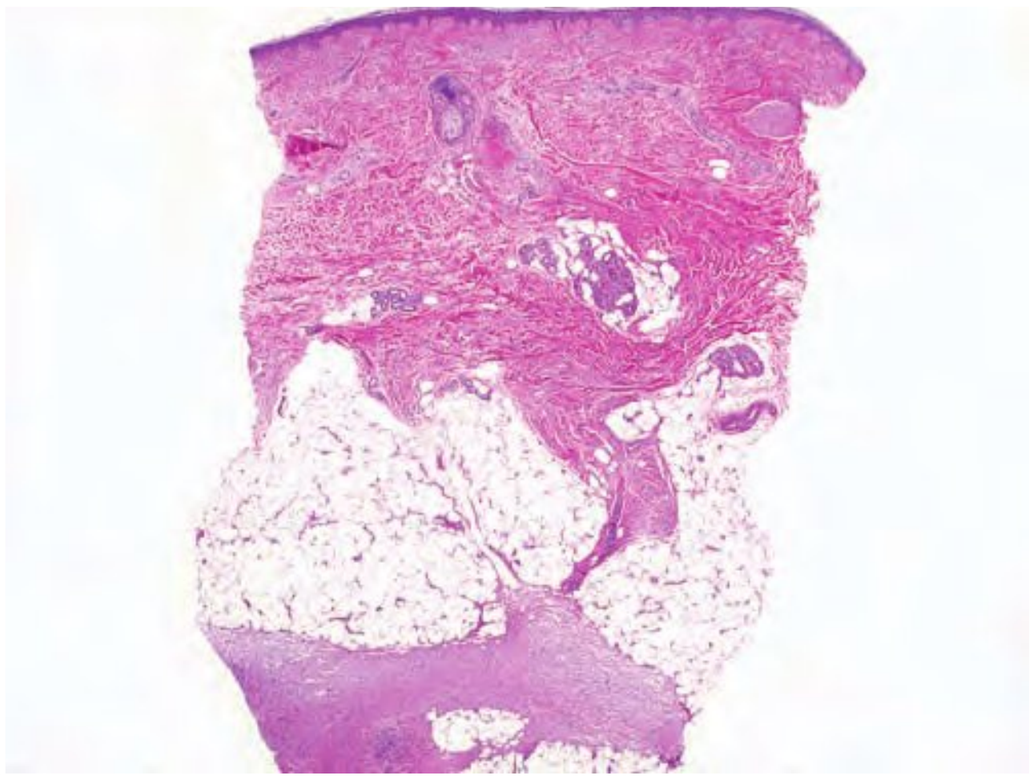
NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis, previously referred to as nephrogenic fibrosing dermopathy, is a systemic disorder characterized by symmetric thickening of the skin of the trunk and extremities. It was first recognized in a group of renal transplant patients in 1997 (131). The nomenclature changed when respiratory symptoms and related cardiac changes were recognized. All patients have some degree of renal impairment (132). Initially dialysis was suspected as a predisposing factor; however, up to 10% of patients had never received dialysis (133). There are equal sex and age distributions. The cause has not been established, despite certain correlations, including one with gadolinium exposure reviewed later (see pathogenesis section) (134,135).

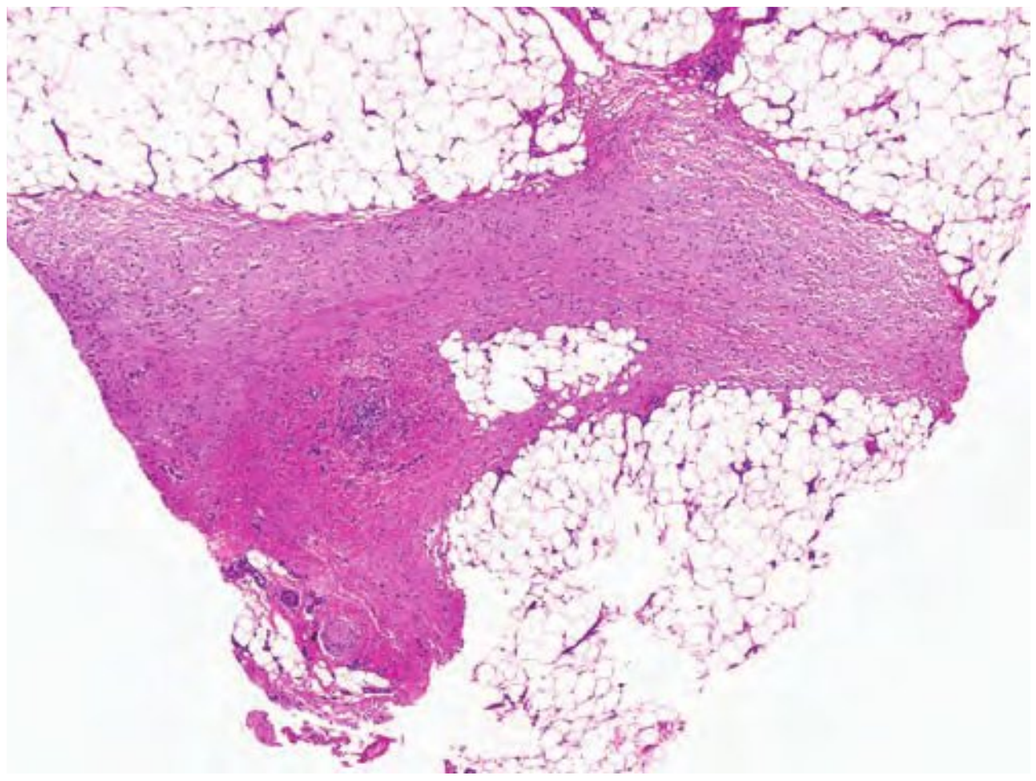
Clinically, nephrogenic systemic fibrosis presents as limited or widespread areas of symmetric thickening and hardening of the skin that may resemble scleroderma. The borders of involved areas may be sharply demarcated, serpentine, or ameboid. The skin becomes smooth and shiny or may acquire a peau d'orange appearance. Involvement over joints may lead to contractures. Although typically asymptomatic, patients may complain of muscular weakness, pruritus, and pain (133,135–137). In contrast to scleromyxedema, the face is typically spared. Pulmonary involvement may give rise to respiratory symptoms. Muscle weakness occurs with involvement of skeletal muscles and fascia. Patients with muscle weakness may have sensory motor polyneuropathy by electromyography and nerve conduction studies. Although cardiac fibrosis has been reported, impaired cardiac function has not been documented (137–140).

Histologic findings of nephrogenic systemic fibrosis may be subtle and require incisional biopsies to include fascia (Fig. 10-14A–C). Sections show spindled fibroblasts that extend into subcutaneous septae and subjacent fascia (Fig 10-14B). Collagen bundles are thickened. Cytoplasmic processes of fibrocytes surround collagen bundles. Such areas may demonstrate factor XIIIa–positive stellate fibroblastic cells and CD68-positive multinucleated giant cells. (Fig. 10-14C–E).

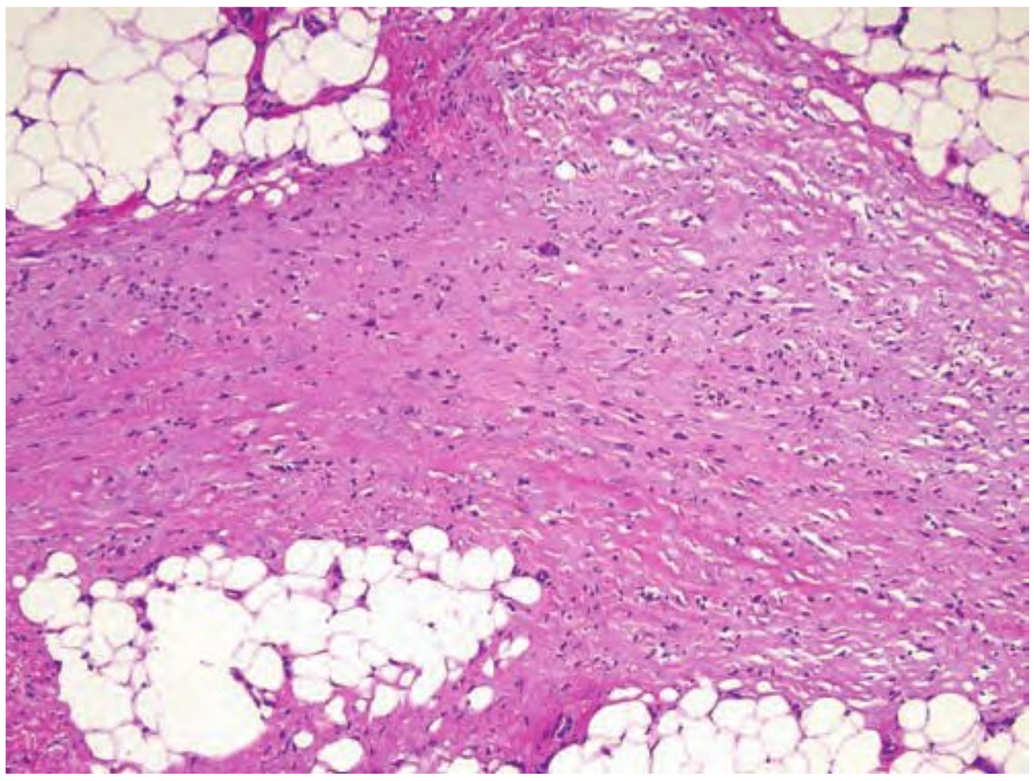
Immunohistochemical stains show fibrocyte reactivity with CD34 in a membranous pattern and procollagen I in a cytoplasmic pattern (133,134). Such cells may represent a class of circulating fibrocytes that home to areas of cutaneous injury and play a crucial role in wound healing. One study showed the presence of myofibroblastic cells in early lesions of nephrogenic systemic fibrosis (141).



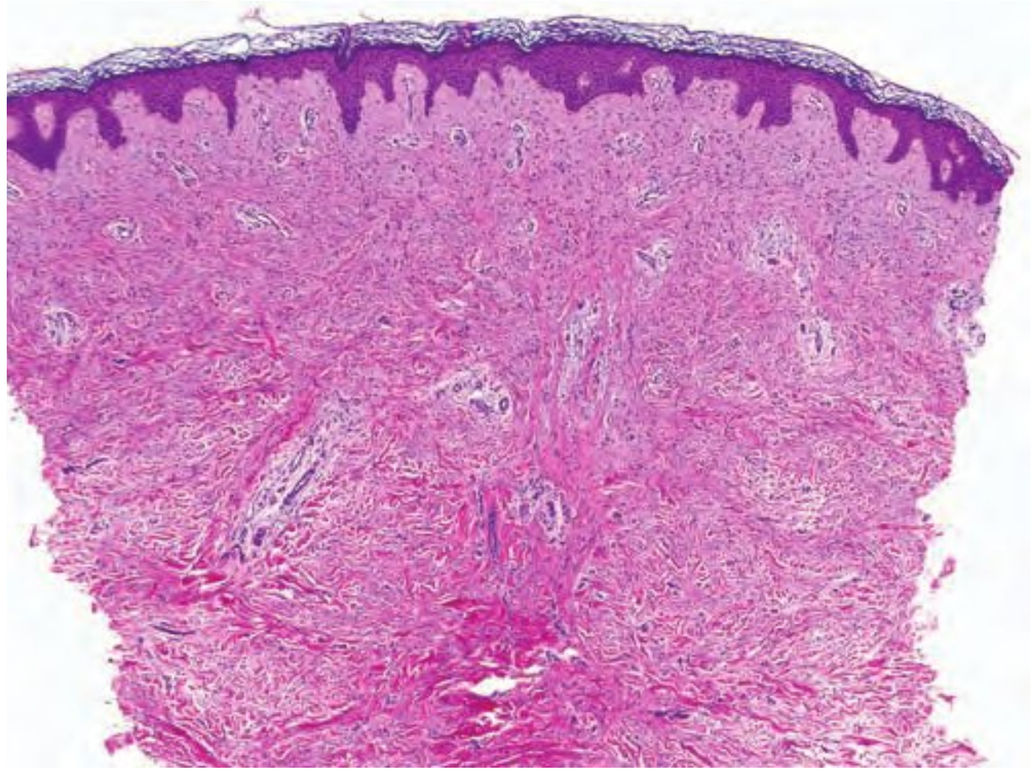
Pathogenesis. Although the diagnosis of nephrogenic systemic fibrosis requires the presence of renal dysfunction, disease onset often correlates closely with acute worsening of kidney function in the setting of chronic disease (135,138). The disease progression can frequently be halted or even reversed if the cause of the worsening can be eliminated and function restored to baseline (132). Other putative factors under scrutiny include procoagulative disorders (including factor V Leiden deficiency, antithrombin III deficiency, protein C and S deficiency and hyperhomocysteinemia), the role of endothelin 1, and gadolinium (137,142,143). The last-named agent is used as a contrast medium in magnetic resonance imaging studies and may trigger development of the disease in acidotic states.



The differential diagnosis includes other fibrosing and sclerodermoid cutaneous disorders. These include scleromyxedema, eosinophilic fasciitis, sclerodermoid graft-versus-host disease, sclerodermoid porphyria cutanea tarda, morphea, and lipodermatosclerosis. Most of these entities can be excluded based on the history and laboratory studies.



ATROPHODERMA OF PASINI AND PIERINI



In atrophoderma of Pasini and Pierini there are areas on the trunk, particularly the back, in which the skin appears slightly depressed and has a slate-gray color but shows no other surface changes. The lesions are asymptomatic, bilateral, symmetric, and sharply but often irregularly demarcated, measuring from 1 to 10 cm in diameter. They often show a "cliff-drop" border, which is largely an optical effect of the slate-gray discoloration. In old lesions, the center of the depressed area may feel slightly indurated.

Histopathology. The histologic changes in early lesions usually are slight and nonspecific, consisting of some thickening of the

FIGURE 10-14. Nephrogenic systemic fibrosis. A: An incisional specimen that shows deep dermal thickening and septal widening. B: Subcutaneous septae are widened by many spindle-shaped fibroblasts. C: High magnification of spindle-shaped fibrocytes, some of which are multinucleated in a thickened subcutaneous septum. Note little residual normal collagen. D: A different example of nephrogenic systemic fibrosis in which fibrocytes are distributed diffusely throughout the dermis. E: High magnification shows multinucleated fibroblastic cells. Note the difference between the spindle-shaped fibrocytes (lower half) and normal collagen bundles (upper half).

collagen bundles and a mild, scattered, chronic inflammatory infiltrate (144). Older lesions show no inflammatory infiltrate, but in the deeper layers of the dermis they may show collagen bundles that not only are thickened, but also appear tightly packed. In addition, indurated areas may show homogeneous, hyalinized collagen bundles (145).

Because the collagen bundles in the skin of the back normally are rather thick, it may be difficult to determine whether the collagen shows any changes. It is therefore desirable to take a biopsy specimen not only from the lesion, but also from normal skin, either from an area nearby or from the opposite side with subcutaneous fat for comparison.

Pathogenesis. Some authors believe that atrophoderma of Pasini and Pierini is a disease entity, as suggested by the original describers. In favor of this view is the observation that in atrophoderma, the atrophy comes first and the sclerosis possibly appears later, whereas in morphea, the sclerosis comes first and the atrophy appears later (146).

Most observers view the clinical presentation of atrophoderma to be distinct from that of morphea: Atrophoderma has an earlier onset (second to third decade) and protracted course of 10 to 20 years, and lesions lack a violaceous ring, which characteristically surrounds lesions of morphea. Microscopic findings show similarities to morphea, however, suggesting that atrophoderma of Pasini and Pierini may be a distinct, abortive variant of morphea (147). To support this view there are instances of coexistent morphea and atrophoderma, as well as reports of transformation of lesions of morphea into atrophoderma. A relationship of this disorder to *B. burgdorferi* infection has been reported but needs more studies to be confirmed (148).

EOSINOPHILIC FASCIITIS (SHULMAN'S SYNDROME)

First described in 1974 (149), eosinophilic fasciitis is a scleroderma-like disorder characterized by inflammation and thickening of the deep fascia. It has a rapid onset associated with pain, swelling, and progressive induration of the skin leading to exaggerated deep grooving of the skin around superficial veins. This disorder is often accompanied by a peripheral eosinophilia, hypergammaglobulinemia, and elevated erythrocyte sedimentation rate and has been associated with aplastic anemia. Other rare associations include polycythemia rubra vera, cutaneous T-cell lymphoma, borreliosis, and autoimmune thyroid disease (150). Simvistatin and phenytoin have been reported to cause eosinophilic fasciitis (151). Eosinophilic fasciitis may have its onset with unusual physical exertion; however, more recently it has been reported in association with L-tryptophan ingestion (152). The latter association is known as eosinophilia-myalgia syndrome, which is clinically and histologically similar to eosinophilic fasciitis.

Eosinophilic fasciitis often involves one or more extremities. The induration may cause a decreased range of motion and, in severe cases, even joint contractures (153). In only a few cases are there lesions on the trunk, and the face is almost invariably spared. In nearly all reported cases, Raynaud's phenomenon and visceral lesions of scleroderma have been absent. Only very few instances of incontestable eosinophilic fasciitis have shown evidence of Raynaud's phenomenon (154) or mild pulmonary fibrosis (155). The disorder has a varied course: Some patients improve spontaneously, others improve with corticosteroids, and still others may have relapses and remissions.

Histopathology. A deep wedge biopsy to skeletal muscle including fascia is essential to making the diagnosis of eosinophilic fasciitis. The fascia is markedly thickened, appears homogeneous, and is permeated by a mononuclear inflammatory infiltrate (Fig. 10-15A–C). In some instances the infiltrate in the fascia contains an admixture of eosinophils (156). The underlying skeletal muscle in some cases shows myofiber degeneration, severe inflammation with a component of eosinophils, and focal scarring; in other cases, however, it is not involved.

In most cases the adipose tissue shows no significant changes, except that the fibrous septa separating deeply located fat lobules are thicker, paler staining, and more homogeneous and hyalinized than normal dermal connective tissue. In other cases, however, the collagen in the lower reticular dermis appears pale and homogeneous, and the entire subcutaneous fat is replaced by horizontally oriented, thick, homogeneous collagen containing only few fibroblasts and merging with the fascia (157).

Pathogenesis. Whereas at first the impression prevailed that eosinophilic fasciitis was a new syndrome, it soon became apparent that the disorder represents a variant of morphea (139). Eosinophilic fasciitis may share features with generalized morphea, including inflammation and fibrosis of the fascia, peripheral eosinophilia, and hypergammaglobulinemia (158). Antinuclear antibodies are present in a significant number of cases (159). The term morphea profunda, analogous to lupus erythematosus profundus, has been applied to this disorder (160). Nevertheless, because of its acute onset in most cases, its usual limitation to the structures underlying the skin, and its tendency to resolve, eosinophilic fasciitis deserves recognition as a distinct variant of morphea (161).

LICHEN SCLEROSUS ET ATROPHICUS

Lichen sclerosus (LS) encompasses the disorders known as *lichen sclerosus et atrophicus*, *balanitis xerotica obliterans* (LS of the male glans and prepuce), and *kraurosis vulvae* (LS of the female labia majora, labia minora, perineum, and perianal region) (162). Lichen sclerosus is an inflammatory disorder of unknown etiology that affects patients 6 months of age to late adulthood. In both male and female patients genital involvement is the most frequent, and often the only, site of involvement. Extragenital lesions may occur with or without coexisting genital lesions.

Lesions of LS are characterized by white polygonal papules that coalesce to form plaques. Comedo-like plugs on the surface of the plaque correspond to dilated appendageal ostia. The plugs may disappear as the lesion ages, leaving a smooth, porcelain-white plaque. Solitary or generalized lesions may become bullous and hemorrhagic.

In male patients, involvement of the glans and prepuce often results in phimosis. Although the literature is dominated by reports of LS in incompletely or uncircumcised men (163), occurrences in circumcised men are reported as well (164). Neoplasms have been infrequently documented in association with LS; however, a cause-and-effect relationship has not been established (149).

In female patients, contiguous involvement of the labial, perineal, and anal areas has been described clinically as "figure 8"

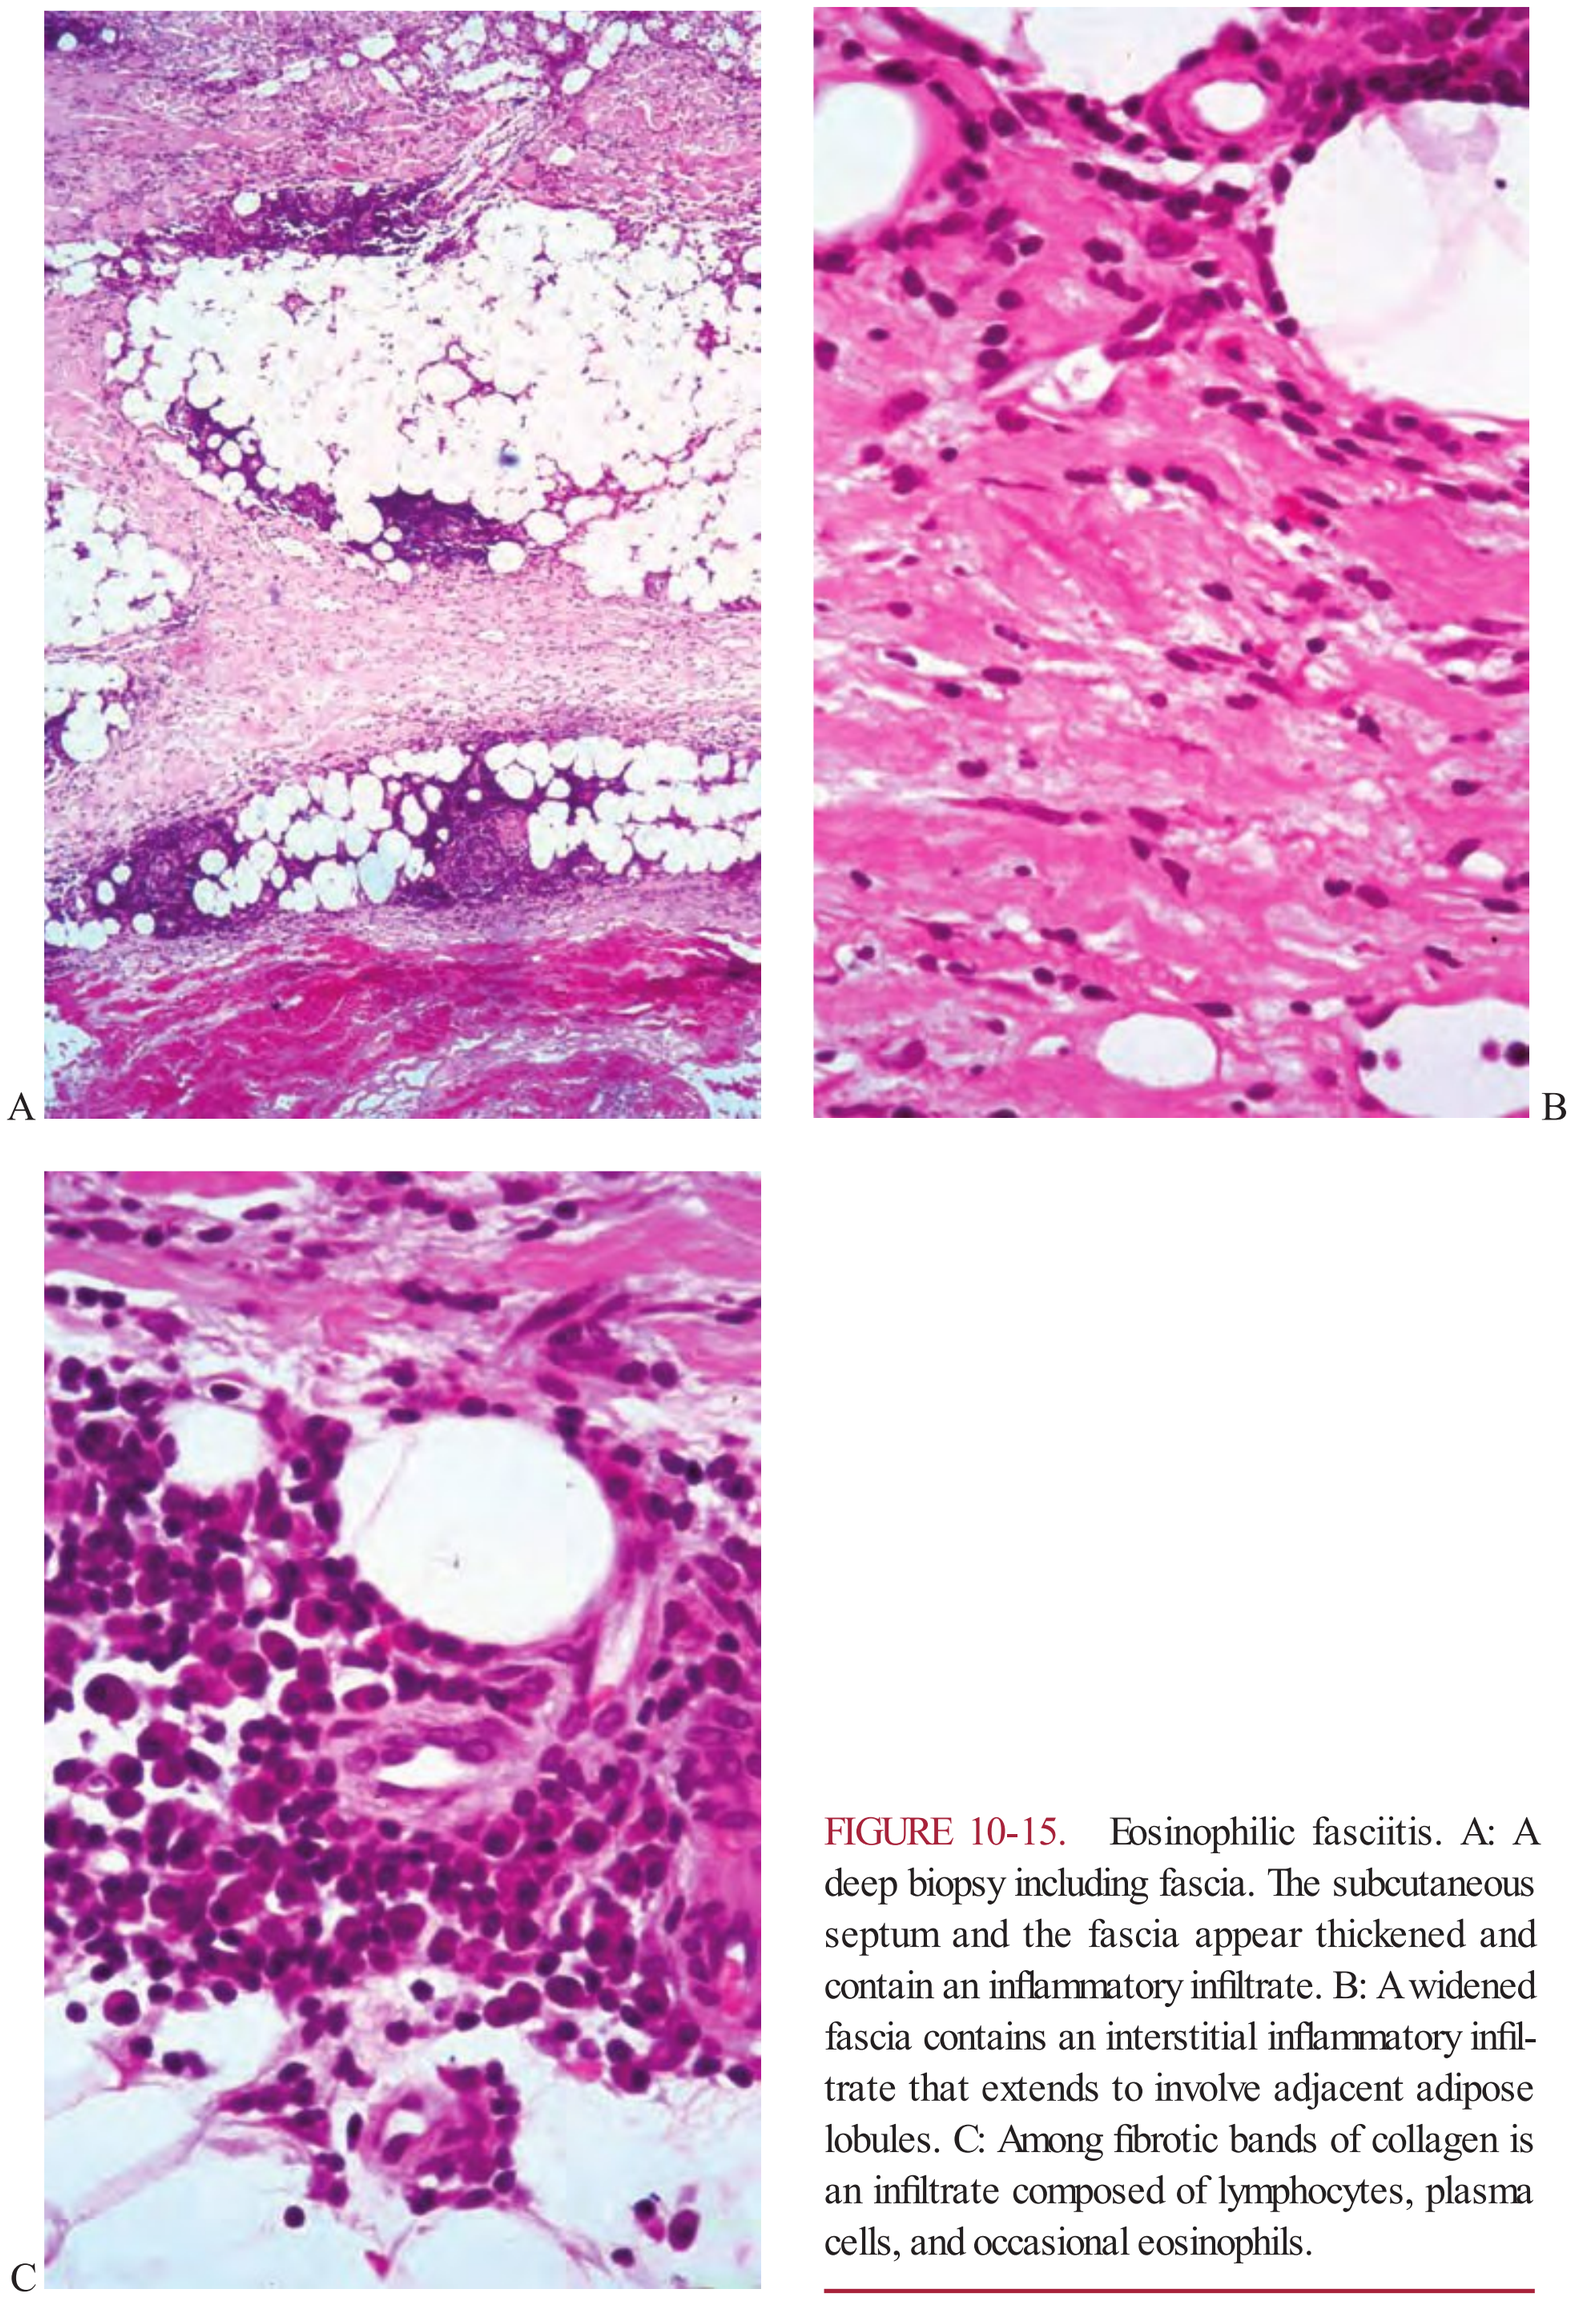

FIGURE 10-15. Eosinophilic fasciitis. A: A deep biopsy including fascia. The subcutaneous septum and the fascia appear thickened and contain an inflammatory infiltrate. B: A widened fascia contains an interstitial inflammatory infiltrate that extends to involve adjacent adipose lobules. C: Among fibrotic bands of collagen is an infiltrate composed of lymphocytes, plasma cells, and occasional eosinophils.

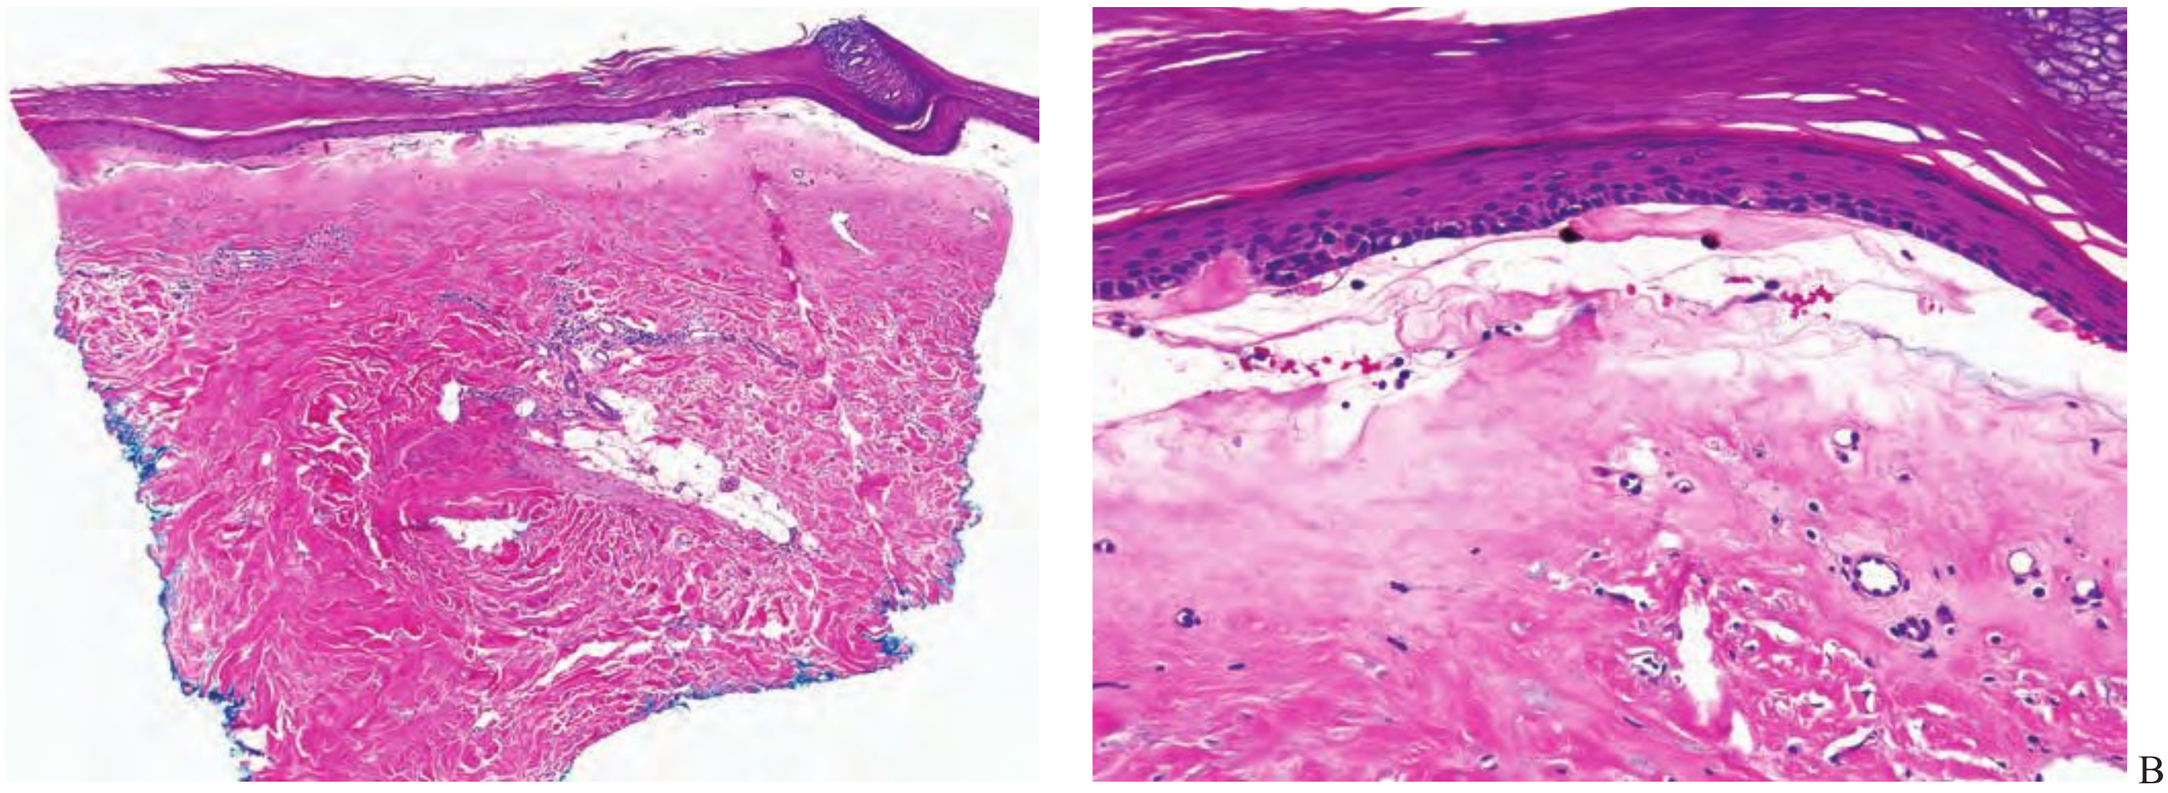
or "keyhole" lesions (165). Many cases of childhood LS in girls resolve by menarche (166). If lesions persist, atrophy of the labia and narrowing of the vaginal orifice may ensue. In contrast to lichen sclerosus et atrophicus of the skin, which rarely itches, there is often severe pruritus in the vulvar region.

The premalignant potential in LS has been debated extensively and remains ill defined. The most recent large population-based study detected a small increased risk of squamous cell carcinoma in patients with LS. Because neoplasms have arisen in areas adjacent to lesions of LS, long-term follow-up of patients with lichen sclerosus et atrophicus of the vulva is advisable.

Of interest, lesions of LS may koebnerize (be provoked by trauma) as well as coexist with morphea (167,168). In extensive cases of morphea, lichen sclerosus et atrophicus may become superimposed on some of the lesions. It is then best

recognized by finding pale superficial dermal collagen, as compared with hypocellular compacted deep dermal collagen, and the presence of follicular plugging (123). Cases of both extragenital and genital LS have also been reported in the setting of graft-versus-host disease (169).

Histopathology. The salient histologic findings in cutaneous lesions of lichen sclerosus et atrophicus are (a) hyperkeratosis with follicular plugging, (b) atrophy of the stratum malpighii with hydropic degeneration of basal cells, (c) pronounced edema and homogenization of the collagen in the upper dermis, and (d) an inflammatory infiltrate in the mid-dermis.



The hyperkeratosis is so marked that the horny layer is often thicker than the atrophic stratum malpighii, which may be reduced to a few layers of flattened cells (Fig. 10-16A, B). The cells of the basal layer show hydropic degeneration. The rete ridges often are completely absent, although they may persist in a few areas and show some irregular downward proliferation. In such proliferations, hydropic degeneration of the basal cells usually is pronounced.

Keratotic plugging of appendageal ostia is often associated with atrophy and disappearance of appendageal structures. Keratotic plugging is not apparent in mucosal lesions. In the latter areas, particularly the vulva, squamous hyperplasia adjacent to the atrophic epidermis can be found in about one third of patients with LS. There may be varying degrees of "dysplasia" consisting of disorderly arrangement of the cells and enlarged, hyperchromatic nuclei. Transition into carcinoma, however, is said to be rare (170).

Beneath the epidermis is a broad zone of pronounced lymphedema (Fig. 10-16A, B). Within this zone, the collagenous fibers are swollen and homogeneous and contain only a few nuclei. They stain poorly with eosin and other connective tissue stains. The blood and lymph vessels are dilated, and there may be areas of hemorrhage. Elastic fibers are sparse and, in old lesions, are absent within the area of lymphedema (171). In areas of severe lymphedema, clinically visible bullae may form; they are found in subepidermal locations (172). Shrinkage within the area of lymphedema may occur during the process of dehydration of the specimen, resulting in the formation of pseudobullae, which often are located intradermally.

Except in lesions of long duration, an inflammatory infiltrate is present in the dermis. The younger the lesion, the more superficial is the location of the infiltrate. In very early lesions and at the periphery of somewhat older lesions, the infiltrate may be found in the uppermost dermis, in direct apposition to the basal layer. Soon, however, a narrow zone of edema and homogenization of the collagen displaces the inflammatory infiltrate farther down, so that, in well-developed lesions, the infiltrate is found in the mid-dermis. The infiltrate can be patchy, but it is often bandlike and composed of lymphoid cells admixed with plasma cells and histiocytes. In old lesions in which the infiltrate is slight or absent, the collagen bundles in the midportion and lower dermis may appear swollen, homogeneous, and eosinophilic, thus appearing sclerotic (hence lichen *sclerosus*). Cases of overlap of morphea and LS may be seen and demonstrate the histologic changes of both disorders in their respective locations of the dermis (Fig. 10-17A–C).

Pathogenesis. Changes in the dermal matrix have been detected in LS. By electron microscopy, collagen fibrils often

FIGURE 10-16. Lichen sclerosus. A: Lichen sclerosus showing a subepidermal zone of pallor. A "trilayered" or "striped" appearance: compact hyperorthokeratotic scale and atrophic epidermis (dark pink/red), a pale dermis (white), and subjacent, variably dense interstitial lymphocytic inflammatory infiltrate (blue) delineating the depth of this process. B: An established lesion, showing a thick hyperkeratotic scale, an atrophic epidermis, and pale superficial dermal stroma with rare lymphocytes and plasma cells. A cleftlike space separates an atrophic epidermis from a pale dermis.

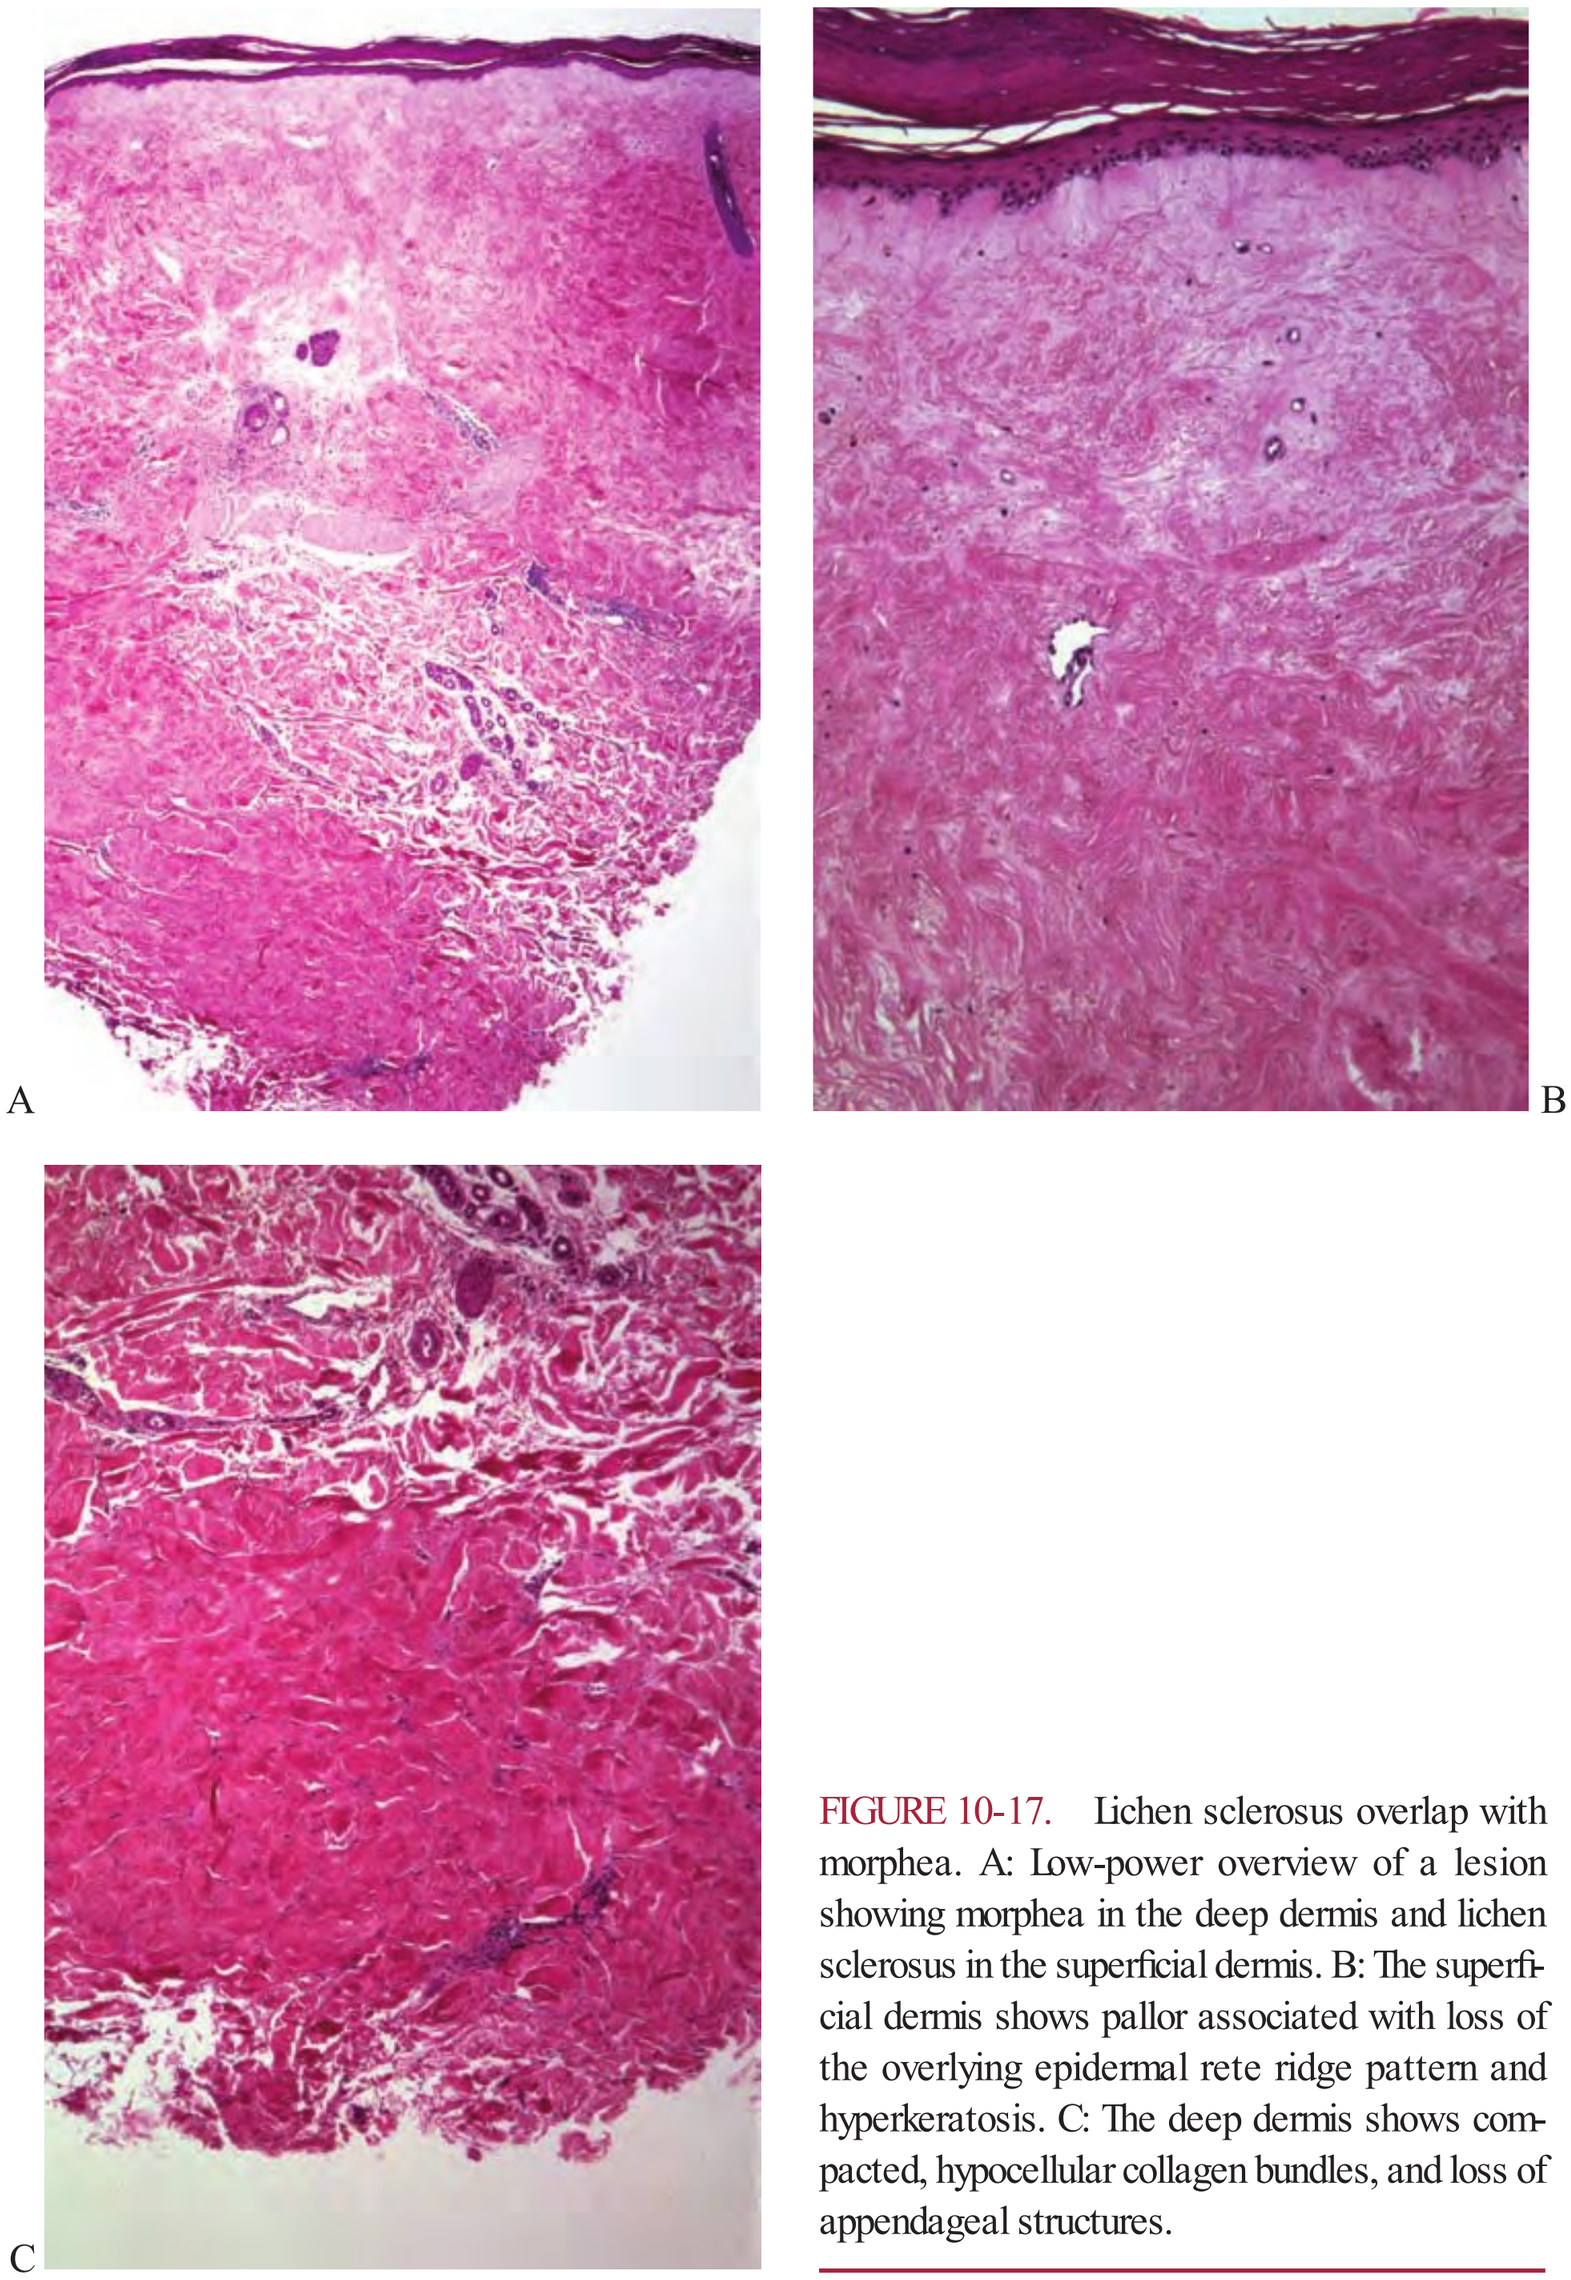

FIGURE 10-17. Lichen sclerosus overlap with morphea. A: Low-power overview of a lesion showing morphea in the deep dermis and lichen sclerosus in the superficial dermis. B: The superficial dermis shows pallor associated with loss of the overlying epidermal rete ridge pattern and hyperkeratosis. C: The deep dermis shows compacted, hypocellular collagen bundles, and loss of appendageal structures.

lack cross-striation, and in cross sections they sometimes have the appearance of empty tubes, suggesting degeneration of collagen fibrils (173). In some areas, new immature collagen of reduced and variable diameter (40 to 80 nm) is seen (174). Ultrastructural studies also have shown degeneration of subepidermal elastin and increases in ground substance (175). The features all suggest an increased rate of matrix turnover or a dysregulated remodeling response. Studies examining the components of the dermal matrix have demonstrated increases in the matrix proteins tenascin and fibrinogen, which serve as scaffold proteins on which new collagen is deposited. Similar increases in tenascin and fibrinogen have been demonstrated in scleroderma and morphea, suggesting that this is may be a nonspecific change (176).

The frequent finding of human papillomavirus alterations in lesions of LS have lead some to consider LS an aberrant immune response to persistent antigenic stimulus. This notion is supported by the presence of LS changes in cases of other

chronic vulvar dermatitides. It has been hypothesized that persistent antigen may lead to the presence of CD8/CD57-positive T cells, which may play a role in tissue remodeling and fibrosis though cytokine elaboration (177).

In the epidermis, intercellular edema separates epidermal cells that show degenerative changes. There is nearly a complete absence of melanosomes within the keratinocytes. Immunoperoxidase and Fontana-Mason stains of melanocytes have shown there is both a loss of melanocytes and decreased transfer of melanosomes to keratinocytes (178).

Differential Diagnosis. Very early lesions may resemble lichen planus because of the apposition of the inflammatory infiltrate to the basal layer. However, the basal cells are not replaced by flattened squamous cells as in lichen planus but appear hydropic, and a subepidermal zone of edema usually has already begun to form in some areas in lichen sclerosus et atrophicus.

Old lesions of lichen sclerosus et atrophicus with thickening and eosinophilia of the collagen bundles in the midportion and lower dermis and only a slight inflammatory infiltrate may resemble morphea. Nevertheless, the epidermis in morphea, although it may be thin, shows neither hydropic degeneration of the basal cells nor follicular plugging, and the upper dermis in morphea has elastic fibers and shows no zone of edema (126). Still, in lesions in which lichen sclerosus et atrophicus develops either secondarily to morphea or simultaneously with it, there are, in addition to the epidermal and subepidermal changes of lichen sclerosus et atrophicus, changes indicative of morphea in the lower dermis and in the subcutaneous fat. A definite diagnosis of both lichen sclerosus et atrophicus and morphea in the same lesion can be made only if the newly formed collagen extends into the subcutaneous fat and consists of faintly staining, homogeneous collagen (179).

FIBROBLASTIC RHEUMATISM

At least 18 cases of this rare condition have been reported according to a recent review (180). It is characterized by a combination of progressive inflammatory arthritis and fibrotic nodules typically involving the skin of the hands, and it may occur in children as well as adults. Patients typically present with the sudden onset of polyarthralgia and develop a progressive inflammatory polyarthritis, with cutaneous nodules typically in the form of periungual papules that may mimic multicentric reticulohistiocytosis. Patches or plaques of erythema, sclerodactyly, and Raynaud's phenomenon may be associated findings. There are no significant laboratory findings. The skin nodules are characterized by mononuclear cell infiltrates, fibroblastic proliferation with myofibroblastic differentiation (181), dermal fibrosis with thickened collagen fibers, and decreased elastic fibers. This condition is variably but often inexorably progressive, but it may be responsive to immunosuppressive therapy, especially in its early stages (182).

CHAPTER 11

Kim M. Hiatt
Thomas D. Horn

Cutaneous Toxicities of Drugs

Perhaps because of its position of high visibility, the skin is reportedly the most common site of drug reactions (1). Cutaneous eruptions attributed to drugs occur at a rate of 2% to 3% of inpatients, with a higher rate, 12%, reported in the intensive care setting (2,3). Morbilliform and urticarial eruptions are the most common overall, as well as in the intensive care setting. They are most often seen in response to antibiotics, antiepileptics, and, in one study, traditional Chinese herbal medications (3,4). Fortunately, the incidence of severe cutaneous drug reactions (Stevens-Johnson syndrome, toxic epidermal necrolysis, exfoliative dermatitis, and drug reaction with eosinophilia and systemic symptoms) is less. These severe reactions are seen in the same general population and are attributed, most commonly, to the same drugs and are reported to affect less than 1 in 10,000 users (1,3). The risk of developing an adverse drug reaction is higher in women, the elderly, patients with Sjögren's syndrome, and those with immune suppression, in particular, patients with systemic lupus erythematosus and acquired immunodeficiency syndrome (4–6). In the intensive care setting, obesity and immune dysfunctions such as antiphospholipid antibody syndrome and dysthyroidism are further risk factors (2).

Drug-related eruptions are attributed to immunologic as well as nonimmunologic mechanisms. Nonimmunologic mechanisms encompass the pharmacokinetics of drugs such as absorption, plasma protein binding, distribution, metabolism, and elimination. Genetic factors influence metabolic pathways, specifically oxidation, hydrolysis, and acetylation and are suggested to be the mechanisms of toxicity reactions such as those that occur in sulfonamide and anticonvulsant toxicities (7). Theories regarding immunologic mechanisms of drug-induced disease include cell-mediated reactions to altered cell surface proteins effecting a lymphocytic response. Molecular mimicry of endogenous peptides modified by binding with ingested drugs has also been suggested (8). In addition, drugs can stimulate an anaphylactic-type reaction by immunoglobulin E (IgE)–mediated or immune complex–mediated pathways. Drug–protein complexes cross-link IgE molecules on sensitized mast cells or basophils, releasing chemical mediators that result in systemic effects, including urticaria, angioedema, anaphylaxis, and anaphylactoid reactions. Immune complex mechanisms rely on persistence of drug antigen in the serum long enough to elicit an antibody response. Finally, antibody-mediated reactions occur as a result of cell-bound drug hapten complexing with IgG antibody, which stimulates complement fixation and cytolysis, as occurs in some cases of drug-associated thrombocytopenic purpura (7). New drug formulations, in particular liposomal and transdermal delivery systems, and the introduction of numerous chemotherapeutic and immune response modulators are accountable for increasing numbers of cutaneous reactions primarily by the nature of their preferential accumulation in target tissues such as skin (9–11). Several medication-related cutaneous eruptions are considered in depth elsewhere in this text but will be mentioned briefly in this context, including urticaria (see Chapter 7), erythema multiforme (see Chapter 9), toxic epidermal necrolysis (see Chapter 9), erythema nodosum (see Chapter 20), erythroderma (see Chapter 9), vasculitis (see Chapter 8), and corticosteroid-induced acne (see Chapter 18).

EXANTHEMIC DRUG ERUPTIONS

Eruptive and efflorescent cutaneous drug reactions are the most common adverse effects of medications (4,5,12–14). Virtually any drug may be associated with a morbilliform rash, which consists of fine blanching papules that appear suddenly, are symmetric, and often are brightly erythematous in white patients. The eruption most commonly starts as erythematous papules on the trunk and becomes confluent with time (Fig. 11-1). The mucous membranes are characteristically not involved. The nonspecific clinical and histologic changes make definitive implication of a specific agent difficult. The most common medications causing morbilliform eruptions are amoxicillin clavulanate, amphotericin B, and metamizole (5,14). The presence of facial edema and systemic hypereosinophilia in conjunction with the morbilliform eruption is a signal for a serious drug eruption: drug rash with eosinophilia and systemic symptoms (DRESS), which reportedly occurs most commonly after exposure to minocycline but has also been reported with exposure to other drugs, including sulfasalazine, carbamazepine, nevirapine, and allopurinol (1,15–20).

Histopathology. The typical morbilliform drug eruption displays a variable, often sparse, mainly perivascular infiltrate of lymphocytes and eosinophils. Eosinophils may be absent. Some vacuolization of the dermal–epidermal junction with

FIGURE 11-1. Morbilliform drug eruption. This eruption occurred in a patient with systemic symptoms (drug rash with eosinophilia and systemic symptoms). (Courtesy of Frances Ramos-Ceballos, MD.)

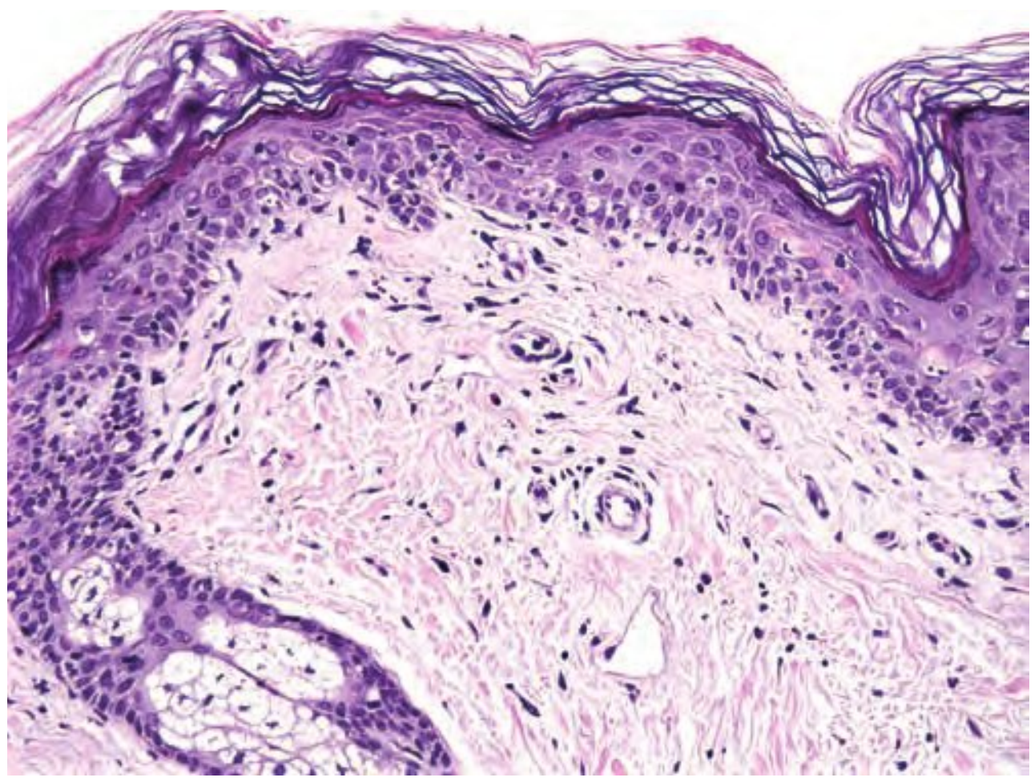

FIGURE 11-2. Drug-induced erythema multiforme. The epidermis has necrotic keratinocytes at all levels of the epidermis and a minimal dermal inflammatory infiltrate. The eosinophils suggest the drug-induced etiology.

few apoptotic epidermal cells may be observed but not to the degree typical of erythema multiforme or toxic epidermal necrolysis. There are no specific histologic features of morbilliform eruption presenting in DRESS.

Differential Diagnosis. Distinction of morbilliform drug eruption from viral exanthem in the absence of eosinophils is generally not possible. More than occasional dyskeratotic epidermal cells should prompt consideration of erythema multiforme, toxic epidermal necrolysis, or fixed drug eruption.

DRUG ERUPTIONS PRIMARILY CHARACTERIZED BY INTERFACE DERMATITIS

The histologic features comprising interface dermatitis (see Chapter 9) include vacuolar alteration of the basilar epidermis, necrotic keratinocytes, flattening of basilar keratinocytes, variable infiltration of the upper dermis by lymphocytes and histiocytes, variable exocytosis, and melanophages. These findings may be induced by drugs in several different but reproducible patterns, including erythema multiforme, toxic epidermal necrolysis, lichenoid drug eruption, and fixed drug eruption.

ERYTHEMA MULTIFORME

Erythema multiforme (EM) is characterized by an abrupt onset of self-limited and occasionally recurring papules and erythematous, edematous macules with concentric zones of color change described as targetoid or "bull's eye." The distribution varies but shows a predilection for the palms and soles. As in the other drug-related cutaneous eruptions, the list of offending agents continues to expand, but it is most commonly attributed to sulfonamides and their derivatives such as the cyclooxygenase-2 inhibitor celecoxib (21); and includes diverse agents such as selective serotonin reuptake inhibitors, 5-fluorouracil, and sestamibi (22–24).

Histopathology. In EM, there is a mild lichenoid infiltrate with dyskeratotic keratinocytes in EM than in others. These necrotic keratinocytes are characteristically found at all epidermal levels in the fully evolved lesion and may become confluent to form a thoroughly necrotic blister roof (Fig. 11-2). (see Chapter 9). In addition, exocytosis of lymphocytes is present. The dermis shows a mild perivascular inflammatory cell infiltrate. The etiology of the process often cannot be determined by the histology; however, a dermal inflammatory infiltrate containing eosinophils and acrosyringeal keratinocyte necrosis would suggest a drug-mediated process (25).

TOXIC EPIDERMAL NECROLYSIS AND STEVENS-JOHNSON SYNDROME

At the other end of the interface dermatitis spectrum, Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are both severe cutaneous eruptions that display diffuse, tender erythema. Blisters may develop in both disorders, as well as mucosal and conjunctival involvement (Fig. 11-3). Fortunately, their incidence is low: 1.2 to 6 cases per million persons per year for SJS and 0.4 to 1.2 cases per million persons per year for TEN (26). TEN is associated with therapeutic drugs in 95% of cases and with immunizations and infections in the other instances. SJS, on the other hand, is only associated with

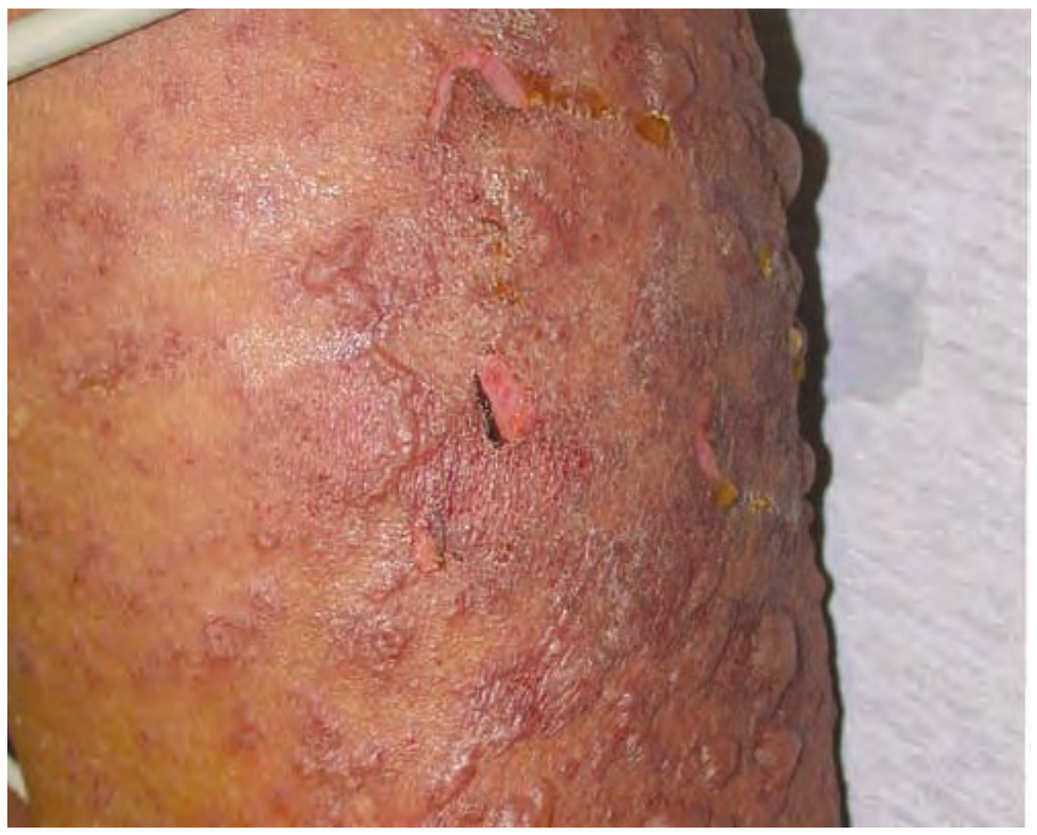

FIGURE 11-3. Toxic epidermal necrolysis. Diffuse blisters with sloughing skin secondary to Dilantin. (Courtesy of Cheryl Hull, MD.)

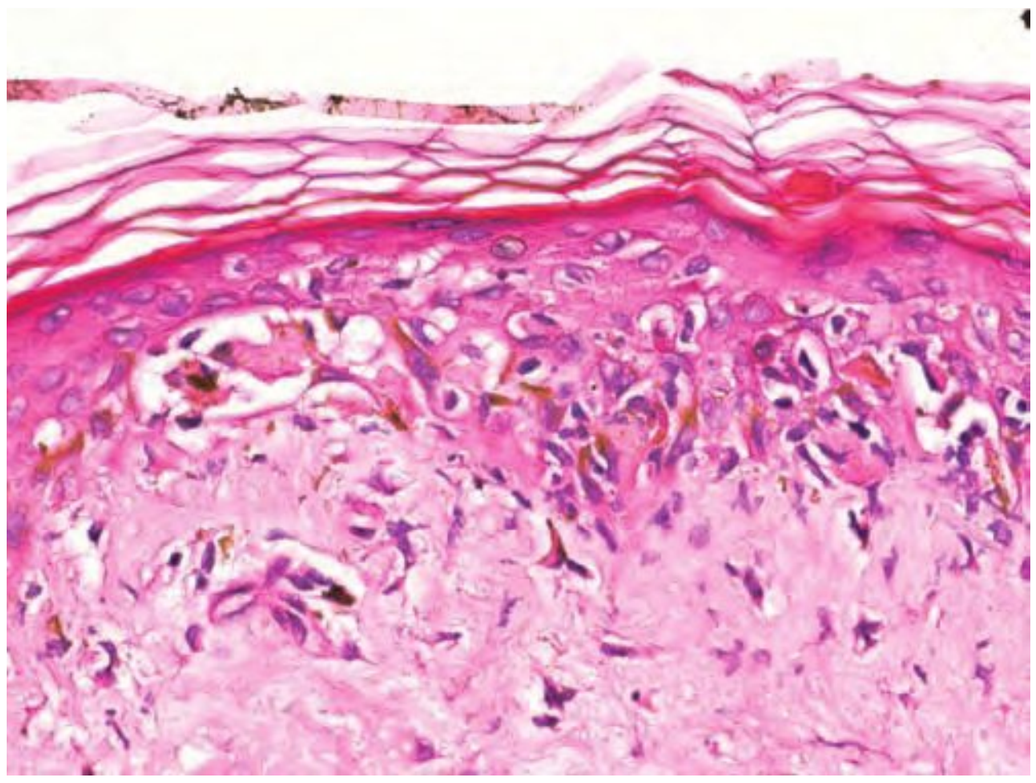

FIGURE 11-4. Toxic epidermal necrolysis. There is extensive dyskeratosis of the epidermis with early blister formation. A mild perivascular lymphocytic infiltrate is seen in the superficial dermis

drugs in 50% of cases (26). The mechanism of epithelial destruction is not clearly defined. However, drug-specific, $CD8^+$ lymphocytes with granzyme-mediated cytotoxicity are suggested to have a role in TEN pathogenesis (27). An overwhelming number of drugs have been associated with SJS and TEN, most commonly antibiotics, nonsteroidal anti-inflammatory drugs, and anticonvulsants. Allopurinol was the drug most commonly associated with SJS and TEN in one study of 379 patients with these two severe cutaneous eruptions (28). Medications associated with increased risk for these entities include sulfonamides, trimethoprim-sulfamethoxazole, phenobarbital, carbamazepine, phenytoin, oxicam, nonsteroidal antiinflammatory agents, allopurinol, doxycycline (29), corticosteroids (30), cyclooxygenase inhibitors (31,32), sustained-release bupropion, nitroglycerine patch, griseofulvin (33), and nucleoside reverse-transcriptase inhibitor (abacavir) (34).

Histopathology. In the spectrum of interface dermatitides, erythema multiforme and toxic epidermal necrolysis display greater keratinocyte necrosis and less inflammation than other disorders. Necrotic keratinocytes are found at all epidermal levels and, as in EM, may become confluent to form a thoroughly necrotic blister roof (Fig. 11-4). Eventual subepidermal bullae may form (see Chapter 9). The etiology of the process often cannot be determined by the histology; however, a dermal inflammatory infiltrate containing eosinophils and acrosyringeal keratinocyte necrosis would suggest a drug-mediated process (25).

LICHENOID DRUG ERUPTION

Lichenoid drug eruption has clinical similarity to lichen planus. Erythematous to violaceous papules and plaques develop on the trunk and extremities in association with drug ingestion. Implicated agents most commonly include quinacrine, quinidine, and gold but also include nonsteroidal antiinflammatory drugs, antihypertensive medications (especially captopril), penicillamine, chloroquine, etanercept, imatinib, sildenafil, terazosin, infliximab, and hepatitis B vaccine (35–41).

Histopathology. Lichenoid drug eruption is similar to lichen planus histologically (Fig. 11-5). In comparison with erythema multiforme and toxic epidermal necrolysis, lichenoid drug eruptions are more heavily inflamed, with a more prominent

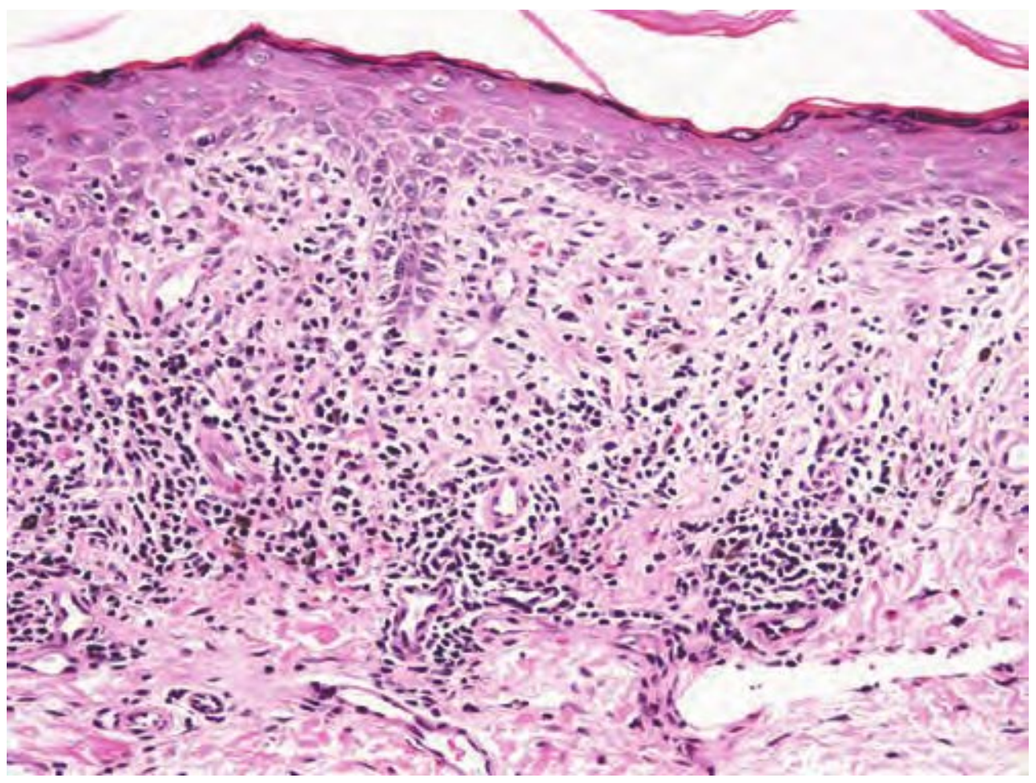

FIGURE 11-5. Lichenoid drug reaction. There is vacuolar change of the basilar layer and scattered apoptotic keratinocytes. Eosinophils in the dermal infiltrate and melanin incontinence are not characteristically seen in the clinically and histologically similar lichen planus.

interstitial pattern. Differentiation from lichen planus may not be possible. Numerous eosinophils, parakeratosis, and perivascular inflammation around the mid and deep dermal plexuses are generally absent in lichen planus.

FIXED DRUG ERUPTION

Fixed drug eruptions (FDEs) show circumscribed erythematous patches that recur persistently at the same site with each administration of the implicated drug. Increasing numbers of lesions may occur with each successive administration. The most common type of FDE consists of one or several slightly edematous, erythematous patches that may develop dusky centers, become bullous, and, on healing, leave pigmented macules. FDEs occur most commonly after the ingestion of trimethoprim-sulfamethoxazole, acetylsalicylic acid, phenolphthalein, tetracycline, barbiturates, and phenylbutazone, but they also occur after ingestion of various other drugs (42).

Histopathology. The histologic changes observed in FDE resemble those of erythema multiforme and toxic epidermal necrolysis. The frequent presence of hydropic degeneration of the basal cell layer leads to "pigmentary incontinence," which is characterized by the presence of melanin within macrophages in the upper dermis (Fig. 11-6). Scattered necrotic keratinocytes with eosinophilic cytoplasm and pyknotic nuclei (often referred to as Civatte bodies, colloid bodies, or dyskeratotic cells) are frequently seen in the epidermis and represent apoptosis. Bullae form by detachment of the epidermis from the underlying dermis. Not infrequently, the epidermis shows extensive confluent necrosis, even in areas in which it has not yet become detached. Confident distinction among fixed drug eruption, erythema multiforme, and toxic epidermal necrolysis based on examination of a skin biopsy specimen alone is not always possible. The inflammatory infiltrate may be composed purely of mononuclear cells or may be polymorphous.

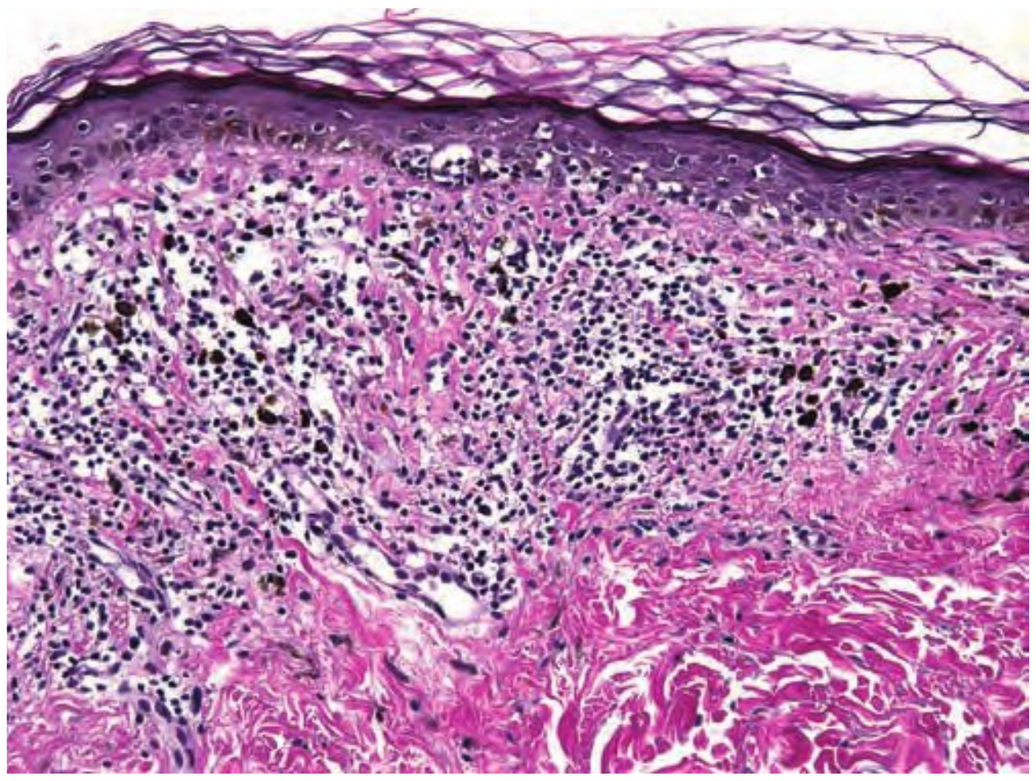

FIGURE 11-6. Fixed drug eruption. This section shows the characteristic lichenoid lymphocytic infiltrate and abundant pigment incontinence with scattered melanophages. In addition, basal vacuolar alteration and dyskeratotic cells occur in the epidermis.

Pathogenesis. On electron microscopic examination, the necrotic keratinocytes are filled with thick, homogenized keratin tonofilaments and show only sparse remnants of organelles and nuclei. Keratinocytes located in the basal cell layer are often the most severely affected cells. The pigmentary incontinence develops when (a) lymphocytes migrate into the epidermis and cause damage to keratinocytes, which become necrotic; (b) macrophages invade the epidermis and phagocytize the necrotic keratinocytes together with their melanosomes; and (c) the macrophages return to the dermis, where they are able to digest all cellular remnants except for the melanosomes, which are resistant to digestion. The intraepidermal lymphocytes are largely represented by $CD8^+$ T cells, whereas the dermal perivascular and interstitial lymphocytes are predominantly $CD4^+$, phenotypically resembling effector memory cells (43). In addition, these $CD8^+$ intraepidermal lymphocytes demonstrate keratinocyte cytolytic activity, indicating their role in the pathogenesis of FDE lesions (44). The process of pigmentary incontinence in FDE is similar to that occurring in incontinentia pigmenti (see Chapter 6). Expression of keratinocyte intercellular adhesion molecule-1 (CD54) is sharply limited to lesional epidermis in fixed drug eruption. Localized induction of this adhesion molecule by drugs may explain the sharply circumscribed clinical lesions (45).

NEUTROPHILIC DRUG ERUPTIONS

Drugs have been implicated in cutaneous eruptions with a neutrophilic infiltrate; these conditions include acneiform eruptions, neutrophilic fixed drug eruption, neutrophilic eccrine hidradenitis, acute generalized exanthematous pustulosis, Sweet's syndrome, and dermatitis herpetiformis–like eruption (46–50). The neutrophilic dermatitis seen as a result of granulocyte repopulation due to exogenous granulocyte colony stimulating factor (G-CSF) is described in the section of this chapter pertaining to eruptions resulting from human recombinant proteins.

ACUTE GENERALIZED EXANTHEMATOUS PUSTULOSIS

In acute generalized exanthematous pustulosis (AGEP), widespread nonfollicular, sterile pustules develop within a period of hours after administration of the offending agent. Although enteroviral infection and mercury exposure are cited as causes, antibacterial antibiotics, most commonly pristinamycin and ampicillin/amoxicillin, are most often implicated, with a broad range of other medications as well, including acetaminophen, quinolones, hydroxychloroquine, alphonamides, terbinafine, and diltiazem (51). Fever, leukocytosis, purpura, and clinical

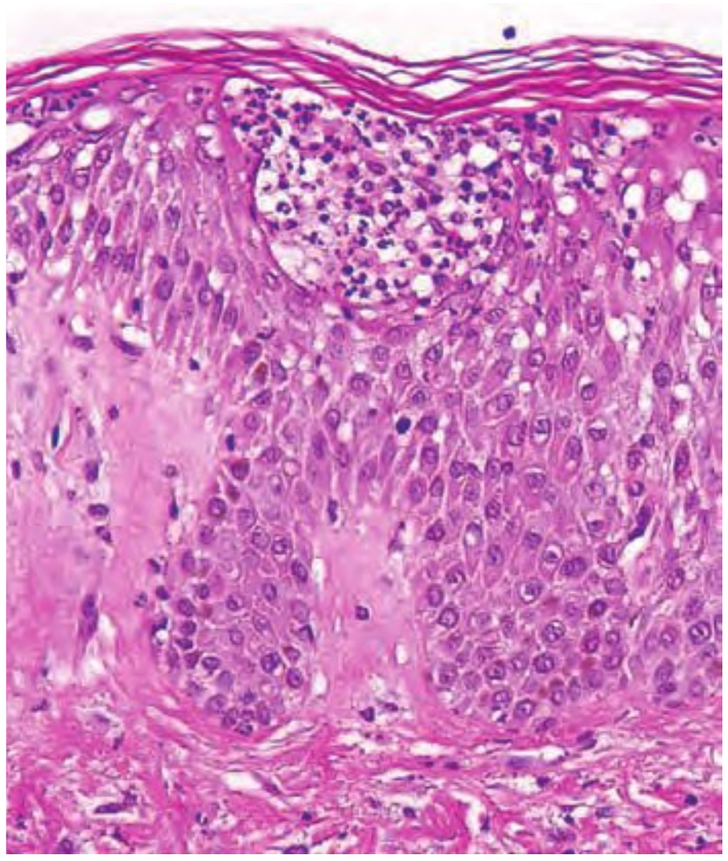

FIGURE 11-7. Acute generalized exanthematous pustulosis. A subcorneal and intraspinous collection of neutrophils is present in the background of mild epidermal edema (spongiosis).

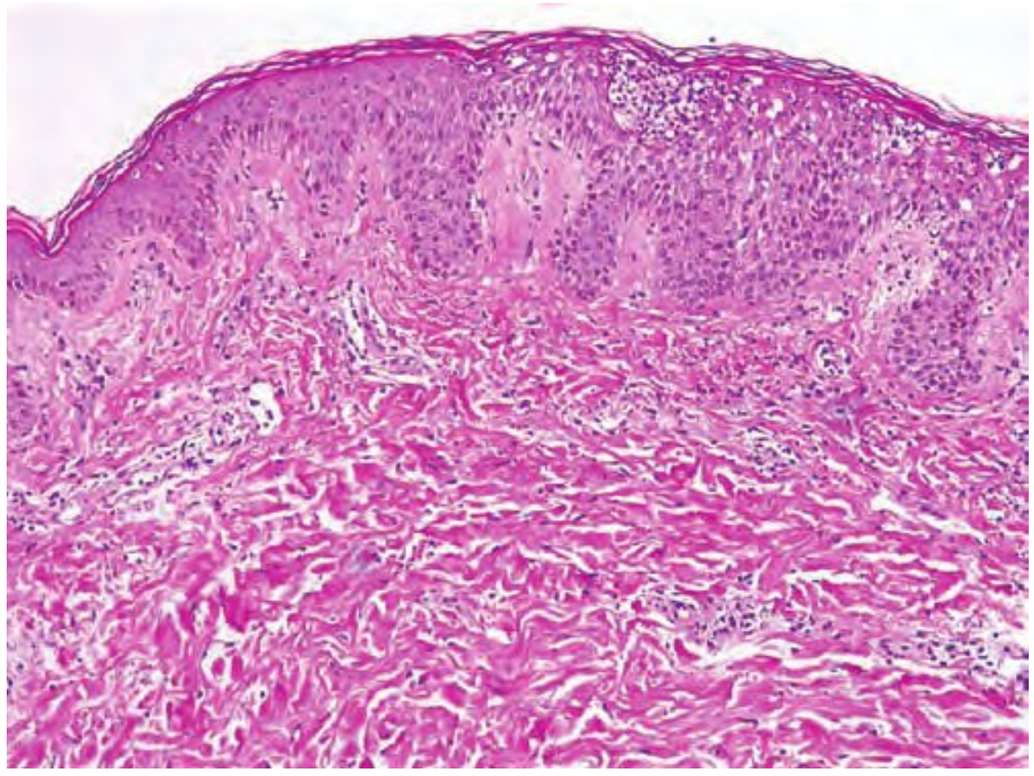

FIGURE 11-8. Acute generalized exanthematous pustulosis. Diffuse spongiosis and a mild upper dermal perivascular inflammatory infiltrate are seen in this case caused by amoxicillin.

features suggesting erythema multiforme accompany the pustules. *In vitro* studies have shown this to be a drug-specific process effected by $CD4^+$ T-cell–mediated release of the neutrophil chemoattractant interleukin-8 (IL-8) (52). T cells from patients with AGEP secrete high levels of IL-8/CXCL8, a potent neutrophil attractant chemokine. In addition, these T cells produce large quantities of granulocyte-macrophage colony stimulating factor (GM-CSF) (53). Unlike drug-induced macular and papular eruptions, there is no upregulation of major histocompatibility complex (MHC) class II expression on keratinocytes.

Histopathology. Biopsies of AGEP have subcorneal or intraepidermal pustules, papillary dermal edema, and a lymphohistiocytic perivascular infiltrate with some eosinophils and neutrophils (Figs. 11-7 and 11.8). Vasculitis and/or single-cell keratinocyte necrosis may be present.

Differential Diagnosis. Based strictly on histologic descriptions, distinction of AGEP from pustular psoriasis, subcorneal pustular dermatosis, and, in some instances, leukocytoclastic vasculitis cannot be made.

DRUG-INDUCED SWEET'S SYNDROME–LIKE ERUPTION

This neutrophilic dermatosis is clinically identical to the non–drug-induced variant of Sweet's syndrome (see Chapter 9). As such, it presents with tender erythematous plaques. Implicated drugs include furosemide, oral contraceptive, and nitrofurantoin (49,54). A localized variation of this is neutrophilic dermatosis of the dorsal hands (NDDH), which presents as pustules and ulcerative plaques on the dorsal hands. Some patients have lesions limited to the dorsal hands, whereas others have additional skin changes elsewhere (55).

Histopathology. A biopsy shows a dermal neutrophilic infiltrate identical to non–drug-induced Sweet's syndrome (see Chapter 9). In NDDH, leukocytoclastic vasculitis is seen on biopsy (56).

TOXIC ACRAL ERYTHEMA

Hand-foot syndrome, palmar-plantar erythrodysethesia syndrome, or toxic acral erythema refers to a transient painful erythema of the palms and soles that becomes edematous and ultimately desquamates. Blisters may form, leaving ulcerated epithelium. Numerous chemotherapeutic agents, including cytarabine, docetaxel, and 5-fluorouracil, have been implicated. The cutaneous lesions attributable to docetaxel—an antineoplastic agent that interferes with normal microtubule function—are not limited to acral sites (57).

Histopathology. Histologically, the skin displays vacuolar degeneration of basilar keratinocytes with eventual cleft formation. Mild epidermal dysmaturation may be seen. Keratinocyte necrosis is also present in the lower third of the epidermis. In the dermis, there is a mild perivascular infiltrate of lymphocytes with few eosinophils.

DRUG-INDUCED SCLERODERMA-LIKE CONDITIONS

Scleroderma-like conditions have been attributed to numerous exogenous agents. Although the pathophysiology is unclear, disturbances in the vasculature and immune system leading to

fibroblastic dysregulation and subsequent deposition of intercellular matrix proteins have been proposed, and telomerase activity appears to serve a protective role (58). Bleomycin, an antitumor agent, is known to cause similar changes in a reversible, dose-dependent fashion in both the skin and the lung due to drug accumulation in these organs deficient in specific metabolic enzymes (59). Multiple cycles of docetaxel are also associated with rapid development of transient scleroderma-like features in dependent areas (60) . Scleroderma-like changes have also been associated with other agents, including phytonadione (vitamin K_1), L-tryptophan, pentazocine, paclitaxel, penicillamine, ergot, bromocriptine, ketobemidone, morphine, cocaine, and appetite suppressants (61,62).

Histopathology. The features are those of idiopathic scleroderma (see Chapter 10), including fibrosis of the dermis and subcutis, adnexal structure entrapment, and atrophy and mild vascular dilation with minimal to no inflammatory infiltrate.

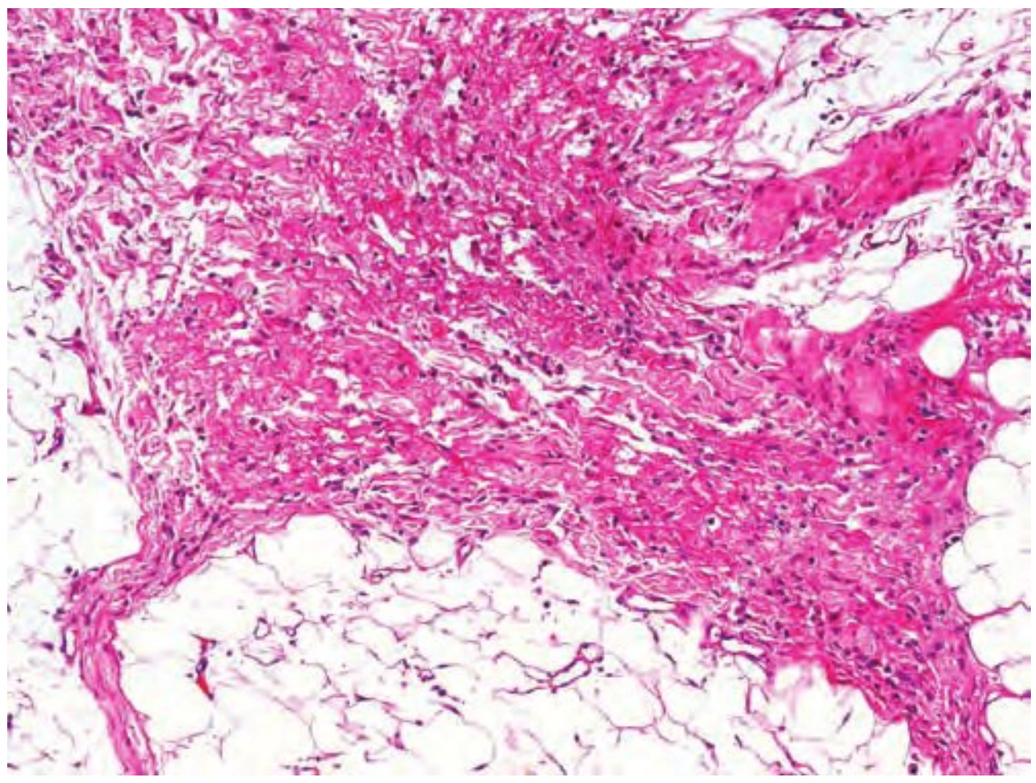

FIGURE 11-9. Nephrogenic systemic fibrosis. The deep dermis shows increased cellularity composed of activated fibroblasts with stellate morphology and occasional multinucleation. Increased collagen and dermal mucin are also present.

NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis (NSF), previously referred to as nephrogenic fibrosing dermopathy, is a progressive multiorgan fibrosing disorder. Although the cause and pathogenesis remain elusive, it has been closely linked to patients with compromised renal function and gadolinium exposure. High morbidity and mortality are associated with NFD. The fibrosis most commonly affects the lower extremities and manifests as dense induration, papules, or plaques. A role for gadolinium in routing the collagen-producing circulating fibrocyte has been proposed (63). A gadolinium-associated systemic inflammatory process that results in mobilization of iron and subsequent tissue injury also has been proposed (63). NSF is covered in detail in the chapter of this book pertaining to cutaneous fibrosing disorders (see Chapter 10).

Histopathology. The biopsy specimen shows mild to moderate increased cellularity in the mid to deep reticular dermis. The cellularity is composed of fibroblasts with activated morphology, large nuclei, occasional multinucleation, and abundant angulated cytoplasm (Fig. 11-9). Increased collagen and dermal mucin are also characteristically seen. The cellularity and collagen deposition may extend along the subcutaneous septae and fascia.

BULLAE AND SWEAT GLAND NECROSIS IN DRUG-INDUCED COMA

A patient who is in a coma as a result of an accident, illness, or a large dose of a narcotic drug may show, within a few hours, areas of erythema at sites of pressure. Usually within 24 hours, vesicles and bullae develop in the erythematous patches. The incidence of bullae depends on the severity of the coma and is highest in patients who subsequently die. Coma caused by carbon monoxide poisoning can also produce the lesions (32). The bullae are located at sites subjected to pressure, such as the hands, wrists, scapulae, sacrum, knees, legs, ankles, and heels.

Histopathology. The epidermis shows varying degrees of necrosis. In areas of complete necrosis of the epidermis, the bullae arise subepidermally, but small intraepidermal vesicles may be seen in areas of only diminished viability showing eosinophilia of the cytoplasm and decreased staining of the nuclei. Where the epidermis is necrotic in its upper layers but not in its lower layers, even large bullae can form intraepidermally.

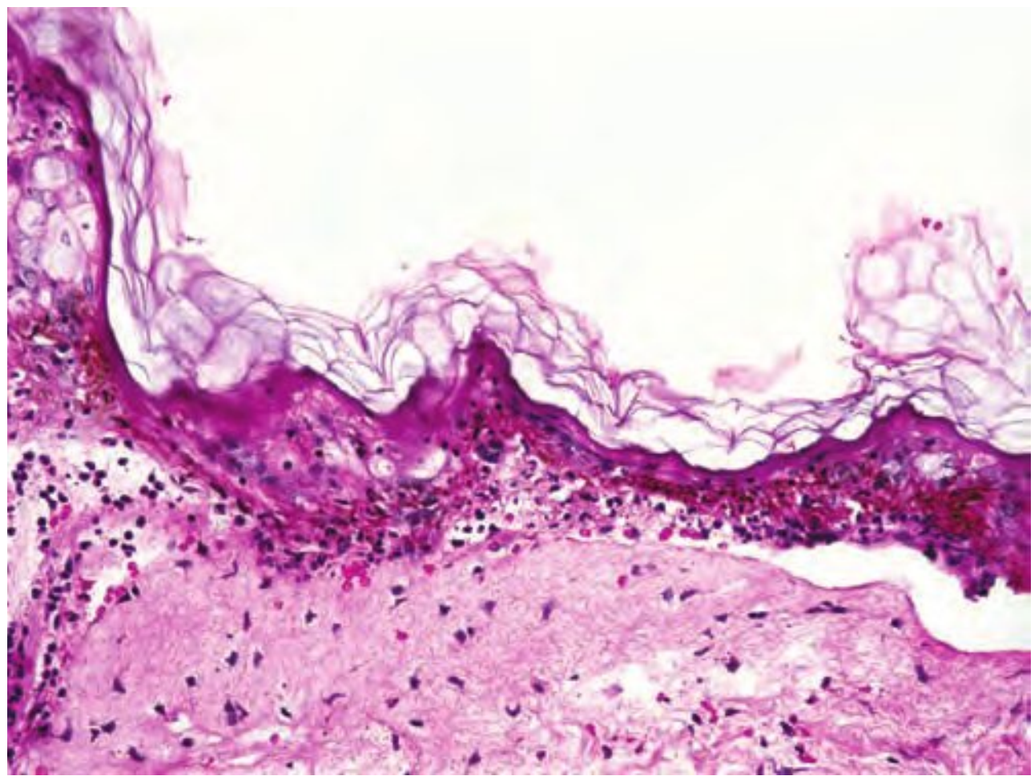

FIGURE 11-10. Drug-induced coma bulla. There is extensive necrosis of the epidermis with subepidermal blister formation. Inflammation in the blister cavity is secondary to adjacent ulceration. The dermis shows only a mild inflammatory infiltrate.

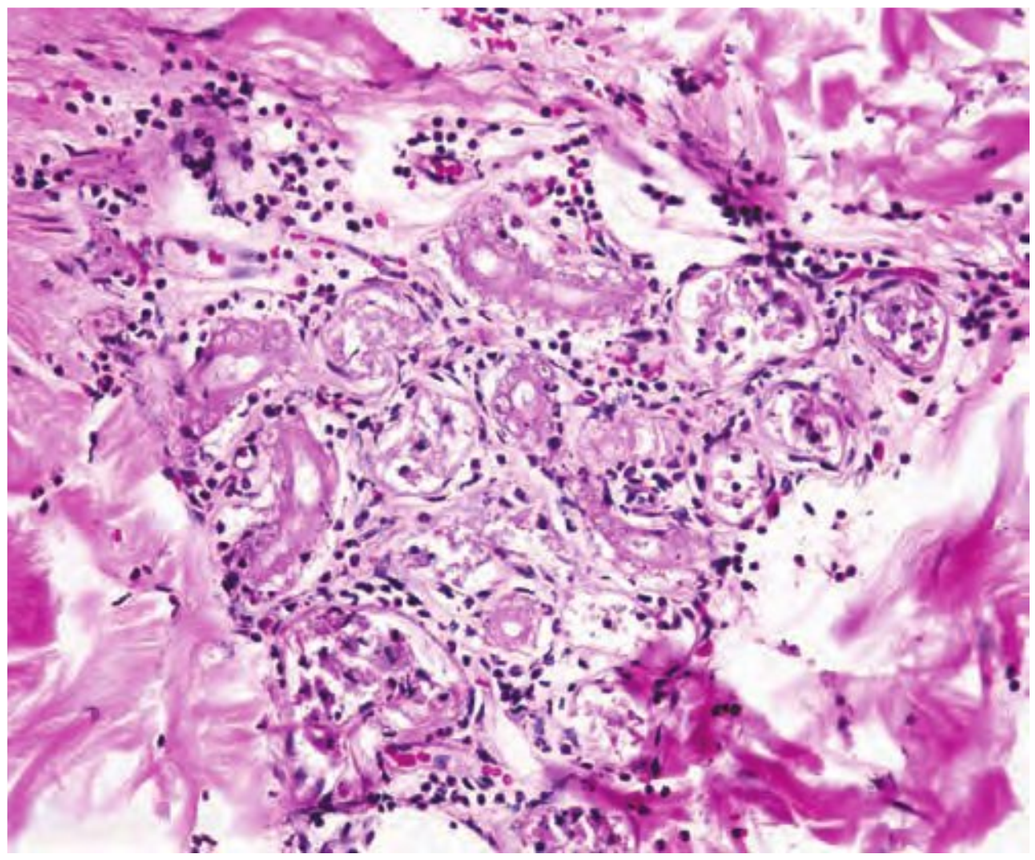

FIGURE 11-11. Coma bulla and sweat gland necrosis. This image shows necrosis of the eccrine coil with cytoplasmic eosinophilia along with absent and pyknotic nuclei.

Blisters may also form in a suprabasal location and may contain some acantholytic cells (Fig. 11-10) (64).

The secretory cells of the sweat coil are the most susceptible to necrosis, which is characterized by eosinophilic homogenization of their cytoplasm and pyknosis or absence of their nuclei. The sweat ducts usually appear less severely damaged but may also show pale staining or necrosis similar to that of the secretory cells (Fig. 11-11) (64). Necrosis may also be seen in the hair follicle, sebaceous gland, and, as mentioned, the epidermis (64). It is of interest that the sweat gland necrosis is limited to areas in which there are skin lesions. In patients who survive, the necrotic sweat gland epithelium is replaced by normal-appearing epithelial cells within about 2 weeks. In many instances, the pilosebaceous units are also affected with sebaceous gland necrosis and occasional necrosis of the outer and inner root sheaths.

The dermis beneath the bullae, and occasionally also the dermis around the sweat glands, contains a sparse polymorphous infiltrate composed of neutrophils, eosinophils, lymphocytes, and histiocytes. In addition, some extravasated erythrocytes are often present.

Vascular changes consist of vessel wall damage associated with a neutrophilic infiltrate (64). Lesions due to a non–drug-induced coma characteristically show fibrinoid thrombi in the vascular lumina (65).

Pathogenesis. The necrosis of the epidermis and sweat glands is a result of both generalized and local hypoxia. The bullae, in turn, are the result of epidermal damage. Coma, whether the result of an accident, an illness, or a drug, causes generalized hypoxia by depressing blood circulation and respiration. In the case of poisoning with carbon monoxide, its binding to hemoglobin acts as an additional factor (66) . Pressure causes further local hypoxia by decreasing blood flow.

DRUG-INDUCED BULLOUS DISORDERS

Several medications are linked to the development of antibody-mediated pemphigus (Table 11-1). Among these, penicillamine is perhaps the most common; however, the growing list of implicated agents includes other thiol-, sulfur-, and amide-containing drugs (67). The majority of cases of penicillamine and other thiol-induced pemphigus present as pemphigus foliaceus and have fewer immunofluorescence findings and a more favorable prognosis on drug withdrawal. Those cases attributed to nonthiol drugs, in particular those with an active amide group, may provoke disease indistinguishable from spontaneously occurring pemphigus vulgaris. Drug induction of subepidermal blisters is also recognized, with vancomycin-induced linear IgA dermatosis as a prime example (68–70). Oropharyngeal pemphigus secondary to interferon-α2a has also been reported (71).

Histopathology. Histologic examination reveals a picture identical to that seen in pemphigus vulgaris and/or pemphigus foliaceus not associated with drugs (72) (see Chapter 9). The autoantibody response to desmoglein 1 and desmoglein 3 is similar in both spontaneous and drug-induced disease (73).

Pathogenesis. Both biochemical and immunologic mechanisms, not mutually exclusive, have been proposed. In the subset of patients in which tissue-bound antibodies cannot be found, a biochemical mechanism has been suggested. These drugs directly bind to keratinocyte membranes, forming bonds that interfere with cell–cell adhesion and resulting in acantholysis (67). Predisposition to development of pemphigus vulgaris is linked to MHC II, specifically human leukocyte antigen (HLA) DRB1 and DQB1 (74). It has been postulated that polymorphisms of the DR4 β chain impart T-cell recognition of exogenous peptides that stimulate autoantibody production by B lymphocytes (75). In addition, immunologic

TABLE 11-1 Drugs Causing Pemphigus

Cephalexin	Cilazapril
Ceftazidime	Lisinopril

acantholysis can be triggered by biochemical events that lead to formation of a neoantigen, with consequent autoantibody production (67). In most thiol-drug–related cases, intercellular antibodies can be demonstrated, indicating that this class of drugs acts primarily through immunologically mediated acantholysis.

DRUG-INDUCED LUPUS ERYTHEMATOSUS

Drug-induced lupus erythematosus resembles mild systemic lupus erythematosus and is characterized by arthralgia or arthritis and myalgia and may be accompanied by serositis, fever, hepatomegaly, splenomegaly, and skin manifestations. The cutaneous lesions are typical of systemic lupus erythematosus with annular erythematous plaques, central clearing, and a peripheral scale (Fig. 11-12) and may erupt days to years after onset of treatment (76,77) . Central nervous system and renal involvement are rare. The drugs most commonly implicated include procainamide, hydralazine, quinidine, chlorpromazine, isoniazid, methyldopa, and propylthiouracil (78). However, the number of medications associated with induction of lupus erythematosus is increasing, with rare reports of terbinafine, docetaxel, anti–tumor necrosis factor-α, adalimumab, and others (60,79–81). It is possible that the development of a systemic lupus erythematosus–like syndrome in a patient under medication with these drugs represents the uncovering of latent systemic lupus erythematosus.

Drug-induced systemic lupus erythematosus can be clinically, pathologically, and serologically indistinguishable from spontaneously arising systemic lupus erythematosus. However, cutaneous and renal manifestations are rare in drug-induced systemic lupus erythematosus, and pleuropulmonary manifestations are somewhat more common than in spontaneous disease. Clinical presentations resembling subacute cutaneous lupus erythematosus secondary to terbinafine have been reported (82,83). Usually, but not always, the clinical and laboratory manifestations subside when the medication is discontinued.

FIGURE 11-12. Drug-induced subacute cutaneous lupus erythematosus. Annular erythematous plaques with mild peripheral scale are seen in this patient on Dilantin. (Courtesy of Donna Pellowski, MD.)

Histopathology. The histologic picture of the cutaneous lesions is the same as in lupus erythematosus (see Chapter 10).

Pathogenesis. As in other autoimmune-related disorders, genetic predisposition, in particular, HLA-DR4, has a role in drug-induced lupus. Antinuclear antibodies are usually present and directed against single-stranded DNA or histones (84). Different drugs appear to be associated with different antihistone profiles (78). Anti–double-stranded DNA antibodies are usually absent. Hypocomplementemia is rare. The occurrence of a lupus band on direct immunofluorescence testing of normal-appearing skin is uncommon (85). The rate of drug acetylation has also been associated with disease onset. Rapid acetylators have a much lower incidence of hydralazine-induced lupus, whereas slow acetylators are at higher risk (86). Additionally, there is evidence that myeloperoxidase produced by neutrophils in conjunction with cells capable of generating superoxides transforms lupus-inducing drugs to cytotoxic products. Elucidation of this process is evolving (78).

DRUG-INDUCED PHOTOSENSITIVITY

Drug-induced photosensitivity can be subdivided into photoallergic and phototoxic drug eruptions. Photoallergic drug eruptions represent a T-cell–mediated reaction.

Photoallergic Drug Eruption

In photoallergy, ultraviolet light alters either the hapten or the avidity with which the hapten combines with the carrier protein to form a complete photoantigen (87). Among the photoallergenic drugs are the sulfonamides; the thiazides, such as chlorothiazide and tolbutamide, both of which are aromatic sulfonamides; griseofulvin; the phenothiazines, such as chlorpromazine; quinine; topical nonsteroidal antiinflammatory medications, including piroxicam; and sunscreens (88,89). A photoallergic drug eruption causes a photocontact dermatitis in all light-exposed areas. Like any allergic contact dermatitis, it causes itching.

Histopathology. The histologic appearance of a photoallergic dermatitis is that of an allergic contact dermatitis and includes spongiosis, mild acanthosis, and a superficial perivascular lymphocytic infiltrate with eosinophils (Fig. 11-13) (90).

Phototoxic Drug Eruption

Certain internally administered drugs, in association with ultraviolet light, may produce a phototoxic dermatitis that resembles intensified sunburn. Among the drugs known to elicit a phototoxic response are all drugs capable of producing a

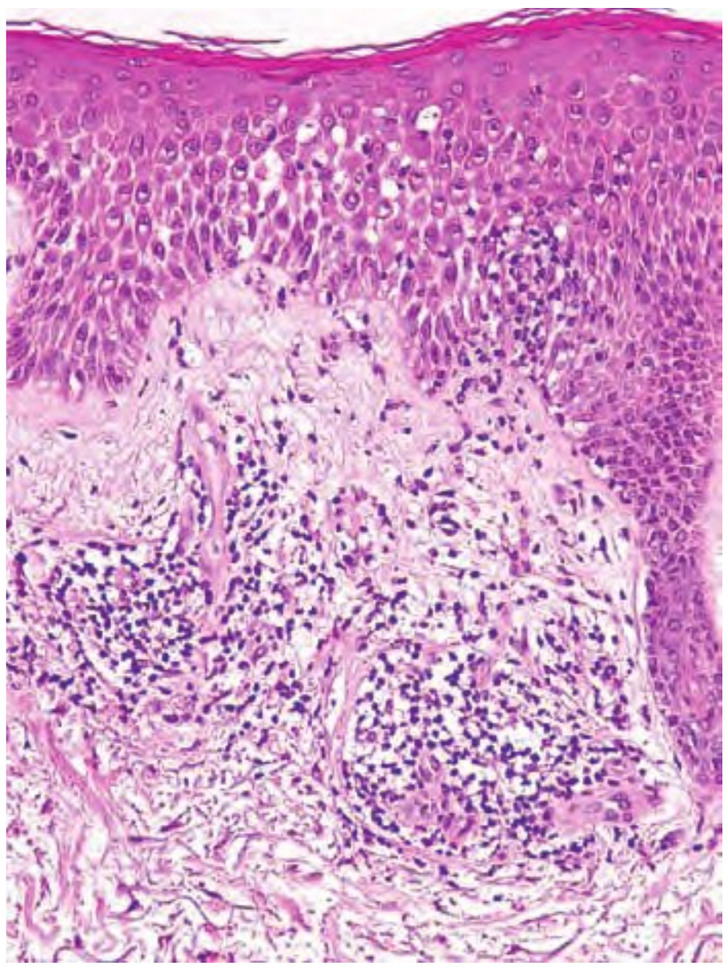

FIGURE 11-13. Photoallergic dermatitis. There is spongiosis with microvesicle formation, exocytosis of lymphocytes, and a perivascular lymphocytic infiltrate admixed with scattered eosinophils.

photoallergic reaction, provided that they are given in sufficiently high concentrations (91). Other commonly prescribed phototoxic drugs are certain tetracyclines, such as demeclocycline hydrochloride and doxycycline, quinolones, and psoralens (3,92).

Histopathology. A phototoxic drug eruption, like a sunburn reaction, shows both vacuolated keratinocytes (sunburn cells) characterized by abundant, pale cytoplasm and apoptotic keratinocytes characterized by reduced, eosinophilic cytoplasm. The dermis shows edema and enlargement of endothelial cells (Fig. 11-14).

PHOTODISTRIBUTED HYPERPIGMENTATION

Certain drugs—in particular, tetracycline, chlorpromazine, diltiazem, amiodarone, imipramine, and desipramine—are known to produce cutaneous discoloration on sun-exposed areas of the skin (94–96). This pigment change results from overproduction of melanin in melanocytes specifically stimulated by the offending drug, lack of melanin clearance due to stable complex formation with the drug, or dermal deposition of the drug, which undergoes an ultraviolet-related change that inhibits clearance (94). In imipramine hyperpigmentation, dispersive spectroscopy studies show that the dermal granules have copper and sulfur, elements normally found in tyrosinase and pheomelanin as well as melanin (97,98). This pigment alteration results in blue, blue-gray, or brown hues. Exposed parts of the bulbar conjunctivae may show brownish pigmentation. Similarly, photodistributed slate-gray, reticulated pigmentation has been described in patients on long-acting diltiazem hydrochloride (94).

Histopathology. In chlorpromazine, amiodarone, imipramine, and desipramine reactions, there is variable amount of melanin in the basal layer of the epidermis. Throughout the dermis, there is considerable accumulation of pigment-laden macrophages, predominantly in a perivascular pattern (Fig. 11-15). The pigment has the staining properties of melanin, in that it stains black with the Fontana-Masson silver stain and is decolorized by hydrogen peroxide. Hyperpigmentation from imipramine results from melanin complexed with drug metabolite, which causes refractile golden-yellow granules that deposit in the superficial and papillary dermis and are visible on light microscopy (Fig. 11-16) (99). In addition, on electron microscopy, electron-dense granules are present within macrophages (98). In patients on long-term chlorpromazine, this melanin-like material is found in many internal organs,

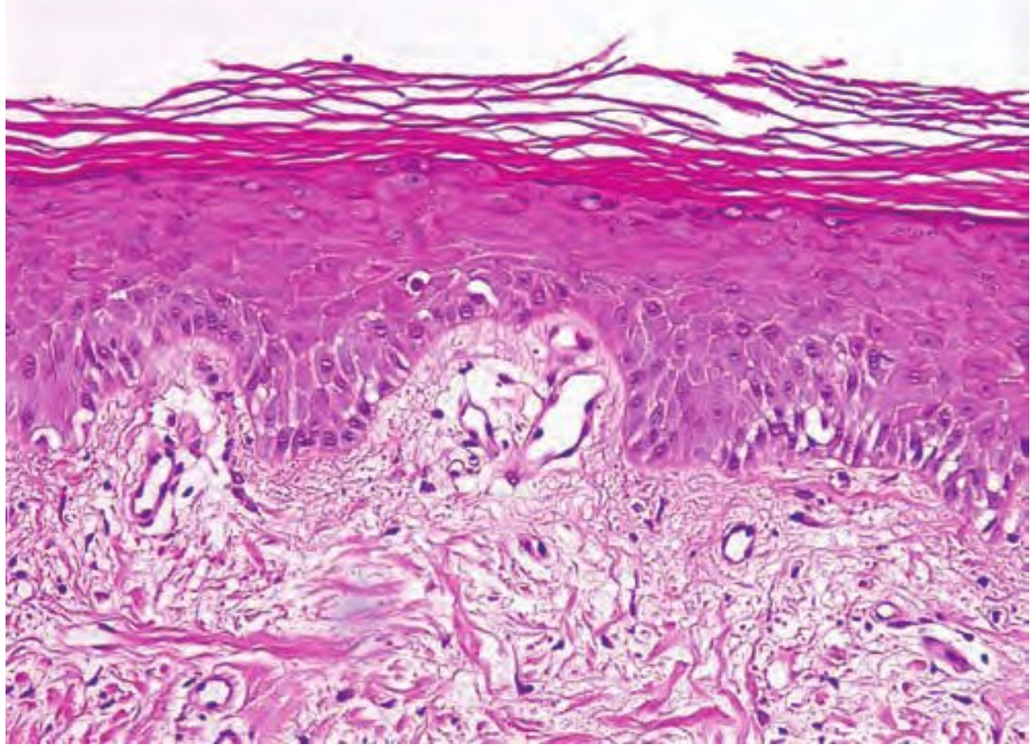

FIGURE 11-14. Phototoxic dermatitis. There are vacuolated keratinocytes and apoptotic keratinocytes in the epidermis. Dermal edema and enlarged endothelial cells are also characteristic.

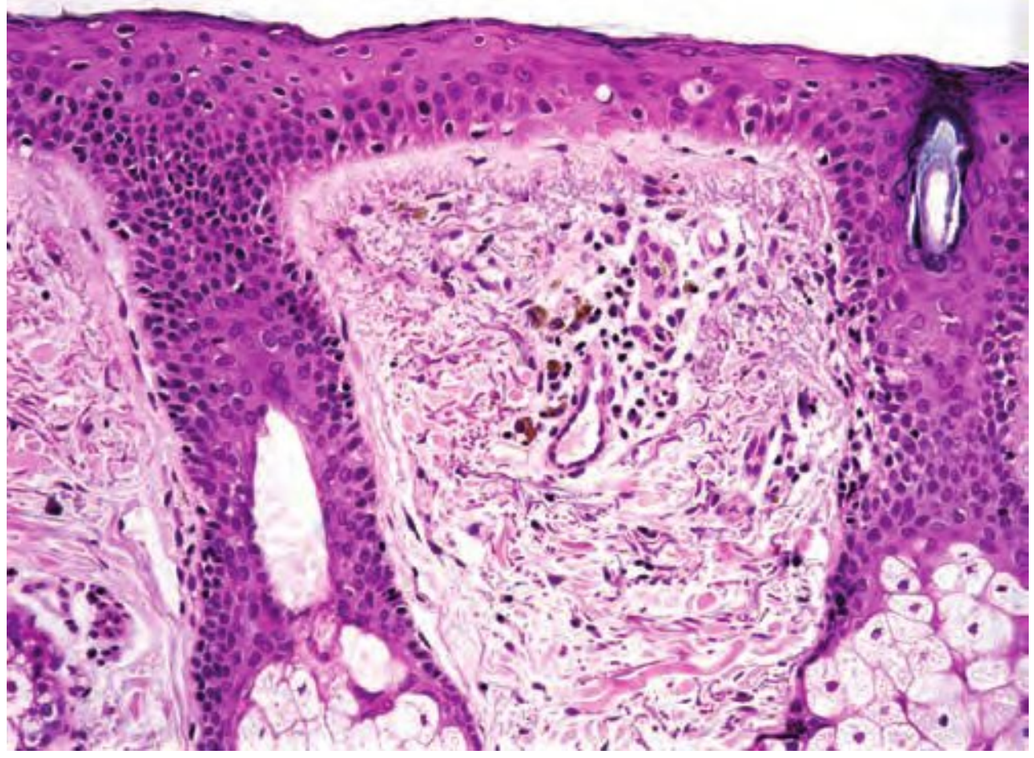

FIGURE 11-15. Chlorpromazine pigmentation. Perivascular pigment-laden macrophages are seen in this case of chlorpromazine pigmentation.

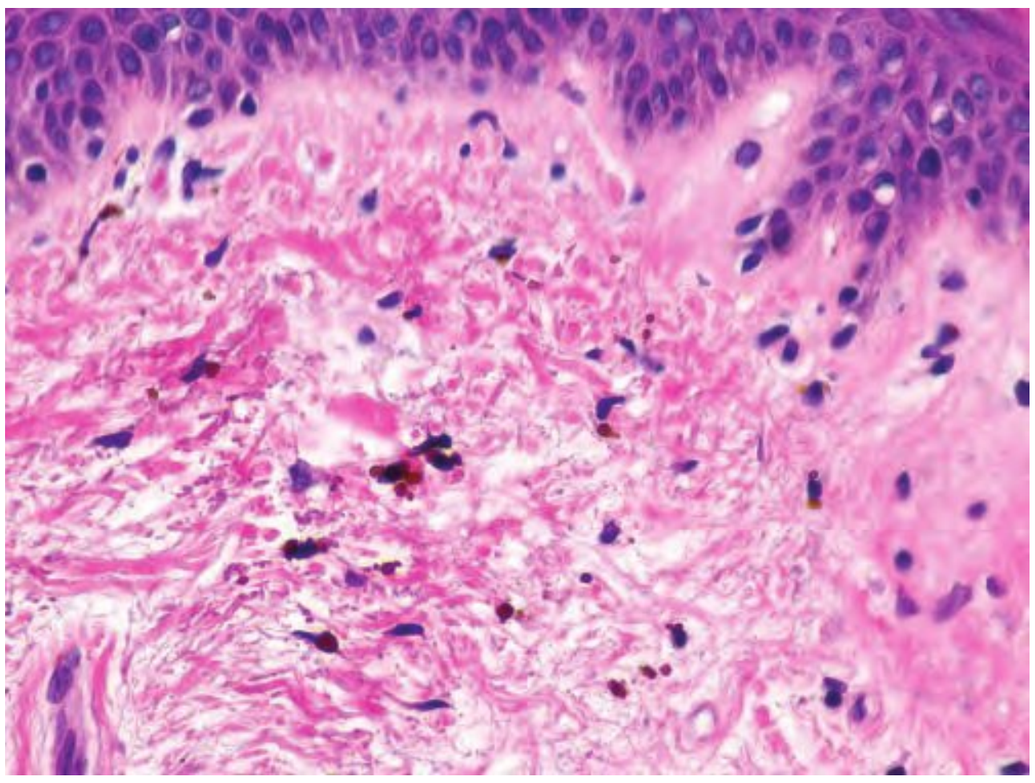

FIGURE 11-16. Imipramine pigmentation. Photodistributed slate gray pigmentation is caused by round, yellow-brown globules in the dermis.

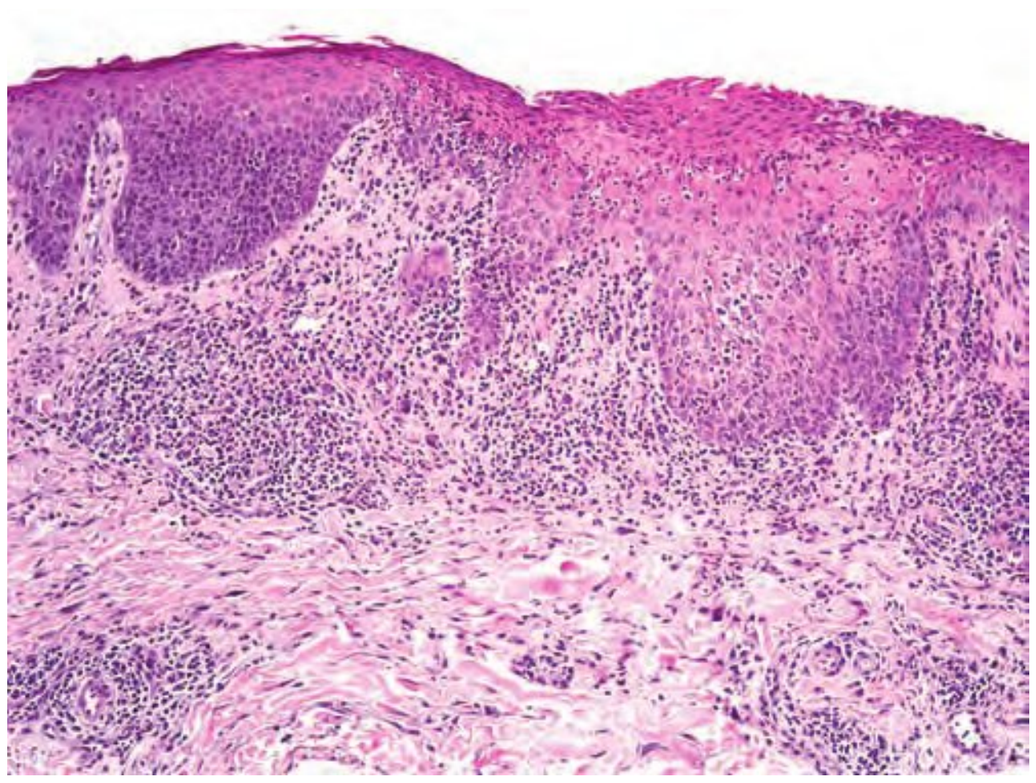

FIGURE 11-17. Cutaneous pseudolymphoma. There is a dense inflammatory infiltrate with exocytosis of atypical-appearing lymphocytes and absence of spongiosis in this Dilantin-induced pseudolymphoma.

throughout the entire mononuclear-phagocyte system, and, to a lesser degree, in the parenchymal cells of the liver, kidneys, and endocrine glands, in myocardial fibers, and in cerebral neurons (100).

In contrast, the diltiazem reactions reveal lichenoid dermatitis with atrophic epidermis and basal vacuolar change. The papillary dermis is expanded with prominent and dilated thin-walled vessels and a sparse perivascular and periadnexal lymphocytic infiltrate (95).

Histogenesis. Electron microscopic examination has confirmed the presence of many melanosome complexes within the lysosomes of dermal macrophages. In addition, 0.2- to 3-μm-diameter, round or bizarrely shaped electron-dense bodies may be seen in macrophages, endothelial cells, pericytes, Schwann cells, and fibroblasts, usually within lysosomes (101,102). Both electron-dense bodies and melanosome complexes may be found within the same lysosome. Although the dense bodies histochemically react like melanin, the striking sulfur peak on microprobe analysis strongly suggests the drug or its metabolite (102) is also present. Because some drugs do bind to melanin (103), it seems likely that the electron-dense bodies represent complexes of melanin with drug. These complexes are subsequently carried from the dermis by way of the circulating blood leukocytes to the various internal organs. In diltiazem-related hyperpigmentation, only melanosomes, without drug or drug metabolite, are seen (104).

DRUG-INDUCED PSEUDOLYMPHOMA SYNDROME

Phenytoin, ethosuxamide, lamotrigine, tattoo, carbamazepine, sodium valproate, gemcitabine, gold, and clonidine patch are among the agents that have been associated with a pseudolymphoma syndrome characterized by generalized lymphadenopathy, hepatosplenomegaly, fever, arthralgia, and eosinophilia (105–107). Cutaneous findings range from a few erythematous plaques or nodules to a generalized macular and papular eruption and generalized exfoliative dermatitis (107). In all cases there is improvement and ultimate clearing when the offending agent is discontinued.

Histopathology. On histologic examination of the skin, the infiltrate is often indistinguishable from that of mycosis fungoides (this syndrome is also known as "pseudo-mycosis fungoides"), in that there are cerebriform nuclei in the dermal infiltrate and Pautrier microabscesses in the epidermis (Fig. 11-17). In cutaneous nodules, the infiltrate may suggest a cutaneous lymphoma of the non-Hodgkin's type because large masses of atypical lymphocytes are present in the dermis and in the subcutaneous tissue. T-cell receptor monoclonality has been demonstrated in some cases (108).

DRUG-INDUCED PSEUDOPORPHYRIA

Ciprofloxacin, voriconazole, nonsteroidal antiinflammatory drugs, and oral contraceptives are among the medications reported to cause cutaneous lesions resembling the blisters of porphyria cutanea tarda (109–113). Unlike porphyria cutanea tarda, other cutaneous manifestations are absent, and no derangement in porphyrin metabolism has been identified. Healing occurs once the medication is discontinued. Implicated drugs include naproxen, furosemide, tetracycline, dapsone, and pyridoxine (114,115).

Histopathology. The blisters resemble the poorly or noninflamed subepidermal bullae of porphyria cutanea tarda (Chapter 17).

Histogenesis. The mechanism by which this reaction occurs is unknown. Unlike porphyria cutanea tarda, no deposits in the skin are revealed by direct immunofluorescence testing (Chapter 17) (115).

CUTANEOUS REACTIONS TO ANTINEOPLASTIC CHEMOTHERAPEUTIC DRUGS

In general, the cutaneous changes brought about by antineoplastic chemotherapeutic agents are the result of their antiproliferative effects disrupting cutaneous cellular metabolism. Clinical manifestations vary.

Hyperpigmentation develops under occluded skin after thiotepa administration. The grouped linear streaks, or "flagellate" hyperpigmentation, on the trunk and extremities are characteristic of bleomycin hyperpigmentation (116,117) (Fig. 11-18). In addition, hyperpigmentation after long-term hydroxyurea therapy is well documented (118,119). Diffuse hyperpigmentation commonly occurs after antineoplastic chemotherapy. Erythema preceding the hyperpigmentation in these settings is minimal or absent.

Inhibitors of the epidermal growth factor receptor have increasing importance in the treatment of solid tumors. These receptors are integral to epidermal development and maintenance. Accordingly, cutaneous reactions due to inhibition is of the receptors are common. In most of these reactions, 85%, occur as an acneiform follicular eruption (120–122).

Anagen effluvium is a well-established effect of the antiproliferative nature of many chemotherapeutic agents. Neutrophilic eccrine hidradenitis presents with erythematous,

FIGURE 11-18. Bleomycin pigmentation. The characteristic linear "flagellate" streaks on the trunk of this patient on bleomycin. (Courtesy of Donna Pellowski, MD.)

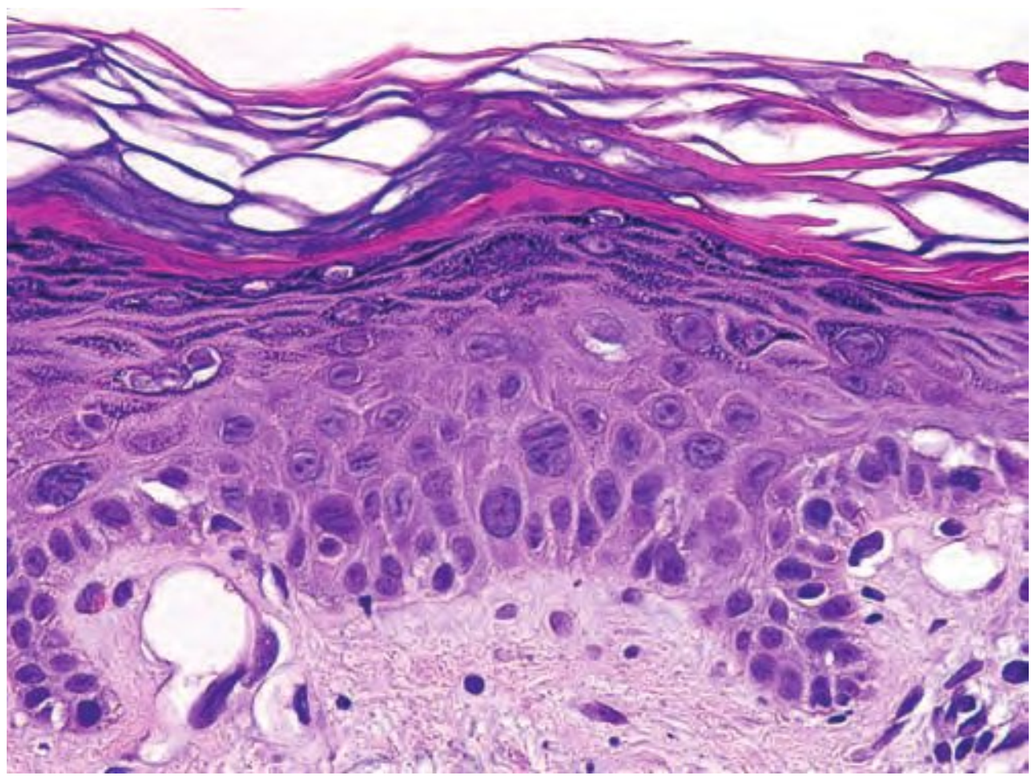

FIGURE 11-19. Mild epidermal dysmaturation due to antineoplastic chemotherapy. Loss of polarity and disorganization of keratinocytes is minimal and confined to the lower epidermal layers in this specimen.

often acral, plaques several days after cytoreductive chemotherapy. Acral erythema unassociated with primary eccrine changes also occurs after chemotherapy (see previous discussion).

Histopathology. Cytoreductive chemotherapy may cause a disruption of the normal pattern of keratinocyte maturation from small cuboidal cells in the basilar epidermis to flattened squamous cells in the stratum corneum. At intervening epidermal levels, keratinocytes are separated by widened intercellular spaces, lose polarity, and display irregular large nuclei, midepidermal mitotic figures, and apoptosis (Figs. 11-19 and 11.20). These changes, referred to as *epidermal dysmaturation*, may be observed in the epidermis after any significant cytoreductive

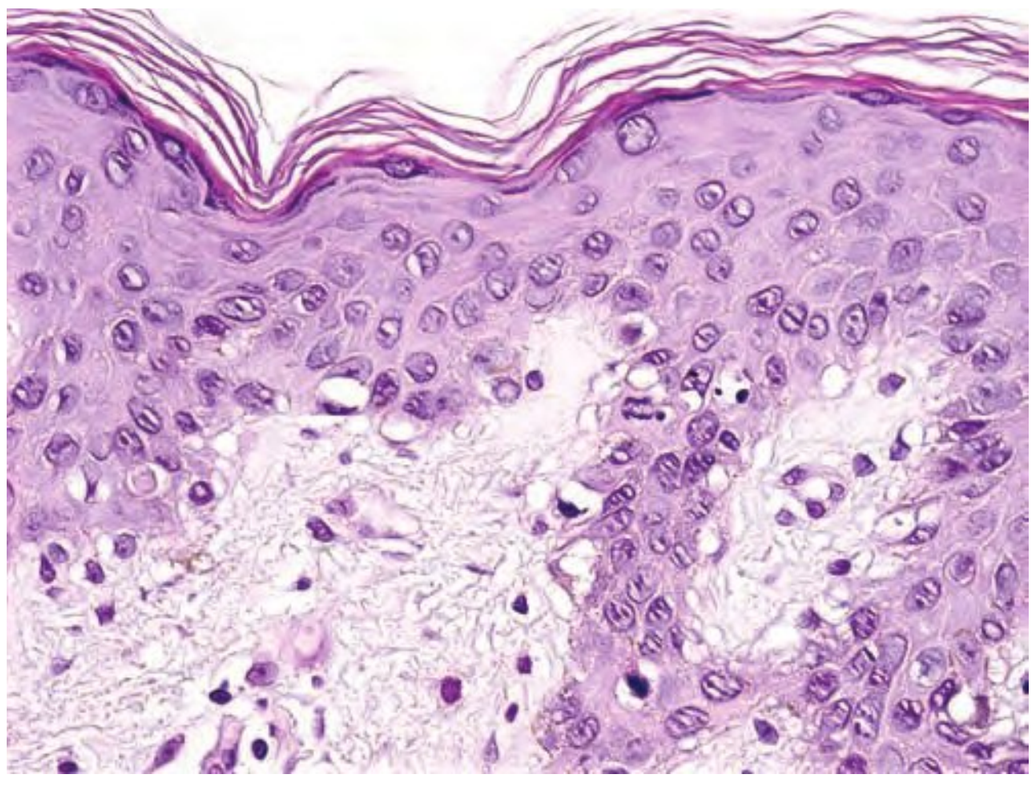

FIGURE 11-20. Severe epidermal dysmaturation due to antineoplastic chemotherapy. Loss of polarity and disorganization of keratinocytes are advanced in this specimen.

therapy and are not necessarily associated with clinical lesions. Upper dermal melanophages often accompany these changes. In this setting, "starburst" mitotic figures are described after systemic etoposide administration (123). Numerous mid- and upper-level mitotic figures (so-called "mitotic arrest") are observed after podophyllotoxin application to condyloma. Etoposide and podophyllotoxin are vinca alkaloid derivatives, disrupting mitotic spindle formation by attaching to microtubule proteins.

Several entities in this section are unified by the theory of drug concentration in eccrine sweat. Specimens from patterned *postchemotherapy hyperpigmentation* show vacuolization of basilar epidermis, melanin incontinence, and apoptosis in occluded skin after administration of alkylating agents (124). Inflammation is sparse or absent. Squamous metaplasia of upper eccrine ducts, *syringosquamous metaplasia*, is described after cytoreductive therapies. The normally cuboidal cells lining the duct display irregularly increased amounts of eosinophilic cytoplasm with associated polymorphous inflammation, fibrosis, and necrosis (Fig. 11-21). *Neutrophilic eccrine hidradenitis* consists of variable infiltration of the eccrine coil by neutrophils and lymphocytes with necrosis of secretory epithelium. Individual cells or whole coils show increased cytoplasmic eosinophilia, degeneration of nuclei, and loss of integrity of cell walls (Fig. 11-22). Edema and mucinous change may be seen in the perieccrine adipose tissue.

Histogenesis. The notion of concentration of antineoplastic chemotherapeutic agents in sweat serves to unify the clinical observation of patterned hyperpigmentation (beneath bandages and electrocardiogram pads in the case of thiotepa) and the histologic observations of neutrophilic eccrine hidradenitis and syringosquamous metaplasia. Changes after antineoplastic chemotherapy likely represent a mix of direct toxic effect on the various constituent cells of the skin with secondary inflammation incited by cell damage. Other chemotherapy-related cutaneous changes may also involve similar mechanisms—namely, intertriginous erosion/ulceration after isophosphamide (125) and flagellate hyperpigmentation after bleomycin. Why specific agents affect specific cell populations in the skin in repeatable fashion is unclear. It is important to note that identification of epidermal dysmaturation assumes considerable importance in establishing the diagnosis of acute graft-versus-host reaction (126). When possible, the inflammation and apoptosis of a graft-versus-host reaction should be sought in areas unaffected or less affected by dysmaturation.

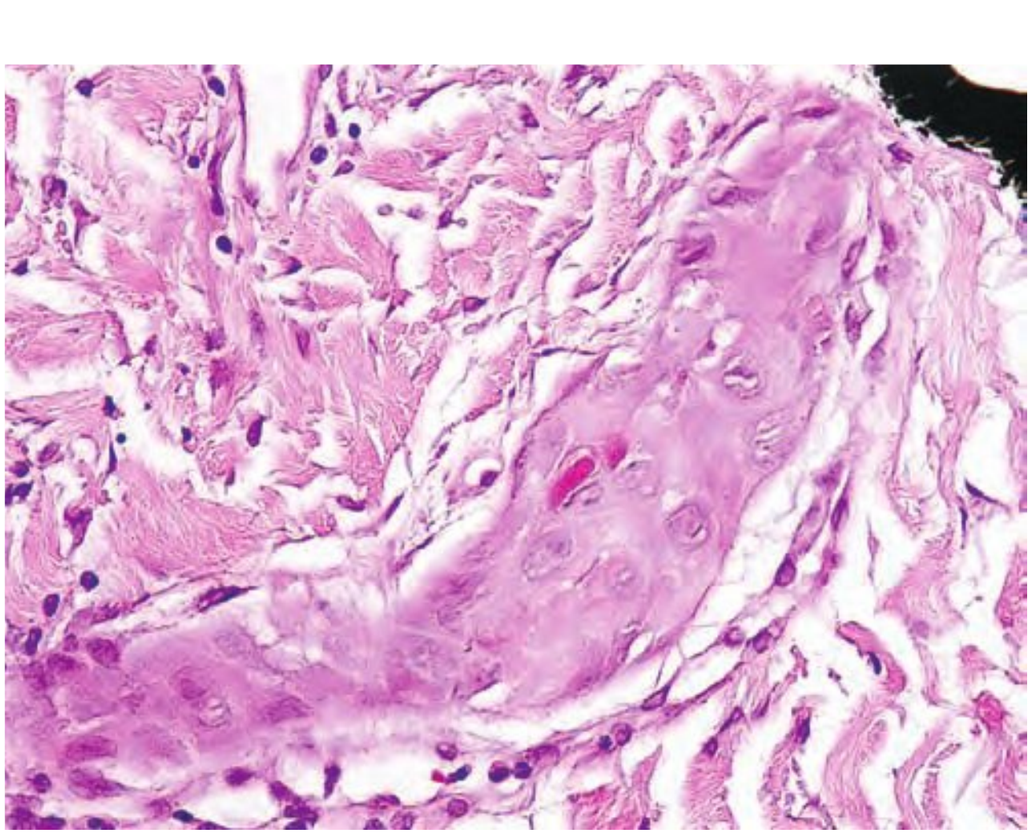

FIGURE 11-21. Syringosquamous metaplasia. This eccrine duct is lined by squamoid cells with ample eosinophilic cytoplasm and large nuclei rather that the normal cuboidal cells.

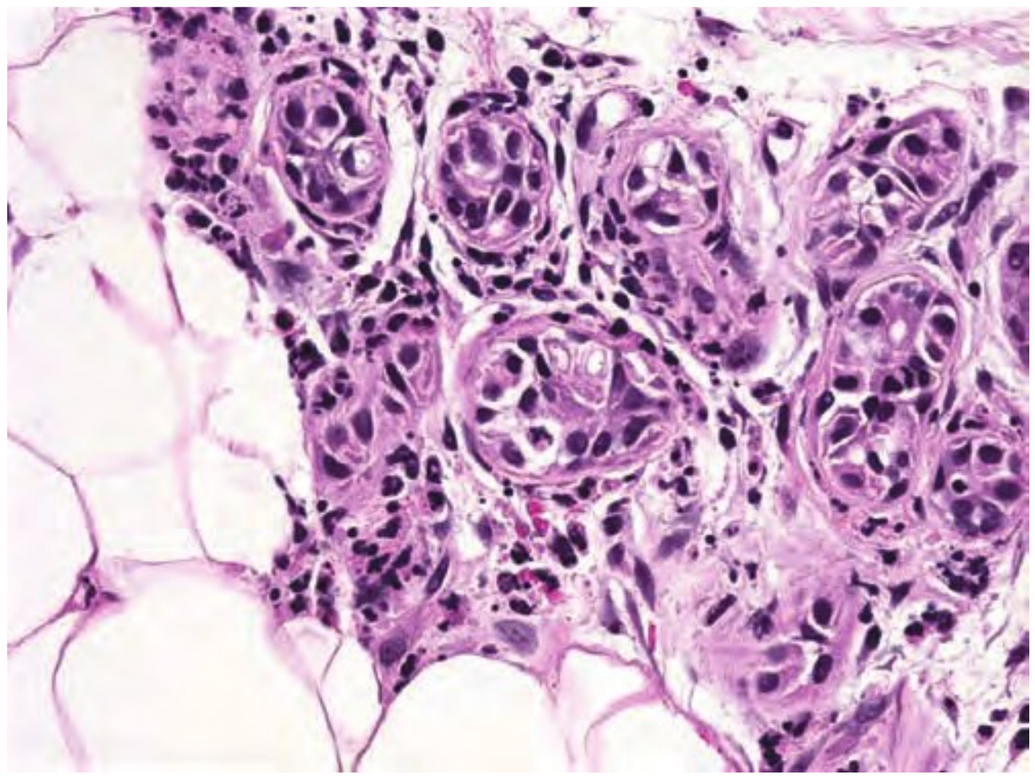

FIGURE 11-22. Neutrophilic eccrine hidradenitis. Neutrophils and lymphocytes are present in the perieccrine adventitia and eccrine coil. Increased cytoplasmic eosinophilia and pyknotic nuclei characterize eccrine necrosis.

CUTANEOUS ERUPTIONS RESULTING FROM ADMINISTRATION OF HUMAN RECOMBINANT PROTEINS

Technologic advances in recombinant DNA research have resulted in the availability of human recombinant cytokines (including colony-stimulating factors) for administration to patients to effect immunologic manipulation for therapeutic benefit. Based on the actions of human cytokines, specific agents are administered, generally to immunocompromised patients, to enhance the number and/or activity of leukocytes, platelets, or erythrocytes. This action is aimed at hematopoietic cells in the marrow and/or mature leukocytes in the peripheral circulation or tissues.

Mucocutaneous effects of systemic administration of at least 13 cytokines have been described (Table 11-2). The findings generally occur (a) at injection sites, (b) as variably distributed eruptions, or (c) as exacerbation or induction of other dermatologic disorders, such as psoriasis.

Etanecept, a recombinant tumor necrosis factor-α receptor fused to the Fc fragment of IgG_2, and recombinant interferon-β

TABLE 11-2 Mucocutaneous Effects of Systemic Administration of Cytokines

Cytokine	Reported association
Interleukin-1 α and β	Phlebitis, mucositis
Interleukin-2	Diffuse erythema, exacerbation of psoriasis, and autoimmune diseases
Interleukin-3	Flushing
Interleukin-4	Edema
Interleukin-6	Erythematosus eruption
Granulocyte-macrophage colony-stimulating factor	Diffuse eruption, Sweet's syndrome
Granulocyte colony-stimulating factor	Neutrophilic dermatoses, vasculitis
Tumor necrosis factor-α	Erythroderma, psoriasis
Tumor necrosis factor-α receptor/immunoglobulin G_2 Fc	Injection site reaction
Epidermal growth factor receptor inhibitor	Acneiforme eruption, psoriatic palmoplantaris pustulosis
Interferon-α	Alopecia, injection-site reaction, exacerbation of psoriasis, severe eczema
Interferon-β	Mostly injection-site reactions, including vasculitis
Interferon-γ	Exacerbated graft-versus-host reactions

1a and 1b have been associated with injection-site reactions, lichenoid dermatitis, and erythema multiforme (35,127).

Recombinant human/mouse monoclonal anti–epidermal growth factor receptor (EGFR) causes a variety of cutaneous eruptions, as might be anticipated based on the role of EGFR in cutaneous homeostasis; 85% of these eruptions are acneiform (120). This eruption of erythematous follicular papules and plaques may occur on the face, trunk, or extremities and is associated with intense pruritis and fever (120).

Granulocyte colony-stimulating factor is used to accelerate repopulation of the granulocytic lineage of hematopoietic cells after bone marrow depletion either from chemotherapy or bone marrow transplantation. Large dermal histiocytes intercalating collagen bundles are characteristically seen as a result of this neutrophil recovery process. In addition, injection-site reaction, pyoderma gangrenosum, Sweet's-like eruption, leukocytoclastic vasculitis, and folliculitis have been attributed to hematopoietic growth factors (128).

When asked to examine a skin biopsy specimen from an eruption suspected to be caused by a cytokine, the pathologist should know the temporal relation between administration of the cytokine and appearance of the eruption, white blood cell count, and actions of the cytokine. Ideally, the cutaneous eruption will have begun soon after initiation of cytokine therapy, and the histopathology of the eruption will relate in some way to recognized effects of the cytokine.

Histopathology. The morbilliform eruption induced by pharmacologic doses of human recombinant GM-CSF illustrates these criteria (128). The upper dermis contains a perivascular and interstitial infiltrate of neutrophils, eosinophils, and lymphocytes (129) (Fig. 11-23). The relative proportion of cell types varies. Macrophages are increased in number and size and may contain melanin when situated in the upper dermis (130). The epidermis may display intercellular edema with exocytosis of inflammatory cells. Vasculitis is absent.

Granulocyte colony-stimulating factor is associated with the development of erythematous plaques that contain numerous neutrophils and upper dermal edema, thus resembling the skin lesions of Sweet's syndrome (128) (Fig. 11-24).

Findings at the site of etanercept injection include a superficial perivascular inflammatory infiltrate composed primarily of lymphocytes, with eosinophils admixed with small numbers of neutrophils and macrophages. Mild dermal edema and vasodilation are also noted (83,127). Interferon injection sites have shown a mild perivascular lymphocytic infiltrate and thrombosis of deep vessels without fibrinoid necrosis (131).

The acneiform eruptions associated with anti-EGFR show florid suppurative superficial folliculitis (120).

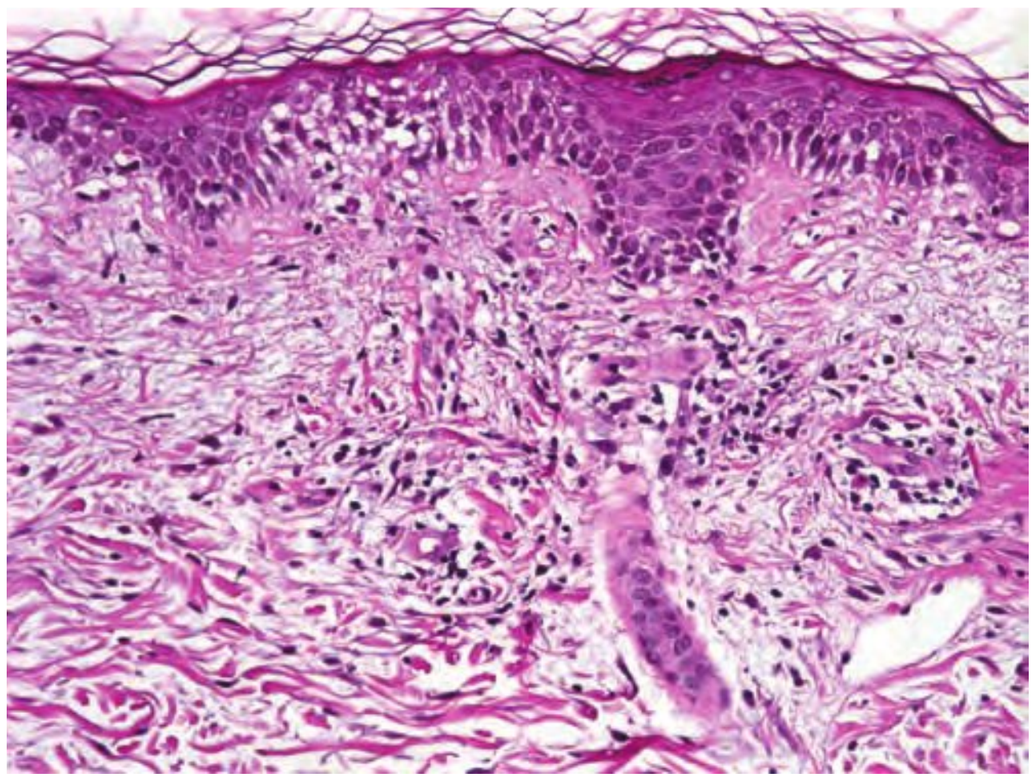

FIGURE 11-23. Granulocyte-macrophage colony-stimulating factor. A diffuse perivascular and interstitial inflammatory cell infiltrate is present with associated vascular dilation and spongiosis.

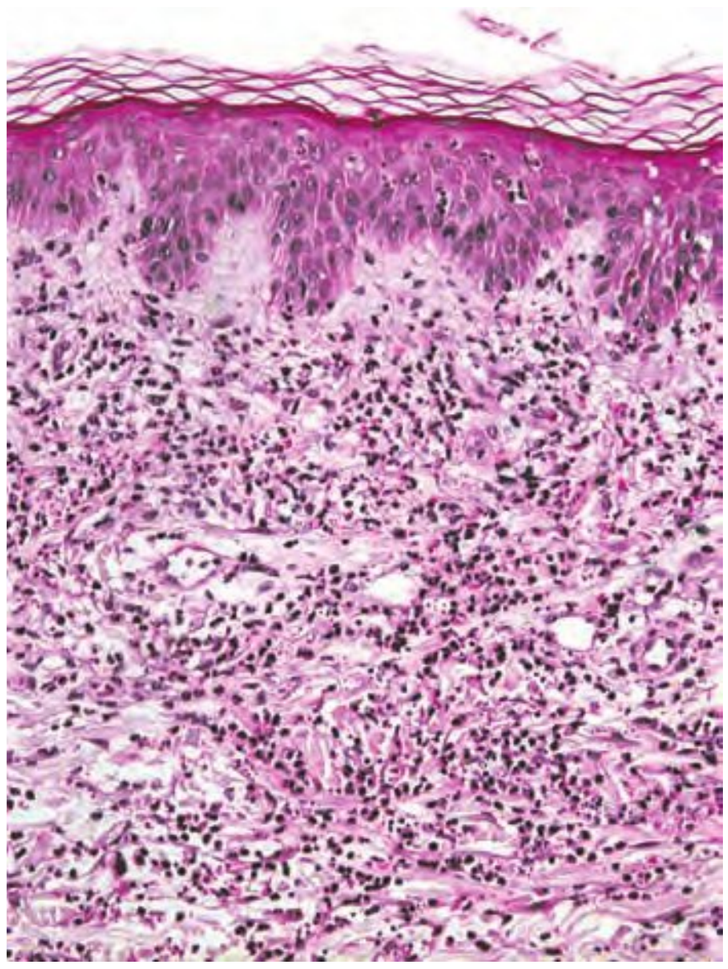

FIGURE 11-24. Granulocyte-macrophage colony-stimulating factor. The density of the inflammatory infiltrate may be florid, resembling Sweet's syndrome, as in this case.

Pathogenesis. In the case of eruptions associated with GM-CSF and G-CSF, the histologic findings relate to the administration and known actions of the cytokine. In a period of peripheral neutropenia, one finds numerous granulocytes in tissue from these eruptions. In addition, the effects of GM-CSF on macrophages are demonstrable in the skin by observing their expanded number and size. Immunostains to macrophage/monocyte markers may be useful to highlight this finding. Injection-site reactions with etanercept are suggestive of a delayed-type hypersensitivity reaction, whereas those of interferon-β suggest enhancement of preexisting disease-related platelet activation (132).

CUTANEOUS MANIFESTATIONS OF ANTIRETROVIRAL THERAPY

Antiretroviral therapy options include protease inhibitors, nonnucleoside reverse transcriptase inhibitors, and nucleoside reverse transcriptase inhibitors. Although exanthematous eruptions and urticaria have been described with the use of these agents, they have also been associated with several unique findings. The lipodystrophy syndrome, identified originally with the use of protease inhibitors and subsequently with the use of nucleoside analogs, is characterized by peripheral lipoatrophy and central adiposity. Protease inhibitors and nucleoside analogs are associated with paronychia with pyogenic granulomas of the lateral nail fold (133). Unique patterns of hyperpigmentation involving nails, skin, and mucous membranes are seen secondary to melanocyte stimulation by zidovudine (6). The patterns of nail pigmentation include entire nail pigmentation, transverse banding, and multiple longitudinal bands of any or all nails of fingers and toes. Leukocytoclastic vasculitis and DRESS are also associated with this group of agents (134).

Histopathology. Histologic features of the lipodystrophy syndrome secondary to protease inhibitors are the same as lipodystrophy from other causes (see Chapter 20).

MINOCYCLINE PIGMENTATION

The prolonged administration of minocycline, a semisynthetic tetracycline, may result in three distinct types of cutaneous pigmentation: (a) a blue-black pigmentation occurring within areas of inflammation or scarring, usually on the face, especially in active or healed acne lesions; (b) a blue-gray pigmentation of previously normal skin, most commonly seen on the legs but also occurring on the forearms; and (c) a diffuse, muddy brown discoloration, sometimes accentuated in sun-exposed areas (135). In addition to that of the skin, nail and scleral pigmentation also occur (136). A systemic minocycline-induced hypersensitivity syndrome presents 2 to 4 weeks after the start of therapy. Symptoms include fever, rash, peripheral eosinophilia, and internal organ involvement (137). Internal organ involvement includes hepatitis or abnormal liver function test results, pneumonitis, and renal abnormalities (137,138).

Histopathology. The histologic picture shows differences among the three types of pigmentation. The focal blue-black pigmentation of the face in the first type is associated with hemosiderin-laden macrophages (Fig. 11-25). In contrast, the blue-gray pigmentation in the second type, most commonly observed on the legs, shows staining for iron and also reacts with the Fontana-Masson stain. The muddy brown

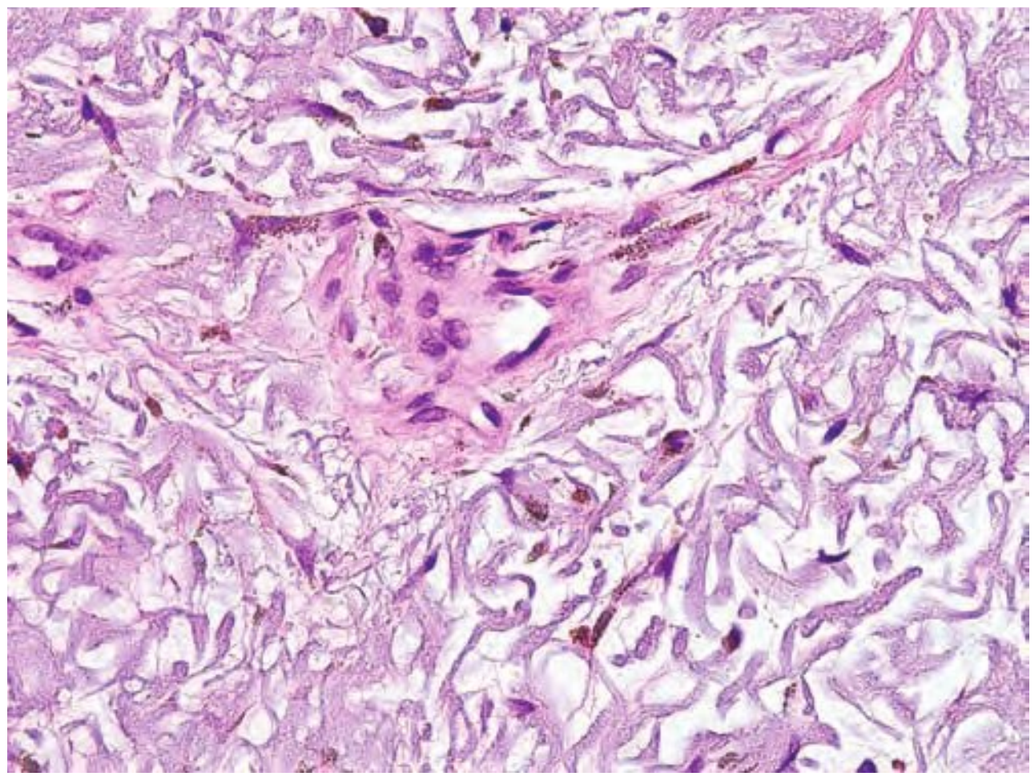

FIGURE 11-25. Minocycline hyperpigmentation. Pigment is present in dermal melanophages and dendritic cells, with a perivascular predominance.

pigmentation in the third type reveals increased melanization of the basal cell layer and melanin within macrophages in the upper dermis.

Histogenesis. It appears likely that the iron-containing pigment in the first two types of pigmentation represents a drug metabolite–protein complex (139). The pigment in the second type, which reacts with the Fontana-Masson stain, does not contain melanin because it does not bleach with hydrogen peroxide. The pigment in the third type reacts like melanin and may represent a phototoxic phenomenon. The pathogenesis of minocycline-induced hypersensitivity reaction has not been elucidated.

CLOFAZIMINE-INDUCED PIGMENTATION

Clofazimine is administered to patients with leprosy and may cause a pink to pink-brown dyspigmentation soon after initiation of therapy. The pigmentation resolves slowly after discontinuation of clofazimine. The most notably involved areas are the obvious leprosy lesions (140).

Histopathology. The upper dermis contains numerous foamy macrophages that possess cytoplasm with brown granular pigment. This pigment stains for lipofuscin but not for melanin or iron.

Pathogenesis. On electron microscopy, the macrophages are found to contain phagolysosomes with either lipid or electron-dense granules with a lamellar substructure consistent with lipofuscin or ceroid pigment (140). The mechanism by which clofazimine causes these changes is unclear.

PENICILLAMINE-INDUCED DERMATOSES

The prolonged administration of penicillamine can cause alterations in collagen and elastic tissue that may result in areas of atrophy of the skin. Anetoderma and serpiginosa elastosis perforans are observed. Alteration of epidermal desmosomal elements may induce pemphigus (see earlier discussion).

Penicillamine-Induced Atrophy of the Skin

Patients on prolonged penicillamine therapy may show atrophy of the skin of the face and neck; light blue, atrophic macules resembling anetoderma; easy bruising resulting in small hemorrhages into the skin followed by milia; or small, white papules at sites of venipuncture in the antecubital fossae (141).

Histopathology. The anetoderma shows diminution or absence of elastic tissue. The areas of easy bruising of the skin and the papules at sites of venipuncture show either diminution or degeneration and homogenization of collagen (142).

Histogenesis. The formation of elastic tissue and collagen involves the participation of aldehydes to produce stable cross-links. By reacting with aldehydes to form thiazolidine compounds, penicillamine impairs the formation of such stable cross-links (143).

Penicillamine-Induced Elastosis Perforans Serpiginosa

Elastosis perforans serpiginosa may occur in patients receiving prolonged treatment with penicillamine. Although the clinical picture does not differ from that of idiopathic elastosis perforans serpiginosa (see Chapter 15), the histologic and electron microscopic features of the altered elastic fibers are unique. Both penicillamine-induced atrophy of the skin and penicillamine-induced elastosis perforans serpiginosa may occur in the same patient.

Histopathology. In comparison with the idiopathic type of elastosis perforans serpiginosa, the penicillamine-induced type, on staining for elastic tissue, shows less hyperplasia of elastic fibers in the papillary dermis, except in areas of active transepidermal elimination (Fig. 11-26). However, in the middle and deep layers of the dermis, a greater number of hyperplastic elastic fibers are present than in idiopathic elastosis perforans serpiginosa. These fibers have an appearance that is specific for penicillamine-induced elastosis perforans serpiginosa. Lateral budding is noted, with the buds arranged perpendicular to the principal fibers. The coarse elastic fibers thus show a serrated, sawtooth-like border and have been aptly compared to the twigs of a bramble bush and have been referred to as "lumpy-bumpy" (141) (Fig. 11-27). Similar changes in individual elastic fibers are observed in nonlesional skin and have been seen in a skeletal artery (142).

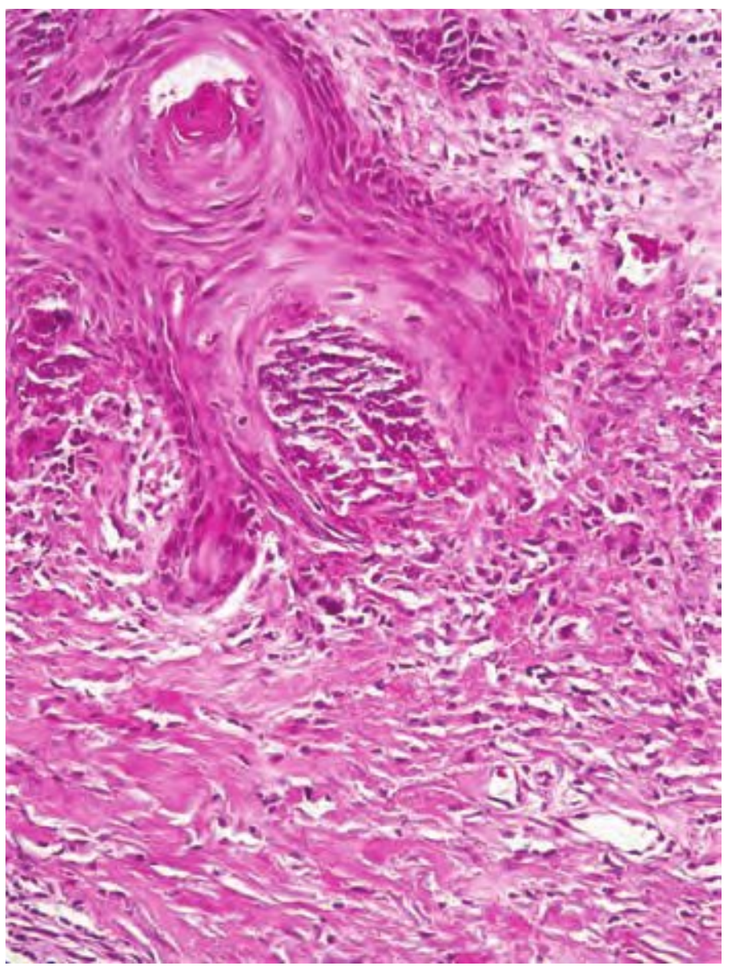

FIGURE 11-26. Penicillamine-induced elastosis perforans serpiginosa. This image shows thickened elastic fibers in the process of transepidermal elimination. The papillary dermal elastic fibers otherwise appear normal on routine stained sections.

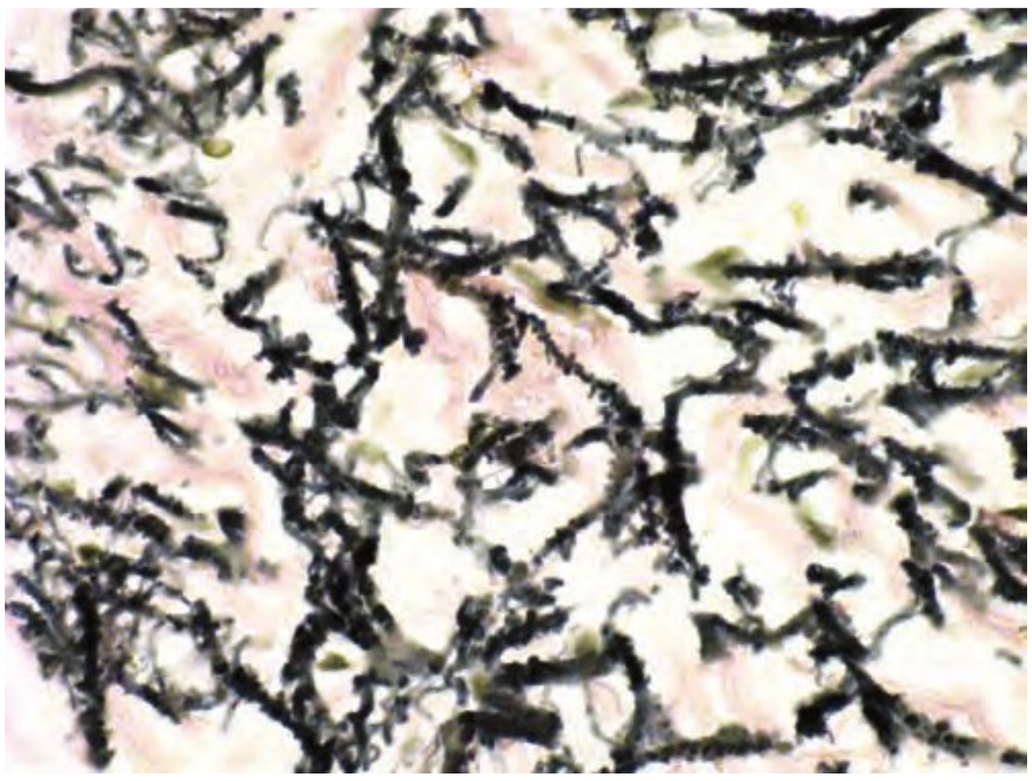

FIGURE 11-27. Elastosis perforans serpiginosa. The classic fibers in the mid dermis show lateral budding characteristic of penicillamine effect. Verhoeff-von Gieson elastic stain.

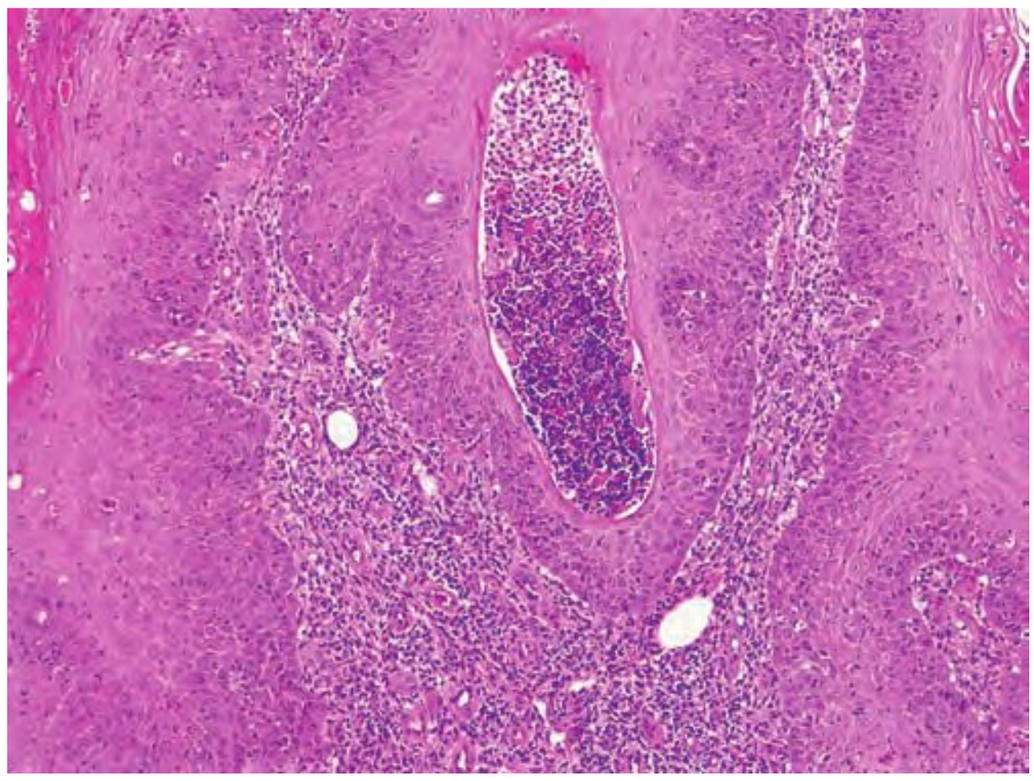

FIGURE 11-28. Bromoderma. There is downward proliferation of the epidermis with a large intraepidermal abscess. A dense inflammatory infiltrate is present in the dermis.

Pathogenesis. On electron microscopic examination, the affected elastic fibers show an inner core that closely resembles a normal elastic fiber with dark microfibrils embedded in electron-lucent elastin. Peripheral to this, a wide, homogeneous, electron-lucent coat is seen that has the appearance of elastin and shows numerous saclike protuberances bulging outward between the adjacent collagen fibers (144).

HALOGEN ERUPTIONS

Ingestion of bromides may cause, besides a pustular eruption, the formation of vegetating, papillomatous plaques called *bromoderma.* The plaques, which usually occur on the lower extremities, often show pustules at their peripheries. Although bromoderma often appears only after prolonged intake of bromides, it may arise soon after administration as well.

Iododerma, usually seen on the face, begins as a rule with multiple pustules that rapidly coalesce into vegetating plaques. Like bromoderma, the plaques of iododerma often show pustules at their peripheries, but they usually show less papillomatous proliferation and a softer consistency than bromoderma, and they often ulcerate. Iododerma is frequently associated with severe systemic signs and symptoms and may be fatal in rare instances (145). Although the eruption usually arises after prolonged ingestion of iodides, it may start within a few days, especially in patients with chronic renal disease. *Fluoroderma* has been described after the frequent application of a fluoride gel to the teeth for the purpose of preventing caries during ionizing radiation to the face (146). The lesions consist of scattered papules and nodules on the neck and in the preauricular regions.

Histopathology. The histologic picture in the halogen eruptions is suggestive rather than diagnostic. The difference between bromoderma and iododerma lies largely in the epidermal changes, which usually are much more pronounced in bromoderma, although there is some overlap. The dermal changes are essentially the same and vary with the age of the lesion.

In early lesions, the dermis in both bromoderma and iododerma shows a dense infiltrate of neutrophils, which, in areas of dermal necrosis, show nuclear dust. There may be intradermal abscesses. Eosinophils are present in most cases and may be numerous. Extensive extravasation of erythrocytes may also be seen. At a later stage, the proportion of mononuclear cells increases, and histiocytes may show abundant cytoplasm or large nuclei. The blood vessels are increased in number and dilated and may show proliferation of endothelium.

The epidermal changes in bromoderma are often pronounced. In addition to papillomatosis, one may observe considerable downward epidermal proliferation, occasionally to such a degree as to produce the picture of pseudocarcinomatous hyperplasia. The acanthosis may center around upper-level follicular epithelium. Frequently, intraepidermal abscesses are present (Fig. 11-28). The intraepidermal abscesses are filled with neutrophils, eosinophils, and some desquamated keratinocytes, most of which appear necrotic, although some resemble acantholytic cells. Some epithelial islands in the upper dermis, instead of enclosing an abscess, are filled with keratin.

In iododerma, the epidermis may be eroded or ulcerated. At the margin of the ulcers, one may find intraepidermal abscesses. In old lesions, pseudoepitheliomatous hyperplasia may be encountered, although usually less than in bromoderma. Fluoroderma has been described only as a mild eruption, but it shares with iododerma and bromoderma the presence of eosinophils, neutrophils, and erythrocytes in the dermis and of microabscesses in the epidermis (146).

Pathogenesis. Even though there is often a very long interval between the first ingestion of iodides or bromides and the appearance of the cutaneous lesion, halogen eruptions appear to be an allergic phenomenon; once a person has become sensitized, the eruption recurs within a few days on the readministration of iodides or bromides. Halogen eruptions probably arise on the basis of delayed hypersensitivity.

ARGYRIA

Argyria is caused by prolonged ingestion or mucosal application of silver salts. When ingested, there is a slate-blue discoloration on the skin, especially in the sun-exposed areas. The oral mucosa, conjunctivae, fingernail beds (but not toenail) (147), intestines, liver, spleen, and peritoneum may also be involved (148,149). Argyria (and chrysiasis) has been reported after acupuncture and in a silversmith following multiple cutaneous punctures by a silver filament (150,151).

Histopathology. In the dermis, there are extracellular fine, small, round, uniformly sized brown-black silver granules, both singly and clustered. The deposition is predominantly extracellular and found in both sun-exposed and unexposed skin. They are present in the greatest numbers in the basement membrane zone surrounding the sweat glands (Fig. 11-29) and in the connective tissue sheaths around the hair follicles and sebaceous glands, in the walls of capillaries, in the arrectores pilorum, and in the nerves (149). Silver granules are also found in the dermal papillae and scattered diffusely throughout the dermis. Elastic tissue stains reveal a predilection of the granules for elastic fibers, which explains the presence of finger-like chains of granules projecting into the dermal papillae (149). In contrast, silver is not seen in the epidermis or its appendages. Although visible in routine stains, dark-field microscopy reveals brilliantly refractile, white particles against a dark background.

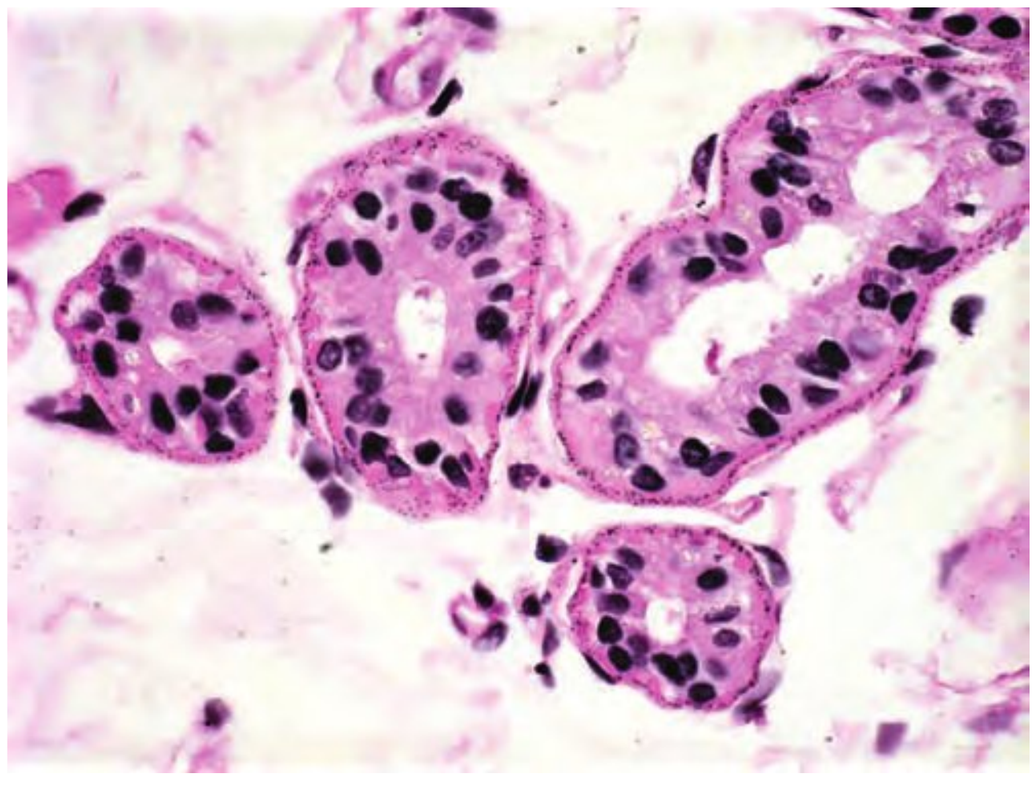

FIGURE 11-29. Argyria. Silver granules are present in the basement membrane surrounding the sweat glands.

In addition to silver, there is an increase in the amount of epidermal melanin, particularly in sun-exposed skin. Melanophages may also be scattered throughout the upper dermis. Deposits of silver are also found in internal organs. Incubation of sections in a solution consisting of 1% potassium ferricyanide in 20% sodium thiosulfate results in decolorization of silver.

Pathogenesis. Electron microscopy reveals extracellular aggregates of irregularly shaped granules varying in size from 200 to 400 nm in diameter but ranging up to 1,000 nm (152).

The increase in the amount of melanin in the basal cell layer and occasionally also in the upper dermis suggests that the presence of silver in the skin may stimulate melanocyte activity. Increased epidermal melanin is observed also with deposits of other heavy metals, such as iron in hemochromatosis (see Chapter 17) and mercury in mercury pigmentation (see later discussion). The pronounced slate-blue pigmentation in exposed skin is caused by increases in both melanin and silver (153).

CHRYSIASIS

Chrysiasis is slate blue discoloration on sun-exposed skin caused by the prolonged parenteral administration of gold salts, generally for the treatment of rheumatoid arthritis and recently secondary to Q-switched ruby laser treatment (154,155).

Histopathology. Gold granules are found predominantly within cells, particularly within endothelial cells and macrophages (156). However, extracellular granules may also be observed. They are larger and more irregularly shaped than silver granules. Although they are also light refractile with dark-field examination, the granules are orange-red birefringent on fluorescence microscopy (157).

Histogenesis. Electron microscopic examination shows the presence of electron-dense, angulated particles within phagolysosomes of endothelial cells and macrophages. X-ray spectroscopic analysis demonstrates a spectrum consistent with the presence of gold (157).

MERCURY PIGMENTATION

Regular application of a mercury-containing cream to the face and neck over many years may produce a slate-gray pigmentation of the skin in the areas to which the cream has been applied. Generally, the pigmentation is most pronounced on the eyelids, in the nasolabial folds, and in the folds of the neck (158). Most mercury-containing creams are no longer manufactured. Traumatic implantation of mercury may also occur.

Histopathology. Irregular, brown-black granules are found in the upper dermis, both extracellularly and within macrophages. In rare instances, granules are seen also in the basal cell layer of

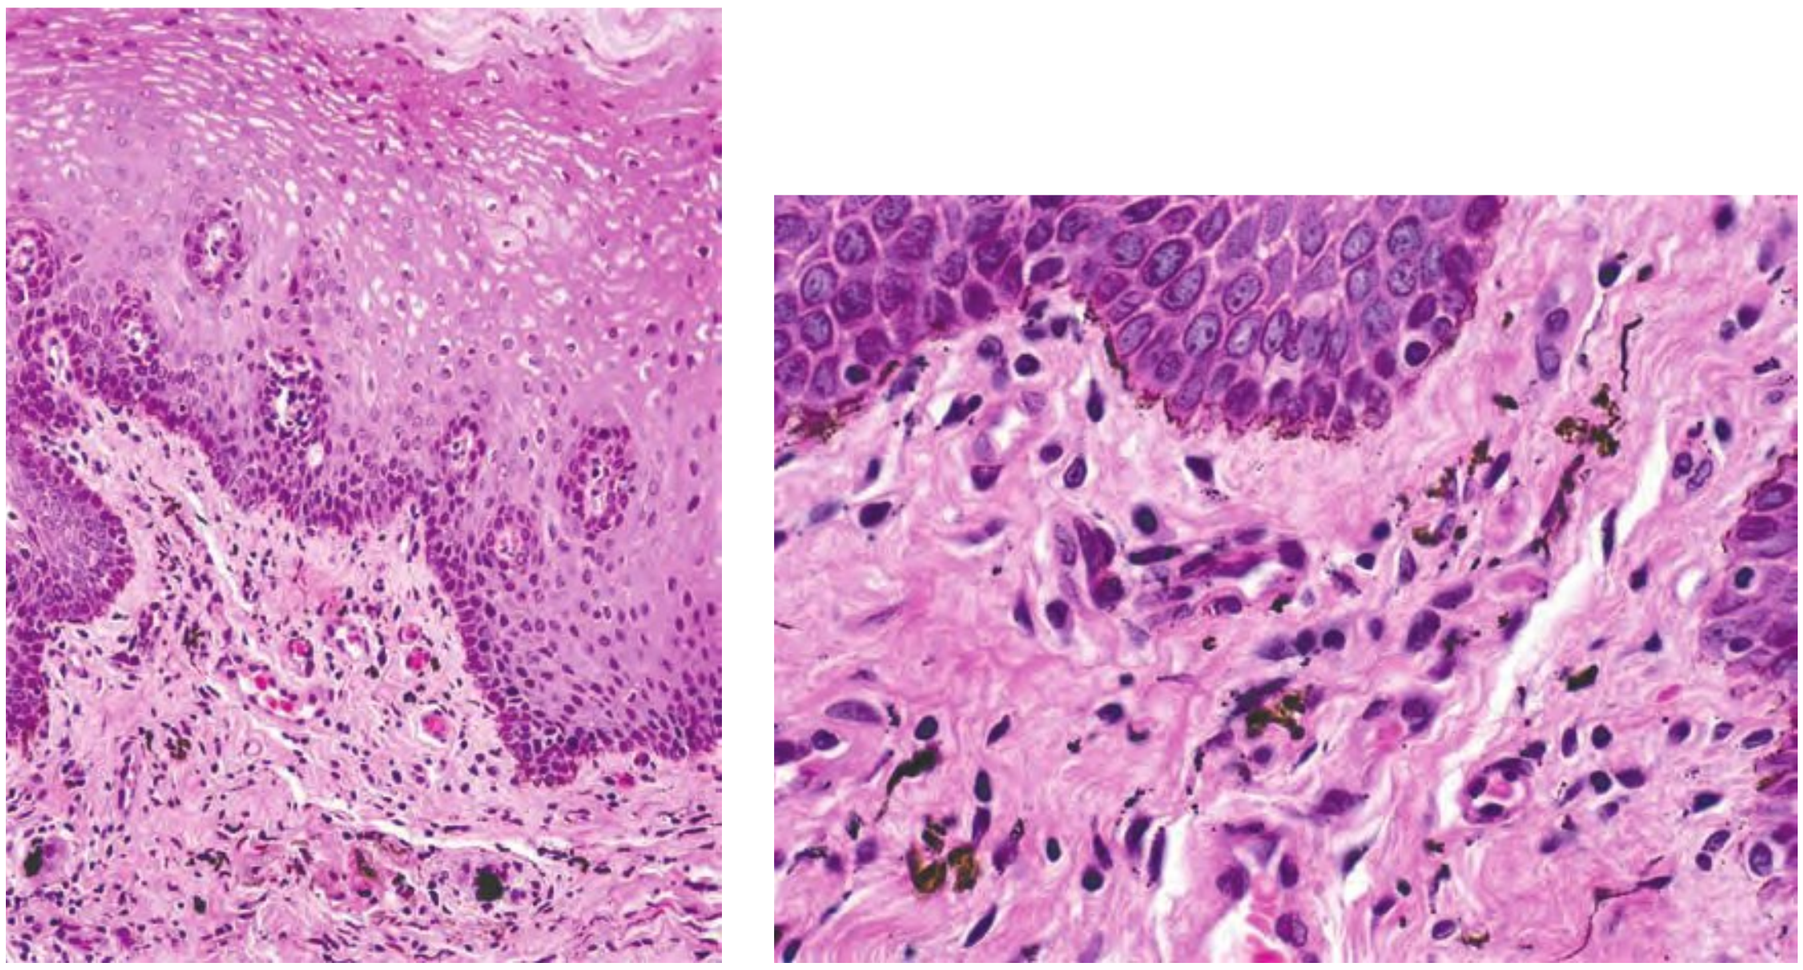

FIGURE 11-30. Mercury deposition. Large, black-brown mercury deposits along with multinucleate foreign body giant cells are seen in the papillary dermis (A) and along the basement membrane (B) in this case of traumatic mercury implantation in the buccal mucosa.

the epidermis. As in argyria and chrysiasis, dark-field microscopy reveals brilliantly refractile granules. Silver staining reveals normal or increased basalar melanin (159). Traumatic implantation of mercury results in variably sized, often large amorphous deposits of mercury in the dermis and subcutis. Chronic changes include dermal fibrosis and granulomatous inflammation (Fig. 11-30).

Pathogenesis. Electron microscopic examination shows the mercury particles, which are approximately 14 nm in diameter, to be aggregated into irregular granules with diameters of up to 340 nm. The granules are associated with elastic fibers as well as along the collagen fibers. In macrophages, they are present within lysosomes or free in the cytoplasm. When seen in the epidermis, the mercury granules lie in the intercellular spaces of the basal cell layer (159).

Because the pigmentation is most pronounced in skin folds that are protected from the sun and there may be no increase in the amount of melanin, it can be concluded that most of the pigmentation is caused by the mercury rather than the melanin.

CHAPTER 12

Eduardo Calonje
John L.M. Hawk

The Photosensitivity Disorders

Cutaneous disorders caused by exposure to ultraviolet radiation (UVR), the so-called photodermatoses, comprise drug and chemical photosensitivity, the DNA repair-deficient disorders, the UVR-exacerbated dermatoses, and the largest and most common group, the idiopathic, probably immunologically based photodermatoses (1). This last group is in turn made up of polymorphic (polymorphous) light eruption (PMLE), actinic prurigo (AP), hydroa vacciniforme (HV), chronic actinic dermatitis (CAD; formerly also sometimes known as *photosensitivity dermatitis and actinic reticuloid syndrome*, or *persistent light reaction*), and solar urticaria (SU) (1–3). Recent work has strongly suggested that these conditions are indeed immunologically mediated, the first four probably being delayed-type hypersensitivity (DTH) reactions against UVR-altered endogenous skin autoantigen, with the differing clinical features between the disorders conceivably being determined by differing cutaneous sites or levels of antigen formation, whereas the last is probably an immediate-type hypersensitivity response against similarly produced cutaneous or circulating substances. Final confirmation of this hypothesis for the putative DTH reactions now requires definitive identification of antigens for the conditions.

Drug and chemical photosensitivity, the DNA repair-deficient disorders, and the UVR-exacerbated dermatoses are considered elsewhere in this book, but the idiopathic, probably immunologically based photodermatoses are discussed in this chapter.

POLYMORPHIC (POLYMORPHOUS) LIGHT ERUPTION

PMLE is a commonly occurring, transient, intermittent, approximately symmetrical UVR-induced eruption of nonscarring, erythematous, itchy papules, plaques, or vesicles of usually only some exposed skin (Fig. 12-1) that is most severe during spring, summer, and sunny vacations and most common in young women (2,3). It is seen most frequently at temperate latitudes, affecting up to one in five subjects of any skin coloring, with attacks following around 15 minutes to a few hours of sun exposure, or occasionally a few days after a period with little exposure such as on vacation, and lasting for hours, days, or rarely weeks before often recurring, sometimes with gradual reduction in severity, from spring until fall. Some but usually not all exposed skin is affected, usually symmetrically, with normally uncovered sites most frequently being spared. Diagnosis is made from the history and clinical findings in the presence of normal circulating antinuclear factor and extractable nuclear antibody titers and of normal urinary, stool, and blood porphyrin concentrations. However, if there is diagnostic uncertainty, lesional histology is generally very helpful, while broad-spectrum or monochromatic skin irradiation may respectively induce the typical eruption or abnormal erythemal or papular responses. Treatment, either prophylactic or remedial, is for the most part effective. Often, the restriction of UVR exposure, use of appropriate clothing, and regular application of high-protection, broad-spectrum sunscreens during exposure are satisfactory for mild disease. In more severe instances, prior to the beginning of summer, four to six weekly courses of broadband or, more commonly, low-dose narrowband (311–312 nm) ultraviolet B (UVB) phototherapy, or slightly more reliably, low-dose psoralen photochemotherapy (PUVA), are usually effective. If an eruption should develop despite these measures, a short course of systemic steroid therapy usually abolishes it quickly. Azathioprine and cyclosporine have rarely been used effectively for very severe disease. The value of other previously advocated medications, such as antimalarials and beta-carotene, has not been confirmed in controlled trials.

Histopathology

The histologic findings vary according to the age of the lesion sampled. Very early lesions show either a normal epidermis or mild spongiosis with focal lymphocyte exocytosis and an underlying mild or occasionally moderate, superficial and deep, perivascular and periadnexal, lymphohistiocytic inflammatory cell infiltrate (2–5) (Fig. 12-2); the lymphocytes have a T-helper phenotype (CD3/CD4 positive). Interestingly, in experimentally induced PMLE lesions, the infiltrate in the first 72 hours postinduction also has a predominant T-helper phenotype but thereafter a mainly T-cytotoxic type (CD3/CD8 positive) (6). Occasional eosinophils and rare neutrophils may also be found. As lesions progress, there is marked edema of the papillary dermis and more prominent dermal inflammation (Fig. 12-3), along with focal interface change and mild hydropic basal cell degeneration in some biopsies (Fig. 12-4);

FIGURE 12-1. Polymorphic (polymorphous) light eruption. Erythematous confluent papules on sun-exposed skin.

in such cases, the histologic picture may resemble cutaneous lupus erythematosus (see next section). Exceptionally, a fairly prominent dermal infiltrate may raise the possibility of lymphoma. In a few cases, the histologic findings may be minimal despite the presence of prominent clinical changes (7).

Pathogenesis. The eruption of PMLE is induced by exposure to UVR, particularly from strong summer sunlight (2,3). Artificial

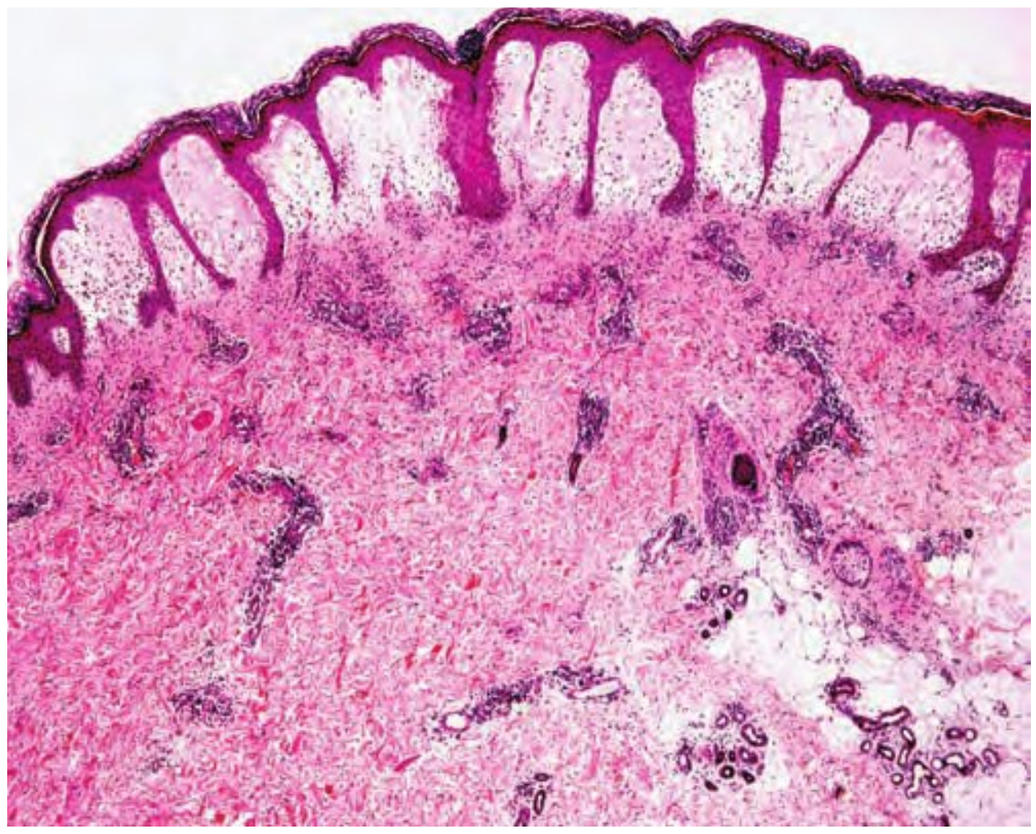

FIGURE 12-3. Polymorphic (polymorphous) light eruption. Established lesion showing prominent papillary dermal edema as well as moderately prominent, superficial and deep, perivascular and periadnexal, mononuclear inflammatory cell infiltrate.

reproduction is less easy, and exact action spectra have not been conclusively determined. Nevertheless, broadly speaking, the responsible wavelengths appear to be UVB in around half of patients and ultraviolet A (UVA) in three quarters, which includes both in one quarter, while visible light has also rarely been incriminated. The eruption itself appears very likely to be a DTH response in view of its pattern of dermal cellular infiltration, cytokine production, and adhesion molecule expression, arguably to UVR-induced, endogenous, cutaneous autoantigen. Further, it appears that a genetically determined impairment of the normal UVR-induced suppression of

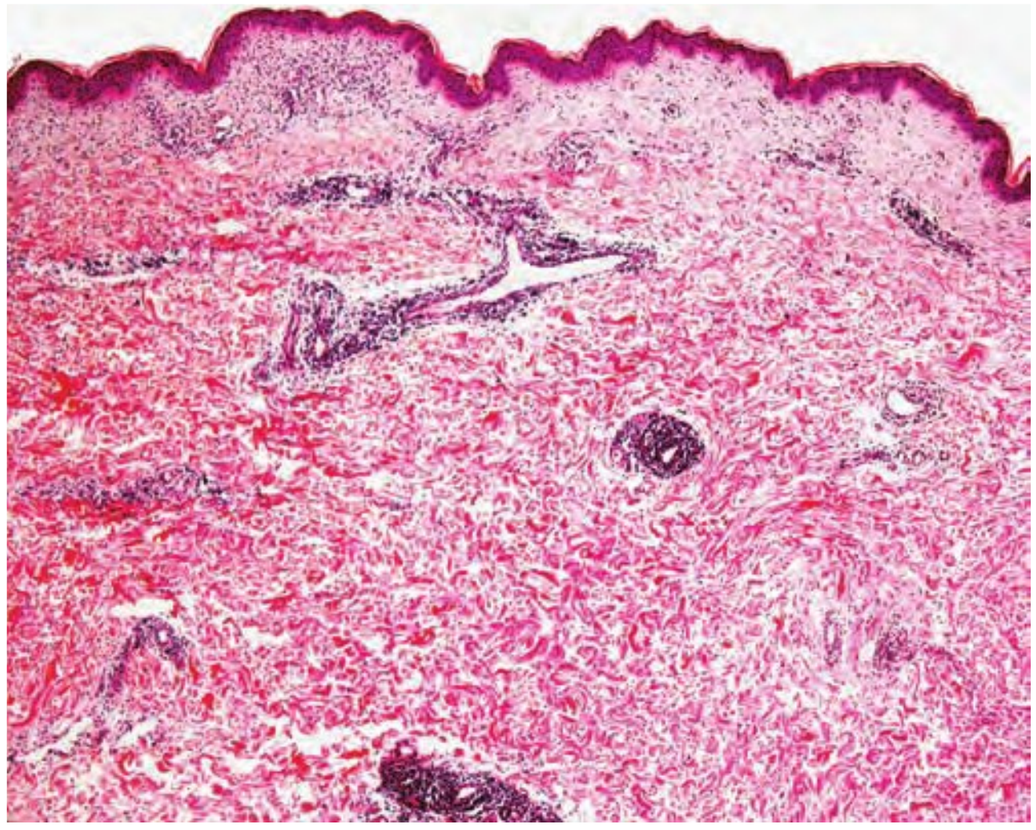

FIGURE 12-2. Polymorphic (polymorphous) light eruption. Early lesion showing superficial and deep, perivascular and periappendageal, inflammatory infiltrate.

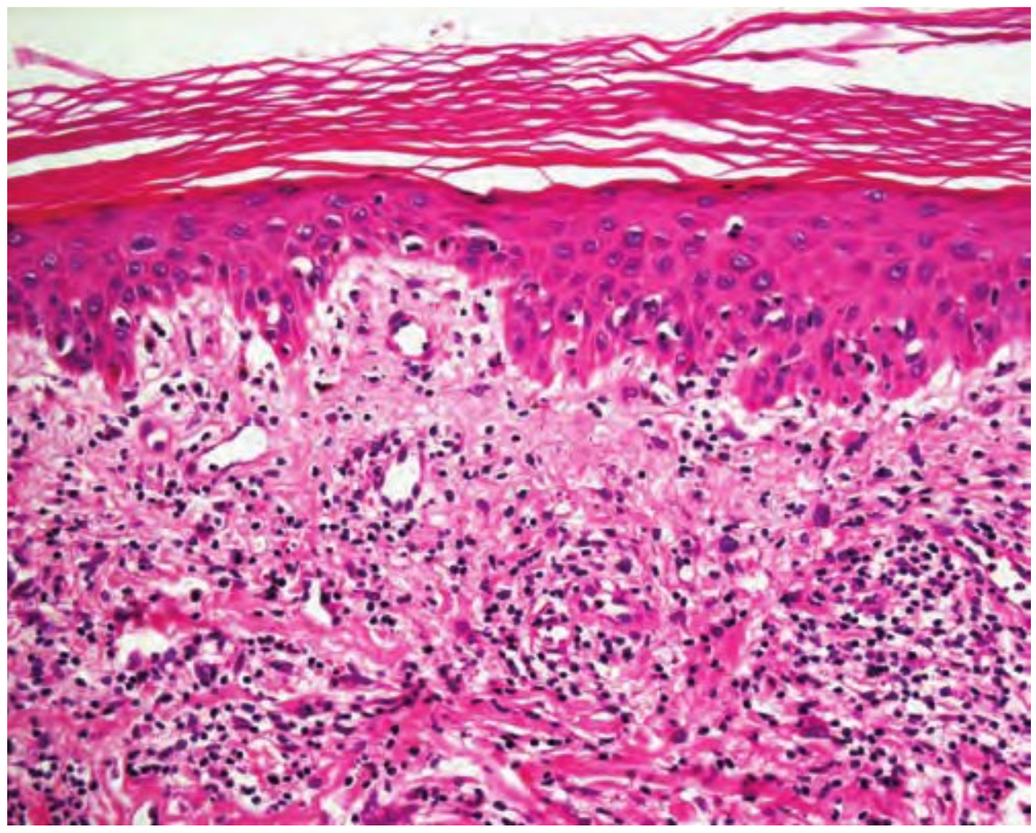

FIGURE 12-4. Polymorphic (polymorphous) light eruption. Mild spongiosis and focal interface change with hydropic degeneration of basal cells; the latter may suggest lupus.

induction, but interestingly not elicitation, of DTH reactions in the skin is responsible (8).

Differential Diagnosis. The diagnosis is generally apparent from the clinical history, in which sun exposure is nearly always clearly incriminated in causing the typical eruption, provided that the circulating antinuclear and extractable nuclear antibody titers and urinary, stool, and blood porphyrin concentrations are normal. Histologically, PMLE must be differentiated from lupus erythematosus, the porphyrias, AP, Jessner's lymphocytic infiltrate, cutaneous T-cell lymphoma, chilblains, and rosacea (2,3). In cutaneous lupus erythematosus, the interface change is more prominent not only in the epidermis but also in adnexal structures, apoptotic keratinocytes are often seen, and papillary dermal edema is not a feature. In addition, dermal mucin deposition may be seen in lupus and is absent in PMLE. AP usually displays changes secondary to excoriation, variable epidermal hyperplasia, and more prominent lymphocyte spongiosis and exocytosis; however, early lesions in both conditions may show very similar microscopic findings, except that dermal edema is usually absent in AP. In Jessner's lymphocytic infiltrate, epidermal changes are absent, there is no papillary dermal edema, and the dermal mononuclear cell infiltrate tends to be more prominent. Cutaneous T-cell lymphoma is only rarely included in the differential diagnosis of PMLE, mainly when the dermal infiltrate is prominent; however, the exocytosis of lymphocytes with irregular nuclear outlines is not a feature of the latter, which usually also shows variable spongiosis. The histology of chilblains is almost identical to that of PMLE, particularly when there is prominent papillary dermal edema, but fortunately the clinical setting of each disease usually allows distinction. Rosacea shows no epidermal change, dermal edema is absent, the dermal infiltrate is mild and surrounds superficial small blood vessels and adnexal structures, and focal lymphocytic exocytosis into hair follicles is often seen.

ACTINIC PRURIGO

AP is an itchy, papular or nodular, excoriated, chronic eruption, usually much worse in summer, of the light-exposed and, to a lesser extent, covered skin of children, usually girls, occurring relatively rarely worldwide, although it is comparatively common among native and mixed-race Americans (2,3). It may often but not always resolve by early adulthood and most often affects the face and distal limbs, while the proximal limbs and forehead beneath the hair fringe, which are less often exposed, are mostly spared. However, the buttocks are sometimes involved through apparent sympathetic immunologic spread. Superficial, pitted, or linear scars may affect the face at sites of previous lesions, whereas chronic cheilitis and conjunctivitis are also possible. In addition, some patients describe acute attacks of rash development following specific sunlight exposure as occurs in PMLE. Therapy is often helpful, consisting in mild cases of restricted sun exposure, the use of protective clothing, the application of high-protection, broad-spectrum sunscreens, and the use of emollients and topical steroids on affected sites, whereas in some cases, prophylactic, low-dose narrowband UVB phototherapy or PUVA, as for PMLE, may be useful, particularly in spring for patients who have cleared of their eruption in winter. Topical calcineurin inhibitors may also perhaps help in such patients, even if not confirmed by formal studies, whereas oral thalidomide clears around three quarters of affected subjects, although a marked risk of teratogenicity and moderate possibility of peripheral neuropathy necessitate great care in its use. Oral immunosuppressive therapy such as with azathioprine or cyclosporine also seems likely to help, if clinically appropriate.

Histopathology. The histology varies according to the clinical evolution (9). Thus, early intact lesions show variable, often mild, epidermal spongiosis and a superficial and deep dermal, perivascular, mononuclear cell infiltration similar to that of PMLE but in the absence of substantial papillary dermal edema (Fig. 12-5). However, this latter finding may be seen in occasional biopsies, and histologic distinction from PMLE may then be impossible, requiring close clinicopathologic correlation (10). Occasional eosinophils are often seen. The lesions of AP are frequently excoriated, such that careful attention should be paid when biopsy is performed to avoid lesions with such prominent secondary changes (Fig. 12-6). Evolving lesions may also occasionally display focal interface change with hydropic degeneration of basal cells, such that distinction from cutaneous lupus may then be difficult (Fig. 12-7). In rare cases, there may be a heavy, superficial and deep dermal, mononuclear cell infiltrate with difficulty in distinction from lymphoma, especially if associated interface changes are present. In older lesions, there is usually variable lichenification (Fig. 12-8),

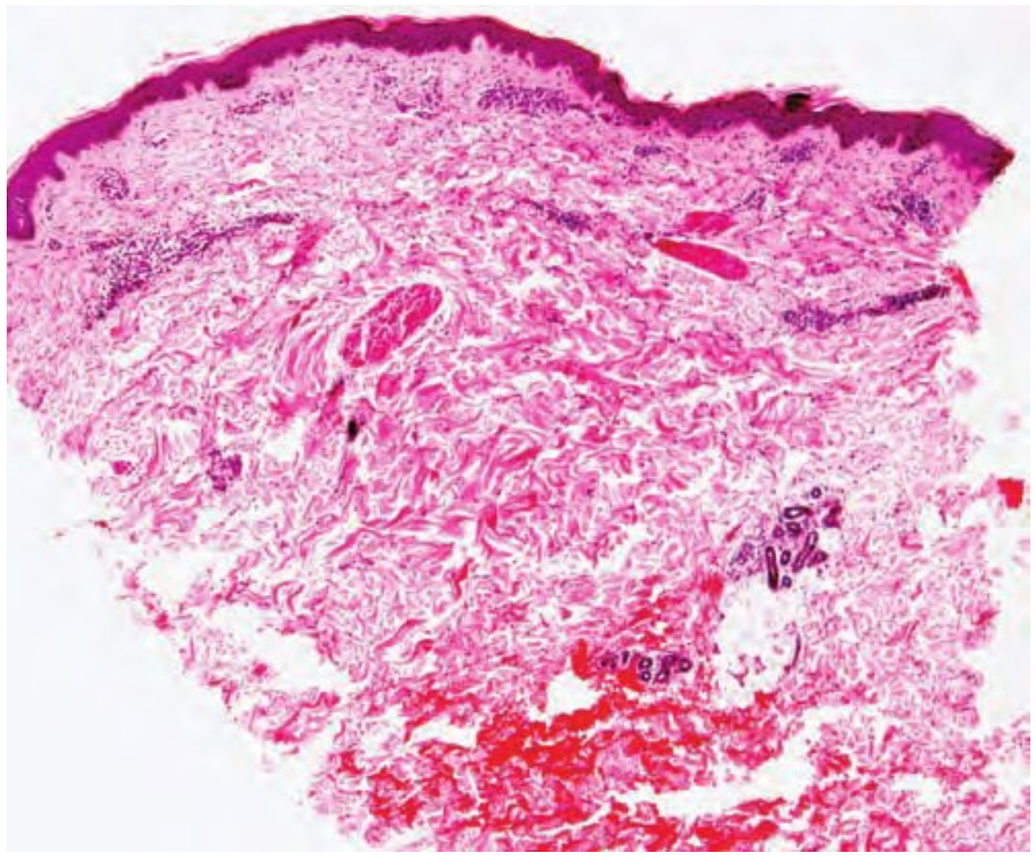

FIGURE 12-5. Actinic prurigo. Early lesion with absence of epidermal change, and mild to moderate, superficial and deep, perivascular and periadnexal, mononuclear inflammatory cell infiltrate.

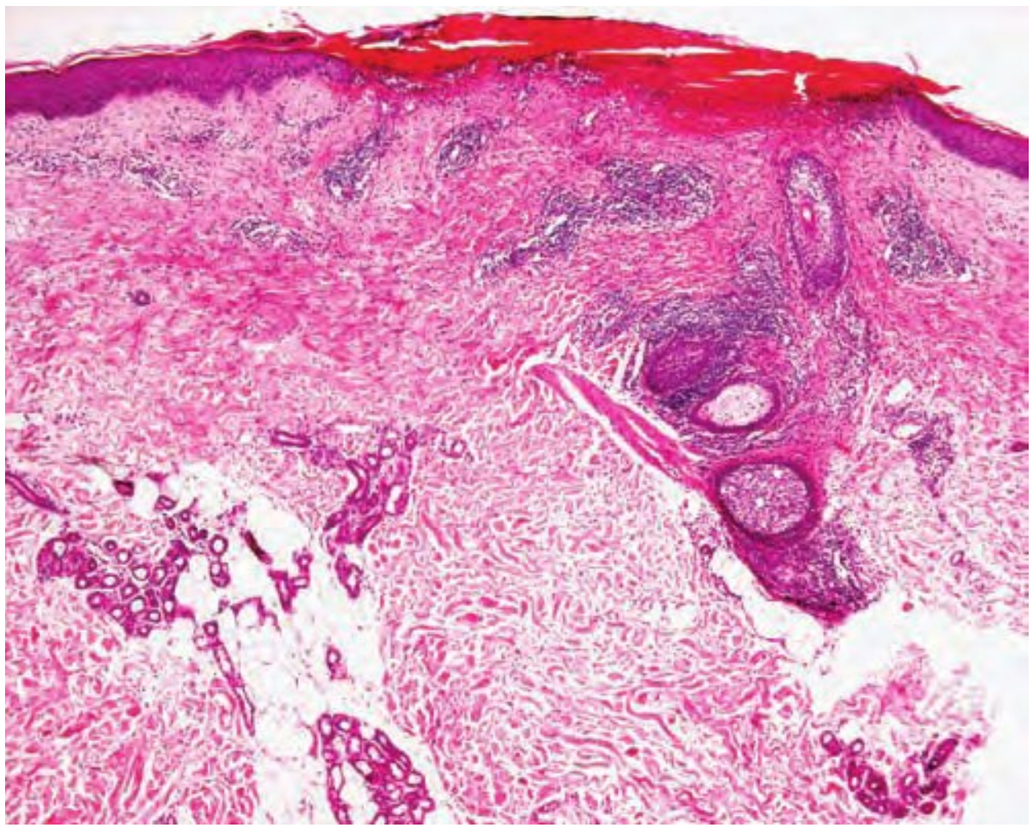

FIGURE 12-6. Actinic prurigo. Prominent superficial necrosis secondary to excoriation and fairly heavy perivascular and periadnexal inflammatory cell infiltrate.

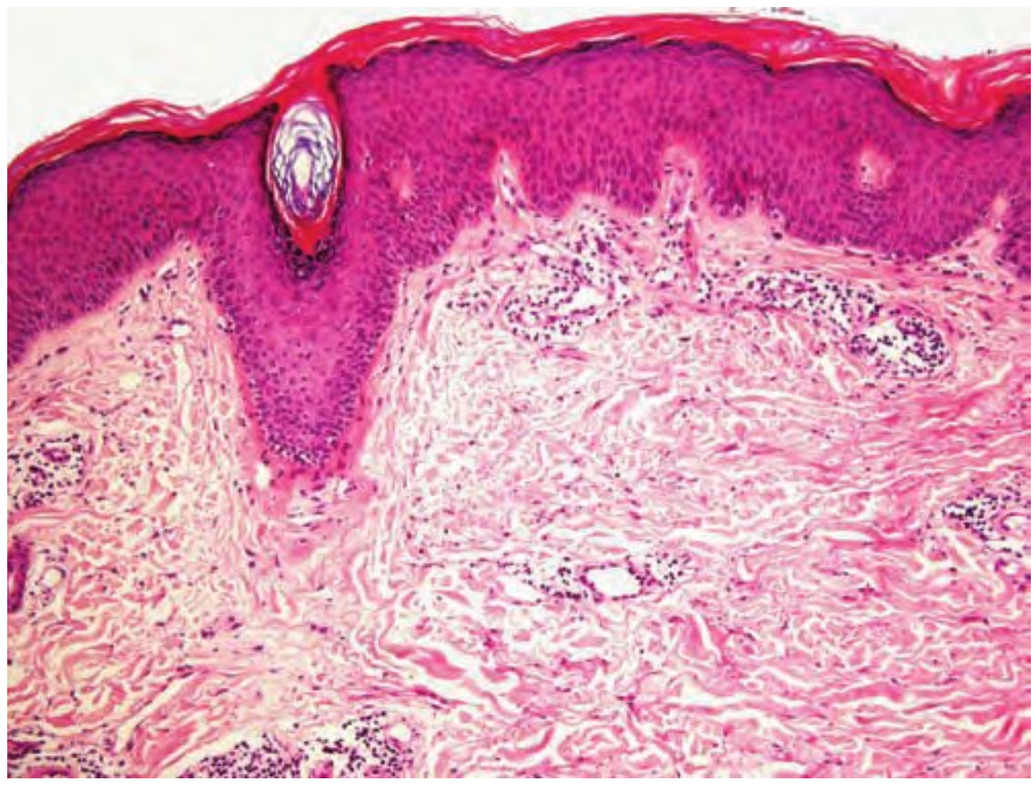

FIGURE 12-8. Actinic prurigo. Older lesion showing lichenification.

focal papillary dermal fibrosis, a moderately heavy mononuclear cell infiltrate, and irregular epithelial hyperplasia similar to the features of chronic eczema, or even prurigo nodularis (2,3). The AP inflammatory cell infiltrate has a T-helper phenotype (CD3/CD4 positive). AP must thus be differentiated from the same disorders as PMLE in its rarer acute form and from other causes of chronic eczema or prurigo in its chronic forms. Finally, although AP histology may often be fairly nonspecific, the lesions of AP cheilitis characteristically show a dense lymphocytic infiltrate with frequent well-formed lymphoid follicles (10,11), a finding regarded as potentially very helpful in cases of diagnostic doubt.

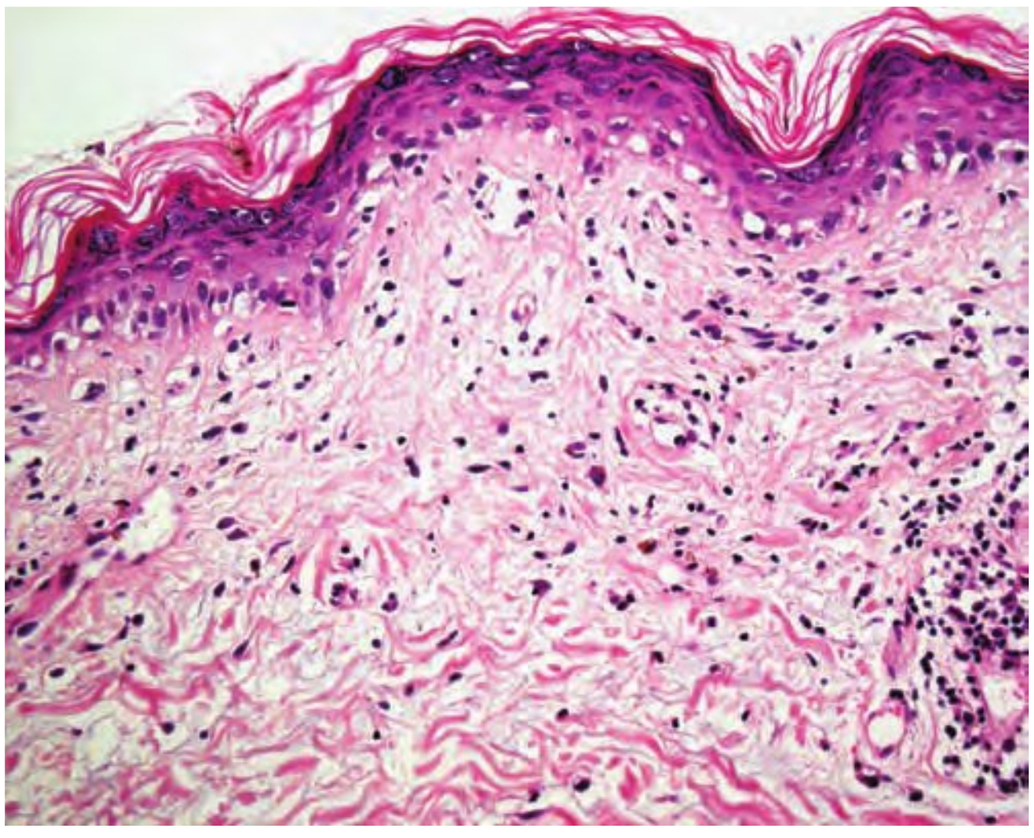

FIGURE 12-7. Actinic prurigo. Interface change may be more prominent than in PLME and histologic distinction from lupus more difficult.

Pathogenesis. UVR exposure appears to be of prime importance in the causation of AP, given the greater severity of the disorder in summer and after sun exposure as well as the relatively frequent abnormal erythemal or papular skin responses to monochromatic irradiation (2,3). Such reactions occur in one half to two thirds of patients, often to UVB wavelengths alone but sometimes also to UVA; responses to broad-spectrum irradiation have not been reported. Further, the clinical behavior of acute attacks of AP, its histologic appearances, its marked familial association with PMLE, and its differentiation from PMLE in large part by the HLA subtypes DRB1*04 (DR4) and more specifically DRB1*0407 (2,3,12), all strongly suggest that it is very likely a genetically prolonged form of PMLE and also a DTH reaction against UVR-induced, cutaneous autoantigen. However, without the isolation so far of proven causative antigen, this is still ultimately speculative.

Differential Diagnosis. AP must be differentiated from PMLE, lupus erythematosus, insect bites, scabies, lymphoma, nodular prurigo, and eczema; its seasonal variation, affected sites, and sometimes positive light tests may assist in this differentiation, as too may its histology, particularly if a lesion is fresh. However, close clinicopathologic correlation is essential for reliable diagnosis. In biopsies with interface change, distinction from lupus erythematosus may be difficult, but in AP, such change is usually very patchy, focal, and limited to the epidermis, while apoptotic keratinocytes are usually absent. If a prominent dermal infiltrate is seen, the diagnosis of T-cell lymphoma may well come into consideration, but cytologic atypia and epidermotropism are lacking in AP. Finally, in its usual chronic forms, the distinction of AP from chronic eczema is impossible on histologic grounds alone.

FIGURE 12-9. Hydroa vacciniforme. Scarring is seen in late stages.

HYDROA VACCINIFORME

HV is a very rare, intermittent, UVR-induced, blistering, scarring eruption of only some exposed skin, usually in children and only rarely in adults (1–3,13–15). The condition generally has onset by 10 years of age, with resolution by early adulthood. Usually sparse, occasionally coalescent, symmetrically scattered, sometimes hemorrhagic vesicles and bullae occurring within hairs of sun exposure are characteristic, particularly of the face, ears, and limbs. These umbilicate and crust over days, healing thereafter in weeks to leave persistent, disfiguring pock scars (Fig. 12-9). Treatment is usually difficult. The restriction of UVR exposure and use of clothing cover are helpful, whereas the careful, regular application of high-protection, specifically broad-spectrum, sunscreens also has efficacy. In resistant cases, courses of prophylactic low-dose UVB phototherapy or PUVA are also helpful on occasion. All other therapies have seemed at best marginally useful.

Histology. The main, very characteristic, histologic abnormality is that of progressive intra- and intercellular epidermal edema leading to prominent reticular degeneration, vesiculation, and finally confluent epidermal necrosis (Figs. 12-10 and 12-11). The vesicles contain fibrin and acute inflammatory cells and overlie a dermal cellular infiltrate of predominantly perivascular lymphocytes, histiocytes, and neutrophils (2,3,13). A vasculitis is not seen. In some cases, there is focal necrosis of the superficial dermis. Prominent secondary changes in late lesions may obscure the characteristic findings.

Pathogenesis. The eruption of HV is clearly inducible by sunlight exposure, whereas artificial induction is more difficult, requiring repeated broad-spectrum or, less reliably, UVB skin exposure, but exact action spectra have not been determined (2,3,13,14). Blood, urine, and stool porphyrin concentrations, lesional viral studies, and circulating viral, antinuclear factor, and extractable nuclear antibody titers are normal. Further, the very PMLE-like clinical features of HV apart from its scarring

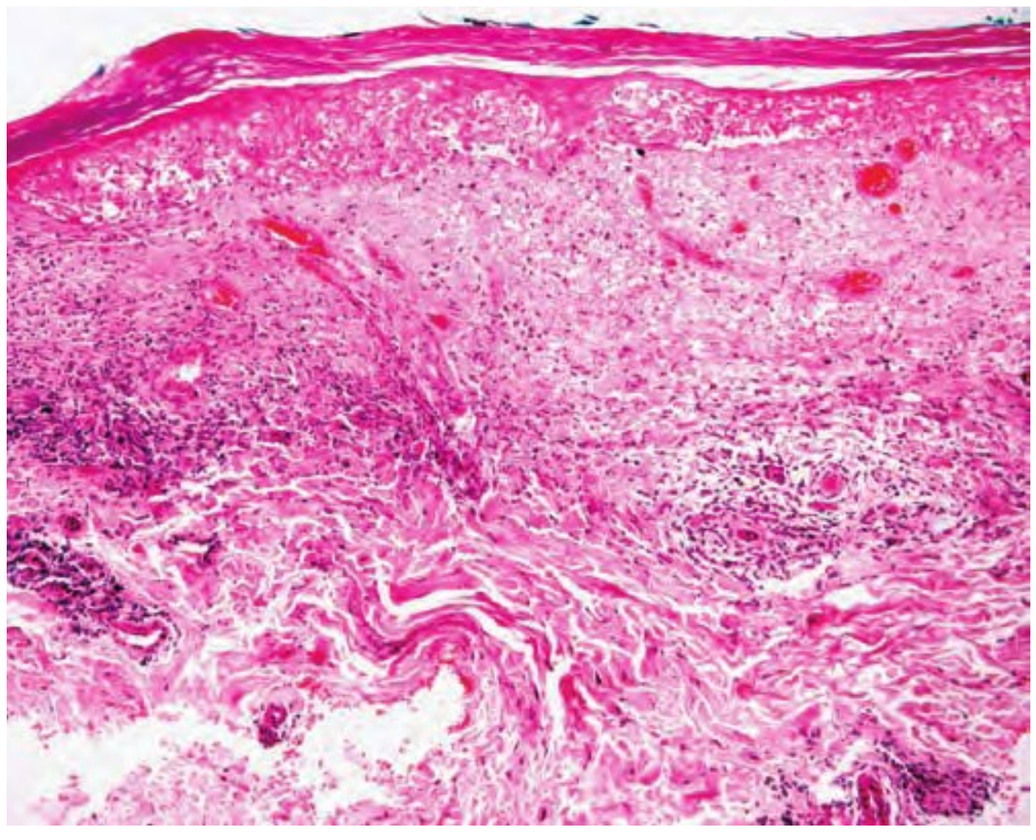

FIGURE 12-10. Hydroa vacciniforme. Prominent confluent epidermal necrosis associated with dermal perivascular inflammatory cell infiltrate.

and PMLE-like dermal perivascular mononuclear cell infiltration together strongly suggest similar pathogeneses for the two disorders; therefore, that HV may also be a DTH-type immunologic response to UVR-induced, endogenous, cutaneous autoantigen. In HV, however, the location of the putative antigen, the presence of a toxic photoproduct, or the intensity of the reaction may conceivably lead to the characteristic scarring.

Differential Diagnosis. HV must be differentiated from cutaneous viral disorders, the porphyrias, lupus erythematosus; and the other idiopathic, probably immunologically based

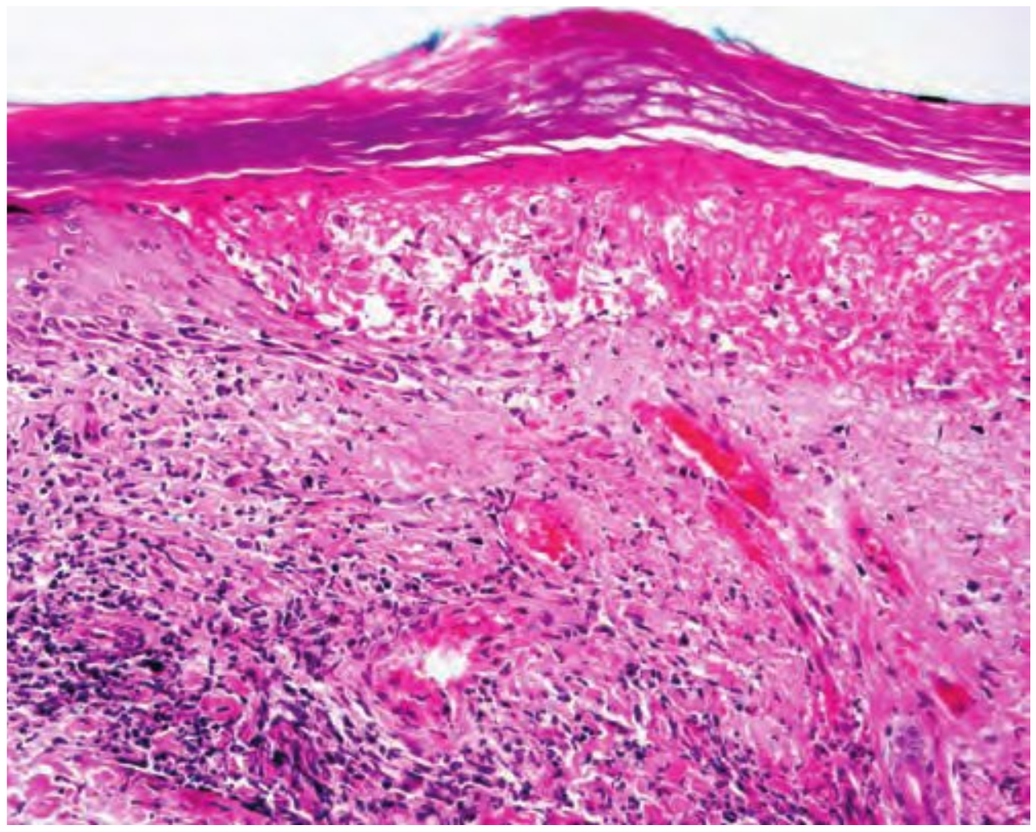

FIGURE 12-11. Hydroa vacciniforme. Marked reticular degeneration of the epidermis at the edge of the lesion and very superficial dermal necrosis with fibrin deposition.

photodermatoses by its clinical features and largely diagnostic histopathology, provided that appropriate viral studies, blood, urine, and stool porphyrin concentrations as well as circulating antinuclear factor and extractable nuclear antibody titers are also normal. The pattern of necrosis is remarkably similar to that seen in viral (including herpetic) infections and hand, foot, and mouth disease. Nevertheless, distinction from herpetic infection is easy, as HV lesional biopsies lack viral inclusions, multinucleated keratinocytes, and nuclei with ground glass appearance; also, hair follicle necrosis is lacking. However, distinction from hand, foot, and mouth disease is more difficult, but the clinical settings of the two diseases are totally different. Finally, a T-cell lymphoma variant with facial necrotic lesions simulating HV has been described in Asian and native Central American Indian children and rarely in adults (16,17), but histologic distinction is not difficult, as atypical lymphoid cells are readily apparent in the lymphomatous infiltrate.

CHRONIC ACTINIC DERMATITIS

CAD (photosensitivity dermatitis and actinic reticuloid syndrome, persistent light reaction) is a rare, persistent, often disabling, UVR- and occasionally visible light-induced eczema of exposed and sometimes also covered sites (2,3,18). It is most common in older men at temperate latitudes and most severe in summer. It may affect previously normal subjects or patients with prior endogenous eczema, photoallergic or allergic contact dermatitis, perhaps oral drug photosensitivity, or maybe rarely PMLE. Allergic contact sensitivity to ubiquitous airborne, occasionally photoactive agents often coexists. There is itchy, scattered or confluent, subacute or chronic eczema of the exposed skin, which may be lichenified (Fig. 12-12), excoriated, or more severely, erythematous, shiny, infiltrated, discrete or coalescent papules or plaques on a background of erythema, eczema, or just normal skin. Erythroderma is also rarely possible. Malignant transformation has been claimed on occasion but never convincingly substantiated, although a CAD response as part of cutaneous T-cell lymphoma itself may perhaps rarely occur (19). UVB- UVA-, and occasionally also visible light-induced pseudolymphomatous CAD, has previously been described as *actinic reticuloid*, UVB-induced eczematous CAD as *photosensitive eczema* or *photosensitivity dermatitis*, and UVB- and A-induced eczematous CAD as *photosensitivity dermatitis*, whereas CAD following photoallergic contact dermatitis has been called *persistent light reaction*. CAD treatment requires care, with the restriction of UVR exposure, wearing of appropriately protective clothing, application of high-protection broad-spectrum sunscreens, and avoidance of exacerbating contact allergens all being necessary but often of only moderate help. Topical calcineurin inhibitors may be useful in some cases, even those that are severe, whereas intermittent oral steroid therapy, low-dose narrowband UVB phototherapy, or probably more reliably PUVA, initially under high-dose oral steroid cover, may also be effective. Failing this, oral immunosuppressive therapy with azathioprine, cyclosporine, or occasionally mycophenolate generally clears the condition, if tolerated. Finally, CAD may often eventually remit (20).

Histology. In early CAD, the histology (2,3,18,21) may resemble that of any other spongiotic process, including eczema and contact dermatitis, with epidermal spongiosis, lymphocytic exocytosis, and a superficial and deep, perivascular, lymphohistiocytic, inflammatory infiltrate. In older lesions, however, there is variable, often marked, acanthosis of the epidermis and infundibular portions of hair follicles (Fig. 12-13), while spongiosis and lymphocytic exocytosis may be focally prominent

FIGURE 12-12. Chronic actinic dermatitis. Extensive lichenification and excoriation.

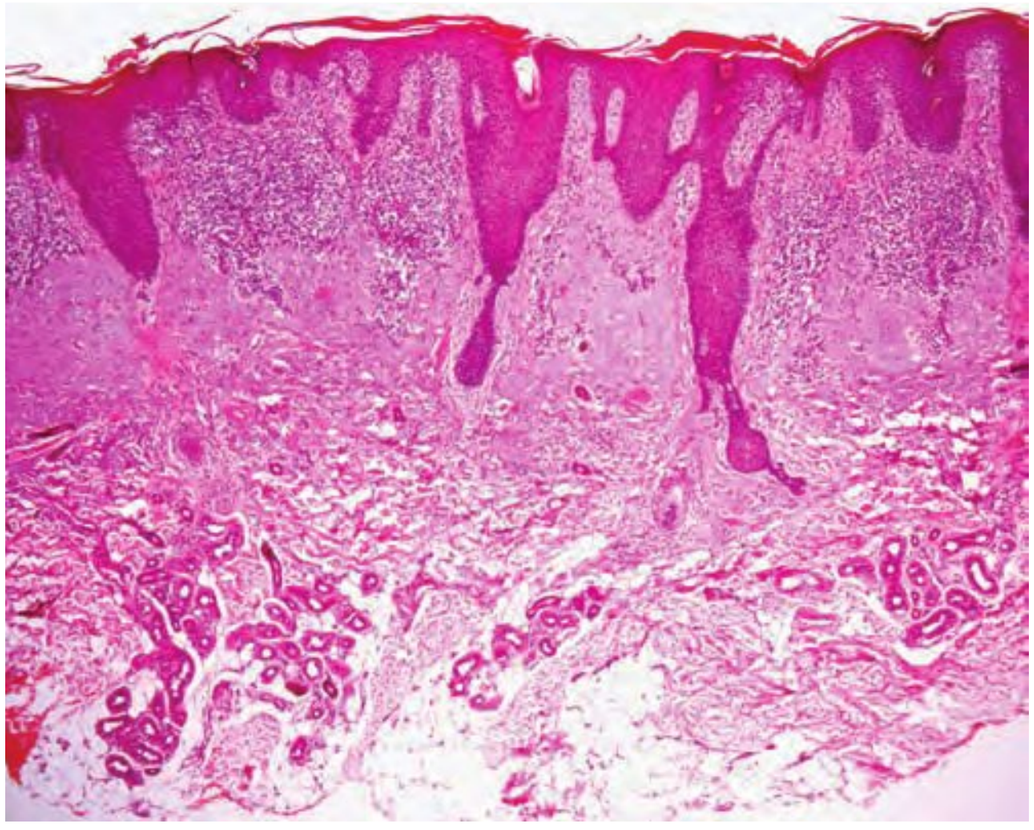

FIGURE 12-13. Chronic actinic dermatitis. Older lesion with prominent hyperplasia of epidermis and infundibular portion of hair follicles.

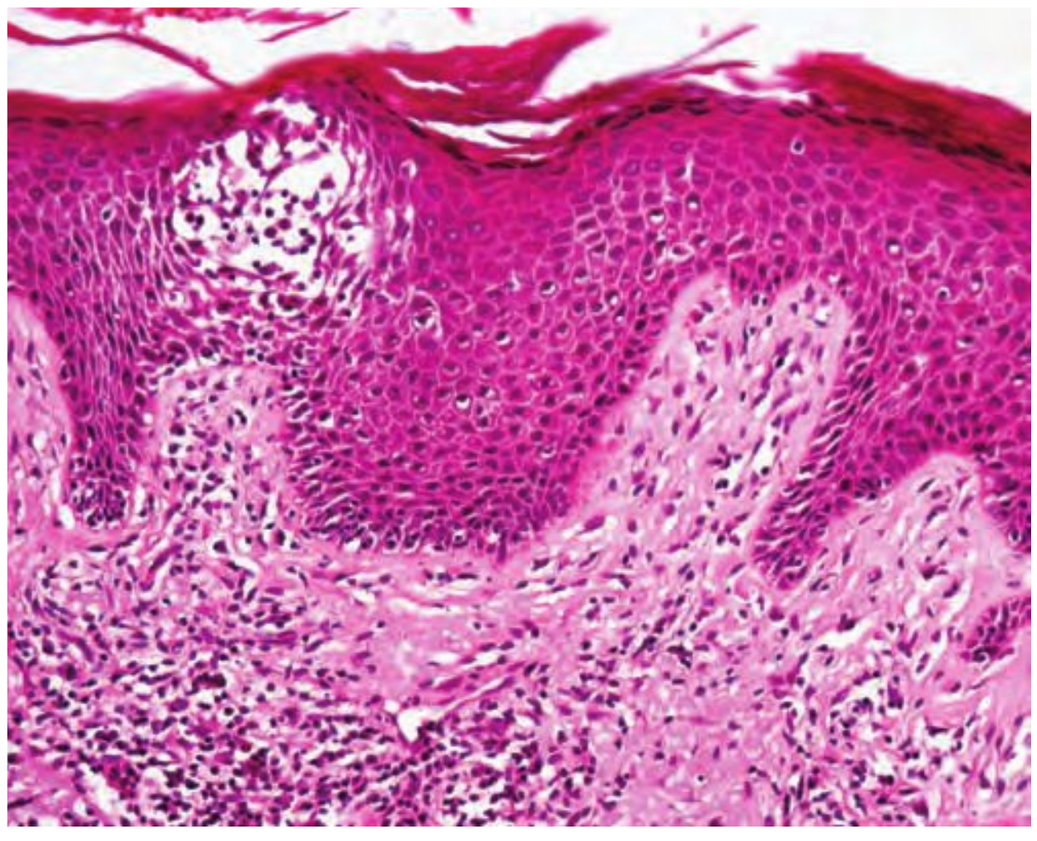

FIGURE 12-14. Chronic actinic dermatitis. Lichenification in association with prominent spongiotic changes and exocytosis of lymphocytes.

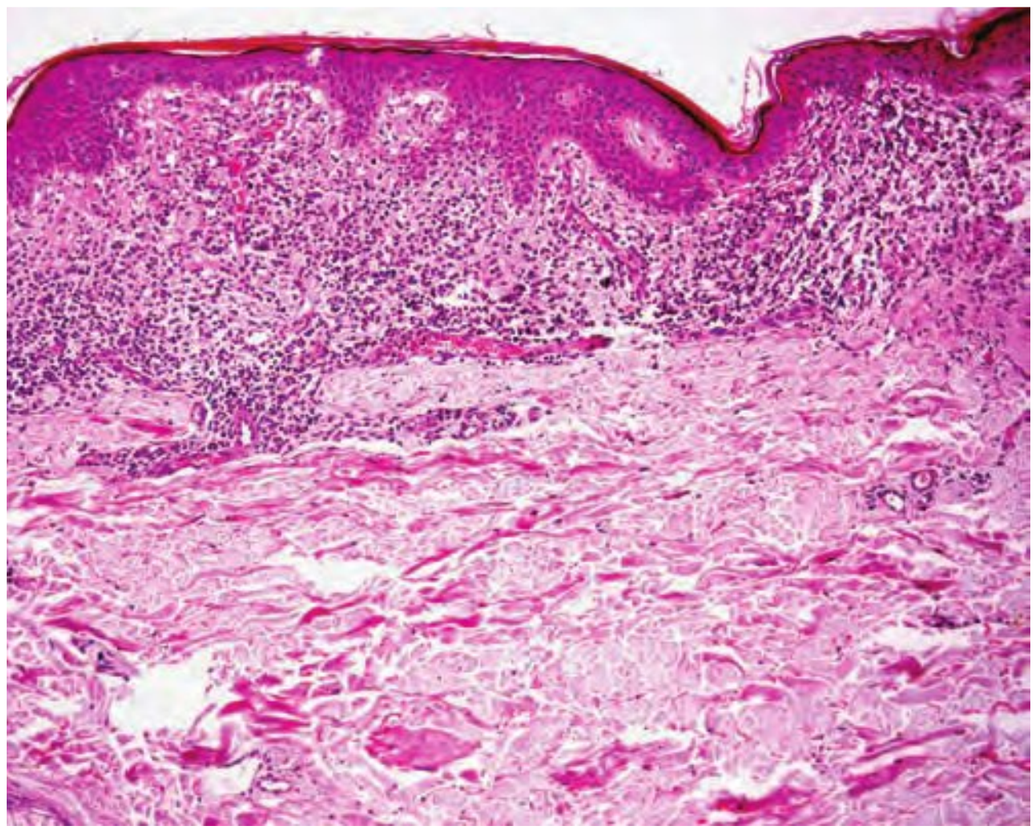

FIGURE 12-16. Chronic actinic dermatitis (actinic reticuloid variant). Prominent superficial dermal mononuclear cell infiltrate focally obscuring the dermal-epidermal junction.

(Fig. 12-14). Secondary changes from excoriation are also frequent in both early and late disease and consist of focal epidermal necrosis, scale-crust formation, dermal–epidermal junction fibrin deposition, and neutrophils with nuclear dust. In addition, there may be occasional Pautrier microabscess-like collections of cells, usually of the Langerhans type. In the papillary dermis, vertically streaked collagen, stellate fibroblasts, and small multinucleated cells, often described as Montgomery giant cells (Fig. 12-15), are frequently present; these latter, however, may commonly occur in any chronic inflammatory process. Deep in the dermis, there is often a predominantly perivascular, usually dense, mononuclear cell infiltrate of mainly T-lymphocytes, histiocytes, eosinophils, and plasma cells; in severe CAD, this may be even more prominent, along with marked focal epidermal lymphocyte exocytosis (Fig. 12-16), and a degree of irregularity of nuclear outline (Figs. 12-17 and 12-18). In such cases, formerly included within the term *actinic reticuloid*, distinction from cutaneous T-cell lymphoma may often be difficult. It has been suggested that the T-lymphocytes in such cases have a diagnostically helpful [predominantly CD8 (cytotoxic) positive] phenotype, and that most other reactive infiltrates and cutaneous T-cell lymphomas are instead mostly

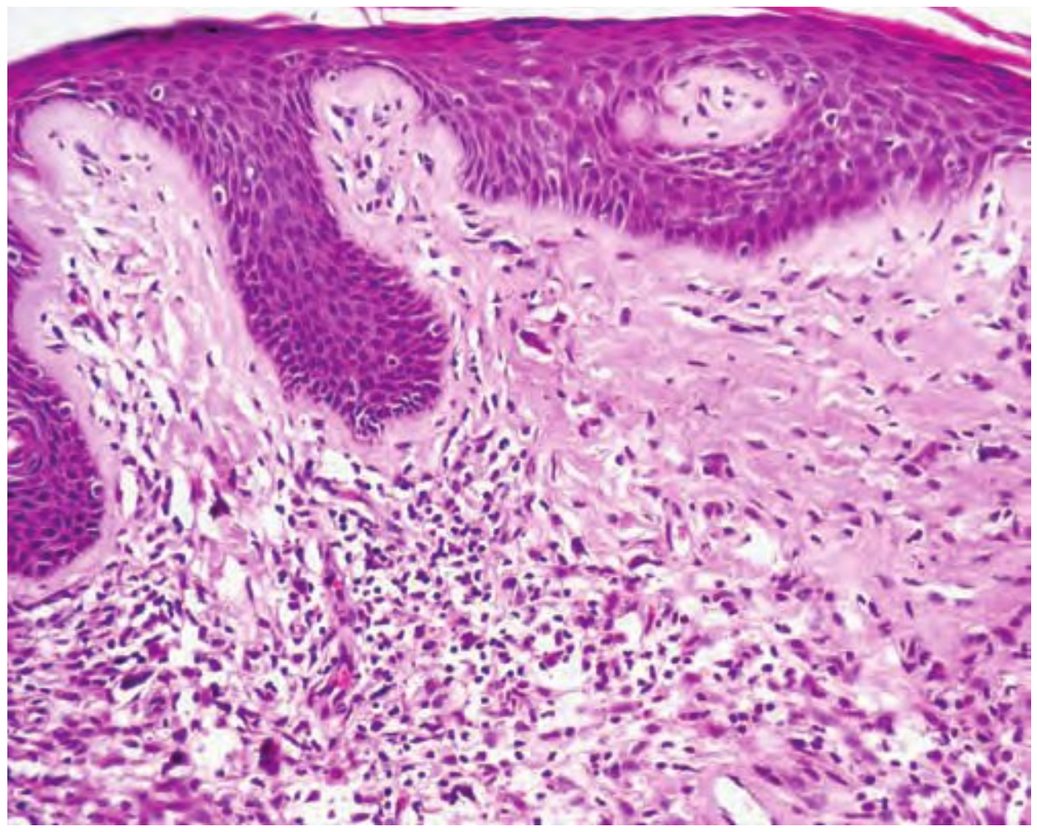

FIGURE 12-15. Chronic actinic dermatitis. Fibrosis of papillary dermis with mononuclear inflammatory cells and scattered small giant cells.

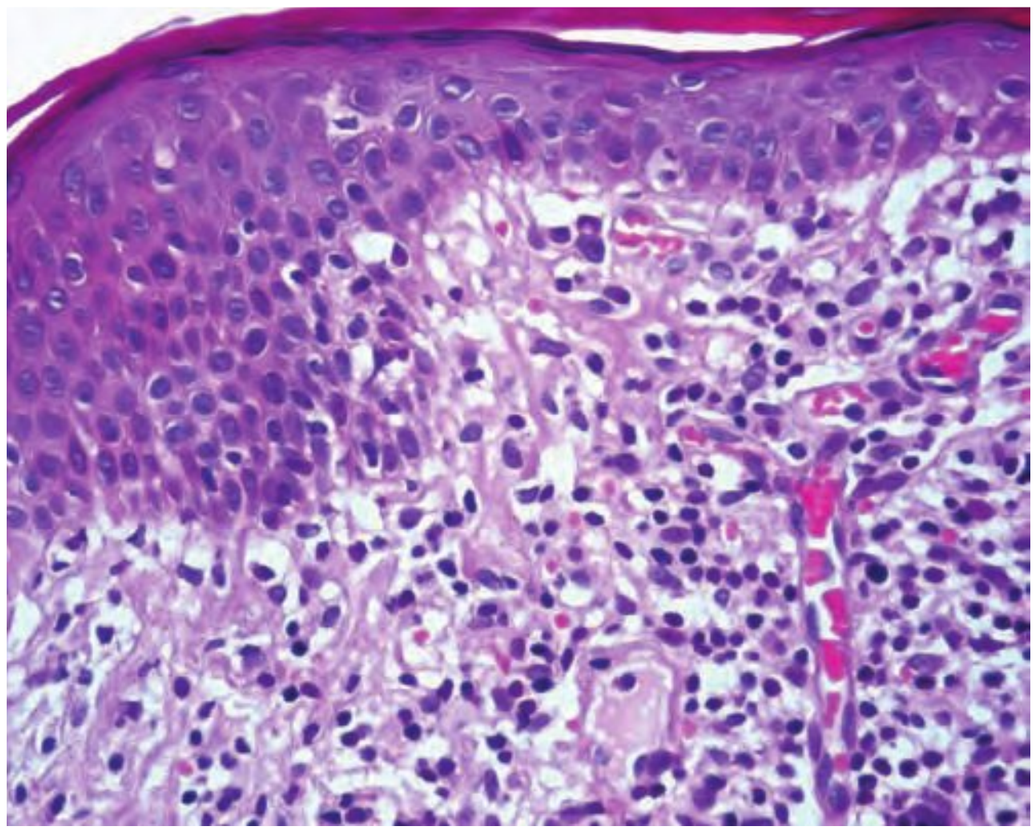

FIGURE 12-17. Chronic actinic dermatitis (actinic reticuloid variant). Focal epidermal exocytosis of lymphocytes, with some displaying irregular nuclear outlines.

CD4 (helper) positive (22). However, personal experience suggests that this is not always so and that infiltrating helper T-lymphocytes often are prominent in CAD as well.

Pathogenesis. CAD is clinically and histologically reproducible at all skin sites in the absence of exogenous photosensitizer, in some patients with just UVB, in some both UVB and UVA, and in rare others all of UVB, UVA, and short visible radiation, whereas the clinical features and pattern of dermal cellular infiltration, cytokine production, and adhesion molecule activation are all essentially indistinguishable from those of allergic contact dermatitis (2,3,18). In that the latter is a known DTH response, it therefore seems highly likely that the same situation applies in the CAD reaction, presumably against photo-activated endogenous, cutaneous autoantigen. Furthermore, action spectrum studies have suggested that the UVR absorber initiating the process may conceivably sometimes be DNA or a similar or associated molecule (23). In addition, it is possible that the airborne allergic contact dermatitis common in CAD may increase cutaneous immune responsiveness and thus putative antigen recognition, or else that the frequently photoaged skin in the disease may lead to diminished normal UVR-induced cutaneous immunosuppression, as apparently occurs genetically in PMLE, and again greater antigen recognition. Finally, slower clearance of antigen may also occur in the aged skin of CAD, again arguably potentiating disease development.

Differential Diagnosis. CAD must be distinguished from other eczemas, in particular the seborrheic and atopic forms, from airborne and topical medicament contact dermatitis, and from cutaneous T-cell lymphoma. However, in that its histologic appearances are indistinguishable from those of other subacute or chronic spongiotic processes, or in its severe forms from cutaneous T-cell lymphoma, a clinical history is essential for firm diagnosis as well. Nevertheless, severe CAD is generally separable from lymphoma by its superficial dermal fibrosis, paucity of cytologically atypical lymphocytes, and at least focal prominent spongiosis.

SOLAR URTICARIA

SU is a rare UVR- or visible radiation-induced wealing of exposed skin. The more common primary SU occurs spontaneously, and the very rare secondary form follows photosensitization to drugs or chemicals (2,3,24). Primary SU is slightly more common in women, with onset at any age but mostly between 10 and 50 years. The eruption develops on exposed skin within 5 to 10 minutes and fades within an hour or two. Regularly uncovered sites such as the face and backs of hands are occasionally spared. A tingling sensation and patchy erythema generally precede separate or confluent wealing, the latter sometimes generalized and in severe instances occasionally associated with headache, nausea, bronchospasm, faintness, or systemic collapse. Secondary SU generally follows exposure to substances such as tar, pitch, dyes, drugs such as the discontinued benoxaprofen, or very rarely endogenous porphyrin in the porphyrias. Avoidance of the inducing radiation, the use of appropriate sunscreens, or in particular adequate doses of nonsedating antihistamines helps approximately half of patients. Resistant cases sometimes respond to low-dose narrowband UVB phototherapy, low-dose PUVA or particularly plasmapheresis, or failing that, very rarely to intravenous immunoglobulin or cyclosporine. However, a proportion of SU patients do poorly with all therapy.

Histopathology. The epidermis appears unremarkable. In the dermis, there is edema as evidenced by mild collagen bundle separation, along with slight, rarely moderate, perivascular and interstitial inflammatory cell infiltration with eosinophils and occasionally also neutrophils and lymphocytes (2,3,24,25) (Fig. 12-19).

Pathogenesis. Any UVR or visible radiation waveband, specific for a given patient, may induce primary SU (2,3,24). Wealing is probably mediated through allergic type I hypersensitivity to cutaneous or circulating, irradiation-induced allergen. Presumed circulating antibodies have also been identified, very likely of the IgE type. In secondary SU, the eruption apparently follows direct nonimmunologic injury after UVR absorption by the responsible chemical or drug and its secondary transfer to adjacent susceptible tissue. Histamine is probably the major chemical mediator in both forms.

Differential Diagnosis. Clinically, SU must be differentiated from other light-induced eruptions by its much shorter time course and characteristic wealing and from other forms of urticaria, particularly that which is heat induced. Histologic distinction, however, is not possible. The porphyrias, drug and chemical photosensitivity, and lupus erythematosus must also be excluded for final diagnosis.

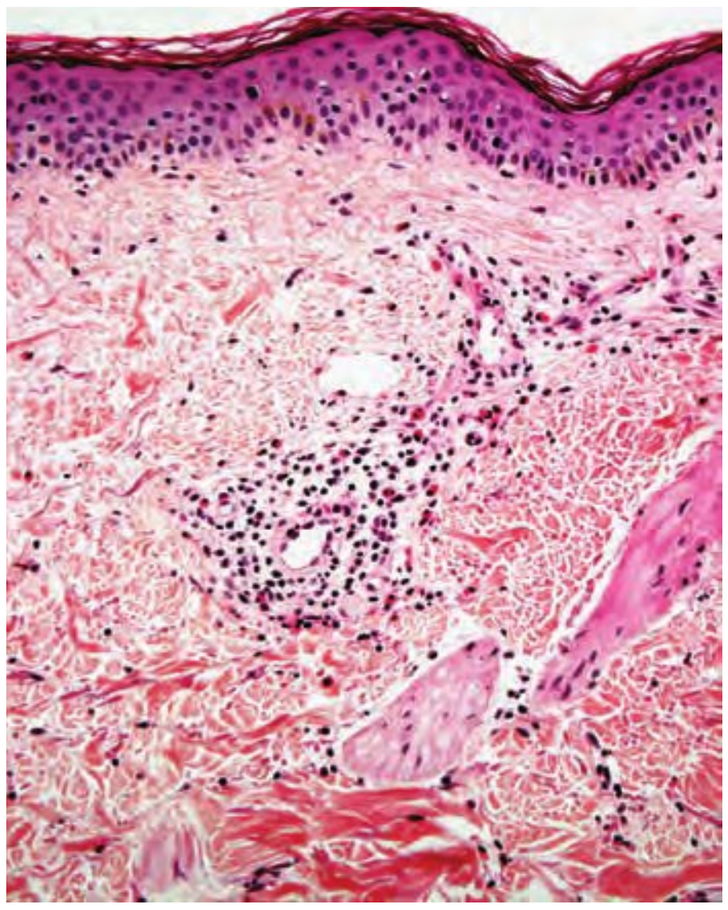

FIGURE 12-19. Solar urticaria. Dermal edema and a mild interstitial and perivascular inflammatory cell infiltrate of lymphocytes and eosinophils.

CHAPTER 13

Jacqueline M. Junkins-Hopkins

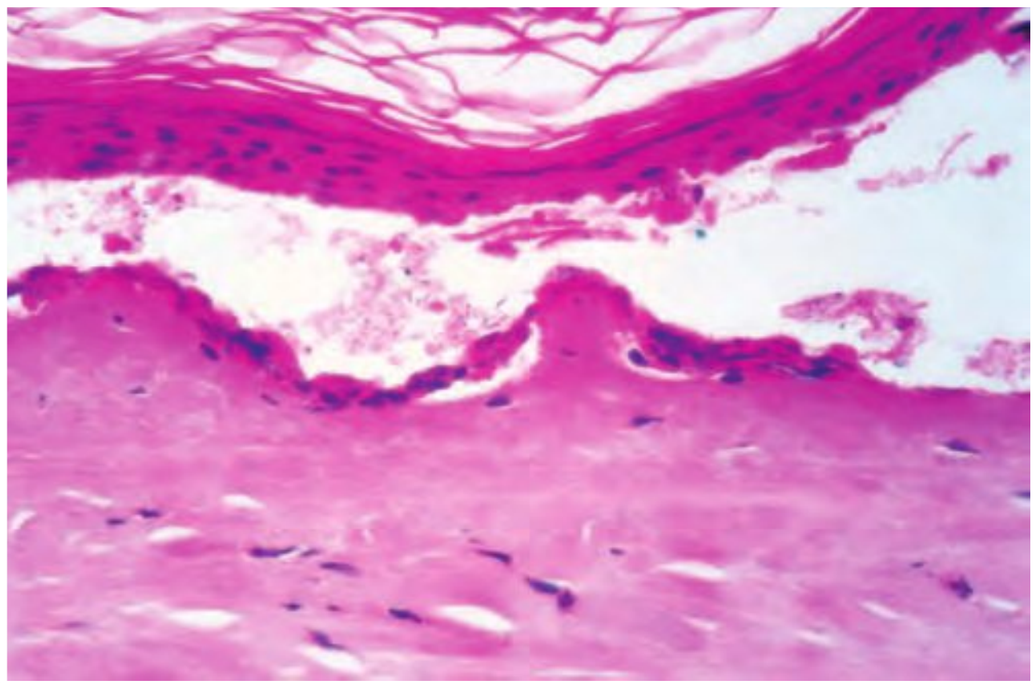
Disorders Associated with Physical Agents: Heat, Cold, Radiation, and Trauma

Physical injury to the skin can result in a number of disorders of the epidermis, dermis, and/or subcutis, depending on the type of agent exposure. Direct injury to the skin by radiation and temperature-associated exposure results in distinct histopathologic skin alterations that will be discussed in this chapter. Disorders due to direct physical injury and surgical-related injury also are discussed; however, cutaneous alterations associated with cosmetic-associated procedures such as reactions to injectable material (e.g., silicone) are discussed elsewhere. Conditions that have other pathogenesis but may be related to temperature or physical exposure, such as Raynaud's phenomenon, physical urticaria, and cold panniculitis, are discussed in Chapters 10, 7, and 20, respectively.

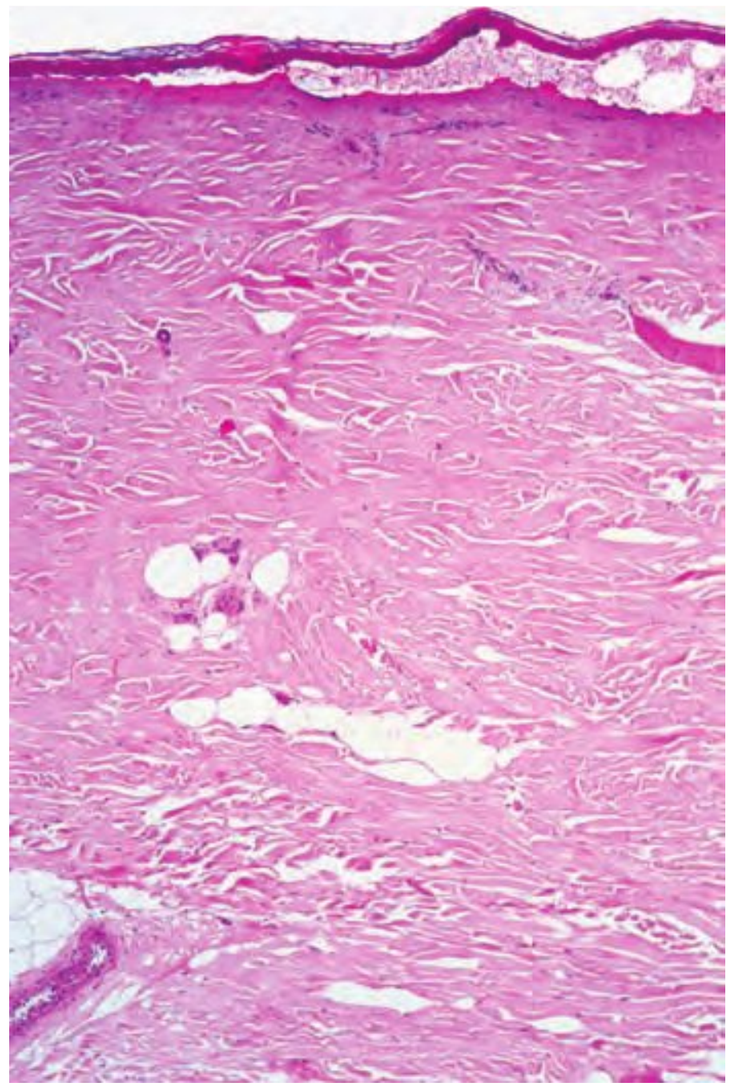
HEAT-ASSOCIATED INJURIES

The effect of heat on the skin is determined by the skin thickness and degree, extent, and duration of the heat exposure. The source of the heat also influences the degree of tissue injury. For instance, dry heat results in charring and desiccation, whereas moist heat results in opaque coagulation. Immersion burns are more severe than flash and splatter burns, and electrical burns result in deep tissue necrosis (1). Exposure of the skin to extreme heat results in a first-, second- or third-degree burn, whereas prolonged or repetitive exposure to less intense heat results in changes of erythema ab igne. Surgery-related electrodesiccation-induced injury also has distinct histopathologic features and is discussed at the end of the chapter.

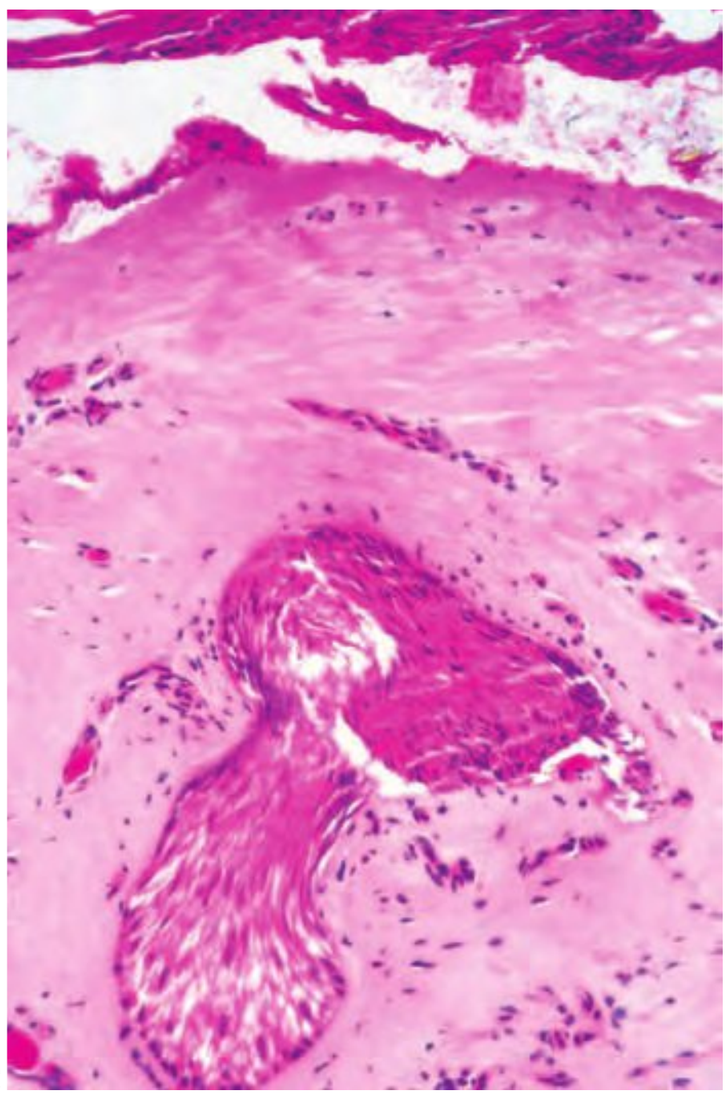
Burns



Burns to the skin may be due to *thermal injury* from flames or hot substances such as scalding water, contact, or flash burns from explosions; *chemical burns*, such as wet cement (2) or mustard gas (3); and *electrical injury*. The end result is similar in all burns, and these are classified according to the depth of injury (4).



Tissue injury from direct exposure to heat is the most common, and is defined by the depth (partial or full thickness) or extent (first, second, or third degree) of tissue injury. The resultant tissue injury is a sequela of the release of inflammatory and vasoactive mediators released due to denaturation and coagulation of proteins and to edema from increased capillary permeability (5). Painful erythema and edema without vesiculation is seen in first-degree burns; vesiculation and blisters characterize superficial second-degree burns, which progress to pallor and anesthesia if both the epidermis and dermis are injured; and third-degree burns show massive necrosis with charring, denuded superficial tissue, granulation tissue, and scar formation (1). Deep second-degree burns and third-degree burns show overlapping features. Secondary bacterial infections may cause the injury of a superficial second-degree burn to extend deeper, with changes similar to a third-degree burn.



Chemical burns may be due to acid or alkalis, the latter of which penetrate more deeply, with delayed pain. Cement burns are an example and tend to occur on the lower extremities, associated with accidental seepage of cement onto clothing or boots (2). Occasionally, there may be burns from marking lines on playing fields. There is burning, pain, erythema, and vesiculation within about 6 to 48 hours of exposure (mean 38 hours). Erosions and necrosis similar to heat burns ensues. Mustard gas (yperite) burns in chemical warfare may be seen even with less than 1 hour of exposure, with a latent period of less than 6 hours. Patients present with pruritus, burning, pain, erosions, erythema, vesicles, bulla, ulceration, edema, and dyschromia, especially hyperpigmentation (3). Involvement of groin and axilla is more common, due to moisture. There may be a toxic epidermal necrolysis (TEN)–like picture.

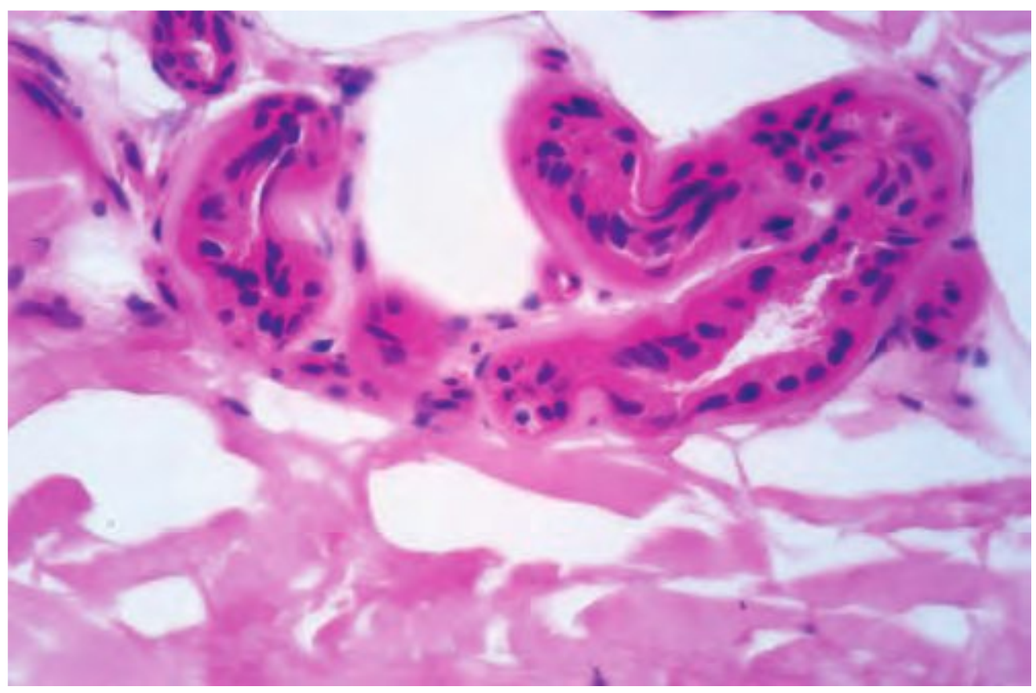
Secondary inflammatory events or malignant conditions may arise at burn sites (see later discussion), and, rarely, neutrophilic dermatosis may be induced by thermal burn injury (6). Eccrine poroma (7), sarcoidosis, neurothekeoma, and schwannoma (8) may also be seen.

Histopathology. The histopathology depends on the degree of tissue damage. There is variable necrosis of the epidermis, dermis, and adnexal structures, with necrosis and eventual sclerotic changes of the dermis. The inflammatory infiltrate is variable and includes neutrophils, lymphocytes, and macrophages. Attempts have been made to estimate the age of the burn

A

B

C

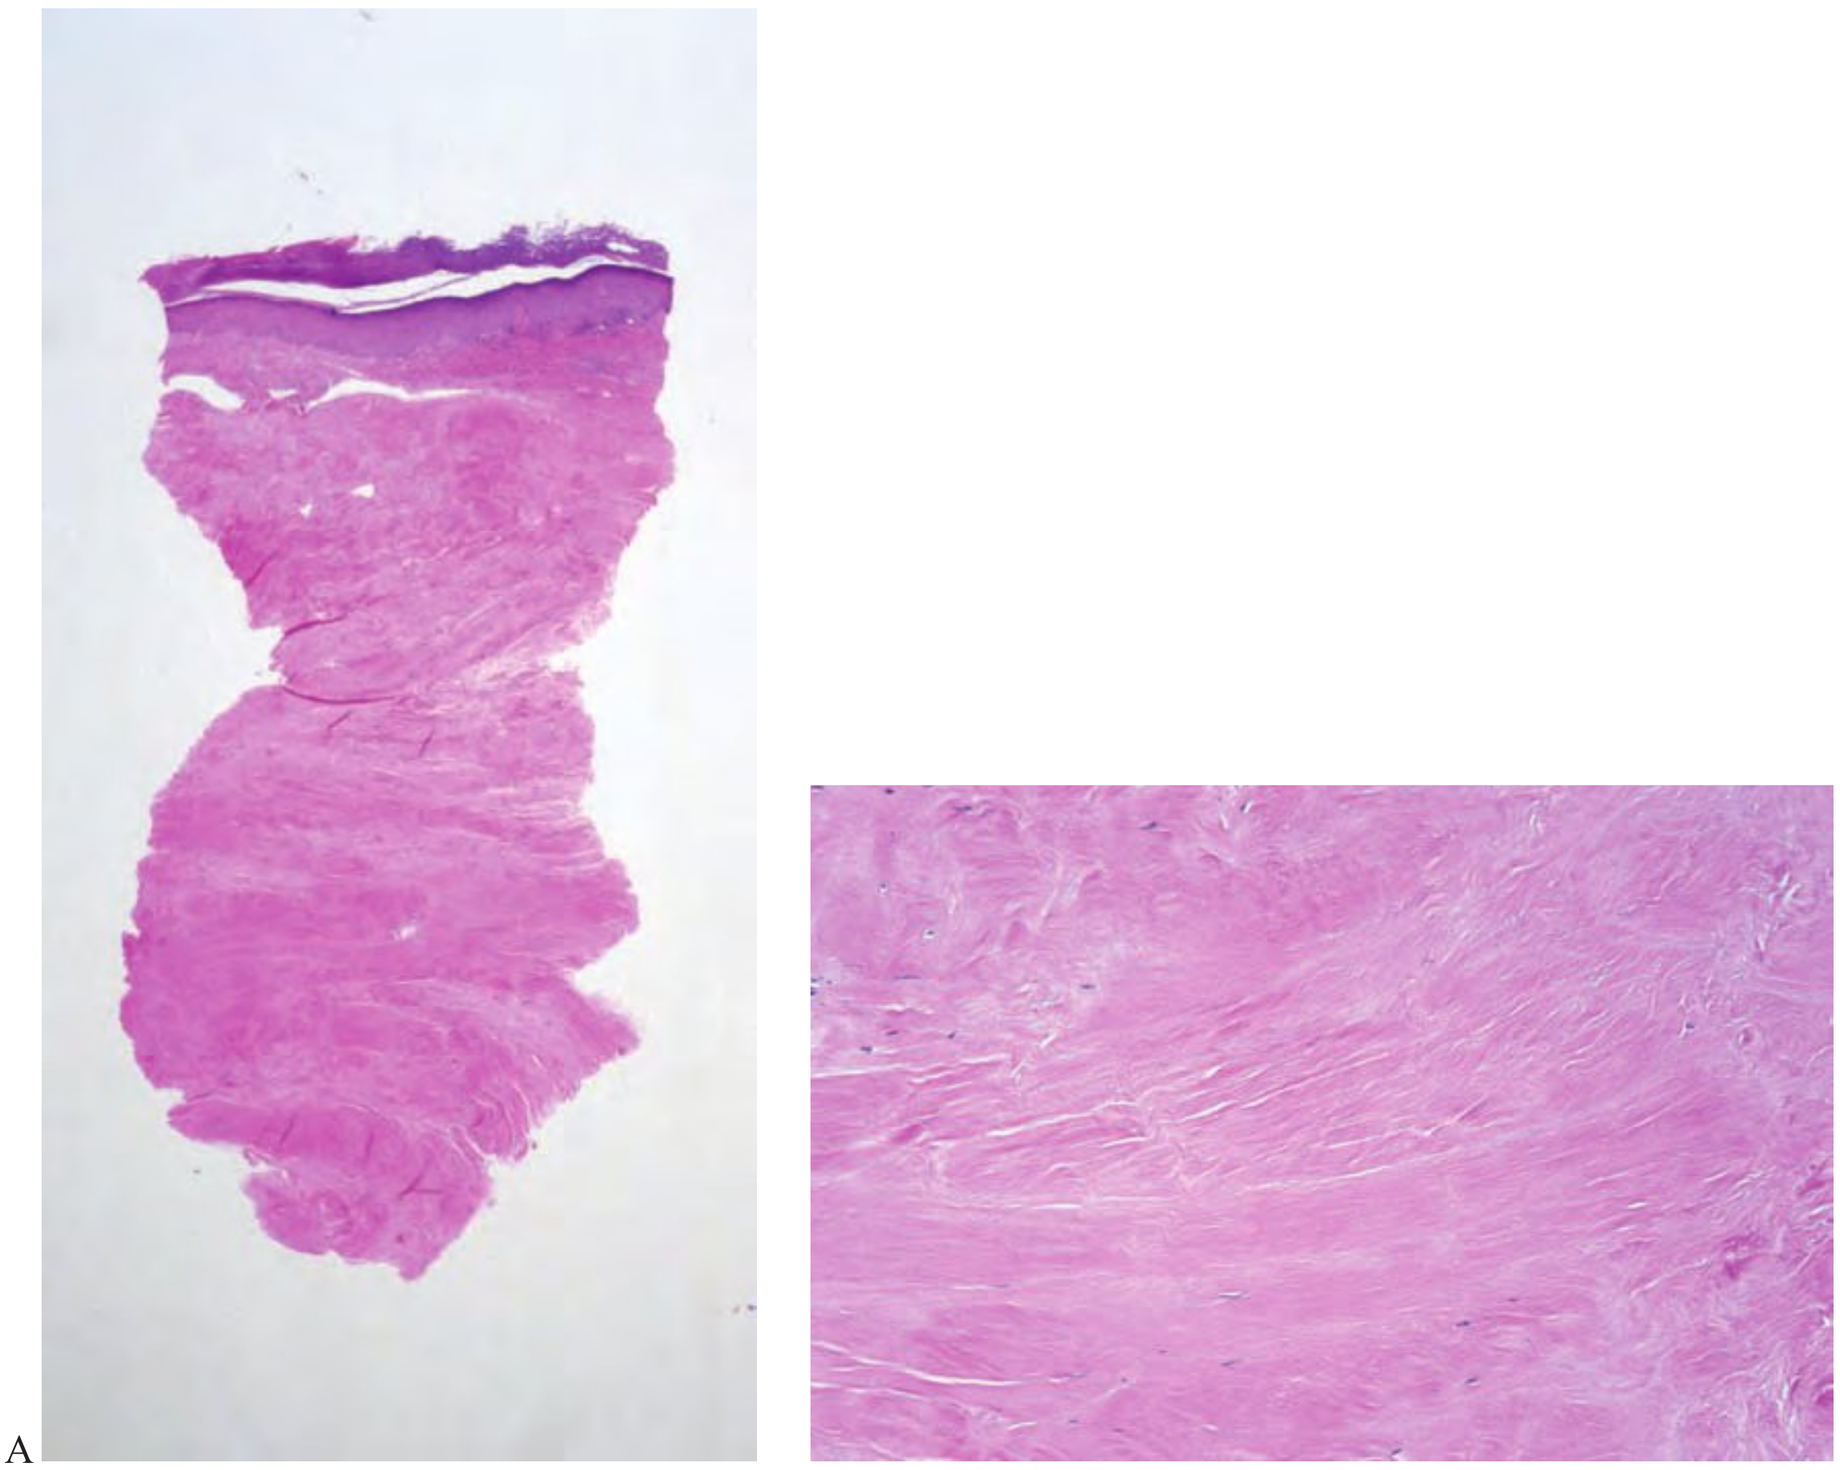


D

FIGURE 13-1. Third-degree burn. A: The epidermis shows full-thickness eosinophilic necrosis resulting in bullous disassociation from the dermis and incipient denution. This bulla formation can be seen in second- and third-degree burns. The collagen shows homogenized necrosis, with loss of distinction between collagen bundles. The fibroblasts are nonatypical, differentiating this from chronic radiation injury. B: There is pandermal eosinophilic homogenized alteration collagen, with necrosis of an eccrine gland. The epidermis shows bulla formation. C: Extension of the injury involving the pilosebaceous units differentiates a third-degree from a superficial second-degree burn. Burn injury to the pilosebaceous unit results in eosinophilic necrosis of the epithelium and elongation of the nuclei. The surrounding stroma shows coagulation of the collagen and vascular thrombosis. D: Eosinophilic alteration of an injured eccrine gland differentiates third- from second- and first-degree burns.

wound based on the degree of neutrophilic and macrophage infiltration (9). Acute inflammation tends to predominate in the first 6 hours to 2 days after injury; however, neutrophils can also be seen in later lesions. The latter may possibly be related to infection, which can often occur. Macrophages tend to be encountered from days 2 to 20, but many cases show a minimal or absent macrophage response. Lymphocytes tend to occur later.

The degree of burn is defined more specifically by the following features:



First-degree burns: Vasodilation is the predominant feature. Epidermal and subepidermal edema may progress to partial-thickness superficial epidermal necrosis. Full-thickness epidermal necrosis differentiates second- from first-degree burns.

Second-degree burns: In superficial second-degree burns, partial- to full-thickness necrosis and edema of the epidermis and subepidermal stroma result in blister formation. Typically, epidermal necrosis and separation from the dermis at the dermal–epidermal junction or within necrotic basilar keratinocytes are seen (Fig. 13-1). Although initially vasoconstriction occurs, the biopsies show prominent vasodilation and edema in the dermis. Necrotic changes may extend into the lower reticular dermis in deep second-degree burns, but the appendages tend to be spared, differentiating a second-degree from a third-degree burn. Apoptosis can be seen in the adnexal structures and dermal fibroblasts of deep partial burns (10).

Third-degree burns: Full-thickness coagulation necrosis of the epidermis and dermis, including the appendages, is seen (Fig. 13-1). The resultant scar is characterized by hyalinized collagen and an absence of adnexal structures (Fig. 13-2).

Chemical burns: Chemical burns may vary, depending on the substance. Dermal and adnexal necrosis similar to thermal burns may be seen. Histopathology of sulfur mustard shows four patterns:

1. Interface dermatitis, with or without necrosis, similar to TEN or erythema multiforme, with hyperpigmentation of the epidermal roof.

A B

FIGURE 13-2. Chronic burn scar. A: The dermis and subcutis are diffusely sclerotic and homogenized, with compete absence of adnexal structures, including arrector pili muscles, differentiating this from radiation injury and scleroderma/morphea. The absence of vascular proliferation and presence of homogenized thickening of the collagen differentiates a chronic burn from a scar from other reparative causes. B: The sclerotic collagen is nearly devoid of fibroblasts, in particular atypical ones, differentiating this from chronic radiation injury.

2. Spongiotic dermatitis, similar to acute contact dermatitis. Bulla formation is often at the dermal–epidermal junction, with or without acantholytic cells. The epidermal roof shows dysmaturation with cellular atypia.
3. Hyperpigmentation of the basal layer of the epidermis with dermal melanophages.
4. Dermal alteration, including coagulation necrosis, low-grade fibrosis with sclerodermoid changes, telangiectases, and perivascular inflammation, without vasculitis (3).

Differential Diagnosis. Radiation dermatitis is differentiated from burn scars by the presence of atypical radiation fibroblasts in the former. Complete absence of the adnexal structures favors a burn scar because the eccrine glands may be spared with radiation. In morphea/scleroderma, there is preservation of eccrine coils, and a lymphoplasmacellular infiltrate may be seen.

Burn Scar–Associated Malignancy

Chronic burn scars are subject to the development of dystrophic calcinosis cutis (11), and carcinomas, especially basal cell carcinomas, may arise acutely within 2 to 3 months after the injury (1). Delayed carcinomas arise after a latency that ranges from 10 to 70 years, with an average of approximately 30 years. There may be a shorter lag time (19 years) if there is poor wound care (12). The tumors most often arise on the extremities but may also arise on the head and trunk. Burn scar–associated cancers include squamous more often than basal cell carcinomas, but malignant melanoma (13), angiosarcoma (14), and anaplastic large cell lymphoma (15,16) may be seen. Squamous cell carcinomas are more often seen with scalding burns, whereas basal cell carcinomas are associated with burns from flames. Welders are also at risk for getting both basal and squamous cell carcinomas due to chronic exposure to both high temperatures and nonsolar ultraviolet radiation (17,18). The occurrence of cancer developing in burn scars was noted in 1860 by Heurteux, and trauma-induced carcinomas were described by Marjolin in 1828; these cancers are more aggressive than their sun-induced counterparts. Metastases may occur in up to approximately one third of the cases. Recurrence is also higher in cancers due to these chronic ulcers. The carcinomas arise from the edges of wounds or from epithelial remnants entrapped in the scar; thus, they may not occur as frequently if there has been grafting (1).

Acute Ultraviolet Burn

Mild ultraviolet-induced burns or sunburns resulting in erythema are characterized by the presence of scattered apoptotic keratinocytes, "sunburn cells," and variable subepidermal edema. Clinical blistering may result from severe burns due to full-thickness epidermal necrosis and/or dermal edema (Fig. 13-3). The preservation of appendages allows epidermal regeneration.

Ultraviolet Recall

This is also known by other names, including sunburn reactivation, sunburn recall, photo recall, and photodermatitis reactivation, and refers to the phenomenon in which a medication induces an acute cutaneous eruption restricted to the area of previous sunburn or ultraviolet (UV) light therapy (18). This is seen especially with methotrexate, but it can also be associated with other chemotherapeutic agents and antibiotics, such as ampicillin and trimethoprim-sulfamethoxazole. Two clinicopathologic presentations may be seen, depending on whether the UV recall reaction occurs days after UV exposure, as is seen with methotrexate, or weeks to months later, as is typically seen with antibiotics. Methotrexate-induced recall phenomenon generally occurs if methotrexate is given 1 to 5 days after sunburn occurs but not if the burn is concomitant or much earlier. This UV recall tends to be associated with pain and burning, with an erythematous to violaceous vesiculobullous eruption (18), and in most cases it is more severe than the initial sunburn. Ultraviolet recall reactions associated with antibiotics (19,20) differ from the methotrexate reaction. These tend to occur at a later interval—weeks to months from the sunburn—with a less severe, pruritic macular, papular; or morbilliform-like drug reaction (19). Changes of toxic epidermal necrolysis have rarely been reported with trimethoprim sulfa (21). The UV reaction with either presentation presents within a few days or within hours of the medication intake. Rechallenge may occur at a shorter interval than the initial reaction and with a more severe blistering reaction (21). It has been proposed that the methotrexate-induced reaction be considered a UV enhancement reaction and those associated with a delayed interval of UV exposure be considered UV reactivation (18).

Histologic features of UV recall are not well documented because the diagnosis is usually made clinically. A review of the literature described several histologic features, most of which indicate an element of interface or cytotoxic dermatitis, characterized by hydropic degeneration, dyskeratotic or apoptotic keratinocytes, dysmaturation, dyskeratosis, or acanthosis. There is also a variable perivascular lymphocytic infiltrate in the papillary dermis, sometimes with erythrocyte extravasation. Neutrophils

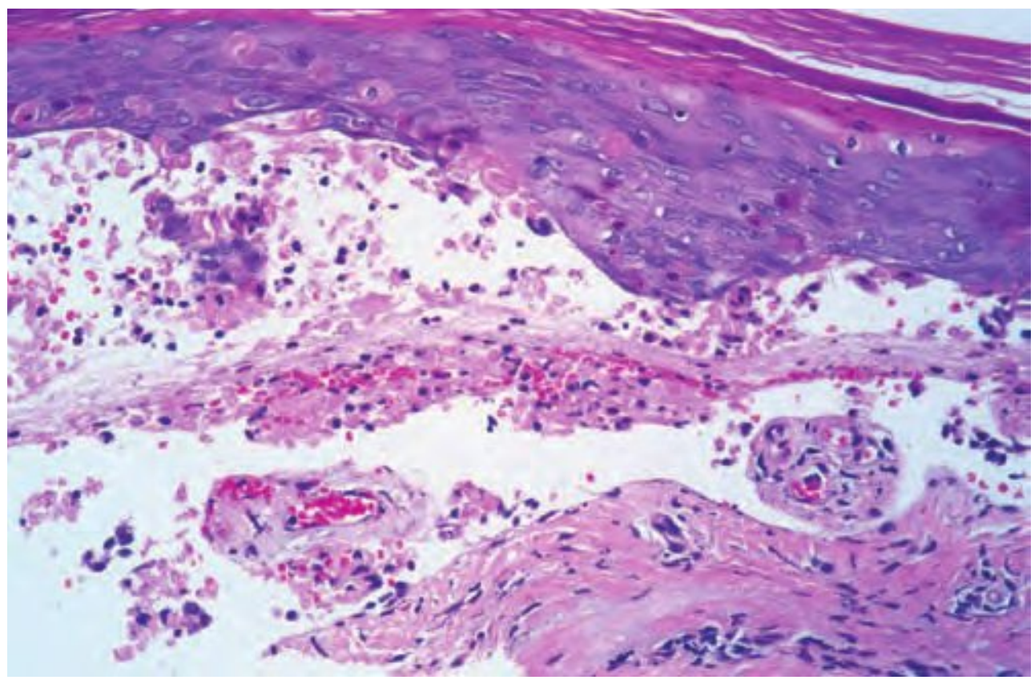


FIGURE 13-3. Acute ultraviolet (UV) radiation burn. This is an example of a UVA-induced burn showing full-thickness dyskeratotic keratinocytes throughout all layers of the epidermis, with subepidermal blister formation.

have been described. Clinical blisters have been associated with extensive epidermal necrosis with intraepidermal bullae formation (18).

ERYTHEMA AB IGNE

Erythema ab igne presents as localized, reticulated, dusky reddish brown patches with variable telangiectasia (Fig. 13-4) associated with repetitive infrared radiation exposure insufficient to produce a burn. Thermal keratoses, squamous cell carcinoma, and rarely bullae may arise in lesions of erythema ab igne (22). Historically, this was typically on the shins, buttock, or lower back associated with repetitive exposure to open hearths or stoves, hot water bottles, or steam heaters. More recently, prolonged repeated contact with heating pads, car seat heaters, laptop computers (23), and hot popcorn kernels

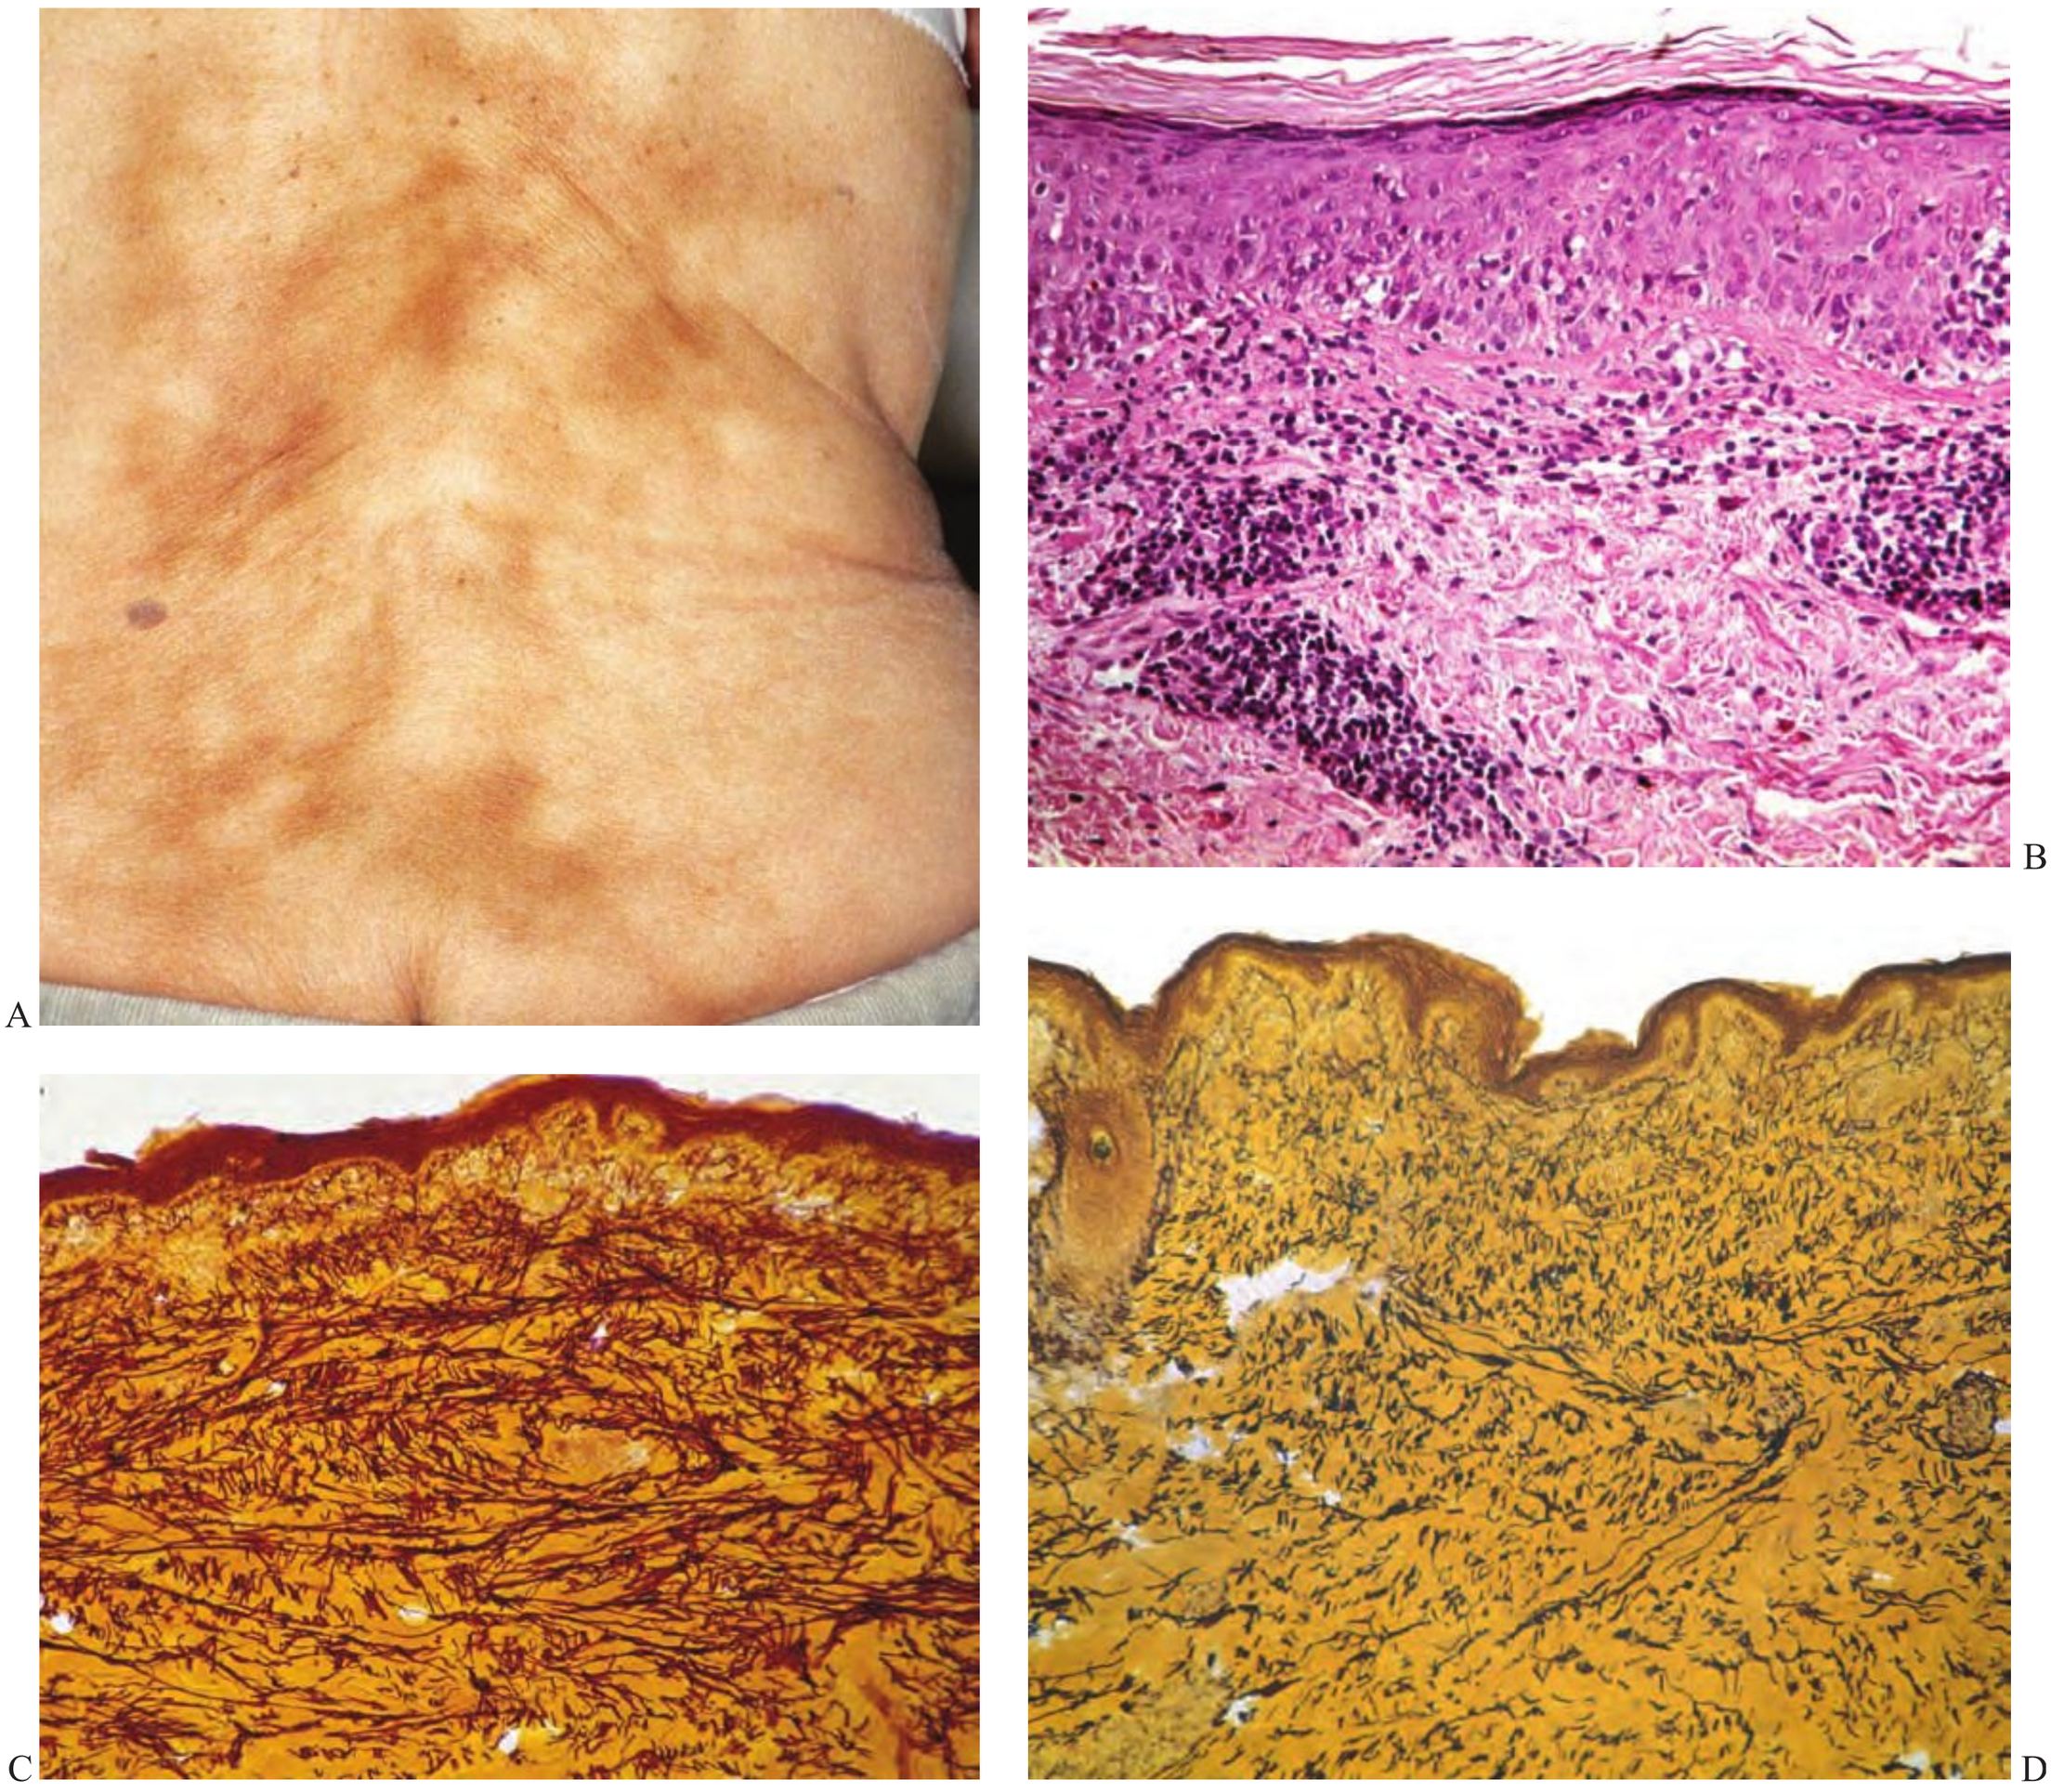

FIGURE 13-4. Erythema ab igne. A: Clinically, reticulated brown patches are seen in erythema ab igne. This may present on the lower back where there has been frequent use of a heating pad. B: Erythema ab igne has variable histologic features. This hematoxylin and eosin–stained biopsy shows a perivascular lymphocytic infiltrate in the superficial dermis that focally disrupts the dermal–epidermal interface. There is no discernible elastic fiber abnormality noted on routine staining. The absence of clumped basophilic elastic tissue differentiates erythema ab igne from solar elastosis. C: Staining for elastic tissue highlights the increased amount of elastic tissue in comparison to uninvolved skin (see panel D), characteristic of erythema ab igne. D: Elastic staining of uninvolved skin, showing a normal distribution of elastic fibers, as compared with panel C. (Photographs courtesy of Waine Johnson, MD.)

used for arthritic pain have been reported to cause erythema ab igne. This may rarely occur in children (24), and it may have a high tendency of recurrence in patients with mental retardation. Rare cases of truncal erythema ab igne due to heat application for pain as a manifestation of abdominal cancer have been reported. (25). The time of onset of erythema ab igne is usually months, but laptop-induced erythema ab igne has been shown to occur within 2 weeks of exposure (26).

Histopathology. Biopsies of erythema ab igne show variable histopathologic features, which are nonspecific in the absence of clinical-pathologic correlation. The biopsy may appear normal on hematoxylin and eosin staining, with the exception of mild acanthosis and hyperpigmentation of the basal keratinocytes. Epidermal atrophy, rete effacement, and pigment incontinence, with additional features of interface dermatitis, characterized by mild basal vacuolization, necrotic keratinocytes, and subtle squamatization, have been described in the early stages (27). The dermis shows dilation and congestion of postcapillary venules and a variable perivascular infiltrate of mild to moderate intensity consisting of lymphocytes, plasma cells, histiocytes, melanophages, mast cells, and neutrophils (27–30) (Fig. 13-4). Elastic stains demonstrate an increased amount of elastic tissue in the upper and mid-dermis. These fibers may be fragmented (22). Alcian blue stains may reveal an increase in hyaluronic acid. Deposition of iron has been described (28,30), but this may reflect the anatomic site of the lower legs (8). Basal keratinocytic atypia and frank squamous cell carcinoma *in situ* have been reported in erythema ab igne of the lower leg (31). Bullous lesions have been described as showing a subepidermal plane of separation associated with epidermal atrophy, rete effacement, and hydropic degeneration of basal cells with melanophages, consistent with a lichenoid tissue reaction (22). Similar cases of bullous erythema ab igne have been attributed to coexisting lichen planus, but this is felt by some to be a manifestation of intrinsic blistering. Direct immunofluorescence on these cases are either negative or show a pattern of immunoglobulin M staining in the papillary dermis consistent with colloid bodies. Ultrastructural investigations of erythema ab igne have been reported (30) and show changes consistent with apoptotic regressive changes of the basal keratinocytes, functional activation of melanocytes, and elastic fiber alterations indistinguishable from actinic elastosis due to chronic ultraviolet radiation. The keratinocyte damage appeared to represent heat-related damage and not a preneoplastic alteration. The vessels are dilated and increased in number. This may rarely present as cutaneous reactive angiomatosis, mimicking a malignant vascular neoplasm or diffuse dermal angiomatosis (32).

Differential Diagnosis. The elastic tissue alteration induced by ultraviolet radiation in solar elastosis is apparent on hematoxylin and eosin stains as solid and homogenized material, as opposed to erythema ab igne, which shows no perceptible elastic changes on routine staining. Erythema chronicum perstans may also show subtle interface dermatitis with pigment dropout but is distinguished from erythema ab igne by the clinical presentation and the absence of increased elastic fibers. A hypersensitivity reaction with interface changes may show some overlapping features, but the clinical history should prompt elastic tissue staining, differentiating the two entities.

RADIATION-INDUCED SKIN ALTERATIONS

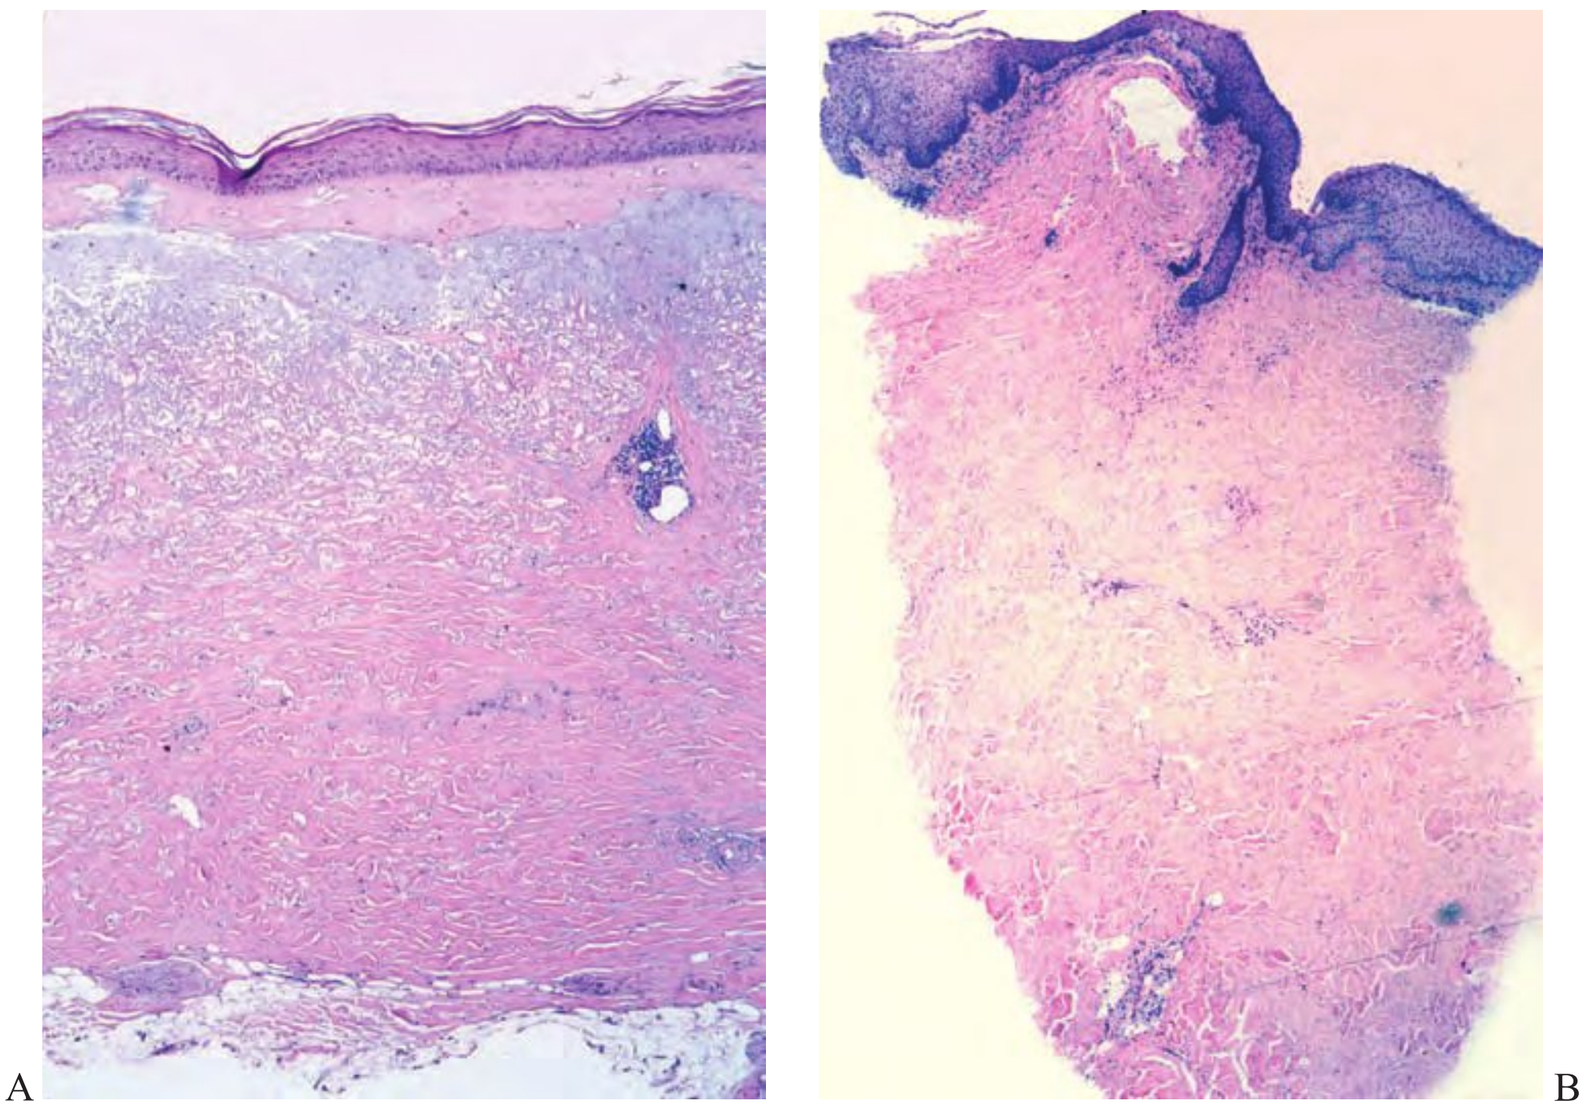
Cutaneous alterations due to irradiation include acute and chronic radiation dermatitis, radiation recall dermatitis, and secondary cutaneous neoplasms. The inflammatory changes that occur in the skin after irradiation, or radiation dermatitis, occur as a result of biochemical changes on X-ray–penetrated cells without a detectable rise in temperature. The resultant injury is determined by the threshold radiation dose. This may occur at the portal of entry or exit. In addition to the dose of irradiation, host factors play a role in the development of radiation dermatitis, such as in ataxia telangiectasia homozygotes, which have up to threefold normal radiation sensitivity (33). Patients with underlying conditions such as connective tissue disease, diabetes mellitus, and hyperthyroid disease have been reported to have an exaggerated reaction to radiotherapy (34). Concomitant use of radiation sensitizers, such as doxorubicin and taxane antineoplastic agents, may predispose an individual to increased acute toxicity reactions to radiation (35). Cetuximab, an epidermal growth factor inhibitor that is often given concurrently with radiation therapy for advanced head and neck squamous cell carcinoma, may be associated with severe (grade 4) radiation dermatitis (36). In contrast, radiation-induced cancer is a stochastic effect, and thus the risk of developing a neoplasm is independent of the dose. Fluoroscopically guided procedures may cause radiation dermatitis in areas of skin not directly in the radiation port, usually the back (34). Radiation recall dermatitis refers to precipitation of an inflammatory reaction limited to a site of a quiescent radiation field induced by administration of medication. Other cutaneous consequences of irradiation include vitiligo (35), lichen planus (36), and bullous pemphigoid (37).

Acute, Subacute, and Chronic Radiation Dermatitis

Changes of acute radiation dermatitis may become apparent between 2 weeks and 3 months post procedure.

Erythema, desquamation, alopecia, xerosis, dyschromia, vascular compromise, and proliferation with telangiectasia, blistering, epidermal and dermal atrophy and necrosis, and ulceration may be seen in the acute phases. Phases of skin injury response have been outlined in detail, and criteria have been put forth by the National Cancer Institute (38). Grade 1 radiation dermatitis includes generalized erythema with dry desquamation. This may be accompanied by pruritus and dyspigmentation. This may be concentrated in the follicles, resulting in alopecia due to injury to the pilosebaceous glands. Grade 2 radiation dermatitis typically occurs in the skin folds after 4 to 5 weeks post treatment of doses 40 Gy or greater and

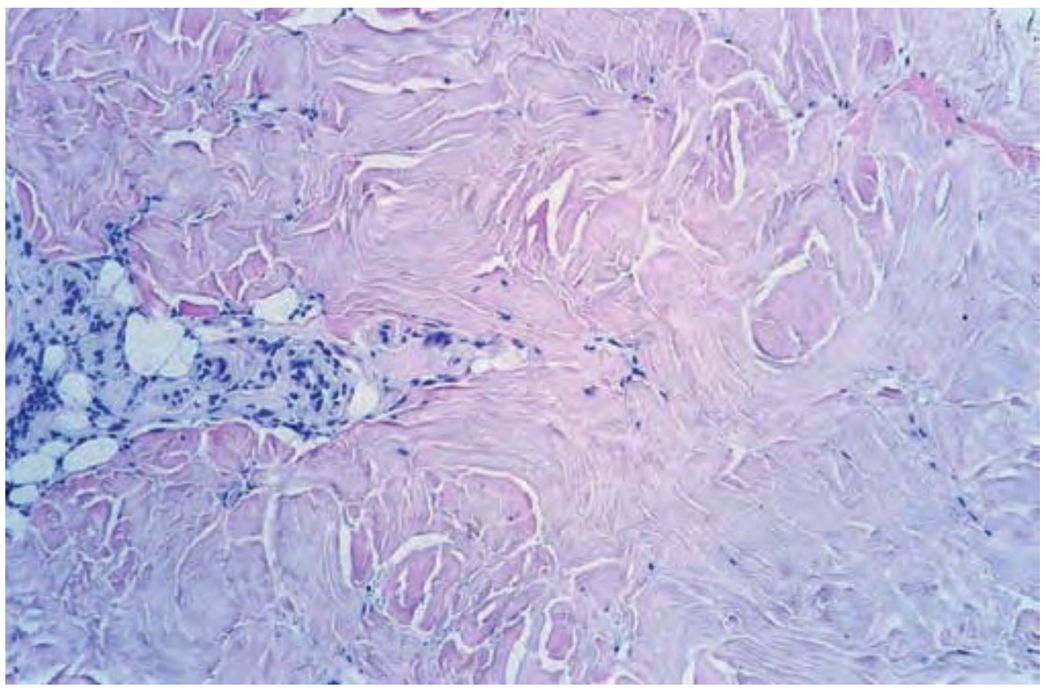
peaks at 1 to 2 weeks after the last treatment. There is persistent tender edematous erythema, which may progress to bullae or focal epidermal necrosis, with fibrinous exudates, termed moist desquamation. Superinfection may occur. In grade 3 there is more-extensive moist desquamation, extending beyond the folds. Grade 4 is characterized by ulceration, necrosis, and hemorrhage. Unresolved acute radiation results in chronic ulceration, fibrosis, and/or necrosis of the deeper structures, termed "consequential late" radiation dermatitis.

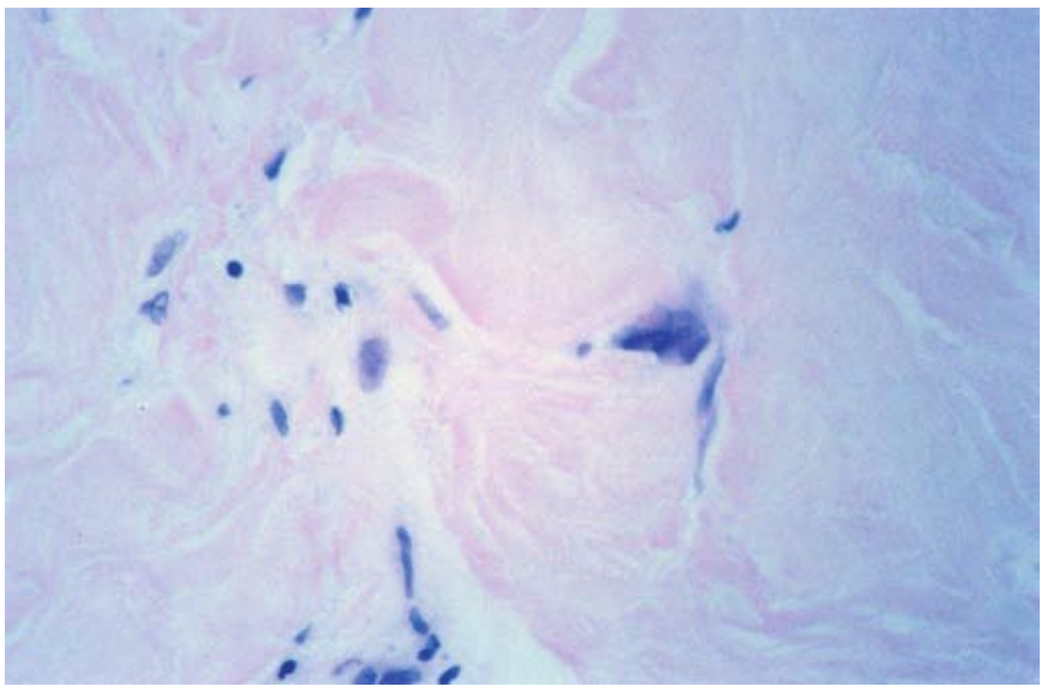


Changes of chronic radiation dermatitis are noted at 1 year post radiation but often represent progression of acute radiation dermatitis and thus may be evident earlier. Epidermal atrophy, xerosis, alopecia, anhidrosis, poikiloderma, hyperkeratosis, telangiectases, and fibrotic thickening of the dermis and subcutaneous tissue are seen. Late-onset dermal necrosis and changes of chronic radiation dermatitis with or without prior acute radiation may be seen years after the initial radiation. Nonhealing ulcers may be seen. Deep megavoltage radiation for noncutaneous malignancies may result in subcutaneous sclerosis that may extend into the underlying skeletal muscle (39).

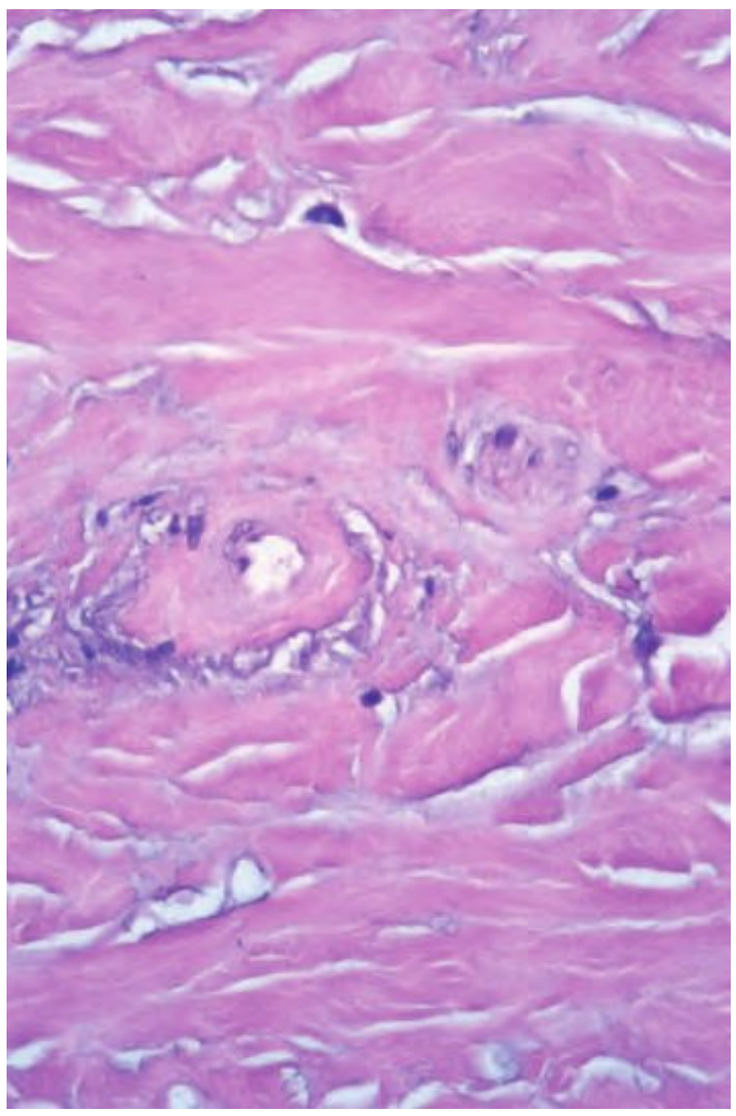
Histopathology. Histopathologic changes of radiation dermatitis vary with the morphologic lesion biopsied (34).

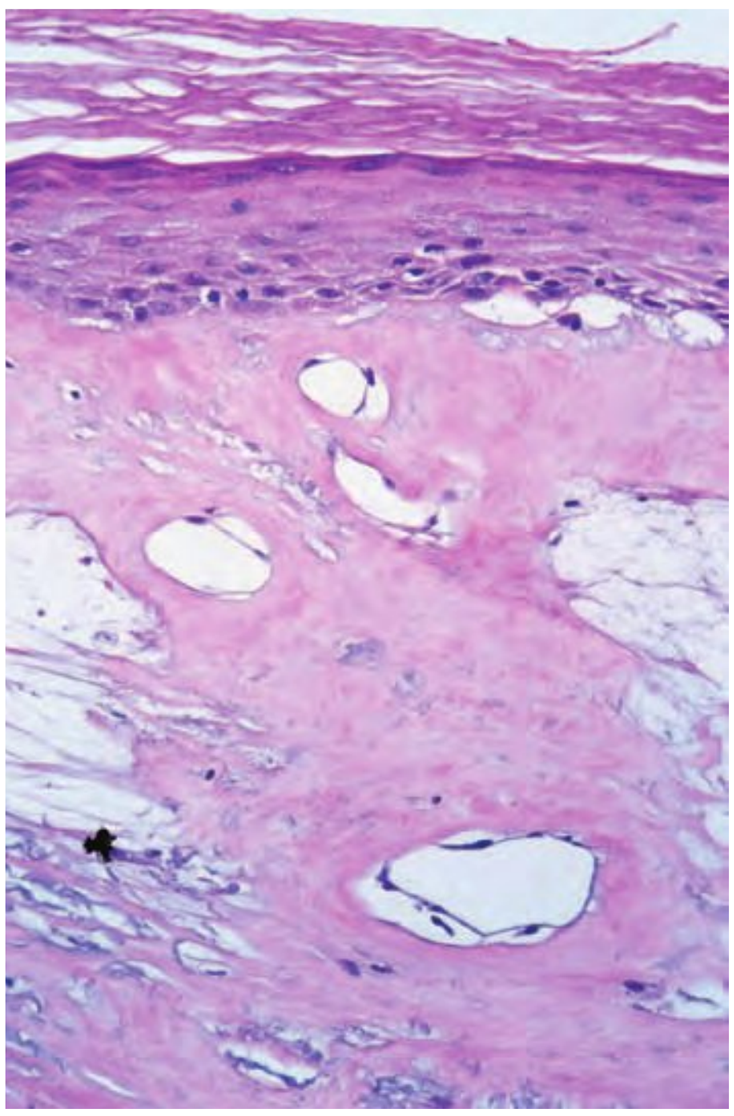
Acute radiation dermatitis is characterized by scattered pyknotic keratinocytes and epidermal edema. Depending on the dose of radiation, epidermal necrosis with blister formation and sloughing of the epidermis (clinically referred to as "moist desquamation") may be seen. Hyperkeratosis is seen with dry desquamation. Dermal changes include dermal and endothelial cell edema, vasodilation, erythrocyte extravasation, and fibrin thrombi of vessels. Variable inflammation is noted throughout the dermis, with involvement of the epidermis. Acute necrotic changes similar to that seen in the epidermis also may occur in the adnexal epithelium, eventuating in absence of pilosebaceous structures. Complete destruction of eccrine glands is not common. In severe radiation injury, necrosis of the epidermis and dermis results in chronic ulceration.



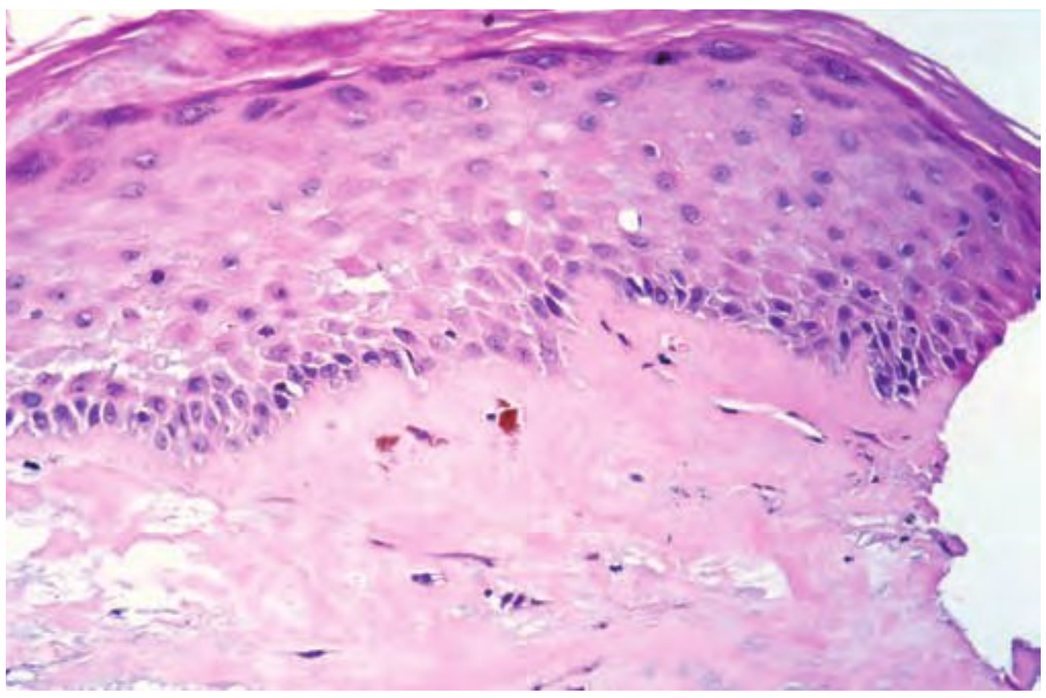


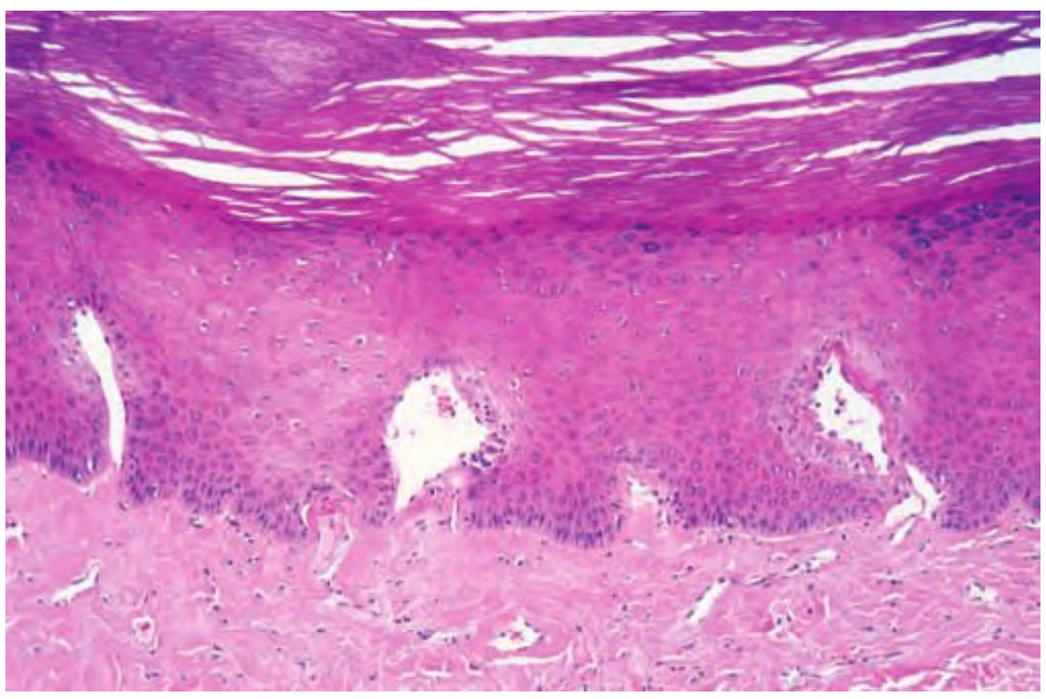
Late-stage or chronic radiation dermatitis is characterized by eosinophilic homogenized sclerosis of the dermal collagen, scattered large, bizarre, atypical "radiation fibroblasts," absence of pilosebaceous units, and vascular changes (Fig. 13-5) (40). The deep vessels show fibrous thickening, sometimes with luminal obliteration and recanalization, whereas superficially, telangiectases are prominent. The epidermal changes include atrophy, hyperkeratosis, and features of an interface reaction (Fig. 13-5). A maturation disorder with nuclear atypia and individual cell keratinization may be seen. Juxtaposed to atrophic areas may be epidermal hyperplasia that may extend downward and encase the telangiectatic vessels.





The origin of the radiation fibroblast is not known. Immunohistochemical studies have shown diffuse positive





A B

FIGURE 13-5. Late-stage radiation injury. A: This biopsy shows features of chronic radiation dermatitis, including epidermal atrophy, pandermal collagen sclerosis with mild lymphocytic inflammation, and absence of hair follicles. B: A rectangular, "squared-off" silhouette due to the sclerotic collagen alteration. This biopsy also demonstrates the variation of epidermal atrophy and hyperplasia that can be seen in radiation dermatitis. (continued)

FIGURE 13-5. Continued. C: There is sclerotic collagen bundle thickening, with compression of eccrine glands. Preservation of eccrine glands differentiates this from a burn scar. D: Large, bizarre and atypical radiation fibroblasts amid the thickened collagen bundles differentiate radiation dermatitis from morphea and third-degree burn scars. These are sparsely scattered, in contrast to atypical cells of a sarcoma. E: Sclerosis of endothelial cells is seen amid thickened sclerotic collagen bundles. F: There is telangiectasia of the upper dermal vessels, with epidermal atrophy and sclerosis of papillary dermal collagen. G: The epidermis shows features of interface dermatitis, with liquefaction of the basal layer, rete effacement, and pigment dropout. H: The epidermis may show hyperplasia, incorporating the underlying telangiectatic vessels between the rete.

cytoplasmic staining of the radiation fibroblasts with antibody to factor XIIIa, with only focal staining with antibody to CD34 in some cells (41). However, others have not demonstrated as consistent factor XIIIa staining. The cells are negative for HHF-35 (muscle-specific actin), and Ki-67, and P53 (42).

Subacute radiodermatitis applies to the phase of radiation injury in which there are overlapping features of acute and chronic radiation dermatitis. The histology is that of interface dermatitis, with basal vacuolization and keratinocyte necrosis (Fig. 13-6) (43). The presence of satellite cell necrosis, characterized by close apposition of necrotic keratinocytes and $CD8^+$ TIA-1 positive T lymphocytes, suggests that cytotoxic lymphocyte-mediated apoptosis is involved in the pathogenesis of subacute radiation dermatitis. (44).

Radiation-induced malignancies include squamous cell carcinomas and basal cell carcinomas predominantly (45), and these often occur in the background of chronic radiation dermatitis. The squamous cell carcinomas display aggressive, metastasizing behavior and include spindled variants. True radiation-induced sarcoma malignancies are less common and usually arise in heavily irradiated tissue with a latent period of 3 to 24 years. These include malignant fibrous histiocytoma, fibrosarcoma, osteosarcoma, liposarcoma, chondrosarcoma, and sarcomas of pluripotential mesenchymal cell derivation (46). Desmoplastic cutaneous leiomyosarcoma has also been reported (47). Mesenchymal sarcomas frequently occur on the chest wall after irradiation for breast carcinoma or Hodgkin's disease (48). Angiosarcomas, including spindled cell variants, may be seen at

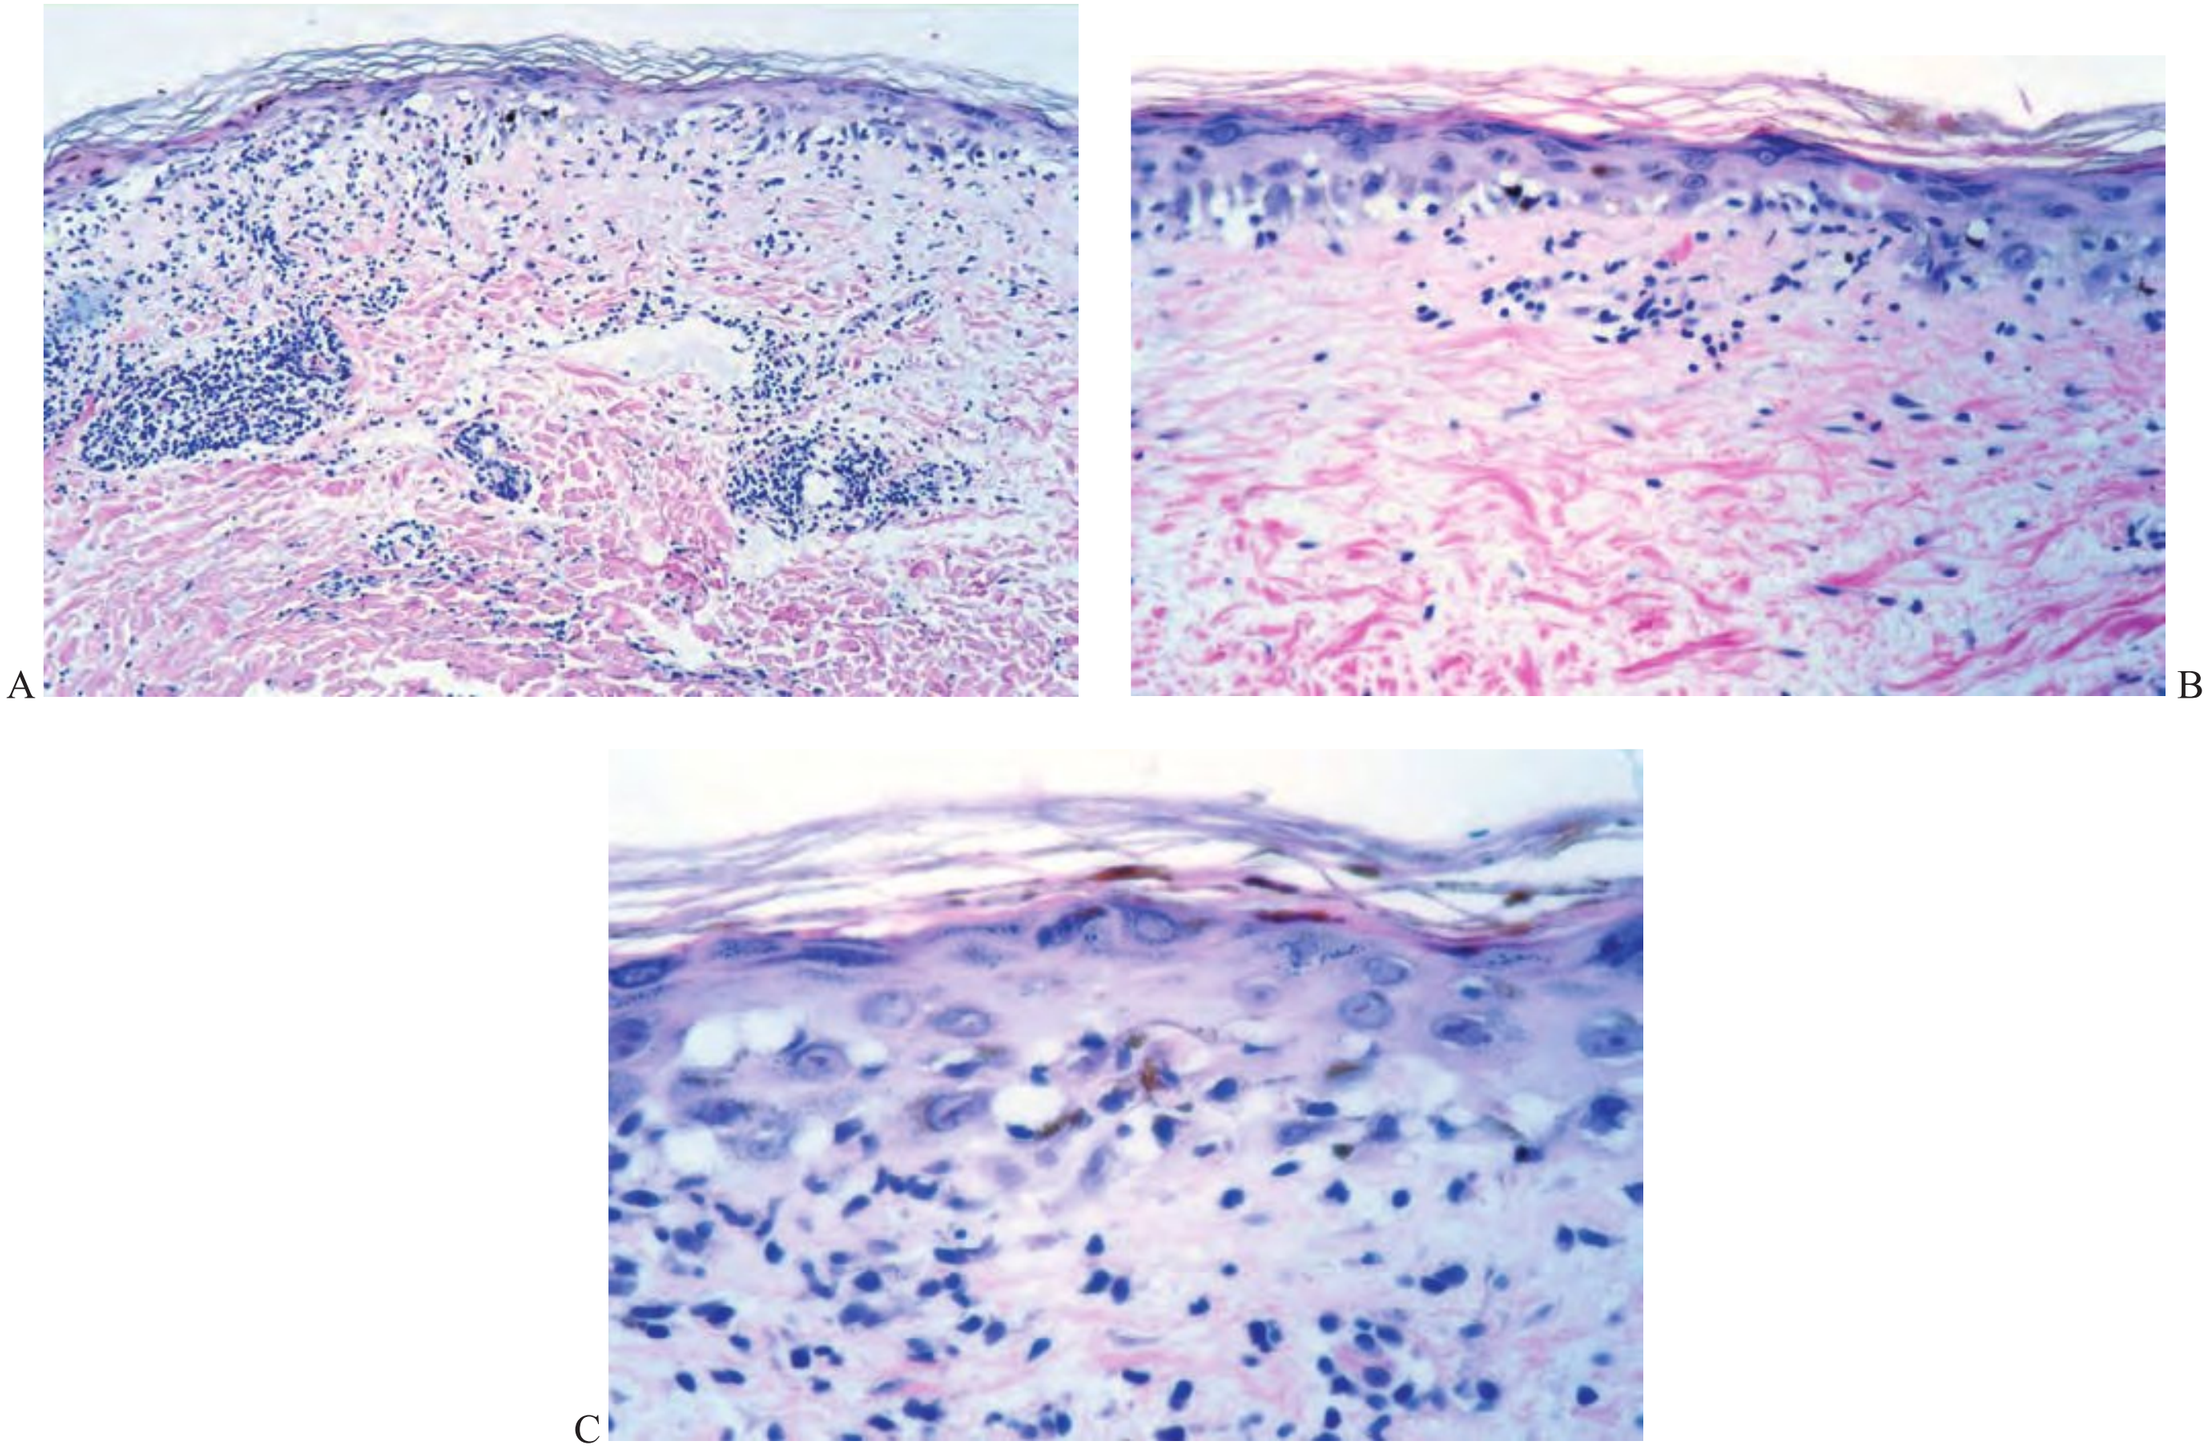

FIGURE 13-6. Subacute radiation dermatitis. A: In subacute radiation dermatitis, there is an inflammatory infiltrate involving the epidermis, papillary dermis, and vessels, without sclerotic collagen alteration. The epidermis is atrophic due to interface dermatitis. B: The interface dermatitis of subacute radiation dermatitis is indistinguishable from those of some other causes of interface dermatitis, such as fixed drug eruption and graft-versus-host disease, requiring clinical information to differentiate these entities. Lymphocytes disrupt the basal cell layer and are associated with vacuolization of the basal keratinocytes, dyskeratotic keratinocytes, and pigment dropout. Note that the collagen is nonsclerotic and the fibroblasts are nonatypical, in contrast to that in Fig. 13-4 B, C, which represent a later stage of this process. C: Satellite cell necrosis, or close approximation of lymphocytes with apoptotic keratinocytes, is seen in subacute radiation dermatitis, as well as in graft-versus-host disease and other cytotoxic dermatoses.

sites of prior irradiation, usually in conjunction with lymphedematous changes (49). Adjacent changes of chronic radiation dermatitis may be seen but are not always present.

Differential Diagnosis. Subacute radiation dermatitis may be indistinguishable from graft-versus-host disease and fixed drug eruption (50, 51). The latter is particularly difficult to differentiate from subacute radiation dermatitis in fluoroscopy-induced cases because the changes often do not occur at the irradiation portal site, and thus the clinician may be unaware of the association with radiation injury. Various hypersensitivity reactions may initially localize at a previous radiation port, simulating acute radiation dermatitis. This includes conditions with overlapping histology, such as erythema multiforme and toxic epidermolysis necrosis, which should be differentiated by the clinical progression of the condition. Morphea/scleroderma is favored over chronic radiation dermatitis by the absence of radiation fibroblasts. Lichen sclerosis may show similar telangiectasia and interface alteration, and there can be similarity in the papillary dermal pallor and homogenization, but the presence of deeper, thickened eosinophilic collagen bundles with radiation fibroblasts favor radiation changes. Clinical correlation may be confirmatory. Deep burn scars show complete absence of all adnexal structures without abnormal fibroblasts, in contrast to radiation sclerosis, in which the eccrine glands are often preserved. Radiation sarcomas should be differentiated from spindled squamous cell carcinoma by immunohistochemical staining (see Chapter 32).

Radiation Recall Dermatitis

Radiation recall dermatitis refers to the development of an acute inflammatory reaction occurring at the sight of a previously quiescent radiation field after infusion or intake of certain medications. This phenomenon has been extensively reviewed (52,53). Typical medications implicated include chemotherapeutic agents, especially the taxane family, methotrexate, and high-dose interferon-α 2b (54), but it has also been reported with antituberculous medication, antibiotics, simvastatin, codeine, and lanreotide, a somatostatin analog (55). It may occur from days to weeks, and sometimes years, after radiation therapy, with an interval ranging from 18 hours to 15 years (median of 40 days) (56). Acute toxicity need not have occurred with the initial radiation. Clinically, there is typically a pruritic macular papular erythematous eruption, which may blister or desquamate. A more severe reaction may occur, especially if the offending drug is given a short interval after the radiation, and may be associated with pain and necrosis. The dermatitis may simulate cellulitis, and rarely fever may be seen. (56). Extracutaneous recall reactions may involve the lung, esophagus, small intestine, musculoskeletal system, mucosa, and central nervous system. There may not be a reaction at all of the previously treated radiation sites. The exact pathophysiology of the reaction is unknown. Radiation recall reactions should be differentiated from radiosensitivity and radiation enhancement, which represents a reaction induced by drugs given less than 7 to 10 days after radiotherapy (52).

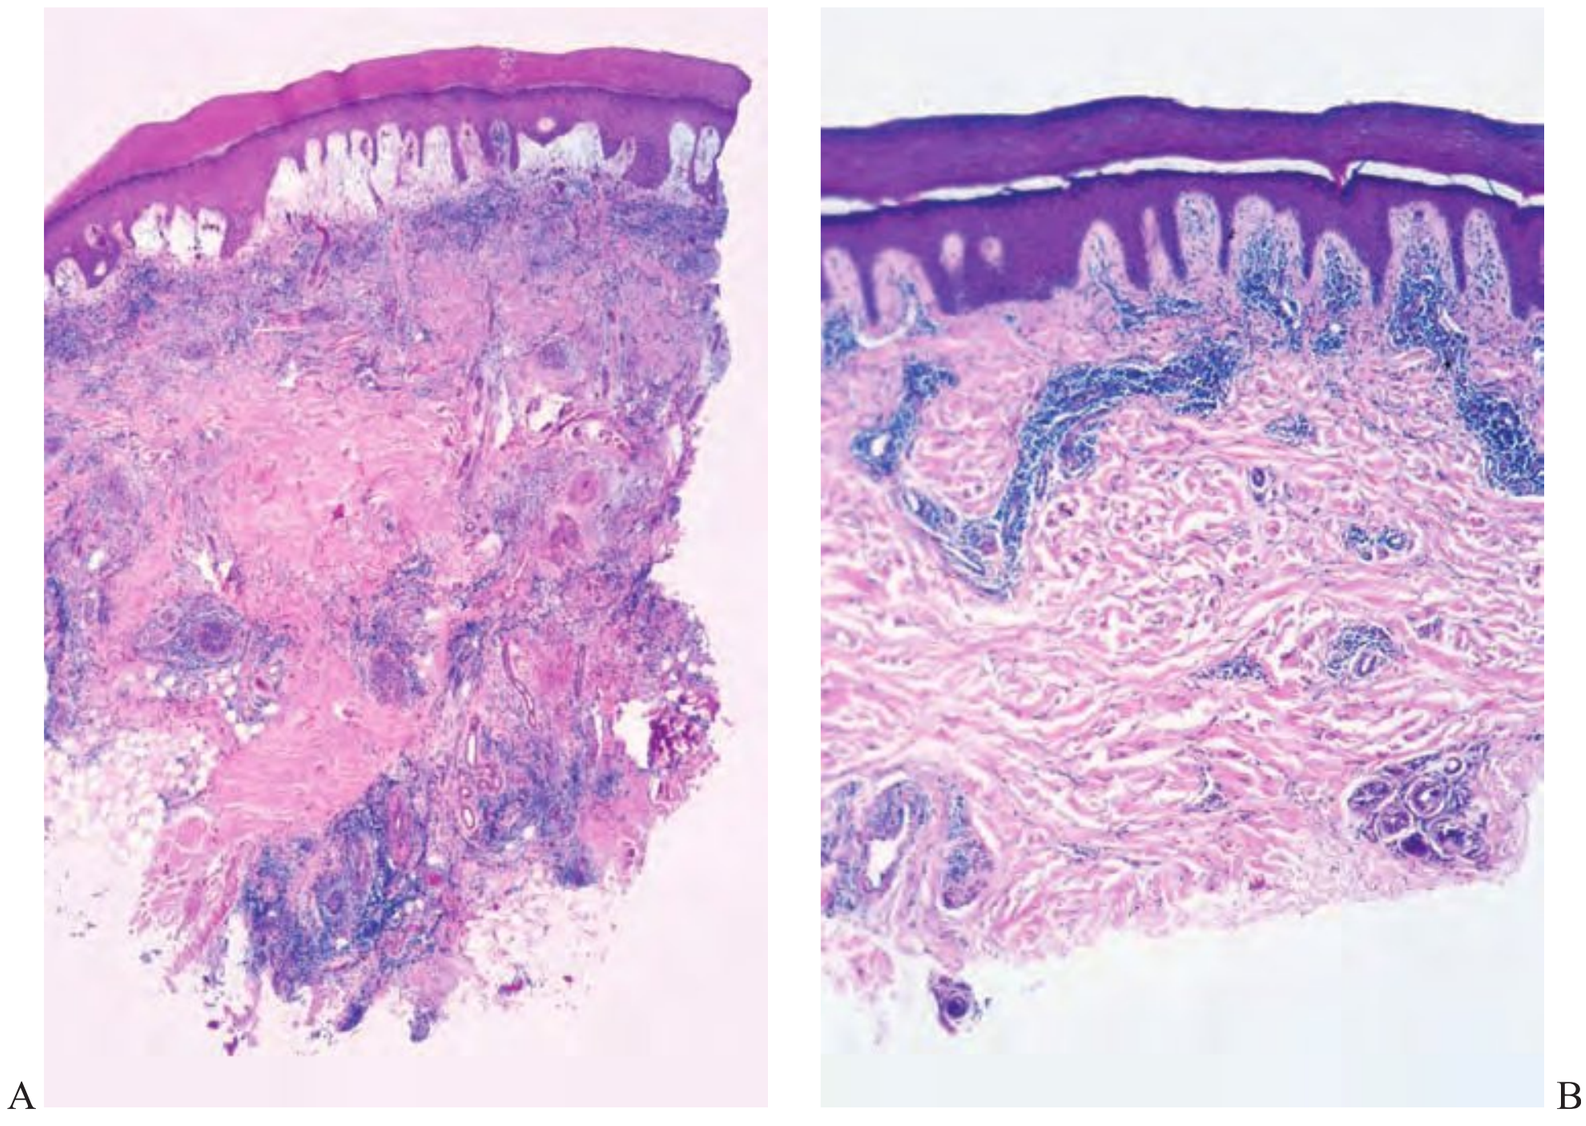
Histopathology. The histopathologic features of radiation recall are not well documented, are nonspecific, and depend on the clinical severity. The histology shows overlap with acute radiation dermatitis. Other features described include psoriasiform epidermal hyperplasia, follicular hyperkeratosis, pustules, basal cell vacuolization, and apoptotic or necrotic keratinocytes (57). Bulla formation due to prominent interface dermatitis may also be observed (58). Dermal changes include vascular dilation, endothelial cell atypia, and a perivascular and interstitial mononuclear or mixed inflammatory infiltrate. There are also features that may reflect an element of prior chronic radiation dermatitis, including fibrosis and radiation fibroblasts.

COLD INJURY TO THE SKIN

Direct injury to the skin due to extremes in cold temperatures can be seen in frostbite and nonfreezing cold injury. In the latter, there is injury above the freezing point associated with wet, immobile, venous stagnation conditions, such as trench foot. Both types of cold injury have a similar pathogenesis, which includes cyclic massive vasoconstriction and excessive vasodilation, endothelial cell leakage, erythestasis, arteriovenous shunting, segmental vascular necrosis—possibly due to decreased clearance of toxic substances—and massive thrombosis (59).

Frostbite

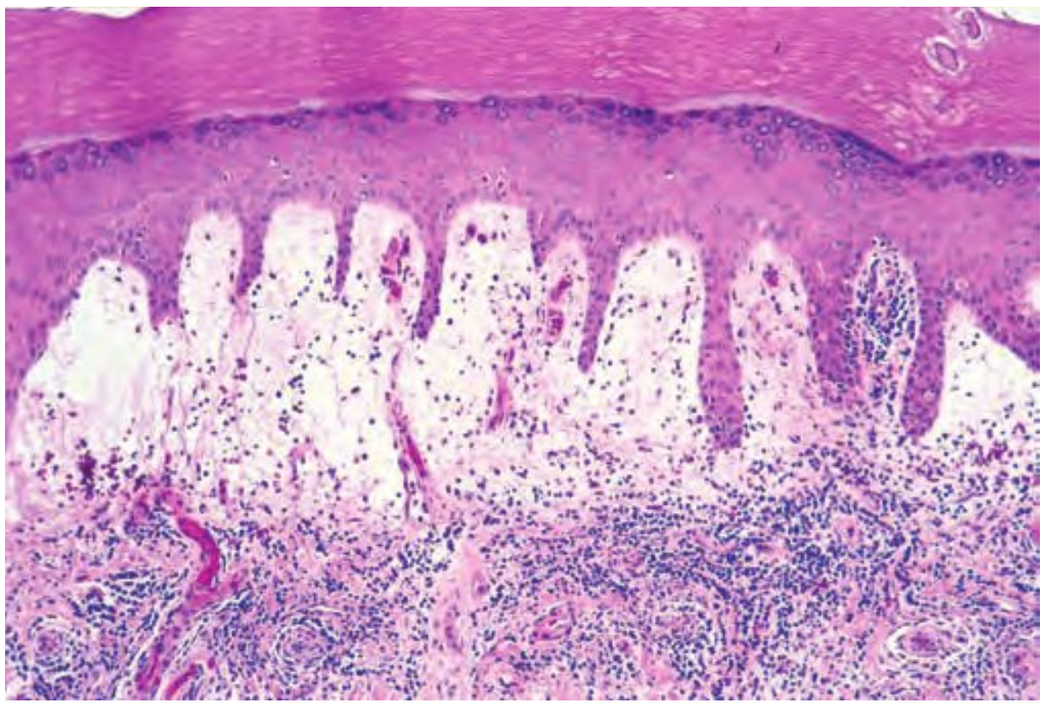
Frostbite is typically seen on acral sites and results from tissue freezing. An increased susceptibility is seen in patients with alcohol consumption, those who wear constrictive clothing, or those with peripheral vascular disease, in smokers, and in individuals exposed to windy conditions. Frostbite can be categorized based on the depth of injury. First-degree frostbite is characterized by erythema and edema after thawing that does not blister and subsides within several days. In second-degree frostbite, there is blister formation within the first 1 to 2 days after rewarming. This is followed by necrotic eschar formation and eventual autoamputation of the affected area. In third-degree frostbite, the entire dermis is edematous and may remain so for 1 month or more (1).

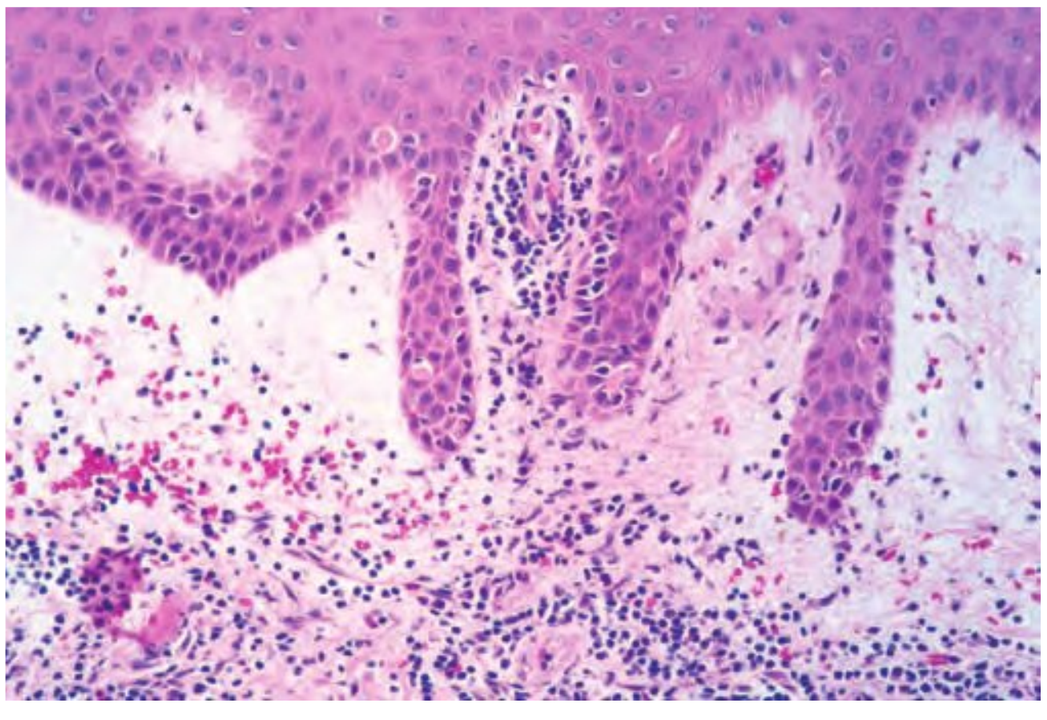


Pernio (Chilblain)

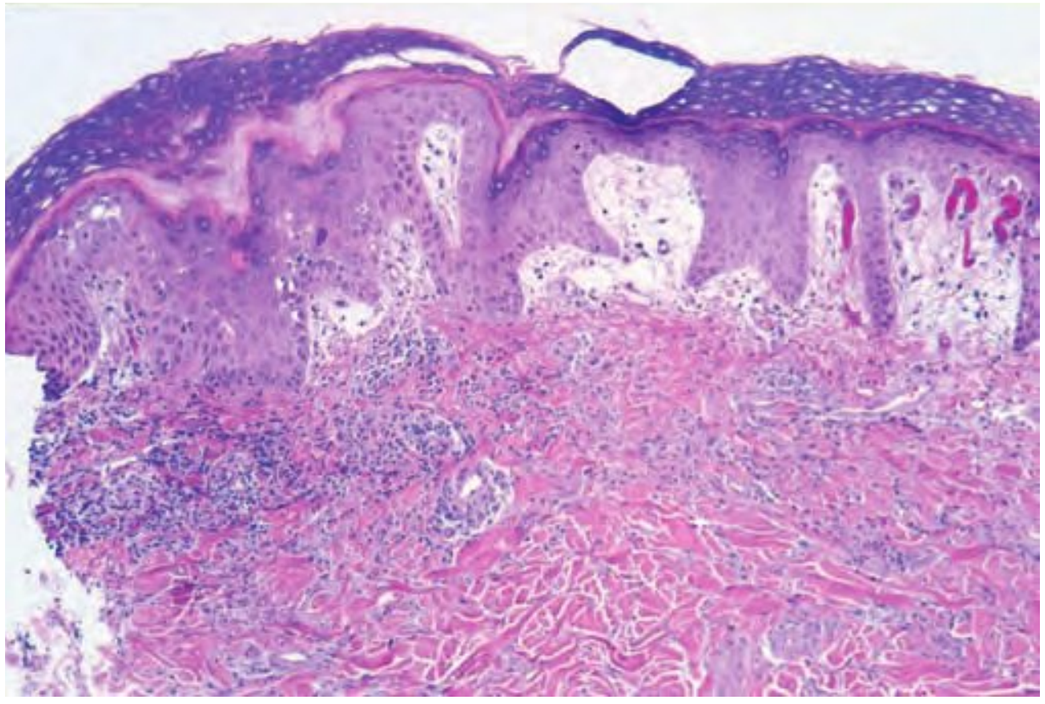
Pernio (chilblain) is a distinct form of cold-induced injury in which humidity, in addition to cold, plays a role in inducing the condition (60). There are acute and chronic presentations. Chilblains classically presents in young to middle-aged women as painful, burning, and/or pruritic erythematous to violaceous or cyanotic macules, papules, deep nodules, and plaques on the fingers, toes, distal extremities, and rarely face. Involvement of the thighs has been described in association with river crossings (60). The acute form is more common in young women. Lesions are noted within 12 to 14 hours of exposure in the acute form and persist for 10 to 14 days. The lesions may become hemorrhagic, bullous, or ulcerated, but they tend to be self-limited. The

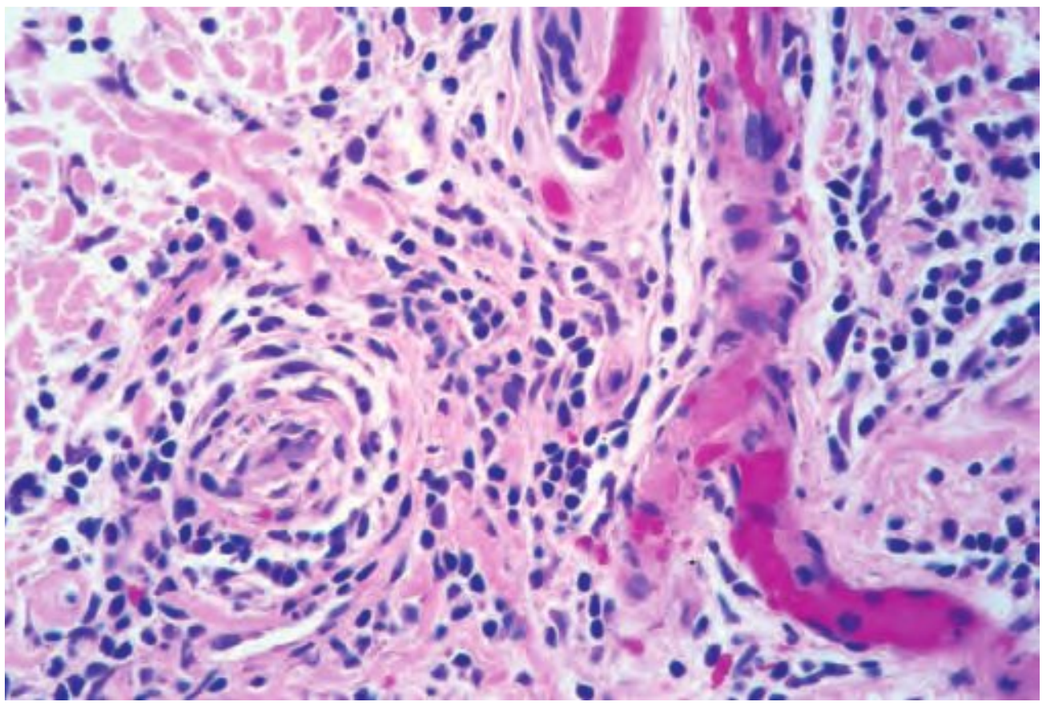
chronic form has overlapping features with acute pernio but occurs in middle-age women and, with repeated winter recurrences, may result in slow-to-heal ulcers and scarring. A genetic predisposition has been implied, as well as a history of peripheral vascular disease (60). A childhood variant has been described and is associated with cryoproteins (62).





Pernio may arise in conjunction with histopathologic, clinical, and serologic features of lupus and is referred to as chilblain lupus erythematosus or lupus pernio (63–68). This may also arise in patients with chronic cutaneous or discoid lupus. Clinically, with the exception of rare verrucous lesions (69), these lesions look similar to idiopathic pernio. The main difference from idiopathic chilblains is that the lesions last for more than 1 month and persist into the hot season, and there is a very strong female predominance (68). These lesions may also arise on nondistal acral sites, such as the knees and elbows. Many of these patients have full-blown systemic lupus erythematosus (SLE), including renal disease and cerebritis; however, other patients with similar persistent chilblains lesions develop SLE in the future. Chilblains lupus may also be associated with Behçet's disease, hypergammaglobulinemia, and type III cryoglobulinemia. Many patients with chilblains lupus have antibodies to SSA/Ro, with associated Raynaud's phenomenon and photosensitivity (66,68); however, others have not found this tight association (70). Patients with chilblain lupus erythematosus may present without overt lupus but are at risk of progressing to systemic lupus erythematosus from 1 to 10 years or so later (66). Rarely, chilblain-like lesions may be seen with leukemia cutis (71) and chronic cocaine use (72).





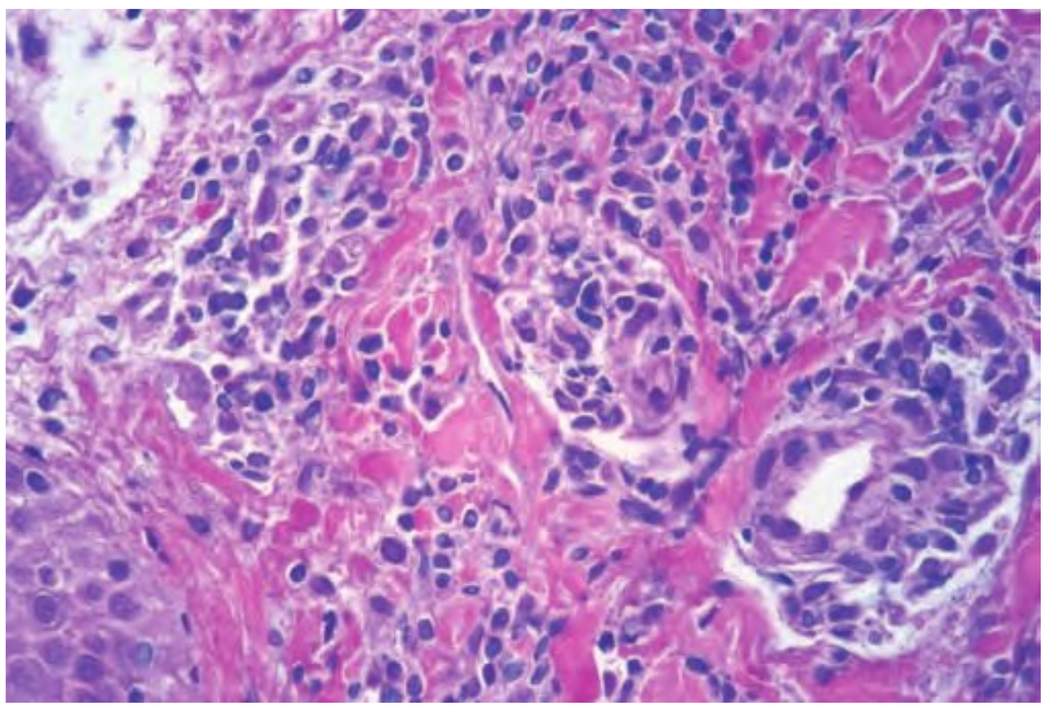
Histopathology. There is a superficial and deep T-lymphocytic infiltrate around the small venules and arterioles in the dermis and subcutis, with accentuation around the deep eccrine coils (Fig. 13-7). The interstitium may also be prominently involved in the superficial dermis. The infiltrate tends to be of moderate intensity but may be dense. The most superficial vessels of the papillary dermis are less involved by the infiltrate but may show congestion. Papillary dermal edema is characteristic, and although it may be quite striking, its presence is variable. A superficial variant exists, lacking involvement of the deeper portions of the tissue but showing papillary dermal edema. Lymphocytic vasculitis, characterized by endothelial cell swelling and edema and infiltration of the vessel walls by lymphocytes, without consistent presence of fibrinoid necrosis is seen (Fig. 13-7) (60). The epidermal changes range from scattered necrotic keratinocytes to epidermal pallor or necrosis. An effacing interface dermatitis is not typically seen in idiopathic pernio. In chilblain lupus erythematosus (lupus pernio), there are dermal changes similar to pernio, but in addition there is an interface dermatitis of lupus, and a positive lupus band test may be seen. Although it may not be possible reliably to distinguish chilblains lupus from idiopathic lupus, one study showed a more prominent perisudoral infiltrate in the latter. An interface dermatitis typical of lupus is not always present (68).

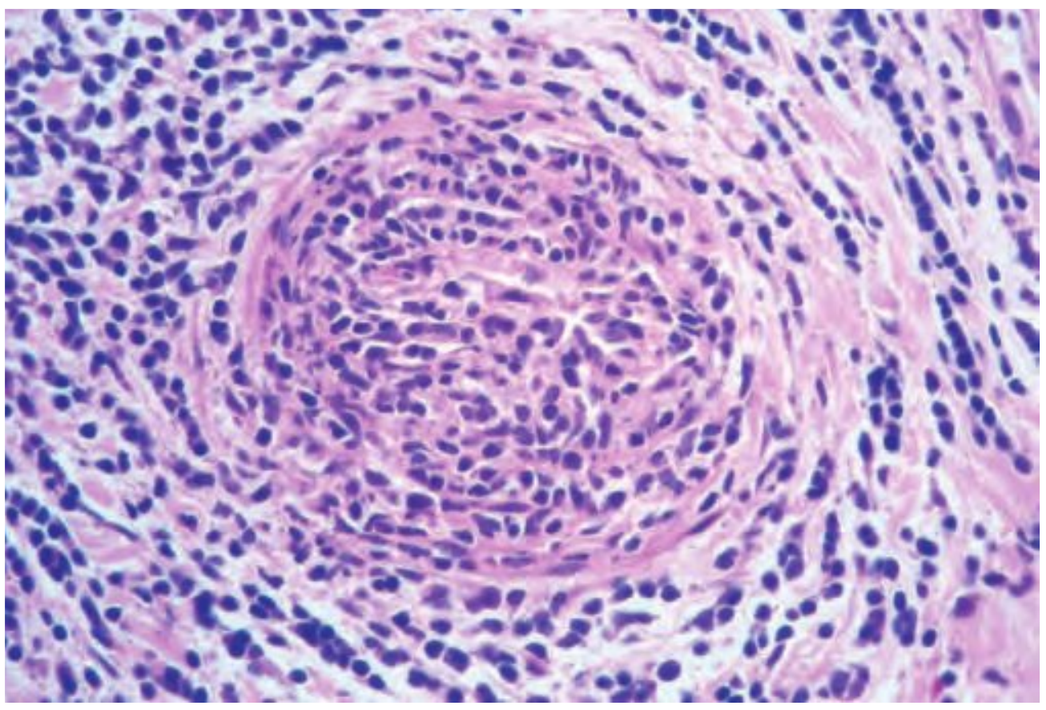
A B

FIGURE 13-7. Pernio (chilblain). A: A superficial and deep perivascular and perieccrine lymphocytic infiltrate involving acral skin with striking papillary dermal edema typifies perniosis. B: Although papillary dermal edema is characteristic, some cases of pernio may lack this feature. The deep perieccrine infiltrate helps to differentiate this from conditions such as erythema multiforme, which may show some similar features. (continued)

C  D 

E  F 





G  H 

FIGURE 13-7. Continued. C: Striking dermal edema may result in incipient dermolytic bulla formation. D: Involvement of the dermal papillary vessels may be minimal. Dyskeratosis may be present, but a frank interface reaction is not seen. If present, lupus or chilblain lupus should be considered. E: The degree of papillary dermal edema may vary. Lymphocytes may be interstitial to bandlike, in addition to perivascular. Prominent vascular congestion is seen in the dermal papilla. F: Various degrees of vascular damage may be seen. Here there is congestion and vasoocclusion with early necrosis of one small venule. In a nearby vessel, there is infiltration of the vessel wall, consistent with the lymphocytic vasculitis of pernio. G: In pernio, the endothelial cells are often swollen and show infiltration by lymphocytes, without evidence of necrotizing vasculitis. H: Medium-sized vessels may occasionally be infiltrated by lymphocytes. A granulomatous, neutrophilic, or eosinophilic component is not seen, differentiating pernio from other known causes of medium-size–vessel vasculitis.

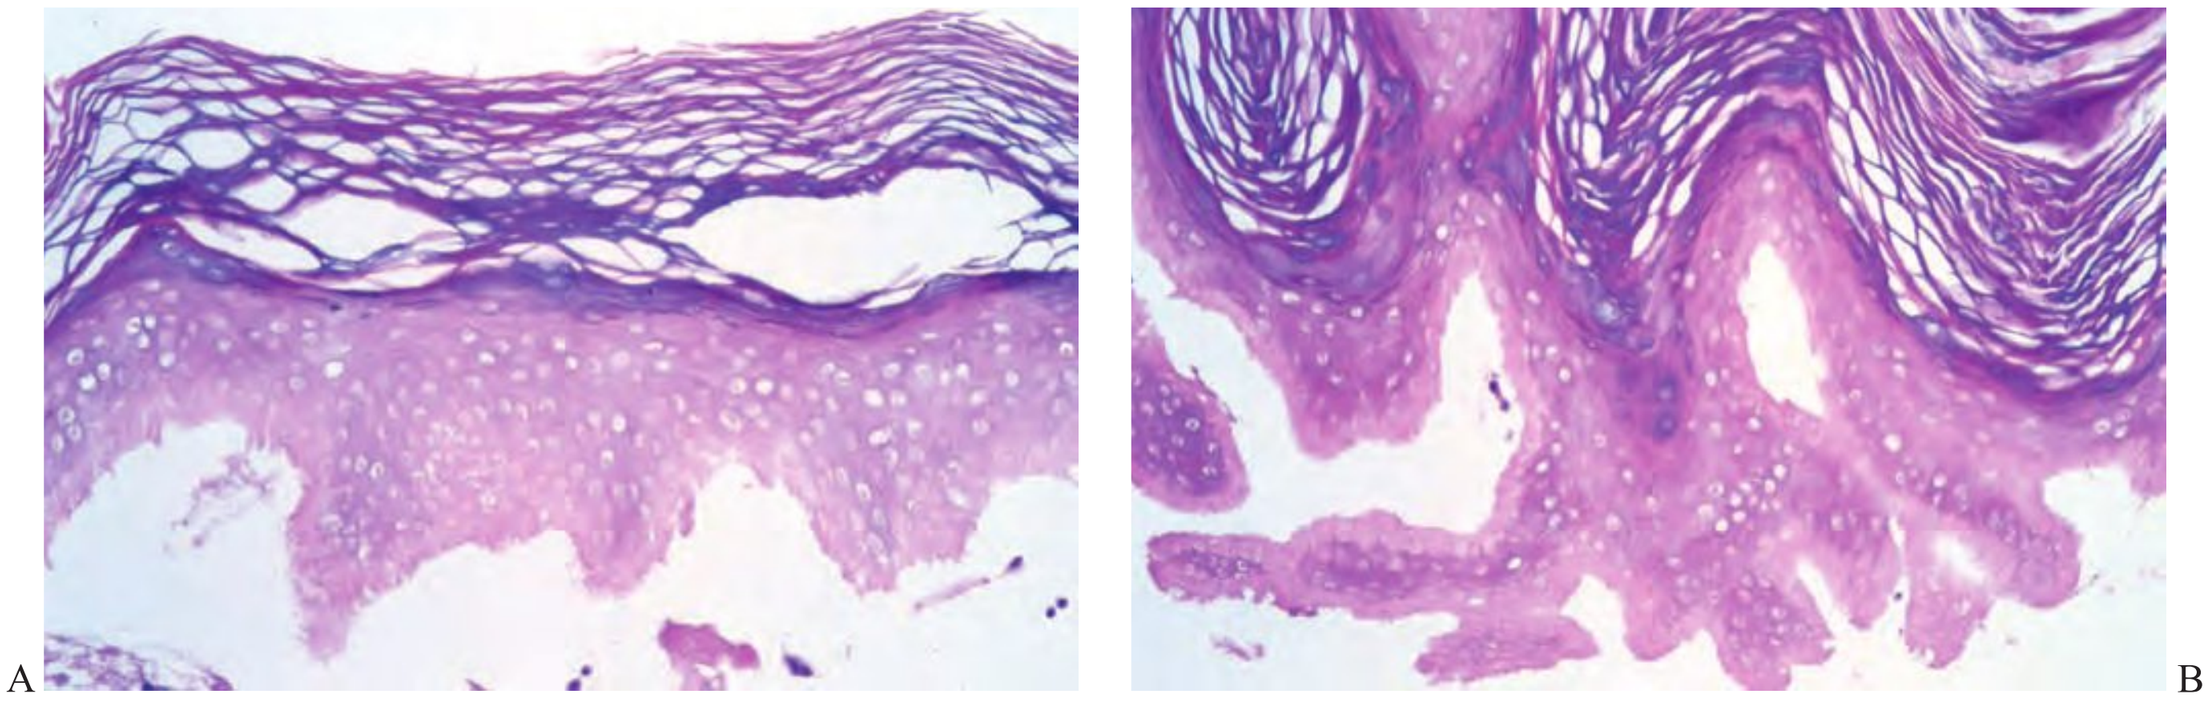


FIGURE 13-8. Cryotherapy-induced cold injury. A: There is pallor of the epidermal keratinocytes, with loss of the cellular outline. B: The cold injury has resulted in a subepidermal bulla. In cryotherapy of this seborrheic keratosis, there has been preservation of the stratum corneum architecture, probably due to the devitalized nature of this portion of the epidermis, whereas the remaining tissue shows homogenization of the epithelium, with dissociation of the epithelium from the dermis in a subepidermal fashion.

Differential Diagnosis. Pernio may be difficult to differentiate from lupus erythematosus. The presence of prominent dermal edema, eccrine coil accentuation of the infiltrate, and spongiosis favor pernio over lupus (65). Diagnostic criteria have been proposed to differentiate chilblain lupus erythematosus from idiopathic chilblains (67). The papular form of chilblains may be difficult to differentiate from erythema multiforme, and it may require clinical history to differentiate the two (73). The deep inflammatory component of pernio differentiates it from acral lesions of erythema multiforme. Polymorphous light eruption, dermal hypersensitivity, erythema annulare centrifugum, and lymphocytic infiltrate of Jessner can show a similar pattern of perivascular lymphocytic infiltrate. The presence of lymphocytic vasculitis and the clinical history of cold-induced acral lesions favor pernio. Other clinical and histologic mimickers of pernio including lesions of rheumatoid arthritis, cryofibrinogenemia, and antiphospholipid syndrome, and others lack the papillary dermal edema of pernio (74). Occasionally, the lymphocytic infiltrate may be so intense as to simulate cutaneous lymphoma, but the absence of atypia and presence of superficial dermal edema favor pernio. If there is cellular atypia, immunohistochemical investigations to exclude leukemia or lymphoma should be pursued.

Cryotherapy-Induced Injury

Cryotherapy is a commonly used tool to destroy benign and premalignant or, on occasion, malignant cutaneous lesions. This procedure may also be employed prior to curettage of keratoses. The dermatopathologist may encounter freeze-related changes in this latter circumstance. Rapid freezing with liquid nitrogen results in the production of highly destructive intracellular ice crystals (5). The extent of injury is determined, in part, by the thickness of the stratum corneum, the length of exposure to the liquid nitrogen, and the degree of pressure applied (75). Cell types differ in their susceptibility to cold injury. The hypopigmentation seen with cryotherapy reflects the susceptibility of melanocytes to this form of injury.

Histopathology. The microscopic features may differ, depending on the interval between cryotherapy and biopsy. Typically in rapid-freeze injury, the keratinocytes show a loss of cell outline, with ghostlike changes or homogenization of the epidermis (Fig. 13-8). This is associated with subepidermal–dermal bulla formation and subepidermal edema. The stratum corneum, being a devitalized structure, is not affected, and thus there is preservation of parakeratosis (75). There may be loss of melanocytes or pigment at the site of a prior cryotherapy site, with melanocytic hyperplasia or pigment dropout in the adjacent skin (5). With more intense cryotherapy, coagulation rather than edema is seen in the dermis. This may result in coagulation necrosis of hair follicles and possibly eccrine glands, and scar formation of the surrounding collagen. A polymorphous infiltrate, which includes eosinophils, has been described (76). Hemorrhage and thrombosis may be seen in the dermal papilla.

CUTANEOUS INJURY DUE TO PHYSICAL TRAUMA

Friction-Induced Blister

Prominent or repetitive shear-induced injury, especially on acral skin, such as the hands and feet, results in bulla formation. This may or may not be accompanied by hemorrhage.

Histopathology. A friction blister has an intraepidermal plane of separation, often beneath the stratum granulosum, in the upper portions of the epidermis (Fig. 13-9). The surrounding

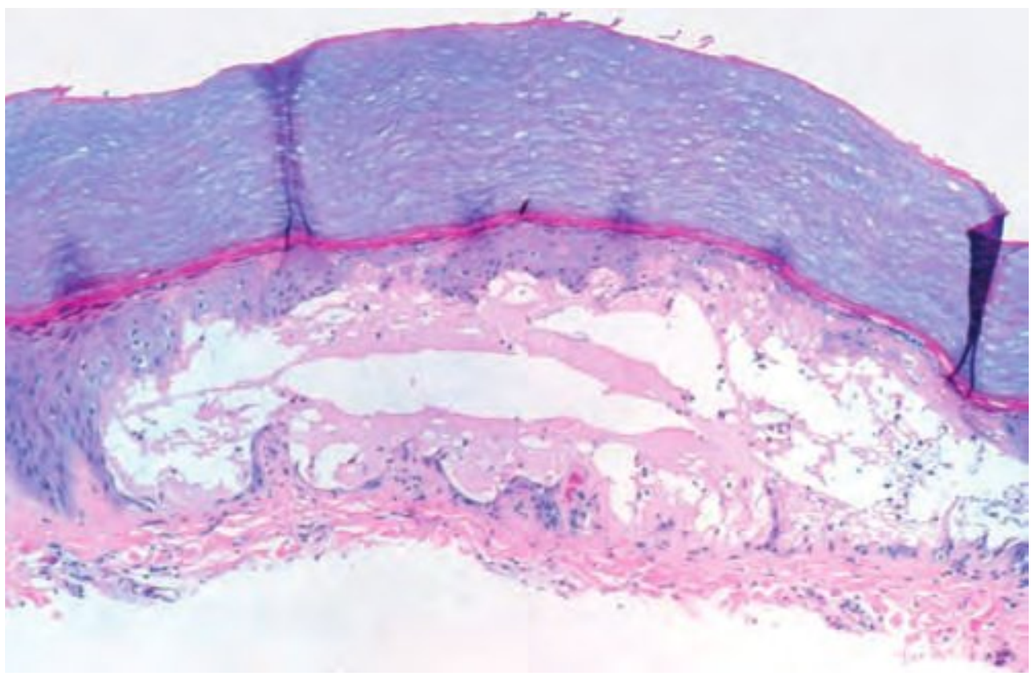

FIGURE 13-9. Friction blister. In friction blisters, one sees a noninflammatory intraepidermal blister, with pallor of the surrounding epidermis. The keratinocytes may show reticular degeneration or other sequelae of cytolysis or shearing.

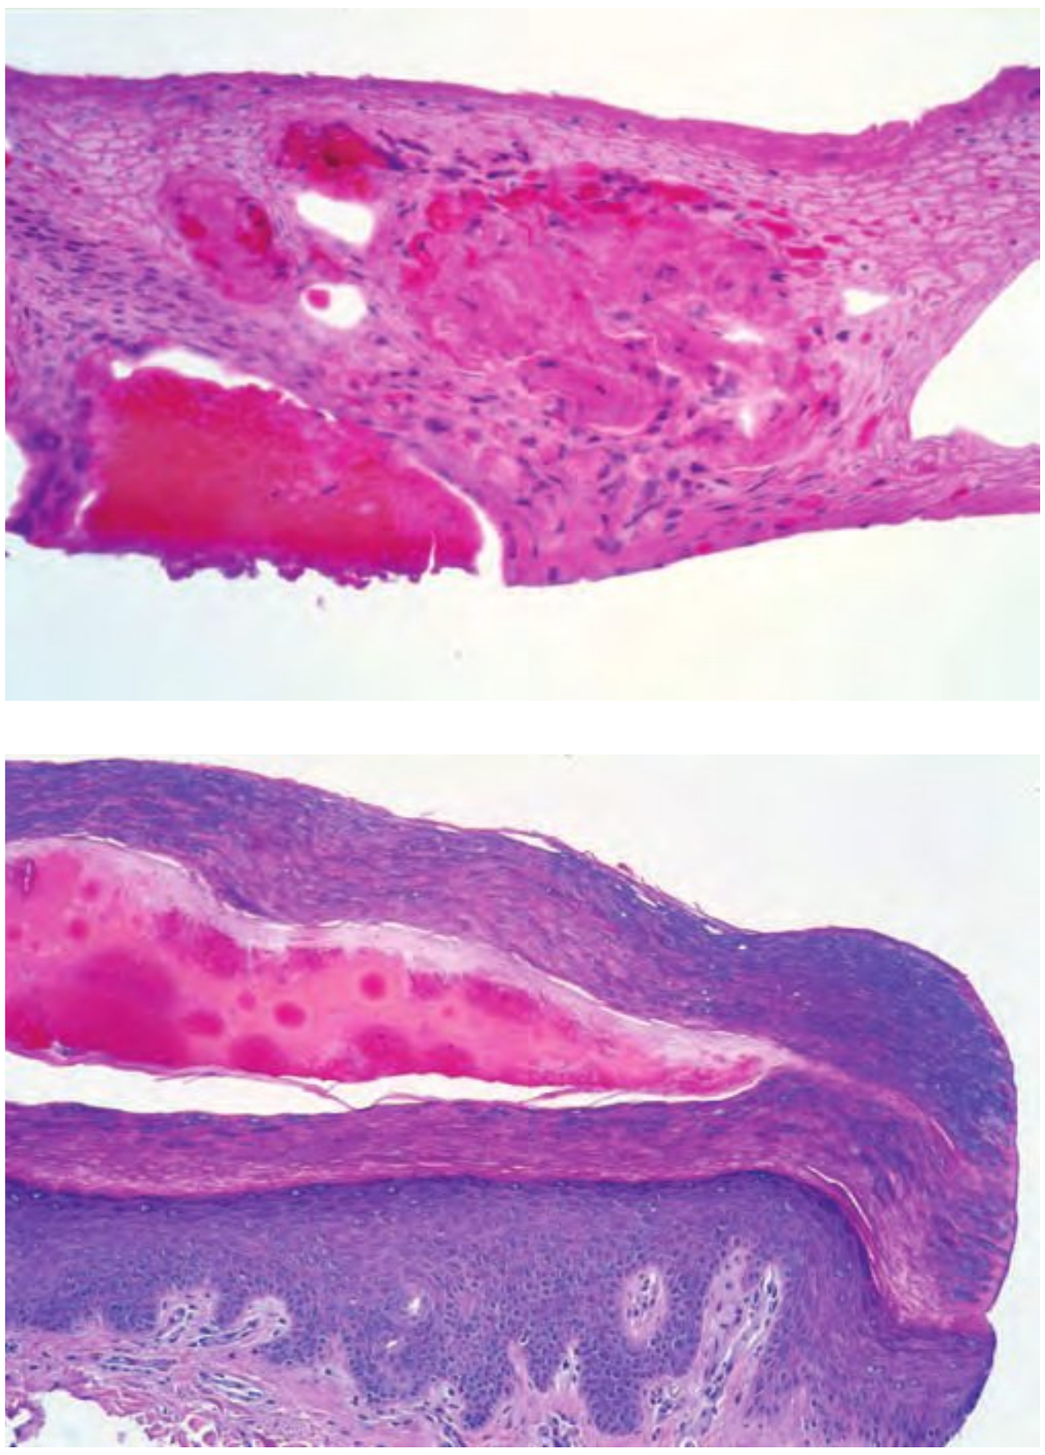
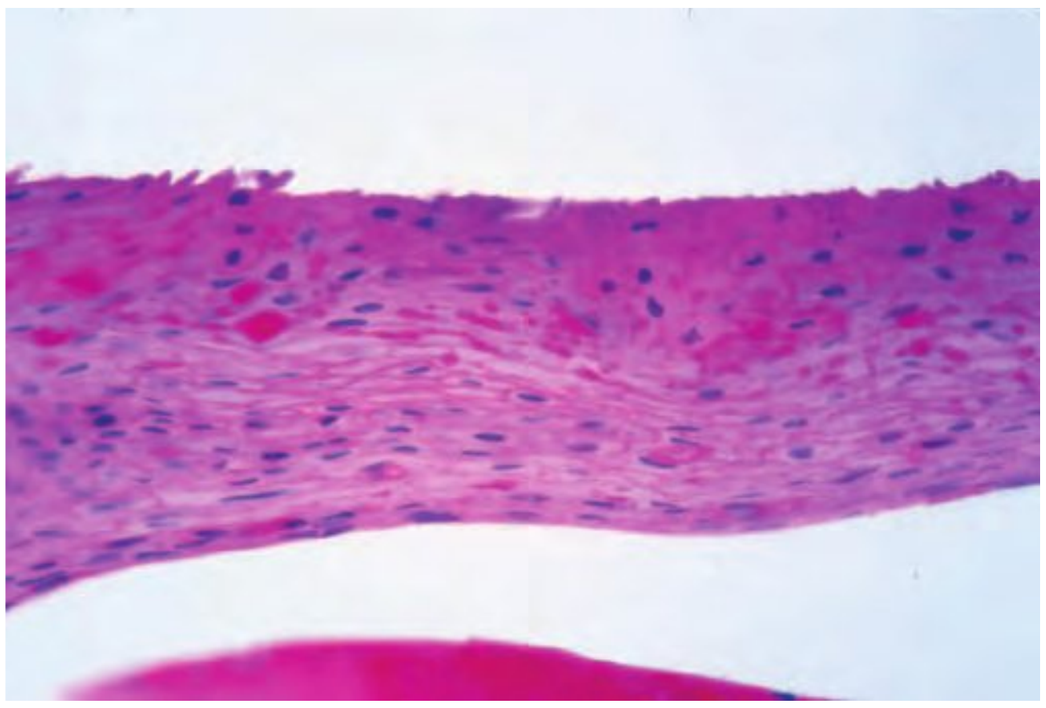


keratinocytes show pallor and loss of the cell outline. The edge of the blister cavity shows a jagged outline. The dermis does not show significant alteration or inflammation.

Differential Diagnosis. Other causes of paucicellular blister should be differentiated from friction blisters. Suction blisters and porphyria cutanea tarda have their plane of separation in a subepidermal location. Epidermolysis bullosa and epidermolysis bullosa acquisita may be acrally located but show a subepidermal bulla and characteristic electron microscopic and immunofluorescence features, respectively (see Chapter 9). Although diabetic bullae are also acral-located noninflammatory blisters and may have a partially intraepidermal plane, they tend to show a more prominently subepidermal split, without cytolytic keratinocytic changes.



Talon Noir (Black Heel, Calcaneal Petechiae)

Talon noir typically presents as an irregular black macule on thickly keratinized acral sites, such as the heels and toes. These are often biopsied to exclude acral melanoma. Talon noir often occurs in association with athletic activity and results from shearing forces that lead to stratum corneal hemorrhage (77).

Histopathology. Often, only the stratum corneum is sampled and shows erythrocytes within layers of a thickened orthokeratotic stratum corneum (Fig. 13-10). Frequently there is parakeratosis. There may be associated serosanguinous fluid, with superficial blister formation. When dermis is incorporated in the biopsy, erythrocytes may be seen in the dermal papillae and epidermis. Iron staining does not highlight this process.

A

B

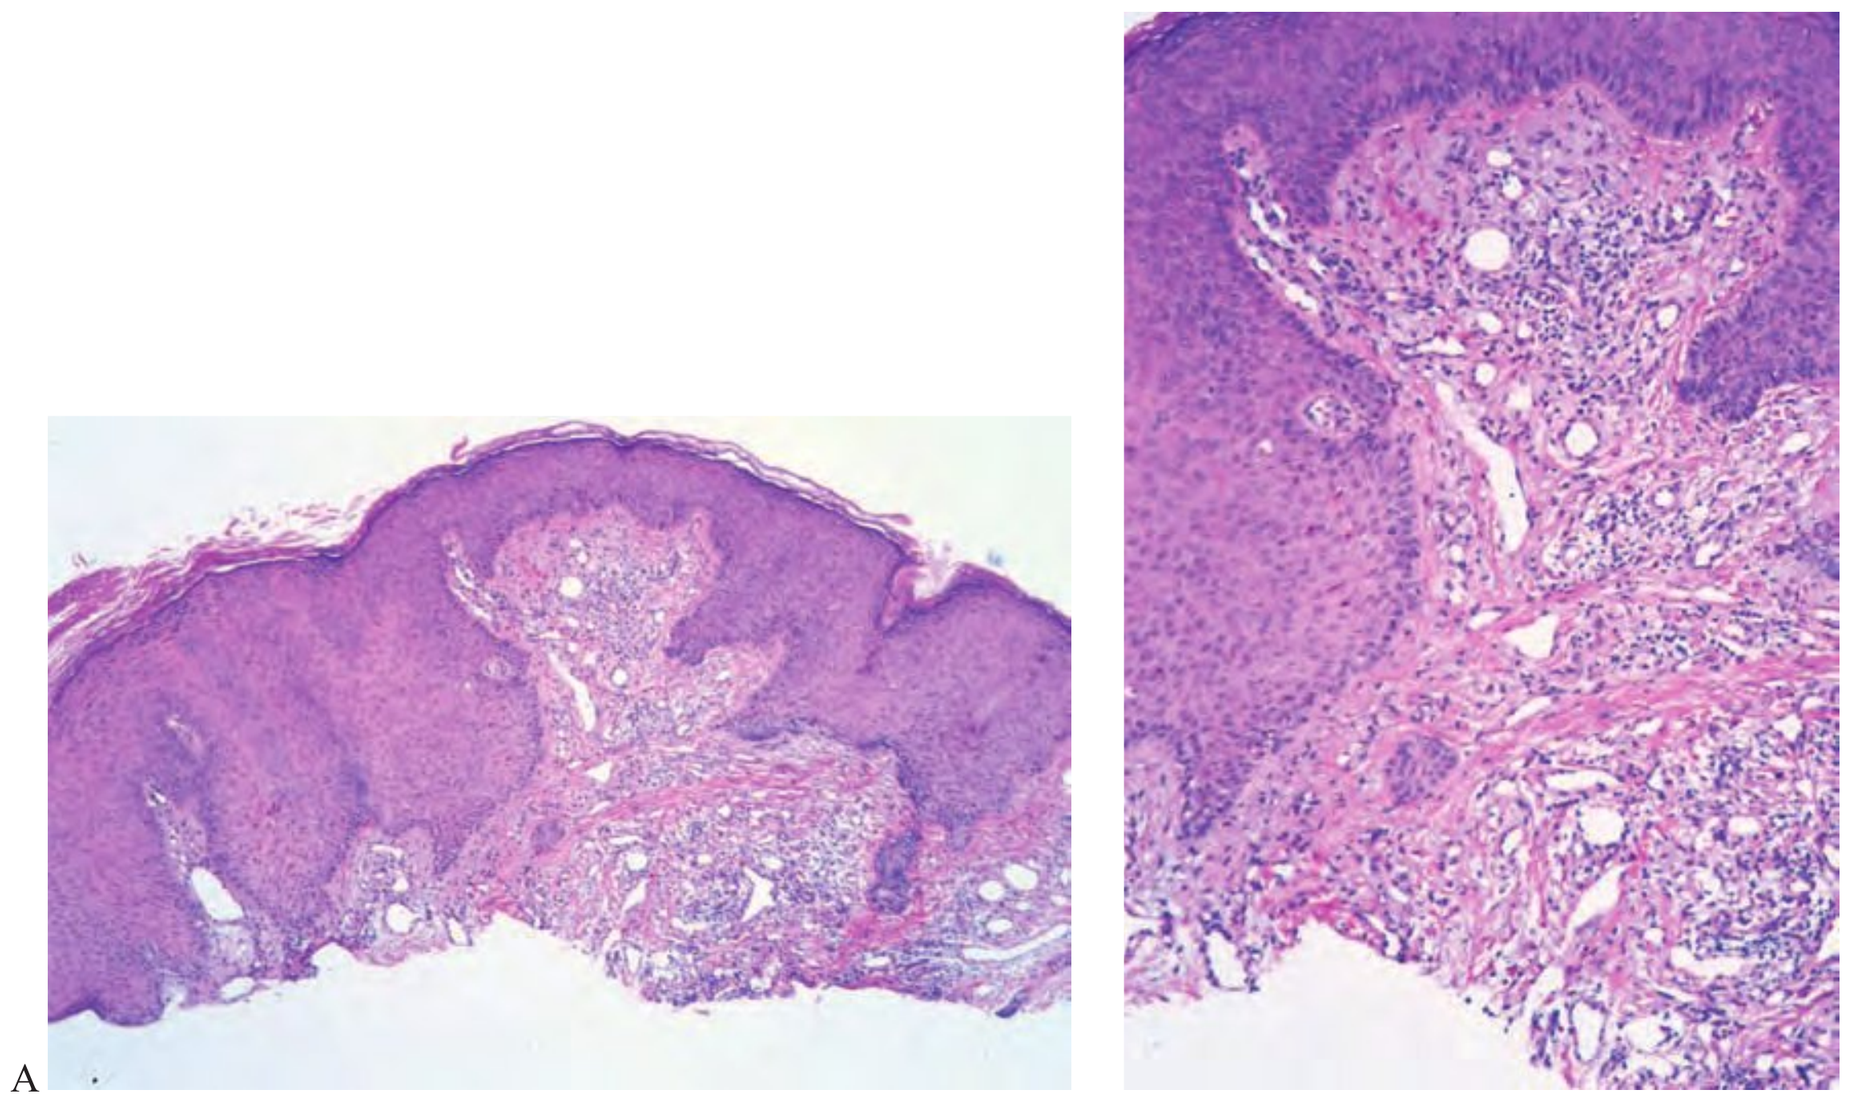
C

FIGURE 13-10. Talon noir (calcaneal petechiae). A: Talon noir occurs on acral skin due to shearing or rubbing trauma, and thus one sees a hyperkeratotic stratum corneum, often accompanied by parakeratosis. Often, only portions of the stratum corneum are sampled. The hemorrhage can be identified as loculated erythrocytes and serosanguinous fluid or as small collections of intracorneal erythrocytes, some of which show degeneration. B: The hemorrhage may present as solitary intact or degenerating erythrocytes within the corneal layers. Hemosiderin will not be apparent on hematoxylin or iron staining. C: There may be features of a friction blister, with intracorneal hemorrhage accompanied by serosanguinous fluid, forming an intracorneal hemorrhagic bulla.

Acanthoma Fissuratum (Granuloma Fissuratum)

Acanthoma fissuratum occurs at the site of chronic low-grade pressure or rubbing trauma at the site where eyeglasses sit on the nose or ear. Clinically, there is a pink- to flesh-colored plaque or nodule with a central depression located on the lateral bridge of the nose near the medial canthus or near the cheek or at the crease between the postauricular scalp and posterior ear, where the eyeglass stem lies. This may be biopsied to exclude nonmelanoma skin cancer.

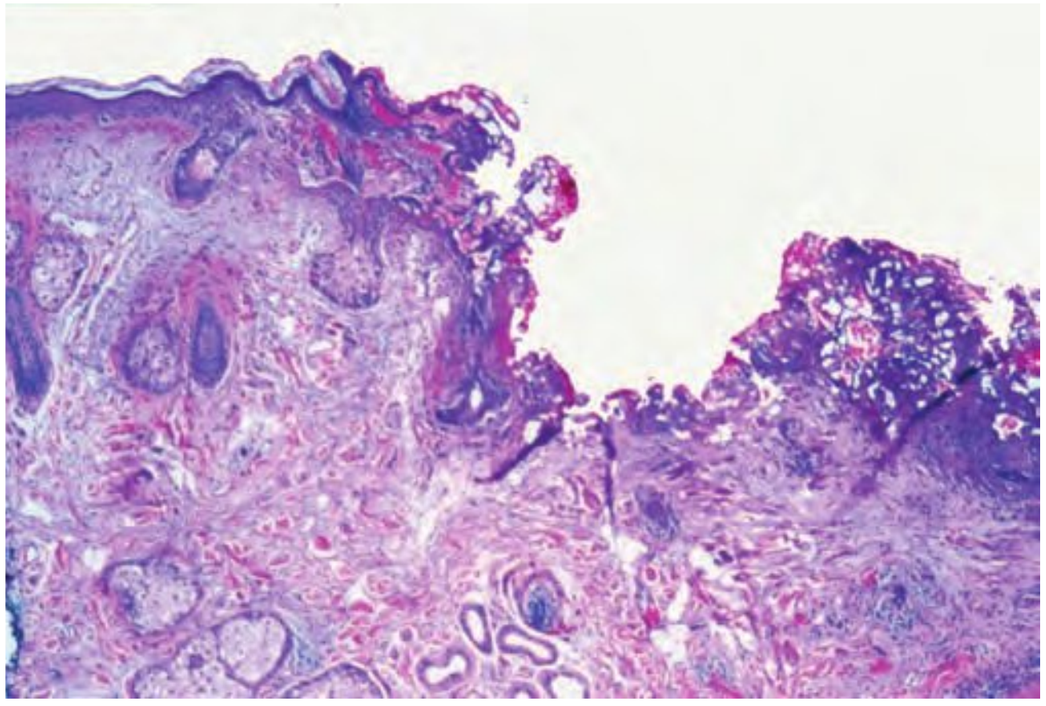
Histopathology. The epidermis shows prominent nonatypical acanthosis with mild orthohyperkeratosis and hypergranulosis. The rete is wide and blunt ended, and centrally there is attenuation of the rete, corresponding to the clinical depression (Fig. 13-11). Spongiosis and parakeratosis may be seen. The dermis shows a proliferation of small, slightly dilated vessels with a fibrotic stroma and variable patchy chronic inflammation.



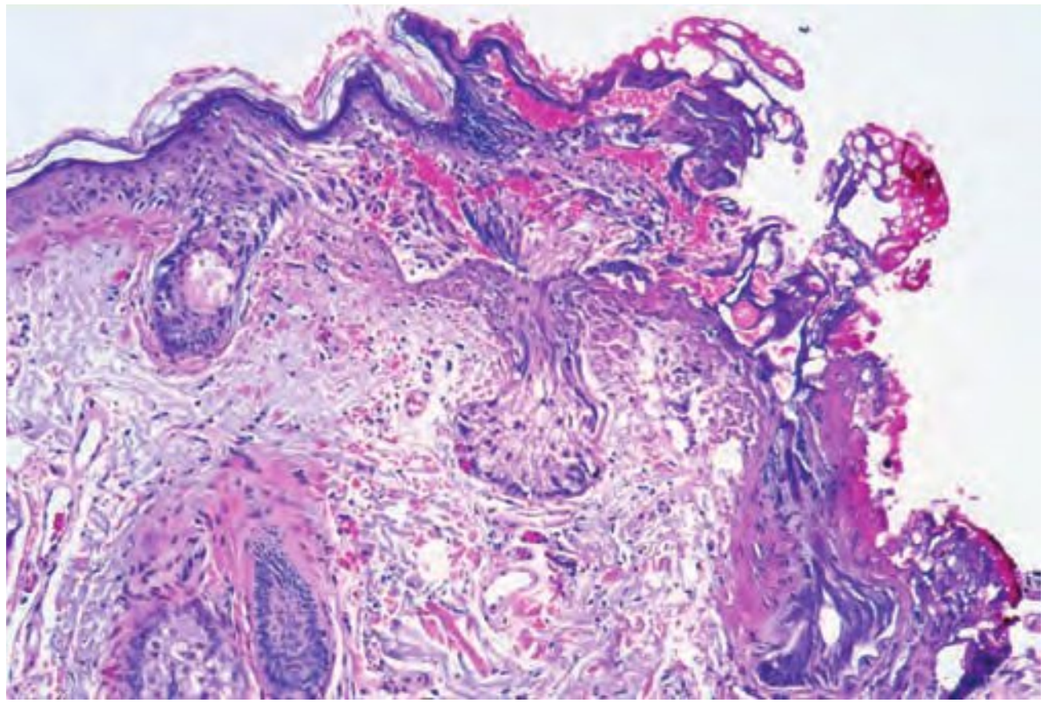
Differential Diagnosis. The epidermal and fibrovascular changes noted in acanthoma fissuratum are similar to those seen in chondrodermatitis nodularis helicis (see Chapter 18). The latter is differentiated by the location on the auricle and the presence of fibrinoid dermal necrosis and cartilaginous changes. Lichen simplex chronicus has some similar features but shows more dermal fibrosis and vertical orientation of the vessels in the dermal papillae.

Surgery-Associated Injury

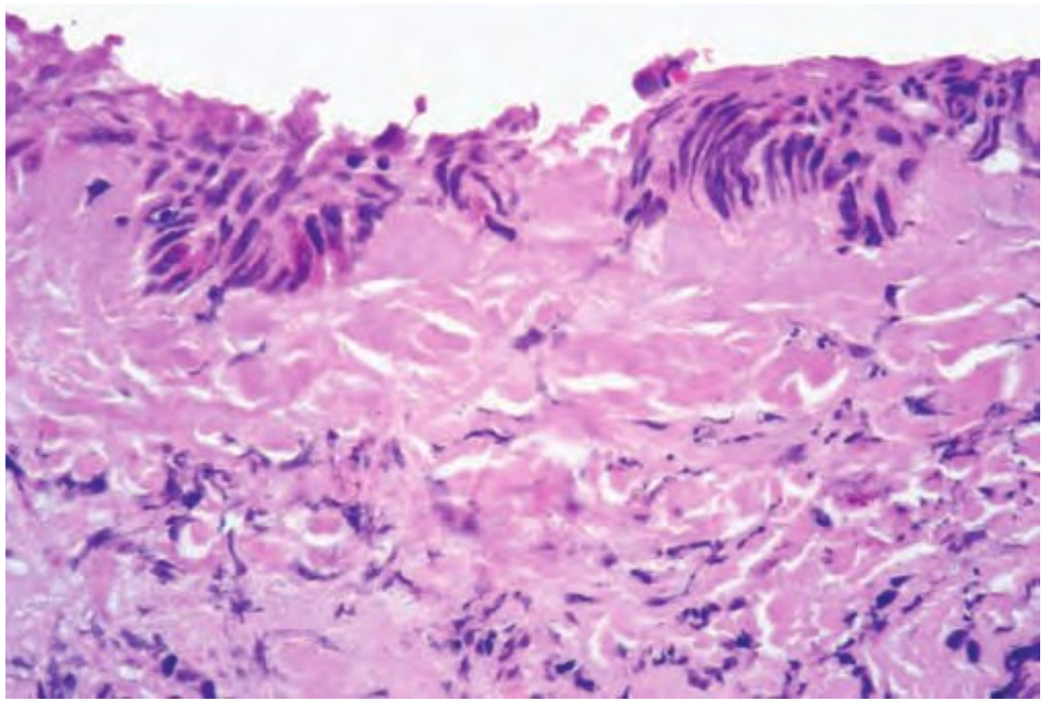
Curettage surgery is frequently performed by dermatologists to biopsy, treat, or "define" a superficial basal or squamous cell carcinoma before excision. Curettage is frequently followed by electrodesiccation to further destroy remaining tumor and/or to assist in hemostasis.

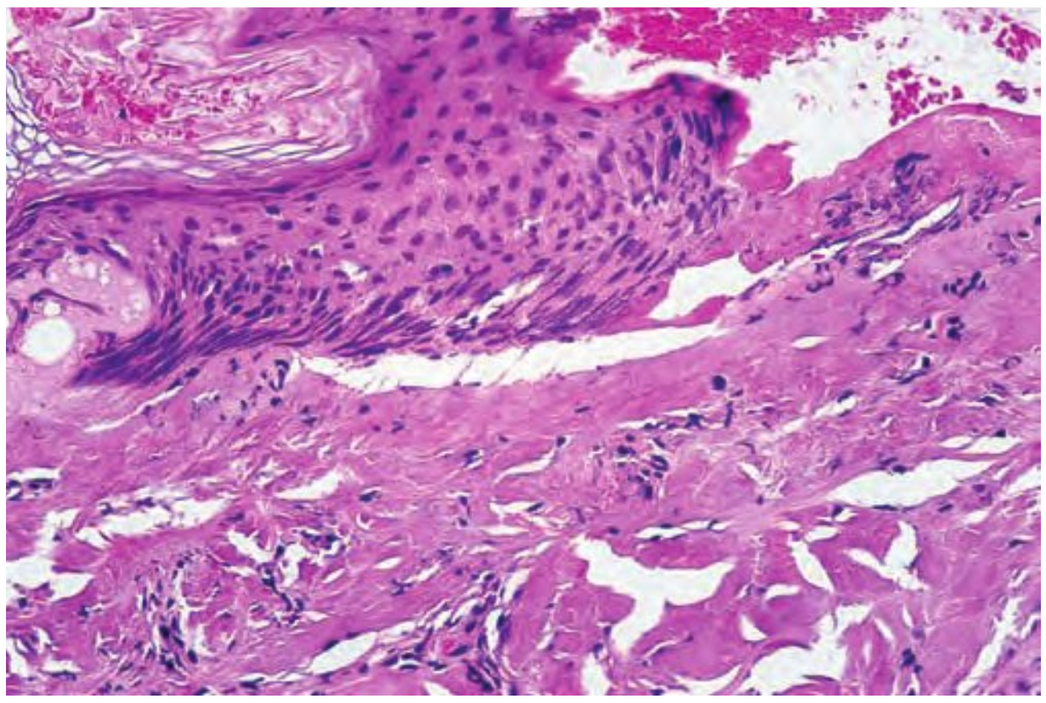


Histopathology. Electrodesiccation-induced injury results in elongation and stretch distortion of the epithelial nuclei (Fig. 13-12). Basophilic collagen necrosis can be seen beneath a recent electrodesiccation-induced surgical ulcer or scar. This may present with lacelike coagulation necrosis of the collagen and epidermis. At a healing biopsy site, foci of this injured collagen may be seen engulfed by multinucleated giant cells. The dermis beneath a recent curettage ulcer base shows edema, vascular dilation, and congestion without coagulation necrosis (Fig. 13-13). Dermal inflammation will be minimal, unless there are residual biopsy-site changes. The epidermis is usually denuded, but there may be partial remnants of attached epidermis without the stretch artifact typical of electrodesiccation.



Differential Diagnosis. The nuclei elongation of electrodesiccation injury should be differentiated from atypia of an actinic keratosis. Atypical melanocytic hyperplasia may show overlap features, but this can be differentiated with immunohistochemical stains for melanocytes (see Chapter 28).





A B

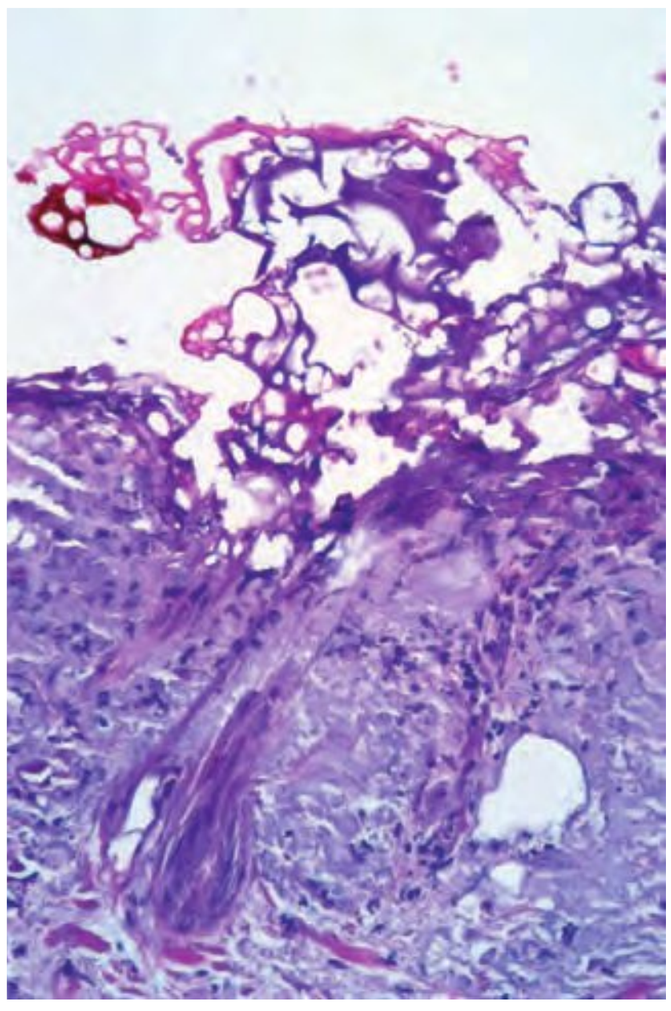


FIGURE 13-11. Acanthoma fissuratum (granuloma fissuratum). A: There is nonatypical acanthosis of the epidermis, with attenuation of the rete centrally. B: Within the dermis, there is a proliferation of slightly dilated small vessels, associated with fibrosis and a variable chronic inflammatory infiltrate. The term "granuloma" is a misnomer because a granulomatous infiltrate is not seen.

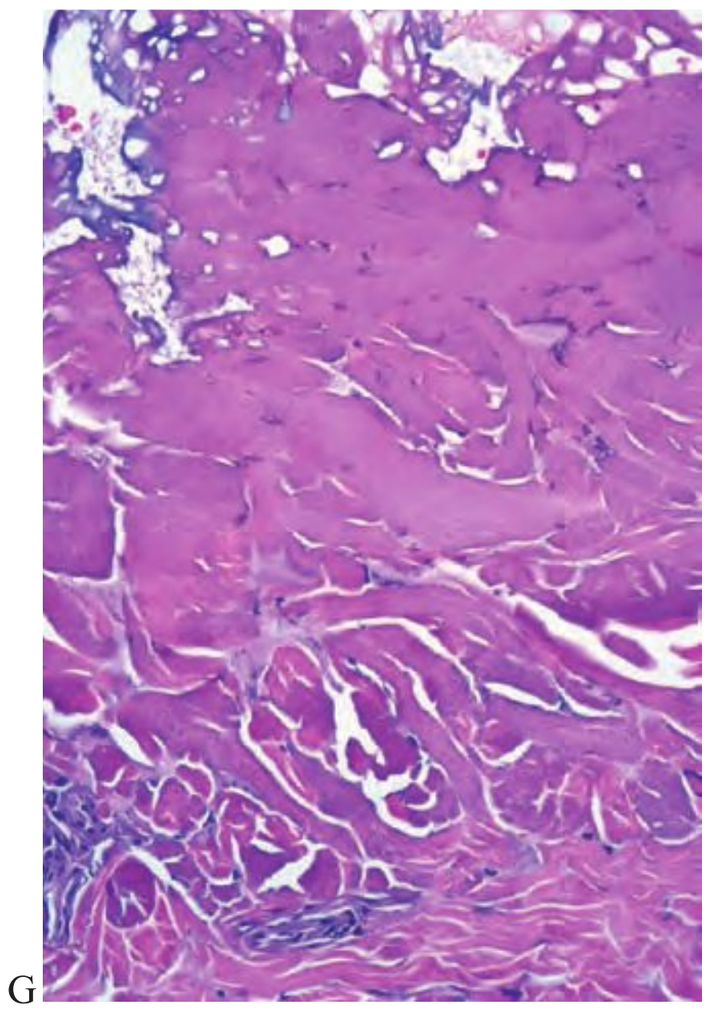
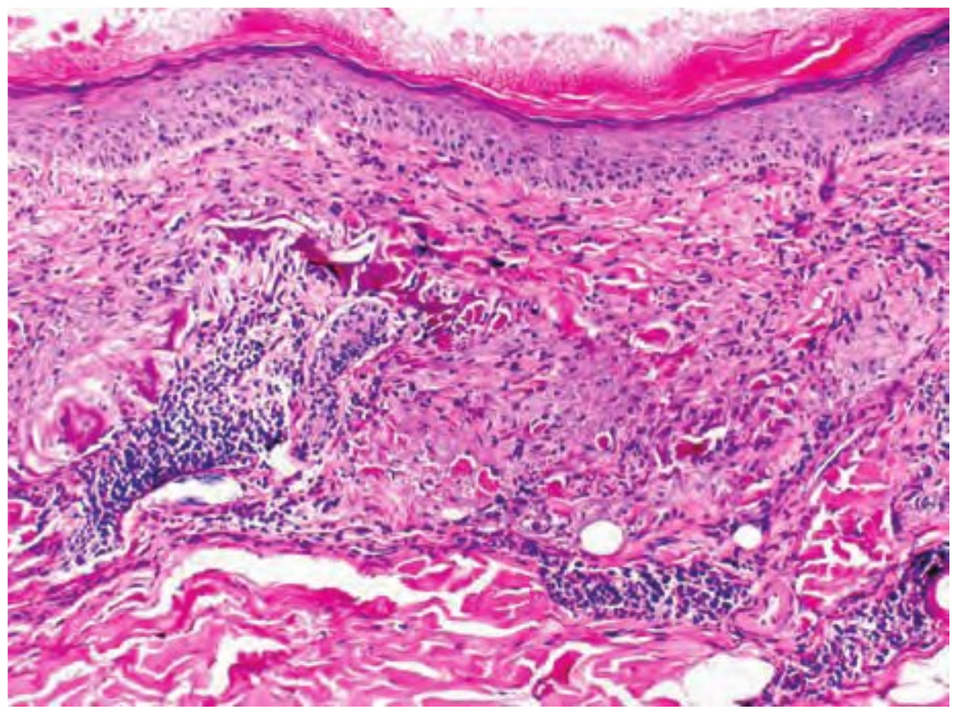
 D



E



F

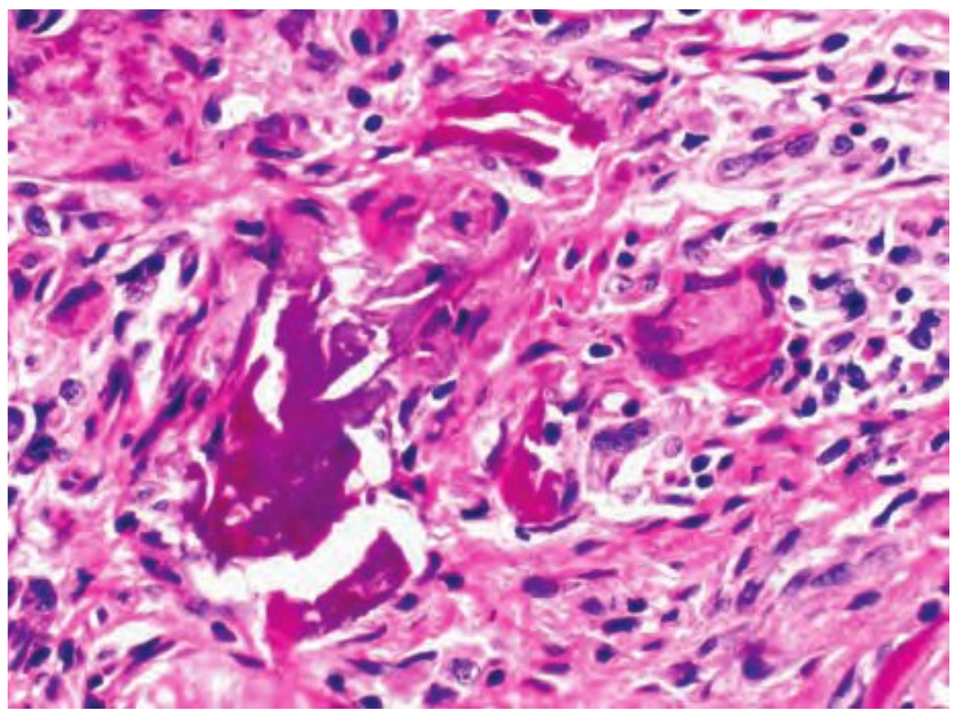


FIGURE 13-12. Electrodesiccation injury. A: There is ulceration of the epidermis and dermis with reticulated lacelike hemorrhagic and basophilic coagulation necrosis of the epidermis and superficial dermis. B: Near the edge of the ulcer, the epidermis and follicular epithelium show elongated alteration of the nuclei, with disassociation and blister formation. C: The epithelial cells typically show elongation of nuclei in electrodesiccation injury. Hyperchromasia of nuclei may be seen, simulating atypia, but the stretch artifact and absence of parakeratosis differentiate this from an actinic keratosis. D: Incipient blister formation can be seen in association with elongation cytolysis of keratinocytes and/or coagulation necrosis of the dermis due to electrodesiccation heat injury. E: Electrodesiccation elongation effects on the follicular epithelium are similar to those seen in the epidermis. This higher-power view highlights the lacelike pattern of coagulation necrosis seen in some cases of electrodesiccation injury. F: Another pattern of electrodesiccation injury, characterized by abrupt basophilic alteration of the collagen and epithelium. (continued)

G

H

I

FIGURE 13-12. Continued. G: The dermal changes of electrodesiccation injury are characterized by homogenized basophilic coagulation necrosis and loss of the distinction between collagen bundles. In contrast, the deeper tissue shows minimally damaged collagen, with distinct separation of the collagen bundles. Superficially there is mild lacelike change. H: Within a healing surgical biopsy site, foci of basophilic desiccated collagen are noted beneath the reparative fibrosis. I: A foreign body reaction to altered collagen is noted, with engulfment of the basophilic injured collagen.

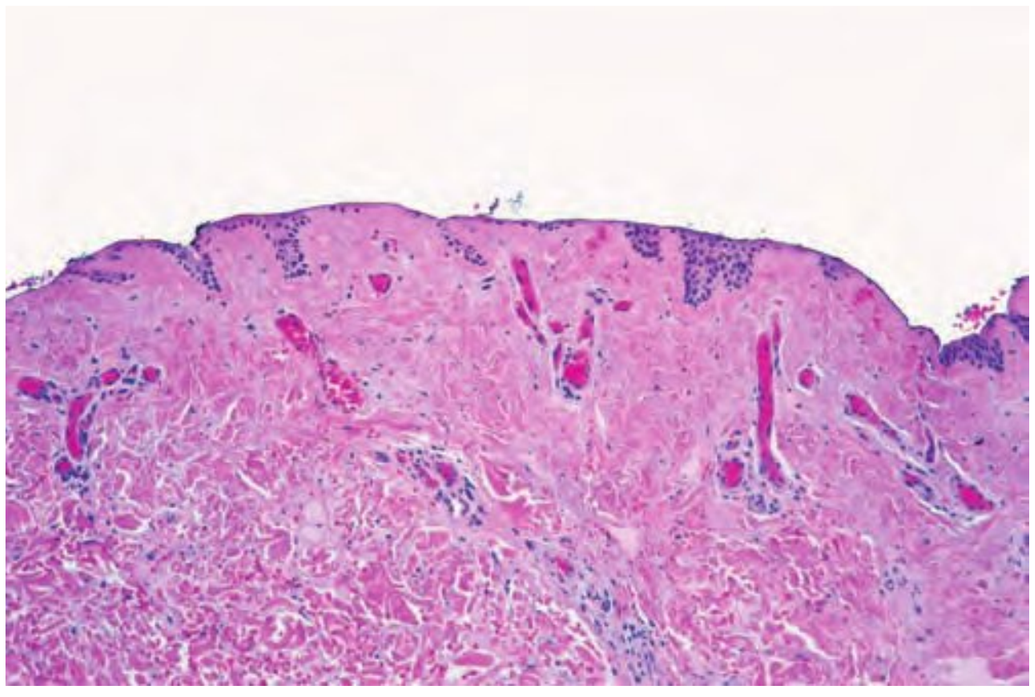

FIGURE 13-13. Curettage-induced ulceration. In contrast to desiccation-induced injury, there is no dermal collagen reaction. The ulcer base typically shows vascular congestion.

Philip E. Shapiro

Noninfectious Granulomas

GRANULOMA ANNULARE

Granuloma annulare is an idiopathic, palisaded, granulomatous condition that is frequently encountered by dermatopathologists. It occurs most commonly in children and young adults but may affect all age groups. Females are affected somewhat more commonly than males. The lesions of granuloma annulare consist of small, firm, asymptomatic papules that are flesh colored or pale red and are often grouped in an annular or circinate fashion (Fig. 14-1). There usually are several lesions, but there may be just one, or there may be many. The lesions are found most commonly on the arms, hands, legs, and feet. The trunk may also be involved, and rare sites of involvement include the palms, penis, ear, and periocular regions (1). Although chronic, the lesions usually subside after a number of years. Unusual variants of granuloma annulare include (a) a generalized form, consisting of hundreds of papules that are either discrete or confluent but only rarely show an annular arrangement (2,3), (b) perforating granuloma annulare, with umbilicated lesions occurring usually in a localized distribution (4–6) and, rarely, in a generalized distribution (7–9), (c) erythematous or patch granuloma annulare, showing large, slightly infiltrated erythematous patches, with a palpable border, on which scattered papules may subsequently arise (10,11), and (d) subcutaneous/deep granuloma annulare, in which subcutaneous nodules occur, especially in children, either alone or in association with intradermal lesions (12–19). The subcutaneous nodules have a clinical appearance similar to that of rheumatoid nodules, although there is no history of arthritis, and there is a greater tendency to occur on the legs, feet, and, occasionally, the head (15,20,21). In adults, similar lesions may be found near the small joints of the hands (22). A very rare, deep, destructive form of granuloma annulare has also been described (23,24).

A correlation between generalized papular granuloma annulare and diabetes mellitus has been observed by several authors (3,23,25). Granuloma annulare has been reported in at least 60 patients with HIV or AIDS, with a greater incidence of generalized disease in this population (27–31). Granuloma annulare–like lesions have also been reported to develop at sites of resolved herpes zoster (32,33) and occasionally in association with tattoos (34), necrobiosis lipoidica (35), and sarcoidosis (36).

Histopathology. Histologically, granuloma annulare shows an infiltrate of histiocytes and a perivascular infiltrate of lymphocytes that is usually sparse. The histiocytes may be present in an interstitial pattern without apparent organization or in palisades surrounding areas with prominent mucin (Figs. 14-2 to 14-5). Patterns between these two extremes occur, and typically a single biopsy will show histiocytes that are not palisaded, are slightly palisaded, and are well palisaded. Although degenerated collagen or small quantities of fibrin may be present (37), increased mucin is the hallmark of granuloma annulare. Increased mucin is almost always apparent on routinely stained sections as faint blue material with a stringy, finely granular appearance. Stains such as colloidal iron and Alcian blue can be used to highlight mucin if it is not clearly apparent. Occasionally, sections will not reveal increased mucin, particularly those lacking a palisaded arrangement of histiocytes. In biopsies with well-developed palisades, the central mucinous area is commonly accompanied by a few nuclear fragments or neutrophils. Plasma cells are present rarely. A sparse infiltrate of eosinophils is seen in approximately half of cases, and occasional biopsies show abundant eosinophils (38,39). Multinucleated histiocytes are present more often than not, but they are usually few and often subtle. They can occasionally be seen to have engulfed short, thick, blue-gray elastic fibers (40). The histiocytic infiltrate is usually present throughout the full thickness of the dermis or the middle and upper dermis, but occasionally just the superficial or the deep dermis is involved (41). Mitotic figures are usually rare (fewer than 1 per 10 high-power fields) but may be as frequent as 7 per 10 high-power fields in rare examples (42).

Rare examples of granuloma annulare show aggregates of epithelioid histiocytes, usually with some giant cells and a rim of lymphoid cells, which resemble the granulomas of sarcoidosis (36,37,41). These usually differ from sarcoidal granulomas, however, by showing poorer circumscription and by lacking asteroid bodies. Vascular changes in granuloma annulare are variable but generally inconspicuous (43). In some instances, however, there are fibrinoid deposits in vessel walls and occlusion of vascular lumina (44).

Among the variants of granuloma annulare mentioned, the usual histologic picture of palisaded and interstitial pattern is found in the generalized form (2). An interstitial pattern predominates in the erythematous and patch variants (10,11).

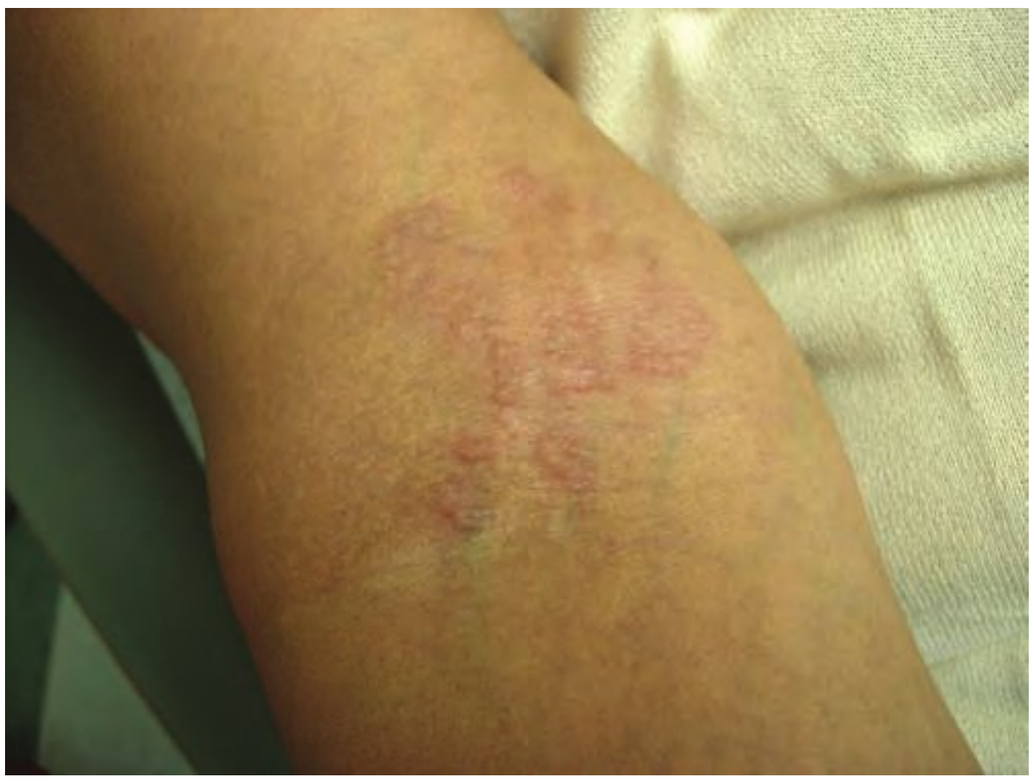

FIGURE 14-1. Granuloma annulare. Raised pink papules in an annular configuration in the antecubital fossa.

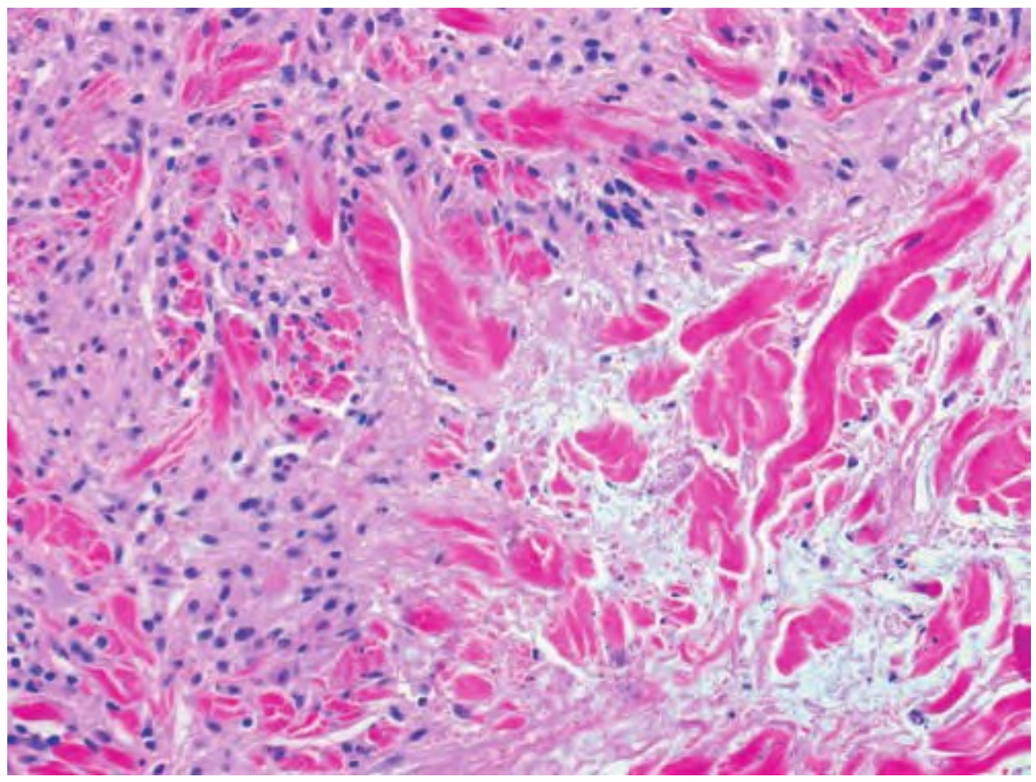

FIGURE 14-3. Granuloma annulare. Histiocytes surround mucin, which shows a feathery blue appearance, and a few fragments of neutrophils.

In perforating granuloma annulare, at least part of the palisading granulomatous process is located superficially and is associated with disruption of the epidermis (4,5,7,8).

The subcutaneous nodules of deep granuloma annulare usually show large histiocytic palisades surrounding mucin and degenerated collagen (Fig. 14-5). These central, degenerated foci exhibit a pale appearance (45); however, examples in which mucin was not apparent or in which the central area appeared more fibrinoid have also been reported (20,21). Thus, subcutaneous granuloma annulare may be histologically indistinguishable from rheumatoid nodule, an appearance that has led to the term *pseudorheumatoid nodule*.

Pathogenesis. The cause of granuloma annulare is unknown. Possible precipitating events in small subsets of patients have included insect bites, warts, erythema multiforme, herpes zoster, exposure to sunlight, hepatitis B vaccine, and tuberculin skin tests (46–49). There is likely an increased incidence and increased disease severity in patients with diabetes mellitus. Thrombi or vasculitic changes have been noted in some examples, and it is possible that what we term granuloma annulare may represent a variety of disease processes.

Electron microscopic examination reveals degeneration of both collagen and elastic fibers in granuloma annulare (37). The macrophages (histiocytes) show a high content of primary lysosomes and considerable cytoplasmic activity with release of lysosomal enzymes into the extracellular space (50). Synthesis of types I and III collagen also occurs, probably as a reparative response (51). A cell-mediated immune response also appears

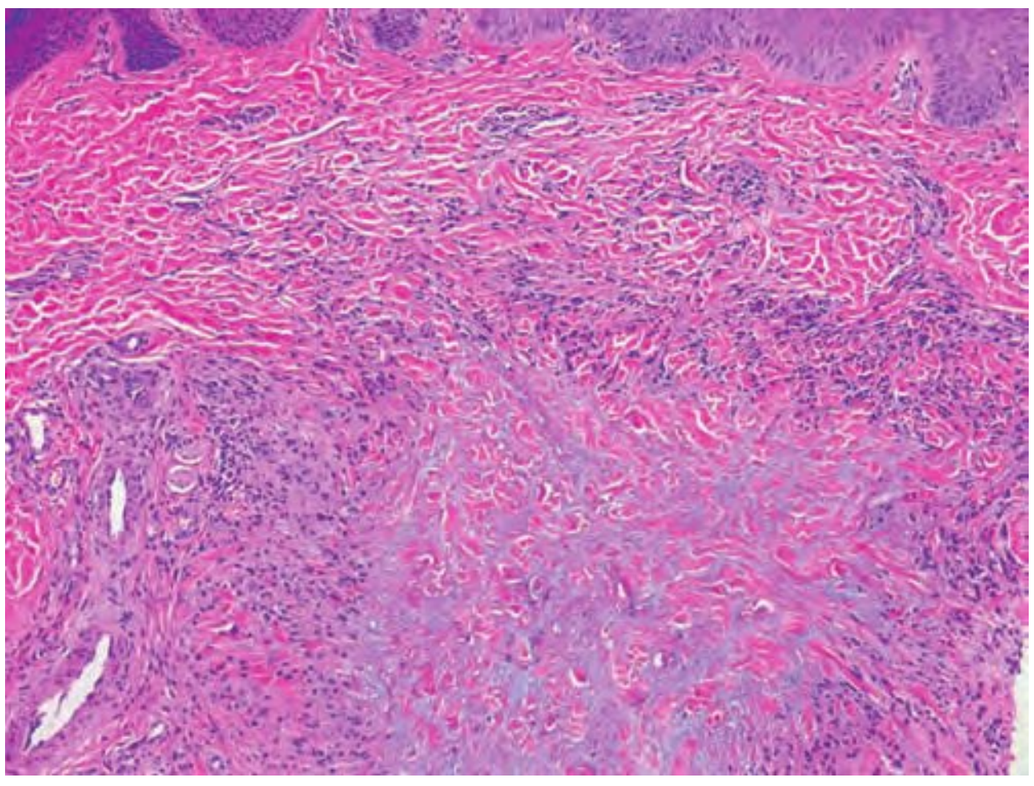

FIGURE 14-2. Granuloma annulare. A palisade of histiocytes surrounds mucin in the upper dermis.

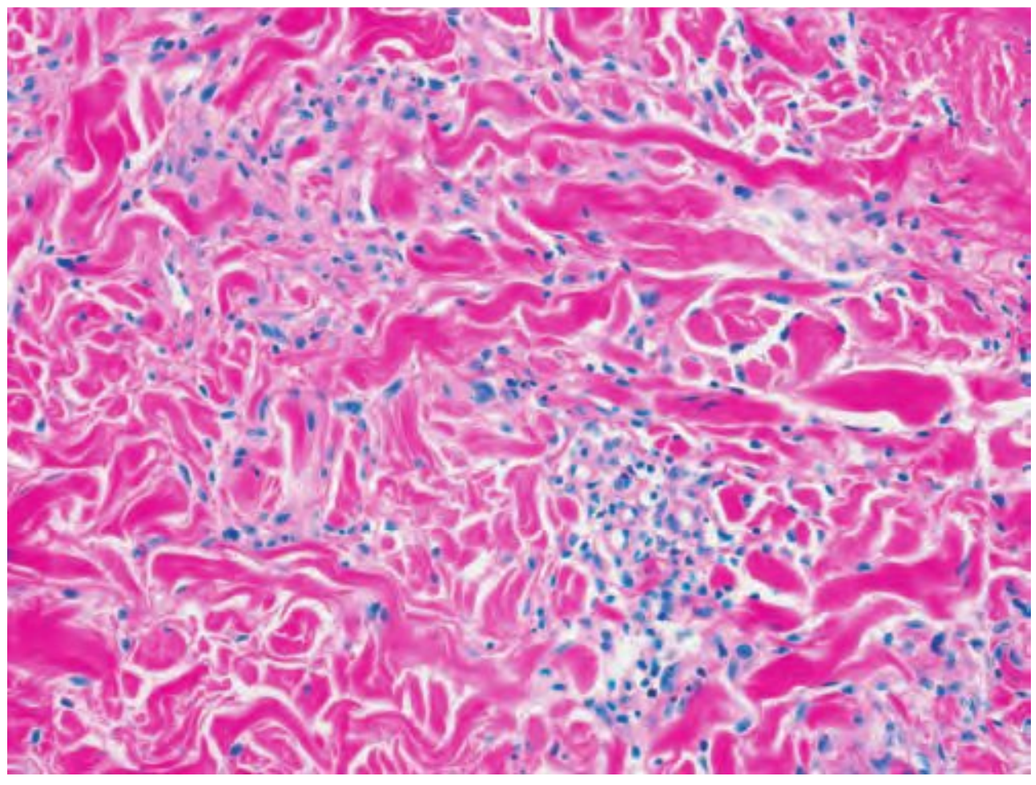

FIGURE 14-4. Granuloma annulare. Interstitial pattern granuloma annulare exhibits histiocytes between collagen bundles and perivascular lymphocytes.

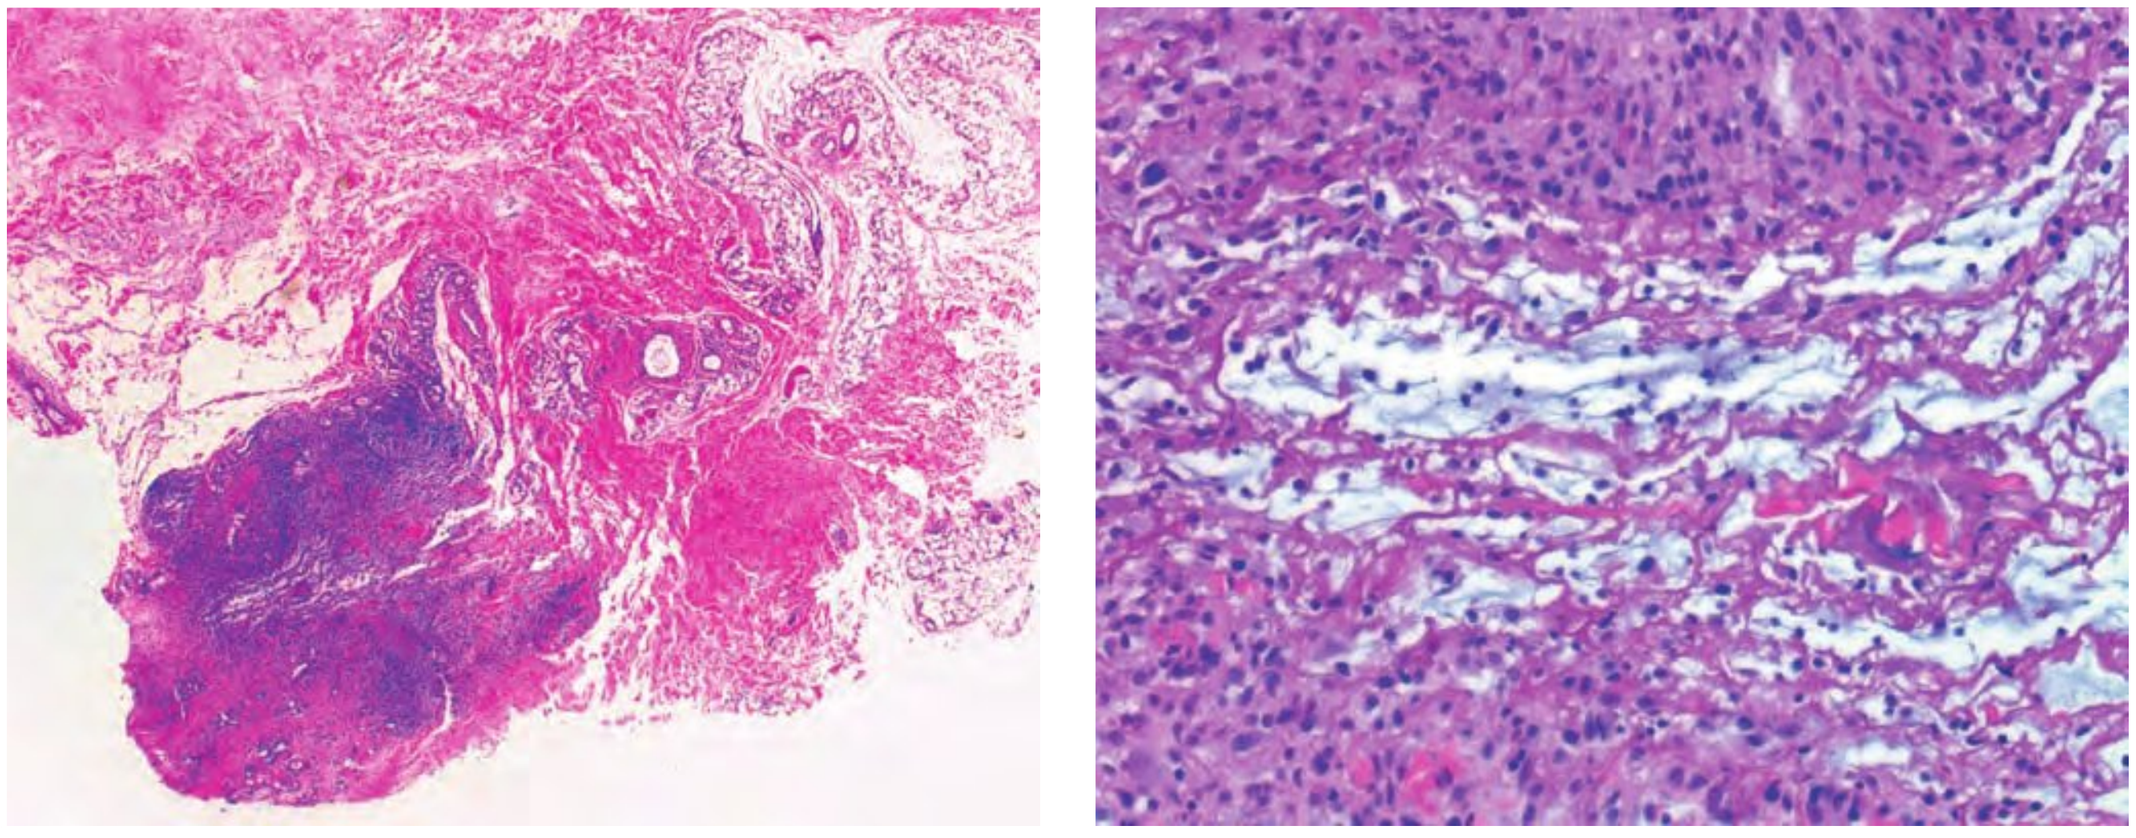

FIGURE 14-5. Deep granuloma annulare. A: A well-circumscribed subcutaneous nodule shows palisaded histiocytes surrounding mucin and fibrinoid material. B: Histiocytes in a palisade surround mucin and fibrinoid material.

to be involved, marked by prominent activated helper T cells (52–54). One immunoperoxidase study of the histiocytic population showed staining for lysozyme but not for other macrophage markers such as HAM 56 or CD-68 (55). Another demonstrated positivity for these two markers (42).

Blood vessel deposits of immunoglobulin M and the third component of complement (C3) have been observed by some investigators (53), but others have found them only rarely (56) or not at all (57). Thus the existence of an immune complex vasculitis in granuloma annulare (53) appears unlikely.

Differential Diagnosis. Granuloma annulare and necrobiosis lipoidica may resemble one another histologically. Although much has been written about the difficulty of separating these disorders histologically (43), the distinction can be easily accomplished clinically in most circumstances (58). Furthermore, although it is true that histologic distinction may be impossible, usually it can be accomplished by using the following criteria: (a) Although either disease may involve the dermis diffusely, necrobiosis lipoidica rarely involves just one focus of the dermis or predominantly the upper half of the dermis, whereas granuloma annulare often does. (b) Histiocytes in palisades that completely encircle altered connective tissue are more common in granuloma annulare, whereas histiocytes in linear array that are horizontally oriented in a somewhat tiered fashion are more typical of necrobiosis lipoidica. (c) Abundant mucin is typical of granuloma annulare and distinctly uncommon in necrobiosis lipoidica. (d) Necrobiosis lipoidica often shows dermal sclerosis and thickened subcutaneous septa, whereas granuloma annulare does not (the sclerosis often produces a straight edge to the sides of a punch biopsy, in contrast to the inward retraction and/or more irregular edge seen in biopsies without sclerosis). Other features that are more characteristic of necrobiosis lipoidica include the presence of a larger number of giant cells, prominent deep dermal plasma cells, and more pronounced vascular changes, including thickened blood vessel walls. Furthermore, necrobiosis lipoidica is more likely to show extensive deposits of lipids or nodular lymphocytic infiltrates in the deep dermis or subcutis (59), although neither feature is commonly seen.

The interstitial type of granuloma annulare, in which palisades of histiocytes are not well developed, is less likely to be confused with necrobiosis lipoidica. This pattern is more likely to be mistaken for a process that can also show a superficial and deep lymphocytic infiltrate, such as the inflammatory stage of morphea, but the subtle presence of histiocytes in an interstitial pattern usually allows a definitive diagnosis of granuloma annulare. Mycosis fungoides can have a granulomatous infiltrate with a granuloma annulare–like pattern (60,61). Such examples of this cutaneous T-cell lymphoma can usually be recognized by the presence of at least some intraepidermal lymphocytes, a dermal lymphocytic infiltrate that is more dense around the superficial plexus than the deep one, and/or a lichenoid component to the infiltrate. The interstitial type of granuloma annulare may also resemble a xanthoma. Distinction is usually possible because in granuloma annulare a foamy appearance to the histiocytes is either completely lacking or very subtle; in xanthoma, at least some of the histiocytes are obviously foamy. In addition, granuloma annulare tends to show an obvious perivascular lymphocytic infiltrate, whereas most xanthomas do not (62). Drug reactions may also mimic granuloma annulare, but these usually show interface changes that allow for their distinction (63). Rarely, infection with *Mycobacterium marinum* may have few neutrophils and may produce a histologic picture resembling interstitial granuloma annulare (64).

Differentiation of subcutaneous granuloma annulare from a rheumatoid nodule is not always possible on histologic grounds, but subcutaneous granuloma annulare is more likely than rheumatoid nodule to show prominent mucin and less likely to show foreign-body giant cells or prominent stromal fibrosis (45).

Finally, it should be remembered that granuloma annulare and other palisading granulomas may be simulated by epithelioid sarcoma, a lesion that may also contain mucin. Clues to epithelioid sarcoma include ulceration, cytologic atypia, necrotic foci that include necrotic epithelioid cells, and history of recurrence. Although atypia tends not to be striking, the epithelioid cells in epithelioid sarcoma usually show more nuclear hyperchromasia and pleomorphism, more mitotic figures, larger size, and redder cytoplasm than do the histiocytes of granuloma annulare (65). Immunohistochemically, epithelioid sarcoma can be distinguished from granuloma annulare by positivity for epithelial membrane antigen and keratins. Whereas a variety of keratins may be present in epithelioid sarcoma, the most common is cytokeratin 8/CAM 5.2, present in 94% of cases (66).

ANNULAR ELASTOLYTIC GIANT-CELL GRANULOMA

Annular elastolytic giant-cell granuloma is the name that is currently in vogue for a condition with unclear nosologic status, and it is uncertain whether it is truly distinct from granuloma annulare (67–69). It almost always occurs on sun-exposed skin, such as the face, neck, dorsum of hand, forearm, and arm, hence the previous name *actinic granuloma* (70,71) (Fig. 14-6). The appearance of lesions after prolonged tanning bed use has been reported (72). However, there are a few reports of similar lesions involving sun-protected sites (73–76). The lesions clinically resemble granuloma annulare. They are typically large, somewhat annular plaques. The border may be serpiginous and is slightly raised, approximately 3 mm wide, and pearly or slightly red or brown. The central zone may show depigmentation and/or atrophy. Smaller papules may also occur, and lesions may be solitary, few, or numerous (70,77,78). Other names under which these lesions have been described include *atypical necrobiosis lipoidica of the face and scalp* (79), *Miescher's granuloma of the face* (78), and *granuloma multiforme* (77). A possibly related process occurs on the conjunctiva (80).

Histopathology. The histologic features are best appreciated in a radial biopsy that contains the central zone, the elevated border, and the skin peripheral to the ring (70,77,78). The central zone shows the hallmark of the disease, that is, near or total absence of elastic fibers, best appreciated with an elastic tissue stain (e.g., Verhoeff-van Gieson) (Figs. 14-7 to 14-9). The collagen in this zone may show horizontally oriented fibers producing a slight scarlike appearance (Fig. 14-7). By contrast, the zone peripheral to the annulus shows an increased amount of thick elastotic material with the staining properties of elastic tissue. The transitional zone at the raised border shows a granulomatous infiltrate with either of the patterns seen in granuloma annulare, that is, histiocytes arranged interstitially between collagen bundles or, less commonly, in a palisade. Occasionally, there are contiguous epithelioid histiocytes in small clusters. Multinucleated histiocytes are conspicuous, usually being large and containing as many as a dozen nuclei, mostly in haphazard arrangement, but sometimes in ringed array. Elastotic fibers are present adjacent to and within the giant cells (Fig. 14-8). Asteroid bodies that stain like elastic fibers may be found in the giant cells (78). The infiltrate also contains lymphocytes and often some plasma cells. Mucin is not present.

Differential Diagnosis. The principal differential diagnosis is granuloma annulare, which may in fact be an artificial distinction.

FIGURE 14-6. Annular elastolytic granuloma. Annular pink plaques, with somewhat serpiginous borders, of the forehead.

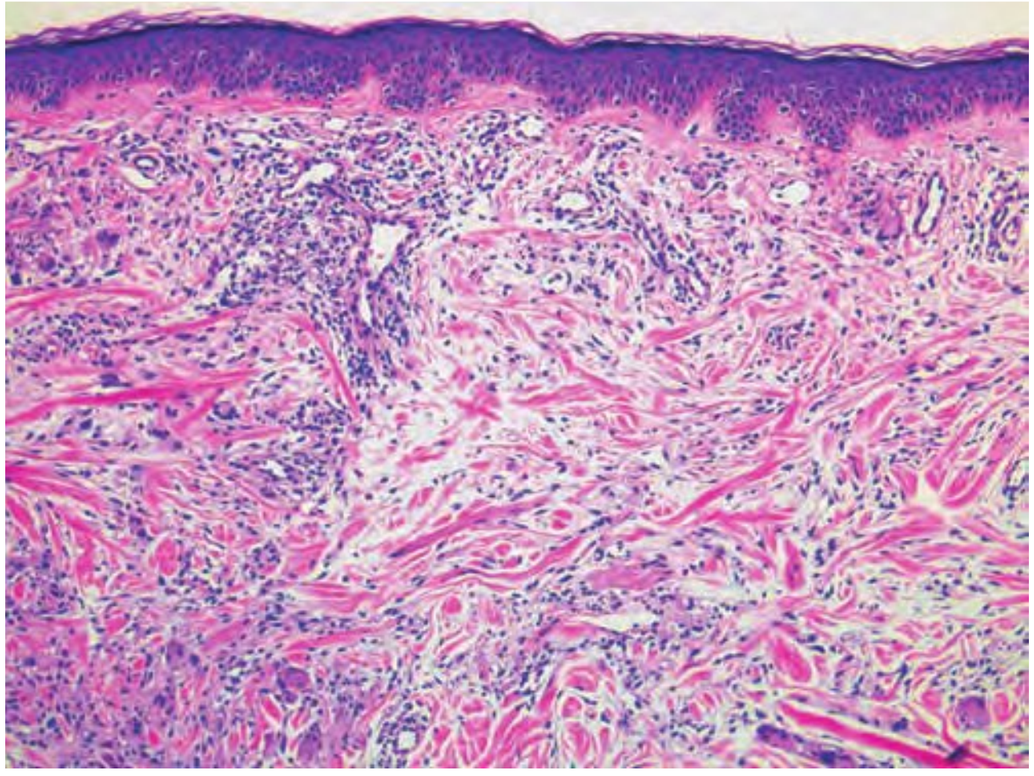

FIGURE 14-7. Annular elastolytic granuloma. Multinucleated histiocytes at left abut connective tissue at the center of the lesion that is slightly fibrotic; mucin is not apparent.

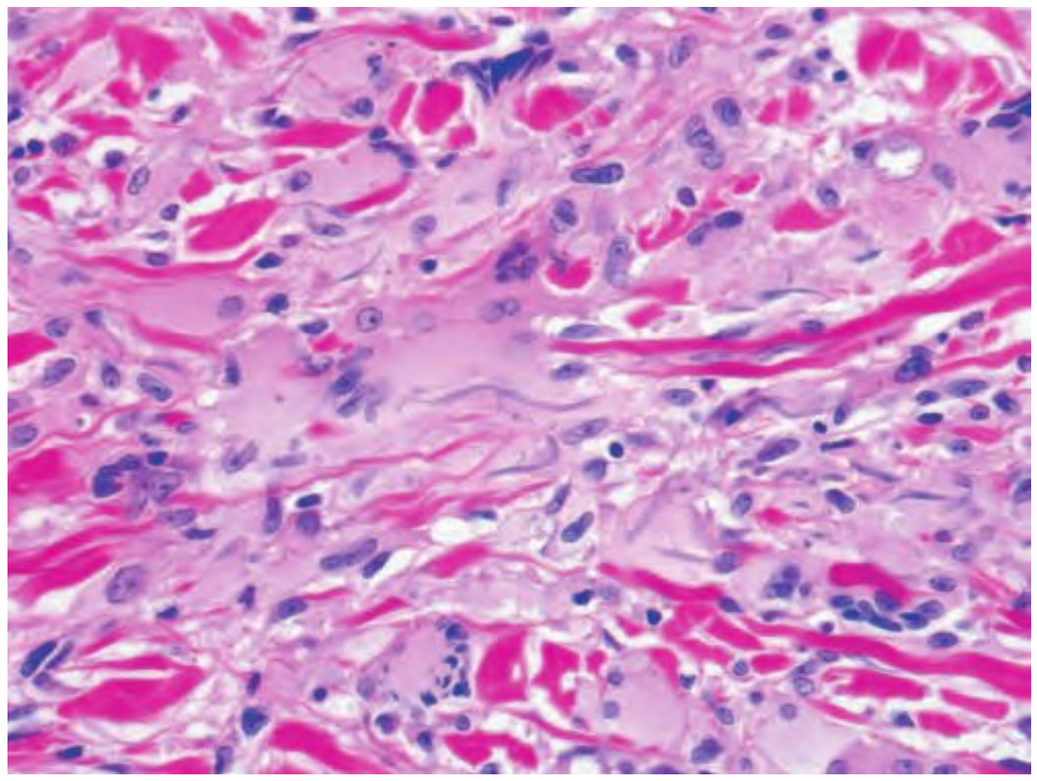

FIGURE 14-8. Annular elastolytic granuloma. Some multinucleated histiocytes have ingested blue-gray elastic fibers.

Because engulfment of abnormal elastic fibers can also occur in granuloma annulare (40) as well as in other granulomatous processes, it has been argued that the elastophagocytosis of annular elastolytic giant-cell granuloma does not qualify it as a distinct entity different from granuloma annulare of sun-damaged skin (68). Although some elastolysis has also been described in granuloma annulare (77), it is the complete loss of elastic tissue in the central zone that has been used as the primary basis for separating the diseases. Other features that have been evoked for distinguishing them are the presence of larger and more numerous giant cells, the absence of mucin in annular elastolytic giant-cell granuloma (70,81), and sparing of areas that lack elastic tissue, such as scars (76).

Necrobiosis lipoidica differs by the lack of a central zone of elastolysis and the presence of degenerated collagen, sclerosis, and, in some circumstances, lipids and vascular changes. Furthermore, annular elastolytic giant-cell granuloma involves mostly the upper and middle dermis, whereas necrobiosis lipoidica tends to affect the deep dermis and sometimes the subcutis at least as much as the upper dermis. Foreign-body granulomas generally have more distinct collections of epithelioid histiocytes, lack zonation in density of elastic fibers, and often have identifiable foreign material.

NECROBIOSIS LIPOIDICA

Necrobiosis lipoidica is an idiopathic disorder typified by indurated plaques of the shins (Fig. 14-10). In 1966, in a large series, Muller and Winkelman reported that two thirds of patients with necrobiosis lipoidica had overt diabetes at the time of diagnosis (82). Of the rest, all but 10% developed diabetes within 5 years, had abnormal glucose tolerance, or had a history of diabetes in at least one parent (26). In a more recent series, only 11% of patients had diabetes at presentation, with an additional 11% developing diabetes or impaired glucose tolerance over 15 years (83). Of all patients with diabetes, fewer than 1% develop necrobiosis lipoidica (26,83). Some reports have suggested that necrobiosis lipoidica heralds more rapid progression of diabetes in patients with that disorder (84).

In well-developed necrobiosis lipoidica, one observes one or several sharply but irregularly demarcated patches or plaques, usually on the shins (85). Usually they are bilateral, and the condition is more often present in women (26). The lesions appear yellow-brown in the center and purplish at the periphery. Whereas the periphery of the lesions may show slight induration, the center of the lesions gradually becomes atrophic, shows telangiectases, and may ulcerate. When lesions first begin, red-brown papules can be observed. In addition to the shins, lesions may be present elsewhere on the lower

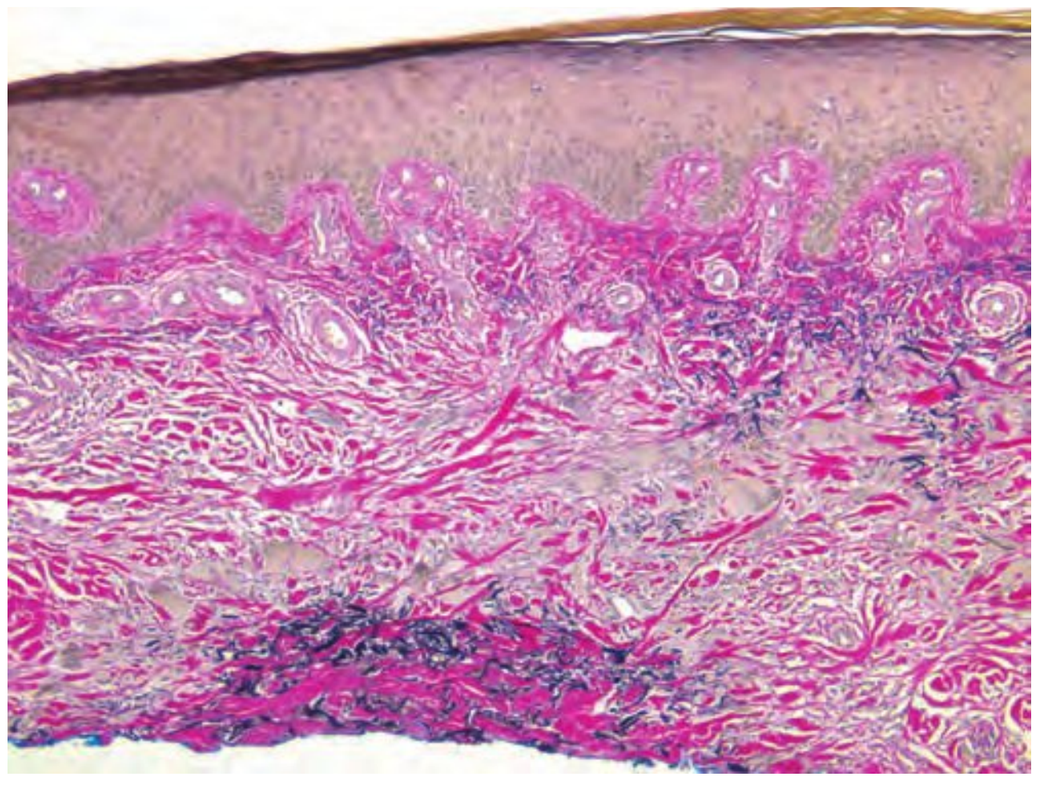

FIGURE 14-9. Annular elastolytic granuloma. Elastic tissue stain shows absence of elastic fibers in the center of the lesion.

FIGURE 14-10. Necrobiosis lipoidica. Waxy, red-brown plaque with central fine telangiectasia on the shin.

extremities, including the ankles, calves, thighs, popliteal areas, and feet. In about 15% of the cases, lesions are present also in areas other than the legs, especially on the dorsa of the hands, fingers, and forearms. Rarely, the head and abdomen are affected. Necrobiosis lipoidica with lesions exclusively outside the legs is extremely rare; it is reported to occur in 1% of patients with necrobiosis lipoidica (82).

Lesions located in areas other than the legs may appear raised and firm and may have a papular, nodular, or plaquelike appearance without atrophy. Clinically they may resemble granuloma annulare (82). Involvement of the scalp by large, atrophic patches occurs occasionally. This is usually seen in association with lesions on the shins and elsewhere (86,87) but also, rarely, in isolation (88–90).

In rare instances, transfollicular elimination of necrotic material takes place in necrobiosis lipoidica, producing small hyperkeratotic plugs within a plaque (91,92). Necrobiosis lipoidica occasionally coexists with sarcoid (93) or granuloma annulare (35). Rare examples of squamous cell carcinoma arising in lesions of necrobiosis lipoidica have been reported (94,95).

Histopathology: On histologic examination, the epidermis may be normal, atrophic, or hyperkeratotic. In some instances, the surface of the biopsy shows ulceration. Usually the entire thickness of the dermis or its lower two thirds is affected by a process that exhibits a variable degree of granulomatous inflammation, degeneration of collagen, and sclerosis (Figs. 14-11 and 14-12). Histologic changes of necrobiosis lipoidica may be seen in subcutaneous septae (96,97). Occasionally only the upper dermis is affected (41,43,58,82). The granulomatous component is usually conspicuous, and the histiocytes may or may not be arranged in a palisade. Occasionally there are just a few scattered epithelioid histiocytes and giant cells. The latter picture is more likely to occur in sections in which sclerosis is extensive, and occasionally in such biopsies several sections must be examined before a granulomatous component becomes apparent. Giant cells are usually of the Langhans or foreign-body type; occasionally, Touton cells or asteroid bodies (98) are seen. If the histiocytes are arranged in a palisade, the palisades tend to be somewhat horizontally oriented and/or vaguely tiered. Occasionally, histiocytes may be seen completely to encircle altered connective tissue, particularly degenerated collagen, but, more commonly, altered connective tissue is incompletely surrounded by histiocytes. This alteration of connective tissue has also been referred to as "necrobiosis." The altered collagen appears different from normal collagen by having a paler, grayer hue and by appearing more fragmented and haphazardly arranged; it may also appear more compact or smudged (Fig. 14-12). Areas of sclerosis with a diminished number of fibroblasts can be seen. A clue to the presence of sclerosis can be found by looking at the edges of the biopsy specimen, which tend to be straight with less of the inward retraction of the dermis ordinarily associated with punch biopsies (Fig. 14-11). Increased mucin is usually inapparent or subtle in contrast to granuloma annulare. Other findings include a sparse to moderately dense, primarily perivascular lymphocytic infiltrate, plasma cells in the deep dermis in some biopsies (Fig. 14-13), involvement of the upper subcutis with thickened fibrous septa, and lipids which may be present in foamy histiocytes (99), which may be inferred from the presence of cholesterol clefts or can be detected extracellularly with special stains on fresh tissue. Cholesterol clefts are rare, seen in less than 1% of cases (100). Deep lymphoid follicles may be present in up to 10% of cases (59). Older lesions show telangiectases superficially. Blood vessels, particularly in the middle and lower dermis, often exhibit thickening of their walls with proliferation of their endothelial cells. The process may lead to partial and rarely to complete occlusion of the lumen. The thickened walls may be infiltrated with periodic acid-Schiff (PAS)–positive, diastase-resistant material (43). Vascular changes of this type are seen particularly near foci containing thickened, hyalinized collagen

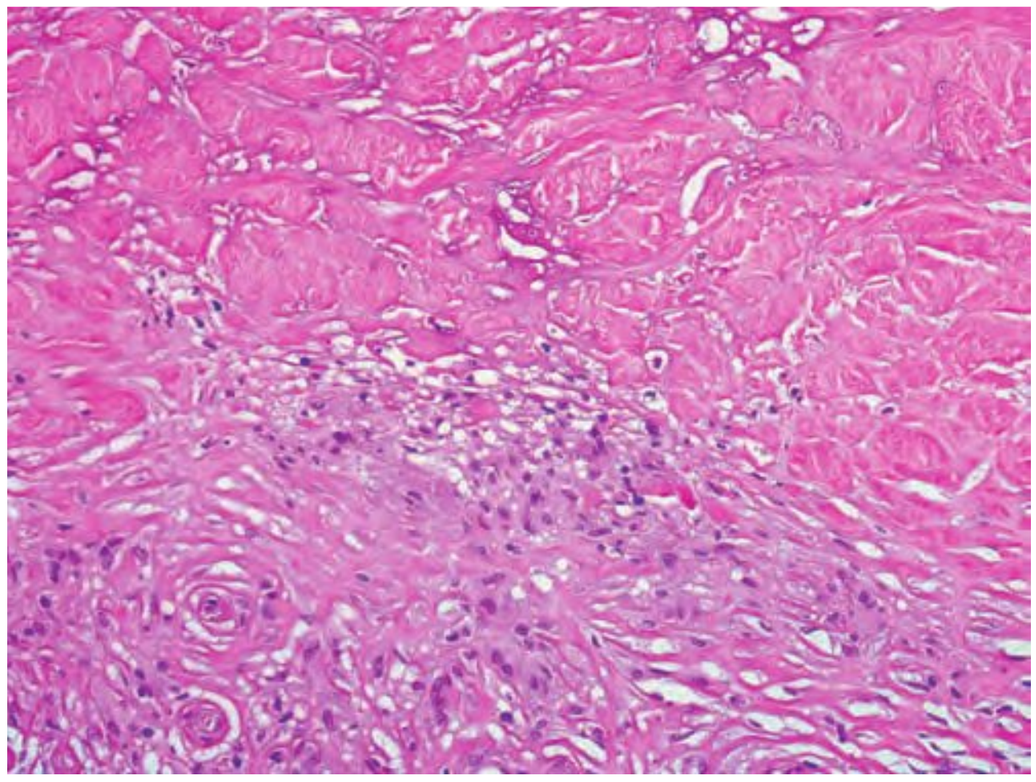

FIGURE 14-12. Necrobiosis lipoidica. Histiocytes, lymphocytes, and degenerated collagen are present.

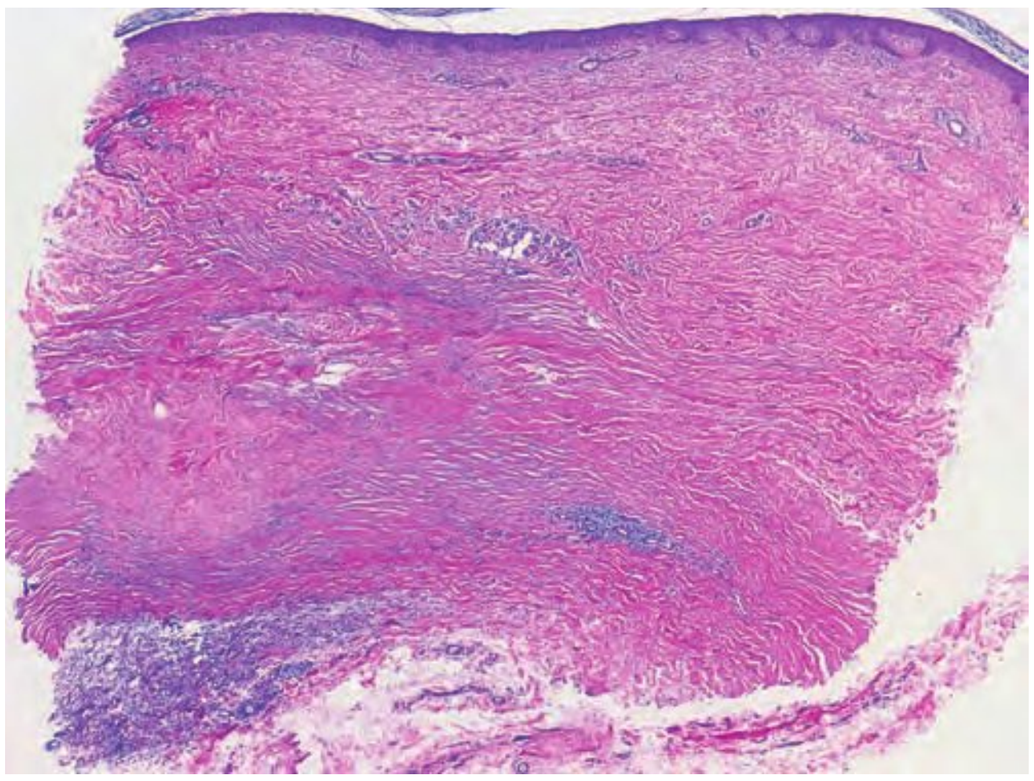

FIGURE 14-11. Necrobiosis lipoidica. The presence of sclerosis can be identified by the relatively straight edges of the punch biopsy. The infiltrate involves the full thickness of the dermis and is arranged in a tierlike fashion.

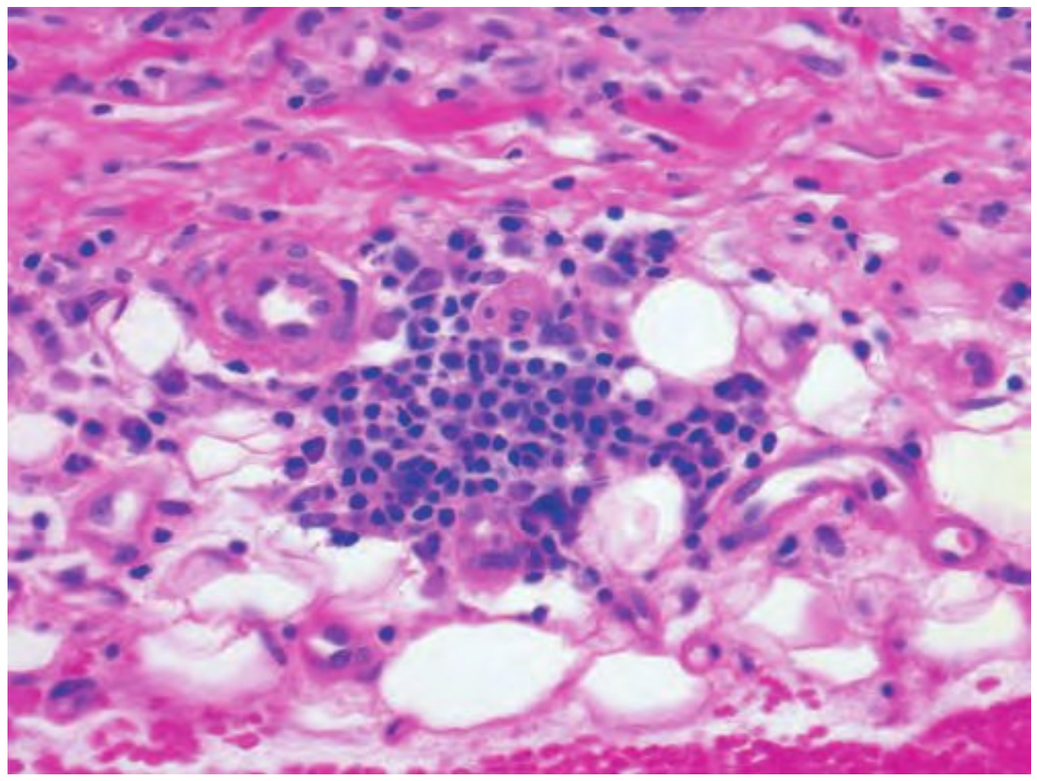

FIGURE 14-13. Necrobiosis lipoidica. Plasma cells at the dermal–subcutaneous junction are a typical finding.

bundles. Whereas the vascular changes often are conspicuous in lesions of the lower legs, they usually are mild or absent elsewhere (89). Histologic findings that are possibly correlated with the clinical presence of diabetes include florid palisading around degeneration of collagen (82) and cholesterol clefts (100).

Pathogenesis. The cause of necrobiosis lipoidica is unknown, and it is unclear whether the degeneration of collagen is a primary or a secondary event (85). Some authors have postulated that the degeneration of collagen is the result of vascular changes secondary to clinical or latent diabetes (101). However, evidence against a vascular cause includes the absence of vascular pathology in approximately one third of biopsies examined (82) and the fact that vessels that are affected are often situated in the lower dermis and are of a larger caliber than the vessels affected by diabetic microangiopathy. Abnormal glucose transport by fibroblasts has also been implicated (102).

Electron microscopic examination shows degenerative changes in collagen and elastin with loss of cross-striation in collagen fibrils. Collagen synthesis by fibroblasts is diminished (103).

Direct immunofluorescence studies have shown that necrobiotic foci contain fibrinogen. Deposits of immunoglobulin and C3 have been found in the vessel walls (104,105), but this is not a consistent finding (106).

Differential Diagnosis. Differentiation of necrobiosis lipoidica from granuloma annulare was discussed in the section on granuloma annulare.

Occasionally, necrobiosis lipoidica shows discrete collections of epithelioid cells that may resemble those seen in sarcoidosis (86). However, significant alteration of the collagen is usually present in necrobiosis lipoidica and absent in sarcoidosis (86).

Necrobiotic xanthogranuloma with paraproteinemia can simulate necrobiosis lipoidica but differs by showing a denser, more diffuse infiltrate with a greater number of foamy histiocytes, Touton giant cells, more extensive inflammation of the subcutis, and greater disruption of normal subcutaneous architecture. Lymphoid follicles and cholesterol clefts are more commonly seen in necrobiotic xanthogranuloma than in necrobiosis lipoidica (107).

Differentiation of necrobiosis lipoidica from annular elastolytic granuloma was discussed in the section on annular elastolytic granuloma.

RHEUMATOID NODULES

Rheumatoid nodules are deeply seated firm masses that occur in patients with rheumatoid arthritis, particularly over extensor prominences, such as the proximal ulna, the olecranon process, and the metacarpophalangeal and proximal interphalangeal joints (108). They may occur elsewhere, such as the back of the hands, over amputation stumps (109), and, rarely, in extracutaneous sites, such as the lung and heart (110,111). The nodules vary in size from a few millimeters to 5 cm and may be solitary or numerous (110). Rarely, rheumatoid nodules show a central draining perforation (112). Rheumatoid factor is almost always found in high titer. Rarely, nodules may precede apparent joint disease (108). The rapid appearance of many small rheumatoid nodules has been reported in some patients treated with methotrexate. This presentation has been termed accelerated rheumatoid nodulosis (113,114). The term rheumatoid nodulosis has been proposed for the clinical presentation of multiple nodules on the hands/elbows with intermittent arthralgias/arthritis but no evidence of systemic rheumatoid arthritis (115). Rheumatoid nodules also occur in occasional patients with systemic lupus erythematosus who do not exhibit rheumatoid arthritis (116–118).

Pseudorheumatoid nodule is a term that has been applied to nodules in the subcutis that mimic rheumatoid nodules histologically but that develop in the absence of joint pain, rheumatoid arthritis, or systemic lupus erythematosus (13,14,21). These occur in children or adults. The subsequent development of rheumatoid arthritis occurs infrequently in adults and rarely, if ever, in children. Because some of these nodules occur in patients with other lesions that are typical of intradermal granuloma annulare (13,14), the nodules are now generally considered to represent a subcutaneous variant of granuloma annulare.

Histopathology. Rheumatoid nodules occur in the subcutis and deep dermis. They exhibit one or several areas of fibrinoid degeneration of collagen that stain homogeneously red (Fig. 14-14). Nuclear fragments and basophilic material are often present, but mucin is almost always minimal or absent (45). These foci of degenerative change are surrounded by histiocytes in a palisade. Foreign-body giant cells are present in approximately 50% of biopsies (45). In the surrounding stroma, there is a proliferation of blood vessels associated with fibrosis. A sparse infiltrate of other inflammatory cells is associated with the histiocytes and surrounding stroma. Lymphocytes and neutrophils are most common, but mast cells, plasma cells, and eosinophils may be present. Occasionally, lipid is seen (13,45). Vasculitis has been described (119) but is

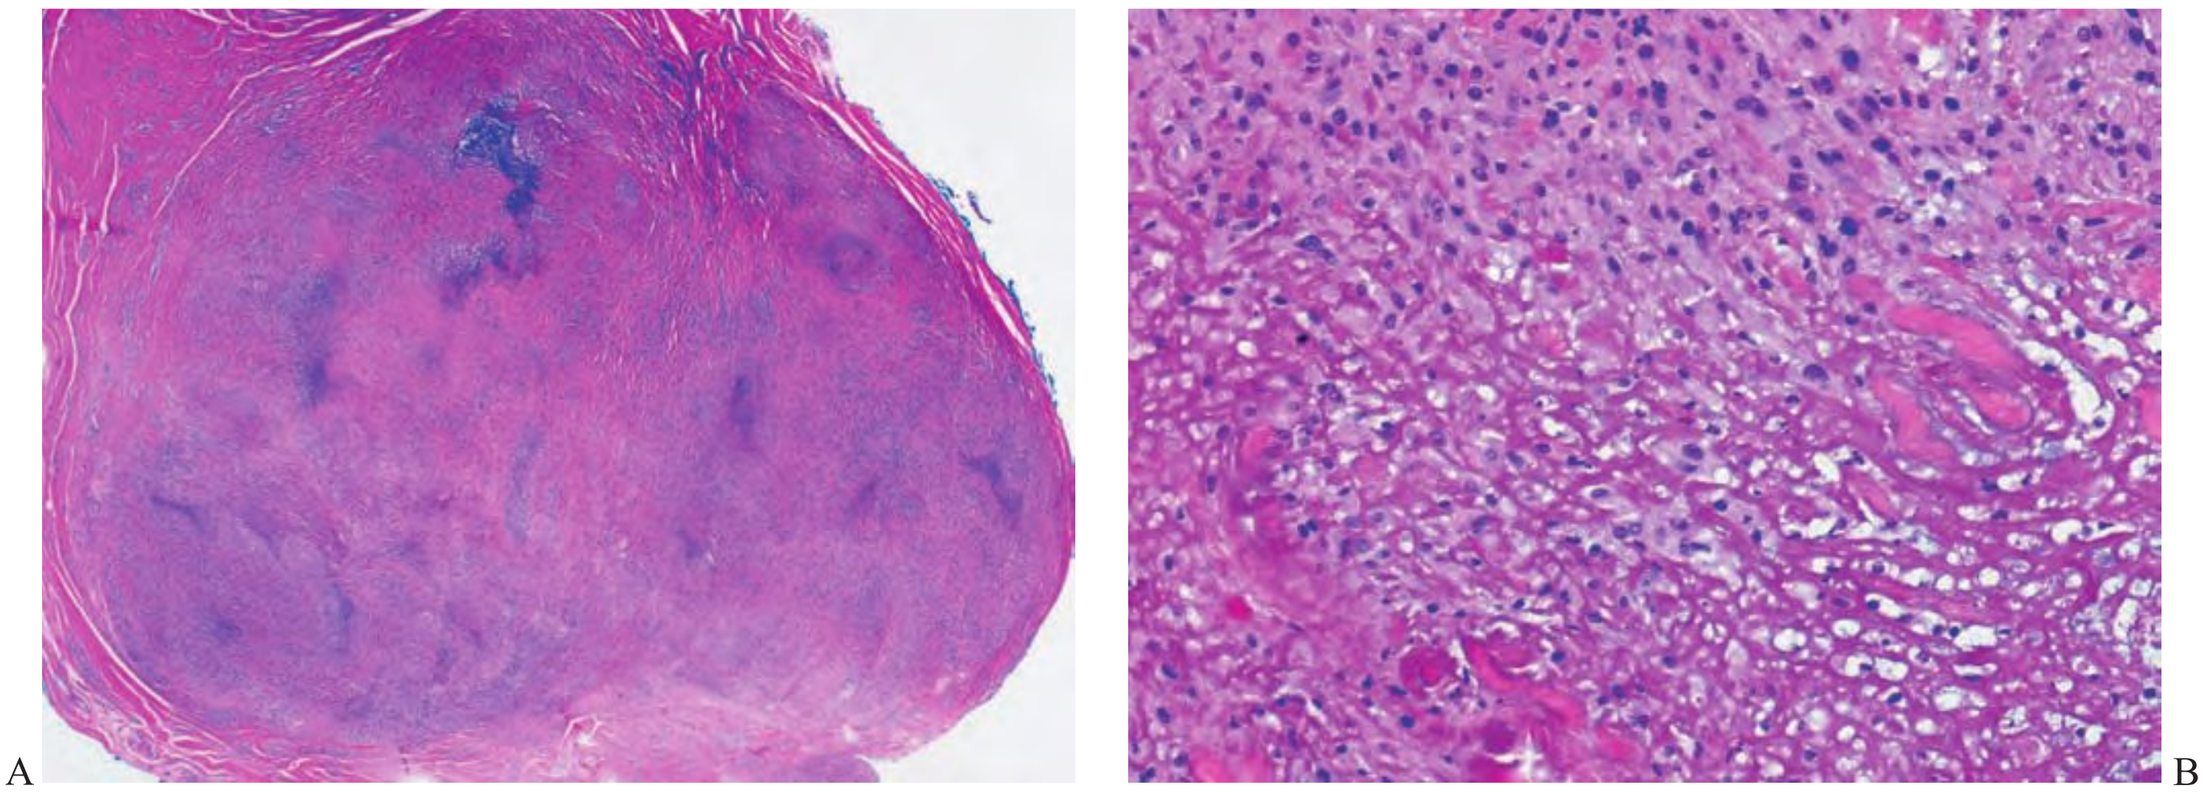

FIGURE 14-14. Rheumatoid nodule. A: A deeply seated, circumscribed nodule exhibits palisading around basophilic material. B: Fibrin is surrounded by histiocytes in a palisaded arrangement.

not usually encountered (45). In perforating rheumatoid nodules, the central fibrinoid material connects to the overlying skin surface (112).

Pathogenesis. Factors that have been implicated in the formation of rheumatoid nodules include trauma, vasculitis, and a specific T-cell–mediated immune reaction (108,120).

Differential Diagnosis. The principal differential diagnosis is subcutaneous granuloma annulare, which was discussed in the section on granuloma annulare. A distinction should be made from epithelioid sarcoma, which was also covered in that section. Nonabsorbable sutures or other foreign material may produce periarticular palisaded granulomas like those of rheumatoid nodule (121,122); in such instances, there should be a history of previous surgery or trauma, and birefringent material may be visible under polarized light. Rheumatic fever produces nodules (rheumatic nodules), especially over the elbows, knees, scalp, knuckles, ankles, and spine (123), which were confused with rheumatoid nodules in the early part of the 20th century. Histologically, a rheumatic fever nodule is less likely to show central, homogeneous fibrinoid necrosis. A palisade of histiocytes is usually not as well developed, and fibrosis is minimal or absent (110,124). Rarely, an infectious process, such as cryptococcosis, can produce a deep, palisaded granuloma. It can be differentiated from rheumatoid nodule because the palisade surrounds primarily necrotic debris and organisms rather than fibrinoid material.

PALISADED NEUTROPHILIC AND GRANULOMATOUS DERMATITIS

In 1983, Finan and Winkelmann reported on 27 patients with a variety of systemic disorders who had cutaneous lesions comprising a palisaded granulomatous infiltrate with prominent neutrophils. These patients often had umbilicated papules and nodules on the elbows and extensor surfaces of the digits (125) (Fig. 14-15). They termed this condition Churg-Strauss *granuloma* or cutaneous extravascular necrotizing granuloma. Of note, only a minority of these patients had Churg-Strauss *disease*, and many had a connective tissue disorder. Others observed similar lesions in patients with rheumatoid arthritis and described them under names such as *rheumatoid papules* (126,127) and *superficial ulcerating rheumatoid necrobiosis* (128,129). In 1994, Chu et al. reported on nine patients with connective tissue disorders and cutaneous lesions similar to those described in the foregoing (130). Biopsies from some of these patients showed histologic changes in early lesions that were judged to be a unique form of leukocytoclastic vasculitis (130). They proposed the term *palisaded neutrophilic and granulomatous dermatitis* to cover the spectrum of lesions in this

FIGURE 14-15. Palisaded, neutrophilic and granulomatous dermatitis. Umbilicated erythematous papules of the elbows.

disorder: early vasculitic lesions, later palisaded granulomatous lesions, and late stage lesions, which resembled necrobiosis lipoidica histologically (but not clinically). *Interstitial granulomatous dermatitis* likely represents a variant of palisaded neutrophilic and granulomatous dermatitis in which patients may present with long, linear, "ropelike" dermal lesions on the trunk, sometimes associated with more typical acral papules and nodules (131,132). Additional patients with similar histologic findings have been reported with other cutaneous manifestations such as plaques, which may be annular (133–135).

Histopathology. There are three, sometimes overlapping histologic patterns in this rare condition: (a) early lesions resembling leukocytoclastic vasculitis, (b) fully developed lesions with a granuloma annulare–like appearance but associated with prominent neutrophils, and (c) a fibrosing, necrobiosis lipoidica–like final stage.

Early lesions show a superficial and deep, diffuse infiltrate of neutrophils with leukocytoclasis, amorphous stringy basophilic debris, and degenerated collagen (130,136). There is vasculitis with unusually broad cuffs of fibrin that separate the vessels from the surrounding basophilic material and altered collagen. Extravasated red cells are scant. Papillary dermal edema is typical, and the epidermis may be ulcerated or hyperplastic.

The fully developed lesions of this condition are more often encountered. They show a palisaded, granulomatous infiltrate with some resemblance to granuloma annulare (130,136) (Figs. 14-16 and 14-17). Whereas vasculitic changes are usually not conspicuous at this stage, neutrophilic dust and intact neutrophils are present in the centers of the palisades, accompanied by thickened, degenerated collagen bundles, fibrin, and mucin (Fig. 14-17).

The uncommonly encountered late or third-stage findings include histiocytes in a palisade around degenerated collagen,

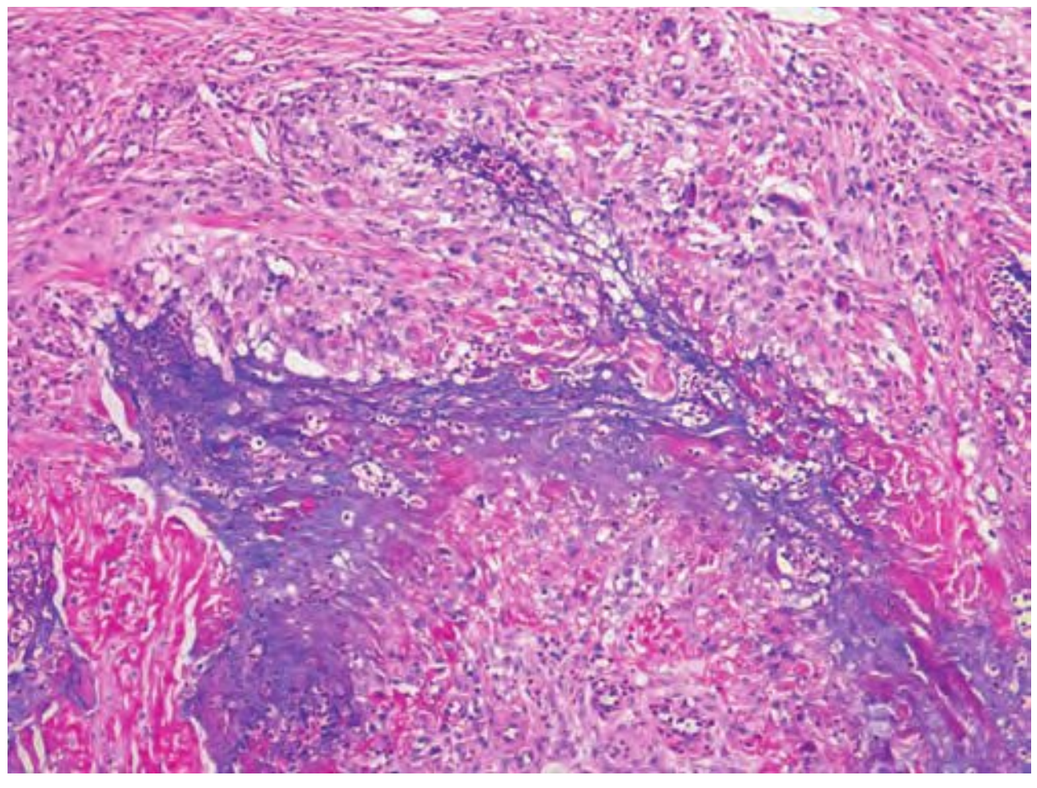

FIGURE 14-16. Palisaded, neutrophilic and granulomatous dermatitis. This fully developed lesion exhibits palisades of histiocytes, associated with neutrophils, basophilic debris, mucin, and degenerated collagen.

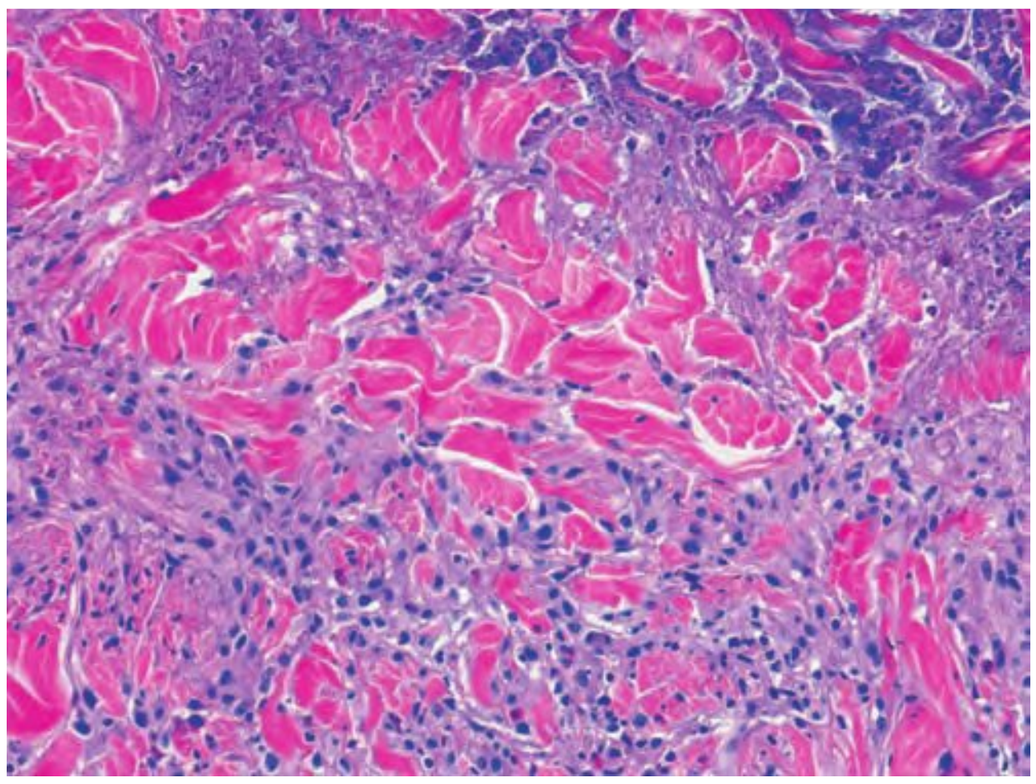

FIGURE 14-17. Palisaded, neutrophilic and granulomatous dermatitis. Neutrophilic dust and intact neutrophils are present in the centers of the palisades, accompanied by degenerated collagen bundles, fibrin, and mucin.

fibrin, and scattered neutrophils (130), with fibrosis in the dermis between the granulomas. Wisps of mucin may be present at the periphery of granulomas but not in their centers. There may also be a sparse, superficial, and deep perivascular infiltrate of lymphocytes and eosinophils.

Pathogenesis. Palisaded neutrophilic and granulomatous dermatitis has been associated with a wide variety of conditions. Whereas most are connective tissue disorders, such as rheumatoid arthritis or lupus erythematosus, others include lymphoproliferative disorders, bacterial endocarditis, inflammatory bowel disease, thyroid disease, diabetes mellitus, and infections (130,137). This condition is believed to represent an unusual immune complex–mediated vasculitis. Immunoglobulin M and C3 have been identified in small-vessel walls. The changes seen in fully developed lesions are believed to be a response to the vasculitic changes accompanying ischemia and enzymatic degradation by neutrophils.

Differential Diagnosis. Early lesions of palisaded neutrophilic and granulomatous dermatitis may be distinguished from other forms of leukocytoclastic vasculitis by the presence of unusually broad cuffs of fibrin around vessel walls, which separate the vessels from abundant basophilic nuclear debris. In addition, compared to most examples of leukocytoclastic vasculitis, early palisaded neutrophilic and granulomatous dermatitis shows a denser infiltrate of neutrophils and more nuclear debris diffusely throughout the dermis.

Fully developed lesions resemble *granuloma annulare* but differ from it by showing less prominent mucin, more fibrin, and thickening of collagen bundles. Whereas granuloma annulare may occasionally show nuclear debris, it is not as prominent as in palisaded neutrophilic and granulomatous dermatitis. This disorder also shows intact neutrophils, whereas

granuloma annulare only rarely does so. *Churg-Strauss disease* may show findings similar to palisaded neutrophilic and granulomatous dermatitis but differs by showing a predominance of eosinophils rather than neutrophils. Lesions of *Wegener's granulomatosis* are more likely to show active vasculitic changes concurrent with the palisaded granulomatous component. Drug eruptions (138) and infections with a palisaded and neutrophilic response may also be seen.

SARCOIDOSIS

Sarcoidosis is a granulomatous disease, often systemic, of undetermined cause. A distinction is made between the rare subacute, transient type of sarcoidosis and the usual chronic, persistent type.

In subacute, transient sarcoidosis, erythema nodosum is associated with hilar adenopathy, fever, and, in some cases, migrating polyarthritis and acute iritis. The disease subsides in almost all patients within a few months without sequelae. Cutaneous manifestations other than erythema nodosum do not occur (139,140). Occasionally, there is enlargement of some of the subcutaneous lymph nodes, such as the submental or cervical nodes (140,141).

In systemic sarcoidosis, cutaneous lesions are encountered in approximately one fourth of patients who are seen in medical departments (142). In contrast, cutaneous lesions are the only manifestation of sarcoidosis in about one fourth of patients with sarcoidosis seen in dermatologic departments (36,143,144).

In the United States, this disorder is much more common and is more severe in African Americans (145,146). It is rare in children (147–149). A rare genetic disorder, Blau's syndrome, may present in childhood and mimic sarcoidosis. This autosomal dominant disorder is marked by granulomatous inflammation of the skin, uveal tract, and joints, sparing the lungs (150,151).

The most common cutaneous lesions of sarcoidosis are brown-red or purple papules and plaques (152) (Fig. 14-18). Through central clearing, annular or circinate lesions may result. When papules or plaques of sarcoidosis are situated on the nose, cheeks, and ears, the term *lupus pernio* is applied (153). This presentation has been associated with upper respiratory involvement and greater disease severity (152,154).

A rare form of sarcoidosis is its lichenoid variant, in which small, papular lesions occur (155). Very rare manifestations of sarcoidosis include erythrodermic, ichthyosiform, atrophic, ulcerating, verrucous, angiolupoid, hypopigmented, alopecic, and morpheaform variants. In erythrodermic sarcoidosis, the erythroderma may be generalized (156) or may consist of extensive, sharply demarcated, brown-red, slightly scaling patches with little or no palpable infiltration (157). In ichthyosiform sarcoidosis, ichthyotic changes favor the lower extremities (158), but at times they also may be present elsewhere on the skin (159,160). Rarely, there are extensive atrophic lesions (161). They may undergo ulceration (162,163). Multiple ulcers have been described also in plaque-like lesions (164). Angiolupoid sarcoid is characterized by a prominent telangiectatic component (165). Lesions of hypopigmented sarcoid appear as macules with or without an associated papular or nodular component (166).

Subcutaneous nodules of sarcoidosis are also rare. Originally described by Darier and Roussy (167), they may occur in association with other cutaneous lesions (157,168) or alone (169). Up to 80% to 90% of patients with subcutaneous sarcoidosis may have associated systemic disease (170). Sarcoidosis has been described in AIDS patients (171), and a transient form of chronic sarcoidosis has been reported in patients with hepatitis C undergoing treatment with interferon alfa and ribavirin (172).

Systemic sarcoidosis occasionally coexists with granuloma annulare (36). Cutaneous lesions of sarcoidosis may localize to areas of scarring, as in herpes zoster scars (173,174). Tattoos (175,176), exogenous ochronosis (177), or other exogenous materials in the skin (178) may serve as a nidus for cutaneous lesions in patients with sarcoidosis. Two studies demonstrated polarizable foreign material in approximately 20% of cutaneous sarcoidal lesions from patients with systemic sarcoidosis (179,180).

FIGURE 14-18. Sarcoid. Pink-brown papules in clusters on the neck.

Histopathology. The lesions of erythema nodosum occurring in subacute, transient sarcoidosis have the same histologic appearance as "idiopathic" erythema nodosum (141).

Like lesions in other organs, the cutaneous lesions of chronic, persistent sarcoidosis are characterized by the presence of circumscribed collections of epithelioid histiocytes—so-called epithelioid cell tubercles—which show little or no necrosis (Figs. 14-19 and 14-20).

The papules, plaques, and lupus pernio–type lesions show variously sized aggregates of epithelioid cells scattered irregularly through the dermis with occasional extension into the subcutis (181). In the erythrodermic form, the infiltrate shows small granulomas in the upper dermis intermingled with numerous lymphocytes (157,182) and, rarely, also giant cells (183). Typical sarcoidal granulomas are found in the ichthyosiform lesions (159), in ulcerated areas (164), and in atrophic lesions (184,185). Verrucous sarcoid exhibits prominent associated acanthosis and hyperkeratosis (186,187). Biopsies of

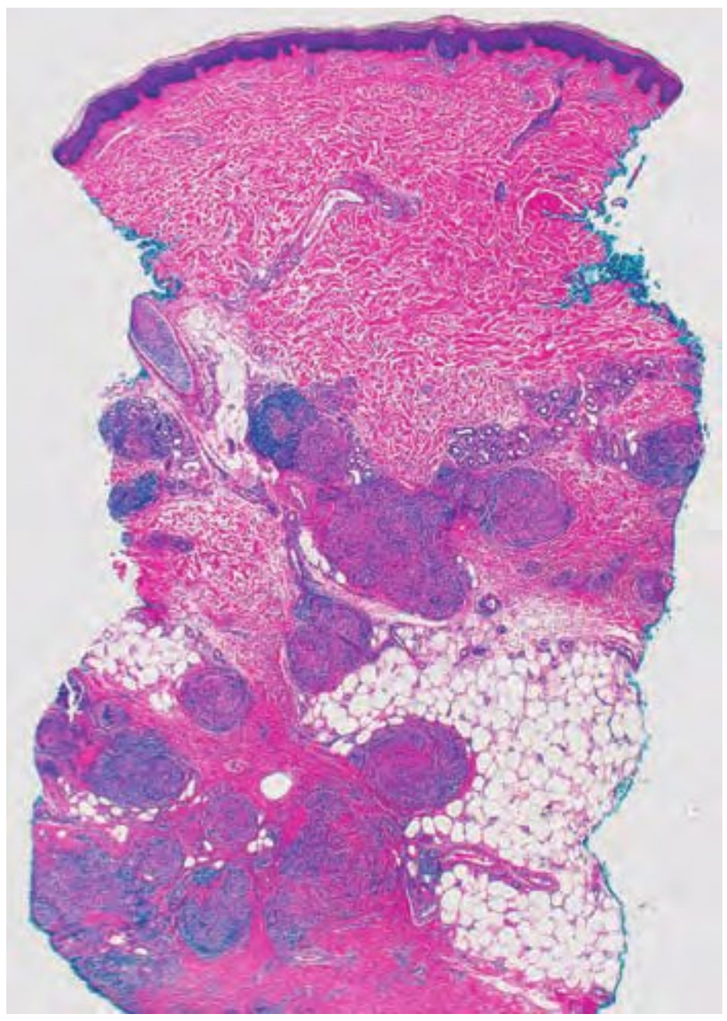

FIGURE 14-19. Sarcoid. There are well-circumscribed, nodular collections of epithelioid histiocytes in the dermis. This example also shows subcutaneous involvement, which is less common than purely dermal involvement.

hypopigmented sarcoid may reveal granulomas, which may have a perineural component or fail to reveal granulomas (188). In subcutaneous nodules, larger epithelioid cell tubercles lie in the subcutaneous fat (169).

In typical cutaneous lesions of sarcoidosis, the well-demarcated islands of epithelioid cells contain few, if any, giant cells. Those that are present are usually of the Langhans type. A moderate number of giant cells can be found in old lesions. These giant cells may be large and irregular in shape. In a minority of cases, giant cells contain asteroid bodies or Schaumann bodies

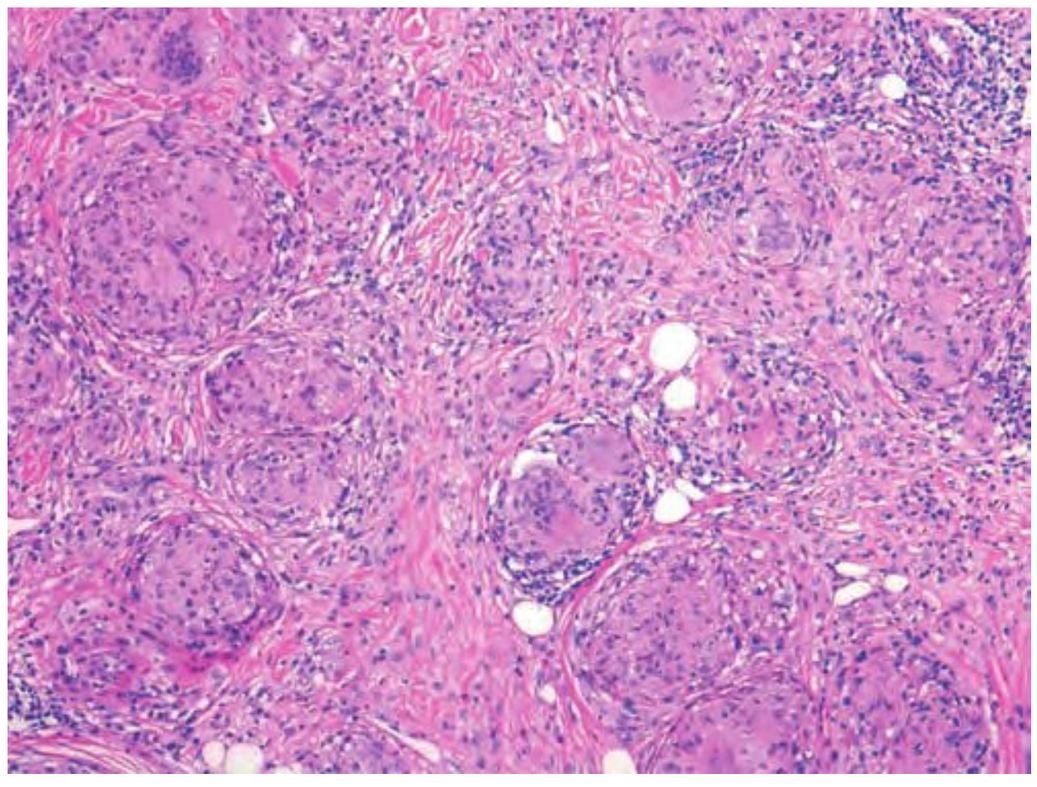

FIGURE 14-20. Sarcoid. Well-circumscribed, roundish collections of epithelioid histiocytes, some multinucleated, with few lymphocytes.

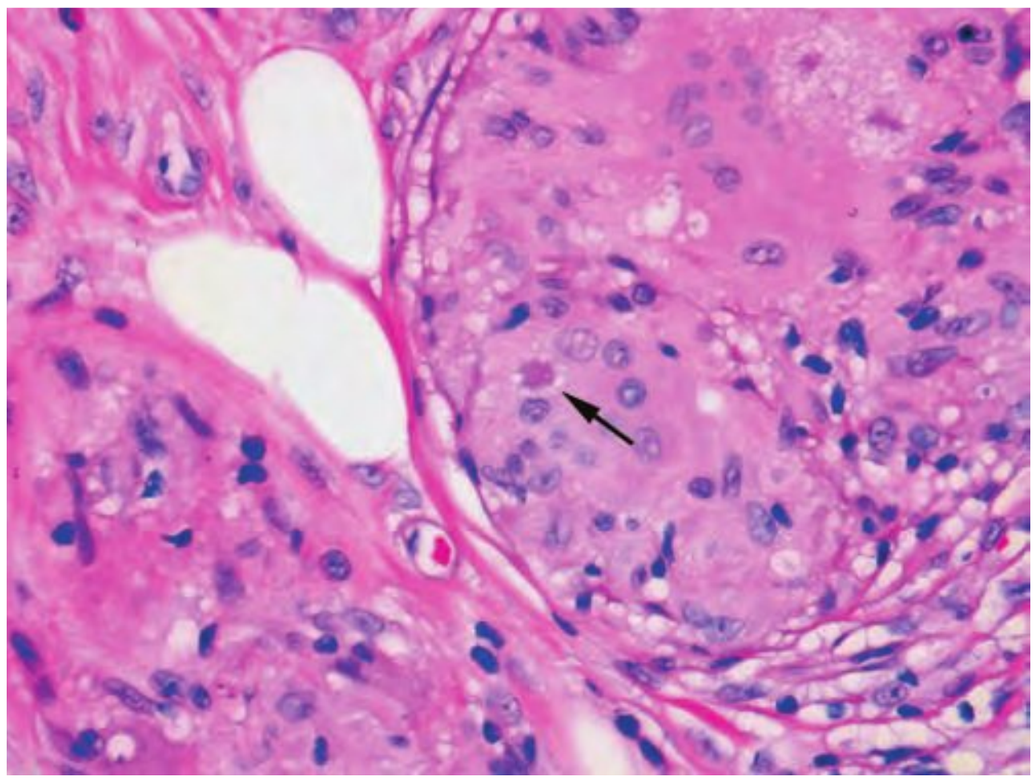

FIGURE 14-21. Sarcoid. Three star-shaped, eosinophilic asteroid bodies are present, one at the arrow and two in the upper right.

(189). Asteroid bodies (Fig. 14-21), which are more common, are star-shaped eosinophilic structures that, when stained with phosphotungstic acid–hematoxylin, produce a center that is brown-red with radiating blue spikes (157). Schaumann bodies are round or oval, laminated, and calcified, especially at their periphery. They stain dark blue because of the presence of calcium. Neither of these two bodies is specific for sarcoidosis: They have been observed in a variety of other granulomas, including those of leprosy, tuberculosis, foreign-body reactions, and necrobiotic xanthogranuloma (190).

Classically, sarcoid has been associated with only a sparse lymphocytic infiltrate, particularly at the margins of the epithelioid cell granulomas (Fig. 14-20). Because of the scarcity of lymphocytes, the granulomas have been referred to as "naked" tubercles. However, lymphocytic infiltrates in sarcoid may occasionally be dense, as in tuberculosis (Fig. 14-22). Occasionally, small foci of fibrin or necrosis showing

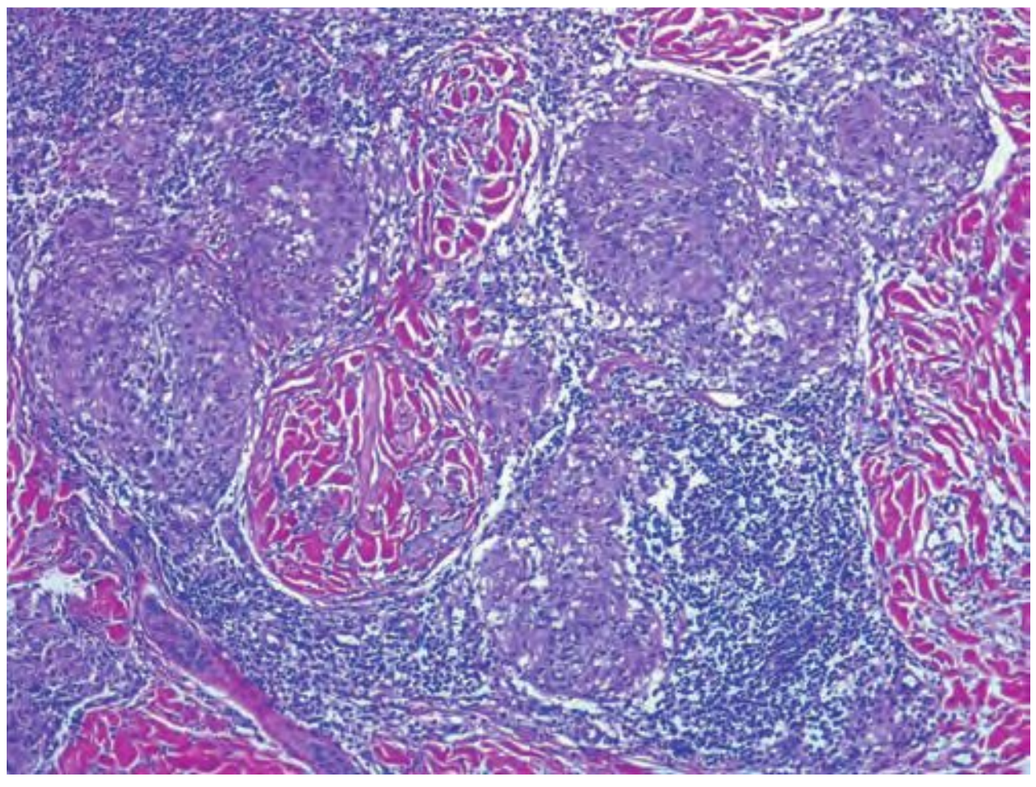

FIGURE 14-22. Sarcoid. A fairly dense lymphocytic infiltrate is associated with the epithelioid histiocytes, a less common finding than the usual "naked tubercles."

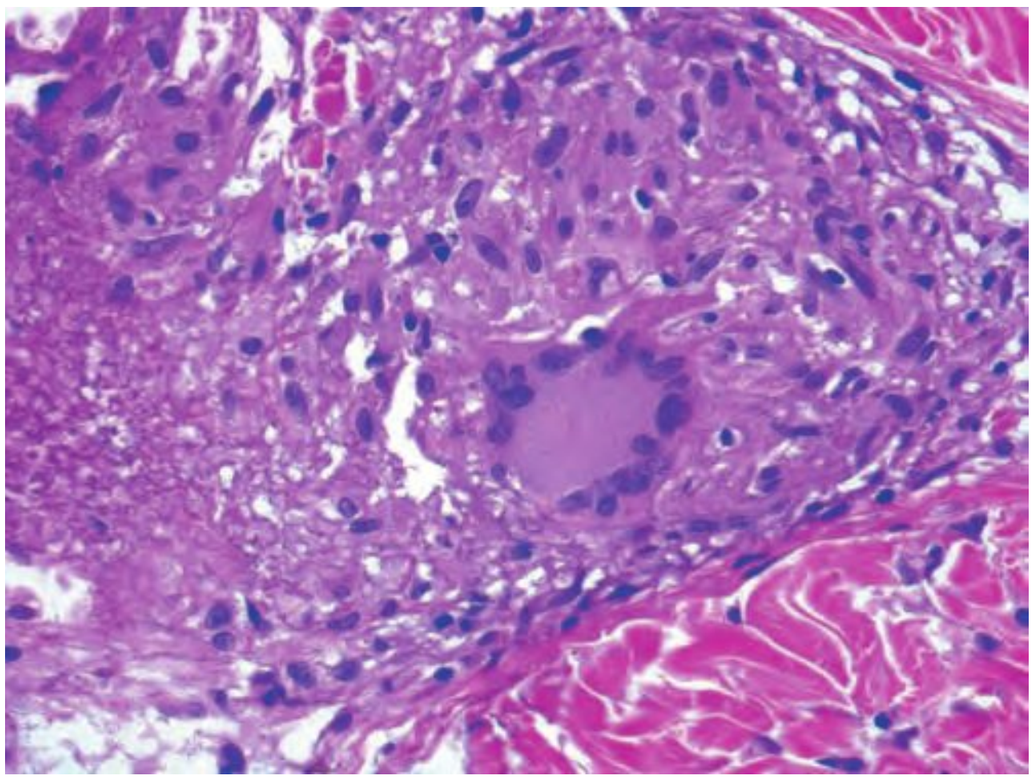

FIGURE 14-23. Sarcoid. On the left is fibrinoid material within the granulomatous component.

eosinophilic staining is found in the center of some of the granulomas (Fig. 14-23) (154,181). A reticulum stain of sarcoid reveals a network of reticulum fibers surrounding and permeating the epithelioid cell granulomas. If the granulomas of sarcoidosis involute, fibrosis extends from the periphery toward the center, with gradual disappearance of the epithelioid cells (181). Fibrosis, however, is minimal to absent in most examples of sarcoidosis, with the exception of the morpheaform variant, where it is prominent (191). Other features that may sometimes be seen include elastophagocytosis, increased dermal mucin, and lichenoid inflammation (192).

Systemic Lesions. The lungs are the most commonly involved organ in the chronic, persistent type of sarcoidosis, and respiratory symptoms are present in approximately 50% of patients (140). The lesions may be either nodular or diffuse with extensive parenchymal fibrosis.

In about 25% of the patients, ocular manifestations occur, most commonly chronic iridocyclitis. Splenomegaly is present in about 17%. In approximately12%, osseous granulomas are present, most commonly in the phalanges of the fingers and toes. Involved phalanges appear swollen and deformed, often sausage-shaped (193). The skull may show circumscribed lytic lesions (194). About 8% of the patients have involvement of large salivary glands, usually the parotid. In about 5%, one encounters paresis of a cranial nerve, most commonly of the facial nerve (140). Oral mucosal involvement occurs very rarely (195). Asymptomatic enlargement of the hilar lymph nodes is present in 70%, of peripheral lymph nodes in 30%, and of the liver in 20% of the patients (140,196).

Sarcoidosis, although usually a benign disease, is fatal in approximately 5% of patients (140,196). The most common cause of death from sarcoidosis is right ventricular failure resulting from massive pulmonary involvement. Pulmonary hemorrhage and superimposed tuberculosis are rare causes of death. Another potentially fatal complication is renal insufficiency resulting from hypercalcemia and hypercalciuria (197) or from sarcoidal glomerulonephritis (198). In very rare instances, death results from massive involvement of the myocardium (199) or liver (200). Hypopituitarism from involvement of either the pituitary gland or the hypothalamus is also a rare fatal complication (201).

The diagnosis of sarcoidosis in a patient with systemic disease is based on clinical presentation, biopsy findings, and exclusion of other granulomatous processes. If skin lesions are present, they are an obvious choice for biopsy. In the absence of skin lesions, a Kveim test was frequently used in the past. The Kveim test involves intradermal injection of antigen derived from heat-sterilized suspension of sarcoidal tissue, particularly spleen or lymph node. The site is sampled 6 weeks later, with a positive result being the formation of a sarcoid-like granuloma (202,203). The test has a sensitivity of about 80%, with false-positive reactions occurring in less than 2% of cases (204). However, Kveim antigen is neither widely available nor approved by the U.S. Food and Drug Administration. It is infrequently used (145). The most accepted alternative approach for confirming a presumptive diagnosis of systemic sarcoidosis is fiberoptic bronchoscopy with transbronchial lung biopsy (205). Endobronchial biopsy has also been shown to be useful (206), as has asymptomatic gastrocnemius muscle biopsy (207). Less specific ancillary tests, such as serum angiotensin-converting enzyme levels, can provide supportive data (146).

Pathogenesis. The cause of sarcoidosis is unknown, and the disease may not have the same pathogenesis in all individuals. Alterations in immunologic status have long been recognized, including hypergammaglobulinemia, impaired delayed-type hypersensitivity reactions to cutaneous antigens (anergy), and a shift of helper T lymphocytes from peripheral blood to sites of disease activity (208). However, these immunologic phenomena may represent a response to an as-yet-unidentified antigen (209). Mycobacteria, especially cell-wall–deficient forms, have been postulated to represent the antigen source (209–212). *Mycobacterium* tuberculosis has been implicated by some studies, whereas others have suggested atypical mycobacteria (212,213). Other infectious causes such as *Rickettsia* (214) have also been suggested.

Electron microscopic examination of epithelioid cells fails to show any evidence of bacterial fragments, unlike the macrophages seen in granulomas caused by mycobacteria, although the cells contain primary lysosomes, some autophagic vacuoles, and complex, laminated residual bodies (215). The giant cells form through the coalescence of epithelioid cells with partial fusion of their plasma membranes. Schaumann bodies likely arise from laminated residual bodies of lysosomes. Asteroid bodies consist of collagen showing the typical 64- to 70-nm periodicity. It seems likely that this collagen is trapped between epithelioid cells during the stage of giant-cell formation (215).

Differential Diagnosis. The histologic differentiation of sarcoidosis from lupus vulgaris may be very difficult, and it is

occasionally impossible. There is no absolute histologic criterion by which the two diseases can be differentiated with certainty. However, as a rule, the infiltrate in sarcoidosis lies scattered throughout the dermis, whereas the infiltrate in lupus vulgaris is located close to the epidermis. Furthermore, sarcoidosis usually shows few lymphoid cells at the periphery of the granulomas, giving them the appearance of "naked" granulomas. By contrast, lupus vulgaris often shows a marked inflammatory reaction around and between the granulomas. The granulomas of sarcoidosis usually show much less central necrosis than the granulomas of lupus vulgaris (216); however, not all biopsies of tuberculosis show necrosis, and some biopsies of sarcoid do. The epidermis in sarcoidosis is usually normal or atrophic. In lupus vulgaris, in addition to atrophy, areas of ulceration, acanthosis, and pseudocarcinomatous hyperplasia are not uncommon. The absence of identifiable mycobacteria with acid-fast stain cannot be used to exclude tuberculosis because the organisms in lupus vulgaris are scarce and may be difficult or impossible to find.

Foreign-body granulomas can also resemble sarcoidosis. Polariscopic examination in search of doubly refractile material, such as silica, should be performed on biopsies suspected of being sarcoidosis. The presence of foreign material does not exclude a concurrent diagnosis of sarcoidosis (189). The papular type of acne rosacea occasionally shows "naked" tubercles indistinguishable from those of sarcoidosis, but unlike sarcoid, they are usually perifollicular.

Tuberculoid leprosy, which may show granulomas in association with only a sparse lymphocytic infiltrate, can also be difficult to distinguish from sarcoidosis. Only 7% of cases of tuberculoid leprosy show acid-fast bacilli, and then only a few, so that they may easily be overlooked (217). The most likely place to find bacilli is within degenerated dermal nerves (the granulomas of tuberculoid leprosy form around dermal nerves that are undergoing necrosis). The granulomas of tuberculoid leprosy show small areas of central necrosis more often than those of sarcoidosis. In addition, the granulomas of tuberculoid leprosy, in contrast with those of sarcoidosis, follow nerves and therefore often appear elongated (218). Clinical correlation may be required to distinguish between these two diseases. For example, in the United States, leprosy virtually can be excluded if a patient has not been in an endemic area (either in a foreign country or where it is carried in armadillos domestically, e.g., Texas and Louisiana) or has not had prolonged close contact with another individual with the disease.

FOREIGN-BODY REACTIONS

Foreign substances, when injected or implanted accidentally into the skin, can produce a nonallergic foreign-body reaction or, in persons specifically sensitized to them, an allergic response (219). In addition, certain substances formed within the body may produce a nonallergic foreign-body reaction when deposited in the dermis or subcutis. Such endogenous foreign-body reactions are produced, for instance, by urates in gout and by keratinous material in pilomatricoma, as well as in ruptured epidermoid and trichilemmal cysts.

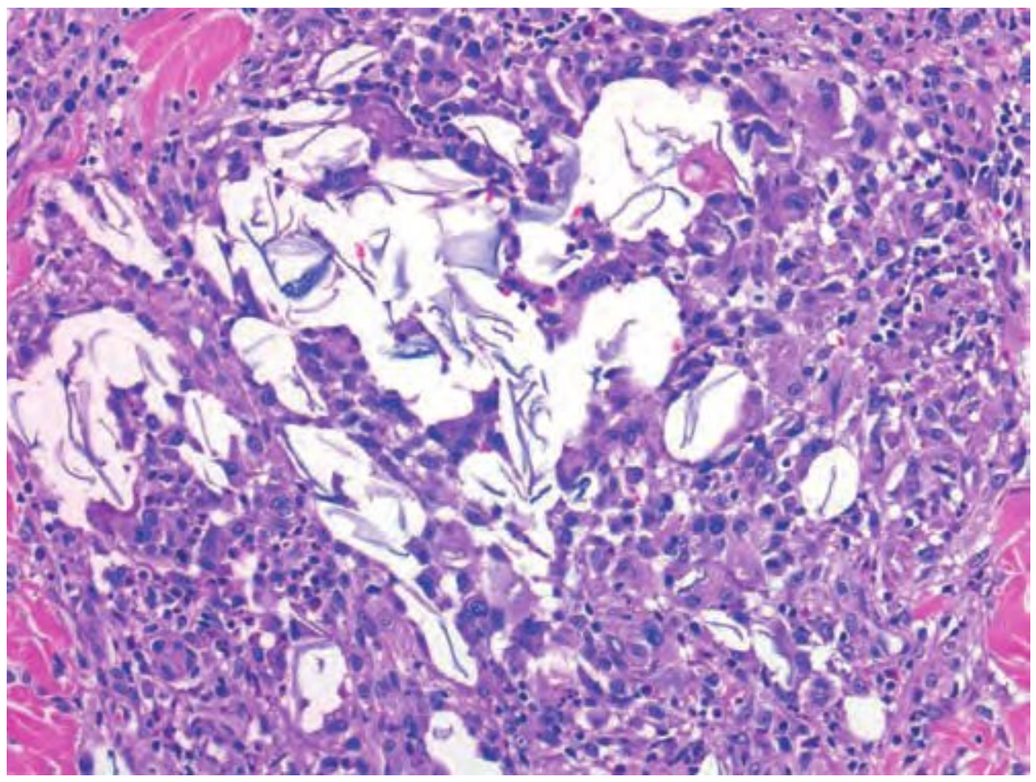

FIGURE 14-24. Ruptured epidermoid cyst. There are neutrophils and histiocytes surrounding cornified cells from the center of the cyst.

Histopathology. A *nonallergic* foreign-body reaction typically shows a granulomatous response marked by histiocytes and giant cells surrounding foreign material. Often, some of the giant cells are of the foreign-body type, in which the nuclei are in haphazard array. In addition, lymphocytes are usually present, as may be plasma cells and neutrophils. Frequently, some of the foreign material is seen within macrophages and giant cells, a finding that of course is of great diagnostic value. The most common cause of a foreign-body granuloma is rupture of a hair follicle or follicular cyst, and sometimes only the cyst contents, rather than residual cyst wall, is identifiable (Fig. 14-24). Exogenous substances producing nonallergic foreign-body reactions include silk and nylon sutures (Fig. 14-25),

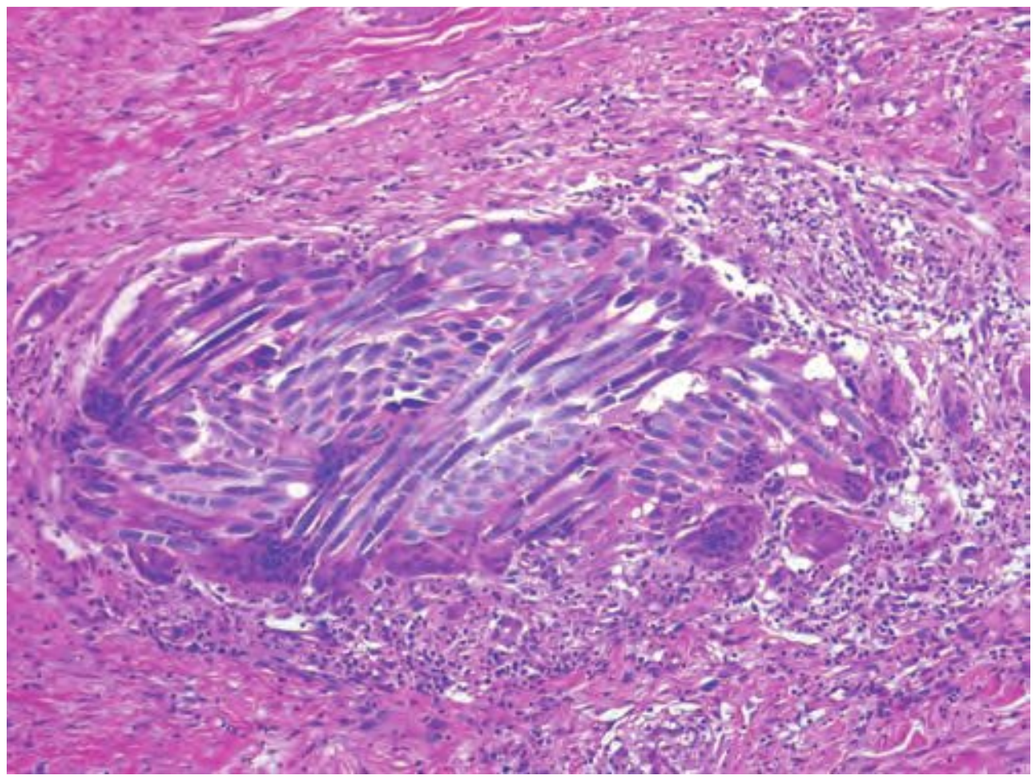

FIGURE 14-25. Foreign-body granuloma caused by nylon suture. The suture is composed of blue-gray, linear material and is surrounded by histiocytes, including many multinucleated foreign body–type giant cells.

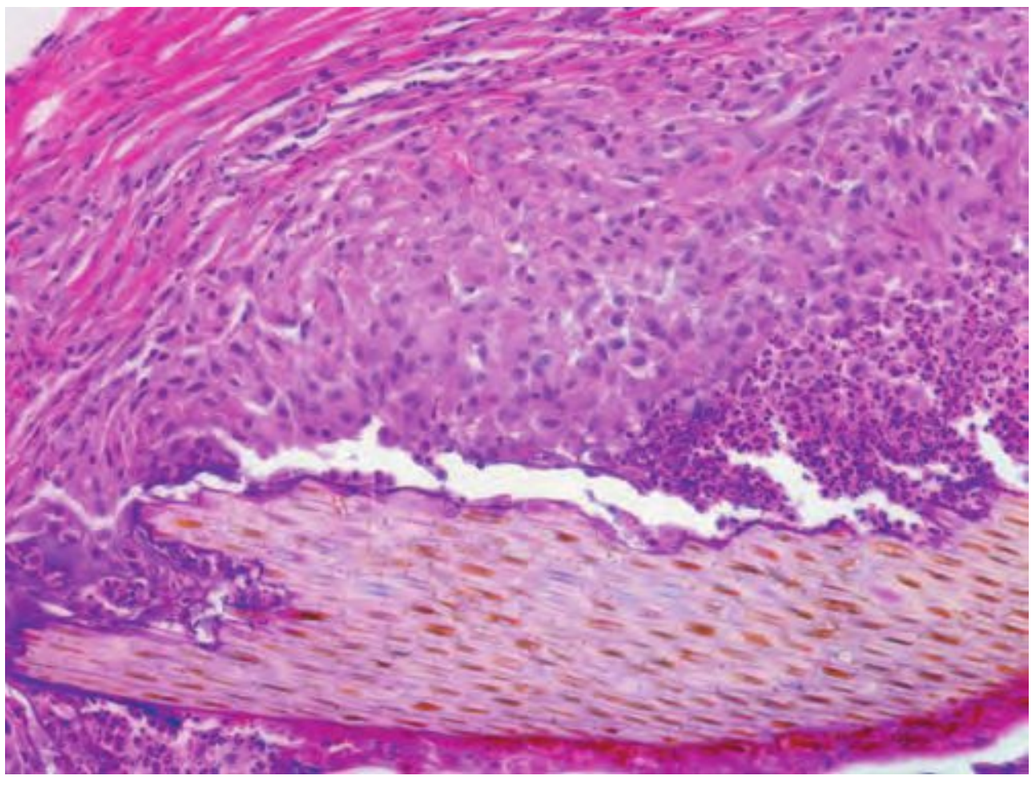

FIGURE 14-26. Foreign-body reaction to a wood splinter. The wood splinter shows an orderly arrangement of rectangular cells, typical of plant material, surrounded by a nodular infiltrate with histiocytes, including multinucleated histiocytes of the foreign-body type, and neutrophils.

wood or other plant material (Fig. 14-26), paraffin and other oily substances, silicone gel, talc, surgical glove starch powder, and cactus spines. Some of these substances—nylon sutures, wood, talc, surgical glove starch powder, and sea urchin spines—are doubly refractile on polarizing examination. Double refraction often is very helpful in localizing foreign substances. Knife marks in the section may be an additional clue to the presence of particulate foreign matter (Fig. 14-27).

An *allergic* granulomatous reaction to a foreign body typically shows a sarcoidal or tuberculoid pattern consisting of epithelioid cells with or without giant cells. Phagocytosis of the foreign substance is slight or absent. Substances that in sensitized persons produce an allergic granulomatous reaction include zirconium, beryllium, and certain dyes used in tattoos. Some substances that at first act as foreign material may later, after sensitization has occurred, act as allergens, as in the case of sea urchin spines and silica.

A histologic decision as to whether a granuloma is of the foreign-body type or of the allergic type is not always possible. A granuloma of the allergic type is more likely to show rounded, well-circumscribed collections of epithelioid histiocytes and less likely to have multinucleated histiocytes of the foreign-body type.

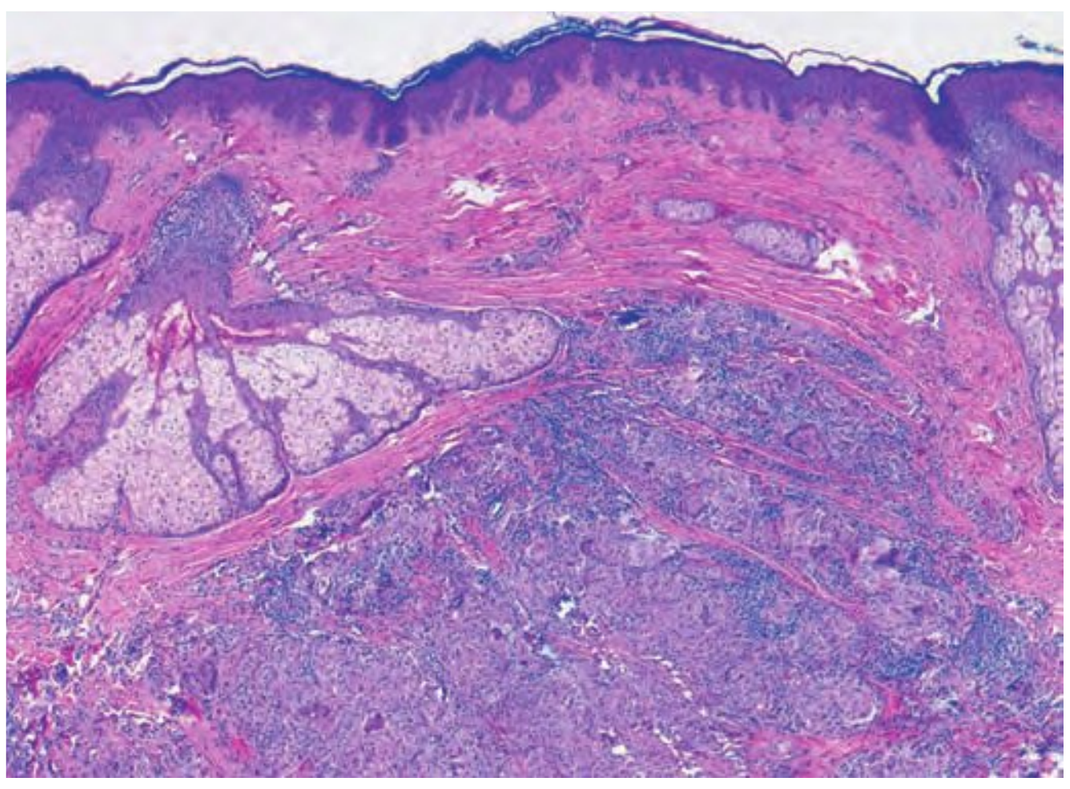

FIGURE 14-27. Foreign-body reaction. There are circumscribed, nodular collections of epithelioid histiocytes, similar to what may be seen in sarcoid, associated with knife marks (diagonally oriented in this photograph), which serve as a clue to the presence of the foreign material, which cannot be seen at this magnification.

Paraffinoma

Foreign-body reactions may occur following injections of oily substances such as mineral oil (paraffin) typically into the breasts (220), genitalia, or scalp (221) for cosmetic purposes. These occur as irregular, plaquelike indurations of the skin and subcutaneous tissue (222,223). Ulcers or abscesses may develop. The interval between the time of injection and the development of induration or ulceration may be many years.

The misleading term *sclerosing lipogranuloma* was given to paraffinoma of the male genitalia because of the disproved assumption that it was a local reactive process following injury to adipose tissue (224,225).

Histopathology. Paraffinomas have a "Swiss cheese" appearance because of the presence of numerous ovoid or round cavities that show great variation in size. These cavities represent spaces occupied by the oily substance (226). The spaces between the cavities are taken up in part by fibrotic connective tissue and in part by an infiltrate of macrophages and lymphocytes. Some of the macrophages have the appearance of foam cells. Variable numbers of multinucleated foreign-body giant cells are present.

In frozen sections of paraffinoma, the foreign material stains orange with Sudan IV or oil red O, although less so than neutral fat (226).

Silicone Granuloma

Reactions to medical-grade silicone have occurred after injection of its liquid form for cosmetic purposes or from leakage or rupture of silicone gel from breast implants. Leakage from silicone breast implants can cause development of subcutaneous nodules and plaques (227). Lesions containing silicone at sites adjacent to and, rarely, distant from areas of injection or implantation may occur (228,229). A localized reaction at injection sites by silicone-coated acupuncture or venepuncture needles has also been reported (230,231).

Histopathology. As in paraffinoma, numerous ovoid or round cavities of varying sizes are seen, resulting in a "Swiss cheese" appearance (Fig. 14-28). These spaces are what remain after the silicone has been removed during processing, although

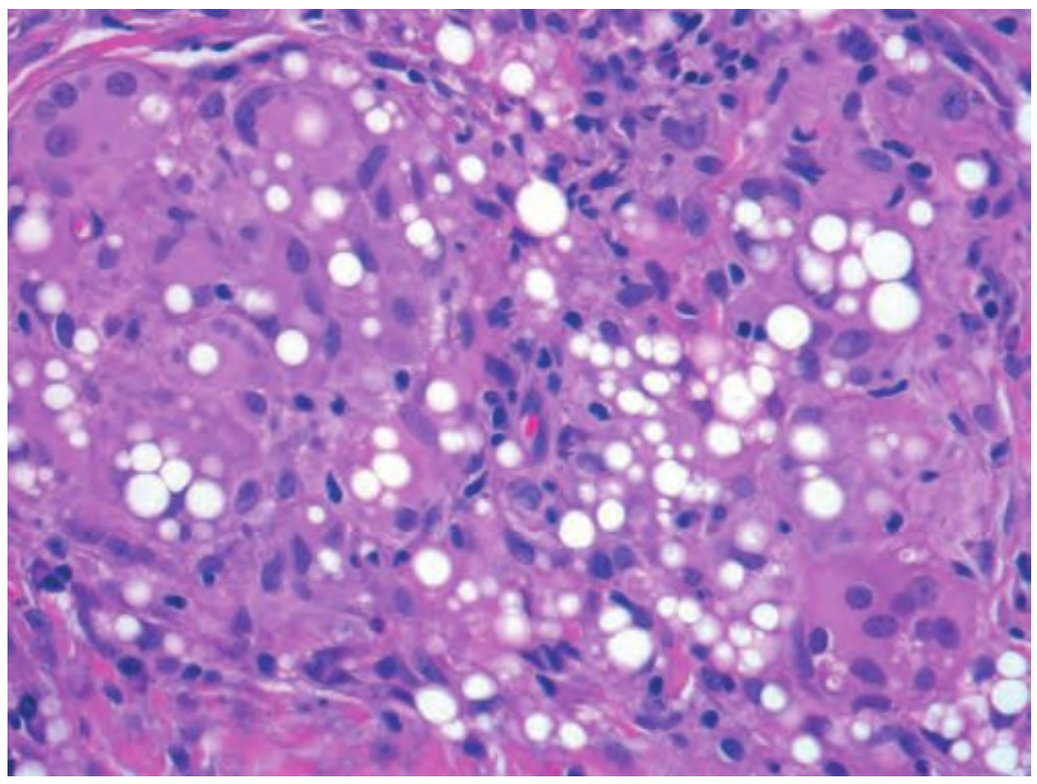

FIGURE 14-28. Silicone granuloma. Silicone used for cosmetic purposes may produce a granulomatous response with a "Swiss cheese" appearance. (Courtesy of John Walsh, MD.)

occasionally scant residual silicone is seen as colorless, irregularly shaped, refractile, nonpolarizable material within the spaces. Histiocytes may be present between the cavities; they can be foamy or multinucleated and accompanied by lymphocytes and eosinophils (227,232). In addition, varying degrees of fibrosis are present. The identification of silicone within a specimen can be facilitated via thick sectioning, dark-field microscopy, and other techniques (233).

Talc Granuloma

Talc (magnesium silicate) may produce granulomatous inflammation when introduced into open wounds. Historically, talc was used as powder on gloves, but this use has been abandoned for many years, and starch is now used for surgical dusting powder (234). However, talc may still be introduced into wounds either because of accidental contamination by a surgeon who uses talcum powder (234) or because talcum may be incorporated into the rubber glove during manufacturing (235). Talc may also be introduced into the skin through topical application of medications (236).

Histopathology. Histologic examination reveals histiocytes and multinucleated giant cells, some of which may contain visible particles of talc. Talc crystals can be needle shaped with a yellow-brown or blue-green hue and appear as white birefringent particles with polarized light (235). Their presence can be confirmed by x-ray diffraction studies (237) or energy-dispersive x-ray analysis (235).

Starch Granuloma

Granulomas may result from the contamination of wounds with surgical gloves powdered with corn starch (238).

Histopathology. A foreign-body reaction with multinucleated giant cells is present. Scattered through the infiltrate, one observes starch granules as ill-defined ovoid basophilic structures measuring 10 to 20 μm in diameter. Most of the granules are seen within foreign-body giant cells. They react with PAS and methenamine silver and, on examination in polarized light, are birefringent, showing a Maltese cross configuration (238).

Cactus Granuloma

Cactus granulomas show, within days or weeks after the injury, tender papules from which cactus spines may still protrude. They may be extruded spontaneously within a few months.

Histopathology. Early papules—a few days after the injury—show fragments of cactus spicules in the dermis that are associated with an intense, perivascular lymphohistiocytic infiltrate containing many eosinophils. After a few weeks, the infiltrate consists of lymphocytes, macrophages, and giant cells (239,240). Sharply marginated spicules are seen within giant cells and lying free in the dermis. The spicules are PAS positive (241).

Pilonidal Sinus

The pilonidal sinus is most often seen in young adult men over the sacrum (242). In barbers, the implantation of human hair in the interdigital web spaces may cause small, asymptomatic or tender sinus tracts (243,244). Similar lesions are even more common within web spaces or in other sites in dog groomers and other animal caretakers (245,246).

Histopathology. Histologic examination reveals a sinus tract lined by squamous epithelium containing one or several hairs, thus resembling a hair follicle. Either the sinus tract encases the hair completely, or, if the hair extends deeper than the sinus tract, one finds at the lower end of the hair a foreign-body giant-cell reaction intermingled with inflammatory cells (243,247).

Sea Urchin Granuloma

Injuries from the spines of sea urchins occur most commonly on the hands and feet. Even if the friable spines have been only incompletely removed, the wounds tend to heal after spontaneous extrusion of most of the foreign material (248,249). However, in some persons, violaceous nodules appear at the sites of injury after a latent period of 2 to 12 months (250).

Histopathology. The nodules are composed largely of epithelioid histiocytes and giant cells (248). Doubly refractile material is present in a minority of the granulomas (249). If remnants of a spine are still present, they are surrounded by leukocytes and many large foreign-body giant cells (249). A minority of patients show nongranulomatous findings, the most common of which is a neutrophilic infiltrate (251).

Pathogenesis. The appearance of sarcoid-like granulomas after a latent interval of months in only a small proportion of the injured patients suggests a delayed hypersensitivity reaction (250). The spines of sea urchins, in addition to the calcified material, contain remnants of epithelial cells (250). The double refraction that may be found in the granulomas may be due to the presence of a small amount of silica in the calcified spines (249).

Silica Granuloma

Silica (silicon dioxide) is present in rocks, soil, sand, and glass. It frequently contaminates accidental wounds, in which it sets up a foreign-body reaction of limited duration followed by fibrosis (252). In the vast majority of cases, silica causes no further sequelae. In exceptional cases, a granulomatous delayed hypersensitivity reaction occurs at the site of the old scar (253). The mean interval for this delayed hypersensitivity reaction is approximately 10 years, but it may be less than 1 year or more than 50 years after the original injury (254). When this reaction occurs, indurated papules or nodules develop at the site of injury.

Histopathology. In silica granuloma, there are groups of epithelioid histiocytes with a lymphocytic infiltrate that tends to be sparse (253–257). Foreign-body giant cells may be abundant or absent, and Langhans giant cells also may be present. If multinucleated histiocytes are not numerous, a picture resembling sarcoid is produced. However, the diagnosis of sarcoidosis may be excluded by clinical information and the presence, especially within giant cells, of crystalline particles varying in size from barely visible to 100 μm in length; they represent silica crystals. When examined with polarized light, these particles are doubly refractile (Fig. 14-29). The presence of silicon can be confirmed by x-ray spectrometric or energy-dispersive x-ray analysis (254,255).

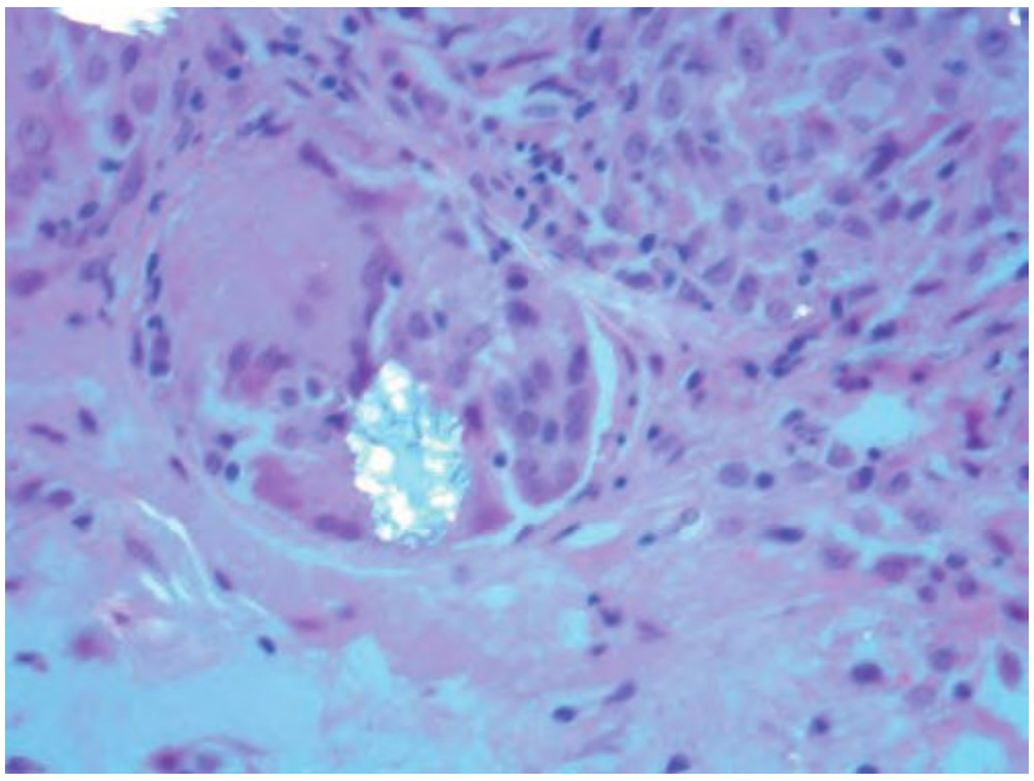

FIGURE 14-29. Silica. Silica, like other foreign materials with a crystalline structure, is doubly refractile when viewed under polarized light.

Pathogenesis. Evidence suggests that the sarcoid-like granulomatous response to silica that occurs long after initial injury represents a delayed-type hypersensitivity reaction (253,254,256,258).

Zirconium Granuloma

Deodorant sticks containing zirconium lactate and creams containing zirconium oxide may cause a persistent eruption composed of soft, red-brown papules in the areas to which they have been applied. Zirconium lactate is no longer present in antiperspirants sold in the United States; however, a granulomatous reaction has also been described in response to roll-on antiperspirant containing aluminum–zirconium complex (259,260).

Histopathology. Histologic examination shows large aggregates of epithelioid cells with a few giant cells and a sparse or moderately dense lymphocytic infiltrate, producing a picture that may be indistinguishable from sarcoidosis (261–263). Because of the small size of the zirconium particles, they cannot be detected on examination with polarized light (261). Their presence, however, can be demonstrated by spectrographic analysis (262) or energy-dispersive x-ray analysis (259).

Pathogenesis. Evidence that zirconium granulomas develop on the basis of an allergic sensitization to zirconium includes the following: (a) They occur only in persons sensitized to zirconium (264), (b) the pattern of granuloma inflammation is like that of other granulomatous dermatitides that have been attributed to delayed-type hypersensitivity reactions, and (c) autoradiographic analysis of experimentally induced lesions in sensitized individuals reveals no zirconium within histiocytes (265).

Reactions to Aluminum

Reactions to aluminum occur most often in the setting of surgical scars secondary to the use of aluminum chloride as a hemostatic agent, although these reactions are not clinically apparent. However, single or multiple persistent subcutaneous nodules may appear several months or even years after the subcutaneous injection of a variety of vaccines or allergen desensitization extracts that are aluminum adsorbed (266). The aluminum adjuvant is believed to prolong the period of activity of the vaccine or desensitization agent, thus increasing the immunologic response.

Histopathology. In surgical scars, the hemostatic agent aluminum chloride can be seen as granular violaceous-to-gray stippled deposits within macrophages (Fig. 14-30).

In subcutaneous nodules at injection sites, the most striking finding in some biopsy specimens is the presence of nodular aggregates of lymphocytes with lymphoid follicles and germinal centers within the dermis and subcutis. There is fibrosis, which may occur in bands that separate the lymphocytic nodules. Eosinophils may be prominent, and the condition may show a pseudolymphomatous appearance (267–269). The granulomatous component consists of histiocytes with ample cytoplasm and, in some cases, a few giant cells or large areas of

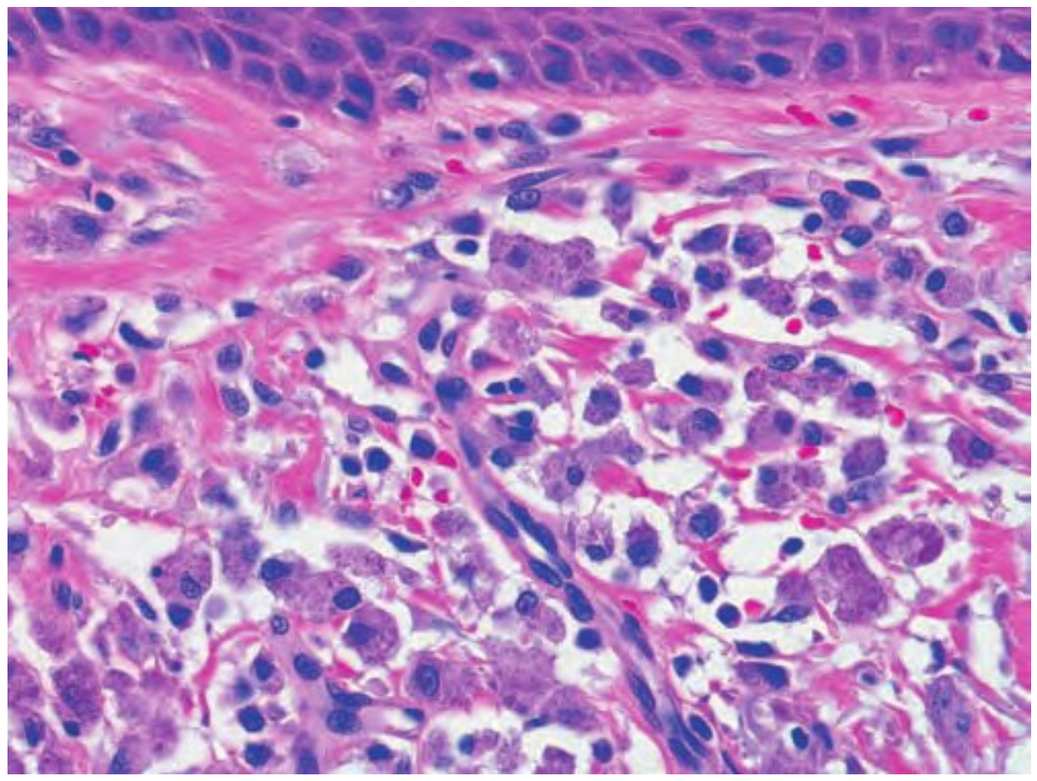

FIGURE 14-30. Aluminum chloride. Histiocytes with purplish granules as a consequence of aluminum chloride used for hemostasis during a previous procedure performed at this site.

eosinophilic necrosis surrounded by histiocytes in a palisade (268). Early lesions tend to show a reaction that is more purely granulomatous (266). Palisading granulomatous reactions have also been reported (270). There may be prominent septal and lobular inflammation of the panniculus (271). In any of the patterns that may occur, a key to making the diagnosis is the identification of histiocytes with abundant violaceous-to-gray granular cytoplasm; these granules contain aluminum and are PAS positive and diastase resistant (267).

Pathogenesis. This condition is believed to represent a delayed hypersensitivity reaction to aluminum. Electron microscopic examination reveals irregular membrane-bound, electron-dense material within macrophages. X-ray microanalysis has shown that the electron-dense material contains aluminum (267).

Titanium Granuloma

Titanium has been implicated rarely in the formation of granulomas, internally and in the skin, the latter as a consequence of body piercing (272).

Histopathology. An infiltrate of histiocytes, lymphocytes, and plasma cells is present, and some macrophages contain minute brown-black particles (272).

Zinc-Induced Granuloma

Local allergic reactions to insulin are not uncommon. However, the granulomatous response, which may occur with zinc-containing insulin preparations, is rare. It may begin with sterile furunculoid lesions (273,274).

Histopathology. The early furunculoid lesions show a dense neutrophilic infiltrate and many birefringent rhomboidal crystals of zinc insulin. Later, fibrosis and granulomatous inflammation develop (274).

Berylliosis

Beryllium granulomas are mostly of historical interest. Up to 1949, beryllium-containing compounds were widely used in the manufacture of fluorescent light tubes. Two diseases resulted from this: systemic berylliosis and local beryllium granulomas. Systemic berylliosis developed in some workers in plants manufacturing fluorescent tubes through inhalation of these compounds. Systemic berylliosis primarily shows pulmonary involvement, which results in death in about one third of the patients (275). Beryllium may reach the skin through blood circulation and cause cutaneous granulomas. However, this is a rare event, having been observed in one series in only 4 of 535 patients with systemic berylliosis (275). The granulomas consist of only a few papular lesions over which the skin remains intact.

Purely local beryllium granulomas occurred in persons who cut themselves on broken fluorescent tubes that were coated with a mixture containing zinc-beryllium silicate (276). The cutaneous granulomas after laceration show, as their first sign, incomplete healing of the laceration, followed by swelling, induration, tenderness, and, finally, central ulceration (277).

Histopathology. The cutaneous granulomas of systemic berylliosis, similar to those of sarcoidosis, show very slight or no caseation (275). The cutaneous granulomas following laceration, in contrast to the cutaneous granulomas of systemic berylliosis, show central necrosis, which may be pronounced (276). A moderately dense infiltrate of lymphocytes may be present, resembling the granulomas of tuberculosis. The epidermis shows acanthosis and possibly ulceration. No particles of beryllium are seen in histologic sections, but its presence in the lesions can be demonstrated by spectrographic analysis (277).

Pathogenesis. Systemic berylliosis develops on the basis of a delayed hypersensitivity reaction (278,279).

Tattoo Reactions

Clinically apparent inflammatory reactions to permanent tattoos, although uncommon, are now seen with greater frequency due to the rise in popularity of tattoos. They have been observed most commonly with red dyes containing mercuric sulfide, such as cinnabar (Chinese red). More recently, there has been a move away from using mercury-containing dyes toward the use of dyes containing other red pigments, such as ferric hydrate (sienna or red ochre), cadmium selenide (cadmium red), and organic dyes, but such mercury-free red dyes may also produce adverse reactions (280,281). Reactions have also been reported with chrome green (282), cobalt blue (283), purple manganese salts (284), yellow cadmium sulfide (285), and iron oxide (286). In some instances, an allergic response to the pigment has been suggested by a positive patch test.

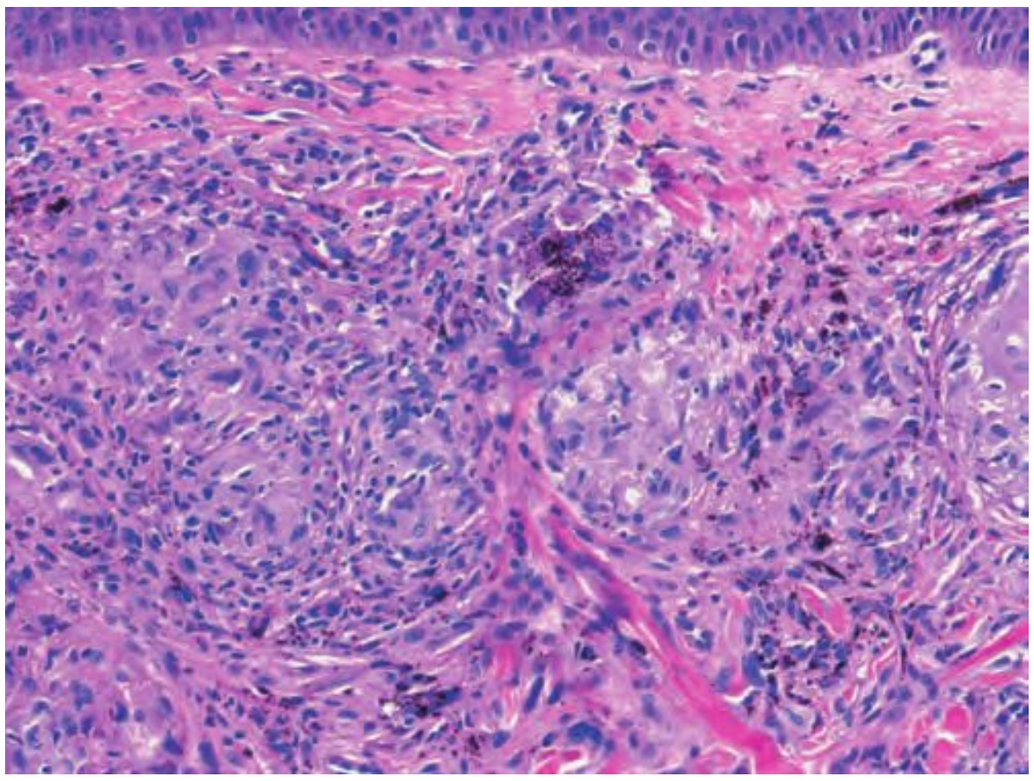

FIGURE 14-31. Decorative tattoo. Granulomatous inflammation in response to pigment used for a tattoo.

Reactions to "temporary" tattoos are rare. Usually comprised of black commercial henna, these tattoos are painted onto the skin surface. The most common reaction is allergic contact dermatitis, but a lichenoid dermatitis, a scarring reaction, and hypopigmentation have been reported (287–291).

Tattoos may also occur due to pigmented materials accidentally implanted in the skin, such as graphite, or due to solutions employed for hemostasis (292,293), particularly Monsel's solution (ferric subsulfate).

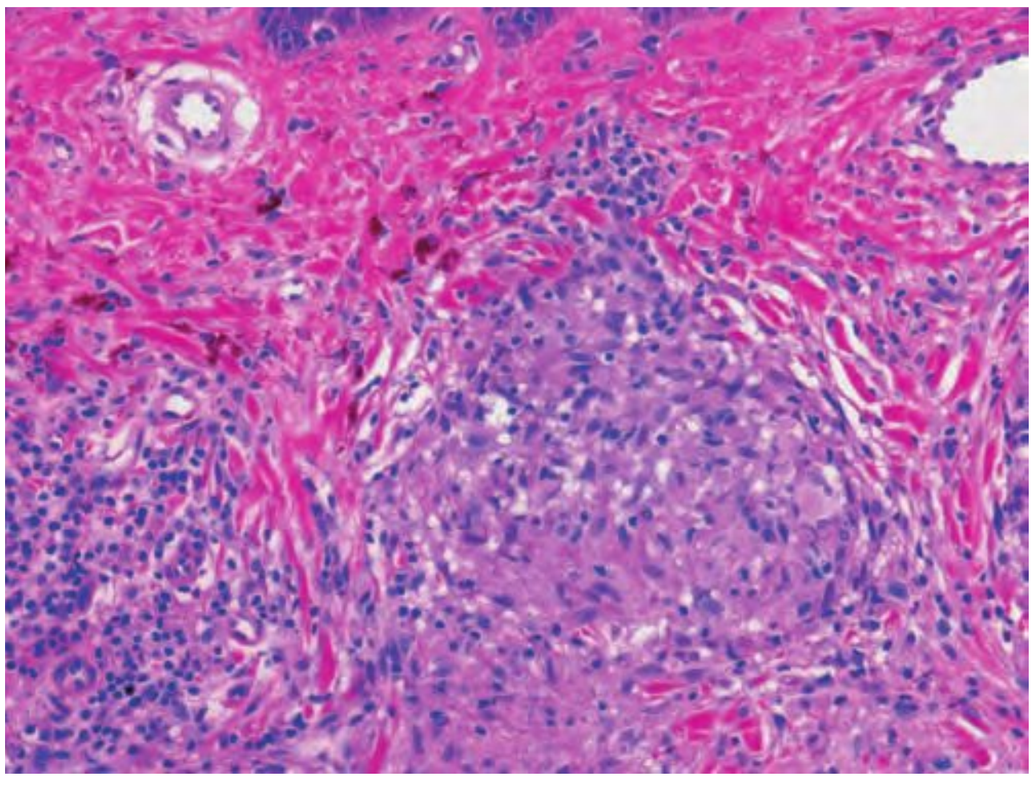
Histopathology. Permanent tattoos that are not clinically inflamed show irregularly shaped granules of dye that are located within macrophages and extracellularly in the dermis (294).

Inflammatory reactions in clinically inflamed permanent tattoos may or may not be granulomatous. Photoexacerbation has been described with reactions to red pigments (280,281) and yellow pigments (285). Nongranulomatous reactions include a perivascular lymphocytic infiltrate with pigment-containing macrophages (280,294), a lichenoid response, which in some instances may resemble lichen planus or hypertrophic lichen planus (280,281,295,296), and a pseudolymphomatous picture with a dense, nodular or diffuse, predominantly lymphocytic infiltrate that also contains histiocytes and coarse tattoo pigment granules (297,298).

Granulomatous reactions may be either of the sarcoidal type (282,299,300) or the foreign-body type (282,286). A tuberculoid pattern has also been described in response to cobalt blue, but this may have been due to a mycobacterial infection (301). The granulomatous responses show tattoo granules scattered throughout the infiltrate. In the sarcoidal type, the infiltrate contains nodules of epithelioid histiocytes (Figs. 14-31 and 14-32), and in the foreign-body type, there are obvious multinucleated histiocytes of the foreign-body type. A sparse or dense lymphocytic infiltrate may be present. In the sarcoidal type of reaction, regional lymph nodes may also show tattoo granules (302). There are some reports of patients with sarcoidal granulomas in their tattoos who also had pulmonary disease (175,299,300,303), uveitis (283,304), or erythema nodosum (299), suggesting a systemic hypersensitivity response to the tattoo, or true sarcoidosis.

Traumatic graphite tattoos show black granules free in the dermis and sometimes within histiocytes (Fig. 14-33). Monsel's tattoos, also typically seen in conjunction with scars, show multinucleate histiocytes containing coarse, brown, refractile pigment (Fig. 14-34), which is positive on staining for iron. Larger, brown, extracellular jagged aggregates of pigment are suggestive of Monsel's tattoo (305). Ferruginization of collagen bundles is typical, and a proliferation of spindled fibrohistiocytic cells may also occur.

Electron microscopic examination of tattoos without an allergic reaction shows that most tattoo granules are located within macrophages, where they often lie within membrane-bound lysosomes. In addition, some tattoo granules are found free in the dermis (306).



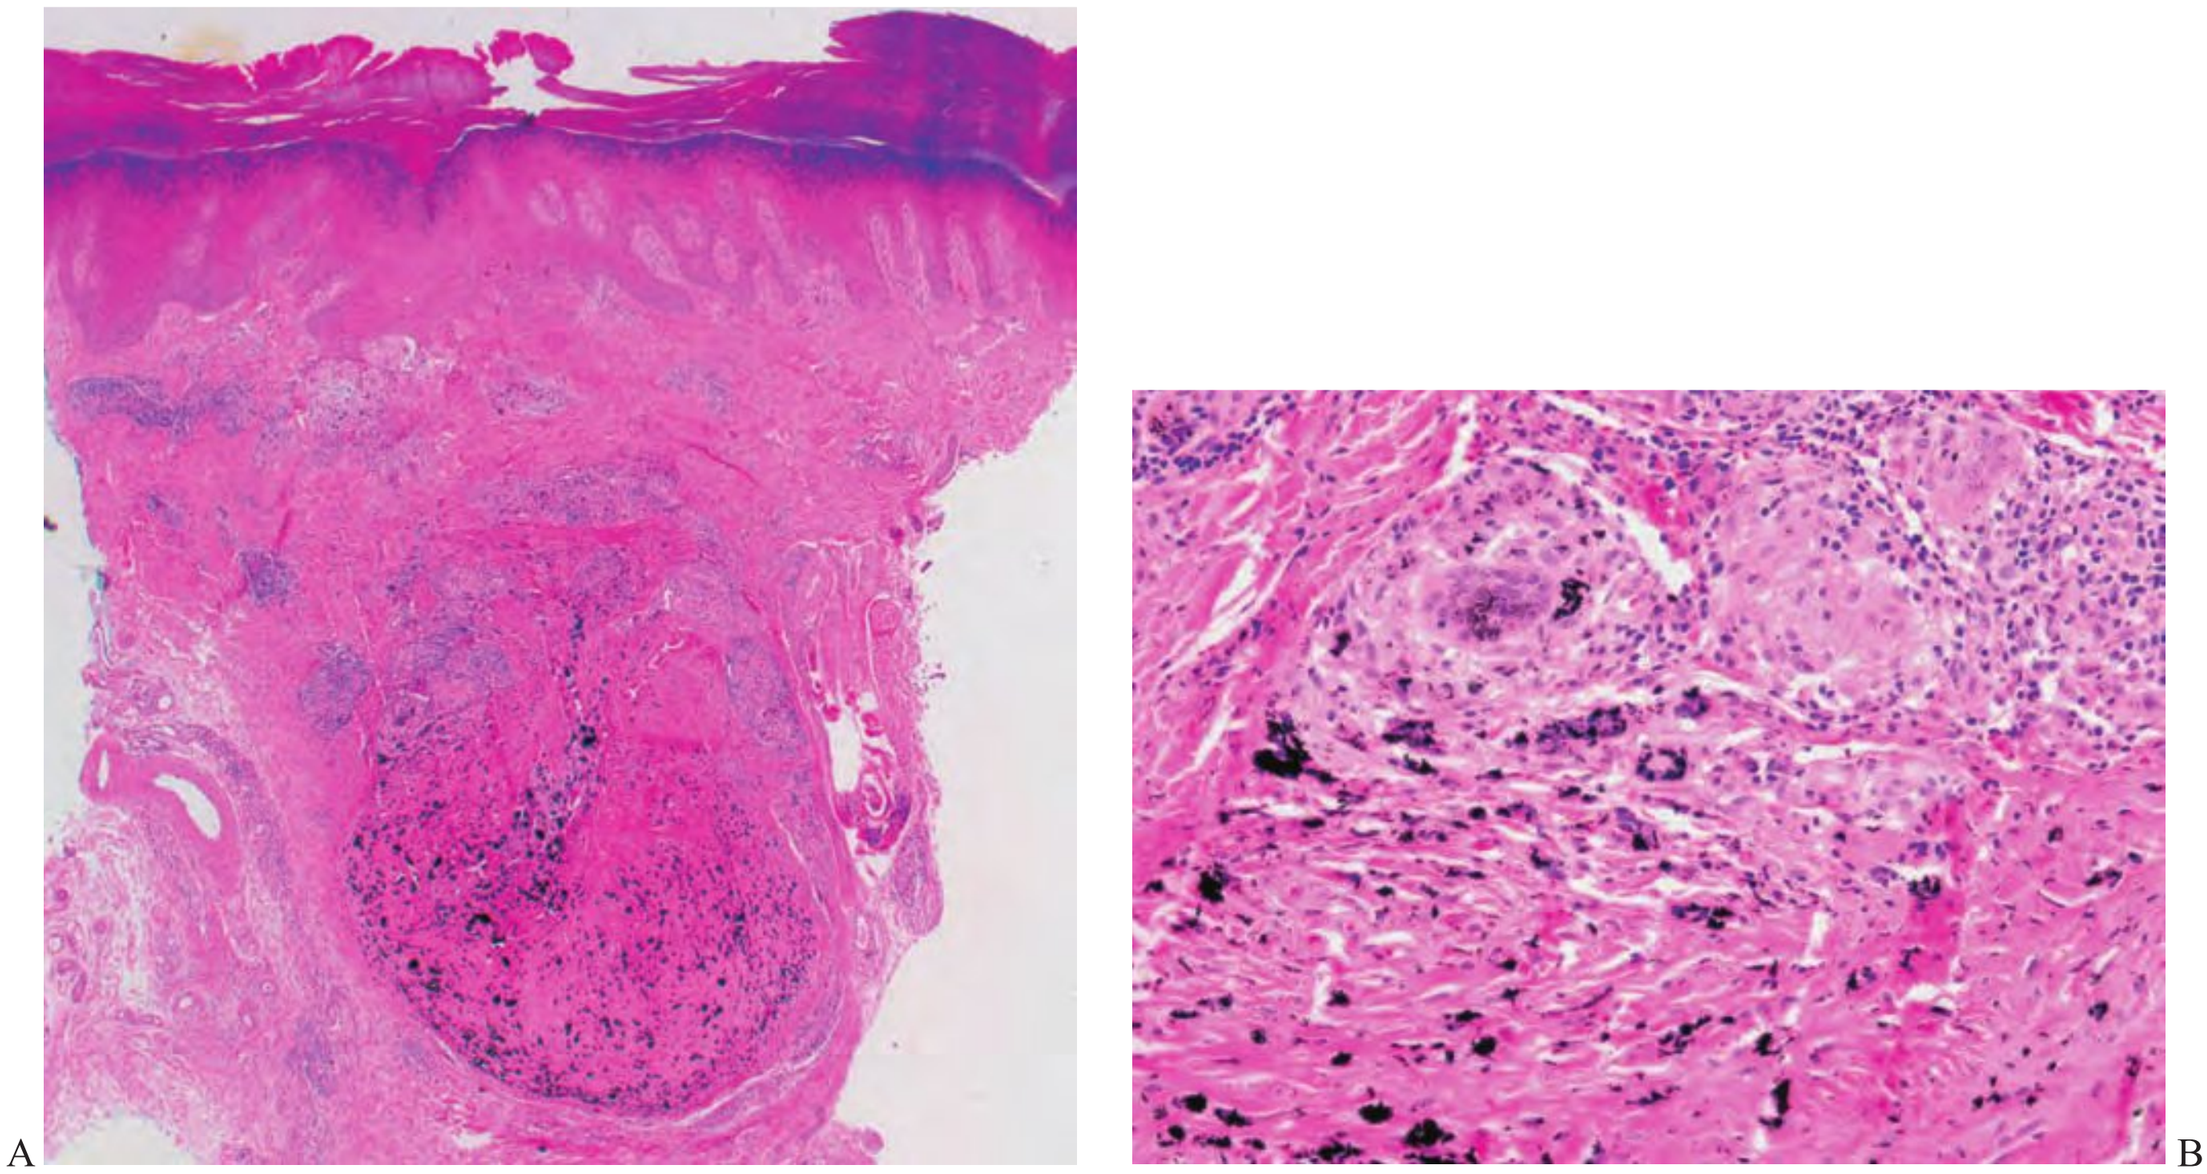


FIGURE 14-32. Decorative tattoo. Granulomatous response to a red tattoo.

Bovine Collagen Implant and Other Tissue Augmentation Materials

Injectable bovine collagen is used for cosmetic purposes, principally on the face to diminish "wrinkles," such as glabellar creases and prominent nasolabial folds. A small minority of patients develop an allergic granulomatous response at the site of injection. This response usually develops within 1 month of injection, is manifested by induration and erythema, and usually resolves spontaneously in less than 1 year (232,307). Hyaluronic acid has also been used for similar cosmetic purposes. Although it is less immunogenic, reactions to this injected material have been reported in approximately 3% of patients (308,309). Recent additions to the soft tissue augmentation armamentarium include synthetic substances such

A B

FIGURE 14-33. Traumatic tattoo from graphite. A: A circumscribed collection of black material is present in the dermis. B: The black material is darker than melanin, and the clumps have irregular shapes and sizes; some are intracellular and some are extracellular. There are also knife marks from the foreign material.

as polymethylmethacrylate (ArteFill, ArteColl) and polydimethylsiloxane (Bioplastique). Adverse reactions to these materials have been reported (310–312), with polymethylmethacrylate and silicone probably being the fillers to which reactions are most commonly encountered.

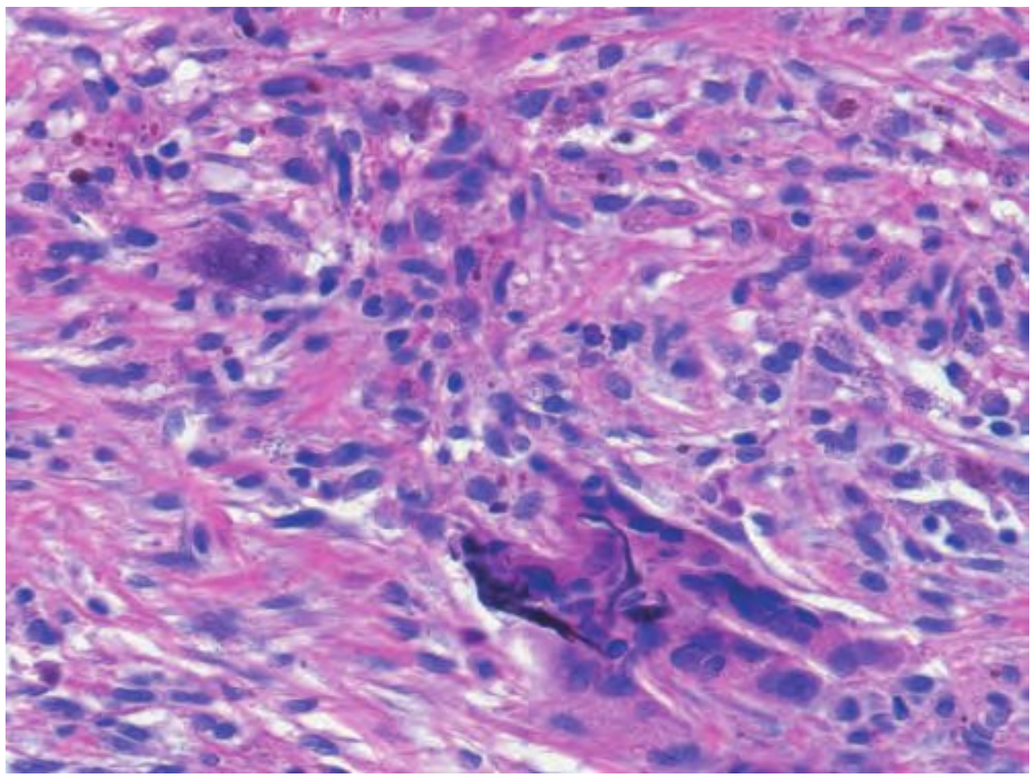

FIGURE 14-34. Monsel's tattoo. Monsel's solution may produce a granulomatous response associated with pigment that is gray-brown, with pigment sometimes in larger clumps.

Histopathology. Bovine collagen differs from native collagen by exhibiting a paler, less fibrillar appearance and by its nonbirefringence when examined with polarized light. It may lie within the center of a palisaded granuloma containing many foreign-body giant cells, or it may be associated with a more diffuse granulomatous reaction. There is a variable associated infiltrate of lymphocytes, eosinophils, plasma cells, and neutrophils that tends to spare the implanted collagen (232).

Biopsies of patients with erythematous raised areas at sites of hyaluronic acid injections have revealed a granulomatous infiltrate with prominent giant cells in most patients. A mild lymphohistiocytic infiltrate without granulomas appears to be less common (308). Polymethylmethacrylate granuloma shows numerous sharply circumscribed, seemingly empty round spaces, uniform in size and shape, mimicking normal adipocytes (310). Epithelioid histiocytes with occasional giant cells surround these spaces. Within them, on lowering the microscope condenser, one notes vaguely visible round, sharply circumscribed, translucent, nonbirefringent foreign bodies. Polydimethylsiloxane granuloma exhibits numerous irregularly shaped spaces distributed diffusely throughout a sclerotic stroma (310). At higher power, nonbirefringent foreign material is apparent within these irregularly shaped spaces, which are outlined by multinucleate giant cells. The histologic findings of other currently used fillers have been described (313–315).

Corticosteroid Deposits

Corticosteroid preparations for intralesional use are suspensions of insoluble crystalline chemicals; soluble corticosteroids are not effective for intralesional use. These suspensions may be identified histologically after injection of triamcinolone or other steroids. Sites where these deposits have been described include the skin (e.g., in keloids), the nasal mucosa, and the Achilles tendon. The material may persist at the site of injection for months or years (232,316).

Histopathology. Corticosteroid deposits are recognizable by their acellular, amphophilic, granular appearance in association with clear spaces. The spaces may represent the sites of dissolved crystals. Uncommonly, birefringent crystals can be seen with polarized light. Inflammation tends to be absent or sparse, but a palisaded granuloma may develop (316–319).

CHEILITIS GRANULOMATOSA (MIESCHER-MELKERSSON-ROSENTHAL SYNDROME)

The classic triad of Miescher-Melkersson-Rosenthal syndrome consists of recurrent labial edema, relapsing facial paralysis, and fissured tongue (320). However, not all patients have the classic triad. In a review of 220 patients, labial swelling was seen in 84%, facial palsy in 23%, and fissured tongue in 60% (320). Whereas monosymptomatic labial edema is recognized as part of the syndrome, lingua plicata by itself is not, because this is not uncommon in the general population. One occasionally observes, either in addition to or in place of swelling of the lips, swelling of the forehead, chin, cheeks, eyelids, or tongue (321,322). Submandibular or submental lymph nodes may be enlarged (323). Swelling of the buccal mucosa, gingiva, and palate also can occur (320). Chronic swelling of the vulva or of the foreskin has been described as a genital counterpart of cheilitis granulomatosa (324,325).

Histopathology. Granulomatous inflammation is not present in all biopsies of clinically involved lips (326). Sections may show simply edema, lymphangiectasia, and a predominately perivascular lymphoplasmacytic infiltrate. The infiltrate is often sparse but may be dense, producing a nodular appearance. If granulomas are present, they are noncaseating and tend to be small and scattered (Fig. 14-35). Collections of epithelioid histiocytes may be poorly circumscribed and are often associated with lymphocytes, but occasionally larger and/or "naked" tubercles are present, producing an appearance similar to that of sarcoidosis (322,323,326–330). Affected lymph nodes may also show granulomatous inflammation (331).

Pathogenesis. The cause of cheilitis granulomatosa is unknown. Idiosyncratic reactions to exogenous factors, such as food additives, have been postulated to be causal in some cases (332,333). A relationship to sarcoidosis, originally assumed by some authors (331), appears unsubstantiated. Likewise, this syndrome appears to be distinct from Crohn's disease, which may also produce granulomatous inflammation of the lip (333,334).

CHEILITIS GLANDULARIS

Cheilitis glandularis is a rare condition marked by persistent enlargement and eversion of the lower lip. Labial salivary ducts appear to be dilated and exude mucoid material or clear fluid that may be accentuated by gentle squeezing (335,336). A papular component may be present (337). Diagnosis is based primarily on clinical features (335). It has been described mostly in adults but also in children.

Histopathology. Various histologic findings have been reported, none consistently, and this condition may not represent a specific disease (see section on pathogenesis).

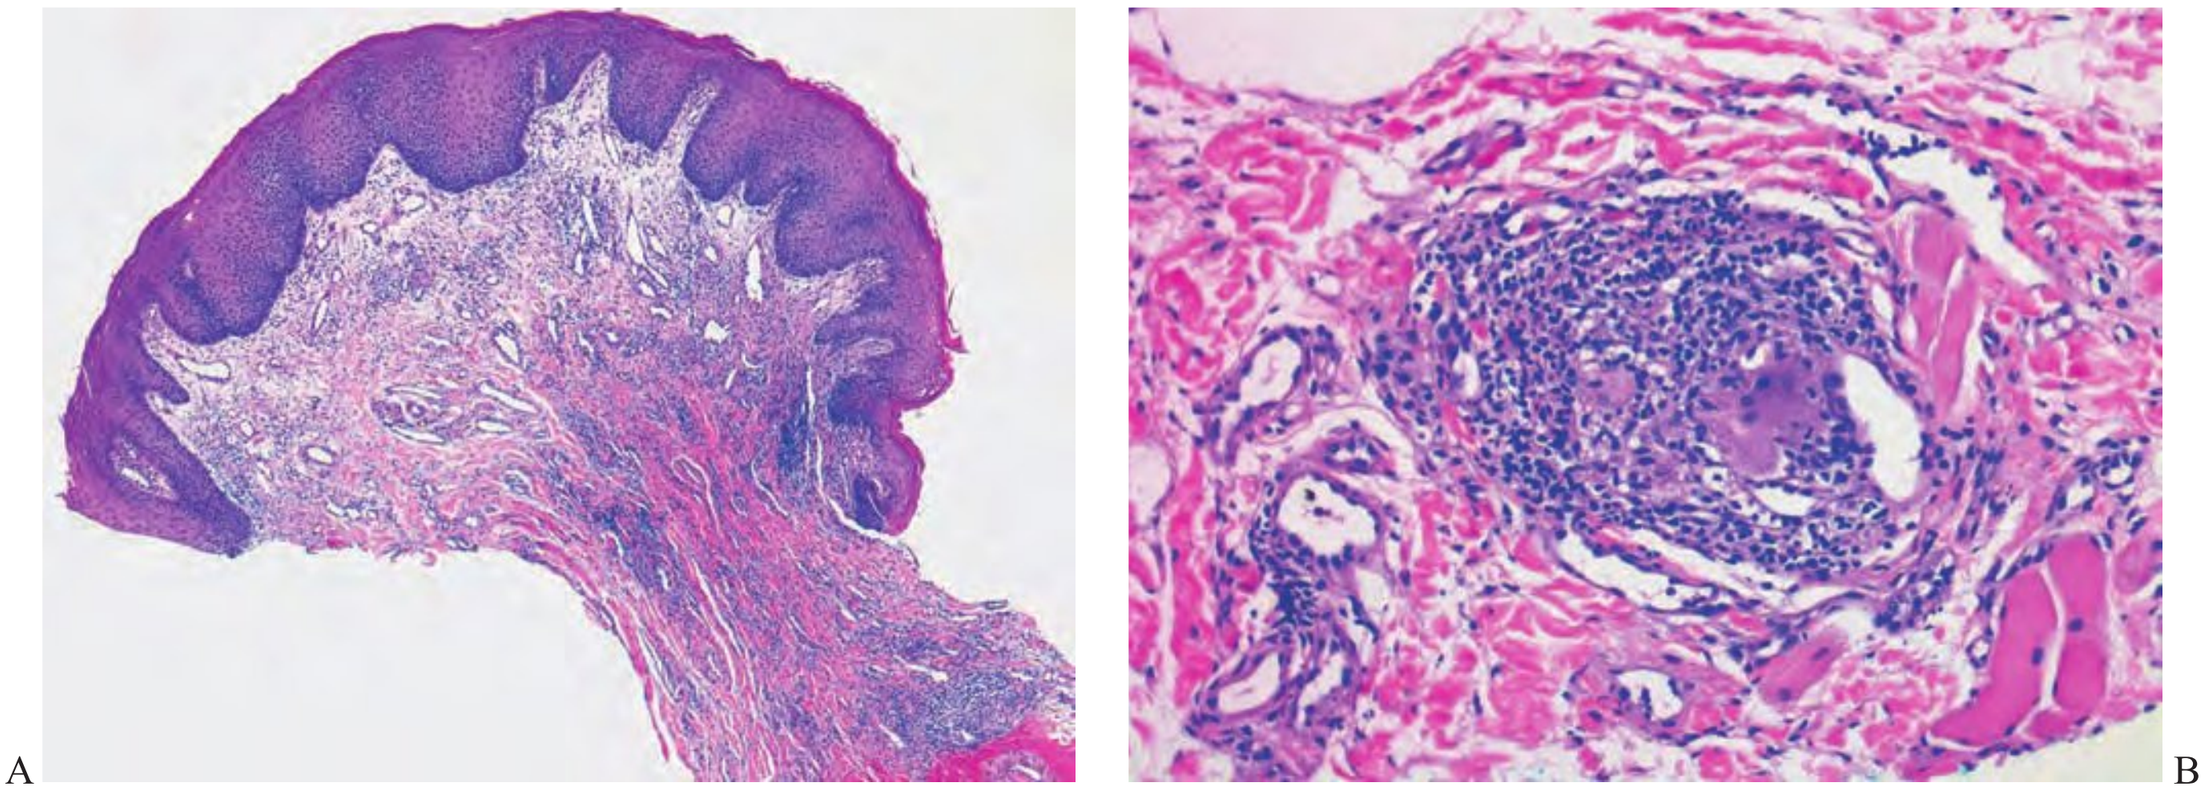

FIGURE 14-35. Cheilitis granulomatosa. A: Biopsy of lip mucosa showing slight vascular ectasia, edema, and a sparse inflammatory infiltrate including lymphocytes. B: A subtle granulomatous component.

Salivary gland hyperplasia, duct ectasia, fibrosis, and inflammation comprising lymphocytes, plasma cells, and histiocytes have been described (336,337). However, any or all of these features may be absent (335). Hyperkeratosis can also occur (335).

Pathogenesis. Cheilitis glandularis is probably caused by several different factors. Marked, chronic sun and wind exposure has been implicated as a common cause, and it has been suggested that this is not truly a disorder of salivary glands because they may appear histologically normal (335). An atopic diathesis, factitious cheilitis, and hereditary factors have also been implicated (335,337). There are older reports in the literature that describe an increased incidence of squamous cell carcinoma in association with cheilitis glandularis (338). This is probably a consequence of actinic damage, which tends to be associated with this condition and may be exacerbated by the eversion of the lip (338).

GRANULOMA GLUTEALE INFANTUM

Granuloma gluteale infantum, first described in 1971 (339), shows asymptomatic, round to oval, smooth papules and nodules irregularly distributed over regions covered by diapers (339–342). The lesions are typically reddish blue in color, ranging from a few millimeters to a few centimeters in diameter. Although usually seen in infants, this condition has also been described in incontinent adults (342,343), and a similar process with an erosive component has been reported in adults with extensive use of benzocaine (344). Although clinically this disorder may appear similar to a granulomatous condition, histologically it is not.

Histopathology. Acanthosis is usually present. A dense, mixed infiltrate is seen throughout the dermis. Lymphocytes, histiocytes, plasma cells, neutrophils, and eosinophils may all be seen (341). In addition, there may be microabscesses composed of neutrophils and eosinophils, as well as extravasation of erythrocytes together with a proliferation of capillaries (339,345). Multinucleated histiocytes or well-developed granulomas are not a feature of the infiltrate. In a few instances, staining with the PAS reaction has revealed spores and pseudohyphae consistent with the presence of *Candida albicans* in the stratum corneum (346), but fungi are often not detected.

Pathogenesis. In nearly all patients described in the literature, the development of granuloma gluteale infantum has been preceded by a diaper dermatitis, which only in some instances has been associated with a *C. albicans* infection (340,345). Topical applications of fluorinated corticosteroid preparations for a prolonged period of time and prolonged wearing of plastic diapers have been implicated, but a consistent cause has not been identified (347). It appears very likely that exogenous factors including irritants and external trauma contribute to this eruption (339,344).

MISCELLANEOUS GRANULOMATOUS LESIONS

Interstitial Granulomatous Drug Reaction

A limited number of patients have been described with annular to solid erythematous plaques on the inner arms, proximal thighs, and intertriginous areas. Implicated agents include antihypertensives, antihyperlipidemics, antihistamines, anticonvulsants, antidepressants (63), tumor necrosis factor-α inhibitors (348), and herbal medications (349).

Histopathology. An interstitial infiltrate of lymphocytes and histiocytes with slight fragmentation of collagen is reported, in conjunction with variable numbers of eosinophils and neutrophils and vacuolar interface change.

Differential Diagnosis Clinical presentation and the presence of vacuolar interface change may be helpful in distinguishing this condition from granuloma annulare and palisaded neutrophilic and granulomatous dermatitis (130).

Zoster-Related Granulomas

Following herpes zoster, patients may present with persistent reddish papules in a zosteriform distribution.

Histopathology. A variety of reaction patterns may be found in zoster-related scars. The most common granulomatous patterns are granuloma annulare–like (350) and sarcoid-like patterns.

Common Variable Immunodeficiency

Patients with common variable immunodeficiency often have multiple cutaneous warts and systemic signs and symptoms that include diarrhea, chronic/recurrent bacterial infections, hepatosplenomegaly, and lymphadenopathy. Patients may also develop periarticular subcutaneous nodules.

Histopathology. Biopsy of the nodules may show granuloma annulare-like (351), tuberculoid leprosy-like (352), sarcoid-like, and/or tuberculosis-like (353,354) granulomas.

Paraneoplastic Phenomena

Patients with hematologic malignancy may sometimes present with granulomatous lesions.

Histopathology. A spectrum of histologic findings has been described, including granuloma annulare–like, annular elastolytic–like, sarcoid-like, and tuberculoid patterns (355,356).

Degenerative Diseases and Perforating Disorders

SOLAR (ACTINIC) ELASTOSIS

Senescent changes in areas of the skin not regularly exposed to sunlight manifest themselves clinically only in thinning of the skin and a decrease in the amount of subcutaneous fat. In contrast, there are often pronounced changes in the appearance of the exposed skin of elderly persons, especially those with fair complexions. These changes, however, are the result of chronic sun exposure (photoaging) rather than of intrinsic (chronologic) aging. In exposed areas, especially on the face, the skin shows wrinkling, furrowing, and thinning. In addition, there may be an irregular distribution of pigment.

Histopathology. In skin not regularly exposed to sunlight, there is a progressive loss of elastic tissue in the papillary dermis with age. Elastic fibers in the papillary dermis are composed of elaunin and oxytalin fibers. Elaunin fibers, which consist of microfibrils and a small amount of elastin, run parallel to the dermal–epidermal junction. Overlying oxytalan fibers, composed solely of microfibrils, form a thin, superficial network perpendicular to the dermal-epidermal junction that ends at the basement membrane zone (see Chapter 3). In middle age, the oxytalan fibers in the papillary dermis are split and fewer than at a young age; in old age, they may be absent (1). Mature elastic fibers in the reticular dermis also undergo changes due to intrinsic aging, becoming fragmented and porous (2).

In the skin of the face exposed to the sun, especially in persons with fair complexions, hyperplasia of the elastic tissue is usually evident on histologic examination by the age of 30 years, even though clinically the skin may appear normal. No white person past 40 years of age has normal elastic tissue in the skin of the face (3). The elastic fibers of the reticular dermis are increased in number, and they are thicker, curled, and tangled.

In patients with clinically evident solar elastosis of the exposed skin, staining with hematoxylin-eosin reveals, in the upper dermis, basophilic degeneration of the collagen separated from a somewhat atrophic epidermis by a narrow band of normal collagen. In the areas of basophilic degeneration, the bundles of eosinophilic collagen have been replaced by amorphous basophilic granular material.

With elastic tissue stains, the areas of basophilic degeneration stain like elastic tissue and therefore are referred to as *elastotic material*. The elastotic material usually consists of aggregates of thick, interwoven bands in the upper dermis (4) (Fig. 15-1A); but in areas of severe solar degeneration, the elastotic material may have an amorphous rather than a fibrous appearance (Fig. 15-1B) and may extend into the lower portions of the dermis rather than being confined to the upper dermis (5).

On staining with silver nitrate, the distribution of melanin in the basal cell layer may appear irregular in that areas of hyperpigmentation alternate with areas of hypopigmentation (5).

Histogenesis. Electron microscopic examination of areas of solar elastosis shows elastotic material as the main component (EM 13). Even though this elastotic material resembles elastic tissue in its chemical composition, it differs significantly in appearance from aged elastic fibers in unexposed, aged skin. Instead of showing amorphous electron-lucent elastin and aggregates of electron-dense microfibrils (see Chapter 3), the thick fibers of elastotic material show two structural components: a fine granular matrix of medium electron density and, within this matrix, homogeneous, electron-dense, irregularly shaped inclusions (6). Microfibrils such as those observed in normal or aged elastic fibers are absent. Immunoelectron microscopy shows that the elastotic material has retained its antigenicity for elastin but not for microfibrils (7). The number and size of elastotic fibers are greatly increased over the number and size of elastic fibers found in normal or aged skin. Extensive amorphous material can be seen around the elastotic fibers and also among the collagen fibrils. Collagen fibrils are diminished in number, with those present often showing a diminished electron density, a diminished contrast in cross striation, and a splitting up into filaments at their ends (8).

Elastotic material is not regarded as a degeneration product of preexisting elastic fibers. Most current findings indicate that elastotic material is composed primarily of elastic tissue, much of which may be newly formed as the result of an altered function of fibroblasts. Evidence of transcriptional activation of the elastin gene in biopsied tissue and fibroblast cultures from sun-damaged skin further supports this. Additional accumulation of elastotic material may be secondary to a disruption of the balance between synthesis and degradation of elastin in photodamaged skin (9).

The elastotic material that histochemically stains like elastic tissue resembles elastic tissue in its chemical composition and its physical and enzymatic reactions. Thus, the amino acid composition of the elastotic tissue resembles that of elastin and differs significantly from that of collagen. In particular, the

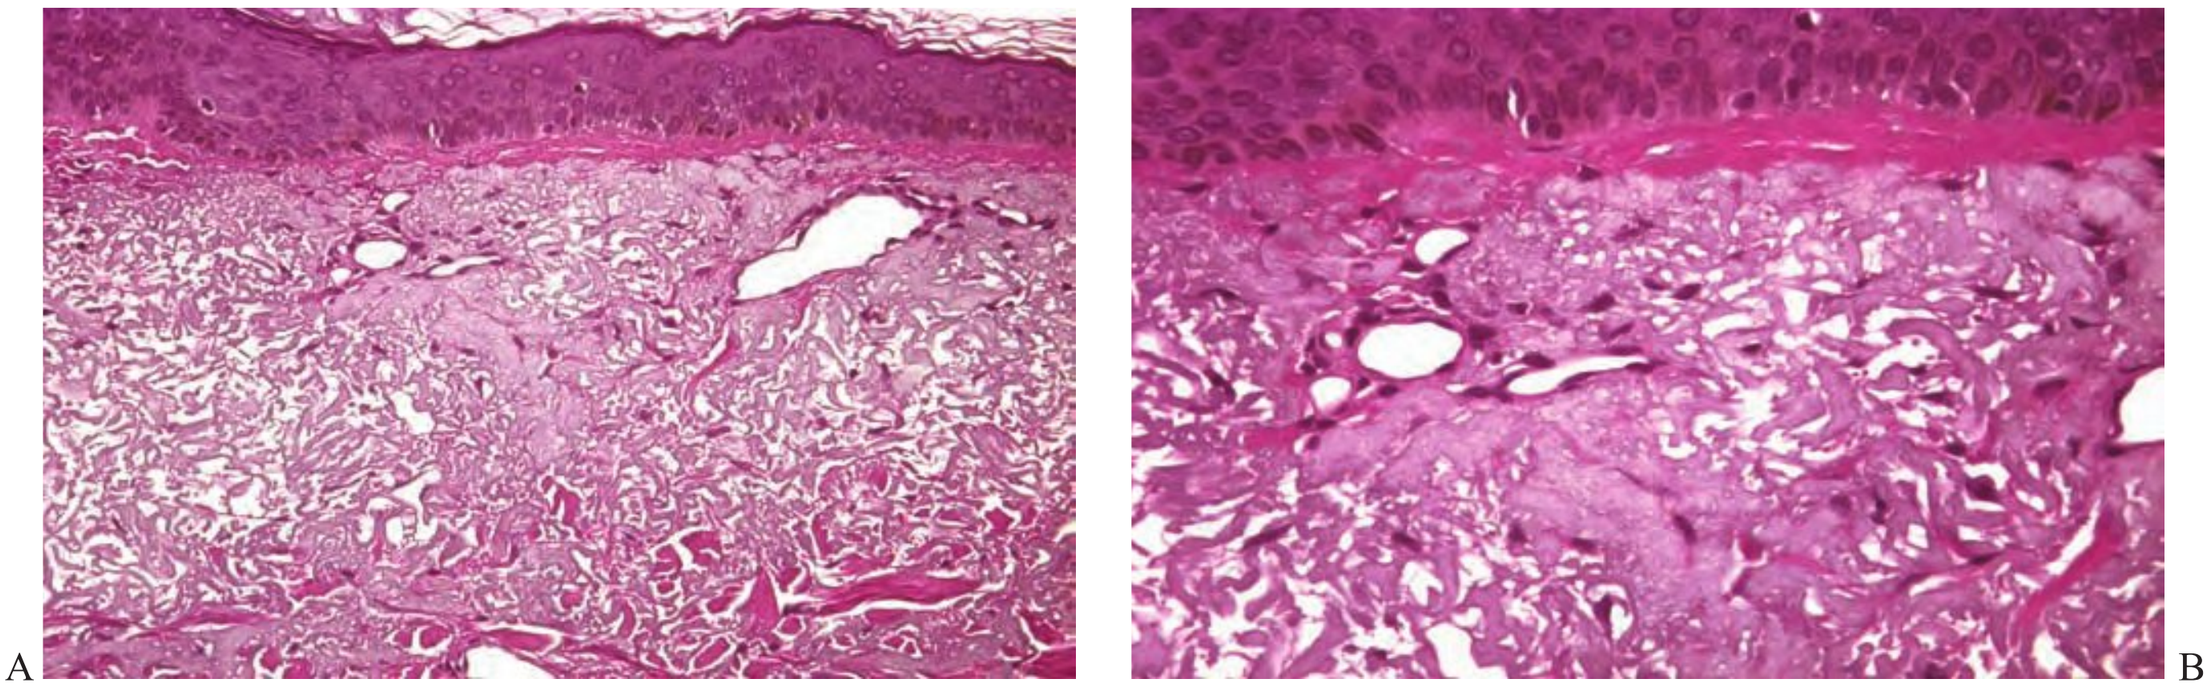

FIGURE 15-1. Solar (actinic) degeneration. A: In the upper dermis, separated from the epidermis by a narrow band of normal collagen, there are aggregates of thick, interwoven bands of the elastotic material. B: Extensive amorphous material can be seen around and among elastic and collagen fibers.

elastotic material, like elastic tissue, has a much lower content of hydroxyproline than collagen (10). Moreover, the elastotic material in unfixed sections shows the same brilliant autofluorescence as do elastic fibers on examination with the fluorescence microscope (11), and both the elastotic material and elastic tissue are susceptible to elastase digestion (12). The elastotic material contains a large amount of acid mucopolysaccharides, as indicated by staining with Alcian blue. A significant portion of these acid mucopolysaccharides may be sulfated because prior incubation with hyaluronidase removes only 50% to 75% of the Alcian blue–positive staining. The basophilia of the elastotic material, however, is not affected by incubation with hyaluronidase (13).

The irregular distribution of melanin in the epidermis observed in some patients with solar degeneration, when studied by electron microscopy, is found to be caused largely by an impairment of pigment transfer from melanocytes to keratinocytes. Although some keratinocytes contain many melanosomes, others contain few or no melanosomes. The latter are surrounded by dendrites laden with melanosomes (14).

Differential Diagnosis. For a discussion of differentiation of solar elastosis from pseudoxanthoma elasticum (PXE), see Chapter 3 and 6.

LOCALIZED EXPRESSIONS OF SOLAR ELASTOSIS

Several clinically distinct forms of localized solar elastosis have been described. In the nuchal region, the skin, after many years of exposure to the sun, may appear thickened and furrowed. This is referred to as *cutis rhomboidalis nuchae*. *Elastotic nodules of the ears* are localized papular and nodular forms of solar elastosis that usually occur on the antihelix (15–18). Severe solar elastosis may also occur as yellowish plaques associated with small cysts and comedones. *Favre-Racouchot syndrome (nodular elastosis with cysts and comedones)* is an example occurring on facial skin lateral to the eyes (19,20). A similar condition occurring on the arms has been termed *actinic comedonal plaques* (21–23). Two other types of circumscribed solar elastosis occurring on the upper extremities are *solar elastotic bands of the forearm* (4,24) and *collagenous and elastotic marginal plaques of the hands* (25–32).

Elastotic Nodules of the Ears

Elastotic nodules are most often seen on the anterior crus of the antihelix (15,16,18) and occasionally on the helix of the ears (17). They are often bilateral. Clinically, they may mimic basal cell carcinomas, amyloidosis, gouty tophi, or chondrodermatitis nodularis helicis (15–18).

Histopathology. Irregular elastotic fibers and clumps of elastotic material are seen in the background of marked dermal solar elastosis (Fig. 15-2A). The fibers and clumps can be highlighted with a Verhoeff–van Gieson elastic stain (17) (Fig. 15-2B).

Favre-Racouchot Syndrome (Nodular Elastosis with Cysts and Comedones)

Favre-Racouchot syndrome is characterized by yellow plaques with multiple open and cystically dilated comedones. The condition typically affects the skin lateral to the eyes in elderly males (19,20,41). However, a case has also been documented on the shoulder (33). Although the condition is usually bilateral, it may be unilateral (34–36). It is thought to be primarily secondary to prolonged solar exposure with the formation of comedones facilitated by an extracellular matrix of compromised structural integrity (2). Smoking may also be a contributing factor in its development (37).

Histopathology. Dilated pilosebaceous openings and large, round, cystlike spaces are lined by a flattened epithelium and

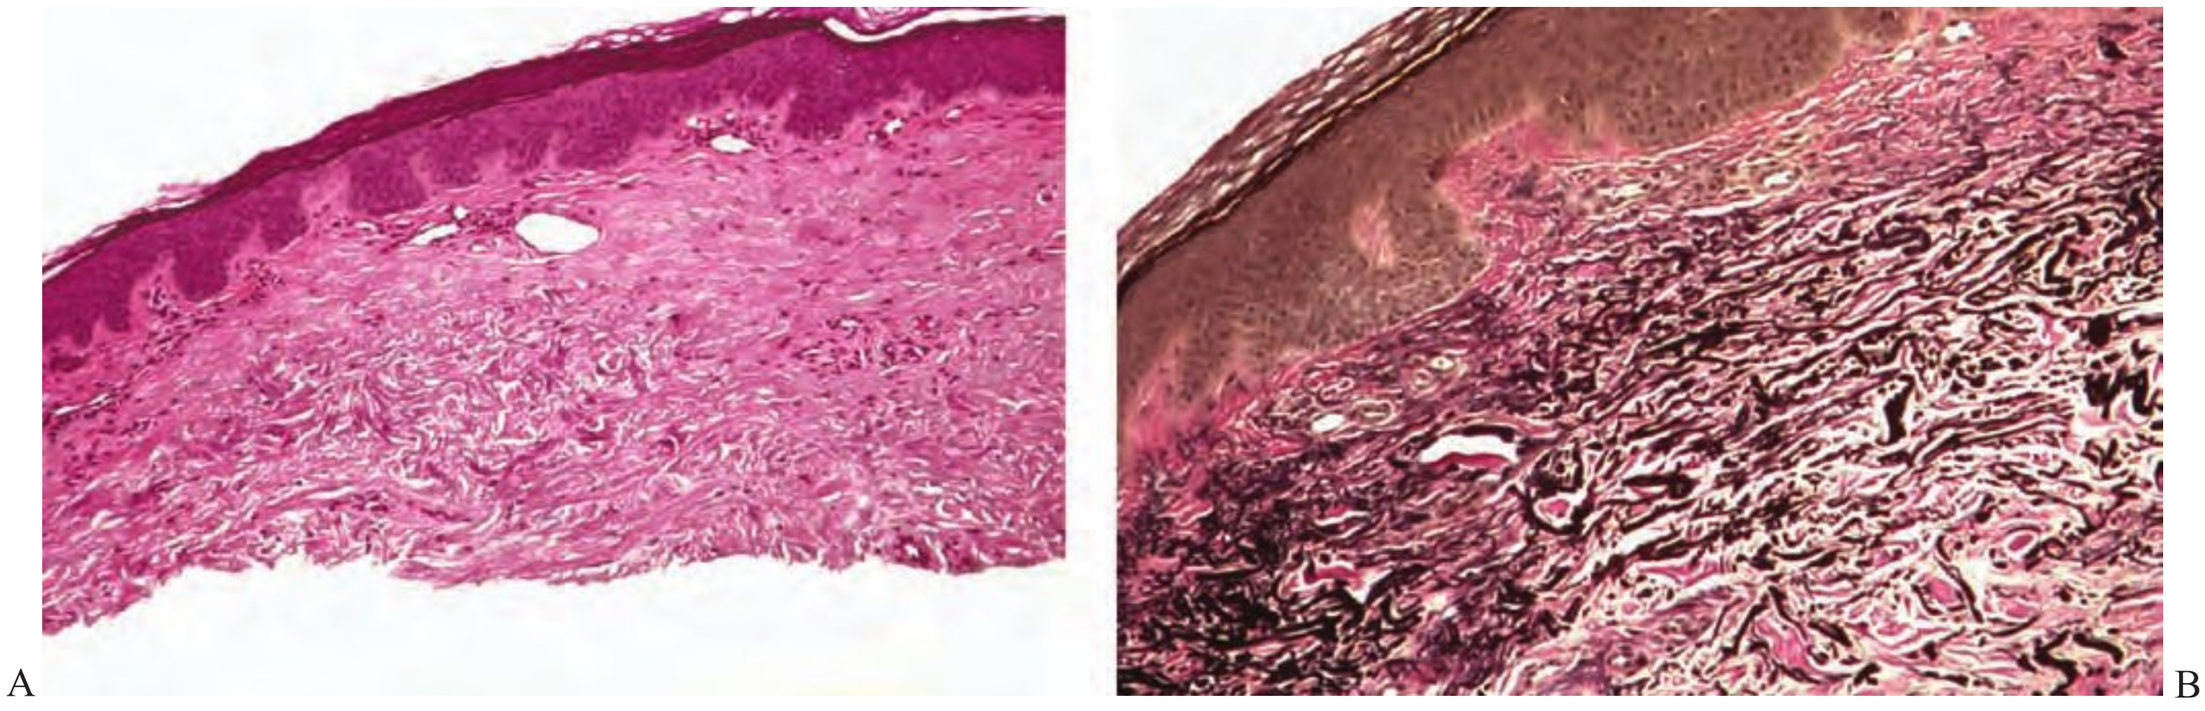

FIGURE 15-2. Elastotic nodule of the ear. A: A dome-shaped papule with marked solar elastosis in the dermis and clumped and irregular eosinophilic material representing degenerated elastic fibers. B: The coarse, clumped material is highlighted with an elastic stain.

represent greatly distended hair follicles (19,20). Both the dilated pilosebaceous openings and the cystlike spaces are filled with layered horny material. Vellus hair shafts and bacteria have been demonstrated within the spaces as well, suggesting that the cystlike spaces may represent closed comedones rather than true infundibular cysts (38). The sebaceous glands are atrophic. Solar elastosis often is pronounced (19), but it may be slight or absent (39). Because the comedones are open, they do not tend to become inflamed (40) (see section on acne vulgaris, Chapter 18).

Actinic Comedonal Plaques

In actinic comedonal plaques, solitary nodular plaques with a cribriform appearance and comedone-like structures occur, often unilaterally, on the arms or forearms (21–23). The plaques are composed of confluent erythematous to bluish papules and nodules. The condition has been described in fair-skinned individuals with a history of chronic sun exposure. They can be found in association with Favre-Racouchot syndrome and may in fact represent an ectopic expression of this entity (22).

Histopathology. Dilated corneocyte-filled follicular lumina are present within areas of elastotic, amorphous material. The overlying epidermis is usually dyskeratotic and atrophic. The histologic findings are quite similar to those seen in Favre-Racouchot syndrome (21,22).

Solar Elastotic Bands of the Forearm

Solar elastotic bands of the forearm consist of soft cordlike plaques across the flexor surface of the forearms (4,24). The bands occur in areas of actinic damage and usually with senile purpura.

Histopathology. Nodular collections of basophilic homogenous amorphous material underlying an atrophic epidermis are conspicuous features. Thickened degenerated elastic fibers within the homogenous material are also observed. Stellate fibroblasts and a perivascular infiltrate of lymphocytes and hemosiderin-laden macrophages are found in close apposition to the elastic fibers. The nodular collections and thickened elastic fibers stain positively with Verhoeff–van Gieson elastic stain (4).

Collagenous and Elastotic Marginal Plaques of the Hands

Collagenous and elastotic marginal plaques of the hands have been described by several names: *elasto-collagenous plaques of the hands* (25), *degenerative collagenous plaques of the hands* (26,28), and *keratoelastoidosis marginalis* (27). This acquired, slowly progressive condition is usually seen in elderly males and consists of groups of linear confluent papules along the medial and lateral aspects of the hands at the juncture of the palmar and dorsal surfaces. The medial aspect of the thumb and radial aspect of the index finger are most commonly affected. The condition closely resembles the genodermatosis, *acrokeratoelastoidosis* (30). However, there is no familial predisposition or involvement of the plantar surfaces. Actinic damage and chronic repetitive pressure or trauma has been implicated in its pathogenesis (27,42,43).

Histopathology. The reticular dermis displays an acellular zone of haphazardly arranged collagen with some bundles running perpendicular to the epidermis (28). The bundles of collagen are admixed with fragmented elastic fibers and distinctive angulated amorphous "basophilic elastotic masses" in the upper dermis. These masses can be demonstrated to contain degenerating elastic fibers and calcium (29).

PERFORATING DISORDERS

The perforating disorders comprise a group of disorders sharing the common characteristic of transepidermal elimination

(TEE). This phenomenon is characterized by the elimination or extrusion of altered dermal substances and, in some cases, by such material behaving as foreign material.

Traditionally, four diseases have been included in this group: *Kyrle's disease* (hyperkeratosis follicularis et parafollicularis in cutem penetrans), *perforating folliculitis*, *elastosis perforans serpiginosa* (EPS), and *reactive perforating collagenosis* (RPC). A fifth entity, acquired perforating dermatosis (APD), which is usually associated with renal disease and/or diabetes mellitus, in which clinical and histologic findings may resemble any of these four diseases, has been added to this group (44). Although TEE is a prominent feature in all of these conditions, it has also been described as a secondary phenomenon in other entities, including such inflammatory disorders as granuloma annulare, one variant of PXE, and chondrodermatitis nodularis helicis. Elastic fibers can be transepidermally eliminated overlying sites of healing wounds. Collagen may be eliminated through keratoacanthomas (45). Needless to say, there is a long list of other conditions that can exhibit TEE as an associated reaction pattern.

Kyrle's Disease

Kyrle's disease is a rare disorder, described by Kyrle in 1916 (46). There is controversy as to whether it represents a distinct entity, an exaggerated form of perforating folliculitis (46,47), or actually comprises a group of disorders with similar epidermal–dermal reaction patterns associated with chronic renal failure, diabetes, prurigo nodularis, and even keratosis pilaris. Therefore, the discussion of Kyrle's disease and perforating disorders seen in chronic renal disease and/or diabetes has a very broad overlap in terms of their clinical and pathologic features.

Clinical Features. This eruption presents with a large number of papules, some coalescing into plaques, numbering in the hundreds and often distributed on the extremities. Although some may appear to involve the follicular units, these lesions are more likely to be extrafollicular. The typical patient is young to middle aged and often has a history of diabetes mellitus. The papules are dome shaped, 2 to 8 mm in diameter, with a central keratotic plug. Excoriations often are found in the vicinity of these lesions. Linear lesions related to possible koebnerization have been described.

Histopathology. The essential histopathologic findings include (a) a follicular or extrafollicular cornified plug with focal parakeratosis embedded in an epidermal invagination, (b) basophilic degenerated material identified in small collections throughout the plug with absence of demonstrable collagen and elastin, (c) abnormal vacuolated and/or dyskeratotic keratinization of the epithelial cells extending to the basal cell zone, (d) irregular epithelial hyperplasia, and (e) an inflammatory component that is typically granulomatous with small foci of suppuration (Fig. 15-3). In most instances, it is important to perform elastic tissue stains and even trichrome stains to exclude perforating elastic fibers, as in elastosis perforans serpiginosa, or collagen fibers, as in RPC (48).

FIGURE 15-3. Kyrle's disease. A large parakeratotic plug containing basophilic debris lies within an invagination of the epidermis. The underlying dermis displays acute and chronic inflammation.

Histogenesis. The primary event is claimed to be a disturbance of epidermal keratinization characterized by the formation of dyskeratotic foci and acceleration of the process of keratinization. This leads to the formation of keratotic plugs with areas of parakeratosis (49–51). Because the rapid rate of differentiation and keratinization exceeds the rate of cell proliferation, the parakeratotic column gradually extends deeper into the abnormal epidermis, leading in most cases to perforation of the parakeratotic column into the dermis. Perforation is not the cause of Kyrle's disease, as originally thought (46), but rather represents the consequence or final event of the abnormally sped-up keratinization. This rapid production of abnormal keratin forms a plug that acts as a foreign body, penetrating the epidermis and inciting a granulomatous inflammatory reaction. A certain similarity exists between the parakeratotic column in Kyrle's disease and that observed in porokeratosis of Mibelli (50). In both conditions, a parakeratotic column forms as the result of rapid and faulty keratinization of dyskeratotic cells, but, whereas in Kyrle's disease the dyskeratotic cells are often used up so that disruption of the epithelium occurs, the clone of dyskeratotic cells can maintain itself in porokeratosis Mibelli by extending peripherally.

Differential Diagnosis. See Table 15-1.

Perforating Folliculitis

Perforating folliculitis is a perforating disorder that has many features overlapping with Kyrle's disease and also comprises one of the clinical and histologic patterns seen in APD. As

TABLE 15-1 Differential Diagnoses of Perforating Disorders

Disease	Primary defect	Distinctive features	Histogenesis
Kyrle's disease	Focus of dyskeratotic rapidly proliferating cells in the epidermis	Follicular or extrafollicular cornified plug embedded in an epidermal invagination associated with epithelial hyperplasia and absence of demonstrable collagen and elastin	Disturbance of keratinization, forming a plug that acts as a foreign body penetrating the epidermis and inciting a granulomatous inflammatory reaction
Perforating folliculitis	Hyperkeratotic plug in follicular unit containing a retained hair	Compact ortho- and parakeratotic plug with degenerated collagen, altered elastin, and mixed inflammatory cell infiltrate including neutrophils	A primary irritant causing follicular hyperkeratosis resulting in a mechanical breakdown of the follicle wall by the hair shaft
Elastosis perforans serpiginosum	Formation of numerous coarse elastic fibers in the superficial dermis	Formation of narrow channel through an acanthotic epidermis with elimination of eosinophilic elastic fibers	Thickened elastic fibers act as mechanical irritants or "foreign bodies"
Reactive perforating collagenosis	Subepidermal focus of altered collagen caused by trauma	Formation of cup-shaped vertically oriented channel with transepidermal elimination of degenerated collagen	Histochemically altered collagen acts as "foreign body"
Acquired perforating disorder	Chronic rubbing due to pruritis, resulting in hyperkeratosis, keratosis, and perforation, possibly in association with other factors such as accumulation of poorly dialyzable substances	A combination of features similar to any of the above disorders	Exogenously altered skin in pruritic diabetics and patients with chronic renal disease

described by Mehregan and Coskey (52), this is a relatively uncommon disorder that usually is observed in the second to fourth decades of life and is characterized by erythematous follicular papules with central keratotic plugs. The lesions are 2 to 8 mm in diameter and tend to be localized to the extensor surfaces of the extremities and the buttocks. The key to making this diagnosis is the clinical and histologic identification of a follicular unit as the primary site for the inflammatory process.

Histopathology. The main pathologic abnormalities consist of (a) a dilated follicular infundibulum filled with compact ortho and parakeratotic cornified cells (Fig. 15-4A); (b) degenerated basophilic staining material, comprised of granular nuclear debris from nuclear neutrophils, other inflammatory cells, and degenerated collagen bundles (Fig. 15-4B); (c) one or more perforations through the follicular epithelium; and (d) an associated perifollicular inflammatory cell infiltrate composed of lymphocytes, histiocytes, and neutrophils. Additionally, altered collagen and refractile eosinophilically altered elastic fibers are found adjacent to the sites of perforation. When serial sections through the specimen are examined, a remnant of the hair shaft can sometimes be found.

Histogenesis. Perforating folliculitis is the end result of abnormal follicular keratinization that most likely is caused by irritation, either chemical or physical, and even chronic rubbing. A portion of a curled-up hair is often seen close to or within the area of perforation or even in the dermis, surrounded by a foreign body granuloma (51).

Differential Diagnosis. In Kyrle's disease, the keratinous plug may be extrafollicular, the perforation usually is present deep in the invagination at the bottom of the keratinous plug, and no eosinophilic degeneration of elastic fibers is found. In addition, epithelial hyperplasia is a significant feature. For a discussion of the differential diagnosis of perforating folliculitis from EPS, see the following section on differential diagnosis for EPS. See also Table 15-1.

Elastosis Perforans Serpiginosa

EPS is the most distinctive of the perforating disorders because it demonstrates the best example of TEE. In EPS, increased numbers of thickened elastic fibers are present in the upper dermis, and altered elastic fibers are extruded through the epidermis. It is a rare disorder that affects young individuals, with a peak incidence in the second decade. Men are affected more often than women. EPS is primarily a papular eruption localized to one anatomic site and most commonly affecting the nape of the neck, the face, or the upper extremities. The

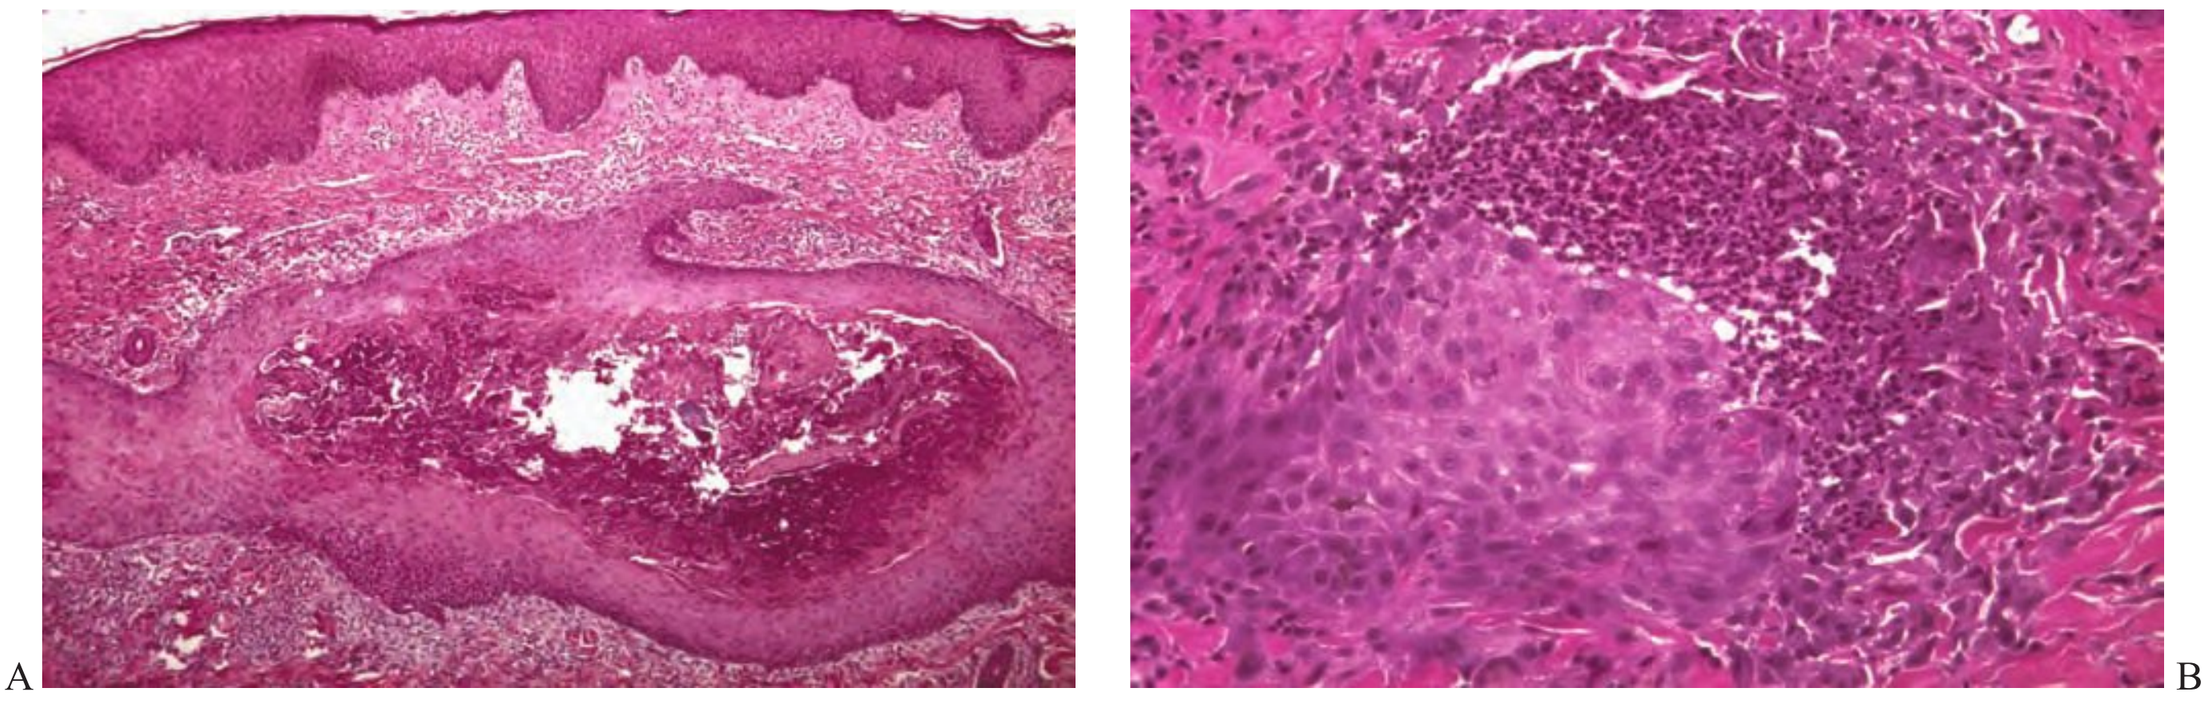

FIGURE 15-4. Perforating folliculitis. A: A widely dilated follicular unit contains a mixture of keratin, basophilic debris, inflammatory cells, and degenerated collagen fibers. B: An area of disrupted follicular epithelium with adjacent associated perifollicular inflammation and alteration of collagen and elastic fibers.

papules are typically 2 to 5 mm in diameter. These papules are arranged in arcuate or serpiginous groups and may coalesce.

Of particular importance is the association of EPS with systemic diseases. The important associations include Down's syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, PXE, and Marfan's syndrome. In addition, on rare occasions, EPS is observed in association with Rothmund-Thompson syndrome or other connective tissue disorders and as a secondary complication of penicillamine administration.

Histopathology. The essential findings include a narrow transepidermal channel that may be straight, wavy, or of corkscrew shape and thick, coarse elastic fibers in the channel admixed with granular basophilic staining debris (Fig. 15-5A, B). A mixed

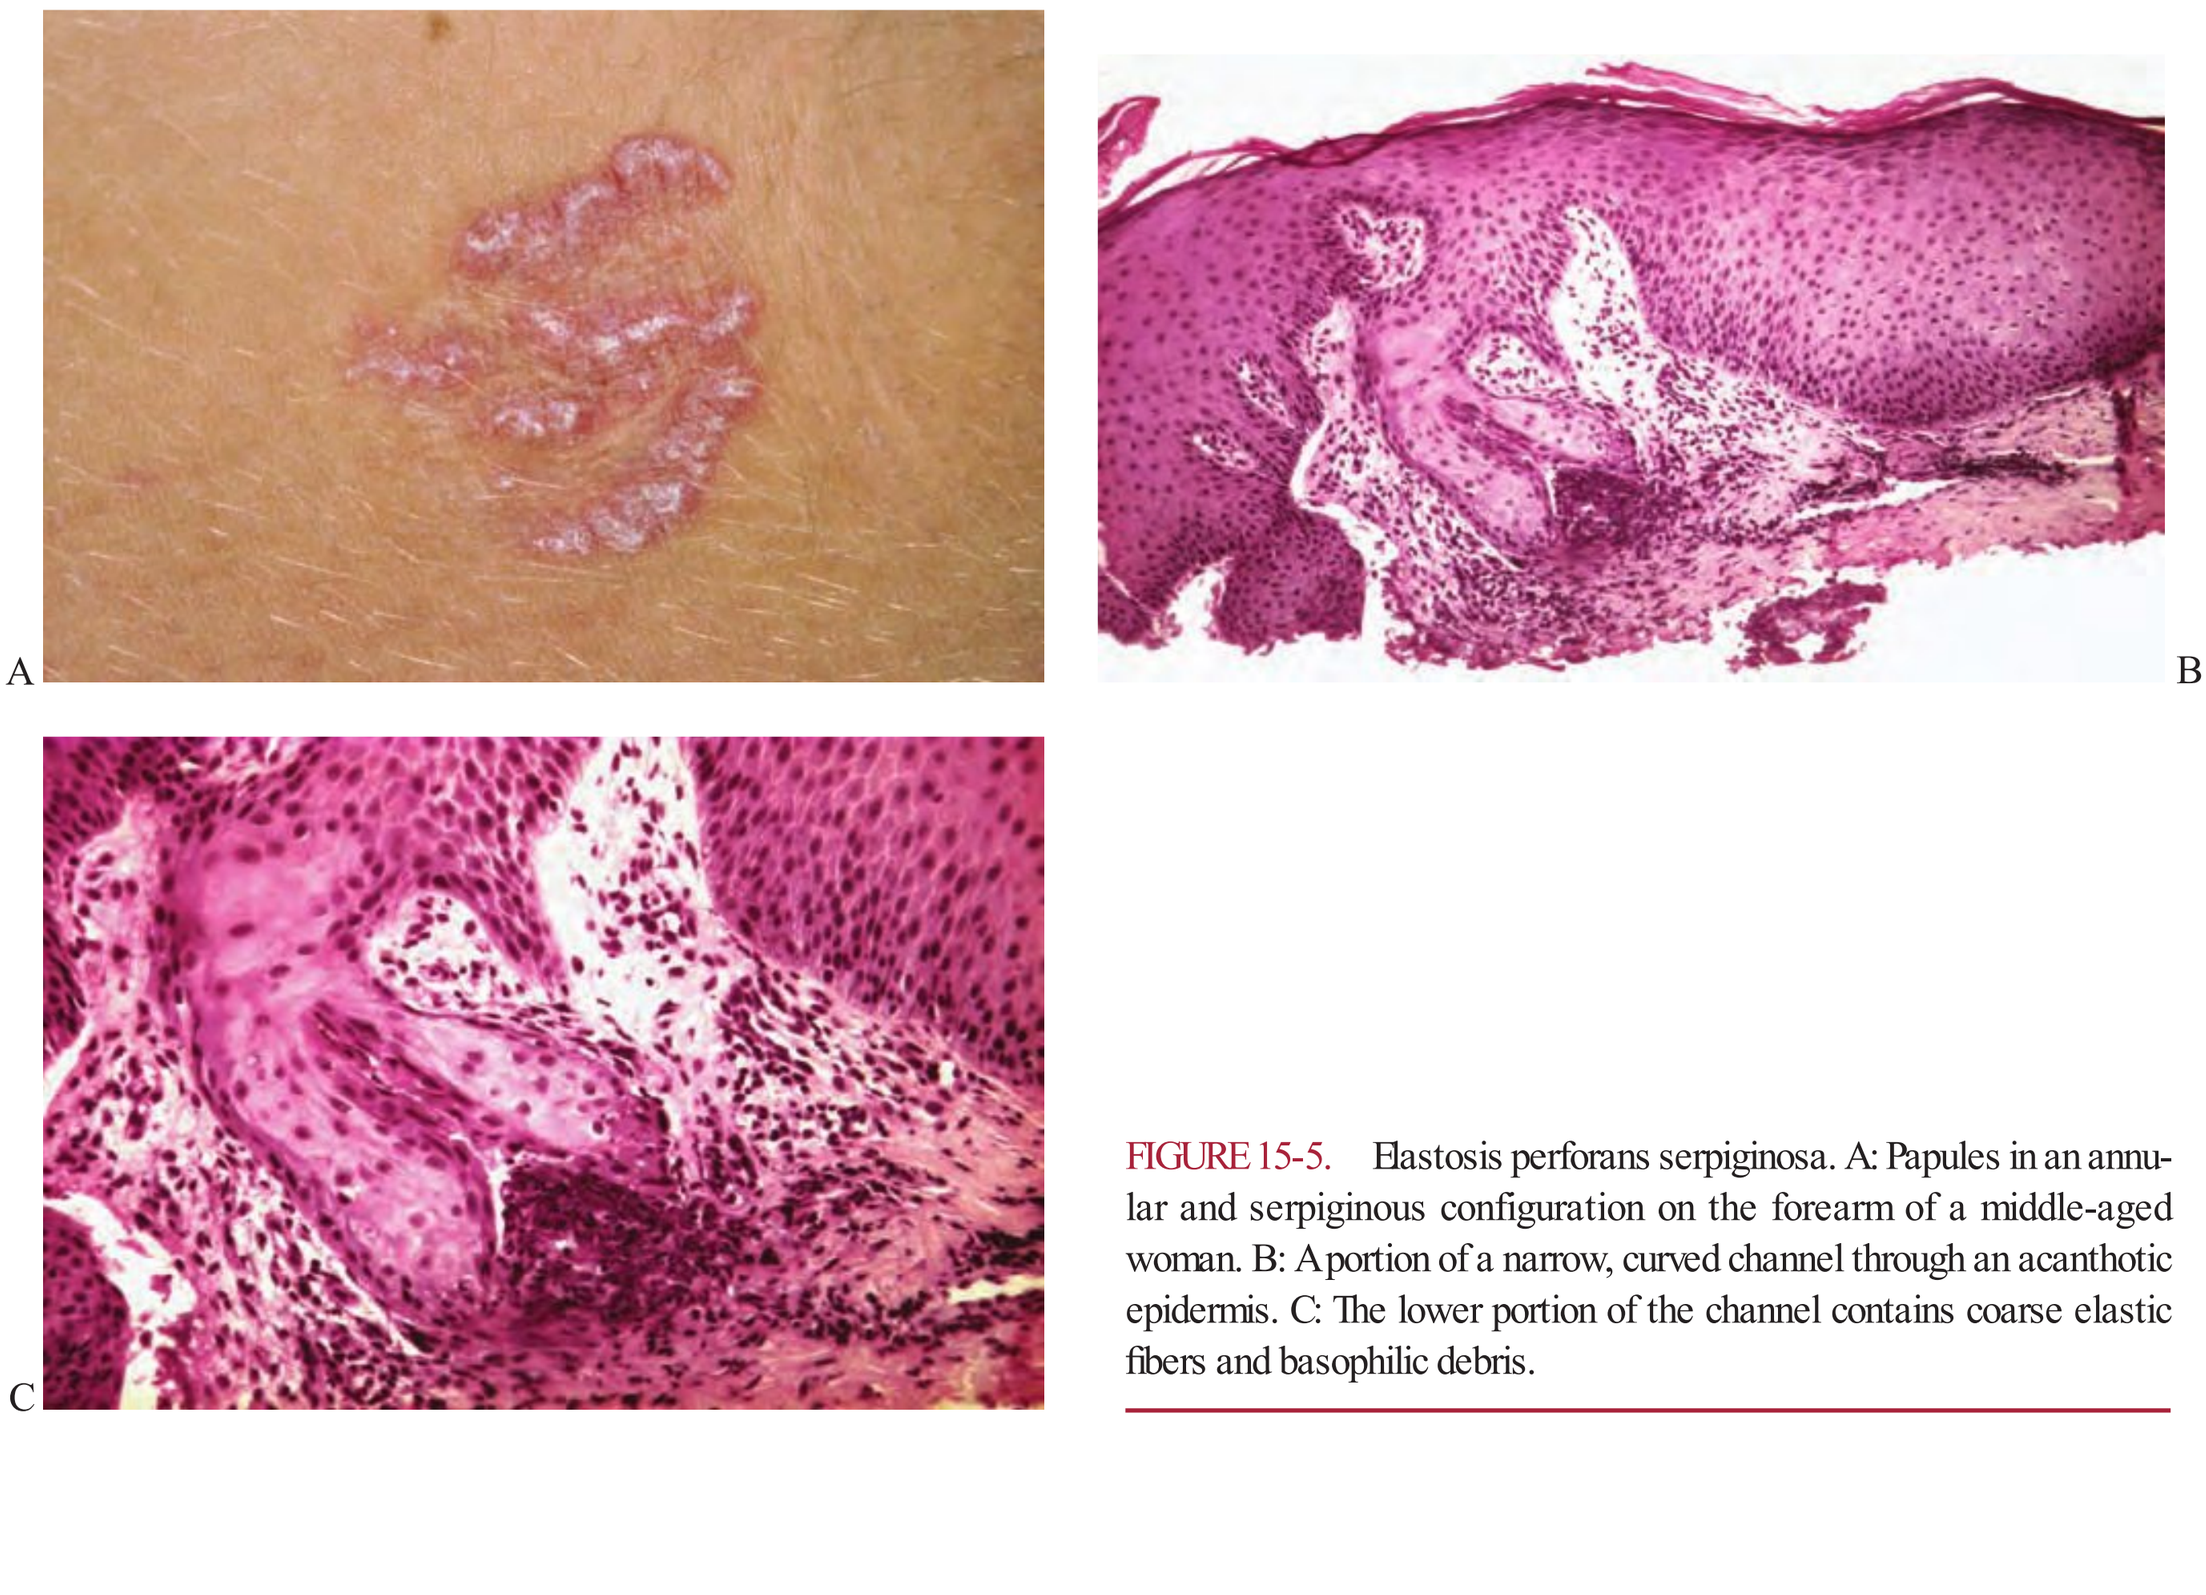

FIGURE 15-5. Elastosis perforans serpiginosa. A: Papules in an annular and serpiginous configuration on the forearm of a middle-aged woman. B: A portion of a narrow, curved channel through an acanthotic epidermis. C: The lower portion of the channel contains coarse elastic fibers and basophilic debris.

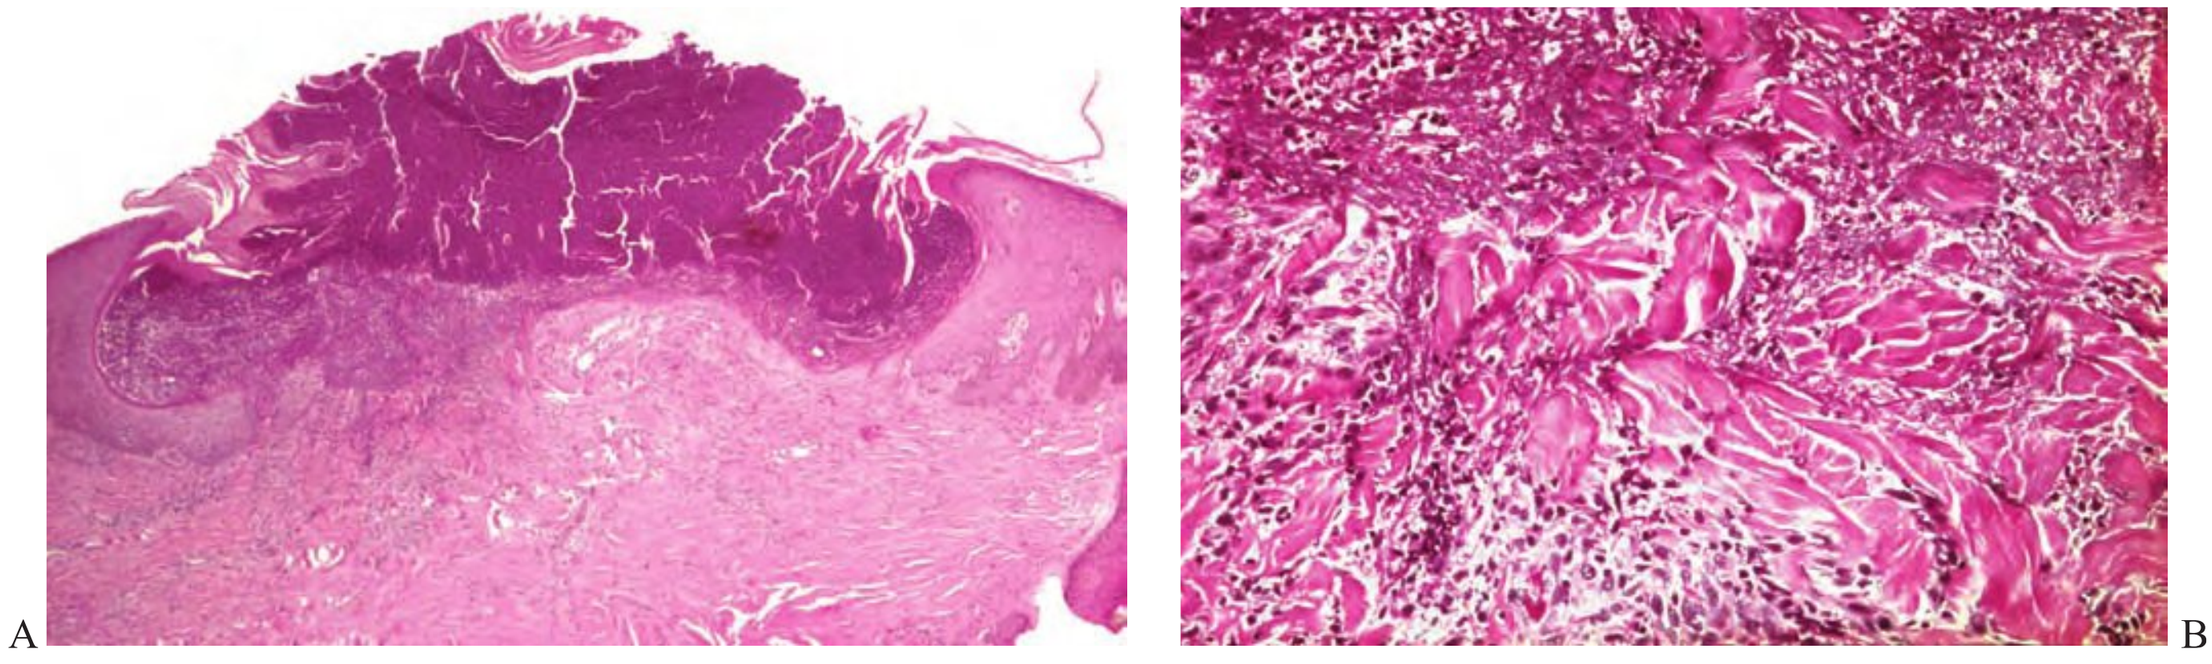

FIGURE 15-6. Reactive perforating collagenosis. A: A shallow, cup-shaped invagination of the dermis containing a mixture of basophilic material and degenerated collagen bundles. The adjacent epidermis displays acanthosis. B: Vertically oriented perforating bundles of collagen are present at the base of the invagination.

inflammatory cell infiltrate accompanies the fibers in the channel. Also observed are abnormal elastic fibers in the upper dermis in the vicinity of the channel. In this zone, the elastic fibers are increased in size and number. As these fibers enter the lower portion of the channel, they maintain their normal staining characteristics, but as they approach the epidermal surface, they may not stain as expected with elastic stains (53).

Histogenesis. The cause of EPS is not known. Because the elastic fibers show no obvious abnormality within the dermis except hyperplasia, it is conceivable that the thickened elastic fibers act as mechanical irritants or "foreign bodies" and provoke an epidermal response in the form of hyperplasia. The epidermis then envelops the irritating material and eliminates it through transepidermal channels. The degeneration of the elastic fibers within the channels probably is caused by proteolytic enzymes set free by degenerating inflammatory cells (53). The channel is formed as a reactive phenomenon through which the foreign bodies are extruded. Because copper metabolism is essential to the formation of elastin (54) and because the administration of penicillamine, a copper chelating agent, has been found to induce EPS (55), it may be suggested that the primary abnormality begins with a defect in the metabolism of this essential element.

Differential Diagnosis (Table 15-1). As in EPS, both Kyrle's disease and perforating folliculitis have a central keratotic plug and a perforation through which degenerated material is eliminated. In addition, perforating folliculitis, like EPS, shows the elimination of degenerated eosinophilic elastic fibers. However, neither of the two diseases shows the great increase in elastic tissue that is observed in EPS in the uppermost dermis and particularly in the dermal papillae on staining with elastic tissue stains.

Reactive Perforating Collagenosis

RPC is a rare perforating disorder in which altered collagen is extruded by means of TEE. True, classic RPC is a genodermatosis that is inherited as an autosomal dominant or recessive trait (56,57). The lesions are precipitated by trauma, arthropod assaults, folliculitis, and even exposure to cold. RPC occurs early in life, and both genders are equally affected.

The primary clinical lesion is a small papule that enlarges to the size of 5 to 10 mm with a hyperkeratotic central umbilication. Often, the lesion appears eroded. These lesions spontaneously regress, leaving superficial scars with postinflammatory pigmentary alteration. Koebnerization is common.

An adult, acquired type of RPC has been described in association with diabetes mellitus and chronic renal failure (58–64) and may be best interpreted as an expression of APD (see text following).

Histopathology. The classic lesion shows a vertically oriented, shallow, cup-shaped invagination of the epidermis, forming a short channel (Fig. 15-6A). The channel is lined by acanthotic epithelium along the sides. At the base of the invagination, there is an attenuated layer of keratinocytes that in some foci appear eroded. Within the channel, there is densely packed degenerated basophilic staining material and basophilically altered collagen bundles. Vertically oriented perforating bundles of collagen are present interposed between the keratinocytes of the attenuated bases of the invagination (Fig. 15-6B). It is important that a Masson trichrome stain be done to confirm that the fibers are collagen.

Histogenesis. The basic process in RPC consists of the TEE of histochemically altered collagen. Nevertheless, as delineated by electron microscopy, the collagen fibrils appear intact, with regular periodicity (61).

Differential Diagnosis. See Table 15-1.

Acquired Perforating Dermatosis

The term *acquired perforating dermatosis* was suggested by Rapini et al. to describe a pathologic process encompassing the various forms of TEE seen in patients with renal disease and/or

diabetes mellitus (65). Differences in clinical and histologic features, such as the presence of koebnerization, or histologic evidence of follicular involvement with or without collagen fibers in the epidermis have variably led to diagnoses of Kyrle's disease, "acquired" RPC, or perforating folliculitis (66–68). Other terms that have been used include *perforating disorder secondary to chronic renal failure and/or diabetes mellitus*, *perforating folliculitis of hemodialysis*, *Kyrle-like lesions*, and *uremic follicular hyperkeratosis* (69–72). Clinically, lesions are frequently pruritic and range from hyperkeratotic papules and nodules resembling Kyrle's disease to RPC-like umbilicated papules, nodules, and plaques to erythematous, follicular papules and nodules mimicking perforating folliculitis (62,65,72). Annular plaques and erythematous pustules have also been described, with histologic features of RPC and perforating folliculitis, respectively (72). The most common location is the extensor surfaces of the extremities, especially lower, but the trunk and head can also be involved (65,72). APD has also been described in renal disease secondary to chronic nephritis, obstructive uropathy, anuria, and hypertension-related nephrosclerosis (62). Cases of APD have also been reported in patients with lymphoma, AIDS, hypothyroidism, hyperparathyroidism and has been associated with pruritis secondary to liver disease, neurodermatitis, "atopic dermatitis," and malignant neoplasia (65,66).

Histopathology. As mentioned, the histologic features of APD are variable, even within different lesions from the same patient. When vertically oriented, Masson trichrome–positive collagen bundles are present within a perforation, the findings are suggestive of RPC. When perforation is associated with a follicle, the findings resemble perforating folliculitis. However, chronic rubbing can lead to superimposed features of prurigo nodularis, thus distorting the follicle and making it unrecognizable. TEE in the absence of follicular involvement, without demonstrable collagen or elastin, is reminiscent of Kyrle's disease. Perforation associated with elastic van Gieson (EVG)-positive elastic fibers within a transepidermal canal, as seen in EPS, has also been described (64,72). Patterson et al. (63) reported a patient who had multiple lesions biopsied, which variably showed histologic features of RPC, perforating folliculitis, and Kyrle's disease. Combined TEE of both elastic and collagen fibers has been observed in four patients with renal disease (65), a finding that has only rarely been described in Kyrle's disease or RPC (68).

Histogenesis. RPC, EPS, and perforating folliculitis exist as distinct perforating disorders when not associated with renal disease and diabetes. At least in the setting of APD, however, the presence of various histologic patterns suggests the possibility of a common underlying mechanism (65). A nearly ubiquitous clinical feature of APD is pruritis. Certainly, lesions are often distributed in areas accessible to scratching, and reducing pruritis can lead to clearance (66). Poor blood supply secondary to diabetic microangiopathy combined with trauma may lead to dermal necrosis, alteration of connective tissue, and TEE (66–68). Others have suggested that a consequence of dialysis is the underlying cause of APD (72). Possible etiologies include disruption of metabolism of vitamins A and/or D (73) or the accumulation of a poorly dialyzable substance in the dermis (70,71). Fibronectin, a glycoprotein of the extracellular matrix, accumulates in the serum of uremic and diabetic patients. It has been suggested that transcriptional induction of fibronectin, possibly by transforming growth factor beta or platelet-derived growth factor, increases epithelial migration and proliferation and leads to TEE (73). APD has been reported in 5% to 11% of patients with chronic renal failure who are undergoing hemodialysis (62,70), and clearance of APD following renal transplant has been reported. However, it has also occurred following transplant in patients with normal renal function (72). In addition, some cases have occurred prior to the start of hemodialysis or in patients who never underwent dialysis (62). Patterson (68) suggests that TEE may represent a "final common pathway" of a variety of dermal and epithelial processes acting alone or in concert.

Differential Diagnosis. See Table 15-1.

PERFORATING CALCIFIC ELASTOSIS (PERIUMBILICAL PERFORATING PSEUDOXANTHOMA ELASTICUM)

In perforating calcific elastosis, also referred to as *periumbilical perforating pseudoxanthoma elasticum*, a gradually enlarging, well-demarcated, hyperpigmented patch or plaque is usually seen in the periumbilical region in middle-aged, obese, multiparous women with hypertension (74). Most patients described have been black (75). The patch or plaque is in some instances atrophic with discrete keratotic papules at the periphery (76); in other instances, it has a verrucous border (77); in still others, it has a fissured, verrucous surface throughout (78). Lesions occurring on the breast have also been described (79,80). Perforating calcific elastosis was initially regarded as cases of EPS coexisting with PXE (81–85). The disorder was later shown to be distinct from EPS (77).

Four patients with perforating calcific elastosis associated with renal failure have been described (75,80,86,87). One patient demonstrated regression of the lesions with hemodialysis (75).

Histopathology. Numerous altered elastic fibers are observed in the reticular dermis. They are short, thick, and curled and are encrusted with calcium salts, as shown by a positive von Kossa stain. They are thus indistinguishable from the elastic fibers seen in PXE (74). As in PXE, the elastic fibers are visible even in sections stained with hematoxylin-eosin, owing to their basophilia (76). The altered elastic fibers in perforating calcific elastosis are extruded to the surface either through the epidermis in a wide channel (77) or through a tunnel in the hyperplastic epidermis that ends in a keratin-filled crater (76) (Fig. 15-7).

Histogenesis. Electron microscopic examination reveals electron-dense deposits of calcium primarily in the central core of

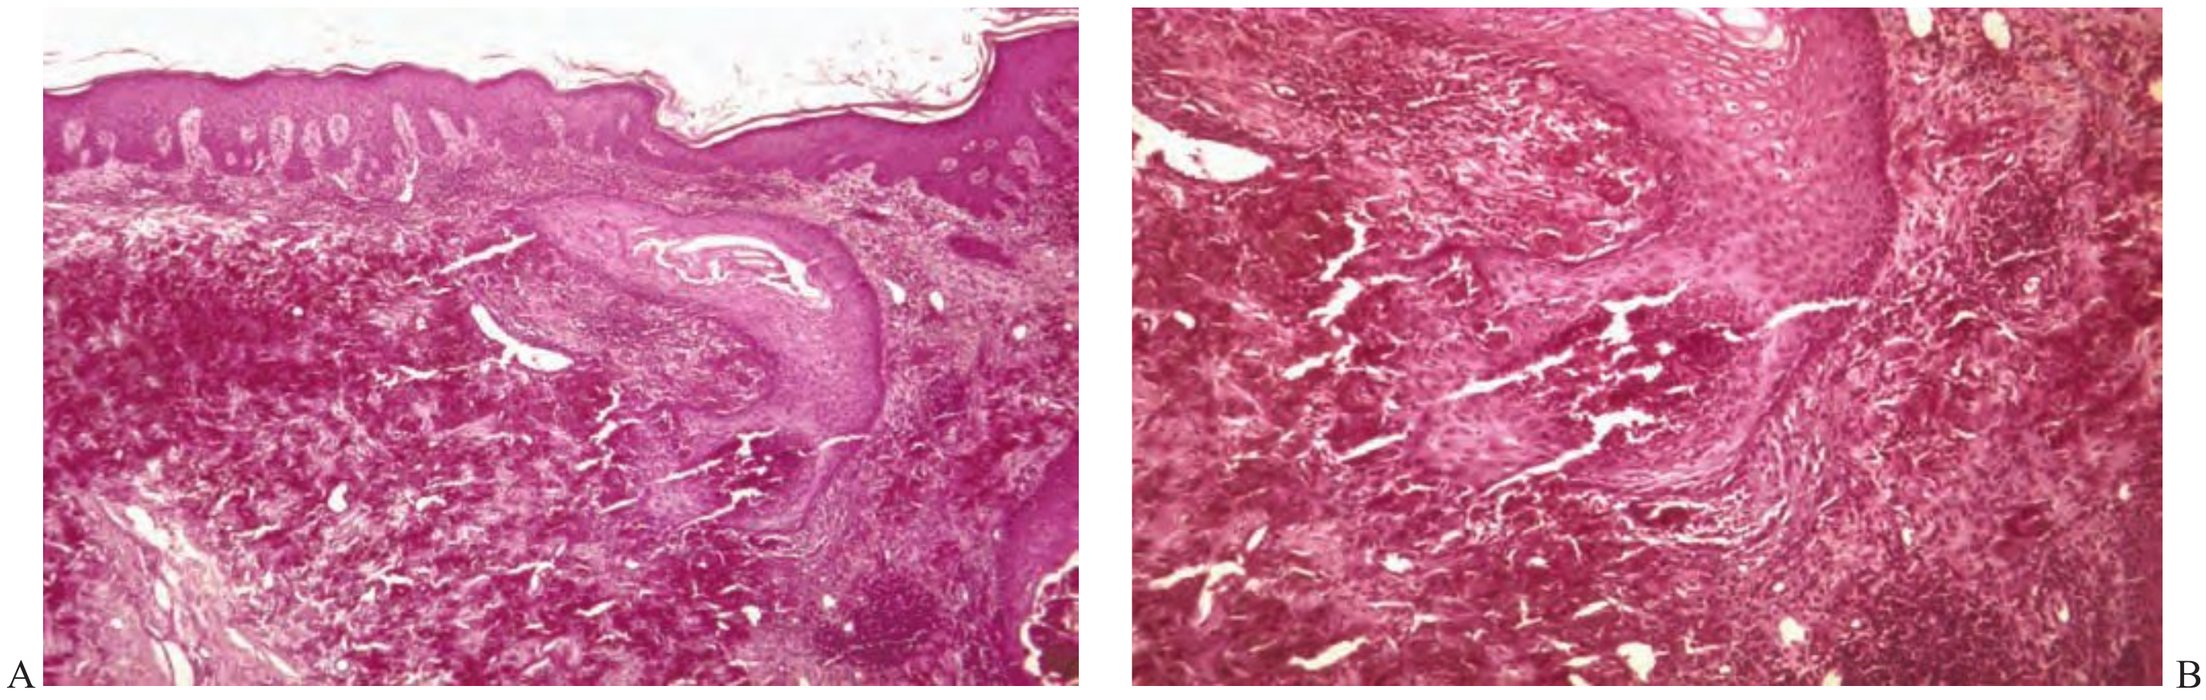

FIGURE 15-7. Perforating calcific elastosis. A: Degenerating elastic fibers encrusted with calcium salts in the reticular dermis surround a distorted transepidermal channel. B: The calcified fibers are in the process of being extruded through the base of the channel.

elastic fibers. Calcification of collagen bundles is also seen (79). The etiologic nature of perforating calcific elastosis has been debated. Some hypothesize that it is an acquired lesion developing as a consequence of local cutaneous trauma from such factors as obesity, multiple pregnancies, ascites, or multiple abdominal surgeries (74,76,79). They cite the characteristic clinical presentation, lack of systemic manifestations, and absence of familial predisposition in most cases. The occurrence of perforating calcific elastosis in patients with renal failure may suggest that conditions resulting in an abnormal calcium phosphate product may produce abnormal calcification of elastic fibers. The occurrence of PXE-like eruptions in patients exposed to saltpeter (calcium-ammonium-nitrate salts) (88) and in one patient with chronic idiopathic hyperphosphatasia (89) supports this concept. Others have argued that perforating calcific elastosis may represent a localized cutaneous expression of hereditary PXE (78). Arguments for the latter theory include a history of hypertension in three quarters of reported patients and angioid streaks in one third of examined patients (75). The presence of perforation is also not distinctive, as the finding has also been noted to occur in lesions of classic hereditary PXE. The disorder may represent a spectrum ranging from a purely acquired form with no systemic manifestations to an inherited form with limited systemic expression.

LATE-ONSET FOCAL DERMAL ELASTOSIS

Late-onset focal dermal elastosis has been described in a small number of elderly patients with lesions clinically resembling PXE (90,91).

Histopathology. Focal elastosis along with an increased accumulation of normal-appearing elastic fibers in the mid and deep dermis are seen (90). No pathologic changes of PXE are present.

Histogenesis. There is an increase in elastin and collagen contents in tested patients as compared with controls. An increase in elastin type I and III collagen messenger RNAs (mRNAs) from patients' fibroblasts has been observed. No change in excreted elastin peptides is noted in affected patients. An overexpression of elastin has been postulated (92).

HYPERKERATOSIS LENTICULARIS PERSTANS (FLEGEL'S DISEASE)

A rare dermatosis first described in 1958, hyperkeratosis lenticularis perstans consists of asymptomatic, flat, hyperkeratotic papules from 1 to 5 mm in diameter, located predominantly on the dorsa of the feet and on the lower legs (93). Removal of the adherent, horny scale causes slight bleeding. In addition to the central horny scale, larger papules often have a peripherally attached collarette of fine scaling. In two reported instances, extensive papular lesions were present on the oral mucosa (94). Other reported sites include the thighs, upper extremities, and ears (95,96).

The disorder starts in late life and persists indefinitely. An autosomal dominant transmission has been noted in several instances (97–99). Unilateral involvement may represent postzygotic mosaicism (100).

Histopathology. In some instances, the histologic picture is nonspecific, showing hyperkeratosis with occasional areas of parakeratosis, irregular acanthosis intermingled with areas of flattening of the stratum malpighii, and vascular dilation with a moderate amount of perivascular lymphocytic inflammation (101). However, it seems that if the specimen is obtained from a well-developed, markedly hyperkeratotic lesion, a characteristic, although not necessarily diagnostic, histologic picture may be revealed. The lesion shows a greatly thickened, compact, strongly eosinophilic horny layer standing out in sharp contrast to the less heavily stained basket-weave keratin of the

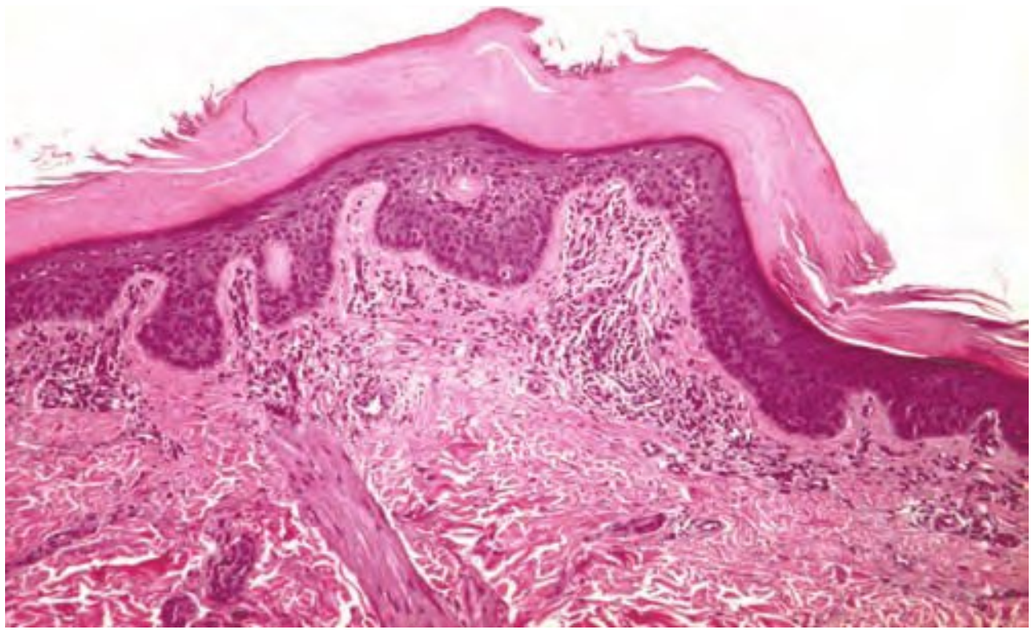

FIGURE 15-8. Hyperkeratosis lenticularis perstans. Dense compact orthokeratosis surmounts an epidermis with focal flattening of the stratum malpighii. A lymphocytic infiltrate is present in the upper dermis.

uninvolved epidermis (95). The underlying stratum malpighii appears flattened, with thinning or even absence of the granular layer (Fig. 15-8).

Acanthosis is observed at the periphery. In some instances, bordering on the central depression, the epidermis at the periphery forms a papillomatous elevation resembling a church spire (93,102,103). Vacuolar alteration and apoptotic cells in the basal layer have been seen in some cases (95,104,105). The dermal infiltrate is composed largely of lymphoid cells and is located as a narrow band fairly close to the epidermis with a rather sharp demarcation at its lower border. Immunohistochemical studies have shown the infiltrate to be predominantly T cells (106–108).

Histogenesis. Under electron microscopic examination, the absence of membrane-coating granules was noted in some cases and regarded as the primary lesion of hyperkeratosis lenticularis perstans (94,99).

A defect in the membrane-coating granules seems likely to play a role in Flegel's disease, because in other cases in which membrane-coating granules were present, the granules lacked a lamellar internal structure and appeared vesicular (109,110). In one case, both lamellar and vesicular bodies were observed, with lamellar bodies greatly predominating in uninvolved epidermis and vesicular bodies in lesional epidermis (111). However, one study of lesional skin from four patients found no such abnormalities in lamellar bodies (112).

Other ultrastructural findings in Flegel's disease that have been described in some cases include Sezary cell-like lymphocytes (113), rodlike intracytoplasmic inclusions (114), and wormlike bodies in histiocytes (111). The significance and role of these findings in the etiology of Flegel's disease is unknown.

STRIAE DISTENSAE

Striae distensae occur most commonly on the abdomen, on the thighs, and in the inguinal region. They consist of bands of thin, wrinkled skin that at first are red, then purple, and finally white.

Histopathology. The epidermis is thin and flattened. There is a decrease in the thickness of the dermis. The upper portion of the dermis shows straight, thin collagen bundles arranged parallel to the skin surface and transverse to the direction of the striae. The elastic fibers are arranged similarly. Fine elastic fibers predominate in early lesions, whereas in older lesions they are thick (115). Within the striae, nuclei are scarce and sweat glands and hair follicles are absent (116).

Histogenesis. The histologic findings support the view that striae distensae are scars. They occur in conditions associated with increased production of glucocorticoids by the adrenal glands. Among these conditions are pregnancy, obesity, adolescence, and especially Cushing's disease (117). In obesity, the increased adrenocortical activity is a consequence of the obesity, and the production of glucocorticoids returns to normal when the body weight is reduced (118). Similarly, the occurrence of striae in nonobese adolescents, as noted in 35% of the girls and 15% of the boys examined, is associated with an increase in 17-kerosteroid excretion (119). Striae may also form in response to prolonged intake of corticosteroids or following the prolonged local application of corticosteroid creams to the skin. The action of the glucocorticoids consists of an antianabolic effect suppressing both fibroblastic and epidermal activity, as tissue culture studies have shown (120).

LINEAR FOCAL ELASTOSIS (ELASTOTIC STRIAE)

Linear focal elastosis (elastotic striae) is an uncommon, but more likely underdiagnosed or underreported, disorder presenting as palpable striae-like yellow linear bands. The disorder was initially described in the lumbosacral region of elderly males (121). Lesions on the thigh and legs have also been reported (122,123). Occasionally, the lesions arise in association with striae distensae (124–127). A number of cases have occurred in individuals younger than age 30 years (128–130).

Histopathology. Abundant fragmented, clumped, and wavy elastic fibers are present between hypertrophic collagen bundles in the mid reticular dermis (11,127). Elongated elastic fibers with split ends resembling a "paintbrush" can be seen (131). A decrease in papillary dermal elastic fibers has been demonstrated in the elastotic striae from one patient with coexistent pseudoxanthoma-like papillary dermal elastolysis (123). Unlike striae distensae, there is no decrease in thickness of the dermis or atrophy of the overlying epidermis.

Histogenesis. Electron microscopic examination reveals fragmented elastic tissue throughout the dermis (121). Widespread elastic fiber microfibrils, some occurring in continuity with intracytoplasmic filaments of fibroblasts, along with sequential maturation of elastic fibers have been observed suggesting an elastogenic process (132). An increased number of elastic fibers

in lesional skin has also been documented (131). It has been postulated that elastotic striae may represent a regenerative process of striae distensae (124,127). This view is supported by the presence of contiguous striae distensae and elastotic striae in several patients. Accumulations of thin elastic fibers have been observed in late stages of striae distensae (133–135). Thus, linear focal elastosis may represent an excessive "keloidal" repair process occurring in striae distensae (127).

PSEUDOXANTHOMA ELASTICUM–LIKE PAPILLARY DERMAL ELASTOLYSIS

Papillary dermal elastolysis, first described in 1992, is a rare, acquired condition consisting of soft coalescent yellow-white papules mainly on the lateral neck and supraclavicular regions of elderly women (123,136–143). The clinical appearance of the skin lesions closely resembles those of PXE. However, no other systemic features of PXE are seen. A similar and possibly related disorder, *white fibrous papulosis of the neck*, is characterized by paler, more discrete and firm papules (144–150). The term *fibroelastolytic papulosis of the neck* has been suggested to encompass the spectrum of the two disorders (150).

Histopathology. There is a marked decrease to an absence of elastic fibers in the papillary dermis (136). Focal elastotic changes in the subpapillary and mid-dermis have also been demonstrated (151). No calcification or fragmentation of elastic fibers is seen. A slight decrease in elastic fibers along with the presence of thickened collagen bundles in the papillary dermis are differentiating features in *white fibrous papulosis of the neck* (146,150).

Histogenesis. Electron microscopic examination confirms the absence of elastic fibers in the papillary dermis along with the presence of immature elastic fibers in the upper reticular dermis. Fibroblasts with prominent rough endoplasmic reticulum with numerous dilatations and elongated dendritic processes are present (136,142). In one patient, formation of loose component fibrils of elastic fibers and elastophagocytosis were seen ultrastructurally (140). Papillary dermal elastolysis has been suggested to be a disorder of intrinsic skin aging due to its histologic similarity (136). However, immunohistochemical studies have shown a decrease in both fibrillin-1 and elastin in affected areas, whereas aged normal-appearing skin demonstrates only a decrease in fibrillin-1. A defect in elastogenesis may contribute to the pathogenesis of the disorder (136,143). The female predominance and the report of a familial occurrence may suggest possible genetic factors (142).

MID-DERMAL ELASTOLYSIS

Mid-dermal elastolysis is a rare disorder, first described in 1977, occurring predominantly on the arms and trunk of middle-aged women (152). Clinically, two patterns are seen. The type-1 pattern consists of widespread, large areas of fine wrinkling along skin cleavage lines. The type-2 pattern consists of small, soft, papular lesions with tiny perifollicular protrusions, leaving the hair follicle itself as an indented center (153,154). These two patterns may coexist in the same patient. Persistent reticulate erythema is a recently described presentation (155). Urticaria (152), erythematous patches (156), or granuloma annulare (157) may precede some of the lesions. These postinflammatory forms of mid-dermal elastolysis have some similarity to a disorder first described in young South African girls termed *postinflammatory elastolysis and cutis laxa* (158–160). In the latter disorder, widespread wrinkling followed an acute phase of firm, erythematous, infiltrated lesions. An overlap with another disorder described as *disseminated nevus anelasticus* is also likely (161).

Histopathology. In this condition, there is a selective absence of elastic tissue strictly limited to the mid-dermis of involved areas (152). The perifollicular protrusions around indented hair follicles result from preservation of a thin layer of elastic tissue in the immediate vicinity of the follicles. This causes the hair follicles to appear retracted while the perifollicular skin protrudes (153). A mild perivascular inflammatory infiltrate of mononuclear cells with occasional interstitial multinucleated giant cells exhibiting elastophagocytosis may be seen (162–164). Electron microscopic examination also reveals fragments of normal-appearing elastic fibers within macrophages (162,165).

Histogenesis. The disorder likely represents a postinflammatory process, although in some cases this may be subclinical or remote. Immunohistochemical evidence of immune activation has been observed in lesional T lymphocytes and endothelial cells (166). The cytokines and elastases produced by inflammatory cells along with elastophagocytosis by macrophages may contribute to the loss of elastic fibers (162). A possible autoimmune mechanism has been hypothesized based on its associations with rheumatoid arthritis (167), silicone mammoplasty, elevated autoantibodies, false-positive Lyme titers (168), lupus erythematosus (169), and Hashimoto's thyroiditis (170). Culture studies performed with dermal fibroblasts from lesional skin showed an 80-fold increase in elastin mRNA and a 2-fold increase in elastolysis compared with normal skin (173). An idiosyncratic reaction to ultraviolet light has also been proposed as an etiologic or exacerbating factor (171,172). Recent studies suggest that ultraviolet exposure may lead to increased expression, by fibroblast-like cells, of elastin-degrading matrix metalloproteinase MMP-9 (174).

MACULAR ATROPHY (ANETODERMA)

Atrophic patches located mainly on the upper trunk characterize macular atrophy, or anetoderma. The skin of the patches is thin and blue-white and bulges slightly. The lesions may give the palpating finger the same sensation as a hernial orifice. Two types of macular atrophy are generally distinguished: the Jadassohn-Pellizzari type, in which the atrophic lesions initially appear red and on histologic examination show an inflammatory infiltrate;

and the Schweninger-Buzzi type, which clinically is noninflammatory from the beginning. However, not every case can be clearly assigned to one or the other of these two types; many clinically noninflammatory cases show an inflammatory infiltrate when examined histologically (175). The justification for distinguishing between the inflammatory and noninflammatory types has therefore been questioned (176). In many patients, new lesions continue to appear over a period of several years. Rare congenital and familial cases have been reported (177–181).

The so-called secondary form of macular atrophy occurs in the courses of various diseases, such as syphilis, lupus erythematosus, tuberculosis, sarcoidosis, and leprosy (182–185). The macular atrophy then represents the atrophic stage of the preceding disease (186). Other cases of secondary anetoderma have occurred in association with porphyria (187), urticaria pigmentosa (188,189), pilomatricomas (190,191), Down's syndrome (192,193), acrodermatitis chronica atrophicans (194), Takayasu's arteritis (195), Grave's disease (196), Addison's disease (196), autoimmune hemolysis (196), systemic scleroderma (196), varicella (197), anticardiolipin and antiphospholipid antibodies (198–204), HIV (205), Sjogren's syndrome (206,207), alpha-1 antitrypsin deficiency (201), B-cell lymphoma (206,208), plasmacytoma (209,210), cutaneous lymphoid hyperplasia (209), angular cheilitis (211), juvenile xanthogranuloma (212,213), and generalized granuloma annulare (214). Macular atrophy has also been observed after iatrogenic procedures such as leech application (215), monitoring electrode placement in premature infants (216,217) hepatitis B vaccination (218), and after prolonged treatment with penicillamine (219).

Histopathology. Early, erythematous lesions usually show a moderately pronounced perivascular infiltrate of mononuclear cells (220–225). In a few instances, however, the early inflammatory lesions show a perivascular infiltrate in which neutrophils and eosinophils predominate and nuclear dust is present, resulting in a histologic picture of leukocytoclastic vasculitis (221,222). Microthrombosis has also been noted in patients with anetoderma and associated antiphospholipid antibodies (209–212).

The elastic tissue may still appear normal in the early stage of an erythematous lesion (223). Usually, however, it is already decreased or even absent within the lesion. In cases in which there is a decrease in the amount of elastic tissue, mononuclear cells may be seen adhering to elastic fibers (220). Elastophagocytosis within macrophages and giant cells may be seen (224).

Long-standing, noninflammatory lesions generally show a more or less complete loss of elastic tissue, either in the papillary and upper reticular dermis or in the upper reticular dermis only (Fig. 15-9). A perivascular and periadnexal lymphocytic infiltrate of varying intensity is invariably present; thus, a distinction of an inflammatory and a noninflammatory type is not justified. In some instances, the involved areas show small, normal elastic fibers, which are probably the result of resynthesis, or abnormal, irregular, granular, twisted, fine fibers (175). Immunofluorescence studies of primary anetoderma have revealed immune deposits in a pattern indistinguishable from that of lupus erythematosus (225,226).

Histogenesis. Electron microscopic examination of lesions reveals a few thin, irregular elastic fibers, with more or less complete loss of the amorphous substance elastin but with relative conservation of the microfibrils. Macrophages, lymphocytes, and some plasma cells are observed. It appears possible that partial destruction by elastases originating in the macrophages occurs, because it is known that the elastases preferentially destroy the amorphous substance of the elastic

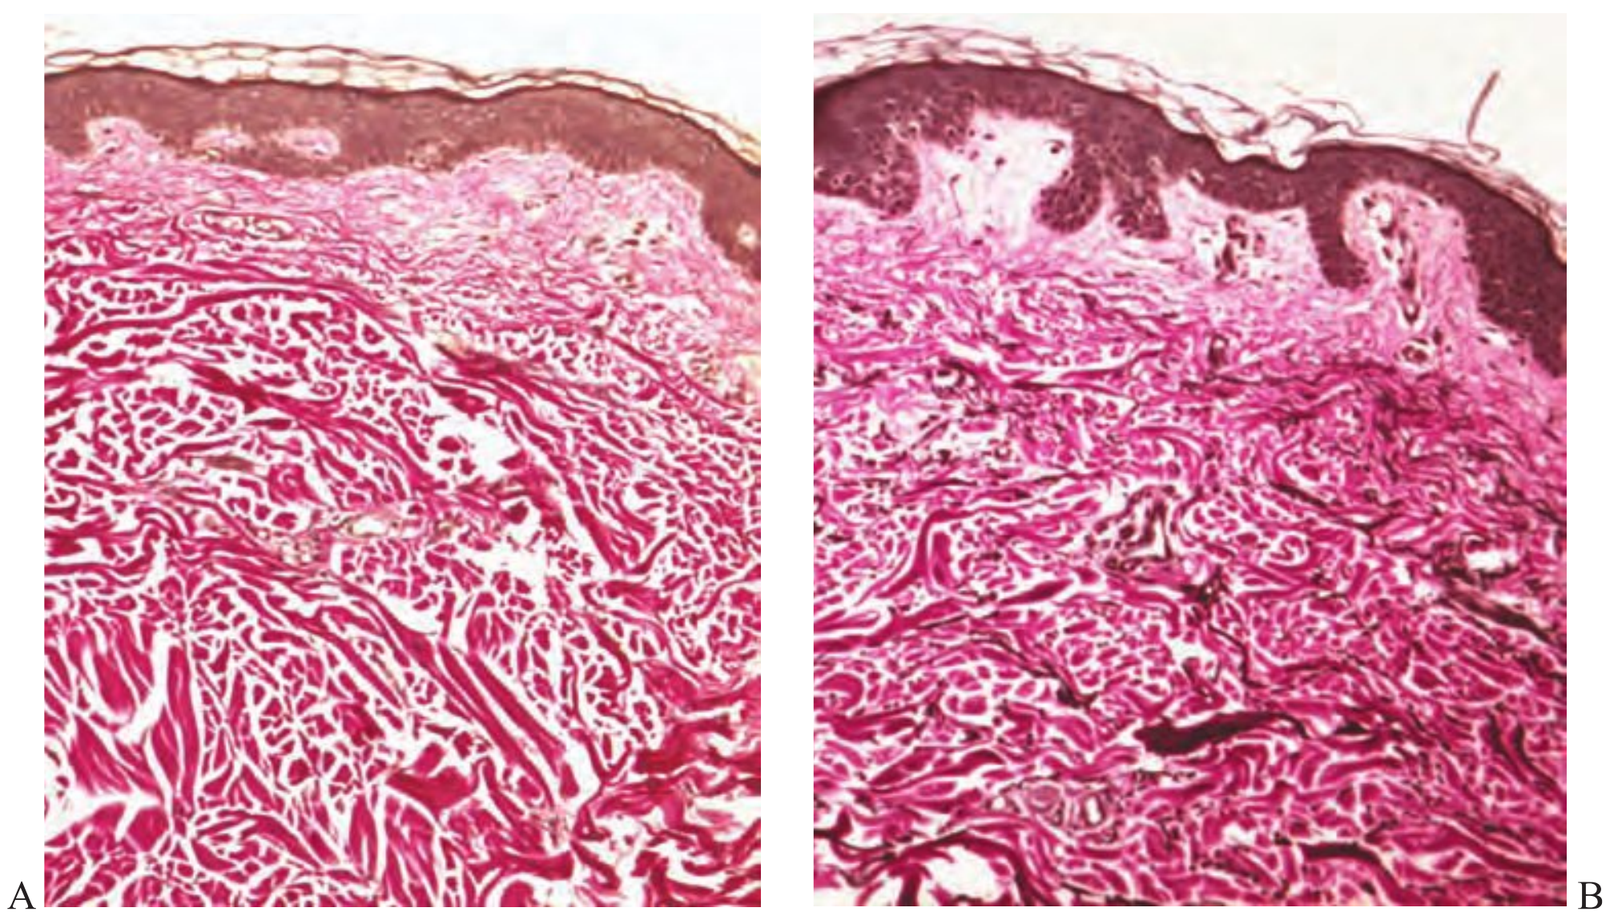

FIGURE 15-9. Anetoderma. Decreased to absent elastic fibers in a case of anetoderma (A) as compared with a normal control (B).

fibers (226). Two elastase-type proteinases, gelatinase A (metalloproteinase-2) and B (MMP-9), have been shown to have increased expression in skin explants from patients with anetoderma (227). Morphometric analysis has demonstrated decreases in the diameter of oxytalan and dermal elastic fibers as well as the volume fractions of pre-elastic and dermal elastic fibers (228). This analysis has been used to differentiate anetoderma from other disorders of elastic tissue such as cutis laxa.

There is increasing evidence for an immunologic basis for anetoderma. In support of this hypothesis is the association of numerous autoimmune disorders and the findings of immune deposits at both the dermal–epidermal junction and dermal blood vessels (196,225). In particular, the association of antiphospholipid antibodies with anetoderma is intriguing. The exact mechanism by which these antibodies may induce lesions remains to be elucidated. Some authors have postulated that microthrombosis produced by antiphospholipid antibodies with resultant ischemia of dermal tissues may induce elastic fiber degeneration (200,203). Others have hypothesized that the antibodies may alter the inhibitors of elastolytic enzymes, thus allowing the destruction of elastic fibers (229).

PERIFOLLICULAR ELASTOLYSIS

Perifollicular elastolysis is a relatively common condition consisting of small, hypopigmented, follicular papules on the face and upper trunk. The papules may protrude or herniate (230–233). There is a strong association with acne vulgaris, and some have suggested the term *papular acne scars* for the disorder (233).

Histopathology. There is an absence of elastic fibers localized to the regions around pilosebaceous units (230).

Histogenesis. Perifollicular elastolysis most likely represents a form of anetoderma related to acne scarring (233). Elastase-producing strains of *Staphylococcus epidermidis* have been found in lesional hair follicles and have been proposed as the causative factor (230,232).

ACRO-OSTEOLYSIS

The term *acro-osteolysis* refers to destructive lytic changes on the distal phalanges. Three types are recognized: familial; idiopathic, nonfamilial; and occupational, which is associated with exposure to vinyl chloride gas. In addition, acro-osteolysis may be a feature of genetic syndromes such as Haim-Munk syndrome, pycnodystosis, Hutchinson-Gilford syndrome, and Hajdu-Cheney syndrome (234–237).

The *familial type* affects mainly the phalanges of the feet and is associated with recurrent ulcers on the soles (238).

The *idiopathic type* affects the hands more severely than the feet. Involvement of the distal phalanges of the fingers causes shortening of the fingers. This variant may be associated with Raynaud's phenomenon. Only one case has been described, with cutaneous lesions consisting of numerous yellow papules 2 to 4 mm in diameter and showing a linear distribution and coalescence into plaques, mainly on the arms (238).

Occupational acro-osteolysis, like the idiopathic type, causes shortening of the fingers due to osteolysis. This variant is often associated with Raynaud's phenomenon and progressive thickening of the skin of the hands and forearms simulating scleroderma. There may be erythema of the hands, and the thickening may consist of papules and plaques (239). The skin of the face may show diffuse induration (240). In addition, there may be thrombocytopenia, portal fibrosis, and impaired hepatic and pulmonary function (241). A variant of occupational acro-osteolysis has been described in guitar players and is believed to be secondary to mechanical stress (243).

Histopathology. The histologic changes in the papules and plaques of idiopathic and occupational acro-osteolysis consist of thickening of the dermis, with swelling and homogenization of the collagen bundles, indistinguishable from scleroderma. Staining for elastic tissue shows disorganization of the elastic fibers, which appear thin and fragmented (238–240).

Histogenesis. Vinyl chloride disease is an immune-complex disorder associated with hyperimmunoglobulinemia, cryoglobulinemia, and evidence of *in vivo* activation of complement (241). The immunologic nature of the disease explains why it is developed by <3% of the workers exposed to vinyl chloride gas (239).

CHAPTER 16

Cynthia Magro
A. Neil Crowson
Molly Dyrsen
Martin Mihm, Jr.

Cutaneous Manifestations of Nutritional Deficiency States and Gastrointestinal Disease

DEFICIENCIES OF VITAMINS, OTHER AMINO ACIDS, AND MINERALS

Scurvy

The manifestations of scurvy, which is due to vitamin C (ascorbic acid) deficiency, have been known for 3,000 years. In 1753, Sir James Lind demonstrated the efficacy of citrus fruits in the prevention of this condition (1,2), which is characterized by follicular purpuric macules with or without follicular hyperkeratosis and corkscrew hairs, ecchymoses, particularly in the pretibial areas, and conjunctival and gingival hemorrhages, the latter associated with gingival hyperplasia (3). Subcutaneous hemorrhage with woody edema of the lower extremities and hemarthrosis may occur (4). Nonspecific aches and pains and impaired wound healing are frequent. Anemia, possibly related to decreased amounts of active folate and blood loss, is present in approximately 75% of individuals (4,5). For humans, the principal source of vitamin C, a substance that cannot be synthesized from glucose derivatives, is fruits and vegetables. Scurvy occurs in individuals such as autistic patients who selectively avoid these foods (6), the elderly, chronic alcoholics, renal dialysis patients, and malnourished displaced refugee populations (7), who also suffer other micronutrient deficiencies when dependent on food aid (8,9).

Histopathology. Follicular hyperkeratosis and perifollicular erythrocyte extravasation without an accompanying vasculopathy are characteristic. Extensive extravasations are usually associated with deposits of hemosiderin within and outside of macrophages. A coiled hair may emanate from the dilated follicular orifice (10).

Differential Diagnosis. Other pauci-inflammatory hyperkeratotic dermatoses that should be considered in the differential diagnosis include keratosis pilaris, vitamin A deficiency, pityriasis rubra pilaris, ichthyosis vulgaris, and a resolving lichenoid follicular hyperkeratotic process such as lichen planopilaris, lichen spinulosus, or lupus erythematosus. Pilotropic T-cell dyscrasia including alopecia mucinosa and frank pilotropic mycosis fungoides can demonstrate prominent follicular hyperkeratosis. Coiled or "corkscrew" hairs are not pathognomonic of scurvy and may be seen in certain ectodermal dysplasia syndromes (11).

Pathogenesis. Most manifestations of scurvy can be attributed to defective collagen synthesis. Lysine and proline hydroxylase enzymes require vitamin C to reduce Fe^{3+} during the reaction. In vitamin C deficiency, the end product, hydroxyproline, which stabilizes the collagenous domain of procollagen, is deficient (3). Individuals with the Hp 2-2 genetic polymorphism of haptoglobin, a hemoglobin-binding antioxidant, have markedly lower levels of vitamin C despite an adequate nutritional supply, establishing a basis for a potential genetic influence (12). Because of the impaired antioxidant ability of Hp 2-2 haptoglobin, there is a higher rate of vitamin C oxidation, which significantly reduces the stability of L-ascorbic acid (13) and decreases its availability to hydroxylase enzymes. Ultrastructurally, the dermal fibroblasts appear shrunken and show a decreased amount of rough endoplasmic reticulum (14). Around these fibroblasts, one observes increased amounts of extracellular filamentous or amorphous material that has failed to polymerize into normal collagen fibrils. The extravasation of red cells is caused by vacuolar degeneration and junctional separation of adjoining endothelial cells and their detachment from the basement membrane in capillaries and small venules (14).

Vitamin A Deficiency (Phrynoderma)

Seen mainly in Asia and Africa, vitamin A deficiency is rare in the United States but may occur after intestinal bypass surgery for obesity (15) or visceral myopathy (16). One reported case in France attributed the phrynoderma to severe combined endogenous deficiencies of vitamins A and C secondary to intestinal malabsorption caused by chronic intestinal parasitic infection by *Giardia intestinalis* (17). Dryness and roughness of the skin along with conical follicular keratotic plugs characterize the cutaneous changes. Night blindness, xerophthalmia, and keratomalacia also occur.

Histopathology. The skin shows moderate hyperkeratosis with distension of the upper part of the follicle by large, horny plugs (15). Sebaceous glands are greatly reduced in size and may

exhibit epithelial atrophy (18). In severe cases both eccrine and sebaceous glands may exhibit squamous metaplasia (19).

Differential Diagnosis. The other causes of a pauci-inflammatory interfollicular and follicular hyperkeratosis are mentioned in the prior discussion of scurvy. Striking orthohyperkeratosis with only minimal parakeratosis, hyperplasia of the epidermis, acantholysis, and a superficial dermal lymphocytic infiltrate with basilar vacuolar change are additional histologic features that distinguish pityriasis rubra pilaris from phrynoderma (20). Superficial dermal fibroplasia with melanophage accumulation is the hallmark of resolved lichen planopilaris, lupus erythematosus, and graft-versus-host disease. Sebaceous gland atrophy has been described in pellagra. Squamous metaplasia of the eccrine apparatus has been seen with methotrexate therapy and graft-versus-host disease. Lymphocyte satellitosis around eccrine ductular cells is an additional helpful clue pointing toward a diagnosis of graft-versus-host disease.

Acquired Vitamin B_3 Deficiency (Pellagra)

The word "pellagra" is derived from two Italian words, "*pelle*," meaning "skin," and "*agra*," meaning "sharp burning" or "rough." Although primarily ascribed to niacin (vitamin B_3) deficiency, other vitamin deficiencies or protein malnutrition (21) appear integral to the development of the pellagra symptom complex. Presenting as cutaneous lesions, gastrointestinal symptoms, and mental changes, pellagra has been ascribed the acronym of the three Ds: dermatitis, diarrhea, and dementia. In the United States, the enrichment of whole-wheat flour with niacin has almost eliminated pellagra, but it is still prevalent in countries such as Mexico and some African nations where cornmeal is the main constituent of the diet, as well as in displaced populations (8,9). Pellagra in the United States and Europe is seen mainly in chronic alcoholics (22) and in patients with anorexia nervosa, malignant gastrointestinal tumors, and intestinal parasitosis (21). Its appearance in carcinoid syndrome is believed to reflect a depression of endogenous niacin production by tumor cell diversion of tryptophan toward serotonin (23). Pellagra has also been reported in patients receiving isoniazid, pyrazinamide, ethionamide, azathioprine, chloramphenicol, and anticonvulsants (24). Isoniazid, a structural analogue of niacin, can cause suppression of endogenous niacin production.

Three basic skin eruptions occur in pellagrins (25,26). The first is a photo-induced eruption that is intensely erythematous and subsequently exfoliates to yield a hyperpigmented residuum. The second eruption comprises painful erythematous erosions in genital and perineal areas possibly induced by pressure, heat, and trauma (21). The increased skin fragility may reflect aberrations in the collagen and elastic fiber content of the skin. Pellagrins may develop a seborrheic dermatitis–like rash involving the face, scalp, and neck. Oral manifestations include beefy, red, cracked lips and a fissured or smooth, red, sore tongue (27). Among the neurologic symptoms are dementia, psychosis, anxiety, defective memory, burning sensations, sudden attacks of falling, dizziness, and headaches. A cause of sudden death is central pontine myelinolysis (21).

Histopathology. Psoriasiform epidermal hyperplasia with hyperkeratosis, parakeratosis, and a lymphocytic perivascular inflammatory cell infiltrate characterize initial lesions. Additional features include scattered necrotic keratinocytes, granular cell layer loss, and architectural disarray with dysmaturation of the epidermis. Depigmentation of the basal layer with accumulation of fat droplets is described, as is vacuolation of cells within the granular and spinous layers (28). Epidermal atrophy, hypermelanosis, vascular ectasia, and sebaceous atrophy characterize end-stage lesions (28). Seborrheic dermatitis–like lesions may show sebaceous gland hyperplasia with follicular dilation. Fragmentation, swelling, and thickening of elastic fibers, swelling of collagen fibers, and merging of elastic tissue with collagen have been described. A morphology indistinguishable from that of necrolytic migratory erythema and acrodermatitis enteropathica has been reported, comprising intracellular edema with vacuolar change of the upper stratum malpighii and keratinocyte necrosis, sometimes accompanied by neutrophilic infiltration of the upper spinous layers, subcorneal pustulation localized to or in isolation from these areas, and folliculitis (21).

Pathogenesis. A deficiency in urocanic acid caused by a reduction in histidine and histidase activity has been postulated as a possible mechanism of photosensitivity in pellagra; urocanic acid protects the skin from ultraviolet (UV) wavelengths by absorbing light in the UVB range (21). Kynurenic acid, a metabolic byproduct of the tryptophan-kynurenine-nicotinic pathway, accumulates in pellagra as a result of a deficiency of nicotinamide, which blocks the formation of kynurenic acid. Kynurenic acid induces a phytotoxic reaction in skin subjected to long-wave UV radiation ranging from 350 to 380 mm (21). Some of the gastrointestinal symptoms may relate to degenerative changes of the dorsal vagal nuclei. The neurologic symptoms may be due to chromatolysis of various cortical and brainstem nuclei (21).

Differential Diagnosis. The histopathology is similar to that of the nutritional dermatoses acrodermatitis enteropathica and necrolytic migratory erythema. In addition, those dermatitides associated with hyperkeratosis, a maturation disarray, and/or scattered degenerating keratinocytes need to be considered, as discussed in the differential diagnosis section of necrolytic migratory erythema.

Congenital Vitamin B_3 Deficiency (Hartnup's Disease)

Named after the family in which it was first described in 1956, Hartnup's disease is a distinctive autosomal recessive syndrome comprising pellagrinous skin (29,30), neurologic abnormalities including mental deterioration and cerebellar ataxia, and abnormal aminoaciduria (31). The intermittent skin eruption is seen primarily in the summer at times of maximal sun exposure and

at times resembles either poikiloderma vasculare atrophicans (32) or, when vesicles are prominent, hydroa vacciniforme (33). Hartnup's disease, in contrast to pellagra, does not respond to treatment with niacin (33).

Histopathology. The histopathology usually resembles that of pellagra. Poikilodermatous lesions manifest flattening of the epidermis and prominent dermal melanophage accumulation (32).

Pathogenesis. An intestinal and renal tubular defect of tryptophan absorption leads to a deficiency in endogenous niacin, accounting for the pellagra-like symptomatology. The genetic abnormality involves a mutation in the gene for SCL6A19 (34,35), a transporter for monoamino-monocarboxylic acids located mainly in the kidney and intestine, which maps to chromosome 5p15 (36). Chromatographic studies of urine show persistent aminoaciduria, particularly of tryptophan and of indolic substances derived from tryptophan (30,32).

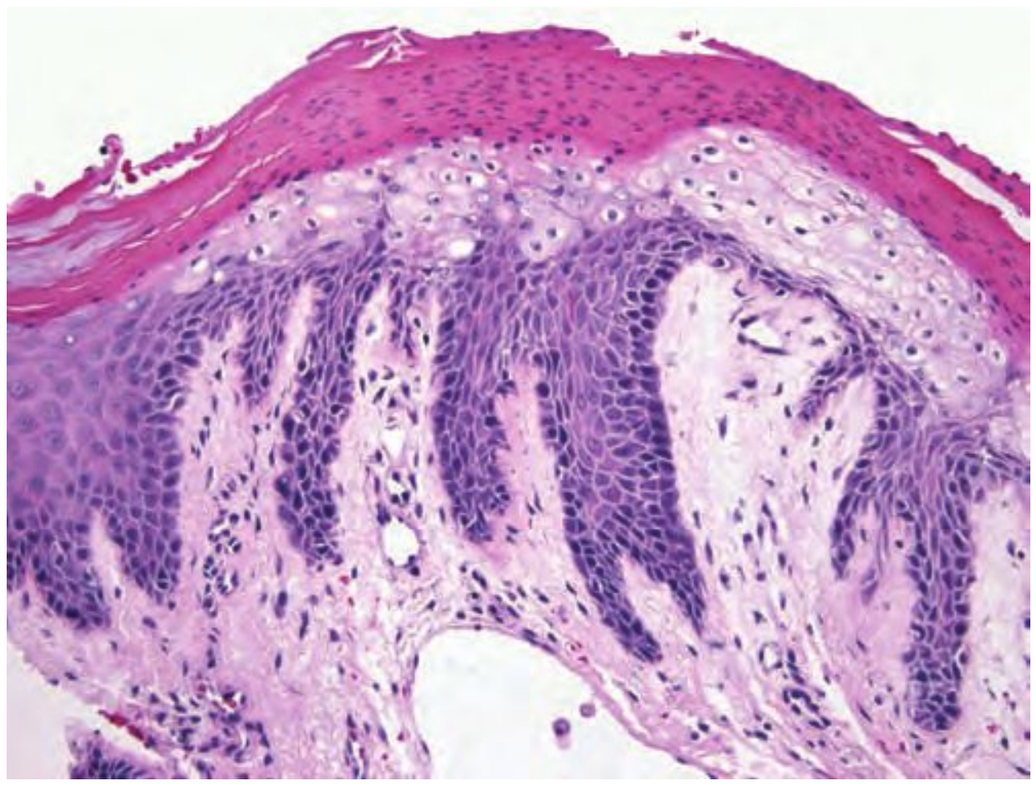

FIGURE 16-1. Necrolytic migratory erythema (glucagonoma syndrome). The lower portion of the stratum malpighii appears viable, whereas the upper portion shows necrolysis or "sudden death." The necrolytic portion manifests cytoplasmic eosinophilic homogenization with pyknotic nuclei.

OTHER FORMS OF NUTRITIONAL DERMATOSES

Necrolytic Migratory Erythema (Glucagonoma Syndrome)

First described in 1942 in a patient with a pancreatic islet cell carcinoma (36), this distinctive dermatosis, which can precede all other symptoms of pancreatic carcinoma by several years (37), is most commonly seen in association with a glucagon-secreting alpha cell tumor of the pancreas. Surgical extirpation of the neoplasm may result in resolution of the eruption, as may amino acid and fatty acid infusion (38,39).

The manifestations of glucagonoma syndrome include cutaneous and mucosal lesions, weight loss, anemia, adult-onset diabetes, glucose intolerance, elevation of serum glucagon levels, and thromboembolism (40). Skin lesions are seen mainly on the face in perioral and perinasal distribution, the perineum, genitals, shins, ankles, and feet and include erythema, erosions, and flaccid vesicular-pustular lesions that rupture easily and often have a circinate appearance due to peripheral spreading. Rapid healing and the continuous development of new lesions result in daily fluctuations of the eruption. Cheilitis, glossitis, brittle nails, and dyspareunia due to mucosal lesions are also reported (41).

Histopathology. The characteristic acute lesion shows abrupt necrosis of the upper layers of the stratum spinosum, which may detach from the subjacent viable epidermis. Keratinocyte degeneration varies from marked hydropic swelling to cytoplasmic eosinophilia and nuclear pyknosis. Neutrophilic chemotaxis to the necrotic epithelium may eventuate in a subcorneal pustule. Chronic lesions have as their hallmark a psoriasiform dermatitis. In both acute and chronic lesions there is architectural disarray, reflecting a maturation defect; it manifests as basal layer hyperplasia, vacuolar change, and a deficient granular layer. The epidermis is surmounted by a broad parakeratotic scale (Fig. 16-1). *Candida* may be noted (42,43).

Pathogenesis. Patients with glucagonoma have sustained gluconeogenesis resulting in a negative nitrogen balance, with protein amino acid degradation, even of epidermal proteins (44). In addition to glucagonoma, necrolytic migratory erythema has been reported with hepatic cirrhosis (45), jejunal adenocarcinoma with hepatic dysfunction, hepatitis B (46), malabsorption with villous atrophy (47), opiate dependency (48,49), and myelodysplastic syndrome (50). Glucagon levels may be normal. A comparable syndrome in dogs develops in the setting of diabetes mellitus and hepatic cirrhosis (43). In all of these conditions, malabsorption and diarrhea lead to isolated deficiencies of certain essential fatty acids, zinc, and amino acids. The pathophysiology may reflect in part a phospholipid fatty acid abnormality in cells due to defective delta-6-desaturase enzyme, which is known to be inhibited by zinc deficiency and excess alcohol intake. In patients with unresectable glucagonoma who manifest necrolytic migratory erythema, infusion of amino acids has resulted in rapid clearing of the cutaneous lesions (51). There is an interesting subgroup of patients with necrolytic erythema in whom the lesions are primarily confined to the dorsum of the feet. These cases are associated with hepatitis C and fall under the designation of necrolytic acral erythema (52). The dermatitis responds to a combination of antiviral therapy and zinc.

Differential Diagnosis. The histopathology is similar to that of other nutritional dermatoses, namely acrodermatitis enteropathica and pellagra. Those dermatitides associated with hyperkeratosis, a maturation disarray, and/or scattered degenerating keratinocytes such as graft-versus-host disease, subacute cutaneous lupus erythematosus, dermatomyositis, pityriasis rubra pilaris, and toxic drug eruptions, particularly those that are photo-induced, should also be considered.

Acrodermatitis Enteropathica

Acrodermatitis enteropathica, first described in 1942 (53), is transmitted as an autosomal recessive trait. Caused by defective intestinal absorption of zinc (54), it usually manifests in the first 4 to 10 weeks of life in bottle-fed infants as an acral and periorificial eruption with intractable diarrhea and diffuse partial alopecia. The skin exhibits areas of moist erythema, occasionally associated with vesiculobullous and/or pustular lesions (55). Untreated cases eventuate in death from malnutrition and infection because of immunologic defects reflecting zinc deficiency, the latter including decreased natural killer cell activity, impaired delayed-type hypersensitivity, and thymic atrophy (56). Paronychia, stomatitis, photophobia, blepharitis, conjunctivitis, corneal opacities, and hoarseness are additional manifestations. An acquired form occurs in patients receiving intravenous hyperalimentation with low zinc content (57), in infants who are fed breast milk low in zinc (58), in patients with Crohn's disease, in patients with ornithine transcarbamylase deficiency (59), in patients with status post pancreaticouodenectomy (60), and in the setting of AIDS nephropathy when proteinuria eventuates in excessive loss of protein-bound zinc (56).

Histopathology. The upper part of the epidermis shows pallor due to intracellular edema and is surmounted by a confluent, thick, parakeratotic scale that may contain neutrophils. There is granular cell layer diminution and focal dyskeratosis. As with necrolytic migratory erythema, there may be architectural disarray and dismaturation. Subcorneal vesicles may be present. The epidermis manifests variable psoriasiform hyperplasia and atrophy and, in a few instances, acantholysis (55,58). Superinfection with *Candida* may occur (Fig. 16-2).

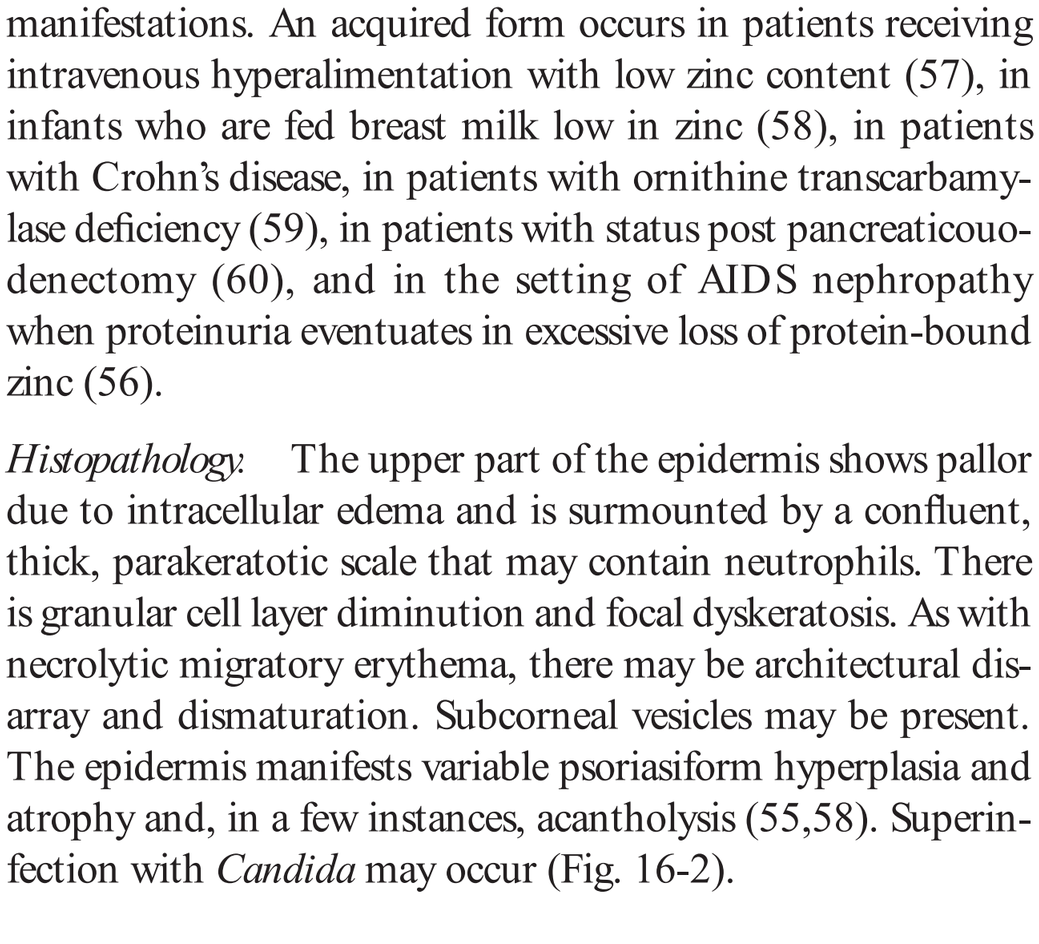

FIGURE 16-2. Acrodermatitis enteropathica. The epidermis demonstrates psoriasiform hyperplasia, dysmaturation, granular cell layer diminution, and vacuolar change. The epidermis is surmounted by a compact parakeratotic scale. Vascular ectasia is also present.

Pathogenesis. Defective intestinal absorption of zinc has been demonstrated in children with acrodermatitis enteropathica (61), resulting in plasma zinc levels well below the normal range of 68 to 112 μg/dL. Oral administration of zinc sulfate results in rapid and complete resolution of the disease. Electron microscopy shows abnormal keratinization with decreased keratohyalin granules and increased number of keratinosome-derived lamellae within intercellular spaces. Keratinosomes contain several zinc-dependent enzyme systems, the metabolism of which may be affected (62).

Congenital zinc deficiency leading to acrodermatitis enteropathica shortly after birth has been linked to a novel mutation in the SLC39A4 gene, localized to chromosome region 8q24.3 (63). The SLC39A4 gene is expressed in tissues involved in zinc absorption, including the stomach, small intestine, colon, and kidney; a mutation alters the protein's function of zinc absorption, causing zinc deficiency (64).

Differential Diagnosis. Pellagra, necrolytic migratory erythema, and acrodermatitis enteropathica share a constellation of histologic features that should suggest a diagnosis of nutritional dermatosis, namely, confluent parakeratosis, granular layer diminution, epidermal pallor and focal dyskeratosis, psoriasiform hyperplasia, and architectural disarray and dismaturation. Such cases can be misdiagnosed as eczema and psoriasis.

Kwashiorkor

Kwashiorkor is a form of protein malnutrition coupled to carbohydrate excess resulting in reduction of a patient's weight by 20% to 40%. Primary manifestations include generalized hypopigmentation that begins circumorally and in the pretibial regions. With disease progression, hyperpigmented plaques with a waxy texture develop over the elbows and ankles and in the intertriginous areas. Dryness, desquamation, and decreased skin elasticity occur. "Crazy pavement" or "flaky-paint dermatosis" describes the extensive desquamation with erosions and fissuring, vesicles, and bullae that may be seen in severe cases (65). Prominent edema can mask the underlying muscle and subcutaneous tissue atrophy (66). Hair abnormalities include a diffuse alopecia, alternating bands of normal and hypopigmented hair referred to as the "flag" sign, and an unusual reddish-brown discoloration called hypochromotrichia (65). Extracutaneous manifestations include cerebral atrophy secondary to loss of myelin lipid (67), diarrhea, hepatic steatosis, and mucosal abnormalities such as a smooth tongue, angular stomatitis, and perianal and nasal erosions.

Histopathology. The histologic picture of skin lesions is not diagnostic but is said to resemble that of pellagra (68). The changes include psoriasiform hyperplasia with hyperkeratosis and increased pigmentation throughout the epidermis or atrophy with irregular shortening and flattening of the rete (68).

Pathogenesis. The etiology of the edema includes reduced capillary blood flow, hypoalbuminemia, and increased peripheral vasoconstriction (69).

CUTANEOUS MANIFESTATIONS OF GASTROINTESTINAL DISEASE

Pyoderma Gangrenosum

First described in 1930 (70), pyoderma gangrenosum was once considered pathognomonic of idiopathic ulcerative colitis but has since been described in association with a wide variety of disorders, including roughly 5% of patients with Crohn's disease. Beginning as folliculocentric pustules or fluctuant nodules, the lesions ulcerate and have sharply circumscribed violaceous, raised edges in which necrotic pustules may be seen. The disease most commonly occurs on the lower extremities and trunk in adults who are 30 to 50 years old. Occasionally it occurs in childhood, affecting the buttocks, perineal region, and head and neck area (71,72). Koebnerization occurs at sites of trauma, including intravenous puncture sites, surgical wounds, and peristomal sites (73). Roughly 70% of cases are associated with inflammatory bowel disease, hematologic disorders including acute lymphoid and myeloid leukemias and myeloma, rheumatologic conditions including rheumatoid arthritis and lupus erythematosus, and hepatopathies (74,75), including chronic active hepatitis, primary biliary cirrhosis, and sclerosing cholangitis (72,76). Both a superficial granulomatous variant (77) and a vesiculopustular variant comprising disseminated vesicles and necrotizing pustules, some follicular based, have been observed without accompanying systemic disease. The vesiculopustular variant has also been seen in association with ulcerative colitis and/or underlying liver disease (76,78). Pyoderma gangrenosum has been associated with the administration of drugs including interferon (IFN)-α in the setting of chronic granulocytic leukemia, the antipsychotic agent sulpride (79), granulocyte colony-stimulating factor (80), the epidermal growth factor-tyrosine kinase inhibitor gefitinib (Iressa) (81), the retinoid isotretinoin (82), and the thionamide propylthiouracil (83).

Histopathology. Pyoderma gangrenosum exhibits a dichotomous tissue reaction, showing central necrotizing suppurative inflammation, usually with ulceration, and a peripheral lymphocytic vascular reaction comprising perivascular and intramural lymphocytic infiltrates, usually without fibrin deposition or mural necrosis (Figs. 16-3 and 16-4). Transitional areas show neutrophils in a loose cuff around the angiocentric lymphocytic infiltrates, defining a mixed lymphocytic and neutrophilic vascular reaction termed a *Sweet's-like vascular reaction* (84,85). Bullous lesions may also demonstrate a Sweet's-like vascular reaction with perivascular disintegrating neutrophilic infiltrates and hemorrhage without mural necrosis or luminal fibrin deposition. At variance with Sweet's syndrome is destruction of the connective tissue framework with resultant tissue pathergy (86,87). Although a leukocytoclastic vasculitis may be observed in areas of maximal tissue pathology, pyoderma gangrenosum does not reflect a primary vasculitis (72). In some cases a necrotizing pustular follicular reaction may be the central nidus of the lesion, particularly in the vesicular pustular variant associated with ulcerative colitis or

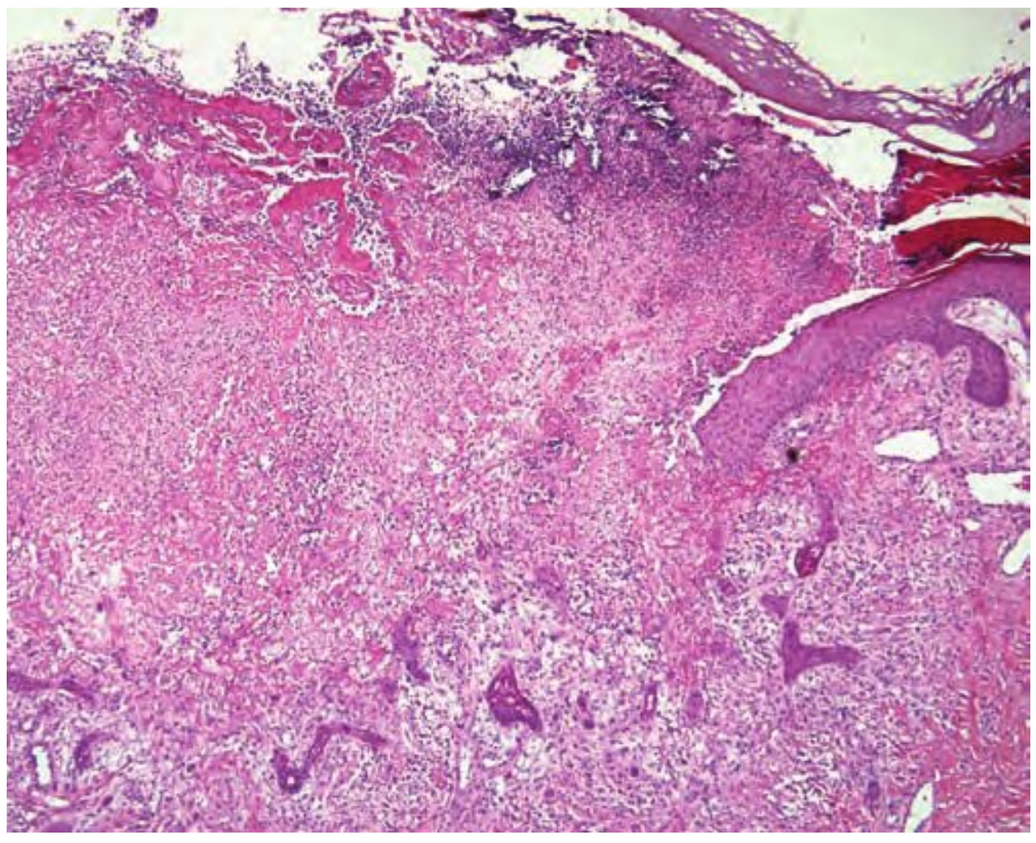

FIGURE 16-3. Pyoderma gangrenosum. The center of the lesion shows a neutrophilic infiltrate with leukocytoclasia and dermolysis. This biopsy is from a patient with Crohn's disease, as evidenced by the presence of multinucleated histiocytes within the infiltrate.

hepatobiliary disease. In the superficial granulomatous variant, florid pseudoepitheliomatous hyperplasia may be observed along with the intraepithelial and superficial dermal suppurative granulomatous inflammation with admixed plasma cells and eosinophils (77). Cases of pyoderma gangrenosum associated with Crohn's disease may have areas of granulomatous inflammation (88).

Differential Diagnosis. Tissue neutrophilia with epithelial undermining and ulceration in the absence of leukocytoclastic vasculitis, fungal, bacterial, or mycobacterial organisms (which, if indicated, may be demonstrable with culture and special stains, e.g., periodic acid–Schiff, Gomori methanamine

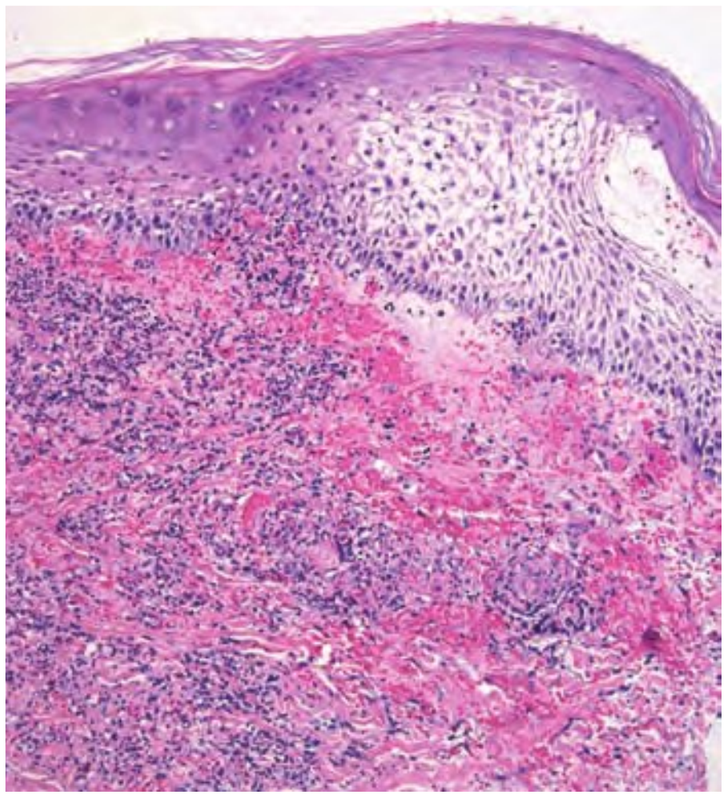

FIGURE 16-4. Pyoderma gangrenosum. The undermined epidermis often shows spongiosis or pustulation.

silver, Brown and Brenn, Gram's, Ziehl-Neelson, and auramine-rhodamine preparations), strongly implicates pyoderma gangrenosum when seen in the appropriate clinical setting (72). An incipient lesion of pyoderma gangrenosum, however, may be indistinguishable from Sweet's syndrome, although the latter is rarely folliculocentric and does not show lysis of dermal collagen or vessel wall necrosis in areas of maximum dermal neutrophilia. In addition, clinical features usually make the distinction possible. Because of prominent follicular involvement, the differential diagnosis should also include other causes of necrotizing pustular follicular reactions with an accompanying vasculopathy, such as mixed cryoglobulinemia, Behçet's disease, rheumatoid vasculitis, herpetic folliculitis, acute pustular bacterid, and pustular drug reactions (89). These other conditions frequently have a necrotizing mononuclear cell or neutrophil predominant vasculitis in contrast to the nonnecrotizing vascular reaction of pyoderma gangrenosum. Other causes of a Sweet's-like vascular reaction include the bowel arthritis dermatosis syndrome, Behçet's disease, idiopathic pustular vasculitis, rheumatoid arthritis, acute pustular bacterid, and Sweet's syndrome (84,85).

Pathogenesis. Direct immunofluorescence testing supports a vasculopathy by virtue of perivascular deposition of immunoreactants, mainly immunoglobulin (Ig) M and C3 (90), in more than half of patients. This change occurs in nonspecific vessel injury and does not support a humoral-based pathogenesis. Defective cell-mediated immunity without humoral abnormalities has been implicated in some patients (91). Immunoelectrophoresis has revealed a monoclonal gammopathy, most commonly of the IgA type, in 10% of patients with pyoderma gangrenosum (92). A recent polymerase chain reaction analysis demonstrated that patients with pyoderma gangrenosum have clonal expansions of T cells in the peripheral blood and skin. These clonal expansions are shared between both sites, suggesting that T cells are trafficking to the skin under the influence of an antigenic stimulus (93). In further support of a potential antigenic stimulus, patients with pyoderma gangrenosum have elevated levels of interleukin-8 (IL-8), a powerful neutrophilic chemoattractant, in both the serum and fibroblasts of affected skin (94).

Bowel-Associated Dermatosis–Arthritis Syndrome (Bowel Bypass Syndrome)

After intestinal bypass surgery for morbid obesity or after extensive small bowel resection, some patients develop an intermittent eruption, mainly on the extremities, comprising purpuric macules and papules that may evolve into necrotizing vesiculopustular lesions. Polyarthritis, malaise, and fever are often associated with and may precede the eruption (95). Although originally called the bowel bypass syndrome, it now bears the more appropriate appellation *bowel arthritis dermatosis syndrome* because a similar picture may develop in patients with diverticulosis, peptic ulcer disease, and idiopathic inflammatory bowel disease (96–99).

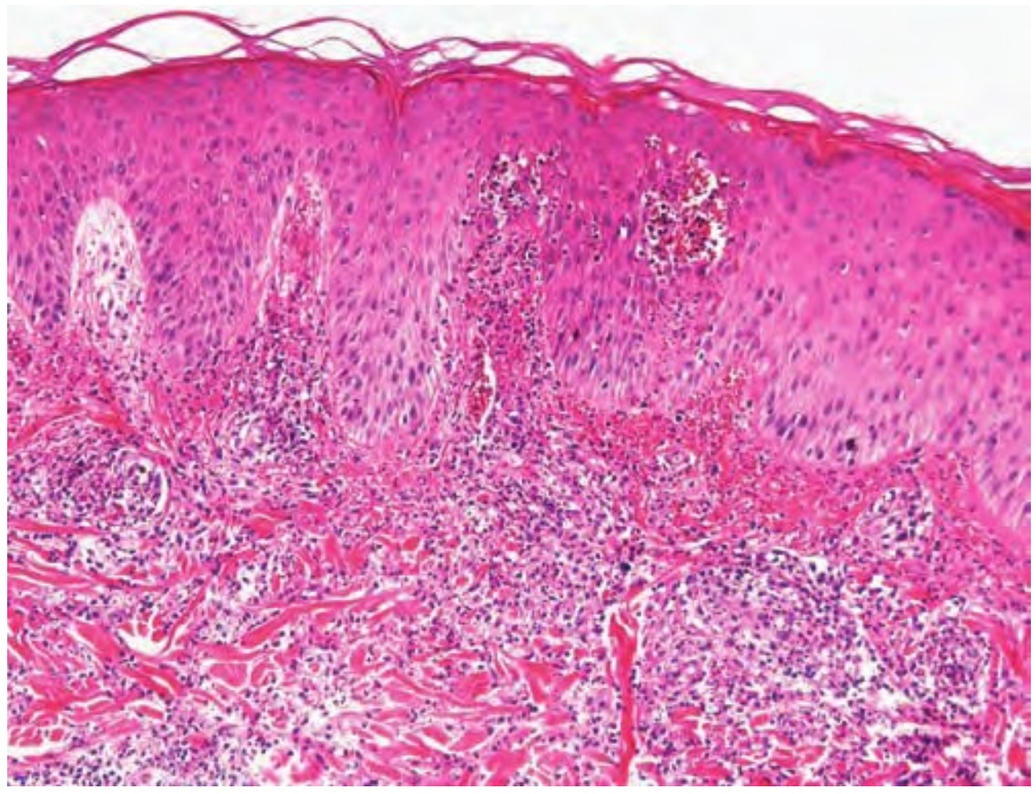

FIGURE 16-5. Bowel arthritis dermatosis syndrome. Pustular vasculitis characterized by dermal papillae microabscess formation along with a leukocytoclastic vasculitis.

Histopathology. Characteristically, there is a perivascular lymphocytic infiltrate with a peripheral cuff of disintegrating neutrophils, erythrocyte extravasation, and absent or minimal fibrin deposition consistent with a Sweet's-like vascular reaction; a leukocytoclastic vasculitis occurs less often (99). Papillary dermal edema may be striking and may lead to subepidermal vesiculation (95). Epidermal pustulation, variable epithelial necrosis, and massive superficial dermal neutrophilia complete the picture (Fig. 16-5) and define pustular vasculitis (95,100).

Pathogenesis. Circulating immune complexes, including those containing cryoproteins, are demonstrable in most patients. The antigenic trigger may be peptidoglycans from intestinal bacteria (96), which are structurally and antigenically similar to the peptidoglycan of *Streptococcus*. The latter exacerbate symptoms in patients with this condition and produce a similar syndrome in animals (96). Direct immunofluorescence testing has shown linear and granular deposits of immunoglobulins and complement along the dermal–epidermal junction and within vessels (96). One study showed *Escherichia coli* antigens in a granular array along the dermal–epidermal junction. Via an indirect methodology, a pemphigus-like pattern of intercellular staining has been reported (96), the significance of which is unclear.

Differential Diagnosis. The differential diagnosis of bowel arthritis dermatosis syndrome includes Sweet's syndrome, incipient pyoderma gangrenosum, and certain of the pustular vasculitides, such as acute pustular bacterid related to antecedent streptococcal infection, such as Henoch-Schönlein purpura (100), septic vasculitis due to *Meningococcus* and *Gonococcus*, Behçet's syndrome, leukocytoclastic vasculitis in patients with a pustular psoriasiform diathesis (101), idiopathic pustular vasculitis, and acute generalized exanthemous pustulosis (85,101). The distinction may be impossible in those conditions that manifest a

Sweet's-like vascular reaction—namely, Behçet's disease, Sweet's syndrome, pyoderma gangrenosum, acute pustular bacterid, and idiopathic pustular vasculitis (85).

SPECIFIC DISEASES

Aphthosis (Behçet's Disease)

Behçet's disease is a symptom complex of oral and genital ulceration and iritis that has a worldwide distribution but is most common in the Pacific rim and eastern Mediterranean (102,103). The presence of oral ulceration plus any two signs of genital ulceration, skin lesions (e.g., pustules or nodules), or eye lesions (e.g., uveitis or retinal vasculitis) is diagnostic.

The cutaneous lesions include erythema nodosum–like nodules, vesicles, pustules, pyoderma gangrenosum, Sweet's syndrome, a pustular reaction to needle trauma, superficial migratory thrombophlebitis, ulceration, infiltrative erythema, acral purpuric papulonodular lesions, and acneiform folliculitis (104,105).

The extracutaneous manifestations are categorized as oral and/or genital aphthae; vasculo-, ocular-, entero-, or neuro-Behçet's disease; renal disease; and arthritis. Oral apthosis recurring at least three times over a 12-month period is essential to the diagnosis (103). In vasculo-Behçet's disease, aneurysms and occlusive venous and arterial main vessel lesions occur. The ocular manifestations include uveitis, hypopyon iritis, optic neuritis, and choroiditis. Entero-Behçet's disease manifests as diarrhea, constipation, abdominal pain, vomiting, and melena. Neuro-Behçet's disease presents as brainstem dysfunction, meningoencephalitis, organic psychiatric symptoms, and mononeuritis multiplex (104). Asymptomatic microhematuria and/or proteinuria are among the renal manifestations. An oligoarthritis may involve the wrist, elbow, knee, or ankle joints. Morbidity and mortality in one large series of Turkish patients were greatest in young males; both the onset and the severity of ocular disease were greatest early in the course of disease, suggesting that the "disease burden" in Behçet's disease is greatest early and that it tends to "burn out" over time (106). However, neurologic and major vessel disease can occur at any time and can have late onset 5 to 10 years into the course of illness (106).

Histopathology. The cutaneous lesions can be categorized histopathologically into two main groups: vascular and extravascular with or without vasculopathy including acneiform.

The pathologic spectrum of the cutaneous vasculopathy encompasses a mononuclear cell vasculitis with variable mural and luminal fibrin deposition; a paucicellular thrombogenic vasculopathy (Fig. 16-6); and a neutrophilic vascular reaction involving capillaries and veins of all calibers. The mononuclear cell reaction may be frankly granulomatous or it may be lymphocytic predominant to define a lymphocytic vasculitis. The neutrophilic vascular reaction may resemble that of Sweet's syndrome (Fig. 16-7) (107) or a leukocytoclastic vasculitis. Diffuse extravascular mononuclear cell– and/or neutrophil–

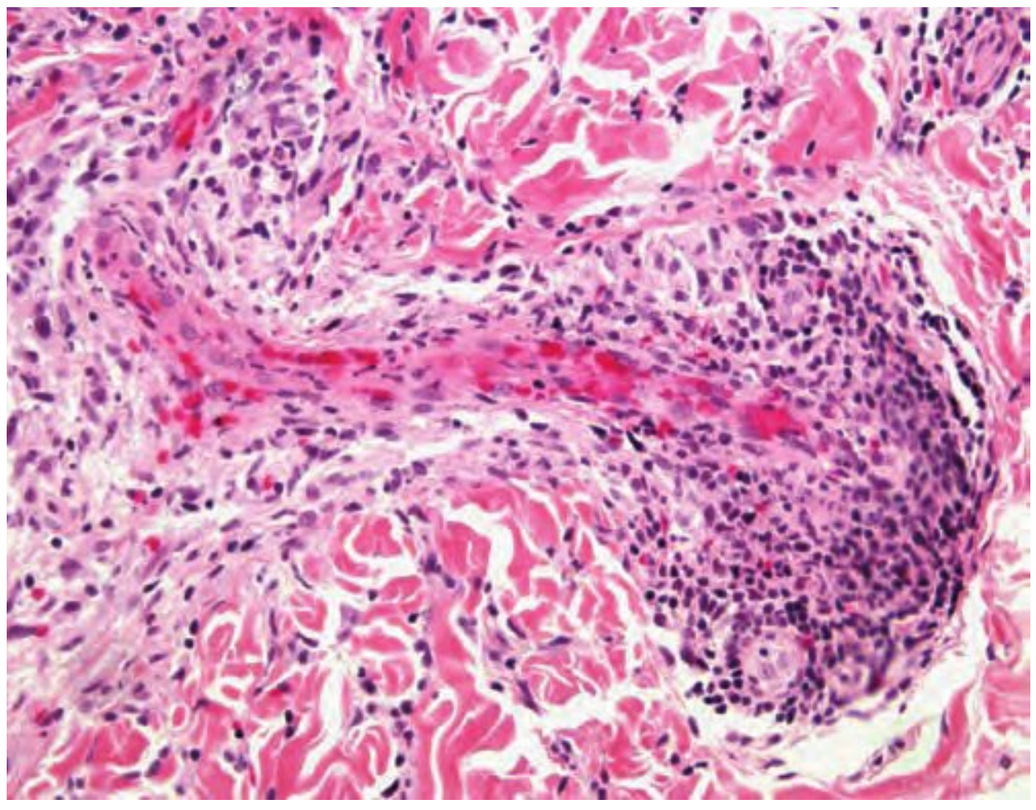

FIGURE 16-6. Behçet's disease. A characteristic vascular reaction pattern is a lymphocytic thrombogenic vasculopathy.

predominant inflammation of the dermis and/or panniculus may occur with or without the aforementioned vascular changes. The histiocytes infiltrating the panniculus may manifest phagocytosis of cellular debris. Suppurative or mixed suppurative and granulomatous folliculitis with or without vasculitis characterizes the acneiform lesions. Acral purpuric papulonodular lesions show a lymphocytic interface dermatitis with lymphocytic exocytosis, dyskeratosis, and a perivascular lymphocytic infiltrate, recapitulating the mucosal histopathology (105).

Extracutaneous lesions histologically mirror the skin changes. Oral aphthous ulcers demonstrate a central diffuse

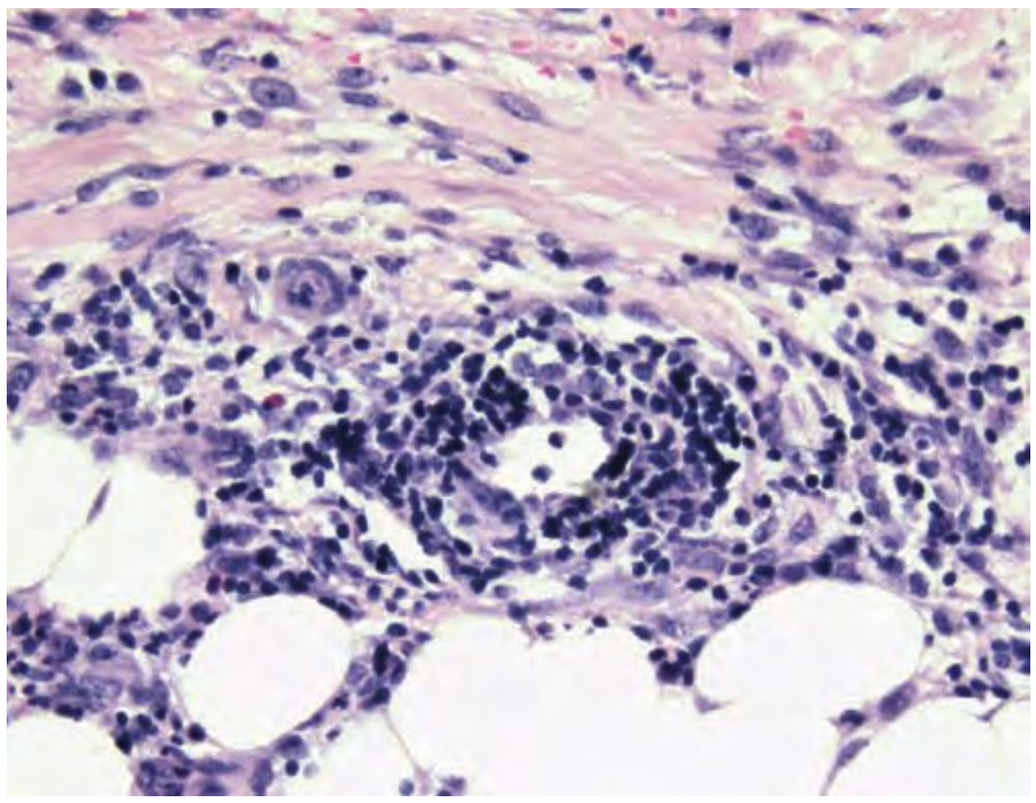

FIGURE 16-7. Behçet's disease. There is a Sweet's-like vascular reaction manifested by angiocentric mononuclear cell and neutrophilic infiltrates with erythrocyte extravasation and leukocytoclasia but without accompanying mural and intraluminal fibrin deposition.

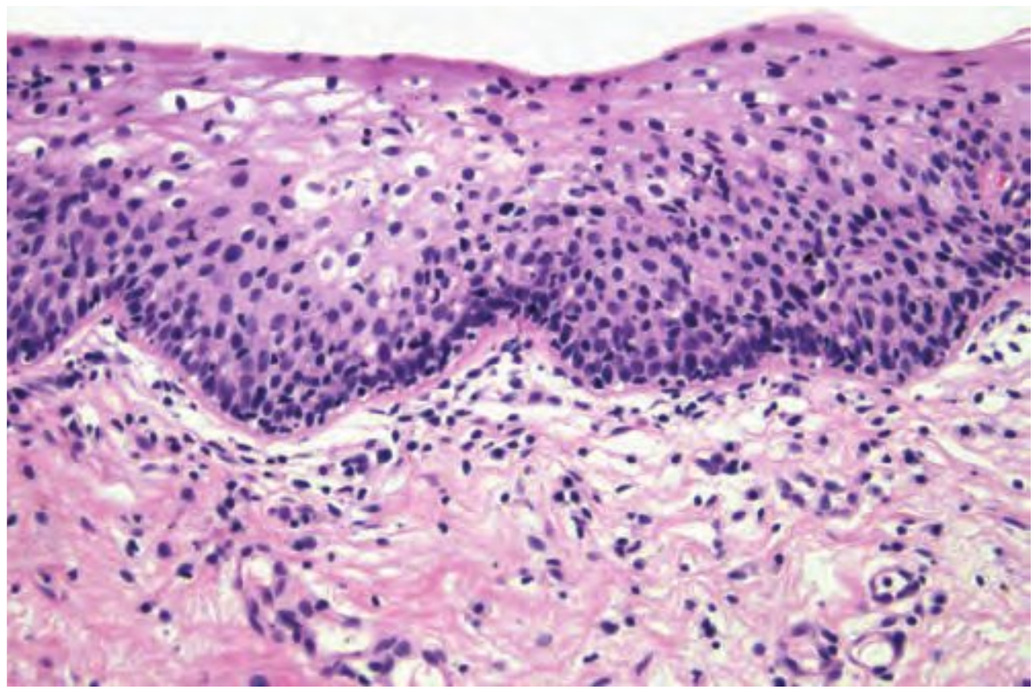

FIGURE 16-8. Behçet's disease. Although the center of an oral or vulvar aphthous ulcer is predominated by a neutrophilic response, biopsies of the periphery typically show a lymphocyte predominate infiltrate both in an extravascular and angiocentric disposition with variable lymphocytic exocytosis.

neutrophilic infiltrate with necrosis of the epithelium and connective tissue pathergy of the submucosa and peripherally a border showing dense lymphocytic infiltration with lymphocytic exocytosis and degenerative epithelial changes. Genital aphthae have the same appearance (Fig. 16-8) (104). The large-vessel arteriopathy represents an ischemic sequelum of a mononuclear cell vasculitis of the vasa vasorum (108), whereas venous thrombosis may be due in part to an underlying hypercoagulable state. A lymphocytic vascular reaction with or without mural and intraluminal fibrin deposition is the histopathology of neuro-, entero-, ocular-, and arthritic Behçet's disease, with other organ changes such as demyelination and intestinal ulceration reflecting resultant ischemia (104). The renal histopathology includes IgA nephropathy, focal and diffuse proliferative glomerulonephritis, and amyloidosis (109).

Differential Diagnosis. The lymphocytic vasculitis observed in Behçet's disease may mimic that seen in association with systemic lupus erythematosus, rheumatoid arthritis (110,111), Sjögren's syndrome, relapsing polychondritis, Degos' disease, and paraneoplastic vasculitis in the setting of lymphoproliferative disease. Granulomatous vasculitis may also be observed in Wegener's granulomatosis, allergic granulomatosis of Churg-Strauss, Crohn's disease, sarcoidosis, acquired hypogammaglobulinemia, a postherpetic eruption (112), paraneoplastic syndrome (related to underlying hematologic malignancy), rheumatoid arthritis, hypersensitivity reactions to certain infections including syphilis and tuberculosis (113), scleroderma, and late-stage lesions of microscopic polyarteritis nodosa (85,100,111). Other causes of a Sweet's-like vasculopathy include Sweet's syndrome, bowel arthritis dermatosis, pyoderma gangrenosum, and idiopathic pustular vasculitis (84). Conditions that combine a vasculitis with a folliculitis include pyoderma gangrenosum, mixed cryoglobulinemia, rheumatoid vasculitis, and bacterid (89).

Pathogenesis. An immunogenetic basis is likely in view of the association with certain HLA types, namely HLA-B5, HLA-B12, HLA-B27, and HLA-B51 (114). A recurring association in patients of Japanese, Turkish, Korean, and Iranian ethnicities is with HLA-B51 (115,116), genetic polymorphisms in the promoter region of tumor necrosis factor-α (TNFα) (117–120), and microsatellite instabilities between these two genes (116,121). Polymorphisms of other cytokines have been identified, including IL-1 (122) and IL-18 (123). Behçet's disease patients have elevated levels of Th1 cytokines IL-12, IFNγ, and TNFα (124); increased Th1-associated chemokine receptors CCR5 and CXCR3 (125), and a lower percentage of plasmacytoid dendritic cells in peripheral blood (126), supporting the proposed Th1-mediated pathogenesis of the disease. Patients have shown a heightened immune response to antigenic components of certain streptococcal species (127,128), *Mycobacterium tuberculosis* (129), herpes simplex (130,131), Epstein-Barr virus, and human immunodeficiency virus (HIV) (132). Underlying abnormalities in T-lymphocyte function may be integral to an aberrant response related to the synthesis by microorganisms and mammalian tissue of a family of polypeptides termed heat shock proteins (HSPs) (133,134) produced by cells exposed to stresses such as increased temperature. Sensitized T cells and T-cell clones specific to the 65-kD mycobacterial HSP have been reported in rheumatoid arthritis (135). T lymphocytes from patients with Behçet's disease in one study exhibit a greater stimulation by this HSP compared to normal controls or patients with unrelated disease (136). The γδ T-cell subset has been shown to be the principal populace that responds to the mycobacterial 65-kD HSP, an observation that may account for the increase in circulating γδ T cells in patients with antecedent streptococcal or mycobacterial infections (137) and in those with active Behçet's disease, in whom an exaggerated response to microbial products in mucosal ulcers is postulated (138). The lymphocytes themselves show resistance to Fas-mediated apoptosis, a finding that may promote lymphocyte-mediated tissue destruction in these patients (139).

Tissue neutrophilia may relate to the presence of HLA-B51, which has been associated with neutrophil hyperreactivity (140). Neutrophil functions are also increased in Behçet's disease (141), which may be due to alteration in expression of Toll-like receptors, regulators of innate and adaptive immunity, on both granulocytes and monocytes (142).

Vascular thrombosis has been attributed to antibody-mediated endothelial injury (143), protein C or S deficiency (144), factor XII deficiency, inhibition of plasminogen activator, and circulating lupus anticoagulant (145–147). A prothrombin gene mutation has recently been described (148). Further evidence of a genetic predisposition to thrombosis is the linkage of HLA-B51 expression and the absence of HLA-B35 as risk factors for venous thrombosis in Turkish patients (115); there is also a statistical linkage between superficial and deep venous thrombosis (149). Elevated serum levels of matrix metalloproteinases MMP-2 and MMP-9 are associated with vasculo-Behçet's disease, particularly thrombotic and aneurysmatic involvement, respectively (150).

The role of nitric oxide (NO) is unclear. Some researchers have shown that patients with active Behçet's disease have significantly higher serum levels of NO than patients with recurrent aphthous stomatitis (151), patients with inactive Behçet's disease, and healthy controls (152), whereas others maintain that there is no difference in NO levels among these groups (153,154), and still others contend that levels of NO are lower in Behçet's patients (155,156). Specific genetic polymorphisms have been identified in the manganese superoxide dismutase gene in Japanese Behçet's patients (157) and the Glu298Asp polymorphism in the endothelial nitric oxide synthase (eNOS) gene in Turkish (158,159), Italian (160), and Korean (161) Behçet's patients. One study did not identify the eNOS polymorphism in Turkish Behçet's patients (162). Others propose that the significantly higher levels of IL-2, IL-6, TNFα, and NO are related to the pathogenesis of Behçet's disease (163).

INFLAMMATORY BOWEL DISEASE

Crohn's Disease (Regional Enteritis)

First described in 1932, Crohn's disease is an idiopathic disorder of the gastrointestinal tract. The diagnosis is based on a constellation of radiologic, pathologic, and endoscopic data, namely deep mucosal fissures, fistula formation, transmural inflammation, discontinuous colonic and small bowel disease with preferential right-sided involvement, and sarcoidal granulomatous and fibrosing inflammation of the mucosa and submucosa (164). Extraintestinal manifestations include fever, anemia, lupus anticoagulant, ophthalmic disease such as uveitis and episcleritis, monoarticular large-joint arthritis, polyarthritis, spondylitis, amyloidosis (165), renal lithiasis with resultant hydronephrosis (166), cerebral vascular occlusions, and a spectrum of cutaneous eruptions.

Skin manifestations, principally restricted to patients with colonic disease, occur in 14% to 44% of patients with Crohn's disease, depending on whether perianal disease is considered a cutaneous manifestation (164). Ulcers, fissures, sinus tracts, abscesses, and vegetant plaques may extend in continuity from sites of intraabdominal involvement to the perineum, buttocks, or abdominal wall, ostomy sites, or incisional scars. When sterile granulomatous skin lesions arise at sites discontinuous from the gastrointestinal tract, the appellation "metastatic Crohn's disease" is applied (167). Clinically, metastatic Crohn's disease presents as solitary or multiple nodules, plaques, ulcers, lichenoid lesions, or violaceous perifollicular papules involving extremities, intertriginous areas, abdominal skin folds, or genitalia (168). Erythema nodosum (169)—the most common cutaneous manifestation of Crohn's disease (164)—and pyoderma gangrenosum develop in 15% and 1.5% of patients, respectively. Palmar erythema, a pustular response to trauma (169), erythema multiforme usually with mucosal involvement (169,170), epidermolysis bullosa acquisita, hidradenitis suppurative, rosacea, secondary cutaneous oxalosis, malabsorption-related acrodermatitis enteropathica (169), vasculitic lesions including benign cutaneous polyarteritis nodosa, and digitate hyperkeratosis reminiscent of punctate porokeratosis are described (171). Cutaneous necrosis as a complication of circulating lupus anticoagulant may also occur.

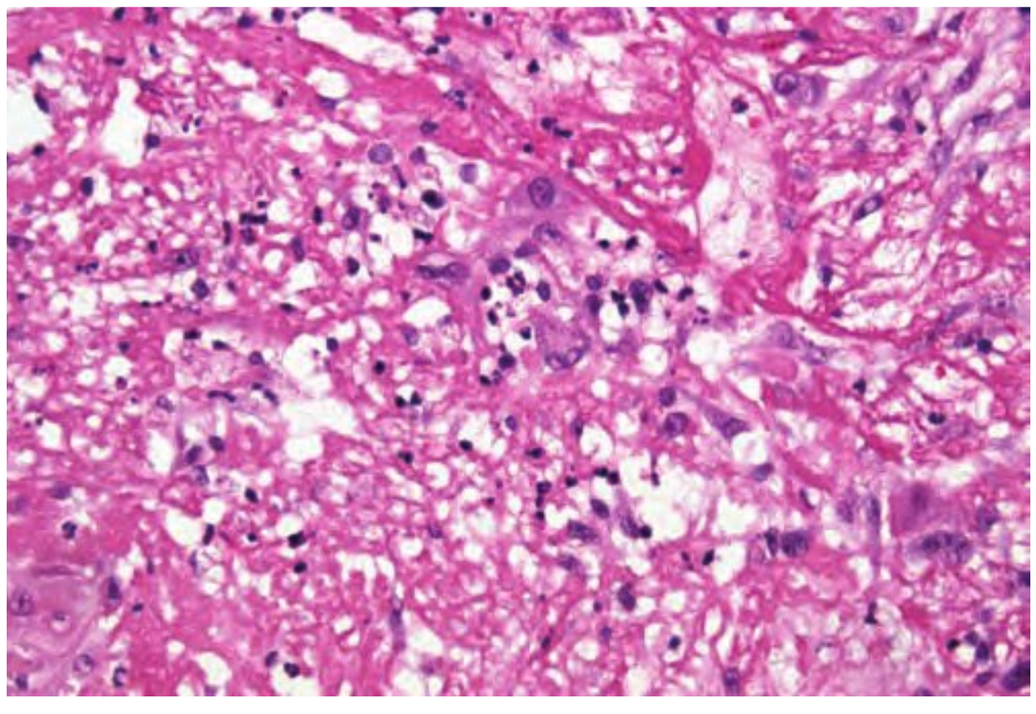

FIGURE 16-9. Crohn's disease: pyoderma gangrenosum. This biopsy shows suppurative granulomatous inflammation with a binucleate histiocyte in the center of the field and a mononuclear cell–predominant vasculopathic reaction patterns; biopsies of metastatic Crohn's disease may show a necrotizing leukocytoclastic and granulomatous vasculitis indistinguishable from cutaneous Wegener's granulomatosis and reminiscent of pyostomatitis vegetans, a prototypic oral lesion of Crohn's disease can be seen.

Oral lesions, manifesting as "cobblestone" lesions, aphthous ulcers, lip swelling, and pyostomatitis vegetans, occur in roughly 5% of patients with Crohn's disease (169).

Histopathology. The perianal mucosal lesions and oral lesions of pyostomatitis vegetans show pseudoepitheliomatous hyperplasia in conjunction with suppurative granulomatous inflammation within the epithelium and subjacent corium (Fig. 16-9). The most frequent histologic patterns seen in metastatic Crohn's disease are nonsuppurative granulomata, which may assume a sarcoidal or diffuse pattern, the latter often in close apposition to the epidermis in the fashion of a lichenoid and granulomatous dermatitis (172) and granulomatous vasculitis. Histologic examination of the erythema nodosum–like lesion may show one of four patterns: (a) septal panniculitis consistent with classic erythema nodosum, (b) dermal-based sarcoidal granulomata (173), (c) a dermal-based small-vessel granulomatous (174) or leukocytoclastic vasculitis, or (d) benign cutaneous polyarteritis nodosa. The latter shows mural infiltration by histiocytes and neutrophils with variable mural fibrinoid necrosis confined to the muscular arteries of the subcutaneous fat (see Fig. 16-12); occasional vessel involvement of the peripheral nerves and skeletal muscle of the affected extremity produce mononeuritis and myositis, respectively (132). A pauci-inflammatory thrombogenic vasculopathy characterizes the cutaneous infarcts associated with lupus anticoagulant. Necrobiosis lipoidica–like or granuloma annulare–like foci (176) may also be seen defined by areas of collagen necrobiosis with concomitant mucin or fibrin deposition and a palisading histiocytic infiltrate. Unlike idiopathic granuloma annulare or necrobiosis lipoidica, there usually

is an accompanying leukocytoclastic vasculitis, thrombogenic or granulomatous vasculopathy, and foci of extravascular neutrophilia (176). Dense neutrophilic infiltration of the dermis accompanied by scattered giant cells has been reported (88,177). We have also seen this pattern of suppurative granulomatous inflammation in concert with the aforementioned necrobiosis lipoidica or granuloma annulare tissue reaction. Cases of lip swelling show nonnecrotizing granulomatous inflammation (169). The histology of pyoderma gangrenosum has been previously discussed. A suppurative panniculitis may also be seen (178).

Differential Diagnosis. The differential diagnosis of sarcoidal granulomatous inflammation in the skin includes sarcoidosis, id reactions to antecedent streptococcal or mycobacterial infections (113), acquired hypogammaglobulinemia, rosacea, paraneoplastic histiocytopathies such as those associated with low-grade lymphoproliferative disease, rheumatoid arthritis, and granulomatous inflammatory reactions to ingested or inoculated inorganic compounds such as silica, zirconium, and beryllium. The lesions resembling benign cutaneous polyarteritis nodosa differ from systemic polyarteritis nodosa by virtue of confinement of the vasculitis to the subcutaneous fat without dermal involvement (175). The changes of pyostomatitis vegetans also should raise the possibility of Wegener's granulomatosis, mycobacterial infection, blastomycosis, and histoplasmosis. The histopathology of the lip swelling may mimic that of Melkersson-Rosenthal syndrome (169). Lichenoid and granulomatous dermatitis calls into consideration the idiopathic lichenoid disorders such as lichen nitidus, certain microbial id reaction states, and also drug reactions such as those to antibiotic, antihypertensive, lipid-lowering, and antihistaminic preparations (172).

Pathogenesis. In the development of Crohn's disease, there is a complex interplay between genetic, immunologic, and environmental factors, which is not completely understood. At least 10 genes have been proposed to play a role; the best studied is *CARD15*/*NOD2*, a gene involved in bacterial recognition by cells involved in innate immunity (179). Three *CARD15*/*NOD2* mutations are associated with Crohn's disease susceptibility, with approximately a 2- to 4-fold risk in heterozygotes and 17- to 40-fold risk in homozygotes (179–181). This dose effect suggests a loss-of-function model and is supported by *in vitro* studies. Speculations claim that the loss of function in innate immunity allows bacterial proliferation and a potential cytokine imbalance allows an inflammatory response from the adaptive immunity, and ultimately causes tissue damage. *In vivo* studies have failed to confirm these speculations and have even generated other hypotheses, including a gain-of-function model (179). Even less is understood about the pathogenesis of skin lesions in Crohn's disease. There is a common morphology shared by the intestinal and cutaneous disease of sarcoidal granulomatous inflammation, suggesting a pathogenetic role for cell-mediated immunity. Circulating immune complexes have been detected in some patients (169) and may play a role in the generation of necrotizing vasculitis; a subset of patients with Crohn's disease has antineutrophil cytoplasmic antibodies. Based on the use of *in situ* polymerase chain reaction methods with a probe seeking bacterial 16rsRNA common to a variety of microbial pathogens implicated in Crohn's disease, bacterial RNA has been shown in the vasculature of the gut in active but not in quiescent cases; the skin lesions are uniformly negative. It would seem, therefore, that the skin manifestations of Crohn's disease are not a bacterial id reaction but rather reflect an autoimmune phenomenon, perhaps involving cross-reacting antibodies between gut- and skin-based antigens (178).

Ulcerative Colitis

Ulcerative colitis is an idiopathic inflammatory bowel disease involving the large intestine, with rectal involvement being almost ubiquitous. It is characterized by glandular destruction and inflammation of variable intensity. Glandular dysplasia eventuating in carcinoma complicates the clinical course, particularly in patients with disease of pediatric onset. Extramucosal associations include chronic active hepatitis, primary sclerosing cholangitis, pulmonary vasculitis (182), chronic fibrosing alveolitis, limited Wegener's granulomatosis of the lung (183), pulmonary apical fibrosis, large-joint monoarticular arthritis, polyarthritis, and ankylosing spondylitis. Cutaneous manifestations may occur, the spectrum of which encompasses vasculitis, erythema nodosum, pyoderma gangrenosum, superficial migratory thrombophlebitis, and cutaneous thrombosis with resultant gangrene (184); the two last-named manifestations are possibly related to underlying lupus anticoagulant or cryofibrinogenemia (185). Pyoderma gangrenosum is more frequently associated with ulcerative colitis than with Crohn's disease and erythema nodosum more frequently with Crohn's disease (Fig 16-10). The

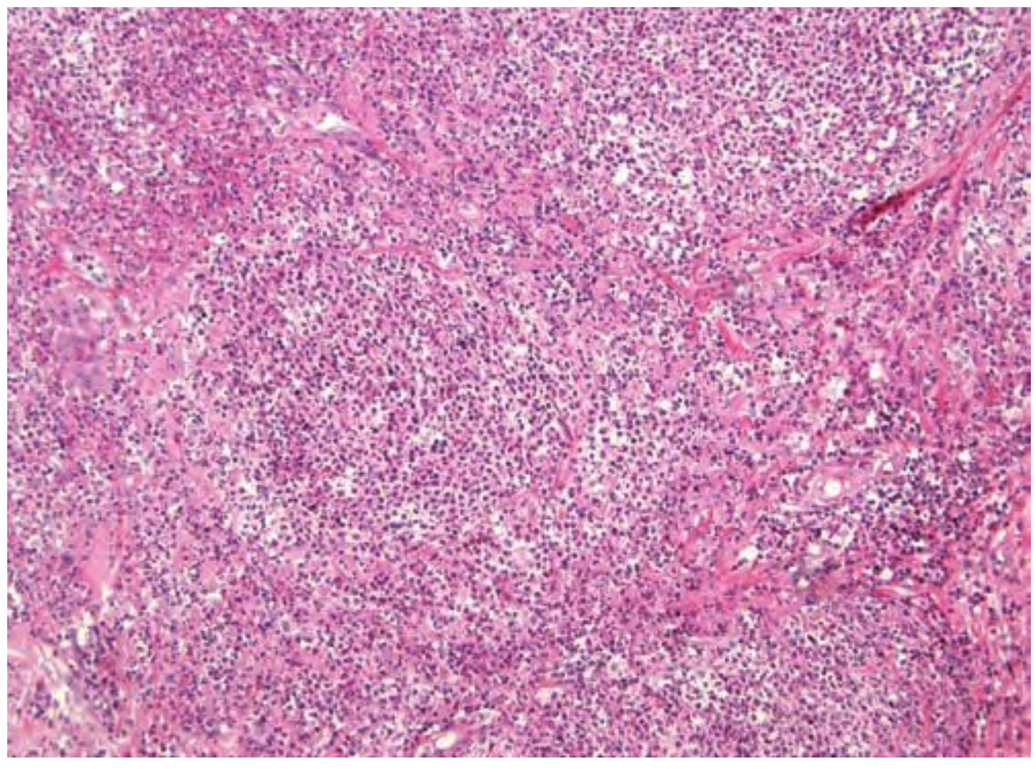

FIGURE 16-10. Ulcerative colitis: pyoderma gangrenosum. There is pronounced neutrophilic dermolysis.

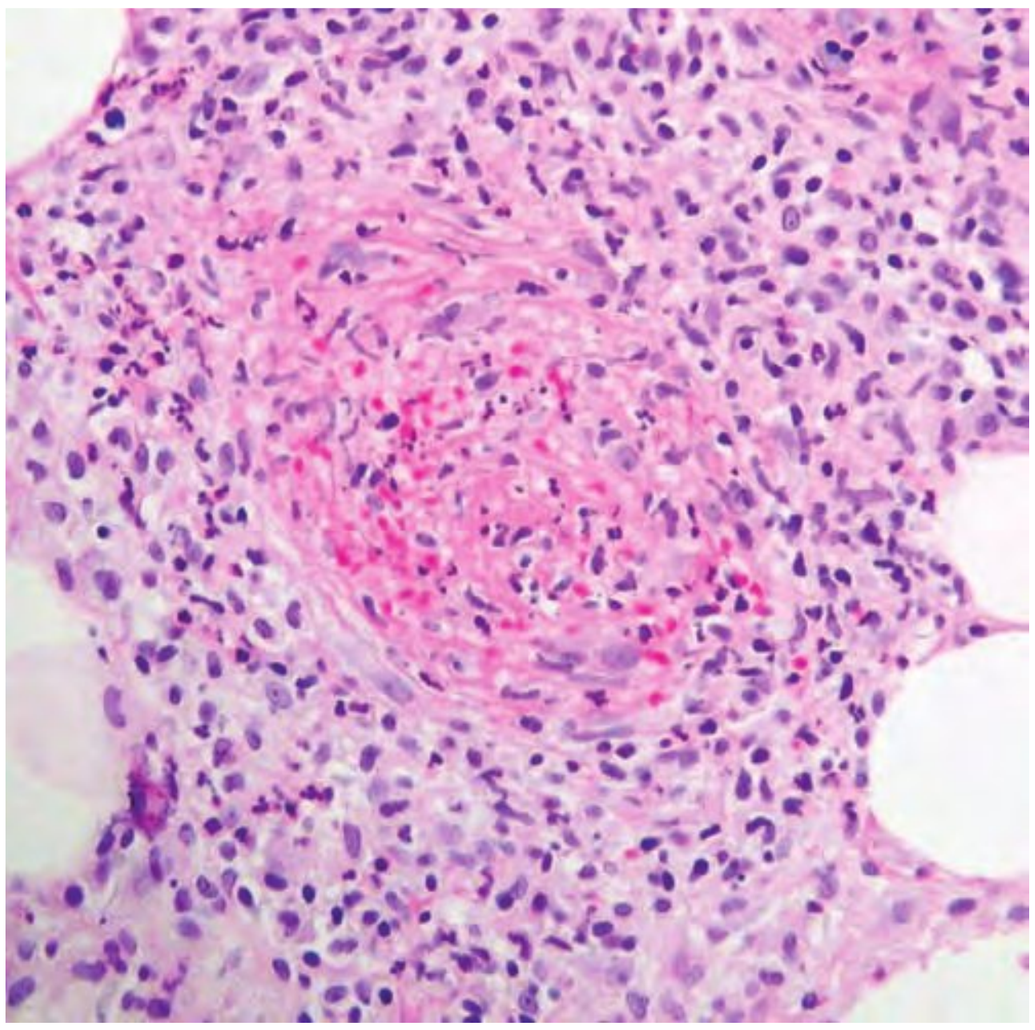

FIGURE 16-11. Polyarteritis nodosa in a patient with ulcerative colitis. Within the subcutaneous fat, the wall of a subcutaneous artery demonstrates striking fibrinoid necrosis and is surrounded and permeated by disintegrating neutrophilic infiltrates unaccompanied by small-vessel involvement. The findings are typical for benign cutaneous polyarteritis nodosa.

lesions of pyoderma gangrenosum also include an unusual disseminated vesiculopustular variant (186).

Histopathology. The histology of pyoderma gangrenosum and erythema nodosum is discussed elsewhere. Cutaneous vasculitis in association with ulcerative colitis includes IgA-associated leukocytoclastic vasculitis (100,187) and benign cutaneous polyarteritis nodosa (Fig. 16-11). A pauci-inflammatory thrombogenic vasculopathy involving vessels throughout the dermis and subcutis characterizes the histomorphology of associated lupus anticoagulant and/or cryofibrinogenemia (185).

Celiac Disease

Celiac disease is a malabsorption syndrome with a prevalence of up to 1% of the adult population of Western countries (188) and is associated with HLA-DQ2 (DQA1*/DQB1*2) in greater than 90% of celiac disease patients (189). It reflects small-intestinal mucosal injury caused by a humoral immune response to ingested gluten and is associated with dermatitis herpetiformis in roughly 25% of cases (188,190,191). A leukocytoclastic vasculitis has also been described in patients with celiac disease (192). A comprehensive review article by Abenavoli et al. illustrates the occurrences of other skin manifestations of celiac disease, including chronic urticaria, hereditary angioneurotic edema, erythema nodosum, necrolytic migratory erythema, psoriasis, and dermatomyositis, among others (189). The presence of IgA or IgG anti–tissue transglutaminase and antiendomysial antibodies is seen in 80% to 90% of patients with active gut mucosal inflammation and has a high specificity for the diagnosis (193). A significant concern with serologic confirmation of the diagnosis is the presence in a minority of celiac disease patients of a selective IgA deficiency; in such patients, however, IgG antitransglutaminase and antiendomysial antibodies are still positive. Underlying mixed cryoglobulinemia may occur, as may mesangial nephritis, the latter a sequela of circulating immune complexes (191,194). Antibodies to transglutaminase may be of pathogenetic significance. Immunofluorescence studies have demonstrated IgA and epidermal transglutaminase (TG3) deposition in the papillary dermis and blood vessel walls of patients with celiac disease. Those patients with concomitant dermatitis herpetiformis showed a stronger intensity of both IgA and TG3 deposition than those without skin lesions (195).

HEPATOBILIARY DISEASE

Sclerosing Cholangitis and Primary Biliary Cirrhosis

Pyoderma gangrenosum, particularly a disseminated superficial vesiculopustular variant (196), and dermatitis herpetiformis have been described in association with sclerosing cholangitis (176). In addition, diffuse superficial pyoderma gangrenosum has been described in patients with ulcerative colitis, an associated finding in 70% of patients with sclerosing cholangitis. Isolated case reports of elastosis perforans serpiginosa with coexisting Down's syndrome (197) and disseminated warts along with primary combined immune deficiency and progressive multifocal leukoencephalopathy have been described in association with sclerosing cholangitis. Lichen planus of the nail (198) and disseminated Langerhans cell histiocytosis (199) have been reported in patients with sclerosing cholangitis. Cutaneous manifestations seen with primary biliary cirrhosis include lichen planus (200), CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia), sarcoidal granulomata (201), and vitiligo (202). There are reports that describe cutaneous amyloidosis (203), pustular vasculitis (204), and cutaneous fungal infections (205) in patients with primary biliary cirrhosis.

Histopathology. Vesiculopustular pyoderma gangrenosum is characterized by a necrolytic subepithelial blister in which massive papillary edema is accompanied by sheets of neutrophils within the blister cavity and prominent leukocytoclasia often centered around follicles. Peripheral to the areas of neutrophilia, angiocentric mononuclear-cell infiltrates with minimal accompanying vascular injury are observed (Fig. 16-12).

Pathogenesis. Although of unclear pathogenetic significance, antineutrophil cytoplasmic antibodies (ANCAs) in a perinuclear (p) pattern have been detected in 72% of patients with primary sclerosing cholangitis and ulcerative colitis (206,207). An atypical pANCA, termed xANCA, with a specificity for a

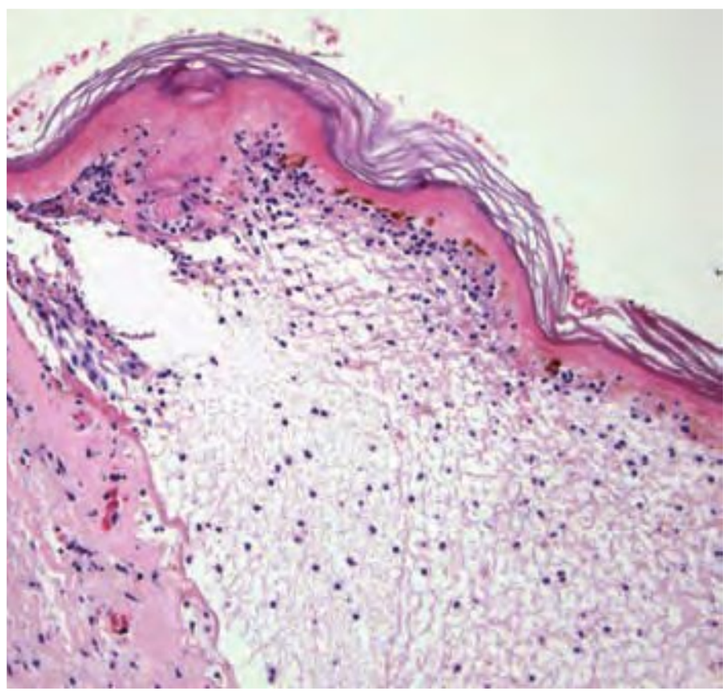

FIGURE 16-12. Vesicular pustular pyoderma gangrenosum. A biopsy of the lesion demonstrated marked subepidermal edema and a subjacent intense neutrophilic and lymphocytic infiltrate with tissue pathergy confined to the superficial dermis.

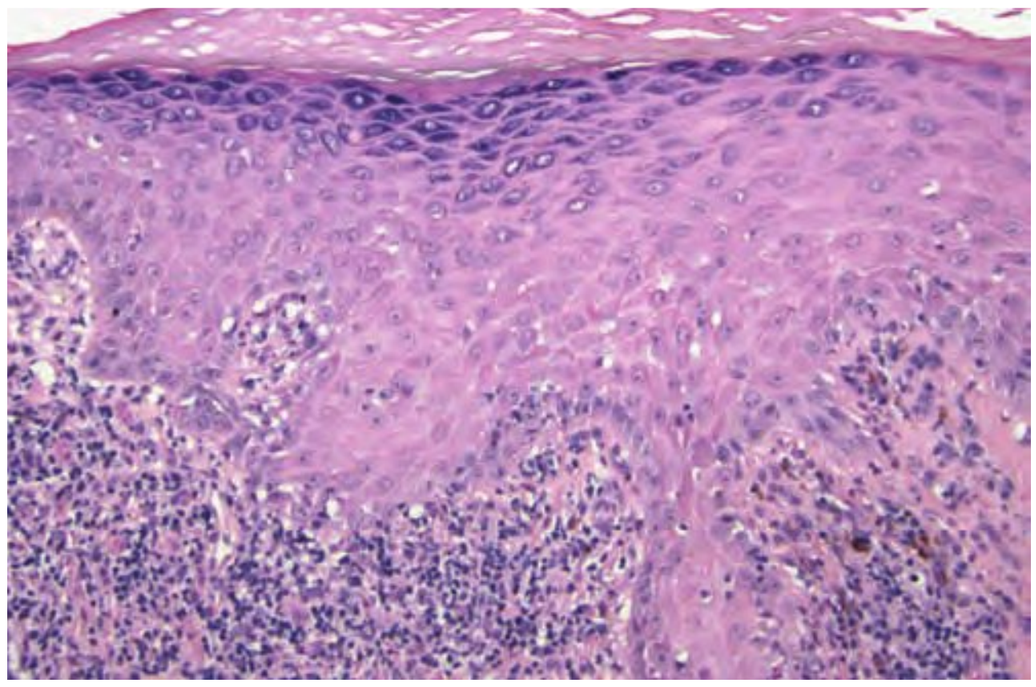

FIGURE 16-13. Lichenoid tissue reaction in the setting of hepatitis C infection. This patient with hepatitis C developed an eruption that was clinically compatible with lichen planus. The histomorphology confirmed the diagnosis by virtue of a dense, bandlike lymphocytic infiltrate in apposition to an epidermis showing colloid body formation.

50-kD myeloid envelope protein is seen in patients with inflammatory bowel disease, autoimmune hepatitis, and primary sclerosing cholangitis (208,209). ANCAs have also been described in Wegener's granulomatosis, microscopic polyarteritis nodosa, and idiopathic crescentic glomerulonephritis. Patients with primary sclerosing cholangitis and concomitant ulcerative colitis (210) have circulating antibodies to colonic epithelial cells (211). An immunogenic basis has also been proposed for primary sclerosing cholangitis in view of the association with HLA-B8 and/or HLA-DR3 antigens.

Hepatitis

Hepatitis can be broadly categorized into infectious and noninfectious causes. Most of the former are viral and are mediated by hepatitis A, B, C, and delta agent, cytomegalovirus, Epstein-Barr virus, and, rarely, varicella, measles, and herpes simplex virus. Chronic active hepatitis of autoimmune etiology is a necroinflammatory disorder of unknown etiology with a predilection for young women (212). Both the clinical presentation and liver chemistry profile may resemble those of infectious hepatitis. Hepatitis C antibodies have been demonstrated in patients with classic autoimmune hepatitis, a finding reputed to represent a nonspecific response that disappears during remission. Conversely, an autoantibody profile mimicking chronic active hepatitis may be seen in hepatitis C (212). Other laboratory abnormalities include anemia, hypergammaglobulinemia, positive lupus erythematosus cell preparations, and positive antibodies to non–organ-specific antibodies, such as antinuclear antibodies, ANCAs, and antibodies to smooth muscle and liver/kidney microsomes (212).

The principal cutaneous manifestations of viral and autoimmune hepatitis are lichen planus, leukocytoclastic vasculitis (213), porphyria cutanea tarda (214), erythema multiforme (215), pyoderma gangrenosum (216), and Gianotti-Crosti syndrome (217). Lichen planus has been reported in patients with hepatitis C, chronic active hepatitis of unknown etiology, and primary biliary cirrhosis (Fig. 16-13) (218). The clinical spectrum of skin lesions in patients infected with hepatitis C comprises photodistributed eruptions, palpable purpura, folliculitis, chilblains-like acral lesions, ulcers, nodules, and urticaria (219). The vasculitis may be on the basis of mixed cryoglobulinemia in the setting of hepatitis C infection (213). Porphyria and erythema multiforme–like eruptions also occur in association with hepatitis C.

Papular acrodermatitis (217) (Gianotti-Crosti syndrome) reflects a primary infection with hepatitis B virus, acquired through the skin or mucous membranes, and comprises a nonpruritic, erythematous, papular eruption on the face, extremities, and buttocks. The eruption usually lasts about 3 weeks and is associated with lymphadenopathy and an acute, usually anicteric hepatitis of at least 2 months' duration that only rarely progresses to chronic liver disease. Hepatitis B surface antigenemia is present (217). A similar eruption may be produced by several other viruses, such as Epstein-Barr virus, coxsackie B virus, and cytomegalovirus (220), in which case there is often no hepatitis or lymphadenopathy. Gianotti-Crosti syndrome has also been reported in children after immunizations with inactivated vaccines for hepatitis A (221), hepatitis B (222), and Japanese encephalitis (223), diphtheria/tetanus/acellular pertussis, and *Haemophilus influenzae* B (224) and after live attenuated oral polio (225) and measles/mumps/rubella vaccines (226). It was reported after inactivated influenza vaccine in an adult (227).

Histopathology. The histologic appearance of the papules in Gianotti-Crosti syndrome includes a moderately dense infiltrate of lymphocytes and histiocytes in the upper and middermis that are found mainly around capillaries that exhibit endothelial swelling, accompanied by erythrocyte extravasation (220). Focal spongiosis, parakeratosis with mild acanthosis, and a focal

interface dermatitis complete the picture (220). The histopathology of lichenoid tissue reactions (Fig. 16-13), pyoderma gangrenosum, erythema multiforme, leukocytoclastic vasculitis, and porphyria cutanea tarda is described in other sections of this book. In our hands, the skin lesions of hepatitis C can be classified by the dominant reaction pattern, the most common being vasculopathies of neutrophilic and lymphocytic vasculitis and pauci-inflammatory subtypes; palisading granulomatous inflammation; sterile neutrophilic folliculitis; neutrophilic lobular panniculitis; benign cutaneous polyarteritis nodosa; neutrophilic dermatoses including neutrophilic urticaria and pyoderma gangrenosum; and interface dermatitis (219). Some patients develop a low-grade lymphoproliferative disease of B-cell lineage cognate to marginal zone lymphoma. Endothelial cell swelling is common. Mixed cryoglobulinemia differs from conventional leukocytoclastic vasculitis by the presence of intraluminal eosinophilic deposits that are strongly PAS positive.

Pathogenesis. The sera of all patients with hepatitis B–induced papular acrodermatitis exhibit hepatitis B surface antigens by radioimmunoassay. Antibodies to hepatitis B surface antigens are not detected during the eruptive phase but only 6 to 12 months after the eruption; patients with antibodies become hepatitis B surface antigen–negative, suggesting a role for humoral immunity in their recovery. As regards the skin lesions of hepatitis C infection, reverse transcriptase *in situ* polymerase chain reaction studies show expression of viral DNA in endothelia in some cases (219).

Acrokeratosis Neoplastica (Bazex's Syndrome)

First described in 1965 (228), this rare but clinically distinctive dermatosis was originally associated with either a primary malignant neoplasm of the upper aerodigestive tract—most commonly squamous cell carcinoma—or metastatic cancer to the lymph nodes of the neck. Other associated malignancies have since been described, including poorly differentiated carcinoma, adenocarcinoma, and small-cell carcinoma among others. Greater than 90% of the patients are male, and most are older than 40 years of age (229). Thickening of the periungual and subungual skin and of the palms and soles occurs initially when the neoplasm is silent. Subsequently, the skin of the ears, nose, face, and trunk and extremities becomes involved and shows a violaceous color, peeling, and fissuring (230,231). The palmar lesions may resemble those of Reiter's disease.

Histopathology. Ill-defined perivascular lymphocytic infiltrates containing a few pyknotic neutrophils in the upper dermis along with mild acanthosis, hyperkeratosis, and scattered parakeratotic foci are described. Eosinophilic and vacuolar degeneration of the spinous layer may be noted (231).

Metabolic Diseases of the Skin

AMYLOIDOSIS

Amyloid

The term *amyloid* is applied to extracellular proteinaceous deposits that are resistant to proteolytic digestion and have distinctive physical properties. Deposits can be localized to a body site or can be "systemic," involving several organs and tissues.

By light microscopy, amyloid appears amorphous, eosinophilic, and hyaline. Characteristic staining qualities distinguish it from other glassy, pink substances. The Congo red stain results in a brick red staining reaction and apple-green birefringence and amyloid stains metachromatically with crystal violet and methyl violet stains. These staining characteristics result from the cross beta-pleated sheet conformation of the polypeptide backbones of the amyloid fibrils. These fibrils are ultrastructurally 8 to 12 nm in width and of indeterminate length. Deposits are derived from more than 25 different proteins, and it has been recommended that classification of amyloidoses be based on the fibril protein whenever possible (1,2).

Historically, the distinction between AL amyloid (primary systemic amyloidosis resulting from a plasma cell dyscrasia) and AA amyloid (secondary systemic amyloidosis) was made utilizing the latter's sensitivity to permanganate. More recently, immunohistochemistry, immunofluorescence microscopy, immunoelectron microscopy, and Western blotting have been used in the identification of fibril proteins and the development of proteomic techniques holds some promise for the future (2–5).

Cutaneous deposition of amyloid can result from any one of several systemic disease processes. However, cutaneous amyloid deposits can also result from local processes limited to the skin.

Systemic Amyloidoses That Involve the Skin: AL (Immunoglobulin Light Chains)

In its systemic form, this disease is also known as *primary systemic amyloidosis*. This uncommon disease results from a plasma cell dyscrasia with production of monoclonal light chains (3). The heart, smooth and skeletal muscle, and other soft tissues, as well as the kidneys, liver, and spleen, are frequently involved. However, deposits can be localized to the skin (and lungs) (2). When they are restricted to the skin, the terms *amyloidosis cutis nodularis atrophicans* and *nodular amyloidosis* have been applied. Heart failure, gastrointestinal bleeding, and renal failure can be fatal complications of the systemic form (6,7). Among cutaneous lesions, petechiae and ecchymoses are most common (7). They are the result of involvement of cutaneous blood vessels and are observed mainly on the face, especially on the eyelids and in the periorbital region (Fig. 17-1A). Minor trauma may precipitate these lesions, referred to by some as *pinch purpura*. In addition, there may be discrete or coalescing papules or plaques. They usually have a waxy color but may be blue-red as the result of hemorrhage into them (8,9). In rare instances, one observes firm cutaneous or subcutaneous nodules or plaques or areas of induration of the skin resembling morphea (10). Bullae that may be induced by minor trauma and may be hemorrhagic occur occasionally (9,11,12). Among oral lesions, macroglossia is common, occurring in 17% of the patients (6) (Fig. 17-1B).

Histopathology. Examination of cutaneous lesions in the systemic form of the disease reveals faintly eosinophilic amorphous, often fissured masses of amyloid deposited in the dermis and in the subcutaneous tissues. Quite frequently, accumulations of amyloid are deposited close to the epidermis. They may or may not be separated from the overlying epidermis by a narrow zone of collagen (Fig. 17-2).

They are rarely deposited around individual elastic fibers (13). The involvement of the walls of blood vessels is responsible for the frequent presence of extravasated erythrocytes. Inflammatory cells are lacking or scarce (12). Bullous lesions are of uncertain pathogenesis. Several mechanisms have been proposed: (a) the formation of clefts within large dermal amyloid deposits (11,12) or (b) from disruption of basal keratinocytes and the basement membrane zone (14).

In the subcutaneous tissue, there may be large aggregates of amyloid with infiltration of the walls of blood vessels and so-called amyloid rings, which are formed by the deposition of amyloid around individual fat cells (12). The fat cells may then appear as if cemented together by the amyloid.

Even if there are no skin lesions, fine-needle aspirates of the abdominal fat often are of use in documenting the diagnosis (15,16) (Fig. 17-3). Tissue biopsies of normal-appearing skin yield positive results in about 40% of all patients (10,17). These biopsies show small deposits in the walls of small blood

FIGURE 17-1. A: Primary systemic amyloidosis—pinch purpura. Note the papules and ecchymotic appearance in the characteristic periocular location. B: Primary systemic amyloidosis—macroglossia. The patient's tongue is enlarged with prominent indentations from continuous pressure against the teeth.

vessels in the dermis or the subcutaneous tissue but occasionally also around eccrine glands and lipocytes. The forearm is the recommended area for biopsy (17).

When localized to the skin, nodular amyloid deposits are surrounded by a dense plasmacytic infiltrate, and production of the immunoglobulin light chains is thought to occur locally (18).

Relationship with Multiple Myeloma. AL amyloidosis results from the production of monoclonal immunoglobulins and/or free light chains, usually lambda light chains, by an abnormal population of B cells. The vast majority of the patients (90%) have monoclonal protein in urine or serum (Bence-Jones protein) (19). If there is overtly malignant plasma cell neoplasia, it is referred to as *multiple myeloma*. Systemic amyloidosis is found in 5% to 15% of multiple myeloma patients. However, the majority of patients with AL amyloidosis do not have overt multiple myeloma. These patients have an underlying B-cell dyscrasia and, despite having no tumor masses, show an increased plasma cell population on bone marrow examination. It is uncertain whether or not this patient population will inevitably develop multiple myeloma.

Pathogenesis. In the systemic form of AL amyloidosis, the amyloid originates from monoclonal immunoglobulin light chains produced by plasma cells in the bone marrow. In the localized form, the amyloid is thought to be produced by the local plasma cell infiltrate, and as in the systemic form, the amyloid protein has immunocytochemical characteristics of AL amyloid (18).

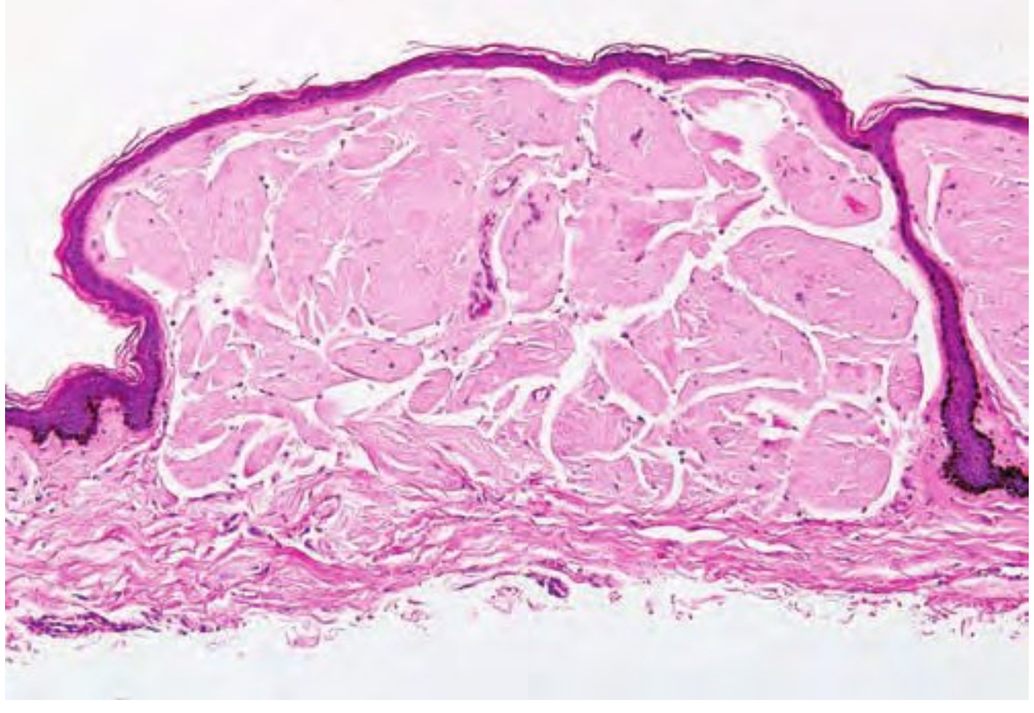

FIGURE 17-2. Primary systemic amyloidosis. There are amorphous, fissured masses of amyloid in the upper dermis. The amyloid material greatly resembles that observed in colloid milium (see Fig. 17-7, page 430).

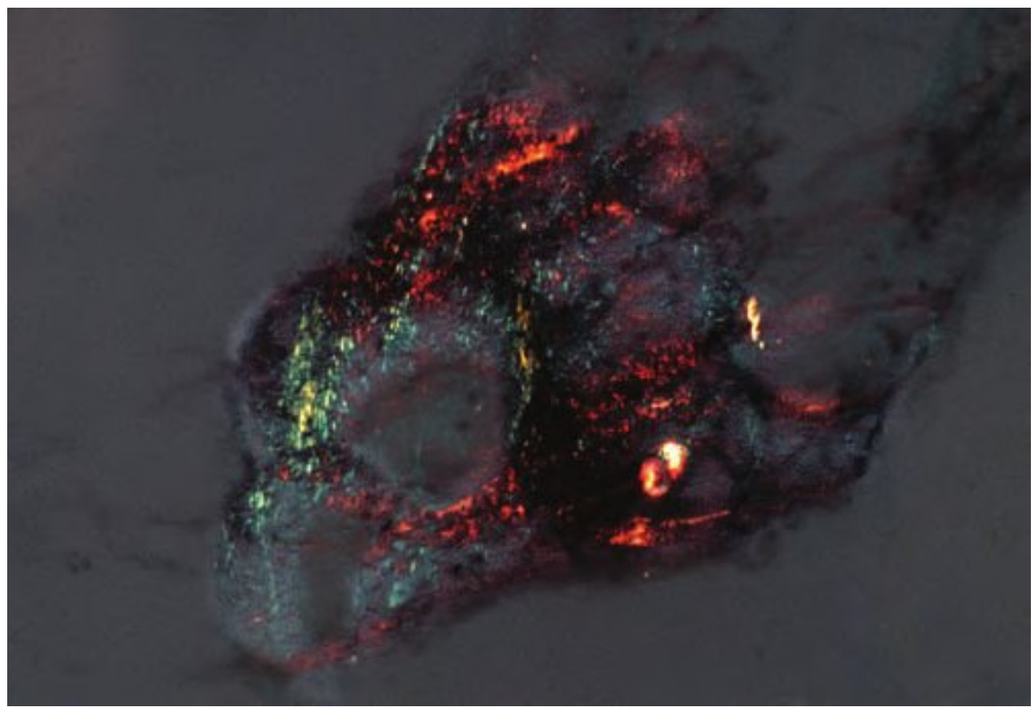

FIGURE 17-3. Primary systemic amyloidosis. Amyloid deposited in subcutaneous fat exhibits green birefringence under polarized light when stained with Congo red in this aspirate from the abdominal fat pad.

Ultrastructurally, amyloid deposits consist of irregularly arranged straight, nonbranching filaments that often appear hollow because their peripheries appear electron dense in comparison with their centers. These filaments are 6 to 7 nm in diameter but are of indeterminate length (20–22).

AA (Serum Amyloid A) Amyloidosis

Also known as *secondary systemic amyloidosis*, AA amyloidosis can result from chronic inflammatory disease or recurring bouts of acute inflammation such as tuberculosis, complications of bronchiectasis, and chronic osteomyelitis. It is now relatively rare in industrialized countries since the development of modern antibiotic therapy, and most cases in the United States and Western Europe are associated with chronic rheumatoid arthritis or related disorders (23). At time of diagnosis, the vast majority of patients have renal insufficiency or the nephrotic syndrome. There are no cutaneous lesions.

Histopathology. AA amyloid is deposited in parenchymatous organs such as the kidneys, liver, spleen, and adrenal. These deposits are found first in the interstitium and blood vessel walls; with progression, the deposits gradually replace the parenchyma. Deposits within the glomeruli and peritubular tissues result in renal failure.

Fine-needle aspiration biopsy of the subcutaneous fat and staining of the aspirated material by the Congo red method is the most sensitive method of diagnosis (15,16,24,25). Tissue biopsy of skin with underlying subcutaneous fat demonstrates deposits of AA amyloid around lipocytes, in blood vessel walls, around eccrine glands, and sometimes free in the dermis (17).

Pathogenesis. AA amyloid is thought to be derived from serum amyloid A (SAA), an acute phase reactant, which is produced in response to inflammation and regulated by cytokines including tumor necrosis factor-alpha (TNF-α) (26). AA protein is then formed when SAA undergoes carboxy terminal cleavage (26–28). This process takes place within lysosomes of macrophages that are receiving antigenic stimulation by a variety of chronic diseases (29). The amyloid is then deposited extracellularly.

Primary Localized Cutaneous Amyloidosis

Lichen Amyloidosis and Macular Amyloidosis

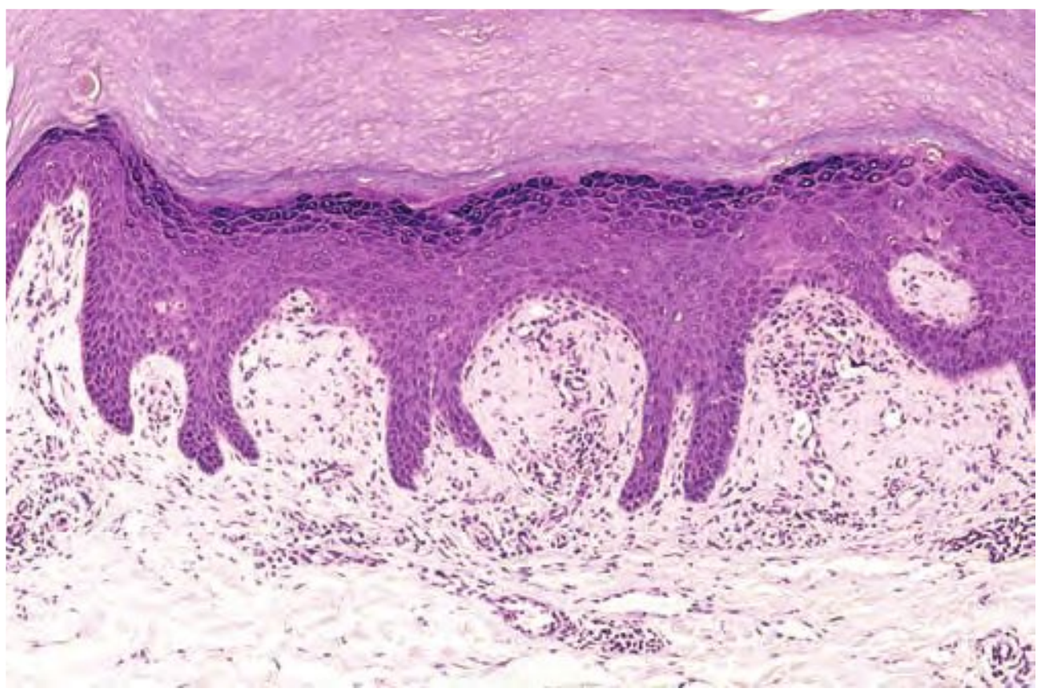
Lichen amyloidosis and macular amyloidosis are best considered as different manifestations of the same disease process. Lichen amyloidosis is characterized by closely set, discrete, brown-red papules that often show some scaling and are most commonly located on the legs, especially the shins, although they may occur elsewhere (Fig. 17-4). Through the coalescence of papules, plaques may form on the legs. These plaques often have verrucous surfaces and then resemble hypertrophic lichen planus or lichen simplex chronicus. Usually, the lesions of lichen amyloidosis itch severely. It is assumed by some authors that the pruritis leads to damage of keratinocytes by scratching and to subsequent production of amyloid (30,31).

FIGURE 17-4. Lichen amyloidosis. There are thin, tan to brown papules coalescing into a larger plaque on the anterior lower leg.

Macular amyloidosis is characterized by pruritic macules showing pigmentation with a reticulated or rippled pattern (Fig. 17-5). Although macular amyloidosis may occur anywhere on the trunk or extremities, the upper back is a fairly common site (32). In Southeast Asia, where macular amyloidosis is common, prolonged friction from a rough nylon towel or a back scratcher is thought to be its cause (33). The eruption

FIGURE 17-5. Macular amyloidosis. Note the rippled appearance of the hyperpigmentation in this close-up photograph of a patient's central upper back, which is a characteristic location.

can be easily passed off as postinflammatory hyperpigmentation by physicians who are unfamiliar with the condition (34).



Macular amyloidosis and lichen amyloidosis sometimes occur together in the same patient, and lichen amyloidosis can arise in a setting of macular amyloidosis, presumably due to scratching (35,36). When treated by intralesional injection of steroids, the lichenoid lesions can become macular.

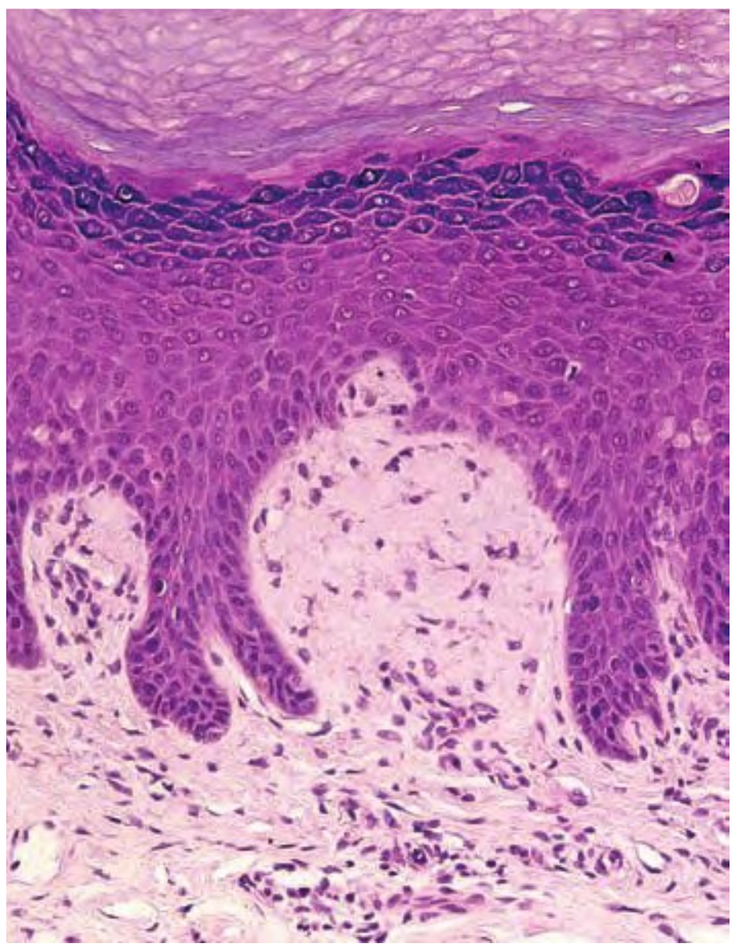
Histopathology. Lichen and macular amyloidosis show deposits of amyloid that are limited to the papillary dermis. Most of the amyloid is situated within the dermal papillae. Although the deposits usually are smaller in macular amyloidosis than in lichen amyloidosis, differentiation of the two on the basis of the amount of amyloid is not possible (34). The two conditions actually differ only in the appearance of the epidermis, which is hyperplastic and hyperkeratotic in lichen amyloidosis. Occasionally, the amount of amyloid in macular amyloidosis is so small that it is missed, even when special stains are used on frozen sections. In such instances, more than one biopsy may be necessary to confirm the diagnosis (37).

In areas in which the entire dermal papilla is filled with amyloid, the amyloid appears homogeneous in both lichen and macular forms. In lesions in which the dermal papillae are only partially filled, as seen more often in macular amyloidosis, the amyloid has a globular appearance and resembles the colloid bodies found in lichen planus (Fig. 17-6). These amyloid bodies in some areas lie in direct contact with the overlying basal cells of the epidermis. Similar colloid bodies are also found in some sections within the epidermis, but in contrast with those located at the dermal–epidermal junction, they do not stain as amyloid. In addition, there often is a striking degree of pigmentary incontinence.

Histogenesis. The light microscopic findings in lichen and macular amyloidosis suggest that degenerating epidermal cells are discharged into the dermis, where they are converted into amyloid. The epidermal origin of the amyloid in lichen and macular amyloidosis is supported by electron microscopy (38,39). Also on electron microscopy, the degenerating epidermal cells resemble the colloid bodies observed in lichen planus. They contain the following components: (a) tonofilaments; (b) degenerated, wavy tonofilaments that are thicker but less electron dense than normal tonofilaments; (c) lysosomes; and (d) typical filaments of amyloid, 6 to 10 nm thick, that are straight and nonbranching (39). It is postulated that the degenerated, wavy tonofilaments are recognized as foreign and are digested

A

B



C

FIGURE 17-6. Lichen amyloidosis. There is hyperkeratosis and epidermal hyperplasia. Dermal papillae are rounded and contain globular deposits of amyloid. (A: Hematoxylin and eosin [H&E], original magnification ×40; B: H&E, original magnification ×100; C: H&E, original magnification ×200.)

by the cell's own lysosomes. Such digestion produces amyloid filaments. A conversion of tonofilaments into amyloid filaments requires that the alpha-pleated sheet configuration of the tonofilaments change into the beta configuration of amyloid (40). However, immunohistochemical studies suggest that components of the lamina densa and anchoring fibrils are also associated with amyloid deposits. Further ultrastructural examination shows disruption of the lamina densa overlying these deposits (41).

On direct immunofluorescence, all specimens of lichen or macular amyloidosis fluoresce positively for immunoglobulins or complement, particularly immunoglobulin M (IgM) and the third component of complement (C3). Staining for kappa and lambda light chains is positive. The immunofluorescent pattern is globular and thus is similar to that of lichen planus, except for the absence of fibrin. It suggests that the globular aggregates of lichenoid or macular amyloidosis, like the colloid bodies of lichen planus, act as a filamentous sponge into which immunoglobulins and complement are absorbed (42).

The epidermal derivation of the amyloid in lichen and macular amyloidosis is supported by histochemical and immunologic findings. In contrast to the amyloid of systemic amyloidosis, the amyloid of lichenoid and macular amyloidosis shows fluorescence for disulfide bonds as normally seen in the stratum corneum, suggesting that cross-linking of sulfhydryl groups occurs in amyloidogenesis (43). Furthermore, immunofluorescence studies with an antikeratin antiserum have shown intense staining of the amyloid for the antikeratin antibody (44).

After full agreement apparently had been reached about the keratogenic origin of the amyloid in lichen and macular amyloidosis, some dissenting opinions were expressed. In one study, amyloid stained negatively for keratin determinants and the positive reactions obtained by previous investigators were regarded as nonimmunologic, because amyloid deposits can easily absorb immunoglobulins (45). Degenerating collagen was regarded as the site of formation of amyloid (46). Other authors found direct amyloid fibril formation at the basal surfaces of living basal cells in lichen amyloidosis (47).

The amyloid that may be found in the stroma or in the adjacent connective tissue of basal cell carcinoma and other epithelial tumors has an appearance on electron microscopy and direct immunofluorescence similar to that of lichen and macular amyloidosis, suggesting that it too is derived from tonofilaments (48). This amyloid also shows positive staining with antikeratin antiserum (44).

Nodular Amyloidosis

Nodular amyloidosis is a rare condition in which nodular deposits of AL amyloid are deposited in the skin but in which there is no apparent systemic involvement. One or several nodules are encountered, usually on the legs (49) or face (50) but occasionally elsewhere. The nodules commonly measure from 1 to 3 cm in diameter. In their centers, the skin may appear atrophic (51). In exceptional instances, plaques are observed (52).

Histopathology. Beneath an atrophic epidermis are large masses of amyloid that extend through the entire dermis into the subcutaneous fat. Amyloid deposits are also found within the walls of blood vessels, in the membrana propria of the sweat glands, and around fat cells (52). A lymphoplasmacytic infiltrate is scattered through the masses of amyloid and at the periphery (18,50,51,53). In addition to clusters of plasma cells, Russell bodies and amyloid-containing foreign body giant cells may be seen (54).

Differential Diagnosis. On a histologic basis, differentiation of nodular amyloidosis from primary systemic amyloidosis is not possible.

COLLOID MILIUM AND NODULAR COLLOID DEGENERATION

There are three types of colloid degeneration of the skin: (a) juvenile colloid milium, (b) adult colloid milium, and (c) nodular colloid degeneration. Juvenile colloid milium and nodular colloid degeneration are very rare.

Juvenile colloid milium has its onset before puberty and shows numerous round or angular, brownish, waxy papules located mainly on sun-exposed areas, particularly the face (55,56). There is a family history in nearly half of the reported cases, and the possibility of a hereditary defect has been postulated (56).

Adult colloid milium, which starts in adult life, is clinically indistinguishable from the juvenile type, except that in some instances it involves the dorsa of the hands in addition to the face and neck (57,58). Sun exposure often seems to be a precipitating factor (55).

Nodular colloid degeneration shows either a single large nodule on the face (59) or multiple nodules on the face (60) or the chin and scalp (61). Sun exposure does not seem to play a role, because in some instances, the lesions are limited to the trunk (62).

Histopathology. The histologic findings differ in the three types of colloid degeneration, because the colloid in the juvenile form is of epidermal origin and that in the other two forms is of dermal origin (55,63).

In juvenile colloid milium, fissured colloid masses fill the papillary dermis. The overlying epidermis is flattened, and basal cells show transformation into colloid bodies (64). Ultrastructurally, the colloid material is found within individual basal keratinocytes above an intact basement membrane and in extracellular aggregates in the dermis. These deposits contain remnants of nuclear membrane material, degenerating cell organelles, and desmosomes. The fibrillary structure is similar to that of amyloid ultrastructurally, although staining with Congo red failed to result in birefringence, and other stains for amyloid were negative in the case reported by Handfield-Jones et al (56).

In adult colloid milium, a narrow zone of connective tissue usually separates the homogeneous masses of colloid located in the papillary dermis from the overlying epidermis

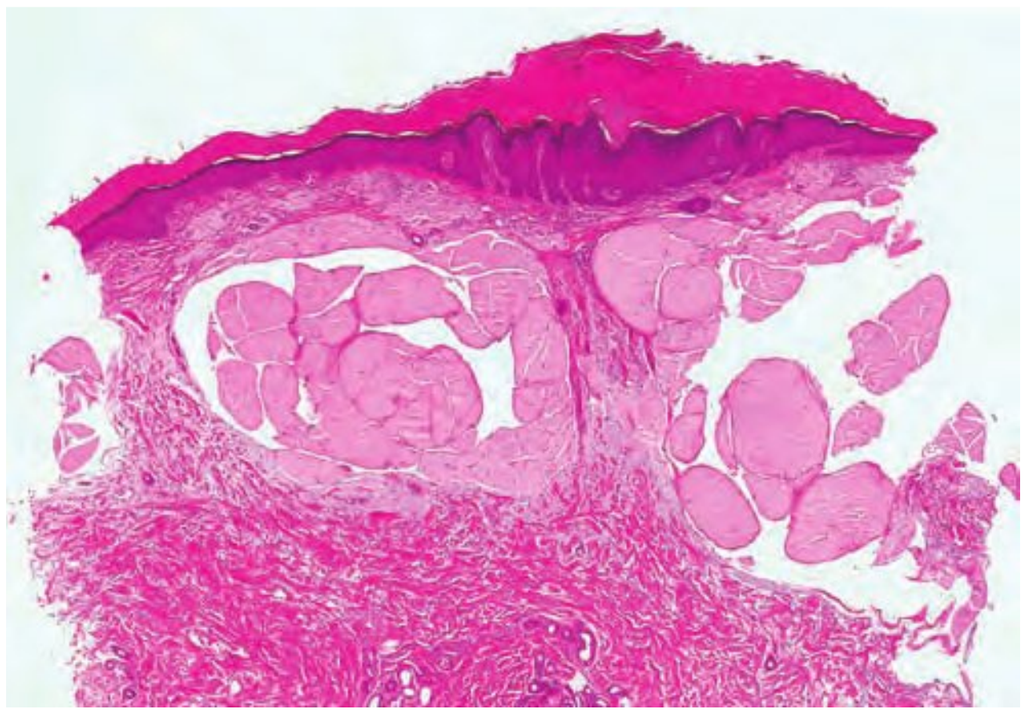


FIGURE 17-7. Colloid milium, adult type. Homogeneous, fissured masses of colloid are present in the uppermost dermis. The colloid material greatly resembles the amyloid material observed in primary systemic amyloidosis (see Fig. 17-2, page 426).

(Fig. 17-7). Elastic tissue staining shows some elastic fibers in this narrow zone of connective tissue (55). In addition, solar elastotic fibers are usually seen at the base of the colloid deposits (65).

In nodular colloid degeneration, the epidermis is flattened. The upper three quarters of the dermis are filled with pale pink, homogeneous material; in some lesions, even the entire dermis is filled with this material (61). Scattered nuclei of fibroblasts are present within the colloid (59). There are scattered clefts or fissures and some dilated capillaries. The hair follicles and sebaceous glands appear well preserved (60).

Pathogenesis. The colloid in all three types shows considerable resemblance to amyloid—not only in its histologic appearance but also in its histochemical reactions (65).

Histochemical staining shows that colloid, like amyloid, is periodic acid-Schiff (PAS) positive and diastase resistant. Staining with Congo red results in green birefringence (sometimes weak), and the colloid fluoresces after staining with thioflavin T (65). However, it does not react with pagoda red and other cotton dyes (66). Serum amyloid P not only is a component of normal and abnormal dermal elastic fibers but reportedly can be stained immunocytochemically in colloid milium (67). Juvenile colloid milium exhibits a positive immunostaining reaction to polyclonal antikeratin antibody. This suggests that the histogenesis of this process may differ from that of the adult form in that the colloid in juvenile colloid milium is more likely derived from keratinocytes (68).

Electron microscopy in a case of juvenile colloid milium has shown that the colloid consists of tightly packed bundles of filaments, 8 to 10 nm thick, in a wavy or whorled arrangement (63). The colloid, which forms by filamentous degeneration of tonofilaments, maintains a cytoid configuration in the dermis and may contain nuclear remnants (68,69).

In adult colloid milium, the colloid masses are seen on electron microscopic examination to consist primarily of a granulofibrillar, amorphous substance. On high magnification, very fine filaments, only 2 nm wide, may be seen embedded in the amorphous substance (55,67). There is rather conclusive evidence that colloid is derived from elastic fibers through sequential degenerative changes. This can be observed at the periphery of the lesion, where colloid is being produced, and within the colloid, where fibrils with a tubular structure and a diameter of 10 nm that are strikingly similar to the microfibrils of elastic fibers can be seen (57). The colloid in adult colloid milium thus represents a final product of severe solar degeneration (67).

The colloid in nodular colloid degeneration, similar to that in adult colloid milium, consists of an amorphous substance and short, wavy, irregularly arranged filaments (61). The diameter of these filaments is 3 to 4 nm (59). These electron microscopic findings exclude nodular amyloidosis as the diagnosis, because in this condition, the filaments have a diameter of about 6 to 7 nm and are long and straight.

LIPOID PROTEINOSIS (HYALINOSIS CUTIS ET MUCOSAE; URBACH-WIETHE DISEASE)

Lipoid proteinosis is a rare disorder that is inherited as an autosomal recessive trait. First described by Siebenmann (70) in 1908, it was established as a distinct clinical and histologic entity by Urbach and Wiethe (71) in 1929. In 1932, Urbach coined the term *lipoid proteinosis* (72).

Clinically, there are papular and nodular lesions on the face. Areas of diffuse infiltration associated with hyperkeratosis are observed on the elbows, knees, hands, and occasionally elsewhere. The papules and nodules on the face cause pitted scars, giving the skin a pigskin-leather appearance. Verrucous plaques can form in areas of friction (73). Beads of small nodules may be present along the free margins of the eyelids. The tongue is firm because of diffuse infiltration. Extension of the infiltration to the frenulum of the tongue restricts normal movement of the tongue, and infiltration of the vocal cords causes hoarseness, which may be present at birth. Convulsive seizures are not uncommon (74,75).

Histopathology. There is extensive cutaneous deposition of amorphous eosinophilic material surrounding capillaries and sweat coils and in the thickened papillary dermis (Fig. 17-8). Focal deposits are found in the deeper dermis. In verrucous lesions, the homogeneous bundles often are oriented perpendicular to the skin surface. This hyaline material is PAS-positive and resistant to diastase digestion. Staining with Alcian blue at pH 2.5 is slightly positive and is sensitive to hyaluronidase digestion (76). The presence of lipids is variable and likely results from adherence of lipids to glycoproteins rather than from abnormal lipid production (77).

Systemic Lesions. Intracranial calcification has been noted quite frequently in x-ray examination of patients with lipoid proteinosis and has been held responsible for convulsive seizures in these patients (74,78). Autopsy findings have established that the calcium is deposited within the walls of capillaries

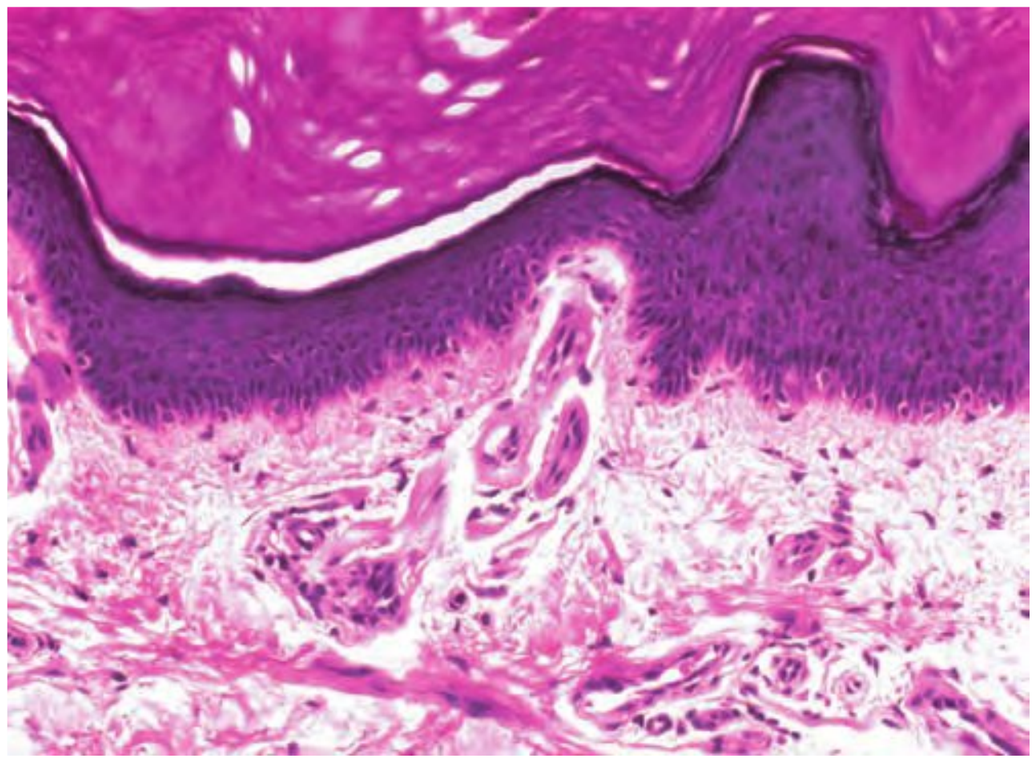

FIGURE 17-8. Lipoid proteinosis. The hyaline material consists of thick mantles surrounding the blood vessels.

located in the hippocampal gyri of the temporal lobes (79). The fact that after decalcification a mantle of PAS-positive material is observed around the endothelium of these vessels indicates that hyalinization precedes calcification of the capillary walls.

The widespread distribution of the pericapillary hyalin deposits has been established by biopsies and autopsies. Deposits have been found in the submucosae of the upper respiratory and digestive tracts and in the submucosae of the stomach, jejunum, rectum, and vagina; in the retina between the vitreous membrane and the pigment epithelium; and in the testes, pancreas, lungs, kidneys, and elsewhere (75,79).

Pathogenesis. Two different substances present in lesions of lipoid proteinosis have the light microscopic appearance of hyalin because they consist of homogeneous eosinophilic material and are PAS positive and diastase resistant (76,80). However, their different appearances and origins become evident on electron microscopy (81,82). One is true hyalin, produced by fibroblasts, and the other represents hyalin-like material consisting of multiplications of basal laminae, produced by a variety of cells.

Lipids are not an essential feature of the disease. They can be removed with lipid solvents without damage to the protein-carbohydrate complex of the true hyalin. This suggests that the lipids are either free or loosely bound to the hyalin (83).

Mutations in the extracellular matrix protein 1 gene (ECM1) have been identified as the cause of lipoid proteinosis (84). The glycoprotein product of this gene is thought to play a functional role in cutaneous physiology and homeostasis. With loss of function of ECM1, there is an accumulation of lipid-like materials in various viscera as well as in the skin as previously described (85).

On electron microscopic examination, three major alterations are noted in the dermis: (a) a considerable thickening of basal laminae; (b) massive depositions of amorphous material (hyalin), predominantly in the upper dermis and around blood vessels (86); and (c) a marked reduction in the number and size of collagen fibrils (82,85). The thickening of the basal laminae in multiple layers is evident around small blood vessels, skin appendages, smooth muscle cells, perineuria, and Schwann cells (87). In contrast, there is almost no multiplication of the basal lamina of the epidermis (87). Around capillaries, basal laminae consist of as many as 20 layers, and occasionally even more, arranged in a concentric "onion-skin" arrangement (86). Interspersed between these layers are fine collagen fibrils in an amorphous matrix. The thickened basement membranes stain intensively for laminin and collagen type IV (82).

A unique feature of hyalinosis cutis et mucosae consists of large depositions of amorphous material in the dermis. The exact chemical nature of this hyaline material is not known, but it is a noncollagenous glycoprotein that contains neither laminin nor fibronectin (82).

The collagen within the areas of hyalin deposits appears as fine but otherwise normal fibrils arranged in bundles or in random fashion. Most fibrils have a diameter $<$50 nm, compared with the usual size of 70 to 140 nm. Involved skin shows a five-fold reduction in collagen type I, the major collagen species of normal skin, and to a lesser extent in collagen type III, as indicated by cell culture studies. As judged by the contents of glycine and hydroxyproline, normal skin contains about 80% collagen, but involved skin in hyalinosis cutis et mucosae contains only 20% collagen as the result of a large accumulation of noncollagenous glycoproteins.

Cultured fibroblasts from lesions of hyalinosis cutis et mucosae have shown an increased synthesis of noncollagenous proteins at the expense of newly synthesized collagens. The hyaline material in hyalinosis cutis et mucosae originates from the overproduction of noncollagenous proteins, most of which are normal constituents of human skin (82).
